(1) The wall rock deformation of the tunnel was mainly suffered the comprehensive influence of many factors like wall rock type, construction method, supporting measures, size of the excavation section, and etc.(2) At the time between 20d and 40d after the excavation of the tunnel, the surrounding convergence, crown settlement and the ground settlement met the requirements, which could support the construction of second lining. (3) After the excavation and supporting construction of the wall rock of upper steps, the stress concentration was appeared at the joint area of steps. Therefore, the interval between the construction of upper step and lower step should not be too long. (4)The numerical analysis method and site monitoring method could be used together to establish a much more comprehensive monitoring technology for tunnel construction.

**Keywords:** shaft station; soft rock; sight instrument; grouting; cable anchor support

**Abstract:** Support of soft rock is a big challenge in all mines at home and abroad. Soft rock is of different kinds of rheological property for geological conditions, mine ground pressure and so on. It brings about really difficult problem to roadway support. In order to ensure safety application and prolong usage, shaft station need to be reinforced. Sight instrument was used to analyze broken conditions. The results show that the broken depth in roof rock is 5~6 m, and greater than 4 m in sidewalls. According to failure characters and sight results, we determine that rock of shaft station belongs to high geo-stress and jointed soft rock. On this basis, technology of grouting reinforcement combined with cable anchor support is carried out. Monitoring results of surface convergence and cable force show that bearing capacity of surrounding rock increases obviously, roadway contraction and floor heave are well controlled.

## Introduction

Pingshan Colliery is located in Qinshui County, Shanxi Province. Most existing roadways in 3# coalbed were broken. Flash coat fractured[1], lining broke for being extruded[2], partial floor fractured, contraction of roadway section was large[3]. All those deformation characters belonged to high stress soft rock [4], it easily expanded for rock dilatation[5], it was of strong rheological property[6]. In order to solve those problems and keep prosperous production, this paper introduces grouting reinforcement technology in Pingshan shaft station and nearby chamber.

## Characters and mechanism of roadway failure

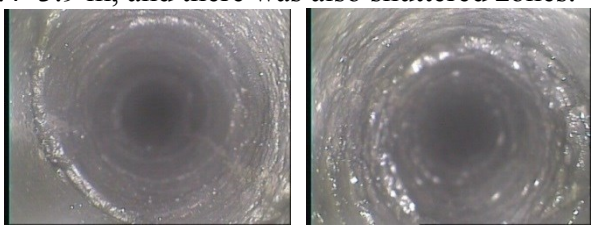
**Geological conditions.** 3# coalbed is mainly mined, burial depth is about 460 m, the thickness of coalbed is 3.70~6.30 m, the average thickness is 5.22 m, the average dip angle is 10°. False roof is sandy mudstone, joint and fracture is fully developed, it easily weathering to sheet structure. Main roof is siltstone, it's about 5.25 m thick. Upper roof is fine sandstone it is 9.55 m thick and stable, protodyaknove's number is 4~6. The floor is mainly made up with mudstone and sandy mudstone, its thickness is 3.55 m, fracture is fully developed with bad integrality. Fissure water in sandstone is the main runoff in roof of 3# coalbed, normal water inflow is 25.21 $m^3$/h, and the maximum is 38.75 $m^3$/h.

**Sight instrument.** In order to test the range of broken zone and internal deformation of surrounding rock, four stations were chosen in shaft station roadway. Take pictures of station 3 for example to explain our test, as is shown in Fig 1 and Fig 2.

Station 1 was located at loopway. Fractures were well developed within 5.5 m in roof, the rock was extremely broken in 2.7 m~5.5 m, roof separation was obvious at 4.8 m, and the rock was of good integrality outside 5.9 m. Broken rock in sidewalls mainly concentrated upon 1.5 m, the rock beyond 1.5 m was of good integrality.

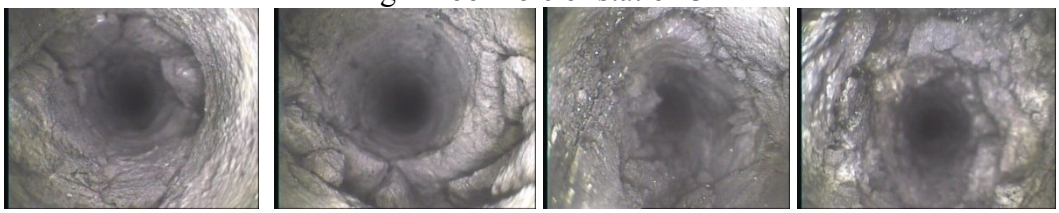
Station 2 was located at heavy lane near auxiliary shaft. The result showed that surrounding rock in this roadway was severely damaged, the broken depth of roof reached to 6.2 m, multiple crushed zone appeared in that range, and fractures were fully developed.

Fig 1 shows roof hole and Fig 2 shows sidewall hole. Station 3 was located at light lane. Roof rock was damaged severely within 4.7 m, fractures were fully developed, especially in 2.2 m~2.8 m, roof separation was obvious. The broken length of sidewall was at least 4 m, because drilling was stopped at 3.95 m. Continuous crushed zone appeared in 1~2.4 m, fractures were well developed in 2.5~3.2, coal was badly broken in 3.4~3.9 m, and there was also shuttered zones.



(a) 0.8 m (b) 4.3 m

Fig 1 Roof hole of station 3



(a) 0.9 m (b) 1.0 m (c) 3.4 m (d) 3.9 m

Fig 2 Sidewall hole of station 3

Station 4 was located at heavy lane. The result showed that joint and fractures were fully developed within 5 m, especially that consecutive crushed zone appeared in coal, hole collapse occurred at 4.9 m.

By analysis results of four stations, we came to a conclusion that the broken depth is 5~6 m in roof of shaft station, multiple large fractures exist within that range. The broken depth in sidewalls can even reach to 4 m, crushed zone in coal is consecutive.

Through representation of roadway failure, geologic structure and lithology, we can figure out that surrounding rock of 3# coalbed belongs to high geo-stress and jointed soft rock, it is composite type. This type of soft rock expands easily for dilatation, and is of strong rheological behavior. Main deformation and failure phenomenon of roadway is broken rock, large contraction and floor heave.

## Reinforce measurements

Mechanism of grouting reinforce is by filling fractures in rock to improve bearing capacity of surrounding rock itself, then the stability of roadway can increase. The process of reinforce is grouting, shaping roadway, support and shotcrete, the order is grouting floor first ,then the sidewalls and roof grouting at last. Take roadway reinforcement in loopway for example, we explain the process of reinforcement construction.

**Reinforce materials.** Cement-based inorganic grouting material was mainly used for reinforce, and high strength polyester would be used in special position. 525# ordinary portland cement mixed with XPM additive was used to compound cement paste. Cement- sodium silicate grout would be used if large-scale mud leakage happened. XPM additive was 8%~10% of cement weight, water cement ratio of cement paste was 0.8:1~1:1.

Keep cement ratio when double grout was used, concentration of sodium silicate was 48~55Be, modulus was 2.8~.2, bulk factor of cement paste and sodium silicate was 1:0.4~1:0.6.

**Grouting parameters of vault and sidewalls.** Both roof grouting holes and sidewall holes are in rows, the row space in loopway is 1600 mm, 1335 mm in waiting chamber, 1300 mm in light lanes and 2400 mm for all the others. Fig 3 shows the sketch map of grouting holes in loopway, diameter of

each hole was Ø36 mm, length of each hole was 8000 mm. Angle of the lowest holes tilted 5° downward, and all the other holes were perpendicular to roadway surface, pre-embedded pipe was used for later grouting, grouting pipes were all 7000 mm long, it grouted all length once, grouting pressure was 4~6 MPa.

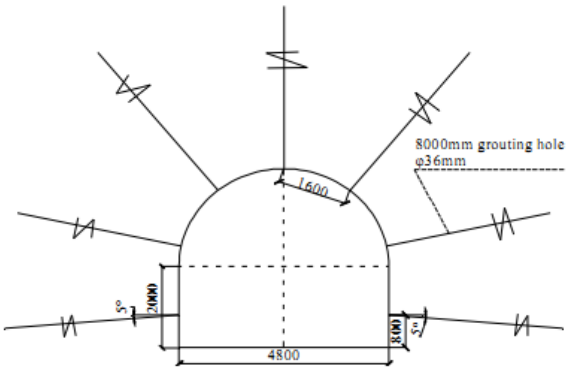


Fig 3 Sketch map of grouting holes

Grouting pressure must be guaranteed during construction, take appropriate measures when leakage occurred, such as, leaking stoppage and regrouting. New grouting holes should be constructed if leakage was severe.

**Grouting parameters of floor.** Grouting holes in floor were in rows, the average row space was 2000mm. Fig 4 shows the sketch map of floor holes. Length of floor holes was 4m, it diameter was 56mm, 3.5 meters long grouting pipes were pre-embedded after drilling construction, at the same time, all puissant cables, 4.3 meters long and diameter 22 mm ,were pre-embedded too, it grouted all length once, grouting pressure was 3 MPa.

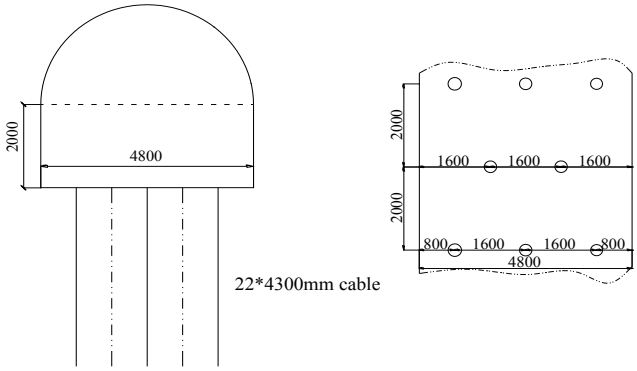

Fig 4 Sketch map of grouting holes and cables in floor

## Support design

Fig 5 shows the sketch map support parameters of cables and anchors in loopway.

**Anchor parameters.** Specification of anchors was Ø22×2400 mm, they were made by high strength deformed steel bar. Two low viscosity resins were used for each anchor, it was K2335 type and Z2360 type, diameter of bolt holes was 28 mm, column space was 800 mm, and row space 1000 mm. All anchors were rectangular and perpendicular to roadway surface, and pre moment of force was 400N·m. Specification of high strength trays was 150×150×10 mm. Steel meshes were welded by Ø6.5 mm steel, grid size was 100×100 mm, specification of meshes was 2.9 m×1.1 m, and steel beams were welded by Ø14 mm steel.

**Cable parameters.** Cables position was rectangular, row space was 2000 mm and column space 1600 mm. They were set between anchor rows, one K2335 resin and two Z2360 resins were used for each cable. Specification of roof cables, made of 1×19 steel strand, was Ø22×8300 mm, they were perpendicular to roadway surface and their preload was greater than 250 kN. Specification of sidewall cables was Ø17.8×5800 mm, they were also perpendicular to roadway surface and their preload was greater than 150 kN.

**Shotcrete.** Strength grade of shotcrete was C20, the thickness of roof and sidewalls concrete was 150 mm. Strength grade of floor concrete was C10.

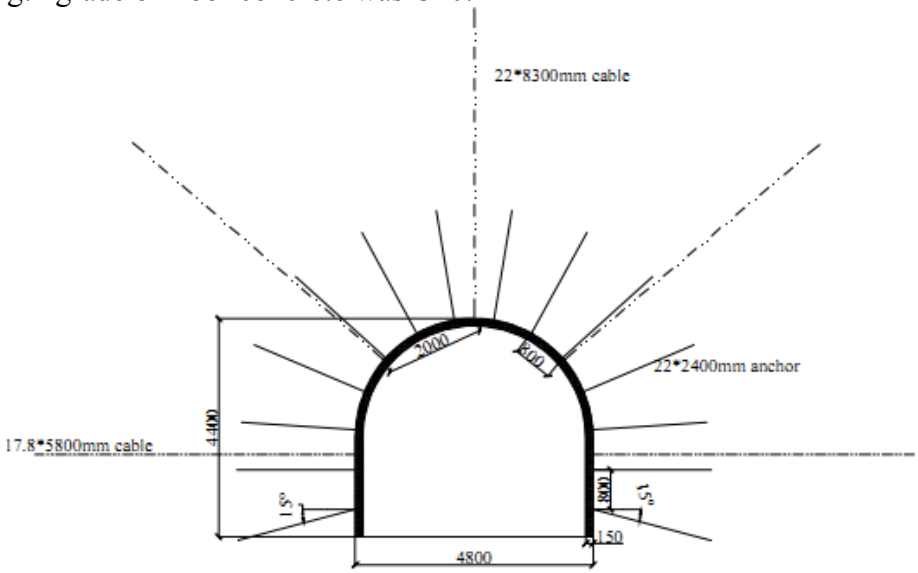

Fig 5 Sketch map of support in loopway

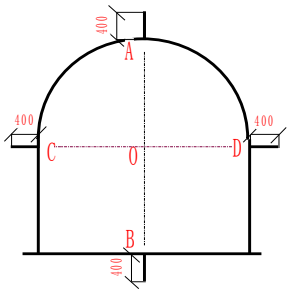
**Floor support parameters.** Sketch map of floor support is shown in Fig 4. Beam steel, diameter 20 mm, were combined with pre-embedded cables after grouting. Specification of floor cables was Ø22×4300 mm, it was made of 1×19 high strength preloaded steel strands. Cables were pre-embedded in grout holes in rows, their preload was greater than150 kN, it would grouting overall length by cement paste. Specification of high strength tray was 300×300×16 mm.

## Rock pressure monitoring

**Analysis of roadway displacement.** Fig 6 shows monitoring section of surface convergence using Cross point method, measuring nails made of wood were 400 mm, their diameter was 32 mm. Measurement accuracy was 1 mm.



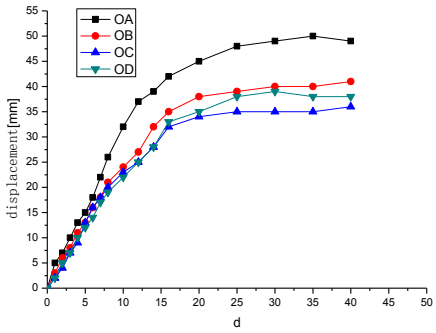


Fig 6 Sketch map of displacement monitoring Fig 7 Curve of roadway displacement

Fig 7 shows curve of roadway displacement with construction days, it's 40 days totally. We can see that in early age, roadway deformation grow faster, until 25 days later deformation become stable. The maximum displacement is roof, it's about 50 mm. Displacement of left sidewall is minimum, it's 37 mm. Convergence of roof-floor is about 87 mm, convergence of sidewalls was about 79 mm, deformation of roadway is small, obvious floor heave and wall caving never appeared, support effect is desired.

**Analysis of cable force.** Fig 8 shows the MGH instrument made in Shandong University of Science and Technology. Fig 9 shows curve of cable force in loopway, it lasted for 28 days, 22# curve shows curve of roof cable, while 17.8# curve shows curve of sidewall cable.

Fig 8 Vibrating wire dynamometer for cable

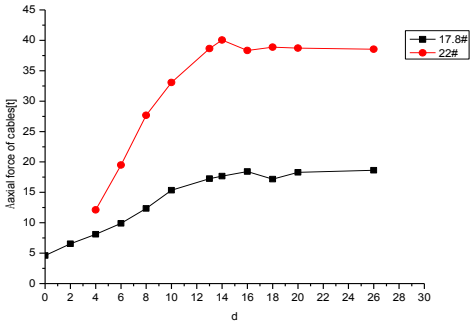

Fig 9 Curve of cable force

Fig 9 shows that roof cable is greater than that of sidewall cable and it grow faster, it tend to stable at 38t after 12 days. The maximum force is about 40 t, so construction quality of cable must be guaranteed. Force of sidewall cable grow gently, it's stable at 14 t after 16 days.

## Conclusions

It has been four years since Pingshan shaft station was reinforced. Roadway of shaft station is of good integrality and stable, its deformation is quite small so far.

(1) Failure area of roof is 5~6 m and greater than 4m of sidewalls, fracture developed fully, the surrounding rock belongs to high geo-stress and jointed soft rock.

(2) Grouting is an effective technology to fracture-developed roadway in soft rock, grouting can fill fractures inside rock, improve its carrying capacity and increase rock integrality, then carrying capacity of rock itself can be made full use of.

(3) Axial force of roof cable is greater than that of sidewall cable, it illustrates the vertical stress of surrounding rock is greater, construction quality of cable should be guaranteed.

**Keywords:** roadway surrounding rock; stability classification; classification index; classification method; research status.

**Abstract.** Stability classification of roadway surrounding rock is of great significance as the prerequisite of safe production in roadway engineering. Based on a great number of issues analysis, the research status of roadway surrounding rock stability classification has been dissected from aspects of classification indexes and methods. At the end, it has put forward that choosing scientific and reasonable indexes, applying combined technology with more than three methods, using new technology and new methods are the three development trends of roadway surrounding rock stability classification research.

## Introduction

The roadway field conditions are changeable and uncontrollable, as the main channel it plays an important role in engineering production. Therefore, making out scientifically stability classification become an important subject for industry experts and scholars. Many achievements have been obtained in this area recent years, mainly on classification indexes and methods. The research status of roadway surrounding rock classification has been studied, and the development trends have been analyzed.

## Research status of classification indexes

The selection of roadway surrounding rock stability classification indexes can directly affect the discriminated accuracy of stability type. Based on the influence extent and selection principles, classification index is the main influencing factors extracted from a great many influence factors. The influence factors are roughly divided into natural factors and mining technical factors. Natural factors are mainly the magnitude and direction of ground stress, the strength and characteristics of rock and coal seam, etc., mining technical factors are mainly roadway width and height, the coal pillar width and service life, etc., as shown in table 1.

The selection of roadway stability classification indexes should follow the principles as below:

(1) Importance: when choosing indexes, the more important factors should be considered while the factors with less affect ignored, and the importance of each index must on the same level.

(2) Independence: each index is independent, revealing a certain property with low correlation to others.

(3) Distinguish ability: the sample data of each index should have obvious difference.

(4) Easy availability: the index can be acquired in field or laboratory, and quantitatively assessed.

(5) Definiteness: the index should be fundamental, with simple meaning, not be confused.

(6) Foresight: the index can be obtained by exploration, to providing roadway support references.

Considering the influence degree and the index selection principle, the most commonly used classification indexes are shown in table 2.

Table 1 The influence factors of roadway surrounding rock stability

| Natural factors | | Mining technical factors | |
|---|---|---|---|
| Surrounding rock strength | Roof strength | The roadway section | Roadway width |
| | Seam strength | | |
| | Floor strength | | Roadway height |
| Ground stress | Self-weight stress | | |
| | Maximum principal stress | Mining size | The ratio of mining to caving |
| | The angle between maximum Principal stress and roadway | | |
| Geological characteristics of coal seam | Thickness of coal seam | | Mining height of coal seam |
| | Angle of coal seam | | |
| | Buried depth of coal seam | | |
| Thickness of roof(floor) | Thickness of immediate floor | | The ratio of immediate roof and mining height |
| | Thickness of immediate roof | | |
| | Thickness of main roof | | |
| Integrity of surrounding rocks | Index of rock Integrity | | |
| | Rock quality designation (RQD) | | The ratio of mining height to roadway height |
| | Structural plane(joint fissure) | | |
| | The angle between structural plane orientation and roadway axis | | |
| Characteristics of strata behavior | First caving span of immediate roof | Other factors | Width of coal pillar |
| | First caving span of main roof | | |
| | Periodic weighting span of main roof | | Service life |
| Role of water | Inrush water | | Coal-mining method |

Table 2 The stability classification indexes of roadway surrounding rock

| | |
|---|---|
| Natural index | Roof strength, Seam strength, Floor strength, Buried depth of coal seam, RQD, |
| | Angle of coal seam, First caving span of immediate roof, Inrush water |
| Mining technical index | Roadway width, Roadway height, The ratio of immediate roof and mining height, |
| | Width of coal pillar |

## Research status of classification methods

There are three system methods in roadway surrounding rock stability classification: classification with single index, classification with comprehensive indexes and classification with multi-index, as shown in Fig.1.

**Classification with single index.** Protogyakonov's coefficient of rock strength is defined in protodyakonov's theory based classification method, as shown in formula (1). The roadway surrounding rock is divided into 15 types in the method. Protodyakonov's theory based classification method is simple to use, but could not specify the surrounding rock integrity.

$$f = \frac{\sigma_c}{10} \tag{1}$$

Where $f$ is Protogyakonov's coefficient, $\sigma_c$ is uniaxial compressive strength.

RQD is the short name of rock quality designation, the RQD value is defined in RQD classification method, as shown in formula (2). This method can reflect the surrounding rock integrity, dividing the surrounding rock into five types. It has better practicability, but could not reflect the influence of jointed rock mass.

$$\mathrm{RQD} = \frac{L_1}{L_2} \tag{2}$$

Where RQD is rock quality designation, $L_1$ is the accumulation length of more than 10 cm core, $L_2$ is the length of the drilling.

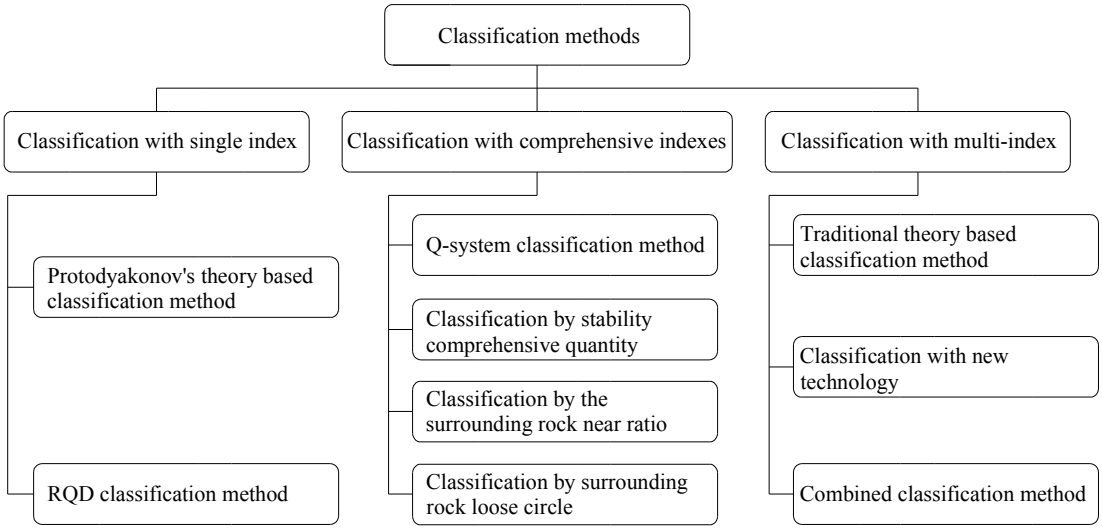

Fig. 1 The stability of roadway surrounding rock classification method

It can be seen that, classification with single index method is simple and easy, widely applied with strong practicability. However, the roadway has complex geological conditions, affected by so many factors that rock joints and fissures, hydrological factors cannot be taken into account with single physical and mechanical index, thus the surrounding rock stability could not be accurately reflected.

**Classification with comprehensive indexes.** The surrounding rock is divided into 9 types by the Q-system classification method, the joint effect is analyzed emphatically, and the comprehensive index Q value is calculated by formula (3). The classification accuracy is improved greatly by the method, as the joint and the ground stress are reflected, but there is some subjectivity in quantitative determination of each index.

$$\mathrm{Q}=\frac{\mathrm{RQD}}{J_{\mathrm{n}}}\times\frac{J_{\mathrm{r}}}{J_{\mathrm{a}}}\times\frac{J_{\mathrm{w}}}{\mathrm{SRF}} \tag{3}$$

Where RQD is quality designation, $J_{\mathrm{n}}$ is the joint number, $J_{\mathrm{r}}$ is the joint roughness, $J_{\mathrm{w}}$ is the joint reduction coefficient of water, $J_{\mathrm{a}}$ is the metamorphic degree of the joint, SRF is the stress reduction coefficient of water.

The stability is divided in to five levels by stability comprehensive quantity method. The surrounding rock comprehensive quantity formula is shown as formula (4).

$$\mathrm{S_g}=\frac{R_{\mathrm{ef}}}{\gamma\times H\times k\times a\times b} \tag{4}$$

Where $\mathrm{S_g}$ is the stability comprehensive quantity, $R_{\mathrm{ef}}$ is effective rock strength, γ is surrounding rock bulk density of, $H$ is buried depth, $k$ is stress concentration factor, $a$ is show coefficient, $b$ is damage coefficient.

The formulas about classification by the surrounding rock near ratio method are shown as formula (5) and (6). It determines the appropriate supporting scheme by the roadway relatively near ratio.

$$\mathrm{K}=0.066H+4.3S_{\mathrm{V}}\times M+24.3\sqrt{G_{\mathrm{L}}}-78\pm0.03 \tag{5}$$

$$\mathrm{U}=2.3\mathrm{K}+3.5 \tag{6}$$

Where K is the relatively near ratio of roof and floor, U is the relatively near ratio of sidewalls, $H$ is buried depth, $S_V$ is filled coefficient, $M$ the mining height, $G_L$ is floor strength coefficient.

Classification by roadway surrounding rock loose circle method divides surrounding rock stability into 6 types according to the loose circle size. The method is easy to operate and widely used, yet there is no analytic expression about the relationship between loose circle size and the influencing factors.

From the analysis above, it can get that with representation and practicability, many influence factors can be comprehensively considered in the composite index of surrounding rock classification method, and a single quantitative comprehensive index is obtained. But in most kinds of the classification with comprehensive indexes method, the indexes focus on several main influence factors that not all the influence factors can be reflected, also, some factors decided by experience would affect the surrounding rock stability judgment.

**Classification with multi-index.** Classification with multi-index method mainly contains traditional theory based classification, classification with new technology and combined classification method, each method consists of variety classification methods, detailed in Fig. 2.

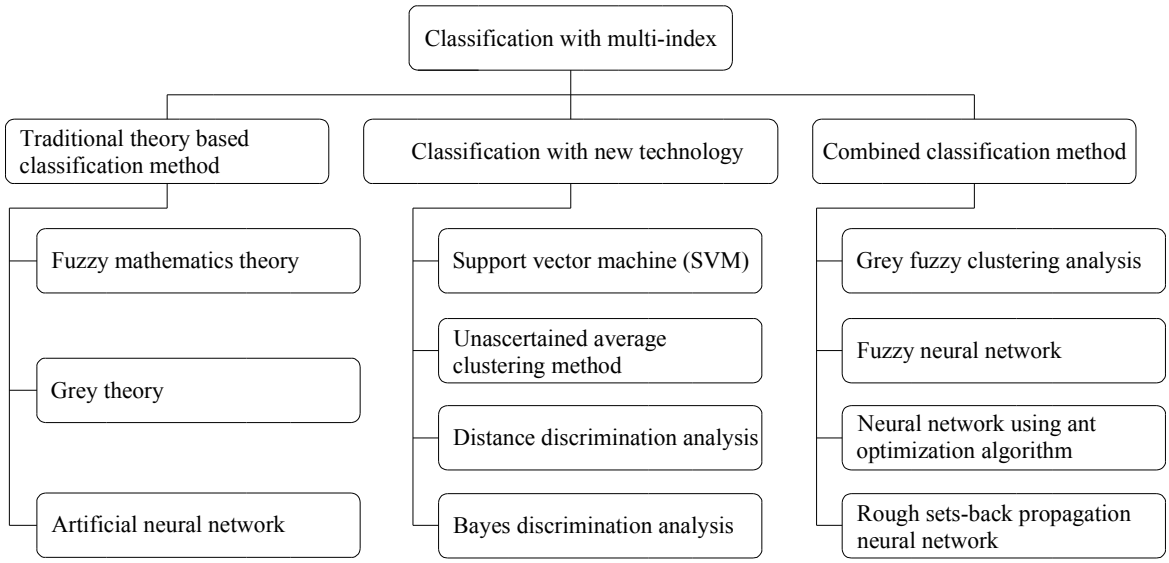

Fig. 2 The multi-index classification method

Traditional theory based classification method contains fuzzy mathematics theory method, grey theory method and artificial neural network method.

With the development of fuzzy mathematics theory, the methods applied in stability classification of roadway surrounding rock are mainly fuzzy cluster analysis, fuzzy discriminatory analysis and fuzzy comprehensive evaluation. First, the seven indexes including dynamic load coefficient were determined, then the surrounding rock stability type in Shenhuo mining was determined base on fuzzy cluster analysis method [1]. The surrounding rock stability fuzzy recognition model was established, and the application instance was studied [2]. The fuzzy comprehensive evaluation was divided into two giant steps, six small steps, with good applicability in Zhengzhou coal group mines [3].

The grey theory is composed by three systems, as shown in figure 3. The grey theory in the stability classification study can be divided as: grey relation analysis, gray model (GM), grey forecasting analysis. Grey relation analysis method is applied to verify the stability classification in Xuzhou mining, and satisfying results were got [4]. The grey model (GM) were established in three steps, on this basis, the new information model GM (1, 1) was got by reducing or increasing new array data, with higher prediction accuracy[5].

Artificial neural network is a highly nonlinear dynamic system with its weights dynamically adjusted by learning and training. The most widely applied one in stability classification of surrounding rock is BP network model, the second widely applied is RBF network model. BP network model is a kind of forward feedback artificial neural network, as shown in Fig. 4. In

Shendong mining roadways, after selecting five classification indexes, the three-layer BP network model was established with its accuracy higher than 95% [6]. RBF network model is three-layer forward artificial neural network, as shown in Fig. 5. In Huangbaici mining engineering, the RBF network classification model was built and expected results gained [7].

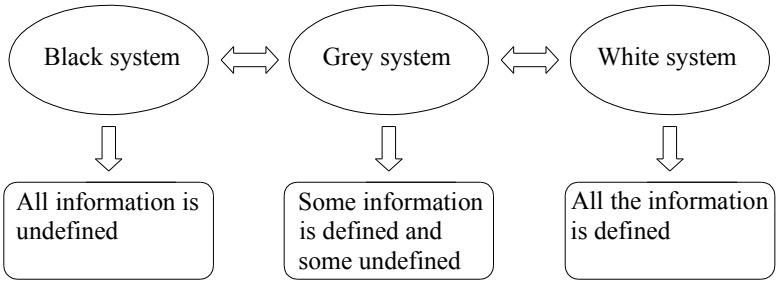

Fig. 3 Three kinds of system

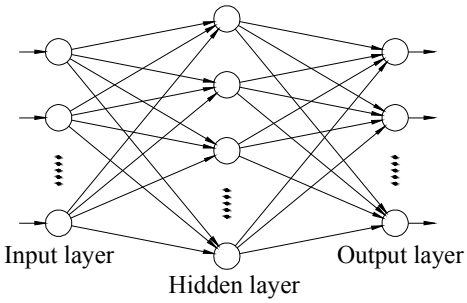

Fig. 4 The structure of BP network model

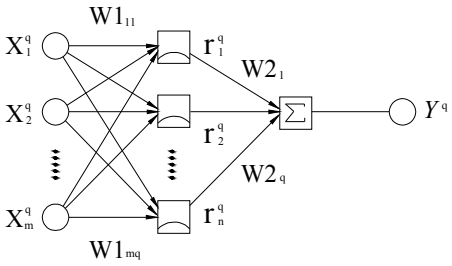

Fig. 5 The structure of RBF network model

Classification with new technology method mainly includes support vector machine (SVM), unascertained average clustering method, distance discrimination analysis and bayes discrimination analysis method. The support vector machine (SVM) classification of one-to-one model was established to classify the mining roadways in Pingdingshan mining [8]. The unascertained average clustering model was established, and the roadway types was accurately predicted [9]. Based on theory of distance discriminant analysis, the corresponding model was built, and practical application showed it had high accuracy in roadway classification [10]. Roadway bayes discriminant model was set up, and the recognition rate was 100% [11].

Combined classification method mainly includes grey fuzzy clustering analysis, fuzzy neural network, neural network using ant optimization algorithm and rough sets-back propagation neural network method. The grey fuzzy clustering analysis model for roadway type identification was established, and applied to the stability classification practice in Jixi mining roadways [12]. The fuzzy neural network model was established, and the practical application proved that the model had faster calculating speed with more accurate classification ability [13]. The neural network model using ant optimization algorithm based on heuristic global optimization was set up, and the stability type of surrounding rock was accurately predicted [14]. The rough sets-back propagation neural network model had high coincidence and tolerance with fast convergence speed, which had been improved in engineering application [15].

The above analysis illustrates that many factors influence the surrounding rock stability, and each one represents a certain property, therefore, choosing main factors as the stability classification indexes is essential for evaluating the surrounding rock stability comprehensively. Classification index is the basis of surrounding rock stability classification, although there is a complicated nonlinear relationship between each index and the surrounding rock stability, the multi-index classification method adopted by the more and more advanced theory technology with high mapping precision, especially the combined methods can foster strengths and circumvent weaknesses, accelerate the operation speed and improve the classification precision.

**Development trends**

(1) Because the stability classification indexes are commonly used as the input part with great importance in stability classification, scientific and reasonable index selection is bound to be one of the development trends in roadway stability classification studies.

(2) Because in the combined methods technology, all the methods can play their advantages and make up the shortcomings of others, ideal classification results can get, what's more, there are still limitations in combined methods that with only two kinds at present, thus combined methods with more than three kinds will become an important development trend in roadway surrounding rock stability research in the future.

(3) With the development of mathematical methods and the improvement of technology, there will be more new technology and methods with more advantages than the traditional, and applying these new technology and methods to surrounding rock stability classification study is the future development trend.

**Keywords:** lining of tunnel, loess cavity, finite element.

**Abstract.** In this article, we focused on changes of mechanical properties in lining of tunnel caused by loess cavity. We established a corresponding model and carried out numerical analysis by using finite element analysis software ADINA, considered the effect of different locations, different size of the cavity and depth of the tunnel. The results showed that change of the mechanical properties has the largest effect on the lining at the arch foot nearby the loess cavity, and it grows with the growth of the cavity‘s size and depth of the tunnel.

## Introduction

A notable feature of the loess in Loess Plateau is the wet collapsibility. When wetted by water, it is likely to collapse. A lot of loess cavities formed by the collapsed loess after rain water infiltration. These loess cavities seriously affect nearby buildings or tunnels. It will be followed by a significant decreased in their mechanical strength. The survey also found that the main factors of tunnel‘s diseases in loess area are the effect of water, especially these cavities changed the force on the lining, severely, it will lead it to deformation, cracking or buckling. For loess tunnel, its lining plays a crucial role.Therefore, analysis changes of mechanical properties of lining of the tunnels in Huangtu Regions taking account of loess cavity is very importent. We focused on changes of mechanical properties in tunnel's lining caused by loess cavity. We established a corresponding model and carried out numerical analysis by using finite element analysis software ADINA, considered the effect of different locations, different size of the cavity and depth of the tunnel.

## Model and Parameters

Calculating model is based on the general loess tunnel, Fig.1 is a cross sectional view of the tunnel. Figure 2 is its finite element model and cell division. The tunnel depth is 12m, lining material of the tunnel is C30 concrete, and the average thickness is 20cm. Mechanical parameters of the lining and loess are shown in Table. We used four-node plane strain parameter unit on the rock, a total of 4,695 units. Lining is divided into 117 beam units. We use cell life and death technology of the finite element method to simulate the appearance of cavity. In the calculation, we assume that the cavity appeared at top, shoulders, waist and arch foot of the lining in the loess (area marked in Fig.2) respectively, and consider the size of the cavity were four grades (25 ~ 30cm, 45 ~ 55cm, 70 ~ 80cm and 95 ~ 100cm).

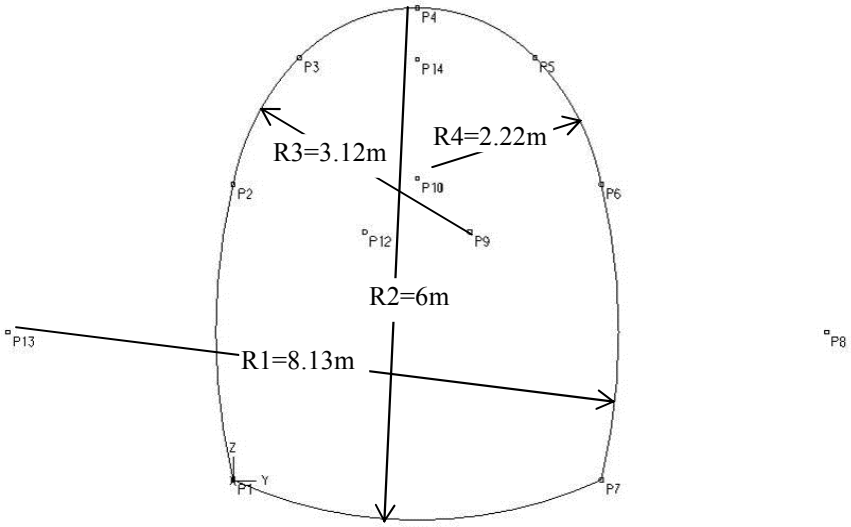

Fig.1 Tunnel section

Table Material Parameters

| | Modulus of elasticity(Pa) | Density($kg/m^3$) | Cohesion (Pa) | Angle of internal friction ($\varphi$) |
|---|---|---|---|---|
| Rock and Soil | 1.5e9 | 1800 | - | - |
| Concrete(C30) | 28.5e9 | 2500 | 0.16e6 | 28 |

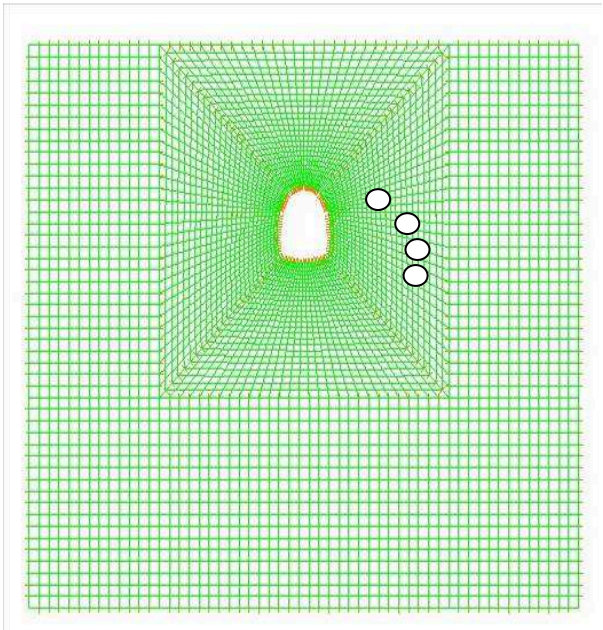

Fig.2 The finite element grids of the model

## Analysis

The results of calculation showed that the appeared cavity destroyed the original force balance on the lining. The internal forces (axial force and bending moment mainly) in the lining has undergone great changes.

**Changes of Internal Forces in the Lining Caused by Different Position and Size of the Cavity.** According to many studies, the main disadvantage of cavity generated is the additional negative axial force and bending moment. The distribution of the additional axial force and bending moment when a cavity appeared at the top of the lining is shown in fig.3.

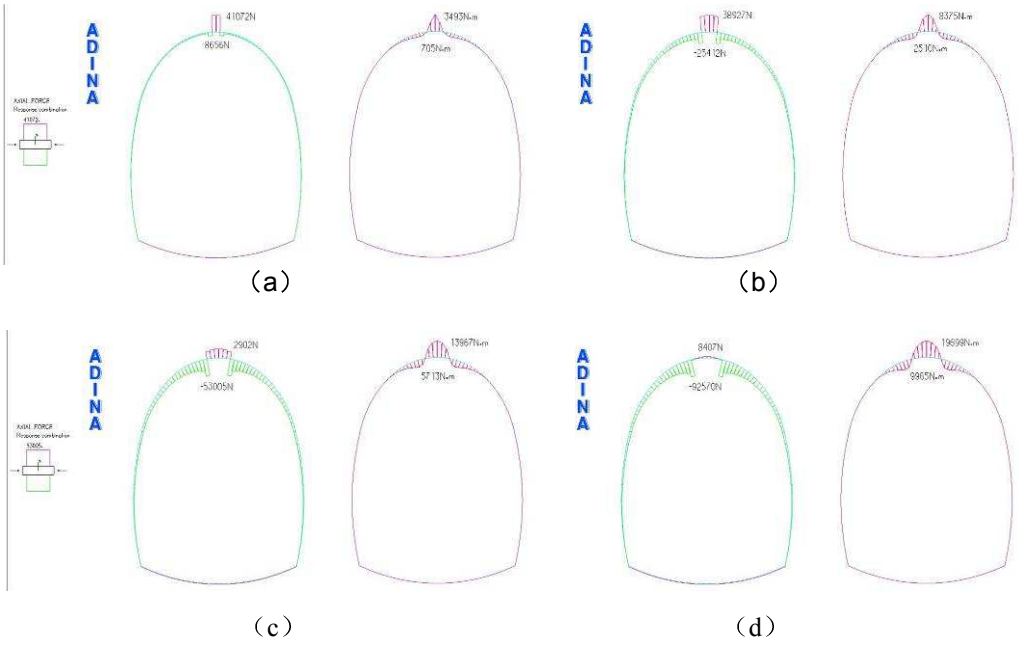

Fig.3 Cavity appeared at the top of the lining

As can be seen, major changes of the internal forces in the lining occur in the vicinity of the cavity. Positive axial force (pressure) occurs in the region appeared cavity, with negative axial force (pull) on sides of it, and negative axial force decreases with the increase of distance of cavity. Additional negative axial force and bending moment are the main disadvantages of the cavity generated.

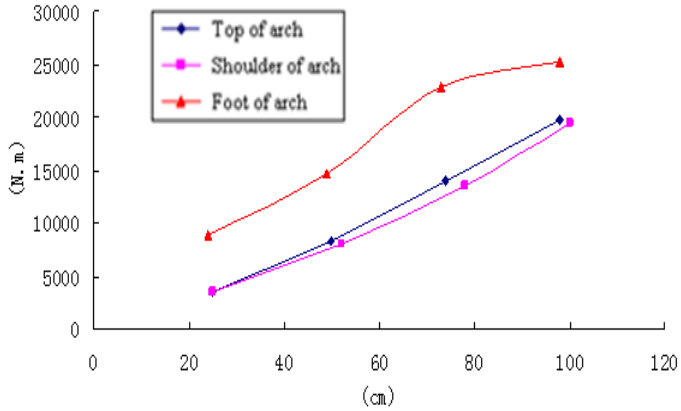

Fig.4 The relationship between additional moment and cavity size at different locations

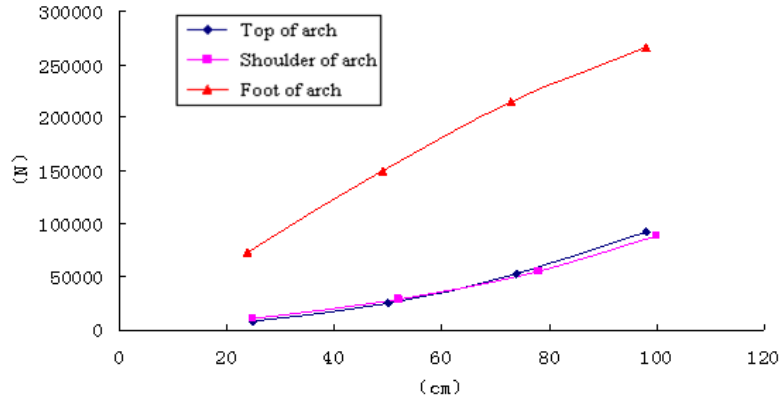

Fig.5 The relationship between additional axial force (pull) and cavity size at different locations

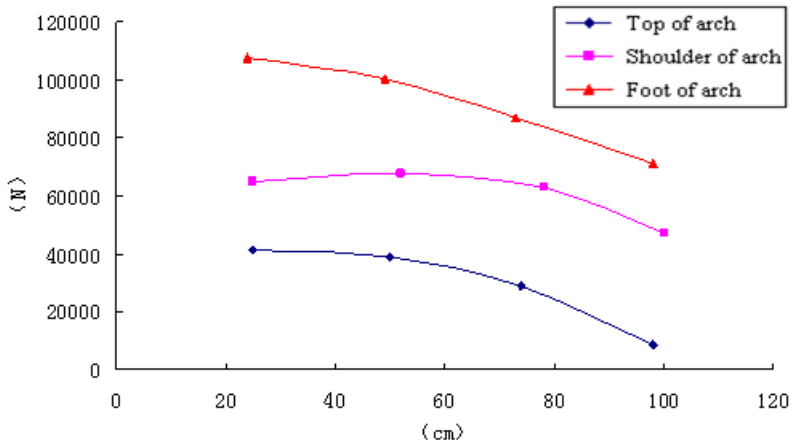

Fig.6 The relationship between additional axial force (compress) and cavity size at different locations

Fig.4, 5 and 6 illustrated that the additional moment and negative axial force (pull) are increased with the increases of the cavity, but a positive axial force (compress) is the opposite. It can be seen, the larger the hole, the more unfavorable for tunnel's safety. It also can be seen the additional internal forces at lining vault, spandrel and foot of the arch generated by the cavity are more than arch waist, bottom of the arch. This point should be noted.

**Changes of Internal Forces in the Lining Caused by Different Depths of the Tunnel.** Considering the tunnel depth at 12m, 20m, 30m, 40m and 50m, and the size of cavity appeared at the top of lining is 50cm. Changes of internal forces in the lining caused by different depths of the tunnel is shown in Fig.7.

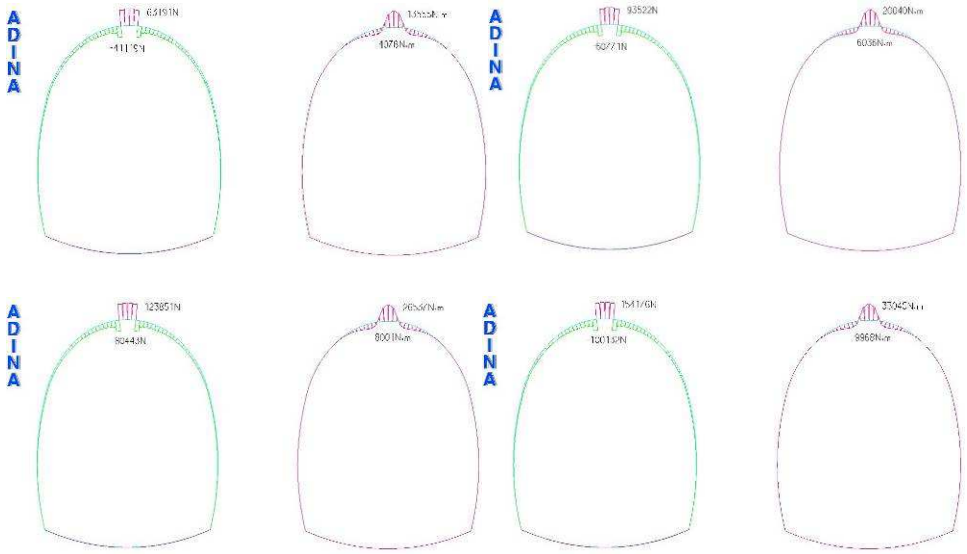

Fig.7 Changes of internal forces in the lining caused by different depths of the tunnel

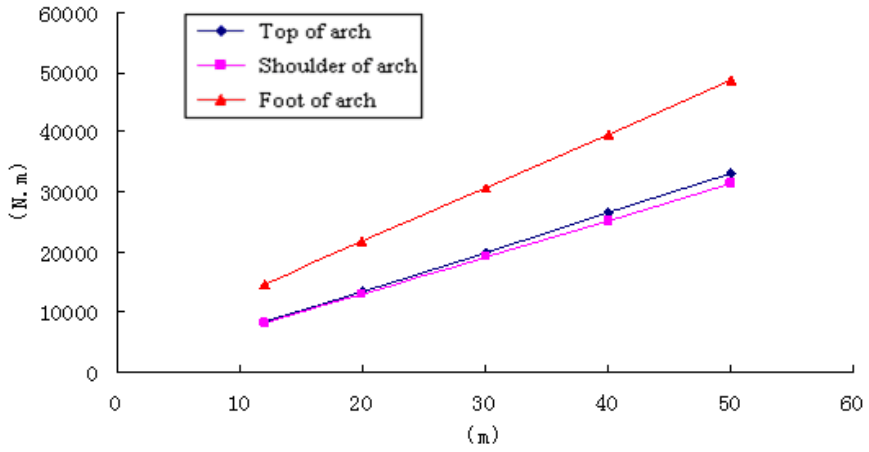

Fig.8 The relationship between additional moment and depths of the tunnel at different locations

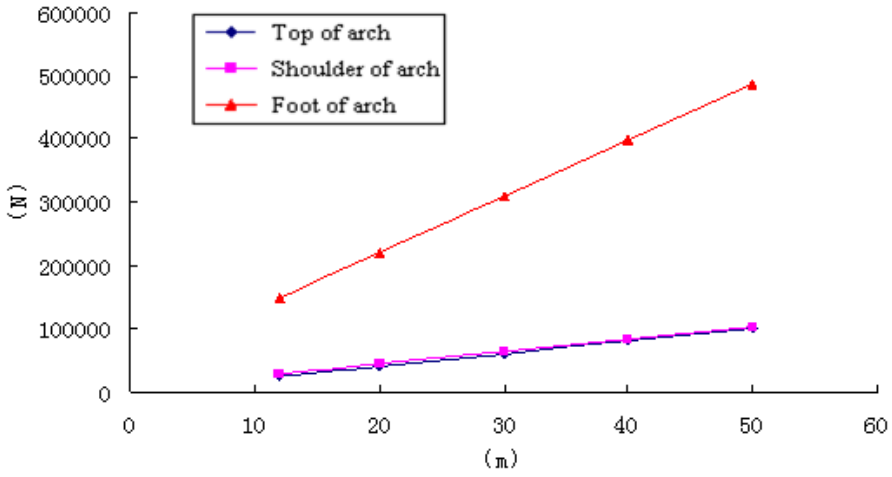

Fig.9 The relationship between additional axial force (pull) and depths of the tunnel at different locations

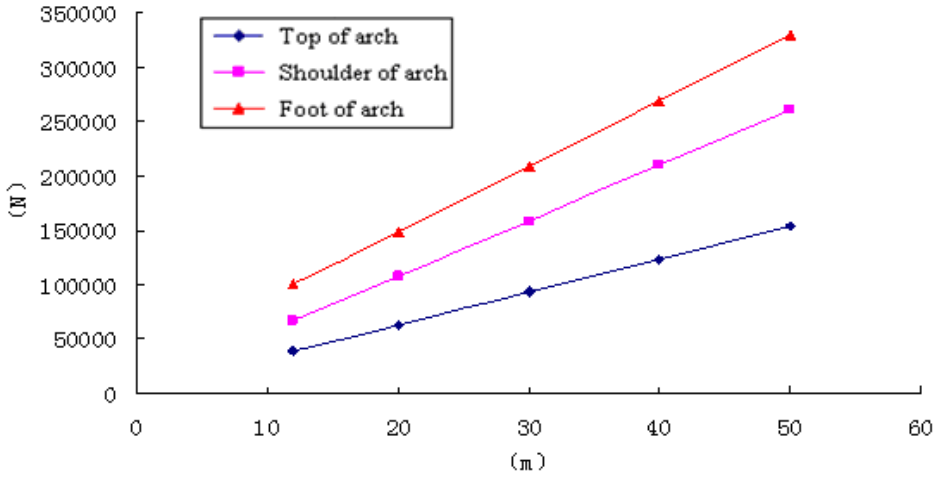

Fig.10 The relationship between additional axial force (compress) and depths of the tunnel at different locations

We can see that the relationship between maximum of additional internal forces and depth of the tunnel is substantially linear, and effect of depth of the tunnel is basically the same when cavity at the dome and spandrels, but with a greater impact on the foot of the arch.

## Conclusion

Due to the loess's nature of the wet collapsibility, it is easy to collapse to produce cavity behind the lining of the tunnel. Cavity changed the mechanical properties of the lining. Through the analysis, we found that different locations, size of the cavity and depth of the tunnel are the main factors affecting the mechanical properties of the lining, and the larger the cavity, the greater the depth of the tunnel, and the lower location of the cavity, the greater the mechanical effects of the cavities on the lining of the tunnel.

**Keywords:** Surrounding Rock Deformation. Fractured Surrounding Rock. Physical and Mechanical Characteristics. Supporting of Roadway.

**Abstract.** Since the excavation of roadway in Shuguang mine No.2 mining area, shotcrete layer has fallen off and the surrounding rock deformation was serious. For studying big deformation of roadway in Shuguang mine No.2 mining area, the paper analyzed fractured surrounding rock physical and mechanical characteristics of No.2 mining area. The results show that the uniaxial compressive strength, uniaxial tensile strength, cohesion, internal friction angle of fractured surrounding rock were very low. And the whole physical and mechanical characteristics were poor. It is the basic reason of big deformation of roadway surrounding rock physical and the important basis of late supporting of roadway.

## Introduction

The design length of rail roadway in Shuguang mine No.2 mining area is 4000m. The service life is 30a. The buried depth is about 500m. The section shape of roadway is vertical wall-round arch with drivage width 4.94m, clear width 4.7m, vertical wall height 1.6m, drivage circular arch radius 2.47m, clear width 2.35m, drivage sectional area 16.99m$^2$, clear sectional area 15.72m$^2$. The purpose of roadway drivage is to meet raw coal transportation, ventilation, traffic, pipeline laying. Due to sedimentary environment, the variation in thickness of 2# upper coal seam is bigger in 1.27~2.48m. The average is 1.73m. The 2# lower coal seam that the thickness is 0~0.94m is local seam. The average is 0.40m. The thickness of mudstone which is parting is 0.8~1.25m. The floor of coal seam is fine sandstone, mudstone or shale. The dip of 2# coal seam is 0~10º and the coefficient of hardness f is 0.6.

Since the excavation of roadway in Shuguang mine No.2 mining area, due to 2# coal of roadway sides with low strength, shotcrete layer has fallen off and the surrounding rock deformation was serious. Surrounding rock of rail roadway damaged diagram is shown in Fig. 1 In order to optimize the support scheme of roadway, reduce the deformation of roadway surrounding rock, maintain the stability of roadway, to physical and mechanical properties test of crushed surrounding rock of roadway, the paper tested and analyzed fractured surrounding rock physical and mechanical characteristics for solving the problem of big deformation of surrounding rock of roadway fundamentally.

Fig. 1. Surrounding rock of rail roadway damaged diagram

## Experimental Preparation

**Experiment Content.** The experiment tests the density, uniaxial compressive strength, elastic modulus, Poisson ratio, uniaxial tensile strength, cohesion, internal friction angle of roadway surrounding rock of immediate roof, sides, immediate floor, and old floor.

**Sample collection.** Sample collection is according to the national standard "Methods for determining the physical and mechanical properties of coal and rock-Part 1: General requirements for sampling" GB/T 23561.1 2009.

The samples used in the experiment were taken from immediate roof, sides, immediate floor, old floor of rail roadway in Shuguang mine No.2 mining area. Due to high ground pressure, the drilling core forming difficulty, we collected uniform mechanical properties, appropriate size, complete block samples to the lab and made into standard specimen [1].

**Specimens Fabricating.** Sample fabricating is according to the specimen processing standard of the national standard "Methods for determining the physical and mechanical properties of coal and rock" GB/T 23561.1-2009 ~ GB/T 23561.16-2010.

Standard specimen fabricating equipment are diamond machine, stone sawing machine, grind stone machine. We has made 45 specimens that 20 specimens for uniaxial tensile test with φ50mm×25mm size and 25 specimens for uniaxial compressive test and triaxial compressive test with φ50mm×100mm size.

**Experimental Instruments.** The main experimental instruments have diamond machine, stone sawing machine, grind stone machine, grinder, vernier caliper, PGC-753e electronic balance, extensometer, XTYE-2000 hydraulic pressure tester.

## Experimental Scheme

Specimen density: The actual diameter and the actual height of the specimen were measured with a vernier caliper. The mass of the rock samples were measured with Adem PGC-753e electronic balance. Then using the formula to calculate density of each test piece, so the average density of the sample was

Uniaxial tensile strength, uniaxial compressive strength, triaxial compressive strength: The uniaxial tensile strength of the specimen were tested by the XTYE-2000 type of hydraulic pressure experiment machine. The loading method was displacement loading. The speed of it was 0.002mm/s, and the interval of experimental data acquisition was 5ms.

## Experimental Process

All the specimens was checked the name and number packets, and checked the machining accuracy and measurements before measured. The specimen color, grain, bedding, joints, cracks, degree of weathering, moisture status and processing problems was described.

**Testing Density of Specimen.** The actual diameter and the actual height of the specimen were measured with a vernier caliper. The mass of the rock samples were measured with electronic balance. Each specimen tests three times, calculating the average.

**Testing Uniaxial Tensile Strength of Specimen.** Uniaxial tensile strength was measured by split tests.

Through both ends of the specimen diameter, draw a straight line along the axis parallel to each other as two loads at baseline, the two pads of the load along the baseline with a rubber band fixed at both ends of the specimen.

Starting pressure testing machine and adjust the pressure system to a working state. The pad assembly of the specimen placed in a pressure plate bearing test machine center, and adjust the spherical seat, so that uniform bearing the specimen, of the pad, the center line of the centerline of the specimen and pressure testing machine in a straight line, and in the specimen plus the protector.

Starting pressure experiment machine, testing machine using displacement control. Pressure is applied to the specimen 0.1kN~0.5kN, and then the speed 0.002mm/s and uniformly loaded continuously until the destruction of the sample up. Specimens should eventually destroy the plane by two pads of the decision, or should be considered invalid experiment.

After the experiment is completed, immediately remove the specimen failure, and sealed with a plastic bag. Fig. 2 (a) shows destroyed specimens after split test loaded.

a. Uniaxial tensile test b. Uniaxial compressive test c. Triaxial compressive test

Fig. 2. Failure sample after pressure experiment

**Testing Uniaxial Compressive Strength of Specimen.** The extensometer to measure the axis and radial strain when loading on the specimen should be properly installed.

Starting the pressure testing machine, and adjusting the pressure system to a working state. The specimen should be placed at the center of the bearing plate of the pressure testing machine, and adjusting the spherical seat to make sure that the centerline of the pressure testing machine, the upper and lower bearing plate, and the specimen are in a straight line, not eccentric. We should make sure the specimen's upper and lower are exerted by uniform force, meanwhile adding a protector outside the specimen. The experimental loading method is as same as the splitting experiment.

After the experiment is completed, immediately removing the damaged specimen, and sealed with a plastic bag. The destroyed specimens under the uniaxial compressive test are shown in Fig. 2 (b).

**Testing Triaxial Compressive Strength of Specimen.** Wiping the two end surface of cushion block. The specimen is placed between the upper and lower pads, so that the three centers was in a straight line. Then the specimen and cushion block were put on Anti - oil sets. The specimen were sealed with a rubber band or sealing tape. The extensometer that measuring specimen axis and radial strain during the loading were properly installed on the specimen. The pad is then placed in the lower part of the center of pressure chamber base, having a good piston pressure chamber cover. Then put the pressure chamber of the specimen placed on a material testing machine, and between the platen, and to the upper and lower pressing plate axis coincides with the axis of the pressure chamber.

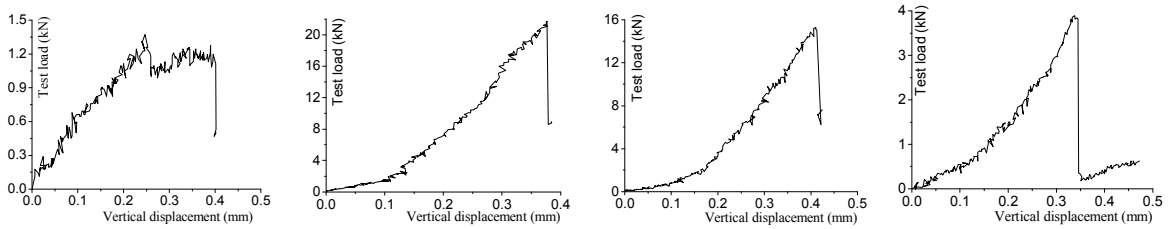
Starting pressure testing machine, and applying pressure 0.1kN~0.5kN to fixed specimens. Then open the pressure chamber vent, start side pressure pump, oiling the pressure chamber, exhaust air while oiling, when the air pressure chamber drain and tighten the vent.

Axial loading, when the pressure is stable between 2kN~10kN, extensometer readings to make adjustments to 0, the starting point as a contingency measure. And then 0.5MP/s loading rate longitudinal load is applied stability until the specimen damage, note the failure load values. After unloading the specimen was removed, and record the damage situation then sealed with a plastic bag. Fig. 2 (c) shows the failure specimens after loading triaxial compression [2-3].

## Experimental Results

Through testing, the basic physical parameters of specimen are shown in Table 1.

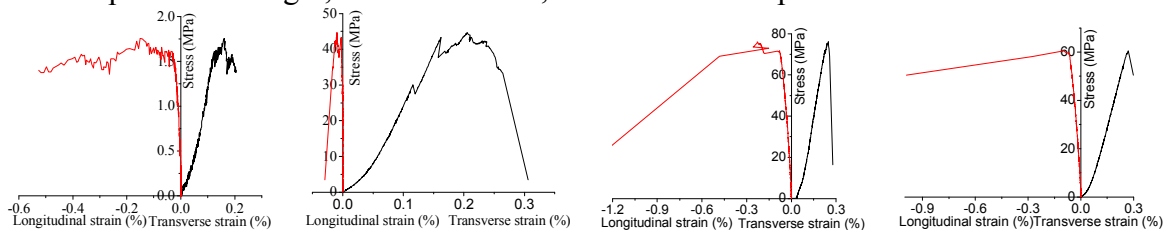
Through testing, the test load-vertical displacement curves are shown in Fig. 3. The uniaxial tensile strength of specimen are shown in Table 1.



a. 2#coal of sides b. sandy shale of immediate roof c. sandy shale of immediate floor d. sandy shale of old floor

Fig. 3. Test load-vertical displacement curves of some samples

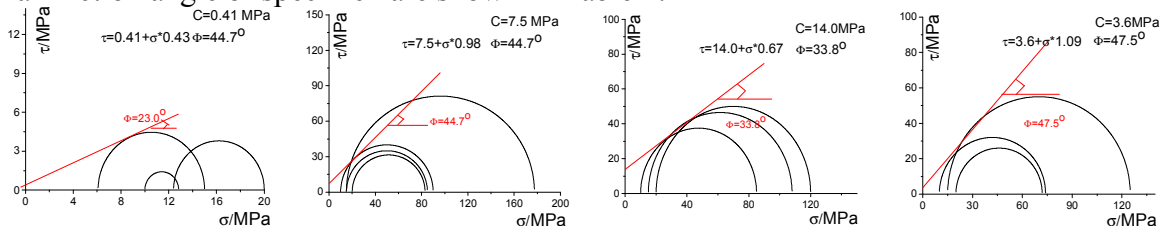
Through testing, the complete stress-strain curves under uniaxial pressure are shown in Fig.4. The uniaxial compressive strength, elastic modulus, Poisson ratio of specimen are shown in Table 1.



a. 2#coal of sides b. sandy shale of immediate roof c. sandy shale of immediate floor d. sandy shale of old floor

Fig. 4. Complete stress-strain curves under uniaxial pressure of some samples

Through testing, the Mohr's circle are shown in Fig.5. The triaxial compressive strength, cohesion, internal friction angle of specimen are shown in Table 1.



a. 2#coal of sides b. sandy shale of immediate roof c. sandy shale of immediate floor d. sandy shale of old floor

Fig.5. Mohr's circle

## Conclusions

Through laboratory test, the paper analyzed fractured surrounding rock physical and mechanical characteristics of No.2 mining area. The physical and mechanical parameters of surrounding rock are shown in Table 1. The Table 1 shows that the strength of coal of sides is poor and very fractured. And it is the key of the roadway supporting. The roadway support strength should be strengthened overall, especially the sides in late supporting.

Table 1 Physical and mechanical parameters of surrounding rock of No.2 mining area rail roadway in Shuguang mine

| Lithology | Position | P(kg/m³) | σ(Mpa) | $\sigma_t$(Mpa) | E(Gpa) | μ | Φ(°) | C(Mpa) |
|---|---|---|---|---|---|---|---|---|
| Coal | Sides | 1.521E+03 | 4.720 | 0.355 | 4.250 | 0.310 | 23.0 | 0.4 |
| Sandy shale | Immediate roof | 2.628E+03 | 106.614 | 9.277 | 41.743 | 0.432 | 44.7 | 7.5 |
| Sandy shale | Immediate floor | 2.658E+03 | 78.037 | 7.594 | 42.918 | 0.456 | 33.8 | 14 |
| Sandy shale | Old floor | 2.628E+03 | 68.004 | 1.544 | 39.481 | 0.367 | 47.5 | 3.6 |

# Finite Element Analysis on Causes of Crack in Large Underground Garage

Bin SHU[1] and Jianhe PENG[2]

[1,2]Anhui and Huaihe River Water Resources Research Institute, Bengbu Anhui, China

492582452@qq.com

**Keywords:** underground garage; crack; finite element method; underground water; expansive soil

**Abstract:** The paper aims to solve the serious and regular crack problems in underground garage. ANSYS finite element software is applied to set up the overall finite element model on floor-foundation and foundation coupling beam-foundation soil in underground garage. Combined with engineering field detection, factors influencing underground garage floor like underground water level, soil expansion caused by water content change in expansive soil, soil poisson ratio, foundation settlement are taken into consideration to find out the causes of cracks. The study is expected to provide reference for similar cases in other projects.

## Introduction

At present, numerical methods like finite element methodand finite difference method, which can deal with complicated boundary and work out high nonlinear problems, have been widely applied to concrete crack analysis. In recent years, due to relatively accurate analysis of the whole process of concrete structure from loading to failure, finite element method can be used to fix the important data like cracking loadand failure load. It can help to do performance evaluationwhen macro cracks exist in present structure, and help to describe and predict propagation characteristicsof the cracks as well[1]. ANSYS finite element software has been applied to do static calculation for the workshopstructure of a power plant, to get the stress and displacement responseof concrete members in generator floorand finally help to analyze the causes of cracks in generator floor of the workshop. Taking reference from the case, this study adopts large general finite element software ANSYS[4-6] to analyze the static force of the running underground garage, to calculate the strain, stress and displacement response with interaction of different loads under running condition, and to explore the causes of concrete cracks in underground garage. The study is expected to provide reference for designing and engineering of similar garages.

## Engineering survey

### 1.1 Site engineering geologic conditions

The geomorphic units of the site are hilllock and clough landform, with mainly clay of late quaternary renewal period（Q3）and partly silty clay of shorter depositional time on clough landform. The whole overburden layer is 28m in thickness, and bedrock strong-weathered zone is 7m in thickness. The engineering site is originally farmland with a fish pond in, featured with soft soil and rich underground water. From top to bottom, the stratum distributes in the following way: ①miscellaneous fill； ② powder clay; ③ clay; ④ clay.

### 1.2 Structure layout

The underground garage is round in shape. The base coupling beam at the bottom of the floor is formed by circumferential ring beam and radial coupling beam.The separate base under the poles is directly connected with base coupling beam and floor. The thickness of the floor is 300mm, and it changes to 400mm when the radius turns more than 57.8m. As for the structure layout of the floor, base and base coupling beam, see Fig 1.

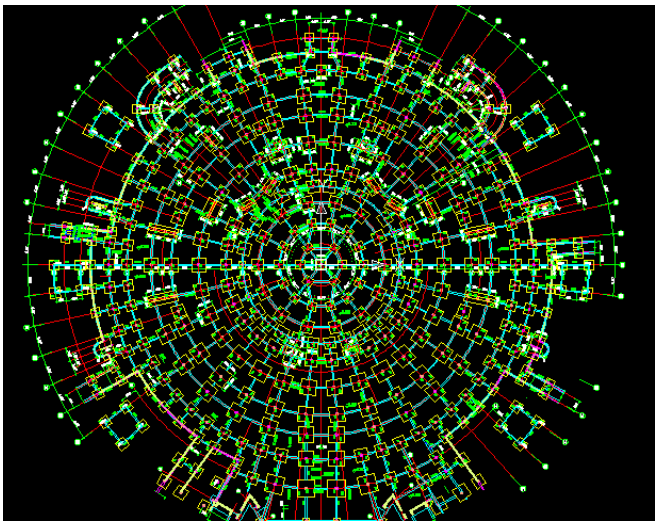

Fig 1 Structure layout of the floor, base and base coupling beam

## Field detection

### 2.1 Crack description

Through detection, there is no crack on poles and beams of first layer. Stripping cracks on wall body of the basement, it can be found that it is surface powder layer that cracks.

Cracks are common in leveling blanket on floor surface, and the most serious cracking lies in the area with radius between 44.6m and 57.8m. Cracks distribute in circumferential and radial way, and most lie in the middle of the floor. The width of crack surface ranges from 0.05mm to 0.2mm.

Through field straddle coring detection, it can be found that cracks are broad on the top and narrow in the bottom. Of 14 sample cores, 12 belong to sloping layer cracks and 2 extend to structure layer of the floor. From sample core surface, he width of cracks in structure layer is less than 0.05mm.

### 2.2 Structure testing

(1) The size of cross section of sampled frame beam can basically meet the design requirement. The appearance is in good condition with no defect like bare bars, voids or pores.

(2) The inferred value of concrete strength of the sampled basement poles ranges from 35.6MPa to 44.5MPa, which meet the requirement of design strength level C35. The inferred value of concrete strength of the sampled beams in first floor ranges from 31.5MPa to 45.4MPa, which meet the requirement of design strength level C30.

(3) The main bars configuration of sampled poles and frame beams, as well as the stirrup configuration in both encryption area and non-encryption area of poles and beams, all meet the design requirement.

### 2.3 Field monitoring

(1) According to the field situation, 3 water-level monitoring holes, namely, hole 1#, hole 2#, hole 3# are set up outside the underground garage. Throughout a rainy season, the water level of hole 1#

becomes 3.38~4.15m higher than the floor, the water level of hole 2# becomes 3.62~4.06m higher, and the water level of hole 3# becomes 2.81~3.78m higher. Monitoring result indicates that underground water level has relationship with surface water.

(2) In cracking area, select some frame poles and floor sample to take settlement observation. No settlement phenomenon is found, which indicates that the construction has been stable in settlement. The deformation of the basement floor has no obvious relationship with the changes of underground water level.

## Establishment of finite element analysis model

On the basis of engineering quality testing result, in order to further analyze the causes of floor cracks, ANSYS software is applied to take simulation analysis for floor-base and coupling beam-soil body structure system. Proper elements are selected to set up a 3d integral model. Factors like head pressure, poisson ratio, expansion ratio and expansion thickness of expansive soil, etc. are taken into consideration. Under different engineering conditions, the stress and strain state of the structure system is analyzed to explore the causes of floor cracks.

### 3.1 Calculation parameters

The physical and mechanical parameters of the floor, base, coupling beam and bottom soil are listed in Table 1.

Table 1 Physical and mechanical parameters of materials

| Item | Bulk density KN/m$^3$ | Elastic modulus MPa | Poisson ratio | Tensile strength MPa | Compressive strength MPa |
|---|---|---|---|---|---|
| C35 Concrete | 23 | 31500 | 0.27 | 1.57 | 16.7 |
| ③$_2$ Clay | 19.5 | 17.5 | 0.2~0.35 | / | / |

Partial coefficients are not considered in load. Pulling stress is positive while compressive stress is negative. The model adopts cartesian right coordinate with x and y as horizontal coordinate axis and z as vertical coordinate axis.

### 3.2 Calculation cases

（1）Underground water level: calculate the head pressure when water level reaches 1m, 2m, 3m, 4m, 5m respectively.

（2）Expansive soil: consider the combination of different values of volume expansion ratio, expansive thickness and poisson ratio: (1)when volume expansion ratio reaches 1%, 1.5%, and 3% ; (2)when the expansive thickness of clay layer ③2 reaches 1.5m, 3m, and 5m; (3)when poisson ratio of clay layer ③2 reaches 0.35, 0.3, 0.25, and 0.2.

### 3.3 Foundation settlement

Loaded by upper structure, the foundation settles with the floor and presses the ground. Therefore, convert the upper structure load on top of foundation as 150 KN/㎡.

### 3.4 Model specification

In this project, floor, foundation, coupling beam and soil body all adopt 3d 4 nodes tetrahedron element. The bottom of ③2 clay layer is constrained in three directions, and the surrounding boundary of ③2 clay layer is constrained in-plane.

## Calculation result analysis

### 4.1 Effect of foundation settlement

Through calculation and analysis, the max value of principal stress of floor is around 0.6MPa, with larger value in the range of 0.35MPa to 0.55MPa. The result can be seen in Fig 3. Therefore, according to the principal stress, under the single influence of structure gravity, foundation settlement has slight possibility to cause floor cracks.

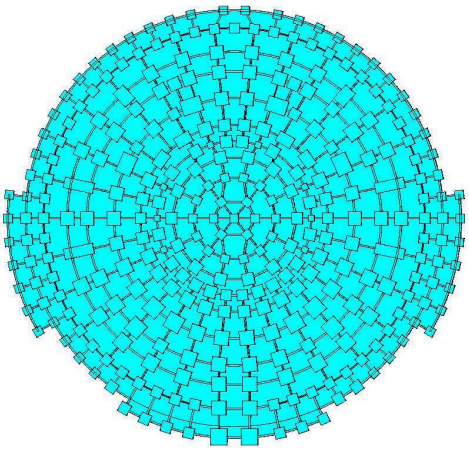

Fig 2 Structure model of floor, foundation and foundation coupling beam

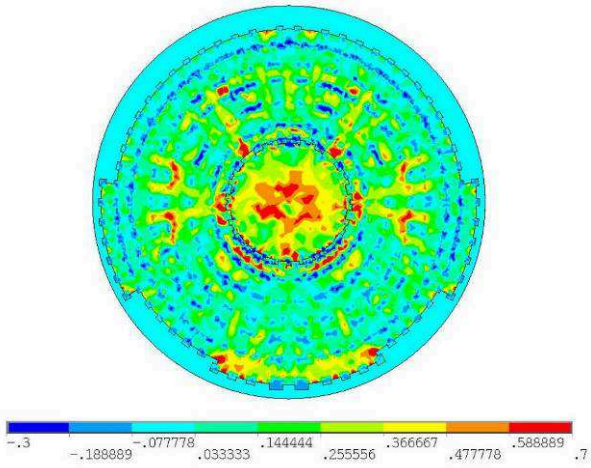

Fig 3 Distribution map of principal stress of floor structure $\sigma_1$ in foundation settlement

### 4.2 Effect of underground water on underground garage

Underground water is an important factor to influence the force on floor. Set the designed water level as 1m, and in engineering, take dewatering measure if water level reaches higher than 1m. Through testing underground water, it is found that underground water can reach as high as 4.15m, which is far beyond the designed level.

Five water heads are considered in calculation. The extreme value of floor stress under different engineering situations can be seen in Table 2.

Calculation result shows: under different underground water pressure, the maximum pulling stress in x, y direction and the maximum of principal stress $\sigma_1$ mainly lie in the middle part of the floor divided by coupling beams with radius between 44.6m and 57.8m. When water head is higher than 4m, the maximum of principal stress $\sigma_1$ reaches beyond 1.57MPa in some areas, which is beyond C35 concrete tensile strength. Detailed results can be seen in fig 4. When water head is higher than 5m, the maximum of principal stress $\sigma_1$ reaches beyond 1.57MPa in many areas. Detailed results can be seen in Fig 5.

Table 2 Extreme values of floor stress under different engineering situations

| Engineering situation / Results | | | 1m Water head | 2mWater head | 3mWater head | 4mWater head | 5mWater head |
|---|---|---|---|---|---|---|---|
| Extreme values of floor stress (MPa) | Pulling stress | $\sigma_{xx}$ | 0.42(few) | 0.6 | 0.9 | 1.1 | 1.5 |
| | | $\sigma_{yy}$ | 0.46 | 0.6 | 0.9 | 1.1 | 1.5 |
| | | $\sigma_{zz}$ | 0.12 | 0.15 | 0.25 | 0.4 | 0.5 |
| | compressive stress | $\sigma_{xx}$ | 0.46 | 0.9 | 1.4 | 1.8 | 2.3 |
| | | $\sigma_{yy}$ | 0.5 | 1.0 | 1.6 | 2.2 | 2.5 |
| | | $\sigma_{zz}$ | 0.25 | 0.5 | 0.8 | 1.0 | 1.4 |
| | Principal stress | $\sigma_1$ | 0.6 | 0.7 | 1.0 | ⩾1.57 (few) | ⩾1.57(many) |
| | | $\sigma_2$ | -0.55 | -1.1 | -1.8 | -2.5 | -3.0 |

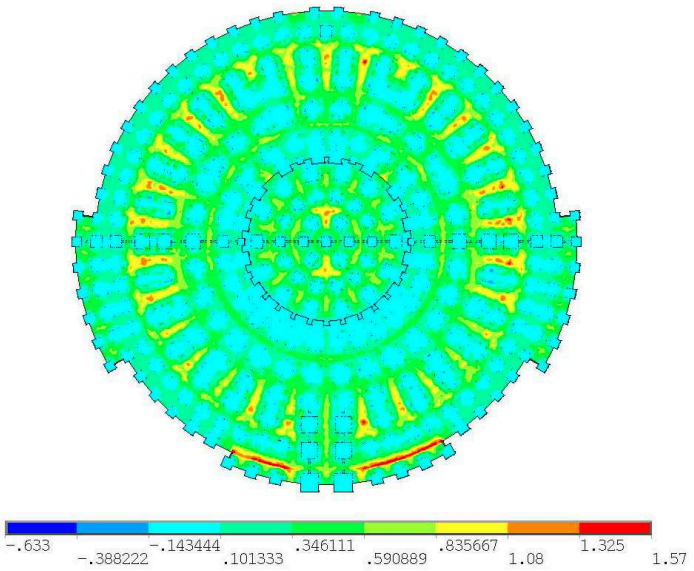

Fig 5 Distribution map of principal stress of floor structure $\sigma_1$ in 5m water head

### 4.3 Effect of expansive soil on underground garage floor

Different expansive ratio, expansive thickness and possible poisson ratio of the soil are considered. The extreme values of principal stress under different engineering situations can be seen in Table 3. Detailed analysis is as follows:

（1）When the floor structure is under the effect of expansive force with different expansive ratio, the maximum pulling stress in x, y direction and the maximum principal stress mainly locate in the middle part of the floor divided by coupling beams with radius between 44.6m to 57.8m. When the poisson ratio is 0.35 and the volume expansive ratio of the floor becomes 1.5%, in many areas the maximum value of principal stress $\sigma_1$ becomes over 1.57MPa; when the expansive ratio reaches 3%, in most areas the maximum value of principal stress $\sigma_1$ becomes over 1.57MPa. The areas where the principal value is beyond C35 concrete compressive strength(1.57MPa) mainly locate in the middle part of the floor divided by coupling beams and many locate in the floor with radius between 44.6m to57.8m. When the poisson ratio is 0.3 and the volume expansive ratio of the floor becomes 1.5%, cracking tales place in a few areas; when the expansive ration reaches 3%

cracking tales place in many areas. When poisson ratio is or less than 0.25 and the expansive ratio is 1.5%, most principal stress is less than 1.57MPa with little possibility to crack; when the expansive ratio is 3%, in many areas of the middle part of the floor divided by the coupling beams, the principal stress is over 1.57MPa with more possibility to crack.

（2）Displacements in x, y directions of the floor structure are slight. Displacement in z direction is comparatively more obvious, with maximum value between 0.7mm to 2mm locating in the floor of radius between 44.6m to 57.8m. Displacement in z direction may cause concrete cracking in upper leveling blanket.

Above all, if expansive soil pressure is only considered, when the volume expansive ratio reaches 1.5% to 3%, the floor structure may crack in some parts or in most areas.

Table 3 Extreme values of principal stress under different engineering situations

| Item \ Engineering situation | | | Poisson Ratio | | | |
|---|---|---|---|---|---|---|
| | Expansive thickness | Expansive ratio | 0.35 | 0.3 | 0.25 | 0.2 |
| Extreme values of principal stress (MPa) | 5m | 1% | ≥1.57 few | 1.1 | / | / |
| | | 1.5% | ≥1.57 many | ≥1.57 a few | ≥1.57 few | 1.4 |
| | | 3% | ≥1.57 many | ≥1.57 many | ≥1.57many | ≥1.57 many |
| | 3m | 1% | ≥1.57 few | 1.0 | / | / |
| | | 1.5% | ≥1.57 many | ≥1.57 a few | ≥1.57 few | 1.3 |
| | | 3% | ≥1.57 many | ≥1.57 many | ≥1.57 many | ≥1.57 many |
| | 1.5m | 1% | ≥1.57 few | 1.0 | / | / |
| | | 1.5% | ≥1.57 many | ≥1.57 a few | ≥1.57 few | 1.25 |
| | | 3% | ≥1.57 many | ≥1.57 many | ≥1.57 many | ≥1.57 many |

### 4.4 Effect of foundation settlement, water head pressure and expansive soil on underground garage floor

Through calculation and analysis, water head pressure and soil expansion caused by water content change in ③2 clay layer are possible reasons for cracks in underground garage floor. The rise of underground water level causes the increase of water head pressure, which further leads to the increase of water content in ③2 clay layer. These elements are mutual influenced to take effect. Meanwhile, the effect of the foundation settlement and pressure on foundation soil as loaded by upper structure can be neglected.

Therefore, it is of necessity to take integral consideration of foundation settlement, water head pressure and soil expansion caused by water content change in clay layer to study the strain and stress of underground garage floor and foundation in skirt building. In the calculation, the upper structure load on foundation top is converted to 150KN/m2; foundation floor is supposed to be subjected to 5m water head pressure; in 1.5m under foundation floor the volume ratio of the soil is supposed to be 1%. Calculation result can be seen in Fig 6. The result shows, the principal stress in many areas of the floor with radius between 44.6m to 57.8m is over 1.57MPa, which may cause cracking in many areas.

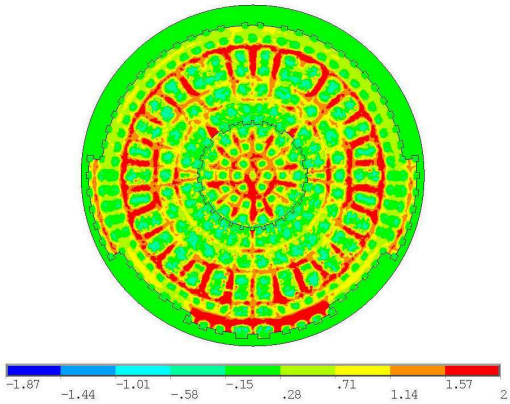

Fig 6 Distribution map of $\sigma_1$ in the floor with co-effect of foundation settlement, underground water pressure and expansive soil (1% expansion ratio)

### 4.5 Integral analysis

Integral analysis under different engineering situations shows, under the single effect of foundation settlement caused by the dead weight of upper structure, it is of slight possibility to crack in larger area of the floor; under the co-effect of foundation settlement caused by the dead weight of upper structure and higher water pressure, the foundation floor cracks; besides foundation settlement and higher water pressure, with extra effect of expansive soil, even if the expansion ratio is only 1%, cracks would become common. The calculation result coincides with the field testing result in distribution rule and position of cracks. The floor cracking has intimate relationship with rich underground water and higher water level, which is the main reason for floor cracking.

## Conclusion

The engineering quality of underground garage is a complicated problem with practical significance. This paper starts from practical engineering background, through field quality testing, adopts finite element method to study the mechanical properties of floor-foundation and foundation coupling beam-foundation soil structure system. It studies the strain and stress of the floor in different engineering situations with effect of underground water level, soil expansion caused by water content, poisson ratio and foundation settlement, and it analyzes the causes of the cracks in underground garage floor. Through calculation and analysis, the following conclusion can be drawn:

1. Effect of underground water on underground garage structure system. As it takes a long span for large underground engineering, usually through wet and dry seasons, with drastic change in water level, the dewatering measure has great effect on engineering quality of underground garage.

2. Effect of expansive soil on underground garage structure system. For the infiltration of the surface water makes the foundation clay expand to produce vertical thrusting force to lead to cracks, engineering investigation and designers need pay special attention to it.

# The Application of Fracture Mechanics in Highway Tunnel Lining Cracking

Songzhou Chen[1,a]

[1]Road & Bridge International Co.Ltd.,South Branch Co.Ltd.,Beijing 101121,China

[a]305934042@qq.com

**Keyword:** Fracture mechanics Highway tunnel Stress intensity factors Cracks

**Abstract**.Lining cracks of highway tunnel has a very important effect on the healthy operation of the tunnel. Establishing the model for concrete fracture mechanics evaluation, we could identify the tunnel lining cracking situation. By using Linear elastic fracture mechanics method we could calculate the stress field of crack in the lining. Separately by different depth we have calculated crack stress intensity factor. We get that growing rates of variation of stress intensity factor as the crack depths increase. So lining tunnel health operations severely cracked.

## Introduction

As a branch of solid mechanics, fracture mechanics is a science and studies the strength of the materials or structures with crack and crack extension rule. According to the mechanical characteristics of the object, fracture mechanics can be divided into the linear elastic and elastic-plastic fracture mechanics [1]. The fracture mode of engineering components can be classified into three basic types: I fracture type (open), II fracture type (slip), III fracture type (tear). From the point of view of mechanics of elasticity, fracture type can be considered to be respectively the plane stress problems, plane strain problems and constant cross-section rods reverse problems (actually belong to the two-dimensional problem). When the fracture problems are in research, the stress intensity factor K is one of the important concept. It is a major determinant of the crack tip stress field strength, is the crack area public factor of stress component value and it also is the important parameter of the crack in engineering component wether it is damaged or not .When the stress intensity factor K is not greater than the material fracture toughness Kc, we think the buckling does not destroy; On the contrary, the engineering materials will lose their job functions.

Because the highway tunnel's geological condition is more complicated, the tunnel design and construction technology development are not yet perfect, during the tunnel service they usually appear all sorts of diseases, such as: water leakage, lining crack and so on. Among them, the healthy operation of the tunnel is mostly affected by the tunnel lining cracking. Groundwater along the inside lining crack seeps into the tunnel and causes corrosion of the internal auxiliary facilities such as ventilation, lighting and the others, at the same time it damages the pavement. If lining crack is not timely and accurate processed, it is likely to affect the normal operation of the tunnel. In this paper, based on the lining cracking problem of a tunnel of Chongqing, We calculate and analyze the theory of fracture mechanics to judge the change of the crack effect on lining structure.

## Concrete Fracture Mechanics

Crack of concrete structure has a decisive influence. Since 1961, when the fracture mechanics were introduced in the research of concrete material, we have been studying the formation, development and characteristics of concrete crack. A branch of the fracture mechanics, concrete fracture mechanics [6] is produced .

Stress environment and crack of concrete structure have direct relation, quantitative description of the instability criterion and model of concrete crack is one of the important research content of concrete fracture mechanics. Because concrete fracture mechanics characteristics mainly include the following[1]: (1) At the crack tip, concrete material has different from metal micro crack zone and it is the decision of the evolution process of concrete crack; (2) Whether in a plane stress problem or a plane strain problem, the load of concrete crack can be easily unified to analysis and research; (3) the fracture toughness of concrete Kc has the very strong scale effect; (4) the cracking of concrete material area and crack area strain are essentially different. The application of fracture mechanics of concrete in tunnel project is mainly reflected by studying the stability of the lining of serious cracks, analyzing the necessity of strengthening and treatment methods.

Fracture mechanics of concrete can be divided into the linear elastic fracture mechanics of concrete and concrete nonlinear fracture mechanics. Through studying the linear elastic fracture mechanics, concrete fracture state can use two kinds of methods: stress field method and energy method.

**Tunnel Lining Crack Analysis**

2.1 Project summary

The tunnel buried depth and its geological conditions is complicated, geological location is longer than the other. For area with poor geological conditions (such as IV, V class of surrounding rock), we adopt Φ 25 hollow grouting anchor spray, spray concrete, steel fiber concrete, the grid steel frame construction support, mold injection of concrete and reinforced concrete lining. In the early stages of the tunnel lining.

2.2 Lining crack type

(1) According to the relationship of fracture strike and tunnel towards, lining crack can be divided into longitudinal crack, ring to crack and oblique crack.

Longitudinal cracks are the lining cracks which parallel to the tunnel axis and they are the most harmful cracks; the ring cracks almost occurred in bad geological location and the mouth of the cave; Oblique belongs to structural cracks. The causes are that tensile stress of inclined section of the tunnel concrete is more than tensile strength and shear stress is more than the shear strength.

(2) According to the fracture fissure feature, lining crack can be divided into a mouth crack (figure1 (a)), silent type, fault type (figure1 (b)) and shrinkage ring type.

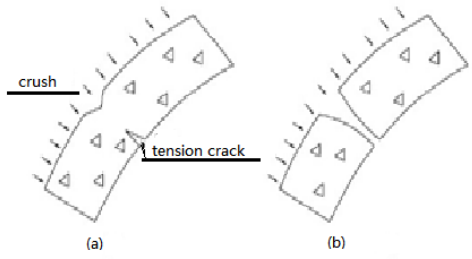

Fig.1. Characteristics diagram of lining fracture

2.3 The detection method and statistics of Lining crack

（1）The field detection techniques of lining crack

At present, the main method of detection of tunnel lining crack' s situation is: the length and width of the cracks were measured with a ruler, the depth of the cracks were mainly determined by drilling or ultrasonic method. The detection methods of development and change of the crack

mainly has: marking grey piece, marking metal plate, marking drill nail and the measuring method of the crack meter and strain gauge.

（2）Lining crack statistics

Lining crack statistics and detection of a highway tunnel's left hole in Chongqing is as follows: On the left side of the wall, there have been 77 arch loin vertical cracks , cracks generally range from the ground to hance, individual crack extended upward to the vault, a total of 17 cracks' width is greater than 0.4 mm; On the left side of the wall, hance, the part of the vault appeared the levels of article 7 of the longitudinal crack, a total of five cracks' width is greater than 0.4 mm. The position with the right side of the wall and hance appears 65 vertical cracks, including 10 cracks craze after fracture closed, 14 cracks have been closely processed. Cracks generally range from the ground to hance, individual crack extended upward to the vault, only 1 crack width is greater than 0.4 mm; At right side of the wall, hance and the vault, there were eight longitudinal cracks and the cracks are about 1.5 m from the ground, individual crack extended upward to the vault, only a crack's width is greater than 0.4 mm. Among them, the longest length of the crack is 1150 cm, the shortest is 10 cm. The typical pictures are shown in Fig.2,Fig.3,Fig.4..

Fig.2Rightarch lumbar transverse cracks on K8+775

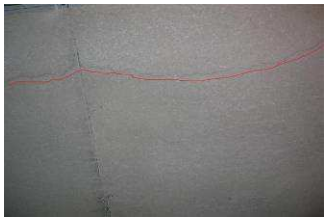

Fig.3 Arch vertical cracks on K10+339

Fig.4 Rightarch lumbar inclined cracks

2.3 Lining crack reason analysis

The cracking reasons of tunnel lining are various: design, construction and service environment and many other factors which could lead to a lining cracks. When tunnel lining appears cracking condition, this explains that the service environment of the tunnel is much more severe than expected design, so the analysis of the causes of cracks on the lining of tunnel is good for maintenance. The major effect of the lining cracking reasons [2, 3, 6] are as follows:

(1) Design reason

According to the error of the hierarchy of surrounding rock' s type, lining option is not adapt to the environment of the surrounding rock, and the actual load of lining caused by the actual under design load is greater than the expected value; Corresponding measures didn't be taken in areas of complex geological situation, as the swelling wall rock section did not take the curved wall of inverted arch lining.

(2) The construction

The hydration of cement, the temperature stress of concrete material itself, improper restrictions, construction method, construction technology, construction organization and management and so on are almost likely to lead to the cracking of concrete lining.

(3) Geological environmental reasons

Bad geology area, geological surrounding rock without surveying and groundwater exploration are likely to cause the cracking of concrete lining.

**Lining structure fracture mechanics calculation**

The situation of cracking of tunnel lining is the large number of longitudinal cracks, arch cracking is in severe cases. Based on the linear elastic fracture mechanics state of knowledge , this paper analysis and research state of lining structure cracks to calculate the stress intensity factor of the concrete through the stress field method and to judge state of concrete crack extension through the change of the stress intensity factor.

3.1 Lining structure fracture mechanics calculation model [2], [3]

When calculating the lining concrete fracture mechanics, the first time is to determine fracture external mechanical environment, the tunnel vault crack force situation can be simplified as working together between vault bending moment $M_d$ and arch axial force $N_d$. Because at the beginning of the tunnel lining adopt single heart round piece of lining structure, so the calculation formula of the vaults of the internal force is shown in Eq. 1:

$$\left.\begin{aligned} M_d &= M_{hp} + \sigma_d M_{d\sigma} \\ N_d &= N_{hp} + \sigma_d N_{d\sigma} \end{aligned}\right\} \quad (1)$$

Respectively, $M_{kp}$ and $N_{kp}$ are the arch structure of bending moment and axial force; $M_{d\sigma}$ and $N_{d\sigma}$ are the arch elastic resistance of bending moment and axial force; $\sigma_d$ is the elastic resistance.

Simplified calculation mode of the vault lining crack fracture mechanics is shown in Fig.5:

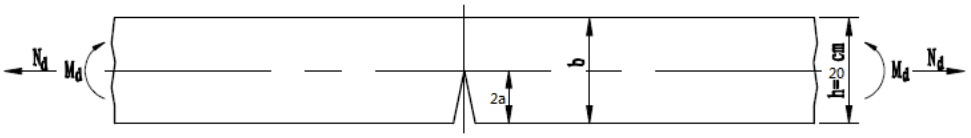

Fig.5 The calculatianal model of fracture mechanics

The thickness of the tunnel initiative lining is 20 cm. Based on the calculation of the different depth of crack fracture mechanics , this paper analyzes the influence of cracks on the lining structure. Taking 2 a = 2~18 cm, vault cracks whose width is b are infinite long slat.

3.2 Stress intensity factor calculation [1], [6], [7]

For the sake of safety, lining crack stress intensity factor were calculated according to the type I fracture; Under the condition of elastic fracture mechanics, the arch axial force and bending moment are regarded as the external load of stress intensity factor. $K_1$ is obtained by linear elastic superposition principle, That is to say as Eq. 2 :

$$K_1 = K_{1M} + K_{1N} \quad (2)$$

I loading stress intensity factor is available type (3) :

$$K = y\sigma\sqrt{\pi a} \quad (3)$$

Among them, y is the shape of the crack factors or load conditions, such as type (4) and (5):

$$y_M = \sqrt{\frac{2b}{\pi a}\tan\frac{\pi a}{2b}}\,\frac{1+0.2(1-\sin\frac{\pi a}{2b})^4}{\cos\frac{\pi a}{2b}} \quad (4)$$

$$y = \sqrt{\frac{2b}{\pi a}\tan\frac{\pi a}{2b}}\,\frac{0.8+\frac{2a}{b}+0.4(1-\sin\frac{\pi a}{2b})^3}{\cos\frac{\pi a}{2b}} \quad (5)$$

$$\sigma_M = \frac{6M}{b^2} \quad (6)$$

$$\sigma_N = \frac{N}{A} \quad (7)$$

Respectively, substitute (6) and (7) into type (3):

$$K_{1M} = 6y_M \frac{\sqrt{\pi a}}{b^2} \cdot M \quad (8)$$

$$K_{1N} = y_N \frac{\sqrt{\pi a}}{A} \cdot N \quad (9)$$

Substitute(8) and (9) into type

$$K_1 = 6y_M \frac{\sqrt{\pi a}}{b^2} \cdot M + y \frac{\sqrt{\pi a}}{A} \cdot N \quad (10)$$

The depth of crack is taken different values between 4 to 18 cm, the change of the stress intensity factor come to the conclusion, such as Tab. 1.

Tab.1 Calculation results of stress intensity factor

| Crack depth: 2a | 2a=2 | 2a=4 | 2a=6 | 2a=8 | 2a=10 | 2a=12 | 2a=14 | 2a=16 | 2a=18 |
|---|---|---|---|---|---|---|---|---|---|
| $K_1$ | $56.5M_d$ $+1.7N_d$ | $68.9M_d$ $+2.0N_d$ | $84.5M_d$ $+2.8N_d$ | $101.1M_d$ $+3.7N_d$ | $120.4M_d$ $+4.9N_d$ | $142.9M_d$ $+6.1N_d$ | $177.2M_d$ $+9.3N_d$ | $212.5M_d$+ $10.6N_d$ | $320.9M_d$ + $18.9N_d$ |

3.3 The result analysis

See from table 1, at the beginning of the lining cracking, stress intensity factor of crack extension grows slowly, but with the increase of crack depth and the change of the stress intensity, the cracks are becoming more and more sensitive. This suggested that the deeper crack depth of tunnel lining structure is most harmful.

## Conclusions

The crack of tunnel lining concrete have very big effect on the healthy operation of the tunnel, particularly because concrete crack was born and the tunnel is in the mountain, once the cracks penetrate the lining, it will cause the seepage water diseases. Effect of corrosion on the lining of steel bar is caused by groundwater. Eventually great influence on the healthy operation of the tunnel comes out. So the calculation of the tunnel lining fracture mechanics plays an important role in the lining of health.

**Key words:** BP neural network; underground engineering structure; damage identification; change rate of curvature

**Abstract:** With the expansion and development of scale of construction on metro engineering, the damage diagnosis and the safety evaluation on underground engineering structure have become vital problems to be solved. This paper raised an idea to distinguish underground engineering structure based on BP neural network: define change rate of curvature of structure, and recognize it as the input scalar of BP neural network, using a reducing unit elastic modulus method to simulate damage location and damage degree, through various set of underground structure extent of damage, recognize the first four order curvature structure change rate as input of BP neural network. The results show that the method using BP neural network can identify the damage degree of underground engineering structure accurately and can solve the damage identification problem of underground engineering structure conveniently and effectively.

## Introduction

During the use of process, due to fatigue load, environmental corrosion, material aging, defect and other reasons, underground structure produce damage accumulation gradually, which reduces structure's bearing capability and the ability to resist natural disasters,so existing structure may have serious damage especially when suffering earthquakes. Hence the analysis of dynamic damage degree of underground structure, then the earthquake damage characteristics of it is particularly important to evaluate. The seismic damage evaluation of the eventual establishment of underground structure damage quantitative evaluation standard under the effect of earthquake, and provide a theoretical basis for the seismic design and seismic rehabilitation of underground structure.

In the recent 30 years, domestic and foreign scientific workers work very fruitful researches in structural damage identification technology. Cawley confirmed that identification of damage existence can be improved according to reduce the frequency and damping structure. Biswas studied structure damage localization according to the structure changes of natural frequency and vibration mode. Mannan studied that using the measured frequency response function of structure can diagnose damage. Cassiots introduces a method using only frequency variation of structure to identify local stiffness reduction. Kunihiko used the finite element calculation model to train BP neural network model,and identify the damage state and damage degree in known strain condition. Xie will use the SVM to the damage detection of composite structures, the results show that the

support vector machine method has a high recognition accuracy. Yu detected structural damage, using the method of dynamic response analysis and the eigenvalues of the perturbation theory.

In this paper, based on a large number of domestic and international relevant damage identification and neural network literature, according to the development prospect of damage identification and artificial neural network, using the finite element ABAQUS program, it combines the modal analysis theory and BP neural network for damage identification of underground structure engineering, meanwhile realizes the identification of damage location and the degree of damage.

**Damage identification of underground structure method based on BP neural network**

Due to dynamic characteristics and physical parameters of the structure are related directly, damage of underground structure will change the dynamic characteristics. But the damage identification method only using dynamic parameters is to identify structure, which often needs math to solve complex inverse problems, and is difficult to be applied to practical engineering. Due to the neural network for its excellent nonlinear mapping ability can make the inverse problem positive, we can combine the dynamic parameter analysis method with neural network technology, and recognize structural damage indicator with kinetic parameters as the characteristic parameters of neural network input to identify structure damage.

BP neural network with its good nonlinear mapping ability becomes the most widespread neural network in the field of application of structure damage diagnosis. BP neural network is multilayer network which makes W-H learning rules general, and can weight train nonlinear differential function, and is also a multilayer feedforward neural network. Transform function of its neurons is S type function, so the outputs is continuous variables between 0 to 1, and this function can realize the arbitrary nonlinear mapping from input to output. The basic BP algorithm includes two aspects: signal propagation and error back propagation. That is to say that the calculation direction of actual output is from the input to the output, while the weights and threshold corrections direction is from the output to the input. The network structure and the algorithm flow chart are as shown in Figure 1 and Figure 2. In the graph, $x_j$ represents the j-th node input in the input layer, j=1,2,⋯,m; $w_{ij}$ represents the weight between the i-th node in the hidden layer and the j-th node in the input layer; $\phi(x)$ represents the driving function in the hidden layer; $w_{ki}$ represents the weight between the k-th node in the output layer and the i-th node in the hidden layer, i=1,2,⋯,q; $a_k$ represents the K-th node threshold in the output layer, k=1,2,⋯, L; $\varphi(x)$ is the driving function of output layer; $O_k$ says the output of the K node in the output layer.

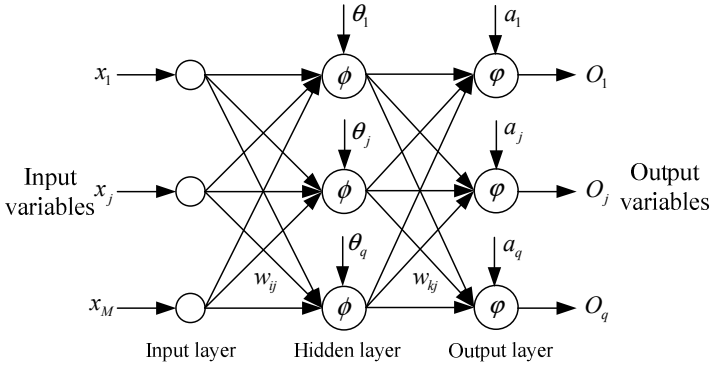

Fig.1 Structure of BP network

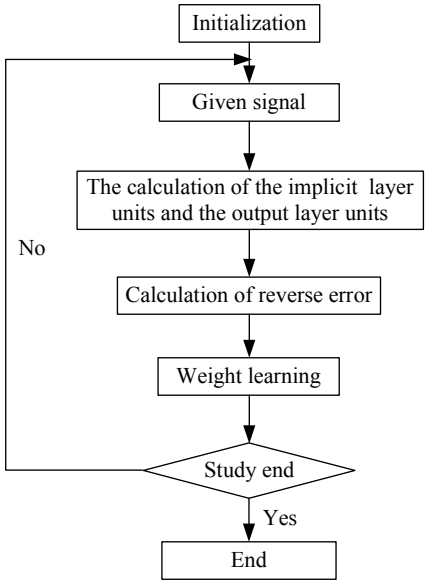

Fig.2 Process of BP algorithm

Considering the input vector of the neural network has a direct impact on the recognition performance of the network, physical quantities of damage location should be the parameters sensitive to the structure of local damage, and are on the trend of monotonous change with the increase of structural damage degree. This paper chooses the curvature change rate as input of neural network, recognizes the damage location and extent as output, to identify the damage location and extent. In this paper, the definition of frequency change rate: suppose the i-th order curvature value of the point k is $\delta_{i,k}$ when the structure has no injury, the curvature value under the i order mode of vibration is $\delta_{i,k}^{*}$ after injury mode, then the curvature change is $\Delta\delta_{i,k} = \delta_{i,k}^{*} - \delta_{i,k}$, and then define relative change rate of the curvature is the sum of change rate of i order curvature $\varepsilon = \sum_{0}^{i} \left| \Delta\delta_{i,k} / \delta_{i,k} \right|$. This paper focuses on studying the influence of structural damage on the change rate of curvature, and effectively predict the structural damage through the change rate of curvature.

In this paper, during the damage identification process, BP network model structure uses three-layer network, and the neurons number in the input layer is 4, and the number of the hidden layer neurons is 6, and output layer neurons number is 4, and the transfer function of the hidden layer neurons uses S type tangent function tansig, and the output layer neuron transfer function uses S type logarithm function logsig. The network training process is a process revising the weights and thresholds constantly, and make the input error of network reach the minimum error by adjusting, and the final training error of this article is 0.0015, so iterating until the network converge.

## Damage identification of underground subway structure

2.1 Analysis model of damage identification of underground structure

Taking Nanjing Metro as the research background, the typical underground tunnel structure as the research object, structure of underground tunnel is simulated by beam element, and the foundation soil were simulated by solid element, and the computational domain foundation width is 120m, and the finite element of grid soil underground tunnel structure system is divided as shown in Figure 3, and the node of underground tunnel structure is as shown in Figure 5. The mechanics material parameters of structure:elastic modulus E=$3\times10^{10}$ Pa, density ρ= 2500kg /$m^3$, Poisson's ratio μ= 0.2. The mechanics material parameters of soil: elastic modulus E =$8\times10^{6}$ Pa, density

$\rho$=1800kg/m$^3$, Poisson's ratio $\mu$=0.35. We can analysis the finite element modal and get the input of the neural network.

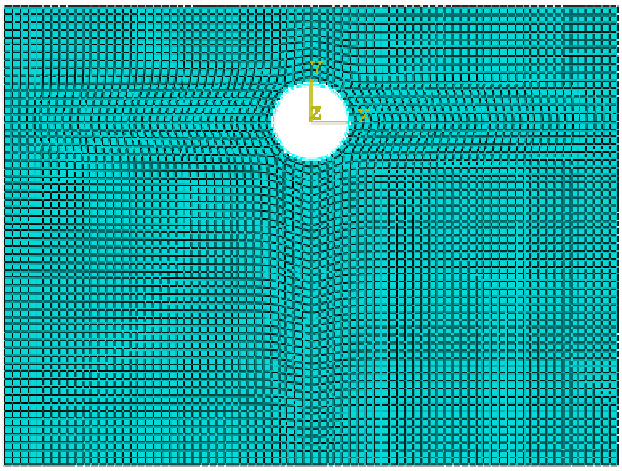

Fig.3 Finite element mesh of soil-underground structure system

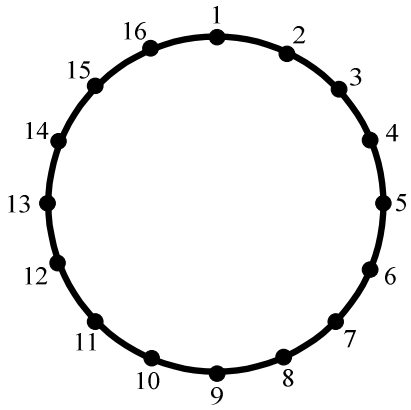

Fig.4 Node diagram of underground structure

2.2 Damage identification of underground subway structures

Damage of structure in essence is local structural stiffness loss, so the analysis on the dynamic damage characteristics of the structure can simplify calculation, assuming the structural damage can be simulated by reducing the elastic modulus of elements. The damage at one position can be simulated with the reduce of the elastic modulus,and the damage degree of the structure can be simulated with the reducing degree of the elastic modulus.

According to the existing research we can know that circular tunnel structure damage in the plane of tunnel about $45^0$ position is the most serious,so we should study No. 3, No. 7, No. 11 and No. 15 node among finite element models for the damage identification of circular underground tunnel structure. Assuming that underground structure around the unit of No.3 node causes damage of 30%, drawing a curve as shown in Figure 6 which shows node changes with the first 4 order change rate of curvature. It can be seen that the curve peak appears in the 3 node position, the change rate of curvature is very sensitive to the damage location, and is not affected by the symmetric structure, therefore we can determine the location of the damage of underground structures according to the rate of 4 order curvature changes in the structure.

In order to determine the variation characteristics of damage degree of underground structure, by calculating the change rate of curvature about the unit in different damage cases, Figure 7 is the curve of the change rate of curvature nodes around No.3node when the damage degree is 10%, 30%, 50%, 70% and 90%. It can be drawn from the chart, the change rate of curvature of structure is sensitive to the damage degree of underground structure, namely in the same damage location, with the increase of the damage degree, numbers of curvature change rate increases.

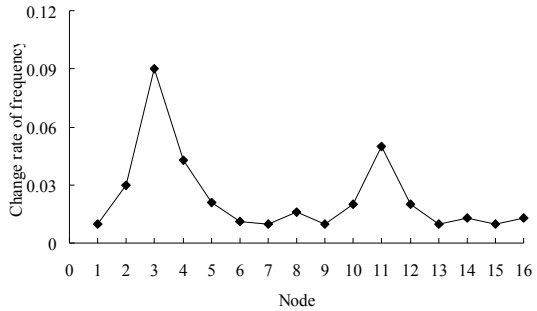

Fig.5 Curve of change curvature rate

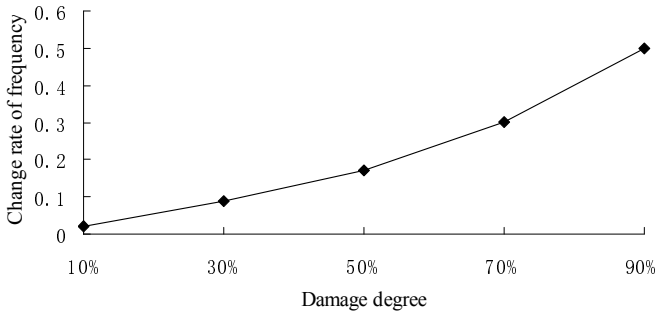

Fig.6 Change curvature rate of node 3

Recognizing a total of 20 sets of data of modal change rate when the damage degree of No.2,No.5,No.8,No.11 node respectively are 10%, 30%, 50%, 70%, 90% as training samples for BP neural network. The output of the neural network (Y1, Y2, Y3, Y4) respectively represent damage situation above 4 units, such as network output (0, 0.5, 0, 0) No.5 on behalf of 50% of the injury on the unit. To train sample, plus the change rate of curvature on the 40% and 80% damage degree as the test sample of the neural network, which is used to test the adaptability of recall memory, interpolation and extrapolation of neural network.

Neural network training error is 0.001398 after BP neural network training 20000 times, then the training halts. Input the test sample set into the trained neural network, and the test results are shown in Table 1, and the errors between the theoretical value and the predicted value are as shown in Figure 7. It can be found that the error between the theoretical value and the predicted value is relatively small, and the predicted values can reflect the damage degree completely based on BP neural network.

Table.1 Damage identification results based on BP Neural Network technique

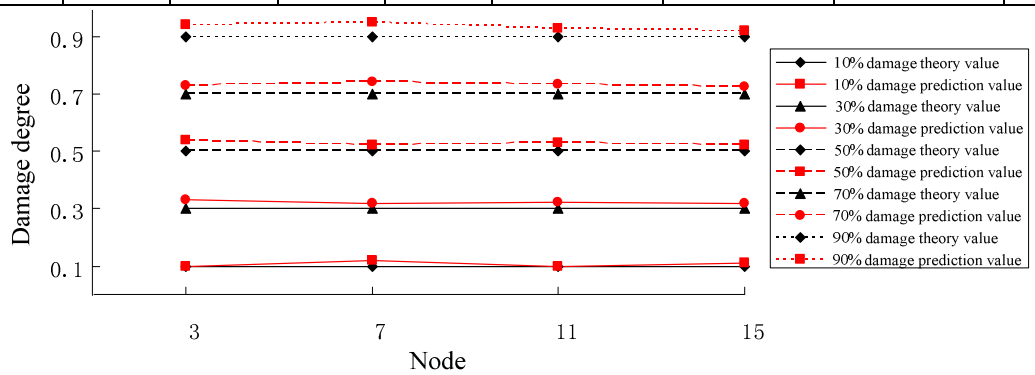

Fig.7 Prediction error curve between the predicted value and the theoretical value under different damage degree

## Conclusions

This paper introduces the method of underground tunnel structural damage identification based on BP neural network method, and analyses metro tunnel structure through ABAQUS finite element computing platform, and combining with the damage identification model of structure BP neural network, we can draw the following conclusions:

(1)it is reasonable to recognize the first 4 order change rate of curvature of underground engineering structure as the damage signature, because the signature is not only sensitive to the damage location, but damage degree is monotone function, and using it as input parameters of BP neural network can obtain the damage identification results.

(2) The trained BP neural network has good associative memory, good interpolation and extrapolation abilities, so that it can accurately identify the damage degree of underground engineering structure, and has high accuracy.

(3) Based on the BP neural network, underground engineering structure damage identification method only needs to consider the structure of the first 4 modes, and it is easy to acquire data, and has high precision, and can simply and effectively determine the damage degree of underground tunnel engineering structure.

**Keywords:** submerged floating tunnel; tether; non-linear free vibration; sag; initial tension

**Abstract.** Taking the free vibration system of a submerged floating tunnel tether as research object, the non-linear free vibration equation was set up. By means of Galerkin method, the partial differential equation was transformed into a set of ordinary ones. The damping ratios of the first four modes were obtained after complex eigenvalue analysis. Subsequently, effects of inclination, sag, initial tension force and length of tether on its modal damping ratios were analyzed. The results show that inclination and sag of tether merely affect the damping ratio of first in-plane mode; they have no effect on the damping ratios of higher order in-plane modes and out of plane modes; the first in-plane modal damping ratio of tether is in direct proportion to its inclination, whereas in inverse proportion to its sag; the first modal damping ratio of tether (both in-plane and out of plane) is in direct proportion to its length, whereas in inverse proportion to its initial tension.

## Introduction

Submerged floating tunnel (SFT), suspending in the water at some convenient depth and fixed to the seabed by means of a suitable anchoring system, is an innovative concept for crossing deep waterways. Compared with long span cable-stayed and suspension bridges, the increase of cost with span length is generally much better for submerged floating tunnels .

Vibration of tether was studied by many experts and scholars. Ge *et al.* [1] investigated the effect of tunnel surge motion on the dynamic response of a tether by considering the forcing and parametric excitations. Chen *et al.*[2] set up vortex-induced oscillation equations of tether and discussed its maximal dynamic shearing force and bending moments. Ge *et al.* [3] investigated vortex-induced vibration of submerged floating tunnel tube-tether coupled model. Luo *et al.* [4] established a nonlinear dynamic model equation of tether and solved it by the secondary development of finite element software. To solve the dynamic response of submerged floating tunnel under current, Xiang and Chao [5] studied the vortex-induced vibration and parametric vibration of tube and tethers.

In this paper, taking the free vibration system of a submerged floating tunnel tether as research object, the non-linear free vibration equation is set up. By means of Galerkin method, the partial differential equation is transformed into a set of ordinary ones. The modal damping ratios of the first four modes are obtained after complex eigenvalue analysis. Subsequently, effects of inclination, sag, initial tension force and length of tether on its modal damping ratios are analyzed.

## Non-linear free vibration model of tether

Fig. 1 shows the nonlinear analytical model proposed for the free vibration analysis of tether. Let $\boldsymbol{Z}=[x(s)\ y(s)]^{\mathrm{T}}$ denote the static configuration of tether, $s$ being a curvilinear abscissa. The dynamic configuration subjected to dynamic loading is described by the displacement $\boldsymbol{U}=[u(z,\ t)\ v(z,\ t)]^{\mathrm{T}}$ measured from the static equilibrium position. $t$ is time and $x$, $y$, $z$ are Cartesian coordinates shown in Fig. 1.

The governing differential equations of the tether motion can be derived using the Hamilton principle

$$\delta\int_{t_1}^{t_2}\int_0^L (Q-V)\mathrm{d}s\mathrm{d}t+\int_{t_1}^{t_2}\int_0^L \delta W\mathrm{d}s\mathrm{d}t=0 \tag{1}$$

In which, $\delta$ is the symbol for variation; $t_1$ and $t_2$ are the limits of the time interval; $L$ is the unstretched length of tether; $Q$ is the kinetic energy density, $Q=\frac{m}{2}(\dot{\boldsymbol{U}})^{\mathrm{T}}\dot{U}$ ; $V$ is the elastic strain energy density, $V=V_i+\frac{EA}{2}\varepsilon^2+T_0\cdot\varepsilon$ , $\varepsilon=(\boldsymbol{Z}')^{\mathrm{T}}\boldsymbol{U}'+\frac{1}{2}(\boldsymbol{U}')^{\mathrm{T}}\boldsymbol{U}'$ ; d$t$ is the differential of time; $\delta W$ is the virtual work density associated with the gravity, dynamic loading and damping force, $\delta W=\delta\boldsymbol{U}^{\mathrm{T}}\left[\gamma_{\mathrm{f}}V_{\mathrm{S}}\cos\theta-\boldsymbol{c}\dot{U}+F_{\mathrm{D}}\right]$.

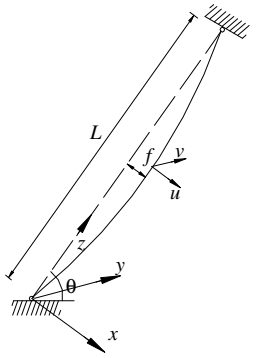

Fig. 1 Non-linear free vibration model of tether

Where $E$, $A$ and $m$ denote the modulus of elasticity, the cross-sectional area and the mass per unit length of unstretched tether respectively; $V_{\mathrm{i}}$ is the elastic strain energy density held in the initial (static) configuration; $T_0$ is the tether tension in the static configuration; $\varepsilon$ is Lagrangian strain; $\gamma_{\mathrm{f}}$ is the buoyant unit weight of tether; $V_{\mathrm{S}}$ is the volume per unit length of unstretched tether; $\theta$ is the tether inclination with respect to the horizontal level; $\boldsymbol{c}$ is viscous damping coefficient of tether, $\boldsymbol{c}=\mathrm{Diag}[c_x \quad c_y]$; $F_{\mathrm{D}}$ is the acting force applied by water per unit length when the tether vibrates.

The static equilibrium position of the tether is approximated by the quadratic parabola, $x=4f\frac{z}{L}\left(1-\frac{z}{L}\right)$.

Simlifying equation (1), omitting balance items under static loads, higher order small amount and small amount of $z$-direction motion, the following non-linear partial differential equation is obtained.

$$m\frac{\partial^2 u}{\partial t^2}+c_x\frac{\partial u}{\partial t}-EA\frac{\partial}{\partial z}(\varepsilon\frac{\partial x}{\partial z})-T_0\frac{\partial^2 u}{\partial z^2}=-F_{\mathrm{D}} \tag{2}$$

$$m\frac{\partial^2 v}{\partial t^2}+c_y\frac{\partial v}{\partial t}-T_0\frac{\partial^2 v}{\partial z^2}=-F_{\mathrm{D}} \tag{3}$$

In which, $H_0$ is the $z$-direction component of tension and $T_0\approx H_0$; $L_{\mathrm{E}}$ is the tether length in the static configuration; $f$ is the static displacement in the middle of tether.

Equation (2) and equation (3) are in-plane vibration equation and out of plane vibration equation of tether respectively. Due to these two equations are similar, here only equation (2) is analyzed in detail.

According to Morison equation, when the tether vibrates, the total acting force induced by water per unit length may be expressed as the sum of the damping force and the additional inertial force

$$F_{\mathrm{D}}=\frac{1}{2}C_{\mathrm{D}}\rho_{\mathrm{w}}D_{\mathrm{t}}\sqrt{\frac{8}{\pi}}\sigma_{\dot{u}}\dot{u}+C_{\mathrm{m}}\frac{\pi D_{\mathrm{t}}^{\ 2}}{4}\rho_{\mathrm{w}}\ddot{u} \tag{4}$$

Where, $D_{\mathrm{t}}$ is the diameter of the tether; $\rho_{\mathrm{w}}$ is the water density and $\rho_{\mathrm{w}}$=1028 kg/m; $C_{\mathrm{m}}$ is the additional mass coefficient and $C_{\mathrm{m}}=1$; $C_{\mathrm{D}}$ is the drag force coefficient and $C_{\mathrm{D}}=0.7$ , In which, $\sigma_{\dot{u}}$ is variance of $\dot{u}$ .

By means of Galerkin method, the partial differential equation is transformed into a set of ordinary ones

$$[\boldsymbol{M}]\ddot{u}+[\boldsymbol{C}]\dot{u}+[\boldsymbol{K}]u=0 \tag{5}$$

Where, $[\boldsymbol{M}]=[\boldsymbol{M}_1]+[\boldsymbol{M}_2]$, $[\boldsymbol{M}_1]$ and $[\boldsymbol{M}_2]$ are mass matrix and added mass matrix of tether respectively; $[\boldsymbol{C}]=[\boldsymbol{C}_1]+[\boldsymbol{C}_2]$, $[\boldsymbol{C}_1]$ and $[\boldsymbol{C}_2]$ are damping matrix of tether and damping matrix provided by water respectively; $[\boldsymbol{K}]=[\boldsymbol{K}_1]+[\boldsymbol{K}_2]$, $[\boldsymbol{K}_1]$ and $[\boldsymbol{K}_2]$ are equivalent stiffness matrix provided by initial tension and dynamic tension respectively.

## Numerical analysis and Results

For the convenience of discussion, the following dimensionless parameter which reflects the sag and tensile property of tether is introduced [6].

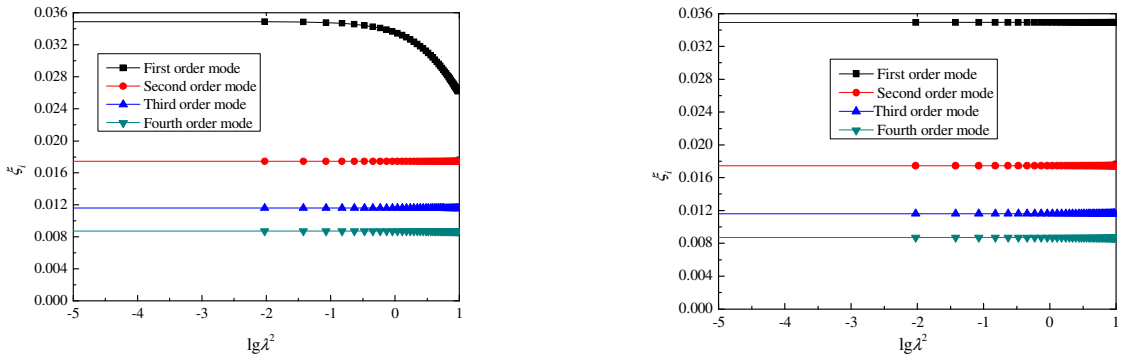
$$\lambda^2 = \left(\frac{\gamma_f V_s L\cos\theta}{H_0}\right)^2 \cdot L/[H_0 \cdot L_E/(EA)] \tag{6}$$

Basic parameters [7] of tether are shown in Table 1.

Table 1 Basic parameters of tether

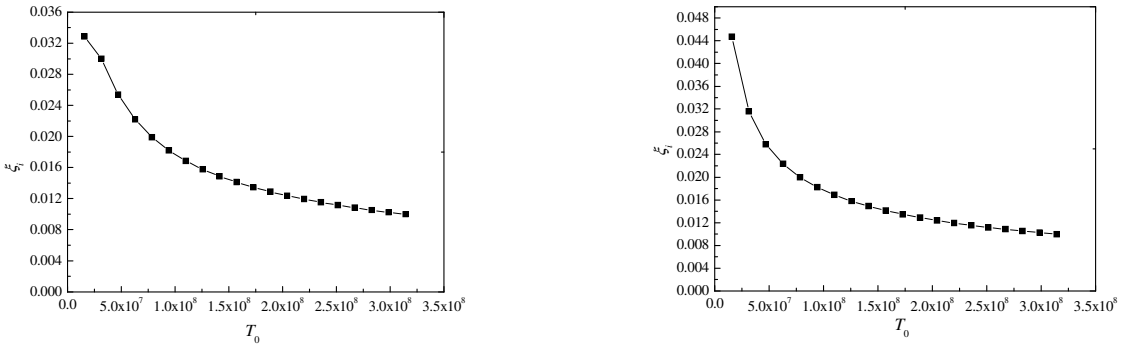
| Length (m) | Diameter (m) | Mass per unit length (kg/m) | Density (kg/m$^3$) | elastic modulus (Pa) | Initial disturbance (m) | Initial tension force(N) |
|---|---|---|---|---|---|---|
| 161.66 | 0.489 | 1474.23 | 7850 | $2.1\times10^{11}$ | 0.001 | $2.572\times10^{7}$ |

**Effect of tether sag on its modal damping ratios.** Changing sag of tether by changing its inclination, effect of tether sag on its modal damping ratios are shown in Fig. 2. It is shown that when tether sag increases, the damping ratio of first in-plane mode decreases, whereas the damping ratios of two to four in-plane modes and first four out of plane modes keep constant. That is to say, similar to tether inclination, tether sag merely affects the damping ratio of first in-plane mode.



(a) in-plane (b) out of-plane

Fig. 2. Relationship between modal damping ratios and sag of tether



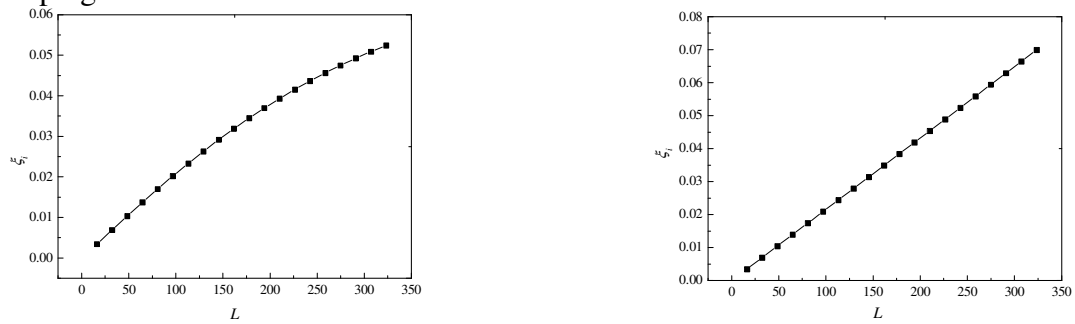
(a) in-plane (b) out of-plane

Fig. 3. Relationship between modal damping ratios and initial tension of tether

**Effect of tether tension on its modal damping ratios.** Effect of tether tension on its modal damping ratios of the first mode (both in-plane and out of plane) are shown in Fig. 3. It can be seen that, due to the influence of tether tension on its vibration period, when tether sag increases, the damping ratios of first in-plane and out of plane modes decrease.

**Effect of tether length on its modal damping ratios.** Effect of tether length on its damping ratios of the first mode (both in-plane and out of plane) are shown in Fig. 4. It is shown that, when tether

length increases, the damping ratios of first in-plane and out of plane modes increase. However, the curve of the first in-plane modal damping ratio is non-linear, whereas that of the first out of plane modal damping ratio is linear.



(a) in-plane (b) out of-plane

Fig. 4. Relationship between modal damping ratios and length of tether

## Conclusions

(1) Inclination and sag of tether merely affect the damping ratio of first in-plane mode; they have no effect on the damping ratios of higher order in-plane modes and out of plane modes.
(2) The first in-plane modal damping ratio of tether is in direct proportion to its inclination, whereas in inverse proportion to its sag.
(3) The first modal damping ratio of tether (both in-plane and out of plane) is in direct proportion to its length, whereas in inverse proportion to its initial tension.

**Keywords:** Paoziling tunnel; water-bursting accident; railroad tunnel engineering; numerical simulation method; water gushing yield forecast;

**Abstract.** Empirical analytic method and theoretical analytic method are usually applied to calculate and predict water gushing yield in the tunnel engineering in the past but have much limitations and errors. Ample water source, hydrodynamic conditions and expedite channels are essential for water-bursting accidents in railroad tunnel engineering. From a lot of study of fractal geometry in rock mass, it is found that the multi-dimension value of fissure network is colligate reflection of the length, the direction, space and the number of fissures, so the value can be used to describe the complicated frameworks in rock mass. But it is a sound tackle to quantities the complicated frameworks. Numerical simulating method is convinced to be applied to calculate and predict water gushing yield of tunnel and underground engineering. It focuses on analyzing texture characteristics of water-containing medium, building hydro-geological conceptual model, and modeling long-term hydrodynamic field development. An experimental application in Paoziling tunnel under-crossing mountain reservoirs in Hunan province was presented in this article, and long-term hydrodynamic field development had been obtained under the condition of drainage from the tunnel, and the gush yield in the tunnel during the process of storing water in the reservoir was also predicted.

## Introduction

Water gushing yield calculation and forecast was one of the fatal problems in constructing process of tunnel and underground engineering. The complexity of texture characteristics of water-containing medium of underground rock mass makes water gushing yield calculation and forecast much more difficult in practice [1]. Two kinds of analytic methods, empirical analytic method and theoretical analytic method were always applied to calculate and forecast water gushing yield in the tunnel engineering in the past but had much limitations and errors [2, 3]. On the other hand, hydro-geological numerical simulating method was seldom used in the past, and, now it was trying to be applied in the tunnel and underground engineering to calculate and forecast water gushing yield [4,5].

The Paoziling railway tunnel in Hu'nan province was a large and deep-buried tunnel with 6640m long. The tunnel passed through the north end of a synclinorium. Danjiang River flows through the nucleus part of the synclinorium. By view of the aspect of physiognomy, the tunnel passed through the surface watershed of Danjiang River, and the river was being cut off for the construction of a reservoir. The reservoir water storage and river seepage might lead to a comparatively large quantity of water gush during the process of excavation and operation of tunnel, prediction and calculation of the water gush in the tunnel under such circumstances was a prominent geological issue for this project.

## Methods

Based on the systematic and theoretical research of the basic geological conditions of the tunnel site, the stress had been laid on the research into the hydro-geological characteristics of the tunnel surrounding rock medium, and hydro-geological physical models had been built up for the construction site. The hydro-geological boundaries and hydro-geological parameters of the

surrounding rocks had been analyzed synthetically, and 3D-Modflow(Modular Three-dimensional Finite-difference Ground-water flow model) by utilizing finite-difference and the equilibrium principle of ground water was carried out on the characteristics of the underground seepage field changing under different influential factors where the tunnel passed, and quantities of water gush at this section of tunnel under the influence of various factors was predicted and calculated.

## Geological conditions of the tunnel site

The tunnel site was situated at the middle section of the southern mountain ridges, in terms of physiognomy. It was an area of low-and-middle hills. The strata were mainly sandstone, siltstone and cleaving stone of the Ordovician system $O_31$, Devonian system $D_2t$ at the tunnel site, having a serious weathering. The thick sandstone and intermediate-thick quartz sandstone were the main water-containing medium, and the fissures were relatively well-developed at the base, having a fine permeability in the horizontal direction, but bad in the vertical direction. The fissures were better-developed in the sandstones than the cleaving stone that was soft and being weathered, with around 0.30m thick. The cleaving stone was a relative water-resisting layer. The 4th stratum was complete-new pluvial, $Q_4^{al+pl}$, slide rock, eluvium, heterogeneous in terms of thickness, the maximum thickness could reach 275m.

The tunnel site was in the sub-tropical area, over the years, the average temperature was 17.60℃, average rainfall 1337mm, average evaporation amount 1536.3mm. The main source of ground water at the site was rain, at the same time, there were seepages from the river and the reservoir to be built and put into operation. Danjiang River passed in direction of NW-SE through the nucleus of the synclinorium, crossing the tunnel axis at D1K73+165 in a bevel angle of 40°, at the left side of the line, with dam 70m high, elevation (at the top of the dam)of 323m, and normal water level of 317.50m(elevation at the top of weir ). The trailing tunnel passed 560m far away from the edge of Danjiang reservoir, and road shoulder elevation was about 245m. The drilling at the river bottom revealed that, because Danjiang River was at the nucleus of the synclinorium, the steep, slant and vertical structural fissures were intensively developed comparatively, especially in the sandstones, thus they had a strong capacity for guiding water.

## The establishment of 3D spatial geological model

3D Spatial Numerical Model was established to forecast the quantity of water gushing yield of the tunnel, with emphasis laid on the characteristics of various factors of the underground seepage field.

## The model region and water flow boundaries

The simulation area took the water divides at the two sides of the river as its flow boundaries which had no water supplies to the computation area. If the upper and lower reaches of the river had side underground inflow and outflow, it would be regarded as the first category of boundary condition, i.e. water-head-fixed boundary. In the vertical direction, the model bottom was selected the position 50m lower than the tunnel axis at the connection with the valley. Therefore, it could be regarded that the place where the tunnel lied as an independent hydro-geological unit. The model, after being established, was illustrated on plane in Fig.1.

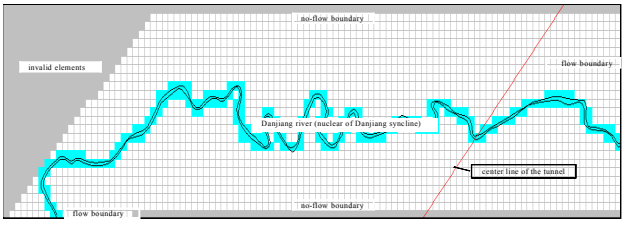

Fig.1 3D spatial numerical model and the types of boundaries

## The Generalization and discrete of the model

It had to be considered the influential factors to the underground water supply resources such as rivers, reservoirs, rainfalls, the seasonal dynamic changes in evaporation amount [6,7].

To partition in accordance with the alteration characteristics of the water-containing medium in vertical direction as revealed in the zone-survey, site-survey materials and drilling materials, the ground surface super stratum was the first layer, taking the nucleus of the synclinorium as the elevation of the emersion of the 2nd base rock above the ground, to partition downward in turn according to different lithological features. In consideration of the limited capacity of computer and speed of computation, the size of the model on plane was 5250×1250m$^2$, subdivided by the use of equipage network grid, each grid was 50×50m$^2$ in size. In the vertical direction, it had been totally delaminated into 10 layers. The whole mode had been totally subdivided into 105×25×10=26250 units, in which the amount of invalid units was about 1/10, as indicated in the Table 1.

Tab.1 The state of delaminating and lithological features of every layer

| Delaminating No. | Average Thickness[m] | Layer-top Elevation of Each Layer[m] | Lithologic Features |
|---|---|---|---|
| 1 | 0.5~275.0 | 322.0 | The Fourth-System of ploluvial, slide rock, strong-air slaked quartz-sand stone |
| 2 | 8.0 | 211.0 | Fresh-weak air slaked thick siltstone, relatively intact |
| 3 | 19.5 | 203.0 | Fresh quartz-sand stone, fissure well-developed |
| 4 | 23.0 | 183.5 | Fresh, intermediate, interbedding of thick quartz-stone and siltstone |
| 5 | 15.0 | 160.5 | Fresh, thick quartz-sand stone, fissure developed |
| 6 | 16.1 | 145.5 | Fresh, intermediate, interbedding of thick quartz-sand stone, fissure relatively developed |
| 7 | 11.2 | 129.4 | Fresh, thick and super-thick siltstone, core intact |
| 8 | 11.0 | 118.2 | Fresh quartz-sand stone, fissure relatively developed. |
| 9 | 10.0 | 108.2 | Fresh siltstone, relatively intact |
| 10 | 20.0 | 88.2 | Fresh quartz-sand stone, fissure relatively developed. |

## The hydro-geological parameters of the water-bearing stratum

(1)Permeability Coefficient *K*

In the whole simulation computation, the determination of the medium permeability coefficient was extremely important [8]. In respect of fissure medium, when most part of fissures was filled up, the permeability coefficient of fissure medium depended on the particle composition and particle size of the medium itself more than being affected by the fissure width [9].

Snow computation method was adopted to seek the permeability coefficient of the rocks through synthetic computation, and to make modifications to the computation results by referring the site or field drilling and water-pumping test results, and the penetration coefficient in vertical direction and taking value was listed in the Table 2.

Tab.2 The values of the water-bearing stratum transmissivity in heterosphere

| Parts | Lithologic Features | Kxx[m/d] | Kyy[m/d] | Kzz[m/d] |
|---|---|---|---|---|
| Nucleus area of the synclinorium at river valley | Siltstone | 0.260 | 0.260 | 0.0260 |
| | Interbedding of sandstone and siltstone | 0.269 | 0.269 | 0.0269 |
| | Sandstone | 0.280 | 0.280 | 0.0280 |
| Two-wing area of the synclinorium at the two sides of the river valley | Siltstone | 0.256 | 0.256 | 0.0256 |
| | Interbedding of sandstone and siltstone | 0.261 | 0.261 | 0.0261 |
| | Sandstone | 0.272 | 0.272 | 0.0272 |

(2) Valid cavity

The rock stratum was taken to the scope of depth 0-90, the part of it with depth larger than 90m.

(3) Make up strength and evaporation strength

In consideration of the impact of topographic gradient, ground-surface plantation, soil towards rain seepage and evaporation strength, made a discount and decrease to the measure value by the corresponding experience coefficient 0.6, so as to be in conformity with the actuality.

(4) Simulation Stress Periods

In accordance with the difference between the rainfall and evaporation amount during different periods, the simulation could be divided into different stress periods, and the duration of simulation was one year, which were totally divided into 12 different migration periods. The parameters of every period of stress were listed in the Table 3.

Tab.3 The evaporation and recharge values in every stress periods

| Stress Periods | Stress Period Ⅰ (month of 12-1) | Stress Period Ⅱ (month of 2-3) | Stress Period Ⅲ (month of 4-6) | Stress Period Ⅳ (month of 7-8) | Stress Period Ⅴ (month of 9-11) |
|---|---|---|---|---|---|
| Evaporation Intensity(mm/d) | 0.000371 | 0.000385 | 0.000821 | 0.001328 | 0.000723 |
| Rainfall Intensity(mm/d) | 0.000592 | 0.001156 | 0.002324 | 0.00171 | 0.000867 |

## Simulation Computing Schemes

Simulation computation mainly took three types of factors that affect the tunnel gush into consideration, and the specific scheme was listed in the Table 4.

Tab.4 The fundamental circumstances of simulating process

| Computation Schemes | Status of ground water current | Duration | Stress Period | Amount of Time Slots | Aim of Simulating Operation |
|---|---|---|---|---|---|
| Ⅰ | Steady current | One year | 10 | 12 | Parameter Checking |
| Ⅱ | Non-steady current | One year | 5 | 12 | Prediction of the gush yield upon excavation under natural status |
| Ⅲ | Non-steady current | One year | 5 | 12 | Prediction of the gush yield upon excavation under the status that the reservoir is at operation. |
| Ⅳ | Non-steady current | One year | 5 | 12 | Prediction of the gush yield upon excavation under heavy rainfall. |

## Results

### Flowing field features of the site and tunnel gushing yield prediction under natural condition

The simulation results of the underground seepage field under the natural state prior to the construction of tunnel had primarily reflected the topographic features of ups-and-downs in the construction area of the tunnel, as Fig.2 shown, which indicated that the parameters selected in the model schemes were reliable.

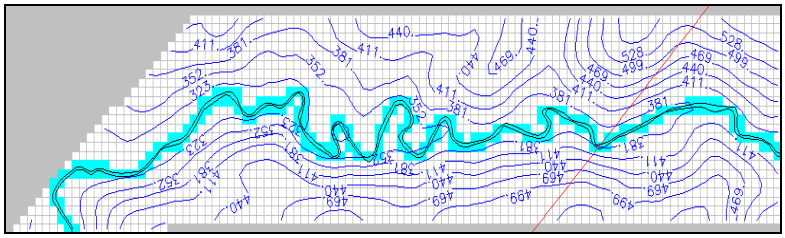

Fig.2 The distribution of natural groundwater seeping field (unit:[m])

Under the natural condition, along with the continuation of the time of water drainage in the tunnel, the depth contours of ground water would gradually shift towards the two sides of the tunnel axis, as Fig.3 shown. The seepage fields had relatively great changed in respect of integral configuration, and depth contours became sparse and the ground water divide occurred. The drainage of water inside the tunnel had greatly lowered down the groundwater position at the two sides of valley. Through the simulation of a complete water year, the gush of water inside tunnel at different periods under natural condition was around 1.614~2.936×$10^4$$m^3$/d.

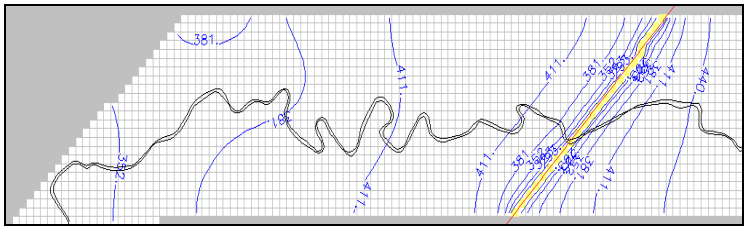

Fig.3 The distribution of ground-water flowing field after 365 days' draining (unit:[m])

**Tunnel gush yield prediction after the completion and putting-into-operation of reservoir**

Along with the continuation of the time of drainage in the tunnel, under the impact from the reservoir, the position of the groundwater divide would gradually shift towards the reservoir. 365 days after the tunnel drained, the impact would reach the rear or tail of the reservoir, as Fig.4 shown. Due to the existence of the ground water divide, the water level of reservoir would not be lowered down at great extent, i.e. the span, scope of the impact of tunnel drainage towards the water storage in reservoir would be limited, and it would not seriously or materially decrease the water volume of reservoir water storage and even dried the storage. The gush inside the tunnel after to the completion and putting-into-operation of reservoir was 2.458～3.208×$10^4$$m^3$/d.

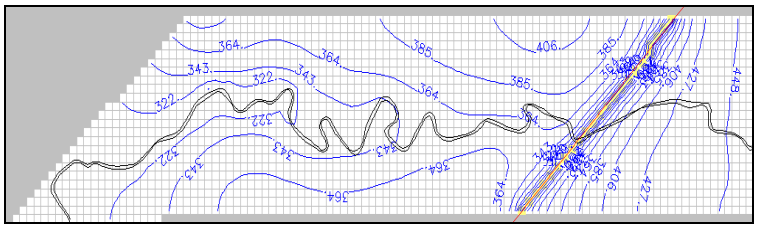

Fig.4 The distribution of ground-water flowing field after 365 days draining with the reservoir running (unit:[m])

**3.3 Tunnel gush yield prediction under the operation of reservoir and heavy rain**

After the completion and putting-into-operation of the reservoir, and under the condition of heavy rain, along with the continuation of time, the depth contours of groundwater would gradually shift towards the two sides of the tunnel, and the scope of influence due to tunnel drainage would be further decreased The extent and scope of impact towards reservoir water storage would be further decreased compared with that in normal years (Fig. 5). Under such condition, the gush in tunnel was 2.522～3.938×$10^4$$m^3$/d.

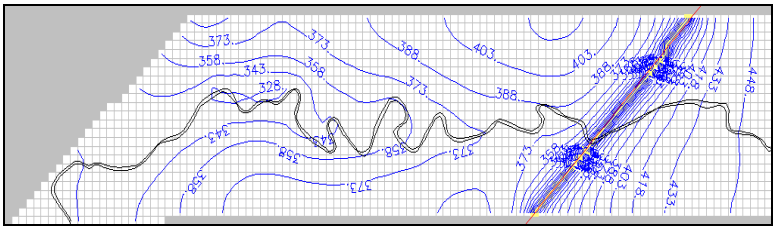

Fig.5 The distribution of ground water field after draining 365 days with the reservoir running and abnormal recharge (unit:[m])

The comparison of the simulation results data and the groundwater flowing fields was shown that, after the completion and putting-into-operation of reservoir, the gush in the tunnel, under the condition of heavy rain, would be increased by 638 $m^3$/d（dry season）～7296 $m^3$/d（rain season）for the different time intervals compared with that in normal years. The operation of reservoir and the heavy rain condition would have a relatively significant impact to the gush yield in this section of tunnel. It was needed to do a good job of the measures of prevention of water gush and water drainage.

## Discussion

By utilizing the numerical simulation method, through medium generation, establishment of spatial physical models, and the determination of boundary conditions, the gush yield of the tunnel has been predicted through simulation during the construction of reservoir. The simulation results have shown the spatial and temporal alteration characteristics of the groundwater seeping fields at the tunnel draining area under the impact of various factors. The numerical simulation method, as a method for predicting and calculating the gush yield in the underground tunnel, is worthy of further research and promotion.

**Keywords:** Lining,Structure Reliability,Rock-Mechanics Model,Monte Carlo Finite Element, Statistical.

**Abstract.** The article proposed the reliability calculation method for tunnel lining design combining Rock-Mechanics model and Monte Carlo finite element method.The reliability calculation model of tunnel lining structure design was established considering tunnel character. The types of the statistical characteristics and distribution of axial force for the big cross section of the loess tunnel structure had been summarized. The study result stated that the method is feasible. It has important theoretical guiding significance to the practice structure reliability design of tunnel and underground engineering.

## Introduction

Based on the fixed value of structure design and the traditional safety coefficient method are used to evaluate the reliability of tunnel lining structure design, the practice proved this method is reliable, but it is based on the fixed parameter, which means can't consider any and the safety of the structure calculation and check computation of uncertainty factors and the variability of design variables, this give accurate evaluation of tunnel lining structure design is safe and reliable planted unable to eradicate the hidden trouble. At the same time, it can also cause waste of construction materials. Professor Guan baoshu in 1989 by quantification theory and fuzzy mathematics method, proposed the railway tunnel surrounding rock classification of forecast and decision criteria [1]; Xie jinchang in 1988, the first professor of single railway tunnel surrounding rock collapse height and lining on the relaxation of load probability and statistics analysis, and its probability distribution function is the best fitting [2]; in 1996 professor Jing shiting experiments on bias of concrete component and puts forward the concrete influence coefficient of eccentric compression member of statistical parameter calculation formula, and the fuzzy reliability and reliability of composite lining is studied [3]; In 2005, the railway tunnel design code (TB1007-2005) [4] lists the probability limit state design method and the meaning of the relevant parameters; 2010 Yang Jianguo, Xie Yongli [5] is introduced about the development direction of tunnel structure reliability theory at present, the main is to develop in the direction of research and the dynamic time-varying structural system.Choose what kind of easy to implement in the field of practical application, however, the theoretical model of? Calculation method and means come from? A random variable how to reasonable value? These are the key problems about the structural reliability theory in the practical engineering application. For this reason, the article will take the loess railway tunnel as the engineering background, and studies loess tunnel lining structure reliability design ,and puts forward a practical method of tunnel lining structure reliability design and calculation method.

## Calculation Model and Calculation Method

Among the four calculation model of tunnel lining structure, the calculation model Rock-Mechanics is a very mature theory calculation model, its famous is simple and reliable numerical data. Therefore,

on the basis of the model and the Monte Carlo method and K-S test,this article calculates and studies the distribution laws of lining structure effect and the mathematical characteristics. About the the parameters and variables of the random number,the paper adopts the relevant datas of based on the theory of the reliability safety evaluation and analysis method of the loess tunnel lining structure [6].

## Lining structure reliability calculation

**The Calculation of Lining Structure Effect.** Based on Hei Shansi tunnel lining finite element mesh Graph(in figure 1) and summary table random numbers' calculating parameters on loess tunnel [6], the paper uses calculating program of a Monte-Carlo finite element to get the 100000 times calculation on structural effect of calculation.At last, the numerical results of the loess tunnel lining structure effect is got. The axial force data of the loess tunnel lining structure arch cross-section is summarizes in table 1.

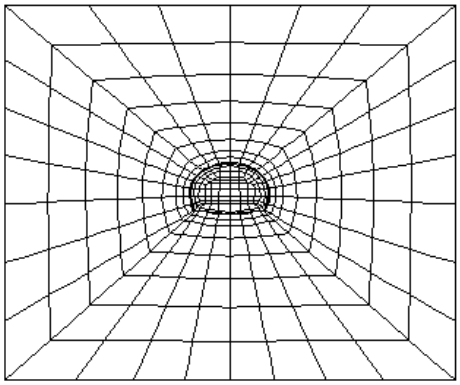

Fig.1 Finite Element Mesh

Tab.1 Summary table on axial force of tunnel arch-top

| The number of iterations | Axial force (kN) | The number of iterations | Axial force (kN) | The number of iterations | Axial force (kN) |
|---|---|---|---|---|---|
| 1 | 934.73 | 6 | 569.56 | 11 | 362.85 |
| 2 | 852.83 | 7 | 619.48 | 12 | 583.28 |
| 3 | 683.58 | 8 | 536.57 | 13 | 536.57 |
| 4 | 585.25 | 9 | 514.18 | 14 | 443.52 |
| 5 | 525.91 | 10 | 623.18 | 15 | 763.27 |
| ⋮ | ⋮ | ⋮ | ⋮ | ⋮ | ⋮ |
| 99986 | 525.64 | 99991 | 563.61 | 99996 | 934.73 |
| 99987 | 362.85 | 99992 | 851.17 | 99997 | 852.83 |
| 99988 | 583.28 | 99993 | 536.57 | 99998 | 683.58 |
| 99989 | 536.57 | 99994 | 548.98 | 99999 | 585.25 |
| 99980 | 461.68 | 99985 | 860.68 | 100000 | 652.36 |

Note: because this page is limited, some data have been slight.

**The Numerical Statistical Analysis.**The paper applies distribution hypothesis and statistical test for numerical results of 100000 effect on Hei Shansi loess tunnel lining structure,and makes the right judgment. To illustrate the calculation method of this article, at the same time, in consideration of the characteristics of the tunnel lining structure, the paper select100000 times axial force datas in the most unfavorable position (vault location) tunnel structure for an example to illustrate that how does the numerical results of the structure effect with the probability distribution assumption and K-S test.

**Drawing Frequency Histogram.**First, the data is sorted through by artificial simple method, then the SPSS statistical software [7] is used to group the 100000 vault section axial force datas to the 13

intervals,finally it draws the loess tunnel lining structure effect results of the numerical frequency histogram, namely the vaults section axial force of loess tunnel lining structure frequency histogram, as shown in figure 2. From figure 2, that obeying positive skewness distribution can be concluded about the vault section axial forces(N) on the loess tunnel lining structure.

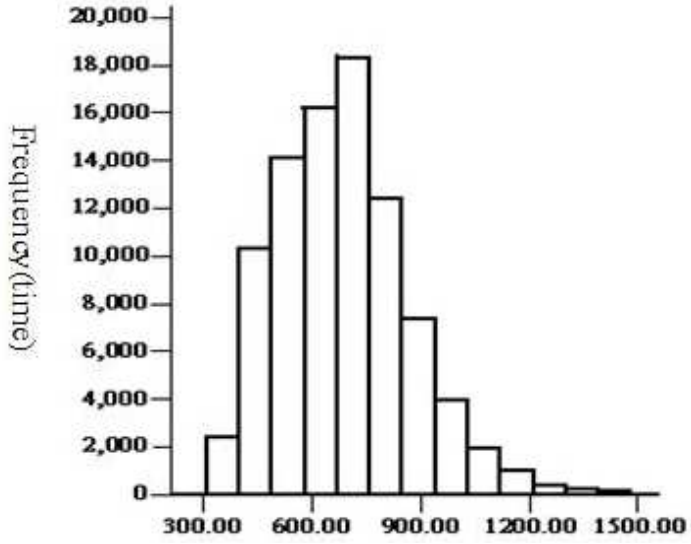

Fig.2 Distribution histogram on axial force of tunnel arch-top in loess tunnel

**The Distribution Rule of Statistical Tests.**According to the general distribution of the article drawing the axial force frequency histogram of tunnel lining structure,combined with previous commonly used type of probability distribution,this paper makes the loess tunnel lining structure arch cross-section function distribution law of axial force (N) approximate to logarithmic normal distribution assumption,and K-S inspection. Arch cross-section (Dn) of the axial force statistics calculation result of 0.0049 is less than the critical value of 0.005, (D100000,0.005),0.0051,therefore it could prove that the axial force of Hei shansi loess tunnel lining structure vault cross section obeies logarithmic normal distribution hypothesis is true. Similarly all axial forces of lining applies logarithmic normal hypothesis test, as shown in the table 2. Through table 4, this hypothesis is accepted, so the distribution types of each section axial force the loess tunnel lining obey the lognormal distribution.

Tab. 2 The hypothesis testing of tunnel each axial force 's distribution types

| Lining section number | statistic | Lining section number | statistic | Lining section number | statistic | Assuming distribution | The critical value | The critical value test results |
|---|---|---|---|---|---|---|---|---|
| 1 | 0.0046 | 12 | 0.0046 | 23 | 0.0046 | Logarithmic normal distribution | 0.0051 | All accepted |
| 2 | 0.0045 | 13 | 0.0047 | 24 | 0.0004 | | | |
| 3 | 0.0043 | 14 | 0.0004 | 25 | 0.0044 | | | |
| 4 | 0.0048 | 15 | 0.0045 | 26 | 0.0046 | | | |
| 5 | 0.0049 | 16 | 0.0048 | 27 | 0.0044 | | | |
| 6 | 0.0046 | 17 | 0.0049 | 28 | 0.0004 | | | |
| 7 | 0.0047 | 18 | 0.0046 | 29 | 0.0046 | | | |
| 8 | 0.0046 | 19 | 0.0044 | 30 | 0.0045 | | | |
| 9 | 0.0044 | 20 | 0.0049 | 31 | 0.0043 | | | |
| 10 | 0.0004 | 21 | 0.0047 | 32 | 0.0048 | | | |
| 11 | 0.0046 | 22 | 0.0045 | 33 | 0.0049 | | | |

## Conclusion

Through the analysis and study of lining structure reliability design in loess tunnel, the paper put forward the concrete method that using the " Rock-Mechanics " model and Monte Carlo finite element method to study structural reliability of the tunnel lining, considering of the successful practice, it greatly promotes the structural reliability theory in the practical application and developmentin the field of tunnel structure reliability design.

According to the analysis results ,this paper put forward that the axial force distribution type of lining structure in Hei shansi loess tunnel obey the lognormal distribution, for the future this provides the theory basis for the design of the other size tunnel lining structure.

In this study, the method of realizing the statistical analysis of data and hypothesis test in terms of tunnel structure reliability theory is practical, for the future there is important significance to the statistical analysis of large amounts of data engineering.

**Keywords:** traffic engineering; choice of transfer manner; example analysis; transfer station of subway

**Abstract.** Two lines intersection is the common transfer manner of the subway. In order to analyze the characteristics and applicability of the two lines transfer manner, this paper analyzes different transfer stations of subways at home and abroad, and evaluate the current use of them, in the views of the form of the intersection of the lines (parallel and intersection), and the relative location between the lines and the stations. Then it summarizes the characteristics and applicability of the transfer manner. Finally, it gives advices of the choices of the two lines transfer stations in different situations.

## Introduction

Transfer station is located at the junction of different subways in the rail transit net. The basic manners of the transfer stations are one-platform-interchange station, station hall transfer station, channel transfer station, and transfer out of the station.

Nowadays, the studies of the transfer stations were mostly in the following areas: The analysis of the basic transfer manners and the method of choice[1]; the summary of the current situation of the built-up transfer stations in a city[2]; or the design forms of the transfer stations[3]. These studies also analyzed the transfer manners and the current situations. They focused on analyzing the basic transfer manners in theory, but lacked in summarizing the transfer manners in concrete metro interchange manners.

Two lines intersection is the common transfer manner of the subway. This paper analyzes different two lines transfer stations of subways at home and abroad, and evaluate the current use of them, in the views of the form of the intersection of the lines (parallel or crossed), and the relative location between the lines and the stations. Then it summarizes the characteristics and applicability of the transfer manner. Finally, it gives advices of the choices of the two lines transfer stations in different situations.

## Parallel Form

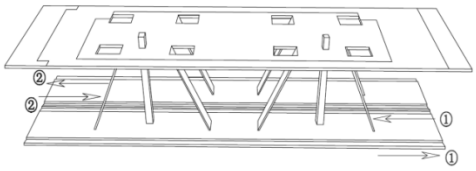
The parallel form can be divided into two types: the lines located in the same elevation, the lines located in different elevation.

**The Lines Located in the Same Elevation**

(1) When the platforms of the lines are independent, they must be related by the change of the height. So the station hall transfer and channel can be chosen.

Sihui Station in Beijing is a station hall transfer station( in figure 1), because of the difference of the engineering standard and the long interval building time. The transfer height is high, and the transfer passenger flow influence the enter and exit flow.

Sanyuanqiao Station in Beijing is a channel transfer station( in figure 2), because of the long distance and the difference of the ticket system. The distance of the transfer is long, but it can disperse the passenger flow.



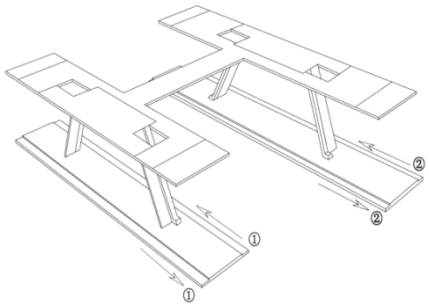


Fig.1 Sihui Station in Beijing Fig.2 Sanyuanqiao Station in Beijing

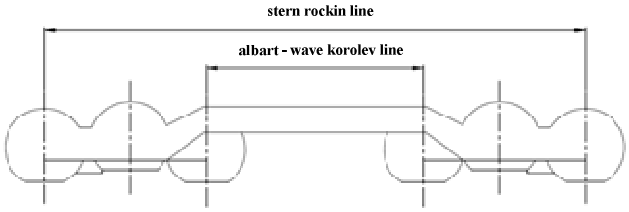
(2) When the different lines are in the same platform because of the previous reservation, the one-platform-interchange can be chosen.

Victory Park Station in Moscow makes up with two parallel island platforms[4]. And the lines in every platform have the same direction but different name. The platforms are connected by the channel in the middle( in figure 3). Most passengers can transfer in the platform, and other direction can transfer through the channel.

Nanchang Station in Hong Kong makes up with 2 is land platforms and a side platform( in figure 4). Most passengers can transfer in the platform, and other direction can transfer through the station hall. The composition of the flow in the station hall is complicated.



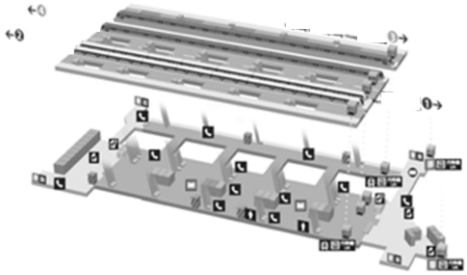


Fig.3 Victory Park Station in Moscow Fig.4 Nanchang Station in Hong Kong

**The Lines Located in Different Elevations**

(1) When the platforms of the lines are independent, the passengers can transfer by the stairs. But the transfer passengers in different directions are not separated, the efficiency of transfer is low.

(2) When different lines are built in the same platform because of the previous reservation, the one-platform-interchange can be chosen.

Laojie Station in Shenzhen can achieve one-platform-interchange because the different lines are located in the same platform.And other transfer can be achieved by stairs( in figure 5)[5]. The passenger flow of different kinds and different directions can be separated.

Andoni Station in Paris is designed malposed( in figure 6)[6]. This form of platform can separate the transfer flow of the different directions, and at the same time it can shorten the detouring transfer time.

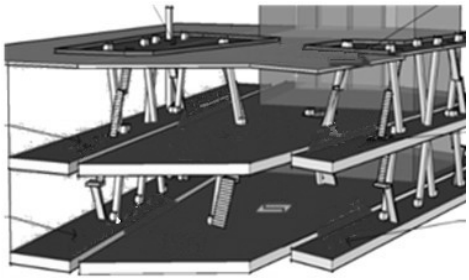

Fig.5 Laojie Station in Shenzhen

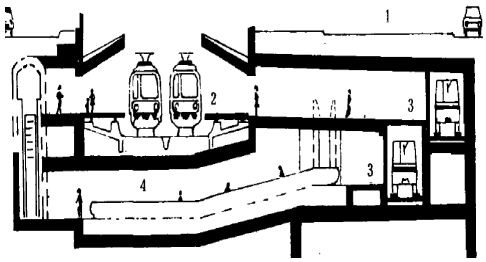

Fig.6 Andoni Station in Paris

**Summary of two Parallel Lines**

The summary of the two parallel lines is shown in Table 1.

Table 1 The summary of the two parallel lines

| Situation of lines | Transfer manner | Applied condition | Advantage | Disadvantage |
|---|---|---|---|---|
| In the same elevation | Station hall | Interval of the built time is long. The standard of the projects is different. The previous reservation is not made. | The two lines can be designed independently. Reservation can be made conveniently. | The transfer height is big. The transfer passenger flow and the enter and exit flow are mixed in the station hall. |
| | Channel | Interval of the built time is long. The standard of the projects is different. The previous reservation is not made or the lines are far. | The two lines can be designed independently. Reservation can be made commodiously. The distance of the transfer is long, and passengers can be dispersed. | The distance of the transfer is long. |
| | Platform & channel | Interval of the built time is short. The previous reservation is made but the lines are far. | One direction of transfer is conveniently; others can evacuate the passengers. | The two lines must be designed dependently. Reservation must be made. |
| | Platform & station hall | Interval of the built time is short. The previous reservation is made. | One direction of transfer is conveniently. | The two lines must be designed dependently. Reservation must be made. |
| In different elevations | Platform | Interval of the built time is long. Or the previous reservation is not made. | The two lines can be designed independently. Reservation can be made conveniently. | The transfer height is big. The transfer flows in different directions have conflicts |
| | Platform & station hall/channel | Interval of the built time is short. The previous reservation is made. | One direction of transfer is conveniently. | The two lines must be designed dependently. Reservation must be made. |

**Crossed Form**

When the subways are crossed, a node is appeared. If the station is located at the node, the relatively convenient transfer can be realized. But if the station can't be located at the node, the relatively convenient transfer can also be realized by reasonable transfer manners.

**Stations Located at the Node**

(1) When the station is located at the node, the most usual transfer manner is the platform-interchange. With the help of the stairs, it make the passengers complete transfer in the platform.

Lianglukou Station in Chongqing has two island platforms, and transfer flow can go to the other lines by stairs( in figure 7). The transfer is very convenient, but the transfer node is few, and the transfer flow in different directions is not separated. The efficiency is low.

(2) When the station is located at the node, the combination transfer manners can enhance the efficiency of the transfer.

Beidajie Station in Xi'an is "十" island-side crossed form. Metro Line 1 to Metro Line 2 is platform-interchange by stairs. Metro Line 2 to Metro Line 1, the transfer flow must pass the station hall( in the figure 8). When the transfer flow is large, the transfer node of side platform can be enlarged, such as Zhongshan Station[7] in Nanchang and Tianfuguangchang Station in Chengdu.

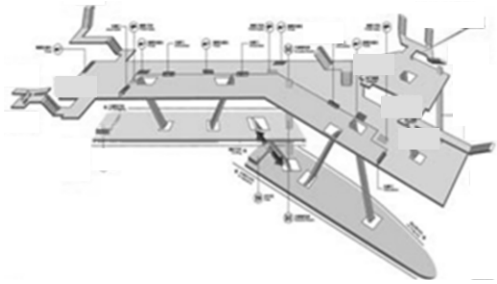

Fig.7 Lianglukou Station in Chongqing

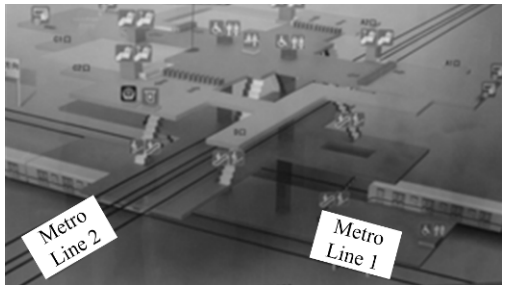

Fig.8 Beidajie Station in Xi'an

Haidianhuangzhuang Station in Beijing is also "十" island-side crossed form, and by setting transfer channel, the transfer nodes are added up to 4( in figure 9). The transfer nodes can scatter the transfer flow, and the efficiency of transfer is enhanced.

Xinjiekou Station in Nanjing is "十" island-island crossed form. Metro Line 2 to Metro Line 1 is platform-interchange by stairs. Metro Line 1 to Metro Line 2, the transfer flow must pass the transfer channel( in the figure 10). This manner separate the transfer passenger flow and the enter and exit flow, and also separate the transfer passenger flow in different directions. But it has only one transfer node, the transfer flow which route is shorter may jam when the flow is large.

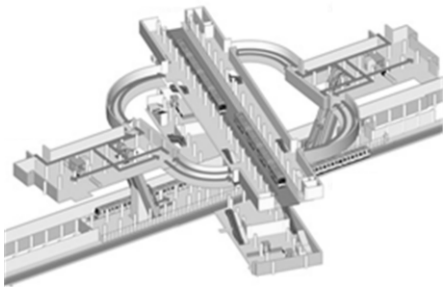

Fig.9 Haidianhuangzhuang Station in Beijing

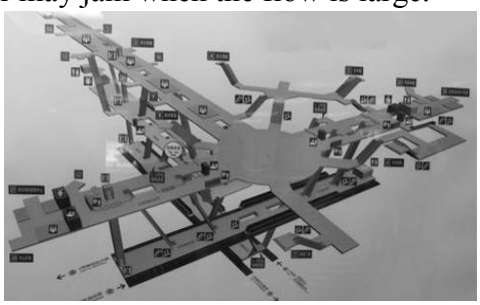

Fig.10 Xinjiekou Station in Nanjing

(2) When the station is located at the node, if the reservation is done, the most convenient transfer manner is the two-direction-platform transfer manner.

Gongyuanqian Station in Zhuangzhou is "十" crossed form, and the platforms is distributed in two flours. In ever flour, there is an island platform and two side platforms, which are separated by

rails(in figure 11). The transfer passengers go to the island platform of the other line from the middle of side platform. Passengers go out of the station from the ends of the side platforms, and the island platforms only allow passengers to get on the trains.

Central Station in Hong Kong is the transfer station of Tsuen Wan Line and MTR Island Line. The island platform of Tsuen Wan Line is on the second floor , in the middle of the side platforms of MTR Island Line( in figure 12). All the directions of the transfer passengers can accomplish transfer in the platforms.

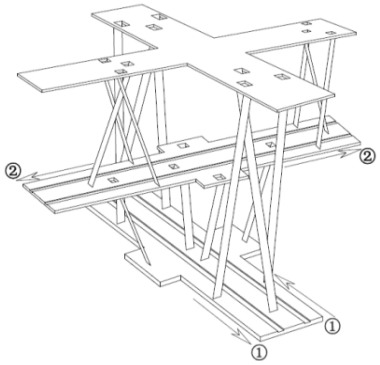

Fig.11 Gongyuanqian Station in Zhuangzhou

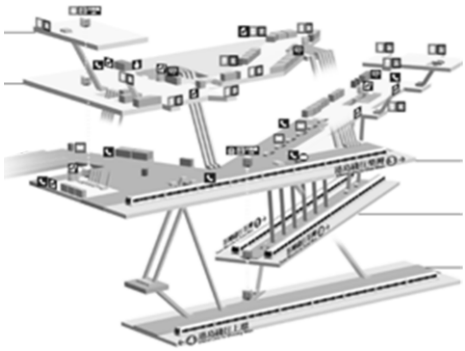

Fig.12 Central Station in Hong Kong

**Stations did not Locate at the Node**

Whether one station or two stations are not located at the crossed node, the transfer channel is employed.

Kowloon Tong Station in Hong Kong is made up of two separated platforms. The side platform of MTR East Rail Line and the island platform are at right angles. The stations has three station halls, and are connected with channel( in figure 13). This transfer manner can separated the transfer passenger flow and the enter and exit flow. But the transfer distance is long.

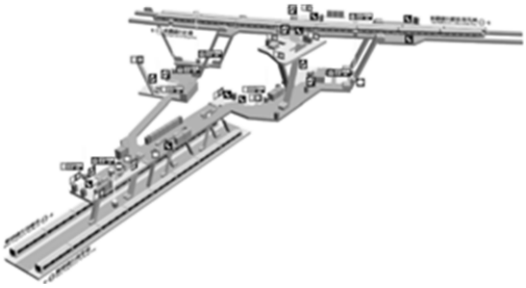

Fig.13 Kowloon Tong Station in Hong Kong

**Summary of two Crossed Lines**

The summary of the two crossed lines is shown in Table 2.

Table 2 The summary of the two crossed lines

| Situation of lines | Transfer manner | Applied condition | Advantage | Disadvantage |
|---|---|---|---|---|
| Stations located at the node | Platform | Interval of the built time is short. The previous reservation is made. | Transfer is conveniently. | The transfer nodes are few. The transfer flows of different directions are not separated. Reservation must be made. |
| | Platform & station hall | The previous reservation is made | One direction of transfer is conveniently. The transfer flows of different directions are separated. | The transfer passenger flow and the enter and exit flow are mixed. The flow in station hall is complex. |

| | | | | |
|---|---|---|---|---|
| | Station hall & channel | | The transfer flow can be dispersed because the transfer nodes are more | |
| | Platform & channel | | One direction of transfer is conveniently. The flows of different properties are separated completely. | The transfer nodes of platform are few, and easy to be jammed. |
| | Bidirectional platform | Interval of the built time is short. The previous reservation is made. | Transfer is the most conveniently. | Reservation must be made. Construction is difficult. |
| Stations did not locate at the node | Channel | Interval of the built time is long. The standard of the projects is different. The previous reservation is not made. | The flows of different properties are separated. The two lines can be designed independently. | The distance of the transfer is long. |

## Conclusion

This paper analyzes different two lines transfer stations of subways at home and abroad, and evaluate the current use of them, in the views of the form of the intersection of the lines (parallel or crossed), and the relative location between the lines and the stations. Then it summarizes the characteristics and applicability of the transfer manner. In the practical design, the transfer manner must be chosen according to specific circumstances.

**Keywords:** Tunnel.Different sections.Numerical analysis.

**Abstract.** In order to build subway station fire emergency group decision-making system, Aim at the subway station fire characteristics in this paper, analyze the problems of emphasis from emergency decision, and group decision method is proposed to use to solve this problem. The method can avoid failure of the overall decision making mistakes because a single decision maker. Found of decision-making group consist of experts, academics, policy-makers, considering several key factor such as professional, academic, expert ratings, weight, to build group decision model .At the same time, evaluation of the subway station fire emergency group decision effectiveness to build subway station fire emergency response system, Ultimately improve the efficiency of emergency response and level of decision-making for subway station.

## Introduction

Project Overvie In China, the cities, where subway has been built and put into operation, include Beijing, Shanghai, Guangzhou, Tianjin, Shenzhen, Hong Kong and Nanjing; meanwhile, in such eight cities as Chongqing, Shenyang, Xi'an, Wuhan, Chengdu, Harbin, Hangzhou and Shijiazhuang subway is under construction. Various countries' experience in developing rail transit shows that China's underground railway traffic will enter an unprecedented period of rapid construction and development after network volume operation is realized for subway[1-2].

## Emergency group decisions on subway fires

In traffic-free times, emergency fire evacuation drills can be conducted in the mid of the car body in the tunnel, to simulate the implementation of local group decisions of evacuation planning. When a fire breaks out in a train in a tunnel, in principle, the train should be driven into the front station as far as possible, where passengers can be evacuated; or else, the train need be pulled up in the tunnel for emergency disposals. Since a lot of smoke will be released during combustion, passengers' tolerance degree of the smoke determines whether to conduct timely evacuation. If the fire starts at the middle of the train, it's feasible to adopt unidirectional evacuation or bidirectional evacuation, thereby to accelerate evacuation velocity[3-5]. Under the condition of bidirectional evacuation, ventilating system should exhaust air towards the driving direction of the train, to ensure that the draught should be selected as an ideal evacuation direction. In the choice of evacuation modes, it's feasible to organize evacuation for the passengers according to the emergency condition, or evacuate them all at the same time to shorten evacuation time. But in the meantime, it's necessary to bear such accident risks as stampede caused by panicky passengers. In view of the above, for the preceding subway fire accident, we work out a set for emergency evacuation planning $S^* = \{S_1, S_2, \cdots, S_7\}$, in which planning $S_1$ expresses that bidirectional and simultaneous evacuation is adopted for the passengers after the train is driven into the front station.

**The implementation of emergency group decisions on subway fires**

In view of the domain knowledge involved in the accident, the emergency command center selects four domain experts to make emergency decisions $D=\{D_1,D_2,D_3,D_4\}$, letting them take part in the evaluation of the emergency evacuation planning. The emergency evacuation planning is mainly described by several attributes, including: Security $(d_1)$ expresses that this plan will be adopted to evacuate the passengers and to expect the possible casualties in the end; Evacuation cost $(d_2)$ refers to the sum of manpower, material resources and financial resources to be needed in the process of the evacuation when this plan is adopted; Accident loss $(d_3)$ refers to the financial loss to be caused and social impact to be produced in the end when this plan is adopted to evacuate the passengers.

**The evaluation of emergency group decisions on subway fires**

According to each expert's domain knowledge, the emergency command center distributes the emergency evacuation plans, to determine the relation between the decision-making experts and the local group decision of the emergency plans. $D_1$ participates in evaluating such planning sets $\{S_1,S_2,S_3\}$, $D_2$ participates in evaluating such planning sets $\{S_1,S_4,S_5,S_6,S_7\}$, $D_3$ participates in evaluating such planning sets $\{S_2,S_3,S_4,S_5,S_6\}$ and $D_4$ participates in evaluating such planning sets $\{S_1,S_6,S_7\}$. Based on the preceding relation of evaluation, all the experts respectively provide the local weights of the evaluation planning $a_{ij}^k\ (k=1,2,3,4)$ for the various attributes $d_i\ (i=1,2,3)$.

Aiming at attribute $d_1$, decision-making expert $D_1$ makes a comparison between $S_1,S_2,S_3$, the plans he participates in evaluating, to assess their performance on security, thinking that $S_3>S_1>S_2$, thus working out that $a_{11}^1=0.312$, $a_{12}^1=0.118$ and $a_{13}^1=0.487$; for attribute $d_2$, expert $D_1$ offers his assessment of the three plans on evacuation cost, thinking that $S_2>S_3>S_1$, thus working out that $a_{21}^1$=0.147, $a_{22}^1$=0.449 and $a_{23}^1=0.287$; in the end, for attribute $d_3$, decision-making expert $D_1$ makes a comparison between these three plans concerning accident losses, thinking $S_3>S_2>S_1$, thus making a preference judgment that $a_{31}^1=0.100$, $a_{32}^1=0.189$ and $a_{33}^1=0.557$. Similarly, the other three decision-making experts respectively make a preference judgment on their own evaluation plan under all properties.

$$x_1=(x_{11},x_{12},\cdots,x_{17})^T=(0.138,0.109,0.257,0.075,0.1778,0.110,0.075)$$

According to the above local weight $a_{ij}^k$, we integrate the opinions of all the experts, to obtain the group weight of such various plans as $S_1,S_2,\cdots,S_7$ under all the properties like $d_1,d_2,d_3$. Decision group $D=\{D_1,D_2,D_3,D_4\}$ thinks that on security, the performance of emergency evacuation plans $S_1,S_2,\cdots,S_7$ is manifested as:

$x_1=(x_{11},x_{12},\cdots,x_{17})^T$ = (0.138, 0.109, 0.257, 0.075, 0.1778, 0.110, and 0.075)

That is, decision group D thinks that on security, all the plans should be sorted this way: $S_3>S_5>S_1>S_6>S_2>S_4>S_7$. Accordingly, decision group D has also given out its group preference about all the decision schemes under such two properties as evacuation cost and accident loss.

According to the result of the group weight of the plans $x_i=(x_{i1},x_{i2},\cdots,x_{i7})^T$, i = 1, 2, 3, we also work out the experts' weight vectors $\sigma_i=(\sigma_i^1,\sigma_i^2,\cdots,\sigma_i^k)^T$, i = 1, 2, 3, under all properties, that is, based on the experts' judgment on the plans' local weight $a_{ij}^k$, we work out each expert's weight, see Tab.4.5. For instance, according to the evaluation of all the experts $D_1,D_2,D_3,D_4$ on emergency

evacuation plans $S_1, S_2, \cdots, S_7$ on security, it's worked out that expert $D_1$ 's weight $\sigma_1^1$ = 0.518, expert $D_2$ 's weight $\sigma_1^2$ = 0.623, expert $D_3$ 's weight $\sigma_1^3$ = 0.699 and expert $D_4$ 's weight $\sigma_1^4$ = 0.320. Similarly, according to each expert's judgment on the weight of evacuation cost and accident loss, the distribution outcomes of the experts' weights are arrived at, as is shown in Tab.1. In addition, we normalize the experts' weights under all properties in Tab.1. The objective function value Z is equal to 0.02679.

Table 1 Emergcntdecision except weights under each attribute

| Property | σ i1 | σ i2 | σ i3 | σ i4 |
|---|---|---|---|---|
| d1 | 0.518 | 0.623 | 0.699 | 0.320 |
| d2 | 0.520 | 0.432 | 0.687 | 0.285 |
| d3 | 0.432 | 0.519 | 0.873 | 0.247 |

**The judgment on the weight of emergency group decisions on subway fires**

After obtaining group weights for the plans, the four decision-making experts $D_1, D_2, D_3, D_4$ respectively use indeterminate information to make a pairwise comparison between the properties $d_1, d_2, d_3$ concerning their degree of importance, to get interval number reciprocal judgment matrixes $\tilde{B}^1, \tilde{B}^2, \tilde{B}^3, \tilde{B}^4$.

Table 2 Weight interval judegement of emergency scenario attributes

| Decision Expert | d1 | d2 | d3 |
|---|---|---|---|
| D1 | [0.362, 0.497] | [0.081, 0.100] | [0.188, 0.217] |
| D2 | [0.435,0.550] | [0.107,0.152] | [0.139,0.231] |
| D3 | [0.344,0.430] | [0.213,0.287] | 0.154,0.187] |
| D4 | [0.280,0.375] | [0.131,0.132] | [0.475,0.413] |

According to the relative formula, we work out that $j^{1'} = j^{2'} = j^{3'} = j^{4'} = 0$, which shows that all the above judgment matrixes $\tilde{B}^1, \tilde{B}^2, \tilde{B}^3, \tilde{B}^4$ are consistent reciprocal judgment matrices. In addition, according to $d_{ij}^{k-} = d_{ij}^{k+} = 0$, we work out the judgment of all the experts $D_1, D_2, D_3, D_4$ on the weight ranges of all the properties $d_1, d_2, d_3$, as is shown in Tab.2. To take decision-making expert $D_1$ for example, the comparison of his three properties' importance can be expressed by interval numbers as [0.362, 0.497,[0.081, 0.100]，[0.188, 0.217] after being calculated.

After normalizing the expert weights under each property, put them into the formula and work out finally that the mean estimated value of attribute weights is that $\overline{w}_1 = 0.473, \overline{w}_2 = 0.137, \overline{w}_3 = 0.179$.

**Result analysis on emergency group decisions on subway fires**

At last, based on the calculations of the plans' group weights and attribute weights, we compute the decision group members' group evaluation value $G_j$ of alternative set. After making a local preference judgment on the scheme set $S^* = \{S_1, S_2, \cdots, S_7\}$, experts $D_1, D_2, D_3, D_4$ gather group's opinions, thinking plan $S_3$ is the best one according to their ordering of optimization preference for all the plans: $S_3 > S_5 > S_2 > S_1 > S_6 > S_4 > S_7$.

Besides, according to the relative formula, we obtain the decision group members' individual local evaluating value $R_j^k$ for alternative offer, as is shown in Tab.3. According to the experts' calculations of the individual local evaluating value in Tab.3, expert $D_1$ sorts his emergency plan set $\{S_1, S_2, S_3\}$ as $S_3 > S_2 > S_1$ according to his own individual preference; expert $D_2$ sorts his emergency plan set $\{S_1, S_4, S_5, S_6, S_7\}$ as $S_5 > S_4 > S_1 > S_6 > S_7$ according to his own individual preference; expert $D_3$

sorts his emergency plan set $\{S_2, S_3, S_4, S_5, S_6\}$ as $S_3 > S_5 > S_2 > S_6 > S_4$ according to his own individual preference; expert $D_4$ sorts his emergency plan set $\{S_1, S_6, S_7\}$ as $S_1 > S_6 > S_7$ according to his own individual preference.

By gathering the experts' individual partial evaluations, we get a group evaluation result basically the same to the experts' individual local evaluation result, only that the group sorts plans $S_6$ and $S_4$ differently from the individual preference of expert $D_2$. When making an analysis on this problem, we find that expert $D_3$ has also participated in evaluating plans $S_4$ and $S_6$. By comparing the weights of expert $D_2$ and expert $D_3$, we find that the group members agree with expert $D_3$ who has greater degrees of importance in sorting and opinions. So here we can view that the group preference is rational.

In addition, the reckoning in Tab.3 also indicates that if consulting expert $D_1$, emergency evacuation plan $S_3$ should be selected for the fire accident. Accordingly, if we only use the individual opinions of experts $D_2, D_3, D_4$ for references, then emergency evacuation plans $S_5, S_3, S_1$ will separately serve as the basis for emergency response. However, such individual decisions of the experts are obvious incomplete. On the one hand, each expert just makes a local decision on the scheme set dependent on his domain knowledge, so there is lack of integral comparability between all the schemes in the set; on the other hand, since we don't gather the individual preferences of the decision experts, the preceding evaluation results have failed to integrate the opinions of the decision group, so individual decision making is lack of effectiveness.

Table 3 Partial pretenence values and ranking of emergency decision expert individual

| proposal | $R_j^1$ | Sort | $R_j^2$ | Sort | $R_j^3$ | Sort | $R_j^4$ | Sort |
|---|---|---|---|---|---|---|---|---|
| $S_1$ | 0.127 | 3 | 0.198 | 3 | —— | | 0.387 | 1 |
| $S_2$ | 0.153 | 2 | —— | | 0.166 | 3 | —— | |
| $S_3$ | 0.387 | 1 | —— | | 0.323 | 1 | —— | |
| $S_4$ | —— | | 0.197 | 2 | 0.109 | 5 | —— | |
| $S_5$ | —— | | 0.189 | 1 | 0.217 | 2 | —— | |
| $S_6$ | —— | | 0.134 | 4 | 0.153 | 4 | 0.353 | 2 |
| $S_7$ | —— | | 0.148 | 5 | —— | | 0.210 | 3 |

## Conclusion

According to the local group decision model presented by this paper, the expert group has made an emergency decision on the subway fire accident, thinking emergency evacuation plan $p_3$ should be adopted, that is, the train should be pulled up in the tunnel and ventilation system should be opened to protect the passengers from poisonous smoke, and the passengers shouldn't be evacuated for the time being.

**Keywords:** Metro; collapse; risk; effect coefficient method; TSP203.

**Abstract.** Tunnel collapse is one of the most common accidents in the tunnel construction of city subway, and risk assessment is a method to measure the magnitude of the collapse risk. In order to effectively identify in advance the risk category of tunnel collapse, an identification method is put forward based on entropy weight method and efficiency coefficient method. On the basis of a comprehensive analysis of factors that affect the collapse, 6 main factors including rock level, tunnel depth, tunnel span, the surrounding conditions, groundwater and construction factors are selected as the evaluation indexes. Through a quantitative description of the evaluation indexes by using the TSP203 geological prediction system, and based on the basic principles of ideal point method, a comprehensive and intelligent evaluation model which can identify the tunnel collapse risk in subway construction is established. Finally, the model is applied to practical engineering, and it shows that the result of risk assessment is consistent with the actual construction conditions, which provides a new perspective on the advancing identification of tunnel collapse risk in subway construction.

## Introduction

With the rapid development of China's urban rail transit construction. The engineering geological conditions become increasingly complex and confronting problem is increasingly challenging . collapse is common disaster in construction of the subway tunnel, most of the domestic construction subway tunnel have occurred collapse more or less.It is not only to bring hinder tunnel construction, but also seriously threat to the safety of equipment and person. Due to the complexity of the surroundings in the city, the tunnel collapse would also have a significant social impact.So the tunnel collapse risk assessment study has important significance.

For subway tunnel collapse risk assessment, the method is generally used engineering experience analogy. That is, by comparing with similar collapse in engineering and engineering-related information to predict the subway tunnels along the route, there are some scholars adopt comprehensive evaluation method for collapse-related information on a comprehensive analysis to analyze different sections of collapse risk. Such as the risk index method, fault tree analysis, Monte Carlo simulation method, AHP, fuzzy evaluation method, influence diagram method,LECD and so on. These methods are more subjective, there are a lot of inconvenience in practice .The collapse risk assessment results are often inconsistent with the actual situation.

## The basic principle of efficacy coefficient method

Efficacy coefficient method also can be called as efficacy function method, based on the principle of multi-objective planning, According to the multi-grade standards, the evaluation index can translate into measurable evaluation scores through conversion function, and then an overall evaluation is obtained according to the evaluation objects , and judge the merits based on the final score, This method is used to evaluate the object with comparison, ordering, and rarely used for classification.We have a new try to apply it to grade the risk .Calculate the maximum and minimum efficiency coefficient for each classification. to determine the efficiency coefficient demarcation point, and make the classification more reasonable. the improved evaluation steps as follows:

2.1 Set the classification standard

Classification standard is the max and min value of corresponding evaluation of some category, the max limit value is the max standard of one category, and the min value is the min standard. set evaluation standard vector is $Y=(y_1,y_2,\ldots,y_m)$ , classification number is m, and standard value number is m+1, classification standard value is $k_j(j=0,1,2,\ldots,m+1)$

2.2 Indentify standard coefficient of standard value

Standard coefficient is the level coefficient of corresponding standard value, Objectively reflect the different levels of evaluation criteria value, it is used to calculate the index of the actual value corresponds to the standard value, the standard value for each category, there is a corresponding coefficient. Standard coefficients is represented with number ranged between 0-1 , record as $\lambda_j$ $(j=1,2,\ldots,m+1)$ .Calculate formulation as follows:

For efficiency index that the larger value is the better:

$$\lambda_j=\begin{cases}1 & k_j \geq x_{\max}\\ \dfrac{k_j-x_{\min}}{x_{\max}-x_{\min}} & x_{\min}<k_j<x_{\max}\\ 0 & k_j \leq x_{\min}\end{cases} \tag{1}$$

For cost-type index that the smaller value is the better:

$$\lambda_j=\begin{cases}1 & k_j \leq x_{\min}\\ \dfrac{x_{\max}-k_j}{x_{\max}-x_{\min}} & x_{\min}<k_j<x_{\max}\\ 0 & k_j \geq x_{\max}\end{cases} \tag{2}$$

In the formulation, $\lambda_j$ is the standard coefficient; $k_j$ is the standard value; $x_{max}$ is the max index; $x_{min}$ is the min index.

2.3 Determine the weight of each index

Entropy method is used here. "Entropy" has been widely used in many fields. In information theory, the information is a measurement of the ordering degree , the information entropy is defined as:

$$e_j=-k\sum_{i=1}^{m}p_{ij}\cdot\ln p_{ij} \quad p_{ij}=r_{ij}\Big/\sum_{i=1}^{m}r_{ij} \tag{3}$$

In the formulation, $k=1/\ln m$ ,$r_{ij}$ is the evaluation of i term under j index， $e_j$ is the confusion degree of j evaluation index, that is, entropy value.

The entropy of the evaluation index j is:

$$w_j=(1-e_j)\Big/\sum_{j=1}^{n}(1-e_j) \tag{4}$$

2.4 Determine the effective coefficient of individual indicators

Efficacy coefficient e single index includes two parts, one is basis score,it is calculated by the standard values of some index.The other one is adjusted score ,it is calculated by the extra part that the index actual value exceed standard values.

The computational formula of basis score is: $b_i=\omega_i\lambda_j$,the computational formula of adjusted score is

$$\varepsilon_i=w_i(\lambda_{j+1}-\lambda_j)\left(\frac{x_i-k_j}{k_{j+1}-k_j}\right) \tag{5}$$

So the effective coefficient of individual indicators is:

$$e_i = b_i + \varepsilon_i = w_i(\lambda_j + (\lambda_{j+1} - \lambda_j)(\frac{x_i - k_j}{k_{j+1} - k_j})) \tag{6}$$

$k_{j+1}$ is upper standard value, $k_j$ is bottom standard value, $\lambda j_{+1}$ is upper standard coefficient,$\lambda j$ is bottom standard coefficient. $\omega_i$ is the weight .$x_i$ is actual value.

2.5 Calculate the total efficiency coefficient

The total efficiency coefficient is the summation of each individual indicators efficacy coefficient. The formula is:

$$E = \sum_{i=1}^{n} e_i \tag{7}$$

2.6 Get the total score in each category and the classification of evaluation object

Plugge the various categories of standard efficiency coefficient values into the formula (1), calculate for total efficiency coefficient corresponding to each category, Determine the classification criteria, and then determine the cave belong to which category.

## Index system in advance of subway tunnel collapse risk evaluation

TSP203 system is Switzerland Ann's measurement technology companies to develop a new generation of advanced geological forecast system. In comprehensive consideration of TSP203 can detect effectively on the basis of the data and the factors influencing the subway tunnel collapse.

This paper selected surrounding rock classification, buried depth, span and surrounding environment, the influence of groundwater and construction management of six major factors as tunnel collapse risk evaluation index. The level of the surrounding rock and groundwater development situation based on TSP203 advance geology forecasting system, tunnel buried depth, span, surrounding environment and construction factor obtained by site investigation.

Based on the experience and the results of previous studies, the tunnel collapse risk is divided 5 Levels, very dangerous, dangerous,normal, safe,very safe, and corresponding risk levels are as follows: I Level, II Level, III Level, IV Level and V Level . The classification of the division of each evaluation is shown in Table 1

Table 1 Indices and criterion for collapse risk assessment

| Collapse risk level | I | II | III | IV | V |
|---|---|---|---|---|---|
| Vp/km/s | 0-1.5 | 1.5-2.5 | 2.5-3.5 | 3.5-4.5 | 4.5-6.0 |
| burial depthH/m | 0-5 | 5-10 | 10-15 | 15-20 | 20-30 |
| spanD/m | 21-30 | 15-21 | 9-15 | 5-9 | 0-5 |
| Groundwater | 0.8-1.0 | 0.6-0.8 | 0.4-0.6 | 0.2-0.4 | 0-0.2 |
| surroundings | 0.8-1.0 | 0.6-0.8 | 0.4-0.6 | 0.2-0.4 | 0-0.2 |
| Construction management | 0.8-1.0 | 0.6-0.8 | 0.4-0.6 | 0.2-0.4 | 0-0.2 |

## Engineering Applications

4.1 Project overview and the tunnel collapse risk classification

Project of Qingdao Metro ( 3 Line) route Shinan District, Shibei District, Sifang District, and Licang District, approx 24.9km. All underground lines, to Qingdao subway's first line, societies that are significant. This paper has the station underground line to licun part of Hexi, include 5subway station and 5 interzone tunnel. The tunnel is single holes and single horseshoe-shaped structure, distance between two hole is 12m, and expanding the section construction of air defense section. According to the survey of geological data, the section thickness of Quaternary 10.1~17.9 metres, mainly consisting of Quaternary holocene artificial filled soil (Q4ml), the flood-alluvial (Q4al+pl) and upper

Pleistocene alluvium (Q3al +PL). Sites dominated by coarse-grained granite bedrock, interspersed with granitic porphyry vein-in the meantime, part of the tunnel under water-rich Sandy layers, construction risk is significant.

4.2 Standard coefficient of standard value of categories

In the establishment of the index system for evaluation of surrounding rock stability, span, groundwater surroundings, construction management belong to the benefit indicators, that is,the higher the value, the lower the stability of the surrounding rock, the greater the risk of collapse in tunnel. The rest indicators are cost index, that is, the lower the value, the lower the stability of the surrounding rock, the greater the risk of collapse in tunnel. The standard value and standard coefficients of each indicators is showen in Table 2.

Table 2 Standard value and standard coefficient of each classification

| level | Vp | | Burial depth | | Span | | Groundwater | | Surroundings | | Construction management | |
|---|---|---|---|---|---|---|---|---|---|---|---|---|
| | SV | SC | SV | SC | SV | SC | SV | SC | SV | SC | SV | SC |
| I | 0 | 0 | 0 | 0 | 30 | 0 | 1.0 | 0 | 1.0 | 0 | 1.0 | 0 |
| II | 1.5 | 0.25 | 5 | 0.17 | 21 | 0.30 | 0.8 | 0.2 | 0.8 | 0.2 | 0.8 | 0.2 |
| III | 2.5 | 0.41 | 10 | 0.33 | 15 | 0.50 | 0.6 | 0.4 | 0.6 | 0.4 | 0.6 | 0.4 |
| IV | 3.5 | 0.58 | 15 | 0.50 | 9 | 0.70 | 0.4 | 0.6 | 0.4 | 0.6 | 0.4 | 0.6 |
| V | 4.5 | 0.75 | 20 | 0.67 | 5 | 0.83 | 0.2 | 0.8 | 0.2 | 0.8 | 0.2 | 0.8 |

4.3 Engineering application

To test the reliability of the model, apply the model to post 4 different hole recognition tunnel collapse risks.TSP203 combined field data and field research to determine evaluation parameters of the tunnel section, as Table 3 below:

Table 3 Assessment of collapse risk factors

| number | $V_p$ | Burial depth | span | Groundwater | Surroundings | Construction management |
|---|---|---|---|---|---|---|
| 1 | 0.91 | 11 | 6.2 | 0.71 | 0.7 | 0.5 |
| 2 | 2.4 | 16 | 11.2 | 0.41 | 0.8 | 0.45 |
| 3 | 3.2 | 13 | 8.1 | 0.26 | 0.3 | 0.5 |
| 4 | 0.37 | 9.5 | 6.2 | 0.82 | 0.95 | 0.3 |

After determining the risk evaluation index of the cave.Carry out dimensionless processing of each index to eliminate size disparity. According to formula (3), establish evaluation cave collapse risk assessment matrix. Based on the theory of entropy formula (4),we can calculate the weighted values for each indicator.The evaluation index weight value are : 0.51, 0.04, 0.07, 0.19, 0.15, 0.04.

Combine standard values ,standard coefficient , each weights and calculation formula(6)(7),we can get the total efficiency coefficient range of collapse risk rating.We can get that level I total efficiency coefficient range is 0~0.2313. Similarly to other levels of total efficiency coefficient range, level II is 0.2313~0.4093, level III is 0.4093～0.5928,level IV is 0.5928～0.7714 ,level V is 0.7714～1.

According to equation (6) and Table 7 for each index value of the evaluation section cave,we can calculate the collapse risk of the evaluation cave.Taking hole 1 as an example for illustration purposes. TSP wave velocities measured to 0.91from table 2 shall have a level II risk, and then from table 4 to its standard value is 0 , standard coefficient is 0, upper standard value is 1.5, upper standards coefficient is 0.25, its weight is 0.51.Thought equation (6) the individual indicators efficiency coefficient of rock wave velocity is:

$$e_{1\cdot} = 0.51\left[0.25 + (0.25-0)\frac{0.91-0}{1.5-0}\right] = 0.0765 \tag{8}$$

In a similar way we can get the rest individual indicators efficiency coefficient. Thought formula (7) we can get that total efficiency coefficient is:

$$E = \sum_{i=1}^{5} e_i = 0.26653 \tag{9}$$

So cave 1 belongs to level I (0.2313～0.4093).The result is showed in table 4.

Table 4 Comparative results of surrounding rock

| number | individual indicators | | | | | | total | level | actual |
|---|---|---|---|---|---|---|---|---|---|
| | $V_p$ | depth | span | groundwater | surroundings | management | | | |
| 1 | 0.0765 | 0.01456 | 0.05537 | 0.0551 | 0.045 | 0.02 | 0.26653 | II | II~III |
| 2 | 0.20094 | 0.02136 | 0.05411 | 0.1121 | 0.03 | 0.022 | 0.44051 | III | III |
| 3 | 0.26979 | 0.01728 | 0.0511 | 0.1406 | 0.105 | 0.02 | 0.60377 | IV | III~ IV |
| 4 | 0.0306 | 0.01256 | 0.05537 | 0.0342 | 0.0075 | 0.028 | 0.16823 | I | I |

## Conclusions

1. This paper presents a method that grade the risk of collapse in front of the subway tunnel face in advance ,which is based on the results of a probe TSP203 and the use of intelligent rock mechanics method. Engineering applications show that the method is practical, workable.It provides a new idea for subway tunnel collapse risk assessment . The idea is universal in solving complex problems in geotechnical engineering.

2. This article apply entropy weight method and effect coefficient method to the subway tunnel collapse risk assessment ,and the risk level compared with the actual results show that this method is accurate. This method is after all just an evaluation and analysis methods, in practical application process, taking into account the factors that affect the risk of subway tunnel collapse, should further improve the evaluation system, and try to adopt a more scientific approach to determine the weight of each index to improve the accuracy.

**Keywords:** geo-grid; reinforced earth-retaining wall; stability analysis; FEM strength reduction; dynamic analysis

**Abstract.** Due to the special mesh structure, geo-grid material can avoid local subsidence of filling material, reduce uneven settlement of soil mass to the largest degree and improve the whole stability of soil mass, so the reinforced earth-retaining wall with geo-grid is widely used in engineering. Meanwhile, researches on its dynamic characters are not enough and it is hard to judge the whole stability of reinforced earth-retaining wall under seismic condition. When unstable failure happens, the location of failure surface can hardly be identified. These disadvantages have seriously limited the development of this supporting method and cause unsafe potentials for engineering. Based on the FEM strength reduction dynamic analysis and combined with practical engineering, the paper conducts stability analysis on the reinforced earth-retaining wall of geo-grid under seismic condition and the research achievements provide a new thinking for the seismic design of reinforced earth-retaining wall with geo-grid.

## Introduction

With the rapid development of the economy in China, the application and the scales of reinforced earth-retaining wall with geo-grid are both increasing. The design should satisfy not only the requirements of static safety but also the requirements of seismic design. The researches corresponding to static condition are comparatively enough relatively mature [1~4]. Studies on the seismic design are few and there is no reasonable standards accepted in engineering. Only a few of research achievements are focused on the stress and deformation characteristics, and the inner stability of the structure of reinforced earth-retaining wall under seismic condition. It is hard to judge the whole stability of reinforced earth-retaining wall dor dynamic loads. When unstable failure happens, the most dangerous failure surface cannot be identified [5~8]. These disadvantages have seriously limited the development of this supporting method and caused unsafe potentials for engineering.

So based on FEM strength reduction dynamic analysis [9,10] and combined with the traditional pseudo-static method, seismic analysis on a certain engineering with high reinforced earth-retaining wall with geo-grid has been conducted in the paper. The calculation results show that the dynamic performance of reinforced earth-retaining wall with geo-grid in the engineering is satisfactory and can reach the requirements of seismic design. The research achievements provide a new thinking for the seismic design of reinforced earth-retaining wall with geo-grid.

## Theory of FEM strength reduction dynamic analysis

①Theories of FEM strength reduction dynamic analysis

Under static condition, FEM strength reduction respectively reduces the parameters of shear strength c and tan φ by c/ω and tan φ/ω till ultimate equilibrium state. The reduction coefficient at the moment

is the safety factor of the slope. At present, the stability analysis under static condition through this method is very mature[11,12].

Under seismic condition, the dynamic magnifying coefficient of slope would increase and the slope is becoming closer to the unstable failure with the reduction of material parameters. And the failure mode of slope under seismic condition is mostly tensile-shear failure, so the reduction of tensile strength should be considered during the strength reduction, that is $\sigma_t'=\sigma_t/\omega$.

②Discussions on the failure conditions

The criteria of unstable failure should be clear if adopting FEM strength reduction to calculate the safety factor. At present, three criteria of unstable failure under static condition are: (1) the transfixion of plastic zone or the equivalent plastic strain from the slope foot to slope top; (2) the mutation of strain and displacement of sliding place in soil mass; (3) the non-convergence of static equilibrium calculation. In static calculation, the transfixion of plastic zone is not sufficient but necessary condition for whole failure of slope [11, 12], so the non-convergence in the calculation is often taken as the criterion of unstable failure.

In the dynamic analysis under seismic condition, the above three criteria can also be used to judge the unstable failure in principle: (1)the transfixion of failure surface (tensile-shear failure surface); (2)the mutation of the displacement of the potential sliding mass. Considering the load is always changing with time under seismic condition, so the displacement would change at any time. Different with the static condition, the mutation of the displacement at a certain moment cannot judge the unstable failure. If the final displacement after dynamic effects mutates, the mutation of the relationship curve between reduction coefficient and the displacement can be identified as the criterion of unstable failure; (3)the non-convergence of displacement or speed can be regarded as the failure criterion. Due to the complication of the dynamic analysis under seismic condition, all the above three criteria should be used to judge the unstable failure under seismic condition.

Compared with other methods, FEM strength reduction dynamic analysis possesses the following advantages: (1)as a complete dynamic method, it does not need to search the failure surface and evaluate dynamic load empirically. The seismic wave can be used directly to evaluate the stability under dynamic condition so as to reduce the influence of artificial assumption; (2) the practical tensile-shear failure surface under seismic condition can be obtained directly; (3) it can take the interaction between rock and soil mass and the supporting structure into consideration to fully reflect the dynamic properties of rock and soil mass, so more reasonable safety factor under dynamic effects can be worked out.

## Practical engineering

In a high embankment engineering in a certain airport, reinforced earth-retaining wall with 60 meters high is constructed. The retaining wall composes of four stages. Each stage is 15 meters high with an inclining angle of 70° . The lengths of geo-grids from the bottom to the top are respectively 45 meters, 37 meters, 30 meters and 25 meters. The vertical interval between geo-grids is 0.4 meters. The platform with 3 meters wide is set every 15 meters along the retaining wall vertically. The comprehensive gradient is 1:2.5, as shown in Figure 1.

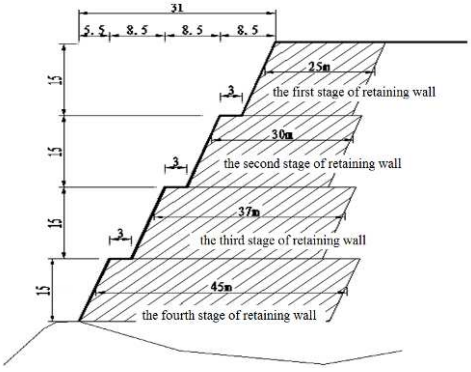

**Fig. 1 Layout of reinforced earth-retaining wall with geo-grid**

The interaction between geo-grid and the soil is simulated through setting coupling spring and the stress transfer satisfies the Mohr-Coulomb criterion. Except press, only tension is considered for the geo-grid material, which is flexible material without flexural rigidity. So the constitutive relationship of the geo-grid element can be simplified as linear elasticity and regarded as one-dimensional element deforming along the axial direction, as shown in Figure 2. If only considering displacement in the horizontal direction, the relationship between the stress and the displacement of node is $\{p\}=[k]^e\{u\}$, where $\{p\}$is the stress on node,$\{p\}=\begin{Bmatrix} p_i \\ p_j \end{Bmatrix}$;$\{u\}$ is the displacement of node,$\{u\}=\begin{Bmatrix} u_i \\ u_j \end{Bmatrix}$; $[k]^e$ is the matrix of element stiffness; $[k]^e=\frac{AE}{L}\begin{bmatrix} 1 & -1 \\ -1 & 1 \end{bmatrix}$; A is the cross section area; L is the element length. The mechanic properties in the shear direction of the geo-grid is shown in Figure 3, where $c_{inter}$ and $\varphi_{inter}$ are the strength parameters of geo-grid and soil interface. The mechanic and physical parameters of rock and soil mass and geo-grid material are shown in Table 1.

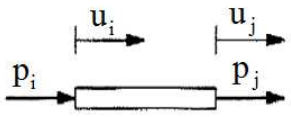

**Fig. 2 Element of reinforced material of geo-grid**

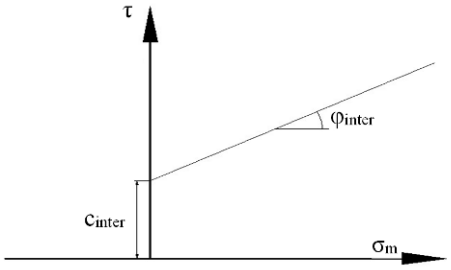

**Fig. 3 Failure line of shear strength**

**Table 1 Physical and mechanic parameters of the materials**

| Material | Unit weight of soil/kN·m$^{-3}$ | Elastic modulus /MPa | Poisson ratio | Cohesion /kPa | Inner friction angle/° |
|---|---|---|---|---|---|
| Backfill soil | 20 | 45 | 0.3 | 10 | 30 |
| Bed rock | 23 | 1600 | 0.14 | 1000 | 33 |
| Geo-grid | - | - | - | 7.0 | 24.23 |

The input seismic wave is Linghe Wave(Linghe, 1995, NS direction) and the peak acceleration is 0.17g, which is larger than the basic fortification intensity 7 degree, but less than 8 degree. In the numerical simulation, bidirectional input is used where the peak acceleration in the vertical direction is 2/3 of that in the horizontal direction. The slope sites is free boundary, which can prevent the reflection of seismic wave on the boundary to simulate the condition of infinite field boundary under seismic condition. Local damping is used to satisfy the requirements on precision of general engineering and the damping coefficient is 0.157.

Through intercepting the major energy section, the duration of inputting seismic wave is 10 seconds. The filtered seismic wave after correcting the baseline is shown in Figure 4. The FEM strength reduction dynamic analysis mentioned above is used to analyze the stability of reinforced earth-retaining wall.

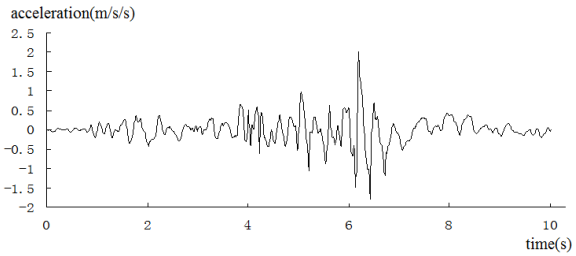

**Fig. 4 Inputting seismic wave**

Stability analysis should be conducted under dead weight condition first to judge whether it can satisfy the design requirement. The mesh of model and the location of data points A~H are shown in Figure 5.

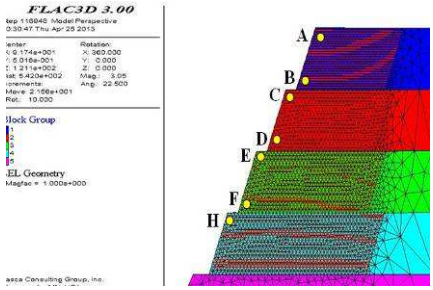

**Fig.5 The mesh of reinforced earth-retaining wall and the location of data points**

The engineering is carried out stage by stage to ensure the safety requirement during construction. The safety factor of each construction stage is obtained through calculation stage by stage, which are shown in Table 2. Under dead weight condition, the safety factor of the engineering is 1.39. At the moment, the maximum stress on the geo-grid is 92.54kN/m and the strength reservation of geo-grid itself is 2.18, which can satisfy the design requirement.

**Table 2 Safety factor of each stage of engineering under dead weight condition**

| Stage | The 4th stage | The 3rd stage | The 2nd stage | The 1st stage |
|---|---|---|---|---|
| Safety factor | 1.75 | 1.58 | 1.45 | 1.39 |

Then the stability analysis under stress field of dead weight and seismic condition is carried out to identify the dynamic safety factor. By adopting FEM strength reduction dynamic analysis, mutation happens in the accumulated displacement after dynamic effects in data point A when the reduction coefficient is 1.17, as shown in Figure 6. Unstable failure can be judged initially and the dynamic safety factor is between 1.14 and 1.18.

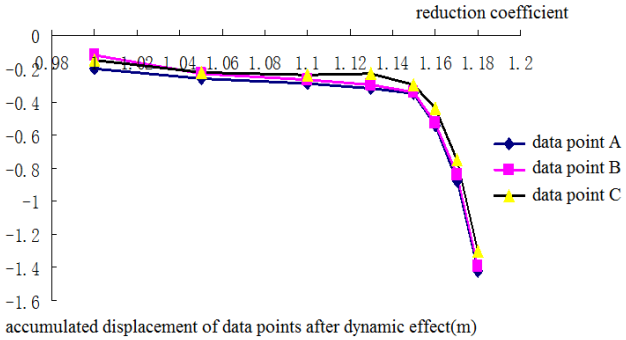

**Fig. 6 Relationship curve between displacement and reduction coefficient of data points after dynamic effect**

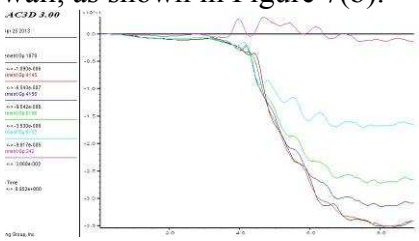
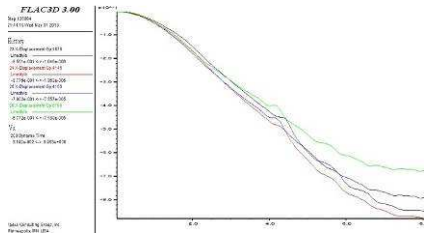
When the reduction coefficient is 1.15, convergence of the displacement after dynamic effect appears in the calculation and the structure can still bear loads. Failure has not happened on the retaining wall, as shown in Figure 7(a). When the reduction coefficient is 1.17, convergence of the displacement does not happen after seismic effects in the calculation and failure happens on the retaining wall, as shown in Figure 7(b).



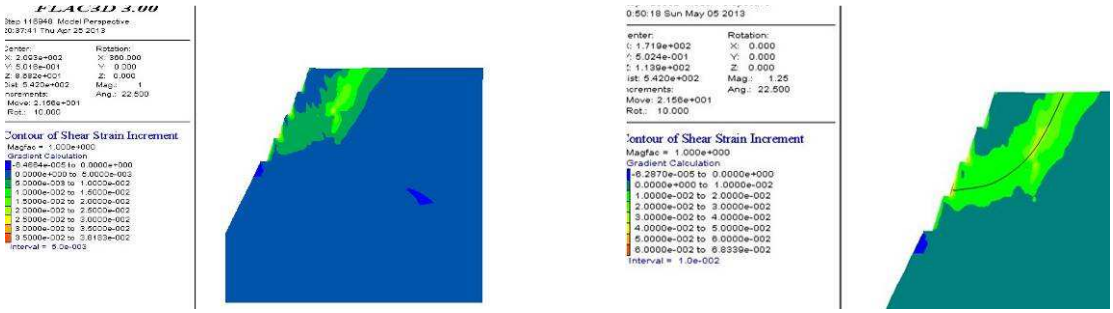
**(a) Reduction coefficient is 1.15.**



**(b) Reduction coefficient is 1.17.**

**Fig.7 Time-history curve of horizontal displacement of each data point under different reduction coefficient**

When the reduction coefficient is 1.15, shear plastic zone transfixes. The max shear strain of the plastic zone is within 3% and most parts are less than 1%, which implies it has the tendency of failure and failure has not happened, as shown in Figure 8(a). When the reduction coefficient is 1.17, the maximum of shear strain is up to 6.8% and the plastic zone transfixes, so failure happens on the retaining wall, as shown in Figure 8(b). In conclusion, the dynamic safety factor of this engineering is about 1.16.



**(a) Reduction coefficient is 1.15.** **(b) Reduction coefficient is 1.17.**

**Fig. 8 Nephogram of shear increment under different reduction coefficient**

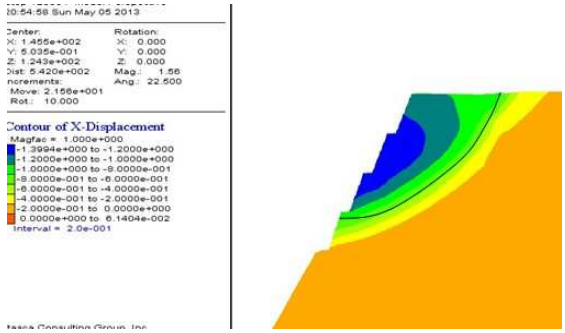


**Fig. 9 Nephogram of horizontal displacement(Reduction coefficient is 1.17)**

The location of failure surface can be identified through the mutation of plastic strain or displacement when unstable failure happens, especially the mutation of plastic strain which is more obvious. The mutation of plastic strain is usually on the point where the max plastic strain is. So the location and morphology of the failure surface can be identified through this principle. If connecting the points where the plastic strain increases in Figure 8(b) , the curve would be the location and morphology of failure surface, as the black curve in Figure 8(b) shows. The change of contour line of displacement in Figure 9 can also illustrate the failure surface. The failure surface identified through these two methods are basically the same, which slides out along the bottom of the third stage of retaining wall.

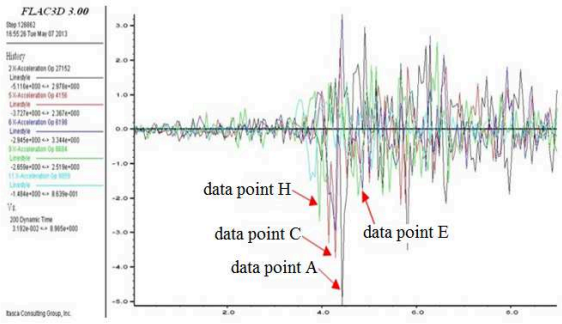

**Fig. 10 Time-history curve of acceleration of each data point**

Figure 10 is the time-history curve of acceleration of the data point on the top of each stage of reinforced earth-retaining wall, which shows the higher the data point, the larger the peak acceleration, the more obvious the magnifying effect is. If defining the ratio of peak acceleration to

the peak value of input seismic wave (0.17g) as the magnifying coefficient of acceleration, it is about 1.29~2.95 under seismic condition.

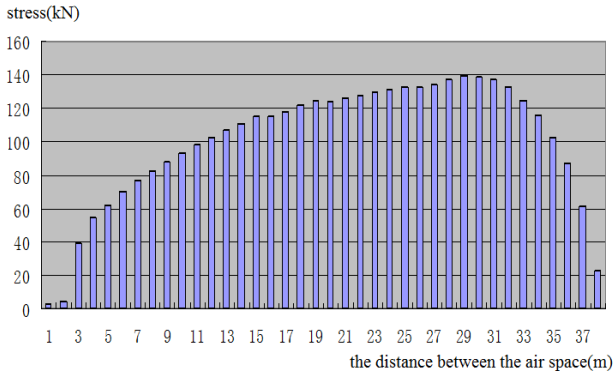

**Fig. 11 Layout of stress on the bottom of the third stage of earth-retaining wall (Reduction coefficient is 1.16)**

Figure 11 is the layout of stress on the bottom of the third stage of earth-retaining wall. The stress on the geo-grid increases linearly from the air space to a certain depth and then reduces gradually. The max tension of the reinforced bar is 139.8kN/m, which is less than the ultimate tension of the reinforced bar (200 kN/m). The strength reservation of the reinforced bar itself is about 1.43 ,so the design requirements of geo-grid under seismic condition can be satisfied.

## Summary

The paper introduces FEM strength reduction dynamic analysis into the seismic design of reinforced earth-retaining wall with geo-grid. Combined with practical engineering, the safety factor, the dynamic response of earth-retaining wall and the location of failure surface of unstable failure under seismic condition can be worked out. The research achievements can provide a new thinking for the seismic design of reinforced earth-retaining wall with geo-grid.

**Keywords:** Yiliang Earthquake, Low-cycle Fatigue, Damage Mechanism

**Abstract.** According to the analysis of the structure, topography, earthquake sequence, and earthquake hazards in September 2012 earthquake of Yiliang County, Yunnan Province, the mechanism of the earthquake damage is given. The low-cycle fatigue, shallow source, topography, population density, seismic capacity of the structure and seismic awareness of the residents is the main damage factor. This research provides a reference to the seismic design of analogous regions.

## Introduction

At 11:19(Beijing time) on September 7, 2012, Yiliang County, Yunnan Province, 5.7 earthquake occurred, with focal depth of 14.0 km. At 12:16 on September 7, 5.6 earthquake occurred, with focal depth of 10.0 km. By 18:00, in Zhaoyang-Yiliang area there had been 72 earthquakes in which 16 ranged from 0 to 0.9 ML, 26 from 2.0 ML to 2.9 ML, 6 from 3.0 to 3.9 ML, 2 from 4.0 to 4.9 ML and 2 from 5.0 to 5.9ML. As at 11:00 on the 9th, a direct result of the earthquake is that 81 people were

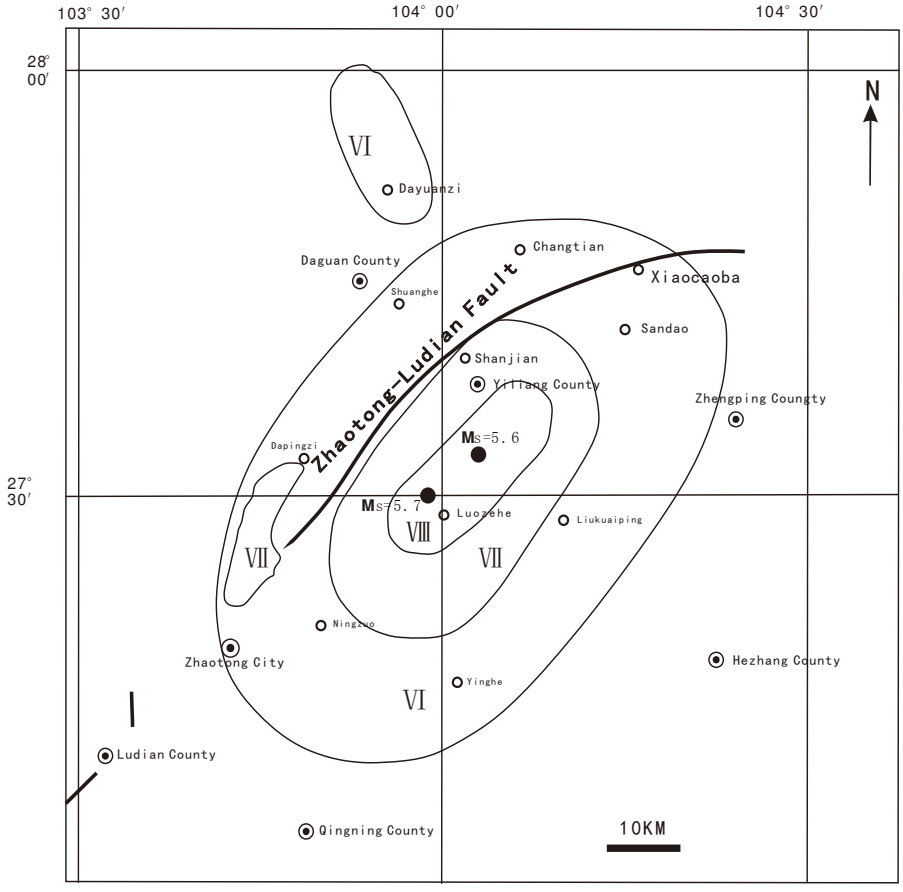

Fig.1 Yunnan Yiliang seismic intensity distribution

killed. On 4 October, triggered secondary disasters caused 19 people to be killed, and the affected population is over 740,000. The earthquake caused direct economic losses of 8.279 billion yuan. In order to clarify the mechanism of damage, in this paper, structure characteristics, topography, and earthquake sequences are analyzed. Figure 1 shows the Yunnan Yiliang seismic intensity distribution.

**Geology and Geomorphology of Yiliang County.** In the disaster area, the terrain shows that the south-west is higher, and the northeast is lower; and that the west-east is narrower and the north-south is wider. The terrain slopes from southwest to northeast, indicating the landforms of deep canyon. The most areas were eroded mountain cut by rivers, and gulling is evident. The peak elevation is 2780m, the lowest elevation 520m, and relative elevation reaches 2260m. There is no doubt that the terrain can help the occurrence of secondary earthquake disaster (Fig.3). After the earthquake, at part of the road on both sides of the mountain in Yiliang County, collapse occurred and huge stones from the mountain slided down. This led to the very serious traffic congestion, and the rescue teams can only go forward on foot, slowing the rescue process. As figure 2 shows, the zone with seismic intensity Ⅷ is located in low-lying valley.

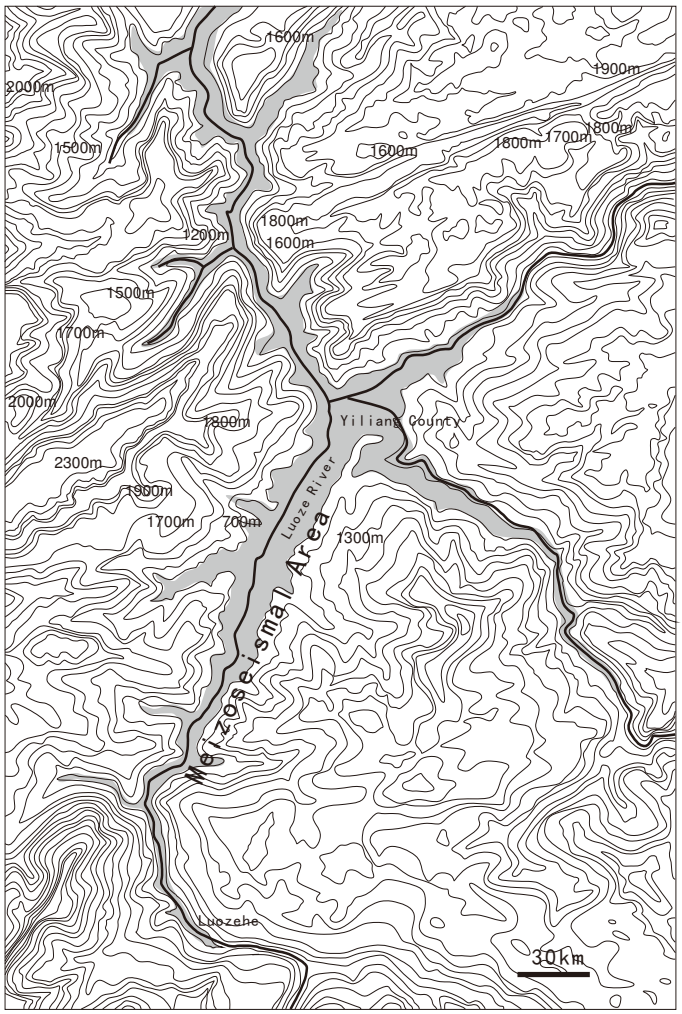

Fig. 2 Topographic maps in disaster area

Fig. 3 Secondary damage

**Structure Features.** In the disaster area, the structure is that of stone concrete, wood and concrete, brick wood, brick concrete, and frame structure (Fig. 4). Generally speaking, the seismic performance of the structures is weak. The reason of poor performance of anti-seismic structure is that the economy is relatively uncultured, and people's awareness is very weak.

Fig. 4 Destruction of wood and concrete structure

**Shallow Earthquake.** The 5.7 magnitude earthquake focal depth is 14 km, and 5.6 earthquake focal depth is 10 km. For shallow earthquake, the focal depth is also shallow. So, although the magnitude of the earthquake is not high, because of the shallow focal depth, the damage is evident.

**The Population Density.** Klose town is 33 km away from the epicenter of Zhaotong City, and 15 km from Yiliang County, and the population density is 205 people per square kilometer, which is twice the average population density of Yunnan Province. Coupled with the time when the earthquake occurred at noon, many people are in the house, and some houses collapsed, causing casualties.

**Low-cycle Fatigue.** When the earthquake make structure vibrate a few to dozens times, a low-cycle fatigue can occur, and lower seismic force can make the structure damage. Low-cycle fatigue is the result for micro cracking to jointly produce significant rupture after many vibrations, thereby destroying the structure.

At 11:19(Beijing time) on September 7, 2012, Yiliang County, Yunnan Province 5.7 earthquake occurred, with focal depth of 14.0 km, and at 12:16 on September 7, 5.6 earthquakes occurred, with focal depth of 10.0 km. Figure 5 is the strong motion records of 5.7 earthquake, recorded in Zhaotong Jing Staion. The peak acceleration of two horizontal components are 51cm/s$^2$ and 56.6cm/s$^2$ respectively. The effective duration about the components was 20 seconds. Figure 6 is the strong motion records of 5.7 earthquake, recorded in Zhaotong Jing Staion. The peak acceleration of two horizontal components are 277.9cm/s$^2$ and196cm/ s$^2$ respectively. The effective duration is much shorter than that of 5.7 earthquake. However, the peak acceleration is very bigger. The difference may

be due to different focal depths, and the focal depth has also effect on duration. Although the peak acceleration of 5.7 earthquake is small, the effective duration is longer, making the structure produce low-cycle fatigue. The effective duration of 5.6 earthquake is small, but peak acceleration is big, so it has great potential for destruction. And that the earthquake of magnitude 5.6 occurred after the 5.7 earthquake is equivalent to increasing the time for earthquake to effect on structure. The superposition of two earthuakes appears more conducive to resulting in low-cycle fatigue. Of course, it is necessary to pay attention to that Zhaotong Jing Station be located in the zone with seismic intensity Ⅶ, and epicentral distance over 20km. It is possible that in epicentral area (with seismic intensity Ⅷ) , the peak acceleration could be higher (no seismic station in epicentral area), the pulse-type ground motion can appear, and the destructive force may be greater. In addition, the two 4 earthquake and many 3 earthquake in the area [1] also help create low-cycle fatigue (3 earthquake often has the power to destroy).

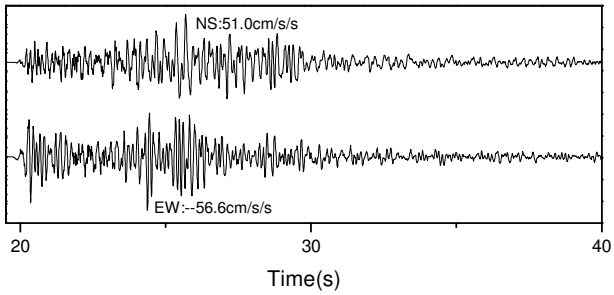

Fig. 5 Strong motion records of 5.7 earthquake in Zhaotong Jing'an Station (the distance of epicenter is 23.52km, and the focal depth is 14km)

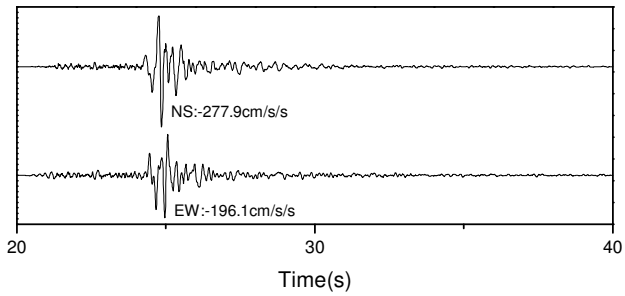

Fig. 6 Strong motion records of 5.6 earthquake in Zhaotong Jing'an Station (the distance of epicenter is 29.35km, and the focal depth is 10km)

## Conclusion

In September 2012 earthquake of Yiliang County, Yunnan Province, the mechanism of the earthquake damage is the low-cycle fatigue, shallow source, topography, population density, seismic capacity of the structure and seismic awareness of the residents.

**Keywords**: Deformation; Hysteretic energy; Steel reinforced concrete piers; Reinforced concrete bridge pier; Multi-modal; Cyclic pushover

**Abstract:** The method of MMCP (modified modal cyclic pushover) which can reflect the dual criterion of deformation and energy was used to make an assessment on seismic performances of the steel reinforced concrete piers and reinforced concrete bridge piers. Then the calculated results were analyzed comparing with the results of dynamic time historical analysis and quasi static test. To some extent, the MMCP analysis may simulate the seismic action. In addition, the MMCP method can also be associated with the design response spectrum, making the evaluation results to be reliable and safe. The results indicate that MMCP applicability analysis also exists in the steel reinforced concrete structure, and the seismic capacity of steel reinforced concrete bridge piers is better than reinforced concrete bridge piers.

## Introduction

In earthquake damage there is a phenomenon: a lot of bridges only got damaged badly without collapse after the first stage of earthquake. However with the repeatedly low intensity of aftershocks, they collapsed. It is generally believed that with the repeated actions of earthquake, a structure will constantly dissipate energy and produce new plastic deformation which will eventually lead to collapse. The cause of the damage of a bridge is it emerges certain deformation and experiences certain process of energy consumption at the same time [6].

This text adopts the type of Ghobarah model:

$$D_G = 1 - \frac{k_f}{k_0} \tag{1}$$

where, $k_0$ and $k_f$ are respectively lateral stiffness of the structure before and after the earthquake.

## The basic principle of Modified modal cyclic pushover[4]

### 1.1.Aseismic maximal displacement evaluation for the multi degree of freedom (MDOF） system

According to the principle of energy spectrum, the result of ESDOF displacement can be obtained. And then according to the principle of energy, ESDOF spectrum displacement can be obtained:

$$S_{d,n} = \sum \Delta S_{d,n} = \sum (\Delta E / \sum_{i=1}^{i=m} F_{i,n}) \tag{2}$$

The transformation based on energy criterion is more stable and the capacity curve reverse problem that neglected model probably can be eliminated.

### 1.2 Assessment for hysteretic energy dissipation of multi-degree of freedom (SDOF) system

Khashaee[1]established the calculation methods based on statistical analysis of a large number of seismic waves on hysteretic energy dissipation of a single degree of freedom system :

$$\frac{E_h}{m} = 0.72(1-\mu^{-1})^{0.7} E_i \tag{3}$$

## Analysis of examples

### 2.1 The numerical example design and finite element model

The model size and reinforcement details are as shown in Table.1 and Fig.2.

**Table.1 Pier design parameters**

| Specimen number | Section size (mm×mm) | Concrete | Axial compression ratio | Steel bone model | Stirrup | Longitudinal reinforcement of column | Reinforcement ratio（%） |
|---|---|---|---|---|---|---|---|
| SRC | 300×300 | c35 | 0.15 | 100x125x6x10 | φ8@100 | 4Φ12 | 3.55 |
| RC | 300×300 | c35 | 0.15 | ------ | φ8@100 | 6Φ25 | 3.27 |

**Fig.2 Example models and fiber section**

### 2.2 The contrastive analysis between the calculation results and the dynamic time history

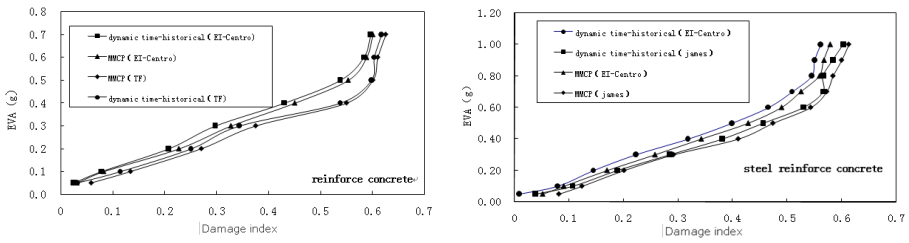

**Fig.3 Whole structure damage evaluation with MMCP method**

It can be seen from the Fig.3, under the influence of El Centro wave, when the earthquake intensity are the same, the damage degree of reinforced concrete bridge piers is smaller than that of the steel encased concrete ones :when the overall damage indexes reach 0.6 (close to collapse [2]), the steel reinforced concrete bridge piers can withstand the EPA 0.89 g of seismic action, and reinforced concrete is only 0.61 g. When the overall damage index is 0.3 (repairable), corresponding

earthquake PGA of steel reinforced concrete bridge piers is 0.41 g, while that of the reinforced concrete bridge piers is only 0.28 g. So the overall seismic capacity of steel reinforced concrete bridge piers is better than the reinforced concrete bridge piers.

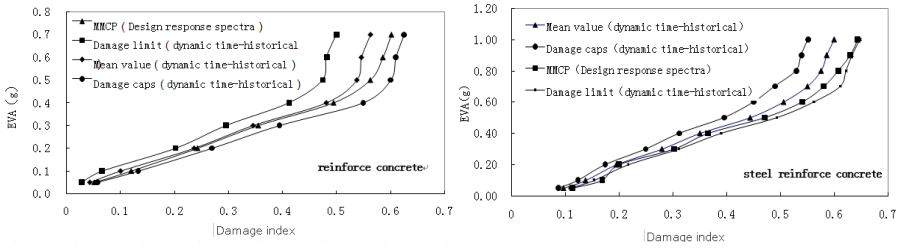

**Fig.4 Analysis for degree of safety with MMCP method using design response spectrum**

Fig.4 gives the calculation result according to MMCP method of the design response spectrum [3]. We can see from the picture, the structural damage values using the MMCP method of design response spectrum in each stage of fortification level are greater than the mean values of dynamic time historical analysis results. Although in most of the range, it is still less than the upper limit of dynamic time historical analysis, but it has a certain degree of safety and economy. The degree of safety and economy depends on the design response spectrum, so the evaluation results are in harmony with the specification. In addition, Fig. 8 also reflects that the seismic resistance of steel reinforced concrete bridge piers is far stronger than reinforced concrete bridge piers.

### 2.3 comparative analysis of calculation and pseudo static test

In ref. [5], Yu Huijun and other scholars have completed the pseudo static test on the ordinary reinforced concrete (RC) and steel reinforced concrete (SRC) column pier model, the test used the loading method of force-displacement hybrid controlled. Every level load has a repeated cycle; Change to the loading method of displacement controlled after the pier enters the yield phase , the hysteresis curves of the two components can be got according to the method that load repeatedly cycles three times per level . They respectively are:

**Table 4 The comparison of test and MMCP**

| By using mathematical analysis software originpro, conduct the hysteresis curve of each level loading for integral to get hysteretic energy dissipation. According to the test process and phenomenon mentioned in the article and the method of MMCP that combined with the design response spectrum in section 3.1 , the results | Slight damage (repairable) | | Secondary damage (repairable) | | Damaged beyond repair | | Serious damage | |
|---|---|---|---|---|---|---|---|---|
| | Vertex displacement | Hysteretic energy dissipation | Vertex displacement | Hysteretic energy dissipation | Vertex displacement | Hysteretic energy dissipation | Vertex displacement | Hysteretic energy dissipation |
| RC(test) | 17.1 | 1746 | 34.2 | 9552 | 51.4 | 19526 | 68.5 | 35629 |
| RC（ MMCP） | 18.3 | 1582 | 36.9 | 8765 | 54.9 | 18624 | 71.7 | 33458 |
| Error （%） | 7.0 | -9.4 | 7.9 | -8.2 | 6.8 | -4.6 | 4.7 | -6.1 |
| | | | | | | | | |
| SRC（test） | 16 | 1896 | 32 | 8832 | 64 | 27156 | 80 | 50789 |
| SRC（MMCP） | 17.2 | 1771 | 35.1 | 8462 | 66.9 | 24837 | 87.2 | 46926 |
| Error（%） | 7.5 | -6.6 | 9.7 | -4.2 | 4.5 | -8.5 | 9.0 | -7.6 |

It can be seen in the table 4: in this paper, the method can accurately predict the hysteretic energy dissipation of structure; For the same damage, error value of MMCP method and pseudo static test result is maintained at below 10%, on the overall, the alignment of the two results appears to be good. Reinforced concrete bridge piers are better at the aspect of ductility and energy dissipation capacity compared with the steel reinforced concrete bridge piers , and they also reflects the better earthquake resistance.

## Conclusions

This paper puts forward the improved multimodal reciprocating pushover (MMCP) method for structural seismic damage assessment. After analysis the following conclusions can be summarized:

(1) MMCP method introduces the structural maximum deformation and hysteretic energy dissipation under earthquake at the same time, and it embodies the reciprocating motion characteristics of structure under seismic action.

(2) MMCP method simulates the seismic effect to some extent, and it can accurately evaluate the structural seismic displacement and the hysteretic energy dissipation demand.

(3) Ductility and deformation capacity of steel reinforced concrete piers is greater than the reinforced concrete ones.

At the same time, this method can also be combined with the design response spectrum, eliminating the problem of selecting wave while analyzing the dynamic time history, which can make the evaluation result universal and reliable.

**Keywords:** Galvanized iron wire, Dynamic tensile test, Strain rate, Dynamic constitutive relationship, Shaking table test

**Abstract.** This paper focuses on the mechanical properties of galvanized iron wire under various conditions of earthquake-type strain rate. The dynamic tensile test of galvanized iron wire was conducted on MTS New 810 electro-hydraulic servo-controlled testing system. The dynamic tensile constitutive relationship of galvanized iron wire was proposed under seismic strain rate. The accuracy of the proposed constitutive relationship of galvanized iron wire was verified by comparing with reinforcing steel.

## Introduction

The galvanized iron wire are widely used in shaking table test, and it is often simulated the reinforcing steel in reduced scale model which also affected by strain rate under seismic action. Dynamic mechanical properties of reinforcing steel are widely illustrated and discussed in literature [1-2]. However, no comprehensive studies are available, aimed at quantifying strain rate effect on galvanized iron wire. The dynamic tensile constitutive relationship of galvanized iron wire should be used in numerical simulation of shaking table test with strain rate effect. Nevertheless, there is no practical model related to this kind of material. In this paper, the dynamic tensile test of galvanized iron wire was carried out under the range of seismic strain rate. The dynamic mechanical properties of galvanized iron wire were investigated. Based on the test results, the dynamic tensile constitutive relationship of galvanized iron wire was obtained.

