**Abstract：** In conventional analysis methods of soil slope, we must presume potential sliding surface at first and then gain the safety factors, judge the stability of slope by the safety factors. In fact, if we know a slope is unstability but don't know where will be slide or failure, we can't adopt effective measures to support and prevent the sliding accidents appearing. This paper use RFPA-Centrifuge to numerical simulate the failure of soil slope with different support measures without presume any potential sliding surface, success to gain the failure process and the corresponding safety factors. From the calculate results of RFPA-Centrifuge, we can find where is the first failure point and all the slide mass. So if we can use good analysis software to simulate the failure process of slope and adopt corresponding support measures before the engineering beginning, the stability of slope will be better and the accidents will be disappeared or reduced.

## Introduction

In conventional analysis methods of soil slope, we must presume potential sliding surface at first and then gain the safety factors, judge the stability of slope by the safety factors[1-3]. In fact, if we know a slope is unstability but don't know where will be slide or failure, we can't adopt effective measures to support and prevent the sliding accidents appearing. The authors of this paper hope to resolve above problems through a numerical analysis method.

## Essential Principle

RFPA (Realistical Failure Process Analysis) is a professional series software to failure process analysis in geotechnical engineering. RFPA-Centrifuge is based on the principle of geotechnical centrifuge model tests, the weights of all cells are increased step by step in a certain coefficient, without change other parameters. At first to calculate stress for given increment of weight in every step, and then check every cell based on a certain criteria, increase next increment and calculate next step if every cell has not change, calculate stress again in current step if some cells be changed until no new changed cell is checked. Repeat continually above process, the relatively weak cell will failure when the load stress over its carrying capacity. The macroscopical failure surface will be transfixed with the amount of fail cells increase continually [4].

## Unstable Criterion

There are two primary unstable criterions in slope analysis software, the first criterion is regarding convergence as the unstable indication of slope which adopting stress and displacement to getting answers in calculate process of finite element methods, the second criterion is regarding connectedness of strain from slop toe to crest as the unstable indication of slope. The finite element calculate adopt whole loading in RFPA-Centrifuge, there are converge results every step, so this method regard the max failure elements as the unstable indication of slope. RFPA-Centrifuge will record automatically the number of failure elements in every loading steps, so this method judge the stability of slope is simple and effective.

The safety factor of RFPA-Centrifuge is defined with the specific gravity of element which failure surface connected divide the initial specific gravity of element, equation is following:

$$\gamma=\gamma_0[1+(n-1)\times\Delta]$$

remark：γ —— the specific gravity of elements when failure surface connected;
$\gamma_0$ —— the initial specific gravity of element;
n —— loading steps when failure surface connected;
Δ —— centrifuge loading coefficient.

$$K=\frac{\gamma}{\gamma_0}=1+\frac{b}{b_0}\cdot(n-1)\cdot\Delta$$

remark：$K$ ——safety factor，$b_0$——size of prototype，b——size of model.

## Engineering Instance of Soil Slope

There is a typical engineering instance in reference [5], the road between Chongqing to Zhanjiang occured slope slippage in Guizhou province. Undercut slip mass 5-6m cause the slope active and continue development, at last being many slide surfaces in soil and airslake layer. It will cause slip mass slide if dig continue with design parameters. So adopted support measures with anti-slide pile adding pre-stressed anchor cable. Typical cross-section and sketch of finite element strength reduce mesh for landslide are showed in Fig.1 and the mechanical parameters are showed in table 1. The sketch of RFPA-Centrifuge is showed in Fig.2, including only anti-slide pile model and anti-slide pile adding pre-stressed anchor cable model.

Table.1 Mechanical parameters of the slope

| Material name | Weight /KN.m$^{-3}$ | Elasticity modulus /MPa | Poisson's ratio | Cohesive strength /kPa | Internal frictional angle /(º) |
|---|---|---|---|---|---|
| Slip mass | 21 | 30 | 0.30 | 25.5 | 24.5 |
| Sliding bed | 24 | $10^5$ | 0.25 | 200 | 30.0 |
| pile(C25concrete) | 24 | $2.9\times10^4$ | 0.20 | Regarding elastic material | |

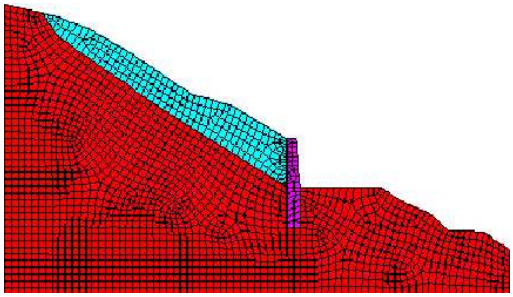

Fig.1 Typical cross-section and sketch of finite element strength reduce mesh for landslide

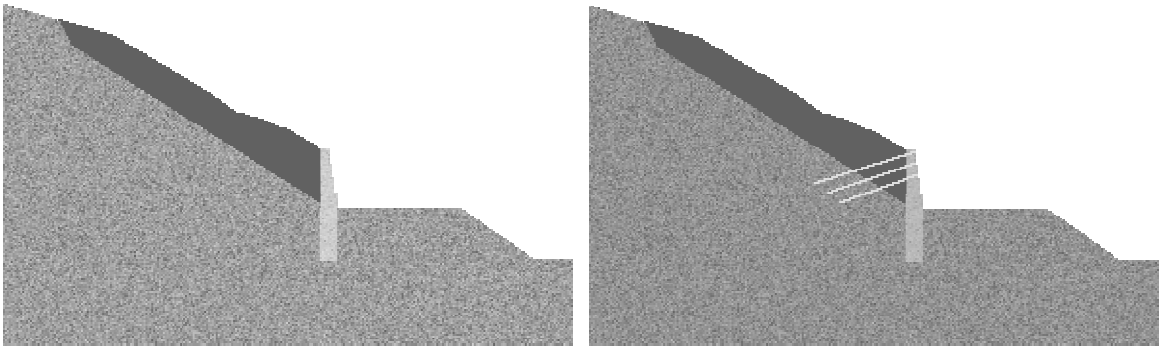
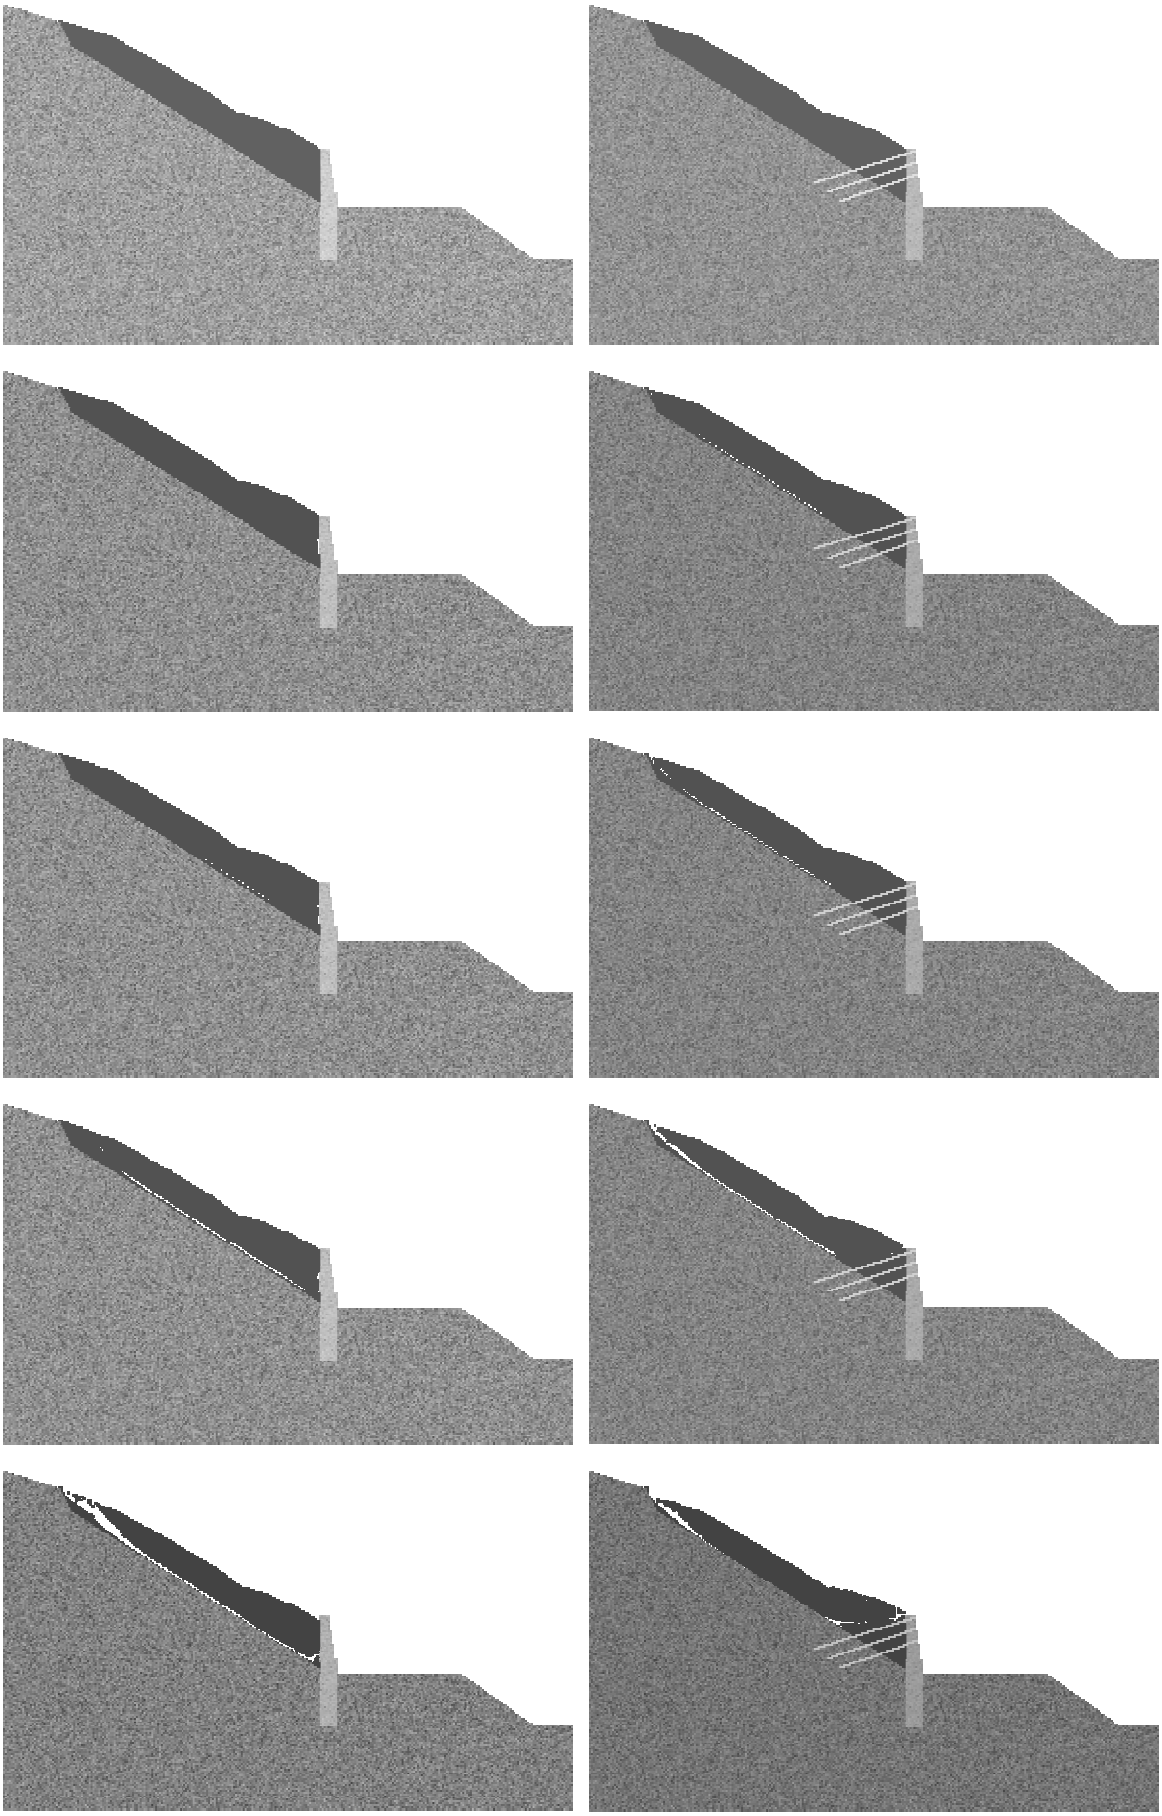


(a) only anti-slide pile (b) anti-slide pile adding pre-stressed anchor cable

Fig.2 Sketch of RFPA-Centrifuge model for landslide

**Numerical Calculation Results**



(a) only anti-slide pile (b) anti-slide pile adding pre-stressed anchor cable

Fig.3 Failure process showed by RFPA-Centrifuge

Fig.3 shows the failure process of landslide with different support measures by RFPA-Centrifuge. From this picture, we can see that the results which anti-slide pile adding pre-stressed anchor cable are same to the result of finite element strength reduce method(showed in Fig.4), the slide surface occurred at the top of anti-slide pile, however the slide surface didn't occurred at the top of the anti-slide pile which adopted only anti-slide pile to support the landslide.

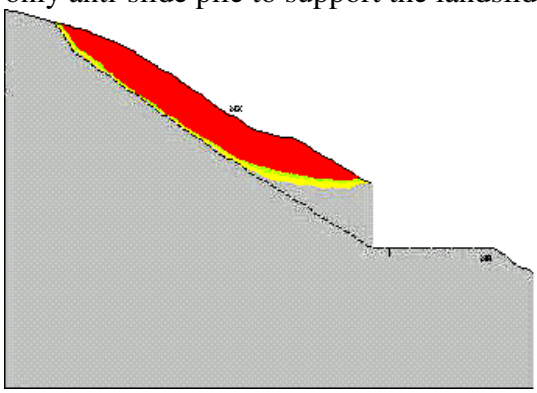


Fig.4 Result of strength reduce method

In calculation results of RFPA-Centrifuge, the safety factor which adopted only anti-slide pile is 1.14, and the safety factor which adopted anti-slide pile adding pre-stressed anchor cable is 1.36. Therefore, we can find that adopted anti-slide pile adding pre-stressed anchor cable, the stability of slope is improved greatly.

## Conclusions

From the calculate results of soil slope with different support measures by RFPA-Centrifuge, we can find that this software can simulate the failure process of slope without presume any potential sliding surface, at the same time we can gain the corresponding safety factors.

Before the engineering beginning, if we can use good analysis software to simulate the failure process of slope and adopt corresponding support measures, the stability of slope will be better and the accidents will be disappeared or reduced.

**Keywords:** MGM (1, n) model, composite foundation settlement, prediction

**Abstract.** In this paper, based on the principle of gray theory, MGM(1,n) multi-variable settlement prediction model was established. Combined with specific examples of projects, settlement of rigid pile composite foundation was predicted, and the prediction results are compared with both prediction results of GM(1,1) gray model which is currently comparatively mature and the settlement observation results. The study shows that it is effective to use MGM(1,n) multivariate gray model to predict composite foundation settlement.

## Introduction

Settlement is an important indicator to measure whether the buildings are security and stability. The purposes of monitoring the composite foundation settlement lie not only in monitoring every moment of settlement in the project, but also in predicting possible settlement at a future time by establishing settlement model which is based on the settlement monitoring data, and then analyzing its security, take measures in advance to minimize or inhibit the harm caused by ground subsidence. Currently, there are a lot of composite foundation settlement prediction methods, such as curve fitting method, regression cut method, determine function method, the gray model method and so on[1]. Composite foundation settlement which is fuzzy and uncertain is affected by many factors. Therefore, to predict foundation settlement using the gray model method which is based on the gray theory is favored by people. Gray theory is to make a scientific prediction of the future state of the system through processing original data, establishing the grey model and calculating the related-parameters of the model. In composite foundation settlement predictions, the gray GM(1,1) model is widely used. Actually, foundation settlement deformations in each monitoring point are not independent, associated with settlement of other monitoring points around and influenced by them. Multi-variable grey model can consider the impact of relevant variables and reflect the settlement law better, thus predict the settlement more accurately [2, 3].

## Establish Multi-Variable Gray Settlement Model

**MGM(1,n) Gray Settlement Model.** MGM(1,n) gray settlement model is a first order ordinary differential equations with n variables. It is promoted from GM(1,1) settlement prediction model in the case of n variables. Let $x_i^{(0)}(k)(i=1,2,\cdots,n)$ be a sequence of n original settlement monitoring, $x_i^{(1)}(k),(i=1,2,\cdots,n)$ is the liner accumulated generating sequence correspondingly, which means

$$x_i^{(i)}(k)=\sum_{j=1}^{k}x_i^{(0)}(j)$$

The first order ordinary differential equations with n variables of MGM(1,n) settlement model is:

$$\left.\begin{aligned}
&\frac{dx_1^{(1)}}{dt} = a_{11}x_1^{(1)} + a_{12}x_2^{(1)} + \cdots + a_{1n}x_n^{(1)} + b_1 \\
&\frac{dx_1^{(1)}}{dt} = a_{11}x_1^{(1)} + a_{12}x_2^{(1)} + \cdots + a_{1n}x_n^{(1)} + b_2 \\
&\vdots \\
&\frac{dx_1^{(1)}}{dt} = a_{11}x_1^{(1)} + a_{12}x_2^{(1)} + \cdots + a_{1n}x_n^{(1)} + b_n
\end{aligned}\right\} \tag{1}$$

Written in matrix form as:

$$\frac{dX^{(1)}}{dt} = AX^{(1)} + B \tag{2}$$

Where:

$$A = \begin{pmatrix} a_{11} & a_{12} & \cdots & a_{1n} \\ a_{21} & a_{22} & \cdots & a_{2n} \\ \vdots & \vdots & & \vdots \\ a_{n1} & a_{n2} & \cdots & a_{nn} \end{pmatrix} \quad ; \quad B = \begin{pmatrix} b_1 \\ b_2 \\ \vdots \\ b_n \end{pmatrix} \quad ; \quad X^{(1)}(t) = (x_1^{(1)}(t), x_2^1(t), \cdots, x_n^1(t))^t$$

Based on integral transformation principle, pre-multiply both side of the equation (2) by $e^{-At}$ can get formula (3).

$$e^{-At}\left(\frac{dX^{(1)}}{dt} - AX^{(1)}\right) = e^{-At}B \tag{3}$$

After the integration in the interval [0, $t$], time-varying settlement model can be got, whose expression is formula (4).

$$X^{(1)}(t) = e^{-At}(X^{(1)}(1) + A^{-1}B) - A^{-1}B \tag{4}$$

**Solve the Model Parameters A and B.** The equation (1) is discretized, and least square method is used to estimate, which can get formula (5).

$$H = (S^T S)^{-1} S^T Y \tag{5}$$

Where:

$$S = \begin{pmatrix} z_1(2) & z_2(2) & \cdots & z_n(2) & 1 \\ z_1(3) & z_2(3) & \cdots & z_n(3) & 1 \\ \vdots & \vdots & & \vdots & \vdots \\ z_1(m) & z_2(m) & \cdots & z_n(m) & 1 \end{pmatrix}; \quad Y = \begin{pmatrix} x_1^{(0)}(2) & x_2^{(0)}(2) & \cdots & x_n^{(0)}(2) \\ x_1^{(0)}(3) & x_2^{(0)}(3) & \cdots & x_n^{(0)}(3) \\ \vdots & \vdots & & \vdots \\ x_1^{(0)}(m) & x_2^{(0)}(m) & \cdots & x_n^{(0)}(m) \end{pmatrix}; \quad H = \begin{pmatrix} a_{11} & a_{21} & \cdots & a_{n1} \\ a_{12} & a_{22} & \cdots & a_{n2} \\ \vdots & \vdots & & \vdots \\ a_{1n} & a_{2n} & \cdots & a_{nn} \\ b_1 & b_2 & \cdots & b_n \end{pmatrix}$$

$$z_i(k)=\frac{1}{2}(x_i^{(1)}(k)+x_i^{(1)}(k-1)),\quad (i=1,2,\cdots,n;k=2,3,\cdots,m)\,.$$

$\hat{A}$ and $\hat{B}$ which are identification values of $A$ and $B$ can be obtained from the matrix H:

$$\hat{A}=\begin{pmatrix}\hat{a}_{11} & \hat{a}_{12} & \cdots & \hat{a}_{1n}\\ \hat{a}_{21} & \hat{a}_{22} & \cdots & \hat{a}_{2n}\\ \vdots & \vdots & & \vdots\\ \hat{a}_{n1} & \hat{a}_{n2} & \cdots & \hat{a}_{nn}\end{pmatrix};\qquad \hat{B}=\begin{pmatrix}\hat{b}_1\\ \hat{b}_2\\ \vdots\\ \hat{b}_n\end{pmatrix}$$

The formula (3) can be written in the form of a discrete model in formula (6).

$$\hat{X}^{(1)}(k)=e^{-\hat{A}(k-1)}(\hat{X}^{(1)}(1)+\hat{A}^{-1}\hat{B})-\hat{A}^{-1}\hat{B} \tag{6}$$

Where: $e^{-\hat{A}(k-1)}=I+\sum_{i=1}^{\infty}\frac{\hat{A}^i}{i!}(k-1)$

The formula (6) is inverse accumulation restored, which can get formula (7).

$$\hat{X}^{(0)}(k)=\hat{X}^{(1)}(k)-\hat{X}^{(1)}(k-1),\quad (k=1,2,3\cdots) \tag{7}$$

When k≤m, $\hat{X}^{(0)}(k)$ is the analog value of the settlement; when k＞m, $\hat{X}^{(0)}(k)$ is the predicted value of the settlement.

**Modeling Precision.** $\delta^2$ which is the average fitting precision of the settlement model is calculated as formula (8).

$$\delta^2=\frac{\sum_{i=1}^{n}V_i^TV_i}{nm} \tag{8}$$

Where: residuals $v_i(k)=x_i^{(0)}(k)-\hat{x}_i^{(0)}(k)$,

$$V_i=(v_i(1),v_i(2),\cdots,v_i(m))^T\quad (i=1,2,\cdots,n;k=1,2,\cdots,m)$$

In projects, the smaller average fitting precision is, the higher the precision of the MGM(1,n) settlement model is.

For ease of calculation, the MGM(1,n) multi-variables gray settlement prediction program is compiled by the author using MATLAB software. In this program, the settlement analog values, the settlement predictive value as well as errors and precision can be quickly calculated after input composite foundation settlement observations.

## Application Examples

A 24 layers high-rise building is 85 meters high, whose main structure is frame structure, using CFG pile composite foundation. Since the beginning of the building construction, four settlement monitoring points (P1, P2, P3, P4) are laid around the building. Setting the settlement observation interval of one month, 16 times of settlement monitoring data is listed in Table 1. Now the previous

12 times of data is used to establish the model, and the last 4 times of data is used to compare with the predicted settlement values.

Table 1. Settlement Observation Data

| Observation points | Settlement /mm | | | | | | | | | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|
| | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9 | 10 | 11 | 12 | 13 | 14 | 15 | 16 |
| P1 | 4.9 | 10.8 | 11.4 | 12.0 | 13.2 | 14.5 | 17.9 | 21.2 | 22.8 | 24.6 | 25.2 | 26.9 | 28.3 | 29.4 | 30.7 | 31.4 |
| P2 | 6.2 | 7.1 | 7.3 | 7.8 | 8.1 | 9.6 | 11.8 | 13.7 | 14.3 | 14.9 | 16.0 | 17.0 | 17.8 | 18.5 | 19.2 | 19.8 |
| P3 | 5.2 | 5.4 | 5.6 | 6.7 | 7.7 | 8.8 | 10.3 | 11.9 | 13.6 | 14.2 | 14.9 | 15.8 | 16.7 | 17.5 | 18.3 | 19.0 |
| P4 | 4.1 | 4.2 | 4.3 | 4.7 | 6.0 | 6.5 | 8.1 | 9.4 | 10.9 | 11.5 | 12.0 | 12.8 | 13.5 | 14.3 | 14.8 | 15.6 |

**Establish the Settlement Prediction Model.** In this example, n=4. According to formula (1) to (7), MGM(1,4) settlement model established on points P1, P2, P3 and P4 is formula (9).

$$\hat{x}_{1i}(1+k) = e^{\overline{A}k}\begin{pmatrix} -194.8559 \\ -115.2984 \\ -116.9452 \\ -99.5635 \end{pmatrix} - \begin{pmatrix} -199.7559 \\ -121.4984 \\ -122.1452 \\ -103.6635 \end{pmatrix} \tag{9}$$

Where:

$$\overline{A} = \begin{pmatrix} -3.0419 & -3.9042 & 1.1453 & -0.0159 \\ -1.9200 & 2.1720 & 1.4568 & -0.5392 \\ -1.0547 & 1.3859 & 1.0733 & -0.8577 \\ -1.1606 & 1.3727 & 1.0567 & -0.5982 \end{pmatrix}; \quad \overline{B} = \begin{pmatrix} -4.9562 \\ -2.4057 \\ -0.6217 \\ -1.9942 \end{pmatrix}$$

The analog values calculated from settlement model which is established using previous 12 times of data are listed in Table 2. It can be seen from Table 2 that all the relative errors of analog values and observation values are less than 0.5%. The average goodness of fit is 0.0773, and the value is relatively small, indicating that the settlement model established by using MGM(1,4) gray model has higher precision and can be used to predict the composite foundation settlement.

Table 2. Settlement Analog Results of MGM(1,4) Model

| Observation sequences | Analog values /mm | | | | Measured values /mm | | | | Residuals /mm | | | |
|---|---|---|---|---|---|---|---|---|---|---|---|---|
| | $x_1$ | $x_2$ | $x_3$ | $x_4$ | $y_1$ | $y_2$ | $y_3$ | $y_4$ | $v_1$ | $v_2$ | $v_3$ | $v_4$ |
| 1 | 4.9 | 6.2 | 5.2 | 4.1 | 4.9 | 6.2 | 5.2 | 4.1 | 0 | 0 | 0 | 0 |
| 2 | 10.86 | 7.19 | 5.27 | 4.09 | 10.8 | 7.1 | 5.4 | 4.2 | 0.06 | 0.09 | -0.13 | -0.11 |

| 4 | 11.86 | 7.52 | 6.58 | 4.83 | 12.0 | 7.8 | 6.7 | 4.7 | -0.14 | -0.28 | -0.12 | 0.13 |
| 5 | 13.07 | 8.40 | 7.63 | 5.67 | 13.2 | 8.1 | 7.7 | 6.0 | 0.17 | 0.30 | -0.07 | -0.33 |
| 6 | 15.20 | 9.87 | 8.99 | 6.86 | 14.5 | 9.6 | 8.8 | 6.5 | 0.70 | 0.27 | 0.19 | 0.36 |
| 7 | 17.87 | 11.59 | 10.49 | 8.20 | 17.9 | 11.8 | 10.3 | 8.1 | -0.03 | -0.21 | 0.19 | 0.10 |
| 8 | 20.54 | 13.19 | 11.92 | 9.48 | 21.2 | 13.7 | 11.9 | 9.4 | -0.66 | -0.51 | 0.02 | 0.08 |
| 9 | 22.82 | 14.48 | 13.16 | 10.56 | 22.8 | 14.3 | 13.6 | 10.9 | 0.02 | 0.18 | -0.44 | -0.34 |
| 10 | 24.61 | 15.46 | 14.22 | 11.46 | 24.6 | 14.9 | 14.2 | 11.5 | 0.01 | 0.56 | 0.02 | -0.04 |
| 11 | 26.03 | 16.23 | 15.14 | 12.23 | 25.2 | 16.0 | 14.9 | 12.0 | 0.83 | 0.23 | 0.24 | 0.23 |
| 12 | 27.27 | 16.92 | 15.98 | 12.95 | 26.9 | 17.0 | 15.8 | 12.8 | 0.37 | -0.08 | 0.18 | 0.15 |

**Subsidence Prediction.** Settlement prediction results (13-16 times) of MGM(1,4) model are listed in Table 3, and the prediction precision is showed in Table 4. It can be seen from Table 4 that the prediction errors of the MGM(1,4) model are in 0.06~0.3 mm, whose fitting precision is 0.0045, compared with GM(1,1) settlement model, it has higher precision, whose prediction values are closer to the measured values.

Table 3. Contrast of Forecasted Settlement Using Three Different Methods

| P4 | | 0.063 | 2.156 | 1.320 |

* $\delta^2$ is the prediction precision; $v$ is mean residual.

## Conclusion

In this paper, multi-variable gray settlement prediction model is established. Using MATLAB software gray settlement model program is developed. With specific project example, the composite foundation settlement is simulated and predicted. The results show, MGM(1,n) gray prediction model has better fitting precision and prediction precision. Based on the settlement monitoring, this model can be used to predict composite foundation settlement. Once the predicted value exception occurs, remedial measures can be taken early enough to ensure the safety of the building.

MGM(1,n) gray prediction model is a nonlinear predictive model, which is a single-point extension model in the multi-points condition considering the related information among the monitoring points. Compared with GM(1,1) model, it has higher analog precision and prediction precision. And MGM(1,n) gray model can get n points prediction values, which need to establish one model, but GM(1,1) model need to establish n models, which need more work. So the MGM(1,n) gray model is more convenient.

To ensure the precision of the settlement prediction, along with the constantly updated monitoring data, old data can be removed, and the latest data can be used to correct prediction model to improve the sensitivity of the model, which can make more accurate composite foundation settlement prediction.

**Keywords:** Adhesion performance. Joint filler. Tensile strength. Humidity.

**Abstract.** Aiming at a new joint filler for pitch concrete pavement, processing it in different condition of water, determining the tensile strength through tensile experiment, analyzes the effect of adhesion performance from joint filler in water surrounding; does analysis to the adhesion performance of the recurrent tensile test in identical water surroundings.It evidenced that the new joint filler is much less affected in water surronuding than rubber modified bitumen,which is made by CARFCO inUSA,what meas that the new joint filler is much better than rubber modified bitumen on adhesion performance.

## Introduction

With the extension of highway asphalt pavement total milestone in chine, because the effect of the presence of water and repeat traffic load, there is a serious disease asphalt pavement[1, 2], and surface cracking is one of the major diseases of the road. Cracks not only undermine the structural integrity of the road, but also reducing the comfort and safety of the road[3, 4], so the research of cracks problems is urgent.

Filling cracks can prevent and stop water infiltration road deep, and delay the further develop of diseases of the road. Filling cracks is an important means of asphalt pavement maintenance department of Early Crack. Caulking material is a common way of repairing cracks. Zhen Wu [5] , who have had a single -component polyurethane caulk synthetic material; Dongchang Zhang [6] , who have developed a new type of long-life sealing material , the main component is silicone; Songqi Shou [7], who had been working on material for polyurethane caulk, and developed a silicone-modified polyurethane prepolymer and two-component polyurethane caulks , and then prepared composite caulking material combined with the advantages of polyurethane caulks and silicone caulks. However, these caulks have their shortcomings, especially sensitive to humidity, furthermore can't play the ideal adhesion effect because of the impact of water. So it's need to develop a new type caulks which is less sensitivity to water. Based on rubber modified asphalt (hereinafter referred to as American products), which is produced by the company of CARFCO in the United States, this paper studies the effect of water on a new sealing material adhesion by tensile test method. It's hope to play a guiding role in preparing caulks, improving the crafts, extending pavement performance, improving the level of road maintenance, saving the cost of long service asphalt pavement.

## Materials and methods

### 1.1 Preparation of materials

A new joint compound ( compatible agent+tackifier+SBS +crumb rubber +stabilizer) was studied. The preparation flowchart is shown in Figure.1.

To ensure the best performance of the asphalt under the same conditions the optimum technic index of modified asphalt was determined: test temperature is 180 ℃, shear rate is 3000r/min, shearing time was 40min, development time was 30min. After the above process and a method of making a new type of joint compound performance index is shown in Table.1.

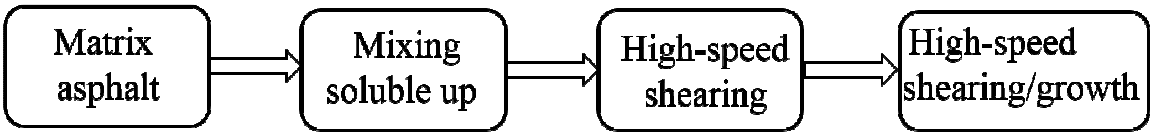

Fig.1. Preparation flow chart of the modified asphalt

Table.1.Performance metrics of a new joint sealant

| Property | New joint sealant | Experimental method |
|---|---|---|
| softening point（℃） | 90.6 | T0605 |
| Ductility（5℃，cm） | 21.6 | T0606 |
| Thixotropic Index（25℃，mm） | 52 | T0604 |
| Elastic recovery（25℃，%） | 94.0 | T0603 |
| TFOT | | |
| Ductility（5℃，cm） | 13.1 | T0606 |
| Thixotropic Index（25℃，mm） | 45 | T0604 |
| Elastic recovery（25℃，%） | 88.2 | T0603 |

**1.2 Tensile tests**

Tensile tests was finished by GF multifunctional road interlayer force tester using mixture cylinder (d=100mm) as specimen. Test tensile rate was first set as 1.2mm/min, and both ends of the specimen were fixed by clamps and stretched till the stretch distance was 2 cm, and then the tensile load and displacement of the specimen were output by the computer. Tensile testing process and real die pictures is shown in Figure.2.

Test pieces were prepared as follows. the mixture cylinder of which diameter was100mm and height was 63.5mm first went through surface treatment. A certain amount of filler material was then heated to 140 ℃ and painted evenly on the surface of the cylinder. The two cylinders butt was jointed by adhesive tape to prevent material spillage. Secondly,test material was placed at room temperature for more than 4h, and three specimens were shaped in each group. Finally, every specimen was placed onto GF multifunctional road interlayer force tester and stretched with failure load recorded, and then tensile strength was calculated according to formul is shown in Eq.1.

$$P=F/A \quad (1)$$

Remark:P – Adhesion strength, Mpa;F-The maximum load,N;A - Drawing area, mm2.

The test results to three decimal places to the arithmetic average of the three test specimens as a result.

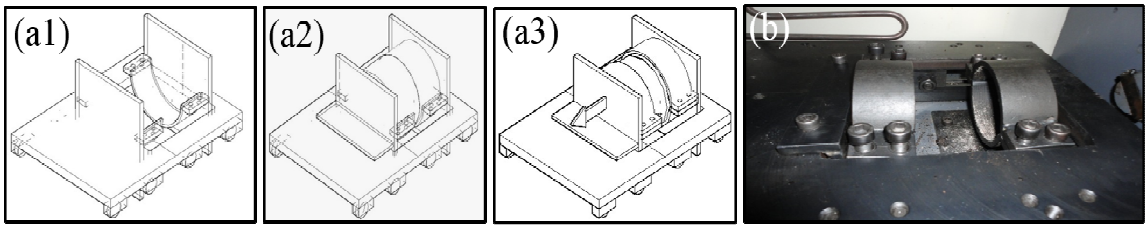

Fig.2. (a) diagram of Tensile test loading process (b) mould real figure

After drawing the specimen, the sealing material has a strong elastic recovery, some time later the test piece is placed spontaneously revert to the state before stretching, Specific specimen state diagram as in Fig.3. Tensile specimens were repeated for 5 cycles, Researching Caulks adhesion variation.The results is shown in Figure.5.

Under different water environments specimen preparation : ( 1 ) on the cylinder surface dust, dried , heated to 140 ℃ of caulking material to the cylinder surface evenly , butt shape. The group measured

the adhesion strength of the dry cleaner environment caulking material . ( 2 ) to clean the surface of the cylinder , into the water ( tap water ) in 40min ~ 60min, wipe the surface and more water will be heated to a caulking material evenly cylindrical surface 140 ℃, the docking molding.The group measured the adhesion strength under wet conditions caulking material . ( 3 ) to clean the surface of the cylinder,into the water ( tap water ) to soak 40min ~ 60min, excess water on the surface without any processing, the material is heated to 140 ℃ of caulk evenly to the cylinder surface,docking molding. The group measured the adhesion strength under water environment caulking material . ( 4 ) for the cylinder surface clean after the heat evenly to caulks 140 ℃,the docking molding into the water ( tap water ) to soak more than 4h . The group measured the specimen under the influence of caulking material to soak adhesion strength .

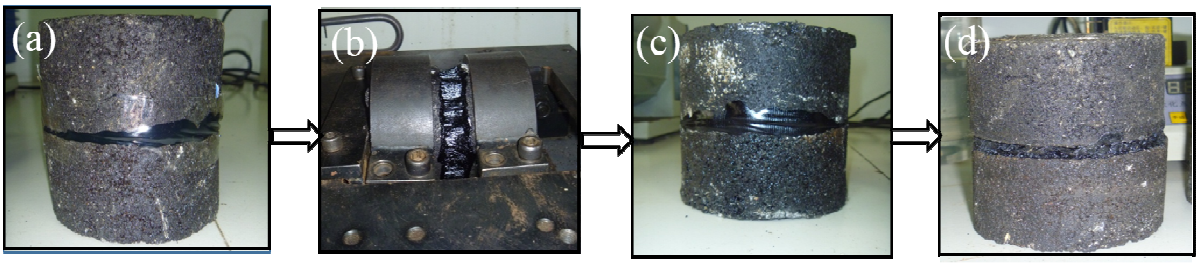

Fig.3. Process state diagram of Specimen tensile (a) original specimen.(b) tensile specimen during process (c) specimen before stretching (d) specimen after stretching

Production scheme will be different between the test piece good road GF multi layer testing tensile strength tester , the peak force recorded test results is shown in Table 2 . Making a set of three test specimens , the result of a test specimen , if more than 10 % of the average , be removed. If two test results of more than 10 % of the average , the group results void.

Table.2. Effect of humidity on adhesion property between United States product and new joint sealant

| Interface environment | New joint sealant（MPa） | | | | | United States product（MPa） | | | | |
|---|---|---|---|---|---|---|---|---|---|---|
| | One | Two | Three | Four | Five | One | Two | Three | Four | Five |
| Planning A | 0.593 | 0.427 | 0.344 | 0.330 | 0.311 | 0.400 | 0.325 | 0.284 | 0.230 | 0.146 |
| Planning B | 0.549 | 0.387 | 0.271 | 0.268 | 0.249 | 0.235 | 0.207 | 0.205 | 0.203 | 0.134 |
| Planning C | 0.540 | 0.362 | 0.277 | 0.245 | 0.217 | 0.221 | 0.192 | 0.183 | 0.170 | 0.112 |
| Planning D | 0.580 | 0.413 | 0.311 | 0.308 | 0.301 | 0.343 | 0.286 | 0.264 | 0.222 | 0.145 |

## Results and analysis

### 2.1 The effect of joint filler on adhesion performance about Humidity

Compared with humidity on the new caulking material impact on the adhesion properties of U.S. products, and its comparative test results is shown in Figure 4.To ensure the accuracy of the test data results , select the first tensile test results as a ratio . The results can be obtained from Figure 4 , the interface environment from the dry - wet - water environment changes , the new joint filler adhesion strength decreased 7.4% and 8.9 %, respectively , specimens less impact on water soaking conditions caulking material adhesion properties , filling sewing material adhesion strength decreased ratio of 2.2%.American products decreased rates were 41.2% and 44.7%,the proportion of the adhesion strength decreased 14.2% under the conditions of the test piece flooding .

The results showed that: the presence of water weakens the adhesion of the joint compound . Analyze the reasons : ① water in the adhesive film formed on the interface of the tiny cracks and

holes to fill on the interface , resulting in the formation of joint compound inaccessible physical anchor , leading to loss of adhesion properties of caulking material [8]; ② caulk first, the adhesive material in the course of the water film instead of contacting the mixture, can not form an effective adhesion; ③ water is much greater than the polarity of the polarity of caulking material, the molecular orientation according to the theory of joint compound has water peeling , leading to loss of adhesive properties of joint compound.

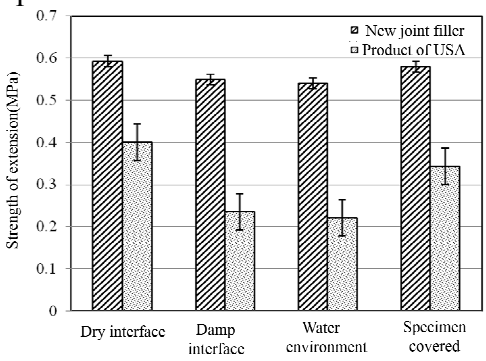

Fig.4. Effect of humidity on adhesion property between United States product and new joint sealant

Contrast adhesion properties of new materials and caulk U.S. products , the impact of the new water sealing material adhesion by less than U.S. products.The new joint compound mixed with thickeners , adhesion thickener provided to ensure that the new caulking material can firmly adhere to the interface , reducing the water may be stripped . In addition , according to the rotational viscosity test results , the United States is greater than the product 's viscosity and consistency of the new joint compound [9,10] , the water film will fill small cracks and holes on the interface , resulting in the loss of material adhesion properties , the impact on U.S. products to far greater than the new caulking material .

### 2.2 Repeated tensile test under the same humidity

(1) The changes of joint filler on adhesion performance on repeated tensile test.

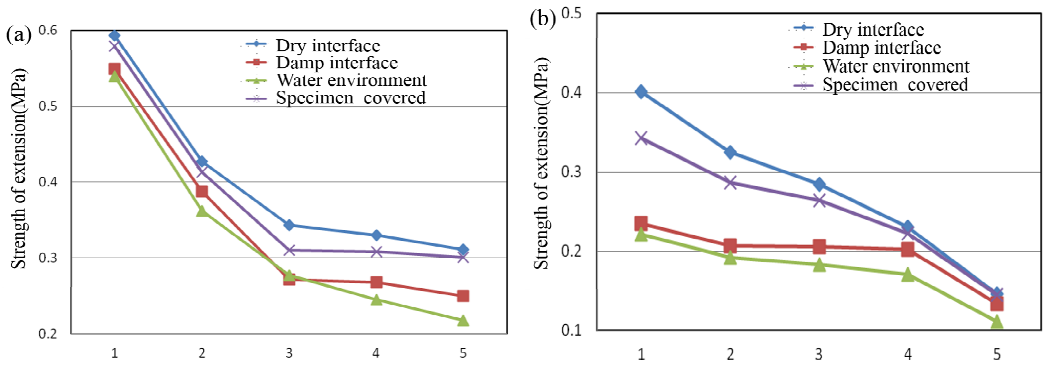

Fig.5. Adhesion property between United States product and new joint sealant（a）new joint sealant（b）United States product

Under different circumstances , the new adhesive caulk material changes have the same pattern: the first three , the new joint filler adhesion strength greater magnitude of change , the next three new caulking material adhesion basically stable. American products in repeated tensile test results with the new caulking material vary, the first four stretching, changing its adherence to a lesser extent , the results of the fifth stretch material adhesion began to have a greater attenuation.

(2) Observation during tensile test

Figure.6 (a) (b) (c) (d) and (a1) (b1) (c1) (d1) can be seen, a good adhesion of the new sealing material, such that it exists in the water film able to firmly adhere to the interface, keeping water

tightness. Greater impact on the adhesion of American products by water, has been cracking during stretching.

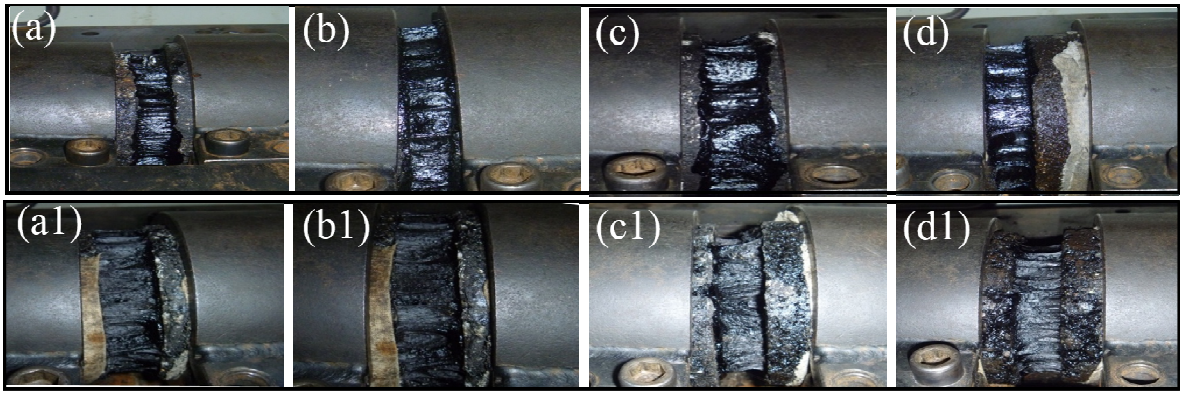

Fig.6. The repeated tensile test results between new joint sealant and United States product with under the same water environment. (a)(b)(c)(d) are results of United States product. (a1)(b1)(c1)(d1) are results of new joint sealant. (a, a1) dry interface, (b, b1) damp interface , (c, c1) water environment,(d, d1) specimen covered

In summary, there is a water film on the one hand the interface hindered caulks anchor role in the formation of interfacial adhesion; hand water caulks cause spalling, resulting in loss of joint compound adhesion properties. For new caulking material, its good adhesion properties to its adhesion properties of the water has little effect on U.S. products, due to the greater consistency and viscosity of the material, its greater impact on the presence of water, resulting in material tensile process appears.

## Conclusions

(1) The presence of a water film interface hinders the formation of joint compound anchor role in the adhesion interface, resulting in loss of joint filler adhesion performance.

(2) Compare U.S. products, new joint filler excellent adhesion performance reduces the sensitivity to water.

(3) Fracture under high humidity conditions, decrease in adhesiveness of the specimen is more serious, the tensile strength greatly decreased..

**Keywords:** fractured rock mass, statistical analysis, probabilistic model, network simulation

**Abstract.** Based on field investigation of random fractured rock mass, the sample parameters are put to statistical analysis, and 2-D fracture network model is established with probability-statistics theory and Monte-Carlo simulation technique. Finally, 2-D fracture network model is formed, which gain fracture distributed regularity in statistical sense, and is of important meaning to describe the fracture geometrical characteristics.

## Introduction

International Society for Rock Mechanics defines discontinuity as a fracture surface of faults, weak surface, most of rock joint, weak schistosity and weak belt caused by various mechanical factors[1]. One of them, rock joint is a crack of rocks, which is no obvious displacement, and is also one of the weak structural plane most extensive developing in upper crustal rocks[1]. These rock joints change the damage and instability way of rock mass. Hence researching distribution features of fractured rock mass is of great engineering significance, is also rock force frontier and hot topic.

Randomness of the distribution of rock mass and the diverse and complex space combination make it a difficult task to describe fractured rock mass accurately. In fact, the fractured rock mass distribution with stochastic uncertain, is also certainly. The distribution parameter values can be statistics, and then a probability model is established. With the rapid development of computer technology, structural plane network technology based on statistics and probability theory is able to widely use in engineering. Monte-Carlo method is adopted in this paper to be used in fracture network model, which can show its geometric characteristics of rock distribution in the study area.

## Theory of fractured rock mass statistical analysis

In the perspective of mathematical statistics, a large amount of sample data is from rock mass structure and reflects the characteristics of them. The sample may be defined as a individual one extracted from rock mass of the structure, and the rock mass structure itself as a collection of all individuals, namely totality[3]. Based on limited data obtained from field investigation of rock mass structure, the general characteristics of rock mass structure are derivated, namely the overall distribution calculated by the sample distribution.

### 1.1 Fitting sample parameter distribution

Some parameters are defined as follows: $x_1, x_2, \ldots, x_n$ as a sample of Populations $X$, statistic for $T = T$（$x_1, x_2, \ldots, x_n$）, probability density function as $f(x)$, with mean $\bar{x}$ and variance $s^2$, a maximum as $b$ and a minimum as $a$. According to statistics of sample characteristics $a$ and $b$, $k-1$ points with $t_1, t_2, \ldots, t_{k-1}$ are selected from sample values in the interval $[a, b]$ to divide into $k$ intervals of $[a, t_1], (t_1, t_2], \ldots, t_{k-1}, b]$, as shown in fig. 1.

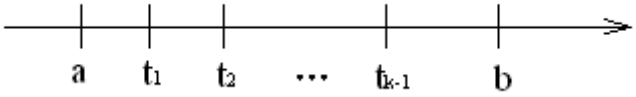

Fig.1 Segmentation interval of random variable

Setting $n_i$ As the number of the interval of $i$ (known as frequency) of sample $x_1, x_2, \ldots, x_n$, and the values of $f(x)$ in interval $[a, b]$ are represented by a histogram of measured data, then a probability density curve is described roughly.

**1.2 Non-parametric hypothesis test**

Hypothesis testing is a process of inference, which judge hypothesis according to the samples: inspection the same of guess distribution $F(x)$ and distribution. Hypothesis test is divided into parameter test and non-parametric test[3]. The former is testing some parameters according to known population distribution, and the latter is to examine some parameters for unknown population distribution.

In the statistical analysis of rock mass structure, population distribution type indicated rock mass structure is unknown normally, at this time its inspection method is non-parameter method[3]. Commonly used methods are fitting inspection of *Pearson* $\chi^2$, $k-s$ test, etc.

**Probability analysis and simulation principle of fractured rock mass**

Owing to limitations of rock outcrops, Some of structural plane trace length measured in the field site are full trace length, while some others are half trace length, some even are abridged part of the trace length with unseen both ends of the trace.

Probability density function of trace length is set as $f(l)$, and probability density of joint trace length is $g(l)$, average of population trace length is $\mu_L$:

$$g(l) = \frac{lf(l)}{\mu_L} \tag{1}$$

Probability density function of half-trace length is set as $h(l)$,and population trace length is $m$, $F(l)$ is cumulative probability of $f(m)$:

$$F(l) = \int_0^l f(m)dm \tag{2}$$

$$g(l) = \frac{1-F(l)}{\mu_L} \tag{3}$$

According to analysis by Priest and Hudson(1998)**,** under the condition of negative exponential distribution, the mean trace length intersect with survey line is$2\mu_L$, while uniform distribution which is $\frac{4}{3}\mu_L$,normal distribution.

Monte-Carlo simulation is based on the measured data of field fracture geometry characteristic parameters, fitting out probability density function of the occurrence, trace length and spacing parameters, and then mapping fissure network with computer[3]. Statistical analysis is carried out on the fracture azimuth firstly, and advantage direction of rock fracture group is determined, then parameters distribution law is fitted to generate random numbers separately for each fracture, which produces random variables of geometric parameters, and calculates halfway point of the crack position, dip angle and train long respectively. This group of crack is generated when the sampling area, generating a second group of fracture group, until all finished growing in a crack in the group are generated. Read the store in a crack in the data, graphic display fracture network, finally output graphics.

## Examples of application

YanJin Bridge Reservoir in RenHua, Guizhou province, is a comprehensive water conservancy for purpose of irrigation, power generation, water supply and travel. Elevation of dam riverbed is 569 m, and normal water level is 650 m. Downstream of right dam abutment is compound brae, whose terrain is steep cliffs with terrain slope Angle of 70 ~ 80°, relative level difference of about 124 m. There is empty face between 597 ~ 660 m elevation of 20 ~ 50 m from dam side downstream. The outdoor layer is fine-crystalline dolomite, dolomite and thin layer of argillaceous dolomite, and weak intercalated layer. For the bedding rock slope, combined with fracture, the dam abutment stability is seriously affected. Therefore, recognizing and describing fracture distribution accurately is particularly important.

### 3.1 Sample parameter distribution fitting

In the right abutment downstream, the dominant orientation is shown by survey data, and three groups of cracks, its occurrence, respectively, are 1)N72°E/80°NW, 2)N23°E/40°SE and 3)N33°W/20°NE. Then fit fissure angle distribution on three groups, as described in Fig.2, Fig.3 and Fig.4.The results show that sample fracture trace length is logarithmic normal distribution.

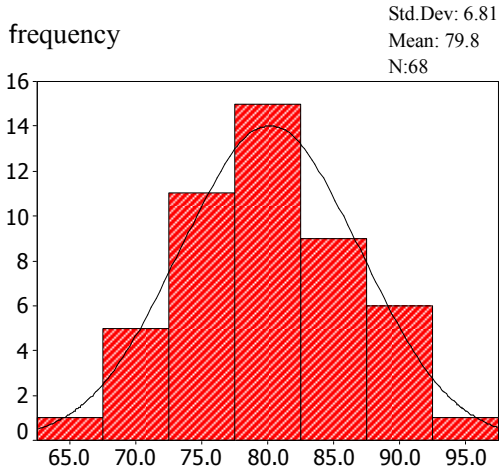

Fig.2 Fracture dip angle in 1)group(°)

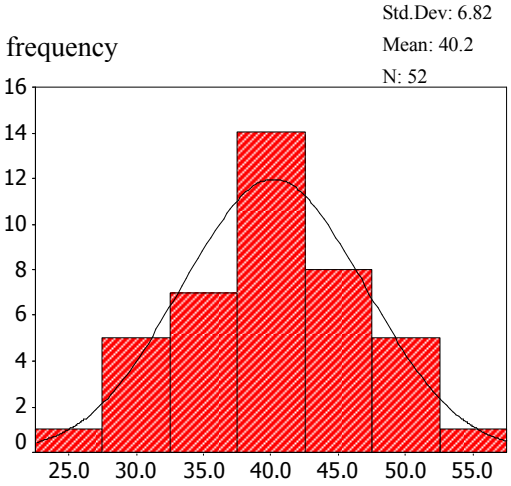

Fig.3 Fracture dip angle in 2)group(°)

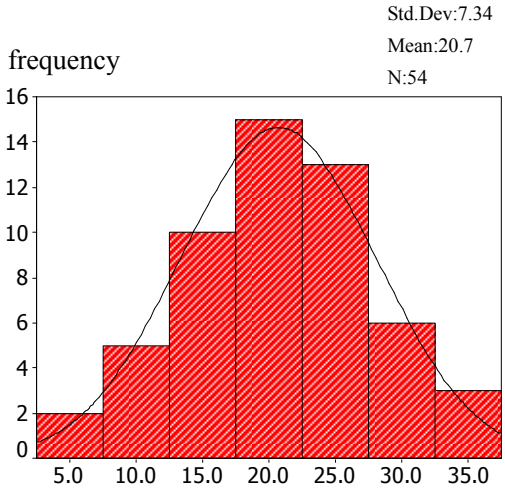

Fig.4 Fracture dip angle in 3)group(°)

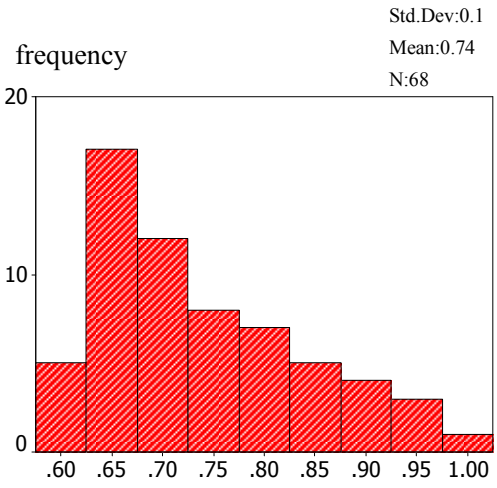

Fig.5 Fracture train length(m)

### 3.2 *pearson* $\chi^2$ fitting testing

Set a sample cumulative probability distribution as $F(x)$, with null hypothesis $H_0$: global cumulative probability distribution function as $F(x)$,and with alternative hypothesis $H_1$: global cumulative probability distribution function not as $F(x)$.

Set $n_i$ As the number of interval $i$ (known as frequency) of sample $x_1, x_2, \ldots, x_n$, and the total samples number as $N$, then the value $\frac{n_i}{N} - p_i$ should be small, otherwise, reject the hypothesis $H_0$ and accept $H_1$ [4]. Under conditions of $H_0$, the Statistic is,

$$\chi^2 = \sum_{i=1}^{k} \frac{(n_i - e_i)^2}{e_i} \tag{4}$$

Take equation(4) to distribution as $\chi^2(k-1-r)$ ,there $r$ is the number of unknown parameters in the overall. On the calculation of, $p_i$ can be replaced by $\hat{p}_i$ [4]. Giving significance level $\alpha$ and distribution tables of $\chi^2(k-1-r)$, $\chi^2_\alpha$ can be obtained. If $\chi^2 \le \chi^2_\alpha$,it means numerator of $\chi^2$ small, then the value $\frac{n_i}{N} - p_i$ is small, which reject the hypothesis $H_0$ ,otherwise, accept $H_1$. The hypothesis test results of angle, trace length of crack are shown in table 1.

Table1 Distribution form of Rock fracture angle and train in the study area( $\alpha = 0.05$)

| statistics | occurrence | sample number | mean | standard deviation | $\chi^2$ | $\chi^2_\alpha$ | distribution form |
|---|---|---|---|---|---|---|---|
| Dip angel | N23°E/40°SE | 68 | 79.8° | 6.81° | 1.334 | 11.143 | normal distribution |
| | N33°W/20°NE | 52 | 40.2° | 6.82° | 1.259 | 11.143 | normal distribution |
| | N72°E/80°NW | 54 | 20.5° | 7.34° | 0.896 | 11.143 | normal distribution |
| train | — | 68 | 0.74m | 0.1m | 5.286 | 22.362 | lognormal distribution |

### 3.3 Generation of two-dimensional fracture network

Two-dimensional fracture network is made up of different length and Angle fracture trace length according to the statistical parameters and generate statistical model. The steps are as follows:

(1)Determine generating area: considering some cracks center in the outside of study area but closing to the border, the train length may be extended to the field, so the fracture area extends outward half an average train length ( $\mu_L/2$) from study area boundary[5].

(2)Determine number of trace center in generated field: frequency per unit area is obtained by $i$ group fracture with statistical data, and the midpoint number of the group fracture in generated field.

(3)Generation of trace crack position, Angle, and train length: picks a random number in (0,1) with congruence method, and generate random variables coordinates $x_i$ and $y_i$ based on normal distribution; generate angle random value based on normal distribution; then generate train length random value based on lognormal distribution. After that, determine position 0f fracture in study area. Finally, two-dimensional fracture network is obtained[5].

It is simulated with VBA, which is second development technology of AutoCAD. The simulation results as shown in figure 6. Combined with actual situation and exploration data, this method was used to simulate two-dimensional fracture network model and in accordance with the actual situation, which find fracture regularity in statistical sense. As can be seen from fig. 5,

fracture for bedding, fracture connectivity rate of Angle 40°is high, which affect the stability of slope seriously. With fracture network diagram, fracture network hydraulic calculation can be got,

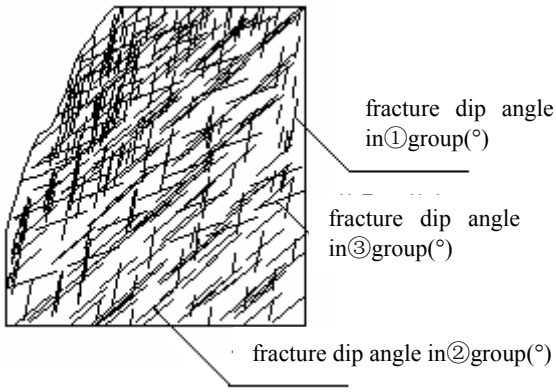

Fig.6 2-D fracture network

and then the connectivity rate and slope stability analysis can further calculated on the basis of network model. Therefore, fracture network diagram is the basic work for the security of engineering.

## Conclusion

(1) The existence of rock fracture damage rock mass integrity, influence on rock mass deformation and failure mode, and control seepage and stability characteristics of rock mass. Therefore, understanding and the way of depicting the existence of fractures accurately is very important.

(2) Because of the complexity of rock fracture, it is hard to describe fracture characteristics with completeness and certainty. Research shows that: fracture characteristics can be described statistically with application method of probability and mathematical statistics, combined with Monte-Carlo simulation technology, rock fracture two-dimensional network is carried out and receive good results.

(3) The secondary development technique programming of VBA is a good way to stimulate fracture, for it is contained in shared memory space with CAD, which has faster application execution speed than C language and VB language. The method can be used for the simulation of rock fracture.

**Keywords:** Pullout test, Interfacial interaction, reinforced band, water content

**Abstract.** Taking steel-plastic composite reinforced band (CAT) and gravelly soil as the test materials, the pullout tests of reinforced band in gravelly soil with different water contents have been carried out by the laminated shear test instrument. The interface friction characteristics between reinforced band and gravelly soil are studied, and the influences of water content on the interaction characteristics are also discussed. Results show that (1) the extraction of reinforced band is a gradual process. The anchor end began to move firstly because of the extensibility of reinforced belt itself. As interface friction gradually transfer backward by, the free end start to move onward, then displacement schedule curves of the anchor end and the free end are gradually parallel, the whole movement of reinforced belt happens immediately. (2) Pulling force and displacement curve of the pullout friction test displays obviously nonlinear characteristics. Pulling force of the reinforced band increases greatly with increasing displacement at the beginning of the test, then decrease with the increasing displacement after the peak value is reached, the force-displacement curves generally exhibit strain soften characteristics. But it present strain hardening trend under greater normal stress, and pullout frictional strength increases with the increasing normal stress. (3) The pullout friction coefficient of the interface is sensitive to water content. It decreases linearly with the increasing water content.

## Introduction

Reinforced soil retaining wall is a kind of retaining structure with certain flexibility and deformation ability, which could improve the soil deformation and its engineering property by shear friction between reinforced band and filling to achieve soil reinforcement stability. As a new flexible structure, reinforced retaining wall has been widely used in various fields such as the highway and railway epaulement, abutment, vertical quay, revetment, and so on. The interfacial characteristic of reinforced material and filling directly determine the safety and stability of reinforced retaining wall. The pullout test and direct shear test are typically used for reinforced soil interfacial interaction for indoor test research (Shi et al. 2009)[1]. Scholars at broad [2-6] obtained a great deal of achievements through pullout test and direct shear test to study interface characteristic of synthetic material and filling. While domestic scholars in China developed related research on the interface characteristic of synthetic material and packing as well. Scholars [7-9] successively carried out the geo-grid and filling pullout test to study the influence of loading mode, packing thickness, compaction degree, reinforcement rigidity, reinforced structure form, buried length, vertical effective stress on the pulling characteristics of reinforced soil. The reinforced materials in the above research are mostly geo-grid or soil fabric and the filling materials are sand or clay, in which little research was made on reinforced

band, and the water content was seldom considered as the factor on the pulling characteristics of reinforced soil. In southwest of China, reinforced band is widely used in embankment and revetment engineering as the reinforcement material. At the same time, the reservoir water level fluctuation will lead to water content change of packing material, which will then affect the stability of the reinforced structure. Therefore, the research on the influence of different water content on the interfacial friction characteristic of reinforced band and characteristics is of great significance.

Based on the reinforced soil retaining wall in a project in Chongqing of China, in which the CAT steel-plastic composite reinforced band and sand gravel are as the test materials, pullout test of reinforced band and gravelly soil with different water content were conducted by using large shear test instrument to study the interface friction characteristic of them. Then the interface friction coefficient was obtained, and the water content's influence on interface friction characteristic was analyzed in the paper to provide reference for reinforced soil engineering.

## Pullout Test

**Test Equipment.** Pullout test was conducted on DHJ60 large scale simple shear apparatus jointly developed by Yangtze River Scientific Research Institute and Huaxi Geotechnical Instrument Research Institute of Sichuan University, This equipment is mainly consisted of vertical and horizontal loading equipments, shear box, stress and displacement data collection system. The equipment adopts the plate frame structure with hydraulic loading method, which horizontal load uses strain type control mode and could achieve step-less speed regulation at 0.03~20mm/min. The upper shear box is composed of 10 overlaying rings, which is 30mm high and numbered from top to bottom. The rolling shafts are equipped between and beside the overlaying rings to minimize the shear resistance. The vertical and horizontal loads are measured by using load sensor, and 100mm resistance type displacement meter is used to measure the overlaying ring displacement, which is exported through eight-channel digital inspection instrument.

**Test material.**The test material is gravelly soil selected from retaining wall site in Chongqing of China, because the largest grain size in the field is greater than 60 mm, in situ grain size distribution need be modified to fit in the test apparatus, which is 60 mm in diameter. The simulation curve of grain size distribution using the Equivalent Weight Replacement method is shown in Figure 1. The reinforcement material used CAT steel-plastic composite reinforced band produced by Chongqing Yonggu Engineering Reinforced Band Co., LTD, which is geo-synthetics composed of carbon spring steel wire wrapped with polyethylene composite band. The product specification is CAT30020B and the width is 30 mm and thickness is 2.0mm.

**Test method.**The soil sample was compacted by layers according to the density and water content requirement. After the soil was filled in lower shear box, the reinforced band assembled with displacement measurement wire was laid on soil sample with equal spacing to ensure the horizontal pulling force and the geotechnical band are in the same horizontal plane. Then the soil sample of upper rings were filled by layer and compacted before rigid bearing plate was covered with vertical stress force exerted to make soil consolidation. After stable consolidation, horizontal load was applied in strain control mode with 0.3 mm/min pullout rate for pullout test, and the horizontal tension and pulling displacement were recorded. When the pulling force reached peak value and eventually stably dropped or displacement occurred at free end of reinforced band with stable movement rate, it was then regarded that the reinforced soil interface had been completely destroyed, and the test could be stopped. During the test process, the water content's influence on reinforced soil interface friction was the key point to consider. In order to increase the test accuracy, 3~5 geo-band equally spaced were laid on the interface (see figure 2).

**Test scheme.**The significant factors that affect the soil interfacial interaction property of reinforced band in the pullout test include normal stress, pulling speed, reinforced material strength, size, and different water content of soil sample, dry density state, and etc. For the actual engineering conditions, the increase of reservoir water level would greatly influence the water content of gravelly

soil, and the change of water content would affect the interfacial interaction characteristic of geotechnical band and sand gravel. Therefore, this paper intends to carry out the pullout test for gravelly soil in three different water contents and reinforced band, and the test scheme is as shown in the table 2.

| 9 | 500 | 0.3 | 3 | 5.7 | 2.24 |

## Test Result Analysis

**Calculation formula.**The interface pulling friction strength is calculated as the formula below:

$$\tau_f = \frac{T_p}{2BL} \tag{1}$$

Where $\tau_f$ is the pulling friction strength; $T_p$ is the total horizontal tension at peak value; B, L is the buried width and length in the soil.

The earth is calculated as below--pulling friction factor of geosynthetics materials:

$$f = \frac{\tau_f}{p} \tag{2}$$

Where p is the normal pressure; $\tau_f$ is the pulling friction strength corresponding to p.

**Pulling force and pulling displacement.** Figure 3 is the time-history curve of pulling force and displacement for reinforced band in test No.1. It can be seen from the graph that when the reinforced band that buried in the sand gravel is subject to a horizontal pull, the stress and deformation are to be generated in the pulling direction. At the beginning of the test, when the pulling force was small, the anchored end was pulled out first with displacement expanded as the pulling force increased, and free end displacement remained unchanged. When the pulling force gradually increased to a certain value, the interface friction was gradually delivered to back end and relative displacement in the reinforced soil increased in slow pace. When the pulling force reached to maximum value, the pulling end and

free end had displacement, the time-interval graph gradually paralleled, and the reinforced band immediately had integral displacement.

**Pullout test graph.** Figure 4 is the relationship between pulling force and displacement of the reinforced band in gravelly soil with three different water contents and in different normal stress. It can be seen from the figure that, the overall trends of the relationship between pulling force and pulling displacement under different water content are basically same, but which showed obvious nonlinear characteristic in the pullout test with the same water content. When the reinforced band was pulled at beginning, the pulling force increased with increased displacement, and the pulling decreased as the pulling displacement increased after the pullout force reached peak value. The pulling graph was featured by strain softening characteristic, but tended to be strain-hardening under greater normal stress. The greater the normal stress was, the higher peak pulling force would reach, which was due to that the contact between reinforced band and gravelly soil particles were more compact. The pulling force mainly comes from friction between the reinforced band and gravelly soil, and the friction resistance is larger required by same displacement produced by reinforced band, thus the peak value of pulling force is higher. The water content of packing material has great influence on interface friction coefficient. Under same normal stress, the higher the water content is, the lower the pulling friction strength will be.

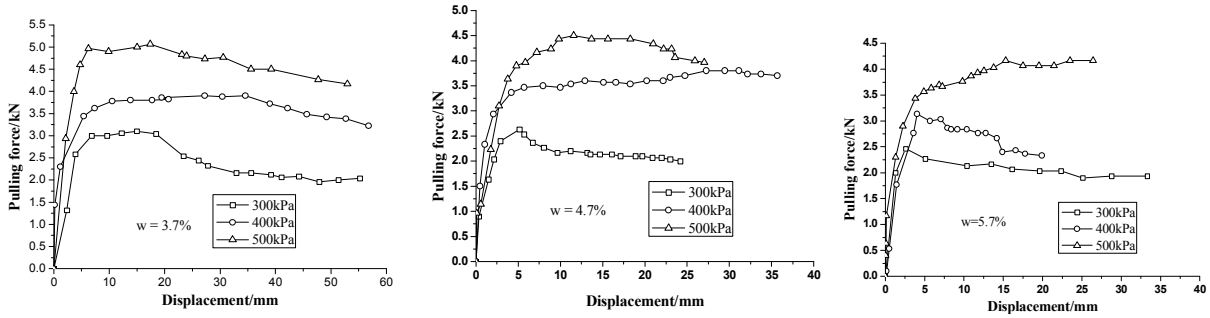

Fig. 4. Graph for pulling force and pulling displacement

Table 3. Results of pullout test

| Test No. | Vertical load p (kPa) | Water content of sand gravel w (%) | Total horizontal tension at peak value $T_P$(kN) | Pulling friction strength $\tau_f$ (kPa) | Pulling friction coefficient $f$ | Average pulling friction coefficient $\bar{f}$ |
|---|---|---|---|---|---|---|
| 1 | 300 | 3.7 | 3.10 | 86.111 | 0.287 | |
| 2 | 400 | 3.7 | 3.90 | 108.333 | 0.271 | 0.280 |
| 3 | 500 | 3.7 | 5.07 | 140.741 | 0.281 | |
| 4 | 300 | 4.7 | 2.63 | 73.148 | 0.244 | |
| 5 | 400 | 4.7 | 3.80 | 105.556 | 0.264 | 0.253 |
| 6 | 500 | 4.7 | 4.50 | 125.000 | 0.250 | |
| 7 | 300 | 5.7 | 2.47 | 68.519 | 0.228 | |
| 8 | 400 | 5.7 | 3.13 | 87.037 | 0.218 | 0.226 |
| 9 | 500 | 5.7 | 4.17 | 115.740 | 0.231 | |

## Conclusions

(1) The pull out of reinforced band is processed gradually. Due to the flexibility characteristic of reinforced band, at the beginning of the test, the anchored end was pulled out first with displacement expanded. When the pulling force gradually increases to a certain value, the interface friction is gradually delivered to back end and relative displacement in the reinforced soil increased in slow pace. When the pulling force reaches to maximum value, the pulling end and free end begin to take

place displacement, the time-history curve gradually paralleled, and the reinforced band immediately had integral displacement.

(2) The relationship between pulling force and pulling displacement in the test shows obvious nonlinear characteristic. When the reinforced band is pulled at beginning, the pulling force increases with increased displacement, and the pulling decreases as the pulling displacement increases after the pullout force reaches peak value. The pulling curve is featured by strain softening characteristic, but tends to be strain-hardening under big normal stress. The pulling friction strength increases as the vertical load increases.

(3) The water content of filling material has great influence on soil interface friction coefficient. Under the same normal stress, the higher the water content is, the lower the pulling friction strength will be. When the water content increases from 3.7% to 5.7%, the linear of average pulling friction coefficient decreases from 0.28 to 0.226, which is decreased around 19%.

[a] t7766@sina.com, [b] zhangdong8821@126.com, [c]771917861@qq.com, [d]1205175890@qq.com

**Key words:** Numerical Simulation; Soundless Crack; Failure Process; RFPA

**Abstract:** The special advantages of Soundless Crack method are safety and environmental protection. Soundless Crack is widely used in stone exploitation, partly crack of brittleness materials such as rock and concrete, and backout of building in city. In these engineering, we must drill many holes for loading Soundless Cracking Agents, but the drilling cost is expensive including human cost and materials cost, at the same time need much time to drill these holes. So we hope to gain the best crack results at the minimum drillhole numbers. This paper used RFPA software to set up some models with different drillhole numbers, gained different failure process of models. Adopted different drilling plan will occur different results. We should drill more holes if we need partly crack smoothly. We can plan the number of drillholes based on our need if we can use RFPA to simulate the failure process before beginning.

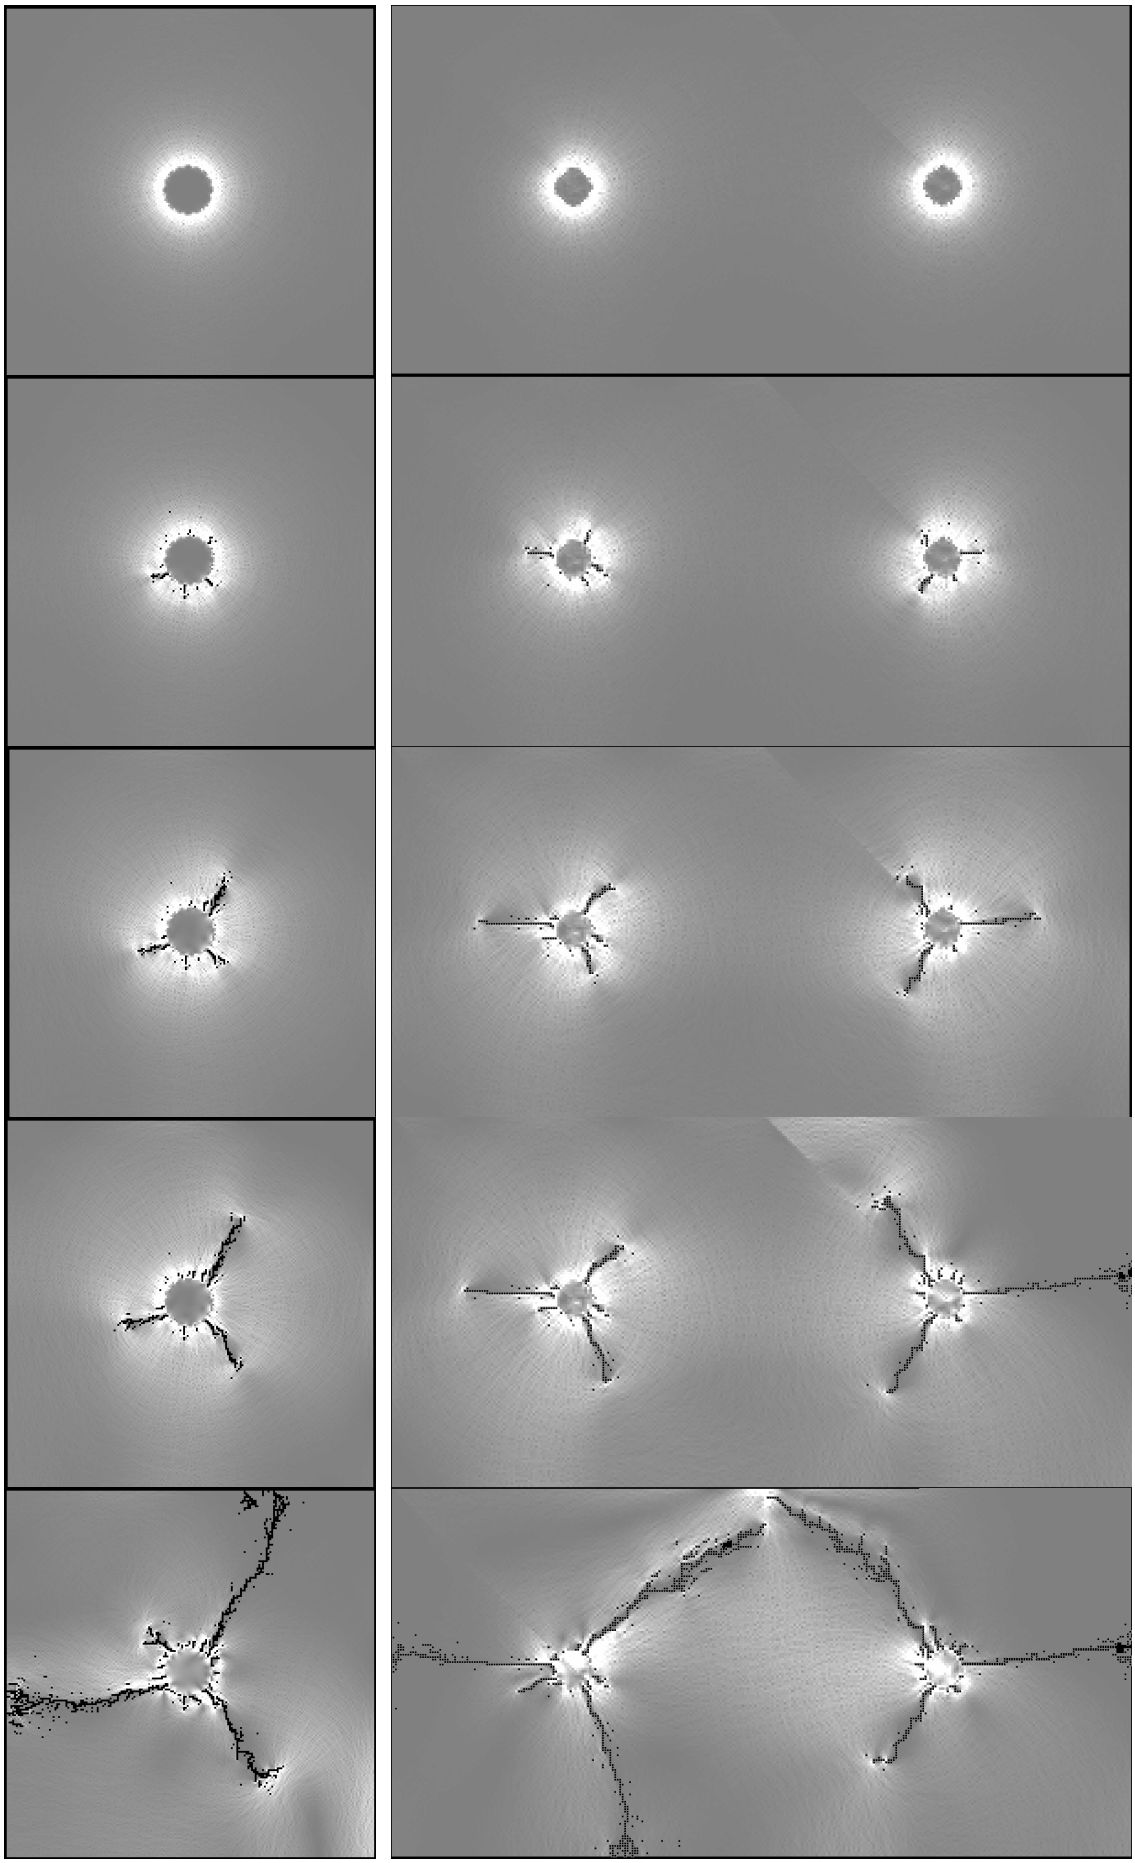
## Instruction

Soundless Cracking Agent(SCA) is a farinose material with high distensibility, mixed with water and then fill into drillholes of rock or concrete, dilation and induration happened at the same time, became a new dilated material which volume increase thrice and produce dilated power above 2.94 million Pa. Producing great dilated power in a period of times and loading to wall of drillholes, beginning appear crackle when tensility inside is bigger than the strength of cracking body, the crackles develop along with the continue action of dilate power, at last the cracking body is broken. Comparing with conventional explosive blast method, the Soundless Crack method low blasting velocity and slow loading, can gain blasting results without shake, noise, fly rock, bad gas, pollution. It is an important complementarity and development for blast technology, and easy to transportation, storage and operation, so it is widely use to building backout, especially in backout engineering which can't use blast method, and stone exploitation and cutting[1-4].

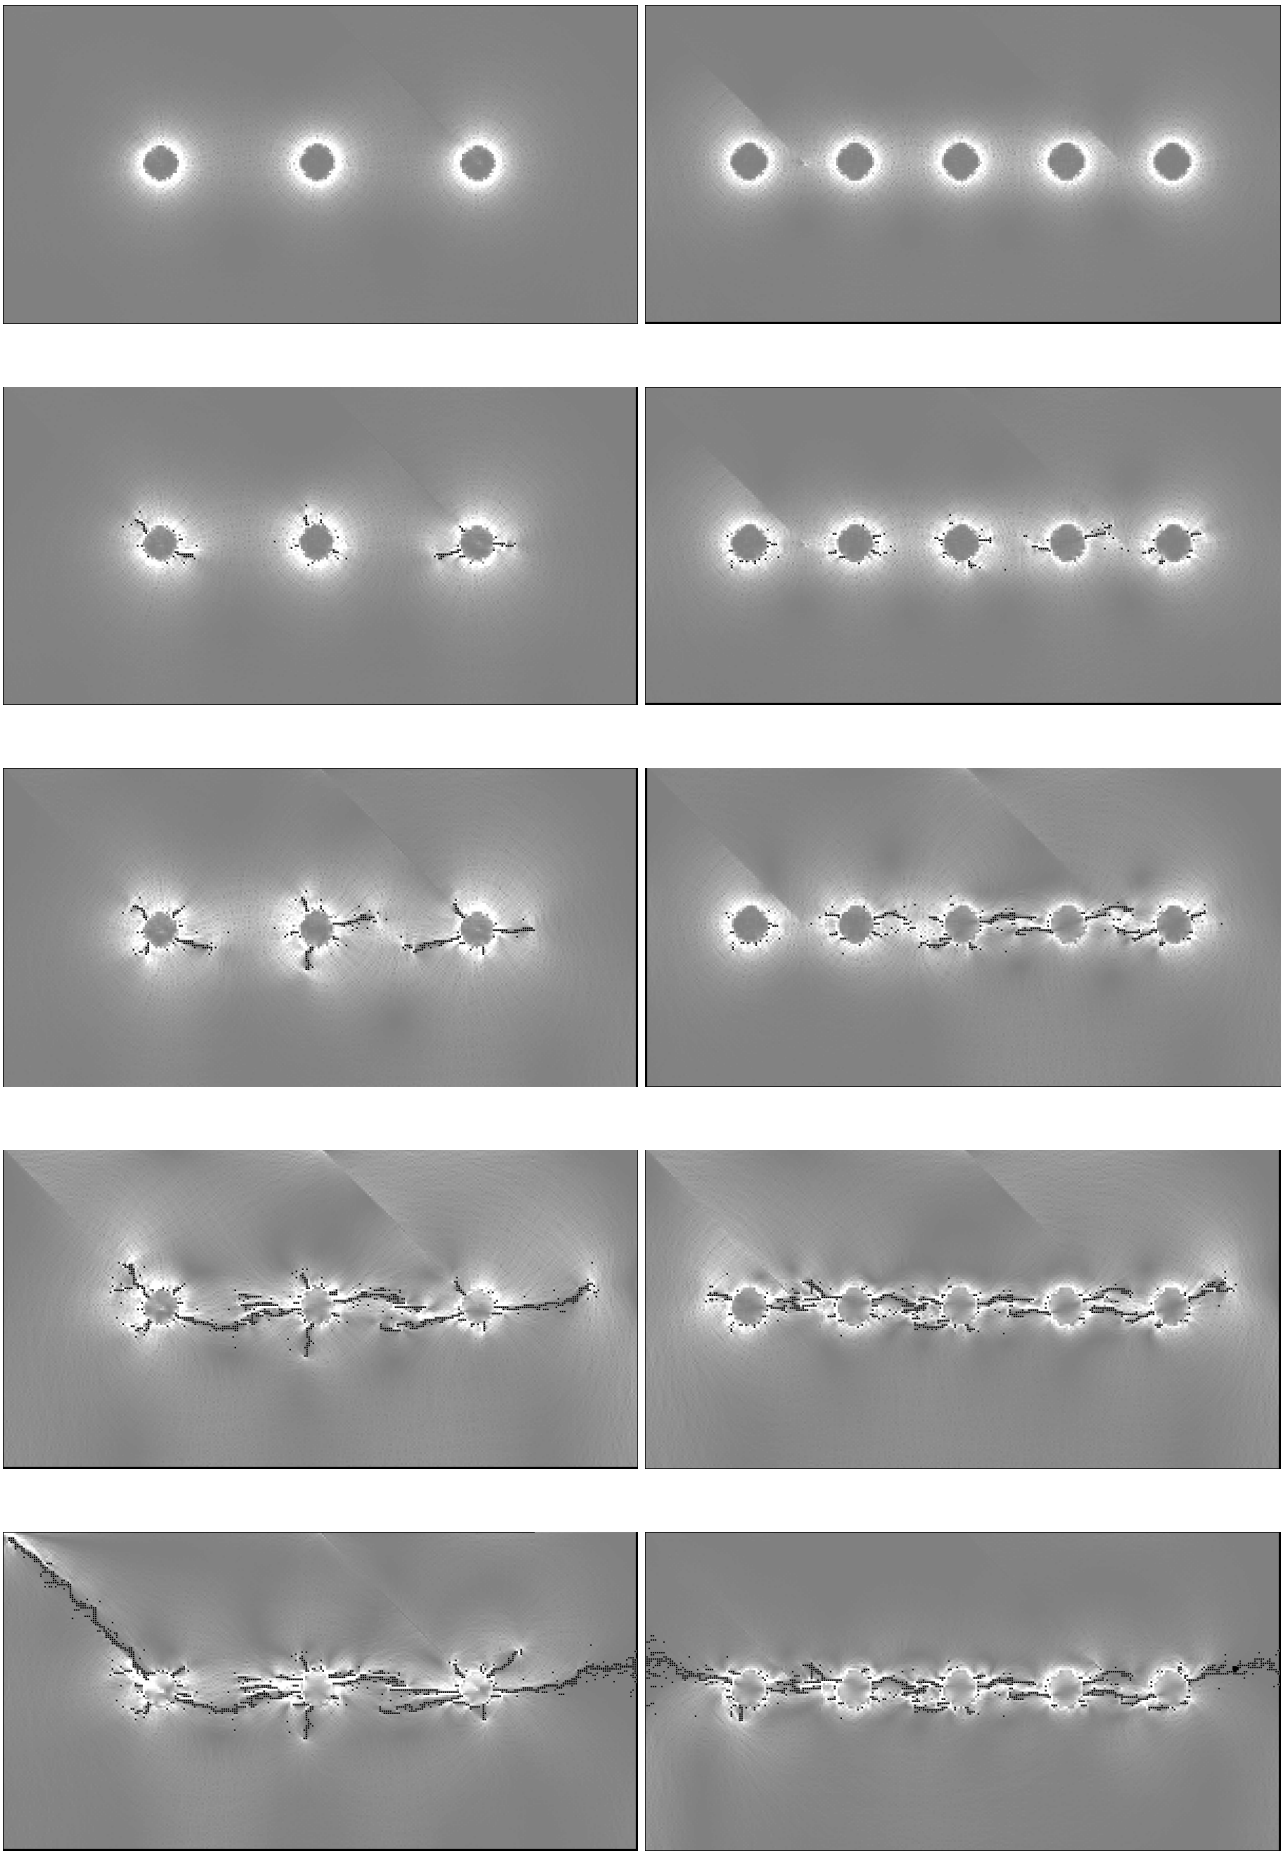
In all Soundless Crack engineering, should drill many holes for filling the Soundless Cracking Agent, but drill holes need cost, so we must gain the requisite results at minimum drillholes number. This paper used RFPA (Realistic Failure Process Analysis[5-7]) to numerical simulation of failure process on soundless crack with different drillholes, hoped to show the primary crackle developing process and provide reference evidence for actual engineering.

## Numerical Models and Results

Primary mechanics parameters of numerical models reference paper[7], the material is concrete, compressive strength is 38.6 MPa and tensile strength is 1.9 MPa, the elasticity modulus is 36977MPa, poisson's ratio is 0.2. Built four type of models, 300*300 mm with one hole in the middle of the model(Fig.1 (a)), 600*300mm with two holes which distance was 300mm(Fig.1 (b)), 600*300mm with three holes(Fig.1 (c)) and five holes (Fig.1 (d)), the calculation results are showed in Fig.1.



（a）300*300mm model （b）600*300mm model with 2 drillholes



（c）600*300mm model with 3 drillholes （d）600*300mm model with 5 drillholes

Fig.3. Failure process of different number of drillholes

## Results Analysis

For the 300*300(mm) model with one drillhole in the middle of the model, there are three stochastic crackles. For the 600*300(mm) model with two drillholes which distance is 300mm, every drillhole has three stochastic crackles too. For the 600*300(mm) model with three drillholes which distance is 150mm, primary crackle connected but some crackle are stochastic. For the 600*300(mm) model with five drillholes which distance is 50mm, primary crackle connected as a beeline.

## Conclusions

From the calculation results by RFPA about soundless crack with different number of drillholes, we can find that the failure process of soundless crack are different because of the drillholes number, we have to drill different holes based on our need, we may drill much less holes if we need to break all of the objective, contrarily, we should drill more holes if we need to crack partly of the objective. If we can know the mechanics parameters of the materials, we can numerical calculation the failure process before drilling, rectify the planning distance between holes to gain the best cracking results. If the parameters are enough nicety, we can calculate the maximum distance between holes while be satisfied with break requirement.

**Keywords:** pile; negative skin friction; model experiment; sand; settlement.

**Abstract.** Accompanied by the substantive construction of domestic ports, the negative skin friction on pile becomes a common problem. In order to provide references for the related experiment research in the future, the designs of model experiments reported in the literatures were emphatically analyzed and compared. Compared to conventional pile model test, the model test on negative skin friction on pile needs to apply load on soil surface and it is difficult to simulate large surcharge by conventional test methods. An experimental scheme which could produce large surcharge load by conventional test conditions is given in this paper. Pile stress, displacement of pile top and layered settlement of soil was tested under different surcharge level. The depth of neutral point and the group effect of NSF are discussed.

## Introduction

Pile foundation is used widely because of good applicability for foundation soil. However, there are still some problems in the appliance of pile foundation, such as negative skin friction (NSF). If the pile foundation passes through the high compressibility of soil, the axial force of pile and the pile settlement will increase when the soil settlement increases and exceeds pile settlement. The strength failure of pile, the failure of pile bearing stratum and the failure of superstructure due to differential settlement may occur in severe case. Therefore it is important to pay attention to the problem of NSF on pile.

The concept of NSF was first presented in the 1930's when Terzaghi and Peck researched on the problem of differential settlement for the building adopted pile foundation. A lot of research on NSF of pile foundation has been conducted. This paper mainly discusses the experiment research on NSF.

## The Experiment Research on NSF

**Field Experiment.** A lot of field experiments of NSF were conducted through the nineteen-sixties and nineteen-seventies [1]. The NSF induced by the settlement of clay under surcharge load was studied mainly which was focused on the dragload and neutral point. The common law of neutral point of pile with different pile bearing stratum was obtained. Furthermore, the adhesion factor $\alpha$ and effective stress friction factor $\beta$ which were back calculated by field experiments provided important references for calculation and design. The measured dragload and neutral point also showed obvious time effect due to the slowness of clay consolidation. After the late 1970's, bitumen coated piles were proposed and some contrast experiments were conducted. The experiment results indicated that the NSF could be reduced effectively by setting up the coating on pile surface. Consequently, this method was used widely as the way to solve NSF.

Accompanied by the substantive construction of domestic ports, the negative skin friction on pile becomes a common problem because bitumen coated steel pipe pile is not widely used. However, the

research in this aspect is relatively lagging in domestic, and many researchers are attracted in field experiment.

**Model Experiment.** Field experiments on NSF, which research contents were relatively homogeneous, were mostly aimed at single pile and were time consuming and labor intensive processes owing to the time for clay consolidation. Unlike field experiments, the number of model experiments was less. In order to study group effect and validate the law from field experiments, there have been some scholars which researched NSF by model experiment and obtained valuable results since 1980's. Some research surveys are shown in Table 1.

Table 1. General Situation of Model Experiments on NSF

| Literature | Material of Pile | Loading Method of Soil (Max. Load) | Main Research Contents |
|---|---|---|---|
| Shibata et al [2] | Thin-Wall Steel Pipe | Rubber Pneumatic Bag (60 kPa) | Group Effect of Vertical and Inclined Pile Groups |
| Toma [3] | Brass Pipe | Rubber Pneumatic Bag (90 kPa) | Relationship Between NSF and Surcharge or Soil Shear Strength |
| Leung et al [4] | Aluminum Pipe | Heaped Load In Centrifuge (70 kPa) | Influence of Load On Pile Top on NSF |
| Charles et al [5] | Aluminum Pipe | Heaped Load In Centrifuge (45 kPa) | Influence of End Condition and Group Effect on NSF |

Model experiments on NSF are also carried out in recent years in China. The methods of the simulation of the surcharge load at soil surface can be divided into heap soil and load by loading plate and jack. Lu [6] studied the NSF on single pile and pile groups by model experiments respectively, and he adopted the method of heaping soil on the surface of clay and the max. value of surcharge load was 11.5 kPa. It can be found that the max. value of surcharge load was small by heaping soil, and that may lead to the soil settlement and the dragload too small. Larger surcharge load can be produce by setting the loading plate on soil surface and loading it. Yang [7] conducted the model experiment on NSF on single pile by using the loading plate, and the max. value of surcharge load was 100 kPa. Yang researched the law of neutral point and the dragload when the rate of water content of silt changed.