## Description of the dynamic tensile test of galvanized iron wire

MTS New 810 electro-hydraulic servo-controlled testing system was used to investigate the dynamic properties of galvanized iron wire, under the approximate seismic range of strain rate between $2.5\times10^{-4}$/s and $2.5\times10^{-1.4}$/s (0.1/s), that $2.5\times10^{-4}$/s as the quasi-static strain rate.

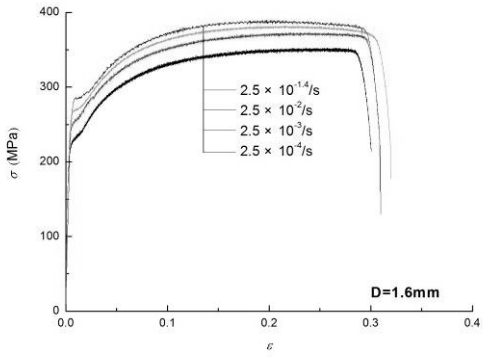
Fig. 1 Test equipment.

Monotonic tensile loading was adopted with the strain rate being kept as constant during loading conditions. Three types of specimen were selected that the diameters were (a) D=1.6mm, (b) D=2mm and (c) D=2.8mm, respectively.

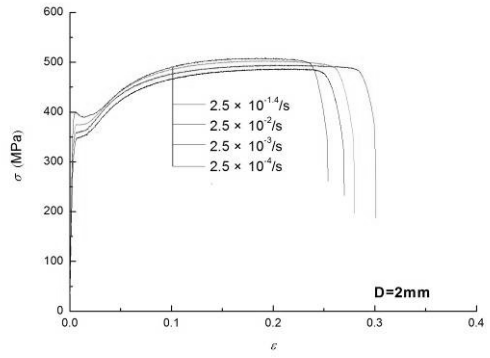
**Dynamic tensile test program on galvanized iron wire**

The tensile stress-strain curves of galvanized iron wire are illustrated in Fig. 2. The stress-strain relationship is quite similar under the different strain rate. Results of yield strength, ultimate tensile strength and yield strain are list in Tab. 1 to Tab. 2.

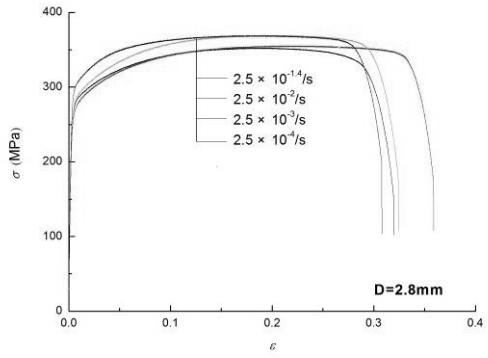
Based on the test results, Young's modulus has no obvious change under different strain rate, in which the mean values of the different conditions are 72023MPa, 71371MPa and 73235MPa. The mean yield strength and ultimate strength increased by 9.14%-20.69% and 3.15%-8.72% respectively when the strain rate increased from $2.5\times10^{-4}$/s to $2.5\times10^{-1.4}$/s . Yield strain increases first and decreases afterwards, it was also recognized that strain rate had negligible effect. Therefore, the mean values of the different conditions are $0.794\times10^{-2}$, $1.701\times10^{-2}$ and $0.671\times10^{-2}$. The ultimate tensile strain also have no obvious strain rate dependent, which the mean values of the different specimens are $22.84\times10^{-2}$, $21.11\times10^{-2}$, $18.29\times10^{-2}$.



(a)



(b)



(c)

Fig. 2 Stress-strain curves of galvanized iron wire

The results of the three types of galvanized iron wire indicate that yield strength and tensile strength increase linearly with logarithmically increasing strain rate. The empirical relationships are the following:

$$\frac{f_{yd}}{f_{ys}} = 1.0 + 0.0456\lg\left(\frac{\dot{\varepsilon}_w}{\dot{\varepsilon}_{w0}}\right) \quad (1)$$

$$\frac{f_{ud}}{f_{us}} = 1.0 + 0.0212 \lg\left(\frac{\dot{\varepsilon}_w}{\dot{\varepsilon}_{w0}}\right) \quad (2)$$

Where $\dot{\varepsilon}_w$ represents the strain rate, $\dot{\varepsilon}_{w0}$=2.5×10$^{-4}$/s is the quasi-static stain rate, whilst $f_{ys}$ and $f_{yd}$ are the quasi-static and dynamic yield strength, $f_{us}$ and $f_{ud}$ represent the quasi-static and dynamic tensile strength.

Tab. 1 Yield strength of galvanized iron wire at different strain rates

| Diameter (mm) | Strain rate (s$^{-1}$) | $f_{y1}$ (MPa) | $f_{y2}$ (MPa) | $f_{y3}$ (MPa) | Mean value (MPa) |

**Comparison of dynamic tensile properties between galvanized iron wire and reinforcing steel**

Li's model [3], Lin's model [4] in China and CEB model [5] in Europe are the several typical dynamic tensile constitutive models of reinforcing steel. Li's model was obtained by dynamic tensile test of reinforcing steel (HPB235, HRB335 and HRB400) under the range of seismic strain rate (2.5×10$^{-4}$/s-2.5×10$^{-1.4}$/s). This model is suitable for the yield strength of reinforcing steel with the range of 235MPa≤$f_{ys}$≤430MPa. Lin's model was obtained by dynamic tensile test of reinforcing steel (HPB235, HRB335 and HRB400) under a higher range of strain rate (2/s-80/s). The model can extrapolate to the range of strain rate less than 2/s which can be proved. CEB model was obtained by dynamic tensile test of reinforcement which the design yield strength is 420MPa under the range of

strain rate less than 10/s. The quasi-static strain rate is $5\times10^{-5}$/s. The proposed model is suitable for the yield strength of galvanized iron wire with the range of 239MPa$\leqslant f_{ys} \leqslant$355MPa.

In order to verify the accuracy of the proposed dynamic tensile constitutive model of galvanized iron wire, Li's and Lin's models of reinforcing steel were selected to compare. The CEB model is only suitable for the yield strength of reinforcement with 420MPa which is not used to compare. The comparing results can be observed in Fig. 4 and Fig. 5. Results show that the dynamic tensile properties of the models are quite similar. Hence, the galvanized iron wire is suitable for repalcing reinforcing steel in shaking table test.

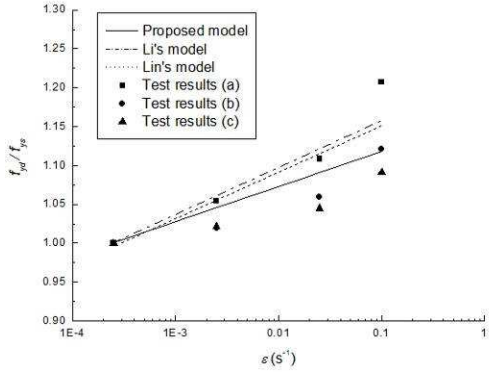

Fig. 4 Comparison of yield strength increasing factor of the proposed model and the other models

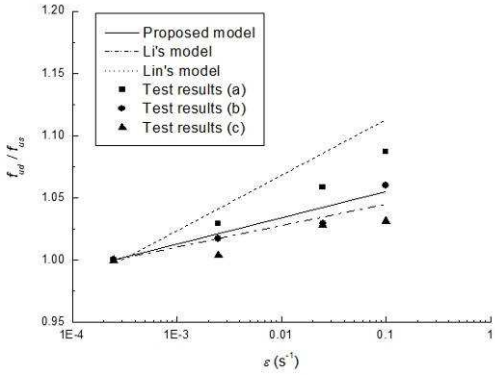

Fig. 5 Comparison of tensile strength increasing factor of the proposed model and the other models

## Conclusions

Based on the previous test results obtained, the following observations can be drawn on the earthquake-type strain rate on the dynamic mechanical properties of galvanized iron wire.

(1) The stress-strain relationships galvanized iron wires were quite similar under various conditions of seismic strain rate. The effects of strain rate causes moderate increases in the yield strength and the ultimate tensile strength. The yield strain, ultimate strain and Young's modulus do not appear to be affected by strain rate.

(2) The dynamic tensile constitutive relationship of galvanized iron wire was proposed. The dynamic mechanical properties of galvanized iron wire are similar to reinforcing steel. Consequently, the galvanized iron wire is suitable for repalcing reinforcing steel in shaking table test.

# Peak Story Drift of a Building Structure Subjected to Earthquakes

Jeng-Hsiang Lin[1, a]

[1] Department of Architecture, Hwa Hsia Institute of Technology, No. 111, Gongjhuan Rd., Jhonghe District, New Taipei City 23568, TAIWAN

[a]hsiang@cc.hwh.edu.tw

**Keywords:** Earthquake ground motion, Building, Peak story drift, Random vibration theory.

**Abstract.** Many studies have demonstrated that the story drift is the critical parameter that is best correlated with damage in buildings. In this study, an approximate solution for mean value and standard deviation of peak story drift at each story of a building structure under earthquake motions was derived, based on random vibration theory. The accuracy was demonstrated by the Monte Carlo simulation solutions. Comparison of the computed results with the available simulation results indicates that the proposed solution is satisfactory. The results of numerical examples show that the period of a building structure plays a major role that affects the peak drift at each story. The peak drift at each story increases as the period of the structure increases.

## Introduction

Conventional building codes emphasize that the methods of seismic-resistant design have the objectives to provide for life safety and damage control [1]. It is not economically feasible to give complete protection to buildings in the event of a worst-case earthquake; it is tacitly accepted that structural damage should be prevented and nonstructural damage minimized in the occasional moderate earthquake and that serious damage or collapse should be prevented in the much rarer severe earthquake [2]. Modern building codes emphasize the philosophy in which the design criteria are expressed in terms of achieving specified performance objectives when the structure is subjected to specified levels of seismic hazard [3]. Performance objectives can be related to the level of damage to the building, and the level of damage can be related to structural response parameter. The performance target can be the structural response parameter attached to a certain threshold. Many studies [4,5] have concluded that the story drift ratio is the critical parameter that is best correlated with damage to buildings. The peak story drift ratio can be used as an indicator representing the structural demands.

Recent developments in earthquake engineering indicate that probabilistic evaluation has been performed increasingly to ensure building performance under earthquakes. The need to evaluate statistical characteristics of peak drift of a building structure during earthquakes is quite apparent.

## Peak Story Drift Analysis

For the analytical procedures presented herein, earthquake excitations were considered as a stationary Gaussian random process with zero mean. Although an earthquake motion is not stationary, during the time of strong motion a typical earthquake is approximately stationary, and good estimates of structural responses can be made using random vibration theory [6]. Thus, the story drifts of a building structure will be stationary Gaussian random processes with zero mean.

**Peak Story Drift.** If $y_i(t)$ and $y_{i+1}(t)$ are, respectively, the lateral displacement time histories at the $i^{\text{th}}$ and $i+1^{\text{th}}$ degree of freedom (or at story floor level *N-i+1* and *N-i*) and $S_i(t)$ is the relative story displacement time history between these two story floor levels, then $S_i(t)$ can be expressed as

$$S_i(t) = y_i(t) - y_{i+1}(t), \qquad i = 1 \quad to \quad N-1 \tag{1.a}$$

$$S_N(t) = y_N(t), \tag{1.b}$$

where $N$ is the number of degree of freedom or the number of stories in the structure. The peak drift at each story of the structure during earthquake motions may be defined as

$$\Delta_i = \sup(S_i(t)), \qquad i=1 \quad to \quad N \tag{2}$$

where "sup" implies the maximum value of the entire range of the relative displacement time history. Thus, $S_i(t)$ may be evaluated once the displacement time histories $y_i(t)$ and $y_{i+1}(t)$ are determined.

**Ensemble Mean Squares of Relative Displacement and Relative Velocity Processes.** For the linear structure systems, the power spectral density function $S_{S_iS_i}(\omega)$ for the relative story displacement process $S_i(t)$ can be given by [7]

$$S_{S_iS_i}(\omega) = S_{aa}(\omega)\left\{\sum_{j=1}^{N}\sum_{k=1}^{N}\frac{1}{M_jM_k}\left(\varphi_{i,j}\varphi_{i,k}+\varphi_{i+1,j}\varphi_{i+1,k}-2\varphi_{i,j}\varphi_{i+1,k}\right)\left(\sum_{l=1}^{N}\sum_{m=1}^{N}m_lm_m\varphi_{l,j}\varphi_{m,k}\right)\mathrm{Re}\left[H_j(\omega)H_k(-\omega)\right]\right\}, \quad i=1 \quad to \quad N-1 \tag{3.a}$$

$$S_{S_NS_N}(\omega) = S_{aa}(\omega)\left\{\sum_{j=1}^{N}\sum_{k=1}^{N}\frac{\varphi_{N,j}\varphi_{N,k}}{M_jM_k}\left(\sum_{l=1}^{N}\sum_{m=1}^{N}m_lm_m\varphi_{l,j}\varphi_{m,k}\right)\mathrm{Re}\left[H_j(\omega)H_k(-\omega)\right]\right\}, \tag{3.b}$$

where $H_j(\omega) = 1/(\omega_j^2 + i2\xi_j\omega_j\omega - \omega^2)$ (4)

$$\mathrm{Re}\left[H_j(\omega)H_k(-\omega)\right] = \frac{(\omega_j^2-\omega^2)(\omega_k^2-\omega^2)+(2\xi_j\omega_j\omega)(2\xi_k\omega_k\omega)}{\left((\omega_j^2-\omega^2)^2+(2\xi_j\omega_j\omega)^2\right)\left((\omega_k^2-\omega^2)^2+(2\xi_k\omega_k\omega)^2\right)} \tag{5}$$

and $f_i(t)$ is the $i^{th}$ component of external force vector. $\omega_j$, $\xi_j$, and $M_j$ are the $j^{th}$ modal undamped natural frequency, damping ratio, and mass of the structure, respectively.

The ensemble mean squares of the relative story displacement process $S_i(t)$ and of the relative story velocity process $\dot{S}_i(t)$ are related to the spectral density function $S_{S_iS_i}(\omega)$ by the equations

$$\sigma_{S_i}^2 = \int_{-\infty}^{\infty} S_{S_iS_i}(\omega)d\omega \tag{6}$$

and $$\sigma_{\dot{S}_i}^2 = \int_{-\infty}^{\infty} \omega^2 S_{S_iS_i}(\omega)d\omega \tag{7}$$

Substituting Eqs. (3.a) and (3.b) into Eqs. (6) and (7) with the assumptions that the one-sided power spectral density function of the input ground motion is relatively smooth with no sharp peaks and the modal damping ratios of the building is small, gives

$$\sigma_{S_i}^2 \cong \sum_{j=1}^{N}\frac{G(\omega_j)}{M_j^2}\left(\sum_{l=1}^{N}\sum_{m=1}^{N}m_lm_m\varphi_{l,j}\varphi_{m,j}\right)(\varphi_{i,j}-\varphi_{i+1,j})^2\frac{\pi}{4\xi_j\omega_j^3} \quad i=1 \quad to \quad N-1 \tag{8.a}$$

$$\sigma_{S_N}^2 \cong \sum_{j=1}^{N}\frac{G(\omega_j)}{M_j^2}\left(\sum_{l=1}^{N}\sum_{m=1}^{N}m_lm_m\varphi_{l,j}\varphi_{m,j}\right)\varphi_{N,j}^2\frac{\pi}{4\xi_j\omega_j^3} \tag{8.b}$$

$$\sigma_{\dot{S}_i}^2 \cong \sum_{j=1}^{N}\frac{G(\omega_j)}{M_j^2}\left(\sum_{l=1}^{N}\sum_{m=1}^{N}m_lm_m\varphi_{l,j}\varphi_{m,j}\right)(\varphi_{i,j}-\varphi_{i+1,j})^2\frac{\pi}{4\xi_j\omega_j} \quad i=1 \quad to \quad N-1 \tag{9.a}$$

$$\sigma_{\dot{S}_N}^2 \cong \sum_{j=1}^{N}\frac{G(\omega_j)}{M_j^2}\left(\sum_{l=1}^{N}\sum_{m=1}^{N}m_lm_m\varphi_{l,j}\varphi_{m,j}\right)\varphi_{N,j}^2\frac{\pi}{4\xi_j\omega_j} \tag{9.b}$$

**Statistics of Peak Drift at Each Story.** For a zero-mean stationary Gaussian story drift process, Lin [7] had shown that mean and standard deviation of the peak drift $\Delta_i$ can be expressed by the approximate relation

$$\bar{\Delta}_i \cong \left(\left(2\ln(\upsilon T)\right)^{0.5} + 0.5772/\sqrt{2\ln(\upsilon T)}\right)\sigma_{S_i} \tag{10}$$

and $$\sigma_{\Delta_i} \cong \pi\sigma_{S_i}/\sqrt{12\ln(\upsilon T)} \tag{11}$$

in which $$\upsilon = \sigma_{\dot{S}}/\pi\sigma_S \tag{12}$$

## Numerical Examples

**Earthquake Power Spectrum.** The smooth earthquake power spectrum, $G(\omega)$, used in Eqs. (8.a), (8.b), (9.a), and (9.b) can be represented by the Kanai-Tajimi expression as follows:

$$G(\omega) = (\omega_g^4 + 4\xi_g^2\omega_g^2\omega^2)G_0 / ((\omega_g^2 - \omega^2)^2 + 4\xi_g^2\omega_g^2\omega^2) \quad (13)$$

where $G(\omega)$ reflects the frequency content during the most intense part of the ground motion and is a one-sided power spectrum, $\omega_g$ is the predominant ground frequency, $\xi_g$ is the ground damping and $G_0$ is a measure of ground intensity. The values $\omega_g = 4\pi$ and $\xi_g = 0.6$ have been suggested for firm ground sites and $G_0$ can be related to the peak ground acceleration, $a$, by

$$G_0 = 0.1461\xi_g a^2 / \omega_g(1 + 4\xi_g^2) \quad (14)$$

**Studied Parameters.** There were 3 cases of building structures having different height and story number, including 4, 8, and 12-story building, to be investigated. For each case, the mean value and the standard deviation of peak story drift at each story of the structure under the Kanai-Tajimi excitations were determined from Eq. (10). The corresponding parameter values of each building are given in Table 1. In each building, the story heights, the story masses, and the modal damping ratios were kept the same. The elastic stiffness of the first story, $Ke_1$, was selected by trial and error method to produce the desired fundamental periods, shown in Table 1. The stiffness ratios of the $i+1^{\text{th}}$ story to the $i^{\text{th}}$ story, $Ke_{i+1} / Ke_i$, were equal to 0.95. The story masses and heights were taken as 454545 kg and 320 cm, respectively. The earthquake intensity, expressed by the peak ground acceleration (PGA), is taken as 0.1g. Time duration equals 30 seconds. The parameters of the Kanai-Tajimi model (Eq. (13)), namely $\omega_g$ and $\xi_g$, are taken as $4\pi$ and 0.6, respectively.

Table 1. Parameter values of buildings investigated in this study

| Story number of building | Fundamental period, T (s) | Stiffness, (*kN/cm*) | Damping (%) |
|---|---|---|---|
| 4 | 0.575 | 4708 | 5 |
| 8 | 0.967 | 6288 | 5 |
| 12 | 1.311 | 7900 | 5 |

**Numerical Results and Accuracy of the Proposed Solutions.** Fig. 1 shows the numerical results of the proposed solutions. As shown in Fig. 1, for each building, the peak drift of a structure under earthquake motions varies with story. Fig. 1 also shows that the peak drift at each story of a building structure increases as the period of the building increases. To demonstrate this observation, the effect of period distribution of a building on the peak drift at each story was investigated.

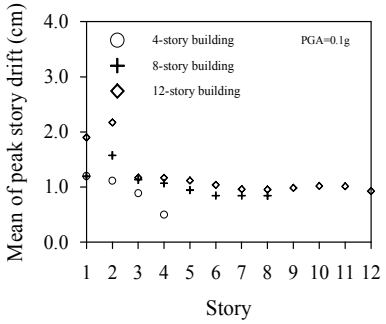

Fig. 1. Story distribution of peak drift.

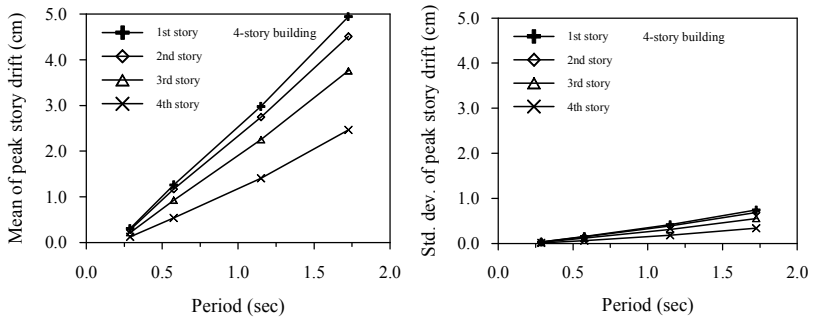

Fig. 2. Effect of period distribution on peak story drift.

To investigate the effects of period distribution on the peak story drift, a 4-story building was studied. Fig. 2 shows the peak drift at each story of the 4-story building increases as the period increases. Thus, the periods of buildings play a major role that affects the peak story drift of buildings. It is noted that the numerical results may change with different buildings and earthquake models. The emphasis is on the approach to evaluate the peak drift at each story of a building structure.

Simulation is frequently applied to estimate extremes or other descriptors of random processes. The accuracy of the proposed solutions was demonstrated by comparing the computed results with the simulation results. For the case of the 4-story building having a fundamental period of 0.575 s, the computed mean values and standard deviations of the peak story drifts are shown in Figs. 3(a) and 3(b), respectively, and the results obtained by the Monte Carlo simulation method are shown also in the figures for comparison. Figure 3 shows that the presented results, as computed from Eqs. (10) and (11), agree well with the simulation results.

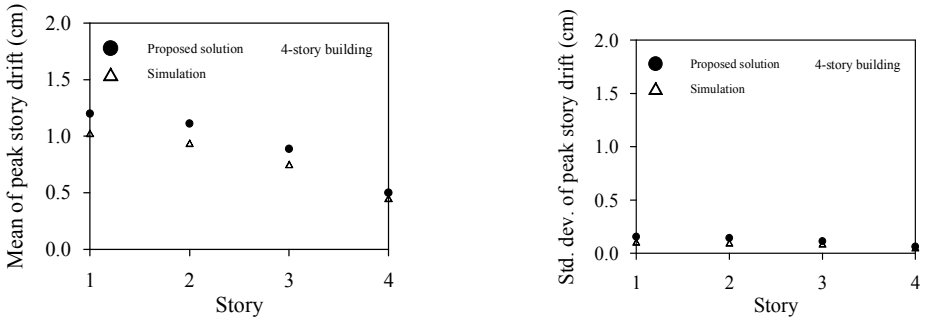

Fig. 3. Comparisons of proposed results and simulation results for peak story drift.

## Concluding Remarks

Based on the assumption of linear elastic structure responses, the spectral approach presented in this study yields a simple closed-form solution for mean value and standard deviation of peak drift at each story of a building structure. From the viewpoint of probability-based design, the need to evaluate the mean value and standard deviation of peak drift at each story of a building structure during earthquake motions is quite apparent and the presented results may be helpful to researchers or practicing engineers for fragility analysis and investigation of possibility of structural malperformance. Detailed procedure of the proposed approach and some numerical examples are presented in this paper. The results of numerical examples show that the period of a building structure plays a major role that affects the peak drift at each story. The peak drift at each story of a building structure increases as the period of the structure increases.

The proposed solution for evaluating the peak drift at each story of a building structure is based on the assumption of linear elastic responses. However, since the responses of structures subjected to major earthquakes may easily proceed to the inelastic range, one must carefully examine the applicability of the presented solutions.

**Keywords:** shear wall, opening, seismic performance, prefabricated

**Abstract.** In order to meet the requirements for using function of structure, openings are often needed to be laid out in shear wall, and the mechanical behaviors of the wall will be significantly influenced. The experimental analysis, establishment of simplified mechanical model and numerical simulation researches on shear wall with opening were reviewed, the research findings on shear wall with opening at home and abroad were summarized, and the seismic behaviors were induced and analyzed. The problems about seismic behaviors of shear wall with opening which need to be solved urgently were pointed out.

## Introduction

Site construction, as a traditional mode of production, is widely applied to the concrete construction in our country for a long time, whose level of industrialization is low, loss of building materials and amount of construction garbage are large, quality of construction is unstable and whole life cycle energy consumption is high, all these disadvantages can't conform to national energy-saving and environmental protection policy. With the rapid development of our country's urbanization and urban modernization, the contradiction between energy and lack of resources is becoming more and more prominent, and the situation of ecological construction and environmental protection is increasingly serious. Housing industrialization, which adopts prefabricated construction methods, is one of the most important ways to realize building energy conservation and emissions reduction. It is estimated that green construction methods can make energy consumption reduced by 20%, water consumption reduced by 63%, timber formwork consumption reduced by 87%, the quantity of construction refuses reduced by 91% per square meter[1]. To realize housing industrialization, the theoretical study related to it must be taken seriously, which can provide theoretical basis for developing prefabricated structure system. Over the past decade , more and more Chinese researchers have paid attention to the study of prefabricated concrete building, lots of relevant technical researches have been carried out by such institutions like Number of units China Academy of Building Research, Tsinghua University, Harbin Institute of Technology, Beijing University of Technology, Southeast University, Hefei University of Technology etc, and also get demonstrated and applied in some real estate development projects of a certain size in Shenyang, Shenzhen, Changsha and other places[2] (refer with: Fig. 1[3]).

Common shear wall often need to be opened in order to meet the requirements for using function and vertical layout in building structures (refer with: Fig. 2[4]). On the one hand, strength and stiffness of the shear wall will be reduced due to the decrease of concrete area and discontinuity of steel bars around the opening, moreover stress concentration can be easy to appear at the corners of opening, which will cause cracks at an earlier stage of loading process and affect using functions. On the other hand, ultimate bearing capacity analysis of shear wall is the main content of RC structures' ultimate bearing analysis and seismic performance evaluation. Ultimate capacity-deformation characteristics of sheer wall are the essential structure parameters in the nonlinear push-over analysis and dynamic time-history analysis, however, in Chinese "Code for design of concrete structures"(GB50010-2010), only strength checking formulas for RC shear wall with openings are listed, rather than ultimate bearing capacity formulas[5,6].Therefore, the effects that openings have on bending strength, shear strength and other seismic performances must be considered when the openings are relatively large or at important parts.

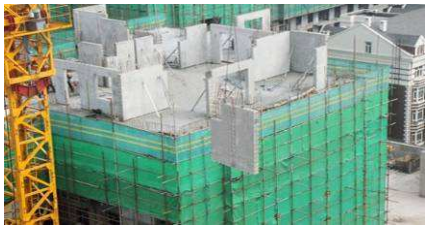

Fig.1 Prefabricated structure site of Brilliance Group

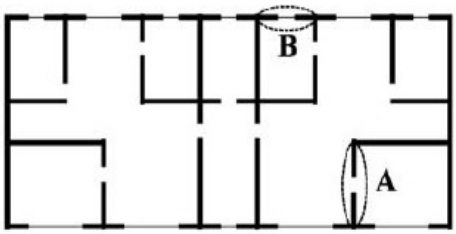

Fig.2 Plane graph of shear wall with openings

For prefabricated composite shear wall with concrete filled steel tube columns, not only the effects that openings have on ultimate bearing capacity, failure mechanism, energy dissipation capacity and other seismic performances need to be considered like common wall, but also it need to take the cooperative performances of prefabricated concrete filled steel tube columns working together with concrete shear wall into consideration. So cooperative working performances of all this structural members when existing openings ought to be further researched, in order to design prefabricated composite shear wall optimally, consequently, this new structure system will have multiple seismic fortification lines indeed.

## Analysis of research status and development in seismic performance of shear walls with opening

Shear capacity and lateral stiffness of the sheer wall are reduced because of the openings, whereas, the ductility and energy-dissipation capacity can be improved effectively when the openings are arranged properly. Bearing mechanism, energy-dissipation capacity, failure mode and other characters of the wall will become extremely complicated due to the impacts of many factors, such as the frame constraint, thickness of wallboard, the size, the position and the form of opening etc. A large number of researches related to this issue are conducted in China and abroad, which have obtained many achievements mainly in three aspects, which lie in experimental analysis, establishment of simplified mechanical model and numerical simulation.

Finite element analysis and experimental research on sheer wall with opening were performed by C.Y.Lin and C.L.Kuo[7](1988). Thirteen 2/3 scale models of shear walls had been tested in order to investigate the effects of different opening sizes and layouts of steel bars along the opening on ultimate strength and performance parameter design after the wall cracking. Test results indicate that the steel bars around the opening have a significant effect on ductility and shear strength of the wall. The shear capacity coming from oblique steel bars can achieve 40% of the yield strength, while the shear capacity coming from the horizontal bars and vertical bars can just achieve 20%. What's more, the paper also points out that shear strength of the sheer wall with opening is affected not only by the width of opening, but also by the height of opening.

A shear wall with an opening was designed according to JASSS by Daisuke Kato, Toshimi Kabeyasawa etc [8] (1995). Strength reduction factors and stiffness reduction factors of the wall with opening provided by JASSS are based on elastic theory or simplified equilibrium equation, which are not suitable for the conceptual design of ultimate strength. Therefore, a seismic design method for shear wall with opening based on ultimate capacity is proposed, and the experimental data of 35 walls coming from seven literatures are compared and analyzed. The results indicate that the data and suggested formula for calculating shear strength are in good agreement, and the formula can be used for structural design.

Present situation of tests on shear wall with RC frame containing opening was summarized by Zhonghan Chen[9](1997). Regularities of this issue are obtained on the basis of rearranging numerical analysis results, and the current simplified calculation formula for strength reduction factor of shear wall with opening was modified. In addition, it also shows that if the openings are off-centren, the shear strength will be further reduced.

Tests and theoretical analysis results of two shear walls with opening at the bottom were summarized by Christopher P. Taylor, Paul A. Cote etc [10] (1998).Two 1/4 scale specimens were

tested under cyclic horizontal loading and constant axial pressure, in order to evaluate the effects of choosing transverse boundary bars depending on displacement-based design method and the effects of choosing horizontal shear bars depending on strut-and-tie model. Test results indicate that the specimens will have stable energy-dissipation capacity and good ductility when designed adopting both of the two methods above, in addition, it also points out that the strut-and-tie model can be an effective tool for designing the discontinuous region of specimens.

The static analysis and dynamic analysis on shear wall with opening was performed by H.-S. Kim and D.-G. Lee using super elements[4](2003).This method was developed on the basis of matrix compensation and had no limit for the quantity , size and location of openings. Through the analysis of engineering examples, it can be concluded that this method is an effective way to analyze the mechanical behavior of the shear wall with opening, which has a high calculation accuracy and can save both computing time and occupancy of computer capacity greatly.

The strain-stress constitutive model for concrete and steel bar under monotonic and cyclic loading on shear walls with opening was established by Mengpu Wang, Xiyuan Zhou etc[11](2005) . In this model, the plane-strain 4-node quadrilateral parametric element was adopted, and also the concrete and the steel bar were considered as a whole unit, in which the bars were dispersed. The cracking, yielding, failure and other nonlinear characteristics of reinforced concrete were also reflected in this model. Meanwhile, on the basis of this model, dynamic equation was solved by using renewal precise time step integration method, in this way, time-history analysis of the shear wall with opening was completed. The calculation results indicate that the time-history curve of top floor displacement based on this method matches well with the curve based on dynamic nonlinear analysis, in addition, this new method takes less computing time.

Tests on 7 specimens of steel reinforced concrete (SRC) low-rise shear walls with opening (one specimen used for comparative analysis is without opening) had been conducted by Lumin Zhou, Jin Gong etc[12](2006). Parameters that investigated in the test were the size of opening and the form of steel skeleton concealed bracing (herringbone and splayed). The test results indicate that the seismic performance of SRC low-rise shear walls is good, and the openings have an influence on the shear strength, the ductility and the energy-dissipation capacity of the walls. Furthermore, with the opening dimensions increasing, the shear strength of the walls decreases but the ductility and the energy-dissipation capacity increase, and the failure characteristics expressed in the tests have a similarity with frame structure. Besides, it also points out that stress concentration is easy to occur around the opening, which leads to the appearance of the first cracks and stiffness reduction, thus the service performance of components are affected. As a result, structural measures like concealed beams and columns are advised to be set around the opening for strengthen.

The accuracy of a manual method for calculating horizontal stiffness of shear walls with opening had been studied by A. Neuenhofer [13](2006). The investigative parameters were the location, the change of height-width ratio and the size of opening. A finite element equation was established and the calculation analysis was conducted combining with Matlab. Through comparing the results of finite element analysis with the results of the manual calculation, it knows that although the manual calculation is complicated, the calculation results are well consistent with horizontal stiffness of shear wall with opening.

By taking the RC shear walls with opening based on shear resistant mechanism (“M-M” model) as the research objects, the existing “M-M” model was modified and the calculating equations for ultimate bearing capacity of the walls were derived by Huailiang Chen and Dachang Zhang etc[14](2007). The experimental values and calculated values for ultimate strength of two models were compared and analyzed on 23 specimens of different reinforcement, sizes and stress statuses. It shows that the calculation results depending on the modified “M-M” model match well with the test results and have high calculation accuracy. The modified “M-M” model can simulate the ultimate strength of RC shear wall with opening very well.

Pseudo-static tests on 1/4 scale shear walls with and without opening were studied by István DEMETER, Tamás NAGY-GYÖRGY etc[15](2008), in order to investigate the seismic behaviors of

prefabricated shear wall with opening and strengthened with fiber reinforced polymer (FRP). The variable parameters were the position of opening and the location of steel bars. On the aspect of axial load, standardized axial stress $v$ (the ratio of induced stress $v_0$ and concrete characteristic strength $f_{ck}$) was referenced, ranging from 0.01 to 0.2 and the horizontal load was controlled by displacement.

Elastic finite element analysis for steel frame-reinforced concrete infill shear walls with opening was performed by Qingjiang Zhang, Yinquan Yu etc[16](2009). According to the principle that lateral displacements will be equal when the structures are under the same lateral force, the shear wall was simplified into a model of cross steel brace. In this case, the distribution of stress and deformation under mono lateral loading were calculated. The calculation results show that the lateral stiffness of steel frame-reinforced concrete infill shear walls with opening can be simulated accurately by the model of cross steel brace, and some measures are proposed to be taken to prevent the concrete in the corner from cracking or crushing prematurely, which will affect the functions of structure.

A large number of tests and finite element analyses on shear walls with large eccentric openings were performed by Dr.Jiyang Wang's team[17-21] (2009~2012). A reduction factor was applied to calculate ultimate lateral bearing capacity and shear stiffness. Results show that the changes of stress transfer mechanism, failure mode, bearing capacity and shear stiffness of walls are all significantly affected by the large eccentric openings. Tests on seismic behavior of two shear walls with single row of steel bars and openings were conducted by professor Wanlin Cao's team[22-24] (2008~2010). The failure mechanisms of walls with different structural measures and forms were studied, and the calculation model on sheer capacity was found by his team. The experimental results are consistent with calculation results. Experimental research on seismic performance of RC composite shear wall with opening was performed by Dr. Zijun Wang's team[25-26] (2011~2012). The results show that the loading process and failure mode of the composite shear walls with opening are similar to those of shear walls with opening, while the prefabricated RC cover for the thermal insulation layer can improve the bearing capacity about 7% and reduce the stiffness degradation. What's more, the shearing frame can make the prefabricated parts and the cast-in-place concrete parts of the RC composite shear wall with opening work together very well.

From the above analysis, it can be seen that researches on seismic behaviors of RC shear wall with opening are relatively active, and lots of achievements have been obtained, which can provide important theoretical bases for the optimization design of the shear walls.

## Conclusions

Though many results on shear wall with opening are obtained, some problems also need to be solved.

1) Although shear capacity and lateral stiffness of the sheer wall are reduced because of the openings, the ductility and energy-dissipation capacity can be improved. And the seismic behaviors of the shear wall will be influenced by the frame constraint, the size, the location of opening etc. However, further researches are still needed to find out the effects of various factors on shear wall with opening.

2) Compared with common shear wall, the researches on prefabricated composite shear wall with boundary frames and openings are relatively less. More researches about the effects that opening has on seismic behaviors of this composite shear wall are required to popularize and apply this structure.

**Keywords:** Y-eccentric braced steel frames; response modification factor; pushover analysis

**Abstract.** In current seismic design procedure, structure base shear is calculated according to the linear elastic response spectra divided by the response modification factor, which accounts for ductility and overstrength of a structural system. In this paper, the response modification factors of Y-eccentric braced steel frames (**YECBF**)designed based on Chinese Code were evaluated by an improved pushover analysis on 12 examples with various stories and spans lengths. According to the analysis results, the effects of fundamental periods, storey numbers, and spans of frames on the behavior factor were studied. In the end, an appropriate response modification factor was proposed for YECBF designed base on Chinese Code.

## Introduction

For building structure remaining elastic during a severe earthquake, it must be designed for large forces; a structure is expected to experience inelastic deformation during a strong earthquake. In most seismic codes such as the ATC (1995) and FEMA (2008)[1-3], the seismic design forces are established by applying a response modification factor R to the earthquake forces that would develop if the structure were to respond elastically. However, the expected inelastic deformations should be limited within an acceptable range to prevent structure failure. Therefore, proper earthquake resistant design requires that the ductility capacity of the structure exceeds the ductility demand imposed by the design earthquake load. In other words, the value of response modification factor $R$ should reflect the capability of a structure in dissipating energy.

Many scholars found that the response modification factor relates to the ductility and overstrength of a given structure [4-10].In the well-known documents such as ATC(1995), he response modification factor was calculated as the product of three factors: overstrength factor, ductility factor, and redundancy factor. FEMA695 (2008) points out that the redundancy factor becomes unity for structures designed using an ultimate strength method. In this case the response modification factor is determined as the product of the ductility factor $R_\mu$ and the overstrength factor $R_\Omega$.

$$R = \frac{V_e}{V_d} = \frac{V_e}{V_y} \cdot \frac{V_y}{V_d} = R_\mu \cdot R_\Omega \tag{1}$$

Figure1 represents a typical structural response, the horizontal axis is lateral roof displacement and the vertical axis is the base shear. The term, $V_e$, represents the force level that would be developed in the seismic-resisting system, if the system is remained entirely linearly elastic for the design earthquake. The term, $V_y$, represents the yield strength of the ideal system. And the term, $V_d$, is the seismic base shear required for elastic design. The terms, $\Delta_e$， $\Delta_y$ ,and $\Delta_d$， are the roof displacements corresponding to the base shear.

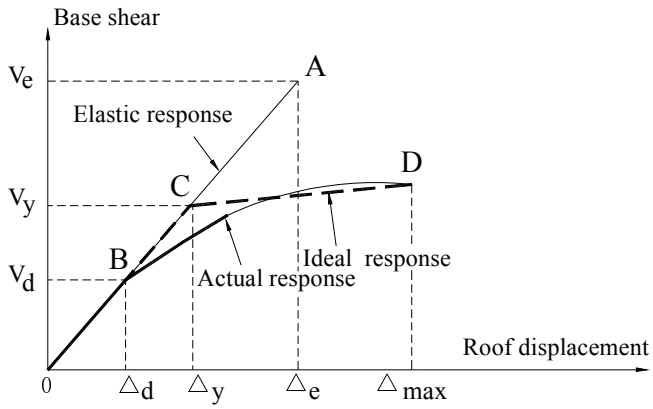

**Figure .1** Illustration of response modification factor

The latest seismic design philosophy in China is reflected in the active Code GB50011-2001(2001) with a cryptical *R* value of 2.8125 disregarding of the ductility capacity of different structures [11-12]. It is very clear that the reserve strength and the ductility of code-compliant buildings vary wildly as a function of building type and building height. Values for response modification factor must address these variations. The objective of this paper is to quantify the *R* values of Y-eccentric braced steel frame system (**YECBF**) complying with Chinese seismic code.

In this paper, a new method for defining the response modification factor was proposed from an improved inelastic pushover analyses considering loading effects and high mode effects. Twelve YECBF examples with different stories and different ratios of storey height to spans were established to evaluate the effects of different design parameters on the response modification factor. Based on the findings, a tentative R value was proposed for the YECBF designed according to Chinese Code.

**Proposed pushover analysis**

Figure 1 shows that the response curve is most important in the quantification of *R* in which inelastic behavior of the building should be explicitly considered. To obtain the response curve of a given structure, the incremental dynamic analysis (**IDA**) is the most rigorous method, but it's computationally demanding and time consuming. Current civil engineering practice prefers to use the pushover analysis method to estimate seismic demands. However, in a typical pushover analysis, both the force distribution and target displacement are based on the assumption that the response is controlled by the fundamental mode and that the mode shape remains unchanged after the structure yields. Obviously, after the structure yields, both assumptions are approximate, especially for high rise building. None of the invariant force distribution can account for the contribution of high modes to response, or for a redistribution of inertia forces because of structure yielding and the associated changes in the vibration properties of the structure.

To overcome these limitations, an improved pushover analysis procedure was proposed: The advised pushover analysis is an approximate adaptive force distribution that attempt to follow more closely the time-variant distributions of inertia forces. The detail of this improved pushover analysis procedures are introduced as follows:

①Recurring to time history analysis, calculate the vertical distribution of horizontal inertial force and the relevant maximum top displacements under three earthquake levels: minor earthquake (**ME**: earthquake have an average return period of 50 years), design earthquake (**DE**: earthquakes have an average return period of 475 years.), and rare earthquake (**RE**: earthquakes have a 2 %~3% probability of being exceeded in 50 years or an average return period of 2475 years). In this course, at least ten appropriate ground motion records should be chosen for each building.

②Adopting the inversed triangle vertical distribution, push the structure until the top displacement ΔME arrived.

③Follow the second step, change the pushover force to the vertical distribution of the horizontal inertial force under ME, push the structure until the top displacement $\Delta_{DE}$ arrived.
④Follow the third step, modify the pushover force as the vertical distribution of the horizontal inertial force under DE, push the structure until the top displacement $\Delta_{RE}$ arrived.
⑤Follow the forth step, calibrate the pushover force as the vertical distribution of the horizontal inertial force under RE, push the structure until the unstable condition is reached.
Mark down the base shear force and top displacement during the entire pushover process. The response curve is then obtained by plotting the base shear value against the roof displacement.

**Method for determining R**

According to Figure 1 and the well known ductility factor theory proposed by Newmark N.M. and Hall W.J. (1982)[13], for a long period structure whose fundamental period is larger than 1.0 second, if the inelastic displacement demand $\Delta$ under DE is determined, the seismic base shear $V_e$ can be easily quantified with the assumption that the elastic displacement $\Delta_e$ equal to the inelastic displacement demand $\Delta$. When $V_e$ of a given structure is determined, the $R$ can be easily determined by Eq.1.In this paper, the inelastic displacement demand $\Delta$ under DE of YECBF is determined by CSM (capacity spectrum method recommended by ATC (1995)). It requires both capacity curves and demand curves be converted in response spectral ordinates firstly.
**Capacity curves.**The displacement and force values of the structural capacity curves obtained from pushover analysis are converted to spectral values as follows:

$$S_{ai} = \frac{V/G}{\alpha_i} \tag{2}$$

$$S_{di} = \frac{\Delta}{\gamma_i X_{i,roof}} \tag{3}$$

Where, $V$ (base shear) and $\Delta$(displacement) represent any point at the pushover curves, $S_a$ and $S_d$ are the corresponding spectral acceleration and displacement values respectively. $\alpha_i$ and $\gamma_i$ are modal mass coefficient and participation factors for the $i$-th natural period. $X_i$, roof is the roof-level amplitude of the $i$-th natural period.
**Demand curves.**The design acceleration response spectrum, which is given in standard $S_a$ (spectral acceleration), versus $T$ (period) format is converted into acceleration-displacement response spectra format (generally known as ADRS format) with the following well-known equation:

$$S_{di} = \frac{T_i^2}{4\pi^2} S_{ai} g \tag{4}$$

Where, $S_{di}$ is the spectral displacement at any point on the acceleration-response spectrum in Chinese Code represented by $S_{ai}$ and $T_i$. Plotting $S_{ai}$ against $S_{di}$ results in the demand curve for the design. Then, the design spectrum is reduced to an inelastic spectrum based on the $R_\mu$-$\mu$-$T$ relationship proposed by Newmark N.M. and Hall W.J. (1982) and Peter Fajfar (1999)[13-14]. For a given level of displacement ductility, Figure 2 shows how to obtain the inelastic design response spectrum (**IDRS**) starting from a linear elastic design response spectrum (**LEDRS**).

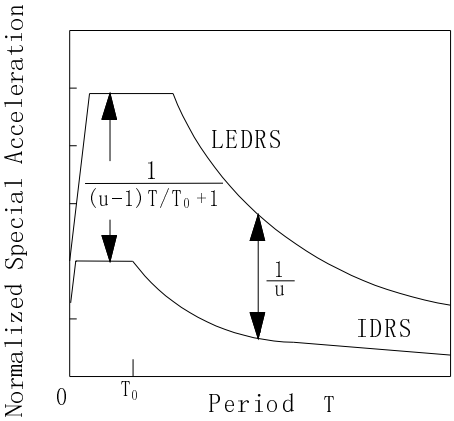

**Figure .2** The Relationship between IDRS and LEDRS

In Figure 2, $\mu$ is the displacement ductility level. $T_0$ is the transitional period, which can was defined by the site character period $T_g$ and displacement ductility level $\mu$( $T_0 = 0.65\mu^{0.3} T_g \le T_g$).

**Displace demand $\Delta$.**When one *i*-th modal capacity curve is graphically superimposed onto a set of demand curves obtained from different ductility levels, one intersection point called the performance point under *i*-th mode is obtained. The corresponding roof displacement $\Delta_i$ under the *i*-th mode can be gained according to Eq.3 .According to the MPA procedure proposed by Anil K.Chopra and Rakesh K.Goel (2002)[15], the demand displacement $\Delta$ of the structure under DE can be calculated as Eq.5:

$$\Delta = \sqrt{\sum_i \Delta_i^2} \tag{5}$$

## R of YECBF

**Model design.**To get a creditable value of response modification factor for the YECBF structures complied with Chinese Code, two groups of analysis models are designed: one group with the same span (6.0 meters) and different storey number of 8, 12, 16 and 20 marked as "Y1-total floors", and the other 8-, 16-storey group with different spans of 5.4m, 6.0m, 6.6m, 7.2m and 7.8m marked as "Y2-total floors-spans". The story height of each model was fixed to 3.6m and the length of all short links which dissipate energy by yielding essentially in shear is 800mm. One important to be mentioned is that in the top floor, all the structure was designed with V-center-braced seismic-resisting system. The plan and elevation configurations for the models are similar to Y1-12 shown in Figure 3 and Figure 4 respectively. All buildings were designed for an eight intensity region with the first design group, and soil conditions were assumed to be a general stiff soil defined as Site Class II in the Code GB50011-2001.The braces were designed to resist all lateral seismic loads. The structural design was carried out using the program SAP2000. Due to space limitations, the quantification procedure of *R* for model Y1-12 was only enumerated. The structural members selected for this model are listed in Tab.1.

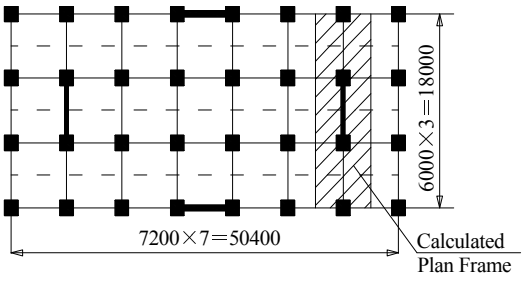

**Figure .3** Plan layout of the model (units: *mm*)

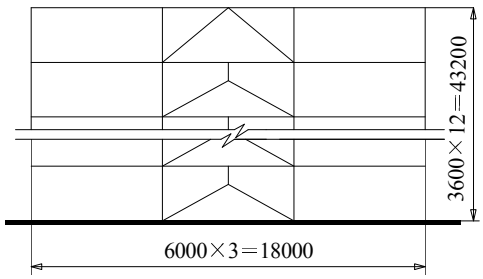

**Figure .4** Configuration of the model (units: *mm*)

**Table .1** Sections of 12-story structure (Q345)

| Story | Interior col. | Links | Exterior col. | Beams | Lean brace |
|---|---|---|---|---|---|
| 1~3 | H650×500×24×30 | H550×200×16×18 | H400×300×12×20 | H450×250×10×14 | H450×300×16×20 |
| 4~6 | H550×400×16×28 | H500×200×16×18 | H400×300×12×20 | H450×250×10×14 | H450×300×16×20 |
| 7~9 | H400×400×12×20 | H400×200×14×18 | H400×300×10×18 | H500×300×10×14 | H400×300×16×18 |
| 10~12 | H400×300×12×18 | H400×200×12×16 | H400×300×10×18 | H500×300×10×14 | H400×300×16×18 |

**Nonlinear dynamic analysis of Y1-12.**To establish the response curve based on the proposed pushover analysis, the force distribution and target displacement under the ME, DE and RE must be defined. Therefore, nonlinear time history analyses were carried out firstly. To avoid event bias, ten ground motion records were chosen from the Pacific Earthquake Engineering Research Center database on the sites located greater than or equal to 10 km from fault rupture. The background information and mean beta spectrum are included in Tab.2 and Figure 5 respectively. In dynamic analyses P-Δ effect was considered by (1.0dead +0.5live), and the equivalent damping is assumed to be 3.5% under ME and DE, but under RE, the damping is defined as 5%. Based on the nonlinear dynamic analyses results, the mean vertical distribution of horizontal inertial force under three earthquake levels for the ten ground motions were picked out. For comparative patency, the horizontal inertial forces were normalized to the same roof value as unit one and plotted in Figure 6. The details of numerical model for nonlinear analysis can be seen in document [16].

**Table .2** Ground motion records for 12-story modal structure

| No. | Records | Station | Durations/Sec. | DT/Sec. | PGA/g |
|---|---|---|---|---|---|
| 12-1 | Coyote Lake 1979 | 57383 Gilroy Array #6 | 27.1 | 0.005 | 0.146 |
| 12-2 | Kocaeli Turkey 1999 | Mecidiyekoy | 44 | 0.005 | 0.054 |
| 12-3 | Loma Prieta 1989 | 57064 Fremont - Mission San Jose | 39.95 | 0.005 | 0.124 |
| 12-4 | Northridge 1994 | 24278 Castaic - Old Ridge Route | 40 | 0.02 | 0.568 |
| 12-5 | Northridge 1994 | 24157 LA - Baldwin Hills | 40 | 0.02 | 0.239 |
| 12-6 | Northridge 1994 | 90015 LA - Chalon Rd | 31.07 | 0.01 | 0.225 |
| 12-7 | Northridge 1994 | 24396 Malibu - Point Dume Sch | 40 | 0.02 | 0.13 |

| 12-10 | Northridge 1994 | 13123 Riverside - Airport | 26 | 0.02 | 0.024 |

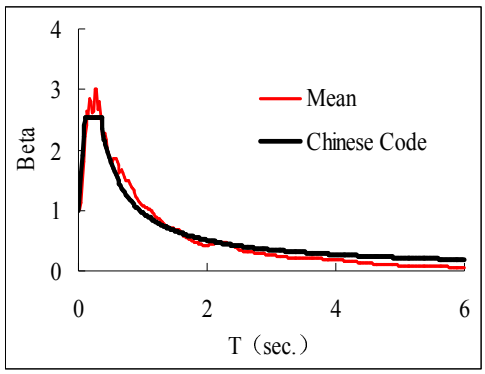

**Figure .5** Mean beta spectrum and Chinese Code beta spectrum

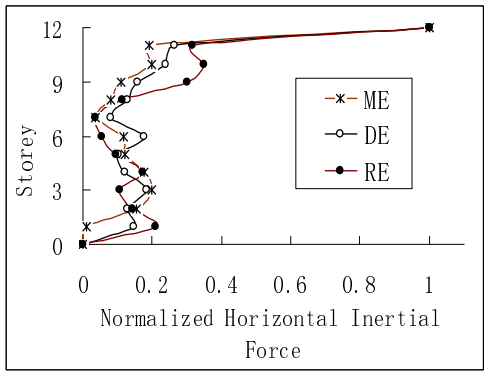

**Figure .6** Distribution of horizontal inertial forces for 12-story model

**R of Y1-12.** According to the proposed pushover analysis in this paper, the actual response curve was plotted in figure Figure 7. Based on the initial stiffness and the energy dissipation equality law, the yield base shear force and yield roof displacement were obtained as 3601kN and 286.9 mm, respectively. According to CSM mentioned above, the ductility factor $\mu$=2 under DE was assumed firstly, step-by-step iterative procedure was carried out until the ductility level is infinitely close to a fix value of μ=1.355.In the end the actual performance point under the first three modes were found as shown in Figure 8( $S_{d1}$=356.5mm， $S_{d2}$=167.6mm and $S_{d3}$=127.8mm, respectively, total mass coefficient is 0.945). Then the demand displacement $\Delta$ was established as 390.8mm according to Eq.3 and Eq.5.

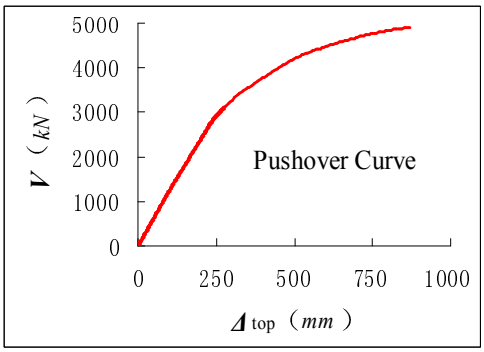

**Figure .7** Response curves of the 12-storey model

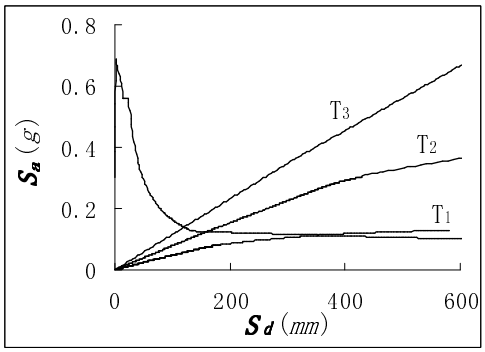

**Figure .8** Performance points for the first three modes under the actual ductility factor $\mu$=1.355

***R* of all models.**The response modification factors of all models were estimated by the same method as illustrated in Y1-12. For space limitations, the detail process were omitted, and only three key base shears $V_d$, $V_y$ and $V_e$ were presented in Table3 along with the response modification factors for each model.

**Table .3** $V_d$, $V_y$ ,$V_e$ and $R$ of all models

| Models | Y1-8 | Y1-12 | Y1-16 | Y1-20 | Y2-8-5.4 | Y2-8-6.6 |
|---|---|---|---|---|---|---|
| $V_e$ (kN) | 4104 | 4916 | 6728 | 7337 | 3635 | 4794 |
| $V_d$ (kN) | 1167 | 1442 | 2027 | 2201 | 1031 | 1362 |
| $V_y$ (kN) | 2350 | 3601 | 4548 | 4941 | 2055 | 3229 |
| $R$ | 3.517 | 3.409 | 3.319 | 3.333 | 3.526 | 3.520 |
| Models | Y2-8-7.2 | Y2-8-7.8 | Y2-16-5.4 | Y2-16-6.6 | Y2-16-7.2 | Y2-16-7.8 |
| $V_e$ (kN) | 5200 | 5287 | 6220 | 7362 | 8325 | 9028 |
| $V_d$ (kN) | 1453 | 1418 | 1773 | 2222 | 2452 | 2647 |
| $V_y$ (kN) | 2848 | 2654 | 4637 | 4916 | 5616 | 6126 |
| $R$ | 3.579 | 3.729 | 3.508 | 3.313 | 3.395 | 3.411 |

Table3 shows that all the response modification factors of YECBF models are larger than the value cryptically prescribed in Code GB50011-2001(2001), the minimum value is 3.313 and the maximum is 3.729 which exceed the Code value about 18% and 33% respectively. The reason is that the fixed $R$ value of 2.8125 in Chinese Code was obtained mainly based on studies of reinforced concrete structures. The ductility capacity and the energy dissipating capacity through inelastic behavior of YECBF is better than reinforced concrete structure, so the Code value disregarding of the ductility capacity of different structures is too little for the Y-eccentric braced steel frame.

## Result analysis

To evaluate the effects of some key design parameters such as fundamental period, storey number and the span length on $R$, response modification factors of the 12 models were plotted in Figure 9~Figure 11 versus the nominalzed periods $T/T_g$ ($T$ is the fundamental period, and $T_g$ is the site character period), the total number of building floors $N$, and the ratios of storey height to spans $\lambda$, respectively. Figure 9～Figure 11 shows that the modification factors of YECBF designed based on Chinese Code decrease as the fundamental period and total storey number increase, but the decrease trend is not obvious. However, for 16-storey buildings $R$ decreases as $\lambda$ increases, but the 8-storey ones just has the opposite trend. Figure 11 also shows that the response modification factors for 16-storey buildings are somewhat smaller than those obtained in 8-storeys ones, but the differences become smaller as the ratios of storey height to spans increase.

## Summary

(1)In this paper an improved pushover analysis was utilized in quantification of $R$ for YECBF. The proposed pushover analysis is an approximate adaptive force distribution and attempts to follow more closely the time-variant distributions of inertia forces, in which the contribution of high modes to response and the redistribution of inertia forces because of structure yielding and the associated changes in the vibration properties of the structure were considered approximately.

(2)To evaluate the response modification factor of YECBF, a new method for defining the behavior factor was proposed according to the general definition of the behavior factor. The elastic design

earthquake force level $V_e$ was determined by an improved capacity spectrum method based on modal pushover analysis procedure proposed by Anil K.Chopra and Rakesh K.Goel (2002) and well known ductility factor theory proposed by Newmark N.M. and Hall W.J. (1982).
(3) To get a creditable value of response modification factor for the YECBF structures complied with Chinese Code, twelve models were designed: one group with different storey number and the other with different spans. Based on the analysis results, the effects of some key design parameters such as fundamental period, storey numbers and the spans length on the response modification factors were evaluated.
(4) In the end, a reasonable $R$ value of 3.5 for the YECBF designed based on Chinese Code was advised.

**Keywords:** infilled wall frame structure; bare frame structure; configuration; seismic performance; time-history analysis

**Abstract.** Using the three-strut model, five types of frame structures, i.e., without infilled walls, with full infilled walls, without bottom-storey infilled walls, without middle-storey infilled walls and without top-storey infilled walls, were studied. The mode analysis and nonlinear time-history analysis were carried out on each model. In order to investigate the effects of infilled walls with different configurations on the seismic behavior of reinforced concrete frame structures, the structural periods, the ratio of $T_t$ to $T_1$ and the maximum interstorey drifts were analyzed. The results indicate that the infilled walls enhance the lateral stiffness of frames, and the configuration of infilled walls has little influence on the calculation of structural periods. It also shows that the weaker storey is formed due to the unreasonable layout of infilled walls, thus leading to the collapse of the whole structures under the seismic action.

## Introduction

The infilled wall frame structures are widely used in practical engineering projects for the advantages of flexible configurations and acquiring more space in buildings. However, there are still some weaknesses existing in the utilization of the infilled wall structures. For example, the irregular configurations of infilled walls are often used for building functions, which would easily form a weak storey due to large difference of lateral stiffness among adjacent stories of structures. Thus, the structures would be damaged under earthquake actions, since the plastic deformation concentrates only in one storey. On the other hand, the irregular configurations of infilled walls would yield large torsional responses, which bring a great damage to the safety of the structures. In practical design, the infilled walls are regarded as non-structural components that their weights are added to the frames. The structural natural period is reduced to consider the impact of stiffness of infilled walls on the seismic behavior of structures. It's illustrated from many earthquake disasters that this approach is too simple to consider the interactions between the infilled walls and frames, which will result in the collapse of the buildings [1-3].

In this paper, five finite element analysis models of the frame structures with infilled walls of different irregular configurations are established adopting the three-strut model. The elasto-plastic time-history analysis is carried out on each model. Taking the structural periods and interstorey drifts as index, the impacts of the infilled wall and its configuration on the seismic behavior of frame structures are studied by comparing with the bare frame structure and can be helpful in practical engineering applications.

**The Mechanical Model of Infilled Wall**

Extensive research were conducted to simulate the mechanical behavior of infilled walls. In 2003, El-Dakhakhni [4] proposed the three-strut model on the basis of the improvement of the equivalent brace model (Fig. 1). The infilled wall is equivalent to three braces that is pinned with the frame. The location and geometric parameters of the three-strut are calculated from the contact length among braces, beams and columns, the area of brace.

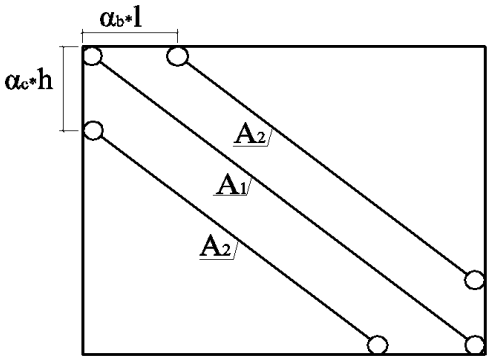

Fig.1 Three-strut model

The parameters, including the coefficient of the contact length $\alpha_b$ and $\alpha_c$ among the infilled wall, beams and columns, and the area of the brace $A_d$ , are the key to the determinations of the location and geometric size of the three-strut model. Due to the mechanical behaviors of the structure changing under the earthquake actions, there are difficulties in the quantification of the parameters. However, the changes can be ignored when only considering the overall seismic response of the structure.

The parameters of infilled walls are calculated by applying the following equations(1)~(6).

$$A_d = \frac{(1-\alpha_c)\alpha_c h_c t_w \frac{\sigma_c}{f_c} + \alpha_b l_b t_w \frac{\tau_b}{f_c}}{\cos\theta} \tag{1}$$

$$\alpha_c h_c = \sqrt{\frac{2(M_{pj} - M_{pc})}{t_w \sigma_{c0}}} \le 0.4 h_c \tag{2}$$

$$\alpha_b l_b = \sqrt{\frac{2(M_{pj} - M_{pb})}{t_w \sigma_{b0}}} \le 0.4 l_b \tag{3}$$

$$\sigma_{c0} = \frac{f_c}{\sqrt{1+3\mu^2 r^4}} \quad , \quad \sigma_{b0} = \frac{f_c}{\sqrt{1+3\mu^2}} \quad , \quad \tau_b = \mu\sigma_b \tag{4}$$

$$A_c = r^2 \sigma_{c0} \alpha_c (1 - \alpha_c - \mu r) \ , \quad A_b = \sigma_{b0} \alpha_b (1 - \alpha_b - \mu r) \tag{5}$$

$$\text{If } A_c > A_b, \ \sigma_b = \sigma_{b0}, \ \ \sigma_c = \sigma_{c0} \frac{A_b}{A_c}; \text{ if } A_c < A_b, \ \sigma_b = \sigma_{b0} \frac{A_b}{A_c}, \sigma_c = \sigma_{c0} \tag{6}$$

where, $h_c$ is the height of the frame column, $t_w$ is the thickness of the infilled wall, $\sigma_c$ and $\sigma_b$ are the normal stress of the contact surface among the infilled wall, beam and column, respectively, $f_c$ is the compression strength of infilled wall, $l_b$ is the calculation span of frame beam, $\tau_b$ is the shear stress of the contact surface between infilled wall and beam, $\theta$ is the angle between the diagonal of the

three-strut and frame beam, $M_{pc}$ is the yield moment of column, $M_{pb}$ is the yield moment of beam, $M_{pj}$ is the minimum value among the yield moment of column, beam and joint, $\mu$ is the coefficient of fraction between infilled wall and frame, the value is 0.7, $r$ is the length ratio of column to beam.

## The Analysis Model of Infilled Wall Frame Structures

A 7-story reinforced concrete frame structure is selected as an example. The height of structure is 3.6 m (see Fig.2). The cross section of the beam is 0.3m×0.5m, and the cross section of column is 0.5m×0.5m. The thickness of the cast-in-place concrete floor slab is 0.1m. The concrete strength is C30, and the longitudinal steel bar of all the beam and column is HRB335, and slab reinforcement and links are HPB235. The thickness of infilled wall is 0.24m. The site fortification intensity is Grade 8; the type of site is Ⅱ; the basic design acceleration is 0.1g; the design earthquake group is the second group; the characteristic period of site is 0.4s. The dead loads are self-weight of structure, and the live loads of floor and roof are 2.0KN/m$^2$.

Five types of analysis models are established according to the requirements of common architectural features and spatial arrangement. Model A represents a bare frame structure. Model B represents a full infilled walls frame structure. Model C represents a frame structure without infilled walls in the first storey. Model D represents a frame structure without infilled walls in the fourth storey. And model E represents a frame structure without infilled walls in the top storey.

The three-strut model is used to capture the mechanical behavior of infilled walls[4,5]. The wall materials are common fried brick. The material physical parameters of the infilled walls are as follows: the elastic modulus is 2.4×103 Mpa, the grade of mortar strength is M5, the grade of masonry strength is MU10, and the weight density is 18 kN/m3. Typical El Centro E-W wave is selected for the time-history analysis with peak ground acceleration of 220 gal according to the code for seismic design of buildings[6].

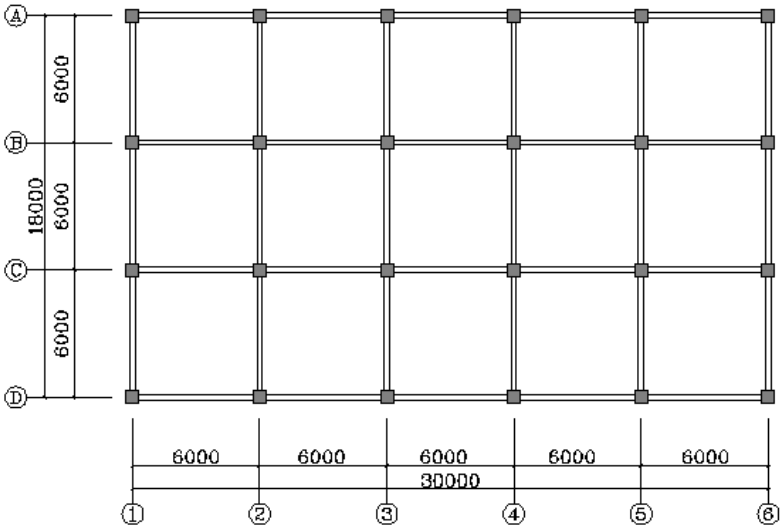

Fig.2 The plan of model

## The Analysis of Numerical Results

**The Analysis of Structural Periods.** The natural periods and the ratio of the first torsional period to the first translational period are calculated through the modal analysis on the five models A-E. The impact of the configuration of the infilled walls on the lateral stiffness and torsional effects of structures are studied, which can be seen in Table 1 and Fig. 3.

Table.1 The periods of frames with masonry infilled walls(S)

| Period \ Type | Model A | Model B | Model C | Model D | Model E |
|---|---|---|---|---|---|
| $T_1$ | 1.058 | 0.612 | 0.688 | 0.688 | 0.602 |
| $T_t$ | 0.944 | 0.538 | 0.610 | 0.608 | 0.529 |
| $T_t/T_1$ | 0.892 | 0.878 | 0.886 | 0.883 | 0.879 |

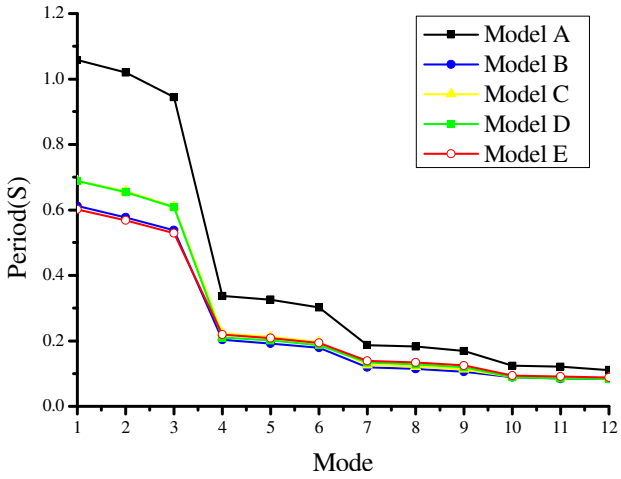

Fig. 3 The periods of frames with masonry infilled walls

It can be seen that the lateral stiffness of the frame structure is significantly enhanced from the contributions of infilled walls. The natural periods of Models B-E are obviously less than that of Model A. For the first three modes, the periods of infilled walls frame structures are 0.5-0.7 times than that of model A. In addition, the natural periods of Models B-E are approximated to each other. Among them, the period of Model B is almost the same to that of Model E. It indicated that the configuration has minor influence on the natural periods of the structures.

It also presented that the ratio of the first torsional period ($T_t$) to the first translational period ($T_1$) should be controlled to ensure that the structures have sufficient torsional stiffness. The ratios of $T_t$ to $T_1$ of Models A-E are less than 0.9, which meet the requirements of the code. Model A has the largest value of 0.892, and Model B has the smallest value of 0.878. The ratios of $T_t$ to $T_1$ of Models C-E have a increasing trend comparing with that of Model A. The torsional effects of structures increase with the ratios of $T_t$ to $T_1$ increasing. It showed that the torsional effects of structures would be exacerbated by the irregular configuration of infilled walls, which would lead to a damage of structure under the earthquake actions.

**The Analysis of Interstorey Drifts of Structures.** Fig. 4 shows that the maximum interstorey drifts of each model under the major earthquake of Grade 7 for the El Centro accelerogram. It can be seen that the configurations of infilled walls have significant impact on the structural interstorey drifts. There is a similar trend for the interstorey drift curves of Model A and Model B. The interstorey drift of Model B is significantly less than that of Model A due to the lateral stiffness of structure is enhanced by the infilled walls. The maximum interstorey drifts of the two models are located at the second storey, and the value of Model B is 0.66 times of that of Model A. The uniform distributions of the interstorey drifts reflect that the distribution pattern of the energy dissipation along the height of the structure is even. Thus, the structure has good ductility. The interstorey drifts of without infilled walls storeys have sudden changes. The structural deformation concentrates in the first storey of Model C, fouth storey in Model D and top storey of Model E. The interstorey drifts of the deformation concentrated storeys of each model are larger than that of the corresponding storey of Model A. For Model E, the interstorey drift of the deformation concentrated storey has grown large by 64%. However, the interstorey drifts of other storeys are significantly smaller than that of Model A. There

are sudden changes in the lateral stiffness of the storey with no infilled walls, leading to the formation of weak storey of the structure. Thus, the structure would be easily damaged under the earthquake action.

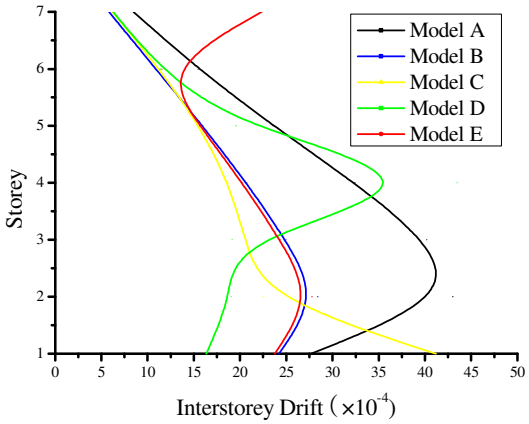

Fig.4 The maximum interstorey drifts of structure with masonry infilled walls

## Conclusions and Suggestions

Five types of RC frame structures are analyzed though the modal analysis and the nonlinear dynamic time-history analysis. Some conclusions are as follows:

(1)The infilled walls enhance the lateral stiffness of the structures. The natural periods of infilled walls frame structures are significantly 0.5-0.7 times less than that of the bare frame structure.

(2)The configurations of infilled walls have minor influence on the natural periods of the structure. The periods of Models B-E are close to each other.

(3)The irregular configurations of infilled walls have major influence on the interstorey drifts of the structure. Due to sudden changes in the lateral stiffness of the structure, the weak storey is formed. As a result, the structures are destroyed during the earthquake. Such structural damages should be avoided in the seismic design.

(4)For the seismic design of the frame structures with infilled walls in irregular configurations, the interaction between the infilled walls and frames should be taken into considered instead of adopting a simplified approach according to the code.

**Keywords:** bottom-business multi-story masonry structure, winged column, earthquake simulation shaking table test, seismic resistant capacity

**Abstract:** Bottom-business multi-story masonry structure is widely used in small and middle towns in the southward in China. In the downtown of Beichuan county which affected by Wenchuan earthquake, more than 80% of this kind of building collapsed. But the Apartment of Beichuan Telecommunication Bureau behaved well earthquake resistant capacity with a moderate damage in the earthquake. The obvious difference between this building and others is the setting of winged columns in the front longitudinal wall of the first floor. For proving the influence of these members in the structure seismic capacity, the earthquake simulation shaking table test of 2 1/5 reduced scale models were designed and carried out. The models dynamic response, acceleration, displacement and strain were measured and collected, that model with winged columns behave well was testified. And the reinforcement method of balancing stiffness and increasing ductility is put forward. The results provide a foundation for the retrofitting design of the existing houses.

## Introduction

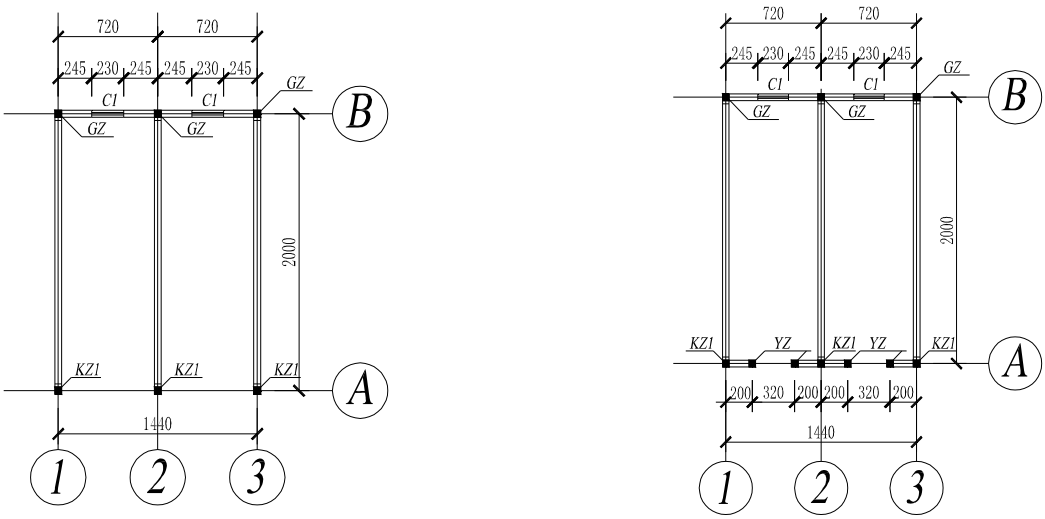
For economy limits and weak disaster prevention consciousness, building seismic capacity is low lead to “weak earthquake vs sever disaster” is a predominant characteristic in China. The bottom-business multi-story masonry structure which is more popular and cause severe damages in small and middle towns in the south of China. According to inadequate statistics, there are about two million such buildings existing in China, and 120 million residents are involved. There are no relative codes in “Seismic Code for Buildings (GB 50011-2010)” of China and no relative research in other countries. But this kind of structure can’t disappear in China because of its advantages. So in this paper, the different elements capabilities between the Apartment of Beichuan Telecommunication Bureau (Fig.1) which behaved well in earthquake and others will be studied by shaking table test.

(a) Face view (b) Back view

Fig.1 Apartment of Beichuan Telecommunication Bureau

**Shaking table test**

Based on prototype of the Apartment of Beichuan Telecommunication Bureau, test models C and D were designed. The models plane view as shown as fig.2. The tests were carried out in key laboratory of earthquake engineering and engineering vibration, Institute of Engineering Mechanics, China Earthquake Administration.

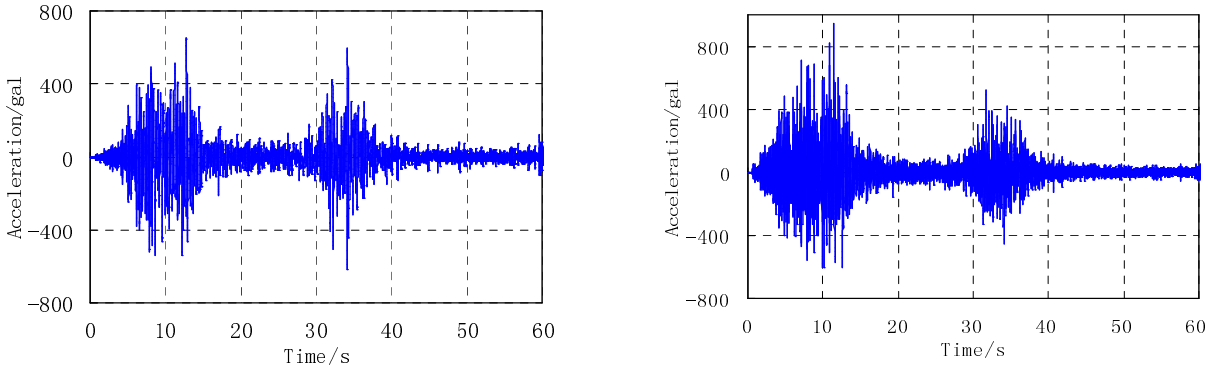


(a) Model C (b) Model D

Fig.2 Model plan view

According to test aim and content, 16 acceleration sensors were placed on vibration table-board and the top of the models; 4 displacement meters were correctly placed and 22 strain gauges were beam column joint, wall pier, area around doors and windows.

Considering the prototype is in Wenchuan, Wolong wave was used in the shaking table tests. The character of the Wolong wave is as shown as fig.3. During the testing, 4 classes earthquake wave were used, the details as shown as table 1.



(a) Y (b) Z

Fig.3 Wolong groud motion

Table.1 Model test operation condition schedule

| | input earthquake motion | input acceleration peak/g | | output acceleration peak/g | |
|---|---|---|---|---|---|
| | | Y(longitudinal) | Z(vertical) | Y(longitudinal) | Z(vertical) |
| 1 | Wolong wave | 0.1 | 0.1 | 0.07 | 0.04 |
| 2 | Wolong wave | 0.2 | 0.1 | 0.14 | 0.05 |
| 3 | Wolong wave | 0.4 | 0.1 | 0.31 | 0.15 |
| 4 | Wolong wave | 0.8 | 0.1 | 0.66 | 0.38 |

**Test analysis**

When PGA=0.08g, two models all in the elastic working condition, the frame cooperate with walls and no cracks appeared.

When PGA=0.14g, fine cracks $45^0$ with the horizontal appeared on two window holes of model C back wall.

When PGA=0.31g, fine cracks also appeared on the frame of model C and the same thing occurred on the two outward lateral walls. The preexist cracks run to radiate cracks around the window. And some reticulate cracks appeared under the window. Boundary cleared block come into being on the wall pier. Whereas, no visible cracks on the frame of model D.

When PGA=0.66g, model C collapse, model D inclined obviously, the degree of inclination reached 1/12. The models suffered four accumulative earthquakes as shown as fig.4.

Fig.4 Model C, D suffered earthquake PGA=0.66g

Before load, after second load (0.14g) and third load (0.31g), longitude natural frequencies were attained, the results as shown as fig.5. From the chart, after 0.31g, the natural frequency of model C reduced about 60%, whereas model D changed a little.

The former three tests acceleration results of models were measured and comparison figure as shown as fig.6. The acceleration amplification first increased and then decreased along with earthquake emotion input. When natural frequency approximately equal to input earthquake emotion, the acceleration amplification reached its maximum values, they are 2.43 and 1.64.

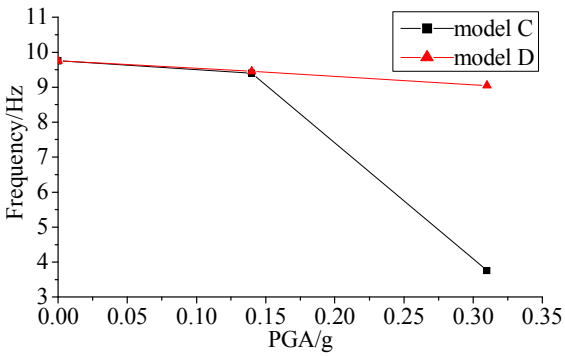


Fig.5 Longitude natural frequency

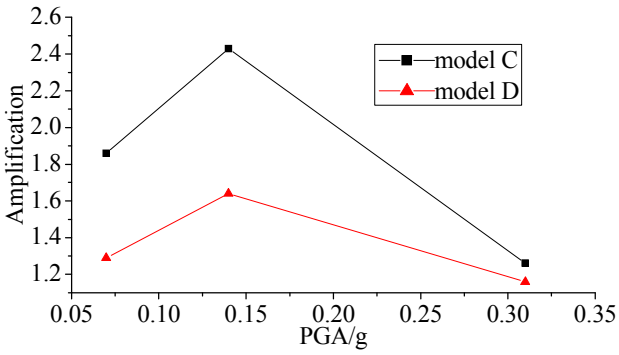

Fig.6 Acceleration amplification

The displacement of platform and model top after each loading were measured and recorded. The relative displacement results after three loading as shown as fig.7. The max relative displacement of model C is 17.87mm and here the degree of relative displacement reached 1/43, that is say bottom-business multi-story masonry structures have some ductility in certain circumstances.

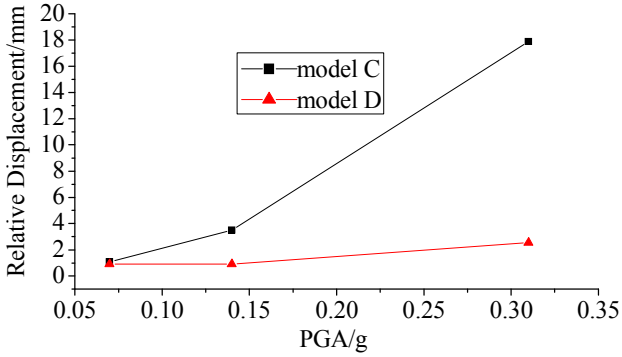

Fig.7 Relative displacement

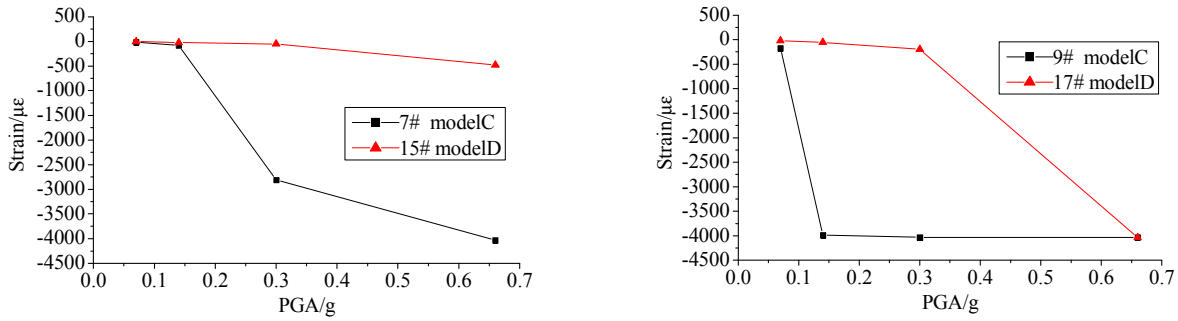
Strain values of two models on the back longitudinal wall and window upside were attained, as shown as fig.8. From the chart, the strain value on the model C back longitudinal wall (7# and 9#) always higher than model D corresponding place (15# and 19#). And after second load (PGA=0.14g), 9# was damaged and out of work, 7# approach its ultimate compressive strength after third load (PGA=0.31g). It testified the back longitudinal wall of normal bottom-business multi-story masonry structure destroied severely than with winged columns.



(a) 7#, 15# (b) 9#, 17#

Fig.8 Strain contrast of model C and model D

## Summary

The front longitudinal wall with winged columns or not may influenced seismic capacity of total structure greatly. Under the same grade earthquake motion, the damage of with winged columns obviously lightly than normal.

From normal model shaking table test phenomenon and results analysis, the back longitudinal wall firstly failure, then the vertical load was bear by other walls, finally the whole building collapsed due to exceeded limit bearing capacity.

Considering with winged columns in front longitudinal wall may provide stiffness, what can balance earthquake inertial forces come from other walls. So, the idea of balancing stiffness between front and back longitudinal walls and increasing the ductility of back longitudinal wall may be a good retrofitting method for bottom-business multi-story masonry buildings.

**Keywords:** RC frame-wall, Shaking table, Dynamic characteristics，Seismic responses, Strain rate

**Abstract.** A 1/5 scaled three-story RC (reinforced concrete) frame-wall model was modeled in microconcrete and fine wire and carried out on the shaking table. The main objective of this paper aimed to investigate the dynamic characteristics, the seismic responses, and the failure mechanisms of the model, also concentrated on the strain rate of concrete on structural members under seismic action. Based on the test results, some significant conclusions are obtained for engineering practice.

## Introduction

The Shaking table test plays an important role in earthquake-resistant design, seismic response analysis and failure mechanisms of structures, and it is capable of reproducing the whole process of earthquake response by various seismic waves [1-2]. Hence, it is important to understand the overall straructural behavior under earthquakes. In this article, a 1/5 scaled RC frame-wall model shaking table test was carried out.

## Description of the model

The model was made of microconcrete and fine wires as shown in Fig.1. The main parameters of the model are illustrated in Fig. 2 and Fig. 3. The total height of the model is 1.98m. The material properties of microconcrete were tested with 18 specimens which were 70mm×70mm×70mm with the mean ultimate compressive strength of 8.41Mpa. The main reinforcing steel in columns and beams were 3mm fine wires. The 0.9mm fine wires were adopted for stirrups in the beams and columns. The 2mm fine wire mesh was used as the reinforcement in two orthogonal directions in walls and slabs.

## Similitude relationship

Generally, in order to make sure that the model behaves the similar dynamic properties to prototype, The model design should according to dynamic similitude theory [3-4]. Based on the capacity and size limit of the shaking table, the main similitude relationships are shown in Tab. 1.

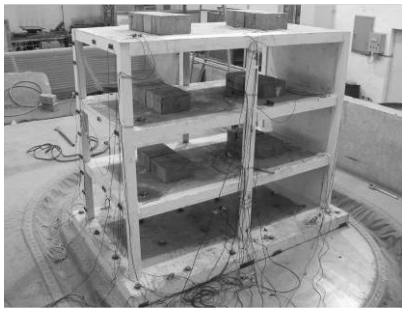

Fig. 1 Test model on shaking table.

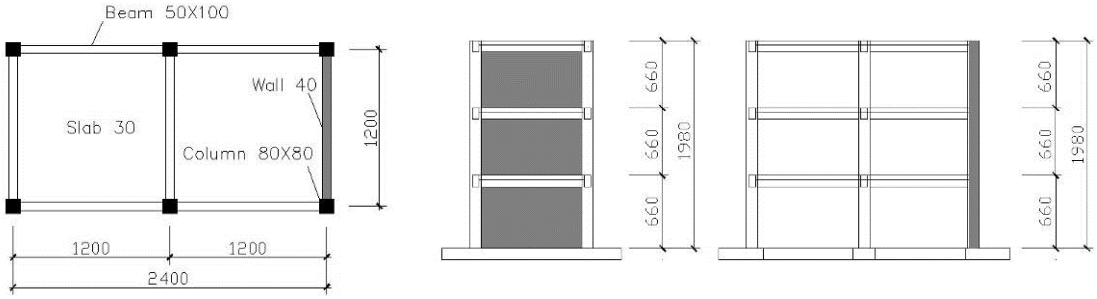

Fig. 2 Parameters of the test model

Tab. 1 Similitude relationship of the model

| Physical quantity | Similarity relationship | Coefficient |
|---|---|---|
| Length | $l_r$ | 0.2 |
| Elastic modulus | $E_r$ | 0.25 |
| Equivalent density | $\overline{\rho_r} = \frac{m_m + m_a + m_{om}}{l_r^3 (m_p + m_{op})}$ | 1.26 |
| Stress | $\sigma_r = E_r$ | 0.25 |
| Deflection | $r_r = l_r$ | 0.2 |
| Time | $t_r = l_r / \sqrt{E_r / \overline{\rho_r}}$ | 0.447 |
| Velocity | $v_r = \sqrt{E_r / \overline{\rho_r}}$ | 0.44 |
| Acceleration | $a_r = E_r / (l_r \overline{\rho_r})$ | 1 |
| Frequency | $\omega_r = \sqrt{E_r / \rho_r} / l_r$ | 2.237 |

**Ground motion input and instruments**

The typical ground motion El Centro wave (N-S component and vertical component) was selected, that the maximum accelerations were 341.7cm/s$^2$ and 206.3cm/s$^2$. The time interval of the records was compressed according to Tab. 1. The target input peak ground accelerations (PGA) of horizontal direction are illustrated in Tab. 2, and the target input peak value of vertical direction was compressed according to the real ratio of the ground motion.

Tab. 2 Test program

| Test No. | Input PGA of x direction (g) | Direction |
|---|---|---|
| WN-1 | 0.05 | x |
| EC-1 | 0.16 | x/z |
| EC-2 | 0.24 | x/z |
| EC-3 | 0.33 | x/z |
| EC-4 | 0.40 | x/z |
| EC-5 | 0.45 | x/z |
| EC-6 | 0.50 | x/z |
| EC-7 | 0.54 | x/z |
| EC-8 | 0.58 | x/z |
| EC-9 | 0.60 | x/z |
| EC-10 | 0.66 | x/z |
| EC-11 | 0.70 | x/z |
| EC-12 | 0.73 | x/z |
| EC-13 | 0.86 | x/z |

Note: WN and EC denote White noise and El Centro records, respectively.

Furthermore, the instrumentation is installed so that overall and local responses of the model could be measured, like accelerations measured by accelerometers, displacements measured by LVDTs and strain rate measured by fiber bragg grating strain sensor.

## Test results

The effective frequencies and damping ratio were obtained from the test as shown in Fig. 3 and Fig. 4. The frequency decreases and damping increases when the model damage progresses. Cracks were found on the column and at the end of the beam of the second story after the EC-3 (PGA=0.33g). The previous cracks spread and new cracks were occurred on other beams and columns after the EC-6 (PGA=0.5g). Finally, some connections of beam and column were almost completely damage, the crushing of microconcrete and buckling of fine wire were observed after the test.

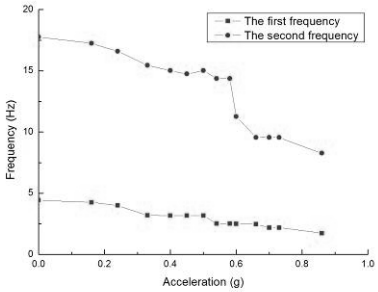

Fig. 3 Effective frequencies

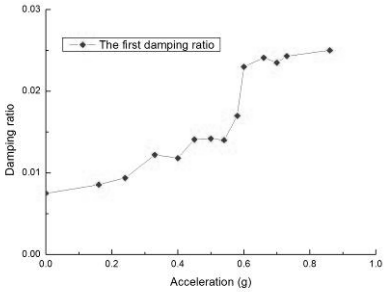

Fig. 4 Damping ratio

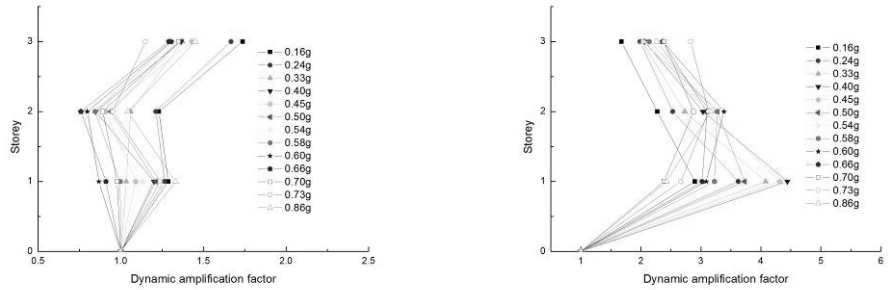
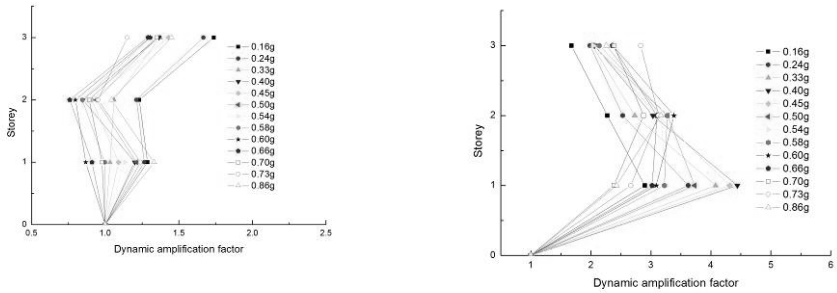


(a) Horizontal direction (b) Vertical direction

Fig. 5 Dynamic amplification factors of stories



(a) Horizontal direction (b) Vertical direction

Fig. 6 Maximum displacement of stories

The horizontal and vertical dynamic amplification factors of stories can be observed in Fig. 5. The maximum displacement of stories can be observed in Fig. 6. It was observed that the dynamic amplification factor of stories decreases when the input acceleration increases, the maximum values

of the horizontal and vertical direction are 1.74 and 4.44, which were located on the top and the first floor, respectively. In other hand, the maximum displacement of stories increases when the input acceleration increases. The maximum strain rate of concrete on structural members of the test model can be observed in Tab. 4.5. The strain rate of concrete increases with the increasing input peak value. The range of strain rate of concrete on beams and columns are $2.0\times10^{-3}$/s to $2.7\times10^{-2}$/s and $6.5\times10^{-3}$/s to $6.8\times10^{-2}$/s under moderate to extrem earthquake action.

Tab. 3 Maximum strain rate of concrete on structural members

| Input PGA of principal direction (g) | Story | Maximum strain rate of concrete on beams ($s^{-1}$) | Maximum strain rate of concrete on columns ($s^{-1}$) |
|---|---|---|---|
| 0.16 | 1 | $2.0\times10^{-3}$ | $1.7\times10^{-2}$ |
| | 2 | $3.2\times10^{-3}$ | $6.9\times10^{-3}$ |
| | 3 | $3.5\times10^{-3}$ | $6.5\times10^{-3}$ |
| 0.40 | 1 | $2.8\times10^{-3}$ | $3.0\times10^{-2}$ |
| | 2 | $6.6\times10^{-3}$ | $1.2\times10^{-2}$ |
| | 3 | $6.8\times10^{-3}$ | $1.7\times10^{-2}$ |
| 0.60 | 1 | $6.1\times10^{-3}$ | $5.1\times10^{-2}$ |
| | 2 | $1.7\times10^{-2}$ | $1.2\times10^{-2}$ |
| | 3 | $8.2\times10^{-3}$ | $2.6\times10^{-2}$ |
| 0.70 | 1 | $9.6\times10^{-3}$ | $5.8\times10^{-2}$ |
| | 2 | $2.7\times10^{-2}$ | $1.5\times10^{-2}$ |
| | 3 | $1.0\times10^{-2}$ | $3.5\times10^{-2}$ |
| 0.86 | 1 | $9.0\times10^{-3}$ | $6.8\times10^{-2}$ |
| | 2 | $2.5\times10^{-2}$ | $1.5\times10^{-2}$ |
| | 3 | $1.9\times10^{-2}$ | $4.5\times10^{-2}$ |

## Conclusions

Based on the shaking table test results obtained, the following observations were drawn:

(1)The frequency decreases and damping increases when the model damage progresses. The dynamic amplification factor decreases and maximum displacement when the input acceleration increases.

(2) The strain rate of concrete increases with the increasing input acceleration. It was observed that the strain rate of concrete are $10^{-3}$ to $10^{-2}$/s under earthquake action.

**Keywords:** self-centering; prefabricated frame joints; finite-element analysis; seismic behavior

**Abstract:** In order to research the self-centering capacity of prefabricated frame joints, this paper designed analysis models of prefabricated frame joint with the finite element software ABAQUS, contrastively analyzed seismic behavior of joint applied pretention and joint without pretention. Joint applied pretention is found to have better self-centering capacity. Then the paper calculated and analyzed the factors of stretching control stress, number of post-tensioned steel. The results show that number of post-tensioned steel has a greater influence on the seismic behavior of the structure, and the stretching control stress has influence in a certain range. The results have some degree of guiding significance for the popularization of prefabricated frame.

## Introduction

The seismic performance of prefabricated structure largely depends on joint's construction[1]. Joints are divided into strong connection and ductile connection. Strong connection usually splices prefabricated component together in the way of cast-in-place and can achieve similar or equivalent strength with the cast-in-place structure. China, Japan and New Zealand mostly use strong connection. Self-centering prefabricated frame adopts ductile connection. By reasonable node structure design, joint acquires well rotation capacity. And when earthquake happens, elasto plastic deformation of the structure is mainly concentrated in the joint, beam and column maintains elastic deformation, residual deformation is small because of self-centering capacity provided by post-tensioned steel's resilience, the structure is easy to repair after earthquake. This paper built one prefabricated frame joints with self-centering capacity and analyzed various influence factors of self-centering capacity and seismic behavior.

## Finite element analysis model

### The basic information about the model

According to current research achievements in China and overseas[2]-[6], adding prestressed tendon in prefabricated frame joint beam can improve self-centering capacity of joint and reduce residual deformation. This paper designed one self-centering prefabricated frame joint JD-1. Prefabricated components buried bellows in column and beam, weared 4 prestressed steel strands in it, stretched strand in post-tensioned method with tension stress of 1000Mpa then grouted the holes. Longitudinal reinforcement and stirrup also used connection method of reserving channel then grouting. Size and reinforcement of analysis model is shown in Fig 1.

## Material constitutive model

The concrete constitutive model uses a damage constitutive model of concrete in ABAQUS program which assumes that the destruction of concrete material is mainly for the cracking and crashing. Yield and damage evolution are controlled by stretching the equivalent plastic strain and compression of the equivalent plastic strain. At the same time, the model also has better convergence.

Longitudinal reinforcement and stirrup uses the ideal elastic-plastic model, poisson ratio of 0.3. The strength of steel will remain the same after steel in tension reaches the yield strength. The finite element model does not consider the bond-slip effect between steel and concrete.

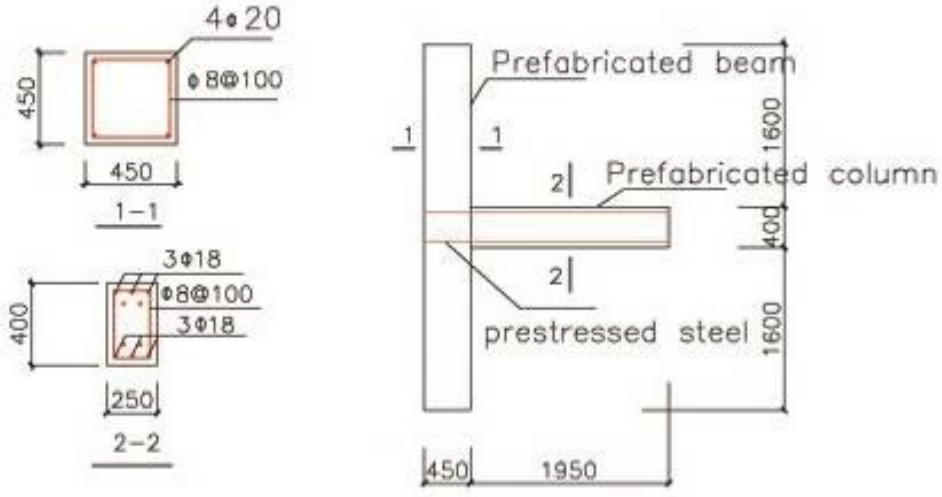

Fig 1 Size and reinforcement details of JD-1

**Boundary conditions and load mode**

Due to frame is statically indeterminate structure, the boundary condition of simulation is very important when study the performance of the beam-column joints. This paper referred to self-centering steel frame joint experiment in Tsinghua University, and adopted "Horizontal column vertical beam" in convenience. The model set hinge supports in both column ends to simulate inflection point of frame column and connected the supports to ground, applied bidirectional horizontal load to simulate seismic action at the top of beam which was seen as free end. The load mode is shown in Fig 2.

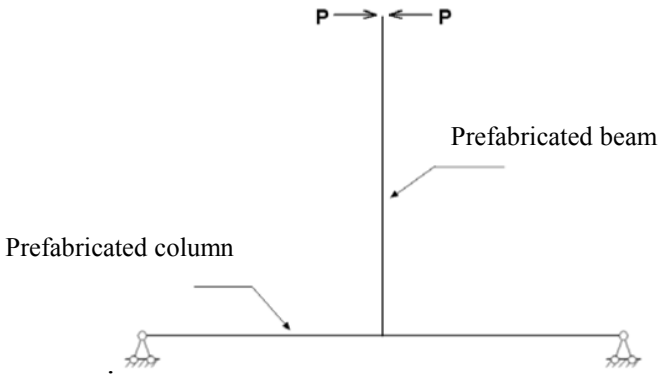

Fig 2 Loading diagram

**Finite element analysis model**

Take specimen JD-1 in the previous section as specimen BASE. Considering the structure's significant influence factors of the stretching control stress and number of post-tensioned steel, this paper designed 3 series of 7 prefabricated frame joints to analyze the influence on joint force property.

**Contrast analysis of joints with prestress and without prestress**

Based on specimen BASE, this paper designed a finite element model JD-BZL without prestress to study the influence of applying prestress on prefabricated frame joints mechanical property.

Specimens under monotonic loading load - displacement curve is shown in Fig 3. Specimens under cyclic loading hysteresis curve is shown in Fig 4, hysteretic loop is shown in Fig 5, skeleton curve is shown in Fig 6.

Fig 3 shows, specimen JD – BZL's initial stiffness and bearing capacity decreases obviously while the yield displacement is larger, specimen BASE's initial stiffness and bearing capacity is larger while the yield displacement is smaller. Fig 4 shows, specimen JD – BZL's self-centering capacity is significantly worse than specimen BASE during Several smaller loading cycle. Fig 5 shows, specimen JD – BZL's dissipation capacity is a little lower than BASE for without prestress. Fig 6 shows, skeleton curve of two specimen are close to load - displacement curve, and specimen JD - BZL stiffness decreases obviously.

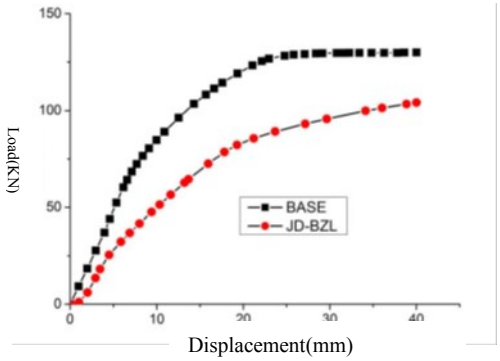

Fig 3 Load-displacement curves of BASE and JD-BZL

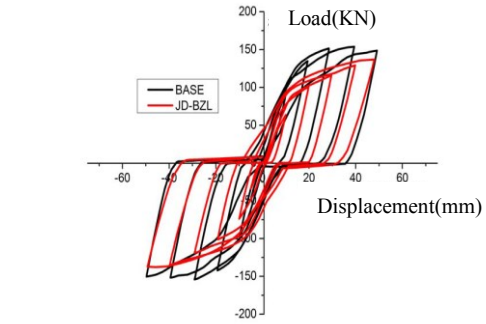

Fig 4 Hysteresis curves of BASE and JD-BZL

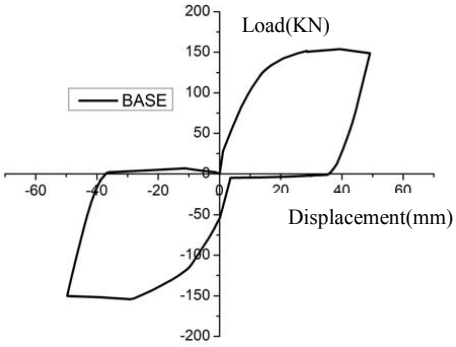
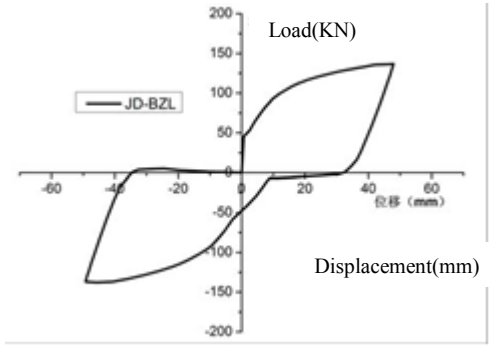


(a) Hysteretic loop of specimen BASE



(b) Hysteretic loop of specimen JD-BZL

Fig 5 Hysteretic loops of BASE and JD-BZL

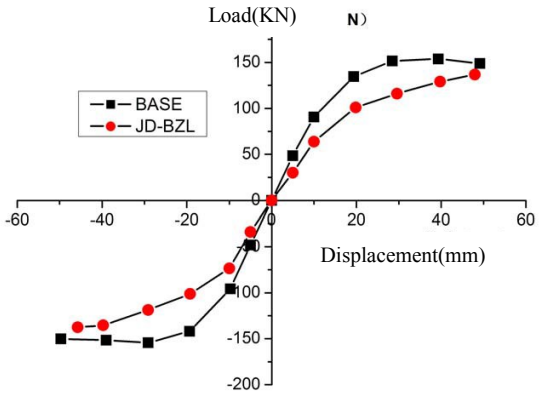


Fig 6 Skeleton curve of BASE and JD-BZL

It can be concluded from the former two chapters, increasing stretching control stress in a certain range can enhance self-centering capacity joint's ultimate strength, stiffness and elf-centering capacity, but it will not work when beyond the range.

**Stretching control stress on the influence of prefabricated frame joints force property**

Based on specimen BASE, this paper designed finite element models JD-1500 and JD-2000 to study the different stretching control stress caused prefabricated frame joints force property. Take specimen BASE as JD-1000 with stretching control stress 1000Mpa. The stretching control stress of specimen JD-1500 is 1500Mpa and the stretching control stress of specimen JD-2000 is 2000Mpa. Specimen under cyclic loading hysteresis curve is shown in Fig 7.

As can be seen in Fig 7, hysteresis curve tracks of three joints are in good agreement with each other except stiffness is slightly different when unloading. In addition, ultimate strength of three joints are mostly the same. This suggests that when stretching control stress came to 1000Mpa, ultimate strength of joint would not increase, and the stiffness and self-centering capacity would not change too much.

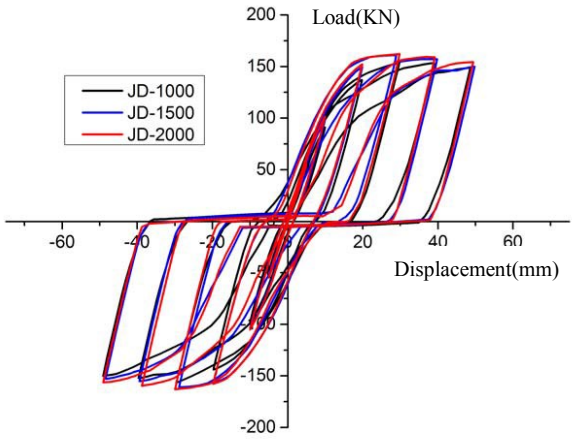

Fig 7 Hysteresis curves of specimens in different stretching control stress

**Number of prestressed steel on the influence of prefabricated frame joints force property**

Based on specimen BASE, this paper designed finite element models JD-2G and JD-6G to study the different number of prestressed steel caused prefabricated frame joints force property. Specimen BASE still had 4 prestressed steel strands, specimen JD-2G had 2 prestressed steel strands and specimen JD-6G had 6 prestressed steel strands. The stretching control stresses of 3 specimens are all 1000Mpa.Specimens under monotonic loading load-displacement curve is shown in Fig 8. Specimen under cyclic loading hysteresis curve is shown in Fig 9, hysteretic loop is shown in Fig 10, skeleton curve is shown in Fig 11.

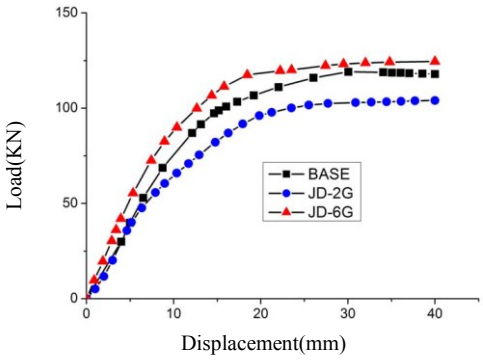

Fig 8 Load-displacement curves of specimens in different number of prestressed steel

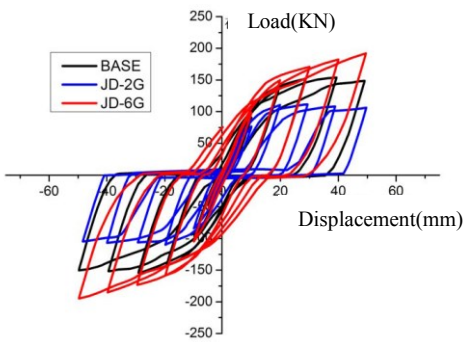

Fig 9 Hysteresis curves of specimens in different number of prestressed steel

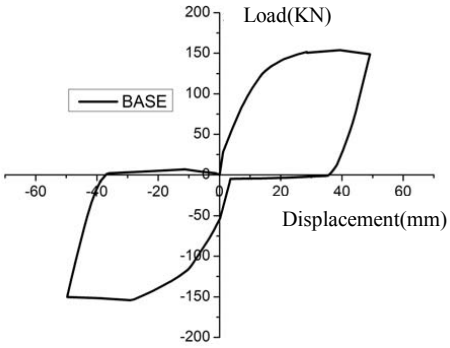
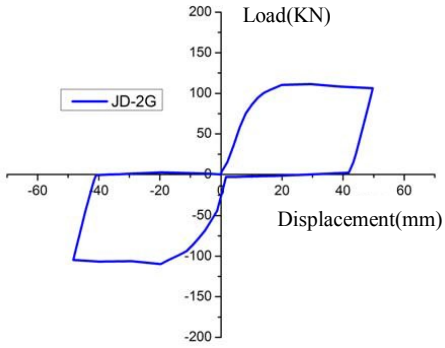
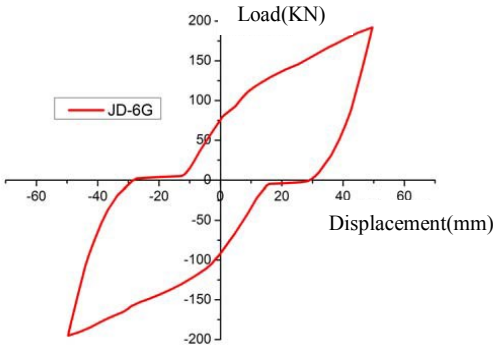


(a) Hysteretic loop of specimen BASE



(b) Hysteretic loop of specimen JD-2G



(c) Hysteretic loop of specimens JD-6G

Fig 10 Hysteretic loops of specimens in different number of prestressed steel

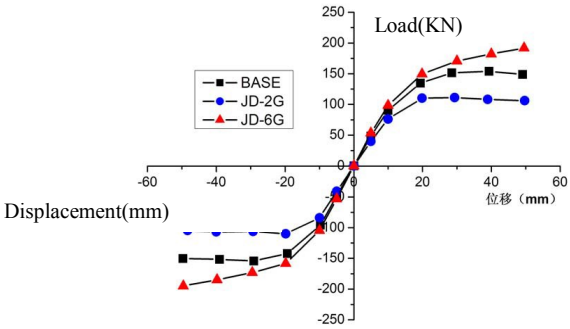


Fig 11 Skeleton curves of specimens in different number of prestressed steel

As can be seen in Fig 8 and Fig 9, specimen JD-2G's bearing capacity and self-centering capacity have a certain decline while JD-6G's have a certain increases. Initial stiffness of 3 joints has a little difference. Fig 10 shows, the number of prestressed steel has a great influence on joint's dissipation capacity, the more post-tensioned steel joint has, the better dissipation capacity joint obtains. Fig 11 shows, JD-2G's initial stiffness is less due to reducing prestressed steel and the joint enters yield phase earlier. JD-6G's initial stiffness is larger and skeleton curve trends slow.

## Conclusions

In this paper, non-linear finite element analysis on self-centering prefabricated frame joint with the finite element analysis software ABAQUS under static load and low-cycle reciprocating load, the main conclusions are as follows:

1) Stretching prestressed steel in prefabricated frame joint can enhance joint self-centering capacity, and increase joint strength and stiffness at the same time, but decrease joint yield displacement.

2) Increasing stretching control stress of self-centering prefabricated frame joint has a significant impact on joint force property. Increasing stretching control stress of joint in a certain range can enhance joint's strength, stiffness and elf-centering capacity, but it will not work when beyond the

range. Ensure that prestressed reinforcement keeps elastic working state in the whole process increasing stretching control stress.
3) With the number of post-tensioned steel in self-centering prefabricated frame joint increasing, self-centering capacity of joint obviously increases, and joint strength, stiffness and dissipation capacity increases at the same time.

# The Effect of Damping on Seismic Performance of Steel Frame

Xinwu Wang [1,a] ,Changjiao Hu [2,b]

[1] Department of Civil Engineering, Luoyang Institute of Science and Technology, 471023, China

[2] School of Civil Engineering,Henan University of Science and Technology,471000, China

[a] wxw197100@sina.com,[b]1246686577@qq.com

**Keywords:**Damping, Steel frame,Seismic performance

**Abstract.**To study the effect of damping on seismic performance of steel frame, using the pseudo dynamic test by inputting damping and no damping to analyze the seismic performance of semi-rigid steel frame. Analysis was focused on the effect of damping on the panel zone strain, story drift and interlayer force.The conclusion was that under the more severe earthquake, the structural damping had effects on the seismic performance of semi-rigid steel frame.

## Intruduction

Damping was a kind of features during free vibration which was due to external influence or structural effect that decreased amplitude of structure and was one of the important characteristics that formed the seismic performance of structure.In the process of the amplitude decreasing, vibration system dissipated energy through different mechanisms of action.When researchers analyzed the seismic performance of steel frame, they often idealized the damping through setting linear viscous dampers or shock absorber in the steel frame that could't reflect the real implication of the damping to the structure.Calculating the damping coefficient of the semi-rigid steel frame and inputting damping value and undamped in the pseudo dynamic test, the variations about displacements ,strains and loads for the semi-rigid steel frame were analyzed. It was concluded that under the more severe earthquake, the structural damping had effects on the seismic performance of steel frame with semi-rigid connection..

## The Calculation Formulas of Structural Damping Coefficient [1,2]

In structural dynamic analysis, through the reasonable selection of damping coefficient, the energy that the mechanism of action dissipated and the energy dissipation by vibration were equal.Before the calculation of damping coefficient, it was necessary to determine the damping ratio that was the ratio of damping coefficient and critical damping coefficient.Viscous damping model was adopted in the practical engineering, and the damping ratio was defined as a constant.The paper employed 0.02 as the damping ratio of steel frame. The Rayleigh damping coefficient method was used to calculate the damping coefficient.

Damping matrix was calculated according to Eq. 1:

$$[C]=\tau_M[M]+\tau_K[K]. \quad (1)$$

$$\tau_M=2(\lambda_i\omega_j-\lambda_j\omega_i)\omega_i\omega_j/(\omega_j-\omega_i)(\omega_j+\omega_i). \quad (2)$$

$$\tau K=2(\lambda i\omega j-\lambda j\omega i)/(\omega j-\omega i)(\omega j+\omega i). \quad (3)$$

In which[C],[M],[K]were mass matrix,damping matrix, stiffness matrix of the structure respectively;$\omega_i$,$\omega_j$ were the circular frequency of vibration mode i,j respectively;$\lambda_i$,$\lambda_j$ were damping ratio of modal i,j respectively, $\lambda_i = \lambda_j = 0.02$.

Circular frequency were solved according to the structural dynamic Eq. 4:

$$[M]\{\ddot{u}\}+[C]\{\dot{u}\}+[K]\{u\}=[M]\{\ddot{u}g\}. \quad (4)$$

Assuming $u_1=\varphi_1\sin(\omega t+\theta)$; $u_2=\varphi_2\sin(\omega t+\theta)$. (5)

Inputting Eq. 5 into homogeneous equation,then got Eq. 6, Eq. 7:

$$-m_1\omega^2\varphi_1+(k_1+k_2)\varphi_1-k_2\varphi_2=0. \quad (6)$$

$$-m_2\omega^2\varphi_2-k_2\varphi_1+k_2\varphi_2=0. \quad (7)$$

$\omega_i$,$\omega_j$ were solved.

Substituting circular frequency $\omega_i$, $\omega_j$ and 0.02 damping ratio Eq. 2 and Eq. 3,$\tau_M$ and$\tau_N$ were solved.Then put them in Eq. 1 to get [C].

## Pseudo-dynamic Test

**Experiment.** The pseudo dynamic test of semi-rigid steel frame (as shown in Fig. 1)which had a scale ratio of 1:2 with two layers, single span and studio was carried out. The steel frame was designed according to the specifications for design of steel structures (GB 50017-2003)[3].The underlying height was 2.2 m, the top height was 2.0 m, span and studio were both 3.0 m.The steel used were Q235 steel, and beams ,columns and subdivision T steel were hot-rolled H steel.Fitting M16 and 10.9 high strength bolts to connect beams ,columns and T steel. The cross section sizes of specimen were followed:

Column:HW175mm×175mm×8mm×11mm;Beam:HW194mm×150mm×6mm×9mm;

T steel: HW500mm×200mm×10mm×16mm.

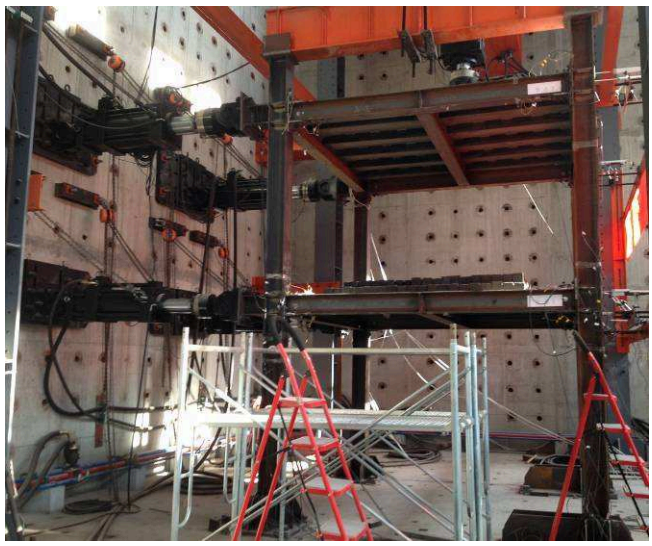

Fig. 1.Test site of steel frame with semi-rigid connection

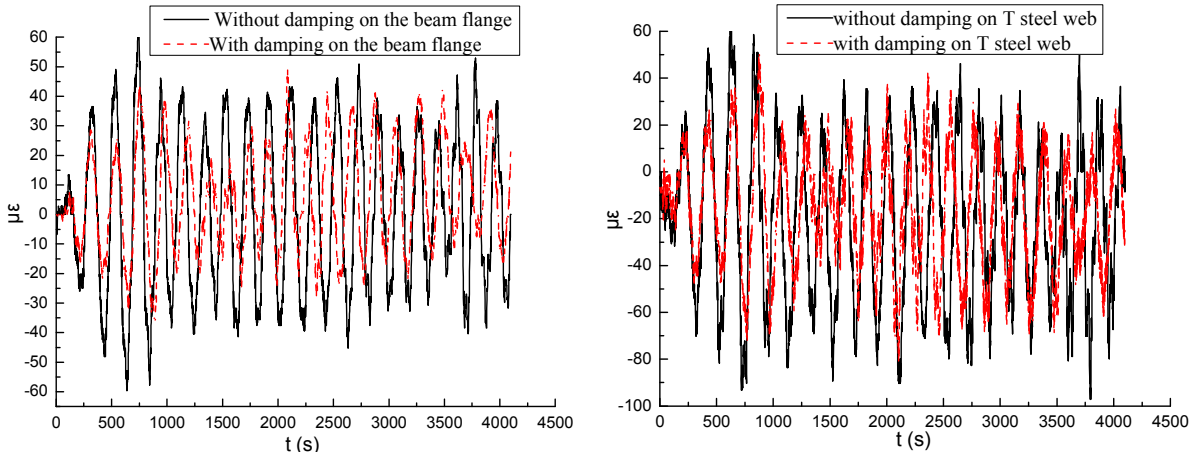
**Test Procedure.** Literature [4] introduced the principle of pseudo-dynamic test.Test equipment included reaction wall, stents, the electro-hydraulic servo loading system and data acquisition system (DH-3816N static signal acquisition instrument).Test loading device equiped four horizontal actuators that two 100t horizontal actuators were at the top story and the underlying frame

decorated two 50t horizontal actuators. The seismic wave of test was EIcentro wave selected according to the "regulations of buildings seismic test method" (JGJ-96) and adopted 70 gal seismic acceleration peak value.Test used mixed load displacement control, and firstly to determine the stiffness matrix, mass matrix and damping matrix of steel frame,m1 = m2 = 5200 kg.Putting the stiffness matrix[K] and mass matrix[M] into the Eq. 1, got the damping matrix [C].Then the specimen was loaded by inputting the damping coefficient and without damping. Using static signal acquisition instrument and displacement meters to measure the panel zone strain and the node displacement and using force sensors and displacement sensors to get load feedback and displacement feedback of steel frame.

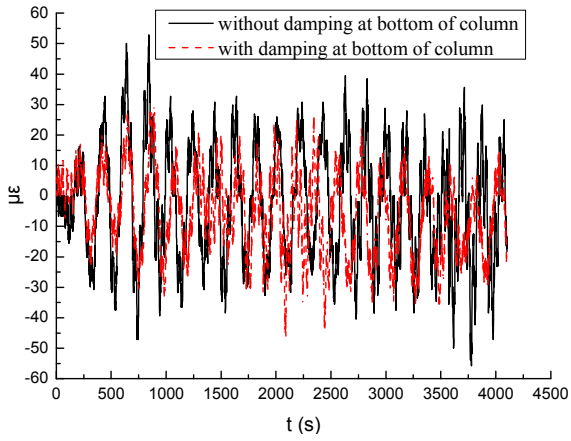
## The Analysis of Test Results

**Panel Zone Strain.**The time history curve of panel zone strain was shown in Fig. 2. (a), (b), (c), (d) diagrams respectively showed the strain at beam end flange, T steel web, the bottom of the column and T steel flange in the undamped and damped.It got that the undamped strain variation amplitude was slightly greater than the damped strain amplitude, but the difference was minor that the damping had little effect on the strain.

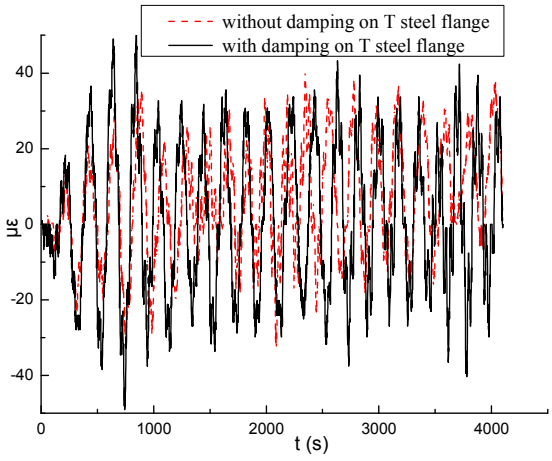


(a) Strain on the beam flange

(b) Strain on T steel web



(c) Strain at the bottom of column



(d) Strain on T steel flange

Fig. 2 .Panel zone strain with and without damping

**Story Drift.**Time history curve of displacement was shown in Fig. 3.It showed that the the peak value of story drift undamped was greater than that with damping, and steel frame without damping had larger sidesway and the response amplitude was bigger.

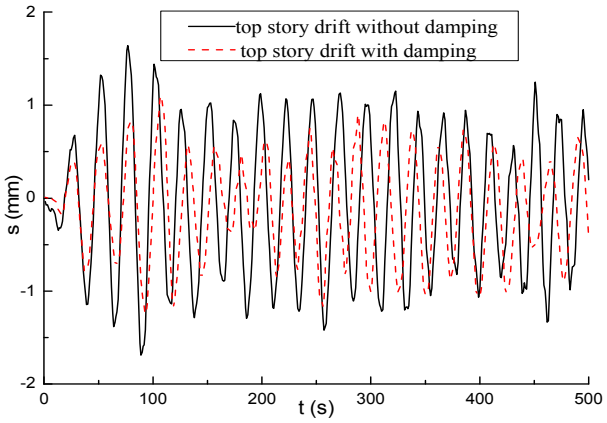


Fig. 3. Story drift

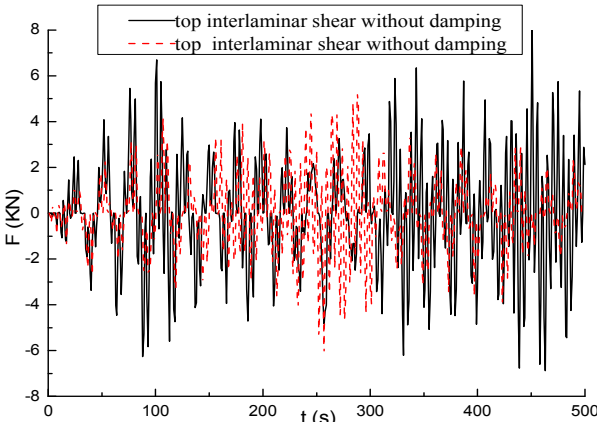

Fig. 4. Interlaminar shear

**Interlaminar Shear.**The time history curve of interlayer shear was shown in Fig. 4 that the load feedback peak of frame with damping was less than undamped frame which showed the maximum of interlayer shear decreased under the influence of damping .

## Conclusions

Through analyzing the test results, it concluded that:

(1) The structural damping had little effects on the strain ,but it had impact on the story drift and interlaminar shear which was in keeping with literature [5].

(2)It also showed that the displacement of steel frame under dynamic loading not necessarily decreased as the stiffness of nodes increasing, and the factors included damping.

(3)Under the effect of damping, the story drift and interlaminar shear peak of the semi-rigid connection steel frame decreased which was contributed to the structural seismic.

## Acknowledgement

**Keywords:** end bearing pile; finite-infinite element; dynamic interaction; interface's mechanical behavior

**Abstract:** Dynamic structural model of saturated soil was introduced, and combining with the finite element program, the finite-infinite element models of end bearing pile foundations was established. Four models of interface between pile and soil including absolutely jointed, slippage, crack, both slippage and crack were considered to study the interface's effect on pile foundation's dynamic characteristics. The results were as follows: the interface's mechanical behavior has a little influence on the distributions of pile section's shearing stress and horizontal displacement. Pile section's shearing stress reaches the maximum near the ground surface when interface is slippage or crack, and reaches the minimum ones when interface is absolutely jointed. Horizontal displacement could be divided into two phases and the ground surface is the dividing line. The interface's behavior greatly changes the distribution of acceleration time-history curve. To different models, the maximum acceleration all appears at the ground surface. On the whole, the interface's behavior has significant influence on end bearing pile, which should be pay attention in the design from now on.

## Introduction

In pile-soil-structure system, for the big difference of material properties between pile and soil on two sides of interface, the deformation and displacement of pile and soil are usually not coordinate with each other. The property of interface has great influence on the dynamic characteristics of pile-soil-structure system under earthquake. However, most of researches are based on the hypothesis of absolutely jointed between pile and soil, or only slippage and no crack. These researches have some extent reasonable for system under small earthquake, but the reaction of system is no longer in elastic stage under moderate and strong earthquakes. The reaction of free field and the interaction of interface will generate permanent deformation in soil, with the inconsistency of movement between pile and the surrounding soil, and the lower tensile strength of soil itself, crack will appear in the normal direction between pile and soil besides the slippage along the tangent direction. In fact, the phenomena of separation between pile and soil, pile sinking or uplifting are very common in earthquake. In addition, the mechanical mechanisms of these two kinds of phenomena are interactional itself. Crack occurred in shallow place will significantly decrease the later resistance of pile and will has adverse effect on vertical bearing capacity of pile when crack occurs in the depths. Both cases will trigger greater slippage of interface, which will affect the extent of crack with dissipating energy at the same time.

On the base of dynamic structural model of saturated soil, finite-infinite element model of single end bearing pile foundation was established in this paper, and to investigate the influence of slippage and crack mechanism between pile and soil on the pile foundation's dynamic characteristics. Four types of interface models will be considered, and the law of influence will also be summarized based on the comparison of the results at last.

**Dynamic structural model of saturated loess**

To consider the structure of saturated loess, the dynamic model that had been put forward by Hu, W.(2008) will be used in this paper. the basic constructed steps of which are as follows: on the base of stain hardening stress-stain relationship of completely remolded loess, the degradation of initial shearing modulus and un-drained strength, which consider the effects of supper pore pressure and the structure's changing, are used to model the cyclic degradation of saturated loess under dynamic loading; The stress share ratio is introduced to describe the structure, and the dynamic model of saturated loess which consider the structure is constituted at last. The physical meanings of other parameters are also presented in Hu, W.(2008). On the base of ABAQUS' redevelopment platform, the structural dynamic model of saturated loess is implemented by Fortran language, e.g., Hibbitt et al.(2002), Xu, Y. J. et al.(2004).

**The finite-infinite element models and estimation of parameters**

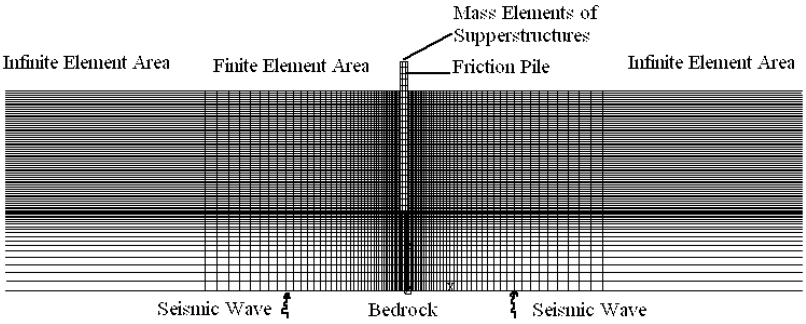

Fig.1 The finite-infinite element model of pile-soil-structure system

The prototype of pile-soil-structure's finite-infinite model is a single column pier which is always used in viaduct. The typical finite-infinite element model of friction pile-soil-structure system is showed in Fig.1. Where the pile is concrete bored pile or manual excavation pile and is treated as elastic, where $E = 20GPa$, $\nu = 0.25$, $\rho = 2.3g/cm^3$. The value of parameters in dynamic model of saturated loess are as follows: $\beta = 1.0$, $\nu = 0.45$, $\phi = 25$, $c = 13kPa$, $c_c = 0.1638$, $c_s = 0.0234$, $K_0 = 1.0$, $K_p = 174.49$, $n_p = 0.9626$, $k_{urp} = 1.6$, $\mu = 2.0$, $H = 0.925$, $\chi = 23.1$, $t = 2.06$, $\Lambda_0 = 0.634$, $\zeta_{\max} = 0.8$, $e_{i\max} = 1\%$, $e_{iult} = 10\%$, $a = -0.4343$, $b = -1$, $\gamma_{sat} = 19.6kN/m^3$, void ratio $e = 1.0$. Pile's length is 30m and the thickness of soil is 50m. The area within a distance of 100m from pile's two sides is finite element region, the outside area is infinite one. The supper-structure is predigested as mass element on the top of pile. In this analysis, the total mass of supper-structure is 200t. The adjusted Koyna horizontal acceleration time-history is imported at bedrock, and the peak value is 100gal.

**Interface model between pile and soil**

The attribute of contact between pile and soil contains two parts [4], tangential effect and normal effect. The former obeys the Coulomb's law to simulate bond-slip between pile and soil, which is showed in Fig.2 and it's expression is as follows,

$$\tau_{crit} = \mu p \tag{1}$$

Where $\tau_{crit}$ is the critical shear stress, $\mu$ is the friction coefficient and $\mu = 0.5$ in this paper, $p$ is the normal contact pressure. The latter adopts exponential pressure-overclosure relationship to model the crack- closure mechanism. It means that when the clearance between pile and soil is large than $c_0$, $p$ is zero; once it's less than $c_0$, the interface begin to transfer pressure. In the calculation, $c_0$ is equal to 0.001m. Along with the diminishment of clearance, $p$ increases in exponential form.

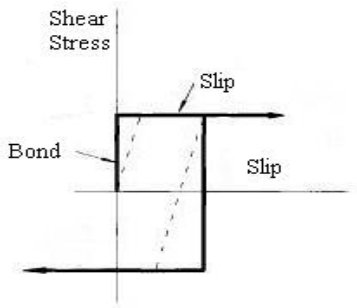

Fig.2 Bond-slip model

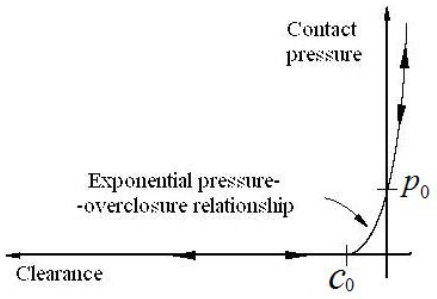

Fig.3 Crack-closure model

**The influence of interface model**

Figure 4 to 6 represent the absolute maximum of pile section's shear stress, horizontal acceleration and horizontal displacement along the depth respectively. Fig.4 shows that the interface's behavior has a little influence on the distributions of pile section's shear stress but has influence on it's value. Shear stress distributes as wavy style from the bottom to the up of pile, and reaches the maximum at ground surface, which reflects the traveling wave effect of earthquake. The reason of it is because of the different propagation velocity of earthquake wave in pile and soil, which gives rise to relative displacement between them, and results to varying pressure. When the interface is absolutely jointed, the pressure at ground surface reaches the minimum 108.6kPa, and for the model of slippage and crack, the pressure reaches the maximum 121.8kPa at the same place, which increases about 12.2%. The cases of only slippage and only crack are between the former two situations, whose value increases about 6.69% and 7.37% than the minimum respectively.

What we can see from the Fig.5 is that the interface's behavior greatly changes the distribution of end bearing pile's acceleration time-history curve. For different interface models, the maximum all appears at ground surface, the value of which is the biggest for absolutely jointed and is the smallest for slippage and crack. At the end of pile, acceleration has the minimum both for absolutely jointed and slippage only, but for the slippage and crack, it has the maximum. The reason may be that the separation between pile and soil cuts off the transfer path of horizontal load when considering crack.

Fig.6 shows that the interface's behavior has a little influence on both of the distribution and value of horizontal displacement. The distribution can be divided into two phases and the ground surface is the dividing line. In the first phase, displacement is almost in line increase with the depth from the bottom. The second phase presents nonlinear increase from the ground surface to the top, and reaches the maximum at the top of pile. The table 1 indicates that when the interface is both slippage and crack, horizontal displacement reaches the maximum and reaches the minimum when the interface is absolutely jointed, with the other cases are among them.

What the Fig.7 shows is the pile's horizontal acceleration time-history curve at -0.5m corresponding with different interface's behavior, which has a great influence on it's distribution learned from the picture. When the interface is absolutely jointed, the acceleration reaches the maximum and reaches the minimum when the interface is both slippage and crack, which is less 25% than the former. This is because of the pile passing through a discontinuity surface of stiffness, the strong constraint of the end is more likely to lead to the interface's relative displacement, which give rise to a big difference between the cases of both slippage and crack and absolutely jointed. Moreover, the interface's bond-slip also reduces the peak acceleration.

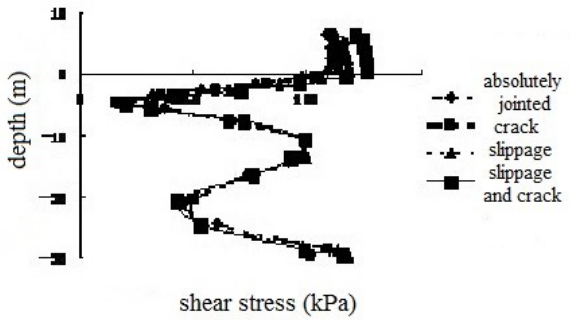

Fig.4 Distribution of shear stress

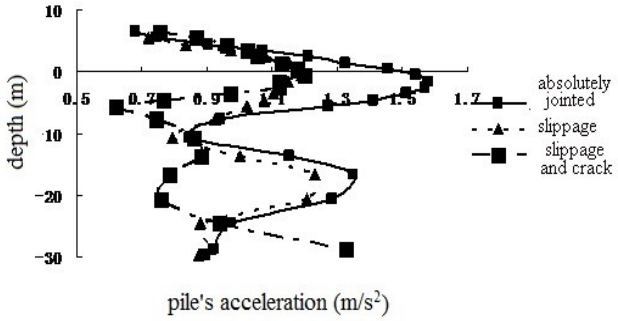

Fig.5 Distribution of horizontal acceleration

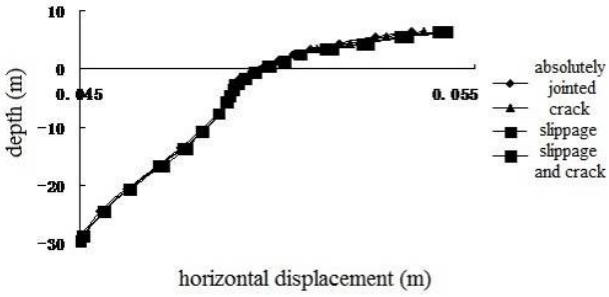

Fig.6 Distribution of horizontal displacement

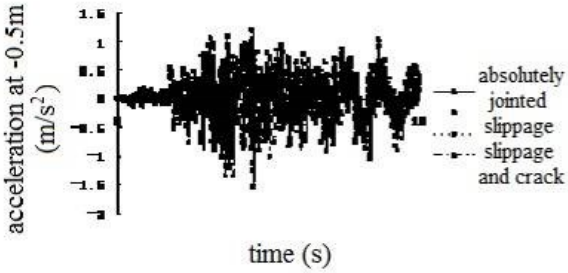

Fig.7 Time-history of horizontal acceleration

## Conclusion

Combining dynamic structural model of saturated soil with finite element program, the finite-infinite element models of end bearing foundations were established. Four situations of interface between pile and soil including absolutely jointed, slippage, crack, both slippage and crack were considered to study the interface's effect on pile foundation's dynamic characteristics. The results were as follows:

1 The interface's mechanical behavior has a little influence on the distribution of pile section's shear stress but has effect on it's value. Shear stress reaches the maximum when the interface is both slippage and crack and arrived at the minimum when the interface is absolutely jointed.

2 The interface's behavior greatly changes the distribution of end bearing pile's acceleration time-history curve. To different kinds of interface, pile's maximum acceleration arrives at the earth's surface, and reaches maximum when interface is absolutely jointed and reaches minimum when interface is both slippage and crack.

3 The interface's mechanical behavior has a little influence on the pile's horizontal displacement, which could be divided into two phases. In the first phase, displacement is almost a straight line up from the end of the pile to the earth's surface. In the second phase, displacement is in an accelerated nonlinear increase from the earth's surface to the top of the pile, and reaches maximum at the top. Horizontal displacement reaches maximum for both of slippage and crack, and reaches minimum for the absolutely jointed.

4 The interface's behavior has serious influence on end bearing pile's dynamic characteristic, which should be emphasized in the studies from now on.

# The Present Situation of Rural Housing and the Seismic Performance Analysis

Han Li[1, a]

[1] Graduate School of Shandong University of Science and Technology, Qingdao, Shandong, China 266590

[a]309083602@qq.com

**Keywords:** security, masonry structure, dangerous point, typical masonry building, seismic time history analysis, system with ring beam and structural concrete column

**Abstrat.** In recent years, the security of rural building has attracted more and more attention. The analysis of the existing problems of rural building summarized the distribution of dangerous points, and the use of finite element analysis method was carried out on the typical farmhouse seismic time history analysis to find out seismic weak places in the masonry structure buildings. Then the study also shows that the system with ring beam and structural concrete column has good reinforcement effect. This study plays an important role in improving the rural housing construction measures and the seismic performance of the building.

## Introduction

In recent years, many earthquakes had taken place in China, and only in 2013, there had happened 23 times that over 5.0 magnitude. The sudden earthquake brought huge economic losses and casualties to the state and local residents. By the analysis, the heavy casualties and losses were mainly caused by the unreasonable details of seismic design. According to preliminary statistic[1], the applicable masonry buildings account for more than 90% in residential buildings, especially in the villages, because of the structures' convenient materials, simple construction and low cost, it become one of the most common structures. Restricted by economic and technical conditions, the rural buildings prone to damage than urban housing. So the seismic analysis of the existing rural housing has very importance practical significance.

Our purpose is aimed at analyzing and summarizing the existing problems of rural buildings in the earthquake, and finding out the dangerous points, then on the basis of the theory of finite element analysis, selecting a typical rural resident structure system for numerical analysis to observe the rural housings' damage that under different details of seismic design. But because there is currently no special rules for the constitutive relations and failure criteria of masonry structure, to a certain extent the accuracy of finite element analysis is limited.

## The present situation of Rural housing

First of all, the rural housings mostly use local materials which their strength is low and lack of cohesiveness, so the integrity of walls is poor, and leads to the structures prone to overall damage or severe local failure in the earthquake. Second, most rural masonry buildings built in before 1989[2], their construction mostly rely on experience and lack of earthquake consciousness, the buildings generally do not set ring beams and structural concrete columns, and most directly to put walls as bearing structures, the lap length of roofs, roof panels, purlins and walls is insufficient, nodes anchoring unreliable, the contact area between structures is small, roofs and roof panels are easy to damage during earthquake and cause casualties. Third, most rural housings' design according to owner's requirements, so the rate of hole is high and leads to the insuffient bearing capacity of walls. Finally, the connection between vertical and horizontal wall is unreliable, it leads to the poor integrity of walls, so it is also one of the main causes of walls that easy to damage.

**The finite element analysis**

**The masonry building plan.** ANSYS has a powerful modeling and solving ability, the ways of modeling are divided into integral and separated ways, our main purpose of modeling is to analyze the damage of integral building and focus on the macro calculation, so we choose integral modeling. Here we do numerical simulation on a typical farmhouse. The farmhouse prototype is shown in fig.1, for the convenience of modeling, we have to simplify the model, main structure dimensions are shown in fig.2.

**Fig.1** Farmhouse prototype

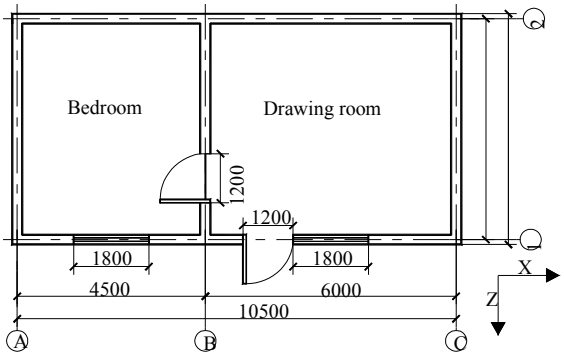

**Fig.2** The masonry building plan

**Finite element models for the masonry buildings.** Because the majority materials of rural house roof are sintering tiles, soils, plant straw, etc., their load through beam purlins pass to the wooden structures, finally to load bearing walls, roof stiffness is smaller than wall rigidity, so in this article, the roof load and purlin load by MASS21 convered on the corresponding position of walls. The self-weight of roof is 2.4kN/m2, structural concrete columns and ring beams are in accordance with the structural requirements for reinforcement, They are reinforced with HRB335, the wall with fired common brick, mortar with M7.5, concrete with C25, modulus of elasticity with 2.7×103MPa, Poisson's ratio with 0.15

The constitutive relation about Masonry structure is not yet clear, and because the masonry compression yield strength is greater than tensile yield strength, so the yield criterion of modeling by means of the criterion of Drucker-Prager[3], it is commonly used in soil mechanics , masonry is assumed to be the ideal elastic-plastic state. Modeling uses Solid45, it can reflect the model of stress and strain under seismic action, and the bottom of the structure is fixed, the finite element model is shown in fig.3.

**(a)** The original structure **(b)** The structure with reinforcement

**Fig.3** Two finite element models of the masonry

**Modal analysis.** By extracting the first 40 modal with the Block Lanczos [4] and analyzing the mode of model, we find that masonry structure maybe occur translation and torsion in the lower order diagram, so the masonry building in less absorption of seismic energy maybe occur vibration even damage, vibration is given priority to with torsion of the gables, then followed by the vertical translation of walls. And through the analysis we find that after setting up the structural measures the natural vibration period significantly improved. The original structure's cycle is 0.15s, and the reinforced structure's cycle is 0.2s. The curve of vibration periods are shown in fig.4 (series 1 from the original structure, series 2 from the structure with reinforcement).

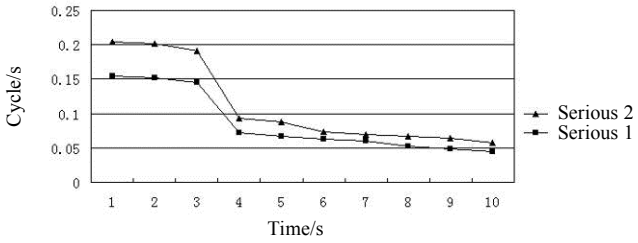

**Fig.4** Curve of vibration periods

**The seismic time history analysis.** In the time history analysis, we select the acceleration from EL-CENTRO earthquake as X, and select the top 20s acceleration, a total of 1000 points, time interval is 0.02s, peak acceleration occured in 3.14s, 3.417m/s2, the curve of acceleration is shown in fig5. According to the peak acceleration of frequent earthquake[5] in 8 degree, we adjust the peak acceleration from EL-CENTRO earthquake.

After constraint all nodes at the bottom of the structure, we get the absolute displacement. By observing the node of gable top, we find the node's displacement is reduced after reinforced. In the first case the maximal displacement is 24.3mm, but the latter is 17mm, so it proves that the structure of the constructional column and ring beam has limited the translational displacement. But while details of seismic design were taken, gable's displacement is still relatively large. Because gables alone connected with purlins, it equivalents to a cantilever structure and prones to whiplash effect[6]. It is visible that gable is still a weak link in seismic strengthening, so during the reinforcement of rural housing, it is necessary to set the annular ring beam on the gables. The curve of gable top displacement is shown in figure 6( series 1 from the original structure, series 2 from the structure with reinforcement ).

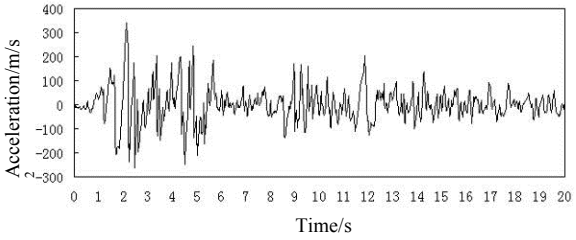

**Fig.5** Acceleration from EL-CENTRO earthquake

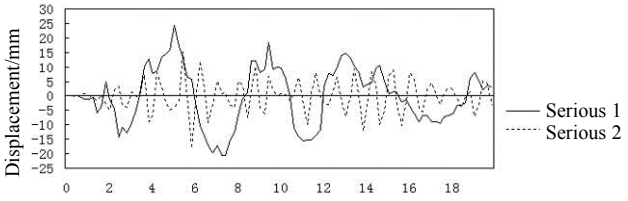

**Fig.6** The curve of gable top displacement

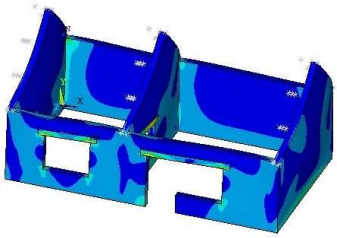
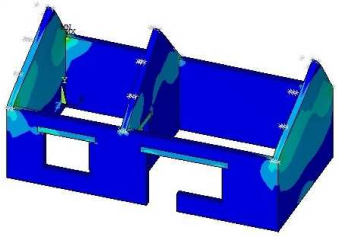
After the time history analysis, we found that under horizontal earthquake action the original structure's stress concentration phenomenon mainly exist in the bottom of the housing and the junction between vertical and horizontal walls. With the earthquake acceleration inputting, the overall stress value increases, in 0.02s, the maximum is $1.2\times10^{-3}$MPa,in 3.14s, the stress reaches 4.47MPa, and the lintel and wall stress value is large different from other places, these places are prone to damage and produce the v-shaped cracks. The damage location and form are as same as the actual seismic building damage locations, it verifies the feasibility of using finite element software simulation. After setting details of seismic design, the phenomenon of stress concentration are significantly reduced, and it mainly appears in the structural column and ring beam, it is visible that the system has good binding effect for masonry wall. The integral framework that they formed can limit the horizontal displacement of structure, enhances the integrity of masonry structure, reduces the appearance of cracks, and effectively makes up for the shortcoming of low wall shear strength. When an earthquake occurs, it can effectively reduce the damaging effect of the structure. However, there are stress concentration occur in structural columns and ring beam, this phenomenon indicates that

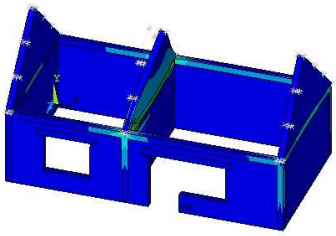
these place prone to damage during an earthquake, so it is necessary to strengthen the link between ring beams, structural columns and walls. The concrete nephogram of stesses are shown in fig.7.



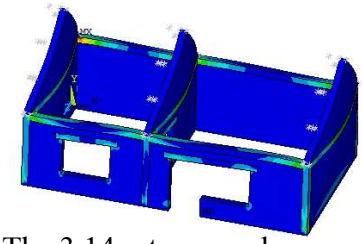
**(a)** The initial stress nephogram of original structure



**(b)** The 3.14s stress nephogram of original structure



**(c)** The initial stress nephogram of the structure with reinforcement



**(d)** The 3.14s stress nephogram of the structure with reinforcement

**Fig.7** The nephogram of stesses

## Conclusion

1)Rural masonry structure houses are destroyed mainly due to the low strength of materials, insufficient bearing capacity of walls, weak connection between the components, and unreliable connection between vertical and horizontal walls, those problems lead to poor housing integrity, so the structure prone to occur serious damage;

2)Through modal analysis we conclude the basic cycle and vibration mode map, and find out that the farmhouse is given priority to gable torsion, followed by the vertical translation. The structure's cycle significantly increased after reinforcement. The original structure's cycle is 0.15s, but the reinforced structure's cycle is 0.2s, the system with ring beam and structural concrete column improved the structure's rigidity, and enhanced the seismic capacity.

3)By the time history analysis we found that ring beam and structural concrete column can form a good framework and effectively limit the horizontal displacement of the structure. Structure's stress concentration was significantly reduced. So we should promote the system with ring beam and structural concrete column, it has very important significance.

# Geotechnical Seismic Isolation System - Further Experimental Study

Wei Xiong[1,a], Mingren Yan[1,b], and Yaozhuang Li[1,c]

[1]Institute of Disaster Prevention and Safety Technology, College of Civil Engineering, Central South University, China

[a]bbbear2002@gmail.com, [b]sinymr@sina.com, [c]liyz@csu.edu.cn

**Keywords:** geotechnical seismic isolation (GSI) system, rubber-sand mixture (RSM), experimental study, shaking-table test

**Abstract.** The isolation effectiveness of the Geotechnical Seismic Isolation (GSI) system was further investigated via a series of prescribed shaking-table tests. The dynamic response of GSI system was also evaluated in detail of this work. A parametric study for assessment of the isolation performance of GSI was conducted by varying experimental key parameters, such as rubber percentage of rubber-sand mixtures (RSM), configuration of the foundation, storey number of the superstructure, and different kinds of seismic acceleration inputs. From the parametric survey, it can be concluded that the GSI system can to some extent attenuate the dynamic response of the superstructure under big earthquake shakings.

## Introduction

Earthquake is one of the most devastating natural hazards on our planet. From the beginning of 21st century, earthquakes have occurred increasingly frequent. In 2008 Wenchuan Earthquake, about 80,000 people lost their lives. The 2010 Haiti Earthquake has caused death toll up to 220,000. About 690,000 lives have died by reason of earthquakes in the first decade of the 21st century.

In order to counterstrike the severe earthquake hazard worldwide, scientists and seismologists have endeavored their abilities to bringing more efficient anti-earthquake methods and ways. Some seismic isolation techniques have been proposed by professionals in these dedications. Zhou *et al*. [1] investigated the dynamic performance of an inter-storey seismic isolation application through analytical simulation on a frame structure. Zhang *et al*. [2] evaluated the seismic isolation behavior of the rubber particles via a series of cyclic shear and shaking-table tests. Tsang [3] proposed an innovative Geotechnical Seismic Isolation (GSI) system facilitating rubber-sand mixtures (RSM), which is especially suitable for the developing countries. The GSI system was then experimentally studied by Xiong and Li [4]. Tsang illustrated the GSI system in [5].

In this paper, the seismic isolation performance of the GSI system was further investigated via a series of shaking-table tests conducted on a 1/3-scale steel frame. A parametric study, for assessing the optimal configuration of the GSI system, was performed in the experiments by varying the key parameters such as rubber percentage of rubber-sand mixtures (RSM), configuration of the foundation, storey number of the superstructure, and different kinds of seismic acceleration inputs. The remainder of this paper has the details.

## Shaking-table experiments on the GSI system

**The Superstructure** As shown in Figure 1, a steel-frame structure was constructed to represent the superstructure, and the scaling factor was determined as 1/3. The detailed information of the model structure was given in Table 1. The structure was designed that it can be assembled/dissembled into one storey or three storeys. The basemat measures 2.7 m × 2.7 m × 0.45 m.

Table 1. The detailed information of the model structure

| Number of storeys | Column and beam | Inter-storey height | Overall height |
|---|---|---|---|
| 1 or 3 | 150 mm ×150 mm | 1.5 m, 1.2 m, 1.2 m | 3.9 m |

**The Soil Box** The dimension of the soil box was 4 m × 4 m × 1 m. In order to lessen the boundary effect of the seismic wave, four plates of sponge, each of which was 0.3 m thick, were pasted against the inner soil box.

**Instrumentation** Vertical and horizontal accelerometers were instrumented within the structure to capture the dynamic response. The instrumentation is given in Figure 1.

**Testing Scheme** A parametric study was carried out to evaluate the dynamic behavior of the GSI system by varying the experimental key factors. These factors include: rubber percentage of rubber-sand mixtures (RSM), configuration of the foundation, storey number of the superstructure, and different kinds of seismic acceleration inputs. Table 2 presents the detailed testing scheme.

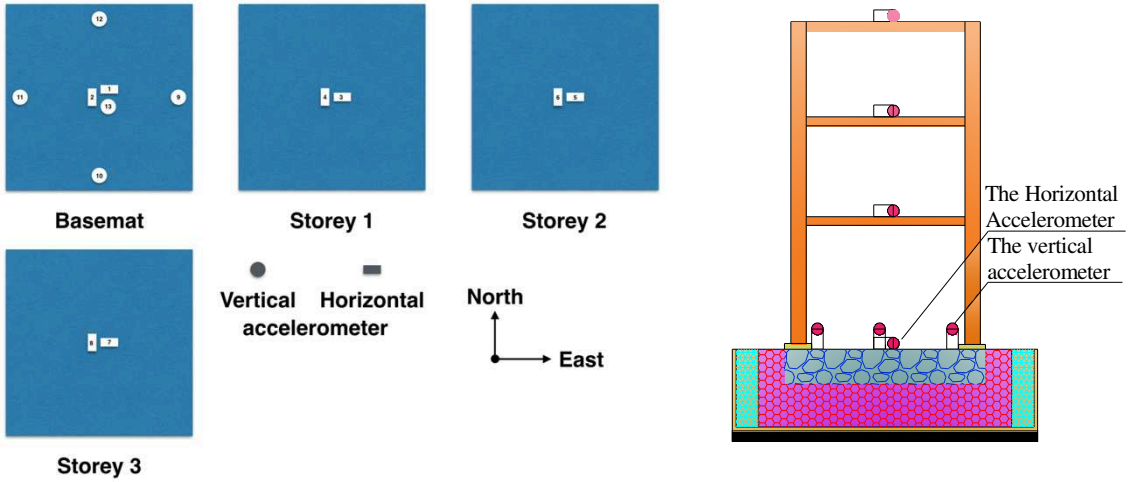

Figure 1. Instrumentation and layout of the structure

Table 2. Detailed testing scheme

| RSM percentage | Foundation configuration | Storey number | Input seismic wave | Case number |
|---|---|---|---|---|
| 0%<br>25%<br>50% | Fixed base<br>Pure sand<br>GSI | 1<br>3 | Kobe<br>Northridge<br>Turkey | 24 |

## Experimental results and its analysis

After processing the experimental data, the comparison between acceleration time histories of different scenarios is presented in Table 3. The selected comparison between acceleration time histories of different scenarios under Northridge seismic wave input is illustrated in Figure 2. The following phenomena can be observed in these experimental results:

1. The pure-sand foundation exhibits the best seismic isolation within the three foundation types (25% RSM, 50% RSM, and pure-sand). Under both Northridge and Kobe shakings, the pure-sand layer has fair attenuation on dynamic response of the superstructure in EW and NS directions.
2. GSI system can reduce the dynamic response of the structure in EW direction under Northridge shakings, yet the isolation performance is inferior to that achieved by the pure-sand foundation. In NS direction, GSI even amplifies the acceleration of the structure, which is in contrast with the pure-sand foundation. The amplitude factor of the GSI system on the horizontal acceleration of the structure is in the range between 4% and 36%. The maximal amplification factor occurred in scenarios with 50% RSM foundation, which is 36%. While for Kobe input, the dynamic response of the structure in both directions is preferably decreased by GSI foundation. Nevertheless the reduction by GSI is lower than that obtained by the pure-sand foundation. The dynamic response of the structure in both directions is magnified with GSI layer when the structure is shaken by Turkey seismic wave. The corresponding amplification factor is within 1.5% to 98.1%.

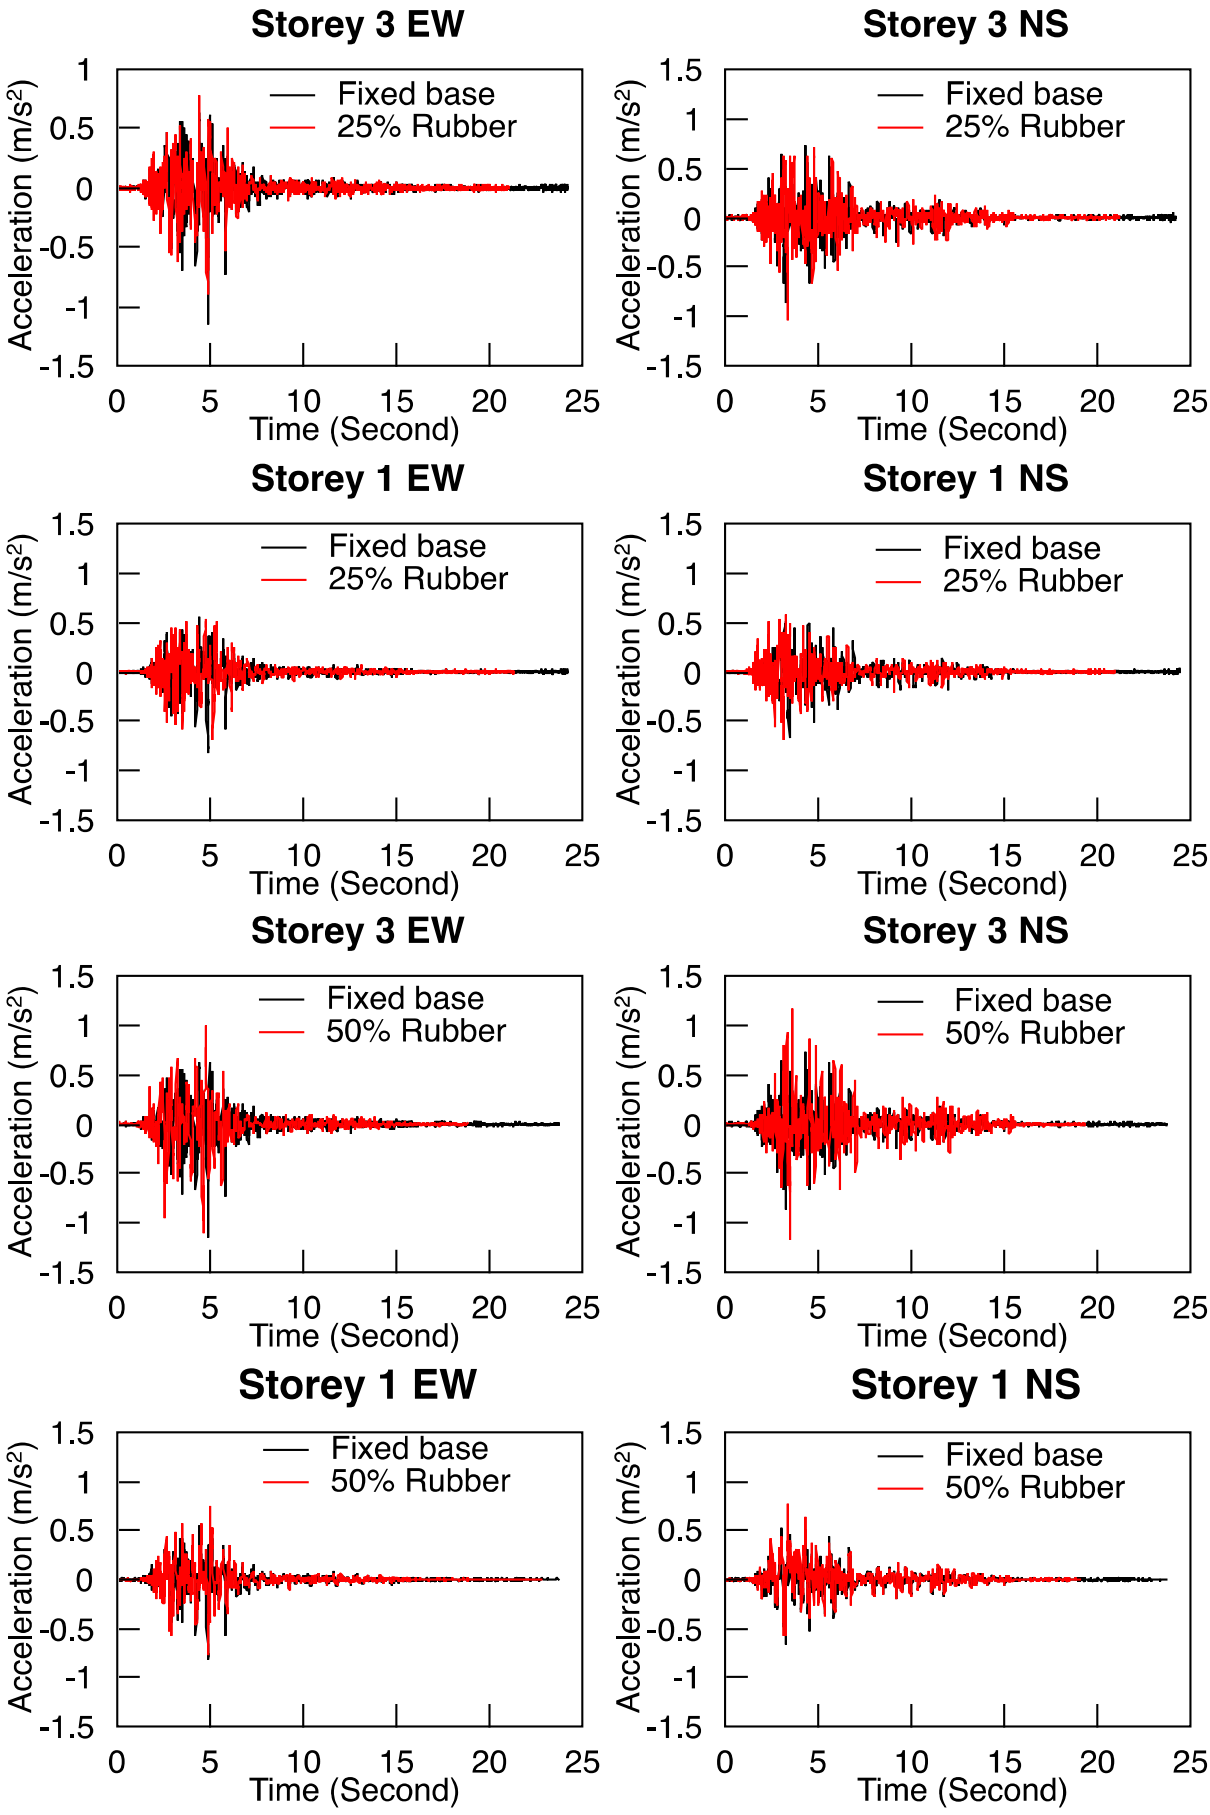

Figure 2. The comparison of different acceleration time-histories, Northridge input.

Table 3. Comparison between the acceleration amplitudes of different scenarios

| Horizontal acceleration amplitude ($m/s^2$) | | FB | Pure sand | % | 25%RSM | % | 50%RSM | % |
|---|---|---|---|---|---|---|---|---|
| Northridge EW | Storey 1 | 0.81 | 0.55 | -32.1% | 0.69 | -14.8% | 0.78 | -3.7% |
| | Storey 3 | 1.16 | 0.67 | -42.2% | 0.89 | -23.3% | 1.10 | -5.2% |
| Northridge NS | Storey 1 | 0.66 | 0.49 | -25.8% | 0.69 | +4.5% | 0.77 | +16.7 |
| | Storey 3 | 0.86 | 0.62 | -27.9% | 1.04 | +20.9% | 1.17 | +36.0% |
| Kobe EW | Storey 1 | 1.04 | 0.77 | -26.0% | 1.04 | 0% | 0.85 | -18.3% |
| | Storey 3 | 1.45 | 1.17 | -19.3% | 1.06 | -26.9% | 1.14 | -21.4% |
| Kobe NS | Storey 1 | 0.95 | 0.64 | -32.6% | 0.77 | -18.9% | 0.78 | -17.9% |
| | Storey 3 | 1.57 | 0.98 | -37.6% | 1.09 | -30.6% | 1.15 | -26.8% |
| Turkey EW | Storey 1 | 0.46 | 0.46 | 0% | 0.80 | +73.9% | 0.56 | +21.7% |
| | Storey 3 | 0.53 | 0.59 | +11.3% | 1.05 | +98.1% | 0.80 | +50.9% |
| Turkey NS | Storey 1 | 0.46 | 0.44 | -4.3% | 0.60 | +30.4% | 0.69 | +50.0% |
| | Storey 3 | 0.66 | 0.63 | -4.5% | 0.67 | +1.5% | 0.97 | +47.0% |

3. In scenarios with Kobe input, the accelerations of the structure are more or less decreased with all three-foundation types. This is due to the relatively large acceleration amplitude of the Kobe seismic wave.

## Conclusions

From the analysis of the experimental data, it can be seen that the pure-sand layer had some attenuation effect on the seismic response of the superstructure. The seismic isolation performance of the GSI system varied noticeably from one seismic acceleration to another. From the investigation of the experimental results, the following conclusions can be made:

1. The seismic isolation performance of GSI is generally inferior to the pure-sand foundation during earthquake shakings, for the RSM layer is too thin in the experiments. The response attenuation of GSI with larger rubber content is greater than that with smaller rubber content.

2. The seismic isolation of GSI is not evident in small earthquakes.

3. The dynamic response attenuation is more prominent in Storey 3 of the structure than that in Storey 1, in both cases of the GSI and pure-sand foundation.

4. The GSI layer must be thicker (up to minimum 5 m, optimum to 10 m or thicker, here to 1.5 m in this experiments) as to achieve more ideal results.

**Keywords:** Seismic dynamic response, fluid-structural interaction, Morison equation, finite volume method, dynamic mesh

**Abstract.** In this paper, we intended to replace the fluid-structure interaction of deep water bridge piers with acceleration-dependent forces during an earthquake. The hydrodynamic pressure on bridge pier groups under seismic excitation is studied using the finite volume method. Different seismic waves with various spectrum components are selected in order to cover frequently encountered cases. The calculated forces of these cylinders are fitted into the Morison equation, and by calculation, the drag force term is negligible, thus the effect of fluid is converted into one added mass term. The paper further calculated the dynamic response of a continuous beam bridge with pier groups in water to check the validity of our proposed method.

## Introduction

With the advancement of communication and transportation, long-span bridges and cross-continent bridges are frequently built, and many of their piers lay in water. The dynamic behavior of these bridges would be different because of the fluid-structure interaction. However, we currently possess no thorough understanding of quantitative details due to the complex nature governing FSI problems, this is particularly true if we were to calculate the seismic response of deep water bridges for the random factors involved. Many scholars seek simplified ways to deal with this problem. Karadeniz[1] analyzed the coupling of seismic ground motion and deepwater waves using spectrum method while assuming the seismic wave as simple random processes. Etemad and Gharabaghi[2] adopted the Nogami model to analyze the joint dynamic effect of earthquakes and waves with same and opposite directions on structures. Bai De-gui[3] implemented the 3D finite element method to model the pier-piles-soil system, they also use Stokes wave theory and Morison equation to analyze the effect of waves and currents. Wei Kai and Wu Yong-ji[4] studied the water-group pile foundation interacted modeling using potential-fluid element in ADINA, and further investigated the relationship between the hydrodynamic influence and geometry of the piles. There are two main topics concerning previous research: analytical methods and numerical methods. Because of the many assumptions, analytical methods would fail to predict accurately in many cases. The numerical methods are powerful tools in analysis and prediction, however, previous research treated the fluid too simply regardless of viscous and turbulence factors. In this paper, we give the detailed CFD analysis of cylinders moving in water according to seismic input, and then present a method suitable for practical usage.

## CFD analysis of cylinders moving in water

In this section, we simplify the piers as rigid cylinders moving in water, and then calculate the pressures on these cylinders using finite volume method. Finite volume method resembles the finite difference method, only differs in that it is more versatile and automatically fluxes conservation.

In order to satisfy the stability condition for the finite volume method, the CFL condition needs to be met:

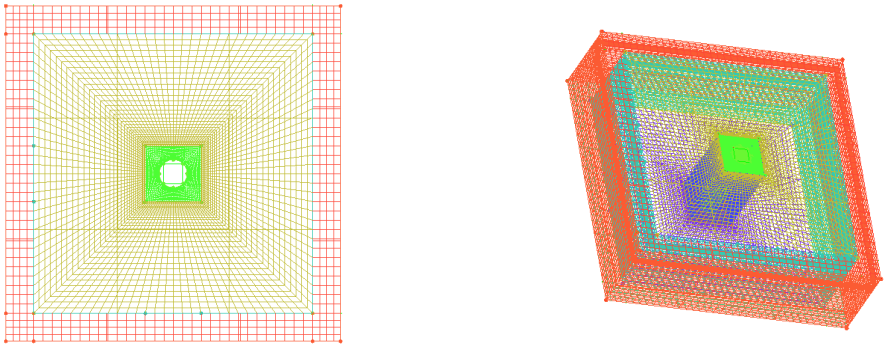
$$C = \Delta t \sum_{i=1}^{3} \frac{u_i}{\Delta x_i} \le C_{max} . \tag{1}$$

Where $\Delta t$ is the time step, $u_i$ and $\Delta x_i$ is the velocity magnitude and grid length in the i direction, $C_{max}$ usually takes 1 for explicit schemes. In calculation, we need only concern the average CFL number among cells.

For CFD analysis, viscous model is also an important factor which affects the calculating results. Here we choose the k-epsilon model, the requirement for first wall layer grid size of the model can be determined by an empirical formula:

$$y^+ = 0.172\frac{\Delta y}{D}Re^{0.9} \approx 30. \tag{2}$$

Our CFD model is a $24m \times 24m \times 8m$ tank filled with 6.5m deep water and air at the rest part, so it is a two-phase flow. A cylinder with 2m diameter is located at the center. In the calculation, the cylinder is moving according to the velocity input (we calculated input cases of sine waves and six seismic waves), thus the grid should be updated per time step, which is essentially a dynamic mesh problem and could be realized by smoothing the mesh using diffusion equation. Due to the requirement of dynamic mesh, two grid zones, one with rigid motion and the other with deforming, is separated. Taken into consideration the above factors and the constraints of CFL number and viscous model, our discretization of the model is shown in the Fig1.

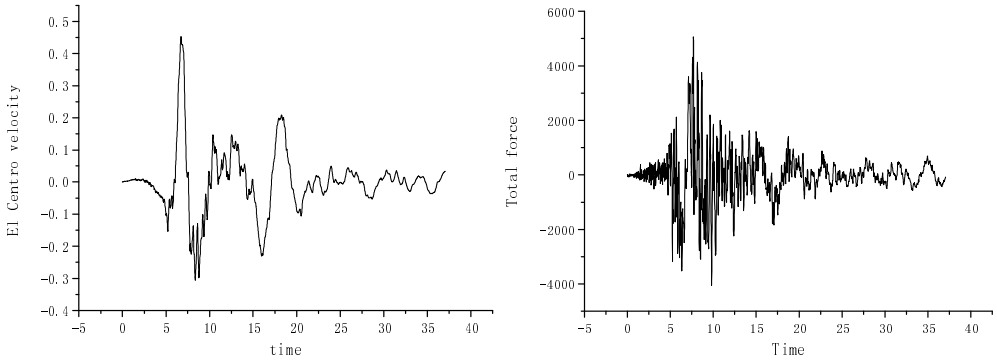


(a) vertical view of grids (b) isometric view of grids

Figure 1: Spatial discretization of calculation domain

In the grid discretization shown in Fig1, there are 367094 elements and 340680 nodes. The grid is refined near the cylinder wall and at the free surface of the water. The boundary conditions at the bottom and the sides are mirror symmetry, and at the top is pressure outlet boundary condition. We use the second order upwind scheme for momentum equation, and the PISO scheme for pressure-velocity coupling term.

6 seismic velocity inputs of various spectrum components were calculated, the typical resulting forces on the cylinder is shown in Fig2.



(a) El Centro velocity input (b) forces of El Centro wave

Figure 2: Typical resulting forces

Having obtained the hydrodynamic forces on these cylinders, we fit the data into the Morison equation, which is initially designed to estimate wave loads on offshore structures [5]. The equation gives the force along the flow direction on unit length cylinders:

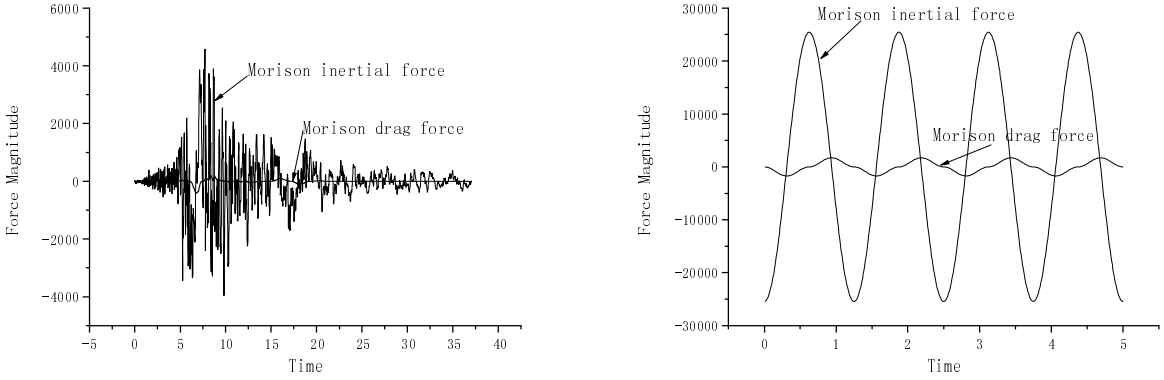
$$F_t = F_m + F_d = \frac{\pi}{4}\rho D^2 C_M \dot{u}(t) + \frac{1}{2}\rho C_D D u(t)|u(t)|. \quad (3)$$

The first term in Eq3 is an inertial force term, and the second term in the formula is a drag force term. Denote the calculated hydrodynamic forces as $F_t$, we use the least square method to calculate coefficients $C_M$ and $C_D$. The calculated coefficients for input waves is shown in Tab1.

Table 1: Least square fit of seismic wave input

| | Coyote | Olympia | El Centro | Parkfield | Gengma1 | Gengma2 |
|---|---|---|---|---|---|---|
| $C_M$ | 0.779 | 0.767 | 0.853 | 0.799 | 0.778 | 0.765 |
| $C_D$ | 3.63 | 5.16 | 2.09 | 3.78 | 19.17 | 18.13 |
| $\|\|F_M\|\|_2/\|\|F_t\|\|_2$ | 97.19% | 95.56% | 97.45% | 98.48% | 95.45% | 94.01% |

From Tab1 we can observe that $C_M$ is approximately 0.8, and $C_D$ fluctuates randomly. Additional calculation of sine waves shows similar results. However, if we compare the force components, the drag force is negligible compared to the inertial force in all cases, and the inertial force term alone is adequate to represent the calculated hydrodynamic force. Two typical graphs of Morison inertial force and Morison drag force in the time domain are shown in Fig2.



(a) Force decomposition of El Centro wave (b) Force decomposition of sine wave

Figure 3: Typical resulting forces

In case of pier groups, we analyzed two piers, four piers, five piers, and nine piers, to take into account the mutual coupling effect between cylinders. We also modeled and calculated block pile caps. The result is similar: Morison drag force is negligible, and Morison inertial coefficient is approximately 0.8, with 10% accuracy. The result accords with the experiments conducted by Sarpkaya [6] Thus, it is concluded that for peer groups, the unit length hydrodynamic force can be approximated as:

$$F(t) = 0.8\frac{\pi D^2}{4}\rho\dot{u}(t) \ . \quad (4)$$

The force direction is opposite to the input pier velocity.

**Hydrodynamic force in structural dynamic equation**

For deep water bridge excited by seismic waves, in the finite element representation of structural dynamics, the uniformly distributed hydrodynamic force is converted to nodal force. The structural dynamic equation can be written as:

$$M\left(\ddot{u} + R\ddot{u}_g\right) + C\dot{u} + Ku + M_w\left(\ddot{u} + R_1\ddot{u}_g\right) = 0 \ . \quad (5)$$

In which $R_1$ is a column vector consists of 1, and $M_w$ is the added mass matrix.

The added mass matrix is a diagonal matrix, and its nonzero terms correspond to the hydrodynamic forces in Eq4. The above structural equation can be arranged as:

$$(M+M_w)\ddot{u}+C\dot{u}+Ku=-(MR+M_wR_1)\ddot{u}_g. \tag{6}$$

From Eq6, we can see that the fluid changes the structural dynamic properties by adding terms in the mass matrix, which decreases structural natural frequencies. If more structural volume is immersed in water, the change would be more drastic.

Eq6 can be computed by direct integration or modal superposition. It should be noted that in modal superposition, due to changes in the mass matrix, the system cannot be decoupled by real modal. The common practice is to transform the quadratic eigenvalue problem $(\lambda^2(M+M_w)+\lambda C+K)\phi=0$ to the state space:

$$(\lambda A+B)s=0. \tag{7}$$

In which $A=\begin{pmatrix}0 & M+M_w\\ M+M_w & C\end{pmatrix}$, $B=\begin{pmatrix}-(M+M_w) & 0\\ 0 & K\end{pmatrix}$.

The computed eigensystem can decouple A and B, and can further be transformed to the original dynamic equation.

## Numerical simulation and analysis

A continuous beam bridge with piers in water is modeled into 417 nodes and 415 beam elements, which is shown in Fig4. The pier groups consist of 4 concrete cylinder piers of 1.2m diameter.

Figure 4: Finite element discretization of a beam bridge

Natural frequencies are calculated with and without water, and the first 20 results are shown in Fig5. From the figure we can see that clear differences occur at the 5th, 6th, and 11th~19th frequencies, which is corresponding to the bending and torsional modes.

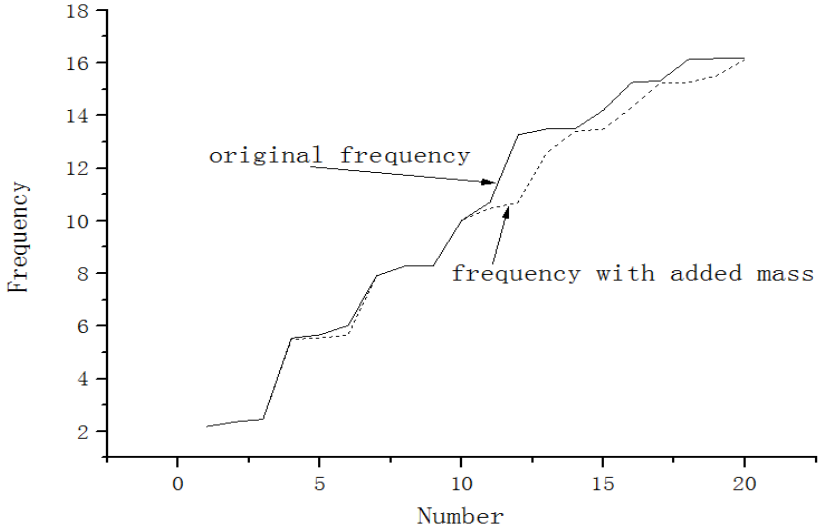


Figure 5: Frequency contrast of structure with and without water

The displacement of this beam bridge excited by the El Centro seismic wave is calculated both in the original structure and in the structure with water, and the maximum displacement in three directions is contrasted for the two cases, which is shown in Tab3.

Table 3: Maximum displacement contrasts on certain DOFs

| | $2^{nd}$ mid-span y | $6^{th}$ mid-span y | $9^{th}$ mid-span x | $9^{th}$ mid-span y |
|---|---|---|---|---|
| Disp, no water[m] | 0.0959 | 0.0937 | 0.0896 | 5.75E-5 |
| Disp, water[m] | 0.0834 | 0.0937 | 0.0831 | 4.990E-5 |
| Relative diff | 14.93% | 0 | 7.8% | 15.16% |

According to the figure , the difference between these two results is not negligible, thus the existence of fluids would change the dynamic property and the response of structures.

## Conclusion

From the above calculation and analysis, we draw the following conclusions:

1. Fluid effect is not negligible in structural seismic response.
2. When the hydrodynamic pressure of vertical structures from seismic excitation is decomposed according to the Morison equation, the drag force term would be negligible compared to the inertial force term.
3. For seismic waves and sine waves, the Morison inertial coefficient for one pier, pier groups, and bridge caps is approximately 0.8. Thus we can approximate the hydrodynamic effect as the time history of forces dependent on structural acceleration.

Further research direction is the direct fluid-structural interaction modeling of bridges to get a more detailed understanding of this problem. Furthermore, a more complicated problem is the joint action of seismic waves, waves and currents, which appears frequently in deep water conditions.

**Keywords:** Lushan earthquake, ground motion, hanging wall effect, topographic effect, directivity effect.

**Abstract.** Lushan earthquake on 20th April, 2013 was another thrust fault earthquake occurred at Longmen Mountain Fault Zone after 2008 Wenchuan Ms8.0 earthquake. Based on ground motion attenuation model, this paper has chosen 45 strong motion records with rupture distance less than 200km, to analyze the hanging wall effect, topographic effect and rupture directivity effect of Lushan earthquake. The results show that hanging wall effect in Lushan earthquake was not obvious as 2008 Wenchuan earthquake; ground motion in mountain areas attenuated with increasing rupture distance more quickly than that in plain areas; rupture directivity effect is obvious for two components of horizontal ground motion, which are fault-perpendicular and fault-parallel components. PGA in the forward rupture area is larger than those in the backward rupture area. With the period increased, the gap between backward and forward rupture area become small, and finally PGD in backward rupture area is greater than those in the forward rupture area.

## Introduction

The Lushan Ms 7.0 earthquake on 20 th April, 2013 caused 188 casualties, 25 missing, 10,000 wounded and tens of billions of economic losses. Lushan earthquake was another big thrust fault earthquake occurred at Longmen Mountain fault zone after the 2008 Wenchuan Ms 8.0 earthquake [1]. In this earthquake, the National Strong Motion Networks Center of China obtained a wealth of strong motion records. Based on ground motion attenuation model, this paper uses ground motion records in Lushan earthquake to analyze the hanging wall effect, topographic effect and directivity effect. The results can provide a scientific basis for ground motion prediction in Southwest China.

Because of the geological characterization of seismogenic fault, directivity of seismic wave propagation process, crustal structure and site effect, hanging wall effect, topographic effect and directivity effect appear in the spatial distribution of ground motion in great earthquakes. Those effects not only complicate the spatial distribution of ground motion, but also influence the various frequency component of ground motion differently, which have increased the bias and variability of ground motion prediction.

Hanging wall effects of ground motion refers to that the ground motion in the hanging wall is greater than that in the footwall with the same rupture distance, which is mainly present in the near-fault areas of dip-slip earthquakes. Earthquake Engineering scientists generally believe that site in the hanging wall is closer to the rupture plane than site in the foot wall with the same rupture distance, and this is the substance of hanging wall effect. Hanging wall effect was discovered very earlier. However, it was not verified until Abrahamson and Someville [2] found a clear hanging wall effect in the strong motion records of Northridge earthquake. Thereafter Yu, Wang[3,4] used the strong motion records in 1999 Chi-Chi earthquake and 2008 Wenchuan earthquake to verify the hanging wall effect again. Then, Chang[5] quantitatively analyzed the hanging wall effect of Chi-Chi earthquake and came up with amplification factor of hanging wall effect on peak acceleration and acceleration response spectrum.

Topographic effect of ground motion generally refers to amplification of the terrain on high frequency component of ground motion, which is closely relative to the shape of the mountain. Ground motion on the ridge is greater than that on the foothills. On the other hand, another topographic effect has attracted the attention of earthquake engineering scientists. For the big earthquake, seismic intensity contour in mountain areas is denser than that in plain area, and seismic intensity in mountain areas attenuate more quickly than that in plain area. This phenomenon has been verified by Hua County Earthquake in 1556 and Wenchuan Earthquake in 2008.

Rupture directivity effect of ground motion refers to that ground motion in the forward rupture area has an accumulated effect and its high frequency component will be greater than usual. However, the sub-source of seismic wave in the backward rupture area arrive at different time, and the long period component will be abundant, which will increase the duration of ground motion. Rupture directivity effect cause spatial variations in ground motion amplitude and duration around fault. Somervile [6] had used strong motion data to build a empirical relations of rupture directivity on ground motion attenuation relations. Liu made a detailed explanation about rupture directivity effect by using dislocation theory.

**Strong motion Data**

Lushan Ms 7.0 earthquake (Epicenter location :30.3 ° N, 103.0 ° E; focal depth: 15 km), occurred in the southern section of the Longmen Mountain fault zone. Chinese Academy of Sciences and Institute of Geophysics both had inverted the focal mechanism of Lushan earthquake, and the two results are similar[7,8]. This paper used the result of Institute of Geophysics , China Earthquake Administration(CEA): Nodal plane Ⅰ, strike 34 °, dip 55 °, slip angle 87 °; nodal plane Ⅱ, strike 220 °, dip 35 °, slip angle of 95 °. As soon as the earthquake happened, CEA had organized a scientific expedition to investigate the outcrop of seismogenic fault, and finally proved there isn't an obvious outcrop. Combined with inversion result and geological evidences, this paper supposed that the length of the seismogenic fault is 60km, its center is the epicenter.

In Lushan earthquake, 83 state strong motion stations in Sichuan province got strong motion records, 45 of which were with fault distance less than 200km. Most state strong motion station were equipped with SYSCOM or ETNA digital accelerographs with full scale of ±2g and band width of 0 ~ 80Hz. Fig.1 displays the location of the 45 state strong motion stations with fault distance less than 200km. According the fault geometry and topographic map of Sichuan province, 45 state strong motion station are classified as four groups, which are hanging wall(mountain area) stations, footwall (plain area)stations, forward rupture area stations and backward rupture area stations. Table 1 shows the classification results. There are more stations in the hanging wall area and forward rupture area than footwall and backward rupture area. Based on the classification, this paper analyzes the strong motion characteristics of Lushan earthquake.

## Ground motion attenuation model

In order to study the hanging wall effect, topographic effect and rupture directivity effect of ground motion in Lushan earthquake, we derives ground motion attenuation model from strong motion data by using statistics method. The ground motion parameters used in this paper are peak ground acceleration (*PGA)*, peak ground velocity (*PGV)*, and spectral acceleration (*SA*) with damping ratio of 5%. Since the mounting azimuth of digital accelerographs has impact on amplitude of ground motion, Boore's method[9] has been introduced. Horizontal acceleration is decomposed into two orthogonal components in any angles, and geometrical mean of the *PGA*, *PGV* and spectral acceleration of two orthogonal components are defined as *GMROTD50(*$T_i$*)*. A penalty function is defined as follows:

$$Penalty(\theta) = \frac{1}{N_{per}} \sum_{i=1}^{N_{per}} [sqrt(Y_1 \times Y_2)/GMROTD50(T_i) - 1]^2 \quad (1)$$

Where,$Y_1$,$Y_2$ are the *PGA*, *PGV* and spectral acceleration of two orthogonal components. $N_{per}$ is the number of period used in the calculation. $T_i$ is the period.

Select the specific mounting azimuth angle θ to minimize the penalty function, and defined the *GMROTD50* atθas *GMROTI50(*$T_i$*)*. *GMROTI50* of *PGA*,*PGV*,*SA* are used to regress the ground motion attenuation model parameters.

Ground motion attenuation model used in this paper is as follows:

$$\log_{10}(Y) = C_0 + C_1 \log_{10}(R + C_2) \quad (2)$$

Where, *Y* are the ground motion parameters, such as the *GMROTI50* of *PGA*,*PGV* and *SA*； *R* is the fault distance; $C_0$, $C_1$, $C_2$ are the regression parameters.

## Strong motion characterization of Lushan earthquake

### 4.1 Hangingwall effect and topographic effect

Strong ground motion data with fault distance less than 200km are used to regress the ground motion attenuation model in equation 2. Fig.2 and Fig.3 demonstrate the fitting of ground motion attenuation model for *PGA* and *PGV*. Fig.4 displays the comparison of attenuation relation curves between hanging wall (Mountain area) and foot wall (Plain area) on *PGA*, *PGV* and Spectral acceleration at period of 0.5 second.

In the near-fault range(fault distance less than 50km), there were 4 strong motion stations in the hanging wall (Mountain area), and 8 stations in the footwall(Plain area).The four stations in the hanging wall were all located in Baoxin county. In comparison of *PGA*, *PGV*, ground motion in the hanging wall didn't looks greater than that in the footwall, except for the station 51BXD. 51BXD is the nearest station to the fault in the hanging wall and *PGA* in 51BXD was greater than 1G. Wen[10]believed that the topographic effect was the main reason for the huge PGA in 51BXD. 51QLY is the nearest station to the fault in the foot wall, with the fault distance of only 3 km. Since it was located in the end part of the seismogenic fault, the ground motion was relatively small.

Overall, hanging wall effect in Lushan earthquake was not obvious as 2008 Wenchuan earthquake, though they both occurred at Longmen Mountain fault zone and with similar focal mechanism. There might be two main reasons for the difference. Firstly, the stress accumulated in the Longmen mountain fault zone had been well released after the Wenchuan earthquake. As a result, the energy and fault size of Lushan earthquake was relatively small. Secondly, according to the investigation of scientific expedition, there was not an outcrop of seismogenic fault in Lushan earthquake, which would weaken the high frequency component of ground motion.

Through the comparison of ground motion in mountain areas and plain areas, amplification effect of terrain was not obvious. In the range of fault distance between 50km to 200km, ground motion in mountain areas attenuated more quickly versus fault distance and was smaller than the ground motion

in plain areas. *PGA* Attenuation relation curves of mountain area and plain area had a junction point at the fault distance of about 40 kilometers, which was similar to the result of Li Xiaojun[11] on the 2008 Wenchuan earthquake.

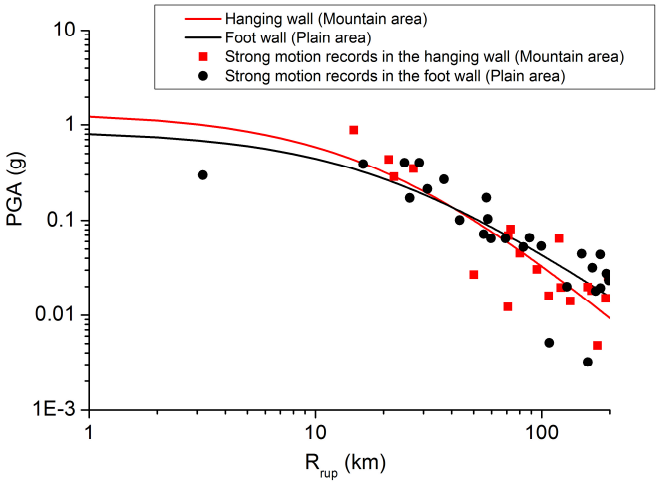

Fig.2 Fiting of attenuation relation curves on PGA

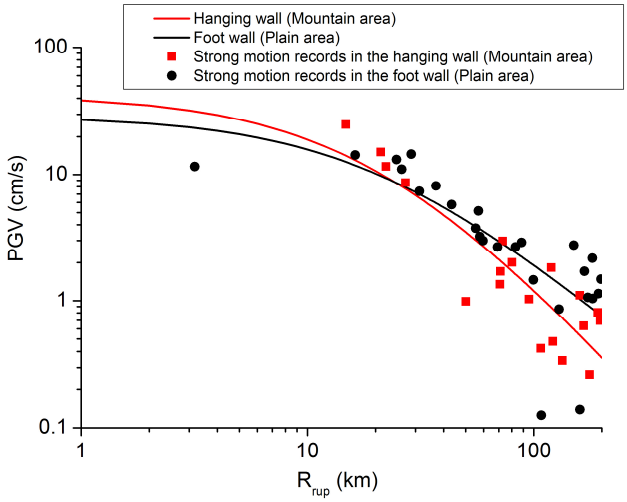

Fig.3 Fiting of attenuation relation curves on PGV

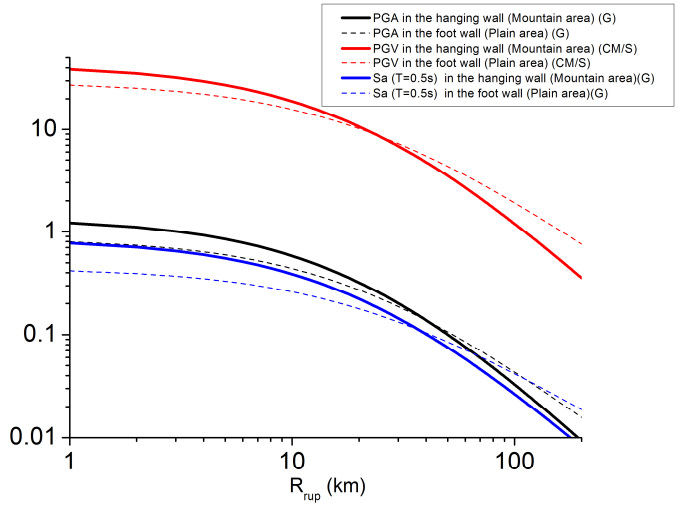

Fig.4 Comparison of attenuation relation curves between Hanging wall (mountain area) and Foot wall (Plain area) on PGA, PGV and Sa (T=0.5s)

### 4.2 Rupture directivity effect

Horizontal component of ground motion has been decomposed into two components, which are fault-perpendicular and fault-parallel components separately. According to the distribution of aftershocks, the rupture direction of Lushan earthquake was southwest. Fig.5 and Fig.6 show the comparison of attenuation relation curves along the rupture direction of *PGA*, *PGV*,*PGD* and spectral acceleration (T=0.5 seconds) between the two horizontal components. Rupture directivity effect on both components is obvious. For *PGA*, the amplitude in the forward rupture area is considerably greater than that in backward rupture area. With period increasing, long period ground motion in backward rupture area is raising, and become equivalent to that in forward rupture area for *PGV*, finally exceed for *PGD*. Both horizontal components have shown this trend.

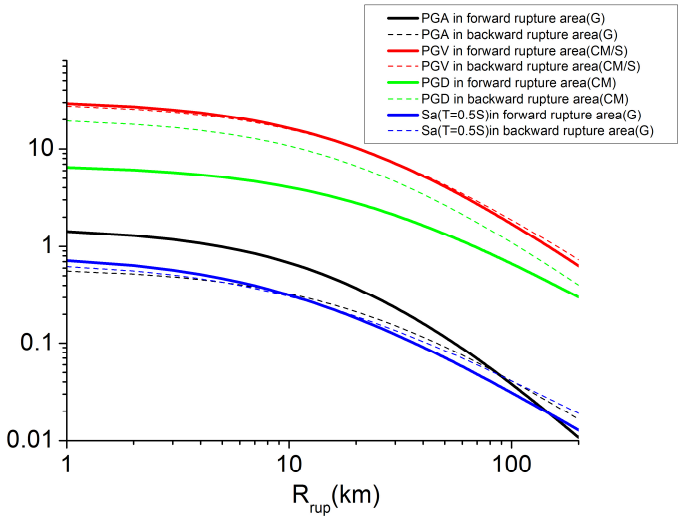

Fig.5 Comparison of attenuation relation curves for fault-parallel component between forward and backward rupture area on PGA, PGV, PGD and SA(T=0.5 s)

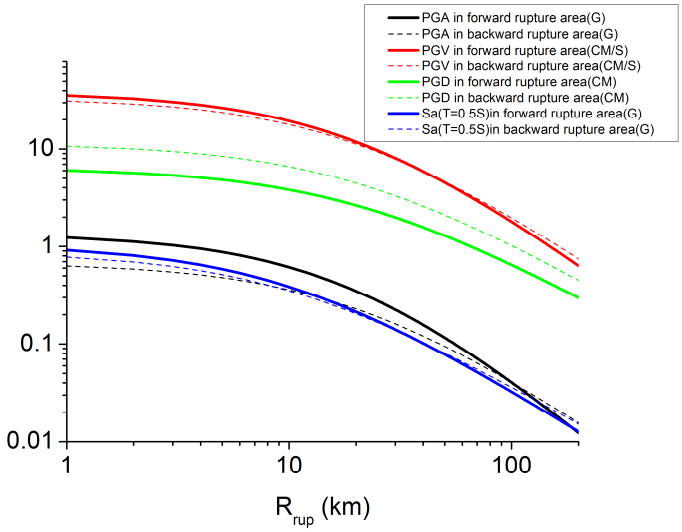

Fig. 6 Comparison of attenuation relation curves for fault-perpendicular component between forward and backward rupture area on PGA, PGV, PGD and SA(T=0.5 s)

### Conclusion

Through statistical analysis of strong motion data, hanging wall effect, topographic effect and rupture directivity effect in Lushan earthquake have been studied in this paper. It is found that:

1. Hanging wall effect is not obvious. From the comparison of *PGA*,*PGV*, ground motion in the hanging wall is not greater than that in the footwall. However, if inferred from attenuation relation curves, ground motion in the hanging wall has a potential of being larger than that in the foot wall.

2. Ground motion in the mountain area attenuated versus fault distance more deeply than that in the plain area.
3. Rupture directivity effect is obvious. In the forward rupture area, high frequency component of ground motion get accumulated and is considerably greater than that in backward rupture area. And in the backward rupture area, ground motion generated by sub-fault arrive at different time , which enlarge the duration of ground motion and increase the long period component of ground motion. This trend has been shown in fault-perpendicular and fault-parallel components of horizontal ground motion.

**Keywords:** seismic bearing , earthquake-reduction and seismic-isolation, hysteretic characteristic

**Abstract:** Since entering the new century, bridge techniques are developing rapidly in our country. When bridge seismic techniques had not reached a certain degree, seismic design of bridge bearings was rarely involved. However, since the amount of the bridges that had collapsed in earthquakes due to the bearings damage were becoming larger, in the design of bridges, seismic design in current bridges has been taken seriously.This paper mainly introduces several widely used seismic bearings and analyzes the structures and hysteretic characteristics of them and forecasts the development direction of seismic bearings.

## Introduction

In the seismic design of bridge, the seismic design of bridge bearings cannot be ignored, and it has been considered to be one of the parts that have comparatively weak seismic performance in the system of bridge. A great part of the damage of bridges that have occurred in earthquakes is the result of the destruction of the bridge bearings. In the survey of the great Hanshin earthquake, Japan found that the number of the bridges' damage, as a result of the destruction of the bridge bearings, has reached twenty-eight percent of the total destruction number.

Bridge bearings will generate varying degrees of damage in earthquake, which may lead to damage of upper structures and bridge piers, and then the beam will slip away or fall down. Bearings will appear tensile damage, shearing damage or the surrounding concrete will generate cracks when the earthquake force is greater than that the bearing can support. It is found that numerous bridges are damaged due to the bearing damage in the survey of the 5.12 earthquake in China.

Bearing damage may lead to transformations of the force transferring path in system of structures, and the transformations have great influence on bridges. In recent years, earthquake-reduction and seismic-isolation techniques are developing very fast. Due to the view of the previous "stiff resistance" approach was no longer applicable, the new opinion of "shock absorption and isolation" was born. Based on the energy concept, using the active control and the passive control or the combination of both, trying to extend the natural vibration period to avoid the energy concentration range, the structure and the ground motion can be separated to reduce the incoming seismic energy and make the energy-dissipating capacity of the structure stronger.

## The Development of Bearings

The world bridge building techniques are changing rapidly, and the types of bridge bearings are also increasing. From steel bearings before the twentieth century 60's to rubber bearings and to teflon plate plane sliding bearings and to spherical bearings, the development shows that seismic performances of bearings and attentions to the design of bearings are increasing.

**Rubber Bearing (RB)**

Rubber bearing is a kind of plate rubber bearings. Plate rubber bearings are divided into unstiffened bearings and stiffening bearings. Unstiffened bearing is made of pure rubber, and its compression deformation under the action of vertical force is too large, and the rubber has lateral expansion. So it is rarely used in the bridge structure.While what plate rubber is more wildly used is the stiffening bearing which is also named rubber bearing.

Laminated rubber bearing is constituted by multilayer thin rubber sheet (5, 8, 11, 15 mm) and thin steel sheet (2, 3, 4, 5 mm),and the two are layered cross each other. It has top flange plate and bottom flange plate, and its shape of plane is circular or rectangular. Its structure is shown in Fig. 1.

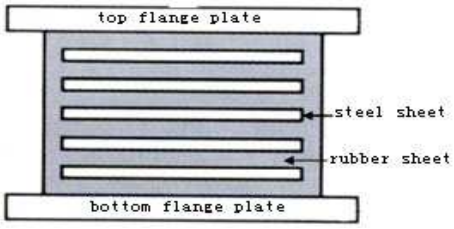

Fig.1 Rubber bearing

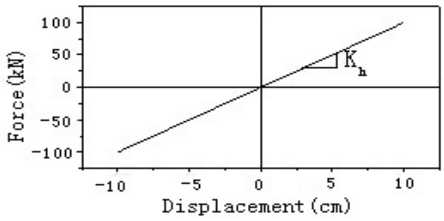

Fig.2 Calculation model of restoring force

The steel sheet in rubber can enhance the bearing stiffness under vertical load and the stability of the bearing under the action of horizontal force.The number, shape and design of the bearing are mainly determined by the size of the vertical load.

Massive experiments show that the hysteretic curve of laminated rubber bearing is long and narrow, and it can be approximately as a linear process. Its calculation model of restoring force is shown in Fig.2.

It shows that laminated rubber bearing almost has no ability of energy dissipation under shear deformation, so when it is used in actual engineering, it must work with other energy-consuming devices.

**Pot Rubber Bearing**

Pot rubber bearings have a rubber plate in a steel pot which can bear pressure and rotation, and use the low coefficient of friction between the stainless steel plate and the teflon to adapt to the request of the displacement of bridge. The bearing capacity of rubber has been actually improved due to the lateral restraint,which can make the rubber in a three-way compression state.

Compared with plate rubber bearings, pot rubber bearings have the advantages of better vertical bearing capacity, allowing larger displacement and flexible rotation. Pot rubber bearings not only have the advantages of low sliding friction coefficient, simple structure and compact structure, but also have the advantages of light weight, low building height, easiness of processing and saving steel,compared with general cast steel roller bearing.

**Lead Rubber Bearing(LRB)**

LRB is formed by inserting a lead rod vertically in the middle of rubber bearing. Lead has good elastic and plastic properties, so it has the ability to dissipate seismic energy during an earthquake. LRB 's structure is shown in Fig.3.

Fig.3 Lead rubber bearing

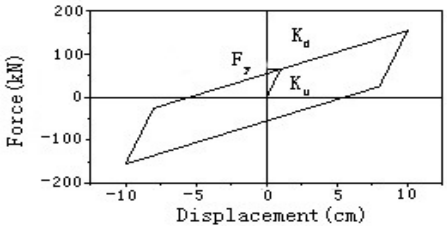

Fig.4 Force - displacement hysteretic model

The yield strength of lead is only 10Mpa, relatively low, but its initial shear stiffness can reach 130Mpa, and its fatigue characteristic is very well under the condition of plastic deformation. Lead rubber bearing has two kinds of stiffnesses,the one is initial stiffness($K_1$) and the other is yield stiffness($K_2$). The value of $K_1$ equals the sum of the value of shear stiffness of lead and rubber, and the value of $K_2$ just equals the value of shear stiffness of rubber.

LRB has excellent hysteretic characteristics, and it has high initial stiffness (more than 10 times of ordinary laminated rubber bearings') .But the resistance caused by temperature and creep is very low. The force - displacement hysteretic model of LRB can be expressed by the bilinear model shown in Fig.4. The area of hysteretic curve increases with the increasing of diameter,the number of lead, and the deformation. This shows that the energy of bearings deformation is higher than the energy which is released when unloading, and the other energy was absorbed by bearings. And that can makes the design of the LRB become very flexible.

**Friction Pendulum System(FPS)**

FPS takes use of the concept of pendulum to extend the natural vibration period to resist earthquake. The sliding surface is a curved surface so that we can utilize the restoring force required by the weight of the structure to make the structure have an effect of automatic resetting and reducing the maintenance work after earthquake. FPS was first proposed by Dr Victor Zayas in 1985. It has developed widely due to having solved the shift problems of many other bearings after earthquake,simple structure and cost-saving.

At present, China has developed six kinds of seismic isolation devices with automatic recovery capability. Among them friction pendulum isolation (FPI) and double spherical aseismic bearings are widely used. Their structures are shown in figure 5 and Fig.6.

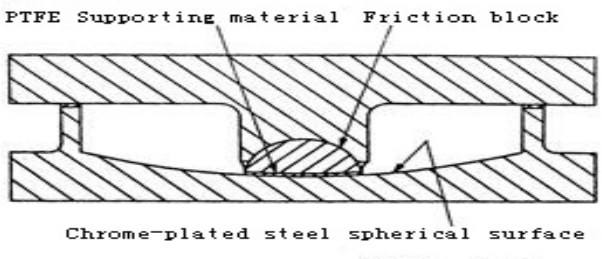

Fig.5 FPI

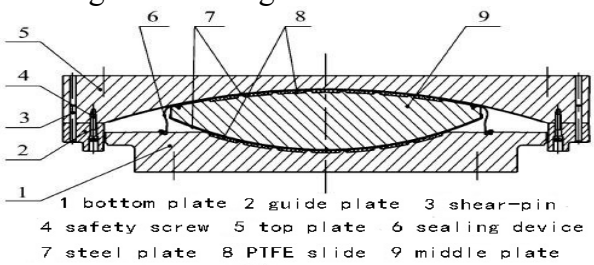

Fig.6 Double spherical aseismic bearing

FPI is shown in Fig.5, which is a lower sliding device and contains a slider with an aspherical surface and a ball type cast steel sliding surface. Both of the surfaces have the same curvature so that they are completely well tangent. Based on this, the compressive stress of the surface under vertical load is uniform. Bearing can slide in any direction, and its size is mainly controlled by the maximum design displacement.

Double spherical aseismic bearing is shown in Fig.6, which is an upper sliding device. Its working principle is similar to FPI's. It has a double spherical ball, a spherical cast steel sliding surface and a steel ball rotation surface. The spherical cast steel sliding surface and the steel ball rotation surface have the same curvature so that they can be also tangent to each other very well. Based on this, the compressive stress of the surface under vertical load is uniform. Bearing can slide in any direction, and its size is mainly controlled by the maximum design displacement.

The force-displacement model of FPS can be described by a bilinear model shown in Fig.7.

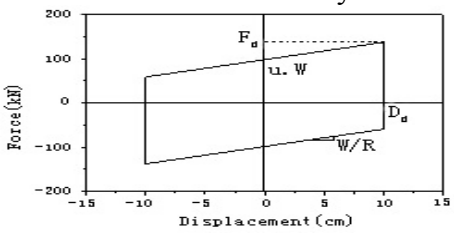

Fig.7 Force-displacement model

**Friction Roller Bearing**

Friction roller bearing is designed according to the phenomenon that the settings of rubber bearing and damper will make the integrated intensity of the structure decreased. For rubber bearing, the tensile strength is not high, when earthquake occurred, steel plate and rubber will be separated. Vertical ground motion will reduce the anti-slip ability of bearings. Rubber bearings don't have the device to limit relative displacement. Therefore, the increase of some relative displacement between beam and pier may lead to the increase of the stress of other piers.The structure of roller friction bearing is shown in Fig.8.

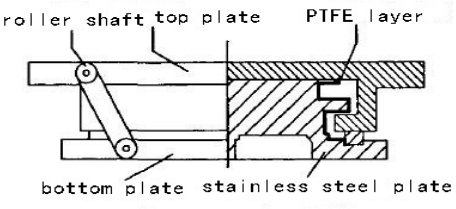

Fig.8 Friction roller bearing

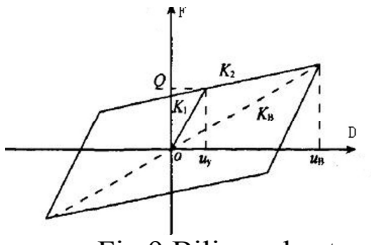

Fig.9 Bilinear hysteretic model

It contains an upper bearing plate and a lower bearing plate, and between the two plates there is a stainless steel plate. And there is a PTFE layer between the stainless steel plate and the bearing plate. The working mechanism of roller friction bearing is that the upper and lower bearing plates generate relative slip with the stainless steel plate to consumes the earthquake energy via sliding friction. Because of the roller, relative slip keeps in a certain range, which is easy to be reset and repaired after earthquake.

Using the bilinear model to simulate the hysteretic characteristics of friction roller bearing and adopting $K_1$(initial stiffness), $K_2$(yield stiffness) and Q(yield strength) as the bearing mechanics parameters,the bilinear hysteretic model of RFB is shown in Fig.9.

**Cable Damping Bearing**

Cable damping bearing is based on pot rubber bearing with additional limiting device. Pot rubber bearing shows the advantages of high vertical bearing capacity and large horizontal displacement, having good energy dissipation properties. However, it does not have the ability of automatic recovery under strong earthquake, which causes that the relative displacement of the main girder and pier is difficult to control. If this situation can not be controlled, after the earthquake the bearing will produce a great deal of residual deformation, which may even lead to falling girder. Based on this, the cable damping bearing under small earthquake and medium earthquake uses the bolt fixed function and utilizes shear bolts to consumpt energy and a cable machine to limit beam's displacement in great earthquake. Cable bearing's structure is shown in Fig.10.

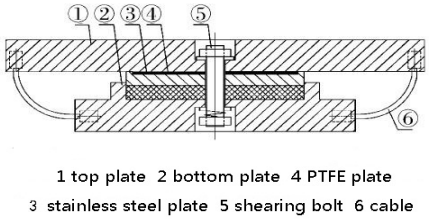

Fig.10 Cable damping bearing

Cable damping bearing belongs to sliding isolation bearing in nature. So it is not sensitive to seismic wave frequency relative to other supports.

Cable damping bearing has advantages of pot rubber bearing and high horizontal sliding ability, for small friction coefficient between PTFE plate and stainless steel plate of upper support. What's more, the cable successfully overcomes the weak horizontal limitation, making the bridge easy to reset after earthquake.

**Elastic-Plastic Falling-Off Prevention Ball Steel Bearing**

Elastic-plastic falling-off prevention ball steel bearing is jointly developed by Fengze Engineering Rubber Technology Development Stock Company.LTD and tongji university. Its structure is shown in Fig.11. The sliding surfaces between the top(base) bearing plate and the ball core can make the bearing meet the need of larger rotation.

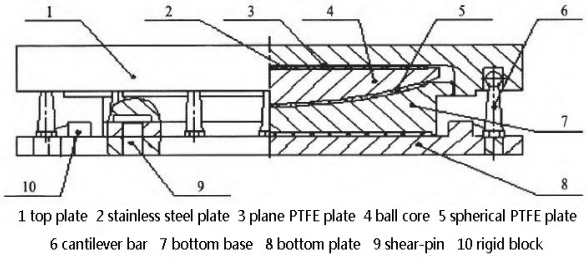

Fig.11 Elastic-plastic falling-off prevention ball steel bearing

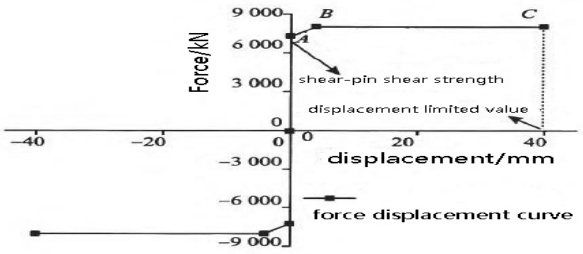

Fig.12 Force - displacement curve

The force - displacement curve of elastic-plastic falling-off prevention ball steel bearing is shown in Fig.12 . The "A" point in the Figure corresponds to the shearing strength of the shear pin (10% of the vertical force), and when the earthquake force is less than the shearing strength,the earthquake force is supported by the shear pin. If the earthquake force is greater than the shear strength, shear pin was cut,and the earthquake force is bearing by the cantilever bar. Cantilever bar has elastic and plastic phase. And when reached the plastic phase,the cantilever bar can dissipate energy.When the

displacement reached to the “C” point, it means that it has reached the ultimate state,and at that time the rigid block can limit the displacement of beam to prevent the girder falling.

## Summary

(1) There are also a large amount of other bearing types, such as height adjustable pot rubber bearing, tension-compression bearing, guide bearings,concrete hinge bearing, cylindrical bearings etc.. In addition, for earthquake-reduction and seismic-isolation,there are lots types of dampers, such as E-type steel damper, arc-shaped steel damper, short arm steel damper, elastic-plastic steel damper, fluid viscous dampers etc.. Some seismic measures may be jointly used to achieve better results.
(2) The seismic design of bearings is one of the most difficult parts in the seismic design of bridges.From the result of the destruction of the bridge in earthquake,there are also a large amount of bridges that were damaged due to the bearing failure. For the existing seismic bearings, their seismic principles are mainly "reduction and isolation", abandoning the thought of "stiff resistance" , and earthquake can be resisted by changing the natural vibration period and adding energy dissipation devices.
(3) Cliffide Flower, maintenance-free after the earthquake (good function of recovery), application of new materials, and simple-reliable structure must be considered together in the seismic design of bearings, and they are the development directions of bearing design. Although seismic bearings have been very mature, it’s very difficult to ensure that the bearing is completely reliable in earthquake. Materials are very important to bearings, and there is no time to delay for finding more powerful and more comprehensive materials. So, it must be the new material bearings that will change the bearing age.

**Keyword:** high-rise building；anti-seismic；human spine；deformation；reset

**Abstract:** With the rapid development of high-rise buildings in our country, the seismic design of structures is becoming more and more important. And the seismic performance of traditional seismic system is not perfect, there are still some room for improvement. This article points out the advantages of the human body vertebra seismic system by comparing the characteristics of the current building aseismic system with the deep analysis of the human body vertebra seismic system and the application of the seismic characteristics of the human body vertebra in seismic design of building structure application foreground is prospected.

## Preface

The human body is like a building, and the bones of the human body is similar to the structural skeleton of the building. The human bones is formed for adapting to the different living environment during the long history. The morphology and structure of the bones are associated with their forces, meeting the most optional design principles. Skeleton has the abilities of anti-vibration, shock resistance and keeping its own balance, so it can provide a good reference for the modern seismic design of building. While the traditional ergonomics in the research of building design is mainly involved in anthropometry, environmental physiology and environmental psychology and so on, which usually takes the morphological features of the human body, human perception, and human response as the objects to study its application of the usage features of buildings, it seldom involves the application of human biomechanical properties in the seismic design of building. For now, our country's building structure design is a very important area in seismic design of building. With the development of high-rise buildings, seismic design of building structure is becoming increasingly important. Our current major seismic components in building earthquake-resistant structures are damper and seismic isolation rubber bearings. Seismic isolation rubber bearings are mainly used for base-isolated. It can significantly reduce the natural frequency of the structure, and is applicable to short period of low-rise and rigid structure. And the deformation damping capacity of the "damper" can only play a role when the structure is at a low speed movement. It is limited when the speed or the acceleration is over the corresponding value.

## Biomechanical properties of human bones.

The functions of human bones are movement, support and protect the body. It is a strong support for human body, functioning as leverage and anchor plates for movements. Human spine is the central axis of the bone of the body which is hard and flexible, also is the activity center of body and the transfer hub of force, enjoying good biomechanical properties. It could be able to bear the stress of squeeze, stretch, bend and rotation.

There are mainly three ways to realize the body vertebra's anti-shock, impact resistance as well as keep its structural balance and stability.

(1)Physiological curvature of the spine: the spine is the connection of vertabrae, intervertebral disc and ligaments. Seeing it from the side, it forms four physiological curves with neck and waist bent forward, chest and sacral backward. And by this, the spine is like an elastic fender which can adjust itself. Other four curves are conducive to maintaining the strength and stability of the intervertebral joints and increasing the adaptability and ability to absorb the impact of the spine.

(2)The elastic deformation of the intervertebral disc: intervertebal disc is a elastic cushion made up of fibrous cartilage, playing the cushion role between the intervertebral body. Under different load, it can absorb shocks and stabilize the spine by generating corresponding deformation.

(3) The elastic deformation of ligament: there are strong ligaments around the spine, which can stand the most tension load of it. By the mutualism between each ligament, it can limit the excessive deformation of the spine and reset the after deformation of the spine.

Support

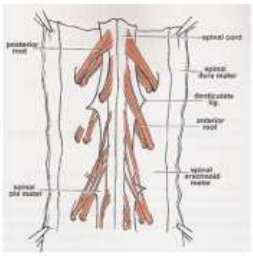
Anti-cut

Cushion
Deformation and energy absorption
Stable spine



Bear tension load
Elastic deformation
Shrink back

**Morphology and mechanical properties of human bones conform to the requirements of building shape and structure performance**

Buildings shape aspect: in order to meet the needs of people's life or production, buildings should have a stable building space firstly. But, speaking of the human thorax, it is a conical bone cage which is flat at both the front and back parts with short front wall and long back wall for adults. It is just like a solid container, playing a role in supporting and protecting chest, abdomen and viscera. Its huge accommodation and perfect body can be a good choice for architectural bionic body.

Building structure: a good building should have good damping characteristics of energy dissipation and could maintain its stability. And the skeleton is the support frame of the body, in addition to support body weight, to protect the internal organs' function, bone in the spine also has the property of resisting to shock, pound and sustaining the balance of human body structure and stable features. Its seismic performance is adapted to the structure of the seismic demand.

**A preliminary attempt to apply the biomechanical properties of human bones in seismic structure design of building.**

**(1) Imitation of spinal shock absorber**

By abstracting the shock absorption of the human body, we apply it to the building structure seismic design. Thus, we designed the imitation of the human body vertebra shock absorber model, which has a kind of ideal seismic performance. See the Fig.1,Fig.2,Fig.3:

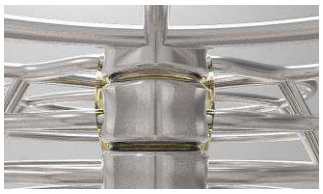


Fig.1

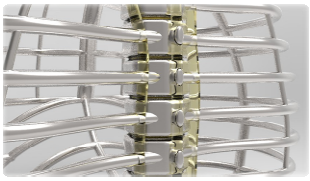

Fig.2

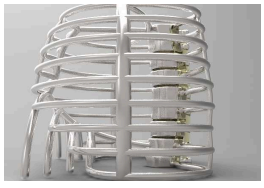

Fig.3

Fig.1, Fig.2, Fig.3 shows the main features of the structure:

1) Imitation of the spine internode shock: the force bearing pole in the middle is similar to the human body's vertebra, and the link between each section is like the joints. Every section is an

absolute rigid body that no distortion occurs. But the internode material has certain elasticity, and could have a small deformation. Between the adjacent internode, it has the cushion effect. Under the different load, it produces the corresponding deformation and it can absorb the shock and keep the integral structure in stable.

2) Imitation of the ligament flexibility reset: the elastic fibers, run through up and down, is similar to human body's ligaments. It can bear the most tension load of the spine and limit the excessive deformation of the spine, making the spine can be reset after the shock absorption of the spine deformation. At the same time, it can also absorb the suddenly imposed enormous amounts of energy and can effectively absorb the shock in the fast loading environment.

3) Imitation of the spinal flexion shock: internode connection and ligaments can realize "spine" as a force rod, which has greater rigidity and can form tiny curvature. Such "spine" is like an elastic curved bar, and is beneficial to maintain the stability of the gravity center of the building and reduce the shocks. Its small curvature increased the adaptability and ability of absorbing the pound of the spine.

**(2) The imitation of human body earthquake-resistant structure**

As mentioned before, the thorax of the human body not only has a large accommodation space, but also has a perfect body, which can accommodate and protect the vital organs. Its function is similar to the peripheral guardrail of the building. Therefore, we use human thoracic model in the shape design of the building, apply the structure and construction of the human spine in design of anti-seismic structures of building and imagine a human-like seismic structure through improvement and innovation.

**Holism**: the whole structure is consists of two bilateral "thorax" and "spine", and the total weight of "thorax" is borne with three parts. The first part is passing from the thorax to the progressive transformation of the four big arches, and most load is borne by the arch; the second part is from the vertical bar at the two sides to the ground; the third part is from the three poles at the top to the "spine". Among them, in the middle of the bilateral structure, a shockproof seam is set up in order to prevent the two of them influence each other in an earthquake.

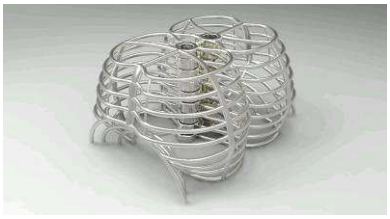

Fig.4

**Forecasting the prospect of applying the human sciences to the seismic design of building**

With the development of bionics, the bionics structure has been more and more widely used in structural design of the building. The common applies are hive-like structure, bamboo-like structure, spider web-like structure and the bird's nest-like structure, etc. But so far, the attention of the human skeleton-like structure is still very low in the construction industry.

In our country, building aseismic level has been developed to a certain stage. At present, the most commonly used domestic seismic components are dampers and rubber isolation bearing. People usually think the damper on the building is similar to the human body joint connection, has the function of deformation and damping; and the shape of the prestressed reinforcement is similar to the shape of the human body's ligament. But it must be stressed that the current damper damping device is much less perfect than the human body's shock absorption system.

First of all, the damper's abilities of deformation and damping are limited by structural motion state, not yet reaching the effect of human joints' damping layer by layer. Second, the damper a poor ability to reset after deformation of shock absorbing, but the ligaments around the human spine can effectively reset after the deformation. In addition, the current dampers and design of building structure is separate, and this make the structure cannot bear the vertical load when it is damping.

While the human's spine is the combination of load and suspension, it can achieve damping under vertical load at the same time, and can effectively reset. It is needed to be clear that the prestressed reinforcement in building is looked as same as the spine, but the load and damping theory of them are totally different. Human's spine is only depend on its own elastic property, allowing a certain deformation of the spine and can also collect rally energy to reset after the deformation of the spine.

## Conclusion

Through the above analysis, we know that it is completely feasible to apply the biomechanical properties of human bones in the seismic design of building structure. The shock absorption mechanism of human's absorption system still has a lot for the seismic building structure to learn from. For example, we can make use of spinal flexion damping principle to study what kind of curvature can maintain the stability of the structure and conducive to the structural damping at the same time. We can also dig the body joints' advantages in shape, structure, etc. And apply to the improvements of the damper damping performance. We can also invent a kind of prestressed elastic reset function according to the principle of elastic reset of the human body's ligament. Human body structure's potential is much far than this in terms of seismic design of building structure. It is like a huge treasure, holding so many secrets waiting for our civil engineer to discover. I believe in the future, the development and utilization of the seismic system of human body structure will make great contribution to the buildings' earthquake prevention and disaster reduction in the 21st century.

**Keywords:** concrete with low longitudinal reinforcement ratio; solid pier; minor earthquake; checking parameters

**Abstract.** Solid concrete piers with low longitudinal reinforcement ratio are extensively used in high-speed railway in China. However, how to check such structures is not specified in current technical codes. Checking these structures by eccentricity and stress indexes is discussed hereby. The moment-curvature relationships for piers of various reinforcement ratios are presented by employing the software UCfyber and these moments are compared with moments calculated by allowable stress approach, moments corresponding to the code-specified permissible eccentricity, moments corresponding to the allowable reinforcement stress and stabilizing moments induced by tensile reinforcement and self weight of the piers, respectively. The results show that the allowable stress approach could be used to check the strength and eccentricity of solid concrete piers with low longitudinal reinforcement ratio in high-speed railway; the restriction on permissible eccentricity may be to a proper extent relaxed for such piers, based on the fact that tensile reinforcement provides an additional stabilizing moment and the reinforcement contributes to the pier's bearing capacity.

## Introduction

Nowadays, high-speed railway is developing rapidly around the world. As for concrete piers used in high-speed railway bridges, there are a variety of types. Solid round-ended slab-type piers, circular piers and rectangular piers are usually used in small-span bridges in Germany, France and other western European countries. And, due to the seismic intensity of western European countries being comparatively low, the seismic action is generally not a controlling factor.[1] In Japan, continuous reinforced concrete rigid-frame bridges with a span of approximately 10 meters and a high reinforcement ratio are extensively used. In China, solid concrete piers are characterized by a reinforcement ratio less than 0.5% in most cases, even in areas of high seismic intensity.[2]. With the strict limitations on longitudinal force induced by rail breaking and transverse stiffness, the section size, stiffness, and weight of bridge piers used in high-speed railway are comparatively great, resulting a large seismic force. Without a proper seismic design, these piers would be prone to damage.

Unfortunately, how to check solid concrete piers with low longitudinal reinforcement ratio under a minor earthquake is not specified in current technical codes. Alternatively, checking method for masonry or common reinforced concrete structures are adopted in practical design, which is not reasonable. The checking method for masonry structures is too conservative for such piers while the checking method for common reinforced concrete structures needs to be further verified. Yanzhong Ju performed pseudo-static testing on ten scale-modelled piers with low longitudinal reinforcement ratios of 0.1% and 0.2%, exploring the relationship between the pier's ductility and shear span ratio, longitudinal reinforcement ratio and hooping reinforcement ratio[3]. Lizhong Jiang, et. al. conduted pseudo-static testing on solid round-ended piers with low longitudinal reinforcement ratios, concluding that the hysteretic curve being of dramatically pinched shape[4]. Shiqiaozhongliang, et.al. performed low-cycle fatigue testing on scale-modelled railway piers with low longitudinal reinforcement ratio varying from 0.12% to 1.66%, and worked out the formulas of displacement ductility coefficient of the piers[5,6]. However, the above mentioned studies focus on energy dissipation capacity and deformability of concrete piers with low longitudinal reinforcement ratio

under a major earthquake, not concerning the problems under a minor earthquake. In this paper, the seismic checking of solid concrete railway bridge piers with low longitudinal reinforcement ratios under a minor earthquake is to be studied.

**Analysis process**

As far as the minor earthquake condition is concerned, the current seismic code requires checking on strength and stability for reinforced concrete piers, and requires checking on eccentricity, strength and stability for plain concrete piers. For reinforced concrete piers, the allowable stress approach is adopted to check the tensile stress of reinforcement and the compressive stress of concrete to ensure they are within a permissible value. For plain concrete or masonry piers, eccentricity design is the major consideration since the pier is prone to cracking under eccentric loading, due to the low tensile strength of plain concrete and masonry. If the cracking is severe, the plain concrete and masonry are vulnerable to moisture erosion. Meanwhile, a large tension zone on the section is not favorable to the stability of the pier. The eccentricity checking is to ensure crack resistance and stability.

However, how to check solid concrete piers with low longitudinal reinforcement ratios is not specified in current technical codes. .This paper is to deal with this problem by performing analysis of the strength, stability and sectional moment-curvature relationship of the pier. The detailed work is listed below.

(1)Analysis of the moment at pier-bottom section by the allowable stress approach

It is well known that the allowable stress approach involves the following basic assumptions:.

a.The assumption of plane section, which means that a plane section before bending remains a plane section after bending.

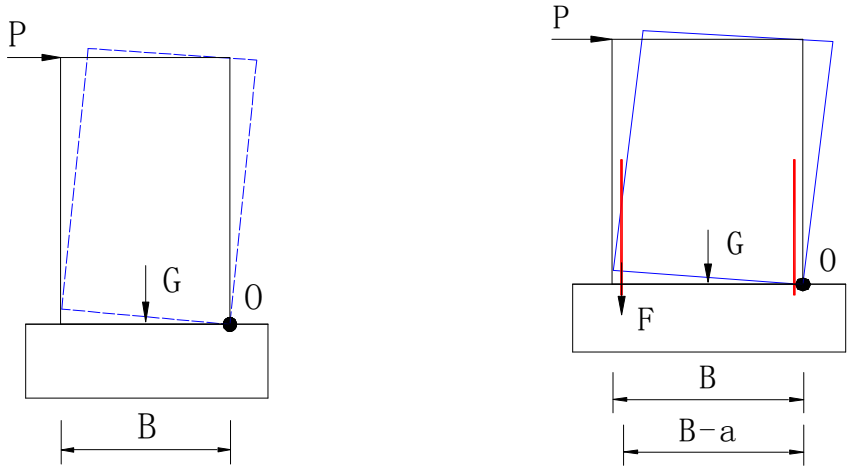
b.The assumption of elastic body, which means that the stress is proportional to the strain (in the compression zone).

c.The tensile strength of the concrete is neglected.

(2) Analysis of the moment corresponding to the code-specified permissible eccentricity.

For a rectangular section, the permissible eccentricity is specified to be 0.8S, where S is the distance between the centroid of the cross section and the extremely compressed fiber. The corresponding moment is M=N×0.8S. The vertical force N at the pier bottom is a resultant force of the concentrated force applied at the pier top and the self weight of the pier.

(3)Analysis of the stabilizing moment



(1) Stabilizing moment produced by the pier’s self weight

(2) Stabilizing moment produced by the tensile reinforcement and the pier’s self weight

Fig.1 Stabilizing moment

The stabilizing moment offered by the pier’s self weight can be calculated as follows:

$$M=G\bullet\ 0.5B \tag{1}$$

The stabilizing moment offered by the tensile reinforcement and the pier’s self weight can be calculated as follows:

$$M=G\bullet\ 0.5B+F\bullet\ (B-a) \quad (2)$$

$$F=n\bullet\ fy\bullet\ As \quad (3)$$

where, F means tensile force of the reinforcement in the tension zone; fy means the yielding stress of the reinforcement; As means the sectional area of a single steel bar; n means the number of the reinforcement bars in the tension zone; a means the thickness of concrete cover; B means the sectional dimension along the direction of horizontal loading.

Overall analysis of the moment-curvature relationship at the pier bottom

The UCfyber software is employed to obtain the moment-curvature relationship of the pier-bottom section. The Mander model is applied in the stress-strain relationship of the concrete while a parabola model is adopted as the stress-strain relationship of the reinforcement.

## Numerical examples

### 2.1 Rounded-ended piers

A double-line simply-supported box-girder bridge is chosen, which has round-ended piers. The pier section comprises a linear segment of 3.4m and two circular segments with a diameter of 2.6m. The weight of the girder over a single span is 14379kN. C30 concrete is adopted for the bridge. The reinforcement ratios of 0.05%, 0.1%, 0.2%, 0.3%, and 0.4% are selected for the pier, respectively. The height of the pier's straight-section is 11m.

#### 2.1.1 The case of longitudinal reinforcement being HRB335

With the longitudinal reinforcement being HRB335, the eccentricity magnification coefficient is shown in Table 1 and Table 2. From the tables, we can see:

(1)For solid concrete piers with low longitudinal reinforcement ratio, the restriction on permissible eccentricity may be to a proper extent relaxed, based on the fact that tensile reinforcement produces an additional stabilizing moment and the reinforcement contributes to the pier’s bearing capacity. With the safety factor being unchanged, the eccentricity of the pier with reinforcement ratios of 0.1%, 0.2%, 0.3%, and 0.4% may be relaxed to 0.90S, 1.0S, 1.1S, 1.2S, respectively.

(2)For the pier with reinforcement ratio less than 0.4%, it is too conservative to base the seismic design on an eccentricity of 0.8S. It is applicable to check the pier’s strength through allowable stress approach, which actually ensures both its strength and stability.

Tab. 1 Results for eccentricity magnification coefficient of pile-bottom section(controlled by stabilizing moment)

| reinforcement ratio /% | moment corresponding to code-specified permissible eccentricity (0.8S)/kN·m | stabilizing moment induced by pier's weight/kN·m | safety factor corresponding to code-specified permissible eccentricity | stabilizing moment induced by tensile reinforcement and pier's weight/kN·m | Inversely computed permissible eccentricity | eccentricity magnification coefficient |
|---|---|---|---|---|---|---|
| 0.05 | 19354 | 23608 | 1.22 | 25600 | 0.87S | 1.08 |
| 0.1 | 19354 | 23608 | 1.22 | 27609 | 0.94S | 1.17 |
| 0.2 | 19354 | 23608 | 1.22 | 31694 | 1.07S | 1.34 |
| 0.3 | 19354 | 23608 | 1.22 | 35456 | 1.20S | 1.50 |
| 0.4 | 19354 | 23608 | 1.22 | 39502 | 1.34S | 1.67 |

Tab. 2 Results for eccentricity magnification coefficient of pile-bottom section(controlled by moment corresponding to allowable stress)

| reinforcement ratio /% | moment corresponding to code-specified permissible eccentricity (0.8S)/kN·m | stabilizing moment corresponding to allowable stress/kN·m | stabilizing moment induced by tensile reinforcement and pier's | Correspondi-ng safety factor | Inversely computed permissible eccentricity | eccentricity magnification coefficient |
|---|---|---|---|---|---|---|
| 0.05 | 19354 | 20300 | 25600 | 1.26 | 0.84S | 1.05 |
| 0.1 | 19354 | 21800 | 27609 | 1.27 | 0.90S | 1.13 |
| 0.2 | 19354 | 24700 | 31694 | 1.28 | 1.02S | 1.28 |
| 0.3 | 19354 | 27200 | 35456 | 1.30 | 1.12S | 1.41 |
| 0.4 | 19354 | 30200 | 39502 | 1.31 | 1.25S | 1.56 |

### 2.1.2 The case of longitudinal reinforcement being HRB400

With the longitudinal reinforcement being HRB400, the eccentricity magnification coefficient is shown in Table 3 and Table 4. From the tables, it can be seen that with the increase of the reinforcement strength, the allowable eccentricity of the pile-bottom section may be further improved. For the pier with reinforcement ratios of 0.1%, 0.2%, 0.3%, and 0.4%, the eccentricity may be relaxed to 0.90S, 1.0S, 1.2S, 1.3S, respectively. For the pier with reinforcement ratios between 0.1% and 0.4%, the permissible eccentricity may be determined by the method of linear interpolation.

## 2.2 Circular piers

A 32m double-line simply-supported box-girder bridge is chosen, which has circular piers. The diameter of the pier's section is 4.0m. The weight of the girder over a single span is 12898kN. C30 concrete and HRB400 reinforcement are adopted for the bridge. The height of the pier is 10m. The results are shown in Tab.5 and Tab.6.

Tab. 3 Results for eccentricity magnification coefficient of pile-bottom section(controlled by stabilizing moment)

| reinforcement ratio /% | moment corresponding to code-specified permissible eccentricity (0.8S)/kN·m | stabilizing moment induced by pier's weight/kN·m | safety factor corresponding to code-specified permissible eccentricity | stabilizing moment induced by tensile reinforcement and pier's weight/kN·m | Inversely computed permissible eccentricity | eccentricity magnification coefficient |
|---|---|---|---|---|---|---|
| 0.05 | 19354 | 23608 | 1.22 | 26410 | 0.89s | 1.12 |
| 0.1 | 19354 | 23608 | 1.22 | 29407 | 1.00s | 1.25 |
| 0.2 | 19354 | 23608 | 1.22 | 35099 | 1.19s | 1.49 |

| 0.4 | 19354 | 23608 | 1.22 | 46088 | 1.56s | 1.95 |

Tab. 4 Results for eccentricity magnification coefficient of pile-bottom section(controlled by moment corresponding to allowable stress)

| reinforce-ment ratio /% | moment corresponding to code-specified permissible eccentricity (0.8S)/kN·m | stabilizing moment corresponding to allowable stress/kN·m | stabilizing moment induced by tensile reinforcement and pier's weight/kN·m | Correspon-ding safety factor | Inversely computed permissible eccentricity | eccentricity magnification coefficient |
|---|---|---|---|---|---|---|
| 0.05 | 19354 | 21160 | 26410 | 1.25 | 0.87s | 1.09 |
| 0.1 | 19354 | 22800 | 29407 | 1.29 | 0.94s | 1.18 |
| 0.2 | 19354 | 26000 | 35099 | 1.35 | 1.07s | 1.34 |
| 0.3 | 19354 | 29200 | 40163 | 1.37 | 1.21s | 1.51 |
| 0.4 | 19354 | 32300 | 46088 | 1.42 | 1.34s | 1.67 |

Tab. 5 Results for eccentricity magnification coefficient of pile-bottom section(controlled by stabilizing moment)

| reinforcement ratio/% | moment corresponding to code-specified permissible eccentricity (0.7S)/kN·m | stabilizing moment induced by pier's weight/kN·m | safety factor corresponding to code-specified permissible eccentricity | stabilizing moment induced by tensile reinforcement and pier's weight/kN·m | Inversely computed permissible eccentricity | eccentricity magnification coefficient |
|---|---|---|---|---|---|---|
| 0.05 | 24737 | 35339 | 1.42 | 38155 | 0.75S | 1.08 |
| 0.1 | 24737 | 35339 | 1.42 | 40969 | 0.81S | 1.16 |
| 0.2 | 24737 | 35339 | 1.42 | 46667 | 0.92S | 1.32 |
| 0.3 | 24737 | 35339 | 1.42 | 52342 | 1.03S | 1.48 |
| 0.4 | 24737 | 35339 | 1.42 | 57419 | 1.13S | 1.62 |

Tab. 6 Results for eccentricity magnification coefficient of pile-bottom section(controlled by moment corresponding to allowable stress)

| reinforcement ratio /% | moment corresponding to code-specified permissible eccentricity (0.7S)/kN·m | stabilizing moment corresponding to allowable stress/kN·m | stabilizing moment induced by tensile reinforcement and pier's weight/kN·m | corresponding safety factor | Inversely computed permissible eccentricity | eccentricity magnification coefficient |
|---|---|---|---|---|---|---|
| 0.05 | 24737 | 27800 | 38155 | 1.37 | 0.78S | 1.12 |
| 0.1 | 24737 | 29600 | 40969 | 1.38 | 0.83S | 1.19 |
| 0.2 | 24737 | 33100 | 46667 | 1.41 | 0.93S | 1.33 |
| 0.3 | 24737 | 37000 | 52342 | 1.41 | 1.04S | 1.49 |
| 0.4 | 24737 | 40400 | 57419 | 1.42 | 1.14S | 1.63 |

From Table 5 and Table 6, it is clear that for the circular pier with reinforcement ratios of 0.1%, 0.2%, 0.3%, and 0.4%, the eccentricity may be relaxed to 0.8S, 0.9S, 1.0S, 1.1S, respectively. .For the pier with reinforcement ratios between 0.1% and 0.4%, the permissible eccentricity may be determined by the method of linear interpolation.

## Conclusions

（1） The solid concrete pier with a reinforcement ratio less than 0.1% can be handled as a plain concrete pier, due to the fact that the permissible eccentricity is increased just to a very limited extent.

（2）For the solid pier with reinforcement ratio between 0.1% and 0.4%, the permissible eccentricity .may be to a proper extent relaxed, based on the fact that tensile reinforcement provides an additional stabilizing moment and the reinforcement contributes to the pier's bearing capacity.

（3）For the circular or rectangular piers with reinforcement ratio between 0.1% and 0.4%, strength checking can be developed through allowable stress approach, which would ensure the sectional strength and the stability of the pier as well.

**Keywords:** shaking table, jerk, multi-variable control, system simulation

**Abstract.** For the shaking table system, the $90^o$ phase shift frequency of the servo valve system is close to the oil column resonance frequency, the bandwidth under the influence of servo valve features was so narrow that it cannot meet requirements. Multi-variable control is presented in this paper by introducing the jerk feedback on the basis of the three-variable control. The theoretical derivation and the system simulation show that: the jerk feedback can reduce the oil column resonance frequency, and decrease the influence of the system performance caused by the servo valve characteristics.

## Introduction

The shaking table is the most direct and the most effective research tool of the engineering seismic field. Since 1890, the Japanese started using mechanical devices to attempt to simulate earthquake[1,2], The United States, Japan, China, Britain and other countries built hundreds of different scale shaking table[3]. At the same time, as the developments of the hydraulic, electronic, automation, sensors, signal processing, control technology, the shaking table realized the transition from analog control to digital control, and the transition from displacement PID control to the acceleration feedback control, then the three-variable control (displacement, velocity and acceleration) become the basic control algorithm of the shaking table[4,5]. The three-variable control of shaking table uses the feedback of displacement, acceleration and the velocity synthesized from acceleration integral and displacement differential to realize a closed loop control. The studies of the domestic and foreign scholars have shown that the actuator cylinder could be positioned by the displacement feedback, the range of the using frequency could be extended by the velocity feedback, and the stability of the system could be improved by the acceleration feedback[6~8]. However, when the $90^o$ phase shift frequency of the servo valve system is close to the oil column resonance frequency, the system characteristics are seriously influenced by the characteristic of servo valve, at the same time the influence caused by the characteristic of servo valve could not be removed by changing the control gains of the three-variable control. The bandwidth of the system is narrow and it could not meet requirements.

In order to solve this problem, the present paper puts forward a multi-variable control algorithm. The multi-variable control algorithm is formed by adding the jerk feedback on the basis of the three-variable control algorithm. The jerk feedback can reduce the oil column resonance frequency, and decrease the influence of the system performance caused by the servo valve characteristics.

## System analysis

### System analysis with the jerk feedback

Jerk, the physical quantity to describe the acceleration's variation, is determined by the acceleration's variation and time. The jerk feedback is introduced in the open loop transfer function of the electro-hydraulic servo system. The system block diagram is shown in the Fig. 1.

In the Fig.1, $u$ is the input signal of the system, $x$ is the output signal of the system, $E$ is the control-error signal, $k_q$ is the flow gain of slide valve near the static working point, $K_c$ is the flow

pressure coefficient of the slide valve near the steady state motion point, $C_c$ is the total leakage coefficient, $v$ is the oil cylinder equivalent volume, $\beta$ is the oil bulk modulus of elasticity, $P_L$ is the load pressure, $A_p$ is the effective pressure area of piston, $M$ is the mass of load, $K_j$ is the gain of the jerk feedback.

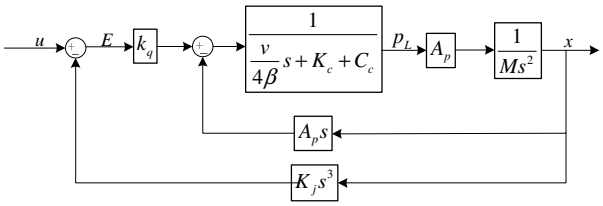

Fig.1 The transfer function diagram with the jerk feedback

The transfer function diagram of the system is：

$$\frac{x}{u}=\frac{k_q}{A_p}\frac{1}{\left(\frac{1}{n_j^2}s^2+\frac{2D_j}{n_j}s+1\right)s} \tag{1}$$

Where

$$\begin{cases}\dfrac{1}{n_j^2}=\dfrac{1}{n_0^2}+\dfrac{k_q k_j}{A_p}\\ \dfrac{2D_j}{n_j}=\dfrac{2D_0}{n_0}\end{cases} \tag{2}$$

$$\begin{cases}n_0^2=\dfrac{4\beta A_P^2}{MV}\\ \dfrac{2D_0}{n_0}=\dfrac{M(K_C+C_C)}{A_P^2}\end{cases} \tag{3}$$

Where $n_0$ is the oil column resonance frequency of the actuating cylinder, $D_0$ is the damping ratio, $n_j$ is the oil column resonance frequency of the system with the jerk feedback, $D_j$ is the damping ratio of system with the jerk feedback.

The equation(2)shows that when the jerk feedback is negative feedback, $k_j>0$, $n_j<n_0$, $D_j<D_0$, the oil column resonance frequency and the damping ratio are decreased, and when the jerk feedback is positive feedback, $k_j<0$, $n_j>n_0$, $D_j>D_0$, the oil column resonance frequency and the damping ratio are improved.

**System analysis with multiple feedback control**

The system with multiple feedback control is formed by introducing the jerk feedback into the three-variable control (the displacement feedback, the velocity feedback and the acceleration feedback). The system block diagram is shown in the Fig.2.

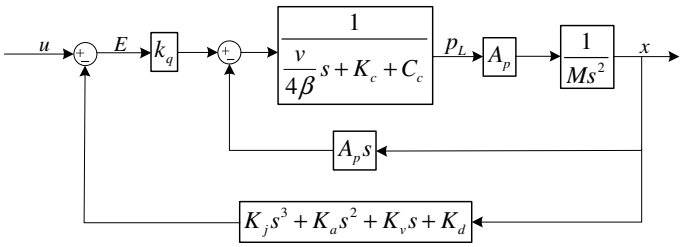

Fig.2 The transfer function diagram with the multiple feedback control

According to the Fig.2, the transfer function diagram of the system is：

$$\frac{x}{u_0}=\frac{k_q A_d}{A_p}\frac{1}{\frac{s^3}{n_0^2}+\frac{2D_0 s^2}{n_0}+s+\frac{k_q}{A_p}(K_{j0}A_j^{'}s^3+K_{a0}A_a^{'}s^2+K_{v0}A_v^{'}s+K_{d0}A_d^{'})} \tag{4}$$

Where $u_0$ is the command signal, $A_d$ is the gain of the displacement input, $A_d^{'}$ is the gain of the displacement feedback, $A_v^{'}$ is the gain of the velocity feedback, $A_a^{'}$ is the gain of the acceleration feedback, $K_{d0}$ is the normalized sensitivity of the displacement feedback, $K_{v0}$ is the normalized sensitivity of the velocity feedback, $K_{a0}$ is the normalized sensitivity of the acceleration feedback, $K_{j0}$ is the normalized sensitivity of the jerk feedback.

Equation（4）can be simplified as

$$x=\frac{A_d}{K_{d0}A_d^{'}}\frac{1}{\frac{1}{k'}\left(\frac{s^2}{n^2}+\frac{2Ds}{n}+1\right)s+1}u_0 \tag{5}$$

Where

$$\begin{cases} A_d^{'}=\dfrac{kA_p}{k_q K_{d0}}=\dfrac{k'A_p}{k_q K_{d0}}\dfrac{k}{k'} \\ A_v^{'}=\dfrac{A_p}{k_q K_{v0}}\left(\dfrac{k}{k'}-1\right) \\ A_a^{'}=\dfrac{A_p}{k_q K_{a0}}\left(\dfrac{2D}{n}\dfrac{k}{k'}-\dfrac{2D_0}{n_0}\right) \\ A_j^{'}=\dfrac{A_p}{k_q K_{j0}}\left(\dfrac{1}{n^2}\dfrac{k}{k'}-\dfrac{1}{n_0^2}\right) \end{cases} \tag{6}$$

$$\frac{1}{n^2}=\frac{\left(1+\frac{k_q K_{j0}A_j^{'}n_0^2}{A_p}\right)}{1+\frac{k_q}{A_p}K_{v0}A_v^{'}}\frac{1}{n_0^2} \tag{7}$$

$$\frac{2D}{n}=\frac{1}{1+\frac{k_q}{A_p}K_{v0}A_v^{'}}\left(\frac{2D_0}{n_0}+\frac{k_q K_{a0}A_a^{'}}{A_p}\right) \tag{8}$$

The equation(7) shows that：

（1）when $K_{v0}A_v^{'}=K_{j0}A_j^{'}n_0^2$, $n=n_0$

（2）when $K_{v0}A_v^{'}>K_{j0}A_j^{'}n_0^2$, $n>n_0$

（3）when $K_{v0}A_v^{'}<K_{j0}A_j^{'}n_0^2$, $n<n_0$

The equation(8) shows that：

When without velocity feedback nor jerk feedback

$$\frac{2D}{n}=\left(\frac{2D_0}{n_0}+\frac{k_q K_{a0}A_a^{'}}{A_p}\right) \tag{9}$$

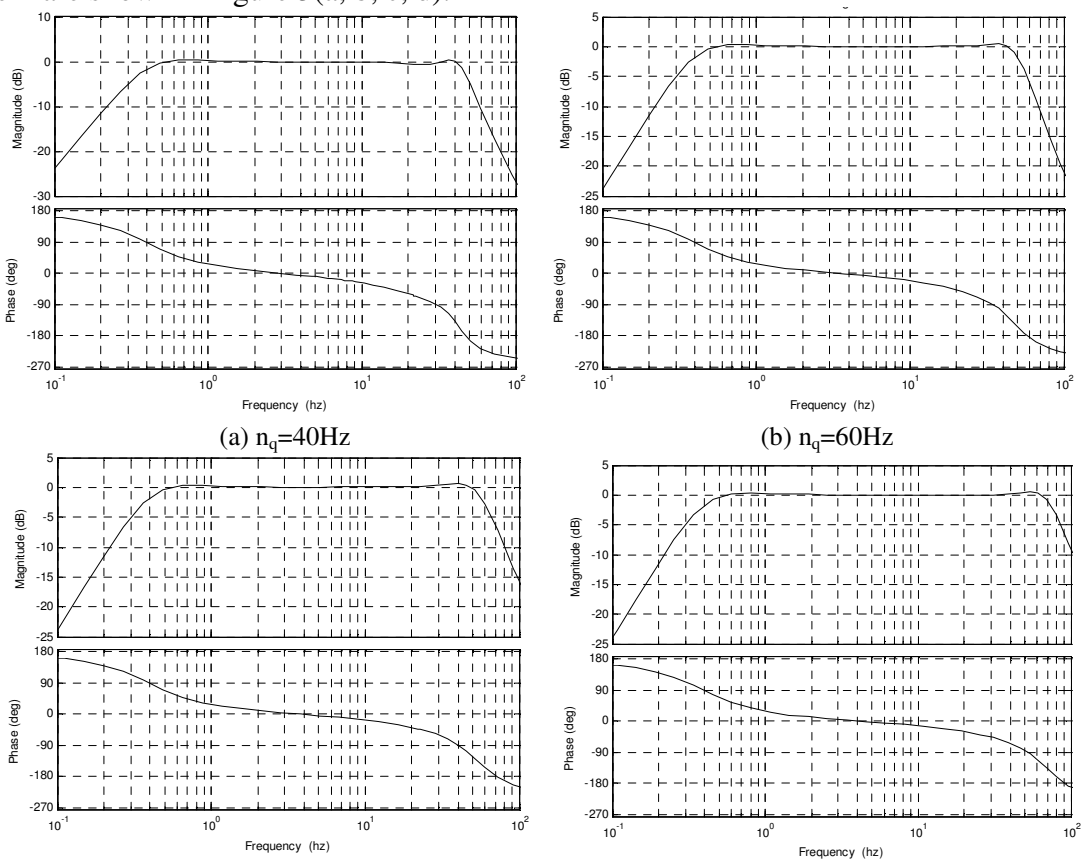
As the existence of the velocity feedback, thus

$$\frac{1}{1+\frac{k_q}{A_p}K_{v0}A_v^{'}}<1 \tag{10}$$

The introduction of jerk is no influence on the system damping, so we can adjust $A_a^{'}$ to reach the needed damping ratio, increase the damping ratio of system, which can improve the oil column resonance frequency and improve the system stability.

**System analysis with different bandwidth of servo valve**

In the control of multiple s with the jerk feedback, analysis was made using the shaking table system with different bandwidth of servo value (40Hz, 60Hz, 80Hz and 100Hz). The frequency responses of the system are shown in figure 3(a, b, c, d).



(a) $n_q$=40Hz (b) $n_q$=60Hz

(c) $n_q$=80Hz (d) $n_q$=100Hz

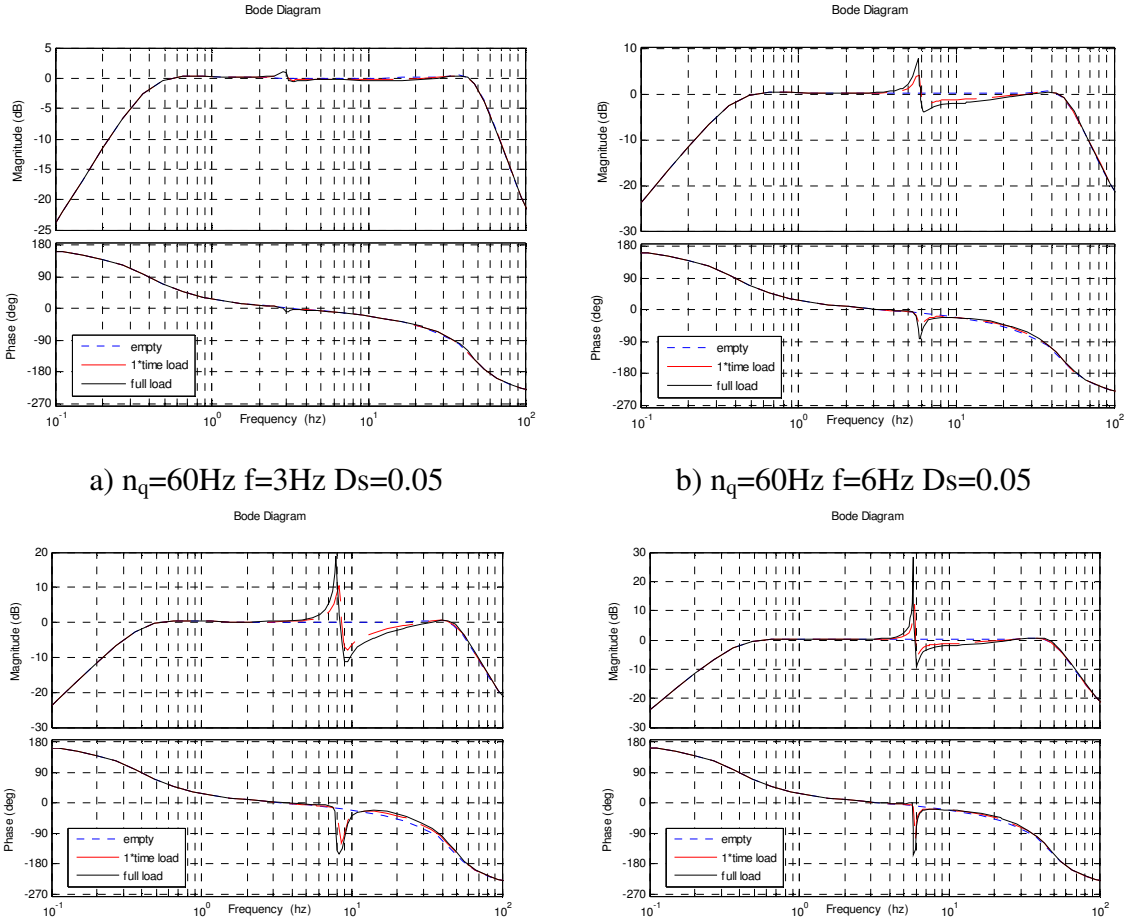
Fig.3 The frequency responses of the system with different bandwidth of servo valve

The Fig.3 shows that the oil column resonance frequency is decreased by the jerk feedback, and the influence of system performance caused by the servo value is reduced. With the multiple control, the system bandwidth is from 0.4Hz to 40Hz when the servo valve frequency is 40Hz, the system bandwidth is from 0.4Hz to 50Hz when the servo valve frequency is 60Hz, the system bandwidth is from 0.4Hz to 65Hz when the servo valve frequency is 80Hz,and the system bandwidth is from 0.4Hz to 75Hz when the servo valve frequency is 100Hz. Obviously, compared with the three-variable control, the jerk feedback can decrease the oil column resonance frequency, reduce the influence of shaking table performance caused by the servo value, thus broaden the system bandwidth.

**System analysis with the interaction between specimen and mesa**

Regarding the specimen as a single degree of freedom, we analyze the system considering the interaction between specimen and mesa on the basis of multi-variable control. We take the system which the $90^o$ phase shift frequency of the servo valve system is 60Hz as an example. The parameters of the system are, $A_d=0.375$ , $A_v=3.01\times10^{-2}$ , $A_a=1.08\times10^{-2}$ , $A_v^{'}=0$ , $A_a^{'}=1.1\times10^{-2}$ , and $A_j^{'}=1.0\times10^{-2}$. The natural vibration frequency of the specimen is 3Hz, 6Hz, or 9Hz. The

damping ratio is 0.05 or 0.02, and the masses of the specimens are different. The frequency responses of the system considering the specimen as a single degree of freedom are shown in figure 4(a, b, c, d).



a) $n_q$=60Hz f=3Hz Ds=0.05 b) $n_q$=60Hz f=6Hz Ds=0.05

c) $n_q$=60Hz f=9Hz Ds=0.05 d) $n_q$=60Hz f=6Hz Ds=0.02

Fig.4 The frequency responses of the system with different specimens

The Fig.4 shows that

(1)Due to interact between specimen and mesa, the system produced a resonance which can impact the signal output of the mesa. The size of the peak is proportional to the quality and the frequency of specimen, and inversely proportional to the damping ratio of specimens.

(2) The oil column can be reduced by adding the jerk feedback, the influence of the system performance caused by the servo valve characteristics can be decreased, and the frequency band of the system can be broadened.

(3) With the multi-variable control, the system in the high frequency region is stable.

## Simulation of shaking table with multi-variable control

According to the transfer function of the shaking table with the multiple control and the shaking table (3m×3m) of the key laboratory of earthquake engineering and structural retrofit(the shaking table performance is shown in table 1), build the control system simulation model in the MATLAB / Simulink, take the wave of El-centro for an example to simulate. The result of simulation is shown in figure 5. Under the multiple control with jerk feedback, the response waveform of shaking table and the expected waveform are in good agreement, its control effect is better than three-variable control. Multi-variable control is very good to improve the control precision of the system.

Table 1 Shaking table performance

| | | | |
|---|---|---|---|
| Platform size | 3m×3m | Counter weight | 6Ton |
| Peak load | 10Ton | Maximum displacement | ±10cm |
| Maximum speed | 60cm/s | Maximum acceleration | 2.0g（Full load）<br>0.9g（empty） |
| Frequency range | 0.1～50Hz | Control mode | acceleration control |
| Working mode | One-way of the level | Wave | Sine、Random、seismic wave |

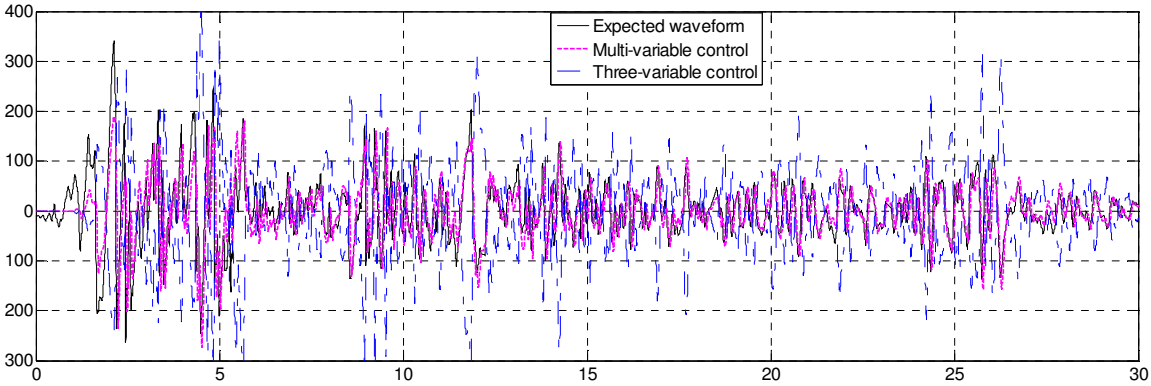


Fig.5 Acceleration time-history curve of the shaking table with multi-variable control

## Conclusions

The influence of the performance of the shaking table system caused by the bandwidth of servo valve was analyzed in this paper. The shortcomings of the existing three-variable control were pointed out. We have put forward a multi-variable control by adding the jerk feedback. Considering the interaction between specimen and mesa, we analyzed the shaking table with the multi-variable control. We draw the following conclusions.

(1) The multi-variable control system was formed by adding the jerk feedback to the three-variable control system. For the system which the $90^{o}$ phase shift frequency of the servo valve system was close to the oil column resonance frequency, the oil column can be reduced by adding the jerk feedback, the influence of the system performance caused by the servo valve characteristics can be decreased, and the frequency band of the system can be broadened.

(2) Considering the interaction between specimen and mesa, the feature of the system in the high frequency area was still relatively ideal. The system was in steady state with the multi-variable control.

(3) Based on the application of the jerk feedback on the shaking table, we have carried on the theoretical derivation and simulation analysis, however, the application still need much testing in practice.

**Keywords:** Lushan Ms7.0 earthquake, data processing, baseline correction, attenuations of PGAs

**Abstract.** At 8:02 a.m. Beijing time on April 20, 2013, an Ms 7.0 earthquake shook the city of Ya'an, China. Until 24:00:00 on 20 July 2013, a total of 339 strong-motion records from 113 free-field stations, 21 records from 1 strong-motion structure array and 1123 groups of aftershock records have been collected, processed and analyzed preliminarily by the China Strong Motion Network Center (CSMNC) in this paper. There are more than 26 stations located within Longmenshan fault zone and all peak ground acceleration (PGA) of records is larger than 50gal. The PGA of Baoxingdiban station reaches 1005.4 gal after zero-line initialization, which firstly breaks through 1g in the mainland of China. Based on the mainshock records, shakemaps of those PGAs are plotted and attenuation relationships of PGAs are presented in this article.

## Introduction

The Lushan earthquake occurred at 8:02 on April 20, 2013 in Sichuan, China, which caused a highly destructive and shallow source earthquake(Ms7.0) with hypocenter located at 30.3°N and 103.0°E at a depth of 13km after "5.12" Wenchuan earthquake. Positioning and earthquake focal mechanisms results show that the earthquake occurred on the Longmenshan fault zone belonging to thrust earthquakes. The fault zone is the boundary line between Plateau block in intense activity and Sichuan Basin blocks in weaker activity, which cuts along the northwestern margin bottom of the Sichuan Basin with 400km in width and 60km in length. And it is a huge tectonic belt with complex scale type. Longmenshan fault zone is constituted by four major faults, which is respectively after the Longmenshan fault (Wenchuan-Maowen fracture), the central fracture (Kitagawa-Yingxiu fracture), the former Hill fault (Guanxian-Jiangyou fracture) and Piedmont buried fault from west to east[1].It is in the southern tip of the Longmenshan fault zone which controls the rupture of Lushan earthquake. The location did not rupture slip when the Wenchuan earthquake occurred. And it is the strongest earthquake have occurred in the Longmenshan fault zone since Wenchuan earthquake[2] . Mainshock and aftershocks distributed in the Pengxian-Guanxian fault lying in the southwestern tip of the Longmenshan fault zone, also located in Coulomb stress increasing region after the Wenchuan earthquake, and both focals are of the similar nature with the major of thrust[3].

Until July 20th, 2013, there has been a total of 114 stations obtaining strong motion records in Lushan earthquake, which distributed in Sichuan, Yunnan, Gansu and Shaanxi province, 83 groups of records are obtained in Sichuan, 27 groups in Yunnan included 7 groups of structure array records, 8 groups in Shaanxi and 2 groups in Gansu, and there were 177 earthquakes which triggered strong motion stations, including 18 times lower than M3.0, 109 times between M3.0 and M4.0, 45 times between M4.0 and M5.0, 4 times between M5.0 and M6.0, and only once of M7.0. There were four times for M5.4 aftershocks within 33 hours after the mainshock. Earthquake sequences distribution is shown in Fig.1, and Lushan earthqukes distribution is shown in Fig.2.

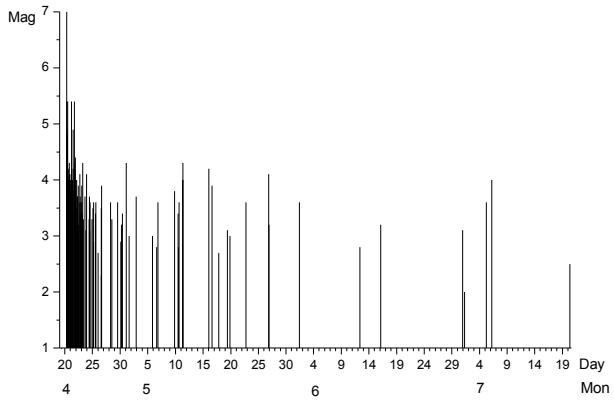

Fig.1 Lushan Earthquake mainshock and aftershocks sequence records

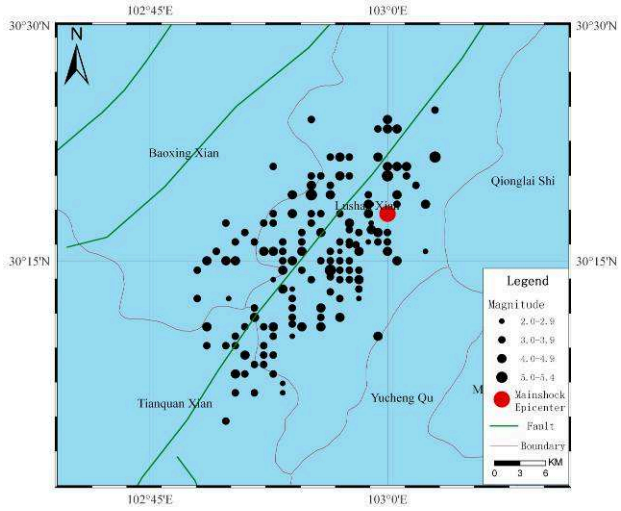

Fig.2 Lushan mainshock and aftershocks epicenter distribution with strong motion

## Collection, Arrangement and Statistical Analysis of Acceleration Records

In Lushan Ms7.0 earthquake, there were totally 120 groups of strong motion events with epicentral distance from 18.5 to 771.2km, which were obtained from Sichuan, Yunnan, Gansu and Shaanxi province. Fixed stations distribution obtaining records is shown in Fig.4. Baoxingdiban strong motion station received the maximum peak ground motion 1005.4gal, and this is the first strong motion record in excess of 1g in the mainland of China. There were 339 strong motion records obtained by strong ground motion station, and the static of peak ground motion is shown in Fig.3. There are totally 22 strong motion records with PGA above 200gal, and 238 strong motion records with PGA below 25gal. There are totally 21 strong motion records obtained by structure array. And there are 21 strong motion records with epicentral distance within 50km shown in table 1. All these stations are equipped with digital instruments with Etna, K2, GSR-18 or MR-2002 type. And most of these instruments apply the SLJ-100 type force-balanced-accelerometer sensors, only few Etna-type strong-motion seismographs are equipped with the ES-T type force-balance-accelerometer sensors. In the records, the frequency range of these seismographs is 0-80Hz, and the sampling rate is 200sps generally. 20 seconds is regarded as pre-event time[4].

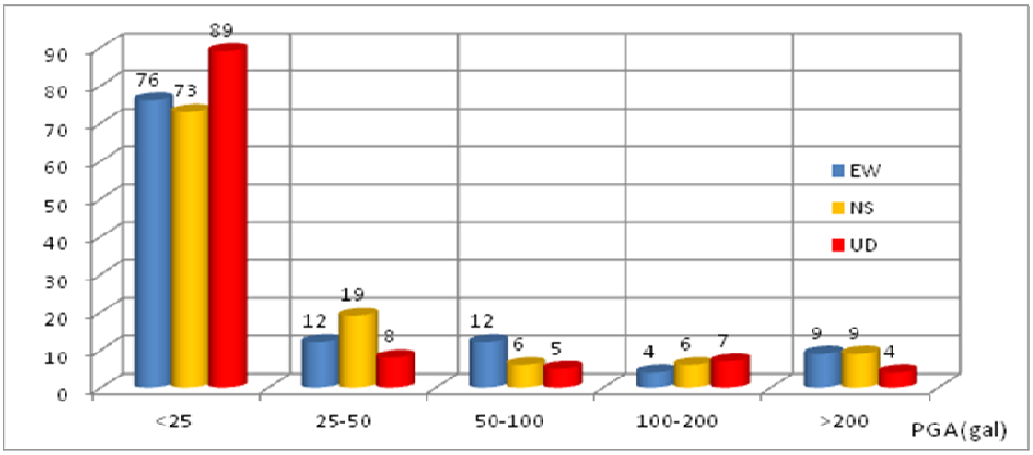

Fig.3 Peak ground acceleration statistics in strong ground motion stations

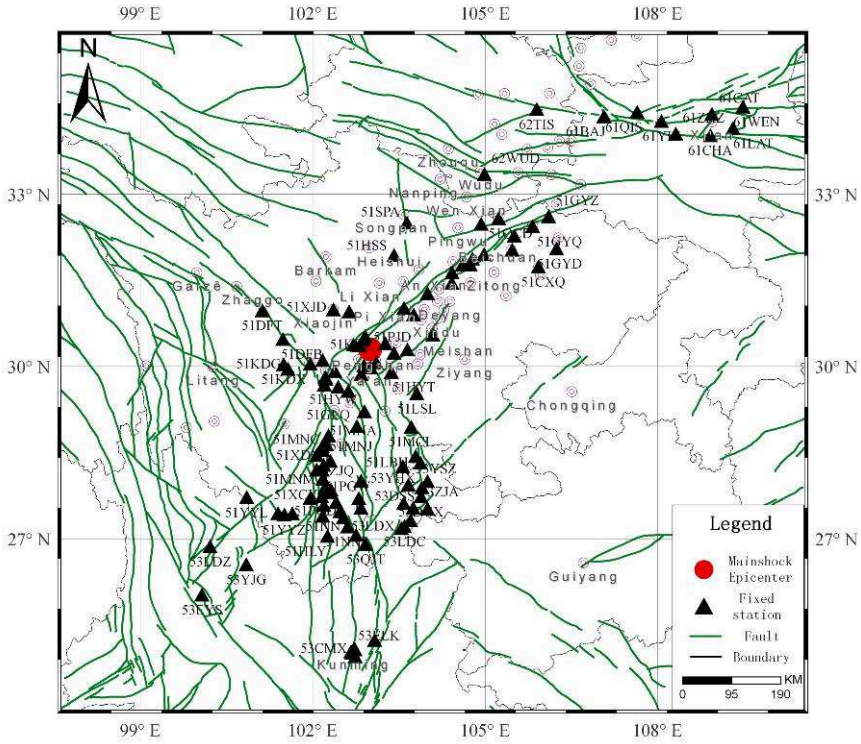

Fig.4 Fixed stations distribution with records obtained from the Lushan $M_S$7.0 Earthquake

when the short-term and imminent prediction of a large earthquake has been released or an earthquake has occurred, the emergency response of the mobile strong ground motion observation is required, which will be essential for capturing the mainshock or the aftershock records[5].After the occurrence of the Lushan earthquake, Sichuan Province Seismological Bureau, Yunnan Province Seismological Bureau (Southwest Regional Strong Motion Network Center) and Hubei Provincial Seismological Bureau carried out 9 strong motion mobile observation points rapidly, while they kept adjusting mobile stations position based on aftershocks distribution and trend so as to obtain strong motion records as precious as possible.

Until July 20, 2013, the National Strong Motion Network received a total of 1123 groups of three -component aftershocks strong motion records from fixed and mobile observation stations. There are 965 groups of strong motion records obtained by Sichuan Province fixed strong motion stations in 91 aftershocks. Southwest Regional Strong Motion Network Center and Hubei Provincial Seismological Bureau has obtained 144 and 14groups of acceleration records respectively in mobile observation stations. Epicentral distances of these aftershocks are from 0.85 to 312.10km. The maximum peak ground acceleration reaches 576.9gal in Lushanfeixian station.The number of strong motion records between M4.0 and M5.0 has reached 48.9 % of total records, while the number of strong motion records more than M5.0 only reaches 12.2 % of total records.

## Data-Processing of Strong Motion Records

The data-processing of strong motion records from this earthquake is carried out by CSMNC, which establishes the conventional procedure: recycling strong motion records and records report card from provincial bureau, preliminary sorting, transition and unification of data-format, metadata entry, zero-line correction of the original strong motion records and uncorrected acceleration time histories plotted in uniform-format routinely. Specifically, the correction process includes Fourier spectrum, response spectrum and the signal to noise ratio of the spectrum analysis. The steps of zero-line correction are as follows:

1. Calculate the average acceleration of the pre-event time of the original acceleration record;
2. The average acceleration is removed from the original acceleration record.

### The Attenuation Relationships of PGAs in Lushan Mainshock

The focal mechanism and finite-fault model for the Lushan earthquake released by Wang Weimin[3] are adopted in this article to calculate the rupture distances (the shortest distance between the station and the fault plane) of 83 stations. Based on the records and the corresponding rupture distances, the attenuation relationships of PGAs can be developed. The ground motion model used in this article is as Equation 1:

$$\log_{10}(PGA) = a + b * \log_{10}(D_{rup} + c) \quad (1)$$

Where PGA denotes the peak ground acceleration in gal; Drup denotes the rupture distance in km; a, b and c are the coefficients to be determined using the method of least-squares and the values of them are listed in Table 1, where σ denotes the regression standard deviation. The corresponding regress curves of three-component PGAs for Lushan earthquake are plotted in fig.5.And comparations of PGAs for three components in the Lushan mainshock are shown as fig.6. With the fault distance increasing, ratios of horizontal PGAs to vertical ones grow larger. However, ratios of EW PGAs to vertical ones are in attenuation trend. For fault distance within 135.3 km, PGAs in EW direction are larger than ones in NS direction. And ratios distributions for horizontal PGA to vertical ones for near-fault stations are shown in fig.6.

Table 1 The list of regression parameters

| direction | a | b | c | σ |
|---|---|---|---|---|
| EW | 4.73016 | -1.52593 | 14.13163 | 0.29422 |
| NS | 4.64835 | -1.48638 | 15.10284 | 0.32145 |
| UD | 4.49273 | -1.54794 | 15.05708 | 0.27166 |

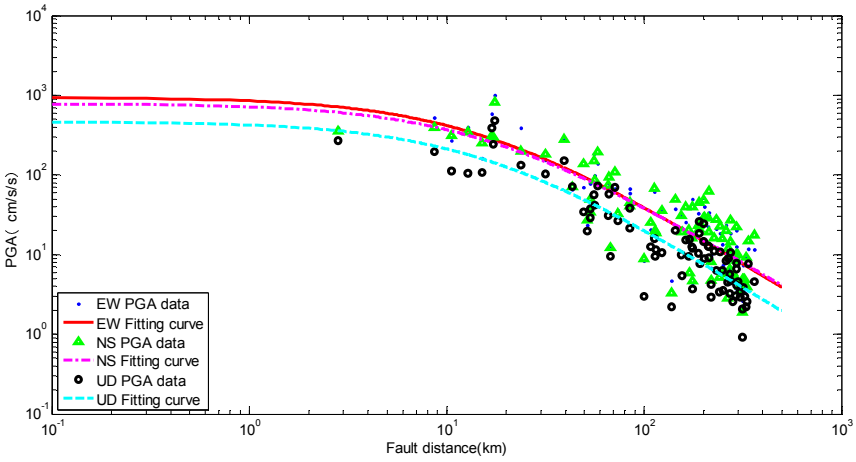

Fig.5 The Lushan earthquake specific regress curves of PGA for the three components

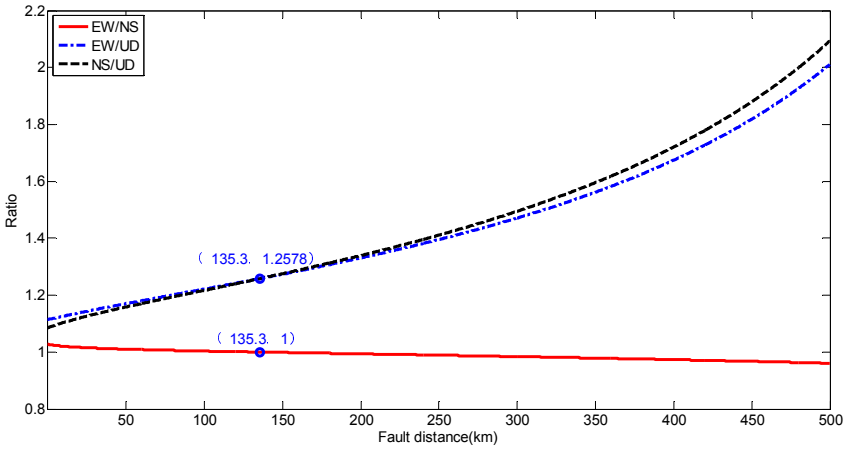

Fig.6 Regress curves comparations of PGA for three components in the Lushan mainshock

## Conclusions

There was another higher magnitude earthquake occurred in Longmenshan fault after the Wenchuan earthquake, and a amount of strong ground motions were obtained by fixed and mobile strong motion stations, which provide an unprecedented opportunity to study the attenuation relationships of strong motion parameters, to revise the seismic ground motion parameter zonation map, and to re-determine the design ground motion parameters. Based on the preliminary analysis in this paper, the following conclusions can be drawn:

1. In the Lushan mainshock, there are totally 120 groups of strong motion records with epicentral distance from 18.5 to 771.2km, among which there are 21 strong motion records obtained by structure station. And a total of 1123 groups of three-component strong motion records from fixed and mobile observation stations in aftershocks.
2. PGA from Baoxingdiban strong motion station reaches 1005.4 gal after zero-line initialization, which fills in the domestic gap in the near-fault strong motion records breaking through 1g.
3. With the fault distance increasing, ratios of horizontal PGAs to vertical ones grow larger, however, ratios of EW PGAs to vertical ones are in attenuation trend. For fault distance within 135.3 km, PGAs in EW direction are larger than ones in NS direction.
4. The large number of records obtained in this event greatly enriches strong motion resourses in Longmenshan and enlarges the database of strong motions in China.

**Keywords:** Mw9.0 Tohoku Earthquake, baseline correction, permanent displacement, Hermit interpolation.

**Abstract.** Permanent displacement identification is one of key topics in near-fault ground-motion research. A new method based on Hermit interpolation and flatness technique is proposed to determine permanent displacements, since the Iwan law is not applicable in Mw9.0 Tohoku earthquake permanent displacement recognition. The method is then tested by coseismic displacements resulted from GPS station nearby. Results show that: the causes for strong motion record baseline drift are very complex so that Iwan method is not suitable for permanent displacements identification in the Mw9.0 Tohoku Earthquake, while the new baseline correction method combining Hermit interpolation and flatness technique is suitable for permanent displacement analysis of near-fault ground motion in 2011 Mw9.0 Tohoku Earthquake.

## Introduction

Japan was struck by a magnitude 9.0 earthquake off its northeastern coast of Honshu at 05:46:23 UTC on March 11, 2011. This is one of the large earthquakes that Japan has ever experienced. The earthquake off the Pacific coast reached Mw9.0 with a focal depth of 24km, and the epicenter was located at latitude 38.1° and longitude 142.9°, which is called Mw9.0 Tohoku Earthquake by Japan Meteorological Agency (JMA) [1]. Obvious horizontal and vertical coseismic displacements received by GPS stations are found by Japanese scholars. In addition, when a strong earthquake happens, engineering structures will suffer from damages due to the permanent ground displacements which have been confirmed in 1999 Chi-Chi earthquake, 2008 Wenchuan earthquake, 2010 Chile earthquake and 2010 New Zealand earthquake.

Due to mutual compression deformation, dislocation or base damage, structures and lifeline system will suffer from damage, collapse or fracture[2]. And even soil liquefaction will occure[3]. The most active and effective measure is to make good seismic design of construction projects in order to reduce future earthquake disaster[4]. Jonathan has analysed earthquake damage on structures, and pointed out that permanent displacements were associated with shallow underground fault dislocation closely. Therefore, in order to discuss the earthquake disaster, permanent displacement associated with strong ground motion is an important research topic. Reasonable theory should be adopted in combination with strong motion data to identify permanent ground displacements to provide necessary reference for the study of earthquake focal mechanisms and engineering seismology.

Baseline correction on near-fault acceleration records has to be applied before further study. Baseline correction methods have been studied by many scholars. Graizer[5] was the first one to advocate the use of least-square fit of baseline correction. Iwan[6] applied a two-point method improved by Boore[7] and Boore & Bommer[8]. Chiu[9] used high-pass filter before integrating acceleration.Wu[10] has also made some improvements on Iwan method to process Chi-Chi

earthquake strong-motion data. Boore & Akkar[11] discussed and presented a new baseline correction scheme based on Monte Carlo technique, and used the noise model to simulate baseline changes. Wang Guoquan[12] offered a new way to correct baseline on the 1999 Chi-Chi mainshock. HaiYing Yu[13] made baseline correction repeatedly on the Wenchuan earthquake near-fault strong motion records. Zhao[14] also proposed a new baseline correction method by using excel spreadsheet. Most baseline correction methods assume that change occurs in limited time points, but it is not easy to automate, and often requires human intervention so as to cause the data processing results vary with different researcher. Therefore, it is the core that how to eliminate baseline drift in strong motion records and give a reasonable approach to identify permanent displacements for the near-fault strong motion data processing. Strong motion stations within 5km away from GPS stations are selected to conduct the study of permanent displacements in the 2011 Mw9.0 Tohoku Earthquake[15]. Iwan law is studied for permanent displacements analysis, and a new identification method is presented to conduct the comparative study with GPS data offered by JPL and California Polytechnic ARIA research team.

**Reasons for Baseline Drift**

One of the fundamental topics on the near-fault earthquake data processing is how to determine the reasonable position and the extent of the baseline drift in acceleration, velocity and displacement so as to provide theoretical basis for correction methods. So much in-depth research on baseline drift has been carried out by many scholars. Hudson[16] agreed that digitization of records, bending and lateral deformation of the recording paper mainly affects middle-period and long-period strong motion records. Trifunac[17] has found that the baseline drift in analog records would occur and the fixed baseline would no longer be a straight line if the recording paper was in irregular lateral movement. Then a fixed baseline waveform reflects the relative lateral recorder irregular movement, which formed strong motion acceleration noise. The development of digital strong motion accelerometers promotes the rapid development of data processing. Although strong motion instruments have been improved greatly on sensitivity, dynamic range, and stability, which has promoted a significant improvement in data quality, however, Chiu [9] has believed that most of the baseline error in analog records still exists in the data with high resolution and high sampling rate. These errors include a constant acceleration baseline drift, low-frequency instrument noise, low-frequency background noise, the initial value in acceleration and velocity, and human error. In summary, the digital strong motion records baseline drift is due to inaccurate response from the instrument, fatigue electromagnetic noise, sensor material, background noise and ground tilt or rotate and bring the pollution of ground vibration signal[12]. But, in fact, reasons for baseline drift are often uncertain. The mechanism of baseline drift is not clear as well adequate tests and the theoretical basis are not enough, therefore, the baseline correction is still an important topic in strong motion data processing.

**Iwan Method**

In 1985, Iwan and other researchers studied PDR-1 and FBA-13 series digital strong motion instruments through experiment and found that baseline drift of acceleration records came from sensor hysteresis with a hysteresis threshold 50gal[18]. Accordingly, the acceleration process was divided into three parts, i.e., the first part which starts from the record beginning till the first reach of greater than50gal; the third part from the last reach of greater than 50gal till the end of the record; and the middle strong motion part in between. Each part of the baseline offset was a constant while the baseline drift occurred in strong vibration stages. The recording process is comprised of two offsets representing the average changes. The physical basis of which is initial acceleration, velocity and displacement is zero; the average velocity should be close to zero at the end of ground motion, the displacement should be zero if no permanent displacement occurred in strong motion stations, on the contrary, displacement should end with the trend of paralleling to the time axis approximately. This method is the first used to test methods determining the cause of baseline drift for digital strong

motion record with great objectivity systematically. Therefore, we apply the method in making baseline correction on 2011 Mw9.0 Tohoku Earthquake strong motion records selected from the k-net Network within 5km from GPS stations. Related data is shown in Table 1. It is not difficult to find that permanent displacements and coseismic displacements are not satisfactorily consistent and even opposite sign appears. For data in Table 1, the permanent displacement extracted from station AKT006 is well consistent with coseismic displacement from GPS stations nearby, however, the east-west permanent displacement is 33.6cm while the coseismic displacement reaches 50.21cm, leading to a relative displacement error 33.08%. The north-south permanent displacement is only -30.71cm, but the coseismic displacement recorded by GPS station reaches -43.68cm, and the relative displacement error is 29.69%. Related displacement time history is shown in Fig. 1.

Since the vertical peak acceleration does not exceed 50gal, the Iwan method is not used. For most strong motion stations, the displacement relative error is too high as to 296% with respect to the GPS stations nearby. Therefore, Iwan law does not apply to permanent displacement identification in Japan M9.0 near-fault strong motion record.

Table 1 Coseismic displacements and permanent displacements for 2011 Tohoku earthquake(Iwan)

| No. | Measure Direction | GPS station code | Coseismic Displacement [cm] | Strong motion Station code | Permanent displacement [cm] | Sphere Distance [m] | Displacement Error（%） |
|---|---|---|---|---|---|---|---|
| 1 | EW | 183 | 50.21 | AKT006 | 33.6 | 26.40 | 33.08 |
| | NS | | -43.68 | | -30.71 | | 29.69 |
| | UD | | 2.90 | | / | | / |
| 2 | EW | 928 | 152.94 | AKT023 | 65.67 | 166.60 | 57.06 |
| | NS | | -79.31 | | -19.86 | | 74.96 |
| | UD | | -4.51 | | 8.86 | | 296.45 |
| 3 | EW | 158 | 36.98 | IWT001 | 2.05 | 726.80 | 94.46 |
| | NS | | -42.06 | | -14.22 | | 66.19 |
| | UD | | -3.08 | | 0.2 | | 93.51 |

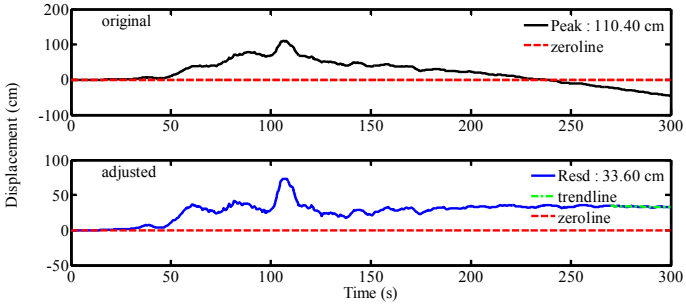

Fig.1 Displacement time history before and after correction(Iwan)

## Hermit Interpolation Baseline Correction Method

In order to prevent the loss and distortion of related time history information, baseline correction methods instead of filtering methods have to be applied for strong motion data processing. Due to complicated acceleration baseline drift with rich high-frequency components, it is very difficult to determine the location and extent of baseline drift accurately in acceleration time history, instead velocity time history can be used. Generally, the baseline of velocity time history is not in linear trend.. Moreover, the baseline trend is more complex in strong shock, so it is difficult to determine its basic shape. One thing is certain that the process of baseline change was continuous, that is, the time history is continuous and derivative. The change process of baseline is smooth instead of abrupt. In order to ensure a better interpolation polynomial approximation to target function, some constraints should be made that interpolation polynomial junction should have the same derivative values with the objective function. As a polynomial interpolation, cubic interpolation function is enough, since

Runge phenomenon is likely to occur with high power number. Therefore, the two-points cubic Hermite interpolation method is used for n+1 orders interpolation problem. And then a piecewise linear interpolation curve connecting two line segments is used to make the transition point continuous and first-order derivative.

In addition, the following assumptions are made:(1) the end and beginning value should be zero or close to zero for acceleration and velocity time histories, and there should not be a obvious baseline drift; (2) PGD does not appear at the end of displacement time history, which located corresponding to the time of PGA or PGV substantially; (3) the displacement trend will tend to approximately parallel to the time axis. The flatness is selected as the judgment parameter to determine the final permanent displacement reasonably as Wu and Wu [19].

Calculation results are shown in Table 2. Relative error is less than 15% for East-West component. Taking staion AK006 for example, the permanent displacement is 46.86cm while the coseismic displacement of GPS station nearby is 50.21cm, that is, the displacement error is only 6.67%. The displacement time histories is shown in Fig. 2. Of course, the vertical permanent displacement is relatively large, which is possibly related to the observed vertical GPS observation defects greatly.

Table 2 Coseismic displacements and permanent displacements for 2011 Tohoku earthquake(Hermit)

| No. | Measure Direction | GPS station code | Coseismic Displacement [cm] | Strong motion Station code | Permanent displacement [cm] | Sphere Distance [m] | Displacement Error（%） |
|---|---|---|---|---|---|---|---|
| | EW | | 50.21 | | 46.86 | | 6.67 |
| 1 | NS | 183 | -43.68 | AKT006 | -49.13 | 26.40 | 12.48 |
| | UD | | 2.90 | | 8.69 | | 199.66 |
| | EW | | 152.94 | | 169.59 | | 10.89 |
| 2 | NS | 928 | -79.31 | AKT023 | -73.06 | 166.60 | 7.88 |
| | UD | | -4.51 | | -2.90 | | 35.7 |
| | EW | | 36.98 | | 31.89 | | 13.76 |
| 3 | NS | 158 | -42.06 | IWT001 | -52.90 | 726.80 | 25.78 |
| | UD | | -3.08 | | -16.92 | | 449.35 |

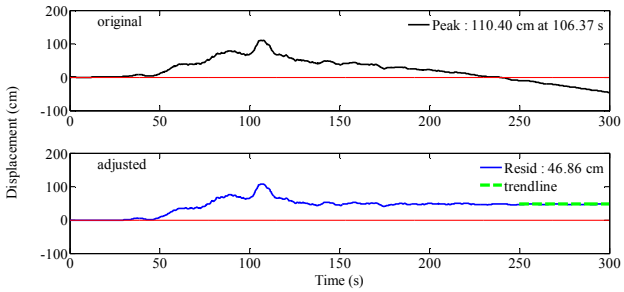

Fig.2 Displacement time history before and after correction(Hermit )

## Conclusions

Through analyzing the causes for strong motion records baseline drift using the strong motion records obtained from within 5km from GPS stations in 2011 Mw9.0 Tohoku Earthquake, we found that the Iwan I law is inapplicable to recognize the permanent displacement so that a combining method of Hermit law and flatness technique is proposed. Main points can be outlined as below.

1. The baseline drift mechanism of record is complex and presently still difficult to determine.
2. The Iwan law is only suitable to analyze the near-fault strong motion records for PDR-1 and FBA-13 stations while it is unable to identify the permanent displacement in 2011 Mw9.0 Tohoku Earthquake.
3. The Hermit interpolation baseline correction method combined with flatness technique has been proved to be efficient to recognize the permanent displacement in Japan.

**Keywords:** shaking table, Parameter Tuning, System Identification, Simulation Validation

**Abstract.** The control parameter of shaking table is one of the key elements which significant influence on the system control performance. An algorithm which uses the model of system identification to theoretically calculate the control parameter is put forward, and then obtains the optimal three-parametric control parameter based on theoretical calculation. Tuning algorithm can get more ideal control parameter and could be applied in shaking table TVC parameter self-tuning.

## Introduction

Shaking table is one of the reliable key instruments in the field of Earthquake Resistant Engineering[1]. The tuning of shaking table control parameter is an important link during its debug process. In general, shaking table often adopts three-parametric control algorithm, thus the rational setup of three-parametric control parameter is essential for shaking table to give play to its control performance[2]. Rational three-parametric control parameter combination can broaden effective bandwidth for a system; on the contrary, it will be very hard to get preconceived control effect and it's possible to lead to shaking table's self-excitation and the damage of equipment[3]. The tuning of shaking table control parameter includes theoretical tuning and empirical tuning. Theoretical tuning calculates controller's control parameter with theoretical derivation based on mathematical model of controlled object. Yang Zhidong[4] employs root-locus method, with graphic mode, to describe all the six parameters' numerical relationship of shaking table closed-loop system pole with feedforward and feedback, but practical system model is very different from theoretical model, and the calculation process is complicated and tedious, which often results in big deviation of the parameter obtained through this method. empirical tuning is concluded by engineering technicians through lots of practice and is based on existing experience. Han Junwei[5] utilizes matching principle of practical frequency characteristic to shaking table system control parameter to conduct theoretical and experimental research. The result shows that tuning principle can guarantee the optimal working state of shaking table; but the tuning process needs a mass of repeated tuning, which is time-consuming and energy-consuming. For a particular control system, a series of tuned control parameters are only suitable to certain working condition, while the practical working condition is changing following the change of controlled object and environmental factors. Therefore, this paper makes use of least square method identification system parameter and combines with theoretical calculation method to gain the optimum control parameter.

## System analysis

### Control principle of shaking table

The system composition of shaking table under the three-parametric control is shown in the Fig. 1 that the displacement, speed and acceleration signal generated by the earthquake wave through three-parametric generators, along with the displacement, acceleration feedback signal collected by sensor, and acceleration feedback signal compounded by the aforementioned two signals form

closed-loop system, which converts electrical signal into hydraulic signal through servo valve, and then drives hydraulic servo cylinder and propels table-board of shaking table and model specimen to vibrate according to the expected signal law[6]. On account of hydraulic control theory, the open-loop transfer function of shaking table can be shown in formula (1).

$$G(s)=\frac{K_v}{s(\frac{s^2}{n_0^2}+\frac{2D_0 s}{n_0}+1)} \tag{1}$$

where, $n_0$ is inherent frequency of hydraulic system; $D_0$ is camping ratio of hydraulic system.

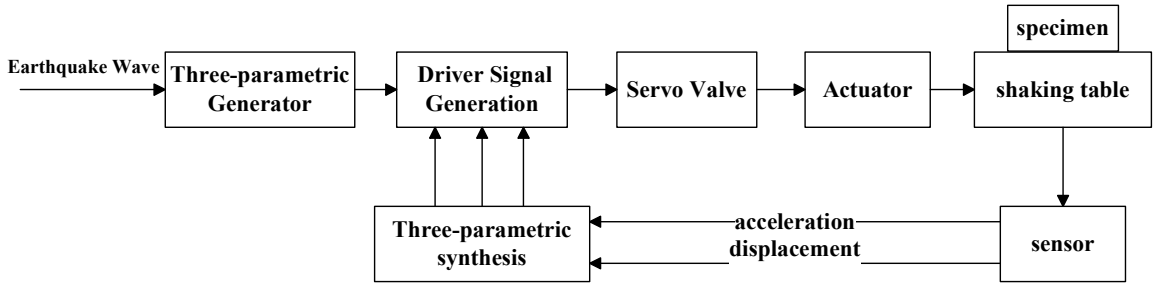

Fig.1 System Composition of Shaking Table

Three-parametric controller is an important constituent part of shaking table control system. Three-parametric control algorithm is to offset the disadvantages of limited bandwidth and damping of shaking table in simple displacement control, so as to better realize acceleration, speed and displacement control in different frequency bands. In three-parametric control, displacement controls low-frequency stage, speed commands mid-frequency stage and acceleration controls high-frequency stage, fulfilling the aim of enlarging system stamping and broadening system frequency band[7,8].

Controller is composed of three-parametric feedback control and feedforward control. Three-parametric feedback controller increases system stamping ratio and resonant frequency, broadens system frequency's sphere of application and strengthens system stability through regulating three feedback coefficients of $k_{af}$, $k_{vf}$ and $k_{df}$. Three-parametric feedforward controller adjusts three feedforward parameters of $k_{ar}$, $k_{vr}$ and $k_{dr}$ to get the cancellation of pole near imaginary axis in closed-loop transfer function, which can further broaden system working bandwidth. Three-parametric control principle schematic diagram is shown in the Fig.2. In the chart, $d_0$ and $v_0$ are two parameters of rejector, and VelSyn is speed synthesizer module.

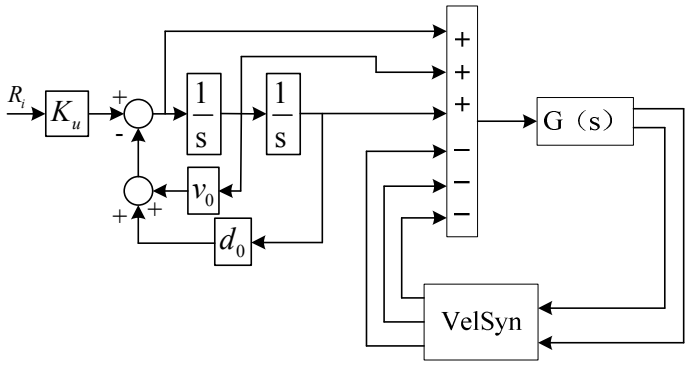

Fig. 2 Three-parametric Control Principle Schematic Diagram

**System analysis Self-tuning based on system identification**

**System analysis under the single influence of displacement feedback**

Since the shaking table adopts acceleration control method, the system can not locate in the situation of open-loop, traditional PID parameter tuning algorithm can not be directly applied in the tuning of shaking table system, thus, under mere feedback of displacement, the block chart of the system is shown in Fig.3. Transfer function corresponding to chart Fig.3 is shown in formula (2).

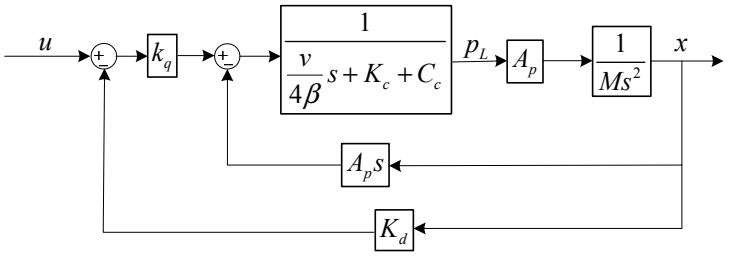

Fig.3 System Transfer Function under Displacement Feedback

$$\frac{x}{u}=\frac{1}{K_d}\frac{1}{\frac{A_p}{k_q K_d}(\frac{s^2}{n_0^2}+\frac{2D_0 s}{n_0}+1)s+1}=\frac{K_v}{s(\frac{s^2}{n_0^2}+\frac{2D_0 s}{n_0}+1)+K_d K_v} \tag{2}$$

where , $u$ is the input signal of the system, $x$ is the output signal of the system, $k_q$ is flow gain of slide valves near steady stale working point, $K_c$ is flow pressure parameter of slide valves near steady state operating point, $C_c$ is sum leakage coefficient, $v$ is volume equivalent to oil cylinder, $\beta$ is oil bulk modulus, $P_L$ is loading pressure, $A_p$ is feasible pressure bearing area of piston, $M$ is loading mass, $K_v$ is open-loop gain, $K_d$ is displacement feedback gain.

**Least Square Method Parameter Identification Principle**

In practical industrial control, control parameter uses theoretical calculation to get original value, and conducts manual regulation in trial test. But control parameter only aims to changeless system model, which is time-consuming without high accuracy[9]. In order to obtain more precise system control parameter, it is necessary to get more accurate system parameter to make use of real system input and output signal, so as to get the optimum system parameter. Least square method is popularly applied into various fields by virtue of its briefness, strong applicability, which can help get better object model. Discrete transfer function of the system can be shown in formula (3). Dynamic procedure mathematical model of the system is shown in formula (4).

$$G(z^{-1})=\frac{b_1 z^{-1}+b_2 z^{-2}+\ldots+b_n z^{-n}}{1+a_1 z^{-1}+a_2 z^{-2}+\ldots+a_n z^{-n}} \tag{3}$$

$$u(k)G(z^{-1})+e(k)=y(k) \tag{4}$$

Further get the following relation:

$$y(k)=-a_1 y(k-1)-a_2 y(k-2)-\ldots-a_n y(k-n)+b_1 u(k-1)+b_2 u(k-2)+\ldots b_n u(k-n)+e(k) \tag{5}$$

where, $u(k)$ and $y(k)$ are input and output quantities during the process, $e(k)$ is noise, $a_k$ and $b_k$ are unknown vector quantities, $k=1,2,...n$ .

The primary idea of Least Squares is to set minimized criterion function as formula (6) shows.

$$J(\theta)=\sum_{k=1}^{N}(y(k)-\varphi^{T}(k)\theta)^{2} \tag{6}$$

where, $\varphi^{T}(k)=\left[-y(k-1)\ \ldots -y(k-n)\ \ u(k-1)\ \ \ldots\ \ u(k-n)\right]^{T}$

$\theta=[a_1\quad a_2\quad \ldots\quad a_n\quad b_1\quad b_2\quad \ldots\quad b_n]$

With minimized criterion, estimated value $\hat{\theta}$ of smallest $\theta$ in the aforementioned function $J(\theta)$ can be obtained so as to confirm system transfer function.

**Tuning Algorithm Principle**

As system parameter calculated by shaking table is very different from practical system parameter, this paper adopts identification method to fit practical mode of the system with identification model being third-order system. The transfer function through identification is shown in formula (7).

$$G(s)=\frac{b}{a_3s^3+a_2s^2+a_1s+a_0} \tag{7}$$

With formula (2) and formula (7), system practical parameter $K_V$, $n_0$ and $D_0$ can be deduced as formula (8) shows.

$$\left.\begin{array}{ll} K_d=\dfrac{a_0}{b} & K_v=\dfrac{b}{a_1} \\ n_0=\sqrt{\dfrac{a_1}{a_3}} & D_0=\dfrac{a_2}{2\sqrt{a_1a_3}} \end{array}\right\} \tag{8}$$

System control parameter can be Related algorithm of document [10] can get system control parameter. Parameter tuning formula is shown in table 1. Procedure of tuning algorithm is shown in Fig.4.

Table 1 Control Parameter Gain

| Three-parametric Feedback Gain | | Three-parametric Feedforward Gain | |
|---|---|---|---|
| Displacement Feedback Gain | $A_d'=\dfrac{k'k_v}{K_d}\dfrac{n^2}{n_0^2}$ | Displacement Feedforward Gain | $A_d=A_d'$ |
| Speed Feedback Gain | $A_v'=\dfrac{k_v}{K_v}\left(\dfrac{n^2}{n_0^2}-1\right)$ | Speed Feedforward Gain | $A_v=\dfrac{2D_cA_d}{\alpha n_c}$ |
| Acceleration Feedback Gain | $A_a'=\dfrac{k_v}{K_a}\left(\dfrac{2Dn}{n_0^2}-\dfrac{2D_0}{n_0}\right)$ | Acceleration Feedforward Gain | $A_a=\dfrac{A_d}{\alpha\beta n_c^2}$ |

where, $k'=\dfrac{n_bn_c}{n_c+2D_cn_b}$; $D=\dfrac{n_b+2D_cn_c}{2n_c\sqrt{1+2D_c\dfrac{n_b}{n_c}}}$; $K_d$, $K_v$, $K_v$ are respectively displacement, speed and sensitivity coefficient; $\alpha$, $\beta$, $C_1$, $C_2$ are integral gain fixed parameters in artificial circuit. $n_c$, $D_c$ are determined by parameter itself.

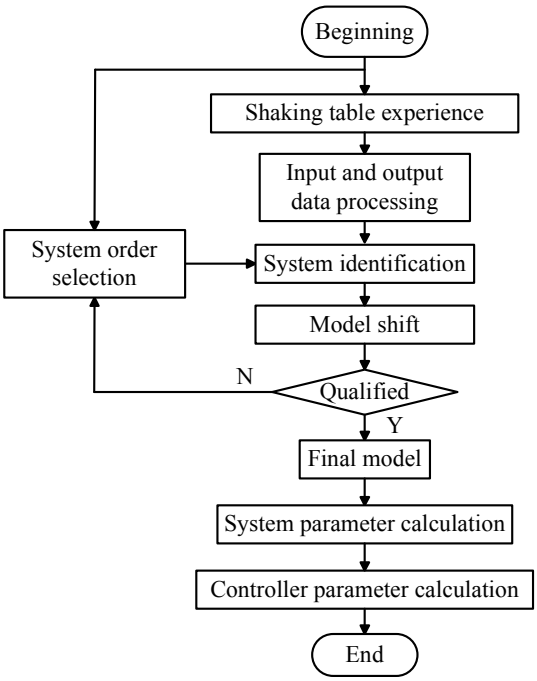

Fig.4 Tuning Algorithm Flow Chart

**Simulated of Parameter Self-tuning Algorithm**

This paper researches on shaking table with the size of 3m×3m . Its performance index is shown in table2. The transfer function of shaking table selected in the consideration of the influence of servo valve and sensor's second order characteristic is presented as formula (9).

$$H(s)=\frac{G(s)G_q(s)}{1+G(s)G_q(s)G_a(s)} \tag{9}$$

where, $G_q(s)=\dfrac{1}{\dfrac{s^2}{n_q^2}+\dfrac{2D_q s}{n_q}+1}$ is transfer function of servo valve; $G_a(s)=\dfrac{1}{\dfrac{s^2}{n_a^2}+\dfrac{2D_a s}{n_a}+1}$ is transfer function of sensor.

The simulation time of this experiment, the interval of sampling time is 0.001s, the input signal is white noise signal of 0.1-50Hz, the maximum acceleration amplitude is 0.1g, the system transfer function of the shaking table in displacement close-loop (neglect servo valve and sensor's second order characteristic) is shown in formula (10).

Table 2 Performance Index of Shaking Table System

| Project | index | Project | index |
|---|---|---|---|
| Platform size | 3m×3m | Counter weight | 6Ton |
| Peak load | 10Ton | Maximum displacement | ±10cm |
| Maximum speed | 60cm/s | Maximum speed | 2.0g（Full load）<br>0.9g（empty） |
| Frequency range | 0.1～50Hz | Control mode | acceleration control |
| Working mode | One-way of the level | Wave form | sine wave, random wave, earthquake wave |

$$G(S)=\frac{1928000}{s^3+26.3s^2+21210s+289300} \tag{10}$$

The transfer function corresponding to the open-loop system is like formula (11):

$$G(s)=\frac{1928000}{s^3+26.3s^2+21210s} \tag{11}$$

Formula (4) can deduce $K_V$=90.9005 , $n_0=145.637$ , $D_0=0.0903$ . The gain calculated values via theoretical calculation are $A_d=A_d'=0.375$ , $A_v'=0$ , $A_v=3.1073\times10^{-2}$ , $A_a'=1.7150\times10^{-2}$ , $A_a=1.1944\times10^{-2}$ .The parameter after being adjusted with the influence of servo valve and sensor's second order characteristic on control parameter values being taken into consideration are $A_d=A_d'=0.375$ , $A_v'=0$ , $A_v=3.3\times10^{-2}$ , $A_a'=1.1\times10^{-2}$ , $A_a=0.9\times10^{-2}$ , system frequency response curve is shown in the Fig.5, which shows within the scope of 0.4-50Hz, amplitude is controlled within ±3dB. This states that within working frequency bandwidth, output signal can well recur input control signal.

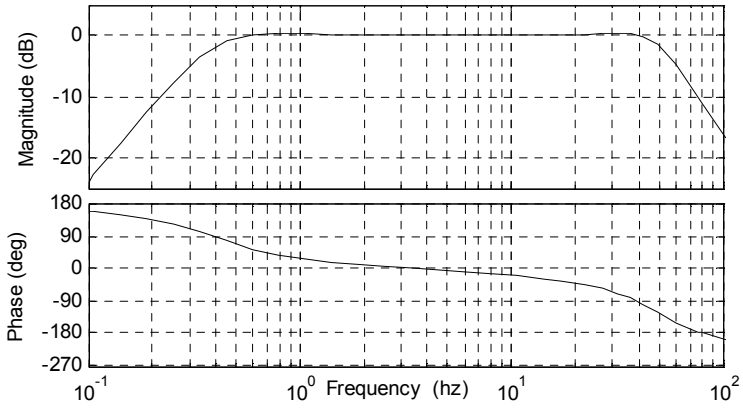

Fig 5: Frequency-response Curve with Regard to Servo Valve and Sensor's Character

## Conclusions

This paper adopts system identification and theoretical calculation method to get three-parametric control system's control parameter, system identification employs least square method, which identifies and gets close-loop transfer function of the system under the single influence of displacement feedback. As the identification method is easy to reach and system property is the real property of practical system, the control parameter obtained by such an identification method is highly precise with good control effect. Simulation calculation shows the control parameter got through system identification fits well with the control parameter got through simulated practical system, which verifies the validity of parameter tuning algorism put forward in this paper. Meanwhile, this method needs fewer debugging times with higher accuracy, and it is very easy to conduct programming realization, thus this is an effective shaking table parameter self-tuning algorism.

**Keywords:** Infilled Wall, Passive Control, Energy-dissipation, Shock Absorption

**Abstract.** Infilled wall is always regarded as a nonload bearing element, its energy-dissipation capacity and impact for the frame structure under earthquake have not been taken seriously. In this paper the function of infilled wall for frame structure was discussed, energy-dissipation capacity of different measures were analysed and compared from the point of passive control theory. This paper provides the reference for the further research of filler wall.

## Introduction

Infilled wall is an important part of frame structure, but it is regarded as outside load in progress of designing. In fact the mechanism between the infilled wall and frame structure is quite complicated, especially under the action of earthquake. As the application of new wall materials and damper, it is more important to do research on performance of new damping infilled wall, and it would provide important reference for promotion of the new wall.

## Research Situation of Energy-dissipation Capacity for Infilled Wall

**Infilled Wall Is Leaved out of Account in Structure Design.** Frame structure is one of the most popular building types in industrial and civil construction. It serves as separate and containment structures in frame structure, and always be regarded as a non-structural element. Since the collaborative working mechanism between infilled wall and frame structure is complex, in the concrete structure design, horizontal and vertical load resistance response of frame is analysed without the consideration of infilled wall, the infilled wall is regarded as a uniformly distributed load and input structure calculation software. The effect that infilled wall works has been considered by simply use of cycle time reduction, such as structure design clear specified, Under the vertical load, internal forces of the frame can be calculated though the layer method. Under the action of wind load and horizontal seismic, internal forces of the frame can be calculated though the D method. High-rise frame structures can be calculated through the matrix displacement method respectively according to the planar frame and space frame by using computer.

However, earthquake damage happened at home and abroad proved that as a non-structural element, infilled wall is still involved in the seismic action. Frame infilled wall's influence on the structure response under seismic action mainly displays in the following two aspects, firstly, existence of the infilled wall changed stiffness of the empty frame and the overall stiffness of the structure level. If the infilled wall was distributed along the vertical direction uniformly, the vertical weak layer would appear at the less infilled wall floor. Under the action of horizontal seismic wave, the weak floor would break firstly, as is shown in Fig.1.

Fig1. Vertical stiffness are uneven, sidesway is large, collapse happened

Similarly, if the infilled wall was distributed along the horizontal direction uniformly, stiffness center of the structure would shift, which would finally amplify the torsion effects of the structure and torsion failure would be inevitable when the quake hit, as is shown in Fig.2.

Fig2. Infilled wall was distributed uniformly, stiffness center shifted, torsion failure happened.

Secondly, infilled wall would restrain beams, columns, walls of the structure. Especially, when there is a large window between adjacent columns. Existance of the infilled wall restrains the deformation of the bottom of the columns and effective length will be shortened, short column will appear, This kind of short column destruction caused structural damage has been confirmed by previous disasters, as is shown in Fig.3.

Fig3. Short columns damage

So the role of infilled wall in frame structure can be summed up in the following two aspects in general. Firstly, infilled wall dissipate the energy that inputed into the structure under earthquake through its own deformation which will finally protect the body. Secondly, along with the seismic

action, frame wall crack gradually, stiffness will reduce, the wall will fall out and collapse. It is often seen that under medium earthquake, main body frame structure has not yet been destroyed while infilled wall has suffered serious damage. The destruction of the infilled wall not only affect the building's using function , increase the repair cost, but also endanger life safety or affect the emergency evacuation when seriously damage. So in the practical engineering, damage of the infilled wall is often regarded as a judgment for structure function under normal play and life safety in earthquake. In current design theory under the background of seismic performance, it is necessary for earthquake engineering to re-examine the infilled wall frame structure seismic shock absorption performance [1,4].

**Measures to Improve the Energy Dissipation Performance of Infilled wall**

Traditional structural anti-seismic concept is using the resistance of the structure to resist seismic action, includes bearing capacity of its own and plastic deformation ability. With the development of society and related disciplines, more reasonable and effective anti-seismic technology [5,6] have been explored, structure control design appears. Structure control design is to inhibit response of structure caused by dynamic load by install energy consumption or damping device on the structure. Structural control [7] is mainly divided into passive control, active control, semi-active control, mixed control, and the intelligent control developed in recent years.

Structure passive control is to point to add a subsystem in certain parts of the structure, or make constructional change on some component of structure in order to change the dynamic performance of the structure system. Passive control has the advantages of simple construction, low cost, ease of maintenance and without external energy support, etc. currently, passive control techniques are widely used in practical engineering, for example, some kind of energy dissipation device is set up between structure and foundation to reduce upwards transport of the seismic energy, finally reduce the vibration of the structure. Passive control of infilled wall has been applied in the following several aspects.

**Make Constructional Change on the Structure to Improve Dissipation Capacity.** On one hand, integrity of the structure that resisting seismic action can be improved by enhance the strength of the component or strengthen the connections between components, as prescribed by seismic code in Clause 3.3.7 [8] paragraph 3, non-structural element attached to the building or roof and nonbearing wall of stairwell should be reliably connected or anchored with the main structure, in case of collapsed hurt or broken during the earthquake. In paragraph 4, as for enclosure wall and partition wall of the frame structure, the adverse impacts on the structure during the earthquake should be estimated unreasonable setting of the main structure caused damage should be avoided. In practical engineering, the masonry structure reinforcement method is mainly used to solve the above problems, for example, Increased aseismic performance of outsourcing wall reinforced concrete facing, Steel mesh and cement mortar layer reinforcement method, Increase the structural integrity by using pressure grouting method, Add ring beam,(constructional column) reinforcement method. Besides in accordance with the design specifications for the corresponding ring beam and constructional column set. The following Rachel steel reinforcement method is used to reinforce the infilled wall. In the process of structure construction, bar is embedded in beams and columns, surrounding reinforced is set in the wall, embedded bar and surrounding reinforced should be twisted together or welded, as is shown in Fig. 4. "L", the distance between reinforcing steel bar, should be considered according to the actual needs. Generally, it is 300 ~ 600 mm. After the house built, wall beams and columns can be directly decorated.

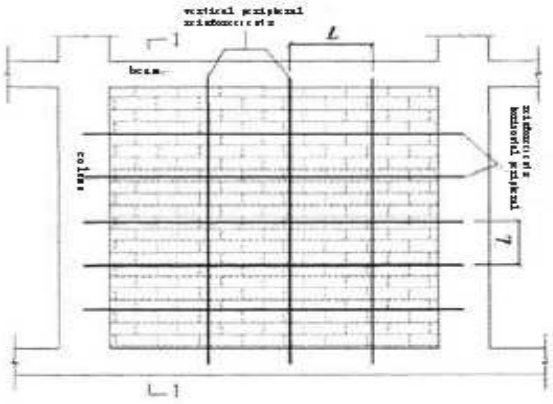

Fig.4 Wall with surrounding reinforcement

**Cooperative Use of Construction Measures and Energy Consumption Components.** It is true that infilled walls of reinforced concrete structure should be released or flexible connected with columns as is advised by Earthquake Resistant Design Code in 13.3.3.2 [9]. But the specification does not give specific practice. Academia rarely does relatively research. Flexible connection has the advantage of reducing the adverse effect that infilled wall acted on frame structure under seismic loading, but, it also undermines the beneficial effects infilled wall acted on the frame under the normal using condition. Energy consumption flexible connection is a new type of connection between the infilled wall and frame, which is improved on the basis of flexible connection method. The specific approach is to release clearance in the upper, left and right part between the wall and main body framework. Put specified damping device or damping in upper, left and right sides of the gap, or both of them. The gaps should also be filled with soft mortar, and connected by active connection plate fixed on the main structure, as is shown in Fig.5 to Fig.7. Through the reasonable design, the damping device (components) can provide a certain amount of connection stiffness to ensure good stiffness for frame structure under normal use condition. Under the action of the earthquake, the relative displacement appears between the wall and the main body frame, then damping device yield energy, stiffness reduce significantly, Thus the negative impact of the infilled wall stiffness for main body frame can be reduced, earthquake energy and earthquake response can also be reduced.

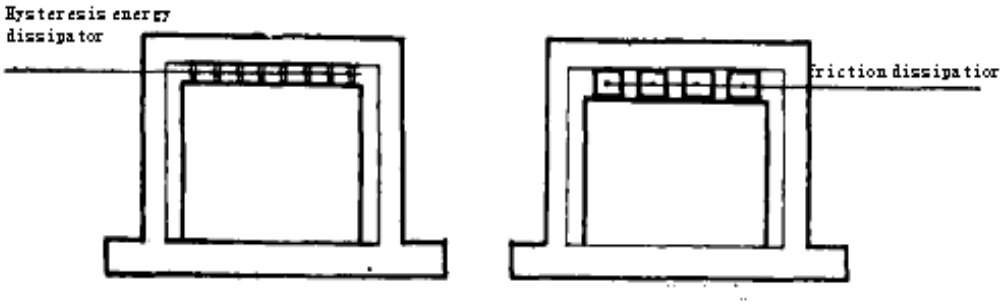

Fig.5 Energy dissipation device set in the crack of the wall

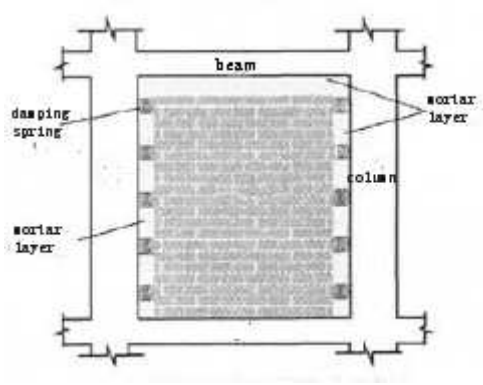

Fig.6 Wall with gaps

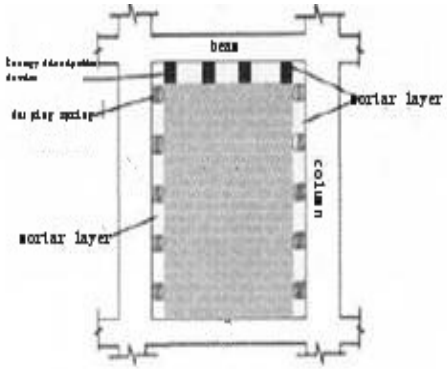

Fig.7 Wall with gaps and damping devices

**Improve the Wall Itself Structure, Make the Wall Itself Become a New Type Damping Wall.** According to the previous earthquake damage of infilled wall, some scholars proposed damping infilled wall frame system. Damping infilled wall frame is to divide a piece of infilled masonry wall into several masonry units; Viscoelastic material layers are set between masonry units. The forming layer is just similar to the viscoelastic damper, which is formed by one layer of steel plate and one layer of viscoelastic material layer. There are gaps between masonry units and frame columns filled with soft article mortar or viscoelastic materials. Viscoelastic damper and new damping infilled wall are shown in Fig.8 and Fig.9. When the frame is acted by earthquake, masonry units of different location will produce relative displacement, viscoelastic material layer shear deformation, absorb and consume the earthquake energy. Finally the wall damage will be reduced or avoided.

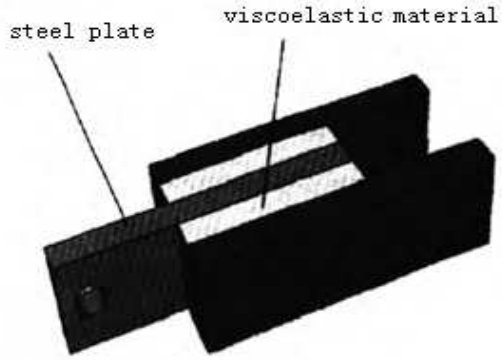

Fig.8 Viscoelastic damper

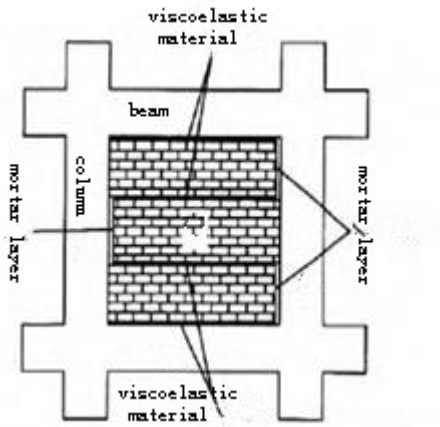

Fig.9 New damping infilled wall

This new framework damping wall has many advantages, the infilled frame wall itself is a damper, and it can improve the energy consumption capability of infilled wall. And it doesn't require additional damping energy dissipation device, viscoelastic layer is added in the middle of the horizontal mortar joint of infilled walls, it will not add difficulty to the construction.

## Conclusion

According to the damage characteristics of infilled wall frame structure, research Situation, need of wall policy and development trend of modern seismic design concept, Research on new type shock absorption performance of the masonry infilled wall is the urgent needs of the engineering practice and environment sustainable development, and will provide a scientific basis for further aseismic design code revision in China.

As we can see from the theoretical and experimental research on infilled wall frame in recent years, because of the existence of infilled wall, there are obvious difference on Mechanical performance between frame structure and empty frame. Stiffness, bearing capacity and energy-dissipating capacity

of the frame structure are also improved compared with empty frame. At the same time, due to the big stiffness the infilled wall cracks earlier and easily when earthquake comes. In view of the advantages and disadvantages of the infilled wall effect on framework, the theory and experimental study has made certain achievement but still not perfect. It is difficult to consider the impact in the design progress. The improvement of the design theory and the reform of wall materials also require further research work. And along with the application of new masonry materials, solid clay brick infilled wall materials used in frame structure are replacing by new masonry materials, But because of a lack of related research on performance of new masonry infilled wall frame structure , At present the rules of the clay brick are still mainly used in the design of infilled wall. Advantage of the performance of new wall materials can not be given full play, and it will hinder the application of new type masonry infilled wall. New damping components and dissipative damping elements based on energy theory have been used in frame wall more and more. Research on Energy dissipation performance of damping and mechanism become more and more urgent. This also provides a new direction for the experimental study on the theoretical analysis and numerical simulation. Carry out research on new aseismic performance of masonry infilled wall frame and designing method will provide the basis for the future new infilled wall frame structure anti-seismic design, and help promoting new wall policy and application of new materials.

**Keywords:** thick transferring plate; seismic design; frame and shear wall structure; overall structure calculation

**Abstract:** With the project case, the seismic performance of girder transfer floor member and the plate transfer floor member were discussed. Contrast calculation was carried out in girder transfer floor member and the plate transfer floor member with SATWE method to analyze its reasonable and unreasonable places. Based on overall structure calculation of a high rise building, the seismic design requirements for buildings applying thick transferring plate have been presented. The conclusion is that the seismic performance of girder transfer floor member is more advantageous and affordable, more convenient and more economical in ingredients.

## Introduction

Today, high-rise building has been developing toward the complex body, and being versatile and comprehensive. A building along the height direction pursues very complex functions as residential, office, entertainment, shopping and other functions. The bottom arranged shopping malls; intermediate floors can be as shops, restaurants and entertainment facilities; upper floors are used for hotel, residential; top floor, also can be designed into the garden, or even a stadium. Such a building has become a complex, which needs to really achieve different structural forms to make these functions come true.

This complex also faces many problems. Central is a small space or medium-sized. The lower requires large column grid, large bays. From a structural and the stress, because of the lower by force, stiffness, requiring multi-wall, column grid density; into the upper part of the force will be reduced, the wall can be reduced, reducing the number of columns, column grid to expand. Such a structure is the structural requirements and building requirements contrary, therefore, the structure must be designed to be "anti-conventional design" [1], that is in accordance with the requirements of the upper column grid building dense, small space, the lower column grid sparse, large space. In order to achieve this arrangement, it leads to a new concept of "conversion structural elements" [2], to set the conversion component of floors, called the conversion layer.

This article focuses on beam conversion structure and plate transfer structure for discussion. Transfer Beams are most widely used because of its simplicity of design and construction, the force clear. And converting the beam layout is very casual, portrait or landscape can be a two-way arrangement. But if and when the column grid to stagger down very much, when used in many places difficult to directly supporting beams, you need to make a plate suspended deck conversion layer. Flexible plate lower column grid conversion layer can be arranged, it doesn't need to be aligned with the upper structure. But it is heavy, and many materials are used.

## Project overview

This works for A sugar mill district revitalization group A city building, building a total height of 52.60 meters (outdoor ground to the eaves), basement (ceiling height of 3.90 m) and 16 floors (one, two-storey 4.50 m, three to sixteen layers of height 3.00 m); gross floor area of 15,619.66 square meters; retail floor area of 3,301.62 square meters; residential portion of the area of 12,318.04 square

meters. The basic wind pressure: W0 = 0.55 kN/m2. Basic snow pressure: S0 = 0.50 kN/m2. Venue Category: Ⅱ class, in the form of building structures: Part frame supported shear wall structure. Floor Structure: Reinforced Concrete Floors cast reasonable service life of 50 years, seismic fortification intensity is 6 degrees; basic design earthquake acceleration: 0.05g, site soil type: supporting layer of soil is soft ground soil, seismic design groups: the first group; class C buildings.

Residential conversion layer above as wall structure, shear seismic rating of four (five layers - the top) level, the conversion layer below the mall for the frame shear wall structure, the framework for the two seismic level, level of seismic shear walls three (-1 layers to four layers).

Figure 1 is architecture elevation.

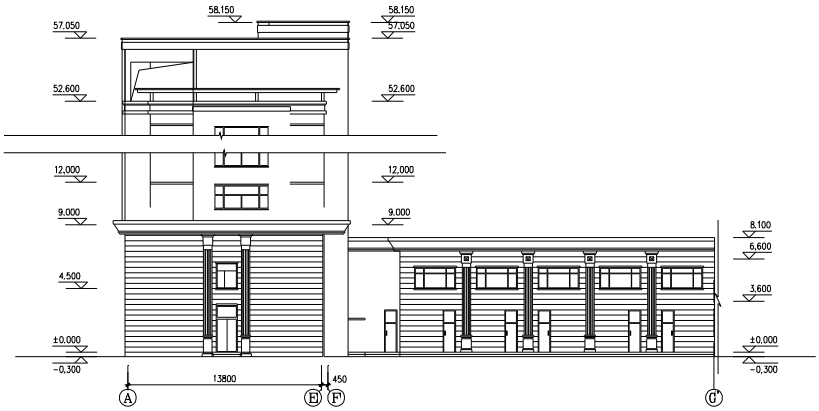

Fig.1 Architecture elevation

**Model selection**

According to architectural requirements, the second layer is determined to convert the ground floor, it is designed for the conversion layer in three cases, the first one is the beam conversion layer (Ⅰ), the second is the 1500mm conversion layer thick (Ⅱ), the third is 1200mm thick slab conversion layer (Ⅲ). In order to ensure a clear contrast to the various programs, so consistent conversion layer superstructure and substructure, but it does not affect the conversion layers thick high.

Program Ⅰ, the main transfer beam breadth is 400mm and height is 1300mm. Select a building expansion joint on the left of the beam layout (Figure 2).

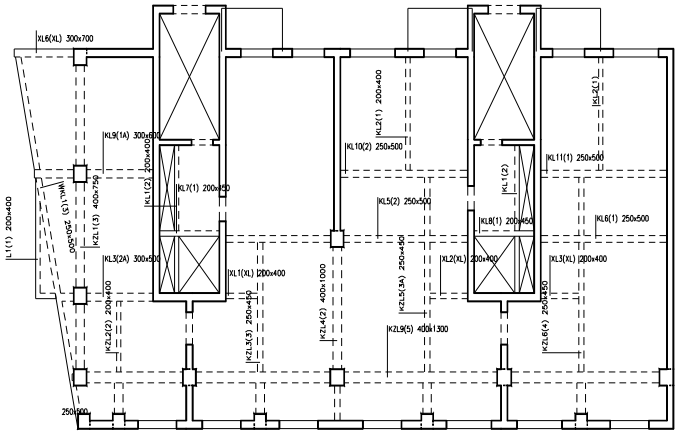

Fig.2 The left of the beam layout

Program Ⅱ, beam in the program Ⅰ will be converted component beam, its breadth is 300mm and height is 600mm. and the floor slab thickness to 1500mm. A building expansion joint is selected on the left of the beam layout.

Program Ⅲ, beams arrangement is the same program Ⅱ, thick slabs only changes to 1200mm.

**Seismic performance analysis and comparison**

Under the current prevailing norms of seismic, in plans for 6 degrees of seismic intensity vertical seismic forces are negligible [3], the project area is located 6-degree, area so is used here only two-way horizontal seismic force is calculated. In this paper, SATWE modeling, rigid floor is assumpted, the overall structure of the lateral deformation resistance between structural displacement and story drift angle OK. Bi-layer average displacement and maximum drift are showed in Table 1.

| 6 | 1/7021 | 1/6949 | 1/6961 | 1/8885 | 1/8711 | 1/8746 |
| 5 | 1/7416 | 1/7324 | 1/7340 | 1/9911 | 1/9678 | 1/9725 |
| 4 | 1/8230 | 1/8112 | 1/8131 | 1/9999 | 1/9999 | 1/9999 |
| 3 | 1/9999 | 1/9999 | 1/9999 | 1/9999 | 1/9999 | 1/9999 |
| 2 | 1/9999 | 1/9999 | 1/9999 | 1/9999 | 1/9999 | 1/9999 |
| 1 | 1/9999 | 1/9999 | 1/9999 | 1/9999 | 1/9999 | 1/9999 |

It can be seen from the table1, in the X, Y bidirectional seismic force, the average displacement scheme floor maximum 5.31mm, than 5.37mm and program two of the two 5.36mm are small. It is not difficult to see that a middle drift, drift and the total displacement is less than scheme two and three, and the scheme three and slightly better than scheme two. It means that the beam layer for seismic performance is better than the transfer plate layer conversion, but also can determine the initial plate thickness increased after the displacement of the structure will also increase. Therefore, the thick plate is not conducive to seismic.

By contrast, also found that each variable change plan model is smaller, and the scheme two and three are the variables. Conversion layer above three models are used for shear wall

structure, stiffness mutation are evident. Also found in the transfer floor layer displacement three schemes are the same, this is due to their stricter torsion, with conversion layers structure will have stiffness mutation in conversion layer, and it is the stiffness mutation will cause the reverse occurred. This type of housing ductility is poor, once the earthquake occurs, torsion failure is sudden failure, and secondary disasters caused are immeasurable.

In the earthquake, due to the existence of the plate, so here to focus a great deal of stiffness and mass, increases suddenly here earthquake, earthquake response will be strong. Not only the thick plate transition layer itself large force, but also because the vertical stiffness of the mutation, adjacent layers has also been considerable force, once the earthquake, and earthquake damage adjacent layer can not be ignored. The plate test showed that, the interaction of vertical force and earthquake force, plate punching failure not only possible, but also may cause shear failure, plate must be three to reinforcement. [4]

## Conclusions

For seismic design, building with the conversion layer transfer can be used in the area of the seismic intensity 6 in transfer slab and beam, but the thick plate transfer should not be used for 7 degrees and 7 degrees above high-rise building. And at 8 degree, for conversion layer the vertical earthquake should be considered. Conversion layer should not be used at 9 degrees. The paper draws the following conclusions:

As long as the structures with transfer, stiffness mutation will happen. The maximum design conversion is required to control the stiffness mutation, and beam transfer layer can better mutation stiffness, the thick plate transition, in fact, the thickness of the plate on the structural displacement change is not significant. The reduced stiffness mutation of the most basic idea is to strengthen the lower, weakening the upper. While the strong column and weak beam is impossible, it is important to ensure the conversion layer stiffness, to ensure the smooth realization of conversion.

The great stiffness, displacement of each scheme in the conversion layer of the interlayer and the interlayer displacement angle will be significantly reduced. For the plate transition layer, although in accordance with the norms of vertical seismic force can be neglected, but the vertical earthquake does exist, one of which is the main reason of seismic performance moderator system is not good, so the conversion layer below the column must strengthen structure, and strictly control the axial compression ratio of column.

The seismic performance of comprehensive analysis of the three models, the girder transfer floor seismic most superior performance, whether it is from the angle of displacement and inter story displacement point of view, is one of the minimum displacement solution. In practical engineering, with thick plate transition layer construction should avoid as far as possible, can also change the architectural layout, let the thick plate structure into beam structure. The thick plate transition is still a big problem in seismic design. Except the design difficulty, the construction is very complex, and the amount of materials and the cost is higher than the girder transfer floor.

**Keywords:** ultimate state, rocking isolation, bridge, spread foundation, extreme earthquakes

**Abstract.** This study is aimed to analyze the ultimate state of bridges with rocking isolation of spread foundations under extreme earthquakes. The Vector Form Intrinsic Finite Element method (VFIFE) is adopted to simulate the failure procedure of bridges with and without rocking isolation. To simulate the highly nonlinear behaviors between soil and foundations, Winkler-based models are established in the VFIFE in this study. A practical five-span bridge with spread foundations is chosen to study the effect of rocking isolation and discuss the influence of altering parameters of bridges. The analytical results are compared between linear soil springs and nonlinear soil springs. Furthermore, the ultimate state of bridges is simulated to realize the dynamic behaviors of bridges under extreme earthquakes.

## Introduction

The rocking of bases resulted in lesser structural internal forces and deformations. Kawashima and Nagai[1] analyzed a five-span bridge with rocking response under three directional ground excitations. The analytical results show that the effect of rocking isolation is significant in reducing the plastic deformation of the plastic hinges at the bottom of columns, whereas it increases the displacements of deck and column. Although some studies show that the spread foundations do not overturn even if the spread foundations are subjected to ground motions with peak acceleration much larger than the equivalent accelerations in the traditional static analysis[2]. The issue of overturning is still critical in spread foundation when exhibiting rocking response. Therefore, this research is aimed to clarify the overturning instability and the isolation effect through ultimate numerical simulation when rocking response occurs in spread foundations.

It is difficult to analyze the ultimate situation of bridges under extreme earthquakes by using the traditional finite element method. Therefore, Vector Form Intrinsic Finite Element method (VFIFE), a new computational method, is selected to be the computational method in this study. The VFIFE developed by Ting et al.[3] is superior in managing the engineering problems with material nonlinearity, discontinuity, large deformation, large displacement and arbitrary rigid body motions of deformable bodies.

## Vector Form Intrinsic Finite Element

The Vector Form Intrinsic Finite Element has been developed based on theory of physics to simulate failure response of a structural system due to applied loads. The first step in the VFIFE analysis is to establish a discrete model for a continuous structure by using a lumped-mass idealization. It is noted that all lumped masses are connected by deformable elements without mass. The equations of motion at each mass or so-called node for all degrees of freedoms are constructed by applying Newton's Second Law of Motion. Assume that a structural system consists of a finite number of particles. A particle designated as $\alpha$ has a mass matrix $\mathbf{M}^{\alpha}$ and a displacement $\mathbf{d}^{\alpha}(t)$ at time $t$. The equations of motion for particle $\alpha$ are

$$\mathbf{M}^{\alpha}\ddot{\mathbf{d}}^{\alpha}(t) = \mathbf{P}^{\alpha}(t) - \mathbf{f}^{\alpha}(t) \quad (1)$$

Where $\mathbf{P}^{\alpha}$ is the applied force or equivalent force acting on the particle; $\mathbf{f}^{\alpha}$ is the total resistance force exerted by all the elements connecting with the particle, or the internal resultant force. Each element without mass is in static equilibrium.

Since the failure progress of structures involves changes in material properties and structural configuration, discrete time domain analysis is essential to solve the equations of motion, Eq. (1). In calculating the internal forces, a set of deformation coordinates is defined for each element and for each time increment. Compared to the traditional finite elements, the unique of the VFIFE is to calculate rigid body motion and element deformations through the de-formation coordinates in each time increment. By doing so, the VFIFE can deal with large displacement, deformation and rigid body motion simultaneously.

## Target Bridge and Analytical Model

The target bridge is a five-span continue bridge with rigid bearings, as shown in Fig. 1. The total length is 5@40 m = 200 m and a width of 12 m, which is supported by four reinforced concrete columns with a height of 12 m in each and two abutments. Spread foundations are designed to support the abutments and columns. The bearings installed on the abutments and columns are roller bearings and hinge bearings, respectively. After hinge bearings rupture, the dynamic friction coefficient in the interface is assumed to be 0.4. The friction coefficient of the roller bearings is assumed to be 0.1.

The spread foundations are embedded in sandy soil with N-value of the standard penetration test over 50. Based on seismic design codes, the spread foundations are 2 m thick, 6.5 m long in longitudinal direction and 7 m wide in the transverse direction. Underlying soils are idealized by soil springs as shown in Fig. 2 to simulate the interaction of soils and foundations. The Winkler springs [4] are used to simulate the nonlinear soil behavior as shown in Fig. 3. The elastic part simulates the far-field behavior while the plastic part simulates the near-field permanent displacement. Figure 4(a) is the analytical model of the vertical and horizontal soil springs while Fig. 4(b) is the model of shear soil springs. Note that the vertical soil springs is of compression only.

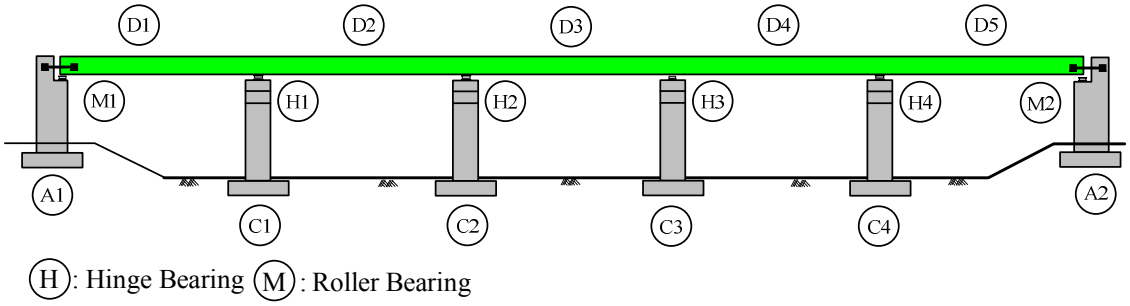

Figure 1. Five-span continuous bridge with roller and hinge bearings

In simulation, the target bridge is subjected to the near-field ground motion recorded at JMA Kobe station in the 1995 Japan Kobe earthquake. In order to observe when the bridge will collapse, the ground acceleration is amplified from 100% to 250% at an increment of 10%.

## Numerical Simulation Results

From the simulation results, the demanded ductility of columns in the analysis case with rocking isolation is smaller than that in the analysis case without rocking isolation shown as fig. 5. The target bridge collapses at smaller ground motion when the rocking of foundation is not considered in analysis. Figure 5 presents the rotation of plastic hinge at the bottom of column C1 in the analysis cases by using linear and nonlinear soil springs, both of which include rocking isolation. It is observed

that the maximum rotation of plastic hinge in the case by nonlinear soil springs is larger than that in the case by linear soil springs.

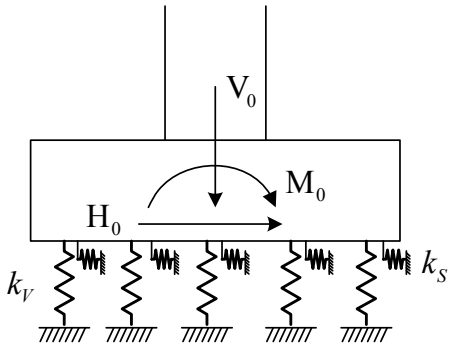

Figure 2. Analysis model of spread foundation

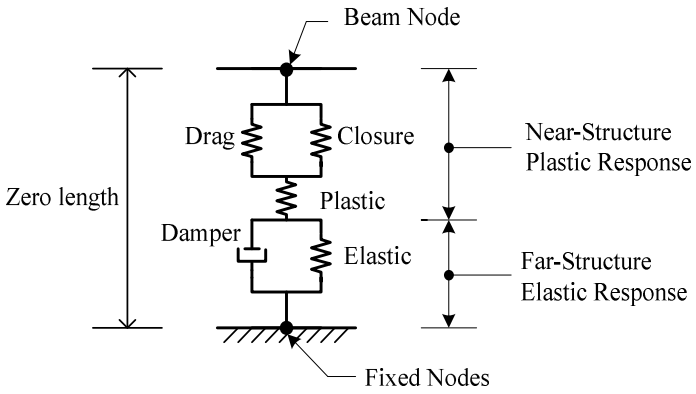

Figure 3. Winkler-based model

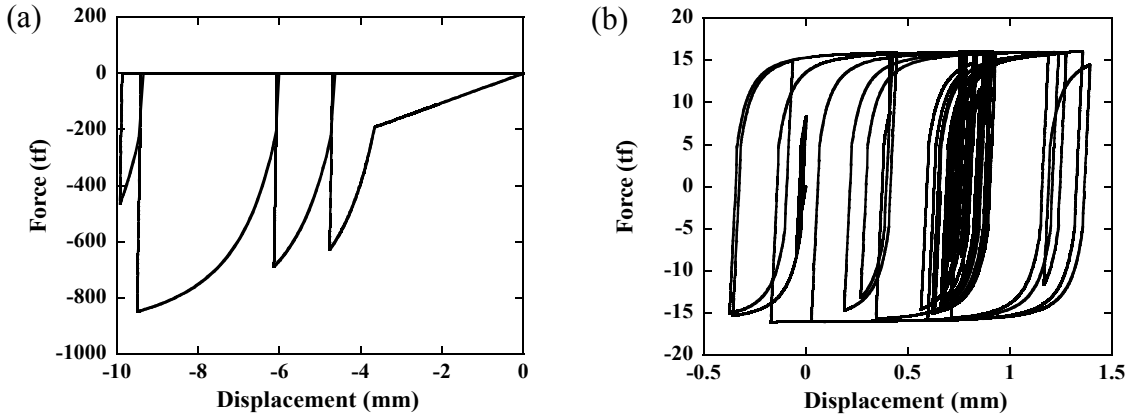

Figure 4. Hysteretic loops of nonlinear (a) vertical soil spring (b) shear soil spring

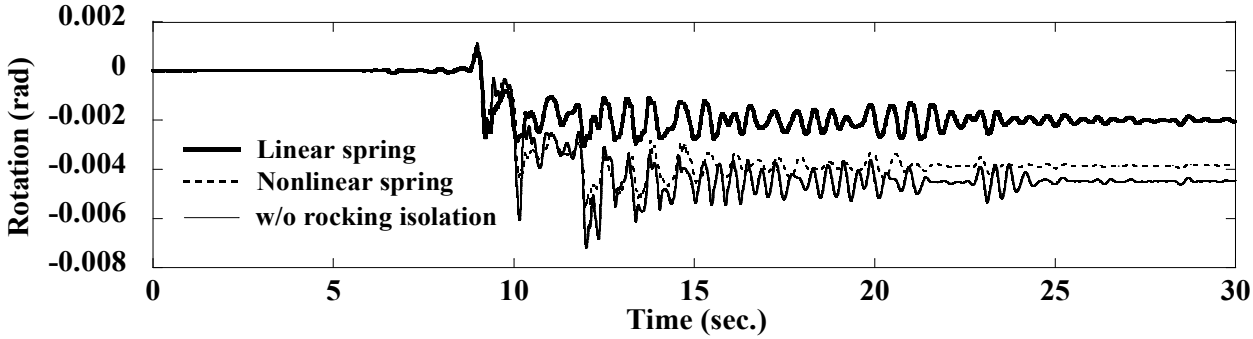

Figure 5. Rotation of plastic hinge at the bottom of column C1

Figure 6 shows the failure procedure of the target bridge with rocking isolation under 180% of the JMA Kobe records. All hinge bearing fracture first. Plastic hinges occur at the bottom of the columns. After the column reaches the ultimate ductility, the column loses the capacity of moment resistance and finally collapse. The deck fall downs with the collapse columns and then unseats from the abutment A1.

## Summary

The effect of rocking isolation of spread foundation for bridges was studied through ultimate analysis by using the Vector Form Intrinsic Finite Element method. A typical five-span viaduct under near-field ground motions was analyzed. The numerical simulation successfully predicts the failure

process of the bridges with rocking isolation under extreme earthquakes. The following conclusions may be obtained from the simulation results presented herein.

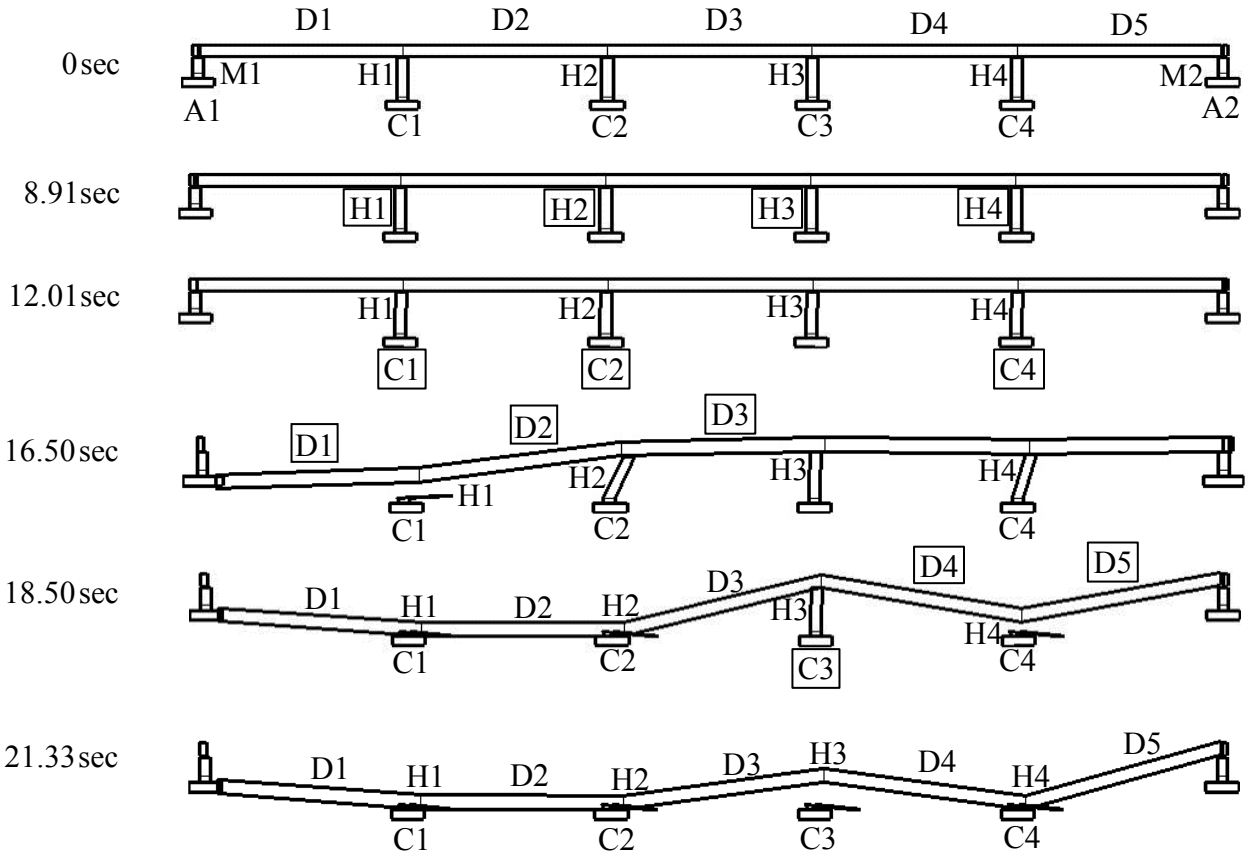

Figure 6. Failure procedure of the target bridge with rocking isolation under 180% JMA G.M.

(1) Compared with the bridge without rocking isolation, the bridge with rocking isolation performs better and collapses at smaller ground motion. It is beneficial to allow the spread foundation to rock for mitigating the seismic response of bridges under strong ground motion.

(2) While adopting linear soil springs to simulate the soil-structure interaction, the displacement of deck would be more conservative and the plastic hinges of columns will be overestimated.

(3) Rocking isolation dissipates the seismic-induced energy of structures to mitigate the damage. However, the permanent deformation of soil after earthquake is another issue for safety of bridges.

# Verification of LSSRLI-1 Applicability on Soft Sites Using Exact Solution

Ruishan Li [a], Xiaoming Yuan [b]

Key Laboratory of Earthquake and Engineering Vibration, Institute of Engineering Mechanics, China Earthquake Administration, 29 Xuefu Road, Harbin 150080, China

[a]lrshan22@hotmail.com, [b]yxmiem@163.com

**Keywords:** seismic analysis; exact solution; LSSRLI-1; soft sites; deficiency.

**Abstract.** LSSRLI-1 is an equivalent linear program which is used for seismic ground response analysis. Since the LSSRLI-1 was proposed by Xiaojun Li in 1989, it played very important role in seismic safety evaluation, solved the inputting problem for dynamic response analysis of structure. Some deficiency was found in the practice, especially when the layered site is soft. Linear exact solution is deduced in the frequency domain.based on the engineering wave theory. A program is compiled in the MATLAB environment, which is used to compare with the LSSRLI-1 results, including the ground response spectrum and the soil strain distribution.

## Introduction

Seismic response analysis of soil deposits is a part of geotechnical earthquake engineering, which deals with the site effects on the propagated seismic wave in the ground. Seismic ground response analyses provide researchers with important results, including design response spectrum, liquefaction susceptibility estimation and seismic slope stability assessment [1]. Available seismic ground response analysis methods are categorized into linear, equivalent linear and non-linear methods that perform the analysis in the time or the frequency domain. These methods defer in their modeling of soil behavior under earthquake loading. The equivalent linear method considered the shear modulus and damping ratio as constants for the whole duration of the earthquake. Compared to the equivalent linear method, the non-linear is mainly dependent on the dynamic constitutive model which is out of complex. Because of its advantages, the equivalent linear method is mostly used in the practice.

In China, the siesmic response analysis is carried out, using the LSSRLI-1 program which was proposed by Xiaojun Li in the 1989. In twenty years of practice, many deficiencies were found, especially when the site is soft.

In this paper, the linear exact solution is deduced based on the engineering wave theory and was compiled into a computer program in the MATLAB environment. To compare with the exact solution, the non-iteration results of LSSRLI-1 were calculated. The comparation includes the ground surface acceleration response spectrum and the soil strain distribution. The dynamic non-linear parameters are dependent on the shear strain of the previous iteration. Thus, the shear strain affects the ground motion, and vice versa.

## Models

The simplified single-layer and double-layer models are demonstrated in Fig.1. In the two kinds of models, the local coordinate of each layer is downward direction, with the origin at the layer top. Each layer is homogeneous and isotropic, and characterized by the thickness, h, mass density, $\rho$, shear wave velocity, $v_s$, and damping ratio, $\xi$. In this paper, three acceleration time histories (Fig.2), with each amplitude regulated to 0.1g, 0.2g, and 0.4g respectively, was used as the input motions. There are totally 4 models with different thickness and shear wave velocity are chosen. Two of them are single-layer model, and the remaining two are double-layer model. The specific parameters of these models are listed in the table 1. The nonlinear curves of shear modulus decreasing and damping ratio increasing with the shear strain, used in this paper was depicted in Fig.3 [2].

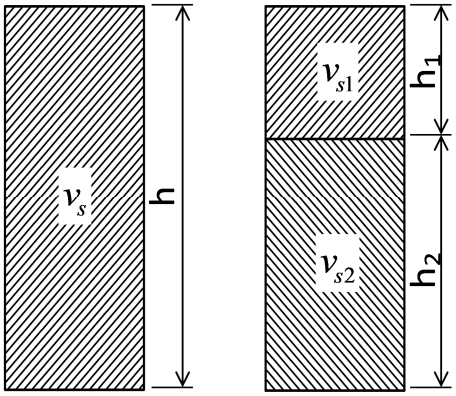

Fig.1 Simplified models of single-layer and double-layer

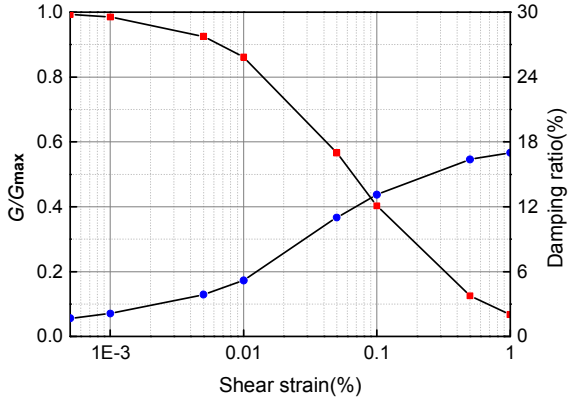

Fig.3 Dynamics non-linear curves

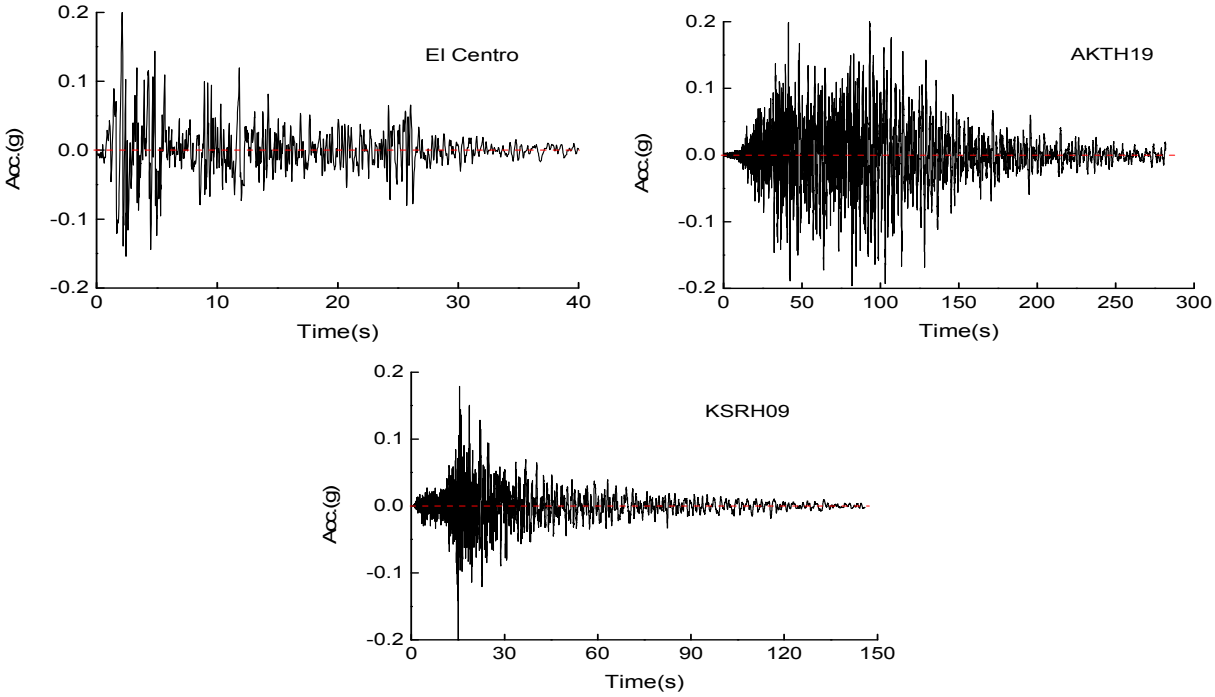

Fig.2 Input accelerations for 0.2g case (El Centro, AKTH19 and KSRH09)

Table 1 Specific parameters of calculation models

| | | | | | |
|---|---|---|---|---|---|
| Single-layer models | No. | $v_s$(m/s) | | H(m) | |
| | 1 | 120 | | 100 | |
| | 2 | 90 | | 120 | |
| Double-layer models | No. | $v_{s1}$(m/s) | $h_1$(m) | $v_{s2}$(m/s) | $h_2$(m) |
| | 3 | 120 | 30 | 180 | 70 |
| | 4 | 90 | 40 | 150 | 80 |

**Exact solution**

Consider the wave equation of motion as:

$$\frac{\partial^2 u}{\partial t^2} = v_s^2 \frac{\partial^2 u}{\partial z^2} + \frac{2\xi v_s^2}{\omega} \frac{\partial^3 u}{\partial z^2 \partial t} \tag{1}$$

A harmonic displacement occurs due to a harmonic load can be express as [1]:

$$u(z,t)=U(z)e^{i\omega t} \tag{2}$$

Using the stationary solution of elastic stress wave propagating in a homogeneous material, considering the complex modulus for hysteretic damping, the transfer functions H($\omega$) of shear strain in soil from the input accelerations can be expressed as follows, as well as the amplification ratio R($\omega$) of ground surface outputs to the inputs [3, 4].

For single-layer models:

$$H(\omega)=\frac{k^*\sin(k^*z)}{\omega^2\cos(k^*h)} \tag{3}$$

$$R(\omega)=\frac{1}{\cos(k^*h)} \tag{4}$$

For double-layer models:

$$H_1(\omega)=\frac{k_1^*\sin\left(k_1^*z_1\right)}{\omega^2\left[\cos\left(k_1^*h_1\right)\cos\left(k_2^*h_2\right)-\alpha\sin\left(k_1^*h_1\right)\sin\left(k_2^*h_2\right)\right]} \tag{5}$$

$$H_2(\omega)=\frac{k_2^*\left[\cos\left(k_1^*h_1\right)\sin\left(k_2^*z_2\right)+\alpha\sin\left(k_1^*h_1\right)\cos\left(k_2^*z_2\right)\right]}{\omega^2\left[\cos\left(k_1^*h_1\right)\cos\left(k_2^*h_2\right)-\alpha\sin\left(k_1^*h_1\right)\sin\left(k_2^*h_2\right)\right]} \tag{6}$$

Where ω is frequency of incident wave; h is the thickness of soil layer; $v_s$ is the shear wave velocity of soil layer; ξ is the damping ratio. They all specifically demonstrated in the Fig.1. $k^*$ is the wave number, which can be obtained from the following formula.

$$k^*=\frac{\omega}{v_s^*}=\frac{\omega}{v_s(1+i\xi)} \tag{7}$$

## Results and Conclusions

The main purpose of seismic response analysis is to obtain the ground surface motions, while what can be used by the engineers directly is the response spectra. So here first shows the ground surface response spectra, calculated by LSSRLI-1 and the exact solution.

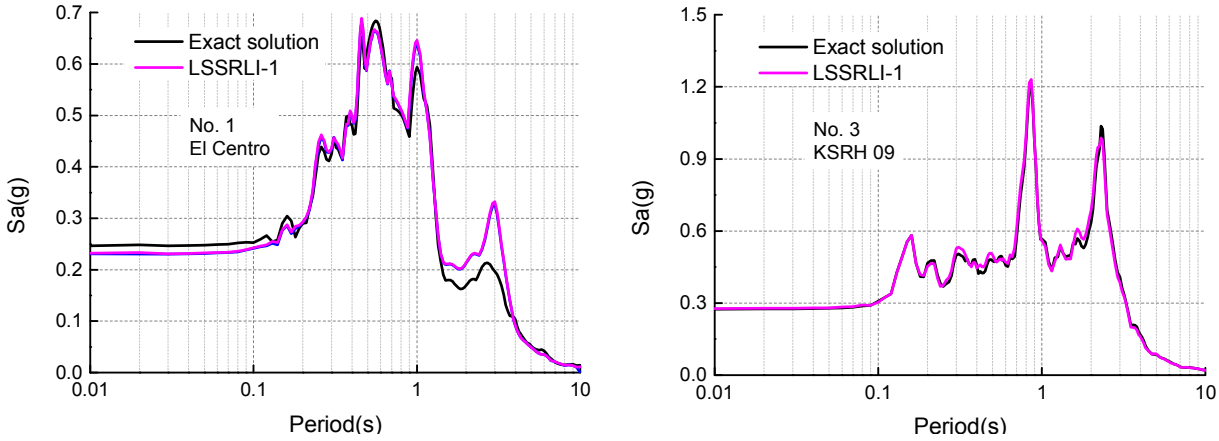

Fig.4 Response spectra of ground surface under 0.2g peak inputs

Fig.4 shows that the response spectra of different models, calculated by exact solution and LSSRLI-1, under different input conditions, agree well with each other. The consistency is independent with soil models and input conditions.

As mentioned before, the soil shear strain distribution affects the ground motion seriously, because the soil dynamic non-linear parameters are dependent on the shear strain. The shear strain distribution, without iteration, were dipicted in Fig.5. To demonstrate how the shear strain affects the ground motion, the program was run for one more time. The dynamic parameters were interpolated from Fig.3, according to the equivalent shear strain.

$$\gamma_{eq} = 0.65\gamma_{max} \tag{8}$$

In equation (8), the $\gamma_{mas}$ is the peak value of shear strain time history. The updated ground response spectrum is illustrated in Fig.6.

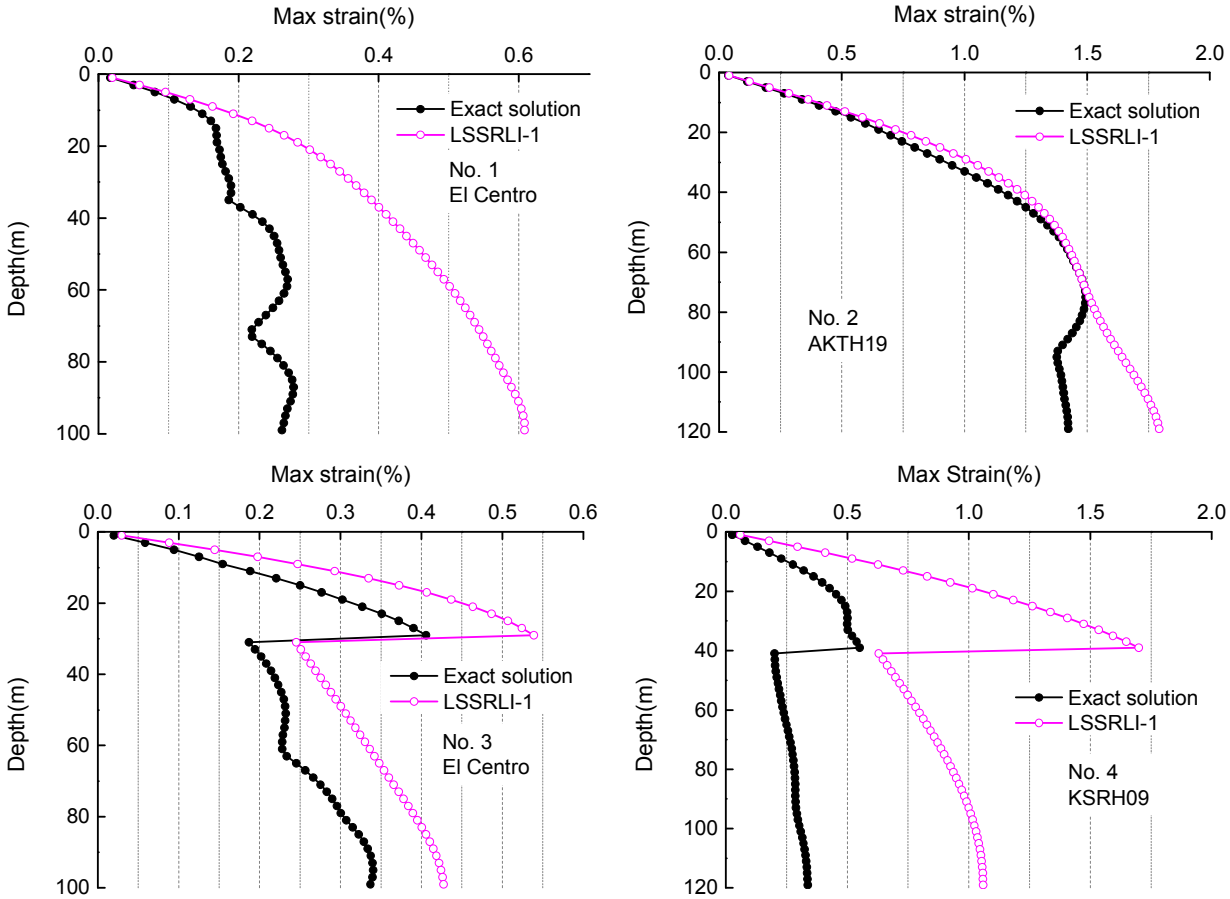

Fig.5 Distribution of shear strain in soil under 0.2g peak inputs

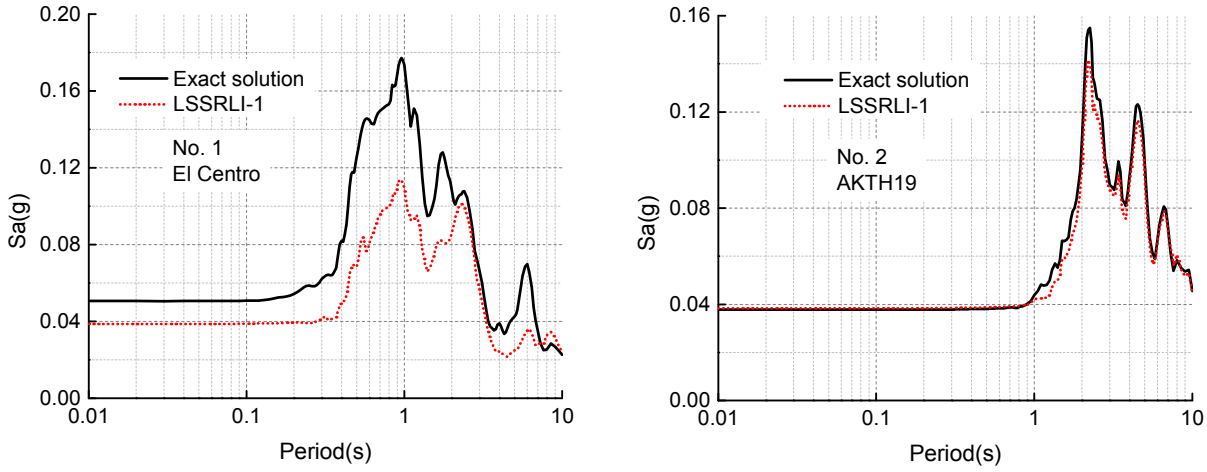

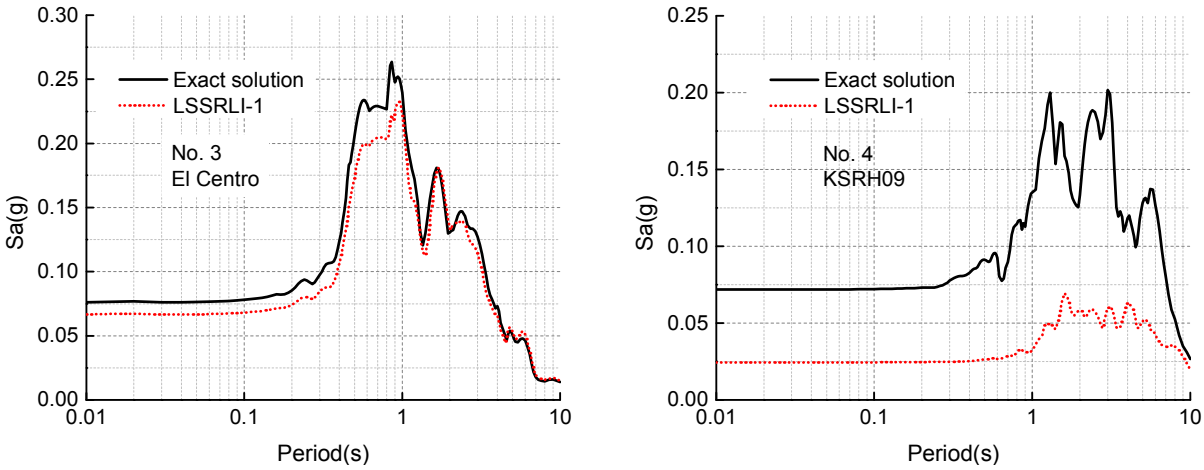

Fig.6 Updated ground response spectrum under 0.2g peak inputs

Fig.5 clearly indicates that the shear strain distributions, calculated by LSSRLI-1 and exact solution separately, differ from each other seriously. In some cases, the LSSRLI-1 results may reach 2.5 times of that of exact solution. Depending on the shear strain distribution in Fig.5, we calculated a series of new dynamic non-linear parameters, using equation (8) and Fig.3. One more iteration was carried out based on the updated parameters. Fig.6 shows that two group of response strctrum curves have much difference, which can not be ngelected. The explaintaton of this phenomenon is that the shear strain affects the ground motion seriously.

We can get a clear conclusion easily that LSSRLI-1 is not suitable for soft sites any more. Its main problem is the calculation method of shear strain distribution, but its ground motion transfer function is correct. This provieds us with a direction for developing the soil seismic response analysis program.

**Keyword:** Elastic-plastic, Time-history analysis, Concrete constitutive relation, Damping, Mesh

**Abstract.** In order to improve the solution of nonlinear time-history analysis for high-rise buildings, the concrete constitutive relation of Chinese code has been modified by using Najar damage theory, and based on the limitation of stable time increment in explicit dynamic analysis, a simplified Rayleigh damping form with tiny stiffness proportional damping is proposed to decrease the damage induced by those high frequencies, at last, the influence of mesh size on stress and damage is also discussed. The numerical results show that these principles are workable for more accurate results.

## Introduction

To ensure the structural performance under expected rare earthquake, deformation verification must be made to avoid overall collapse. On the other hand, the damage time-history and damage level of the main members are also very important for the structural optimization.

Analysis of nonlinear time-history is the most useful tool for the results mentioned above. Due to the nonlinear problems—those with large deformations and/or nonlinear material response, especially the complex nonlinearity of concrete, it is very difficult to obtain an ideal solution. At the same time, the efficiency of analysis is also a key point because of the large volume of high buildings. Limited by these two factors, explicit dynamic method has more advantages than the implicit dynamic method. Compared to the implicit dynamic analysis procedure, each increment in explicit method is relatively inexpensive because there is no solution for a set of simultaneous equations, and it would not suffer from the convergence of iterations needed for implicit method. Even like this, it would still take more than dozens of hours to analysis a high-rise building under a one-minute seismic wave by using parallel solvers. So the engineers may have to confront the balance between reliability of solution and efficiency.

By using the explicit method presented in software for nonlinear time-history analysis, reliable definition of materials, suitable selection of elements and reasonable meshing scheme may be the most important works for solving the questions discussed before, thus the nonlinear time-history analysis was made for a high-rise building combined with Abaqus/Explicit for achieving more reasonable FEA model.

## Constitutive model of concrete

Different with researchers, engineers prefer to use those constitutive models of concrete which are more simply and reliable to ensure the mechanical reliability, such as Mander model[1] and the model in the Chinese 'Code for design of concrete structures'[2].

For the constitutive model presented in Chinese 'Code for design of concrete structures', in which the tension skeleton curve of concrete is as follows:

$$\sigma = (1- d_t) E_c \varepsilon \tag{1}$$

$$d_t = \begin{cases} 1-\rho_t[1.2-0.2x^5] & x \le 1 \\ 1-\dfrac{\rho_t}{\alpha_t(x-1)^{1.7}+x} & x > 1 \end{cases} \tag{2}$$

The compression skeleton curve of concrete is：

$$\sigma = (1- d_c) E_c \varepsilon \tag{3}$$

$$d_c = \begin{cases} 1-\dfrac{\rho_c n}{n-1+x^n} & x \le 1 \\ 1-\dfrac{\rho_c}{\alpha_c(x-1)^2+x} & x > 1 \end{cases} \tag{4}$$

By these equations, the damage curve is also defined together with the skeleton curve. According to the performance in engineering, this definition may lead to excessive concrete damage though the skeleton curves are reasonable. Compared with this, the damage definition of Najar[3] based on energy is more suitable [Fig.1].

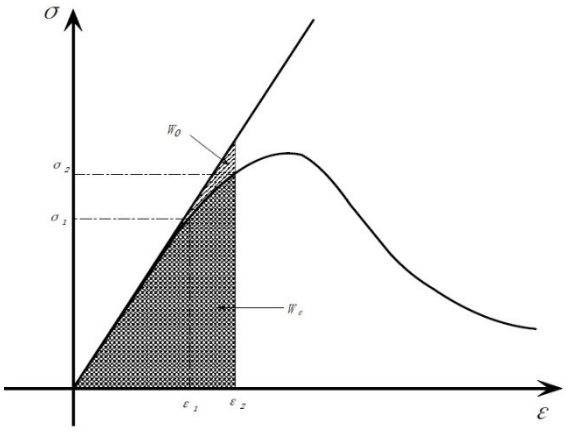

Fig.1 Najar's damage theory

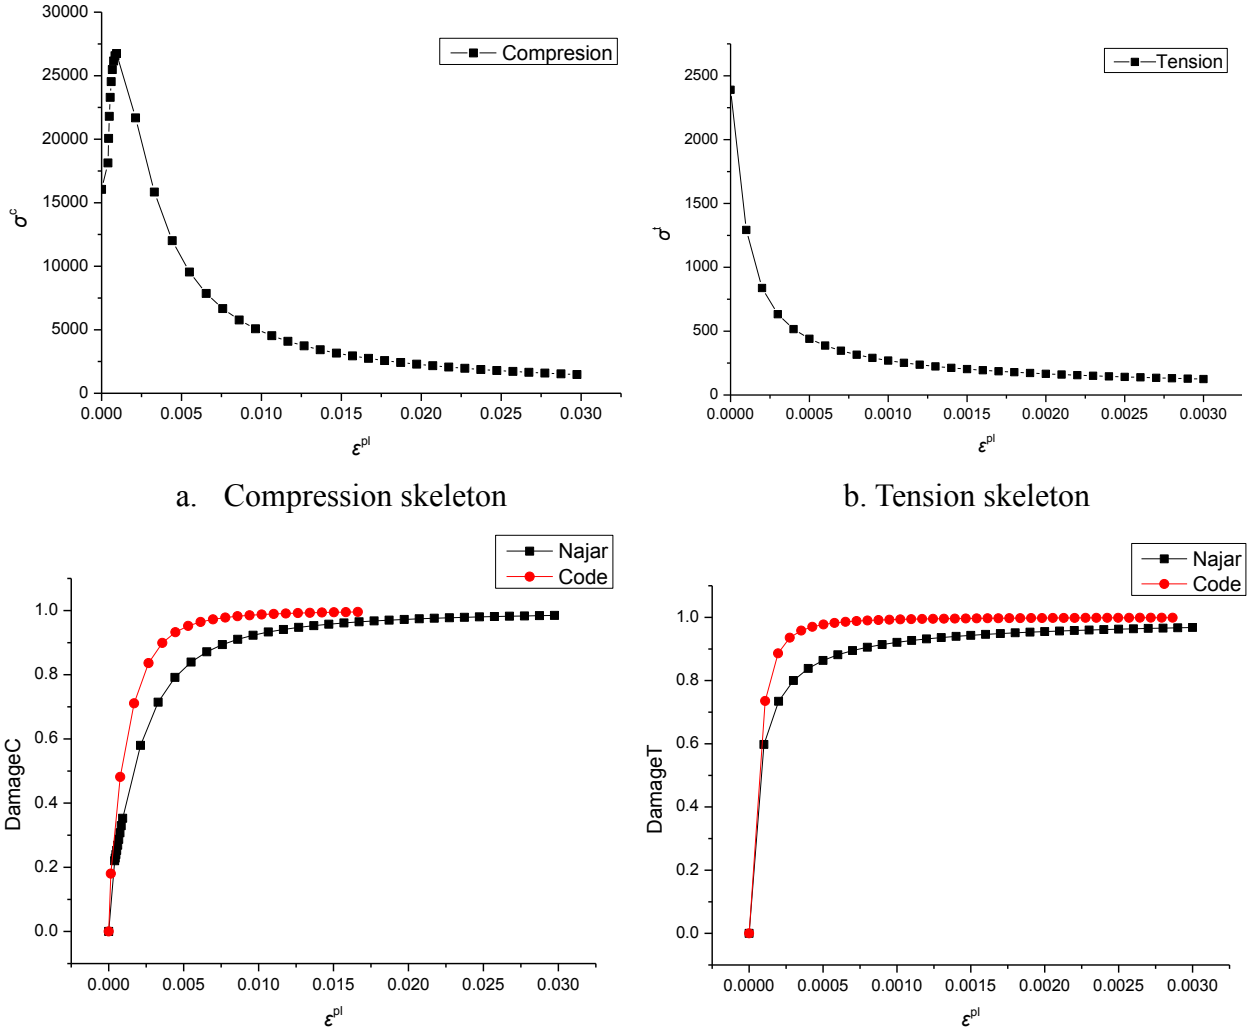
Combined the skeleton curve with Najar's damage definition, a new concrete constitutive model can be formulated out. As an example, the curves of C40 for these two models are shown in Fig.2.



a. Compression skeleton b. Tension skeleton

c. Compression damage d. tension damage

Fig.2 Constitutive model of concrete

**Damping model**

Modal damping has the merit of simulating the damp of each mode accurately in a large range of frequency. On the other hand, for the merit of longer time increment, Rayleigh damping is still used as the main damping form of many software especially for the nonlinear direct integration method. In Abaqus/Explicit, users have to choose Rayleigh damping instead of modal damping which is not available, it can be written as:

$$\mathbf{C} = \alpha\mathbf{M} + \beta\mathbf{K} \tag{5}$$

Where $\alpha$ is the parameter of mass proportional damping and $\beta$ is the parameter of stiffness proportional damping.

By the fundamental frequency $\omega_1$ and an important high frequency $\omega_i$, a low level damping can be achieved by Rayleigh damping between these two frequencies, for those frequencies higher than $\omega_i$, the vibration can be damped by the monotonically increasing damping level.

Because of the relationship between damping and stable time increment in explicit method as follows：

$$\Delta t \le \frac{2}{\omega_{\max}}\left(\sqrt{1+\xi_{\max}^2}-\xi_{\max}\right) \tag{6}$$

It can be derived that the influence on stable time increment of $\alpha$ is nearly negligible, but even a small $\beta$, which is the same order of magnitude as the initial stable time increment without damping, may make the stable time increment reduce by about 50%[4]， so usually it is advised to neglect the stiffness proportional damping in explicit method， for engineering applications, by neglecting $\beta$， a simplified damping model can be expressed only with $\alpha$.[5]：

$$\alpha = \frac{4\pi\xi}{T} \tag{7}$$

This simplified damping model is an inverse ratio function about periods. If using the fundamental period to formulate $\alpha$, it cannot damping the high frequencies efficiently, especially for the vertical vibrations. From the numerical results, although these vibrations cannot affect horizontal response significantly, but the damage induced by vertical vibration will be different more or less.

A suitable stiffness proportional damping without more loss of efficiency can be taken into account as shown in Fig.3

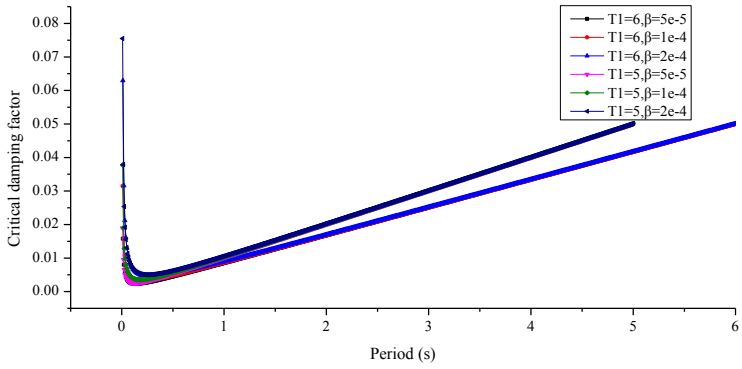


Fig.3 Rayleigh Damping model

**Mesh control**

Limited by the results transfer between Abaqus/Standard and Abaqus/Explicit, shell element S4R or S3R can be used for simulating wall and plate. Reduced integration usually provides more accurate results and significantly reduces running time. But when reduced integration is used with first-order (linear) elements, hourglass control should be required， Therefore, when using first-order reduced-integration elements, hourglass must be checked through the artificial strain energy. A finer mesh not only can reduce the artificial strain energy but also can achieve smooth solution and more accurate damage results.

Engineers are used to design the building structures with meshes larger than 1m. With coarse meshes, the results of structural global response such as displacement angle and base shear are precise enough, but the numerical error of shell stresses usually cannot be neglected especially for those elements in wall-beams and short-leg walls. The variation of reinforcement induced by mesh size may not be significant because of the adjustments and combinations of internal forces require by national code. For the nonlinear time-history analysis under expected rare earthquake，the results of damage depend on the stress precision seriously and different mesh size may lead to different final results.

**Numerical example**

Nonlinear time-history analysis of a high-rise building shown in Fig.4 has been performed with Abaqus/Explicit, comparison of global indexes, energy curves and damage of members has also been made to verify these principles discussed in this paper.

From the results listed from Fig.6 to Fig.9, Different mesh size may achieve similar displacement history, but the numerical error of damage in shell elements may not be negligible and a small stiffness proportional damping can decrease the stiffness degradation of plates significantly.

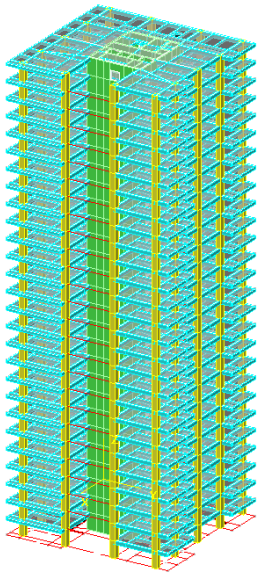

Fig.4 Model of high-rise building

The seismic wave with the peak acceleration equal to 220gal is shown in Fig.5.

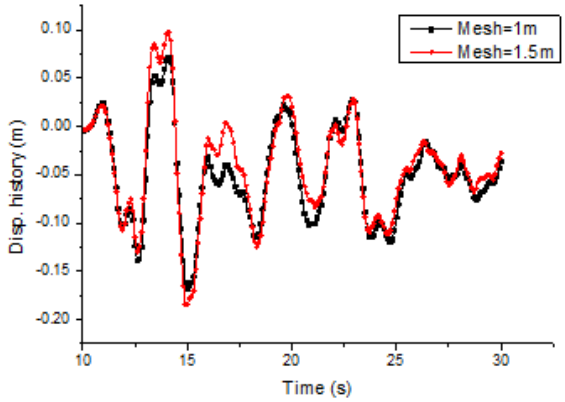

Fig.6 Top displacement history

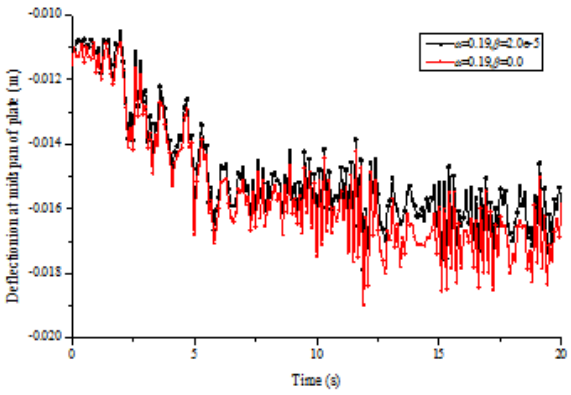

Fig.7 Deflection history of one plate

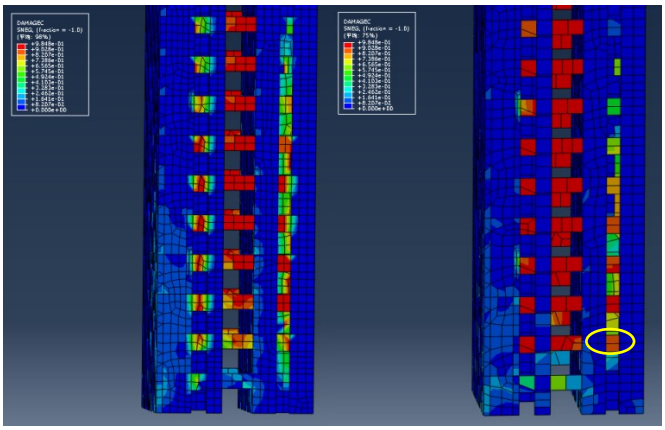

Fig.8 DamgeC of walls(1m vs 1.5m)

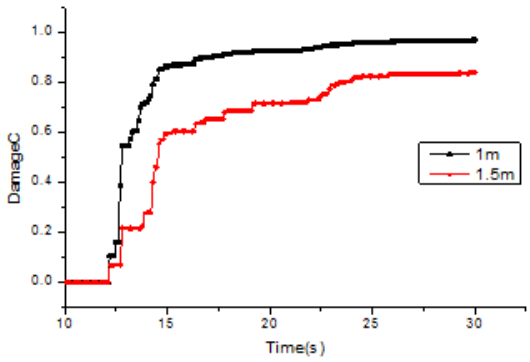

Fig.9 DamageC of selected wallbeam

**Summary**

In order to achieve reasonable solutions of nonlinear time-history analysis for high-rise structures, at first, Najar damage definition has been introduced into the concrete constitutive relation presented in Chinese code. Secondly, although it will decrease the stable time increment dramatically, suitable stiffness proportional damping still can ameliorate the damage without more less of efficiency. And at last, finer mesh size is usually needed more than elastic analysis for hourglass control and precise stress and damage results.

# Influence of saturation degree on deamplification of $P_1$ wave through multilayered porous media

Mehiaoui Hadjebar Mahdia Yasmina[1, a *], Hadid Mohamed.[1,b] and Berrah Mounir Khaled[2,c]

[1] National School of Public Works, Rue Sidi Garidi, Algiers, Algeria

[2] Department of Civil Engineering, Ecole Nationale Supérieure Polytechnique, 10 Avenue Hassan Badi, Algiers, Algeria

[a]mahdia_y@yahoo.fr, [b]hadid_mohamed2003@yahoo.fr, [c]mkberrah@yahoo.fr

**Keywords:** $P_1$ wave; deamplification; coherency; porous media; saturation degree.

**Abstract.** The deamplification model developed by Zendagui et al. has been adapted in this study for the case of $P_1$ wave propagation in porous media in order to investigate the effect of saturation degree on motion coherency at depth. The input wave amplitude distribution function is generated compatibly with the suitable free field coherency model and the top wave amplitudes are evaluated using the transfer matrix method following the Biot's theory. The results show that even if the saturation degree decreases slightly below the complete saturation, it influences the coherencies of horizontal and vertical motion due to $P_1$ wave incidences. Elsewhere, the generation process shows that in this case, the wave front content, necessary to produce a coherency identical to the Luco and Wong model at the free field, is more focus with less intensity than required in the case of a complete saturation.

## Introduction

Because most of seismic arrays are installed on the surface, spatial variability of seismic motion at depth is not directly observable. The approach consisting on estimating the statistical properties of seismic motion at any point in the half space on the basis of the statistical properties obtained on the surface is known as the stochastic deconvolution of earthquake motion. Its basic methodology has been established by Kausel and Pais [1]for the case of a half space. Later, Zendagui et al. [2,3] extended this formulation to the case of *P* and *SV* waves propagating in a multilayered soil.

The analysis of dynamic transient phenomena in fluid-saturated porous media is of great interest in earthquake geotechnical engineering and geophysics because of its relationship with soil liquefaction problems. According to the widely accepted Biot's theory [4] the wave propagation pattern is different comparing to standard wave elastic theory. Therefore, the deconvolution process must be adapted to the case of porous media. The deamplification approach is extended in this paper to the case of multilayered poro-elastic media excited by $P_1$ wave incidence. Elsewhere, the input wave amplitude distribution function is generated compatibly with the suitable free field coherency model. This is done in order to improve the original process. Furthermore, many studies [6-8] indicate the influence of the saturation degree on the porous media dynamic response. A parametric study investigating the effect of this parameter, on the motion coherency at depth, is presented.

## $P_1$ waves stochastic deamplification process

Supposing that $N$ trains of uncorrelated plane waves are propagating into a half-space with different incident angles $\theta_j$, the vertical and horizontal displacements induced are then

$$u(x,y,t)=\sum_{j=1}^{N}u(x,y,\theta_j,t) \quad ; \quad v(x,y,t)=\sum_{j=1}^{N}v(x,y,\theta_j,t). \tag{1}$$

The displacement field is supposed homogeneous, its free field cross-correlation can then be expressed in terms of the horizontal offset $\lambda = x' - x''$ and the temporal shift $\tau = t' - t''$ as follows

$$C_{uu}(\lambda,0,\omega) = E\left[\sum_{j=1}^{N} u(x',0,t')\, u^T(x'',0,t'')\right] \quad ; \quad C_{vv}(\lambda,0,\omega) = E\left[\sum_{j=1}^{N} v(x',0,t')\, v^T(x'',0,t'')\right]. \tag{2}$$

By Fourier transforming these functions with respect to temporal shift $\tau$, spatio-spectral cross density functions are obtained.

$$S_{uu}(\lambda,0,\omega) = \int_{-\infty}^{+\infty} C_{uu}(\lambda,0,t)\, e^{-i\omega t} d\omega \quad ; \quad S_{vv}(\lambda,0,\omega) = \int_{-\infty}^{+\infty} C_{vv}(\lambda,0,t)\, e^{-i\omega t} d\omega. \tag{3}$$

The power spectral density function is giving as [3]: $S_j(\omega)=g^2(\theta)S(\omega)$, with $g^2(\theta)$ being the relative amplitude of the wave trains which depends, in general, on the incidence angle [3]. The deamplification process consists on determining the cross-spectral density function at any depth $y$ from the surface ones.

$$S(\lambda,y,\omega) = \Im_k\left[\mathbf{T}\Im_\lambda[S(\lambda,0,\omega)]\mathbf{T}^T\right]. \tag{4}$$

This allowes to calculate soil motion coherency at any soil depth $y$.

$$\gamma(\lambda,y,\omega) = \frac{S(0,y,\omega)}{S(\lambda,y,\omega)}. \tag{5}$$

However, the relative amplitude of the wave trains $g^2(\theta)$ must first be determined. In 1996, Iguchi and Hanamura [9] presented a closed form solution for the amplitude estimation of incoming waves that corresponds to a coherency free field model. In this paper, the well known Luco and Wong [5] model is adopted and the following simple equation is adopted for the amplitude distribution function

$$g^2(\theta) = e^{-(\varphi-\theta)^2/\beta}. \tag{6}$$

$\varphi$ is the mean incident angle with respect to the vertical and $\beta$ is a coherency degree dependent parameter determined by an iterative process.

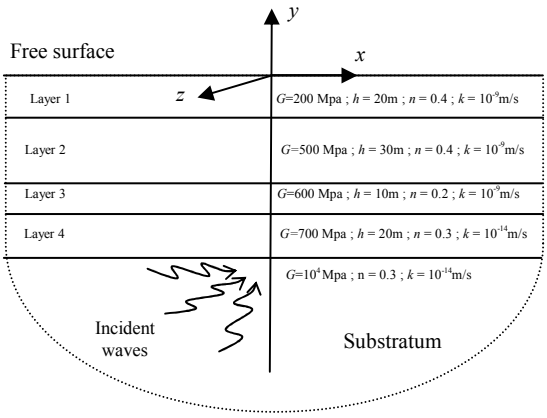

Fig. 1: Numerical example

Table 1 Common material properties of the soil layers

| | |
|---|---|
| $\rho_S$ Density of solid grains [kg/m$^3$] | 2610 |
| $K_s$ Bulk modulus of solid grains [Pa] | 36 $10^9$ |
| $K_w$ Bulk modulus of water [Pa] | 2.2 $10^9$ |
| $\upsilon$ Poisson ratio | 0.25 |
| $\xi$ Damping | 0.05 |

**Numerical example**

Let us consider a multi layered viscoelastic porous soil overlying a substratum as shown in Fig. 1. Each layer is characterized by its shear modulus (G), porosity (n) and permeability (k). All the soil layers are considered fully water saturated and their common geotechnical characteristics are

summarized in table 1. In the cas of $P_1$ wave incidence, the computed surface coherencies are plotted in fig. 2 for two values of the Luco and Wong incoherence parameters [5]. This procedure permits to generate the waves amplitudes intensity function as shown in figure 3. The values of parameter $\beta$ are found iteratively.

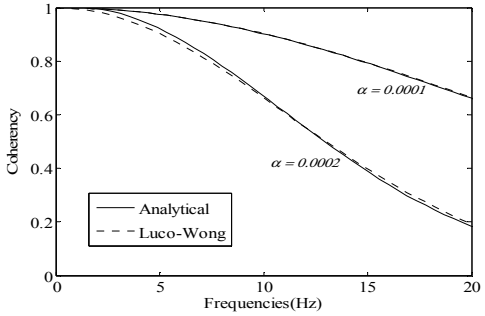

Fig. 2: Examples of coherencies computed at the free surface for $\lambda = 50$ m

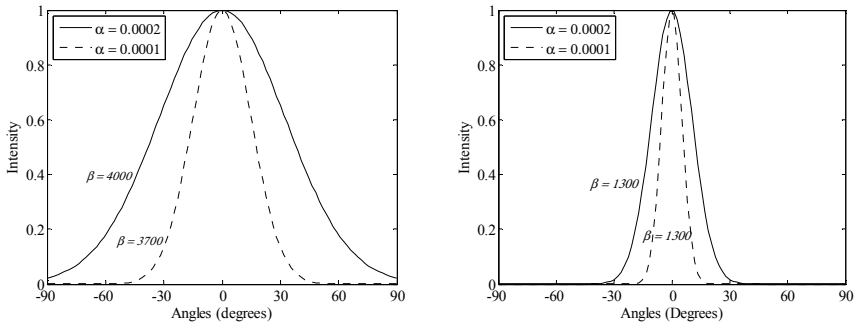

Fig. 3 : Examples of identified intensity function for $\varphi = 0°$ (a) $S_r = 100\%$ (b) $S_r = 98\%$

The deamplification procedure is executed in order to determine the spatio-spectral density function in depth. The transfer function between the soil surface and an elevation $y$ in the soil is evaluated using the exact stiffness matrix method. The coherencies at the top and the bottom of the multilayered soil are shown in figures 4 and 5.

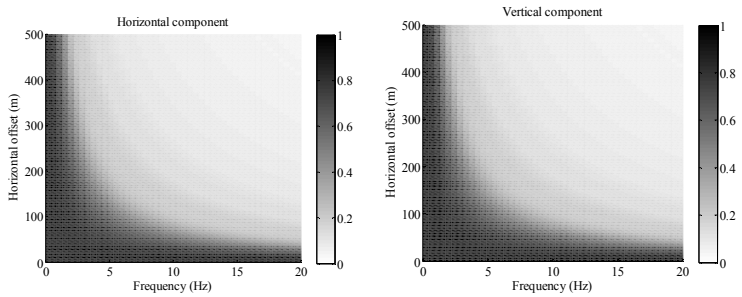

Fig. 4: Free field coherencies

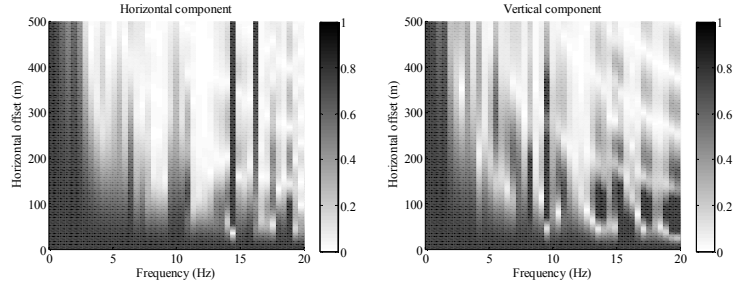

Fig. 5: Coherencies at 80 m depth for $S_r = 100\%$

Yang [6-8] indicates that a slight decrease in the saturation degree may have significant influence on soil dynamics responses. In this topic, coherency has been evaluated using the same example here before but for a different saturation degree *Sr* = 98% (see fig 3 and 6).

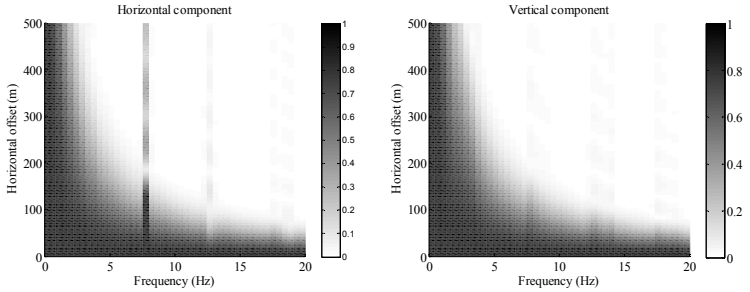

Fig. 6 : Coherencies at 80 m depth for Sr = 98%

## Conclusion

The deamplification process has been extended herein for the case of poro-elastic multilayered soil profile. Numerical example has been presented in the case of $P_1$ wave train incidence. The input wave amplitude distribution function has been generated according to the Luco and Wong coherency model and the coherencies have been calculated for complete saturation (*Sr*=100%) and fully saturation (*Sr*=98%). The results showed that saturation degree modifies both input wave amplitude distribution and coherencies. The generated wave front content is more focused with less intensity in the case of fully but not complete saturation whereas deconvoluated coherencies of complete saturation case are more important.

# Precise Integration Method of Pseudo-dynamic Testing of Structures

Haibo Wang[1,a], Rong Liu[2,b]

[1,2]School of Civil Engineering, Central South University, Changsha Hunan, China 410075

[a]haibarg@csu.edu.cn,[b]liurongcsu@sina.com

**Keywords:** pseudo-dynamic test of structures; precise integration method; predict-correct method; central difference method

**Abstract.** Based on nonlinear precise integration method, two new numerical integration methods of pseudo-dynamic test of structures are presented. One is explicit predict-correct, four order accuracy and multistep method avoiding calculating the inversion of the state matrix. The other is implicit predict-correct, four order accuracy and multistep method that need calculate the inversion of the state matrix. Since their accuracies are superior to the central difference method by enlarging time step and their stabilities are better, the structural systems of multi-degree of freedom could be well tested and the testing work would be largely reduced. Finally, a pseudo-dynamic test of combined tube structure has been executed with the explicit multi-step method.

## Introduction

Proposed for the first time by a Japanese scholar Professor M.Hakuno in1969, the pseudo-dynamic test method is a structural anti-seismic test method combining cybernation with structural test effectively. It can be used for the earthquake simulation test of large-scale structure. Then the structure restoring force can be measured directly from the specimen with no theoretic hypothesis. Different from numerical integration method, it does not require to assume restoring force behavior in advance that can get from the reaction force and displacement in actuator during the test. Since restoring force behavior is provided through test device synchronously, it avoids the errors originated from the behavior assumptions during the computer numerical simulation and improves the computer simulation accuracy of structural dynamic response. Advantage of the method is that it can be used to do anti-seismic experiment in large-scale, high-proportion models even the structural prototypes. And since the load process is gradual during the test, the structure destruction process can be observed in detail[1].

Numerical integration methods of pseudo-dynamic testing can be divided into two categories, explicit and implicit integration methods[2]. Explicit integration methods mainly include the central difference method, explicit Newmark method and modified Newmark method. Implicit integration methods mainly included Newmark- $\beta$ method and $\alpha$ - method. It is well known in the numerical analysis of the structure that the calculation accuracy of implicit methods is obviously better than explicit methods. In addition, explicit methods are conditionally stable and higher efficiency for each time step, but in order to ensure its stability the time step must be small. Implicit integration methods can be through appropriate choice of parameters to ensure the integration stability, so a larger time step can also be applied. Since explicit integration methods do not require iteration and are easy to operate in test, the majority of the current application is explicit integration methods, generally not the implicit methods. But researchers have been exploring to apply implicit methods to pseudo-dynamic testing. P.B. Shing and M.T. Vannan[3,4,5] have had detailed discussions on these issues such as the accuracy and error analysis of $\alpha$ - method for the pseudo-dynamic experiments. Qiu Fawei[6]has taken reinforced concrete frame structure as an example to study implicit $\alpha$ - method and its application in the substructure pseudo-dynamic test. Both in the theory and calculation disadvantages of these methods are not high precision, large artificial damping and that does not reflect the high frequency components.

Based on nonlinear precise integration method, combined the precise integration method[7] with the predict-correct Adams-Bashforth-Moulton multi-step method[8], two new numerical integration

methods of pseudo-dynamic testing are established. One is explicit predict-correct, fourth-order accuracy and multistep method avoiding calculating inversion of the state matrix, the alternative is implicit predict-correct, fourth-order accuracy and multistep method that need calculate the inversion. Due to the high calculating precision of these methods, pseudo-dynamic testing can be accomplished by enlarging time step and multi-degree of freedom structural systems could be well tested. Numerical examples show that these methods will largely reduce the testing work and have good practicality compared to central difference method. Finally, a pseudo-dynamic test of combined tube structure has been executed with the explicit multi-step method.

**Precise integration method of pseudo-dynamic testing**

There is a time interval for the processed earthquake record. It is usually 0.02s and difficult to express with continuous function. However, single-step method need to find an intermediate function value through continuous load function, therefore it can not be used for pseudo-dynamic test. And since the Adams method has poor stability and accuracy, it can not be though. The following discussion is how to apply multi-step predict-correct method with enlarged time step to numerical simulation examples of pseudo-dynamic testing.

The motion differential equation for Pseudo-dynamic test can be expressed as Eq. 1.

$$M\ddot{x}(t)+C\dot{x}(t)+r(x,t)=f(t) \tag{1}$$

Where $M$ and $C$ are $n\times n$ order mass matrix, damping matrix respectively and $\ddot{x}(t)$, $\dot{x}(t)$, $x(t)$ and $f(t)$ are $n$ order motion acceleration, velocity, displacement and load vector of particle respectively. $r(x,t)$ is $n$ order restoring force vector of particle.

In the pseudo-dynamic testing the mass matrix $M$ is known and the damping matrix $C$ is usually considered to be a given linear damping or ignored, so $f(t)=-M\ddot{x}(t)$ is known as $\ddot{x}(t)$ is the input ground motion acceleration.

Eq. 1 can be converted into a first-order differential equation as Eq. 2.

$$\dot{v}(t)=Hv(t)+R(v,t)+F(t) \tag{2}$$

Where

$$v(t)=\begin{Bmatrix} x(t) \\ M\dot{x}(t)+\dfrac{Cx(t)}{2} \end{Bmatrix},\quad R(v,t)=\begin{Bmatrix} 0 \\ -r(x,t) \end{Bmatrix},\quad F(t)=\begin{Bmatrix} 0 \\ f(t) \end{Bmatrix},\quad H=\begin{bmatrix} -\dfrac{M^{-1}C}{2} & M^{-1} \\ \dfrac{CM^{-1}C}{2} & -\dfrac{CM^{-1}}{2} \end{bmatrix}$$

Or when the initial stiffness $K_0$ has been considered, then

$$R(v,t)=\begin{Bmatrix} 0 \\ K_0x(t)-r(x,t) \end{Bmatrix},\quad H=\begin{bmatrix} -\dfrac{M^{-1}C}{2} & M^{-1} \\ \dfrac{CM^{-1}C}{2}-K_0 & -\dfrac{CM^{-1}}{2} \end{bmatrix}$$

This article is analyzed with the post form.

With the index matrix introduced, Eq. 2 can be turned into the same solution integral equation as Eq.3

$$v(t_{k+1})=e^{H\Delta t}v(t_k)+\int_{t_k}^{t_{k+1}}e^{H(t_{k+1}-\tau)}R(v,\tau)d\tau+\int_{t_k}^{t_{k+1}}e^{H(t_{k+1}-\tau)}F(\tau)d\tau \tag{3}$$

Where $v(t_{k+1})$, $v(t_k)$ are respectively the values of solving vector at time $t_{k+1}$ and $t_k$.

**The explicit method avoiding calculating inversion of the state matrix of pseudo-dynamic testing.**

As the first n terms of $R(x(t_{k+1}),t_{k+1})$ is 0, the precise integration multi-step solving process in Eq. 3 can directly be used for pseudo-dynamic test of structures then turn into explicit method. Specific implementation is as follows:

(1) Solve predetermined applying displacement $x(t_{k+1})$

$$v(t_{k+1}) = e^{H\Delta t}v(t_k) + \frac{\Delta t}{24}\left(19G(t_k) - 5G(t_{k-1}) + G(t_{k-2})\right) + w(t_{k+1}) \tag{4}$$

Where $G(t_k) = e^{H\Delta t}R(v(t_k),t_k)$, $G(t_{k-1}) = e^{2H\Delta t}R(v(t_{k-1}),t_{k-1})$, $G(t_{k-1}) = e^{3H\Delta t}R(v(t_{k-2}),t_{k-2})$

$w(t_{k+1})$ is the high precision integral formula Cotes [8], and it can be expressed as Eq. 5.

When $\Delta t = 2\Delta t"$ (note: $\Delta t"$ is the interval for seismic records, for example if $\Delta t"$ = 0.02s, then $\Delta t$ = 0.04s)

$$w(t_{k+1}) = \frac{\Delta t}{6}\cdot\left[e^{H\Delta t}F(t_k) + 4e^{H\cdot\frac{1}{2}\Delta t}F(t_k + \frac{\Delta t}{2}) + F(t_{k+1})\right] \tag{5a}$$

When $\Delta t = 3\Delta t"$

$$w(t_{k+1}) = \frac{\Delta t}{8}\cdot\left[e^{H\Delta t}F(t_k) + 3e^{H\cdot\frac{2}{3}\Delta t}F(t_k + \frac{\Delta t}{3}) + 3e^{H\cdot\frac{1}{3}\Delta t}F(t_k + \frac{2\Delta t}{3}) + F(t_{k+1})\right] \tag{5b}$$

When $\Delta t = 4\Delta t"$

$$w(t_{k+1}) = \frac{\Delta t}{90}\cdot\left[7e^{H\Delta t}F(t_k) + 32e^{H\cdot\frac{3}{4}\Delta t}F(t_k + \frac{\Delta t}{4}) + 12e^{H\cdot\frac{1}{2}\Delta t}F(t_k + \frac{\Delta t}{2}) + 32e^{H\cdot\frac{1}{4}\Delta t}F(t_k + \frac{3\Delta t}{4}) + 7F(t_{k+1})\right] \tag{5c}$$

It can be seen from Eq. 5 that the different values of $\Delta t / \Delta t^*$ are to select the different integration methods and actually it uses the each-step seismic wave information within $\Delta t$ to improve its calculating accuracy.

If time interval of the test is too long, the method accuracy will be decreased and the test points will also be reduced. Generally it can be based on the test accuracy requirements to take $2\Delta t" \sim 4\Delta t"$.

(2) Once $v(t_{k+1})$ has been solved, it means $x(t_{k+1})$ is known. The displacement $x(t_{k+1})$ can be exerted by the actuator, then the restoring force $r(x(t_{k+1}),t_{k+1})$ would be obtained in this step. $R(x(t_{k+1}),t_{k+1})$ is known then apply it to the following formula

$$v(t_{k+1}) = e^{H\Delta t}v(t_k) + \frac{\Delta t}{24}\left(9R(v(t_{k+1}),t_{k+1}) + 19G(t_k) - 5G(t_{k-1}) + G(t_{k-2})\right) + w(t_{k+1}) \tag{6}$$

Where the meaning of the parameters is the same to Eq. 4.

The whole process of pseudo-dynamic test could be completed with Eq. 4 to Eq. 6. Gauge head values (Note: the first three steps values after calculating) can be calculated by the linear assumption for displacement and the use of the initial stiffness. In the initial stage of the earthquake, the seismic wave peak is usually small so the assumption should be supposed to be feasible.

**The implicit method calculating inversion of the state matrix of pseudo-dynamic testing.**

Implicit pseudo-dynamic integration method calculating inversion of the state matrix can use the above explicit pseudo-dynamic integration method as the basis for estimates. Its steps of implementation are presented as follows:

(1) Firstly, the displacement $x^0(t_{k+1})$ can be calculated with Eq. 4 and estimated then achieved by using the actuator.

(2) Measuring the restoring force of the step $r(x(t_{k+1}),t_{k+1})$, you can get $R(x(t_{k+1}),t_{k+1})$ and computer $v(t_{k+1})$

$$\begin{aligned} v(t_{k+1}) = e^{H\Delta t}\Big[v(t_k) + H^{-1}c_0 + \left(\Delta t H^{-1} - H^{-2}\right)c_1 + \left(\Delta t^2 H^{-1} - 2\Delta t H^{-2} + 2H^{-3}\right)c_2 + \\ \left(\Delta t^3 H^{-1} - 3\Delta t^2 H^{-2} + 6\Delta t H^{-3} - 6H^{-4}\right)c_3\Big] - H^{-1}c_0 + H^{-2}c_1 - 2H^{-3}c_2 + 6H^{-4}c_3 + w(t_{k+1}) \end{aligned} \tag{7}$$

Where the expression of $w(t_{k+1})$ can get from Eq. 5 and

$$\begin{cases} c_0 = R_{k+1} \\ c_1 = \dfrac{-11R_{k+1} + 18R_k - 9R_{k-1} + 2R_{k-2}}{6\Delta t} \\ c_2 = \dfrac{2R_{k+1} - 5R_k + 4R_{k-1} - R_{k-2}}{2\Delta t^2} \\ c_3 = \dfrac{-R_{k+1} + 3R_k - 3R_{k-1} + R_{k-2}}{6\Delta t^3} \end{cases} \tag{8}$$

Where $R(v(t_i),t_i)$ is short for $R_i$.

Thus $x^1(t_{k+1})$ can be obtained.

(3)If $\left|x^1(t_{k+1}) - x^0(t_{k+1})\right| \le \varepsilon$ then take $x^1(t_{k+1}) = x^0(t_{k+1})$ and execute the next step; otherwise, use actuators to achieve $x^1(t_{k+1})$ then take $x^0(t_{k+1}) = x^1(t_{k+1})$ and perform the (2) step. ($\varepsilon$ is a smaller number to control accuracy and the desirable is 0.02mm.)

(4) $k = k+1$, if $k >$ the total number of steps, end the test; otherwise perform the first step.

Gauge head calculation of the implicit method is the same to the explicit method discussed previously in this article. Since this method is implicit, the test for each step may need multi-step to complete, thus the workload is increased.

## Analysis of examples

Due to various errors, the pseudo-dynamic test of structures is not repeatable. So the testing examples are difficult to select .The impact of round-off errors has been only considered in this paper. The accuracy for controlling the actuator displacement is taken as 0.01mm and the force is 0.01kN. Take the calculated value of refine segmentation direct integration method [7] as the ratio. Since the central difference method and the explicit Newmark-$\beta$ method are the same in essence, then the central difference method is compared with the explicit and implicit multi-step method mentioned in this paper about errors.

**Example 1:** For a structural system of single degree of freedom, the motion equation is Eq. 13

$$M\ddot{x}(t) + C\dot{x}(t) + r(x,t) = 0.4Mg\sin 2\pi t \tag{13}$$

Where $M = 50$t, damping ratio is 0.05, the initial elastic stiffness $K = 28.8$kN/mm, g = 9.80665. The earthquake lasts for 10s, displacement unit is mm and force unit is kN. Take the restoring force $r(x(t),t) = Kx(t)(1 - 0.0015x^2(t))$.

The controlled time step for the central difference method to calculate is 0.02s and the time step of the explicit multi-step method and the implicit method in this article is 0.04s. The actual calculated displacement and the calculated errors of the three methods are shown in Fig. 1and Fig. 2.

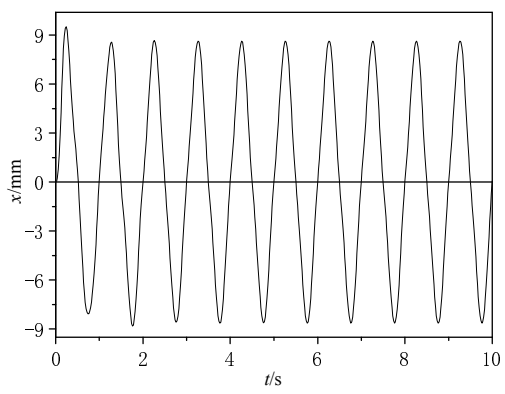

Fig.1 Displacement time-history curve of calculation

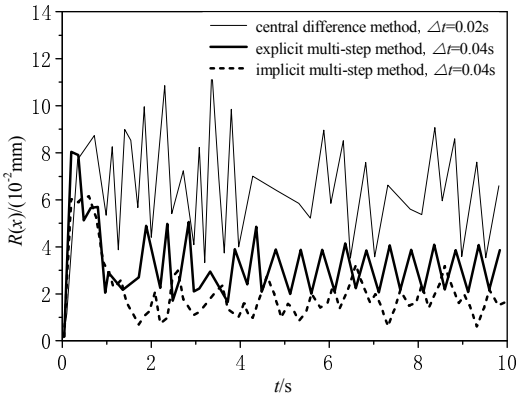

Fig.2 Enveloping diagram of displacement error

**Example 2:** The author has completed the steel tube-in-tube structure model of the equivalent two degrees of freedom without considering the impact of damping. The input seismic wave is a sine wave, the prototypical peak acceleration is 0.40g, the time lasts for 10s, the equivalent mass $m_1$ = 2016kg and $m_2$ = 1464kg; the time step $\Delta t$ can be solved by similarity coefficient, the prototypical time step is 0.02s and the time step $\Delta t$ = 0.00422s. Displacement unit is mm, force unit is kN. Assuming that its pseudo-dynamic test equation can be written as Eq. 14

$$10^{-3}\times\begin{bmatrix}2.016 & 0\\ 0 & 1.461\end{bmatrix}\begin{Bmatrix}\ddot{x}_1\\ \ddot{x}_2\end{Bmatrix}+\begin{Bmatrix}r_1\\ r_2\end{Bmatrix}=0.4\alpha g\sin(10\pi t)\times\begin{bmatrix}2.016 & 0\\ 0 & 1.461\end{bmatrix} \tag{14}$$

Where the restoring force is taken as Eq. 15

$$\begin{Bmatrix}r_1\\ r_2\end{Bmatrix}=\begin{bmatrix}28.9 & -12.0\\ -12.0 & 8.8\end{bmatrix}\left(\begin{Bmatrix}x_1\\ x_2\end{Bmatrix}-4\begin{Bmatrix}\sin(0.05x_1)\\ \sin(0.05x_2)\end{Bmatrix}\right),\quad \alpha=2.41,\quad g=9.80665,\quad \pi=3.14159. \tag{15}$$

The controlled time step for the central difference method to calculate is 0.00422s and the step of the explicit multi-step method and the implicit method in this article is 0.01688s. The actual calculated displacement and errors of the three methods are shown in Fig. 3, Fig.4 and Table 1.

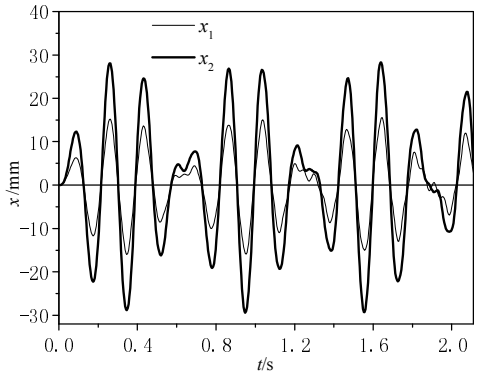

Fig.3 Displacement time-history curve of calculation

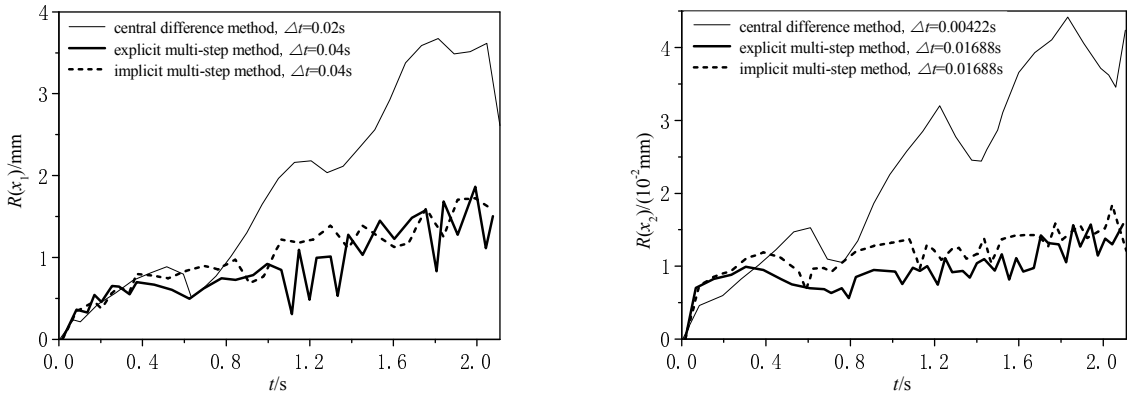


(*a*) $R(x_1)$ (*b*) $R(x_2)$

Fig.4 Enveloping diagram of displacement error

Table1 Displacement error of calculation (%)

| Example | Step (s) | Example 1 | Step (s) | Example 2 | |
|---|---|---|---|---|---|
| Relative error | | $R^*(x)$ | | $R^*(x_1)$ | $R^*(x_2)$ |
| The center difference method | 0.02 | 1.21 | 0.00422 | 22.92 | 15.0 |
| The explicit method | 0.04 | 0.85 | 0.01688 | 11.62 | 5.36 |
| The implicit method | 0.04 | 0.65 | 0.01688 | 10.75 | 6.34 |

Note: The above error is relative and $R^*(x_i) = \left|\max(R(x_i)) / \max(x_i)\right| \times 100\%$.

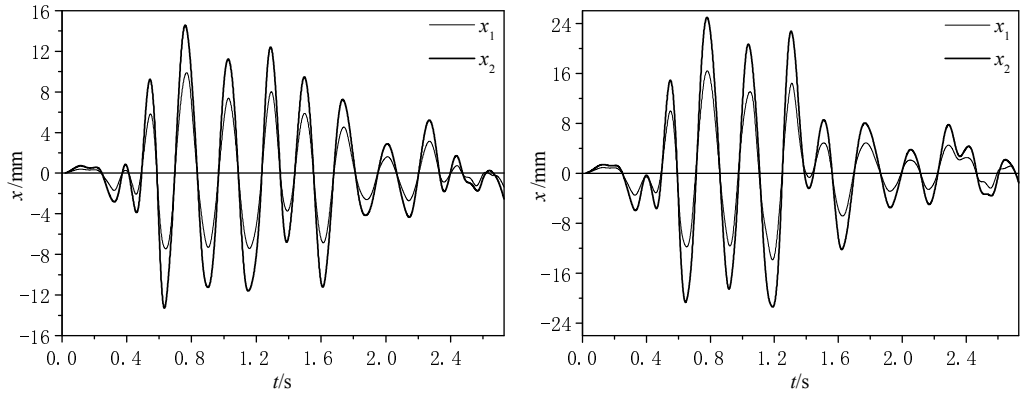
By comparing example 1with 2 (Figure 2, Figure 4 and Table 1) some conclusions can be drawn: (1) Whether it is for systems of single degree of freedom or two degrees, with the time step increased the accuracy of the explicit and the implicit multi-step method in this article is better than the central difference method; (2) The central difference method for a pseudo-dynamic testing system of single degree of freedom is high accuracy algorithm but poor for the system of two degrees of freedom; (3)For non-linear example1 since the displacement peak occurs in the initial stage , there will be large errors for the explicit and implicit multi-step method in this stage. During the actual pseudo-dynamic testing process, you can avoid this situation (The displacement peak in the actual seismic action is generally not presented in the initial stage); (4) For a system of single degree of freedom, the accuracy of the implicit method is obviously higher than the explicit method. But for a system of two degree of freedom, there is no advantage for the implicit method. Since the implicit method requires iterative to complete the test, the workload will be some increase. Therefore the explicit method is more practical.

## Applied research

Based on the above explicit numerical integration method of pseudo-dynamic testing, the pseudo-dynamic testing [10] of the steel-concrete composite tube-in-tube structure model of the equivalent two degrees of freedom has been completed by the author. Consider the linear Rayleigh damping. The input seismic wave is Elscentro N-S wave and the prototypical acceleration peaks are 0.62g, 1.00g respectively. The time lasts for 10s, the equivalent mass $m_1$ = 9413kg, $m_2$ = 6363kg; the time step $\Delta t$ can be solved by similarity coefficient and the prototypical time step is 0.02s and $\Delta t$ = 0.00546s.The acceleration similarity coefficient is1.34. Displacement unit is mm and load unit is kN. Its pseudo-dynamic test equation can get from Eq. 7. Where (before the acceleration reaches the peak (0.62g and 1.00g) the initial stiffness are $K_{01}$ and $K_{02}$ respectively)

$$C=\begin{bmatrix} 0.1385 & -0.04963 \\ -0.04963 & 0.05270 \end{bmatrix},\quad K_{01}=\begin{bmatrix} 45.983 & -20.093 \\ -20.093 & 16.284 \end{bmatrix},\quad K_{02}=\begin{bmatrix} 33.01 & -16.78 \\ -16.78 & 15.07 \end{bmatrix}$$

Time step of the explicit multi-step method is 0.02184s, namely the test points are 1/4 for the central difference method. At the height of testing load point the displacement time-history curve of the two acceleration peaks are measured as Fig.5.



(*a*) 0.62g (*b*) 1.00g

Fig.5 Displacement time-history curve of test by two peak ground acceleration

## Conclusions

(1) Based on non-linear precise integration method, two numerical integration methods of pseudo-dynamic testing including explicit and implicit have been derived with four order accuracy. Both can be used for pseudo-dynamic testing system of multi-degree of freedom.

(2) Since the calculated precision of the methods is high, the pseudo-dynamic testing structural systems of multi-degree of freedom can be completed by enlarging time step. Analysis of the examples and applied research in the paper have shown that the workload in these methods will be exponentially less than the central difference method and more practical.

(3) Since the implicit method requires iterative to complete the test, it will increase the workload. Therefore the explicit method is higher value in practical.

**Key words:** Performance-based engineering, RPS2000, Finite element, Nonlinear analysis, Seismic design, Finite reliability analysis.

**Abstract.** The performance-based engineering approach, as opposed to prescriptive rules of code-based design, is based on simulation of real structural behavior. Reliability of the expected performance state is assessed by using various methodologies based on finite element nonlinear static pushover analysis and specialized reliability software package.
Reliability approaches that were considered included full coupling with an external finite element code based methods in conjunction with either first order reliability method or importance sampling method. The building considered in the actual study has been designed against seismic hazard according to the Moroccan code RPS2000.

## Introduction

The finite element method is currently the dominating tool for simulating structural behavior. A coupling of this method with reliability analysis algorithms leads to the finite element reliability method described in this work. The first coupling between FORM (first-order reliability method) reliability analysis and the finite element method is found in Der Kiureghian and Taylor [10]. Since then, a number of advances have been reported, including those by Liu and Der Kiureghian [11], Gutierrez et al.[12], Zhang and Der Kiureghian [13], Der Kiureghian and Zhang [14], Sudret and Der Kiureghian [15], Imai and Frangopol [16], Haldar and Mahadevan [17], and Frier and Sorensen [18]. Such methods address the key issue in performance-based engineering. Based on performance criteria mandated by the client or the society, probability estimates for reaching specified structural performance thresholds are computed. In addition, sensitivity and importance measures for the model parameters are available.
Finite element reliability analysis (FERA) has been developed to account for uncertainties in structural analysis. The input parameters of the finite element model are provided as random variables to account for uncertainty in the material, geometry, and loading parameters. Subsequently, the probability of response events is computed. This is achieved by defining limit-state functions (also referred to as performance functions) in terms of response quantities of the finite element analysis.

Finite element reliability analysis using full coupling between a finite element code and reliability methods such as the FORM and Monte Carlo methods tend to be computational time consuming for practical problems which could include a large number of random variables. At each iteration, the limit-state function and its derivatives are to be evaluated through finite element computations. An effective method which combines FORM and subsequent importance sampling around the most probable failure point has been proposed by (Haukaas and Der Kiureghian [19]. The Importance Sampling Method (ISM) requires only a limited number of evaluations of the limit-state function (and its gradient with respect to the random variables) to find the approximation point, followed by efficient importance sampling analysis centered at this point. In this last reference, Haukaas and Der Kiureghian [19] have presented numerical examples involving comprehensive nonlinear finite element models with approximately 500 random variables were presented.

**Finite element seismic reliability analysis of buildings**

The performance-based engineering approach is based on simulation of real structural behavior. This feature sets it apart from classical prescriptive rules associated to code-based design. The client or government regulations prescribe desired performance objectives, which are translated into decision variables or functions and serve defining performance criteria.

Applying reliability analysis methods in the context of performance-based engineering uses the specified performance functions as performance criteria or limit-states. The term failure denotes then the event of not meeting a given performance criterion. It is then important to know how to translate such performance requirements into explicit performance functions attainable by finite element structural analysis.
In this work reference is made to the performance level introduced by the Moroccan seismic code RPS 2000, [20], which intends limiting the building roof displacement ratio. Other performance criteria introduced to distinguish performance-based engineering states with regards to earthquake events could be for example those defined according to the Federal Emergency Management Agency [21].In this case, the performance states include: operational performance for which the event does not affect the occupants or functioning of the building; immediate occupancy performance for which the occupants can immediately return to the building after the seismic event; life safety performance and collapse prevention performance.
The client or code regulations determine in general an acceptable hazard level for each of these performance requirements. For an earthquake event with probability, say, 50% in 50 years, immediate occupancy performance may be demanded. On the other hand, for an earthquake event with probability 2% in 50 years only life safety performance may be desirable. A formal similarity could be stated between the limit-state in the present work according to RPS 2000 and the collapse prevention limit-state according to FEMA.
In this work, finite element analysis was performed by means of OpenSees platform. The beam-column element used is a displacement-based element having the aptitude to take into account distributed plasticity that develops through fiber cross-sections. The element uses the stiffness formulation approach. A user-selected number of integration points along the element can be prescribed. The fiber cross-sections are composed of uniaxial material models.

Material models for steel, unconfined concrete in girders and column cover regions and confined concrete in column core regions that are used in the actual work correspond respectively to the uniaxial smoothed bi-linear steel material and uniaxial smoothed concrete material.

**Estimation of performance probabilities and response statistics**

The primary concern in structural reliability analysis is to estimate probabilities of failure to achieve predefined performance. In the simplest case of one performance function, the component reliability problem is formulated as

$$p_f = \int_{g(x)\leq 0} f(x)dx \tag{3.1}$$

Where $p_f$ is the probability of failure, $x$ is the vector of random finite element model parameters, $g(x)$ is the performance function and $f(x)$ is the joint PDF of $x$.Note that the integration is over the set of random variables $x$,which in finite element reliability analysis can be large. Closed-form solutions of Eq. (3.1) are unavailable except for a few special cases. For this reason, a number of methods have been developed for the purpose of solving the integral approximately. These include the first- and second-order reliability methods, FORM and SORM, sampling analysis, response surface methods and numerical integration schemes. The latter method is usually not a feasible

alternative when the number of random variables is greater than 3 or 4. Furthermore, in finite element reliability analysis, it is desirable to limit the number of evaluations of $g$ and its gradient. This makes methods such as FORM, SORM and importance sampling (IS) tractable, while it excludes the crude Monte Carlo sampling scheme for problems with small failure probabilities. A common aspect of FORM, SORM and IS is that they all employ the so-called design point. This is the most likely point in the failure domain, when the variables are transformed to the standard normal space. As such, this is the ideal point for approximating the limit-state surface separating the safe and failure domains. FORM
analysis estimates the failure probability by approximating the limit-state surface by the tangent hyper-plane at the design point. SORM analysis estimates the failure probability by approximating the limit-state surface by a quadratic surface tangent at the design point. An IS analysis may subsequently use the design point as the center of sampling to obtain an improved estimate of the failure probability. The options for FORM and IS analysis are implemented in OpenSees. The framework for SORM analysis is also implemented in OpenSees. However, this option is currently limited to a simple algorithm to estimate the ¯first principal curvature for the fitting paraboloid using a method developed by Der Kiureghian and DeStefano [22].

Before proceeding to discuss methods that address the probability integral in Eq. (3.1), the method available in OpenSees for computing second moments of response quantities are described. These statistics of the response describe the propagation of uncertainties through the finite element model.

**Form**

FORM analysis addresses the reliability problem in Eq. (3.1) by means of two key operations. Firstly, we find the design point in the transformed uncorrelated standard normal space. Secondly, we approximate the limit-state surface at this point and make use of the properties of the standard normal space to obtain the probability estimate. The first item can be a challenging task in nonlinear finite element reliability analysis.

The distance from the origin of the standard normal space to the design point, denoted $y^*$ ,istermed the "reliability index" and denoted $\beta$ .The first-order probability estimate is then found as

$$p_f \approx p_{f1} = \Phi(-\beta) \tag{4.1}$$

where $\Phi(.)$ denotes the standard normal CDF. It is common to define the "alpha vector" as the negative normalized gradient row vector at the design point, i.e.,

$$\alpha = -\frac{\nabla G}{\|\nabla G\|} \tag{4.2}$$

Where $\nabla G = \left[\frac{\partial G}{\partial y_1} \ldots \frac{\partial G}{\partial y_n}\right]$.In terms of $\alpha$ ,the reliability index is given by $\beta = \alpha y^*$.

Additionally, $\alpha$ is one of several parameter importance measures available as a by-product of FORM analysis. Such measures are valuable in practical engineering design. They can also be used to reduce the number of random variables in a model.

**Importance Sampling Analysis**

In the crude Monte Carlo method the sampling distribution is centered at the mean point. Since failure events tend to occur in the tail regions of probability distributions, this implies that a large

number of samples are required to obtain good failure probability estimates. A concern in finite element reliability analysis is that the large number of evaluations of the performance function may be computationally costly. This inhibits the use of crude Monte Carlo sampling in most finite element reliability applications. By centering the sampling distribution near the failure domain, a far more efficient sampling scheme is obtained. This is the basic idea behind the importance sampling method. By introducing an indicator function $I(y)$ such that $I(y)=1$ if $g(x)\le 0$ ,and $I(y)=0$ otherwise,we can rewrite Eq. (3.1) as follows (Ditlevsen and Madsen ) [23].

$$p_f = \int_{\Omega_y} I_y \varphi(y) dy = \int_{\Omega_y} \left( I(y) \frac{\varphi(y)}{f(y)} \right) f(y) dy \tag{5.1}$$

Where $\Omega_y$ denotes the entire standard normal space, $\varphi(.)$ is the joint standard normal PDF and $f(y)$ is a joint PDF which must be non-zero within the region where $I(y)=1$ .It is observed that the last integral in Eq. (5.1) is an expectation of the random variable $I(y)\frac{\varphi(y)}{f(y)}$ relative to the distribution $f(y)$ .This expectation can be estimated by generating statistically independent realizations of the random variable $I(y)\frac{\varphi(y)}{f(y)}$ derived from the distribution $f(y)$ .The average of this sample is an unbiased estimator of the expectation and, thus, of $p_f$ .Crude Monte Carlo sampling analysis results when $f(y)$ is selected identical to $\varphi(y)$ so that the distribution is centered at the mean point, i.e., the origin in the standard normal space. In IS analysis the center of the sampling distribution is shifted to a point selected by the user, e.g., the design point (Melchers ) [24].

The sampling analysis implemented in OpenSees evaluates Eq. (5.1) by repeatedly generating a vector $\bar{y}$ of independent and normally distributed random numbers with zero means and unit variances. $\bar{y}$ is then transformed according to $y = y_{center} + L\bar{y}$ where $y_{center}$ is a user-provided mean vector and $L$ is the Cholesky decomposition of a user-provided covariance matrix $\sum$ .The mean vector defines the center of the sampling density. The most effective choice is the design point. The covariance matrix is typically chosen as a unit matrix. Increasing (decreasing) the value of a diagonal element of $\sum$ leads to a broader (narrower) sampling density along the axis of the corresponding random variable. Off-diagonal elements may be added to make the sampling distribution elongated in preferred directions.
The vector $y$ is transformed back into the original space $x = x(y)$ where the performance function $g(x)$ is evaluated for this realization of the random variables. $I(x)$ is assigned a value based on the outcome of $g(x)$ .The variable $q(y) = I(x(y))\frac{\varphi(y)}{f(y)}$ is then evaluated with the following expressions for the joint PDF in the standard normal space, $\varphi(y)$ , and the sampling density $f(y)$ :

$$f(y) = \frac{1}{(2\pi)^{n/2}\sqrt{\det \sum}} \exp\left[ -\frac{1}{2}(y - y_{center})^T \sum^{-1} (y - y_{center}) \right] \tag{5.2}$$

$$\varphi(y) = \frac{1}{(2\pi)^{n/2}} \exp\left[ -\frac{1}{2} y^T y \right] \tag{5.3}$$

Where $n$ is the number of random variables.

The probability of failure is estimated as:

$$p_f \approx p_{f,sim} = \bar{q} = \frac{1}{N}\sum_{i=1}^{N} q_i \tag{5.4}$$

Where $q_i = q(y_i)$ and $N$ is the number of samples. A measure of accuracy of the probability estimate is the variance of $p_{f,sim}$ ,which noting that $q_i$ are statistically independent and identically distributed, is given by:

$$\mathrm{Var}\left[p_{f,sim}\right] = \sum_{i=1}^{N} \frac{1}{N^2}\mathrm{Var}\left[q_i\right] = \frac{1}{N}\mathrm{Var}\left[q\right] \tag{5.5}$$

Where $\mathrm{Var}\left[q\right]$ is the common variance, which is estimated from the generated sample using the well-known formula:

$$\mathrm{Var}\left[q\right] \approx \frac{1}{N-1}\left[\sum_{i=1}^{N} q^2{}_i - \frac{1}{N}\left(\sum_{i=1}^{N} q_i\right)^2\right] \tag{5.6}$$

Substituting Eq. (5.6) into Eq. (5.5), the variance of the probability estimate is:

$$\mathrm{Var}\left[p_{f,sim}\right] \approx \frac{1}{N(N-1)}\left[\sum_{i=1}^{N} q_i{}^2 - \frac{1}{N}\left(\sum_{i=1}^{N} q_i\right)^2\right] \tag{5.7}$$

Thus, we only need to store the sums of the $q_i$ and the $q_i{}^2$ values. In OpenSees, the coefficient of variation of the probability estimate

$$\mathrm{c.o.v}\left[p_{f,sim}\right] = \frac{\sqrt{\mathrm{Var}\left[p_{f,sim}\right]}}{p_{f,sim}} \tag{5.8}$$

is computed and monitored. The sampling is repeated a user-defined number of times, or until the above c.o.v. estimate falls below a specified target.

**Implementation in OpenSees**

OpenSees is regarded as a collection of software components rather than a packaged code. This software architecture is facilitated by an object-oriented programming approach. The developer creates objects, or, abstractly, classes, instead of focusing on the procedural attributes of the problem. The objects contain data members and member functions and may interact by calling each other's member functions. The member functions perform operations on the data members of its object, or on data that is passed to the member function at run-time.

Haukaas and Der Kiureghian [19] extended OpenSees with objects to perform reliability analysis in combination with finite element analysis. The analysis part of these implementations contains a number of analysis tools that are employed in our implementations. **Figure1** shows an overview of the reliability module, where the analysis-domain decomposition is emphasized. The analysis tools are shown with a particular symbol to be data members of the reliability analysis, while the various

analysis types are shown to be sub-classes of the generic reliability analysis. The reliability analysis performs operations on the reliability domain, which include random variables, correlation coefficients, and limit-state functions. Eight analysis types that facilitate FOSM, FORM, SORM, sampling analysis, parametric reliability analysis, system reliability analysis, out-crossing analysis, and visualization of the limit-state function were initially available.

The developments in this work benefit strongly from the organization of OpenSees into a collection of analysis tools. The existing analysis tools for reliability analysis in OpenSees include probability transformation, determination of search direction and step size in the search for the MPP, search algorithms to determine the MPP, random number generation, etc. These and others are listed in **Figure 2**, where it is emphasized that they are data members of the reliability analysis, which thereby can make use of them in the analysis.

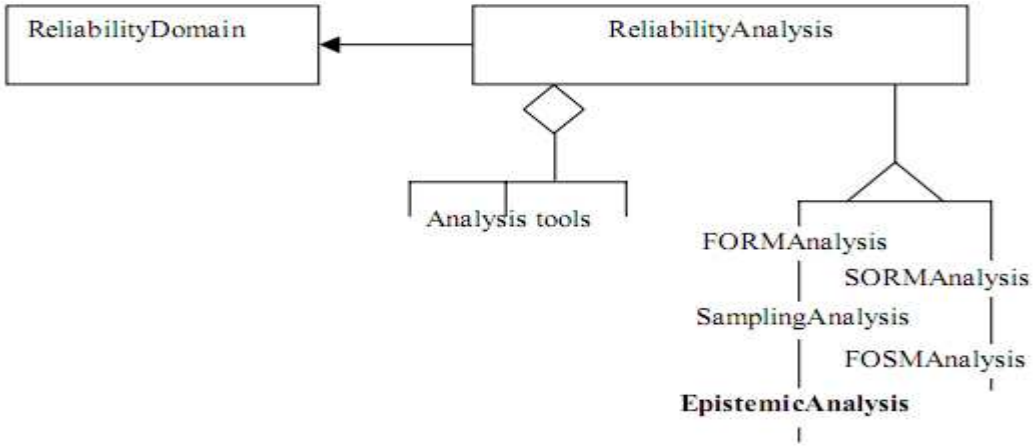

**Fig. 1**

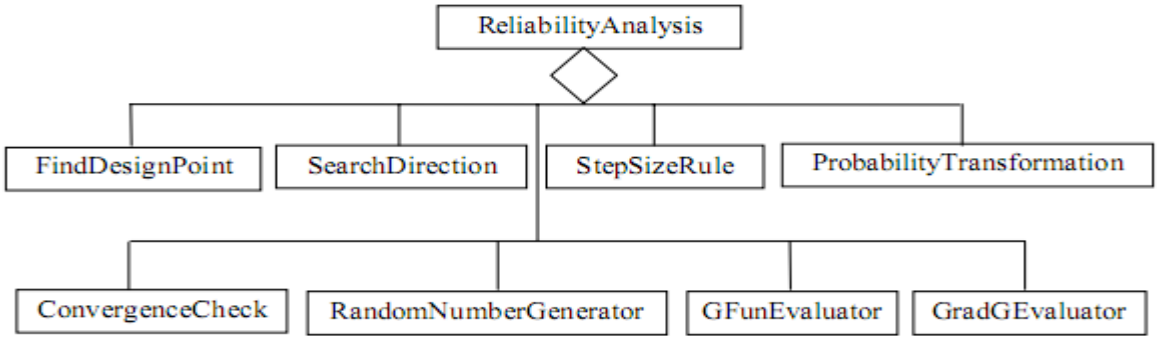

**Fig. 2**

**Numerical Example**

Consider the three-storey, two-bay reinforced concrete structure in **Figure 3**, **Figure 4** and **Table 1** for reliability analysis. The material properties of the concrete and reinforcement steel and load parameters are modelled as aleatory random variables, as detailed in **Table 2**, **Figure 5**, **Figure 6** and **Figure 7**. These are intended to model the inherent, irreducible uncertainty in the finite element model parameters.This limit-state function seeks the probability that the horizontal displacement at the roof of the structure exceeds 0.4% of the building height, when deterministic lateral seismic is evaluated according the Moroccan seismic code RPS2000 recommendations for a given geographic zone, soil site, ductility coefficient and building priority. The limit state function writes

$$g(x) = 0.004\,x9000 - u_4 \tag{7.1}$$

Where $u_4$ is the horizontal displacement, in units of mm, of node 4 from a static nonlinear pushover-type analysis. .Reliability analyses are performed with FORM and MCS for limit-state function in Eq. (7.1). The results are summarized in **Table 3**.

**Table 1: Applied vertical loads at the RC structural nodes**

| Nodes | Vertical seismic load (KN) |
|---|---|
| 2, 10 | $W_2 = W_{10} = 141.6$ |
| 3, 8, 11 | $W_3 = W_8 = W_{11} = 94.4$ |
| 4, 12 | $W_4 = W_{12} = 47.2$ |
| 6 | $W_6 = 283.2$ |
| 7 | $W_7 = 188.8$ |

**Table 2: Uncertainty modeling of the random variables of the reinforced concrete buildings**

| | Distribution | Mean | Coefficient of variation | Standard deviation |
|---|---|---|---|---|
| Steel reinforcement material parameters: | | | | |
| $f_y$ | Lognormal | 500 (MPA) | 0.05 | 25 (MPA) |
| E | Lognormal | 200000 (MPA) | 0.05 | 10000 (MPA) |
| $\alpha$ | Lognormal | 0.02 | 0.05 | 0.001 |
| Confined concrete material parameters: | | | | |
| $f'_{c,cc}$ | Lognormal | 44.24(MPA) | 0.15 | 6.636(MPA) |
| $f'_{cu,cc}$ | Lognormal | 35(MPA) | 0.15 | 5.24(MPA) |
| $\varepsilon_{c,cc}$ | Lognormal | 0.003 | 0.15 | 0.00045 |
| $\varepsilon_{cu,cc}$ | Lognormal | 0.015 | 0.15 | 0.00225 |
| Unconfined concrete material parameters: | | | | |
| $f'_{c,uc}$ | Lognormal | 30(MPA) | 0.15 | 4.5(MPA) |
| $f'_{cu,uc}$ | N/A | 0.0(MPA) | N/A | N/A |
| $\varepsilon_{c,uc}$ | Lognormal | 0.003 | 0.15 | 0.00045 |
| $\varepsilon_{cu,uc}$ | Lognormal | 0.006 | 0.15 | 0.0009 |
| Lateral loads: | | | | |
| P4 | Lognormal | 56.64 (KN) | 0.2 | 11.328 (KN) |

## Conclusions

Within the framework of the same methodology of reliability analysis (either full coupling ), the approximate method FORM does not give the same results than the more precise modified Monte Carlo ISM Method. In general, FORM overestimates the probability of failure.The obtained results have shown that full coupling reliability analysis conducted with ISM is recommended because FORM analysis could exaggerate sometimes the probability of failure.Influence on reliability data of the chosen PDF's to model uncertainties is very significant when considering full coupling reliability analysis.

In order to perform reliability analysis of seismic performance based design, huge care should be given to selection of PDF's that model parameters uncertainties (these should be is general identified through experiments).These conclusions could not be generalized without precautions to other problems dealing with reliability analysis and thorough analysis is needed to assess performance of the various methodologies.

**Keywords:** shape memory alloys; push-over analysis; time-history analysis.

**Abstract.** This paper proposes an energy dissipation device based on shape memory alloys（SMA）for frame structures. By setting anchorage device below and near the inflection point of the first storey columns, a set of force cable and energy dissipation cable using SMA are installed symmetrically in the anchorage device and the bottom of them fixed in the ground. Analytical study including the push-over and time-history analysis were investigated by ANSYS finite element program to a new CFST frame and an ordinary CFST frame. Studies have shown that the device can effectively control the structural displacement response and acceleration response, dissipating large amounts of earthquake energy. Therefore, the energy dissipation devices had a better value and prospects in engineering.

## Introduction

Frame structures are widely used in structural systems. In order to avoid the collapse of frame structures, the key structural components cannot be seriously damaged under strong earthquakes. Consequently, anti-seismic requirements are "strong column-weak beam", "strong shear-weak bending" and "strong node-weak elements". For frame structures, the design idea is to make the beam produce plastic hinges firstly, which can avoid the loss of stability of the structure, leading to collapse. However, practice has shown that plastic hinges, due to the uncertainty of earthquake action and some factors not fully taken into account in structural design, frequently occurred at the column end in frame structures. This phenomenon is caused by the fact that the overall shear force applied to the building by an earthquake is higher at the base (A. Plumier et al. 2005), in addition, as a result of the largest P-delta effects at the bottom storey of structures, the bottom storey columns is more prone to damage and their repair after an earthquake is very difficult.

As an attempt to provide an idea to solve this problem, the paper firstly presents an energy dissipation device based on shape memory alloys for frame structures. Later, Static push-over analysis and time-history analysis were calculated to investigate the seismic performance of the device. Calculation results shows that it is effective to mitigate the damage of frame columns by the device, which also has the advantage of some degree of energy-consuming and easiness to repair after the earthquake.

## Working Principle

For frame structures, under the seismic action, the structural column generally produces an inflection point, and usually one-way bending deformation occurred below the inflection point. According to the deformation of frame columns under earthquake, the paper proposes a new energy dissipation device, as was shown in Figure 1. By setting anchorage device below and near the inflection point of the first storey columns, a set of force cable and energy dissipation cable are installed symmetrically in the anchorage device and the bottom of them fixed in the ground.

Under an earthquake, columns generate deformation, but mainly one-way bending occurs below the inflection point. In this case, anti-torque is applied to the column by the tension force cables,

which can reduce the moment of the first storey columns. At the same time, the earthquake energy is dissipated through repeated non-linear deformation by the energy dissipation cables. Energy dissipation cables consisted of SMA ropes and force cables consisted of wire ropes.

SMA is a kind of super-elastic material and has been applied in many areas due to their high power density, solid state actuation, high damping capacity, durability and fatigue resistance. When integrated with civil structures, SMA can be passive, semi-active, or active components to reduce damage caused by environmental impacts or earthquakes（G. Song et al. 2006, Jin-Ho Roh et al. 2008, Qiang Pan et al.2007）.

In engineering applications, SMA generally has to go through repeated tensile cycle test until their performance stabilizes. The super-elastic strain of SMA is generally 8% ～10%, and its hysteresis loop is relatively full. By a device installed in the structure, SMA can dissipate lots of seismic energy under the earthquake with little residual deformation.

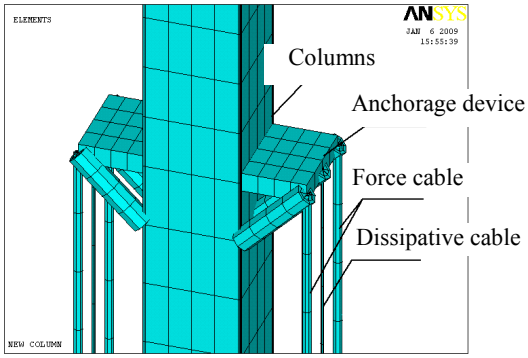

Fig.1 New Energy Dissipation Device

Fig.2 Tensile test site

**Analytical Model**

In the section, two one-span, one-storey CFST (concrete-filled steel tube) frames are investigated to validate the workability of the proposed design device. The first one is an ordinary CFST frame, while the second one is a CFST frame with a set of force cable and energy dissipation cable symmetrically installed. According to the working principle discussed above, ANSYS finite element program is used to carry out the push-over and time-history analysis of the two frames. The FEM model of new energy dissipation device is shown in Figure 1.The steel tube and steel beam used in the model is Q235 with yield strength of 235MPa, and the diameter of force cable is 28mm, with yield strength of 335MPa. The diameter of SMA bar is 10mm. The super-elastic deformation behavior of shape memory alloy was studied through material test, and its stress-strain curves were equivalent to multi-linear model (shown as Fig.2 and Fig.3).

Solid 65 elements are used to simulate concrete, and solid 45 elements are utilized in the modeling of steel tube and steel beam. The used steel was assumed to behave as an elastic plastic material. Link10 element was used to simulate wire ropes while Solid 185 element is adopted to simulate SMA. This kind of element is a special element of ANSYS to represent the material property of SMA.

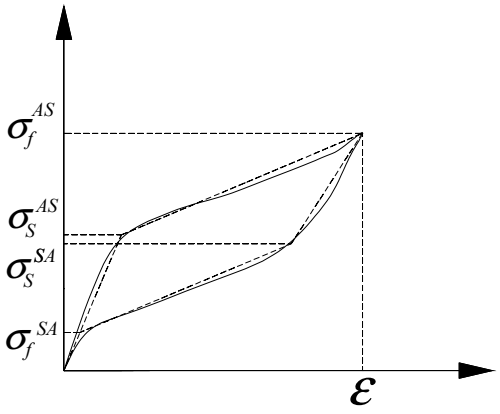

Fig.3 Equivalent linear stress-strain curves

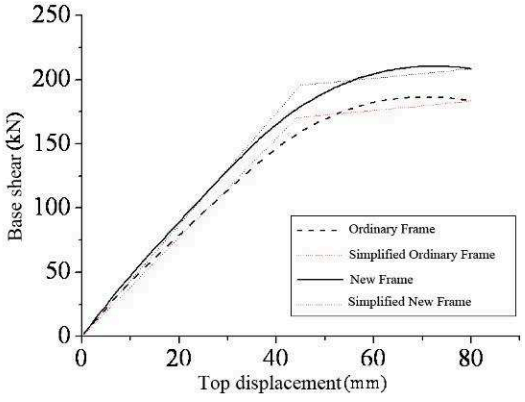

Fig. 4 Base shear-top displacement of common frames and new frames

### Static Analysis

For a detailed comparison of the performance of two frames, static push-over analysis and low cyclic loading analysis were conducted.

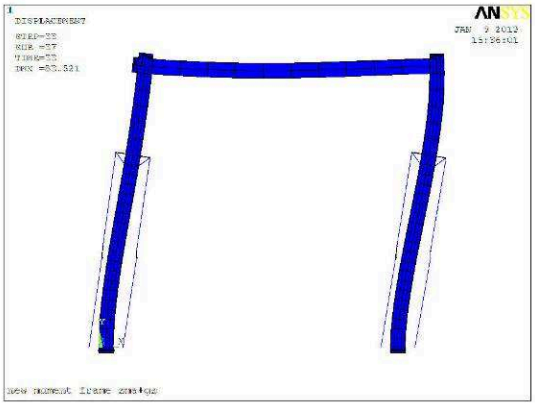

Fig.5 Deformation of new frame

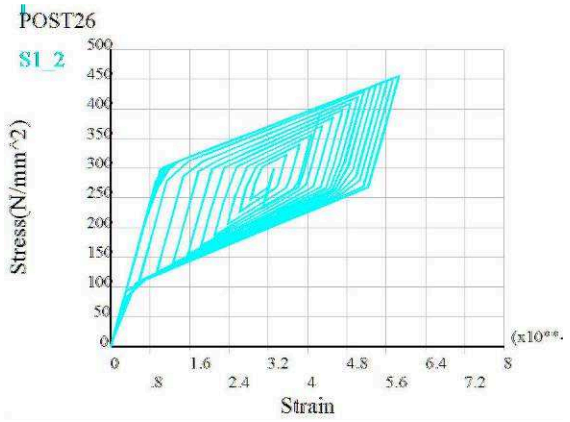

Fig.6 SMA Hysteretic energy curves

An axial load of 3480kN was first applied until the axial-load ratio of the CFST column reached 0.4. Then, displacement controlled load was applied with the level maximum displacement of 80mm until storey drift angles of both frame reached 1/73. In this case, both of frames have been yielding. The base shear-top displacement of common frames and new frames obtained from the analysis are shown in Figure 4 and the deformation of the new frame is shown in Figure 5.

From the base shear-top displacement curves, we can find the deformation of both frames is stable. Due to the action of force cable, maximum bearing capacity of the new frame is higher than the common one by 13%. To compare the yield shear force of both frames, the method proposed by FEMA-273 is used to calculate the base yield shear force of the two frames.

The yield shear force of the ordinary frame is 170.246kN, and the yield displacement is 44mm, while the yield shear force of the new frame is 195.672kN, with yield displacement of 45mm. In other words, the yield shear force of the new frame is 1.15 times higher than ordinary frame. And its yield displacement is also larger than ordinary frame. The Initial stiffness of new frame is 4.352kN/mm with the post-yield stiffness of 0.362kN/mm, and the stiffness degrading ratio is 8.3%; the initial stiffness of ordinary frame is 3.857kN/mm with the post-yield stiffness of 0.369kN /mm, and the stiffness degrading ratio is 9.6%. With the similar stiffness degrading ratio, the new frame has a higher bearing capacity. The SMA hysteretic energy curves is very full, which indicates that the SMA can dissipate a large amount of seismic energy(shown as Figure 6).

### Dynamic Time-history Analysis

In order to further study the effects of force cable and energy dissipation cable, and especially investigate the effects of energy dissipation cable, a dynamic time-history analysis was studied in this section. The El Centro waves were input as seismic waves. Seismic wave peak was 200cm/s$^2$.

In the section, a total of three kinds of structure were compared, the first for ordinary CFST frame, named Frame1; the second CFST frame only setting force cable, named Frame 2; the third CFST frame setting both force cable and energy dissipation cable, named Frame 3.

#### 5.1 Displacement Control Effect

As was show in the Figure 7 and Table 1, the displacement-time curve of three kinds of frame was compared. During the whole course of time history, Frame 1 has maximum displacement, and its maximum displacement reached 55mm, at the same time, its maximum inter-story drift angle reached 1/109; Frame 2 has maximum displacement of 42mm while Frame 3 has maximum displacement of 37mm, and their maximum inter-story drift angles reached 1/143 and 1/162 respectively. Frame 2 has control effects of 23.6%, while frame 3 has control effects of 32.7%. Hence, comparing with Frame 2, Frame 3 has the better control effects.

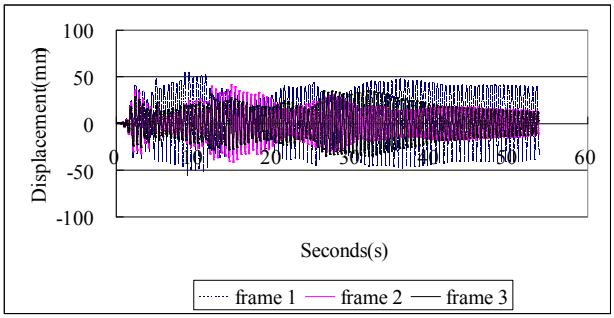

Fig. 7 Comparison of displacement-time curve

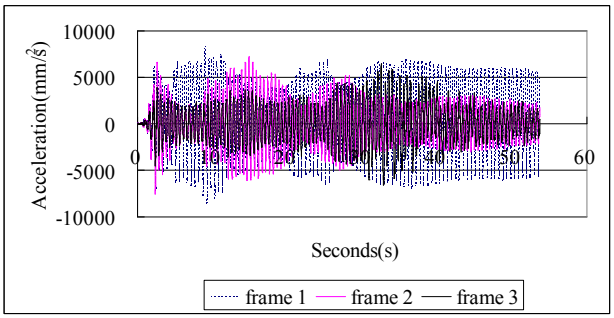

Fig.8 Comparison of acceleration-time curve

Table 1 Comparison of Displacement Control Effects

| Frame 1 | Frame 2 | Frame 3 |
|---|---|---|
| 55mm | 42mm | 37mm |
| Control effects | 23.6% | 32.7% |

Table 2 Comparison of Acceleration Control Effects

| Frame 1 | Frame 2 | Frame 3 |
|---|---|---|
| 8410mm/s$^2$ | 7245 mm/s$^2$ | 6497 mm/s$^2$ |
| Control effects | 13.9% | 22.7% |

5.2 Acceleration Control Effect

As was shown in the Figure 8 and Table 2, the acceleration-time curve of three kinds of frame was compared. During the whole process of time history, Frame 1 has maximum acceleration of 8410 mm/s$^2$; Frame 2 has a maximum acceleration of 7245 mm/s$^2$, while Frame 3 has a maximum acceleration of 6497 mm/s$^2$. Frame 2 has control effects of 13.9%, while Frame 3 has control effects of 22.7%. So, comparing with Frame 2, Frame 3 has the better control effects.

## Conclusions

This paper firstly proposed a new energy dissipation device to mitigate the damage of columns, by setting a set of force cable and energy dissipation cable symmetrically near and below the inflection point, the structural bearing capacity can be improved effectively. It should be noted that force cable has better control effects to the response of displacement and acceleration, but the control effects of energy dissipation cable was not remarkable, because it did not reached enough plastic strain. So, lots of work was still to be done to study the energy dissipation capacity of SMA. Another advantage of the new energy dissipation was that when the cable was damaged under strong earthquakes, it can be easily replaced.

**Keywords:** Ancient timber structure, Damage of mortise-tenon joint, Energy dissipation, seismic performance.

**Abstract.** This research investigated the influence of mortise-tenon joint before and after damage on seismic performance of ancient lifted-beam timber structure. Dynamic responses of an ancient timber structure under various earthquake intensities were analyzed by ANSYS to extract the M-θ hysteresis loops of mortise-tenon joints before and after damage. The area of the largest hysteresis loop was taken as quantitative indicator to measure energy dissipation of mortise-tenon joints. The results shows that if some mortise-tenon joints were damaged, they dissipated much less earthquake energy decreasing by 31.8%-38.5%, and top displacement of structures increased by 1.79%-5.96% correspondingly. Moreover, the displacement under 8-degree-fortification, 7-degree-rare earthquake intensity increased most obviously. Therefore, energy dissipation of mortise-tenon joint is a main indicator to the assessment of seismic performance of a damaged ancient timber structure.

## Introduction

Chinese ancient timber structure is part of the cultural heritage of all human beings with great historical and cultural value. But centuries of exposure to the natural environment has destroyed existing ancient timber structures more or less. These damages will inevitably influence the structural bearing capacity, especially seismic performance. Seismic performance of ancient timber structure has been studied from several perspectives, seismic mechanism[1,2], shaking table test[3,4], restoring force model[5], and strengthening methods[6]. But there has not been any research on seismic performance of damaged ancient timber structure. Research has indicated that mortise-tenon joint is a major dissipative component in an ancient timber structure; therefore the damage of mortise-tenon joint has an important influence on the seismic performance of ancient structure. Studying this influence will provide a theoretical base for evaluating the seismic resistance of existing ancient timber structure.

In this research an ancient lifted-beam timber structure was simulated numerically as finite element model, the structural seismic response before and after damage were analyzed assuming some damage locations and extent in the structure. Then the areas of the hysteresis loop of mortise-tenon joint before and after damage were compared to measure the influence of damaged joints on the structural seismic performance.

## Finite Element Model of an Ancient Lifted-Beam Timber Structure

**Simulation of the ancient timber structure.** Jiayou Palace timber structure was modeled by finite element analysis software ANSYS shown in Fig. 1. In this model the mortise-tenon joint was simulated by element COMBINE39 with nonlinear generalized force-deflection capability which can be used to model the semi-rigid connection. 30% stiffness reduction is assumed to simulate mortise-tenon joint damage, the damage locations were shown in Fig. 2.

According to the parameter of mortise-tenon joint given by H.Y.Zhang[7] and Y.H.Yang[8], the M-θ model for the mortise-tenon joint before and after damage were shown in Fig. 3.

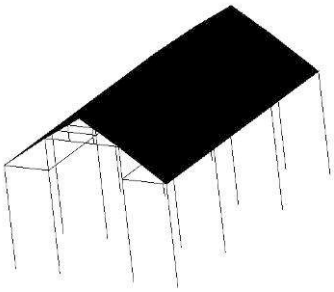

Fig. 1. FE model

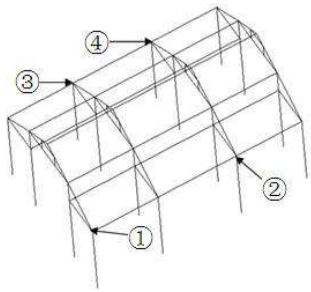

Fig. 2. Damage locations

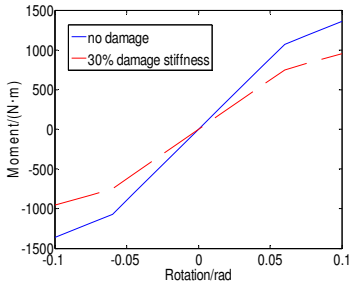

Fig. 3. The M-θ model

**Dynamic characteristic analysis.** Frequencies and mode shapes of original and damaged structure were extracted respectively. The results showed that structural modes before and after damage were almost the same, the 1, 2 and 3 modes are longitudinal, lateral translation, and torsional shape respectively, tiny changes in frequency were shown in Table 1.

Table 1: Frequencies before and after damage

| conditions | First order | Second order | Third order |
|---|---|---|---|
| original | 1.2193 | 1.4582 | 1.6984 |
| damaged | 1.2194 | 1.4580 | 1.6982 |
| Change rate | 0.008% | 0.014% | 0.012% |

Table 1 shows that Frequencies of the structure before and after damage change slightly, hence, the change of structural seismic performance is mainly due to the change of energy-dissipating capacity caused by joint damage.

## Seismic Response and Analysis of Energy Dissipation

To investigate the seismic performance of ancient lifted-beam timber structure, EL-CENTRO earthquake wave was chosen as input, shown in Fig. 4, to analyze the seismic response and energy dissipation of mortise-tenon joint under 7, 8 and 9-degree seismic fortification intensities. According to Code for Seismic Design of Buildings, the peak accelerations of EL-CENTRO wave under conventional earthquake, medium earthquake and rare earthquake were shown in Table 2.

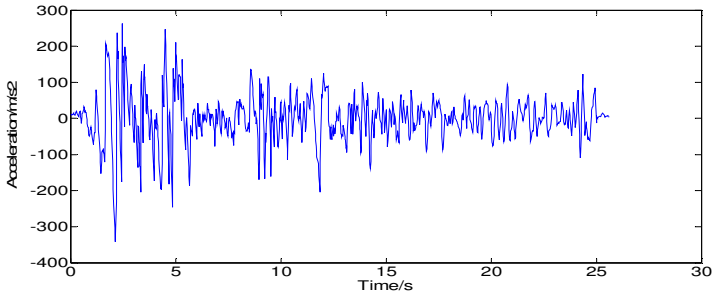

Fig. 4. EL-CENTRO earthquake wave

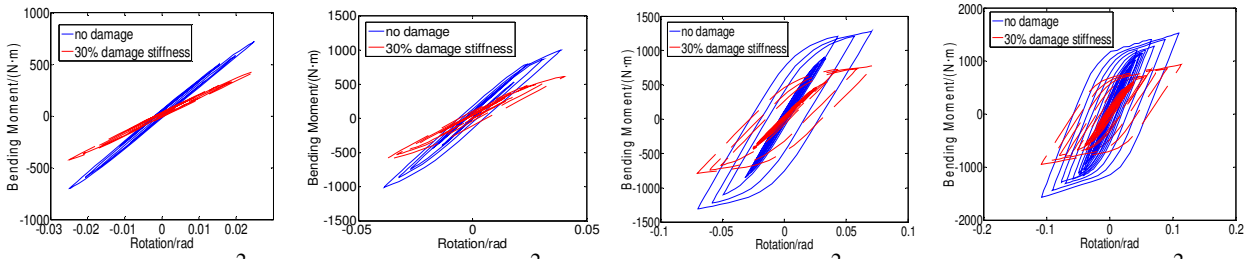
Table 2. The peak ground acceleration ($m/s^2$)

| Earthquake intensity | 7-degree | 8-degree | 9-degree |
|---|---|---|---|
| conventional earthquake | 0.35 | 0.7 | 1.4 |
| medium earthquake | 1 | 2 | 4 |
| rare earthquake | 2.2 | 4 | 6.2 |

Table 2 indicates the peak ground acceleration of 7-degree rare and 8-degree medium earthquake, and that of 8-degree rare and 9-degree medium earthquake were respectively closer. Hence, only the peak ground accelerations of 0.35, 0.7, 1.4, 2.2, 4.0 and 6.2 m/s$^2$ were taken into consideration. The seismic responses of the structure before and after damage were analyzed under different earthquake intensities. The M-θ curves of mortise-tenon joint ③ were extracted. Some results were shown in Fig. 5. Some top displacements time-history curve were shown in Fig. 6-7 as well.



(a) 1.4 m/s$^2$ (b) 2.2m/s$^2$ (c) 4 m/s$^2$ (d) 6.2 m/s$^2$

Fig. 5. Hysteresis curves of mortise-tenon joints before and after damage under various accelerations

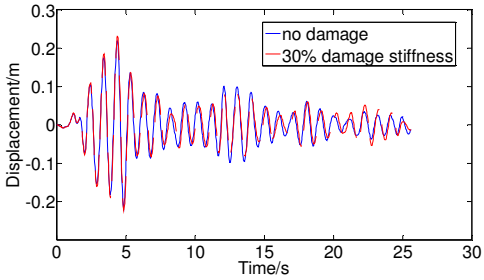


Fig. 6. Displacement curve at 2.2 m/s$^2$

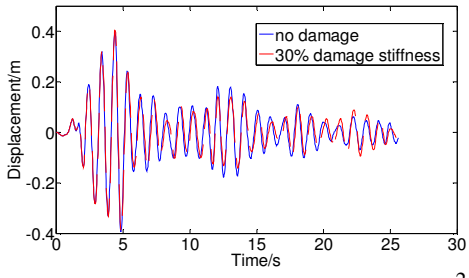

Fig. 7. Displacement curve at 4 m/s$^2$

Fig.5-7 showed when the peak acceleration of earthquake was less than 1.0 m/s$^2$, the structure works mainly in the elastic phase, mortise-tenon joint has hardly dissipated any earthquake energy, the only difference of the hysteresis curves before and after damage is stiffness reduction; When the peak acceleration were 1.4m/s$^2$, mortis-tenon joint started to work in elastic-plastic phase, long and narrow hysteresis loop has formed under earthquake, it has already begun to dissipate some energy, but not much, and the damaged mortise-tenon joint entered first into elastic-plastic phase; When the peak acceleration reached 2.2m/s$^2$, both mortise-tenon joints before and after damage functioned totally in elastic-plastic phase, quadrilateral hysteresis loop has formed under earthquake, and energy-dissipation increased apparently, the hysteresis loops of mortis-tenon joint before and after damage were similar, the comparison of their energy-dissipation needs further study; When the peak acceleration reached 4m/s$^2$, mortise-tenon joint entered elastic-plastic phase as soon as the structure started vibrating, the full hysteresis loop were formed, energy-dissipation brought into full play, joint rotation reached 0.08, structural top displacement was about 0.4m, displacement angle was 0.15, mortise-tenon joint would occur obviously looseness, structure would destroy in this phase; In the case of 9-degree rare earthquake, hysteresis loop of mortis-tenon joint was enlarged, and if the structure could work still, joint rotation will reach 0.12, the structural top displacement would reach 0.62m, tenon will dropped out, and structure will collapse completely.

## Results and Discussion

Since it is difficult to judge qualitatively the influence of mortise-tenon joint damage on seismic response, quantitative analysis is needed, the maximum displacements of structure under different earthquake acceleration were shown in Table 3, where $d_o$ and $d_d$ were the maximum top displacements of the original timber structure and damaged structure respectively, $e$ was the displacement change ratio, where $e=(d_d- d_o)/ d_o$.

Table 3 Maximum top displacement before and after damage

| peak ground acceleration[m/s$^2$] | 0.35 | 0.7 | 1.4 | 2.2 | 4.0 | 6.2 |
|---|---|---|---|---|---|---|
| $d_p$ [m] | 0.035 | 0.07 | 0.14 | 0.218 | 0.396 | 0.614 |
| $d_o$ [m] | 0.036 | 0.0723 | 0.148 | 0.231 | 0.409 | 0.625 |
| $e$[%] | 2.86 | 3.29 | 5.71 | 5.96 | 3.28 | 1.79 |

Table 3 showed that structural top displacement under different earthquake intensity rised slightly from 1.79% to 5.96% when stiffness of mortise-tenon joint reduced by 30%, which was because structural stiffness decreases resulted from the damage of mortise-tenon joint. The $e$ distribution indicated: when the peak ground acceleration values were 1.4m/s$^2$ and 2.2m/s$^2$, the top displacement increased most sharply, the change rates are 5.71% and 5.96% respectively; when the peak ground accelerations were 0.35m/s$^2$ and 0.7m/s$^2$, the top displacement increases by approximately 3%; when the peak ground acceleration values were 6.2m/s$^2$, the top displacement increased only by 1.79%.

The energy dissipation of mortise-tenon joint was measured by the area of hysteresis loops. The larger is area of hysteresis curves, the more energy dissipation there is. The hysteresis loop's area of mortise-tenon joint③ is shown in Table 4, where $A_{eo}$ and $A_{ed}$ is the hysteresis loop area of original and damaged mortise-tenon joints③ respectively, $e_A$ is the area change ratio, where, $e_A=( A_{ed} - A_{eo})/ A_{eo}$.

Table 4 Equivalent viscous damping coefficient

| peak ground acceleration [m/s$^2$] | 0.35 | 0.7 | 1.4 | 2.2 | 4.0 | 6.2 |
|---|---|---|---|---|---|---|
| $A_{eo}$ | 0.0490 | 0.1969 | 2.267 | 15.44 | 104.25 | 261.4 |
| $A_{ed}$ | 0.0302 | 0.1211 | 1.539 | 10.53 | 67.99 | 166.4 |
| $e_A$[%] | -38.4 | -38.5 | -32.1 | -31.8 | -34.8 | -36.3 |

Table 4 showed that with the increase of peak ground acceleration, energy-dissipation of mortise-tenon joint increased significantly no matter there's any damage or not. But compared to the original joints, damaged joints dissipated much less earthquake energy, the decreasing rate ranged from 31.8% to 38.5%.

## Conclusion

The research investigated the influence of mortise-tenon joint damage on seismic performance of ancient Lifted-beam timber structure. It is proved that structural top displacement increased slightly and energy-dissipation of mortise-tenon joints decreased by approximately 31.8-38.5% because of the damage of mortise-tenon joint, which affected the seismic capability of the ancient timber structure significantly. Therefore the energy-dissipation of mortise-tenon joints is a significant parameter to evaluate the seismic performance of damaged ancient timber structure.

**Keywords:** capacity spectrum method, inelastic spectra, strength reduction factors, Romanian seismic design code

**Abstract**. During recent years, an increasing number of studies advocate the application of the capacity spectrum method based demand diagrams computed directly from inelastic response spectra, as an alternative to the basic formulation of the method, which uses elastic spectra computed for single degree-of-freedom oscillators with modified characteristics to account for inelastic behavior. When demand diagrams are based on the code-specified elastic spectrum, inelastic spectra are typically determined by dividing the elastic spectrum by strength reduction factors. The paper presents the application of the method, based on strength reduction factors computed with a unified analytical expression, deduced by the author in previous studies. The expression and is valid both for broadband and narrow band ground motions. Taking as a starting point the newly-enforced elastic design spectra in the 2013 edition of the Romanian seismic design code, the method is exemplified for the capital city, Bucharest. It is shown that, for the analyzed case, the use of the proposed strength reduction factors leads to results that are very close to those obtained by the "classical" nonlinear static procedure used in the code. This suggests a good potential for the implementation of the capacity spectrum method in the Romanian code, based on these factors.

## Introduction

The Capacity Spectrum Method (CSM) is an important component of the present generation of seismic codes. Proposed by Sigmund Freeman in 1975 [1], the method combines the nonlinear static analysis of the structure and the nonlinear dynamic analysis of a set of linear-elastic single degree-of-freedom systems (SDOF) with modified characteristics to account for inelastic behavior effects. Due to its intuitive and relatively simple approach, the method is largely used, being also implemented in several regulatory or pre-regulatory documents. During recent years, several proposals have been made for the improvement of CSM, aimed to increase the accuracy of results and to enhance its applicability.

The paper investigates the possibilities of using CSM by ensuring compatibility with the new edition, enforced starting from January, 1, 2014, of the Romanian seismic design code, P100-1/2013 [2]. Even though the code includes the nonlinear static procedure among the prescribed analysis methods, CSM is still not included. Based on previous studies performed by the author [3, 4, 5], a proposal is formulated for CSM application in the new Romanian regulatory context.

## Brief presentation of the capacity spectrum method

The steps of CSM, as described in [6, 7], are briefly presented in the following.

1. The base shear – roof displacement relation is determined, by nonlinear static analysis, for the considered structure.

2. The resulting force and displacement values are converted into values for an equivalent SDOF system, by using the following relations:

$$D = \frac{D_n}{\Gamma_1 \Phi_{n1}}, \quad (1) \qquad A = \frac{Q_B}{M_1^*}, \quad (2)$$

where

$$\Gamma_1 = \left(\sum_{i=1}^{n} m_i \Phi_{i1}\right) \Big/ \left(\sum_{i=1}^{n} m_i \Phi_{i1}^2\right), \quad (3) \qquad M_1^* = \left(\sum_{i=1}^{n} m_i \Phi_{i1}\right)^2 \Big/ \left(\sum_{i=1}^{n} m_i \Phi_{i1}^2\right). \quad (4)$$

In the above equations, $n$ is the number of stories of the structure, $m_i$ – lumped mass at the $i$-th floor level, $\Phi_{i1}$ – the $i$-th floor element of the fundamental mode eigenvector ($i$=1, ..., $n$), $D_n$ – roof displacement of the structure, $M_1^*$ – effective modal mass for the fundamental vibration mode, $\Gamma_1$ – modal participation factor for the fundamental vibration mode. By this conversion, the "*capacity spectrum*" [7] or the "*capacity diagram*" [6] is obtained.