In conclusion, different experiment devices were designed to simulate surcharge load and studied NSF on pile. The method of heaping soil on soil surface does not need high requirement of experiment condition, but the data measured may be small and deviation may be large. The method of setting rubber pneumatic bag on soil surface can produce large surcharge loading (such as, Shibata [2] and Toma [3]), but the requirement of experiment condition is much higher. The method of setting loading plate on soil surface also can produce large surcharge load, but it just applied to single pile experiment. By contrast, centrifuge experiment shows great advantages.

## A Simple Model Experiment for NSF

**Test Description.** This paper suggests an experimental scheme which could realize large surcharge load by simple experiment conditions. The model experiment apparatus of pile groups are shown in Fig. 1. Reinforcing bands is welded on tank side to reduce the tank deformation caused by applying surcharge load on soil surface. The settlement plates are set on several soil layers inside and outside the pile groups in order to measure layered settlement. The down loading plate, which is prepared from 20 mm thickness steel plate and opened holes for model piles and settlement plates, is put on the sand surface. The up loading plate, which is prepared from 30 mm thickness steel plate and welded with four legs, is put on the down loading plate. The surcharge load on soil surface is simulated by the jack which uses down and up loading plate to ensure the surface load uniform. Two balance beams and small counterforce frame are fixed at tank wall. The model pile can be step-loaded by using

weight or jack. Pile stress, displacement of pile top and layered settlement of soil can be tested under different surcharge level.

According to the above method, a single pile test was conducted firstly. Model pile, which was embedded in 1 m thick homogeneous saturated sand bed, was prepared from thin-wall steel pipes of 1.4 m length, 40 mm outer diameter and 1.18 mm thickness with strain gauges at the inner wall of pipe pile. The load on pile top was step-loaded to 250 N, and the surcharge load was step-loaded to 120 kPa.

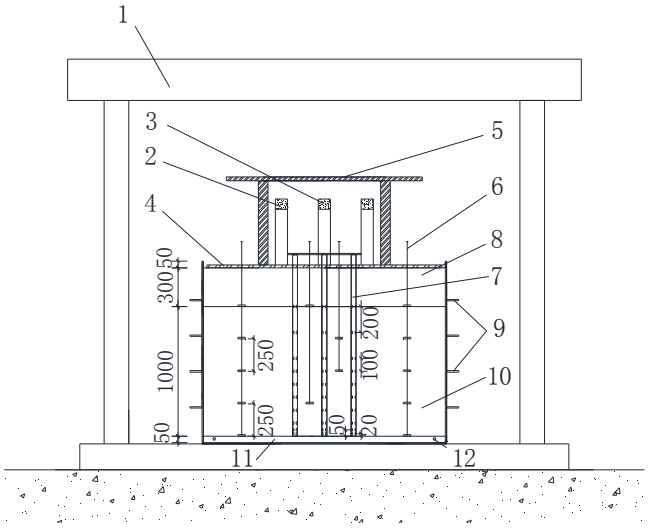

Fig. 1. Layout of model test (mm): 1-big counterforce frame; 2-balance beam; 3-small counterforce; 4-down loading plate; 5-up loading plate; 6-settlement plate; 7-model pile; 8-sand surcharge; 9-reinforcing band; 10-sand; 11-gravel sand; 12-drain valve.

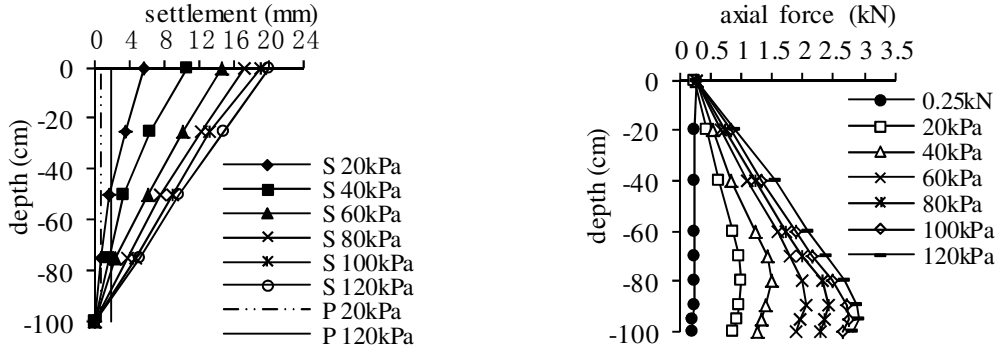
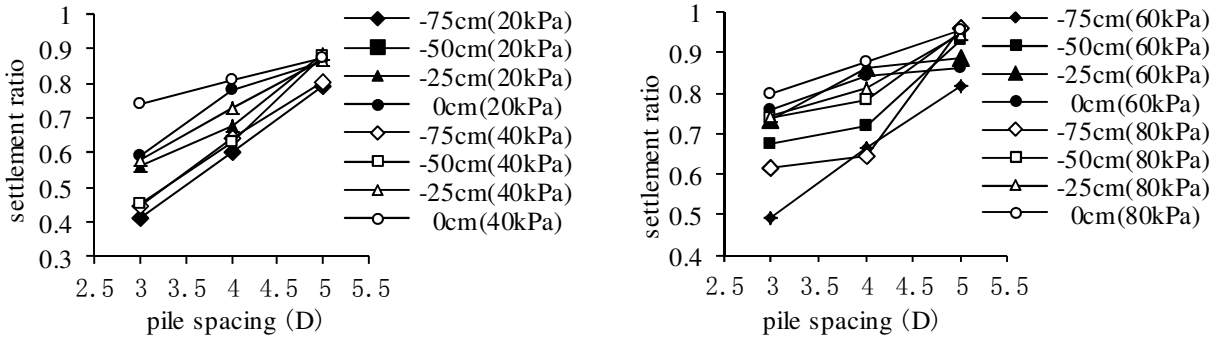


(a) (b)

Fig. 2. The test result of single pile: (a) The layered settlement of soil and the single pile settlement; (b) The relationship between axial force of pile and surcharge load on soil surface.



(a) (b)

Fig. 3. The soil settlement ratio inside and outside pile groups: (a) surcharge load 20 kPa - 40 kPa; (b) surcharge load 60 kPa - 80 kPa

**Results and Discussion.** The test result is shown in Fig. 2. Fig. 2(a) shows that the layered settlement of soil increases with the increase of surcharge load, but the increment decreases. The axial force of pile indicates that the depth of neutral point varies from 0.8 L (the length of pile in soil) to 0.95 L and the dragload varies from 0.77 kN to 2.64 kN as shown in Fig. 2(b). The effect of NFS is obvious in the test.

In order to study the NSF of pile groups, four different tests, such as 3×3 pile group test with pile spacing of 3 D (pile diameter), 4 D and 5 D under different surcharge load were designed. The group effect coefficient of NFS can be characterized by relative settlement of the soil inside and outside the groups. The soil settlement ratio inside and outside pile groups is shown in Fig. 3. The test result indicates that the ratios of inner to outer settlements increase with the increase of pile spacing or surcharge load, and decrease with the increase of soil depth. When pile spacing reaches 5 D, the soil settlement ratio is close to 1 and the difference between the inside and outside settlement is little.

## Conclusions

Accompanied by the substantive construction of ports in China, the problem of NSF on pile is needed to pay more attention. Some useful conclusions can be obtained by the model experiment.

(1) The model tests of NSF on pile and pile groups in sand, which surcharge load was simulated by sand and the jack with down and up loading plate, were designed and conducted. The axial force of pile, the settlement of pile top and the layered settlement of soil were obtained under different surcharge load.

(2) When the surcharge load was step-loaded from 0 kPa to 120 kPa, the axial force of pile indicates that the depth of neutral point varies from 0.8 L to 0.95 L in the tests. According to the test result of soil settlement ratio inside and outside pile groups, it indicates that the group effect can be ignored when pile spacing reaches 5 D.

**Keywords:** Strength Deduction Method; Foundation Pit; Support of Foundation Pit; Continuous Wall; Finite Element; Estimation on Stability

**Abstract:** In geotechnical engineering, the support pattern regularly applied is continuous wall, whose high security, strong adaptability, good stability and other characteristics have been widely appraised in engineering circles. This paper use Midas to build the three-dimensional research model on varied construction stages of foundation pit, in which the foundation pit applies the scheme of combing continous wall and inner support. Further more, this paper makes estimation on the machenical stability in varied construction stages of foundation pit and use strength deduction method to analyze the stress and strain conditions of foundation pit in different working states, the results acquired from which researches have certain reference to the engineers.

## Introduction of the Model

### 1.1 The Characteristics & Applicable Scope of Continuous Wall

The underground continuous wall is applicable to soft soil, sand soil or other places with high requirements. The main benefits is good waterproof performance, high structural security[1], capability of combing construction with jamb wall of basement and good integration. However, it is also featured by hard construction technology, slow construction speed, high requirement for machinery and large occupation of site[2].

### 1.2 Building of Model

This three-dimentional support system of foundation pit chooses the scheme of combining underground continuous wall and inner support. The foundation pit is rectangular shape with excavated depth of 18m, length of 22m and width of 12m. Within the foundation pit, angle braces and cross braces are seperately applied in four corners and horizontal direction with a section of supporting beam: BxH=900x700mm. The soil mass is divided into claypan and decomposed rock; regarding to claypan, we set elastic modulus E to be 6e4kpa, cohesive strength c to be 45kpa, angle of internal friction φ to be 12° , gravity of soil mass γ=18KN/m3, saturation gravity γsat=22KN/m3, and poisson ratio v to be 0.35; in the second interface of decomposed rock, we set elastic modulus E to be 3.4e45kpa, cohesive strength c to be 65kpa, angle of internal friction φ to be 40° , gravity of soil rock mass γ=22KN/m3, saturation gravity γsat=21KN/m3, and poisson ratio v to be 0.3. The reinforcing cage and concrete placement shall be applied in the underground continuous wall, which will conform to the the construction technology and process of underground continuous wall during construction; while the wall thickness shall be 700mm. See Fig. 1 & 2 below for the three-dimensional model of foundation pit.

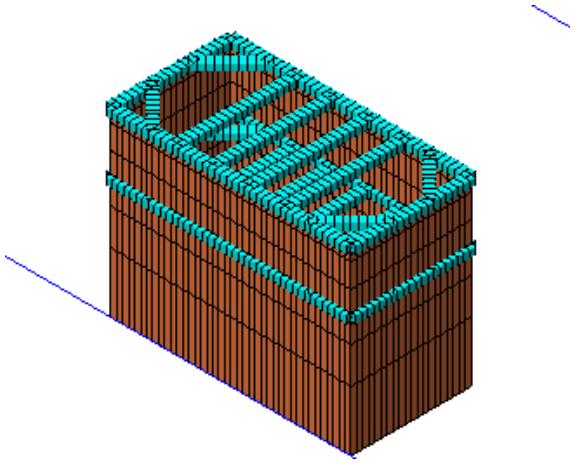

Fig. 1 Combined System of Underground Continuous Wall and Internal Support for Foundation Pit

## Examination of Results of Varied Construction Stages

### 2.1 The Displacement Change in Varied Construction Conditions

The deformation monitoring and control in foundation pit construction are focal contents of informatization construction, therefore, it is essential of an immediate monitoring to the displacement change after completion of varied construction conditions in the construction. See Fig. 3～11 below for the displacement change of foundation pit in varied construction stages.

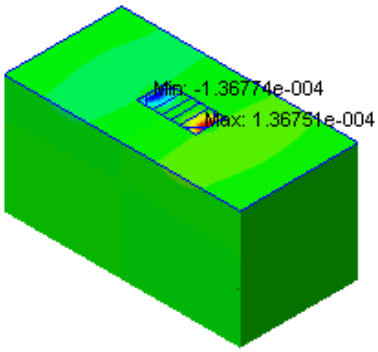

Fig. 2 Displacement along X Direction of Foudation Pit after Excavation 1

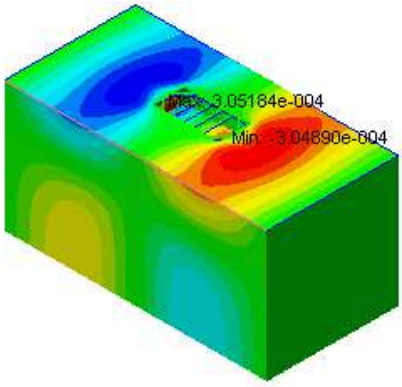

Fig. 3 Displacement along X Direction of Foudation Pit after Brace 1 and Excavation 1

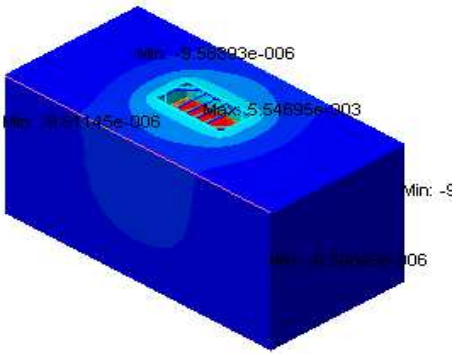

Fig. 4 Displacement along Z Direction of Foudation Pit after Excavation 1

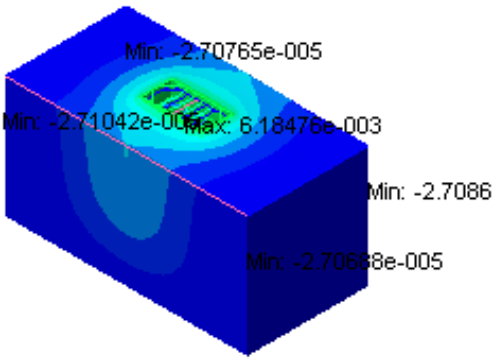

Fig. 5 Displacement along Z Direction of Foudation Pit after Brace 1 and Excavation 2

### 2.2 Comparison of Bracing Internal Force

As it includes many result options of internal forces within the varied construction conditions such as axial force, shear force and bending movement, so this paper chooses the change conditions of representative Fy and My. The result indicates that the internal force Fy changes in the horizontal direction along two left/right ends of cross brace with a large value; and the large section of My distributes in brace ends and midspan positions, of which the ends bear large compressive stress and the midspan produces upper blending and deformation. See Fig. 12～13 below.

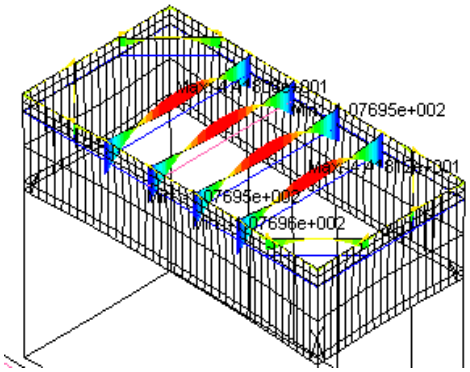

Fig.6Distributuon of $M_y$ during Brace 1 and Excavation 2

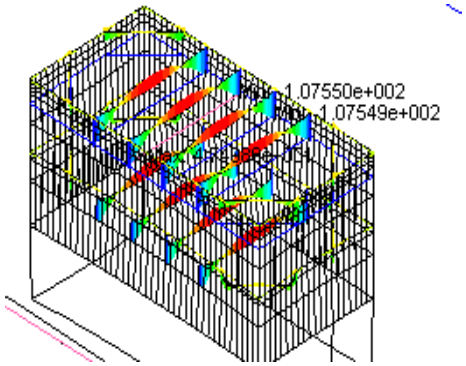

Fig.7 Distributuon of $M_y$ during Brace 2 and Excavation 3

### 2.2 Internal Forces of Continuous Wall

Under various conditions, there are also many forcing conditions of continuous wall, therefore, this paper chooses the internal force along X direction as reference. See Fig. 16 & 17 below for the the internal force along X direction of continuous wall.

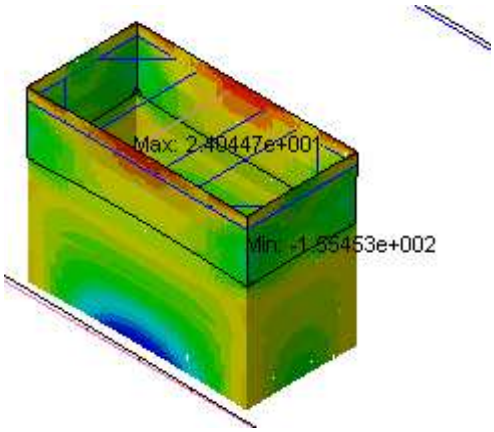

Fig. 8 Internal Force along X Direction of Continuous Wall after Brace 1 and Excavation 2

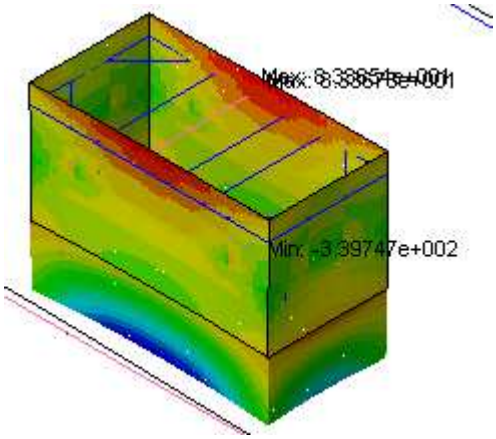

Fig. 9 Internal Force along X Direction of Continuous Wall after Brace 2 and Excavation 3

### Conclusions

This paper use Midas-GTS to build a three-dimensional calculation and analysis model for varied construction stages of foundation pit, in which the foundation pit applies a bracing system of combining underground continuous wall with inner braces and the construction procedure is divided into three stages: excavation1, brace 1 followed by excavation 2, and brace 2 followed by excavation 3. After operation and analysis, the displacement changes, internal force and stress of

inner bracing, internal force and stress changes of underground continuous wall are examined in directions of X, Y and Z of foundation pit during varied construction stages. Due to so many datas of varied costruction conditions in analysis, only several datas such as displacement changes in varied costruction conditions, Fy and My changes of inner bracing and the distribution condition of internal force along X direction of underground continuous wall are selected to get conclusions as follows:

The model built seems too conservative; in varied construction stages, the displacement changes along X and Y directions of foundation pit are all very small as to be less than 1mm, so does it along Z direction; the maximum displacement in final construction stage is about 6.31mm.

[2] School of Highway, Chang'an University, Xi'an 710064, P.R. China

[a]mdtmhyq@163.com

**Key words:** Bailong River; debris flow; character; hazards assessment

**Abstract:** Earthquake can cause heavy casualties and property losses immediately, and induced a mass of secondary mountainous disasters such as collapse, landslide and debris flow. Collapse and landslide provide abundant incompact solid matter for movement of debris flow directly, which makes the debris flow ravines be active in a long period in the future. Taking one debris flows on Bailong River as an example. Based on the analysis of the valley features and the forming condition scientific prediction for the trend of the debris flow activities and estimates the hazards situations have been achieved.

## Introduction

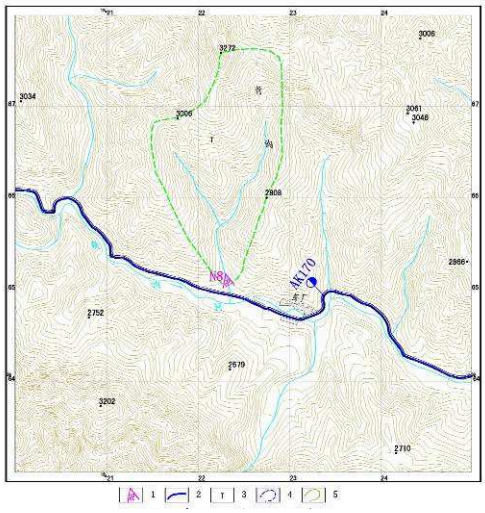
southern of Gansu is the severe earthquake disaster area, and is one of the landslide, debris flow distribution area, its geological hazard development degree, frequency , scope and damage is in the first place in China[1] .

it has an important significance for people's life, property and hydropower Project construct to research the formation condition and motion feature of debris flow, predict its develop tendency and hazard.

## Formation Condition of Debris Flow

### 2.1 Terrain Condition

The gully lies in middle-mountain of Bailong River right bank, Its area is 2.6 km$^2$ with the shape of "willow-leaf-alike', the highest elevation is 2430m, lowest elevation is 900m, relative height difference is 1530m. the length of the main gully is 10.15km, and the shape is "U" in downstream, there are many waterfall scarps along main gully. As a whole, the terrain condition of the gully is beneficial to water collecting in short time, surface and brunch gully water gain energy in main gully quickly, then the scale and peak of debris flow in main gully will upgrade quickly. It provides a beneficial condition for debris flow.



### 2.2 Recharge Condition of Solid Mass

There are precipitous topography, loose rock, developed Weathering, Influence of geological structure and earthquake in the gully, disasters such as collapse, landslide are very developed. These will supply rich solid loose mass for debris flow. ① Landslide: According to Investigation, there are 18 landslides in the gully. Including 220 loess-bedrock landslides, 2 loess landslides, 2 bedrock landslide. ② Collapse and slump: earthquake induced many collapses and slumps; it becomes the resource for soiled material for debris flow. Collapse masses are bedrock and loess-bedrock collapses in the gully. most of them are loess collapse. ③ Gully bed debris: debris distributed in channel and entrance of debris flow, the shape is cone at entrance. ④ Slope loose debris: Include slope coprolite and wash, loose loess and weathered clastic stones and etc.

A lot of researches show that the critical rainfall of debris flow in southern of Gansu is 15-20mm per hour, 8-10mm per ten minutes; it is the lowest district in Gansu province. In this area, the maximum rainfall is 90.5mm per 24 hours, 40mm per hour, 16.2mm per 10 minutes. Since 1939, the rainfall of 25~50mm/ day is 2-3 times per year, 50~75mm/day and more than 75mm/day is about 2-3 times per 10 years. There is a concentrate rainfall, with a character of intensity rainstorm, and local heavy rainfall, all of these supply a hydrodynamic condition for debris flow.

## Influence Evaluation for hydropower project

### 3.1 Prediction of Risk Range

The risk range of debris flow is the region where may be damaged by debris flow. in this paper, once and maximum debris flow accumulation range model was used, which mentioned by paper [7], a model of debris flow was appropriately readjusted combined with field survey of the gully debris flow and related parameters from indoor and field tests. The accumulation pattern after debris flow of the gully was speculated when reservior is full and empty.

Prediction model of debris flow accumulation range:

$$a = 0.49312 \tag{1}$$

$$l = 2.5748\left(V \times G \times r_c / \ln r_c\right)/3 \tag{2}$$

$$d = 0.254/\left[V \times r_c /\left(G_2 \times \ln r_c\right)\right] \cdot 1/3 \tag{3}$$

Where, a is the area of once debris flow accumulation（$m^2$）; $l$ is the length of maximum accumulation（m）; D is the depth of once debris flow accumulation（m）.V is once solid loose mass maximum recharge capacity（$m^3$）; G is the accumulation area slope (°); rc is the gravity of debris flow($g/cm^3$);

Applicable condition, when $r_c$=1and G=0, the model is unfit, prediction accuracy is average relative error of a is 11.83%； prediction accuracy is average relative error of 1 is 9. 5%； Prediction accuracy is average relative error of d is 7.8%.

When the area of once debris flow accumulation is predicted with this model, once solid loose mass maximum recharge capacity can use the calculation result of once debris flow solid loose mass, G is the accumulation area average slope, longitudinal gradient is 3° ~5° , the average value is 4° , gravity is designed frequency unit weight of debris flow. Let designed parameters to the above mentioned formula, the area of once debris flow accumulation parameters with designed frequency can be calculated. Calculation parameters and accumulation range of the gully is showed in table 1.

**Table 1 Calculation parameters of designed frequency and accumulation range**

| designed frequency P（%） | 5 | 3.333 | 2 | 1 |
|---|---|---|---|---|
| V($10^4m^3$) | 9.2 | 12.2 | 14.8 | 18.5 |
| G（° ） | 4 | 4 | 4 | 4 |
| $r_c$ ($g/cm^3$) | 1.75 | 1.75 | 1.75 | 1.75 |
| $a$($m^2$) | 35940 | 43194 | 52073 | 56991 |
| $l$(m) | 269.8 | 296.4 | 325.1 | 340.5 |
| $d$(m) | 4.53 | 4.7 | 4.9 | 5.2 |

From the calculation results of accumulation forecasting model for every frequency of the gully debris flow, debris flow of 50—year frequency and 100—year frequency can reach upper damsite and open diversion canal, this will lead to the Direct threaten of sludge buried, impaction and scouring. Debris flow of 50—year frequency and 100—year frequency also can reach the other bank of Bailong river, and it is possible to block the river and form dammed lakes, it will threat to the safety and operation of downstream hydropower station. It will not be sludge buried by debris flow to Wuguan expressway and , Chengyu railway. From the calculation results of every frequency flow accumulation model, the debris flow has a little effect for middle dam-site.

### 3.2 Prediction of River Blocking

Debris flow always takes a lot of solid loose mass into Main River. If there are too much solid mass, Main River may be blocked, and there will come to a provisional dam, after some time, the impoundment will cause dam-break. In addition, sediment clogged also will cause a part of riverbed deposit and River course change, then a large number of sediments are inputted in Main River, sediment content of Bailong river will increased, and power generation benefit and coastal flood control will also be affected. Take conversion coefficient of false or true volume ratio to 0.8, then the scale of once debris flow blocking at the entrance is:

$$W_t = \frac{0.8W}{C_V - P_S C_V} = \frac{(\frac{1}{2\tan 14^\circ} + \frac{1}{2\tan\varphi}) \times 0.8B \times H^2}{C_V - P_S C_V} \tag{4}$$

Where, $W_t$ is the total amount of solid mass($m^3$)； B is the width of Main River (m); H is the depth of Main River (m), take 5; $\varphi$ is internal friction angle of debris flow (°)， take 25; $C_v$ is the volume concentration of soil in debris flow, take 1.45; Ps is the weight percentage between sand and soil in flow, take 0.21.

The amount of once debris flow enter hydropower station can be calculated by the flowing formula

$$V_{s0} = \alpha_p \times V_s \tag{5}$$

Where, $V_{s0}$ is the volume of debris flow entering into hydropower station under some designed frequency（$m^3$）; $V_s$ is total quantity of debris flow solid mass under some designed frequency（$m^3$ ）; $\alpha_P$ is storage factor of debris flow solid mass under some designed frequency.

$\alpha_P$ of 100—year frequency can be gotten by from near entrance accumulation character investigation and analysis inverse computation during blocking the river, other frequency can be get by analyzed combing with experience, then storage amount of once debris flow can be gotten. The lifetime of station is set to 100 years, assume there are 10 times debris flow of 10—year frequency, 5 times of 20—year frequency, twice of 50—year frequency, once of 100—year frequency. Then the possible maximum storage amount is show in table 2.

**Table 2 The possible maximum storage amount（$10^4m^3$）**

| items | Designed frequency P（%） | | | |
|---|---|---|---|---|
| | 10 | 5 | 2 | 1 |
| Once storage amount under every frequency | 1.82 | 2.14 | 3.95 | 5.55 |
| Possible times | 10 | 5 | 2 | 1 |
| storage amount | 18.2 | 10.7 | 7.9 | 11.1 |
| storage amount of 100—year frequency | 56.42 | | | |

Calculation results show that, the maximum possible storage amount of debris flow solid mass is $56.42\times10^4m^3$ during life tome of the station, if adopting upper dam site, total storage capacity is $220\times10^4m^3$， so it is significantly compared that debris flow affect storage capacity of upper dam site. It is relatively smaller for middle damsite.

## Conclusions

Wudu region of southern of Gansu province is one of the most serious hazards of debris flow. the basin area of the debris flow gully has abundant of loose mass, The main hazards are landslides, collapses and appearance erosion, it belong to viscous debris flows, the flow rate of 100—year frequency is 351m3/s, these will have a threaten of buried and impact washing, and blocking the river.

**Keywords:** retention capacity, ruins, matric suction, shrinkage

**Abstract.** The soil water characteristic curve (SWCC) has been tested during the drying process. In order to define the relationship between suction, degree of saturation and void ratio, fitting models of SWCC was established. Studies have shown that the shape of SWCC of three kinds of samples (taken from Jiaohe, Gaochang and Jiuzhoutai) was similar to the inverted "S", the relationship between water content and matric suction was inversely proportional. Under the condition of the same moisture, the matric suction of the Jiaohe and Gaochang samples were greater than the Jiuzhoutai samples, and the changes of pore water pressures showed the same trend. The degree of saturation began to decrease when the water content reduced to the air entry value. When the degree of saturation was greater than 90%, the volume of soil samples contracted significantly, and when saturation is below 80%, volume shrinkage stopped.

## Introduction

A large number of ancient earthen architecture ruins were left along the Silk Road in arid and semi-arid areas of northwest region, and these earthen ruins were constructed by clay or sand, or by directly digging raw soil, or by utilizing sun-dried mud bricks [1]. Compared with rocks, the soil is characterized by low strength and weak water resistance, which determines that it is extremely difficult to protect the earthen cultural ruins, especially the immovable earthen architecture ruins preserved in the open air. Benefiting from the unique climatic conditions of being arid and rainless, some open-air earthen ruins in the northwestern region have been preserved well until now. However, due to the physical and chemical weathering, the function of building materials (mainly the soils) continually degraded. These earthen ruins were suffering from devastating damages [2-4]. So it was a priority to carry out the work of conservation in earthen ruins.

## Experimental Materials and Methods

**Experimental Materials.** Test soil samples are taken from Jiaohe ruins and Gaochang ruins located in Turpan city, Xinjiang province. The region surrounding Turpan belongs to continental warm temperate zone arid desert climate, and the annual precipitation is 16.2mm. However, there were several times of heavy storms with precipitation reaching 40~50mm in the history. In addition, the recorded maximum daily temperature difference was 21.9°C (July 1994), the maximum ground temperature reached 44.5°C [5]. Engineering drilling ascertained that the ruins were located on the alluvial or lake stratum which is mainly composed of silt, clay, and fine sand inter-bedded layer.

Under rainfall conditions, soils on the ruins' surface a first saturated, mud are formed. After the rain, as the moisture content reducing, mud turns to crust. At the same time, shrinkage cracks on the surface of crust generate and expand during the drying process [4]. Therefore, remolded soils which are initially saturated are chosen to test for the study. In order to contrast the test data, loess samples retrieved from Jiuzhoutai in Lanzhou are selected as the comparative samples. To avoid the impact of

large particles in the soils, soil samples are sieved. The diameter of the mesh is 1mm. In tests, automatic laser particle size analyzer (Mastersizer 2000) is used in particle test, and Powder X-ray diffractometer (X'Pert Pro MPD) is used in mineral composition test. Other parameters of physical properties are tested according to the Standard for Soil Test Method (GB/T50123-1999). The test results are listed in Table 1, Table 2 and Figure 1.

Table 1 Physical properties of the soil samples

| sample | specific gravity | Liquid limit /% | Plastic limit /% | Plasticity index | Clay /% | silt /% | sand /% | specific urface area/$m^2 \cdot g^{-1}$ |

Particle size frequency curve Cumulative grain size curves

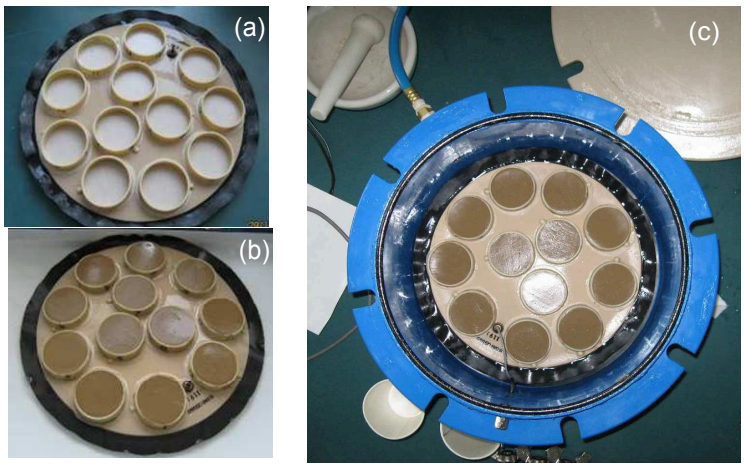
Fig.1 Grain size distribution curve of soil samples

**Test principle.** With the decreasing of water content, the matrix suction is increasing during the shrinkage of the saturated soils. The relationship between the matrix suction and water content during the drying process is defined by the soil water characteristic curve (SWCC). In this paper, the pressure plate extractor (Figure 2) is used to test the SWCC of ruins' soil samples.

Fig.2 Photograph of the 15bar pressure plate extractor

Test principle of pressure plate extractors: A wetted porous ceramic plate is backed by a fine mesh screen which also provides a passage way for the extracted solution, and is further sealed by a rubber membrane backing. The soil samples are placed directly onto the ceramic plate and are saturated on the plate. After bolting the extractor lid onto the Extractor, air pressure may be increased to the value of the test. (0.1 to 1500kPa). As soon as air pressure inside the chamber is raised above atmospheric pressure, the higher pressure inside the chamber forces excess water through the microscopic pores in the ceramic plate. The high pressure air , however, will not flow through the pores since they are filled with water and the surface tension of the water at the gas-liquid interface at each of the pores supports the pressure much the same as a flexible rubber diaphragm. At any given air pressure in the chamber, soil moisture will flow from around each of the soil particles and out through the ceramic plate until such time as the effective curvature of the water films throughout the soil are the same as at the pores in the membrane. When the air pressure in the Extractor is increased, flow of soil moisture from the samples starts again and continues until a new equilibrium is reached. At equilibrium, there is an exact but opposite relationship between the air pressure (positive force) in the extractor and the soil suction (negative force). Water content by weight or by volume can be determined for the sample that was at equilibrium with the pressure in the extractor.

**Test procedure.** The process of sample preparation is the same with the one mentioned in reference [8]. The saturated mud is still chosen as the initial sample. Prior to testing, the 15bar pressure plate is first put under the water until it is fully saturated. Then, remove the pressure plate onto the table, put the cutting rings on the pressure plate, putting a piece of round filter paper underneath each ring, then squeeze the mud out of the V-type plastic bag into the rings, smooth the top of mud samples in the rings, and then place them together into the extractor. Exert different pressures on the extractor. In each pressure level, when it is in equilibrium, open the extractor, take out a set of samples to test the water content, and then recover the extractor exert the next pressure. Repeat the above steps until it reaches the set pressure value. The test process is shown in Fig.3.



a. saturate the pressure plate b. pour the mud into cutting rings
c. placed the samples into pressure plate extractors

Fig.3 Testing process of the SWCC

## Analysis and Discussion of Test Results

The obtained values of water content versus imposed suction are plotted in Fig. 4. Fitting formulas and associated parameter values of corresponding curves are given in Table 3.

The results showed that the shape of SWCC is substantially similar for the 3 kinds of samples, water content and suction showed an inverse relationship. From the slope variation of the curve, when the suction at the range of 90-500kPa, with gradually decreasing of water content, suction increased slowly. When the suction is less than 90kPa or greater than 500kPa, with gradually decreasing of water content, the suction increased rapidly.

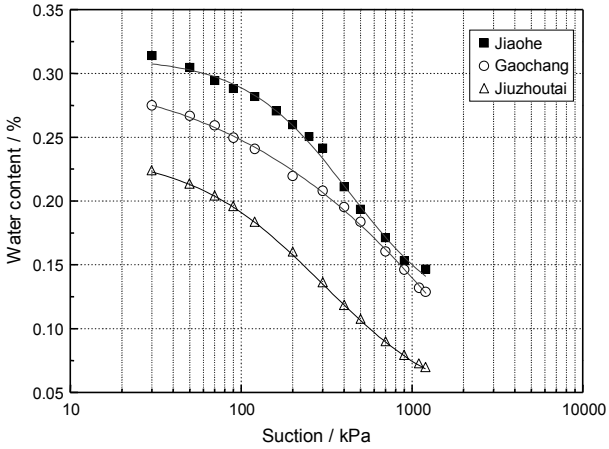


Fig.4 Soil shrinkage characteristic curves of three kinds of samples

Table 3 Fitting formulas and parameters

| Sample | Fitting formula | Parameters | Correlation coefficient |
|---|---|---|---|
| Jiaohe | $y=\beta+\frac{\alpha-\beta}{1+(x/\gamma)^{\lambda}}$ | $\alpha=0.3132$<br>$\beta=0.10289$<br>$\gamma=428.322$<br>$\lambda=1.42626$ | $R^2=0.99557$ |
| Gaochang | | $\alpha=0.30788$<br>$\beta=-0.24682$<br>$\gamma=4510.09$<br>$\lambda=0.55311$ | $R^2=0.99855$ |
| Jiuzhoutai | | $\alpha=0.23677$<br>$\beta=0.03352$<br>$\gamma=299.72$<br>$\lambda=1.1317$ | $R^2=0.99983$ |

Seen from the figure, at the same water content, suction values of Jiaohe and Gaochang samples are greater than that of Jiuzhoutai samples. And when the suction values are the same, the water content of Jiuzhoutai samples is lower than that of the others. It can be concluded that under the condition of the same water content, the pore water pressure of Jiaohe and Gaochang samples are lower than that of Jiuzhoutai samples. According to Kelvin capillary model equations, under the condition of same pore pressure, the pore water pressure (negative) decreases as the curvature radius of the gas-liquid interface decreases. In other words it is that the pore pressure decreases as the pore radius decreases [6-7].

The SEM photographs of three kinds of samples are presented in Fig. 5. As can be seen from the photographs, the pores of Jiaohe and Gaochang samples are significantly smaller than that of Jiuzhoutai samples. The corollary above is proved to be correct.

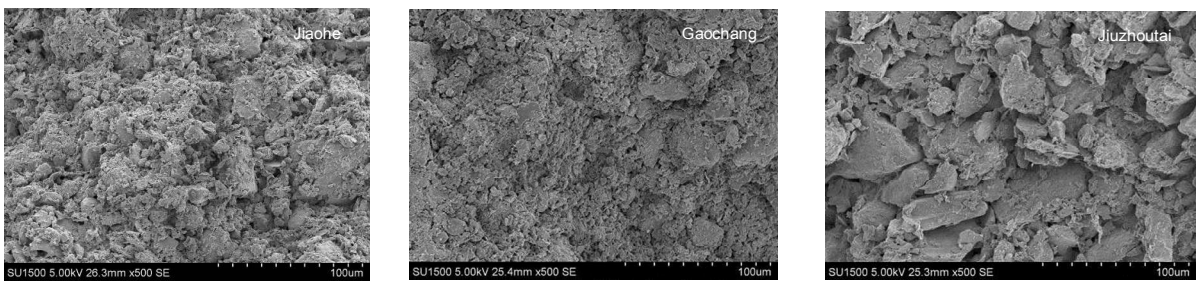

Fig.5 SEM photographs of three kinds of samples

Based on the data of SWCC and the results gained from reference [8], the corresponding s-e (suction-void ratio) and s-$S_r$ (suction-degree of saturation) curves are given in Fig. 6-7. The figures show that with the evaporation of water, the suction increases, and the degree of saturation decreases, along with reducing of the void ratio and the shrinking of samples volume.

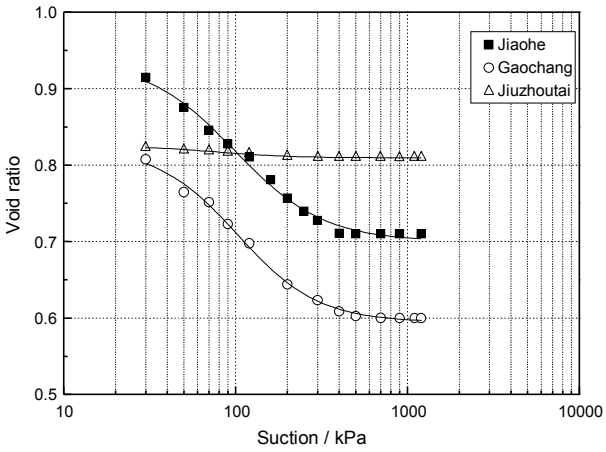

Fig.6 Relationship between suction and void ratio

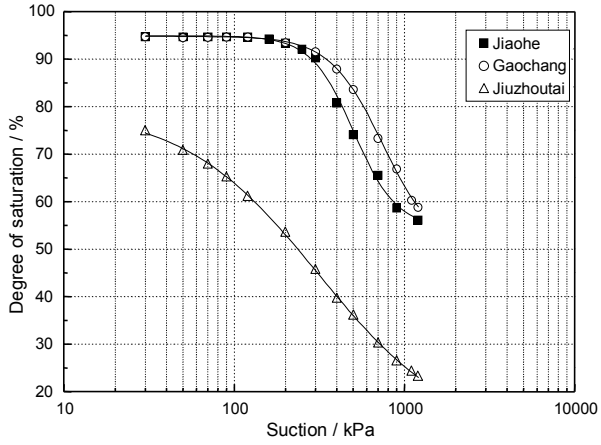

Fig.7 Relationship between suction and degree of saturation

Fig.6 shows that when the suction increases to a certain extent, the void ratio of samples remain unchanged, the corresponding point is defined as the shrinkage limit suction (SLS). The SLS should be consistent with the suction which is gained at the shrinkage limit water content. Fig.7 shows that in the early dryness for the Jiaohe and Gaochang samples, the decrease in water volume results in an equal decrease in bulk soil volume, with the internal pores still being fully saturated, so the degree of saturation remains unchanged. With the decrease of water content, air enters the internal pores, since then, the degree of saturation begins to decrease, until the water content reach to the humidity of the ambient air outside, the decrease can stop and reaches a certain value. For the Jiuzhoutai samples, the situation is different. Due to the presence of large particles, in the early dryness of the Jiuzhoutai samples, the decrease in water volume results in an smaller decrease in bulk soil volume, so air quickly enters the internal pores, resulting in the decrease of degree of saturation in the early period[9].

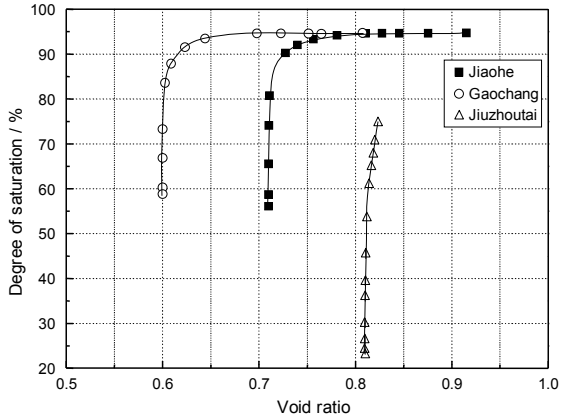

Fig.8 Relationship between degree of saturation and void ratio

During the drying process of samples, the relationship between degree of saturation and void ratio is given in Fig.8. It shows that when the degree of saturation is higher than 90%, the void ratio of Jiaohe and Gaochang samples changes very obviously. As the degree of saturation continues to decrease (in the range of 80-90%), the reduced amplitude of void ratio becomes smaller. When the degree of saturation is lower than 80%, decrease of the void ratio stops. For the Jiuzhoutai samples, because of the large particles skeleton, the volume of the soil samples change a little, so the amplitude of the void ratio shows a similar trend, i.e., little change.

**Conclusions**

(1) The results show that the shape of SWCC of three kinds of samples taken from jiaohe, gaochang and jiuzhoutai is similar to the inverted letter S, the relationship between water content and matric suction is inversely proportional.

(2) Under the condition of the same water content, suction values of Jiaohe and Gaochang samples are greater than that of Jiuzhoutai samples. And when the suction values are the same, the water content of Jiuzhoutai samples is lower than that of the others. It can be concluded that under the condition of the same water content, the pore water pressure of Jiaohe and Gaochang samples are lower than that of Jiuzhoutai samples.

(3) When the water content reaches the air entry value, the degree of saturation begins to decrease, when the degree of saturation is below 80%, decrease of the void ratio stops, the main shrinkage process of samples volume usually occurs before the degree of saturation reduces to 90%.

**Keywords:** ABAQUS finite element method, anti-slide pile, soil slope, stability

**Abstract**

The research uses the method of three-dimensional finite element analysis combined with the actual project application to study the slope reinforced by anti-slide pile. The research analyses the influence of reinforcement that the anti-slide exert on the soil and shows the changes of the sliding surface properties by establishing the finite element numerical model. The conclusion can be made that the ABAQUS finite element method is visual and practical. The study is of great benefit to the actual engineering.

## Introductions

Landslide is one of the most common accidents in the project. Many factors cause the landslide that will seriously affect the safety of traffic and people's lives once it happens. In the study of prevention and control of landslide, a variety of engineering measures are put forward. The methods of anti-slide pile which are widely used occupy the important position. Materials making anti-slide piles include the earliest application of piles, the steel pile and the most widely used reinforced concrete pile. Different from common pile foundation, anti-slide pile mainly bears lateral loads, which is similar with the stress characteristics of the beam. However, the sliding surface and the effect of soil resistance make it a kind of statically indeterminate structure which is different from that of the simple beam. According to the plenty of research on slide problems and the anti-slide pile by theoretical studies ,numerical model and field monitor conducted by scholars at the country and abroad.This article utilizes ABAQUS finite element and Shear Strength Reduction Factor method to demonstrate the effect of anti-slide pile, on the basis of previous studies and combined with the actual project.

## SSRF (Shear Strength Reduction Factor)

**1.1 Introduction of Shear Strength Reduction Factor.** Shear Strength Reduction Factor is presented by Zienkiewicz and his colleagues, which widely adopted by many scholars now. They proposed a shear strength reduction factor ($F_r$). Under the condition of invariable loads, $F_r$ means maximum shear strength in the soil dividing by the actual shear stress produced by external load.
In a limit condition, actual shear stress produced by external load is equal to minimum shear strength that is same as shear stress identified after reduction. Shear strength parameters can be expressed as Eq.1

$$C_m = \frac{c}{F_r}$$

$$\varphi_m = \tan^{-1}\left(\frac{\tan\varphi}{F_r}\right)$$

**Eq.1 Shear strength parameters**

In the equation $C$ and $\varphi$ are shear strength in the soil, $C_m$ and $\varphi_m$ are the actual shear stress produced by external load. $F_r$ is shear strength reduction factor. The initial value of $F_r$ is little enough to ensure stability of soil. The value of it does not increase until soil slope becomes instability

**1.2 The advantage of SSRF compared with other method.** (1) Complex landform and geology slope can be easily calculated. (2) Take soil constitutive relation and effect of deformation on stress

into consideration. (3) Simulate the shape of slip plane; the shape of slip plane is usually determined by the shear strain or displacement increment (4) Consider combined action between soil and supporting structure (fore poling, soil nailing, surface, etc.) (5) No necessary to premise the shape of slip surface and no need to slice.

**1.3 SSRF in ABAQUS.** From the basic principle, the essence of SSRF is that $C$ and $\varphi$ gradually reduce by time which results in a unit of the internal force beyond the yield surface. The stress cannot be bear will be gradually transferred to the soil around the unit. After the sliding surface appears, soil becomes instability. The parameters of the material in ABAQUS can change with temperature and field variables; can be easy to implement process of the decreased strength parameters. The followings are the procedure:

Step1. We should define a field variable; usually reduction factor is equal to the field variable.

Step2. Material parameters that are changed with field variables are realized in this step.

Step3.When analysis starting, we specify the magnitude of field variables .At the same time, gravity is working. To avoid destruction, $F_r$ is quite little even less than 1.

Step4. In the subsequent analysis steps, Fr increases linearly. When the calculation aborted (Numerical convergence), we analyze results. By evaluation criterion of instability, we work out the safety factor.

## Establishment of the numerical model

**2.1Model overview.** There is a soil slope reinforced by an infinite long friction pile . The height of soil is 10.0 m with a 2 in 3 slope; Diameter of the anti-slide pile is 0.8 m; pile length is 15.5 m; pile spacing is 4 times the pile diameter; the position of the pile is 10.5 m away from slope foot.

**2.2 The establishment of the initial state**

(1) Definite the model size according to the general situation . We should reserve zone of pile on the soil when establishing the parts of soil and pile, like **Fig.1.**

(2) Set up the material and sectional property. The soil obeys Mohr - Coulomb model (an ideal linear elastic), at the same time the pile is suppose to be elastic material. Soil and pile parameters list as **Table 1**.

(3) Analysis step is used to apply gravity load as the initial stress state to realize strength reduction

**Table.1 Parameters of the numerical model**

| Materials | Density /kg·m$^{-3}$ | Poisson's ratio | Young's modulus/ MPa | Cohesion /Kpa | friction angle/° |
|---|---|---|---|---|---|
| Soil | 1900 | 0.3 | 60 | 35 | 35 |
| Pile | 2400 | 0.25 | 30 000 | | |

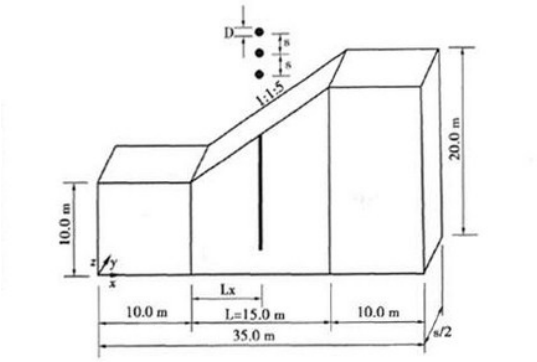

**Fig.1 Establishment of the model**

**2.3 Realization of interaction.** Contect between pile and soil has a great influence on the calculation results. The numerical model set up interaction property at the beginning and use the algorithm of master-slave surface. The master one is surface of pile, to the contrary soil is the slave surface. Normal contact obeys hard contact. We use penalty function as frictional characteristic with 0.51 as its friction coeff

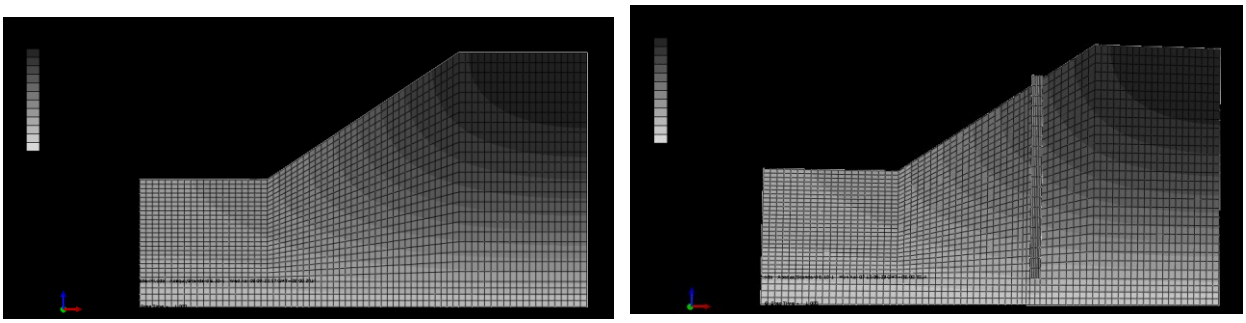
**2.4 Boundry conditons.** Given full consideration to the actual working condition, the numerical calculation model of boundary conditions are as follows:

(1) Restrain x displacement both side of model.(2) Restrain y displacement front and back(3) Fixed bottom of model ,that is to say, restrain three orientations displacements.(4) Restrain y displacement of the symmetry plane on the pile

**2.5 Realization of strength reduction.**Import data from the initial stress state, then modify the material properties and add *Reduce* analysis step to realize linearly increasing of field variable.After that , creat job and submit it.

## Calculation results analysis

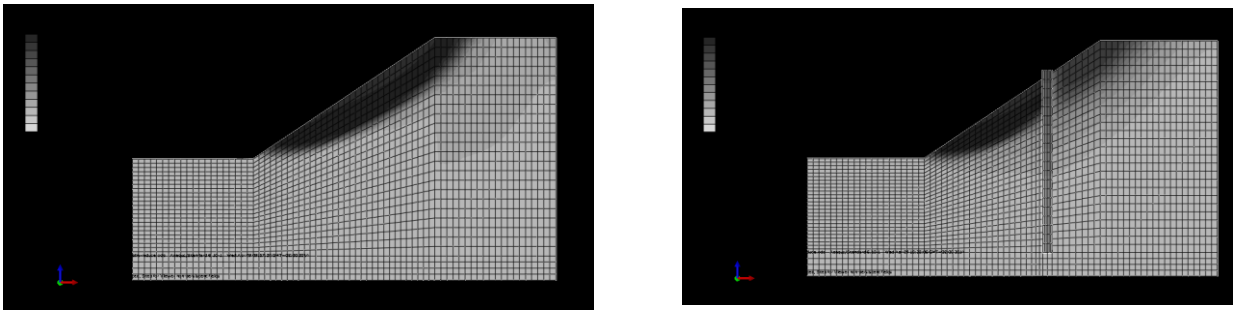
**3.1 The analysis of the initial state.** It is initial but the most importment when ground stress is balanced at the beginning. As shown in **Fig.2**, displacements are calculated respectively before and after the reinforcement. Existence of anti-slide pile makes the settlement of roadbed overall reduced, but the effect is not obvious.



**A.non-pile** **B. with pile reinforcement**

**Fig.2 Displacements before and after the reinforcement**

**3.2 After considering strength reduction.** Continuous sliding zone of slope has been formed before reinforcement, nonetheless, the existence of the anti-slide pile make great difference on cloud picture of displacement increment. The anti-slide pile effectively prevented the sliding of upper soil, and as a result, the overall circular slip surface does not appear. But the preceding soil still could be pulled away from the anti-slide pile, the thrust of soil is borne by pile.



**A.non-pile** **B. with pile reinforcement**

**Fig.3 Displacement increment before and after the reinforcement**

**3.3 Deformation of the pile and the soil pressure of the pile body**

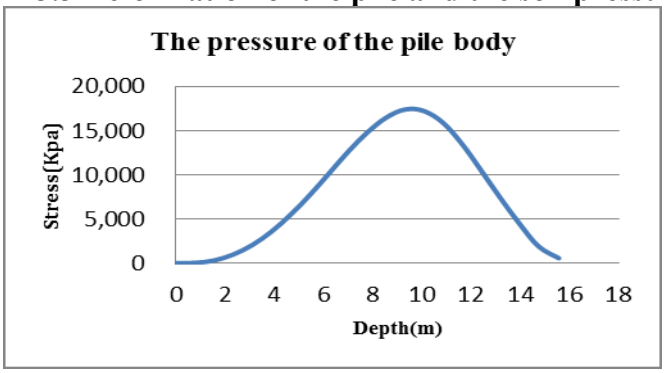


**Fig.4** Soil pressure of the pile body

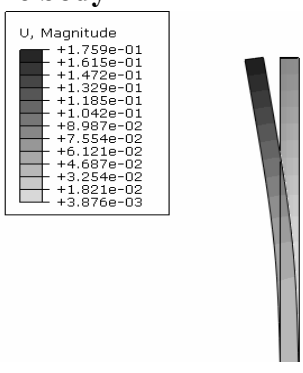

**Fig.5 Deformation of the pile**

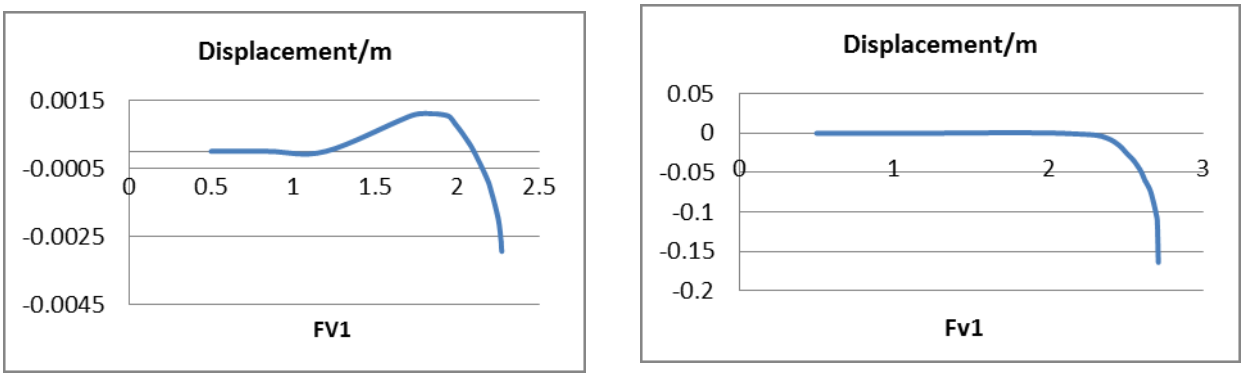
**Fig.4** pile pressure value maximum at a depth of 10 m that is easy to destory.
Buckling deformation of pile is given in **Fig.5**, and shows the top of the pile produced bending deformation, while the lower present a good anchor that is a typical long pile deformation model.



**A.non-pile** **B. anti-slide pile**

**Fig.6 The relationship between FV1 (Fr) and U1**

By **Fig.6**, the displacement of the inflection point is taken as the evaluation standard. the safety coefficient of reinforced soil is 2.20, while before reinforced is 2.50. The strengthening effect of anti-slide pile is obvious.

## Conclusions

(1) Accuratly prediced instability of slip crack surface form and potential destory location before and after reinforcement, at the same time proved the correctness of the numerical simulation.
(2) In the initial stress state, the impact of the anti-slide pile is not so big for the displacement of soil, but for the vertical stress distribution has great influence.
(3) It sets the anti-slide pile in the soil of the reinforced soil mass in front of the safety coefficient increases sharply when considering strength reduction. The thrust of soil is borne by pile which effectively reduce the deformation of the pile and inhibit the formation of sliding zone when soil pulled away from the pile.

**Keywords:** Composite foundation with cement-fly ash-gravel piles; design optimization analysis; pile-soil interaction; thickness-diameter ratio.

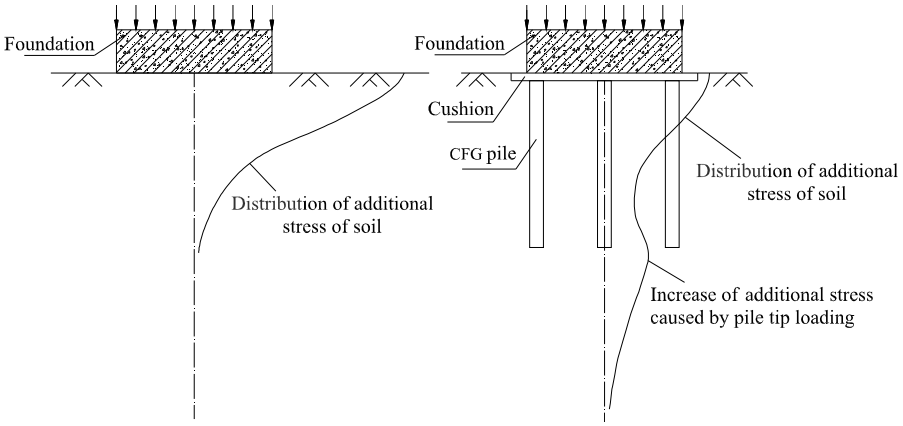
**Abstract.** Based on theoretical analysis and experimental result, the principle as well as the interaction between pile and soil, the design parameters of composite foundation with cement-fly ash-gravel piles (CFG piles for short) are optimized, which are pile length, pile diameter, pile spacing, pile strength and thickness of cushion layer, in order to put forward the reasonable design parameters for reaching economic and reasonable target. Through the optimized analysis, it is put forward that bearing stratum of pile tip should select a relatively better soil layer, the diameter of CFG pile is usually appropriately to select between 350mm and 500mm, it is usually appropriately to select larger pile spacing under the permissible range between 3*d* and 5*d* being ruled by standard, it is appropriately to enlarge the pile diameter to reduce the requirement of pile strength in high rise and super high rise building which requiring bearing capacity of single pile is high, and the thickness of cushion layer is appropriately to select between 0.4 and 0.6 times of the pile diameter.

## Introduction

The technology of composite foundation with cement-fly ash-gravel piles (CFG piles for short) was invented by Institute of Foundation Engineering of China Academy of Building Research around 1990 [1, 2]. This kind of composite foundation, because of the existence of cushion layer, achieved interaction between pile and soil. It was applied in multistoried building at first, and extended into high-rise and super high-rise building widely through more than twenty years of scientific research and engineering practice. Remarkable economic and social benefit is obtained. There are five design parameters in design of composite foundation with CFG piles, which are pile length, pile diameter, pile spacing, pile strength and thickness of cushion layer. How to optimize the design parameters of composite foundation with CFG piles, in order to reach the purpose of the economic and reasonable, is discussed in this study.

## Pile Length Optimized

**Distribution of Vertical Stress Field in Soil.** The distribution of additional stress of the soil along the depth in natural foundation and composite foundation with CFG piles are shown in Fig. 1.



(a) Natural foundation (b) Composite foundation with CFG piles

**Fig. 1 Distribution of additional stress of the soil along the depth**

It can be drawn from Fig. 1 that there is a world of difference between the distribution of additional stress of the soil along the depth in natural foundation and composite foundation with CFG piles. The additional stress of the soil among piles is increased in the tip of piles, as the action of piles tip load.

**Present Problems and Measurement.** During composite foundation design with CFG piles, it usually selects the bearing stratum at pile tip according to investigation report at first, then preliminary determining the pile length.

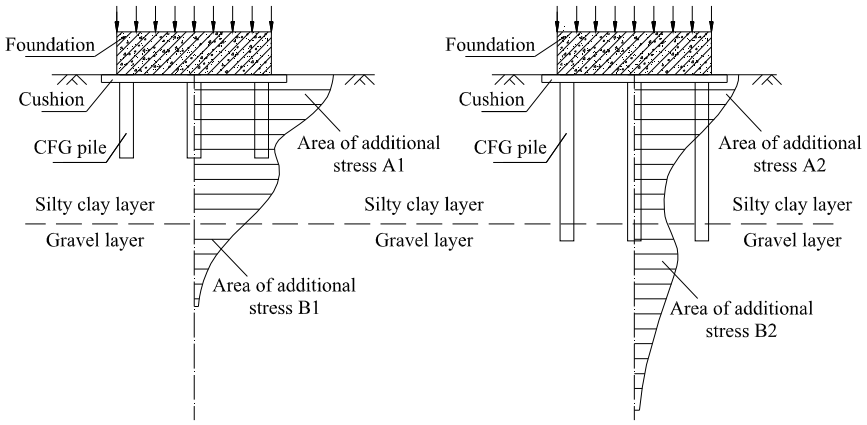
The bearing stratum of pile tip is usually appropriate to select the soil layer, whose bearing capacity and compression modulus are relatively higher (such as gravel layer), as the additional stress of the soil among piles is added for piles tip loading around the tip of piles. However, it caused a lot of problems for the relatively low of bearing capacity and compression modulus soil layer (such as silty clay layer) is selected as the bearing stratum of pile tip by a lot of designers in many projects. The dotted line above is silty clay layer in Fig. 2, and below is gravel layer which has a relatively higher of bearing capacity and compression modulus. Two kinds of piles are designed in Fig. 2, which are short pile (shown in Fig. 2a) and long pile (shown in Fig. 2b), and the bearing stratums of pile tip are silty clay layer and gravel layer.

Under the same loading effect, two kinds of composite foundation with CFG piles can be analyzed as following:

First, above the dotted line in Fig. 2, assuming A1 is the area of additional stress of composite foundation with short CFG piles in Fig. 2a, and it is bigger than A2 in Fig. 2b. Therefore, the settlement of composite foundation with short CFG piles above dotted line is much more than the composite foundation with long CFG piles. Second, below the dotted line in Fig. 2, assuming B1 is the area of additional stress of composite foundation with short CFG piles in Fig. 2a, and it is smaller than B2 in Fig. 2b. Thus, the settlement of composite foundation with short CFG piles bellow dotted line is less than the composite foundation with long CFG piles. But overall, the settlement of composite foundation with short CFG piles is bigger than the composite foundation with long CFG piles. Furthermore, the bearing capacity of single short pile is smaller than the long pile, for both pile length and the bearing stratum of pile tip, as the long pile has a relatively better bearing layer because the bearing capacity and compression modulus are relatively higher.

Therefore, considering both bearing capacity and deformation, it leads problem to increase the numbers of piles because of adopting the short piles scheme. Assuming it only needs three hundred long piles, and it may need five hundred short piles. It causes the increasing of wasted mixtures, reducing the construction efficiency and bringing adverse effects about constructed piles as the numbers of piles increased.

Thus, during foundation design with CFG piles composite, the relatively better bearing layer should be selected as the bearing stratum of pile tip, whose bearing capacity and compression modulus are relatively higher. So it can control the overall deformation better, play the end resistance of pile tip well, and also avoid the uneven settlement building which may cause by the large changing of the ground lithology. The higher the bearing capacity and compression modulus of the pile tip bearing stratum are, the faster the building settlement stability is [1].



(a) Composite foundation with short CFG piles, (b) Composite foundation with long CFG piles

**Fig. 2 Distribution of additional stress of the soil among piles along the depth**

**Pile Diameter Optimized**

Characteristic value of single CFG pile bearing capacity can be assumed by following [4]:

$$R_a = u_p \sum_{i=1}^{n} q_{si} l_{pi} + \alpha_p q_p A_p \quad (1)$$

Where, $u_p$ is circumference of pile, $q_{si}$ is the side resistance characteristic value of the *i* soil layer around pile, $l_{pi}$ is the thickness of the *i* soil layer of pile length within the range, $q_p$ is the characteristic value of pile tip resistance, $A_p$ is sectional area of the pile, and $\alpha_p$ is play coefficient of pile tip resistance, which can be taken as 1.0 for CFG pile.

Supposing bearing capacity provided by unilateral concrete is $f_{Ra}$, and it can be written as follow,

$$f_{Ra} = R_a / V \quad (2)$$

Supposing pile length is $l_p$ ($l_p = \sum_{i=1}^{n} l_{pi}$), then needed mixtures of one single pile can be calculated as following,

$$V = \pi d^2 l_p / 4 \quad (3)$$

$f_{Ra}$ can be calculated from Eq. 1, Eq. 2 and Eq. 3,

$$f_{Ra} = 4 \sum_{i=1}^{n} q_{si} l_{pi} \Big/ (d l_p) + q_p / l_p \quad (4)$$

Based on Eq. 4, when the side resistance characteristic value $q_{si}$, characteristic value of pile tip resistance $q_p$, and pile length $l_p$ are determined, the larger the pile diameter $d$ is, the smaller the bearing capacity $f_{Ra}$ provided by unilateral mixture is.

The changing of bearing capacity value $f_{Ra}$ provided by unilateral concrete with the pile diameter under the same condition is shown in Table 1 and Fig. 3.

**Table 1 $f_{Ra}$ changing with the pile diameter under the same condition**

| Pile diameter (m) | Pile length (m) | $R_a$* (kN) | Needed mixture of one single pile ($m^3$) | $f_{Ra}$ ($kN/m^3$) |
|---|---|---|---|---|
| 0.3 | 10 | 324.99 | 0.71 | 460.00 |
| 0.6 | 10 | 734.76 | 2.83 | 260.00 |
| 0.9 | 10 | 1229.31 | 6.36 | 193.33 |
| 1.2 | 10 | 1808.64 | 11.30 | 160.00 |
| 1.5 | 10 | 2472.75 | 17.66 | 140.00 |
| 1.8 | 10 | 3221.64 | 25.43 | 126.67 |

*Side resistance characteristic value $q_{si}$ is 30kPa and pile tip resistance characteristic value $q_p$ is 600kPa.

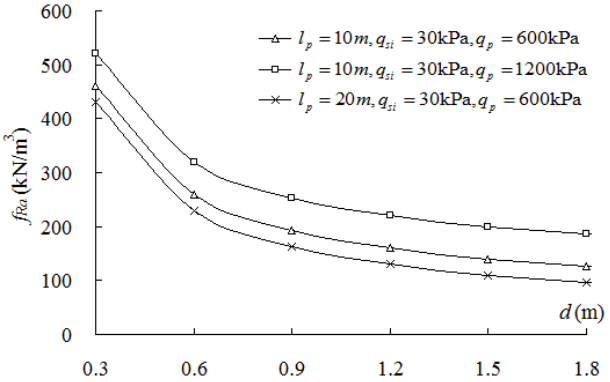


**Fig. 3 $f_{Ra}$ changing with the pile diameter under the same condition**

It can obtain from Table 1 and Fig. 3 that the larger the pile diameter is, the lower the bearing capacity value $f_{Ra}$ is, which is provided by unilateral concrete under the same condition. So the thick pile is not economic. The smaller the pile diameter is, the larger the pile specific surface area is, and the bearing capacity value provided by unilateral mixture is the higher. However, the construction quality can not be controlled easily if the pile diameter is too small. Therefore, the diameter of CFG pile is usually appropriate to select between 350mm and 500mm, when the requirement of bearing capacity of single pile is not high.

## Pile Spacing Optimized

A project has adopted the construction technology of composite foundation with CFG piles to reinforce in northeast China. The pile diameter is 500mm, pile length is 15m, and pile spacing is 1.5m. The bearing stratum of pile tip is silty clay ⑤ layer (shown in Fig. 4). It is happened fleeing bore while piling, and it is still fleeing bore while jumping the pile spacing (pile spacing is 3.0m). Through analyzing, it is caused by the pile spacing, which is too small as it is only 3*d* (*d* is the pile diameter). It is easy happening fleeing bore at the silty clay ② layer and saturated silt ④ layer. After redesigning, the pile diameter is 400mm, pile length is 24m, bearing stratum of pile tip is coarse sand ⑥ layer, and pile spacing is 5*d* (*d* is the pile diameter). Few fleeing bore is happened while piling. The pile spacing should be determined to meet the design requirement of bearing capacity of composite foundation, control the settlement of building, soil characteristics, and construction technology. The pile spacing is not the smaller the better. Considering from the angle

of construction, it should enlarge the pile spacing as possible, in order to prevent adverse effect on piled pile from new piling pile.

Pile spacing can be adjusted by changing pile length, under the condition of bearing capacity and deformation requirements, and it should select a relatively better bearing layer used as the bearing stratum of pile tip, whose bearing capacity and compression modulus are relatively higher. It is usually appropriate to select larger pile spacing, under the permissible range between 3*d* and 5*d* being ruled by standard [4] (*d* is the pile diameter).

**Pile Strength Optimized**

According to "Technical code for ground treatment of buildings" (JGJ 79-2012) [4], when does not need making depth correction of bearing capacity of composite foundation carrying on embedded depth of foundation, it should meet the following requirement,

$$f_{cu} \geqslant 4\lambda R_a / A_P \tag{5}$$

Where, $f_{cu}$ is the cube compressive strength average value of pile body cubic (the side length of the cube is 150mm) of 28 days under the standard curing condition (kPa); $R_a$ is characteristic value of single pile bearing capacity (kN); $A_p$ is section area of pile ($m^2$); $\lambda$ is exerting coefficient of single pile bearing capacity.

Determining single pile bearing capacity of $R_a$, assuming pile diameter is $d$ , the pile strength is $f'_{cu}$ , and it can be written as the following,

$$f'_{cu} = 4\lambda R_a / A_P = 16\lambda R_a / (\pi d^2) \tag{6}$$

Base on Eq. 6, when single pile bearing capacity of $R_a$ is determined, the smaller the pile diameter is, the higher the pile strength is. The pile strength and corresponding strength grade of concrete under different conditions are shown in Table 2 and Fig. 5.

**Table 2 Pile strength and corresponding strength grade of concrete under different conditions**

| Pile Diameter (m) | $R_a = 500$kN | | $R_a = 1000$kN | |
|---|---|---|---|---|
| | Pile strength (MPa) | Concrete strength | Pile strength (MPa) | Concrete strength |
| 0.3 | 25.48 | C30 | 50.96 | C65 |
| 0.6 | 6.37 | C15 | 12.74 | C15 |
| 0.9 | 2.83 | C15 | 5.66 | C15 |
| 1.2 | 1.59 | C15 | 3.18 | C15 |
| 1.5 | 1.02 | C15 | 2.04 | C15 |
| 1.8 | 0.71 | C15 | 1.42 | C15 |

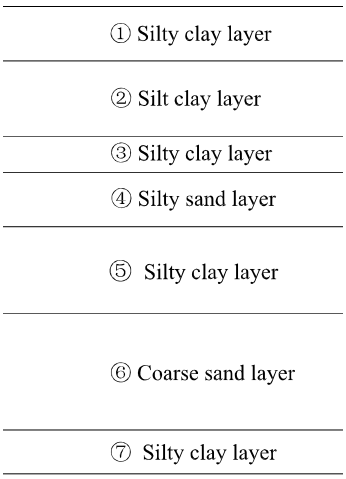

**Fig. 4 Schematic diagram of typical geological profile of ground**

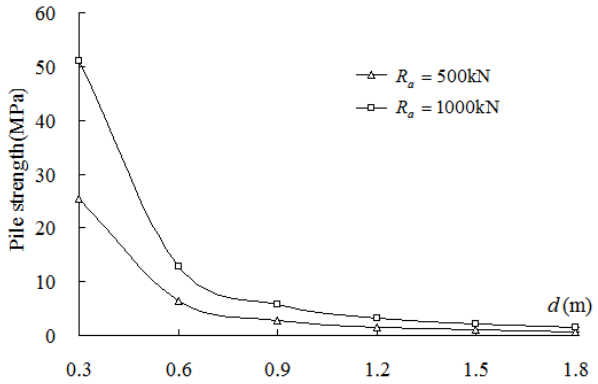

**Fig. 5 Pile strength and corresponding concrete strength under different conditions**

It can be obtained form Table 2 and Fig. 5 that the smaller pile diameter is, the higher pile strength is. Under the same condition of pile diameter, the larger bearing capacity of single pile is, the higher pile strength is. Thus, pile diameter is usually appropriate to select between 350mm and 500mm, while the strength grade of concrete is between C15 and C40. It is appropriate to enlarge the pile diameter to reduce the requirement of pile strength in high rise and super high rise building, which requiring higher bearing capacity of single pile.

### Thickness of Cushion Layer Optimized

The technology of cushion layer is the key technology of composite foundation with CFG piles. The existing of cushion layer guarantees the soil among piles to work throughout under normal condition, achieve interaction between pile and soil, and take important part in improving the distribution loading of pile and soil in foundation.

Therefore, the thickness of cushion layer is one of the main factors of exerting coefficient of pile and soil bearing capacity, which is usually expressed as thickness-diameter ratio (the ratio of the thickness of cushion layer to pile diameter is defined as thickness-diameter ratio). When the rigidity foundation and pile diameter is given, the thicker cushion layer is, the smaller the exerting coefficient of pile bearing capacity is, and the thinner cushion layer is, the smaller the exerting coefficient of soil bearing capacity is. It can define the ratio of pile top stress to characteristic value of single pile bearing capacity is $\lambda_1$, and the ratio of soil stress to characteristic value of foundation bearing capacity is $\lambda_2$, when the loading reaches the characteristic value of composite foundation bearing capacity.

The tests indicate that the smaller thickness-diameter ratio is, the larger exerting coefficient of single pile bearing capacity is, and exerting coefficient of bearing capacity of soil among piles is the smaller. The tests also indicate that larger thickness-diameter ratio is, the smaller exerting coefficient of single pile bearing capacity is, and exerting coefficient of bearing capacity of soil among piles is the larger. The exerting coefficient of single pile and soil bearing capacity is more fully, when the thickness-diameter ratio is in the range of 0.4 to 0.6 (shown in Fig. 6).

Thus, the thickness of cushion layer is appropriately to select between 0.4 and 0.6 times of the pile diameter. The appropriate material of cushion layer includes medium sand, medium sand, graded sand-gravel and gravel, etc.

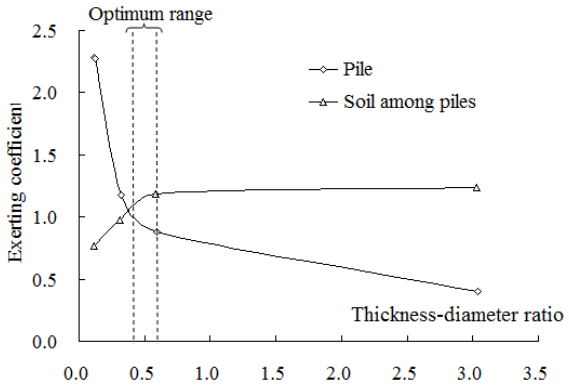

**Fig. 6 Relationship curve for exerting coefficient of single-type-pile and soil bearing capacity of composite foundation with CFG piles and thickness-diameter ratio [5]**

(When the loading reaches the characteristic value of composite foundation bearing capacity)

## Conclusions

The following conclusions can be drawn from this study.

(1) Bearing stratum of pile tip should select the soil layer, whose bearing capacity and compression modulus are relatively high.

(2) Diameter of CFG pile is usually appropriately to select between 350mm and 500mm, when the requirement of bearing capacity of single pile is not high.

(3) Pile spacing should be determined to meet the design requirement of bearing capacity of composite foundation, control the settlement of building, soil characteristics, and construction technology. The pile spacing is not the smaller the better. Considering from the angle of construction, it should enlarge the pile spacing as possible in order to prevent adverse effect on piled pile from new piling pile. Pile spacing can be adjusted by changing pile length, under the condition of bearing capacity and deformation requirements, and it should select the relatively better bearing layer for the bearing stratum of pile tip, whose which bearing capacity and compression modulus are relatively higher. It is usually appropriately to select larger pile spacing, under the permissible range between 3*d* and 5*d* being ruled by standard (*d* is the pile diameter).

(4) Pile diameter is usually appropriately to select between 350mm and 500mm, while the strength grade of concrete is between C15 and C40, in multistoried building, which requiring bearing capacity of single pile is not high. It is appropriately to enlarge the pile diameter to reduce the requirement of pile strength in high rise and super high rise building, which requiring bearing capacity of single pile is high.

(5) Thickness of cushion layer is appropriately to select between 0.4 and 0.6 times of the pile diameter. The appropriate material of cushion layer includes medium sand, medium sand, graded sand-gravel and gravel, etc.

**Keywords:** Composite foundation with rigid long and short piles; Thickness-diameter ratio; Exertion of bearing capacity; Thickness of cushion

**Abstract**. Composite foundation can be designed as long and short piles that lie on different bearing strata with high bearing capacities. Researches have shown that for foundation with sufficient stiffness, the ratio of the thickness of cushion to pile diameter (thickness-diameter ratio) plays an important role on the exertion of bearing capacities of pile and soil between piles. Traditional method just applies equal thickness-diameter ratio to design composite foundation with long and short piles, which hinders the exertion of bearing capacity of composite foundation. To overcome this defect, this paper studies the relations between thickness-diameter ratio and the exertions of bearing capacities of pile and soil between piles. The design method of thickness-diameter ratio for composite foundation with long and short piles is also proposed in this study.

## Introduction

When there are two bearing strata with high bearing capacity in the different buried depths of foundation soil, within the reasonable ranges of pile length and spacing of composite foundation with rigid pile, if short piles are used, bearing capacity can satisfy requirement, but the deformation of foundation is likely to be too large. If long piles are applied, both bearing capacity and deformation can satisfy requirement, but bearing capacity may be too high, which induces conservation and waste of the project. In this condition, composite foundation can be designed as long and short piles that lie on different bearing strata [1 - 3].

If composite foundation with long and short piles is applied, it is optimal that long pile, short pile and soil between piles reach their bearing capacities simultaneously, which means that the exertion coefficients of bearing capacities of long pile ($\gamma_1$), short pile ($\gamma_2$) and soil between piles ($\beta$) all equal 1.0. To achieve this goal, the current existing problems are: (1) Determining how to adjust parameters of composite foundation to fully exert the bearing capacity of pile. (2) Under what conditions that the bearing capacities of pile and soil between piles reach their characteristic values simultaneously?

Researches [4 - 6] have shown that for foundation with sufficient stiffness, the ratio of the thickness of cushion to pile diameter (thickness-diameter ratio) plays an important role on the exertion of bearing capacities of pile and soil between piles. Traditional method just applies equal thickness of cushion and pile diameter to design Composite foundation with long and short piles,

which hinders the exertion of bearing capacity of composite foundation. To overcome this defect, this paper studies the relations between thickness-diameter ratio and the exertions of bearing capacities of pile and soil between piles. The design method of thickness-diameter ratio for composite foundation with long and short piles is also proposed in this study.

## Exertion of bearing capacities of pile and soil between piles using equal thickness-diameter ratio

**Exertion of bearing capacities of pile and soil between piles for composite foundation with single pile type.** Fig. 1 shows the relations between $\alpha$ and exertion coefficients of bearing capacity of pile ($\gamma$) and $\beta$ when the bearing capacity of composite foundation with single pile type reaches its characteristic value.

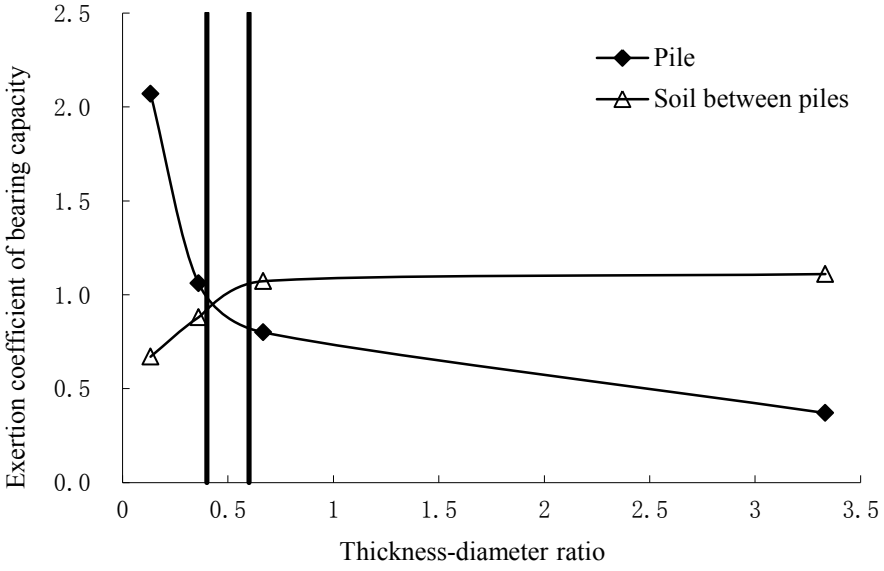

**Fig. 1 Relations between thickness-diameter ratio and exertion coefficients of bearing capacities of pile and soil between piles for composite foundation with single pile type (when the loading equals the characteristic value of bearing capacity for composite foundation)**

From Fig. 1, it can be seen that $\gamma$ decreases with the increase of $\alpha$. when $\alpha \leq 0.361$, the bearing capacity of pile can be fully exerted while the bearing capacity of soil between piles cannot be fully exerted. If $\alpha = 0.133$, $\gamma$ could reach as high as 2.07 which means that ultimate bearing capacity of pile is reached. But $\beta$ is just 0.67 in this condition. When $\alpha \geq 0.667$, the opposite trend is observed. The bearing capacity of soil between piles can be fully exerted while $\gamma$ is all along lower than 1.0. When $\alpha = 3.333$, $\gamma$ is only as low as 0.37.

The optimal range of $\alpha$ for composite foundation with single pile type is 0.4-0.6. Within this extent, the ranges of $\gamma$ and $\beta$ are 0.82-0.98 and 0.93-1.06.

**Exertion of bearing capacities of pile and soil between piles for composite foundation with long and short piles.** Fig. 2 shows the relations between $\beta$ and $\gamma_1$ *and* $\gamma_2$ when the bearing capacity of composite foundation with long and short piles reaches its characteristic value using equal $\alpha$.

From the figure, it can be seen that the bearing capacities of long pile, short pile and soil between piles cannot be fully exerted simultaneously (close or a little bit higher than the characteristic value of bearing capacity) if the same $\alpha$ is used. when $\alpha = 0.333$, the bearing capacities of long pile and short pile are over exerted, which are close to their ultimate bearing capacities, while $\beta$ is just 0.61. When $\alpha = 0.667$, $\gamma_1$, $\gamma_2$ and $\beta$ are 0.65, 0.96 and 1.17 respectively, which means that except long

pile, the bearing capacities of short pile and soil between piles can be exerted. When $\alpha \geq 1.333$, exertion Coefficients of bearing capacities of long and short piles are relatively low and the bearing capacities of piles cannot be fully exerted.

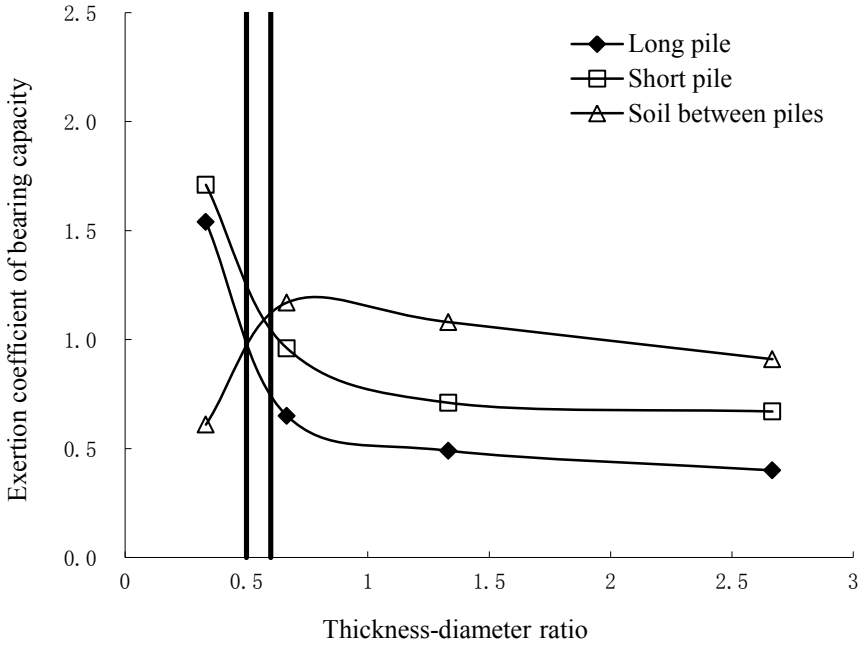

**Fig. 2 Relations between thickness-diameter ratio and exertion coefficients of bearing capacities of long pile, short pile and soil between piles for composite foundation with long and short piles (when the loading equals the characteristic value of bearing capacity for composite foundation)**

The optimal range of $\alpha$ for composite foundation with long and short piles is 0.5-0.6 using the equal $\alpha$. Within this extent, the ranges of $\gamma_1$, $\gamma_2$ and $\beta$ are 0.75-0.98, 1.04-1.25 and 0.98-1.12, respectively.

**Exertion of bearing capacities of pile and soil between piles for composite foundation using different thickness-diameter ratios**

Under the condition that equal $\alpha$ is used, it is difficult that the bearing capacities of long pile, short pile and soil between piles are fully exerted just by the means of adjusting the value of $\alpha$.

Table 1 shows the values of $\gamma_1$, $\gamma_2$ and $\beta$ when the bearing capacity of composite foundation with long and short piles reaches its characteristic value using equal thickness-diameter ratio.

From the table, it can be concluded that:

- If the fixed pile diameters are used and the thickness of cushion is increased for short pile and decreased for long pile, when the bearing capacity of composite foundation reaches its characteristic value, $\gamma_1$ is higher than the condition that the same thickness of cushion is used. Although $\gamma_2$ decreases slightly, the bearing capacity of soil between piles can be fully exerted. The bearing capacity of composite foundation with different thicknesses of cushion is larger than the condition that equal thickness of cushion is used.
- If the fixed thicknesses of cushion are used and the diameter of long pile are increased, when the bearing capacity of composite foundation reaches its characteristic value, $\gamma_1$ is higher than the condition that the equal pile diameter is used. Although $\gamma_2$ decreases slightly, the bearing capacity of soil between soils can be fully exerted.

- For long pile, if the thickness of cushion is decreased and the pile diameter is increased at the same time, $\gamma_1$ can be increased more rapidly.

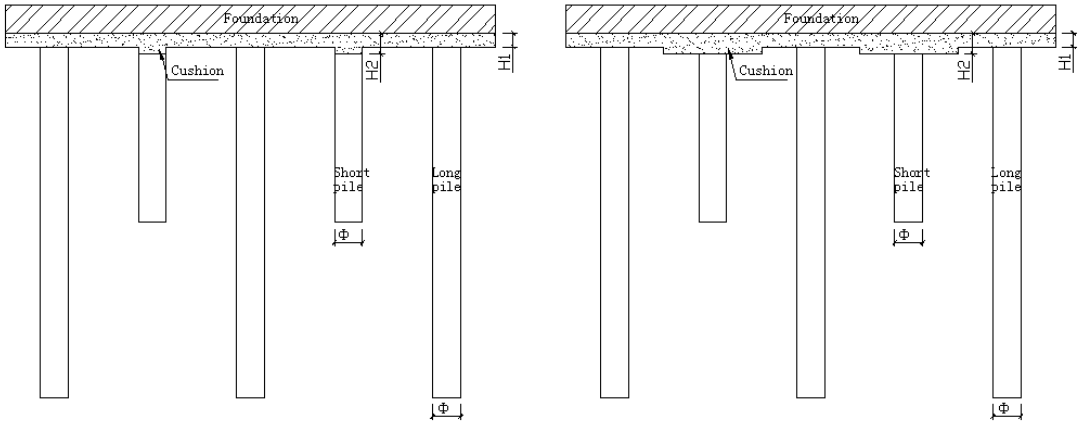
**Table 1 Exertion Coefficients of pile and soil between piles for composite foundation with long and short piles using different thick-diameter ratios**

| Test No. | Design method | $\alpha$ of long pile | $\alpha$ of short pile | $\gamma_1$ | $\gamma_2$ | $\beta$ |
|---|---|---|---|---|---|---|
| 1# | Equal pile diameter and different thicknesses of cushion | 0.333 | 0.667 | 1.02 | 0.89 | 1.14 |
| 2# | Equal thickness of cushion and different pile diameters | 0.341 | 0.5 | 0.95 | 0.88 | 1.10 |
| 3# | Different thicknesses of cushion and pile diameters | 0.333 | 0.5 | 0.90 | 0.97 | 1.12 |

**Design method of different thickness-diameter ratios for composite foundation with long and short piles**

On the premise that the bearing capacity of soil between piles are fully exerted, the bearing capacities of long pile, short pile and soil between piles can be exerted in an ideal combination by applying different $\alpha$ for long and short piles. The suitable ranges of $\alpha$ for long and short piles are 0.35-0.5 and 0.5-0.65. If there is no big difference between the bearing capacities of long pile and short piles, it is suggested to adopt lower value for long pile and higher value for short pile, or vice versa.

There are two design methods of $\alpha$ for composite foundation with long and short piles: (1) fixing pile diameter, $\alpha$ can be changed by using different thicknesses of cushions for long pile, short pile and soil between piles (Fig. 3); (2) Fixing the thickness of cushion, $\alpha$ can be changed by using different pile diameters for long and short piles (Fig. 4).

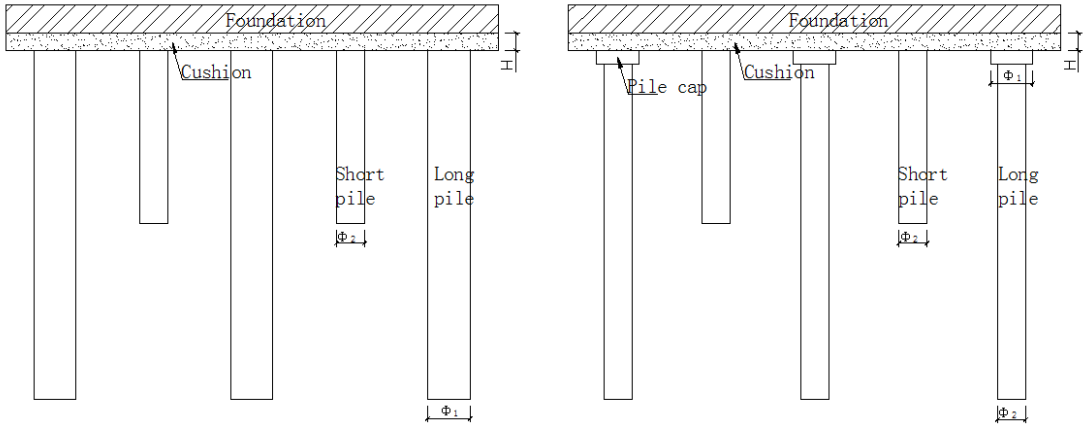


(a)Thickness of cushion is changed based on the areas of long and short piles

(b) Thickness of cushion is changed only within the range of short piles

**Fig. 3 Illustration of different thicknesses of cushion for composite foundation with long and short piles**

Fig. 4 (b) is another kind of method that changes the pile diameter. Smaller $\alpha$ can be achieved by applying pile cap and increasing cross section of pile top.



(a) The diameters of long and short piles are different

(b) The diameters of long and short piles are the same and pile cap are used for long pile

**Fig. 4 Illustration of different pile diameters for composite foundation with long and short piles**

It should be noted that when applying different $\alpha$ to design composite foundation with long and short piles, although decreasing the thickness of cushion can increase the bearing capacity of long pile, if the cushion is too thin, stress concentration will appear on the pile top, which is adverse to the punch resistant capability of foundation slab. Moreover, when the foundation bears horizontal loads, horizontal loads will also concentrated on the pile top, which violates the basic principal of composite foundation that mainly vertical loads are born. Therefore, the aim of adjusting the thickness of cushion is not to make the bearing capacities of long and short piles fully exerted. In other words, to ensure that pile doesn't punch the foundation and there is no excessive stress concentration on the pile top, it is not practical to make $\gamma$ equals 1.0. The usefulness of cushion for composite foundation with rigid pile is that it can ensure the exertion of bearing capacity of soil between piles and make the bearing capacities of long and short piles exerted in a relatively high level, which maximizes the total bearing capacity of composite foundation.

## Conclusions

This paper studies the relations between thickness-diameter ratio and the exertion of bearing capacities of pile and soil between piles of composite foundation with long and short piles. The following conclusions can be drawn from this study:

(1) The ratio of thickness to diameter for composite foundation with rigid reinforcement has a great influence on the exertion of bearing capacity of pile and soil between piles. The optimal range of $\alpha$ of composite foundation is 0.4-0.6.

(2) if $\alpha$ remains constant and is in the range of 0.5 and 0.6, the exertion coefficients of bearing capacity of long pile is less than that of short pile which is further less than that of soil between piles. It is difficult that the bearing capacities of long pile, short pile and soil between piles are fully exerted just by the means of adjusting the value of $\alpha$.

(3) The method of applying different $\alpha$ should be used in the design of composite foundation with long and short rigid piles. The suitable values of $\alpha$ for long and short piles are 0.35-0.5 and 0.5-0.65. If there is no big difference between the bearing capacities of long pile and short pile, it is suggested to adopt lower value for long pile and higher value for short pile, or vice versa.

(4) There are two design methods of $\alpha$ for composite foundation with long and short piles: (i) fixing pile diameter, $\alpha$ can be changed by using different thicknesses of cushions for long pile, short pile and soil between piles. (ii) Fixing the thickness of cushion, $\alpha$ can be changed by using different pile diameters for long and short piles.

**Keywords:** Highway slope, rain infiltration, seepage, safety factor

**Abstract.** The work condition of the highway, which is usually built in mountainous regions, is complex relative to the ordinary road. Slope instability accident caused by the seepage of rainwater usually occurred in the rainy season. The mechanism for seepage failure of slope was investigated by used the Mohr-Coulomb criterion and the principle of effective stress. The effect of rain intensity on slope stability was equivalently instead by the effect of moisture content on slope stability. The influence of moisture content on the safety factor of slope stability was further calculated according to the Bishop's method. The degeneration of safety factor follow to the moisture content was presented in the percentage.

## Introduction

With the development of transportation construction, there is a steady increase of road constructions in mountain area, but it is inevitable to build higher and dig deeper in the process of such constructions. Moreover, the roads were destroyed by continuous heavy rainfall, such as erosion of gaps that cause landslides. If not treated in a timely, it will cause more serious consequences (Wang, 1994). By the analysis of geomorphic and geologic characteristics of Chongqing, Lin (2001) concludes that when the rainfall intensity is greater than or equal to 100mm /d, the stability is poor and the slopes which are on the fringe of steady state may possibly transformed, partially damaged; When the rainfall intensity is greater than or equal to 150 mm/d, the fragile slopes will be transformed, damaged, collapse, and even cause the disasters of landslides and mud avalanche. Shimada (Shimada, et al., 1995) used finite element method to analyze the value of the slope stability. The influenced factors, such as the rainfall intensity, rock and soil strength were also investigated. The result shows that safety factor value of slope model observably reduces as the rainfall intensity increase; in term of rock-soil water retention curve closed to the saturated, a little change of matrix suction can result in significant reductions for slope safety factor. A key step of analysis the slope stability under the rain seepage is to determine the unsaturated soil's stability coefficient which is associated with water content. If the calculating capacity of the limiting equilibrium method can describe the changing process of safety factor, the reliable parameters for the slope safety protection will be provided to further guide the preventive works. According to the unsaturated earth drained shear strength theory, the influence of water content on unsaturated shear strength was analyzed in this paper. The calculation of slope stability under the rain seepage condition was carried out by applying simplified Bishop's method.

## Influence factors

**Geographical and geological influences.** Complex geological environment of the mountain is an important factor for the slope stability, especially fault unconformity mountain, creating the conditions for the surface runoff, which decline strength of soil and rock, seriously affecting highway slope stability.

**Rainfall infiltration and surface runoff influences.** A large number of construction cases show that more than ninety percent slope instability accident was occurred under condition of rainfall (Sun, et al., 1998). The main reason for this phenomenon is that pore water pressure and soil pressure rise with the increase of rainfall intensity and emerges seepage force to reduce cohesive force and friction

angle, which leads to the decrease of soil strength and slope stability. So this can be looked as a transformation process from unsaturated soil to saturated soil.

**Water influences.** Mohr-Coulomb raised the theory of unsaturated soil from the experiment of sand.

$$\tau_f = c + \sigma \tan \varphi \tag{1}$$

Where $\tau_f$ is the shear strength, $\sigma$ is stress on the sliding surface, $c$ is soil cohesion, $\varphi$ is Angle of internal friction of soil. As Fig.1 shown, where O is the center of the circle of the sliding surface, R is radius, $AD$ is the sliding surface, W is soil self weight. According to the limiting equilibrium method, we have

$$K = \frac{\tau_f \hat{L} R}{Wa} \tag{2}$$

Where, $K$ is the safety factor of slope stability, $\hat{L}$ is the length of the sliding surface, $a$ is the horizontal distance between O and the landslide body center of gravity. Equation (2) shows that the safety factor degenerated with the increase of the moisture content.

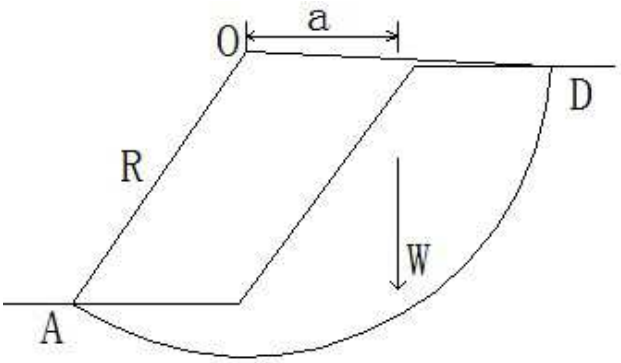

**Fig.1 Overall slope stability analysis**

## Analysis

With the rapid development of applied mathematics, many analysis methods for slope stability has presented, which can be generally classified as certain analysis method and uncertain analysis method. Limiting equilibrium method needs to split the unsaturated soil, according to the inter-slice force of soil that can be classified as Fellenius' method(Bishop, 1995), Bishop's method( Bishop,1995) and Janbu's method(Janbu,1954). Bishop's method proposed by Bishop in 1950, compared with other methods, it is easier to acquire and has more accuracy, which applies to soil slope and rock slope with broken and loose structure, it is considered as the most common method to calculate the safety factor of the sliding surface. This paper uses simplified Bishop's method.

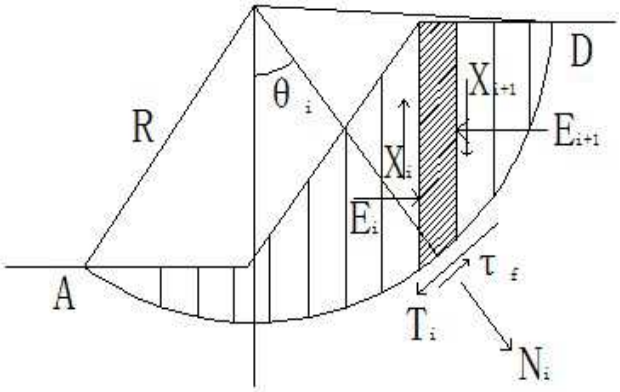

**Fig. 2 Schematic stress analysis of soil**

As Fig.2 shown, the limit equilibrium equation is

$$T_i = \frac{N_i \tan\varphi + c_i l_i}{K},$$

Where $T_i$ is tangential force, $N_i$ is normal force, $c_i l_i$ is cohesion.

According to force balance, we have:

$$W_i + X_{i+1} - X_i - T_i \sin\theta_i = N_i \cos\theta_i \quad (3)$$

$$N_i \cos\theta_i + T_i \sin\theta_i = W_i + \Delta X_i \quad (4)$$

Where $W_i$ is the soil self weight of *i*-th section, $X_i$ is the inter-force of adjacent soil body, $\theta_i$ is radius angle, where $\Delta X_i = X_{i+1} - X_i$ .By Eqs.2, 3 and 4,we have :

$$T_i = \tau_{f_i} l_i = \frac{c_i l_i + N_i \tan\varphi}{K}$$

$$N_i = \frac{W_i + \Delta X_i - \frac{c_i l_i}{K}\sin\theta_i}{\cos\theta_i + \frac{\sin\theta_i \tan\varphi}{K}}$$

Where $\Delta H_i = H_{i+1} - H_i$, it is negligible, so

$$K = \frac{\sum_{i=1}^{n} \frac{1}{m\theta_i}(W_i \tan\varphi_i + c_i l_i \cos\theta_i)}{\sum_{i=1}^{n} W_i \sin\theta_i}$$

Written in the form of effective stress:

$$K = \frac{\sum_{i=1}^{n} \frac{1}{m\theta_i}(W_i - u_i l_i \cos\theta_i)\tan\varphi_i' + c_i' l_i \cos\theta_i}{\sum_{i=1}^{n} W_i \sin\theta_i} \quad (5)$$

It does not meet the conditions of moment equilibrium apparently with respect to that the normal force between soils tripe makes no difference to the slope safety factor, but this method proves the theoretical of closed theory, moment equilibrium of the landslide and the limit equilibrium theory. The slope safety factor calculated by Bishop's method reduces with the increase of moisture content in the soil as can be seen from the Eq.5,which is very detrimental to slope stability.

The research material was taken form bare soil of Northeast Forestry University, Harbin (Jiang, et al., 2009).The direct shear test under the condition of 100kpa, and the results were as follows:

**Table 1. Test results**

| Moisture content $\omega$ （%） | Cohesion $c(kpa)$ | Angle of internal friction $\varphi$ (°) |
|---|---|---|
| 10 | 17.225 | 25.2 |
| 12 | 14.902 | 24 |
| 14 | 13.648 | 22.5 |
| 16 | 12.477 | 20 |
| 18 | 11.389 | 19 |
| 20 | 10.385 | 17 |

According Eq.1, we can calculate the shear strength of soil body under difference moisture content as follow:

**Table 2. $\omega$ and $\tau_f$**

| Moisture content $\omega$ | 10% | 12% | 14% | 16% | 18% | 20% |
|---|---|---|---|---|---|---|
| $\tau_f$ （kpa） | 64.28 | 59.42 | 55.06 | 48.87 | 45.82 | 42.88 |

Table 2 shows that the shear strength declines with the increase of moisture content in the soil. According Eq.2, we can calculate the safety factor reduced percentage with the moisture content ranged from 10% to 20% as shown below:

**Table 3. Computational results**

| Moisture content $\omega$ | 12% | 14% | 16% | 18% | 20% |
|---|---|---|---|---|---|
| relative reduction ratio of stability coefficient | 7.56% | 14.34% | 23.97% | 28.72% | 33.29% |

## Conclusion

The main conclusions can be drawn as follows:
(1)The slope safety factor will be lower under the condition of rainfall seepage.
(2) As increase of rainfall intensity, the moisture content will be increased and the factor of slope stability will be reduced, which will lead to decrease of the slope safety factor.
(3)More attention be should taken in the engineering where the soil has high moisture content.

# Study on the Lateral Displacement of Super-long Pile under a Asymmetrical Surcharge Load in Soft Clay

Qi Li[1, a], Xiaoli Lu[2,b]

[1]College of Machinery and Engineering, Taishan University, Taian, Shandong 271000, China

**Keywords:** soft clay; super-long pile; pile side displacement; surcharge load; ABAQUS

**Abstract.** The pile will have a large lateral displacement in soft soil under the role of heaped load. Based on Biot consolidation theory, combined with a certain highway project, a three-dimensional FEM model is established, the process that the soil lateral deformation under heaped load lead to the pile side displacement was simulated. On the ground of the former result, the influence factors for the displacement of pile top and the pile displacement field distribution are analysed. The results show that, the building load area, load grade and the distance from loading area to pile have a major influence on the pile side displacement. On the other hand, the load on pile top have a very small contribution for stability of anti side displacement. The buildings nearby the area of pile foundation should be given attention in practical engineering.

## Introduction

At present the research on passive pile in deep soft foundation is much less than that on active pile. Chinese freeways are mainly distributed in the southeast area. The coastal freeways take quite a large proportion in these ways. In coastal area, the foundations are mostly soft soil. The characteristics of soft soil is weak, low strength, high compressibility, low permeability, prone to plastic flow and so on[1] and it has caused great difficulties to the foundation treatment of road engineering. Therefore, using pile foundation to meet the requirements of settlement and stability in coast section with deep soft soil. However, if there is surcharge load on deep soft foundation where is the construction sector of expressway pile, the load will be transferred to the pile by the soil around. The pile will be caused great accessional vertical settlement and lateral displacement[2]. This will lead to cracking or destroying of pavement.

In this paper, based on the Biot consolidation theory[3], combined with the case that a super-long pile have undergone the effect of the role of heaped load in coastal tideland reclamation area, a 3D elastic-plastic finite element model is established. On the ground of the former result, the influences on the deformation and displacement of pile which come from different load area or different distance are analysed.

## Description of the Finite Element Model

**Project Background.** A coastal highway project which goes by the coastal tidal flat partly, intend to use Pile supported viaduct to go through. Similar geological conditions for the bridge, located in the coastal reclamation zone. The upper layer is soft soil, whose thickness is about 30m. It is mainly silt and silt clay. And its property is poor. The middle layer is mainly thick layer of mild clay and clay, where hard plastic and soft plastic appear alternately. The lower layer is hard plastic clay , gravel and cobble layer.

**Mode**l. By using the finite element software ABAQUS[4], the 3-D model was established according to the geological data of bridge pile foundation and the size of the pile foundation which were provided in construction design stage. The center of pile cross-section is the origin of coordinates. The horizontal soil boundary is X= ± 100m, Y= ± 100m.The gravity direction is used as

Z axis direction. We use a circular pile whose diameter is 2m, length 90m, buried depth 77m, to drive into the bearing layer (gravel and silt) 2m.The 3-D model is shown in fig. 1.

**Working conditions**.According to the distance from loading area to the pile (L=10m, 20m, 30m) and the area of heaped load(S=100m$^2$, 200m$^2$), the working conditions are divided into 6 conditions(as shown in fig. 2). We considered the pile top load which is 0 or 4700kN in each condition.The load with 4700kN is design load in traffic conditions. The surcharge loading method is asymmetrical.

## Calculation Parameters

The soil is seen as an elasto-plastic body, the constitutive model based on Mohr Kulun model and the simulation of pile is elastic[5]. The pile is loaded from 0 to 100kPa step by step. There is 10kPa in each load level for 15 days. The whole loading cycle is 150 days. The bottom boundary of model with all displacement constraint is undrained boundary. The boundary around with horizontal displacement constraint is undrained boundary also. In addition to the surcharge load area, the surface of soil is drainage boundary. The parameters of pile and soil are shown in table 1.

Table 1. Soil/Pile Calculation Parameters[6,7]

| Layer/Pile | Depth (m) | $E$ (MPa) | $v$ | $\gamma$(kN/m$^3$) | $C$(kP$_a$) | $\varphi$(°) | Permeability Coefficient（m/s） | |
|---|---|---|---|---|---|---|---|---|
| | | | | | | | Horizontal | Vertical |
| Silt Clay | 30 | 2 | 0.35 | 17.9 | 12.0 | 2.5 | $3\times10^{-8}$ | $3\times10^{-8}$ |
| Silty Clay | 75 | 25 | 0.25 | 20.0 | 65.0 | 20.0 | $10\times10^{-8}$ | $10\times10^{-8}$ |
| Gravel and Silty Sand | 80 | 6,500 | 0.20 | 25.3 | 10.0 | 35.0 | $2\times10^{-4}$ | $2\times10^{-4}$ |
| Clay | 100 | 25 | 0.25 | 22.1 | 65.0 | 20.0 | $8\times10^{-8}$ | $8\times10^{-8}$ |
| Pile | 77 | 30,000 | 0.17 | 24.0 | / | / | / | / |

## Results and Analysis in the condition of L=10m

As shown in fig. 3, we selected the point M in pile-top as calculation point.The displacement changes of pile foundation in X direction which is caused by surcharge load in action period are calculated. We also analyzed the linear OP's displacements on the pile in fig. 3 at the end of loading.

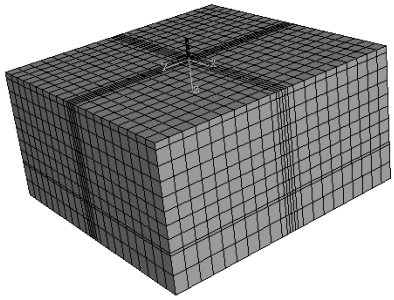

Fig. 1. Finite Element Model

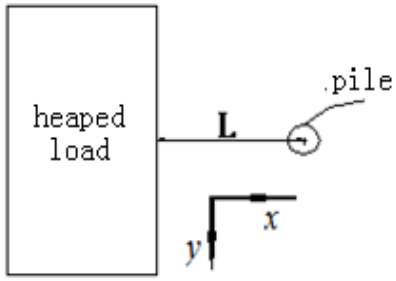

Fig. 2. Relative Position of Heaped Load and Pile

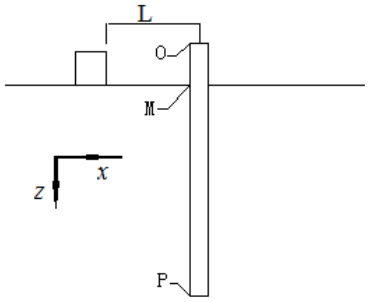

Fig. 3. Relative Position of Calculation point

The displacements of point M in X direction when L=10m and S＝100m2 or S＝200m2 are respectively shown in fig. 4 and fig. 5.

From fig. 4, we can see that the horizontal displacement of M is having an increasing rise with the increase of load level. The maximum is 21.2mm when the surcharge load is 100kPa. The analysis shows that the horizontal displacements of pile are affected obviously by the load level. We must emphatically consider this influence in practical engineering. As shown in fig. 4, the two curves are the lateral displacements of pile which have pile-top load of 0 and 4700kN, respectively. The shift of point M with pile-top load is less than that without pile-top load. Its fig shows the pile-top load has a stabilizing effect on pile foundation.

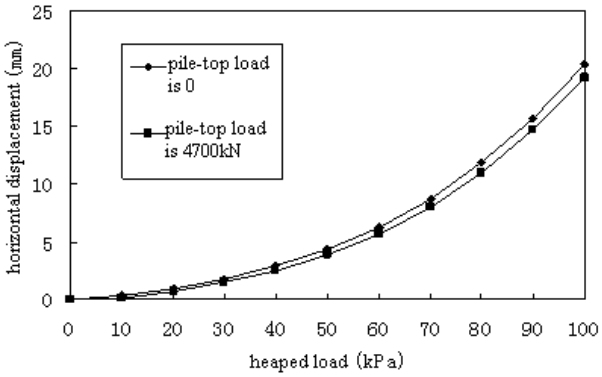

Fig. 4. Horizontal Displacement of M in L=10m, S＝100m$^2$ Condition

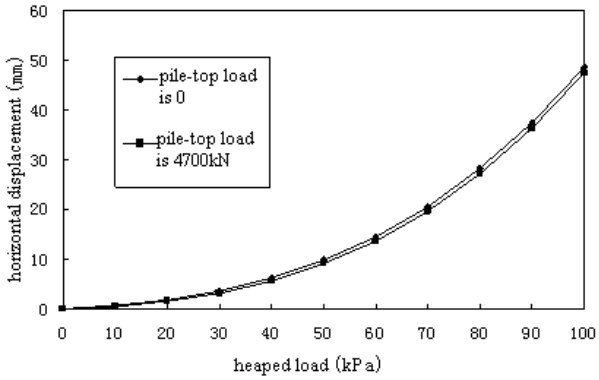

Fig. 5. Horizontal Displacement of M in L=10m, S＝200m$^2$ Condition

From fig. 5, we can see that, when S＝200m$^2$, the low of horizontal displacement of M is similar as the S＝100m$^2$, but the overall value is about 2.4 times larger than the case of S＝100m$^2$. The maximum displacement of S＝200m$^2$ is 48.5mm when the load is 100kPa. The analysis shows that the horizontal displacements of pile are affected obviously by the surcharge load area. So, in practical engineering, large area loading should be tightly restricted nearby the pile in soft clay.

After the end of loading, the linear OP's displacements on the pile when L=10m and S＝100m$^2$ or S＝200m$^2$ are respectively shown in fig. 6 and fig. 7.

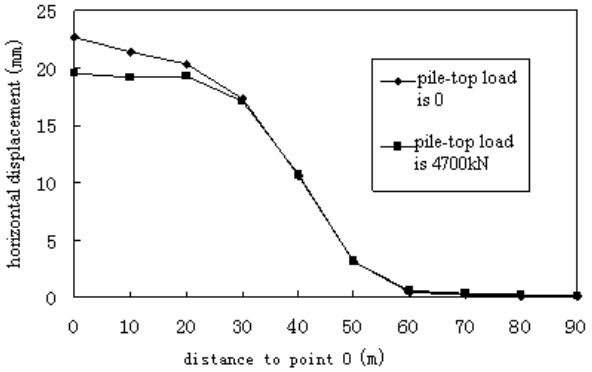

Fig. 6. Horizontal Displacements of Linear OP in L=10m, S＝100m$^2$ Condition

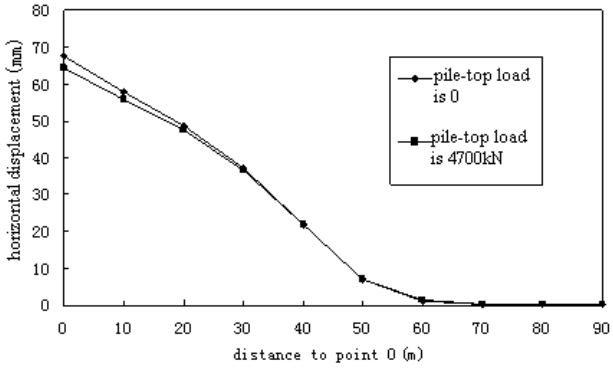

Fig. 7. Horizontal Displacements of Linear OP in L=10m, S＝200m$^2$ Condition

As shown in fig. 6, that's more than other points the horizontal displacements of point O with pile-top load and without pile-top load, which have amounts of 19.5mm and 22.6mm, respectively.Because the pile hadn't tilted absolutely, the lateral displacements of linear OP decreased slowly from pile-top to the ground. In the silt soil, the displacements started to decrease rapidly, it is only 3mm in the 50m depth. At length farther than 60m, the shift is close to 0, it shows that in this depth the effects of heaped load on soil deformation have almost disappeared.

Fig. 7 shows that the horizontal displacements of point O with pile-top load and without pile-top load are 64.4mm and 67.1mm respectively, they are larger than the amounts of S＝100m$^2$ condition. The pile body was in a state of incline

## Comprehensive and Comparative Analysis in Different Conditions

From the L=10m conditions,we can see that the influence of pile-top load for pile's lateral displacements is very small, and it is smaller in L=20m and L=30m conditions. So here we selected all conditions with 4700kN pile-top load to analyze comprehensively. The extreme displacements of pile were shown in table 2.

As we can see from fig. 8, the horizontal displacement of M is having an increasing rise with the increase of load level in all conditions. With the same area and the same load, the horizontal

displacement of M which caused by less distance from loading area to the pile is large then others. With the same distance and the same load, the displacement caused by larger load area is larger then others. The maximum displacement is 47.4mm when the heaped load reach 100kPa in the condition of S＝200m$^2$, L＝10m. In general, in the condition of a more heaped load, it's influence in the horizontal displacement of M will be significantly diminished with the increase of distance to pile foundation and the decrease of load area.

As we can see from fig 9, the maximum displacements of points on linear OP are in the condition of S＝200m$^2$, L＝10m, and their maximum value is 64.4mm. The horizontal displacements of the pile vary with the depth. The point which has maximum horizontal displacement is not fixed, If the heaped load is far from the pile, the maximum displacement point will be stability in the lower of silt soil. If the heaped load could make the pile in a state of incline, the maximum horizontal displacement appear at the top of pile. Now the influence for practical engineering which caused by the pile's displacements will not be ignored. Moreover, at 47m depth below the ground, 60m far from the pile top, the shift is close to 0 in all conditions, it shows that in this depth the deformation of soil caused by heaped load is very small. In the soil above the depth of 47m to the clay layer on top, the shift increases rapidly. In the silty clay, the increase is slowing down, the displacement even appear to decrease if the heaped load area is far from the pile enough.

Table 2. Extreme Displacements of Pile

| Conditions | Maximum Displacement of M (mm) | Maximum Displacement of Points on Linear OP (mm) |
|---|---|---|
| S=200m$^2$, L=10m | 47.41 | 64.36 |
| S=100m$^2$, L=10m | 19.27 | 19.49 |
| S=200m$^2$, L=20m | 21.51 | 23.79 |
| S=100m$^2$, L=20m | 9.56 | 11.58 |
| S=200m$^2$, L=30m | 15.73 | 16.95 |
| S=100m$^2$, L=30m | 7.40 | 8.39 |

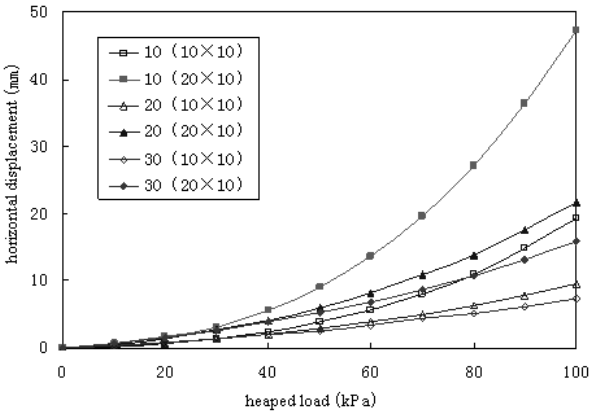

Fig. 8. Horizontal Displacement of M in Different Conditions

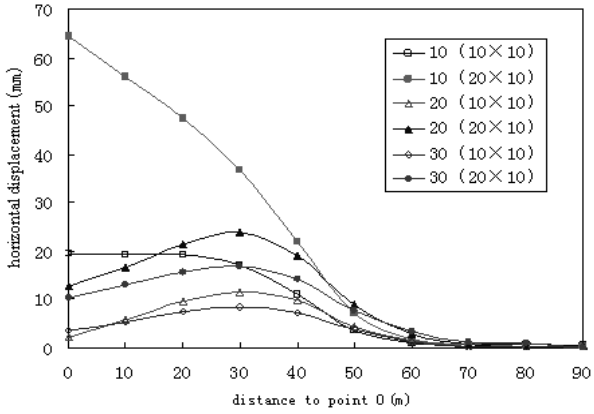

Fig. 9. Horizontal Displacements of Linear OP in Different Conditions

## Conclusions

The pile-top load has certain contribution to the stability of the pile for standing up to the lateral displacement of soil. But the contribution is too small to be ignored in practical design.

The heaped load area and load level have a great influence on the lateral displacements of pile foundation, the lateral shifts unlinearly increases with the increase of the load area or the load level in the same distance from heaped load to pile. So the buildings with super-large area or high-rise should be avoid nearby the pile in soft clay. At the same time, the surcharge load should be loaded synchronously and symmetrically as far as possible.

The horizontal displacements of pile decrease with the rais of distance from heaped load to the pile. If heaped load area is too close to the pile foundation, it will cause large lateral shift. For the project analyzed in this paper, the distance proposed from heaped load area to pile foundation should be more than 15m.

**Keywords:** Shield Launching, Vertical Frozen Soil Wall, Freeze Pipe Spacing, Temperature Field

**Abstract.** Determining the freezing pipe spacing, the freezing reinforcement required range and method, acquiring the development and distribution patterns of frozen soil wall temperature field are the key issues needed to be addressed when using vertical freezing method for the soil reinforcement at shield shaft. Based on the shield launching project of the cross-river shield tunnel of Nanjing subway line 10 and the finite element numerical analysis software, the development and distribution patterns of different distance between freezing pipes of the vertical frozen wall are studied. The numerical simulation shows that, it is feasible to use the numerical model to simulate the temperature field of vertical frozen wall. Decreasing the distance between freezing pipes causes a greater impact on the temperature field. When freezing pipe spacing increases to 0.1m, frozen wall cross-lap time increases of about 1 day. With the freezing pipe spacing increasing, the cross-lap time increases linearly. The temperature of frozen wall decreases with the distance between freezing pipes decreasing, and the strength of frozen wall is more uniform. Results and conclusions form this research may play a useful role to aid designs of similar projects in future.

## Introduction

The methods of reinforcement for Shield shaft end typically include deep mixing method, high-pressure rotary-spray method, SMW working method, artificial freeze method, grouting method, plain concrete pile method, and dewatering method. Soil reinforcement can be performed with single or multiple methods. These reinforcement methods can be categorized into two types: (1) chemical reinforcement methods (e.g., high-pressure rotary-spray method, deep mixing method, grouting method, plain concrete pile method); (2) physical reinforcement methods (e.g., artificial freeze method, dewatering method) [1]. For soft soil region, the reinforcement can be carried out through vertical frozen working method, as mixing pile and rotary-spray pile methods could not be made due to the limitation of ground conditions. The vertical frozen method can also be used when severe water or soil leaking were found at hand-hole after chemical reinforcement. Vertical frozen working method is designed based on tabular frozen reinforcement theory. In this method, a certain number of vertical frozen holes are placed at the end of shield shaft. The frozen soil curtains at the holes resist soil and water pressure of broken shield, preventing the collapse of soil and mud from falling into the working well [2]. Based on the shield launching project of the cross-river shield tunnel of Nanjing subway line 10 and the finite element numerical analysis software, this paper studies the development and distribution patterns of different distance between freezing pipes (0.6m, 0.8m, 1.0m, 1.2m and 1.4m) of the vertical frozen soil wall.

## Engineering Background

The total length of Nanjing subway route-10 is 41.4 km, with 20 stations. The river tunnel (double-lane single tunnel) is constructed with large diameter shield tunneling. According to exploration data, the east side shield launching well is located at high water pressure sandy strata, and the characteristics in this strata behave high porosity, high ground water pressure, and low strata load capacity. Under unfavorable geology conditions and high water pressure, it is under high risk to have shield-launching works. Therefore, the soil body at the end of shield shaft should be reinforced.

According to the conditions discussed above, this launching project applies the method with tri-axial deep stirring pile + vertical frozen. The detail of this method is summarized here: the primary reinforcement type usesΦ1000@750 tri-axial stirring pile. The reinforcement region covers 5 m at both sides of shield shaft. Ground dielectric constant elevation is reinforced to 6m away from arch bottom, and longitudinal reinforcement is 17 m along the working direction of shield. To improve the cementation strength of enclosure structure between stirring pile and middle airshaft, two vertical freezing pipes are placed along the working direction outside of enclosure structure at the east shield well with both array spacing at pipe spacing of 800 mm.

Vertical frozen are arranged with two-row frozen holes in a flower arrangement way. The distance between row A and diaphragm retaining wall is 0.4 m, and the distance between row A and B is 0.8 m. Hole-spacing is 0.8 m. Total number of frozen hole is 57, with 29 placed at row A and 28 at row B. The length of each hole is 31.152m, and depth of hole is 1775.7m. Frozen pipes used here are Φ127×4.5mm seamless steel pipes. Φ48×3.5mm seamless steel pipes are used as fluid supply pipes. During formable period of freezing, brine temperature is in the range of -28℃～-30℃, and brine temperature is in the range of -25℃～-28℃ during freezing maintain period. It is noted that the duration of formable period of freezing is 30 days.

## Construction of Three-dimensional Model

The computational model for temperature field used here is transient heat conduction model with phase transition. According to the suggested frozen-hole arrangement plan, this study applies the simulation of half region to obtain the best computation efficiency due to symmetry of the problem. The origin of coordinate is selected on the ground right above the tunnel face, and longitudinal length (x axis)×transverse width (y axis)×vertical height (z axis) =3m×12m×32m. Two-row frozen is applied as the vertical frozen method in a flower arrangement way. The distance between row A and diaphragm retaining wall is 0.4 m, and the distance between A and B is 0.8 m. Hole-spacing is 0.8 m (this sentence is duplicated). The number is 14.5 for row A and 14 for row B. The frozen pipe diameter is 127 mm, with each frozen-hole length of 31.152m. This simulation applies four-node mesh format, and finer meshes are placed close to the frozen pipes. Total element in the model is 815788, with 149000 nodal points.

Table. 1 Physical thermal parameters after cement improvement

| Soil type | Density /(Kg·m$^{-3}$) | Water content/% | Hear conductivity / ( KJ·m$^{-1}$·d$^{-1}$·℃$^{-1}$ ) | | Specific heat /(KJ·Kg$^{-1}$·℃$^{-1}$) | | Latent heat /(×10$^{8}$J/m$^{3}$) | Temperature of freezing/ (℃) |
|---|---|---|---|---|---|---|---|---|
| | | | Unfrozen soil | Frozen soil | Unfrozen soil | Frozen soil | | |
| Cement soil | 2040 | 11.6 | 180 | 205 | 1.60 | 1.66 | 0.81 | [-2,0] |

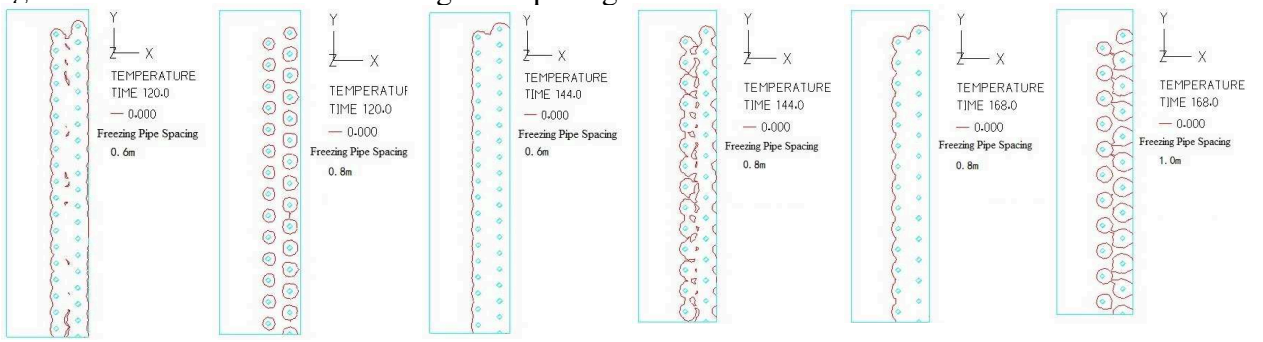
Table.2 The cooling plan of brine temperature

| Time/d | 0 | 1 | 5 | 10 | 15 | 20 | 30 | 40 |
|---|---|---|---|---|---|---|---|---|
| Temperature/℃ | 30 | 0 | -12 | -20 | -25 | -28 | -30 | -28 |

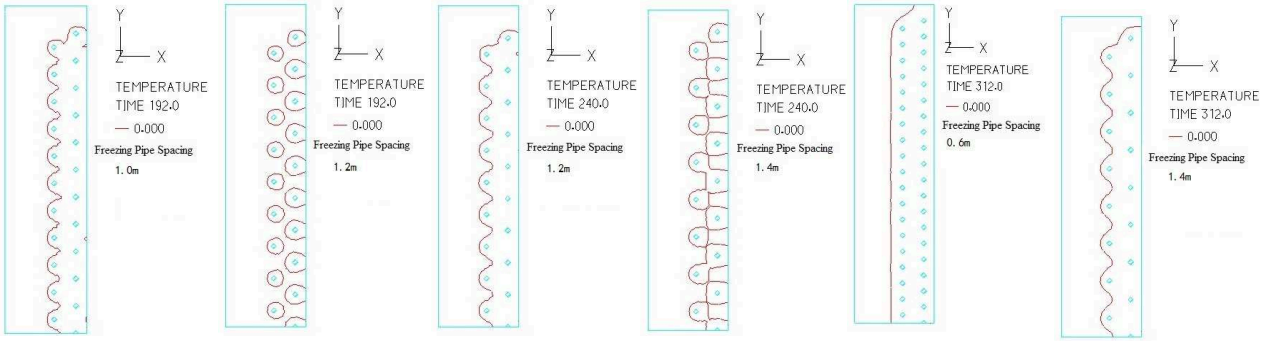
The soil frozen experiment is carried out with the soil samples taken from the project site. Physical thermal parameters after cement improvement by tri-axial deep stirring pile are listed in Table 1. Due to the reinforcement of the end with tri-axial deep stirring pile, the ground temperature under effect of cement hydration heat would increase by approximately 10℃. Typically constant temperature at 10 m under ground is 19-20℃. Therefore, the initial temperature of ground under cement reinforcement is set as 30℃ before freezing. The temperature at the boundary of the model is kept constant. The outside boundary of the computational area is treated as adiabatic boundary, and the frozen pipes surface is treated as thermal loading boundary. The brine temperature is used as the boundary loading, and the cooling plan of brine temperature during formable period of freezing is listed in Table 2. According to this plan, the freezing time is set to be 40 days, with each step of 24 hours.

**Computation Results and Analysis of Temperature Field**

Figure 1 shows the different freezing tube spacing z = 0 cross-section at different times 0 ˚C isotherm.



a) 5 days after frozen b) 6 days after frozen c) 7 days after frozen



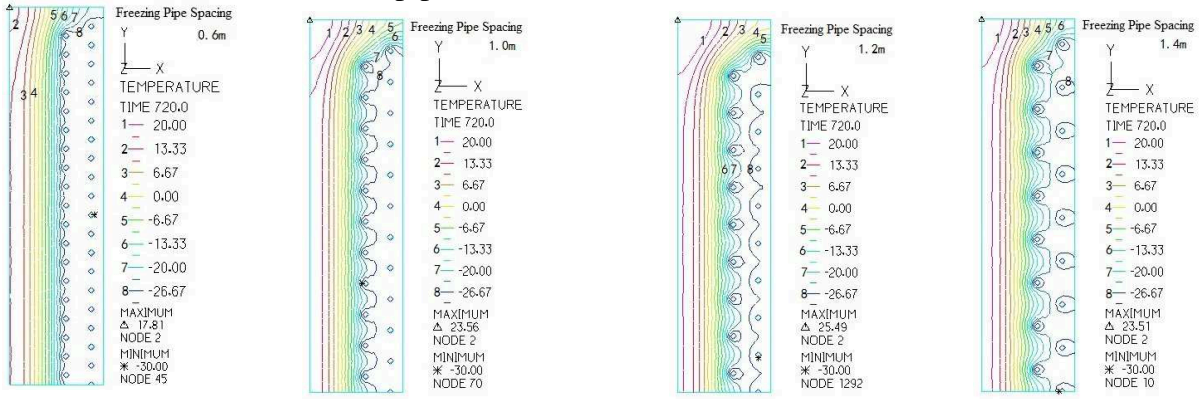
d) 8 days after frozen e) 10 days after frozen f) 13 days after frozen

Fig.1 0˚C isotherm for z=0 profile at different times of varied freezing pipe spacing

It can be seen: in the frozen pipe unpaid ring 0 ˚C isotherm to freeze a circle concentric pipe distribution, A row cylindrical frozen permafrost development speed tube formation is greater than B row cylindrical tube formed frozen permafrost, which mainly because the B row around the tube is not frozen permafrost a large range of heat exchange and thermal convection more, so the development of permafrost cylindrical slower. Frozen pipes freeze single-row spacing of 0.6m tube 4 days began to freeze pay in circles, frozen 5 days between rows and rows of circles began to pay freeze 6 days to form a continuous vertical wall of permafrost. Freezing tube spacing 0.8m single and double row frozen pipes from freezing circle began to pay 6 days, 7 days form the overall frozen permafrost wall. Freezing tube spacing 1.0m in freezing day 7 A row of freezing pipes and tubes not yet pay freeze row B ring, but the row between the row and start mutual exchange rings. The reason is the distance between each row of freezing pipes 1.0m, while the distance between the rows and rows of 0.8m, due to the heat from the exhaust and the exhaust heat is less than the distance between each row of freezing pipes between the rows and rows of it first began to pay between laps. Freeze 8 days, A row of freezing, there are still unfrozen area between the tube and the building envelope. Permafrost frozen nine days to form a vertical wall. Freezing tube spacing 1.4m slowest lap time of delivery, frozen for 10 days between the first row and the rows start mutual exchange rings, when frozen soil wall forming a continuous 13 days. With the freeze time increases, the vertical distance between the different freezing pipes freeze wall continues to develop, deliver laps zero isotherm curvature gradually slows tending to straight line, increasing the wall thickness of the permafrost.

Time seen, different spacing freezing pipes freeze wall post to form a closed loop time that vertical wall were frozen: frozen pipes spaced 0.6m for the six days, freezing pipes spaced 0.8m to 7 days, freeze tube spacing of 1.0m 9 days, freezing tube spacing 1.2m for the 11 days, freezing tube spacing 1.4m for the 13 days. Post spacing of 0.6m lap time than 1.4m when the seven days ahead of time, reducing the visible effects of freezing tube spacing on the temperature field is more significant. The freezing tube spacing increases every 0.1m, freeze wall post lap time increased by about one day. With the freezing tube spacing increases, frozen wall post lap time increases linearly.

Frozen pipes by different spacing z = 0 cross-section 30 days of freezing temperatures contours can be seen in Figure 2: 30-day freeze, freezing tube spacing between 0.6m and 0.8m of B row frozen pipe and envelope (blue area) are concentrated in the temperature of -26.67 ˚C, continuous and uniform thickness 1.2m. Freezing tube spacing 1.0m of -26.67 ˚C isotherm at reducing the scope of the package, freezing tube spacing 1.2m when the blue area is divided into two parts, exhaust temperature between B and A row of frozen pipes concentrated in -20 ˚C ~ -26.67 ˚C, A row between the tube and the envelope freezing temperatures are concentrated in -26.67 ˚C. When the temperature of the freezing tube spacing 1.4m blue area is mainly focused on the following -20 ˚C, -26.67 ˚C isotherm only appear in each row A frozen pipe around.



a) Freezing pipe spacing 0.6 b) Freezing pipe spacing 1.0 c) Freezing pipe spacing 1.2 d) Freezing pipe spacing 1.4

Fig.2 Temperature contour of z = 0 section frozen for 30 days for different freeze pipe spacing

## Summary

(1) Different tube spacing freeze pay freeze wall to form a closed loop of time that the walls were vertical permafrost: Spacing 0.6m for the six days, seven days spaced 0.8m, 1.0m spacing is 9 days, spaced 1.2m 11 days, 13 days 1.4m spacing. Exchange lap time than when the spacing distance between 0.6m 1.4m seven days ahead of time, reducing the visible effects of tube spacing freezing temperature field is more significant.

(2) Each frozen tube spacing increases 0.1m, freeze wall post lap time increased by about one day. With the freezing tube spacing increases, frozen wall post lap time increases linearly.

(3) Freeze tube spacing, the lower the curtain vertical permafrost temperature, the more uniform vertical wall strength permafrost formation.

**Keywords:** Foundation treatment, Vacuum preloading, Site test, Shear strength

**Abstract.** On the basis of engineering project using underwater vacuum preloading method to strengthening the soft foundation, under the specific geological conditionsthis article analyzes the construction technology and reinforcement mechanism of underwater vacuum preloading of the soft soil foundation. By indoor soil test of Reinforcement of soil before and after processing, compared the change and improve of soil shear strength indexes before and after the reinforcement, it is verified that the underwater vacuum preloading method is a effective mean in handing soft ground, and can be further promoted as a means of handling soft ground along the coastal area of China.

## Introduction

With the development of high heavy buildings in coastal cities, Traditional foundation treatment methods cannot satisfy the requirement of engineering practice, Some composite foundation treatment methods and new foundation treatment technology have been applied in engineering practice. The soft soil foundation underwater vacuum preloading is one of composite foundation treatment technology.The water pulled out when vacuum is as a heap of cargo stack preloading, using the vacuum produced by negative hydrostatic pressure and the membrane water load, to speeding up the progress of consolidation and the strength of the soft soil.In order to develop and disseminate underwater vacuum preloading technology, combining an engineering example in the coastal area, this article analyzes the application problems reinforcement mechanism of underwater vacuum preloading technology handing soft ground and evaluates of reinforcement effect

## Project Overview

The project is a more multi-storey, small high-level, high-rise and high-rise residential buildings in China, in which the main residential area is 11~32 layer, 41~100 m above the ground, has 1~2 layers basement embedded in the depth of 7.20 m. The frame and shear wall or frame shear wall structure are used in this project. The original landform types of the venue is the coastal tidal flats, by the artificial reclaimed, the terrain is relatively flat, the surface elevation is about 2.0~3.0 m, the venue leveling elevation is 5.9 m. But the surface water in the southwest, southeast and northeast of the field is long-standing existed, whose depth is about 1.00 m. By surveying, each hole orifice elevations are measured between 1.60~3.82 meters. In view of silt soft soil layer which appeared saturated flow state is thick of 0.00~18.40 m has widespread distribution in this area and the overlying filling being owe consolidation soil, with an average of about 7.2 m, has a high water content, high thixotropic , low intensity, for reducing the adverse effects of consolidation settlement which occurred in the soft soil layer in the stage of the project being completed. So this silt soft soil layer venue will use underwater vacuum preloading method to reinforce foundation.

From top to bottom soil name and lithology abased on drilling results are shown in table 1.

**Table 1. The name, Thickness and Status of Soil Layer**

| Number | Soil Name | Thickness (m) | Geotechnical Condition |
|---|---|---|---|
| ① | Artificial Filled Soil | 1.00~2.70 | Loose State |
| ② | Artificial Filled Soil | 0.80~7.70 | Loose State |
| ③ | Sludge | 2.60~8.70 | Saturation and Flowing Plastic |
| ④ | Sludge | 2.00~10.00 | Saturation and Flowing Plastic |
| ⑤ | Gravelly Cohesive Soil | 3.40~8.90 | Saturation and Flowing Plastic |
| ⑥ | Completely Weathered Granite | 2.50~8.60 | Earthy |
| ⑦ | Intensely Weathered Granite | 3.70~8.60 | Soil Clip Pieces |
| ⑧ | Moderately Weathered Granite | 4.80~10.10 | Core Into Earthy |

## The Construction Process

Place the sand blanket after site clearing , make the curtain of construction clay and drive plastic drainage plate (Type B plastic drainage plate of the SPB100 series, section size 4×100mm),layout vacuum lines (PVC outer membrane type filter tubes, pipe diameter>50mm), inbuilt vacuum probe, inbuilt monitoring devices, excavation pressure membrane channel, pave earthwork cloth, vacuum membrane, fill the cofferdam and impoundment while evacuating (pour the water being pumped into the cofferdam, forming constant water load), after prepressing the load 90 days, go on evacuating if the degree of consolidation can not meet the requirements, otherwise, unloading, completion and acceptance can be performed.

## The Reinforcement Mechanism of Underwater Vacuum Preloading

Underwater vacuum preloading method is a vacuum stack preloading method that combines surcharge preloading with vacuum preloading; it is more effective to treat soft foundation. Vacuum negative pressure and positive pressure to heap load could add to form vacuum stack preloading method. Vacuum preloading method technology is that in first lay sand cushion layer in soft foundation, burying vertical drainage well, and then cutting off from the atmosphere using closing membrane buried in the grave, through embedding shaft vacuum suction. Passing air exhaust forms negative pressure in sand cushion layer and drainage well. Pore water continuously discharge from drainage well in back pressure to strengthen soil. In engineering construction of Underwater vacuum preloading method, vacuum conditions need to extract a large number of groundwater, together with auxiliary seal measures of membrane. Membrane water storage can play a role of sealing membrane to ensure the membrane under vacuum degree; it also could have the effect of preloading load. The actual load is equal to the membrane under vacuum preloading load and the sum of membrane water pressure load. In vacuum load and membrane water pressure load, pore water was ruled out slowly and the volume decrease slowly, foundation consolidation deformation, and the same time, with the super hydrostatic pressure disappearing gradually, effective stress increase gradually, the strength of the foundation soil increasing gradually.

## Vane Shear Strength Test

This project adopts vane shear strength test to evaluate treatment soft ground test data. So it could get the objective and scientific evaluation of soft foundation treatment effect.

The vane shear strength test gets undrained shear strength Cu that mainly reflects the vertical plane strength of the soil. This experiment adopts resistance strain type cross slab, using static sounding instrument injection device to press the cross slab into different test depth. With the help of a rotary vane head gear torque device, using LMC - D310 static microcomputer of soil resistance torque, so as to calculate the shear strength unearthed. Vane shear strength test structure shown in table 2.

**Table 2. Vane Shear Strength Test Statistics**

| Items | Intensity Index (kPa ) | Statistical Depth (m) | Range Value (m) | Average Value (kPa ) | Standard Deviation | Coefficien of Variation | Standard Values (kPa ) |
|---|---|---|---|---|---|---|---|
| Before the vacuum preloading | Cu | 0~5.0 | 16.92~26.59 | 20.12 | 3.335 | 0.166 | 17.86 |
| | Cu' | 0~5.0 | 4.05~7.87 | 5.90 | 1.441 | 0.244 | 4.92 |
| | *S*t | 0~5.0 | 3.03~4.18 | 3.49 | 0.396 | 0.144 | 3.22 |
| After the vacuum preloading | Cu | 0~5.0 | 19.39~31.82 | 25.05 | 3.000 | 0.120 | 23.84 |
| | Cu' | 0~5.0 | 5.92~10.15 | 7.92 | 1.030 | 0.130 | 7.50 |
| | *S*t | 0~5.0 | 3..05~3.29 | 3.17 | 0.075 | 0.024 | 3.14 |
| Before the vacuum preloading | Cu | 5~10.0 | 18.93~29.74 | 25.41 | | | |
| | Cu' | 5~10.0 | 5.39~8.78 | 7.10 | | | |
| | *S*t | 5~10.0 | 3..33~4.02 | 3.60 | | | |
| After the vacuum preloading | Cu | 5~10.0 | 19.44~39.00 | 25.68 | 5.110 | 0.200 | 23.33 |
| | Cu' | 5~10.0 | 6.27~11.22 | 8.05 | 1.500 | 0.190 | 7.36 |
| | *S*t | 5~10.0 | 2..99~3.48 | 3.19 | 0.150 | 0.050 | 3.12 |
| After the vacuum preloading | Cu | >10.0 | | 30.19 | | | |
| | Cu' | >10.0 | | 9.82 | | | |
| | *S*t | >10.0 | | 3.07 | | | |

Indicated: Cu: Undrained shear strength of undisturbed soil;
Cu': Undrained shear strength of remoulded soil;
*S*t: Sensitivity of clayey soil.

From the table 2 it can be see clearly that after treatment the average value of shear strength for the undisturbed soil is 25.40, in which within 0~5 meters deep the average shear strength of undisturbed soil is increased by 24.50%,the average shear strength of remoulded soil is increased by 34.24%; within 5~10 meters deep the average value of shear strength is increased by 1.06%, the average shear strength of remoulded soil is increased by 13.42%, under 10 meters the shear strength of the silt soft soil is 30.19 kPa, in other depth within the scope of the test results, the average shear strength of undisturbed soil and remoulded soil are also increased. The vane shear strength changes before and after the foundation treatment are shown in table 3.

**Table 3. Vane Shear Strength Average Value Comparison Table Before and After The Foundation Treatment**

| Stage | | Depth (m) | | |
|---|---|---|---|---|
| | | **0~5.0** | **5.0~10.0** | **>10.0** |
| **Before Soft Ground Treatment** | **Cu** | 20.12 | 25.41 | 30.19 |
| | ***St*** | 3.49 | 3.60 | |

| | ***St*** | 3.17 | 3.19 | |
| **Decrease Ratio** | **Cu** | 24.50% | 1.06% | |
| | ***St*** | 9.17% | 11.39% | |

From table 3 it can be clearly see that the vane shear strength were increased of the silt soft soil layer depth within the scope, in which the vane shear strength within the scope of 5 meters of the top silt layer is significantly increased, below 5 meters the vane shear strength is increased slightly, sensitivity of soil in detecting depth range are reduced to a certain extent, in a word, the underwater vacuum preloading method has a certain effect in the consolidation processing of soft soil.

## Conclusions

- Underwater vacuum preloading has a certain reinforcement effect for mud soil in coastal region.
- Underwater vacuum preloading can improve the shear strength of mud soil.
- Underwater vacuum preloading can lower the sensitivity of mud soil.

**Keywords:** Reinforced soil foundation, Bearing capacity, Influencing factors, Finite element method

**Abstract.** The reinforced soil foundations have been widely used in various geotechnical engineering applications, such as bridge approach slab, bridge abutment and so on. However, many problems of reinforced foundation still need to be solved and the behavior of the reinforced foundation requires further study. Therefore, finite element analyses were conducted on unreinforced and reinforced clay subgrade soil to evaluate the influence of various factors affecting the performance of strip footing on studied soils. Conclusions are drawn: the effective reinforcement depth is about 1.5B for the reinforced soil and it is independent of the geogrid type; At a given settlement, the bearing capacity of the footing decreases with the increase in reinforcement spacing, with larger decrease rates at small spacings; A geogrid with a tensile modulus ranging from 5MPa to 25MPa will maximize the benefits of the reinforced soil footing, etc.

## Introduction

The concept of reinforced soil as construction material is based on the existence of soil-reinforcement interaction due to tensile strength, frictional and the adhesion properties of the reinforcement and was first introduced by the French architect and engineer Henri Vidal in the 1960s. In the past three decades, reinforced soil foundations (RSF) have been widely used in various geotechnical engineering applications, such as bridge approach slab, bridge abutment, building footings, and embankment.

Researchers have shown that the inclusion of reinforcement in soil foundations is a cost-effective solution to increase the ultimate bearing capacity or reduce the settlement of shallow footings compared to the conventional methods. The most common type of reinforcement used in soil foundation applications are geogrids.

Meanwhile, the improve performance of reinforced soil foundation can be attributed to three fundamental reinforcement mechanisms as described below: (a) Rigid boundary; (b) Membrane effect; (c) Lateral restraint effect [1].

In order to get more behavior of the RSF, the influence of various factors on the performance of footings on reinforced soil foundation was investigated by finite element analyses. The factors are as follows: spacing between reinforcement layers, tensile modulus of reinforcement, soil-reinforcement interaction coefficient, optimum top spacing for the single-layer and multi-layer reinforced soil, footing width, etc. The influence of these factors will be discussed in the following sections [2].

For each case, the load-deformation curve, obtained from the finite element simulation, was used to determine the ultimate bearing capacity and settlement of the footing. The benefits of RSF were assessed in terms of the bearing capacity ratio (BCR) and settlement reduction factor (SRF).

## The fundamental behavior of the reinforced soil foundation

The influence of the location of first reinforcement layer (H) on the BCR is discussed in this section, based on the FEM analyses for the footing (B=1.2m) placed on single-layer, two-layer and three-layer geogrid-reinforced soil systems with varying depth.

In the single-layer reinforcement case, the BCR increases first with the increase of the depth ratio (H/B) and then decrease after a threshold value of H/B. This threshold depth ratio (H/B) is around 0.5, where the BCR gets the highest value. The variation of the BCR with depth ratios (H/B) is similar in the two-layer and three-layer reinforcement cases. However, the threshold depth ratio slightly decreases with the number of reinforcement layers around 0.4 in two-layer reinforcement case and around 0.3 in three-layer reinforcement case [3].

The design of reinforced soil foundations requires the determination of the effective depth of the reinforced zone, below which reinforcement will not have appreciable benefit on footing performance. To identify the effective depth, finite element analyses were conducted on a footing (B=1.2m) using three types of geogrid reinforcements placed uniformly either at 30cm interval or 60cm interval.

Three types of geogrid (I, II, and III) were included to investigate the dependence of effective depth on geogrid's properties. Type I geogrid has a relatively low tensile modulus, Type II has a medium tensile modulus, and type III represents a stiff geogrid.

For each type of geogrid, a series of finite element analyses were conducted with the number of reinforced layers increasing till the reinforced depth reaches 2.5B. The bearing capacity ratio was calculated from load-deformation curves for each case.

What can be seen from Fig. 1(a) (for the 30cm reinforcement spacing, the number of reinforcement layers increases from one to ten) and Fig. 1(b) (for the 60cm reinforcement spacing, the number of reinforcement layers increases from one to five), the BCR of the reinforced footing increased as the number of reinforcement layers increased, but at a decreasing rate. For the 30cm spacing cases, there is no significant improvement in the BCR when the number of reinforcement layers exceeds 6, which corresponds to a depth of 1.5B=1.8 m. Similarly, no further significant improvement in BCR was achieved for the 0.6 m spacing as the number of layers exceeds 3, which is also corresponds to 1.5B depth. Accordingly, the effective reinforcement depth expressed as the strip footing's width will be equal to 1.5B for the soil in question.

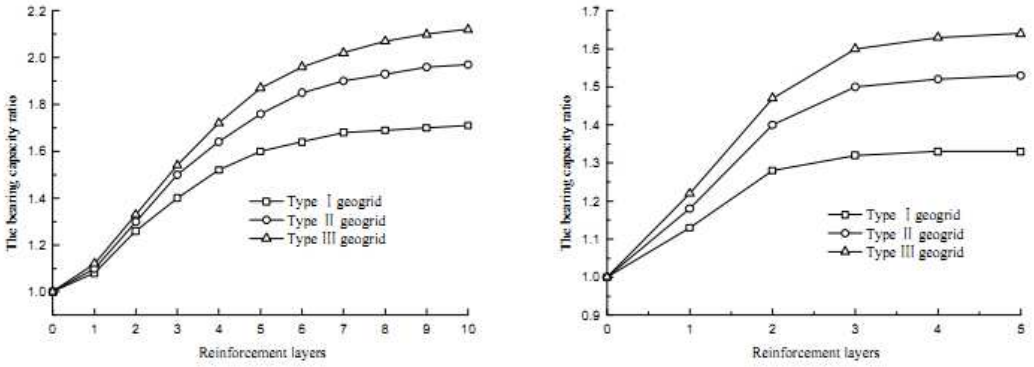
As seen in Fig. 1(a) and Fig. 1(b), the improvement trend in BCR is the same for all the three types of geogrid that been investigated, which also indicated that the effective reinforcement depth is independent of the geogrid type.

## Influence of various factors on the bearing capacity ratio

### Reinforcement Spacing

The effect of reinforcement spacing on the footing's bearing capacity and settlement was investigated by changing the spacing of reinforcement layers within the effective reinforcement depth of 1.5B. A series of finite element analyses were conducted on the footing- reinforced soil model using three geogrid types placed at five different spacing. The following reinforcement layers configurations were considered: three layers with 60cm spacing, four layers with 45cm spacing, six layers with 30cm spacing, nine layer with 20cm spacing, and twelve layers with 15cm spacing. For each case, the BCR and the settlement reduction factor (SRF) at the ultimate load capacity of a 3-layer Type II reinforced soil were calculated. The results show that at a given settlement the

bearing capacity of the footing decreases with the increase in reinforcement spacing, with larger decrease rates at small spacing. Besides, the footing settlement at the ultimate load capacity of a 3-layer Type II reinforced soil is smaller for closer reinforcement spacing. The reduction effect of footing settlement is more remarkable when the spacing ratio reduced.



(a) 30cm spacing (b) 60cm spacing

Fig. 1 Variation of BCR with reinforcement layers

**Reinforcement Tensile Modulus**

A series of finite element analysis were conducted for each tensile modulus using 3, 6 and 9 layers of reinforcement placed within the effective depth of 1.5 B at a uniform spacing. Regardless of the number of reinforcement layers, the footing with geogrids of higher tensile modulus has a larger bearing capacity. Moreover, this modulus-related increase in the BCR is more remarkable at lower geogrid stiffness and gradually weakens as the tensile modulus of geogrid exceeds 35MPa. At the same time, the SRF decreases with the increase in reinforcement tensile modulus at a gradually reducing rate. In general, the study indicates that a better reinforcement effect in terms of higher ultimate bearing capacity and smaller settlement can be achieved from higher tensile modulus of the geogrid. In addition, a geogrid with a tensile modulus ranging from 5MPa to 25MPa will maximize the benefits of the reinforced soil footing [4]. No more significant improvement is achieved when the tensile modulus of geogrid exceeds 35MPa.

**Geogrid-Soil Interaction**

The influence of the geogrid-soil interaction coefficient on the BCR and SRF is examined when the coefficients range from 0.4 to 0.8 with equal interval of 0.1. The results show that, as the interaction coefficient increases, the BCR increases and SRF decreases for all studied geogrid reinforced soil footings, which means that better interaction between soil and geogrids always provide better performance of RSF. On the other hand, the increase rate in the BCR or the decrease rate in the SRF is relatively independent of the type of geogrids.

**Footing Embedment Depth**

The variation of the BCR and the variation of SRF with footing embedment depth were analyzed using the FEM model. With the increase of the embedment depth for the footing, both the BCR and the SRF slightly decrease at an approximately linear manner. There is a slight reduction trend of the BCR with the increase of the embedment depth, which can be explained by the fact that the increase

of the embedment depth increases the bearing capacity of the unreinforced footing more than that of the reinforced footing [5].

### Footing Width

In this section, the effect of footing width on the BCR and SRF of reinforced soil footings was studied by changing the width of strip footing from 0.9 m to 1.8m. The results show that with the increase of footing width, both the BCR and the SRF decrease at a linear manner. It is due to larger increase in the bearing capacity of the unreinforced footing compared to the reinforced footing brought up by the increase of the footing width, which consequently causes a decrease trend in the BCR. And thus it can be concluded that increase in footing width cannot bring more benefit in increasing BCR, however, it can reduce more footing settlement. The benefit in reducing the settlement can be explained by the fact that wider footing can distribute overlying load in a wider range and thus the corresponding settlement reduces.

### The Friction Angle and Cohesion of Soil

The effect of soil friction angle on the BCR and SRF of reinforced soil footings was studied by varying it from 25°to 45°while all the other parameters of the soil remained unchanged. The effect of cohesion was also analyzed else.

The results show that with the increase in friction angle or cohesion, both the BCR and SRF decreased, which means that the increase in friction angle and cohesion of soil cannot bring benefit in increasing its bearing capacity. This can be explained that the increase in friction angle or cohesion results more increase in the bearing capacity of the unreinforced soil compared to the reinforced soil, which consequently causes a decrease in the BCR.

## Conclusions

The effective reinforcement depth is about 1.5B for the reinforced soil and it is independent of the geogrid type; At a given settlement, the bearing capacity of the footing decreases with the increase in reinforcement spacing, with larger decrease rates at small spacing; A geogrid with a tensile modulus ranging from 5MPa to 25MPa will maximize the benefits of the reinforced soil footing; Better interaction between soil and geogrids always provide better performance of RSF; With the increase in the embedment depth of the footing, both the BCR and the SRF slightly decrease at an approximately linear manner; Increase in footing width cannot bring more benefit in increasing BCR, however, it can reduce more footing settlement; With the increase in friction angle or cohesion, both the BCR and SRF decreased.

**Keywords:** open-pit copper mine; soil-like slope; the acid wastewater; instability mechanism

**Abstract.** Combined with the engineering geological conditions and geological characteristics of soil-like slope in a certain open-pit copper mine, based on the experiments and theoretical analysis, the instability mechanism of soil-like slope under the action of acid mine wastewater is researched. Because the acid wastewater goes into the weak structural plane, reacting with the constitutional materials and fillings in slopes, the react change the microstructure of the rock and soil, and replace, dissolve the components, causing the cohesion and internal friction angle of slope reducing eventually and slope failure.

## Introduction

With the rapid development of social and economic, human's demand for mineral resources is growing, environmental problems arise from the growing mine drainage, and the pollution will become a global problem which will gradually attract people's attention [1,2]. The widest pollution and the greatest harm of mine drainage is acid mine drainage AMD (Acid Mine Drainage). Reported in the literature, 70% acid in the water is from the mine drainage [3]. According to incomplete statistics [4], in all accidents of open-pit copper mine, about 70% are due to the instability mechanism of slope, and most of the instability of slope are soil-like slope, and acid mine drainage leading to the destroying of metal mine slope is a special way. The soil-like slope in open-pit mine occur all types of slope instability or landslide events constantly, which caused a huge threat and loss to the production and life of mine enterprises.

At present, the experimental research about the mechanical properties and corrosion mechanism of soil-like slope in the role of acid mine drainage domestic and foreign has been reported rarely in domestic and foreign, and mostly related research is about the erosion or corrosion mechanism of reinforced concrete under acidic water conditions or cement soil, or research on acidic soils. This thesis based on laboratory experiments and theoretical analysis reveals the instability mechanism of soil-like slope in open-pit copper mine, which provides a theoretical basis for the maintenance and reinforcement of the mine's slope.

## Project Overview

The copper mine lies in Jiangxi Province. Its length from north to south is 1700 m, width from east to west is 600-900 m, and its open-pit mining highest elevation is 475 m, the lowest elevation design is -26.0 m, and the maximum height of the slope of 501 m, which is a large open pit mines. The mine belongs to the subtropical monsoon climate, and the climate is warm and humid, annual average rainfall is 1908.9 mm. In this region the stratum mainly include Cambrian, Triassic, Jurassic, Quaternary and early of Yanshan magmatic intrusions and dikes class. Its geological structure is relatively simple, and it doesn't found that there is major fault fracture zone passing.

Following an inspection, the shallow surface soil of the mine's slope behaves the whole strongly weathered, reddish brown, brown, gray, gray brown, and other blended color. the mine's slope is original rock structure, and the structure is not easy to identify, feldspar has kaolinised, is gray, quartz is granular, whose size is generally 0.3-3mm, part is 5-10mm, and the slope's fissures are developed,

where there is a large of Fe, Mn and filling. Lower part of the rock is mixed rock which is slightly weathered, and was reddish brown, brown, gray, gray brown and other blended color. It is granular and massive structure, less fissures in which there is a small Fe, Mn. The core show short column-shaped and pieces blocks, and the lithology is better. The open-pit mine's slope belongs to soil-like slope (Fig. 1).

Fig.1 Copper mine's soil-like slope

**The instability mechanism of soil-like slope**

Soil-like slope is between the rock slope and soil slope .It is composed of soil material substance or crushed rock which is formed by the weathering of original rock and they retain and some inherited the structure surface of the original rock.Soil-like slope of mine have the characteristics of the soil-like slope, apart from this it also contains large amounts of sulfide minerals [5], which produces highly acidic water after reaction with water and air, and the acidic water can take place chemical reaction with the contacted slope body very easily. The chemical reaction will change the composition of slope body's skeleton and internal molecular structure, reducing the cohesion and internal friction angle of slope body and making slope easier instability.

**The formation mechanism of acidic water.** The major waste rock of metal mine are minerals mica, quartz and pyrite. The acid mine drainage is mainly produced by the weathering of pyrite, and the water quality changes depending on the oxidation of pyrite caused by [6,7]. During the reaction, the sulfide, water, oxygen is involved, bacteria (mainly iron and sulfur Bacillus subtilis), redox potential, temperature and so on are the reaction conditions. Part of the chemical reaction equation is as follows:

$$2FeS_2 + 7O_2 + 2H_2O \rightarrow 2Fe^{2+} + 4SO_4^{2-} + 4H^+ \quad (1)$$

$$4Fe^{2+} + 10H_2O + O_2 \rightarrow 4Fe(OH)_3 + 8H^+ \quad (2)$$

$$4Fe^{2+} + O_2 + 4H^+ \rightarrow 4Fe^{3+} + 2H_2O \quad (3)$$

$$FeS_2 + 14Fe^{3+} + 8H_2O \rightarrow 15Fe^{2+} + 2SO_4^{2-} + 16H^+ \quad (4)$$

Taking the water around the area of projects, founding that the components of environmental water's quality are complex, and its pH value is about 3.23, which belongs to the strong acidic water, moreover the water contains strong erosion and contains a lot of heavy metal ions, which in addition to Pb ions, other content of Cu, Zn, Cd plasma seriously overweight.

**Study on mechanical characters of soil-like slopes by acid mine drainage.** Combined with the engineering geological, some samples are taken. The surface of rock and soil slope and the deep of rock and soil are taken and both are three groups. Three tests are respectively conducted for compression test, direct shear test and the longitudinal wave velocity tests.

**Compression test results analysis.** Based on the results analyzed for drainage in project area, $H_2SO_4$ is formulated as solution of pH 3.23, and put the six groups of samples into the solution, observe the changes in compressive strength for 0d, 5d, 10d, 15d, 20d. The results are shown in table 1 and Fig. 2. The test results show that with the increasing of immersion time, the compressive strength of rock and soil in surface and deep show a decreasing trend, and the compressive strength of the surface is less than the deep.

**Direct shear test results analysis.** Each sample is carried out shear test, and take the results of the sample into regression analysis, then gain the parameter of shear strength of the corresponding state of the soil .The parameter are cohesion(c)and internal friction angle (Φ), the results are in table 2, Fig. 3

and Fig. 4. According to the test results, the shear strength of the surface is less than the deep. With the growth of time of the effect in the acidic solution, the shear strength of rock and soil in surface and deep shows a decreasing trend.

Table 1 Compression test results

| | 2 | 11.845 | 11.958 | 3555 | 3275 |
| | 3 | 11.765 | 11.924 | 3550 | 3267 |
| The deep of rock and soil | 1 | 10.689 | 10.795 | 3842 | 3547 |
| | 2 | 10.364 | 10.468 | 3836 | 3529 |
| | 3 | 10.562 | 10.627 | 3839 | 3531 |

## Conclusion

Because soil-like slopes have weak structural plane, so their failure forms are very different to general rock slopes and soil slopes. And in the weak structural plane produce a large number of capillary pores due to weathering, these fissures or pores will become the center of acidic mine water absorption , while soil-like slopes' joints and cracks filled with a lot of rocks, clay minerals siliceous and carbonate rocks, which are highly corrosive under acidic conditions. Therefore, the instability mechanism of soil-like slopes along the weak structural plane mainly lies in the acid mine drainage go into the weak structural plane, react with the constitutional materials and fillings in slopes, the react change the microstructure of the rock and soil , and replace, dissolve the components. As a result the cohesion and internal friction angle of slope reduce eventually, so that causing slope failure. Meanwhile, acid mine drainage will increase the size of weak structural plane and bring new fracture which increase the probability of slope failure.

In summary, when analyze the stability of soil-like slope in open-pit copper mine and reinforcement it, not only should pay attention to the structural characteristic of soil-like slope, but also particularly attention to the comfortable drainage design, reduce the slope runoff and reduce erosion damage due to the effect caused by acid mine drainage, improve the cohesion and angle of internal friction of rock and soil, and effectively improve the physical and mechanical properties of rock and soil.

**Key wards:** slope stability, critical sliding field, geometric form, optimum design

**Abstract.** The optimum design of final highwall is a multivariable and complex technical problem that every change in any factor will influence the stable state. Based on the history-case, this paper applied the critical sliding field to search the critical slip and evaluate the stability of slope with different geometric forms. Comprehensively compared the global and local slope stability and its economic benefits, finally achieved the optimum design of final highwall.

## Introduction

In the design of open-pit mining projects, the slope angle concerns both enterprise's revenue and resource's utilization. The angle of slope has a significant impact on the stability of the slope, the economic benefits of open-pit mining and the safety of the life and equipment. Therefore, the slope stability is a key factor of normal production in open-pit mine. It is significant to design the maximum slopes angle under the condition of the established safe reserve.

Jinchuan quartz mine mining will enter final highwall mining stage. Many parts of the slope have different degree of deformation and failure. The production states can affect the company's economic benefit. Therefore, how to determine the optimum slope angle becomes a problem to be solved. This paper do some research on the subsequent deep level mining and the optimum design of final highwall, aiming at ensure the slope stability, reducing the loss rate of mineral resources, so as to achieve maximum economic benefits.

## Engineering geological conditions and mining profile

Mining area which is high in northwest while low in southwest belongs to hilly terrain. After years of exploration, the area formed an open pit which is low in the middle while relatively high on the other three sides including the south side, the west side, and the north side, all of which have become slopes with multistep shape. The middle area which has some simple roads connecting to working platform is relatively flat. The top of north slope is almost covered with waste mining rock while some local area is bedrock exposed. There are many cracks on the earth's surface which is near to slope boundary. The mining area has experienced many faulting activities and the fracture has fully developed.

The mining basin distributed in a stripe shape extending towards northeast and southwest. The stratum consists of lower Paleozoic erathem, Devonian system, Permo-carboniferous system, Tertiary strata and quaternary strata. The exposed layer below natural ground consistbreccia, sandstone, slate and so on. There are some pieces of fault fracture zone and coal between local layers.

The stope is a deep sunken open pit with 1000 meters long, 390 meters wide and 160 meters high. The elevation of the lowest platform is 1756 meters. The height of the slope is about 90 meters except for the lower unfinished part which is about 50 meters. So it's the key point that how to

make the best of ore resources while the slope is kept stable. This paper talked about how to design this slope using Critical slip field method.

## The fundamentals of optimum design

**The residual thrust method.** The residual thrust method assumes that the force between two slices is parallel to the bottom plane of the previous block, when the sliding force is greater than the anti-sliding force, it will have a trend of downward sliding [1-3]. The formula is as follows:

$$P_i = F_s w_i \sin\theta_i - \left(w_i \cos\theta_i - P_{i-1}\sin\Delta\theta_i\right)\tan\phi_i - c_i l_i + P_{i-1}\cos\Delta\theta_i , \quad (1)$$

or $$P_i = F_s w_i \sin\theta_i - w_i \cos\theta_i \tan\phi_i - c_i l_i - P_{i-1}\psi_i , \quad (2)$$

where $P_i$ and $P_{i-1}$ are the remaining force of blocks, $F_s$ is safety factor, $w_i$ is the block weight, $c_i$ is cohesion, $\phi_i$ is angle of friction, $\theta_{i-1}$ is the upper block bottom angel, $\theta_i$ is the nether block bottom angel, $\Delta\theta_i = \theta_i - \theta_{i-1}$, $\psi_i = \cos\Delta\theta_i + \sin\Delta\theta_i \tan\phi_i$ is thrust coefficient. Safety factor $F_s$ is calculated by iterating, $F_s$ is the solution when $P_{n+1} = 0$.

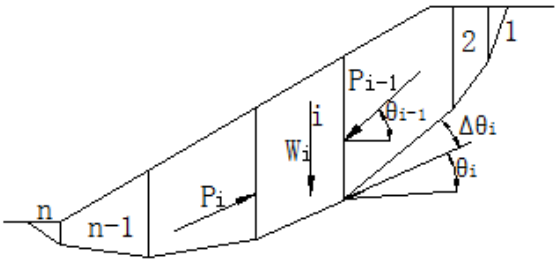

Fig 1 Residual thrust method calculation icon

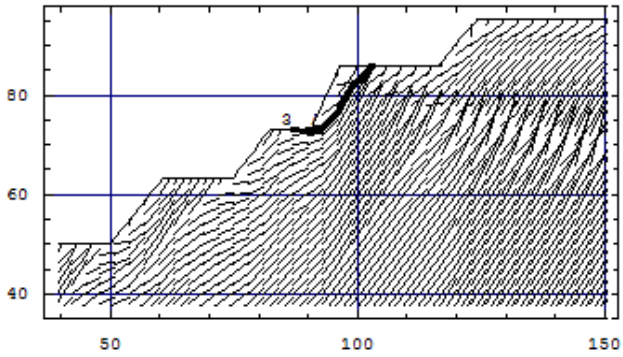

Fig2 The critical sliding surface of present slope in 3-3 profile

**Fundamental of critical sliding field method.** Critical sliding field method is on basis of residual thrust method, probing the critical sliding surface under the condition that exit and entry is specified. The slope is divided into a number of dangerous blocks, and the contact surface is divided into several points for the search. When given a safety factor, the slope body's strength expressed by a uniform proportion, the arbitrary point has a sliding direction and the maximum remaining thrust P. When researching, the direction of nether bulk' maximum residual thrust is the most dangerous sliding direction, and so on to get the maximum residual thrust slip surface [4-6]. Adjusting the safety coefficient of $F_S$ when the maximum residual thrust is zero to get the critical sliding field, and which is the most dangerous slip surface.

## The optimum design and analysis of slope angle

**Design standards.** In the process of open-pit mining, the maximum allowable slope angle should be calculated under the premise that the FOS (factor of safety) is greater than 1.05. In this study the method of Ordinary, Bishop, Janbu, and Morgenstern-Price are used to analysis slope stability. The search for dangerous sliding surface and the analysis for stability of slope are based on

the limit FOS that the minimum value of the four methods is greater than 1.05. If the residual thrust of the sliding surface is zero or near zero, then the angle of this slope is the maximum allowable value under the condition of the established safe reserve, which can meet the requirements of optimization slope angle.

Table 1 Parameters of faults and physical properties of rocks

| | C (Kpa) | Φ(°) | γ(KN/m³) | E(Mpa) | μ |
|---|---|---|---|---|---|
| rubble | 26 | 26 | 16.5 | 1038 | 0.15 |
| sandstone | 109.44 | 29.75 | 26.2 | 1520 | 0.14 |
| killas | 147.06 | 28.05 | 27.8 | 1192 | 0.21 |
| shattered fault zones | 20 | 23.8 | 22 | 88 | 0.26 |
| quartzite | 148.2 | 29.3 | 27 | 1798 | 0.24 |

**The sliding surface search of critical state for present slope.** This paper takes jingchuang open-pit mine north wall as a case to search and analysis the final highwall's critical sliding surface. The engineering geological condition is shown in the figure 3, and the parameters of stratum are shown in the table 1. The dangerous sliding surface of present slope is searched on the premise of the allowable minimum FOS at 1.05. Based on this residual thrust, the minimum of FOS is found out while the residual thrust is zero. And then, figure out the maximum slope angel by optimum design. After systematic search, the maximum residual thrust is closed to zero when the slope angle is 32°. This angle is in accordance with the current slope angle， it illustrates that the present situation of the slope basically meets the safety requirements in engineering. The global slope is stable, but local failure occurs at the steps as shown in figure 2. So the deep level mining chose to mine directly along this angle.

**Optimum design for deep mining.** 3-3 profile's engineering geological distribution as shown in figure 3. Including quaternary diluvial layer adopting the mechanical parameters of sandstone, carbonaceous mudstone and extrusion belt adopting mechanical parameters of fault fracture zone, mixed zone cladding on the slate using the mechanical parameters of gravel. Exploit the deep resources extending mining at the angle 32° downwards, considering the comprehensive economic rationality, it only allows its depth down to 1706 levels. Under this condition, make an optimum design, and through the sliding surface search and evaluating slope stability, the maximum residual thrust near to zero when $F_S$ = 0.982. The minimum stability coefficient in the four calculation methods is only 0.94, with a mean of 0.99.Therefore, the slope stability does not meet the safety requirements.

Against the formation distribution characteristics and the analysis of engineering geological conditions, it can be found that the main cause of instability in the profile is mass strength of fracture zone rock range from 1756 to 1732 levels is low. Carrying capacity of the slope waist insufficient, thus inducing the instability and failure of slope as a whole after deep mining. Reducing the overall slope angle makes stripping amount too large causes poor economic benefit. Through a series of scheme comparison and analysis, reduce local slope angle appropriately in order to ensure the safety of the fracture zone. Then considering the strength characteristics of slate below 1732 levels, increase its deep slope angle to form a convex type slope can reduce the stripping amount and increase production [7,8], so as to guarantee the whole slope angle of the same or slightly changed.

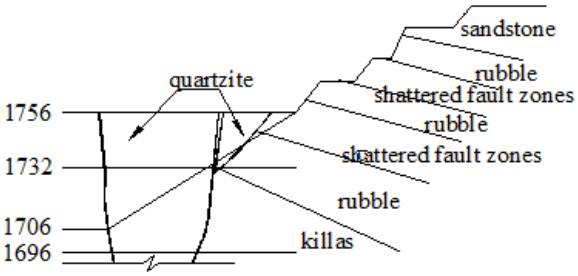

Fig3. 3-3 profile by extending deep mining at 32° plan and stratigraphic distribution

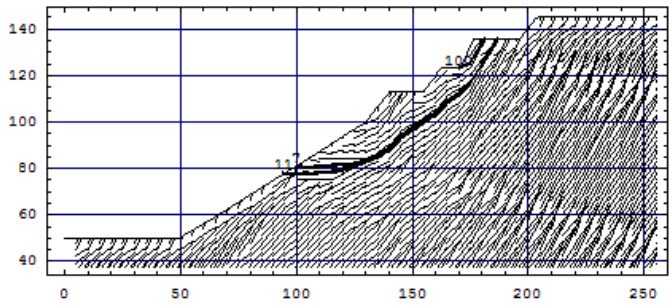

Fig4. Slope sliding surface of 3-3 profile by extending deep mining at 32 °

Firstly, optimize the design of the upper fracture zone of slope, through a series of calculation and analysis, when mining the fault fracture zone at 23°, the bearing capacity of the bottom of the fracture zone can meet the safety requirements, namely first by extending the deep to 1732 levels at 23°, to ensure the local stability of slope. Then taking the $F_S$ = 1.05, search the slope lower slope , get the lower slope Angle was 40°, the integral sliding surface maximum residual thrust is close to zero ( figure 5). The whole slope Angle is 32°, which allows extending down to 1708 levels. The convex type slope's minimum stability coefficient through the four calculation methods is above 1.05, with a mean of 1.14 (table 2), the overall stability meets the engineering requirements. finally, by setting a series of safety coefficient for the slope sliding surface analysis, get when FS = 1.02, the local slope's maximum residual thrust is close to zero (figure 6), the slope's minimum stability coefficient through the four calculation methods is above 1.05, with a mean of 1.10, the local slope stability either meets the engineering requirements.

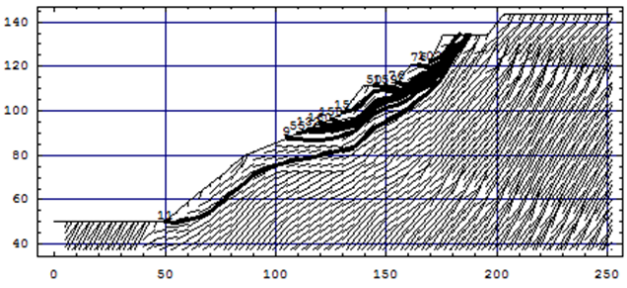

Fig5. Overall slope sliding surface of 3-3 section by extending deep mining at 32 ° +40 °

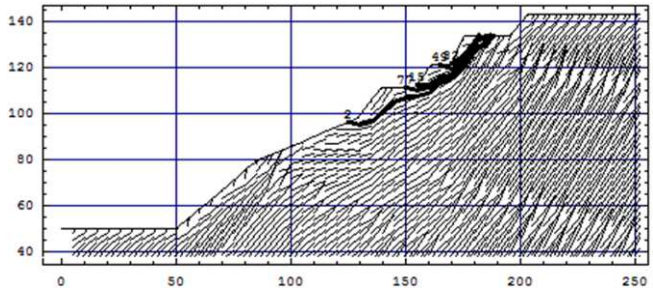

Fig6. Local slope sliding surface of 3-3 section by extending deep mining at 32 ° +40 °

Finally, design exploitation angle is 32°+23°+40°, the whole slope angle for 32, with a raised top and a concave bottom, which is just like convex type slope of combination. The plan is to ensure the overall stability of the slope and promoted the local stability of the slope, so as to achieve to meet the overall stability under the premise of exploiting resource at maximum level. The optimum design of final highwall provides a new train of thoughts, can reduce the magnitude of t scheme design, simplify the design process.

Table 2 Slope stability evaluation results of 3-3 profile

| evaluation content | Current slope angle（°） | Extending slope angle（°） | Overall slope angle（°） | Ordinary | Bishop | Janbu | M-P | Mean value |
|---|---|---|---|---|---|---|---|---|
| overall | 32 | 23+40 | 32 | 1.10 | 1.22 | 1.10 | 1.13 | 1.14 |
| local | 32 | 23+40 | 32 | 1.07 | 1.16 | 1.05 | 1.13 | 1.10 |

## Conclusions

Based on the residual thrust method, critical slip field theory determines accurately sliding surface of slope has important theoretical significance and practical application value. Its main advantages are that it can eliminate the influence of artificial factors, ensure the actual reliability of the evaluation, and avoid the same project with different evaluation conclusion by different technical personnel.

According to jinchuan quartz open-pit mine resources occurrence characteristics and engineering geological conditions, critical slip field theory is applied to the optimization design to the final highwall's research. In consideration of the special engineering geological conditions and mining method based on economy, convex type slope mining scheme is presented in this paper, its main characteristic is to use such control measures local fracture zone slope angle gently, hard segment steep, to ensure that the overall slope stability, so as to ensure the effective resource development and safety production.

**Keywords:** Underwater vibrating compaction; Scattering-filling rubble stone layer; Effect analysis of parameters; Theoretical analysis.

**Abstract.** This paper studied on the underwater vibrating compaction technology of scattering-filling rubble stone layer. At HongKong-Zhuhai-Macao bridge project, in order to satisfy the project time limit, underwater vibrating compaction technology with hydraulic hammer instead of conventional dynamic compaction technology was used to tamp scattering-filling rubble stone layer with no dead angle in a short time. Owing to the shortage of engineering example, the theoretical analysis was needed before field application. In this paper, the rubble stone layer and the vibration system were simplified to a mechanical model. Vibration system's work on rubble stone was obtained by mathematical derivation, and effects of parameters were analyzed. The result shows that work on scattering-filling rubble stone layer increases with the increase of system quality, equivalent damping, exciting force and angular velocity and decreases with the increase of equivalent stiffness, water stiffness and buoyancy.

## Introduction

To promote economic development, Chinese government invested about 700 billion yuan to build the HongKong-Zhuhai-Macao bridge[1]. In the project, the foundation treatment in immersed tube section of tunnel and islands project used stone bed compaction technology. The total length of stone bed is about 4.8 kilometers. The width is about 42 meters. The thickness is about 1.9 meters. On the stone bed, there is scattering-filling rubble stone layer with 0.6 meters thick. The maximum water depth of the scattering-filling rubble stone layer is 44 meters. The scattering-filling rubble stone layer should be tamped to make it more compact and smooth.

Figure 1 The vibrating compaction system

Conventional dynamic compaction technology could not tamp the scattering-filling rubble stone layer with no dead angle in a short time due to the project construction period. Therefore, a new underwater damping method was needed. The construction unit of the bridge was to be used

underwater vibrating compaction method with hydraulic hammer. The vibrating compaction system is shown in Fig. 1. Owing to the shortage of engineering example, the theoretical analysis was needed before field application.

In this paper, the scattering-filling rubble stone layer and the vibrating compaction system were simplified as a mechanical model. The work equation was obtained through mathematical derivation. And effects of system parameters were analyzed. The work of this paper provided theoretical support for underwater vibrating compaction technology.

## Establishment and Solution of the Vibration Equation

Supported by available literature [2-4], the vibrating compaction system and the rubble stone layer were equivalent to a simplified model which was composed of quality, spring and damping.

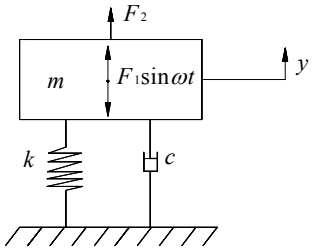

Figure 2 Simplified mechanical model

Fig. 2 shows the simplified mechanical model. In the model, the positive direction of vertical displacement is upward. In Fig. 2, parameter $m$ is compaction system quality. Parameter $k$ is equivalent stiffness of rubble stone layer. Parameter $c$ is system equivalent damping. Parameter $c$ contains two parts: equivalent damping of $c_1$ rubble stone layer and water damping $c_2$. Parameter $F_1$ is exciting force amplitude. Parameter $F_2$ is buoyant force of compaction system. Parameter is angular velocity.

According to the vibration model, the vibration equation was established.

$$my'' + \left(c_1 + c_2\right) y' + ky = F_2 - W + F_1 \sin \omega t \,. \tag{1}$$

The characteristic equation of Eq. 1 is shown in the following equation.

$$r^2 + \frac{c_1 + c_2}{m} r + \frac{k}{m} = 0 \,. \tag{2}$$

According to the practical engineer, the following equation can be obtained.

$$\left(\frac{c_1 + c_2}{m}\right)^2 - 4\frac{k}{m} = \frac{\left(c_1 + c_2\right)^2 - 4mk}{m^2} < 0 \,. \tag{3}$$

Then Eq. 2 has two conjugate complex roots as following equation.

$$r_{1,2} = \frac{-\left(c_1 + c_2\right) \pm i\sqrt{4mk - \left(c_1 + c_2\right)^2}}{2m} \,. \tag{4}$$

General solution of the homogeneous equation corresponding to Eq. 1 is shown in Eq. 5.

$$Y = e^{\alpha t}\left(C_1 \cos \beta t + C_2 \sin \beta t\right) \,. \tag{5}$$

In Eq. 5, $C_1$ and $C_2$ are arbitrary constants. $\alpha = -\frac{(c_1 + c_2)}{2m}$, $\beta = \frac{\sqrt{4mk - (c_1 + c_2)^2}}{2m}$.

Because $\pm i\omega$ are not the roots of the characteristic equation, Eq. 1 has the following special solution.

$$y = Q + R_1 \cos \omega t + R_2 \sin \omega t . \tag{6}$$

$$y' = -\omega R_1 \sin \omega t + \omega R_2 \cos \omega t . \tag{7}$$

$$y'' = -\omega^2 R_1 \cos \omega t - \omega^2 R_2 \sin \omega t . \tag{8}$$

Substitute above three equations into Eq. 1. Then the following equation will be obtained.

$$\left(kR_1 - m\omega^2 R_1 + (c_1 + c_2)\omega R_2\right)\cos \omega t + \left(kR_2 - (c_1 + c_2)\omega R_1 - m\omega^2 R_2\right)\sin \omega t + kQ = F_2 - W + F_1 \sin \omega t \tag{9}$$

Comparing Eq. 9 on both sides, in order to make sure the equation correct at any moment *t*, the following three conditions are needed.

$$R_1 = \frac{(c_1 + c_2)\omega}{2mk\omega^2 - k^2 - m^2\omega^4 - (c_1 + c_2)^2 \omega^2} F_1 . \tag{10}$$

$$R_2 = \frac{m\omega^2 - k}{2mk\omega^2 - k^2 - m^2\omega^4 - (c_1 + c_2)^2 \omega^2} F_1 . \tag{11}$$

$$Q = \frac{F_2 - W}{k} . \tag{12}$$

Then the general solution of Eq. 1 is shown in following equation.

$$Y = e^{\alpha t}\left(C_1 \cos \beta t + C_2 \sin \beta t\right) + \frac{F_2 - W}{k} + R_1 \cos \omega t + R_2 \sin \omega t . \tag{13}$$

Initial conditions of Eq. 1 are shown in Eq. 14.

$$\begin{cases} Y\big|_{t=0} = 0 \\ Y'\big|_{t=0} = 0 \end{cases} . \tag{14}$$

According to Eq. 13 and Eq. 14, Eq. 15 and Eq. 16 will be obtained.

$$C_1 = \frac{W - F_2}{k} - R_1 . \tag{15}$$

$$C_2 = \frac{1}{\beta}\left(R_1 \alpha - \frac{W - F_2}{k}\alpha - \omega R_2\right). \tag{16}$$

Now parameters in Eq. 13 all have a clear expression. Eq. 13 is the vibration displacement.

In order to observe the variation of the displacement y, give a set of parameters: $m$=35×10$^3$ kg, $k$=4.2×10$^7$ N/m, $c_1$=1.5×10$^5$ N•s/m, $c_2$=1×10$^4$ N•s/m, $F_1$=1456 kN, $F_2$=70 kN, $\omega$ =1846π rad/min. Taken these parameters into Eq. 6, the time displacement curve will be obtained. The curve is shown in Fig. 3.

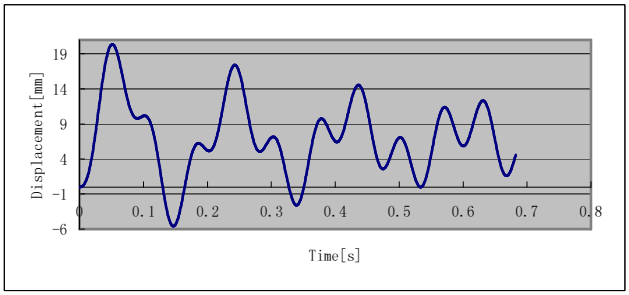

Figure 3 Displacement-time curve

In Fig. 3, the regularity of displacement-time curve is poor. It is very difficult to calculate system work according to the displacement shown in Fig. 3.