3. The 5%-damped linear acceleration spectrum is plotted in ADRS [7] (or "*A-D*" [6]) format, with the spectral (pseudo)accelerations, $A$, on the ordinate, and the spectral displacements, $D$, on the abscissa. The displacements are computed with the formula $D = [T^2/(4\pi^2)]A$, where $T$ is the vibration period. By this, the "*demand spectrum*" [7] or the "*demand diagram*" [6] is obtained.
4. The diagrams obtained in steps 2 and 3 are plotted on the same chart.
5. Dynamic nonlinear analyses are performed for a series of linear-elastic SDOF systems, with successively updated values of the equivalent eigenperiod, $T_{eq}$, and of the equivalent viscous damping, $\xi_{eq}$. The two characteristics are computed as functions of the period, damping, ductility and assumed hysteretic law. Based on their values, demand diagrams are determined, for various values of the ductility, μ. The target displacement (displacement demand) is found as the point for which the ductility value is the same, both on the capacity and on the demand diagram.
6. The displacement demand is converted back to roof displacement, with Eq. 1. Depending of the position of this value on the base shear – roof displacement diagram, the force and displacement demands for the structure are obtained.

**Use of inelastic spectra in the capacity spectrum method**

In order to improve the precision of the model, Chopra and Goel [6] proposed that, instead of modifying the characteristics of linear systems to account for nonlinear behavior, as in step 5 of the method, inelastic spectra computed for various values of ductility are used. If the demand diagrams are obtained based on linear-elastic code spectra, inelastic spectra can be determined by dividing elastic spectra with strength reduction factors. Strength reduction factors, $R_\mu$, are defined as in Eq. 5, by the ratio between the minimum yield strength, $F_e$, required in order that the systems behaves elastically under the considered seismic action and the yield strength $F_y$, corresponding to the attainment of a specified ductility, μ. In Eq. 5, $A$ and $A_y$ are the accelerations corresponding, respectively, to the two situations. Several analytical expressions have been proposed for these factors, among which those of Newmark and Hall [8], Miranda and Bertero [9], Vidic et al. [10].

$$R_\mu = \frac{F_e}{F_y} = \frac{MA}{MA_y} = \frac{A}{A_y}. \quad (5)$$

**Application of the CSM for compatibility with the new edition of the Romanian seismic code**

To apply CSM in its improved variant, described in the previous section, inelastic response spectra were determined, based on the elastic design spectra in the newly-enforced edition of the Romanian seismic design code, P100-1/2013. For this purpose, strength reduction factors were used, as determined in previous studies of the author [3, 4], from the analysis of ground motions recorded during the strong Vrancea (Romania) earthquakes of 1977, 1986 and 1990.

A analytical expression of $R_\mu$ was proposed in [3] (Eq. 6), where, for broadband motions, $\chi$ is the vibration period, $T$, while for narrow-band motions, $\chi$ is the ratio between $T$ and the predominant period of the ground motion, $T_g$:

$$R_\mu = \mu^{\frac{\chi^2 + C_1\chi + C_2}{C_3\chi^2 + C_4\chi + C_5}}. \quad (6)$$

In the following, the application of the method is illustrated for the capital city of Bucharest where, due to the soft soil conditions, a design spectrum with a corner (control) period, $T_C$, of 1.6 s is specified by the P100-1/2013 code. This period value was also found to characterize the predominant period of the ground motion, $T_g$, for strong earthquakes. The coefficients in Eq. 6, adequate, according to [3], for Bucharest (narrow frequency band motions, values with 10% probability of exceedance) are listed in Table 1.

Table 1. Values of the coefficients in Eq. 6

| $\chi = T/T_g$ | $C_1$ | $C_2$ | $C_3$ | $C_4$ | $C_5$ |
|---|---|---|---|---|---|
| 0.01...0.75 | 0 | 0 | 1 | 0.254 | 0 |
| 0.75...5 | -1.829 | 0.929 | 1.348 | -2.668 | 1.403 |

Inelastic spectral displacements, $D$, were computed, for various ductility values, with Eq. 7 and the demand diagrams in Fig. 1 were determined.

$$D = [T^2/(4\pi^2)]\, A\mu/R_\mu. \quad (7)$$

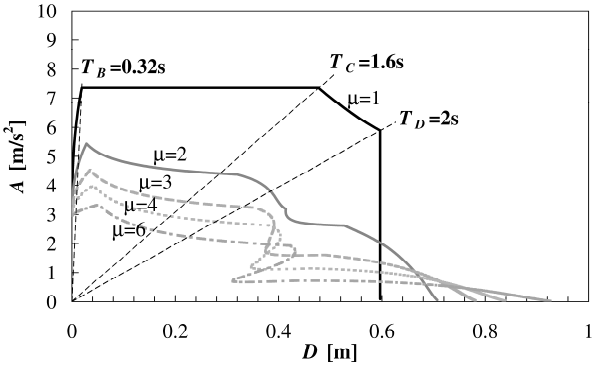

Fig. 1. Demand diagrams for Bucharest, determined based on the elastic design spectrum in the P100-1/2013 code

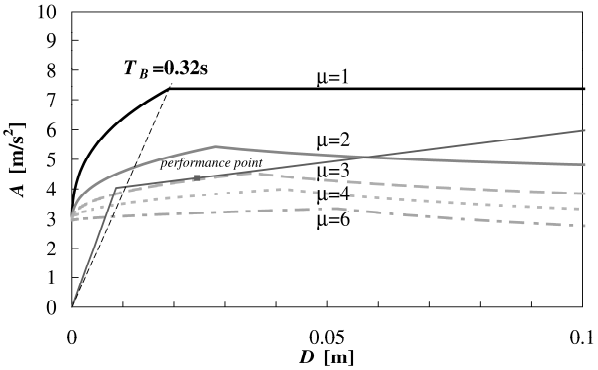

Fig. 2. Results of validation performed for a shear wall structure

In a first evaluation, the demand diagrams in Fig. 1 were used to determine the target displacement for a reinforced concrete shear wall building for which, previously, a nonlinear static analysis of the building was performed according to the P100-1/2013 provisions. The bilinearized base shear – roof displacement curve, as well as the performance point obtained according to the code are shown in Fig. 2, corresponding to a ductility $\mu = 2.84$. It can be noticed that this point is very close to the intersection between the capacity diagram of the building and the demand diagram for $\mu = 3$, which

shows a very good agreement between the results obtained by the two methods. Further systematical analyses are necessary to completely validate the adequacy of the proposed $R_\mu$ expression for use in the capacity spectrum method.

## Conclusions

An application of the improved variant of the capacity spectrum method, based on the use of inelastic spectra, was presented, aimed for compatibility with the newly-enforced Romanian seismic design code, P100-1/2013. By using a unified analytical expression of the strength reduction factors, proposed by the author in previous studies, demand diagrams were determined, for various ductility values, from the elastic design spectrum specified by the code. The encouraging results obtained by a preliminary validation against the "classical" nonlinear static procedure included in P100-1/2013 showed that the method could be successfully implemented in the code.

The application also pointed out the importance of developing reliable expressions of strength reduction factors, accounting for their variation with period, ductility and spectral content of seismic motion. This would allow, among others, enhancing the accuracy of results obtained by the capacity spectrum method and an easier implementation of its improved version in seismic design codes.

[a]wl_8395@126.com,[b]sophie.masako@gmail.com

**Keywords:**BoreholeArrays, Strong Seismic Records, Amplification Effect, Predominant Period.

**Abstract.**This paper states the comparison research of calculation results from program LSSRLI-1 and program SHAKE2000,with the strong seismic records as well asthe site soil conditions by using borehole arrays. The analytical results show thatthe site soil conditions havean amplification effect on the seismic PGA and response spectrum values, however, the actual seismic records are not consistent with the program calculations on the amplification effect.Besides,the site soil conditions also have an altering effect on the predominant period of seismic response spectrum, where actual seismic records and program calculation results of the altering effect are not the same either.

## Introduction

Seismic damage documents indicate that site soils havegreat impact on the seismic motion of bedrock. In comparison with the bedrock motion, the surface motionhas a big difference in the amplification and the spectral characteristics. This site soil impact on the amplification and spectral characteristics of the bedrock motion is called site effect, which has become earthquake expert's main concerns.

The most effective and direct method to study the site effect is to establishborehole arrays, which have strong-motion instruments set at different depth of the same site. In this way, the impact of site soils on the seismic motion can be analyzed by comparing strong seismic records of the surface with those ofthe bedrock [1]. The actual seismic records indicate that in general the amplification effect of the site soil on the earthquake exists [2].

When conducting risk analysis and determination design of the seismic motion, usually the input seismic motion of the bedrock is determined at first, thenthe site inner cover soil's impact on the input seismic motion is considered on the basis of the dynamic soil properties by using soil response analysis program to calculate the surface motion. The soil dynamic parameters arenormally obtained from in situ testing and indoor soil testing, but the soil testing will disturb the soil sample and make the soil's original stress statehard to recover, which has great impact on the dynamic parameters [3]. Meanwhile, due to the limitation of soil response program, the calculation results and the actual seismic records would have some difference.

Based on strong seismic records of Xiangtang-3 borehole array, calculations of the surface motionby program LSSRLI-1 and program SHAKE2000 have been carried out, and the comparison of the actual seismic records with the calculation results,as well as the corresponding analysis are reported in this paper.

## Introductionfor Xiangtang-3borehole array

Tangshan Xiangtanglocal site borehole arrayswere established in 1992, whileits No.3 borehole array was a newoneduring its renovation and expansion project in 2000. Xiangtang-3 borehole array was put into use in December, 2000 and has obtained several strong seismic records by now [4].

Xiangtangborehole array is located in Luan village, Hebeiprovince, and its location terrain is flat with quaternary stratigraphic soil and Archean metamorphic rock. With a total depth of 47m, the array goes across the entire soil layers reaching weakly weathered rock. It is determined to be type-II

through the drilling and shear wave velocity test, and correspondinghistograms and shear wave velocity diagram are shown inFig. 1.

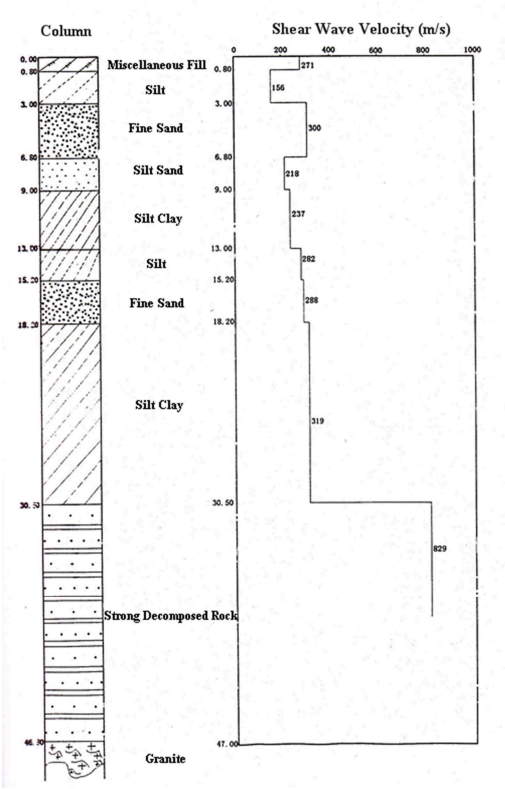

**Fig. 1**Site drilling histogram and shear wave velocity distribution diagram

**Table 1**Bulk density and consolidation pressure of soil samples

| Sample No. | Depth（m） | Density（g/cm$^3$） | Consolidation pressure |
|---|---|---|---|
| 1 | 1.0-1.2 | 1.84 | 0.5 |
| 2 | 3.8-4.0 | 1.94 | 1.0 |
| 3 | 7.8-8.0 | 1.96 | 1.0 |
| 4 | 10.1-10.3 | 1.87 | 1.0 |
| 5 | 14.1-14.3 | 2.08 | 1.5 |
| 6 | 19.0-19.2 | 1.94 | 2.0 |
| 7 | 23.4-23.6 | 1.98 | 2.5 |
| 8 | 27.5-27.7 | 2.01 | 2.5 |

Through the indoor soil testingof rock-soil samples, the bulk density, consolidation pressure, dynamic shear modulus ratio $G_d/G_{dmax}$, as well as the relationship between dampingratio and shear strain at different depths have been determined.

Table 1 shows the bulk density and the consolidation pressure of soil samplesat different depths of No.3 array. Table 2 and Table 3 show the nonlinear properties (dynamic shear modulus ratio and damping ratio)of soil samples.

## Introductionfor Program

In order to do the comparison analysis with Xiangtang-3 borehole array's strong seismic records, two kinds of soil response analysis programs, LSSRLI-1 and SHAKE2000, have been used to calculate the seismic response of site soils.

In 1989,LiaoZhenpeng[5] proposed the equivalent linear resolving method of surface soil response. Base on this method, Dr. LiXiaojun usedFORTRAN language to program the LSSRLI-1, which was then widely used in engineering applications of seismicrisk analysis and safety evaluation. Ascribed to its theoretical basis of the equivalent linear approach, the programcan be suitably applied to calculate the soil seismicresponse under strong motion.

In 1970, Dr. Per Schnabel and Professor John Lysmer[6]programmed SHAKE, which was officiallyissued in 1972 at the University of California, Berkeley Earthquake Engineering Research Center. The equivalent linear approachalso forms the theoretical basis of program SHAKE, which is nowadays the most popular program in the soil seismic response analysis. The program hasseveral modified versions and the latest version of SHAKE2000 has been applied in this paper.

## Selection of seismic records

Ever since the official implementationin Dec. 2000, Xiangdang-3 borehole array has recorded several strong motions, according to which is relevant researches have been done.

Selected fromChina National Strong Motion Network Center, the acceleration records of 47m underground and surfaceat Xiangtang-3 borehole array have been applied in this paper.These two seismic records both include 8200 points for the acceleration time history witha time interval of 0.005s. Table 4 shows the specific information of the selected seismic records.

**Table 4** Seismic record information

| Centre | Magnitude | Epicentral Position | Hypocenter Depth | Time |
|---|---|---|---|---|
| Luan-Village | 3.8 | 39:48'N 118:46'E | 30 | 2002/5/6 |

Fig. 2 and Fig. 3 are acceleration and Fourier spectrum of seismic records at 47m underground of Xiangtang-3 borehole array.

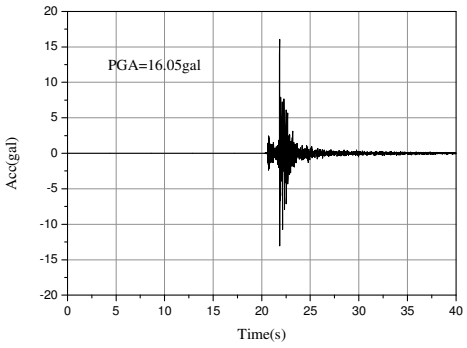

**Fig. 2**Acceleration of47munderground

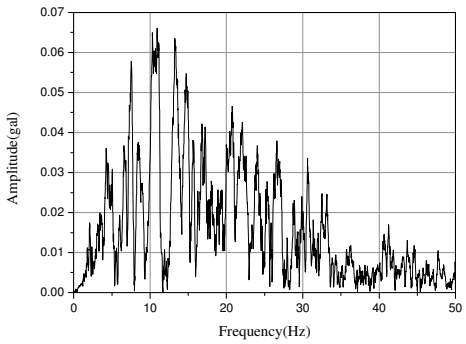

**Fig. 3** Fourier spectrum of 47m underground

## Calculation Analysis

Takingthe above seismic records of 47m undergroundat Xiangtang-3 borehole array as the input seismic motion and Xiangtang-3 borehole array's section as the calculation section, LSSRLI-1 program and SHAKE2000 program has respectively calculated the surface acceleration and response spectrum, which have beencompared with the actual surface records for consistence analysis in this paper.

Fig. 4, Fig. 5 and Fig. 6 separately shows the actual surface acceleration record, LSSRLI-1 program calculated surfaceacceleration and SHAKE2000 program calculated surface acceleration.

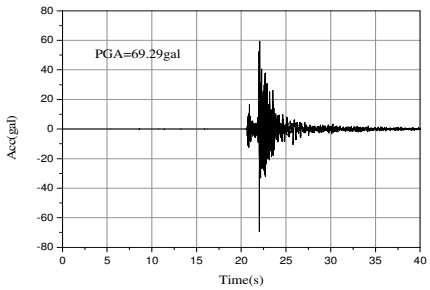

**Fig. 4**Actual surface accelerationrecord

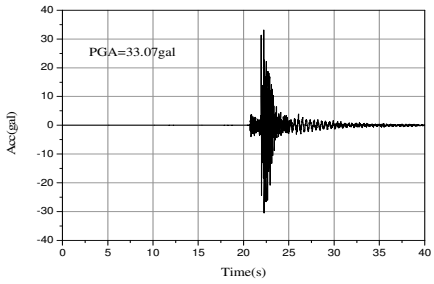

**Fig. 5** LSSRLI-1 calculated surface acceleration

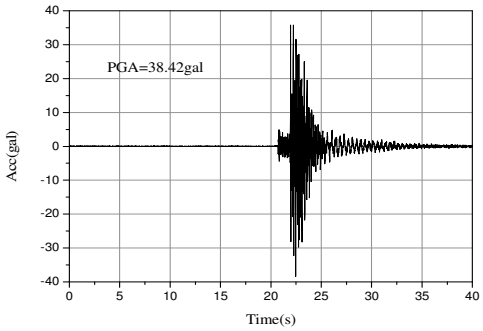

**Fig. 6** SHAKE2000 calculated surface acceleration

Seismic damage documents and borehole strong seismic records indicate the amplification effect of site soils on the seismic motion, whichis directly reflectedby PGA's amplificationof the seismic acceleration. By comparingthe input seismic motion of Fig. 2 with the output seismic motion of Fig. 4, Fig. 5 and Fig. 6,both actual seismic records and calculation results of LSSRLI-1 and SHAKE2000 show the amplification of PGA. However, the amplification effect shown by the actual seismic records is more significant rather than that shown by the calculations.

Fig. 7 shows the actual underground acceleration records of Xiangtang-3 borehole array.Fig. 8 shows the actual surface acceleration records of Xiangtang-3 borehole array, as well as the calculated response spectra of LSSRLI-1 and SHAKE2000.

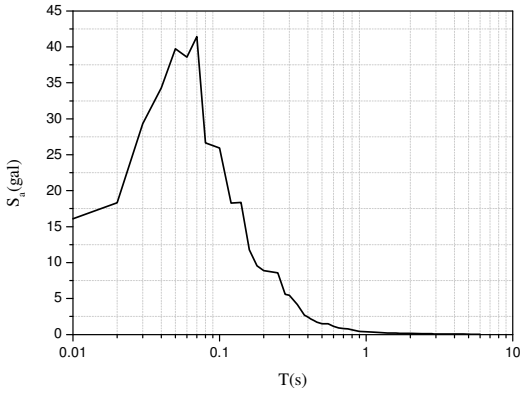

**Fig. 7**Input seismic response spectrum

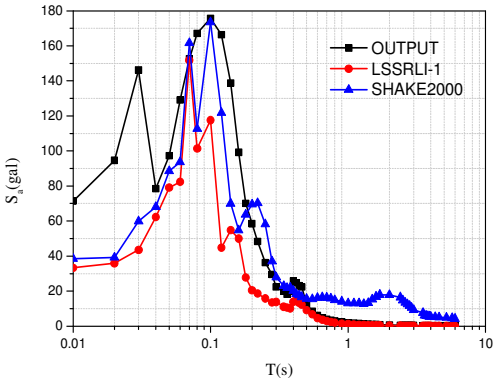

**Fig.8** Output seismic response spectra

Seen from Fig. 7and Fig. 8, site soils havean altering effect on the acceleration response spectrum but this altering effect shown bythe actual seismic records is not the same as that shown bythe calculation results of LSSRLI-1 and SHAKE2000, which is reflected on two aspects.Firstly, the actual seismic records and the calculation results of LSSRLI-1 and SHAKE2000 show different amplification effect on the response spectrum values;secondly, the altering tothe predominant periodof response spectrumshown bythe actual seismic records and the calculation results of LSSRLI-1 and SHAKE2000 are not the same.

## Conclusion

Through the comparison analysis between borehole array strong seismic records and the program' s calculation results, it is concluded that site soil conditions havean amplification effect on PGA, with the amplification effect shown by the actual seismic records being more significant. Besides, site soil conditions also havean amplification effect on the response spectrum values, though the amplification effect and the altering to the predominant periodof response spectrum shown by actual seismic records and program calculation results are different.

# RESEARCH ON PERFORMANCE-BASED SEISMIC LEVELS OF NONSTRUCTURAL COMPONENTS

Haihua Zhu[1, a], Guo Zhao[1,b]

[1]Institute of Civil Engineering, Henan University of Science and Technology, Luoyang, China 471023

[a]zhuhh010@163.com, [b]zhaofuture@163.com

**Keywords:** Non-structural components; Performance-based seismic design; Performance levels.

**Abstract.** By research of the functional classification, seismic fortification performance objectives and quantified targets of non-structural components, according to the case of earthquake destruction in non-structural components, analyzed the reasons for the destruction . proposed three functional classification;Based on performance-based seismic design theory, proposed four level seismic performance objectives division and quantify seismic indicators of inter story displacement angle.

## Introduction

With the social economic development and people's living standards improve, the demand for residential security needs to gradually shift to comfort. Thus, the cost proportion of nonstructural components in the total construction increase gradually. Analysis of the cost of building a pointed out: In recent years, due to the decoration technology improves, structural cost accounted for only about 30% of the total construction cost. The structural members of a house in the quake did not destruction, but nonstructural components destroyed, it means a loss of 70% -80% of the total cost of construction ,and very difficult to repair. So many countries in the world began to increasingly more attention to the seismic safety of nonstructural components.

## Destruction Analysis of nonstructural components

Investigation performance of non-structural components in the earthquake, summarizes the earthquake effects and the destruction laws on nonstructural components is the fundamental basis of seismic design of nonstructural components

## Non-structural wall

Nonstructural wall including partition wall ,enclosure wall, etc. .The main reason of the nonstructural wall is destruction during an earthquake is the main structure deformation, interlaminar lateral displacement, partition wall connections and seams are not reliable, reasons for itself material, uncoordinated of partition wall stiffness and the main structure stiffness etc.. Figure 1 is a common form of destruction to non-structural wall.

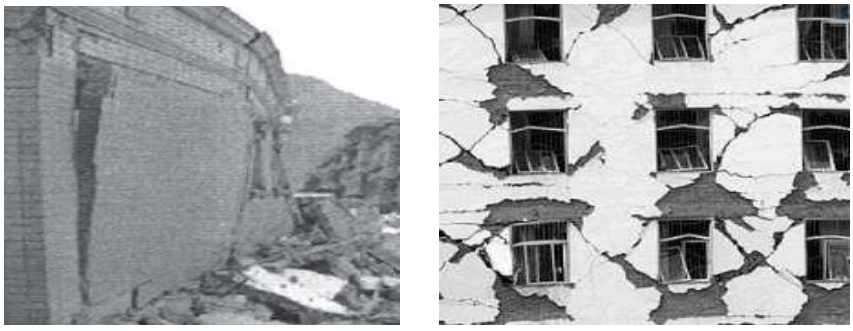

Figure 1 Nonstructural wall destruction

**Stairs**

The destruction of the stairwell is often serious than other parts, leading to evacuation difficulty, Cause secondary disasters. The main reason of the destruction is stair platform elevation is inconsistent with the adjacent room floor, different reactions between rigid stairwells and other parts of houses cause large relative movement. Figure 2 is a common failure form of stairs.

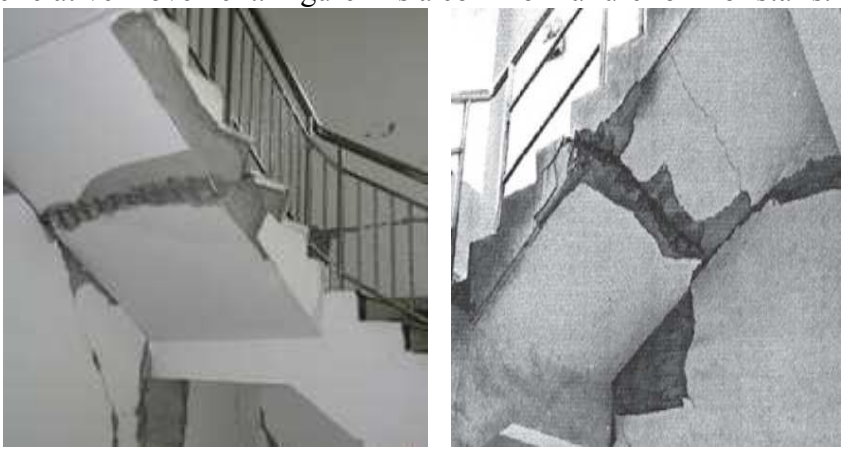

Figure 2 The destruction of the stairs

**Prominent roof components**

The main component is a prominent roof stairwell, the elevator, equipment room and other facilities。A lot of damage domestic and foreign showed, in the event of a strong earthquake, as "whiplash effect", the main structure has not destruction or minor damage, but the partial highlight structure has taken place serious damage or even collapse, which damage was generally more severe.

The main reasons of the destruction: the anchor is not firm or anchorage old failure; The second is due to seismic amplification by the large inertia force. Figure3 is a common failure form of non-structural components prominent roof.

Figure3 The destruction of non-structural components prominent roof

**The classification of nonstructural components**

Seismic design of nonstructural components usually include architectural nonstructural components and architectural affiliated mechanical and electrical equipments, The code for seismic design of buildings (GB 50011-50011 ) explained in detail to it. Just like for different types of buildings in different seismic performance objectives, these wide variety of nonstructural components in the seismic design can not be generalized to reach the same kind of seismic performance. In order to achieve the security requirements, while avoiding the waste due to the excessive demands of its safety

in design for all non-structural components, refer to the relevant specification[1,2], the non structural components in accordance with the functions are divided into three categories.

Class Ⅰ, In addition to nonstructural components class Ⅱ, Ⅲ. Such as partition walls, ceilings, furniture etc., These components can be easily removed or can be repaired within a short time in the devastation.

Class Ⅱ,Components maintain the main architecture function, and provides emergency escape. Such as stairs,evators,large air conditioning equipment etc. .

ClassⅢ,Components can bring secondary disasters. Such as gas pipelines, water tank, water pipelines etc..

**Seismic performance target of nonstructural components**

The performance levels is that in a certain probability of earthquake, performance level owners hope can achieve. Performance-based seismic design theory is first proposed at the twentieth century in the early 1990s by American scientists and engineers, aroused great interest in earthquake engineering researchers in Japan and Europe, and launched various studies. In recent years, Chinese scholars also started the research on this theory[3,4]. Compared with the traditional three earthquake goals "minor earthquake not damage, moderate earthquake can repair, strong earthquake not fall," the performance-based seismic design theory is more advanced, more flexible, more responsive to current needs

Table 1 does a comparison between conventional design and performance-based design process from the target performance, design methods ,the selection of test methods and finally achieve the performance level, etc. . [5]

Table 1 Comparison of conventional design and performance-based design

| | conventional design | performance-based design |
|---|---|---|
| performance level | Specifications give | Owner explicitly set |
| Design methods and test methods | Using specification design methods Meet the requirements of specification | Designers choose proper method |
| Performance achieved | The actual level of performance is not clear | The actual level of performance is clear |

In this paper, considering the seismic performance of different types of non-structural components, reference to the relevant information and in accordance with non-structural components, the seismic performance objectives are divided into four classes:

Class1-Full operation. Refers to the building's and equipment's function at the time of the earthquake or after earthquake can continue to maintain, structural components and nonstructural components may have minor damage, but the building structure intact.

Class2-Basic operation. The basic function of architecture is not affected, the key and important part of the structure and indoor items is not damaged, non structural components may be damaged, but after the general repair or without repair can continue to use.

Class3-Dysfunction.Refers to the basic functions of building are affected, damage to nonstructural components heavier but not completely lost the use of function, life safety can be guaranteed.

Class4-Loss of function. Refers to the basic functions of the building no longer exist, there is serious damage to nonstructural components, loss of function.

According to the different categories earthquake standards and nonstructural components division, Table 2 determines its basic performance levels of different types of non-structural components.

Table 2 Performance levelss of all nonstructural components

| | full operation | basic operation | dysfunction | loss of function |
|---|---|---|---|---|
| Multi-case earthquake | II , III | I | | |
| Design earthquake | III | II | I | |
| Rare case earthquake | | III | II | I |

**Quantitative design indicators of nonstructural components**

The above are qualitatively classified and described on the performance of the target, But for the actual project, the quantitative indicators and more aspects of designer use. From what we know of the connection form of nonstructural components and structural, Structural deformation where the nonstructural components location is the main cause of its destruction. Therefore, Using the inter story displacement angle as the damage index of non structural components is appropriate[6]. The literature suggests that when the interlayer lateral displacement angle reaches l / l000, non-structural elements likely to suffer damage, which have a certain reference value for us to Determinate elastic inter story displacement angle as the performance criterion of non structural components[7].

**Summary**

Nonstructural components is an important part of the building structure, its seismic performance has important effect on the seismic performance of building structure .in practical engineering, must attach great importance to them. In this paper, the performance levels and performance levels of non-structural components were studied, analyzed results are as follows:

According to non-structural components of damage cases presented its classification criteria.

Seismic performance levels suitable for non-structural components are proposed: full operation, basic operation, dysfunction, loss of function.

Suggested that using inter story displacement angle as a quantitative indicator of nonstructural components to do performance-based seismic design.

# Research on Seismic Damage of Buildings in the Beichuan Earthquake

Fan Wang[1, a *], Chen Ning[2, b]

[1]State Key Laboratory of Subtropical Building Science, South China University of Technology, Guangzhou 510640, China

[2]Architectural Design and Research Institute, South China University of Technology, Guangzhou 510640, China

[a]33204981@qq.com, [b]1259769156@qq.com

**Keywords:** Seismic damage investigation; RC frame building; Pushover analysis; Seismic design

**Abstract.** This paper mainly discusses seismic damage of RC frame buildings in Beichuan county based on the investigation on the spot. The building damage forms are classified and component failures are analyzed. Applying finite element analysis software, the performance of RC frame buildings under severe earthquake is simulated and the components plastic hinge development is researched. The analysis results are made a comparison with real damage of buildings in this paper and some suggestions are proposed to seismic design.

## Introduction

On may 12, 2008, an 8.0 earthquake happened in Sichuan province. A mass of buildings damaged or destroyed during the earthquake. Beichuan county is one of major disaster areas, which located in northwest of Sichuan province, at approximately 104°E and 32°N. Its position is extremely close to the earthquake epicenter. According to The Chinese seismic intensity scale [1], the earthquake intensity of Beichuan county can be classified to 10 level or even higher. Under such big earthquake, the buildings tend to have elastic-plastic deformation. Through the analysis, the components failure and the development of hinges, this paper try to find the weak part of RC frame building and give some suggestions to reinforce it. Finite element analysis software PUSH of PKPM program is used to simulate buildings behavior in strong earthquake.

## Masonry Structures Seismic Damage Investigation

Masonry structure is commonly used in medium-and-small towns or countries. In Beichuan county, lots of apartment, schools, office buildings and shop stores are made of masonry. However, weak connection between mortar and blocks make masonry structures demonstrate brittleness. From the investigation results, masonry structure buildings damaged heavily in the earthquake. According to their failure characteristics, we classify damaged masonry buildings into 4 categories including collapsed buildings, overturned buildings, heavily damaged buildings with cut-through vertical fracture and partly damaged buildings with cross shear fracture in the wall.

The heavily damaged buildings failure mechanism can be attributed to supporting components failure for insufficient bearing capacity or oversized displacement. Usually, the weak storey of masonry structure is the first storey. Most buildings destroyed or overturned as a result of

supporting wall became invalid. The cut-through vertical fracture in some masonry buildings appeared mainly because these buildings didn't set ring-beams or tie-columns. This kind of structures usually have low integrity.

**RC Frame buildings Seismic Damage Investigation**

RC frame structure is also a common structure form in Beichuan county, which is applied in business-living building, office building, government building and factory. Contrasting to masonry structure, RC frame structure performs superior in major disaster area. Through the study on damaged RC frame buildings, we can find that heavily damaged frame buildings usually developed hinges at component ends in the 1st storey or the 2nd storey. Other damage forms contain enclosure structure failure and filler wall fracture. Few frame structures completely collapsed, basically achieving national standard "non-collapse during severe earthquake" requirement. However, it's far from satisfaction that most plastic hinges appeared at column ends prior to beam ends. It's obvious that the design of most frame structures hasn't accorded with strong column-weak beam requirement.

**Analysis of RC Frame Structure Seismic Performance**

Lately, static elastic-plasticity analysis (pushover analysis) is widely applied to evaluate seismic performances of structure. Based on it, the capacity spectrum method is used to get the structure performance point, which is the intersection point of structure acceleration-displacement response spectrum and structure demand spectrum. The point reflects the structure maximal displacement and maximal acceleration under certain seismic effect.

**Seismic Performance of Low-rise and Mid-rise Frame Structures**

In order to analyze structure seismic performance under severe earthquake, six frame structure building models are established applying EDPA&PUSH software of PKPM program. These models have the same typical floor and the number of storey for each model is from 2 to 7. Except for different storey number, the plan size and components of the typical storey are identical. One of 5-storey frame structure model abridged general view and its typical floor is showed in Fig.1.

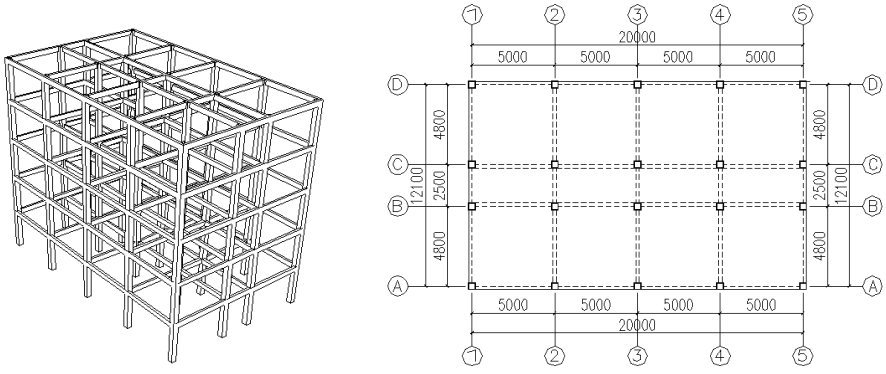

Fig.1 5-storey frame structure model and its typical floor (mm)

All models use 200mm×500mm RC beam and 300mm×300mm RC column. By pushover analysis on them, we obtain performance point of frame structures with various storey numbers under 8 level earthquake. In performance point status, structure model's base shear, peak displacement and maximal displacement angles are obtained (see Table 1).

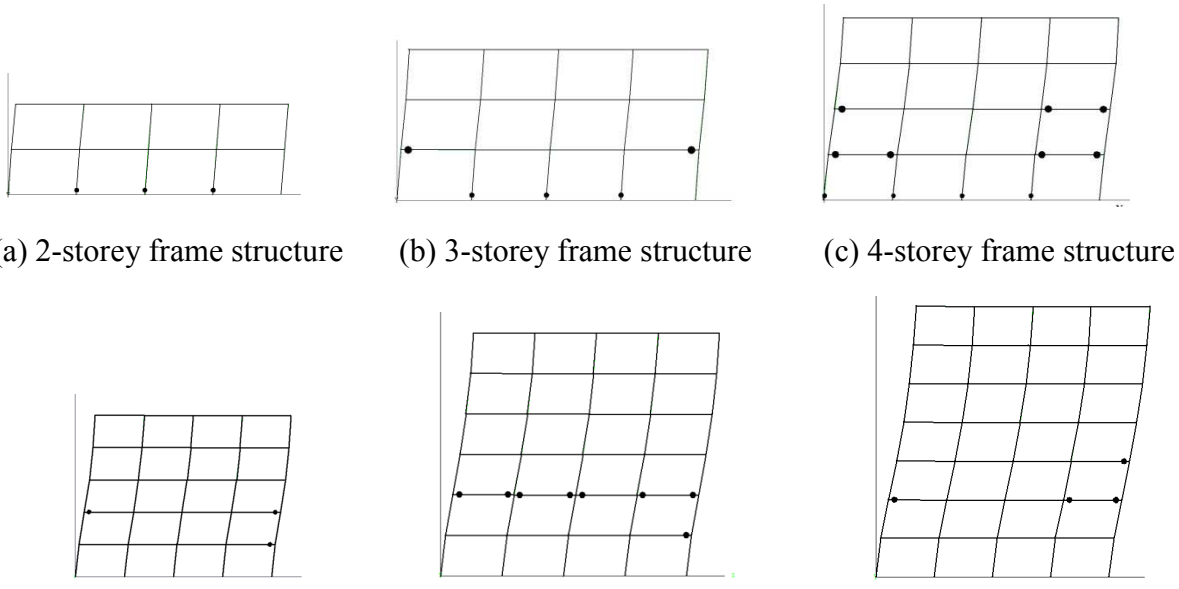
Table 1 The seismic performance of frame structure under severe earthquake

| Model | Base shear (kN) | Peak displacement (mm) | maximal displacement angle | Storey of maximal displacement angle |
|---|---|---|---|---|
| 2-storey structure | 1996.2 | 41 | 1/156 | 2nd |
| 3-storey structure | 2019.3 | 62.6 | 1/127 | 2nd |
| 4-storey structure | 2043.1 | 88.1 | 1/113 | 2nd |
| 5-storey structure | 1980.8 | 118.6 | 1/101 | 2nd |
| 6-storey structure | 2256.5 | 155.1 | 1/93 | 2nd |
| 7-storey structure | 2530.6 | 214 | 1/77 | 2nd and 3rd |

It is showed from the table above that the 2nd storey has the maximal displacement angles for medium height frame structures at performance point. In the same earthquake, the amplification of base shear is not as remarkable as peak displacement while frame structure storey numbers increase. Maximal displacement angle appears steadily at the 2nd storey, almost unaffected by storey numbers. The 2nd storey should be paid more attention when designing a medium height frame structure.

**Research on Frame Structure hinge development**

Under gradually increasing lateral force, frame structure will come into elastic-plastic state. Hinges appear along with components continuous displacement. The first hinge positions of six frame structure models are showed in Fig.2. The solid line represent beam and column components, the black dot represent the first hinge positions under increasing lateral force.



(a) 2-storey frame structure (b) 3-storey frame structure (c) 4-storey frame structure

(d) 5-storey frame structure (e) 6-storey frame structure (f) 7-storey frame structure

Fig.2 The first hinge positions under increasing lateral force

From pushover results of 2-storey frame structure to 7-storey frame structure, it is learned that low-rise buildings tend to develop hinges at column end firstly while mid-rise buildings tend to develop hinges at beam end. The 1st storey is usually the place where the hinges appear mostly for low-rise frame buildings. Unlike low-rise buildings, the first hinges appear mainly at beam end of 2nd or 3rd storey for mid-rise buildings. In addition, low-rise frame buildings present a bending failure under intensive seismic force, while for mid-rise buildings, a shear failure instead.

Through the analysis on place where hinges development firstly, we could find the weakest position of a frame building under severe earthquake. By strengthening these weak components, or adjusting components position, serious seismic damage may be relieved or avoided.

Except the results above, attention should be paid that many factors influence the development of hinges. On the one hand, fixed end of column is usually considered at foundation top, where surrounding soil will provide restraint to column footing because of buried depth from ground surface to foundation top. On the other hand, frame beams and concrete floor are concreted integrally, so the stiffness of beam is enhanced by floor board. Reinforced steel bars may enhance bearing capacity of beam end by 8% to 40%. Generally, the restraint from floor board is ignored when analysis and designing a frame structure, so many hinges developed at column end instead of beam end for column end lacking of lateral restraint. Also, the influence of filler wall in frame structure is not taken into account when we use a FEA software to analyze it. Under real seismic force, filler wall and floor board will restrict beam in two directions, which could improve bearing capacity of beams further. The damage situation in Beichuan county proved the analysis above.

## Conclusions

Based on building seismic damage investigation in Beichuan county and results of static elastic-plasticity analysis on multilayer RC frame structure buildings, some conclusions and suggestions are listed as follow.

(1) Masonry structure building has a low anti-seismic capacity. In area where earthquake happens frequently, this kind of structure should be carefully designed and constructed. Ring-beam and tie-column could improve integrity of masonry structure immensely.

(2) RC frame structure performs superior to masonry structure under seismic effect. Yet the strong beam weak column phenomenon is common based on investigation. The reinforced steel bar should improve relatively in column components when designing a frame structure.

(3) Maximal displacement angle of RC frame building usually appears steadily at the 2nd storey in performance point status. Under severe earthquake, the 1st storey or 2nd storey is usually the weakest position of RC frame structure. Constructed measures should be taken to enhance this part of structure.

# Seismic Analysis of 5-span High-speed Railway Continuous Girder Bridge

Jianhu Guo[1, a], Mingqi Lu[1, b]

School of Civil Engineering, Beijing Jiaotong University, Beijing, 100044, China

[a]598263599@qq.com, [b]593434137@qq.com

**Keywords:** High-speed Railway Continuous Girder Bridge; Vibration Mode; Seismic Effect; Performance Requirements.

**Abstract.** In recent years, with the development of high-speed rail in China，bridge has a higher proportion in the lines. Every year earthquake occurs many times accidentally in China. In order to ensure the target performance of bridges under earthquake action, we need to be based on the seismic analysis. Only have a deep knowledge of seismic effect discipline, can we enable to guide seismic design economically and reasonably and achieve predetermined target performance. Our study shows that the main vibration mode is a combination of the longitudinal or lateral translation or the revolution around Z axis. Under high-level earthquake, the maximal displacements of side piers and the fixed pier are larger, the maximal longitudinal pier shaft moment of the fixed pier (No.3) or No.5 pier in lateral direction is larger. But the value that exceeds the yield moment is small, which indicates that the development of plasticity is little. The longitudinal shear force of the bearings on the same pier are the same, bearings fixed longitudinally own the largest value. Even bearings whose lateral directions are fixed on the same pier own larger forces. Seen from average maximum values of bearings, all bearings are at the second stage, meeting the requirements that we don't need to repair or slightly repair the bridge to make it act normally once after an earthquake.

## Introduction

Earthquake is one of natural disasters which people have to be faced with. Earthquake disasters and their secondary disasters do enormous economic losses and casualties to human beings, and *seismic design of building structures is an active measure*. Nowadays, our country is devoted to building high-speed railways, the total mileage already built and under construction has reached tens of thousands of kilometers. Considering hydrology, geology, interchange, in order to ensure the line smooth, traveling comfortable and safe and reduce the occupancy of land, we choose bridges, which are taking a bigger percentage of the total length of railways being built. The proportion of bridges in the line has reached 70%-80% [1,2,3]. Therefore, study about the seismic effect discipline of high-speed railway bridges has the urgently realistic meaning. So we enable to guide the seismic design economically and reasonably and achieve the predetermined target performance. In this article, we take the 5-span high-speed railway continuous girder bridge in Tianjin-Qinhuangdao passenger dedicated line as an example, *the article analyses the discipline and characteristics of the bridge's seismic effect under high-level earthquake*.

## Establishment of the Finite Element Model

**Outlines of the Project and Layout Drawing.** The railway bridge is across Jingshan in Fengnan. The total length of beam body is 301.5 meters, the calculation spans of longitudinal girder from one side to another are, in order, 45 m, 70 m, 70 m, 70 m, 45 m. The following Fig. 1.1 shows the 5-span continuous girder bridge.

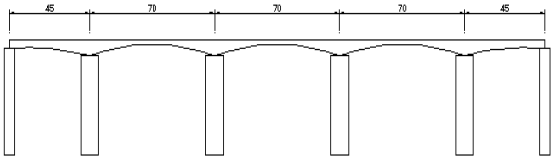

Fig. 1.1 5-span continuous girder bridge

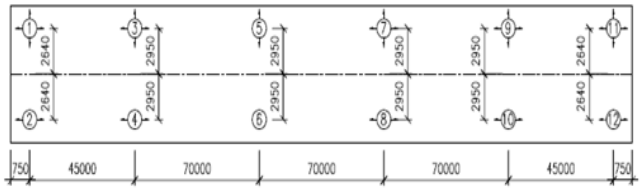

Fig. 1.2 The layout of the bearings

From left to right, the piers are, in order, No.1, No.2, No.3, No.4, No.5, No.6. The corresponding heights of piers are 12.75 m, 10 m, 10.5 m, 11 m, 13.5 m, 16.75 m. The No.3 pier is the fixed one, the site classification is the Second according to Code for seismic design of railway engineering.

Fig. 1.2 shows us the layout of all bearings. The No.5 bearing is laterally movable, the No.6 one is fixed in both directions, No.2, No.4, No.8, No.10, No.12 are longitudinally movable, No.1, No.3, No.7, No.9, No.11 are movable in both directions.

**Definition of Bearings.** While structure is under earthquake, different work stages are classified based on the damage of bearings [4,5]. Fig. 1.3 and Fig. 1.4 respectively give definitions of movable and fixed bearings.

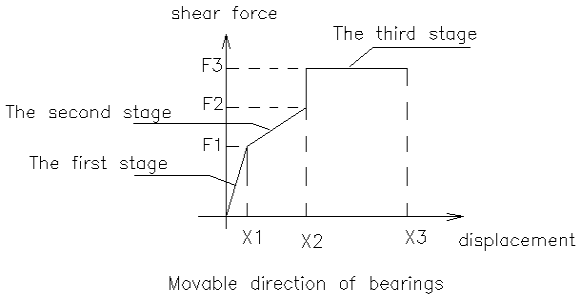

Fig. 1.3 The definition of movable bearings

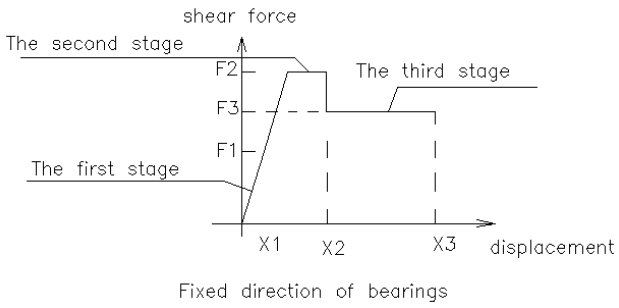

Fig. 1.4 The definition of fixed bearings

**Mode Analysis.** Through above works and analysis of engineering drawings, the finite element model of the whole bridge is created in SAP2000 [6,7,8,9,10,11]. In order to ensure accuracy, the model is further modified with considering the SSI effect [12]. By the calculation, spring stiffness is applied to each bottom of all piers. Carry out the analysis of mode and the 1st to 12th vibration modes and periods influence the structure greatly .The main vibration modes are shown in Fig.1.5.

Mode2，T=0.594s Mode4，T=0.452s Mode5，T=0.401s Mode6，T=0.380s

Fig. 1.5 Main modes and periods of the bridge

Seismic survey tells us the earthquake damage of bridges occurs in longitudinal or lateral direction, especially in longitudinal direction. The damage of bearing anchoring is mainly caused by clipping not by tugging, which indicates earthquakes' horizontal components play a role in vibration control. Consequently, we only consider the horizontal components in the seismic design [11].

The article calculates fifty modes, we conclude that the main vibration mode is a combination of the longitudinal or lateral translation or the revolution around Z axis. That is the second mode-the fixed pier bends longitudinally and the beam body drifts longitudinally, the fourth and sixth mode-the beam body vibrates antisymmetrically in lateral direction, the fifth mode- the beam body vibrates symmetrically in lateral direction.

### Analysis of Seismic Effect under High-level Earthquake

**Seismic Record Events.** Select 8 (ACHL, 1058, ASUL, FOR, L4B, LRIV, MEL and RIV) seismic record events from the Pacific Earthquake Engineering Research Center (PEER) database. The PGA of high-level earthquake is 0.38g .Through calculation, we adjust the amplitude modulation.

**Average Maximal Displacement of Pier Shaft and Beam Displacement (mm).** The following Fig. 1.6 and Fig. 1.7 respectively show the trends on average maximal displacements of pier shaft and maximal displacements of the beam in longitudinal and lateral directions.

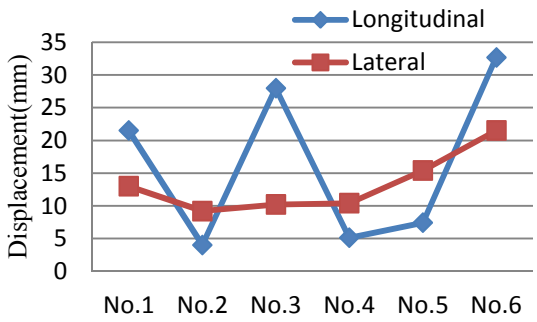

Fig. 1.6 The average maximal displacement of pier shaft

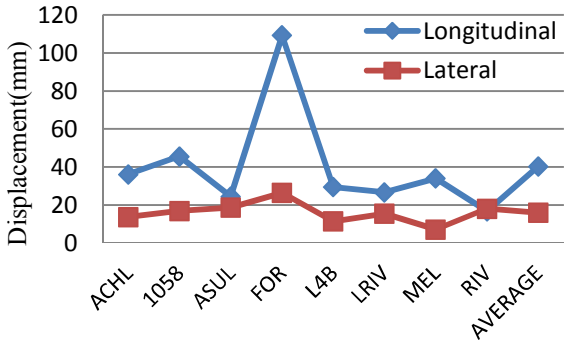

Fig. 1.7 The maximal displacement of the beam

From Fig. 1.6, it can be observed that the average maximal displacements of pier shaft in both directions have the same trends that decrease firstly and then increase from the fixed pier to side piers. In longitudinal direction the displacements of No.1, No.3 and No.6 piers are larger. The value of No.6 pier is the largest, which is relevant to the characteristics of side piers that their heights are taller and sections are smaller. The value of No.2 pier is smaller, which is 9.8% smaller laterally and 85.7% smaller in longitudinal direction than the No.3 pier. The value of No.1 pier, No.3 pier and No.6 pier are separately 39.5%, 63.6% and 34.3% longitudinally larger than that in lateral direction.

On the whole, the average maximal displacements of intermediate piers adjacent to the fixed one are smaller, whereas, the fixed and side piers have larger response. Therefore, we should not only pay attention to fixed piers but also the tall and slender side piers.

It can be seen from Fig. 1.7, the maximal displacement of the beam appears to be the largest when under FOR. Contrast with FOR, values of other 7 events seem to be small and approximate. This is closely related with its own characteristics of the event. Characteristics of the seismic waves are mainly affected by the amplitude, spectrum and duration time. While the spectrum is affected by the hypocenter, route of transmission and site condition, the article uses the Second site classification, and the PGA is 0.38g when imported in the software. Although these two parameters are consistent, there are lots of differences in respective characteristics among different events. The lateral value is 7.8% smaller than that in longitudinal direction except RIV. The longitudinal maximal displacement is 40.3 mm and 15.9 mm laterally, which will certainly influence the location of seismic side retainer, the size of expansion joint and requirements for bearings' deformation, with the implication that seismic designers must consider all the factors above.

**Average Maximal Moments of Pier Shaft (kN·m)**. In order to contrast clearly, Table 1.1 lists the piers' yield moments. Fig. 1.8 shows the maximal moments of pier shaft attached to each record event.

Table 1.1 The yield moments of pier shaft

| Piers No. | No.1 | No.2 | No.3 | No.4 | No.5 | No.6 |
|---|---|---|---|---|---|---|
| Longitudinal Yield Moment | 95030 | 394000 | 398400 | 405800 | 407400 | 95030 |
| Lateral Yield Moment | 195700 | 754300 | 769900 | 912200 | 911100 | 195700 |

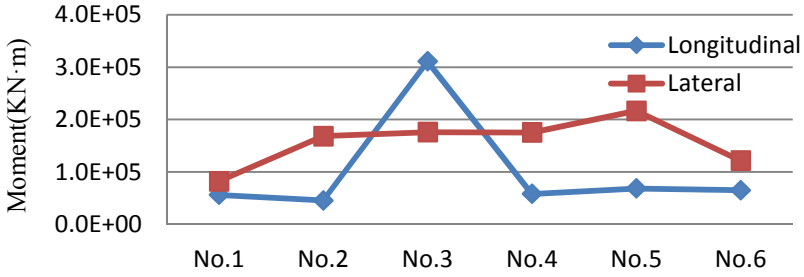

Fig. 1.8 The average maximal moments of pier shaft

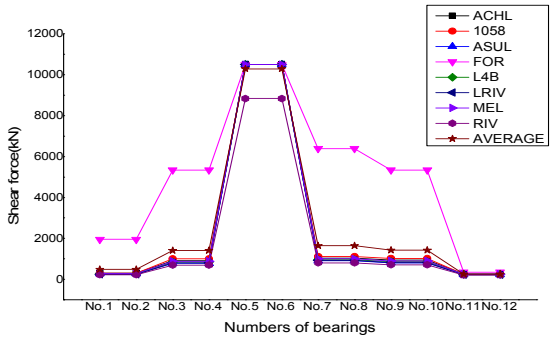
From Fig. 1.8 we can see that the No.3 pier has the largest moment longitudinally which implies the bottom section of the fixed pier is the most dangerous. But the average value does not reach the yield point, which is 22% smaller than the yield moment. Other piers' values are closed to each other, the value of the No.2 pier is a little smaller and the No.5 a little larger. The value of No.6 pier is closed to its yield moment, it is 31.6% smaller. Looking laterally, the piers' average values appear to increase firstly and then decrease. The value of No.5 pier reaches the largest, the No.1 is the smallest and then the No.6. All values are smaller than the yield moments and the NO.6 pier is the most closed to the yield value.

From the above analysis of average values, we know *the bridge is in elastic phase under high-level earthquake*. The whole structure does not need to be repaired or to be slightly repaired.

**Maximal Longitudinal and Lateral Forces of Bearings (kN).** Fig. 1.9 shows us the maximal longitudinal forces of bearings under high-level earthquake. And Fig. 2.0 gives us forces in lateral direction.



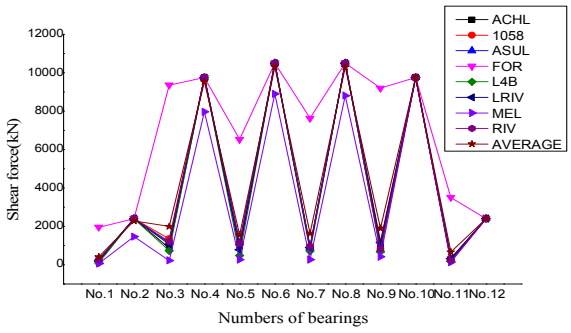


Fig. 1.9 Maximal longitudinal forces of bearings Fig. 2.0 Maximal lateral forces of the bearings

In Fig. 1.9, for longitudinal direction, the No.5 and No.6 bearings are fixed. When the beam body is drifting, the displacement is mainly caused by the No.3 pier's bending longitudinally. Besides, forces of No.5 and No.6 bearings are the largest, which are 6 to 49 times larger than others. Movable bearings transfer less shear force during strong earthquake events. Seismic energy mainly transfers from the substructure to the superstructure through the fixed bearing. The inertial force produced by the superstructure transfers to substructure by the fixed bearing as well [11].Therefore,

the longitudinal fixed bearing is the most easily being damaged. Once damaged, the beam body will easily move abnormally and begins to collide with the abutments, which we should focus on while designing. The two bearings on the same pier suffer the same forces in longitudinal direction. What is more, in this direction their shear forces and displacements curve are also the same, which indicates that the stress states of bearings are consistent and simultaneous. That is closely related to the setting conditions of bearings. The bending of fixed pier vibration mode provides the condition.

From Fig. 2.0, for lateral direction, values of bearings on side piers are smaller. Even number bearings own larger forces on the same pier and they are about 3.7 to 6.7 times than corresponding odd number bearings. Shear forces of odd number bearings are 2.4 to 4.7 times larger than bearings on side spans. It is related to the setting of even number bearings, for they are fixed laterally. No.6 and No.8 bearings are more easily being damaged, No.4 and No.10 bearings take the second place. So bearings of intermediate spans should be taken more care while designing.

**Maximal Longitudinal and Lateral Displacements of Bearings (mm).** Seen from Fig. 2.1, the

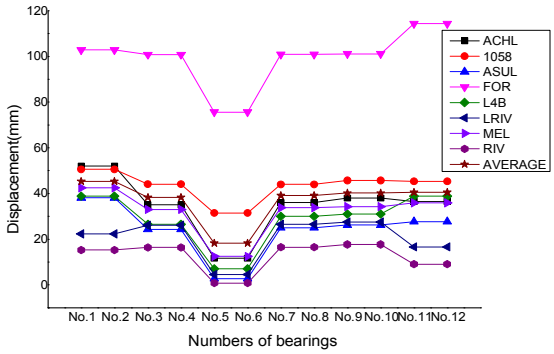

Fig. 2.1 The maximal longitudinal displacements of bearings

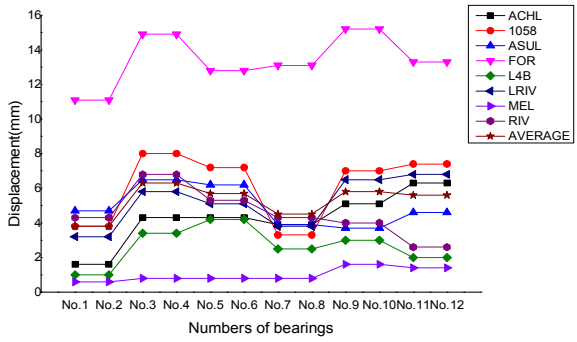

Fig. 2.2 The maximal lateral displacements of bearings

longitudinal view, No.5 and No.6 bearings own smaller displacements but larger shear forces so that the bearing bolts' stress will balloon and more easily be clipped. Besides, while under FOR event, all bearings go into the *third* stage except No.11 and No.12 bearings. This phenomenon indicates bearings are likely to be destroyed. Similarly, Fig. 2.2 considers response in lateral direction. Even number bearings' shear forces are larger because odd number bearings are movable and even number bearings are fixed laterally. While no matter in longitudinal or lateral direction, their displacements are the same. It is reasonable because each of the bearings is anchored in the pier top and the bottom of the beam whose stiffness are high enough. From *average views*, all bearings are at the *second* stage, meeting the performance requirements that bearings needn't to be repaired or slightly repaired after earthquake.

## Conclusions

Through our study, we draw some conclusions above, in short:

1. The main vibration mode is a combination of the longitudinal or lateral translation or the revolution around Z axis.

2. The average maximal displacements of the fixed and side piers have larger response. We should not only pay attention to fixed piers but also the tall and slender side piers.

3. The longitudinal maximal displacement is 40.3 mm and 15.9 mm laterally, which will certainly influence the location of seismic side retainer, the size of expansion joint and requirements for bearings' deformation, so seismic designers must consider all the factors.

4. As shown by the results of maximal moments of pier shaft, the bridge is in *elastic* phase under high-level earthquake. The whole structure does not need to be repaired or to be slightly repaired.

5. The longitudinal fixed bearing is the most easily being damaged. Once damaged, the beam body will easily move abnormally and begins to collide with abutments. The stress states of bearings on the same pier are consistent and simultaneous. Bearings' Shear forces in lateral direction on side piers are smaller. Even number bearings own larger forces on the same pier.

6. Through values of average displacements of bearings， we know bearings are all at the second stage, which indicates the bridge does not need to be repaired or to be slightly repaired. So *it exactly meets the performance requirements for important bridges.*

# Seismic Performance Analysis of Steel Frame With Wedge Devices Based on the Energy Dissipation

Jinsong Lei[1,a], Wenxia Luo[2,b], Jialong Jiang[1,c] , Wen Zhang[1,d]

[1]College of Civil Engineering and Architecture, Southwest University of Science and Technology, Mianyang, Sichuan, 621010, China

**Keywords:** Wedge Devices, Steel Frame, Low Cyclic Load, Energy Dissipation, Time History Analysis

**Abstract.** The steel frame with wedge devices is a kind of shock structure based on the node energy consumption. The seismic performances of steel frame with wedge and ordinary steel frame model under low cycle reciprocating load simulation analysis and time history analysis under earthquake loads are analyzed by using finite element software, compared the respective energy dissipation performance and seismic performance, the results show that the wedge spring damping device can effectively control story drifts of structure, reduce the seismic response of structure, and well consume the seismic energy, so the structure of the new column bases with wedge spring devices show better seismic performance.

## Introduction

Due to the steel has excellent toughness and ductility, making steel structure has the power and repeat resistance changes in the role of the good ability, so the steel structure building is generally thought to have a better seismic performance. With the severity of the damage from the earthquake, the shock energy research of steel frame has become more important, steel frame structure damping system to reduce seismic by energy consumption, according to the energy dissipation mechanism can be divided into the shock absorption system and the energy consumption damping system two stages of development.

External energy dissipation system is set up some extra energy dissipation devices in the steel, mainly seismic energy consumption by energy dissipation devices to achieve damping purposes. Some of the commonly used engineering measures is :(1)In the Beam-column joints set energy dissipation device to form energy dissipation nodal points, when the sides way of a structure produce angle changes, energy dissipation device participate in energy dissipation. By spring and wedge to screw up of a new type steel column base, the device through the sliding of the wedge, spring deformation and plastic elongation of the screw to control column base displacement, at the same time consume earthquake energy, to achieve the effect of dissipater of shock, this is a new technology researched by Japan. (2)Between the steel connection setting various Energy-dissipated brace, including ordinary center support, prevent buckling support, with the support of the damper etc. [1, 2]. Setting Energy-dissipated brace can form multiple resist lateral force system, under the effects of earthquake, support for all before destroying almost horizontal load happen axial deformation, and the frame that did not effected by horizontal load almost happened only bending deformation; After damage in support stiffness rapidly reduces the earthquake action reduced sharply, at this time the framework for horizontal load. So the support frame system support have the function of the fuse, make structure subject do not damage, and have good seismic performance. In this paper the new steel frame of the energy dissipation were analyzed with the method of finite element simulation, and the low weeks reciprocating load of the simulation analysis to the single wedge with steel frame have been down, and the deformation characteristics, the hysteretic curve and skeleton curve are analysed, through the comparative analysis of maximum displacement, relative storey displacement, inter-story

drift of five-story with a wedge of steel frame which are under the earthquake effect and figure out the displacement and accelerated speed of time history analysis curve.

## Wedge of Steel Frame Energy Dissipation Principle

Japan Kobe earthquake in 1995, a large number of steel structure column base have suffered serious damage, according to the damage characteristics, a new shock absorber that consist of bolt, spring and wedge block [3], make the column foot basis than the ordinary type column foot smaller layer between the corner, but the ability to absorb seismic energy is not reduced, the principle is shown in Fig. 1. Ordinary column foot slip caused by the bolt of plastic elongation, shown in Fig. 2. And wedge column foot can improve this slip-column foot by spring to push the wedge cut into the gap, every time the loading and unloading are for always origin, showing the no-slip-type hysteretic characteristics, shown in Fig. 3. The device through the wedge block sliding, spring deformation and screw plastic elongation to consume earthquake energy, achieved the effect of damping energy dissipation.

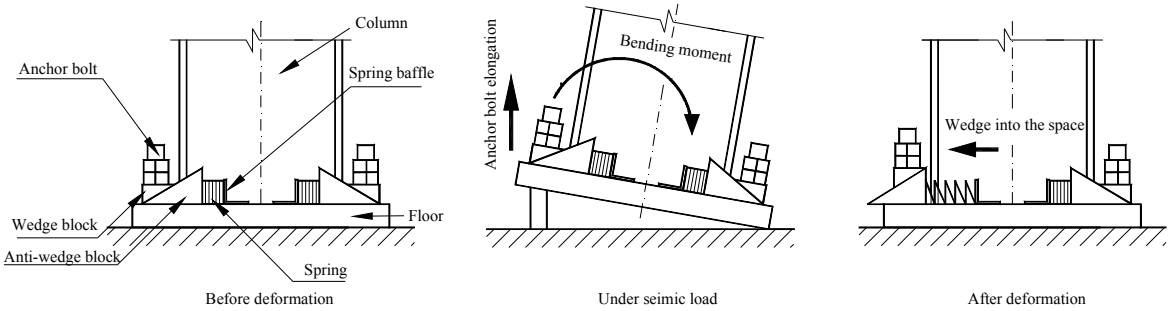

**Fig. 1** Wedge device principle diagram

0⇒1⇒…

**Fig. 3** The exposed-column base with wedge devices

## Finite Element Analysis of Single Layer Non-slip Steel Frame

**Loading method.** Low cyclic loading test simulation analysis method is essentially a static nonlinear analysis. Compared with the static elastic-plastic analysis, the difference is that the horizontal loads is reciprocating direction, and each cycle load of amplitude is changing, each cycle by multiple load of steps, getting the bearing capacity of the structure component, stiffness, deformation capacity, the hysteretic curve, energy dissipation capacity and structure of failure mechanism, they apply to structure seismic performance analysis, especially the analysis of the structure of shock energy consumption [4].In this paper the simulation analysis for convenience, all adopt the displacement as loading control index, loading system shown in Fig. 4.

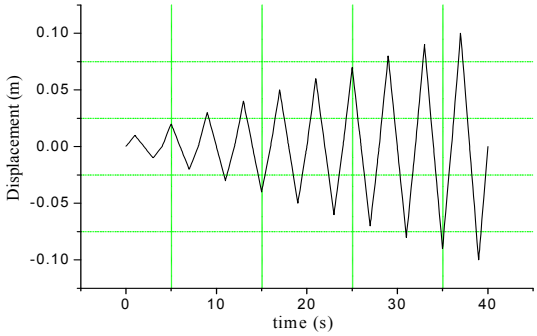

**Fig. 4** Load displacement graph

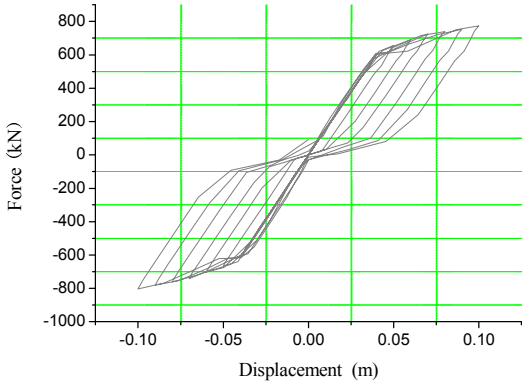
**Finite element analysis model.** This paper using the finite element software ANSYS to single wedge with steel frame, ordinary steel frame low cyclic reciprocating load of the simulation analysis,4 meters high, span of 6m,each frame beam-column is the same size, member section dimensions are shown in Table 1.

**Table 1** Member section dimensions

| Component type | Height (mm) | Width (mm) | Webs thickness (mm) | Flange thickness （mm） |
|---|---|---|---|---|
| Frame beams | 400 | 200 | 8 | 13 |
| Frame column | 400 | 400 | 13 | 21 |

**Load-displacement curve**. To compare the hysteresis characteristics of the steel frame with wedge and ordinary steel frame, when doing the experiment of low cyclic loading simulation analysis, horizontal displacement load imposed in the framework of vertex, and take the load point location of the load-displacement curves are analyzed, Fig. 5 and Fig. 6 are the two kinds of steel framework of the load-displacement curves.



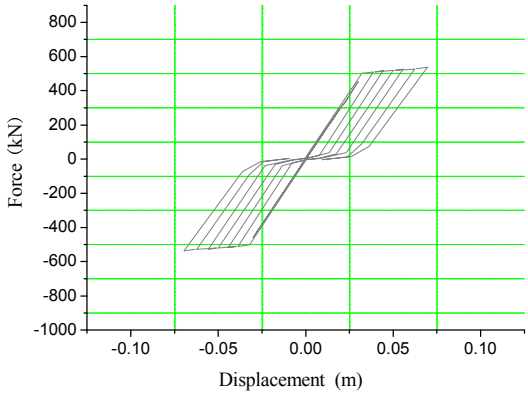


**Fig. 5** Wedge with steel frame load-displacement curve **Fig. 6** Ordinary steel frame load-displacement curve

The comparative analysis of load - displacement curve shows good ductility with a wedge of steel framework, stiffness than ordinary steel frame and carrying capacity is better also, due to cyclic loading, when the bolt was pulling up, there will be a space between the bolt and backplane, rebound after the spring compression, wedge immediately cut the gap generated by the plastic elongation of the bolt, so every time the loading and unloading are for always uninstall origin, present non-slip type characteristics, the hysteretic curve area of each significantly increased, better energy dissipation capacity and ordinary steel frame ductility is poorer, carrying capacity is also significantly smaller, since the loads, the gap made by bolts of plastic elongation is not restored, further increase of plastic deformation based on the original when re-loaded, therefore, each loading and unloading is not always origin and show the characteristics of Sliding, the hysteretic curve area is significantly reduced and then the consumption ability is bad. This shows that wedge with steel frame has better performance of energy consumption than the ordinary steel frame.

**Time History Analysis of Multi-layer Wedge Steel Frames Under Seismic Action**

**Model Design.** Two kinds of steel framework for 5 layers, storey height is 4m, total height 20m, horizontal three cross 6×3×6m, based on the plane of the truss model theory, take the transverse specimens of a framework for the establishment of the finite element model, section size, the material properties and analysis unit have the same simulation analysis with single-layer low-cycle reciprocating load. Because the plane model, boundary conditions are: The upper structure plane all constraint, only allowed to happen turn the motion in the plane. beam-column connections is rigid joints entity. Support and framework of the connection as hinges, two kinds of model and basic connections are embedded solid.

**Time History Analysis Under Earthquake.** According to 8 degrees fortification intensity, occurred earthquake, input EI Centro North-south seismic records [5], according to the <Code for seismic design of buildings> the am earthquake acceleration, adjusting the maximum acceleration of peak 4m/s$^2$, time interval 0.02s, take the first 20 s to the analog input seismic waves and take 0.05 to the damping ratio of the entire structure of the elastic-plastic analysis in the rare earthquake, comparative analysis of the results in Table 3-4, time history analysis and the acceleration time history analysis shown in Fig. 7 and Fig. 8.

**Table 3** Seismic response of the El Centro(NS)-wave under the action of ordinary steel framework

| Layer number | maximal displacement (cm) | relative storey displacement (cm) | Inter-story drift （rad） | acceleration (cm/s$^2$) |
|---|---|---|---|---|
| 1 | 1.1329 | 1.1329 | 1/353 | 218.935 |
| 2 | 2.6561 | 1.5232 | 1.5232 | 373.003 |
| 3 | 4.1808 | 1.5247 | 1/262 | 507.286 |
| 4 | 5.4034 | 1.2226 | 1/327 | 634.372 |
| 5 | 6.6389 | 1.2355 | 1/323 | 758.294 |

**Table 4** Seismic response of the El Centro(NS)-wave with a wedge of steel framework

| Layer number | maximal displacement (cm) | relative storey displacement (cm) | Inter-story drift （rad） | acceleration (cm/s$^2$) |
|---|---|---|---|---|
| 1 | 0.6237 | 0.6237 | 1/641 | 278.546 |
| 2 | 1.4679 | 0.8442 | 1/474 | 309.752 |
| 3 | 2.3647 | 0.8968 | 1/446 | 341.892 |
| 4 | 3.0626 | 0.6979 | 1/573 | 375.289 |
| 5 | 3.7411 | 0.6785 | 1/589 | 409.506 |

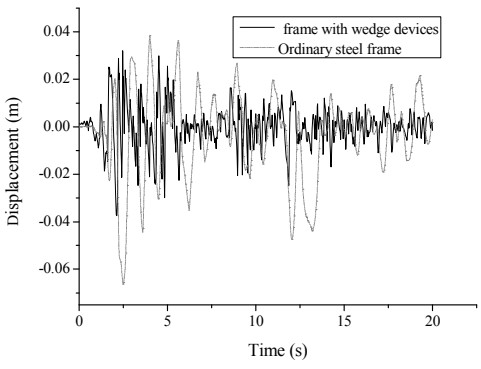

**Fig. 7** Top floor displacement-time curve

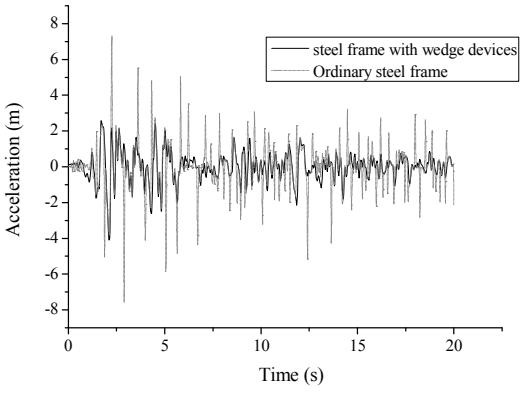

**Fig. 8** Top floor acceleration-time curve

From the comparison and analysis of the Table 3-4 and Fig. 7-8, the regularities are found: (1) As the floors increase, the maximum displacement of both the two steel frames are increase under rare occurrence earthquake. Compared with the ordinary steel frame, a wedge steel frame has a better performance on the maximum displacement, it shows the displacement reaction reduce about 44%; (2) The interlayer displacement of a wedge framework has been under control; (3) After analyze the Inter-story drift of models, we can get that the wedge with steel frame inter-story drift is smaller than

the ordinary steel frame because of the seismic control effects. According to the code for seismic design of buildings, the limit of elastic displacement angle between the layers is 1/300 of High-rise steel structure and the limit of elastic displacement angle between the layers is 1/50 of High-rise steel structure. But the limit of elastic displacement angle between the layers is 1/80 of energy dissipation device, ordinary frame cannot meet this requirement and the other two models can do; (4) The accelerated speed of the three steel frame reach the maximum. In the top storey, and the acceleration response reduce about 46% of the wedge block structure [6].

## Conclusions

Both the Simulation Analysis under low cycle reciprocating load effect and the time history analysis under the earthquake of wedge with steel frame and ordinary steel frame show that:
(1) The hysteric curve characteristics of ordinary steel frame is sliding, while the hysteric curve characteristics of wedge with steel frame is Non-slip type due to the spring-return and wedge block cut which made its uploading and downloading in the original point from the beginning to the ending.
(2) The energy dissipation of wedge with steel frame is excellent owe to the full hysteric curve. Comparing with ordinary steel frame, all the bearing capacity, stiffness, ductility deformability and energy consuming are better.
(3) The wedge device can strengthen the capacity to resisted earthquake of nodal point of wedge with steel frame, made it always under control and have an excellent anti-seismic performance under the rare earthquakes, but the higher deformation displacement and acceleration of ordinary steel frame made it can not meet the specification.
(4) Low cost, constriction convenient, and good anti-seismic performance all are the merits of wedge device. Therefore, it is a really good seismic node which should be researched deeply and used widespread.

**Keywords:** Masonry structure, Sliding damping, Rubber beam, Hysteretic curve, Seismic performance

**Abstract:** This paper presents a technology of sliding damping which could resist ground frost heaving. In the technology, setting the low-grade mortar bond of the upper and lower ring beams to achieve slip shock absorption, and setting the rubber beams to achieve shear deformation limiting. By rubber beam shear performance test,the shear strengthof the rubber beam has been acquired.In the paper, the finite element software has been adopted to simulate the seismic performances of common wall and sliding damping wall structures under low cyclic reversed loading, the hysteretic curves between the bottom shear and the top displacement of the walls. The researchresults show that sliding damping ring beam has the very good function on dissipatingseismic energy and reducing seismic action.

## Introduction

In recent years, with the aseismic attention'simprovement of rural building, some scholars began to research easy isolation and damping technology for village and town construction, such as Professor WanlinCao[1], [2]of Beijing University of Technologyhas developed a base isolation structure with double control device,the devicewas consist with upper and lower beam, graphite plate-glass cloth-graphite sliding isolation layer, and the limit steel bar.Professor ShoupingShang [3], [4] of Hunan University has developed a reinforced-asphalt compound isolation layer between foundation and ground ring beam, and Professor YingminLi [5]of Chongqing University has developed two simple seismicenergy dissipation technologies of arranging-rubberbeam inwalls and laying asphalt-sand cushion on foundation beam.

Based on the successful experiences of the related technology, in view of the high earthquake intensity and ground frost heave are the most important hazards for low-rise buildingin Xinjiang,a kind of sliding damping technology withbuilt-in rubber beam of ring beam has been put forward in this paper,which is not only achieve the effect of shock absorption, but also can eliminate ground frost heaving damage through the base ring beam. Its layout program is: Settings built-in rubber damping ring beam at the outdoor ground level, which consists of two layers are bonded as a whole by a mortar layer, as shown in Figure.1. The damping system working principle is: under the effect of small earthquakes, the low-grade mortar doesn't craze, the aseismic structure relies on its own aseismic capability to realize the fortification goal of "No damage with smallearthquake"; under medium and strong earthquakes, the ring beam divides into two parts, the main structure can slideintegrally with the upper ring beam, the rubber beam can limitshear deformation, the injuries of the upper structure mitigate effectivelyto achieve thefortification goal of'mendable in Moderate Earthquakes and no collapsing with strong earthquake". Through the base ring beam Settings, the danger of ground frost heaving force to the structure's integrity could be eliminated.

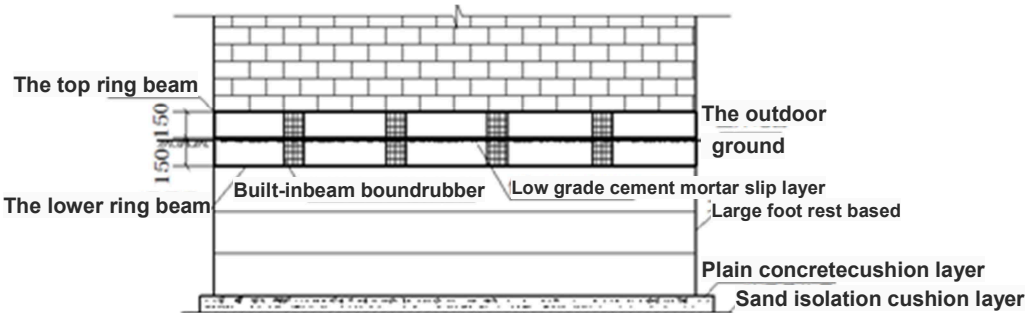

Fig.1Arrangement ofsliding damping system

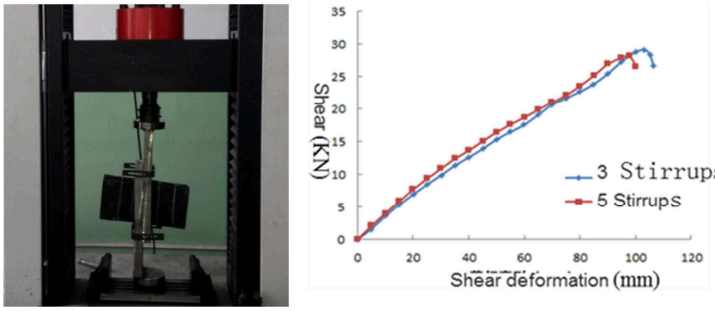
Based on the study of the shear performance of the individual rubber beam and presupposing reasonableslippageof upper structure, theseismic performances of common wall pieces and slip damping wall pieces were analyzedby ABAQUS software, working principles of suspension system were verified, which could lay a foundation for subsequent experimental study.

## Experimental study on shear behavior of rubber beam

Rubber beam as an important damping element, its damping effect is mainly done through its shear deformation under horizontal earthquake action. Therefore, the shear properties of rubber beams were tested in this paper, the size of the upper and lower ring beam is $150\times240$, the thick of mortar in the middle layer is restricted at 10mm, rubber beam size is set as $310\times150\times80$, shear properties of two conditions withthree wire hoop and five wire hoop were studied, the results show as Fig. 2 (b).



(a)Test loading device (b) Shear performance curves of rubberbeams

Fig. 2 Test loading device and test results

The following conclusions can be reached from the test results in Fig. 2: 1) There is little change of shear behaviorsbetween restricted by three and five wire hoop,in the overall, the shear strength is mainly decided by the shear stiffness of the cross-section, the rubber beam'slimiting amount of deformation is around 100mm, the ultimate shear capacity is about 30KN; 2) the shear P-Δ relationship embodied in a linear deformation before failure, after the shear failure, the intensity decreases rapidly. Therefore, rubber beam can be simplified as the level spring in the numerical simulation, each rubber beam's shear stiffness is taken as 300000N / m.

## Comparative Study of the monolithic wall seismic performance

**Modeling.** In this paper, the seismic performance of slip damping ring beam walls and common wall comparison were analyzed by ABAQUS software, thewall size of model is $240\times2800\times3000$, the structural columns on both sides are $240\times240$, the top was a pressure beam that analog upper load. Integrated model was used to simulate the upper wall, interior walls are simulated by 8-node hexahedral linear reduced integration unit (C3D8R), material constitutive used plastic damage model;spring unit were set at the both ends of the wall to simulated beam shear properties of rubber, mortar's slipping damping performance was simulatedthrough the friction surface (coefficient of

friction $\mu = 0.4$ ), This article used the coulomb friction model to analog slipping of the mortar layer, the main surface used the contacting property of "surface-to-surface contact" in interaction module to definite the masonry wall, the minor surface is the low-grade mortar layer [6] (Analysis model shown in Fig.3).

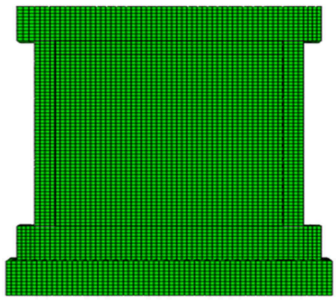


Fig. 3 Finite element analysis model

**Theloading system.**The low cycle alternating loading system was used, beginning with the force control loading stage,ending with the displacement loading control.For damping wall, the ultimate displacementwas 100mm,and for the common wall, the ending of loading was the appearance of severe pressure damage of wall.

**Experimental results and analysis.**Fig. 4 shows the hysteretic curvesof the base shear and the top displacement of the walls under two kinds of conditions, from the figure can draw the following conclusions:1)The hysteretic curve shape of common wallvaries from straight at the beginning to spindle gradually,it shows the three stages of Elasticity, cracking, and elastic-plastic. After entering the elastic-plastic stage, each loading cycle has some residual deformations,the hysteretic loop area increases gradually, The carrying capacity begins to declineafter reaching the ultimate load (300KN), the hysteretic loop area increases obviously shows that the wall damage is serious. On the other hand, in the damping wall, hysteresis curve shape is regular, each load cycle almost has no residual deformation, closing to the ideal energy consumption model, the hysteretic loop area is much larger than the ordinary wall; 3) The base shear of damping wall maintains at about 35KN, the base shear of damping wall is far less than common wall's,it shows that, under the condition of ensuring rubber beam limiting displacement. The sliding damping ring beam can achieve a good energy dissipation effect.

## Conclusion

This paper used research methods that combining experimental research and numerical simulation, the slip dampingwall and common walls' seismic performance were studied. Following conclusions could be drawn:

1) Rubber beam's shear capacity of the size $310\times150\times80$ is 30KN, the ultimate shear deformation is 100mm. Its shear strength and deformation capacity mainly related with Shear stiffness of the cross-section.

2) The damping walls reflect good ability of energy consumption under low cyclic loading. Compared with the common wall,the base shear of walls could be greatly reduced,the upper part of the structure could reciprocating sliding together with the ring beam,the upper structure almost keep the elastic state.

**Keywords:** Hybrid structure, Viscous damper, Seismic reduction, Strong earthquake.

**Abstract.** This article focuses on the effect of viscous damper on seismic performance of steel-concrete hybrid structure under strong earthquake. The result shows that viscous damper has effect on seismic reduction and control. The story lateral displacement, story drift rotation and energy dissipation-seismic can be reduced effectively by viscous dampers. The maximum value of vibration-reduction ratio is 36.0%, 67.9%, 36.9%. It is different effect on seismic reduction by different earthquake ground motion. Response of earthquake amplifies under Pasadena earthquake wave than the others.

## Introduction

In recent years, steel-concrete hybrid structure for high-rise building has been widely used. This structure has many advantages on the plane layout and force defense system. But under strong earthquake this structure has been damaged seriously, such as two high-rise buildings in Japan in 1992 [1], so there is a debate on the seismic performance of the structure system.

The traditional methods were restricted by economy, construction and using spatial. This way will increase the stiffness of structure and also expand the seismic energy input the structure. The dampers can provide damping force for structures and the stiffness of structure isn't changed by viscous dampers. Compared with other dampers, the model of viscous dampers is relatively simple and widely used in practical projects [2]. Nonlinear time-history analysis method was used in this paper to study the anti-seismic performance. The effect of viscous damper on anti-seismic performance was analyzed under strong earthquake.

## General situation of the project and Computation models

**The project**. The project is a 15-storey steel-concrete hybrid structure of 60 m with steel framework and concrete shear wall [3]. The design basic acceleration of ground motion is 7 degree (0.1g). The measure grade of shear wall and frame is Ⅰ and Ⅱ respectively. The structural plane is shown in Fig. 1.

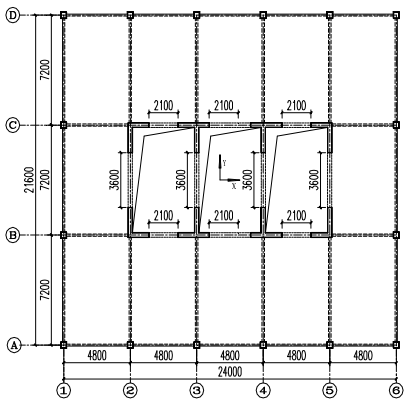

Fig. 1 Structural plane (mm)

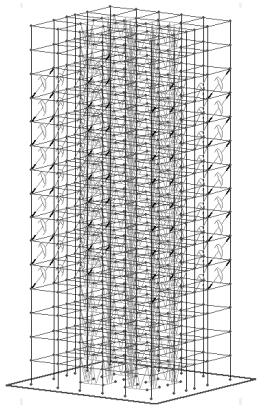

Fig. 2 3D model

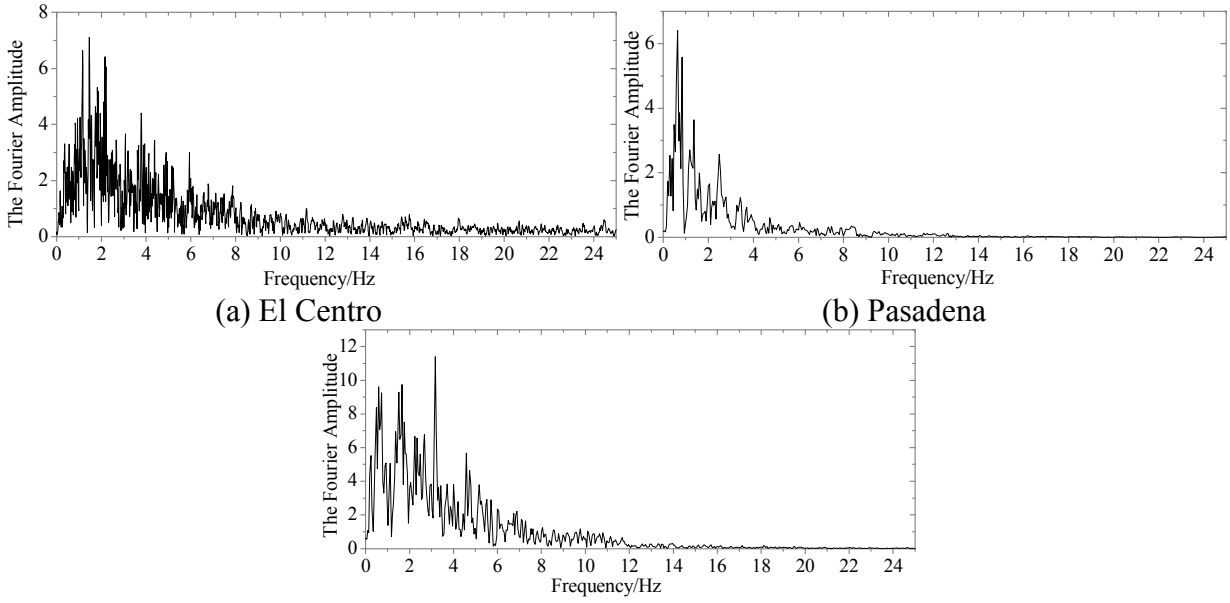
The dead load on the floor and roof is 6.0 kN/m$^2$ and 7 kN/m$^2$ respectively. The live load on the floor and roof is 2.0 kN/m$^2$. The dead load on the beam is 1.5 kN/m.

**Computation models**. The nonlinear dynamic time-history analysis is carried out by CANNY program [4]. There are 720 beam elements, 300 column elements, 180 wall elements and 72 damper elements. The 3D model of structure is shown as Fig. 2. The dampers set up on the floor from 5 to 13, where the story drift rotation is much larger than that of the other stories.

## Earthquake ground motion and Analysis cases

**Earthquake ground motion**. In order to analyze the dampers' effect on seismic reduction under different earthquake ground motion, there are three earthquake waves selected: El Centro(1940), Pasadena(1952), San Fernando(1971). The maximum acceleration and occurrence time are shown as 341.7gal at 2.14s, 46.5gal at 6.9s, 137.86gal at 12.54s. Fourier frequency domain graphs (FFT) of the three earthquake waves are shown as Fig. 3.



(a) El Centro (b) Pasadena

(c) San Fernando

Fig. 3 Fourier frequency domain graphs

From the Fig.3, it could be observed that the El Centro energy focus on 1.0-2.5Hz, the maximum energy at 1.4648Hz; Pasadena energy focus on 0.3-0.7Hz, the maximum energy at 0.6348Hz; San Fernando energy focus on 1-4Hz, the maximum energy at 3.1738Hz. Analysis of vibration modal, the structure's fundamental frequency is 0.6334Hz near the Pasadena's frequency of maximum energy. The structure resonance occurs under earthquake ground motion of Pasadena.

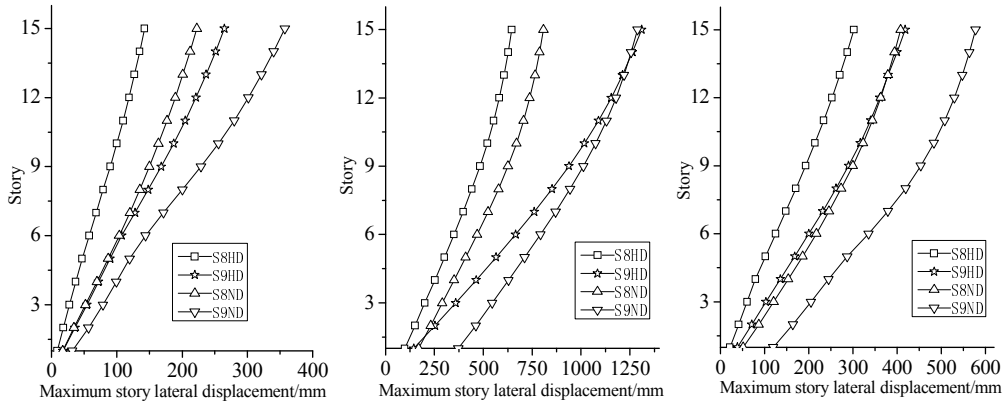
**Analysis cases**. The structure without and with viscous dampers are called non-control and additional damper structure. There are 4 analysis cases as shown in Table. 1.

Table. 1 Main analysis cases

| Number | Seismic intensity | Damper | Case |
|---|---|---|---|
| 1 | 8-degree seldom (0.40g) | Without | S8ND |
| 2 | | With | S8HD |
| 3 | 9-degree seldom (0.62g) | Without | S9ND |
| 4 | | With | S9HD |

**Analysis of different cases**

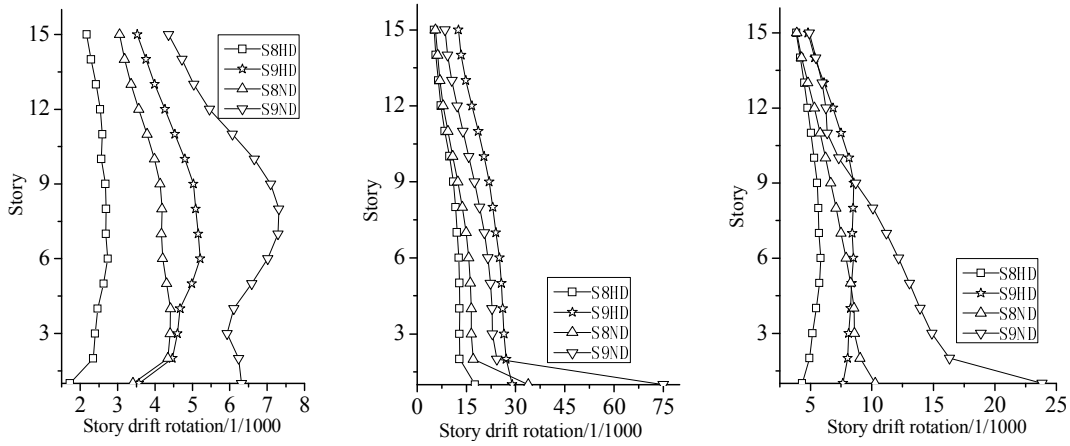
**The maximum story lateral displacement**. The maximum story lateral displacement in direction Y under different cases is illustrated in Fig. 4. In 9 degree seismic seldom intensity, the maximum story lateral displacement is too much under Pasadena earthquake wave. The components of structure are serious damaged. The story lateral displacement of stories with viscous dampers is reduced effectively under the other earthquake waves. The maximum value of vibration-reduction ratio is 36.0%.



(a) El Centro (b) Pasadena (c) San Fernando

Fig. 4 The maximum story lateral displacement

**Story drift rotation.** The story drift rotation of non-control structure and additional damper structure are shown in Fig. 5. The first story drift rotation occurred saltation under Pasadena earthquake wave in 8, 9 degree seismic seldom intensity. It could be observed that the components of this story appeared nonlinear deformation. Seismic reduction and control are not evident only depend on increasing dampers. The story drift rotation of stories with viscous dampers is reduced effectively under the other earthquake waves. The maximum value of vibration-reduction ratio is 67.9%.



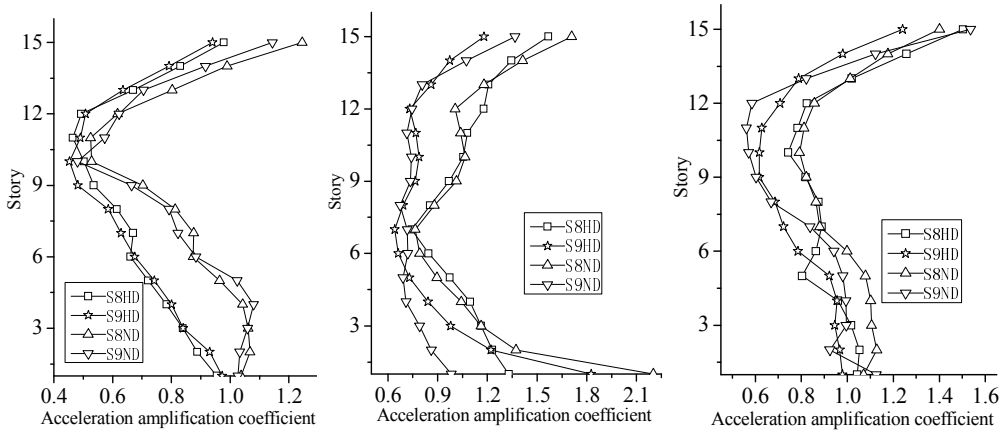
(a) El Centro (b) Pasadena (c) San Fernando

Fig. 5 Story drift rotation

**Acceleration amplification coefficient.** The story drift rotation of non-control structure and additional damper structure are shown in Fig. 6. In 8 and 9 degree seismic seldom intensity, the acceleration amplification coefficient changes a great deal in value. The maximum value of vibration-reduction ratio is 25.2% and 27.5% respectively.

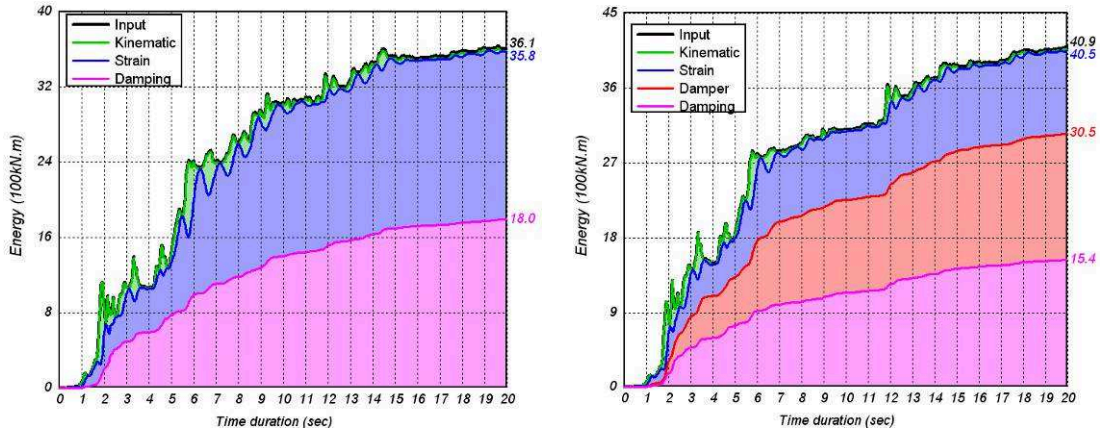
**Analysis of energy**. The input energy and the balance with the system dissipated energy (strain energy, damping energy, damper energy and kinematic energy) under El Centro earthquake wave in 8 degree seismic seldom intensity are shown as Fig. 7. Under El Centro earthquake wave, the input energy of non-control structure is 3610kN·m and additional damper structure is 4090kN·m. In spite of

the input energy increases after additional damper, energy dissipation of the dampers is 1510 kN·m. The ratio of the dampers' energy is 36.9%.



(a) El Centro (b) Pasadena (c) San Fernando

Fig. 6 Acceleration amplification coefficient



(a) No damper (b) Have dampers

Fig. 7 Analysis of energy under El Centro earthquake wave

## Conclusion

The seismic performance of uncontrolled structure and energy dissipation structure is analyzed. The main conclusions are summarized as follows:

(1)The viscous dampers can reduce the story drift rotation, the story lateral displacement and energy dissipation-seismic of structure.

(2) Under different earthquake ground motion, seismic performance of the structure is different. As the paper expound above, the maximum energy at 0.6348Hz of Pasadena. It is nearly 0.6334Hz of the structure's fundamental frequency. Response of earthquake amplifies under Pasadena earthquake wave than the others.

# Simplified Dispersion Curves of Earthquake Love Wave for Rotational Seismic Motion Estimation

Yuewei Liu[a], Hongnan Li[b]

Faculty of Infrastructure Engineering, Dalian University of Technology, 116024, China

[a]wmhansen@163.com, [b]hnli@dlut.edu.cn

**Keywords:** phase velocity, dispersion, simplified dispersion curve, Love wave, rotational motion, stiffness matrix

**Abstract.** In the simulation of the rotational seismic ground motion, the apparent velocity of Love wave is always assumed to be equal to the S wave velocity of top layer of the site approximately, with the dispersion of surface wave not being fully considered. In this paper, the effect of the velocity structure to the Love wave dispersion is discussed based on the stiffness matrix theory. It shows that to assume the velocity to be equal to the S wave velocity of the top layer may greatly overestimate the low frequency rotational seismic motion. A simplified dispersion curve, is suggested for rotational seismic ground motion simulation. The shape of the bilinear curve is shaped by 3 parameters. They are the corner frequency, the minimum phase velocity and the velocity ratio. The parameters are affected by the velocity structure of the site.

## Introduction

The rotational ground motion is not considered directly due to lack of the recorded rotational ground motion. Some simplified theoretical methods were developed to simulate the rotational motion from the translation motion for rotational seismic design of structures[1]. The apparent velocity of the incidence wave is one of the key parameters in these methods.

The earthquake wave contains several types of components, such as the P wave, S wave, Rayleigh wave and Love wave. The apparent velocity of Love wave is dispersed. The transfer matrix theory and the stiffness matrix method are some of the way to research the wave dispersion[2,3]. The methods are widely applied in earthquake wave inverse, earthquake exploration and other fields. But the methods have not been introduced to the rotational earthquake motion simulation by civil engineers, because they are too complicated. The apparent velocity of Love wave is assumed to be equal to the S wave velocity of the upper layer of the site[4,5]. It is not reasonable. Li considered a two-layer space, a low-velocity layer above an elastic half-space, and derived calculation formulations of phase velocities with frequency dispersion[6]. The formulations are simple, containing no matrix operation. Since the wave velocities of earth's surface change distinctly along its depth, the two-layer space is too simple.

This paper will introduce the methods based on the stiffness matrix theory to calculate the phase velocities of Love wave in multi-layer half space, and present a simple way to determine the apparent velocities of surface waves that can be used for rotational seismic ground motion estimation.

## Stiffness matrix theory

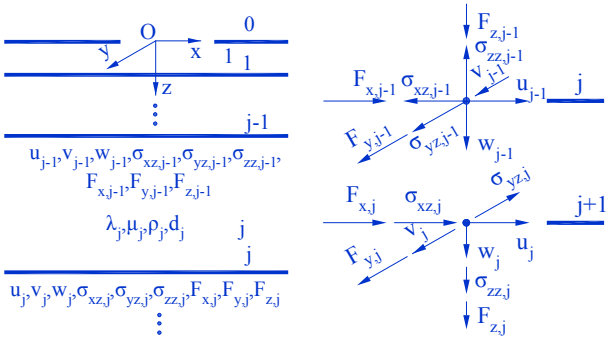
Generally, the surface of earth is layered and the wave velocities of the medium are increasing along the depth of the layers. Thus, consider a multi-layer isotropic elastic half space shown as Fig.1 (a). In the figure, j is the layer number, $\lambda$ and $\mu$ are the Lame constants, $\rho$ is the density, d is the thickness of layer, u, v and w are the displacements of layer, $\sigma$ is the stress on the interface and F is the exterior force. Let the Love wave propagate along x, so the Love wave is in the x-y plane. In the layer j, the wave equation is (the subscript j is omitted if no confusion rises)[7]

$$\begin{bmatrix} F_{y,j-1} \\ F_{y,j} \end{bmatrix} = \mu_j b_j \begin{bmatrix} -cth(bd) & \csc h(bd) \\ \csc h(bd) & cth(bd) \end{bmatrix} \begin{bmatrix} v_{j-1} \\ v_j \end{bmatrix} \tag{1}$$

where

$$b = \sqrt{k^2 - k_\beta^2} \quad (k > k_\beta) \ , \ k = \omega / c \ , \ k_\beta = \omega / \beta \ , \ \beta = \sqrt{\mu / \rho}$$

in which c is the velocity of Love wave, k is the wave number, α and β are the velocity of P wave and S wave, respectively, and ω is frequency. The direction of displacement and force are shown in Fig. 1(b).



(a) (b)

Fig. 1. Multi-layer half space. (a) Layers. (b) Direction of displacement, stress and force

Subdivide the layers to ensure the thickness of the subdivided layers in the calculating process were small enough, so bd is small. Using the Taylor expansion, one has

$$cth(bd) \approx \frac{1}{bd} + \frac{bd}{3} \quad , \quad \csc h(bd) \approx \frac{1}{bd} - \frac{bd}{6} \tag{2}$$

At the same time, in the free condition, F=0, one has Eq. (4) after transmutation from Eq. (2)

$$\left( \begin{bmatrix} -\frac{\mu}{d} + \frac{\omega^2 \rho d}{3} & \frac{\mu}{d} + \frac{\omega^2 \rho d}{3} \\ \frac{\mu}{d} + \frac{\omega^2 \rho d}{3} & -\frac{\mu}{d} + \frac{\omega^2 \rho d}{3} \end{bmatrix} - k^2 \begin{bmatrix} \frac{\mu d}{3} & \frac{\mu d}{6} \\ \frac{\mu d}{6} & \frac{\mu d}{3} \end{bmatrix} \right) \begin{bmatrix} v_{j-1} \\ v_j \end{bmatrix} = 0 \tag{3}$$

If $[v_j, v_{j-1}]^T \neq 0$ , Eq. (4) must be satisfied as follows

$$\left\| \begin{bmatrix} -\frac{\mu}{d} + \frac{\omega^2 \rho d}{3} & \frac{\mu}{d} + \frac{\omega^2 \rho d}{3} \\ \frac{\mu}{d} + \frac{\omega^2 \rho d}{3} & -\frac{\mu}{d} + \frac{\omega^2 \rho d}{3} \end{bmatrix} - k^2 \begin{bmatrix} \frac{\mu d}{3} & \frac{\mu d}{6} \\ \frac{\mu d}{6} & \frac{\mu d}{3} \end{bmatrix} \right\| = 0 \tag{4}$$

Assembling Eq. (4) by layers, k and c can be obtained.

**Velocity of Love wave in some sites of China**

In some regions of China, the velocity structures, described by the statistic expressions as Eq. (5), are shown in Table 1[8].

$$\beta = q_1 H^{q_2} \tag{5}$$

where $q_1$ is β of the first layer, H is the depth of the layer, $q_2$ is the parameter which denote the increasing grades of β.

The dispersion curves are plot in Fig. 2.

**Simplified dispersion curve**

**Parameters.** For civil engineers who are engaged in structure rotational seismic design, the method above to calculate the dispersion curve of Love wave is so complicated that the reasonable simplification is needed. As shown in Fig.2, the dispersion curve can be simplified into a bilinear curve with a horizontal segment and a bias. The shape of the bilinear curve is controlled by 3 controlling parameters, $f_c$, $c_{\min}$ and $\zeta$. They are defined as follows:

Table 1 Distribution of S wave velocity in some regions of China and controlling parameters of the simplified curve

| NO. | region | soil type | $q_1$ / m/s | $q_2$ | $v_{s,30}$ (m/s) | $c_{\min}$ (m/s) | $\varsigma$ | $f_c$ (Hz) |
|---|---|---|---|---|---|---|---|---|
| 1 | Beijing | sandy soil | 110.0 | 0.309 | 240.4 | 187.8 | 2.2 | 2.7 |

**Simplified dispersion curve**

**Parameters.** For civil engineers who are engaged in structure rotational seismic design, the method above to calculate the dispersion curve of Love wave is so complicated that the reasonable simplification is needed. As shown in Fig.2, the dispersion curve can be simplified into a bilinear curve with a horizontal segment and a bias. The shape of the bilinear curve is controlled by 3 controlling parameters, $f_c$, $c_{\min}$ and $\zeta$. They are defined as follows:

(1) $f_c$ is the corner frequency. It is the turning point of the bilinear curve. When the frequency is higher than $f_c$, the simplified dispersion curve is horizontal. When the frequency is lower than $f_c$, the simplified dispersion curve is declining.

(2) $c_{\min}$ is the minimum phase velocity. It is the velocity along horizontal line. It can also be regarded as the phase velocity at 20Hz since the range of earthquake frequency that the structure engineering takes into consideration is usually between 0.1Hz and 20Hz.

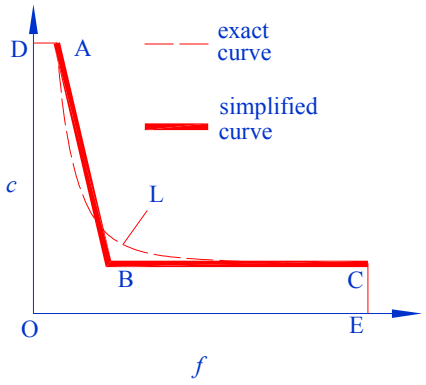
(3) $\zeta$ is the velocity ratio, defined as $\zeta = c_{0.1} / c_{\min}$, where $c_{0.1}$ is the phase velocity at 0.1Hz.

**Corner frequency.** It is shown in Fig.2 that the dispersion curve is smooth. There is no obvious turning point to distinguish the 2 segments. The corner frequency is determined by the following work:

As shown in Fig. 3, on the exact dispersion curve, let point A be (0.1, $c_{0.1}$), let point C be (19.6, $c_{\min}$) ($c_{\min} = c_{19.6}$, $c_{19.6}$ is the phase velocity at 19.6Hz). Find a point B ($m$, $c_{\min}$) to ensure the area $S_{ODABCE} = S_{ODĒE}$. The point B is considered as the turning point, $f_c$ is considered to be equal to $m$.

The corner frequencies are shown in Table 1. They are between about 1.7-6.4 Hz in these sites in Table 1. $f_c$ is related to $q_1$ tightly. The relation is shown in Fig.4. The fitting formula of $f_c$ with $q_1$ is as follows

$$f_c = 0.025q_1 + 0.06 \tag{6}$$



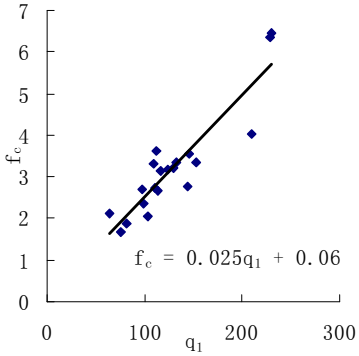


Fig.3. Determination of the corner frequency Fig.4. Corner frequency

**Minimum phase velocity.** $c_{\min}$ is close to the S wave velocity of the first layer, because in high frequency region, the phase velocity of Love wave is affected by the upper layers of earth's surface mainly. In civil engineering, $v_{s,30}$ is an effective S wave velocity of the layers between 0-30m, and is commonly used to distinguish the site type and to determine the seismic load of structures. It is defined by Eq. (7)

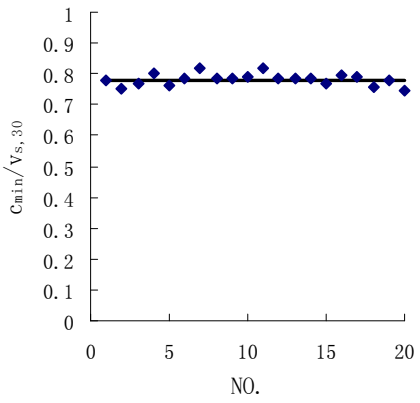
$$v_{s,30} = \frac{\sum d_i}{\sum (d_i / \beta_i)}, \sum d_j = 30m \tag{7}$$

It is practicably to find the relation between $c_{\min}$ and $v_{s,30}$ rather than the relation between $c_{\min}$ and the S wave velocity of the strict first layer. $c_{\min}$ and $v_{s,30}$ of the sites are shown in Table 1 and Fig.5. They show that $c_{\min}$ is close to $v_{s,30}$, as described by Eq.(8).

$$c_{\min} \approx 0.70 - 0.85 v_{s,30} \tag{8}$$

**Velocity ratio.** $\zeta$ are shown in Table 1. $\zeta$ is related to $q_2$ tightly. The relation is shown in Fig.6. The fitting formula of $\zeta$ with $q_2$ is Eq. (9) as follows

$$\zeta = 0.71 \exp(3.69 q_2) \tag{9}$$



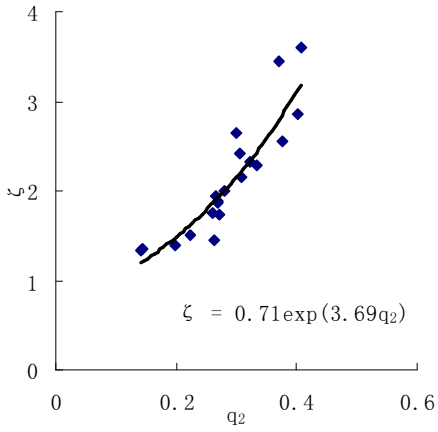


Fig.5. Minimum phase velocity Fig.6. Velocity ratio

## Conclusion

Based on the stiffness matrix theory, the effects of the velocity structure of site on dispersion curve are discussed in this paper. It shows that the dispersion curve can be simplified into a bilinear curve with a horizontal segment and a bias. The simplified dispersion curve is shaped by 3 parameters, $f_c$, $c_{\min}$ and $\zeta$. The parameters is suggested based on the statistic data of some sites in China.

**Keywords:** self-centering; precast concrete frame; finite element analysis; seismic performance.

**Abstract.** Self-Centering structure is a kind of new structure, which aims for reducing the residual deformation of structure after the earthquake. In order to research the Seismic Behavior of Self-centering Prefabricated concrete frame, a new joint applied with prestressed tendons and a traditional joint are designed in this paper with the finite element software ABAQUS. The seismic performances of them are contrastively analyzed. The new joint is found to have better self-centering capacity. Then two plane frame models are analyzed. The result shows that the frame applied with prestressed tendons has some capacity of self-centering and enough energy dissipation effects.

## Introduction

Prefabricated construction is a construction structure of industrial production. It has advantages of high quality, fast construction and so on. Seismic behavior is the key point in the study of prefabricated structure. The seismic principles of "three standards and two phase" in China allow the structure to enter the stage of elastic-plasticity in moderate or major earthquake. It makes large residual deformation and high repairing cost after the earthquake, though it protects the people's safety [1-3].

Self-Centering structure is a kind of new structure, which aims for reducing the residual deformation of structure after the earthquake. The research of Self-Centering structure originated from the study on prefabricated prestressed concrete frame with unbonded tendons. A lot of research have been done on Self-Centering steel frame structure. Prestressing technique was first applied to steel frame to realize the capacity of Self-Centering by J.Ricles [3]. A new kind of steel frame joint was studied by Pan Peng [4-5], which uses post-tensioned (PT) high-strength steel to tie the beam on the column to resist moment and provide self-centering force. However, research achievements on Self-Centering concrete structure are not sufficient. A kind of new self-centering post-tensioned precast connections (PTED) was proposed by Meng Shaoping [6].

A new kind of precast concrete joint is studied, which has the capacity of self-centering. This new joint uses post-tensioned high-strength steel and dry joint method. The post-tensioned reinforcements tie the beam on the column to resist moment and provide self-centering force. In order to study the seismic performance of such joint and the overall frame structure, the finite element software ABAQUS is used to analysis the capacity of self-centering and seismic behavior.

## Study on Self-Centering joint

The current domestic and international research indicates that adding post-tensioned tendons in prefabricated concrete beams can improve displacement restoring capacity, and reduce residual deformation after the earthquake [7]. Therefore, a self-centering prefabricated prestressed concrete frame joint JD-1 is designed in this paper, as shown in Fig.1. And a common prefabricated concrete frame joint JD-2, which is late poured in joint core region, as shown in Fig.2. Dimensions and reinforcement of these two joints are identical. In order to make the finite element model truly reflect the stress state of the joints in the actual project, the paper model is designed as an exterior joint of a general frame.

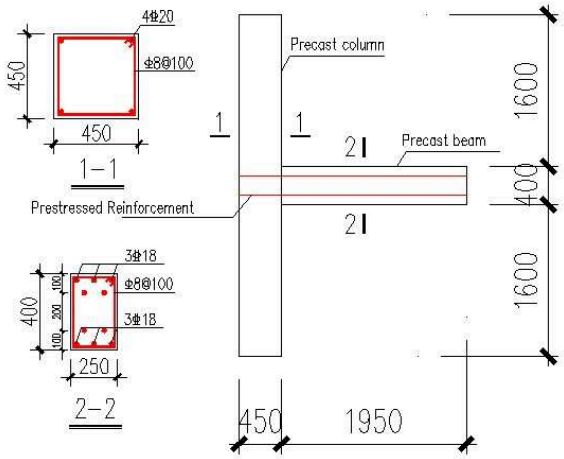

Fig.1 Size and reinforcement of JD-1

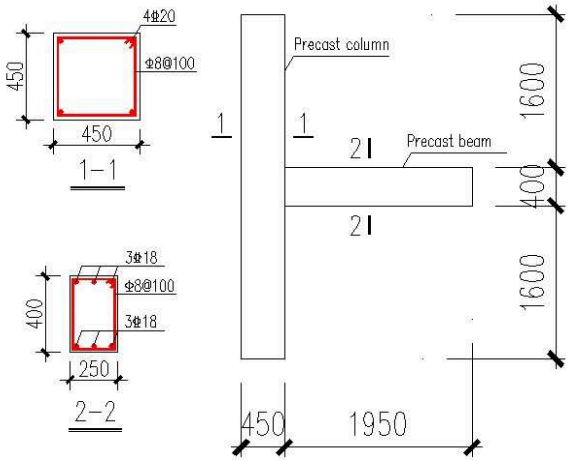

Fig.2 Size and reinforcement of JD-2

A dry method is used to splice joint JD-1. 4 steel strands are put in the corrugated pipe, which are buried in the joint before pouring the concrete. Then tendons are prestressed before hole grouting. Joint JD-2 is constructed by traditional method. A distance from the joint core region is left for cast-in-place.

Beam-column longitudinal reinforcement are HRB400 rebar, the stirrups are HPB335 reinforced, and the strength grade of concrete is C45. Nominal diameter of tendons are 15.2mm, tensile strength is 2000Mpa. 1000Mpa was applied to tendons in the pre-tensioning stage.

**Material constitutive relationships**

Concrete Damaged Plasticity model in ABAQUS program are selected as concrete constitutive model in this paper. The model assumes the destruction of the concrete material to crack and crush. Yield and failure surface evolution is controlled by tensile and compression equivalent plastic strains. The model also has better convergence. Therefore, this model is used to simulate the nonlinear behavior of concrete in this paper. The constitutive relationship proposed in Appendix C of GB 50010-2010 is used to describe the concrete stress-strain relationship.

The stress-strain relationship proposed in Appendix C of GB 50010-2010 is used for rebar and tendon in this paper. The slope of polygonal line's first ascent is the young's modulus of rebar and tendon. Rebar begin to enter Strengthen period after yield platform and the Strengthen period is simplified to a straight line. Maximum strain of the yield platform is assumed as $\varepsilon s=4\varepsilon y$. Ideal elastoplastic model is used only in tendon. Bond-slip effect is not considered in the paper.

**Boundary and loading conditions**

Since boundary conditions is very important to the performance of the frame joint, a "horizontal column and vertical beam" mode is used in this model, as shown in Fig.3. The loading procedure of JD-1 is divided into 2 stages. Firstly tendons are stretched, and then monotonic and cyclic load are applied to the edge of the beam. There is only one loading stage in JD-2. In these two analysis models, C3D8R element is used for concrete and T3D2 element for rebar and tendon, as shown in Fig.4.

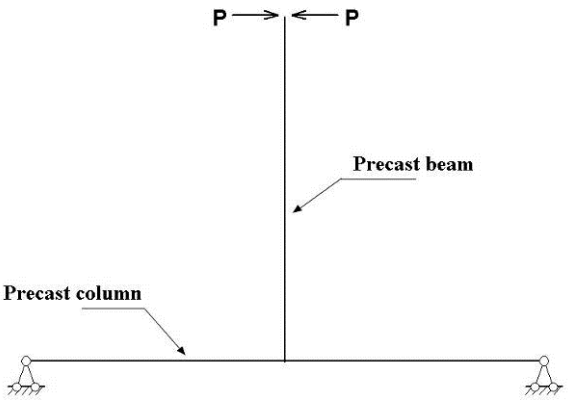

Fig.3 Loading diagram

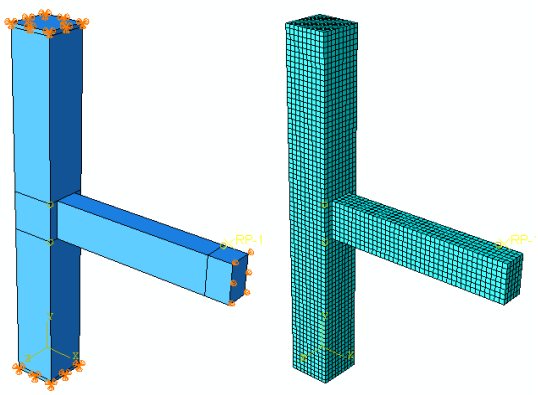

Fig.4 Finite element analysis model

**Analysis of load-displacement curve**

The load-displacement curves of JD-1 and JD-2 under monotonic load are shown in Fig.5. It can be seen that bearing capacity of JD-1 is higher than JD-2. in the path of the curves, JD-2 has larger initial stiffness, but firstly enter into the elastoplastic stage. Although JD-1 has a lower initial stiffness, it is still in the elastic stage when the displacement is 5mm. the yield displacement of JD-1 is 16.97mm, while JD-2 is 10.85mm.

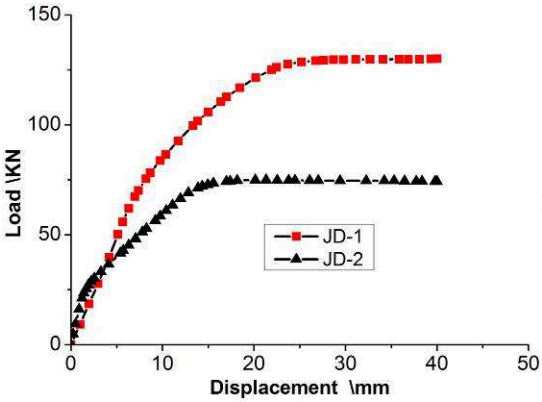

Fig.5 Load-displacement curve comparison

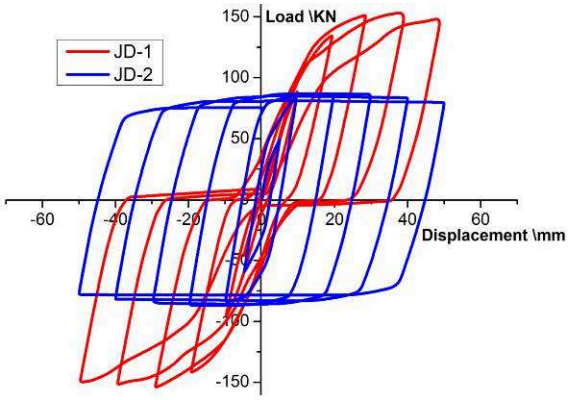

Fig.6 Hysteresis curve comparison

**Analysis of hysteresis curve**

The hysteresis curves of JD-1 and JD-2 are shown in Fig.6. It can be seen that the hysteresis curve of JD-2 is in spindle type under cyclic loading. This graphics type indicates large energy dissipation effects and good seismic performance. Although the curve of JD-1 is not as plump as JD-2, the displacement returned to zero after each cycle, indicating that JD-1 has a better displacement restoring capacity. On the other hand, the curve of JD-1 shows a clear "double flag" shape, which indicates good energy dissipation performance.

## Study on overall frame

In order to analysis the seismic performance of Self-Centering overall frame, a one-floor single-span Self-Centering plane frame model ZFW-F1 is built. Another one-floor single-span plane frame HJ-F1 is also built for comparison. All the parameters of these two frames are the same, except for the post-tensioned tendons in ZFW-F1. The span of the frame is 5m, and the storey height is 4m. The column section is 400mm×400mm, and the beam section is 250mm×500mm.the model of ZFW-F1 is shown in Fig.7.

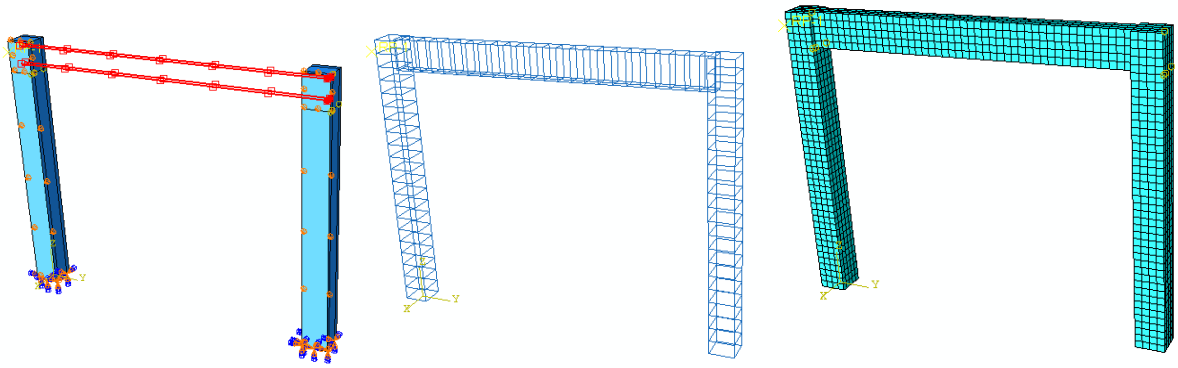

Fig.7 Finite element analysis model

The procedure of the analysis can be divided into 3 steps: Firstly, tendons are prestressed. Secondly, vertical force is loaded on the top of the columns. Then monotonic loading and low reversed cyclic horizontal loading are applied to the frame.

**Analysis of load-displacement curve**

Monotonic loading is applied to the two frame models to get the load-displacement curve, shown in Fig.8. It can be seen that the initial stiffness of ZFW-F1 is lower than HJ-F1, but the load capacity of ZFW-F1 is higher than HJ-F1.

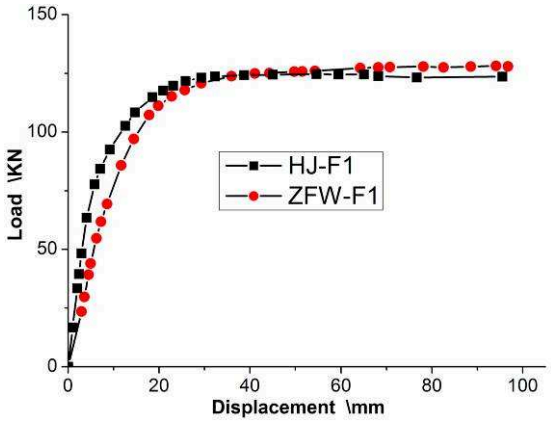

Fig.8 Load-displacement curve comparison

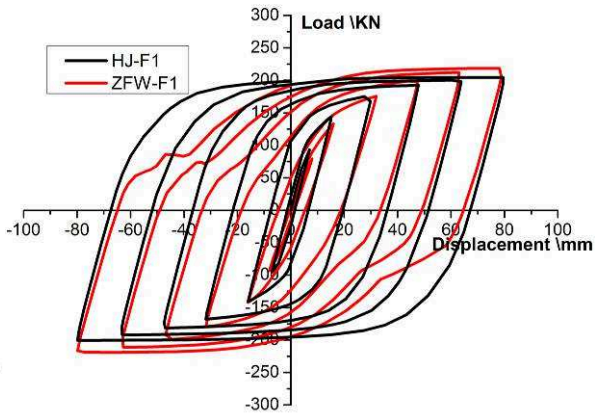

Fig.9 Hysteresis curve comparison

**Analysis of hysteresis curve**

The hysteresis curves of ZFW-F1 and HJ-F1 are shown in Fig.9. It can be seen that ZFW-F1 has some capacity of self-centering. The residual deformation of ZFW-F1 after each cycle is much lower than HJ-F1. On the other hand, the energy dissipation effects of both frame are similar.

## Conclusions

In this paper, a new kind of self-centering prefabricated prestressed concrete frame joint JD-1 is analysed by ABAQUS, compared with a prefabricated traditional joint JD-2. Then a Self-Centering plane frame ZFW-F1 is analysed, compared with a common frame HJ-F1. The conclusions are as follows:

1) Self-centering joint JD-1 performs better in bearing capacity than the traditional joint JD-2, but the initial stiffness of JD-1 is lower.

2) The hysteresis curve of JD-1 shows a clear "double flag" shape, indicating good self-centering characteristic and enough energy dissipation effects.

3) The initial stiffness of ZFW-F1 is lower than HJ-F1, but the load capacity of ZFW-F1 is higher than HJ-F1. ZFW-F1 has some capacity of self-centering and enough energy dissipation effects.

**Keywords:** advanced detection; side detection; Radon transformation.

**Abstract.** This paper mainly discusses that the tunnel seismic advance detection is applied in mine geo-hazard detection. Separating the field seismic data of mine by radon transformation and migrating the data through advance way and side way, we accomplished advance and side detection simultaneously by one-time shot seismic data. Case study was carried on at Qinshui basin Yangmei No.5 mine field, and detection results mainly coincide with out-crops, demonstrating that our method can be one reference in mine geo-hazard detection.

## Introduction

Seismic exploration is an effective geophysical methods along with the development of petroleum industry, It has popularized and been effective in coal mine geological exploration recently. With the deepening depth of coal resources exploration, the resolution of seismic exploration has been difficult to meet the geological demands for safety and mining efficiency. The shortage mainly reflected in the detection of changes of coal bed thickness, imaging of subtle faults, small falls and columns, and discerning of denudation belt. In addition, data acquisition and processing will face many problems in the area of multiple seam and inclined coal mine. Due to its high resolution, detection distance, strong anti-interference ability, strong pertinence, mine seismic achieved more and more attention in recent years, and it has become a hot spot of mine geophysical research. Li modeled the elastic wave field stimulated by point-source or plane wave source in the coal mine roadway [1]. Seismic wave field and propagation characteristics of various wave patterns in different models were analyzed by Yang[2]. The principles and application of mine seismic data acquisition were studied by Hu[3]. The work above just focuses on advanced detection research, and has not considered the side geological conditions detection. Mine seismic data acquisition is mainly conducted for the tunnel advance detection, which often does not include the mine side, while the side information is also critical to the safety production of coal mine. In view of this, on the basis of previous research studies, the author uses one-time seismic data simultaneously to detect the mine advance and side.

## Principle of Mine Seismic Detection

The basic principle of seismic exploration is based on the difference of wave impedance of different medium. Generally it could be divided into three parts: acquisition, processing and interpretation.

Figure 1 illustrates how the mine seismic data is acquired. Seismic waves triggered from each shot point will be received as effective signal by geophones bringing along information of different interface's wave impedance. The following aspects should be considered in data acquisition process.

Selection of geometry parameters, including the sampling rate, group interval and the minimum offset. According to the past working practice, frequency of coal roadway seismic data and rock roadway data is generally no more than 3000Hz and 5000Hz respectively, with the sample rate

0.05ms and 0.08ms. The highest frequency of Nyquist frequency recovery is 6250Hz and 10000Hz respectively, which can meet the requirements of data acquisition. Small group interval will lose far offset data, while big interval will affect the consistency of events, also the geometry the actual mine should be considered. Minimum angle offset is set according to the angle between the direction of main and advance anomaly interface and the direction of the face tunneling. When the angle is small, converted wave can be induced due to small offset, and when the angle is large, you will need to increase minimum offset. The actual detection results shows bigger minimum offset will weaken the signal and then damage the resolution.

Geological conditions and geometry of mine may differ tremendously. Hence we can make the appropriate adjustments to the observation system according to the site, to ensure the smooth construction.

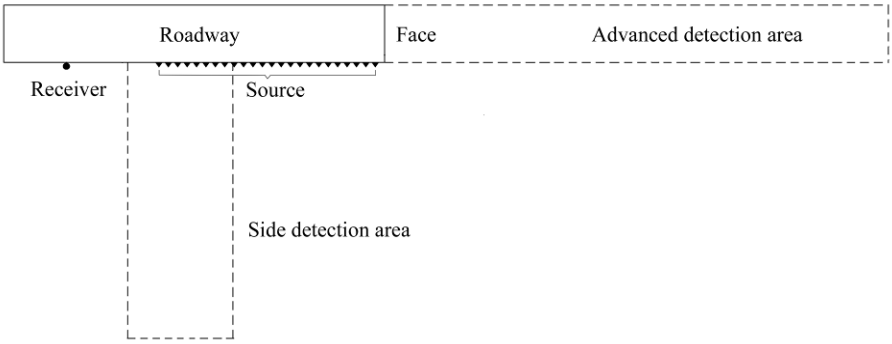

Fig.1 Sketch of seismic data acquisition

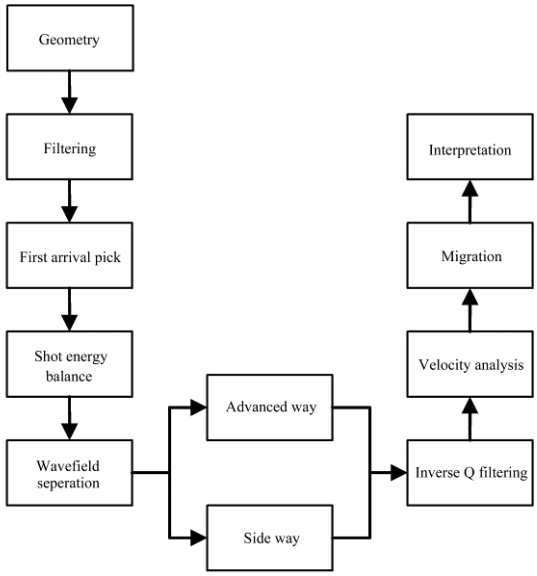

Fig.2 Seismic data processing flow chart

Mine seismic data processing includs 3 steps, the establishment of geometry, separation wave field and migration.The specific details of the process flow are shown in Figure 2. Firstly we establish geometry, input the group interval, receiver and roadway geometry information to the processing system, and then there will be filtering of seismic data applied in order to eliminate sound waves, surface waves and artificial noise. Then we pick up first arrivals of the filtered seismic data, using the least squares method for early correction of each channel seismic to calculate the direct wave velocity for subsequent processing and analysis. As the shots fired, the energy source may not be completely consistent in each channel, so we need to balance the data for the accuracy of processing. The wave field of the data is then separated, and the geophones receive the seismic signals from all directions of shod head in front, rear and side. The advance detection only need to use seismic reflection signals

from shod head front, and side may only need information from side direction to detect. There are 3 method for wave field separation: Radon transform, FK dip filtering and median filtering.Due to shortage of mine seismic data, the latter two methods are not effective. We use Radon transform to do wave separation. After that Q filtering processing is applied on the seismic wave field, to compensate the amplitude and frequency attenuation during propagation. Then migration will be carried out for advance and side seismic data. There are many seismic migration algorithm, due to the limitations of the mine seismic data, we selected Kirchhoff pre-stack depth migration. Finally, interpret the results, the geophysical results will be translated into geological information.

## Case study

To identify the geological conditions mine advance and side and provide reference for tunneling and mining face, we conduct mine seismic. Because the existence of The PVIs, we rigorously design the geometry. Also due to the relatively uneven north side and the gas discharge tube, we set up geometry on the south side. We have 24 shots, one geophone, a sampling rate of 0.05ms, sampling points of 6000, shots spacing of 1.5m, minimum offset of 18m. In order to prevent loosening of wall of roadway and surface wave interference, we have borehole depth of 1.5m, borehole with the wind and air pressure with seal mud of 1m to ensure process consistency.

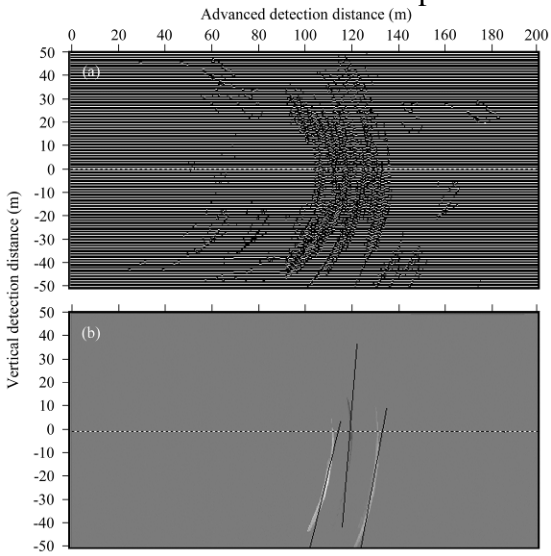

Fig.3 Advanced detection results

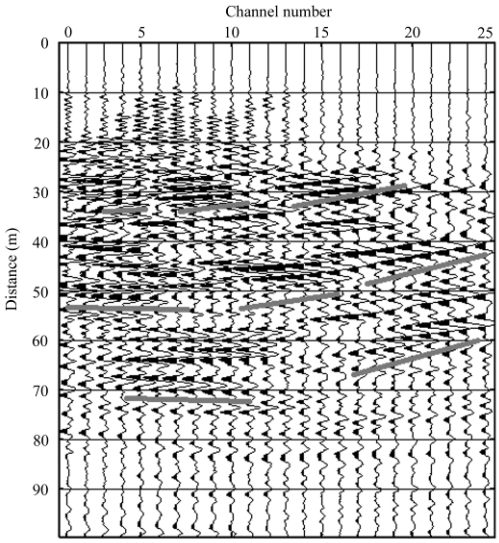

Fig.4 Side detection results

After mine seismic data processing we have results of Figures 3 and Figures 4, where Figure 3 (a) shows migration profile of mine advance, and Figure 3 (b) shows extracted amplitude anomalies interface. The horizontal-axis of Figure 3 represents the distance in the advance direction, the zero point means the geophone position, and the vertical axis represents the distance from the geophone to the top and the bottom plate in the vertical direction. During interpretation, position of the zero point will be moved to the shod head. There exists strong impedance area about40m-60m in front of shod head, with a very large impact scope and a chaos wave field. Figure (b) illustrates that 3 extracted high-amplitude interfaces can be observed, which shows the alternating impedance polarity from negative to positive and back to negative. Through geological analysis, a preliminary predict is made that the anomaly is a collapse column. Generally the column range will be smaller than the anomaly area, but here because the wave field collapse column is more complex and multiple waves are easy to generate, the anomaly range images larger. Figure 4 shows the result of mine side. By migration profile analysis, a strong wave impedance exists in the south mine side between 30m-70m within the detection area, but the continuity of the events is poor , so these anomalies are unlikely to be indicated as faults.

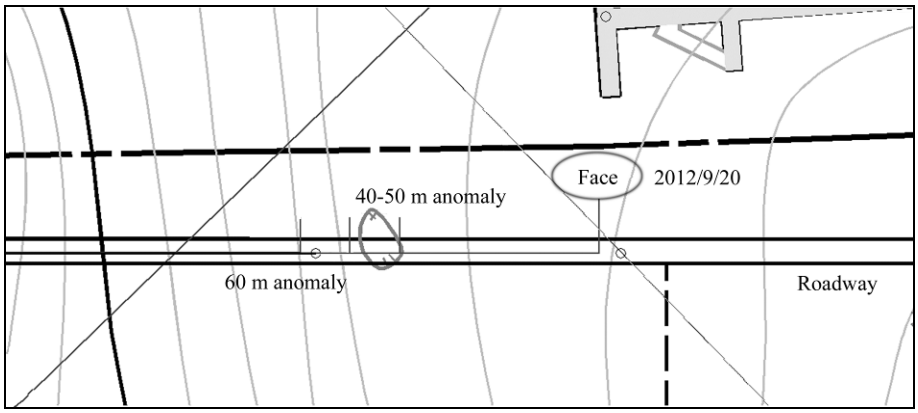

Fig.5 Geological plan

Verified excavation is done and shown in Figure 5. The marked the position of Face shows where the face of the roadway. A small flat oval-shaped collapse column is found at 38m-46m, which composed of limestone from the collapsed roof, well cemented and no water conductivity phenomenon. And it is the reason why the impedance is large and mutiple extist. Verified drilling in Southern side indicate a certain degree of fragmentation in 30m-60m range in coal formation, so the results match our prediction.

## Conclusions

Based on previous studies conducted on the mine seismic applied research, the following conclusions are made: The high resolution, strong anti-interference ability, highly targeted and reliable results of seismic mine detection do have some advantages on predicting fall columns and other geological anomalies in mine exploration. We did pioneer study on simultaneous detection of mine advance and side, by using Radon transform. We separated the seismic wave field of advance and side, and image the two at the same time through pre-stack time migration. The detection of mine advance mainly uses the experience of tunnel advance detection for reference, so there is a solid theoretical basis. But for the detection of mine side there are few studies. The small detection area and shallow detection depth are the focuses of improving direction.

# Study on the Anti-seismic Performance of New Swing Structure System based on PUSHOVER

Liu Di[1, a]

[1] College of Architecture and Civil Engineering，Shangqiu Normal University，Shangqiu Henan 476000，China

[a]Liudi@sqnc.edu.cn

**Keywords:** Swing Structure System, Pushover, Opensees

**Abstract.** Swing structure is added to the current frame structure for forming the new swing structure system. In this paper, by taking the existing structure as an example, the anti-seismic performance of the new swing system is analyzed with pushover method and the current earthquake resistant design code, and influence of swing rigid frame with different stiffness ratios on the anti-seismic performance of the new structural system is discussed. According to the results, by setting swing rigid frame with different stiffness ratios, it can enhance the bearing capacity and ductility of the structural system remarkably, coordinate the deformation model of the structural system, give full play to the energy-dissipating capacity of the structure, and improve the anti-seismic performance of the structure.

## Introduction

During major disaster, the architectural structure should not only protect people's lives and properties, and some facilities, such as hospitals, fire control and communication command center, etc. should also be responsible for the rescue after disaster and recover the production. However, according to the statistical analysis of previous disasters, it is not difficult to discover that the destruction of construction structure usually exceeds the expected design target. Therefore, for a long time, mangy new structural systems, such as energy dissipation structural system, isolated structural system, recoverable functional structure system, etc. have been proposed successively on the basis of several traditional structural systems by domestic and foreign engineering technologist and scientific researchers. The basic thought is to enhance the safety degree of the agricultural system, to alleviate the damage to the main body of the structural element during the disaster, so as to avoid the severe damage and collapse of the architecture.

In this paper, new swing structural system design is proposed on the basis of previous studies. According to the current code for seismic design of building, the anti-seismic performance level of new swing structure system is discussed with PUSHOVER method, aiming to draw related conclusions for providing references for the judgment of post-seismic injury degree of the related new structural system, which will provide greater selection space for the decision makers and designer of engineering construction.

## Calculation model

According to the statistics of current earthquake damage, during the earthquake process, plastic hinge may occur easily in the top and bottom of the column in frame structural system, which may give rise to the destruction of weak story. Meanwhile, damages to the rest layers are within the expected range. Therefore, the new swing structural system design proposed in this paper is an auxiliary structure attached to the traditional structure system by taking the light strong steel or concrete filled steel tube as the main anti-seismic component of the structural system, and swing structural system is formed. In this paper, an existing reinforced concrete frame structure is redesigned on the basis of the original residential building with general structural design software

PKPM, according to the *Code for Design of Concrete Structures a*nd *Code for Seismic Design of Building*.

The residential building is a six-floor reinforced concrete frame structure. The first floor is a parking lot, with no filler walls, while the above floors are residences, with horizontal and longitudinal filler walls. Considering the influence of filler walls, the rigidity of the bottom layer is remarkably smaller than the upper floors. The earthquake fortification intensity of the building is 8, falling into the second group of Level II, the characteristic site period is Tg=0.4s, the story height is 3.0m, and the floor is 120mm in thickness. The overall effect of PKPM finite element model is shown in figure1. The dead load of the floor in the model is 5.0kN/m$^2$, the live load is 2.0kN/m$^2$, and the combination coefficient is 0.5. The strength grade of concrete is C30, and that of non-structural component if C25, the longitudinal bar is HRB335, the stirrup is HPB235, the transverse reinforcement and the tendon is HPB235.

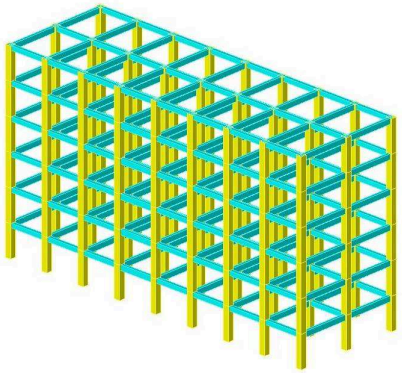

Fig. 1 PKPM Finite Element Model

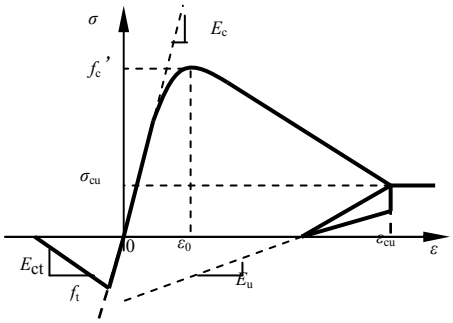

Fig. 2 Uniaxial Material Concrete 02

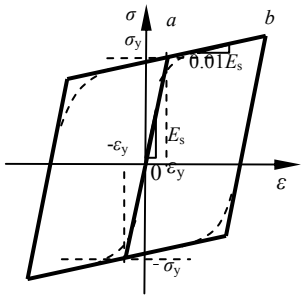

Fig. 3 Uniaxial Material Steel 02

The beam column of the reinforced concrete frame, as well as the beam column and support of the swing rigid frame is simulated with nonlinear Beam Column fiber unit, while the constitutive relation model is the uniaxial material concrete 02 of OpenSees, and the constitutive relation model is shown in figure 2. The constitutive relation model of the steel tube employed by the rebar and concrete filled steel tube is the uniaxial material steel 02 in OpenSees, and the constitutive relation model is shown in figure 3.

In this paper, the finite element method model of the reinforced concrete frame structure and light swing structure system is constructed respectively with the finite element software of Opensees. The finite element model is named as RC and modeli respectively, as shown in table 1.

Table 1 The Finite Element Model

| Stiffness ratio | 0.0100 | 0.1000 | 0.2500 | 0.5000 | 0.7500 | 1.0000 |
|---|---|---|---|---|---|---|
| Swing structure system | M1 | M2 | M3 | M4 | M5 | M6 |

**Model loading plan**

In this paper, the static elastic-plastic analysis of the self-adaption model is realized with Tcl/Tk based on the OpenSees calculation procedure. According to the loading of horizontal yawing force based on the displacement control, the side force is updated every five steps. The horizontal displacement increment takes the 0.02% structural height. Meanwhile, the P-Δ second-order effect is considered, but the interaction with the power of the structure is not considered.

**Selection of performance index**

Before the pushover analysis of static power based on displacement, the performance objective of the light swing structure system is determined according to the current earthquake resistant design code. The earthquake resistant design code of year 2010 takes the control objective of the interlayer

displacement angle under different collapse states aiming at the vertical component, and the maximum inter-layer displacement angle control objective under different collapse states corresponding to the reinforced concrete frame structure is taken as the basis of performance point selection.

According to the related requirements of the engineering practice and current seismic design of buildings in China, the performance objective of the light swing structural system is selected on the basis of the original frame structure, for further improving and guaranteeing the anti-seismic performance of the structure, namely it will not be destructed severely at 8.5 degree and collapse at 9 degree.

**Pushover result analysis**

According to the previous calculation method, the top displacement-base shear curve of the structural model can be achieved, as shown in figure 4.

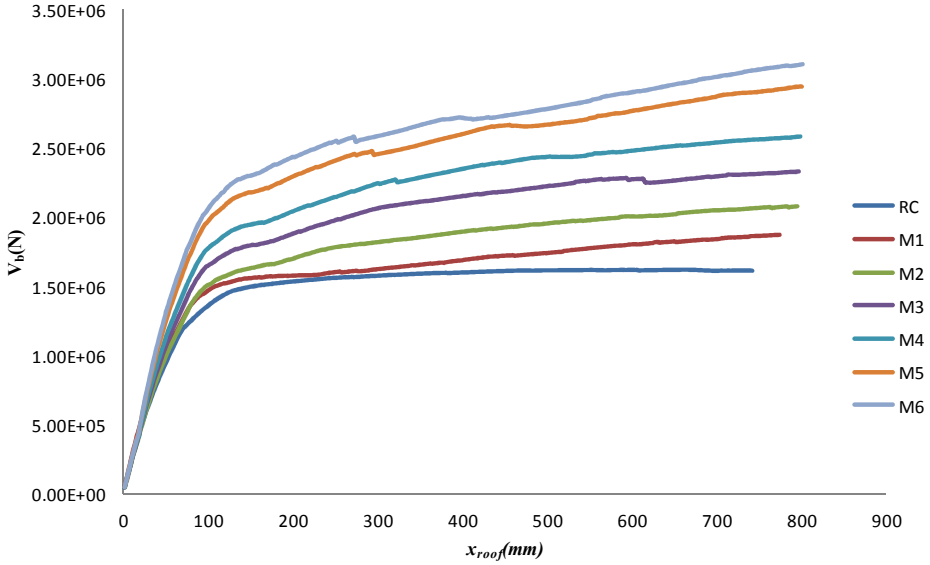

Fig. 4 The top displacement-base shear curve

After the pushover curve of each structural system is obtained, according to equation 1-2, it can be transformed as Sa-Sd curve, namely the relation curve of the spectral acceleration and spectral displacement.

$$S_a = \frac{V_b}{aW} \tag{1}$$

$$S_d = \frac{x_{roof}}{\Gamma \phi^{roof}} \tag{2}$$

According to equation 3, as well as the current anti-seismic code, the demand spectrum curve is established, and the two shall be combined for iteration, thus to achieve the performance point. According to the index of the performance point, if it reaches the anti-seismic performance objective can be achieved can be estimated.

$$S_d = \frac{T^2}{4\pi^2} S_a \tag{3}$$

The power spectrum and demand spectrum curve in A-D coordinate of the frame structure is shown in figure 5.

The earthquake demand spectrum of the reinforced concrete structure intersects as at 7 and 8 degree, and according to the performance point, it can be worked out that the spectrum displacement is 0.05019m, the equivalent damping ratio is 14.756%, and at this moment, it has already entered the plastic stage. At 8 degree, the spectrum displacement is 0.1082m, and the equivalent damping ratio is

21.409%. The maximum inter-layer displacement angle of the bottom at 7 degree is 1/188, and it is 1/52 at 8 degree.

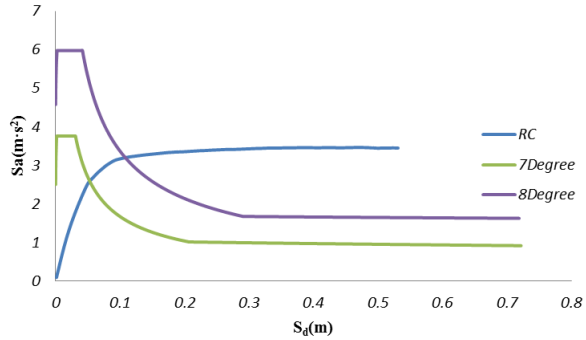

Fig. 5 The top displacement-base shear curve of RC

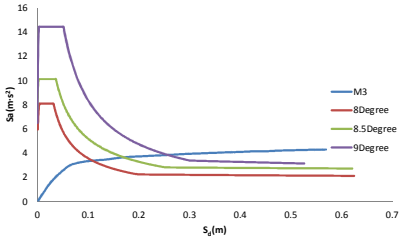

Fig. 6 The top displacement-base shear curve of M3 mode

After the pushover analysis of static force is conducted for M1-M6, it can be discovered that M3 has already reached the requirement of anti-seismic performance objective. The power spectrum and demand spectrum curve of M3 model in A-D coordinate is shown in figure 6. The earthquake demand spectrum of the light swing rigid structure system intersects as at 8, 8.5 and 9 degree. According to the performance point, it can be calculated at the spectrum displacement is 0.1178m, and the equivalent damping ratio is 24.559%. At this moment, it has already entered the plastic structure. At 8.5 degree, the spectrum displacement is 0.1737m, and the equivalent damping ratio is 28.829%. At 9.5 degree, the spectrum displacement is 0.2864m, and the equivalent damping ratio is 34.935%. The maximum inter-layer displacement angle of the bottom layer is 1/226 at 8 degree, 1/98 at 8.5 degree and 1/57 at 9 degree.

## Conclusion

It is not difficult to discover after the analysis of computing result based on the elastic-plastic pushover analysis that:

(1). The overall bearing capacity and ductility of the swing rigidity structure is better than that of the reinforced concrete frame structure.

(2). In major earthquake, more structural components of the swing rigid frame shall participate in the overall anti-seismic work of the structure, and more component may enter the plastic stage, which may result in the remarkable increase of damping ratio.

(3) The performance objective shall be selected rationally, and according to the performance objective, the parameters of the structural system shall be selected, for it can not only improve the anti-seismic performance of the structural system, but also consider the cost control and design requirements.

**Keywords:** traditional dwellings; Zhuangke; field research; seismic issues

**Abstract.** Qinghai is a multi-ethnic region, mainly living in the eastern agricultural areas Han, Hui and Tu, mainly living in the southwest area of animal husbandry Tibetan and Mongol. In order to adapt to the cold, arid, windy and long sunshine time climate of Qinghai, people created a unique style of traditional vernacular dwelling, Zhuangke. This unique architectural form is mainly with wooden frame bearing, matching with brick walls or rammed earth walls. Such buildings are mostly villagers themselves built according to past experience; do not involve seismic design, resulting in a great security risk. Through the field investigation of ten natural villages, this article has a deep understanding of the seismic performance of Zhuangke. Based on survey data, this paper presents its structural safety and seismic performance problem.

## Introduction

Qinghai is a multi-ethnic region, the province with an average elevation of 3,000 meters, is a typical plateau continental climate, with dry, little rain, windy, alpine-cold and long sunshine time, etc. Qinghai inhabited by the Han, Hui, Tu and Salar ethnic groups. Traditional dwellings in Qinghai are affected by geographical position and local customs, and become a unique form of local-style dwellings, Zhuangke.

Zhuangke is the basic form of Han, Tu, Hui and Salar's local-style dwelling houses. It is a load-bearing wood frame construction. Combined with the national characteristics, Zhuangke made different decorative timber frame, as shown in Fig. 1. The main enclosure walls are rammed earth walls, adobe walls and brick walls (Fig. 2).

The research of Qinghai Zhuangke has begun in the 1970s. Most of the current studies are to explore the adaptability to natural environment from residential function, courtyard layout and construction technology, and do not involve the study of seismic performance. The ten natural villages for research involves Han, soil, back and Sala, including Huzhu County, Xunhua County and Ledu County. Through the field investigation of traditional dwellings for the three main ethnic in Qinghai, this article has a deep understanding of the seismic performance of Zhuangke. Based on survey data, this paper presents its structural safety and seismic performance problem. Detailed analysis of each question is as follows.

## Research Analysis

Through the analysis of field research found that currently there are the following seismic weaknesses of Zhuangke: the lack of connection measures for enclosure walls and roof trusses, the shallow embedment of column base, inadequate connections for columns and walls, without overlapping measures in vertical and horizontal wall junction, the big stiffness differences of walls and timber frame. Detailed analysis of each question is as follows.

Fig. 1 The national decoration of Zhuangke

(a) Traditional Zhuangke (b) Newly-built Zhuangke

Fig. 2 The different structure form of traditional and newly-built Zhuangke

**The lack of connection measures for enclosure walls and roof trusses.** There is no connection between roof and wall body, and nor between purlin and gable (Fig.3).The mechanical properties of wood components and walls are much different, and there is no valid connection between the two. In the earthquake, the two can't keep working together, leading to the knot in vertical and horizontal wall cracking and making wall into a monolithic wall. Due to the lack of effective connection between gables and purlins, gables are prone to out-of-plane instability. So the probability of gables' collapse is higher than the vertical wall.

Fig. 3 The connection measures for enclosure walls and roof trusses

**The shallow embedment of column base.** The survey finds poles mainly are placed directly on the base block, as shown in Fig. 4. Under earthquake, horizontal seismic action can only be transferred by friction of column's end face. This force's transfer road is easy to cause column foot sliding, even lead to column foot slipped from base blocks, and finally cause the timber frame collapsed.

Fig. 4 The embedment of column base

**Inadequate connections for columns and walls.** Some of Zhuangke's pillars are all wrapped by the wall, some are partly wrapped, and others separate from the wall (Fig. 5). It is obvious that there is no reliable connection between retaining walls and pillars, so under the earthquake action, the damage of walls would occur before the timber frame. Between a timber frame beams are usually joggle, so their joints' stiffness and strength are low. After the destruction of the wall, the building will lost the main component to resist lateral force. In the larger horizontal earthquake, the mortise-tenon joints start loosening, and then the building will appear lateral deformation in the direction of the weaker stiffness. When the lateral deformation is much larger, the whole structure will collapse.

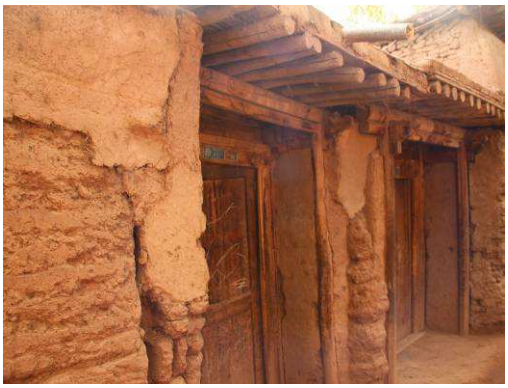
(a) pillars are all wrapped (b) pillars are partly wrapped (c) pillars separate from the wall

Fig. 5 The relationship between the pillar and wall

**Without overlapping measures in vertical and horizontal wall junction.** The junctions of vertical and horizontal walls are rickety, which is prone to produce vertical cracks. Because of the lack of connection measures, the junction of gable walls and back walls will crack and damage. Especially when pillars are wrapped by walls (Fig.6), due to the pillars weaken the cross section of the wall, the walls' integrity decreases.

**The big stiffness differences of walls and timber frame.** The greater weight of the wall, its deformation is lower. The larger stiffness difference between the wall and the wooden skeleton makes the wall easily to collapse in the earthquake. Rammed earth walls are more likely to be collapsed in the earthquake, and the damage of brick walls is not serious. And the construction process of adobe walls and rammed earth walls are labor-intensive and time-consuming. Due to rainfall, walls would severe damaged (Fig. 6) and need regular repair. So the villagers prefer to use brick walls as enclosure walls. So in economically developed areas, new-built Zhuangkes mainly

use brick walls instead of rammed earth walls and adobe walls, which were widespread used. Although walls' material improved, but the block walls mainly do not take necessary seismic measures.



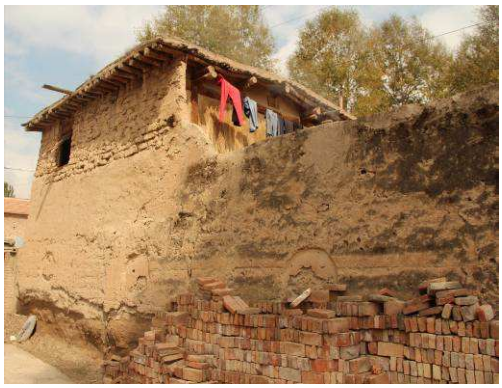


Fig. 6 The damage of walls

## Conclusions

In order to adapt to the cold, arid, windy and long sunshine time climate of Qinghai, people created a unique style of traditional vernacular dwelling, Zhuangke. Such buildings are mostly villagers themselves built according to past experience; do not involve seismic design, resulting in a great security risk. There are many seismic performance problems and seriously affect the structural safety. How to solve the questions, to improve the seismic performance and structural safety of Zhuangke is the main direction of the future research. Only by improving the seismic performance of Zhuangke, enhance the safety of traditional houses in Qinghai, and promote the long-term inheritance of the national characteristics.

**Keywords:** Uncertainty correction; Ground motion; Attenuation; PSHA

**Abstract**. The uncertainty of ground motion attenuation and its correction in PSHA is deal with in this paper. Mean values and standard deviations of random errors of three attenuation relationships of NGA-west1 are analyzed statistically from the data base released by the project. The dependences of the mean and deviation on magnitude, distance and peak ground acceleration are checked by the data base. The fact of mean values varying with acceleration is revealed obviously. Ground motion parameter Y is adopted into the probability density function of random error in a form of subsection. Finally, a suggestion to improve the correction is presented as subsection correction in the paper. The result of a case study by suggested procedure shows that the corrected acceleration is slightly higher than that of the traditional correction at the start of hazard curve, and is significantly lower than that of the traditional correction at the end of the curve, if the mean of random error decreases with acceleration.

## Introduction

Due to the lack of the seismic and geological data and poor understanding of effect of focal mechanism, seismic wave transmission and the local site conditions on PSHA, there must be a lot of uncertainty in the result, in which the uncertainty of attenuation relationship is dominant. Corresponding correction naturally become an issue for people, and the large increase of risk in low probability has been controversial.

Probabilistic seismic hazard assessment, PSHA was founded more than forty years ago, and have been adopted in seismic hazard assessment world wide [1, 2], while it was queried on and off. The uncertainty process is one of the most focuses in the debates. Some researchers pointed out that overestimation happened in some PSHA projects come from unreasonable correction of uncertainty of ground motion attenuation [3-5]. Esteva revealed the fact that the distribution of the random error of motion attenuation was accord with Normal distribution, and developed a correction procedure. He mentioned that variation of the random error was obvious, so that to take into account the error in PSHA is especially important [6]. Ang and Der Kiureghian suggested a procedure to combine the uncertainty of the attenuation into inherent uncertainty of ground motion by means of total probability formula, after seismic hazard estimated from a mean attenuation relationship [7]. It is called as ‘correction’ now, and its rationality is queried since there are often some large increases on the corrected hazard especially at very low exceeding probability range.

As part work of an ongoing project of basic issues in seismic hazard assessment (51178151) supported by NSFC, the improvement of uncertainty correction have been deal with. This paper presents just a preliminary result.

**Ground motion attenuation relation and its uncertainty**

Attenuation relation predicts a ground motion parameter for given magnitude and distance with simplification on source mechanism, wave propagation and local site condition. Survey and analysis in several decades show the fact that there is always a quite large variation in ground motion, even if from similar magnitude, depth, distance and site condition, for whatever which motion parameter [8, 9]. In general, attenuation relationship of ground motion could be represented as following formula

$$\ln Y = f(M, R) + \varepsilon \tag{1}$$

where $Y$ is for motion parameter, e. g. peak ground acceleration; $M$ for magnitude, $R$ distance, f for a function form, $\varepsilon$ is for the difference between $\ln Y$ and $f(M, R)$, called as random error above. From the fitting principle, $\varepsilon$ must have a Normal distribution with 0 mean, i.e. the standard deviation $\sigma$ is the only numerical character. It is not hopeful to attempt reduce the $\sigma$ obviously by means of adding any more variable, or expending data base from accumulated observing data. The following figure shows that clearly [10].

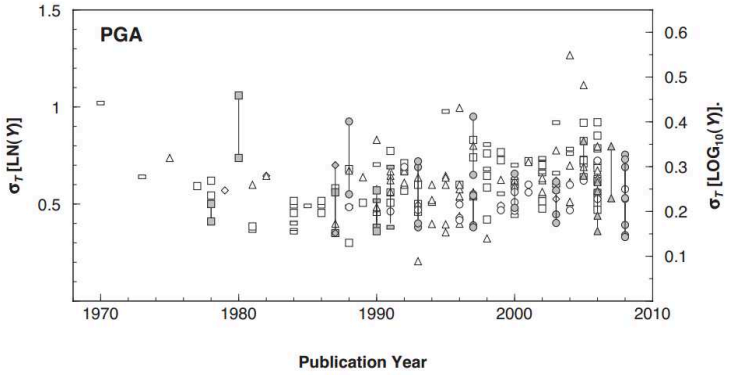

Figure 1 The variation of $\sigma$ with publication year

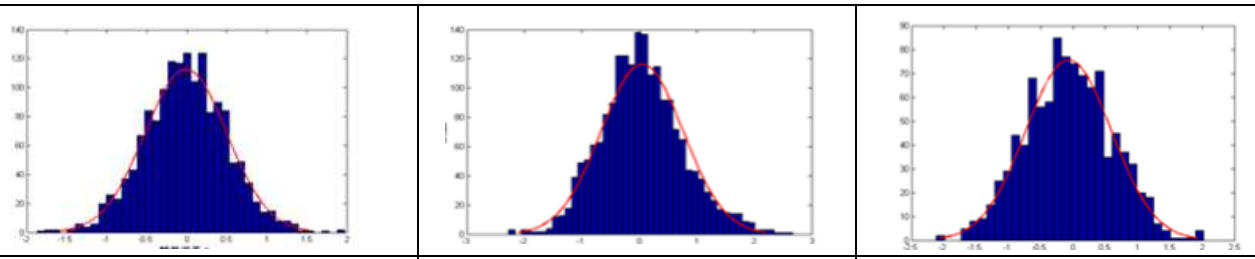
It is obvious that $\sigma$ represents the inherent randomness, error from simplification, and validity of the function form $f$, the latter could be considered as result of ignorance on attenuation [11].

NGA project released a good data base of ground motion, and worked out three attenuation relationships with $\sigma$ values of acceleration 0.52, 0.72 and 0.67. The corresponding distributions are shown in Fig. 2, where C-B is for Campell-Bozorgnia [12], C-Y for Chiou-Youngs [13] and Id for Idriss [14].



| C-B relation | C-Y relation | Id relation |
|---|---|---|

Figure 2 Histograms and the corresponding Normal distribution curves

The mean and $\sigma$ of $\varepsilon$ of the three relations in total and in three magnitude groups, are listed in table 1. In the table, there are three values in each grid separated by '/' respectively for C-B (left), C-Y (middle) and Id (right).

Table 1 The numerical characters of $\varepsilon$ of the three relations in magnitude groups

| Magnitude | Number of data | Percentage (%) | Mean | $\sigma$ |
|---|---|---|---|---|
| [4.5, 5.5) | 264/369/90 | 17/19/9.1 | -0.068/0.073/0.354 | 0.623/0.726/0.742 |
| [5.5, 6.5) | 349/995/603 | 22.5/51.3/61.1 | -0.103/0.064/-0.062 | 0.502/0.632/0.634 |
| [6.5, 8.0) | 938/576/294 | 60.5/29.7/29.8 | 0.037/-0.193/-0.210 | 0.481/0.566/0.645 |
| In total | 1551/1940/987 | 100 | -0.012/0.048/-0.067 | 0.516/0.715/0.666 |

The same values in four distance groups are listed in table 2, where * is for no data in that group.

Table 2 The numerical characters of $\varepsilon$ of the three relations in distance groups

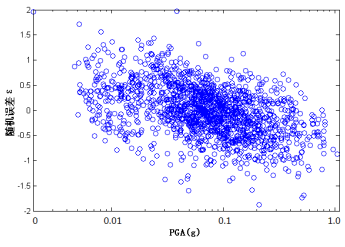
| Distance (km) | Number of data | Percentage (%) | Mean | $\sigma$ |
|---|---|---|---|---|
| (0, 10] | 115/157/55 | 7.4/8.1/5.6 | 0.056/-0.074/-0.147 | 0.474/0.716/0.708 |
| (10, 50] | 680/1182/329 | 43.8/60.9/33.3 | -0.030/0.099/-0.018 | 0.543/0.715/0.664 |
| (50, 100] | 500/601/409 | 32.2/31.0/41.4 | -0.013/-0.021/-0.093 | 0.498/0.710/0.667 |
| (100, 200) | 256/*/174 | 16.6/*/17.6 | 0.008/*/-0.072 | 0.492/*/0.646 |
| In total | 1551/1940/987 | 100 | -0.012/0.048/-0.067 | 0.516/0.715/0.666 |

The same values in three acceleration groups are listed in table 3.

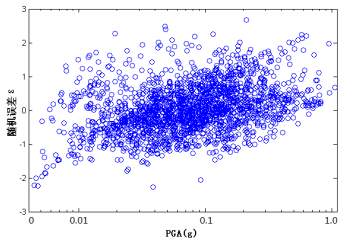
Table 3 The numerical characters of $\varepsilon$ of the three relations in acceleration groups

| Acceleration (g) | Number of data | Percentage (%) | Mean | $\sigma$ |
|---|---|---|---|---|
| (0.02, 0.1] | 971/1166/800 | 63/60.1/79.7 | 0.139/-0.132/-0.160 | 0.496/0.682/0.620 |
| (0.1, 0.4] | 500/673/171 | 32/34.7/17 | -0.233/0.280/0.237 | 0.457/0.673/0.729 |
| (0.4, -) | 80/101/33 | 5/5.2/3.3 | -0.474/0.584/0.596 | 0.435/0.646/0.525 |
| In total | 1551/1940/987 | 100 | -0.012/0.048/-0.067 | 0.516/0.715/0.666 |

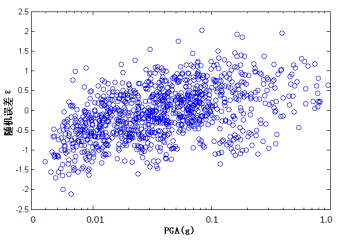
From the tables, one can find that the numerical characters do not vary with magnitude and distance obviously, or no clear trend of variation with magnitude and/or distance, but the absolute value of mean decreases with acceleration very clearly while $\sigma$ is quite stable. This trend is clearer in Fig. 3.



C-B



C-Y



Id

Figure 3 The distribution of $\varepsilon$ with acceleration

An improvement to distribution of random error is suggested from the above findings as Normal distribution with same $\sigma$ and subsection mean, $f_y(\varepsilon)$. To define the $f_y(\varepsilon)$ in subsections from situation that a continuous function of the mean on acceleration can not be developed from the limited data at present

**Subsection correction of uncertainty of ground motion attenuation in PSHA**

From the total probability theorem, the correction formula with $f_y(\varepsilon)$ could be expressed as

$$P(Y_c > y) = \int_{-3\sigma}^{3\sigma} P(Y > ye^{-\varepsilon}) f_y(\varepsilon) d\varepsilon \tag{2}$$

where $Y_C$ is for the corrected ground motion parameter, e. g. acceleration; $Y$ is for the uncorrected one; $f_y(\varepsilon)$ the probability density function of $\varepsilon$ with a stable $\sigma$ and different means in some acceleration subsections.

For a given acceleration y, in the $i^{th}$ subsection among $(y_0, y_1], (y_1, y_2]\ldots\ldots(y_{n-1}, y_n]$, the correction formula could rewritten in detail as

$$\mathrm{P}(Y_C > y) = \int_{\mu_i-3\sigma}^{\mu_i+3\sigma} P(Y > ye^{-\varepsilon}) f(\varepsilon) d\varepsilon \tag{3}$$

where $\mu_i$ is the mean of $\varepsilon$ in the $i^{th}$ subsection.

For the purpose to get a set of more even subsections with their own detail mean, a statistics of in four acceleration groups are again worked out. The result from data without those with small acceleration is listed in table 4. The resulted hazard curves as an example are shown in Fig. 4.

Table 4 The mean values of $\varepsilon$ of C-B relation in four acceleration groups

| Acceleration (g) | Number of data | Percentage (%) | Mean | $\sigma$ |
|---|---|---|---|---|
| (0.01, 0.05] | 388 | 29.7 | 0.135 | 0.468 |
| (0.05, 0.1] | 442 | 33.8 | -0.006 | 0.390 |
| (0.1, 0.2] | 276 | 21.1 | -0.120 | 0.438 |
| (0.2, 1.0) | 201 | 15.4 | -0.231 | 0.442 |
| In total | 1307 | 100 | -0.027 | 0.452 |

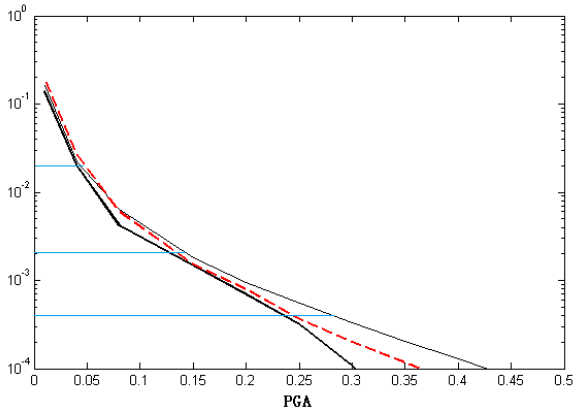


Figure 4 The hazard curves for an engineering site

One can see from the figure that the acceleration for a given exceeding probability by subsection correction is smaller than that by correction with mean 0, especially for the low exceeding probability.

## Conclusion

In order to improve the representation of random error of ground motion attenuation, three NGA-west1 relations are checked and analyzed statistically by their own data bases. The result shows that the error distributions are Normal with stable standard deviation and a varied mean. It is true but not sure for all attenuation relationship published up to know. To take the findings into account, a subsection probability density function is suggested in this paper, and a subsection correction of the uncertainty of attenuation relation in seismic hazard assessment is also presented. Result of a case study shows that hazard curve by subsection correction is lower than that by correction with mean 0, i. e. the acceleration for a low given exceeding probability by subsection correction is obviously smaller than that by correction with mean 0.

The NGA-west 2 data base was released in 2012, and then the attenuation from those data would published soon, therefore the contribution of the paper is just a preliminary suggestion, but is really interested.

# Average Damage Ratio and Earthquake Damage Matrix of Non- engineered Building in Seismogenic Provincial Regions in China

XING Juehui, LU Ming[a], ZHAO Yamin, YU Yan

[1]Institute of Crustal Dynamics, China Earthquake adminstration, Beijing100085,China

[a] luming6@yeah.net

**Keywords:** non-engineered building; seismic damage assessment; damage ratio; average damage ratio; earthquake damage matrix

**Abstract.** Non-engineered buildings are most of self-built house, which locate in rural area in China. The structural defect of non-engineered buildings could reduce seismic capacity. The damage of these buildings are the main cause of earthquakes casualties and economic losses. The main types of the building structures include the wooden house, soil and wood house, brick and wood house and masonry house. It is the seismogenic provincial regions for Xinjiang, Qinghai, Gansu and Yunnan in China. Based on the four type houses in the four regions, 104 earthquake disaster loss reports were selected from 1990 and 2013. This article focused on the analysis of house damage data. This article proposes "the average damage ratio" concept, which takes one provincial region as an area and studies the whole area data. Due to a combination of multiple and differenteffects of earthquakes within one provincial region, the average damage ratio can be on behalf of the damage ratio, and reflects the non-engineered building characteristics in the provincial region. And then the article demonstrates that the earthquake damage matrix of different house types in these four provinces area. The earthquake damage matrix provides a more reliable basis for the earthquake disaster evaluation in rural area.

## Introduction

Non-engineered buildings are not only informally designed and constructed, but also have much structural defect and high vulnerability. China should face and admit the facts that non-engineered buildings are widely used in the country, and the largest engineering group leading to huge losses and casualties in earthquakes. Most of the earthquakes and heavy disasters occurred in the western region in China, such as Xinjiang, Qinghai, Gansu, Yunnan and Sichuan. It is necessary to carry out seismic capacity study of non-engineered buildings in these regions.

The non-engineered buildings in China are mainly located in rural areas, and mainly self-built house. Because the national area is vast and the natural and the humanistic environments are much different, these same type houses have much different in various regions. The seismic damage ratio of buildings is the most direct performance of the quantitative seismic capacity. It is the basic work of the closest to the actual to research on the damage ratio of different types of buildings from earthquake survey data.

## Earthquake Survey Method and Data Sources

### *Site Survey Methods*

It has been more than 20 years for the earthquake disaster assessment to step into the scientific and standardized track in China. The earthquake disaster assessment explores in Datong-Yanggao earthquake in 1989. The first regulation of the earthquake damage assessment enacted in 1993. The earthquake damage assessment officially started as a responsibility of national and provincial earthquake administration bureaus since 1993. The assessment method in practical work continuously improved and refined. The earthquake damage assessment method has already become national standard since 2005[1].

Building damage survey is the core of China's earthquake disaster assessment. The site assessment method is summarized as follows:

a. Sample survey methods including restrictions regulations of survey path and sampling rate.
b. Identify structure type.
c. Assessment on the level of damage and construction area statistic.
c. Comprehensive assessment and classification of intensity area.
d. Calculation of various types of house and different levels of the damage ratio for each seismic intensity.
e. Calculate the total loss of all types of house by using the unit house area cost, different levels of damage loss ratio and the damage ratio of buildings.

The damage ratio just reflects house damage only one earthquake, because the damage ratio obtained from one seismic event. It can be analyze the seismic capacity of the houses in the affected areas.

In summary, the damage ratio of buildings contains four key elements, which are as house types and destruction grades, specific earthquake and its intensity area.

However, to understand the house seismic capacity and to establish the damage matrix in a greater area, the more information of the damage assessment data need to obtain, and more analysis need to finish.

*House Damage Data Sources*

This paper analyzes the house damage data of the 188 earthquake damage assessment reports from 1990 to 2013. Ultimately selected data are from the available, more reliable 104 reports, which earthquake events are shown in the Table1 to Table2.

**Table1 Xinjiang Earthquake Directory**

| Time | Place | Magnitude | Time | Place | Magni-tude | Time | Place | Magni-tude |
|---|---|---|---|---|---|---|---|---|
| 1993.12.1 | Kashen | 6.0 | 1998.6.25 | North of Akesu | 5.2 | 2003.2.24 | Bachu-Jiashi | 6.8 |

## Non-engineered Building Types and Average Damage Ratio

*The Non-engineered Building Types*

According to the survey data, buildings can be divided into two categories, After earthquake-proof building and non-engineered building. The main types of the non-engineered buildings include wooden house, soil and wood house, brick and wood house and masonry house, shown in Table 5.

**Table 5 The non-engineered building types and code**

| | The non-engineered building types | code |
|---|---|---|
| 1 | wooden house | A1 |
| 2 | soil and wood house | A2 |
| 3 | brick and wood house | A3 |
| 4 | masonry house without seismic design | B |

The types and codes of each kind house consistent with The Chinese Seismic Intensity Scale[5].

*Average Damage Ratio*

Within an appropriate range of large area, the houses of the same type have no or a little change in the structure, the damage ratio of houses can be analyzed in quantitative combining multi-earthquake damage data. This article proposes " the average damage ratio " concept, which takes one provincial region as an area and studies the whole area data of under multiple and different earthquakes. Due to a combination of multiple effects of earthquakes within one provincial region, the average damage ratio can be on behalf of the damage ratio in the provincial region.

The average damage ratio is calculated as the Eq.1- Eq.2.

According to the The Chinese Seismic Intensity Scale [5], the damage ratio $\lambda_i$ is as follows,

$$\lambda_{ij} = A_j \Big/ S_j \tag{1}$$

$i$ --- damage level of house.

$j$ --- type of house structure.

$A$ --- the sum construction area of j type houses which damage level is i in a seismic intensity area.

$S$ --- the total construction area of j type houses in a seismic intensity area.

The calculation of average damage ratio considers damage ratio $\lambda_i$ of multi- earthquakes under one same seismic intensity area, $\overline{\lambda_i}$ is as follows,

$$\overline{\lambda_{ij}} = \frac{\sum_{k=1}^{n} \lambda_{ij}^{\ k}}{n}. \tag{2}$$

$i$ --- damage level of house.

$j$ --- type of house structure.

$k$ --- earthquake serial number.

$n$ --- earthquake occurrences for statistics.

$\overline{\lambda_i}$ --- average damage ratios under a certain damage level $i$.

$\lambda_i$ --- damage ratios under a certain damage level $i$.

*Average damage ratio of the 4 provincial regions*

According to the above definition, the average damage ratios are calculated for the various type house of non-engineered buildings. All of the data are from Xinjiang, Qinghai, Gansu and Yunnan in China. Fig.1-Fig.4 show that the average damage ratios of the same type house are much different in various provincial regions.

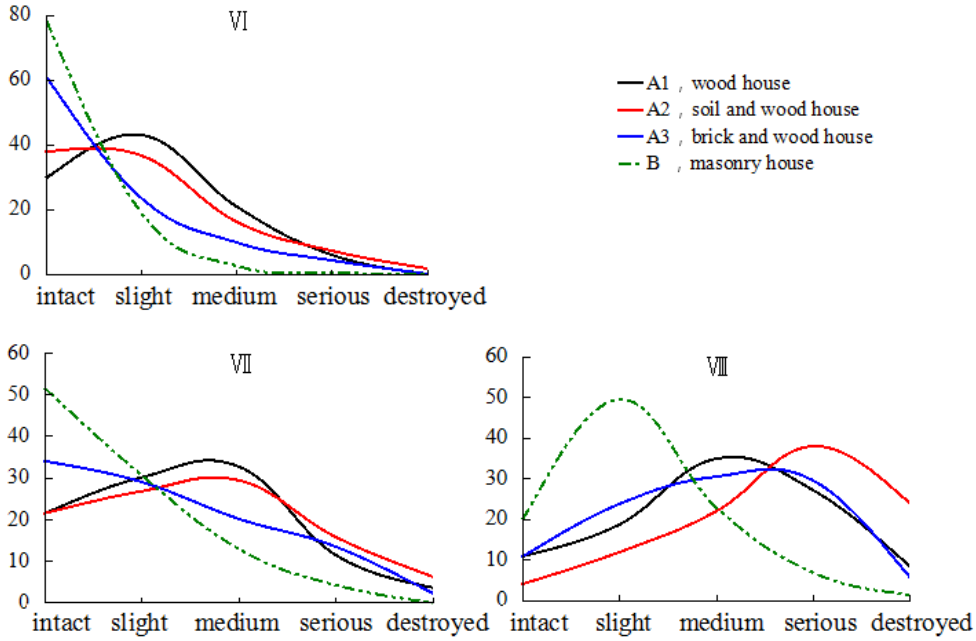

**Fig.1 Damage Ratio of House in Gansu**

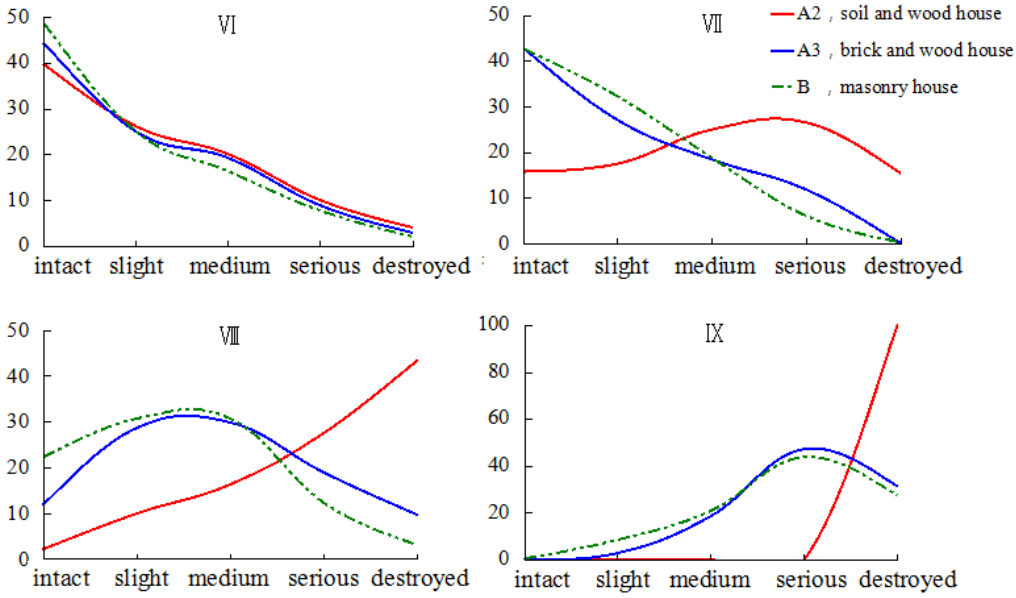

**Fig.2 Damage Ratio of House in Qinghai**

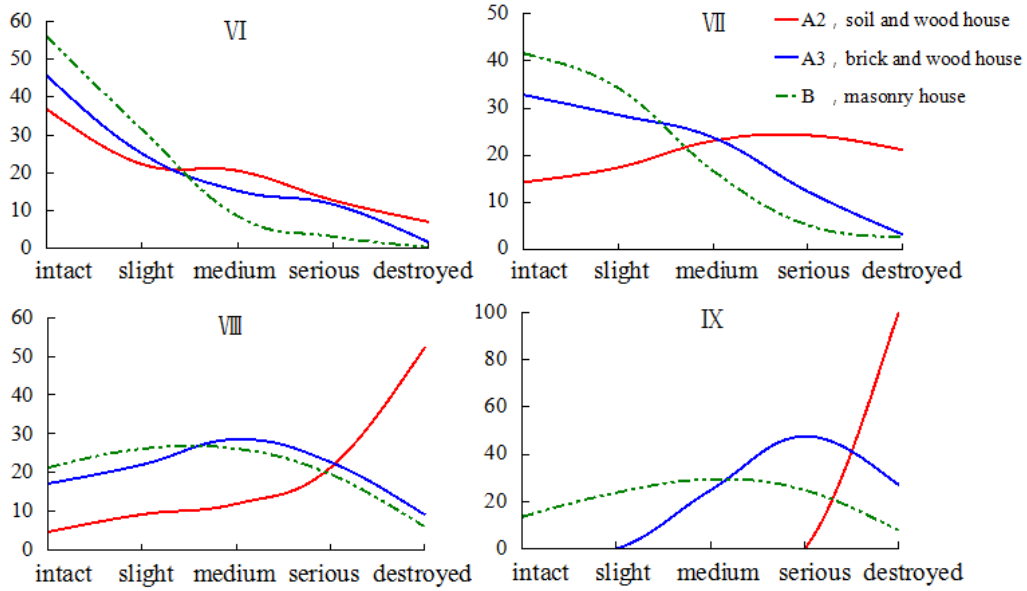

**Fig.3 Damage Ratio of House in Xinjiang**

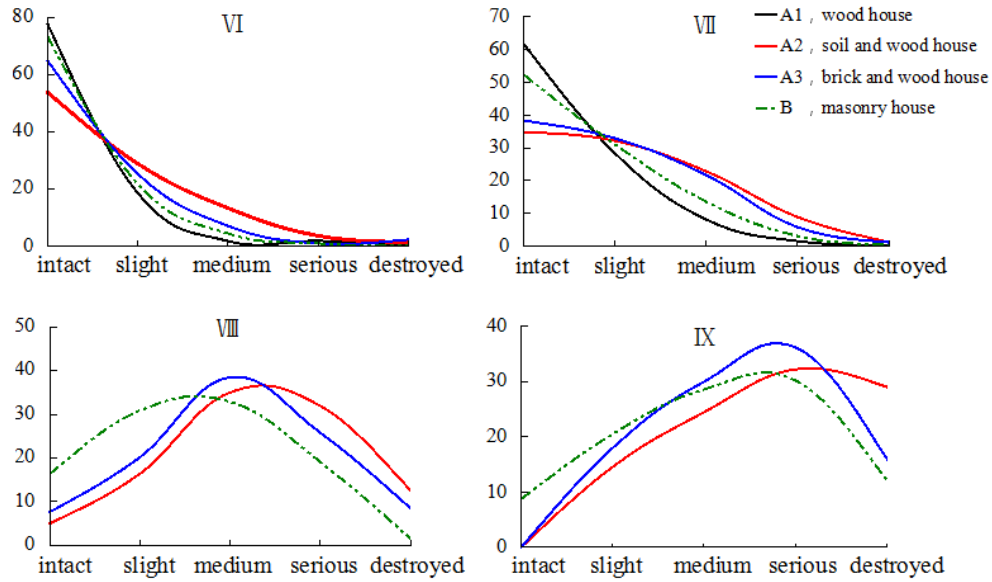

**Fig.4 Damage Ratio of House in Yunnan**

### Earthquake Damage Matrix of Non-engineered Building

The earthquake damage matrix can be obtained by analyzing a large number of building damage survey data of multi earthquakes. The matrix indicates the probabilities of different damage level of house under a seismic intensity.

Through earthquake damage matrix, it is objectively and reasonably to analyze the seismic capacity of various types of house, and evaluate or predict the extent of house damage.

According to the average damage ratio of the non-engineered buildings, earthquake damage matrix can be obtained, which reflects the house characteristics and the seismic capacity in Xinjiang, Qinghai, Gansu and Yunnan provincial region respectively, shown in Table 6-Table 9.

**Table 6 Xinjiang Earthquake Damage Matrix**

| housetype | damage / intensity | intact | slight | medium | serious | destroyed |
|---|---|---|---|---|---|---|
| soil and wood house | Ⅵ | 37.0 | 22.4 | 20.5 | 12.8 | 7.3 |
| | Ⅶ | 14.3 | 17.3 | 23.1 | 24.3 | 21.0 |

| | Ⅷ | 16.1 | 30.8 | 32.8 | 19.0 | 1.3 |
| | Ⅸ | 8.8 | 20.6 | 28.5 | 30.1 | 12.0 |

## Conclusions

The article studied non-engineered buildings in seismogenic provincial regions in China. What the features are that these buildings are not only informally designed and constructed, but also exist much structural defect and high vulnerability. Non-engineered buildings exist widely in China, and are the largest engineering group led to huge losses and casualties in earthquakes.

The damage data of the study are from 104 reports of earthquake damage assessment from the 1993 to 2013 in Xinjiang, Qinghai, Gansu and Yunnan in China.

This article proposes " the average damage ratio " concept, which takes one provincial region as an area and studies the data of earthquake damage assessments in the whole area. Due to a combination of different effects of earthquakes within one provincial region, the average damage ratio can be on behalf of the damage ratio in the provincial region. On the other hand, the damage ratio just reflects such house damage of only one earthquake.

The earthquake damage matrix indicates the probabilities of different damage degree of house under differential seismic intensity. The article gives respectively the earthquake damage matrixes of the non-engineered buildings in Xinjiang, Qinghai, Gansu and Yunnan of China, which provide a more reliable basis for the earthquake disaster evaluation in these rural areas.

**Keywords:** collapse-resistance measure; the bottom frame structure; earthquake; collapse model

**Abstract.** The bottom frame structure, with serious earthquake damage, occupies a large proportion in the houses collapsed in earthquakes. However, because it is economic and practical, it is still widely used. Based on the understanding of the seismic performance of bottom frame structure, this paper determines to study seismic measures of the bottom frame structure. The current seismic measures can be divided into two major categories: strengthening key components and avoiding key components, therefore this paper adopts the method of strengthening parts which are easy to collapse for reinforcement, under the premise of meeting the stiffness ratio between reasonable layers, adds wing wall to improve the capacity of resisting collapse of the structure and pinpoints the efficiency of adding wing wall in the capacity of resisting collapse through quantitative analysis. Although there are differences in the improvement of the capacity of resisting collapse under different seismic waves, adding wing walls reasonably can greatly improver the anti-collapse capacity of the structure..

## Introduction

The structural collapse is the main cause of casualties caused by the earthquake. In Wenchuan Earthquake, the collapse of houses with bottom frame structures is a common phenomenon, and in Beichuan County, the rate of this structural collapse has reached 80%. Houses with bottom frame structures are universal in middle-sized and small cities in the south of Yangtze River in China, according to rough statistics, there exist more than 20 million houses of this kind and more than 120 million residential population at the present in China. Researches on seismic measures of this structure for the improvement in the anti-collapse capacity of houses with this structure have been an urgent social need. (Fig. 1)

(a) (b)

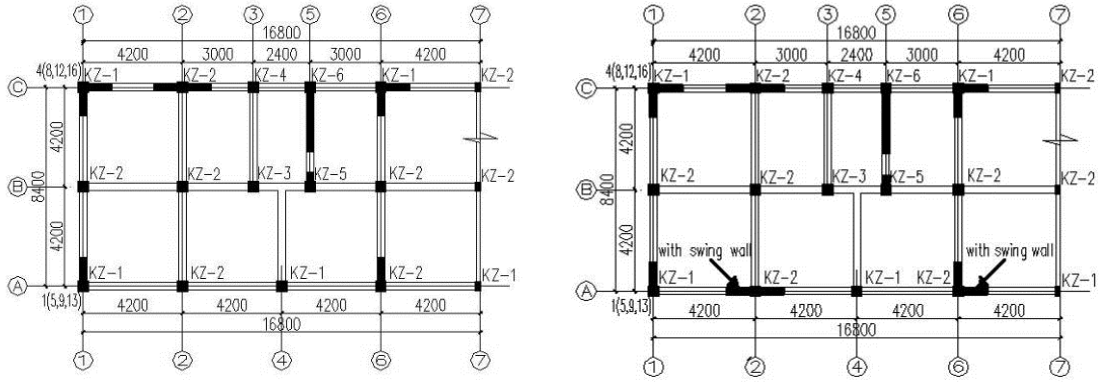
Fig. 1 Collapse of ground floor[1]

**Major characteristics of earthquake damage and suggestions on anti-collapse**

The main forms of the bottom frame structure collapse include collapses of the bottom frame layer, transition layer and the whole structure, among which, the collapses of the bottom frame layer and the whole structure are caused by the damage in the bottom frame layer. In addition, local damage of the structure occurs firstly in the bottom frame layer in most cases. Therefore, reducing the damage in the bottom frame layer is the major measure for avoiding the collapse of the bottom frame structure. Due to commercial purposes, the earthquake resistant wall of the bottom frame structure is usually arranged in the back facade of the structure, nearly no shear wall is set on the longitudinal side of the structure. Although this can meet needs in the commercial use, it is prone to lead to torsion failure of the structure in earthquakes. Therefore, taking commercial use into consideration, it is necessary to set up wing walls in the front of the structure as much as possible to reduce the eccentricity of the structure seismic damage to the structure. Therefore, based on quantitative analysis on the role of wing walls setting up on the front of the bottom frame structure, the following numerical analysis has been conducted.[2]

**The comparison analysis on the anti-seismic collapse of the bottom frame structure**

**Design information** According to the current design code, the shear wall structure on the 7°0.15g area of the first layer in the bottom frame is designed, the structure is located at the site of the second category with a total height of 4 layers, where, the bottom layer is 4.5m high, the rest layers are 3m high, the bottom frame column is 400 × 400mm2, the frame beam 300 × 600mm2, the thickness of the reinforced concrete earthquake resistant wall is 300mm, and the upper masonry structure is sintered brick MU10, the mortar is M10, mortar, the grade of concrete strength is C30, the longitudinal reinforcement is HRB335 and the stirrup is HPB300, comparison analysis on the earthquake response is conducted between cases with and without front wing wall. The structural plane layout is shown in Figure 2. Where, the lateral stiffness ratio between structural layers in the structure without wing wall is 1.93 and the lateral stiffness ratio of the structure with swing wall is 1.02. It can be found that the structural layout is more uniform and symmetrical after setting swing wall and the eccentricities of structural barycenter and steel center have been greatly improved, details can be seen table 1.



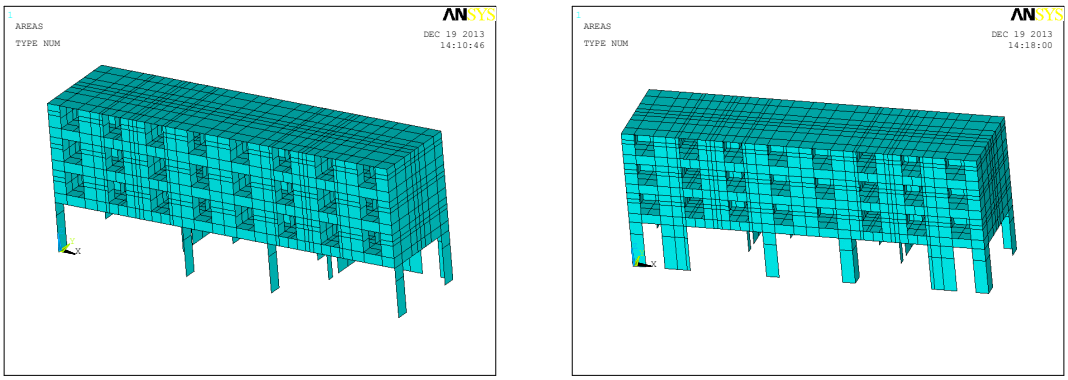
(a) Without Swing Wall (b) With Swing Wall

Fig.2 The structure arangement

Table 1 The eccentricity of the structure

| | Barycentric Coordinate | | steel center Coordinate | | Centroid Coordinate | | Barycentric Eccentricity | | Centroid Eccentricity | |
|---|---|---|---|---|---|---|---|---|---|---|
| | X | Y | X | Y | X | Y | X | Y | X | Y |
| Without Swing Wall | -0.0021 | 0.4805 | -0.0021 | 2.8302 | 0 | 0 | -0.0021 | 0.4805 | -0.0021 | 2.8302 |
| With Swing Wall | -0.0021 | 0.1694 | -0.0021 | 0.4600 | 0 | 0 | -0.0021 | 0.1694 | -0.0021 | 0.46 |

**Comparison analysis between finite elements** The bottom frame structure finite element model in ANSYS, multilinear isotropic model is adopted in concrete and masonry, multilinear isotropic model is adopted in steel to simulate, and the element type adopts SOLID65. The interaction between soil and structure is not taken consideration, while the material nonlinearity is not, the fixed form is used in the bottom structure and its finite element model is shown in Figure 3.



(a) Without Swing Wall (b) With Swing Wall

Fig.3 The FE model

311 seismic wave, the Wolong seismic wave and Ya'an seismic wave are input respectively and are conducted simulation. It is compared and found that there are the following improvements on the the seismic performance of the bottom frame structure after adding swing wall:

1. The displacement of the bottom frame structure decreases significantly, especially on the side adding swing wall.(Fig. 4(a), (b))
2. With the increase of layers, the trend of decrease in displacement declines gradually. (Fig. 4(b), (c))
3. There is a significant control effect on the vertical displacement and displacement on the side adding shear wall.
4. There are significant differences in anti-seismic effects caused by different seismic waves. (Fig. 4(b), (d) , (e))

It can be seen that adding shear wall on the front without affecting the commercial use has improved the seismic performance of the structure with lower cost. It is suggested that stipulating the minimum shear wall ratio on the back of the bottom frame structure in design, so as to reduce the seismic damage caused by the torsional deformation of the structure and improve anti-seismic capacity of the structure.

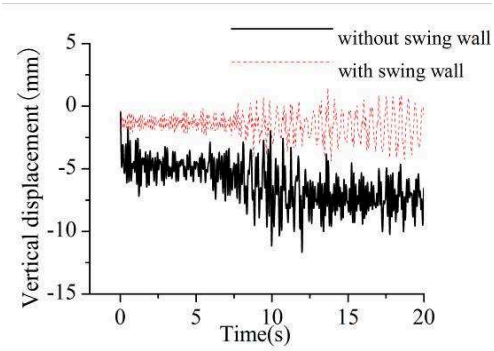
(d)Displacement on Z of point 1 under Wolong wave



(e) Displacement on Z of point 1 under Yaan wave

Fig.4 The comparison of seismic performance of structure

## Conclusions

In view that the bottom frame structure is economical, practical and widely used with serious seismic damage, and its collapse rate is high in practical earthquake, and reinforcing the key part and adding swing wall in the bottom layer under the premise of meeting requirements in regulated and reasonable stiffness rate between layers, has achieved great anti-seismic effect. At the same time, analysis on anti-seismic effects of different seismic waves has been conducted, and it is found that though there are differences in the anti-seismic effect between different seismic waves, they have achieved better effect. The displacement of the bottom frame structure has decreased significantly, especially on the side adding swing wall; with the increase of layers, the trend of decrease in displacement declines gradually; There is a significant control effect on the vertical displacement and displacement on the side adding shear wall; and there are significant differences in the anti-seismic effects caused by different seismic waves.

**Keywords:** hydraulic structure, artificial boundary condition, gravity dam-foundation system, dynamic analysis, seismic wave

**Abstract.** ANSYS was used to focus on comparative analysis of several artificial boundary conditions that are widely used in engineering applications. The accuracy and stability of dynamic analysis results were then analyzed in details of a semi-infinite foundation with different artificial boundaries and different frequency input loads. Lastly, the seismic response of a gravity dam-foundation rock system was explored numerically. Experimental results revealed the simulation accuracy of artificial boundaries was closely related to the dynamic characteristics of input load and the elastic wave velocity. When the input load frequency was high, only the material with comparably higher elastic wave velocity could maintain the stability of the artificial boundary. Viscoelastic artificial boundary is practically simple and can better simulate the semi-infinite material elastic recovery ability and energy radiation outside the boundary.

## Introduction

Over the recent decades, the research of dynamic interactions of gravity dam-foundation under seismic action has made a certain progress. With the development of computer technologies and experimental techniques, the measurement data with respect to model test, earthquake monitoring and in situ observation has been accumulated continuously[1]. However, the better combination of structural dynamic response and seismic wave still needs further study. Nowadays, there exists quite a number of artificial boundary simulation techniques in the interaction analysis of dam-foundation rock, such as viscous boundary[2], viscoelastic boundary[3], transmitting boundary[4-5] and paraxial approximation boundary[6-7]. Nevertheless, under the condition of different materials, the simulation accuracy of different artificial boundaries vary, and there is rare comparison research of the simulation results under different calculation conditions for these artificial boundaries. For this reason, using ANSYS to simulate a semi-infinite foundation with different artificial boundaries, including viscous boundary, elastic boundary, viscoelastic boundary, fixed boundary and extended boundary, this paper conducted a comparative analysis of the dynamic responses under different frequency input loads, as well as the calculation accuracy and stability of these boundaries. Then, the seismic response of a viscoelastic boundary gravity dam-foundation rock system was analyzed in details, which thereby provided with a reference to anti-seismic analysis for similar engineering projects.

## Common Artificial Boundary Theory

**Viscous Boundary.** The viscous boundary, brought up by Lysmer et al[2], takes into consideration of impact of wave energy dissipation over soil dynamic properties. The setting idea of such

boundary is to set dampers at the boundary which absorb the energy of lay scattered waves, that is, to apply damping forces along the normal and tangential directions at the calculation area boundary, then to transform the damping forces to equivalent concentrated forces at the boundary nodes, eventually to calculate the damping forces along the two directions of every boundary nodes. The expressions they obtained of normal stress σ and tangential stress τ of the boundary nodes with relation to horizontal displacement u and vertical displacement w are shown as follows:

Bottom Boundary:

$$\left.\begin{aligned}\sigma &= a_H \rho v_p w \\ \tau &= b_H \rho v_s \dot{u}\end{aligned}\right\} \quad (1)$$

Side Boundary:

$$\left.\begin{aligned}\sigma &= a_v \rho v_p w \dot{u} \\ \tau &= b_v \rho v_s \dot{w}\end{aligned}\right\} \quad (2)$$

Where: $\dot{w}$ and $\dot{u}$ are the velocity components along normal and tangential directions of the boundary nodes; $v_p$ and $v_s$ are the velocity of compression wave and shear wave of the incident wave; $a_H$ , $b_H$ , $a_v$ , $b_v$ the non-dimensional numbers which reflect the non-damping characteristics; $\rho$ is the density of material.

In the case of viscous boundary, high accuracy of calculation results is achieved when the incident wave is normal to the artificial boundary; while it is not so satisfactory when the incident wave is close to parallel to the boundary. Because the viscous boundary has the advantages of clear physical meaning, simple to deal with and easy to realize in common software, it is therefore widely used.

**Viscoelastic Boundary**. By adopting a similar derivation method with viscous boundary, Deek derived the viscoelastic boundary based on the assumption that the two-dimensional scattered wave was cylindrical wave[3]. This boundary is equivalent to continuously distributed paralleling spring-damper systems set on an artificial truncated boundary, of which the parameters of spring module and damper module are expressed as:

$$\left.\begin{aligned}K_b &= 0.5\frac{G}{R} \\ C_b &= \rho c\end{aligned}\right\} \quad (3)$$

Where: $\rho$ is the material density; $G$ is the shear modulus; $R$ is the distance between scattered wave source and artificial boundary, which is the vertical distance to the boundary in this calculation model; $c$ is the wave velocity in the material; velocity normal to the boundary is compression wave velocity $c_p$, and that parallel to boundary is shear wave velocity $c_s$; $K_b$ and $C_b$ are the spring and damper forced on the artificial boundary.

Viscoelastic boundary is an elastic boundary when neglecting the damper, and in turns a viscous boundary when neglecting the spring. It can be seen from the viscoelastic boundary expressions that the boundary conditions is capable of simulating not only the propagation of scattered wave from finite field to infinite field, but also the elastic recovery ability of material. Besides, since the concept of viscoelastic boundary is clear and easy to realize using finite element, it is widely used for the interaction analysis of soil structure, as well as the modal analysis of such system[8-11].

## Dynamic Response and Analysis under Different Input Loads

### Calculation Model.

To verify the simulation results of different artificial boundaries under different frequency input loads, the dynamic response of a linear elastic semi-infinite foundation was analyzed under three different frequency triangle impulse loads. Figure 1 is a semi-infinite spatial model, where $-1.0 \le x \le 1.0\text{m}$, $0 \le y \le 2.0\text{m}$; the mesh size is $\Delta x = \Delta y = 0.05\text{m}$. 5 boundaries were applied on this artificial boundary, including viscous boundary, elastic boundary, viscoelastic boundary, extended boundary and fixed boundary, where *R* is the vertical distance from the input point to the artificial boundary. The whole calculation was realized in ANSYS and Newmark was adopted for time integral, which is unconditional stable[12]. The viscous boundary and viscoelastic boundary was simulated by COMBIN14 module, and the extended boundary took the calculation results of a 30-m side length model as exact solution. The material parameters of the calculation models are: elasticity modulus $E = 2.5\text{Pa}$, mass density $\rho = 1.0\,\text{kg}/\text{m}^3$, Poisson's ratio $\nu = 0.25$, load time step $\Delta t = 0.05\text{s}$, material damping is taken as 0 for better understanding of the adsorption of radiation damping to the energy around the boundary. Figure 1 shows the load action range, and Figure 2 is the curves of three different frequency triangle impulse loads.

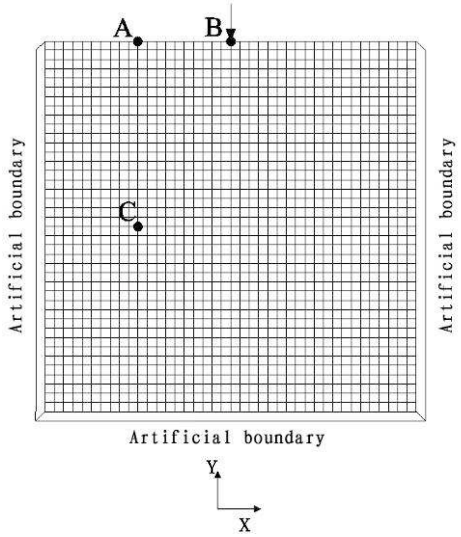

Fig.1 Input Seismic Source Load

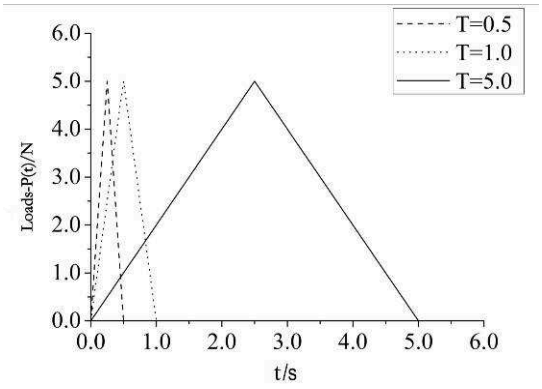

Fig.2 Finite Element Model

### Results and Analysis.

Figure 3 – Figure 6 are the displacement response time curves of five boundary conditions monitored from point *A*, *B*, *C* under different input load action timings and different material shear wave velocities. It can be seen from these 8 figures that the type of artificial boundary has an obvious impact on the displacement of monitoring point. The farther the distance from the boundary base is, the greater the impact becomes of the boundary type to the calculation results. Compared with other boundary conditions, the results of viscoelastic boundary are more close to accurate solution, and as response time increases, there exists drift phenomenon at the viscous boundary which is mainly determined by the characteristics of the damper itself. Under the conditions of fixed boundary and elastic boundary, there exist different levels of oscillation for the displacement of monitoring point, and it exhibits serious distortion in the case of fixed boundary. By comparing Figure 3, 4 and 6, it can be found that with a constant material spear velocity, by reducing the

frequency or increasing the period of seismic source load, the simulation results of viscoelastic boundary can be improved properly. From Figure 4 and 5, it can be seen that with constant seismic source frequency, the simulation results of viscoelastic boundary get worse by simply increasing the elastic wave velocity. In general, with higher frequency and higher material elastic wave velocity, the simulation results become better. Therefore, both seismic load frequency and material characteristics have critical impacts on dynamic response. It is important to select the frequency range properly as well as taking into consideration of impact of materials.

**A Dynamic Finite Element Example of Gravity Dam-Foundation System**

**Calculation Model.** A concrete gravity dam has the following parameters: height = 101m, crest elevation=74m， dam top width = 16m, upstream normal storage level = 64m, designed flood level = 63.88m, check flood level = 67.68m, and the shock strength = 7. The material parameters are: elasticity modulus of dam body concrete and dam foundation rock is 25.5 GPa and 18.0 GPa , respectively, Poisson's ratio are 0.167 and 0.2, respectively, concrete volume-weight is $24000\,\text{N/m}^3$ , and the foundation rock volume-weight is $29000\,\text{N/m}^3$ . In the case of dynamic analysis, dynamic elastic modulus is 30% larger than static elastic modulus. Figure 7 is a finite element model of gravity dam-foundation rock system simulated in ANSYS, with foundation depth of upstream, downstream, and dam foundation itself being twice of the dam height. With the design response spectrum regulated in *Hydraulic Structure Seismic Design Code* (DL5073 - 2000) being the target spectrum, an artificial seismic wave (time interval = 0.02s, acceleration peak = 0.1g, and duration = 30s) was synthesized using trigonometric series. During calculation, a horizontal

equivalent nodal force was applied at artificial boundary node in the bottom. Figure 8 are the acceleration - time, velocity - time and displacement - time curves of artificial seismic wave.

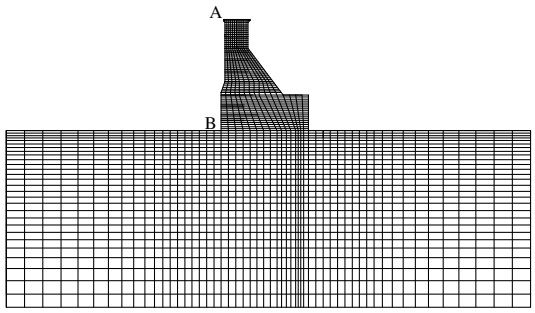

Fig.7 Dam-foundation system finite element model

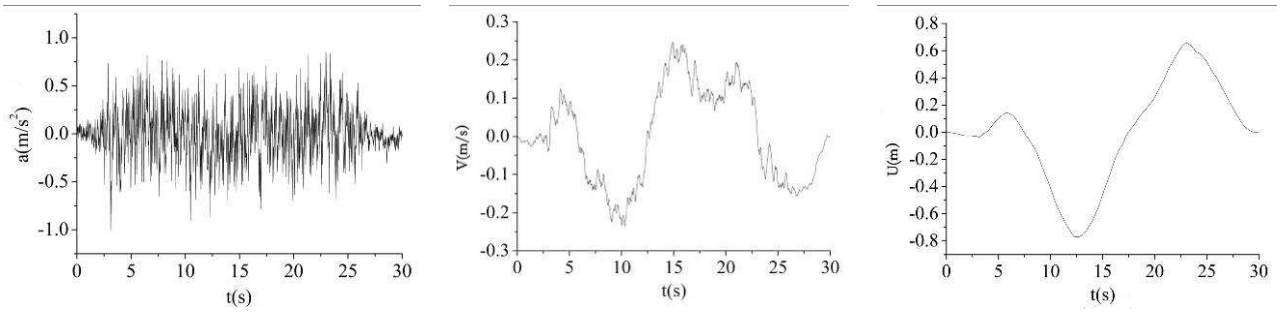
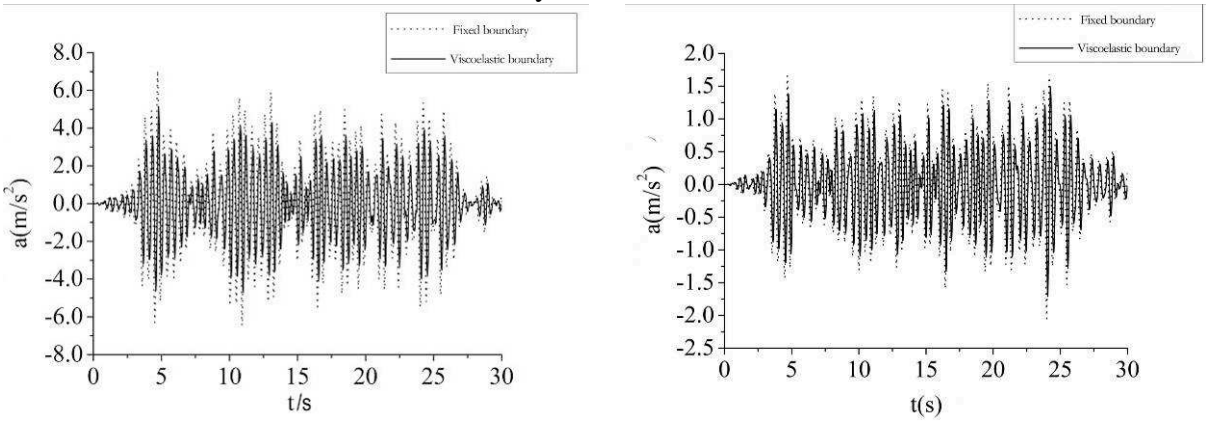


（a）Acceleration （b）Velocity （c）Displacement

Fig.8 Artificial seismic wave curves

**Results and Analysis.**

Figure 9 is the acceleration – time curve along X direction of dam top node *A* and dam foundation node *B* under viscoelastic and fixed boundary conditions.



（a）Node A at the crest of dam （b）Node B at the bottom of dam

Fig.9 Acceleration time history curve under two boundary conditions at nodes A, B

From Figure 9, it can be seen that, comparing with conventional fixed boundary of massless foundation, the gravity dam – foundation rock system with viscoelastic artificial boundary that taking into consideration of foundation radiation damping shows a clear weakening in peak acceleration response of both dam top and foundation, with the weakening range being 20% ~ 30%. This method avoids the reflection of seismic wave on the fixed boundary and considers the impact of foundation radiation damping, which makes the dynamic analysis results more conform to the real situation.

## Conclusion

Using ANSYS, this paper analyzed the dynamic responses of a semi-infinite foundation under different artificial boundary conditions and their impact factors. The conclusions are as follows:

1）Different artificial boundary conditions directly impact the dynamic interaction results of structure – foundation. The accuracy of dynamic analysis results is directly influenced by the selection and simulation of artificial boundary conditions. Thereinto, the viscoelastic artificial boundary condition has the advantages of simple principle, easy to realize, fine simulation results and good stability.

2）The simulation results of viscoelastic artificial boundary are related to not only the material parameters, but also the frequency or period of the seismic source load. When the seismic source has a higher frequency, the corresponding higher material elastic wave velocity will result in a good simulation results under viscoelastic artificial boundary condition.

3）At last, a numerical analysis of seismic response over a concrete gravity dam – foundation rock was conducted, which proved the impact of infinite foundation radiation damping is not negligible.

# Dynamic analyses of a Self-anchored Suspension Bridge under Seismic Excitations

Wang Cheng[1, a], Wang Yanxu[1,b]

[1] Roadway Construction Project Management Center of Beijing Municipal Roadway Administration Bureau, 100031, Beijing，China

[a]postwc@126.com, [b]postwyx@126.com

**Keywords:** self-anchored suspension bridge; response spectrum; time-history method; artificial seismic wave; seismic response.

**Abstract.** The seismic response of the Wusong bridge was analyzed though the response spectrum method and the time-history method by adopting the MIDAS/CIVIL. The analysis results show that the longitudinal displacement of the main girder is much larger under longitudinal seismic input, so some inhibiting device or dampers should be used to avoid impacting. There is not coupling between longitudinal and lateral seismic excitations, while the seismic response of moment and shear force at the bottom of the main tower is much larger. On the contrary the seismic response of main beam and the main cable should be calculated under the longitudinal and vertical seismic excitations because of the coupling between the both of them. Furthermore, the artificial seismic wave fitting standard response spectrum was generated to conduct the time-history analysis and the results are much larger than the results from the response spectrum method.

## Introduction

The development of self-anchored suspension bridge in China started in the last two decades. Through the engineering practice in the last ten years, the construction technology of it has reached the international advanced level. As the self-anchored suspension bridge has unique advantages of elegant, pleasing appearance in the form of medium-span city bridges, a large number of self-anchored suspension bridge have been built in recent years. At the same time, complete set of specialized research on the anchor suspension bridge was carried out. But research in the aspects of a long-span self-anchored suspension bridge anti-seismic and damping is relatively weak. At home and abroad, the existing codes for seismic design of bridges don't provide any detailed provisions about the seismic performance of this type of bridge; just treat them as distinct bridges and gives only seismic conceptual design principles. Although some research of the seismic performance of self-anchored suspension bridges has got some useful conclusions, most research was aimed at a certain bridge[1-5]. Generally speaking, the research of the seismic performance of self-anchored suspension bridges is relatively weak. Considering the differences between bridges, the regular pattern of the seismic response of this kind of bridges should be specially considered.

## Dynamic characteristic calculation

The finite element model of the bridge was built by MIDAS/CIVIL. The main girder and the main tower were simulated by space beam elements. Suspenders and the main cables were simulated by the cable element that only subjected to tension. The rendering of finite element model of the overall structure is shown in Figure 2. The dynamic characteristic analysis is shown in Figure 3.

## Seismic response analysis

### Response spectrum analysis

Response spectrum method is simple and straightforward calculation. In the program stage, peak values of the bridge can be getting by a smaller amount of calculation under earthquake. For seismic calculation of bridge, the most important thing is the peak response of structure under earthquake. This is also the reason for that response spectrum method is widely favored by bridge designers.

The Wusong Bridge is located at Ⅶ degree area of the seismic intensity zoning map in China. The peak of ground motion acceleration is 0.1g in this area. Based on "Guidelines for Seismic Design of Highway Bridges", the bridge is divided into Class A, the intensity standard of seismic fortification is 7 degrees, and the peak of designed basic ground motion acceleration is taken as 0.10g in the horizontal direction. According to the Chinese "Guidelines for Seismic Design of Highway Bridges" promulgated in 2008, the designed horizontal maximum acceleration response spectrum is 0.296g from calculation, which is larger than the effect value of previous seismic code

Reference to the measured data of other long-span suspension bridges, such bridge the damping ratio of this type of bridge is small. So in this response spectrum analysis, the damping ratio is set to 0.02. Based on "Guidelines for Seismic Design of Highway Bridges " , the type of site soil of this bridge is Class Ⅱ. Figure 5 shows the horizontal design acceleration response spectrum of this bridge. The vertical design acceleration response spectrum is getting with the horizontal design acceleration response spectrum multiplied by a factor of 0.65. In order to satisfy the accuracy requirements, in this response spectrum analysis, the top 100 vibration modes are selected and combined with the CQC method.

Table 1 shows the seismic response of the main girder and the main cable under earthquake input, and table 2 shows the seismic response of the main tower under earthquake input. Under longitudinal seismic input, longitudinal and vertical vibration of the main tower and the main beam is very small, almost no lateral vibration. The structure deformation is performed with longitudinal drift of the main girder and longitudinal swing of the main tower. The larger longitudinal displacement of the main girder determines the design of connected components such as bearing. The design of concrete self-anchored suspension bridge is dominated by the bending moment of the root–section of the bridge tower. Under lateral earthquake input, the deformation is performed with lateral vibration of the main tower and main girder; the vertical and horizontal vibration of the main tower and main girder of this bridge is not obvious; and the earthquake action almost have no effect on the main cable internal forces. Under vertical earthquake input, the vertical, lateral and longitudinal vibration of the main tower and the main girder of this bridge are not obvious; structure deformation is performed with longitudinal swing of the bridge tower and vertical vibration of the main girder.

Tab.1 The dynamic response of the girder and main cable based on response spectrum method

| | bottom | 3572.60 | 557.90 | 315.00 | 8764.00 | 3181.70 | 0.00 | |

**Response spectrum analysis**

In this analysis, artificial seismic waves meeting the requirements of the codes, are generated with MATLAB, which are based on the trigonometric series superposition method. First, get the design acceleration response spectrum, according to the design code, the actual type of the bridge site and design intensity. Secondly, transform the design acceleration response spectrum into a power spectrum. Then artificial seismic waves can be generated from inverse Fourier transform of the

random phase of the Fourier amplitude spectrum, which is obtained from the power spectrum. After the artificial seismic waves generated, adjust its intensity values based on regulatory requirements. Finally, get artificial seismic waves matching the design response spectrum, which can be used for the bridge seismic analysis. The artificial seismic waves shown in Figure 4 are generated from the design acceleration response spectrum, which is matching the design response spectrum. The total duration is taken as 20s, and Δt is taken to be 0.01 s.

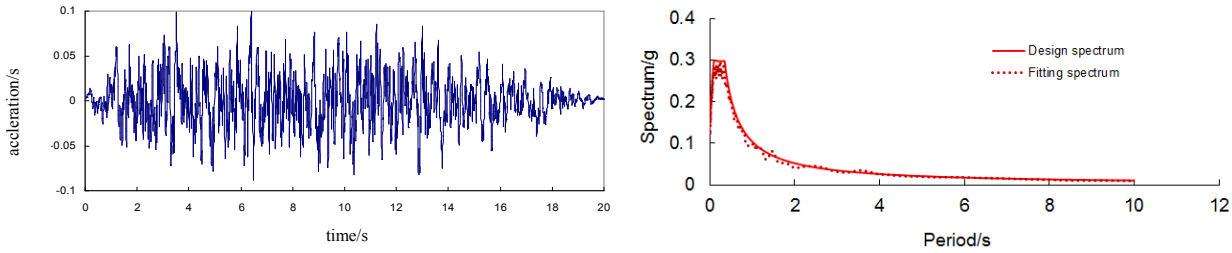

Fig.4 Artificial seismic wave matching the design response spectrum

Table 3 and Table 4 shows the seismic response of the main beam, the main cable and the main tower based on the time history analysis method. By comparing with table 1 and table 2, seismic response obtained from time history analysis method is consistent with the result of response spectra analysis method, but the peak value is slightly different. In general, response peak value get from time history analysis method is larger than the result of the response spectrum method. So the response spectrum method can be used for preliminary design, and time history analysis method is more reasonable and reliable for detailed design.

## Summary

This article is based on a seismic response analysis of self-anchored suspension bridges, and the main results are as follows:

(1) Under longitudinal seismic input, concrete self-anchored suspension bridge is performed with longitudinal drift of the main beam and longitudinal swing of the bridge tower. Results show that the longitudinal displacement of the main girder is much larger so some inhibiting device or dampers should be used to avoid out-of- codes displacement and connective component's bad working.

Internal force doesn't control the design of the main beam and the main cable, and the root section is the main control section during the tower design.

(2) Under the lateral seismic component action, the performance of concrete self-anchored suspension bridge is dominated by lateral vibration, but the internal force and deformation of the bridge tower and main girder is small ,because of its gate type bridge tower with big lateral stiffness.

(3) Under the vertical earthquake component action, concrete self-anchored suspension bridge is characterized by vertical and longitudinal vibration. In this condition, the internal force and deformation of the bridge tower are little, having no decisive effect on design. Impact on the main beam is significant; peak of the vertical bending moment of the main beam is located near the pier top of the side span. Combined with the main cable anchorage zone with complex stress state, this area should be taken into consideration in the design.

(4) The time-history analysis results are much larger than the results from the response spectrum method. Response spectrum method is suitable for the preliminary design or the Plan formulation. And time history analysis results are advisable for component detailed design.

**Keywords:** Morison equation; Inertial coefficient; Accurate algorithm; Approximation algorithm.

**Abstract.** In order to study the effect of hydrodynamic pressure acted on pile-pier structure in deep water, an investigation on the inertial coefficient is developed. Based on the Morison equation, the usual suggested value is analyzed, especially the noncircular slender cylinder is considered. Besides, the effect of scale of structure is studied, including accurate algorithm and approximation algorithm. Study results indicate that the Morison equation is also applied to noncircular slender cylinder, and the value of inertial coefficient is influenced by the scale of structure. Moreover, the calculated results of accurate algorithm and approximation algorithm are consistent within a certain range, so the choice of calculation method should be governed by the required precision.

## Introduction

In recent years, the mechanical property of submerged structure or component has been brought into researchers' sights[1]. When the earthquake occurs, the dynamic interaction between the submerged structure and surrounding water will cause the threats to the safety of bridge system. During the past decades, many theoretical methods and experimental studies have been performed to investigate the effect of hydrodynamic pressure for bridge or other structures under seismic excitation[2-4].

For the research purposes, this problem should be appropriated to simplify. Morison et al. introduced the Morison equation which has been widely used to estimate the hydrodynamic pressure on the small scale structures[5].

In this paper, an investigation on the effect of hydrodynamic pressure acting on pile-pier structure is developed, especially the main content focus on the inertial coefficient.

## Inertial coefficient

**Governing equations.** The Morison equation of unit cylinder can be expressed as:

$$f = C_M \rho A\ddot{u} - C_m \rho A\ddot{x} + C_D \frac{\rho}{2} D[\dot{u} - \dot{x}]|\dot{u} - \dot{x}| \tag{1}$$

Where, $f$ is defined as wave force; $C_M$ , $C_m$ and $C_D$ are, respectively, the inertial , added mass and drag coefficients; $\dot{u}$ and $\ddot{u}$ are , respectively, the in-line water particle flow velocity and acceleration; $\dot{x}$ and $\ddot{x}$ are , respectively, the in-line velocity and acceleration of cylinder.

There are two problems for the calculation of wave force by Morison equation, which are the appropriate wave theory and relevant hydrodynamic coefficient. Since the Morison equation was presented, many researchers have carried out a large number of model tests and field observation, but the data of hydrodynamic coefficient including inertial coefficient $C_M$ and drag coefficient $C_D$ show larger discreteness. In this paper, the inertial coefficient $C_M$ will be analyzed.

**Suggested value.**

For noncircular slender cylinder, the cross-sectional area is used to replace the area of circle in the Morison equation. Figure 1 shows the inertial coefficient $C_M$ which based on the test results of Zhu[6].

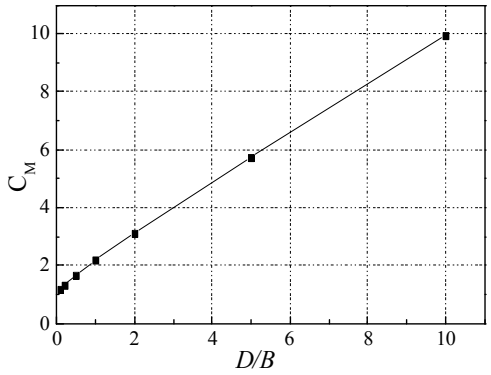

Figure 1 The correspondence between the rectangular cross-section with different length and width and inertial coefficient

Based on the curvilinear trend by the length-width ratio, the approximate formula of the equivalent inertial coefficient $C'_M$ can be obtained:

$$C'_M = 1.067 + 1.091 \times \left(\frac{D}{B}\right)^{0.909} \tag{2}$$

Based on the calculated results by Eq. 1 and *Code of Hydrology for sea Harbour*[6], the inertial coefficient used for several typical sections is listed in Table1.

Table 1 The inertial coefficient used for several typical sections

| Shape of cross-section | | Area | $C_M$ |
|---|---|---|---|
| Circle | Direction of motion, D | $\frac{\pi D^2}{4}$ | 2 |
| Square | Direction of motion, D, D | $D^2$ | 2.19 |
| Rectangle | Direction of motion, B, D | $DB$ | $C'_M$ |

**Effects of different factors**

**The sensitivity**. Based on the theoretical results of Ju[7] and Liaw[8] , the inertial force can be expressed as:

$$f_I = C_M \rho \frac{\pi D^2}{4} \frac{\mathrm{d}^2 \mathrm{u}}{\mathrm{dt}^2} \tag{3}$$

$$C_M = 1 + M_w \Big/ \frac{\rho \pi D^2}{4} \tag{4}$$

$$M_w(z) = \frac{p_1^I(z)}{\phi_1(z)} \tag{5}$$

$$p_1^l(z) = 4\rho_w D \sum_{m=1}^{N} \frac{I_{1m}}{(2m-1)} E_m(\lambda'_m, \frac{D}{2}) \cos(\alpha_m z) \tag{6}$$

$$E_m(\lambda'_m, \frac{D}{2}) = \frac{K_1(\lambda'_m, \frac{D}{2})}{K_0(\lambda'_m, \frac{D}{2}) + K_2(\lambda'_m, \frac{D}{2})} \tag{7}$$

$$I_{1m} = \int_0^{H_w} \phi_1(z) \cos(\alpha_m z) \mathrm{d}z \tag{8}$$

$$\lambda'_m = \alpha_m = \frac{(2m-1)\pi}{2H_W} \tag{9}$$

In Eq.7, $K_n$ is the modified Bessel function of order n of the second kind.

Based on Eq. 4- Eq. 9, the calculated results was shown in Figure 2. From the Figure 2, for small scale, when the height of water level remains constant, the distribution of $C_M$ along the height of structure is tending towards stability under water level. But the variance starts to get bigger with increasing diameter.

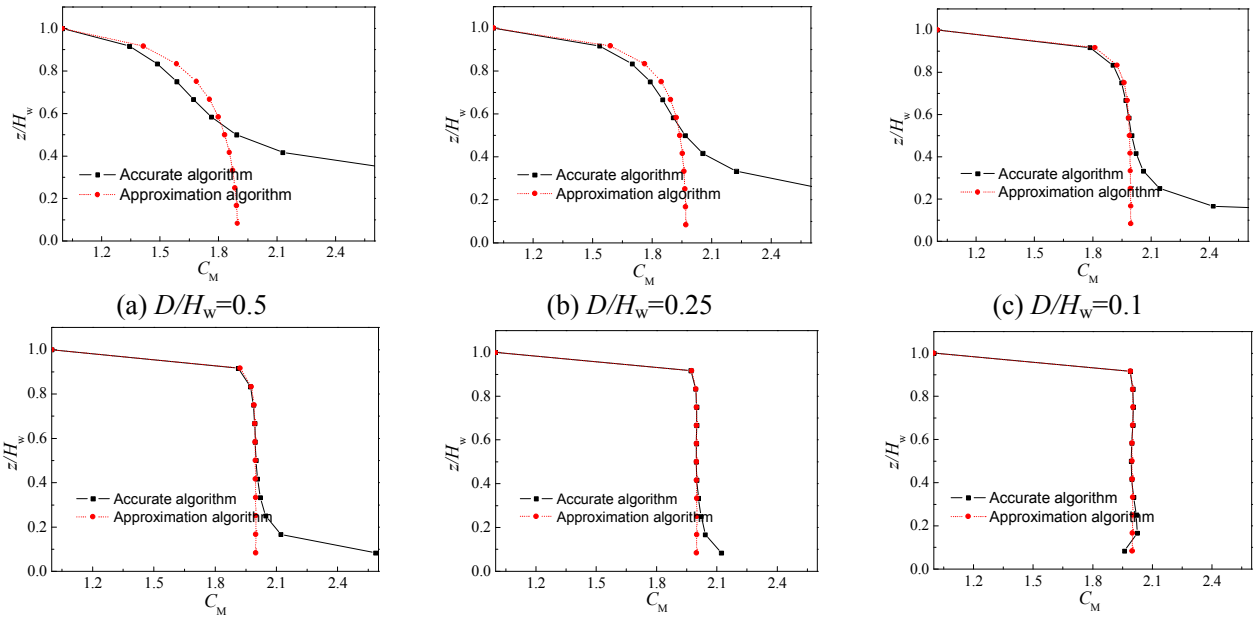
For the general seismic ground motion, in view of the excitation frequency, the effect of free surface wave and compressibility of fluid can be neglected when the inertial coefficient is analyzed.

**Approximation algorithm**. If the effect of mode of vibration may be neglected, the Eq. 5 can be simplified as:

$$M_w(z) = p_0^l(z) \tag{10}$$

The Eq.10 is equivalent to the $\phi_1(z)$ in Eq.8 replaced as $\phi_0(z) = 1$.The calculated results are shown in Figure 2.

By comparing with the accurate algorithm, for small scale, when the height of water level remains constant, the distribution of $C_M$ along the height of structure is tending towards consistent under water level. But the variance starts to get bigger with increasing diameter. The comparison among different diameter is shown in Figure 3. It indicates that the smaller scale and the more deviation from the suggested value.



(a) $D/H_w$=0.5 (b) $D/H_w$=0.25 (c) $D/H_w$=0.1

(d) $D/H_w$=0.05 (e) $D/H_w$=0.025 (f) $D/H_w$=0.01

Figure 2 Comparison of distributions of inertial coefficient calculated by different algorithm

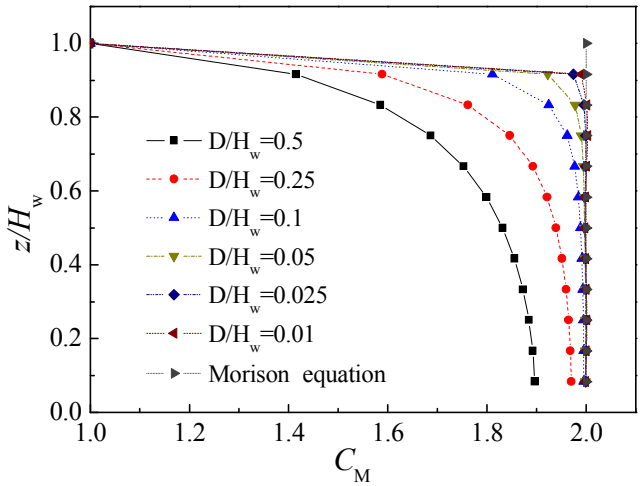


Figure 3 The distribution of inertial coefficient calculated by approximation algorithm

## Conclusion

This paper presents the investigation on inertial coefficient in calculating the hydrodynamic pressure acting on the deepwater structure. Based on the Morison equation, the usual suggested value is analyzed, especially the noncircular slender cylinder is considered. Besides, the effect of scale of structure is studied, including accurate algorithm and approximation algorithm. The conclusions deduced from the results of the investigation indicate that the Morison equation also applied to noncircular slender cylinder, and the value of inertial coefficient is influenced by the scale of structure. Moreover, the calculated results of accurate algorithm and approximation algorithm are consistent within a certain range, so the choice of calculation method should be governed by the required precision.

**Keywords:** precast shear wall structure; concealed bracing; hysteresis curve; seismic behavior; seismic ductility

**Abstract.** Aiming at the horizontal connection joint of the precast shear wall structure, this paper presents a new-type horizontal wall-to-wall connection. Based on the ABAQUS finite element analysis platform, an accurate finite element model of shear connection joints was built. By quasi-static numerical tests, the seismic behavior of the proposed connection of the precast shear wall system was analysed and compared with that of the traditional cast-in-place connection. The numerical results show that the seismic performance of the presented connection, such as deformability and energy-dissipation capacity, is slightly lower than that of its cast-in-place counterpart.

## Introduction

It is a basic trend of the building and housing industrialization, promoted by Chinese government, to develop precast concrete structures in order to realize the overall goal of low carbon, green, energy-saving and sustainable building. In consideration of the lack of knowledge of how the precast concrete shear wall system performs under seismic loading conditions, the use of this type of construction should be treated with caution in China, one of the most seismically active nations in the world. For precast concrete load-bearing shear wall panels, behavior of the connections greatly influences structural integrity of the entire structure. Therefore, in order for precast concrete shear wall panel systems to gain acceptance and be a competitive construction system in Chinese seismic regions, the anti-seismic behavior of the connections between the precast members must be studied. At present, many Chinese researchers, such as Jiaru Qian [1], Zhengxing Guo, etc. [2-4], are working to understand the seismic performance of such a system mainly by comparison with that of its equivalent cast-in-place system.

In this paper, An abaqus-based nonlinear finite element (FE) analysis under low-cyclic loading is implemented in order to understand the seismic performance of the proposed connection way of precast shear walls in comparison with that of the cast-in-place connection way.

## Description of FE modeling

The horizontal joint specimens are models of localized regions in the precast shear wall which contain the horizontal joint connections. Three kinds of FE models of horizontal joint specimens were considered. Specifically, the first one (PSW-2) was built to simulate the proposed wall-to-wall connections for precast shear wall structures, which was reinforced by using a herringbone concealed bracing with Φ16 bars between the upper and lower walls, as shown in Fig.1. The second one (CSW) was built to simulate its cast-in-place counterpart (Fig.2), which used the "*tie*" connection to link the upper wall with the lower ground base beam; the third one (PSW-1) was built

to simulate the conventional connection for precast shear wall, which had the same reinforcing bars as the CSW model, but used frictional contact elements to connect the upper wall with the ground base beam. The vertical reinforcement of all these wall models was deformed bars of grade HRB 335, while the stirrups of the boundary elements and the horizontal distributed reinforcement of the models were applied with grade HPB 300. The C35 concrete was used for the three models. The main material properties for steel and concrete are presented in Table 1.

Table 1 Elastic mechanical properties of materials

| Model type | Elastic modulus(Mpa) | Poissom ratio | Compressive strength（Mpa） | Tensile strength （Mpa） |
|---|---|---|---|---|
| Concrete | $2.648\times10^4$ | 0.167 | 16.7 | 1.57 |
| HRB335 | $2.0\times10^5$ | 0.3 | 300 | 300 |
| HPB300 | $2.0\times10^5$ | 0.3 | 270 | 270 |

There was a loading beam (rigid body) on the top of the upper wall for all these wall models, which was subjected to a vertical uniform load . For all models, the axial compression ratio was set to 0.15. The steel mesh arrangement for all the FE models are shown in Fig.3 and Fig. 4.