With further analysis, the displacement $Y$ can be split into two parts: $y_1$ and $y_2$.

$$\begin{cases} y_1 = e^{\alpha t}\left(C_1 \cos \beta t + C_2 \sin \beta t\right) \\ y_2 = \dfrac{F_2 - W}{k} + R_1 \cos \omega t + R_2 \sin \omega t \end{cases}. \tag{17}$$

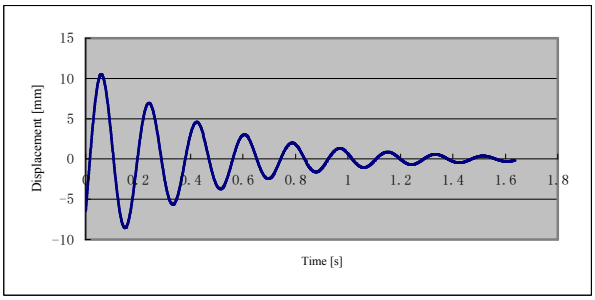

Figure 4 $y_1$ displacement-time curve

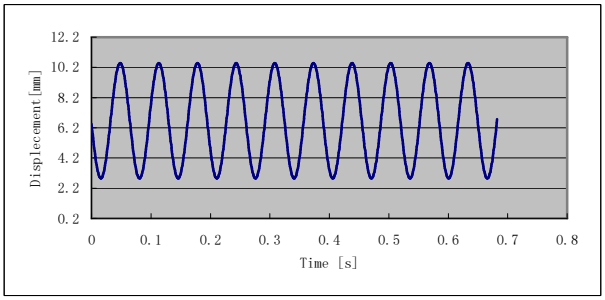

Figure 5 $y_2$ displacement-time curve

In Fig.4, the displacement $y_1$ attenuates along with time periods. Through the attenuation trend, displacement $y_1$ will attenuate to zero in a few seconds. A vibrating compaction period is at least a few minutes in practical project. So the contribution of displacement $y_1$ to the vibrating compaction process is very small. Displacement $y_1$ can be neglected in the whole compaction period.

In Fig.5, displacement $y_2$ is a harmonic function of time. It is stable in the whole compaction process. It is the steady-state response of the system. Therefore, the contribution of displacement $y_1$ is neglected, and only the contribution of displacement $y_2$ is considered in the vibrating compaction progress in this paper.

Displacement $y_2$ can be changed to Eq. 18.

$$y_2 = \frac{F_2 - W}{k} + R\sin\left(\omega t + \varphi\right). \tag{18}$$

In Eq. 18, $R = \sqrt{R_1^2 + R_2^2}$, $\varphi = \arctan\dfrac{R_1}{R_2}$.

The vibrating velocity is shown in Eq. 19.

$$v = y_2{}' = R\omega\cos\left(\omega t + \varphi\right). \tag{19}$$

In actual project, the compaction system works on the rubble stone layer when the system moves downward. When the compaction system moves upward, it doesn't work on rubble stone layer. And one part of system's work is used to overcome buoyancy and resistance of water. So the work on

rubble stone layer is equal to the difference between the work when compaction system moves upward and the work done by buoyancy and water resistance.

According to Eq. 19, in time 0~T, the time span when compaction system moves downward is $\left[\frac{\pi-2\varphi}{2\omega},\frac{3\pi-2\varphi}{2\omega}\right]$. Then the system work on rubble stone layer is shown in Eq. 20.

$$P=\int_{\frac{\pi-2\varphi}{2\omega}}^{\frac{3\pi-2\varphi}{2\omega}}\left(F_2-W+F_1\sin\omega t\right)dy_2-\int_{\frac{\pi-2\varphi}{2\omega}}^{\frac{3\pi-2\varphi}{2\omega}}c_2 v dy_2=2\left(W-F_2\right)R-\frac{1}{2}\pi F_1 R\sin\varphi-\frac{1}{2}c_2R^2\omega\pi\,. \tag{20}$$

**Determining Method of Equation Parameters**

Supported by available literatures [5], determination of equivalent stiffness is shown in Eq. (21).

$$k=\frac{1.1E}{1-\nu^2}\sqrt{BL}\,. \tag{21}$$

In Eq. 21, $k$ is equivalent stiffness and its unit is N/m. $E$ is elastic modulus and its unit is Pa. $\nu$ is Poisson's ratio. $B$ is the width of vibration plate and its unit is m. $L$ is the length of vibration plate and its unit is m.

Table 1 Interpolation table of damping ratio

| Mass ratio $b$ | Poisson's ratio | | | | | | |
|---|---|---|---|---|---|---|---|
| | 0 | 0.25 | 0.30 | 0.35 | 0.40 | 0.45 | 0.50 |
| 20 | 0.196 | 0.207 | 0.215 | 0.224 | 0.234 | 0.245 | 0.257 |
| 40 | 0.139 | 0.147 | 0.153 | 0.160 | 0.167 | 0.176 | 0.185 |
| 60 | 0.114 | 0.121 | 0.126 | 0.131 | 0.137 | 0.144 | 0.152 |
| 80 | 0.099 | 0.105 | 0.109 | 0.114 | 0.119 | 0.125 | 0.132 |

Equivalent damping can be determined by Eq. 22 [5,6].

$$\mathrm{c}=2\mathrm{D}\sqrt{mk}\,. \tag{22}$$

In Eq. 22, $D$ is damping ratio. $D$ can be determined through Table 1 with certain mass ratio and Poisson's ratio. Mass ratio $b$ can be calculated by following equation.

$$b=\frac{m}{\rho r_0^3}. \tag{23}$$

In Eq. 23, $\rho$ is the density of rubble stone layer. $r_0$ is the equivalent radius of vibration plate. $r_0=0.56\sqrt{BL}$.

Water damping is related with properties of water and the shape of vibration compaction system. The effect of system shape is even larger than water properties. The determination of water damping needs field test.

## Effects Analysis of Parameters

In order to analyze effects of parameters on system work, give a set of parameters: $m$=30×10$^3$ kg, $k$=4×10$^8$ N/m, $c_1$=1×10$^6$ N•s/m, $c_2$=1×10$^5$ N•s/m, $F_1$=1400 kN, $F_2$=60 kN, $\omega$ =1800π rad/min. Change a parameter with 10% amplitude 4 times when other parameters remain unchanged, and collect the changed parameter and corresponding system work in a vibration cycle as shown in Fig. 6~12, then effects of parameters are obtained.

Fig. 6 is the influence curve of system quality on the system work, which shows that the system work on rubble stone layer increases with the increase of system quality. But the relationship between quality and the work is not linear. The curve is downward convex. With the increasing of system quality, the influence on system work is more and more heavy.

Fig. 7 is the influence curve of equivalent stiffness on the system work, which shows that the system work on rubble stone layer decreases with the increase of equivalent stiffness. The relationship between equivalent stiffness and the system work is not linear. The curve is downward convex.

Fig. 8 is the influence curve of equivalent damping on the system work, which illustrates that the system work on rubble stone layer increases with the increase of equivalent damping. The relationship between equivalent damping and the system work is not linear. The growth of system work is smaller and smaller with the increase of equivalent damping.

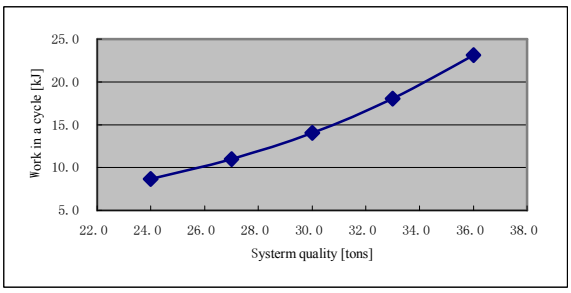

Figure 6 Effect of system quality on system work

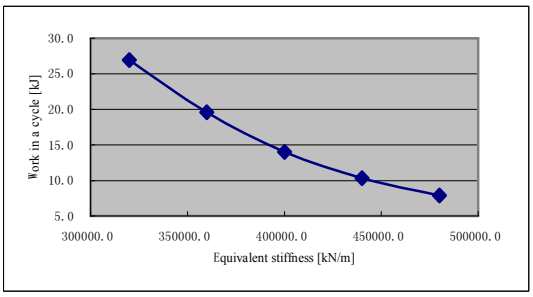

Figure 7 Effect of equivalent stiffness

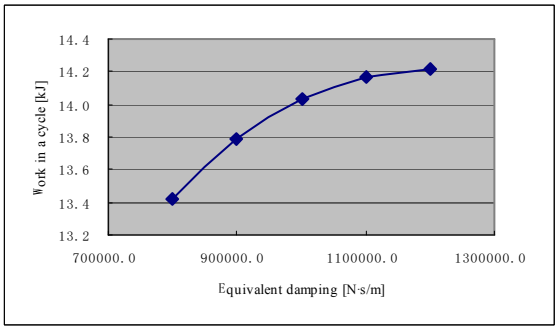

Figure 8 Effect of equivalent damping on system work

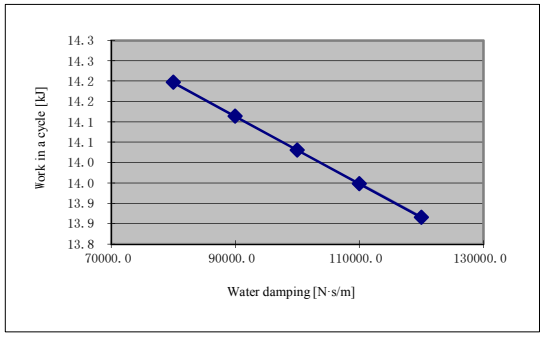

Figure 9 Effect of water damping

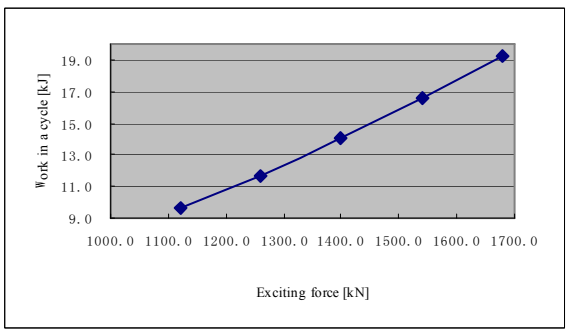

Figure 10 Effect of exciting force on system work

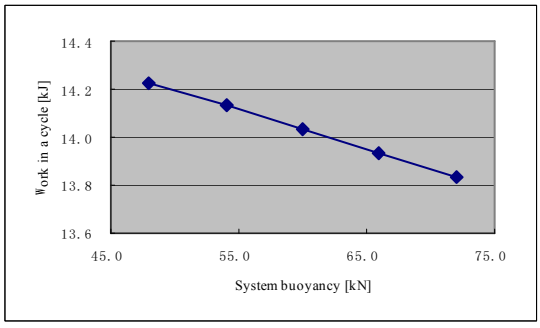

Figure 11 Effect of buoyancy on system work

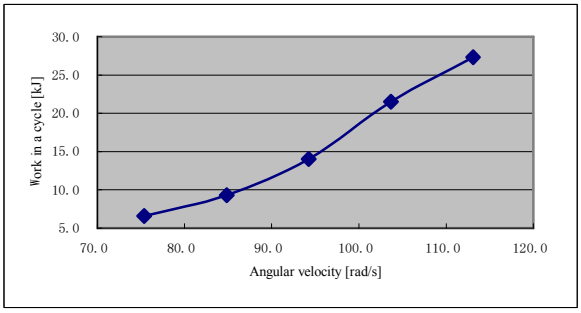

Figure 12 Effect of angular velocity on system work

Fig. 9 is the influence curve of water damping on the system work, which shows that the system work on rubble stone layer almost linear decreases with the increase of water damping.

Fig. 10 is the influence curve of exciting force on the system work, which demonstrates that the system work on rubble stone layer almost linear increases with the increase of exciting force.

Fig. 11 is the influence curve of buoyancy on the system work, which gives that the system work on rubble stone layer decreases with the increase of buoyancy. The relationship between buoyancy and the system work is almost linear.

Fig. 12 is the influence curve of angular velocity on the system work, which presents that system work on rubble stone layer increases with the increase of angular velocity. The relationship between angular velocity and the system work is not linear.

The above analysis shows that the work on scattering-filling rubble stone layer increases with the increase of system quality, equivalent damping, exciting force and angular velocity and decreases with the increase of equivalent stiffness, water stiffness and buoyancy.

## Conclusions

This paper investigated on the underwater vibrating compaction technology of scattering-filling rubble stone layer. Vibration compaction system and rubble stone layer were simplified to a mechanical model and the vibration equation was established. Through rigorous mathematical derivation, this paper gave equations of the vibration displacement, the vibration velocity and the system work on rubble stone layer. Lastly the influence of parameters on the system work was analyzed. The results show that the work on scattering-filling rubble stone layer increases with the increase of system quality, equivalent damping, exciting force and angular velocity and decreases with the increase of equivalent stiffness, water stiffness and buoyancy. This study can provide theoretical support for underwater vibrating compaction technology of scattering-filling rubble stone layer. It has important theoretical and engineering significance.

**Key words**: heterogeneity; crack propagation; macroscopic property; failure characteristic

**Abstract**: A three-dimensional DEM numerical model for analyzing rock failure process was developed by taking heterogeneities on microscopic scale into account with statistical mechanic. Failure processes of a series of rock samples with different heterogeneities were numerical simulated by uniaxial compressive tests. The influences of microscopic heterogeneity on macroscopic mechanical properties and failure behaviors were investigated. The results demonstrate that the numerical tests are able to illustrate the crack propagation occurring in different stages, and to predict the characteristic stresses and strains. With the increasing of heterogeneity index, except for Poisson's ratios and crack damage strains that almost maintain constant, deformation parameters as well as characteristic stresses and strains increase following exponent functions. As heterogeneity increases, elasticity deformation of rock samples becomes longer, volume compression reduces, brittle failure characteristic presents more significant, failure mode changes from "X" pattern to coalescence surface pattern forming through the whole rock samples.

## Introduction

Rock can be represented as an assembly of cemented mineral grains which can be described by its internal microstructures. The intact crystalline rock consists of a variety of mineral grains of different sizes, and of close contacts between mineral grains and microscopic defects in the form of cracks and holes [1]. Such microscopic structure causes rock to be a heterogeneous material. Heterogeneity is one of most important factors determining mechanical behaviors of rocks. Hence, taking heterogeneity into account for an investigation on rock failure process is a fundamental research for rock engineering.

However, heterogeneity is difficult to be described in laboratory even with the most advanced techniques. Therefore, some researches have been carried out concerning methods to mimic heterogeneity. Tang et al. [2] studied the failure processes of rock specimens with different heterogeneities under uniaxial compressive loading using a rock failure process analysis code (RFPA2D) by assuming mechanical properties subordinate to a statistical distribution. Ke et al. [3] studied the effects of mesoscopic heterogeneous material parameters on macroscopic mechanical behavior by employing a virtual internal bond model. Luo et al. [4] carried out an investigation into relationship between macroscopic and mesoscopic mechanical properties of heterogeneous rock materials based on types and contents of minerals. Lan et al. [1] developed a grain-based universal distinct element model and studied crack propagation in brittle rock samples with different heterogeneities. Xu et al. [5] studied mesoscopic structures of heterogeneous materials based on digital image processing technique. The macroscopic heterogeneity performed by rock samples under uniaxial or biaxial compressive loading is primarily caused by microscopic heterogeneity. Hence, numerical simulation method which is able to take microscopic heterogeneity into account is regarded as an effective tool for investigating rock mechanical behaviors. However, most researches were carried out using two-dimensional numerical model, which is not able to reflect the spatial distribution of heterogeneity.

Continuum medium models based on the assumption of homogeneity are not be able to describe local failure caused by heterogeneity of rock itself [3]. In comparison, Distinct element method (DEM), developing for analyzing rock mechanical behaviors originally, is a suitable method for studying the failure behavior of rock and describing crack propagation and rock fracture both from the macroscopic and microscopic point of views. In addition, DEM is able to deal with material failure from micro crack to macro failure and does not require the formulation of complex constitutive models. This method is therefore often used to investigate mechanical behavior and failure mechanism of rocks recently. The bonded particle model (BPM) proposed by Potyondy and Cundall [6] has drawn attention for its ability to reproduce the main mechanical behavior of Lac du Bonnet granite using DEM uniaxial and triaxial compression tests. Wang and Tonon [7]developed a distinct element code and applied it to model the mechanical behavior of a crystalline rock such as Lac du Bonnet granite. Christian et al. [8] proposed a progressive failure model and reproduced many features observed during rock failure experiment.

The approach and benefits of DEM are compelling, but the literature using this method to study the effects of heterogeneity on rock mechanical behaviors is rarely reported.

Thus, based on statistics characteristic of microscopic mechanical properties in rock material [9], a statistical distribution function was used to describe heterogeneity of rock sample and implemented into three-dimensional bond contact model. A series of uniaxial compressive tests on rock samples with different heterogeneities were simulated. The effects of microscopic heterogeneity on macroscopic mechanical properties and failure processes were investigated. Some significant conclusions were obtained finally.

## DEM Numerical Method

**Mechanical Response.** The mechanical response of bond contact model was established firstly through reasonable theoretical derivation, and then it was verified by a series of laboratory tests on the cemented samples [10]. Fig. 1(a) presents the normal mechanical response which is composed of tension and compression directions. In tension, the normal contact force $F_n$ between two particles is a product of normal stiffness coefficient $\bar{k}_n$ and tension displacement $u_n$ before its value reaches the normal bond strength. When the force arrives at the normal bond strength, the bond is broken and the normal force abruptly reduces to zero. In compression, the contact force is always a product of $\bar{k}_n$ and compression displacement, $u_n$. Fig. 1(b) presents the tangential force-displacement relationship. The shear force increases linearly with the increasing of tangential displacement $u_s$ up to shear strength. After the peak value is reached, the bond breaks and tangential force drops to the residual frictional shear strength. In Fig 1(c), the mechanical response on rolling contact direction is similar to that on tangential direction, the moment, $M$, is a product of rolling stiffness, $\bar{k}_r$, and relative rolling rotation $\theta$, and then it drops to zero.

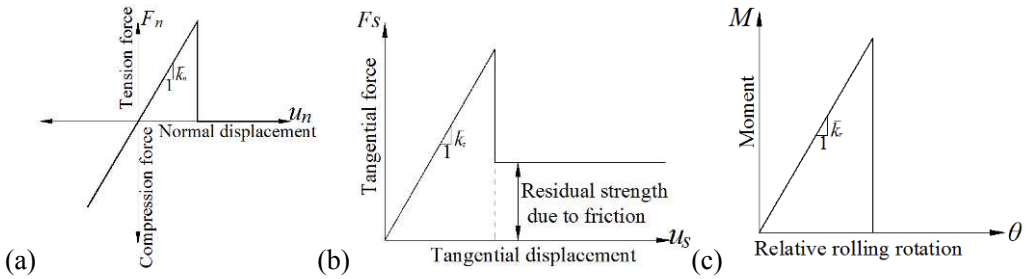

Fig. 1 Mechanical response of bond contact model: (a) normal mechanical response; (b) tangential mechanical response; (c) rolling mechanical response.

**Strength Envelope.** The normal stress and shear stress are derived by the beam theory, simplifying the microscopic bonded particles as a macroscopic beam, as shown in Fig. 2. The strength envelope bond contact model obtained by a simple transformation of the originally proposed equation is expressed by:

$$\sigma_c = -\frac{F_n}{A} + \frac{|M^s|\overline{R}}{I} \tag{1}$$

$$\tau_c = -\frac{|F^s|}{A} + \frac{|M^n|\overline{R}}{J} \tag{2}$$

where $\sigma_c$ and $\tau_c$ are the maximum tensile stress and the maximum shear stress, respectively; $A$, $I$ and $\overline{R}$ are the area, moment of inertia and radius of parallel bond, respectively.

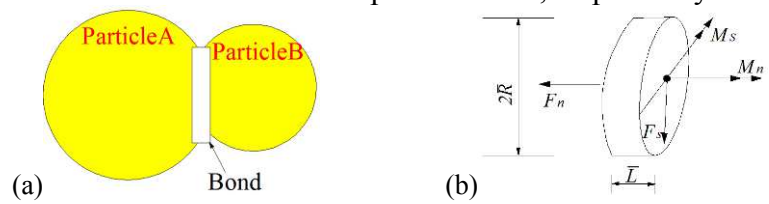

Fig. 2 Bond and its applied forces in bond contact model: (a) bond; (b) applied forces.

## Generation of DEM Rock Samples with Different Heterogeneities

DEM procedures for generating rock samples with different heterogeneities were compiled. Radius expansion method was employed to generate DEM rock samples. The samples were composed of 14923 particles with a maximum diameter of 1.05 mm, a minimum of 0.6 mm, and an average ($d_{50}$) diameter of 0.825 mm. The numerical samples are 30 mm wide, 30 mm long and 60 mm high. The initial void porosity is 0.35, which is representative of a dense sample, as shown in Fig. 3(a). After the generation, the sample was consolidated in 1D under the specific vertical pressure by lowering the top rigid wall and uprising the upper rigid wall with fixed side walls until the equilibrium state. Force distribution presenting in Fig. 3(b) shows that the force is distributed uniformly. In order to obtain densely packed and well-connected assembly, floating particles that have less than the specified contact number were deleted and simultaneously the radii were expanded aiming at increasing contact number. After these processes, the final average contact number arrived at 4.18, which satisfies the requirement of rock sample.

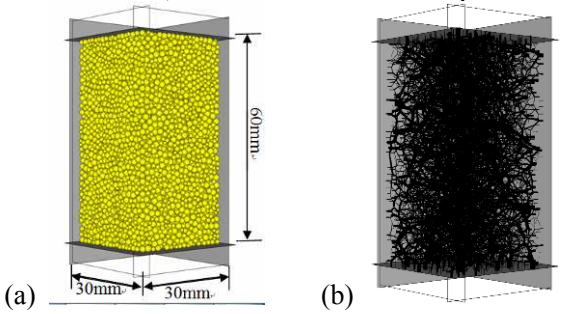

Fig. 3 DEM rock sample and force distribution

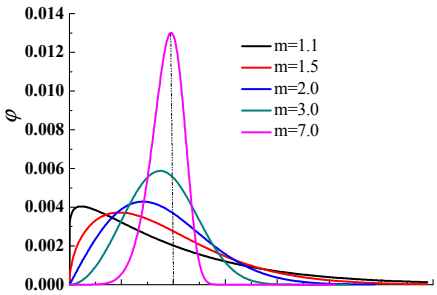

Fig. 4 Weibull distributions

Table 1 Microscopic parameters used in DEM simulation

| particles | | | |
|---|---|---|---|
| Density $\rho_s$ | Mean elastic modulus $E_0$ | Ratio between normal stiffness and tangential stiffness $k_n/k_s$ | Friction $\mu$ |
| 2360 $kg/m^3$ | $2.0\times10^{10}$ P$a$ | 2.5 | 0.5 |
| Interparticle bonds | | | |
| Mean elastic modulus $E_0$ | Ratio between normal stiffness and tangential stiffness $k_n/k_s$ | Mean tensile strength of bonds $\sigma_0$ | Mean tangential strength of bonds $\tau_0$ |
| $2.0\times10^{10}$ P$a$ | 2.5 | $2.0\times10^{7}$ P$a$ | $6.0\times10^{7}$ P$a$ |

For heterogeneity, the material properties for particles and interparticle bonds are randomly distributed throughout the samples by following a Weibull distribution:

$$\varphi = \frac{m}{\sigma_0}\left(\frac{\sigma}{\sigma_0}\right)^{m-1} e^{\left[-\left(\frac{\sigma}{\sigma_0}\right)^m\right]} \tag{3}$$

where $\sigma$ is the bond strength and $\sigma_0$ is the mean strength of interparticle bonds. For an elastic modulus $E$ of particles and interparticle bonds, the same distribution is used. $m$ is homogeneity index implies a more heterogeneous material and vice versa, as shown in Fig. 4.

Tab. 1 presents the microscopic parameters for particles and interparticle bonds used in DEM simulation. According to Ref. [6], the ratios between normal stiffness and tangential stiffness for particles and interparticle bonds were chosen to be 2.5. The friction coefficient 0.5 was used for particles. The elastic and strength parameters illustrating in Tab. 1 were finally selected by adjusting microscopic parameters until the mechanical properties obtained were consistent with experimental data. Eight samples with different heterogeneity indexes, m = 1.1, 1.5, 3.0, 7.0, 15.0, 30.0, 80.0, 300.0, representing materials for relative heterogeneity to relative homogeneity (Fig. 4)

## Numerical Simulation Results

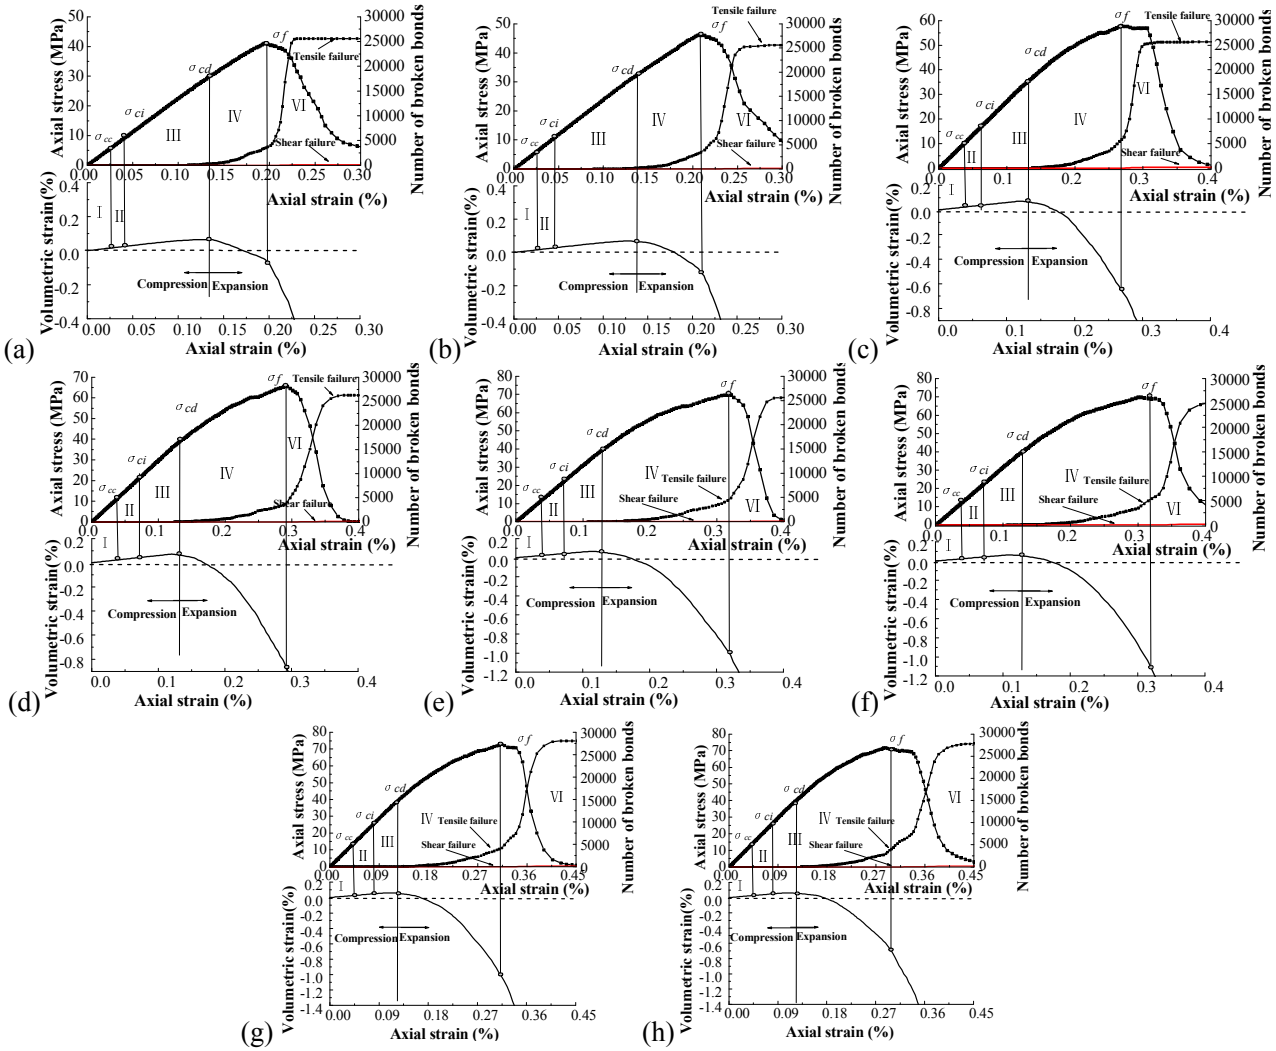

Fig. 5 Relationships between stress, the number of broken bonds, volumetric strain and axial strain obtained from DEM uniaxial compressive tests: (a) m=1.1; (b) m=1.5; (c) m=3.0; (d) m=7.0; (e) m=15.0; (f) m=30.0; (g) m=80.0; (h) m=300.0.

**Effects of Heterogeneity on Macroscopic Mechanical Behaviors.** Fig. 5 presents the stress-strain relationship and the number of broken bonds with axial strain obtained from numerical uniaxial compressive tests. The macroscopic failure of the rock samples is caused by the initiation and propagation of micro cracks which can be identified by looking at the history of the number of broken bonds in the DEM simulation (Fig. 5). In addition, all strains were computed by monitoring the motion of pairs of gauge particles that lie along the global coordinate axes at the centers of the sample faces in order to remove the influence of overlap between wall and boundary particle. The failure process of the DEM rock sample can be classified into five distinct stages as follows:

*Stage I*. Crack closure region. No crack occurs and the compression deformation is mainly from closure of original material defects. This region may or may not be present depending on the initial crack density and crack geometry. However, stress-strain relationship is almost linear which is different from experimental observation. Such discrepancy may arise from the fact that the DEM sample is consolidated before loading which leads to partial closure of initial pores.

*Stage II*. Elastic deformation region. No new cracks generate since number of broken bonds remains zero at this stage. Likewise, elastic deformability plays a dominant role because the relationships between stress, volumetric strain and axial strain are all linear.

*Stage III*. Crack initiation and stable growth region. The onset of failure indicates the start of third region and the corresponding stress is referred to as crack initiation stress, $\sigma_{ci}$, in DEM simulations. As a result of crack generation, stress and lateral strain against axial strain depart from linearity. Moreover, the volumetric strain reaches its peak value at the end of this phase due to the increasing rate of lateral strain exceeding that of axial strain.

*Stage IV*. Crack damage and unstable growth region. The axial stress level at the volumetric strain reversal marks the beginning of this stage, and it is referred to as crack damage stress, $\sigma_{cd}$. Besides, it can be observed by the slope of the number of broken bonds-axial strain curve that cracks generate rapidly, which is in good agreement with the main characteristic of the unstable crack region in real rocks.

*Stage V*. Post peak region. Appearance of the peak stress $\sigma_f$ marks the beginning of the post-peak behavior. After the peak, both lateral strain and volumetric strain responses display a continuing dilation, while a residual strength determined by friction is reached. Similarly to axial stress, the relationship between broken-bond number and axial strain tends to stabilize.

Moreover, Fig. 5 shows that crack number and type is almost unrelated with heterogeneities. As heterogeneity index increases, elastic deformation region increases, volumetric strain reduces before crack damage stress, the failure characteristic in post peak region become more significant. These conclusions drawn from Fig. 5 are in agreement with other numerical simulations [2].

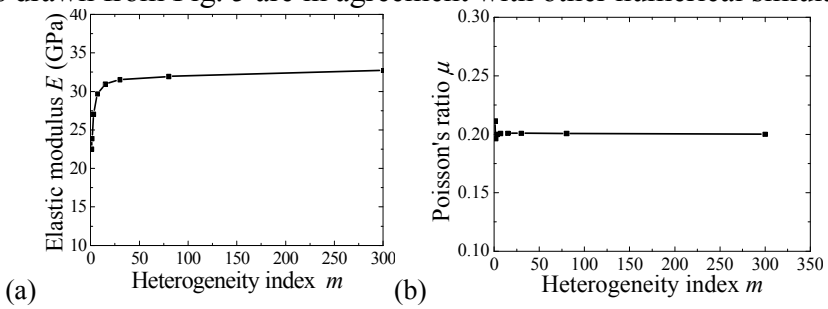

Fig. 6 Relationships between deformation parameters and homogeneity indexes: (a) elasticity modulus; (b) Poisson's ratio

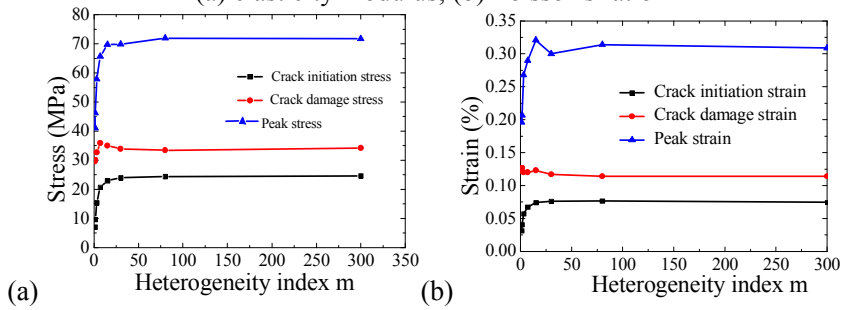

Fig. 7 Relationships between characteristic stresses, characteristic strains and homogeneity indexes: (a) characteristic stresses; (b) characteristic strains

Fig. 6 presents the relationships between deformation parameters and heterogeneity indexes. It is shown that with the increasing of heterogeneity index, elastic modulus increases rapidly first, and then reach stabilizing, but Poisson's ratio almost keeps a constant value. Fig. 7(a) shows that crack initiation stress, crack damage stress and peak stress increase with the heterogeneity index up until a constant value. In Fig. 7(b), the variation on crack initiation strain and peak strain are similar with that on stress. However, crack damage strain almost unchanged.

As mentioned above, when the heterogeneity index is higher, much more deformation and strength parameters of bonds approach mean values shown in Tab. 1. These bonds may reach limit state and break simultaneously. However, for samples with lower heterogeneity indexes, the microscopic parameters are so distinct that cracks initiate and failure surfaces develop much more easily, which causes mechanical properties lower.

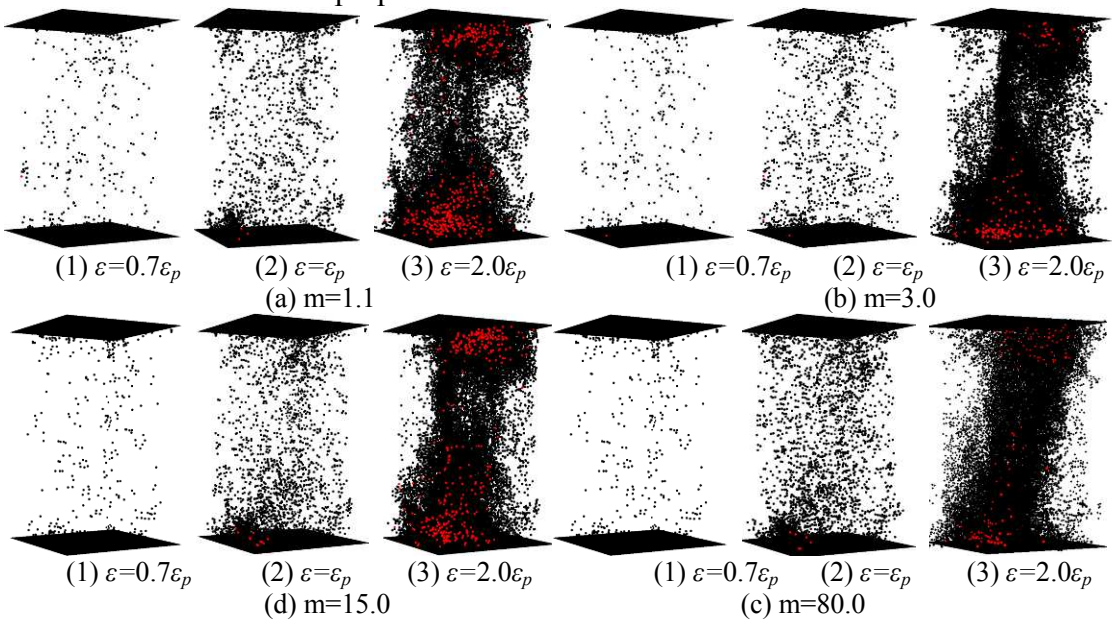

Fig. 8 Broken bond distributions of heterogeneous DEM rock samples under different axial strains

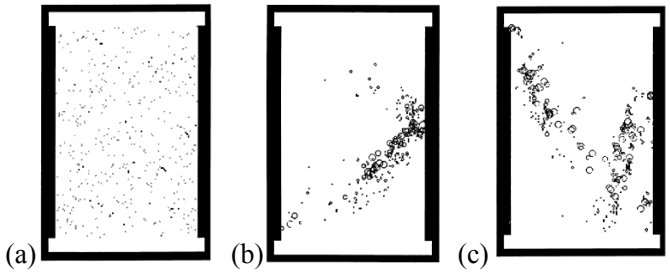

Fig. 9 Plots of simulated AE locations obtained from RFPA$^{2D}$ simulation:
(a) 56% peak stress; (b) 100% peak stress; (c) 92% peak stress [2].

**Effects of Heterogeneity on Failure Progresses.** Fig. 8 presents broken bond distributions of four heterogeneous DEM rock samples under different axial strains. $\varepsilon_p$ represents peak strain when stress reaches peak value. For broken bonds shown in Fig. 8, red indicates shear-induced bond failure for which bond shear strength has been exceeded and black implies tension-induced bond failure for which tensile strength has been exceeded.

It can be seen that the onset of failure in the samples subjected to uniaxial compressive loading is first indicated by the formation of isolated fractures caused mainly by tensile broken bonds. Such local fracturing is almost not affected by heterogeneity indexes, only results from tension stress concentration. When the strain reaches axial strain $\varepsilon_p$, broken bonds began to localize. This characteristic becomes more significant with the increasing of heterogeneity index. The broken bond distributions at the strain 2.0$\varepsilon_p$ are influenced by heterogeneity remarkably. For samples with a lower heterogeneity index, most of fractures distribute along the loading surfaces, "X" failure pattern appears. As heterogeneity index increases, fractures diffuse from ends to center, samples express coalescence surface failure mainly caused by tension-induced broken bond. The failure progress is in good agreement with other simulation as shown in Fig. 9. In rock mechanics, shale often presents local failure, while homogeneous basalt and granite presents coalescence surface failure.

## Conclusions

Three-dimensional DEM numerical model incorporated with random assignment code for taking heterogeneities on microscopic scale into account was used to analyze rock failure process. A series of rock samples with different heterogeneities were numerical simulated by uniaxial compressive tests. The influences of microscopic heterogeneity on macroscopic mechanical properties and failure behaviors were investigated. The following conclusions can be made from this study:

(1) The proposed three-dimensional DEM numerical model was successfully calibrated to match the five-stage stress-strain and volumetric strain-axial strain relationships. In addition, the recorded evolution of the number and type of bond failures not only can be used to identify crack propagation stages but also can predict the characteristic stresses and strains.

(2) Fracture number and its type developed in DEM samples are almost unrelated with heterogeneity. However, with the increasing of heterogeneity, elastic deformation region become longer, volumetric strain reduce, brittle failure characteristic after peak stress presents more significant. These results are in good agreement with other simulations.

(3) Except for Poisson's ratios and crack damage strain that almost maintain constant, deformation parameters as well as characteristic stresses and strains increase following exponent function.

(4) As heterogeneity increases, failure modes change from "X" pattern to coalescence surface pattern forming through the whole rock sample, but tension-induced cracks initiate first and the proportion of these cracks is higher.

Note that one of our main aims was to establish an effective method to describe rock heterogeneity, and apply the advantages of DEM simulation means to analyze mechanical behaviors of rock. One of our future works is to use this method to simulate boundary-value problems and compare with experiment data, such as the instability of rock slopes.

**Keywords:** soft clay; shear strength; structure of soft soil; degree of consolidation.

**Abstract.** Mohr-Coulomb strength theory is the most widely used in practical engineering, however, it is difficult to predict the cohesion and internal friction angle precisely. In fact, soft clay's shear strength varies with the change of stress path and consolidation history, so it is vital to predict the shear strength in different construction phases, and the influence of soil structure is necessary to be taken into consideration to predict the shear strength under under arbitrary degree of consolidation. This study proposed a simple shear strength fomula under arbitrary degree of consolidation considering the enfluce of soil structure. The derived formula is much more convenient to plug the changing strength index into program.

## Introduction

One of the most important researches of soil mechanics is the shear strength, which is used in the research of the stability of slope, the bearing strength of foundation soil and the calculation of retaining wall pressure. How to predict the shear strength's changing is vital to the practical engineering. At present, effective stress method proposed by Zen Guoxi(1975)[1] and effective consolidation stress method proposed by Zhao Lingwei and Shen Zhujiang(1962)[2], He qun(2005)[3] studied the shear strength's changing rule with the changing degree of consolidation via many soil tests. Yang Rongchang(2001)[4] studiedthe relationship between shear strength and arbitrary degree of consolidation on the base of stress path.

## Derivation of the undrained shear strength

Zen Guoxi[1] proposed a method which can predict the change of shear strength with the changing of degree of consolidation. He suggests that the shear strength of foundation soil grows continuously as the increasing degree of consolidation. The shear strength of foundation is shown as follows,

$$\tau_f = \eta(\tau_{f0} + \Delta\tau_f). \tag{1}$$

Where $\tau_{f0}$ is the natural shear strength before loading, $\Delta\tau_f$ is the increase of shear strength because of consolidation, $\eta$ is the reduction coefficient considering the shear slid

Yang Rongchang(2001)[4] get the cohesion and internal friction angle of arbitrary degree of consolidation as follows,

$$\begin{cases} \sin\phi_i = \dfrac{U_i \sin\phi_{cu}}{1-(1-U_i)\sin\phi_{cu}} \\ c_i = \dfrac{(1-U_i)(1-\sin\phi_{cu})}{1-(1-U_i)\sin\phi_{cu}} \dfrac{c_u}{\cos\phi_i} \end{cases}. \tag{2}$$

where $U_i$, $c_i$ and $\varphi_i$ is the soft clay's intensity index under the arbitrary degree of consolidation. $c_{cu}$ and $\phi_{cu}$ is the intensity index under consolidated undraind case. $c_u$ is the intensity index under unconsolidated undrained case.

The index $c_{cu}$ and $\phi_{cu}$ is obtained from consolidated undrained test. In order to find the relationship between strength under arbitrary degree of consolidation and unconsolidated undraind test index ($c_{cu}$ and $\phi_{cu}$), the relationship must be established between the index under arbitrary degree of consolidation ($U_i$, $c_i$ and $\varphi_i$) and unconsolidated undraind test index ($c_{cu}$ and $\phi_{cu}$), which has been derived by Yang Rongchang, then this paper establish the relationship between the intensity index ($c_i$ , $\phi_i$) and shear strength of soft clay under arbitrary degree of consolidation.

The angle between failure surface and the surface major principle stress surface is 45°. In Fig.1, the strength at point c is the consolidated undraind strength $\tau_c$ .

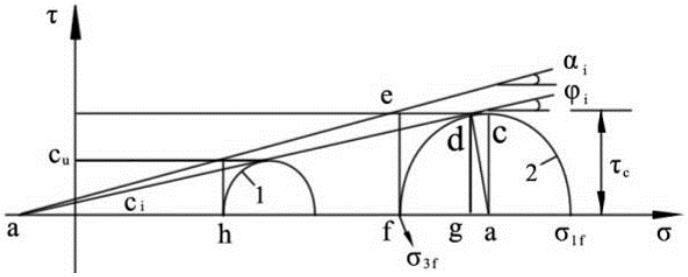

**Fig.1 The increase of shear strength under arbitrary degree of consolidation**

As shown in Fig.1, stress circle 1 is the initial state circle which correspond to the strength of natural soft clay, stress circle 2 is obtained from undraind test under the arbitrary degree of consolidation($U_i$) when the confining pressure increases by $\Delta\sigma_3$. One can obtain the follos from Fig.1,

$$fb = cb = bd = ef = \tau_c \tag{3}$$

$$af = ab - fb = \frac{bd}{\sin\phi_i} - fb = \frac{\tau_c}{\sin\phi_i} - \tau_c \tag{4}$$

$$\tan\alpha_i = \frac{ef}{af} = \frac{\tau_c}{\frac{\tau_c}{\sin\phi_i} - \tau_c} = \frac{\sin\phi_i}{1-\sin\phi_i} \tag{5}$$

$$\tau_c = af\tan\alpha_i = (c_i\cot\phi_i + \sigma_{3f})\tan\alpha_i = (c_i\cot\phi_i + \sigma_{3f})\frac{\sin\phi_i}{1-\sin\phi_i} \tag{6}$$

Formula (6) can be transferred to formula (7) ,

$$\Delta\tau_c = \frac{\sin\phi_i}{1-\sin\phi_i}\Delta\sigma_{3f} \tag{7}$$

Where $\Delta\tau_c$ is the increase of shear strength.

The soft clay always been a K0 consolidation state in field, the above formula (6) and formula (7) is limited. The general method to solve this trouble is establishing a relationship as follows,

$$\begin{cases} \sigma_{3f} = \frac{1}{2}(1+K_0)\sigma_z & (a) \\ \sigma_{3f} = \frac{1}{3}(1+2K_0)\sigma_z & (b) \end{cases} \tag{8}$$

Where $\sigma_z$ is the vertical consolidation stress. Then formula (6) can be changed to formula (9),

$$\begin{cases} \tau_c = [c_i\cot\phi_i + \frac{1}{2}(1+K_0)\sigma_z]\frac{\sin\phi_i}{1-\sin\phi_i} & (a) \\ \tau_c = [c_i\cot\phi_i + \frac{1}{3}(1+2K_0)\sigma_z]\frac{\sin\phi_i}{1-\sin\phi_i} & (b) \end{cases} \tag{9}$$

where $\sin\phi_i$ and $c_i$ is the same with formula (2). The increase of strength is obtained from formula (7),

$$\begin{cases} \Delta\tau_c = \dfrac{1}{2}(1+K_0)\dfrac{\sin\phi_i}{1-\sin\phi_i}\Delta\sigma_z & (a) \\ \Delta\tau_c = \dfrac{1}{3}(1+2K_0)\dfrac{\sin\phi_i}{1-\sin\phi_i}\Delta\sigma_z & (b) \end{cases} \tag{10}$$

**The influence of soft clay's structure on strength**

According to the influence of structure on the clay's strength, the envelope line can be assumed that the line can be divided into two parts, as shown in Fig.2. Critical stress $\sigma_{pc}$ correspond to the intersection of those two part of lines, the natural strength $c_u$ can be obtained from effective consolidation stress method, those two lines indicate three strength index ( $c_{cu1}$, $\phi_{cu1}$ and $\phi_{cu2}$ ), the first part of the line's strength index are $c_{cu1}$ and $\phi_{cu1}$, that of the second part of the line are $c_{cu2} = 0$ and $\phi_{cu2}$, then the natural structural soft soil's undrained strength can be divided into two part to be normalize.

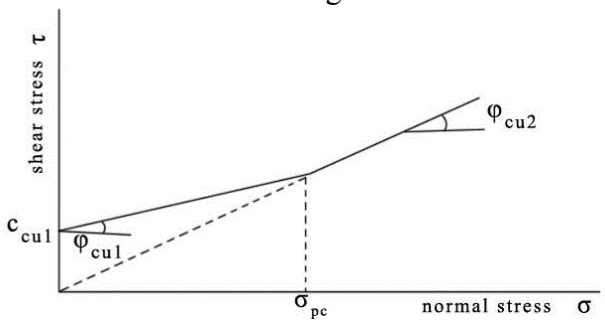

**Fig.2 The strength of structural soft clay(Shen Zhujiang, 1998)**

The strength of structural soft clay under arbitrary degree of consolidation can be wriiten as follows,

$$\tau_c = [c_i \cot\phi_i + \frac{1}{2}(1+K_0)\sigma_z]\frac{\sin\phi_i}{1-\sin\phi_i} \tag{15}$$

Where $\sigma_z$ is the vertical consolidation stress at field.

Then if $\sigma \le \sigma_{pc}$ ( $\sigma$ is effective stress, $\sigma_{pc}$ is the critical stress)

$$\begin{cases} \sin\phi_i = \dfrac{U_i \sin\phi_{cu1}}{1-(1-U_i)\sin\phi_{cu1}} \\ c_i = \dfrac{(1-U_i)(1-\sin\phi_{cu1})}{1-(1-U_i)\sin\phi_{cu1}}\dfrac{c_u}{\cos\phi_i} \\ c_u = \dfrac{\cos\phi_{cu1}}{1-\sin\phi_{cu1}}c_{cu1} + \dfrac{1}{2}(1+K_0)\dfrac{\sin\phi_{cu1}}{1-\sin\phi_{cu1}}\gamma h \end{cases} \tag{16}$$

If $\sigma > \sigma_{pc}$

$$\begin{cases} \sin\phi_i = \dfrac{U_i \sin\phi_{cu2}}{1-(1-U_i)\sin\phi_{cu2}} \\ c_i = \dfrac{(1-U_i)(1-\sin\phi_{cu2})}{1-(1-U_i)\sin\phi_{cu2}}\dfrac{c_u}{\cos\phi_i} \\ c_u = \dfrac{1}{2}(1+K_0)\dfrac{\sin\phi_{cu2}}{1-\sin\phi_{cu2}}\gamma h \end{cases} \tag{17}$$

Or

$$\tau_c = [c_i \cot \phi_i + \frac{1}{3}(1 + 2K_0)\sigma_z]\frac{\sin \phi_i}{1 - \sin \phi_i} \tag{18}$$

If $\sigma \le \sigma_{pc}$

$$\begin{cases} \sin \phi_i = \dfrac{U_i \sin \phi_{cu1}}{1 - (1 - U_i)\sin \phi_{cu1}} \\ c_i = \dfrac{(1 - U_i)(1 - \sin \phi_{cu1})}{1 - (1 - U_i)\sin \phi_{cu1}} \dfrac{c_u}{\cos \phi_i} \\ c_u = \dfrac{\cos \phi_{cu1}}{1 - \sin \phi_{cu1}} c_{cu1} + \dfrac{1}{2}(1 + K_0)\dfrac{\sin \phi_{cu1}}{1 - \sin \phi_{cu1}} \gamma h \end{cases} \tag{19}$$

If $\sigma > \sigma_{pc}$

$$\begin{cases} \sin \phi_i = \dfrac{U_i \sin \phi_{cu2}}{1 - (1 - U_i)\sin \phi_{cu2}} \\ c_i = \dfrac{(1 - U_i)(1 - \sin \phi_{cu2})}{1 - (1 - U_i)\sin \phi_{cu2}} \dfrac{c_u}{\cos \phi_i} \\ c_u = \dfrac{1}{2}(1 + K_0)\dfrac{\sin \phi_{cu2}}{1 - \sin \phi_{cu2}} \gamma h \end{cases} \tag{20}$$

The line of strength turns at the critical point, which suggests that the structure of the soft clay can't be ignored. Formulas of (16), (17), (19) and (20) are the derived expression of undrained strength under arbitrary degree of consolidation considering the soil's structure.

## Summary

This study proposed a simple shear strength fomula under arbitrary degree of consolidation considering the enfluce of soil structure.Tthe increase of the undrained strength under arbitrary degree consolidation is the same with that of effect consolidation stress method, while the derived formula in this paper is much more convenient to plug the changing strength index ($c_i$, $\phi_i$) into program combing with the formula proposed by Yang Rongchang. Soil's structure has a great influence on the strength, the strength considering this influence is obtained.

**Keywords:** Slope treatment, Stability monitoring, Displacement rate, Warning.

**Abstract.** Through doing spot monitoring on stability of slope engineering management of Longmenhao Primary School, this paper does analysis on monitoring data for one month. Analysis results show that all of accumulation maximum displacement, change rate of horizontal displacement and accumulation maximum settlement of slope of Longmenhao Primary School do not surpass warning value thus knowing that slope of this section is basically stable which also provides references for stability detection analysis of engineering management.

## Introduction

Cracking and settlement appeared on the ground of slope crest when 52m long and 7.5-8.0m high of cut slope were dug on the foundation trench of 1# rib-plank anchored bolt retaining wall on Tushan Road on September 21, 2013. Through actual measurement, width of the crack was 1 to 12cm and settlement was 1 to 34cm. The crack, running parallel to side slope direction, lied along the ground beam on the west side of teaching building of Longmenhao Primary School which tended to be closed from south to north. Maximum values of horizontal displacement and settlement of side slope existed between south side of it which was the original Longmenhao Kindergarten and teaching building. Pile foundation at south-west corner of teaching building was exposed. Bulge crack appeared on the rock mass of retaining wall foundation trench side slope where slope toe squeezed cut and hillslope locally collapsed. Width of deformation body range was 13 to 20m and length of it was about 60m whose horizontal displacement direction was basically perpendicular to side slope trend. This very deformation body endangered the safety of teaching building and teachers and students (including 979 students and about 80 teachers).

Fig.1 Side Slope Engineering Management of Longmenhao Primary School

**Monitoring Significance.** Rail transit Line 6 of Chongqing City starts in tea garden city sub-center of Nan'an District and ends in Beibei District whose route crosses Yangtze River and Chialing River, runs through five administrative districts of Nan'an District, Yuzhong District, Jiangbei District, Yubei District and Beibei District, connects three CBD of Danzishi, Jiefangbei and Jiangbeicheng also prospective administration center and Dazhulin, Lijia and Cai Jia Zu Tuan.

As foundation trench of track loop at the bottom of Tushan road in this project is deep, side slope height above the road is high and the section upside is teaching building of Longmenhao Primary School, disturbance during construction process would influence the teaching building thus influencing teaching security. Also because this project would plan to construct Ramp B. The minimum distance between Ramp B and house plane of Longmenhao Kindergarten in which the digging of ramp may present influences on the structure safety of kindergarten house (as shown in Fig.1). Therefore it seems particularly important to monitor the side slope of Longmenhao Primary School and Kindergarten.

**Monitoring Purposes.**Through monitoring measurement data accumulation and displacement-time curves, influencing degree of deep foundation trench of Line 6 and construction of Ramp B on side slope of Longmenhao Primary School and Kindergarten should be decided to adopt relevant protective measures in time to guarantee the safety of teaching buildings of Longmenhao Primary School and Kindergarten.

**Monitoring Work Content.**Contents of monitoring measurement on foundation trench and side slope engineering of Longmenhao Primary School in Nan'an District, Chongqing City include settlement of side slope outside teaching building, horizontal displacement of side slope outside teaching building and deep displacement of side slope outside teaching building whose time interval is September 29 - Octorber 29 during which details of the finished workload are presented in Tab.1.

Tab.1 Monitoring Measurement on Workload List of this Stage

| Sequence Number | Monitoring Items | Unit | number of the first stage |
|---|---|---|---|
| 1 | settlement of side slope outside teaching building | dot.times | 648 |
| 2 | horizontal displacement of side slope outside teaching building | dot.times | 276 |
| 3 | deep displacement of side slope outside teaching building | dot.times | 493 |

## Monitoring Program and Data Analysis on Engineering Management of Side Slope

**Settlement of Side Slope Outside Teaching Building.** Setting work of monitoring point CJ1+~CJ8 on settlement of side slope outside teaching building of Longmenhao Primary School was finished on September 28, 2013. Changing rate and accumulative variation of each observing point in the first stage are seen in Tab.1 and their relevant tendency charts are in Fig.2.

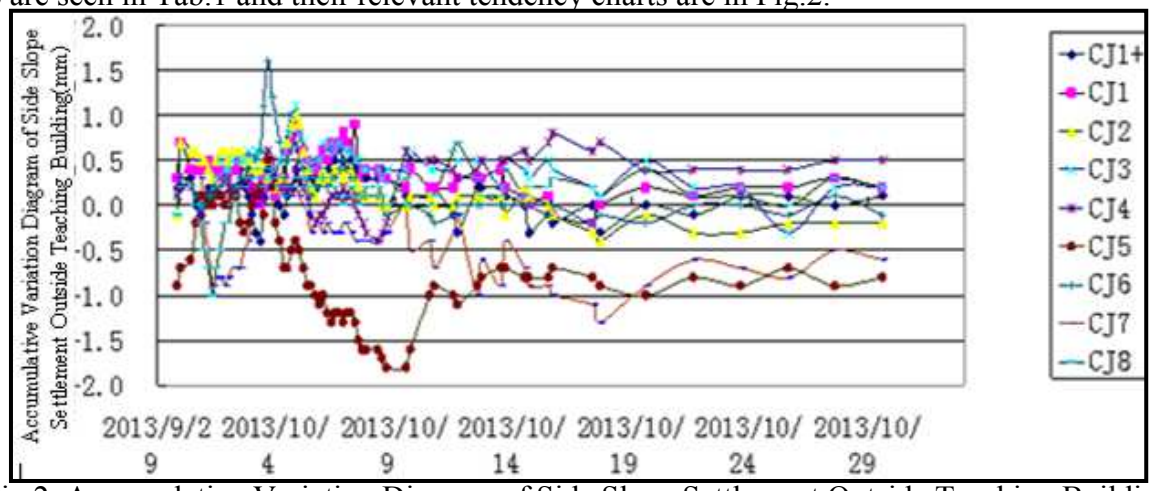

Fig.2 Accumulative Variation Diagram of Side Slope Settlement Outside Teaching Building

**Horizontal Displacement of Side Slope Outside Teaching Building.** Setting work of monitoring point W1~W4 on horizontal displacement of side slope outside teaching building of

Longmenhao Primary School was finished on September 28,2013.Changing rate in X, Y directions and accumulative variation of each observing point in this stage are seen in Tab.2 and their tendency charts are in Fig.3-Fig.4.

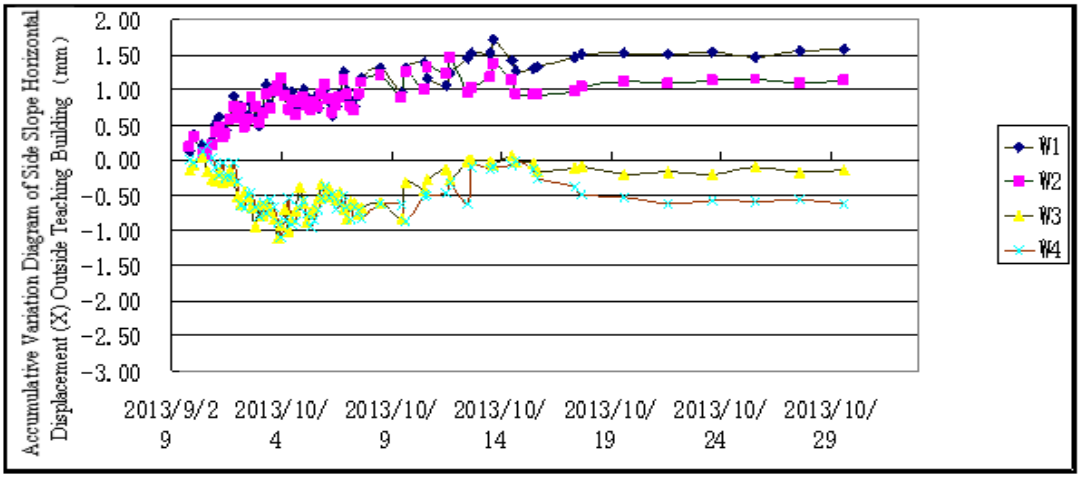

Fig.3 Accumulative Variation Diagram of Side Slope Horizontal Displacement (X) Outside Teaching Building

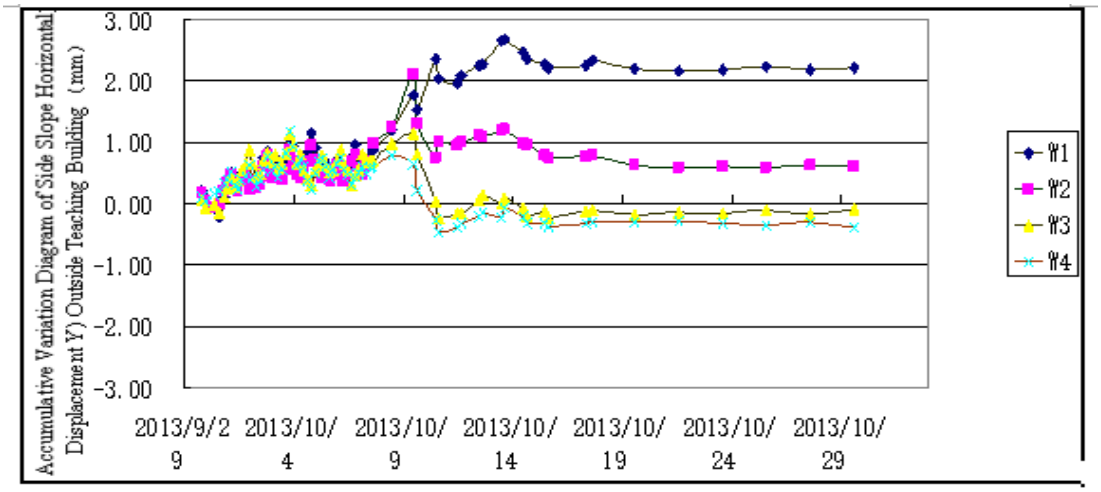

Fig.4 Accumulative Variation Diagram of Side Slope Horizontal Displacement(Y)Outside Teaching Building

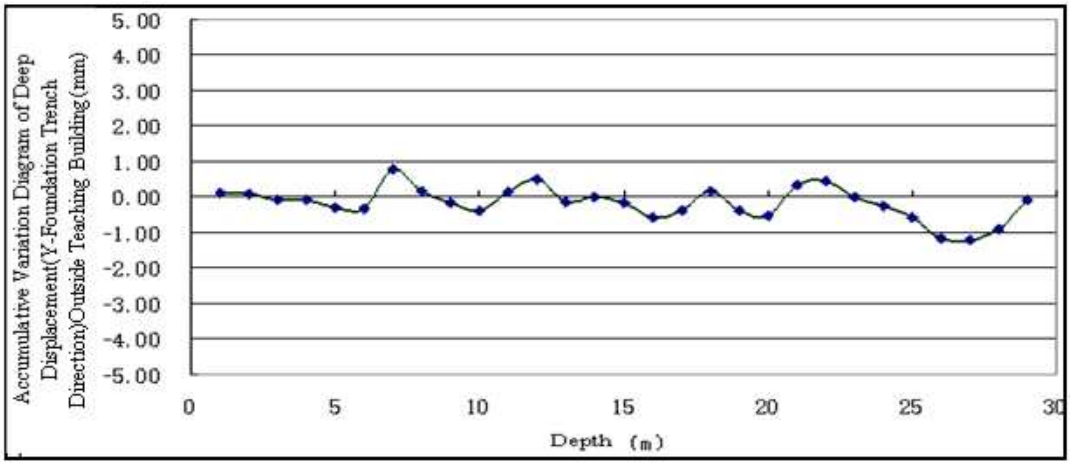

Fig.5 Accumulative Variation Diagram of Deep Displacement (Y-Foundation Trench Direction)Outside Teaching Building

**Deep Displacement of Side Slope Outside Teaching Building**. Setting work of monitoring section on deep displacement of side slope outside teaching building of Longmenhao Primary School

was finished on September 28, 2013. Changing rate in Y, X directions and accumulative variation of observing points in each depth in this stage are seen in Fig.5-Fig.6 .

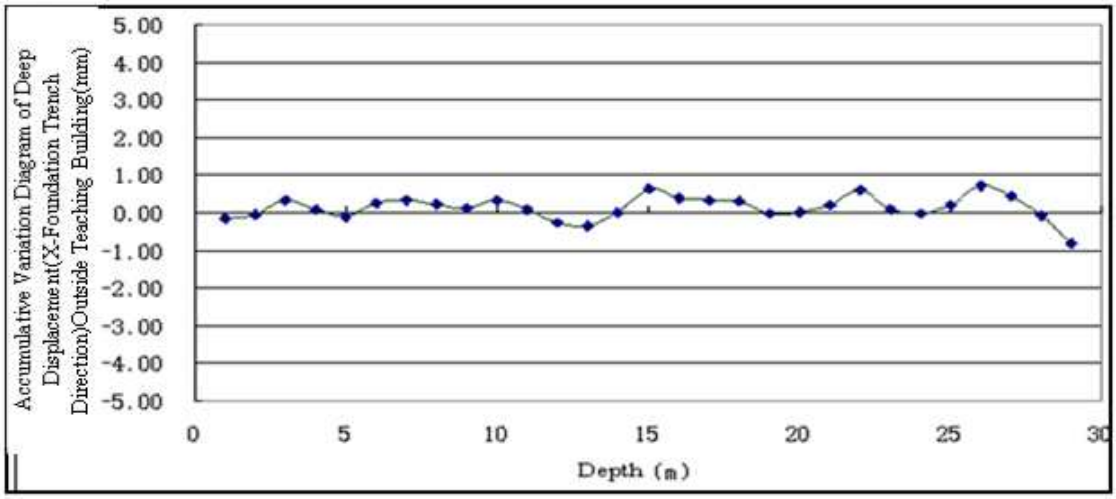

Fig.6 Accumulative Variation Diagram of Deep Displacement
（X-South Side）Outside Teaching Building

**Prewarning Value and Controlling Value of Side Slope**

According to 9.2.12 Rule in GB50843-2013 and combining with monitoring condition of site operation, it is protocoled that prewarning value of side slope displacement towards inside of foundation trench is 4mm/d whose opposite direction is 3mm/d and cumulative maximum horizontal displacement is 20mm or horizontal displacement rate keeps to be more than 2mm for three consecutive days. Meanwhile controlling value is 8mm/d whose opposite direction is 5mm/d. Prewarning value of settlement of side slope is 4mm/d whose opposite direction is 3mm/d and controlling value is 8mm/d whose opposite direction is 5mm/d.

**Summary**

Analyzing through the data above, it is seen that accumulative maximum horizontal displacement of side slope of Longmenhao Primary School does not surpass prewarning value, changing rate of horizontal displacement during consecutive days does not exceed prewarning value, settlement and horizontal displacement of side slope outside teaching building tend to be stable, changing amplitude of deep displacement of side slope is small and side slope is basically stable. Therefore it is suggested that monitoring should be continued.

# The stability of 3D-geomat in different slope gradient

Guangyue Wang, Jianpeng Zhang and Yuanshuai Sun

School of Civil Engineering, Shandong University, Jinan, Shandong, 250061, China

wgyue@sdu.edu.cn, 569031356@qq.com,570582410@qq.com

**Keywords:** 3D-geomat; safety factor; finite element; stability

**Abstract.**3D-geomat protective slope is a new type of protective slope form which combines the 3D-geocell with the planting grass. Because the complex and dense spatial structure can tie the slope soil and has a reinforced effect on the slope surface, it has the advantage in soil and water conservation and ecological protection, and it gets more and more widely used in the present engineering construction. By using the finite element model, we compare the whole stability in the 3D-geomat slope and unprotective slope under the condition of different slope gradient. And then we get the relative results.

## Introduction

In recent years, with the development of the economic and construction in our country, the projects of highway, railway and road are increasing, a lot of artificial slope appear, but the scour erosion, soil erosion and local landslide also exist on these slopes [1].As a new type of technology in ecological slope protection, the 3D-geomat has the effect on soil and water conservation and ecological protection, and it has been developing rapidly in recent years. Liansheng Li and Yuzhong Huang get the result that the comprehensive cost of the 3D-geomat can reduce investment by 47% than other slope protection by using the method of field test [2]. Hengin Xiao, Zhao Wang and Jinfeng Zhang systematically analyzed the designed mechanics index of the 3D-geomat, and solved the corresponding problem in some extent [3]. Xiaolu Liu and Henglin Xiao detail the establishment of protection system in 3D-geoamt slope through selecting material in different slope and the grass in different areas [4]. In this paper, by using the finite element software ABAQUS, based on practical engineering, we apply the method of numerical simulation, and analyze the integrity of the slope for the presence or absence of the 3D-geomat in different slope gradient.

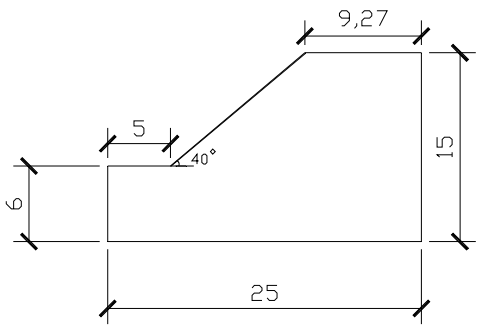
## The solid model in finite element

**Modeling.** The first contract section K18+132~K18+250 between Wei Jie and Ma Duan in Qing-Hong expressway uses the technology of 3D-geomat grassed slope.

The engineering parameters: the soil of slope is homogeneous; the total height is 15m; the slope angle is 40° and the type of the 3D-geomat grassed slope is EM4.

Based on the practical engineering, we use three-dimensional model, the vertical depth is 10m, the length of the slope is 15m and the height of the slope is 9m.

The geometry size is shown in figure 1(unit/m) and the three-dimensional view of the slope is shown in figure 2:



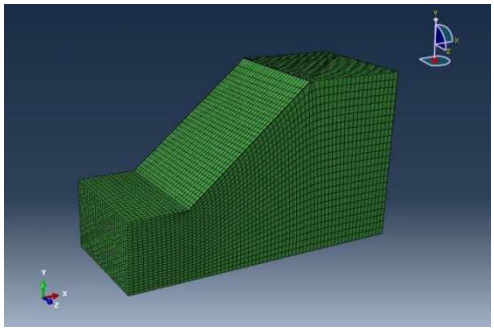


Fig.1 The geometry size of the model Fig.2 The three-dimensional view of the slope

**Mesh dividing.** The structure of 3D-geomat is a net in space. For the slope soil section, because it involves the rainfall infiltration, we use the hexahedral element--C3D8P, which possesses pore pressure degree of freedom. This kind of element has eight degrees of freedom (including pore pressure degree of freedom), the soil slope is divided into 42000 units. In order to make the calculation of the model easy to converge when simulating the numerical calculation, the continuous medium model in which the slope soil and the reinforced soil of 3D-geomat has the same nodes but varies in nature of the material is adopted. The whole model has a total of 46098 nodes. The mesh dividing of the model is shown in figure 3:

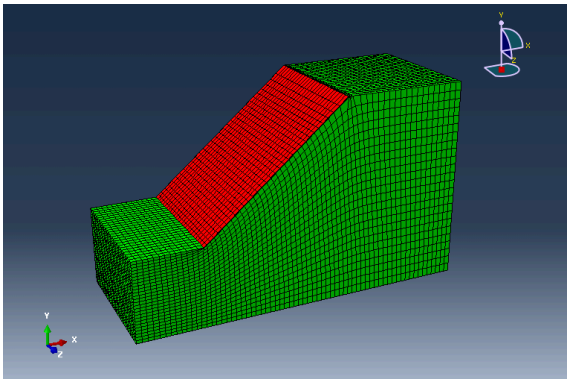

Fig.3 The mesh dividing of 3D-geomat protective slope

**Boundary conditions.** Because the slope is continuous as a whole, the model is taken as part of the overall slope to analyze, the boundary is defined as (As shown in figure 4):

(1)Limit the degree of freedom of the normal direction of the four facades.

(2)Limit the degree of freedom of three directions for x, y, z at the bottom of the model.

(3)We set the boundary conditions of the static water pore pressure that have a linear increase with depth below the water level in front facade and behind facade of the slope. The bottom, the front facade and behind facade sets the undrained boundary condition.

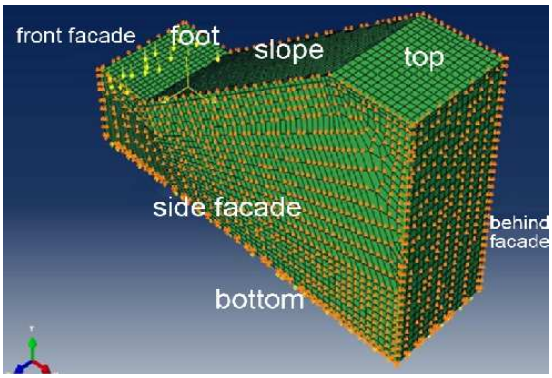

Fig.4 Boundary sketch

## The analysis of computing results

**Calculating parameter.** The calculating parameters of the model are shown in table 1

Table 1 Calculating parameters of slope model

| Material | Elasticity modulus | Poisson's ratio | Cohesive force | Internal friction angle | Dry density | Permeability coefficient |
|---|---|---|---|---|---|---|
| Soil | 20 | 0.3 | 24 | 20 | 1.81 | 1.2E-6 |
| 3D-geomat | 60 | 0.25 | -- | -- | -- | 1.2E-6 |

**The analysis of computing results in the different slope gradient.** The figure 5 gives us the changing rule of the safety factor in the different slope gradient. From the picture, we can see that along with the increase of the slope angle, the safety factor decreases accordingly, and the decrease trend of the safety factor becomes gradually slow. The variation of the safety factor is very small when the slope angle increases to 50 °.The two curves also shows that the difference of the safety factor is greater when the slope angle becomes larger. That is to say, the protecting effect of the 3D-geomat is more and more obvious with the increase of slope angle.

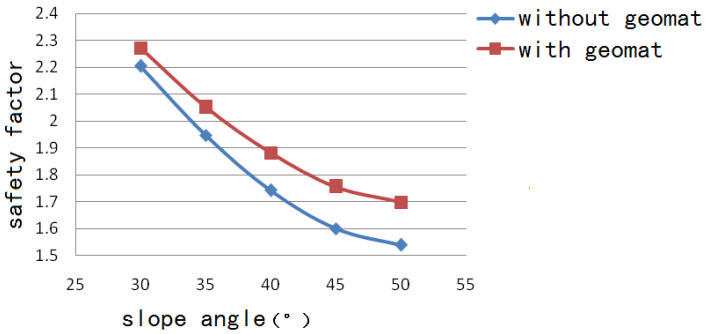

Fig.5 The changing curve of the safety factor in the different slope angle

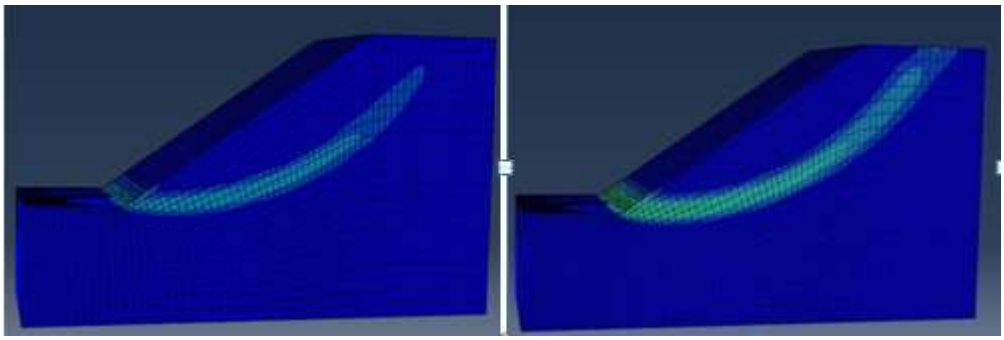
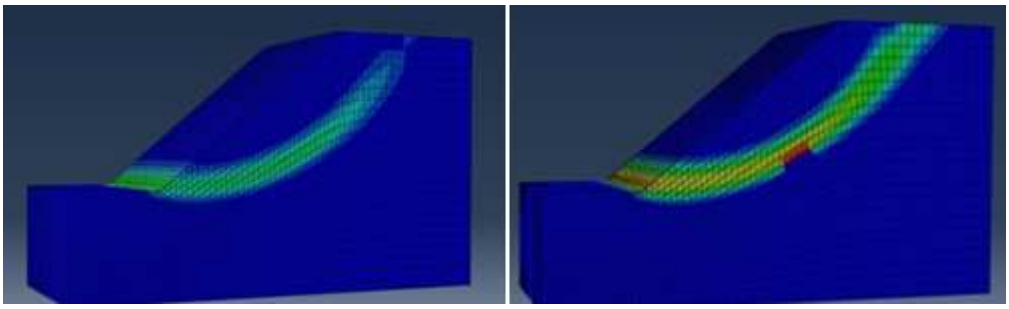


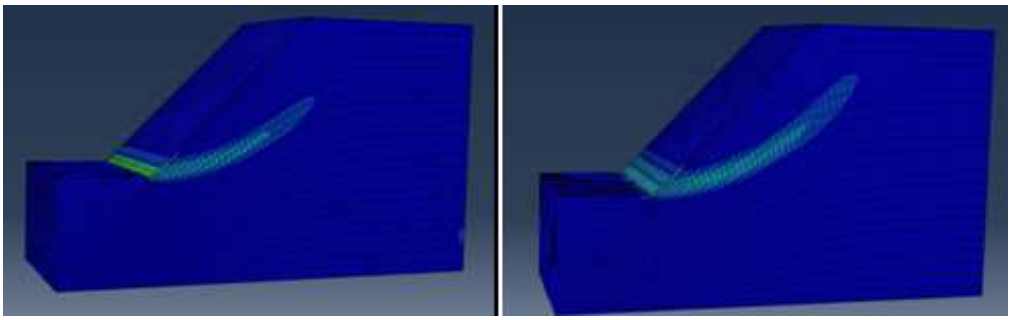
Without protection Protection with geomat

Fig.6 The comparing cloud picture in the same slope angle (35°)



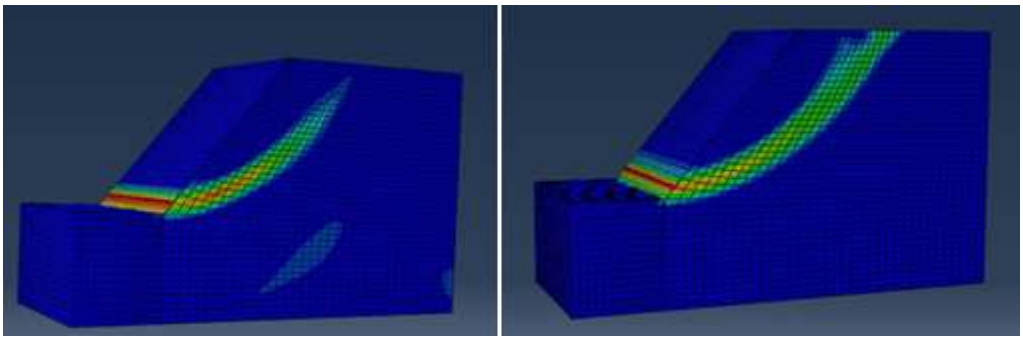
Without protection Protection with geomat

Fig.7 The comparing cloud picture in the same slope angle (40°)



Without protection Protection with geomat

Fig.8 The comparing cloud picture in the same slope angle (45°)



Without protection Protection with geomat

Fig.9 The comparing cloud picture in the same slope angle (50°)

According to figure 6 to 9, we know that the plastic strain range with 3D-geomat is larger than the slope without 3D-geomat under the same condition of rainfall infiltration, and the protective effect

increases with the increase of slope gradient within a certain scope of slope gradient. So the 3D-geomat has an enhanced effect on the stability of the slope.

## Conclusions

(1)The 3D-geomat has an enhanced effect on the stability of the slope.
(2)It has a significantly protective effect in the range of 30° to 50° of the slope angle.
(3) The protective effect increases with the increase of slope angle.

# Monitoring and Analysis on the Supporting Structure for Deep Foundation Pit

Haixia Sun [1, a], Ke Zhang [1,b], Sili Chen [1,c]

[1]Shenyang University of Technology, Shenyang 110870, Liaoning, China

[a]sunhx99@126.com, [b]805850569@qq.com, [c]chen1458@sina.com

**Keywords:** deep foundation pit, fender pile, deformation, monitoring

**Abstract.** This article mainly expounds the importance of in-situ monitoring on the construction process of deep foundation pit. Taking the deep foundation pit of some Shenyang metro station for example, the deformation features of the supporting structure and the internal and external of foundation pit is analyzed, according to the monitoring data of the fender pile displacement during the excavation of deep foundation pit. The conclusion is obtained that the timely and accurate in-situ monitoring information is necessary to guaranteeing construction safety. We should pay more attention to the excavation speed and exert the interior support timely during the excavation of foundation pit to avoid large deformation and danger. The analytical results of monitoring data shows that the whole stage of foundation pit excavation is stable and the fender pile with internal supports can guarantee the stability of foundation pit.

## Introduction

Lots of foundation pit engineering is focused on the poor geological conditions, narrow construction site, complicated construction conditions and built-up area. In this condition of the foundation pit supporting system can not only ensure the safety of the excavation and supporting structure , but also the safety and normal use of the surrounding building and municipal facilities. That is to say that environmental effects problem exists in the foundation pit engineering. Strengthen the in-situ monitoring of deep foundation pit, it is more important to guide the construction of deep foundation pit. In deep foundation pit engineering, the deformation of fender structure and foundation pit plays an important role in guiding the design and construction. Give deformation forecast for each construction stage to monitoring has more practical significance in deformation analysis, so as to make timely construction decisions, optimize the construction process, and ensure the construction safety.

## Project profile

This station adopted open construction. Hun River high floodplain, Hun River new fan, and Hun River old fan stratum consists of a set of sedimentary layer which gradually turn fine grain into coarse grain. They generally consist of clay, silt, medium sand, coarse sand, gravel, sand, gravel soil, silt and little fine sand. Local area part of the stratum is missing. The southwest of station is 5 to 7 storey residential building, the northeast is a standard factory and sanitation, and the northwest side is a hotel. The south of Road construction has 66 kv high voltage towers in the green belt. The station underground pipeline: there are 12 plastic communication cable with a diameter of 0.1 meters and gas pipe (iron) with a diameter of 0.3 meters; The sewage pipe under the middle of the north of Road Construction about 3.3 meters to the edge of the structure, there is a east-west sewer with cross-section 2.4 m×1.8 m in the south of the station about 23 meters.

The principal building envelope adopted 1000 @1200 bored piles, the pile structure diagram was shown in the fig.1.

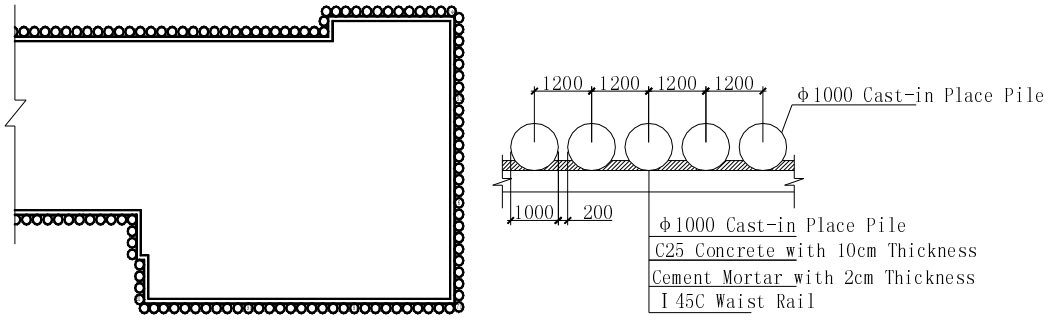

**Fig.1**. Building envelope of foundation pit

**Monitoring program of construction**

Monitor the displacement of fender piles during the metro construction, provide timely and reliable information for proprietor to assessing the environment effects of metro construction, and make a timely and accurately forecast to the possible risks of environment safety.

**Monitoring items and monitoring instrument.** Monitoring items is including horizontal displacement on the pile top and pile inclinometer. Monitoring instrument includes: Leica TCRA1201R300 total station, deformation observation for indium ruler, inclinometer ROCTEST RT-20, and dip tube;

**Measuring point layout standard.** Lay one monitoring point every 15 meters, combining with foundation pit characteristics. Monitor 3-4 times after constructing the fender pile and top beam. Monitor once during the process of foundation pit excavation every 1-2 days. Monitor once during the construction of the principal part 3-7 days.

**Monitor and control standard.** Adopt class Ⅲ monitoring and management for Code for shot crete-bolt construction method of railway tunnel(TBJ108-92) and cooperate with displacement rate as monitoring and control datum, that is to say, take three-quarters of allowed values as warning value, one third of allowed values as a reference. The values between the warning value and allowable values is called warning range, it should give warnings when the measured value is in this area, and the construction countermeasures should be discussed and adopted to prevent the end displacement more larger. In the table, $U_0$ as measured value; $U_n$ as allowable value. The foundation pit is stable if the measured value below the reference value.

**Monitoring allowable value.** Due to the foundation pit excavation depth is more than 14 meters and has pipeline and other municipal facilities in the three times of excavation depth, so the foundation pit belongs to the first level protection level in the deformation control of Shenyang metro foundation pit. In accordance with the relevant rules, regulations, similar engineering experience and relevant requirements of first level foundation pit, the engineering monitoring allowed values are shown in the following table 2.

**Table 2** Monitoring measurement value $U_n$

| Monitoring program | Monitoring Value (mm) | Design Value (mm) | The displacement rate control (mm/d) |
|---|---|---|---|
| Displacement of pile top | 30≤0.2%H | 40 | 2mm/day |

Note: H is the depth of foundation pit

The set and application of the displacement control index must be used with the displacement rate control index at the same time. Compared with the displacement, displacement rate control index has a clear physical meaning. It reflects the development trends along with the time of deformation.

**Monitoring time.** The monitoring of program conducted from April 2006 to August 2007, that is, since the construction of foundation pit building envelope until the end of the main work engineering. In implementation, each monitoring program and relevant construction process are synchronous, and

do some corresponding adjustment according to the adjustment of construction schedule to ensure the monitoring timely and accurately.

**Monitoring results and analyze**

Taking monitoring data of four stakes from No.1 to No.4 as an example in the south for example, shown in fig.2, analyze the process of foundation pit excavation and offset condition of inclinometer.

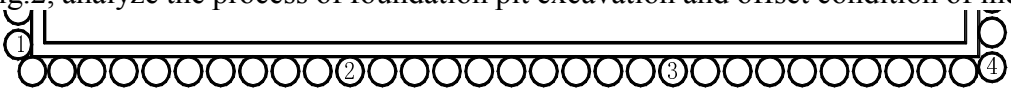

**Fig.2**. Pile position of foundation pit monitoring in the South

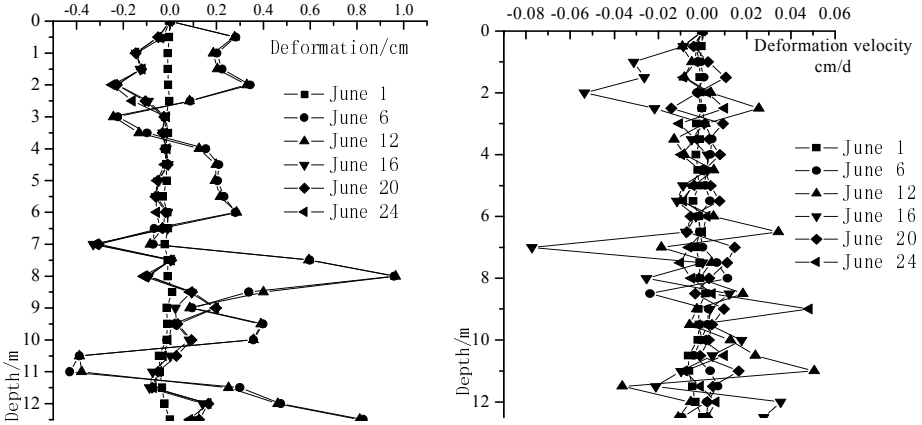
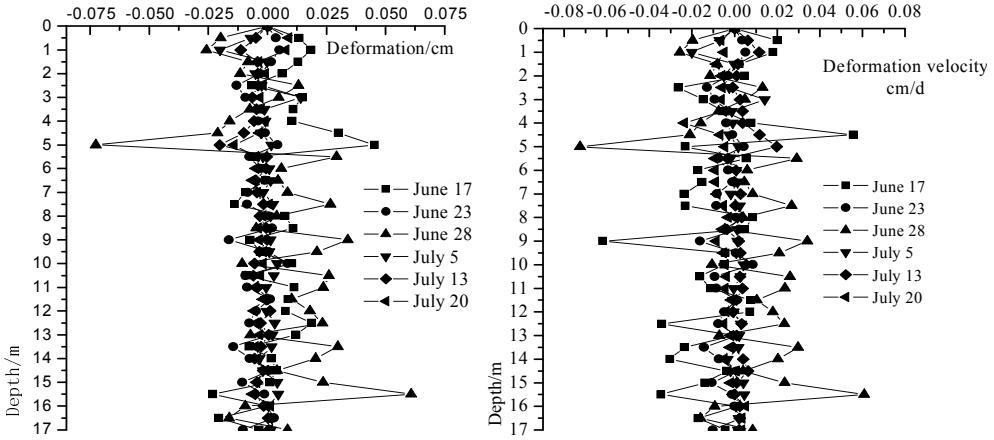
The offset curve obtained from monitoring of survey is shown in Fig3. The positive value indicated the displacement fronts on the inside of foundation pit, and the negative value indicated the displacement fronts on the outside of foundation pit.



a) Deformation b)Deformation velocity

**Fig.3**. Displacement curve of 1 pile

Seen from the fig.3, in 6th of June and 12th of June appeared relatively large displacement at the depth of 8.0 meters and 12.5 meters, then the displacement tends to stability. Because the excavation depth of foundation pit is more than 10 meters, and the second corner brace steel support is not applied, resulting in larger pile displacement. Deformation is reduced and stabilized after applied corner brace 16 days later. In the June16th, the displacement velocity is fairly large at the depth near 7 meters, and the direction is to the periphery of foundation pit. This is because that the applying of the second steel supports. The accumulative displacement and displacement velocity do not exceed the limit value, and indicates the excavation of foundation pit and supports are reasonable.



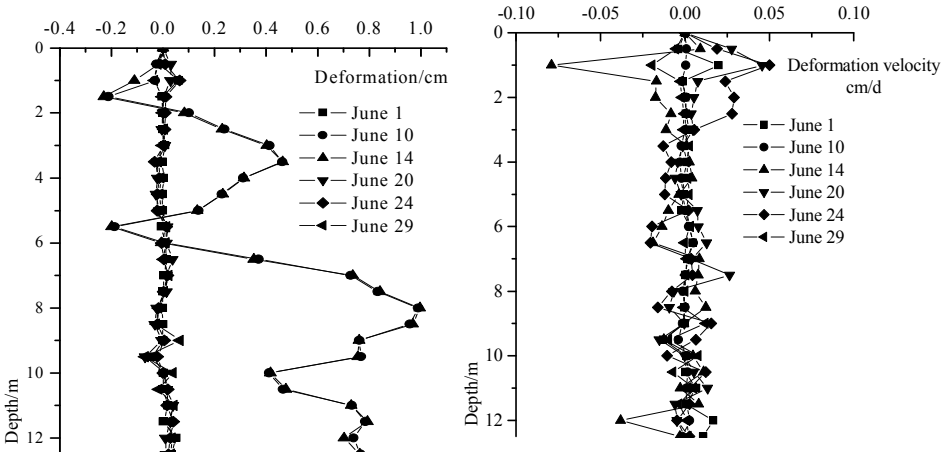
a) Deformation b)Deformation velocity

**Fig.4**. Displacement curve of 3 pile

Seen from the fig.4, at the depth of 5 meters in the foundation pit on June 17th, accumulative displacement increases suddenly, the pile deformed to the inside of foundation pit. By June 28th, the

pile caused larger deformation to the outside of foundation pit. This is because the second steel support is applied in June 28th. Meantime, at the end of pile the deformation is to the inside of foundation pit. The measurement of the displacement rate change is basically the same as the accumulative displacement trend. The accumulative displacement and displacement variation speed do not exceed the limit value.

It can be seen from the fig.5, the accumulative displacement measured on June 10th and on June 14th is larger. The largest accumulative displacement is close to 1 cm, which appeared at the depth of 8 meters. The displacement mutation also can be seen at the depth of 4 meters. After applied the second steel support on June 20th, the displacement tends to stabilize, the value is much small. The variation of displacement velocity value is very small. The accumulative displacement and displacement velocity do not exceed the limit value.



a) Deformation b)Deformation velocity

**Fig.5**. Displacement curve of 6 pile

## Conclusions

Timely and accurate in-situ monitoring information is the prerequisite to ensure the safety of construction. Excavation rate should be paid more attention during the excavation of foundation pit, and applied internal support timely in order to avoid excessive deformation and danger.

The analytical results of monitoring data shows that the whole stage of foundation pit excavation stability is good and the fender pile with internal supports can guarantee the stability of foundation pit.

**Keywords:** soil liquefaction, buried pipeline, floatation response

**Abstract.** In this paper, the formulae are deduced for the floatation response of pipeline buried in liquefied soil. The beam model based on the theory of beam on elastic foundation is used for the pipeline buried in non-liquefied and liquefied soil. The soil property is nonlinear, the floating force induced by the soil liquefaction is related to the position of pipeline, is nonlinear also. For the convenience and simplification of analysis, the nonlinear increment element method was used and lots of numerical analysis was conducted, including: the floatation response of pipeline buried in homogeneous soil, the floatation response of pipeline buried in non-homogeneous soil, and the floatation response of pipeline buried in discontinuous liquefied area. The influential factors on the floatation response of buried pipeline buried in liquefied soil including spring stiff of liquefied soil, the initial deformation, the length of liquefied area, the axial force acting on the pipeline, the material of pipeline, and the diameter of pipeline. The calculation results of discontinuous liquefied area draw a significant conclusion that for a long liquefied area, to make the soil non-liquefied in the middle of liquefied area may decrease the length of liquefied area and reduce the flotation displacement of pipeline greatly.

## Introduction

Buried pipeline is the important part of city's lifeline. During an earthquake, not only the buried pipeline itself get damaged and the economical loss is large, but also the damage of buried pipeline will induce the functional loss of the lifeline system and severe secondary hazard. The earthquake field observations show that there are three major causes of damage to buried pipeline during earthquakes: soil liquefaction, fault movement and seismic ground shaking. Soil liquefaction is one of the major causes to the damage of buried pipeline. The damage investigations revealed that the damage ratio of pipeline (number of breaks/per km) has much larger values in liquefied soil compared with that in shaking ground without liquefaction. The difference of earthquake response of buried pipeline in liquefied soil and that without liquefaction lay in that, the buried pipeline in liquefied soil not only suffer the earthquake shaking acting on the pipeline along or transverse to pipeline axis, but also the pipeline suffers the floating force due to soil liquefaction. The floating force make pipeline deformed in the vertical plane along the pipeline axis, and will make the pipeline get out the ground surface, which is called pipeline floatation. The floatation response of pipeline will make pipeline seriously damaged. All the theoretical and experimental study on the floatation response have got lots of beneficial results, but some conclusion are not the same such as: the effect of the length of liquefied region on the floatation response; the effect of axis force on the floatation response; the effect of pipeline depth on the floatation response, and so on. It shows that the study on floatation response of buried pipeline in liquefied soil is complicated so that need further study and the results need to be verified in the future earthquake.

**Analysis Method**

During an earthquake, the liquefaction of soil will make the soil shear strength much smaller than that without liquefaction, and also add a floating load on the pipeline buried in, those two reasons make the buried pipeline to float upward, and the pipeline will deform upward in the vertical plane through the pipeline axis. In some situations the pipeline may partly get out of the surface of ground and get damaged seriously. So the occurrence of floatation response of buried pipeline needs two conditions: a) is that the constraint force of soil acting on the pipeline is small enough. Experimental study shows that the constraint force of liquefied soil on the pipeline is 1/3000 to 1/1000 of the value without liquefaction; and b) is that the floating force that the liquefied soil acting on the pipeline is larger than the sum of the weight of pipeline and the weight of material transported in the pipeline.

Basing on the principals of virtual work, the beam model based on the theory of beam on elastic foundation is used for the pipeline buried in non-liquefied and liquefied area (figure 1), the equilibrium equations can be write as follow:

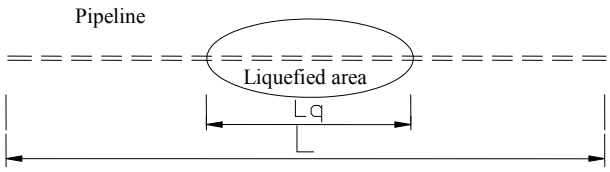

Figure 1 Pipeline buried in non-liquefied and liquefied soil

$$\int M\delta w''dx - \int \bar{N}\,\delta\varepsilon_a dx + \int P_s \delta w dx - \int P_f \delta w dx + \int P_g \delta w dx = 0 \tag{1}$$

Where,

M is the bending moment, and express as $M=EI\,w''$;
EI is the bending stiffness of pipeline section;
w is floatation response of pipeline;
$\bar{N}$ is the axial force acting on the pipeline;
Pg is the weight of pipeline and the material in the pipeline;
Pf is the floating force on the pipeline and induced by the soil liquefaction. The floating force is varied with the position of pipeline in the liquefied soil shown in figure 2. There are three occasion: a) when the pipeline is totally in the liquefied soil (w≤H-R), the floating force is $F_f = \gamma_s \pi R^2$; b) when the pipeline is partly out the surface of ground (H-R≤w≤H+R), the floating force is $F_f = A_s\gamma_s = \pi\gamma_s R^2(\pi - \varphi + \frac{1}{2}\sin 2\varphi)$; and c) when the pipeline is totally out the surface of ground (H+R≤w), the floating force is zero;

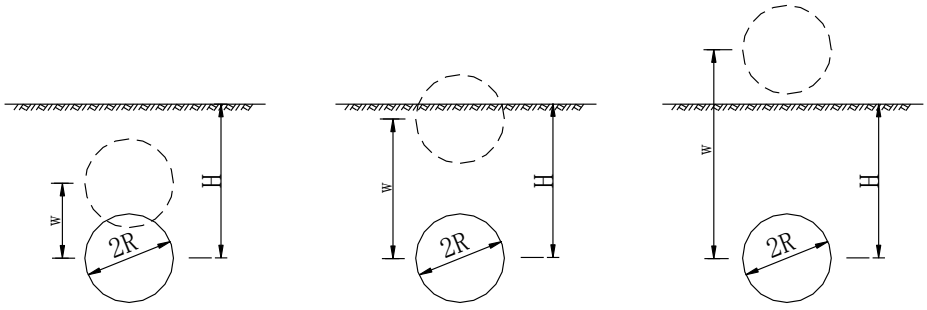

Figure 2 The positions of pipeline in liquefied soil

$\gamma_s$ is the density of liquefied soil;
H is the buried depth of pipeline;
R is the diameter of pipeline;

. $A_s$ is the sectional area of pipeline under the ground surface; and $\varphi = \frac{1}{2}\cos^{-1}(\frac{H-w}{R})$;

$\varepsilon_a = \frac{1}{2}(w'')^2$ is the axis deformation induced by the lateral deformation of pipeline;

Ps is the soil lateral constraint force on pipeline, and is nonlinear force, shown in figure 2. In the non-liquefied region, the soil lateral constraint force is express as:

$$P_s = \begin{cases} K_d w & \mathbf{w} \le \mathbf{0} \\ K_u w & \mathbf{0} < \mathbf{w} \le \bar{\mathbf{w}} \\ \bar{P}_s & \bar{\mathbf{w}} \le \mathbf{w} \end{cases}$$

where， $K_d$ , $K_u$ are the spring constants when pipeline moves down or move up respectively, $\bar{P}_s$ is the largest constraint force when pipeline moves upward, and $\bar{\mathbf{w}}$ is the displacement related with $\bar{P}_s$ . In the liquefied region, $P_s$ =0 or a very small value.

By the finite element method (see reference 1, 2, 3 for detail deduction), equation (1) change to:

$$[K_p + K_s - K_N - K_f]\{w\} + \{P_g\} - [K_p - K_N]\{w_g\} = 0 \quad (2)$$

Equation (2) can be express in increment as below:

$$[K_p - K_N]\{w_g\} - [K_p - K_N]\{w_0\} - \{P_g\} - \{P_{s0}\} + \{P_{f0}\} \ [K_p + K_s - K_N - K_f]\{\Delta w\} = \quad (3)$$

Where,

$K_p$ is the bending stiffness matrix of pipeline;

$K_s$ is the constraint stiffness matrix of soil on pipeline;

$K_N$ is the axial force stiffness matrix of pipeline or geometric stiffness matrix;

$K_f$ is the floating force stiffness matrix;

$\{\Delta w\}$ is the floatation response increment vector;

$\{w_0\}$ is the calculating floatation displacement result vector of last step, and is the input of next step;

$\{w_g\}$ is the initial deformation vector of pipeline;

$\{P_g\}$ is the weight vector of pipeline and material transported in pipeline;

$\{P_{s0}\}$ and $\{P_{f0}\}$ are the initial soil constraint vector and the initial floating force vector in the calculation step respectively, and the their values are calculated from $\{w_0\}$.

The floatation response vector $\{w\}$ is obtained by using iterative method to equation (3).

**Numerical Calculation Results**

During the calculation of the floatation of buried pipeline, the initial deformation of pipeline is assumed to be: $w_0 = A_0 \sin\frac{\pi}{L}x$ and $\theta_0 = A_0 \frac{\pi}{L}\cos\frac{\pi}{L}x$, here, L is the length of liquefied region. The convergent criterion is $|\Delta w_i| \le 0.001$. The thickness of the pipeline is 0.01m, the outer diameter of the pipeline is 0.4m, the length of the pipeline is 200m, the bending stiffness of pipeline (EI) is 2.64×108Nm2, the density of liquefied soil (γs) is 2.0×104N/m3, and the average density of pipeline (γg) is 7.65 × 103N/m3.Some calculation results of pipeline floatation response in homogenous liquefied soil are shown in figure 3 to figure 6.

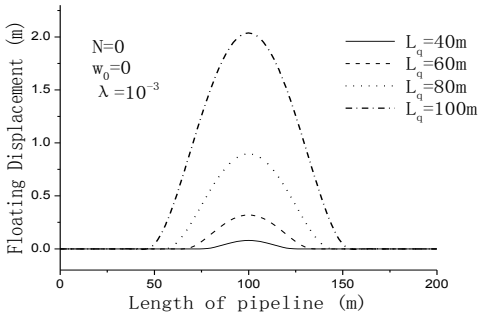

Figure 3 The effect of length of liquefied region

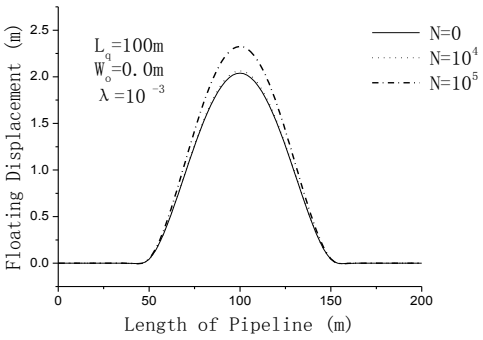

Figure 4 The effect of axial force

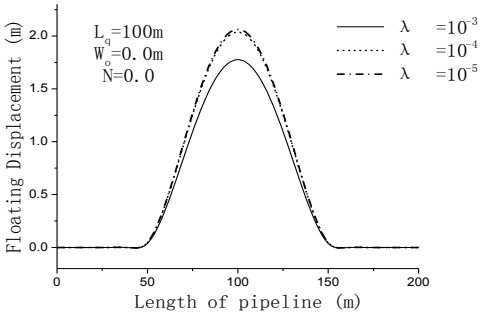

Figure 5 The effects of spring constant

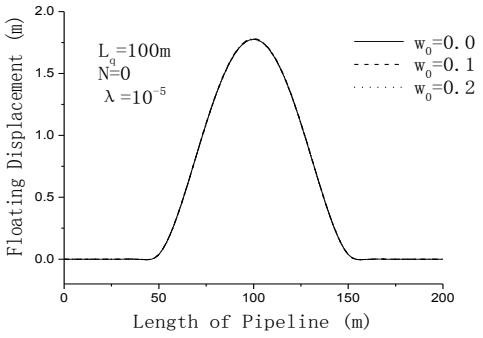

Figure 6 The effect of initial deformation

Figure 3 gives the effect of the length of liquefied region on the floatation of the buried pipeline. It shows that the floatation response varies with the length of liquefied region greatly, a smaller length of liquefied region gets a smaller floatation, and this is in agreement with the experimental results [4], but as the length of liquefied region gets larger, the floatation becomes larger rapidly, and this can not be simulated in the laboratory test. Figure 4 gives the results of the effect of axial force on the floatation response. It can be seen form figure 4 that the floatation response of buried pipeline gets lager when the axial force gets larger, and when the axial is too large, the pipeline would be unstable, and the iteration procedure is not convergent. Figure 5 gives the effect of the spring constant of liquefied soil on the floatation of pipeline, and it shows that a lower spring constant makes the floatation lager. Figure 6 gives the effect of initial deformation on the floatation, and shows that the initial deformation of the pipeline has little effect on the floatation of buried pipeline. From the calculation, it can be seen that the bending strain is larger when the length of liquefied region and the axial force get lager.

Figure 7 to figure 11 give the calculation results of pipeline floatation buried in two different liquefied soils. Figure 7 gives the effects of two kinds of soil constraint on the floatation response. It can be seen that the maximum flotation displacement occurs in the area with smaller soil spring stiffness. The effects of nonlinear soil constraint and the initial deformation, the length of liquefied area, and the axial force acting on the pipeline is the same as in homogenous soil.

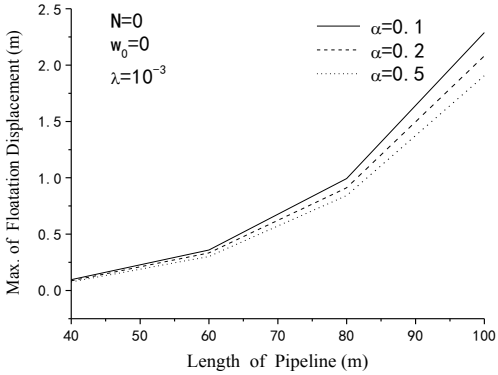

Figure 8 Effect of length of liquefied region

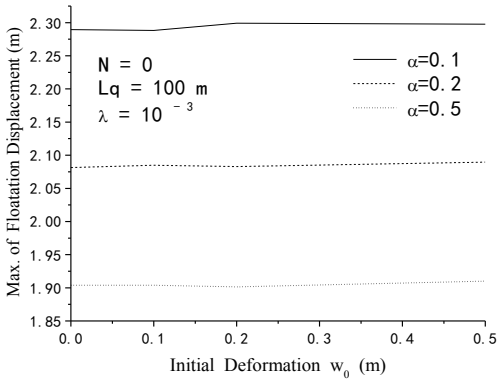

Figure 9 The effect of initial deformation

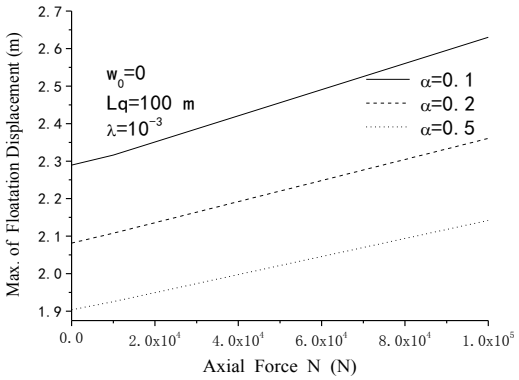

Figure 10 The effect of axial force

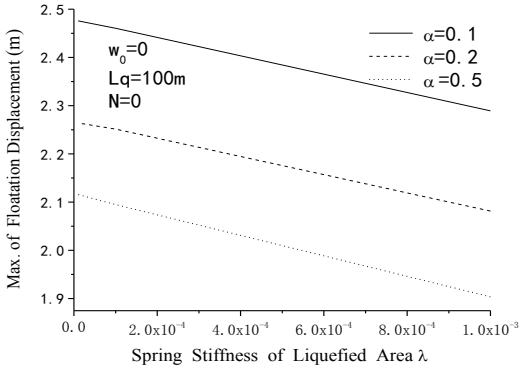

Figure 11 The effects of spring constant

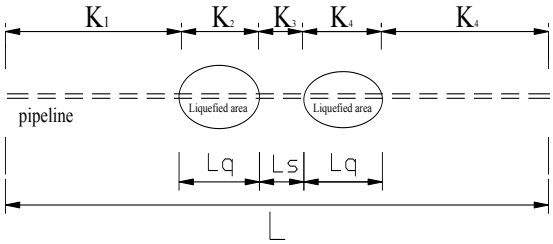

Figure 12 Discontinuous liquefied region

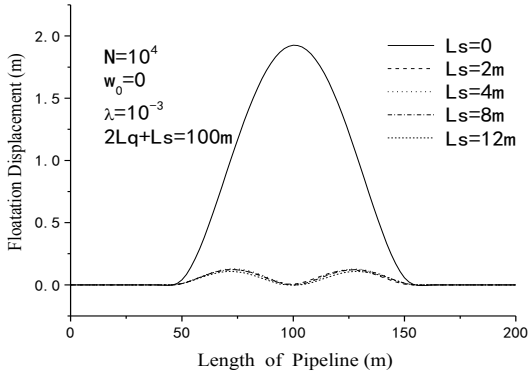

Figure 13 Effect of length of Ls

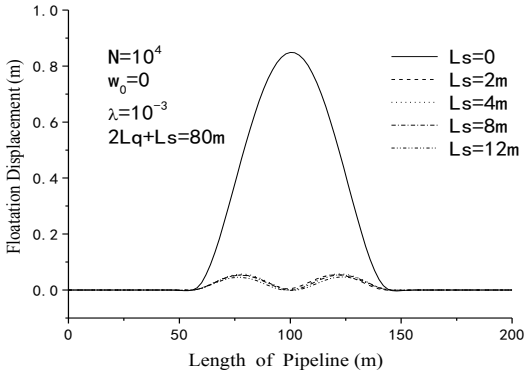

Figure 14 Effect of length of Ls

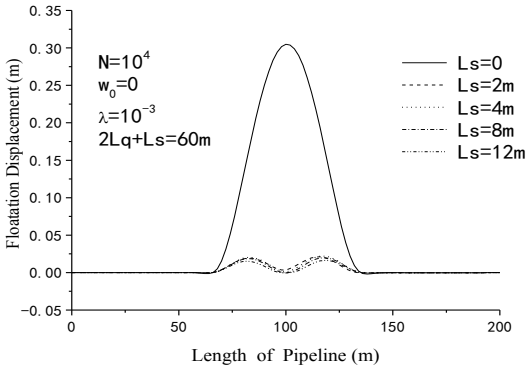

Figure 15 Effect of length of Ls

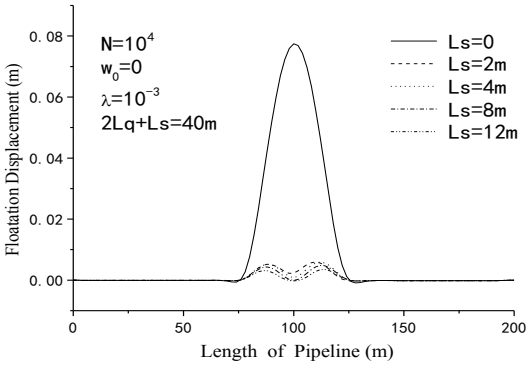

Figure 16 Effect of length of Ls

Figure 13 to figure 16 give the calculation results of pipeline floatation response in discontinuous liquefied region as shown in figure 12. The figures give respectively the floatation response of buried pipeline, when the whole length of liquefied area and the length of intermediate non-liquefied area are different. It can be seen from the figures that the intermediate part of liquefied area, that is no-liquefied soil part, will decrease the floatation response obviously. In all the calculations, the peak

value of floatation response is nearly the same value and varied little with the length of intermediate non-liquefied area.

## Conclusion

1) In homogeneous soil, the length of liquefied region has very large effect on the floatation of buried pipeline, and the floatation displacement gets larger as the length of liquefied region gets longer.
2) In homogeneous soil, the axial force has some effect on the floatation response, and larger axial force makes lager floatation displacement.
3) In homogeneous soil, the spring constant of liquefied soil has a great effect on the floatation response, and a lower spring constant of liquefied soil makes the floatation displacement lager.
4) In homogeneous soil, the initial deformation of the pipeline has little effect on the floatation of buried pipeline.
5) The effects of the axial force on the pipeline, the initial deformation, and the equivalent spring stiffness of liquefied soil on the floatation response in no-homogeneous soil are the same with the results of homogeneous soil.
6) The maximum floatation displacement of pipeline occurs in the area with smaller soil spring stiffness in two kinds of soils. The soil is much more no-homogeneous, the floatation response is much bigger
7) The calculation results of two liquefied soil with non-liquefied intermediate part draw a significant conclusion that for a long liquefied area, to make the soil non-liquefied in the middle of liquefied area may decrease the length of liquefied area and reduce the flotation displacement of pipeline greatly.
8) Based on the calculation results, to dispose the liquefied soil, the length of disposed area is 2m can achieve a good effect of reducing the floatation. In addition, when the length of liquefied area less than 40m, the floatation response of pipeline is very small. These conclusions can be referenced in actual engineering.

**Keywords:** the Diaphragm Wall; Construction Monitoring; Data analysis.

**Abstract:** Working well of nanjing city latitude three pass by river channel project is taken for example. Underground continuous wall was adopted in this project. Detailed monitoring scheme was formulated and lots of date was obtained by foundation pit. The monitoring data changed sharply analysis shows that the maximum horizontal displacement and the maximum strut axial forces is located near the excavation surface and along with the soil excavating. After structure construction, the change of deformation and internal force of enclosure structure gradually became stable. The theoretical analysis and test results are tend to be consistent. But this two have certain differences due to the influence of various factors.

## Introduction

Foundation pit engineering is a kind of high risk project. Once the accident happened, the projects not only suffer from delays and cost overruns but also endanger surrounding buildings, people's life and property safety. In this paper, base on the monitoring date of working well of latitude three pass by river channel project, the law of displacement and internal force were studied.

## Engineering situation

The shortest distance of work well and Yangtze river levee is about 53 m. The safety grade of Work well palisade structure is grade I. Table 1 shows the soil physical properties of the work well.

Table 1 Physico-mechanical properties of soils and rocks

| The number of Layer | The name of Geotechnical | Bulk Density/ γ | Poisson Ratio/ν | Coefficient of Lateral Earth Pressure/ξ | Coefficient of quick shear tests/ | | Coefficient of Subgrade Reaction | |
|---|---|---|---|---|---|---|---|---|
| | | | | | | | Late-ral | Horizon-tal |
| | | [kN/m3] | - | - | [kPa] | [°] | [m/d] | |
| ①0 | Miscellaneous Fill | 18.4 | 0.35 | 0.53 | / | / | 5 | / |
| ②1 | Clay | 18.3 | 0.39 | 0.65 | 30 | 4.9 | 15 | 18 |
| ②2 | Mucky Silty Clay | 18.1 | 0.42 | 0.72 | 16 | 2.6 | 8 | 8 |

The thickness of the diaphragm wall is 1.2 m, the excavation depth is 25.783 m, the deep of diaphragm wall is 44 m and the size of diaphragm wall is 20 m × 20 m. The build-in depth of the diaphragm wall is 18.217 m and the toe of wall insert in the ③1 layer silty clay. By the way, two - row reinforced concrete support structure and four - Row steel support structure (Φ 609 x 16 steel pipes) composes support structure system. Fig.1 shows the elevation drawing of work well.

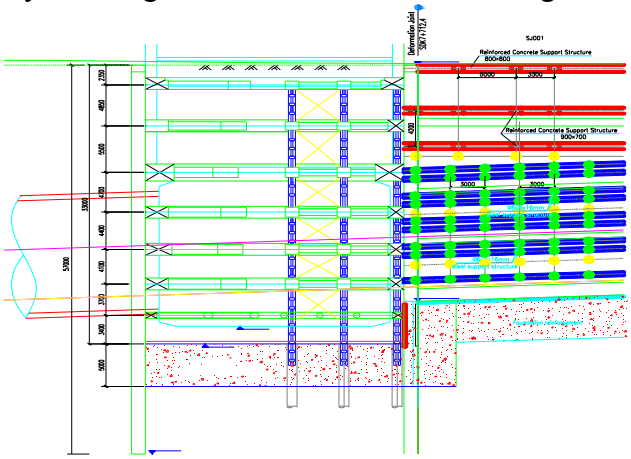

Fig.1 Elevation drawing of monitoring sites in deep excavation pit

## The monitoring items and test point arrangement of Foundation pit

After a comprehensive consideration, the monitoring items (see table 2) and test point arrangement (see fig.2) are determined.

Table 2 Comparison between initial stresses and stresses got in the back analysis

| Test Item | Ground settlement | Horizontal and Vertical displacement for pile, wall and soil | Strut axial forces | Lattice column settlement | Ground water | Deflection of diaphragm wall |
|---|---|---|---|---|---|---|
| Test instrument | Electronic Level | Electronic Level, Inclinometer | Axial Force and Strain Testing Sensor | Electronic Level | Water Level Gauge | Electronic Level, Electronic Theodolite |

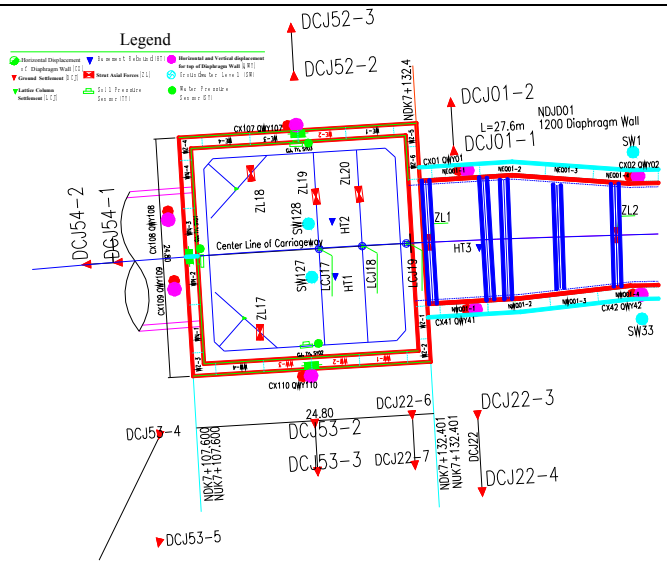

Fig.2 Plane layout of monitoring sites in deep excavation pit

## Monitoring data analysis

### Displacement data analysis for top of diaphragm wall

There are totally four displacement monitoring points for diaphragm wall, including horizontal and vertical displacement, which are QWY107, QWY108, QWY109 and QWY110. Fig.3 shows the displacement–time curves.

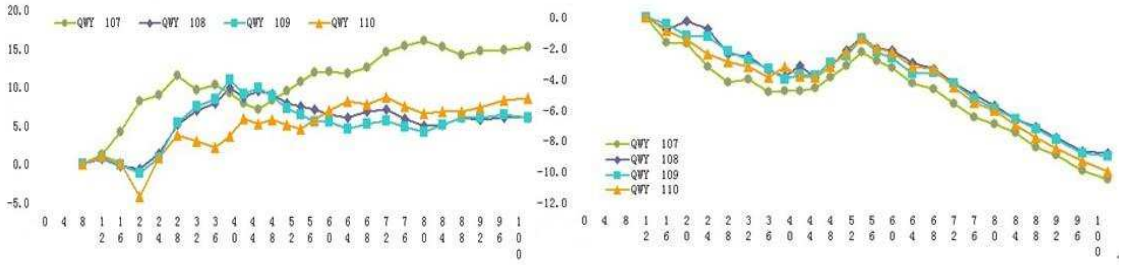

Fig.3 Horizontal and Vertical displacement(mm)-time(Day) curves of diaphragm wall

The fig.3 illustrates that, with the excavation, the horizontal direction of diaphragm wall start to Migrate to pit inside and the Vertical direction of is settlement. The maximum vertical displacement point is located in test point QWY107 and the cumulate depth change is 10.5 mm. At the same time, the maximum horizontal displacement point is also located in test point QWY107 and the cumulate change is 15.2 mm. The reason why the maximum displacement change test point is QWY107 is that it is just seated near road. At present, all measuring points are in safe.

**Displacement data analysis for Lattice column**

There are totally three displacement monitoring points for lattice column, which are LCJ17, LCJ18 and LCJ19. Fig.4 shows the settlement–time curves of lattice column.

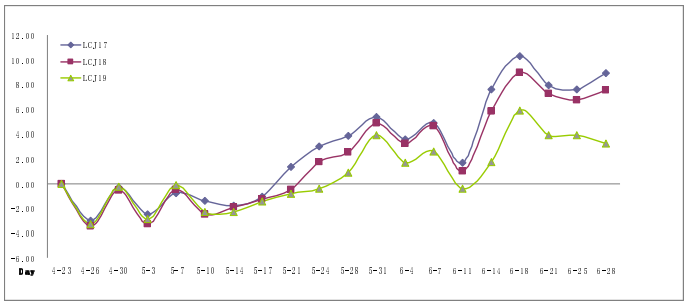

Fig.4 Lattice column settlement(mm)-time(Day) curves

With the excavation, difference rebound of lattice column increase furtherly and the biggest difference value is 5.7 mm. The maximum cumulate change test point is located in LCJ17 and the value is 9.1 mm; The change rate is the highest with test point LCJ17 and LCJ18, the value of which is -0.7mm/d which are all in safe.

**Horizontal displacement data analysis for diaphragm wall**

There are totally four displacement monitoring points for horizontal displacement of diaphragm wall, which are CX107, CX108, CX109 and CX110. Fig.5 shows the curves of horizontal displacement vs depth .

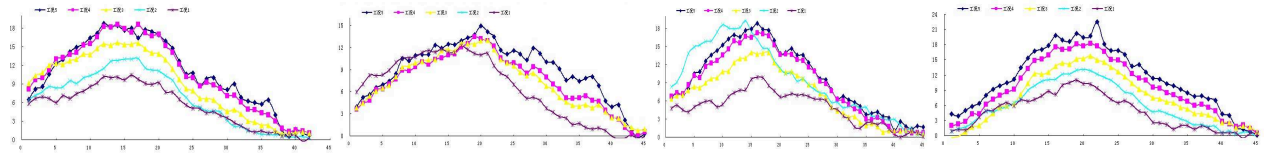

Fig.5 Horizontal displacement(mm) vs. Depth(m) for CX107, CX108, CX109 andCX110

With the excavation, the horizontal displacement increase and the position of maximum horizontal displacement gradually move down. The characteristics of each curves in fig.5 is that deformation of both side is small and the middle is larger. The range of each maximum horizontal displacement of test points , changing from 15 mm to 25 mm, is even.

**Strut axial forces data analysis**

There are totally twenty-eight axial force testing sensors. Fig.6 shows the curves of horizontal measuring inner axial force-time

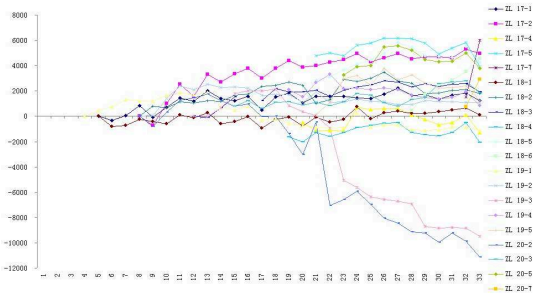

Fig.6 Horizontal Measuring inner axial force(KN)-time(Day) curves

With the excavation, the strut axial forces of each support structure increase. And the support stucture which increasing fast is near the bottom of foundation pit. After construction of baseplate, each strut axial forces tend to be stable. The maximum strut axial force test point is ZL17-7, which is up to 17515.5 KN; The change rate is the highest also with test point ZL17-7, the value of which is 15393.5KN/d.

## Water and soil pressure data analysis

There are totally three soil pressure sensors and three water pressure sensors, which are SY01, SY02, SY03 and TY01, TY02, TY03.. Fig.7 shows the curves of soil and water pressure-time.

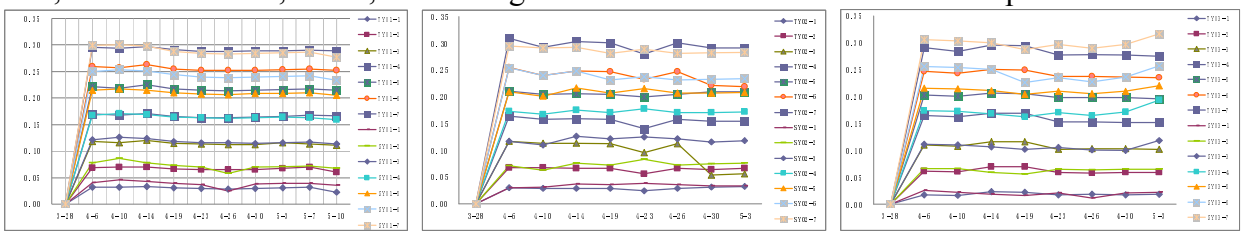

Fig.7 Soil and water pressure(Mpa)-time(Day) curves for TY01\SY01, TY02\SY02 and TY03\SY03

The maximum water pressure test point is SY3-7, which is up to 0.30 Mpa and the maximum water pressure test point is TY1-7, which is up to 0.27 Mpa, which are all in contorl.

## Conclusions

In order to ensure the safety of life and property for people, it is necessary to monitor the construction of foundation pint. Through monitoring and analyzing the working well of latitude three pass by river channel project, the law of displacement and internal force were studied, which can guide the construction and design of other similar engineering structure.

# Experimental Study on Bearing Mechanism of Jacked Pipe Pile in Sand

Jiatao Wang[1, a *]

[1]Department of Civil Engineering, Shandong Water Polytechnic, Rizhao, Shandong, China

[a]wy_wjt@126.com

**Key words:** Jacked pipe pile; side resistance; tip resistance

**Abstract:** Study on bearing mechanism of jacked pipe pile in sand is useful of optimizing the pile foundation design, and the research of the regularity of side resistance and tip resistance of pile has a very important theoretical significance. In this paper, a new effective method is used to test the tip resistance of the jacked pipe pile during the press-in process, and then the side resistance can be deduced [1]. Based on the field tests, the inherent laws of interaction between pile and soil in sand is explored, which provides some theoretical basis for the pile foundation design and engineering application.

## Introduction

In recent years, jacked pipe pile has been widely used in industrial and civil buildings, railways, highways, bridges, ports and other projects in China. Study on bearing mechanism of jacked pipe pile in sand soil will have a very important theoretical significance and application value. Therefore, the correct understanding of the bearing capacity of piles is of great significance in the design of the project [2].

Based on the field tests, the inherent laws of interaction between pile and soil in sand is discussed, which provides some theoretical basis for the pile foundation design and engineering application.

## The pile foundation test

**Preparations for the tests.** A steel pipe pile is used in this test, with the thickness of 6mm, the length of 2.8m, and the diameter of 500mm.

In order to measure the value of the pile tip resistance of the pile, a special testing device is used in this test, as shown in Figure 1.

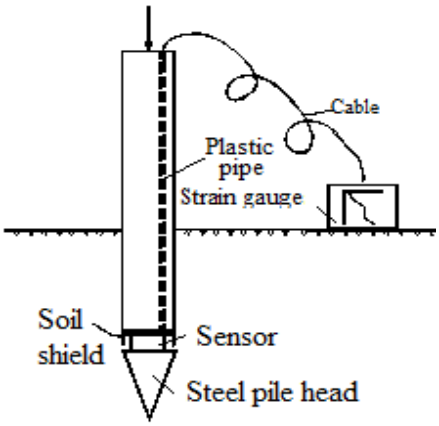

Fig.1 Testing device of pile tip resistance

Different from the traditional test of jacking force measurement, in this test a self-made pile pressure sensor is placed near the end of pile [3], [4]. After the sensor is done, curve of the

relationship between stress and strain is calibrated in laboratory. Then transported to the site, install the pile, forming a whole pile. Lead by the pile tip force sensor embedded in a thin plastic tube inside the pile piercing, connected to the intelligent resistance strain gauges.

At the construction site, static pile driver is used to press pile into the soil. After the stability of soil, the static load test is carried on. During the static load test, the strain of the pile can be measured by the testing device. Then tip resistance is got, which can be based on to get the pile side resistance. The test is divided into two parts: one is the measurement of the steel pipe piles indentation process; another is the measurement process of the static load test after the consolidation of the soil.

**Steel pipe pile press-in process.** Test site soil is fine sand. Groundwater level is 5.5m. Shear strength of sand ($C$) is of 5 kPa, and $\phi$ is of 36 degrees.

The strain is recorded during pipe pile press-in process, and then pile the tip resistance is obtained. Since the total pile resistance is known, the pile side resistance can be got. It can be seen from the data of the test, pile side resistance increases with the buried depth increase, but reaches a certain depth basically unchanged; also can be seen that at the same depth, the lateral friction decreases with the increase of the length of the pile buried in soil. Pile resistance is not like some of the information referred tip resistance accounted for the major part of the total, the proportion of both pile resistance is a variable value. The ratio of pile side resistance and tip resistance to total jacking force is shown in Figure 2, in which R1 is the ratio of pile tip resistance to total jacking force, R2 is the ratio of pile side resistance to total jacking force.

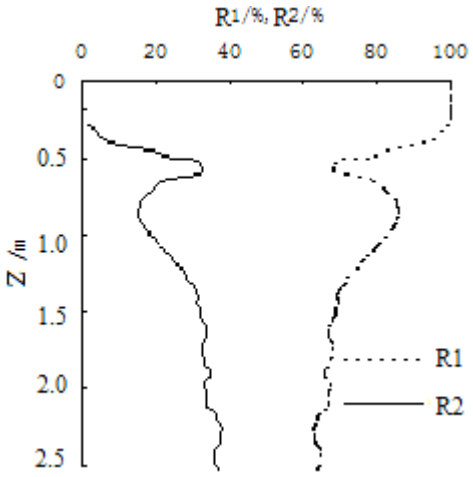

Fig.2 The ratio of pile side resistance and tip resistance to total jacking force

It can be seen from Figure 2, under the experimental conditions of the sand soil, when the pile end through non-hard soil, the pile side resistance is larger than the tip resistance, not like some of the information referred tip resistance is always accounted for the major part. In fact, only when pile tip reaches a hard layer, the pile tip resistance will dramatically increase, as a major part of the total resistance of the pressure pile.

**The static load test**

The static load test is carried on after ten days of the construction of the jacked pipe pile [5], [6]. During the process of the test, the pile strain is measured to get the pile tip resistance and side resistance, which can be seen in Figure3 and Figure 4.

It can be seen that the tendency of pile p-s curve in pile static load test is different from the pile press-in test. Comparison of two curved shape, analyze its variation, the P-S curve is divided into three stages [7]: the elastic stage, the yield stage, and the failure stage, shown in Figure 3. In the

elastic stage, the load is increased from 0KN to 200KN. The P-S curve of the pile top is basically linear, the pile top settlement changes from 0mm to 10.5mm, while pile end settlement is small, essentially unchanged. In the yield stage, the load is increased from 200KN to 300KN, P-S curve of the pile top and end both appear as curved segments, the pile top settlement increased to 34mm, and the pile end settlement also increased to 16mm. In the failure stage loads of 300KN to 350KN, both pile top and pile end P-S curves occur a sharp decline, and the pile top settlement reaches 73mm, pile end settlement to 53mm.

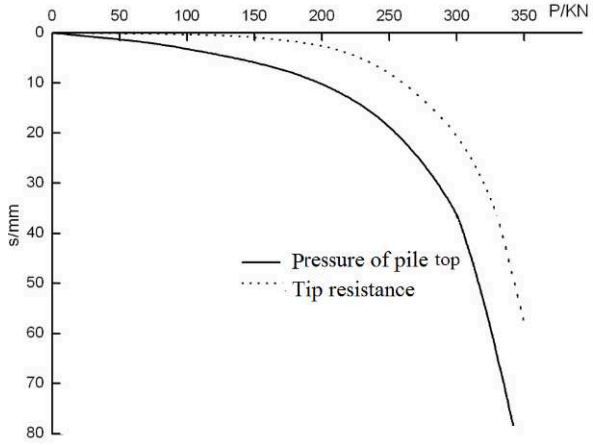

Fig.3 Curves of pressure -settlement

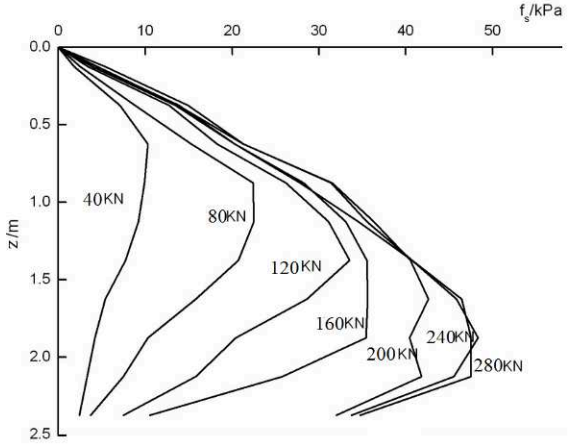

Fig.4 Curves of pile side friction under different levels load

Distribution curves of pile side friction under different levels load in the site load test are shown in Figure 4. It can be seen from figure that the value of side friction along the pile increases at the first, but decreases at last. In the same location, pile-soil friction resistance increases rapidly at first, but with the increasing of the load, growth slows or even decreases. That's to say, with the increasing of the load, the upper load along the pile height gradually pass on to the end of the pile, and the soil at the end of pile occurs the plastic deformation.

As can be seen from the above analysis of single pile settlement laws in sandy soils: the elastic stage, suffered a smaller load, pile load is mainly undertaken by the pile skin friction, tip resistance basically do not play. But when the load reaches 200KN, the yield stage beginning, the pile tip resistance began to play, and now the pile frictional resistance has largely played to the limit. The load continues to increase, the pile tip resistance gradually plays a main role to bear the increased load, and pile end began piercing distortion. When the load increases to 300KN, tip resistance plays a critical point, to yield, which lead to piercing damage. Large settlements occur both in pile top and pile end, and then the failure of the whole pile occurs.

## Summary

(1) The basic principle of this test method is obtained by measuring the pile strain to get pile tip resistance, and then calculates the pile side resistance. It's a good solution to the shortcomings of traditional test methods.

(2)It can be seen from the pile site indentation test that pile side resistance increases with the buried depth, but reaches a certain depth basically unchanged; also can be seen that at the same depth, the lateral friction decreases with the increase of the length of the pile buried in soil. During the press-in process, when buried shallow depth of the pile, because the pile lateral friction is not fully played, the pile tip resistance accounts for a larger proportion of pile resistance; with the increasing of the piles buried depth, the cumulative value of the pile side friction also increases, the proportion of pile side resistance will increase.

(3) The tendency of pile p-s curve in pile static load test is different from the pile press-in test [8]: the elastic stage, suffers a smaller load, pile load bears mainly by the pile skin friction, tip resistance basically do not play; but he pile tip resistance begins to play when the yield load reaches, and the pile side resistance has largely played to the limit at this time. If the load continues to increase, the pile tip resistance gradually plays a main role to bear the increasing load and pile end begins piercing distortion. When the load achieve to a critical point, the tip resistance comes to yield.

(4) According to the current pile foundation design specifications, the load used in the pile design is generally in the elastic stage and the tip resistance has not been effectively play [9]. It is necessary to consider the bearing capacity of larger settlement of pile top, give full play to the role of pile tip resistance, so as to reduce the project cost, and to optimize the design of pile foundation.

# On Stability and Deformation of Slurry-trench Affected by Formation Equipment

Maoyin Shi[1, a], Fugui Song[1,b]

[1]The Key Laboratory of Road and Traffic Engineering, Ministry of Education, Tongji University, Shanghai 200092, China

[a]1234462@tongji.edu.cn, [b]623031143@qq.com

**Keywords:** slurry-trench; formation equipment; instability mechanism; deformation

**Abstract**. A synthesized investigation is conducted of trench formation machine's effect on trench wall in soft soil area. The failure pattern of the slurry-trench is analyzed by means of 3D FEM based on strength reduction method. The investigation shows that the global instibility occurs in the superficial layers and speads along the trench segment. The grab movement in slurry has an instant impact on the trench wall and may cause local instability. The overload and construction technique of trench formation equipment are both important concerns during trench construction to ensure safetry.

## Introduction

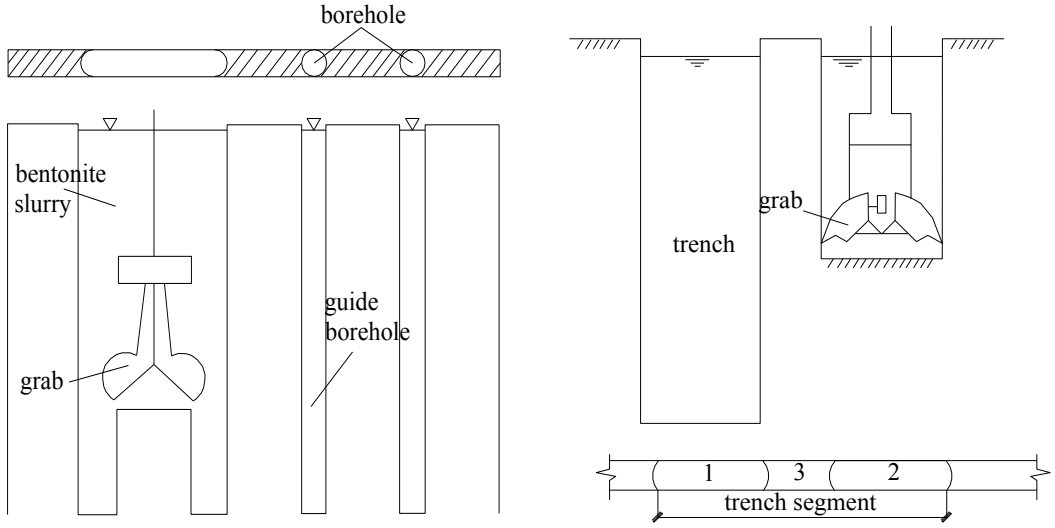
With the advantages of high stiffness, high security and small deformation of support structure, diaphragm wall is widely used in excavation especially in complicated environment with high protection demands. During the diaphragm wall construction, because of lateral unloading, trench excavation may cause lateral deformation and vertical settlement. In soft soil area, trench wall may collapse. It's accepted that trench excavation is the most important stage of diaphragm wall construction and it is key to improving construction efficiency and project quality[1].

The stability of trench wall mainly depends on bentonite slurry in the trench. There has been some research on the instability mechanism of trench wall and factors that influence trench stability. Scholars researched the influence of the slurry property, soil condition, underground water, additional ground load, trench shape and size et al[2-5]. However, the effect of trench equipment and its excavation techniques on trench wall stability and deformation is rare. The paper makes an investigation of the trench formation equipment and its effect on the trench wall.

## Techniques of the trench equipment by hydraulic power

The trench machine by hydraulic power is widely applied in trench excavation. The grab cut soil with gear and the soil is took out with the bucket. When raised up onto the ground, the grab opens its bucket and dumps the soil.The process continues until the trench is completed.The grab activity is shown in Fig.1a).

Common trench segments are 3.8~7.2m wide generally. The trench is excavated by one grab or several grabs. The excavation order of several grabs is shown inFig.1b).



a) Drill and grab workmanship b) Excavation order of wide trench

Fig.1 Working patterns of hydraulic grab

Except big float rock and bedrock, trench equipment with hydraulic grab adapts in kinds of soils, such as clay, sand and gravel soil. It makes little noise and little vibration with high efficiency and accuracy. Most is equipped with bore-hole surveying and correcting device to correct the verticality of trench wall when necessary.

In the paper, equipment effect is investigated in two aspects: the machine itself and construction technique. The machine itself is divided into two parts: the weight itself and its vibration. To be precise, the technique factor means the impact of slurry flow on the trench wall caused by the grab's moving up and down in slurry.

**Project background**

The soft clay in a station pit of Ningbo Rail transit is investigated. The main soil layers are shown in Table 1. There is mainly clay and silty clay, sandwiched with clayey silt ③$_1$, 1.7m thick. The soil is of high rheology. The trench is 6m wide, 1m thick and 46m deep. The guide wall is 0.25m thick and 1.8m deep and 1m wide along the ground.

Table 1 Soil properties

| Soil layer | Thickness[m] | $\gamma$[kN/m$^3$] | $E_{s0.1\text{-}0.2}$[MPa] | $\Phi$[°] | $c$[kPa] | $K_0$ | $qu$[kPa] |

**Effect of the trench machine itself**

The analysis is conducted from two perspectives: additional static load and dynamic load caused by vibration. In this part, 3D numerical modeling is used to investigate the instability mechanism of trench wall and the effect of the equipment.

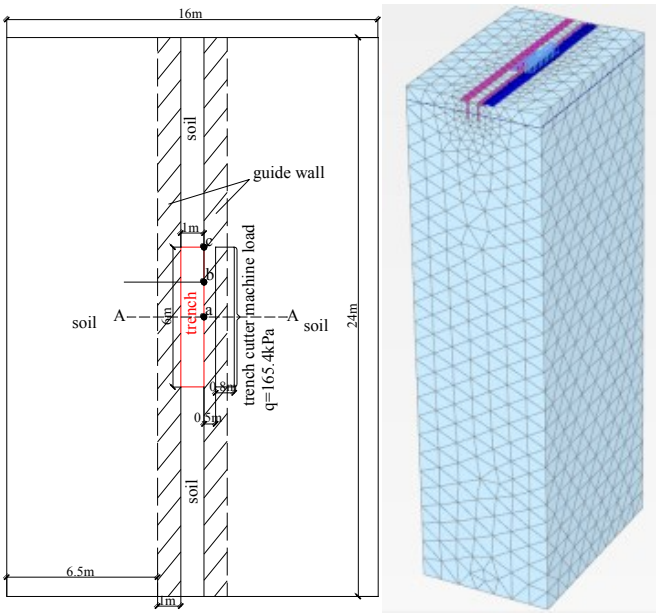
**Static load of the machine weight.** The static load of the machine weight shall be considered as ground overload. Because of the existence of the trench, the overload effect cannot be calculated with Boussinesq method. To analyze the instability pattern of the trench with ground overload，a 3D FEM based on strength reduction method is set up. As shown in Fig.2a), the trench size is 6m(wide) ×1m(thick)×46m(deep), and the model size is 24m(wide) ×16m(thick)×60m(deep).

The specification of the trench machine is shown in Table 2. The machine load is simplified as uniformly distributed load 165.4kPa, 0.8m×6m and located 0.5m away from the trench wall.

Table 2 Specification of the trench cutter machine

| Type | Unit | Jintai SG40A |
|---|---|---|
| Weight of main machine | t | 63 |
| Grab weight | t | 18.344 |
| Track length | mm | 5680 |
| Track width | mm | 800 |

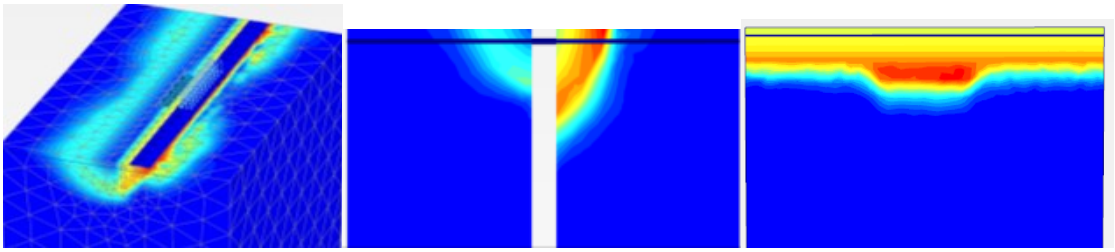
By means of the finite element model based on strength reduction method, aimed at the typical soft soil layer ② in Ningbo, the 3D instability mechanism and its failure mode under overload is investigated. The soil is simulated with 15-node triangular element of high order and Mohr-Couloumb elastoplastic constitutive model. Reduction coefficient $R_i$ is used to reflect the stiffness relationship between contact surface and the soil. $R_i$ =0.65. The criterion of instability is to form a complete plastic zone. The model grid is shown in Fig.2b).



a) top view b)3D finite element model grid

Fig.2 FEM model of trench with machine load

The slide face is shown in Fig.3. Changes occur within the superficial layer, approximately 6m from the ground surface (see Fig.3a)). The upside of the guide wall is cut off by the tension of the deformed soil below. The soil below the guide wall bulges towards the trench, namely ‘necking down’ in clay soil (see Fig.3b)). The plastic zone spread along the trench width(see Fig.3c)).

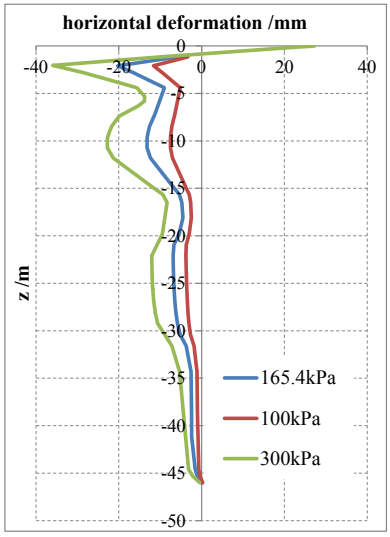


a) 3D instability pattern b) slide face on cross-section A-A c) incremental deformation of trench wall on load side

Fig.3 The instability pattern of trench under machine load condition

The lateral deformation of the trench wall is investigated with 3D FEM. The intersecting line of cross-section A-A(see Fig.2a)) and the trench wall on load side is picked out. With different overload values, the horizontal deformation follows the same rule but variable values (see Fig.4). The soil right below the load is firstly compressed. Due to the elastic guide wall, the topside of the wall tends to deform towards the load side. The deformation decreases along the trench depth. In the soft clay ② 2-2, the deformation rebounds a little then goes on attenuation.

The maximum horizontal deformation towards the trench under the machine weight 165.4kPa is 20mm. The deformation increments with the incremental load value tends to be larger and approaches to shear failure. For safe sake, the trench cutter equipment should be chosen reasonably according to the soil condition and it's necessary to reinforce the superficial layers and to lay thick steel panel under the machine to decrease the uniformly distributed load.



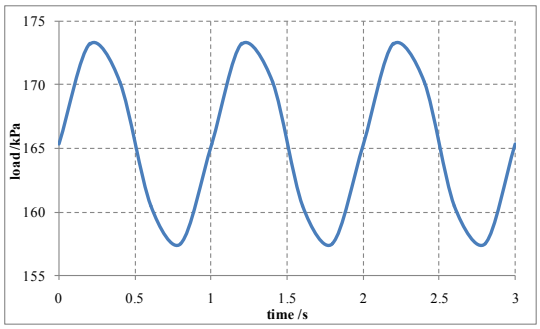


Fig.4 Horizontal deformation of trench centerline Fig.5 Dynamic load curve over time

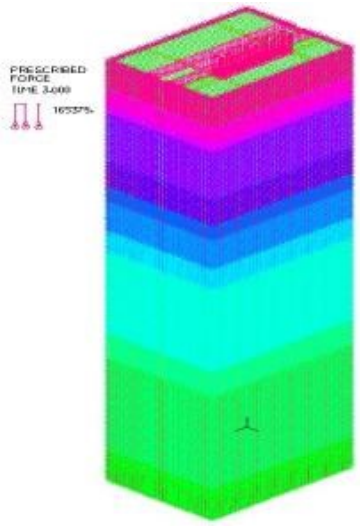
**The machine vibration.** Addition to the overload, the mechanical vibration is inevitable. It may change the soil properties and lead to large deformation and further endanger the stability of the slurry-trench.

To investigate the instant elastic deformation of the trench wall and then to evaluate the instantaneous safety during the trench exposure period, 3D numerical modeling is conducted. The soil is modeled with 3D-Solid material. The slurry-trench size is above-mentioned. The model size is 12m×9m×48m. The dynamic load is simplified as sinusoidal load as shown in Fig.5 whose cycle is 1s and the value is G±5%G. Viscoelastic artificial boundary is set at the fourvertival sides and the bottom of the model to simulate the radiation damping of continuum. With the damping, the scattered wave made by the structure and load goes through the boundry without rebounding And the model domain can be smaller thereby to reduce the computing time. The model is shown in Fig.6.



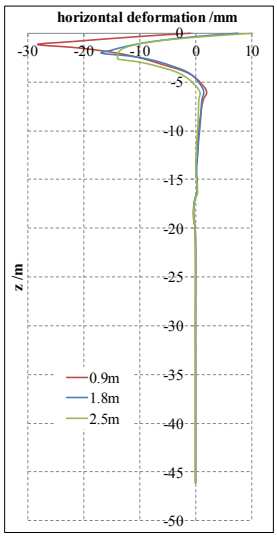


Fig.6 FEM model Fig. 7 Horizontal deformation of trench centerline with different guide wall depth

Pick the centerline of the trench wall (the intersecting line of cross-section A-A and the trench wall on load side.) as the object. With the dynamic load, the trench wall tilts towards the trench(see Fig.7). The influence range is from the ground surface to 6m below, which is similar to the static load situation. As shown in Fig.7, with the deepening of the guide wall, there shows a reduction of the horizontal deformation. When the depth changes from 0.9m~1.8m and 1.8m~2.5m, the deformation reduces 35.7% and 16.7% respectively. We can assume that there is an optimal guide wall depth *h*. When the guide wall is deeper than *h*, the deformation of trench wall would decrease but with a small amplitude. In practice, the guide wall shall be reasonably determined based on soil condition and surrounding environment to fulfill the balance between the effect and cost.

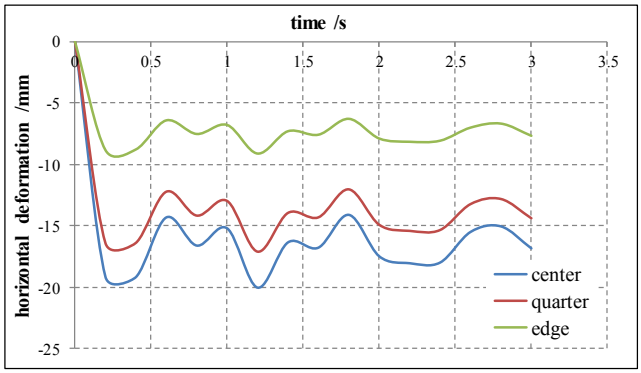

Fig.8 Horizontal deformation of typical points on trench wall

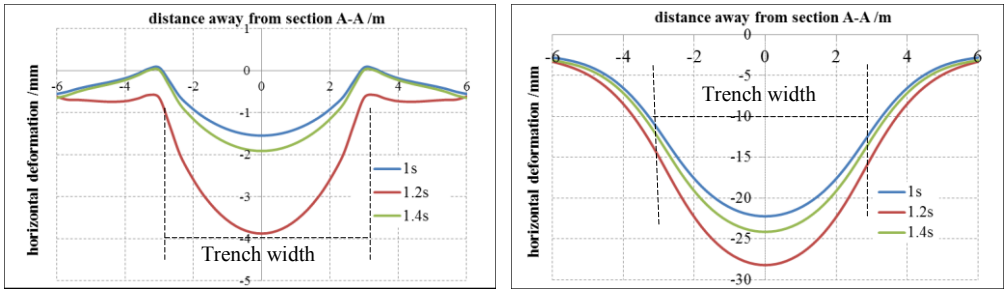
To investigate the response characteristics of trench wall deformation with time, three typical points are picked out. They are of the same elevation and respectively locate at the center of the trench wall(a), 1/4 trench width away from the centerpoint(b) and at the edge of the trench(c). Their deformations along with the loading time are shown in Fig.8. The deformation curves follow the same rule but of different values. At the beginning of the loading, the deformation develops linearly towards the trench and then fluctuates at a magnitude level.

The nearer to the centerline of the trench, the larger deformation occurs, which ss easily found in Fig.9. The instant deformation of the horizontal lines 0.9m and 1.8m below the ground is shown in Fig.9. At the edge of the trench segment at -0.9m, there is a border of the guide wall and the surrounding soil. So there is a sudden change. The deformation along the trench width makes a tank towards the trench similar to the Peck subsidence tank. The characteristic of horizontal deformation of trench wall under dynamic loads shall be described with Peck subsidence formula if necessary.



a) -0.9m b) -1.8m

Fig. 9 Horizontal deformation of trench wall cross-section in different depth

The numerical analysis of trench wall by simplifying the machine weight as static and dynamic load shows that the change caused by the machine mainly occurs in the superficial layers. The influence recesses rapidly along the soil down. The result follow the law obsevered in the centrifuge test by W. Powrie and C.Kantartzi[6] and the elasoplastic FEM analysis by P. Oblozinsky[7]. Instability in upper layers is the main pattern of instability especially under three-dimension conditions.

**Movement of the grab**

Trenches become deeper and several crawls are necessary to make a trench segment. The grab has to move up and down frequently. The moving velocity will cause the flow of the slurry. Moving up arouses negative pressure on the trench wall and moving down causes positive pressure. Repeated movements may greatly impact the slurry wrap on the surface of the trench wall and make adverse effects on local stability of the trench.

The paper deals with the effect of working technique as a hydromechanics problem. If slurry flow changes from laminar flow to turbulent flow, the risk of slurry wrap being damaged and local instability will increase sharply. Ref.8 and 9 analyzed the effect of velocity of grab movement $v_w$ on the stability of trench wall. The velocity of slurry flow is calculated with Eq.1.

$$v_s = \frac{A_w v_w}{A_k - A_w} \tag{1}$$

The equivalent hydraulic diameter of slurry flow is as Eq.2

$$D = \frac{4(A_k - A_w)}{p_{kw}} \tag{2}$$

Where $A_k$-$A_w$ is the cross-section area of slurry flow; $P_{kw}$ is the wetted perimeter of slurry flow. The Hedstrom number can be calculated with Eq.3.

$$H_e = \frac{\tau_s D^2 \rho_s}{\mu_s^2} \tag{3}$$

The corresponding Reynolds number is as Eq.4.

$$Re = \frac{v_s D \rho_s}{\mu_s^2} \tag{4}$$

Where $\rho_s$ means the fluid density， t/m$^3$; $v_s$ means the average flow velocity, m/s; $\mu_s$ means the fluid dynamics viscosity, kPa·s.

By the relationship between friction coefficient and Hedstrom number together with Reynolds number of Bingham fluid, we can figure out whether the slurry flow is laminar flow or turbulent and then determine the moving speed of the grab.

The excavation orifice diameter of a 1m-diameter grab can generally reach 1.2m. Assume that the grab moves down the trench at 1m/s, the flow speed of slurry will be 2.27m/s according to Formula 1 and 2. The equivalent hydraulic diameter is 0.2m. As for the slurry, assume $\tau_s$=6.7×10$^{-3}$kPa, $\mu_s$ =8×10$^{-6}$ kPa·s, $\rho_s$ =1.03t/m$^3$ with Eq.3 and 4, the Hedstrom number and the Reynolds number are 4.32×106 and 5.8×104 respectively. The critical corresponding Reynolds number from laminar to turbulent is 5.0×104. If the moving velocity of the grab is over 1m/s, the slurry flow may turn into turbulent flow[9]. Thus, the operation velocity of the trench cutter machine shall be restricted into a reasonable level to ensure safety.

## Conclusions

Trench formation equipment plays a remarkable role in trench excavation. In this paper, a thorough investigation is carried out of how the formation machine works and its effect on the trench wall stibility and deformation.The overload and workmanship of the formation machine are both negative.

The 3D failure mechanism is derived from the 3D FEM based on strength reduction method. It shows that the additional load on ground surface mainly influence the range of 6m below ground surface, namely superficial layer instability. Static and dynamic analysis reach to the same conclusion. In the background project in Ningbo, the maximum deformation caused by formation equipment is 20mm. The horizontal deformation curve across the trench segment is similar to the Peck subsidence tank. The analysis method and results shall be a reference for similar projects.

The grab's moving up and down in slurry may lead the slurry flow into turbulence. The turbulent flow may greatly impact the trench wall and take the slurry wrap away from the trench sidewall. It makes a risk of local instibility. For safe sake, assume the laminar flow is necessary. According to the Bingham fluid theory, the reasonable velocity of the grab movement is 1m/s.

**Keywords:** moisture-elasticity, inhomogeneity, induced deformations, thick-walled shells, moisture transfer, soil, clay

**Abstract**: The numerical-analytical solution of the axisymmetric problem of moisture-elasticity for hollow spherical soil massive is provided. We consider the steady-state water transfer. Inhomogeneity of the array due to the dependence of the deformation modulus on the soil moisture. Stress state of the array caused by forced deformations and uneven pressure rebuff of the soil. The method for solving non-axisymmetric problems with radial inhomogeneity in polar coordinates is described. Diagrams on the stress fields in homogeneous and inhomogeneous formulations of the problem are provided. It describes a method of calculating radial inhomogeneous axisymmetric problem of theory of elasticity for thick-walled spherical shell.

## Introduction

Typical problem of moisture-elasticity is the problem of pipeline rupture. In the present study we considered this problem for an inhomogeneous spherical soil array. At relatively low depth of cavity the pressure of the ground on the outer surface of array is uneven. The paper investigates the effect of external pressure and mass forces on the stress state of a spherical array with cavity. We consider the problem of pipeline rupture at a depth *H*. Assuming that the water extends from the hole along the spherical surface we consider an array of spherical radius *b at condition a<<b<H,* where *a* – radius of water source. Thus pressure on the outer surface of the array is a variable and the unevenness of pressure is balanced by the mass forces $\gamma$ (Fig. 1).

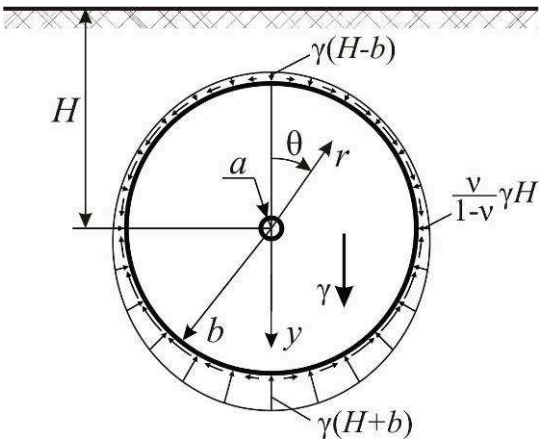

Fig. 1 The settlement scheme

## Moisture transfer

Problem of the distribution of moisture in solids is described by Fick's second law [1, 2] and corresponds to the diffusion process. We have considered a stationary process of moisture conductivity with Dirichlet boundary conditions:

$$\frac{\partial^2 w}{\partial r^2}+\frac{2}{r}\cdot\frac{\partial w}{\partial r}=0;\quad r=a:\quad w=w_s;\quad r=b:\quad w=w_0. \tag{1}$$

Here $w_s$ – moisture of saturated soil, $w_0$ – natural moisture of soil. The solving of problem (1) has a form:

$$w(r)=\frac{a\cdot b\cdot(w_s-w_0)}{b-a}\cdot\frac{1}{r}-\frac{a\cdot w_s-b\cdot w_0}{b-a}. \tag{2}$$

It is known that in many soils (clay, loess, peat) at moistening the Deformation modulus is reduced [3]. For example for clay this dependence can be approximated by the function:

$$E(w) = E_0 \cdot (w/w_s)^{-\alpha}, \tag{3}$$

where $E_0$ – deformations modulus for de-moisturized clay. Below we use next values: $E_0 = 19.88$ MPa; $w_s = 0.363$; $\alpha = 2.4$.

**Calculation of stress state**

The problem is solved in spherical coordinates $r, \theta, \varphi$. In view of the axial symmetry with respect to the axis $y$ (Fig. 1), we assume $w = 0$, $\frac{\partial}{\partial \varphi} = 0$. From the Duhamel-Neumann relations we obtain expressions for the stresses:

$$\begin{aligned}
\sigma_r &= \lambda \cdot \left( \frac{\partial u}{\partial r} + \frac{2u}{r} + \frac{1}{r} \cdot \frac{\partial v}{\partial \theta} + \frac{v}{r} \cdot \operatorname{ctg}\theta \right) + 2\mu \cdot \frac{\partial u}{\partial r} - 3K \cdot \varepsilon_f; \\
\sigma_\theta &= \lambda \cdot \left( \frac{\partial u}{\partial r} + \frac{2u}{r} + \frac{1}{r} \cdot \frac{\partial v}{\partial \theta} + \frac{v}{r} \cdot \operatorname{ctg}\theta \right) + 2\mu \cdot \left( \frac{1}{r} \cdot \frac{\partial v}{\partial \theta} + \frac{u}{r} \right) - 3K \cdot \varepsilon_f; \\
\sigma_\varphi &= \lambda \cdot \left( \frac{\partial u}{\partial r} + \frac{2u}{r} + \frac{1}{r} \cdot \frac{\partial v}{\partial \theta} + \frac{v}{r} \cdot \operatorname{ctg}\theta \right) + 2\mu \cdot \left( \frac{u}{r} + \frac{v}{r} \cdot \operatorname{ctg}\theta \right) - 3K \cdot \varepsilon_f; \\
\tau_{r\theta} &= \mu \cdot \left[ r \cdot \frac{\partial}{\partial r}\left( \frac{v}{r} \right) + \frac{1}{r} \frac{\partial u}{\partial \theta} \right]; \quad \tau_{r\varphi} = 0; \quad \tau_{\theta\varphi} = 0.
\end{aligned} \tag{4}$$

Here $\lambda, \mu$ – Lame parameters, $K$ – the bulk modulus, $\varepsilon_f$ – forced (humidity) strains. The latter are determined by the formula

$$\varepsilon_f = \int_{w_0}^{w} \beta(w) dw, \tag{5}$$

where $\beta$ – swelling coefficient. If $\beta$=const [3] $\varepsilon_f = \beta(w - w_0)$.

Substituting (4) into the equations of equilibrium we obtain an analogue Lame equations but unlike them having dependence of mechanical characteristics on the coordinates. If we consider only the radial inhomogeneity of the material, these equations take the form:

$$\begin{aligned}
&\mu \cdot \nabla^2 u + 3(\lambda + \mu) \cdot \frac{\partial \varepsilon_{av}}{\partial r} - \frac{2\mu}{r^2} \cdot \left( u + \frac{\partial v}{\partial \theta} + v \cdot \operatorname{ctg}\theta \right) + 3\frac{\partial \lambda}{\partial r} \cdot \varepsilon_{av} + 2\frac{\partial \mu}{\partial r} \cdot \frac{\partial u}{\partial r} - 3\frac{\partial}{\partial r}(K \cdot \varepsilon_f) + R = 0; \\
&\mu \cdot \nabla^2 v + \frac{3(\lambda + \mu)}{r} \cdot \frac{\partial \varepsilon_{av}}{\partial \theta} + \frac{\mu}{r^2} \cdot \left( 2\frac{\partial u}{\partial \theta} - \frac{v}{\sin^2 \theta} \right) + \frac{\partial \mu}{\partial r} \cdot \left( \frac{1}{r} \cdot \frac{\partial u}{\partial \theta} + \frac{\partial v}{\partial r} - \frac{v}{r} \right) - \frac{3}{r}\frac{\partial}{\partial \theta}(K \cdot \varepsilon_f) + \Theta = 0.
\end{aligned} \tag{6}$$

We seek a solution of (6) as expansions of functions $u$ and $v$ in series of Legendre polynomials [4]:

$$u(r,\theta) = \sum_{n=0}^{\infty} u_n(r) \cdot P_n(\cos\theta); \quad v(r,\theta) = \sum_{n=1}^{\infty} v_n(r) \cdot \frac{\partial P_n(\cos\theta)}{\partial \theta}. \tag{7}$$

Volume loads and forced deformations included in the system of equations (6)can also be expanded in Fourier series in Legendre polynomials:

$$R(\theta) = \sum_{n=0}^{\infty} R_n \cdot P_n(t); \quad \Theta(\theta) = \sum_{n=1}^{\infty} \Theta_n \cdot \frac{\partial P_n(t)}{\partial \theta}; \quad \varepsilon_в(r,\theta) = \sum_{n=0}^{\infty} g_n(r) \cdot P_n(t), \tag{8}$$

where the expansion coefficients $R_n$, $T_n$ and $g_n$ are defined by:

$$R_n = \frac{2n+1}{2}\int_{-1}^{1} R(t)P_n(t)dt; \quad \Theta_n = \frac{1}{\int_{-1}^{1}\left(\frac{\partial P_n(t)}{\partial\theta}\right)^2 dt}\int_{-1}^{1}\Theta(t)\frac{\partial P_n(t)}{\partial\theta}dt; \quad g_n(r) = \frac{2n+1}{2}\int_{-1}^{1}\varepsilon_{\text{в}}(r,t)P_n(t)dt. \tag{9}$$

After the series expansions of all components of the system (6) we can obtain a number of systems of two ordinary differential equations for the functions $u_n(r)$ and $v_n(r)$ for each $n$:

$$(\lambda+2\mu)\cdot u_n'' + \left[\frac{2(\lambda+2\mu)}{r} + (\lambda+2\mu)'\right]\cdot u_n' - \left[\frac{n\cdot(n+1)\cdot\mu + 2(\lambda+2\mu)}{r^2} - \frac{2\lambda'}{r}\right]\cdot u_n +$$

$$+ n\cdot(n+1)\cdot\left[-\frac{\lambda+\mu}{r}\cdot v_n' + \left(\frac{\lambda+3\mu}{r^2} - \frac{\lambda'}{r}\right)\cdot v_n\right] - 3(K\cdot g_n)' + R_n = 0; \tag{9}$$

$$\mu\cdot v_n'' + \left(\frac{2\mu}{r} + \mu'\right)\cdot v_n' - \left[n\cdot(n+1)\cdot\frac{\lambda+2\mu}{r^2} + \frac{\mu'}{r}\right]\cdot v_n + \frac{\lambda+\mu}{r}\cdot u' + \left[\frac{2(\lambda+2\mu)}{r^2} + \frac{\mu'}{r}\right]\cdot u_n + \Theta_n = 0.$$

Given that $\varepsilon_{\text{f}} = \varepsilon_{\text{f}}(r)$; $R = -\gamma\cdot\cos\theta$; $\Theta = \gamma\cdot\sin\theta$ in (9) we will have:

$$g_0(r) = \varepsilon_{\text{f}}\cdot P_0(t) = \varepsilon_{\text{f}}(r); \quad R_1 = -\gamma; \quad \Theta_1 = \gamma, \tag{10}$$

Others $g_i = R_i = \Theta_i = 0$.

The boundary conditions in stresses can be written as:

$$r = a: \quad \sigma_r = 0; \quad \tau_{r\theta} = 0;$$

$$r = b: \begin{cases} \sigma_r = -\gamma\cdot(H - b\cdot\cos\theta)\left(\dfrac{\nu}{1-\nu} + \dfrac{1-2\nu}{1-\nu}\cdot\cos^2\theta\right); \\ \tau_{r\theta} = \dfrac{\gamma}{2}\cdot(H - b\cdot\cos\theta)\dfrac{1-2\nu}{1-\nu}\cdot\sin 2\theta. \end{cases} \tag{11}$$

Presenting stress (4) in the form of series (7) (11), we obtain

at the boundary $r = a$: $\sigma_{r,n}^a = 0$; $\tau_{r\theta,n}^a = 0$, $n = 0, 1, 2, 3$;

at the boundary $r = b$:

$$\sigma_{r,0}^b = -\frac{1+\nu}{1-\nu}\cdot\frac{\gamma\cdot H}{3}; \quad \sigma_{r,1}^b = \frac{3-\nu}{1-\nu}\cdot\frac{\gamma\cdot b}{5}; \quad \sigma_{r,2}^b = -\frac{1-2\nu}{1-\nu}\cdot\frac{2\gamma\cdot H}{3}; \quad \sigma_{r,3}^b = \frac{1-2\nu}{1-\nu}\cdot\frac{2\gamma\cdot b}{5};$$

$$\tau_{r\theta,1}^b = \frac{1-2\nu}{1-\nu}\cdot\frac{\gamma\cdot b}{5}; \quad \tau_{r\theta,2}^b = -\frac{1-2\nu}{1-\nu}\cdot\frac{\gamma\cdot H}{3}; \quad \tau_{r\theta,3}^b = \frac{1-2\nu}{1-\nu}\cdot\frac{2\gamma\cdot b}{15}.$$

Thus the final solution has the form $u = \sum_{n=0}^{3} u_n(r)\cdot P_n(t)$; $v = \sum_{n=1}^{3} v_n(r)\cdot\frac{dP_n(t)}{d\theta}$.

**Results and discussion**

Numerical solution of the system (9) with boundary conditions (11) was implemented in the software package Matlab. In calculations other than the initial data specified after equation (3) we used the following values: $a$ = 0.25 m; $b$ = 2.5 m; $H$ = 5 m; $\gamma_s$ = 26.95 kN/m$^3$; $\beta$ = 0.6; $\nu$ = 0.4. Fig. 2 shows the distribution of stresses $\sigma_r$ and $\sigma_\theta$ for the characteristic values of the angle $\theta$. The curves $\sigma_\varphi$ is almost completely coincide with the stresses $\sigma_\theta$ that usually happens for spherical bodies in problems with central symmetry. In turn, the shear stresses are much smaller

than normal stresses. Computations have shown that the highest values $\tau_{r\theta}$ do not exceed 0.03 MPa, which is two orders of magnitude less than the mean values of normal stresses. The dotted lines in Fig.2 show the curves corresponding to the homogeneous array for the average value of the deformation modulus $E_{\text{cp}} = \int_a^b E(w(r))dr/(b-a) = 64.68$ MPa at $\theta = 45^\circ$.

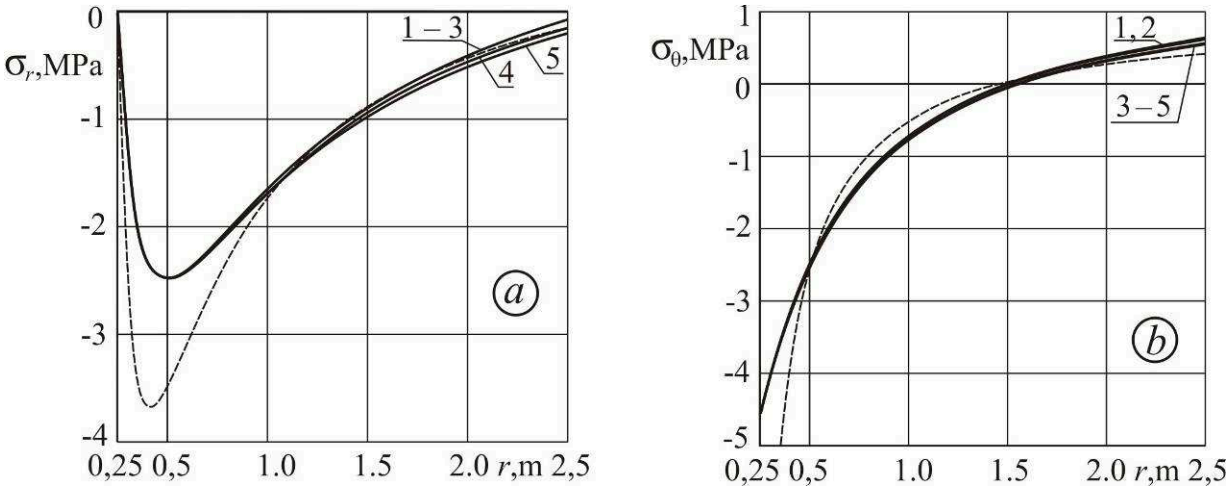

Fig. 2. Distribution of the stresses $\sigma_r$ (*a*) and $\sigma_\theta$ (*b*) along the radius for different values θ:
$1 - \theta = 0$; $2 - \theta = \pi/4$; $3 - \theta = \pi/2$; $4 - \theta = 3\pi/4$; $5 - \theta = \pi$.
—— considering inhomogeneity; - - - - excluding inhomogeneity.

**Conclusions**

Comparing values of the stresses $\sigma_r$ and $\sigma_\theta$ for the inhomogeneous ground (solid lines) at different directions (different $\theta$) we can note that they are almost identical. Small differences are near $r = b$. These differences are due to different soil pressure on the outer surface of the array. In general, the contribution the account of influence of pressure on the stress state near the cavity is negligible compared to the stresses caused by the swelling soil. Hence we can conclude that the problem can be solved in a simpler - centrally symmetric formulation excluding the variability of soil pressure.
Particular attention should be paid to Influence of Inhomogeneity on the stresses. Tear the outer contour of array there are tensile stresses that can be dangerous for soil.

**Keywords:** Landslides, Slope Monitoring, Software Design, Visual Basic.

**Abstract.** The slope monitoring is an important part of the slope engineering. Through the reasonable monitoring, the engineers can get all kinds of information and the state of slope stability; provide scientific basis for the forecast about instability. Facing various methods and diverse information, the engineers can not consult books and make project efficiently. Based on the objective of safe construction, a database system including a comprehensive range of information about monitoring design, construction technology and equipment is built by achieving the design ideas of rapid and concise. By utilizing the development tools of Visual Basic and database platform of Access, the monitoring guidance system is developed with the consultation, editing, and analysis functions. The system provides a complete slope monitoring information platform to guide the engineering staff to quickly and accurately develop the design of slope monitoring.

## Introduction

Slope is formed in the natural gravity or the human action of soil or rocks, and is one of the most basic geological environments of human engineering activities, as well as the most common form of engineering construction [1]. As one of the three global major geological disasters (earthquakes, floods, landslides and mudslides), the collapse of slope has the frequent, widespread and catastrophic features and is a serious threat to national property and people's lives [2]. To ensure the security and stability of the slope, the monitoring must be carried out during the construction and operation of slope engineering [3]. Through the reasonable monitoring, the engineers can get all kinds of information and the state of slope stability [4].

Facing various methods and diverse information, the engineers can not consult books and make project efficiently. Based on the objective of safe construction, a database system including a comprehensive range of information about monitoring design, construction technology and equipment is built by achieving the design ideas of rapid and concise. By utilizing the development tools of Visual Basic and database platform of Access, the monitoring guidance system is developed with the consultation, editing, and analysis functions. The system provides a complete slope monitoring information platform to guide the engineering staff to quickly and accurately develop the design of slope monitoring.

## The guidance system composition

The core of this system design is to establish a comprehensive slope monitoring information database and rapidly and accurately guide the slope monitoring. In the guidance system, database system that has the largest amount of information is the core module and the most important part of the slope monitoring application. Database system consists of four modules: slope type module, monitoring content module, equipment module, and specification file module. The interface of the system is shown in figure1.

**Slope type module.** According to the thickness of slope, the scale of slope, hydrological conditions, structural types of rock mass, the deformation and failure modes of slope, we classify different types of slope in detail, recommend monitoring items and introduce the engineering examples.

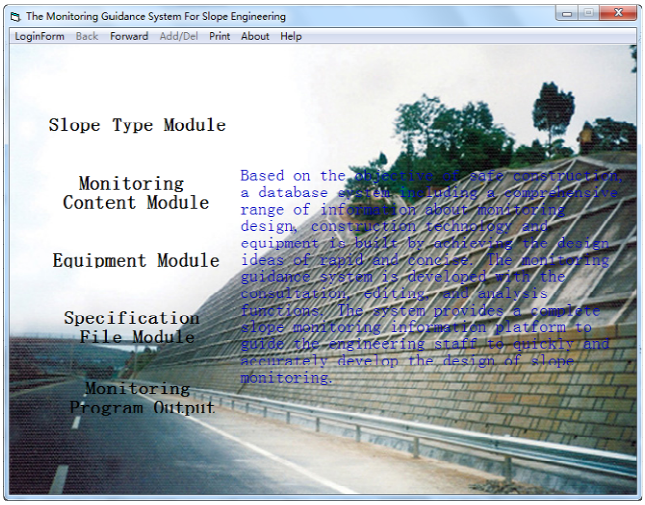

Fig. 1 The interface of the system

The slope failure classification and its influencing factors is the basis of slope treatment. Different slope failure types have the corresponding different monitoring method. According to the movement forms soil slope deformation and failure can be divided into collapse, overturning and sliding, lateral extension, flow and complex. The main types of rock slope failure includes wedge landslide, circular arc sliding surface landslide, the plane sliding of the landslide, collapse, accumulation landslide and so on. Therefore, this system is mainly described all these types of slope damage and monitoring techniques in detail [5]. The classification of slope type is shown in figure 2. And introduce of tractive slope is shown in figure 3.

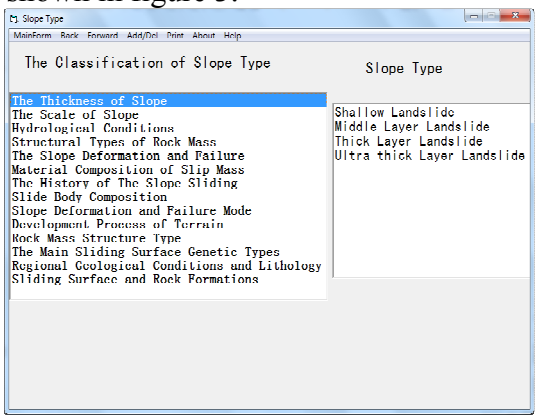

Fig .2 The classification of slope type

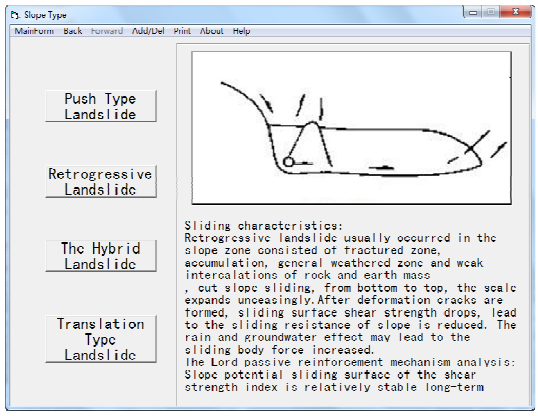

Fig .3 The introduce of tractive slope

**Monitoring contents module.** Geology factors are the foundation of creating landslides; and the non-geological factors will induce and speed up the development of landslides. Therefore, during slope monitoring, we need to grasp the main geological factors, and to carry out specific analysis on various inducing factors. Based on this view, monitoring content module divides the main monitoring items, such as the displacement monitoring, stress and strain monitoring, subsidence monitoring, groundwater monitoring [6].

In monitoring method, the system shows the measured parts, measuring point arrangement and monitoring period, monitoring frequency and early warning system and so on.

**Equipment module.** At present a lot of techniques and methods are used in the slope safety monitoring, from the traditional total station, inclinometer tube, pressure gauge, rain gauge and displacement meter, to the new type of GPS, TDR, laser range finder and so on [7].

So this equipment module introduces primarily detection equipment which has been widespread used in monitoring. This module also shows each instrument appearance, function, method of

application, manufacturer, and instrumental assessment. CX-6C fiber-optic gyroscope is introduced in figure 4.

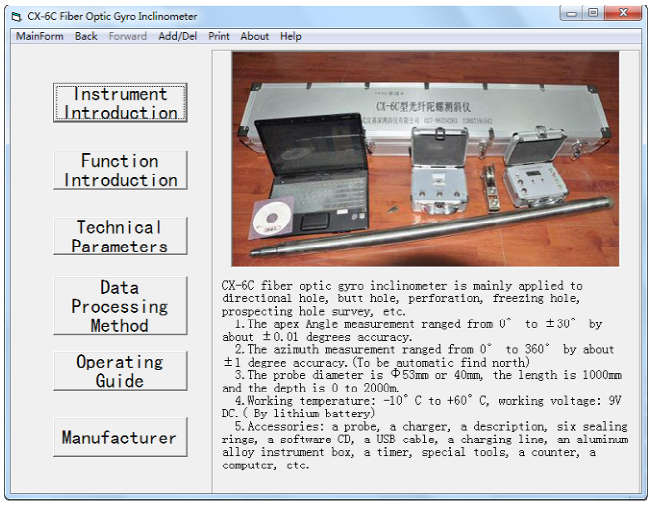

Fig. 4 The introduce of CX-6C fiber-optic gyroscope

**Specification file module.** We collected various specifications and regulations to make the users manage the download tasks more conveniently. And the system provides the monitoring program output and print to help engineers.

## Engineering application

Chaancun super-huge landslide in Dalian City of Liaoning Province was accelerating to slide since 2006. The human engineering activities led to the partial resurrection of the old landslide, and then the new landslide formed. The Chaancun landslide is a trust load caused landslide.

According to the collected landslide information, this system software recommends some monitoring programs and through the comparison with monitoring programs in practical engineering which shown in table 1. We can see some monitoring projects, equipment, and many other categories is approximately same, so the system has good guidance, auxiliary function and practical value. But some of the projects are not given, so this system is not perfect, which also needs follow-up improvement.

Table.1 Correlation Programs

| Monitoring contents | The actual monitoring programs | the system recommendation |
|---|---|---|
| The surface monitoring | Displacement monitoring of landslide surface (Scaling meter monitoring, GPS and total station monitoring) | The surface deformation monitoring (total station, theodolite, telescopic, GPS) |
| displacement monitoring | Deep displacement monitoring | Deep displacement monitoring |
| The water monitoring | Rainfall monitoring | Environmental factors monitoring(Measuring rainfall) |
| The pressure monitoring | Anti-slide pile rock pressure monitoring | |
| Hydrological monitoring | Groundwater dynamic monitoring | Hydrological monitoring |
| Others | change the surface crack, human engineering activities | Seam underground deformation monitoring |

## Conclusions

(1) In the face of all kinds of slope monitoring methods and monitoring information, to improve labor productivity, the author who utilizes the development tools of Visual Basic and database platform of Access, develops the monitoring guidance system for slope engineering with characteristics of reliability, versatility and scalability.
(2) The establishment of this system has the Open permissions, so engineers can create accounts; add new information of engineering tests. The system provides a complete slope monitoring information platform to guide the engineering staff to quickly and accurately develop the design of slope monitoring.
(3) The engineering application shows that the system has a beneficial effect on guiding engineering monitoring project, determining the monitoring scheme. But this system information is still insufficient, and the function is not perfect, so it still need to improve in the future.

# The application of BP artificial neural network in geotechnical engineering

Na Zhao

Department of Construction Engineering, Jinan Engineering Vocational College, Jinan, China

zhao_na00@163.com

**Keywords:** Time sequence; Forecasting; BP artificial network

**Abstract.** Based on MATLAB, the article apply BP artificial neural network theory on the forecasting problem of time sequence in geotechnical engineering, and find it is an effecting way to solve the forecasting problem of time sequence in geotechnical engineering.

## Introduction

Mechanical behavior of geotechnical engineering is a very complex system. The stress state of the whole system and rock mechanical properties are unclear. [1] However, a good mathematical model can correctly reflect the real relationship between the input (output) and the state of the real system. The artificial neural network is just to meet these characteristics. Artificial Neural network algorithm does not have superiority compared with the classical, but a distinct advantage when the conventional methods can not solve or poorly. It is often an effective tool especially on the mechanism question and laws do not understand, or the system can not be expressed with mathematics formula expressing. The artificial neural network can find rules contained in samples through the study and analysis of samples. Provided by MATLAB toolbox for professional field, users can focus on algorithm, and complete the programming with a few lines of a simple statement.

## Basic Principles

BP artificial neural network consists of input nodes, output nodes, and one or more layers of hidden nodes. The guiding ideology of network learning is the correction in the network weights ($W_{ij}$, $T_{li}$) and threshold (θ), so that the error function (E) along the gradient descent. Three layer BP artificial neural networks are represented as input nodes $X_j$, hidden nodes $Y_j$, and output nodes $O_l$. The network weight between the input nodes and hidden nodes is $W_{ij}$ the weight between the hidden nodes and output nodes is $T_{li}$. When the desired output of the output node is $t_l$, BP artificial neural network model computation formula is:

The hidden nodes output formula is:

$$y_i = f(\sum_j w_{ij} x_j - \theta_i) = f(net_i)$$
$$net_i = \sum_j w_{ij} x_j - \theta_i \quad (1)$$

The output node calculating formula is:

$$o_l = f(\sum_i T_{li} y_i - \theta_l) = f(net_l)$$
$$net_l = \sum_i T_{li} y_i - \theta_l \quad (2)$$

The weight of output layer correction formula is:

$$T_{li}(k+1) = T_{li}(k) + \eta\delta_l y_i$$
$$\delta_l = (t_l - o_l)\cdot o_l \cdot (1 - o_l) \quad (3)$$

The common transfer functions in MATLAB are Tansig, logsig and purelin. As an output layer, linear function (purelin) output value maybe any size, so the linear function can be used as a transfer function between the hidden layer and output layer in tunnel engineering time series prediction.

**The realization of MATLAB neurons**

The initial weights and thresholds of neurons are 0. The artificial neural network can be trained after the initialization of weights and threshold. During the training, network weights and threshold should be adjusted constantly to reduce the value of network performance function (net.perform.fcn), so that it reaches the predetermined requirements. The default value of the artificial neural network performance function is the MSE (network output and target output mean square error). BP artificial neural network minimizes the network performance function by calculating of the performance function gradient, and then adjusts the weights and threshold along the negative gradient direction.

The k-th loop adjustment formula:

$$x_{k+1} = x_k - \alpha_k g_k \quad (4)$$

Where:

$x_k$ ——the current weights and thresholds,

$g_k$ —— the current gradient,

$\alpha_k$ —— the learning rate.

To train the network by using the momentum of gradient descent function is not only faster convergence rate and the introduction of a momentum, but also effectively avoids local small problems in the network training.

$$\Delta W(k+1) = -a_k g_w(k) + mc \times \Delta W(k-1)$$
$$\Delta\theta(k+1) = -a_k g_b(k) + mc \times \Delta\theta(k-1) \quad (5)$$

Where:

$g_w(k)$, $g_b(k)$——the weights and threshold gradient of current performance function,

$a_k$——the learning rate,

$mc$——the momentum coefficient，value between 0 ~ 1.