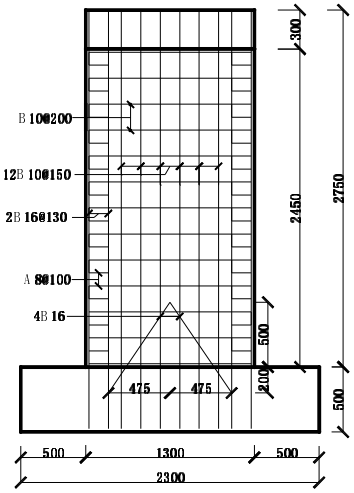

Fig.1 Reinforcement map of the PSW-2 model

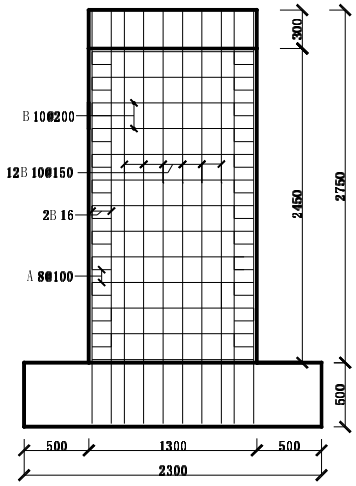

Fig.2 Reinforcement map of the CSW and PSW-1 model

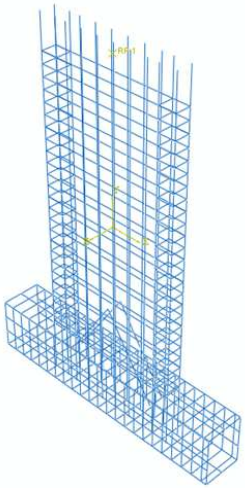

Fig.3 Steel mesh of the PSW-2 model

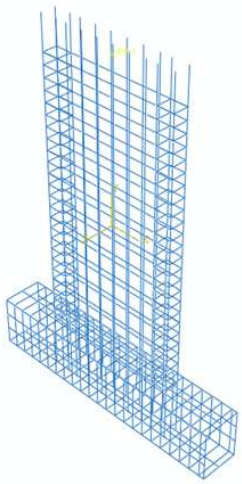

Fig.4 Steel mesh of the CSW and PSW-1 model

**Numerical results of the finite element analysis**

The area hysteresis curve encircles reflects the energy dissipation capacity of a structure. By applying cyclic loads on the three models, we obtained different hysteresis curves of the three

wall-to-wall connections, as shown in Fig.5, Fig.6 and Fig.7, and hence we drew the skeleton curves in Fig .8.

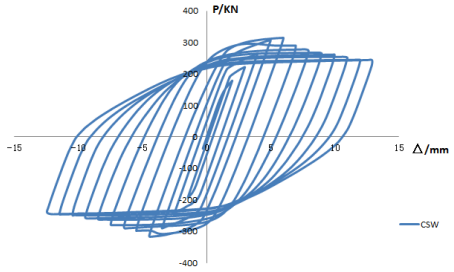

Fig.5 Hysteresis curves of CSW

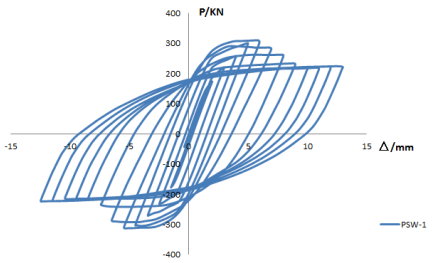

Fig.6 Hysteresis curves of PSW-1

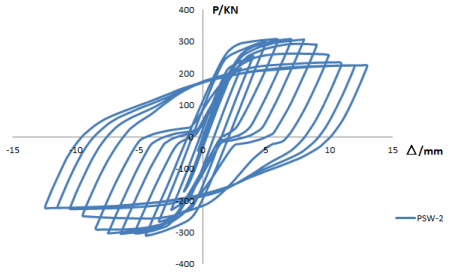

Fig.7 Hysteresis curves of PSW-2

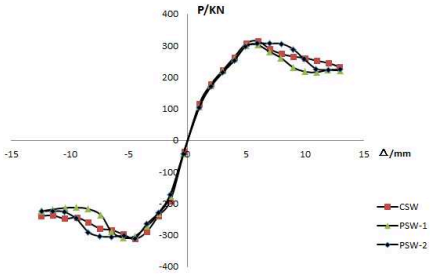

Fig.8 Skeleton curve comparison

Table 2.Hysteresis loop area

| Model Type | The area that hysteresis curve encircles |
|---|---|
| CSW | 3184 $mm^2$ |
| PSW-1 | 1969 $mm^2$ |
| PSW-2 | 2637 $mm^2$ |

Table 2 calculates the area that the hysteresis curve encircles for these models. The results show that the hysteresis curves for the CSW model encircles the largest area. But for the PSW-1 model and the PSW-2 model, the latter has a 30% area increase, compared with the former, which shows that the concealed bracing in the PSW-2 model takes a positive effect on energy dissipation performance of the model.

Table 3.Loading-displacement relation of the hysteresis curves [5-6]

| Model type | Yield load $P_y / KN$ | Yield displacement $\Delta_y / mm$ | Ultimate load $P_u / KN$ | $\Delta_o / mm$ | Ultimate displacement $\Delta_u / mm$ | Displacement ductility $\mu = \Delta_u / \Delta_y$ |
|---|---|---|---|---|---|---|
| CSW | 178.8 | 2.00 | 3151 | 5.99 | 8.98 | 3.97 |
| PSW-1 | 169.9 | 1.98 | 302.5 | 5.95 | 5.95 | 3.02 |
| PSW-2 | 172.9 | 1.97 | 307.2 | 5.89 | 7.17 | 3.63 |

Table 3 indicates the loading-displacement relation of the hysteresis curves for the three models. We can see from Table 3 that the CSW model has the best seismic performance, compared with the other two models. For the PSW-1 model and the PSW-2 model, the ultimate displacement of the latter has a 20.5% increase, which means that the concealed bracing in PSW-2 model makes a better deformation capacity.

Fig.9 shows the stiffness degradation curves of the models. It is easy to see that the initial stiffness of the CSW model is a little larger than that of the other two, but there is no obvious difference in the stiffness degradation trend of all the models.

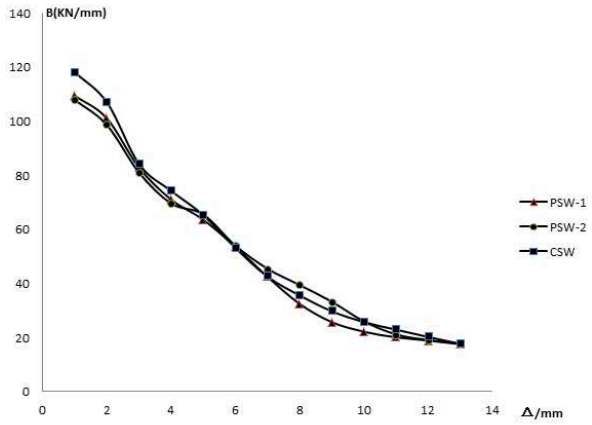

Fig.9 Stiffness degradation curve of the three models

## Conclusion

In this paper, we develop an ABAQUS-based three dimensional finite element method to study a new-type concealed bracing connection of precast shear wall structures. By comparison with the equivalent cast-in-place shear wall systems, the following conclusions can be drawn:

(1) The new connection by setting concealed bracings at the regions of joints has a good seismic performance, which can balance the easy and rapid assembly technology for precast shear wall systems, with the reliability of connection joints.

(2) Structural design of the concealed bracing connection for precast shear wall systems need to be further optimized. And some difficulties, such as reinforcement design and location set-up of concealed bracings under different axial pressure ratios, are still worth studying.

**Keywords:** Near-fault pulse-like ground motion, Base-isolation building, Seismic response, Nonlinear time history analysis.

**Abstract.** The seismic response of the base-isolated structure can be reduced significantly in the far-field region compared to the conventional seismic structure. However, near-fault ground motions with velocity pulse may cause the adverse influence on the seismic performance of the base-isolation building, which needs to be investigated deeply. In this paper 6 ground motions with velocity pulse are selected as the input, and the seismic response of a 9 layers conventional seismic RC frame building and comparative base-isolation building with lead-core rubber bearings are obtained by nonlinear time history analysis. The result indicates that base-isolation building with lead-core rubber bearings are of good aseismic performance under the near-fault ground motions with velocity pulse.

## Introduction

The basic characteristics of near-fault ground motion include the concentration of strong ground motions, surface rupture, rupture directivity effect, large velocity pulse and hanging wall effect [1]. For all of these basic characteristics, the large velocity pulse with very high energy has the greatest influence on the engineering structures, and the seismic responses (such as stress, displacement, ductility and etc.) of structures subjected to velocity pulse are much greater than those ground motions without velocity pulse[2]. In the far-field region, the seismic response of the base-isolated structure can be reduced significantly. However, near-fault ground motions with velocity pulse may cause the adverse influence on the seismic performance of the base-isolation building, which needs to be investigated deeply [3-7]. This paper established a conventional seismic building and a comparative base-isolation building with lead-core rubber bearings, input 6 typical strong motion records with velocity pulse, calculate dynamic response of aforesaid structures to analyze the seismic performance of the lead-core rubber bearings subjected to the near-fault ground motions with velocity pulse.

## Calculation models

The model of conventional seismic building is 9 layers reinforced concrete frame structure, the height is 32.4m, the material is C30 concrete, and the beam-column layout as figure1. The sizes of components are as follow: beam is 600mm×400mm, column is 650mm×650mm and floor thickness is 100 mm. Reinforced concrete beams and columns are equivalent to homogeneous rod units, the floor is equivalent to shell element, the material characteristics mainly on the characteristics of concrete. In the process of calculation, considering bending deformation, shear deformation of the beam element and bending deformation, shear deformation, axial deformation of the column element, assuming the floor absolutely rigid in its own plane and neglecting the out-of-plane stiffness.

35 lead rubber bearings GZY600 are putted between each column base and column to set up a base-isolation building model. In nonlinear analysis lead rubber isolation bearings are simulated by biaxial nonlinear hysteresis unit. Lead rubber isolation bearing GZY600 parameters are as follows:

vertical stiffness is 2614000 KN/m, equivalent stiffness is 1859 KN/m, equivalent damping ratio is 27.2%, stiffness before yield is 6519 KN/m, stiffness after yield is 1003 KN/m, and yield strength is 94.2 KN.

The first three natural vibration period of the conventional seismic building model are 1.066s, 1.034s and 0.962s. And the first three natural vibration period of the base-isolation building model are 1.980s, 1.712s and 1.593s.

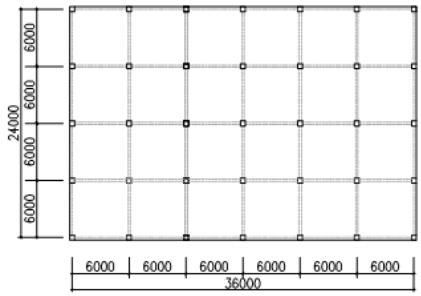

Fig1. Standard floor plan (mm)

## Algorithm

The algorithm of base-isolation structure nonlinear time history analysis is fast nonlinear analysis (FNA), FNA method is an effective method to nonlinear analysis, in this method, the nonlinear is treated as external load, considering the nonlinear load and correction the modal equation.

## Selected ground motions

Select 6 near-fault pulse-like velocity ground motions as input, the parameters are shown in table1, the acceleration and velocity time histories of the ground motions are shown in figure2.

Table1. Selected ground motions

| code | earthqueke | magnitude | station | component | site | duration |
|---|---|---|---|---|---|---|
| A1 | Northridge（1994） | 7.1 | Newhall-W.Pico Canyon Rd | comp046 | B/C | 20.48s |
| A2 | Imperial Valley(1979) | 6.5 | E07 | compSN | B/C | 20.48s |
| A3 | Imperial Valley(1979) | 6.5 | E04 | compSN | B/C | 20.48s |
| B1 | CHI-CHI（1999） | 7.6 | TCU75 | compEW | D | 40.96s |
| B2 | CHI-CHI（1999） | 7.6 | TCU76 | compEW | D | 40.96s |
| B3 | CHI-CHI（1999） | 7.6 | TCU129 | compEW | D | 40.96s |

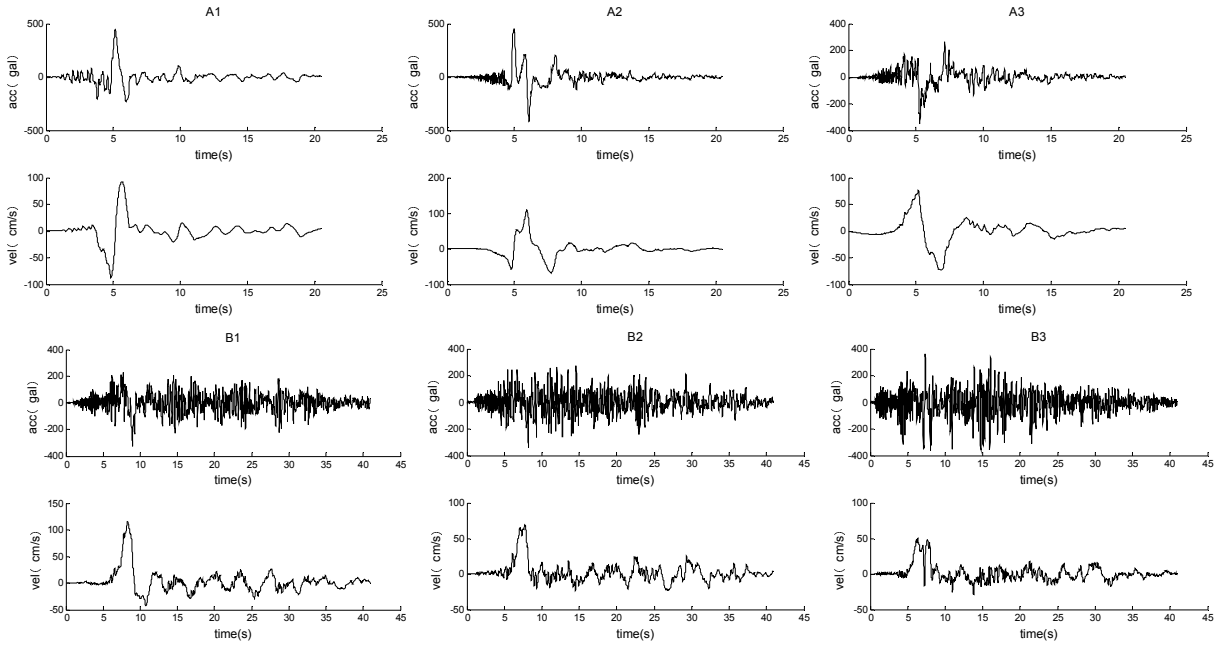

Fig.2 Acceleration and velocity time histories of the ground motions

## Acceleration response

Figure3 is the acceleration response time history of the base-isolation building model and the conventional seismic building model subjected to the ground motions of table1. Comparing with the conventional seismic building, the top story acceleration response is reduced significantly to 1/2-1/5. This means that the seismic action of the superstructure of the base-isolation building is greatly decreased.

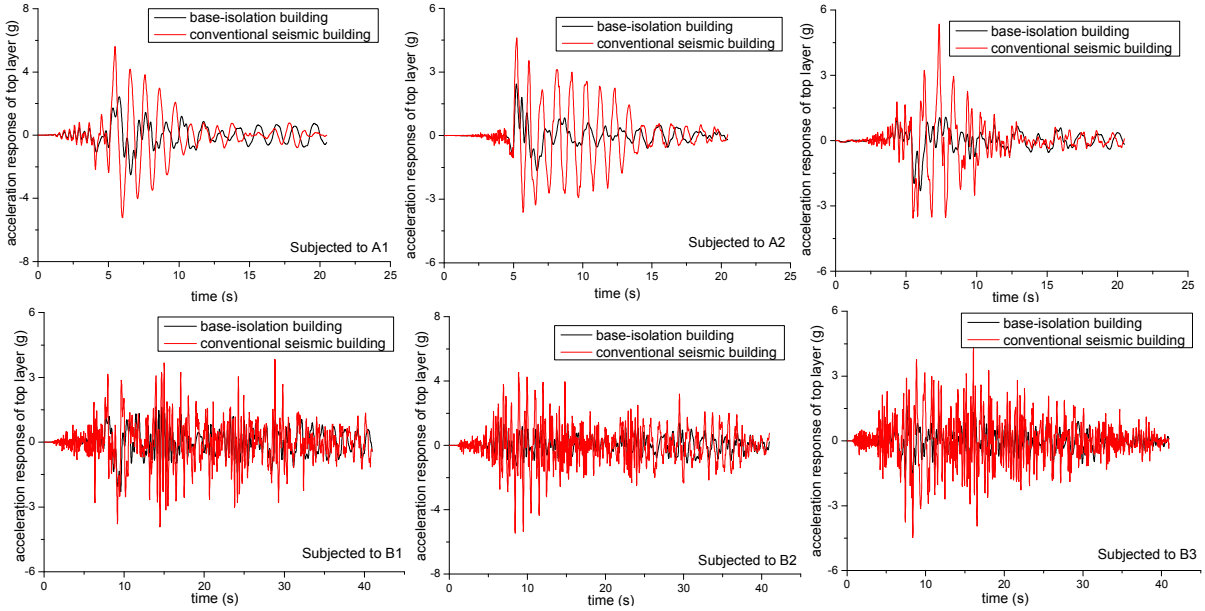

Fig.3 Acceleration response of top layer

## Base shear

Table2 is the X direction base shear of the base-isolation building and the conventional seismic building subjected to the pulse-like velocity ground motions in table1. It can be learned that the base bear of the base-isolation building model is obviously lower than the conventional seismic building model; the base isolation device reduces the structural base shear.

Table2. Maximum base shear of X direction

| Model | maximum base shear（KN） | | | | | |
|---|---|---|---|---|---|---|
| | A1 | A2 | A3 | B1 | B2 | B3 |
| Base-isolation building | 9129 | 6427 | 7559 | 8081 | 4433 | 4621 |
| Conventional seismic building | 15107 | 10371 | 11139 | 9881 | 8122 | 8128 |
| proportion（%） | 61% | 62% | 68% | 82% | 55% | 57% |

## Story drift response

Story drift response is an important index to represent the degree of structure seismic damage. Figure4 is the story drift response of the base-isolation building model and the conventional seismic building model subjected to 6 pulse-like velocity ground motions in table1. The story drift of the superstructure of the base-isolation building is effectively reduced comparing with the conventional seismic building. The horizontal displacement of the base-isolation building focuses on isolation floor bearing. The story drift of the 3-5 layer of the conventional seismic building are larger than the other layer.

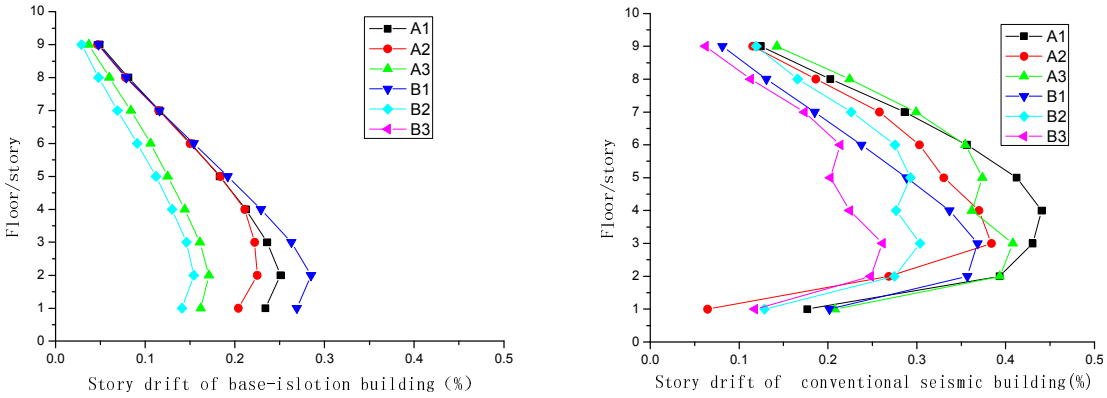

Fig.4 Story drifts response

## Conclusions

6 pulse-like velocity near-fault ground motions are selected as the input, and the seismic response of a 9 layers conventional seismic RC frame building and comparative base-isolation building with lead-core rubber bearings is obtained by nonlinear time history analysis. Compared with the conventional seismic building, the top floor acceleration response, the X direction maximum base shear and the story drift of base-isolation building significantly reduced. The result indicates that base-isolation building with lead-core rubber bearings are of good aseismic performance under the near-fault ground motions with velocity pulse.

**Keywords:** submarine flexible pipeline; seismic response; fluid-structure interaction; dynamic analysis

**Abstract.** Submarine pipelines are described as the lifeblood of offshore oil and it is crucial to ensure the seismic safety of the submarine pipelines. Based on the fluid-structure interaction numerical analysis method and by using finite element software ADINA, the analysis models of the free long-span submarine flexible pipelines under earthquakes were established. By employing dynamic time-history method, the influences of fluid-structure interaction on the seismic response of the submarine pipelines were researched. The results showed that the peak normal stress and the peak displacement of submarine pipelines' mid-span considering the influences of the fluid-structure interaction are greater than those without considering the influences, and the influences of the fluid-structure interaction on the seismic response of the submarine pipelines will increase with the increase of the submarine pipelines' diameter.

## Introduction

It's difficult to lay submarine pipelines, and maintenance is a burden as well. Submarine pipelines leakage will cause serious economic loss and marine environment pollution. Submarine pipelines are designed flat out on the bottom of the sea, but long span will occur due to the fact that current scour, submarine topography, pipeline stress concentration and so on [1,2]. And on dynamic performance, there is a big difference between land pipelines and submarine pipelines [3,4]. But there is no seismic design code of submarine pipelines at present [5]. In this paper, based on the fluid-structure interaction numerical analysis method and by using finite element software ADINA, the seismic response of free long-span submarine flexible pipelines has been studied, in order to explore the influences of the fluid-structure interaction on the seismic response of the submarine pipelines.

## Finite element model

### Model parameter

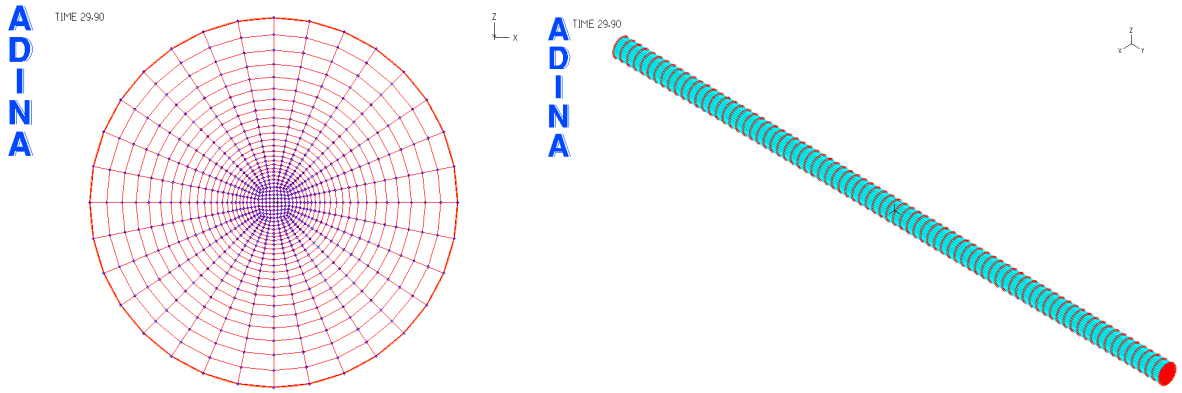
Four submarine pipelines whose diameters are 0.1m, 0.2m, 0.3m and 0.4 m were selected as the calculating model. Main parameters of the model are shown in Table 1.

Table.1. Main parameters of the model

| No | Main parameters | Unit | Value |
|---|---|---|---|
| 1 | Length of the pipe | $[m]$ | 30 |
| 2 | Density of the pipe | $[kg \cdot m^{-3}]$ | 7850 |
| 3 | Modulus of elasticity | $[GPa]$ | 200 |
| 4 | Diameter of the pipe | $[m]$ | 0.1~0.4 |
| 5 | Pipe wall thickness | $[m]$ | 0.01 |
| 6 | Poisson's ratio | – | 0.3 |
| 7 | Density of sea water | $[kg \cdot m^{-3}]$ | 1030 |

The whole calculation domain is a cylinder whose diameter is ten times more than submarine pipelines' diameter and both ends of submarine pipelines extended five meters. With infinite

boundaries to constrain the flow field, the Potential-based fluid element is used for the water and the number of Potential-based fluid is 49920. Consolidation is used to constraint the ends of submarine pipelines. The Shell element is used for submarine pipelines and the number of Shell is 2304. Calculation model is shown in Fig.1.



(a) Cross-section mesh (b) Whole mesh

Fig.1. Calculation model

**The earthquake wave input**

Three earthquake acceleration time-history curves were selected from PEER Ground Motion Database. Assuming that submarine pipelines are located in zone 9 degrees of seismic intensity, then each of the peak acceleration time-history curves were adjusted to 0.4g [6]. As shown in Table 2.

Table.2. Selected free-field ground motions

| No | earthquake record | location | PGA [g] | amplitude modulation index | interval |
|---|---|---|---|---|---|
| 1 | 1940 El Centro | Imperial Valley | 0.313 | 1.278 | 0.02 |
| 2 | 1994 Northridge | Hollywood | 0.245 | 1.633 | 0.01 |
| 3 | 1995 Kobe | Shin-Osaka | 0.212 | 1.887 | 0.01 |

**Calculated work condition**

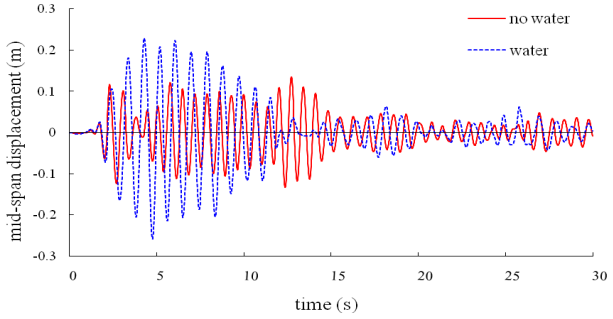
The finite element model has been analyzed in the following two conditions: (1) considering the fluid-structure interaction, three types of earthquake load have been applied to submarine pipelines; (2) not considering the fluid-structure interaction, three types of earthquake load have been applied to submarine pipelines.

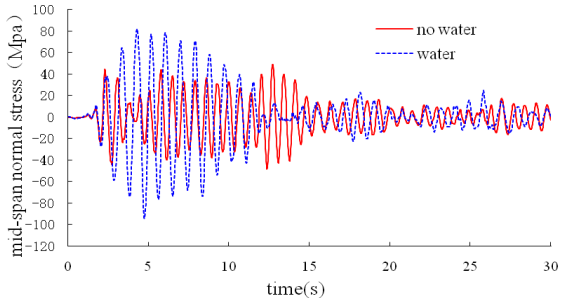
**Analysis of computing result**

According to the two kinds of working conditions, earthquake waves have been input along the X direction in the model. The seismic response time-history analysis has been completed. The normal stress and the displacement of the submarine pipelines' mid-span were the results which have been focused on.

The mid-span normal stress time-history curves and the mid-span displacement time-history curves of submarine pipelines which diameter is 0.2m under the action of three earthquake waves are shown in Fig.2~4.

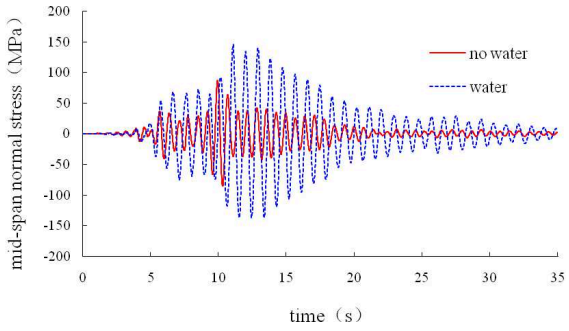
Figure.2~4 indicated that: (1) whether to consider the fluid-structure interaction or not , the changing trends of the mid-span normal stress time-history curve and the mid-span displacement time-history curve are basically identical; (2) the peak normal stress and the peak displacement of submarine pipelines' mid-span appeared at different moment in two the situations which considering the fluid-structure interaction and not considering, also the peak normal stress and the peak displacement of submarine pipelines' mid-span considering the influences of the fluid-structure interaction are greater than those without considering the influences.

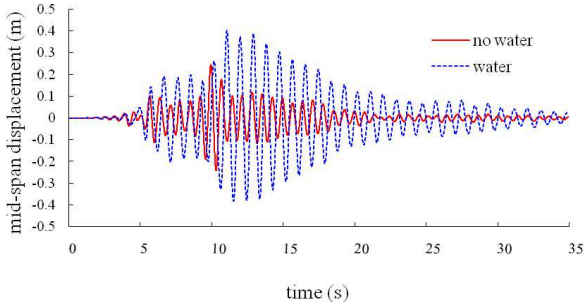




(a) The mid-span normal stress time history curve (b) The mid-span displacement time history curve

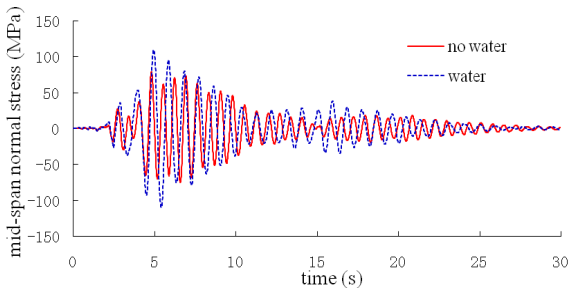
Fig.2. El Centro earthquake wave response

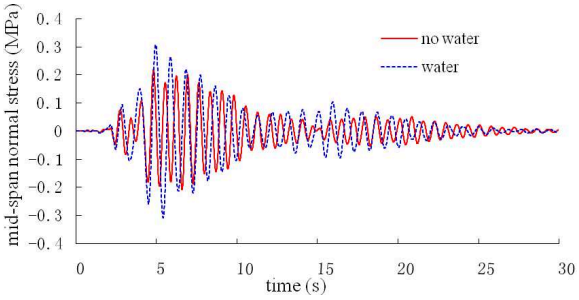




(a) The mid-span normal stress time history curve (b) The mid-span displacement time history curve

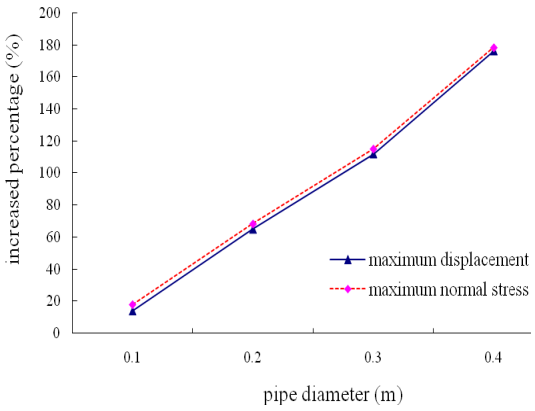
Fig.3. Northridge earthquake wave response

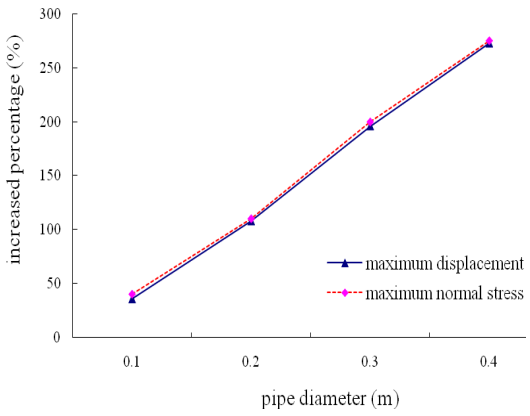




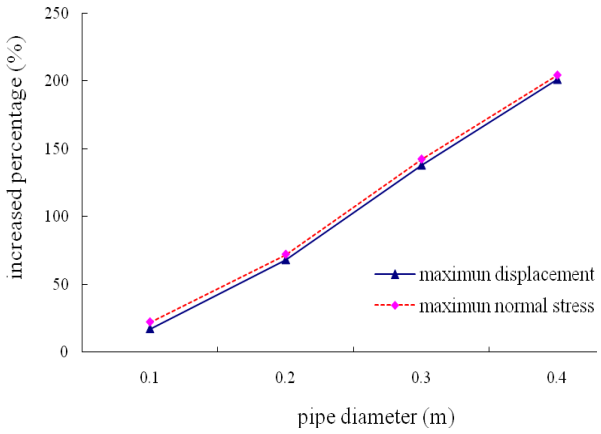
(a) The mid-span normal stress time history curve (b) The mid-span displacement time history curve

Fig.4. Kobe earthquake wave response





(a) EI Centro earthquake wave (b) Northridge earthquake wave



(c) Kobe earthquake wave
Fig.5. The increased percentage

The increased percentage of the maximum normal stress and the maximum displacement of submarine pipelines' mid-span considering the influences of the fluid-structure interaction were compared with the one that without considering the influences of the fluid-structure interaction are shown in Fig.5.

Figure.5 indicated that: the increased percentage of the peak normal stress and the peak displacement of submarine pipelines' mid-span showed growth trend with submarine pipelines' diameter. In other words, with the increase of the pipe diameter, the influence of the fluid-structure interaction on the seismic response of submarine pipelines will be greater.

## Conclusions

In this paper, based on the fluid-structure interaction numerical analysis method and by using finite element software ADINA, the seismic response of free long-span submarine flexible pipelines has been studied. The results showed that: (1) the peak normal stress and the peak displacement of submarine pipelines' mid-span considering the influences of the fluid-structure interaction are greater than those without considering the influences; (2) the influences of the fluid-structure interaction on the seismic response of the submarine pipelines will increase with the increase of the submarine pipelines' diameter.

**Keywords:** SRC frame-RC core wall, Earthquake Collapse, Collapse-resistant Design

**Abstract.** To study Steel reinforced concrete frame-reinforced concrete core wall (SRC frame-RC core wall) hybrid structure earthquake damage evolution and collapse mechanism, this paper holds the earthquake collapse mechanism, seismic collapse analysis and collapse control strategies as the mainline, establishes performance degradation and collapse criterion characterization based on structure dynamic characteristics, adopts incremental dynamic analysis (IDA) method to complete the prototype structure collapse-resistant test and quantitative assessment of seismic collapse analysis and determine the main factors that affect the structure collapse-resistant properties. Through numerical analysis to reveals the mechanism of the earthquake collapse and obtains optimal collapse model, and proposes methods and measures of collapse-resistant design for such structure, which has practical significance for enhancing the ability of high-level hybrid structure to earthquake.

## Introduction

Collapsed buildings caused heavy casualties in the earthquake, how to integrate the ideas of collapse-resistant design, seek reasonable collapse model of structural and improve the structure seismic collapse-resistant capacity is important. Steel and concrete composite structure have been widely used in high-rise buildings in recent decades with its high carrying capacity, excellent performances of ductility, SRC frame-RC core wall hybrid structures are more used in High-rise building in China. However, a lot have been built SRC frame-RC core wall hybrid structure have not been tested in strong earthquake, the corresponding structural design specification does not have specific provisions and technical requirements to prevent collapse, and lacking of information and research related to earthquake damage. Based on the research abroad, the research status, problems of SRC frame-RC core wall hybrid structures collapse-resistant performance were reviewed, and future research directions are suggested in this paper, which can provided a reference for SRC frame-RC core wall hybrid structure collapse-resistant design and seismic design.

## Research Status

The SRC frame-RC core wall hybrid structures have attracted extensive attentions from many scholars around the world. Through seismic performance experiments and numerical simulation of hybrid structure, scholars researched the seismic response and failure characteristics, experimental model, seismic calculations, which can provide the basis for the seismic design criteria and construction requirements for seismic design. Xilin Lv et al. [1] and Peifu Xu et al. [2] conducted a lot of tall frame-core wall structure quasi-static test or simulated earthquake shaking table according to the actual project respectively.

David [3], Graham [4], Xinzheng Lu et al. [5] applied high-precision numerical finite element model to analysis structure seismic collapse, Park [6] proposed earthquake damage assessment model based on the principle of energy, Leiming Zhang et al. [7] put forward agency guidelines as a criterion for judging the structure collapse. Sasani [8] verified the capacity and the existing evaluation methods of structure to resistant progressive collapse by experimental method.

## Existing problems

Although many scholars' research had show that through rational design, SRC frame-RC core wall hybrid structure are fully able to meet current seismic requirements, but such structure engineering applications there have been some problems to be solved:

1) The lateral stiffness of the frame and the concrete core wall is difference, and the concrete core wall borne the most earthquake action. Under rare earthquake, plastic hinges mainly appear on the concrete core wall, the plastic hinge mechanism is unfavorable to seismic, once the core wall occurs large deformation and serious damage, the outer frame will cause instability or partial collapse of the entire structure.

2) Current research on the hybrid structure most contrary to a particular practical engineering structures, the existing research does not clearly reflect the collapse mechanism of such structures under earthquake, can not accurately assess the influence of various factors for collapse-resistant properties of such structure. With the refinement of experimental methods, to accurately reproduce the mechanical behavior of the structure during the earthquake, the damage evolution and the development process of collapse under destruction is an effective method, which is the foundation to propose effective and feasible strategy to control SRC frame-RC core wall structure failure mode.

3) Structural collapse is a complex numerical process from continuum to non-continuum, numerical models have high demands, most current numerical simulation research focused on the overall collapse of the seismic behavior, and more concentrated in SDOF frame structure on the overall level of collapse, for tall frame-core wall hybrid structures collapse simulation studies under earthquake are less.

4) Currently the judgment criteria and evaluation indicators suitable for SRC frame-RC core wall hybrid structure earthquake collapse are less, the existing guidelines can't reflect effects of the load magnitude and action path changes to structure cumulative damage, due to the structural collapse is a complex unstable problems, collapse criterion and damage assessment indicators of SRC frame-RC core wall hybrid structure should be identified in the overall hierarchy.

## Collapse-resistant design

Future studies on the collapse-resistant of SRC frame-RC core wall hybrid structure should hold the collapse mechanism of earthquakes, seismic collapse analysis and collapse-resistant design countermeasures as the main line, the research technology roadmap shown in Fig.1

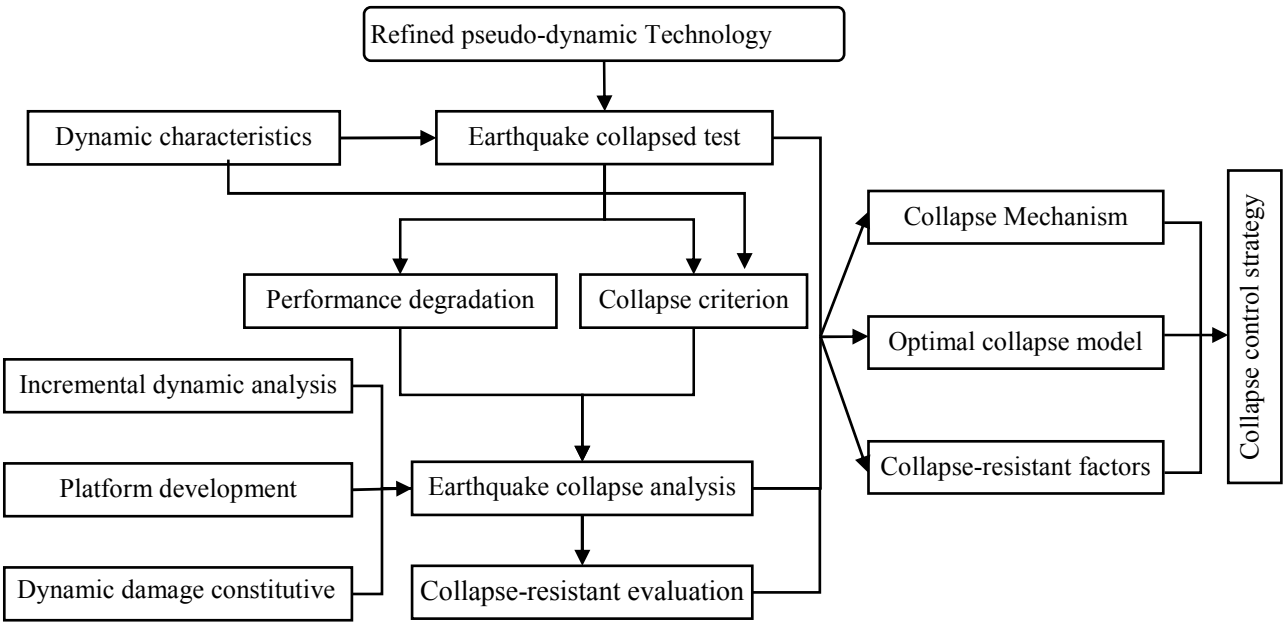

Fig. 1 The main line and research technology roadmap

**1) Conduct earthquake collapse experiment of SRC frame-RC core wall hybrid structure based on pseudo dynamic technology.** Conduct SRC frame-RC core wall hybrid structures scale model pseudo dynamic experimental study, to simulate complex mechanical behavior and collapse process of such hybrid structures under earthquake damage. By experiment to explore the structural damage path, the collapse mechanism and the collapse criterion under the earthquake, to study collaborative work performance of RC core wall and SRC frame under different ground motion parameters and different force stage.

**2) Establish structural seismic collapse criterion based on structural dynamic characteristics.** Structural collapse is a very complex nonlinear dynamic process, describe the structure damage performance and degradation characteristics under cyclic loading based on structure dynamic characteristics is the trend of future development. Through quantitative assessment by studying the changes of structural frequency from damage to collapse under earthquake, taking into account higher mode effects on seismic response, leading into modal participation factor, building relationships with structural degradation rate between the dynamic characteristics, further to establish characterization methods and collapse criterion to access the performance degradation based on the frequency of the vibration mode.

**3) Numerical analysis of seismic collapse of SRC frame-RC core wall hybrid structures.** Based on the finite element method, considering the element nonlinear numerical model (element birth and death) and the contact nonlinearity, considering the bond-slip behavior of steel and concrete according to preliminary basic research, by secondary development, introducing structural collapse criterion based on dynamic characteristics, to have a better results when the simulated structure from the continuous state to a fully discrete state status.

**4)Adopt incremental dynamic analysis (IDA) methods to assess the performance of collapse-resistant.** The structure elastic-plastic differential equation of motion is

$$[M]\{\ddot{x}(t)\}+[C]\{\dot{x}(t)\}+[K]\{x(t)\}=-[M][R]\{\ddot{x}_g(t)\} \tag{1}$$

where $[M]$, $[C]$, $[K]$ are the global mass matrix, viscous damping coefficient matrix, stiffness matrix respectively; $[R]$ is the unidirectional ground motion direction cosine column vector; $\{\ddot{x}(t)\}$, $\{\dot{x}(t)\}$, $\{x(t)\}$ are the acceleration, velocity, displacement of structure relative to the ground at t; $\{\ddot{x}_g(t)\}$is the ground motion acceleration at t. Formula (1)at $t+\Delta t$ moment also is established,

$$[M]\{\ddot{x}(t+\Delta t)\}+[C]\{\dot{x}(t+\Delta t)\}+[K]\{x(t+\Delta t)\}=-[M][R]\{\ddot{x}_g(t+\Delta t)\} \tag{2}$$

We can obtain the structure incremental motion equations with Formula 1 subtracts Formula 2,

$$[M]\{\Delta\ddot{x}\}+[C]\{\Delta\dot{x}\}+[K]\{\Delta x\}=-[M][R]\{\Delta\ddot{x}_g\} \tag{3}$$

Where $\{\Delta\ddot{x}\}=\{\ddot{x}(t+\Delta t)\}-\{\ddot{x}(t)\}$, $\{\Delta\dot{x}\}=\{\dot{x}(t+\Delta t)\}-\{\dot{x}(t)\}$, $\{\Delta x\}=\{x(t+\Delta t)\}-\{x(t)\}$, $\{\Delta\ddot{x}_g\}=\{\ddot{x}_g(t+\Delta t)\}-\{\ddot{x}_g(t)\}$

The IDA method based on the above equation(3), by inputting the gradually incremental seismic records intensity, until structural damage calculation model collapses, hold the ground motion intensity measures(IM) as indicators of structural collapse-resistant, to evaluate structure seismic collapse-resistant, When $N_c$ earthquakes recorded (the total number record is $N_t$) collapsed at a ground motion intensity, the $N_c/N_t$ called the structure collapse possibility under ground motion intensity. The ATC-63 Committee [9] suggests

$$IM=S_a(T_1)/S_a(T_1)_{MEC} \tag{4}$$

Where $S_a(T_1)$ is the structure first period spectral acceleration, $S_a(T_1)_{MEC}$ the structure first period design spectral acceleration to criterion under Maximal Considered Earthquake, for china seismic code

$$S_a(T_1)_{MEC} = \alpha(T_1)_{MEC} g \quad (5)$$

Where $\alpha(T_1)_{MEC}$ is the horizontal seismic influence coefficient to period $T_1$ under maximal considered earthquake (MCE), and $g$ is acceleration of gravity.

Apply IDA method based on nonlinear dynamic time history analysis, by introducing material dynamic damage constitutive, considering initial damage and damage evolution in the analysis process, to find out the SRC frame-RC core wall properties and response under different earthquake intensity. Through statistical analysis of structural response-seismic strength parametric curves and combining with structural collapse criterion, to determine the critical earthquake standards.

5)**Analysis of SRC frame- RC core wall hybrid structure collapse-resistant factors and collapse control.** Based on the seismic collapse test and IDA results, conducting local and global sensitivity parameters analysis for the overall structure collapse-resistant capability, to definite the Structure collapse-resistant capability under multi-parameter coupling, get the best collapse-collapse-resistant mode and put forward collapse-resistant design countermeasures for such structure

## Conclusion

In this paper, SRC frame-RC core wall hybrid structures collapse-resistant under earthquake, the research status and existing problems are analyzed. Through prototype structure model collapse-resistant test, the IDA method and numerical analysis to set up collapse mechanism, collapse criterion, reveal dynamic catastrophic failure mechanism, and propose quantitative evaluation method of collapse-resistant and collapse-resistant design measures.

**Keywords:** specially shaped column; RC frame; nonlinear seismic response analysis; seismic performance

**Abstract:** According to the code and technical regulation, a irregular RC frame with specially shaped columns have been designed, which situated at the area of fortification intensity 7. Subsequently, the nonlinear dynamic analysis has been carried out for the structure by inputting ground motions in two directions. After summing up the calculation results, this paper have examined seismic performance of the structure under the rare seismic actions and given a primary evaluation on the structure to see if it achieves the predetermined seismic aims. It indicates that the structure designed the codes can achieve the predetermined seismic aims under the rare earthquake.

## Introduction

In recent years, a lot of experimental research and theoretical analysis have been done on the frame structure of special-shaped reinforced concrete columns, due to the urgent needs of engineering practice. Experimental studies were focused on special-shaped column member and the frame structure model shaking table tests. Although the small number of trials have been done on the overall structure, also obtained some of research results. Existed experimental studies show that the frame structure of special-shaped columns is in the elastic stage with the input of small earthquakes, the shape of deformation curve is a type of flexure-sheer, between the wall and the general framework. The structure of shaped column has better integral stiffness and self lighter. The frame with specially shaped columns lack of earthquake-resistant performance embody in some aspects that cross-section with a serious asymmetry, core region of the node is relatively weak, the section weakened severely after the concrete cover fall off, cross-section design needs improvement and so on.

However, due to experimental study under restriction of equipment and funding, it is unpractical to conduct a series larger size of over-all structure of dynamic or static tests. At present it is not deep enough for study that nonlinear analytical method of integral space of the frame with special-shaped columns. There is not a nonlinear analytical method and tool to reflect main stress characteristics of structure with reinforced concrete special-shaped columns and has been widely recognized. Elasticoplastic deformation of structure can not be practical, there is unclear to whether the design of structure can meet requirements for earthquake fortification of " no collapse under major earthquake". Therefore , it is necessary to carry out research for special seismic non-linear dynamic response analyses of the frame with shaped columns. This article use finite element flexibility method based on fiber model beam-column elements to adopt triaxial non-linear earthquake response analyses on the frame construction with irregular shaped columns under the action of mono directional lateral earthquake and inspect earthquake-resistant behavior of the frame in accordance with the specifications designed under the rare earthquake level.

## Analytical mode

According to the code and technical regulation in Chinese, a irregular RC frame with specially shaped columns have been designed, which situated at the area of fortification intensity 7(0.10g). Fundamental natural period of structure is 0.84 second. Figure.1 show layout of the structure and Reinforcement in columns and beams.

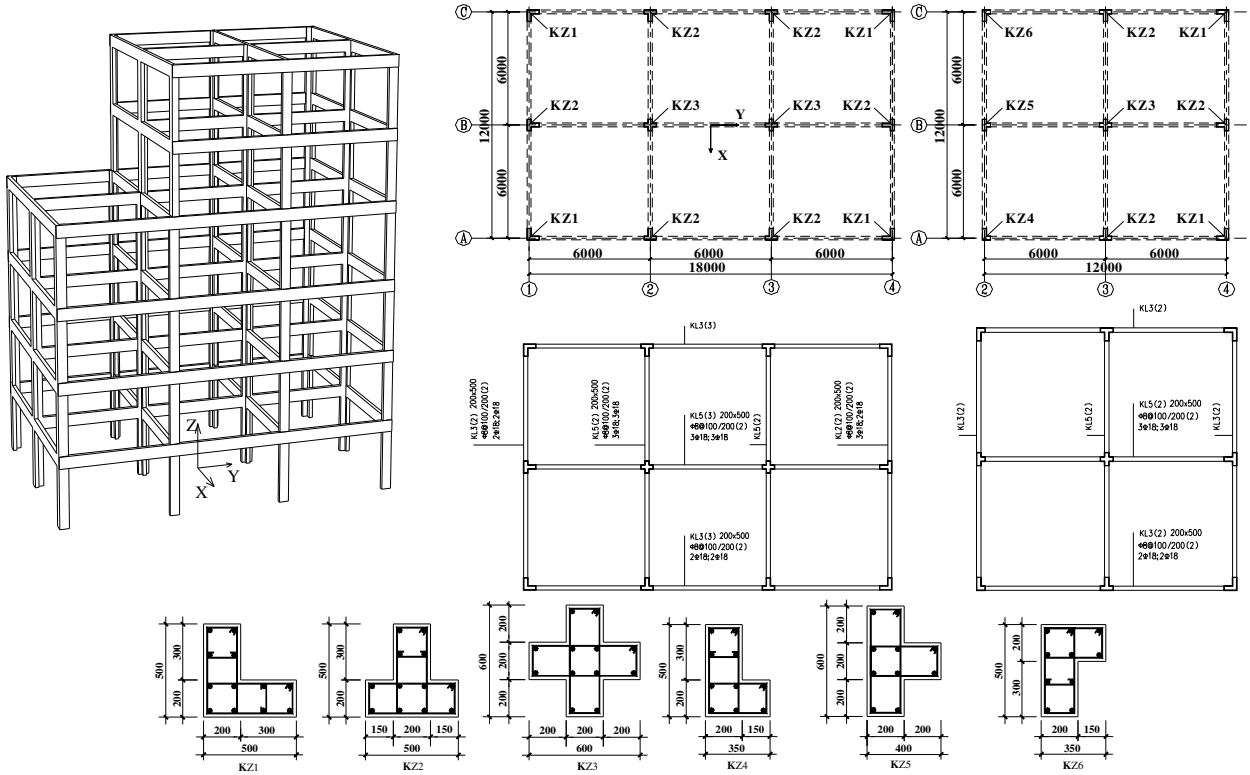

Fig.1 Layout of the structure and Reinforcement in columns and beams

Use SAP2000 to calculate elastic horizontal shift for structure. Maximum inter-story drift angle of the structure is 1/1181 under frequent earthquake, satisfy the requirement of design specification (1/550). And the calculative results show in the Table 2, which show that the structure is torsional irregularity.

Table 1 Ratio of the floor's maximum inter-story drift and the mean inter-story drift

| Floor | 1 | 2 | 3 | 4 | 5 | 6 |
|---|---|---|---|---|---|---|
| Ratio | 1.18 | 1.19 | 1.20 | 1.21 | 1.18 | 1.17 |

The axial-load ratio of L shaped,T shaped,cross-shaped column are 0.34,0.55,0.70, not in excess of the specified limits of the axial-load ratio 0.50,0.55,0.70.

This article adopt nonlinear dynamic analytic procedure of fiber model of beam-column elements formation based on flexibility method that cross-section of beam-column element is discretized into a number of vertical fiber, ignoring the shearing effect and considering each fiber in a unidirectional stress The fiber model also consider lateral constrained influence in the uniaxial stress-strain relationship, and use plane-section assumption to create beam-column element stiffness matrix for calculating the nonlinear relationship of force and deformation of the total cross section on the basis of uniaxial stress-strain relationship of corresponding fibrous materials. Analytical procedures used in this article has been verified efficiency and accuracy of analysis on the level of general rectangular column member and structure. This program not only can output stem end force and displacement of unit, but also output each specified internal force and deformation of section and the value of stress-strain of the fibers, which can fully examine response of macro and micro levels for structure.

This article select "3+1" waves, crude seismic wave which distinguish are USA00641, USA00707, IND00364, artificial wave is ACC5. Use SAP2000 to conduct response spectrum analysis and

elastodynamic time history analysis for structure, checking whether chosen seismic wave satisfy afferent requirement of criterion. The calculative results show in the Table 2, chosen seismic wave can well satisfy the requirement of criterion.

Since the structure of irregular layout , two horizontal directions on the selected seismic waves are input along the X and Y direction, while the amplitude ratio in X and Y direction is 1:0.85.

Table 2 Base shear by elastic dynamic analysis and modal analysis at seismic intensity 7(0.10g)

| wave | USA00641 | USA00707 | IND00364 | ACC5 |
|---|---|---|---|---|
| Shear of response spectrum analysis | | 206 | | |
| Shear of elastodynamic history analysis | 187 | 181 | 169 | 201 |
| Ratio | 0.91 | 0.88 | 0.82 | 0.98 |
| Average ratio | | 0.90 | | |

## Organization of the Text

In this paper, the response from the overall performance of the structure (such as inter-story drift angle, inter-story twist angle) to a single member state (such as the moment-curvature relationship of cross-section, the stress and strain of fiber) will be inspected. Since only input the ground motion along the X-axis under the rare earthquake, examine the response along X-axis of the structural response.

The maximum inter-story drift angel, inter-story twist angel and the maximum displacement are shown in Table 3, Figure.2 and Figure.3. The ratio of the maximum inter-story drift of the two edges and the mean inter-story drift are shown in Table 4. The moment-curvature of the column of the first floor and the beam of the second floor are shown in Figure.4(only USA00707) . The maximum strain of fiber structural beams and columns are shown in Table 5 after inputting four seismic wave(peek acceleration is 2.2m/s$^2$).

[1]—the first floor [2]—the second floor

Table 3~5,Fig. 2~4 refer:

1. The maximum inter-story drift angel, twist angel and displacement of the structure on four waves: the inter-story drift of the both edges in each story is diffrernt, the maximum inter-story twist

angel of each story is 0.00086rad(as there is the difference of 15.48mm in the maximum displacement between two edges of the first floor at the same time); the maximum inter-story drift angel of left edge and right edge is 1/259 and 1/156, the maximum displacement is 60.7mm, equivalent 1/297 to the total height; the maximum ratio of the maximum inter-story drift of the two edges and the mean inter-story drift is 1.32, and occur in the fourth floor.

2. The moment-curvature of beams and columns: the beams all have not yielded during the process; the columns all have yielded, but each degree is not deep.

3. The strain of beam and column section: For the beams, either the maximum concrete compressive strain or maximum reinforced tensile strain occur in the second floor. The maximum compressive strain which is 0.0110 has a far distance from the ultimate compressive strain of concrete witch is 0.004. The maximum tensile strain of reinforced which is 0.00163, has a certain distance from the yield tensile strain of reinforced. For the columns, the middle column has a larger compressive strain than the side column and the side column has a larger compressive strain than the corner column. The maximum compressive strain which is 0.00329 has a certain distance from the ultimate compressive strain which is 0.004. But the corner column has a larger tensile strain of reinforced than the middle column and side column. The tensile strain of reinforced is 0.00258, which is 1.3 times of the yield tensile strain of reinforced.

## Conclusions

On the basis of the nonlinear seismic response analysis of reinforced concrete frame with shaped columns, refers to the relevant norms, procedures and documentation, the evaluation results of the overall seismic behavior are as following:

1. The evaluation of seismic behavior according to the general failure criteria:

For the fortified target “no collapsing with strong earthquake”, the overall evaluation of structural failure criterion adopts the allowance of inter-story drift angel is 1/65. Under the rare earthquake, the maximum inter-story drift angel of left and right edge is 1/259 and 1/156. Therefore, according to the general failure criterion, the structure accordance with the code and technical regulation in Chinese in 7(0.10g) degree zone can meet the target of “no collapsing with strong earthquake”.

2. The evaluation of seismic behavior according to the local failure criteria:

Under the rare earthquake action, the steel in the ground floor columns are different levels of yield, while the compressive strain of concrete has quite a distance from the ultimate compressive strain; the steel in all beams has not yielded.And the moment-curvature hysteretic curve of beams and columns has not yielded obviously. Therefore the structure can meet the “no collapsing with strong earthquake” request. But according to the sequence of the emergence of the hinges, the beam-hinge doesn’t emerge while the column-hinge emerges in the bottom of columns. So the sturcture can’t form a beam-column hinge energy dissipation mechanism of beam-hinge energy dissipation first, column-hinge energy dissipation secondary. The bearing capacity doesn’t reduce significantly under rare earthquake.

In summary, according to the current design specification and technical regulations in chinese, the reinforced concrete frame with shaped columns of fortification intensity 7(0.15) degree, site Ⅱ, first set of the classification of design earthquake can basically meet the request “ no collapsing with strong earthquake”.

**Keywords:** Slope; Frame structure; Soil-structure interaction; Seismic wave; Seismic response

**Abstract:** The seismic response of step-terrace frame structure is affected by the slope. Considered soil parameters of slope, the floor numbers and span numbers of layers below the scarp, 45 step-terrace frame example structures were designed, and three excitations at bedrock were selected to analyze the example structures response with dynamic time-history analysis method. The research indicates that when the other conditions are the same, the soil becomes softer, or structure's span numbers on the slope becomes larger or the slope becomes higher, the dynamic interaction between slope and step-terrace frame structure becomes more obvious. When the inputted ground motion at slope foot is adopted and the slope soil is soft, the seismic response of structure without soil-structure interaction is smaller than that of with soil-structure interaction.

## Introduction

Step-terrace frame structure refers to the structure whose foundation is on two or more different elevations and the structure's bottom is connected to different level of foundations. This kind of structure makes good use of the slope height space, reduces the excavated slope volume and has some applications in mountain city. Compared with ordinary frame structures, step-terrace frame structures have particularities in seismic design. Liu Li-ping et al.[1] summarized the existing hillside building structure and put forward the problems we should pay attention to in seismic design of the hillside building. Wang Li-ping et al.[2] studied methods to control lateral stiffness in step-terrace structure and put forward some suitable norms of the lateral stiffness controlling for step-terrace structure, and design suggestions were given in the paper. Zhao Yao et al.[3] put forward a simplified analytical model for step-terrace structure and analyzed the problems of anti-overturning stability. Shan Zhi-wei et al.[4] preliminarily discussed whether there exist any differences on seismic response of step-terrace structure between the whole analytic model with the soil-structure interaction considered and the model with the bottom fixed, which showed that soil - structure interaction had a significant effect on the seismic response of step-terrace structure. The existing research about step-terrace structure focuses primarily on the seismic response and seismic performance control, etc. Step-terrace frame structure's seismic response is inevitably affected by slope, so it is necessary to regard the slope and step-terrace frame structure as a system to analyze the seismic response characteristics.

Focusing on the research and realization of step-terrace frame structure on the slope, this paper analyzed the seismic response characteristic of the step-terrace frame structure when soil parameters of slope and the floor number and span number of layers below the scarp changed, to provide theoretical basis for seismic design of step-terrace frame structures.

## Analytical Model

Slope and slope toe within 1 meter are assumed to be composed of soil mass, and bedrock below. Step-terrace frame structure crosses between the slope crest and slope toe. As shown in figure 1, an analytical model of step-terrace frame structure on the slope system was built. The sides of the analytical model used free boundary. In order to reduce the influence on seismic response by artificial boundary, the calculation range of both side boundaries was set to 1200m. The bottom used fixed boundary to simulate bedrock. Besides, the damping in analytical model used Rayleigh damping. The ground motion was inputted at the bedrock surface. In order to take consideration of the interaction between slope and Step-terrace frame structure under the seismic action, different heights of slopes and different soil parameters of slopes were designed. The total floors' number of structure remained constant, varying the floor number and span number of layers below the scarp was adapted to the variation on height of slope and scope influenced by slope.

According to the paper[5], USA00418, USA03011, USA03028(three bedrock waves) were chosen as inputted ground motion, besides, their amplitudes were modulated to 0.18m/s$^2$, as shown in figure 2.

Fig. 2 Seismic acceleration time-history for the analytical model

## Example Design

Considered soil parameters of slope, the floor number and span number of layers below the scarp, 45 examples were designed which include 5 types of soil parameters and 9 types of structures. Soil parameters of slope are shown in Table 1. All of the structures are 9 floors. The number of layers below the scarp is 1, 3, or 5 respectively, and the span number of layers below the scarp is 1, 2 or 3respectively. Frame structures' parameters are shown in Table 2, where the beams' density is an adjusted density.

The thicknesses of frame structures' floor and roof plates are both 150mm. Live load on floors is 2kN/m$^2$. Live load on roofs is 0.5kN/m$^2$. Beams' bearing load width is 6m. Considered the contribution of dead load and live load on the bearing range of plates which was resulted by the seismic action, an adjusted density was used instead. T-shaped beams whose flange widths were 2m were used to take place of primary frame beams to consider the contribution made by floor plates to the stiffness of beams. The foundations of the frame structure used piles whose diameters were 800mm, and their strength grade of concrete was C30.

The examples were named as XX-X-X, which respectively represent the soil type of slope, the floor number of layers below the scarp and the span number of layers below the scarp. Soil types were written as TA, TB, TC, TD,D, which respectively represented the soil type A, B, C, D and rock. For example, TA-3-2 means the slope's soil type is A, its number of layers below the scarp is 3, and its span number of layers below the scarp is 2.

Table 1 Soil Parameter of Slope

| | Elasticity modulus (MPa) | Poisson's ratio | Density ($kg/m^3$) | Shear wave velocity(m/s) | Damping ratio |
|---|---|---|---|---|---|
| Soil A | 70 | 0.3 | 2000 | 116 | 0.05 |
| Soil B | 200 | 0.3 | 2000 | 196 | 0.05 |
| Soil C | 600 | 0.3 | 2000 | 339 | 0.05 |
| Soil D | 1400 | 0.3 | 2000 | 519 | 0.05 |
| Rock | 6500 | 0.3 | 2500 | 1000 | 0.05 |

Table 2 Material Parameters of Structure

| Type | Floor number | Section size (mm x mm) | Concrete's strength grade | Elasticity modulus ($10^4N/mm^2$) | Adjusted Density ($kg/m^3$) | Damping ratio |
|---|---|---|---|---|---|---|
| Columns | 1-4 | 650x650 | C30 | 3.0 | 2400 | 0.2 |
| Columns | 5-9 | 550x550 | C30 | 3.0 | 2400 | 0.2 |
| Roof beams | 9 | 500x250 | C30 | 3.0 | 11100 | 0.2 |
| Floor beams | 1-8 | 500x250 | C30 | 3.0 | 9600 | 0.2 |

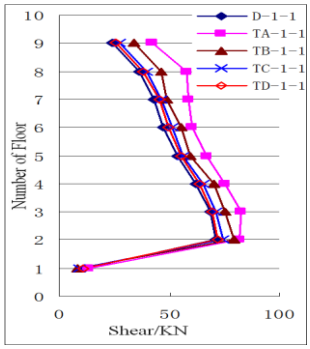
**Seismic Response Analysis**

Three bedrock waves (in Fig.2) were selected to the 45 examples for the dynamic time-history analysis. The average results of the 3 wares were putted forward. The peak value of story shear and peak value of inter story displacement of 9 structures with different soil parameters were comparative analyzed.

**Story Shear**

The peak value of seismic story shear of 9 structures with different soil parameters are shown in Fig.3. From Fig.3a to Fig.3i, it is visible that the seismic story shears of the structures on the slope with different soil parameters which change from soft to hard has been gradually reduced. The peak value of seismic story shear of structure on the rock slope is small. It illustrates that when the other conditions are the same, if the soil of slope becomes softer, it can result the dynamic interaction between slope and step-terrace frame structure becomes more obvious. Compared among Fig.3a, Fig.3b and Fig.3c, it's shown that the more the structure spans' number on the slope is, the larger the seismic story shear is when the soil parameters of slope are the same. It illustrates that when the other conditions are the same, if structure's span number on the slope becomes more, it can result the dynamic interaction between slope and step-terrace frame structure becomes more obvious. Compared among Fig.3a, Fig.3d and Fig.3g, it's shown that the higher the slope is, the lager the seismic story shear is when the conditions of slope soil parameter and structural height are the same. It illustrates that when the other conditions are the same, if the slope becomes higher, it can result the dynamic interaction between slope and step-terrace frame structure becomes more obvious.

It is shown that the seismic story shear of the structure on rock slope is the smallest while the structure on soil slope is the largest when the inputted ground motion at slope foot is adopted. It illustrates that without considering the slope and structure's dynamic interaction the calculated seismic story shear becomes smaller when the ground motion is inputted at the slope foot, so it tends to be unsafe with this calculation method.



(a) 1 layer and 1 span below scarp

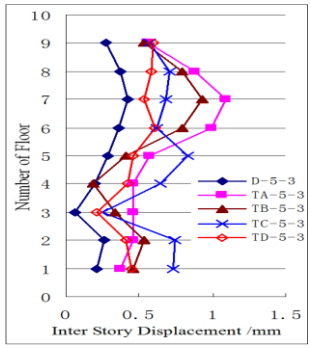
(b) 3 layer and 2 span below scarp



(c) 5 layer and 3 span below scarp

Fig. 4 Peak value of inter story displacement of those structures with different soil parameters

**Inter Story Displacement**

The peak value of inter story displacement of those structures with different soil parameters are shows in Fig. 4. The rules are similar to the structure example's seismic story shear in Fig.3. The softer the soil is, the larger the inter story displacement is when the structure is in the same condition. The larger the structure spans' number on the slope is, the larger the inter story displacement is when the soil parameters of slope are the same. The higher the slope is, the lager the inter story displacement is when the conditions of slope soil parameter and structural height are the same. Those further illustrate the interaction between slope and step-terrace frame structure can't be ignored under the seismic action.

## Conclusions

Through analysis of the 45 step-terrace structure on the slope examples, conclusions are as follows:

(1) When the other conditions are the same, if the soil of slope becomes softer, or structure's span number on the slope becomes more or the slope becomes higher, it can result the dynamic interaction between slope and step-terrace frame structure becomes more obvious.

(2) When the slope soil is soft, slope has a great effect on seismic response of the step-terrace frame structure, dynamic interaction between the slope and step-terrace frame structure can't be ignored.

(3) When the inputted ground motion at slope foot is adopted and the slope soil is soft, the seismic response of structure without soil-structure interaction is smaller than that of with soil-structure interaction.

**Keywords:** curved girder bridges; seismic response; finite element model; regular bridge simplification conditionspublisher to produce a keyword index.

**Abstract.** A radius of curvature 20 times greater than the deck width of the bridge (R≥20b) is required as a specification in the regular bridge simplification conditions of the seismic response of curved girder bridges. Selecting benchmark bridges and employing parameter analysis method, this article studies on the effect of R/B value of the curved girder bridge on the response ratio of the seismic response calculated using the finite element model and that using a regular girder bridge. This study shows that on conditions that the deck width of the bridge is constant, the smaller the radius of curvature and the larger the B/R value (i.e., the smaller the R/B value) of the curved girder bridge are, the greater the difference between the seismic response of the curved girder bridge and the result calculated with a regular girder bridge is, and the difference is more significant under traverse seismic effect than that of longitudinal seismic effect. On conditions that the radius of curvature is constant, the impact of the change of B/R value due to the deck width change of the bridge on the difference between the seismic response of the curved girder bridge and the result calculated with a regular girder bridge is insignificant. Compared with the deck width of the bridge, the difference between the seismic response of the curved girder bridge and the result calculated with a regular girder bridge is more sensitive to the radius of curvature.

## Introduction

Curved girder bridges can well overcome the limits of topographical and ground object and satisfy the continuity of the overall route alignment, and they are extensively applied in urban viaducts, interchanges projects and high-grade highways both domestically and abroad. Due to the structural properties, curved girder bridges greatly differ from straight girder bridges when under stress. “Bending-torsion coupling” effect is dominant in curved bridges, and the greater the curvature is, the more significant the coupling effect becomes. In particular, such bending-torsion coupling effect is amplified by the ground motion, as to make the damage to the curve girder bridge duo to seismic effect more severe.

To date, studies on seismic response of curved girder bridges mainly focus on two aspects: the determination of the worst input angle of the seismic wave and the determination of the principles in the simplified anti-seismic computation of curved girder bridges [1~4], but there are fewer studies on the ratio of the radius of curvature to the bridge width [5~9].Regarding regular girder bridge simplification conditions in the seismic response of curved girder bridges, this article studies the effect of the ratio of the radius of curvature to the deck width of the bridge on the seismic response, employing as the benchmark the response ratio of the seismic response of the straight bridge finite element model to the result calculated with a regular girder bridge.

## The regular girder bridge simplification of the benchmark bridge

Straight girder bridges with deck width of 10.5 m, 5.25 m and 21 m respectively are chosen as benchmark bridges in this article.

Typical highway single-spaned concrete straight box girder bridges are chosen as benchmark bridges, and finite element modeling is performed using MIDAS. The elevation view, the cross sectional view and the main girder sectional view are shown in figures. 1, figures. 2 and figures. 3.

Setting B type as the bridge type, 0.45 s as the group characteristic period, type II as the ground type, level 7 as the fortification level, and 0.1 g as the peak value of the basic ground motion acceleration in horizontal design, the maximum of the acceleration response spectrum in horizontal design can be derived that $S_{\max} = 0.1g$ .

The piers are solid rectangular ones, with height of 11.7 m. The width of the pier bases is 1.3 m along the bridge and 2.8 m across the bridge. Two piles with diameter of 1.5 m and length of 43.5 m are chosen as the base. The total height of the pedestal and padstone is 0.3 m, the layout of pedestals are fixed ones and shifting ones along the bridge, and pedestals across the bridge are all fixed ones. The upper structure applies C50 concrete, the piles apply C40 concrete, and the deck pavement of the bridge adopts asphalt concrete with thickness of 10 cm.

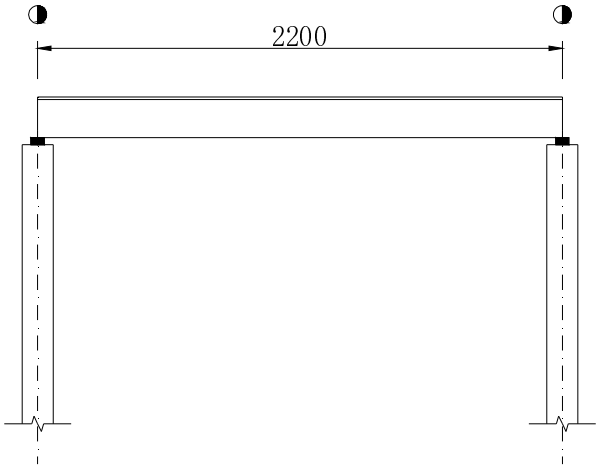

Fig. 1 Elevation view of the bridge (unit: cm)

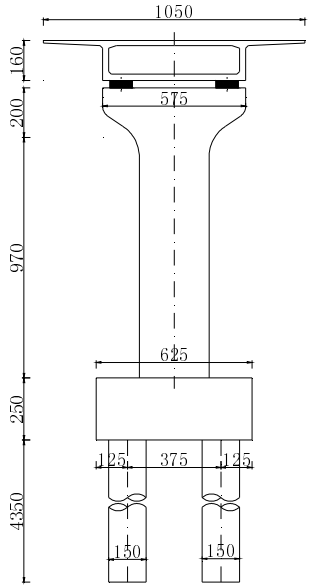

Fig. 2 Cross sectional view of the bridge (unit: cm)

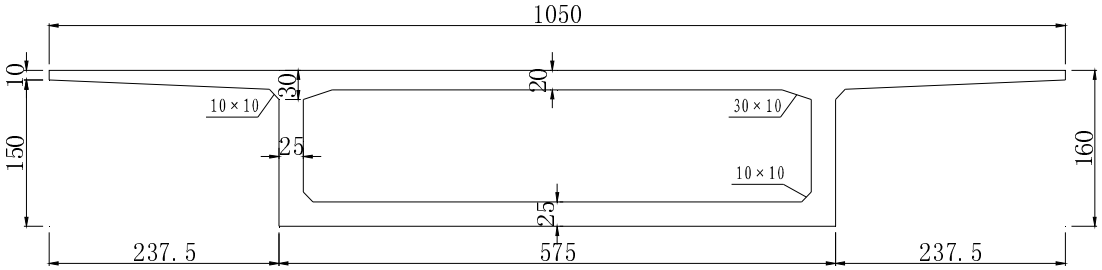

Fig. 3 Sectional view of the main girder (unit: cm)

All the main girders and piers of the bridge are modeled using beam elements. The self-mass is converted by lumped mass. The second phase load is also converted into mass. The rigidity of the pedestals in three rotational directions is set to 0. For the degree of freedom in three translational directions, the large-scale rigidity is set for the constrained degree of freedom, and the sliding degree of freedom is set to be 0.The piers and pile caps are in rigid connection, and the bases are modeled as a six-spring model.

**Target parameter analysis of seismic response**

Introduce straight girder bridges for comparison, set the target parameter as the reciprocal (B/R), and the radius of curvature of the straight bridge here is regarded as $R = \infty$ .Change the target parameters in two cases: (1) keep B constant, and the value of B/R changes with R; (2) keep R

constant, and the value of B/R changes with B. The following is presumed: (1) the benchmark straight girder bridge is regarded as a model free of error, i.e., the response ratio of the result calculated with a regular girder bridge to that calculated using finite elements is taken as the benchmark; (2) The sum of the pier base bending moment along the bridge and across the bridge is taken as the combined bending moment of the pier top.

Table 1 The finite element model parameters list

| | R(m) | B(m) | R/B | B/R | Central angle(°) | Girder length(m) |
|---|---|---|---|---|---|---|
| Model 1 (benchmark) | ∞ | 10.5 | ∞ | 0 | ∞ | 22 |
| Model 2 | 210 | 10.5 | 20 | 0.05 | 6 | 22 |
| Model 3 | 105 | 10.5 | 10 | 0.1 | 12 | 22 |
| Model 4 | 52.5 | 10.5 | 5 | 0.2 | 24 | 22 |
| Model 5 | 26.25 | 10.5 | 2.5 | 0.4 | 48 | 22 |
| Model 6 (benchmark) | ∞ | 5.25 | ∞ | 0 | ∞ | 22 |
| Model 7 | 210 | 5.25 | 40 | 0.025 | 6 | 22 |
| Model 8 | 105 | 5.25 | 20 | 0.05 | 12 | 22 |
| Model 9 | 52.5 | 5.25 | 10 | 0.1 | 24 | 22 |
| Model 10 | 26.25 | 5.25 | 5 | 0.2 | 48 | 22 |
| Model 11 (benchmark) | ∞ | 21 | ∞ | 0 | ∞ | 22 |
| Model 12 | 210 | 21 | 10 | 0.1 | 6 | 22 |
| Model 13 | 105 | 21 | 5 | 0.2 | 12 | 22 |
| Model 14 | 52.5 | 21 | 2.5 | 0.4 | 24 | 22 |
| Model 15 | 26.25 | 21 | 1.25 | 0.8 | 48 | 22 |

(1) The first case: B is kept constant, and the value of B/R changes with R. The deck width of the bridge is set that B = 10.5 m, 5.25 m, 21 m respectively, and the radius of curvature R, is changed to carry out comparative analysis on the seismic response, the corresponding models of which are models 1-5, models 6-10 and models 11-15. Listed are only the seismic responses of each model when B = 10.5 m (The hand calculation values in the table denote the seismic response calculated with the regular girder bridge).

Based on the results, the effects of the changing B/R on the response ratio of the first order vibration mode response period and of the pier base bending moment when B is constant (10.5 m) are illustrated respectively, as in the following figures 4 and figures 5.

Figures 4 and 5 show that, when B is constant, due to the longitudinal and traverse seismic effect, the response ratio of the first order vibration mode period and of the pier base bending moment are both in an increasing trend as B/R increases, and on condition that the deck width of the bridge is constant, the larger the value of B/R is (i.e., the smaller the value of R/B is), the greater the difference between the seismic response of the curved girder bridge and the result calculated with a regular girder bridge is. Specifically, the increases of the response ratio of the first order vibration mode period are smaller, all within 10%, and the increases of the response ratio of the pier base bending moment are greater. Due to the traverse seismic effect, when B/R = 0.5 (R/B = 2.5), the result coming

from finite element model is already 40% larger than that calculated with the regular girder bridge, and the result of longitudinal seismic effect is also 20% larger.

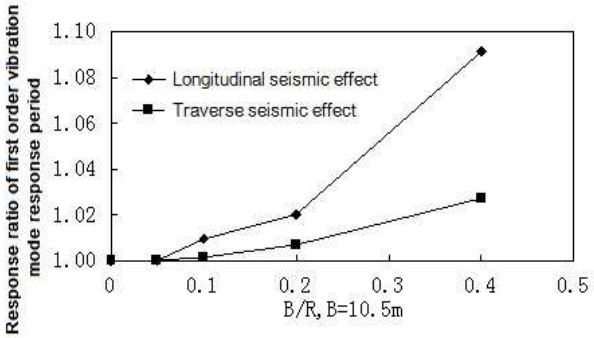

Fig. 4 Changing pattern of the response ratio of first order vibration mode period

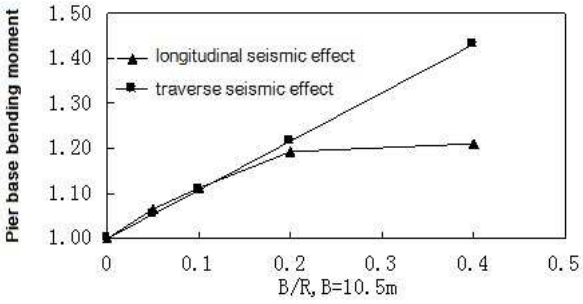

Fig. 5 Changing pattern of the response ratio of the pier base bending moment

As for the case of B = 5.25 m, 21 m, the changing patterns due to the seismic effect are similar to the above case that B = 10.5m. Without showing the detailed data table, only the changing patterns of the corresponding response ratio of the first order vibration mode response period and of the pier base bending moment are illustrated, as shown in figures 6- figures 9.

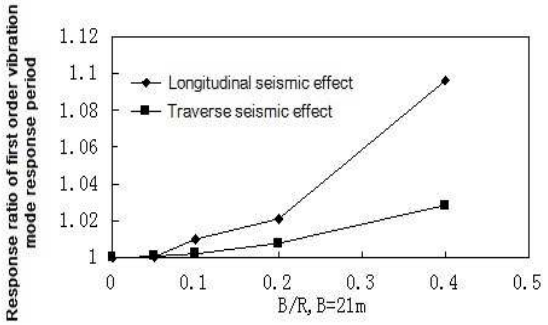

Fig. 6 Changing pattern of the response ratio of first order vibration mode period

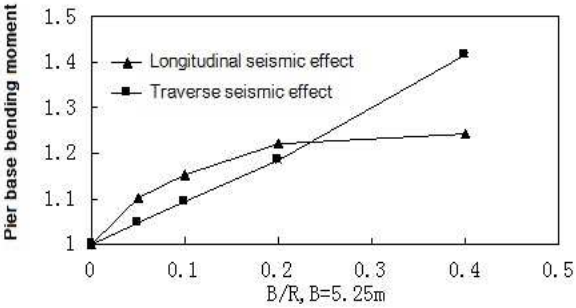

Fig. 7 Changing pattern of the response ratio of the pier base bending moment

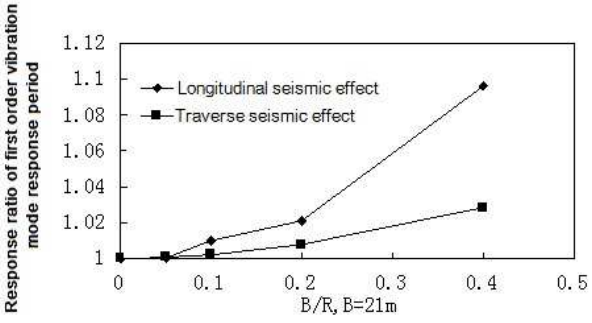

Fig. 8 Changing pattern of the response ratio of first order vibration mode period

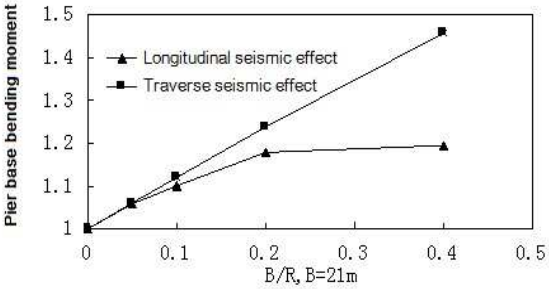

Fig. 9 Changing pattern of the response ratio of the pier base bending moment

As shown in figures 6- figures 9, with respect to different deck widths of the bridge, the changing patterns of the response ratio of first order vibration mode response period and of the pier base bending moment are similar. There is only slight difference in relative rate of rise between longitudinal and traverse seismic effects.

(2) The second case: R is kept constant, and the value of B/R changes with B. The radius of curvature is set that R = 210 m, 105 m, 52.5 m respectively, and the deck width of the bridge B, is changed to carry out comparative analysis on the seismic response, the corresponding models of which are models 7, 2, 12, models 8, 3, 13, and models 9, 4, 14. Listed are only the seismic responses of each model when R = 105 m (The hand calculation values in the table denote the seismic response calculated with the regular girder bridge).

Figures 10- Figures 15 show that, when R is constant, due to the longitudinal and traverse seismic effect, the changes of the response ratio of the first order vibration mode period and of the pier base bending moment are both insignificant, or, on condition that the radius of curvature is constant, the impact of the change of B/R value due to the deck width change of the bridge on the difference between the seismic response of the curved girder bridge and the result calculated with a regular girder bridge is insignificant. Specifically, the changes of the response ratio of the first order vibration mode period are mostly within 1%, and although the changes of the response ratio of the pier base bending moment are slightly greater, they are mostly within 10%.

## Conclusion

A radius of curvature 20 times greater than the deck width of the bridge (R≥20b) is required as a specification in the regular bridge simplification conditions of the seismic response of curved girder bridges. Selecting benchmark bridges and employing parameter analysis method, this article studies on the effect of R/B value of the curved girder bridge on the response ratio of the seismic response calculated using the finite element model and that using a regular girder bridge. This study shows: (1)

On conditions that the deck width of the bridge is constant, the smaller the radius of curvature and the larger the B/R value (i.e., the smaller the R/B value) of the curved girder bridge are, the greater the difference between the seismic response of the curved girder bridge and the result calculated in a regular girder bridge is, and the difference is more significant under traverse seismic effect than that of longitudinal seismic effect. (2) On conditions that the radius of curvature is constant, the impact of the change of B/R value due to the deck width change of the bridge on the difference between the seismic response of the curved girder bridge and the result calculated in a regular girder bridge is insignificant.

Compared with the deck width of the bridge, the difference between the seismic response of the curved girder bridge and the result calculated with a regular girder bridge is more sensitive to the radius of curvature, so more attention should be paid to the radius of curvature when determining whether a curved girder bridge can be simplified into a regular girder bridge in computation. If the radius of curvature R is too small, simplification into regular bridges in computation lacks reasonableness even for the curved girder bridges satisfying the specification requirement that R≥20B.

**Keywords:** Response Spectra, Seismic Coefficient, Magnification Factor, Characteristic Period

**Abstract.** Rare study is done on floor response spectrum of super-high rise building, but it is an important condition for the seismic response analysis of floor subsidiary structure. Therefore, based on the early calculation model of China Financial Information Mansion, the floor response spectrum is calculated under different input ground motion. The floor and ground response spectrum is compared with each other from the seismic coefficient, dynamic amplification coefficient, characteristic period and the form of response spectrum. The results shows that: the floor seismic coefficient and the magnification coefficient are greater or smaller than the ground ones, the biggest difference of which is nearly 1 times; all the floor character period are greater than the ground ones, the biggest difference of which is over 60%; there are obvious differences between the floor and ground dynamic magnification factor spectra form under some conditions, of which the second peak of the former one is probably very large, even near to the peak of the first one, while the latter has no such phenomenon. Therefore, during the process of calculating the seismic response of floor subsidiary structure, it is necessary to consider the change of floor seismic coefficient, dynamic magnification factor, characteristic period and spectra form based on the main structure.

## Introduction

China Financial Information Mansion, Z15 Tower and tower in southern district no. 3 of Beijing Olympic are all designed with glass curtain wall at the high position of them. But the seismic influence coefficient curve of *Chinese code for seismic design of building* adopted in calculating the earthquake action of curtain wall is set up based on ground motion, yet the actual motion that inputs into glass curtain wall is the floor motion. So, it becomes one of the focuses of civil engineers on what the difference is between them. The seismic influence coefficient curve is another form of acceleration response spectra, so the research on seismic influence coefficient curve can be changed to study the acceleration response spectra. A great deal of research about the floor acceleration response spectrum is done for nuclear reactor plant [1-4], and less study is done for ordinary civil building, especially there is few study done for super high rise building[5-7]. Therefore, the difference between ground and floor acceleration response will be discussed based on the early calculation model of China Financial Information Mansion.

## Selection of input ground motions

In order to analyze the difference between ground and floor acceleration response spectra, four typical ground acceleration time history curves are selected, which is near to the site classification of Chinese code from "Ⅰ" to "Ⅳ". All the ground motions are adjusted according to the same dimension. The

adjusted peak ground acceleration (*PGA*) is 0.05g, 0.1g, 0.2g and 0.4g separately, which corresponds to the seismic precautionary intensity 6, 7, 8, 9 . The main information of the ground acceleration is listed in table.1, in which $T_p$ is the characteristic period of them.

**Table.1 The main iformation of the selected ground motions**

## Early calculation model of China Financial Information Mansion

Steel and reinforced concrete composite structure is adopted in China Financial Information Mansion. The total height of it is 360m, and the total width of it is 55m. Glass curtain wall is designed nearly at the elevation from 267m to 345m. Several forms of structure are designed during the stage of designing, one of which is adopted in this paper. Because the main object of this study is to analyze the difference between ground and floor acceleration response spectra , there is no effect on the study result even though the models set up based on the early and final design are different. The characteristic periods ($T_p$) of the former 20-order modes of the early calculation model are listed in table 2.

**Table 2 The character periods $T_p$ of the former 20-order modes of the early calculation model**

| mode | $T_p$（s） | mode | $T_p$（s） | mode | $T_p$（s） | mode | $T_p$（s） |

## Analysis of floor response spectra characters

**Analysis Content of Response Spectra.** The design response spectra of China seismic code [8] is provided as the form of seismic influence coefficient ($\alpha$) curve, shown as Eq. 1,

$$\alpha = k\beta = \begin{cases} (0.45+5.5T)\alpha_{\max} & 0 \le T < 0.1 \\ \alpha_{\max} & 0.1 \le T < T_g \\ \left(\dfrac{T_g}{T}\right)^{0.9} \eta_2 \alpha_{\max} & T_g \le T < 5T_g \\ \left[\eta_2 0.2^{\gamma} - \eta_1 (T - 5T_g)\right]\alpha_{\max} & 5T_g \le T < 6.0 \end{cases} \tag{1}$$

where, $k$ is seismic coefficient, $\beta$ is dynamic magnification coefficient, $\alpha_{max}$ is the maximum value of seismic coefficient, $\eta_1$ is adjustment coefficient for adjusting the slope of descent phase, $\gamma$ is attenuation index, $\eta_2$ is damping adjustment coefficient, $T$ is structural natural vibration period, $T_g$ is characteristic period. There are different kinds of calculation methods for calculating $T_g$ and they are compared in reference [9]. Because this study is intended to analyze the difference of $T_g$ between the floor response spectrum and the ground response spectrum, the popular one is adopted, which is expressed as $T_g = 2\pi EPV/EPA$. *EPV* and *EPA* are effective peak velocity and effective peak acceleration separately [9].

Because $\alpha_{max} = k\beta$, the analysis of floor response spectrum can be instead by analyzing the seismic coefficient and dynamic magnification coefficient spectrum, yet the analysis of dynamic magnification coefficient spectrum can be instead by analyzing the maximum value $\beta_{max}$ , $T_g$ and the shape of it. So, in the following, the ground and floor response spectra of China Financial Information Mansion will be compared and analyzed from the above four aspects.

**Analysis of Seismic Coefficient.** The time history response of early calculation model of China Financial Information Mansion is calculated with the select ground motion as input ground motion. The floor acceleration time history is extracted from the results, and by using them as input motion, the seismic coefficient, $\beta_{max}$, $T_g$ and shape of dynamic magnification coefficient ($\beta$) spectrum of different floor, site classification and intensity degree are also obtained, shown as table3, 4, 5 and fig.1. In these tables, 6, 7, 8, 9 is intensity degree.

From table 1, it can be seen that the relationship of floor seismic coefficient and ground seismic coefficient is related with site category and the location of floor: the maximum floor seismic coefficient appears in floor 10, 70, 20 and 60 for site category from Ⅰ to Ⅳ, which has no obvious law for the location of maximum floor seismic coefficient; the seismic coefficient is either greater or less than the ground seismic coefficient, the maximum ratio ($R$) of the maximum floor seismic coefficient to the ground one is 1.63, the minimum one of which is 0.90. This is mainly because the characteristic period of ground motion is different, which will induce the seismic response of the main structure different. So it can be concluded that it's necessary to consider the change of seismic coefficient for calculating the seismic response of attachment structure.

**Table 3 Seismic coefficient of different site category and floor lacation**

| floor No | Site Ⅰ | | | | Site Ⅱ | | | | Site Ⅲ | | | | Site Ⅳ | | | |
|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|
| | 6 | 7 | 8 | 9 | 6 | 7 | 8 | 9 | 6 | 7 | 8 | 9 | 6 | 7 | 8 | 9 |
| ground | 0.05 | 0.1 | 0.2 | 0.4 | 0.05 | 0.1 | 0.2 | 0.4 | 0.05 | 0.1 | 0.2 | 0.4 | 0.05 | 0.1 | 0.2 | 0.4 |
| 10 | 0.05 | 0.09 | 0.18 | 0.36 | 0.05 | 0.11 | 0.21 | 0.43 | 0.05 | 0.1 | 0.2 | 0.4 | 0.05 | 0.11 | 0.21 | 0.43 |
| 20 | 0.03 | 0.05 | 0.1 | 0.2 | 0.05 | 0.09 | 0.18 | 0.36 | 0.06 | 0.12 | 0.25 | 0.5 | 0.06 | 0.11 | 0.23 | 0.45 |
| ... | ... | ... | ... | ... | ... | ... | ... | ... | ... | ... | ... | ... | ... | ... | ... | ... |
| 60 | 0.02 | 0.04 | 0.08 | 0.17 | 0.03 | 0.06 | 0.12 | 0.24 | 0.05 | 0.1 | 0.2 | 0.4 | 0.08 | 0.16 | 0.33 | 0.65 |
| 70 | 0.03 | 0.06 | 0.11 | 0.22 | 0.06 | 0.12 | 0.24 | 0.48 | 0.05 | 0.09 | 0.18 | 0.37 | 0.07 | 0.14 | 0.29 | 0.58 |
| 80 | 0.01 | 0.03 | 0.05 | 0.1 | 0.05 | 0.09 | 0.18 | 0.36 | 0.06 | 0.11 | 0.23 | 0.46 | 0.1 | 0.19 | 0.39 | 0.78 |
| $R$ | 0.90 | 0.90 | 0.90 | 0.90 | 1.20 | 1.20 | 1.20 | 1.20 | 1.24 | 1.24 | 1.24 | 1.24 | 1.63 | 1.63 | 1.63 | 1.63 |

**Analysis of $\beta_{max}$.** From table 4, it can be seen: the maximum of $\beta_{max}$ appears in floor 10, 70, 20 and 60 for site category from Ⅰ to Ⅳ, which is not always the same with the location of the maximum seismic coefficient; the floor $\beta_{max}$ is either greater or less than the ground $\beta_{max}$, but the maximum one is always larger than the ground $\beta_{max,}$ and the difference value of them may be very large; the maximum ratio ($R$) of the maximum $\beta_{max}$ to the ground one is 1.98, the minimum one of which is 1.52, which shows that the main structure has amplification effect on the ground acceleration time history. So it can be concluded it's necessary to consider the change of $\beta_{max}$ for calculating the seismic response of attachment structure.

**Analysis of $T_g$.** From table 5, it can be seen: the maximum $T_g$ appears in floor 80, 60, 80 and 80 for site category from Ⅰ to Ⅳ, which has no obvious law but they always appears in high location of the main structure; the floor $T_g$ is always bigger than the ground one, and the difference degree declines for site category from Ⅰ to Ⅳ; the maximum ratio of the floor $T_g$ to the the ground one is 1.66, the minimum one is 1.20. So it can be concluded that the floor $T_g$ is smaller than the ground $T_g$ and it's necessary to consider the change of $T_g$ for calculating the seismic response of attachment structure.

**Table 4 $\beta_{max}$ of different site category and floor location**

Analysis of the Shapes of β Spectrum. To compare the ground and floor shapes of β spectrum, the β spectrums of ground, 20-floor, 40-floor, 60-floor and 80-floor are extracted. Because the difference of βmax and Tg is analyzed in the above, in the analysis of the shapes of β spectrum, the βmax of each β spectrum is adjusted to 2.5 in proportion, and at the same time, the Tg of each β spectrum is also adjusted to the location of the maximum βmax in proportion. The adjusted β spectrum is shown in Fig.1.

From fig.1, it can be seen for site category Ⅰ, the maximum β first appeared in β spectrum is obviously higher than the second appeared one, such as the maximum β of the 20th-floor is 2.5, the second maximum one is 1.4, the difference between them is 78%, and furthermore the difference of some floors decreases with site category changing from Ⅰ to Ⅳ, such as for site category Ⅱ, the difference of the 60th-floor is 40%, yet for site category Ⅲ and Ⅳ, this difference is less than 4%. It can be concluded that the shapes of floor and ground β spectrum may be different greatly, and there may not only one peak value in β spectrum for the participation of high mode vibration mode. So, large difference may be made during the process of calculating the seismic response of attachment structure, if ground design spectrum is adopted directly.

## Conclusions

It can be concluded from the above results:

The maximum floor $k$ and $\beta$ is either greater or less than the corresponding ground one, and this difference is relevant to the floor location and site category. The floor $T_g$ is always bigger than the ground one, and the difference degree decreases with the site category from Ⅰ to Ⅳ, and on the high floor, this difference may be very large. So it's necessary to consider the changes of $k$, $\beta$ and $T_g$ when calculating the seismic response of attachment structure.

There may be great difference between ground and floor $\beta$ spectrum, the second peak value of which even can almost reach to the first peak value, and this difference is related with site category and floor location. So it's necessary to consider the changes of $\beta$ spectrum when calculating the seismic response of attachment structure.

Because there may be great difference between ground and floor $k$, $\beta$, $T_g$ and shapes of $\beta$ spectrum, time history analysis is necessary for calculating the seismic response of attachment structure.

# Time-Frequency Analysis of Non-stationary Ground Motions Via Multivariate Empirical Mode Decomposition

Yanwen Su[1, a], *Guoqing Huang[1, b], Liuliu Peng[1, c]

[1]School of Civil Engineering, Southwest Jiaotong University, Chengdu 610031, China

[b]ghuang1001@gmail.com

**Keywords:** Time-frequency analysis; Multivariate Empirical Mode Decomposition; Hilbert transform; Non-stationary ground motions; Correlation.

**Abstract:** In this paper, MEMD-based scalogram and coscalogram, and instantaneous frequency spectral are proposed to characterize the data derived from the multivariate non-stationary process. The scalogram and instantaneous frequency spectral capture spectral evolution of each component while the coscalogram reveals embedded intermittent correlation between two components. Compared with scale-based scalogram and coscalogram, frequency-based instantaneous frequency spectral provides more detailed portrayal for multivariate data. The effectiveness of the proposed MEMD-based time-frequency analysis framework is validated by numerical examples of uniformly and generally modulated ground motions.

## Introduction

In engineering community, the ground motions typically show non-stationary characteristics. Although wavelet transform have good time-frequency resolution, essentially it requires a series of a priori base functions. To circumvent this difficulty, Huang et al. [1, 2] introduced empirical mode decomposition (EMD). However, since mode mixing and mode misalignment exist in EMD approach, EMD is majorly limited to univariate non-stationary processes. Recently, Rehman and Mandic [3, 4] have introduced multivariate empirical mode decomposition (MEMD), which is suitable for analyzing n-variate non-stationary data. The advantage of MEMD is that it can produce the same number of intrinsic mode fuctions (IMFs) for the multiple signals, and align the corresponding IMFs from different channels across the same frequency range. Based on MEMD, it is possible to establish time-frequency description framework for multivariate non-stationary processes, especially, the time-frequency correlation analysis for two non-stationary processes.

In this study, the time-frequency analysis for multivariate non-stationary processes is proposed based on MEMD. MEMD-based scalogram and coscalogram, and instantaneous frequency spectral are developed to capture spectral evolution and intermittent correlation hidden in non-stationary multivariate data. The example of uniformly and generally modulated ground motions are used to evaluate MEMD-based time-frequency analysis framework.

## Theoretical Background

### *Multivariate Empirical Mode Decomposition*

EMD and EEMD perform well for the univariate signal, whereas they often fail in characterizing the multivariate signal. One major reason can be attributed to mode misalignment. Even if the numbers of IMFs for all components of multivariate signal are identical, spectral contents (or scales) for the IMFs on the same level may be significantly dissimilar. With the help of the newly-developed MEMD [3, 4], each component in the multivariate signal can be decomposed simultaneously so that the IMFs are matched both in the number and scale. Hence, mode and scale alignment can be achieved and the characterization of the multivariate signal becomes available.

Suppose a multivariate signal $\{\mathbf{x}(t)\}=\{x_1(t),x_2(t),\cdots x_p(t)\}$ with $p$ components. The $p$-dimensional multiple envelopes can be defined by projecting the signal along multiple directions in $p$-dimensional space and then interpolating their extrema. Subsequently, the local mean shall be determined by averaging these envelopes [4]. Since the estimation of the local mean can be regarded as an approximation of the integration of all the envelopes along multiple directions in a $p$-dimensional space, the accuracy of this treatment is largely dependent on how uniformly the direction vectors are chosen. The low-discrepancy Hammersley sequence (quasi-Monte Carlo sampling) will be used to generate direction vectors in that these vectors will be more uniformly distributed over other schemes, such uniform angular sampling. The direction vectors in $p$-dimensional space can be equivalently represented as points on the corresponding unit ($p$-1) sphere. The IMFs of the non-stationary $p$-variate signal can be obtained by following algorithm.

1, Generate $N$-point Hammersley sequence via sampling on a unit ($p$-1)-sphere;

2, Calculate projections of the input signal $\{\mathbf{x}(t)\}$ along direction vectors $v^{\theta_n}$, for $n=1,2,\cdots N$ (the whole set of direction vectors), where each projection is denoted by $q^{\theta_n}(t)$;

3, Find the time instants $\{t_i^{\theta_n}\}_{n=1}^N$ corresponding to the maxima of the set of projected signals $\{q_i^{\theta_n}(t)\}_{n=1}^N$;

4, Interpolate $[t_i^{\theta_n},\mathbf{x}(t_i^{\theta_n})]$ to obtain multivariate envelope curves $\{\mathbf{e}^{\theta_n}(t)\}_{n=1}^N$ using cubic spline;

5, Determine the mean of envelope curves,

$$\boldsymbol{\mu}(t)=\frac{1}{N}\sum_{n=1}^{N}\mathbf{e}^{\theta_n}(t). \tag{1}$$

6, Extract the "detail" $\mathbf{c}(t)$ using $\mathbf{c}(t)=\mathbf{x}(t)-\boldsymbol{\mu}(t)$. If the 'detail' $\mathbf{c}(t)$ satisfies the stoppage criterion for a multivariate IMF, step (2)-(5) will be carried out to obtain the 2nd, 3rd and higher order IMFs. The stoppage criterion for MEMD is identical to that proposed by Huang et al. (1998) in EMD.

*Hilbert Transform*

For any mono-component signal $y(t)$, complex analytic form $z(t)$ of the signal can be constructed by Hilbert transform (HT), i.e.,

$$z(t)=y(t)+iH[y(t)]=a(t)e^{i\phi(t)}. \tag{2}$$

where $H[y(t)]=(P/\pi)\int_{-\infty}^{\infty}y(s)/(t-s)ds$ is HT, in which $s$ is the variable of integration and $P$ denotes the Cauchy principle value; $i=\sqrt{-1}$; the instantaneous amplitude (IA) and phase are given by

$$a(t)=\sqrt{y(t)^2+(H[y(t)])^2}\ ;\ \phi(t)=\tan^{-1}\{H[y(t)]/y(t)\}. \tag{3}$$

Based on Eq. (2), instantaneous frequency (IF) is defined as the derivative of instantaneous phase.

$$f(t)=\frac{1}{2\pi}\frac{d}{dt}\phi(t). \tag{4}$$

## MEMD-based Time-frequency Analysis

The frequency analysis framework will be presented in followings. Firstly, all components in a $p$-variate signal $\{\mathbf{x}(t)\}$ are decomposed simultaneously into IMFs using MEMD. Then the HT will be adopted to estimate instantaneous frequencies (IFs) and instantaneous amplitudes (IAs) of the IMFs. Thus each component of the multivariate signal $x_j(t)$ can be expanded as

$$x_j(t)=\sum_{m=1}^{M}c_{jm}(t)=\mathrm{Re}[\sum_{m=1}^{M}a_{jm}(t)e^{i\int\omega_{jm}(t)dt}] \tag{5}$$

in which $c_{jm}(t)$ represents the $m$th IMF of component signal $x_j(t)$; Re denotes real part; $a_{jm}(t)$ and $\omega_{jm}(t)$ are the IA and IF of $c_{jm}(t)$, respectively.

According to Eq. (5), MEMD scalogram of $x_j(t)$ can be defined by squared IAs of IMFs, which is expressed as

$$s_{jj}^m(t) = a_{jm}^2(t) \ . \tag{6}$$

Clearly, MEMD scalogram can be plotted on a time-scale plane, which reveals the spectral evolution of the component process. Analogously, if the products of corresponding IAs from two different component processes are also represented on the time-scale plane, MEMD coscalogram can be obtained. The MEMD coscalogram of the two components $x_j(t)$ and $x_k(t)$ is defined as

$$s_{jk}^m(t) = a_{jm}(t)a_{km}(t) \ . \tag{7}$$

This coscalogram uncovers the elusive correlation between two components of multivariate process.

An alternative to represent non-stationarity is directly based on the frequency, which is similar to the well-known Hilbert instantaneous frequency spectral. The definition of IF spectral for $x_j(t)$ based on MEMD is given by

$$S_{jj}^m(t,\omega) = a_{jm}^2(t)\delta[\omega - \omega_{jj}^m(t)] \ . \tag{8}$$

where $\delta(\cdot)$ represents the Dirac delta function and $\omega_{jj}^m(t)$ is IF for *m*th IMF of component $x_j(t)$.

## Applications

In the following, a uniformly modulated (with amplitude non-stationarity) and a fully non-stationary (with both amplitude and frequency non-stationarities) ground motions are considered to illustrate the efficacy of MEMD-based time-frequency framework.

*Uniformly modulated ground motions*

Consider a uniformly modulated multivariate non-stationary processes consisting of ground motions at two locations $\{x(t)\} = \{x_1(t), x_2(t)\}^T$ with 150m distance where $x_1(t) = A_1(t)\overline{x}_1(t)$ ; $x_2(t) = A_2(t)\overline{x}_2(t)$ ; and $A_1(t)$ and $A_2(t)$ are the modulation functions defined as [5]

$$A(t) = \frac{\exp(-ct) - \exp(-dt)}{\max[\exp(-ct) - \exp(-dt)]} \ . \tag{9}$$

with c=0.125 and d=0.25 for $A_1(t)$; and c=0.25 and d=0.5 for $A_2(t)$. It is noted that modulation function $A_1(t)$ changes more slower than $A_2(t)$.

The power spectral of the corresponding stationary processes $\overline{x}_1(t)$ and $\overline{x}_2(t)$ are identical, described as

$$K_0(f) = 4\pi S_0 \frac{f_g^4 + 4\zeta_g^2 f_g^2 f^2}{(f^2 - f_g^2)^2 + 4\zeta_g^2 f_g^2 f^2} \tag{10}$$

in which $S_0$=0.1cm$^2$/s$^3$, $f_g$=15/(2$\pi$)Hz and $\zeta_g$=0.25.

The auto evolutionary power spectral density (EPSD) of $x_1(t)$ and $x_2(t)$ are given as

$$S_{kk}(f,t) = A_k^2(t)K_0(f), \quad (k = 1,2) \ . \tag{11}$$

and the cross EPSD of $x_1(t)$ and $x_2(t)$ are described as

$$S_{12}(f,t) = A_1(t)A_2(t)K_0(f)Coh_{12}^0(f) \ . \tag{12}$$

The coherency function between $x_1(t)$ and $x_2(t)$ is given as [e.g., 5]

$$Coh_{12}^0(f) = \rho(d_{12}, f)\exp\left(-i2\pi f \frac{d_{12}}{v_{12}}\right) \tag{13}$$

$$\rho(d_{12}, f) = \beta\exp\left[-\frac{2d_{12}}{\alpha\theta(f)}(1-\beta-\alpha\beta)\right] + (1-\beta)\exp\left[-\frac{2d_{12}}{\theta(f)}(1-\beta-\alpha\beta)\right] \tag{14}$$

$$\theta(f)=\theta_0\left[1+(\frac{f}{f_0})^b\right]^{-1/2} \tag{15}$$

where $d_{12}$ represents the distance between two locations, and $d_{12}$=150m; $v_{12}$ is the wave propagation velocity, and $v_{12}$=2000m/s; $\alpha$=0.147; $\beta$=0.736; $\theta_0$=5210m/s; $b$=2.78; and $f_0$=1.09Hz.

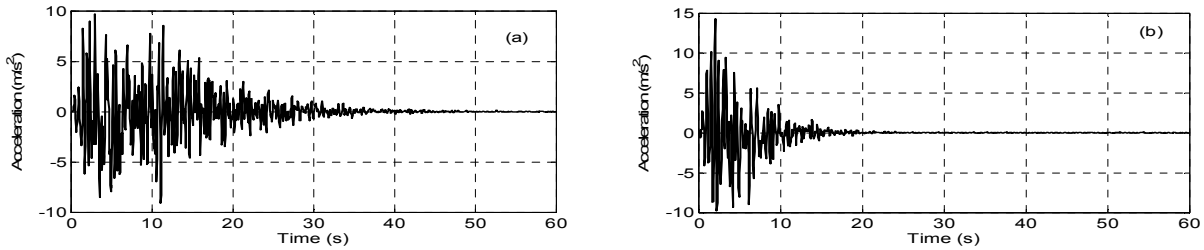

**Fig. 1. Simulated non-stationary ground motions with separable EPSD**

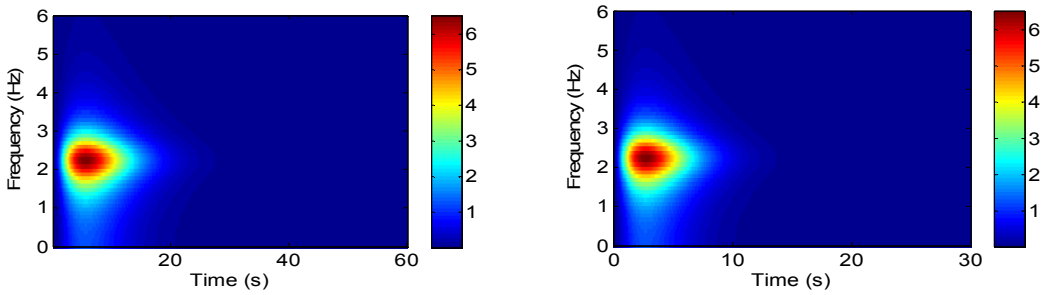

(a) location 1 (b) location 2

**Fig. 2. The target EPSD results**

The ground motions samples of $\{x(t)\}$ are generated by first simulating $\{\overline{x}(t)\}=\{\overline{x}_1(t),\overline{x}_2(t)\}^T$ via the spectral representation method (SRM) [6], and then multiplying the corresponding modulation functions. The simulation results of non-stationary ground motions at the two locations are shown in Fig. 1(a-b), and the target EPSD results are displayed in Fig. 2(a-b). The target spectral of the first and second locations indicate that the frequency vary from 0-6Hz with dominate freqeuncy of 2.5 Hz, and the mainly energy of the first location concentrate in time of 0-20s, while the energy of the second location concentrate in time of 0-10s.

MEMD is carried out for these two simulated samples, respectively. MEMD results are shown in Fig.3 (a-b). Note that 11 IMFs for each ground motion are obtained. Clearly, MEMD generates the same amount of IMFs and has a reliable performance in mode alignment.

The MEMD scalograms and coscalogram of the ground motions at two different locations are presented in Figs. 4(a-c). Note that the bright red and yellow colors represent high intensity energy, while the blue color represents low intensity energy. In scalograms, it is observed that the 1st-3rd IMFs contain large energy, while the 7th-11th IMFs have negligible energy for ground motions at both locations. In time domain, the dominant energy varies in the interval of 0-20s for the first location and 0-10s for the second location, which is consistent with Fig. 2. In Fig. 4(c), the light patches in the coscalogram enable us to detect the intermittent correlation between this two different ground motions. The resulting coscalogram of these two processes shows the distinct correlation of the 2nd and 3rd IMFs. Clearly, these two samples are well correlated in the lower frequency, which may result in large structural responses.

Fig. 5(a-b) give a sharp description of the time-varying frequency contents. It is seen that, the energy and frequency content vanish until the time of 40s for the first location, and of 20s for the second location. IF spectrals give the energy variation with time. Clearly, the time-varying rate of frequency content is slight, which is attributed to the estimate of the frequency from phase information. Overall, frequency content is approximate to time invariable. On the other hand, the

amplitude non-stationarity can be found for both samples. Both observations reflect the time-frequency characteristics of the uniformly modulation ground motions. The frequency-based approach also provides the consistent results with that based on the scale in Fig. 4. Also the dominate frequency can be found to be around 2.5 Hz from Fig. 5, which consists with Fig. 2.

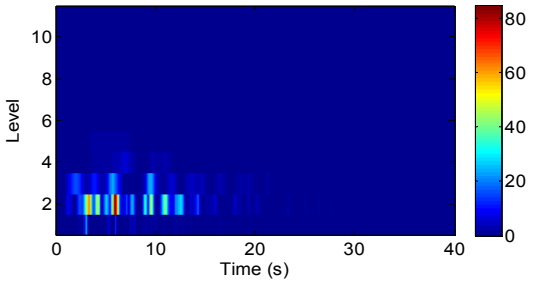
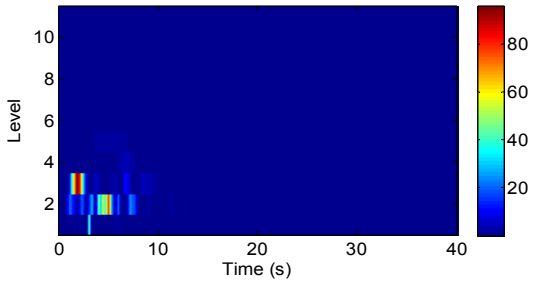
(b) location 2

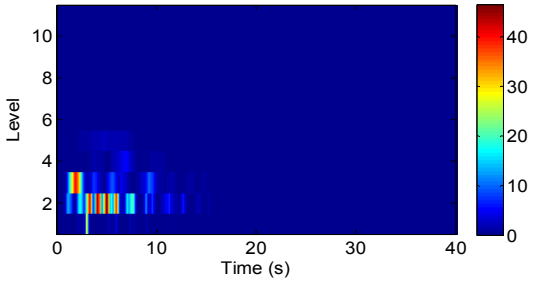
**Fig. 3. MEMD results**



(a) scalogram, location1



(b) scalogram, location2



(c) coscalogram

**Fig. 4. MEMD scalograms and coscalogram**

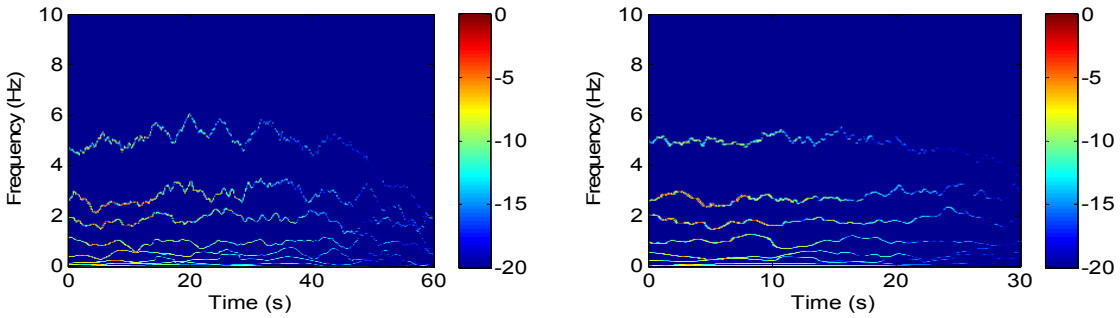


**Fig. 5. IF spectral**

*Generally modulated ground motions*

Consider a more general multivariate non-stationary processes consisting of ground motions at two points $\{x(t)\}=\{x_1(t),x_2(t)\}^T$ with 1200m distance along the direction of wave propagation. The EPSD presented in [7] is used, as shown in following equation

$$S_{kk}(\omega,t)=S(\frac{\omega}{5\pi})^2 e^{-0.15t}t^2 e^{-(\frac{\omega}{5\pi})^2 t},\quad (k=1,2)\,. \tag{16}$$

where $S$ was set to 0.03.

By comparison with Eq. (11) and Eq. (12), Eq. (16) describes a non-separable EPSD because of the variables of time and frequency cannot be decoupled. Hence, this is a fully non-stationary processes with both amplitude and frequency non-stationarities. The coherency function between $x_1(t)$ and $x_2(t)$ have the identical form with Eq. (13-15), but different parameters. Herein, $v_{12}$=2000m/s; $\alpha$=0.0186; $\beta$=0.636; $\theta_0$=31200m/s; $b$=2.95; and $f_0$=1.51Hz.

Nonstationary process simulation can be conducted by improved SRM [8]. The simulated results of non-stationary ground motions are shown in Fig. 6. The target EPSD is displayed in Fig. 7, which the frequency varies from 0-4Hz and the large energy occurs during 0-20s.

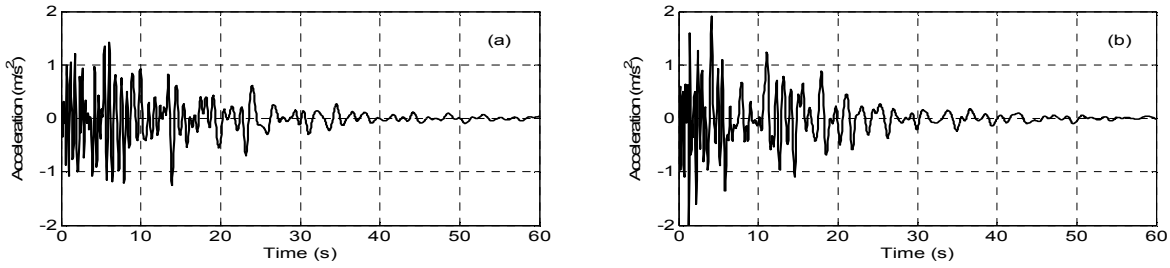

**Fig. 6. Simulated non-stationary ground motions with non-separable EPSD**

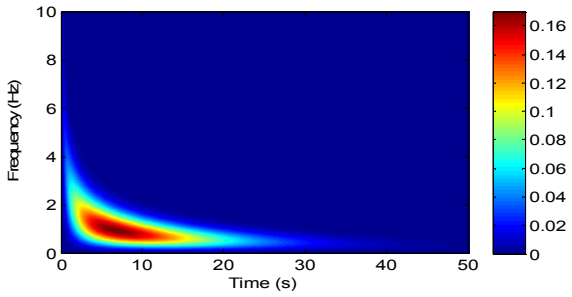

**Fig. 7. The target EPSD result**

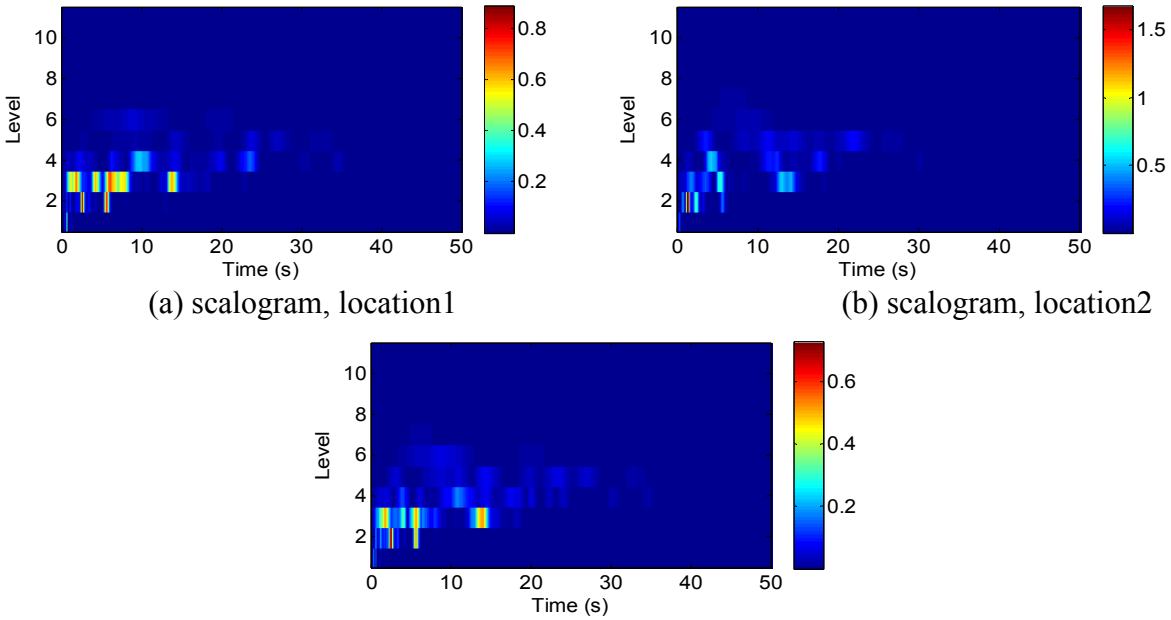
MEMD is employed to decompose two simulated samples, respectively and the total of 11 IMFs are acquired. Herein, MEMD results are not shown for brevity. MEMD scalogram and coscalogram are displayed in the following Fig. 8.



(a) scalogram, location1 (b) scalogram, location2

(c) coscalogram

**Fig. 8. MEMD scalograms and coscalogram**

The scalograms and coscalogram results plotted in Fig. 8 are consistent with those in Fig. 7. In scalograms, the evolution of energy can be observed in various scales. It is also found that the majority of the energy of the ground motion concentrates in the lower frequency region. For the first location, the 2nd-4th IMFs contain large energy. Similarly, the most of energy spread over the 2nd, 3rd and 4th IMF components for the second location. The dominant energy varies in the interval of 0-15s for both locations. Fig. 8(c) reveals the correlation between two ground motions. It is seen that the largest correlation is relevant with the 2nd and 3rd IMF components within time duration of 0-15s.

Fig. 9 illustrate the information regarding the variation of energy intensity and frequency content. It is found that the larger energies are observed around 0-2Hz during the duration of 0-20s. The IF spectral indicates the presence of high frequency energy early in the ground motions, which attenuates with time, that is, a sharp frequency non-stationarity can be detected. It is shown that this non-stationarity in frequency content can have a significant effect on the response of both linear and nonlinear structure [9]. On the other hand, amplitude non-stationarity can also be found. Therefore, for general full non-stationary ground motions, both of frequency non-stationarity and amplitude non-stationarity hiding in the non-stationary process can be discovered.

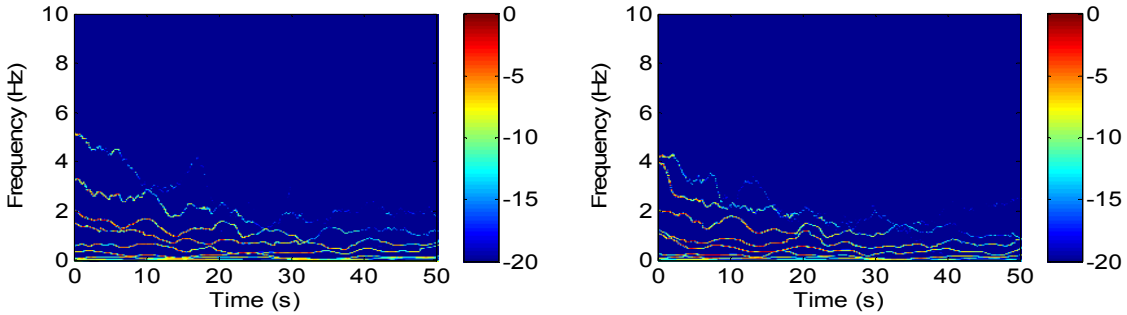


**Fig. 9. IF spectral**

## Conclusions

This study proposed a new adaptive time-frequency analysis framework for multivariate non-stationary processes based on MEMD. In this framework, MEMD was used to decompose multivariate data and subsequently the meaningful IA and IF were estimated by Hilbert transform. Compared with EMD, the superior features of the mode (both of number and scale) alignment and

less mode mixing processed by MEMD provided an opportunity to analyse the non-stationarity embedded in the multivariate process, especially, the elusive intermittent correlation between two components. Furthermore, MEMD-based scalogram and IF spectral were suggested to describe the evolutionary characteristics of non-stationary component process, while coscalogram was developed to reveal the elusive intermittent correlations between two different component processes. The application of the proposed approach to uniformly and generally modulated ground motions had verified the efficacy of MEMD-based time-frequency description framework and thus helped to capture the time-frequency characteristics of the non-stationary processes.

**Keywords:** ANSYS, Intake tower, Earthquake, Power spectral density (PSD) analysis

**Abstract.** In this paper, the power spectral density method based on ANSYS is carried out to study the intake tower finite element model under an earthquake. A power spectral density function is obtained and disposed to be smooth. Then it is used to study the intake tower when the seismic wave occurs in the direction of flow and perpendicular to the direction of flow .This study provides theoretical basis for reinforce and transform of the intake tower structure.

## Introduction

Earthquake is a natural disaster which causes enormous losses to human. The anti-seismic capacity of hydraulic structures is becoming more and more important. The spectral density method has risen in the recent 30 years. This method is based on probability theory and mathematical statistics and it is the most scientific method to study a random process[1-4]. This paper uses spectral density method to study the intake tower to calculate the largest displacement, providing theoretical basis for reinforce and transform of the structure. At last, the security of the intake tower is assessed from the viewpoint of probability.

## Calculation of seismic power spectral density curve

In order to represent a random process Y(t) roundly, the interdependence between two random variables at different time needs to be studied. So define correlation function:

$$R_Y(t_1,t_2)=E[Y(t_1)Y(t_2)],\qquad \tau=t_2-t_1$$

Power spectral has the Fourier transform relationship with correlation function:

$$S_Y(\omega)=\frac{1}{2\pi}\int_{-\infty}^{\infty}R_Y(\tau)e^{-i\omega\tau}d\tau$$

Correlation function has the inverse Fourier transform relationship with Power spectral

$$R_Y(\tau)=\int_{-\infty}^{\infty}S_Y(\tau)e^{i\omega\tau}d\tau$$

From the relationship above, the seismic wave within a limited duration can be transformed into the self-correlation function. Then the self-correlation function was transformed into the power spectral density function using FFT method[5-6].

Considering that vertical bearing capacity of the structure is large, the test only applied horizontal seismic load to the structure. The records of a North-South river are neat, so the test used its seismic record curve as load to affect the structure. The peak ground acceleration is$1.5\,m/s^2$ and it is smaller than the earthquake in degree nine. Therefore, all accelerations multiplied by 3.33. The amplified acceleration duration curve is shown in fig.1

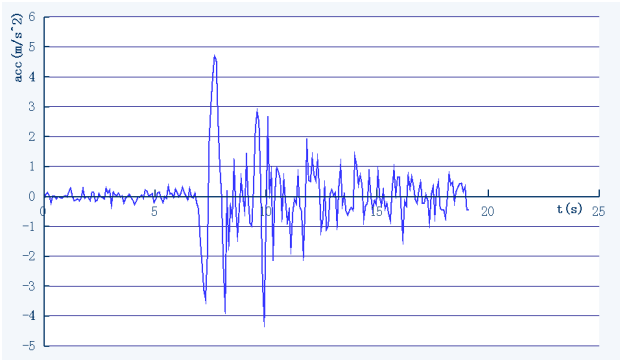

Fig. 1 The amplified north-south river records

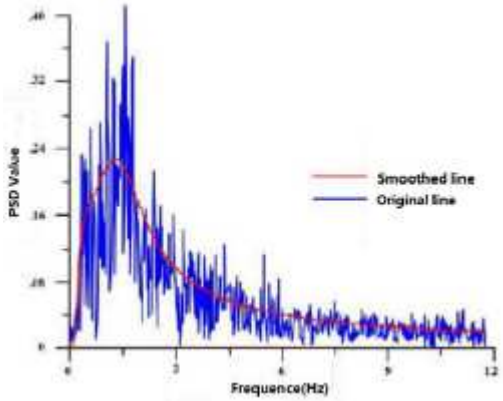

Fig. 2 Diagram of Seismic wave power spectral density calculations

The diagram of Seismic wave power spectral density calculations in fig.2 is obtained from the amplified north-south river records in fig.1. Then the PSD curve was disposed to be smooth.

## Finite element analysis of seismic power spectral density

In this paper, the power spectral method based on ANSYS is taken to calculate the displacement and stress of the structure when seismic wave contented a normal distribution occurs. The diagram of seismic wave power spectral density calculations is shown in fig 2. When the research is carried out, two situations when the seismic wave occurs in the direction of flow and perpendicular to the direction of flow are both considered.

The output from spectral density calculations based on ANSYS is a random variable which contents a normal distribution. The normal distribution of a random variable can be described by mean and variance well in mathematics. The earthquake process is a random process with a mean equaling to 0. Therefore, the output can be described absolutely just by variance. The probability is 68.3% when random variable is within $\pm 1\sigma$, 95.4% within $\pm 2\sigma$, 99.7% within $\pm 3\sigma$.The calculation only extracts the result within $\pm 1\sigma$.

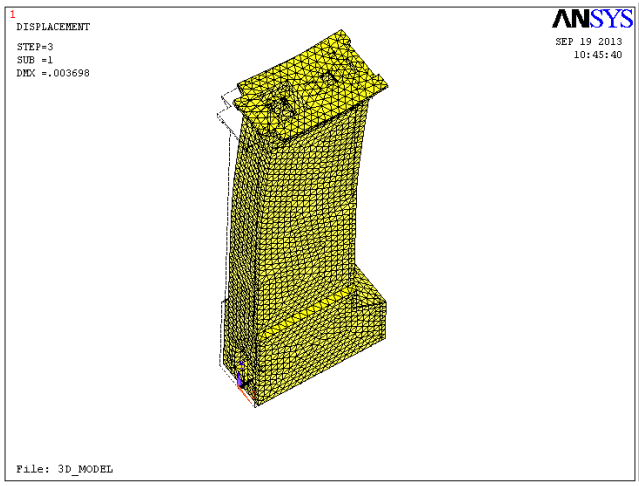

Fig.3 Structure seismic PSD excitation $1\sigma$ results downstream direction

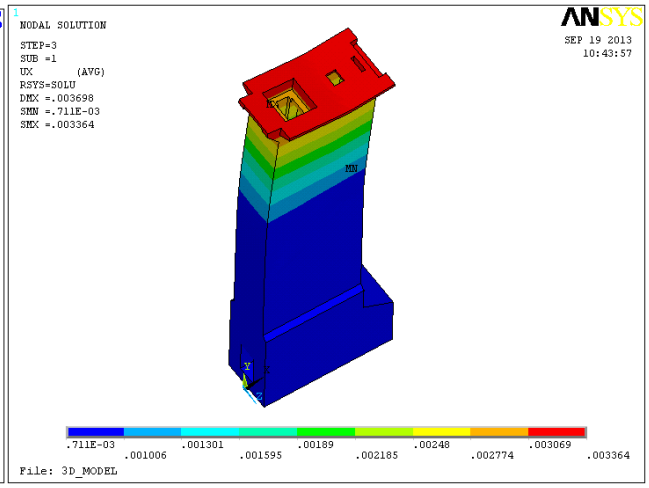

Fig.4 Structure seismic PSD excitation downstream direction $1\sigma$ displacement nephogram

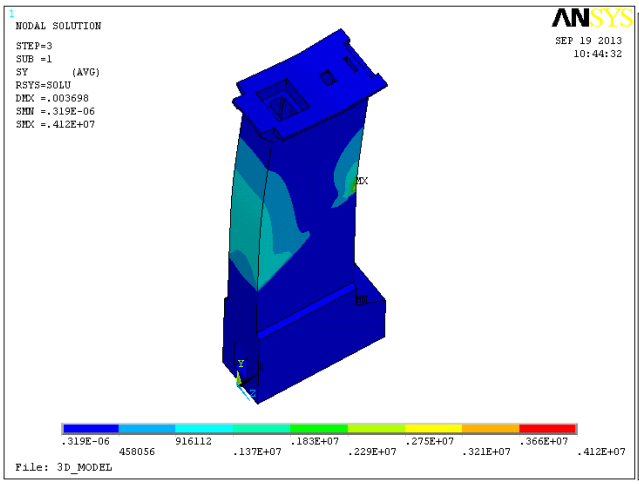

Fig.5 $1\sigma$ First principal stress distribution under the excitation of the of seismic PSD spectrum

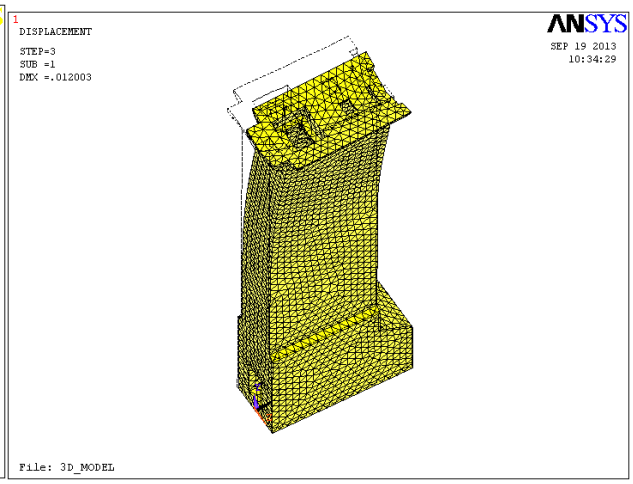

Fig.6 Structure seismic PSD excitation $1\sigma$ results vertical flow direction

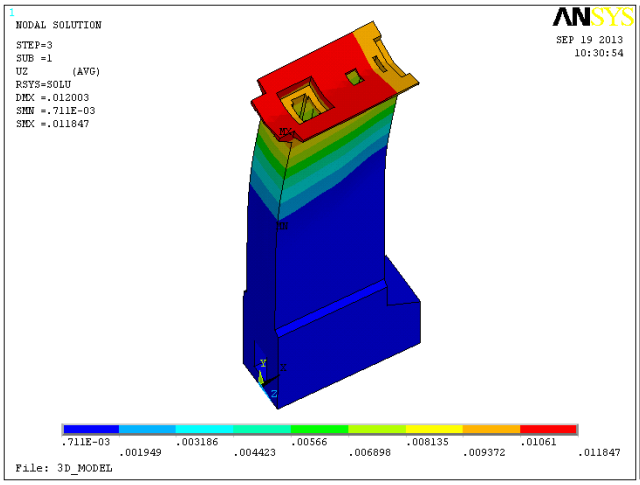

Fig.7 Structure seismic PSD excitation vertical flow direction $1\sigma$ displacement nephogram

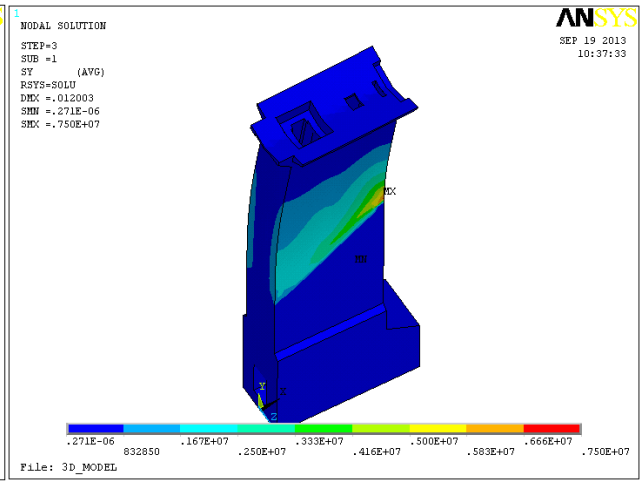

Fig.8 $1\sigma$ First principal stress distribution under the excitation of the of seismic PSD spectrum

From fig.3, fig.4 and fig.5, it is seen that the structure has displacement in the direction of flow when the seismic wave occurs in the direction of flow. The displacement is a random variable which contents a normal distribution.The largest $1\sigma$ displacement is 0.3364 cm, which occurs in the top of the structure. The overall deformation of the structure is accord with its second order vibration mode. The $1\sigma$ first principal stress is 4.12 MPa. It occurs in the constraints because excessive constraints cause oversize reaction. Therefore, this part still needs enough attention and it is better to reinforce it by reinforcements.

From fig.6, fig.7 and fig.8, it is seen that the structure has displacement perpendicular to the direction of flow when the seismic wave occurs perpendicular to the direction of flow. The displacement is a random variable which contents a normal distribution.The largest $1\sigma$ displacement is 1.1847cm, which occurs in the top of the structure. The overall deformation of the structure is accord with its first order vibration mode. The $1\sigma$ first principal stress is 7.5 MPa. It occurs in the constraints because excessive constraints cause oversize reaction. Therefore, this part still needs enough attention and it is better to reinforce it by reinforcements.

## Summary

In this paper, the PSD method based on ANSYS is taken to calculate the displacement and stress of the intake tower when seismic wave contented a normal distribution occurs. The result shows that

the probability of dehiscence is above 68.3% when structure is under an earthquake and the maximal displacement occurs in the top of the structure. It means that it is very likely that the top of the structure rip off under the earthquake in degree nine.Therefore, it is necessary to strengthen the top of the structure by reinforcements or other methods.

# STUDIES ON SEISMIC MEASURES TO IMPROVE MASONRY INFILLED WALL

Yao-jun ZHANG [1,a] Xu-sheng DUAN [1,b] Xin-yuan WANG [1,c] cui-ling ZHOU [1] Yong SUN *

[1]Civil Engineering and Water Conservancy College of Shandong Agriculture University , Taian China

[a]email:wugenshui@163.com, [b]email: tumudxs@126.com,[c]email:dianawxy@gmail.com

**Keywords:** masonry infilled wall ; earthquake action ; seismic fortification measures

**Abstract.** brittle nature of masonry infilled wall and the wrong connection with the main structure , resulted in the destruction phenomenon in the earthquake . Based on the destruction phenomenon ,this paper analysis the Earthquake damage of masonry infilled wall , according to code for seismic design of buildings(GB50011—2001) and code for seismic design of masonry structures(GB50003—2011) , some seismic fortification measures were proposed in this paper aimming to improve seismic capability of infilled wall, thereby alleviate loss caused by earthquake.

Masonry material is widely used in china because of its low cost and easy availability. Masonry infilled wall is popular in frame structure and frame-shear wall structure. However, in recent earthquakes happened in china, especially in Wenchuan earthquake and Lushan earthquake, the performance of masonry structure is barely satisfactory. In areas where seismic intensity reached 7 degrees, 8 degrees, and 9 degrees, the main structure of many structures that are well designed were not destructed, however the destruction of infilled wall was very common instead. For example, the new teaching building of Lushan middle school , which was built after the 512 great earthquake in 2008 according to the standard construction of anti eight degree seismic intensity, was damaged in the latter earthquake, especially for the frame filled walls. The large scale cracking of masonry infilled walls in seismic region and the possibility of immediate collapse of some masonry walls caused the structure unserviceable. The buildings were rated as danger in seismic emergency assessment. For buildings that are classified as second seismic precaution criterion, such as medical buildings and buildings in middle school and primary school, the function of the building was interrupted after earthquake, which has great influence to the society. The increased rehabilitation cost led to unnecessary economic loss.

Because of the fast economic development and fast improvement of living standard in China, higher seismic capability for buildings is widely expected. In our existing "three level" seismic precautionary target, it is common sense and urgent need for engineers to improve the seismic capability of non-structural components, prevent or alleviate seismic damage of these walls and to take efficient design method and seismic measures.

## 1.Seismic damage performance of masonry infilled walls

### 1.1 Seismic damage caused by irregular plane and vertical structural assembly of walls.

The main building structure is regular in plane and vertical assembly, but the masonry infilled walls are irregular, which is shown in two aspects: 1. walls are rare in one side, but dense in the other side. This would cause the stiffness eccentricity of actual structure and torsion failure during earthquake; 2. To form large space for ground floor, fewer walls are assembled, while more walls are assembled in upper structure, forming a up-rigid-down-soft structure. During earthquake the structural deformation concentrated in the bottom of the structure, which caused excessive deformation in bottom and severe destruction such as collapse of walls. As indicated in Fig.1

**1.2** Inappropriate connection between masonry infilled wall and the main structure

Masonry infilled wall built between the columns and the michinaga breast wall because of windows on the wall opened to the columns , which forms the actual built-in function for frame column. The column constrained by rigid constraints from the breast which makes the effective length of column

shorter, becomes short column .then the seismic shear force subjected by the column increases ,as a result , shear failure of the column occurrs. oblique cracks appears on the column in the range of window heigh , even brittle failure happens as shown in Fig. 2 . Interior masonry partition which isn't built to the top of the frame beam in frame structure and single-story factory buildings ,or exterior wall which is built partially between the concrete columns,would also cause the frame column becoming into a short column and lead to shear failure.

Fig.1

Fig.2

**1.3 Seismic hazard diversity of masonry infilled wall caused by different types of structural**

The deformation of frame structure is given priority by shear deformation in horizontal earthquake action . As a result, the story drift of the bottom floor is much larger and the destruction of the masonry infilled wall at the bottom floor is the most serious.However the deformation of frame - wall structure in horizontal earthquake action is between the bend and shear deformation. The story drift of the upper structure is larger .Therefore, the upper infilled walls are damaged heavier.

**2.Measures for strengthening seismic capability of masonry infilled wall**

The main reason for the destruction of the masonry infilled wall is: The low shear capacity , The small deformation capacity, The invalid connection between wall and frame. The wall tend to be damaged on shear-failure or scattered in horizontal earthquake action. When the strength and stiffness of masonry infilled wall which is built in the middle of the frame column and beam is bigger, the horizontal earthquake produced by earthquake shocks on the wall will push the frame, which would cause the destruction of the beam-column joints. Some requirements can be found in "code for seismic design of buildings'' (GB50011-2010) in China, which specifies that a seismic adverse effect on frame should be estimated to obviate the destruction of the main structure caused by these unreasonable arrangement of the frame infilled walls and partition walls.

**2.1 The plane and vertical arrangement of Masonry infilled wall should be regular**

Masonry infilled wall is different from the light partition wall, although it is also a nonstructural component. To a large extent masonry infilled wall can change the dynamic characteristics of structure because of its bigger lateral stiffness and influence the seismic performance of the whole structure. So we cannot arrange masonry infilled wall as random . In order to avoid torsional vibration because of eccentricity of structure in earthquake shocks ,the plane arrangement of walls should be uniform and symmetric ,and the vertical arrangemen should be consistent in order to avoid the adverse increase of shear force for frame in floor where the infilled wall is interrupted. If there are functional requirements that masonry infilled wall can't be built in the bottom floor, We need to consider the practical layer stiffness, including the stiffness of the infilled wall. In addition ,some bracing can be designed in the bottom floor to adjust the stiffness ratio between the layers and avoid the formation of the weak floor.

**2.2 Ameliorating connection of masonry infilled wall and column**

The connection of masonry infilled wall and frame or single-story factory affect the dynamic performance and seismic capacity of the whole structure. The influence on frame will be different as the different ways is used in the connection between the two things.

Code for seismic design of buildings specifies that: when the length of the wall is larger than 5m, tie bar should be used between the top of the wall and the beam; when the length of the wall is larger

than 8m or is twice the floor height, reinforced concrete structural columns should be used. When the height of the wall is larger than 4m， horizontal tie beam along the whole length of the wall which is connected to columns should be used in the middle of the wall. In earthquake zone, cracks can be found in walls whether code for seismic design is complied with or not. X-cracks can be found in walls between structural column and frame column, as indicated in Fig3. The author presents that when the length of walls is larger than floor height, it is appropriate to use structural columns and horizontal tie beam. With the coordination of structural column and horizontal tie beam, it is possible to limit the development of cracks and to prevent collapse of walls. As indicated in Fig.4.

Fig.3

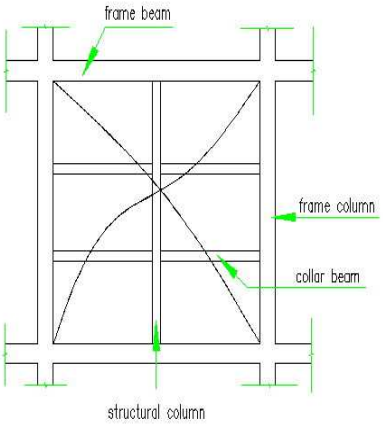

Fig.4

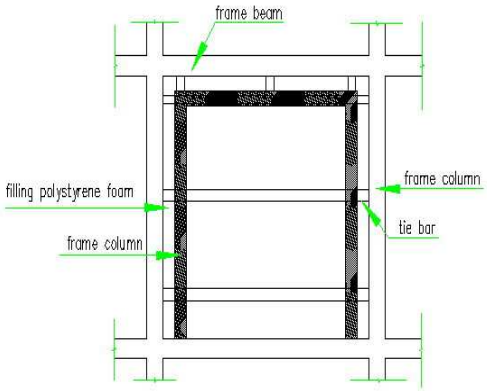

Fig.5

In addition, flexible connection can also be adopted between masonry infilled walls and frame. If using this kind of connection, when calculating frame structure only the weight of the masonry infilled wall should be considered while the influence of its stiffness and strength could be ignored. If intercolumniation of the main structure is small, and the length of the masonry infilled wall is not large, the author presents that the disconnection way of the wall and the main body can be used as shown in Fig. 5. Gaps should be reserved between both ends of the infilled wall and the frame column, so as between the top surface of wall and frame beam. polystyrene foam plastic slat or polyurethane foam material, and silicone rubber or other elastic sealing materia can be used in sealing the gaps between the frame and the wall. The size of the gap can be determined according to the allowed frame structural deformation between layers in the basic and rare earthquakes, which should not be less than 20mm. The structural columns should be set on both ends of the infilled wall (In construction of the structural columns within masonry infilled wall, there is no need to set combed joints). The distance between structural columns should not be too large, the vertical reinforcement in structural columns should be joined with the embedded parts or reserved steel in the frame beam. The reserved tie bars in frame column can be anchored in the structural columns in walls. Every 500mm 2Φ6 tie bars should be set between wall and structural columns. The length of tie bars extended into the wall should be determined according to the requirements of seismic code. In order to ensure out-plane stiffness of the masonry infilled walls, level collar beam or reinforced concrete belt could be added along the height direction of the wall. The disconnection of the infilled wall and frame beam-column is in order to

reduce the beam-column's incremental launching affection and constraints which are produced by the masonry infilled wall in earthquake and to avoid the damage of the frame. Grip iron can also be used in the releasing connection of the masonry infilled wall and frame.

**2.3 improving the shear resistance of masonry infilled wall**

Material strength grade of masonry infilled wall should not be too low,Otherwise, when the frame has a slight change , masonry infilled wall might crack, and easy to be damaged,even causing casualties and property losses in accidental loads or low horizontal earthquake action，Masonry infilled wall consists of block and mortar,In the case of shear-compressive failure and shear-bond failure ,The strength of the block almost doesn't impact on shear strength of masonry .But mortar strength has a direct effect on shear strength of masonry whatever kinds of damage . Especially in shear-compressive failure and shear-bond failure , The increase of mortar strength is more obvious to improve the shear strength of masonry. Therefore, When choosing materials of masonry infilled wall, mortar strength should be appropriate to be improved, so as to improve the shear resistance capacity of the wall.

In concrete-block wall, a core column can also be set. The shear capacity of masonry infilled wall is also influenced by concrete in core column. Due to its own shear strength of concrete in core column and 'hook-action'between core column and masonry wall , the shear strength of masonry infilled wall is improved greatly with the increase of concrete strength in core column.

**2.4 Ensure the construction quality of the wall**

When the masonry infilled wall builded , the full degree of horizontal mortar joint , the thickness of horizontal mortar joint , The moisture content of the brick and masonry bond are related to the construction quality of masonry wall.If the construction quality of the wall is ignored , the seismic resistance of the wall will be reduced.so we can't neglect the construction quality for the wall is designed not to support certain loads.

## 3 Conclusion

Masonry infilled wall can't adapt to the movement and deformation produced by the frame (including frame-wall structures )because of its brittle nature and poor integrity . After a series of earthquakes , a large number of cracks and collapses had been seen.At present , lightweight wallboard is still unable to be used widely in our country ,while the application of masonry infilled wall is common .More attention must be payed to the concept design and details of seismic design of masonry infilled wall,which Can greatly reduce the seismic damage of buildings, reduce the economic loss and the threat to people's life and property caused by the earthquake.

**Keywords:** Earthquake action; Response spectrum; vertical action; Site coefficient; Characteristic period

**Abstract.** In order to further regulate the vertical earthquake action in seismic design specification, to overcome the unreasonable and inconvenient flaws in certain conditions by using vertical to horizontal spectra ratio function, the feasibility of stipulating vertical design response spectrum with the same way of horizontal one is deal with in this paper.

1513 sets of three component records during 64 earthquakes from NGA-west1 database are selected and grouped by magnitude, distance and site conditions. Average acceleration response spectrum of each group is generalized to get the corresponding mean maximum amplitude and effective peak acceleration EPA. Furthermore, some groups with EPA in an interval are merged into one. Once again, the parameters, such as maximum amplitude and characteristic periods of each final grouping are acquired by the same way. The former is divided by the corresponding horizontal value for site category, to obtain the site coefficient for vertical action. Finally a preliminary suggestion of vertical site coefficient and characteristic period are presented. Comparison of observed data with results from the new suggestion and those from spectral ratio shows that the improvement of this study is obvious.

## Introduction

As well known, vertical ground motion plays an important role on damage of engineering structure during earthquake [1]. However, engineers for seismic design think highly of horizontal earthquake action stipulated in seismic design specification, since there is no lateral support on the upper part of the most engineering structure, and there is always more redundancy in structure capacity to vertical load in general. In checking calculation for seismic design of large scale and/or complex structure, the combine effect of actions at two or three directions should be taken into account. In most of seismic design codes, vertical action is stipulated simply as the half or two third of the horizontal one, i.e. the all amplitudes of design acceleration spectrum are scaled by the same reduction ratio, while the shape of the spectrum keeps the same as the horizontal one[2]. In those specifications that the vertical action is specially stipulated, the design spectrum is scaled by a spectral ratio that provides the reductions in different period ranges, so the shape of vertical spectrum could be different from the horizontal one[3], or by other spectral parameters also could define different spectrum for the vertical action from the horizontal one[4]. The shortcomings of the former are pointed out and a preliminary result of the latter is presented in this paper.

**The necessity to modify the relative provisions in Guidelines for Seismic Design of Highway Bridges (GSDHB)**

GSDHB provides vertical design spectra by vertical to horizontal (V/H) spectral ratio, constant 0.65 for rock site, ratio function for soil site as follows [3].

$$\mathrm{R}=\begin{cases}1.0 & T<0.1\\ 1.0-2.5(T-0.1) & 0.1\le T<0.3\\ 0.5 & T\ge 0.3\end{cases} \tag{1}$$

where T is for period in second. The horizontal spectra is provided as

$$S=\begin{cases}S_{\max}(5.5T+0.45), & T<0.1s\\ S_{\max}, & 0.1s\le T\le T_g\\ S_{\max}(T_g/T), & T>T_g\end{cases} \tag{2}$$

where，$S_{\max}$ is the maximum amplitude of the spectrum; $T_{\mathrm{g}}$ is characteristic period in second. The $S_{\max}$ is defined as

$$S_{\max}=2.25C_iC_sC_dA \tag{3}$$

where A is design basic acceleration of ground motion from seismic zoning map; $C_i$ is the important coefficient, takes value of 1.0 for type A bridge; $C_s$ the site coefficient; $C_d$ the damping adjustment coefficient, 1.0 for damping ratio 0.05. The $C_s$ is a new one to emphasize the effect of local site condition on $S_{\max}$, not only on the character period $C_s$ is not related with vertical action provision directly, but is necessary to provide the action with same way for horizontal one. The same provision is adopted in Specification of seismic design for highway engineering [5].

The idea to do with this way is from the two facts, spectral ratio is much more stable than spectral parameters in statistics, and the number of vertical motion data is just about half of the horizontal one, not enough for statistics to take into account the various A values and site categories. However, for soil site, there should be a slope segment from $T_g$ to 0.3 second on the vertical spectrum curve, and there should be one more decreasing segment from 0.3 second to $T_g$ with rate faster thane $\mathrm{T}^{-1}$ if $T_{\mathrm{g}}$ less than 0.3 second, neither easy nor reasonable in design. This fact shows the necessity to present a new modification in this paper.

**Data base from NGA-west1 and the preliminary grouping**

Data base from NGA (Next Generation Attenuation) program in the United States are adopted in this paper. Totally 1513 recording sets during 64 earthquakes with magnitude 4.2 to 7.9 from 1952 to 2003, are chosen with 4 criterions, PGA no less than 200 gals, recorded at ground or at basement or the first floor in building less than three stories, data on site condition is available, and data of response spectra, earthquake parameters, data of observation stations are also available. Recording data is not adopted if there is no vertical record in a set.

Data grouping is the key step in spectra parameters since the A value depends on $S_{max}$ that varies with magnitude, distance and site condition. The preliminary grouping on site category as I，II and III by Chinese site classification criterion, but category IV can not be taken as a group since the data is too few, just 6 in 1513; on magnitude as [4.5，5.5]，（5.5，6.5]，（6.5，7.5] and（7.5，8.5），in brief M5, M6, M7 and M8 respectively, the number of record sets are 251, 340, 496 and 420; on distance as（0，10]，（10，30]，（30， 50]，（50，100]，（100，200]，the corresponding number of record sets are 53，252，313，339，274 and 276. The numbers of each grouping are listed in table 1.

Table 1 The data set numbers in preliminary groupings

| Site category | Distance | M5 | M6 | M7 | M8 | Total |
|---|---|---|---|---|---|---|
| I | 0-10 | 3 | 5 | 4 | 3 | 15 |
| | 10-30 | 11 | 8 | 23 | 6 | 48 |
| | 30-50 | 9 | 17 | 21 | 8 | 55 |
| | 50-80 | 8 | 12 | 19 | 18 | 57 |
| | 80-120 | 7 | 3 | 22 | 18 | 50 |
| | 120-200 | 2 | 0 | 4 | 21 | 27 |
| II | 0-10 | 4 | 13 | 11 | 4 | 32 |
| | 10-30 | 28 | 77 | 52 | 16 | 173 |
| | 30-50 | 51 | 89 | 48 | 29 | 217 |
| | 50-80 | 55 | 49 | 76 | 54 | 234 |
| | 80-120 | 35 | 16 | 61 | 69 | 181 |
| | 120-200 | 3 | 7 | 96 | 75 | 181 |
| III | 0-10 | 0 | 5 | 1 | 0 | 6 |
| | 10-30 | 4 | 8 | 18 | 1 | 31 |
| | 30-50 | 9 | 8 | 10 | 14 | 41 |
| | 50-80 | 8 | 13 | 13 | 14 | 48 |
| | 80-120 | 9 | 8 | 8 | 18 | 43 |
| | 120-200 | 5 | 2 | 9 | 52 | 68 |

**Acquiring of EPA values and the final grouping**

From each group, a mean acceleration response spectrum is obtained by simple arithmetic average. Then the mean spectra are generalized from eq. (2). An example for site category II, M6 and distance 80-120 km is shown in Fig. 1.

Equivalent peak acceleration EPA is acquired from the maximum amplitude of the generalized spectrum for each group by means of dividing the maximum amplitude by the constant 2.25 in eq. (3). The EPA here for grouping is for horizontal component, since A on seismic zoning map is defined as horizontal one and for site category Ⅱ. Therefore, the final grouping is decided as EPA 0.05, 0.1, 0.15, 0.2, 0.3, and 0.4g with value ranges of no larger than 0.05, 0.05 to 0.13, 0.13 to 0.18, 0.18 to 0.25, 0.25 to 0.35, and no less than 0.35g. The corresponding distance R and magnitude M intervals are R∈（10，200] and M∈ [4.5，5.5]，R∈（50，200] and M∈（5.5，6.5], R∈（80，200] and M∈（6.5，7.5] for EPA 0.05g; R∈（30，50] and M∈（5.5，6.5], R∈（50，80] and M∈（6.5，7.5], for EPA 0.1g; R∈（10，30] and M∈（5.5，6.5], R∈（30，50] and M∈（6.5，7.5], for EPA 0.15g; R∈[0，10] and M∈ [4.5，6.5]， R∈（10，30] and M∈（6.5，7.5] for EPA 0.2g; R∈[10，50] and M∈ [6.5, 8.5) for EPA 0.3g; R∈[0，10] and M∈ [6.5, 8.5) for EPA 0.4g, according the statistical result.

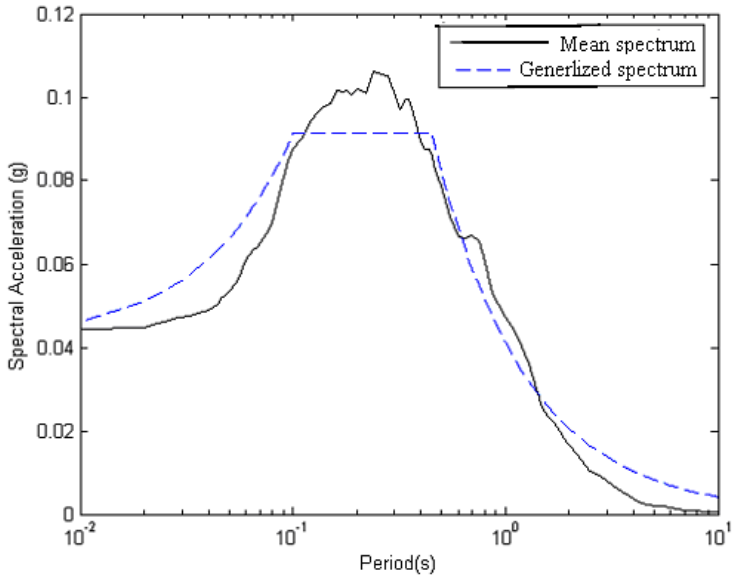

Figure 1 An example of mean spectrum and its generalized one

**A preliminary suggestion of vertical action**

Once again, the $S_{max}$ of each final group are acquired from the same way as mentioned above. This two step procedure is very significant to avoid the mistakes to grouping with PGA or $S_{max}$ of the original records.

The site coefficient values could be obtained from the ratios of vertical $S_{max}$ for site category I, II and III to the corresponding horizontal ones for category II. The suggested values generalized to keep the small increment as 0.05, are listed in table 2. One can see from the table that the average value for site category I is about 0.65, and getting larger as A value increasing for the other two site categories.

Table 2 Vertical site coefficient values suggested by the paper

| A<br>Site category | 0.05g | 0.1g | 0.15g | 0.2g | 0.4g |
|---|---|---|---|---|---|
| I | 0.70 | 0.55 | 0.50 | 0.55 | 0.80 |
| II | 0.60 | 0.60 | 0.70 | 0.75 | 1.00 |
| III | 0.50 | 0.65 | 0.75 | 1.20 | 1.20 |

The characteristic period values could be acquired from the mean generalized spectra for the 6 groups and 3 site types, and the results are listed in table 3. One can see from the table, the characteristic period of vertical component is shorter than that of horizontal component, and not change so much with the site category.

Table 3 The characteristic period values acquired in the paper

| A<br>Site category | 0.05g | 0.1g | 0.15g | 0.2g | 0.4g |
|---|---|---|---|---|---|
| I | 0.18 | 0.25 | 0.21 | 0.18 | 0.28 |
| II | 0.31 | 0.35 | 0.19 | 0.18 | 0.15 |
| III | 0.27 | 0.24 | 0.15 | 0.15 | 0.15 |

## Conclusion

Based on a new data base from NGA-west1, the values of site coefficient and characteristic period for vertical component are acquired statistically by the same way for horizontal one, listed in table 2 and table 3.

It shows that this way is better than the way of spectral ratio, not only the vertical spectra always keep shapes with three segments, but also the deviations of the observed data to spectra suggested in this paper. Of course, the spectral ratio in eq. (1) was obtained from data base with some differences from the one adopted in this paper.

A new data base with much more records was released in 2012 as NGA-west2 by NGA project. The final suggestion should be from the result of the new data, so the suggestion of this paper is just a preliminary one that shows the possibility to stipulate vertical earthquake action in seismic design specification by the same way for horizontal action. The parameters for site category should be inferred further from the limited data and variation trend of the parameter with site category.

**Keywords:** Assembled precast concrete residence, Finite element, Seismic response analysis, Interbedded drift angle

**Abstract.** Assembled precast concrete structure is composed of precast element, which needs to be assembled and connected as the main force component. It is propitious to the development of building industrialization, enhancing production efficiency and promoting green building. Seismic response of a 6 storey assembled precast concrete residence was analyzed based on finite element software ANSYS. The results show that stiffness of assembled precast concrete residence is larger, and all of interbedded drift angles comply with stipulations of the standard.

## Introduction

A large number of repetitive work is completed by prefabricated production line in assembled precast concrete, which is high mechanization and automation. Combining with standardization of component, work efficient could be improved greatly and construction period could be shorted[1]. Compared to traditional residence, industrialized residence, represented by assembled precast concrete residence, saves more concrete and steel and promotes the recycling of waste. Assembled precast concrete residence is one of building structure development directions in China.

RL Hutchinson et al.[2] had a research on 9 shell walls connected by post-tensioned method, analyzing failure mechanism and characteristics of node. Sritharan S et al.[3] did a pseudo-dynamic test of 5-storey prefabricated concrete structure. Huiying Wang et al.[4] analyzed mechanical performance, deformation characteristics and internal force distribution characteristics through the loading experiment of composite slab. Weiwei Sun et al.[5] proposed two new unbonded post-tensioned assembled concrete couped short-pier shear wall structures. Seismic response of a 6-storey assembled precast concrete residence in Liaocheng was analyzed based on finite element software ANSYS.

## Project overview

The assembled precast concrete residence (shown in Fig.1) is located in Liaocheng, Shandong Province, with a total construction area of 5595.39m$^2$, 6 stories high, each storey height being 3m. Floor slab is made of PK prefabricated composite slab, and external wall is made of composite thermal insulation wallboard. The node connection pattern is embedded column, concealed coping made of current pouring concrete.

The thickness of wallboard and floor are 160mm and 100mm respectively, with the cross sectional dimension of embedded column and concealed coping being 160mm×300mm. Concrete grade is C30, and steel grade is HRB335.

Fig. 1 The assembled precast concrete residence

**finite element model**

The finite element model was established by the way of integrated model. Wallboard and floor were simulated by Solid65, with rebar simulated by parameter setting. Horizontal and vertical reinforcement ratio were 0.2% and 0.25% respectively. Boundary condition is limiting UX, UY, UZ and rotation of three directions. The finite element model is shown in Fig. 2.

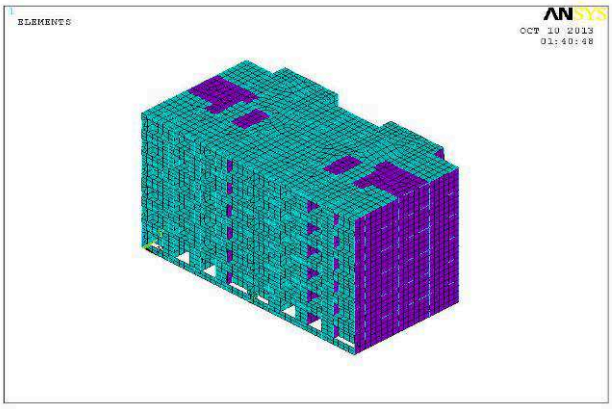

Fig. 2 Finite element model

**Analysis of dynamic characteristics**

Modal analysis to the finite element model was made through Block Lanczos provided by ANSYS, and the 5 order natural vibration period and frequency was got, as shown in Table 1.

Table 1 Natural vibration period and frequency

| order | natural vibration frequency（Hz） | natural vibration period（s） |
|---|---|---|
| 1 | 12.208 | 0.082 |
| 2 | 14.237 | 0.070 |
| 3 | 15.909 | 0.063 |
| 4 | 28.512 | 0.035 |
| 5 | 33.895 | 0.029 |

The first vibration mode of the structure is X-direction horizontal vibration, and the second is Y-direction horizontal vibration, with the third and forth being torsion. The vibration modes are shown in Fig. 3~6.

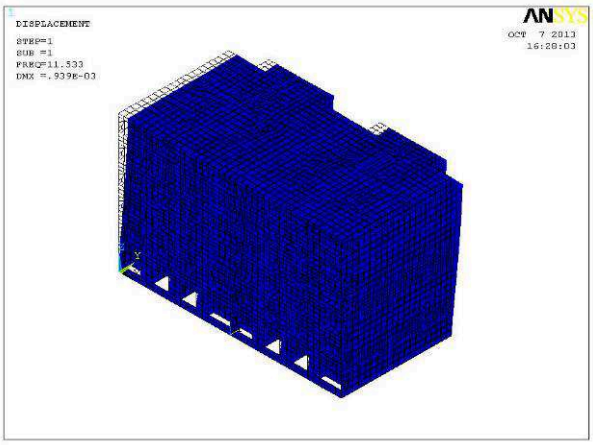

Fig. 3 The first vibration mode(X-direction)

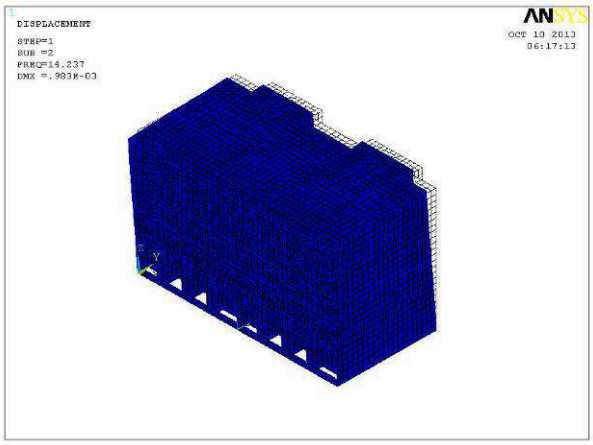

Fig. 4 The second vibration mode(Y-direction)

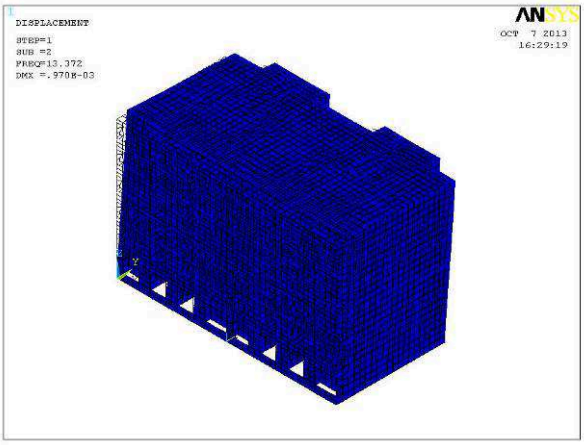

Fig. 5 The third vibration mode(torsion)

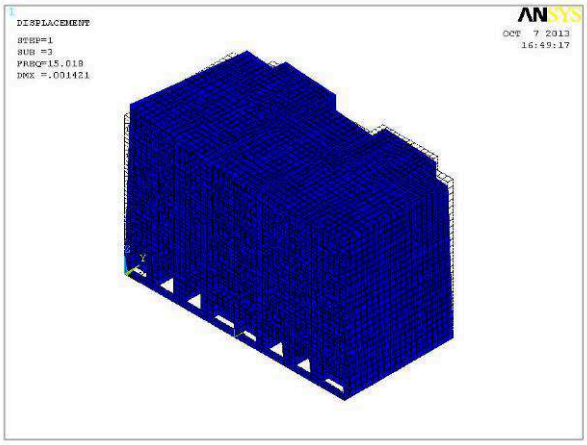

Fig. 6 The forth vibration mode(torsion)

## Seismic response analysis

Seismic response analysis of structure is closely related to peak acceleration, duration of earthquake, and properties of soil. Seismic fortification intensity of Liaocheng is 7, and seismic acceleration is 0.15g, with site category being Ⅲ. According to frequently occurred earthquake, the maximum value of earthquake acceleration used by time-history analysis is 35cm/s$^2$, so Elcentro wave was chosen to analyze. Some of displacement time history curves are shown in Fig. 7~8.

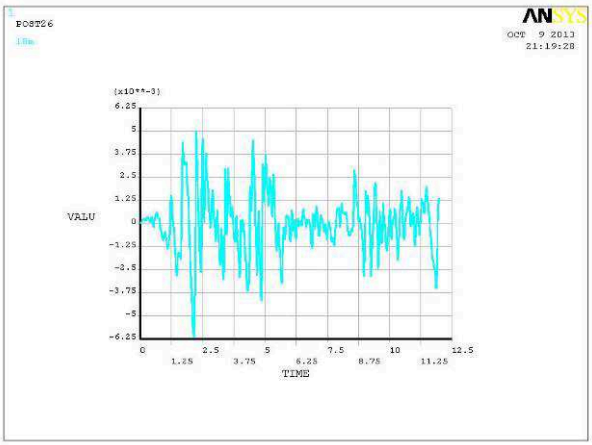

Fig. 7 H=18m (Y-direction)

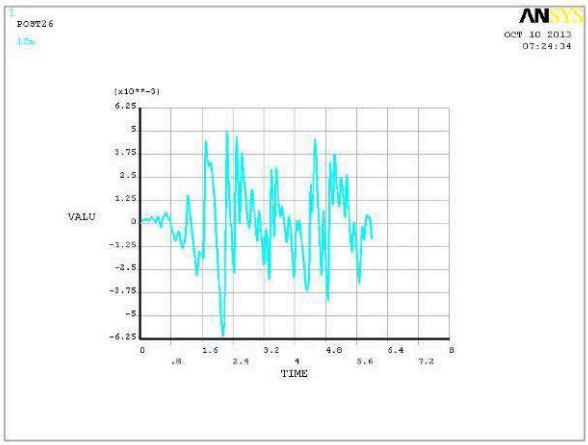

Fig. 8 H=12m (X-direction)

The maximum displacements of each floor were got by analyzing the displacement time history curves, and interbedded drift angles (shown in Table 2) were calculated.

Table 2 Interbedded drift angle

| | Each floor roof | Storey (m) | maximum displacement (mm) | interbedded drift angle | specification limit |
|---|---|---|---|---|---|
| Y-direction | 18 | 3 | 6.25 | 1/3500 | 1/1000 |
| | 15 | 3 | 5.4 | 1/3300 | |
| | 12 | 3 | 4.5 | 1/2500 | |
| | 9 | 3 | 3.28 | 1/3000 | |
| | 6 | 3 | 2.3 | 1/2600 | |
| | 3 | 3 | 1.125 | 1/2666 | |
| X-direction | 18 | 3 | 7.9 | 1/3750 | 1/1000 |
| | 15 | 3 | 7.1 | 1/3529 | |
| | 12 | 3 | 6.25 | 1/2068 | |
| | 9 | 3 | 4.8 | 1/1875 | |
| | 6 | 3 | 3.2 | 1/1875 | |
| | 3 | 3 | 1.6 | 1/1875 | |

By the above calculation, the integral rigidity of the structure is large, with no weak storey existed, and the interbedded drift angles less than the standard value. So the material parameter and geometric parameter of the assembled precast concrete structure all meet the requirements.

## Conclusions

By analyzing seismic response of assembled precast concrete structure, conclusions are shown as follows:

(1) The first vibration mode of the structure is X-direction horizontal vibration, and the second is Y-direction horizontal vibration, with the third being torsion, whose natural vibration frequencies are 12.208Hz, 14.237Hz and 15.909Hz respectively.

(2) In the 7 degree seismic fortification intensity area and Ⅲ site category, making the thickness of wallboard and floor be 160mm and 100mm, concrete grade be C30, and steel grade be HRB335, the integral rigidity of the structure is large, with no weak storey existed, and the interbedded drift angles less than the standard value. So the assembled precast concrete structure meet the requirements.

**Keywords:** Seismic Design, Ultimate Displacement, Timber Structures, Tenon-mortise Joints, Chinese Ancient Buildings, axial compression ratio.

**Abstract.** The available methods to determine the ultimate displacement of the building structures have been put forward, and the disadvantages of the methods are analyzed. According to the seismic design theory based on displacement of structures and reinforcement standard of Chinese ancient architecture, which refers to the modern structural engineering requirements, the ultimate displacement of the timber structure on Chinese ancient buildings, which is under the obvious P-Δ second-order effects, has been studied. The ultimate displacement and the drift ratio limit value of different axial compression ratio are determined by the experiments and Theoretical calculation. The results of the study of ultimate displacement can provide the technical support for the rehabilitation of the ancient timber buildings.

## Introduction

Traditional seismic design is a kind of design based on strength, which controls the structural capacity by the ultimate capacity of the buildings[1,4]. With the research and studies of the structural capacity step by step, it is realized that the dissipation of deformation capacity and energy capacity is the key reason for the collapse of timber structure. So, it is reasonable to make the seismic design based on the ultimate displacement. It is most important thing for seismic design to the timber structure of ancient buildings to create the stable criterion with the large earthquake.

## Determination Method of the Ultimate Displacement

**The ultimate displacement of the timber structure on the code.** According to the specification of the strengthening and maintenance to ancient timber buildings, the drift ratio limit value of the timber structure is 1/30 in the deformation checking of seismic design. So, the ultimate deformation of the timber structures of ancient buildings is expressed as follows:

$$\Delta u = [\theta]_p = \frac{1}{30} H \tag{1}$$

In the formula, "H" is equivalent to the height of the column of timber structure, $[\theta]_p$ is equivalent to the elastic-plasticity drift ratio limit value.

**The ultimate displacement based on the residual horizontal capability.** In engineering, the residual horizontal capability is defined as the 85 percent or 75 percent of the biggest horizontal capability, and the corresponding elastic-plasticity displacement is the ultimate displacement. As is shown in fig.1, the biggest horizontal capability of the structure column is as $P_{max}$, the $0.85P_{max}$ is the residual horizontal capability whose corresponding displacement of the $0.75P_{max}$ is $\Delta u2$.

**The anti-overturning of the timber structure of ancient buildings.** As is shown in fig.2 of the reference [5], the anti-overturning ultimate displacement is confirmed that the biggest horizontal inertial force of earthquake $F_E$ is confirmed as follows:

$$F_E = \mu G_w \tag{2}$$

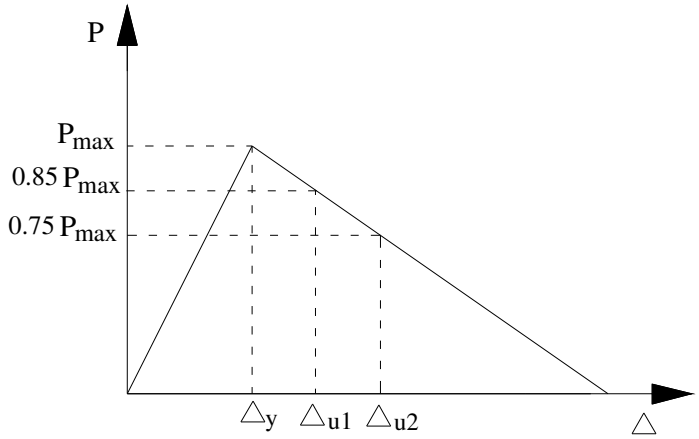

Fig.1 Ultimate displacement based on the residual horizontal capability

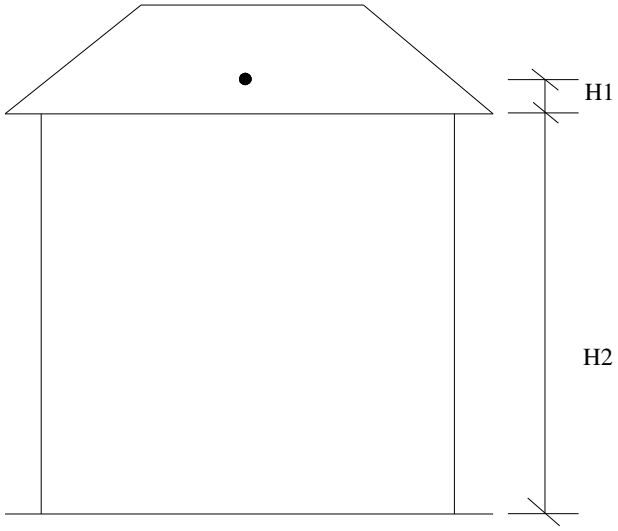

Fig.2 Calculation sketch of ancient timber buildings

The total overturning of earthquake $M_e$ is conformal as follows:

$$M_e=F_E(H_2+H_1/3)=\mu G(H_2+H_1/3) \tag{3}$$

The anti-overturning moment which is proved by the weight of the structure is confirmed as follows:

$$M_R =G[0.5L-\Delta u] \tag{4}$$

$$\Delta u = 0.5L-u(H+h/b) \tag{5}$$

The premise of the ultimate displacement formula creation above the wooden frame to resist overturning is assumed as the upper structure rigidity good rigid block, and only one side of the pivot around the state. In fact, a typical ancient timber structure is composed of a base, column layer and frame layer which are three relatively independent parts.

The connection between the timber components is mortise and tenon joint, which makes the ancient timber structure not be an absolute rigid. The self vibration period of this type of structure is longer. Under horizontal earthquake action, it is easy to produce the column frame swing instead of the whole structure. In addition, the rational control of high aspect ratio is used to prevent the

possibility of overturning the wooden structure in the structure layout of Chinese ancient timber architecture, which is in references [6][7][8].

**Method to determine the ultimate displacement in this paper**

There are a lot of factors which influence the ultimate displacement of the timber structure such as the material strength of the timber, rigidity of the tenon-mortise joints and the axial compression ratio. There is a obvious P-Δ second-order effects in the timber structures whose lateral displacement is big, because of the semi-rigid tenon-mortise joints. So, it is more important for the axial compression ratio to the ultimate displacement of the timber structure. The ultimate displacement and the drift ratio limit value of different axial compression ratio is shown in the table1.

From the table1, we can see that With the increase of axial compression ratio, the ultimate displacement was decreased by using calculation method1 and method2. This paper determined the ultimate displacement under different axial compression ratio, met the limit displacement required maintenance and strengthening of ancient timber buildings technical specification (referred to as the standard value of value) as the standard.

Table1 Ultimate displacement and the drift ratio limit value of different axial compression ratio

| Structure number | | compression ratio | Method1 | | Method2 | | | |
|---|---|---|---|---|---|---|---|---|
| | | | $\triangle_u$ (mm) | $\theta_p$ | $\triangle_{u1}$ (mm) | $\theta_{p1}$ | $\triangle_{u2}$ (mm) | $\theta_{p2}$ |
| Result1 | KJ1 | 0.1 | 50 | 1/30 | 25.21 | 1/60 | 30.17 | 1/50 |
| | KJ2 | 0.1 | 50 | 1/30 | 20.13 | 1/75 | 22.04 | 1/68 |
| | KJ3 | 0.1 | 50 | 1/30 | 19.47 | 1/77 | 22.41 | 1/68 |
| | KJ4 | 0.1 | 50 | 1/30 | 26.33 | 1/56 | 32.26 | 1/46 |
| | Average value | 0.1 | 50 | 1/30 | 22.79 | 1/65 | 26.50 | 1/56 |
| Result2 | Th1 | 0.1 | 50 | 1/30 | 38.10 | 1/40 | 44.64 | 1/34 |
| | Th2 | 0.09 | 50 | 1/30 | 41.69 | 1/36 | 50.20 | 1/30 |
| | Th3 | 0.08 | 50 | 1/30 | 44.10 | 1/34 | 56.27 | 1/26 |
| | Th4 | 0.07 | 50 | 1/30 | 47.91 | 1/32 | 63.66 | 1/23 |
| | Th5 | 0.06 | 50 | 1/30 | 53.44 | 1/28 | 72.91 | 1/21 |
| | Th6 | 0.05 | 50 | 1/30 | 61.06 | 1/25 | 85.37 | 1/18 |

**Conclusion**

From table1, the ultimate displacement in this paper is confirmed as follows:

When the range of the axial compression ratio is $u<0.06$, the ultimate displacement is the 1/30 of the timber column; When the range of the axial compression ratio is $0.06<u<0.09$, the ultimate

displacement is the 1/40 of the timber column; When the range of the axial compression ratio is u>0.09, the ultimate displacement is the 1/50 of the timber column.

**Keywords:** Collapse Margin Ratio, Expected Annual Loss, Survival Probability, Incremental Dynamic Analysis, Probability of Collapse

**Abstract.** Incorporating the probability of seismic hazard, expected annual earthquake loss with different collapse margin ratio (*CMR*) has been studied in this paper. Nonlinear simulation models of reinforced concrete (RC) frames were analyzed using incremental dynamic analysis (IDA) under continuous earthquake intensity. The analytic results from four examples of RC frames show that the expected annual loss has negative correlation with the *CMR* of the concerned structures, and seismic loss basically decreases with increasing *CMR* at given ground motion intensity. The proposed idea herein could be regarded as a promising improvement on the quantification of earthquake loss estimation by utilizing *CMR* of structures.

## Introduction

Structural seismic damage prediction is to calculate cost of repair or reconstruction of structures under earthquake. Pacific Earthquake Engineering Research Center has proposed performance-based earthquake engineering that uses earthquake loss to quantify specific structure seismic performance [1,2,3].

The methodology has four steps including seismic hazard analysis, structural analysis, damage analysis and loss analysis. A total probability triple integral equation incorporating these mentioned steps is proposed. This is done by quantifying the rate of exceedance of a level of ground shaking; inter-relating the level of ground shaking with structural response and quantifying the likelihood of facility closure given a certain level of damage. Dhakal and Mander [4] used four-integral formula to estimate expected annual loss and converted the seismic risk into economic loss. The story-based loss estimation method improved and simplified the PEER method which became efficient and less computationally expensive than previous approaches [5]. Limiting the amount of time and resources spent on the loss estimation process will hopefully facilitate the acceptance of performance-based seismic design methods into the practical engineering community. So the earthquake loss assessment should rise to the building-level. The global damage index has been used to quantify building-level damage as the ratio between repair costs over the total replacement value of the building [6].

However all these methods do not give the seismic capability index of structure before earthquake loss is calculated. A methodology to assess seismic anti-collapse capacity was described in the Applied Technology Council project (ATC-63) [7], and the collapse margin ratio (*CMR*) introduced in ATC-63 is a reasonable index to evaluate total seismic capacity of a structure. Each structure has a *CMR* easily manipulated. Bigger is the *CMR,* larger seismic capacity has the structures [8]. Hence, the objective of this paper is to build a relationship between *CMR* and earthquake loss based on IDA method, which can provide an insight into new earthquake loss assessment method.

## Theoretical direct earthquake loss estimation framework

The used method herein is based on the PEER framework formula, involving four-steps as follow, and considering the collapse safety margin by collapse margin ratio (*CMR*) of structures [1].

$$\lambda(DV) = \iiint G(DV \mid DM) \left| dG(DM \mid EDP) \right| \left| dG(EDP \mid IM) \right| \left| d\lambda(IM) \right| \tag{1}$$

*DV* is quantitative measure used to assess seismic performance. *DS* defines different discrete states of the structure which includes the requirement of tasks specific repair. *EDP* is used to describe the seismic response of the structure such as peak or transient displacements and/or accelerations. *IM* defines the intensity of the earthquake hazard to the structure. The process of loss estimation incorporating *CMR* is shown as follow.

**Seismic hazard analysis**

Seismic hazard model describes the occurrence over time of a given ground motion intensity *IM* (e.g. structural fundamental spectral acceleration is used in this paper). This relation, commonly known in the form of a ground-motion IM and annual rate of exceedance $\lambda(IM)$, is expressed by the following power law equation [9]:

$$\lambda(IM)=k_0\cdot(IM)^{-k} \tag{2}$$

Where, $k$ and $k_0$ are empirical constants. Seismic hazard curves are given in Fig.1 (a) and (b).

**Collapse margin ratio of structure and collapse probability**

On the basis of fragility curve, ATC-63 report [7] gives a definition of *CMR* to quantitatively identify seismic safety margin of structures. *CMR* is the ratio of the median intensity of the collapse level ground motions, $IM_{50\%}$, to the maximum considered earthquake intensity, $IM_{MCE}$. IDA is the default procedure as suggested in ATC-63 report in which a number of strong ground motion are deliberately selected and a series of collapse intensities can be obtained correspondingly at the collapse-critical state of the structure of concern. With the results from IDA, collapse fragility can be defined through a cumulative distribution function which relates the ground motion intensity to the probability of collapse $P(C|IM)$.

$$CMR=IM_{50\%}/IM_{MCE} \tag{3}$$

**Structural response analysis**

Based on IDA method, structural response *EDP* due to differences in ground motions of the same intensity *IM* is obtained. The following equation Eq.4 assumes that *EDP* at given *IM* is lognormally distributed, see [3] for more details.

$$P_{CMR}(EDP>edp\mid IM)=\Phi_{CMR}\left(\frac{\ln edp-\mu_{\ln EDP|IM}}{\sigma_{\ln EDP|IM}}\right) \tag{4}$$

**Loss analysis and build relationship between CMR and loss**

When combining the probability for being within a damage state for a given *EDP* together with the associated loss ratio for each damage state, the loss ratio for that *EDP* is found. The total probable financial loss due to earthquakes of a given probability is the sum of the corresponding values for damage states, this can be written as Eq.5 [5]:

$$E_{CMR}(L_T\mid IM)=\sum_{j=1}^{5}P_{CMR}(DS_j\mid IM)\cdot L_{j,DS_j}\cdot P_{CMR}(NC\mid IM)+P_{CMR}(C\mid IM) \tag{5}$$

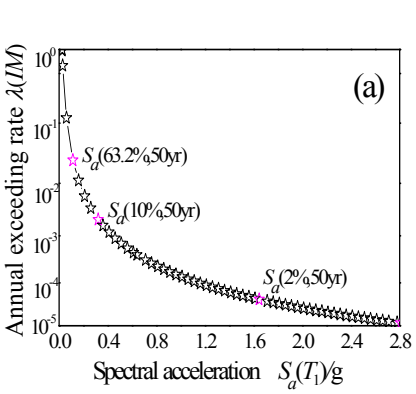
Combining directly with the ground motion hazard to get the mean and variance of the loss occurred on a per annum basis, see Eq.6:

$$\lambda_L=\int E_{CMR}(L_T\mid IM)\left|\frac{d\lambda(IM)}{d(IM)}\right|d(IM) \tag{6}$$

Where, $P_{CMR}(DS_j|IM)$ and $L_{j,DSj}$ are the respective probability and loss ratios for the $j^{th}$ damage state of structure with *CMR*.

**Example**

In this section, four reinforced concrete structures with different *CMR* have been used to verify the proposed method. These structural *CMR* curves have no intersection, see in Fig.2. Structural parameters and detailed design of these structures can be found in the reference [6]. The results of IDA are shown in Fig.2 and Fig.3, (horizontal axis of Fig.2 normalized by spectral acceleration of MCE then *CMR* can be obtained in Fig.3). $CMR_1$=2.61, $CMR_2$=2.06, $CMR_3$=1.51, $CMR_4$=1.46, so $CMR_1>CMR_2>CMR_3>CMR_4$.



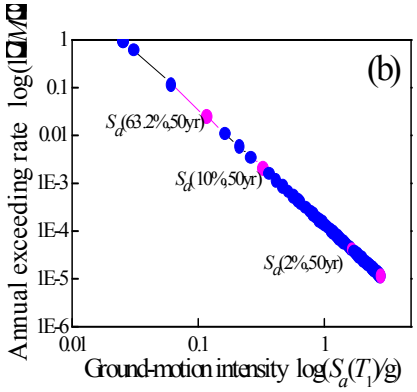


Fig.1 Seismic hazard in (a) linear coordinate (b) log-log coordinate

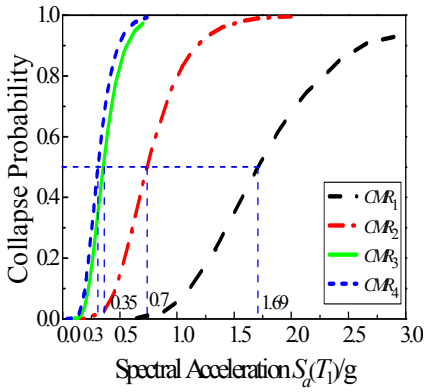

Fig.2 Collapse probability Curves

Fig.4 shows survival probability curves of structure with different *CMR* at a given damage level. It can be seen that a high value of *CMR* denotes a great survival probability at the same ground motion intensity. Consequently increased *CMR* can decrease damage probability of structure before collapse. The expected earthquake loss ratio basically decreases with increasing *CMR* at given ground motion. Each line represents a ground motion $S_a(T_1)$ continuously increasing from bottom to top and filling the whole rectangular space that consist of loss ratio and *CMR*, see in Fig.5. The relationship of loss ratio and *CMR* at five given intensity is shown in Fig.6.

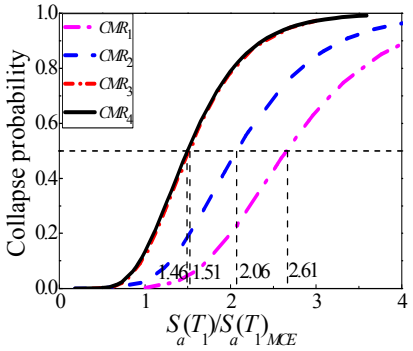

Fig.3 Collapse probability curve $S_a$ normalized by $S_{a,MCE}$

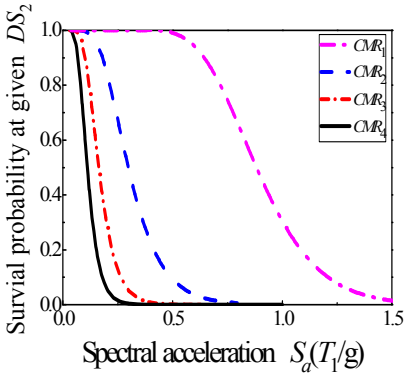

Fig.4 Survival probability at given damage state with different *CMR*

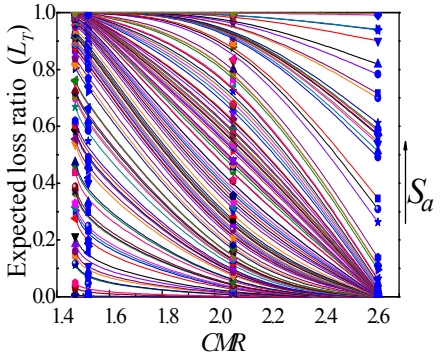

Fig.5 Curves of earthquake losses varying with *CMR* at continuous intensity

As shown in Fig.7, the earthquake loss ratio has negative linear relationship to *CMR* at design basic earthquake and maximum considered earthquake intensity respectively. Expected loss ratio at annual probability of *IM* is given in Fig.8. The loss ratio becomes smaller as the annual exceeding probability becomes bigger. Annual expected loss is the area beneath curve which calculated from Eq. 6, $CMR_1$ is the largest one among these four structures, while structural expected annual loss with $CMR_1$ is the smallest one significantly.

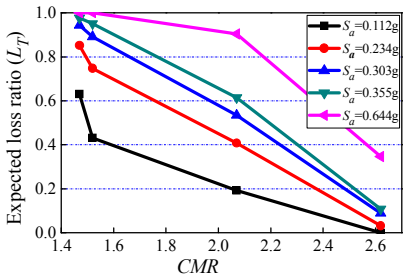

Fig.6 Curves of earthquake losses varying with *CMR* at five given intensity

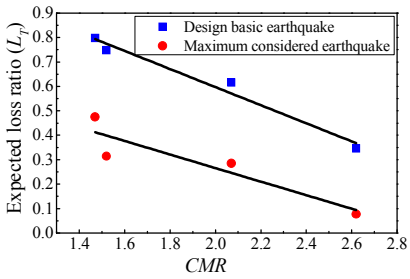

Fig.7 Negative linear relationship between loss and *CMR*

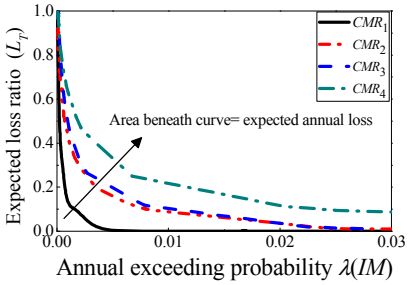

Fig.8 Annual earthquake losses with different *CMR*

## Conclusion

An approach to associate *CMR* with expected annual loss ratio of structure has been established. The results show that seismic expected annual loss decreases with increased *CMR* at a given ground motion intensity, but reduction rate of loss over *CMR* depends on the ground motion intensity. Expected annual loss ratio has negative relationship with *CMR* and can be reduced by improving *CMR* of structure.

# Earthquake Mitigation Effect Analysis Of Hysteretie DamPers In Steel frame

Chao Xu [1, a], Yongfeng Niu [1,b] and Yongxie Zhao [1,c]

[1]School of Civil Engineering,Jilin Jianzhu University,Changchun,China

[a]tianya880217@126.com, [b] yongxiezhao@163.com, [c]1140416324@qq.com

**Keyword:** Mild steel dampers; Steel Frame; Hysteretic loop; ABAQUS

**Abstract:** This paper analyses the frame without mild steel dampers and the frame installed the new T- type , box –type and S-type mild steel dampers by FEM ABAQUS. The results shows the frame installed the new mild steel dampers have smaller yield displacement and the fuller hysteresis curve at low cyclic load, but the initial stiffness, yield strength , stiffness after yielding are greater. Research shows that the new type mild steel dampers have good energy performance, and have the better effect to seismic framework.

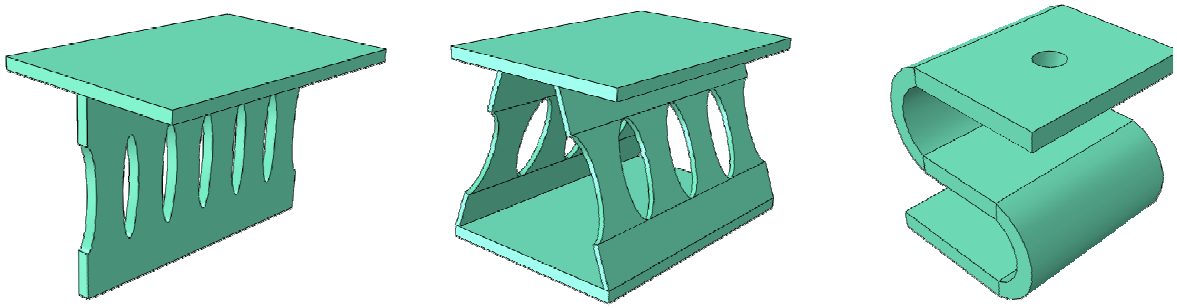
## Introduction

Earthquake disaster since ancient severely threat to human's survival and development. For example the Tangshan earthquake in 1976, and after 32 years later, the Wenchuan earthquake in 2008, even the Yushu earthquake in 2010, has caused serious personal and property losses. With the improvement of science and technology and people's living standard, the ability of prevent earthquake disasters has been improved, the structure of the damping control technology has get more and more researchers' attention both at home and abroad due to its characteristic of economy applicable energy consumption, simple structure, convenient maintenance, and the better damping effect. so the technology has become an effective method to dissipate earthquake energy.

The method of Earthquake energy dissipation and vibration is controlling the structure expected deformation by setting energy dissipation devices, so that the structure of subject does not occur serious damage under the severe earthquake, in which , the mild steel damper as a reasonable energy dissipater because of its low yield point, the higher flexibility and ductility, the better deformation tracking ability, the lesser effect on its performance by environment and the temperature, and it can absorb a lot of energy in the elastic-plastic deformation process, also low steel cost etc., has on the agenda gradually.

## Material selection

The new T- type , box –type and S-type mild steel dampers are showed in Fig. 1.Which are made from steel Q235, material constitutive relation uses ideal elastic-plastic material model , the relevant parameters in Table 1.In the Table 1, $f_y$ is yield stress, $f_b$ is ultimate strength, E is modulus of elasticity, $\varepsilon_y$ is yield strain and $\varepsilon_u$ is ultimate strain.Steel Frame use section steel HW176×204×12×12, steel support are pipes in Outer diameter of 50mm and inside diameter of 30mm.



T- mild steel damper box- mild steel damper S- mild steel damper

Table 1.Relevant performance parameters of Q235 steel

| $f_{y(\mathrm{N/mm^2})}$ | $f_{b(\mathrm{N/mm^2})}$ | $E(\mathrm{N/mm^2})$ | $\varepsilon_y$ | $\varepsilon_u$ |
|---|---|---|---|---|
| $235\times10^6$ | $370\times10^6$ | $210\times10^9$ | $1.119\times10^{-3}$ | $4.669\times10^{-3}$ |

**Loading model**

The model test loading model used displacement control loading method, often controlling load though Yield displacement or a percentage of the maximum the maximum displacement between layers. Displacement control loading method can be divided into three types according to the different Load amplitude: variable amplitude loading , amplitude loading and mixing amplitude loading.This article select variable amplitude displacement loading mode, appling horizontal displacement load on the coupling point. For the Fig.2:

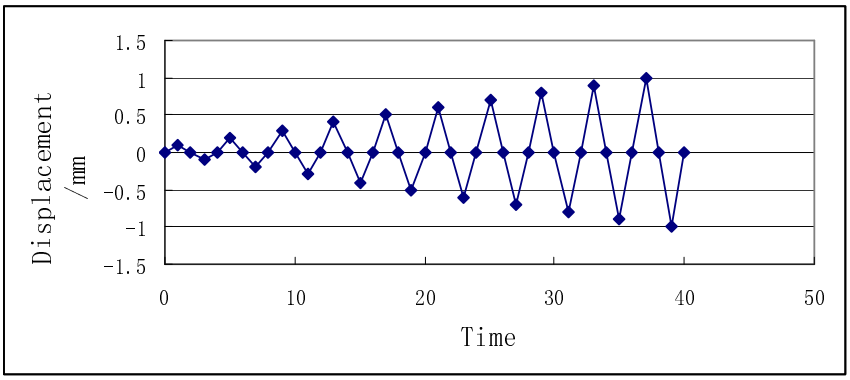

Fig.2 Displacement control loading method

**ABAQUS Simulation**

**4.1 Model building**

This paper modeling selects a layer framework façade,and computational model for a certain simplification,including:

1.It is considered full consolidation , no relative slip between beams, the support plate and the inclined column , dampers and the upper and lower surfaces connected with it;

2,Framework's deformation force only considered within the plane.

3.The connection of bottom of supporting inclined steel column to the beam seen as full consolidation.

### 4.2 Impact of mild steel dampers to the frame structures seismic performance

#### 4.2.1 Study on steel frame seismic performance without mild steel dampers

Fig.3 shows steel frame's Mises stress cloud and force - displacement hysteresis curve without mild steel dampers under cyclic load.

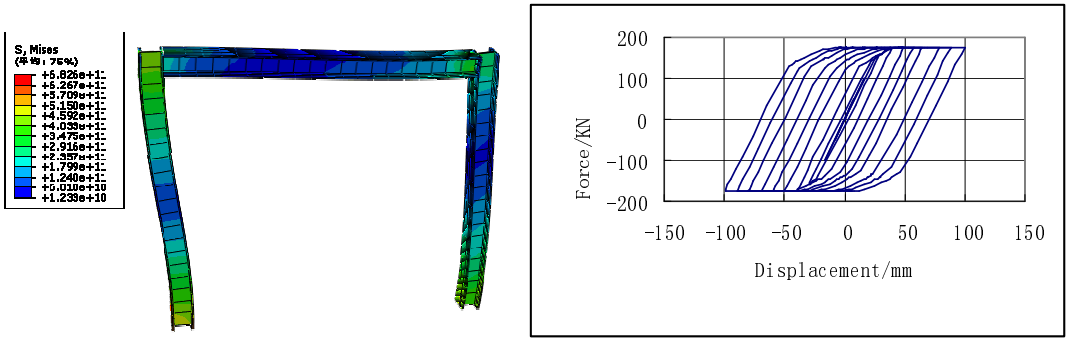

Fig.3 Framework is not installed damper

#### 4.2.2 Study on steel frame seismic performance with new mild steel damper

In Fig. 4-7 shows the Mises stress cloud and force - displacement hysteresis curve which framework with new T- type , box –type and S-type mild steel dampers under low cyclic load.

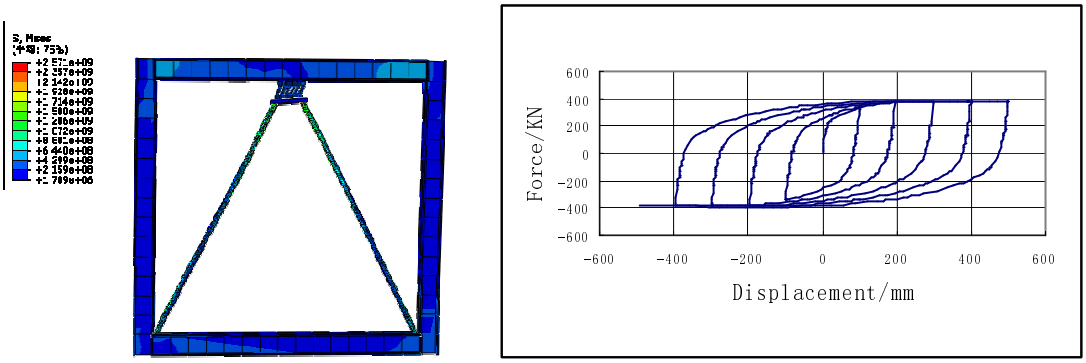

Fig. 4 Framework with new T- type mild steel damper

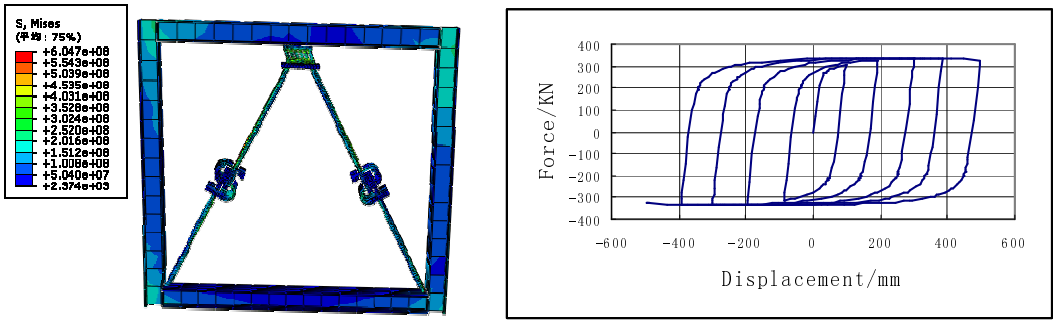

Fig. 5 Framework with new S-T- type mild steel damper

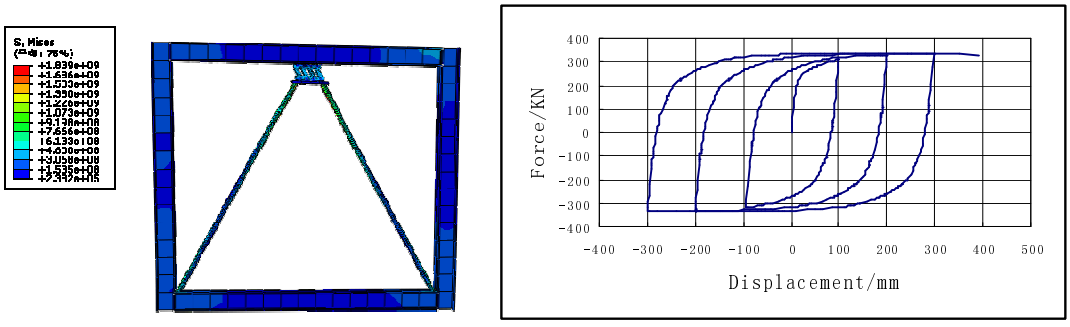

Fig. 6 Framework with new box- type mild steel damper

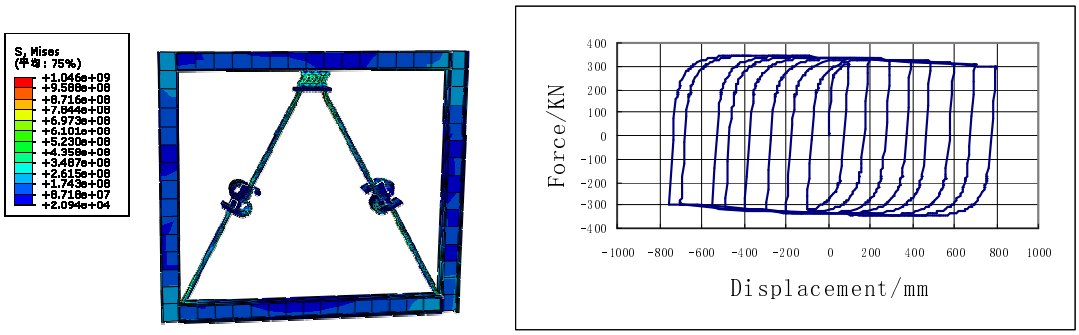

Fig. 7 Framework with new S-box- type mild steel damper

### 4.2.3 The results contrast

The model in Fig. 3-7 is divided into five conditions,they were frame without mild steel dampers, and frame install T, S-T, box, S-box. Calculation results in Table 2

Table 2. Calculation results

| Specimen No. | Not Installed | *T* | *S-T* | *box* | *S-box* |
|---|---|---|---|---|---|
| Yield displacement/mm | 29.51 | 26.78 | 28.75 | 27.26 | 25.13 |
| Yield force/KN | 158.35 | 255.29 | 260.84 | 255.04 | 297.20 |
| Initial stiffness $/10^3$ MP | 5.366 | 9.532 | 9.044 | 9.356 | 11.827 |
| Post-yield stiffness $/10^3$ MP | 0.319 | 5.468 | 3.255 | 6.499 | 0.822 |
| Equivalent damping ratio | 0.64 | 1.02 | 1.147 | 0.98 | 1.23 |

## Conclusion

We can see from the calculation results. Yield displacement of frame installed mild steel dampers are greeter than the not installed ones, but which have the bigger yield force,initial stiffness,post-yield stiffness and equivalent damping ratio, it is that framework in the case of mild steel dampers installed to advance into the plastic state. And frames have full hysteresis curves under low cyclic load. So the structure can absorb seismic energy very well and with good energy performance after installing the mild soft steel dampers.

# Analysis of earthquake damages and seismic reinforcement of bridges

Bingbing Fan[1, a], Canhui Zhao[1,b], Long Zhang[1,c] and Liang Li[1,d]

[1]School of civil engineering of Southwest Jiaotong University, Chengdu,Sichuan province,China

[a]wudifan90_05@163.com, [b]zch2887@home.swjtu.edu.cn, [c]13658087657@163.com, [d]ll19890219@126.com

**Keywords:** earthquake, old bridges, seismic damage of bridges, seismic reinforcement of bridges

**Abstract:** In recent years, with the frequent occurrence of earthquakes, the impact of earthquakes on the bridge has been increasing. Every time the earthquake occurred, bridges there almost got varying degrees of damages, hindering the normal traffic and losing the important role as emergency rescue and disaster relief channels and emergency shelters. Therefore, the seismic loads must be taken fully into account in the bridge design and seismic strengthening of bridge is necessary. Besides, the old bridges already put into normal operation must be reinforced appropriately according to the site condition. This paper described the various types of seismic damage of bridges and summarized several methods of seismic reinforcement of bridges.

## Introduction

As an important part of highway and railway lines, the bridge not only plays a vital role in protecting the traffic, but also promotes the economic development. In recent years, there are frequent earthquakes, such as the Chi -Chi Earthquake in Taiwan (1999), the Sichuan Wen chuan Earthquake (2008) and the East Japan Earthquake (2011). Study on aseismic design of bridges gradually got attention, during which seismic strengthening is essential. It is very important to carry out the seismic capacity evaluation and take appropriate measures to reinforce old bridges in seismic areas for they were short of consideration of earthquake resistance in the initial design.

## Seismic damage on bridges

Forms of bridge earthquake damages could be obtained by consulting earthquakes happened in history. Those earthquakes almost occurred at the junction of tectonic plates, belonging to tectonic earthquake. Because of the mountain terrain the bridges are mainly beam bridges and arch bridges. According to the form damages would be divided into the following categories:

**Simple-supported bridge**

For the main beam, due to the discontinuity, the effect of seismic force will produce large longitudinal displacement, causing the occurrence of girder falling. The lateral displacement of the main girder may cause large displacement of supports or even bearing cavity and supports might be thrown out. Bridge deck pavement may have extrusion uplift, crushing and cracking damage. Failure modes of crushing, against the ear and water stop opening often happen to the expansion joints.

Constraint block restricting the transverse displacement of the main beam show shear failure or directly is bumped to fly. The pier may incline due to falling beams. The entire pier may crush because stirrups in pier are insufficient or unreasonable. Cracks might appear at the top and end of the pier and the coping. Gravity abutment suffer wall crack damage or even collapse while pile column abutment and ribbed slab abutment often appear cracks in the column, rib cracking, ear wall cracking, retaining wall collapse and other forms of damage. Sandy and Light clay loam ground where the underground water level is high will produce the sand liquefaction under earthquake, leading to failure of the foundation.

**Continuous bridge**

In the earthquake the longitudinal displacement of the bridge girder is small because of its continuity. However, for continuous beam frame bridge and continuous beam bridge having part of the piers and beam consolidation, the girder could crack since the piers restrain its longitudinal

displacement. But the small longitudinal displacement of the beam will produce larger displacement outside the curve along the radial direction when the bridge is not straight. Because the main beam is continuous, a cross-falling beam will completely change internal forces of the remaining spans, may resulting in collapse of the whole bridge. Laminated rubber bearing is less prone to roll and curl due to the large plane size and thickness, but the bolts will suffer shear failure and flexural failure. Basin rubber bearing will show damages like the limiting block's destruction, pre buried bolts' being sheared and seat connection failure.

The continuous beam bridge pier is divided into fixed pier and non fixed pier according to the connection between the pier and girder. In general the fixed pier' s damage is severer, especially when the bridge is a curved bridge with sharp radius. Piers may tilt due to earthquakes and lack of stirrups configuration and small section size. The plastic hinge occurs at the top or bottom of the pier. Joins between tie beams and piers could be destroyed. Seismic damages of foundation of continuous bridge are similar to that of simple-supported bridge but that the damages often emerge on the whole beam for its continuous statically indeterminate structure when subjected to secondary geological disasters.

**Arch bridge**

For the arch bridge, lateral stability is weaker than that of longitude. The vault and arch foot are more prone to crack transversely. Besides, transverse cracks may emerge at the main arch in solid arch bridge. Transverse connection between rib arches is likely to break. These damages usually happen to reinforced concrete arches. As for masonry arch, it either crack or crush because of its filler. Solid arch often show damages like cracks at the side wall and joint between side wall and main arch cut with dislocation. In general, cross wall and web arch crack occur at arch bridges with web arches.

Since the main arch is very sensitive to the defection of the arch foot, gravity masonry structure with big rigidity is usually used for pier. So the pier either suffers slight damage or collapse directly. Bridge abutment may have cracking at front wall and side wall. Earthquake damages of foundation have the similar but clearer impact on the arch bridge to that on the beam bridge.

## Seismic reinforcement of bridges

**Guidance**

According to the importance of structure, the bridge structure can be divided into two categories. One is the general structure, the other is the important structure. For the former, low reinforcement level can be performed, while the later needs higher reinforcement level.

Generally the upper structure is designed to be the flexible structure so that stress and displacement are in elastic stage during the earthquake. Dropping beam is mainly induced by large vibration of the lower structure and different vibration of different piers. Thus the lower structure is the key of seismic strengthening and more measures should be taken to ensure its strength and stability.

**Methods**

As is seen, the damage can be divided into more partial and less overall destruction. Common method now for those bridges still can work is taking corresponding repair measures. For bridges not having suffered the earthquake, reinforcement should be carried out on each component or appropriate steps need be taken to improve the overall structure ductility.

1 Measures to prevent the beam dropping:

(1) Use the cable restraint device

Setting the cable constraint is the most common method for simply-supported bridge, being able to reduce the longitudinal displacement of the main girder. Vertical clearance between the beam and the lower pavement should be ensured.

(2) Set the splice plate connecting device

For the steel beam, splice plate can be used to connect the web so that the main beam is continuous in the abutment. It is generally applicable to a straight bridge. But the construction is not very convenient because positions of support, transverse beams, and stiffeners may need to be changed.

(3) Install lever

In the expansion joints and joints between hinges and the upper structure the levers could be installed. In 1971, California adopted this method and gott the best effect for disaster reduction at the minimum cost.

(4) Increase bearing area of the hinge support

Local damages in hinge support, for example, the concrete falling off, mainly due to the smaller actual available size than the original design size. Thus, increasing the bearing area will not only reduce the damages but also avoid falling beam in some way.

(5) Strengthen the cap beam

the cap beam is destroyed mainly by lack of flexural and shear strength. The common measure is adding backing plate in which prestressed reinforcements are set on the cap beam.

(6)The pipe seat extender

If a longer restraint device is hoped to be used, the longitudinal displacement may increase, causing the girder fall. So it is necessary for the longer restraint device to work with a pipe seat extender. The pipe seat extender of a strong pipe will be set in the cored hole or the formed hole. The cored hole may be lifted up in vertical if the elastic rubber pads need to be replaced. If the longitudinal restraint device is shorter than The pipe seat extender, the former will yield first, making the later not work. So, longitudinal restraint device must be compatible with seismic displacement of the hinge node.

(7) Set limitator

When bridges withstand transverse excitation, the relative displacement can be restricted by limitators. Limitators are now in common use in America and Japan. In America, adjacent spans are connected in transverse, longitude and vertical at bearings. While in Japan, limitators are used with many different materials and kinds, such as flexible connectors and steel connectors. Now a novel method is using memory alloy limitator to reinforce simply-supported girder bridges. Memory alloy limitator will still be in the elastic range under large deformation. Its super elasticity will reflect a significant effect when restricting the relative displacement of adjacent spans of the multi-span simply supported bridge.

(8) Add the lateral support

In general, lateral rigidity between the beams is supplied by the lateral support systems or diaphragms, resisting loads of wind, earthquake and so on. Adding support, stiffening rib and diaphragm near the bearing helps to reinforce lateral stiffness at bearings so that lateral displacement will be decreased under the earthquake.

2 Steps to prevent the destruction of bridge pier:

(1) Increase support section of pier appropriately

For masonry pier, pier damages show two extreme kinds like slight damage and collapse because of the limited bearing capacity. Increasing support section of pier is able to add its bearing capacity when materials can not be changed.

(2) Set horizontal and vertical constraints

The weak of bridge pier appears in the plastic hinge position. According to the expected locations(top and bottom of the pier) of plastic hinges the horizontal and vertical external constraints can be set to enhance the flexural ductility and shear strength. What foreigners mostly use is reinforcing steel casing outsourcing and reinforcement technology of FRP composite materials. Compared to other reinforcement materials, FRP composite materials show advantages of easy and rapid construction, high reliability and good durability, will being greatly used in the future.

(3) Set column cage

For reinforced concrete pier, setting the column cage will limit the radial expansion strain at the plastic hinge area in certain circumstances. Experimental results show that if the radial expansion

strain is limited below 0.001, the reinforced connector will kept consolidate and produce full plastic moment capacity of the section. Contrary to limiting radial strain, when provide enough constraints in the plastic hinge region, over 0.001 of radial expansion strain will be allowed so that a hinge may be formed. Using column cage could improve the ductility, the flexural and shear capacity of bridge piers. Nowadays, common column cages are steel column cage, concrete cage, advanced composite material cage and wire wrapped cage. Different material cages have different range of applications.

3 Reinforcement of foundation:

Analysis of many foundations of different types indicates that only increasing the flexural and shear capacity dose not have much of obvious effect, for the increase of the flexural capacity will lead to the increase of earthquake force transmitting from the column to the foundation. So increasing column strength should coordinate with foundation reinforcement.

General methods of foundation reinforcement are adding an overlay to improve the base shear capacity, broadening foundation equably and increasing the contact area . Another approach is to put the foundation anchor into soil or connect the pile with cap via the connecting rod passing through the foundation.

4 Use seismic isolation and special energy dissipation device:

(1) Foundation isolation

Setting the isolation device between the upper structure and foundation to prevent earthquake energy transferring to the upper structure will reduce the seismic response. This technology is not universal for the old bridge because of expensive reinforcement and hard construction. But many new designed and built bridges have adopted this technology.

(2) Isolation bearings

Lead rubber bearing, high damping rubber bearing and the friction pendulum isolation bearing are the commonly used isolation bearings. Lead rubber bearing formulates when a lead is inserted into the middle of laminated rubber bearing. In earthquake lead yields and the stiffness is reduced, prolonging the natural period of vibration. High damping rubber bearing is made of sulfides of high damping rubber materials and steel members, with the shape is similar to natural rubber bearing but has good damping performance. Friction pendulum isolation bearings dissipate energy by friction damping, which can be used to adjust the vibration period of the whole bridge structure system to reduce Seismic response.

(3) Add energy dissipation device

Damper is a common energy dissipation device with many kinds such as the metal yield damper, friction damper, viscoelastic damper and viscous damper. The same principle is taking use of damping to reduce seismic energy and effect of earthquake. Energy dissipation devices have been adopted by many bridges at home and abroad, showing good reduction effect in the earthquake.

## Summary

Seismic reinforcement of the bridge is of great significance for the large impact imposed by the earthquake. This paper has carried out a detailed description of the various forms of destruction of the bridge and made a summary of the current common strengthening methods. Each method has its characteristics and suitable scope. I hope this paper can provide some reference to seismic strengthening of existing bridges. With the advance of science and technology, there will be new thought about seismic design of bridges and new technologies will be used for seismic reinforcement.

**Keywords:** Base isolation; story isolation; shaking table test; natural vibration period; damping ratio; damping effect

**Abstract:** The shaking table tests are conducted on a 5-floor steel frame model with a scale down of 1:6. The traditional anti-seismic structure and isolation structures with isolation layer in different position are adopted. The results indicate that the natural vibration periods of isolation structure are longer than anti-seismic structure, and when the isolation layer is located in a lower position, the period becomes longer and the damping effect is better.

## Introduction

Isolation is a new protective technology of Engineering damping in aseismic engineering field. Isolation technology can effectively solve many problems, and the seismic response of isolation structure is reduced by avoiding the site predominant periods.

Significant progress has been achieved over the past years on the practice and research of base isolation structure, and a lot of projects have adopted, then the design of base isolation structure in our country is received in *code of aseismic design of buildings*. The isolation device is installed between foundation and superstructure in base isolation system, it can significantly reduce the lateral stiffness of the structure, increase the structural nature period in order to avoid the predominant period, efficiently dissipate seismic energy and to reduce seismic response.

Story isolation is a new development of isolation technology, seismic response is controlled by story isolation structure with setting isolation layer between shear walls or top of columns and floor[1]. Isolation layer is an important influencing factor in the damping mechanism of the story isolation structure, within the scope of certain frequency ratio, when the location of isolation layer is approach to the base of the structure, its mechanism is similar to that of base isolation; when the location of isolation layer is approach to the roof of the structure, its mechanism is similar to that of TMD[2].

For comparing and analyzing the damping effect of base and story isolation structures, shaking table tests are performed. Because lager story drift will cause destruction of the structure, and lager absolute accelerations can create intense felt of the earthquake under seism action, story drift and absolute accelerations have a linear relationship with damping effect of structures. So this article discusses the damping effect of story drift and absolute acceleration about base and story isolation structures.

## Structure Model

Because different damping mechanisms of story isolation structures are shown with isolation layers in different position, in this test, isolation layers are located at first-layer column upper end (hereinafter, 1st CUE); second-layer column upper end (hereinafter, 2nd CUE)and fourth-layer column upper end (hereinafter, 4th CUE) respectively.

The shaking table tests are conducted on a 5-floor steel frame model with a scale down of 1:6, which simulate traditional anti-seismic structure (hereinafter, TASS) , base and story isolation structures.

In order to facilitate the replacement of isolation layer, the tests applies analogous theory to design a steel frame model which are composed of two-layer and one-layer models, each model is pulled together with different combinations. Sketch of model frame is shown in Figure 1 and different combinations of model is shown in Figure 2.

After being calculated, one-layer steel frame model weighs 160kg and the top model weighs 48kg. Depending on the outcome of our detailed design, there might need 800kg counter-weights connected to the each layer of model, so total models weigh 6000kg, similarity coefficient of structural model is shown in table 1.

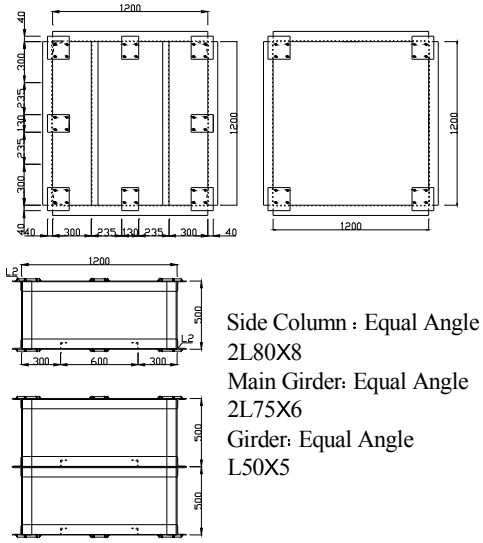

**Fig.1 Sketch of Model**

**Tab.1 Similarity Coefficient of Structural Model**

| physical quantity | symbol | dimension | Similarity Coefficient |
|---|---|---|---|
| length | $S_l$ | L | 1/6 |
| elasticity modulus | $S_E$ | $ML^{-1}T^{-2}$ | 1 |
| stiffness | $S_k$ | $MT^{-2}$ | 1/100 |
| acceleration | $S_a$ | $LT^{-2}$ | 8/3 |
| Time | $S_T$ | T | 1/4 |
| velocity | $S_v$ | $LT^{-1}$ | 2/3 |
| displacement | $S_x$ | L | 1/6 |
| Mass | $S_m$ | M | 1/1600 |

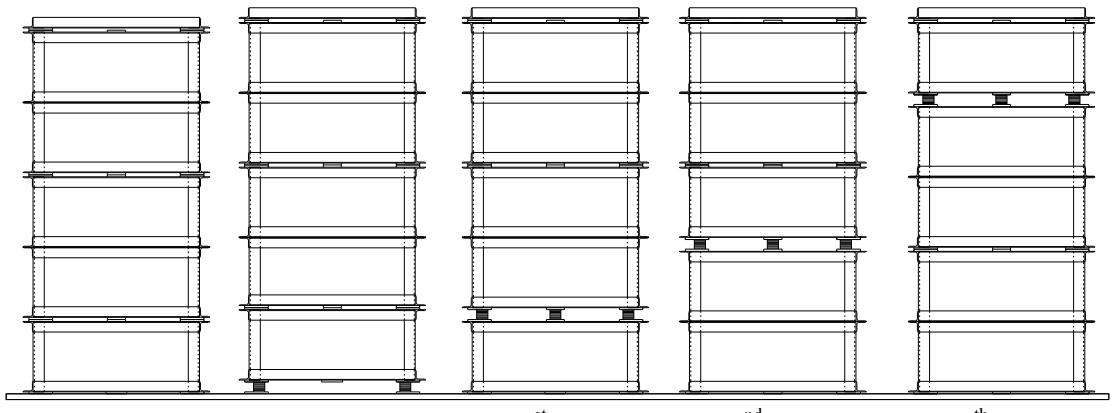

**Fig.2 Isolation Way of Different Combinations**

## Isolation Bearing Model

Non-lead rubber bearings (GZP80) which contain natural rubber are used in this test, the concrete size and mechanical property are shown in Table 2.

**Tab.2 Concrete Size and Mechanical Property of Isolation Bearing**

| Serial Number | Parameters | Parameter Values | Serial Number | Parameters | Parameter Values |
|---|---|---|---|---|---|
| 1 | Outside Diameters (mm) | 90.0 | 10 | Steel Plate Aggregate Thickness(mm) | 19.0 |
| 2 | Inside Diameters(mm) | 80.0 | 11 | Hole Diameter(mm) | 20.5 |
| 3 | Total Height(mm) | 59.0 | 12 | The First Form Factor | 20 |
| 4 | Connection Plate Thickness(mm) | 10.0 | 13 | The Second Form Factor | 4 |
| 5 | Rubber Layer Thickness(mm) | 1.0 | 14 | Pressure Bearing Area($mm^2$) | 4700 |
| 6 | Rubber Storey Number | 20 | 15 | Damping Ratio | 0.07 |
| 7 | Rubber Aggregate Thickness(mm) | 20.0 | 16 | Permissible Lateral Displacement(mm) | 44.0 |
| 8 | Steel Plate Aggregate Thickness(mm) | 1.0 mm | 17 | Lateral Stiffness(kN/mm) | 91.0 |
| 9 | Steel Plate Storey Number | 19 | 18 | Vertical Stiffness(kN/mm) | 70.0 |

## Shaking Table Test

### 4.1 Loading and Collection Device

The shaking table test finished in Key Laboratory of Earthquake Engineering and Structural Retrofit (Beijing University of Technology). The specific technical parameters of seismic shaking table are as follows:

(1)Table size:3m×3m; (2)Table Self-weight:6t; (3)max load:10t; (4)frequency range: 0.1~50Hz; (5)max acceleration of no-load:2.5g; (6)max acceleration of full-load: 1.0g; (7)max displacement:±127mm; (8)max velocity: ±600mm/sec; (9)max torque:30t×m.

The collection devices which include three sensors (ICP, SW-1 and SW-3) and data acquisition system (IMC), ICP is installed in table-board, the middle part of girders and the middle part of floor beams in isolation superstructure, which collect absolute acceleration; SW-3 is installed in each layer to collect story drift; SW-1 is installed in isolation layer to collect displacement of isolation layer specially. Based on the above, seven ICP, five SW-3 and one SW-1 is used in the tests.

### 4.2 Seismic Wave

According to the selection principle of seimic wave, Taft (NS) and Elcentro (NS) are chosen, seismic duration is compressed into a quarter on the basis of simulated law and seismic peak acceleration is adjusted to 0.4g.

### 4.3 Test Conditions

The shaking table tests contain TASS, base isolation structure and story isolation structures with different isolation layers. Four rubber bearings are adopted in isolation layer. Test conditions are shown in Table 3.

**Tab.3 Test Conditions**

| Test Condition | Isolation layer position | Seismic wave |
|---|---|---|
| 1 | $1^{st}$ CUE | Elcentro |
| 2 | | Taft |
| 3 | $2^{nd}$ CUE | Elcentro |
| 4 | | Taft |
| 5 | $4^{th}$ CUE | Elcentro |
| 6 | | Taft |
| 7 | TASS | Elcentro |
| 8 | | Taft |
| 9 | Base Isolation | Elcentro |
| 10 | | Taft |

## Test Results and Analysis

By literature [5], elastic and plastic permissible displacement of model is 1.67mm and 10mm respectively because the story height is 500mm; By literature [6], when absolute acceleration exceed 0.53g, people may feel uncomfortable. With stronger absolute acceleration, we can feel greater discomfort.

For each test, the acceleration input can't completely the same, in order to contrastive analysis on vibration results of model in different test conditions, accelerations are normalized. Assume structure model is in linear elasticity, normalization can be calculated below:

$$\text{Normalized response value} = \frac{\text{Design acceleration amplitude}}{\text{Measured acceleration amplitude}} \times \text{Actual acceleration amplitude}$$

In order to intuitionistic compare the damping effect of base and story isolation, this article introduced a concept of damping ratio. Definition:

$$\text{Damping ratio} = \left(1 - \frac{\text{Peak response of (TASS} - \text{story isolation)}}{\text{Peak response of TASS}}\right) \times 100\%$$

### 5.1 Dynamic Characteristics of Structural Model

Through Analysis, dynamic characteristics of TASS, base isolation, 1st CUE, 2nd CUE and 4th CUE are shown in Table 4.

**Tab.4 Dynamic Characteristics**

| Structural Style | Natural Period (sec) | Equivalent Damping Ratio |
|---|---|---|
| TASS | 0.152 | 0.021 |
| Base Isolation | 0.699 | 0.062 |
| 1st CUE | 0.685 | 0.065 |
| 2nd CUE | 0.606 | 0.063 |
| 4th CUE | 0.334 | 0.061 |

Through Table 4, we can see:

(1) Natural Period of TASS is much lower than other isolation structure, that is close to the Elcentro Period and syntony likely occur. In different isolation structures, natural period of base isolation structure is the longest than others, when the position of isolation layer rise, natural period of story isolation fall.

(2) Equivalent Damping Ratio of TASS is much lower than other isolation structure, and that is in keep with steel structure; equivalent damping ratios of base and story isolation structure approach to the design damping ratio of rubber bearing, so damping ratio of rubber bearing should be adopted in isolation superstructure.

### 5.2 Seismic Analysis of TASS

Through the normalized processing, story drifts and absolute accelerations of TASS are shown in Table 5.

**Tab.5 Seismic Analysis of TASS**

| Floor | Elcentro | | Taft | |
|---|---|---|---|---|
| | Story displacement (mm) | Absolute Acceleration (g) | Story drift (mm) | Absolute Acceleration (g) |
| 1 | 0.99 | 0.733 | 0.88 | 0.549 |
| 2 | 0.76 | 0.925 | 0.71 | 0.814 |
| 3 | 1.14 | 1.129 | 1.31 | 1.100 |
| 4 | 0.39 | 1.227 | 0.40 | 1.238 |
| 5 | 0.28 | 1.453 | 0.31 | 1.360 |

Through Table 5, we can see:

(1) Peak acceleration of model increases with the rising of floor; maximum story dispplacement occur in the third floor, and in others, story drift decreases with the rising of floor.

(2) Whatever seismic wave is used, peak accelerations of all floors are far exceeded 0.53g, and that might be strong felt; story drifts of all floors are lower than elastic permissible displacement, and the structure will not damage in earthquake.

### 5.3 Absolute Accelerations of Base and Story Isolation Structures

Through the normalized processing, Peak acceleration of base isolation structure, 1st CUE, 2nd CUE and 4th CUE are shown in Figure 3.

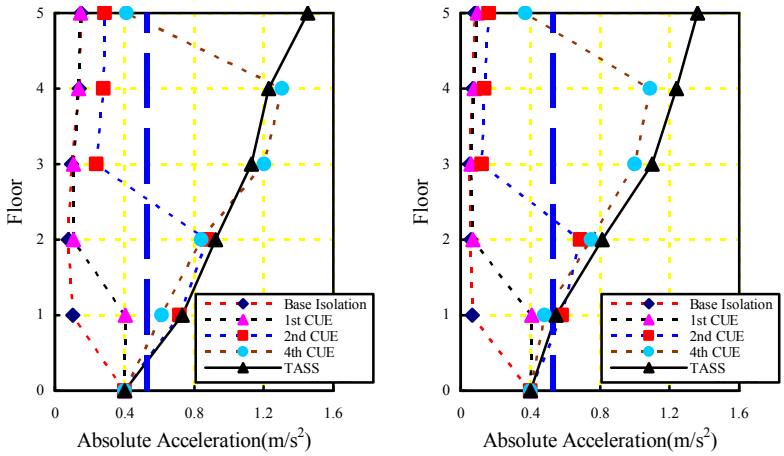
Through the Figure 3, we can see:

(1) Absolute acceleration damping effect of base isolation is superior to that of story isolation.

(2) Damping effect of absolute acceleration decrease with the rising of isolation layer; when isolation layer is located at first-layer column upper end, damping effect is similar to that of base isolation.

(3) When isolation layers are located at second-layer and fourth-layer column upper end, peak absolute acceleration in the substructure of story isolation is close to or slightly greater than that of TASS.

(4) No matter what kind of isolation structures, peak absolute accelerations in superstructure of story isolation are all below 0.53g, so there is no felt in earthquake.



(a)Elcentro (b)Taft

**Fig.3 Peak Absolute Accelerations of Structural Model**

### 5.4 Story Drifts of Base and Story Isolation Structures

Through the normalized processing, Peak story drifts and damping ratios of base isolation structure, 1st CUE, 2nd CUE and 4th CUE are shown in Table 6.

**Tab.6 Peak Story drifts and Damping Raitos of Base and Story Isolation Structures**

| Base Isolation | | | | Story Isolation | | | | | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|
| | | | | 1st CUE | | | | 2nd CUE | | | | 4th CUE | | | |
| Elentro (mm) | Damping Ratio (%) | Taft (mm) | Damping Ratio (%) | Elentro (mm) | Damping Ratio (%) | Taft (mm) | Damping Ratio (%) | Elentro (mm) | Damping Ratio (%) | Taft (mm) | Damping Ratio (%) | Elentro (mm) | Damping Ratio (%) | Taft (mm) | Damping Ratio (%) |
| 0.004 | 99.5 | 0.002 | 99.7 | 0.006 | 99.3 | 0.005 | 98.4 | 0.04 | 95.5 | 0.02 | 93.5 | 0.09 | 89.8 | 0.08 | 74.2 |
| 0.06 | 89.1 | 0.04 | 93.0 | 0.06 | 89.1 | 0.03 | 92.5 | 0.12 | 78.2 | 0.06 | 85.0 | **5.44** | — | **4.24** | — |
| 0.05 | 97.1 | 0.03 | 98.4 | 0.08 | 95.4 | 0.05 | 96.2 | 0.30 | 82.8 | 0.09 | 93.1 | 0.28 | 49.1 | 0.16 | 60.0 |
| 0.13 | 86.2 | 0.08 | 91.6 | 0.12 | 87.2 | 0.06 | 91.5 | **7.32** | — | **8.17** | — | 0.41 | 76.4 | 0.30 | 77.1 |
| 0.14 | 90.4 | 0.09 | 94.3 | **7.94** | — | **3.47** | — | 0.32 | 66.0 | 0.10 | 85.9 | 0.46 | 51.1 | 0.37 | 47.9 |
| **16.14** | — | **11.50** | — | 0.17 | 88.4 | 0.09 | 89.8 | 0.35 | 76.0 | 0.23 | 73.9 | 0.52 | 64.4 | 0.47 | 46.6 |

Through Table 6, we can see:

(1) No matter what kind of isolation structures, peak story drifts is much lower than that of TASS.

(2) When isolation layer is located at first-layer column upper end, damping effect of story drift is significant and similar to that of base isolation.

(3) Damping effect of story drift decrease with the rising of isolation layer.

## Conclusion

After analysis, we can see, as follows :

(1) No matter what kind of isolation structures, Natural period is much longer than that of TASS, and when the position of isolation layer rise, natural period of isolation fall. Base on this, the seismic response of isolation structures is reduced by avoiding the site predominant periods.

(2) equivalent damping ratios of base and story isolation structure are in accordance with design damping ratio of rubber bearing, and when earthquake occours, isolation structures can absorb energy from seismic wave, then rubber bearings dissipate energy in form of damping energy and hysteretic dissipated energy.

(3) Compared with TASS, no matter what kind of isolation structures, absolute accelerations and story drifts can be reduced effectively.

(4) when the location of isolation layer is approach to the base of structure, infrastructure displacement and superstructure acceleration of the isolation layer both significant reduce, its mechanism is similar to that of base isolation; when the location of isolation layer is approach to the roof of structure, not obvious change between infrastructure displacement and superstructure acceleration, its mechanism is similar to that of TMD.

# Vulnerability analysis of existing buildings under seismos

Xianhong Meng[1,a] , Guozhi Yang[1,b]

School of Civil Engineering, Shenyang Jianzhu University, Shenyang China, 110168

[a] cexhmeng@sjzu.edu.cn, [b] yangctrlx@163.com

**Keyword:**Structural vulnerability, Existing buildings, Nonlinear static method, Risk Assessment

**Abstract.**By studying the structure of vulnerability analysis and abroad , on their respective merits and defects were compared and analyzed to select the best of vulnerability research methods. Combined with the existing building characteristics, the nonlinear static method on both the vulnerability analysis of old buildings also applicable conclusions. Effective solution to the existing buildings under earthquake disaster risk assessment.

## Introduction

In recent years, Earthquakes Disaster occur frequently. According to a domestic data from Domestic Disaster Prevention Committee indicate the extent of the earthquake damage on the existing old buildings is much higher than the implementation of the new specification seismic building measures[1] . Research the damage of existing building structures under the Earthquake, have guiding significance for the improvement of the structure design of the future and post disaster restoration stage.

The research method of vulnerability can be roughly divided into four categories: Experience Class, SEMI computing classes, Experimental study class, Calculation of the class. By analyzing the characteristics of four research methods, concluded the computational analysis class research methods in the study of vulnerability also applies to existing buildings. This paper studies the different buildings and different structure forms of existing buildings.

## Experience class vulnerability research methods

Vulnerability research began in the seventy s of the 20th century. This approach is in considering the uncertain factors on the basis of earthquake, according to the researchers of judgment and set up. It called the experience research methods. It was first proposed by America scholar Whiteman in 1973 [2]. It can be a wide range of estimates and judgments for a variety of types of building structure in a region. It can be a wide range of estimates and judgments [3].

In China, this type of research method appeared in the late 20th century. Yang Yucheng , Li Dahua issued a system PDSMSMB-1 in 1990 . The earthquake test and practical application show, the system is easy to use to predict results that can be achieved expert level [4]. Scholars Shi Lili, Qiao Jianping, have thorough research to the Wenchuan area after the disaster vulnerability zoning [5]. Contribution Weighted Overlay Model what they proposed made the research method more perfect.

The characteristics of experience research method is limited. In the house of the investigation can not be controlled in the number of samples. The factor affects the further development and application of the method.

**SEMI computing class vulnerability research methods at home and abroad**

Scholars Madas P and Elnashai A S have put forward a semi empirical calculation method. Scholar Lv Dagang put forward the structural reliability analysis with empirical formula based on probability [6]. Zhou Yanlong, Zhang Peng proposed the seismic vulnerability analysis is an important research direction of the seismic performance of the structure [7]. The method that Ding Yang used in the paper Seismic Damage Assessment Of Vulnerability Curves Based On Concrete Column was simple and reliable [8]. Scholar Liu Jingbo, Liu Yangbing studied in the steel-concrete composite structure seismic performance and seismic fragility problems [9].

This method also has many deficiencies.Although there are some theoretical basis for sample collection, but not representative.The differece between structures is great, and it is hard to spread.

**Experimental study abroad class of vulnerability research methods**

Scholars Aycardi and AM Reinhorn analyze the structure of vulnerability using vibration table by simulating seismic waves. Wang Dongwei, Zhu Xiaoqing proposed the experimental method based on pushover analysis of seismic vulnerability of building structures and failure correlation [10].Yi Zhiqian, Zhao Zhi pointed out that the peak acceleration vibration parameters refering to the standard promulgated in 2001 [11]. Scholars Zhu Nanhai, Ye Jihong made the theory of vulnerability [12]. Their study is based on experimental studies .