**Engineering applications**

The rock classification surrounding Guanyin Temple tunnel of Yunfang highway is more, the change is much. As the density of exploration is limited, so that the actual tunnel rock classification may be different with the rock information provided by survey report used when the design, and could be occur many cases like the bad geological condition and surrounding rock large deformation which can not be proved. Tunnel structure is the outcome of combined action of surrounding rock and tunnel support. In order to give full play to the self bearing capacity of surrounding rock on the premise of rock and support safety, and to achieve the purpose of the

security in the economic and reasonable support conditions, the site must be achieve information construction by monitoring and measuring.

Monitoring group conducted a month of ZK175 +800 uninterrupted continuous observations, and forecasted by input BP artificial neural network after inputting new data everyday. Through the analysis of the dynamic data and forecast for a few days, the group analyzed surrounding rock stress change and forecast the future situation, and then got the following data in Table 1.

Table 1 ZK175+800 section peripheral displacement measurement value

| time ( d ) | value ( mm ) | time ( d ) | value ( mm ) | time ( d ) | value ( mm ) |
|---|---|---|---|---|---|
| 1 | 0.250 | 10 | 1.778 | 19 | 1.870 |
| 2 | 0.510 | 11 | 1.793 | 20 | 1.871 |
| 3 | 0.889 | 12 | 1.813 | 21 | 1.878 |
| 4 | 1.222 | 13 | 1.849 | 22 | 1.878 |
| 5 | 1.415 | 14 | 1.871 | 23 | 1.878 |
| 6 | 1.665 | 15 | 1.809 | 24 | 1.880 |
| 7 | 1.599 | 16 | 1.843 | 25 | 1.883 |
| 8 | 1.650 | 17 | 1.854 | 26 | 1.880 |
| 9 | 1.776 | 18 | 1.862 | 27 | 1.882 |

The group fitted the artificial neural network established in the construction process, predicted the later displacement around the tunnel by training the network, and continuously trained network with the emergence of new measurement data. In the process of network learning new data, we found that basic network could found the tunnel peripheral displacement convergence regularity basically. The prediction would be more accurate with the increase of learning data. The 10th, 14th, 20th, 25th days learning prediction error curve as Figure 1.

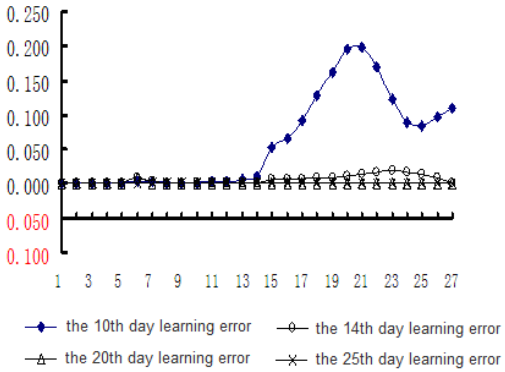

Figure 1 Simulation error curve

## Conclusions

Based on the monitoring data learning and prediction of Guanyin Temple tunnel, the comparison results of the forecast data and subsequent measurement showed that: BP artificial neural network has the characteristics like broad applicability, learning ability, can quickly grasp the regularity between input and output, etc. With the increase of the amount of information and ongoing training, multilayer BP artificial neural network can not only better fitting of the known data, but also has good prediction function. With the help of practical toolbox in MATLAB, the user can no longer consider complex programming process and more focused on algorithms, and more easily achieve the requirements of the different neural networks. In addition MATLAB has a powerful graphics functions, users can directly find the changing rule of the physical system. In short, it is an effective

way for the tunnel measurement data processing and prediction by using the MATLAB-based BP artificial neural network.

**Keywords:** renovation and expansion project; Numerical Simulation; Slope excavation; Stability

**Abstract** Slope stability analysis requires detect and control the stress and strain timely. Familiar with the slope‘s stress and strain changes in excavation process has important guiding significance for the actual construction. In this paper, choose a slope in Guangxi freeway renovation and expansion process as the research object. Use FLAC3D to analysis the stress and displacement simulation results of this slope excavation step by step. Summarize the excavation regular pattern.

## Introduction

Slope excavation and unloading change the stress state of rock, it have a greater impact on the stability. Many scholars do research on excavation and slope stability. Luyu Zhang et al[1] use strength reduction calculated slope safety factor; Haichen Hu[2] use slope software analysis slope excavation stability; Yuhui Xiao et al[3] studied the deformation mechanism of slope excavation; Jian Zeng et al[4] and Hongmei Tang et al[5] use laboratory experiments to simulate the rock slope excavation process; Minghui Yang et al[6] analysis the stress and strain about multi-stage slope excavation simply. On the basis of these studies, analysis of the shear strain increment contours, main stress contours and displacement contours in each excavation step basis on the slope in Guangxi freeway renovation and expansion project. And set up a series of monitoring points to monitor displacements to provide a reference for the actual construction of slope excavation

## Numerical model

The slope is mainly by gravelly silty clay, strongly weathered layer and mid-weathered layer. The main mechanical parameters are shown in Table 1.

Table 1 Mechanical parameters table

| Lithology | Heavy ($KN/m^3$) | Cohesion (KPa) | Angle of internal friction ( ° ) | The bulk modulus （MPa） | The shear modulus （MPa） |
|---|---|---|---|---|---|
| gravelly silty clay | 18.5 | 28 | 18 | 33 | 20 |
| Strongly weathered layer | 21 | 35 | 23 | 370 | 243 |
| Mid-Moderately weathered layer | 24 | 80 | 40 | 5200 | 4800 |

The slope model as shown in Figure 1. It has three level slope(10m each), length of 75m, the rate of three level slopes are: 1:1,1:1.25 and 1:1.5, 2m platform. The model is total of 4147 nodes and 3430 units. Setting horizontal constraints on both side of this model, the bottom set of rigid constraints, fixed all the nodes in the y-direction deformation. The material of this model select Mohr-Coulomb elastic-plastic material, yield criterion using Mohr-Coulomb criterion, the convergence criterion using the relative convergence criterion(Calculate termination when the maximum unbalanced force and the typical internal force ratio is less than 10-5) .

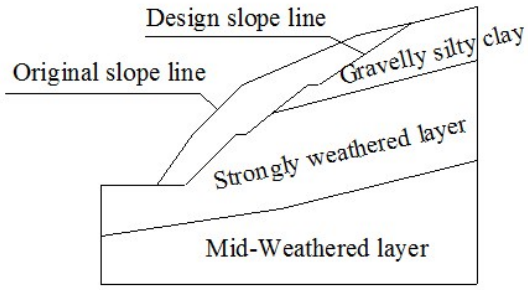

Figure 1 Schematic of slope

## The simulation results analysis

Before the slope excavation, use strength subtraction to get the slope safety factor. It's 1.16,which less than the slope stability boundary value of 1.20. The potential landslide include excavation parts. The slope safety factor is 1.29 after excavation completely, which in a stable state, so only need to take general ecological protection. Analysis the stress and strain contours of three steps of the excavation respectively.

## Numerical analysis of the first step in slope excavation

When the first excavation step is done, the safety factor is up to 1.26. The shear strain increment contour shows that the third layer do not appear the shearing deformation slope area. Potential sliding surface is transfer to the first and second slope. The shear strain increment value of the first level slope midpoint is the largest. Figure 2 and Figure 3 show the third and the first principal stress contour after first step excavation. Only the slope surface presented tensile stress, the maximum tensile stress up to 17.7 KPa in Figure 2. And in Figure 3, the maximum tensile appear in the second slope up to 9 KPa.

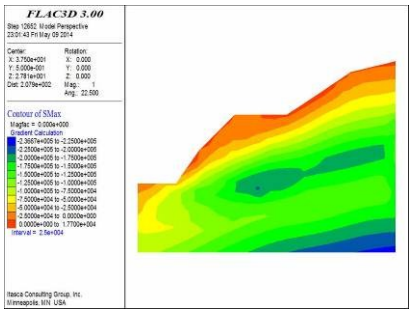

Fig.2 The third principal stress contour

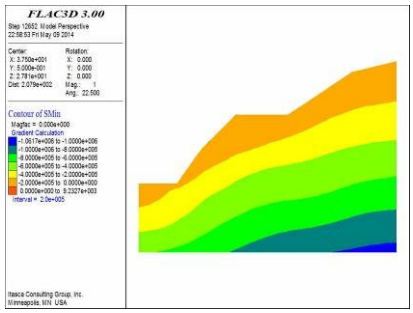

Fig.3 The first principal stress contour

Figure 4 and Figure 5 are the horizontal and vertical displacement contour. And the strain is mainly concentrate on the first and second slope. Figure 4 shows the biggest increment of the shear strain, which the horizontal displacement is also the biggest, up to 18.6cm. From figure 5, top of the second slope area get the maximum 12.5cm, the whole slope top also deformed 4cm.

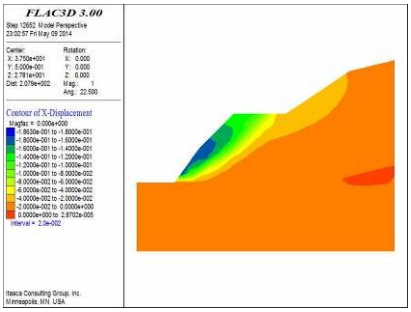

Fig.4 Horizontal displacement contour

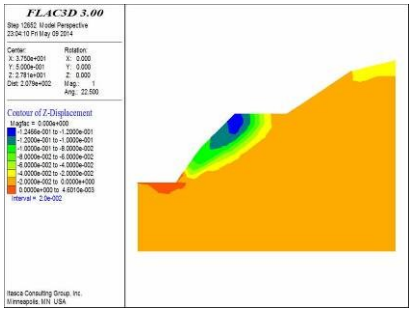

Fig.5 Vertical displacement contour

### Numerical analysis of the second step in slope excavation

When finished the second step excavation, the safety factor of slope increased to 1.42. Internal of the third level slope has appeared shear stress. Figure 6 and Figure 7 show the third and the first principal stress contour after the second step. We can see the maximum tensile stress value is 31.8 KPa appeared in the first and third level from figure 6. And figure 7 show us the maximum tensile stress increased to 46.4 KPa, the distribution is increase too.

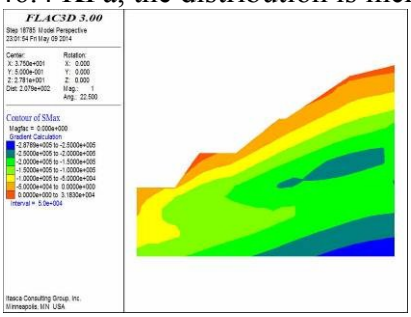

Fig.6 The third principal stress contour

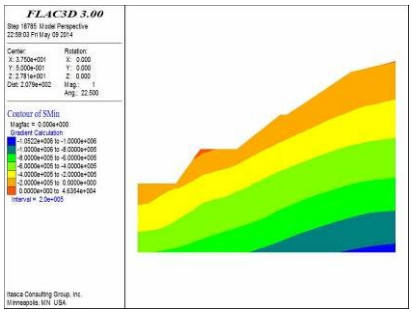

Fig.7 The first principal stress contour

Figure 8 is horizontal displacement contour. It shows bigger displacement area and the maximum 11.5cm appeared in the second and third level slope. It's decreasing in both sides. Figure 9 is vertical displacement contour. Top of the third level slope reaches a maximum value 14.3cm.

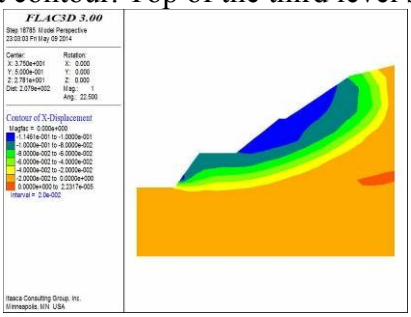

Fig.8 Horizontal displacement contour

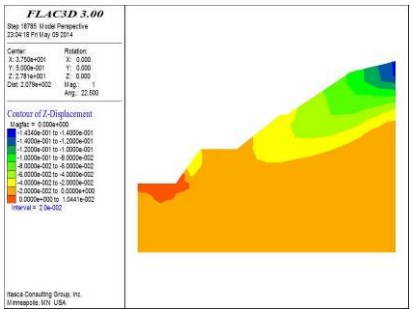

Fig.9 Vertical displacement contour

### Numerical analysis of the third step in slope excavation

The slope safety factor dropped to 1.29 after this step. But it is still larger than the slope stability boundaries. So it doesn't need special supporting. The distribution of shear strain increment and principal stress are the same, but the third principal stress value doesn't. The maximum tensile stress value dropped to 18.6KPa.

Figure 10 and Figure 11 are displacement contours. Figure 10 tells the area of the maximum horizontal displacement move downward, and the value is increased to 18.4cm. The maximum vertical displacement is 19.7cm from figure 11.

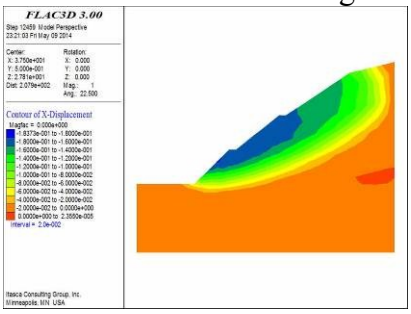

Fig.10 Horizontal displacement contour

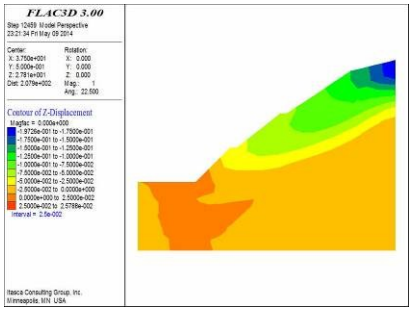

Fig.11 Vertical displacement contour

### Changes in displacement about monitoring points during excavation

Set a monitoring point in the toe and crest and waist of the slope at each level. Also in the top of the whole slope and pavement near the toe set up monitoring points. Figure 12 and Figure 13 are various monitoring points change in slope excavation process.

With the excavation proceeds, the constitutive relation rock mass deterioration, resulting in reduced rock strength and increased deformation. From the view of figure 12, the horizontal displacement of all monitoring points up to the maximum when the excavation is complete. Monitoring points show the shape of a parabola. From the view of figure 13, with the excavation proceeds, displacement of the first to the fifth monitoring points has increase, the sixth to the last monitoring points do not reflect the obvious regular pattern. But they still exhibit resilience characteristics.

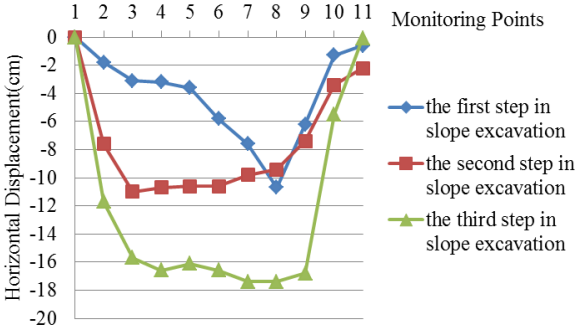

Fig.12 Monitoring points horizontal displacement

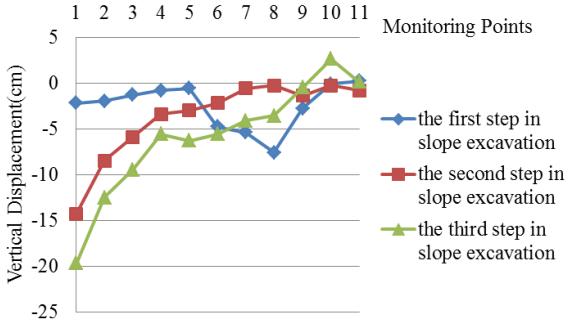

Fig.13 Monitoring points vertical displacement

## Conclusions

(1) Stress in the initial excavation is vary greatly, with the excavation progresses, the stress distribution will stabilize, but the stress of change still occurs.

(2) Strain increases in whole excavation slope. Every excavation will produce a potential sliding surface and horizontal displacement around the surface shear export is much larger. The export is generally appears in the recently completed excavation slope toe or waist. Vertical displacement showed resilience characteristics.

(3)In multi-level slope excavation process, early should be control the original slope stability. Reinforce monitoring the original potential export. In the late should be noticed the completed slope stability. Reinforce monitoring the completed slope toe area and take support measures appropriately.

## Acknowledgement

This project obtained the funding of the scientific research and technology development projects of Guangxi(1298011-2) and Hunan Science and Technology Project (2014FJ3067)

# On Fire Severity of Flammable Gas

WU Wen-zhong

Xi'an University of Science and Technology, China

E-mail: wuwenzhong@tju.edu.cn

**Keywords:** coalmine fire; flammable gas; fire severity; fire severity coefficient

**Abstract.** Flammable gases's fire need more attention in spontaneous combustion study of coalmine. Their premixed combustion is modeled to deduce the corresponding temperature-time function. Basing on this function curve and Simon Ingberg's early reports, their fire severity classification theory is established, including definition and equation of their fire severity, and definition of fire severity coefficient along with calculation of those coefficients of ordinary flammable gases. Applying this theory to a certain coalmine, calculate and audit fire severity of its 6 designed fire scenarios, in servitude to guidelines for fire protection technology there, and references for fire severity comparison among similar coalmines.

## Introduction

Undermine fires, a kind of severe incidents, burn much coal source, and also release flammable gas, to induce gas or coal dust explosions. Every year many such incidents are reported of much property and personnel loss in coalmines[1-3]. However, current research status of mechanism and extinguishing methods of spontaneous combustion of coal mine focus on its spontaneous combustion propensity, temperature rise, and little attention has been paid to flammable gas fire, and few reasonable fire protection measures are taken for the fight against this kind fires during the spontaneous combustion.

At normal Oxygen percent, coal oxidizes with CO, $CH_4$, $C_2H_4$, $C_2H_6$, $C_2H_2$ etc. flammable gases products too. During coal oxidization and temperature rise, CO first appears at 32℃, $C_2H_4$ first appears at 100.9℃[4]. $CH_4$ releases before, during and after mining. US EPA reported that the methane release from coalmine amounts to 8% of total methane release in mankind activity worldwide[5,6].

At undermine, existing CO, $CH_4$, $C_2H_4$, $C_2H_6$, $C_2H_2$ etc. flammable gases, mix with sufficient Oxygen at reasonable temperature, and light to fire or explosion, therefore, except for preventing inner-reason fires, coalmine fire protection should audit CO, $CH_4$, $C_2H_4$, $C_2H_6$, $C_2H_2$ etc. flammable gases fire and their severity, and design fire protection system, in order to hinder or delay severity state coming, and control fire evolution, to ensure miner evacuation success and coal lane structure safety.

We start from a mathematical model for flammable gas premixed combustion, and calculate its temperature-time function; basing on the function and Simon Ingberg's fire severity definition, establish fire severity classification theory for flammable gas, including: calculation equation of its fire severity, definition of its fire severity coefficient and their calculations of common flammable gases; apply this theory to audit flammable fire severity in a certain coalmine, suppose fire protection measures to prevent most severe flammable fires, in servitude to guidelines for fire protection and extinguishing in this mine.

## Temperature-time function for flammable gas premixed combustion

CO, $CH_4$, $C_2H_4$, $C_2H_6$, $C_2H_2$ etc. may mix with Oxygen, and cause fire or explosion lighted by a spark or at enough temperature. Suppose a flammable gas (Fuel, F) mixes with Oxygen (Oxygen, O) in a closed mining area of fixed volume (Fig.1), and burns at appropriate temperature (Temperature, T) into a transient fire[7]. The properties of the gaseous mixture are uniform in the area, and constant and equal specific heats. We adopt a control volume enclosing the burning area of the constant

volume, fixed mass, with ambient temperature, and there exists the following energy conservative equation

$$mc_v \frac{dT}{dt} = \dot{Q}_R - \dot{Q}_L = \alpha t^2 \tag{1}$$

where: $\dot{Q}_L$ -conductive heat loss, $\dot{Q}_R$ -chemical energy release rate of gaseous mixture, $\alpha$ -fire performance coefficient, $kW/s^2$ . And gets temperature-time function for flammable gas premixed combustion

$$T(t) = \frac{\alpha}{3mc_v} t^3 + constant \tag{2}$$

where: $t_0$ -initial time of burning, s; $T_0$ -initial temperature of mixture; $m$ -mass of mixture; $c_v$ -specific heat.

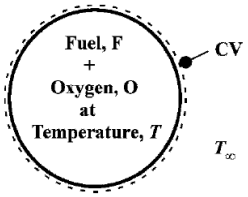

Fig.1 Flammable gas premixed combustion model.

**Flammable gas fire severity**

From the known temperature-time function for its premixed combustion in undermine, we can define and calculate flammable gas fire severity following Simon Ingberg, and then define its fire severity coefficient, and calculate those of common flammable gases out of their thermal property, for reference in auditing fire scenario and designing fire protection system.

In the 1920s Simon Ingberg defined fire severity as an area under the time-temperature curve above a base temperature, and the fire severity in two fires is equal when the areas under their time temperature curves are equal[8-10]. Denote flammable gas fire severity as $R_g$ , fire time $t$ , temperature-time function $T(t)$ as Eq.(2), the base temperature line $t_0 = 0$ , and initial temperature $T_0$=0 , then we have flammable gas fire severity and its coefficient $r_g$ :

$$R_g = \frac{\alpha}{12mc_v} t^4 = r_g t^4 \tag{3}$$

At assumption that a flammable gas performs a fast fire with a stoichiometric reaction and neglected diffusion effects, and those known specific heat capacities of common gases[11,12], specific heat capacity and mass of mixtures of Oxygen and 1mol gases, from Eq.(3) we calculate coefficients of 1mol common flammable gases fire severity as Tab.1.

TABLE 1. FIRE SEVERITY COEFFICIENTS OF COMMON GASES

| Gas[a,b] | $r_g$ (K•s$^{-3}$) | Gas[a,b] | $r_g$ (K•s$^{-3}$) |
|---|---|---|---|
| $H_2$ | 0.084 | CO | 0.083 |
| $CH_4$ | 0.031 | $C_2H_2$ | 0.021 |
| $C_2H_4$ | 0.015 | $C_2H_6$ | 0.012 |
| $O_2$ | 0.183 | | |

a. Normal atmospheric temperature and pressure: 1atm, 25℃; b. Mass of gas is 1mol.

## CASE STUDY: AUDIT FLAMMABLE GAS FIRE SEVERITY IN A CERTAIN COALMINE

Out of a certain coalmine, adopt its coal sample 1500 g for oxidization test at stable 30 ℃ with air flow 50 ml/min and continually rising temperatures, and record those indicative gases release in the process of spontaneous combustion for predicting coal fire[4]:

CO: at 32℃, first appears 5ppm; before 66.5℃, CO releases slowly within 19-135ppm; at 66.5℃, CO jumps to 279ppm; at 73.5℃, CO reaches to 324ppm; inside 73.5-113.4℃, CO release rises greatly from 200ppm to 1300ppm.

$C_2H_4$: first appears at 100.9℃, and releases slowly before 176.8℃, then rises greatly up to 330.61ppm from 199.9℃.

$C_2H_2$: at 262.8℃, first appears 39ppm; at 269.2℃, $C_2H_2$ releases its maximum 75ppm, which drops gradually to 0ppm at 326.3℃.

At 457.0℃, CO, $CH_4$, $C_2H_4$, $C_2H_6$, $C_2H_2$ release 14115, 19928, 270.61, 2906.2, 0ppm respectively.

We calculate and compare fire severity of these gases by Eq.(3) as Tab.2 out of this record with fire time about 50s[13]:

TABLE 2. FIRE SEVERITY COEFFICIENTS OF COMMON GASES IN THE DISCUSSED COALMINE

| Temperature level | fire severity (K•s) |
|---|---|
| 406-440℃ | $R_{C_2H_2} = 7.797\times10^{-7}$ |
| 520-630℃ | $R_{C_2H_4} = 2.841\times10^{-7} > R_{C_2H_6} = 1.969\times10^{-8}$ |
| 641-750℃ | $R_{CO} = 2.733\times10^{-8} > R_{CH_4} = 4.058\times10^{-9}$ |
| >750℃ | $R_{g,\,total} = R_{C_2H_2} + R_{C_2H_4} + R_{C_2H_6} + R_{CO} + R_{CH_4} = 1.115\times10^{-6}$ |

Table 2 shows that fire prevention measures at this coalmine can be divided into two categories: (1) should keep coal temperature below 32℃ to prevent its oxidization releasing flammable gases; (2) after the coal oxidization, should extract gases to deduce the concentrations of those flammable gases, and keep temperature below 406℃ to prevent their ignition.

## CONCLUSIONS

We establish fire severity classification theory for flammable gas, and apply it to audit flammable fire severity in a certain coalmine, for guidelines to fire protection in this coalmine and other coalmines too.

1) The mathematic model for flammable gas mixed combustion is founded, and its fire temperature-time function is derived from the energy conservation law inside this combustion;

2) From this fire temperature-time function and Simon Ingberg's early fire severity definition, fire severity classification theory is established for flammable gas, including definition and equation of its fire severity, and definition of its fire severity coefficient along with calculation of those coefficients of ordinary flammable gases;

3) Applying this theory to a certain coalmine, calculate and audit fire severity of its 6 designed fire scenarios in oxidization. Fire prevention measures at this coalmine directly come from the oxidization test and fire severity calculation of the indicative flammable gases.

**Keywords:** open pit to underground; covered rock; backfill; natural classification.

**Abstract.** The cover of the open pit to underground natural phenomena on the use classification of the mine caving mining ventilation, temperature, dilution and other indicators of ore loss have a more significant impact, but when the coating in the filling to form a reasonable natural grading, domestic research is still in the blank stage. In this paper, the background for the study of Shougang iron ore Xingshan, using theoretical analysis, physical simulation, field trials and other research tools, the coverage of the open pit to underground layer of backfill laws of the natural classification system for in-depth analysis of the results come Miaogou iron waste rock dump using artificial backfill to form a reasonable hierarchical structure and thickness of the natural cover is feasible.

## Introduction

At present there are many methods to form the cover of open pit to underground, to the Miaogou, it is are the most suitable method by backfilleding with waste dump[1,2].

There are mines into underground mining.Zhang Guojian[3] through the experimental confirmed that natural phenomenon of classification is objective existence in loose rock overburden of sublevel caving mining. Based on the loose rock mass characteristics and analysis of flow mechanics theory, Zhang zhijun[4,5]studied the ore loose rock overburden moving law in the process and reveals through physical simulation.The loose body of overburden rock flows naturally graded phenomenon, and then he provided theoretical of gradation composition for the formation of rock overburden.

## Influence factors of cladding backfill natural classification analysis

Backfill powder in the gravitational potential energy and movement will produce natural grading, the degree of natural grading and distribution of grain group will be restricted by the followed factors.

- Influence of the packing of the abandoned and dumping height abandoned
- Back to the filler particle size composition
- Rough and hard degree of the initial slope surface

## Back to the filler natural hierarchical physical simulation experiment research

### *Experimental Model*

Physical model is shown in Fig. 1, and scale model is 1:50.

**Ratio of the sample.**After the screening test material is a mixture of different size stones, the total number of stone 1000kg. Size ratio shown in Table 1.

**Simulation program.**Analog scraper shovels in the model 30m, 40m, 50m elevation backfill material simulation test.

### *Natural Classification Thickness Analysis*

Backfill different thickness grading down unloading height simulation shown in Table 2.

**Fig.1 Test model**

**Table 1 Size ratio of material**

| No. | Particle diameter mm | Percentage sieve | Cumulative percentage sieve |
|---|---|---|---|
| 1 | >20 | 13.40% | 13.40% |
| 2 | 16-20 | 2.80% | 16.20% |
| 3 | 10-16 | 26.00% | 42.20% |
| 4 | 5-10 | 33.00% | 75.20% |
| 5 | 2-5 | 23.20% | 98.40% |
| 6 | <2 | 1.60% | 100.00% |

**Table 2 Backfilling height of the natural grading**

| Backfilling height | | Particle size | | | Particle simulation size | | |
|---|---|---|---|---|---|---|---|
| MH/cm | SH /m | Fine /cm | Medium /cm | Coarse /cm | Fine /m | Medium /m | Coarse /m |
| 60 | 30 | 15.5 | 26 | 18.5 | 7.75 | 13 | 9.25 |
| 80 | 40 | 22 | 37 | 21 | 11 | 18.5 | 10.5 |
| 100 | 50 | 41.5 | 27 | 31.5 | 20.75 | 13.5 | 15.75 |

In the simulation process, Initial backfill poor mobility, natural classification is not obvious. After reaching a certain size, graded phenomenon is very obvious. Down by the backfill unloading height simulation of different thickness grading backfill different tables and pour unloading height simulate the final result can be seen naturally hierarchical classification is divided into three parts, fine-grained, medium-grained, coarse-grained. With the backfill down unloading height increases, the fine and coarse backfill layer thickness showed a rising trend, medium grain backfill layer thickness decreased after the first growth trend.

***Natural Classification Particle Size Analysis***

Physical simulation test backfill height of 50m analogue reverse unloading at 30m, 40m on the basis of, only the natural classification particle size analysis simulation 50m height were analyzed. Backfill naturally graded fine, medium-grained, coarse three-part feature such as shown in Table3-5.

**Table 3 Fine ratio after grading in test**

| No. | Particle diameter mm | Sieve | Percentage sieve | Cumulative percentage sieve |
|---|---|---|---|---|
| 1 | >20 | 26 | 2.60% | 2.60% |
| 2 | 16-20 | 22 | 2.20% | 4.80% |
| 3 | 10-16 | 268 | 26.80% | 31.60% |
| 4 | 5-10 | 386 | 38.60% | 70.20% |
| 5 | 2-5 | 292 | 29.20% | 99.40% |
| 6 | <2 | 6 | 0.60% | 100.00% |

According to backfill naturally graded fine, medium-grained, coarse ratio of three parts can be seen in Table:

- **Fine Fraction.**Particle size less than 5mm accounted for 29.8%, 5 ~ 16mm is 65.4%, 16 ~ 20mm of 4.8%.
- **Medium-grained.**Part.Particle size less than 5mm accounted for 10.6%, 5 ~ 16mm is 75.8%, 16 ~ 20mm is 13.6%.
- **Coarse Fraction.**Particle size less than 5mm accounted for 0%, 5 ~ 16mm is 44.8%, 16 ~ 20mm is 55.2%.

**Table 4 Grain ratio after grading in test**

| No. | Particle diameter mm | Sieve | Percentage sieve | Cumulative percentage sieve |
|---|---|---|---|---|
| 1 | >20 | 110 | 11.00% | 11.00% |
| 2 | 16-20 | 26 | 2.60% | 13.60% |
| 3 | 10-16 | 402 | 40.20% | 53.80% |
| 4 | 5-10 | 356 | 35.60% | 89.40% |
| 5 | 2-5 | 104 | 10.40% | 99.80% |
| 6 | <2 | 2 | 0.20% | 100.00% |

**Table 5 Coarse ratio after grading in test**

| | | | | |
|---|---|---|---|---|
| 1 | >20 | 456 | 45.60% | 45.60% |
| 2 | 16-20 | 96 | 9.60% | 55.20% |
| 3 | 10-16 | 428 | 42.80% | 98.00% |
| 4 | 5-10 | 2 | 2.00% | 100.00% |
| 5 | 2-5 | 0 | 0.00% | 100.00% |
| 6 | <2 | 0 | 0.00% | 100.00% |
| 1 | >20 | 456 | 45.60% | 45.60% |

***Nature dump site grading test analysis***

Process of forming a cover layer of artificial backfill and dump is rock row down the principle is the same, this paper do this scene 20m high dump were naturally graded field test, field test model shown in Fig.1.

**Natural Classification Thickness Analysis.**Dump site naturally graded fine, medium-grained, coarse obvious effect of three parts, field measurements after dump toe point elevation natural grading and classification conversion obtained after fine grading thickness 7.5m, medium grain 6.7 m, coarse 5.8m.

**Table 6 Fine ratio after grading**

| No. | Particle diameter mm | Sieve | Percentage sieve | Cumulative percentage sieve |
|---|---|---|---|---|
| 1 | >100 | 22 | 2.20% | 2.20% |
| 2 | 60-100 | 20 | 2.00% | 4.20% |
| 3 | 40-60 | 48 | 4.80% | 9.00% |
| 4 | 20-40 | 101 | 10.10% | 19.10% |
| 5 | 10-20 | 206 | 20.60% | 39.70% |
| 6 | 5-10 | 342 | 34.20% | 73.90% |
| 7 | <5 | 261 | 26.10% | 100.00% |

**Table 7 Grain ratio after grading**

| No. | Particle diameter mm | Sieve | Percentage sieve | Cumulative percentage sieve |
|---|---|---|---|---|
| 1 | >100 | 108 | 10.80% | 10.80% |
| 2 | 60-100 | 126 | 12.60% | 23.40% |
| 3 | 40-60 | 272 | 27.20% | 50.60% |
| 4 | 20-40 | 197 | 19.70% | 70.30% |
| 5 | 10-20 | 138 | 13.80% | 84.10% |
| 6 | 5-10 | 88 | 8.80% | 92.90% |
| 7 | <5 | 71 | 7.10% | 100.00% |

**Natural Classification particle size analysis.**Natural classification of different size rock select a representative sample of 3 points, depending on the circumstances of each sampling point sampling 1000kg. The rock samples were sieved turn over 100mm, 60mm, 40mm, 20mm, 10mm, 5mm, 5mm smaller than the sieve, sieve diameter, respectively, after weighing the rock, and recording weight; 100mm above the rock with ruler to measure, and then ,they are recorded and weighed. Screening results are shown in Table 6-8.

**Table 8 Coarse ratio after grading**

| No. | Particle diameter mm | Sieve | Percentage sieve | Cumulative percentage sieve |
|---|---|---|---|---|
| 1 | >100 | 260 | 26.00% | 26.00% |
| 2 | 60-100 | 281 | 28.10% | 54.10% |
| 3 | 40-60 | 162 | 16.20% | 70.30% |
| 4 | 20-40 | 101 | 10.10% | 80.40% |
| 5 | 10-20 | 82 | 8.20% | 88.60% |
| 6 | 5-10 | 61 | 6.10% | 94.70% |
| 7 | <5 | 53 | 5.30% | 100.00% |

According to the natural grading dump fine, medium-grained, coarse three-part matching table can be seen: the fine fraction less than 5mm diameter accounted for 26.1%, the grain diameter portion and a coarse fraction is greater than 100mm 36.8%.

Through physical simulation test and field test dump can be seen in the natural grading backfill reasonable physical simulation of natural thickness and particle size effects and hierarchical structure.Miaogou Iron status pit cover into the desired structure and thickness of the coating layer to determine the step height of the backfill 50m.

## Conclusions

In the paper, the forming by natural grading of Miaogou‘s cover is studied and the conclusions is obtained.

- Main factors affecting natural classification are the dumping height, the backfilling particle sizes, the degree of rough and hard slope.
- The natural grading process, initial natural classification is not obvious. After reaching a certain size, grading phenomenon is very obvious.It is divided into three parts, fine-grained , medium-grained , coarse-grained. With the backfill down unloading height increases, the fine and coarse backfill layer thickness increasing trend in grain backfill layer thickness decreased after the first growth trend.
- Through simulation test, Backfilling method by natural classification to form a high-level cover is simple , reliable, short construction period and good economic returns .

**Keywords:** Rock fracture; Fluid flow; Local cubic law; Geometrical discrete-equivalent model

**Abstract.** The cubic law (CL) is one of the most commonly applied physical laws for flow through rock fractures and fractured media, but many studies indicate that the CL is often not adequate. We investigate the establishment conditions of valid applying the "cubic law" to flow in fractures. A dimensional analysis of the N-S equations yields three conditions for the applicability of cubic law, as a leading order approximation in a local fracture segment with parallel walls. These conditions may not be met in many natural rock fractures as whole and demonstrate that the "cubic law" should be exactly applied in local segments (local cubic law, LCL). In this way, a new 2D discrete equivalent model for natural rough fractures is introduced, and its equivalent aperture and flow formulation are derived. By comparing the developed model and experimental results of different fractures, good accuracy was found, and the model was validated. The model could be useful for theory studies of flows through real rock fractures.

## Introduction

In natural crust, the matrix permeability is negligible compared to the permeability of fractures, and the rock mass' hydraulic behavior is controlled by fractures. In such situations, the development of realistic and robust predictive models of flow and transport requires a thorough understanding of the physical processes that govern flow in individual fractures. Understanding and quantification of fluid flow through fractured rocks are important for several industrial activities and research topics, such as reservoir exploitation for water supply, petroleum, geothermal research, heat storage, and the safe design of disposal sites for domestic, industrial, and nuclear waste [1].

Traditionally, single fractures have been idealized as a set of parallel plates to obtain a tractable mathematical description of fluid flow, namely, the cubic law (CL). Because of its simplicity, the CL has been studied extensively and has become the primary governing law for flow in rock fractures [2, 3]. In a rigorous sense, the CL works the best for fluid flow in a highly idealized fracture with smooth and parallel fracture surfaces, such as saw tooth and stepped profiles [4]. In these cases, the fracture hydraulic behavior is expressed by the effective aperture term. However, field observations show that natural fractures are very unlikely to have smooth and parallel surfaces [5], and many laboratory experiments [6] and field measurements [7] indicate that the classical view is not adequate for describing flow. It is difficult to establish the CL in rock fractures that are rough-walled conduits with tortuose paths. Although more advanced conceptual models [8, 9] have been introduced in recent years, an alternative model for flow in fractures has yet to be generally accepted.

In light of the above discussion, we re-address the entire issue and begin by examining the conditions of applying the CL directly from the Navier-Stokes equation. Section 2 presents an order-of-magnitude analysis based on 2-D cross sections of a fracture. In section 3, we propose a new 2-D discrete-equivalent model for natural rough-walled fractures on the basis of CL conditions and develop its equivalent aperture and flow formulation. Finally, in section 4, we evaluated the model with the experimental results of fractures with different geometries.

**A Study of Applicable Conditions for the CL**

The incompressible flow of Newtonian fluid in rock fractures can be described by mass and momentum conservation equations. In 2-D fractures, for example, the fracture in Fig. 1, those Equations is written as follows:

$$\frac{\partial u}{\partial x}+\frac{\partial v}{\partial y}=0, \tag{1}$$

$$\rho\left(u\frac{\partial u}{\partial x}+v\frac{\partial u}{\partial y}\right)=-\frac{\partial P}{\partial x}+\mu\left(\frac{\partial^2 u}{\partial x^2}+\frac{\partial^2 u}{\partial y^2}\right), \text{ and} \tag{2a}$$

$$\rho\left(u\frac{\partial v}{\partial x}+v\frac{\partial v}{\partial y}\right)=-\frac{\partial P}{\partial y}+\mu\left(\frac{\partial^2 v}{\partial x^2}+\frac{\partial^2 v}{\partial y^2}\right) \tag{2b}$$

where $u$, $v$ is the flow velocity, $\mu$ is the fluid viscosity, $\rho$ is the fluid density, and $P$ is the hydrodynamic pressure. The Eq. (2) is called the Navier-Stokes equation.

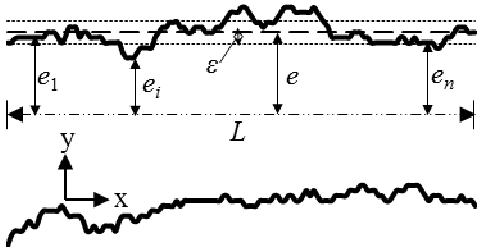

Fig 1 A rock fracture with aperture 2$e$ and length $L$.

In Fig. 1, $e_i$ is the test point aperture in a fracture, with $i$ from 1 to $n$. For a typical value of $e$ to be representative, the variation of $e_i$ must be limited over the length $L$, as follows:

$$e_i = e + o(\sum e_i). \tag{3}$$

$o(\sum e_i)$ is the infinitesimal of $\sum e_i$. It can be regarded as a very small amount here, $o(\sum e_i) \ll e$, so $(e_i - e)/e \ll 1$. We can include the roughness of the upper and lower walls:

$$\varepsilon = \max\left(\frac{\sigma_u}{e}, \frac{\sigma_l}{e}\right) \ll 1, \tag{4}$$

where $\varepsilon$ is called the non-dimensional roughness parameter, and $\sigma_u$ and $\sigma_l$ are the root mean square ( rms ) roughnesses (i.e., the rms deviations from the means) of the upper and lower walls, respectively, averaged over the length $L$ (Figure 1). This is the first and basic condition for valid application of the CL.

With the first condition (4), we can denote a typical velocity by $U$. Using (1), we can obtain the following:

$$v = \int_0^y \frac{\partial u}{\partial x} dy \tag{5}$$

Performing an order-of-magnitude analysis of (5), we obtain the approximate relations that $v$ is an order of $U\frac{e}{L}$. If the ratio of $e$ and $L$ is such that

$$\delta = \frac{e}{L} \ll 1, \tag{6}$$

And $u$ is an order of $U$, then $v \ll u$, $v$ is negligible relative to $u$, and (2b) can be written as follows:

$$\frac{\partial p}{\partial y} = 0 \Rightarrow p = p(x). \tag{7}$$

We can analyze the ratio of inertia and viscosity stress in (2a):

$$\frac{|\text{Inertia}|}{|\text{Viscosity}|}=\frac{\rho\left|u\frac{\partial u}{\partial x}+v\frac{\partial u}{\partial y}\right|}{\mu\left|\frac{\partial^2 u}{\partial x^2}+\frac{\partial^2 u}{\partial y^2}\right|}=\frac{\rho\left|u\frac{\partial u}{\partial x}\right|}{\mu\left|\frac{\partial^2 u}{\partial x^2}+\frac{\partial^2 u}{\partial y^2}\right|}\sim\frac{\rho}{\mu}\frac{U\frac{U}{L}}{\frac{U}{L^2}+\frac{U}{e^2}}=\frac{\rho Ue}{\mu}\frac{\delta}{\delta^2+1}=\text{Re}\times\delta \tag{8}$$

where $\text{Re}=\rho Ue/\mu$ is the Reynolds number in the fracture. From (8), we know $\frac{\partial^2 u}{\partial x^2}\Big/\frac{\partial^2 u}{\partial y^2}=\delta^2/1$ and $\frac{\partial^2 u}{\partial x^2}\ll\frac{\partial^2 u}{\partial y^2}$. Therefore, the condition

$$\text{Re}\times\delta\ll 1\ , \tag{9}$$

makes both terms on the left-hand side of (2a) negligible; thus, (2a) can be written as follows:

$$-\frac{\partial P}{\partial x}+\mu\frac{\partial^2 u}{\partial y^2}=0\ . \tag{10}$$

By combining (7) and (10) and integrating $u$ along the cross section, the CL is gotten as follows:

$$q=\int_e udy=-\frac{e^3}{12\mu}\frac{\partial P}{\partial x}=-\frac{e^3}{12\mu}\frac{\Delta P}{L} \tag{11}$$

where $\Delta P$ is the pressure drop across the fracture. In this case, the rough-walled fracture can be approximated as a pair of smooth parallel plates, and its aperture is the distance of parallel plates.

With the above conditions (4), (6), and (9), we can obtain the condition for the application of the CL in rock fractures:

$$\begin{cases}\max(\varepsilon,\delta)\ll 1 & (a)\\ \text{Re}\times\delta\ll 1 & (b)\end{cases} \tag{12}$$

The two geometric conditions (for $\varepsilon$ and $\delta$) in (12a) are somewhat dependent upon each other. On one hand, the length may not be too long because as we extend it, $\varepsilon$ will increase. On the other hand, we cannot minimize $\varepsilon$ by making the length shorter because of the condition on $\delta$. In fact, the geometric condition (12a) may be hardly met by many real rock fractures as a whole because of their long length and wall roughness, which is why researchers[6,7] conclude that the CL is not adequate for fluid flows in rock fractures. Our experiment also confirms this view [10].

Otherwise, it is obvious from (12b) that the Reynolds number and fracture roughness are coupled. The smaller $\delta$ is, the more assurance there is of the applicability of the CL for high Reynolds numbers. Similarly, the smaller the Reynolds number is, the more applicable the CL is for rough-walled fractures. Obviously, for smooth parallel plates, as long as the fracture is long enough ($\delta\to 0$), the CL will be very applicable for laminar flow ($\text{Re}\le 2300$). Usually, the length is long, and the aperture is small in natural rock fractures, which ensures a sufficiently small $\delta$; the Reynolds number is also not large, so condition (12b) can be met.

## A Discrete-Equivalent Model for Fluid Flow in 2-D Rock Fractures

To effectively use the CL, we must develop a geometric model suitable for analyzing the fluid flow behavior in fractured rough rock based on the applicable conditions. The analysis in the previous section shows that the CL is not applicable for fluid flow in rough-walled fractures because their rapidly varying wall geometry and long lengths mean condition (12a) cannot be met. To solve this problem, we 'break down' the fracture to shorter segments. As long as the discretizing method is appropriate for ensuring a reasonable length and roughness in each segment, then CL condition (12a) can be easily satisfied. In addition, if the Reynolds number is not large (say, ~100), condition (12b) is also met easily. Thus, the CL can be applied to the flow in each fracture segment. It is implied here that CL behavior should not be assumed correct or incorrect for the entire fracture; rather, it should be

studied on a local basis (segment), and the CL may be applicable only locally for natural rock fractures, hence the name local cubic law (LCL).

Based on the above principle, we derived a more general method for discretizing fractures. First, we divide the fracture equally along its flow direction into short segments with possibly appropriate lengths, ensuring every location with a rapidly varying aperture is 'broken down'; then, we assemble adjacent segments whose apertures vary gently as one segment, as shown in Fig. 2. The entire fracture is discretized as a stepped profile (dashed line), and the aperture of the 'break down' location is presented as a jump. In this case, conditions (12) is easily met in each segment, and we can apply the LCL to analyze the flow behavior in fractures.

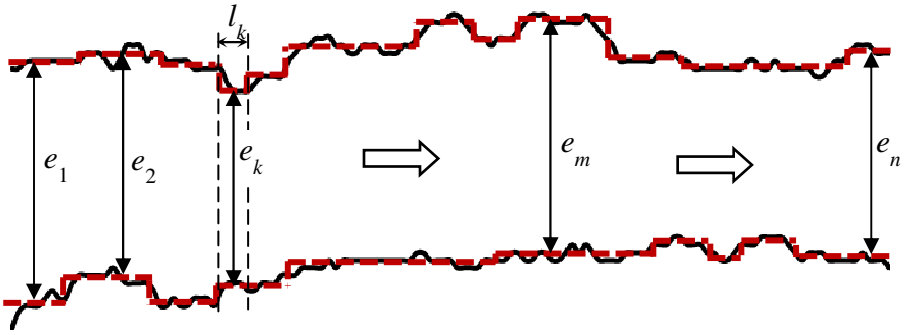

Fig. 2. 2-D discrete-equivalent model for rough-walled fracture

The flux through each segment in Fig. 2 can be calculated as follows:

$$q_k = \frac{e_k^{\,3}}{12\mu}\frac{\Delta P_k}{l_k},\ k = 1,2,\cdots,n, \tag{13}$$

where $\Delta P_k$ is the pressure drop of the $k$th fracture segment due to $q_k$, and $l_k$ and $e_k$ are the length and aperture, respectively.

For each segment fracture, the Mass Balance equation leads to the following:

$$q_1 = q_2 = \cdots = q_n = q. \tag{14}$$

Combining (13) and (14),

$$\Delta P_k = 12\mu q\frac{l_k}{e_k^{\,3}},\ k = 1,2,\cdots,n. \tag{15}$$

The total $\Delta P$ of the main fracture is the sum of $\Delta P_k$ for all segments, but it is obtained by ideal assumptions, and we need to consider the tortuosity effect; thus, we introduce a tortuosity factor $\tau$:

$$\Delta P = \sum_{k=1}^{n}\Delta P_k = 12\mu q\tau\sum_{k=1}^{n}\frac{l_k}{e_k^{\,3}}. \tag{16}$$

By comparing Eq.(11) and (16), and considering $L \simeq \tau\sum_{k=1}^{n} l_k$, the effective aperture can be calculated as follows:

$$e_{eq} = \sqrt[3]{\sum_n l_k \Big/ \sum_n \frac{l_k}{e_k^{\,3}}}. \tag{17}$$

From Eq. (16), the flow through main fracture can be calculated as follows:

$$q = \frac{1}{12\mu}\frac{\Delta P}{\tau\sum_n l_k / e_k^{\,3}}. \tag{18}$$

If a fracture is discretized by the same size $l$, Eq. (18) can be written as follows:

$$q = \frac{1}{12\mu}\frac{\Delta P}{\tau l}\frac{1}{\sum_n 1/e_k^3}. \quad (19)$$

## Discussion

To illustrate the reasonableness of our model, we completed physical experiments of fluid flow in some rough-walled fractures. The typical rough curve-JRC profiles in rock mechanics is used in the test. We selected the first, third, sixth and ninth curves and combined each of them with a plate to form 4 types of two-dimensional fractures; each fracture length is 100 mm, and the minimum aperture is 0.51 mm. By using experimental results, our model and the previous classical CL are analyzed and compared, as shown in table 1. The error of the average aperture method compared to the measured results is large, whereas our method is comparatively good. However, in the case of a large Reynolds number, the error increases significantly because the applicability of the LCL in flows with high Reynolds numbers is poor (condition (12b)). The correction and application of our model to flows with high Reynolds numbers needs to be studied further.

Table 1 Comparative analysis of test results according to classic CL and our model

| No. | $P_s$/Pa | $q_s/10^{-3}m^3/s$ | $e_p$/mm | $q_p/10^{-3}m^3/s$ | Error($q_p$) | $e_d$/mm | $q_d/10^{-3}m^3/s$ | Error($q_d$) | Re |
|---|---|---|---|---|---|---|---|---|---|
| 1-P | 486.5 | 0.165 | 0.91 | 0.26799 | **62%** | 0.82 | 0.18208 | **10 %** | 278 |
| | 98.2 | 0.035 | 0.91 | 0.05409 | **55%** | 0.82 | 0.03675 | **5%** | 59 |

Note: the subscripts *s*, *p* and *d* stand for results measured by physics experiment, calculated by the CL of the average aperture and by formulas (18) of the equivalent aperture, respectively.

## Conclusions

Based on the presented results, the following conclusions were obtained:

(1) By performing an order-of-magnitude analysis on the Navier-Stokes equation for a general rough-walled fracture, we obtain three conditions under which the CL is an adequate approximation of the flow: a) the fracture must be long enough relative to its aperture so that $\delta = e / L \ll 1$; b) over its length, the relative roughness parameter $\varepsilon$ must be limited to $\varepsilon \ll 1$; and c) inertial effects must be limited via $\mathrm{Re}\times\delta \ll 1$.

(2) According to these conditions, it follows that it is difficult to apply the cubic law for rock fractures as a whole; the law is only applicable in local segments of fractures (as local cubic law). When analyzing fluid flow in rock fractures through the cubic law, the matter should be discussed not simply from a global perspective but also from a local one.

(3) To make the cubic law effectively applicable for fluid flow in rough-walled rock fractures, we developed a new discrete-equivalent model and deduced the expression of an equivalent aperture and flow-calculating formula from 2-D perspectives. Compared with the experimental results of different rough-walled rock fractures, this model was validated. The model can effectively provide flow analysis in real rock fractures.

**Keywords:** rock mass quality classification; calcareous sandrock and conglomerate rock; elastic wave velocity; corrosion

**Abstract.** The hydro-electrical power station is planned to be built on the Jinsha River. The regional geologic structure is complex. On the basis of the geological engineering conditions and rock mass quality classification, the change of wave velocity of rock mass is used to analyze systematically the control function of corrosion of calcareous sandstone over rock mass quality. The modificatory standard of rock mass quality classification and the system of rock mass quality classification in the hydroelectric station have been carried out. The main results can be taken as the basic data and the theoretical proofs to evaluate the engineering rock mass stability.

## Introduction

The hydro-electrical engineering is planned to be built on the Jinsha River， with its damheight of 156m and installed capacity of 3000MW. The regional geologic structure is complex. The rock mass is mainly composed of Jurassic sandrock and conglomerate. The calcareous sandrock and conglomerate rock in the understratum will be corroded by the effect of groundwater. The corrosion depresses the rock mass strength, which influences the stabilization and deformation of dam foundation. Therefore, it is extremely important to make the rock mass quality classification correctly and reasonably in evaluating anti-slide stability of rock mass of dam foundation, making full use of utilizable rock mass and developing appropriate engineering measures.

Many methods on the classification of rock mass quality have been proposed at home and abroad since the middle of last century, but they are all specific to the non-soluble rock. In recent years, with the development of engineering construction in karst areas, rock mass quality little of these areas also has been studied [1,2]. However, the studies are mainly focused on carbonate rock, and pay little attention on sandrock and conglomerate [3].

In this paper, based on the geological engineering conditions and rock mass quality classification, the velocity of elastic wave in rock is used to analyze the control function of corrosion of calcareous sandstone over rock mass quality. The modified standards of rock mass quality classification and the system of rock mass quality classification of the hydroelectric station has been carried out. The main results can be taken as the basic data and the theoretical proofs to evaluate the engineering rock mass stability.

**Basic engineering geological conditions of the dam area**

The rock mass in the dam is mainly composed of Jurassic sandstone, conglomerate, siltstone and pelitic siltstone. The conglomerate fine sandstone and pebbled fine sandstone which are on the understratum of the dam will generate corrosion in the direction of stratification or steep-dipping fissure under the effect of groundwater. The results are large karst cave, calcium loss, semi-bonded sandy soil and white soft plastic kaolin in the fissure or levels.

Fracture structure is poorly developed in the dam site, and the main structure consists of fold, compresso-crushed zone and minor fault, with illtrastfatal-shearing belts and tectonic joints companion fold.

**Basic rock mass quality classification and corrosion degree**

Rock mass quality evaluation are the basis of rock mass stability analysing. Many classification methods of domestic and overseas consider the following factors of rock hardness, intactness of the rock, structure plane and its permeability as the basis of comprehensive evaluation.

The surrounding rock engineering geological classification of hydroelectricity, Standard for engineering classification of rock masses and RMR-system have been used in the rock mass quality classification.

According to the engineering geological properties of rock mass and references after the paper, the corrosion of sandstone and conglomerate can be divided into four grades (Table 1). The intensity grades of corrosion development is shown in Table 1.

Tab. 1 The intensity grades of corrosion development

| Corrosion | Line corrosion ratio (%) | Engineering geological properties |
|---|---|---|
| Highly corroded | 10~20 | Distributed mainly of solution pipe，crack-shape karst cave and cave. |
| Moderately corroded | 5~10 | Distributed mainly of solution fissure，pore and groove. |
| Slightly corroded | 0~5 | Distributed mainly of geodes, solution pores and solution pockmarked face. |
| Uncorroded | 0 | Rock mass was uncorroded and rock was well cemented. |

**Control effect of calcareous sandstone dissolution on rock mass quality**

Corrosion reduces rock mass integrity and wave velocity. And the quantitative analysis of the control effect of sandstone dissolution on rock mass quality is the problem. And the method of rock mass elastic wave velocity is analysed below.

The value of elastic wave velocity is a synthetic index to rock mass quality which depends on rock property, rock mass structure and rock mass existing condition. Therefore it is widely used in hydroelectric project.

The varying curve of wave velocity of rock mass in figure 1 presented that the change of wave velocity correlates with not only rock weathering and character (highly weathered is greater than slightly weathered, sandstone is greater than aleuvite and mudstone), but also rock corrosion.

Based on the adits datas, the results are reflected in table 2 from the datas of the relationship of wave velocity, rock weathering, rock character and corrosion.

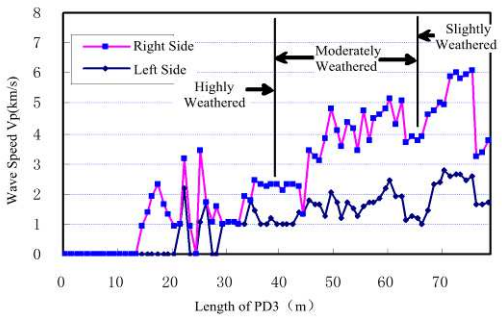

Fig. 1 Change of wave velocity of rock mass

Tab.2 The relationship of wave velocity, rock character and corrosion

| Weathering | Highly weathered | | | Slightly weathered | | | |
|---|---|---|---|---|---|---|---|
| rock character | sandstone | aleuvite | conglomerate | sandstone | | aleuvite | |
| corrosion | uncorroded | uncorroded | uncorroded | uncorroded | Slightly corroded | uncorroded | Slightly corroded |
| Length of adits | 5 | 6 | 2 | 9 | 3 | 14 | 3 |
| Average wave velocity (Km/s) | 1.34 | 1.41 | 2.06 | 2.79 | 1.46 | 2.36 | 1.37 |
| maximum | 1.58 | 1.97 | 2.08 | 3.54 | 1.47 | 3.37 | 1.43 |
| minimum | 1.08 | 1.09 | 2.03 | 2.07 | 1.45 | 1.18 | 1.33 |

Figure 2 indicates that few exploration adits are highly weathered or slightly weathered, and most of them are not corroded. And on the whole, it reflects good corresponding among rock property, weathering degrees and longitudinal wave velocity.

The datas of rock mass classification systems can be used to analyse the relationship with wave velocity. Figure 2 indicates the two aspects correlates very well.

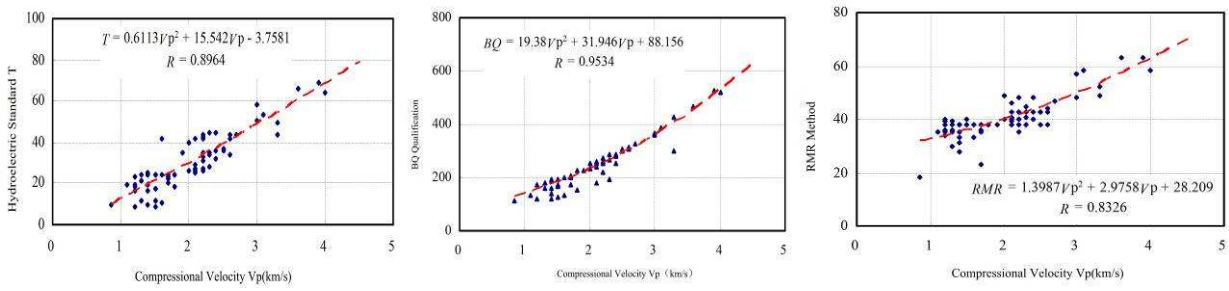

Fig.2 The relationship map of wave velocity and classification data

Combine the relationship of corrosion and wave velocity in table 2 with the formulas of rock mass quality classification systems and wave velocity, the influence of corrosion on rock mass quality classification can be achieved.

The relationship of wave velocity and rock mass quality classification systems in figure 2 can be presented by the following formulas:

$$T = 0.6113V_p^2 + 15.542V_p + 3.7581$$

$$BQ = 19.38V_p^2 + 31.946V_p + 88.156$$

$$RMR = 1.3987V_p^2 + 2.9758V_p + 28.209$$

From the formulas, the variation tendency of corrosion ratings on rock mass quality can be achieved. Table 3 lists the analytical datas of conglomerate and sandstone (take BQ qualification for example).

Tab.3 The influence of corrosion ratings on rock mass quality

| rock character | corrosion | Length of adits | Average wave velocity (Km/s) | BQ rating | Decreased rating | BQ class |
|---|---|---|---|---|---|---|
| conglomerate | uncorroded | 11 | 2.52 | 291.73 | | Ⅳ |
| | Slightly corroded | 3 | 1.90 | 218.82 | 24.99% | Ⅴ |
| | Moderately corroded | 5 | 1.46 | 176.11 | 39.63% | Ⅴ |
| | Highly corroded | 1 | 1.00 | 139.48 | 52.19% | Ⅴ |
| sandstone | uncorroded | 65 | 2.15 | 246.42 | | Ⅳ |
| | Slightly corroded | 11 | 1.68 | 196.52 | 20.25% | Ⅴ |
| | Moderately corroded | 14 | 1.44 | 174.34 | 29.25% | Ⅴ |
| | Highly corroded | 14 | 1.40 | 170.87 | 30.66% | Ⅴ |

The result shows that rock mass quality is decreased obviously due to the corrosion of rock cement. And on the whole it decreased one order of magnitude.

## Conclusion

Corroded rock have great differences with uncorroded rock. Corrosion will reduce integrity of rock. This is extremely unfavorable in dam foundation deformation and stability against sliding. Besides, the increases of corrosion degree will reduce the wave velocity and rock mass quality. The analysing of the change of wave velocity of rock mass is used to analyze systematically the control function of corrosion of calcareous sandstone over rock mass quality. It not only has carried out the relationship between rock mass quality and wave velocity, but also has achieved the quantitative evaluation of rock mass quality. It shows that the rock corrosion will lead to a distinct weakening of rock quality, and on the whole it decreased one order of magnitude. The main results can be taken as the basic data and the theoretical proofs to evaluate the engineering rock mass stability.

# Dynamic Mechanism Research on the Tectonic Activation of Anninghe Rift

Junqi Liu [a], Yusheng Li [b]

State Key Laboratory of Geohazard Prevention and Geoenvironment Protection (Chengdu University of Technology), Chengdu, Sichuan, 610059, P. R. China

**Keywords:** Rift, Activation, Lithosphere, Mantle convection, Plastic flow, Dynamic mechanism

**Abstract.** Anninghe rift is located on the western edge of Yangtze Block next to Tibetan Plateau, along the axis of a continental paleorift zone, Panxi paleorift. Recent studies have found that an upward mantle convection system existed since the late Pliocene in the deep lithosphere of a long and narrow area controlled by Anninghe fault. Lithospheric temperature distribution in the area has characteristics similar to that in Baikal and other modern rifts. A mantle upwelling area was in a constant state of "pull-subsidence." Brittle rock mass of the shallow crust cracked into the new secondary subsidence blocks. A thick lacustrine sedimentary sequence of continental subsidence type developed. These all indicate that Anninghe rift is in an obvious tectonic activation state. It is believed that the tectonic activation of Anninghe rift has been produced by both horizontal squeeze from a plastic flow of the upper crust and expansion from mantle uplift. The pressure from the plastic flow of the upper crust is slightly greater than the expansion stress from the uplifting of lithosphere. Under this specific geodynamic environment, whether the tectonic activation of Anninghe rift can continue depends on the thermal motion rate of deep mantle materials and the eastward migration of the crustal materials of Tibetan Plateau.

## Introduction

During an international geophysical year and upper mantle planning in the 1950s, it was not only affirmed that oceanic rifts and continental rifts formed a worldwide unified system, but also found that the formation and function of the rifts were associated with some universal effects deep in the earth[1].

Anninghe rift is located on the western edge of Yangtze Block next to Tibetan Plateau (Fig. 1), along the axis of a continental paleorift zone, Panxi paleorift. Accompanied by Permian Emeishan basalt overflow, the earthen crust was drastically tensioned and ruptured. This continental rift with dome-shaped volcano pattern had sustained development during the Indo-Chinese epoch. During the late Pliocene when activities gradually weakened of the lithosphere, a main fracture system in the paleorift zone closed up[2]. Recent studies indicate that there have been mantle uplift and heat convection accompanied by significant crustal expansion in Anninghe rift. It is not clear if this phenomenon means that the paleorift was activated from a dormant state[3]. Comprehensive geological and geophysics investigations as well as earthquake-structure and crustal deformation measurements were researched to study tectonic rift activation and to put forward a new dynamic mechanism of rift activation.

## Regional geophysical field and deep structure

According to crustal rock's electrical, magnetic and density data[4] (Fig. 2 left), the lithospheric electrical structure in Anninghe main tectonic belt is considerably different from that on either side of the belt. The low-resistivity layer of the crust and upper mantle is thinner and shallower and even disappears in some places. The shallowest low-resistivity layer in the upper mantle is only 80 km.

Regional crustal thickness varies from 39 ~ 43 km in Sichuan basin to 60 ~ 70 km in Tibetan Plateau. There is a north-south trending mantle uplift belt in the center of Anninghe rift[5] (Fig. 2 right). A high gravity anomaly zone is centered on Xichang. Massive high density basic and ultrabasic abnormal substances exist in the lithosphere.

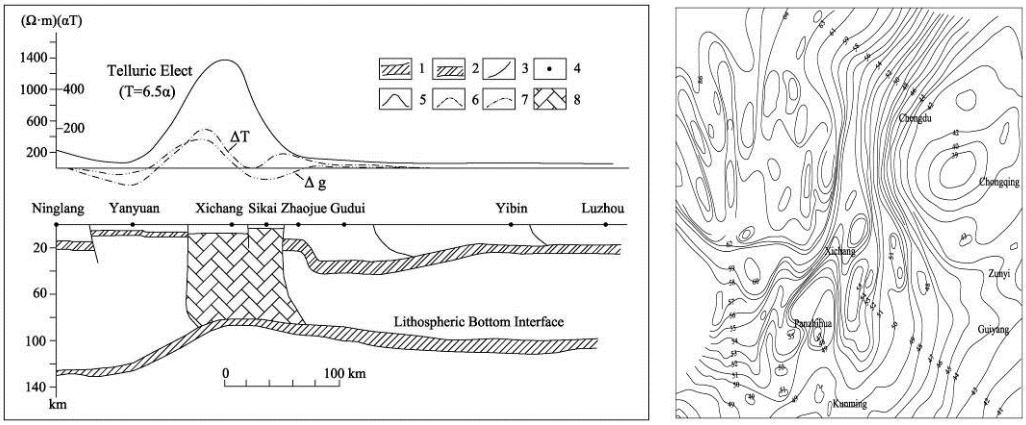

Fig. 2 Magneto telluric sounding profiles in Anninghe rift (left) and regional crustal thickness (right)
(left: 1- Shell low resistance layer, 2- The upper mantle low-resistivity layer, 3- Faults, 4- Magneto telluric sounding points, 5- The resistivity curve, 6- Voyage ΔT curve, 7- Δg curve, 8- High resistance anomaly.)

## Activity characteristics of the main boundary faults of Anninghe rift

We found an active main boundary fault developed along the eastern side of the valley via geological surveys, very low frequency electromagnetic method (VLF) and micro-dose α radiation measurement. According to crustal deformation data from leveling measurements of nearly 30 years (Table 1), the

main boundary fault is left-lateral strike-slip with strong compression as a whole. But it is not to be ignored that some sections had pull - normal fault activities (Fig. 3). Based on analysis of GPS data from a crustal movement monitoring network, the fault left-lateral slip rate is 2.5 ~ 6.0 (±1.8) mm/yr while the horizontal pull rate is 0 (±2) mm/yr[6].

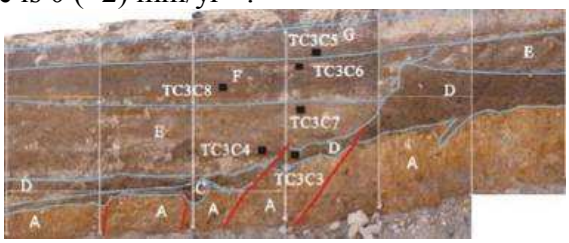

Fig. 3 Trench in northern section of main boundary fault

Table 1 Slip rate of main boundary fault

| Fault | Geological Survey (mm/a) | | GPS and Levelling (mm/a) | |
|---|---|---|---|---|
| | Left-lateral dislocation rate | Vertical dislocation rate | Left-lateral dislocation rate | Vertical dislocation rate |
| North Section (Shimian - Mianning) | 4.0~6.2 | 0.9~1.4 | 2.54~3.58 | 0 (±2) |
| North Section (Mianning - Xichang) | 5.0~7.2 | 1.8~0.73 | 5.3～6.0 | |

**Rift type fault basin of late Pliocene**

The Pan-Xi paleorift began a new round of rift expansion in the late Pliocene ($N^3_2$) after a lengthy "dormant" closing process from late Cretaceous (K) to Pliocene ($N_2$). Under control of the north-south trending boundary faults, Xigeda formation ($Q_{1x}$) was deposited in the fault basin with primarily lacustrine sediments of clay - silt layers in a strip along the Mianning – Xichang – Panzhihua within 120 km. The "fault-deposition" process lasted until the early Middle Pleistocene ($Q_2$) which successively deposited fluvial-lacustrine-swamp sediments of Dajingliangzi formation ($Q^1_{2d}$) on Xigeda formation. Crust settlement at this stage reached more than 2000 m in total or a rate of more than 1.30 mm/yr.

During the late Middle Pleistocene ($Q_2$) the rift zone crust turned into a "squeeze-closing" state from a "pull–subsidence" state. Boundary fault activities turned into "compression-reverse fault" from "pull-normal fault" (Fig. 4 left). Folding deformation also occurred in Xigeda formation ($Q_{1x}$) within the rift (Fig. 4 right).

During the early Late Pleistocene ($Q_3$), the rift was active again. Strong normal fault activities occurred along the boundary fault. The crust continued "pull–subsidence" and it lasted until the early Holocene ($Q_4$). Total "pull-subsidence" at this stage is more than 300 m with a subsidence rate of approximately 1.94 mm/yr.

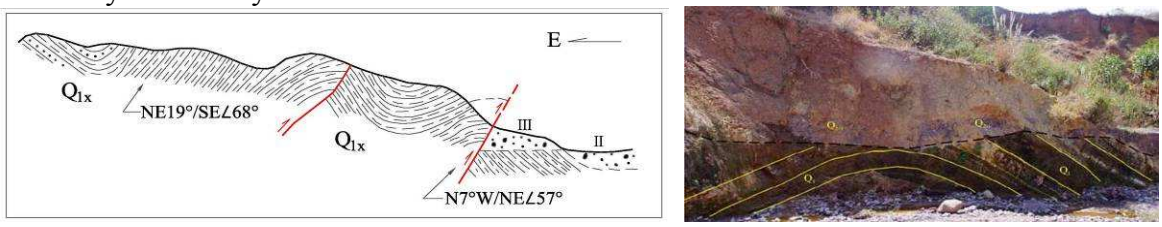

Fig. 4 The reverse fault activity of boundary fault of Anninghe rift (left) and the fold deformation in Xigeda formation ($Q_{1x}$) (right)

**Characteristics of tectonic rift activation and dynamic mechanism**

**Characteristics of Anninghe tectonic rift activation.** The deep lithosphere is still an upwelling system within mantle convection of Anninghe rift. Terrestrial heat flow measurements of this region

indicate that temperatures of 1100 ~ 1200 ℃ at the 80 ~ 90 km depth (Fig. 5 left) have reached the critical value of a molten mantle rock. When lithospheric temperature distribution of Anninghe region is compared to that of Baikal rift[7], shallow crust temperatures of Anninghe rift are lower than those of Baikal rift, but deep geothermal temperatures are approximately the same. This suggests that the deep crust of Anninghe rift still has similar characteristics with a modern rift, which is an important indication of rift activation.

Mantle upwelling caused changes in regional stress field, resulting in the upwelling area to be in a continuous crustal "expansion–pull–subsidence" state and the brittle rock mass of the shallow crust cracked into the new secondary subsidence blocks (Fig. 5 right). Recent measurements (Table 2) indicate that Anninghe rift is still in a state of continuous subsidence with a crust subsidence rate of 3.9 ~ 5.6 mm/yr. Obviously the rift zone was in a constant state of tectonic activation.

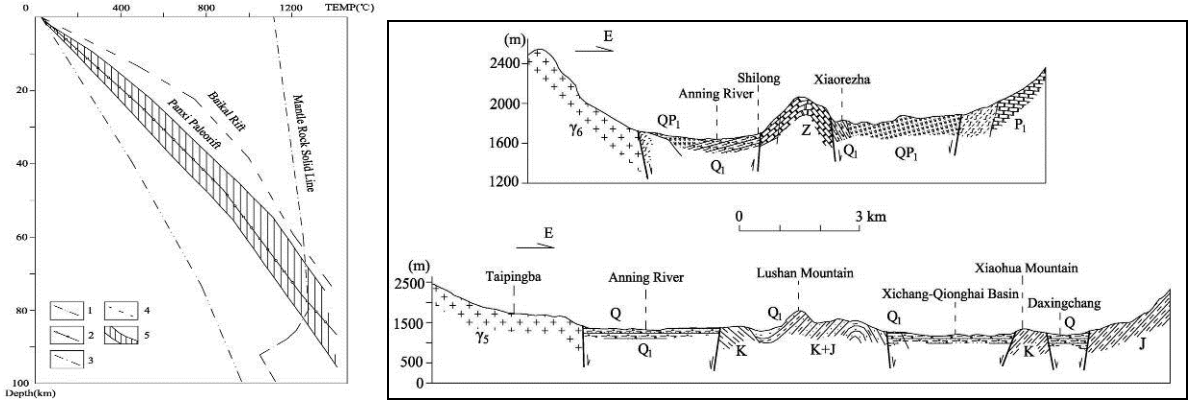

Fig. 5 Lithosphere temperature of Anninghe rift (left) and geologic structure profile (left: 1- Global average of geologic body with the same age, 2- Lithospheric temperature distribution of Aninghe rift, 3- Mantle rock solid line, 4- Lithospheric temperature distribution of Baikal rift, 5- Lithospheric temperature range in Anninghe region.) (right: Above - northern section of rift. Below - southern section of rift.)

Table 2 Vertical crustal deformation measurement results of Anninghe rift

| Measuring Position | | Deformation Rate (mm/yr) | Deformation Gradient (mm/km) |
|---|---|---|---|
| Measuring Section | Length (km) | | |
| Mianning-Shimian | 126.4 | + 4.7 | + 0.3 |
| Xindian-Mianning | 139.5 | - 4.4 | - 0.3 |
| Mianning-Dechang | 150.0 | - 5.6 | - 0.4 |
| Xichang-Dechang | 79.0 | - 4.7 | - 0.6 |

**Crustal dynamics mechanism of rift activation.** Regional P-wave and S-wave tomographic image cross section (Fig. 6 left) indicates that presence of an obvious Vp and Vs lower abnormal layer at a depth of approximately 16-26 km in the crust. This low-velocity layer is separated by a high speed and therefore high density rock mass in Anninghe valley. Those have some association with upper crust's block movement and mantle thermal motion.

Previous studies[8] have confirmed that a widespread southeastward plastic flow exists in the crust at this depth on the eastern edge of Tibetan Plateau including Anninghe valley. This flow drove an oblique collision of the west Sichuan-Yunnan fault block to the east Yangtze Platform, maintaining high compressive stresses in Anninghe fault at the contact zone. Focal mechanism solutions of modern earthquake reflect the existence of the stress state (Table 3). On the other hand, upward moving high temperature molten mantle rock is constantly penetrating through the lower crust into the shallow crust of the brittle fault zone, generating high fluid pressures and stresses. After moving into higher mantle, the molten rock gradually cooled to normal temperatures of the lithosphere and its temperatures dropped below the solid limit of a pyrite. Thus the rock lost characteristics of low speed seismic waves associated with a molten mantle rock. A high density rock mass was formed with high speed seismic wave characteristics in Anninghe valley and blocked the continuation of the

low-velocity layer at a 16 ~ 26 km depth. This condition also greatly increased stress accumulation in the crustal rock mass.

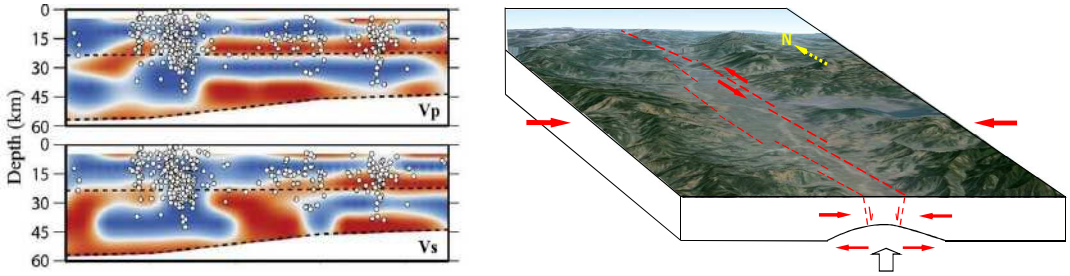

Fig. 6 Cross section of regional P-wave and S-wave tomographic image (left) and power source model of rift activation
(left: White dots indicate earthquakes. Red indicate low-speed. ANF – Anninghe rift. SY - Sichuan-yunnan fault block. YT - Yangtze Platform)

Table 3 Focal Mechanism Solutions of Anninghe Rift

| Time | Epicenter | | Ms | Nodal Plane A | | | Nodal Plane B | | | P | | T | | N | |
|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|
| | | | | Strike | Dip | Dip Angle | Strike | Dip | Dip Angle | Azimuth | Elevation | Azimuth | Elevation | Azimuth | Elevation |
| 1952.9.30 | 28°18′ | 102°12′ | 6.7 | 65 | NW | 75 | 354 | NE | 40 | 128 | 21 | 13 | 45 | 235 | 36 |
| 1962.2.27 | 27°36′ | 101°54′ | 5.5 | 65 | NW | 61 | 356 | NE | 87 | 301 | 18 | 45 | 23 | 183 | 61 |
| 1972.5.7 | 27°58′ | 101°19′ | 4.8 | 91 | N | 80 | 4 | E | 76 | 138 | 3 | 47 | 17 | 235 | 73 |

Based on the above analysis, tectonic activation of Anninghe rift was produced by both horizontal squeeze from a plastic flow of the upper crust and a tensile stress from the mantle uplift (Fig. 6 right). This pull - squeeze effect from the deep and shallow crusts has been in constant development and adjustment since the late Pliocene. It has not reached equilibrium at present time.

## Conclusions

Mantle uplift and heat convection exist in Anninghe rift along the axis of the Pan-Xi paleorift zone. The nearly north-south trending paleorift tectonic system is completely included in modern plate movement because of the movement between the crustal blocks. Especially the NWW trending compressive stress from the crustal material of Tibetan Plateau eastward drifting is slightly larger than the expansive stress from the present lithosphere uplifting. Under the specific geodynamic environment, whether the tectonic activation of Anninghe rift can continue its development depends on the thermal motion rate of deep mantle material and the eastward migration state of the crustal material of Tibetan Plateau. It is not impossible for the magma activity and crustal rifting to reappear in tectonic activation with Anninghe rift as the center.

**Keywords:** Fractured rock；Rock mass hydraulics；Discrete Fracture Network Model；Shortest seepage path.

**Abstract:**Fractured rock is a combination of rocks and fractures,the fractures which are ubiquitously distributed in fractured rock mass often constitute the flow and migration path of underground fluid and radionuclide.Discrete Fracture Network Model (DFN) was built with in-situ observations to evaluate the hydraulic conductivity tensor of rock masses.The fractures relation pattern with corresponding algorithm is given on the basis of computational geometric,and then the graph theory is employed as the mathematical model to represent the mutual positional relation of fractures.And then,with the use of Dijkstra algorithm, the hydraulic conductivity tensor could be obtained.

## Introduction

There are many different fractures,which,as with rocks, form a complex fracture network,in the rock masses.The permeability of the rock masses is very important to a pre-selected area for high-level radioactive waste repository.As the computer technology develops,the fractures relation pattern with corresponding algorithm is given on the basis of computational geometric,and then the graph theory is employed as the mathematical model to represent the mutual positional relation of fractures in 3D space[1](Wang and Yang,1992).And then,discrete mathematics was introduced to the research on the connectivity of the fractures in the rock masses[2](He and Liao,1995).The connectivity of fractures and permeability of volcanics were obtained though Discrete Fracture Network Model with the application of graph theory[3](2002,Park and Kim).In this paper,on the basis of graph theory,the relations between fractures were got by spatial geometry,and Dijkstra algorithm was applied to obtain the shortest seepage path in the rock masses.

## Spatial relationships between fracture disks

Getting the spatial relationships between fracture disks is the first step to this study.In the case of fracture is treated as a flat disk,there are many different spatial relationships between fractures.It is essential to get the intersecting line between each two related fracture disks,and the coordinates of the intersecting line can be obtained by Spatial geometry.

**Parallelism of two fracture disks.**Whether there is a intersecting line between every two disks depends on the coordinates of the centers and the normal directions of the fracture discs.But,if they parallel to each other,it indicates that there are no intersecting line between the selected fractures,and if not,further works should be done to get the coordinates of the intersecting line.

**Intersection of two fracture disks.**When solving the intersection of non-parallel fracture disks,the disks are assumed to be planes.But the size of fracture disk is limited indeed,even the planes of the fracture disks intersect,the real fracture disks may have no intersecting line(Fig 1).

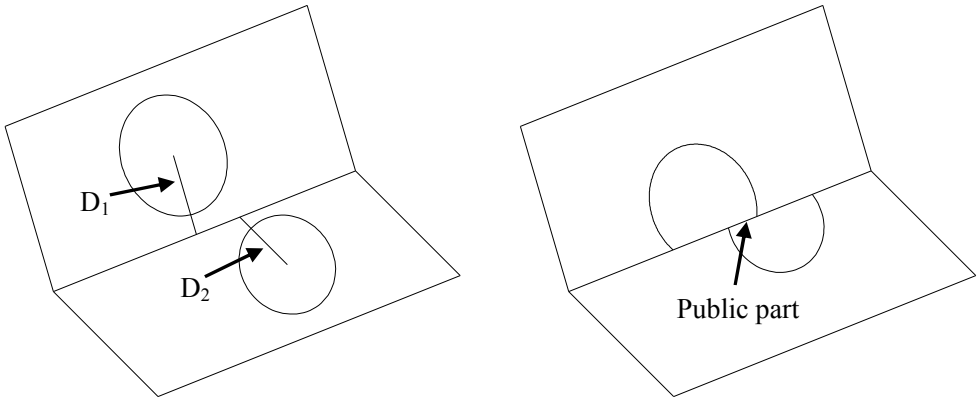

Fig.1 Planes of the fracture disks intersect

Then the $D_1$ and $D_2$,as shown in figure 1,are applied to judge the intersection of the two disks,if $D_1 \le r_1$ and $D_2 \le r_2$ ($r$ is the radius of the fracture disk),the the public part of the intersection line is the intersection line of the fracture disks.

**The real intersection line.**If the intersection points of the line L and the disk are assumed to be $(x_{11}, y_{11}, z_{11})$ and $(x_{12}, y_{12}, z_{12})$,then L can be written, in a general form, as

$$L_{p1} : \frac{x - x_{11}}{x_{12} - x_{11}} = \frac{y - y_{11}}{y_{12} - y_{11}} = \frac{z - z_{11}}{z_{12} - z_{11}} = t \tag{1}$$

Similarly

$$L_{p2} : \frac{x - x_{21}}{x_{22} - x_{21}} = \frac{y - y_{21}}{y_{22} - y_{21}} = \frac{z - z_{21}}{z_{22} - z_{21}} = t \tag{2}$$

Solve equation (1) and (2) with simultaneous equation approach.If the simultaneous equation has two different solutions,the fracture disks have real intersection line,otherwise not.

**Storage and representation of graph**

There are two different methods to store the graph—adjacency matrix and adjacency list.Adjacency matrix is a method that represents the graph as two arrays,but since the model has huge number of fractures inside,the arrays are too large to operate for the computer,adjacency list takes up less storage space(Fig 2).In this paper,adjacency list is used to store the relations of each two fracture disks.

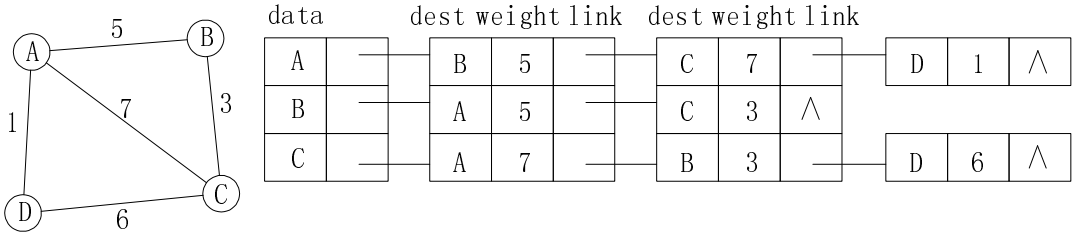

Fig.2 Adjacency list to store the graph

The weight in the adjacency list represents the time $T$ that water flows from one fracture disk to another.

$$T = \frac{L}{v} \tag{3}$$

According to Darcy's law

$$v = k \cdot i \tag{4}$$

Then

$$T = \frac{L}{k \cdot i} \tag{5}$$

According to Fig 3,the shortest time that water flows between two connected fracture should be written as

$$T = T_1 + T_2 = \frac{L_1}{K_1 \cdot i} + \frac{L_2}{K_2 \cdot i} \tag{6}$$

Where $L_1$ , $L_2$ represent the distances between the centers of the disk and the center of the intersection line. $K_1$ , $K_2$ corresponds to the permeability coefficient of $L_1$ , $L_2$ .

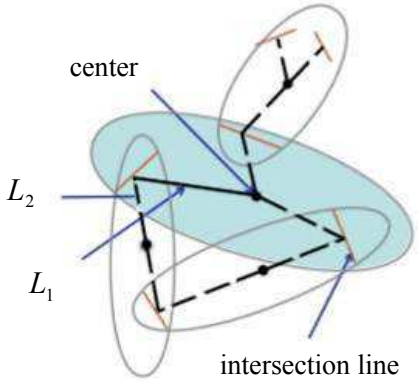

Fig.3 Water flows between fractures

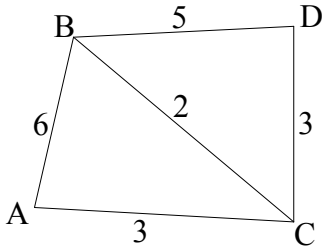

Fig.4 Data network structure

**Search for the shortest seepage path**

When all the time that water flows between each intersected fractures are obtained,the graph of the fractures of the DFN model is built up.Dijkstra algorithm is applied to search the shortest seepage path between two specified fracture disks.The Dijkstra algorithm can get the nearest node(fracture disk) that intersects the node specified each time,until the path reach the specified terminal point,if the terminal point is reachable.It is based on the ascending order,and is correct unless the weight of every node in the graph can be negative.Table 1 shows the operations Dijkstra algorithm takes to process the graph of Fig 4.

Table 1 Detailed algorithm process of Dijkstra algorithm

| step | S set | T set |
|---|---|---|
| | | T=<B, C, D> |
| | Take A,S=<A> | A→B=6 |
| 1 | The shortest:A→A=0 | A→C=3 |
| | Set A as specified node, | A→D is unreachable |
| | | Shortest path:A→C=3 |
| | Take C,S=<A, C> | T=<B, D> |
| 2 | The shortest:A→A=0,A→C=3 | Shortest path:A→C→B=5(A→B=6) |

| | | |
|---|---|---|
| | Set C as the specified node,A→C=3 | Now A→B=5 |
| | Take B,S=<A, C, B> | T=<D> |
| 3 | The shortest:A→A=0, A→C=3, A→C→B=5 | Shortest path:A→C→B→D =10（A→C→D =6） |
| | Set C as the specified node,A→C→B=5 | Now A→C→D=6 |
| | Take D,S=<A, C, B, D, > | |
| 4 | The shortest:A→A=0,A→C=3,A→C→B=5, A→C→D=6 | T is empty,done |

## Engineering Application

In this paper,the DFN model was built with datas got though in-situ observations of Jijicao district,Beishan,gansu,China.All the 5125 fractures,in the model,are divided into three sets(Table 2&Fig.5).

Table 2 The parameter of the fractures

| set | Direction/° | Dip/° | Volume density/ $m^3$ |
|---|---|---|---|
| 1 | 48.4 | 87.24 | 0.01441 |
| 2 | 220.09 | 3.16 | 0.00374 |
| 3 | 300.04 | 87.13 | 0.026646 |

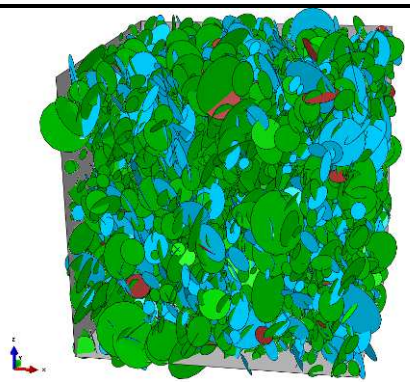

Fig.5 Water flows between fractures

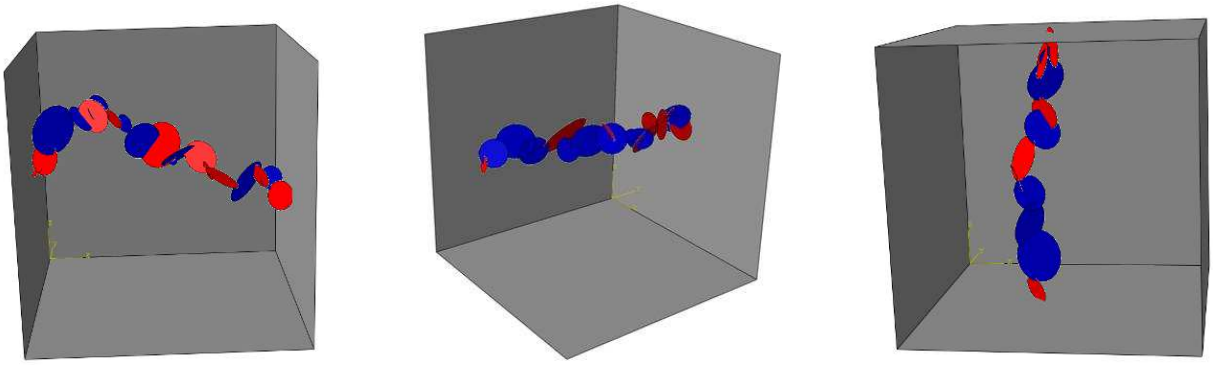
As the the permeability coefficient of the closed fractures,compared with opening fracture, is quite small,the closed fractures and filled fractures are deleted.After getting all the intersection lines of each two fracture disks,the graph of the fractures in the model is obtained.Then,the shortest path of every two fractures is available by using Dijkstra algorithm.Fig 5 shows three different shortest path in three different directions.



a) W—E a) S—N a) T—B

Fig.6 The shortest paths of three different directions

West to East:1475→623→3541→4088→1230→5080→74→1930→3501→202→3063→1999→798→1693→906→3365→604→2064→1473,go though 19 fractures.
South to North:1334→4476→3565→4370→641→2702→4922→2621→1343→3425→3769→4423→355→1255→1666→1354→2424→614,go though 18 fractures.
Top to Bottom:708→3051→963→2021→1689→3465→1707→439→3102→4102→3674→1563,go though 12 fractures.

## Conclusion

Discrete Fracture Network Model,based on the in-situ observations,is a very useful method to evaluate the hydraulic conductivity of rock masses.The intersections of each two fracture disks is the precondition to build the graph of the fractures in the model.And the Dijkstra algorithm is a very affective algorithm to obtain the shortest seepage path between the specified fractures,it helps a lot to get the equivalent direction permeability coefficient

**Keywords:** Chenghe-Second coal mine, No.5 coal seam, fault structure, fractal theory

**Abstract.** Based on the collected geological exploration and underground mining data, this thesis has analyzed the development feature of faults of No.5 coal seam in Chenghe-Second coal mine and obtained fractal law of fault structure by fractal statistics. The result shows that the faults have a good self-similarity on the plane distribution and obvious fractal characteristics and that the larger the fractal dimension, the higher the complex degree of fault structures.

## Introduction

Chenghe-Second coal mine is located in western Chenghe mining area of Shaanxi province and its approved production capacity has reached 0. 69 million tons per year after several transformation and expansion. So far, the mine has fully formed mechanized mining pattern. The main mining area is third mining area of second level, the two working faces of which are both mined mechanically, and the main coal seam is No.5 coal seam in Taiyuan Formation of Upper Carboniferous Series. With the increasing strength of mining and extent of mechanization, mine geological structure , especially fault structure has a more obvious influence on production and construction of mine. This thesis has researched fractal features of No.5 coal seam of Chenghe-Second coal mine and summarized its development laws according to the result, which has a certain guiding significance for safety production of the mine.

## Chenghe Mining Area Survey

Chenghe mining area across Chengcheng and Heyang counties of Shaanxi Province, is a medium-sized mining area located in eastern Weibei coal field [1]. The mining area is 67 km long, 30 km wide, and covers an area of 1718 square meters [2]. The coal seams formed in the Carboniferous-Permian and geological reserves is 8.58 billion tons. Among them, the main coal seam is No.5 coal seam, the quality of which mostly is lean coal, partly meager coal.

In terms of plate motion, The mining area lies on the border of Erdos plots and Weihe basin and is bounded on the east by Lvliang uplift and Taihang uplift, Fenhe graben system developes between which, on the south by Qinling folded belt and on the west by thrust structural belt and Liupanshan structural belt. This geotectonic background determines that the structural feature of the mining area on the whole is a monoclinal structure sloping towards the north with east-west and north-west faults and secondary folds along the strike and lean.

## Fault Feature of Chenghe-Second coal mine

The basic structural feature of Chenghe-second coal mine is a monoclinal structure with strike EW, dip to N and dip angle 20°. The large and medium-seized faults are relatively fewer, and small-seized faults comparatively develop.

**Large and medium-sized faults.** Within the range of mining right of Chenghe-second coal mine, 4 large and medium-seized faults that are all normal faults and located in the north of the coal mine have been discovered, including 1 EW strike fault and 3 NE strike faults. The four faults are Fangjiahe

fault, Mjiahe fault, Duanzhuang fault and Nanyao fault from west to east. Among them, Mjiahe fault and Duanzhuang fault are a set of en echelon faults, and the southern side of Fangjiahe fault and Majiahe fault, strike NE, both turn into near EW.