The advantage of this approach is that the structural model can use the historical data to meet the requirements of free choice, but this approach severely limits the number of received , size, laboratory equipment and the conditions of the test sample to a certain extent.

**Calculation analysis class vulnerability research methods at home and abroad**

The fourth kind of method is Calculation analysis class.This method is divided into two kinds：Dynamic analysis,The static elastic analysis.

The static elastic analysis.This kind of method is to choose real or artificial seismic wave using the static elastic analysis method to analysis the capacity spectrum and demand spectrum of the structure, and further get the analysis of structure vulnerability curve. Foreign Madas P proposed nonlinear static structural damage probability method to analyze fragility curves.[13]

The function of structural vulnerability with the method of the static elastic analysis:

$$\mathrm{P}\ (D \geq d_i \mid S = S_k) = \varphi\left[\frac{1}{\beta_d} \ln\left[\frac{S_k}{M_d}\right]\right]$$

Tips: P(D≥di|Sk) means the damage probability of not less than a certain state of Di at a given Sk damage. Md means the median of the damage state of d. βd means the standard deviation of d. φ means the cumulative standard normal distribution function(CDF).

Dynamic analysis. This method uses the artificial or natural seismic wave seismic load, so as to be sure with the control the loading. Scholar Liu Yangbing has carried on the analysis to the seismic capacity probability of reinforced concrete structure, get the fragility curve [14]. Scholar Zhu Jian has conducted the research to the reinforced concrete structure seismic risk analysis and vulnerability analysis, finally gets the relationship between them [15]. Wang Mengfu scholars studied the dynamic increment method in the application of the high-level structure [16].

Compared the four types, it is shown in Table 1.

Table 1

| The types | The main features | Main defects |
|---|---|---|
| Experience study | With general, housing constructions and regional differences with the result of analysis is more obvious | Sample size is not to be controllable, lack of inference to be based on |
| Semi empirical calculation | Combining the probability formula of structural reliability analysis method is simple and easy | Not representative , analyze large differences |
| Experimental study | The test results are convincing, easy to get the fragility curves, but the spectrum of single | Restrict factor is large. Eg: Equipment |
| Simulation analysis | Reflect the general with the random characteristics of nonlinear, meet the requirements. | The process of analysis is complex |

It can be seen from the above table : computational analysis in four categories vulnerability research method is more reasonable and reliable.

**conclusion**

After comparing the analysis methods in the field of structure vulnerability according to the literature from home and abroad, we can conclude that the calculation methods and analysis is reasonable method in this paper. From the table we can see that the existing buildings including masonry, reinforced concrete structure, frame structure, steel structure. It is consistent with the the previous studies.Therefore, we can study the existing building vulnerability by analysis of calculation method.The buildings are divided according to different time and intensity,it provides the seismic safety evaluation, earthquake disaster prevention and provide the basic materials of seismic design method based on reliability.

**Keywords:** Response spectrum analysis; Large-span and large-cantilever; Complete Quadratic Combination (CQC);Transfinite structure; Midas/gen procedure

**Abstract.** In this paper, based on the Midas/gen platform, a three-dimensional finite element model(FEM) for a transfinite stadium with a large-span and large-cantilever roof , located in Shenyang, was used to study its potential responses to seismic activities. In the numerical analysis, an earthquake spectrum stipulated by the Chinese Seismic Code(GB50011-2010) was adopted to calculate the bidirectional horizontal displacements by the Complete Quadratic Combination(CQC) method on the basis of the response spectrum analysis. The computational results indicate that the maximum displacements in both of the two horizontal directions locate at the top of this structure, i.e. the transfinite part of the roof.

## Introduction

With China's architectural structures to top, large and modern development, more and more buildings in China , or some parts of them, are constructed beyond the limitation of the Chinese Seismic Code[1-2]. According to the relative regulations of the Code, Shaking table model tests and numerical simulations for these structures should be performed in advance.The target stadium presented in this paper is constructed in Shenyang, the capital of Liaoning Province in Northeastern China , the finite element model (FEM) of which is shown in Fig.1. In the figure of the FEM, a transfinite part is emphasized.

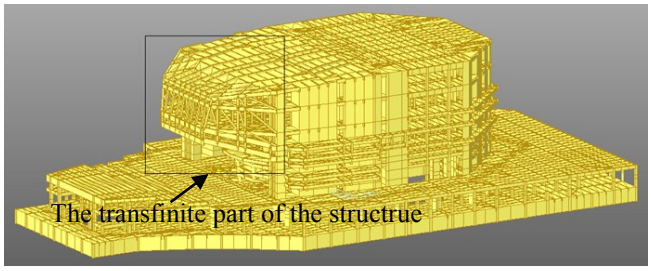

Fig.1 FEM of the target stadium

Because of existence of the transfinite part, it is necessary to numerally simulate the seismic characteristics of the whole structure, especially that of the transfinite part in this stadium. Therefore , a response spectrum analysis was developed in this paper to determine the potential responses to earthquake activities.

## Finite element modelling

With rapid development in computer technology and computational mechanics algorithms, three-dimensional finite element analysis has become a routine design tool of complex structures. Based on the Midas/gen platform, four kinds of elements were employed in establishing the FEM of the objective structure: beam elements, suitable for nonlinear large rotations and strians, were employed to model the columns and beams. Truss elements were used to model the brace. Meanwhile, slab elements and wall elements were used to simulate the mechanical properties of the floors and shear walls in the structure.

**Modal Analysis**

On the basis of the modal-analysis modules in the Midas/gen software, we developed a computational modal analysis for determining the natural frequencies and mode shapes of a structure. The first 10 modes were extracted and the mode shape for each individual mode was depicted, as shown in Table 1. And the former 5 ordered vibration shapes were drawn in Fig.2. From Table 1 and Fig.2, we can see that the stiffness of the transfinite part of the structure is relatively weaker, and hence the transfinite part of the structure is sensitive to earthquakes, as compared with any other parts of the structure.

Table 1 Summary of the former 10-ordered inherent frequencies and mode shapes

| Orders | Circular Frequency (rad/sec) | Natural Frequency (cycle/sec) | Cycle (sec) | vibration direction |
|---|---|---|---|---|
| 1 | 802673 | 1.3158 | 0.7600 | horizontal（swing along the shorter axis） |
| 2 | 13.5757 | 2.1606 | 0.4628 | horizontal（swing along the longer axis） |
| 3 | 16.9179 | 2.6926 | 0.3714 | Vertical (the large cantilever end) |
| 4 | 18.3346 | 2.9180 | 0.3427 | 1st Vertical (the transfinite part of the roof) |
| 5 | 19.6556 | 3.1283 | 0.3197 | 2nd Vertical (the transfinite part of the roof)<br>1st Torsional (the roof) |
| 6 | 20.7467 | 3.3019 | 0.3029 | 1st Torsional (the whole structure) |
| 7 | 20.8804 | 3.3232 | 0.3009 | 2nd Torsional (the whole structure) |
| 8 | 22.7797 | 3.6255 | 0.2758 | 3rd Torsional (the whole structure) |
| 9 | 23.5038 | 3.7407 | 0.2673 | 2nd Torsional (the roof) |

**Response spectrum analysis of the structure**

For earthquake-resistant designs, a structure should meet performance requirement at two different levels, depending upon the magnitude of earthquake actions[3]. The first level of performance essentially requires structural response in the elastic range without significant structural damage

under a moderate earthquake action, and the second level of performance requires that the structure does not collapse under a severe earthquake event with rare occurrence. The target structure in this paper is located in Shenyang, the capital of Liaoning Province, where there are hard soil deposits with a short predominant period. According to the Seismic Zoning Map in China, the construction site is in a region of 7 degree seismic intensity. A response spectrum has been defined based on the design response spectra stipulated in the Chinese Seismic Code(GB50011-2010), as shown in Fig.3. The first 20 translational-torsional coupling modes were used to calculate the seismic response of the structure by the Complete Quadratic Combination (CQC) method on the basis of the response spectrum analysis[4]. The damping ratio of the structure was assumed to be 5% for all 20 modes. And the seismic responses in the two orthogonal directions were calculated correspondently.

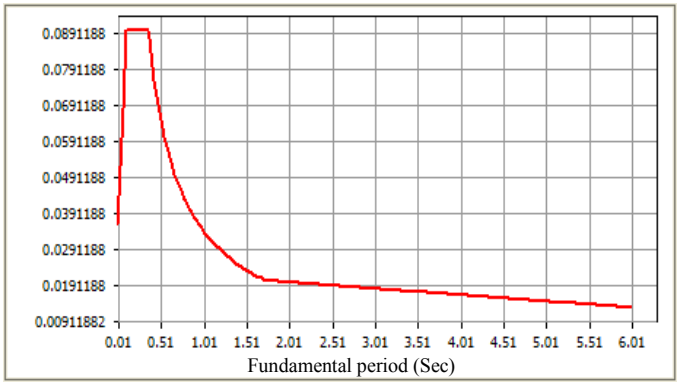

Fig.3 Design response spectrum

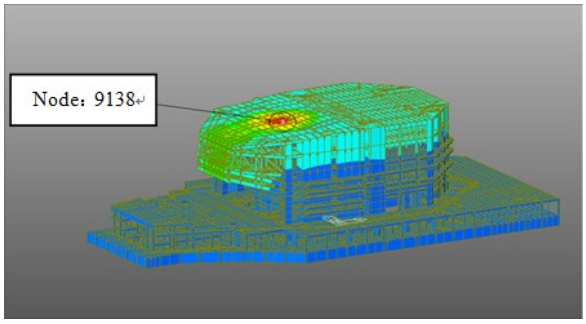

Fig.4 Displacement contour in x direction

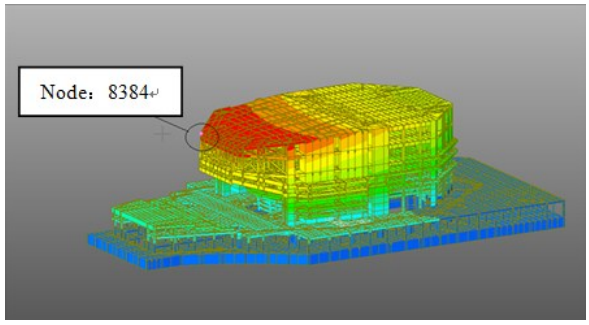

Fig.5 Displacement contour in y direction

Table 2 Maximum displacements of the key nodes of the transfinite part at different elevations

| Elevation（m） | Node | y-direction excitation | |
|---|---|---|---|
| | | $D_{y-direction}$（m） | $D_{x-direction}$（m） |
| 46.896 | 8420 | 0.006858 | 0.001348 |
| 42.9 | 7905 | 0.006014 | 0.001388 |
| 31.937 | 6669 | 0.004267 | 0.001576 |
| 28.337 | 9024 | 0.003939 | 0.001546 |
| Elevation（m） | Node | x-direction excitation | |
| | | $D_{x-direction}$（m） | $D_{y-direction}$（m） |
| 46.896 | 8419 | 0.006656 | 0.001341 |
| 42.9 | 7904 | 0.006014 | 0.001379 |
| 31.937 | 6668 | 0.004265 | 0.001559 |
| 28.337 | 9025 | 0.003939 | 0.001528 |

Through the response spectrum analysis, displacement contours in x direction and y direction subjected to x-direction excitation and y-direction excitation are shown in Fig.4 and Fig.5, respectively. The results of the response spectrum analysis indicate that the maximum displacements

in both directions locate in the region of the transfinite part of the structrue, which means that the transfinite part of the structrue is the most sensitive to earthquakes. Table.2 shows that the maximum displacements of key nodes of the transfinite part of the structure at different elevations. In Table 2, the maximum displacements in the y direction are larger than those in the x direction, which can be attributed to the greater x-directional lateral stiffness of the whole model. The story shear forces of the transfinite part of the structure at different stories are shown in Table 3. At the same story, the y-direction story shear forces under y-direction excitation are larger than their x-direction counterparts.

Table 3 Story shear forces of the transfinite part of the structure

| Story | Elevation（m） | Excitation direction | Story shear force | |
|---|---|---|---|---|
| | | | X-direction (N) | Y-direction (N) |
| 12F | 42.90 | X | 8611.50 | 416.41 |
| 8F | 20.45 | X | 33058.00 | 1423.20 |
| 4F | 12.30 | X | 38604.00 | 1421.20 |
| 1F | 0.00 | X | 39201.00 | 1569.50 |
| 12F | 42.90 | Y | 325.68 | 9806.40 |
| 8F | 20.45 | Y | 1326.00 | 36629.00 |
| 4F | 12.30 | Y | 1466.40 | 39921.00 |
| 1F | 0.00 | Y | 1569.50 | 42663.00 |

## Conclusions

A study on the dynamic characteristics and seismic responses of a large-cantilever stadium structure was presented in this paper. Based on the Midas/gen platform, a 3D finite element model of the structure was established to investigate the seismic performance of the structure by using the response spectrum analysis. The seismic analysis results of the structure indicate that the transfinite part of the structure is the weakest link of the whole structure if it is attacked by earthquakes in future. Therefore, it should be much careful when a structrue, or a part of it, needs to be designed beyond the Code limitation.

# A two-dimensional numerical model for shallow water flows over variable topographies

Biao Lv, Shaoxi Li

Key Laboratory of Engineering Sediment, Ministry of Transport, Tianjin Research Institute for Water Transport Engineering, Tianjin, 300456, China slxlvbiao@163.com

**Keywords:** shallow water flows; well-balanced Roe-type scheme; Finite-volume formulation; bed slope source term;

**Abstract.** Based on well-balanced Roe's approximate Riemann solver, a numerical model is developed for the unsteady, two-dimensional, shallow water flow with variable topographies. In this model, an efficient methods are applied to treat the source terms and to satisfy the compatibility condition on unstructured grids. In the method, different components of the bed slope source term are considered separately and the compatible discretization of the components is presented. The newly developed model is verified against analytical solutions and measured date, with good agreement.

## Introduction

The discretization of the shallow water (SW) equations has received considerable attention in the past two decades and many upwind scheme have successfully solved channel flows [1-3]. However, their use in the presence of irregular topographies usually problematic, due to the imbalance between the source terms and the flux gradients [4]. In fact, most shock-capturing finite volume schemes for the SW equations, are obtained by using approximate Riemann solvers which have been originally designed for hyperbolic systems without considering the source terms. Therefore, in the presence of source terms, those schemes may lead to oscillations.

In the stagnant conditions, the water should stay at rest over variable bottom topography without influence from outside. Jin [5] developed the interface method, which preserves the steady-state condition up to second-order accuracy on structured grids, but his approach is not directly usable on unstructured grids. Mohammadian et al. [6] developed a numerical model using the Roe's method which satisfies the *C* Property. However, although their scheme is mass conservative, it is not fully conservative since the gravity terms are not discretized in a conservative manner.

In the paper, a numerical model is developed to solve shallow flows with variable topographies on unstructured grids. The developed model is shown to satisfy the *C* property when combined with Roe's scheme and the surface gradient method for calculating the water depth at the interface. Moreover, the proof of the *C* property is also presented. The model is applied to three numerical tests to show the performance of the scheme over variable topographies.

## Mathematical formulation

The two-dimensional governing equations are obtained by integrating the Navier-Stokes equations over the flow depth. The continuity and momentum equations are written as

$$\frac{\partial U}{\partial t}+\nabla E=S \tag{1}$$

with $E=(F,G)$, in which

$$U=\begin{pmatrix} h \\ hu \\ hv \end{pmatrix},\quad F=\begin{pmatrix} hu \\ hu^2+0.5gh^2 \\ huv \end{pmatrix},\quad G=\begin{pmatrix} hv \\ huv \\ hv^2+0.5gh^2 \end{pmatrix},\quad S=S_0+S_f=\begin{pmatrix} 0 \\ ghS_{0x} \\ ghS_{0y} \end{pmatrix}+\begin{pmatrix} 0 \\ -ghS_{fx} \\ -ghS_{fy} \end{pmatrix} \tag{2}$$

where *u* and *v* are velocity components in the *x* and *y* directions respectively; h is water depth; *g* is gravitational acceleration; $(S_{0x},S_{0y})$ are bed slopes in the *x* and *y* directions, respectively; $(S_{fx},S_{fy})$ are

friction slopes in the $x$ and $y$ directions, respectively. In this study, the friction slopes are estimated by the Manning formula

$$S_{0x}=\frac{\partial z}{\partial x},\quad S_{0y}=\frac{\partial z}{\partial y},\quad S_{fx}=\frac{n^2u\sqrt{u^2+v^2}}{h^{4/3}},\quad S_{fy}=\frac{n^2v\sqrt{u^2+v^2}}{h^{4/3}} \tag{3}$$

where $z$ is the distance between the bed surface and the reference level and $n$ is Manning's roughness coefficient.

## Discretization and algorithm

**Calculation of the fluxes.** A cell center finite volume method will be formulated over a triangular control volume, where the variables stored at the centre of the cells are represented as piecewise constants. From Eq.(1) the conservative equation over the area of the $i$th control volume can be written:

$$\frac{\partial U_i}{\partial t}A_i+\sum_{k=1}^{NS}E_k^*dl_k=\int_{\Omega_i}S\mathrm{d}\Omega \tag{4}$$

where $A_i$ is the area of the control volume $\Omega_i$; $E_k^*$ is the convective fluxes; $dl_k$ is the length of control volume boundary; $NS$ is the number of control volume boundary.

The convective fluxes $E_k^*$ are calculated by a Roe's scheme. Details of the convective fluxs discretization have been described in Ref.[7].

**Calculation of bed slope term in irregular topographies.** As mentioned before, the bed slope term is considered separately in the source term (2). This usually leads to an imbalance between the water surface gradient term ($0.5gh^2$) and the bed slope term, and consequent produces the numerical error. For example, in complicated topographies with the stagnant initial condition, the water will not remain stagnant.

In order to avoid the numerical error, an efficient method is introduced in this paper.

**Method. Considering different components of the bed slope term separately.** By considering different components of the bed slope term separately, the source and the flux gradient terms are inherently balanced.

Here, the bed slope term is written as

$$\begin{aligned}gh\frac{\partial z}{\partial x}&=g\frac{\partial(hz)}{\partial x}-gz\frac{\partial h}{\partial x}=0.5g\frac{\partial(hz)}{\partial x}+0.5g\frac{\partial(hz)}{\partial x}-gz\frac{\partial h}{\partial x}\\&=\underbrace{0.5g\frac{\partial(hz)}{\partial x}}_{B_1}+\underbrace{0.5gh\frac{\partial z}{\partial x}}_{B_2}-\underbrace{0.5gz\frac{\partial h}{\partial x}}_{B_3}\end{aligned} \tag{5}$$

where

$$B_1=\frac{0.5g}{A_i}\left(\frac{h_1^L+h_1^R}{2}z_1\Delta y_1+\frac{h_2^L+h_2^R}{2}z_2\Delta y_2+\frac{h_3^L+h_3^R}{2}z_3\Delta y_3\right) \tag{6}$$

$$B_2=\frac{0.5gh_i}{A_i}\left(z_1\Delta y_1+z_2\Delta y_2+z_3\Delta y_3\right) \tag{7}$$

$$B_3=\frac{0.5gz_i}{A_i}\left(\frac{h_1^L+h_1^R}{2}\Delta y_1+\frac{h_2^L+h_2^R}{2}\Delta y_2+\frac{h_3^L+h_3^R}{2}\Delta y_3\right) \tag{8}$$

**Proposition.** The numerical scheme presented in previous sections, satisfies the C property with (5)-(8).

**Proof.** The stagnant condition leads to

$$(uh)_i^{n+1}A_i=(uh)_i^nA_i-0.5g\Delta t(h_1^2\Delta y_1+h_2^2\Delta y_2+h_3^2\Delta y_3)+\Delta tA_i(B_1+B_2-B_3) \tag{9}$$

$$=(uh)_i^nA_i-0.5g\Delta t(h_1(h_1-z_1)\Delta y_1+h_2(h_2-z_2)\Delta y_2+h_3(h_3-z_3)\Delta y_3)+\Delta tA_i(B_2-B_3) \tag{10}$$

$$=(uh)_i^nA_i-0.5g\eta_0\Delta t(h_1\Delta y_1+h_2\Delta y_2+h_3\Delta y_3)+\Delta tA_i(B_2-B_3) \tag{11}$$

and

$$\begin{aligned}(B_2-B_3)A_i &= 0.5gh_i((h_1-\eta_1)\Delta y_1+(h_2-\eta_2)\Delta y_2+(h_3-\eta_3)\Delta y_3)\\ &\quad -0.5gz_i(h_1\Delta y_1+h_2\Delta y_2+h_3\Delta y_3)\\ &= 0.5g(h_i-z_i)(h_1\Delta y_1+h_2\Delta y_2+h_3\Delta y_3)+0.5g\eta_0 h_i(\Delta y_1+\Delta y_2+\Delta y_3)\\ &= 0.5g\eta_0(h_1\Delta y_1+h_2\Delta y_2+h_3\Delta y_3)\end{aligned} \tag{12}$$

Substituting (12) in (11) we obtain

$$(uh)_i^{n+1}A_i=(uh)_i^n A_i \tag{13}$$

Hence, the *C* property holds.

## Model applications

In order to focus on the performance of the numerical scheme, three examples are proposed herein for variable topographies.

**Propagation of a smooth save over a bump.** The numerical experiment takes place in a square pool 1m×1m. At the centre of the pool a symmetric bump in the bottom is mathematically defined in the form

$$z(x,y)=\max\left[0.0,0.25-5*\left((x-0.5)^2+(y-0.5)^2\right)\right] \tag{14}$$

The ability of the methods to preserve the initial steady state in time is analysed. We start from still water as the initial condition covering partially the bump in a frictionless domain fully closed by vertical wall.

$$H=0.1\,\text{m},\quad u=0\,\text{ms}^{-1},\quad v=0\,\text{ms}^{-1} \tag{15}$$

The domain is discretized by 3122 triangular grids.

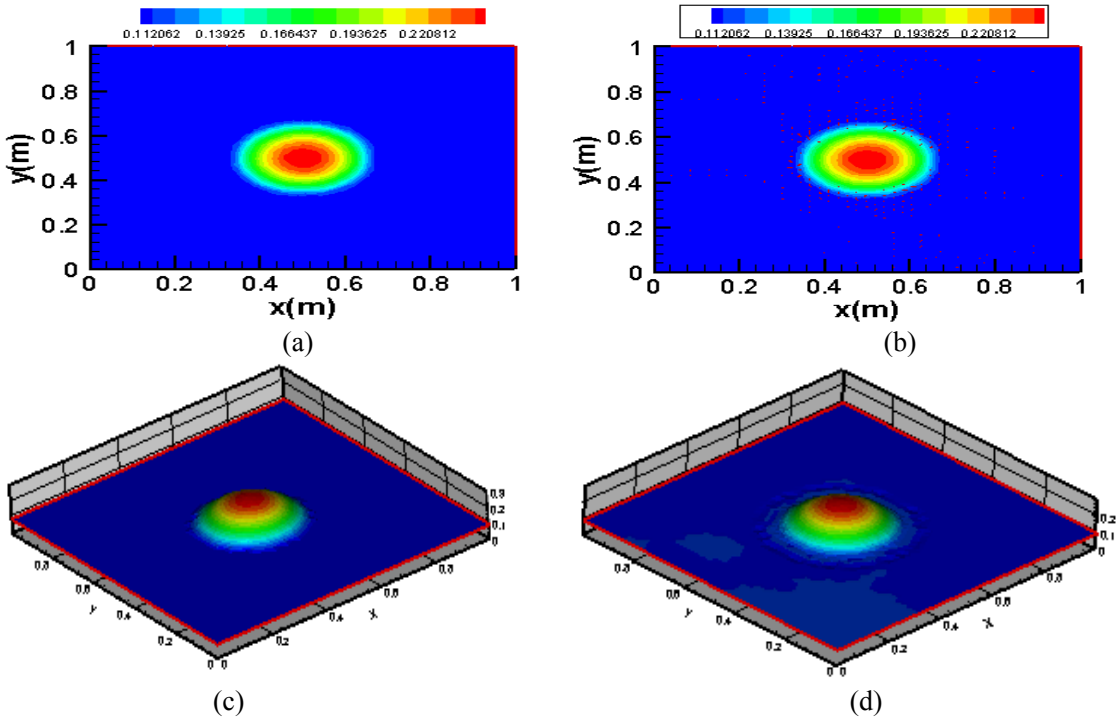

Fig.1 Iso-contour water levels and velocity field (a,b) and free surface (c,d) of steady state in a closed pool using the method (a,c) proposed here and using an upwind method (b,d) in this test case.

The upper plots in Fig.1 show the iso-contour water levels together with the velocity field. Lower figures show the free surface. On the left the results are obtained using the method in this paper while on the right the upwind scheme is used. It can be seen that water easily jumps over the bump in the latter case showing the presented scheme preserve the *C* property, directly related with mass conservation.

**Steady flow over a bump.** The topography is new defined as

$$z(x)=\begin{cases}0.2-0.05(x-10)^2 \; if\; 8<x<12\\ 0 \qquad\qquad otherwise\end{cases} \tag{16}$$

Depending on the initial and boundary conditions, the flow may be subcritical, transcritical (with or without a steady shock), or supercritical. The analytical solution of this problem is given in Reference [10]. The domain is discretized by 2566 triangular grids.

Three different cases are considered below by imposing downstream and upstream boundary conditions for the water depth ($h$) and discharge ($hu$), respectively:

(1) Transcritical flow without shock: $h$=0.66 m only when the flow is subcritical and $hu$=1.53 $m^3$/h.

(2) Transcritical flow with shock: $h$=0.33 m and $hu$=0.18 $m^3$/h.

(3) Subcritical flow: $h$=2 m and $hu$=4.42 $m^3$/h.

The surface profiles are plotted in Fig.2 and Fig.3. They show good agreementd with the analytical solutions. The computed water discharges are also compared in Fig.4-Fig.6 with the analytical ones, which show a very small numerical oscillations.

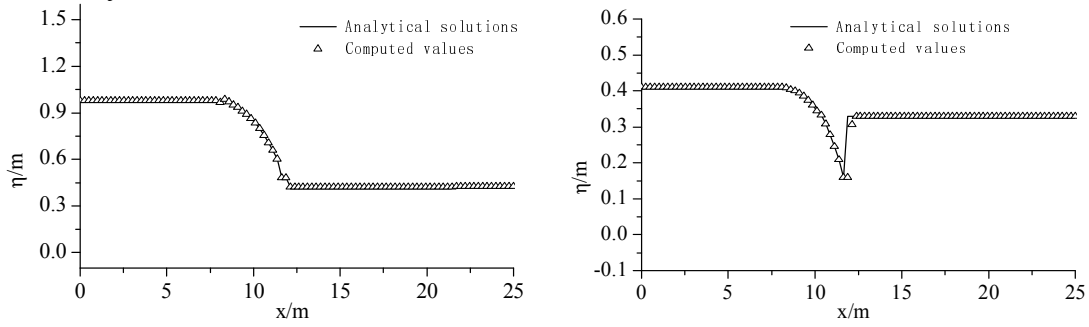

Fig.2 Water surface elevation in steady trans-critical flow without a shock (a) and with a shock (b).

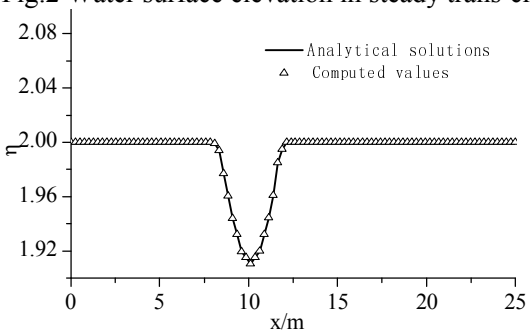

Fig.3 Water surface elevation in steady sub-critical flow

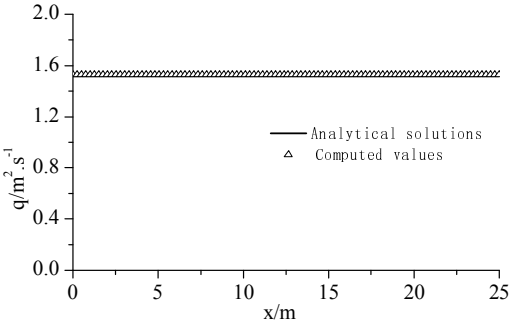

Fig.4 Water discharge in steady transcritical flow without a shock.

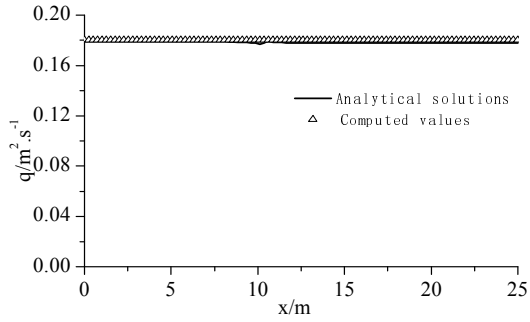

Fig.5 Water discharge in steady transcritical flow.

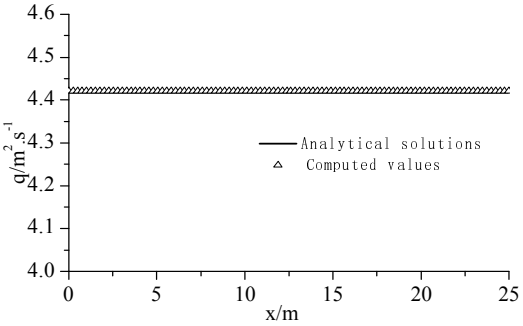

Fig.6 Water discharge in steady subcritical flow with a shock.

**Application to the Bohai sea.** The Bohai Sea is a semi-enclosed sea, which connects with the Huanghai Sea. The tidal wave from the Huanghai Sea propagates through the Bohai Strait into the Bohai Sea. In Bohai Sea the tidal movement is one of the prominent hydrodynamic processes. Fig.7 show the topography of the Bohai Sea and the locations of the gauging points. *AB* is the open boundary. Six conditions have been considered: Bayuquan, Jinzhou port, Jingtang port, Tanggu, Huanghua port and Penglai port, respectively. There are 6973 nodes together which forms 13221 triangular meshes. The time step is 36 s. Fig.8 show the water surface elevation comparisons at six

gauging points in 25h. Tidal current field distribution of Bohai Sea are shown in Fig.9. It can be drawn that the numerical model is reasonable and can be applied to study the tidal currents in Bohai Sea.

## Conclusions

In this paper, an efficient method have been applied to treat the bed source terms and satisfy the compatibility property on unstructured grids. Numerical confirmation of the compatibility property of the two-dimensional shallow water flow model proposed by the authors is presented. Contrary to many available schemes, our approach can be easily implemented on unstructured grids and it takes advantage of being flexible for complicated geometry boundaries with irregular topography. Good agreement between numerical results and experimental data indicates the capability and efficiency of model for the simulation the complex flow phenomenon with irregular topography .

**Keywords:** inversion; Gravity dam; material parameter; least square; regularization

**Abstract.** A regularization based method of inversely analyzing the material parameters for the gravity dams is presented in this paper. The measured noise of the displacement often leads to the ill-posed solutions of the dam inversion. A least square scheme was adopted for the inverse analysis by using of the displacement measurements, and the L-curve algorithm was proposed to perform the regularization in the inversion computation. The proposed method actually utilizes the sensitivity of the measured displacements with respect to the sub-regional material parameters. Thus a simplified algorithm was developed to calculate the sensitivity coefficients by using the standard finite element procedure. To investigate the effectiveness of the proposed method, the numerical simulations on a concrete gravity dam were carried out. The results demonstrate that the presented method can accurately obtain the material parameters of the dam by using of the inverse analysis, which has the potential for assessing the integrity of the gravity dams.

## Introduction

With the continuous development of monitoring technology, some scholars prefer to use dam safety monitoring data for inversing the dam material parameter, and this method has been approved to be available. Among them, the displacement back analysis based on displacement measurement information became a common method of dam material parameter inversion. There are three main methods which can solve the optimization problem of the inversion process: the traditional non-linear optimization method, the intelligent optimization algorithm and the combination of the former [1,4]. Research on the first kind of optimization method has been started for a long time, it is easy to operate and its solution accuracy is relatively high. Thus, the concrete dam parameter inversion method used in this paper is regularization algorithm. In the progress of solving this problem, the sensitivity coefficient will be used. In this paper, an easy method of calculating sensitivity coefficient was deduced.

## Inversion process and principle of the material parameter

Because of the influence of the Poisson's ratio on the deformation of dam is very small, this paper only consider the elastic modulus as the research object. The expression of objective function [1] is given below,

$$\min(f(\widehat{E}))=\sum_{i=1}^{N}(u_i(\widehat{E})-u_i^0)^2. \quad (1)$$

Here $\widehat{E}$ is a vector which consists of each concrete-dam partition elastic modulus. $u_i(\widehat{E})$ represents the crest displacement. $u_i^0$ is the observation value. $N$ is the number of water level points.

The material parameter inversion progress is to make the objective function reach the minimum. Gauss-Newton algorithm is commonly used for solving unconstrained optimization problems, this method needs a coefficient matrix. This matrix might became an ill-conditioned matrix because of the

effect of the measurement error [2]. The ill-conditioned matrix may make the results deviated from the actual value. In order to solve this problem, Tikhonov proposed a regularization method, this method can improve the ill-condition of the coefficient matrix through introducing a regularization factor. After adding a regularization factor, the original aim function is transformed as follows [3]:

$$\min(f(\widehat{E}))=min\left\{\sum_{i=1}^{N}(u_i(\widehat{E})-u_i^0)^2+\mu^2\sum_{i=1}^{n}(E_i-E_i^0)^2\right\}. \tag{2}$$

Here $\mu^2$ is the regularization factor. $E_i$ is elastic modulus after iteration. $E_i^0$ is the elastic modulus before iteration. The following is the inversion procedure based on Matlab software:

1) Establishing a finite element model of the gravity dam, different material partitions use different material parameters. Set the step size θ to 0. Based on the superposition principle, the global stiff matrix can be assembled by each partition stiff matrix,

$$\{K\}=\{K_1\}+\{K_2\}+\ldots+\{K_n\}. \tag{3}$$

Where $\{K\}$ is the global stiff matrix, $\{K_i\}$ is the partition stiff matrix. Assume the dam concrete and foundation rock is linear elastic, if the elastic modulus value of partition $j$ is $E_j$, $\{K_j\}$ can be written as:

$$\{K_j\}=E_j*\{K_j\}^e. \tag{4}$$

Here $\{K_i\}^e$ is the partition geometric stiff matrix. It can be calculated through making the elastic modulus of partition $i$ to 1, the others($i\neq j$) to 0. Put Eq. 4 into Eq. 3,we can obtain:

$$\{K\}=\sum_{i=1}^{n}E_i*\{K_i\}^e. \tag{5}$$

2) Calculating the global stiff matrix $\{K\}^\theta$ through using Eq. 5. The crest displacement vector can be calculated by:$\{u_\theta\}=inv(\{K\}^\theta)*\{f\}$.Then, compute the aim function value of step $\theta$;

3) Calculating the sensitivity coefficients matrix $A_\theta$ and coefficient matrix $Q_\theta$. The following is the expression of $A_\theta$,

$$A_\theta=\begin{pmatrix}\frac{\partial u_1^\theta}{\partial E_1} & \frac{\partial u_2^\theta}{\partial E_1} & \frac{\partial u_3^\theta}{\partial E_1} & \cdots & \frac{\partial u_N^\theta}{\partial E_1}\\ \frac{\partial u_1^\theta}{\partial E_2} & \frac{\partial u_2^\theta}{\partial E_2} & \frac{\partial u_3^\theta}{\partial E_2} & \cdots & \frac{\partial u_N^\theta}{\partial E_2}\\ \vdots & \vdots & & \ddots & \vdots\\ \frac{\partial u_1^\theta}{\partial E_n} & \frac{\partial u_2^\theta}{\partial E_n} & \frac{\partial u_3^\theta}{\partial E_n} & \cdots & \frac{\partial u_N^\theta}{\partial E_n}\end{pmatrix}. \tag{6}$$

Where $\frac{\partial u_i}{\partial E_j}$ is sensitivity coefficient which can be got through Eq.9. Its solution procedure is given in Part 3. $Q_\theta$ is expressed as $Q_\theta=A_\theta*A_\theta^T$ ;

4) Use the L-curve algorithm to determine the regularization factor $\mu_\theta$;

5) Add the regularization factor to the Gauss-Newton normal equation $(Q_\theta+\mu_\theta^2 I)\,p^\theta=-g_\theta$, $g_\theta=A_\theta*(\{u^t\}-\{u^0\})$. Solve this normal equation, the elastic modulus increment vector $p^\theta$ is got;

6) Compute the new iteration elastic modulus vector by add $p^\theta$ to $\widehat{E}^\theta$, $\widehat{E}^{\theta+1}=\widehat{E}^\theta+p^\theta$. Judge the convergence rule, if $min\{f(\widehat{E}^\theta)\}<fmin$, then stop iteration computing, output $E^\theta$ and $min\{f(\widehat{E}^\theta)\}$, else, $\theta=\theta+1$, go to step 2).

**Solving process of the sensitivity coefficient**

Assume the dam is equivalent linear elastic, according to the physical equation of the finite element method:

$$\{K\}\{u\}=\{f\}. \tag{7}$$

Here, $\{K\}$ is the global stiff matrix of the dam, it is relevant to the geometry and material parameter. Compute the partial derivative of $E_i$ on both side of Eq. 10, then

$$\{K\}\frac{\partial\{u\}}{\partial E_i}+\frac{\partial\{K\}}{\partial E_i}\{u\}=0,$$
$$\frac{\partial\{u\}}{\partial E_i}=-\{K\}^{-1}\frac{\partial\{K\}}{\partial E_i}\{u\}. \tag{8}$$

According to Eq. 5, $\frac{\partial\{K\}}{\partial E_i}=\partial(\sum_{i=1}^{n}E_i*\{K_i\}^e)/\partial E_i$. In this formula, $\{K_i\}^e$ is the partition geometric stiff matrix, so it has nothing to do with $E_i$. The partial derivative is $\frac{\partial\{K\}}{\partial E_i}=\{K_i\}^e$,put it into Eq. 9, the sensitivity coefficient is obtained,

$$\frac{\partial\{u\}}{\partial E_i}=-\{K\}^{-1}\{K_i\}^e\{u\}. \tag{9}$$

**Proof calculation and analysis**

Take the dam cross-section in Fig. 1 as geometric model, establishing a finite element model. Assume the actual elastic modulus value for each partition is *($E_1$=15GPa, $E_2$=20GPa, $E_3$=25GPa, $E_4$=20GPa*), the Poisson's ratio is $\mu_1=\mu_2=\mu_3=0.17$, $\mu_4=0.22$, the density of dam concrete unified take $\rho^c=2350kg/m^3$, the foundation rock density take $\rho^r=2700kg/m^3$. The finite element model is meshed by plane strain element, there is 1916 elements, 3900 degrees of freedom. Compute the crest displacement under water pressure, body-weight, uplift pressure and silt pressure. Take the compute $\{u^r\}$ value plus 1% random error as observation displacement $\{u^0\}$, it can be expressed by $\{u^0\}=\{u^r\}\pm rand[-0.01,0.01]*\{u^r\}$. If the actual modulus can be inversed through the process above, then the algorithm is useful for solving material parameter inversion problem. Tab.1 is the inversion parameter changes table for each step. It can be seen that the aim function was convergent in step 3. The convergence speed is fast. The relative error of the inversed results and actual values is given in Tab.2. It is relatively small. The deformation of relative error is $\Delta_i=[(\widehat{E}_i-E_i^0)/E_i^0]\times100\%$. These results can indicate that this algorithm is practicable. In the inversion progress described above, the water level vector is $\{H_i\}=\{76,77,78,79,80\}$, the initial iteration elastic modulus is $\{\widehat{E}^0\}=$ ($E_1$=10GPa,$E_2$=15GPa,$E_3$=20GPa,$E_4$=15GPa), the convergence rule is $f_{min}<2e\text{-}7$.

Table 1 Changes of the iteration parameters

## Conclusion

In this paper a method for solving the sensitivity coefficients was presented. This method makes it more fast and accurate to compute the sensitivity coefficients. A program that can fast and effectively inverse the materials parameter of the gravity dam was proposed. The effectiveness of the new method is verified by the numerical simulations. The results show that the proposed method has some advantages such as rapid convergence speed, high convergence accuracy and good stability.

# An new approximate formula for contracted depth in Quadratic parabola shaped channels

Fengling Li

Department of architecture and civil engineering , Huizhou University ,

Huizhou, Guangdong, 516007, China

mmlflmm@163.com

**Key word :** irrigation channels; quadratic parabola; contracted depth; approximate solution

**Abstract:** On the basis of summarizing the predecessors' research, based on the contracted depth basic equation mathematical transformation of quadratic parabola shaped sections, the interrelation between dimensionless contracted depth and the dimensionless parameter were analyzed, we obtain the approximate formula for contracted depth in Quadratic parabola shaped channels, it is simpler and accurate, It's maximum relative error are less than 0.12% in the utility range.

## Introduction

At present, many scholars studied on theoretical or iterative formula for contracted depth and normal depth of quadratic parabola shaped section[1-5]. The approximate solution on contracted depth of quadratic parabola form channel has not been well studied. In this paper, through to mathematical transformation for the contracted depth basic equation of quadratic parabola shaped section. Introducing the dimensionless parameters, analyzing the relationship between dimensionless contracted depth and the dimensionless parameters, according to the water and wastewater engineering norms and hydraulic engineering norms, we get calculation formula for contracted depth in quadratic parabola shaped channels

## Quadratic parabola cross-section contracted depth basic equation [4]:

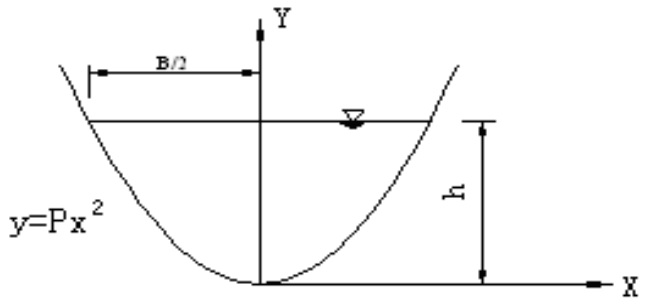

Fig1. Cross-section of quadratic parabola-shape

$$E_0 = h_c + \frac{Q^2}{2g\phi^2 A_c^{\,2}} \tag{1}$$

Where： $E_0$： total head in the contraction section ( $m$ ), $h_c$： contracted depth ( $m$ ), Q - flow, ($m^3/s$), $g$： Acceleration of gravity( $m/s^2$ ), $\phi$ - Velocity coefficient, $A_c$ - water sectional area, ($m^2$).

Where: $A_c = \frac{4}{3} P^{-\frac{1}{2}} h_c^{\frac{3}{2}}$ (2)

In order to study convenient, we are defining dimensionless contracted depth $\alpha$

$$\alpha = \frac{h_c}{E_0} \tag{3}$$

Combine equation (1), equation (2) and equation (3), we get the Simultaneous equation, and then we can obtain a equation for the contracted depth of the quadratic parabola shaped channels.

$$\left( \frac{9Q^2 p}{32g\phi^2 {E_0}^4} \right)^{\frac{1}{3}} = \alpha(1-\alpha)^{\frac{1}{3}} \tag{4}$$

Suppose K is non-dimensional parameter,

$$k = \left( \frac{9Q^2 p}{32g\phi^2 {E_0}^4} \right)^{\frac{1}{3}} \tag{5}$$

The equation can be as follows:

$$k = \alpha(1-\alpha)^{\frac{1}{3}} \tag{6}$$

**An approximate calculation formula of dimensionless contracted depth**

Adopting trial and error method, making a computation program to gradually optimized fitting, we get an approximate calculation formula for dimensionless contracted depth of quadratic parabola shaped cross section:

$$\alpha_1 = k(1.6k^{3.64} + 0.21k + 1)^{1.77} \tag{7}$$

**Formula evaluation**

When setting different dimensionless contracted depth $\alpha \in [0,0.50]$ of quadratic parabola shaped cross section, non-dimensional parameter k can be figured out according to equation(6), dimensionless contracted depth $\alpha_1$ can be figured out according to equation(7)， and then to calculate the relative error $\Delta = \frac{\alpha_1 - \alpha}{\alpha} \times 100$ .On the basis of results listed in Table 1，Maximum relative error is less than 0.12%, The results show that the precision meets the needs of project.

**Table 1 Non-dimensional Parameter Contracted Depth Calculation Error**

**Calculation contracted depth application example**

It is known that the parameters of Quadratic parabola shaped channels $y = 0.25x^2$ . Where：total head $E_0 = 10.31m$ , velocity coefficient $\phi = 0.95$ , solved the contracted depth $h_c$ when the flow $Q = 220 m^3/s$ .

**Answer:**

Firstly, to calculate dimensionless coefficient K;

Using Formula（5）to calculate $k = \left( \frac{9Q^2 p}{32 g \phi^2 {E_0}^4} \right)^{\frac{1}{3}} = 0.324023$

Using Formula（7）to calculate $\alpha_1 = k(1.6k^{3.64} + 0.21k + 1)^{1.77} = 0.380183$

Using Formula（3）to calculate $h_c = \alpha E_0 = 3.920$ (exact value is 3.918 m) relative error is 0.05%.

**Conclusion**

The approximate calculation formula the absolute maximum relative error of contracted depth was 0.12% respectively in the utility range. It can satisfy the demand of practical engineering.

**Keywords:** The middle reaches of the Yangtze River, bottomland change, waterway conditions, Influence

**Abstract.** This study Base on the HuangLianzhou heart beaches and Shejiwang tidal flat of years of evolution, revealing the relationship between HuangLianzhou heart beaches and Shejiawan tidal flat erosion and Waterway conditions, and explore affecting factorsof the waterway poor conditions , which have a guiding significance for the solution to the current problem of the river channel.
Since the water storage of the Three Gorges Project, which subject to change on runoff and sediment, the middle reaches of the Yangtze River 'balance is broken, an increase in the length of the water, resulting in a lot of relaxation of the original section of marshland erosion, wide and shallow river to development, has gradually become a more unstable river type. Year of data in a limited variation between the marshland and waterways conditions become blurred, but relative to the increasingly grim situation waterways, water and sediment study islet in the new era of changing characteristics and relationship with the channel changing conditions but is engineering practice urgent need to solve the problem. In this paper, the recent variation of marshland landscape of the Middle Yangtze River LiyushanWaterway study [1,4], based on similar problems existing Liyushan waterway landscape studies, to provide a reference for waterway management.

## Waterway Overview

Liyushan Waterway landscape located at the end of the middle reaches of the Yangtze River, then put on a Gepaiji waterway, until next Wuxue waterways, long 13km (Figure.1). The middle of the river long maintained two narrow width slightly curved shape to relax, Waterway in the middle relaxed Panjiagang to the left bank plate Gonglongwan presence elongated side beach, beach side called Shejiawan, in the heart of partial relaxation of the right bank of the river segment kept bent Beach, namely HuangLianzhou heart Beach. HuangLianzhou section into the dry season will be relaxed about the two branches, bending the right slot, narrow and deep; left slot straight. Wide.

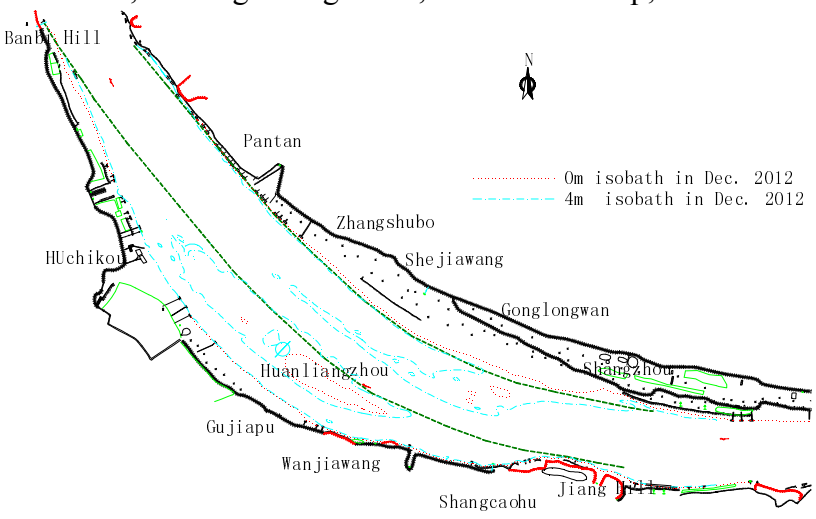

**Figure.1,River Regime Chart of Liyushan waterway**

Prior to 1998 Liyushan Waterway of Huang Lianzhou rely on the right bank of the landscape, in the form of side beaches, more stable, middle river channel, a good channel conditions. 1998 ~ 2008 Beach rushed back to the right and was cut Huang Lianzhou beach gradually developed heart formation, but relatively small-scale, local waterways often not satisfied 4 5m construction standards. Since 2008, Huang Lianzhou beach heart of a certain size, the North line width groove depth at 200m above 4.5m, etc. Overall, the north channel inlet and outlet points exist sandbags shallow water and sediment in adverse conditions

**Changes of erosion and river bottomland**

**Huanglianzhou heart beaches**

Right after the Three Gorges reservoir shore beach with red back, Huanglianzhou heart beaches form, since the heart of North Beach Huanglianzhou groove formed longitudinally little change; But the larger lateral position changes, the maximum amplitude at about 800m .

April 2008 before the beach is relatively small Huanglianzhou heart slowly silting smaller Huanglianzhou the silting process, the rapid development of deep red South Passage, north width shallow channel changing conditions and poor; April 2008 until January 2010, and in the heart Huanglianzhou Beach develop into a certain size, growth slowed South Passage, North Passage of the conditions improved markedly, this process Huanglianzhou despite some erosion, but still much larger than the range 0m line deposition cycle 2005 to 2008; 2010 to a relatively large amount of water, until February 2011, heart Beach siltation occurs, the area increases, the beach top siltation. The past two years, Huanglianzhou heart again in beach erosion state, south trough development, beach area continues to decrease heart of the dry season, in March 2012 the North remains shallow trough export package, the minimum depth of 3.8m; until April 2013, the occurrence of cardiac Beach the trend of erosion, beach body size has been reduced, but the beach crest elevation change little.

**Shejiawan side beach**

Since the mid-century, Shejiawan convex side beach shore beaches as long-standing , Shejiawan side beach 0m line changed little. Gorges reciprocating cyclical trends Shejiawan low beach erosion since Impoundment.

2003-2008 before Shejiawan whole red beach side retreat, head alternating erosion mainly in the red tail scour relatively large, since 2008 silt washed down the beach side. 2008 Beach rushed back to the right before the original period Huang Lianzhou develope into a certain size. In recent years, the two sides on the edge of the shallow beach area sections were washed back ( Figure 2 ) , in October 2007 where beach side development, the shallowest depth of about 0m ( sailing base , the same below ) ; until April 2008 , while beach substantial erosion, the maximum scour depth of about 7m; until September 2009 , while beach erosion reversal of deep grooves , the deepest water depth of about 10m; until November 2012 , the occurrence of large-scale deposition deep grooves , most shallow depth of about to 2.5m; until April 2013 , while beach erosion into the groove again , the maximum scour depth of about 6m. The above changes show that Shejiawan beach side bar high when part of the basic stability, low magnitude larger beach erosion and sediment under certain conditions, while the disc home Harbour and flood sediment silt is easy to fall into the beach , and in the dry season are red Beach into the slot ( Figure.2 ) reciprocating cyclical trends .

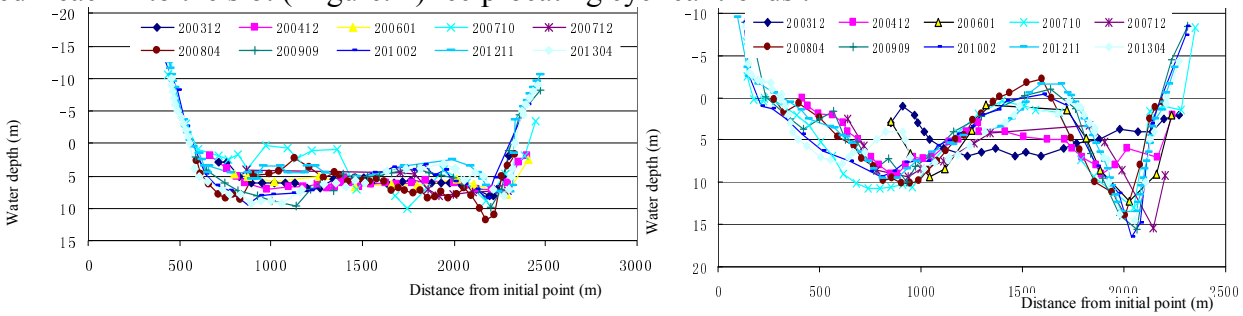

**Figure.2,Huanglianzhou near the characteristic change in erosion**

**Changes of marshland and waterways**

**Huanglianzhou heart beaches and Shejiawan side beach relationship analysis**

Before the Three Gorges Project , when Huanglianzhou beach erosion body atrophy , because power is more mainstream right, Shejiawan beach side beach at the edge of the hydrodynamic necessarily weaker, low beach beach beach side edge will be fully developed . When Huanglianzhou heart beach development , indicating that the water main axis of power left , sediment waters off the beach in the heart Huanglianzhou silt ,Huanglianzhou Chau body Expand , deep grooves abutting a certain degree of deviation from the mainstream Huanglianzhou body power , deep grooves difficult to obtain sufficient erosion, Shejiawan side beach beach erosion edge lower back . Prior to 1998, Shejiawan shore beach side bar and right shift ( Fig. 3) , such as the 1986 Huang Lianzhou side beach is relatively large , compared Shejiawan beach side development, but due to the mainstream of the 1990s, the South side, Huang Lianzhou erosion atrophy, the following paragraph on the right side of beach Shejiawan significantly developed . Therefore, Shejiawan beach and right on the shore side beach there is an obvious shift in the correspondence.

Since the Three Gorges Project , subject to significantly reduce the impact of sand , Shejiawan beach side beach and Huanglianzhou shift in the relationship between heart obvious . For example , from April 2008 to January 2010 ,Huanglianzhou Heart Beach, Shejiawan side beach segments have different levels of erosion, and the lower section of beach side Shejiawan siltation occurs ; January 2010 to February 2011 Huanglianzhou heart Beach, beach segments Shejiawan side siltation in varying degrees , and Shejiawan side beach erosion occurred following paragraph ; February 2011 to February 2012 Huang Lianzhou some beach erosion heart , Shejiawan slight edge segments beach erosion , the following paragraph Shejiawan side beach has siltation ; February 2012 to April 2013 Huanglianzhou heart beach erosion further reduced, Shejiawan side beach segments have siltation, erosion next paragraph , but exports form a shallow trough north ridge(Fig. 4).

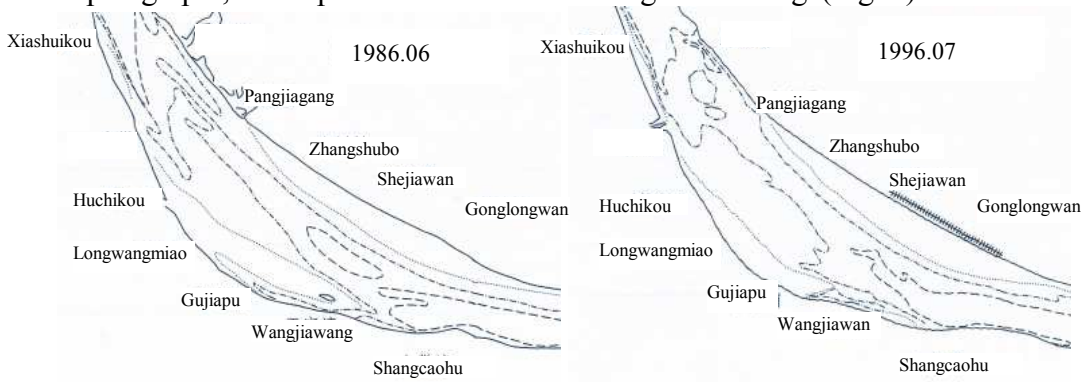

**Figure.3, Before 1998 Shejiawan and the right side beach shore beaches change**

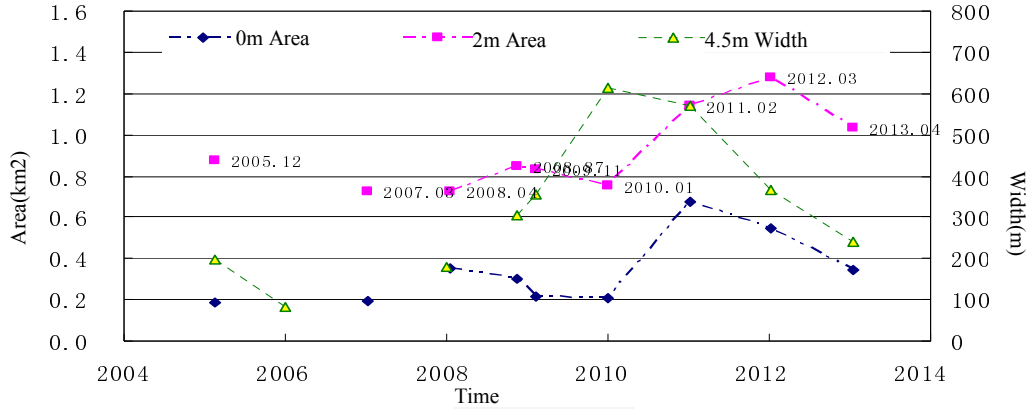

**Figure.4, Huanglianzhou area and 4.5m minimum width change**

**Recent changes in characteristics of marshland and waterways**

Right before the Three Gorges reservoir shore beaches due to be cut , relaxed segments form the dry north-south pattern of two slots , slots in a given period in southern bypass certain conditions, the pros and cons of the North Passage of the condition depends on the fairway on both sides of the boundary conditions change , that is, from the size of the heart and its changes Huanglianzhou beach and beach side Shejiawan common decision. Beach erosion when Huanglianzhou contraction , indicating longer flows through the heart of mainstream left edge of the beach , beach heart downsizing , downsizing heart beach , while the left edge of the beach abuts the heart of the main channel also developed ; same time as the more mainstream power right, SheJiaWan beach side beach at the edge of the hydrodynamic necessarily weaker, low beach -side edge of the development, expansion and development of the right side of beach , which narrowed the North Passage dry river is conducive to the main channel fairways improve conditions.When Huanglianzhou heart beach development,indicating that the water main axis of power left , sediment waters off the beach in the heart Huanglianzhou silt ,Huanglianzhou body scale , deep grooves abutting a certain degree of deviation from the main stream Huanglianzhou body power , deep grooves difficult to obtain sufficient erosion ; while Shejiawan side beach beach erosion edge lower back, dry river width increases, the channel condition is becoming worse. Therefore,can not be isolated from Huanglianzhou Island to correlate changes in body size or bad channel conditions, from both sides of the fairway boundary change considerations. After the Three Gorges reservoir , if there is enough sediment sources ,Huanglianzhou will vary with changes in dynamic conditions and or increase or decrease when increasing the channel conditions may be poor , otherwise good ; key is that when Huanglianzhou appears to promote its increasing when hydrodynamic conditions , if Huanglianzhou Chau body is small, and not enough sand source development of its size , its channel conditions than the larger continents body worse , because the smaller body means the North Passage Island more Shejiawan side beach beach flood low- margin growth in the dry river is great , this dynamic conditions , the adverse effects of water withdrawal cyclical process of erosion on the north passage down the fairway will be highlighted. Meanwhile if there is cause Huanglianzhou downsizing beach beach body hydrodynamic conditions, when the larger beach Huanglianzhou ,compared to the current channel conditions with better hydrodynamic conditions.

**Conclusions**

Before the impoundment of the Three Gorges Huanglianzhoure and Shejiawan beach body stable, and there is correspondence between the shift; after previous smaller Huanglianzhou Three Gorges reservoir silting process in South trough scour depth development rapid, shallow north width, changing channel conditions and poor in2008. Beach after Huanglianzhou develops into a certain size, growth slowed South Passage, North Passage of the conditions improved markedly in 2008

Due to the right shore beach Three Gorges reservoir is cut, which formed the dry northern and southern sections and relaxed groove pattern, a period of time in the South Passage shunt certain conditions, and the pros and cons of the North Passage of the condition depends on the both sides of the fairway boundary conditions and sediment volume changes, from the size of the heart and its changes Huanglianzhou beach and beach side Shejiawan joint decision cannot be isolated from the body size variation Huanglianzhou continents to associate good or bad channel conditions.

Affected by the great flood of 1998 imports of river scour depth development of the right side of the mainstream right-swing, the right shore beach cut; combined with water and sediment interception affected by the Three Gorges Project, North and South were scouring trough occurred while broadening the river, Huanglianzhou development, gradually formed the dry river-slot pattern, the Three Gorges reservoir destroy the correspondence between bottomland and waterway conditions.

**Keywords:** arc dam, vibration, hydrodynamic load

**Abstract.** It is difficult to get a theoretic answer to the water flow load features of high dam flood discharge. Through direct measurement of water flow load features by arranging a surface pressure cell, the complicated point-surface conversion was avoided, and the shock load and surge load features were obtained. For the dam body outlet wall pressure, isolated the fluctuating load applied to the plunge pool floor and the downstream dam surface, the impact of the fluctuating load to the arch dam dynamic response at the flood discharge flow outlet was obtained, and then the equivalent fluctuating load on each discharge flow outlet was obtained by using flow-induced vibration back analysis. The test shows that the energy of the shock load and the surge load mainly centers in a frequency range between 0~1Hz, the shock load is about 2.5-6 times that of the surge load, and the surge load is about 4 times that of the outlet wall pressure.

## Introduction

The flood discharge mode of an arch dam can be divided into two modes: dam body flood discharge and bank side flood discharge. The dam body flood discharge refers to flood discharge by setting surface, mid-level (bottom) outlets as drainage galleries for flood discharge, while bank side flood discharge refers to flood discharge by the bank side spillway or flood discharge tunnel. Dam body outlet flood discharge can simplify the pivot arrangement and reduce engineering cost for flood discharge. In particular, with the development of underground opening technology and the use of modern construction method, the problem of the two major structures (flood discharge buildings and power station) occupying the riverbed position has been solved satisfactorily. For this reason, the mode of dam body outlet flood discharge has been used in many large arch dam pivotal projects in China, such as Ertan, Xiaowan, Xiluodu, Jinping, Goupitan and Laxiwa, etc.

The large power of high dam flood discharge leads to a very large flood discharge current load. Whether this flood discharge load will generate or not, through the foundation and the bank bedrock, a dynamic excitation to a high dam, resulting in the dam body and the dam abutment generating a flow-induced vibration that exceeds the allowable range, is a significant issue that relates to the engineering safety of a high arch dam.

The flood discharge load applied to a dam body includes the shock load and surge load in the downstream riverbed, the dam body outlet fluctuating wall pressure and the storm wave load. The magnitude of the storm wave load can be calculated according to some measured data, such as the wind speed, the wave height and etc. However, the determination of the flood discharge current load, including the shock load, the surge load and the dam body outlet fluctuating wall pressure, is more difficult. In particular, though a lot of work has been done in respect of the shock load [1-4], little is known about the amplitude and the frequency of the flood discharge current fluctuating load and the point-surface conversion, therefore, it is relatively a reliable method of obtain the flood discharge current load by model test.

**Test Establishment**

Xiaowan high arch dam was selected for the model test, the model scope includes the whole dam body (including the surface outlet, mid-level outlet and bottom outlet), and the downstream river stilling basin. The model scale was 1:150.

$P_D'$ represents the dynamic load generated by the submerged impinging jet striking the downstream riverbed; $P_L'$ represents the dynamic load directly applied to the dam body by the discharge flow-induced surge in the plunge pool; $P_K'$ represents the dynamic load generated by the discharge flow to the outlet wall. These fluctuating loads are continuously distributed random loads, and the fluctuating pressure at each point changes with the spatial position and the time. To avoid the complex point-surface conversion, a pressure cell was used in the test to measure various current loads.

To test the surface fluctuating load, a $32\times15\,cm^2$ surface pressure cell was arranged on the plunge pool floor. When the surface outlet discharged flood separately, the pressure cell was installed on the floor chainage 0+165 $m$. When the mid-level outlet discharged separately, the pressure cell was installed on the floor chainage 0+290 $m$. When they discharged jointly, the installation chainage was 0+210 $m$. A $32\times15\,cm^2$ surface pressure cell was also arranged on the arch dam downstream dam to measure the surface fluctuating pressure of the surge in the plunge pool to the downstream dam. As the mode of action and position of the fluctuating load acting on the outlet was very complex and hard to measure directly, a test method was used to isolate the fluctuating load acting on the plunge pool floor and the arch dam downstream dam (the method was to draw away the falling overflow so that it would not strike the plunge pool), to obtain the impact of the fluctuating load on the discharge flow outlet to the arch dam dynamic response, and the flow-induced vibration back-analysis[5] was used to solve the “equivalent” fluctuating load on each discharge flow outlet, and to establish a correlativity between the flood discharge flow head and the “equivalent" fluctuating load.

**Results and Discussions**

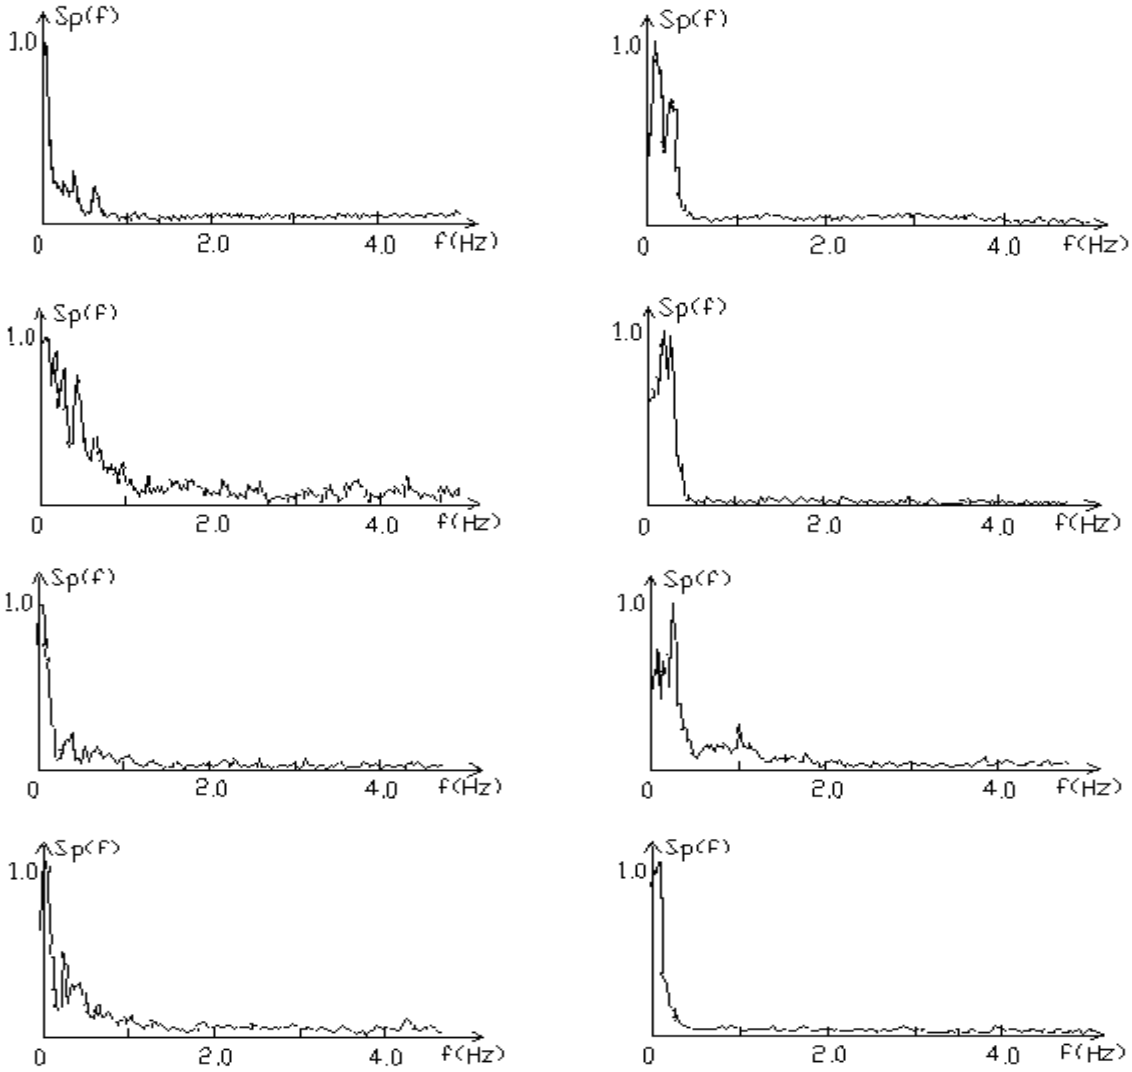
The testing results of $P_D'$ and $P_L'$ for various discharge flow working conditions of Xiaowan arch dam are shown in Table 1:

Table 1 Overall fluctuating load of Xiaowan high arch dam (root mean square value) [KPa]

| Working condition | Check flood level joint flood discharge | | Design flood level joint flood discharge | | Normal pool level surface outlet separate flood discharge | |
|---|---|---|---|---|---|---|
| | Shock | Surge | Shock | Surge | Shock | Surge |
| Root mean square value of the load | 22.0 | 4.90 | 19.6 | 4.80 | 18.2 | 3.70 |

Generally speaking, the shock fluctuating load to the plunge pool floor increases monotonically with the decrease of the downstream depth of water; and the overall surge fluctuating load to the dam body downstream surface shows little change with the downstream water level, and it generally increases slightly with the downstream depth of water; both the fluctuating loads generally increase with the rise of the upper level. With different combinations of the upstream and downstream water level, the root mean square value of the shock overall fluctuating load on the floor is usually 2.5~6 times that of the surge overall fluctuating load on the dam body downstream surface, and the specific value of the two decreases with the increase of the downstream water depth. The surface fluctuating pressure to the plunge pool floor generated by the flood discharge is the greatest at the joint flood discharge, mid-level outlet separate flood discharge is lightly higher than the surface outlet flood discharge while the hydrodynamic shock pressure measured with a piezometric tube shows that the surface outlet flood discharge is higher than the mid-level flood discharge. The analysis indicates that rolling magnitude in the plunge pool generated by the mid-level outlet discharge is larger than that of the surface outlet, and the synchronous action scope of the fluctuating pressure is great, therefore, the

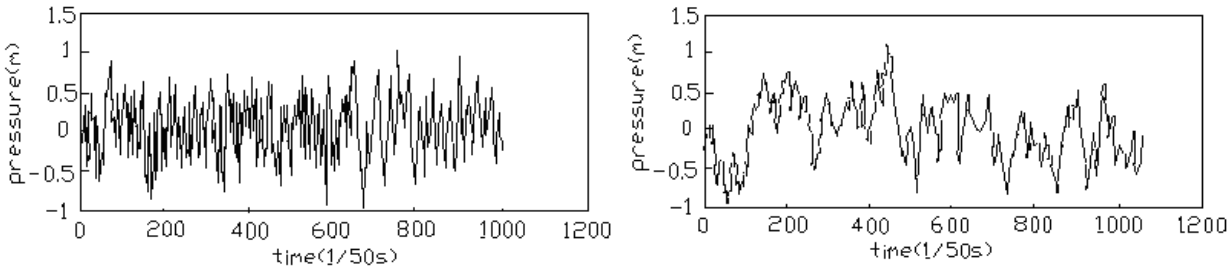
amplitude reflected on the surface fluctuating pressure is that the mid-level outlet discharge is slightly higher than the surface outlet discharge. The typical time history pressure is shown in Fig. 1.



Shock fluctuating load spectrograph Surge fluctuating load spectrograph

Fig. 1 Typical surface fluctuating load spectrograph

The energy of the overall fluctuating load is distributed in a frequency scope of 0~5Hz, and mainly concentrates in a frequency scope of less than 1Hz , which belongs to a low frequency fluctuation. The frequency spectrum of the overall (surface) fluctuating load is shown in Fig. 2.



Shock fluctuating load hydrograph Surge fluctuating load hydrograph

Fig. 2 Typical surface fluctuating load hydrograph

The fluctuating pressure $P'$ acting on the discharge outlet side wall can be regarded as having a relation with the kinetic head $U^2/2g$ as follow:

$$P' = \alpha U^2/2g . \quad (1)$$

α should change with the flow regime, and the overall fluctuating load on the outlet can be regarded as being in direct proportion to the fluctuating pressure $P_K^{'}$ and the action area $A^{'}$. Let the action area and the discharge area have: $A^{'}$=βA, then the overall fluctuating load on the outlet has:

$$P_K^{'} = \alpha \frac{U^2}{2g} \beta A = C_f Q \sqrt{H} \tag{2}$$

Where $Q$ is the discharge quantity, calculated in $m^3/s$, and $H$ is the acting head in the outlet, calculated in $m$. The dynamic response under the fluctuating load on the discharge flow outlet is measured through isolating the plunge pool shock and surge fluctuating load, then the "equivalent" fluctuating load is analyzed from the feedback, the mid-level outlet overall fluctuating load $C_f$ can be obtained, which may be taken as $9\times10^{-3}$, and the surface outlet overall fluctuating load $C_f$ can be taken as $7\times10^{-3}$.The outlet overall fluctuating load of the outlet can be estimated in line with the above formula. Normally, 1/4 of the downstream surge can be taken as the outlet overall fluctuating load.

## Conclusion

The floor block would not be acted upon by an uplift force if the plunge pool floor joints are in a good condition, but would bear a significantly large shock load. In this paper, the surge load applied to the dam face downstream and the shock load applied to the plunge pool floor are measured through a model test, the load root mean square value under a specific upstream and downstream water level is given, the relation of magnitude between the two is studied and the respective frequency spectrum is provided.

As it is impossible to measure directly the outlet fluctuating wall pressure of the dam body, the method of isolating other flood discharge flow load is applied, so that the response is generated entirely from the outlet wall pressure, and then the outlet wall pressure load can be obtained by back-analysis on this response. Finally, 1/4 of the downstream surge can be used as the outlet overall fluctuating load for approximate analysis.

**Keywords:** plastic concrete; numerical simulation; seepage field; cut-off wall

**Abstract.** By numerical calculation, it analyzed the seepage effects of plastic concrete cut-off wall in in construction period. On construction period, the seepage flow from inside of channel to outside at unit length is 0.753m$^3$/h. The seepage flow from under plastic concrete cut-off wall is 0.646m$^3$/h which is 85.79% of total seepage flow. Under certain condition on operation period, the seepage flow from inside of channel to outside at unit length is 0.394m$^3$/h. The seepage flow from under plastic concrete cut-off wall is 0.358m$^3$/h which is 90.86% of total seepage flow. Under another condition on operation period, the seepage flow from inside of channel to outside at unit length is 0.249m$^3$/h. The seepage flow from under plastic concrete cut-off wall is 0.236m$^3$/h which is 94.78% of total seepage flow. In It showed the plastic concrete cut-off wall has obvious effect.

## Introduction

In hydraulic projects, the seepage problems of main structures is an important practical problems which must be solved in the process of design and construction[1].The ordinary treating measures are concrete cut-off wall. It uses special machines to make grooves and holes on the permeable foundation of covering layer and to pump mud into them. The mud fixes the walls of grooves and holes. And then, it uses conduit to pour concrete into grooves and holes which replaces mud. The continuous concrete wall is constructed to cut off seepage flow.

Plastic concrete cut-off wall develops to solve problems of rigid concrete cut-off wall. It uses mixed materials of clay and bentonite to replace some cement in ordinary concrete. It is a soft wall[2].

It established mathematical model of geotechnical seepage by numerical analysis[3]. Under different operating conditions in construction and operation periods, it concretely analyzed the effect of plastic concrete cut-off wall in tailing water channel of hydropower station which can give references to solve similar problems.

## Calculating conditions

According to problems concerned in design and construction, it chose classic cross sections to simulate which referred to seepage field, seepage stability and seepage flow discharge in construction period, and forecasted seepage field in operation period. Table 1 shows the calculating conditions.

Table 1 Calculating conditions

| No. | condition | Elevation of water level outside channel（m） | Elevation of water level inside channel（m） |
|---|---|---|---|
| 1 | construction period | 420.00 | 398.00 |
| 2 | no hydropower unit operating | 419.00 | 411.00 |
| 3 | one hydropower unit operating | 410.00 | 403.50 |

**Numerical calculation of FEM for effect of plastic concrete cut-off wall in construction period**

In construction period, in numerical simulated zone, the elevation of bottom is 360m and the elevation of top is 420.5m. The horizontal distance is from center line to 156m left far away. Meshing the computation zone, there are 4259 elements and 2372 jets. The FEM model is shown in Fig 1.

According to simulation calculation of seepage field in construction period, the results are got. The overflow of saturation line is under drift sand and gravel filling layer. The elevation of overflow is 402.50m. In unit length, the seepage flow discharge from outside of channel to inside of channel is $2.0905\times10^{-4}m^3/s$. The seepage flow discharge under plastic concrete cut-off wall is $1.7942\times10^{-4}m^3/s$. That means, in unit length, the seepage flow discharge from outside to inside of channel is $0.753m^3/h$ and the seepage flow discharge under plastic concrete cut-off wall is $0.646m^3/h$.

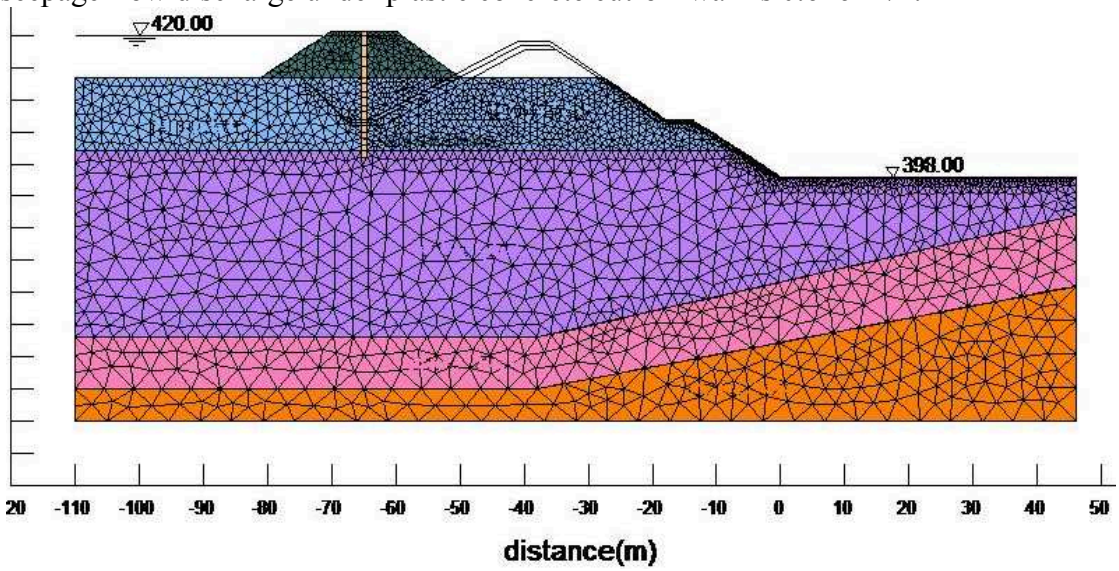

Fig 1 Grids meshing of FEM in computation zone in operating condition of No.1

It shows that there is 85.79% of total seepage flow discharge from outside to inside of tailing water channel through cut-off wall. Cut-off wall has good effect. The seepage flow discharge of $0.753m^3/h$ from outside to inside of tailing water channel is allowed in construction process.

In Table 2, the hydraulic slope in cut-off wall is 3.76～7.90 which is less than allowable hydraulic slope and makes seepage stable.

Table 2 Hydraulic gradients in front of and behind cut-off wall

| Y value of cut-off wall | Hydraulic slope of in front of cut-off wall | Hydraulic slope of behind cut-off wall |
|---|---|---|
| 4.01E+02 | 4.31E+00 | 3.76E+00 |
| 4.02E+02 | 7.02E+00 | 5.76E+00 |

| 4.04E+02 | 6.27E+00 | 6.27E+00 |
| 4.05E+02 | 6.30E+00 | 5.25E+00 |
| 4.06E+02 | 6.31E+00 | 6.31E+00 |
| 4.07E+02 | 7.90E+00 | 7.90E+00 |
| 4.07E+02 | 6.33E+00 | 5.28E+00 |
| 4.08E+02 | 6.32E+00 | 6.34E+00 |
| 4.09E+02 | 6.25E+00 | 6.29E+00 |
| 4.10E+02 | 6.18E+00 | 6.24E+00 |
| 4.11E+02 | 6.13E+00 | 6.19E+00 |
| 4.12E+02 | 6.09E+00 | 6.16E+00 |
| 4.14E+02 | 5.09E+00 | 5.13E+00 |
| 4.15E+02 | 6.11E+00 | 6.14E+00 |

| | | |
|---|---|---|
| 4.17E+02 | 6.10E+00 | 5.12E+00 |
| 4.18E+02 | 6.10E+00 | 6.13E+00 |
| 4.20E+02 | 5.08E+00 | 4.39E+00 |
| 4.21E+02 | 7.62E+00 | 7.64E+00 |

In Table 3, it is shown that the pore water pressure head changes from 17.7m in front of cut-off wall to 5.30m behind cut-off wall. Cut-off wall has an obvious influence on decreasing pressure head. The decreasing of pressure head of pore water is very good for stability of channel seepage. Table 3 shows cut-off wall plays an important role.

**Numerical calculation of FEM for effect of plastic concrete cut-off wall under operating condition in operation period**

There are two operating conditions in operation period of hydropower station. They are operation condition of No.2 and operation condition of No.3 For the two operation conditions, the grids meshing of FEM are same. In the numerical simulation zone, the elevation of bottom is 360m and the elevation of top is 419m. The horizontal distance is from center line of tailing water channel to 156m left far away. Meshing the computation zone, there are 4259 elements and 2372 jets. The FEM model is shown in Fig 2.

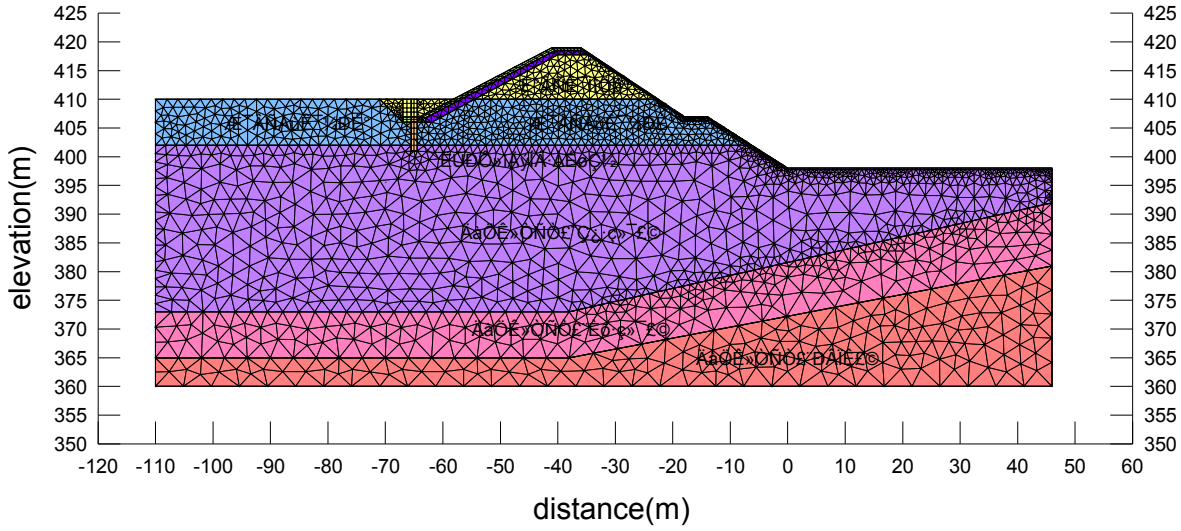

Fig 2 Grids meshing of FEM in computation zone in operating condition of No.2 and No.3

### 3.1 Numerical calculation of FEM for effect of plastic concrete cut-off wall under operating condition of No.2

According to calculation results , the factors of seepage field in calculation zone are got. In unit length, the seepage flow discharge from outside of channel to inside of channel is $1.0948\times10^{-4}m^3/h$. The seepage flow discharge under plastic concrete cut-off wall is $9.9583\times10^{-5}m^3/h$. It means that 90.86% total seepage flow discharge goes under plastic concrete cut-off wall. The plastic concrete cut-off wall has a good effect.

In Table 4, because of plastic concrete cut-off wall occurring, the pressure head changes from 16.9m in front of cut-off wall to 9.54m behind of cut-off wall.

Table 4 Pressure head at elevation of 402m under operation condition of No.2

### 3.2 Numerical calculation of FEM for effect of plastic concrete cut-off wall under operating condition of No.3

According to calculation results , the factors of seepage field in calculation zone are got. In unit length, the seepage flow discharge from outside of channel to inside of channel is $6.9140\times10^{-5}m^3/h$. The seepage flow discharge under plastic concrete cut-off wall is $6.5565\times10^{-5}m^3/h$. It means that 94.78% total seepage flow discharge goes under plastic concrete cut-off wall. The plastic concrete cut-off wall has a good effect.

In Table 5, it is shown that the pressure head at left of cut-off wall is 7.92m, in the middle of cut-off wall 5.57m and behind cut-off wall 3.23m. The pressure head decreasing through cut-off wall is 4.69m. After cut-off wall, the pressure head decreasing through drift gravel and sand layer is 1.69m.

Table 5 Pressure head at elevation of 402m under operation condition of No.3.

## Conclusions

(1) According to simulation calculation of seepage field in construction period, in unit length, the seepage flow discharge from outside to inside of channel is0.753 $m^3/h$ and the seepage flow discharge under plastic concrete cut-off wall is 0.646 $m^3/h$. There is 85.79% of total seepage flow discharge from outside to inside of tailing water channel through cut-off wall.

(2) According to simulation calculation of seepage field under operating condition of No.2, the seepage flow from inside of channel to outside at unit length is 0.394m3/h. The seepage flow from under plastic concrete cut-off wall is 0.358m3/h which is 90.86％ of total seepage flow. The decreased hydraulic head through plastic concrete cut-off wall is 7.36m which is 90% of total decreased hydraulic head.

(3) According to simulation calculation of seepage field under operating condition of No.3, the seepage flow from inside of channel to outside at unit length is 0.249 m3/h . The seepage flow from under plastic concrete cut-off wall is 0.236m3/h which is 94.78％ of total seepage flow. The decreased hydraulic head through plastic concrete cut-off wall is 4.67m which is 72% of total decreased hydraulic head.

**Keywords:** MIKESHE, hydrologic cycle, hydrologic response, water environmental management

**Abstract.** In order to comprehensively analyse hydrological environment system of watershed, it is particularly important to couple the surface water and groundwater for better underding the entire hydrologic cycle. Guishui river basin, located in Beijing, was selected as the research area to build a MIKE SHE hydrological integrated model to simulate the surface runoff. The hydrologic response in the Guishui river basin was explored. This study will enrich the experience of the domestic application about MIKESHE model and provided scientific basis for regional water resources planning and management. In the paper, the development process and present research situation of integrated hydrological models were overviewed, concluding the principle of model structure. Considering the water environment issues in the study area (such as water pollution, water resource utilization, watershed underlying surface, climate change, etc.), the integrated hydrological model was setup based on MIKESHE for the simulation year of 2005 to 2010. The preliminary results showed that it is feasibile to apply the MIKESHE model in the study area for water environmental management. Furthermore, some valued suggestions and perspectives about the water environmental problems in the study for the future were provided.

## Introduction

With the social economy developing, the population increasing and urbanization since the 21st century, the human living environment has suffered different levels of pollution and destruction, so the water environment becomes a top priority. Recently in a series of domestic water pollution which has threaten the survival of Human being and sounded the alarm to strengthen water environment management. Because the groundwater has a close relationship with surface water in the hydrologic cycle, so the coupling research of surface water and groundwater is particularly important for comprehensive watershed hydrological simulation environment system analysis.

The hydrological cycle system is an open process containing a highly complex multi-factor interaction. Distributed hydrological model based on physical basis is the important means to describe the hydrologic cycle. MIKESHE model is a typical representative of distributed hydrological model, which covers the main process of the hydrological cycle, including evapotranspiration, infiltration, surface runoff, saturated flow, unsaturated flow, and open channel flow.

## Model Description

**MIKESHE integrated hydrological model overview.** In 1969 Freeze and Harlan proposed a distributed water model framework based on water dynamic partial differential equations of physics[1]. In 1982, in the European Union fund, the British Institute of hydrology, France SOGREAH consulting company and the Danish Hydraulic Institute jointly developed the earliest SHE model which was most representative[2]. Model requires hydrological parameters with strong physical meaning which can be determined by watershed characteristics and hydrological experiment

. At the aspect of the hydrological model large numbers of research is made in foreign but there is a few works in our national. For example, In 2008, Liu Chenfeng applied the distributed hydrological model MIKE SHE to simulate the artificial forest ecosystem hydrological process of poplar (P. - eur americanacv.) [3]. In the 1992 , J.C.BATHURST had carried on the analysis to the SHE distributed hydrological model from the structure, which was applicable to the prediction of land use change an d climate change impacts on hydrological cycle. [4].In 2002 R. F. V á zquez, J. Feyen J. Berlamont et al. simulated drainage in the basin in Belgium (586 km ²) through the dynamic application code of MIKE SHE hydrological model. [5].

**Characteristics and Application of MIKE SHE Model.** It is the basic characteristics of MIKESHE distributed that the model uses the conservation of energy， mass and momentum. Compared to the empirical hydrological models , MIKESHE can calculate a point or a surface hydrological response process based on the spatial structure and the parameters. The model fully consider the the influence by rainfall, climate change, land use and watershed underlying surface changes on river basin for water generation and concentration. Coupling between groundwater and surface water has great advantages which can simulate the interactive process of river flow, water quality， water level, and underground runoff. The development of GIS spatial data analysis and processing platform also provides technical support [6] for this type of distributed surface and groundwater model.

MIKE SHE hydrological model has been widely used in the world to manage water resources and ecological environment between surface water and groundwater, mainly items as follows in table1:

Table1 Application of MIKESHE model [7]

| | |
|---|---|
| Ecological evaluations | • Groundwater management |
| Water quality remediation | • Environmental impact assessments |
| Impact of land use and climate change | • Aquifer vulnerability mapping |
| Contamination from waste disposal | •Impact of agriculture |
| Soil and water management | • River basin management and planning |
| Wetland management and restoration | • Floodplain studies |

The model uses two-dimensional layered structure. Vertical dimension of watershed hydrological processes and parameters,from top to bottom, includes canopy interception layer, snowmelt runoff layer, soil infiltration, unsaturated layer, and underground runoff saturated runoff layer.Basin is divided into small grids of different scale in the horizontal dimension.The main hydrological process of the model can be expressed by the mass, momentum and energy conservation finite-difference PDE.It can be also expressed by empirical equations.The figure(Fig.1) is shown below.

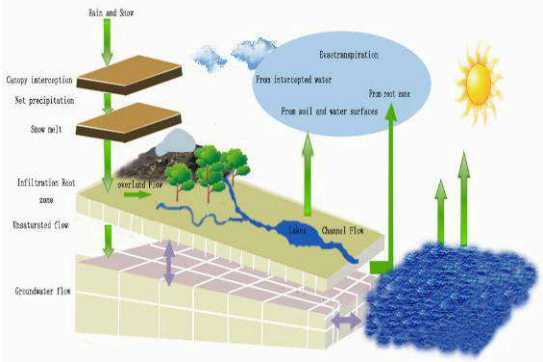

Fig.1 Hydrologic processes simulated by MIKE SHE

The model uses the modular structure, with different hydrological processes, forming a unified model of hydrological cycle system. Basic modules : 1 water movement module (WM); 2 water quality module (WQ) [1]

## Methodol

**Data Preparation.**Yanqing County belongs to the continental monsoon climate. Located in the transition zone of semi-arid and sub-humid, Yanqing County has a mild climate, cool in summer and warm in winter. The long-term average precipitation is 429 mm. The basin area is 632.5 square kilometers, and the average annual rainfall is 429mm.The prepared data include DEM, land use distribution, basin river network, meteorological data, soil, groundwater conductivity and other parameters. Watershed position is shown in Figure 2.

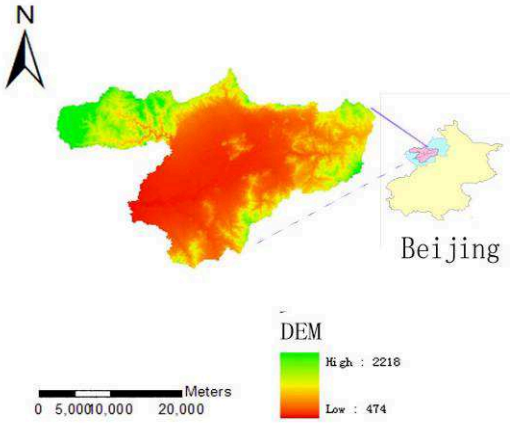

Fig. 2 Guishui river basin of Yanqing

**Simulation.** MIKE SHE model processes the data of hydrologic cycle and input prepared data to the model. Simple process is shown in figure3.

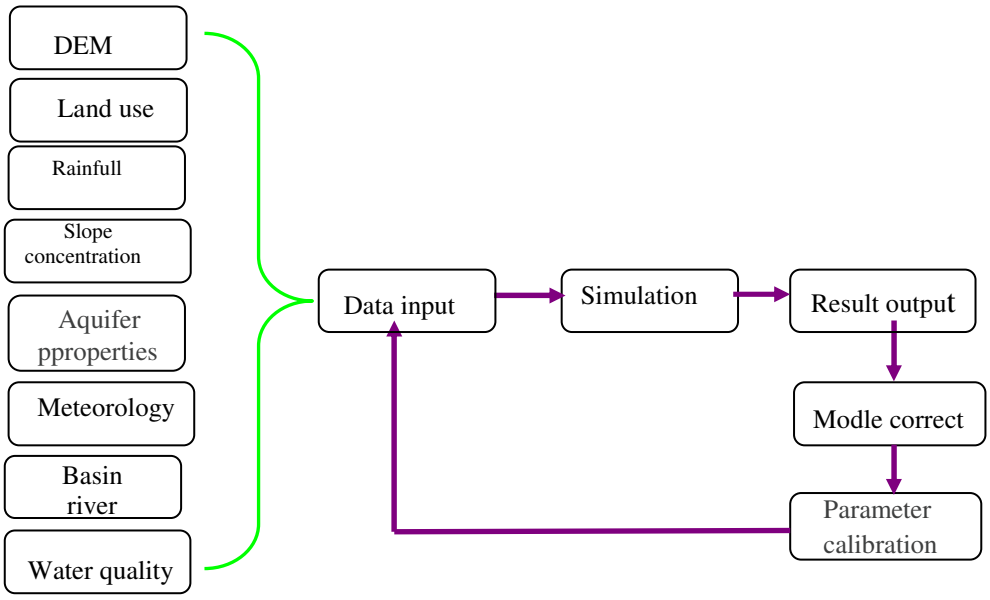

Fig.3 . Process of Simulation

This study inputs the GIS data, the hydrological parameters of the DEM data etc. into the MIKE SHE model in Guishui River Basin. The research area is divided into cell based on X, Y direction, NX=100, NY=100, and mesh size is 500m. Preprocessed data conclude actual evapotranspiration data in 2005-2010(fig4), land use maps in1980 (fig5) and 2005(fig6) etc.

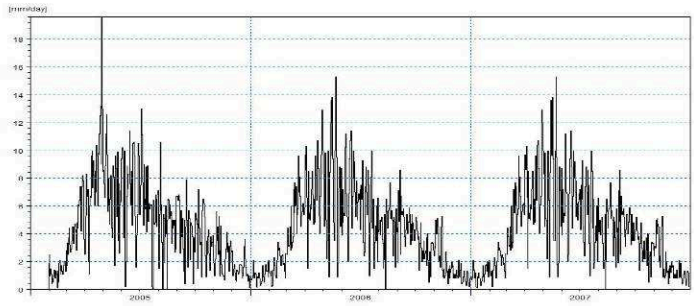

Fig. 4 Evapotranspiration of the year of 2005-2010

The model divides the basin using the Tyson polygon method and adopts rainfall data of 6 stations in the year of 2005 -2010. These six rainfall stations represent the division of the basin, as shown in the Fig 5.

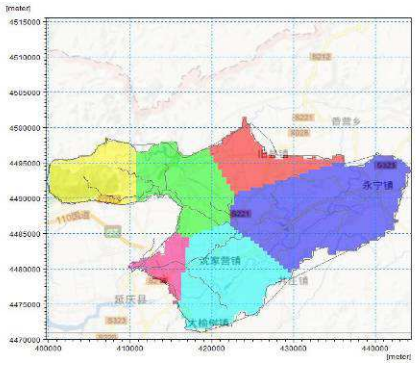

Fig.5 Tyson polygon

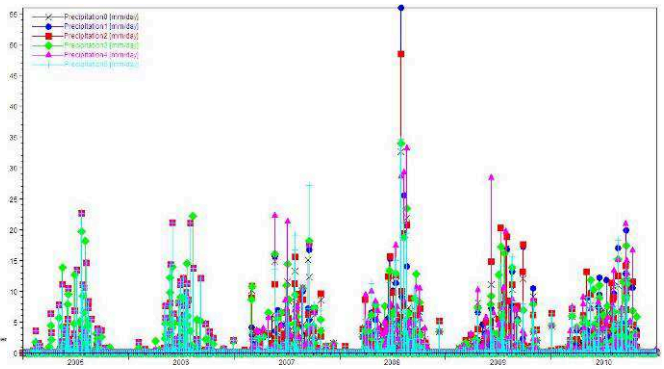

Fig.6. Rainfall of 6 stations in the year of 2005 -2010

MIKE11 one-dimensional water quality model is coupled to the MIKE SHE. The water exchanges between channel and subsurface saturated zone. The river recharge groundwater when the river water level higher than water table, it is opposite instead. Water exchange between saturated zone and river basin is shown in figure --. Surface water environment pollution will cause the cross contamination with groundwater, Process of water quality change in the unsaturated zone, the zone of saturation, river, and overland flow is simulated by using model Different spatial levels detailed data and information provide the important basis for the management of water environment.

## Conclusion and Implication

The integrated hydrological model was setup based on MIKESHE for the simulation year of 2005 to 2010. The preliminary results showed that it is feasibile to apply the MIKESHE model in the study area for water environment management. Furthermore, some valued suggestions and perspectives about the water environmental problems in the study for the future were provided.

(1)How to get physical characteristics of basin conveniently, economically and accurately, such as elevation, land use, soil, vegetation and other attributes.

(2)To build reasonable coupling between MIKESHE model and other related models solve the specific problem of water environment,, such as seawater oil pollution, groundwater pollution control and local river engineering analysis and so on.

(3)Considering apply model and hydrological information system into wider range of aspects, such as the prediction in river channel water level of traffic flow, agricultural irrigation and check of conservancy facilities, etc.

[a]bachir.achour@larhyss.net , [b]ali_bedjaoui@yahoo.com

**Keywords:** Rough Model Method, Pressurized conduit, Trapezoidal shaped conduit, Turbulent flow, Discharge, Energy slope.

**Abstract.** Through the Rough Model Method (RMM) an explicit calculation is proposed to solve the complex problem of the design of a pressurized trapezoidal shaped conduit characterized by three linear dimensions. Firstly, the method is applied to a rough model of the same shape in order to establish the equations governing its geometric and hydraulic characteristics. These equations are then secondly used to easily deduce the required linear dimensions of the current conduit by introducing a non-dimensional correction factor. The application of the obtained relationships requires only a strict minimum of data. All relationships provided in this article are applicable to the entire domain of the turbulent flow. Practical examples are taken to enable the hydraulic engineer to better understanding the advocated method and to observe the facility with which design of such a geometric profile can be performed.

## Introduction

In the field of hydraulics, three main problems may arise in the practice of hydraulic engineer. The first problem concerns the computation of the discharge in order to determine the discharge capacity of a channel or conduit. Generally, this problem can be solved explicitly by combining the Darcy-Weisbach and Colebrook-White relationships, expressing the energy slope and the friction factor respectively. The second problem concerns the computation of the energy slope in order to adjust it if necessary. Determining the energy slope is an implicit problem since the Darcy-Weisbach relationship uses the friction factor whose expression is itself implied. For this reason, some authors have proposed approximate relationships for friction factor, especially for pipes [1, 2, 3]. The third problem is related to the design of the channel in order to determine its linear dimensions. For most geometric profiles of channels or conduits, the design is often a complex problem [4] and its basic relationships are implicit. To solve the problem of the design, the hydraulic engineer uses very laborious graphical methods or iterative procedures [5, 6, 7]. The three main problems that we have just cited involve the combination of three basic relations, namely Darcy-Weisbach, Colebrook-White and Reynolds number relationships [1, 2, 3]. Reynolds number is a dimensionless number that expresses the ratio of inertial forces to viscous forces and quantifies then the relative importance of these two forces under a given flow conditions. Despite the fact that these three basic relations are complete and that they contain all the parameters governing the turbulent flow, however they do not allow to express the linear dimensions of the channel in an explicit form. For every geometric profile of known channels, it is often necessary to find approximate relationships to solve the problem of design. Regarding the pressurized trapezoidal shaped conduit, the literature does not disclose any study related to the three main problems of the turbulent flow. This type of profile is nevertheless widely used in practice as water supply lines, sanitary sewers, culverts and storm drains or penstocks as well. For this reason, the main objective of this paper is to contribute to enrich the literature by studying this conduit under pressurized condition of the flow. Our focus will be especially on its design, contributing significantly to this problem. Three linear dimensions characterize this channel and will be determined by clear, reliable and particularly explicit methods. The problem of the design will be solved by a new theoretical approach known as the Rough Model

Method (RMM) [1]. The three basic equations of turbulent flow are applied to a rough conduit model characterized by an arbitrarily assigned relative roughness value. This is a referential rough model from which the required linear dimensions are directly deduced. Resulting RMM equations are not only explicit but also cover the entire domain of Moody diagram [8], corresponding to Reynolds number $R \geq 2300$ and relative roughness varying in the wide range [0; 0.05]. Note that the RMM has been recently successfully applied to the design of a pressurized vaulted rectangular conduit [9].

**Basic equations**

The relationships on which the study is based are simple well known hydraulic equations namely, Darcy-Weisbach equation, Colebrook-White equation and Reynolds number formula.
The energy slope of a conduit or channel is given by the Darcy-Weisbach relationship as:

$$J = \frac{f}{D_h}\frac{Q^2}{2gA^2} \tag{1}$$

where $Q$ is the discharge, $g$ is the acceleration due to gravity, $A$ is the wetted area, $D_h$ is the hydraulic diameter and $f$ is the friction factor given by the well known Colebrook-White formula as:

$$\frac{1}{\sqrt{f}} = -2\log\left(\frac{\varepsilon / D_h}{3.7} + \frac{2.51}{R\sqrt{f}}\right) \tag{2}$$

where $\varepsilon$ is the absolute roughness and $R$ is the Reynolds number which can be expressed as :

$$R = \frac{4Q}{P\nu} \tag{3}$$

where $\nu$ is the kinematic viscosity and $P$ is the wetted perimeter.

**Referential trapezoidal rough model**

The application of the rough model method (RMM) is based, for the sake of calculation, on a referential rough model shown in Fig.1b.

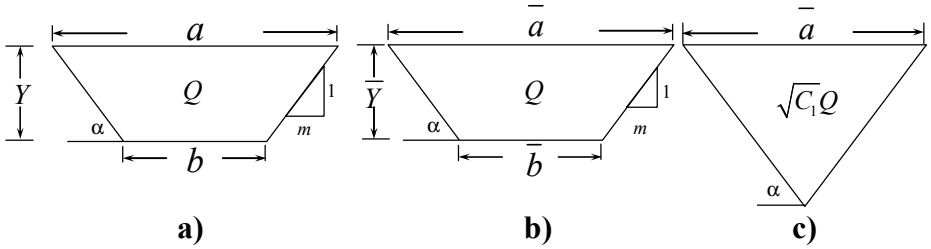

Fig. 1: Geometric elements of the studied conduits.
a) Pressurized trapezoidal conduit, b) Trapezoidal rough model, c) Triangular rough model

The pressurized trapezoidal shaped conduit subject of this study is shown in Figure 1a. It is characterized by three linear dimensions, namely the horizontal dimensions "$a$" and "$b$" and the minimum height "$Y$". The linear dimensions of the rough model shown in Figure 1b are distinguished by the symbol "$\bar{}$". The section is characterized by a side slope $m$ horizontal to 1 vertical. The rough model we consider is a pressurized trapezoidal conduit characterized by $\bar{\varepsilon} / \bar{D_h} = 0.037$ as the arbitrarily assigned relative roughness value. The chosen relative roughness value is so large that the prevailed flow regime is fully rough. Thus, the friction factor is $\bar{f} = 1/16$ according to Eq. 2 for $R = \bar{R}$ tending to infinitely large value. Applying Eq. 1 to the rough model leads to:

$$\bar{J} = \frac{\bar{f}}{\bar{D_h}}\frac{\bar{Q}^2}{2g\bar{A}^2} \tag{4}$$

Bearing in mind that $\overline{D_h} = 4\overline{A}/\overline{P}$ and $\overline{f} = 1/16$, Eq. 4 can be rewritten as:

$$\overline{J} = \frac{1}{128g}\frac{\overline{P}}{\overline{A}^3}\overline{Q}^2 \tag{5}$$

The wetted perimeter $\overline{P}$ and the water area $\overline{A}$ are expressed in different forms, depending on the chosen linear dimension.

If one selected the linear dimension "*a*", then $\overline{P}$ and $\overline{A}$ are respectively:

$$\overline{P} = \overline{a}\left[C_1 - (C_1 - 2)\overline{\beta}\right] \tag{6}$$

$$\overline{A} = \overline{a}^2\frac{(1-\overline{\beta}^2)}{4m} \tag{7}$$

where $C_1 = \sqrt{1+m^{-2}} + 1$, $\overline{\beta} = \overline{b}/\overline{a}$.

If the chosen linear dimension is "*b*", then $\overline{P}$ and $\overline{A}$ can be written respectively as:

$$\overline{P} = 2\overline{b}\left(1 + C_1\overline{Y}^*\right) \tag{8}$$

$$\overline{A} = \frac{\overline{b}^2}{m}\overline{Y}^*\left(1 + \overline{Y}^*\right) \tag{9}$$

where $\overline{Y}^* = \frac{m\overline{Y}}{\overline{b}}$.

Finally, when the chosen linear dimension is "*Y*", $\overline{P}$ and $\overline{A}$ are then given respectively by the following relationships:

$$\overline{P} = 2m\overline{Y}\left(C_1 + \overline{Y}^{*-1}\right) \tag{10}$$

$$\overline{A} = m\overline{Y}^2\left(1 + \overline{Y}^{*-1}\right) \tag{11}$$

**Computation of the linear dimension "*b*"**

**Fundamental equations**

To determine the linear dimension "*b*" by the RMM, it is necessary to establish the equation of the flow in the trapezoidal rough model shown in Fig.1b. In addition, the following data must constitute the data of the problem: the discharge *Q*, the energy slope *J*, the side slope *m* or the angle $\alpha$ (Fig.1), the linear dimension "*a*", the absolute roughness $\varepsilon$ and the kinematic viscosity $\nu$.

Assume $\overline{J} = J$ and $\overline{Q} = Q$. Applying Eq. 5 to the trapezoidal rough model, along with Eq. 6 and Eq.7, one can obtain the following relationship:

$$Q^* = \frac{\sqrt{2}\left(1-\overline{\beta}^2\right)^{3/2}}{\left[C_1 - (C_1-2)\overline{\beta}\right]^{1/2}} \tag{12}$$

where $Q^*$ is the relative conductivity expressed as:

$$Q^* = \frac{m^{1.5}Q}{\sqrt{g\overline{J}a^5}} \tag{13}$$

Eq. 12 can be easily rewritten under the following form:

$$Q^{*\,2/3} = \left(\frac{2}{C_1}\right)^{1/3}\frac{1-\overline{\beta}^2}{\left(1-\frac{C_1-2}{C_1}\overline{\beta}\right)^{1/3}} \tag{14}$$

Calculation showed that, for all values of $m$ and $\overline{\beta}$, one can write:

$$\frac{C_1 - 2}{C_1}\overline{\beta} < 1 \tag{15}$$

The inequality (15) allows to observe that the function

$$\left(1 - \frac{C_1 - 2}{C_1}\overline{\beta}\right)^{1/3}$$

may be subject to a limited development. For a limited development of second order, one can write:

$$\left(1 - \frac{C_1 - 2}{C_1}\overline{\beta}\right)^{1/3} \approx 1 - C^*\overline{\beta} - \left(C^*\overline{\beta}\right)^2 \tag{16}$$

where :

$$C^* = \frac{C_1 - 2}{3C_1} \tag{17}$$

Inserting Eq. 16 into Eq. 14, leads to:

$$Q^{*\,2/3} = \left(\frac{2}{C_1}\right)^{1/3} \frac{1 - \overline{\beta}^{\,2}}{1 - C^*\overline{\beta} - C^{*2}\overline{\beta}^{\,2}} \tag{18}$$

Eq. 18 can be reduced to:

$$Q^* = \sqrt{\frac{2}{C_1}}\left[\frac{1 - \overline{\beta}^{\,2}}{1 - C^*\overline{\beta}(1 + C^*\overline{\beta})}\right]^{3/2} \tag{19}$$

Eq. 19 is in fact a second order equation in $\overline{\beta}$ which can be written as:

$$\overline{\beta}^{\,2} - \frac{C^* q^{\,2/3}}{1 - C^{*2} q^{\,2/3}}\overline{\beta} + \frac{q^{\,2/3} - 1}{1 - C^{*2} q^{\,2/3}} = 0 \tag{20}$$

where:

$$q = Q^*\sqrt{\frac{C_1}{2}} \tag{21}$$

One can easily show that the real root of Eq. 20 is as:

$$\overline{\beta} = \frac{C^* q^{2/3} + \sqrt{(C^* q^{2/3})^2 - 4(q^{2/3} - 1)(1 - C^{*2} q^{2/3})}}{2(1 - C^{*2} q^{2/3})} \tag{22}$$

Note that in Eq. 22 only $\overline{\beta}$ is unknown, since $C^*$ and $q$ are the known parameters.

An intense program of calculation showed that the Eq. 22 is an excellent approximate relationship applicable for a wide range of trapezoidal rough models, provided $\overline{\beta} < 1$, $\alpha \le 75°$.

When the discharge in the rough triangular model, corresponding to $\overline{\beta} = 0$, is equal to $\sqrt{C_1}Q$, the linear dimension $\overline{a}$ is the same in the triangular and trapezoidal rough models (Fig.1). For the discharge $\sqrt{C_1}Q$, the relative conductivity given by Eq. 13 becomes:

$$Q^* = \frac{m^{1.5}\sqrt{C_1}Q}{\sqrt{gJ\overline{a}^{\,5}}} \tag{23}$$

For $\overline{\beta} = 0$, Eq. 19 along with Eq. 23 leads to:

$$\frac{m^{1.5}\sqrt{C_1}Q}{\sqrt{gJ\overline{a}^{5}}} = \sqrt{\frac{2}{C_1}} \tag{24}$$

Thus, one can deduce the following equations:

$$Q^* = \frac{m^{1.5} Q}{\sqrt{gJ\bar{a}^{-5}}} = \frac{\sqrt{2}}{C_1} \tag{25}$$

$$q = Q^* \sqrt{\frac{C_1}{2}} = \frac{1}{\sqrt{C_1}} \tag{26}$$

$$\bar{a} = \left( \frac{m^3 Q^2 C_1^{\,2}}{2gJ} \right)^{1/5} \tag{27}$$

Eq. 27 expresses the linear dimension $\bar{a}$ of the trapezoidal rough model when the discharge is $\sqrt{C_1}Q$. This relation is of particular interest, since it allows to explicitly calculating the linear dimension $\bar{a}$ of the trapezoidal rough model for the known values of the parameters *m*, *Q*, *g* and *J*.

**Non-dimensional correction factor of linear dimension**

The RMM states that any linear dimension "*L*" of a conduit and the linear dimension "$\bar{L}$" of its rough model are related by the following equation, applicable to the whole domain of the turbulent flow:

$$L = \psi \bar{L} \tag{28}$$

where $\psi$ is a non-dimensional correction factor of linear dimension, less than unity, which is governed by the following relationship [10] :

$$\psi \cong 1.35 \left[ -\log \left( \frac{\varepsilon / \overline{D_h}}{4.75} + \frac{8.5}{\bar{R}} \right) \right]^{-2/5} \tag{29}$$

where $\bar{R}$ is the Reynolds number in the rough model given by :

$$\bar{R} = \frac{4Q}{\bar{P}\nu} \tag{30}$$

**Computation steps of the linear dimension "*b*"**

For the given following data *Q*, *J*, *m* (or $\alpha$), *a*, $\varepsilon$ and $\nu$, the steps below are recommended to compute the required dimension linear "*b*" of the pressurized trapezoidal conduit shown in Fig.1a.

1. Compute $C_1 = \sqrt{1 + m^{-2}} + 1$, $C^*$ using Eq. 17 and *q* by the use of Eq. 26.
2. Applying Eq. 22, the parameter $\bar{\beta}$ is then worked out. Note that at this step of calculation, the computed value of $\bar{\beta}$ corresponds to a discharge equal to $\sqrt{C_1}Q$.
3. Compute the corresponding linear dimension $\bar{a}$, according to Eq. 27.
4. Apply Eq. 6, Eq. 7 and Eq. 30 to determine the wetted perimeter $\bar{P}$, the water area $\bar{A}$ and the Reynolds number $\bar{R}$, respectively. The hydraulic diameter $\overline{D_h} = 4\bar{A}/\bar{P}$ is then worked out.
5. Knowing $\overline{D_h}$ and $\bar{R}$, compute the non-dimensional factor of linear dimension $\psi$ by the use of Eq. 29.
6. Assign to the trapezoidal rough model the linear dimension $\bar{a} = a/\psi$. This change in dimension corresponds to the discharge *Q* and the relative conductivity $Q^* = m^{1.5} Q / \sqrt{gJ(a/\psi)^5}$ according to Eq. 13. It mainly results in the equality $\bar{\beta} = \beta$ given by Eq. 22. The parameters $C^*$ and *q* must be calculated by applying Eq. 17 and Eq. 21 respectively.
7. Once $\beta$ is calculated, the required value of the linear dimension "*b*" is finally $b = a\beta$.

**Example 1**

Compute the linear dimension "*b*" of the pressurized trapezoidal conduit shown in Fig.1a, for the following data:

$Q = 0.399\,m^3/s$, $J = 10^{-3}$, $\alpha = 45°(m = 1)$, $a = 1.6\,m$, $\varepsilon = 10^{-4}\,m$, $\nu = 10^{-6}\,m^2/s$

1. The parameter $C_1$ is : $C_1 = \sqrt{1+m^{-2}} + 1 = \sqrt{1+1^{-2}} + 1 = \sqrt{2} + 1 = 2.41421356$

   According to Eq. 17 and Eq. 26, $C^*$ and $q$ are respectively:

   $$C^* = \frac{C_1 - 2}{3C_1} = \frac{\sqrt{2}+1-2}{3\times(\sqrt{2}+1)} = \frac{\sqrt{2}-1}{3\times(\sqrt{2}+1)} = 0.05719096$$

   $$q = \frac{1}{\sqrt{C_1}} = \frac{1}{\sqrt{2.41421356}} = 0.64359425$$

2. Using Eq. 22, the parameter $\overline{\beta}$ is:

   $$\overline{\beta} = \frac{C^* q^{2/3} + \sqrt{(C^* q^{2/3})^2 - 4(q^{2/3}-1)(1-C^{*2}q^{2/3})}}{2(1-C^{*2}q^{2/3})} = 0.526983224$$

3. According to Eq. 27, the linear dimension $\overline{a}$ of the triangular rough model flowing a discharge $\sqrt{C_1}Q$ is:

   $$\overline{a} = \left(\frac{m^3 Q^2 C_1^2}{2gJ}\right)^{1/5} = \left(\frac{1^3 \times 0.399^2 \times 2.41421356^2}{2\times 9.81\times 10^{-3}}\right)^{1/5} = 2.162517506\,m$$

   This value of $\overline{a}$ is also that of the trapezoidal rough model shown in Fig.1b, flowing the discharge *Q*.

4. Applying Eq. 6, Eq. 7 and Eq. 30, the wetted perimeter $\overline{P}$, the water area $\overline{A}$ and the Reynolds number $\overline{R}$ are respectively:

   $$\overline{P} = \overline{a}\left[C_1 - (C_1 - 2)\overline{\beta}\right] = 2.162517506\times\left[2.41421356 - (2.41421356-2)\times 0.526983224\right] = 4.748736989\,m$$

   $$\overline{A} = \overline{a}^2\,\frac{(1-\overline{\beta}^2)}{4m} = 2.162517506^2 \times \frac{(1-0.526983224^2)}{4\times 1} = 0.844442498\,m^2$$

   $$\overline{R} = \frac{4Q}{\overline{P}\nu} = \frac{4\times 0.399}{4.748736989\times 10^{-6}} = 336089.3652$$

   Thus, the hydraulic diameter $\overline{D_h} = 4\overline{A}/\overline{P}$ is then:

   $$\overline{D_h} = 4\overline{A}/\overline{P} = \frac{4\times 0.844442498}{4.748736989} = 0.7112986\,m$$

5. According to Eq. 29, the non-dimensional correction factor of linear dimension is:

   $$\psi = 1.35\left[-\log\left(\frac{\varepsilon/\overline{D_h}}{4.75} + \frac{8.5}{\overline{R}}\right)\right]^{-2/5} = 1.35\times\left[-\log\left(\frac{10^{-4}/0.7112986}{4.75} + \frac{8.5}{336089.3652}\right)\right]^{-2/5} = 0.75604689$$

6. Assign to the trapezoidal rough model the following linear dimension according to Eq. 28:

   $$\overline{a} = \frac{a}{\psi} = \frac{1.6}{0.75604689} = 2.116270849\,m$$

   The new value of the relative conductivity is then:

   $$Q^* = \frac{m^{1.5}Q}{\sqrt{gJ(a/\psi)^5}} = \frac{1^{1.5}\times 0.399}{\sqrt{9.81\times 10^{-3}\times 2.116270849^5}} = 0.61831569$$

   Applying Eq. 21 results in:

   $$q = Q^*\sqrt{\frac{C_1}{2}} = 0.61831569\times\sqrt{\frac{2.41421356}{2}} = 0.67933363$$

7. Inserting the computed values of $C^*$ and $q$ into Eq. 22, one may obtain:
   $\overline{\beta} = \beta = 0.499948303 \approx 0.5$
8. Finally, the required value of the linear dimension "$b$" is then:
   $b = a\beta = 1.6 \times 0.5 = 0.8\ m$
9. One can continue the calculation by writing that the minimum height $Y$ of the pressurized trapezoidal conduit is:
   $$Y = a\frac{1-\beta}{2m} = 1.6 \times \frac{1-0.5}{2 \times 1} = 0.4\ m$$

**Computation of the linear dimension "*a*"**

**Fundamental equations**

In order to compute the linear dimension "*a*", it is necessary to establish the equation of the flow in the trapezoidal rough model. Furthermore, the linear dimension "*a*" is dependent upon the following data, namely the discharge $Q$, the energy slope $J$, the side slope $m$ or the angle $\alpha$ (Fig.1), the linear dimension "*b*", the absolute roughness $\varepsilon$ and the kinematic viscosity $\nu$.

Since "*b*" is the chosen linear dimension, the wetted perimeter $\overline{P}$ and the water area $\overline{A}$ of the trapezoidal rough model is then given by Eq. 8 and Eq. 9 respectively. For $\overline{J} = J$ and $\overline{Q} = Q$, applying Eq. 5 to the trapezoidal rough model results finally in:

$$Q^* = 8\frac{\left[\overline{Y}^*\left(1+\overline{Y}^*\right)\right]^{3/2}}{\left(1+C_1\overline{Y}^*\right)^{1/2}} \tag{31}$$

where the relative conductivity $Q^*$ and the relative height $\overline{Y}^*$ are expressed respectively as:

$$Q^* = \frac{m^{1.5}Q}{\sqrt{g\overline{J}\overline{b}^5}} \tag{32}$$

$$\overline{Y}^* = \frac{m\overline{Y}}{\overline{b}} \tag{33}$$

As we can see, Eq. 31 is implicit towards the relative height $\overline{Y}^*$. We will expose in what follows two methods for its analytical resolution. Note that Eq. 31 can be easily rewritten as:

$$Q^{*2/3} = 4\frac{\overline{Y}^*\left(1+\overline{Y}^*\right)}{\left(1+C_1\overline{Y}^*\right)^{1/3}} \tag{34}$$

Let us assume:

$$z = \left(\overline{Y}^* + \frac{1}{2}\right)^2 \tag{35}$$

Thus, Eq. 34 becomes:

$$Q^{*2/3} = 4\frac{(\sqrt{z}-1/2)(\sqrt{z}+1/2)}{\left[1+C_1(\sqrt{z}-1/2)\right]^{1/3}} \tag{36}$$

or :

$$Q^{*2/3} = 4\frac{z-1/4}{\left[1+C_1(\sqrt{z}-1/2)\right]^{1/3}} \tag{37}$$

Developing Eq. 37 results in:

$$z=\frac{1}{4}+\left(\frac{Q^*}{8}\right)^{2/3}\left[1+C_1(\sqrt{z}-1/2)\right]^{1/3} \tag{38}$$

Eq. 38 is in the following form:

$$z=a_0+\theta\phi(z) \tag{39}$$

where:

$a_0=1/4;\ \theta=(Q^*/8)^{2/3};\ \phi(z)=\left[1+C_1(\sqrt{z}-1/2)\right]^{1/3}$

According to Lagrange's theorem [11], the function $f(z)$ is given in terms of an infinite series, corresponding to:

$$f(z)=f(a_0)+\sum_{i=1}^{\infty}\frac{\theta^i}{\Gamma(i+1)}\left\{\frac{d^{i-1}}{dx^{i-1}}[f'(x)\phi^i(x)\right\}_{x=a_0} \tag{40}$$

In our case, one can write:

$f(z)=\sqrt{z}-1/2=\overline{Y}^*,\ f'(x)=\frac{1}{2\sqrt{x}}$ and $f(a_0)=\sqrt{a_0}-1/2=0$

Thus, according to Eq. 40, the relative height $\overline{Y}^*$ can be expressed as:

$$\overline{Y}^*=\sum_{i=1}^{\infty}\frac{(Q^*/8)^{2i/3}}{\Gamma(i+1)}\left\{\frac{d^{i-1}}{dx^{i-1}}\left(\frac{\left[1+C_1(\sqrt{x}-1/2)\right]^{i/3}}{2\sqrt{x}}\right)\right\}_{x=1/4} \tag{41}$$

The function $\Gamma$ is defined as $\Gamma(i+1)=i!$

Eq. 41 gives the exact value of the relative height $\overline{Y}^*$. However, the exact solution is obtained at infinity and one should truncated the series at an $i$ order such that the difference between $\overline{Y_{i+1}}^*$ and $\overline{Y_i}^*$ is the smallest as possible.

We can also provide, for solving Eq. 31, a numerical process which consists in approaching successively the solution. For this, observe that $z$ is greater than 1/4 according to Eq. 35 for $\overline{Y}^*>0$. Consider then, as the first value of $z$, $z_0=1/4$. According to Eq. 38, compute the next values of $z$ i.e.:

$$z_1=\frac{1}{4}+\left(Q^*/8\right)^{2/3}\left[1+C_1(\sqrt{z_0}-1/2)\right]^{1/3},$$

$$z_2=\frac{1}{4}+\left(Q^*/8\right)^{2/3}\left[1+C_1(\sqrt{z_1}-1/2)\right]^{1/3}$$ …and so on.

The process stops when $z_i$ and $z_{i+1}$ are sufficiently close. This is the numerical procedure that we will apply in the calculation of the linear dimension "*b*" of the pressurized trapezoidal conduit, through a practical example.

**Computation steps of the linear dimension "*a*"**

The calculation of the linear dimension "*a*" requires the following data: $Q$, $J$, $m$ (or $\alpha$), $b$, $\varepsilon$ and $\nu$. For these, the following steps are useful for calculating the linear dimension "*a*".

1. Compute $C_1=\sqrt{1+m^{-2}}+1$
2. Assume $\overline{b}=b$ and determine the relative conductivity $Q^*$ according to Eq. 32.
3. For $z_0=1/4$ and using Eq. 38, compute:

$$z_1=\frac{1}{4}+\left(Q^*/8\right)^{2/3}\left[1+C_1(\sqrt{z_0}-1/2)\right]^{1/3}$$

Once $z_1$ calculated, determine :

$$z_2 = \frac{1}{4} + \left(Q^* / 8\right)^{2/3} \left[1 + C_1(\sqrt{z_1} - 1/2)\right]^{1/3}$$

.....

$$z_{i+1} = \frac{1}{4} + \left(Q^* / 8\right)^{2/3} \left[1 + C_1(\sqrt{z_i} - 1/2)\right]^{1/3}$$

Stop the calculation procedure when $z_{i+1} \approx z_i$ .

4. For $z_i$ , compute the relative height $\overline{Y}^*$ by the use of Eq. 35 which leads to $\overline{Y}^* = \sqrt{z_i} - 1/2$ .
5. With the known values of the parameters $C_1$ , $b$ and $\overline{Y}^*$ , determine the wetted perimeter $\overline{P}$ and the water area $\overline{A}$ according to Eq. 8 and Eq. 9 respectively. Deduce then the hydraulic diameter $\overline{D_h} = 4\overline{A} / \overline{P}$ and the Reynolds number $\overline{R}$ by the use of Eq. 30.
6. Knowing $\overline{D_h}$ and $\overline{R}$ , use Eq. 29 for the calculation of the non-dimensional correction factor of linear dimension $\psi$ .
7. Assign to the trapezoidal rough model the following dimension linear $\overline{b} = b / \psi$ according to Eq. 28. This change in dimension results in the equality $\overline{Y}^* = Y^*$ .
8. Compute the new value of the relative conductivity $Q^* = m^{1.5} Q / \sqrt{gJ(b/\psi)^5}$
9. With $C_1$ and the new value of $Q^*$ , compute the values of $z$ following the same steps described in 3.
10. Once the final value of $z$ determined, use Eq. 35 to compute $Y^*$ which can be expressed as:

$$\overline{Y}^* = Y^* = \frac{mY}{b} = \sqrt{z} - 1/2$$

leading to :

$$Y = \frac{b}{m}(\sqrt{z} - 1/2)$$

11. Finally, the required value of the linear dimension "$a$" is obtained applying the following equation given by geometrical considerations on Fig.1a:

$$a = b + 2mY \tag{42}$$

**Example 2**

Compute the linear dimension "$a$" of the pressurized trapezoidal shaped conduit shown in Fig.1a, for the following data using the numerical process described in 5.2:

$Q = 2.78 m^3 / s$ , $J = 10^{-3}$ , $\alpha = 60° (m = 0.577350269)$ , $b = 1m$ , $\varepsilon = 10^{-3} m$ , $\nu = 10^{-6} m^2 / s$

1. The parameter $C_1$ is:

$$C_1 = \sqrt{1 + m^{-2}} + 1 == \sqrt{1 + 0.577350269^{-2}} + 1 = 3$$

2. According to Eq. 32 for $\overline{b} = b$ , the relative conductivity $Q^*$ is:

$$Q^* = \frac{m^{1.5} Q}{\sqrt{gJb^5}} = \frac{0.577350269^{1,5} \times 2.78}{\sqrt{9.81 \times 10^{-3} \times 1^5}} = 12.3122999$$

3. With the values of $C_1$ , $Q^*$ and $z_0 = 1/4$ , the numerical process described in 5.2 converges at the eighth step of calculation. The final result is : $z_8 \approx z_7 = 2.39006687$
4. According to Eq. 35, the relative height $\overline{Y}^*$ is:

$$\overline{Y}^* = \sqrt{z_8} - 1/2 = \sqrt{2.39006687} - 1/2 = 1.04598411$$

5. Applying Eq. 8 and Eq. 9 for $\overline{b} = b$ results respectively in:

$$\overline{P} = 2\overline{b}\left(1 + C_1 \overline{Y}^*\right) = 2\times 1\times\left(1 + 3\times 1.04598411\right) = 8.27590466\ m$$

$$\overline{A} = \frac{\overline{b}^2}{m}\overline{Y}^*\left(1 + \overline{Y}^*\right) = \frac{1^2}{0.577350269}\times 1.04598411\left(1 + 1.04598411\right) = 3.70670454\ m^2$$

Thus:

$$\overline{D_h} = 4\overline{A}/\overline{P} = 4\times 3.70670454 / 8.27590466 = 1.79156464$$

$$\overline{R} = \frac{4Q}{\overline{P}\nu} = \frac{4\times 2.78}{8.27590466\times 10^{-6}} = 1343659.75$$

6. The non-dimensional correction factor of linear dimension $\psi$ is then:

$$\psi = 1.35\left[-\log\left(\frac{\varepsilon/\overline{D_h}}{4.75} + \frac{8.5}{\overline{R}}\right)\right]^{-2/5} = 1.35\times\left[-\log\left(\frac{10^{-3}/1.79156464}{4.75} + \frac{8.5}{1343659.75}\right)\right]^{-2/5} = 0,78268959$$

7. Assign to the trapezoidal rough model the following linear dimension according to Eq. 28:

$$\frac{b}{\psi} = \frac{1}{0.78268959} = 1.27764571\ m$$

8. The new value of the relative conductivity is then:

$$Q^* = \frac{m^{1.5}Q}{\sqrt{gJ(b/\psi)^5}} = \frac{0.577350269^{1.5}\times 2.78}{\sqrt{9.81\times 10^{-3}\times 1.27764571^5}} = 6.67333997$$

9. Using the computed values of $C_1$ and $Q^*$, we have determined the value of $z$ according to the numerical process described in step 5.2, for $z_0 = 1/4$. We found that the process converges at the eighth step of calculation corresponding to: $z_8 \approx z_7 = 1.56260904$.

10. According to Eq. 35, the relative height $Y^*$ is then:

$$\overline{Y}^* = Y^* = \frac{mY}{b} = \sqrt{z_8} - 1/2$$

$$\text{or : } Y = \frac{b}{m}(\sqrt{z_8} - 1/2) = \frac{1}{0.577350269}(\sqrt{1.56260904} - 1/2) = 1.29911365\,m \approx 1.3\,m$$

11. According to Eq. 42, the required value of the linear dimension "*a*" is finally:

$$a = b + 2mY = 1 + 2\times 0.577350269\times 1\,3 \approx 2.5\,m$$

**Computation of the linear dimensions "*a*" and "*b*" for "*Y*" imposed**

**Fundamental equations**

The last problem that we must solve is the determination of the linear dimensions "*a*" and "*b*" when the height of the conduit is a given data. Thus, the data of the problem are namely the discharge *Q*, the energy slope *J*, the side slope *m* or the angle $\alpha$ (Fig.1), the height of the conduit "*Y*", the absolute roughness $\varepsilon$ and the kinematic viscosity $\nu$. For these, the RMM can establish the equation of the flow by applying Eq. 5 to the pressurized trapezoidal rough model shown in Fig.1b, according to the theoretical development that follows. Remember that since the height *Y* is imposed, the wetted perimeter $\overline{P}$ and the water area $\overline{A}$ are governed by Eq. 10 and Eq. 11 respectively. In this section, assume once again $\overline{J} = J$ and $\overline{Q} = Q$. Inserting Eq. 10 and Eq. 11 into Eq. 5, one can write:

$$J = \frac{1}{64g}\frac{\left(C_1 + \overline{Y}^{*-1}\right)}{m^2\overline{Y}^5\left(1 + \overline{Y}^{*-1}\right)^3}Q^2 \tag{43}$$

where $\overline{Y}^*$ is governed by Eq. 33. Note that since $C_1 = \sqrt{1 + m^{-2}} + 1$, then:

$$m^{-2} = C_1(C_1 - 2) \tag{44}$$

Using Eq. 44, Eq. 43 can be rewritten as:

$$Q^{*2} = 64\frac{\left(1+\overline{Y}^{*\,-1}\right)^3}{C_1(C_1-2)\left(C_1+\overline{Y}^{*\,-1}\right)} \tag{45}$$

where the relative conductivity $Q^*$ is expressed as :

$$Q^* = \frac{Q}{\sqrt{gJ\overline{Y}^5}} \tag{46}$$

Let us assume:

$$z = 1+\overline{Y}^{*\,-1} \tag{47}$$

Inserting Eq. 47 into Eq. 45 and rearranging, results in:

$$z^3 - \frac{C_1(C_1-2)Q^{*2}}{64}z - \frac{C_1(C_1-2)(C_1-1)Q^{*2}}{64} = 0 \tag{48}$$

We thus obtain a cubic equation in $z$ without second-order term. Its discriminant is:

$$\Delta = \left[\frac{\sqrt{C_1(C_1-2)(C_1-1)}\,Q^*}{8\sqrt{2}}\right]^4 \times \left(1-\frac{\sqrt{C_1(C_1-2)}}{12\sqrt{3}(C_1-1\ )}Q^*\right)\left(1+\frac{\sqrt{C_1(C_1-2)}}{12\sqrt{3}(C_1-1)}Q^*\right) \tag{49}$$

Eq. 49 shows that two cases arise:

1. $Q^* \le \frac{12\sqrt{3}(C_1-1)}{\sqrt{C_1(C_1-2)}}$, then $\Delta \ge 0$. The real root of Eq. 48 is:

$$z = \frac{Q^*\sqrt{C_1(C_1-2)}}{4\sqrt{3}}ch(\gamma/3) \tag{50}$$

where the angle $\gamma$ is governed by :

$$ch(\gamma) = \frac{12\sqrt{3}(C_1-1)}{Q^*\sqrt{C_1(C_1-2)}} \tag{51}$$

Taking into account Eq. 47, the relative height $\overline{Y}^*$ is such that:

$$\overline{Y}^{*-1} = \frac{Q^*\sqrt{C_1(C_1-2)}}{4\sqrt{3}}ch(\gamma/3) - 1 \tag{52}$$

2. $Q^* \ge \frac{12\sqrt{3}(C_1-1)}{\sqrt{C_1(C_1-2)}}$, then $\Delta \le 0$. The real root of Eq. 48 is:

$$z = \frac{Q^*\sqrt{C_1(C_1-2)}}{4\sqrt{3}}\cos(\gamma/3) \tag{53}$$

The angle $\gamma$ is given by:

$$\cos(\gamma) = \frac{12\sqrt{3}(C_1-1)}{Q^*\sqrt{C_1(C_1-2)}} \tag{54}$$

According to Eq. 47, the relative height $\overline{Y}^*$ is:

$$\overline{Y}^{*-1} = \frac{Q^*\sqrt{C_1(C_1-2)}}{4\sqrt{3}}\cos(\gamma/3) - 1 \tag{55}$$

Eq. 52 and Eq. 55 give the exact value of the relative height $\overline{Y}^*$.

**Computation steps of the linear dimensions "*a*" and "*b*" for "*Y*" imposed**

In this section, the known parameters of the problem are the discharge *Q*, the energy slope *J*, the side slope *m* or the angle $\alpha$ (Fig.1), the height of the conduit "*Y*", the absolute roughness $\varepsilon$ and the kinematic viscosity $\nu$. To compute the linear dimensions "*a*" and "*b*", simply follow the calculation steps below.

1. Compute $C_1 = \sqrt{1+m^{-2}} + 1$, $C^*$ using Eq. 17 and $q$ by the use of Eq. 26.
2. Applying Eq. 22, the parameter $\overline{\beta}$ is then worked out.
3. Compute the corresponding linear dimension $\overline{a}$, according to Eq. 27.
4. Apply Eq. 6, Eq. 7 and Eq.30 to determine the wetted perimeter $\overline{P}$, the water area $\overline{A}$ and the Reynolds number $\overline{R}$, respectively. The hydraulic diameter $\overline{D_h} = 4\overline{A}/\overline{P}$ is then deduced.
5. Knowing $\overline{D_h}$ and $\overline{R}$, compute the non-dimensional factor of linear dimension $\psi$ by the use of Eq. 29.
6. Assign to the trapezoidal rough model the linear dimension $\overline{Y} = Y/\psi$ according to Eq. 28. This change in dimension corresponds to the discharge $Q$ and the relative conductivity $Q^* = m^{1.5}Q/\sqrt{gJ(Y/\psi)^5}$. It mainly results in the equality $\overline{Y}^* = Y^*$ given by Eq. 52 or Eq. 55, in accordance with the sign of the discriminant $\Delta$.
7. Compute then $\overline{Y}^{*-1} = Y^{*-1}$ using Eq. 52 or Eq. 55.
8. Bearing in mind that $\overline{Y}^{*-1} = \dfrac{\overline{b}}{m\overline{Y}} = Y^{*-1} = \dfrac{b}{mY}$, the required linear dimension "*b*" is then:

$$b = mY\overline{Y}^{*-1} \tag{56}$$

9. From geometrical considerations carried out on Fig.1a, the needed linear dimension "*a*" is such that:

$$a = b + 2mY \tag{57}$$

**Example 3**

Compute the linear dimensions "*b*" and "*a*" of the pressurized trapezoidal shaped conduit shown in Fig.1a, for the following data:

$Q = 1.7\,m^3/s$, $J = 2\times10^{-4}$, $Y = 1.3\,m$, $\varepsilon = 10^{-3}\,m$, $\alpha = 60°(m = 0.577350269)$, $\nu = 10^{-6}\,m^2/s$.

1. The parameter $C_1$ is:

   $$C_1 = \sqrt{1+m^{-2}} + 1 = \sqrt{1+0.577350269^{-2}} + 1 = 3$$

   According to Eq. 17 and Eq. 26, $C^*$ and $q$ are respectively:

   $$C^* = \frac{C_1 - 2}{3C_1} = \frac{3-2}{3\times3} = \frac{1}{9}$$

   $$q = \frac{1}{\sqrt{C_1}} = \frac{1}{\sqrt{3}}$$

2. Using Eq. 22, the parameter $\overline{\beta}$ is:

   $$\overline{\beta} = \frac{C^*q^{2/3} + \sqrt{(C^*q^{2/3})^2 - 4(q^{2/3}-1)(1-C^{*2}q^{2/3})}}{2(1-C^{*2}q^{2/3})} = 0.596343232$$

3. According to Eq. 27, the linear dimension $\overline{a}$ of the triangular rough model flowing a discharge $\sqrt{C_1}Q$ is:

   $$\overline{a} = \left(\frac{m^3Q^2C_1^2}{2gJ}\right)^{1/5} = \left(\frac{0.577350269^3\times1.79^2\times3^2}{2\times9.81\times2\times10^{-4}}\right)^{1/5} = 4.179707537\,m$$

   This computed value of $\overline{a}$ corresponds also to the value of the same linear dimension of the trapezoidal rough model.

4. Applying Eq. 6, Eq. 7 and Eq. 30, the wetted perimeter $\overline{P}$, the water area $\overline{A}$ and the Reynolds number $\overline{R}$ are respectively:

$$\overline{P} = \overline{a}\left[C_1 - (C_1 - 2)\overline{\beta}\right] = 4.179707537 \times \left[3 - (3-2) \times 0.596343232\right] = 10.04658231\ m$$

$$\overline{A} = \overline{a}^2 \frac{(1-\overline{\beta}^2)}{4m} = 4.179707537^{\ 2} \times \frac{(1 - 0.596343232^2)}{4 \times 0.577350269} = 4.874509694\ m^2$$

$$\overline{R} = \frac{4Q}{\overline{P}\nu} = \frac{4 \times 1.7}{10.04658231 \times 10^{-6}} = 676847.09$$

Thus, the hydraulic diameter $\overline{D_h} = 4\overline{A} / \overline{P}$ is:

$$\overline{D_h} = 4\overline{A} / \overline{P} = \frac{4 \times 4.874509694}{10.04658231} = 1.94076335\ m$$

5. The non-dimensional correction factor of linear dimension $\psi$ is then:

$$\psi = 1.35\left[-\log\left(\frac{\varepsilon / \overline{D_h}}{4.75} + \frac{8.5}{\overline{R}}\right)\right]^{-2/5} = 1.35 \times \left[-\log\left(\frac{10^{-3} / 1.94076335}{4.75} + \frac{8.5}{676847.09}\right)\right]^{-2/5} = 0.78189471$$

6. Assign to the trapezoidal rough model the following linear dimension according to Eq. 28:

$$\overline{Y} = \frac{Y}{\psi} = \frac{1.3}{0.78189471} = 1.66262795\ m$$

The new value of the relative conductivity is then:

$$Q^* = \frac{m^{1.5} Q}{\sqrt{gJ(Y/\psi)^5}} = \frac{0.577350269^{1.5} \times 1.7}{\sqrt{9.81 \times 2 \times 10^{-4} \times 1.66262795^5}} = 10.7674218$$

7. Calculation shows that:

$$Q^* \le \frac{12\sqrt{3}(C_1 - 1)}{\sqrt{C_1(C_1 - 2)}} = 24$$

We can thus conclude that the relative height $\overline{Y}^*$ is governed by Eq. 52 in which the angle $\gamma$ is given by Eq. 51 as:

$$ch(\gamma) = \frac{12\sqrt{3}(C_1 - 1)}{Q^*\sqrt{C_1(C_1 - 2)}} = \frac{12 \times \sqrt{3} \times (3-1)}{10.7674218 \times \sqrt{3 \times (3-2)}} = 2.22894584$$

leading to $\gamma = 1.4400673$ *radians*

Applying Eq. 52 results in:

$$\overline{Y}^{*-1} = \frac{Q^*\sqrt{C_1(C_1 - 2)}}{4\sqrt{3}} ch(\gamma / 3) - 1 = \frac{10.7674218 \times \sqrt{3 \times (3-2)}}{4 \times \sqrt{3}} ch(1.4400673 / 3) - 1 = 2.00798717$$

Finally, according to Eq. 56 and Eq. 57, the required linear dimensions "*b*" and "*a*" are respectively:

$$b = mY\overline{Y}^{*-1} = 0.577350269 \times 1.3 \times 2.00798717 = 1.50710551 m \approx 1.50\ m$$

$$a = b + 2mY = 1.5 + 2 \times 0.577350269 \times 1.3 \approx 3\ m$$

## Conclusions

The main purpose of the study was to design a pressurized trapezoidal shaped conduit by the use of a new method known as the Rough Model Method or RMM. The design consisted in calculating the three linear dimensions that characterize the conduit, considering the strict minimum of data. The principle of the RMM has consisted in judiciously applying the three basic equations of turbulent flow to a referential rough trapezoidal shaped model for which the equations of the flow has been established. These equations were subsequently used to derive explicitly the searched linear dimensions by the use of a non-dimensional correction factor of linear dimension whose major role has been highlighted. The calculation made use of mathematical considerations, such as limited development, successive solution approach, or third-degree equations that have been effectively resolved by trigonometric and hyperbolic functions. The explicit steps of calculation were clearly

presented and one can observe the degree of their simplicity. Practical examples have been taken to better explain the calculation procedure.

**Keywords:** navigation conditions; engineering effects; braided reach

**Abstract.** The evaluation of the effects of regulation engineering in Jiayu-Yanziwo reach is presented through the process of: (a) the introduction of study area and regulation works; (b) the establishment of a two-dimensional flow and sediment numerical model; (c) the evaluation of regulation works effects. According to the phenomenon of river process, a series of engineering to prevent the sand bar from erosion are designed. The effects of prevent works is simulated by 2D numerical model verified with measured data. After impound of the prevent engineering, the min navigation width while depth is 3.7m is greater than 150m, the good navigation conditions will maintained in next decade.

## Introduction

In the middle Yangtze River, exist in a large number of a branching channel. Sand bar and channel changes frequently with different water and sediment conditions, which often cause great deterioration in waterway conditions [1]. In generally, navigational will become worse if sandbar erosion and channel sedimentation. This problem appeared on many reach, such as Shashi, Wuguizhou, Jiepai reach. Since Jiepai waterway regulation project implemented in 1994, waterway regulation engineering has become the most effective way to solve navigation problem. In the process of engineering design, accurately performance evaluation is the most important part [2].Due to complex constrained factors, effects of evaluation work is quite difficult. After decades of development, three evaluation methods, including measured data analysis, physical model, mathematical model, has been formed. The mathematical model method is increasingly popular in the study of engineering effect evaluation with its feature of efficiency, flexible and small cost, which also shows high availability in simulating results[3,4]. This paper take Jiayu-Yanziwo reach as an example , the cause and solution of navigation engineering was identified, then the waterway conditions after the project carried out in ten years were simulated by a 2D flow-sediment mathematical model ,which was established and verified by recently measured data..

## Study Area and Background

**Study Area.** Jiayu-Yanziwo reach located in Hubei province, was key navigation obstruction reach of the middle Yangtze River(Fig.1). Recently, the minimum channel maintenance measure is 3.5m×80m×750m, assurance rate of 98%. At 2020, this criterion will be raised to 3.7m×150m×1000m. In Jiayu reach, water flow be divided into three branches by Huxian Island and Fuxing Island, the left branch is the main navigation way because its water depth deep enough. In Yanziwo reach, exports is controlled by Yinjiazhou node, the right bank Fuliang Island exists, water flow is divided into two channel by Yanziwo beach. The main branch periodically in the swing around branches, navigation channel is not stable.

**Plan of Regulation Engineering Works.** The main problem of Jiayu reach is erosion at the left edge of Huxian Island, the head beach of Fuxing Island, split ratio increases in the middle channel. In Yanziwo reach, the right branch erosion and split ratio increases, the import of left branch bandwidth,

flow is hard to focus wash navigation channel. To solve above problems, pavement works to protect bench from erosion are proposed. The final scheme is shown in Fig.1, one fishbone-bench protection belt is applications in head of Fuxing Island at Jiayu reach, and in Yanziwo reach, one fishbone-bench protection belt is carried out in head of Yanziwo bench, two bed protection belt in tail.:

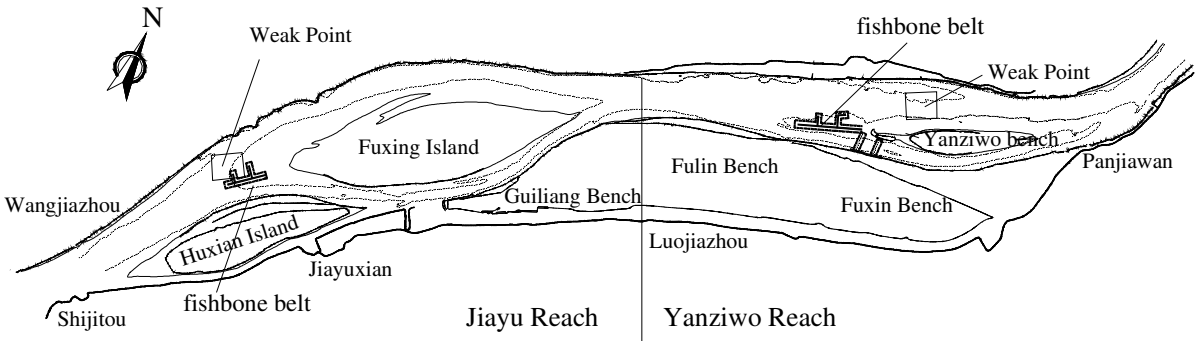

**Fig.1 Sketch of Jiayu-Yanziwo reach**

## Method

In this paper, a 2D flow-sediment mathematical model is adopted to evaluate the effects of regulation engineering on navigation condition.

**Model Theory.** Control equations of the model are as follows:

(1) Flow continuity equation

$$\frac{\partial H}{\partial t}+\frac{1}{C_\xi C_\eta}\frac{\partial}{\partial \xi}\left(huC_\eta\right)+\frac{1}{C_\xi C_\eta}\frac{\partial}{\partial \eta}\left(hvC_\xi\right)=0 \tag{1}$$

(2) Flow momentum equation

$\xi$ direction:

$$\frac{\partial u}{\partial t}+\frac{1}{C_\xi C_\eta}\left[\frac{\partial}{\partial \xi}\left(C_\eta u^2\right)+\frac{\partial}{\partial \eta}\left(C_\xi vu\right)+vu\frac{\partial C_\eta}{\partial \eta}-v^2\frac{\partial C_\eta}{\partial \xi}\right]=-g\frac{1}{C_\xi}\frac{\partial H}{\partial \xi}$$
$$-\frac{u\sqrt{u^2+v^2}n^2g}{h^{4/3}}+\frac{1}{C_\xi C_\eta}\left[\frac{\partial}{\partial \xi}\left(C_\eta\sigma_{\xi\xi}\right)+\frac{\partial}{\partial \eta}\left(C_\xi\sigma_{\eta\xi}\right)+\sigma_{\xi\eta}\frac{\partial C_\xi}{\partial \eta}-\sigma_{\eta\eta}\frac{\partial C_\eta}{\partial \xi}\right] \tag{2}$$

$\eta$ direction:

$$\frac{\partial v}{\partial t}+\frac{1}{C_\xi C_\eta}\left[\frac{\partial}{\partial \xi}\left(C_\eta vu\right)+\frac{\partial}{\partial \eta}\left(C_\xi v^2\right)+uv\frac{\partial C_\eta}{\partial \xi}-u^2\frac{\partial C_\xi}{\partial \eta}\right]=-g\frac{1}{C_\eta}\frac{\partial H}{\partial \eta}$$
$$-\frac{v\sqrt{u^2+v^2}n^2g}{h^{4/3}}+\frac{1}{C_\xi C_\eta}\left[\frac{\partial}{\partial \xi}\left(C_\eta\sigma_{\xi\eta}\right)+\frac{\partial}{\partial \eta}\left(C_\xi\sigma_{\eta\eta}\right)+\sigma_{\eta\xi}\frac{\partial C_\eta}{\partial \xi}-\sigma_{\xi\xi}\frac{\partial C_\xi}{\partial \eta}\right] \tag{3}$$

(3) 2D non-equilibrium suspended sediment transport equation

$$\frac{\partial hS_L}{\partial t}+\frac{1}{C_\xi C_\eta}\left[\frac{\partial}{\partial \xi}\left(C_\eta huS_L\right)+\frac{\partial}{\partial \eta}\left(C_\xi hvS_L\right)\right]=$$
$$\frac{1}{C_\xi C_\eta}\left[\frac{\partial}{\partial \xi}\left(\frac{\varepsilon_\xi}{\sigma_s}\frac{C_\eta}{C_\xi}\frac{\partial hS_L}{\partial \xi}\right)+\frac{\partial}{\partial \eta}\left(\frac{\varepsilon_\eta}{\sigma_s}\frac{C_\xi}{C_\eta}\frac{\partial hS_L}{\partial \eta}\right)\right]+\alpha_L\omega_L\left(S_L^*-S_L\right) \tag{4}$$

(4) Riverbed deformation equation

$$\gamma_s \frac{\partial Z_L}{\partial t} = \alpha_L \omega_L (S_L - S_L^*) \quad \text{L=n1…n2} \qquad (5)$$

The discrete format of equations was finite volume method. Numerical method, boundary conditions and other solution on key problems as movable boundary technique could be found in the reference [5, 6].

**Model Calibration and Validation**. There are 300*100grid points in Shijitou to Panjiawan 35km long, model parameters were determined by the data measured in 2012, The roughness in beach was in the range of 0.025 to 0.032, and in channel was about 0.014 to 0.026. Fig.2 shows the velocity distribution, the verification of Erosion and deposition distribution was shown in Fig.3.The above comparison between calculated and measured values proved that, this model could simulated the characteristics of water and sediment transport in this reach accurately, and be used to carry out the work of trend forecasting and evaluation of programs.

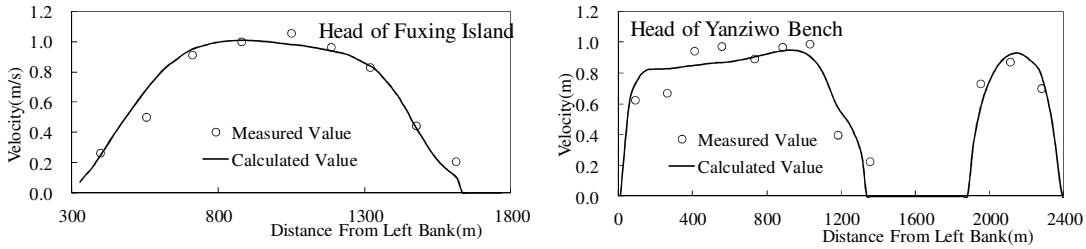

**Fig.2 Verification of velocity distribution (Q=11400m$^3$/s)**

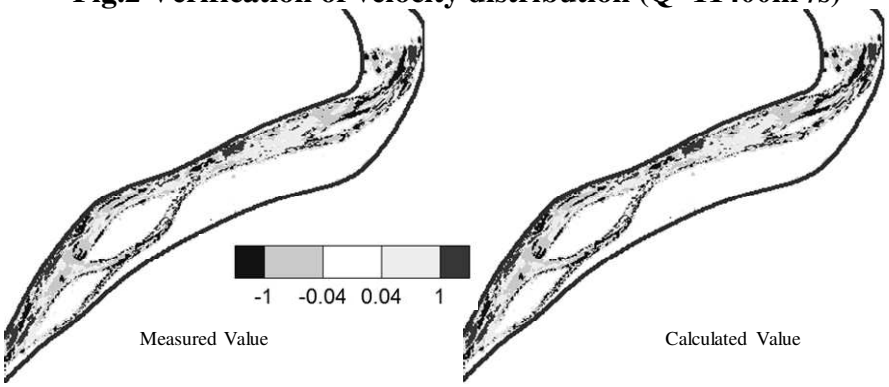

**Fig.3 Comparison between calculated and measured values of erosion distributions from 2011-2012.**

**Numerical simulation condition**. Flow and sediment process of 2006-2010+1998+2006-2009 were employed in the calculation of the navigation results after the regulation projects. The initial terrain was November 2011's.

## Results

**Navigation Condition**. The morphology of Fuxing Island and Yanziwo Bench which periodically scouring and silting has been maintained after impound of engineering. Fig.4 shows the min premise navigation width while navigation depth is 3.7m in inlet of left branch at Jiayu and Yanziwo reach. The result shows that, compared the non-engineering, navigation width is increased largely, such as 2016, the width in Jiayu reach is 180m than non-engineering, hinders navigation problem is resolved. In 2014, 2016, 2018, 2020, 2022, the width of Jiayu reach are 360m, 350m, 190m, 300m ,350m, Yanziwo reach are 270m, 320m, 380m, 330m, 290m. No matter when, width of channel are great than 150m, the min required width. Thus, the good navigation condition is maintained after the project.

**Adverse effects**. Artificial engineering construction will cause adverse effects, causing adjustment of river regime or increase the flood pressure, so small adverse effects was the premise of projects construction. The simulation result of water dynamics in conditions of no-engineering and later

engineering shows that, the max change value of near-bank velocity is 0.01m/s, water level is 0.007m, diversion ratio of right branch is 0.21%. The impoundment of the projects cannot cause significant changes of flow conditions.

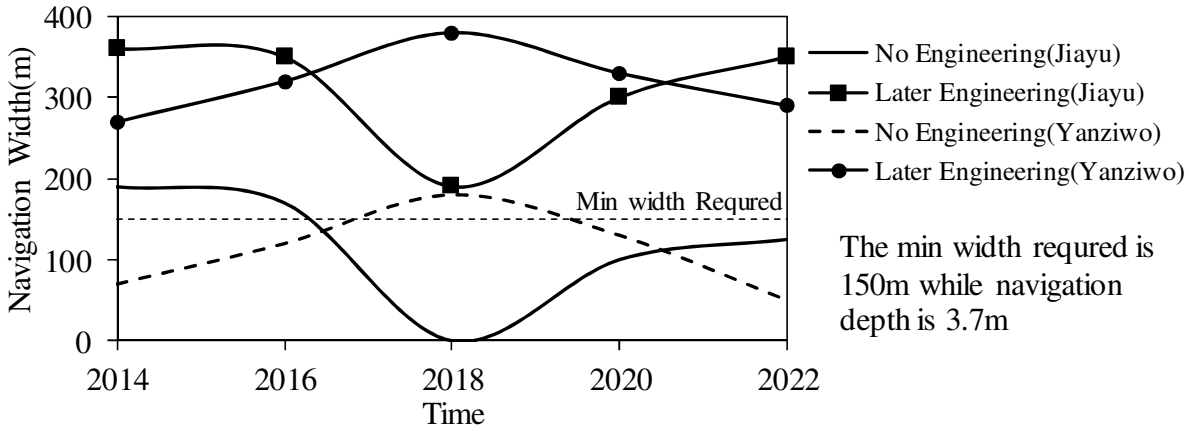

**Fig.4 The min navigation width in the future decade**

## Conclusions

(1) One 2D flow-sediment mathematical model established in this paper could simulated the characteristics of water and sediment transport in Jiayu-Yanziwo reach accurately, and be used to carry out the work of trend forecasting and evaluation of programs.

(2) The effects of navigation engineering simulated show that, good navigation condition is maintained in next decade.

**Key words:** Cemented sand and gravel, static and dynamic properties

**Abstract**: The static and dynamic triaxial shear tests and deformation tests on CSG (cemented sand and gravel) are conducted with different amount of added cementing materials. The mechanical indexes and parameters have obvious increments with mixing of cementing material and accumulation of curing days. However the increments will become mild with further adding of cementing material. The deformation curve of CSG test sample is similar to the curve of sand-gravel sample without mixing with any cementing material, and they both follow the trend of semi-logarithmic decrement law. The dynamic permanent deformation of CSG increases with the increments of confining pressure, consolidation stress and dynamic stress. Thus this deformation still can be calculated using the constitutive model of dynamic residual deformation proposed by Zhujiang Shen Academician.

## Introduction

CSG (Cemented Sand and Gravel) is a new type of material for dam construction works and it is produced by adding cement, coal ash and water to rock based material such as riverbed gravel or excavation muck which can be easily found near dam sites, and mixing them with simple device. The physical properties of CSG change from granular material into concrete material with this mixing of cementing material [1]. The cement sand and gravel (CSG) dam owes the advantages both of the concrete faced rock-fill dam (CRFD) and roller compacted concrete (RCC) gravity dam. Engineering experience compared with RCC dam demonstrated that it has low requirement of foundation, rapid speed in construction and low cost. Compared with CFRD dam that nearly a half of material can be saved, it also can reduce the influence on the nature environment. It is clear that CSG dam will find wide application in the future [2-3]. Because of these advantages of CSG dam, it has attracted much attention of experts abroad [4-10]. The physical property of CSG is not fully understood yet. At present, researches on physic-mechanical property of CSG material are based on the concrete theory and usually the uniaxial compression test is adopted to study the CSG physical properties.few experimental studies on dynamic property of CSG can be found in the literature. In our research herein, both static and dynamic properties in mechanics and deformation of different CSG are investigated using triaxial tests, and the influences of different mixed cementing material on CSG are also discussed.

## Test Method

Natural sand and gravel was used as the aggregate for tests and its gradation is shown in Table 1. The mass density of aggregate was controlled as 2.29g /cm$^3$. Static tests were classified into four groups: without any cementing material, with 60kg/m$^3$, 80kg/m$^3$, 90kg/m$^3$ of cementing materials. The cementing material was cement and coal ash. The cement was P.O.42.5R and coal ash was

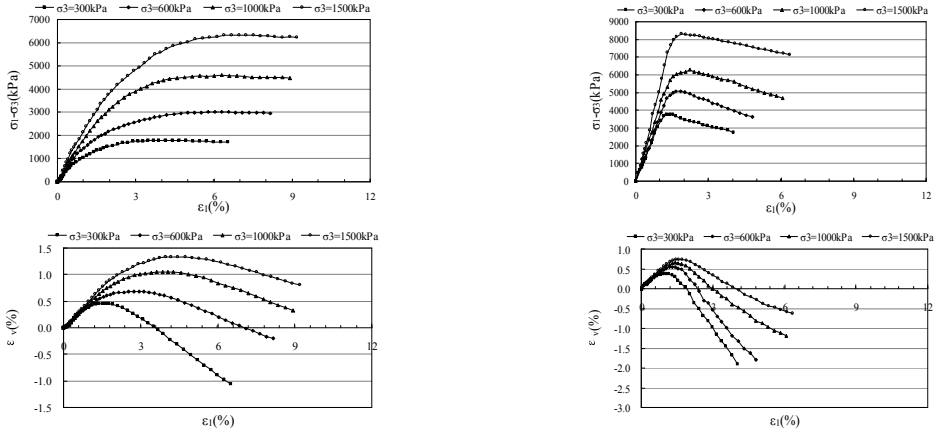
secondary ash, and their mixed ratio was 6:4 in weight. The water cement ratio was set to 0.8 and the curing days was 28. One more compared test for CSG with 80 kg/m$^3$ of cementing material was also conducted with a curing days of 90. The dynamic triaxial tests were classified into two groups: without any cementing material and with a cementing material of 40 kg/m$^3$ P.O.42.5R cement. The water cement ratio was 0.8 and the curing days was 28.

Table 1 The aggregate gradation

| Name | Percent of particle size range（%） | | | | | |
|---|---|---|---|---|---|---|
| | 60~40 mm | 40~20 mm | 20~10 mm | 10~5 mm | 5~1 mm | 1~0 mm |
| Sand and gravel | 25.8 | 24.8 | 16.5 | 11.4 | 9.0 | 12.5 |

## Test Results and Discussion

**Static triaxial test results.**The test samples were prepared artificially with the same dimension of $\Phi 300\times 700$ mm, different amounts of cement, coal ash and water were added into different test samples. The confining pressure were set to 4 levels, 300 kPa, 600 kPa, 1000 kPa and 1500 kPa, during the test procedure and the test results are shown in Figrue 2.



No cementing material 60 kg/m$^3$ cementing material (curing for 28 days)

Figure 2 Results of static triaxial tests

the elastic nonlinear Duncan model is adopted to process the experimental data and the calculated experimental parameters are listed in Table 2.

Table 2 Parameters of Duncan model in triaxial shear test

| Sample | Cementing (kg/m$^3$) | Curing days | $c$ (kPa) | $\varphi$ (degree) | $K$ | $n$ | $R_f$ | $G$ | $F$ | $D$ |
|---|---|---|---|---|---|---|---|---|---|---|
| Sand- gravel | 0 | e/ | 163.2 | 40.9 | 1220.2 | 0.32 | 0.64 | 0.39 | 0.12 | 7.25 |
| CSG | 60 | 28 | 617.8 | 40.6 | 2641.7 | 0.28 | 0.14 | 0.37 | 0.08 | 13.25 |
| | 80 | 28 | 766.9 | 40.2 | 3369.5 | 0.24 | 0.13 | 0.38 | 0.09 | 13.20 |
| | | 90 | 842.1 | 40.5 | 3644.2 | 0.26 | 0.10 | 0.40 | 0.10 | 15.00 |
| | 90 | 28 | 842.3 | 39.9 | 3742.5 | 0.23 | 0.11 | 0.38 | 0.09 | 13.95 |

The results indicate that:

The peak value of damage increases with the increment of adding cementing material after consolidation grouting. However the $\varphi$ value, which is an indication of linear intensity, decreases a bit, while the c value has an apparent increasing. Fine grained sand and rough gravels will cement to each other after adding the cementing material, which makes the bite force be strong, thus increase the intensity of the sand and gravel material. The increased intensity of material leads to a low sensitivity to its confining pressure. The relationship between peak values of damage $(\sigma_1-\sigma_3)_f$ under their respective levels of confining pressure and intensity index $\varphi$ is listed in Table 3. Under the confining pressure of 300 kPa, the peak value of damage increases by 1969 kPa to 3153 kPa. With an increment of confining pressure to 1500 kPa, the peak value of damage only increases a bit with an increased value of 1988 kPa- 3035 kPa. The damage peak value is not

sensitive to confining pressure since the increased values under high and low confining pressure are almost the same. Therefore, a decreased $\varphi$ value and an increased c value can be observed from our results.

The peak value of damage increases by 31.4%-109.7%, and the model parameter K increases by 116.5 % with the increment of added cementing material from 0 kg/m$^3$ to 60 kg/m$^3$. The peak value of damage increases by 6.9%-19.1%, while the model parameter K increases by 27.6 %, if the added cementing material is increased from 60 kg/m$^3$ to 80 kg/m$^3$. In the end, with the added cementing material be increased from 80kg/m$^3$ to 90kg/m$^3$, the peak value of damage increases by 2.3%-5.3%, and the model parameter K increases by 11.1 %. The results of different amount of added cementing materials indicate that the mechanical properties of CSG become stronger (larger) with more added cementing material, while this increment in intensity will be mild essentially.

Different curing days test was conducted for the same amount of added cementing material of 80kg/m$^3$ and the results show that, the peak value of damage increases by 3.0%-8.2%, and the model parameter K increases by 8.2%-13.5% with the increment of curing days from 28 to 90. In other words, the intensity of CSG has already reached 92.5%-95.8% of its fracture strength within 28 curing days.

Table 3 Damage peak values and intensity indexes

| Sample | Cementing material (kg/m$^3$) | Curing days | Peak value of damage (kPa) | | | |
|---|---|---|---|---|---|---|
| | | | Confining pressure 300kPa | Confining pressure 600kPa | Confining pressure 1000kPa | Confining pressure 1500kPa |
| Sand-gravel | 0 | 0 | 1794 | 3011 | 4587 | 6331 |
| CSG | 60 | 28 | 3763 | 5067 | 6276 | 8319 |
| | 80 | 28 | 4483 | 5538 | 6690 | 8892 |
| | | 90 | 4768 | 5962 | 7233 | 9275 |
| | 90 | 28 | 4723 | 5883 | 6881 | 9095 |

**Dynamic triaxial test results.**The CSG test samples were installed on the dynamic triaxial machine after curing. Dynamic modulus and dynamic residual deformation were investigated.

The relationship between modulus of dynamic shear $G_{d\max}$ and averaged principal stress $\sigma_m$ are shown below:

$$G_{d\max} = kP_a\left(\frac{\sigma_m}{P_a}\right)^n \tag{1}$$

The dynamic parameters *K* and *n* are listed in Table 4.

Table 4 Test results of dynamic modulus

| Sample | Cementing material (kg/m$^3$) | Curing days | *K* | *n* |
|---|---|---|---|---|
| Sand-gravel | 0 | 0 | 2312 | 0.36 |
| CSG | 40 | 28 | 3771 | 0.24 |

The Figure 4 shows the dynamic properties of CSG increases a lot after adding a 40 kg/m$^3$ cementing material, and the parameter K of modulus of dynamic shear increases by 1.63 times. The dynamic shear modulus is not that sensitive to the averaged principal stress $\sigma_m$ due to the increment of itself intensity, thus make the dynamic shear modulus coefficient *n* be small.

For the tests of dynamic residual deformation, The final axial dynamic strains and dynamic volumetric deformations under different confining pressure, consolidation ratios and dynamic stresses are plotted in Table 5.

Table 5 Maximum axial dynamic strains and dynamic permanent volumetric deformations of CSG with 40kg/m3 cementing material

| Consolidation ratio $k_c$ | 1.5 | | | 2.0 | | |
|---|---|---|---|---|---|---|
| Confining pressure $\sigma_3$/kPa | Dynamic stress ratio $\tau_d / \sigma_3$ | Max. axial dynamic strain $\varepsilon_a$/% | Max. dynamic volumetric strain $\varepsilon_v$/% | Dynamic stress ratio $\tau_d / \sigma_3$ | Max. axial dynamic strain $\varepsilon_a$/% | Max. dynamic volumetric strain $\varepsilon_v$/% |
| 300 | 0.4 | 0.05 | 0.10 | 0.5 | 0.11 | 0.09 |
| | 0.8 | 0.10 | 0.19 | 1.0 | 0.16 | 0.17 |
| 600 | 0.4 | 0.11 | 0.14 | 0.5 | 0.18 | 0.12 |
| | 0.8 | 0.21 | 0.27 | 1.0 | 0.28 | 0.23 |
| 1000 | 0.4 | 0.15 | 0.19 | 0.5 | 0.26 | 0.19 |
| | 0.8 | 0.33 | 0.34 | 1.0 | 0.48 | 0.31 |
| 1500 | 0.4 | 0.22 | 0.22 | 0.5 | 0.36 | 0.22 |
| | 0.8 | 0.50 | 0.39 | 1.0 | 0.66 | 0.36 |

As can be seen from Figure 4 and Table 5, the dynamic permanent deformation of CSG with an added 40kg/m$^3$ cementing material increases a lot with the respective increment in confining pressure, consolidation stress and dynamic stress. When there is an increase in confining pressure, the increments of axial dynamic strain, amplitude of dynamic strain and dynamic permanent volumetric strain are also observed. When there is an increase in consolidation stress, an increment of dynamic permanent shear deformation and a reduction of amplitude of dynamic strain can be found. If the test sample is under the same confining pressure and consolidation stress, the axial dynamic strain, amplitude of dynamic shear strain and dynamic permanent volumetric deformation increase with the increment of dynamic stress applied on that CSG sample.

The residual deformation curves before and after consolidation grouting are shown in Figure 5. The deformation curve of CSG test sample with an added 40kg/m$^3$ cementing material has a similar trend as the curve of sand-gravel sample without adding any cementing material. They both follow the semi-logarithmic decrement law. Thus the experimental parameters can be analyzed according to the constitutive model of dynamic residual deformation [19] given by Zhujiang-Shen Academician. The increment of dynamic residual volumetric strain $\Delta\varepsilon_v$ and the increment of residual shear strain $\Delta\gamma_s$ can be calculated through equations below:

$$\Delta\varepsilon_v = c_1(\gamma_d)^{c_2} \exp(-c_3 S_1)\frac{\Delta N_L}{1+N_L} \tag{2}$$

$$\Delta\gamma_s = c_4(\gamma_d)^{c_5} S_1 \frac{\Delta N_L}{1+N_L} \tag{3}$$

among equations, $\Delta N_l$ and $N_l$ are the increment and accumulation of equivalent vibration times. $c_1$, $c_2$, $c_3$, $c_4$, $c_5$ are the five parameters of dynamic residual deformation. Those parameters are listed as Table 6.

Table 6 Comparisons of dynamic residual deformation model parameters

| Sample | Cementing material (kg/m$^3$) | Curing days | $c_1$ (%) | $c_2$ | $c_3$ | $c_4$ (%) | $c_5$ |
|---|---|---|---|---|---|---|---|
| Sand-gravel | 0 | 0 | 0.41 | 0.72 | 0 | 5.23 | 0.81 |
| CSG | 40 | 28 | 0.21 | 0.60 | 0 | 3.14 | 0.50 |

The CSG dynamic residual deformation characteristics have been improved a lot with adding of the 40kg/m$^3$ cementing materials. The figures 4 shows there are obvious reductions of both residual axial deformation and residual volumetric deformation under the same stress conditions. The model parameter of dynamic residual axial strain has decreased by 48.8% and the parameter of dynamic residual volumetric strain has reduced by 40.0%.

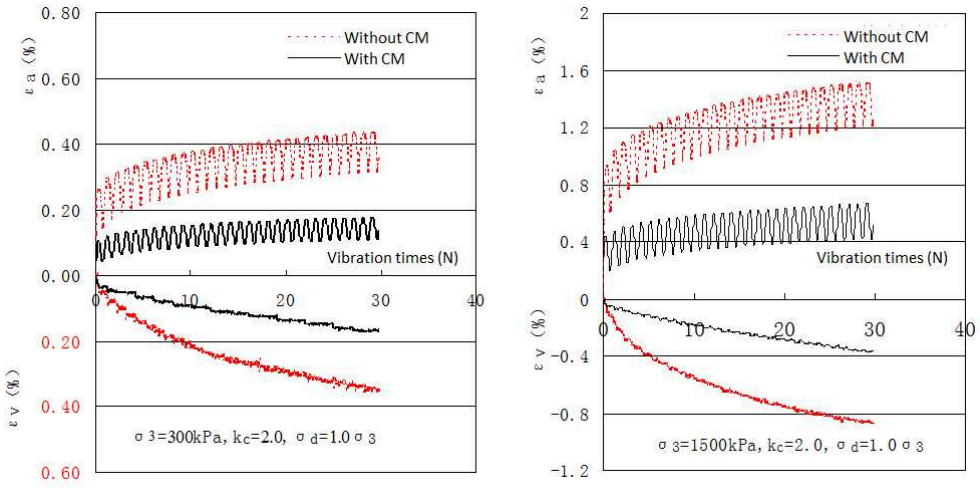


Figure 4 Comparsions of dynamic residual deformations with and without CM (cementing material)

## Conclusion

From the studies of mechanics and deformation of CSG material using both static and dynamic triaxial test methods, the following conclusions can be drawn:

The peak value of damage for CSG material increases obviously with the increment of added cementing material. However, the linear intensity index $\varphi$ may have a decrement, while the index c will have an obvious increment with the adding of cementing material. In general, the mechanical indexes increase with the adding of cementing material and this increment will become mild in the end. The peak value of damage and model parameter K of CSG increase with the increment in curing days from 28 days to 90 days,

The sand-gravel material show a reduction of damage ratio from 0.64 to 0.11 with the increased amount of cementing material. The strain-stress curve of CSG material can change from nonlinear type into the linear elastic type. To summarize, the CSG changes from elastic-plastic material into linear elastic material with the increment of added cementing material.

The deformation curve of CSG with an adding of cementing material has a similar trend as the curve of sand-gravel sample without adding any cementing material, and they are matching with the semi-logarithmic decrement law. The confining pressure, consolidation ratio and dynamic stress have significant influences on the CSG dynamic permanent deformation. The enlargement of pressure or stress will increase the permanent deformation of CSG.

# Finite element analysis of stress deformation of earth-rock dam on narrow valley

Fu-yong Chu[1, a]

[1]School of Civil Engineering, Lishui University, Lishui, Zhejiang 323000, China

[a]cfy1976@hhu.edu.cn

**Keywords:** core rockfill dam; finite elements; stress deformation; narrow velley.

**Abstract:** The three-dimentional finite element analysis is adopted to simulate and cauculate the stresses and deformations of a certain core rockfill dam on narrow velley, with Duncan-Chang E-ν model during its completion and operation periods by incremental loading. The results show that the stresses and deformations of core rockfill dam on narrow velley are allowble and the design proposal is reasonable, which provides the theoretical basis for similar engineering.

## Introduce

With the development of dam construction technique, height of domestic earth-rock dam has reached the 300m[1]. As a important dam type, earth-rock dam play an important role. If a certain dam will be constructed on some bad geological condition such as thick overburden layer, earth-rock dam often has competition and even is the unique choice.

During the past few decades, A Large number of research on sress deformation of earth-rcok dam has been carried out by many scholars abroad, and have obtained certain achievements[2-7]. However, research on sresses deformations of earth-rcok dam on narrow valley is relative less. On the other hand, with the development of computer simulation technology, three-dimensional finite element(FEM) technique is often used to analyze the stress and deformation of rock-fill dam, which provides a theoretical basis for the preliminary design of the dam.

Therefore, the FEM stress and deformation of rock-fill dam on narrow valley in completion and test-operation period are analyzed by the Duncan Chan model in this dissertation. The resuts of research provide the theoretical basis for similar engineering.

## FEM Model

The maximum height of a certain rock-fill dam on narrow velley is 136m and the maximum height of the bedrock is about 92.5m. The major materials of the rock-fill dam are as shown in figure 1. When unit grids are divided, the majority elements such earth rock material and concrete etc are usually divided into eight nodes hexahedron element, and the minority elements are divided into six nodes pentahedron or divided into four nodes tetrahedron. The graph of 3D FEM mesh, is as shown in figure 2.

During the calculation of 3D FEM, the process of construction stage and operation stage of dam body is considered. The rock-fill material of dam body is using Duncan Chan model[8]. The model parameters of calculation are as shown in table 1. In order to simulate the discontinuity

appearing on the contact place between the concrete and earth-rock, Goodman joint element of zero thickness is set.

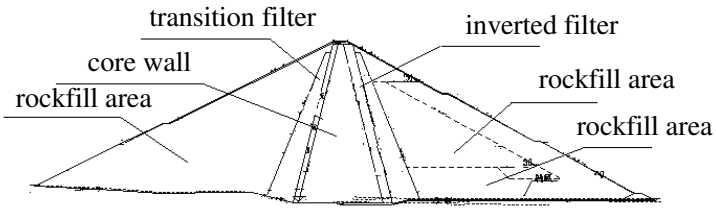

Figure 1 Typical sections and materials district

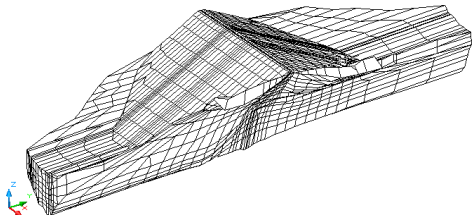

Figure 2 3D FEM mesh

## Analysis of calculation results

The rock-fill dam on narrow velley is analyzed by using 3D FEM under Duncan Chang E-ν model, whose maximum deformation and related stress are listed in the table 2. Table 2 show that there are some differences between in completion and in test operation period on the stress and deformation characteristics. Now stress and deformation of dam body and cutoff wall will be analyzed specially.

Table 2 Three dimensional FEM schems and values of stress and deformation

| working condition | maximum of dam body settlement (cm) | maximum of horizontal displacement to upstream (cm) | maximum of horizontal displacement to downstream (cm) | maximum of top of cutoff wall settlement (cm) | maximum horizontal displacement of top of cutoff upstream (cm) | $\frac{\sigma_z}{\gamma h}$ |
|---|---|---|---|---|---|---|
| completion | 126.43 | -28.62 | 34.70 | -8.53 | 1.12 | 0.601 |
| Test operation period | 121.49 | -19.09 | 38.66 | -8.06 | 21.58 | 0.595 |

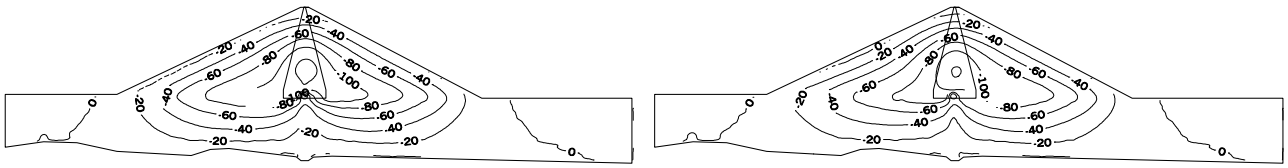
Note: $\sigma_z/\gamma h$ is the average ratio between vertical stress of each unit of core in valley and gravity stress valley in the range of 1/3～2/3 height of dam.

## Deformation characteristics of dam body

Contour of longitudinal Settlement and Contour of longitudinal horizontal displacement of core wall in operation and test operation period are given in figure 3. It is shown that the deformation distribution law during compelition and in test operation period are almost same.

Fig 3(a) and s fig 3(b) show that the maximum settlement of the dam body in completion and test operation are both on nearby the place of 1/3 height of dam. The maximum settlement of the dam

body in completion is 126.43cm, which account for the 0.93percent of height of dam and the maximum settlement of the dam body during test operation is 121.49cm, which account for the 0.89 percent of height of dam. From the data of the maximum settlement of the dam body in completion and test operation we can see that the data in test operation is slightly smaller, which mainly because of the buoyancy of water.

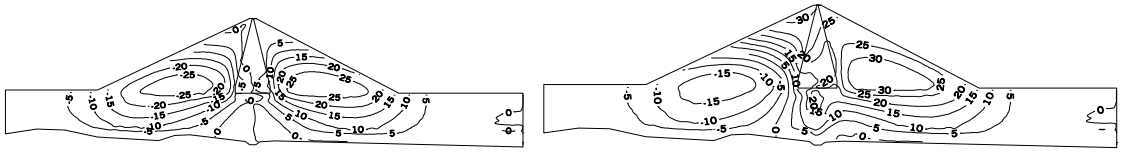


(a) completion (b) test-operation period

Figure 3 Contour of longitudinal Settlement of core wall (unit: cm)

Contour of longitudinal horizontal displacement of dam body along the river during compeliton and test operation period are given in figure 4. It is shown that the deformation distribution law of dam body along the river during compelition and in test operation period are almost same.

Figure 4(a) and figuire 4(b) show that the horizontal displacement along the river during completion and test operation period both show that the law to the downstream because of effect of water load. And the displacement of dam body along river to the downstream during completion is 34.7cm, which is descreased by 11.4% than the result during test operation period ..

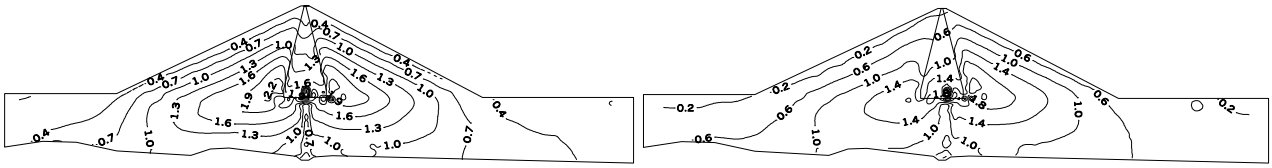


(a) completion (b) test-operation period

Figure 4 Contour of longitudinal horizontal displacement riveralong(unit: cm)

**Stress characteristics of dam boy**

Contour of longitudinal major principal stress and contour of longitudinal minor displacement of dam body during completion and test operation period are given in fig 5～fig 6. Fig 5(a) and figuire 5(b) show that the major stress distribution law of dam body during completion and during test operation period are almost same, that is, which uniformly reduce along the altitude. Among them, the maximum of the major stress under during test operation period is 1.97MPa, which is increased by 3.14% than that during complition. On the other hand, the value of $\sigma_z/\gamma h$ during compliton is more bigger than that during test operation period which shows that arc effect of core during complication is more obvious.

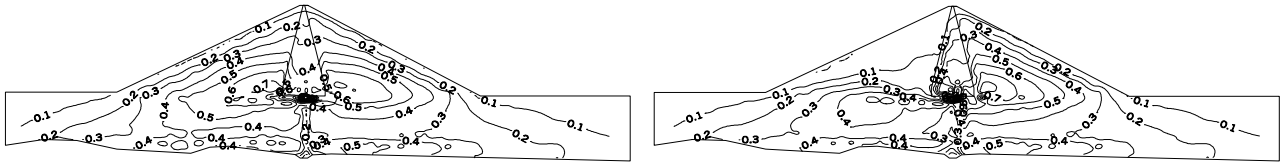


(a) completion (b) test-operation period

Figure 5 Contour of longitudinal major principal stress (unit: $MP_a$)

Fig 6(a) and figuire 6 (b) show that the minor stress of dam body appears phenomenon of stress centralization at nearby the place of 1/3 height of the bottom of dam body, and the distribution law

of minor stress distribution law of dam body during completion and during test operation period are almost same. It is worth mentioning, there is no appear tensile stress at the range of dam body. Among them, the minor stress of dam body during complition is 0.03MPa and that of dam body during test operation period is 0.04MPa.



(a) completion (b) test-operation period

Figure 6 Contour of longitudinal minor principal stress (unit: $MP_a$)

**Summary**

Through comparative FEM analysis of earth rockfill dam on narrow valley during complition and during test operation period, the differences of stress and deformation between during complition and during test operation period are analyzed especially and some conclusions are obtained as following:

(Ⅰ) The maximum settlement of the dam body during test operation period is more bigger than that during complition, and they are both less than one percent which shows that stresses of dam body are all in the reasonable range.

(Ⅱ) The Result shows that arc effect of core during complication is more obvious than that during test operation period. Therefore, some reasonable measures must be adopted during compliton.

(Ⅲ) For the earth-rock dam on narrow valley, the rheology of rockfill and humidification characteristics are both needed to be concered, which has great influence for the stess and deformation. Related research remains to further expansion.

# Philosophical Reflections on Chinese Water Resource Management

Yingfei Liu [1, a], Benqing Ruan [1,b] and Congcong Xie [1,c]

[1]China Institute of Water Resources and Hydropower Research,China,100038

[a]yfliu@iwhr.com, [b]ruanbq@iwhr.com, [c]cc_xie1990@163.com

**Keywords:** Chinese water resource management, Governing by nature, Philosophical Reflections, Lao Tzu's philosophy.

**Abstract.** Water is crucial to production, and is the foundation of ecology. Building a reasonable management system for water resources is necessary and important, and it's an inevitable requirement of our strategy of sustainable development. In the management of behavior, philosophical base determines the behavior trends. With the development of socio-economic development, the strategy of water resources management has changed a lot in China. In this paper, the problems caused by improper water resources management modes and by overly governing by people are discussed and a series of water management reform proposals are developed on the bases of the ancient Chinese management philosophy. The paper then gets the conclusion that the water resource management reform is actually following the management path from "governing by people" to "governing by nature".

## Introduction

Water is crucial to production, and is the foundation of ecology. Building a reasonable management system for water resources is necessary and important, and it's an inevitable requirement of our strategy of sustainable development. In the understanding of the relationship between man and water, people generally experienced from the "Unconstrained water use" when the amount of water supply was greater than the demand, to the "Unregulated exploitation of water resources" when the amount of water supply and demand was balanced, to "water crisis" now. Awareness and management mode of water resource is developing with the rapid growth of economic and social development and is gradually perfecting. However, as any scientific management, we should explore the general principles and philosophy of water resources management. In the management of behavior, philosophical base determines the behavior trends. "The central committee of the communist party of the state council on accelerating the development of water conservancy reform decision" [1]claims that the strict management of water resources is a way to accelerate the transformation of economic development strategic initiatives. How to carry out strict management of water resources? What is the future development of Chinese water resources management model? What kind of philosophical path water management should follow? These are major theoretical problems the water conservancy decision makers are facing.

## The conditions of water resources management development

Water management is mainly about the social water cycle management which attaches on the natural water cycle[2]. Before the late 70s, when China's economic development was relatively backward, the water resources was far more than the demand, therefore, there was no need for regional co-ordination of government management. Household's water intake modes and the manners were determined by themselves. In the 80s, with the rapid development of economy and city construction, industry water consumption was increasing. A lot of constructions were carried out in waterhead areas, which led to the local water supply contradictions. However, in this period, the contradiction with water is not so prominent between the sectors. After the 80 s, the obvious contradiction between supply and demand of water resources is showed with the rapid economic development and the sharply increasing population. In order to get a reasonable water resources development, State is required to exercise on

behalf of the ownership of water resources management for unified planning and scheduling to satisfy various departments and industry needs.

## Current water management problems

**Decentralized management.** The state-owned institutions manage water resources respectively according to the division of duties. In some areas, water resources management is even delegated directly to local governments. For example, water conservancy administrative departments are responsible for the management of large rivers, while municipal departments are responsible for the management of urban water supply and drainage, while environmental protection departments are responsible for the conservation and management of water environment, and so on. Since water resources management content is dispersed into different sectors (such as water conservancy department, urban construction department, environmental protection department, etc.), it is difficult to achieve the goal of unified planning and the intelligent use of water resource. Since the public sectors are only responsible for their own management activities, it is difficult to implement effective water management measures. In addition, the lack of communication between those departments causes the contradictions and conflicts occur frequently. All these factors lead to the low efficiency of utilization and allocation of water resources.

**Low Water resources management level.** Water management is mainly focus on water supply management, namely water conservancy project management, with the purpose only to maximize meet the demand of production and domestic water. This management mode is a kind of extensive management mode, which is not only intensified the contradiction between supply and demand of water resources, but also brings a series of ecological problems. In addition, the unconstrained concept of water use and the utilization of water resource mode of identifying the needs by supply, led to the increasing water demand.

**Lack of proper water management regulations.**With the economic and social development and water conditions change, the relevant legal provisions have been unable to meet the actual needs. The existing water management regulations have been difficult to regulate water management activities. Imperfect management system results in particularly serious water pollution and waste. Relevant policies and regulations liability provisions are too rigid and difficult to operate. The government crackdown on illegal behavior is not enough, and the water administrative enforcement is lax. In addition, the lack of incentive mechanism of the comprehensive utilization of water resources and protection, has restrained the high efficient and sustainable water resources utilization in technological innovation and scientific and technological progress.

## Philosophy of “governing by nature”

The eternal topic of ancient Chinese philosophy is the pursuit of the harmonious relationship between human and nature. Chinese philosophy pays more attention to the concept of harmony and order, which may provide an answer for the dilemma in the current water resources management. " Lao tze " is a famous political science book, which emphasizes the nature as the core value, and with “governing by nature” as the achievement of the method. The book put metaphysics, dialectics and the “governing by nature” to an organic whole[3], and its management ideas such as“powers as cook fresh" and so on are regarded highly by managers at home and abroad. "Doing nothing" is the core of a Lao tze thought idea, and it is a necessary measure and the way of Lao tze to achieve natural world. Lao tze’s "doing nothing" is not inaction, but the meaning of "governing by nature", namely " As long as you follow the way of nature, everything can be done well." Do things complying with the requirements of the nature is "governing by nature", while against the nature is called " governing by people ".Lao tze, whose thought is generally regarded as metaphysics, is not easy to be understood and is rarely adopted by modern scientific management. But getting rid of the limitations of the ancient philosophy, Lao tze’s thought has an important significance for water resources management in the modern China. Review of China's water resources management process, the government have

changed mode of water resources management, from decentralized management to centralized management, from decentralisation to centralized power, from governing by people to governing by the regime. It is a kind of proof of the philosophy idea of "conforming to the nature of all things without artificial interference." "Governing by people" and "governing by nature", seems to be incompatible, but as methods, they are both the means to achieve the ultimate goal of "governance". The "good governance" in the modern management should strengthen the government public administrative functions and expand the market-oriented reform of urban management.

## The philosophy path of the development of China's water management

At present, the water resources management system in most developed countries is relatively mature, however, the system constructions of water management in developing countries are lacking. In the developing country, the organization form of water resources protection, legal system, administrative system, non-governmental organizations and the technology of protection of water resources have gradually become the study hotspot. In general, the water resources management in China changes from 70 s "doing nothing" to "can do" in recent 20 years, and will present the philosophy of "governing by nature- governing by people- governing by nature" path to the future development,. We think the future of China's water resources management will present the following trend:

**Unified management.** The basic contents of "governing by nature" is integrity, that is to say, the nature and human beings are inseparable as a whole. Since the existence and the change of the universe is an integral system, we should keep the universe as a whole orderly and harmonious. Science and time will prove that the holistic concept is correct. If the harmonious is destroyed by people, it will cause the change of the whole world. The harmony idea has a guiding significance to the sustainable development of economy and society. Since water resources is in the natural hydrological cycle of precipitation - runoff - evaporation, the natural property of water requires it is treated as a complete system for unified management, rather than artificial division management which is separately governed by urban and rural areas, by surface water and groundwater. Therefore, the use of water resources should form a "headwater – water supple - water use- drainage - sewage treatment" circulatory system. Besides, new public management reforms that include of change of government function, government authorization, the enterprise management mode, competition mechanism, etc, should be reference to the water resources management system reforms in order to improve the operational efficiency of the water administration department.

**Comprehensive management.** Water management is a broad concept, which should include the aim, object, method, content and the laws and regulations that ensure the normal order of the management of water resources, as well as the social foundation that ensure water management[4]. The development and utilization of water resources should be in the whole environment, such as social and economic environment. Water resources management is a comprehensive management, such as surface water, groundwater, wastewater, and should be organically combined with the economic structure, ecological system and social development, etc. Water resource forms a natural system according to the river basin, so only the unified management by river basin can provide a rational allocation. In healthy social water cycle process[5], drainage water quality does not destroy the natural water cycle, which relate to environment and ecology. Water management should focus on improving the utilization ratio of water and water repeating utilization efficiency, and reduce the water consumption and water consumption per unit of GDP, so as to realize the social water cycle in harmony with the natural hydrological cycle.

**Governing by both the government and the market.** Water resources management will absorb the market mechanism. The government's management of water economy has reference to the planned economy management mode, but too many "promising and rule" make the market does not play its due role. The government should take the market as a guidance, formulate reasonable water price and pollutant emission standards, in order to implement cost recovery. Besides, the government should establish the reasonable water price system, according to the demand supply ability and

dynamic adjustment of water level of science and technology, and also establish perfect water price accounting to the supervision and management system. The particularity of water resource market determines the water resources allocation can't be completely mediated by the market, therefore, the future water resources management model will change to the model of combination of government and the market.

**Establishing integrated river basin management system.** The legislations and practices of world's developed countries and regions, have reflected the development trend of integrated river basin management, that is, from the traditional watershed management to ecosystem-based integrated watershed management changes, and achieved good results. China should establish integrated river basin management system in order to put economic development, social welfare and environmental sustainability integration, to fit our water resources development, utilization, protection and management needs. In addition, with the establishment of water markets, water disputes will be increasing, so deal with water disputes water resources management will become an important work. Currently there is urgent need for a unified and complete clear responsibilities, rigid, operable water laws and regulations.

**Establishing mechanism of public participation.** In the Lao Tzu's philosophy, system alone will not solve all problems if people's inner state isn't improved, and water management also abides by this principle. Only people improve the inner realm, can they consciously carry out conservation of water resources activities. Only people with the idea of protection of water resources, the harmony of man and nature can be achieved. Through publicity activities to enhance the community's concern for water resources, so that everyone enhanced awareness of water conservation, with "saving" way to build a resource-saving and environment-friendly green living.

## Conclusion

Nature is the way the universe works, and it is a unified and spontaneous action. Everything in the world and every change has its inevitability and has to run through cooperation. History has proved that the development of science and technology often need to pay a heavy price. However, rational human beings should learn from ancient philosophy, instead of killing the goose that lays the golden eggs, that is, beyond the limit load of resources and environment. The ultimate goal of water resources management is to make the limited water resources to create the greatest social and economic benefits as well as the best ecological environment, or, with a minimum investment to meet the demand of the social and economic development of water resources. In order to make the limited water resources can give full play to support and guarantee the development of economy and society, we must philosophize on water resources management, and seek the solution of the "bottleneck" of water management. By complying with the natural law, can we realize the "no exception" target by "governing by nature", and promote the optimal allocation of water resource conservation, utilization and effective protection.

**Key words:** vertical, slotting, impervious wall, gasbag.

**Abstract:** Continuous vertical slotting technology is used in underground excavation, where the underground slots are separated into several sections taking advantage of the elasticity and flexibility of gasbags to construct flexible and rigid underground continuous impervious walls with different materials.

## Introduction

Tension over water resources has arisen, especially in the northern area, with the development of China's economy. Water storage architectures and river engineering projects such as reservoirs and barrages are constantly constructed to alleviate the problem.

In order to solve the seepage problem of newly built reservoir, river foundation and levee body, we have gone further and more extensive in researches on imperviousness technology, proposing and developing technologies of various forms. The research and application of these technologies, among which vertical plastic spreading imperviousness technology is a more functional one, have solved practical problems in engineering to a large extent.

In the massive practical engineering applications of vertical plastic spreading imperviousness technology over the years, quite a few problems have been detected. Therefore, we've come up with an idea of impervious wall construction based on continuous vertical slotting technology and started relevant research on the development and expansion of the technology.

## Two key links in vertical plastic spreading imperviousness technology

Research on vertical plastic spreading imperviousness technology is a scientific research task raised in 1987 by Water Resources Research Institute of Shandong Province. The technology was first brought up as a functional imperviousness technology aiming at the seepage and deformation problems existed in plain reservoir dams and river embankments, is now widely used in areas such as tailings dams and landfill pollution prevention.

Vertical imperviousness of levees, according to the ultimate goal of general design, is to build a vertical impervious curtain in corresponding position. Vertical plastic spreading imperviousness technology is realized following such steps: dedicated slotting machines dig continuous slots of certain width and depth vertically in reservoir dams, river embankments and other soils wanting imperviousness, and then lay geomembrane inside the slots, forming impervious curtains with geomembrane as the main body.

There are two key links within this technology: slotting and geomembrane laying.

(1) Slotting

Slotting is to dig continuous slots of certain width and depth in soil layers with dedicated slotting machines for geomembrane laying.

Depth and length of the slots are determined by the designer according to the geological and other specific conditions on site, while the former depth is generally controlled within 16 meters due to the performance limit of slotting machine.

Width of the slots, usually at around 0.3m, is subjected to the geomembrane laying process requirements; this could meet the demand for geomembrane laying and backfill amount in most engineering projects.

(2) Geomembrane Laying

Geomembrane laying is the main purpose of the technology; among the many laying methods, membrane rod method and direct laying method are more common.

In membrane rod method, a bundle of geomembranes, with width slightly larger than the depth of slots, is rolled up on a membrane rod and set vertically in a slot; with its free end fixed, it could be moved forward along with the slotting machine by a certain traction on the rod the geomembranes on the rod could thus be laid in the slot; a new bundle will be connected to the exhausting one to continue the procedure. Geomembranes are laid vertically in the slots in this way to form a curtain. This method is intuitive, easy to operate and reliable.

Direct laying method is where geomembranes are directly sunk into the slots excessive geomembrane length in each sinking is inadvisable; the depth shall consist with that of the slots, usually at 5-8m. Overlapping length of the follow-up geomembranes with the previous is required to guarantee their continuity; weight is commonly applied to their bottom when sinking. This method shall be chosen after prudent consideration when slots are at a fast accumulation speed.

**Problems**

Years of vertical plastic spreading imperviousness technology spreading and applying has seen various problems, including slot accumulation, animal and plant penetration, engineering adaptability etc.

The problem of slot accumulation is ubiquitous within the engineering application process; there are differences between its speed, quantity and size, though. Some soil has higher particle content; it accumulates faster and thicker, adding up the difficulty and even effecting the quality of geomembrane laying procedure-the laying could be lacking in depth and facilities might be buried.

Burrows are often found in levee slopes during engineering, with termite nests being the most common ones; these do much damage to geomembrane impervious bodies, making them more seepaging-prone. On the other hand, plants are widely distributed on most levees; those with developed roots have a strong penetration of geomembranes. The plants die and wither, but the numerous holes remain on the impervious bodies, leaving risks of seepage.

Researches found that geomembrane has a general aging resistance of at least 50 years, which could hardly qualify some projects. This is another defect of the technology.

Despite the fact that impervious curtains containing mainly geomembranes are low at costs and faster in construction, the above problems have restricted the development of the technology to some extent. Replacing impervious materials using current slotting technology could be an assumption to solve the problems, only if the following key technology problems are tackled. First, the now available slots are continuous; theoretically their width and depth are fixed while the length could be prolonged. Long slots shall be separated into several sections if concrete or other impervious materials are applied; fast separation speed is required as slotting shall not be ceased during construction to reduce the siltation volume-many as the techniques, none of them could adapt the high speed of current slotting machines. Second, it is crucial to develop one or more impervious materials for the slotting technology. Third, multifunction cars could be developed to simplify the wall grouting and slot separating procedure during construction for higher efficiency.

**Discussion on several key technologies**

We have, based on the above assumptions, discussed and started relevant research work.

(1) High-speed slot separation technology

Low-head continuous diaphragm wall is widely used now in hydraulic engineering; sequenced and slotted grouting or coupling adding is used in construction, complexing its procedures, slowing its speed, disabling its continuity, and risking its quality. The wall separating and joining methods have shown under-development; they could hardly meet the needs of current project in cost, speed, quality and other aspects.

Gasbag technology has an extensive application in ocean engineering hoisting, transportation, collision preventing and other areas; the new gasbag is characterized by strong stress resistance, good abrasion resistance, high intensity and fine reusability. A heterotype of gasbag could be developed based on these advantages for slot separation to better solve the above mentioned problems.

So far we have completed the process design work on heterotype gasbag separation body and some of the achievements have been applied for patents.

(2) Impervious material

The main currently used continuous diaphragm wall materials are concrete, cement mortar, and self-solidifying mortar. But considering from the costs and slot adaptation aspects, reinforced self-solidifying mortar applied better to the technology.

Given the ubiquity of slot accumulation, research shall orientate toward the full utilization of soil aggregate from the accumulation-reinforced self-solidifying mortar could be formed by adding a certain proportion of cement, bentonite, other common wall materials and extra to-be-studied additives to it. Relevant work is in progress, aiming at lower costs, and full utilization of local materials, good imperviousness, and good adaption to deformation capacity.

(3) Multifunction Car

The placement and recovery of slot separation bodies, together with wall grouting are two important links during construction; combining the two could add up convenience to construction and improve production efficiency. The process design of multifunction car is in progress, and part of the achievements has been applied for patents.

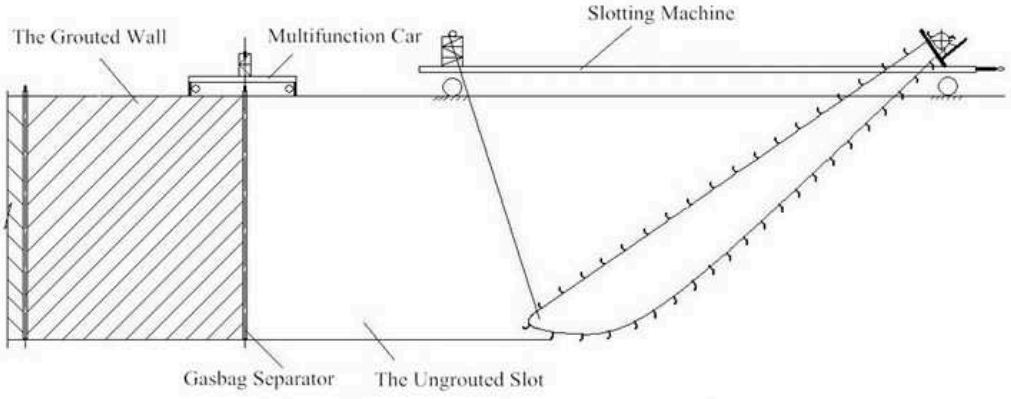

*Diagram of Slotting Technology and Impervious Wall Construction*

Illustrated above is a diagram of current slotting technology and impervious wall construction. The construction process can be included as follows: the currently well-developed slotting machine could dig continuous slots during construction; multifunction car could be used to place gasbags for separation on slotting-slot collapse could be reduced to maximum extent; grouting system from the multifunction car is then used to grout the slots, followed by removing the gasbag separation bodies from the slots with its lifting & recovery system; this whole process of impervious wall construction is finished as the holes are refilled with the same wall material.

## Conclusion

Years of vertical plastic spreading imperviousness technology application has seen good economic and social benefits, making it one of the main technologies in fundamental imperviousness area. Meanwhile, its limitations have been gradually recognized; its core technology of slotting, nevertheless, has great advantages and promising prospects. The simple process and low costs of the slotting technology is the foundation of this research.

The research makes a combination of slotting process, slot separation technology and special wall materials, while taking full advantage of the grout within slotting process and other material characteristics for impervious wall construction. It fills some gaps of vertical plastic spreading technology, and acts as a new imperviousness technology of high practicability.

# Research of Eco-compensation among Basin Cascade Hydropower Station Development and management

Xinmin Zhou[1, a], Meng Zhao[2,b]

[1]Hanzhong Huanghe Medium-Sized Hydropower Development Co．Ltd．Xi'an 710061,China.

[2]State Key Laboratory Base of Eco-Hydraulic Engineering in Arid Area （Xi'an University of Technology),710048, China.

[a]526451716@qq.com, [b]myles.910129@gmail.com

**Keywords:** Eco-compensation, cascade hydropower stations, environmental impact.

**Abstract.** Eco-compensation was involved in many subject area, and the concept and connotation of Eco-compensation were discussed from the multi-disciplinary perspective by the scholars of different research areas. Hydropower, as one kind of green energy,is an important component of the China's energy development. Owing to the delay of the cumulative effect on ecological environment caused by hydropower development, the unbalanced distribution of interests between the cascade hydropower stations, and the mass of industry and departments involved in cascade hydropower development, Eco-compensation system of the cascade hydropower development is becoming more complicated.For this reason, it is significant to analyze the environmental impact during cascade hydropower development, and to establish a full Eco-compensation mechanism for the cascade hydropower development. In this paper, the basic framework of the Eco-compensation system includes five parts: the subject, the object of compensation, compensation standards and methods of determining compensation, forms of compensation, process control of compensation, then the content of these five aspects was detailed. On this basis , the problems which should be solved urgently in the cascade development of Eco-compensation mechanisms have been advised,these discussion and analysis will provide some reference for the further research and practice.

## Introduction

The development(CHSD) of these basin cascade hydropower stations,which include Lancang river, Jinsha river, Huanghe, Dadu river, Wujiang and Hongshui river,speed up the process of hydropower development(Yun-long, 2006),concurrently the development of hydropower resources produces the negative influence to ecological environment. The distribution of ecological and related economic benefit is unfair between the protectors and beneficiaries, destroyers and victims for the ecological environment.The beneficiaries have the ecological benefits freely,the protectors cannot get the economic incentives,the destroyers failed to take responsibility and cost of the environment destroyed, and the victims cannot obtain economic compensation.The distortion of the relationship between ecological protection and economic interests is not merely facing great difficulties in ecological protection and water conservancy construction but also affecting the balance between the different regions and other ecological protection and construction.In order to ensure the river basin water resources and ecological protection as well as economic development, the performance of environmental protection responsibility of hydropower developers should be promoted,we should establish the Eco-compensation system of cascade hydropower stations development and bring the system into the environmental impact assessment which has important significance(H. WANG, 2008).

The Cascade hydropower stations is different from the independent hydropower stations in the aspect of the water use, operation scheduling, production management and external contact etc.Concurrently the cumulative effect from the Cascade hydropower stations development on the ecological environment has delayed,the distribution imbalance of interests is between the different cascade hydropower stations, the Cascade hydropower stations is involved in many departments and industries which make the Eco-compensation system of cascade hydropower stations development

more complicated.At present,there are a lot of researches on hydropower development including Eco-compensation theory,ecological value theory and environmental impact prediction in China(RUAN, XU, & ZHANG, 2008).However, these focus on the single hydropower stations,the Cascade hydropower stations research is less.This paper tries to design an integrate framework for the Eco-compensation system of cascade hydropower stations development to introduce briefly some concept such as the subject of Eco-compensation,the object of Eco-compensation,the standard of Eco-compensation and the method of standard determination, the form of Eco-compensation,the action or process control of Eco-compensation in this system and to give some reference and enlightenment for the further research.

**the Connotation of the Eco-compensation System in CHSD.**

Due to the Eco-compensation involved with many fields of study,different scholars in the field of study discuss the concept and connotation of the Eco-compensation from the different views of subject.Hydropower development of Eco-compensation can be defined the series of activities in the compensation, recovery, comprehensive treatment etc. on the ecological system, natural resource and pollution of the environment which have destroyed by hydropower development and related industry(Lv, 2003).

The scale and characteristic of the CHSD determine the important impact on the environment.Reasonable Eco-compensation system should be fully considered its environmental effect,social effect and ecological effect and make these effects convert to economic information feedback to the planning and management of the national economy,in this way the theory and method can be offered for feasible scheme of solving environmental problems (C. Wang, 1994).According to the current market economy system and the environmental protection laws and regulations, the CHSD Eco-compensation should follow some basic principles:(1) valley ecology and system theory principle,(2) environmental resources and pay for the use of the principles of sustainable development, (3) the ecological threshold value and internalization principle of the external cost .

**the CHSD Eco-compensation System**.

The CHSD Eco-compensation system should include the following five aspects of content:(1) the Eco-compensation subject,(2) the Eco-compensation object,(3) the Eco-compensation standard and ESTABLISH standard approach,(4) the Eco-compensation forms,(5) the Eco-compensation action and process controller, here are emphasis on fifth point because in the current conditions active and conscious the compensation rarely appears.

**2.1Eco-compensation Subject**.

Hydro developers is an important subject of Eco-compensation.The CHSD Eco-compensation is involved in water conservancy, shipping, power, irrigation, flood control, ecological, environmental protection, tourism and so on, there is a single department not running normally.At present in China,only the government can represent the organization of whole basin in the public interests and can play a role in the CHSD Eco-compensation,and it can properly solve the contradiction between the basin ecological construction and the economic development ,and it has the ability to resolve the environmental problems which cannot be solved spontaneously by market with regard to making laws and system, the macroeconomic regulation and control, policy and financial support,and it will become a leading role in the CHSD Eco-compensation(WU & CHEN, 2007).

**2.2Eco-compensation Object.**

First of all, the basin CHSD changed the utilization of the original water and soil resources .For example the reservoir discharged lower water temperature have an influence on agricultural and fishery production efficiency and output,and the reservoir may increase the underground water level in the future to cause the salinization of cultivated land around(FU, CHEN, & XIE, 2009), therefore the Eco-compensation subject must make up to the local governments, units and individuals whose interests are affected to make corresponding compensation.Secondly, the compensation of the ecological environment and the public environment is important and difficult. Because the environmental influence by CHSD is delaying,a lot of ecological problems appear after the accumulation of a long time , once the ecological balance is destroyed ,it will make a great of loss and the local residents need to spend a lot of manpower and finance to protect the environment and

establish a new ecological balance. These loss including biodiversity, soil erosion, water pollution as well as geological disasters, cannot be directly measured and compensated in economic way,and need long-term environmental monitoring and protection to prevent the happening of the adverse consequences in the future.All of these forms of compensation for the ecological environment and public environment, in essence, are repair and protection to ecological environment(CAO & LIU, 2010).Finally the ecological environmental protectors and residents in the reservoir area pay for the protection of the basin ecological environment, which profoundly impact their economic benefit and ecological benefit, and the local government need to compensate for them.

**2.3the Eco-compensation Standard and Establish Standard Approach**

Eco-compensation standard is the core of Eco-compensation in the CHSD and it is related to the effects of Eco-compensation and the bearable ability of the Eco-compensation object. Only when the government make a scientific and reasonable evaluation for ecological loss can we construct Eco-compensation mechanism successfully.

**2.3.1the Basis of Compensation Standard**

The calculation basis of CHSD Eco-compensation standard can be considered generally from the following six aspects:

(1) Ecological cost estimation. We must have to evaluate the impact, which will be caused by the CHSD. But most of the environmental impact is not directly measured by market value and is hardly expressed in money. In this condition we will need to use the substitute market method, by estimating the cost of the same amount and quality of ecological services and product,to infer the costs of the impact in CHSD.

(2) To calculate the profit of ecological environmental beneficiaries.Ecological beneficiaries did not pay for own products and services enjoyed,which makes ecological environmental protectors not get right reward ,and the beneficiaries need to pay these reward for them. Therefore, the Eco-compensation standard can be calculated by the market trading price of the product or service and the quantity of trading .

(3) To calculate the cost of ecological environmental recovery. The CHSD will cause the destruction of vegetation, water and soil loss, water resource wastage and biodiversity reduction in some areas, then these will directly affect ecosystem services function of water conservation, water and soil conservation, landscaping, climatic regulation and biological feed in these areas. Therefore, according to the principle of whoever damage recovery, we need to calculate the cost of environmental improvement and ecological environmental recovery as a reference for the Eco-compensation standard.

(4) To calculate the value of ecosystem services. The standards in the index and estimates of the value still lack an unified standard and has a larger gap between the compensation ability of ecosystem service function and realistic compensatory ability. Therefore, generally in accordance with the ecosystem services function to calculate the compensation standards is only as a reference and theoretical limit of compensation(Chen, 2010).

(5) The willingness to pay of Eco-compensation subject.Willingness to pay is the developer and beneficiaries of the CHSD who are willing to pay the amount of economic compensation money for the CHSD.

(6) Payment capacity. Local fiscal capacity and CHSD payment capacity is an important aspect and must be considered in the process of CHSD Eco-compensation.

**2.3.2the Establishment of Standard Approach**

According to the research at home and abroad, for the Eco-compensation, using ecological service function value assessment is difficult directly as compensation and is operable with the loss of opportunity cost accounting.The establishment of Eco-compensation standard is usually measured from two aspects:on the one hand, how much is the cost of ecological environment which will be protected and which will be constructed by the Eco-compensation subject in the CHSD area;on the other hand, how much is the value of ecological resources themselves and the other ecological value which has destroyed by the CHSD.At present,establishing standard approach basically has the following five methods:

(1) Cost-effect method. This method is based on ecological resources provided by environment effect to calculate the effect of quantitative values.

(2) Income loss method. This method is mainly evaluating the benefits of ecological resources from the point of the loss of ecological resources.

(3) Travel cost method.This method is established on the Recreation demand patterns and mainly applied to evaluate the specific tourist area. It is the most widely used in developed countries as an indirect evaluation method(Qiu-cheng, 2009).

(4) Market valuation method.Ecological change will lead to the change of productivity and the cost of production. Therefore,this kind of change can be calculated the value of ecosystem products and services.

(5) Survey evaluation method.In order to obtain the individual value of ecological products and services, we must obtain the money maximum amount of willingness to pay for ecological products and services(F. Wang, 2006).

**2.4the Eco-compensation Forms**

The government compensation and market compensation are consist of the Eco-compensation forms.Government compensation can be interpreted the compensatory way of government's fiscal transfer payment and policy support to implement compensation mechanism.The compensatory way can be divided into money, objects, policy, economic cooperation and technical support,which is shown in Fig.1 below.

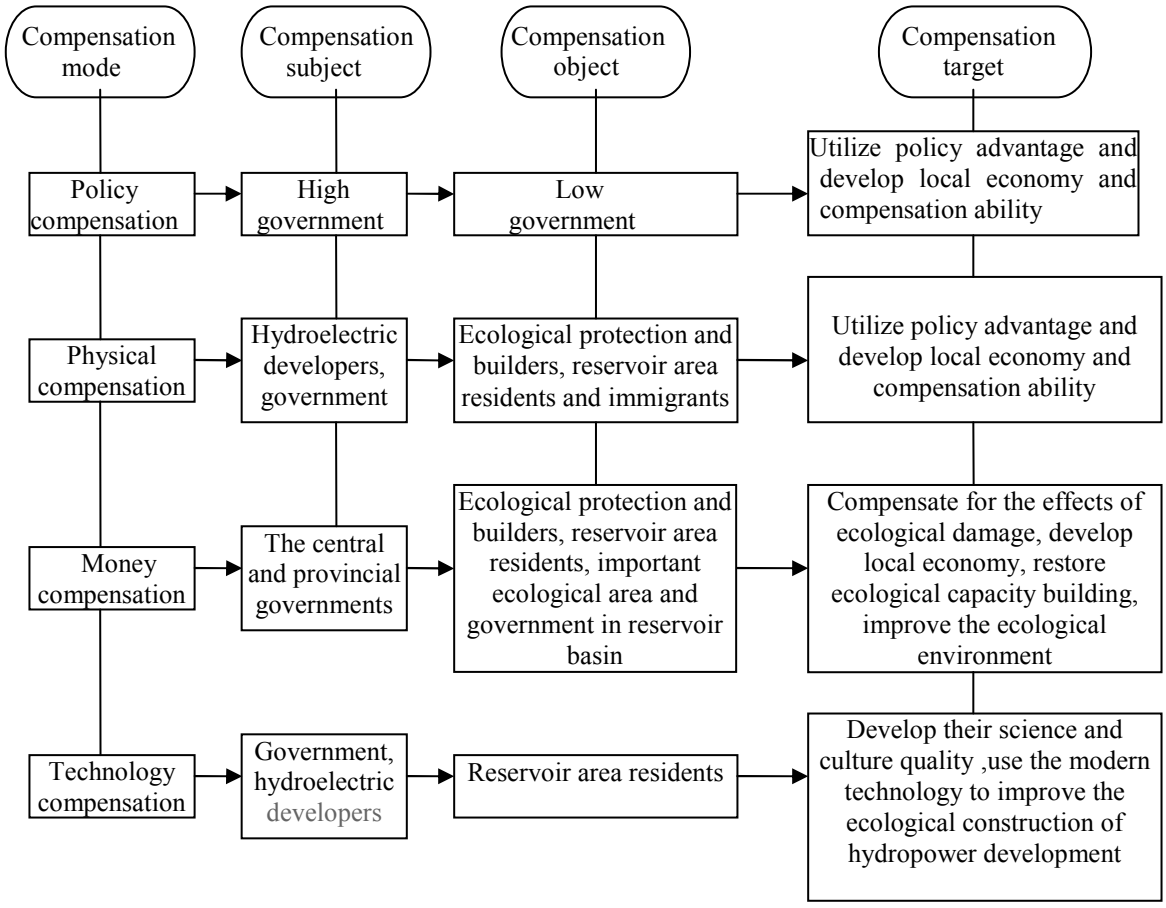

**Fig.1 Schematic Diagram of Compensation**

Market compensation is the voluntary negotiation between the Eco-compensation subject and object in the river basin upstream and downstream under the guidance of the government implement.The main way of market compensation can be used from two aspects:on the one hand,to adopt the model of basin water agreement implements rewards and punishments or compensation according to the standard. On the other hand, the water right transfer and emissions trading mechanisms is carried out(Jun, Huiyuan, & Jinnan, 2005).

**2.5the Eco-compensation Action and Process Controller**

In order to rationally develop and utilize the hydroelectric resource and reliably protect the ecological environment,under the current circumstances, our nation and local government need to summarize practical experience of the Eco-compensation and more strengthen law enforcement of the environmental protection and carry out the necessary and compulsory administrative intervention. We must involve the hydroelectric resource Eco-compensation into standardized and legalized track.

**the Problems Existing in the CHSD Eco-compensation**

Because the current cumulative effect research of ecological environment of river basin CHSD is not very deep and the CHSD joint operation technology is complexity and its benefit compensation mechanism is pluralism.There exist the following problems in the CHSD Eco-compensation mechanism, which will be established(Mao, 2009):

(1) The cumulative effect of ecological environment impact on Eco-compensation.The cumulative effect is the superposition and expanding of human activity space-time distribution impact on ecological environment(ZHONG, LIU, & GENG, 2007).

(2) The compensation benefits between the hydropower stations have some impacts on the Eco -compensation.The hydropower stations joint development and operation can save investment, shorten the construction period, increase the capacity, improve the management level and has obvious advantages. But the benefits of the investment subject between the hydropower stations would be changed,this part of the change is the watershed of compensation benefits. How to define and apportion these benefits is a problem to be solved in utilization of river basin water.

(3) Strengthen and increase the consciousness of public participation in Eco-compensation.The CHSD Eco-compensation, as a kind of economic means, is the redistribution of economic interests involving many Eco-compensation subjects and benefit adjustment. Therefore, this will need all social classes and the public active participation in the process of determining the CHSD Eco-compensation and especially pay close attention to opinion of the disadvantaged(Li, 2009).

# Research on Channel Regulation Parameters of Daijiazhou Reach in Middle Yangtze River

Wanli LIU [1, a]

[1] Key Laboratory of Engineering Sediment of Ministry of Communications, Tianjin Research Institute for Water Transport Engineering, Tianjin 300456, China

[a]tjtgliuwanli@163.com

**Keywords:** regulation water level; regulation width; channel regulation parameters

**Abstract.** Channel regulation parameters include two important indicators, the regulation water level and regulation width. Through shoal-full water level method, bed-forming discharge method and experience method, the regulation water level was presented. At the same time, through calculation method and experience methods used in sufficient depth channel, the channel regulation width was put forward. The relevance between the regulation water level and regulation width was established. The specific regulation parameters were adopted in Daijiazhou reach.

## Introduction

Determining reasonable regulation parameters is the most important technical work in channel regulation [1-2]. Channel regulation parameters include two important indicators, the regulation water level and regulation width, and the two indicators are relevant. In the past, the correlation analysis of channel regulation parameters had not been studied through theoretical research and quantitative analysis. Therefore, on the basis of previous researches, it is necessary to study on regulation parameters relevance, in order to promote the development of channel regulation subject.

## Basic situation about projected river reaches

Daijiazhou reach located in in the middle Reach of the Yangtze River. It connects with Shazhou channel upward and Huangshi channel downwards. The total length is about 34 km (as shown in Fig.1), which includes Bahe channel and Daijiazhou channel. From the Ganyinge to Bahekou is the Bahe channel, length is about 14 km, the plane morphological is straight to relax. From the Bahekou to Huifengji is the Daijiazhou channel, length is about 20 km, the plane morphological is the micro bend branch, Daijiazhou channel is one of shallow channel in the middle Yangtze River.

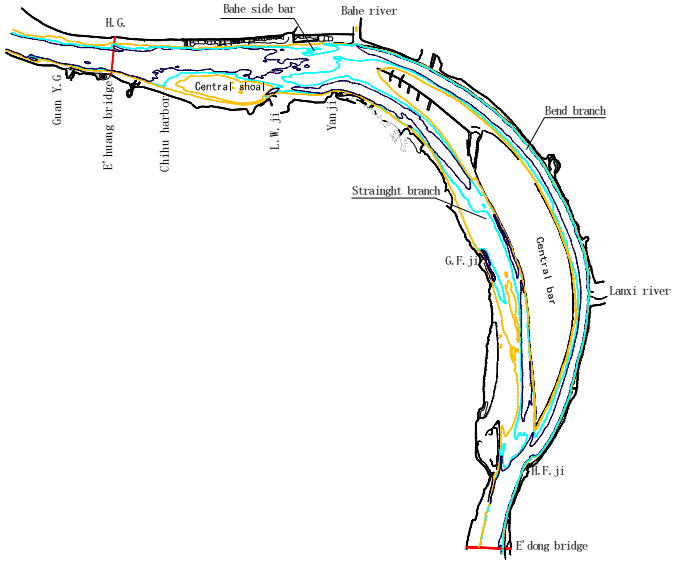

Fig.1 River regime of Daijiazhou reach in middle Yangtze river

The channel regulation target is 4.5 m ×200 m×1050 m; the navigation guaranteed rate is 98%. In order to achieve the channel regulation target, channel regulation engineering needs to be carries. Choosing the reasonable channel regulation parameters is the basic to determine the channel regulation project [3].

**Regulation water level**

In order to determine the regulation water level, this paper uses the bank full water level method, bed forming discharge method and experience method.

**The shoal-full water level method.**

This paper uses the average elevation of the side shoal as the regulation water level. Channel verification show that, when the new island beach full, tall and outstanding, the straight channel conditions was significantly improved. Since 1984, when the channel condition is good in the straight channel, by statistics the bank full water level of the low beach, calculate the side shoal every year average based on the navigation 0.8 m~1.6 m.

**The bed-forming discharge method.**

The river bed formation is concerned with the size of the flow, frequency and gradient, to determine the approximate regulation water level, this paper uses the $Q\sim Q^2JP$ curve (as shown in Fig.2).

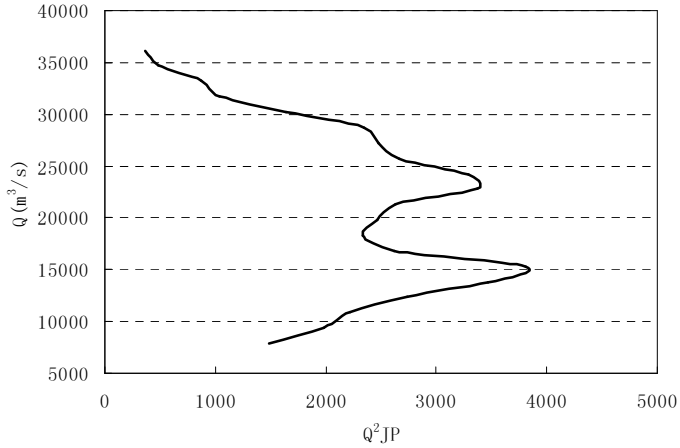

Fig.2 The relationship between Q and $Q^2$ P

It can be seen that the two river bed forming peak discharge is obvious, and regulation water level can be intended to be the second level bed flow corresponding. In the $Q\sim Q^2JP$ Curve, corresponding to the second bed building discharge (flow discharge is 15324 $m^3/s$), the corresponding water level is 11.64 m, higher than the design water level above 3.8 m.

**The Experience method.**

According to Riverbed revolution and channel regulation [1], the Riverbed Evolution and Renovation", regulation water level is higher than the general design water level above 0.7 m ~ 1.5 m.

According to the existing engineering experience data and other shoal regulation research results in the Yangtze River[3-5], it has a reference to determine the regulation water level (as shown in Table 1). By the statistics, as a general rule, the regulation level generally is higher than the design water level 2.5 m ~3 m. Considering the regulation water level deriving primarily based on the data before storage, using these experiences to after storage may have certain deviation. Considering the Three Gorges after 175 m impoundment, at present, the river dry season water function has been given to full play, the channel conditions has improved, the construction elevation should be lower than implementation project before storage, and as the reservoir impoundment, if the river bed undercutting, at the same mass flow dry water level will decreased, while the elevation relatively short project will relatively increase with dry water level decreasing, thus win the good channel dimension security, which is equivalent to through a spur dike engineering to form the good and favorable high beach.

Table1 The existing research results of water level in the middle and lower Yangtze river

| channel | Jiepai | Luxikou | Luohuizhou | Wuxue | Zhangjizhou south | Dongliu |
|---|---|---|---|---|---|---|
| Above the design water level（m） | 3.0 | 3.0 | 3.0 | 2.5 | 3.0 | 3.0 |

**Regulation width**

Through calculation method and good experience method, the channel regulation width is put forward.

**The calculation method.**

According to Waterway regulation Engineering technical standards, the regulation width calculation formula as follow:

$$B_2 = KB_1\left(\frac{H_1}{\eta H_2}\right)^y$$

Where $B_1$=water surface width when the regulation water level before renovation; $B_2$=regulation width (m); $H_1$=section average water depth under the regulation water level before renovation; $H_2$=channel design section average water depth under the regulation water level; K=1.0, η =1.0, y=4/3.

The calculation parameter into the formula getting the Bahe channel regulation width is 1193m, the straight channel regulation width is 911m (as shown in Table 2).

Table2 The regulation width calculation value

| Channel/ branch | $B_1$（m） | $H_1$（m） | $H_2$（m） | $B_2$（m） |
|---|---|---|---|---|
| Bahe channel | 1700 | 4.6 | 6 | 1193 |
| Bend channel | 630 | 4.3 | 5 | 515 |
| Straight channel | 1150 | 4.2 | 5 | 911 |

**The experience method in sufficient depth channel.**

When Daijiazhou Reach channel condition is good and the beach type is relatively good, the excellent river cross-section transition section has choose as the simulation object, establish the correlation between the river width under the regulation water level and the minimum water depth within the provision navigation width under the design water level (as shown in Fig.3). From the figure, Bahe channel average river width of is about 1200 m, straight channel average river width is about 900 m.

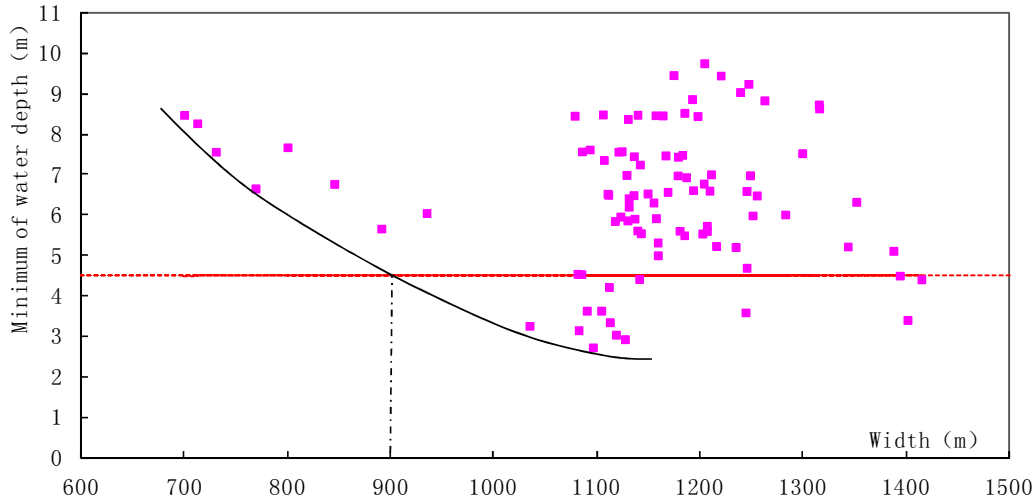

Fig.3 The relationship between the river width and the minimum water depth

**Determine the regulation parameters**

According to the conservation principle, this paper derived the regulation parameters relational expressions:

$$(B_0 - B_2)\frac{1}{n}(H_1 - H_2)^{5/3} J^{1/2} = (B_1 - B_2)\frac{1}{n} H_1^{5/3} J^{1/2}$$

Where $B_0$=low water river width; $B_1$=straight channel regulation width I (900 m); $B_2$=straight channel regulation width II; $H_1$=corresponding depth under regulation level I (8.84 m); $H_2$=corresponding depth under regulation level II. The $B_0$, $B_1$, $H_1$ into the formula, when the straight channel regulation width ($B_2$) is 850 m; the straight channel regulation width narrow 50 m, which compared to $B_1$, $H_2$ is about one meter lower than $H_1$.

At the same time, by physical model and mathematical model [6-7], the engineering effect for different height, different length were tested and calculated. When the regulation water level is 7.84 m, the regulation width is 850 m; when the regulation water level is 8.84 m, the regulation width is 900 m, the two values all are considered to be appropriate.

**Conclusions**

The channel regulation parameters were studied by using several methods. The results showed that the two channel regulation parameters are relevant, and the correlation expression was proposed. Based on the physical model and mathematical model of Daijiazhou reach in middle Yangtze river, the engineering effect for different structure height and length were tested and calculated. It turned out that when the regulation water level is 7.84 m, the regulation width should be 850 m, meanwhile, when the regulation water level is 8.84 m, the regulation width should be 900 m. The both sets of figures are considered to be appropriate, and it can be well applied to engineering implementation.

# Research on the Feasibility of Water Diversion Project

Lihua Zhang[1,a] , Guanghui Wang[2,b] and Xiaohui Hao[3,c]

Water Resources Research Institute of Shandong Province, Ji'nan,Shandong,250013, China

[a]lily9804@126.com, [b] 691388339@qq.com, [c] 541077436@ qq.com

**Key words:** Water Resources Shortage; River and Reservoir Networking; Regulating Reservoir (Diversion and Storage Reservoir); Water Pumping Station; Long Distance and High Lift Water Delivery

**Abstract:** The research on the feasibility of Feicheng Water Diversion from Dawen River Project is based on a thorough investigation in the actual condition of water resources in Feicheng city. It is found that on the one hand this city has been suffering from water shortage, while on the other hand it has allowed most of the water flowing away in vain from Dawen River, which runs through this area. To resolve this contradiction, this research demonstrates the feasibility of networking of Dawen River and Shangzhuanglu Reservoir through engineering measures to realize the optimal allocation of water resources

## Project Introduction

Located in the west of Mount Taishan, Feicheng city is one among the basic economic competitiveness top 100 in national country-level, among the most regional power top 100 for national small and medium-sized cities and among provincial ecological economy top 10. However, its multi-year average total water resources is 260,000,000$m^3$ , and per capita water resources is 271$m^3$ , taking up only 12% of that of the country,84% of that of the province and 76.3% of that of the Taian city. With the rapid development of the construction of small towns and local industries at present, water consumption will grow gradually, and the shortage of water resources has become the bottleneck restricting local economic development.

Runing through the south of Feicheng, with a length of 36.42km within this city, Dawen River is one of the main guest water resources in Feicheng city. The water from Dawen River runs through with a great amount, but with a very low utilization rate. In order to overall use these surface water resources, some project measures are presented after field reconnaissance, relevant information reference and consultations with the local authorities. These measures will be used to divert the remaining water from Ansun Trunk Canal to Shangzhuanglu reservoir for regulation on the condition of meeting the needs of Ansun Irrigation area, which will make the preliminary target of realizing the water supply to urban and Bianyuan industrial park, and maximizing the utilization of the guest water resources from Dawen River.

## The Necessity of Project Construction

2.1The project construction can solve the increasingly prominent contradiction between supply and demand of water resources

With a multi-year average precipitation of 658.8mm, Feicheng city is seriously poor in water. Its rainfall has a large interannual variation and is distributed uneven temporally and spatially, which are easy to cause alternating droughts and floods or continuous draughts. It is estimated that the

water shortage of the whole city is 106,000,000 $m^3$ at the 75% guaranteed rate in current year. At the same time, the excessive exploitation of underground water due to large water consumption has caused an overdraft area of 256$km^2$ underground [1]. This increasing prominent contradiction between water supply and demand makes it very necessary to implement the water diversion project to maximize the surface water availability to meet the requirements for industrial and agricultural development.

2.2 Project construction is necessary for agricultural irrigation

There are 5 small (I) and 13 small (II) reservoirs with total utilizable capacity of 10,099,000 $m^3$ in the Shangzhuanglu reservoir controlling basin, which makes the inflow water relatively inadequate. According to the operation situation of reservoirs in many years, their perennial inflow water is about 3,000,000 $m^3$, which is much lower than the utilizable capacity of 10,140,000$m^3$ and is not able to meet the requirements of irrigation for 21,000 acres of area. The implementation of this water diversion project will enlarge the effective irrigation area in Shanzhuanglu and improve the guaranteed rate of irrigation.

2.3 Project construction can meet the needs of water supply for ecological purpose in urban area

Longshan River runs across Feicheng city from west to east. It twists and turns like a long jade belt, making a belt shape of park in the south of the city. However, its natural look and the surrounding landscape are diluted due to the upstream shortage and serious siltation. This water diversion project will divert the water from Shangzhuanglu reservoir to Longshan River through pipes to meet the need of ecological water use in urban area.

**The feasibility of project construction**

3.1The water resources can meet the needs of diversion project

The inflow water of Dawen River comes from the series of data measured from 1956 to 1999 and the deducted calculation of data from 2000 to 2007 in Linwen hydrological station, which is located in the upstream 3km from Zhuanshe dam. It is analyzed from above data that the inflow water are 780,000,000$m^3$ , 370,000,000$m^3$ and 120,000,000$m^3$ respectively under the guaranteed rate of 50%, 75% and 90%.

Water balance calculation result shows, in the condition of inflow guaranteed rate of 90% and full load operation of Water Diversion Project, the first-stage project can divert 34,670,000 $m^3$ of water from Sun Trunk canal per year to ensure water supply of both 5,000,000$m^3$ per year for industrial and urban purpose respectively and 16,150,000 $m^3$ for agricultural purpose along its way and for ecological purpose in Xiaohui River, the second-stage project can divert 34,670,000 $m^3$ of water from Sun Trunk canal per year to ensure water supply of both 10,000,000$m^3$ per year for industrial and urban purpose respectively and 6,160,000 $m^3$ for agricultural purpose along its way and for ecological purpose in Xiaohui River

Therefore, the water resources can meet the needs of water diversion project.

3.2 It is technologically feasible for water diversion project

Shangzhuanglu reservoir is medium-sized. Its flood control and water storage capacity were improved greatly with its utilizable capacity reaching 10,140,000 $m^3$ after 2010, when it fulfilled its enforcement task. The water diversion project can fully use its larger utilizable capacity to divert the water to meet the needs of water supply for industrial purpose in dry seasons.

Three pipelines will be set for the water diversion project. There are no obvious block buildings along the lines, and the pumping stations and pipelines have a good geological and topographical condition, which makes an easy construction possible. Therefore, the project is technologically feasible.

The Zhanghou reservoir under construction has both regulation and wetland purification function. The inflow water from Ansun Trunk canal will be purified preliminarily after running through Zhanghou Reservoir.

3.3The water diversion project is economically feasible

According to the preliminary financing draft, the project from intake gate to Shangluzhuang reservoir will be invested by government, the fund of the middle part from Shangzhuanglu reservoir to urban section will come from government investment half, while the other half comes from bank loan, the fund of the other part of the project from Shangzhuanglu reservoir to Bianyuan industrial park will come from bank loan totally. In normal flow year, with full load operation, the cost of water diversion for industrial purpose will be ￥1.01/ $m^3$ for the first stage and ￥0.80/ $m^3$ for the second stage of the project, the cost of urban water diversion will be ￥1.24/$m^3$ for the first stage and ￥0.97/$m^3$ for the second stage. Therefore, it is economically rational to implement this water diversion project.

## General programming

4.1Project scale

The designed water flow is 2$m^3$/s. The industrial and urban water supply is both 5,000,000$m^3$ per year for the first stage and is both10, 000,000$m^3$ per year for the second stage. According to the above specifications, this project is belonged to medium-sized water diversion project, and is rated as grade III. The main constructions like water transmit project, pumping station, and sluice are graded as level 3.

4.2 Overall deployment

The project of water diversion from Dawen River consists of water intake project, water transmitting project and pumping stations, etc. Its overall deployment is as follows:

Set an intake sluice in the eastern side of Zhanghou Hollow dam of Ansun Trunk canal and transmit water to Zhanghou reservoir, and there in the pumping station the water will be pressurized and then transmitted into Shangzhuagnlu reservoir through the pipelines set along the Xiaohui river, waiting for regulation. After being pressurized in the down stream of reservoir, the water will be diverted to Bianyuan industrial park through pipelines. At the same time, set Moshan pumping station in the upstream of Shangzhuanglu reservoir, where the water will be pressurized and then diverted to Feicheng city through the set pipelines

## Main construction

5.1 Water intake project

Intake sluice and regulating sluice will be set in the eastern side of Zhanghou hollow dam of Ansun trunk canal. Both sluices have two holes, each 2.0m wide. The sluices have steel doors with a height of 2.5m and piers and plates with reinforced concrete structure.

The channel of Xiaohui River, located in the upstream of Zhanghou hollow dam, has formed into a rather large area of wetland due to its low-lying location. In this project, the wetland will be built into a small (II)-sized reservoir with capacity of 300,000 $m^3$ by dredging and down digging, and renovating on both sides of its embankment.

In order to facilitate the operation management of water diversion project, the top of dam will be designed to be 6m wide and be paved with asphalt according to traffic requirements, and the altitude will be determined by the flood control plan of Xiaohui River channel

5.2 Water transmitting project

The water pipeline is divided into three sections. The first one, with two RPMs of diameter 1000mm, is 9km long from Zhanghou Pumping station to Shangzhuanglu reservoir. The second one is 12km long from Shangzhuanglu reservoir to industrial park. It has also two RPMs with diameter of 600mm, of which one will be set in the first stage and the other will be set in the second stage. The third line is 18km long from Moshan Pumping station to Feicheng city. One RPM with diameter of 800mm and one RPM with Diameter of 600mm will be set in the first stage and second stage respectively.

5.3 Pumping station

There Pumping stations will be constructed, including Zhanghou pumping station, Shanghzhuanglu Pumping station and Moshan pumping station. Zhanghou Pumping station will be located in the north of Zhanghou reservoir, Shangzhuanglu Pumping station will be in the downstream of its reservoir and Moshan pumping station will be in the original address where Moshan pumping station was located.

The designed water flow of Zhanghou Pumping station will be $2m^3/s$ and the designed lift height will be 50m, according to which, three single stage double suction centrifugal pumps will be applied for the first stage, and five will be applied for the second stage, among which one is used for emergency.

The designed water flow of Shangluzhuang Pumping station will be $0.25m^3/s$ for the first stage and $0.50m^3/s$ for the second stage with a designed lift height of 30m. Two single stage double suction centrifugal pumps will be applied for the first stage, and three will be applied for the second stage, among which one is used for emergency.

The designed water flow of Moshan Pumping station will be $0.5m^3/s$ for the first stage and $0.7m^3/s$ for the second stage with a designed lift height of 70m. Four single stage double suction centrifugal pumps will be applied for the first stage, and five for the second stage, among which one is used for emergency.

## Conclusion

The water diversion project from Dawen River is a multi-purpose project mainly used for industrial purpose, and also for agricultural and urban ecological purpose. On completion of the project, the annual water flow will reach 34,960,000 $m^3$ and the annual water supply scale will reach 10,000,000 $m^3$, which can meet the needs of Bianyuan industrial park, and can also meet the needs of urban area for ecological purpose to improve the local ecological environment to become a new economic growth point locally. Therefore, this project is technically and economically feasible, and will bring notable benefits in economy, society and environment.

# Simulation Method of Particle Size Scale for Fine Sand Model

Wanli LIU[1, a] , Xiaofei LIU[1], Peijiu YUE[1]

[1] Key Laboratory of Engineering Sediment of Ministry of Communications, Tianjin Research Institute for Water Transport Engineering, Tianjin 300456, China

[a]tjtgliuwanli@163.com

**Keywords:** movable-bed model; gravity similarity; resistance similarity; particle size scale

**Abstract.** In sediment movable bed model, the basic similar conditions include the flow movement similar and the sediment movement similar. In water flow movement similar conditions, the velocity scale of the Freund's similarity and resistance similarity is inconsistency, and the flow resistance is the function of bed material grain size and flow intensity. In sediment movement similar, the particle size scale forms are not consistent too, and they are also related to the flow conditions, so the sediment partial size scale is difficult to determine. According to the research, the similar conditions can be focused on primary and secondary one, and put the primary one as the design basis. In view of the waterway regulation, the regulation flow discharge should be the design basis, others allowed a certain deviation; In the straight reach, resistance similarity should be the design basis, Freund's similarity allowed a certain deviation; In the bend reach, the Freund's similarity and resistance similarity should be simultaneously satisfied; For the bed load model, the incipient motion should meet similarity condition; The suspended sediment model should meet the sediment suspension similarity; For the non-uniform sediment, median particle size should be the design basis. According to the above principles, the sediment particle size scale can be determined.

## Introduction

Plain rivers are generally the fine sand river bed. In the model design, the basic similar conditions include the water flow movement similar and the sediment movement similar conditions. In addition to Freund's similarity, other similar conditions all include particle size scale. So the particle size scale is the key scale in the movable bed model design (as shown in Fig.1). Because the similar conditions of theoretical foundation are different, so the particle size scale is inconsistent, and they are related to the flow conditions. Due to the flow conditions of the two scales are also inconsistent, the contradictions are intricate too. How to correctly and reasonably determine the particle size scale is a major problem in the movable bed model design. So far, researches on this problem are still insufficient [1-5]. So it is necessary to carry on the further research and put forward the design method about the particle size scale.

Fig.1 The fine sand simulation of movable-bed model

**Basic similar conditions**

**Flow movement similar conditions.**

The flow movement similar conditions are as follows:

Gravity similarity:

$$\lambda_U = \lambda_h^{1/2} \tag{1}$$

Resistance similarity:

$$\lambda_U = \lambda_h^{2/3} / \lambda_n e^{1/2} \tag{2}$$

**Sediment movement similar conditions.**

The sediment movement similar conditions are as follows:

Sediment starting similarity:

$$\lambda_{U_0} = \lambda_U \tag{3}$$

Sediment suspension similarity:

$$\lambda_\omega = \lambda_U / e^m \tag{4}$$

Where $\lambda_U$ =average velocity scale; $\lambda_h$ =average flow scale; $\lambda_n$ =roughness scale; e=model variable rate, that is the reciprocal of slope scale; $\lambda_{U_0}$ =incipient motion velocity scale; $\lambda_\omega$ =sediment deposition velocity scale; m=prototype sediment suspension index function, the change interval from 0.5 to 0.75, the average value is 0.63.

**Determine the incipient motion velocity**

**Incipient motion velocity of prototype sediment.**

At present, most of sediment incipient motion velocity formula lack the natural river measured data, in principle, which cannot be used to estimate the prototype natural rivers. If the measured bed load sediment transport rate and velocity curves exist, which can be conveniently extended to sediment transport rate close to 0, this velocity is approximated the incipient motion velocity; if there is no field data, the following equation is suggested [4], that is:

$$U_0 = 0.512\sqrt{\frac{r_s - r}{r}}[D^{3/4} + 2.5(0.7 - \varepsilon)^4 / D]^{1/2} h^{0.2} \tag{5}$$

Where $U_0$ =prototype incipient motion velocity(m/s); $\gamma_s$ =sediment bulk density; $\gamma$ =water bulk density; D=sediment grain size; $\varepsilon$ =sediment porosity, general the value is 0.4.

It should be pointed out, natural river water, sediment and bed sand sizes are varied, so no matter what prototype incipient motion velocity determining methods are approximate.

**Incipient motion velocity of model sediment.**

The following equation is suggested for cohesive model sediment, that is:

$$U_0 = 1.14\sqrt{\frac{\gamma_s - \gamma}{\gamma} gD}\left(\frac{h}{D}\right)^{1/6} \tag{6}$$

Cohesive model sediment can still use formula (5), model sediment incipient motion velocity is not only related with $\gamma_s$ and D, but also related with the physical and chemical properties of materials, formula (5) and formula (6) can only be used to estimate, finally need to be confirmed by flume experiment.

**Determine the roughness**

**Prototype roughness.**

Manning formula is uniform flow resistance equation, where n is the solid circles along the average roughness, for movable bed, the bed roughness is constituted by surface (sand) and form (sand wave) resistance. Natural river is general non-uniform flow, still use the Manning formula, the river is processed as the quasi uniform flow, so its roughness meaning will be widen, not only including the original intention, but also including the partial loss, which caused by plane form and morphology

changes along the River, N is an average comprehensive roughness, which is reversed by the measured water surface curve. Natural rivers at all flow levels, the riverbed composition and the bed form are inconsistent, plane form and morphology are also inconsistent, comprehensive roughness change, all flow levels roughness should be calculated obtained, at least in the flood, medium and dry flow.

**Model roughness.**

To determine the model roughness is a difficult problem, usually measured by flume experiment. As mentioned above, the compound roughness including local resistance, only in the geometric similarity normal model may be similar. With rectangular tank measurement roughness as model roughness is only a kind of approximate, the greater changes of prototype plane modality and section morphology, the deviation is greater.

In the uniform flow high flow state district (movable plane bed), Manning coefficient of the sediment bed can be estimated by the Zhang Youling formula, that is:

$$n_m = 0.0166 D_m^{1/6} \tag{7}$$

## Bed load model test design

**Basic field data.**

(1) The bed sediment grading curve, $D_{50}$, $D_{95}$, $D_5$ etc;

(2) All levels of flow water depth, flow velocity and Manning coefficient;

(3) The relation curves of measured bed load sediment transport rate and flow velocity.

**Similar conditions choice principles.**

Bed load model should satisfy formula (1) to (3). The combined solution formula (1) and (2), available:

$$n_m = n_p e^{1/2} \Big/ \lambda_h^{1/6} \tag{8}$$

The combined solution formula (1) and (3), available:

$$U_{om} = U_{op} \Big/ \lambda_h^{1/2} \tag{9}$$

The combined solution formula (2) and (3), available:

$$\lambda_{U_0} = \lambda_U = \lambda_h^{2/3} \Big/ \lambda_n e^{1/2} \tag{10}$$

or, $$U_{om} = U_{op} e^{1/2} n_p \Big/ n_m \lambda_h^{2/3} \tag{11}$$

In the formula (8) to (11), $n_p$, $n_m$ and $U_{op}$ are the flow condition function, at all flow levels, to meet the similar requirement is very difficult. Therefore, according to the nature of research problem, the principle of emphasize and choice as follow:

(1) Straight or micro bend, braided reach, resistance similarity is the main, should be meet. The gravity similarity can be appropriate deviation, the deviation degree as follow:

$$\Delta F_r = \left(1 - \lambda_U / \lambda_h^{1/2}\right) \times 100\% = \left(1 - \lambda_h^{1/6} / \lambda_n e^{1/2}\right) \times 100\% \tag{12}$$

According to the experience, straight reach deviation degree should not exceed 50%; the micro bend and braided reach deviation degree should not exceed 30%.

(2) In the curved reach, the gravity and resistance similarity is very important, should also be meet, at least in the key flow levels should be meet, meet the formula (8), in other flow levels, resistance similarity can be appropriate deviation. Resistance similarity deviation degree without practical experience, Xie Jianheng puts forward, as far as possible, the hydraulic elements from caused by the resistance deviation from locate in observation accuracy range, generally not more than 5% [3].

Because the resistance similarity deviation, the actual occurrence depth scale is $\lambda_h'$, velocity scale becomes $\lambda_U'$, because flow scale invariant, there is:

$$\lambda_Q = \lambda_L \lambda_h^{3/2} = \lambda_L \lambda_h' \lambda_u' = \lambda_l \lambda_h'^{5/3} / \lambda_n e^{1/2} \tag{13}$$

$$\lambda_h' = \lambda_n^{3/5} e^{3/10} \lambda_h^{9/10} \tag{14}$$

$$\lambda_U' = \lambda_h^{3/5} / \lambda_n^{3/5} e^{3/10} \quad (15)$$

Hydraulic elements deviation degree as follow:

$$\Delta\lambda_h = \frac{\lambda_h - \lambda_h'}{\lambda_h} = \left(1 - \lambda_n^{3/5} e^{3/10} \Big/ \lambda_h^{1/10}\right) \times 100\% \quad (16)$$

$$\Delta\lambda_U = \frac{\lambda_h^{1/2} - \lambda_U'}{\lambda_h^{1/2}} = \left(1 - \lambda_h^{1/10} \Big/ \lambda_n^{3/5} e^{3/10}\right) \times 100\% \quad (17)$$

Because the discharge per unit width unchanged, flow velocity increased, water depth decrease, in formula (16) and formula (17), the symbol is opposite.

(3) Both the straight reach or curved reach, in the key flow levels, the starting similar conditions should meet, which are the formula (11), in other flow levels, the movable requirements should meet, i.e.:

$$U_m > U_{om} \quad (18)$$

## Suspended load model test design

**Basic field data.**

In addition to the 5.1, prototype suspended load grading curve is needed.

**Similar conditions choice principles.**

Suspended load model should satisfy formula (1) to (4). According to Zhang Ruijin settling velocity formula, the particle size scale can be calculated by equation (4):

$$\lambda_d = 0.0179 \frac{d_p \omega_p}{\nu \lambda_\omega} \{[1 + 121.6 \frac{\gamma_{sm} - \gamma}{\gamma} g \nu (\frac{\lambda_\omega}{\omega_p})^3]^{1/2} - 1\} \quad (19)$$

There is one more restriction condition in Suspended load model, at all flow levels, at the same time, to meet the basic similar conditions, the difficulty greatly increased, therefore need to emphasize and choice.

(1) The primary and secondary selection of water flow movement similar conditions is same as the bed load.

(2) The suspended similar firstly meet the formula (4). The suspended load exercise intensity is biggest in flood period during the river bed deformation, and the suspended load is in an absolutely dominant position, so $\lambda_U$ should be designed according to flood discharge. The incipient motion similar should be a secondary importance, but in order to meet the low water channel deformation similarly, the regulation discharge should meet the incipient motion similar, and other flow discharges meet the condition of the formula (18).

## Conclusions

The movable bed model sediment particle size scale involves many complex factors, so the similarity is difficult to be fully satisfied. Even if some minor conditions and influence factors deviation are allowed, and makes some simplify, the programs are still very tedious and complicated. On the other hand, the model sediment, the model materials and the geometry scale are more restricted, which result in the design being very difficult. Based on theoretical research, the design principles of particle size scale for model sand were put forward. Base on the principles, the design methods of the particle size scale were put forward.

**Keywords:** Hydro-junction；Hub downstream；Bridge area；Overlapping area；Regulation scheme；Navigation security.

**Abstract.** The article has used the technical route of data analysis, physical model test and ship model tests combining, studied the navigation technology of waterway in area below QianWei hydro-junction and bridge sections overlapping in Minjiang River, then proposed the regulation scheme, which effectively improved navigation conditions in the region, finally summarized and put forward the navigable protection technologies and measures in area below hub and bridge area.

## Forward

In the inland waterways, the shiplock entrance area and connecting section, or bridge area channel are all regions of high requirements to navigable flow conditions, but also need to focus on navigation security. The study involved the channel in entrance area and connecting section below Qianwei hub in MingJiang River, also involved QianWei bridge area channel, in particular, need to point out which also involves overlapping segments between connecting section and the bridge area waterways, navigable environment is extremely complex. Therefore, specialized research on navigation security technology is necessary, which to guarantee the safety of navigation. The approaches of analysis, physical model and ship model tests combined are adopted to study the regulation scheme in district below hub and bridge area, it ensure that the relevant requirements of navigable flow conditions. Meanwhile, combined inland shipping information technology and inland channel navigable technology, put forward new generation of navigation protection technology at complex district to assure navigation security in specialized conditions, which guarantees the safety of navigation.

## General situation of the reach

Qianwei navigation power junction located is faintly-curved reach, and about 18.km upstream of dam axis is Min Dong bridge building，where the right bank has lenient ZhenJiangBa and ChaYuBa pebbles sandbars, and the two total length 4650m, right of which is deputy branch.

Affected by the downstream HuNiBa pebble sandbar jacking at the left side, the mainstream gradually began toward to right and crossing the river since the LeYi freeway MingDong bridge downstream approximately 1km, and about 300m upstream of dam axis mainstream flow straightly

along the right bar, the left of which HuNiBa pebble sandbar about 1800m, at its widest point approximately 500m, on the left is deputy branch, beginning to flow when the discharge reaches about 4000$m^3$/s .

The river width of HuNiBa reach is about 200 ~ 250m in the dry season, while bankfull in flood season the maximum width up to about 1100m，then HuNiBa pebble sandbar in approximately 1.2km downstream of the dam axis flooded basiclly, under riverbed gradually become relatively narrow, Minjiang River Qianwei bridge has been built is located, away from the axis of the Qianwei hub upstream about 1.45km, and dists HuNiBa shoal tail about 300m. Qianwei bridge main navigation spans 240m, its left and right side of the vice-hole span of 60m, the main hole basically across the river bridge area flood, in various periods of low water navigable waters.

**Hub Overall Layout**

The main hydraulic structures of qianwei project layout from right to left as follows: right bank gravity dam, lock (and the right of the lock section reserved for second-tier shiplock position), 28-hole flood (flushing) gates, right bank emergency gate storage slot dam section, powerhouse and installation section, left bank gravity dam（including fish passage section.

**Below dam and bridge area channel regulation research**

The reach of studied area is more complex, hub located is Zhongzhou sandbar, where less than 300m downstream is Qianwei Bridge, which main navigable hole towards to sandbar tail. while the hub constructed, its downstream approach entrance area from the bridge is only about 730m, the river on behalf of the ship using 1 +2 × 1000t pushing fleets, entrance zone length is 2.5 times the master of 400m. While according to standard regulations, the bridge district range of bridge upstream 4 times captain to downstream 2 times of representative ship, namely upstream 640m to downstream 320m, so the ship get out about 90m of entrance have also entered the bridge area waterways, overlapping range of about 310m, both the entrance aream, connecting section or bridge area waterway are different from the general area of natural waterways, require more to the navigable flow and waterway conditions.

**4.1 Navigable flow conditions research of approach entrance area and the connecting section in shiplock downstream**

The results showed that when the discharge Q≥ 4000$m^3$ / s, the entire current from the upstream left side power-station tailrace rushed straight to the dry main channel at the end of downstream approach entrance area, where biol, swirling water coexist, and formed a wide range of circulation zone on the right of approach entrance area, so the transverse velocity and circulating flow in approach entrance area all can not meet the "standard" requirement under various discharge.

**4.2 Navigation flow condition analysis in bridge area**

According to the experimental research purposes, determined surface velocity observed that range of bridge upstream 600m to downstream 300m waterway. According to the experimental observation: under various discharges, there existed a wide range of large transverse velocity in bridge area upstream.

Thus, the navigable flow conditions in approach entrance area and bridge area under present shiplock designs are poor, far beyond the standard specifications, in urgent need to carry out regulation research.

### 4.3 Regulation measures of Navigation flow conditions in below dam, bridge area

Based on Qianwei hub layout characteristics, riverbed terrain below dam, combined the observational data analysis of velocity, modifications mainly by adjusting the excavation region of the riverbed downstream the dam, controlling flood (flushing) gates opening sequence and opening height in order to achieve smooth transfer of discharged flow, so the velocity distribution uniformity and minimize or eliminate the flow regime. The main improvement measures include:

（1）Enlarge the excavation scope of riverbed at power station tailrace downstream left side

Appropriately shift the levees of power station downstream to left bank, and enlarge the excavation scope of riverbed in dam downstream left side, to guide the power station tail water and main stream discharged from the dam offseting to left appropriately, change the unfavorable situation of mainstream rushing to approach entrance area. Remediation excavation elevation remains 315m, while attention to the protection of Qianwei bridge pier that has been built.

（2）Appropriate retaining original riverbed terrain along the left side of shiplock

Retain original riverbed terrain along the shiplock and under approach entrance area, in order to achieve the purpose of sepatating or weakening the discharged mainstream expanding to entrance area.

（3）Reasonable adjust the opening way of flood (flushing) gates

While the upstream discharge over the station full-load flow, first properly open the floodgates closed to shiolock, and then turn the control to open the flushing gates and closed floodgates from left to right, in order to achieve the perpose of smoothing transfer of discharged water flow and improving the harmful regime in approach entrance area.

After the regulation implementated, by expanding the excavation scope of riverbed at power station tailrace downstream left side, appropriate retaining original riverbed terrain along the left side of shiplock, adjusting the opening way of flood (flushing) gates and other measures，effectively smooth the the flow downstream of the dam, the phenomenon of flow discharged straight into the under entrance area tail disappeared, and biol, swirling water and return current regimen has disappeared (or maximum compressed), velocity peak decreases, the velocity distribution tends to be uniform, navigation flow conditions have greatly improved in entrance area, bridge area(including overlapping section) at various discharges.

## Complex navigation security technologies

The study involves entrance area below Qianwei dam, connecting section，but also involves Qianwei Bridge waterway area, in particular, need to point out that also involves overlapping channel of connecting section and the bridge area, navigable environment is extremely complex. Therefore, need for specialized navigable security technologies to protect the safety of navigation.

### 5.1 Navigation protection technology and the implementation in hub downstream and bridge area

（1）Implementation of navigable flow conditions sensing measurement technology in real time at waterway site

By arranging multiple water level, velocity, visibility, wind conditions automated collection and transmission system along the range of entrance area to Qianwei Bridge downstream 2km, transer the data be collected in real time to waterway navigable command center;

（2）Real-time numerical simulation forecasting and security decision-making platform development research

Conduct real-time numerical simulation forecasting and security decision-making platform development in hub downstream to Qianwei Bridge channel. Use the waterway natural data returned in real time from sensing at site to calculate in real-time, given the scale and navigable waterway conditions, and relying on GIS gives live three-dimensional image, achieving the navigation conditions display of above special district in real time, providing support for navigation decision-making.

（3）Ship security monitoring and management system under all-weather and complicated navigation conditions

By integrating the safe distance control technology of ship sailing, intelligent beacon navigation technology of BeiDou system integrated with AIS, construction nearby or crossing the river warning systems, protecting ship sailing safety in night of an integrated technology formed from night ship collision avoidance equipments etc, establish the ship security monitoring and management system and set of technologies under all-weather and complicated navigation conditions, to protect the safety of ships at night navigation.

（4）Equip new water ship/person emergency alarm and rescuing, accident traceing system in complicated navigacable district

The reach that navigable flow conditions complex, ship traffic heavy, especially night navigation achieved, put forward higher requirements to the maritime search and rescue. The locating and rescuing system aimed to personnel falling into the water and vessel inland including: ① all-weather inland ship and staff in distress positions tracking and rescuing system in real time; ②personnel intelligent lifesaving facilities with function of automatic positioning; ③AIS Class B portable search and rescue system suitable for small ship safety supervision; ④Intellisense and automatic alarm shipborne equipment based on the sailing state of ship in distress;⑤shipborne AIS navigational information facilities applied to ship accident traceing.

**5.2 Complex navigation security assurance measures**

After the completion of shiplock of Qianwei hub, the ship will sail through the mouth area and the connecting section directly into the bridge area waterways, navigation conditions subject to various restrictions, inevitably affect the safety of navigation. If not on-site management and security protection to the water area, once the accident, will bring significant economic losses and adverse social impact. Therefore must be taken and established measures to protect the ship pass the region safely, improving the navigation environment and maintaining good navigation order, and ensuring the safety of bridge and ship.

（1）Synthesize navigable conditions and ship model testing of Qianwei hub shiplock upstream and downstream waterway, it is recommended $Q = 11000m^3 / s$ is the highest navigable discharge, $Q = 12000m^3 / s$ to limit navigable discharge.

（2）Suggest to establish a reasonable way to open the gates of the hub, take certain restrictive navigable measures, maneuver carefully, in order to ensure safe navigation of ships.

（3）In order to protect the safety of navigation in bridge area, it should improve water safety supervision mechanism, equip necessary security infrastructure and take long-term security maintenance, bridge area waterway equip completely of navigation mark, bridge opening mark and other facilities, and water safety supervision facilities, etc.

（4）When the ship either upstream or downstream through the waterway in bridge area, should be familiar with navigable situation of waterways in advance, particularly pay attention to grasp the bridge clearance height, maximum height of the own ship, draught, height of tide and time of tide in bridge district, etc. Meanwhile, should consciously abide bridge navigation regulations, aviod the situation of overtaking, sailing tied with others boats.

（5）Strengthen the implementation and application of above navigation security protection technology, and coordinate closely with the patrol boats at site.

（6）Strengthen the training of the crew, increase the navigation rules and navigation environment propaganda.

## Conclutions

（1）The study involves entrance area below Qianwei dam, connecting section，but also involves Qianwei Bridge waterway area, in particular, need to point out that also involves overlapping channel of connecting section and the bridge area, navigable environment is extremely complex. The approaches of analysis and physical model combined are adopted to study the navigation flow conditions in reach below hub and bridge area, determined the waterway regulation scheme.

（2）Put forward the navigable protection technology in hub downstream reach which under complex conditions ( dam downstream and bridge area connecting), establish related measures to protect the ship pass the region safely, improving the navigation environment and maintaining good navigation order, ensuring the safety of bridge and ship.

**Keywords:** sandy pebble Reach, riverbed erosion and deposition, basic law

**Abstract.** After the Three Gorges Reservoir, sandy pebble Reach incoming water and sediment conditions has change, the changes of incoming water and sediment conditions might make sandy pebble reach riverbed scouring-erosion variation. This paper study on sandy pebble reach riverbed erosion and deposition basic law after the Three Gorges Reservoir, and provide the decision basis for large-scale system renovation in the middle Yangtze River.

## Channel Overview

In the middle Yangtze River, sandy pebble Reach from Yichang to Dabujie, total length is about 116.4 kilometers. Sandy pebble reach is divided into two sections, the upper and lower sections. The upper section from Yichang to Zhicheng is called Yizhi reach, plane modality mostly is the straight micro bend, Yizhi reach mainly contains Yichang and Yidou channel. The lower sections from Zhicheng to Dabujie, plane modality mostly is the bending braided, mainly contains Lujiahe and Zhijiang~Jiangkou channel.

## The median and flood riverbed erosion and deposition basic law

(1)After the Three Gorges reservoir, sandy pebbles reach riverbed overall performance consistency erosion.

After the Three Gorges reservoir, in addition to 2008, sandy pebbles reach median and flood riverbed appear a little deposit, the rest of the year median and flood riverbed show erosion. Because of the inter-annual incoming water and sediment conditions changes, the inter-annuals erosion intensity is different, but there is a basic feature, which is the big waters, the erosion intensity is big, the small water, the erosion intensity is small. Such as: in 2006, the inflow is small, so the erosion intensity was only about 0.2 $m^3$ / km, in 2005, the inflow is big, the erosion intensity is 38.0 $m^3$ / km.

(2) After the Three Gorges reservoir, sandy pebble reach median and flood riverbed erosion intensity is bigger before 175 m than after 175 m.

Before 175m water storage, sandy pebbles reach median and flood riverbed erosion intensity was about 171.7 $m^3$ / km, accounting for 71.2% of the total erosion intensity, after 175 m water storage, median and flood riverbed erosion intensity gradually weakened.

(3) After the Three Gorges reservoir, before the 175 m water storage, sandy pebbles reach median and flood riverbed erosion intensity shows inter-annuals sample size; after the 175 m water storage, median and flood riverbed erosion intensity gradually weakened.

Before 175 m water storage, the erosion intensity alternate size between inter-annuals, that is last year lager erosion intensity, next year small erosion intensity; after 175 m water storage, the erosion intensity showed a trend of continuous weakening.

After the Three Gorges reservoir, from analysis the changes of sandy pebbles reach incoming water and sediment conditions, we can see, sandy pebbles reach median and flood erosion intensity change rule along time was adapted to the incoming water and sediment condition changes. After the Three Gorges reservoir, Yichang hydrological station small runoff, the low flow rate increases year by year, sediment discharge and sediment concentration greatly reduced, suspended sediment median diameter taper, a large number of coarse grain sediment was blocked in the library district, reservoir discharge's "clear water sand" is considered unsaturated sediment, therefore sandy pebble reach overall performance consistency erosion. Incoming water and sediment conditions inter-annual changes cause the erosion intensity inter-annuals changes, such as in 2005 years, the inflow is big, the riverbed erosion intensity is strong; in 2006, the inflow is small, the riverbed erosion intensity is weak, inter-annuals median and flood riverbed erosion intensity are not of uniform size, with the further development of scour, sand pebble riverbed sediment showed a certain degree of coarsening, the riverbed formed on the surface coarsening layer and prevent further erosion, before 175 m water storage, the riverbed erosion intensity is big, after 175 m water storage, the erosion intensity is small.

Table 1 Median and flood riverbed erosion intensity statistics

| Start-stop | length (km) | year | Dry riverbed | shoal | Median and flood riverbed |
|---|---|---|---|---|---|
| Yichang~Zhicheng | 60.8 | 2003 | -47.9 | -14.0 | -61.9 |
| | | 2004 | -27.0 | -6.8 | -33.8 |
| | | 2005 | -35.7 | -2.3 | -38.0 |
| | | 2006 | -0.7 | 0.5 | -0.2 |
| | | 2007 | -36.2 | -1.6 | -37.8 |
| | | 2008 | -3.6 | 4.8 | +1.2 |
| | | 2009 | -20.8 | -4.4 | -25.2 |
| | | 2010 | -18.3 | 1.2 | -17.1 |
| | | 2011 | -12.9 | -0.4 | -13.3 |
| | | 2012 | | | -13.3 |
| | | 2003~2012 | | | -239.4 |

Remark: " +" deposit, "-" erosion.

(4) After the Three Gorges reservoir, from Yichang to Dabujie, sandy pebbles reach follow the general rules, in hub downstream erosion intensity gradually weakened from top to bottom, sandy pebbles reach plane modality and riverbed composition uneven changes along the way, so that the riverbed erosion along the way were also unevenly distributed.

Early in the Three Gorges reservoir, sandy pebbles reach riverbed erosion intensity gradually weakened, near the dam, the total erosion intensity in Yizhi Reach should be slightly larger than in Lujiahe Reach.

However the movable bed composition makes it possible to scour. Riverbed composition changes along the way, so that the riverbed erosion intensity along the way was unevenly distributed. The riverbed composition strong impact, the erosion amount and erosion intensity were small; the

riverbed composition weaker impact, the erosion amount and erosion intensity were big. In the three sandy pebbles reach, Yichang reach erosion amount was smaller, Yidou and Lujiahe reach erosion amount represent over 90%, so from 2002 to 2012, sandy pebbles riverbed erosion mainly located in Yidou and Lujiahe reach.

(5) After the Three Gorges reservoir, sandy pebbles reach rebuilding balance process is a gradually top-down development.

Yizhi reach is mainly composed of Yichang and Yidou channel, after the Three Gorges reservoir, in 2003, Yichang channel riverbed erosion intensity show the biggest, in subsequent years riverbed erosion intensity decreases, the riverbed erosion intensity shows inter-annuals alternate size; from 2003 to 2009, Yidu channel riverbed erosion intensity reach maximum, to 2010, riverbed erosion intensity began to abate, but still outweigh the Yichang channel.

Lujiahe reach is mainly composed of Guanzhou and Lujiahe channel, after 2009, Lujiahe reach appeared substantial erosion. after the Three Gorges reservoir, Guanzhou channel overall performance consistency erosion, 2009 years ago, Guanzhou channel was adjusted by narrow erosion and deposition, after 2009 GuanZhou channel riverbed erosion intensity become bigger, especially after entering the trial impoundment, GuanZhou channel riverbed erosion intensity rapidly increases, from 2010 to 2012, GuanZhou channel riverbed erosion intensity totaled 1.85 million $m^3$ / km, accounting for 64% of the total erosion intensity. 2006 years ago, Lujiahe channel riverbed show deposition; from 2006 to 2009 , median and flood riverbed showed just as small cumulative erosion; after 2009 Lujiahe channel occurred significant erosion, from 2008 to 2012 Lujiahe channel riverbed erosion intensity is 98.6 $m^3$/ km, accounting for nearly 70% of total erosion intensity.

Before 2006, ZhiJiang ~ jiang channel riverbed erosion has no significant response to the incoming water and sediment conditions changes, riverbed erosion and deposition shows inter-annual alternate size; from 2006 to 2009, median and flood riverbed erosion intensity increased, with the exception of 2006 ~ 2010 waterway regulation engineering implementation, riverbed slightly deposition, 2010 years later, median and flood riverbed erosion intensity significantly increased.

Therefore, with the development of the three gorges reservoir, sandy pebbles reach rebuilding balance process is a gradually top-down development, the maximum erosion intensity section already move to Lujiahe channel.

**The dry riverbed erosion and deposition basic law**

(1) Dry riverbed erosion and deposition basic law are basically the same with median and flood riverbed erosion and deposition.

Table 1 shows: sandy pebbles reach dry riverbed and riverbed erosion and deposition variation along time is basically consistent.

(2) Dry riverbed deformation is the main part of riverbed deformation.

After the Three Gorges reservoir, limited by the boundary conditions, sandy pebbles reach dry riverbed deformation is the main part of riverbed deformation, the erosion mainly concentrated in the dry riverbed. With the Three Gorges water level higher, dry riverbed erosion amount proportion is constantly increasing.

For example, in Yizhi reach, from October 2002 to October 2011, dry riverbed erosion intensity is 203.1 $m^3$ / km, the median and flood riverbed erosion intensity is 226.1 $m^3$/ km, dry riverbed erosion intensity accounts for 90%, shoal erosion intensity is 230.2 $m^3$ / km, accounts for only 10%. Dry riverbed erosion intensity is greater than shoal erosion intensity; the erosion body locates in the

low flow channel. Yizhi reach in the Three Gorges first two years operation, dry riverbed erosion intensity accounted for less than 80%, to 2009, the riverbed scouring almost entirely from the low flow channel.

(3) Sandy pebbles reach thalweg performance for the cut.

After the Three Gorges reservoir, Yichang channel is mainly composed of longitudinal incised. From October 2002 to October 2011, Yichang channel thalweg longitudinal section cut an average of 1.7 meters, and the maximum scour depth is 5.4 meters.

After the three gorges reservoir, Yidu channel relative to Yichang channel, erosion intensity is bigger, from October 2002 to October 2011, Yidu channel thalweg longitudinal section cut an average of 5.3 meters, and the maximum scour depth is 18.0 meters.

Guanzhou channel right branch thalweg are relatively stable, the import section thalweg is high and convex, between 2010 and 2012 imports section thalweg accretion, thalweg show substantially. And for the left branch, the left branch import section is relatively stable, the middle and lower section thawleg substantial cut, from 2009 years ago the uneven variety is generally below the 10 meters.

Lujiahe channel, due to the sand and stone deep grooves layer can be washed limited, after the three gorges reservoir, the sand and stone thalweg elevation stable, in addition to 2005 to 2006, the sand thalweg elevation significantly changed, from 2006 to now, thalweg elevation basically stable, sand and stone thalweg have bigger difference.

After the Three Gorges reservoir, ZhiJiang ~ jiangkou channel thalweg also showed some degree cut. ZhiJiang ~ Jiangkou channel are also scouring and deposition, but overall performance scouring, its characteristic is: above ZhiJiang erosion intensity is less than under ZhiJiang, the deep groove erosion intensity is greater than the high convex shoals.

**Shoals erosion and deposition basic law**

(1)Sandy pebbles reach shoal also overall performance erosion, but the shoals erosion intensity compared with the dry riverbed erosion intensity is small.

After the Three Gorges reservoir, sandy pebbles reach shoal also overall performance erosion, erosion intensity compared with the dry riverbed erosion intensity is small. Such as: in 2003, dry riverbed annual average erosion intensity is 479000 $m^3$ / km, and shoal annual average erosion intensity was only about 140000 $m^3$ / km; in 2005, dry riverbed average annual erosion intensity is 357000 $m^3$ / km, and the shoal annual average erosion intensity was only about 23000 $m^3$ / km; in 2007, dry riverbed average annual erosion intensity is 362000 $m^3$ / km, and the shoal annual average erosion intensity was only about 16000 $m^3$ / km.

(2) Sandy pebbles reach high beach erosion intensity slightly larger than low beach erosion intensity.

Sandy pebbles reach, from October 2002 to October 2011, high beach annual average erosion intensity is 133000 $m^3$ / km; the low beach annual average erosion is 98000 $m^3$ / km, high beach erosion intensity slightly bigger than the low beach erosion intensity.

**Conclusions**

Through field research, data compilation and analysis, this paper study on the basic law of the sandy pebble Reach riverbed erosion and deposition after the Three Gorges Reservoir, the main conclusions can be summarized as the following aspects:

(1) After the Three Gorges reservoir, sandy pebbles reach riverbed overall performance consistency erosion;

(2) After the Three Gorges reservoir, sandy pebble reach median and flood riverbed erosion intensity is bigger before 175 m than after 175 m;

(3) After the Three Gorges reservoir, before the 175 m water storage, sandy pebbles reach median and flood riverbed erosion intensity shows inter-annuals sample size; after the 175 m water storage, median and flood riverbed erosion intensity gradually weakened;

(4) After the Three Gorges reservoir, from Yichang to Dabujie, sandy pebbles reach follow the general rules, in hub downstream erosion intensity gradually weakened from top to bottom, sandy pebbles reach plane modality and riverbed composition uneven changes along the way, so that the riverbed erosion along the way were also unevenly distributed;

(5) After the Three Gorges reservoir, sandy pebbles reach rebuilding balance process is a gradually top-down development;

(6) Dry riverbed erosion and deposition basic law are basically the same with median and flood riverbed erosion and deposition; dry riverbed deformation is the main part of riverbed deformation; Sandy pebbles reach thalweg performance for the cut;

(7) Sandy pebbles reach shoal also overall performance erosion, but the shoals erosion intensity compared with the dry riverbed erosion intensity is small; sandy pebbles reach high beach erosion intensity slightly larger than low beach erosion intensity.

**Keywords:** horizontal velocity distribution; sediment numerical model; allocation of the erosion and deposition area

**Abstract.** In this article, the horizontal flow velocity in natural rivers was studied, and its formula was established based on the theoretical analysis. Then some key parameters in the formula were determined by regression analysis based on large amount of measured data in the middle reaches of the Yangtze River. This formula can be widely applied in the allocation of the erosion and deposition area in 1D sediment numerical models.

## Introduction

The formula of the horizontal velocity distribution in natural rivers has a wide application in the hydraulic engineering and the river training. Especially in the 1D sediment mathematical models, it is important to allocate the erosion and deposition area along the section direction, since the 1D model gives only the total erosion and deposition area. At present, plenty of the studies have been carried out to solve this problem based on theoretical analysis and experiment researches [1-11]. The achievements of these studies usually have some difficulties in the actual applications since the clear division of the beach and groove is required in natural rivers, while the shapes of the sections in natural rivers are usually ever-changing, and it is hard to get a clear division of the beach and groove. As a result, it is an effective way to solve the specific problems through the basically analysis and the regression analysis based on measured data. In this article, the horizontal flow velocity in natural rivers was studied, and its formula was established based on the theoretical analysis. Then some key parameters in the formula were determined by regression analysis based on large amount of measured data in the middle reaches of the Yangtze River. This formula can be widely applied in the allocation of the erosion and deposition area in 1D sediment numerical models.

## Theoretical Analysis

For the straight rivers, application of the Chezy Formula can be applied to the points of the sections, extended from the situation of the average of the section. For the situation of the total section, the average velocity can be written as:

$$U = C\sqrt{RJ} \tag{1}$$

In Eq.1, $U$ is section average velocity, $C$ is the Chezy parameter, $R$ is the hydraulic radius, and $J$ is water surface slope. $C$ can be determined based on the Manning formula:

$$C = R^{1/6}/n \tag{2}$$

In Eq.2, $n$ is the integrated roughness coefficient of the cross section. By Substituting Eq. 2 into Eq. 1, the cross section velocity can be written as:

$$U = \frac{\sqrt{J}}{n} R^{2/3} = KR^{2/3} \tag{3}$$

In Eq. 3, $K$ is defined as:

$$K = \frac{\sqrt{J}}{n} \tag{4}$$

By assuming that the parameter $K$ remains the same along the section, the velocity of the specific points in the section can be written as:

$$U_i = KR_i^{2/3} \tag{5}$$

At present, Eq .5 is widely used in most of the applications to allocate the erosion and deposition area in 1D sediment numerical models. From the derivation process in the up text we can see that the parameter $K$ is closely related to the resistance of the river bed surface, and relatively large errors will be caused because of the simple assuming that the parameter $K$ remains the same along the section.

In China, most of the alluvial rivers have the compound cross sections consisted of beaches and grooves, such as the lower reaches of the Yangtze River and the Yellow river, main stream of the Huaihe River and Songhuajiang River. For most cases, the shapes of the cross sections in natural rivers are ever-changing, and it is hard to give a clear division of the beaches and grooves. As a result, it is usually difficult to apply the formula, which is based on the clear division of the beach and groove, to resolve the actual problems. According to the up analysis, by assuming that K is non-uniform along the cross section, the relationship of the point velocity $U_i$ and the average velocity $U$ can be written as:

$$\frac{U_i}{U} = \frac{\sqrt{J_i}}{\sqrt{J}} \frac{n}{n_i} \frac{R_i^{2/3}}{R^{2/3}} \tag{6}$$

It can be seen from Eq. 6 that the relationship between $U_i$ and $U$ is closely related to those of the water depth, roughness and water surface slope. Assuming that the water surface slope is the same in each area of the cross section, Eq. 6 can be simplified as:

$$\frac{U_i}{U} = \frac{n}{n_i} \frac{R_i^{2/3}}{R^{2/3}} \tag{7}$$

In Eq. 7, $n/n_i$ closely is related to the distribution of the resistance along the cross section. The parameter, relative bank width was introduced to solve the transverse distribution of the flow resistance [12, 13]:

$$n_i = \frac{n}{f(\eta)} \left( \frac{J_i}{J} \right)^{1/2} \tag{8}$$

In Eq. 8, $\eta=y/B$ is relative bank width, $y$ is the distance from initial point, $B$ is the river bank width. By plotting the data measured in Laijiapu, Tiaoguan, Tiepu and Dongshi reaches of Yangtze River and Yellow River, the expression is obtained as:

$$f(\eta) = A\eta^2 + B\eta + C \tag{9}$$

Before the actual usage of Eq. 9, the location of the cross section in the bend river needs to be firstly confirmed, and this brings some difficulties to the application in 1D river hydraulic mathematical model. Actually, in natural rivers, the water level is always in the changing process, the amplitude of the $\eta$ variation is fairly large for different water levels. As a result, the application the relative bank width brings some extra difficulties. In 1D model, the relative flow depth, $H/H_i$ can be easily to be derived, so it is taken instead of the relative bank width in this article. Then by the simple assuming that the water surface slope is the same in each area of the cross section, the relative flow velocity can be written as:

$$\frac{U_i}{U} = f(\lambda) \tag{10}$$

In Eq. 10, $\lambda=H_i/H$ is the relative flow depth.

**Regression Analysis**

A good deal of measured data of the velocity transverse distribution was collected to define the key parameters in the function $f(\lambda)$. The total number of the measured sections is 118, which were measured in Yichang, Yidu, Lujiahe and Shashi reaches downstream from Three Gorges reservoir,

ranging from March, 2003 to February, 2009. The information of the measured data was showed in Table 1.

**Table 1** Information of the measured data

| Reach name | Date of measurement | Number of the sections |
|---|---|---|
| Yichang | March, 2003 | 5 |
| Yidu | March, 2003 | 4 |
| | October, 2004 | 4 |
| | April, 2005 | 4 |
| Lujiahe | March, 2003 | 11 |
| | February, 2004 | 17 |
| | March, 2005 | 5 |
| | March, 2006 | 5 |
| | January, 2007 | 5 |
| Shashi | November, 2004 | 17 |
| | November, 2005 | 6 |
| | September, 2006 | 10 |
| | March, 2007 | 4 |
| | May, 2007 | 6 |
| | February, 2009 | 15 |

It can be seen from Eq. 6 that $U_i/U$ is partially proportional to $(R_i/R)^{2/3}$. Since $H_i/H$ is basically equal to $R_i/R$ in natural rivers, $(H_i/H)^{2/3}$ can be taken as one of the parameters in $f(\lambda)$. In the physical concept, the greater the pressure is, the greater the resistance would be. In the river flow, the bigger the water depth is, the greater the pressure would be. As a result, the bigger the water depth is, the greater the resistance would be. Combining the investigation of Eq. 9, the simple assumption can be given as:

$$n/n_i = A\left(H_i/H\right)^2 + B\left(H_i/H\right) + C \tag{11}$$

By substituting Eq. 11 into Eq. 7, the $f(\lambda)$ can be expressed as:

$$f\left(\lambda\right) = A\lambda^{8/3} + B\lambda^{5/3} + C^{2/3} + D \tag{12}$$

Results of the regression analysis base on the measured data showed in Table 1 are as follows:

$$A = -0.011873 \quad B = -0.13063 \quad C = 1.18042 \quad D = -0.066352 \tag{13}$$

Fig. 1 gives the contrast of measured values and calculated values carried out by using Eq.12 with parameter value in Eq. 13.

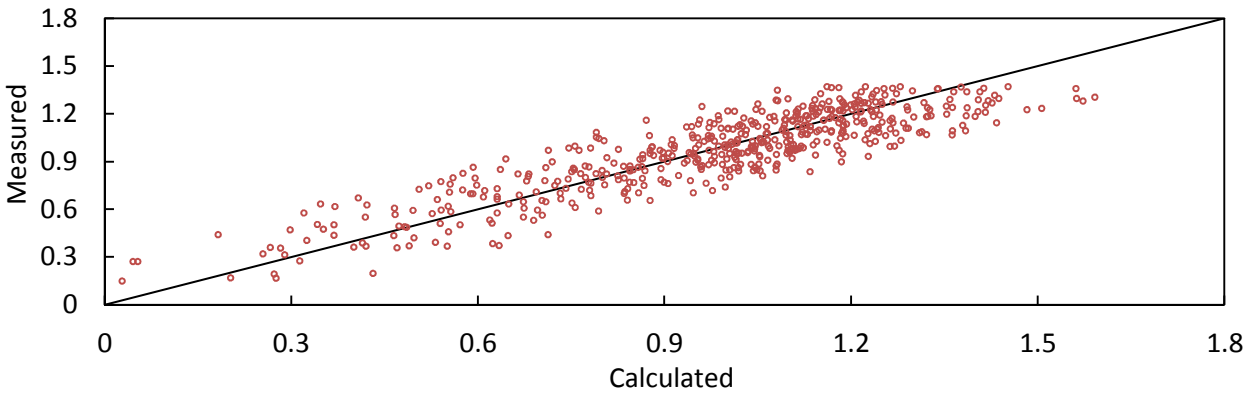

**Figure 1** Contrast of measured and calculated values

**Summary**

In this article, the horizontal flow velocity in natural rivers was studied, and its formula was established based on the theoretical analysis. Then the key parameters in the formula were determined by regression analysis based on large amount of measured data in the middle reaches of the Yangtze River. This formula can be widely applied in the allocation of the erosion and deposition area in 1D sediment numerical models.

**Keywords:** Plunge pool slab, Uplift force. Power spectrum

**Abstract.** The impact of the flood discharge water flow from a high dam is rather great on the slab of a plunge pool, and may cause damages to the plunge pool and consequently endangers the dam body safety. Therefore, a reverse arch slab model was established on the base of a study on and a simulation of the rational scale of gaps between the plates of the plunge pool slab. The model was an arch ring containing 7 slabs. The uplift force time history of each slab was measured, and the uplift force power spectrum and probability density were analyzed. The test result shows that the uplift energy mainly centers in 0-15Hz frequency bandwidth, and mostly within 1Hz. It belongs to a low frequency and big amplitude vibration.

## Introduction

As the flood discharge power of a high dam is rather great, the impact of the flood discharge water flow is tremendous on the slab of a plunge pool, and may cause damages to the plunge pool and consequently endangers the dam body safety. Therefore, it is significant to the dam safety to understand the failure mechanism of the plunge pool.

The failure of the plunge pool is caused by the uplift force. As there are construction joints between the building blocks of the plunge pool slab, the high speed impact jet flow not only acts on the top surface of the slab, but also transmits to the bottom surface of the slab through the joints when the waterstop between the joints is damaged. There is a phase difference between the top surface and the bottom surface of the slab, which leads to the bottom surface pressure greater than the top surface pressure of the slab at a certain moment, and forms an uplift force. At present, there are various opinions about the propagation law of hydrodynamic pressure in the joints.

GRehbinder [1] put forward a seepage flow model. Zhao Yaonan et al [2] came up with a water body oscillation model. V. Fiorotto et al [3] first introduced a transient flow model, and analyzed the propagation features of the pulsating pressure in the joints, seeing the water body in the joints as a pulsating pressure propagation media. Liu Peiqing et al [4,5] analyzed the propagation features of the pulsating pressure in the joints and they thought that the pulsating uplift force acting on the slab block is caused by the different propagation speed of the pulsating pressure wave on the top and bottom surface of the block rather than simply an issue of the phase difference. And they provided a prediction formula for a maximum possible uplift force. The above research results are generally divided into three models: the seepage flow model, the water body oscillation model and the transient flow modal. Both the seepage model and the water body oscillation model regard the water body in the joints as doing some movement, therefore the transfer of pressure depends on the propagation of the moving water body. In fact, as the size of the joints is very small, these two models cannot satisfactorily explain the features of the rapidly changing pulsating pressure in the joints. The transient flow model believes that the pressure in the joints propagates in the form of a wave, and the water body in the joints as the propagation media of the pressure wave, may better conform to the actual situation.

At present, studies in various aspects have been made on the time average and pulsating hydrodynamic pressure and the magnitude and spectral characteristics of the uplift force, etc. and have achieved important results, but so far no recognized conclusions have been drawn. Due to

limited existing prototype projects and difficulties in prototype observation, and also because of the complicated water flow pattern in a plunge pool, it is difficult to have an accurate theoretical analysis on it, and therefore the study on the load characteristics of the plunge pool still largely dependants on model experiments.

## Test Principle

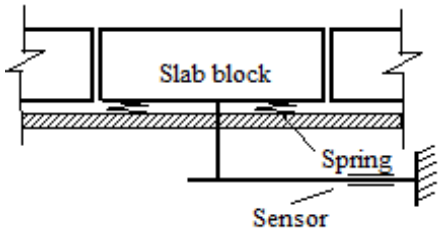
Slab analogue simulation must meet the similarity of the hydraulic conditions and that of structural dynamic conditions. This needs to be guaranteed from two aspects: an elastic material that meets the hydraulic conditions and the structural dynamic similarity; correctly simulate the size of the joints of the pulsating pressure propagation between the blocks.

A hydro elastic model that uses added weight rubber as the test material can simultaneously meet the hydro condition and structural dynamic condition [6], therefore, the first aspect is easy to meet.

The width of the joints must also be taken into consideration so that the joints are similar to those of the prototype. Perspectives are inconsistent theoretically and practically as the joint water flow is rather complicated. We preliminarily think that this joint flow belongs to the scope of laminar flow where the Froude number no longer applies. Therefore, it is incorrect to reduce the joint width according to the model length scale $\lambda_L$. According to document [7], if the geometric scale is 100, the joint width scale will be 3.16. That is, the size of the joints in the prototype is actually at the same order of magnitude with that of the model joints. Therefore, when the similarity of the joint flow field for the model and for that of the prototype is met, the pressure pulsation is also met. In principle, the joint size between the blocks should not be controlled by geometric similarity. This judgment provides a realistic basis for the model test.

## Test Establishment

When studying the slab block uplift force in the model, assuming there was no friction between each block, therefore, the anti-floating stability calculation method for an individual block was the same regardless of a flat slab or a reverse arch slab. See Fig. 1 for the uplift testing device.



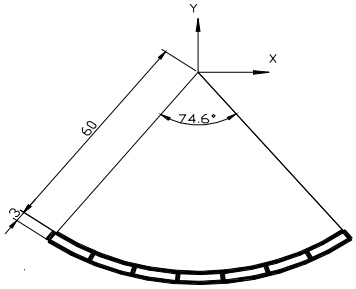


**Fig. 1 Diagram of the uplift testing device of the model** **Fig.2 Geometric features of a reverse arch slab**

Each block was supported on the model slab by 4 springs, and the slab was linked to the sensor by a metal rod. When setting the instrument to zero in static water, the measured value in the model was the uplift force applied to the block. This method of directly measuring the uplift force on the whole block not only avoided the trouble of requiring a point-area conversion when measuring a single point pressure previously, but also had an advantage of an intuitive and definite physical significance.

We conducted an uplift force analogue simulation on a plunge pool slab in accordance with the above simulation principle and test method. This reverse arch slab central angle was 74.6°. the transverse jointing for every 10m formed an arch ring, with the width of the arch ring of 10m. The longitudinal jointing divided uniformly the arch ring into 7 blocks, with the block thickness of 3m. The geometric features are show in Fig. 2

Material features of the slab:

Slab: Submerged weight $\gamma$=14,500 $N/m^3$; elastic modulus E＝25 $GPa$; Poisson ratio $\mu = 0.17$.

Bed rock: Unit weight: $\gamma$=25,000 $N/m^3$; elastic modulus E＝22 $GPa$; Poisson ratio $\mu = 0.22$.

Anchor bar: Unit weight $\gamma$=78,000 $N/m^3$; elastic modulus E＝200 $GPa$.

The model was designed according to gravity criteria, and the geometric scale was 1:100. See Table 1 for each parameters of the model.

**Table 1. Uplift test model scale on reverse arch slab**

| Physical quantity | Quantity of flow | Flow rate | Time | Acceleration | Force | Intensity of pressure |
|---|---|---|---|---|---|---|
| Scale | 100000 | 10 | 10 | 1 | 1000000 | 100 |

## Results and Discussions

The test recorded 4,096 groups of uplift synchronous data, and the statistic features of the test results are shown in Table 2.

**Table 2. Uplift synchronous test statistic results on reverse arch slab [Pa]**

| Load | Block 1 | Block 2 | Block 3 | Block 4 | Block 5 | Block 6 | Block 7 |
|---|---|---|---|---|---|---|---|
| Maximum | 79991 | 152520 | 83780 | 51010 | 83780 | 94396 | 53353 |
| Average | 21661 | 29830 | -6159 | -48960 | -6159 | 24406 | 14413 |
| $\sigma$ | 15010 | 27670 | 25030 | 20070 | 25030 | 11240 | 8390 |
| Maximum of 3σ assurance | 66600 | 112800 | 68800 | 11100 | 68800 | 58100 | 39600 |

See Fig. 3 for the uplift force time history:

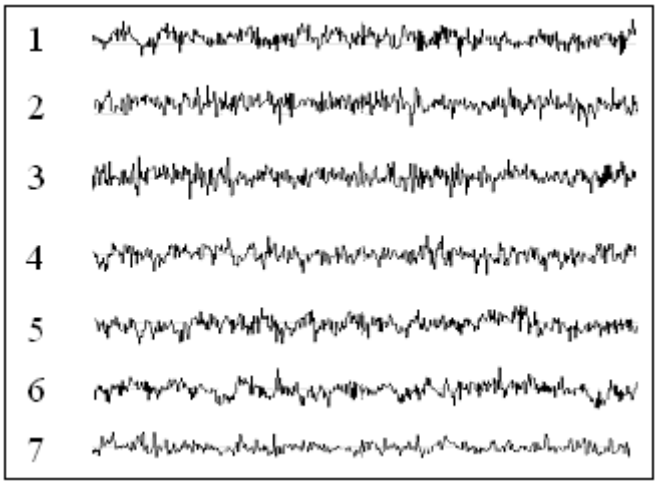

**Fig. 3 Measured load hydrograph of the model reverse arch slab block**

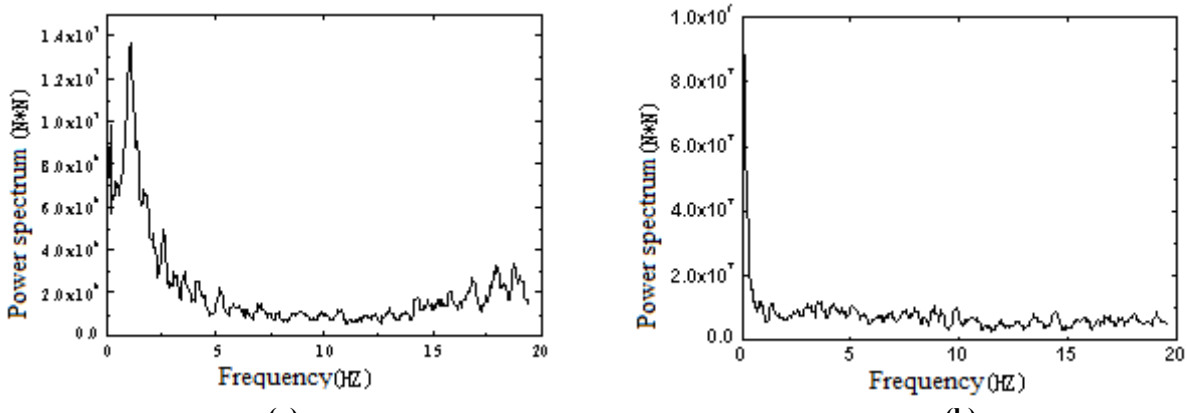
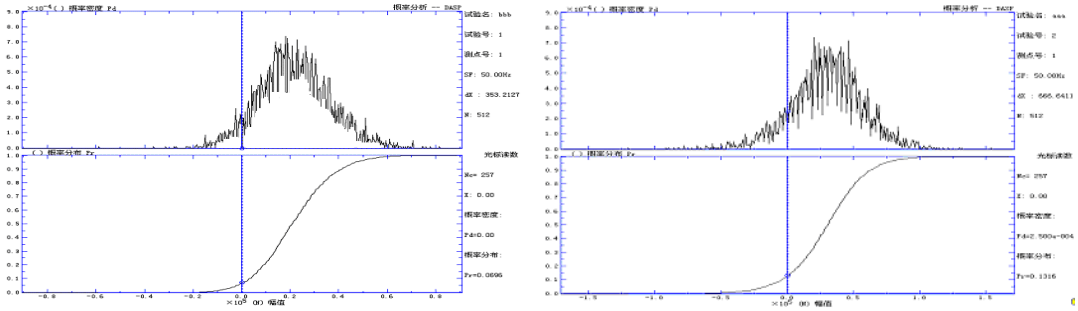
It can be seen from the Table 2 that block 2 has the maximum uplift force, and block 1 is in a moderate position of 7 blocks in terms of the uplift force applied to it. Below is an analysis on the power spectral density and probability distribution of block 1 and block 2, respectively in order to find out the magnitude –frequency characteristic of the uplift force. The uplift force power spectrum features of each block are show in Fig. 4, and the probability density and probability distribution are shown in Fig. 5.



**(a)** **(b)**

**Fig. 4 The uplift force power spectrum. (a) block 1. (b) block 2.**



(a) (b)

**Fig. 5 The uplift force probability density and probability function. (a) block 1. (b) block 2.**

Due to the measurement error in the model test, and due to the difference between the model water flow pattern and the prototype, the difference of the uplift force magnitude between each block is great, but the spectrum is basically the same. It is believed that they are all subject to normal distribution. The above figure indicates that the energy mainly centers in 0-15Hz frequency bandwidth, and mostly within 1Hz. It belongs to a low frequency and big amplitude vibration. The oscillation of other blocks also has the similar features.

## Conclusion

The slab block is acted on by an uplift force when the plunge pool slab joints are damaged. A reverse arch plunge pool slab block test is designed according to the scale 1:100 in this paper, which indicates that the uplift force on each block of the reverse arch slab has some differences but they belong to the same order of magnitude. The oscillation energy mainly concentrates within 11Hz. It belongs to a low frequency and big amplitude vibration.

# The direct solution on normal depth of an egg-shaped section tunnel

Hui Wen

Department of architecture and civil engineering , Huizhou University

Huizhou, Guangdong, 516007, China

wenhui-hzu@163.com

**Key words:** hydraulics; egg-shaped section; normal depth; direct method

**Abstract:** An egg-shaped is consisted of four parts: One arc bottom, two side circular arc arch and one circular arc roof umbrella arch. It is complex shape. Aiming at traditional methods there are complicated and the defects of inaccurate. on the basis of summarizing the predecessors' research, Based on the normal water depth basic equation mathematical transformation of egg-shaped sections, the interrelation between dimensionless water depth and the dimensionless parameter were analyzed, We use the power function as the formula form, with minimum residual standard deviation as the goal, the coefficients of the formula can be calculated based on the theory of optimization and regression. Then, we get calculation formula for normal water depth. This formula is not a piecewise function, and need not to choose the suitable formula according to the dividing flow. The results can be directly calculated. Results of the example calculation and error analysis showed that the maximum relative error of normal water depth was 0.675% respectively in the utility range (The ratio of water depth divided by height of tunnel is from 0.05 to 0.85). Using this algorithm, above 92 % of the computation error on normal water depth was less than 0.25%. The average error of the formulas was not more than 0.118% .The hydraulic calculation formula will be widely used in engineering design and project management due to its high accuracy and simple form.

## Introduction

At present, many scholars studied on calculation formula for normal water depth of circle, and city-opening section, solve practical problems in engineering[1-2]. An egg-shaped has the following characteristics[3]:1. Through the same flow its section width which is smaller, more conducive to the layout of the underground pipeline; 2. because of section height is greater than the width, Its vertical bearing capacity is greater than the other forms; 3. Through the same flow, its section height greater than the other forms, this would provide facilitating for manual dredging and maintenance; 4. It is suitable for rapid changes of flow, particularly during small flow through large diameter. It has the advantages of high velocity, high ability of anti sedimentation. So it is most commonly used in Foreign city sewage, rainwater pipeline engineering. Now, The direct solution on normal water depth of egg-shaped section tunnel has not been well studied. In this paper, through to mathematical transformation for the uniform flow equation of egg-shaped section, introducing the dimensionless parameters ,analyzing the relationship between dimensionless depth and the dimensionless parameters, according to the water and wastewater engineering norms and hydraulic engineering norms, we get calculation formula for normal water depth.

**Water cross-section of egg-shaped**

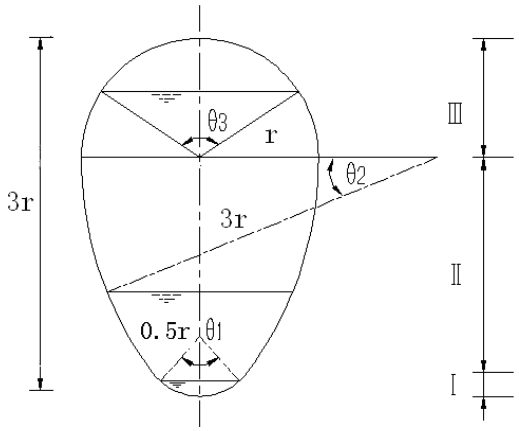

Fig.1 Zonal plan for calculating normal depth of an egg shaped cross-section.

**Hydraulic parameters of egg-shaped cross-section**

X- dimensionless normal water depth. $X = h/3r$ (1)

Three situations can be divided according to the dissimilarity of dimensionless depth X:

Table 1 Hydraulic parameters

| The range of dimensionless depth | The formula |
|---|---|
| I region<br>$0 < X \le \frac{1}{15}$ or $0 < \theta_1 \le 1.85459$ | $A = 0.125\,\mathrm{r}^2(\theta_1 - \sin\theta_1)$<br>$\chi = 0.5\,\mathrm{r}\theta_1$<br>$\theta_1 = 2\arccos(1-6X)$ |
| II region<br>$\frac{1}{15} < X \le \frac{2}{3}$ or $0 \le \theta_2 < 0.64350$ | $A = \mathrm{r}^2[3.02333 - 9\theta_2 - (3\cos\theta_2 - 2)(3\sin\theta_2 - 2\tan\theta_2) + 4\tan\theta_2]$<br>$\chi = \mathrm{r}(4.78830 - 6\theta_2)$<br>$\theta_2 = \arcsin(\frac{2}{3} - X)$ |
| III region<br>$\frac{2}{3} < X \le 1$ or $0 < \theta_3 \le \pi$ | $A = \mathrm{r}^2[4.59413 - 0.5(\theta_3 - \sin\theta_3)]$<br>$\chi = \mathrm{r}(7.92990 - \theta_3)$<br>$\theta_3 = 2\arccos(3X-2)$ |

**Uniform flow basic equation**

$$Q = \sqrt{i}A^{5/3}n^{-1}\chi^{-2/3} \quad (2)$$

Where: Q - discharge, $m^3/s$, i - channel bottom slope, $A$ - water sectional area, $m^2$, n – rough coefficient, $\chi$ - wetted perimeter, m.

**Ascertaining the suitable range of the dimensionless depth**

Literature shows that the free space above the water level require not less than 15 % of the whole cross-sectional area of the tunnel. exceeding this range is meaningless[4].

$$\frac{A}{A_0} = 0.85 \tag{3}$$

Where: $A_0$ - the area of egg-shaped cross-section

$$\frac{\left[4.59413 - 0.5\left(\theta_3 - \sin\theta_3\right)\right]r^2}{4.59413\, r^2} = 0.85 \tag{4}$$

This equation is the triangle transcendental equation, trying calculating solution are $\theta_3 = 2.19163$, $X = 0.81911$。Consider the appropriate extension, the upper limit value is 0.85, According to the actual most engineering application situation, the Lower limit value is 0.05.

**Implicit function expression of normal water depth of egg shaped cross section**

$$\frac{nQ}{\sqrt{i}\,r^{\frac{8}{3}}} = \begin{cases} \dfrac{\left[0.125\left(2\arccos(1-6X) - \sin\left(2\arccos(1-6X)\right)\right)\right]^{\frac{5}{3}}}{\left[\arccos(1-6X)\right]^{\frac{2}{3}}}, & 0 < X \le \dfrac{1}{15} \\ \dfrac{\left[3.02333 - 9\arcsin(\frac{2}{3}-X) - \left(3\cos(\arcsin(\frac{2}{3}-X)) - 2\right)\left(3\sin(\arcsin(\frac{2}{3}-X)) - 2\tan(\arcsin(\frac{2}{3}-X))\right) + 4\tan(\arcsin(\frac{2}{3}-X))\right]^{\frac{5}{3}}}{\left[4.78830 - 6\arcsin(\frac{2}{3}-X)\right]^{\frac{2}{3}}} & \dfrac{1}{15} < X \le \dfrac{2}{3} \\ \dfrac{\left[4.59413 - 0.5\left(2\arccos(3X-2) - \sin\left(2\arccos(3X-2)\right)\right)\right]^{\frac{5}{3}}}{\left[7.92990 - 2\arccos(3X-2)\right]^{\frac{2}{3}}} & \dfrac{2}{3} < X \le 1 \end{cases} \tag{5}$$

**A direct calculation formula for dimensionless normal water depth**

$$M = \frac{nQ}{\sqrt{i}\,r^{\frac{8}{3}}} \tag{6}$$

In order to study convenient, assume

By the optimization method of fitting, the direct calculation formula for dimensionless normal water depth of egg shaped cross section was obtained:

$$X = 0.420M^{0.523} + 0.002M^{3.164} + 0.003 \qquad M \in [0.015151, 3.152211] \tag{7}$$

**Formula evaluation**

Table 2. Distribution of relative error

| The correct dimensionless depth $X^*$ | Dimensionless coefficient $M$ | The calculation dimensionless depth $X$ | Relative error $\Delta$ (%) |
|---|---|---|---|
| 0.050 | 0.015151 | 0.049948 | -0.104 |
| 0.100 | 0.061020 | 0.100287 | 0.287 |
| 0.200 | 0.234791 | 0.199861 | -0.069 |
| 0.300 | 0.514979 | 0.300080 | 0.027 |
| 0.400 | 0.891784 | 0.399973 | -0.007 |
| 0.500 | 1.348380 | 0.499217 | -0.157 |
| 0.600 | 1.862754 | 0.598803 | -0.199 |
| 0.700 | 2.408678 | 0.700433 | 0.062 |
| 0.800 | 2.932281 | 0.800376 | 0.047 |
| 0.850 | 3.152211 | 0.844263 | -0.675 |

We investigation 10000 data within the common project , The results show that largest relative error is less than 0.675% . The average error is only 0.118%, which is less than 0.25% accounted for 92%.

**Calculation normal water depth application example**

It is known that the parameters of egg shaped cross section. The top arch radius $r = 2.5m$ , bottom slope $i = 1/1000$ , rough coefficient $n = 0.014$ , solved the normal water depth h when the flow $Q = 78\, m^3/s$ .

Answer:

Firstly, to calculate dimensionless coefficient M;

$$M = \frac{nQ}{\sqrt{i}\, r^{\frac{8}{3}}} = 2.9995$$

Using Formula（6）to calculate

Using Formula（7）to calculate $X = 0.420M^{0.523} + 0.002M^{3.164} + 0.003 = 0.8136$

Using Formula（1）to calculate $h = 3rX = 6.102$ (exact value is 6.107 m) relative error is 0.085%.

**Conclusion**

The simple approximate formula has high accuracy, Within the suitable range of the engineering, the absolute maximum relative error is 0.675%. It can satisfy the demand of practical engineering.

# The Study of Available Water Resources in Northern Shaanxi

Xi-jun Wu[1,2]

[1]Department of Construction Engineering, Yulin College, Yulin, China

[2]State Key Laboratory Base of Eco-hydraulic in Arid Area (Xi'an University of Technology), Xi'an, China

Wxj0826@163.com

**Keyword:** Northern Shaanxi; water resources; available water resources; surface water; groudwater

**Abstract:** In order to alleviate the contradictions about water resources shortage and socio-economic development in Northern Shaanxi, the water resources and their availability were studied. Through use the method of surface water resources deducte river ecological basic flow and flood discharge, calculated the surface available water resources and total available water resources of Northern Shaanxi, summarized their distribution characteristics. Study result showed that the available water resources of Northern Shaanxi is low, only 1.6 billion $m^3$, available rate is 40%, water resources and their availability principally distribute in Yulin.

## Introduction

Under the influence of global climate change, large-scale economic development and other multiple factors, China's water resources situation is undergoing new changes, so need to analyze and estimate available water resources [1]. Available water resources is both the conditions of comprehensive plan saving, configuration, development, utilization and treatment measures of regional water resources, and the basis of analysis water resources carrying capacity [2]. Northern Shaanxi is China's major energy and chemical industry base, water resources shortage, the contradiction between supply and demand of water resources increasingly sharp in recent years [3].

## Study Area and Research Methods

**Study Area**. North Shaanxi include Yulin and Yan'an two city of Shaanxi province, has abundant coal, oil and natural gas resources, is the rare resource-rich region of China. The region area is 80,300 km2, altitude 900-1500 m, in the central part of the Loess Plateau, drought and less rainfall, severe shortage of water resources. North Shaanxi average annual rainfall is 454.3 mm, 65% concentrated in July, Aug and Sep, rainfall showed a decreasing trend from south to north. Runoff variation regularity and characteristics is basically same with rainfall, this leading to uneven distribution in spatial and temporal of water resources. Fig 1 is the river system diagram of North Shaanxi.

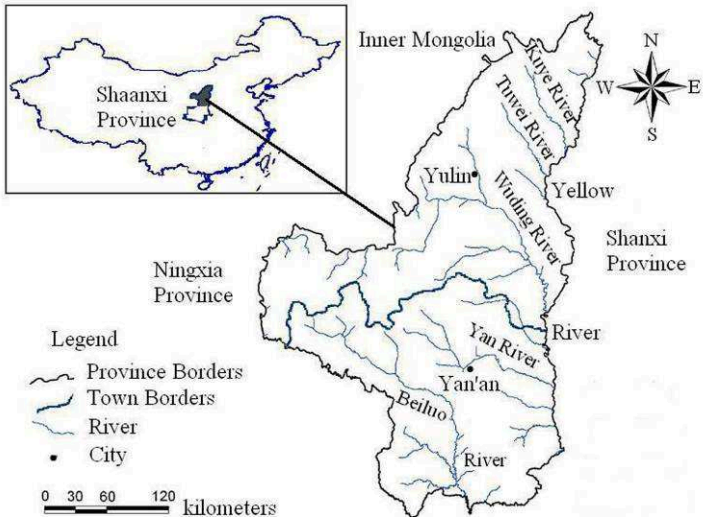

Fig. 1 The river system diagram of Northern Shaanxi

**Research Methods and Data Sources**. According the mastered data and materials, make the average annual surface water resources deduct the river ecological basic flow and flood discharge, take available surface water resources [4], the product of groundwater recharge and mineable coefficient is available groundwater resources, then calculate the available water resources of different regions and rivers, summarizes its characteristics and law. The data comes from "Shaanxi Water Conservancy Statistical Yearbook" [5] and" Shaanxi Water Resources Integrated Planning" [6], also references the "Shaanxi Water Function Regionalization "and other materials. As data source is not consistent, so the data may have some deviation.

## The Available Water Resources in North Shaanxi

**Calculation Methods**. Available water resources, it refer that in the foreseeable period, based on consideration of life, production and ecological environment water, the one-time maximum water can be used in total water resources[7]. Available water resources including available surface water and available groundwater, it was the addition of both then deducted repeat amount. The repeat amount was the ditch seepage of plain shallow groundwater and the exploitation of field infiltration recharge. The following is estimated formula [8]:

$$W_a=W_{s,a}+W_{g,a}-W_r \quad (1)$$

Wa is available water resources; Ws,a is available surface water; Wg,a is available groundwater; Wr is the repeat between both.

The surface water resources including the water can't be used and impossible used. The water can't be used must satisfied river ecological basic flow, and avoid the ecological environmental degradation and destruction. The impossible used water was unable to use and limited by various factors and conditions, it is the flood that beyond project largest storage capacity and supply capacity [9]. Surface water resources deduct the river ecological basic flow and the flood discharge, get available surface water resources. With formula (2) expression [10]:

$$W_{s,a}=W_s-W_e-W_f \quad (2)$$

Ws is surface water resources; We is river ecological basic flow; Wf is impossible used flood discharge.

The simple methods calculate river ecological basic flow is certain proportion of surface water resources. Flood water resources deducted reservoir stored water resources and water consumption in flood period is the flood discharge.

**Calculation Steps.** Based on the collected data, according to the above method calculate the available water resources in North Shaanxi. Calculation steps as follows, results as Table 1.

1) Confirm the river ecological basic flow: according to the domestic and foreign research results and the author's Weihe ecological base flow research [11], the river ecological basic flow of North Shaanxi was considered as 20% average annual runoff.

2) Flood water resources: according to the statistics of runoff in North Shaanxi, July to October is flood period, and the water resources of 4 months flood period is about 60% of the annual runoff.

3) Surface water consumption in flood period: because water consumption is average, and flood period is 4 months, so the surface water consumption in flood period is one-third of annual surface water consumption.

4) Flood discharge water: flood water resources deducted reservoir stored water resources and surface water consumption in flood period, the reservoir stored water resources and water consumption in flood period select maximum statistical data of each year, this paper is the 2010's data.

$$W_f=W_{f,s}-W_{r,s}-W_{u,s} \quad (3)$$

Wf,s is flood water resources; Wr,s is reservoir stored water resources; Wu,s is surface water consumption in flood period.

5) According to the formula (2), make the annual average surface water resources deduct river ecological basic flow and the flood discharge, get available surface water resources.

$W_{s,a}=W_s-W_e-W_f$

$=W_s-0.20W_s-(0.60W_s-W_{r,s}-W_{u,s})$

$=0.80W_s-(0.60W_s-W_{r,s}-W_{u,s})$

If: $0.60W_s-W_{r,s}-W_{u,s}\leq 0$, $W_{s,a}=0.80W_s$

If: $0.60W_s-W_{r,s}-W_{u,s}>0$, $W_{s,a}=0.20W_s+W_{r,s}+W_{u,s}$

Table. 1 The available surface water resources of North Shaanxi unit:100 million $m^3$

| District | ecological basic flow | flood discharge | reservoir stored water | water consumption of flood period | available surface water |
|---|---|---|---|---|---|
| Yulin | 3.69 | 3.37 | 4.42 | 1.37 | 9.48 |
| Yan'an | 2.58 | 4.90 | 1.16 | 0.50 | 4.24 |
| North Shaanxi | 6.27 | 8.27 | 5.58 | 1.87 | 13.72 |

From Table 1 we can know, North Shaanxi surface water available rate is low, the main reason is the flood discharge too much, about 827 million m3, the principal pathway increase available surface water is to reduce flood discharge in future, this can be achieved by constructing lots reservoirs and micro water storage engineering. Even in Northern Shaanxi unable to use temporarily, if can staggered with Yellow River mainstream flood peak, the flood discharge of North Shaanxi can also become Yellow River available water resources. [12].

**Available Groundwater Resources.** The Shallow available groundwater resources refers to the maximum amount of water allowed to be taken out from underground aquifer that in the condition of economic reasonable, technology feasible, water quality deteriorative, won't cause underground water level continued decline, land subsidence and other environmental geological problems. Although regional hydrogeology condition analysis, according to the total groundwater recharge, underground water level observation, actual yield, and other material, carries on simulation and calculation, confirm the mineable coefficient, and then calculate available groundwater resources of region.

$$W_{g,a}=\rho W_{g,r} \quad (4)$$

$W_{g,a}$ is available groundwater; $\rho$ is groundwater mineable coefficient; Wg,r is groundwater recharge;

According to relevant materials and calculation [6], the North Shaanxi annual average groundwater recharge is 1.04 billion m3, average mineable coefficient is 0.55, so the available groundwater resources in North Shaanxi is 571 million m3, including 458 million m3 of Yulin.

**Available Water Resources.** Through the above result, according to formula (1), we can get the total available water resources in North Shaanxi, Table 2.

Table. 2 Available water resources in North Shaanxi unit:100 million $m^3$

| District | Surface water | Groundwater | Repeat | Total | Rate |
|---|---|---|---|---|---|
| Yulin | 9.48 | 4.58 | 2.76 | 11.3 | 0.42 |
| Yan'an | 4.24 | 1.12 | 0.57 | 4.79 | 0.35 |
| North Shaanxi | 13.72 | 5.71 | 3.33 | 16.09 | 0.40 |

It can be get from Table 2, Northern Shaanxi available surface water, available groundwater and available total water respectively is 1.372 billion m3, 571 million m3 and 1.609 billion m3, now can satisfied the water demands, but due to uneven distribution, some area available water resources is still very shortage. It is predicted that in 2015 the water demand in North Shaanxi will be 1.5 billion m3, 2.4 billion m3 in 2020, at that time, only through the Yellow River water diversion to meet the demand. In North Shaanxi the available water resources spatial distribution law is same with water resources, water available rate is 40%, far less than 60% of GuanZhong region, it also have the potential of increasing available water resources by engineering measures. Table 3 is the water resources and availability of primary rivers in Northern Shaanxi.

Table. 3 The available water resources of primary rivers in Northern Shaanxi unit:100 million m3

| River | Water resources | Availble water resources | Rate |
|---|---|---|---|
| Wuding River | 13.08 | 5.63 | 0.43 |
| Yan River | 2.82 | 0.80 | 0.28 |
| Beiluo River | 9.50 | 4.26 | 0.45 |
| Kuye River | 6.30 | 0.95 | 0.15 |
| Tuwei River | 3.50 | 1.40 | 0.40 |
| Total | 35.20 | 13.04 | 0.37 |

## Conclusions

To sum up, in North Shaanxi the water resource is lacking, distribution is uneven, groundwater accounts for big ratio, and ecological environment is fragile, after 1980's surface runoff decrease obviously. It can be get through the calculation and analysis of available water resources, North Shaanxi available water resources is few, only 1.6 billion m3, and the available rate is 40%, but also have the increasing potential, as water resources, available water resources mainly distribute in Yulin; Future in North Shaanxi, the main way increased available water resources is the engineering measures to reduce flood discharge and divert water from Yellow River, and non-engineering measures to save water resources.

**Key words:** Lumped Mass Method, Flexible Mattress, Downstream Sinking, Mechanical Characteristic

**Abstract:** Downstream sinking technology of flexible mattress has wide application in erosion protection, berth firm and bank protection. During sinking of flexible mattress, the distance get gradually between the landing position of the mattress and the laying mattress ship, then the suspense length and mattress's self-weight are also increase because of the ship's move. Therefore the tension in mattress is also change continuously, so the calculation of the tension becomes difficult. By using lumped mass method, the mattress can be separated into several lumped mass which are connected using non-mass springs, with the laying distance increase, the length and self-weight of the mattress can be increase gradually, and according to forces equilibrium equation, the tension and profile of the mattress can be obtained.

## Introduction

Stability of a dam depends on steadity of the dam's protective bottom in waterway regulation engineering. As a new type protective bottom structure, flexible mattress with concrete ballast which is made from geotextiles and concrete ballasts has wide application in erosion protection, berth firm and bank protection because of its antifilferability, isolation, erosion protection, wholeness and applicability.[1]

When a flexible mattress is sank, general a downstream sinking way is used, because it can suit better the erosion deformation of riverbed after engineering. But during downstream sinking, the distance is bigger between the landing position of mattress and laying ship because of the ship's movement, so the mattress length and its self-weight are increase continuously, then the tension's calculation becomes difficult because of the various length and its self-weight. For security, a calculation method of the tension is needed.

Lumped mass method[2] is that, the continuous mattress is separated into several element, the mass of every elements are located even to element's ends, and every elements are connected by non-mass springs, considering the weight of mattress, buoyance, tension of laying ship to mattress, and apply force of hydrodynamic, establishing the force equilibrium equation of element. Solve for the tension of element mattress and using the relation of tension's change and mattress geometry change which is caused by it, and iterating gradually. Then the tension and profile of mattress with various length and self-weight can be just obtained.

**Calculation Modal**

A flexible mattress consists of a mat and fasten ballasts to it, the mat consists of geotextile and a longitudinal stiffening rib, the rib sews on the mat along the length direction, its length is same as the mat's length, the ends of the rib are made up into rings easy to connect of mattress body, sets of two fasten strip sewed on between the rib and mat cloth along transverse are used to tie ballasts. Longitudinal stiffening rib with a certain width is made from polyacrylic, it sewed on mat cloth at intervals of distance. The ballast is a concrete block, it has a certain dimension (length×width×thickness), between each block has a certain distance, and disposed even on the mat.

For a flexible mattress with concrete ballasts, the mass of concrete block is too much more than the mass of geotextile, stiffening rib and tie strip, so the mass of mat cloth, stiffening rib and tie strip can be ignored. Let the concrete block treat as a lumped mass, then the flexible mattress is just treated as a mattress modal which consists of many lumped mass and non-mass mat.

Let mattress is separated into n elements along the longitudinal, the two ends of every element are lumped mass (concrete ballast), the middle is mat (mat cloth and stiffening rib), their centers are taken as the centers of every element. The below end of first element is landing point of mattress on the riverbed, the upper end of nth element connected the roll of laying ship. As shown as Fig.1, the mass of every element are distributed to the ends of a element, that is, the mass of every element is sum of the half mass in two ends, and applied on the center of the element, hydrodynamic acting force applied also on the center, as shown as Fig.2.

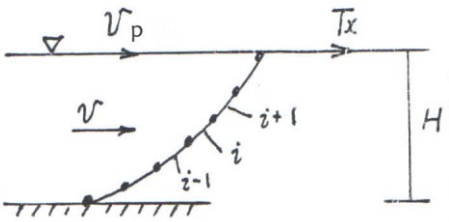

Fig.1 Model of mattress

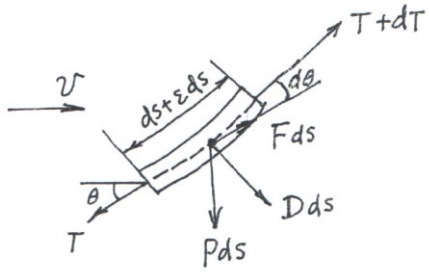

Fig.2 Forces acting on element

Where,

$P_i$ — sum of the half weight under water in two ends of $i$ th element

$D_i$ — normal component of hydrodynamic acting force of $i$ th element

$F_i$ — tangential component of hydrodynamic acting force of $i$ th element

$T_{x_i}$ ——horizontal component of tension in $i$ th element

$T_{y_i}$ ——vertical component of tension in $i$ th element

- Geometry of micro segment of mattress body

Take any micro segment on mattress body, then

$$dx = (1+\varepsilon)ds \cdot \cos\theta \quad (1)$$

$$dy = (1+\varepsilon)ds \cdot \sin\theta \quad (2)$$

where, $\varepsilon = \frac{\Delta S}{S} = \frac{T}{EA}$ (3)

$\varepsilon$ ——expansion of unit length of mattress body $T$ ——tension in mattress body

$E$ ——elastic module of mattress body $A$ ——section area of mattress body

- Mechanic analysis of micro segment of mattress body

What apply to any micro segment of mattress body are: tensions $T$ and $T+dT$ in the ends of the micro segment of mattress body ( $dT$ is the change of the tension), the weight P under water of the ballasts in ends, and the normal component D and tangential component F of the hydrodynamic acting force to the segment.

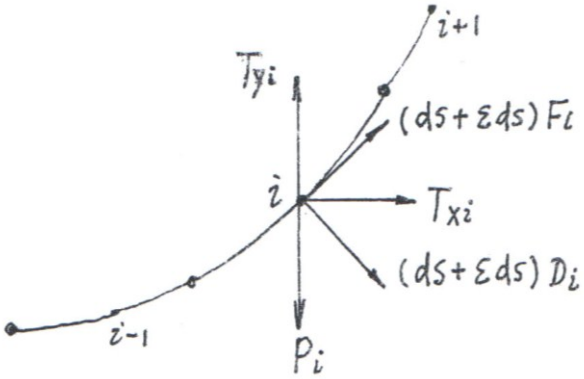

Fig.3 Forces acting on micro segment of mattress body

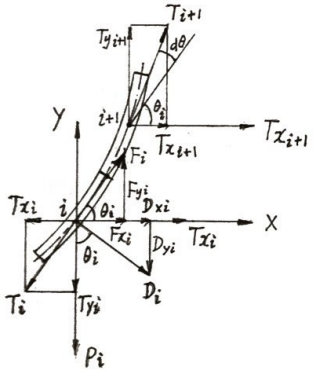

Fig.4 Forces acting on element

From Fig.3, the force equilibrium equation of the micro segment can be established

$$(T+dT)\cos d\theta - T - Pds\cdot\sin\theta + F(1+\varepsilon)ds = 0 \quad (4)$$

$$(T+dT)\sin d\theta - Pds\cos\theta - D(1+\varepsilon)ds = 0 \quad (5)$$

Where,

$dT$ —— the change of tension $d\theta$ —— the change of angle

$ds$ —— the length of micro segment

P—— sum of the half weight under water in two ends of micro segment

Formula (4) is divided by $ds$, then $\frac{T+dT}{ds}\cos d\theta - \frac{T}{ds} - P\sin\theta + F(1+\varepsilon) = 0$

When $d\theta \to 0$, $\cos d\theta \to 1$, then above can be written as

$$\frac{T+dT}{ds} - \frac{T}{ds} - P\sin\theta + F(1+\varepsilon) = 0$$

That is $\frac{dT}{ds} = P\sin\theta - F(1+\varepsilon)$ (6)

As same as above, formula (5) is divided by $ds$, then

$$\frac{T+dT}{ds}\sin d\theta - \frac{Pds}{ds}\cos\theta - \frac{D(1+\varepsilon)ds}{ds} = 0$$

When $d\theta \to 0$, $\sin d\theta \to d\theta$, then above formula can be written as

$$(T+dT)\frac{d\theta}{ds} - P\cos\theta - D(1+\varepsilon) = 0$$

That is $T\frac{d\theta}{ds} + \frac{dT\cdot d\theta}{ds} - P\cos\theta - D(1+\varepsilon) = 0$

$dT\cdot d\theta$ is ignored, then $\frac{d\theta}{ds} = \frac{1}{T}\left[P\cos\theta + D(1+\varepsilon)\right]$ (7)

- Mechanical analysis of element

For any element $i$, its one end's tension is $T_i$, in the other end has tension $T_{i+1}$ of the neighboring element $i+1$, besides, has also the sum $P_i$ of the half weight under water of ballasts in the ends, and the normal component $D_i$ and tangential component $F_i$ of hydro-dynamic acting force. As shown as Fig.4.

Then the force equilibrium equation of element $i$ can be obtained.

$$T_{x_{i+1}} = T_{x_i} - F_i \cos\theta_i (ds + \varepsilon ds) - D_i \sin\theta_i (ds + \varepsilon ds) \quad (8)$$

$$T_{y_{i+1}} = T_{y_i} - F_i \sin\theta_i (ds + \varepsilon ds) + D_i \cos\theta_i (ds + \varepsilon ds) + P_i \quad (9)$$

$$T_{i+1} = \sqrt{T_{x_{i+1}}^2 + T_{y_{i+1}}^2}, \quad (10)$$

where

$T_{x_i}, T_{x_{i+1}}$ — component in X direction of the tension in element $i$ and $i+1$, respectively

$T_{y_i}, T_{y_{i+1}}$ — component in Y direction of the tension in element $i$ and $i+1$, respectively

$D_i, F_i$ — normal and tangential component of hydrodynamic acting force to element $i$, respectively

Hydrodynamic acting force to an element is[3]

$$\sum F = \rho Q \beta V = \rho (VA) \beta V = \rho A \beta V^2$$

Its normal component $D = \rho A \beta V^2 \sin^2\theta$ (11)

Its tangential component $F = \rho A \beta V^2 \cos^2\theta$ (12)

where

$\rho$ ——density of water $(1000 kg/m^3)$ $Q$ ——flow of river

$A$ ——passage section area of an element

$\beta$ ——momentum calibration coefficient, $\beta = 1.02 \sim 1.05$

$V$ ——average velocity of flow at passage section, here we take index number formula about velocity of flow and $n = \frac{1}{7}$, then the relation between the velocity of flow at various height to riverbed and that of water plane can be obtained:

$$V = V\mathrm{p}(\frac{y}{H})^{\frac{1}{7}} \quad (13)$$

Where,

$V$ ——velocity of flow at height $y$ to riverbed

$V_p$ ——velocity of flow at water plane

$y$ ——height to riverbed $H$ ——depth of river

So the normal and tangential component of hydrodynamic acting force of $i$ th element can be written as, respectively

$$D_i = \rho A_i \beta \left[ V_P \cdot (\frac{y_i}{H})^{\frac{1}{7}} \right]^2 \sin^2\theta \quad (14)$$

$$F_i = \rho A_i \beta \left[ V_P \cdot (\frac{y_i}{H})^{\frac{1}{7}} \right]^2 \cos^2\theta \quad (15)$$

where

$\mathrm{A_i}$ ——passage section area of $i$ th element, is equal to $(y_{i+1} - y_i) \times$ width of mat cloth.

$y_i$ ——height of the center of $i$ th element to riverbed

Because the number and direction of two tensions in neighboring element $i$, $i+1$ are all changed, that leads to the center positions and the angles to horizontal direction of elements $i$, $i+1$ are also changed, as shown as Fig.5, and

$$x_{i+1} = x_i + (ds + \varepsilon ds)\cos\theta_{i+1} \quad (16)$$

$$y_{i+1} = y_i + (ds + \varepsilon ds)\sin\theta_{i+1} \quad (17)$$

$$\theta_{i+1} = \theta_i + d\theta_i \quad (18)$$

From formula (6), ( 7)

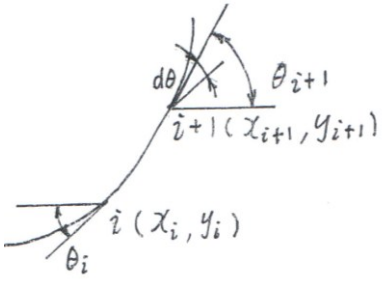

Fig.5 Geometry of neighboring element

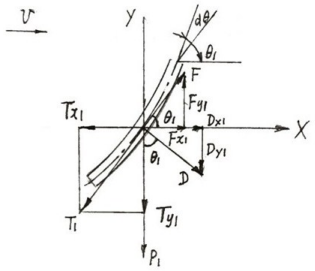

Fig.6 Forces acting on the first element

$$ds_i = \frac{dT_i}{P_i \sin\theta_i - F_i(1+\varepsilon)} = \frac{T_i d\theta_i}{P_i \cos\theta_i + D_i(1+\varepsilon)}$$

Then $$d\theta_i = \frac{dT_i}{T_i} \cdot \frac{P_i \cos\theta_i + D_i(1+\varepsilon)}{P_i \sin\theta_i - F_i(1+\varepsilon)} \quad (19)$$

Where $$dT_i = \sqrt{(dT_{x_i})^2 + (dT_{y_i})^2} \quad (20)$$

$$dT_{x_i} = T_{x_{i+1}} - T_{x_i} \quad (21)$$

$$dT_{y_i} = T_{y_{i+1}} - T_{y_i} \quad (22)$$

From formula (16) ~ (18), if every length $ds$ of laying mattress are know, then the central position and azimuth of next element $i+1$ are depended on the change $d\theta_i$ of angle to horizontal direction of the preceding element $i$, and from formula (19), $d\theta_i$ is depended on the tension $T_i$ and its change $dT_i$ of the element, hydrodynamic acting force and the weight $P_i$ under water of the ballast.

But in the first element of mattress, has only the weight under water of ballast and hydrodynamic, as shown as Fig.6, so the force equilibrium equation of the first element is

$$F_{x_1} + D_{x_1} - T_{x_1} = 0 \quad (23)$$

$$F_{y_1} - D_{y_1} - T_{y_1} - P_1 = 0 \quad (24)$$

From (23), ( 24)，we obtained the tension of the first element

$$T_{x_1} = F_{x_1} + D_{x_1} \quad (25)$$

$$T_{y_1} = F_{y_1} - D_{y_1} - P_1 \quad (26)$$

And $$T_1 = \sqrt{T_{x_1}^2 + T_{y_1}^2}$$

According to above, the calculation flow chart of profile and tension of mattress can be obtained, as show as Fig.7.

According to the result of calculation, connecting the coordinates ( $x_i$, $y_i$, $i = 1 \cdots n$) of whole elements, we can obtain the profile of mattress, also according to tensions of every element ($i = 1 \cdots n$), the tensions diagram can be obtained.

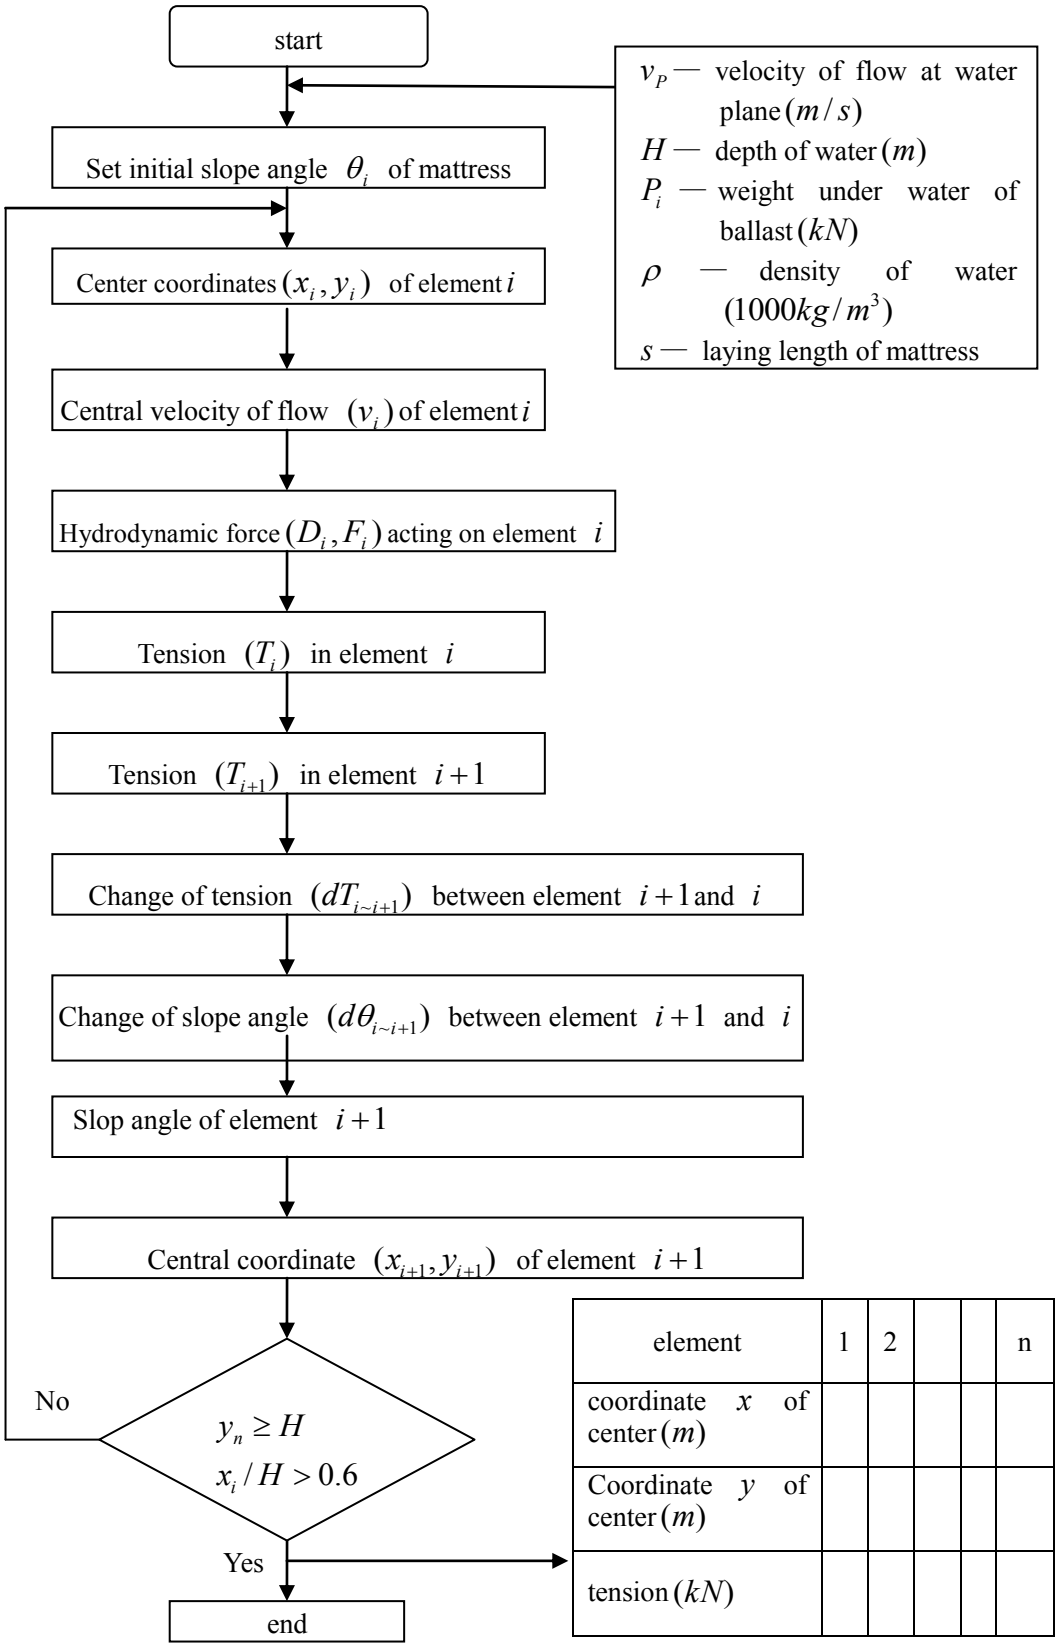

Fig. 7 Calculation flow chart

**Example**

A downstream sinking technology applied on a waterway. The depth of water is 8.5m, the velocity of flow at water plane is 0.89m/s. Suppose the relative movement displacement $\Delta x$ is taken as 0.6H, width of the mattress is 22m, the width of stiffening rib is 7cm and set one at interval of 25cm along the width direction, the ballast is made from concrete block with $40cm \times 26cm \times 12cm$, the mass of mattress under water of unit area is $W_1 = 64.12kg/m^2$. Solve for the tension and profile of mattress in downstream sinking.

- Suppose conditions:
  (1) Calculate the tension and profile of mattress with unit width (1m)
  (2) Divided elements along the longitudinal direction, the length of every element is $S = 1m$
  (3) Taking $\beta = 1.05$
  (4) No consider the elastic deformation of mat (cloth and rib), that is $\varepsilon = 0$
- Result
  (1) The profile and tension of the mattress are shown as Fig.8.

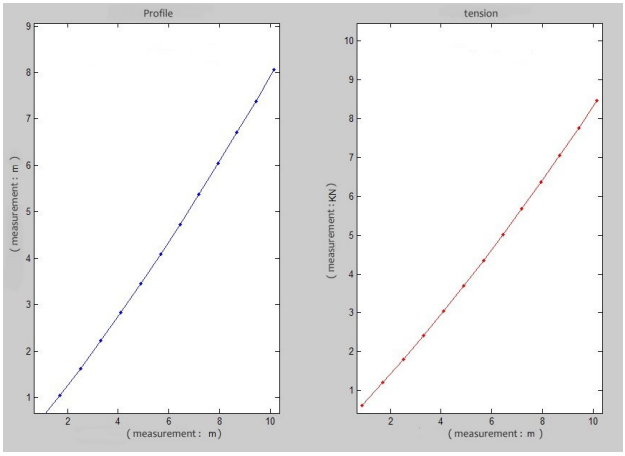

Fig.8 Profile and tension of mattress in $H = 8.5m$, $v_P = 0.89m/s$

(2) The coordinates X, Y of every element's center, raters of slop of tangent and tension are show as table 1.

| Element | 1 | 2 | 3 | 4 | 5 | 6 | 7 |
|---|---|---|---|---|---|---|---|
| Coordinate $x$ of center $(m)$ | 0.866 | 1.701 | 2.518 | 3.322 | 4.114 | 4.897 | 5.670 |
| Coordinate $y$ of center $(m)$ | 0.5 | 1.050 | 1.627 | 2.222 | 2.832 | 3.455 | 4.088 |
| Rate of slope of tangent | 0.577 | 0.659 | 0.706 | 0.741 | 0.770 | 0.796 | 0.818 |
| Tension $(kN)$ | 0.616 | 1.197 | 1.802 | 2.421 | 3.052 | 3.694 | 4.346 |
| Element | 8 | 9 | 10 | 11 | 12 | 13 | 14 |
| Coordinate $x$ of center $(m)$ | 6.436 | 7.195 | 7.946 | 8.691 | 9.430 | 10.162 | 9.403 |
| Coordinate $y$ of center $(m)$ | 4.73 | 5.383 | 6.043 | 6.710 | 7.384 | 8.065 | 10.215 |
| Rate of slope of tangent | 0.840 | 0.860 | 0.878 | 0.896 | 0.913 | 0.929 | 1.469 |
| Tension $(kN)$ | 5.008 | 5.679 | 6.361 | 7.052 | 7.753 | 8．463 | 11.583 |

## Conclusion

By using lumped mass method, the profile and tension of mattress in downstream sinking can be obtained. The advantages of the method are:

(1) Physical meaning of the mathematical equation is clear.
(2) High calculation efficiency.
(3) Being suited to the analysis of non-linear, non-uniform mattress.

**Keywords:** bend reach; navigation obstruction；ship model; necessary width

**Abstract**：The flow of bend reach is complicated, which is difficulty for intersection of shi p,and is accident prone. According to the lower reaches of the Hanjiang River MaKou reac h of ship model test results, the relationship between channel width and flow are summarized when ship navigation sail in bend reach, which indicated that at approximately the same spee d, navigation width of sailing through the bend upward are much smaller than down. As velo city or flow angle increases, the ship track width is broader, and channel width is also broader . the ship control and peer safety management points are forwarded in the lower reaches of Hanjiang river bend, which can provide reference for similar engineering design and researc h of waterway.

## Navigable river bend ship safety awareness

The river bend channel, not only bending but also narrow, which limited the ship curved scale and increase the difficulty of ship maneuvering. For channel improvement project of the river bend, not only width and depth of the navigation problem, but also flow velocity, flow pattern and width of ship in corners ship attitude and track are considered. The distribution of flow velocity is not uniform, so that the ship motion situation is more complex[1]. The results are not very well in study of curved route and route in advanced channel bends River, Therefore, in study of channel regulation, it is necessary for high grade waterway regulation scheme optimization and navigation safety guarantee to conduct ship model test, studying the problem in running posture, through the elbow river when the track width, curvature radius of large tonnage ships, At present, only straight navigation single line and double line width calculation formula is given in the "waterway regulation engineering technical specifications (JTJ312-2003)" on the general channel , for the bending section of the channel width about how to determine and calculate is not clear. The 3static calculation of track width, the distance between the ship and the ship away from the shore Line width for navigation calculation formula is only considered, the dynamic factors caused by water flow and induced yaw pitch etc is not considered."Standard inland navigable inland waterways in 2004" pointed out that the bending section width should be widened at base line segments on the channel width, widening value can be determined by calculation or experimental study [2].

For curved channel, channel conditions have great effect on navigation safety. Curved cha nnel must have a certain width and depth conditions for navigation [3-4], at the same time, the radius of curvature of the channel should not be too small. The ship through the windingchan nel, smaller bending radius of curvature , bigger fleet scale, urgent flow , ship angle, drift ang le and yaw angle are larger, which leading addition channel width and track width increase,

and navigation is difficulty [5]. The route planning and line layout of bend channel is different l ine channel, the general layout principle:entrance slightly expanded (gradient),bendingtop sectio n widest,export of curve become narrow. In general , widening the channel bends is in the co rners of the inside, but also in the medial and lateral curve equivalent widening. Afterwidening , straight channel smooth connection enable the smooth water flow.

**General situation of typical shoal**

MaKou beach located in the lower reaches of the Hanjiang River, it is from Yang Chi Kou down to the ZhuJiahe, full-length is10.9km. MaKou beach is typical bend river with narrow width. Both sides have dikes, and the dikes are all with embankment. Because the constraint of dikes and revetment , wing of mainstream is limited, which belongs to typical two river one embankment. Last century, Makou experienced development process of forming –development -natural cut offs. in the face of the flood in 1983 , tin bend ended the evolution of natural cut off, forming a new bend, which shortened 5.9km than old .When in middle and low water b ending radius is only 400m with poor conditions. By influence of cross-strait dike, curve evol ution is restricted and curvature radius is invariable. The navigation obstruction of Makou bea ch is mainly of small radius of curvature and ship crossing difficult, at the same time, ben d obstacle is the concave deep grooves exist or development also influence for bend widthfor navigation.

**Ship model test under different flow conditions**

The ship navigation situation of curving bend is in downstream over the bay, side to side. The ship speed is large, and speed reducing is slow, control ability is poor after stopping. Ship speed of countercurrent is slow and easy to control. Because of the bigger velocity andlow angle when ship is sailing in the stream bend, ship to the low potential side drift faster [6].Makou beach belongs to the typical curved channel, bending angle is140 degree, navigation obstruction of Makou reach is mainly of small radius of curvature and ship crossing difficult,planning channel scale is 2.4m * 90m * 500m(depth x double width * bending radius), but in the curved section of ship safety rendezvous navigation width needs to be widened, specific width need to be determined through test.

**Conditions of bend flow and width test of the ship curved fairway.** Multiple groups of ship model under different flow conditions of Makou beach are tested [7]. The width of channel of bend inlet, bend top and outlet section is studied. Flow velocity, flow direction andwidth of relationship between statistics on two-way navigable under different flow conditions are shown in Table 1~ Table 3, in the sheet flow rules of pointing to convex bank is "-". The transition section in the upper inlet bend or changeover portion, the maximum velocity profile is often biased point. After entering the curve, the mainstream gradually shifted to the side of concave bank, at the top of the bend part of partial on the concave bank, transversegradient enhanced water, with curved, gradually recover in the flow momentum side ofconcave bank concentration, transverse gradient to has turn away. This kind of change of the bend flow have an effects on the maneuvering ship, the adjustment is along with the water change.

The inlet of curve (Table1): the channel width of ship increases with increase of lateral velocity. when the direction of flow point to concave bank, which much influence the width down. Ship is easy to drift to the concave bank as extrusion of ship model by oblique flow, which lead to stern to starboard deviated from midline ion; When the water toward the con vex bank, operation is difficult upward and width is slightly larger; The problem is mainly t he width beyond the route down in inlet section, ship model convert the upstream navigatio n width.

Table.1 The relationship between flow conditions and the ship curved fairway width in entrance section of bend

| flow($m^3$/s) | velocity(m/s) | Flow direction(°) | Track width (down)m | Track width (upward)m | Necessary width m |
|---|---|---|---|---|---|
| 447 | 1.38 | -4 | 54 | 28 | 125 |
| 1500 | 1.41 | 7 | 60 | 25 | 131 |
| 2500 | 1.43 | -4 | 62 | 40 | 135 |
| 5000 | 1.85 | 3 | 54 | 26 | 128 |
| 447 | 1.25 | 8 | 42 | 25 | 93 |
| 447 | 1.21 | 3 | 27 | 32 | 85 |
| 5000 | 1.89 | -5 | 58 | 38 | 140 |

The top bending section (Table2): the velocity is smaller than flow velocity of inlet ben d , but the necessary width is large. The flow turn to the concave, and the angle is large. Witht he increase of flow rate, width is also larger. Track width is widest in the top bend , which as great impact on the ship model ship model down. It needs manipulate large rudder angle t o adjusting motions and avoiding ship starboard meeting concave bank .Track width is 55~95 m down ;navigation width of ship model was affected by upward flow direction, track width d own is wider, so upstream ship is close to the convex bank , though flow velocity is very s mall , Upward navigation width increases as corresponding angle increase .

Table.2 The relationship between flow conditions and the ship curved fairway width in urved roof of bend

| flow($m^3$/s) | velocity(m/s) | Flow direction(°) | Track width (down)m | Track width (upward)m | Necessary width m |
|---|---|---|---|---|---|
| 1500 | 0.98 | 10 | 63 | 30 | 161 |
| 2500 | 1.08 | 13 | 70 | 34 | 150 |
| 5000 | 1.56 | 15 | 86 | 36 | 185 |
| 447 | 0.65 | 16 | 55 | 36 | 130 |
| 4000 | 1.72 | 16 | 85 | 40 | 182 |
| 5000 | 1.84 | 16 | 90 | 45 | 185 |
| 9000 | 2.05 | 25 | 93 | 55 | 215 |

Outlet section of bend (Table 3):The flow is relatively smooth in outlet section, the ship width increases with the velocity of flow. Velocity is small without cross flow, but because tra ck zone width is larger in the curved top,it needs some time to adjust state in top bend.Wi dth of outlet section is still exceed the prescribed navigation width of straight section.
Ship upward in outlet section is relatively easy to secure, upward track zone width is influe nced small by the variation of the flow velocity ,basically in the range of 25~40m. The shi p curved width is smaller than bending width in the top section under the same flowcondition s .

Table.3 The relationship between flow conditions and the ship curved fairway width in outlet section of bend

| flow($m^3$/s) | velocity(m/s) | Flow direction(°) | Track width (down)m | Track width (upward)m | Necessary width m |
|---|---|---|---|---|---|
| 447 | 0.94 | 0 | 49 | 26 | 102 |
| 2500 | 1.43 | 2 | 68 | 30 | 132 |
| 447 | 0.85 | 4 | 60 | 30 | 110 |
| 815 | 1.08 | 0 | 58 | 30 | 114 |
| 447 | 0.90 | 0 | 45 | 25 | 131 |
| 5000 | 1.95 | 6 | 72 | 35 | 168 |
| 9000 | 2.42 | 7 | 81 | 40 | 195 |

**Summary.** The test showed: the ship sail through bending, in order to turn and overcome the influence of bend flow,it need to produce significant drift and additional width for navigation , and with the increase of channel flow velocity, the route of the ship also produce a certainl ateral drift. navigation width of sailing through the bend upward are much smaller than down. The same fleet at approximately the same speed, sailing through the same bend, the width upw ard is smaller than down. That is to say, the same fleet line can through bend upward, but it is not sure downward .As velocity increasing down, track width is greater, and change is obv ious.

## Conclusion

For ship navigable conditions of curved river , factors affecting the safety of ships through t he main curve include radius of the curve, flow velocity , mainstream and flow channel angle designed of bend .Any factors changed will change the ship curved lines and curved width [8].A nalysis of the width of track cornering test on multi ship with running posture,rudder angle, forak ou beach, velocity and direction are bent on ship (especially downward curved) have great infl uence on the track width. For the improvement of channel condition, optimized space of the curvature radius is small. For the flow velocity and direction, it has optimization space, espec ially in the design route, as far as possible according with the current mainstream bend flow path, design ship curved route. At the same time, with the addition of some renovation proje ct to adjust and optimize the flow curve, which make it fitting design route, security will great ly enhanced.

In order to improve the safety of navigation in channel, channel management department need to complete set safety warning device, strengthen training, improve the driver safety technology . From the influence of ship integrated analysis of curved factors, ship turning operation needs to pay attention to the following points: (1) navigators should accurately grasp channel hydrological data. Drivers need to make detailed analysis and Research on bending leg before sailing. (2) The ship sailing in the corners should slow down properly. Because the ship by the bend flow produced by the action of drift, and ship drift with the increase of speed and increase. Properly reduce speed to reduce the transverse drift. (3) With a small rudderangle operation to correct heading drift. The ship from the bend down, because flow dynamic axis near the convex bank, can be appropriate to concave small rudder angle corrected heading drift; the ship from the bend upward with the opposite. The curve is concave convex surface river flow from flow, flow is the opposite, but the overall effect of lower surface flow by cross flow, so the ship should be close to the point of some. The ship to the concave side by rudder should be carefully, and suitable for small rudder angle. (4) Shipshould navigate near bend channel flow dynamic axis to avoiding occurrence of loxodrom.(5) Ship should be accompaniedby sound signals to remind other boat to striving for collision avoidance.

# Data Assimilation of River Networks Using Extended Kalman Filter

Yifan Chen[1, a], Jinglin Qian[1, b]

[1]Zhejiang Institute of Hydraulic & Estuary, Hangzhou 310020, China

[a]zjucoolboy@163.com, [b]qjlhz@163.com

**Keywords:** river network; data assimilation; extended kalman filter

**Abstract.** In order to improve the accuracy of river network hydraulic model, extended kalman filter was used for real-time updating model states. In a simulation example of a river network composed of 14 channels, it systematically analyzed the effects of process and measurement noises on state correction. The results show that the extended kalman filter is able to effectively carry out data assimilation of non-linear river network system, and big process noise in combination with relatively small measurement noise is recommended for state correction.

## Introduction

Research on real-time correction technology, which is to improve flood simulation and forecast of river network hydraulic model, is an important subject. Fread[1,2] applied kalman filter in the FLDWAV model developed by USA National Weather Service. Shiiba [3] used reduced rank square root method coupling kalman filter to deal with colored noise. Ge Shouxi [4] took observable variables, roughness coefficients and both as state variables, respectively, combining with kalman filter. Zhou quan [5] proposed an alternate correction method which alternates stage and discharge as state variables. Romanowicz [6] used kalman filter combined with adaptive prediction technology for Severn River stage correction, according to the real-time data received form sensors. Madsen [7] and Wu Xiaoling [8, 9] introduced spatial information based on gain matrix into optimizing process noise matrix.

Advantages of kalman filter include hige-speed computing, small required compute memory and ease of error analysis, which are useful for real-time updating system states. Up to now, the standard kalman filter for linear system and extended kalman filter for non-linear system have been developed. On the basis of nonlinearity of river network hydraulic model, extended kalman filter is adopted for real-time state correction in the present paper.

## Mathematical model

In general, river network hydraulic equations can be expressed as:

$$\boldsymbol{F}(\boldsymbol{X},t)=0 \tag{1}$$

Where $\boldsymbol{F}$ represents a group composed of the hydraulic equations, and the Saint-Venant equations are used to describe one-dimensional flow motion in the present paper. $\boldsymbol{X}$ is the state variable vector, and $t$ denotes the time.

After discretizing hydraulic equations along the space and the time coordinates with consideration of process white noise (refer to the reference [10]), Eq. (1) is finally rewritten as:

$$\boldsymbol{X}_k=\boldsymbol{\Phi}_k(\boldsymbol{X}_{k-1},k-1)+\boldsymbol{\Gamma}_k(\boldsymbol{X}_{k-1},k-1)\boldsymbol{W}_k \tag{2}$$

Where $\boldsymbol{\Phi}_k$ denotes the non-linear state equations at time step $k$-1, $\boldsymbol{\Gamma}_k$ is the noise weighting matrix, $\boldsymbol{W}_k$ is the process noise vector with average equal to zero.

If measurement instruments are distributed in river network, measurement equations with consideration of measurement white noise can be defined as:

$$\boldsymbol{Y}_k=\boldsymbol{H}_k(\boldsymbol{X}_k,k)+\boldsymbol{V}_k \tag{3}$$

Where $\boldsymbol{Y}_k$ is the measurement variable vector, $\boldsymbol{H}_k$ denotes the measurement equations at time step $k$, $\boldsymbol{V}_k$ is measurement noise vector with average equal to zero.

Combining Eqs. (2) and (3), non-linear dynamic system of river network can be expressed as:

$$\begin{cases} \boldsymbol{X}_k = \boldsymbol{\Phi}_k(\boldsymbol{X}_{k-1}, k-1) + \boldsymbol{\Gamma}_k(\boldsymbol{X}_{k-1}, k-1)\boldsymbol{W}_k \\ \boldsymbol{Y}_k = \boldsymbol{H}_k(\boldsymbol{X}_k, k) + \boldsymbol{V}_k \end{cases} \tag{4}$$

The non-linear system of above equations needs a linearization. With the assumption that corrected state variable vector $\hat{\boldsymbol{X}}_{k-1}$ have been got at time step *k*-1, Eq. (4) can be linearized as, using Taylor one-order expansion:

$$\begin{cases} \boldsymbol{X}_k = \dfrac{\partial \boldsymbol{\Phi}_k}{\partial \hat{\boldsymbol{X}}_{k-1}} \boldsymbol{X}_{k-1} + [\boldsymbol{\Phi}_k(\hat{\boldsymbol{X}}_{k-1}, k-1) - \dfrac{\partial \boldsymbol{\Phi}_k}{\partial \hat{\boldsymbol{X}}_{k-1}} \hat{\boldsymbol{X}}_{k-1}] + \boldsymbol{\Gamma}_k(\hat{\boldsymbol{X}}_{k-1}, k-1)\boldsymbol{W}_k \\ \boldsymbol{Y}_k = \dfrac{\partial \boldsymbol{H}_k}{\partial \hat{\boldsymbol{X}}_{k/k-1}} \boldsymbol{X}_k + [\boldsymbol{H}_k(\hat{\boldsymbol{X}}_{k/k-1}, k) - \dfrac{\partial \boldsymbol{H}_k}{\partial \hat{\boldsymbol{X}}_{k/k-1}} \hat{\boldsymbol{X}}_{k/k-1}] + \boldsymbol{V}_k \end{cases} \tag{5}$$

Where $\dfrac{\partial \boldsymbol{\Phi}_k}{\partial \hat{\boldsymbol{X}}_{k-1}}$ is linear state operator, $\dfrac{\partial \boldsymbol{H}_k}{\partial \hat{\boldsymbol{X}}_{k/k-1}}$ is linear measurement operator.

Referring to the reference [11], the extended kalman filtering algorithm with its calculation procedure shown in Fig.1 is expressed as:

1. State prediction

$$\hat{\boldsymbol{X}}_{k/k-1} = \boldsymbol{\Phi}_k(\hat{\boldsymbol{X}}_{k-1}, k-1) \tag{6}$$

2. Error variance prediction

$$\boldsymbol{P}_{k/k-1} = \frac{\partial \boldsymbol{\Phi}_k}{\partial \hat{\boldsymbol{X}}_{k-1}} \boldsymbol{P}_{k-1} \left[ \frac{\partial \boldsymbol{\Phi}_k}{\partial \hat{\boldsymbol{X}}_{k-1}} \right]^T + \boldsymbol{\Gamma}_k(\hat{\boldsymbol{X}}_{k-1}, k-1)\boldsymbol{Q}_k \boldsymbol{\Gamma}_k(\hat{\boldsymbol{X}}_{k-1}, k-1)^T \tag{7}$$

3. Gain matrix

$$\boldsymbol{K}_k = \boldsymbol{P}_{k/k-1} \left(\frac{\partial \boldsymbol{H}_k}{\partial \hat{\boldsymbol{X}}_{k/k-1}}\right)^T \left[\left(\frac{\partial \boldsymbol{H}_k}{\partial \hat{\boldsymbol{X}}_{k/k-1}}\right) \boldsymbol{P}_{k/k-1} \left(\frac{\partial \boldsymbol{H}_k}{\partial \hat{\boldsymbol{X}}_{k/k-1}}\right)^T + \boldsymbol{R}_k\right]^{-1} \tag{8}$$

Where $\boldsymbol{R}_k$ is observational error covariance.

4. State correction

$$\hat{\boldsymbol{X}}_k = \hat{\boldsymbol{X}}_{k/k-1} + \boldsymbol{K}_k[\boldsymbol{Y}_k - \boldsymbol{H}_k(\hat{\boldsymbol{X}}_{k/k-1}, k)] \tag{9}$$

5. Error variance correction

$$\boldsymbol{P}_k = (\boldsymbol{I} - \boldsymbol{K}_k \frac{\partial \boldsymbol{H}_k}{\partial \hat{\boldsymbol{X}}_{k/k-1}}) \boldsymbol{P}_{k/k-1} \tag{10}$$

**Case study**

The layout of a hybrid river network is shown in Fig.2, and its section data and boundary conditions can be found in the reference [12] in details.

Tests regarding the impact of different process noise and measurement noise on data assimilation are carried out. Node stage variables are taken as state variables, and three cascaded solving method [10] is adopted for solving Eq. (2). In the tests, it assumes that two gauge stations are set at the 9th node denoted as station 1 and the 13th node denoted as station 2. Stage process noises $W_k$=0.005, 0.01, 0.02m are tested in combination with three different measurement noises $V_k$=0.005, 0.01, 0.02m, respectively, as shown in table 1.

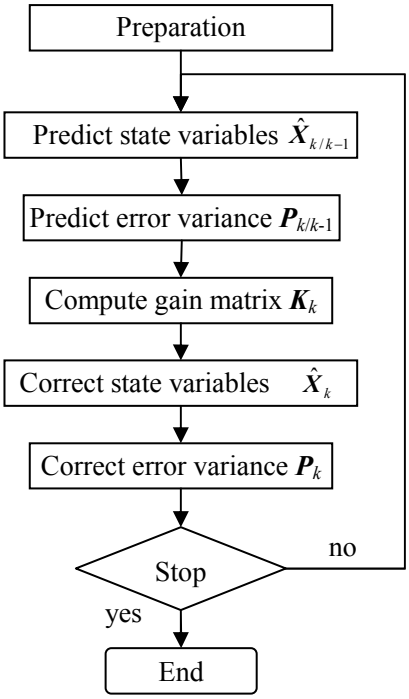

Fig.1 Flowchart of extended kalman filter

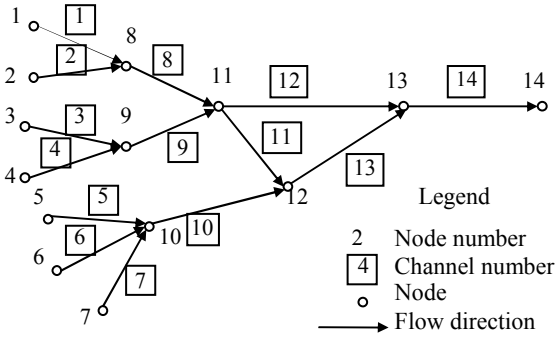

Fig.2 The schematic diagram of a river network

Table 1 Set of tests (√: succeed, ×: fail)

| $W_k$/m | $V_k$/m | | |
|---|---|---|---|
| | 0.005 | 0.01 | 0.02 |
| 0.005 | √ | √ | √ |
| 0.01 | √ | √ | √ |
| 0.02 | √ | √ | √ |

Figs.4 and 5 show the effects of process noise $W_k$ and measurement noise $V_k$ on real-time correction of state variables at gauge station 1 and 2, respectively. Compared to Fig.3, it is noticeable that state variables corrected using extend kalman filter are much more accurate than that without correction, i.e. , extended kalman filter presented in this paper is useful for updating hydraulic model states of non-linear river network system. After some time steps of correction, the errors are close to zero. We can also find that the smaller the measurement noise $V_k$ is, the smaller is the error. However, the smaller the process noise $W_k$ is, the bigger is the error.

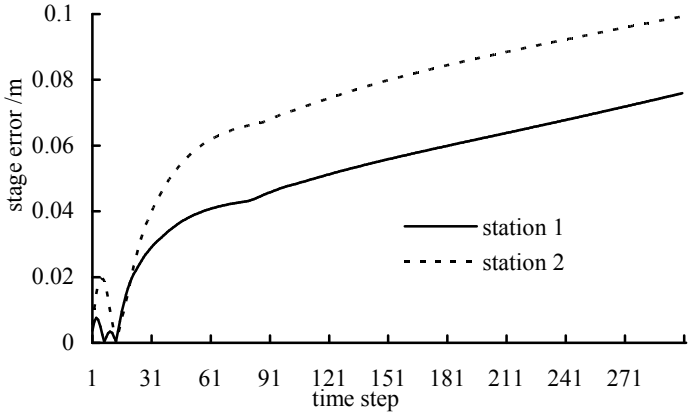

Fig.3 Hydrograph of errors between simulated and observed stage at stations 1, 2 without correction

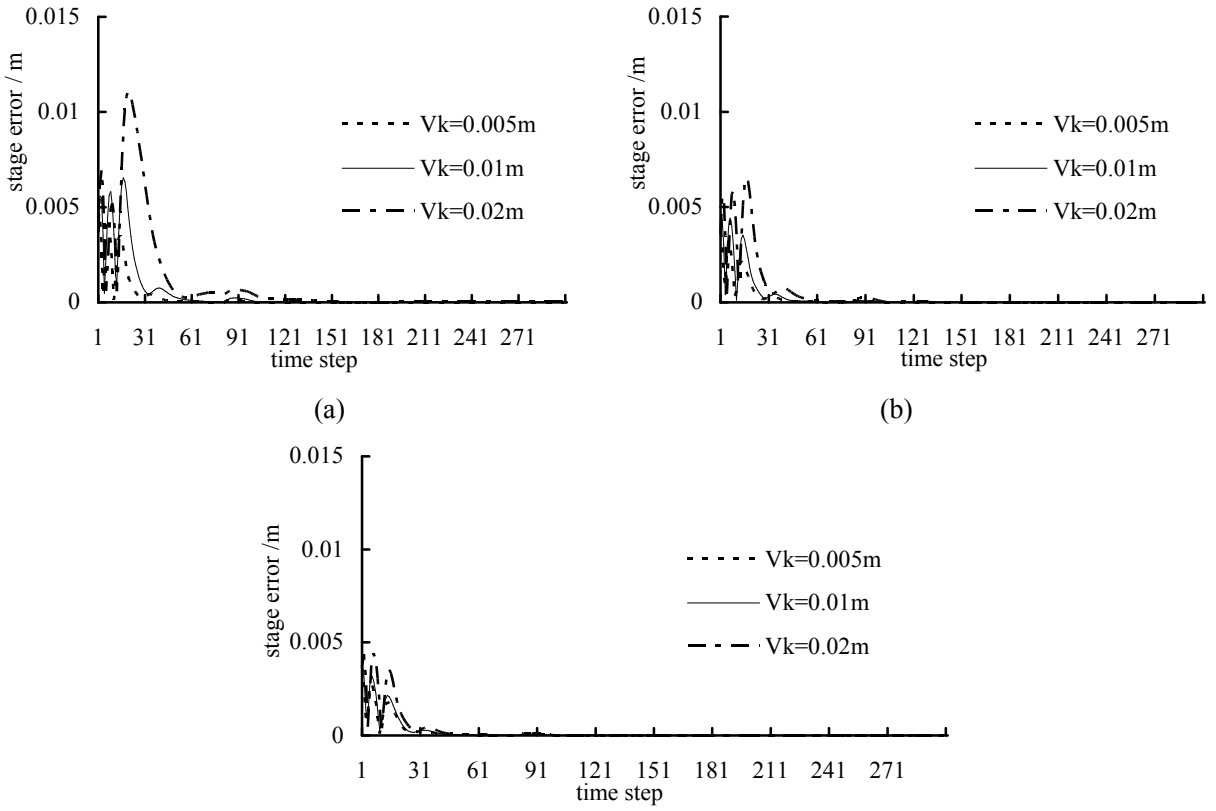

Fig.4 Hydrograph of errors between corrected and observed stage at station 1
(a) $W_k$=0.005m; (b) $W_k$=0.01m; (c) $W_k$=0.02m

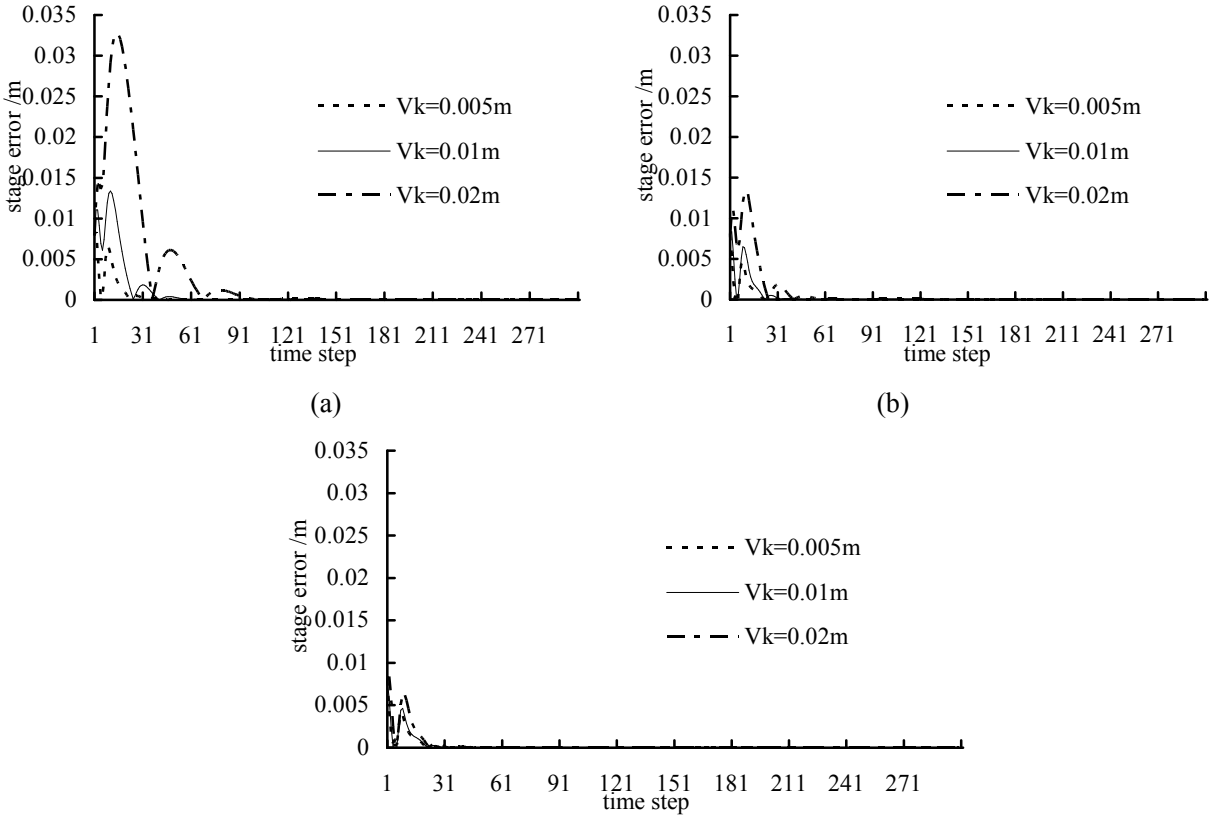

Fig.5 Hydrograph of errors between corrected and observed stage at station 2
(a) Wk=0.005m; (b) Wk=0.01m; (c) Wk=0.02m

## Conclusion

A robust model for real-time state correction for non-linear river network system combining with extended kalman filter is developed in the present paper. Tests taking account of both process noise and measurement noise are carried out to examine their effects on dada assimilation. The numerical results show that extended kalman filter can effectively improve the accuracy of river network hydraulic model. Furthermore, correction with big process noise, small measurement noise yields better results than that with small process noise, big measurement noise.

**Keywords:** hydraulic engineering; tailing dam; seepage stability; saturation line; numerical analysis.

**Abstract.** Understanding the influences of water level on seepage stability of tailing bay is an important topics in hydraulic engineering design. The seepage stability of tailing bay under different water level was calculated with the numerical simulation software FLAC3D and the change laws of water pore pressure and saturation line in the dam was analyzed. The results show that the saturation line in the dam is a parabolic curve and the pore pressure changes in layers. With the increasing of water level, the saturation line in the heaping dam ups rather obviously while it is not obvious in the initial dam. The maximum pore pressure in the bottom of the dam increases with the relationship of water level up, the shallow of the saturation line is in the heaping dam heel.

## Introduction

As it can be seen from some accident cases of tailing dam, almost all of the tailing dam accident are associated with water, it is because of the tailing dam is both the storage of tailing and water, and the presence of water makes the geotechnical problems of tailing dam engineering become more complicated[1-3].

Except for the specification of the characteristics of initial dam and the slope ratio of the tailing dam from the initial engineering design, in the operation period, other factors are all of dynamic changes with the interaction of water. Water is the key influence factor of the deformation and stability of dam. Saturation line is the lifeline of tailing dam, its location is one of the most important parameters in the analysis of stability, and it is also an important characteristic of distinguish tailing dam safety or not. So it is very meaningful to study the water seepage behavior in the tailing dam.

The saturation line of the tailing dam is different from common earth-rock dam. The influence factors on saturation line include: the water table, the drainage of initial dam and rainfall, etc. In general, some measures are helpful to control the saturation line, however, when it comes to rainstorm and flood, the seepage stability of the dam is not guaranteed[4-5].

In this paper, the seepage stability of tailing dam under different water level was analyzed with the numerical simulation software FLAC3D, the water lever is 15 meters, 20 meters and 25 meters, respectively, the results can provide certain references for the similar hydraulic engineering.

## Numerical computational model

In this paper, finite difference program FLAC3D based on the Fast Lagrangian Method was used to calculate and analyze influences of water level on seepage stability of tailing bay. The numerical computational model was shown in Fig. 1, in which the heaping dam size was based on the initial engineering design. Horizontal displacement constraints and vertical displacement constraints were set in the right and bottom of the numerical computational model, respectively. The grid meshing was shown in the Fig.2.

According the functions of FLAC3D, the saturation table was just the interface between up zero and down zero of water pore pressure, so in this paper pore water pressure nephogram were used for not only showing the location of the saturation line, but also showing the distribution law of pore pressure in the dam.

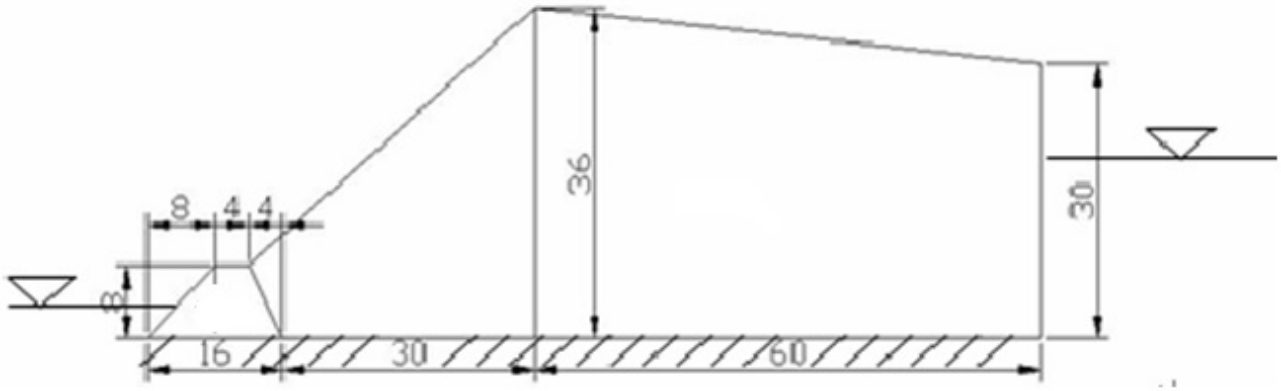

Fig.1 Numerical computational model and boundary conditions

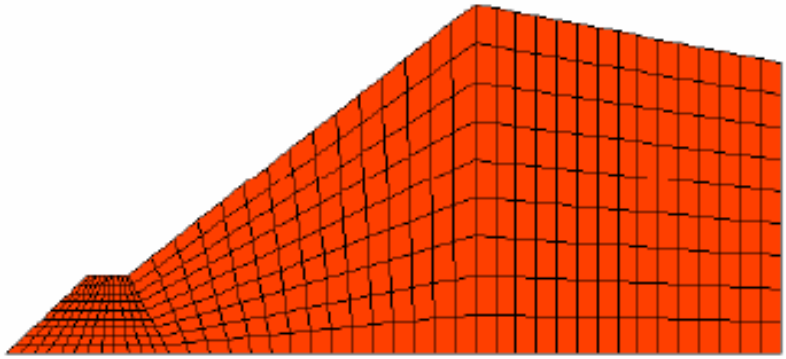

Fig.2 Grid meshing

**Material Properties**

During the numerical analysis, the Mohr-Coulomb model was adopted to simulate the soil behavior of elastic-plastic deformation. Based on the data of engineering geologic examination, the soil was divided into four layers(light mild clay mild, mild clay mild, mild clay mild and sandstone from the top down) and the initial dam. The bottom of the dam was sandstone, which was treated as impervious layer. The physical and mechanical properties of foundation soil was illustrated in Tab.1. According to Equation (1) and (2), the bulk modulus and shear modulus can be converted from elasticity modulus.

Bulk Modulus: $$K=\frac{E}{3(1-2\upsilon)} \quad (1)$$

Shear Modulus: $$G=\frac{E}{2(1+\upsilon)} \quad (2)$$

Tab.1 The physical and mechanical properties of soil layers

| soil class | ω（%） | $e$ | $\rho$（kg/m$^3$） | $E_s$（MPa） | $K_{20}$（cm/s） | $c$（kPa） | $\varphi$（°） |
|---|---|---|---|---|---|---|---|
| initial dam | - | - | 2100 | - | $20\times10^{2}$ | 0 | 40 |
| light mild clay mild | 23.1 | 0.83 | 1970 | 12.3 | $2.0\times10^{-5}$ | 13.4 | 24.0 |
| mild clay mild | 17.6 | 0.74 | 2000 | 10.65 | $3.4\times10^{-4}$ | 16.8 | 24.6 |
| mild clay mild | 16.5 | 0.68 | 2020 | 3.92 | $3.2\times10^{-4}$ | 20.1 | 25.0 |
| sandstone | - | - | 2110 | 4.62 | - | - | - |

**Results**

In order to analysis the influences of water level on the seepage stability, three cases of water lever had been put forward in this paper, the water lever is 15 meters, 20 meters and 25 meters, respectively. The numerical analysis results were shown in Fig.3~Fig.5. In Fig.6, the saturation lines were drawn under different water levels.

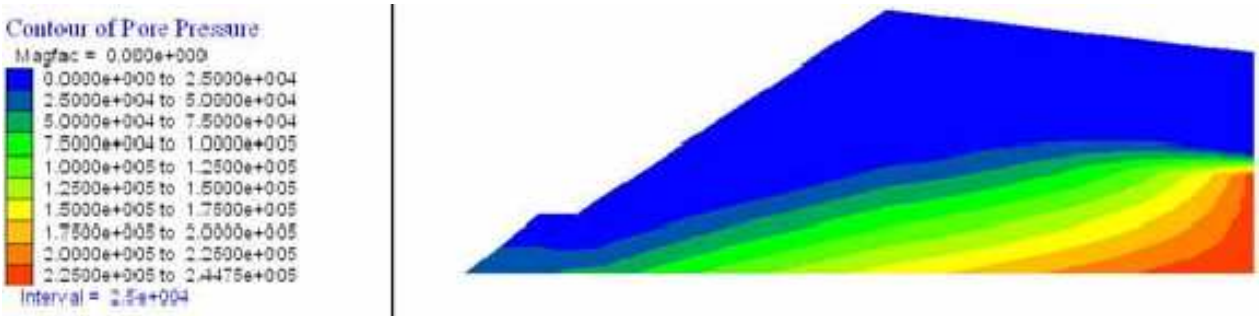

Fig.3 The saturation line when the water level is 15 meters

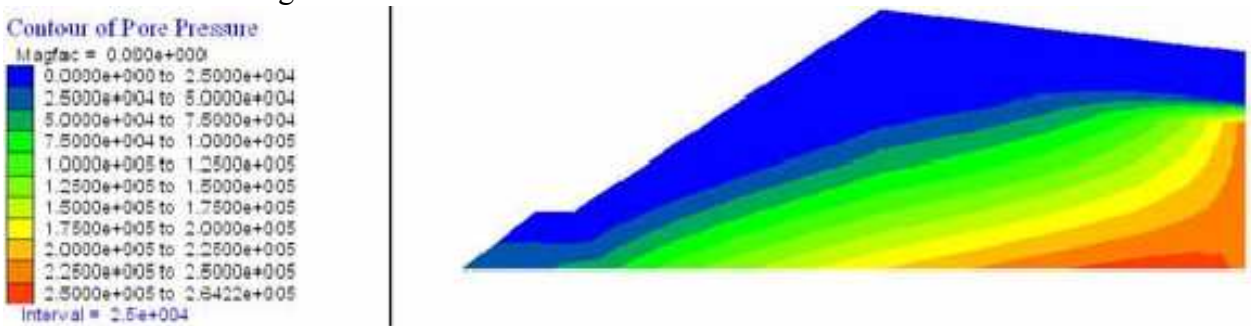

Fig.4 The saturation line when the water level is 20 meters

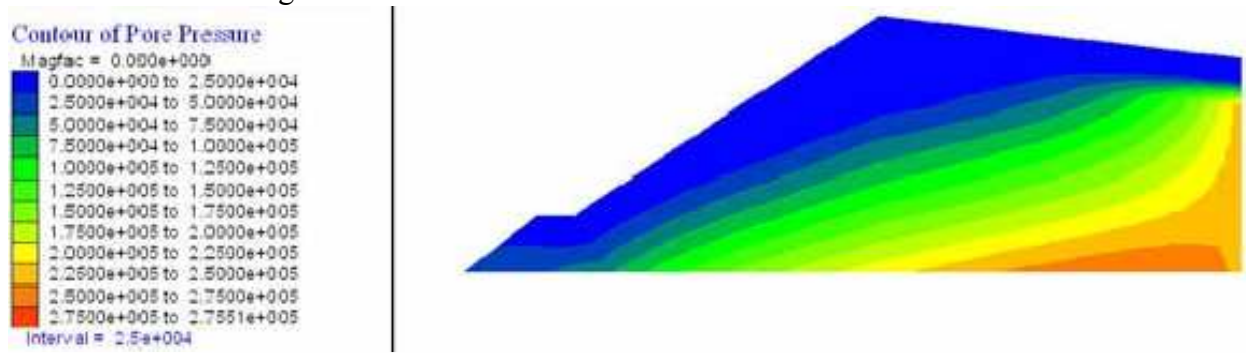

Fig.5 The saturation line when the water level is 25 meters

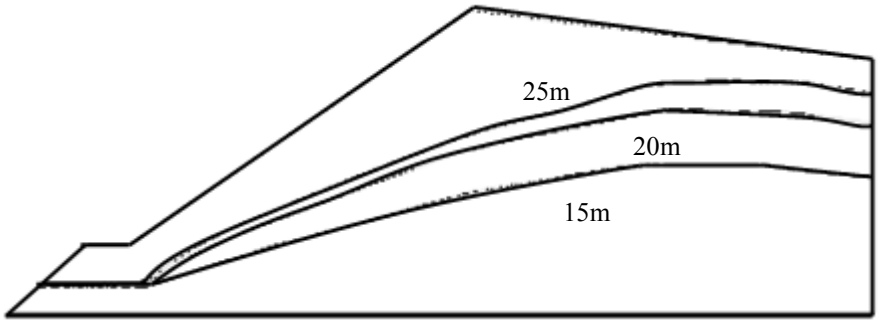

Fig.6 The saturation lines with different water levels

As we can see from Fig.3 to Fig.6, the saturation line in the dam is a parabolic curve and the pore pressure changes in layers. With the increasing of water level, the saturation line in the heaping dam ups rather obviously while it is not obvious in the initial dam. The maximum pore pressure in the bottom of the dam increases with the relationship of water level up, As the water level increases from 15 meters to 25 meters, the maximum pore pressure in the tailing dam increases from 244kPa to 275kPa, the shallow of the saturation line is in the heaping dam heel.

**Some suggestions for strengthening tailing dam**

Improve the stability of the tailing dam is mainly through change the seepage conditions, drop the height of saturation line, short the ratio of tail dam slope and speed up the consolidation of tailing dam.

(1)Drop the height of saturation line is mainly through improving the dam drainage, draining away water from the dam, finally improving the shear strength and slope stability of tailing dam.

(2)Reverse compaction in the downstream of slope toe of the tailing dam to improve the slope stability and enhance the antiskating force of tailing dam, and setting inverted filter to accelerate draining away water from the tail dam, speed up the consolidation of tailing dam and improve the slope stability.

(3)Shorten the ratio of slope to improve the slope stability of tailing dam, however, it is a contradiction with the capacity of reservoir and should coordinate the various interests between the capacity of reservoir and the slope stability of tailing dam.

(4)Strengthening the dam and speeding up the consolidation of tailing dam, such as setting anti-slide piles, setting the row the system and grouting technique, etc.

**Conclusions**

Based on the data of engineering geologic examination, the paper mainly conducts numerical analysis towards influences of water level on seepage stability of tailing bay, accordingly the following conclusions can be made: that the saturation line in the dam is a parabolic curve and the pore pressure changes in layers. With the increasing of water level, the saturation line in the heaping dam ups rather obviously while it is not obvious in the initial dam. The maximum pore pressure in the bottom of the dam increases with the relationship of water level up, the shallow of the saturation line is in the heaping dam heel. In addition, some reasonable suggestions were given to improve the stability of the tailing dam, can provide some references for practical engineering.

# Experimental study on the air-cooling of concrete aggregate

ZENG Miao[1], GUO Chaohong[1], KANG Zhiming[2], GUAN Wei[2], LU Fei[2],

WANG Gang[1], TANG Dawei[1]

([1.] Institute of Engineering Thermophysics, Chinese Academy of Sciences, Beijing 100190;

[2.] PowerChina Xibei Engineering Corporation Ltd, Xi'an 71000 )

**Keyword:** Concrete aggregate; air cooling; temperature distribution; flow resistance; porosity

**Abstract:** The temperature distribution and the flow resistance of air-cooled concrete aggregate are investigated in order to provide engineering guidance for the energy economization and design optimization. First, an aggregate bin is down-scaled and installed on an indoor experiment table, then tests are performed for different aggregate sizes and different inlet air velocity, with or without upper air duct. The results show that with the decrease of aggregate size, the temperature distribution turns more uniform, but the flow resistance increases; with the increase of wind velocity, the cooling rate is enhanced, but meanwhile the flow resistance is increased. So for different size of aggregates, an optimal wind velocity exists. Having an upper air duct not only enhances the cooling rate but also increases the cooling uniformity.

## Background

Concrete construction in hydro-structure, cement hydration heat leads to a sharp rise of temperature in the concrete. Natural cooling of mass concrete is insufficient, and inside and outside temperature variation generates thermal stress. To prevent the concrete cracks due to thermal stress, the highest temperature inside the concrete must be strictly limited[1,3]. One of the most effective ways is to pre-cool one or more materials of the concrete to reduce the concrete outlet temperature. Air-cooling is the most widely applied measures of pre-cooling. Concrete aggregate is cooled in a semi-closed bin by the cold air flowing through the lower side air intake, after exchanging heat with the aggregate from the top of the bin, heated cold air returns through the upper back air return vent to circulate. However, due to air flow leakage, fan selection does not match well with the aggregate and bin structure is unreasonable, pre-cooling efficiency is only 20-25% in actual engineering applications, which causes great waste of cooling capacity[2,6].

In this paper, the influence of aggregate size, inlet flow rate and the presence of upper air duct on the temperature change and flow resistance of aggregate is analyzed in to acquire necessary data for establishing a highly accurate simulation model to lay the foundation for developing a specialized software, and to improve the efficiency of pre-cooling in engineering applications.

## The similarity principle and the experimental set-up

### 2.1 The similarity principle

Experimental conditions are selected on the basis of real project and similarity principle. Only with the same form of differential equations, the phenomenon is to be able to involve a similar problem. The similar physical phenomenon must have the equal criterion. The similar heat transfer

phenomenon must have the same Nusselt number $Nu$. $Nu = \alpha d/\lambda$, λ is the thermal conductivity of aggregate, d is the diameter of aggregate, the convective heat transfer coefficient α is the function of Reynolds number $Re$ and Prandtl number $Pr$, $Pr$ is the physical parameter of air. It's considered that if the air of experiment and actual situation have the same $Re$, they have the similar heat exchange. When the two fluids have the similar movement, which must have the equal $Re$. $Re = ul/\upsilon$, $\upsilon$ is the air physical parameter, $l$ is the distance of adjacent aggregates, $u$ is the velocity, and therefore the air flow rate in experiment must equal to the real project[4,5,7]. In other words, if the air flow rate of experiment is identical with the actual, which can be considered to have the similar movement and heat exchange.

2.2 Experimental system

The real project: (1) cool aggregate bin size (length × width × height): 5m x 5m x11.5m, inlet \ outlet height difference: 4.6m;

(2) inlet \ outlet Size: 0.8m x 0.8m;

(3) air inlet louvre size (L × H): 4.8mx 0 1m; number: 16;

(4) inlet velocity: 25m / s;

(5) particle packing density: 1600 kg/m3 (true density: 2500 kg/m3).

Experiment: (1) cool aggregate bin size (L × W × H): 1m × 1m ×2m, inlet \ outlet height difference: 1m; inlet \ outlet size: 0.16mx 0.16m (reduced scale 5:1);

(2) piercing blinds duct size: 0.9m×0.01m; quantity: 16;

(3) inlet velocity: 21 ~ 35m / s, the porosity: 0.4 ~ 0.5;

(4) inlet air temperature is lower than the aggregate temperature of about 10 ℃;

(5) the kinds of aggregate of experiment are small(5 ~ 20mm), middle (20 ~ 40 mm), large(40 ~ 80 mm).

According to the air volume balance:

$$Q_{GC} = A_{HJM}.u_{HJM} = A_{JFK}.u_{JFK} \quad (1)$$

$$= 5 \times 5 \times v_{HJM} = 0.8 \times 0.8 \times 25$$

Wherein, $Q_{GC}$ is the total air, $A_{HJM}$ is the cross-sectional area, $u_{HJM}$ is the average cross-sectional speed, $u_{JFK}$ the inlet speed.

By the formula (1) can be obtained average cross-sectional speed,: $u_{HJM} = 0.64\text{m/s}$

The aggregate gap flow rate:$u_{KX} = \frac{u_{HJM}}{\varepsilon} = \frac{u_{HJM}}{0.3\sim0.5} = 2.13\sim1.28\ \text{m/s}$ (2)

Where, ε is the porosity of the aggregate (concrete aggregate porosity in the range of 0.4 to 0.5).

Experimental principle is to keep the aggregate gap flow rate constant, the total air of experiment: $Q_{SY} = A_{HJM}.u_{HJM} = 1 \times 1 \times 0.64 = 0.64\text{m}^3/\text{s} = 2304\text{m}^3/\text{h}$

Blower selection parameters: Flow rate $Q_{SY} = 0.64\text{m}^3/\text{s} = 2304\text{m}^3/\text{h}$

In actual engineering the blower pressure head is about 1000Pa ~ 2500Pa, flow path of cold air is 5m; flow path of cold air in experiment is about 1m, so pressure head in experiment is less than 500Pa.

The final choice of fan model and parameters:

Model: Cy-3.2A; inlet air flow can be adjusted; rated flow 2996$\text{m}^3/\text{h}$; pressure head 1300Pa; power 2.2KW.

At the Aggregate bin inlet and outlet pressure sensors are respectively arranged for measuring the flow resistance of the material layer; anemometer is installed at the inlet to monitor the cold air flow. The real experimental system is shown in Figure 1.

The three aggregate sizes, with or without up-duct and speed are combined to form the 12 kinds of experimental conditions as shown in Table 1. Figure 2 shows the arrangement of the temperature measuring point in the bin, most experimental conditions are chosen for the measurement section 1 to 5, 1,7 two conditions selected measurement section 0-4 layers, 11 selected section -1 to 3 layers.

Experimental procedures:

(1) charge and record the aggregate weight and volume, and then calculate the aggregate porosity;

(2) Check the sealing of the bin, adjust the valve of blower to control air flow;

(3) Start the blower, record the measuring point temperature, import/output pressure, speed real-time;

(4) Run for at least one hour, then stop the blower, and save the measurement data;

(5) discharge aggregate, replace the type of aggregate in the order of large, middle, and small, and add or cancel the upper-duct, and repeat the previous four steps.

## Discussion of experimental results

### 3.1 Aggregate temperature variation

Initially, the aggregate's temperature is average close to room temperature. Centerline temperature on section 0 is low, because section 0 is under the inlet duct, which connected with the outdoor directly through the blower, and the outdoor temperature is about 5 ℃, so the temperature at the center line of the section 0 is low. For all conditions, from the section at the inlet to the section at the outlet, the temperature is gradually increased. Therefore, all the conditions of cooling trend is the same: the section close to the inlet duct cooled first, farther from the inlet duct cooled later. For all operating conditions, the cooling trend on each section is the same: the aggregate temperature on the back facade is the fastest, on the front facade is the slowest; as time goes on, the aggregate temperature on section gradually tends to balance to the inlet air temperature. This is

because the cold air flow resistance in inlet duct is small, the air could flow directly through the duct and change flow direction to the both sides of the duct until after encountering the back façade. So, the inlet duct and the back façade's intersection region will produce cold accumulation, aggregate cool fastest. The law of aggregate cooling is: in the center of the inlet duct, the vertical aggregates have the same cooling trend. As shown in figure 3, in the center of the inlet duct, the upper and lower temperature fields are substantially symmetrical. In other words, the aggregates are not simply cooled in the region from inlet to outlet, below the inlet duct, the aggregate will obviously be cooled.

1200S 2400S 3600S

Case No.3 Temperature field in the center section with upper-duct

Fig4. Temperature field of large aggregate with and without upper-duct

Figure 4 shows the comparison of large aggregate temperature between the situation with and without upper-duct. Because the inlet air temperature is different, so do not compare the temperature gradient only compare isotherms distribution. As can be seen from the figure, at the front facade aggregate cool more easily and the temperature field has better uniformity in the case with upper-duct. Figure 5 shows the comparison of average temperature change of a middle aggregate with and without upper-duct. Only under the conditions of similar speed are the initial temperature and inlet air temperature comparable. From the figure, the situation with upper-duct whose average temperature cooling rate of the aggregate is slightly faster.

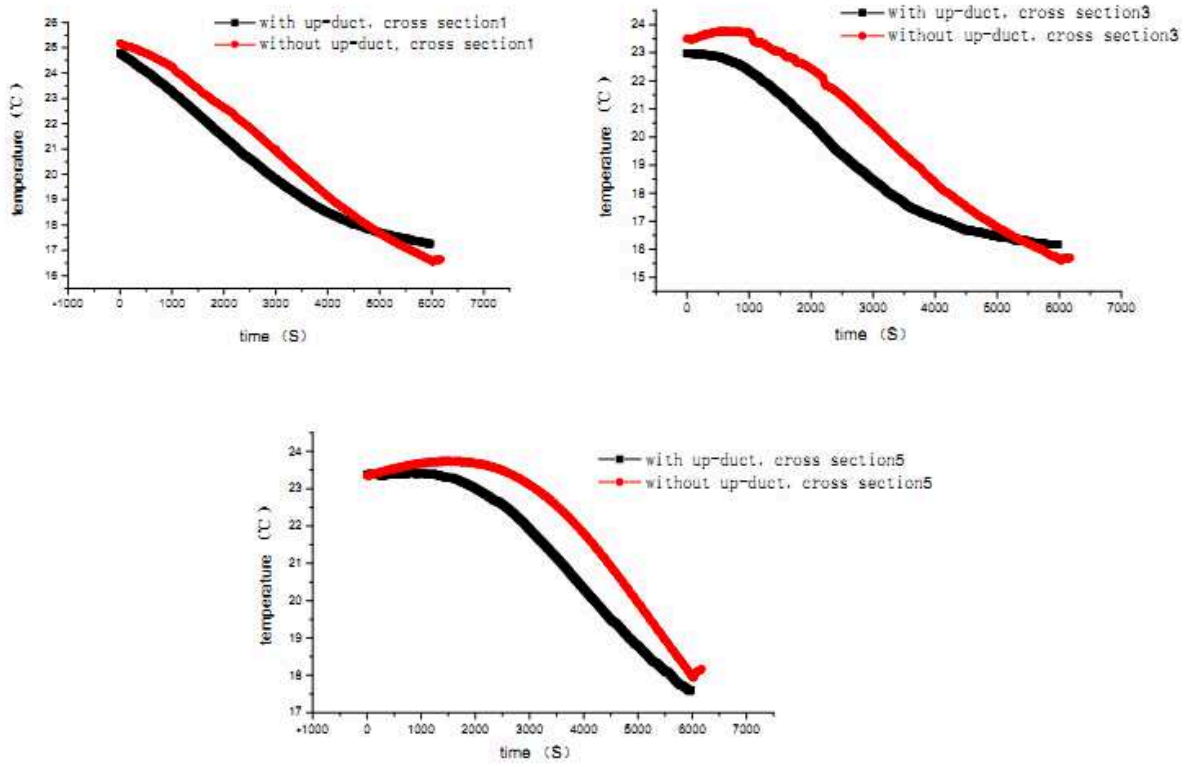

Fig.5 Average temperature of middle aggregate in three cross sections with and without upper-duct(No. 5, 8)

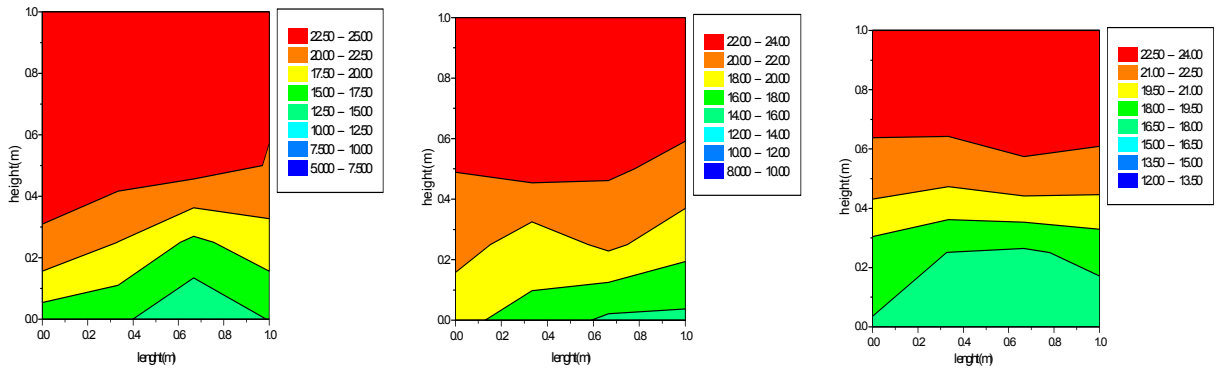
The greater porosity or smaller aggregates average diameter, the more uniform temperature distribution in the cross section. From figure 6, the small aggregate has the most uniform temperature distribution on center section, second is middle aggregate, the most uneven is large aggregate. The main reason is that the porosity of large is 0.417-0.439, middle is 0.434-0.451, small is 0.455-0.461, the small aggregate has the greatest porosity. And because the small aggregate has the greater void density, the air flow and temperature field distribute more uniformly.

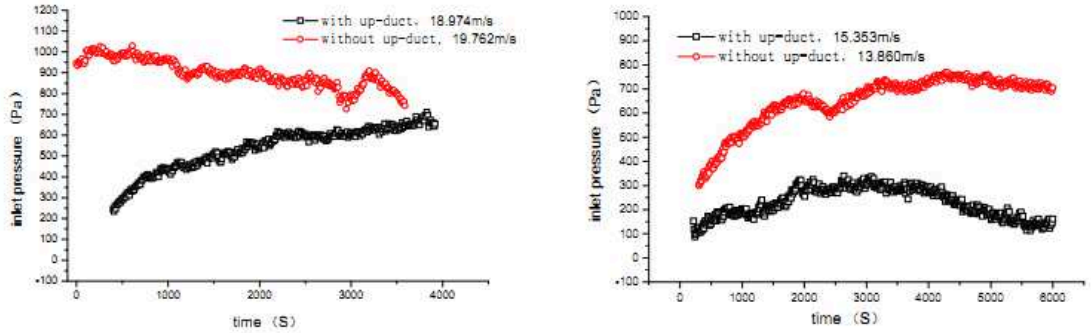


large middle small

Fig.6Centre section temperature of large, middle, small aggregate with upper-duct at 1200s

3.2 Aggregate drag variation

Figure 7 is a graph of relationship between air speed and pressure. From the figure, as the intake air flow rate increases, the drag in the bin increases. When the air quantities are close, for example the air flow rate of 17.94 ~ 19.13m/s, the aggregate diameter is smaller, the pressure grows more obviously. This is because the smaller the diameter of the aggregate, the smaller the gap, the greater the flow resistance of air flow in it. Comparison with and without the upper-duct conditions data is showed in the situation of without up-duct, in which the pressure is large and increasing trend is evident, while in the situation of with upper-duct, the pressure is obviously lower than without the upper-duct.



large middle

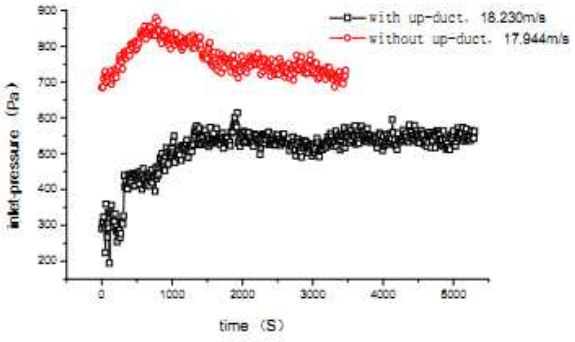


Fig7. Pressure distribution with and without upper-duct

## Conclusion

Experimental results of this work show that, the upper and lower temperature fields are substantially symmetrical with respect to the center of the inlet duct. The temperature in the section closest to the inlet duct is the lowest, and the back facade is cooled faster than the front facade, so the inlet duct should not be too close to the discharge port.

With the increase of the intake air flow rate, the aggregate cooling is enhanced, but meanwhile the air flow resistance increases; with the decrease of aggregate diameter, the temperature distribution turns more uniform, but the pressure drop grows more obviously. So there is an optimum value of the air velocity for the cooling of different diameter aggregates.

It is also found that at the situation of without upper-duct, the pressure drop is large and the increasing trend is clearly, pressure drop increases at a power function of the gap speed; at the situation with upper-duct, the pressure drop is small and increases to approach a certain value, the cooling rate of aggregate average temperature is slightly smaller, and the temperature field is more uniform. Thus, considering both the temperature uniformity and the flow resistance, the situation with upper-duct has evident advantage.

**Keywords:** Rock-fill dam; Duncan E-B model; particle swarm optimization neural network; orthogonal test method; sensitivity analysis.

**Abstract.** Sensitivity analysis of model parameters is a rock fill parametric inversion analysis method to determine the unknown parameters. Traditional sensitivity analysis is basically a lot of trial or the method of single factor analysis based on a large amount of calculation, but, unable to reflect the real situation. The method of particle swarm optimization based on neural network based nonlinear mapping relationship between model parameters and displacement to finite element simulation of dam deformation. Basing on the orthogonal design, the methods of range analysis and variance analysis method were used for sensitivity analysis of the parameters of Duncan E-B model and the impact of various parameters on the dam displacement, and then it can be as the parameters of rock fill dam provide basis for determining the unknown parameters inversion.

## Introduction

In the process of formulating the layout and measures of rock-fill dam (CFRD), the accuracy of structural deformation to a large extent depends on the accuracy of chosen mechanics parameters in the mechanical calculation [1]. As one of the common models used in the mechanical calculation and parameter inversion of concrete face rock-fill dam (CFRD) [2], Duncan E-B model is used to determine the mechanical parameters of CFRD in the displacement back analysis. Because of too many model parameters in the constitutive model, there are still problems in solving the model parameters through limited field information. Discrete degree is a major characteristic in Rock mechanical test, as well as high cost of experiment but a small amount of test. Then get the mechanical parameters with large errors and poor representation. The reliability will be smaller if the above parameters are used in the deformation calculation. Sensitivity analysis method should be used to effectively evaluate the parameter perturbation's effect on results of stability analysis and determine the major and minor mechanical parameters and optimize the arrangement of rock mechanics test scheme [3].

Sensitivity Analysis determines the sensitivity degree through the analysis on the attributes of model parameters. According to the theoretical analysis and engineering experience, some parameters which has the smaller influence on the output variables are get rid of, and the strong sensitivity of parameters are considered in the practical research to reduce the complexity of the research process of model parameters. Not only is the accuracy of results improved in the very great degree, but also the corresponding problem can be solved using the ranking results of sensitivity factors [4]. In this paper, basing on the PSO-NN (particle swarm optimization optimizing neural network) and orthogonal combination method, a network model of intelligent algorithm was built to analysis the sensitivity of parameters of Duncan E-B model combining with range analysis and variance analysis method, not only can the interaction between various parameters be considered, but the amount of calculation can be reduce and make the method simple and accurate.

**The Theoretical Basis and Concrete Steps of the Analysis of Rock-fill Parametric Sensitivity**

Particle swarm algorithm is simple, fast convergence and high robustness, strong global search capability, fast search speed, high efficiency, can be massively parallel computing to speed up the calculation, and do not need to use the feature information of the problem itself, can make up for the local minimum problem of BP neural network. BP neural network uses a local search method to compensate the problem of particle swarm accuracy. The key of particle swarm optimization neural network is to establish a mapping between particle swarm particle dimensions of space and connection weights neural networks and to make neural networks mean square error as a function of particle swarm adaptation [5].

Accordingly, the particle swarm optimization and artificial neural network algorithms are combined to create particle swarm optimization neural network model to simulate the t finite element analysis and do the displacement calculation. Nerve grid structure input and output layer nodes are 8, hidden layer is set to 11, the use of particle swarm optimization BP neural network weights and thresholds, the population size of the algorithm is N = 50, the largest of the algorithm execution iterations is $T_{max}$ = 300, cognitive learning factor is $c_1$ = 1.5, social learning coefficient is $c_2$ = 1.5, the flight speed of control sub is $V_{max} = 0.1X_{max}$, inertia weight ω with the increase in the number of iterations is reduced from 0.9 linear as 0.4, L-M error indicator algorithm is 0.0001, using MATLAB toolbox written PSO BP neural network program, the learning process shown in Figure 1.

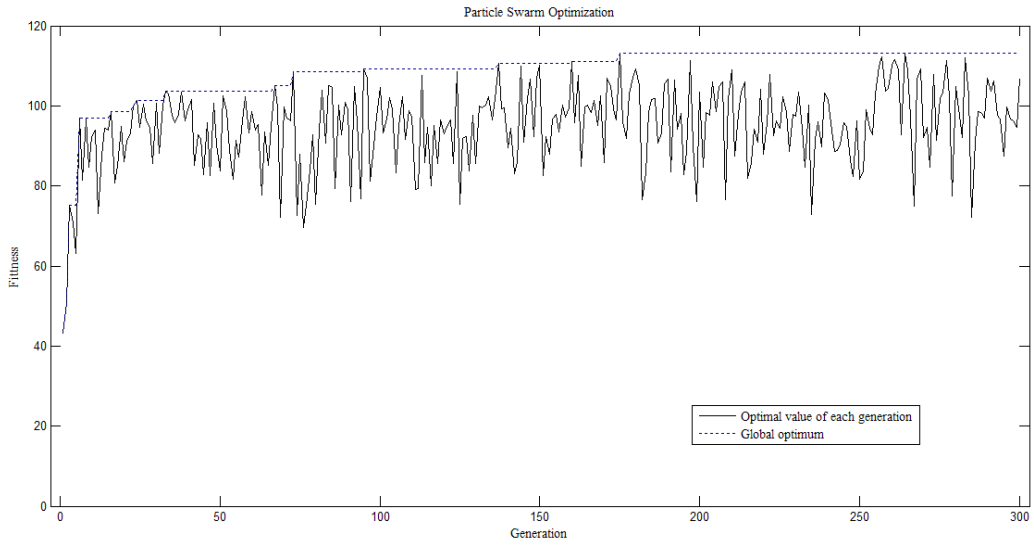

Fig. 1 The learning process of particle swarm optimization BP neural network

By learning and training process, particle swarm optimization neural network already contains inherent nonlinear relationship between parameters and displacement to determine the right input and output layer weights and thresholds. Orthogonal design [6] is one of the multivariate sensitivity analysis methods commonly used, which is based on orthogonal table, high efficiency, quick and economical method of experimental design is mainly based on orthogonally the selection of representative points, has two basic characteristics in the selection of representative points: neat comparability and balanced dispersion. This test method is designed to pick out from a comprehensive test of the sample points with orthogonal nature of the sample points as a test basis, these sample points possess representative, and the orthogonal design just with fewer numbers of experiments can identify each model factors affecting the degree of influence. In this paper, on the basis of this method, range and variance analysis method is used to analysis variance for Duncan E-B model parameter sensitivity analysis.

**Sensitivity analysis of the model parameter**

**The program of orthogonal experimental design.** Duncan E-B model has eight parameters, as shown in table 1.According to the suggested values of roller compaction test results of the scene of the Shuibuya and the calculating parameters of Duncan E-B model, the material calculation parameter values in the form can be determined. According to the principle of orthogonal test[7], select the program of orthogonal test for $L_{18}(2^1\times3^7)$, that is in the constitutive model, of which one parameter bit level has two, the rest seven parameter bit levels have three, because it is relatively simple to determine the dry density of rock-fill, and the dry density of the material shown in the table are the smallest difference, so choose the bit level of the dry density is 2, the rests are 3 bit levels, factors of bit level as shown in table 2, the chosen orthogonal table as shown in table 3.

**Tab.1 Material calculation parameters**

| **Material** | $\rho_d$ /(g·cm$^{-3}$) | K | m | $K_b$ | n | $\varphi_0$ /(°) | $\Delta\varphi$ /(°) | $R_f$ |
|---|---|---|---|---|---|---|---|---|
| maximum | 2.10 | 800 | 0.05 | 400 | 0.25 | 50 | 8.4 | 0.78 |
| minimum | 2.25 | 1200 | 0.20 | 800 | 0.45 | 56 | 10.5 | 0.85 |

In the table above, $\rho_d$ is density; K is cardinal of tangential modulus; n is index of tangential modulus; $R_f$ is damage ratio; $K_b$ is bulk
modulus; m is modulus index.

**Variance components method of the parameter sensitivity analysis.** To evaluate the degree of sensitivity of each parameter by the size of the rank difference belongs to intuitive analysis, but the size of the rank difference does not have a comparatively objective evaluation standard. In order to solve this problem, in this paper, we re-analyzed the data variance, analysis of variance is resolved by the sum of squared residuals, constructing F statistic, test the significance of factor effect and interaction effect. Based on the theoretical calculation method of analysis of variance, write computing program, using SAS software, calculated the sum of squared residuals of each factors, due to the output of the software to take up the space is larger, in order to save space, to adjust the format of the results, omit a level of average output data, results as shown in table 5.

In table 5, the S1-V is Vertical displacement of sample 1; the S1-V is horizontal displacement; so is the S2-V and S2-H. The value of F is statistical quantity value, the greater the value of P, the lower the sensitivity degree of the parameters. From the results of table 5, the size of the sensitivity degree of the 8 parameters is shown below:

In Sample 1, the parameters' sensitivity priority in subsidence displacement is $Kb>\varphi_0>m>n>R_f>\rho_d>K>\Delta\varphi$; the parameters' sensitivity in horizontal displacement is $n>K>\Delta\varphi>m>\varphi_0>K_b>\rho_d>R_f$;

In Sample 2, the parameters' sensitivity priority in subsidence displacement is $K_b>K>\rho_d>m>n>\Delta\varphi>\varphi_0>R_f$; the parameters' sensitivity in horizontal displacement is $K>K_b>m>n>\rho_d>\Delta\varphi>\varphi_0>R_f$.

And, when $P<0.05$, the factors have a significant effect on the test results, or that the factors are the main factors that influence the experimental index. However, the results show that the value of eight parameters factor P more than 0.05, therefore it need further analysis, obtains a new analysis of variance table. For settlement displacement and horizontal displacement gradually eliminate the least significant factor, using the same program to calculate every step of variance table, if finally get a factor of $P<0.05$, indicating that the factor is a very significant factor, on the contrary, if the element has not a value of $P<0.05$, indicating that none of these factors significantly affect the results.

The settlement displacement and horizontal displacement of the sample 1,2, have made the most insensitive factors, the results show that the settlement displacement weed out the three parameters, the remaining elements of the $P<0.05$;horizontal displacement weed out the most sensitive factors remaining 7 factors, P value is still>0.05. The result indicates that Duncan E-B model has little effect on the horizontal displacement, and has a great effect on the settlement displacement. Therefore, the parameters inversion analysis of stone of rock-fill dam, mainly anti-settlement displacement analysis, the results are reliable. Comparing the analysis with analysis of variance, the difference between the two is not great, indicating the results are reliable.

## Conclusions

This paper uses the method of particle swarm optimization algorithm of neural network combined with orthogonal design method to achieve a sensitivity analysis of Duncan E-B model, using analysis of variance, combined with SAS software to calculate the effect of the settlement and horizontal displacement, the results can be used as parameters to be inversed parameters inversion process determine the concrete face rock-fill dam reference. Using orthogonal experiment design Samples, greatly reducing the number of tests and calculations, but using this design method can reflect the inherent law in essence, but also improve work efficiency.

The sensitivity analysis of Duncan E-B model showed that, the influence of K, Kb, n, m on the settlement of displacement are more significant, but the impact of the model parameters horizontal displacement is not very significant, therefore, in the process of rock-fill dam inversion analysis, suggestions focusing on the point of vertical settlement of rock-fill dam displacement observation values of Duncan E-B model parameters of inversion analysis.

**Keywords:** Groundwater monitoring technology, Aquifer, Multilevel monitoring technology

**Abstract.** In order to investigate the groundwater level and quality, and study the groundwater contaminant in vertical and the dynamics relation in different aquifers, the place of sampling and monitoring need to be installed in the relevant position of the aquifers to differentiate groundwater from different aquifers. In recent years, groundwater monitoring and sampling system has made great progress, this paper focuses on the current study and development of groundwater monitoring well technology, and analyses the development and the applied direction of monitoring well technology from single-well monitoring to multi-level monitoring, which would provide scientific references for domestic related and groundwater contaminant.

## Single-well monitoring

In the groundwater monitoring, the way of monitoring is a single well or a group wells that are different depth single wells in China from 70s to 90s. The single well often is complete well (Fig.1), that is a well with drilling multiple aquifers, and drilling holes in the well pipe with the aquifers. So the groundwater in the well is mixed level and mixed water quality; A group wells is in the same area drilling different depth single wells, and every well only monitors one aquifer, other aquifers must be sealed, a group wells can achieve monitor the goal of aquifer water level and quality[1], group wells need to make sure the numbers and the depth of the monitoring wells depending on the drilling data (Fig. 2).

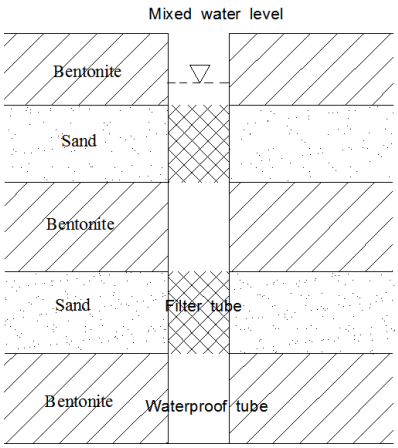

Fig.1 Single well monitoring mixed water

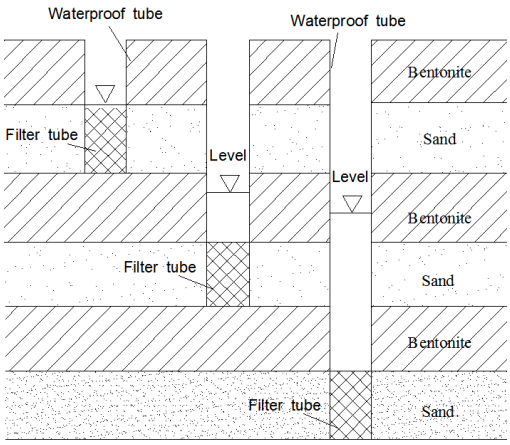

Fig.2 Group wells monitoring different aquifers

Single-well technique carrys on construction according to the requirement of the hydrogeological drilling procedures, site hydrogeological drillings on the basis of hydrogeological mapping and geophysical prospecting and chooses an appropriate drilling method according to mechanical and physical properties of rocks, drilling, as well as pore size, depth, and construction conditions. Construction procedures include drilling, changing pulp, lowering pipe, filling gravel material, sealing water, washing well and so on. Drilling hole wall, the size and depth of the pore should be checked and the drilling as well as the bottom of the hole should be cleaned up before lowering pipe. First, approximately 0.2m thick clean sand or gravel is placed in the bottom of the hole, and then pipes of monitoring well are installed vertically in the center of the hole and filter pipes are installed in the monitoring aquifer. After the well pipes installation is complete, filter material is filled around the filter pipes. The filter material should be extended about 0.5m above the top of the filter pipe during reclamation. Being sealed water on the top of the filter pipes through filling clay ball, the thickness of sealing water should be more than 5m. The annular gap between the borehole and well pipe should be backfilled with clay after sealing water.

Single-well punches each aquifer in the vertical and without sealing water by stratification, groundwater in the single-well mixed monitoring wells is mixed up the entire groundwater within monitoring length. Groundwater contamination plume is usually thin and highly stratified, and the table, quality and temperature of water in single-well monitoring wells all come from the mixed aquifer, the real pollutant concentration and pollutant distribution of groundwater are concealed[2]. Therefore, the data collected does not accurately reflect the characteristics of specific groundwater. Group-well monitoring wells can monitor the water table and water quality in different aquifers. Although its advantages are simple and easy to construct, the disadvantages is the large number of drills, the large area covering, expensive, the longer period and the inconvenience of monitoring and management in single monitoring well. The pipe material of monitoring wells use steel or cast iron pipe during this period. However, this material is easy to corrode and is difficult to maintain and its life is also very short. With the development of the technology of groundwater monitoring, the accuracy of groundwater monitoring is increasingly high demand. The technology of groundwater monitoring is developing towards the technology of single span multi-level monitoring.

## The monitoring technology of multi-pipe in a well

The monitoring technology of multi-pipe in a drill that is also called nested monitoring well[3] is respectively to choose different length of pipe under the monitoring to the selected monitoring layer, then backfilling gravel in aquifer and backfilling clay in impermeable layer, to realize different aquifers monitoring and sampling in a well. Monitoring pipe material is PVC pipe, just as Fig.3 which is the structure of 3 pipes in a well. ① pipe monitors unconfined aquifer, ② pipe monitors the first confined aquifer and ③ pipe is the second confined aquifer, all of which coarses sand respectively are

backfilled in the aquifer. Backfilling clay in impermeable layer can achieve artificial sealing in monitoring well, which will monitor different aquifers of groundwater.

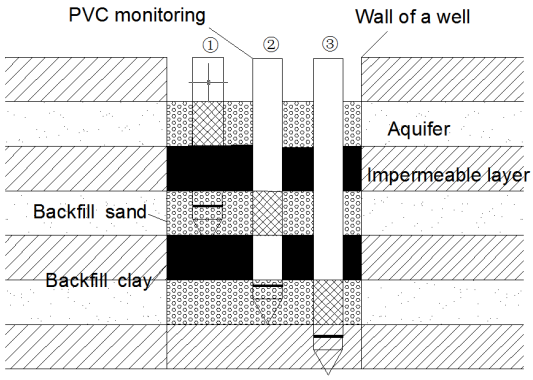

Fig.3 The structure of 3 pipes in a well

The national project of "The groundwater monitoring of multi-pipe in a well" which organized and implemented by Henan Academy of Geological Environment Monitoring in 90s, which conducted the multi-pipe monitor installation. The project team implemented groundwater monitoring wells demonstration project of "The naked drill four times as well" by using PVC-U plastic pipe in the west of Zhengzhou city. The single well can monitor depth up to 350m, that is a well with a hole monitoring four aquifers, which groundwater aquifers monitoring depth is 70~82m, 172~190m, 250~268m, 316~328m. Drilling structure of "The naked drill four times as well" project was designed as 0~200m, which depth aperture is 600mm, depth is 200~350m,aperture is 450mm.In the drilling process of drilling without the metal pipe protecting wall, and in the absence of pipe without wall protecting, the technology of four pipes in a drill, it has four times working procedures with step by step into the well from down to up program( downing pipe - casting gravel - sealing ) just as Fig.4, then washing well and pumping test by air compressor and drill pipe which the diameter is 50mm, was conducted respectively in a well.

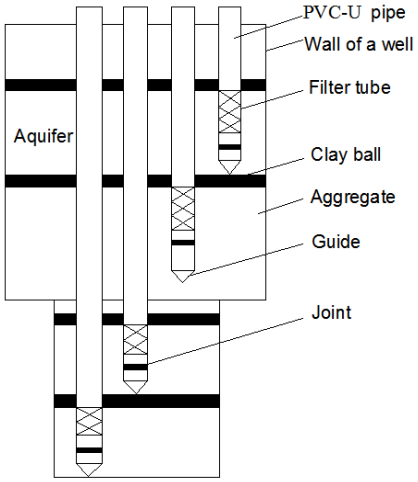

Fig.4 The process of "The naked drill four times as well"

The multi-pipe technology is able to achieve monitoring more than one aquifer of water in a well, and solve the aging problem of groundwater monitoring, that is a technology with settling some technical problems such as the quantity of monitoring hole into the hole, large area, investment, the inconvenience of monitoring and management and so on[4]. Furthermore, it has the advantage by using PVC-U plastic pipe of light quality, low cost, no corrosion, no scaling etc.But this technology has some technical issues in the process of promoting the use. When the well depth is 350m, monitoring aquifers is 4, it need to construct four times with four monitoring pipes which install into the well more than 1000m. It should be sealed up surrounding many monitoring pipes (monitoring pipe number is consistent with the monitoring layers). It is very difficult to seal in different aquifers, which must make sure seamless among the pipes, or it will cause the string between the aquifers.

Besides, the more monitoring aquifers, the more monitor pipes, the bigger diameter is required about the well, it also has certain requirements about rigs and drill. For our current drilling technology, it does not suitable to layer for deep and multi-layered groundwater and will cause a big waste of materials with the increase in monitoring horizon and technical difficulty of layered plugging wells.

At present, the groundwater monitoring wells in China are mostly mixed wells. With the increasing amount of groundwater exploitation and deepening study of environmental problems caused by groundwater overdraft, level of refinement, it requires that the groundwater should be stratified sampling, monitoring and analysis to know the hydraulic connection between each aquifer and convective changes of groundwater contamination. So monitoring technology should be changed from single monitoring well to a multi-pipe monitoring well, just as nested monitoring wells construction technology in spite that it has some problems such as the big diameter of wells and the number of monitoring pipes, and in order to solve the problem, it gradually developed continuous multi-channel monitoring technology internationally.

**The continuous multi-channel monitoring technology**

In order to improve the investigation and monitoring level of groundwater pollution, research and development of multi-channel monitoring system is an important direction of groundwater monitoring technology development. The developed countries such as Europe, America, Canada and Japan are the leader in groundwater monitoring which has formed continuous multi-channel monitoring technology. It can obtain water levels and samples for every aquifer accurately in a well, which is a important technology with improving PVC pipe, which is designed multiple channels in a pipe, and each channel can be monitored for a target aquifer. The process of PVC monitoring pipe design is shown in Fig.5, Fig.5-a is continuous three-channel monitoring pipe, which can monitor three-aquifer and Fig.5-b seven-channel can monitor seven .This monitoring pipe must be installed in accordance with the aquifer characteristics of drilling, dividing the target aquifer position, the corresponding block in position of monitoring of drilling pipe, so as to achieve the requirement of target aquifer. Besides, installing this pipe can use the conventional drilling techniques, thereby arrive the multi-level with sealing in impermeable layer.

The continuous multi-channel technology is currently more advanced in monitoring groundwater contaminant which is also called CTM system in Canada. This pipe can make 3 or 7 channels from high-density polyethylene (HDPE) pipe [5], which 3 channels diameter of pipe is 28mm with the channel diameter 9.5mm, and the 7channels-pipe is 43mm with channel diameter 10mm and 9.5mm, and the standard length is 30m, 60m, 90m.With the developed technology of drilling well, installing pipe and sealing impermeable layer, the depth can arrive to 150m.

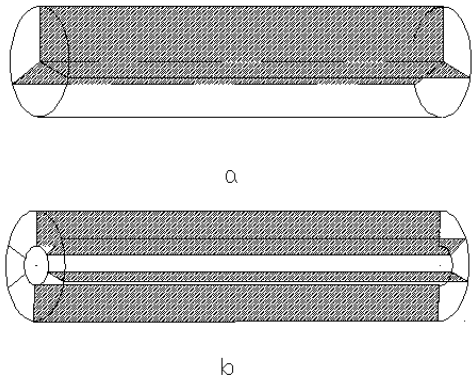

Fig.5 a and b are respectively 3 and 7 channel PVC monitoring pipe

Compared with other monitoring wells, it can arrive to monitor seven different aquifer in a well, without large diameter of drill, the advantages are: samples less be polluted, inexpensive, saving a lot of PVC pipes, installing easy, and it is only one pipe that sealing more easier than the multi-pipe, and can avoid stringing between aquifers, sealing easy and reliable around one pipe. High-resolution data can improve the accuracy of the information underground contamination, making it easier to control precisely dynamic changes in groundwater level water quality and improve the efficiency of

monitoring wells. So far, application of this technology in foreign countries is given priority to monitor shallow groundwater pollution, which monitoring depth is between 20~50m; in the application of monitoring Jinan springs, monitoring depth is up to 150m, which can achieve monitoring the water level and water quality simultaneously to analysis the hydraulic connection between each aquifer and further analysis the origin of spring. But as the depth increases, the requirements of corresponding installation, stratified sealing technology are much higher.

The continuous multi-channel technology is more advanced groundwater monitoring system in the world, with modular processing of monitoring pipe and simple construction, and it is only one pipe which reduces the installed times than multi-pipe. But the channel diameter is small, for example, the channel diameter of 3-channel pipe is 9.5mm invented by Solinst Company in Canada, the middle one of the 7-channel is 9.5mm, others are10mm. As a result, the measurement and collection of groundwater level should be matched with dedicated micro-level gauge and sampler.

**Waterloo Multilevel Groundwater Monitoring Technology**

The Waterloo System is used to obtain groundwater samples, hydraulic head measurements and permeability measurements from many discretely isolated zones in a single borehole[6].The system uses modular components which form a sealed casing string of various casing lengths, packers, ports, a base plug and a surface manifold. This allows accurate placement of ports at precise monitoring zones,such as fig.6. Monitoring pipes attached to the stem of each port indicidually connect that monitoring zone to the surface. The standard system is built on 2"Sch. 80PVC TO fit 3"-4" boreholes and uses 3 ft long packers. Stainless steel components .

An important consideration in planning an investigation involving the installation of deep multilevel wells with Waterloo Systems is the “planned” location for each well[7], such as the precise location, monitoring port and the sealing location. Water Resources Research Institute of Shandong Province designs and installs the system in Jinan to monitor the groundwater, the process is:Constructions the well and records the lithology and aquifer; designs the monitoring location according to the drilling; Once the multilevel wells were constructed, engineers installs the Waterloo Groundwater Monitoring Systems on surface; It can be put them into the wells as soon as the modular components are assembled; at last, the impermeable layer must be sealed. According to the project schedule, the depth of well is 250m in Jinan, 6 aquifers, The lithology of aquifers is Quaternary, Teriary, Diorite Intrusion, Carboniferous-Permian, the Ordovician Limestone. It took 40 days to construct the drill and 3 days to instill the Waterloo System. Although installation of the Waterloo systems was a time consuming prcess, the pay-off was in the ease of groundwater sampling. Because the system are permanently installed, the time in the field for decontaminating sampling equipment is eliminated. Purge valumes are also small, thereby minimizing purging time and water disposal costs.

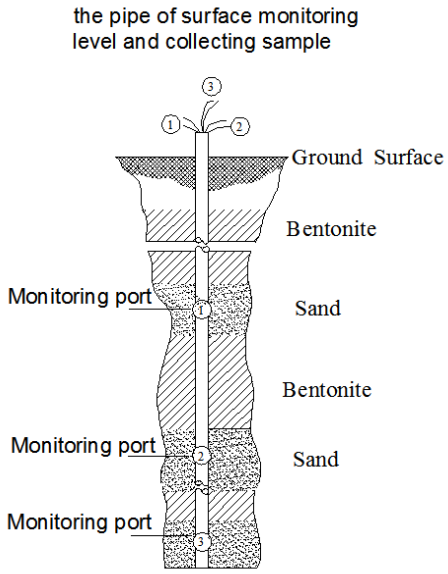

Fig.6 The waterloo multilevel system

Compared with traditional monitoring wells,the advantages of the multilevel are: Obtaining detailed 3D date of floe and concentrations;Geting date integrity; Reducing project costs; Purging and sampling times reduced; Fewer drilled hole; Reducing site disturbance; Variety of monitoring options.But the system is complex, we must accurately grasp the stratigraphic information, the port location and the monitoring location , and so on. So, the engineer must be trained professionally, and the work must be careful, accurate.

## Conclusion

This article introduces the situation and development of the groundwater monitoring in China and other countries, it has realized the three-dimensional groundwater monitoring from single well to many pipes in a well that every pipe monitoring an aquifer, to multilevel monitoring. It can be known well the different aquifers water level and water quality in a single well, especially it provides site assessors with a better understanding of three-dimensional groundwater flow and the distribution of contaminants in the subsurface. Remediation strategies can then be targeted more precisely, focusing efforts in the most effective manner. Multilevel monitoring is important for the research the contamination of groundwater, the hydraulic connection of different aquifers and the origin of spring, and it provides advanced technical support and construction experience for the next step of groundwater monitoring.

**Keywords:** cascaded reservoirs, eco-hydrology, mitigation of the tributaries confluence,

**Abstract.** For studying the impacts of the tributaries confluence on the hydrological processes in the downstream reaches of the four cascaded reservoirs in the downstream of Jinshajiang River, this paper simulated the daily discharge at the outlet of the cascaded reservoirs and along the reserve mainstream in typical years with the operation programming of the reserve and MIKE11 hydrodynamic model, and eco-hydrology indicators were selected and calculated by IHA to quantify the hydrology process. The result showed that at Xiangjiaba Gauge Station discharge on April and May increased by about 100%, the discharge in low flow year decreased by 50% and the timing of annual 1-day minimum discharge has significantly alteration. The confluence of Minjiang River could effectively mitigate the impacts of the cascaded reservoirs on eco-hydrology of the downstream of the confluence, but the mitigation of others three tributaries were not significant. Moreover the pre-flood high flow in the downstream of the Minjiang River confluence increased by 50%, and other indicators alteration were not significant.

## Introduction

As the primary driving force of river ecosystems, the natural flow regime plays a critical role in sustaining native biodiversity and ecosystem integrity[1-2]. River management for the main purpose of social and economic benefits, such as power generation, irrigation, navigation, has greatly changed the natural flow regime. The alteration of the flow regime can lead to significant changes in the physical, chemical, geomorphic and biological processes of aquatic ecosystem, which in turn may result in negative consequences on ecosystem product and serves[3-5].

The downstream reach of Jinshajiang River is one of the cases with enormous hydropower resources. There are four cascaded reservoirs construction or planning, respectively Xiangjiaba(XJB), Xiluodu(XLD), Baihetan(BHT) and Wudongde (WDD)(Fig.1), are mainly used for power generation, meanwhile taking flood control, irrigation and navigation into consideration as well. The total regulated storage capacity of the four reservoirs is $2.0\times10^{10}$ $m^3$, and the storage coefficient during the reservoirs operation is up to 13.4%. There is a national reserve for the Rare and Endemic Fishes located in the downstream of the reservoirs, where the intensive spawning grounds, feeding grounds, and wintering grounds for all kinds of the rare and endemic fish can be found. The cascaded reservoirs operation will have impact on eco-hydrological process in the downstream of the reserve, and then effect the fish growth and reproduction in the reserve.

The tributaries carrying water, sediment and nutriment can give rise to the change of hydrology, geomorphology and biological distribution in the mainstream, then mitigate the impact of reservoir operation on downstream [6-8]。 Many domestic existing studies about the influence of these cascaded reservoirs are primarily focus on control cross-section in the downstream of reservoirs [9-11], however, it is unclear about the eco-hydrology alteration in the downstream of these tributaries entry point. If

the tributaries confluence within the reserve could mitigate the impact of the cascaded reservoirs, it has great significance for the protection for the rare and endemic fishes of the reserve.

This paper simulated the hydrological process along the reserve reaches before and after operation in typical year, to evaluate the combined impact of the cascaded reservoirs and the tributaries confluence on the ecological alterations along the mainstream in the reserve.

## Methods

**Study area.** For the maintenance of the unique natural habitat and abundant aquatic biodiversity in the upper Yangtze River, the National Nature Reserve for the Rare and Endemic Fishes in the Upper Reaches of the Yangtze River (NNRARSF) was established. The range of the reserve is from 1.8 km below XJB reservoir to Songgai Town in Chongqing in the mainstream of Yangtze River and partly tributaries reaches (Fig.1). The major protected species are for the Chinese paddlefish, Dabry's sturgeon, and Chinese sucker, along with another 67 endemic species of the Upper Yangtze.

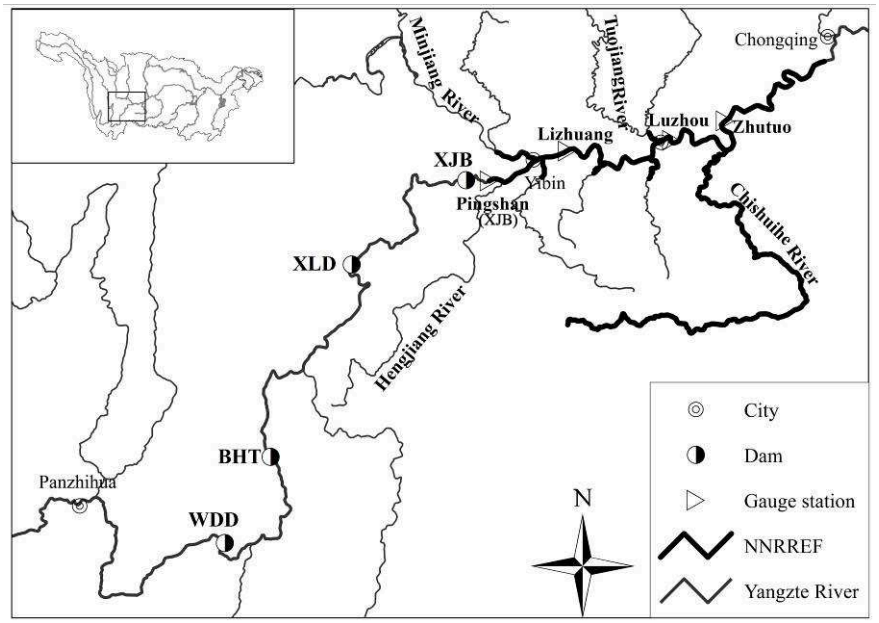

**Figure 1 Location of the cascaded reservoirs and the Gauge Station**

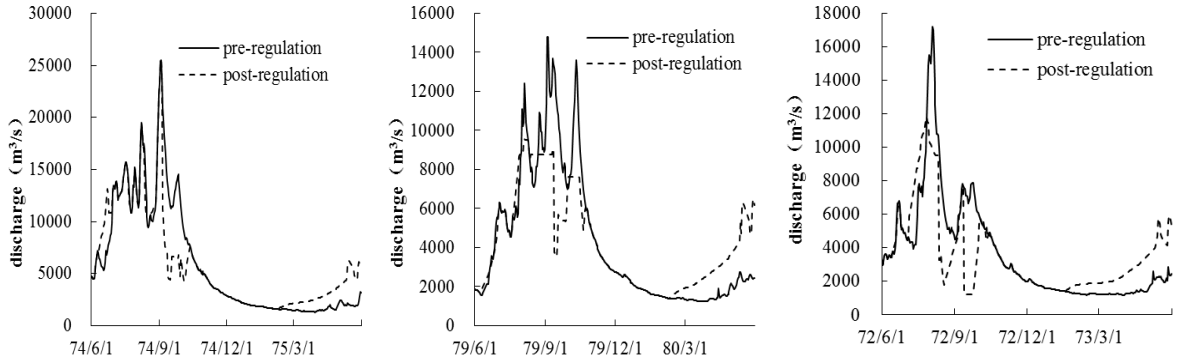
**Gauge Station.** Pingshan Gauge Station was located in the upstream of the reserve, and XJB Gauge Station was instead of Pingshan when the XJB reservoir was built. Therefore, the flow at Pingshan and XJB Gauge Station represent inflow of the reserve before and after regulated respectively. The daily discharge of Lizhuang, Luzhou, Zhutuo Gauge Station represent the hydrological process below confluence of Minjiang River, Tuojiang River and Chishuihe River. The daily discharge at the stations above-mentioned could reflect the hydrological process along the reserve mainstream.

**Indicators of Hydrologic Alteration.** There are many quantitative index of hydrological process, and Olden think that the Indicators of Hydrologic Alteration can reflect a wealth of information represented by these index through the redundancy and choice of 171 hydrological indicators [12]. The Indicators of Hydrologic Alteration (IHA version 7.1) is a statistical package that computes 33 parameters or indices from historic flow or stage records. These parameters can be placed in five groups that are relevant to ecological conditions: (1) magnitude of monthly water conditions, (2) magnitude and duration of annual extreme conditions, (3) timing of annual extreme conditions, (4) frequency and duration of high and low pluses, and (5) rate and frequency of condition changes (Richter et al. 1996). These parameters provide information on ecologically significant features of surface and ground water regimes influencing aquatic, wetland, and riparian ecosystems. For example, the timing of annual extreme discharge conditions would affect the life cycles of organisms that are

adapted to the natural flood cycle [13-14]. Due to discrete time series data and research objectives, this paper chose those indicators except for frequency and duration of high and low pluses.

**Reservoirs combined operation model.** Based on the measured discharge from 1965-1999 at Pingshan Gauge Station, 1974, 1979 and 1972 was choose to stand for the high flow year, the normal flow year and the low flow year, and every hydrological year is from June 1 to May 31 next year. Using reservoir operation scheduling, the four reservoirs combined operation model was established for the purpose of the maximum generated energy, considering the minimum relese discharge of XJB resevoir 1200 $m^3/s$, and developed the POA algorithm for solving optimization model. Fig 2 showed the daily discharge at Pingshan Gauge Station before regulatin and XJB Gauge Station after regulation in different typical year.



（a）high flow year （b）normal flow year （c）low flow year

**Fig.2 Comparisons between the measured flow at Pingshan Gauge Station for unregulated condition and the simulated flow at Xiangjiaba Gauge Station for regulated condition**

**Hydrodynamic model.** MIKE11 was used to simulate the flow and water level from Pingshan Gauge Station to Zhutuo Gauge Station. The flow at Pingshan and XJB Gauge Station as upper boundary was input, and the water level at Zhutuo Station as lower boundary, the discharge of Hengjiang, Minjiang, Tuojiang and Chishuihe as boundary. The dischage in 2001 for calibration model parameter, the discharge in the normal year for testing the model, the measured and simulated daily table at Luzhou Gauge Station was shown as Fig.3.

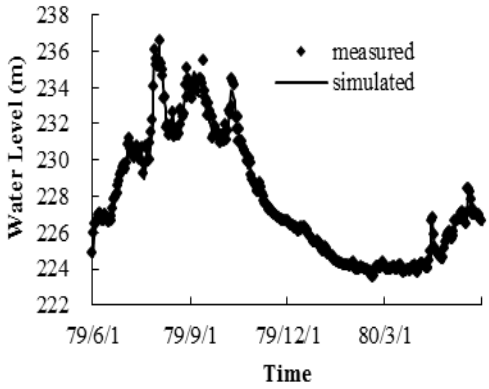


**Figure 3 Comparison of the measured and simulated water level at Luzhou Gauge Station**

## Result

**Variation in the ecohydrological indicators.** Table 1 and Table 2 show the variation in the eco-hydrological indicators at XJB and Zhutuo Station. The indicators at XJB would be changed significantly after the reservoirs regulation. The monthly discharge from March to May increased by more than 50% in different typical year, up to 131% on May in high flow year. The timing of the 1-day minimum discharge was significantly changed, especially retardation time in low flow year up to 165 days, when the reservoir was in storage period. If the eco-hydrological process in the reserve changed

as significantly as XJB Station, the growth and reproduction of the fishes would be influenced negatively.

The change of most indicators at Zhutuo Station was smaller than at XJB Station. The change rate of the monthly dischage from March to May in differently typical year was from 32% to 57%, and the timing of 1-day minimum discharge was ahead of 36, 8, 67 days in respectively high, nomal, low flow year. It indicated that the tributaries confluence could effectively mitigate the impacts of the cascaded reservoirs on eco-hydrology in the downstream.

**Tab.1 The change rate of the eco-hydrological indicators at Xiangjiaba and Zhutuo Gauge Station**

**Tal.2 The change of the timing of annual 1-day maximum and minimum discharge**

| Typical yerar | Timing of 1-day min | | Timing of 1-day max | |
|---|---|---|---|---|
| | XJB | Zhutuo | XJB | Zhutuo |
| high | -53 | -36 | 0 | -27 |
| nomal | -42 | -8 | -30 | -4 |
| low | 165 | -67 | -7 | 0 |

“-”:ahead , “+”: delay

**The change in indicators along the mainstream.** As shown in the Table 1, the indicator alteration between XJB and Zhutuo Station is not completely equal. For example, the change rete of 1-day, 3-day and 7-day minimum discharge at Zhutuo Station is larger than at XJB Station, and other indcators is smaller . The ecological hydrology indexes are divided into four categories, respectively long-term discharge, short-term discharge, timing of extreme discharge and rate and frequency of change. The long-term discharge includes monthly discharge, 30-day mean discharge and 90-day mean discharge, and the short-term discharge includes 1-day, 3-day, 7-day mean discharge.

The long-term discharge indicators. Taking the discharge on May for an example, it was analyzed of the variation in the long-term indicators along the river. As shown in Fig.4a, the variation rate of the discharge on May at Lizhuang Station decreased by more than 50% in different typical year, while the difference among Lizhuang, Luzhou and Zhuotuo is less than 10%. For long-term discharge indicators, the tributaries confluence did not change the difference along mainstream between pre-regulation and post-regulation, but the discharge increasing due to the tributaries confluence caused the change rate decrease. The discharge on May at XJB increased by more than doubled after regulation while increasing by about 50% at Zhutuo, but the variable amplitude was 2800$m^3$/s both at XJB and Zhutuo Station.

The indicators of short-term discharge. Taking 1-day minimum discharge for an example, the variation tendency in short-term discharge may be differnt in high, normal and low flow year (Fig.4b). In low flow year, 1-day minimum discharge at XJB was 1180 $m^3$/s before regulation, emerged in low flow period; while after regulatin it wasesigned minimum release discharge 1200$m^3$/s and emerged in storage period, basically the same as pre-regulation. 1-day minimum discharge at Lizhuang, Luzhou and Zhutuo emerged in low flow period both pre-regulation an post-regulation, and the reservior regulation caused the minimum discharge increase by about 400$m^3$/s， therefore, the change rate was larger than XJB. In normal and high flow year, the minimum discharge at XJB after regulation still emerged in low flow period. The variation of the minimum discharge at the four stations was essentially the same in normal flow year, while in high flow year the variation at Lizhuang, Luzhou and Zhutuo was smaller than at XJB. For the short-term indicators, the tributaries confluence may lead to the variation in the timing with distance, so the change rate along the mainstream was different.

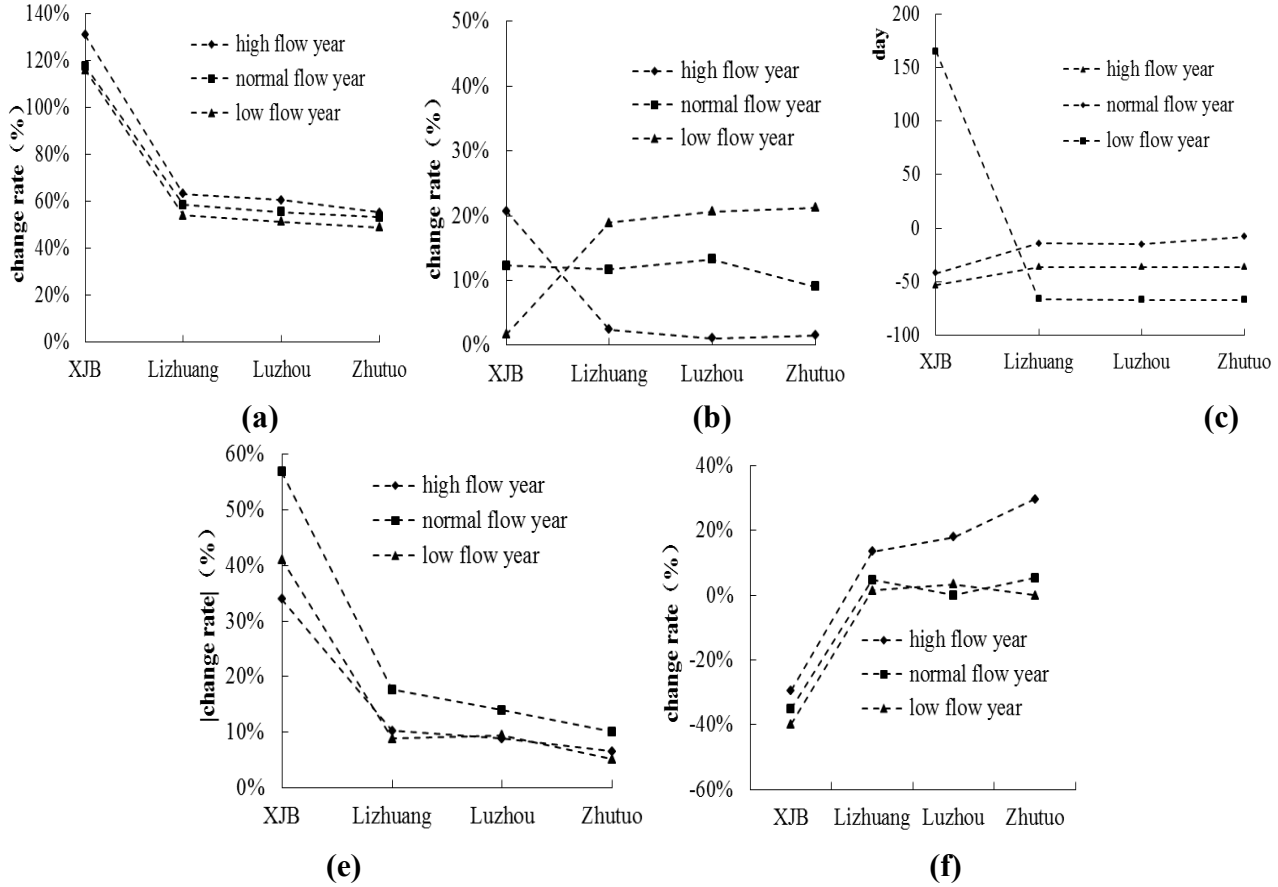

**Fig.4 The variation along river in (a) the discharge on May, (b) the 1-day minimum discharge, (c) the timing of minimum discharge, (d) the rise rate and (f) the number of reversals**

The indicators of timing. Fig.4c showed the variation in the timing of minimum discharge along the mainstream before and after regulation. Due to the regulation of the cascaded reservoirs, the timing of minimum discharge at XJB in low flow year was in storage period (not in low flow period). The minimum discharge at Lizhuang, Luzhou and Zhutuo was in advance about two month, but still in low flow period. The minimum discharge at all stations in normal and high flow year emerged in the low flow period, and the variation with distance was not significant.

The rate and frequency of change. The variation tendency in rise and fall rate with distance was same, taking the rise rate as an example. The absolute value of variation in rise rate decreased with distance in different typical year as shown in Fig.4e. The number of reversals at XJB decreased by 30% after regulation, and the variation at Lizhuang, Luzhou and Zhutuo almost was equal to 0 in low and normal year, but increased in high flow year (Fig.4f).

## Discussion

**Impact of the tributaries confluence.** It was conclued by above anlysis that the eco-hydrological characteristic at Lizhuang, Luzhou and Zhutuo was almost identical. The runoff of the Minjiang accounts for 60% of the runoff of Pingshan Station, and Hejiang, Tuojiang and Chishuihe accounts respectively for 6%, 11% and 7%. The confluence of Minjiang could effectively mitigate the impacts on eco-hydrology in the downstream of the confluence, and the mitigation of others three tributaries were not significant. It was the reason why the eco-hydrological process in the downstream of the Minjiang River confluence did not change significantly with distance.

The typical year chose is before 1980 when there was not large constructed reservoir. Since 20th century, there are several reservoir built in the Yalongjiang and Minjiang，including Ertan reservoir impounding in 1999 and Pubugou reservoir impounding in 2010, the regulated storage capacity respectively $33.7\times10^8 m^3$ and $38.8\times10^8 m^3$. The reservoir in tributaries has influenced on hydrology at Zhutuo Station, and the Fig.5 shows the variation in discharge on January since 1991. The increase after 2000 and the maximum discharge in 2011 are related with the reservoir operation. In addition, the total regulated storage capacity all planning reservoir in the Daduhe River ( a tributary of Minjing) is up to $105.5\times10^8 m^3$, and the effect of the reservoir operation in the tributary may weaken the mitigation effect of tributaries confluence.

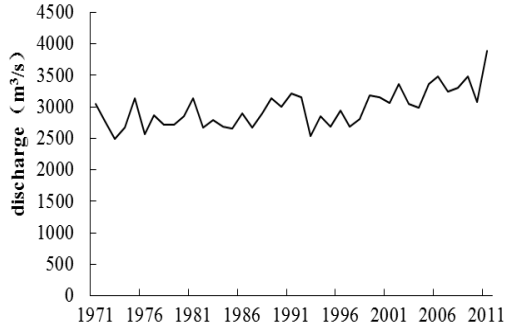

**Fig.5 The temporal variation in the discharge on January at Zhutuo station**

**Ecological impact of the eco-hydrology alteration.** The reaches in the downstream of the Minjiang River confluence play an important role in maintaining the natural habit integrity. The increase (<20%) in the minimum discharge caused by reservoir operation could result in increasing in water depth, perhaps in favor of the fish wintering. The increase in the pre-flood high flow may impact the fish spawning and migration. Because the spawning in autumn is not the main behavior in the reserve [15], the decrease in the discharge during the storage period would not have significant impact on the fish reproduction.

**Impact of the cascaded reservoirs on the other habitat factors.** The cascaded reservoir operation would also cause changes in water temperature, dissolved oxygen and sediment and other

processes, accompanied by changes in the hydrological regime. While the four cascaded reservoirs combined operated, the 34 species of fish with reproduction record in the reserve will be affected by water temperature variation [16]. From the existing monitoring results, the dissolving oxygen in the reserve has not been influenced significantly by current reservoir operation since the XJB and XLD reservoir impounded. But the clean water may destroy the balance of sediment transport in the reserve, which would have a greater impact on fish habitat and nutrients.

**Impact of reservoir regulation.** According to the current flood control scheduling, the cascaded reservoirs need to lower water level to flood water level in pre-flood high flow period, which will produce higher flow than natural conditions. The effects of high flow and flood pulse on sediment erosion will impact adversely on the fish within the reserve, so the maximum flow should be confined considering the ecological demands [15]. The flood diversion areas in the middle reaches of Yangtze River could substitute perhaps for flood control by cascade reservoirs at Jinsha River downstream as flood risk management alternative [17]. In addition, if the joint optimal operation with in both tributaries and mainstream was carried out, the influence on the reserve ecosystem would be reduced.

## Summary

The cascaded reservoirs have great impacts on eco-hydorlogy at XJB station, and the import of the Minjiang could mitigate the influence on the eco-hydrology in the downstream of the entry point of Mingjiang. The pre-flood high flow increaced by about 50% in the downstream of the Minjiang confluence, and other eco-hydrological indicators changed slightly, which may have less impact on the fish.Taking the impacts of the tributaries reservoirs on confluence discharge into consideration, the mitigation effect of tributaries confluence may weaken. The effect of variation in other habitat factors on the fish may be greater than the variation in eco-hyrology due to cascaded reservoirs operation. The further research on the impact on other environmental factors needs to be carried out, to provide theoretical basis and technical support for the ecological operation of cascade reservoirs and the reserve management.

**Keywords:** Arch dam, Optimization design, FEM, Sequential Quadratic Programming method

**Abstract:** The sequential quadratic programming method is introduced in arch dam shape optimization design. In the optimization computation, the arch dam volume is taken as objective function, and the calculation is realized by automatically considering loading process, equivalent stress computation and simulation of shape optimization for arch dam based on FEM. A parabola arch dam is used as a numerical example. The result shows that the optimized figure is much safer and more practical, which indicates that the SQP method is an effective way for optimization design of arch dam shape.

## Introduction

The geometric shape of arch dam is a main factor to influence its safety and stability. And it will also affect the project cost. Accordingly, considering the safety and economy, it is very important to optimize the geometric shape of arch dam [1].

Optimization design of arch dam Shape, which belongs to constrained nonlinear programming problem, is to find out the optimal shape of dam at the given boundary conditions and constraints by means of mathematical programming method.

There are many optimization methods in recent years, such as complex method [2-3], generalized multiplier method, general reduced gradient method, and sequential quadratic programming method (SQP method) [4-5].

The SQP method, which combines the advantages of the steepest descent algorithm, quasi-Newton method, POWELL conjugate gradient algorithm and BFGS variable metric algorithm, has high computational efficiency and is recognized as the best algorithm for solving smooth nonlinear programming problem. In this paper, the SQP method will be introduced in optimization design of arch dam shape.

## Definition of the problem

Model of arch dam configuration optimization is expressed as seeking for optimization variable $X=[X_1, X_2, ..., X_n]^T$ to make the objective function to minimum, and meeting the constraint conditions on geometry and structural responses such as stress, displacements and natural frequencies, etc.

*(1) The description of the geometric model of arch dam*

Geometric model of arch dam is used to describe the geometry, size and location of arch dam. Usually, the successive type geometric model is adopted on the shape design of arch dam. Upstream face curve, downstream face curve, middle face curve, and thickness of arch ring all can be used to describe the geometric model of arch dam. In this paper, a parabola arch dam is used as an example. Based on that, the middle face curve and thickness of arch ring are used to give the description of the geometric model of arch dam.

Fig.1 shows us the arch crown cantilever, which is the highest beam in arch dam. The section of arch crown cantilever can be defined as long as the curve *Yc(z)* of middle face and the thickness *Tc(z)* of arch crown cantilever has been defined.

Fig.2 shows us the horizontal arch ring of arch dam. The geometric model of horizontal arch ring can be described by the arch axis function *Yi* and the thickness of arch ring *Ti*.

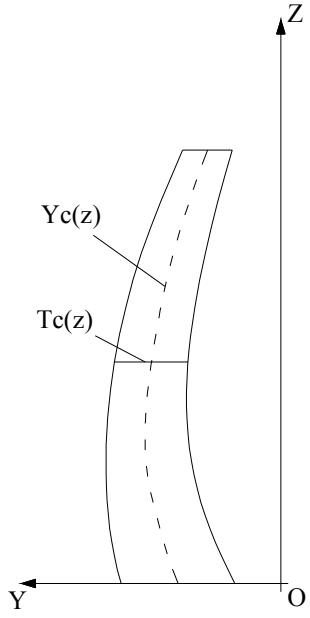

Fig.1 Arch crown cantilever

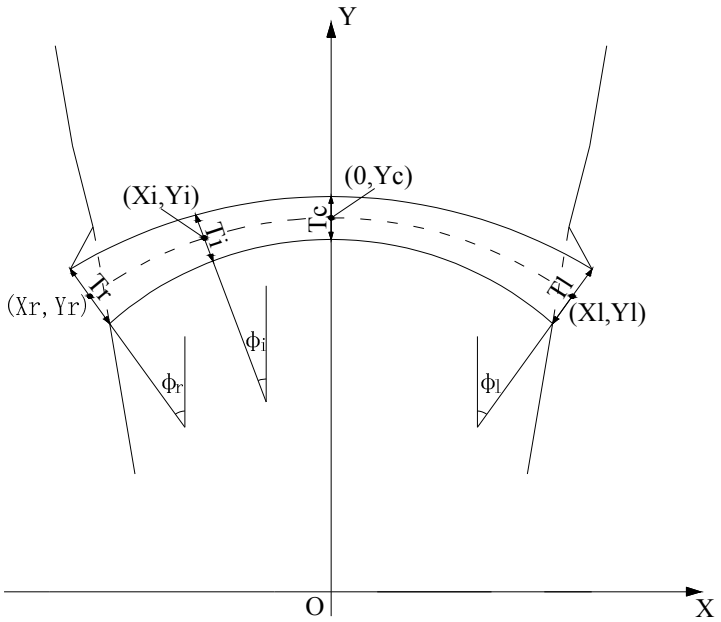

Fig.2 Horizontal arch ring

According to the parabolic equation, every point on center line of arch can be written as:

$$Yi = \begin{cases} Yc - Xi^2/(2\times Rcr) & (Xr \le Xi \le 0) \\ Yc - Xi^2/(2\times Rcl) & (0 < Xi \le Xl) \end{cases} \tag{1}$$

Thickness *Ti* of arch ring can be expressed as:

$$Ti = \begin{cases} Tc + (Tr - Tc)\times(1-\cos\phi i)/(1-\cos\phi r) & \phi r \le \phi i \le 0 \\ Tc + (Tl - Tc)\times(1-\cos\phi i)/(1-\cos\phi l) & 0 < \phi i \le \phi \end{cases} \tag{2}$$

Where: *Yc* is *Y* coordinate of centre of crest circle. *Xl(Xr)* is *X* coordinate of left(right) arch abutment. *Rcl(Rcr)* is arch centerline's curvature radius of crest cantilever of left(right) semi-arch. *Rcr(Rcl)* can also be written with *Yl(Yr)* which is *Y* coordinate of left(right) arch abutment, $Rcl = Xl^2/2\times(Yc-Yl)$, $Rcr = Xr^2/2\times(Yc-Yr)$. *Tc* is thickness of arch crown cantilever, *Tl(Tr)* is thickness of left(right) arch abutment.

*(2) Optimization variables*

Optimization variables of arch dam shape optimization are used to describe the arch dam's configuration. By changing them, the configuration of arch dam can be adjusted neatly to ensure the feasibility of seeking for the optimum configuration. For a parabola arch dam, the configuration of arch dam can be described by above 8 variables(in Eq.1~2), each of which can be written as following thrice function of z coordinate axis:

$$F = a + b\times\frac{Z}{H} + c\times(\frac{Z}{H})^2 + d\times(\frac{Z}{H})^3 \tag{3}$$

*(3) Objective function*

Usually, the lowest cost or dam concrete earthwork is used as objective function in arch dam configuration optimization.

$$V = \int_{zbot}^{ztop} A(z)dz \tag{4}$$

Where: *zbot* and *ztop* separately represent dam base elevation and crest elevation，*A(z)* is Area of Horizontal arch ring.

*(4) Constraint conditions*

Constraint conditions are parameters designed to ensure safety and convenience. For arch dam, the main constraint conditions include geometry constraint conditions, stress constraint conditions, and so on.

1) Constraint of the minimum of dam top thickness: $t_{\min} - \overline{t_1} \geq 0$

2) Constraint of maximum overhanging angle of upstream and downstream faces: $m_1 - \overline{m}_1 \leq 0$

3) Constraint of maximum center angle at control elevation: $\varphi_{\max} \leq [\varphi]$

4) Stress constraint conditions can be expressed as follows: $|\sigma_t|_{\max} \leq [\sigma_t]$; $|\sigma_c|_{\max} \leq [\sigma_c]$

Where: $\overline{t_1}$ is allowable thickness. $\overline{m_1}$ is allowable overhanging degree. $[\varphi]$ is allowable center angle. $[\sigma_t]$ and $[\sigma_c]$ separately denote the allowable tensile stress and compression stress.

**Math model**

The mathematical model of optimization of arch dam shape can generally expressive as follows.

Objective function: min *f(x),* and Constraint function: s.t. *c(x)=0 i=1,2,...,m* (5)

Where: design variable $\{x\}=[x_1,x_2,...,x_n]^T \in R_n$, objective function *f(x)* and constraint function *c(x)* are functions defined in $R_n$.

The problem above can be written as following unconstrained problem by applying Lagrange function.

$$\min L(x,\lambda) = f(x) + \lambda^T c(x) \tag{6}$$

Where $\lambda = (\lambda_1, \lambda_2, \cdots, \lambda_m)$ is Lagrange Multiplier.

The extreme value condition of unconstrained optimization problem (K-T condition) is:

$$\nabla L(x,\lambda) = \nabla f(x) + \nabla c(x)\lambda = 0 \quad \text{and} \quad c(x) = 0 \tag{7}$$

Where, $\nabla c(x) = [\nabla c_1(x), \nabla c_2(x), \cdots, \nabla c_m(x)]$, $\nabla c_j(x) = [\frac{\partial \nabla c_j}{\partial x_1}, \frac{\partial \nabla c_j}{\partial x_2}, \cdots, \frac{\partial \nabla c_j}{\partial x_n}]^T$, $j = 1,2,\cdots,m$

Obviously, the solution of Eq.(7) is optimal solution of unconstrained problem(6). We can solve the Eq.(6) by applying Newton method, and the iterative formula can be written as:

$$x^{(k+1)} = x^{(k)} - G_{(k)}^{-1}\nabla L(x^{(k)}, \lambda^{(k)}) = x^{(k)} - G_{(k)}^{-1}(\nabla f(x^{(k)}) + \nabla c(x^{(k)}))\lambda^{(k)} \quad \text{and}$$

$$x^{(k+1)} = x^{(k)} - \nabla c(x^{(k)})^{-1} c(x^{(k)}) \tag{8}$$

Where, $G_{(k)}^{-1}$ is the Hesse inverse matrix of Function $L(x,\lambda)$ at point $x^{(k)}$. Avoiding Hesse Matrix inversion，a variable matrix $H_{(k)}$ is introduced to approximate Hesse Matrix during the iterative process(Approximation method will be introduced later).

Therefore Eq.(8) can be modified as:

$$\begin{bmatrix} H & \nabla c(x) \\ \nabla c(x) & 0 \end{bmatrix} \begin{bmatrix} d \\ \lambda \end{bmatrix} = -\begin{bmatrix} \nabla f(x) \\ \nabla c(x) \end{bmatrix} \tag{9}$$

Where, $d = x^{(k+1)} - x^{(k)}$, $x = x^{(k)}$, $\lambda = \lambda^{(k)}$, $H = H^{(k)}$.

Eq.(9) is just iterative equation of K-T condition(7) by applying Newton method. It's easy to prove that iterative formula (9) is also the K-T condition of the following QP problem:

$$min \quad \frac{1}{2}d^T Hd + \nabla f(x)^T d \qquad \text{and} \qquad s.t. \ \ \nabla c(x)^T d + c(x) = 0 \tag{10}$$

Because the Lagrange function of the QP problem is:

$$L(d,\lambda) = \frac{1}{2}d^T Hd + \nabla f(x)^T d + \lambda^T [\nabla c(x)^T d + c(x)] \tag{11}$$

Thus, the *K-T* condition of local minima can be written as:

$$\nabla_d L(d,\lambda) = Hd + \nabla f(x) + \nabla c(x)\lambda = 0 \quad \text{and} \quad \nabla_\lambda L(d,\lambda) = \nabla c(x)^T d + c(x) = 0 \tag{12}$$

From the discussion above, we master the mainly basic steps of the SQP method. Firstly, we gain the solution of QP problem (10) by applying Newton method on *K-T* conditions(7) of question(5). Then by solving QP problems (10), we get a new iteration point $(x^{(k+1)}, \lambda^{(k+1)})$, and start a new iteration. And after that, we repeat the steps above until we get approximate optimal solution.

**Numerical examples**

In this section, a parabola arch dam is used as an example. The main parameter of the dam can be described concisely as follows:

*(1) Calculation parameter*

The height of dam is 92m. The silt saturation is 18.5KN/m$^3$. The silt internal friction angle is 14°. Material parameters of the dam concrete are: volume weight of $\gamma_c$ = 24KN/m$^3$, poisson ratio of $\mu_c$ =0.1667, linear expansion coefficient of $\alpha=0.7\times10^{-5}$/℃, elastic module of $E_c$=25.5GPa. internal friction angle of dam f=14°.

Material parameters of the foundation rock are: elastic module of 14.2GPa, Poisson ratio of 0.25, linear expansion coefficient of $1.0\times10^{-5}$/℃ and bulk density of 27KN/m$^3$.

Dam base elevation is assumed to be 0. Temperature load is shown in Table 1. In this calculation we only consider the condition of fixing the location of arch abutment during the optimization. Then the objective is to find the smallest arch dam volume by mainly adjusting following four variables in the calculation: the thickness of crown cantilever, the thickness of left arch abutment, the thickness of right arch abutment, and arch centerline's curvature radius of crest cantilever. And all the other parameters can be described by these variables.

Table 1 Temperature load

| Elevation (m) | 0 | 20 | 40 | 60 | 80 | 92 |
|---|---|---|---|---|---|---|
| Tm(℃) | 2.71 | 0.66 | -0.25 | 0.02 | 1.39 | 5.84 |
| Td(℃) | 14.37 | 12.46 | 13.19 | 11.36 | 6.80 | 0 |

*(2) Constraint conditions*

The main constraint conditions in this calculation are as follows. Allowable overhanging degree is 0.3. Allowable center angle is 110°. Allowable tensile stress is 1.5MPa. Allowable compression stress is 5.0MPa.

*(3) Calculation result and analyzing*

The stress computation adopts 3D linear elastic FEM. The optimizing mesh mainly adopts Eight-node hexahedron element, supplemented by tetrahedron and prism for the transition of boundary and rock structure. Comparison of characteristic parameters before and after optimization is shown in Table 2. Considering the figures above, the calculation will converge in about 7~8 iterative operations, which shows that SQP method has high computational efficiency.

What's more, comparing the shape after optimization to the shape before optimization, the bottom thickness has been obviously reduced, while both maximum overhanging degree and maximum center angle increase, making the whole body turns to be more convex to upstream. The dam volume of parabola configuration decreases from primary $17.7\times10^4m^3$ to $14.7\times10^4m^3$ by 17%. After optimization the maximum principle tensile stress of dam body is 1.48MPa and the maximum principle compression stress is 4.96MPa. The indexes can meet the stress control standards basically.

Therefore, the configuration after optimization is obviously better than the before one. And SQP method is proved to be an effective method for optimization design of arch dam shape.

Table 2 Comparison of characteristic parameters before and after optimization

| | before optimization | after optimization | Allowable value |
|---|---|---|---|
| Dam volume ($10^4m^3$) | 17.7 | 14.7 | ------ |
| Max overhang degree at upstream | 0.152 | 0.198 | 0.3 |
| Max overhang degree at downstream | 0.223 | 0.266 | 0.3 |
| Max center angle | 86.22° | 86.60° | 110° |
| Max tensile stress（MPa） | 0.95 | 1.48 | 1.5 |
| Max compression stress（MPa） | 3.933 | 4.96 | 5.0 |

## Conclusions

The sequential quadratic programming method is introduced in optimization design of arch dam shape in this article. A sample computation is done by using the program developed by the author. The results indicate that after optimization, the shape of arch dam is thinner, and the geometrical curvature is increased in some degree, the volume is decrease in nearly 17%, the tensile and pressure stress almost reach the constrain boundary, means the shape reaches the best shape in theory. Convergence is reached after 7~8 iterations, indicating the program is efficient and stably.

**Keywords:** unsteady flow; spread regularity; rapid characteristic analysis; channel improvement

**Abstract:** After the completion of the hub on river, its scheduling unsteady flow generated an adverse impact on the downstream navigation. In this paper, according to the unsteady flow data of PingBan hub in Nanpanjiangjiang River in Guizhou province, researched unsteady flow spread characteristics and rule in hub downstream channel. Studies have shown that: unlike general water level changes in hub downstream, the waterlevel amplitude attenuation along is not obvious in researched reach; Clear the concept of unsteady flow additional velocity, additional slope，through this theory reveals the ship ascending rapids mechanism difficultly under unsteady flow condition. On this basis, proposed channel regulation methods and measures in hub downstream, which provided support for the hub downstream channel regulation.

Nanpanjiangjiang and Beipanjiang river all originate MaXiong mountain in ZhanYi County of YunNan Province, the two river joins at the vicinity of ZheXiang in Wangmo County of Guizhou Province and named HongShui River, belongs to ZhuJiang river system, is the main tributaries of upper main stream Xijiang River，which is an important channel to the sea in southwest region, and also is high-grade channel that Ministry of Transport planned. Longtan hydro-power station in HongShui River located in Tian'e County of GuangXi Province, which is currently under construction only next to the Three Gorges hydropower project, backwater to BaiDi shoal tail of Nanpanjiangjiangjiang River. From fluctuating backwater zone tail of BaiDi shoal upstream to upper PingBan hub is water level not linking-up reach, 28km long, which has many rapids at this range, together with the effects of unsteady flow by power station scheduling, made the navigation conditions very complex in hub downstream, increase the difficulty at water level not linking-up reach. For channel regulation, we must first analyze rapids, currently it is a technical problem in unsteady flow condition, this paper carried out research on the above theory, provides assistance to the channel regulation below the dam.

## General situation of the reach

Nanpanjiang River originate in south of MaXiong Mountain in ZhanYi County of YunNan Province, where to the confluence full-length 914km, drop 1873.7m, average slope of 2.05 ‰; The length of HuangNi river mouth to confluence in Guizhou Province is 266km, drop 428m, average slope 1.6 ‰.

Nanpanjiang River located in hilly areas. Pingban hub as a reverse regulation hub of TianShengQiaoⅡ Hydropower Station, has a certain role to cut daily regulation of which impact on downstream water level fluctuation amplitude; According to analysis, the water level ranged up to 3m ~ 4m daily in Pingban hub downstream, hours ranged up to 1.3m ~ 1.8m, still can not meet the security requirements of navigation.

Effected by water and sediment regulation of station upstream, the overall riverbed deformation and sediment problems in Nanpanjiang river are not serious, riverbed material mainly composed of bedrock, gravel, partly pebbles and coarse sand. Large slope, fast-flowing, poor flow regime, severe navigation flow conditions, and daily regulation further exacerbated the regime. Now Pingban hub to confluence 114.2km reach the standard of Ⅳ waterway, waterway scale of 1.6m×50m×330m(width × depth × bend radius), using 95% guaranteed rate of navigable which can sail 500t self-propelled motor vessels.

## Hub Overview

### 2.1 Longtan Hydropower Station

Longtan Hydropower Station is located in Guangxi province Red River upstream from the Tian'e county 15km, the fourth in cascade on the Hongshui River, involving the reservoir area in Guangxi and Guizhou provinces (regions). Recent years have the ability to regulate, privileged to electric power generation, incorporating with flood protection, navigation improvement overall efficiency, the station has gone to oprate on December 7, 2009.

### 2.2 Pingban Hydropower Station

Pingban Hydropower Station is Nanpanjiang river comprehensive development and utilization of the third cascade, linking up with TianShengQiao station(Ⅱ) upstream and Longtan station downstream. Hydropower station located in Longlin County of Guangxi province, on the Nanpanjiang river of Xinzhou river mouth upstream 200m, is a boundary river station crossing Guangxi and Guizhou provinces. Station normal pool level 440m, dead water level 432m, total reservoir capacity 310 million $m^3$, regulating capacity 101 million $m^3$, of daily regulation reservoir. By august 2005, all generator units put into operation.

## Unsteady flow rule, spread characteristics and effects on navigation conditions research

In order to develop water resources better in the river, TianShengQiao station(Ⅰ), (Ⅱ), Pingban as well as downstream Longtan hydropower station on river efftcted by flood control scheduling and electric power dispatching, which that unsteady flow of station discharged will have a significant impact on waterways navigation.

### 3.1 Spread laws and features of unsteady flow that daily regulation station generated in hub downstream

According natural waterway observation data analysis under unsteady flow conditions of Nanpanjiang river daily regulation station, sorting out the unsteady flow characteristics as follows:

3.1.1 Daily flow changes frequently

One of the features of unsteady flow, the discharge varies greatly, and the water level fluctuated wildly, changes frequently.

Under natural conditions, the average daily discharge and water level of reach are relatively stable in the dry season, and level amplitude is small, only change greatly in flood season due to the mountain rivers. After Pingban plant operated, the process of discharge changed obviously and discharge distribution was uneven, it may sudden change to several thousand from several hundred, and flow changes without regularity，which is extremely unfavorable for shipping.

3.1.2 The water level changes greatly and amplitude attenuation unconspicuous along the flow in hub downstream

Due to friction, channel storage, irregular cross-section and other factors, unsteady flow process to occur attenuation in spreading，velocity decreases, wave height becomes smaller, unsteady flow effects weaken and gradually stabilize stream.

According to data analysis of water level changes in Pingban plant downstream, daily water level fluctuation amplitude up to 3m ~ 4m, hour level luffing also reach 1.3m ~ 1.8m, level luffing great. Banba wharf located 2km downstream of Pingban hub, Baidi shoal located downstream of the Banba 67.4km, where the lowest end of Longtan hub fluctuating backwater zone in Nanpanjiang river. Seen from the figure, the hub discharged unsteady flow caused great level amplitude in Banba wharf which near the hub，and while the unsteady flow spreading from Banba wharf to downstream, wave crests became smooth along, and wave height attenuated somewhat but slower in rate of decay, the biggst wave height attenuation generally below 0.5m despite spreading more than 60 kilometers, the unsteady flow waveform changed little and peak valley is still evident, the flow showed significant unsteady flow characteristics, different from the general hub downstream unsteady flow propagation characteristics.Generally as the hub discharge spreading distance increases, wave crest tend to flat and wave trough raise, wave height reduce significantly, and after the longer distance it shows certain steady flow characteristics.

3.1.3 Wave crest flow decreasing with the wave trough flow ascending along the river

In the processs of hub discharged unsteady flow spreading along the river, because of the impact of channel storage capacity(natural river has the function of remaining surplus and supplying deficiency, storage more for reserve), peak vally overlap each other and gradually decay along the flow . Maximum flow of Pingban station is 888$m^3$ / s, the minimum is 82$m^3$ / s, when the unsteady flow spread to downstream the maximum flow decreases and minimum flow increases gradually.When it comes to Baidi shoal tail, the maximum flow and minimum flow become 798$m^3$/s, 106$m^3$/s，wave crest spread to Baidi shoal from Pingban hub takes about 9 hour.

Seen from the above, the amplitude of variation of wave crest flow and wave trough flow are further small to general in the process of unsteady flow spreading, similar to reasons of water level changes, tmainly due to the channel storage and resistance becoming smaller along the river.

3.1.4 Wave crest and trough velocity decreasing along the flow

Due to the impact of riverbed slope (riverbed slopes gradually slow down from upstream to downstream), the velocity of Wave crest and trough spreading slowly diminished.

### 3.2 The daily regulation unsteady flow in Pingban hub downstream effect on navigation conditions

The daily regulation unsteady flow in Pingban hub downstream effect on navigation conditions mainly in water depth, velocity and slope changes at stations downstream，due to the long distance of studied reach and rapids too much, take Yanzishi shoal ( away from Pingban 11.4km)as an example. Yanzishi shoal located at water lever not linking-up reach between Longtan hub and Pingban hub, whcih is "bottleneck" reach of Nanpanjiang river transportation, play a role in controlling both the grade of waterway and capacity of Nanpanjiang river. Power station scheduling cause water level of discharge fluctuated greatly and exacerbated the rapids obstructing navigation, the impact on the channel as follows by unsteady flow calculation:

①Water depth

The design flow of the river is 275$m^3$/s, corresponding design depth of 1.6m, counted the instantaneous flow process in January 1～4, 2008 of Pingban station: it is 38 hours that the flow less than design flow in total of 85 hours of discharge process, when the discharge wave spread to Yanzishi shoal it's only 35 hours, which can not meet the requirements of navigation guaranteed rate.