**Small-sized faults**. Within the range of mining right of Chenghe-second coal mine, 101 small-seized faults have been discovered in coal series and also 200 small-seized faults in mined area of No.5 coal seam.

Main strike of the small-seized faults in coal series is NW (about 315°) and the faults along near NE (about 40°) comparatively develop (Fig. 1).

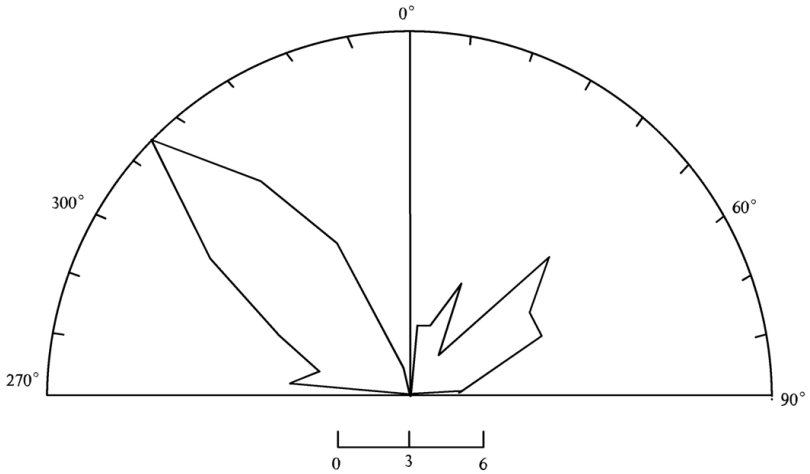

Fig.1 Statistics on strike of small-seized faults of No.5 coal seam

Main lean of the small-seized faults in No.5 coal seam is SW (about 225°), the faults along NE (about 55°) and SE (about 140°) comparatively develop, and along NW (about 315°) are fewer (Fig. 2).

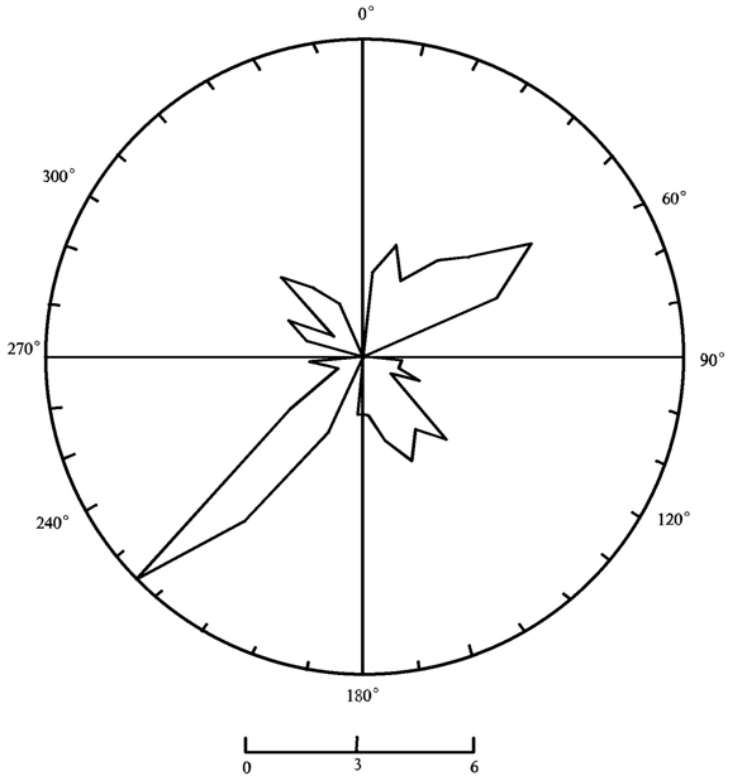

Fig.2 Statistics on lean of small-seized faults of No.5 coal seam

**Fractal Research of Fault Structure**

Based on the existing maps and data, this thesis has researched fractal features of No.5 coal seam of Chenghe-Second coal mine by input editing and spatial analysis two subsystems and scatter diagram module of Microsoft Office Excel.

First, dividing the coal mine into several grids with side length r and counting the total number of grids in which faults develop as reducing it with the ratio of 0.5 [3]. In order to attain fractal goal, the side length in this thesis is $r_0$=1000m, $r_1$=500m, $r_2$=250m and $r_3$=125m.

If the statistical result meet the following formula:

$$N(r)=Cr-D. \quad (1)$$

Where, it can be shown that fault structure has self-similarity within a certain range if C is a constant, and D is the fractal dimension.

And then, calibrating the numerical points in double logarithmic coordinate system. If fault structure has self-similarity, a fitting line can be getten from Ln(N(r))-Ln(r)scatter diagram, whose slope is -D and formula is:

$$Ln(N(r))=a+(-D)\ln(r). \quad (2)$$

Thus, the fractal dimension D and correlation coefficient R can be derived.

The correlation coefficient R of fault structure of each mining level is larger than 0.992 and the fractal dimension D is 1.6243, 1.684 and 1.0577 respectively, namely the fractal dimension of second level is largest, then first level and third level's is smallest. It can be concluded that complex degree of fault structures of second level is highest, followed by first level and third level's is lowest (Table 1).

Table 1 The fractal dimension D and correlation coefficient R of fault structure of each level

| Level | Fractal dimension D | Correlation coefficient R |
|---|---|---|
| First level | 1.6243 | 0.9985 |
| Second level | 1.684 | 0.9986 |
| Third level | 1.0577 | 0.9923 |

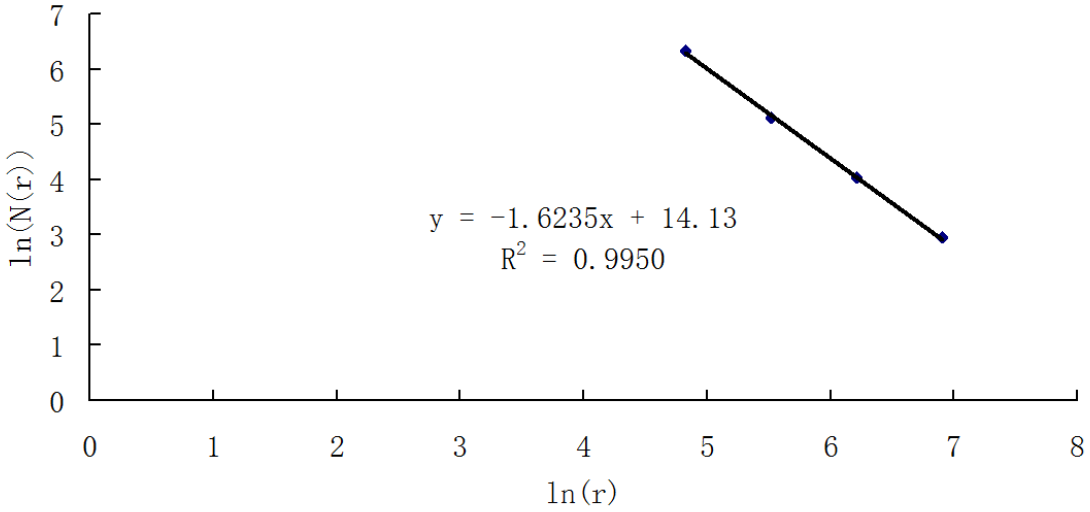

Fig.3 The Ln(N(r))-Ln(r) fitting line and fractal dimension of fault structure of No.5 coal seam

The result that the fractal dimension D of fault structure of No.5 coal seam is 1.6235 and the correlation coefficient R is 0.995 shows that fault structure of Chenghe-Second coal mine has good a self-similarity and meets fractal laws (Fig. 3).

## Conclusions

Bsed on structure features and fractal theory, the following conclusions could be obtained.

(1) 4 large and medium-seized faults have been discovered, which are all normal faults and have a obvious directivity.

(2) 200 small-seized faults in mined area of No.5 coal seam have been discovered, which are almost normal faults. Their main strike is NW, then near NE.

(3) The fractal dimension D of fault structure of No.5 coal seam is 1.6235 and the correlation coefficient R is 0.9950, which shows that fault structure of Chenghe-Second coal mine has a good self-similarity and obvious fractal features.

(4) The fractal dimension D of each level: second level > first level > third level, and the correlation coefficient R is larger than 0.9923, which shows that the larger the fractal dimension, the higher the complex degree of the structure [4] and the more the influence on safety production.

# The Application of Reservoir Geo-modeling Technology in Section07, Ticleni Oilfield

Lingyun Pang

Postdoctoral Programme of China Industrial Economic Security Research Center,

Beijing Jiaotong University

**Keywords**:Geo-modeling, Section07, Stochastic Modeling, Lithofacies Model

**Abstract:** In the study of reservoir geo-modeling in Ticleni oilfield, structural model, the spatial framework of the geo-model was firstly constructed based on seismic and petrophysical data and integrated geological background analysis. Then the variogram function was analyzed based on petrophysical data and sedimentary setting analysis, and the litholofacies model was established. Finally, the property models were constructed with reservoir physical property controlled by lithofacies model. Therefore, the quantification of geological study achievements and the distribution of reservoir physical property are effectively combined, which provides the foundation for the sequent reservoir development of Section07.

## Introduction

Ticleni Oilfield was discovered in 1950, and section07 is one of the sections of the field. Totally 18 wells has been drilled in section07 up to Year 2013, among which 10 are function wells and only 2 are producing wells currently. The oilfield has entered the Middle-Later Period of development and transferred from high water-cut stage to full water cut stage, reserve-production balance to out of balance. Remaining oil mainly distributes in the place with poor porosity and permeability of reservoir, which make it much more difficult to be discovered. All the problems above are mainly due to the inner heterogeneity of reservoir. The traditional geological study, which focused on the qualitative description on reservoir, can't satisfy the command of reservoir description at Middle-Later stage of oilfield development. In order to tap potential of old oilfield and improve the exploration and exploitation level, fine description on reservoir is of great necessity [1]. 3 Dimension geo-modeling technology- a method closely combining of mathematics and reservoir geology, can quantify the shape, structure and parameters of reservoir, and thus well characterize subsurface condition of reservoir [2].

## Geological Background

Section07 is about 4.95km$^2$ and situated in the western side of Getic Depression, Dacic Basin, Romania. The structure characteristics of the basin are controlled by contractional movement in Middle to Late Miocene and extension movement in Paleogene to early Miocene. Oil reservoirs in Section 07 are mainly occurred in faulted monocline structural trap, and the whole stratigraphic units incline to southwest generally. Sandstone and mudstone are major lithology developed in shoreland facies. There are totally 18 wells in this section, among which 10 wells with petrophysical and production data were used in geo-modeling (Fig.1) The target formations are Sarmatian Formation and Helvetian Formation in Miocene, which are divided into 7 layers totally from top to bottom-Sa_VI, He_tr He_I, He_II, He_III, He_IV, He_V and He_VI (Sa is short for Sarmatian, He is short for Helvetian). History production occurred in geo-zones of He_tr, He_I and He_II.

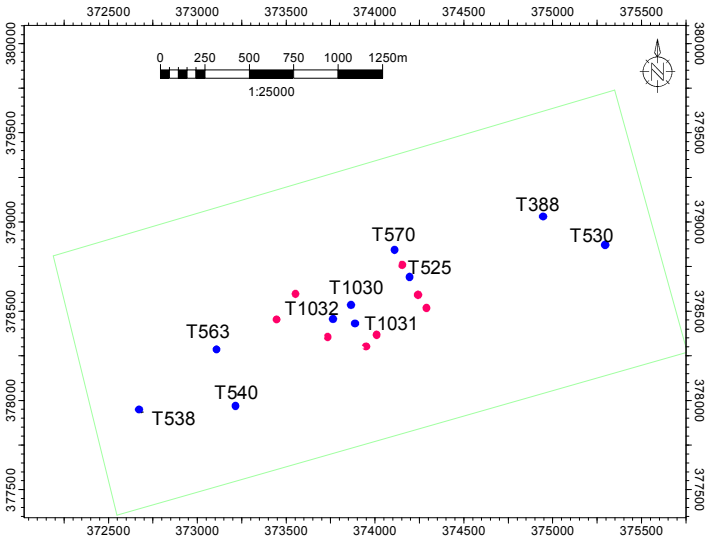

Fig. 1 Well Position of Section 07, Ticleni Oilfield

## Structure Model

Structure model is the basis of reservoir modeling, which provides the 3 dimensional spacial framework for the property modeling [3]. The fault model and the horizon model compose the structure model. The 60m×60m×10m gridding density for scaled geo-model and 30m×30m×1m for fine geo-model were adopted based on well density in the work area. The details of the process are as follows: firstly, fault model was constructed with interpreted seismic fault data and breakpoint data penetrated in wells; secondly 8 horizons were made through well tops data and controlled by seismic surface; finally the structural model of this section was constructed with Kriging (Fig.2). The structural model shows that the whole structure of the section is an NW-SE trend monoclinal structure with the structural high near well T1032.

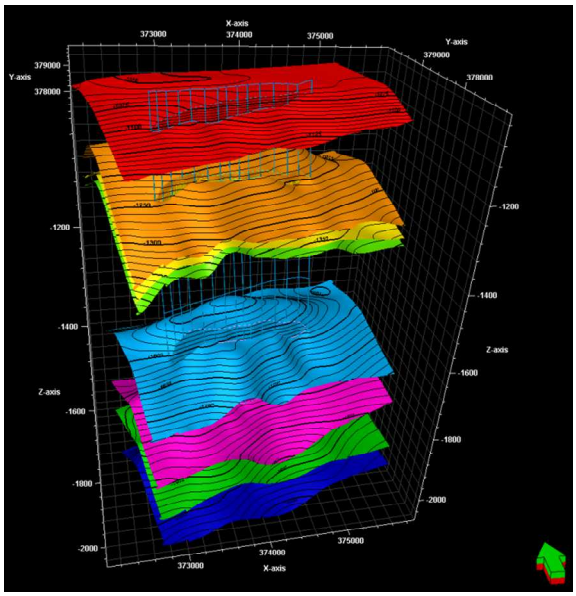

Fig. 2 Fault Modeling of Section 07, Ticleni Oilfield

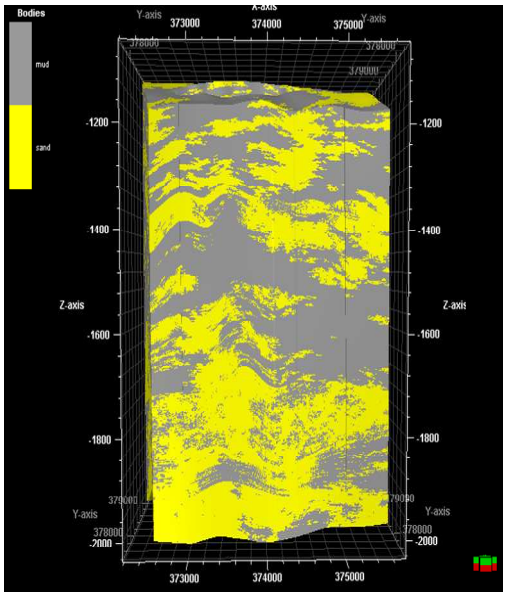

Fig. 3 Fault Modeling of Section 07, Ticleni Oilfield

## Lithofacies Model

According to the sedimentary setting and petrophysical analysis, the reservoir sandbodies in Section07 are mainly shoreland sands. The reservoirs of shoreland sedimentary environment are mainly composed of sand stone. The single sand body is of great thickness and multi-bed sand bodies superimposed. The distribution of sand bodies as well as the macroscopic heterogeneity of reservoir

are controlled by the sedimentary facies[4], while the spatial distribution of porosity and permeability etc. is mainly up to the spatial distribution of lithology. The property modeling in this paper is constrained by litholofacies model.

The sedimentary environment of section07 is shoreland and the provenance direction is NW-SE, therefore, the sand bodies of shaoreland are supposed to distribute along NE-SW strike across the provenance direction. The azimuth then is determined as NEE, and the lithofacies model is established based on the analysis above with well logging interpretation achievements of 10 wells (Fig.3).

## Property Model

The ultimate purpose of reservoir geo-modeling is to construct the model of reservoir parameters [5] (porosity, permeability, oil saturation and net to gross ratio), which can reflect the physical property of subsurface reservoir. Due to the heterogeneity and aeolotropy of reservoir physical property, deterministic modeling couldn't reflect the spatial variation of reservoir physical property [6]. Therefore, the stochastic modeling technology is adopted during this study. The property models, including porosity model (Fig.4), permeability model (Fig.5), water saturation model(Fig.6) and net to gross ratio (NTG for short) model (Fig.7), are constructed under the control of lithofacies with sequential Gaussian.

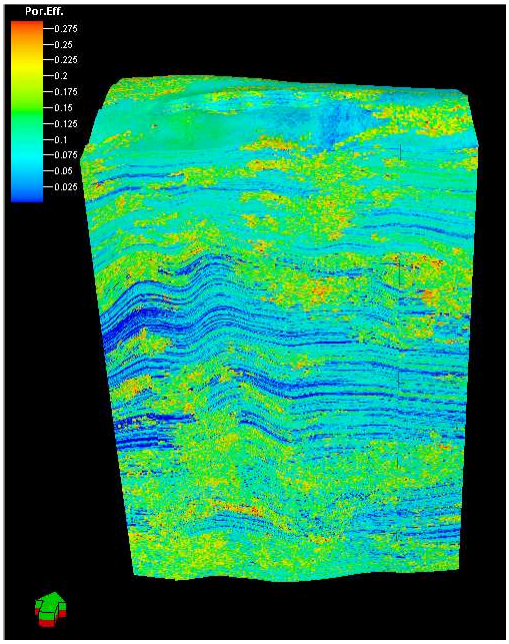

Fig.4 Porosity model

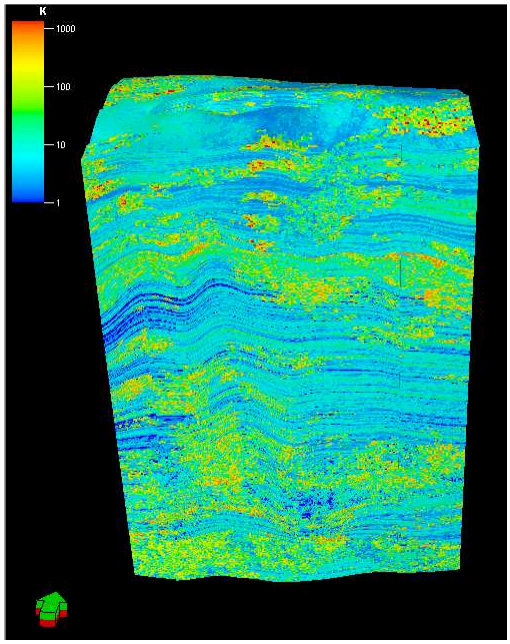

Fig.5 Permeability model

## 5.Reserv Match

Oil and gas reserve is related directly to the static parameter of the reservoir geo-model, and the distribution of porosity, permeability, water saturation and shale content determines the spatial distribution of the hydrocarbon in reservoirs. The heterogeneity and uncertainty of these parameters causes the uncertainty to reserve distribution and volume. Based on the geo-model of section07, the oil reserve was calculated by gridding with volumetric method. The influences of reservoir heterogeneity were fully considered in the reserve calculation, which greatly enhanced the accuracy. The reserve match showed that the relative tolerance of stock tank of STOIIP (147.5MMbbl ) to stock tank of original oil in place (STOOIP for short, value is141.4 MMbbl) 4.3%, which indicates the STOIIP matches well with STOOIP and the geo-model of section07 is relatively reliable.

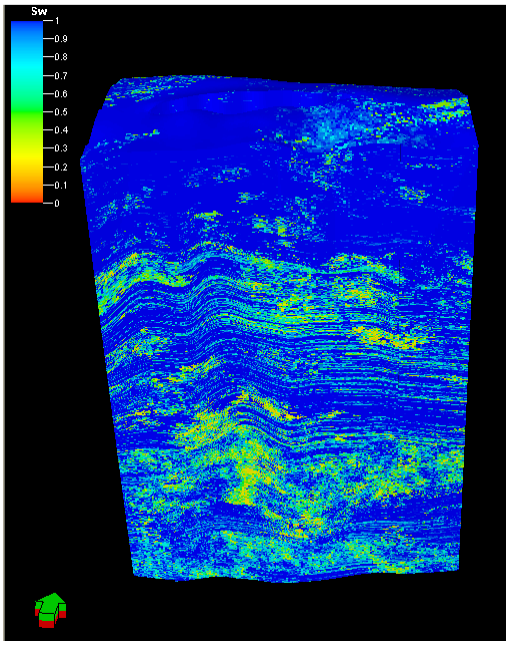

Fig.6 Water saturation model

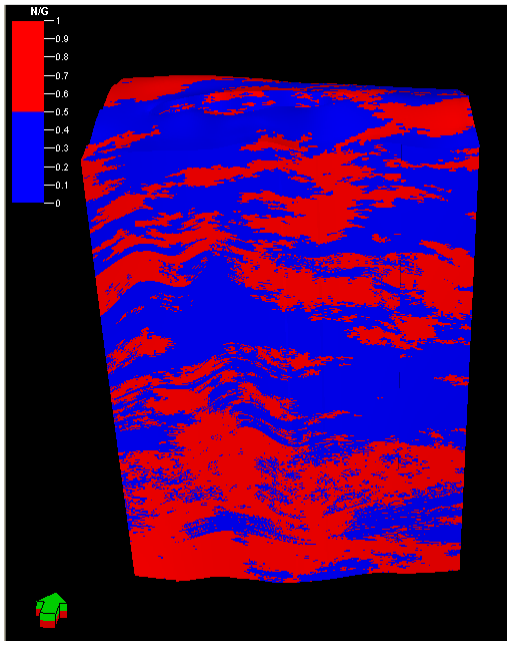

Fig.7 NTG model

## 6. Conclusion

1) There are many algorisms in the modeling software of Petrel, and suitable algorisms should be chosen to construct geo-model according to the real characteristics and data of different section.
2) Seismic, well logging and geologic data are synthetically applicated during the geo-modeling. Multiple data combine and constrain with each other, which as a result greatly improved the accuracy of the model and well characterized the reservoir.
3) The sedimentary microfacies wasn't divided in this study due to the lack of necessary data. The study about sedimentary facies need to be done deeply in the future, which would constrain the model make it much more close to the real geology and more reliable.

**Keywords:** Rock masses classification;Geological evaluation; RMR; The 3rd mining area of Jinchuan.

**Abstract.** This paper takes the No. 1 ore body of Jinchuan 3rd mining area as an example, obtains the corresponding relation of surrounding rock quality evaluation index and spatial location.Through RMR rock classification method , using Rockware modeling system and limited geological informations, the statistical analysis of RMR and RQD showed that the rock of No. 1 ore body belongs to III~V type. Its rock mass is between normal to unstable. Through Rockware modeling system, we established the 3D rock properties model of UCS, RQD and RMR, and found that in the 5 to 6 rows of east hanging wall exists rock not conducive to the block caving method which belongs to the type of V. Finally, Statistical analysis was made based on the numerical model of strata. We find that , basically ,the rock block has good cavability because it belongs to the IV type of rock masses. However when design blocks and manage drawing, we must pay particular attention to the III type of rock, which is of moderate stability, and the V type of rock, which is less stable. All of these make a useful exploration for the research of key technology in the field of the interior of the earth.

## Introduction

We always want to fully describe the characteristics of deep rock mass. However there is no good method for comprehensive description of underground rock mass because of the unpredictability of the underground rock. So, when we want to classify or evaluate the quality of underground rock mass, the geological information is gained often based on sampling or drilling such as roadway joint investigation, geological exploration drilling and so on. There are two questions. For one, except for the number of quantitative information, there is so much qualitative information, such as the roughness of joints, the waviness of rock formation, the filling in the rock fractures and the description of the groundwater. When we carry on geological exploration or drilling logging, we must quantify the qualitative factors with certain technology to provide the basis for the classification of surrounding rock. The characteristics of these qualitative descriptions play an important role in the quality evaluation of the rock mass. For another, in order to obtained the predict result of the ore rock quality, we must obtain the quality evaluation index of surrounding rock and the corresponding relations between the space position and the rock mechanics parameters of ore body. All of information obtained through drilling need to be treated by stages and also comprehensively.

Jinchuan copper nickel sulfide deposit is a large scale deposit located in Jinchang, Gansu province. The ore grade is low in the 3rd mining area of Jinchuan, so the plan is to adopt the block caving method to mine ore. This methos has lower production cost and higher production efficiency. Because the block caving method has certain requirements for the quality of surrounding rock and ore body (The ore body has characteristics as the following: full of crannies, instable, large thickness, large inclination angle, good stability of the surrounding rock).As the resuilt the classification and the quality evaluation of the rock mass has special significance for the cavability, caving blocks and the mining management etc. Based on the survey data, JIA Ming-tao et al [2] speculated the RMR at the

regional of above 1554m level using geostatistical estimation method. They think that the ore rock cavability is mainly grade III. The collapsibility is good to very good. LIU Ye-ke[3], XIE Ben-xian[4] and their groups, from the Central South University, amend the RMR method, to reflecting characteristics of deep underground rock mass. YU Wei-jian, GAO Qian[5,6] from University Of Science and Technology Beijing conducted micro experimental study of deep rock mass in the 3rd mining area of Jinchuan. When analyzing the mechanical properties and the rheological law of tectonic zone of surrounding rock, they found that the rock mass has low strength because there are so many mineral crystal structures in the rock mass .The paper further points out that part of the rock is of high porosity, and easily expanse when touching and mud. These cases show that adopt caving method in the 3rd mining area of Jinchuan is suitable, but we need pay close attention to the problem of argillization when ore drawing management. The conclusion has an important guiding significance for our research.

So many literature shows that the cavability of the rock mass of the 3rd mining area of Jinchuan is good, however there are many disadvantage to the block caving method through careful study. So, how do we evaluate the quality of rock mass in a scientific way, and to provide some guidance for mining design and drawing management? This paper takes the No. 1 ore body of Jinchuan 3rd mining area as an example, uses the method of RMR surrounding rock classification, Rockware modeling tool and so on, introduces the classification and quality evaluation of rock-mass based on limited geological information.Capitalizing on these conclusions, we can take concrete technical response, to ensure that the ore mining more scientific and efficient in the premise of safety.

## Statistical Analysis of The Partial Drilling Mining

**RMR surrounding rock classification.** After the method of RMR surrounding rock classification was introduced in the year 1973~1975[8], it continued to add data and widely spread in the world. It uses the 6 indicators as the basic parameters.They are the uniaxial compressive strength of rock, rock quality designation(RQD), joint spacing, joint conditions, groundwater conditions and the correction coefficient. These indicators are determined by the relationship between the joint surface range to the foundation, together with the slope and the excavation direction. Among those parameters, there are quantitative parameters such as the uniaxial compressive strength, rock quality designation etc, and qualitative parameters such as joint conditions, groundwater conditions etc. RMR is a method which combins both qualitative and quantitative information. It can fully reflect the importance of qualitative indicators to the quality evaluation. The method of RMR is so flexible and simple that it meets the demand of qualitative information. As a result, when referring to the statistical analysis of the drilling mining, we use RMR surrounding rock classification.

**Analytical results.** The statistical analysis mainly described in detail the classifi-cation index of RMR changes along the borehole of the 12 bore-holes. Figure 1 shows the relationship between the surrounding rock quality RMR with depth, which from the borehole of Zk02. Table 1 shows the analysis results of RMR and RQD, from 10 boreholes.

## Statistical modeling based on drilling cycle

In order to research the spatial variation of rock mass quality and cavability of the lean ore that comes from the No. 1 ore body of the 3rd mining area in detail, we adopted statistical analysis of drilling hole data, used Rockware modeling system, and established the three-dimensional characteristics model of UCS,RQD and RMR(or cavability). Figure 2 shows the 3D distribution model of UCS, Figure 3 shows the 3D distribution model of RQD and figure 4 shows the 3D distribution model of RMR.

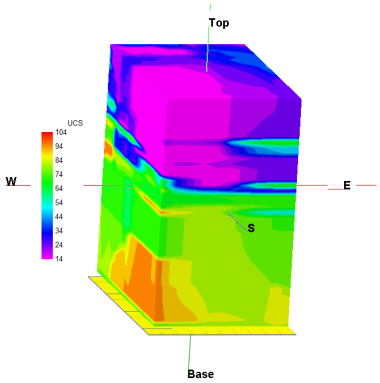

Fig. 2 The UCS model of the rock from No. 1 ore

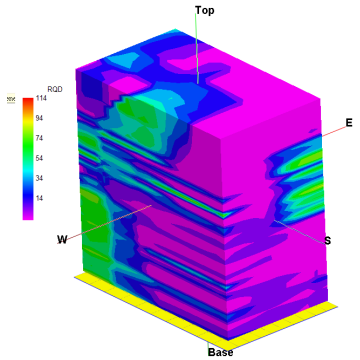

Fig. 3 The RQD model of the No. 1 ore

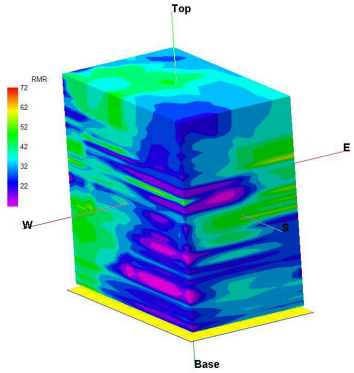

Fig. 4 The RMR model of the No. 1 ore

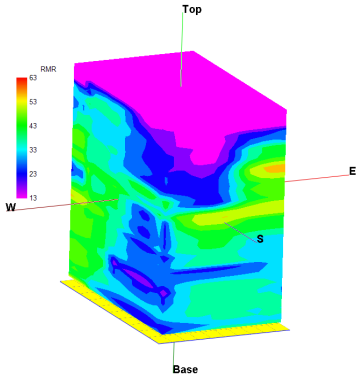

Fig. 5 The RMR ore block model

## Segment statistics of drilling and the three dimensional cavability model

In order to analyze and predict the cavability of the ore rock, we built Cavability evaluation model using Rockware modeling system according to the data of segment statistics of drilling. Figure 5shows the RMR ore block model which is based on rock drilling section. It clearly shows a stable

state of mining of No. 1 orebody rock, that is the eastern 5 ~ 6 of hanging wall which affected by the fault F8 belongs to class V. When block design and drawing management, we must pay attention to this kind of broken surrounding rock.

## The results of formation statistical analysis

In order to established numerical analysis model, we need to perform statistical analysis according to the formation that is divided the stratigraphic for the hanging wall rock, lean ore and the footwall rocks. Statistical analysis results of drilling the formation in Table 2. Table 2 shows the results of statistical analysis of surrounding rock and ore body.

## Conclusion

We can obtain the following conclusion based on the analysis results of drilling to statistics:

(1)The RMR of drilling change relationship with depth is complex. Besides individual drilling, the change is not very obvious, need to be further analysis.

(2) Generally speaking, the classification of rock mass that comes from the No. 1 orebody in the 3rd mining area, belongs to class III~V. Its stability ranges from the general to the unstable rock mass.

(3) Using the line eighth as a boundary line, we can divided the No. 1 orebody into two ore block. One is the eastern block and the other is the western block. The eastern block belongs to class III,IV, and the western block belongs to class IV (only the footwall rock of line 11 belongs to class III). Thus the eastern block rock mass is slightly better than the west ore block.

(4)The hanging rock is worse than the footwall rock of the eastern block. The hanging rock belongs to class IV, and the footwall rock belongs to class III.

(5)The rocks of western block are basically the same, both belong to class IV

Based on the RMR model which established by the classified data of drilling section, we can reach the conclusion that the line 5~6 of hanging wall in eastern block belongs to class V. When performing

block design and drawing management, we must pay attention to this kind of broken surrounding rock.

Through the establishment of numerical model, and the statistical analysis performed according to the formation, we can reach the conclusion that

(1) Generally speaking, there is a difference between hanging wall to the footwall. The surrounding rock in the hanging wall (RMR=31) is worse than in the footwall(RMR＝34). They both worse than the lean ore body（RMR=40）.The RMR mean value of the whole rock mass is 35, wchih belongs to the class IV. The whole rock has good cavability.

(2) The statistical analysis results based on the 10 holes shows that there are some variability exists among the hanging rock, the footwall rocks and the ore body. The variability of hanging rock is the minimum ($V$=0.092),and the footwall is the maximum($V$=0.234) while the variability of the lean ore body is smaller than footwall($V$=0.214).

(3)Generally speaking, the surrounding rock classification of the No. 1 orebody in the 3rd mining area belongs to the class IV. Ore body belongs to the upper of class IV, and the hanging wall and footwall rock belongs to the mean of class IV.

(4)Although the quality of the whole rock belongs to the type of class IV, from the RMR contour map we can see that there are some rock belongs to the medium stable rock (belongs to class III)in the footwall rock of line 5~6 (e.g. zk01 and ZK03 drilling in the table 2, RMR＝51) while he hanging wall belongs to instable rock(classV). It's unfavorable for the block caving of the eastern block in the No. 1 orebody, we must pay attention to this situation.

**Keywords:** Jinsha River area, Qinglong landslide, genesis mechanism

**Abstract.** Qinglong landslide is a very typical landslide in the central region of Yunnan Province water source diversion reservoir area of the Jinsha River. The geological background of the landslide region is introduced,including Landform, stratum lithology and geological structure and hydrogeological condition. Based on the collected geological data and according to the results of site investigation, the complete picture of Qinglong landslide is provided. Then the image of 3d vision is made. The longitudinal profile and cross-sectional profile are drawn. At last, The genesis mechanism of Qinglong landslide is analyzed from the point of landform, Rock mass structure and Geological structure. The study is helpful to understand the status of other landslides and can provide the basis of appraisal of reservoir bank stability.

## Introduction

QingLong Landslide is located in the upper reaches right bank in the central region of Yunnan Province water diversion of the Jinsha River. The distance between QingLong landslide and Aluogong dam site is about 34.537km. The volume of QingLong landslide is about $0.38 \times 10^8 m^3$.This landslide is a very typical one in the area. The genesis mechanism analysis of this landslide is very helpful to understand the status of other landslides and can provide the basis of appraisal of reservoir bank stability [1, 2].

## Geological Background of the Landslide

**Landform** The reservoir region is located in the north of Hengduan Mountains and the upper reaches of the Jinsha River. The main mountain ranges and river system are about north-south distributed, and the development is obviously controlled by regional structures. High mountains, deep valleys, and steep topography are the main characteristics of the global topography. The landform is extremely high relief extra-high zone of mountain and extremely high relief high zone of mountain. The relative height difference in the reservoir region is higher than 1000m, and the biggest height difference is higher than 2,800m. The elevation in most of the region is between 2200m to 4200m.

**Stratum Lithology and Geological Structure** The stratum in the reservoir region is South China strata. The exposure stratum in the reservoir are Gerong Formation, Qiongcuo Formation, Ranlang Formation, Gangdagai Formation, Qugasi Formation,Bolila Formation, Adula Formation, Dongwang Formation and other Formations. The outcropped lithologies are magmatite, metamorphic rocks and sedimentary rocks.

In addition, the S-N trending fracture structures in the reservoir are extremely developed, and the scales of these fault fractures are quite differently [3].

**Hydrogeological Condition** In the reservoir, tectonism is very strong. Wrinkles and fractures are well developed. The neotectonic activity is very active. The fractures, strata and rock, landform and climate are obviously different between the south, central and north regions. These conditions have

immediate impaction for the occurrence, distribution, enrichment and supply, runoff, excretion and hydrochemical characteristics, geothermal activity of underground water.

The supply of the underground water in the reservoir region mainly depend on rainfall. the pore water in loose rocks and the Karst ground water also can accept the supplement of the underground water in adjacent aquifers and surface water. The routes of underground water runoff are very short. The recurring cycles effects are strong. It has the characteristics of supplying from near areas and excreting in the near regions. The dynamic changes of springs are obviously impacted by seasons.

## Geological Characteristics of the Landslide

Qinglong landslide is located in Qinglong village which is situated in the right bank of the reservoir tail upper reaches. The shortest distance from the leading edge to the Jinsha River is 132m. The plane form of the landslide is the shape of irregular rectangle. The length is 1284m, and the width is 840m. The distribution elevation range is between 2100 and 2390m. The area is 86.3×104 m2. the average thickness is about 45m. the main trend is S24°W. The trend of bank slope in upper reaches is about S54°E. The trend of leading edge bank slope is S47°W.

Fig.1 Qinglong Landslide complete picture

Qinglong landslide mainly develops in the stratum of the first section of Lower Permian (west part). Site investigation shows that the bed rock of the landslide is Greenschist. The degree of weathering of the bed rock is moderate to intense. The joints in the rock mass are well developed, and the rock mass is broken relatively. The earth surface is smooth. The grain size of the deposition is mainly between 20 cm to 30 cm, and the content is about 80%. The maximum grain size is 50cm, and the content is about 5%. Fig.1 shows the complete picture of Qinglong landslide.

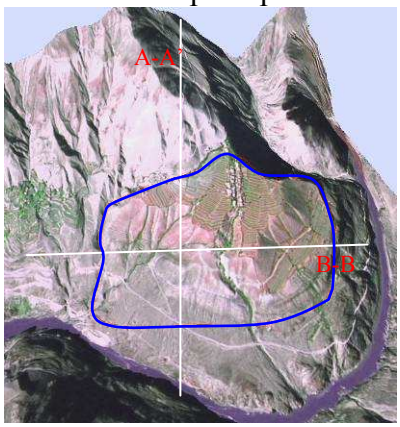

Fig.2 The image of 3d vision
of Qinglong Landslide

The Digital three-dimensional images of Qinglong landslide are established using the remote sensing images in the range of the landslide and combining DEM digital information [4, 5]. Then, the representative profiles of the landslide are arranged as shown in Fig.2.

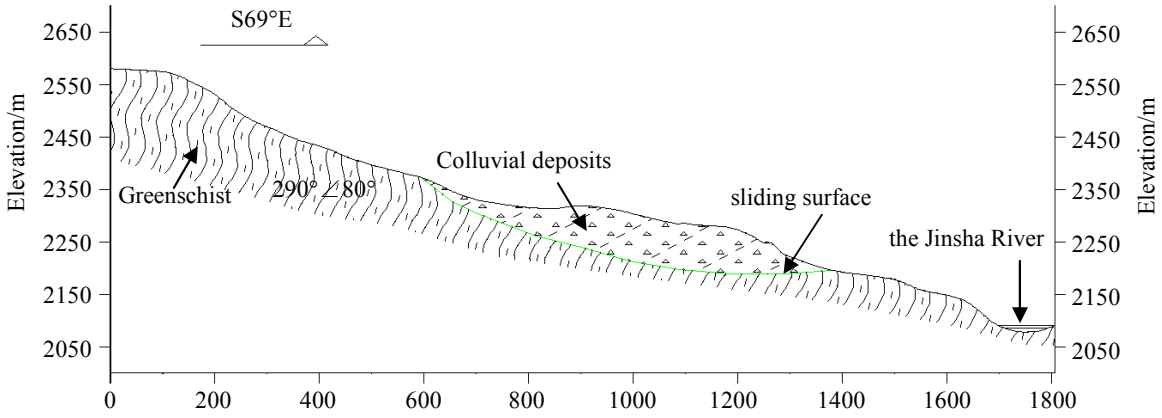

Fig.3 Qinglong longitudinal profile

Based on the 3D digital model of the landslide, the longitudinal section of the landslide is built from the bed rock in the trailing edge to the leading edge along the main distribution trend of Qinglong landslide as shown in Fig.3. The transverse section is built along the normal direction as shown in Fig.4.

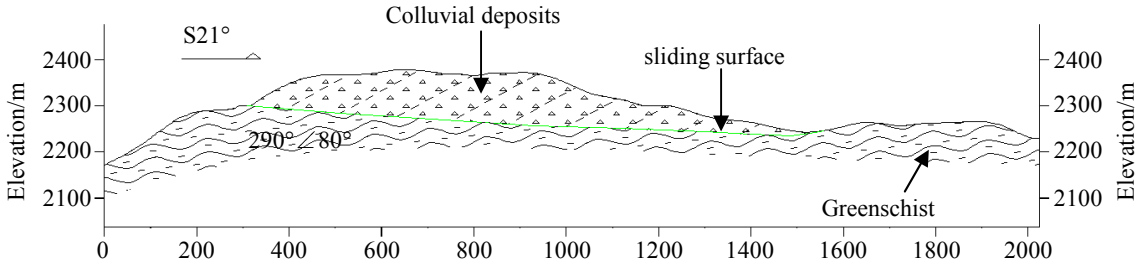

Fig.4 Qinglong cross-sectional profile

Fig.3 shows that the terrain of the trailing edge area of the landslide where the bedrock outcropped is very steep. There is a platform in the back of the landslide and its gradient is very small. Since its front part is seriously eroded, the leading edge of the landslide is steep. The elevation of the leading edge is 2198m, and the elevation of the trailing edge is 2374m. The relative elevation is 176m. The average thickness is about 45m, and the thickest part is about 89m. According to the arranged reservoir water level which is 2090m, the landslide will not be submerged after impounding.

Fig.4 shows that topographic undulation of the landslide is relatively sharp.

## Conclusions

The main features of Qinglong landslide are shown above. Then the buckling failure conditions of QingLong Landslide will be analyzed.

(1) Landform

Fig.3 shows that the relative elevation between the leading edge and the trailing edge is 176m. Both the top slope and the bottom slope are very steep. In addition, both boundaries of upper and lower reach are gullies. So the upper, lower and front boundaries are free. Furthermore, there is a river bend near the landslide. This geomorphology is beneficial to unload. To sum up, there are advantages for the slope's deformation and movement to the free surfaces under the effect of gravity.

(2) Rock mass structure

The bed rock of the landslide is mainly greenschist in the stratum of the first section of Lower Permian (west part). According to the results of site investigation, the degree of weathering is moderate to intense, and the output pattern is medium-thin. The stratum is trend to the inside of the slope steeply. In addition, the joints and cracks are well developed. The most rock masses in the accumulation zone are comparatively broken. Toppling deformation of the stratified rock mass to the

outside of the slope in the leading edge and upper reach under the gravity is found in the site investigation. The angle between the trend of the slope in the leading edge and the trend of the stratum is 27°. This condition is the base of the bed rock's toppling deformation. The two gullies in the upper and lower boundaries release the rock mass's constraint to the rock in the accumulation zone. This is an advantage of the bed rock's deformation. To sum up, the combination of the layer dipping toward to the inner slope steeply and the well developed joints in the rock mass is harmful to the stability of the slope rock mass.

(3) Geological structure

Some small faults are found in several districts in site investigation, and these faults are very short. The results show that tectonic stress impacts slightly the roc mass stability in accumulation zone.

In conclusion, we infer the mode of Qinglong slope failure is bend-rip failure.

**Keywords:** Clay shale, Triaxial tests, Mechanical strength, Rock mechanics

**Abstract.** The basic physical and mechanical characteristics of Clay shale in Bayingobi Basin of Inner Mongolia have been investigated by using supersonic testing system, rock mechanical testing system, and rock triaxial testing system. The results indicate that the deep clay shale of this region is characterized by high density, high mechanical strength, low deformation and strong brittleness. More specifically, according to the tests, because of their relative small particle size, the carbonate grains of clay rocks in this region are distributed more uniformly, and the average clay mineral content is comparatively low, as a result, the deep clay shale of this region are featured by large internal friction angle and high mechanical strength.

## Introduction

Clay shale, as one generally-accepted type of the important candidate surrounding rocks for underground waste disposal, is characterized by good self-healing and low permeability features. Currently, Amann studied the brittle behavior of deep clay shale of Opalinus, Switzerland [1-2], and almost simultaneously, Brapi carried out the investigation on the fracture mechanics characterization of clay shale in this region[3]. Liu Yuemiao conducted relevant research on the basic physico-mechanical behavior and time-temperature effects of crystalline rocks in Beishan district, Gansu province[4]. It is noteworthy that great achievements have been made by foreign researchers for the study on the physico-mechanical properties of clay shale taken as the waste disposal surrounding rock [5-9], however, much less relevant research has been carried out in China. In view of this, a series of research on the physical and mechanical characteristic of clay shale Baiyingobi Basinnde has been performed in this paper, which is intended for providing valuable information and technical supports for the construction of waste disposal repository and computational analysis of deep rock mechanics.

## Distribution of seriously destroyed dams in Wenchuan earthquake

## Physical property of clay shale

The amount-product method was adopted to measure the natural density of clay shale rock mass in this region, with the sample sizes taken as φ50×100 and Φ50×25 respectively. Figure 1 shows the natural density of deep clay shale rock mass in Bayingobi Basin varying with depth. It is shown that the density ranges from 2.26 to 2.6 g/cm3. The density of clay shale with the depth range of 570m-650m is relatively high, concentrating within the scope of 2.4 and 2.6 g/cm3. Generally the density of clay shale increases with depth.

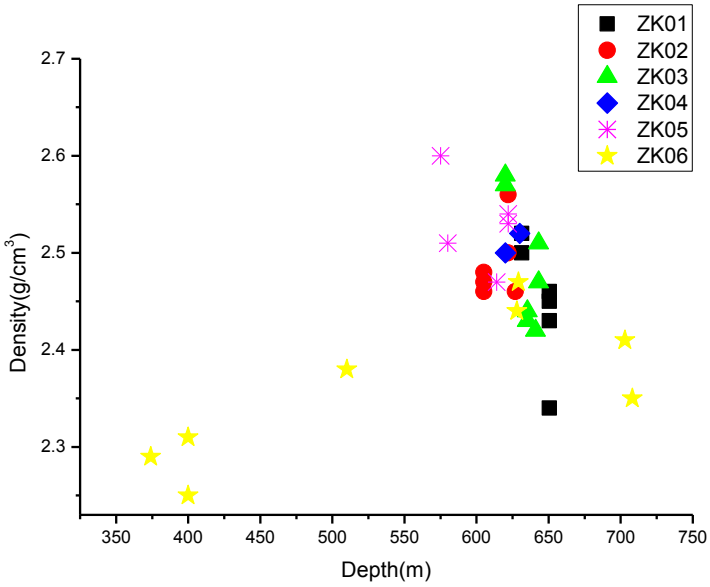

**Fig.1 Bulk density (in natural condition) varying with depth**

By making use of RSM-SY5 intelligent acoustic testing machine, the acoustic wave penetrative method was adopted to measure the compressive wave velocity of the rock samples with the size of φ50×100. Figure 2 indicates that the compressive wave velocity of clay shale in Bayingobi Basin, not closely related to the depth of rock, ranges from 3226 to 5263 m/s. Even at the same depth, the compressive velocities of clay shale differ largely from each other. The clay shale in this region is considered as anisotropic material, due mainly to that the compressive wave velocity is widely dispersed. From figure 3 it is shown that the compressive velocity increases with the increasing density of rock mass, nevertheless, affected by the composition, structure and fabrics of sedimentary rock, the clay rocks even with the same wave velocity take on certain scattering features.

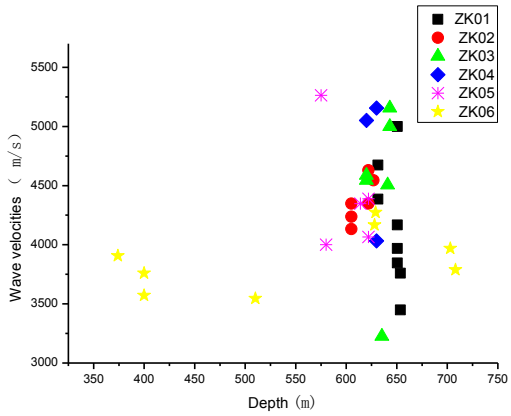

**Fig.2 Wave velocities varying with depth**

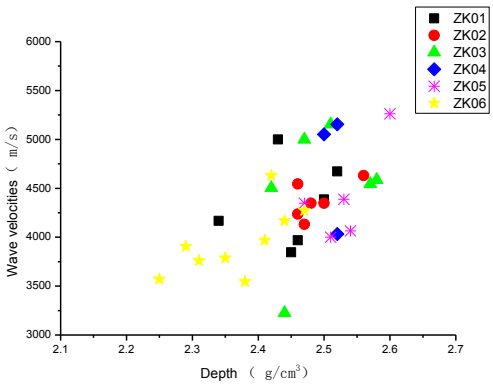

**Fig. 3 Wave velocities varying with bulk density**

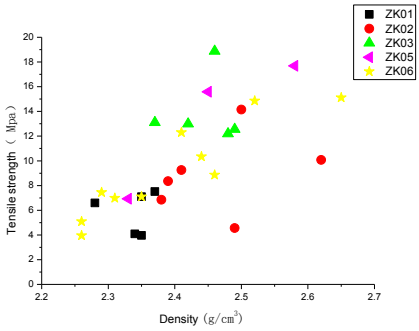
## Mechanical properties of clay shale

Brazilian split tests were conducted to measure the tensile strength and uniaxial compressive strength of the rock samples with the size of φ50×25and φ50×100 respectively. Figure 4 shows the tensile strength of clay shale varying with density. It is indicated that the distribution of tensile strength is strongly scattered, within the range of 5MPa~16MPa. Besides, the tensile strength of clay shale in this region increases with the increasing density, and a positive correlation is shown between these two parameters.

The clay shale of this region is rich in carbonate composed mainly by calcareous cement, which leads to its relative high tensile strength. By analyzing the chemical cements of the clay shale in this region, we found that the carbonate content ranges from 12.51% to 17.19%； through microscope it can be

observed that the particle sizes of carbonate grains are relatively small, most concentrating on about 40μm, and the grains are distributed more uniformly, which probably leads to the higher strength of clay rocks in this region than that of other clay rocks of the similar type.



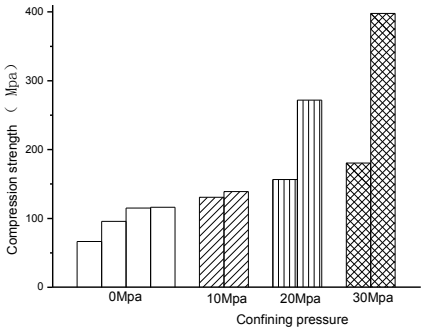


**Fig.5 Compression strength under confining pressure** **Fig.4 Tensile strength varying with bulk density**

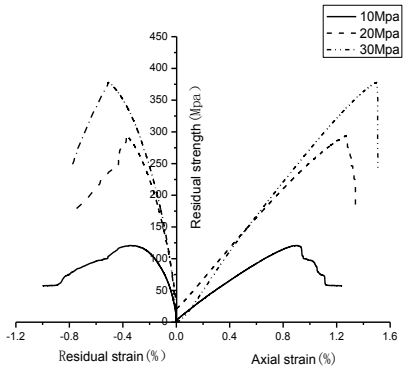
Large rock triaxial testing system was adopted to measure the triaxial compressive strength of rock samples of the size φ50×10, with the confining pressures set as 10Mpa, 20Mpa and 30Mpa respectively. The testing results are shown in Figure 5.



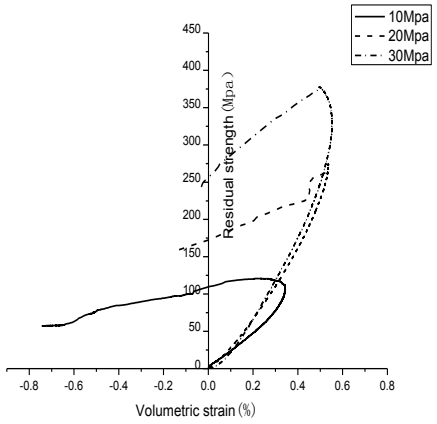


**Fig.6 Stress-strain curves of clay rock under different confining pressure** **Fig.7Stress-volumetric strain curves**

As shown in Figures 6, 7, with the increase of confining pressure, the axial breaking strength and residual strength of clay shale gradually increase. It is shown from the stress-strain curves that under different confining pressures, the clay shale takes on brittle failure characteristics after the peak stress. The stress-strain curves after the peak stress show that this type of clay shale can be considered as unsteady rupture propagation, that is, the peak stress dramatically declines, accompanied by the phenomenon of rapid volume expansion, so that the strain softening characteristics can be reflected. With the increasing confining pressure, the failure modes of rock transform gradually from brittle tensile failure, tensile-shear failure to shear failure. Under the confining pressure of 10Mpa, the clay shale shows brittle tensile failure mode, which belongs to the wedging tensile-shear failure modes. Many micro-cracks in the samples gradually form small longitudinal fractures, and are assembled into two sides of the wedge block by tensile forces. When the confining pressure increases up to 30Mpa, the clay shale of Bayingobi Basin shows weak-plane shear failure mode, also called single inclined-surface shear failure modes, in which many micro cracks form gradually small tensile cracks, and are interconnected and assembled into shear fractured zone by ultimate loads . according to the above testing results the strength envelope and Mohr-Coulomb strength curves of clay shale in Bayingobi Basin can be obtained, as shown in Figure 8, from which the cohesion and inner frictional angle are respectively obtained as 1.52Mpa and 59° .

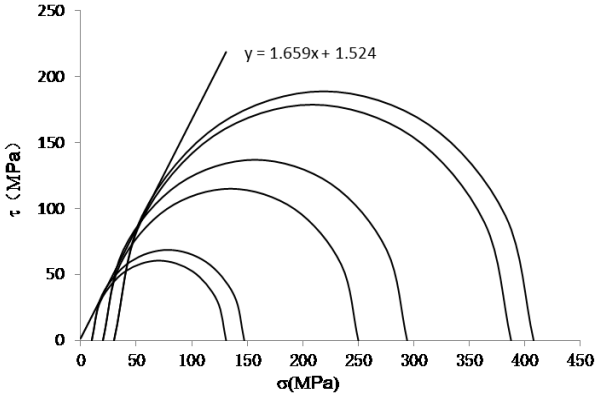

**Fig.8 Mohr-Coulomb strength curve**

## Conclusions

The deep clay shale of Bayingobi Basin, Inner Mogolia is characterized by such physical properties as high density, large compressive velocity and intact rock structures. The testing results show that the tensile strength and uniaxial compressive strength of the clay rocks in this region are relatively high. With the increasing confining pressures, the triaxial compressive strength, elastic modulus and passion ratio gradually increase. Under different confining pressures, the clay shale rock takes on the brittle failure modes after the peak stress. However, with the increasing confining pressures, the failure modes of clay rocks gradually transform from brittle tensile failure to shear failure modes.

**Keywords:** geometry characters, fault system, fault growth, mechanics .

**Abstract.** Architectures of fault systems play important role in stability and mechanics of rock mass. While growth mechanism of faults is intrinsic controler for architectures of fault systems. This paper presents a case on faulting in the dam area of an oversized hydropower in Southwestern China. The faults in this area are mostly strike-slip faults with shallow brittle deformation characters, extending tens to hundreds of meters. These faults can be divided into four groups which are formed during two generations corresponds to two periods of tectonic events. Growth model of these faults have been built based on geologic and mechanic data. The first generation of faults was formed based on preexisting joints. While the secondary generation emerge only if the existing faults become critically misaligned during rotation of the primary stresses. The criterion laws for formation of secondary faults are suggested. According to the growth model, we can predict placement of secondary faults in space. Conversely, when geometry and space characters of the fault systems are known, we can estimate mechanic parameters and tectonic environments of the rock mass.

## Introduction

Fault systems are first order structure surfaces which separate natural rock mass to be discontinuities [1, 2]. Architectures of fault systems are essential factors for stability and mechanics of rock mass [3]. Generally, faults derived from joints, cracks or secondary small faults. These fractures grow by linkage of neighboring ones through splay faults [4]. Succedent tectonic events may restart existing faults for they have lower cohesion. Whereas new fault will form when the primary fault becomes critically misaligned with the rotating principal stresses [5]. All above processes strictly comply with certain mechanics and geometry rules [2]. This makes it possible to quantitative predict 3D architecture of fault systems if the mechanics parameters and tectonic background of rock mass are known. It proved to be a difficult process for geometry data of fault systems are hard to obtain. Great or oversized geologic engineering area, however, provide excellent places for Quantitative analysis of fault systems because of large scale engineering excavation.

This paper presents plenty of geometry data of 261 fault traces in dam area of an oversized geologic engineering in Southwestern China, and contributes to give a quantitative analysis of the growth mechanism of these faults.

## Geological setting

The Baihetan dam area locates in downstream of Jinshajiang River between Ningnan county, Sichuan province and Qiaojia county, Yunnan province in southwestern China. This area belongs to western margin of Yangtze plate. Sediment records represent relatively stable shallow sea environment since Paleozoic with several uplifting movements. It transformed to foreland environments during Jinshajiang orogen events in Mid Triassic, and was activated by New Tethys events during Quaternary.

Continuous subduction of Indin Plate to Tibet caused lateral extrusion of Tibet terranes during Neogene. The Xianshuihe fault zone (Fig. 1, $F_1$) is the northeastern boundary of the extrusion and

presents left-lateral strike-slip with an average rate of ~10 mm/yr. The $F_1$ extends southeastward to Yangtze plate along Anninghe fault ($F_3$), Zemuhe fault ($F_4$) and Xiaojiang fault ($F_6$). All above 4 faults are restarted ancient faults, and now are seismogenic ones. The $F_3$ and $F_4$ composes folding lines which will increase sliding resistance of the fault zone. The Daliangshan fault zone ($F_5$) links the $F_1$ and $F_6$ directly and forms a perfect arc together with $F_1$ and $F_6$. Geological data indicate that the non-seismogenic $F_5$ is composed of six fault segments (Fig. 1). These segments are separated by spacers and compose left-lateral right-stepping echelon fault systems despite Yuexi fault (Fig. 1, No. ③) which shows reverse sense. Remote and field data suggests that the $F_5$ was a developing younger fault which will replace the $F_3$ and $F_4$ and is a potential seismogenic zone [6].

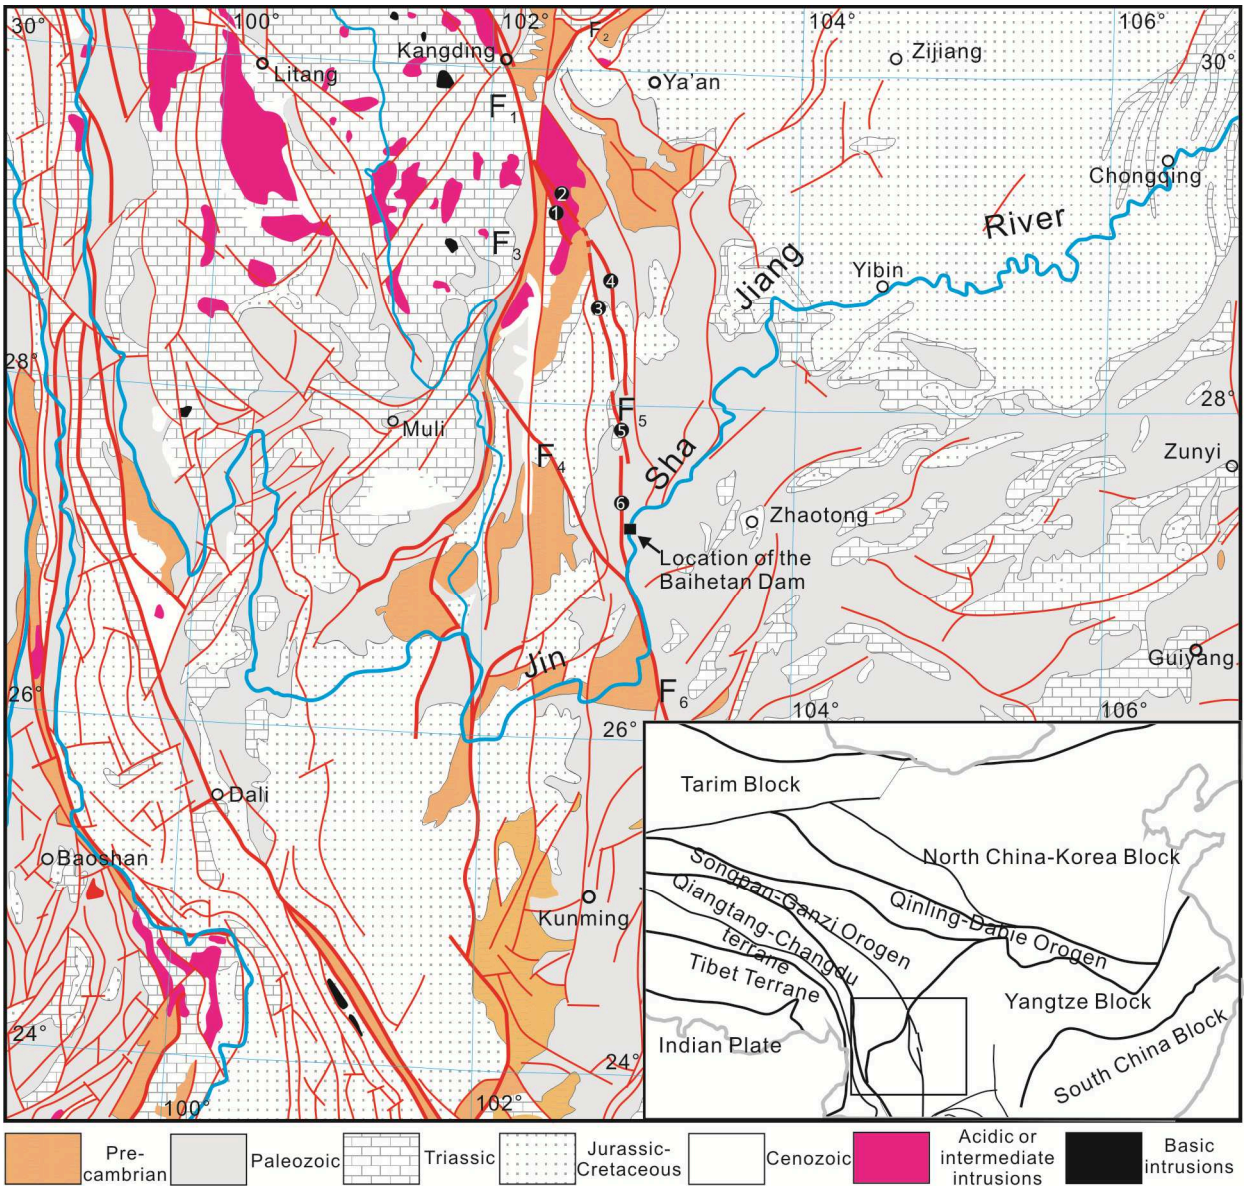

Fig. 1 Sketch tectonic map of Baihetan area and its neighborhood
($F_1$, Xianshuihe fault; $F_2$, Longmenshan fault; $F_3$, Anninghe fault; $F_4$, Zemuhe fault; $F_5$, Daliangshan faultl; $F_6$, Xiaojiang fault; Black number represent different segments of $F_5$)

## Geometry data

The Dam area is ~5 km away from Daliangshan fault which constraints structural processes of this area. Strata in this area are mainly Permian basalt eruption sequences that are covered by Triassic clastic rocks with an unconformity surface. The beds dip to 130° with an angle of 15~20°. Faults extending tens to hundreds meters are abundant while large faults are rare. The faults in this area are

mostly strike-slip ones with shallow brittle deformation characters. Four groups of faults, trending N55°-59°, N32°W, N33°E and SN respectively, can be observed, all with steep dipping.

About 53% faults strike N55°-59° (simplified as G1). These faults extend hundreds of meters while spacing 50~60m. Breccias and gouge can be seen in fault zones of 0.5~5m width. Two phase of shear sense can be seen in G1. Earlier shear sense show left-lateral transpressional sense, and was superposed by later right-lateral transtensional sense. The N33°E-trending ones (about 10%, G2) also record two periods of shearing, right lateral transpressional shearing in early stage and left lateral transpressional shearing sense in later stage. The G1 and G2 cut each other and show conjugate characters.

Another dominated group of faults strikes N32°W (G3), occupying 31% of total. These faults extend tens to hundreds of meters, and are smaller than G1. The G3 mainly presents left-lateral transpressional shearing, while a small part show two periods of movements similar as G1. The G1 faults constrains and terminates G3 ones. Geologic data indicate that G3 may secondary faults of G1.

The SN-trending faults (G4) are rare and constitute 2% of total faults. Generally, the G4 extends less than 300 m with 10~40 cm in width. These faults show reverse sense and superposed to tension in late stage. The G4 was cut and reformed by G1, indicating that the G4 was older than G1.

Joints and other fractures can also be grouped to four groups, corresponding to G1 to G4.

## Growth and mechanics of fault systems

According to former studies, two periods of tectonics can be identified after Triassic, namely Yanshanian Events (YE) and Xishanian Events (XE), respectively. The YE caused during Jinshajiang orogen event with major stress of W-E in late Mesozoic. While XE caused by southeastern extrusion of Tibet with a clockwise rotation of primary stress in late Quaternary.

**YE period.** Although frequency of fissures of N55°-59° (G1) and N33°E (G2) faults are quiet different, they have the same scales, corresponding kinematic processes, and opposite shearing sense. Especially they cut each other. All above evidences suggest flat conjugate characters. The acute angle 2θ between G1 and G2 is about 90°. According to Coulomb Criteria Eq.1, the angle of internal friction φ is close to zero. The rock mass show quasi-plastic characters. It means that the failure developed in high confining pressure. The maximum principal stress points to N79°E, approaching to W-E.

$$\theta = 45^{\circ} - \frac{\varphi}{2} \tag{1}$$

The SN-trending faults (G4) are also formed during this period, for they were cut and rebuilt by left-lateral G1 faults locally. The G4 dips to W steeply and shows reverse characters. These faults parallel with regional fold axis, and formed under W-E compression. They are initial products of regional folding event.

A small part of N32°W-trending (G3) faults present as fastigiate splay faults of G1. This part of G3 has the same kinematic patterns with G1. These faults are formed during shearing of G1 and are contrasted by G1.

**XE period.** The Indian plate subducted below to and collided with Tibet terranes in ~65Ma. Succedent continuous convergence of these two blocks cause a rapid uplift and southeastwards extrusion of Tibet in recent 10 Ma. The stress field rotated in clockwise accordingly. New stress may firstly restart existing faults for they have lower cohesion. G1 faults transformed to right-lateral transtensional ones during this period, for the $\sigma_1$ rotated to parallel with the G1. Whereas new faults G3 are formed when the primary fault G1 becomes critically misaligned with the rotating principal stresses.

The critical rotation angle of stress field is calculated by Coulomb failure criteria. According to rock mechanics, the angle of residual friction is equal to angle of internal friction and the cohesion of faults approaches to 0. The Coulomb criteria for forming a new fault and for sliding on a preexisting fault are given in Fig. 2. New faults can be formed only if the $L_1$ is catched not later than $L_2$.

The θ is the angle between maximum principal stress ($\sigma_1$) and fault. φ is internal friction angle of rock mass. $C_0$ is cohesion of the rock mass. and the $\theta_0$ without rotation equals to φ. Assuming that and the rock mass is isotropic. The critical angle of rotation, α, can be decided by Eq.2.

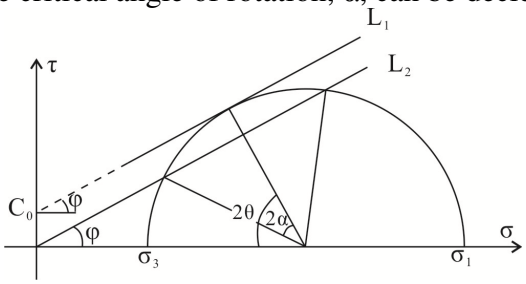

Fig. 2 A Mohr diagram with two failure criteria: $L_1$ for new faults and $L_2$ for preexisting faults

$$\alpha = \arcsin[\frac{C_0}{(\sigma_1 - \sigma_3)}\cos\varphi]^{\frac{1}{2}} \tag{2}$$

According to stress test by hydraulic fracturing method, the $\sigma_1$ of G3 points to N45°W. Thus, the θ and φ of G3 are about 13° and 64° respectively. The φ is similar with modern measured values in lab. Thus, an apparent uplift of research area happened during G1 to G3, and the G3 should be formed recently. According to in situ mechanic test data of the dam area, the $C_0$ and ($\sigma_1$-$\sigma_3$) are 1.7 Mpa and 5 Mpa respectively. Accordingly, the α is about 23°. The α' in field is 23~25°, and is consistent with α. The presents of G3 concerns with ($\sigma_1$-$\sigma_3$), thus the G3 may firstly formed in the base of G1 ones.

## Conclusions

1.Four groups of faults can be observed, trending N55°-59°W, N32°W, N33°E and SN respectively. N55°-59° trending and N33°E trending faults are conjugated ones originated from existing conjugate joints in late Mesozoic, and restarted during late Quaternary during tectonic extrusion of Tibet. The N32°W trending faults composes two genesis. A small part of the faults are splay faults of N55°-59° trending faults, while most of N32°W ones are second generation faults which are formed recently because of the rotation of the stress field.

2. According to Eq.2, the critical angle between G1 and G3 is 23°, which is consistent with field survey. The G3 may firstly formed in the base of G1 ones. Mechanic parameters and tectonic environments of the rock mass can be estimated when geometry and space characters of the fault systems are known.

**Keywords:** Sleeve valve tube, Micropile, Gob, Stretching fractured zone

**Abstract.** Due to the early years of mining makes Gob fracture zone, the deformation of rock fracture zone, and gradually developed through. Located in the mined-out area causing tension within fractured zone of discontinuous deformation region arsenal varying degrees of ground and walls to crack, great security risk to the normal operation of the arsenal caused. Project uses Sleeve Valve Pipe and Steel Pipe Micropile reinforcement scheme. This paper describes the details of the reinforcement mechanism, the construction process, technical requirements and quality assurance measures. Practice has proved that the joint reinforcement program can continue to crack the wall of effective governance to ensure the safe operation of the security arsenal.

## Introduction

The object of reinforcement is arsenal, the north side of the mountain was originally cut from artificially, overall terrain located south than in the north end, located in a mining area of tension cracks band of discontinuous deformation region. The mine is fully mechanized coal mining methods and more, because of early mining makes mining district fracture zone, the deformation of rock fracture zone, and gradually developed through. Result in powder keg on the west side, the north and other areas with varying degrees of ground and walls to crack, great security risk to the normal operation of powder keg, shown in Fig. 1. Preliminary analysis of the region's mining area is a typical tensile fracture with discontinuous deformation Engineering venue. Because crack is not fully developed, reinforced area undulating terrain, lush vegetation surrounding the building, the use of surface coverage or lime slurry formed loess cover, then slip through the flower tube grouting body ineffective. Therefore, using the Sleeve Valve Pipe and Steel Pipe joint reinforcement methods Micropile to governance in the deformation of mining area.

Fig. 1. Arsenal wall cracking case

**Reinforcement Design**

Scholars has already to study Sleeve Valve Pipe equipment, materials and technology and other engineering applications technology [1, 2], or the mechanism of Splitting Grouting soil [3].The project has been the precedent for using Micropile in reinforce landslide areas, mechanism and failure mode of bearing micropiles. More for scholars to study the effect of pile group, load distribution, In practice [4, 5, 6, 7]. But the first time to use Sleeve Valve Pipe and Steel Pipe micro-piles in mining area reinforcement works of stretching fractured zone, with engineering practice.

This design is determined that the scope of grouting based on the size and distribution of the surface cracks, and arranged drilling and grouting in the walls of the arsenal outside. According to the cracks arsenal to determine the scope of this grouting in the northwest corner of the wall, the grouting regions as shown in Fig. 2.

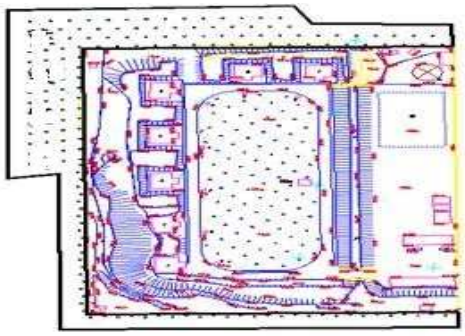

Fig. 2. Reinforcement Design

As shown in Fig. 2, grouting holes are arranged in a powder keg west, south and north wall of three side walls, which are arranged outside the northwest corner of the 4-row drilling, and north of the northwest corner of the location of the hole spacing of 7m, was plum-shaped layout, arranged two rows in the south and the southwest corner of drilling. North and south of the hole spacing 10m, row spacing of 1m, designed from the inside to the outside hole depth was 37m, 61m, 84m and 108m. Greater than 40m deep hole drilling the first hole aperture Φ89mm, secondary sweep the hole diameter is Φ130mm, adjustable hole depth is greater than the 40m Φ89mm and less than 40m deep hole drilling hole aperture Φ89mm until the final hole. Were arranged grouting hole of 168, with a total footage of 9922m, wherein the outer row of grouting holes 63, footage 4461m, the row of grouting holes of 105, footage 5461m.

When drilling depth, hole depth greater than 40m under way to take a top-down sub-grouting grouting, in principle two sections, the upper section using Sleeve Valve Pipe. Sleeve Valve Pipe tip, shown in Fig. 3, after grouting, 72 hours to sweep holes under the section with the orifice closed grouting, down into the PVC pipe flowers, flower tube from the bottom of the hole shot pulp mouth is not greater than 0.5m. When the hole depth is less than 40m, into full-bore Φ76mm using welded steel modded Sleeve Valve Pipe. After the completion of all grouting pipe, no longer pull.

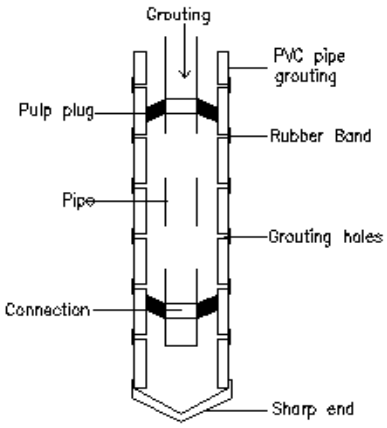

Fig. 3. Sleeve Valve Pipe Schematic

**Joint reinforcement mechanism**

**Sealing surface water.** As shown in Fig. 4, using of the sleeve valve pipe grouting technology can effectively solve the fractured zone take slurry grouting common problem, forming a slurry pulp to cover the surface, filling fractured zone to prevent infiltration of surface water increased arsenal slip, wall cracking.

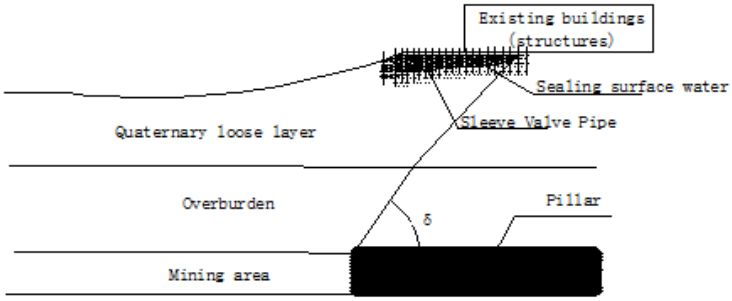

Fig. 4. Sealing surface water

**Moving angle increases.** Sleeve Valve Pipe and Steel Pipe Micropile combined to make mining area stretching fracture belt soil, rock to form a whole, improve friction belt slippage, while steel insert stable rock, but also raise bring slip friction resistance, increasing the angle of the mining area to move the angle shown in Fig. 5.

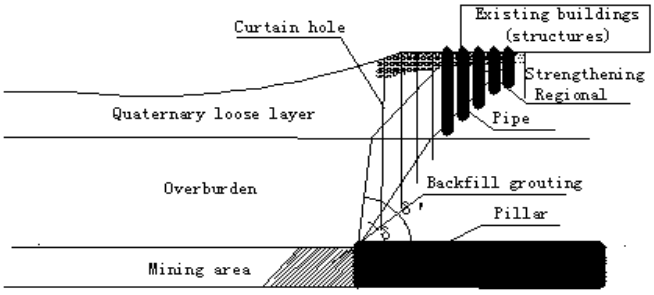

Fig. 5. Moving angle increases

**After moving angle shift.** Steel Pipe Micropiling through the deep slip reinforcement to improve the strength of the rock, while part of the slurry through the cracks into the mining area, filling a part of the mining area, the mobile angle mining area after the shift, as shown in Fig. 6.

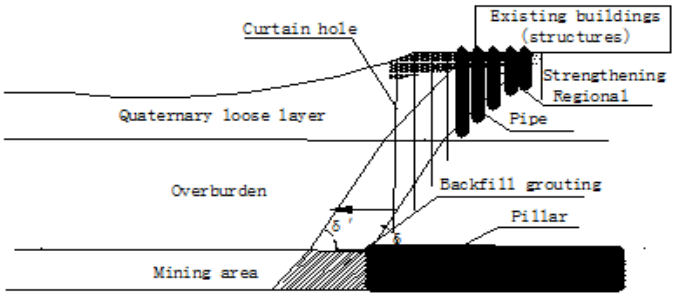

Fig. 6. After moving angle shift

**Construction technical requirements**

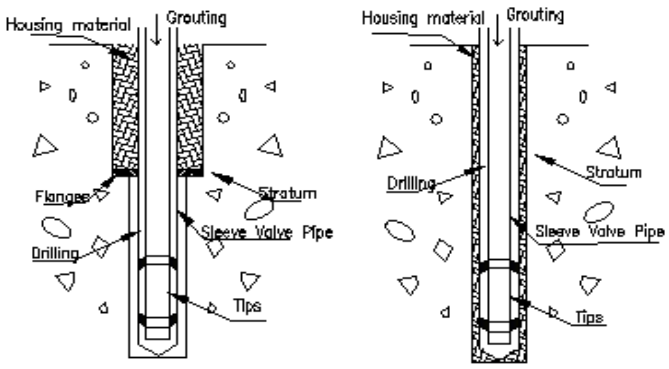
**Technical Requirements of Drilling.** Drilling structure: Aperture of drilling which depth more than 40m is ϕ89mm, when swept the hole diameter is ϕ130mm and more than 40m adjust to ϕ89mm; if depth of drilling less than 40m ,drilling aperture is ϕ89mm until the final.

Ending standard: depth of the final hole is less than 944m elevation, and drilled into the stable bedrock 1m.

Inclined requirements: Hole deviation should be less than 1 °. In the drilling process hole inclination measurement and calibration should be carried out to ensure that drilling is vertical, in order to create good working conditions for normal grouting.

Washed requirements: All holes are drilled by use of water. And holes are washed to make crack to flow and protect the best grouting effect before grouting.

sealing: Using cement mortar that water-cement ratio is 0.5:1 or 1:1 block all drilling after grouting. Greater than 40m drilling, method of the upper sealing using sets of shell material, lower segment seal by use of chuck (DN125mm flange), and using grout seal from 5 to 8m in hole. If depth of drilling is less than 40m, the way of sealing is sets of shell material. As shown in Fig.7.



(a) Hole depth>40m (b) Hole depth<40m

Fig. 7. Sealing structure

**Technical requirements of grouting.** Pressure: At the beginning of grouting, test should be implemented that water is pressurized and time of test is not less than 10min, then converted into static pressure grouting. Pressure of orifice is controled not less than 1.5Mpa in the end.

Parameters: Water-solid ratio: 1:1 to 1:1.2, solid ratio (cement: fly ash): 3:7. Before grouting materials should be done a slurry mixture ratio test in the laboratory (with ratios of 1:1; 1:1.1; 1:1.2). It should be tested that dry material content per unit slurry, slurry density, initial and final setting time and stones rates.

The end standard of grouting: The final grouting pump pressure gradually increased.when grouting pressure is 1 ~ 1.2MPa , pump the amount is 15L/min, and stable 10 ~ 15min, grouting ends.

If a large number of surface cracks run pulp and adjacent drilling collusion, intermittent grouting should be taken immediately, intermittent time is not less than 48h, no more than 72h. When reached the end standard of grouting, grouting stops.

**Quality assurance measures.** Grouting holes are constructed in accordance with from the outside to the inside. Each row of holes sharing I, II. Isequence hole first are construct, II construction sequence hole again

In the grouting process , ground-based observations and underground observation are conducted. Ground-based observations include units grout, grouting, pressure, concentration of slurry and time. Underground observation Including plasma leakage and changes of underground water inflow.

## Conclusions

Existing buildings which is located at tensile fracture in mining area are regarded as objects. The width of gap with tensile fractured zone is small, and slurry is resist to flow. Forming a complete set of construction technology reinforce existing buildings which is located at tensile fracture in mining area. Advanced and innovative technology embodied in the following:

Sleeve Valve Pipe Technology effective solve the problem that when using the traditional method of grouting pulp run, pulp.

Joint reinforcement approach highlights the economic "green green philosophy and overcomes that the existing range of traditional grouting reinforcement is not clear, conservative design, the consumption of pulp, and higher project cost defects.

**Keywords:** evolution characteristics, permeability, porosity, mudding weak permeability media, nonlinear flow, geological engineering.

**Abstract.** Concepts of flow permeability, flow permeability coefficient and flow porosity were presented to investigate changes of permeability and porosity of mudding weak permeability media with nonlinear flow. Formulas of flow permeability, flow permeability coefficient and flow porosity were presented to study the evolution characteristics. Results show that permeability and porosity of mudding weak permeability media nonlinear flow increase with pressure gradient or hydraulic gradient of nonlinear flow, while permeability and porosity of high permeability media Darcy flow are constant. The results can provide a test and calculation of micro porosity with a new method and can provide engineering safety of mudding weak permeability media nonlinear flow with scientific basis.

## Introduction

Groundwater can flow through all kinds of rock and soil media [1-3] and is an important factor inducing geological disasters [4]. Permeability and porosity are important physical property parameters of rock and soil materials. Several researchers have investigated permeability or porosity of porous media such as Collins [1] and Scheidegger *et al*. [2]. Brace *et al*. [3] discussed permeability of granite under high pressure. Fox *et al*. [4] discussed engineering geological problems. Bai *et al*. [5] described water resource characteristics. Neuman *et al*. [6] estabilshed conceptual models of flow and transport in the fractured vadose zone. Kong *et al*. [7] presented problems of advanced mechanics of fluids in porous media. Peng *et al*. [8] analyzed permeability of sandstone under different confining pressures.

The present work has been undertaken in order to analyze the evolution characteristics of permeability and porosity of mudding weak permeability media nonlinear flow. Concepts of flow permeability, flow permeability coefficient and flow porosity are presented to investigate the evolution characteristics. Influence of nonlinear flow of fluid on the permeability or the porosity is considered in the concepts to provide prevention of geological disasters with scientific basis.

## Physical Model

Mudding weak permeability media are assumed to be made up of capillaries. An equivalent model of porous media seepage is used to study mudding weak permeability media.

## Mathematical Model

**Mathematical Model of Pore Radius.** A partial differential equation for groundwater flow is given by equation (1) provided that the coordinate axes are assumed oriented parallel to the principle axes of the media.

$$r_{\mathrm{a}} = 2\left(\frac{2K}{n}\right)^{1/2} \tag{1}$$

where $r_a$ is average pore radius of porous media, $K$ is absolute permeability of porous media, $n$ is porosity of porous media. Change rate of average pore radius of porous media is

$$\dot{r}_K = \left(\frac{2}{nK}\right)^{1/2} \tag{2}$$

Correlation for permeability of porous media and permeability coefficient is

$$k = \frac{K\nu}{\mathrm{g}} \tag{3}$$

where $k$ is permeability coefficient of porous media system, $\nu$ is Kinematic viscosity of water, g is acceleration of gravity. So there are

$$r = 2\left(\frac{2k\nu}{n\,\mathrm{g}}\right)^{1/2} \tag{4}$$

and

$$\dot{r}_k = \left(\frac{2\nu}{n\,\mathrm{g}\,k}\right)^{1/2} \tag{5}$$

where $\dot{r}_k$ is Change rate of average pore radius of porous media.

**Formulas of Flow Permeability and Flow Porosity.** Flow in mudding weak permeability porous media is nonlinear flow as equation (6), which is different from Darcy flow [Deng, 2004].

$$\mathbf{v}\left(a_1 + \frac{a_2}{1 + a_3 v}\right) = -(\nabla p - \rho \mathbf{g}) \tag{6}$$

where $v$ is flow velocity of fluid in mudding weak permeability porous media, $a_1, a_2, a_3$ are coefficients respectively, $\nabla p$ is pressure gradient, $\rho$ is fluid density. Flow permeability of mudding weak permeability porous media is defined as

$$K_\mathrm{d} = \mu v / |\nabla p| \tag{7}$$

where $K_\mathrm{d}$ is flow permeability of mudding weak permeability porous media, $\mu$ is dynamic viscosity coefficients. Flow permeability coefficient of mudding weak permeability porous media is defined as

$$k_\mathrm{d} = \rho g v / |\nabla p| \tag{8}$$

where $k_\mathrm{d}$ is flow permeability coefficient of mudding weak permeability porous media. Flow porosity of mudding weak permeability porous media is defined as

$$n_\mathrm{d} = n\left(\frac{K_\mathrm{d}}{K}\right)^{1/2} \tag{9}$$

where $n_\mathrm{d}, n$ are flow porosity and porosity of mudding weak permeability porous media.

**Results and Discussion**

Changes of $r_a$ and $\dot{r}_a$ with $K$ are shown in Fig. 1. Changes of $r_a$ and $\dot{r}_a$ with $k$ is shown in Fig. 2. Schematic diagram of nonlinear flow and Darcy flow is shown in Fig. 3. Nonlinear flow curve is shown in Fig. 4. Changes of $K_d$ with $i$ is shown in Fig. 5. Changes of $k_d$ with $i$ is shown in Fig. 6. Changes of $n_d$ with $i$ is shown in Fig. 7.

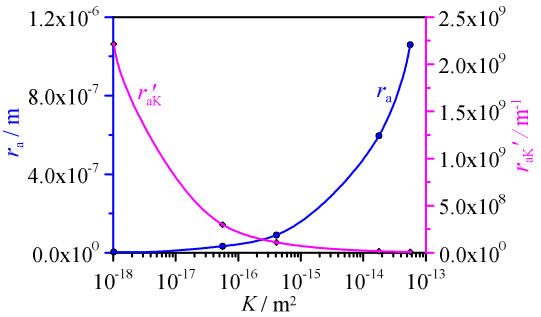

Fig. 1 Changes of $r_a$ and $\dot{r}_a$ with $K$

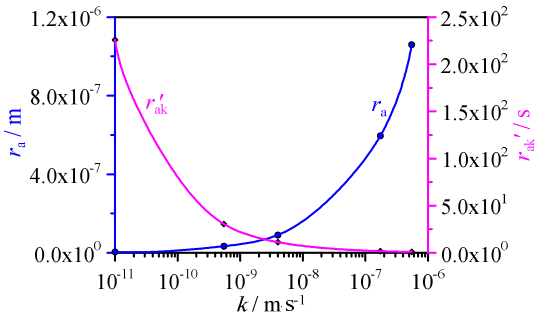

Fig. 2 Changes of $r_a$ and $\dot{r}_a$ with $k$

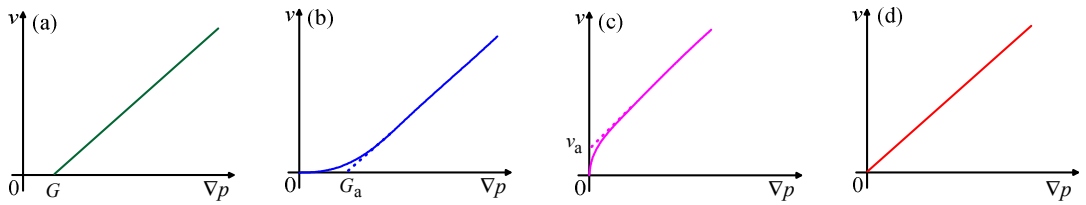

Fig. 3 Schematic diagram of nonlinear flow and Darcy flow

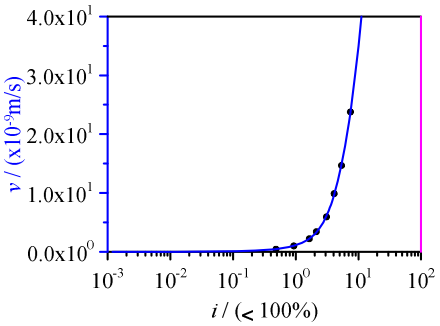

Fig. 4 Nonlinear flow curve

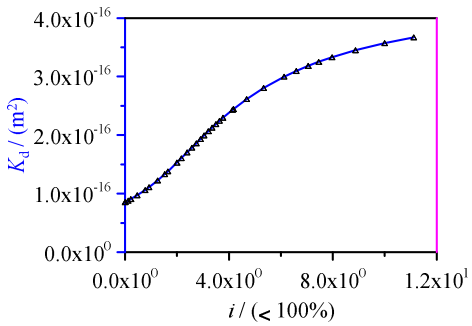

Fig. 5 Changes of $K_d$ with $i$

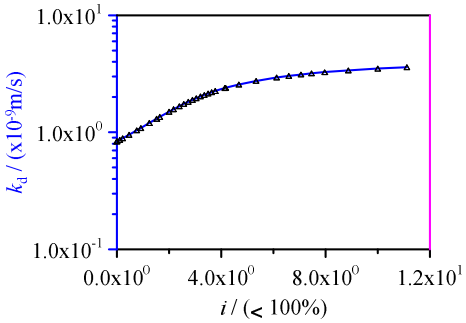

Fig. 6 Changes of $k_d$ with $i$

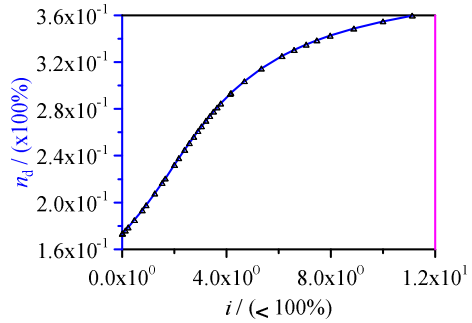

Fig. 7 Changes of $n_d$ with $i$

Fig. 1and Fig. 2 show that average pore radius of porous media decreases significantly with permeability and permeability coefficient. Pore channels of mudding weak permeability porous media are fine and the specific surface area is great so that solid-liquid interface molecular interaction is strong. Nonlinear flow has different kinds of possible flow curves different from Darcy flow curve in Fig.3. Nonlinear flow curve of mudding weak permeability porous media in Fig. 4 is similar to

schematic diagram (b) of nonlinear flow in Fig. 3. It is well known that permeability, permeability coefficient and porosity of Darcy linear flow in porous media do not change with hydraulic gradient changing. But Fig. 5, Fig. 6 and Fig. 7 show that permeability, permeability coefficient and porosity of nonlinear flow in mudding weak permeability porous media increase with hydraulic gradient respectively. Formulas of flow permeability, flow permeability coefficient and flow porosity provide micro and nano-scale pore of mudding weak permeability porous media with calculation method.

## Conclusions

In this work, concepts of flow permeability, flow permeability coefficient and flow porosity were presented to investigate changes of permeability and porosity of mudding weak permeability media with nonlinear flow. Formulas of flow permeability, flow permeability coefficient and flow porosity were presented to study the evolution characteristics. Permeability and porosity of mudding weak permeability media nonlinear flow increase with pressure gradient or hydraulic gradient of nonlinear flow, while permeability and porosity of high permeability media Darcy flow are constant. The results can provide a test and calculation of micro porosity with a new method. The results can provide engineering safety of mudding weak permeability media nonlinear flow with scientific basis.

# Stability analysis of gypsum mine goaf surface based on discrete element method

Xiumin Liu, Congxin Chen, Kaizong Xia, Pinglu Huang

（State Key Laboratory of Geomechanics and Geotechnical Engineering, Institute of Rock and Soil Mechanics, Chinese Academy of Sciences, Wuhan 430071, China）

Xiuxiu8311@163.com

**Keywords:** gypsum mine, pillar, filling method, caving goaf, discrete element method

**Abstract:** Considering rock joints, the discrete element method was used to study gypsum mine surface short-term and long-term stability. Filling method and caving method were selected as the surface treatment. Through comparison, Caving method is more suitable for handling the gob of gypsum mine. Surface movement angle and subsidence angle were obtained on the basis of the plastic zone, surface tilt rate and surface horizontal strain, and whereby draw a goaf risk areas to guide residential relocation. The research methods and conclusions in this paper can provide reference for the study of the empty area stability in gypsum mining currently.

## Introduction

Gypsum mine generally use room and pillar mining method leaving in continuous pillars [1]. For water softening, the carrying capacity of gypsum mine is greatly reduced and result in gob roof collapse layer by layer, which can easily lead to a wide range ground subsidence .

Currently, a lot of research about the mechanism of ground subsidence has conducted caused by mining gypsum[2-5], and numerical simulation methods [6-8] has been widely used in mining engineering. Relative to the finite element method and finite difference method, discrete element method is adapted to calculate joints developed rock mass, so it is more suitable to Simulate and analyze the rock loose caused by mining and caving and other mechanical behavior.

In this paper, the discrete element method (UDEC) was used in Jing-Hua gypsum mine numerical simulation to analyze the goaf short and long term surface stability. By comparing the treatment effect of filling method and caving method, put forward some reasonable proposals to handling gob geological disasters. It has great significance in mechanism study and ground subsidence prevention of gypsum mine gob.