②Velocity

Because the discharge of unstead flow changes along with the time, and thus its hydraulic indicators such as water level, velocity and others change the same time, compared unsteady flow with the steady flow there will be an additional velocity. What's called additional velocity refers to the velocity of unsteady flow at different time points in a period of time, and the difference between the velocity of steady flow disgcharge that equal to average disgcharge of unstead flow during the same period generated is additional velocity, that $\Delta V= V-\overline{V}$, mainly to describe the impact of unsteady flow changes on vessel navigation.

Counted the instantaneous discharge of Pingban in January 1～4 ,2008 total 85 hours: the average discharge was 412 $m^3$/s during that period, research shows that: the instantaneous velocity at wave crest is bigger than velocity in average flow, and at wave trough time most of the instantaneous velocity are less than or equal to the velocity under average flow; At wave crest time (2008-1-2 2008-1-2 12:00 ~ 23:00) the additional velocity is maximum which reached to 3.15m/s at represent section when discharge of 412$m^3$ / s, and the same time which the maximum instantaneous velocity of 3.84m/s, additional velocity of 0.69m/s. The Yanzishi shoal flow torrential in natural conditions, it will further increase the velocity if coupled with the unsteady flow, which is not conducive to

③Additional slope

Additional slope refers to the slope of unsteady flow at different time points and distances in a period of time, which the difference between the slope of steady flow disgcharge that equal to average disgcharge of unstead flow during the same period generated is additional slope, that $\Delta J= J-\overline{J}$, mainly to describe the impact of unsteady flow changes on vessel navigation.

The rapids slope at wave crest is bigger than slope under average flow, at wave trough time most of the instantaneous rapids slope are also bigger than slope under average flow, only a small part period which is smaller than rapids slope under average flow. At wave crest time (2008-1-2 11:00) the additional slope is maximum which reached to 2.20‰ when discharge of 412$m^3$/s, and the same time the instantaneous slope of 2.79‰，additional slope of 0.59‰. From the results we can see: it

will form additional slope in waterway when the water level rise abruptly, which have certain adverse effects on ship sailing conditions.

## Channel improvements and regulation measures in daily regulation station downstream

### 4.1 Channel regulation in in daily regulation station downstream

The water level and discharge amplitude of daily regulation station are large, and water depth not enough in dry season that the consistency of navigation was damaged; water level rise and drop precipitous which affect the waterway stability, so it requires channel regulation in daily regulation station downstream by needed.

(1)Regulation principles

Take the Nanpanjiang river bedrock reach, based on the causes of rapids, adopted the measures of reef explosion, cuting mouth and regulating structures, etc., eliminated or reduced adverse flow regime, slowed down the velocity, facilitates navigation of the ship safely.

(2) Regulation methods

Dominated riverbank protection, strengthening revetment, removal the part of cusp, smooth shoreline，stabilize the current and reduce the mainstream swing. Regulating structures should adopt the low dam, because the Low dam safety and stability is better resistant to water level rise and drop precipitous.

### 4.2 Channel stabilization measures in daily regulation station downstream

Daily regulation station impact on downstream channel: first the water level and discharge amplitude of daily regulation station are large, and water depth not enough in dry season that the consistency of navigation was damaged; water level rise and drop precipitous which affect the waterway stability. Need to take appropriate measures, including: ①stabilize base flow and limit the minimum discharge flow; ②egalization of optimizing dispatch management

## Conclutions

The paper accorded to the unsteady flow data of PingBan hub in Nanpanjiang River in Guizhou province, carried out the research and conclusions are as follows:

(1)The unsteady flow propagation characteristics and rule in hub downstream channel research indicated that: unlike general water level changes in hub downstream, the water level amplitude attenuation along the river is not obvious.

(2)Put forward the concept of additional velocity and additional slope, revealed the ship ascending rapids difficultly mechanism under unsteady flow condition.

(3) Proposed channel regulation methods and measures in hub downstream, which provided support for the channel regulation in hub downstream.

# 3D Dynamic Numerical Simulation of Water Flow in Stilling Basin with Flaring Gate Pier

Chun Qiu, Chenglan Liu

Sichuan College of Architecture Technology, Deyang, 618000, China

Email: qiu3216@163.com

**Keywords:** Dynamic numerical simulation; VOF method; X Shaped flaring gate pier; Stilling basin

**Abstract.** 3D numerical simulation is carried out for the water flow in stilling basin with X shaped flaring gate pier when the radial gate uses four different opening velocities. The space-time change law of hydraulic characteristics is obtained. The water level in the stilling basin is relatively higher while using lower opening velocities during the processes. The negative pressure exists on weir surface while the relative opening degree is less than 0.55; the maximal pressure on the slab of ogee section and stilling basin increases and moves to downstream with the gate opening. The results can provide important basis for shape optimization of practical engineering.

## Introduction

Flaring gate pier and stilling basin is used widely as an important energy dissipater. Many numerical and experimental researches on it have been carried out recently. Y.L.Li, P.Gao[1,2] studied the velocity field in a stilling basin by numerical simulations. T.Zhang[3] simulated the water flow of FGP and the steps. H.G.Ni[4] gave a simplified hydraulic calculation method for flaring gate pier and stilling basin.

Z.X.Liang[5] studied the style designing of X shaped flaring gate piers. C.Qiu[6,7] studied the dynamic property of the water flow in stilling basin with Y shaped flaring gate pier. In this study, 3D numerical simulation on water-air two-phase flow in stilling basin with X shaped flaring gate pier is carried out by using RNG $k-\varepsilon$ model while the radial gate uses four different opening velocities, i.e., $\omega_1 = 0.2697 rad/s$ , $\omega_2 = 0.0539 rad/s$ , $\omega_3 = 0.0269 rad/s$ , $\omega_4 = 0.0135 rad/s$ corresponding to four opening times: $t_1 = 3s$ , $t_2 = 15s$ , $t_3 = 30s$ , $t_4 = 60s$ .

## Numerical model and running conditions

The fundamental equations are as follows

Continuity equation $$\frac{\partial \rho}{\partial t} + \frac{\partial \rho u_i}{\partial x_i} = 0 \tag{1}$$

Momentum equation

$$\frac{\partial \rho u_i}{\partial t} + \frac{\partial}{\partial x_j}\left(\rho u_i u_j\right) = -\frac{\partial p}{\partial x_i} + \frac{\partial}{\partial x_i}\left[\left(\mu + \mu_t\right)\left(\frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i}\right)\right] \tag{2}$$

$k$ equation

$$\frac{\partial(\rho k)}{\partial t} + \frac{\partial(\rho u_i k)}{\partial x_i} = \frac{\partial}{\partial x_i}\left[\left(\mu + \frac{\mu_t}{\sigma_k}\right)\frac{\partial k}{\partial x_i}\right] + G_k - \rho\varepsilon \tag{3}$$

$\varepsilon$ equation

$$\frac{\partial(\rho\varepsilon)}{\partial t} + \frac{\partial(\rho u_i \varepsilon)}{\partial x_i} = \frac{\partial}{\partial x_j}\left[\left(\mu + \frac{\mu_t}{\sigma_\varepsilon}\right)\frac{\partial \varepsilon}{\partial x_i}\right] + \frac{C_{1\varepsilon}\rho\varepsilon}{k}G_k - C_{2\varepsilon}\rho\frac{\varepsilon^2}{k} \tag{4}$$

Where $\rho$ and $\mu$ are the density of the averaged volume fraction and molecule viscosity, $p$ is modified pressure; $\mu_t$ is turbulent viscosity coefficient related to turbulent kinetic energy $k$ and turbulent viscosity dispassion ratio $\varepsilon$, which can be expressed by the equation as $\mu_t = \rho C_\mu \frac{k^2}{\varepsilon}$; $C_\mu$ is an empirical constant. The constants in the equations include, $C_{1\varepsilon}$=1.42, $C_{2\varepsilon}$=1.68, $C_\mu$=0.085, $\sigma_k$=0.7179, $\sigma_\varepsilon$=0.7179.

The length and the width of the whole computational region are 6.10m and 0.30m, respectively. The origin of coordinate system is set at the intersection of the crest of overflow dam and the centerline of the floor of the stilling basin, where the axes of X, Y and Z can be seen from Fig.1. a). Fig.1. b).show the map of grids of radial gate and X shaped flaring gate pier.

The inlet of the head water reservoir is divided into two parts; the upper and lower are both pressure inlet. The pressure function relation is used to control constant water level of reservoir. Pressure inlet is also applied on top of reservoir, spillway and stilling basin. The outlet is pressure outlet; others are solid boundary conditions.

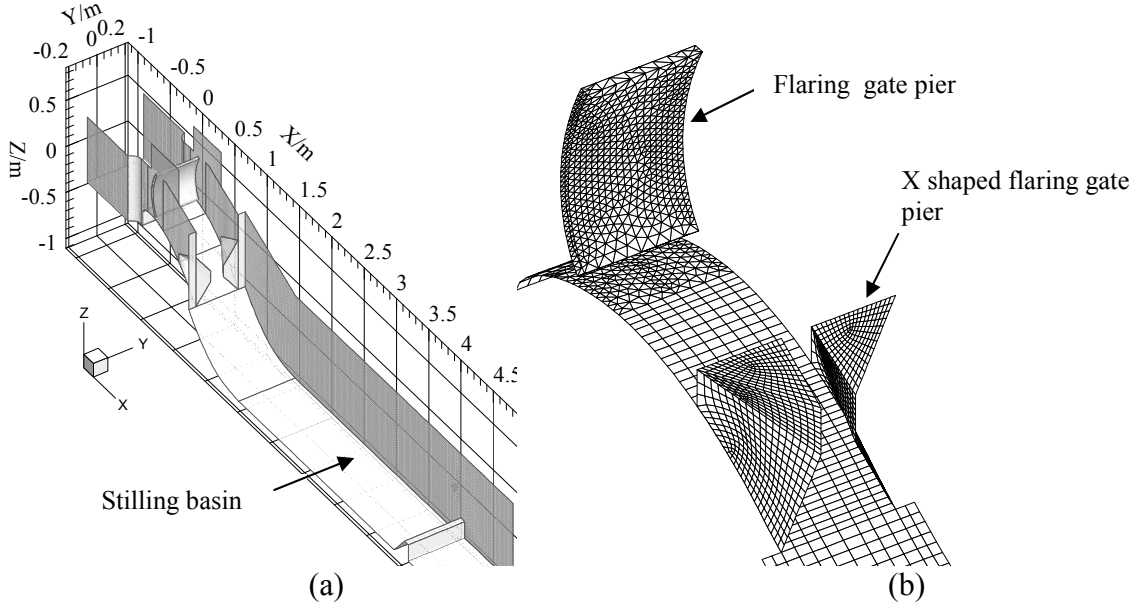

Fig.1 a) Numerical simulation region b) Map of grids of particular region

**Water Surface Profile**

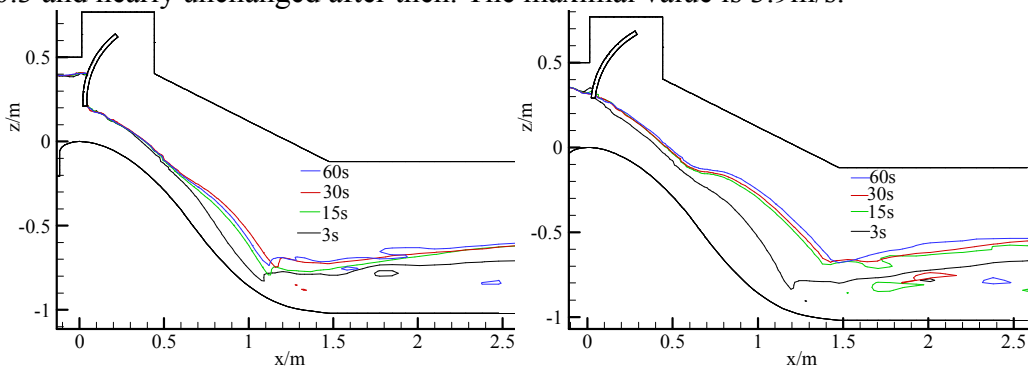
From Fig.2 we can see that the depth of the mainstream becomes larger and larger with the increase of the relative opening degree (e). For the three different long opening times, water crown is formed at e=0.5 because of the deflection of side walls of the flaring gate piers, but the water crown appears until e=0.7 while using $t_1$. The height of the water crow corresponding to the lower opening velocity is always larger than that corresponding to the higher one during the whole process, and the difference is especially obvious while e>0.4; the impact caused by the water jet is also relatively larger because of the lower water level. This is the problem that the attention should be given.

During the process, water level before radial gate drops seriously at e=0.7, which is the transition period of sluice flow and weir flow. The phenomenon is also observed in model experiment.

Fig.3 shows the distribution of the velocity in the middle section of the spillway while using $t_4 = 60s$. The maximal velocity located at ogee section appears at e=0.3; the peak value is 4.4m/s and nearly invariant after than. The velocity of water flow in the stilling basin is relatively small because the water is strongly aerated and turbulent.

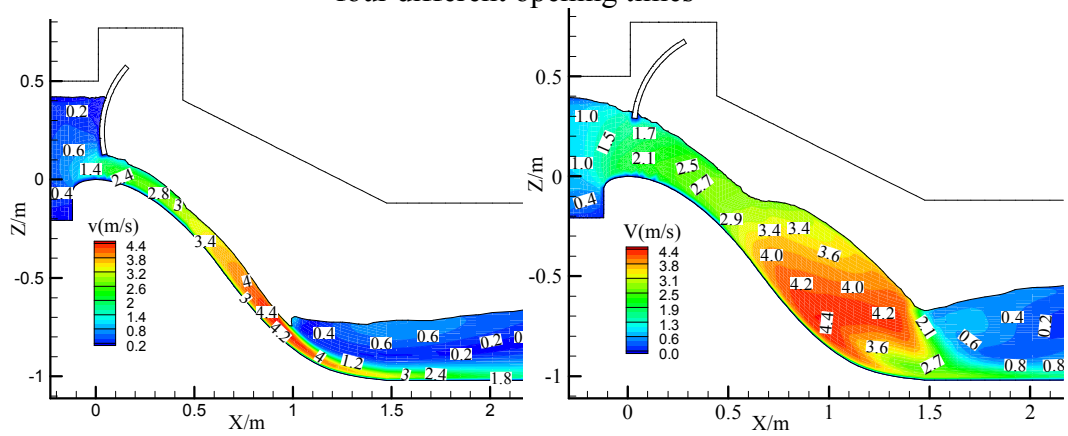
Velocity field of x=0.7m (the outlet of the X shaped flaring gate pier) at four different opening degrees is shown in Fig.4. The water profile near the side walls is higher than that in the middle

section part while e=0.7 because of the rapid flow shock wave caused by the side walls of flaring gate pier. The phenomenon will disappear if e<0.6. The velocity of the section increases according to time before e=0.3 and nearly unchanged after then. The maximal value is 3.9m/s.



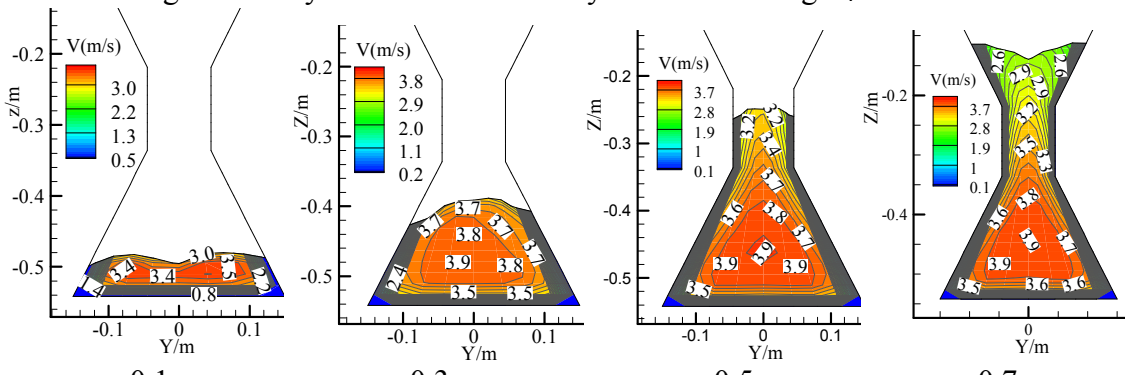
e=0.5 e=0.7

Fig.2 Comparison of the water surface profile along the middle section of overflow weir under the four different opening times



e=0.3 e=0.7

Fig.3 Velocity fields of the section y=0m while using $t_4 = 60s$



e=0.1 e=0.3 e=0.5 e=0.7

Fig.4 Velocity distribution of the cross section x=0.7m at different openings by using $t_3 = 30s$

**Pressure characteristics**

The pressure characteristics on the slab of stilling basin according to the opening degrees are shown in Fig.5. The maximal pressure on the floor is located at the rear part of stilling basin while e<0.7, which is mainly because the water jet is situated at the anti-arc region. With the water jet becomes longer, the impact region reaches the foreside of the stilling basin at e=0.7, and the value of the pressure is 6200Pa. During the whole opening process, negative pressure is always observed on the surface of X shaped flaring gate pier, which is the condition must be considered during the primary design.

The pressure distribution along the centerline of overflow dam and the stilling basin is shown in Fig.6. It can be seen that pressure of spillway before x=0.1 decreases with the opening, because the pressure is mainly static pressure produced by the water body in the reservoir. The water level of reservoir decreases according to the opening, so the pressure accordingly decreases.

The maximal pressure on the floor of stilling basin is rising and the location of maximal value shifting to downstream with the time for the water jet becomes longer, and the maximal pressure is 6109Pa while e=0.75. Negative pressure emerging at lower part of weir crest(x=0.6) sustains about 19s and disappears after e=0.5; the peak value is 193.5Pa, which is the basis for shape optimization. .

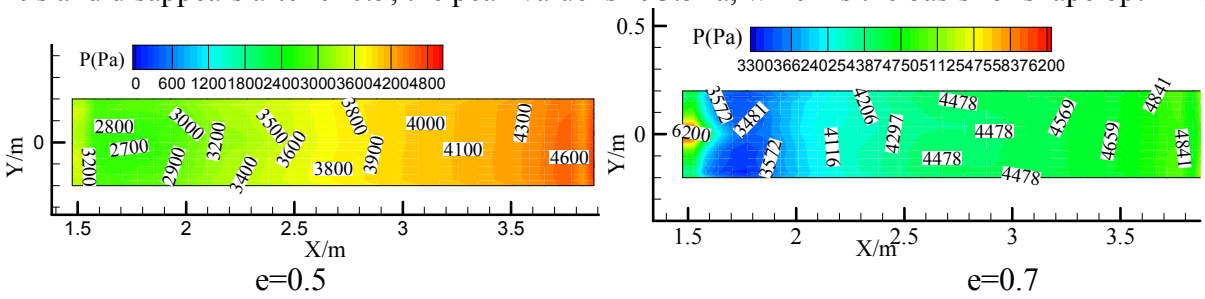


Fig.5 Distribution of the pressure on the floor of stilling basin while using $t_4 = 60s$

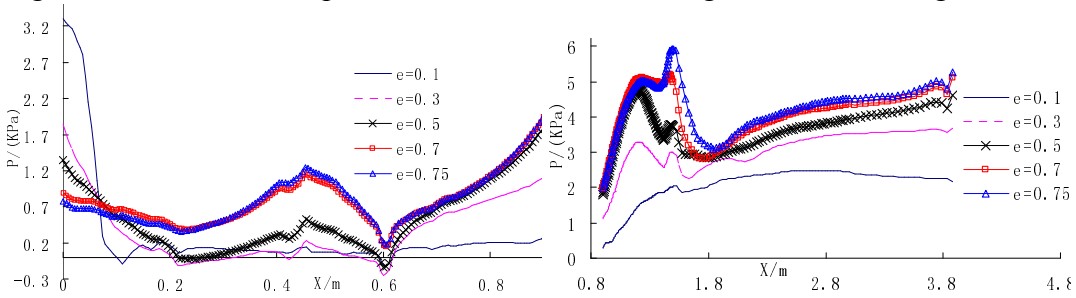

Fig.6 Variation of pressure distribution on the middle section of the spillway surface and the slab of stilling basin at $t_3 = 30s$

## Conclusions

3D dynamical numerical simulation is carried out for the unsteady flow of X shaped flaring gate pier and stilling basin by using RNG $k-\varepsilon$ model and dynamic mesh technology. The water surface profile corresponding to the four different opening velocities is analyzed. Velocity distribution is reflected in detail; the pressure distribution on the floor of weir surface and stilling basin are also pointed out. The results can provide important reference for run mode of finished hydraulic engineering.

# Finite Element Analysis of Seismic Response of Exposed Steel Penstock in Hydropower Station

Yuan Liu[1, a], Changzheng Shi[1, b] and Hegao Wu[1, c]

[1]State Key Laboratory of Water Resources and Hydropower Engineering Science, Wuhan University, Wuhan, Hubei, 430072,China

[a]lyuan@whu.edu.cn, [b]scz4@163.com, [c]wbf1988@vip.sina.com)

**Keywords:** Exposed penstock, Earthquake, Sliding support, Finite element method, Dynamic time-history analysis

**Abstract:** Using finite element method, the seismic responses of an exposed steel penstock in a hydropower station were analyzed. The results show that the penstock is constrained weakly due to the expansion joint and sliding supports, so the penstock can adapt to the deformation during the earthquake well, and the stress caused by the earthquake is small which will be benefit for the strength and safety of the penstock. However large acceleration and displacement in transverse direction may be induced under strong earthquake, in addition, the penstock will be likely to jump apart from supports in vertical direction. So it is better to equip caging device to limit transverse sliding and vertical jumping in an appropriate range in order to ensure the safety and stability of the whole structure.

## Introduction

Possessing the advantages of definite mechanical feature, convenient maintenance and inspection, simple structure and excellent anti-seepage ability, the exposed steel penstock has been widely used in small and medium scaled hydropower stations and water diversion projects [1]. But horizontal displacement and temperature stress may be induced by installation deviation or temperature change [2]. In order to reduce the influence of aforementioned factors, expansion joint is usually set between two adjacent anchorage blocks, and meanwhile sliding supports are adopted to make the steel pipe deform relatively freely in horizontal direction. However, relative motion may occur between the pipe and support piers under earthquake due to the small stiffness of the structure, and the pipe may even fall from the supports, leading to serious destruction.

So far a few studies have been done on the dynamic behaviors of exposed steel penstock by prototype test and finite element method. The prototype vibration test of exposed steel penstock with large diameter in Baishan hydropower station showed that the probability of substantial vibration of inclined section in transverse and vertical direction was large [3]. The dynamical finite element analysis of exposed steel penstock for inverted siphon indicated that the sliding supports were the weak connecting component during earthquake [4]. In practical engineering, due to the contribution of vertical caging device, the probability that penstock separated from supports and jumped upward entirely was small. So far, there is no seismic damage cases of exposed steel penstock, but analogous cases existed in bridge structures. According to the introduction in the article [5], support piers displaced in Wenchuan earthquake, furthermore, the decrease of the contact force between support and bridge span led to the decrease of friction force between bridge and pier, so it was more likely to cause seismic damage such as girder falling, and it also brought out the pounding between support piers and above structure, such as the support impacting damage of

Nielsen Bridge in Kobe earthquake in Japan of 1995 [6]. So in this paper, the dynamic analysis of an exposed steel penstock in a hydropower station with high head was conducted by finite element method using software ANSYS in order to discuss the movement characteristics of the penstock during the earthquake.

**Finite element analysis**

**Model details**

One inclined segment of exposed steel penstock between two anchor blocks in a hydropower station was studied in this paper, of which the overall length was 73.33 m. The penstock with an inner diameter of 2.5 m and a shell thickness of 38 mm bore the internal water pressure ranging from 4.62MPa to 5.00MPa. 9 sliding supports were arranged along pipeline numbered consecutively 1#~9# from upstream to downstream, and the distance between adjacent supports was 7.5 m. One expansion joint was set between the upstream anchor block and support 1# (see Fig.1).

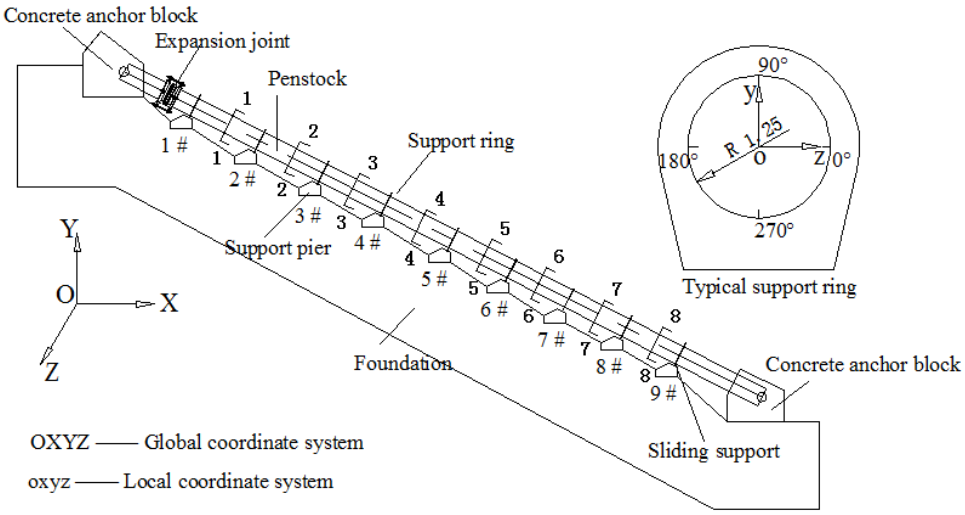

Fig.1 Layout of the exposed steel penstock

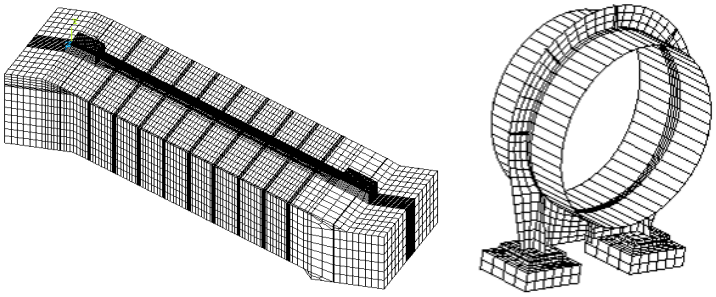
According to dimensions of the structure, a finite element model was established, including steel penstock, support rings, sliding supports, concrete anchor blocks and support piers, expansion joint and foundation. The concrete structure and rock were simulated by solid element, while the steel structures simulated by shell element, the expansion joint was simulated by beam element whose axial stiffness equalled to the stiffness of expansion joint. In order to simulate the contact and sliding behaviors between the two sliding surfaces of the support, contact and target elements were set of which the interaction followed the coulomb's friction law, and the friction coefficient was 0.1. The finite element model was shown in Fig.2. The material mechanical parameters were list in Table.1.



(a) (b)

Fig.2: (a) FE model (b) Meshes of support

Table.1 Material mechanical parameters

| Material | Elastic Modulus(GPa) | Poisson Ratio | Bulk Density(kN·m$^{-3}$) |
|---|---|---|---|
| Steel | 206 | 0.3 | 78.5 |
| Concrete | 25.5 | 0.167 | 25.0 |
| Bedrock | 5 | 0.2 | 26.0 |

**Calculation conditions**

The earthquake wave shown in Fig.3 with the peak ground acceleration 2.76 m·s$^{-2}$ was chosen in the dynamic analysis. Time-history analysis method was adopted in the analysis with the time step of 0.02 s [7,8]. The earthquake wave was input from X, Y, Z three directions simultaneously, however the peak acceleration in the horizontal direction was 2.76 m·s$^{-2}$, and 1.84 m·s$^{-2}$ in the vertical direction. The foundation was regarded as massless base and only the elasticity was taken into account.

During the calculation, static analysis was executed first to gain the displacement and stress status of the structure subjected to internal water pressure and dead loads which was used for the basic state of seismic analysis. To simplify the calculation, the dynamic interaction between water and pipe was ignored, but the inertial effect of water quality was considered through the mass element attached to the pipe wall along the pipeline [9]. The upstream and downstream surfaces of the bedrock were constrained in normal direction, and the bottom surface was constrained completely, and others were regarded as free boundary.

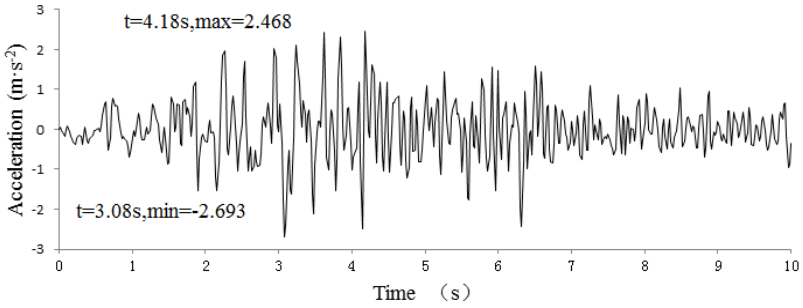


Fig.3 Acceleration time-history in horizontal direction

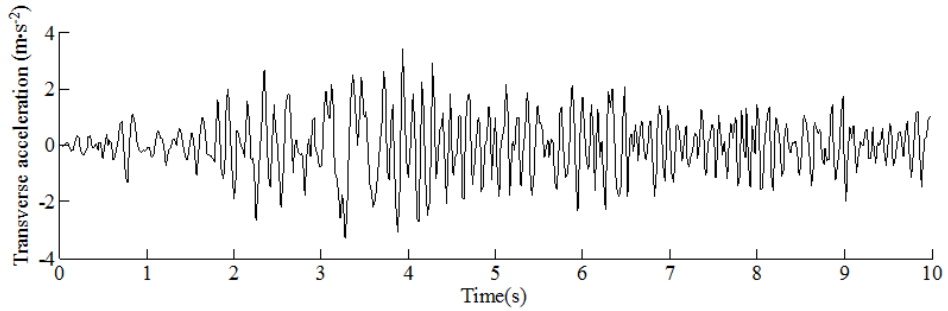
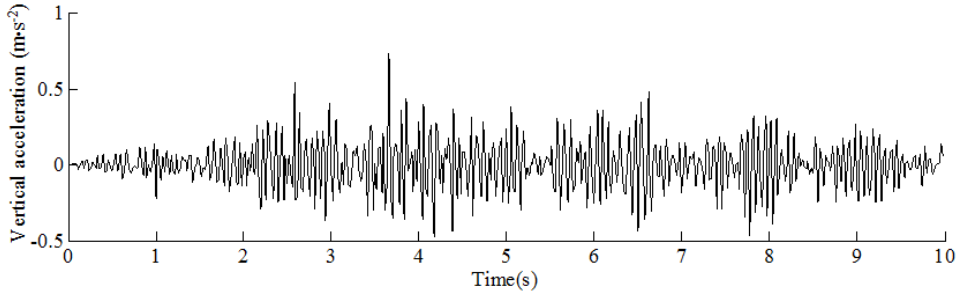
**Result and analysis**

Two anchor blocks are set at two ends of the penstock, which fix the penstock on the slope, so the responses of anchor blocks and pipes buried in anchor blocks are small under the earthquake, while the responses of other pipe sections are relatively obvious. In order to analyze the dynamic response distribution law along the pipeline, the mid-span section between adjacent support piers numbered section 1～8 consecutively (shown in Fig.1) are analyzed carefully. Later analyses mainly focus on the section 4 located at the middle span of the pipeline to make description of the dynamic response in each direction.

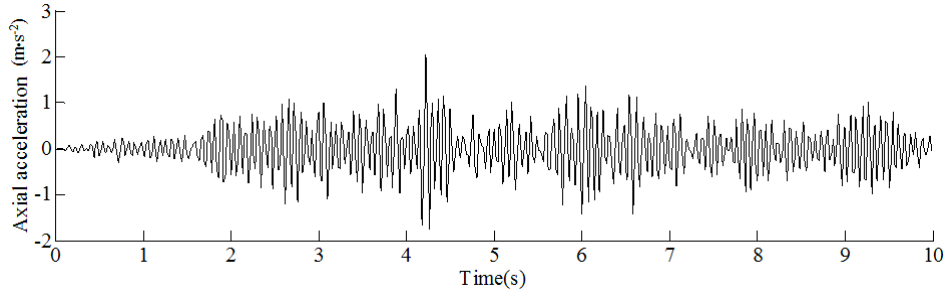
**Acceleration response.** The time-history curves of acceleration of waist point (0°) on section 4 under each direction are shown in Fig.4, and the acceleration responses of most parts of the structure are similar to this point. As shown in Fig.4, the acceleration of specific point reaches the peak acceleration during the period of 3 to 5 s in each direction, which is slightly later than the input wave.



(a) transverse acceleration



(b) vertical acceleration



(c) axial acceleration

Fig.4 Time-history of the acceleration of waist point on section 4-4 in each direction

The peak acceleration of all specific sections in each direction is shown in Table.2. The largest peak acceleration in axial and vertical direction both appear at the middle section of pipe under the earthquake, and transverse peak acceleration is nearly symmetrical about center point of the pipeline. The peak acceleration reaches 2.58 $m \cdot s^{-2}$, 1.15 $m \cdot s^{-2}$ and 3.43 $m \cdot s^{-2}$ in axial, vertical and transverse direction respectively, and the acceleration in transverse direction is obviously larger than the other two.

Table.2 Peak acceleration of specific section in each direction

**($m \cdot s^{-2}$)**

| Direction | Section | | | | | | | |
|---|---|---|---|---|---|---|---|---|
| | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 |
| axial | 1.54 | 2.09 | 2.43 | 2.58 | 2.54 | 2.30 | 1.87 | 1.30 |
| vertical | 1.23 | 1.21 | 1.15 | 1.15 | 1.14 | 1.15 | 1.21 | 1.21 |
| transverse | 2.71 | 3.47 | 2.03 | 3.43 | 3.39 | 2.17 | 3.38 | 2.89 |

**Dynamic displacement response analysis of exposed steel penstock.** During the earthquake, the movement of steel penstock represents the characteristics of reciprocating motion on the support piers in horizontal direction and jumping up and down in vertical direction. However the influences of earthquake on the movements in three directions are distinct. Though the pipe could jump up

from the piers during the earthquake, the height of jump doesn't exceed 1.0 mm due to the action of gravity of pipe and water. Because the stiffness of the pipe in transverse direction is much smaller than the stiffness in axial direction, the movement in transverse direction is more obvious. For long-distance and large-span exposed steel penstock with expansion joint and sliding supports, transverse stiffness is usually not enough, so that the penstock swings from side to side and the transverse displacement relative to the support piers is large as shown in Fig.5. Fig.6 illustrates the peak relative displacement of each section in three directions along the pipeline. The maximum transverse displacement occurs at middle part of the pipe, and the value reaches 10.8 mm. Large sliding in transverse direction between pipe and supports will destroy supports easily and make the penstock drop down from support piers, which is not benefit for the safety and stability, so it should be restricted in an appropriate range in practical project.

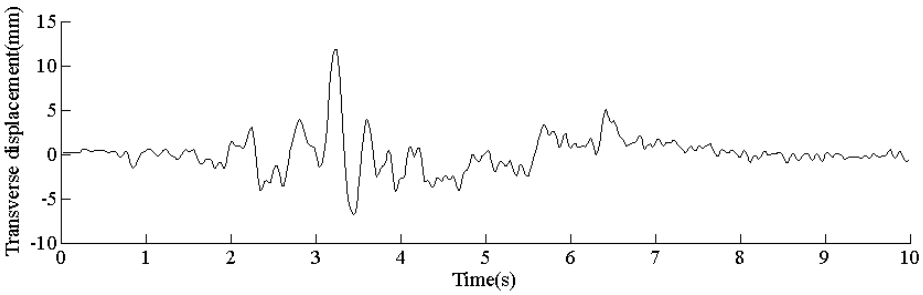


Fig.5 The time-history of transverse displacement of section 4 relative to support 5

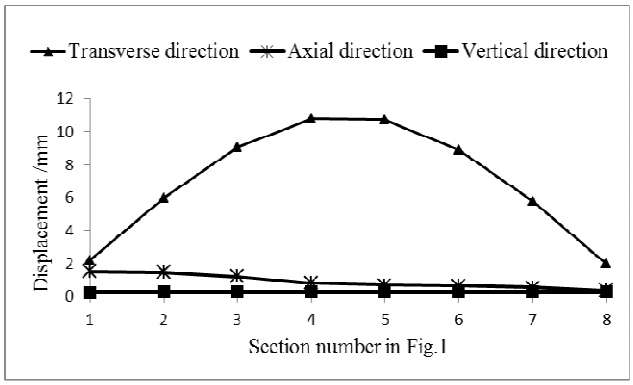

Fig.6 Peak displacement relative to support piers of each section caused by earthquake

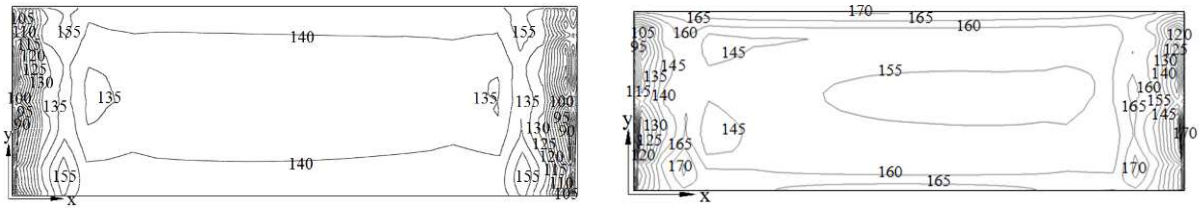
**Stress analysis.** Fig.7 describes the Mises stress envelope diagram of pipe segment between support 4 and 5 under static loads and earthquake. Under the static loads of which the chief load is internal water pressure the steel pipe mainly subjects to tensile force in circumferential direction, and the stress is uniform along axis except the parts adjacent to support ring. Under the earthquake the regularities of stress distribution are similar to the state under static loads, but the stress value increases by 20~30 MPa. It illustrates that under the earthquake the stress is still controlled by internal water pressure mainly, and the effect of earthquake load on stress is slight because of the ability of the penstock to move freely in horizontal direction. The results show that the penstock can adapt to the deformation induced by the earthquake well attributing to the sliding supports and expansion joint, so the stress and deformation caused by the earthquake is small, which will be advantageous to ensure the strength and safety.



(a) under static loads (b) under earthquake

Fig.7 Mises stress envelope diagram of pipe segment between support 4 and 5 (MPa)

## Conclusion

The penstock can adapt to the deformation during the earthquake well attributing to the sliding supports and expansion joint, and the stress caused by earthquake changes slightly compared to the stress caused by static loads. So the strength of penstock will not be threatened by earthquake obviously. However the earthquake will induce transverse acceleration and displacement, and large relative transverse sliding between penstock and supports may occur due to the weak constraint of expansion joint and sliding supports under strong earthquake, especially at the middle part of the penstock which is away from the constraint of anchor blocks both at upstream and downstream ends. Aforementioned phenomenon is disadvantageous to ensure the strength and safety, so it is better to equip relevant caging device to limit the relative displacement in an appropriate range.

**Keywords:** Joint regulation and storage; surface water; groundwater

**Abstract.** Based on the regulating principles, the modes of joint regulation and storage of surface water and groundwater in Rushan River Basin are simulated using multi-objective programming method. The study suggests two modes as "two dry years and one normal year" and "four dry years and one wet year". The results indicate the guarantee rates of water supply are improved, with increasing the exploitation quantity in dry years and the recharge in wet years. The study provides a strong guarantee for water resources regulation and promotes the sustainable development of regional water resources.

## Introduction

The coastal area of Shandong Province lacking water resources is one of the serious water shortage areas. With the development of social economy, the phenomenon that water demand is greater than supply has become more and more prominent. The imbalance of that has gradually started to hinder the local economic sustainable development [1-2]. Increasing the scale of transferring water is hardly to solve the problems of local water resources fundamentally. The concept of " Resources Water " should be taken as the guiding ideology [3], and the problems during the development and utilization of water resources in the area are needed to realize adequately. Based on this, sustainable development and utilization of surface water and groundwater could be obtained with reason and effect.

In order to further promote the water supply and demand balance for Rushan River Basin, the joint regulation of surface water and groundwater is studied with the liquidity, systematicness, regulatory and recoverability of water resources. It can improve the utilization of water and alleviate the harm to ecological environment due to groundwater over exploitation [4]. There is great application value for optimal allocation and improving the management of water resources.

## Basic situation of study area

Rushan River Basin located in RuShanShi Midwest of Shandong Province, belongs to the low mountains and hills in Jiaodong Area. The alternating distribution of mountains, hills and plains are presented with a total area of 1015.80 $km^2$. The basin is a typical warm temperate maritime monsoon climate with four seasons. Winter is not severe cold, and summer is not very heat. There are such characteristics as warm climate, small temperature difference, long sunshine time and abundant rain. The water resources are surface runoff and underground latent water with the mean annual rainfall of about $5.77\times10^8m^3$. Surface water accounts for $4.3\times10^8m^3$ and groundwater accounts for$1.47\times10^8m^3$. The per capita consumption is much lower than the national average because of serious water shortage. So the rational utilization and effective protection of water resources are very urgent.

## Situation of exploitation and utilization of water

The total catchment area is about 232.7$km^2$ with an active storage of $2.254\times10^7m^3$. There are 54 small reservoirs, and they are annual regulation. The water supply capacity depends on the size of

active storage and the volume of incoming water. The projects of surface water storage are shown in Table 1.

Tab.1 Water storage projects of surface water in Rushan River Basin

| Projects | Amount | Catchment area ($km^2$) | Total storage (million $m^3$) | Active storage (million $m^3$) | Major function (water supply) |
|---|---|---|---|---|---|
| Longjiaoshan Reservoir | 1 | 277 | 107.89 | 59.16 | Domestic, industrial, agricultural |
| Taiyi Reservoir | 1 | 28 | 18.96 | 12.50 | Industrial and agricultural |
| Yuanli Reservoir | 1 | 15 | 10.98 | 7.00 | Agricultural |
| Small Reservoir | 54 | 92.6 | 20.60 | 11.65 | Agricultural |
| Ponds | 297 | 140.1 | 16.33 | 10.89 | Agricultural |

Special hydrogeological structure and economic development strategy of Rushan River Basin determine the overall layout of groundwater development and utilization. Water for urban and rural residents depends on the exploitation of shallow groundwater, and there are 1134 electromechanical wells.

## Joint regulation and storage

Groundwater over-exploitation will cause the water lowering and the ground subsidence [5]. A joint regulation should be reasonable arrangement and efficient utilization of surface water and groundwater resources. The principles in the study are full use of precipitation, regulating use of surface water, protective exploitation of groundwater. In case of consecutive dry years, the premise is to avoid destroying the environment. It can be properly depleted aquifer space to increase the amount of groundwater supply sparing capacity. Then increasing the quantity of groundwater recharge is carried out to recover the water level during wet years. This method can improve the guarantee rate of water supply [6].

Water resources in Rushan River Basin are precipitation, surface water and groundwater. And utilizations of water are domestic, industrial and agricultural irrigation water. Surface water can transform into groundwater using recharge measures through Rushan River. The groundwater reservoir located in downstream is used to adjust surface water and groundwater in time.

**The classifications of water.** When the water supply is less than demand, a high level of water supply should be ensured and low-level be reduced. Based on the use of water in the area, the first and second and third grade water use sectors are domestic, industrial production and agricultural irrigation water, respectively. The reservoirs with low adjustment ability are priority to supply water, then reservoirs with high ability are used to supply water. The order is medium-sized reservoirs and ponds, Longjiaoshan Reservoir, groundwater reservoir, respectively.

**The objective function.** The objective is the minimum of water deficiency as

$$\min f(x) = \sum_{w=1}^{W} \sum_{u=1}^{U(W)} \left[ F_u^W - \sum_{s=1}^{S(u)} x_{su}^w \right]. \tag{1}$$

Where $f(x)$ is water deficit; $W$ expresses the amount of region; $F^w{}_a$ represents the water demand of $w$ region $u$ user; $U(w)$ is the amount of user in $w$ region; $S(u)$ is the amount of headwater with single direction in $w$ region; $x^w{}_{su}$ is the water supply quantity of $s$ headwater to $w$ region $u$ user.

**The constraint conditions.** Water constraints consist of water demand and supply constraints. Water demand constraint represents to ensure the water quantity for different users. Water supply constraint refers to the supply for users must not exceed the ability of the headwater provided [7].

1) The available water is expressed by

$$\sum_{w=1}^{W} \sum_{u=1}^{U(w)} x_{au}^w \le R_a, \sum_{w=1}^{W} \sum_{u=1}^{U(w)} x_{su}^w \le R_s^w. \tag{2}$$

Where $x^w{}_{au}$ is the water supply quantity of $a$ headwater to $w$ region $u$ user; $R_a$ is the available water of $a$ headwater; $R^w{}_s$ is the available water of $s$ headwater; other symbols are same with equation (1).

2) The carrying capacity of water is presented by

$$x_{au}^{w} \le Q_{a\max}^{w}, x_{su}^{w} \le Q_{s\max}^{w}. \tag{3}$$

Where $Q^{w}_{amax}$ is the maximum carrying capacity of $a$ headwater to $w$ region; $Q^{w}_{smax}$ is the maximum carrying capacity of $s$ headwater to $w$ region; others are same with equation (2).

3) The water demand is expressed by

$$G_{u\min}^{w} \le \sum_{s=1}^{S(w)} x_{su}^{w} + \sum_{a=1}^{A} x_{au}^{w} \le G_{u\max}^{w}. \tag{4}$$

Where $G^{w}_{umin}$ is the minimum water demand of $w$ region $u$ user; $G^{w}_{uman}$ is the minimum.

4) The water balance of Longjiaoshan Reservoir is expressed by

$$\begin{cases} U_{i+1} = U_i + W_{come} - \sum W_{use} - W_{loss} (i = 1,2,...,108;1,2,...,180) \\ 750.00 \le U_i \le ActiveStorage, U_{108} \ge 750.00, U_{180} \ge 750.00 \end{cases}. \tag{5}$$

Where $U_{i+1}$, $U_i$ are the storage capacities of reservoir at the beginning and ending of $i$ period; $W_{come}$ is the inflow; $W_{use}$ is the use; $W_{loss}$ is the total of evaporation and leakage and surplus water.

5) The water balance of groundwater reservoir is expressed by

$$\begin{cases} V_i = V_{i+1} + Rp_i + Rs_i + Rb_i + Ar_i - Dp_i - E_i (i = 1,2,...,108;1,2,...,180) \\ 0 \le V_i \le 1618.40, U_{108} \ge 809.2, U_{180} \ge 809.2 \end{cases}. \tag{6}$$

Where $V$ is storage capacity, and $V_0$ is the one second of the maximum; $R_p$ is precipitation infiltration recharge; $R_s$ is surface water infiltration recharge; $R_b$ is lateral recharge; $A_r$ is artificial recharge; $D_p$ is the exploitation; $E_i$ is the evaporation.

## Results and Discussion

The calculation of adjusting Longjiaoshan Reservoir and groundwater reservoir shows that the uneven rainfall is presented with water depletion in dry season and water residual in flood season. According to the precipitation data from 1961 to 2010 hydrological year, Rushan River Basin continuously appears four dry seasons from 1980 to 1984, however, from 1986 to 1988 and from 1991 to 1993 are the two dry years. From the supply perspective, the modes of "four dry years and one wet year" and "two dry years and one normal year" are selected as modes of regulation and storage to improve the probability of water supply.

**The "two dry years and one normal year".** Based on the principle of joint regulation, the mode of "two dry years and one normal year" is simulated after calculating the actual water demand and reservoirs pondage, as shown in Table 2.

Tab.2 The mode of "two dry years and one normal year" before and after regulation.

| Hydrological year | Domestic water (million $m^3$) | | | | Agricultural water (million $m^3$) | | | |
|---|---|---|---|---|---|---|---|---|
| | Before | | After | | Before | | After | |
| | Supply | Deficiency | Supply | Deficiency | Supply | Deficiency | Supply | Deficiency |
| 90% | 10.95 | 12.775 | 23.725 | 0.00 | 15.1287 | 53.3522 | 10.4776 | 58.0034 |
| 75% | 10.95 | 0.00 | 10.95 | 0.00 | 8.7645 | 20.3803 | 27.396 | 1.7488 |
| 50% | 10.95 | 0.00 | 10.95 | 0.00 | 3.9132 | 0.00 | 3.9132 | 0.00 |

In 90% hydrological year with water shortage, the domestic water should be ensured preferentially. The simulation increases groundwater of $1.2775\times10^{7}m^3$ for domestic water and decreases groundwater of $4.65\times10^{6}m^3$ for irrigation, then the total increasing exploitation of groundwater is $8.1239\times10^{6}m^3$. In 75% hydrological year with adequate water for production and livelihood, the simulation increases groundwater exploitation of $1.86315\times10^{7}m^3$ for agricultural irrigation. And in the flood season it increases the recharge of $1.85916\times10^{7}m^3$. In 50% hydrological year, it increases the recharge of $8.1638\times10^{7}m^3$. At last, the water table can be restored. Compared to the results of before and after joint regulation of surface water and groundwater, the effect is presented better,

**The "four dry years and one wet year".** In 75% hydrological year, the simulation ensures that there is no deficiency of domestic water. Increasing agricultural water of $1.8923\times10^7m^3$ and the recharge of $1.24465\times10^7m^3$ in flood season is taken. In 25%, the recharge of $7.2041\times10^6m^3$ is increased in flood season, as shown in Table 3.

Tab.3 The mode of "four dry years and one wet year" before and after regulation.

| Hydrological year | Agricultural water (million $m^3$) | | | |
|---|---|---|---|---|
| | Before | | After | |
| | Supply | Deficiency | Supply | Deficiency |
| 75% | 8.7645 | 20.3803 | 27.6875 | 1.4573 |
| 75% | 8.7645 | 20.3803 | 27.6875 | 1.4573 |
| 75% | 8.7645 | 20.3803 | 27.6875 | 1.4573 |
| 75% | 8.7645 | 20.3803 | 27.6875 | 1.4573 |
| 25% | 0.00 | 0.00 | 0.00 | 0.00 |

By simulating the scheme of joint and storage, it not only eases the shortage of water resources in Rushanhe Reservoir Basin, but also avoids the threat of a potential flood in dry years. It improves the utilization of water resources and promotes the sustainable development of regional water resources.

## Summary

According to the imbalance of supply and demand water in Rushan River Basin, the joint and storage of surface water and groundwater is simulated during the 25%, 50%, 75% and 90% hydrological years. The study proposes two modes as "two dry years and one normal year" and "four dry years and one wet year". The first one suggests to increase groundwater of $1.2775\times10^7m^3$ for domestic water and decrease $4.65\times10^6m^3$ for irrigation in 90%. In 75%, the agricultural water of $1.86315\times10^7m^3$ and the recharge of $1.85916\times10^7m^3$ are increased. And in 50%, the increasing recharge of $8.1638\times10^7m^3$ is obtained. The second mode shows the increasing agricultural water of $1.8923\times10^7m^3$ and the increasing recharge of $1.24465\times10^7m^3$ in 50%. And in 25%, the recharge of $7.2041\times10^6m^3$ is increased in flood season.

**Keywords:** Fuzzy Matter-element Method, Comprehensive Evaluation, Rain-flood Resources, Utilization Efficiency, Rushan River

**Abstract.** Using fuzzy mater-element method, the comprehensive utilization efficiency of rain-flood resources in Rushan River is assessed. The uncertainty of the comprehensive utilization efficiency is processed by the fuzzy principle. Then the representative indexes are selected, and the standard values of indexes are indicated. After normalization, the close degree and weight coefficient are calculated. On basis of that, the rating membership of the comprehensive utilization efficiency is for grade II, equal "good". So the paper concludes that the utilization of rain-flood resources in Rushan River Basin is feasible and effective. It provides follow-up support for the research of the utilization of rain-flood resources.

## Introduction

Comprehensive assessments for utilization efficiency of rain-flood resources include quantitative evaluation of economic and ecological effects and qualitative evaluation of social effects. It is a multiple attribute decision making process, including incompatible problems of single index evaluation results [1]. In addition, the demarcation of rain-flood resource utilization effects is fuzzy. Fuzzy element analysis method gives huge advantage in dealing with fuzzy incompatible information [2]. As a consequence, the vague principle is a logical and effective method to deal with this problem. In order to provide a new reference method for the evaluation of rain-flood resources, comprehensive utilization efficiency is assessed by using fuzzy element method based on entropy [3] in Rushan River.

## Basic situation of study area

Located in Jiaodong Peninsula, Rushan River Basin belongs to typical warm temperate maritime monsoon climate. The median annual rainfall is 747.7 mm. The interannual variation of rainfall is obvious, with minimum annual rainfall of 338.4 mm (1999), while the maximum is 1358.9 mm (1964). In addition, precipitation is distributed unevenly across per year. The rainfall in flood season accounted for 75.2% of the annual total, and most of it is concentrated in July and August[4]. Perfect storage projects for rainwater collection are available in the basin. Surface water storage space is sufficient as having one large reservoir, two medium reservoirs, 354 small reservoirs. There are 13 regulating dams with the ability of impound flood are distributed on Rushan River. Meanwhile, Rushan River Underground Reservoir is at the downstream of Rushan River, which a natural rich water zone.

## Fuzzy element evaluation of comprehensive utilization efficiency

It is a complex, multi-level comprehensive evaluation process to evaluate the comprehensive efficiency of rain flood resources utilization, because of not only numerous evaluation indexes, but also the fuzziness and uncertainty existing in effects and relative relationship. The effect evaluation standard, evaluation index and its characteristic values are considered as matter elements by using

matter-element analysis theory, and then the measured data and evaluation level are normalized to obtain the grade limit values (classical domain and joint domain), close degree and weight coefficient [5]. Fuzzy matter-element model is established for comprehensive efficient evaluation of rain-flood resources in Rushan River Basin.

$$R = \begin{bmatrix} M & C_1 & x_1 \\ & C_2 & x_2 \\ & \vdots & \vdots \\ & C_n & x_n \end{bmatrix}$$

**Normalization of evaluation index system.** Comprehensive evaluation indexes are selected to reflect the development and utilization status of rain-flood resources in the basin. There are seven comprehensive evaluation indexes, and $C_1$ is effective irrigated area (10000 acres); $C_2$ is vegetation coverage ratio (%); $C_3$ is recharge volume of groundwater (106 $m^3$); $C_4$ is water consumption per capita ($m^3$); $C_5$ is standard waterlogged area ratio (%); $C_6$ is flood utilization ratio in flood reason (%); $C_7$ is dirt to diameter ratio (%). Table 1 shows the true values of the seven indicators for comprehensive evaluation of rain-flood resources utilization. And five standard parameter values are given in Table 2. The five grade levels ranging from I to V list as excellent, good, fair, acceptable and poor, respectively.

Table 1 True values of comprehensive evaluation indexes

| Index | $C_1$ | $C_2$ | $C_3$ | $C_4$ | $C_5$ | $C_6$ | $C_7$ |
|---|---|---|---|---|---|---|---|
| Value | 30.5 | 45.4 | 30 | 26.54 | 75 | 28 | 8.3 |

Table 2 Standard parameter values of comprehensive evaluation indexes

| Grade | $C_1$ | $C_2$ | $C_3$ | $C_4$ | $C_5$ | $C_6$ | $C_7$ |
|---|---|---|---|---|---|---|---|
| I | 35 | 65 | 45 | 40 | 90 | 50 | 5 |
| II | 30 | 50 | 30 | 30 | 75 | 30 | 7 |
| III | 25 | 30 | 20 | 25 | 60 | 25 | 9 |
| IV | 20 | 20 | 15 | 20 | 50 | 15 | 12 |
| V | 10 | 10 | 5 | 10 | 30 | 10 | 15 |

Comprehensive effect index for the rain-flood resources utilization are normalized. For positive related indicators, such as the effective irrigated area, vegetation coverage ratio, etc., are normalized according to the equation (1). While the negative related indicator (dirt to diameter ratio, for instance) is standardized according to the equation (2). True valves and standard parameter values of comprehensive evaluation indexes after normalization are shown in Table 3 and 4, respectively.

$$d_i = 1 - (x_i - x_5)/x_i \quad d_i = 1 - (x_i - x_5)/x_i \tag{1}$$

$$d_i = x_i / x_5 \tag{2}$$

Table 3 True values after normalization

| Index | $C_1$ | $C_2$ | $C_3$ | $C_4$ | $C_5$ | $C_6$ | $C_7$ |
|---|---|---|---|---|---|---|---|
| Value | 0.328 | 0.220 | 0.167 | 0.377 | 0.400 | 0.357 | 0.553 |

Table 4 Standard parameter values after normalization

| Grade | $C_1$ | $C_2$ | $C_3$ | $C_4$ | $C_5$ | $C_6$ | $C_7$ |

**Fuzzy matter element model for comprehensive evaluation.** After normalization, we determined the class domain ($R_I$-$R_V$) and joint domain ($R_B$) of the standard fuzzy elements. And then, fuzzy matter element model M was obtained for comprehensive efficiency evaluations in Rushan River .

$$R_{\mathrm{I}}=\begin{bmatrix} B_{\mathrm{I}} & C_1 & (0,0.286) \\ & C_2 & (0,0.154) \\ & C_3 & (0,0.111) \\ & C_4 & (0,0.250) \\ & C_5 & (0,0.333) \\ & C_6 & (0,0.200) \\ & C_7 & (0,0.333) \end{bmatrix} \quad R_{\mathrm{II}}=\begin{bmatrix} B_{\mathrm{II}} & C_1 & (0.286,0.333) \\ & C_2 & (0.154,0.200) \\ & C_3 & (0.111,0.167) \\ & C_4 & (0.250,0.333) \\ & C_5 & (0.333,0.400) \\ & C_6 & (0.200,0.333) \\ & C_7 & (0.333,0.467) \end{bmatrix} \quad R_{\mathrm{III}}=\begin{bmatrix} B_{\mathrm{III}} & C_1 & (0.333,0.400) \\ & C_2 & (0.200,0.333) \\ & C_3 & (0.167,0.250) \\ & C_4 & (0.333,0.400) \\ & C_5 & (0.400,0.500) \\ & C_6 & (0.333,0.400) \\ & C_7 & (0.467,0.600) \end{bmatrix}$$

$$R_{\mathrm{IV}}=\begin{bmatrix} B_{\mathrm{IV}} & C_1 & (0.400,0.500) \\ & C_2 & (0.333,0.500) \\ & C_3 & (0.250,0.333) \\ & C_4 & (0.400,0.500) \\ & C_5 & (0.500,0.600) \\ & C_6 & (0.400,0.667) \\ & C_7 & (0.600,0.800) \end{bmatrix} \quad R_{\mathrm{V}}=\begin{bmatrix} B_{\mathrm{V}} & C_1 & (0.500,1.000) \\ & C_2 & (0.500,1.000) \\ & C_3 & (0.333,1.000) \\ & C_4 & (0.500,1.000) \\ & C_5 & (0.600,1.000) \\ & C_6 & (0.667,1.000) \\ & C_7 & (0.800,1.000) \end{bmatrix} \quad R_{\mathrm{B}}=\begin{bmatrix} B & C_1 & (0,1.000) \\ & C_2 & (0,1.000) \\ & C_3 & (0,1.000) \\ & C_4 & (0,1.000) \\ & C_5 & (0,1.000) \\ & C_6 & (0,1.000) \\ & C_7 & (0,1.000) \end{bmatrix} \quad R_{\mathrm{M}}=\begin{bmatrix} M & C_1 & 0.328 \\ & C_2 & 0.220 \\ & C_3 & 0.167 \\ & C_4 & 0.377 \\ & C_5 & 0.400 \\ & C_6 & 0.357 \\ & C_7 & 0.553 \end{bmatrix}$$

**Weight coefficient and close degree.** Correlation function values of individual eigenvalue are calculated according to the following equations:

$$\omega\ (x_i, X_{ij}) = \left| x_i - \frac{1}{2}(a_{ij}+b_{ij}) \right| - \frac{1}{2}(b_{ij}-a_{ij}) \qquad i=1,2,...n \tag{3}$$

$$\omega\ (x_i, X_{iB}) = \left| x_i - \frac{1}{2}(a_{iB}+b_{iB}) \right| - \frac{1}{2}(b_{iB}-a_{iB}) \qquad i=1,2,...n \tag{4}$$

$$K_j(x_i) = \frac{\omega\ (x_i, X_{ij})}{\omega\ (x_i, X_{iB}) - \omega\ (x_i, X_{ij})} \tag{5}$$

Where, $\omega$ is the distance between eigenvalue and standard values; K(x) is the correlation function values of the individual eigenvalue.

The weight coefficients of eigenvalues were determined, and membership degree was calculated. Calculate the membership degree before close degree. The greater close degree, the closer distance from evaluated sample to standard level. Therefore, categories can be divided based on close degree. When $K_j = \max K_j$ (M), then assess thing M belongs to grade j. The equations to calculate weight coefficient and membership degree are following.

$$\alpha_{ij} = b_{ij} / \sum_{i=1}^{n} b_{ij} \quad i=1,2,...n \quad j=1,2,...,m \tag{6}$$

$$K_j(M) = \sum_{i=1}^{n} \alpha_{ij} K_j(x_i) \tag{7}$$

Where, $\alpha_{ij}$ is weight coefficient; K(M) is membership degree.

Table 5 Close degree

| $K_{ij}$ | $K_{i1}$ | $K_{i2}$ | $K_{i3}$ | $K_{i4}$ | $K_{i5}$ | $K_{i6}$ | $K_{i7}$ |
|---|---|---|---|---|---|---|---|
| $K_{1j}$ | 0.148 | 0.432 | 0.500 | 0.507 | 0.200 | 0.786 | 0.971 |
| $K_{2j}$ | 1.105 | -4.704 | 0.000 | 0.486 | 1.000 | 6.500 | 1.233 |
| $K_{3j}$ | 0.017 | -0.084 | 0.000 | -0.058 | 0.000 | -0.062 | -0.095 |
| $K_{4j}$ | 0.282 | 1.055 | 1.000 | 0.066 | 0.333 | 0.136 | 0.117 |
| $K_{5j}$ | -0.016 | 0.101 | 0.000 | 0.130 | 0.000 | 0.071 | 0.241 |

Calculate close degree and weight coefficient by using equations (3) - (7), and the results are presented in Table 5 and Table 6, respectively

Table 6 Weight coefficient

| $\alpha_{ij}$ | $\alpha_{i1}$ | $\alpha_{i2}$ | $\alpha_{i3}$ | $\alpha_{i4}$ | $\alpha_{i5}$ | $\alpha_{i6}$ | $\alpha_{i7}$ |
|---|---|---|---|---|---|---|---|
| $\alpha_{1j}$ | 0.171 | 0.092 | 0.067 | 0.150 | 0.200 | 0.120 | 0.200 |
| $\alpha_{2j}$ | 0.149 | 0.090 | 0.075 | 0.149 | 0.179 | 0.149 | 0.209 |
| $\alpha_{3j}$ | 0.139 | 0.116 | 0.087 | 0.139 | 0.173 | 0.139 | 0.208 |
| $\alpha_{4j}$ | 0.128 | 0.128 | 0.085 | 0.128 | 0.154 | 0.171 | 0.205 |
| $\alpha_{5j}$ | 0.143 | 0.143 | 0.143 | 0.143 | 0.143 | 0.143 | 0.143 |

**Results and comparison**

Comprehensive correlation values of each element about different grades I-V can be calculated according to Tables 5 and 6 and the equations (1) - (2).

$K_{\mathrm{I}}(M)=0.5028$; $K_{\mathrm{II}}(M)=0.803$; $K_{\mathrm{III}}(M)=-0.044$; $K_{\mathrm{IV}}(M)=0.3638$; $K_{\mathrm{V}}(M)=0.087$

It can be seen that $K(M)=\max K_{\mathrm{j}}(M)=K_{\mathrm{II}}(M)$ from the above results, so the evaluation result is grade II, meaning good.

**Conclusions**

A comprehensive evaluation for utilization efficiency of rain-flood resources was conducted by using the fuzzy matter-element evaluation method in Rushan River. It considered economic, social, ecological factors fully, which could avoid one sidedness of evaluation causing by the single factor. Evaluation results provide a reliable basis for the development of Rushan River Basin. The comprehensive evaluation grade for utilization efficiency of rain-flood resources is grade II, which meaning good. It indicated that under the precondition of continuing original social, economic and ecological state, the comprehensive effects tend to be good after utilization program of rain-flood resource implemented. As a consequence, the coordinated development degree of the basin should have been further improved.

**Keywords:** Huangmaohai bay, Tidal current, Sediment, Mathematical model.

**Abstract.** Yamen channel is the important sea-route from Yinzhou Lake to Gaolan harbor in Zhuhai city through Huangmaohai Sea. Based on the recent hydrologic data and the seabed change, the numerical model is validated, and some advanced dredging plan for Yamen channel is simulated in the movement of tidal current and sediment, and the number of the sediment silting in channel is calculated. The result shows that there are some preponderance for the east channel in the tidal current and sediment, and the sediment is filling up in the mouth bars mostly. Moreover, the east channel has the potential to improve the channel standard, which can be developed firstly in the common condition.

## Introduction

Yamen channel is an important sea-route through Huangmaohai Sea, which total distance is about 38.0km from the Yamen entrance to the Hebao Island and Gaolan Island. Yamen entrance is upward to Hutiaomen Channel, downward to Huangmaohai Sea. Hutiaomen Channel is straight to the stream Xijiang. Now, the ship with 5000-ton can pass Yamen channle by regulated. The length of Yinzhou Lake inside Yamen entrance is about 30.0km, with the width of 1.5km to 2.0km, and the depth is between 8.0m to 15.0m. The berths with 10,000 tons can be build on both sides of Yunzhou Lake. Gaolan Port in Zhuhai city under construction on the east side of Huangmaohai Sea will compose harbor group with other ports within Yinzhou Lake(Chen Huizhen, 2000). It can be seen that there is great practical significance to construct the Yamen navigable channel and enhance its shipping ability.

Chinese scholars have done a lot of exploration and research in the selection of the east route and the west route as to advance the Yamen channel navigable standards since the first groove excavation was tested in the ford of Huangmaohai Sea in April 1994. Wu-Jiang Lu (1995) has concluded the deposition rate in the mouth bar is small and it's location is moving to the sea gradually, using fixed-bed thick water-sediment model test to calculate and analyse the mouth bar on the eastern route of Yamen Channel. According to the measured data and numerical results, Rui-Jie Li(2005) confirmed the main parameters in chamfer siltation formula, and estimated siltation intensity and volume of different channel dredging options, and thought the whole channel siltation was not serious, and the channel and the sea was in the balance of micro-silt basically status. By estimating siltation in intensity and volume at the extreme hydrological conditions of different options about Yamen channel, Jian Ding (2005) thought there was a greater siltation in Yamen channel and the water area during the typhoon, tide, large flood at the same time, and siltation under the flight path of the west Channel at the role of big storms is much larger than that of the east channel. Huanmaohai Sea was suspended sediment transporting, and the silting deposition of Yamen channel after excavation was also caused by the suspended sediment mainly. However, the hydrological data used in prophase studies are measured in 1992, and the data of landform scour-and-silt was surveyed in 1990. Now the

excavation works of Yamen channel available for the 5000-ton ship is completed in November 2006. So it is necessary to adopt the recent hydrological observation, landform scour-and-silt data to analyze and evaluate the Yamen Channel.

## Channel Scour and Silt

Three topographic surveys under water in channel have been carried out in the June, August and October of 2007 since Yamen channel was completed in November 2006. According to above 4th sea-route surveyed data of Yamen channel, the scour-and-silt intensity of channel is calculated and its temporal and spatial distribution is analyzed, combined with the water and sediment environment in Huanmaohai Sea. The results show that Huanmaohai Sea is belonged to a typical tidal estuary, and the Yamen channel with 5000-ton has the character "South High, North low and the central prominent". And the seasonal changes is present that it's silting in flood season and scouring in dry season. Annual siltation was about 1.8 million m3 in the main excavation part of Yamen channel, and the number of main groove siltation was 1,650,000 $m^3$(more than 90%). There is scoured sometimes or silted sometimes on the east and west slope with the seasons, and its deposition is rarely, so the total deposition of both slope is only hundreds of thousands m3. The main siltation is located in the mouth bar, and the number of siltation in the channel is about 920,000 m3, of which 710,000 m3 in groove channel, and east and west slope respectively 90,000 and 120,000 m3. The impact of slope stability of the sea route on the groove should merit our attention. The character of siltation in Yamen channel can be summarized as that siltation intensity is high in southern and low in northern, and the mouth bar much higher, and the siltation is significant in floods seasons and weak in dry seasons, the slope scouring or silting sometimes, impacting the adjustment of groove. Four group topographic surveyed data of groove channel above can provide strong support for the validation of numerical model in this paper.

## Dredging Project

Through several analysis of channel topographic survey data after Yamen channel dredging completed, the mouth bar of east channel (KP9-KP17) is still the main siltation segment, and the average siltation intensity is about 1.0 meters annually. 5000-ton ship can pass normally through the maintenance dredging. The west channel keeping the natural water depth can meet 3000-ton ships to run. To enhance the navigation capacity of the Yamen channel, the designed department puts forward the west channel upgraded to 5000 tons (7.7m water deep) and the east channel to 30,000 tons (-11.5m) of the two designed options. By using the tidal current and sediment mathematical model, the tidal current and sediment movement are simulated and the channel sediment siltation is calculated, and some conclusion would be avaluable for the designing the Yamen channel’s shipping standard.

## Tidal Current and Sediment Movement

From the Huanmaohai Sea falling current pattern in Fig.1, the tide current inside bay is mostly reversing current restricted by the shore boundary. The current in Huanmaohai Sea is divided into east, central and west three-ply by Dajin island, Hebao island, Damang island and other islands. The middle entrance (from Dajin island to Hebao island) is the main water way for the tidal current in Huanmaohai Sea. As the water depth in east entrance larger, the tidal current flow is larger than that in the western. The falling tidal current is divided into three part through three entrances inside the bay, and the three-ply current is gathered together and upward to the top of bay. There is near 10 degree angle between the direction of west channel and falling tidal current, and the direction of east channel is basically consistent with tidal current. Compressed by Damang island and Sanjiaoshan island near KP8, the velocity of flood tide and ebb tide is bigger than other channel segments. The channel dredging will be not produced significantly impact on Huangmao bay at the hydrodynamic

environment, and the current flow is adjusted along groove only in the water near channel, the depth of excavation larger, the phenomenon more significant.

The distribution of sediment concentration is showed in fig.2, which is simulated under the ebb tide in Huanmaohai Sea. The distribution of sediment concentration is present that large inside bay and small outside, large in deep groove and small in side shoal, big during ebb tide and small during flood tide. The maximum sediment concentration is in the deep waters of the central bay during ebb-tide, for the bed load on bay waist arising due to tidal current. The sediment concentration along the west channel is more than 0.40kg/m$^3$, and the sediment concentration along the east channel is smaller relatively, however the sediment concentration is still around 0.30kg/m3 in the mouth bar. So it can be seen that water and sediment environment near the east channel is more superior than that of west channel.

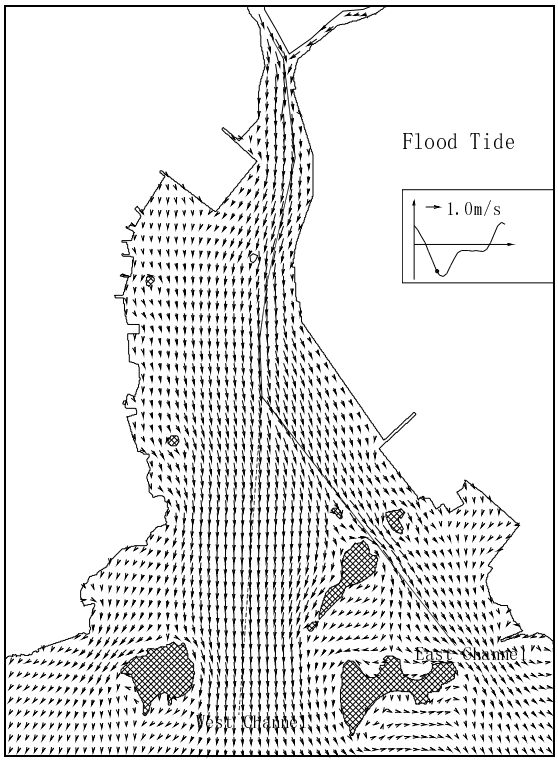

Fig.1 Falling Current Pattern

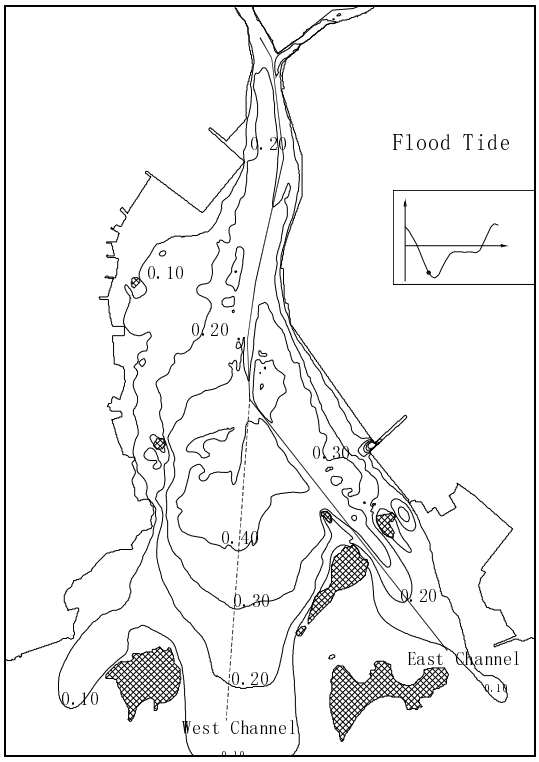

Fig.2 Sediment Distribution in Falling Current

**Siltation along Channel**

The siltation in groove along the west channel of 5,000 ton and the east channel of 30,000 ton are calculated by the model combined with validated parameters, and the distribution of the silting intensity along the west channel and east channel are seen Fig.3 and Fig.4 respectively. The siltation along the west channel is relatively mild, and the average siltation intensity is 0.38m annual. When the water depth of the west channel dredging to 7.7m (fitted to 5,000 tons), the siltation intensity is increased widely, expressed the increase gradually from south to north, but the southern section of the channel is near that of natural status, and the siltation intensity in northern section is the largest, which largest siltation thickness is 1.76m annual. The average siltation intensity is 1.13m annual after the west channel dredging completed, added 0.75m annual than before. Siltation along the east channel is showed saddle-shaped distribution which is highest on the north section, slightly higher on the southern section and slightly lower in middle. Constrainted by terrain, the flow cross-section of channel near KP8 is narrowed down and velocity is increased, and the siltation near this groove is smallest. When the depth of east channel dredged to 11.5m, the siltation intensity along channel is increased in general, and the increase of siltation intensity is small in southern section (KP0-KP8) and slightly larger in northern section, so it is present increasing 0.33m annual than before as a whole. It can be seen that the sediment accretion amount of east channel is less than that of west channel, and the east channel has further potential to improve the shipping standard under the same circumstance.

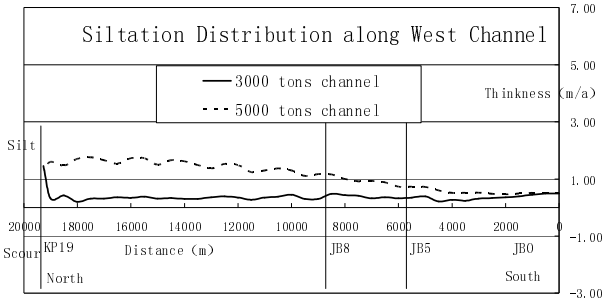

Fig.3 Siltation Distribution along West Channel

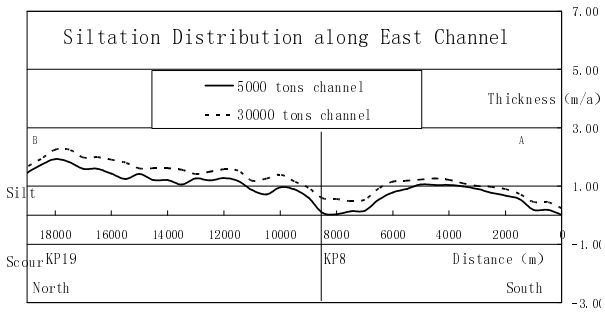

Fig.4 Siltation Distribution along Eest Channel

## Conclusion

The hydrological data in 2006 and change of terrain in the east channel are adopted as validation information in this model. Through simulating and calculating the project of the west channel with 5,000 tons and the east channel with 30,000 tons, the results show that there is an angle changes between the direction of the west channel and the flow direction of tidal current, and the siltation in groove is serious high where the sediment concentration is higher, which is consistent with the results of previous studies. The environment of water and sediment are relatively better in the east channel, and the sediment siltation is mainly located on the mouth bar. The siltation along channel does not increase much under 30,000 tons standard through maintenance dredging normally. Therefore, the east channel has further potential to enhance the shipping standards, and it can be preferential chose to develop under the same conditions.

**Key words:** Seawall; Monitoring; Layered settlement; Vane shear strength; Settlement prediction

**Abstract:** The foundation of Wenzhou shoal project is soft and deep. The stability control issue of building seawalls on the deep soft foundation was solved by using a composite foundation treatment of plastic drainage plates and geotextile, combining with the in-situ monitoring. The in-situ monitoring data of Wenzhou shoal project was analyzed and the settlement prediction analysis was conducted. Basing on the conventional exponential curve fitting method, the settlement prediction model is presented for the classified construction on soft foundation. Considering the non-linear of deformation and soil consolidation with load changes, the model used the settlement deformation characteristics under the last load to predict the settlement development under the next load.

## Introduction

Wenzhou shoal located outside the Oujiang Estuary, between Lingkun island (belong to Ouhai district of Wenzhou City) and Niyu island (belong to Dongtou county of Wenzhou City), was a development relatively complete and largest tidal resources within the Oujiang estuary area. Wenzhou shoal Lingni seawall full length 14.5 kilometers was currently the longest sea-crossing dike in China. Dike elevation was 5.8m~6.3m, by 50 years tide control standard design, crest road width 10.5m with double lane. The original foundation ground elevation was -3.0m~-1.0m. The surface soil was composed of newly sedimentary mud flow or mud, with thickness of 0.5m~1.0m. The foundation soils within 40 m depth were composed of high water content, high compressibility, high dexterousity, low strength muck and mucky soils [1,2]. The physical and mechanical indexes of soil foundation were shown in Table 1. The soft foundation was treated with Prefabricated Vertical Drain (PVD) + geotextile + overburden layer, where spacing and depth of the PVD were 1.4m ~1.5m and 20m ~22m respectively. The typical cross-section schematic was shown in Fig. 1.

In order to ensure the smooth progress of seawall construction, to grasp the foundation consolidation and intensity changes, must carry on the comprehensive safety monitoring in the seawall during filling, to ensure security and stability of the seawall. In this paper, the ground surface settlement, pore water pressure, horizontal displacement and layered settlement of Wenzhou shoal Lingni seawall during construction were systematically analyzed. Basing on the measured settlement data analysis, the empirical formula was presented for the calculation settlement during construction.

## In-situ monitoring program

In order to ensure the stability of seawall foundation in filling process, to master deformation law of foundation soil in preloading period, as well as the choice of the reasonable construction schedule, in-situ monitoring instruments were buried in Lingni seawall during construction, to monitor ground settlement, layered settlement, horizontal displacement, vane-shear strength and pore water pressure. In-situ monitoring instrument layout schematic diagram of Section K11+050 was shown in Fig. 2.

## Analysis of in-situ monitoring results

### 3.1 Ground surface settlement

As applying the first level load, the sedimentation rates were initial generally greater than the 30mm/d, even more than 100mm/d, but they decayed very quickly. On the third day the sedimentation rates usually less than 30mm/d, after 5 days ~10 days less than 10mm/d, after 3 months the sedimentation rate gradually reduced to 1mm/d ~2mm/d, and has kept near the rate. When applying the first level to the fifth level loads, immediate settlement is obvious, especially the first level load. The sedimentation rate was significantly associated with the load (or filling thickness). To apply over-load not only made sedimentation rate abnormally increase and the attenuation of sedimentation rate was relatively slow. Before applied the second level load，the settlement rate of D9-1 measuring point (which located on the axis of Section K10 + 850) was 3 mm/d. When apply the second level load(i.e. filling thickness 2.52m which was greater than the design filling thickness 2.0 m), although the seawall foundation did not appear instability phenomenon, but the maximum sedimentation rate is as high as 87 mm/d, after nearly 12 days the sedimentation rate was down to 10 mm/d. Therefore, the construction technology which applied multi-stage loading and reduced each level load could significantly reduce the immediate settlement. According to statistics, the immediate settlement accounted for 25%~30% of the total settlement during the construction.

Further studies showed that over-loading could result in a range of foundation where shear stress of soil reached the critical value and elastic deformation developed into plastic deformation, even may occur the whole damage of foundation [3,4,5]. Even if the foundation did not appear obvious instability phenomenon, excessive shear deformation could cause destruction of the foundation soil structure, which would be very unfavorable for post-construction settlement control.

### 3.2 Layered settlement

The soft soil foundation of this project was composed of soft clay layers with different properties. This project applied layered settlement monitoring to find out the compression of each soil layer, to determine consolidation degree of different depths. Fig. 3 shows the observation results of layered settlement located on the axis of Section K11 + 050.

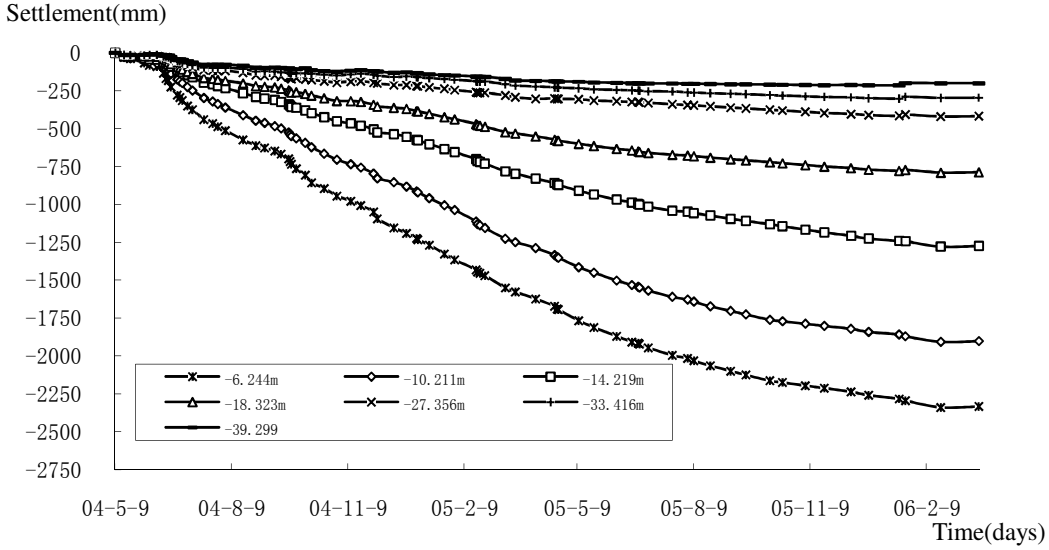

**Fig. 3.** The curves of layered settlement on the axis of Section K11 + 050

The observation results showed that when the project completed, the settlement occurred mainly in the board area, and accounted for approximately 72% of the settlement amount. It indicated that the role of the drainage board to accelerate consolidation settlement is significant. The settlement of underlying deep soft soil layers accounted for about 20% of the total settlement. The underlying deep soft soil layers mainly experienced vertical drainage and its consolidation time was long,

which would cause the sustainable development of large post-construction settlement [3]. Design should take measures to make the most settlement of foundation complete in construction period, effectively reduce the post-construction settlement and a series of problems which post-construction settlement could bring to the subsequent structure engineering.

### 3.3 Horizontal displacement

Fig. 4 shows variations of horizontal displacement with depth at south side of repression layer of Section k11 + 050. The observation results showed that in the initial stage of loading, the horizontal displacement of foundation soil mainly occurred in the board area; the largest displacement was located at -10 m elevation. With the increase of load, especially after applied the third and the fourth level loads, the horizontal displacement developed toward the deep.

After filling repression layer up to its design elevation, only filling soil in the center of seawall, the increasing trend of horizontal displacement decreased. It indicated that repression layer played a good back pressure effect.

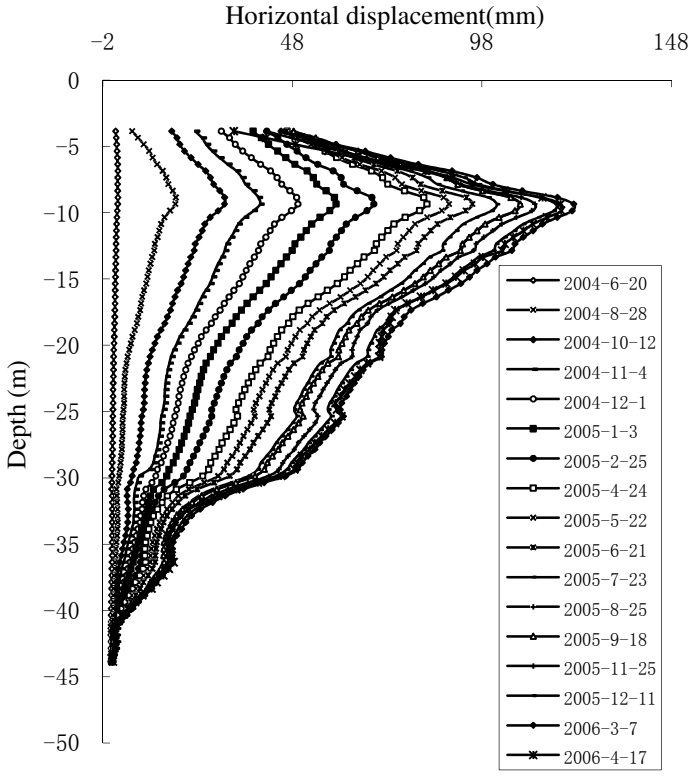

**Fig. 4.** Variations of horizontal displacement with depth at south side of repression layer of Section K11 + 050

### 3.4 Pore water pressure

Fig. 5 shows variations of excess pore-water pressure with time on the axis of Section K11 + 050. The observation results showed that excess pore-water pressure dissipated significantly in the board area. It indicated that the role of the drainage board to accelerate the consolidation of seawall foundation was very significant. When the project completed, the average degree of consolidation of foundation was more than 80%, and the pore pressure in underlying deep layers slowly dissipated. During loading, the pore-water pressure coefficient B is generally 0.3 ~ 0.5 (below -12.5 m elevation), which was in the normal range. The B value is the excess pore-pressure divided by the total load. The pore-pressure monitoring data showed that the pore-pressure increased in the underlying deep layers of foundation during load interval. It was due to viscous effect of soil skeleton, the upper thick layer of clay delayed the dissipation of pore-water pressure in deep layers. Due to the stress relaxation effects of the soil skeleton, the increase of pore-pressure which the deep

layers produced in unit time exceeded its dissipation, so resulting in the pore-water pressure increase [6,7].

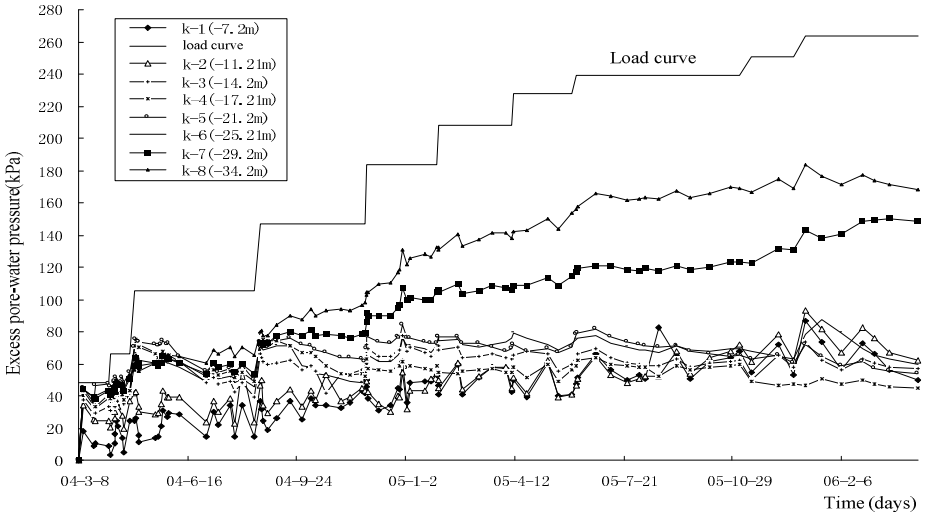

**Fig. 5.** Variations of excess pore-water pressure with time on the axis of Section K11 + 050

### 3.5 Vane shear strength

In order to evaluate the effect of foundation treatment, two groups of vane strength tests were carried out at Section K11 + 050, in which a group in early stage of loading, another group in later stage of loading. Contrast of two groups of vane strength test results was shown in Table 2.

The test results showed that the soil strength in the board area of dike foundation and repression layer has significantly increased, where the soil strength of dike foundation grew more pronounced. In drainage plate processing area, the soil strength increase of muck and sand interbedded layer (Ⅲ 1) was most pronounced. Comparing with the drainage plate processing zone, the strength of the underlying soil layers increased but not significantly. It indicated that the role of the drainage board to accelerate consolidation of seawall foundation was very significant.

**Table 2** Contrast of two groups of vane strength test results

| Layer Code | Soil layer | Depth range (m) | Vane strength increase of repression layer (kPa) | Vane strength increase of dike foundation (kPa) |
|---|---|---|---|---|
| $Ⅲ_1$ | muck and silt interbedded | 0～6 | 27～32 | 36～40 |
| $Ⅲ_2$ | muck | 6～21 | 8～26 | 10～30 |
| $Ⅲ_3$ | muck | 21～30 | 3～5 | 3～6 |

### Settlement prediction

Due to lack of detailed geotechnical parameters of foundation soils, it was difficult to accurately calculate the reserved settlement of seawall. At present, the settlement curve fitting which basing on the field measured settlement was an accepted more reasonable settlement prediction method. Basing on the traditional exponential curve fitting method, a new model of settlement prediction was presented for the classified construction on soft foundation. Considering the non-linear nature of deformation and the soil consolidation nature with load changes and combining with the characteristics of grading construction, the model used the settlement deformation characteristics under the last load to predict the settlement development under the next load.

Based on the hypothesis that settlement development was in line with the exponential curve, the settlement fitting equation under the No. i level load could be expressed as Eq. 1:

$$S_{ti} = S_{0i} + (S_{li} - S_{0i})[1 - \alpha_i e^{-\beta_i (t - t_{0i})}] \quad (1)$$

where: $t_{0i}$ is initial time of settlement curve fitting under the No. i level load; $S_{0i}$ is the settlement corresponding to time $t_{0i}$ under the No. i load; $S_{li}$ is final settlement under the No. i level load; $\alpha_i$, $\beta_i$ are undetermined parameters under the No. i level load.

If the No. i level loading period was longer, $S_{li}$, $\alpha_i$ and $\beta_i$ parameters of the above equation could be determined by the exponential curve fitting, basing on the measured settlement. By studying variation rule of $\alpha_i$ and $\beta_i$ under all level loads, the settlement under the No. i+1 level load could be predicted. Contrast of measured settlement and predicted settlement according to this method was shown in Fig. 6.

Further studies showed that the predicted settlement which considering soil consolidation nature with load changes, can better predict the settlement in construction period under various level loads and the post-construction settlement within a certain period of time.

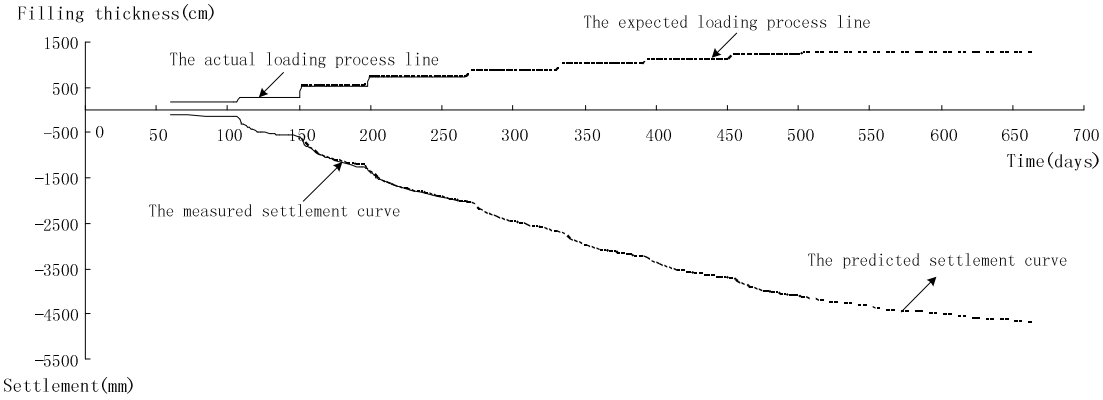

**Fig. 6.** Contrast of measured settlement and predicted settlement on the axis of Section K 8 + 850

## Conclusions

(1) During Wenzhou shoal seawall construction, by in-situ monitoring, engineer may at any time to master the foundation deformation and drainage consolidation, determine the loading time, loading rate control, dynamic guide the engineering construction.

(2) For stack and preloading drainage in deep soft soil foundation, the loading rate must be strictly control. Over-loading could result in a range of foundation where shear stress of soil reached the critical value and elastic deformation developed into plastic deformation, even may occur the whole damage of foundation. Even if the foundation did not appear obvious instability phenomenon, excessive shear deformation could cause destruction of the foundation soil structure, which would be very unfavorable for post-construction settlement control.

(3) Prefabricated vertical drain was suitable for the soft foundation treatment, which effectively shortened drainage distance of foundation soil, accelerated consolidation of foundation soil, increase strength of foundation, reduced the grated load interval, and speeded up the construction progress.

(4) The settlement of underlying deep soft soil layer accounted for 20% of the total settlement. The underlying deep soft soil layers mainly experienced vertical drainage and its consolidation time was long, which would cause the sustainable development of large post-construction settlement. Design should take measures to make the most settlement of foundation complete in construction period, effectively reduce the post-construction settlement and a series of problems which post-construction settlement could bring to the subsequent structure engineering.

**Keywords:** hydropower station, exposed penstock laid on ground, DL/T 5141-2001, ASCE No.79, allowable stress, load combination.

**Abstract.** In this paper, differences by using selected three typical specifications—DL/T 5141-2001 (Chinese), ASCE No.79 in the version of 1993(American) and ASCE No.79 in the version of 2012 (American)—in structural design of exposed steel penstock were explored. A practical example about exposed penstock laid on ground applied in hydropower station was also used to analyze specifications clearly. The result shows that the main differences between Chinese and American specifications are allowable stress and load combination. The former is direct factor of calculating exposed penstock shell thickness. Therefore, ASCE No.79 (2012) designs the minimum wall thickness, followed by DL/T 5141-2001 and the last is ASCE No.79 (1993), which is correspondingly contrary to sort by allowable stress. Basically, ASCE No.79 (2012) defines lower safety coefficient for exposed penstock, which is identical with authoritative rules of pressure vessels in the U.S.A and EU. The safety of DL/T 5141-2001 has been proved via rich engineering experience and this specification is recommended for Chinese projects. Besides, ASCE No.79 (2012) is recommended.

## Introduction

The specification for design of steel penstocks for hydroelectric stations (DL/T 5141-2001) was formulated and promulgated by China renewable energy engineering institute (CREEI) in May 2002. It plays significant role in design of Chinese steel penstocks. Besides, there are some other kinds of widely used specifications for steel penstocks or pressure vessels in the world, such as "Unfired pressure vessel" issued by European Committee for Standardization (EN 13445-2002), ASCE Manuals and Reports on Engineering Practice No.79"Steel Penstocks" promulgated by American Society of Civil Engineers (ASCE No.79), "ASME Boiler & Pressure Vessel Code" enacted by American Society of Mechanical Engineers (ASME BPVC). The design principles, methods and load combinations are different among each other. Xu et al. [1] raised the concept of equivalent safety coefficient based on yield strength and tensile strength respectively, which was used to evaluate safety level of several representative penstocks codes of hydropower stations and pressure vessels standards in China and other countries (e.g. U.S.A, Japan). It emphasized safety level of each specification but did not involve specific design method of one type of steel penstocks. The actual mechanical behavior of steel penstocks was not used to compare design results.

The exposed penstock laid on ground is supported by a series of buttresses. An anchor block at the turning is set up to fix penstock. There is an expansion joint between two anchor blocks to adapt to relative deformation [2]. This paper aims at analyzing exposed penstock laid on ground using DL/T 5141-2001 [3] and ASCE No.79 (the version of both 1993 and 2012) [4,5]. If unspecified type is after ASCE No.79 in this paper, something in common is discussed. In view of one practical project, depending on actual mechanical behavior, the design results also reflect the differences analyzed.

**Comparison on design methods between two standards**

**Design principles.** DL/T 5141-2001 adopts limit-state design method based on theory of probability, the design equation is characterized by partial factors. ASCE No.79 adopts allowable stress method. The basic principle of stress classification is introduced into both of them.

After all, stress of each calculation point should meet strength requirement. According to above two standards, the fourth strength theory is recommended as

$$\sigma=\sqrt{\sigma_\theta^{\,2}+\sigma_x^{\,2}+\sigma_r^{\,2}-\sigma_\theta\sigma_x-\sigma_\theta\sigma_r-\sigma_x\sigma_r+3(\tau_{\theta x}^{\,2}+\tau_{\theta r}^{\,2}+\tau_{xr}^{\,2})}\le[\sigma] \quad (1)$$

where $\sigma$ is the equivalent stress, also known as von Mises stress; $[\sigma]$ is allowable stress of steel; $\sigma_x$ is axial normal stress, $\sigma_\theta$ is circumferential normal stress, $\sigma_r$ is radial normal stress, all are positive as tensile stress, $\tau_{\theta x}$ , $\tau_{\theta r}$ and $\tau_{xr}$ are shear stress.

**Allowable stress.**The basic principle of stress classification is introduced into both. DL/T 5141-2001 differentiates stress into general primary membrane stress, local primary membrane stress and local primary membrane stress plus primary bending stress. ASCE No.79 differentiates stress into primary stress and secondary stress, where primary stress is divided into general primary membrane stress, local primary membrane stress and primary bending stress.

In DL/T 5141-2001, the allowable stress is calculated by

$$[\sigma]=\frac{1}{\gamma_0\varphi\gamma_d}f \quad (2)$$

where $\gamma_0$ is coefficient for importance of structure depending on security level, $\varphi$ is coefficient for design condition, $\gamma_d$ is structure coefficient depending on type of stress and working condition, $f$ is design value of steel strength.

In ASCE No.79, the allowable stress is defined as

$$[\sigma]=K\times S \quad (3)$$

where $K$ is coefficient for increasement of stress according to type of stress and working condition, $S$ is basic allowable stress intensity. ASCE No.79 in version of 1993 formulates that, the basic allowable stress intensity should be the lesser of one-third of the minimum specified tensile strength or two-thirds of the minimum specified yield strength. The version of 2012 formulates that the basic allowable stress intensity is the smaller of tensile strength/2.4 or yield strength/1.5. Table 1 gives allowable stress of two kinds of rolled steel.

**Table 1 Allowable stress in DL/T 5141-2001 and ASCE No.79 under normal condition[Mpa]**

| Type of steel | Standards | General primary membrane stress | Local primary membrane stress | local primary membrane stress +primary bending stress | local primary membrane stress +primary bending stress+secondary stress |
|---|---|---|---|---|---|
| Steel with high tensile strengt | DL/T 5141-2001 （16-50mm） | 231 | 285 | 337 | — |
| | ASCE No.79 (1993) | 203 | 305 | 305 | 610 |
| | ASCE No.79 (2012) | 254 | 381 | 381 | 610 |
| Q345R | DL/T 5141-2001 （≤36mm） | 181 | 223 | 264 | — |
| | ASCE No.79 (1993) | 157 | 235 | 235 | 470 |
| | ASCE No.79 (2012) | 196 | 294 | 294 | 470 |

**Service conditions and load combinations.** DL/T 5141-2001 differentiates service conditions into lasting condition, intermittent condition, occasional condition and contains six types of load

combinations. By contrast, there are normal condition, intermittent condition, emergency condition, exceptional condition, construction condition and hydro-test condition in ASCE No.79. Each service condition has its own load combination. Relatively speaking, load combinations in ASCE No.79 are more comprehensive. Considering length, normal condition (lasting condition) is the only one to be used in comparison on design of exposed penstock. It is governing factor as well.

As previously mentioned design principle of DL/T 5141-2001 that the design equation is characterized by partial factors, all loads including dead loads and live loads have corresponding partial factors. However, ASCE No.79 assign a value of 1.0 to all load factors. As for exposed penstock, partial factors of hydrostatic pressure are all equal to 1.0 in DL/T 5141-2001 and ASCE No.79.

Analytic equations for calculation of the equivalent stress of steel are simplified. The finite element method, by contrast, is more visual and accurate and easily accepted by engineers. Therefore, finite element software ANSYS is used to help designing a practical exposed penstock in above three specifications in this paper.

## Application

**FEM model.**An anchor block amounts to a fixed end and penstock between two anchor blocks is independent. Based on a practical project, a length of exposed penstock between two anchor blocks was designed using both DL/T 5141-2001 and ASCE No.79. The diameter is 2.5m with internal water pressure of 5.86 to 6.35Mpa (Hydrostatic pressure and water hammer pressure are all contained). Finite element model, shown as Fig.1, consists of steel penstock, expansion joint, supporting ring, sliding support, anchor block and rock foundation with 17 meters in width and 10 meters in depth. Steel penstock and supporting ring are modeled by shell element. Solid element is used to model concrete anchor block and rock foundation.Supporting ring is set above support at intervals of 8m, in which face to face contact elements are used to simulate sliding effect with friction coefficient 0.1, shown as Fig.2. Bellow expansion joint is modeled by truss element and equivalent stiffness is 5.8MN/m. Foundation is normally restrained at surrounding and bottom side. The thickness of penstock shell is confirmed in normal condition and load combinations based on DL/T 5141-2001 and ASCE No.79 are the same. Self-weight including steel, concrete and water, internal water pressure and temperature load are combined into the model. The preliminary wall thickness is calculated by

$$t = \frac{Pr}{[\sigma]} \qquad (4)$$

where t =penstock shell thickness required to resist the design pressure P (mm);

P=internal pressure (at centerline of pipe) (MPa);

r=inside penstock radius (mm);

$[\sigma]$=allowable stress of steel.

The penstock shell thickness applying allowable stress of steel with high tensile strength in DL/T 5141-2001 and ASCE No.79 (1993 and 2012) respectively are 36mm, 32mm and 40mm, which do not contain thickness that used to resist rusting, abrasion or errors in manufacturing (2mm in general).

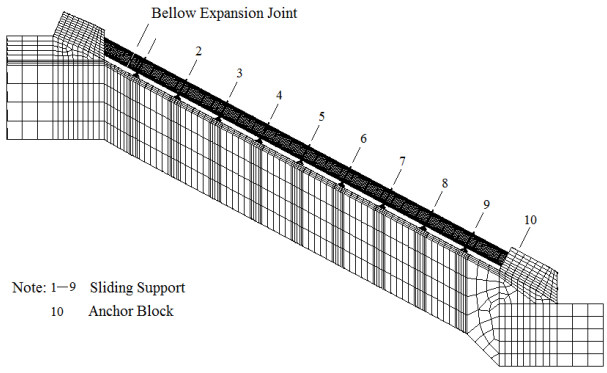

**Fig. 1 FEM model**

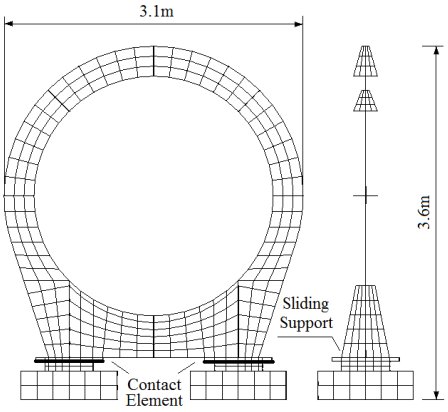

**Fig. 2 Supporting ring**

**Result.**The exposed steel penstock can be separated into three basic regions for mechanical behavior: (1) Shell outside stiffener or discontinuity ( Middle layer of shell is general primary membrane stress and surface layer is local primary membrane stress plus primary bending stress ); (2) Shell at stiffener or discontinuity ( Middle layer is local primary membrane stress and surface layer is local primary membrane stress plus secondary stress); (3) Stiffener itself is treated as general primary membrane stress at middle layer. These aforesaid regions are numbered as 1, 2 and 3 respectively. The chief design purpose is to meet requirement in Table 1 in whichever region.

Figure 3~4 reflect mechanical behavior of exposed steel penstock using DL/T 5141-2001. The equivalent stress of steel is mainly caused by hoop stress. Shell at stiffener has less stress because that hoop deformation is restricted by supporting ring. The local primary membrane stress, local primary membrane stress plus bending stress and local primary membrane plus secondary stress are all much less than allowable stress. Penstock shell thickness is controlled by general primary membrane stress, which belongs to region 1. 36mm (calculated thickness) is what given to penstock shell, also is the supporting ring. Generally speaking, it is a principle that supporting ring has about same thickness with adjacent penstock shell, which is out of welding. Figure 3 shows that general primary membrane stress across region 1 do not exceed 231 MPa, the exactly numerical value of allowable stress for steel with high tensile strength. When it comes to ASCE No.79, the above mentioned value changes but other method and mechanical behavior are uniform. That is to say, general primary membrane stress is still the key point for penstock shell thickness.

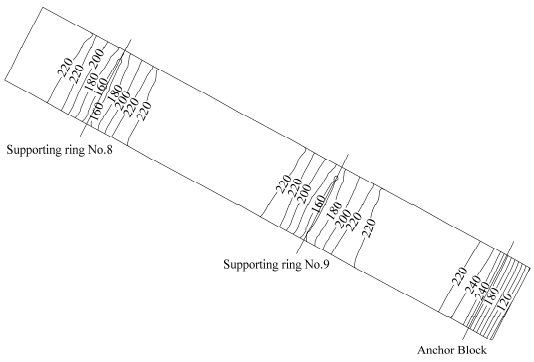

**Fig. 3 Contours of von Mises stress at middle layer of penstock**

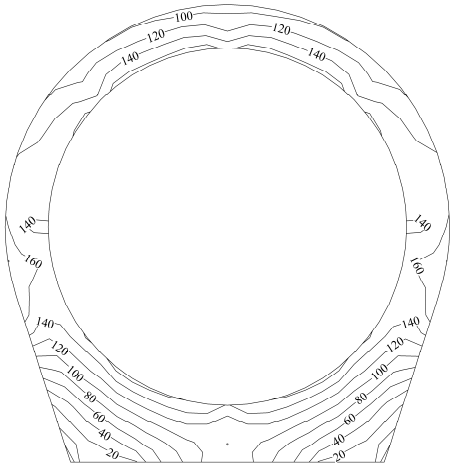

**Fig. 4 Contours of von Mises stress at middle layer of supporting ring**

## Disscusion

**Direct reason.**Generally, the diversion system of hydropower station includes several continuous segments of exposed penstock between two anchor blocks. Each should be designed separately with

previously introduced method. Internal water pressure gradually increases from upstream to downstream which are numbered consecutively 1~11, as shown in Table 2. For this project, the ultimately defined penstock shell thickness is shown in Table 2

The numerical value of allowable stress for steel used to welding into penstock shell, is direct factor to determine the wall thickness in whichever specification. ASCE No.79 (2012) defines the maximum allowable stress, followed by DL/T 5141-2001 and ASCE No.79 (1993). Sort by thickness of penstock shell proves to be correspondingly contrary.

**Table 2 Design Results**

| Pipe segment | DL/T 5141-2001 | | ASCE No.79 (1993) | | ASCE No.79 (2012) | |
|---|---|---|---|---|---|---|
| | Penstock shell thickness (mm) | Type of rolled steel | Penstock shell thickness (mm) | Type of rolled steel | Penstock shell thickness (mm) | Type of rolled steel |
| 1 | 14 | A | 16 | A | 14 | A |
| 2 | 20 | A | 22 | A | 20 | A |
| 3 | 24 | A | 26 | A | 22 | A |
| 4 | 28 | A | 30 | A | 26 | A |
| 5 | 22 | B | 26 | B | 20 | B |
| 6 | 26 | B | 30 | B | 24 | B |
| 7 | 30 | B | 34 | B | 28 | B |
| 8 | 34 | B | 36 | B | 30 | B |
| 9 | 36 | B | 40 | B | 34 | B |
| 10 | 38 | B | 42 | B | 34 | B |
| 11 | 40 | B | 46 | B | 38 | B |

Note: For rolled steel, 'A' represents Q345R; 'B' represents steel with high tensile strength up to 600MPa.

**Fundamental reason.** By using DL/T 5141-2001, the conventionally so-called safety coefficient of allowable stress is resolved into several partial factors like Eq. 2. While ASCE No.79 sets it directly shown as Eq. 6. For comparative purpose, this study adopts the concept of equivalent safety coefficient from reference [1]. It is a coefficient synthesizing partial factors for loads and material properties. For exposed penstock, only considering hydrostatic pressure and water hammer pressure, it is defined as

$$K = \frac{\gamma_0 \varphi \gamma_d \gamma_s (\gamma_{Q1} + \gamma_{Q2} \rho_h)}{1 + \rho_h} \tag{5}$$

$$[\sigma] = \frac{f}{K} \tag{6}$$

where $\gamma_0$, $\varphi$, $[\sigma]$ and $\gamma_d$ are same meaning as that in Eq. 2; $\gamma_{Q1}$ is partial factor of hydrostatic pressure and $\gamma_{Q2}$ is partial factor of water hammer factor; $\gamma_s$ is partial factor of steel yield strength or tensile strength; $\rho_h$ is ratio of water hammer pressure to hydrostatic pressure; $f$ is yield strength or tensile strength of steel. Values of factors above are shown in Table 3. The safety coefficients or equivalent safety coefficients, both are called safety coefficient for short, of above-mentioned three specifications are listed in Table 4, where $K_y$ is safety coefficient of yield strength and $K_t$ is that of tensile strength. Besides, some American and European authoritative rules for construction of pressure vessels such as EN 13445-2002, "ASME Boiler & Pressure Vessel Code, Section 8 Division 2, Alternative Rules, Rules for Construction of Pressure Vessels" (ASME BPVC-VIII-2) with two versions of 2004 and 2007 are also contained to contrast and learn.

Frequently-used steel types for penstock in hydropower station are listed in Table 1. As to other types used, both yield strength and tensile strength changes a little. Ratios of the former to the latter all

exceed 0.67 for two types, so $K_t$ is used to determine allowable stress in ASCE No.79. Apparently, these three specifications compared mainly in this paper have different safety coefficients. ASCE No.79 (2012) defines the minimum safety coefficient, followed by DL/T 5141-2001and ASCE No.79 (1993), same sort as design thickness and adverse sort with allowable stress. That is, ASCE No.79 (2012) has relatively lower safety level for exposed penstock. Renewed specifications have all boosted allowable stress based on tensile strength of steel with yield ratio more than 0.625. Some authoritative rules of pressure vessels in the U.S.A or European Union (EU) evaluate alike level in their latest version. The progress of rolled steel and welding technology contribute a great share in the revolution. Considering acceptability of engineers participating in whichever work of design, supervision, construction or investment, ASCE No.79 (2012) is recommended. Attentively, China has implimented DL/T 5141-2001 and rich engineering experience (e.g. sky lake and south motain hydropower station using exposed penstock) proves it safe. So DL/T 5141-2001 is still appropriate for Chinese projects.

**Table 3 Common values of partial factors in DL/T 5141-2001 (Exposed penstock, Q345R)**

| $\gamma_0$ | $\varphi$ | $\gamma_d$ | $\gamma_{Q1}$ | $\gamma_{Q2}$ | $\gamma_s$ | $\rho_h$ |
|---|---|---|---|---|---|---|
| 1.1(Class I), 1.0(Class II) | 1.0(Lasting condition), 0.90(intermittent condition), 0.85(occasional condition) | 1.6 | 1.0 | 1.1 | 1.08(yield strength) 1.63(tensile strength) | 0.1~0.4 |

**Table 4 Values of K according to several specification (Exposed penstock, Q345R)**

| Country or region | Type of specification | Name or code | $K_y$ | $K_t$ |
|---|---|---|---|---|
| CHINA | Steel penstock | DL/T 5141-2001 | 2.0 | 2.9 |
| U.S.A | Steel penstock | ASCE No.79 (1993) | 1.5 | 3.0 |
| U.S.A | Steel penstock | ASCE No.79 (2012) | 1.5 | 2.4 |
| U.S.A | Pressure vessel | ASME BPVC- VIII -2 -2004[6] | 1.5 | 3.0 |
| U.S.A | Pressure vessel | ASME BPVC- VIII -2-2007[7] | 1.5 | 2.4 |
| EU | Pressure vessel | EN 13445-2002[8] | 1.5 | 2.4 |

Note: Values for DL/T 5141-2001 are suitable for steel penstock of class I in lasting condition and $\rho_h$ values 0.3.

## Conclusions

From comparison of designing exposed penstock using DL/T 5141-2001(Chinese) and ASCE No.79(American), it comes to several conclusions as follows.

(1) Differences of rules: DL/T 5141-2001 adopts limit-state design method based on theory of probability, the design equation is characterized by partial factors. ASCE No.79 adopts allowable stress method. The basic principle of stress classification is introduced into both of them. Calculation of allowable stress is main difference. ASCE No.79 (2012) defines the maximum allowable stress, followed by DL/T 5141-2001 and the last is ASCE No.79 (1993).

(2) Differences of design results: For general, exposed penstock shell thickness is confirmed by general primary membrane stress. Allowable stress is direct factor when calculating wall thickness. Consequently, Sort by wall thickness leads to just inverse order compared with that by allowable stress.

(3) Differences of safety level: The basic reason for differences of design results is safety level of each specification. Though ASCE No.79 (2012) has relatively lower level among the three, it is same as renewed version of rules for pressure vessels in the U.S.A and EU which are authoritative. It is related to higher quality of rolled steel and welding. So, ASCE No.79 (2012) is recommended for international projects because it may be convenient to pass though examination and save investment. Attentively, DL/T 5141-2001 is safe according to accumulated engineering experience and it is suitable for Chinese projects for same reason.

**Keywords:** small hydropower; substitutive fuel; ecology; construction; development

**Abstract.** The project of substituting small hydropower for fuel (SHPF project in short) in China has been implemented for ten years and has achieved significant economic, social and ecological benefits. The construction, completion situations, results and major experience of the SHPF project are summarized. The existing problems are analyzed. Some suggestions are given for the construction and management of similar projects in future.

## Basic situations

### (1) Planning of SHPF Project

The rural residents in China have used firewood and straws as their domestic fuel for a long time. The excessive deforestation has caused vegetation deterioration in some regions, leading to ecological deteriorations such as severe soil erosion and air pollution. In order to fundamentally solve the rural fuel problem in mountainous regions and to consolidate the achievements of Grain to Green Programme (GTGP) and Natural Forest Conservation Program (NFCP), the Chinese government has decided to implement the SHPF project.

In 2003, the Ministry of Water Resources (MWR) of P. R. China carried out the pilot work of the SHPF project in 26 counties in Sichuan, Yunnan, Guizhou, Guangxi and Shanxi Provinces (Autonomous Region), the installed capacity has an increase of 58 000 kW, and it has benefited 0.22 million populations.

In 2006, MWR expanded the SHPF project to 81 pilot items, the installed capacity has an increases of 0.150 million kW and the annual generating capacity is 210 million kWh, and it has benefited 0.633 million populations.

Since 2008, MWR has fully implemented the SHPF project and aimed at 1022 items by the year of 2015, with an increase of installed capacity of 1.7056 million kW and the annual generating capacity of 2.438 billion kWh, which will benefit 6.7771 million populations.

### (2)Progress of SHPF Project

By the end of 2012, MWR had arranged 163 items of the SHPF project, among which 26 were implemented in 2003 and 81 in 2006. Besides, MWR had planned to implement 56 items from 2009 to 2015. Up till now, 139 items have been completed and are continuing to bring the benefits.

## Implementation Effect of SHPF Project

The SHPF project is an important measure to develop low-carbon economy, circle economy and to establish resource-conserving and environment-friendly society. It manifests the concept of "Human-oriented" and the striving for building a beautiful China. It is also a people-benefit project, and it will lighten the burden on farmers, adjust the energy structure in rural areas and realize ecological, social and economic benefits.

### (1)Realization of considerable ecological benefits

The statistics show that the 139 completed projects have brought the installed capacity of hydropower station of 393 640 kW, and 266 684 kW of which is brought by the small hydropower stations. The installed capacity has electrified 258 511 households, i.e., 973 535 populations. The SHPF project has a total investment of 3.07171 billion RMB Yuan. The calculated results indicate that the project has an

annual reduction of firewood consumption of about 0.242 million t and provides the electricity of 242.26 million kWh per year, with a direct reduction of $CO_2$ emission of 0.223 million t. Accordingly, the forest area of 310 000 $hm^2$ will be preserved, bringing carbon sequestration 630 000 t and oxygen release of 560 000 t to the air. Furthermore, the soils of 474 000 t per year will be conserved, and nitrogen of 796 t, phosphorus of 263 t and potassium of 7897 t can be avoided.

**(2)Great improvements in rural living conditions**

Using the clean energy, the farmers minimize the harm of polluted gas produces by the firewood and coal consumption. Their hard physical labor and accidents for firewood in the hills may be avoided, and it may help them to change the outmoded customs and enjoy the healthy and convenient modern life. All these will improve the farmers' overall qualities and thus facilitate the construction of rural material progress and the development of a harmonious society in the pilot area.

**(3)Increase of farmers' income, reduction of their living cost and improvement of long-term wealth creation**

In the pilot areas, a large number of labor forces are free from some strenuous manual work like cutting firewood. The SHPF project helps an average household to spare the workload that may otherwise have to be done by one laborer for fifty days. The farmers utilize this extra-time to go out as migrant workers or engage in all kinds of sidelines, by which each household can receive an increase in their income from hundreds to thousands RMB Yuan. After the implementation of the SHPF project, each household can reduce its electricity bill, ranging from 100 to 200 RMB Yuan.

**(4)Stimulating development of other industries and new rural construction**

Along with the concept of "Human-oriented", the local governments in most pilot areas take the SHPF project as a golden opportunity to integrate resources. By combining the new rural construction, they make the overall plans to utilize the fund for rural health, road building and other supportive means so as to give full play to farmers' initiative in road building and improvement of water, kitchens, pens and latrines, which will comprehensively promote the environment renovation in the rural areas of China.

**Major experiences**

**(1) Formulation of policies and determination of responsibility**

During the construction process of the SHPF project, all provinces (autonomous regions) have formulated different management methods to guide their construction, management and fund use of the SHPF project according to their own situations.

**(2)Integration of multi-channel investment and cooperation of various departments**

The counties (districts and towns) of most pilot items can organize various departments of water resources, forestry and communications to integrate multi-channel investment of seismic rehabilitation, poverty alleviation, mountainous resettlement, domestic water safety and village roads. They can also combine the small hydropower stations with rural electrification construction to improve the pilot areas by full use of the policies of returning farmland to forests and farmer-benefiting.

**(3)Extensive propaganda and active participation of inhabitants**

The SHPF project is a systematic engineering and directly relates to the inhabitants' benefits, change of rural backward production and living styles and promotion of farmers' living quality. The governments at various levels hold mobilization and group meetings to extensively delivery the policy, character and significance of the SHPF project. The inhabitants understand their responsibilities, rights and duties and actively support and participate in the project construction so as to build a satisfactory situation for the smooth implementation of the SHPF project.

**(4) Normal operation and management for sustainable efficiency of SHPF project**

All the provinces (autonomous regions) have formulated the three-right separation management system of ownership right, operation right and utilization right of the SHPF project, defined the responsibilities and duties of the management agencies at various levels, specified the power supply

and utilization order and signed an agreement with the SHPF project consumers to not cut trees and to protect ecological environment. They have also prepared the relevant management institutions and methods for the consumers' responsibilities and duties for the power supply and utilization and eco-environmental protection. Accordingly, the management mechanism for the long-term satisfactory operation of the SHPF project has been established.

## Major problems

**(1)Need for optimization of overall project layout**

At present, the SHPF project is distributed across most provinces in both northern and southern areas of China. Due to cold winter, water endowments, abundant coal and convenient transportation, the mountainous regions in northern areas of China are not suitable places for the SHPF project. Meanwhile, the project cannot be implemented in some counties or cities in need owing to the exclusion in the prescribed scope in China.

**(2)Improvement for selection of pilot areas**

The economic conditions in some pilot areas are satisfactory. Hardly any difference in "substituting fuel wood with SHPF electricity" can be seen between those areas and the surrounding non-project areas. The discounted electricity price does not stimulate the replacement for fuel, and the local government and public are not active in participation.

In addition, there are still many non-project mountainous regions with poor economic conditions. The farmers use a large sum of firewood instead of electricity as domestic fuel, which is a threat to the local environment. It is urgent for us to implement the SHPF project to arouse the farmer's initiative to use electricity and their awareness to protect and improve the ecological environment.

**(3)Innovation of construction modes**

Most provinces don't have ideal conditions for developing and constructing power supply points. The investment is relatively high. Several provinces have already halted the development of small hydropower stations as well as the next stage of the project plan. If we insist on giving priority to building new stations and supplying electricity nearby, it will be more difficult for us to carry out the project. Hence, the construction modes need innovation.

## Suggestions

**(1)Optimization of overall project layout**

The people in the northern areas of China mainly use coal and straws for heating. It's advisable to reduce the SHPF project in the north areas and expand it to the southern areas of China, such as the southwest areas and the middle and lower reaches of Yangtze River. The local government in the northern areas of China should take other measures to solve the farmers' heating problem. For those places where the SHPF project is necessary, the pilot programs should be continued if reasonable.

**(2)Cautious selection of pilot areas**

Besides the consideration of the areas of GTGP and NFCP as well as the key management regions of soil erosion, it is preferable that the selection conditions should include the farmers' poverty, climate and environmental sensitivity. The limited fund should mainly be used to help the regions with low income and heavy burden on environmental protection. Only in this way can the effect of the project be better. Moreover, it will help regulate the psychological imbalance of the farmers in the surrounding non-project areas.

It is suggested that the planning of the SHPF project both at national and provincial levels should be amended. By regarding the county as the unit, the government should implement the project gradually and programmatically based on the demand.

**(3)Establishment of encouragement and withdrawal mechanism**

We should implement a progressive pricing for the electricity produced by the small hydropower. Within the specified electricity range, the smaller the hydro-electricity is consumed, the lower the electricity price is. That is, the "encouragement" for farmers to use electricity instead of firewood or

straws. Furthermore, the withdrawal mechanism for the small hydro-electricity should be established. The agreements of small hydro-electricity supply should clarify the length of its discount service. Once the per capita net income (PCNI) reaches a certain level (better off), the small hydro-electricity should withdraw from the area. Another region will be chosen as the pilot area so as to consolidate and expand the sustainable benefits of small hydropower stations.

**(4)Extension of construction modes**

In addition to building new power stations, each province can adopt different modes based on its own situation. Either reconstructing old power stations or purchasing the existing small hydropower stations is advisable. We'd better shorten the construction period and bring the benefits of project as soon as possible. The national policies of mandatory scraping should be implemented gradually in order to force the aged, inefficient and nonrenewable hydropower stations to withdraw from the market, which in turn it will create more opportunities for the more rational development of the water resources as well as their provision for the public welfare.

## Summary

The SHPF project is a livelihood and moral engineering to alleviate farmers' burden and to adjust rural energy structure and to realize ecological, economic and social benefits. The SHPF project directly serves the rural areas and farmers, protects and improves the ecological environment, promotes the production and living conditions in the rural areas, and raises the farmers' income. It is necessary and significant for the realization of sustainable development of rural economy and society and the establishment of well-off society. The pilot items provide some experience for the extensive implementation of the SHPF project and promote its full construction and implementation in China.

Therefore, in order to raise the government's decision-making level and the investment benefits, the following procedures are adopted: (1) the experience and lessons from the construction and management of the SHPF project are summarized; (2) the efficiency and the existing problems are scientifically evaluated; (3) the construction and management of the SHPF project is further improved; (4) the guidelines, principles, object, layout, investment direction and countermeasures of the SHPF project are rationally determined.

**Keywords:** tunnel engineering, excavation procedure, numerical simulation, FLAC[3D].

**Abstract:** The phenomenon of spalling at Baihetan Hydropower Station is influenced by such factors as the stress redistribution in surrounding rock, the local stress concentration and also poor properties of disturbed belt. In this paper, a series of numerical simulation were carried out and some beneficial conclusions were gained as follows: 1) the ratio of maximum shear stress and uniaxial compressive strength is more rational in the prediction of spalling and can give confident explanation for "V" shape pits; 2) the in-situ geo-stress direction is in accordance with NNE and NE.

## Introduction

Baihetan Hydropower Station is located in the lower reaches of the Jinsha River. In-situ investigation shows that different intense spalling occurs in surrounding rock after excavation with 0.5-3m depth "V" shape pits. In this paper, a series of numerical simulation work were carried out in order to explain the spalling phenomenon. Finally, by analyzing the simulation results, we give some beneficial conclusions which could provide scientific reference and important technical support for spalling prediction in the constructing process of the rock engineering deeply mined in hard brittle rock mass.

## Computation Model

According to the testing tunnel position, a simulation model was established as Fig 1 which are PD62-1, PD62-2 and PD62-3. For the purpose to explain the principal stress affection for rib spalling, four groups of stresses were structured which were 23MPa (maximum horizontal principal stress), 16MPa (minimum horizontal principal stress), 8MPa (vertical stress) with the direction of NNW(N20° W), NNE(N20° E), NE( N45° E) and NEE( N65° E).

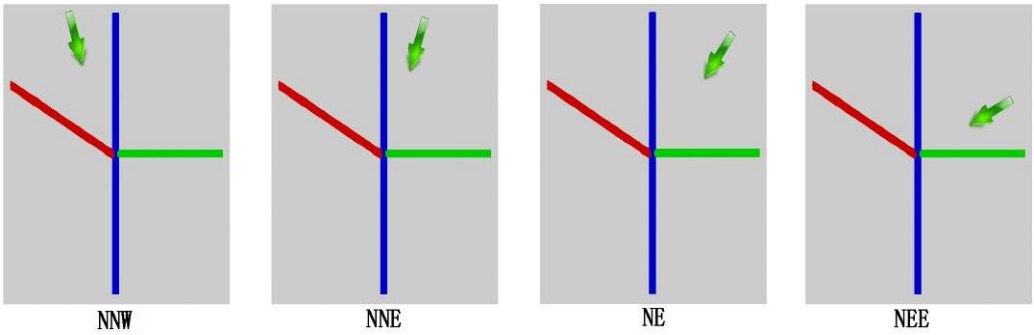

Fig. 1 Different Principle directions

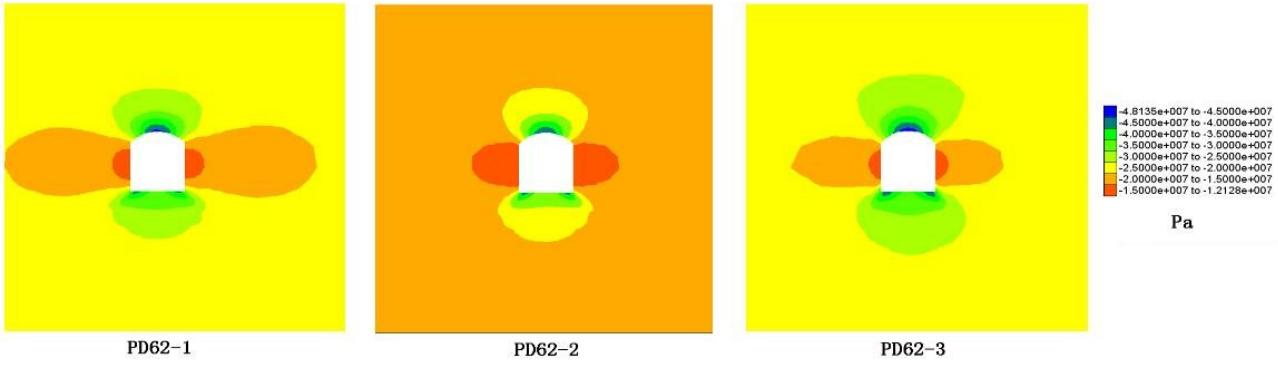
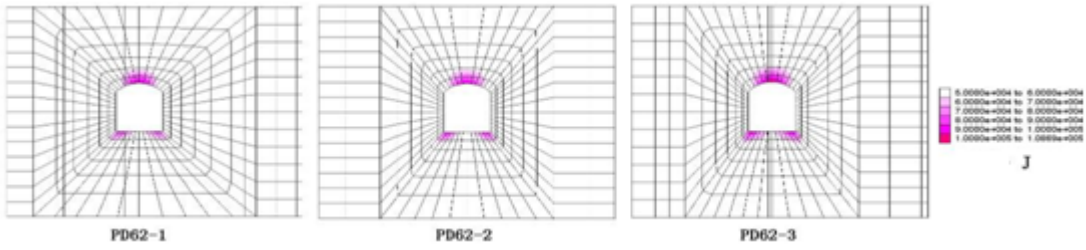
## Results

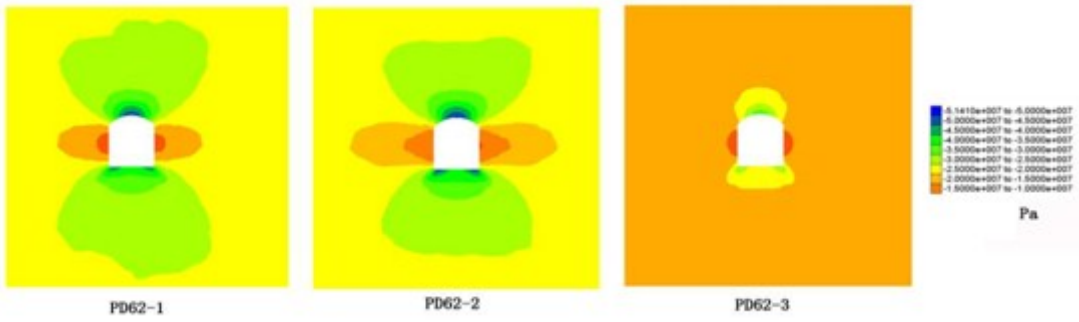
For the reason that high geo-stress condition and different mechanical properties of aphanitic basalt, rock mass deterioration model which is proved reasonable for the evaluation of brittle rock under high stress was adopted[1-3]. The results of maximum principal stress and energy release rate were gained as follows by fig 2.



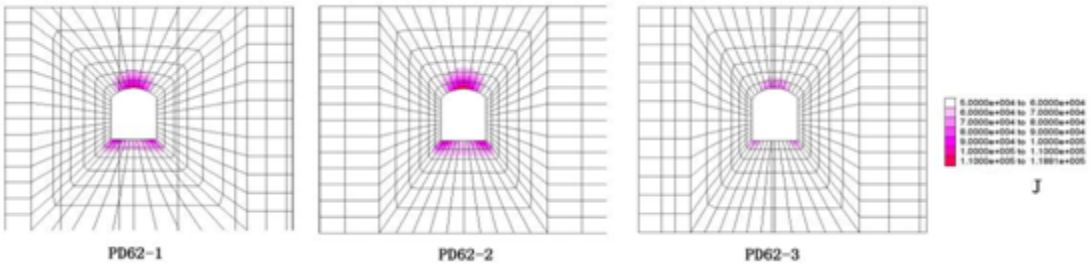
(a). maximum principal stress of NNW geo-stress



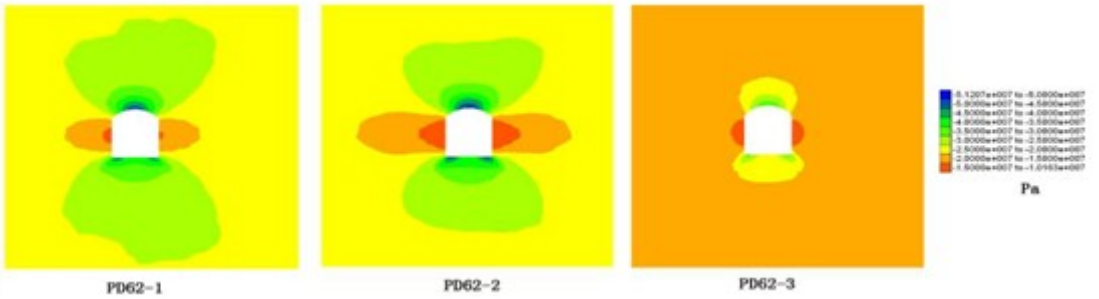
(b). energy release rate of NNW geo-stress



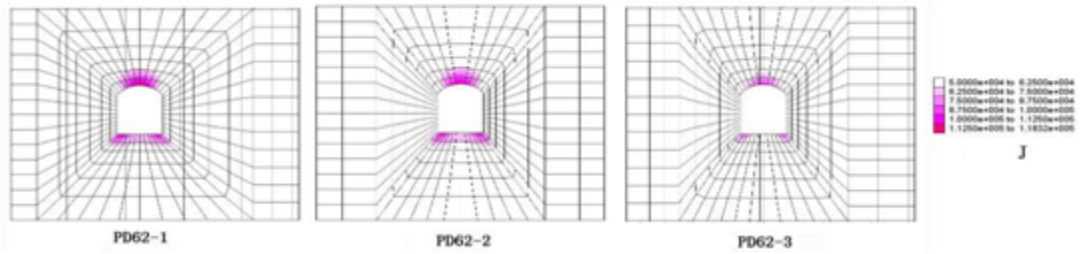
(c). maximum principal stress of NNE geo-stress



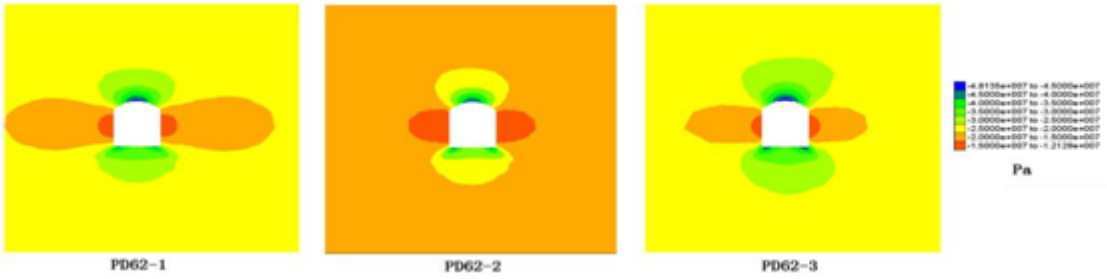
(d). energy release rate of NNE geo-stress



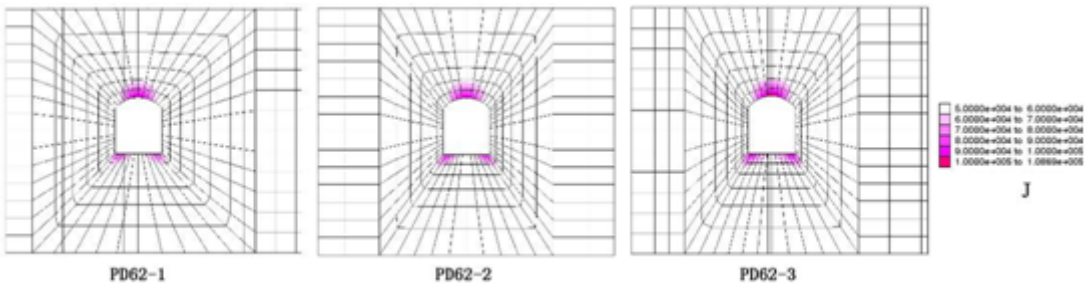
(e). maximum principal stress of NE geo-stress



(f). energy release rate NE geo-stress



(g). maximum principal stress of NEE geo-stress



(h). energy release rate of NEE geo-stress

Fig 2.Results under different geo-stress directions

**Analysis and Conclusions**

Generally speaking, stress redistribution usually occurs after excavation of tunnel and caverns and rib spalling can be considered as a kind of brittle failure for hard rock induced by local stress concentration[4-5]. As a non-ejection brittle failure, rib spalling is the result of stress redistribution in surrounding rock. So, 《Standard for classification of engineering rock masses》gives a definition by the ratio of uniaxial compressive strength and maximum initial vertical hole axis stress ( $R_c / \sigma_{\max}$ ) as an rule for brittle rock burst. In this definition, stripping and off block occurs with more new fractures when $R_c / \sigma_{\max}$ is 4-7. Secondary stress field in surrounding rock is of obvious difference due to different cavern shape. Furthermore, the brittle failure extent is also of great difference due to different shear stress. So, Russene provides another index which is $\sigma_\theta / \sigma_c$ ( $\sigma$ is maximum shear stress , $\sigma$ is uniaxial compressive strength ) and gives that low-amplitude brittle failure (rib spalling) occurs when $\sigma_\theta / \sigma_c$ is 0.2-0.3. By the results of simulation and in-situ testing at the top of the tunnel, the value of $\sigma_\theta / \sigma_c$ is 0.32 and rib spalling occurs and this is in accordance with in-situ condition. So we can safely come to the conclusion that rib spalling probably occurs at the top of testing tunnel which is the reason of "V" failure that proved by numerical simulation. Meanwhile, by statistical results of spalling intensites, we can know that the in-situ geo-stress direction is in accordance with NNE and NE.

**Keywords:** Bridge; Flood Controlling; Water Level; Flow Velocity

**Abstract.** It was convenient to go through the river after the building of bridge, but the flow water around the bridge can be influenced seriously. The level of water will become high and the velocity will reduce because of the influencing of resistance water by the bridge pier, and the level and the velocity of downstream water decreased. Between the bridge piers the velocity will increase where the water was extruded. All of these will have an effect to the safety of bridge and river flood controlling. In this paper, a 2D numerical model is established to simulate the variation of the level and velocity after the bridge was built, and to learn the effecting of the bridge on the flood controlling.

## Introduction

While the economic of the coastal and along the river had developed greatly, the human beings built a large number of bridges on river and made the traffic much more convenient. But, all of them could threat the safety of flood controlling, and also bridge scour pit endanger their safety. Therefore, before the bridge would be built, it need to analysis the variation of flow water and the level of water, velocity and calculate the depth of local scour around the bridge by all kind of construction. And so it provided technical for the construction of bridge. A 2D numerical model **i**s established to study the effecting of bridge construction to the flow of river and the research will provide reference for similar projects.

## Numerical Mode

The river which is 20km long and 250m wide is influenced by tides significantly called tidal river, the vertical average slope is 0.2‰. The cross-section is compound, the bottom of river is -1.0m, on both sides of the elevation of the volume is 5m. Both of sides are plain and low-lying terrain and the river is influenced by the tide jacking. While the flood flow is more than 2000$m^3$/s, it will be overflowing. So the river is two-way and alluvial river. A once-in-a-century flow is about 5000 $m^3$/s,and the average level of high tide is 4.2m off the coast. The bridge will be treated as solid boundary because of so many bridges and docks along the river. Others are computed by increasing roughness.

The continuity equation, momentum equation of tidal current and sediment transport equation in numerical model are discretized using FVM (Finite Volume Method):

$$\frac{\partial \varsigma}{\partial t}+\frac{\partial Hu}{\partial x}+\frac{\partial Hv}{\partial y}=0 \tag{1}$$

$$\frac{\partial Hu}{\partial t}+\frac{\partial Huu}{\partial x}+\frac{\partial Huv}{\partial y}=-gH\frac{\partial \varsigma}{\partial x}-\frac{\partial H\overline{u'u'}}{\partial x}-\frac{\partial H\overline{u'v'}}{\partial y}+\frac{\tau_{sx}-\tau_{bx}}{\rho}+fHv \tag{2}$$

$$\frac{\partial Hv}{\partial t}+\frac{\partial Huv}{\partial x}+\frac{\partial Hvv}{\partial y}=-gH\frac{\partial \varsigma}{\partial y}-\frac{\partial H\overline{v'u'}}{\partial x}-\frac{\partial H\overline{v'v'}}{\partial y}+\frac{\tau_{sy}-\tau_{by}}{\rho}-fHu \tag{3}$$

Where u and v are the flow velocity components on the direction of x-y, $\varsigma$ is water lever, $H$ is total water depth, $\rho$ is water density, $f$ is Coriolis affect coefficient, $\tau_{sy}$ and $\tau_{by}$ is shearing force acting on water surface and riverbed respectively.

According to the contents of research, tasks and project area terrain conditions and to be similar with the water flow movement ,the numerical model calculate the range of bridge for upstream and downstream of 2.5km.It is established with the latest measurement bed topography to calculate the verification and engineering. The grid of the model is equidistant in order to reflect the scale, make the mesh density around the bridge. The local terrain and the grids about upstream and downstream are shown in Fig.1. Validation process of tide and flood calculation shows that the coefficient of roughness is 0.018 when the tide influence, and it is 0.028~0.030 effected by the flooding. The time step is 0.5s while the simulation is run off.

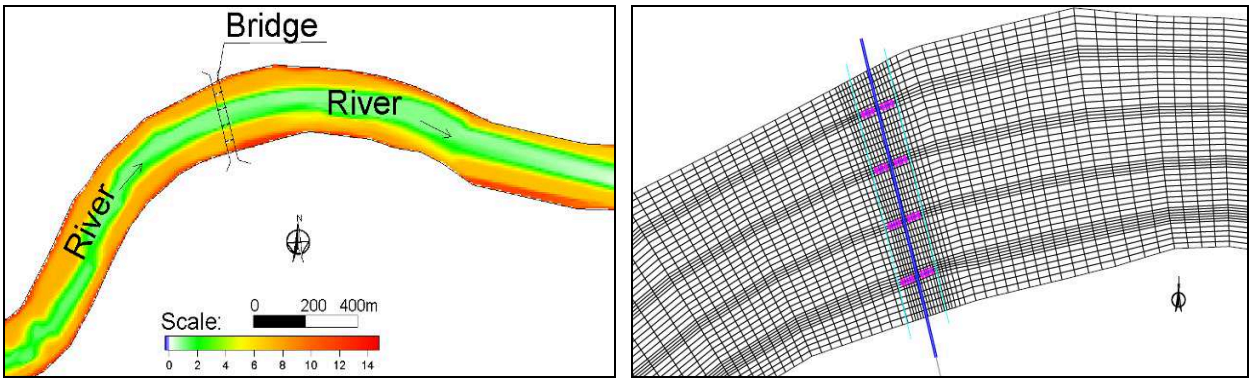

Fig.1 The local terrain and the grid

## Influence of bridge on flood controlling

**Influence on the water level.** The bridge will have an impact on the level of water after it will be built. The upstream increase and the downstream reduced. Fig.2 is the distribution of water level after the project, from the calculation results, the height of the maximum backwater is 20.9cm, the height of maximum backwater is 4.5cm near shore. The level of upstream which 25m away form the pier axis increase 6-8cm.

**Influence on the flow velocity.** Fig.3 is the variation of velocity after the project. Form the result of diagram and calculation, it shows that water flow around the bridge pier and the velocity decreases in the areas of both upstream and downstream. But the velocity of near shore and the intermediate of piers are increase .It can increase by 0.7m/s in front of piers and decrease by 2m/s behind, the maximum of velocity can increase by 0.2m/s in the intermediate of piers. In the upstream, 25m far away form the axis of bridge ,the velocity of water reduced by 0.1m/s. Fig.4 is the distribution about the variation of velocity about the 100m and 300m in the upstream ,the front and behind of bridge ,the 100m and 300m in the downstream. It concludes six sections (CS1-CS6). From the distribution of velocity, obviously, it increased between the bridges (CS3-CS4). Affected by the bridge pier, the velocity increased in the downstream about 100m away, and it reduced in the area of rear cover. The project could not influence the areas of 300m far away, and the flow rate is less than 0.06m/s.

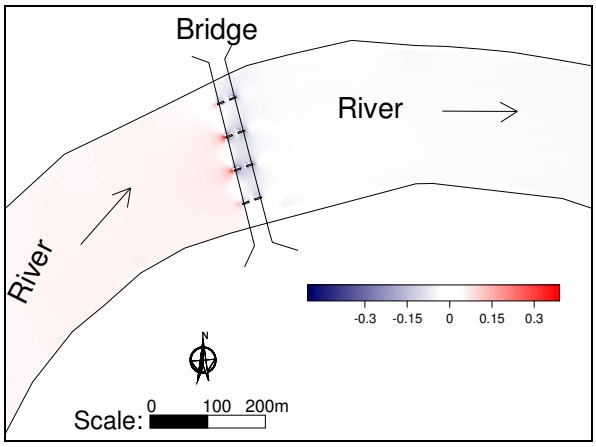

Fig. 2 The distribution of level

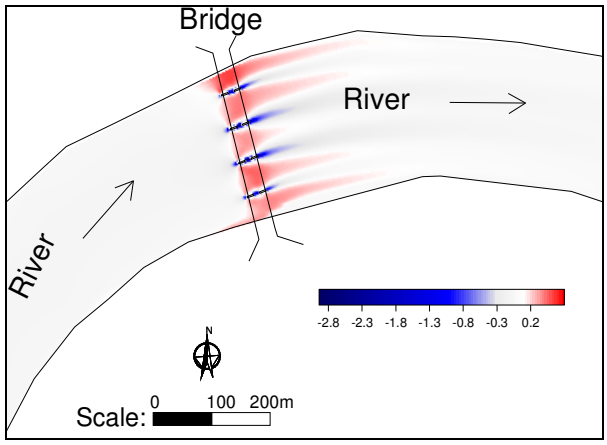

Fig.3 The distribution of local velocity

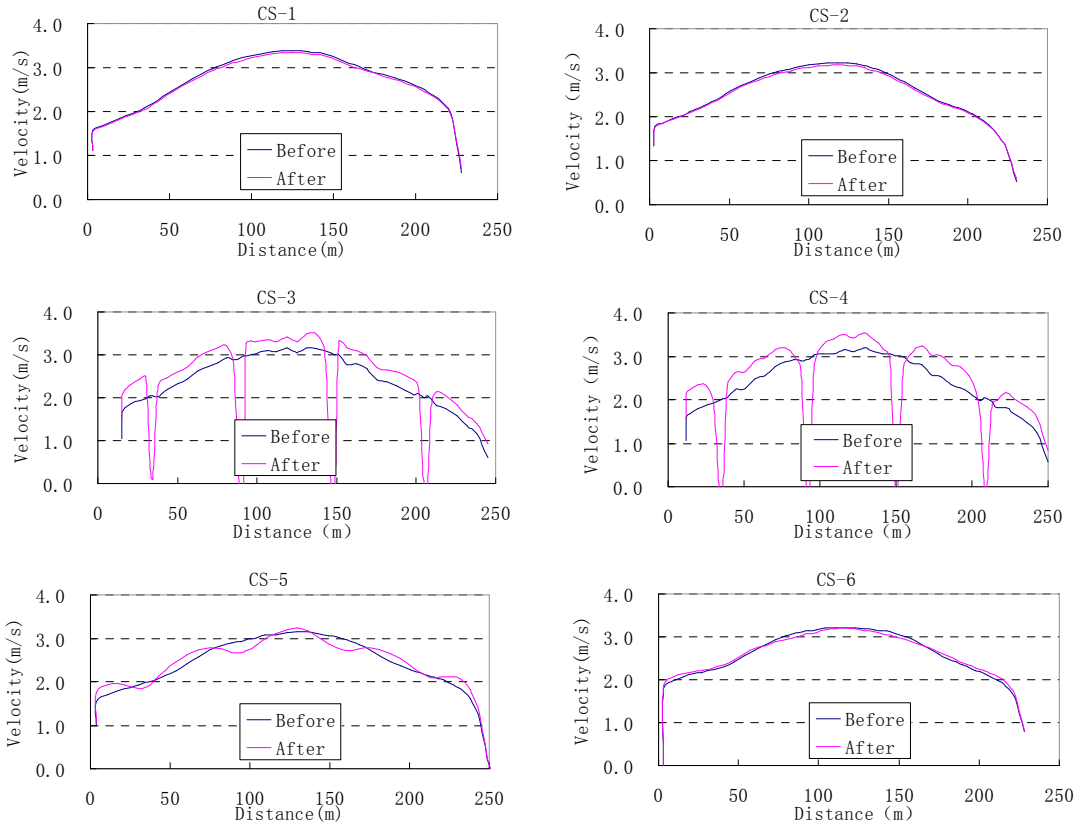

Fig.4 The distribution of velocity about different sections

## Local scour

By the block of flow to the pier, the flow regime changes dramatically, the streamline bend sharply, and it forms vortex near the bed surface so it scour the sediment around the piers to form a local scour pit. According to *The specification of survey and design to highway and bridge* (Chinese industry standard JTJ062-91), the formula can be used to calculated the local scour of bridge pier about the cohesive soil river.

$$H_b = K_\xi B^{0.6} I_L^{1.25} V \qquad (4)$$

Where $H_b$ is the depth of local scour about the piers , $K_\xi$ is the coefficient of type pier, $B$ is the width of piers, $I_L$ is the liquidity index of cohesive soil, $V$ is the flow velocity .

According to the geological condition around the bridge, the form of bridge and once-in-a-century, when the $K_{\xi}$ is 1.0, $B$ is 4.8m, $I_L$ is 0.5, $V$ is 3.15m/s, though the formula of local scour can calculate the depth of scour.

$$H_b = 4.8^{0.6} \times 0.5^{1.25} \times 3.15 = 3.39(m) \quad (5)$$

The result which estimated by the empirical formula showed that the depth of local scour is about 3.39m and less than the depth of piers ,so it impact little on the safety of the bridge.

## Conclusions

A 2D Numerical Model is established to calculate the variation of the level and velocity of water according to the latest terrain, before and after the bridge was built, calculate the depth of local scour by using the method of empirical formula and movable bed model. Basically got the following conclusions:

(1)The influence of the piers to the level of water: After the bridge construction, the backwater can reach by 20.9cm in front of the pier. It is about 1.5km in the upstream and downstream while the backwater can influence along the bridge axis, and the generally indicate high is 5.0-7.0cm upstream along the axis of bridge.

(2)The influence of piers to the velocity of water: When the bridge is completed, the areas of 1km in the upstream and downstream, the velocity can be changed in 1 cm/s.100m-300m away in front of the bridge, the velocity of both sides is not change obviously and the deep groove of the central river reduced. The velocity of bridge between increased, so does the shore.

(3)Because there are so many old bridge along the river and the deck of bridges are low enough so that while the large flood it is easily jam the span and make the level of water to raise, so it should consider this situation in the design of the bridge.

## Acknowledgments

The project is financially supported by Ministry of Transport major special science and technology projects of China (Grant No. 201132874640) and Ministry of Water Resource's Nonprofit Special Funds for Science Research of China (Grant No. 201201070).

# Monthly rainfall Analysis in west part of Chongqing

Lin qin[1, a], Junying Jin [1*],Qian Zhang[1] and Dake Wang[1]

[1]College of Resources and Environment, Southwest University, Chongqing, 400715, China

[a]swuqinlinaa@163.com, *Corresponding author:junyingjin@126.com

**Keywords:** Monthly Rainfall, Rainfall Distribution, Normal Distribution Analysis.

**Abstract.** Rainfall information is critical in understanding the hydrologic balance on a global scale and the complex interactions among the small-and large-scale components within the hydrologic cycle[1]. In this study, the monthly rainfall data from 1976 to 2006 at the stations of Rongchang, Dazu, Tongliang and Yongchuan were used to analyze the statistical characteristics and trends of rainfall changes in the west of Chongqing. The average monthly rainfall at Rongchang, Dazu, Tongliang and Yongchuan were 89.4mm, 83.5mm, 88.3mm and 84.8mm in thirty years. The probability distribution of rainfall is a normal distribution. Moreover, the histogram of frequencies showed a clear tendency toward a obvious seasonality of the rainfall distribution [2].

## Introduction

One of the most important aspects of climate variable that requires thorough investigation is the time distribution of monthly rainfall and its historical changes. Rainfall is the most important climatic change since it gives rise to opposite phenomena such as drought and floods. In order to develop an effective management strategy, it is paramount to understand and assess the impact of the rainfall resource on the ecosystem[3]. A mass of studies on rainfall variability have been undertaken all over the world using various statistical procedures. A significant reduce in the number of rainy days and a significant increase in the rainfall intensity values have been identified in many places in the world, such as America and China.

Chongqing is located in the junction of the Yangtze River and the Jialing River in a humid subtropical monsoon climate. With an area of approximately 82402.95km$^2$.The average elevation is 400m and the average precipitation is 1200mm/y. The mainly terrain type are mountainous and hilly. We chose four stations rainfall data in the west of Chongqing to analyze the rainfall distribution characteristic. The average value for the four regions at Rongchang, Dazu, Tongliang and Yongchuan is considered the most representative for Chongqing[4].

In this study, the distribution of monthly rainfall in the west of Chongqing were analyzed at four stations using data from 1976 to 2006; then the questions were discussed as follows:(1) Are there any trends in the monthly rainfall for different parts of Chongqing? (2) Is there any obvious normal distribution in the monthly rainfall for different parts? (3) Are the monthly rainfall patterns stable or variable? In this study, mathematical statistics methods and ensemble canonical correlation were used to study the rainfall features.

## Methodology

The statistical methods such as the Linear trend analysis and Mathematical statistical methods were used in order to obtain the monthly rainfall characteristics parameter such as the average value, the minimum value, the maximum value, the coefficient of variation and etc. Using the linear correlation methods to establish the linear regression equation. By means of T test method tests whether hydrological sequence significant trend [5].

The formulas of statistical characteristic are as follows:

$$t = \frac{x - \bar{x}}{s_x} \tag{1}$$

Where. $\bar{x}$ :averagae value of series x ,$s^x$ :standerd deviation of series x

$$p = \frac{m - 0.375}{n + 0.25} \tag{2}$$

$$x_{cal} = \bar{x} + t * s_x \tag{3}$$

$$y_{cal} = \bar{y} + t * s_y \tag{4}$$

Where.m :rank n: amount of total data series.

A characteristic of a normal distribution is that data represented by this distribution on probability paper plot a straight line. The horizontal axis of this paper expresses probability of exceedence, p, or non-exceedence, q, on a non-linear scale and the vertical axis the values analyzed. In order to plot the distribution in a spreadsheet the scale of the horizontal axis has to be linear. A linear scale is obtained in terms of the normalized value t, derived from a normal distribution which is related to the probability of exceedence (or non-exceedence).

## Results and Analysis

### Monthly rainfall distribution

Based on the 31years monthly rainfall data on four rainfall stations, that is Rongchang station, Dazu station, Tongliang station and Yongchuan station, monthly rainfall distribution of Chongqing are shown in figure 1.

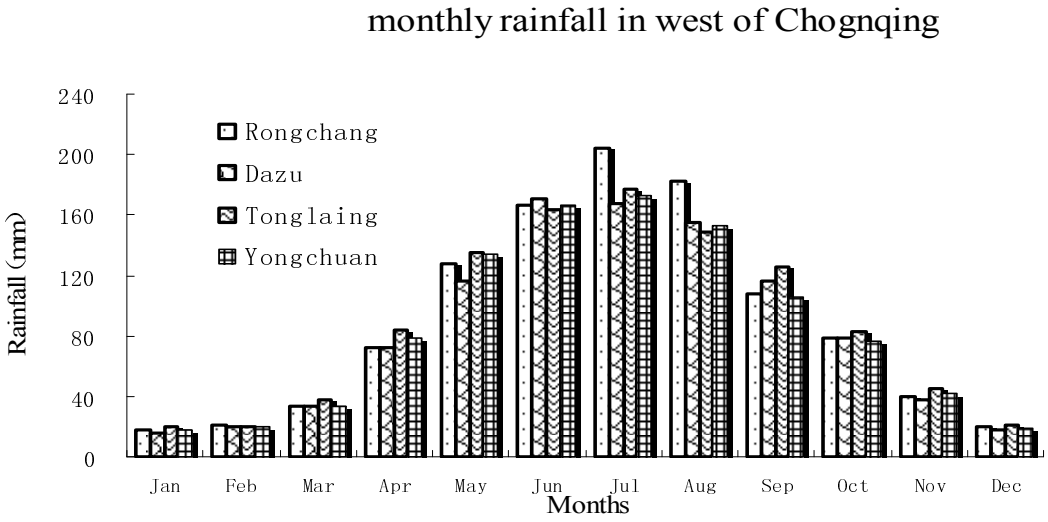

Fig. 1 Average monthly rainfall in the west of Chongqing

Fig.1 showed that the rainfall was uneven distributed all over the year, the rainfall mainly focused on June, July and August, the total rainfall amount of these three month were almost 48.75% of total annual rainfall. It is very clear to know these lots of rainfall may lead to serious flood which can bring disaster to west of Chongqing.

In contrast, the rainfall in Dec, Jan and Feb was very low, the rainfall amount of these three month were only 6% of total amount of annual rainfall, and these three month were low flow seasons in Chongqing, and droughts might occur frequently, which led to serious problems to the whole areas, for example, water shortage will make agriculture yield reduction, also have bad effects on industries, domestic etc.

Also, the figure 1 showed that average monthly rainfall data range from a minimum of 3.7mm in January at Dazu to a maximum of 596.6mm in July at Rongchang and denote a seasonality of the distribution.

For the seasonal rainfall distribution, the percentage of rainfall in spring(Mar-May.), summer(Jun-Aug.), autumn(Sep-Nov.), winter(Dec-Feb.) were 22%, 52%, 20%, and 6% respectively.

The average monthly rainfall at Rongchang, Dazu, Tongliang and Yongchuan were 89.4mm, 83.5mm, 88.3mm and 84.8mm in 30-year.

**Annual rainfall distribution**

The average of annual rainfall distribution is showed in figure 2 based on four rainfall stations.

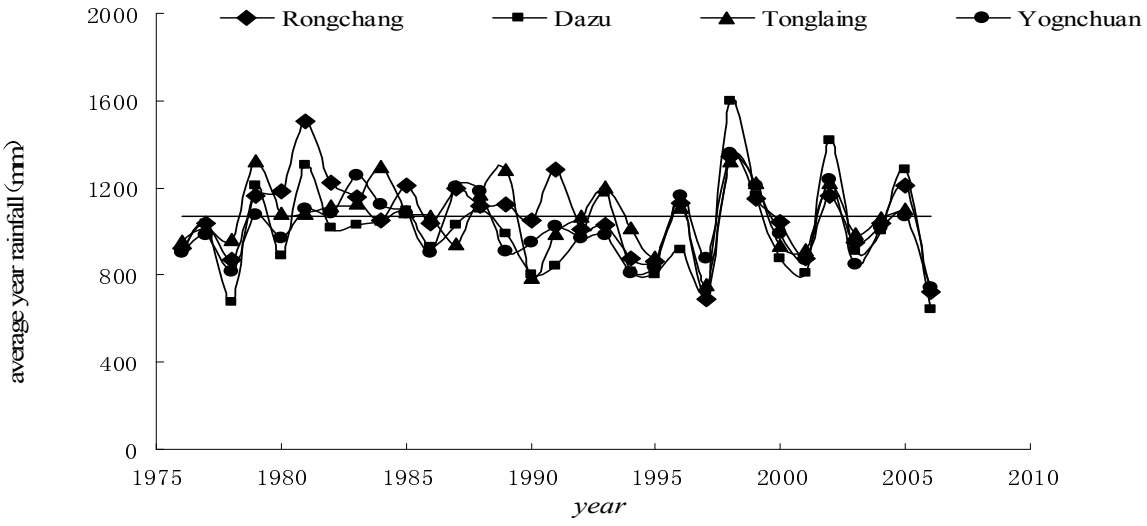

Fig. 2 The average annual rainfall in the west of Chongqing

Fig.2 showed that the average of annual rainfall over the west of Chongqing is quite variable and irregular. The highest annual rainfall was 1601.3mm in 1998, and based on the survey, a serious flood happened around China in 1998. The lowest average annual rainfall just was 639.7mm in 2006. Before 1998 there is no significant trend in the rainfall patter. During 1998 to 2006 there is fluctuation cycle about 5~6 years.

Compared with the average annual precipitation, there are 12-year high flow years, and 19-year dry years. A higher rainfall concentration, represented by greater percentages of the yearly total precipitation in a few very rainy days, has the potential to cause floods and also droughts phenomena. As a consequences, it will increase economic and life losses.

**Normal distribution analysis**

The normal distribution and lognormal distribution of monthly rainfall was analyzed based on the rainfall data of January for four rainfall stations, the results were showed in figure 3.

From the figure 3, we can noticed that the frequency distribution of monthly rainfall values is skewed and the one with the logarithm of the monthly rainfall values is not. The frequency distribution of ln(x) looks more like a normal distribution.

The frequency distribution of ln(x) is more like a normal distribution. And the frequency distribution of monthly rainfall values is not so that confirm to the distribution of normal.

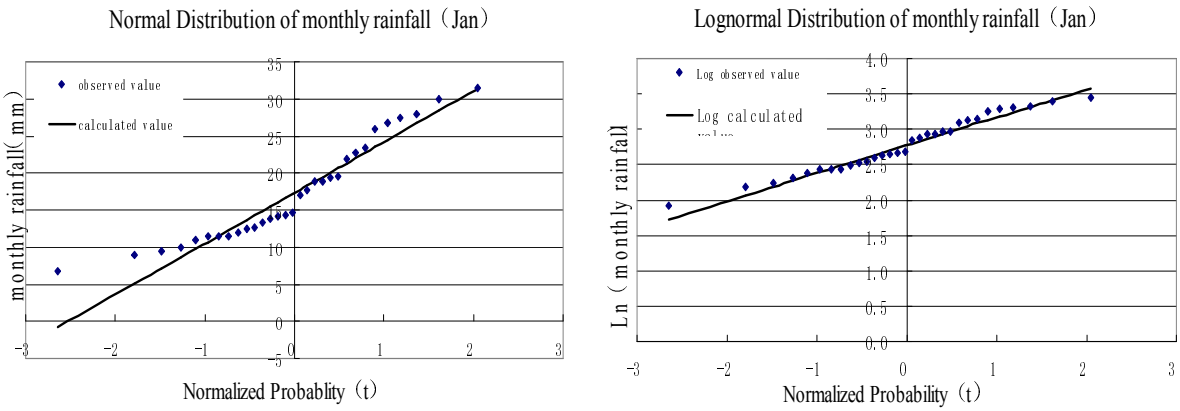

Fig. 3 Normal and Lognormal distribution of monthly rainfall

## Summary

The analysis of monthly rainfall distribution throughout the year is extremely important because of its high impact on environmental phenomena like floods, droughts, soil erosion and slope stability, but also on water management.

The paper took the west of Chongqing as an example, analyzed the variation characteristics and variation trend estimation and accumulation departure, and revealed the complex structure of monthly rainfall in the west of Chongqing in multiple time scale. The results showed that the monthly rainfall in the west of Chongqing is relatively stable. The rainfall variation was different in the four seasons, and the rainfall increased in summer and autumn， and decreased in spring and winter, moreover, it showed the period and mutation point of rainfall sequence in different time scale, and identified the main cycle[6].

**Keywords:** Middle Route Project of SNWT; excavated channels; drainage cushion; water pressure head; seepage field regulations; numerical simulation.

**Abstract.** The seepage field regulation is important for the stability canal liner plate and slope for along the Middle Route of the South-to-North Water Transfer Project, especially for stretches excavated in expensive soil area with groundwater level. In order to analyzing the rationality and efficiency of seepage regulation measures comprehensively, a typical section was modeled, and the seepage field was simulated with the 3D finite element technology. The distribution of seepage field was analyzed and the seepage control measures were compared. The results show that water pressure on the underside of canal pavement would be reduced significantly by the measures, such as the measure of drainage cushion with drainage holes which open just when ground water level is higher than the canal water level, the measure with drainage cushion replaced by the drainage board. The differences among the two kinds of measure were compared. Their application conditions were discussed and proposed.

## Introduction

The Middle Route of the South-to-North Water Transfer Project is an oversize inter-basin water transfer project. The main canal will be operated under complex conditions of climate and groundwater, the channel water level will also change with water scheduling, and the maintenance conditions will be experienced during the period of water supply, so the effective seepage control measures is key to the engineering safety and effective operation [1]. The seepage control goal is the stability of drainage slopes and channel lining board in areas of high groundwater drainage excavation section. The dewatering sand cushion and the geomembranes and drainage holes are set below the channel bottom as the seepage control measures during in preliminary design of excavation section, some drainage holes are as seepage control measures for canal slope and the expansive soils is be replaced by cement soils along the canal expansive soil slope. The design idea is applicable and effective under most conditions[2], but sand cushion of drainage slopes is a higher cost and the cushion thickness is difficult to strictly control in the excavation channel, the construction progress takes more time and effort, there are many other negative factors during construction.

## A brief introduction to the FEM of three dimensional seepage

The seepage calculation of excavated channel involves precise simulation methods of solving seepage free surface, drain holes, summarized as follows.

### 2.1 Procedure of Nodal Virtual Flux for Unconfined Seepage Filed

In unconfined seepage problem, the free surface of seepage is nonlinear boundary. The location of the free surface, the line of exit points and the real domain of seepage are unknown first, which need iteration to obtain the solution to the unconfined seepage problem. The procedure of nodal virtual flux

that is progressively developed and perfected in the references [3~6] can solve this problem conveniently without mesh modification and the relevant iteration formula is as follows.

$$Kh = Q - Q_2 + \Delta Q \quad (1)$$

Where K, h and Q are the conductive matrix, the vectors of hydraulic head and the nodal equivalent flux related to the total calculation domain of $\Omega=\Omega_1+\Omega_2$, respectively; $\mathbf{Q}_2$ represents the vector of virtual nodal equivalent fluxes; $\Delta Q = K_2 h$ denotes the vector of the nodal fluxes which are contributed by virtual elements and transient elements in the virtual domain $\Omega_2$; $\Omega_1$ denotes the real domain of seepage below free surface of seepage and $\Omega_2$ denotes the virtual domain of seepage located above the free surface.

**2.2 Simulation of Seepage Behaviors of Drainage hole**

There are many drainage measures including a lot of drainage holes which play a role of water discharge and pressure relief in the seepage filed in the channel or dam foundation, if the location of free surfaces at the holes is higher than the top surfaces, the holes are fully filled with seepage water, otherwise there is no water overflowing out from the holes in bottom or slope of channel. The holes action is required on both the theory and algorithms rigorous simulation techniques to solve the drainage holes of its impact on seepage field; The procedure of simulation of holes is progressively developed and perfected in the references [4] can solve this problem conveniently without mesh modification and the drainage hole relevant iteration formula is the "equivalent nodal flow method" [7] in each hole, its mathematical formulation is as follows Eq. 2:

$$Q(x_i) = -\sum\sum K_{ji}^{e} (h^{it})^{e} \quad (2)$$

Where in each symbol, drainage holes and validation of solving specific references [4]. This overhaul of the channel flow calculations, channel slope holes handle that uses the method.

## Effect Analysis of Seepage Control of Canal

### 3.1 Project overview

A three-dimensional section of a typical canal seepage model was modeled in the Middle Route of the South-to-North Water Transfer Project in Xi chuan County, Henan Province, there are holes and geomembranes in seepage control of the South-to-North Water Transfer Project in areas of high groundwater drainage excavation section in the preliminary design. the typical cross-section shown in Figure 1. The measure of drainage cushion is replaced by the drainage board in this article (optimization case). Calculation parameters are shown in Table 1.

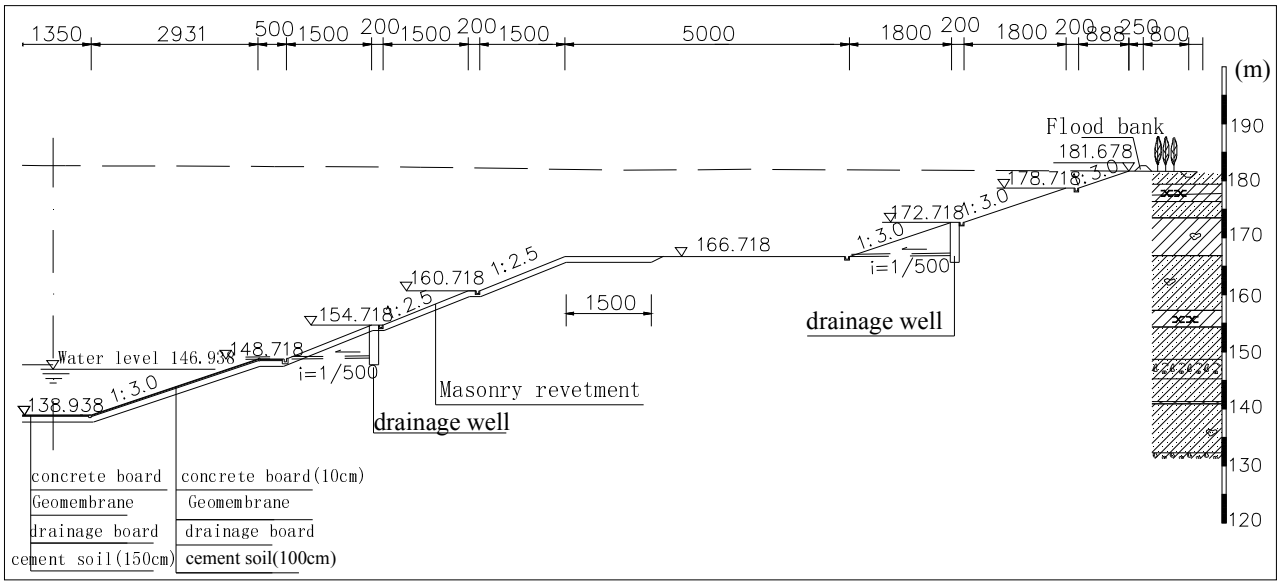

**Fig.1 The section of typical canal**

**Table 1 The permeability coefficient of the typical canal**

| number | formation | Permeability coefficient |
|---|---|---|
| 1 | Silty clay (0~3m) | $1.0\times10^{-4}$ |
| 2 | silty clay (3~7m) | $5.0\times10^{-5}$ |
| 3 | silty clay (under 7m) | $5.0\times10^{-6}$ |
| 4 | silty clay | $1.2\times10^{-6}$ |
| 5 | clay | $8.0\times10^{-7}$ |
| 6 | sand cushion | $1.0\times10^{-3}$ |
| 7 | backfill | $1.0\times10^{-5}$ |
| 8 | concrete underlay board | $1.0\times10^{-11}$ |
| 9 | drainage board | $1.0\times10^{-1}$ |

### 3.2 Research Programs and Model

The dewatering sand cushion（thickness 25cm） and the geomembranes and three ranks drainage holes（the spacing of two holes is 10m, the layout of holes is along channel center and slope feet longitudinal）are set below the channel bottom as the seepage control measures during in preliminary design of excavation section. The expansive soils is be replaced by cement soils along the canal expansive soil slope(the cement soils thickness is 150cm under the first level stairs and 100cm under second stairs). The canal drainage wells are layout at altitude of slope is 154.7m and 172.7m, the well diameter is 1.5m and the spacing is 20m between the two wells.

The one of optimization measures is that the sand cushion is replaced by the drainage board grid in channel slope and channel bottom (Figure 2). There are four calculation cases, including cases of operation period and maintenance period, the detailed introduction of cases is the table 2.

**Table 2 The calculation cases**

| number | Programs description | Notes |
|---|---|---|
| F1 | Channel water level 146.938m;holes spacing is 10m; sand cushion(thickness 25cm,Permeability coefficient $1.0\times10^{-3}$cm/s), drainage wells; other parameters in table 1. | preliminary design case; operation period |
| F2 | Channel water level 138.938m, other same F1. | maintenance period |
| F3 | drainage board grid (coefficient $1.0\times10^{-1}$cm/s,4×4m);other same F1.. | optimization case; operation period |
| F4 | Channel water level 138.938m in bottom; other same F3. | optimization case; maintenance period |

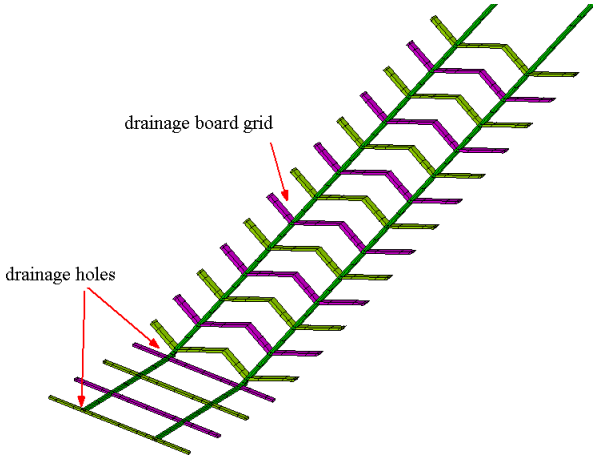

**Fig.2 Drainage board grid models**

The model is one side of the channel center, the calculation results is affected by the range of the upper boundary references [9], the distance is 600m between upper boundary and sloping top, upstream water level is 181.6m, Downstream water level is 146.938m, downstream water level is 138.938m in maintenance period; the level of the bottom of model is 90m.The model bottom and the

boundary of symmetry are impervious boundary, the channel slope is drainage boundary; the holes and the wells are treated with the theory in referece[4]. The model element is 6 sided 8-node element, the drain hole is modeling with real element, the node number of F1 model is 77 126 and the element number is 70 817. F1 grid is shown in Figure 3.

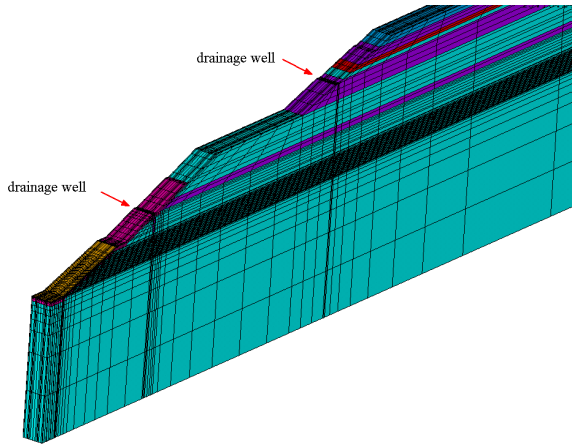

**Fig.3 3-D FEM meshes of the channel**

### 3.3 Analysis and comparison of calculation results

In this paper, the effect of seepage control is analyzed with the characteristics of seepage field and the maximum pressure head in bottom lining plate in operation period and maintenance period. The water pressure head difference is the value between the statistical point and drainage water depth.

#### 3.3.1 Effect of seepage control of F1

Results indicate that effect of seepage control is clear and the seepage control measures is reasonable, the water head pressure correctly reflects the effects of boundary conditions and control measures of the cases from Figure 4~5.

The case F1 is the preliminary design case, the seepage field distribution is slight impacted by the well of first level stairs, seepage free surface is near the foot of the channel platform, the water head pressure is low under bottom of lining board(Figure 4), the water head difference is 0.10m in the channel lining board(Table 3), which is enable to the lining board stability. The case F2 is the maintenance period case of preliminary design, The figure 5 results show that the exit points of seepage flow is at foot of the continental slope, the two ranks wells are below the seepage free surface in the channel slope. The water head difference of F2 is 0.15m, which is higher than the result of F1 in the channel lining board, but it is also to meet the requirements of stability of channel lining board[1]. In conclusion, the seepage control measures are reasonable for this channel section in preliminary design case.

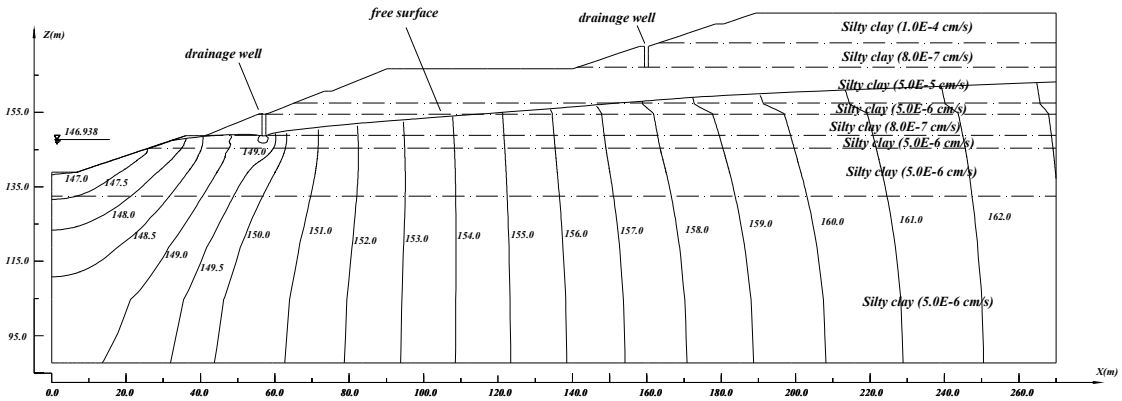

**Fig.4 The water head contour of case 1 (unit: m)**

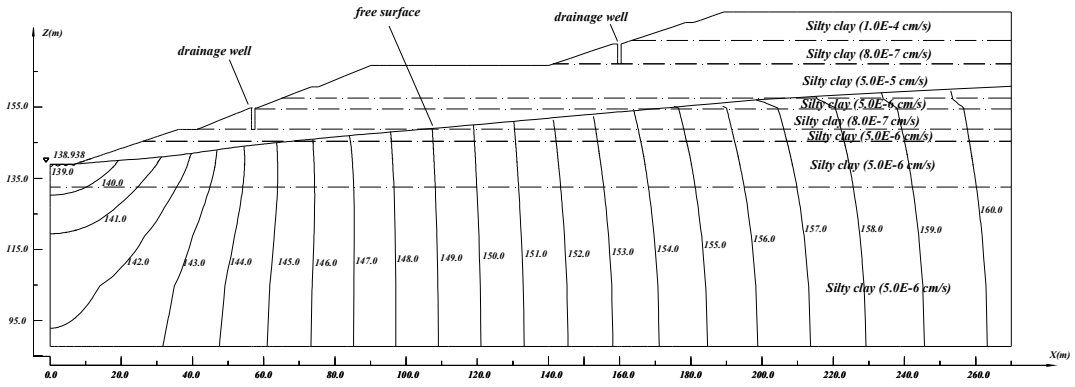

**Fig.5 The water head contour of case 2 (unit: m)**

### 3.3.2 Effect of optimization case

The measure of drainage cushion is replaced by the drainage board in F3, the water pressure distribution is sparse in the bottom and slope of channel(Fig 6), the water head difference is 0.05m in the channel lining board. The seepage field distribution is impacted by the well of first level stairs slightly, water pressure distribution is similar to F1 near the wells.

The case F4 and F2 are same to maintenance period, but permeability coefficient of drainage cushion is difference of 100 times between the two cases, the water head contours of distribution are more similar, drainage wells are above at the free surface in drainage slope (Figure 6, Figure 7). The maximum water pressure head difference is 0.11m in the channel lining board in case F4. So, the drainage cushion is replaced by the drainage board is also effective, and the measures are relatively more economical and easy construction.

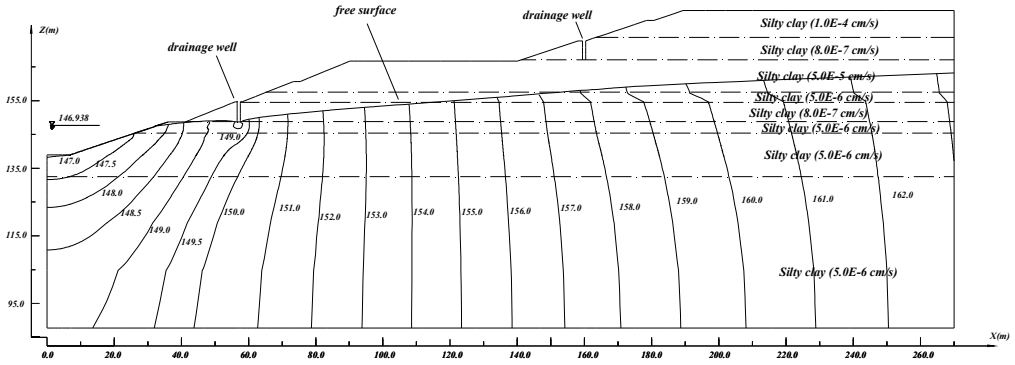

**Fig.6 The water head contour of case 3 (unit: m)**

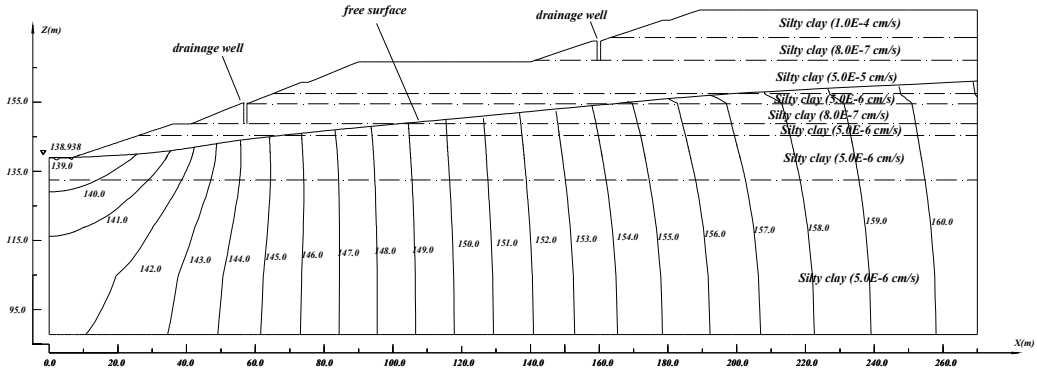

**Fig.7 The water head contour of case 4 (unit: m)**

### 3.3.2 Control measure's effect comparison

Former section research suggests that the water pressure of operation period is higher than the water pressure in maintenance period, so the lining board stability is controllable in maintenance period, the maximum water pressure head difference is 0.15m in the channel lining board in preliminary design case. But the water pressure head difference is 0.11m in the case F4, at same time, the drainage cushion is instead of the drainage board grid (coefficient $1.0\times10^{-1}$cm/s). These results

Indicate that affection of seepage control of drainage board grid is obviously, its biggest advantage is low cost and easy construction.

**Table 3 The maximum water pressure heads of cases**

| case | F1 | F2 | F3 | F4 |
|---|---|---|---|---|
| maximum water head difference / m | 0.10 | 0.15 | 0.05 | 0.11 |

## Conclusion

(1).The measures of preliminary design and optimization of seepage control measure has a significant effect, which can be able to guarantee the stability of channel lining board. Through the drainage holes which open just when ground water level is higher than the canal water level, gravity drainage and seepage field of self-regulation can be realized.

(2). The measures with drainage cushion replaced by the drainage board, not only can reduce costs, facilitate construction and reduce the difficulty of quality control, and even improve the seepage control effect. However, the permeability of the drainage board material is necessary to strictly control the quality of the indicators, and in the long run to avoid leakage.

**Keywords:** Hsiao-Ching River Basin, Jinan City, Precipitation, Trend Analysis, 1956-2007.

**Abstract.** Monthly precipitation data from Huangtai Bridge Station were used to study seasonal and annual precipitation characteristics and trend. The covered time-period is from 1956 to 2007. Different methods including linear regression, 5-year moving average, anomalies in decadal scale and the Mann-Kendall test were applied in the study. Nearly two-thirds of the total rainfall amount is concentrated in summer, with autumn and spring months to follow, and only about 3% in winter. An increasing trend in spring months is found. It starts in 1978, becomes significant after 2002, and probably continues into the future. A decreasing trend is recorded in winter and begins in 1980. No significant trend is found in summer, autumn and yearly precipitation. The same fluctuations are observed between summer and annual precipitation indicating the dominant influence of the summer season.

## Introduction

Hsiao-Ching River has played an important role in flood control, drainage and irrigation in Shandong Province. It is the only river of the province having navigable inland waterways and sea shipping and its navigation history has extended nearly 900 years. The river has a total length of 237 km and a catchment area of 10336 $km^2$, which originates from Jinan springs and flows into Bohai Sea from west to east through Jinan, Zibo, Binzhou, Dongying and Weifang [1,2]. Hsiao-Ching River in Jinan City has a total length of 70.5 km and a catchment area of 2792 $km^2$. The catchment contains 18 tributaries whose drainage areas cover more than 30 km2. Major tributaries are seasonal and begin in hills, which are located in the south bank of the main river [3,4]. Hsiao-Ching River is the most important river of Jinan city and has become ecological corridor, economic and cultural corridor historically. The river is the city's only river draining off the floodwater, the frequent occurance of floods has caused loss of the facilities and human lives in history, including the most recent extreme rainstorm and flash flood event happened on 18th July 2007 [5,6]. Good understanding of rainfall changes is therefore crucial to urban flood security and sustainable development [7,8]. The purpose of this study is evaluating rainfall characteristics and trends during past 50 years in Hsiao-Ching River catchment of the city.

## Materials and Methods

Huangtai Bridge hydrological station is located in the east of Jinan city and is one of the key national stations, which was built in 1916. It is the boundary between the upper and middle reaches of the Hsiao-Ching River. The continuous precipitation data of the station are a representative example of the catchment in the city. Monthly precipitation data from Huangtai Bridge Station are used to study seasonal and annual precipitation characteristics and trend. The covered time-period is from 1956 to 2007. Different methods including linear regression, 5-year moving average, anomalies in decadal scale and the Mann-Kendall test are applied in the study.

## Results and Discussion

**Precipitation characteristics.** The seasonal and annual characteristics of precipitation in the Hsiao-Ching River basin of Jinan city from 1956-2007 are shown in Table 1. The basin has an average annual precipitation of 682.8mm, a maximum of 1140.7mm in 1962 and a minimum of 297.5mm in 1968. Small wet-dry change of annual precipitation is observed by the relative lower max/min value (3.85) and Cv value (0.31). In seasonal scale, summer precipitation indicates the highest percentage (66.4%) of the year, autumn and spring follow up with 16.8% and 13.5% respectively, and the winter only accounts for 3.3%. Cv values in all seasons are significantly higher than in the whole year. The highest value of 0.65 is found in winter and its max/min value reaches up to 283.0, reflecting an apparent wet-dry change. Cv and max/min values in other seasons range from 0.40 to 0.53 and from 6.8 to 15.0, which showed a smaller wet-dry change.

Table 1 Precipitation characteristics from 1956 to 2007

| | Average | | Cv | Maximum | | Minimum | | Max/Min |
|---|---|---|---|---|---|---|---|---|
| | value(mm) | percent | | value(mm) | year | value(mm) | year | |
| Spring | 92.3 | 13.5% | 0.49 | 209.4 | 1980 | 30.8 | 1981 | 6.8 |
| Summer | 453.5 | 66.4% | 0.40 | 870.1 | 1962 | 78.3 | 1968 | 11.1 |
| Autumn | 114.5 | 16.8% | 0.53 | 293.2 | 1961 | 19.5 | 1981 | 15.0 |
| Winter | 22.6 | 3.3% | 0.65 | 56.6 | 1989 | 0.2 | 1995 | 283.0 |
| Annual | 682.8 | 100% | 0.31 | 1144.7 | 1962 | 297.5 | 1968 | 3.85 |

**Trends for seasonal precipitation.** A positive trend is noticed in spring season by linear regression and 5-year moving average analysis (see Fig.1a). Spring precipitation anomalies in decadal scale indicate that the late 1950s, 1970s and 1980s has been dry years over past 50 years and the precipitation tends to rise since the 1970s (see Table 2). Fig. 1b illustrates the normal and the retrograding curve (UF and UB curve) of the Mann-Kendall test at the 95% significance level. An increasing trend is recorded after 1978, which becomes sharp after 2002.

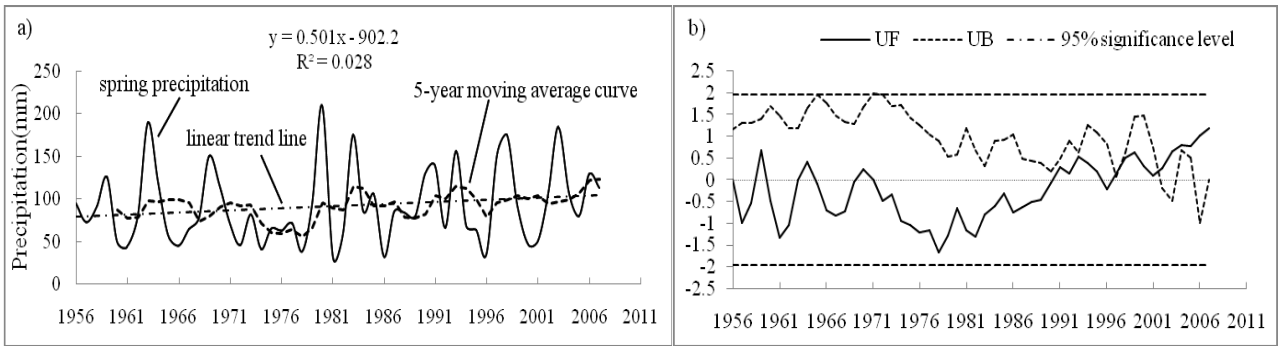

Fig. 1 Trend analysis of spring precipitation

| | 1956-1960 | 1961-1970 | 1971-1980 | 1981-1990 | 1991-2000 | 2001-2007 |
|---|---|---|---|---|---|---|
| Spring | -5.71% | 2.40% | -15.31% | -5.99% | 7.96% | 19.70% |
| Summer | -4.98% | 1.53% | 10.01% | -12.17% | 2.15% | 1.39% |
| Autumn | -27.70% | 12.85% | 4.37% | -15.42% | 8.75% | 4.71% |
| Winter | 16.57% | 2.46% | 20.91% | -9.69% | -8.36% | -22.67% |
| Annual | -8.19% | 3.46% | 6.03% | -11.62% | 3.06% | 4.52% |

No significant trend is recorded in the results of linear test of summer and autumn precipitation. 5-year moving average analysis reflects similar wet-dry fluctuations in summer and autumn (see Fig.2a and Fig.3a). Also the results of precipitation anomalies in decadal scale in summer are in good

agreement with the results in autumn. Dry years are found in the late 1950s and 1980s, and wet years are found in the 1960s, 1970s, 1990s, and afterwards until the end of the examined period (see Table 2). MK trend test shows that summer precipitation began to fluctuate since the late 1950s, and the abrupt change is occurred in 1961 and1965 (see Fig.2b). In autumn, the application of MK test cannot identify an observable trend and the abrupt change is found in different decades (see Fig.3b).

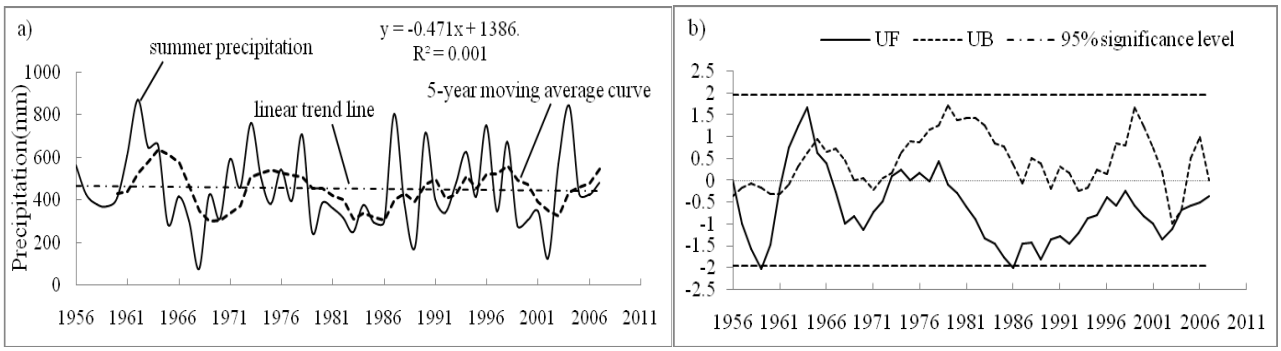

Fig. 2 Trend analysis of summer precipitation

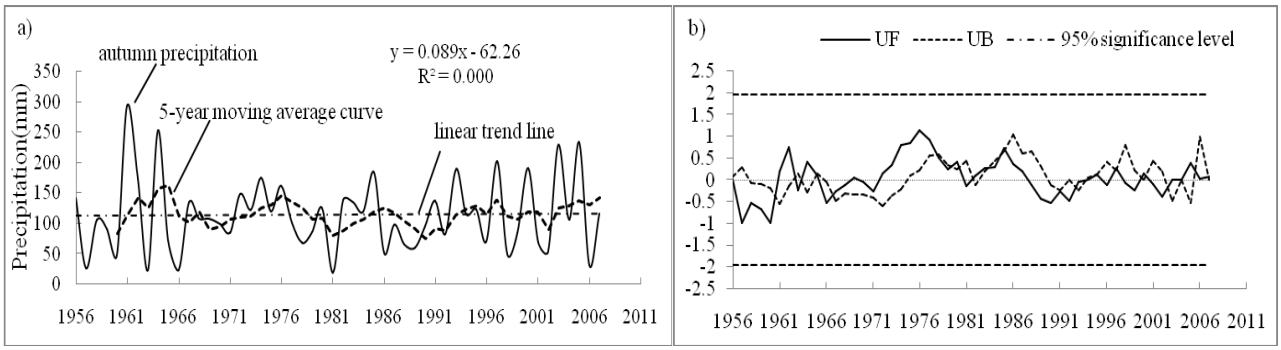

Fig. 3 Trend analysis of autumn precipitation

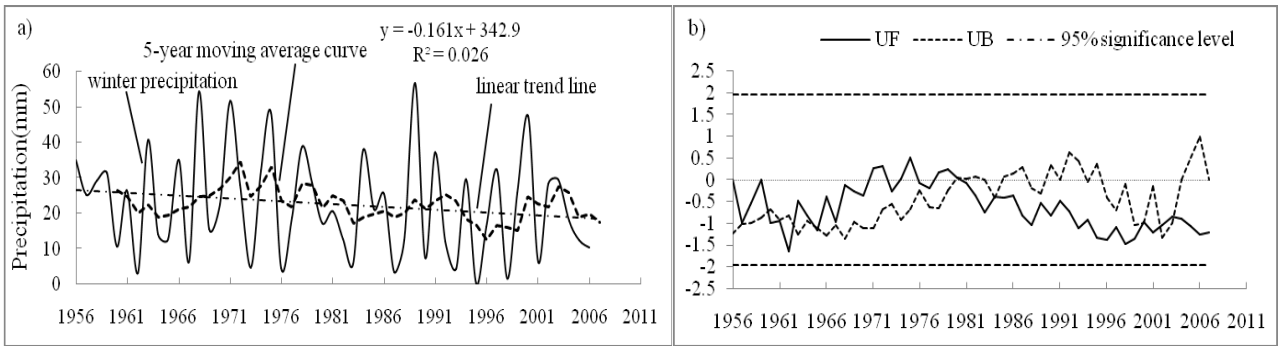

Fig. 4 Trend analysis of winter precipitation

The precipitation trend in winter is decreasing over time (see Fig.4a). Wet years are recorded since the 1980s and dry years afterwards (see Table 2). The MK test indicates twice abrupt changes in 1963 and 1980 (see Fig.4b).

**Trends for annual precipitation.** As shown in Fig. 5a, no significant linear trend is found in annual precipitation. The 5-year moving average curve has the same fluctuations with summer months. The change of anomalies in decadal scale (see Table 2) and UF curve of the MK test (see Fig.5b) are also consistent with the trend in summer. Abrupt changes are mainly recorded in the 1960s and after 2000. These results show the dominant contribution of summer rainfall to the whole year, and the positive trend in spring and the negative in winter have little impact on it.

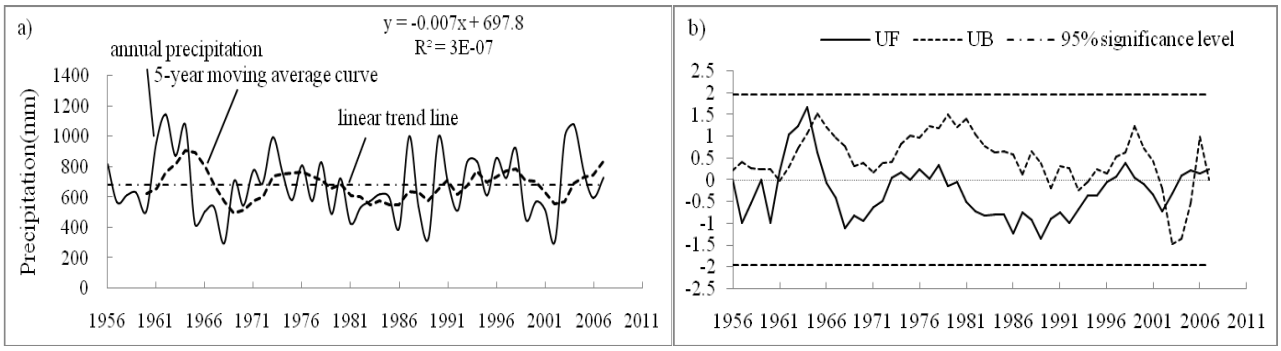

Fig. 5 Trend analysis of annual precipitation

## Conclusions

The Hsiao-Ching River basin in Jinan city has an average annual precipitation of 682.8mm and it is very unevenly distributed. The percentage during summer reaches 66.4% of the year, the autumn and spring follow up and the winter only accounts for 3.3%. The wet period in spring season is recorded in the 1990s and afterwards. An increasing trend in spring precipitation starts in 1978 and becomes sharp after 2002, reflecting the possibility of a continuously positive trend in the future. The decreasing trend is found in winter season and begins in 1980. Then the dry period occurs after the 1980s. As for summer and autumn, no significant trend is found and the wet and dry period almost occurs alternately. The abrupt change in summer precipitation is recorded in 1961 and 1965, and in autumn is found in different decades.Abrupt changes of yearly precipitation are recorded in the 1960s and after 2000. The same trend and fluctuations are observed between summer and annual precipitation, recognizing the main influence of the summer season.

# Research on Structure Design of U type canal of seepage-proofing

Jinglu Sun[1, a], Bing Zhang[1, b],Shoujie Zhang[1,c]

[1] Heilongjiang Province Key Laboratory of Engineering in seasonal frozen soil area, Heilongjiang Academy of water conservancy, 150080, China

[a]sunjinglu74@163.com

**Keywords:** Structure design, U-type canal, Seepage-proofing.

**Abstract.** New U (moment) implements the optimum water section of rectangular slot structure, besides all advantages of the traditional U and T-shaped slot in the canal seepage, also has advantages of reducing covers area of higher performance and price ratio. The kind of canal seepage control structure is upgrading products of the traditional U and T-shaped slot. In this paper, through design research on new U (moment) slot structure, giving U (moment) slot structure size, it can provide technical support for the product development of new type U (moment).

## Introduction

"U" shaped groove structure widely has been used in water conservancy project, especially in the small and medium-sized sluice dam, culverts, and aqueduct, and this structure form was used usually for import and export connection segment [1].U-shaped channel slot is the best form having integrated hydraulic, engineering economy, covers an area and so on[2]."U" shaped section is close to the best water hydraulic cross section of concrete channel. Wetted perimeter is shortest, and mechanical performance is good. Good anti-seepage effect, simple construction, quick progress, integrity is strong [3-8].The kind of structure can reduce the loss and the dosage of concrete in construction process, shorten the construction period, and reduce the project cost. It can alleviate the traffic inconvenience, such as better seepage prevention effect, improve the utilization of water resources, and achieve the goal of the water-saving irrigation [9].

According to statistics of the ministry of water resources of rural water conservancy department, at present, in our country defense system of floods integrated is not perfect enough, for a long time, our country irrigation district ageing, disrepair, functional decline phenomenon such as common, especially the field channel is not perfect, benefit of water conservancy facilities is difficult to play. Most of the irrigation and water conservancy facilities in our country were planned in the sixties and seventies of the last century, farmland irrigation and drainage system, inefficient irrigation and drainage channels. With the development of the new rural construction, energy saving, environmental protection, improve productivity have become the urgent need, a large number of promotion in farmland channel system concrete u-shape canal engineering can effectively exert the benefit of irrigation and water conservancy facilities. Concrete u-shape slot is used in concrete masonry materials of plain concrete or reinforced concrete channels. Because cast-in-situ construction of U slot is difficult, the current use prefabricated more. Usually length is 50-100cm, cross-sectional size is 30-100cm, with wide groove depth of 25-100cm, wall thickness of 3 ~ 5cm. there was a kind of the homemade steel model, with a small vibrator inserting vibrating. But concrete needs certain curing period, so it is not economic to adopt a lot of steel model in period of construction. Also having the method of vibration precast and rolled plate way such as prefabricated concrete u-shaped slot, but quality of the u-shaped was poor[10-11].

As development of comprehensive agricultural and increase of basic farmland water conservancy project investment, u-shaped channel has been more and more widely used. So the design and related technology of the u-shaped channel is very important [12]. In 2011 the Central Committee issued 1 document, holding the highest specifications of water conservancy work conference, starting in 2012 four provinces in the northeast "save and increase food operation". But under the lateral canal to the field "last one kilometer" is the most weak link, irrigation and water conservancy is low standard,

poor matching, aged disrepair and benefit attenuation, "the last kilometer" problem of farmland irrigation and drainage is increasingly prominent.

## Research on new U (moment) tank structure design

**Formulate concrete technology parameters of new type U (matrix).**The compressive strength of concrete is C50, frost resistance coefficient is F300.

**Structure size design of new U-shaped (moment) slot.** New U (moment) slot structure diagram is shown in Fig.1 and Fig.2. New u-shaped groove parameters (matrix) are shown in Table 1.

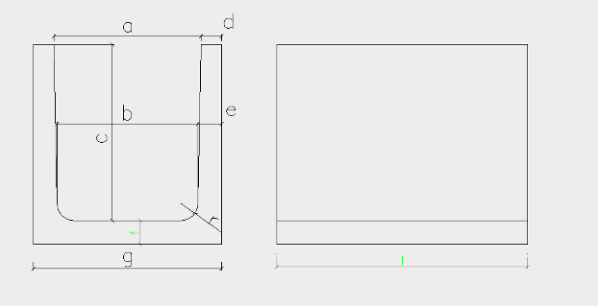

Fig.1. New type U (moment) diagram

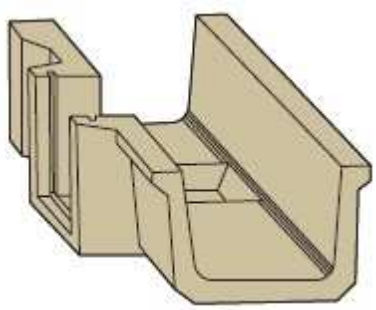

Fig.2. Intake schematic

Table1. New u-shaped groove parameters (matrix)

| Specifications | Section size (mm) | | | | | | | | | quality (kg) |
|---|---|---|---|---|---|---|---|---|---|---|
| | a | b | c | d | e | f | g | r | l | |
| 300*400 | 300 | 270 | 400 | 40 | 55 | 55 | 380 | 40 | 2000 | 295 |
| 400*500 | 400 | 360 | 500 | 40 | 60 | 60 | 480 | 60 | 2000 | 394 |
| 500*600 | 500 | 460 | 600 | 70 | 90 | 80 | 640 | 80 | 2000 | 720 |
| 600*700 | 600 | 550 | 700 | 70 | 95 | 95 | 740 | 80 | 2000 | 929 |
| 1000*1000 | 1000 | 920 | 1000 | 80 | 120 | 120 | 1160 | 100 | 2000 | 1696 |

**Stability calculation of new type U (moment).** According to reference literature [13], stability analysis and calculation of design strength grade of concrete is C30, strength of concrete tensile is $R = 17.5kg/cm^2$, the safety factor is $k = 2.5$, plastic influence coefficient of the tension zone of the concrete $r = 1.55$ and wet density of soil $\gamma = 1.8t/m^3$, internal friction Angle $\Phi = 26^0$, the bending moment of the concrete can satisfy the demands of earth negative bending moment. The concrete is C50 and is adopted for copper coated fiber in this article, so its tensile strength is higher.

## Construction technology of new type U (moment)

**Construction machinery and equipment.** Farm transporter can be adopted that is suitable for agricultural transportation in the field. According to the engineering actual situation, a certain type of excavator was adopted. New bucket shape is triangle width not less than 2200 mm.

**Construction process of new type U (moment).** construction process of new type U (moment) irrigation canal seepage is including of construction preparation, earthwork excavation and filling to check slot, canal bottom sand cushion layer , transportation, bonding expansion water sealing strip, reviewing elevation - lifting new type U (torque) , backfill components ,testing, inspection and completion of acceptance. The Construction process was shown in Fig.3.

(a) (b)

(c) (d)

(e) (f)

Fig.3. Construction process

**Technology advantage of New type U (moment) construction**

Length of new U (moment) slot is 2000 mm, is four times for a traditional u-shaped channel seepage of trapezoidal channel of the length of 500 mm. water inlet, complete equipments and supporting components are easily installed, simple, more convenient and quick construction speed. Construction mechanization degree of new U (matrix) slot is high and easy to control quality.

**Conclusions**

Prevention effect of prefabricated u-shaped slot is good as a kind of channel lining material. Because it can focus on production, technology is simple, easy to guarantee quality. Because of the continuous manufacture of u-shaped slot, the thinner of thickness determines the characteristics of its low cost. Because its contact area is large with the ground, so the foundation of strong adaptability, poor geological place still can be use.

It is suitable for small and medium-sized water channel, and U-shaped slot is not affected by the influence of underground water, soil, topography, climate, such as irrigation channels. It is very convenient for demolition if the line will be reformed, so the kind of structure has very good adaptability and flexibility.

New type U (moment) product truly achieve the best filling cross-section. Besides having the advantages of traditional u-shaped slot in the canal seepage, but also having high mechanical properties, excellent durability, good environmental performance, assembly quality and high cost performance. The structure is a kind of upgrading products of the traditional U-shaped slot. It can solve "the last kilometer" problem of the farmland irrigation channels. Through the research on the new type U (moment) construction technology, the technology can for provide the reference for product application of the new type U.

**Keywords:** Estuary with Sluice；Numerical Model；Sediment Transport；Siltation Characteristics

**Abstract.** Siltation in the rivers downstream of floodgates is serious in China, making the discharge capacity of rivers decrease obviously and threatening the flood control in upper rivers. Tidal wave deformation is one conclusive dynamic factor leading to siltation downstream of floodgates in estuaries. A 2-D numerical model of tide and sediment transport is established to simulate the distribution of sediment siltation downstream of the floodgate, and several conclusions are obtained in this paper which can provide some theoretical basis for the prediction and analysis of the siltation characteristics in lower reach caused by floodgates in estuaries.

## Introduction

In order to defend against tides for the development of agricultural production, lots of sluices have been built in coastal areas of China since 1950s, with the number of about 300 now. Siltation in the rivers downstream of floodgates is very serious in China and according to statistics, among the 58 sluices with the drainage flow of over 100$m^3$/s in Jiangsu province, 5 almost are silted up, 15 are in severe siltation and the other 38 are relatively less silted. Besides, in the 35 estuaries with sluice constructed in Haihe River basin, there are 22 in serious siltation, where the upper and lower reaches are universally silted, causing the river drainage capacity reduced by 60%. Siltation in the rivers downstream of floodgates makes the discharge capacity of rivers decrease obviously and threatening the flood control in upper rivers, and influencing the agricultural production. Therefore, it is vital to do research about siltation downstream of floodgates.

Study on siltation downstream of floodgates in China began with research on Sheyang estuary by G.R. Dou (1963), showing that tidal wave deformation was main factors leading to sedimentation downstream sluice. Tidal wave deformation and reflection usually occur under the influence of river morphologic resistance when it comes into the estuary, which will be more evident in the estuaries where floodgates have been built. Tidal wave will be reflected fully by floodgate, and tidal wave properties change from progressive wave to standing wave, there being a significant phase difference between hydrographs of flow velocity and tide level. Besides, high tide level rises while low tide level goes down, duration of flood tide is shortened and mean depth of flood tide decreases while those of ebb tide go opposite. Therefore, flow velocity of flood tide increases and that of ebb tide decreases, respectively. Sediment transport capacity of flood tide is enhanced relative to ebb tide due to the change of hydrodynamic characteristics, so that the sediment which is carried into the river by flood tide cannot be taken back to estuary by ebb tide, and then deposited in the lower reach downstream the floodgate.

## Numerical Model and the Calculation Schemes

To study the sediment characteristics in lower reach caused by floodgates in estuaries, a 2D numerical model of the tidal currents and sediment transport is built based on the prototype of the floodgate in the estuary of the Sheyang River. The actual morphology of the estuary of the Sheyang River is simplified and applied as the open sea condition of the model. The open boundary of the model is about 12 km from the estuary, near the -15m contour. In addition, the area covered by the model between its South and North boundaries is about 21km wide (Fig.1). In the model, the approach channel was simplified into a 10km-long and 660m-wide compound channel. The bottom of the inner passage of the approach channel is about 220m wide, with its elevation at -9.0m. Side slope of the passage is 1:8, and the bottom elevation of the point bar is at about 0.0m.

The hydrodynamic boundary condition of the model is designed on the basis of the actual condition in the estuary of the Sheyang River. The high tide level is at 3.75m and the low tide level is 0.75m (Fig.2). The hydrodynamic condition of the open sea remains unchanged in the study. Fig.3 is the calculation topography and grid of the numerical model, the calculation grid number is 125×101=12625. The grids in lower reach of floodgates are refined, and the minimum feature size is 15m, the maximum feature size 400m in coast outside.

Fig.1 Domain of model boundary

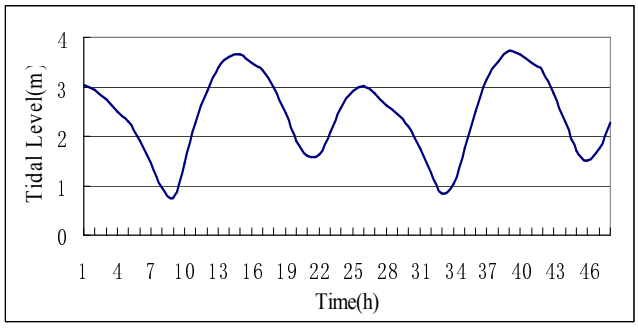

Fig.2 Design curve of tide on outer boundary

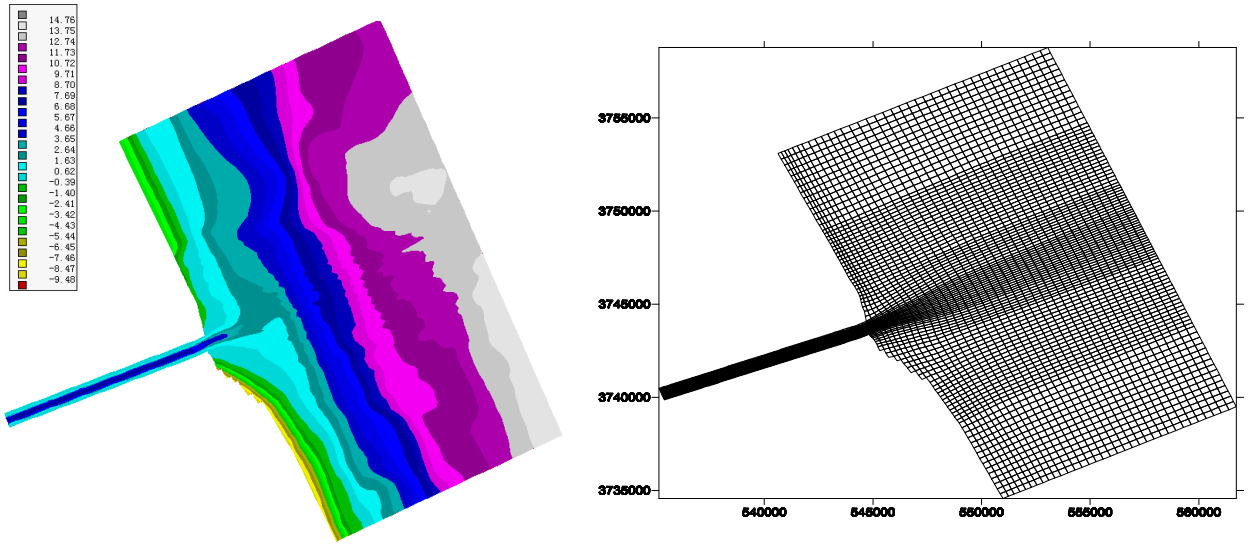

Fig.3 The calculation topography and grid of the numerical model

The continuity equation, momentum equation of tidal current and sediment transport equation in numerical model are discretized using FVM (Finite Volume Method):

$$\frac{\partial \varsigma}{\partial t}+\frac{\partial Hu}{\partial x}+\frac{\partial Hv}{\partial y}=0 \tag{1}$$

$$\frac{\partial Hu}{\partial t}+\frac{\partial Huu}{\partial x}+\frac{\partial Huv}{\partial y}=-gH\frac{\partial \varsigma}{\partial x}-\frac{\partial H\overline{u'u'}}{\partial x}-\frac{\partial H\overline{u'v'}}{\partial y}+\frac{\tau_{sx}-\tau_{bx}}{\rho}+fHv \tag{2}$$

$$\frac{\partial Hv}{\partial t}+\frac{\partial Huv}{\partial x}+\frac{\partial Hvv}{\partial y}=-gH\frac{\partial \varsigma}{\partial y}-\frac{\partial H\overline{v'u'}}{\partial x}-\frac{\partial H\overline{v'v'}}{\partial y}+\frac{\tau_{sy}-\tau_{by}}{\rho}-fHu \tag{3}$$

$$\frac{\partial HS}{\partial t}+\frac{\partial HuS}{\partial x}+\frac{\partial HvS}{\partial y}=\frac{\partial}{\partial x}(H\varepsilon_x\frac{\partial S}{\partial x})+\frac{\partial}{\partial y}(H\varepsilon_y\frac{\partial S}{\partial y})+\alpha\omega(S_*-S) \tag{4}$$

River bed evolution can be calculated by next formula:

$$\gamma_0\frac{\partial \eta_s}{\partial t}=\alpha\omega(S-S_*) \tag{5}$$

Incipient motion estimate formula of cohesive sediment and sediment transport capacity of tidal currents and waves are key parameters in numerical model of tide and sediment transport. Dou (1999) analyses the group characteristics and the movement characteristics of cohesive sediment, and deduced a calculation formula for starting velocity including bulk density effect, according to the effect of cohesive force between fine particles, water depth and bulk density etc.

$$u_c=k'\left(\ln 11\frac{h}{\Delta}\right)\left(\frac{\Delta}{\Delta_*}\right)^{1/6}\sqrt{3.6\frac{\rho_S-\rho}{\rho}gd+(\frac{\gamma_0}{\gamma_0^*})^{2.5}\frac{\varepsilon_0+gh\delta(\delta/d)^{1/2}}{d}} \tag{6}$$

Where $k'$ is coefficient ($k'$=0.26 for impending motion, $k'$=0.32 for little motion, $k'$=0.41 for general motion), $\Delta$ is the roughness height of bed surface ($\Delta$=1mm for d$\leqslant$0.5mm, $\Delta$=2d for d>0.5mm), $\Delta_*$=20mm, $\rho_S$ and $\rho$ are the density of sediment particles and that of water respectively, $\gamma_0$ and $\gamma_0^*$ are the dry volume weight and the stable dry volume weight of the sediment on the bed surface. $\varepsilon_0$ is synthetic parameter of cohesive force whose value is related to the physcical and chemical properties of the particle materials, and also to the origanic content and siltation environment for cohesive soil, $\varepsilon_0$=1.75cm$^3$/s$^2$ for natural sediment. $\delta$ is the parameter of water film thickness, and $\delta=2.31\times10^{-5}$cm.

Luo (1997) deduced a calculation formula for sediment transport and carrying capacity for different wet densities of fluid mud, an overall verification of the calculation formula is made, and satisfactory results are obtained, showing that the calculation formula can be used as practical formula for the study of engineering-related sediment problems.

$$S^*=0.296\gamma_s\left(\frac{\gamma}{\gamma_w}\right)^{12.8}\frac{V^2}{gD} \tag{7}$$

Where $\gamma_w$ is wet densities of fluid mud，$\gamma$ is densities of water, $\gamma_s$ is densities of sediment, $V$ is water velocity under the common action of tidal currents and waves, $D$ is water depth.

**The Siltation Characteristics in Lower Reach Caused by Floodgates**

The change curve of tidal level, current velocity and sediment concentration where is 4km length downstream floodgates are shown in Fig.4. It shows that hydrodynamic characteristics changed after building sluices include the duration and mean water depth of flood tide decreases, the averaged velocity of flood tide increases while those of ebb tide change in the opposite direction, and the high tide level is heightened while the low one goes lower. Flow velocity of flood tide increases and that of ebb tide decreases, respectively. Sediment concentration of flood tide is enhanced relative to ebb tide due to the change of hydrodynamic characteristics, so that the sediment which is carried into the river by flood tide cannot be taken back to estuary by ebb tide, and then deposited in the lower reach downstream the floodgate.

Fig.5 shows the distribution of sediment siltation downstream the floodgate which simulated by numerical model. It can be found that deposition thickness near the floodgate is larger than siltation thickness in estuarine, there is a slope from floodgate to estuary. The distribution characteristics of sediment siltation downstream the floodgate keeps consistent with the measured data.

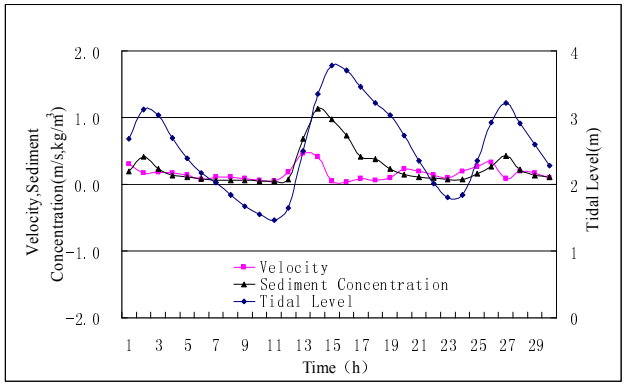

Fig.4 The change curve of tidal level, current velocity and sediment concentration

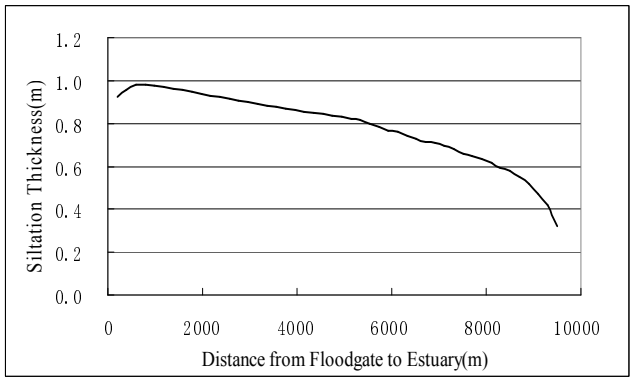

Fig.5 The distribution of sediment siltation downstream the floodgate (one year)

## Conclusions

The simulation results of tide current and sediment transport numerical model show that tidal wave deformation after building sluices makes the ratio increases of flood tide velocity and ebb tide velocity, and the sediment which is carried into the river by flood tide is larger than by ebb tide. Because coastal bottomland can provide enough sediment resource in the period of flood tide, while sediment deposited in lower reach of floodgates can't be eroded by bb tide. The simulation results can reflect the processes of siltation downstream the floodgate in estuaries.

**Keywords:** hydraulic engineering; earth dam; saturation line; time effect.

**Abstract:** In dam seepage line monitoring process, dam saturation line "inverted siphon" phenomenon appeared. In order to study the time effect, indoor model test were done. The dam seepage line rules and conditions were determined. The results show that when the reservoir water level dips, the dam seepage line with the decreasing of the water level will drop. But the changing has lagged far behind. Hysteresis and permeability dam, seepage path length, the upstream water level and other factors related to the rate of decline.

## Introduction

The dam and homogeneous clay core dam are mostly good clay impervious core wall. Earth dam project management, invasive lines are important means of monitoring and analysis of dam safety. According to some dam monitoring data , the dam seepage line had "inverted siphon" phenomenon contrary to the traditional theory. To further verify and explain these phenomena, it was necessary to theoretical research the dam seepage and infiltration line performance[1]. Model test was designed to study the phenomena.

Based on the experimental data and the theoretical analysis, this paper studied the time effect of rock fill dam seepage line. The dam seepage line rules and conditions were determined. Its particularity and universality was studied and a universal theory was found. Traditional theory of seepage line was fixed. Water levels fall in the front of the dam and dam body seepage line within will be reduced with the decreasing of water level before dam. Analysis and interpretation of the causes of the phenomenon and the factors were useful to guide project management and ensure the safety of the dam.

## Model test

### Similarity scale

The most intuitive way to research dam seepage problems was sand tank model tests. In order to re-play the natural state of water, the model must be based on a certain scale than similar criteria.

Its initial state was bound to be established on the downstream water level when unsteady seepage caused by water level falling was considered[2]. A certain moment, the steady flow field, the time scale is the same as the stable seepage[3]. Generally take prototype model materials natural material, so that make the model and the prototype of the hydraulic gradient and the permeability strength were completely equal, in order to maximize the prototype situation.

### Model dimension

Homogeneous earth dam of cohesive soil was used in model. The length of the general hydraulic structure model scale was 20 ~ 120 . According to reservoir dam section size, typical model was 1.0 m high and 0.2 m wide. Dam bottom width was 2.5 m[4]. Along the dam axis length was 1 m. In order to protect the dam slope stability, dam upstream and downstream dam surface used geotextile and sandy pebble slope, model section as shown in Fig.1.

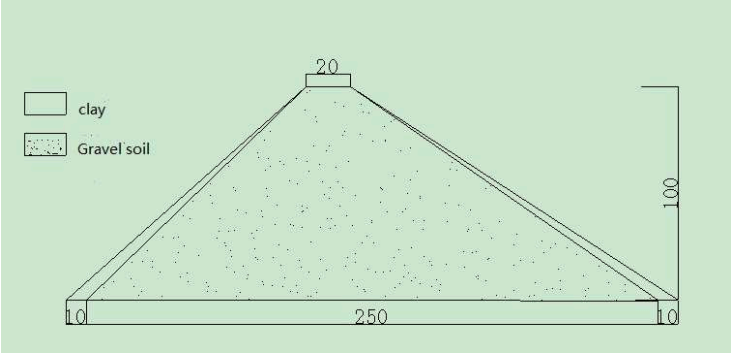

Fig.1 Cross-sectional dimension of model(unit: cm)

According to the similarity criterion, the 1/40 scale model was designed and placed in the tank model.Using 10 mm thick steel plate as the model of tank, the main stress components at the same time to facilitate the observation experiment phenomenon[5].For easy observation of the change of water level, piezometric tube arranged at the side of the glass. Piezometric tube arrangement was shown in Fig.2.

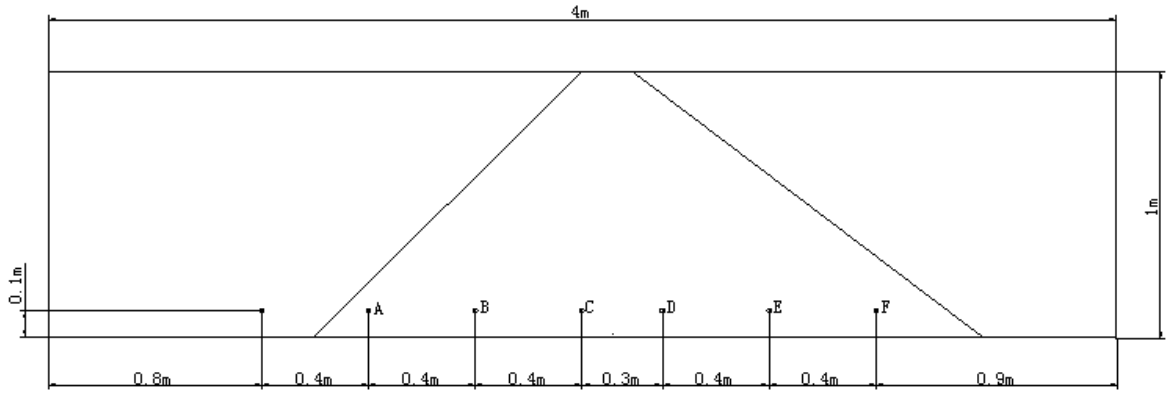

Fig.2 Piezometric tube arrangement

Toughened glass was used on both sides . The strength of toughened glass was big and had high transparency.This could ensure the safety in the process of observation.The casing cofferdam contacted surface with model to prevent steel corrosionand the relative slip crack leakage, etc. In order to prevent the dam and model slot interface around the seepage phenomenon, rubber strips were prepared in the tub. Detailed design was shown in Fig.3.

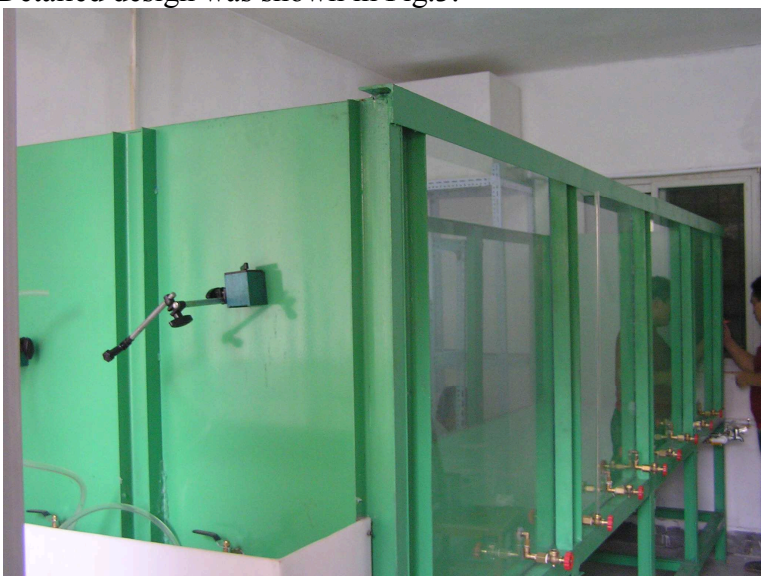

Fig.3 Sand tank model experimental device

## Result Analysis

### Hysteresis

Three groups of model test results showed that when the water level upstream of the dam became lower, the saturation line will decreased with the decreasing of the water level. But changes in the dam seepage line laged behind the dam water level. Fig.4 was the result of second model.

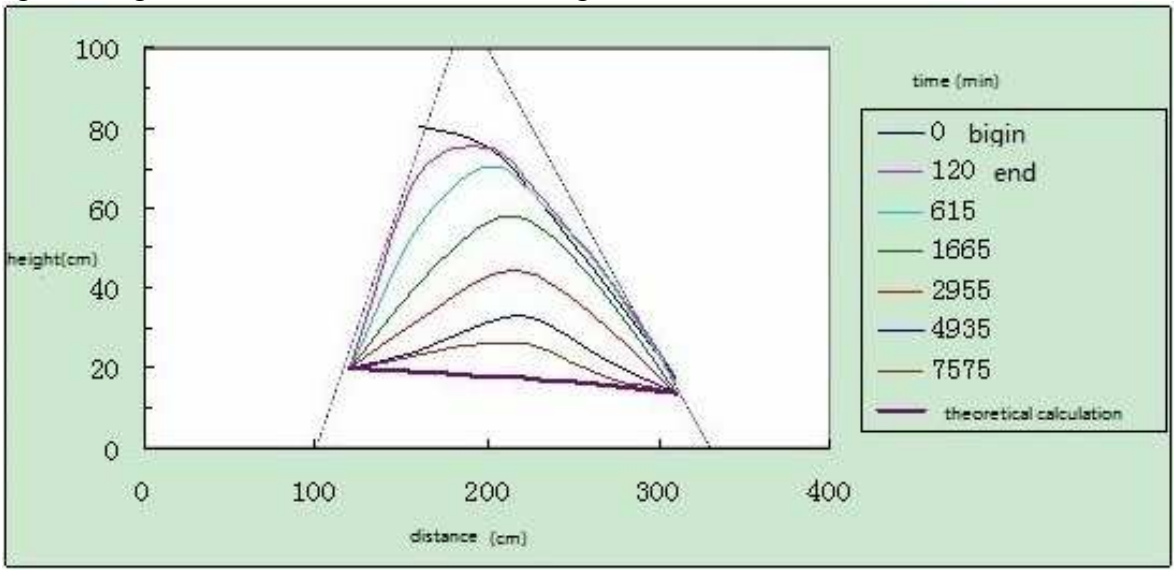

Fig.4 The result of second model.

The time to start was made zero moment. As can be seen from the Fig.4, the dm seepage line had obvious hysteresis, saturation line shaped like a parabola opening down. When the saturation line stability, its shape was still a certain degree of anti-arc. The highest point of the dam seepage line growth in the horizontal position changing over time, beginning with the passage of the downstream direction, after a period of time and gradually moved back upstream.

### Lag time

Analysis the difference of the testing process of each piezometric water level and the actual measured value between the final stable value over time change process, the length of the lag time would be ensured. Fig.5 was the second set of model test measured pressure tube dam water level and the actual measured value difference between the final stable value over time diagram, take time to turn on the water started at time 0.

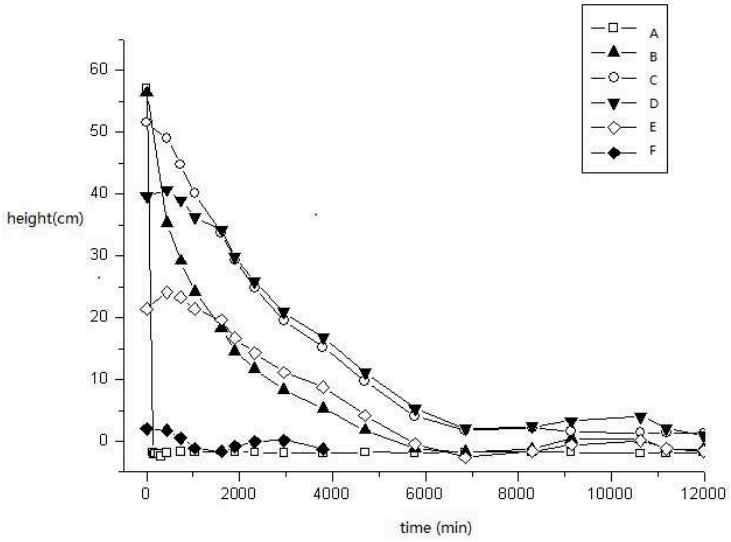

Fig.5 The stability of piezometer

As can be seen from the Fig.5, the decline in the water level of the dam, different piezometer location, the water level changed at different rates, piezometric level changed in the middle of the dam slow, steady time was needed.

## Conclusions

Water levels fall in the front of the dam and dam body seepage line within will be reduced with the decreasing of water level before dam. It lags the changing of water level in the front of the dam.

By comparing the experimental model, the dam and the dam seepage line lag time was related to filling density (permeability) . The more loose, the bigger the permeability coefficient, the shorter the saturation line lag time; The larger dam filling density, the smaller the coefficient of permeability.

Time to turn on the water level drops the total time of 2/3, the effects of lag on the upstream slope of the dam seepage stability and strength and stability of the dam saturation line the largest reservoir in the actual operation of the process, the time should be strengthened and dam seepage stability monitoring.

**Keywords:**Environment temperature, Irrigated area, Temperature rebound, Thermal conductivity, Simulation analysis, Heat preservation benzene board

**Abstract.**For a temperature rebound in the irrigated high arch dam during the construction period, using finite element method to research the influence of environment temperature to temperature rebound of the irrigated high concrete arch dam. Assuming that the initial temperature of the dam concrete is the joint grouting temperature. This paper presents a simulation of the temperature rebound of the high arch dam which is caused by the monthly average environment temperature, and performs sensitivity analysis to research the influence of thermal conductivity and surface heat preservation on the temperature rebound. According to the analysis,when the high arch dam sealing temperature is lower than the dam site annual average temperature, the dam site temperature inevitably would flow backward,slowly,to the irrigation area.The larger the thermal conductivity is,the quicker the temperature rebound speed will be. And benzene board insulation can reduce concrete temperature rebound rate, if the heat preservation benzene board is thicker,the temperature rebound rate is smaller.

## Introduction

When the age of concrete of high arch dam reaches more than 120 days, and the temperature of concrete reaches the sealing temperature, then begin to conduct joint grouting. Sealing temperature is the reference temperature of temperature load in arch dam, it directly influences the arch dam rising temperature load and dropping temperature load. If the sealing temperature is low, it will be beneficial to reduce the tensile stress in the dam, currently we usually conduct joint grouting at annual average temperature or slightly below the annual average temperature. Take Ertan dam, Xiaowan, Xiluodu and Jinping high arch dams for example, the annual average temperature at dam site are 19.8 ˚C, 19.1 ˚C, 19.7 ˚C and 17.2 ˚C respectively, and Sealing temperature are 12.0 ~ 16.0˚C, 12.0 ~ 17.5˚C, 12.0˚C~ 16.0˚C and 13.0˚C~ 15.0˚C respectively. And it will take several years to construct mass concrete before water storage. In recent years, high concrete arch dam temperature monitoring shows that there is a great temperature rise in joint grouting area (already irrigated area) after the end of the second-phase water circulation , even some irrigated area has 3 ~ 4˚C temperature rebound after 180days~360days. The great temperature rebound and the lasting time are considered by construction units. High arch dams generally use high content fly ash concrete, for example, the mixing quantity of fly ash is 30% in Xiaowan and Ertan ,it is 35% in Xiluodu and Jinping. Since the hydration of fly ash concrete depends on the CaO,which is the secondary product of cement hydration, therefore the heat release speed is slow, Zhang Guoxin etc.[1] consider that late heat release of high content fly ash concrete is the main reason of temperature rebound of irrigated area, during the middle cooling circulation, the age of concrete is long enough, although majority of the cement hydration heat release has been complete, the high content fly ash concrete will continue to release heat slowly for a long time. For the joint grouting temperature is below the dam site annual average temperature, Huang Yaoying etc.[2] analysis the temperature rebound based on the theory of natural cooling circulation or temperature rebound , in his opinion , he maintains that the main reason of temperature rebound is the environment temperature flowing backward slowly to the irrigated

area. That the physical causes of a temperature rebound whether is mainly caused by high content fly ash late heat release or by environment temperature flowing backward is still controversial. So this paper analyzes the influence of environment temperature to internal temperature of high concrete arch dam with temperature field simulation program. Due to the heat preservation effect of upstream and downstream of benzene board has a great influence on calculation results, we perform sensitivity analysis with the equivalent heat transfer coefficient on it.

**Quasi Stable Temperature Field Calculation Principle**

Mass concrete temperature heat conduction equation is as follows[3]

$$\frac{\partial T}{\partial \tau} = a\left(\frac{\partial^2 T}{\partial x^2} + \frac{\partial^2 T}{\partial y^2} + \frac{\partial^2 T}{\partial z^2}\right) + \frac{\partial \theta}{\partial \tau} \tag{1}$$

Where $a$ is thermal diffusivity , it can be expressed as $a = \frac{\lambda}{c\rho}$, and $a, \lambda, \rho$ is thermal conductivity, specific heat and density respectively.

To the irrigated high concrete arch dam, because the age of concrete has reached more than 120 days, most of the cement hydration heat release has been complete.Currently we are lack of adequate analytical data on high content fly ash late heat release, this paper mainly studies the influence of environment temperature to temperature rebound of the irrigated area.Assuming irrigated concrete $\frac{\partial T}{\partial \tau} \neq 0$, $\frac{\partial \theta}{\partial \tau} = 0$. so Eq.(1) can be simplified as quasi stable temperature heat conduction equation

$$\frac{\partial T}{\partial \tau} = a\left(\frac{\partial^2 T}{\partial x^2} + \frac{\partial^2 T}{\partial y^2} + \frac{\partial^2 T}{\partial z^2}\right) \tag{2}$$

During construction period, because both upstream and downstream are cofferdam, dam has not yet been filling , so the irrigated area is belong to the third temperature boundary condition

$$-\lambda \frac{\partial T}{\partial n} = \beta(T - T_a) \tag{3}$$