## Engineering background

Jing-Hua gypsum mine located in Jingmen, Hubei province. Ore is layered, flat seam occurrence, to 150°, tendency to 240° , inclination of 8 ~10°, seam thickness average 10.4m. It mainly contains lump ore and mud quality gypsum. The rock deposit upper is siltstone containing cream, low-intensity, easily to softening, relax in water.

The ore-body is medium thick and stable tilt. It is design to use the room and pillar mining method according to the ore-body occurrence conditions and engineering geological conditions. By design, the mine geometric parameters of room and pillar are: stope long axis generally 50m, width

7m, pillar size 4 m × 4m, Gob height 7m. There is left 2.5m thick gypsum as a protective top layer in gob top.

The geological section is shown in Figure 1. Cross-sectional is width 923.5m horizontal, 208m in vertical direction from surface to -100m.

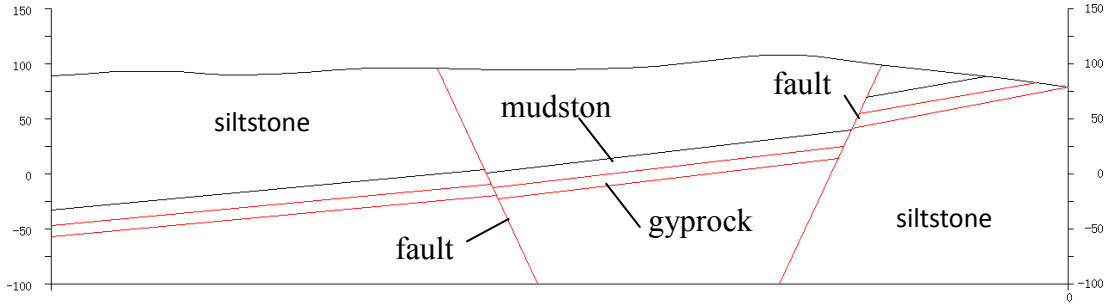

Fig. 1 Geological Sketch of Calculation Cross Section

Considering the lithology, bed thickness, rock quality, and its influence of surface deformation in gypsum mining process, the rock mass is mainly divided into siltstone, mudstone and gyprock three categories eventually. Mine rock mechanical parameters used in calculation is shown in Table 1.

The rock surface structure was considered in the calculation, and its parameters was selected based on similar geological structure of surface in gypsum mine, as shown in Table 2. About the filling method using in gypsum mine management, the physical and mechanical parameters of filling body was selected in accordance with related engineering experience, as shown in Table 3.

Tab.1 Mechanical Parameters of Rockmass

| Lithology | density KN/m$^3$ | E GPa | compressive strength MPa | Tensile strength MPa | cohesion MPa | Φ(°) | Softening Coefficient | μ |
|---|---|---|---|---|---|---|---|---|
| Siltstone | 24 | 3 | 22.3 | 0.74 | 1.86 | 48.5 | 0.588 | 0.28 |
| Mudstone | 24 | 2 | 16.6 | 0.18 | 0.5 | 45 | 0.5 | 0.3 |
| Plaster Rock | 23 | 4 | 27.6 | 0.81 | 2.8 | 40 | 0.825 | 0.28 |

Tab. 2 Rock Interface Parameters

| Tensile strength of joints (N/m) | Normal stiffness of joints (N/m) | Shear stiffness of joints (N/m) | Joints friction angle (°) | Joints adhesion(N/m) |
|---|---|---|---|---|
| $1.0\times10^6$ | $1.0\times10^9$ | $1.0\times10^9$ | 40 | $1.0\times10^6$ |

Tab. 3 Mechanics Parameters of Filling-body

| Lithology | Density KN/m$^3$ | E GPa | Compressive strength (MPa) | Tensile strength (MPa) | Cohesion (MPa) | Φ(°) | Softening Coefficient | μ |
|---|---|---|---|---|---|---|---|---|
| | 10 | 1 | 22.3 | 0 | 0 | 40 | 0.588 | 0.15 |

**Calculation model and scheme**

In order to analyze gob surface deformation and get rock movement law, covering the long-term stability of the overburden after taken caving method or filling method goaf treatments, it is arranged to calculate the following four scenarios:

Option One: calculate the short term stability based on the average pillar size (6.0m × 4.0m), ore room size (8.0m × 7.0m).

Option Two: calculate the long-term (several years after closure) empty area stability according to the average pillar, stope size of gypsum gob.

Option Three: Calculate the stability of the goaf after caving method.

Option fore: Calculate the stability of the goaf after filling method.The calculated cross section meshing grid were shown in Figure 2.

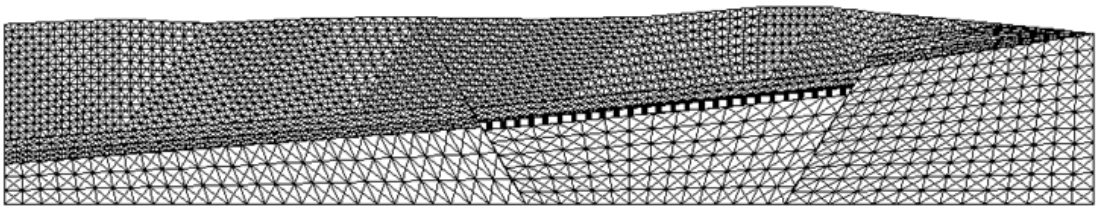

Fig. 2 Calculation Model

**Results analysis**

Plastic zone and total displacement contour were obtained by calculating under the fore program a, as shown in in Figure 3 to Figure 10 specificly. Analysis of the results shows that:

(1) Underground mining causes some extent deformation of the surface in Jinghua gypsum mine in the short term. According to the plastic zone(Fig.3), it can be seen there is no overall damage on the gob overburden. But 2m ~ 3m thick (Fig.7) of the top - safeguarding layer came into plastic losing the protective effect of the mined area. In addition, mining has resulted in tensile or shear plastic deformation of local surface area , it means there will be generating cracks and other geological disasters.

（2）According to the long-term stability analysis, years later JingHua underground mined-out area will be filled with water, so the top of the pillar and protective top - layer will soften due to flood damage, and the strength will be greatly reduced. The existence of faults is in control of the gob rock movement pattern.The overburden will have overall slip along the fault(Fig.4). The displacement contour (Fig.8) shows that the maximum horizontal displacement of the surface is0.53m, the maximum vertical displacement is 2.2m, and the maximum total displacement is 2.2m.

（3）If adopted caving goaf method, it can cause a huge overburden deformation and large-scale ground subsidence (Fig.5). The maximum displacement of the surface is 0.71m, the maximum vertical displacement is 2.75m, the maximum total displacement is 3.0m (Fig. 9)

（4）After filling the mined area, the overburden also has some distortion(Fig.6). The maximum horizontal displacement of the surface is 0.25m, the maximum vertical displacement is0.78m, the maximum total displacement is 0.80m (Fig. 10). But it will not cause massive surface collapse.

(5) Through the gypsum gob plastic zone graph after caving method applying, the ground movement angles on both sides of the border can be calculated, which are basically the same with the fault dip angle.

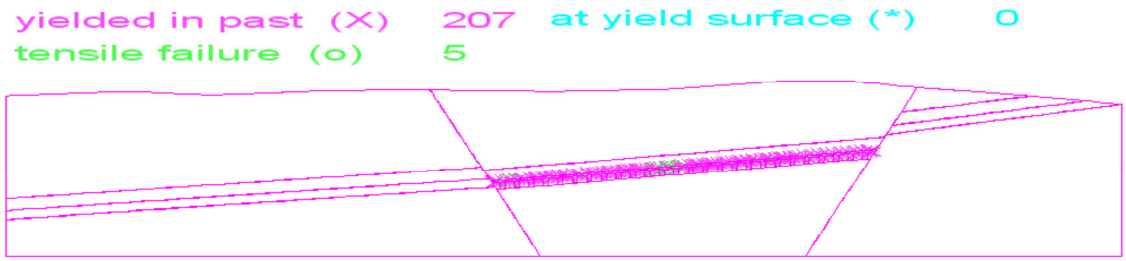

Fig.3 Plastic zone of gob in short term

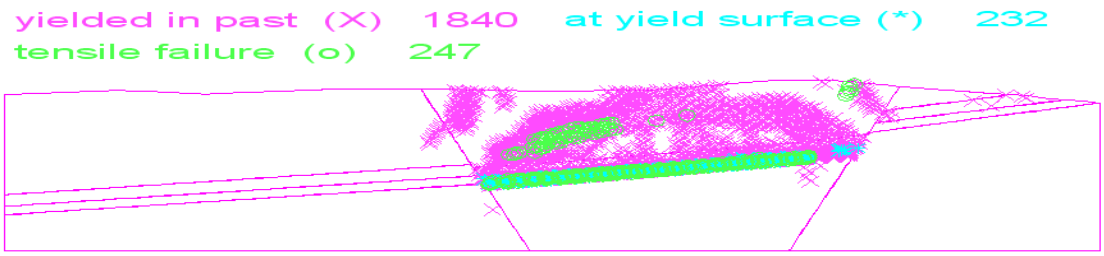

Fig.4 Plastic zone of gob in long term

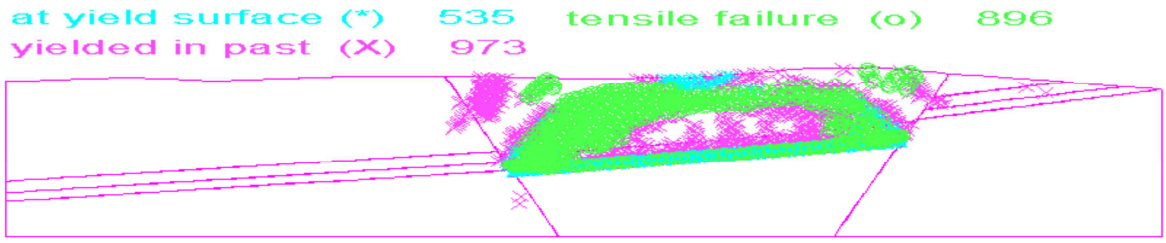

Fig.5 Plastic zone of gob after caving treatment

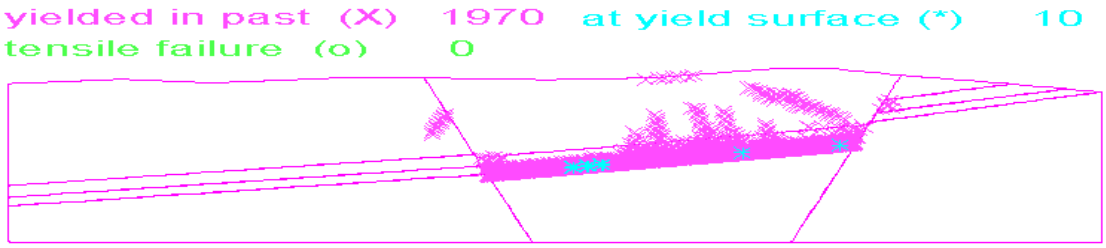

Fig.6 Plastic zone of gob after filling treatment

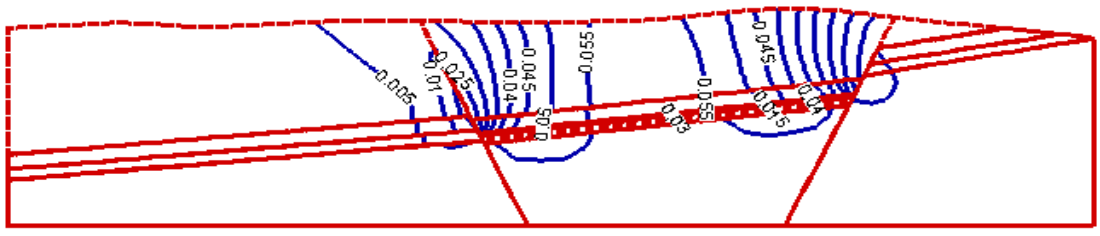

Fig.7 Displacement contours of gob in short term

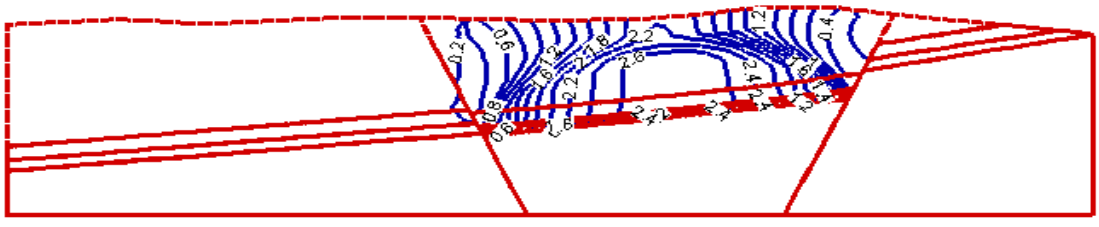

Fig.8 Displacement contours of gob in long term

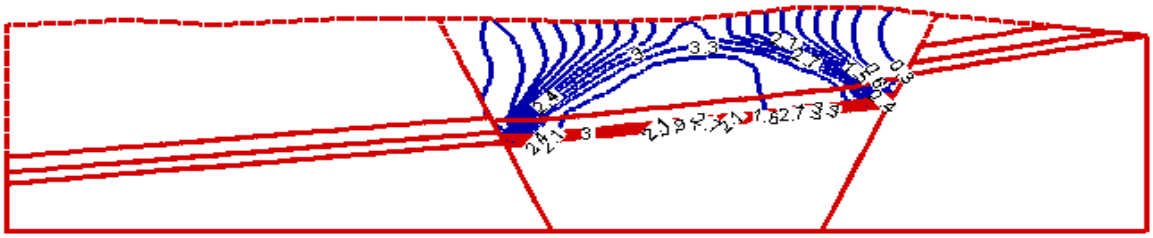

Fig.9 Displacement contours after caving treatment

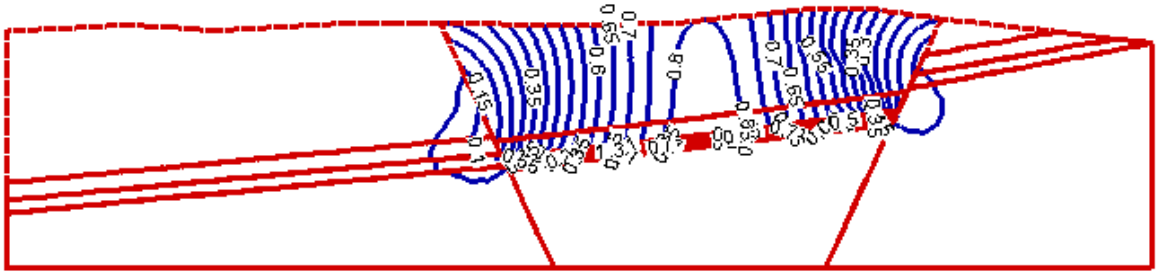

Fig.10 Displacement contours after filling treatment

## Conclusions

The results show that JingHua gypsum mine gob will not occur overall damage of overburden in the short term, only small local regional pillar roof may occur collapse. However, if not remediate, the gob will become a long-term source of potential dangers. According to the geological conditions ， underground mined-out area will be filled with water, and the top of the pillar and the upper protective claystone layer will soften, eventually the strength will be greatly reduced and lead to a wide range of surface subsidence.

Caving method and backfill are two effective treatment methods. It is recommended forced caving treatment for JingHua gypsum mine goaf, with Comparing the calculated effects the two Control Methods, and considering the gob treatment cost, technical, economic feasibility, and experience at the successful application of the caving method.The residents within the moving angular range should be relocated also.

# Automated Analyzer，LOI and Other Methods for determination of Soil Organic Carbon

Yiyu Zhang[1, a *],Weihua Zhang[1,*]

[1]College of Resources and Environment, Southwest University, Chongqing, China
[a]email,948223274@qq.com; *Corresponding Author:swuwater@126.com

**Keywords:** SOC determination, Automated Analyzer, LOI, Comparison

**Abstract.** SOC as a significant quantity for the global carbon cycle, makes great sense in soil management and future climate scenario. With more and more researches carried out on SOC, methods used to the determination of SOC have being formed: automated analyzer, LOI and some others, such as using climate change information and remote sensing technique. The objective of this paper is to discuss advantages and disadvantages of automated analyzer (C-N analyzer) and LOI, and provide some references in selecting the appropriate measuring methods of SOC for the readers.

## Introduction

Soil, as the largest carbon pool in the terrestrial biosphere, plays a significant role in the global carbon cycle and climate change. Minor changes in soil organic carbon (SOC) storage can impact atmospheric carbon dioxide concentrations [1]. Estimates of SOC stock are required to assess the role of soil in the global carbon cycle[2]. Moreover, SOC is not only a vital parameter for administering soil fertility and erosion resistance[3], but also is essential for the calculation of future climate scenarios and to detect the potential for C sequestration or emission[4].

Laboratory methods for the determination of SOC demand to consider several factors, including the ease of use, health and safety concerns, cost, sample throughput and comparability to standard reference methods[5].The measurement methods which are prevalently adopted in laboratory can be divided into two general approaches of spatial extrapolation, which are described as: “measure andmultiply” and “paint by numbers” by Schimel[6]. In this paper, we put emphasis on the former one, comparing Loss-on-ignition (LOI) with an elemental analyzer and several other methods of the determination of SOC.

Compared to time-consuming and costly elemental analyzers, LOI as an inexpensive and reliable technique is more likely to be carried out in general laboratories and has being widely used in laboratory by soil scientists, geographers, geologists and limnologists for decades. Actually, some other methods are also applied varying with different circumstances of the determination of SOC, such as in situ methods[7] or climate change[8].

Our objective in this paper is 1) to discuss advantages and disadvantages of these major methods and 2) to provide some references in selecting the appropriate measuring methods of SOC for the readers.

## Automated analyzer

For the determination of SOC, A C-N analyzer is usually carried out. The automated technique is simple and accurate, and can not only be used for the automated analysis of 15N or 13C in plant and soil samples, but can also determine %N and %C on weighed samples. During carbon determination, the factors which have impacts on the rate of sample throughput can range from a matter of seconds for gravimetric measurements to minutes for the other techniques. Where a multi-sample autoloader is available, it allows a batch of samples analyzed simultaneously. Moreover, analyses can be carried out and then perform other sample preparations while the first batch of samples are analyzed [5].

Despite the simple and accuracy, it has been shown that automated methods yield more precise results than methods quantified manually [9]. Resulting from the initial purchase of the instrument

which can range up to $20,000 or more, the cost is high and may not be feasible. What's more, for some soil samples, the approach often involves pretreatment with acid to remove carbonate for calcareous soils, which may erode the instrument and interfere with C analysis in soil samples. It also leads to a time-consuming and cost for the machines [10].

## LOI

With increasing consciousness of environmental conservation, compared with the possible effects of dichromate on the environment produced by the traditional Walkley-Black method, LOI has been proposed to be an inexpensive and convenient method which is being widely used to measure soil organic carbon (SOC) and soil organic matter (SOM). LOI involves the two main procedures: combustion of samples at high temperatures and measuring weight loss after ignition[11,12], avoiding chromic acid wastes efficiently.

While in practical application, summarized by Konen, a significant factor limiting the comparability of results is that some investigators converted their LOI measurements to SOC concentration while others estimated SOM[12]. Tab.1 shows some consequences of the determination of SOC by different investigators.

Tab.1 Comparison of LOI Methods to Determine SOC

| LOI Equation | Region | Land Use | Soil Type | Depth | Combustion Temperature | Time |
|---|---|---|---|---|---|---|
| LOI = $W_{dry\ soil}$ - $W_{soil\ after\ combustion}$)/$W_{dry\ soil}$×1000[12] | USA | variously cultivated, uncultivated | clay, sand (more) | A Ap AB | 360℃ | 2h |
| Organic C%=-1.054+0.508LOI[13] | Scotland | natural profile, cultivated soils | 6 soil sub groups | 247mm | 800-900℃ | 30min |
| $LOI_{550}$=2.51+1.67TOC<br>$LOI_{550}$=-0.232+1.72TOC +0.0851C (C-%clay)[14] | New Zealand | cultivation permanent grassland | sand loam clay | 0~136cm | 550℃ 450℃ | 5h |
| $SOC_{LOI}$=($SOM_{LOI}$-4.189)/1.792[15] | China | dessert, shrub, cropland, grassland | brown desert Soil | 5 layers | 375℃ | 17h |

From the table, it is apparently to find that factors vary from temperatures and time of LOI to the expression of results in response to the Konen's viewpoint. In reality, in 1982 the problems had been noted by Nelson and Sommers that the wide range of factors used to convert SOC to SOM [16]. With the increased interest in C sequestration and the quantification of soil C, we believe it is critical to use LOI predictive equations for SOC, not SOM [12].

The LOI method measures the organic matter capacity of soils, but it seems difficult to transition the organic matter to a C basis, owing to the C content of organic matter not consistent and variations with vegetation type, degree of decomposition, age, and other factors[17]. In some specific horizons, overestimates organic matter may result from heating to temperatures above 150℃ driving off hygroscopic and interlayer water from clays and allophane. Other overestimation errors can be caused by CO2 release from carbonates in calcareous soils and possible decarboxylation of organic function groups, and the loss of water from hydroxyl groups in sesquioxides and octachedral sheets in phyllosilicate layers[15].According to many researches , Salehi concluded that LOI method has been widely used for estimating SOM in a muffle furnace at 360℃ for 2 h[18,19,20] and at 300, 450, and 600℃ for 2 h[21].This can be taken as a reference to choose temperatures and time of LOI.

As the distribution and conversion of SOC, relationships between LOI and SOC are developed differing in mineralogy (Carbonates are investigated more) and use of soils. For the LOI method, soil is oxidized at a high temperature (500-575℃), and the mass loss is proportional to the organic

matter content of the soil, Carbonates remain stable at temperatures used for analysis and will not be measured by the LOI method[22,23]. Thus LOI method should be maintained below 440℃, to avoid the destruction of any inorganic carbonates that may be present in the samples. Moreover, another concern with LOI is that under the temperatures used to combust the samples, some clay minerals may lose structural water or hydroxyl groups, which will increase the total sample weight loss leading to an overestimation in organic matter content. Optimum as it burnt most organic carbon destroyed less inorganic carbon, caused less clay structural water loss, and used less electrical energy. A combination of temperature around 375℃ and 16-17 hours results in a good LOI-SOC relationship, thus providing accurate estimates of SOC in many soil groups [15].

While inadequate for measurement where high accuracy is required, we can take advantage of determination of organic carbon through LOI for exploratory soil surveys where rough estimation of organic matter is required [24]. Furthermore, LOI when published datasets that tend to contain abundant information on LOI but fewer data on directly determined organic C%, by establishing regional relationships between LOI and C%[13].

## Other methods

Soil organic carbon stock is a significant proportion for the total organic carbon pool, and thus any small change in SOC may have great impact on atmospheric CO2 concentration. Many models, such as the DNDC (DeNitrification-DeComposition) or Daisy and RothC, were developed to predict the relationships between SOC change and climate change[8], which can be applied to the determination of SOC.

Based on remote sensing and spectroscopic measurements in the field, new in situ soil C methods are proposed where sample processing time and their subsequent analysis are absent or discontinuous[7].Certainly, many techniques in other fields can also be introduced to measure the soil organic carbon

## Conclusion

The approaches, automated analyzer, LOI and others, to estimate SOC , dominate in different areas. When accurate measurement is required and adequate fund are available, automated analyzer can be applied.LOI may be more appropriate when rough SOC estimation is needed, cost is limited and certain values (such as LOI information) are provided. We can also combine techniques and factors in other fields with determination of SOC, for instance, the meteorology and the remote sensing.

**Keywords:** fractured rock mass; volumetric joint count; fracture spacing; stochastic fracture network; Monte Carlo method

**Abstract:** Volumetric joint count $J_v$ is an important parameter to evaluate the development of fractures. It is a fundamental representative for the strength and permeability of rock masses. However, $J_v$ cannot be directly measured in field. In this study, an indirect method is applied for its estimation. The main procedures are as follows: firstly, the volumetric joint frequency $f_i$ is assumed for $i$ th fracture set, and then a series of 3D stochastic discrete fracture networks (DFNs) are generated using the Monte Carlo method according to $f_i$ ; secondly, a survey line is drawn perpendicular to the fracture set in the each fracture network generated, the fracture spacing is measured along the survey line, then the average fracture spacing and its variance coefficient are calculated from all the DFNs; thirdly, by repeating the above two steps for different $f_i$ assumed, the relevant average fracture spacing and its variance coefficient are obtained, and two relation curves are built up between $f_i$ and the average fracture spacing (or its variance coefficient); fourth, the exact $f_i$ is estimated through this relation curve between $f_i$ and the average fracture spacing according to the exact fracture spacing measured in situ; finally, $J_v$ is calculated by summing the exact $f_i$ of all fracture sets up. In this study, this indirect method is applied in the rock masses of Xiaowan Hydropower Station. The result shows that the fracture spacing will reduce and its variation coefficient becomes stable as $f_i$ increases.

## Introduction

In nature, a rock mass usually contains a large quantity of fractures with complicated distribution. Therefore, its strength and permeability are quite different from an intact rock. Due to being the weakness, fractures are the key to control the strength and permeability of fractured rock masses[1,2]. As a result, the fracture growth level becomes an important indicator to value the quality of rock masses in engineering.

Volumetric joint count $J_v$ is generally adopted to quantitatively evaluate the fracture growth level at present. But owing to the restriction of surveying on site, $J_v$ only can be deduced from limited boreholes and limited exposures (e.g. slope surfaces or underground caverns). So far, scholars[3-6] have published a series of papers on the above issues. But these methods are mostly based on analytical formulas and experience coefficients, and the calculation results for $J_v$ may have large difference to the exact $J_v$ in situ. Therefore, Zhang et al. (2012) [7] used 3D fracture network to solve the problem, from which the relation curve between the line frequency and $f_i$ for each fracture set can be built and the $J_v$ can be calculated by summing the calculation $f_i$ of all fracture sets up.

In this paper, 3D fracture network is applied to build up two relation curves for each fracture set: the first one is between $f_i$ and the average fracture spacing, and the other one is between $f_i$ and the variance coefficient of spacing. The exact $J_v$ can be evaluated according to the first curve. By using 3D fracture network the indirect method is applied in the rock masses of dam foundation of Xiaowan

hydropower station based on field surveying data, which shows that the indirect method is feasible and has attractive advantages in practical engineering projects.

## Monte Carlo method

Monte Carlo method[8], also known as random sampling method, is based on probability and statistics theory, from which some complex problem can be solved by using electronic computers. Along with the rapid development of electronic technology, Monte Carlo method is widely applied in the areas of mathematics, physics and engineering technology.

In this paper, Monte Carlo method is used to generate stochastic parent DFNs, the procedure for the calculation of $J_v$ can be formulated in Fig 1:

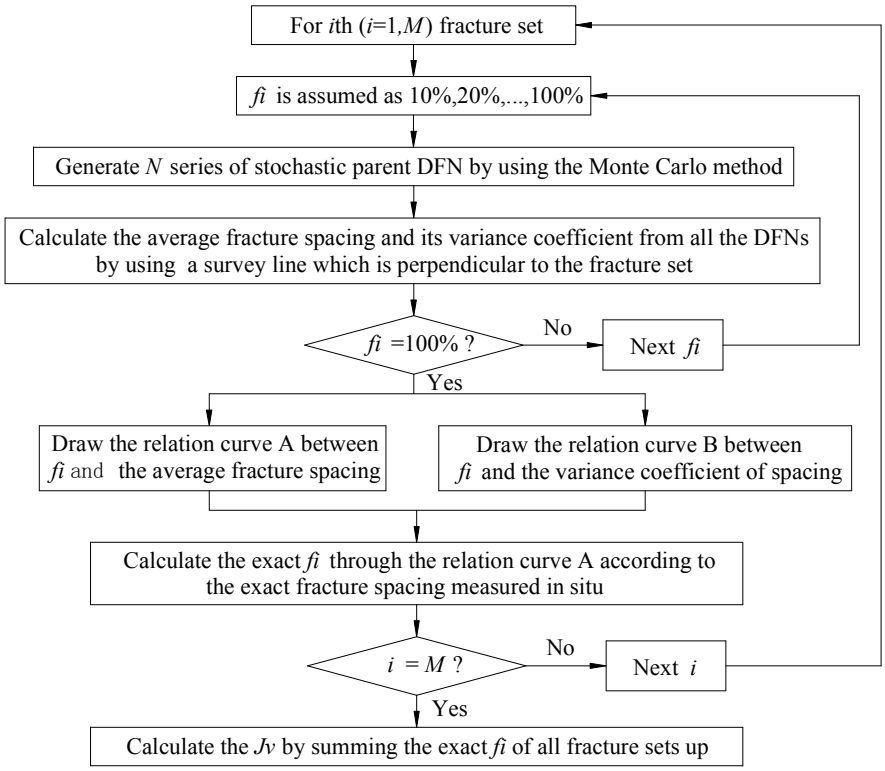

Fig. 1 The determination of $J_v$ flowchart

In Fig.1, the variance coefficient is used to measure the variance of the average fracture spacings calculated from N series of DFNs. The equation for the variance coefficient can be obtained as

$$\alpha_i = v_i / m_i \tag{1}$$

where, $\alpha_i$ is the variance coefficient; $v_i$ is the sample variance of the average fracture spacings from N series of DFNs; $m_i$ is the average fracture spacing from N series of DFNs.

## Calculation of fracture spacing

This part mainly focuses on how to determine the fracture spacing by using 3D fracture network. Based on the probability models of fractures measured in field, *M* sets of stochastic discrete fractures are generated in a large region of size $am \times am \times am$, in which the *o-xyz* coordinate system is built as follow: the origin is in the surveying center; the x-axis towards east, the y-axis towards north and the z-axis towards upright.

The number of fractures for the *i*-th fracture set is determined according to

$$N_i = f_i \times V \tag{2}$$

where, $f_i$ is the volumetric joint frequency for the i-th fracture set; $V$ is the volume of the survey region.

In order to measure the facture spacing for the i-th fracture set, a survey line is built up in the region, which includes the following main requirements: (1) the survey line takes the length of $L_i = a/3$ for avoiding the boundary effect; (2) the survey line has a midpoint at the origin $(0,0,0)$ and it should be perpendicular to the fractures as well. The equations for describing the survey line can be expressed as

$$\begin{cases} x_i = \sin\theta_i \times \sin\varphi_i \\ y_i = \sin\theta_i \times \cos\varphi_i \\ z_i = \cos\theta_i \\ \sqrt{(x_i^2 + y_i^2 + z_i^2)} \le (L_i / 6) \end{cases} \tag{3}$$

where, $L_i$ is the length for the *i*-th survey line; $\varphi_i$ is the average dip direction for the *i*-th fracture set; $\theta_i$ is the average dip angle for the i-th fracture set.

The fracture shape is assumed to be a disc, and the equations for describing any fracture can be formulated as

$$\begin{cases} A(x-x_0) + B(y-y_0) + C(z-z_0) = 0 \\ (x-x_0)^2 + (y-y_0)^2 + (z-z_0)^2 \le D^2/4 \end{cases} \tag{4}$$

where, $(x_0, y_0, z_0)$ is the center coordinates of a fracture; $D$ is the diameter of the fracture; $A, B, C$ is the coefficients for the equation.

The number of intersections between the i-th survey line and the i-th fracture set can be determined by solving the equations（3）and（4）simultaneously. Then, the average spacing[9] for the i-th fracture set can be calculated as

$$d_i = L_i / N_i \tag{5}$$

where, $d_i$ is the average spacing for the i-th fracture set; $N_i$ is the number of intersections.

## Engineering application

Xiaowan Hydropower Station is located at the upper reach of Mekong River. This paper takes the rock masses with weak weathering in the left bank as a research object. There are three main fracture sets in the rock masses: the first set is steep dip along the river, the second set is steep dip across the river, and the third set is low-angle dip along the river. According to the in-situ investigation and measurement, the probability models and relevant parameters of fractures are listed in Table 1. The *o-xyz* coordinate system is built as follow: the origin is in the surveying center; the x-axis towards east, the y-axis towards north and the z-axis towards upright.

Table 1 Probability models and relevant parameters of fracture sets

| Fracture set | Spacing | | | Dip direction | | | Dip direction | | | Trace length | | | Central point | Aperture (mm) |
|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|
| | Probability model | μ (m) | σ (m) | Probability model | μ (°) | σ (°) | Probability model | μ (°) | σ (°) | Probability model | μ (m) | σ (m) | | |
| 1 | Logarithm normal | 0.37 | 0.57 | Normal | 95.60 | 13.49 | Normal | 89.35 | 6.37 | Normal | 2.01 | 0.37 | Uniform | 0.16 |
| 2 | Negative exponent | 0.47 | 0.47 | Uniform | 11.09 | 7.96 | Normal | 79.64 | 10.08 | Logarithm normal | 2.23 | 1.48 | Uniform | 0.02 |
| 3 | Negative exponent | 0.60 | 0.74 | Uniform | 270.3 | 18.62 | Logarithm normal | 39.91 | 8.82 | Logarithm normal | 2.08 | 1.41 | Uniform | 0.16 |

For each fracture set, $f_i$ is assumed from 10% to 100%. For each $f_i$, M=50 DFNs are generated in a large region of size 60 m×60 m×60 m. According to the relevant parameters for the fracture sets (Table 1), three survey lines are built up using the equation (3). Then the average spacing and its variance coefficient for M=50 DFNs can be calculated.

Fig. 2 shows the relation curve between $f_i$ and the average fracture spacing for all fracture sets. Based on the the exact fracture spacing (Table 1), the exact $f_i$ for the three fracture sets can be calculated from the relation curve (Fig 2):

$$f_{j1} = 0.512\,; \quad f_{j2} = 0.174\,; \quad f_{j3} = 0.210 \tag{6}$$

Then $J_v$ can be calculated as

$$J_v = f_{j1} + f_{j2} + f_{j3} = 0.896 \tag{7}$$

Fig. 3 shows the relation curve between $f_i$ and the variation coefficient for all fracture sets. These results show that:

(1) The larger $f_i$ is, the smaller the average fracture spacing is.

(2) When $f_i$ is equal to 50%, the variation coefficient of fracture spacing tends to be stable.

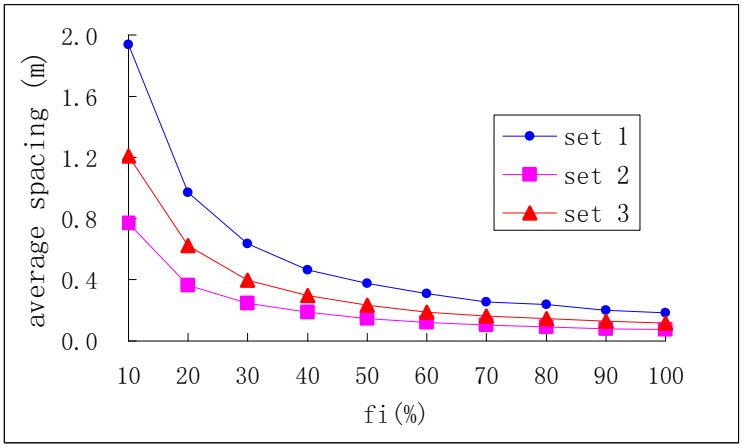

Fig. 2 The relation between $f_i$ and the average fracture spacing

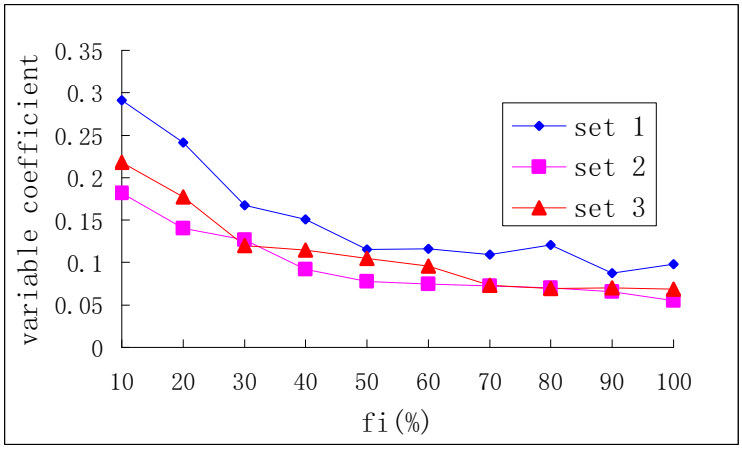

Fig. 3 The relation between $f_i$ and the variation coefficient

## Summary

This paper shows an indirect way to determine $J_v$ of fractured rock masses using Monte Carlo method. The engineering application shows that the fracture spacing will reduce and the variation coefficient becomes stable as $f_i$ increases. The suggested method is feasible and worth to be popularized in practical engineering projects.

**Keywords:** Clay minerals; Linxia basin; Paleoclimate; Palygorksite

**Abstract.**Linxia basin is a late Cenozoic fault-block basin along the border between the Tibet plateau and the Loess plateau in Northwestern China. Its formation and sediments' record may be directly affected by the structural dynamics and the uplift of the Tibet Plateau. For this reason, we studied the mineral characteristics of the Maogou formation of Miocene sediments using X-ray diffraction (XRD) and scanning electron microscopy (SEM). The XRD results showed that quartz, chlorite, illite, calcite, plagioclase, orthoclase, kaolinite, and trace palygorskite are present throughout the sequence of the cross-section in Linxia basin. In contrast, gypsum and ankerite occur occasionally in the upper portion of the Miocene deposits. The content of calcite varied with layers in the profile and was relatively concentrated in mudstone. Chlorite and illite were observed transforming into palygorskite under SEM observation. Based on the mineral characteristics and the change of mineral composition, especially the clay minerals, it could be inferred that an arid environment prevailed in the region with warm and cold intervals during Miocene time.

## Introduction

Located on the northeastern margin of the Tibetan plateau, the Linxia basin is a late Cenozoic fault-block basin along the border between the Tibet plateau and the Loess plateau. The formation and uplift of the Tibet Plateau has a profound influence on its origin and evolution.Because of its unique geological location and complete lithologic sequences, the Linxia Basin has been studied extensively recently. Most of these studies were focused on paleomagnetism, pollen, fossils, and particle size distribution of the sediments. Significant achievement has been made on determination of stratigraphy, ages of rock formation, as well as the environmental markers related to low resolution paleoclimate (Chen et al., 1996; Fang et al., 1997; Zhong et al., 2001; Cao et al., 2004; Qiu et al., 2004; Deng, 2004; Song et al., 2005). These results show that the basin was formed about 30 Ma. As a paleo-lake basin, it was in a closed system in Quaternary and most part of Tertiary. The mineral components of the sediments are made of clay minerals, feldspar, quartz, calcite, and gypsum. Clay minerals formed from weathering on the surface will change as the sedimentation and burial processes proceeded. The formation of new clay minerals as well as the transformation of previously formed clay minerals was closely related to the environment.Thus,by studying the mineral association of the clay minerals,their relative ratios, their structural characteristics,and the transformation of different clay minerals, we could deduce the source region of the clay minerals, the type of weathering, and the climate and the geo-environment when these minerals were formed. Using the clay mineral assemblage and detailed mineral characteristic analyses, Hong et al. (2007) studied the paleoclimatic evolution subsequent to the initial-stage of uplift of the Tibetan plateau using Oligocene sediments in Linxia basin. Their results suggested relatively small fluctuations in climate conditions during the Oligocene epoch while an increased erosion of soils and poorly weathered parent rock in

more elevated or high-relief source areas might occurred in the late Oligocene. In the current study, we investigated the mineralogical characteristics of the clay minerals in the Miocene sediments of Linxia Basin using XRD, SEM and other techniques in order to extend our discussion with our sister paper (Hong et al., 2007) on the study of paleoclimate and geologic environment in this basin.

## Geology of the area

Geographically, the Linxia basin is located in Linxia, Gansu province, northwestern China. The study area is a mountain front fault depression basin among Leijishan fault, south Qinling fault, and Mt. Mahanshan (Fig. 1).

The Maogou cross section is located in a stream valley in Dongxiang County, Linxia basin (Fig. 1). The total thickness of the strata is 443 m. The sediments are Tertiary red deposits. The sediments of Zhongzhuang, Shangzhuang, Dongxiang, and Liushu formations were deposited at 21.8 – 5.41 Ma. Based on their lithologic units, the cross section can be divided into three sedimentary sequences. Conglomerate, sandstone, and siltstone derived from river deposits occur on the bottom of each sequence. The top of each sequence is made of massive mudstone, reflecting a progressive wet environment. Among the three sequences, the mineral composition of the mudstone in the lower sequence is more uniform. Vertical gypsum veins or spotted gypsum can be found in the lacustrine mudstone in the middle sequence. Within the mudstone of the upper sequence, micrite bands of different thickness with bluish gray color are often seen.

Based on the lithologic characteristics, the Maogou cross section can be divided into 17 layers (Shi et al., 1998) ,Based on field geological observation and the trend in lithologic changes, we decided to choose samples from layers 2, 3, 11, 15, and 17 for further study. The samples are named b-2, b-3, b-11, b-15, and b-17.

## Materials and methods

**Sample preparation.**amples were collected based on their lithological characteristics. Each sample is split into three portions. The first portion is used for mineral composition analysis by XRD. The second portion was used for clay mineral analyses. The samples were soaked with distilled water, stirred and the clay fraction was separated from the coarser particles by sedimentation methods. Both oriented samples and ethylene glycol saturated samples were prepared.

**Instrumental analyses**.X-ray analysis was performed using a Rigaku Dmax-IIIA X-Ray Diffractometer, with a CuKα radiation, Ni filter, a voltage of 35 kV and current of 30 mA. The slits were 1º for divergence and anti-scattering slits, 0.3 mm for receiving slit. X-ray diffraction patterns were recorded using continuing scan at a speed of 4º/min and a 2θ resolution of 0.02º.

Representative pelite samples were selected and then platinum-coated. The analyses were undertaken on a JSM-5610 SEM at an accelerating voltage of 20 kV and a beam current of 1–3 nA.

## Results and discussion

**XRD analyses.**The XRD patterns of the natural pelite samples from the Miocene sediments at Linxia basin is shown in Fig. 2. The major minerals are quartz (Q), calcite (C), chlorite (Ch), illite (I), mixed layer of illite/smectite (I/S), feldspar (F), ankerite (An), and gypsum (Gy). Their characteristic diffraction peaks are 3.34, 3.03, 14.26, 10.00, 15, 3.19, 2.90, and 7.60 Å.Oriented XRD patterns of the clay fractions before and after ethylene glycol (EG) saturation are plotted in Fig. 3. For the peaks of 10 and 14 Å, no shift in position was found after glycerol saturation, indicating that the clay minerals are illite and chlorite. Also, a shift of peaks after EG saturation is indicative of mixed layered (I/S) or smectite. Furthermore, trace amount of palygorskite (Pa), whose characteristic diffraction peak (110) is 10.53 Å, is seen in some samples. Semi-quantitative analyses were carried out using internal standard methods (Brindley, 1980; Zhang et al., 2003) to determine the mineral content of present clay minerals. The results from the five representative samples are listed in Table 1. The relative

amounts of clays minerals in clay fractions are listed in Table 2. The kaolinite contents varied from 10 to 15%, illite from 42 to 53%, chlorite from 11 to 23%, while I/S from 15 to 30%. Sample b-11 had the highest amount of chlorite and lowest amount of I/S (Table 2). Illite and chlorite are characteristic of cold regions and deserts marked by very low rates of weathering and areas of steep relief where mechanical erosion interferes with soil formation (Robert and Kennett, 1994; Pandarinath et al., 1999). The fact that all layers in the section contain chlorite and illite indicates that the climatic environment in Linxia basin didn't have much fluctuation during the Miocene epoch and the area was dominated by dry climate. In addition, the trend of chlorite content varied from low to high, and then from low to high again, indicating that the climate environment experienced two cycles from cold and dry to mild and wet. Gypsum precipitation is a good indicator of dry climate, while sample b-11 contains 35-40% gypsum. These results showed that the overall transition of the climate in the region was from cold and dry to wet climate. In the course of transition, there was an episode of even dryer climate condition. Sample b-17 contained about 5% ankerite, indicating that the lake water was rich in iron when the carbonate sediments were deposited. Considering that palygorskite is formed from hydrolysis of chlorite in sediments, the excess iron in solution derived from hydrolysis of chlorite could be responsible for ankerite precipitation, which again indicating dry climate condition. Geochemical studies along the Maogou section showed that the Linxia basin had a relatively cold and wet climatic condition in Miocene (Zhong et al., 1998), which agrees well with this study using mineralogical properties of the clay minerals as an indicator of climate changes. An et al. (2001) identified three stages of evolution of Asian climates with the first stage characterized by enhanced aridity in the Asian interior (Including Linxia basin) and onset of the Indian and east Asian monsoons, about 9±8Myr ago. However, an increase in sedimentation rate influenced by climate change and erosion rates occurred in Linxia basin at the beginning of Pliocene (Zhang et al., 2001).

**SEM analyses.**Observation of electron microscopic images reveals that individual crystals of the clay minerals form curvy thin plates, while the aggregates of the minerals showed random orientation of the platy minerals. On the edges of the platy clay minerals, fibrous minerals of 1-2 μm long can be observed (Fig. 4a). Some of these fibers appear curvy (Figs. 4b, c). Fibrous minerals can also be found on the edges of many sheet-like and platy mineral grains. EDS analyses showed that the major chemical composition of the platy minerals were Si, Al, and K. Thus, the host platy minerals are illite (Fig. 4d), whose presence is verified by X-ray diffraction analyses. The sheet-like minerals have chemical composition of Si, Al, Mg, and Fe, indicating that the minerals are of chlorite type (Figure not shown). Well developed fibrous minerals are present in aggregates. Each individual mineral is 4-6 μm long and 0.1 μm in diameter. They are twisted and mingled in all different directions, showing the characteristics of palygorksite (Fig. 4c). Their EDS analyses showed that the major chemical composition was Si, Al, Mg, and Fe with trace amount of K, in compliance with the chemical composition of palygorskite (Fig. 4e). In the X-ray diffraction patterns, a minor 10.52 Å diffraction peak, caused by (110) reflection of palygorskite can be seen, confirming the presence of palygorskite. Clay minerals as secondary minerals are commonly present in all types of sedimentary rocks. Their chemical composition and mineral association are very sensitive to the changes in climate and environment (Manalt et al., 2001; Médard, 2000; Perederij, 2001). Most of these clay minerals in the sediments are produced from chemical weathering on Earth's surface and settled out with the sediments. However, their chemical composition as well as crystallinity will change during burial and lithification processes. The changes are strongly affected by the geochemical and geothermal environment (Meng et al., 2005). In addition, the formation of clay minerals are also affected by the pH and salinity of the solution, the surface temperature as well as the chemical composition of the parent rocks, among which solution pH and temperature will strongly affect the hydrolysis process (Lu, 1997). Thus, the characteristics of crystal structure, crystal morphology, and mineral association will reflect the geo-environmental conditions when these minerals were formed to certain degrees.

Illite is a relatively stable mineral commonly found in the sediments. It is formed at an environment that has a higher $K^+/H^+$ ratio, under strong physical weathering, weak leaching, and weak alkaline conditions. As most illite was derived from weathering of K-feldspar, it is commonly used as an

indicator of neutral to weak alkaline terrestrial environment (Chen and Miu, 1996). The SEM (Fig. 4a) revealed growth of fibrous palygorskite (1-2 μm in length) along the edges of the illite. This phenomenon is produced in aqueous solution under a surficial sedimentary environment.

Palygorskite is a fibrous phyllosilicate. The basic structure of palygorskite can be described as being composed of 2:1 ribbons that are linked to each other laterally by single basal oxygen. It is formed in desert environment under arid or semiarid condition (Tateo et al., 2000; Khadkikar et al., 2000) and is a characteristic mineral found in eolian loess deposits as well as in the weathered product of micrite in arid and semiarid region, thus could be used as an indicator mineral for arid and semiarid environment (Singer, 1984). It is produced by authigenesis from solutions having high $SiO_2$ and MgO activity, low $Al_2O_3$ activity, and at pH 8–9 (Chen, 1991). Sedimentary-type palygorskite is commonly associated with other sedimentary minerals such as sepiolite, carbonate minerals, sulfate minerals, montmorillonite, cherts, quartz, serpentine, chlorite, and is found in the transition zone in a depositional basin. (Wang et al., 1993).

From the electron microscopic images (Fig. 4c) we can see that aggregates of fibrous crystals are found in the pore space of particles in the sediments. The crystals are about 6 μm long, have well developed faces, form radial growth pattern. Intergrowth can be seen in between different particles. These fibrous palygorskite grow and replace the platy clay minerals on the edges. In some places where the replacement was more thorough, the crystals are complete made of palygorskite crystals. However the aggregates of the palygorskite crystals still preserve the shape of original mineral grains. Some grains showed complete transition to palygorskite. From the shape of the aggregates of the fibrous palygorskite and the replacement of palygorskite crystals for clay mineral grains, it can be seen that the palygorskite was of authigenic origin (Verrecchia and LeCoustumer, 1996). Furthermore, from the fact that dolomite was found in the sediments in sample b-17, it can be seen that the soil environment in the area was high in Mg activity, thus promoting the formation of palygorskite(Bozkaya and Yalçin, 1995).

The fine characteristics found on quartz surfaces are also an important indication for the analysis of depositional environments and sedimentary facies (Chen et al., 1996). Many dissolution etches were found on the surface of quartz crystals under the observation of electron microscopic observation. The etches showed regular patterns, most of them form a triangular shape (Fig. 4f). As the dissolution of quartz occurred at media having a higher solution pH, it can be inferred that the water in the sedimentary basin was somewhat alkaline. Under such alkaline environment, the silicon derived from quartz dissolution can facilitate the formation of palygorskite.

Due to hydrolysis, chlorite is converted into palygorskite along the edges and in the factures. The presence of palygorskite showed that the environment was alkaline, similar to the observation of quartz dissolution. The silicon and magnesium produced from hydrolysis of chlorite and quartz provided the chemical condition for the formation of palygorskite. The authigenic palygorksite found in the sediments showed that the climate of the region was dominated by dry climate in late Miocene epoch, in agreement with the observation from clay mineral association study.

## Conclusion

Results from X-ray diffraction analyses of the sediments in Linxia geologic section showed that the mineral composition was made of chlorite, illite, orthoclase, plagioclase, quartz, calcite, and small amount of gypsum. Among these minerals, the illite content could be as high as 53%, and I/S as high as 30%, indicating that the climate of the source region of the sediments was dominated by semi-arid climate with occasional warm or cold periods. Sample b-11contains 35-40% of gypsum. The presence of gypsum provides a solid evidence of the regional climate change and reveals a graduate transition of the environment to arid condition. The study showed that in Miocene epoch Linxia basin was dominated by arid climate. Although short intervals with warm and cold climatic conditions were documented in the sediment, overall the climatic condition was relatively stable.

Palygorskite is a good indicator mineral formed in arid and semiarid environment. The magnesium released from hydrolyses of chlorite provides the necessary chemistry for palygorskite to form. Fibrous minerals were also found around the edges of illite in the sediments, again showing that extensive hydrolyses among the clay minerals in the sediments. The wide presence of authigenic palygorskite in the sediment of Linxia basin confirms that the climate in the region was dominated by arid climate in Miocene time.

**Keywords:** Geologic factor；development factor；early warning system；monthly average decline range

**Abstract.** The development effect of Song Fangtun Oilfield is mainly restricted by two factors which are geology and exploitation. In view of the main control factors in oilfield development, we selected two indexes,monthly average decline range and water content escalating rate to establish early warning system of blocks development effect. The system which has great practical application value, is sensitive to reflecting the monthly variation process of block development effect, and plays a certain guiding role in the development effect during the whole year.

## Introduction

Song Fangtun oilfield is located in Sanzhao Depression area at the the central of the northern is on the Songfangtun nose structure, and the southern is on the Mofantun nose structure. These two nose structure are developed in the process of Songliao Basin occurrence and development, under the background of the base rock appendices on the ancient central uplift zone, at a long time. The formation thickness is getting thinner from the north to the south. Song Fangtun oilfield belongs to the eight plant of the Daqing oilfield,which has been put into the early development,parts of the block have entered the high-water exploration period. The reservoir rocks in Song Fangtun oilfield is hybird sandstone with shale high content,upper cement contant.Since 1983, through four development phases such as experiment exploration, fast production, stable yields and technical tackle, the oilfield development effect continue to be improved, because the oil development is more delicate and scientific. So far, Song Fangtun oilfield is divided into 30 development block, the cumulative recovery degree is 11.6%, composite water cut reaches 57.14%.

## The main control factors of oilfield development

**Areal structure.**The early production of the wells at the top of the structure is relatively high, the water content is smaller, while those at the lower part of the structure the early production is relatively low, the water content is larger. This is due to gravitational differentiation, most water injection drives from the higher structure part to the lower part, and the larger difference is the greater driving force. For example Fang 76-103 located in the higher tectonic area of Song Fangtun oilfield produced 7.5 tons oil per day in the early stage, the composite water cut is 2%, while Fang 82-92 located in the lower part produced 2.7 tons oil, the composite water cut reached 3.4%.

The sand deposition in Song Fangtun oilfield mainly controlled by the northern provenance sedimentary system, developes three kinds of sedimentary types: channel sand, body sand sheet and sand sheet of non-subject. Both in the vertical and plane, the underwater distributary channel sand has the strongest water intake intensity and liquid production, followed by delta body sand sheet and sand sheet of non-subject (Table 1). The microfacies differences caused the reservoir development effect imbalance in the profile and plane[1].

Table 1 Comparison between water intake intensity and liquid production per unit thickness of different sedimentation types in Song Fangtun Oilfield

| Sedimentation type | Hygroscopic intensity ($m^3$/m.d) | Liquid production per unit thickness ($m^3$/m.d) |
|---|---|---|
| Channel sand | 2.84 | 7.41 |
| Body sand sheet | 2.10 | 5.23 |
| Sand sheet of non-subject | 1.81 | 4.71 |

**Reservoir physical property.** The oilfield development effect, especially the oil production situation of well, all have inseparable connection with reservoir physical property[2]. Under the same degree of reserve recovery, if reservoir physical property is better, and the thickness is greater, the oilfield development situation is better. Compared three development blocks in the Song Fangtun oilfield, we can see that under the same degree of reserve recovery, the greater the permeability, the higher the oil production rate (Table 2).

Table 2 Correlation table of reservoir physical property

| Block | Porosity (%) | Permeability (mD) | Effective thickness (m) | Degree of reserve recovery (%) | Oil production rate (%) |
|---|---|---|---|---|---|
| F407 | 20.98 | 114.92 | 7.9 | 8.12 | 0.87 |
| F3 | 19.77 | 53.39 | 4.0 | 8.49 | 0.70 |
| F148 | 19.42 | 45.44 | 2.4 | 8.44 | 0.16 |

**Well pattern.**Song Fangtun oil field used square pattern, pattern water flood area of inverted nine spot injection pattern, injection-production well ratio is 1:3. This water injection is more flexible, if absorbing capacity of input wells is high, which can meet the needs of oilfield development, we can carry out this way. If asorbing capacity of input wells is lower, which can not meet the needs of oilfield development, then the number of input wells can be properly increased in the suitable place to make injection-production well ratio kept at 1:3.

**Water content escalating rate.**Water content escalating rate is is the central index to evaluate the oilfield development effect, only fully understand rules of oilfield water content escalation, find out which factors are inevitable, which factors are artificial, which can be adjust by later measures, then we can provide scientific and reasonable base for adjustment decision and oilfield development, to lay a solid foundation for high production and stable yields of oilfield[3].

## Early tracking and warning system of development effect

**Selecting principle of early-warning index.**During the selection of index, there are three principles to be insisted: (1)Accurate sensitive principle, early warning indexes should be able to reflect the

main aspects of block development effect change accurately and sensitively. (2)Fully reliable principle, the authority and statistical caliber of early-warning indexes should be consistent, meanwhile the number of statistical data samples should be large enough to meet the needs of the forecast and adjustment. (3)Match principle, early-warning indexes should be matched with the specific elements and warning method.

**Production decline rate.** Production decline rate is the percentage of production decline in unit time, and is an important index to evaluate oilfield development effect. Therefore, to realize the effective control of production decline, is an important work for oil field to improve development effect[4]. There are mainly four aspects to analyze influence factors of Song Fangtun oil field production decline over the years: firstly improvement of well spacing density can slow down production decline rate; secondly the adjustment of water flooding regime in proper time can effectively slow down production decline; thirdly if the initial oil production rate is higher,the water line advances faster and cause the high decline, finally is high deliverability can bring high decline, and high deliverability for several years, will exacerbate subsequent years of oil decline[5].

**Monthly average decline range.** Monthly average decline range: the average decline range every month which is compared withe annual decline rate of peak production in last year.

$$Qn=Qo\times(1-D)^{n} \quad (1)$$

$$d=1-(1-D)^{1/12} \quad (2)$$

Among them: D—Annual decline rate of peak production till some year, %; d—Monthly decline of peak production by the end of some year, %; Qn—Annual output of oil, $10^4$t; Qo—Peak production, $10^4$t; n—Decreasing fixed number of year, year.

The monthly average decline range of block A in Song Fangtun oilfield was 1.63%, since January 2012, and the block development effect began warning. The development effect continue to be worse in the February. We began to take measures in March, the decline rang fall below 1.66%. The decline rang continue to decrease in the April, the development effect fell below the warning area, even got in the good area(Table 3).

Table 3 Alternation of monthly average decline range in block A between January to May in 2012

| Block | Monthly average decline range in 2012(%) | | | | |
|---|---|---|---|---|---|
| | January | February | March | April | May |
| | 1.63 | 3.45 | 1.65 | 1.01 | 0.7 |
| A | Monthly development effect in 2012 | | | | |
| | January | February | March | April | May |
| | warn | bed | warn | good | good |

**Monthly average water content increase.** Monthly average water content increase is the difference between the monthly average water content in certain month and the annual average water content in last year. Supervise the monthly average water content increase, especially analyze and adjust the block which water content increase is more than 5%, make a warning signal to the block which water content increase between 3% and 5%, to control the increase of water content.

The annual average water content rate of block B in Song Fangtun oilfield was 54.8%, since January 2012, the monthly average water content rate was 2.6% more than the annual average water

content rate in 2001. The increase rate reached 4.5% in the February (Table 4),and the block development effect began warning. The water content escalating rate fell back to 3% in May, the development effect turn better.

Table 4 Alternation of water content increase in block B between January to May in 2012

| Block | Monthly water content increase in 2012(%) | | | | |
|---|---|---|---|---|---|
| | January | February | March | April | May |
| | 2.6 | 4.5 | 6 | 4.1 | 2.8 |
| B | Monthly development effect in 2012 | | | | |
| | January | February | March | April | May |
| | good | warn | bed | warn | good |

## Conclusions

The main geologic factors that influence the development effect of Song Fangtun oilfield are structure, sedimentary system reservoir physical property and so on. Different development feature different geologic feature. The block located in the high structural part and developing well reservoir condition, will occupy the vantage ground in the process of development.

The main development factors that influence the development effect of Song Fangtun oilfield are well pattern, development mode, production decline rate, water content escalating rate and so on. The final development effect of oilfield will be improved by choosing appropriate well pattern type and development mode and emphasizing the control of decline rate and water content increase in the process of development.

Select two indexes, monthly average decline range and water content escalating rate to establish early warning system of blocks development effect, which has great practical application value, is sensitive to reflecting the monthly variation process of block development effect, and plays a certain guiding role in the development effect during the whole year.

# Stability Analysis of Puzi Landslide in Chongqing

Kai He [a], Chun-li Chen [b]

Department of Geological Engineering, Chang'an University, Xi'an, 710054, China

[a]hekai2005@163.com, [b]chen_chunli@126.com

**Keywords:** geohazard, landslide, stability analysis, rainstorm condition

**Abstract.** The boot-shaped landform is steep for upper part and gentle for lower part, which is suffering from serious landslide and collapse hazards, and the Puzi landslide studied in this paper is in boot-shaped landform. Stability analysis of Puzi landslide was taken on the detailed analysis of the tectonic setting, formation lithology and the meteorological hydrological conditions. The result demonstrates that the Puzi landslide is on the critical to unstable state. And it is possible to integral slide under the influence of rainstorm or continuous rainfall and has higher risk of geohazard. It is recommended that people settled in the landslide area should be relocated and early warning monitoring should be carried out immediately. The results will offer technical support to prevent and relieve of geohazard in mountainous areas of southwest China.

## Introduction

Puzi landslide is located in Jinfo Mountains in Toudu town, Nanchuan district of Chongqing. Because of the special geological conditions in Jinfo Mountains, there is boot-shaped landform, which is steep for upper part and gentle for lower part, hardness-upward and softness-downward[1,2]. In such geological conditions, the area of gentle slope in front of the cliff is in face of serious landslide disaster besides dangerous rocks collapse from steep cliff behind. This kind of landslide is one of the typical geologic hazards all over the southwest China. Based on the Puzi landslide, the stability analysis of this kind of landslide was carried on in this paper. The results will offer technical support to prevent and relieve of geohazard in southwestern mountainous areas of China.

## Geology setting

Jinfo Mountain located in Nanchuan district of Chongqing. There is horizontal layered limestone which is easy to form cliff landform. In such special geological conditions, with precipitation, earthquake and increasing human activities, Jinfo Mountain is one of the areas with serious collapse and landslide geohazard [3-5].

**Geologic structure.** Puzi landslide is near the east wing of Jinfo syncline. The axis of Jinfo syncline is in the direction of NE~SW, the dip direction of west wing is 106～115°, the dip angle is 40~50°; while the dip direction of east wing is 290～310°, and the dip angle is 4～11°. It is typical partition wall style structure with broad and gently syncline core. As a result there are approximately horizontal stratums in study area.

**Strata and lithology.** The strata in Jinfo area from top to bottom are the Quaternary colluvium and diluvium ($Q_4^{col+dl}$), elurium and diluvium ($Q_4^{el+dl}$), made land ($Q_4^{ml}$), Changxing formation limestone of upper Permian ($P_2c$), limestone of Longtan formation ($P_2l$), Maokou formation limestone of lower Permian ($P_1m$), limestone of Qixia formation ($P_1q$), limestone of Liangshan formation ($P_1l$) and Hanjiadian formation silty shale of middle Silurian period ($S_2h$).

The main lithology is limestone, shale and clay rock (bauxite). The cliff is limestone with bauxite at the bottom. The lower slope is weak shale covered by the Quaternary colluvium and diluvium, formed the landform hardness-upward and softness-downward that easy to landslide.

**Climate and hydrology.** The landslide area has a subtropical warm and humidity climate and the vegetation is well developed. The region is blessed with plentiful rain and a mild climate, it is mostly

foggy and less sunshine. The climate possesses distinct vertical zonation that the mean annual temperature decreased with the decreasing of altitude, while the rainfall increased. According to the weather data of Nanchuan District, the mean annual temperature of this area is 14.3℃, the maximum and minimum temperature are 36℃ and -10℃. The annual frost-free period is 200 days. The annual average precipitation is 1170.2mm and the annual evaporation is 1134.9mm. The rainfall is intense and the maximum of the daily rainfall is 112.78mm. But rainfall of each season are very uneven season, May to August is the rainy season, in which period the rainfall is 80% of the whole year, and December -through-February is the dry season. Surface river is not developed, the Bozhi river flow from east to west 3km south of the Puzi landslide is the main river in this area and its river bed is the lowest datum of erosion with elevation of 720～780m. The concentrated and abundant rainfall becomes one of important factors of the landslide.

## Stability Analysis of the Landslide

**Landslide characteristic.** The toe of repture surface of the Puzi landslide is located in the the common border of the cliff and flat ground, bounded by gully and a small ridge on the two sides. The landslide is 800m long and 350m wide. The thickness of the landslide body is 10～40m. The slope angle of is 10° at the top and 20° at the lower part, and the slope aspect 120°. The landslide is large thrust load caused landslide with volume $700\times10^4 m^3$ and the damage scope $0.366km^2$(Fig.1). The elevation is 1260m at the top and 1000m at the toe, the relative difference in elevation is 260m.

The deformation characteristics are cracks 1～5cm wide appear in the rooms on the top of the slope, horizontal displacement at 0.5～10m and vertical displacement at 20～30cm. There are subsidence and deformation every year. It's very hard to preserve water for the paddy fields and there are varying degrees of collapsing on the slope. The cracks grown in width and depth recently, and the deformation of the rooms became violent. Some of the construction became dangerous substandard house.

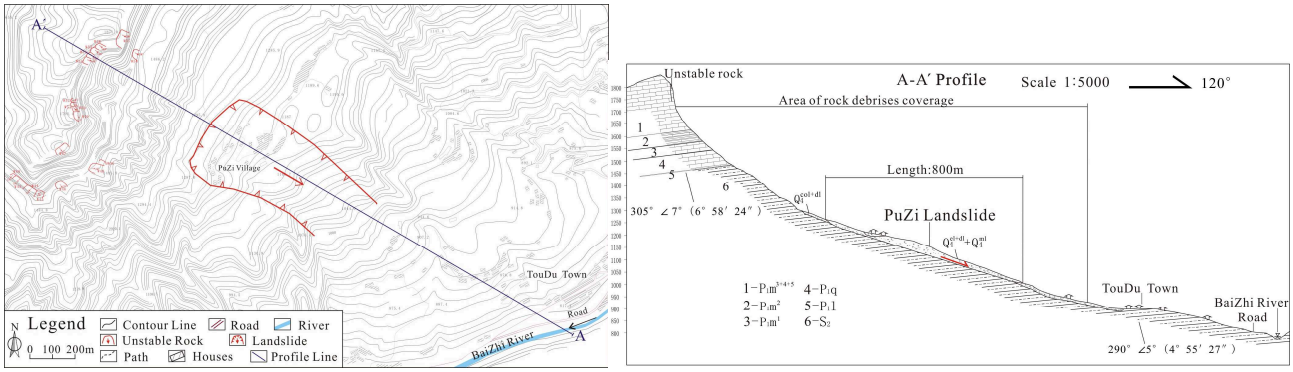

Fig.1 Plan view and A-A' profile of Puzi landslide

**Stability calculation of landslide.** The sliding surface of Puzi landslide is approximately broken-line type. According to the transfer factor method recommended by *China code for investigation of prevented and cured engineering of geological hazard* (DB50/143-2003), a stability calculation was carried out (Fig.2). Computation formulas are as follows.

$$Fs = \frac{\sum_{i=1}^{n-1}\left(R_i\prod_{j=i}^{n-1}\Psi_j\right)+R_n}{\sum_{i-1}^{n-1}\left(T_i\prod_{j=i}^{n-1}\Psi_j\right)+T_n} \quad (1)$$

$$\Psi_j=\cos(\theta_i-\theta_{i+1})-\sin(\theta_i-\theta_{i+1})\tan\varphi_{i+1}. \quad (2)$$

$$\prod_{j=i}^{n-1}\Psi_i = \Psi_i\times\Psi_{i+1}\times\Psi_{i+2}\ldots\Psi_{n-1} \quad (3)$$

$$R_i=N_i\tan\varphi_i+C_iL_i. \quad (4)$$

$$T_i=W_i\sin\theta_i+Z_i\cos\theta_i+D_i\cos(\beta_i-\theta_i). \quad (5)$$

$N_i=W_i\cos\theta_i-Z_i\sin\theta_i+D_i\sin(\beta_i-\theta_i)$. (6)

$D_i=\gamma_w h_i l_i \cos\theta_i \sin\beta_i$. (7)

$Z_i=W_i\omega$. (8)

Where,

Fs—Stability factor;

$W_i$—Gravity of block *i* (kN/m), including self-weight and additional load;

$R_i$—Force for anti-sliding of the block *i* (kN/m);

$N_i$—Normal component of force on the sliding surface for block *i* (kN/m);

$\varphi_i$—Internal friction angle for block *i* (º);

$C_i$—Cohesiveness for block *i* (kPa);

$L_i$—Length of the sliding surface for block *i* (m);

$T_i$—Sliding component of force on the sliding surface for block *i* (kN/m), $T_i$ can be negative when its direction is of opposite to sliding direction;

$\Psi_j$—Transfer factor of surplus sliding force transfers from block *i* to block *i+ 1*(j=i);

$Z_i$—Seismic force of block *i* (kN/m);

$D_i$—Hydrodynamic pressure of block *i* (kN/m);

$\beta_i$—Hydraulic gradient of block *i* (º);

ω—Seismic factor, the factor value is 0.05;

$h_i$—Height between underground water level to the sliding surface for block *i* (m).

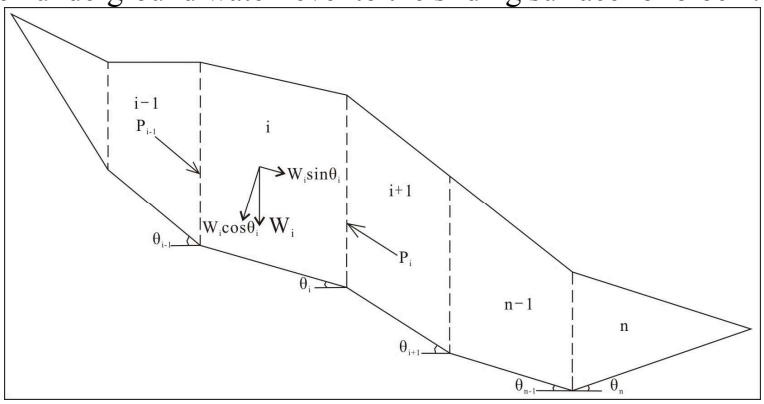

Fig.2 Schematic of landslide stability analysis.

All parameters in Fig.2 have the same meanings as Eq.1~Eq.8

The value of C and φ for potential sliding surface are hard to determined, so the regional empirical value was referred to. The unit weight of sliding mass is 21kN/m$^3$ for natural condition and 21.50kN/m$^3$ for saturated condition. C and φ of sliding zone is 19.1kPa and 17.23° respectively for natural condition, 18.00kPa and 16.90° respectively for saturated condition.

This calculation aimed to provide basis for landslide stability evaluation. Calculation load was composed of self-weight, the building load, hydrodynamic pressure and seismic force.

(1) Load.

Self-weight: The weight of the slide mass. Under the nature condition, The part above the underground water level use natural unit weight, while under the underground water level use buoyant unit weight.

The building load: There were little construction in this calculation section, so ignore the building load in calculation.

Hydrodynamic pressure: $D_i=\gamma_w h_i l_i \cos\theta_i \sin\beta_i$, Its direction is the same with the hydraulic gradient, calculate with different underground water level in each conditions.

(2) Calculation condition

According to the loading combination, landslide stability calculation could be divided into two working condition:

Condition No.1: Natural condition, self-weight + groundwater load in current situation.

Condition No.2: Rainstorm condition, self-weight + groundwater load in rainstorm situation.

Based on the project above-mentioned, Puzi landslide stability evaluation was carried out as requested by the *China code for investigation of prevented and cured engineering of geological hazard*. According to the computed results, stability factor for Puzi landslide is 1.019 under natural condition (condition No.1), while the Landslide stability factor is 0.963 under rainstorm condition (condition No.2). Contrasted the $F_s$ with table 1, it is shown that Puzi landslide is on the critical to unstable state in current situation, and instability in rainstorm situation.

Table 1 Partition of Landslide stability state

| Landslide stability factor $F_s$ | $F_s \geqslant F_{st}$ | $F_{st} > F_s \geqslant 1.05$ | $1.05 > F_s \geqslant 1.0$ | $F_s < 1.0$ |
|---|---|---|---|---|
| Landslide stability state | Stable | Metastable | Understable | Unstable |

Note: $F_{st}$ is landslide stability safety factors. The value for Puzi landslide is 1.15.

Because of the loose structure of sliding mass and poor strength, the stagnant water zone would be formed on the surface between bed rock and soil after rainwater infiltrated by rainstorm or continuous rainfall [6]. Silty shale prone to soften by groundwater soaked, as a result, strength of sliding zone reduction steeply, promoting the slope sliding. Puzi landslide could threaten 17 families (more than 90 people) which settled in the influence area of this landslide. It is advised that people settled in the landslide area should be relocated and early warning monitoring should be carried out immediately.

## Conclusions

Based on the research result, the following understanding and conclusions have been got.

(1) The China southwest mountainous area with boot-shaped landform steep for upper part and gentle for lower part is vulnerable to collapse and landslide hazards.

(2) As known from calculation, the stability factor of Puzi landslide is 1.019 and the landslide on the critical to unstable state under natural condition; the stability factor of Puzi landslide is 0.963 and the landslide is unstable under rainstorm condition. It is possible to slide under the influence of continuous rainfall or rainstorm, and there are high disaster risk.

(3) Considering the twofold impact of collapse and landslide, it is recommended that people lived in Puzi landslide area should be relocated and disaster monitoring and warming should be made as soon as possible.

**Keywords:** Tectonic movement, river terrace, loess plateau, loess landslide, landslide cycle.

**Abstract.** Landslide investigation in the center part of loess plateau reflects that most of large-scale old and ancient landslides lie on river terraces at different heights, but the small ones usually occur along the sides of V-shaped loess valleys, which implies that there is an inherent connection between the landslides and the erosion action. Since river terraces were formed by intermittent uplift of the crust, which controls the features of river erosion and the thickness of loess on the terraces. The analysis of typical loess landslides in this region shows that during relative static period, lateral erosion was dominated, so river valley was widened, which induced some large-scale landslides because the toe of slope was strongly eroded. While during the uplift period, vertical erosion was dominated, and the loess began to deposit on the terraces above water level, with the downcutting of the river, a narrow V-shaped valley formed, and then small loess landsides occurred on both sides of the rivers. Therefore, intermittent crustal uplifts not only led to the formation of multi-degree of terraces, but also induce alternative occurrence of large-scale and small loess landslides.

## Introduction

The northern Shaanxi is located in the center part of the Loess Plateau, with the total area of 92,521 $km^2$. The rivers here are the tributaries of the Yellow River as shown in Fig.1, which formed a river network cutting the Loess Plateau into the landform of ridges and domes penetrating with wide valleys and narrow gullies [1]. With the evolution of the landform, loess landslides become a serious geological hazard frequently occurring in this region, which not only caused huge losses of lives and property to local residents, but also restricted the sustainable development of local economy. In recent years, we carried out systematic investigations on landslides in northern Shaanxi, and the analysis for the geomorphic features of landslides shows that there is internal relation between the formation of landslides and the evolution of river terraces and gully. For example, there are about 30 ancient landslides distributing on the third terrace along the sides of Dazhuanghe River, Ganquan County. Landslides mainly occurred on the second terrace, on the south side of the Koujiahe River in Huangling County. On the south side of Jinghe River, landslides mainly developed on the first terrace. And a great many of new landslides and collapses occur on both sides of deep ditches on the edge of Luochuan loess platform. Based on the observations above, the paper intends to discuss the correlation among landslides, river terraces, and tectonic movement so as to reveal the temporal-spatial law of the formation of loess landslides in this region.

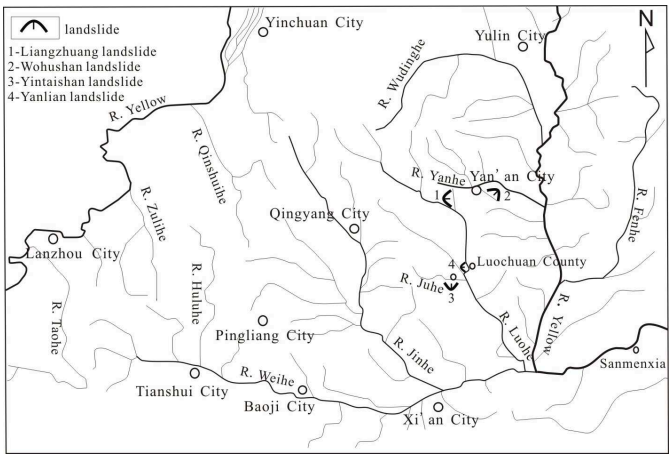

Fig.1 River system on the Loess Plateau (Accorrding to Lei X.Y, 2006)

**The stratum structure of the loess and the evolution of river terraces in loess plateau**

Loess is a kind of wind blown sediment, which only deposits on the stratum above the underground water level. The northern Shaanxi is located in the center of the Ordos basin in the Mesozoic era, where deposited a set of thick clastic material of river-lake facies. During the early Tertiary, crustal uplift led to the close of the lake-basin sediment. In the early to middle Pliocene ($N_2$), subsidence of the basin created a favorable condition for the deposit of the huge thickness of red mudstone and sandstone formation. At the end of Pliocene, the uplift of the loess plateau, including the northern Shaanxi, ended the lake-basin environment. Because of unequal uplift within the basin, secondary basins were created and the modern pattern of the Yellow River system formed. The original basins have being received a relative broad and thick loess deposit, where were manifested as the modern loess platforms (high lands with flat top). Luochuan loess platform is the largest one in northern Shaanxi, of which has a successive loess sediment of Quaternary. A loess profile in Potou village, Luochuan County, locating at the west side of Heimugou gully, has been accepted as the Luochuan standard loess section, on which the Quaternary paleoclimate and stratigraphic studies have been carried out in detail. In the early of the last century, according to the field characters, Liu D.S. (1984) divided the loess strata into three lithostratigraphic units. Those are Malan loess, Lishi loess, and Wucheng loess from upper to lower, traditionally known as $Q_3$, $Q_2$ and $Q_1$ respectively[2]. Beside the three typical units, A thin layer of 1-2m thick Holocene deposit($Q_4$) coves on the top, which consists of a layer of dark brown bed down and a brown-yellow bed up, of which, the former is called loam($S_0$) and the later is called Holocene loess($L_0$).

Because of frequent changes of climate in the Quaternary, the sediment are not uniform in composition and structure in the whole, but occurs as that the brown-yellow loess bed and the brown-red paleosol bed interbeded, reflecting the interchange of the climate. Loess represents the product of dry-cold climate, while paleosol, as well as the loam, represents that of warm-wet climate. Loess strata on Potou profile is made up of more than thirty loess-paleosol sequences reflecting that there had been more than thirty climatic fluctuations in Quaternary. Malan loess is the first layer of typical loess on the top, which is a set of uniform loose material, light in color, corresponding to last glaciations. Lishi loess includes the the first paleosol to the fifteenth loess sequences. Of the above loess, the ninth ($L_9$) and fifteenth ($L_{15}$) loess layer having a relative higher thickness and coarse particles represent the deposition under abominable climatic conditions, and the fifth paleosol ($S_5$) is a quite thick layer consisting of three sub-paleosols with two thin loess beds among them. So $L_9$, $L_{15}$ and $S_5$ are considered as the marked beds for identification of the loess stratigraphy in the field. Wuchen loess is consisted of frequently interbeded paleosol and loess beds with high content of calcium and stiff of properties, so it is called as lithoid loess. Below the Wuchen loess underlies the Neocene red clay.

Since 1980s，by radio active $C_{14}$ measurement, paleo-magnetism age and correlation of the isotope curves among the oceanic core holes and the loess sections, a detail dating has been made for the loess strata. According to result, the loess in Quaternary is divided into Holocene ($Q_4$), upper Pleistocene ($Q_3$), middle Pleistocene ($Q_2$) and lower Pleistocene ($Q_1$) Series. The boundary of Holocene and upper Pleistocene is located at the bottom of the black loam, aged at about 11 thousand years. That of upper and middle Pleistocene is located at the bottom of the first paleosol ($S_1$) aged at 128 thousand years. And that of middle and lower Pleistocene is located in the eighth loess ($L_8$) aged at 730 thousand years corresponding to B/M boundary of paleomagnetism. The boundary of lower Pleistocene and upper Pliocene is located on the top of red clay or bottom of the loess, a little higher than the B/M boundary of paleomagnetism. The age of M/G boundary is 2.47 million years, so the boundary of the Quaternary and Tertiary is considered as 2.50 million years or so. It ca be seen that the early lithologic units and the present chrono-stratigraphic units do not agree with completely. A composite stratigraphy of the Luochuan standard loess section is shown in Table 1.

The loess deposit is continuous on the loess platforms while that on river terraces depends on their uplift age. The older and higher the terrace is, the thicker and more loess beds the terrace undertaken.

In the Quaternary, the Loess Plateau uplift intermittently and the multi-level terraces developed. The evolution process of a terrace generally consists of two phases: lateral erosion phase and down cut phase[3]. During the static tectonic period, a river has lateral erosion and the riverbed is widened, while during the uplift period, it cut down vertically to form a new narrow riverbed and the original riverbed and floodplains become a terrace. The new riverbed would be the next terrace in the forth coming static-uplift cycle. In northern Shaanxi, the intermittent uplift of tectonic movement leads to the development of terraces distributing along the riversides. The surfaces of the terraces have been entirely covered by loess. Yue L.P, Lei X.Y, et. al (1997), who have studied the Luohe River terraces in northern Shaanxi, suggested that generally there are terraces ranging from first to fifth in this region with sandstone in Triassic Period as the bases[4]. Among the terraces, the base of the fifth terrace ($T_5$) is 55m above the riverbed, on which lies the loess-paleosol sequences from $L_0$ to $S_{11}$ with the total thickness of 78m. The base of the fourth terrace ($T_4$) is 20m above the riverbed, on which lies the loess-paleosol sequences from $L_0$ to $S_9$ with the total thickness of 60m. The base of the third terrace ($T_3$) is 10m above the riverbed, on which lies the loess-paleosol sequences from $L_0$ to $S_7$ with the total thickness of 45m. The base of the second terrace ($T_2$) is 5m above the riverbed, on which lies the loess-paleosol sequences from L0 to S2 with the total thickness of 10m. The base of the first terrace ($T_1$) is a layer of cultivated soil with the thickness about 1m and the underlying is the black loam, as figure 2 shows[5].

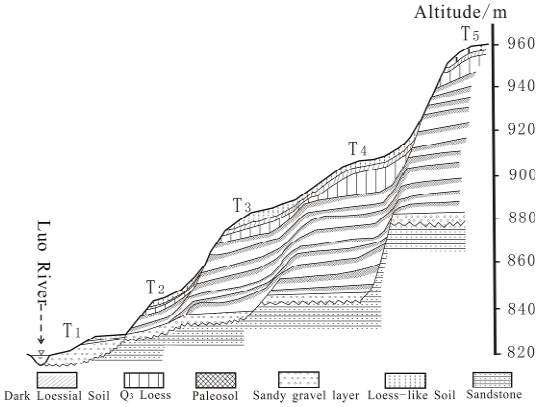

Fig.2 Loess section of the terraces of the Luohe River(According to Lei X.Y, 2001)

Correlating the loess or paleosol on the terraces in Fig.2 and their ages in table 1, the uplift time of the each terrace corresponding to the crustal uplift and static time has been determined as shown in table 2. It can be seen that the northern Shaanxi experienced seven times of the crustal uplift during the quaternary corresponding to seven times of erosion. The first uplift built up the outline of the loess plateau. With the rivers flew out the area, modern pattern of the river system formed. The second to

sixth uplift correspond to the formation of the first to fifth terraces while the seventh uplift corresponds to the rise of the high floodplain and the formation of modern river bed.

Table2. Correlation between crustal movement and the stratum structure of loess on the river terraces in Loess Plateau

| Absolute Age/10000a | Crust Movement | Formation | Erosion Period |
|---|---|---|---|
| 0-0.4 | River bed | MS | 7 |
| 0.4-1.0 | High flood plain | | |
| 1.0-2.3 | $T_1$ uplift | $L_0$ | 6 |
| 2.3-12.0 | $T_1$ widen | $S_0$ | |
| 12.0-17.0 | $T_2$ uplift | $L_1$ | 5 |
| 17.0-62.0 | $T_2$ widen | $S_1$-$S_2$ | |
| 62.0-66.0 | $T_3$ uplift | $L_2$ | 4 |
| 66.0-82.0 | $T_3$ widen | $S_3$-$S_6$ | |
| 82.0-85.0 | $T_4$ uplift | $L_7$ | 3 |
| 85.0-123.0 | $T_4$ widen | $S_8$-$S_9$ | |
| 123.0-127.0 | $T_5$ uplift | $L_{10}$ | 2 |
| 127.0-170.0 | $T_5$ widen | $S_{10}$-$S_{11}$ | |
| 170.0-178.0 | River formation | $Q_1$ | 1 |
| 178.0-250.0 | Loess deposit | $Q_1$ | |
| 250.0 | Overflowing of the paleo- lake | | Plantation surface |

**Correlation between landslides and the river terraces**

Landslides mostly occurred on the sides of the rivers. Investigation in the northern Shaanxi shows that most of old and ancient landslides shear out on different stages of the terraces, commonly on the first to third terraces, while the small loess landslides and collapses occur on the sides of V-shaped loess gullies [6,7].

The ancient landslides on the third terrace formed in 170-620 thousand years ago, which are generally large in size, clear in boundary, round and steep in back scarp with a armchair form. At present, this type of landslide is in an extra-stable state, the main reason is that after a long time of erosion, the residual sliding deposits have left a little, even the most sliding bed are outcropped, therefore, there are no material for revival. In addition, high position of the landslides keeps them from the extensive action by rivers or human engineering activities. Therefore, they have no threat to the life and activities of the people.

The Liangzhuang landslide is illustrated as the typical example mentioned above. The landslide is located on the right bank of the Dazhuanghe River in Liangzhuang Village, Shimen Town, Ganquan County (Fig.1). The boundary of landslide is obvious, and the sliding bed is almost bare (Fig.3). There is three terraces (T1-T3) on the river side here, where the first is about 2m above the riverbed to the top; the second is about 5m from above the riverbed to the base; the third terrace is about 12m above the riverbed to the base on which the landslide lies (Fig.4).

Fig.3 Overview of Liangzhuang landslide

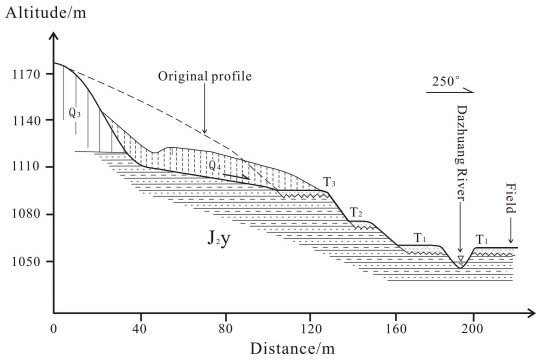

Fig.4 Main section of Liangzhuang landslide

The landslide occurred after the third terrace had been formed. During this period, the tectonic movement tended to be stable, so the riversides were eroded while the space of the second terrace was widening, as a result, the loess deposited on the third terrace slipped along the bedrock of the terrace base.

The landslides lying on the second terrace formed during 23-120 thousand years before present. They are usually large in scale and have multiple scarps. Most of the landslide deposits are remained on which gullies, sinkholes and cracks developed by long term erosion, so they allow amount of surface water seepage in. In addition, the toes of the landslides are usually cut for housing and road construction, so the landslides often revive.

The Wohushan landslide, located on the east side of the Wohushan Mountain, is a typical case for this type of landslide. left bank of the Nanchuan river, about 2 kilometers to the south of Yan'an railway station (Fig.1), with a dust-pan shape in plane view and about 280m in length, 260m in width, $105\times10^4 m^3$ in volume, multiple back scarps(Fig.5). The landslide had at least twice down sliding (Li T.L, 2006). There are three terraces ($T_1$-$T_3$) developed on the left bank of Nancuan River. The first terrace is flat and broad, and the widest part is about 200m. The second and the third are covered by loess deposit, which were revealed by the boreholes on the landslide (Fig.6). The bed rock base of the second terrace is 10-13m above the riverbed on which the landslide sheared out. The third terrace is buried deep in the slope.

Fig.5 Overview of Wohushan landslide

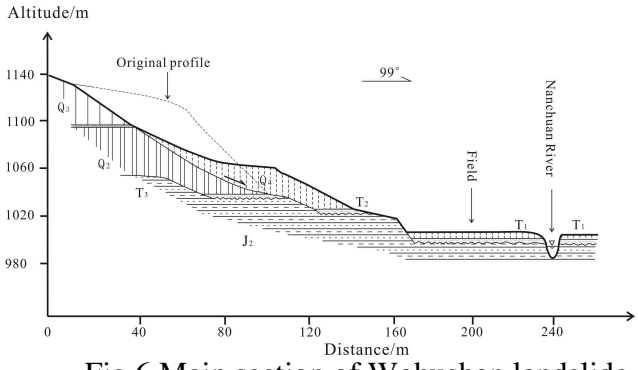

Fig.6 Main section of Wohushan landslide

The old landslides locating on the first terrace occurred during 4-10 thousand years before the present time. They are large in scale, clear in boundary and complete in form. Many villages distributed on the landslides since the terrain gets to be flatter after sliding, as a result, a great deal of domestic or irrigation water penetrates in or along fractures on the deposits, which causes the landslide being easily revival.

Yintaishan landslide is a typical example of such one, which is located at west side of the Yintai Mountain, and the left bank of the Juhe River, in Yintai Village, Qiaoshan Town, Huangling County (Fig.1). It is an old landslide of Early Holocene, with a length of 150m, a width of 300m, and a thickness of 10-12m in the toe and 25-30m in middle. Surprisingly, the whole Yintai Village is located on the landslide, which lies on the first terrace of the left Juhe river bank(Fig.7). The

interbedded sandstone and mudstone under the terrace deposit exposes at the both sides of the river (Fig.8).

Fig.7 Overview of Yintaishan landslide

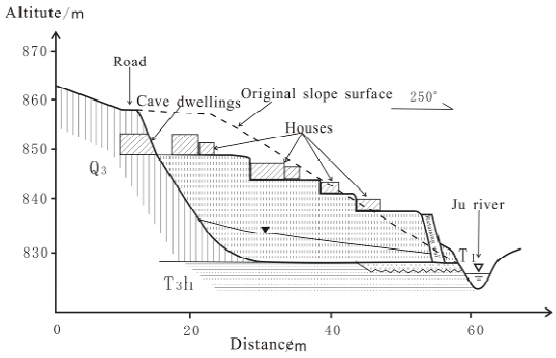

Fig.8 Main section of Yintaishan landslide

Small-size landslides are usually developed on both sides of the V-shaped deep gully with clear boundaries and steep back scarps. The landslides make the margin of the loess platform move backward and threaten the nearby residents and infrastructures. Meanwhile, the gullies are easy to be dammed by the landslide deposits. Take the landslide in Luochuan Oil Station as an example. It is located in the former Luochuan Oil Station (Fig.1), which lies on the top of a V-shaped valley side. The valley is 50m in depth and 100m in width (Fig.9 and Fig.10). In January 2009, when the landslide occurred, the main facilities of the oil stations slipped into the gully, resulting in 1.5 million yuan RMB of direct economic losses. The landslide has a steep back scarp and a height of 8m, a width of 65m, and thickness of 15m.

Fig.9 Overview of Old gas station landslide

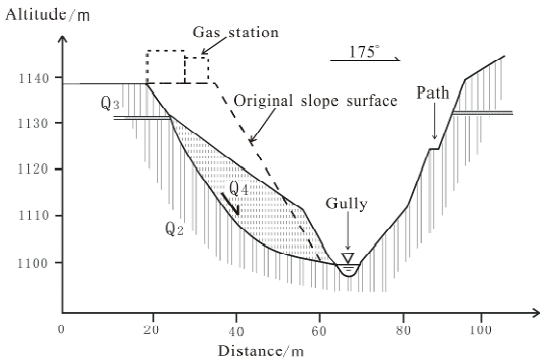

Fig.10 Main section of Old gas station landslide

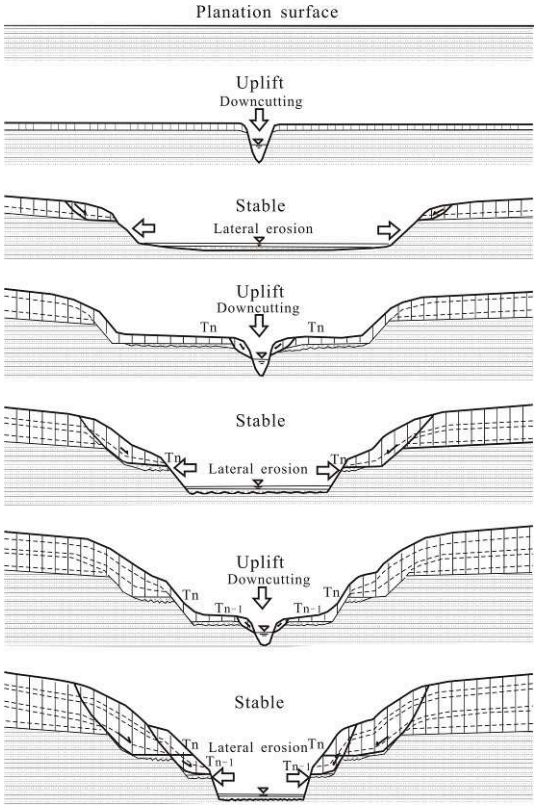

Fig.11 The relationship between the periodicity of landslide and terraces

The typical cases of landslides on different terraces in northern Shaanxi described above, under the control of tectonic movement, show that there is inherent connection between river terraces and landslides. In the first period of tectonic uplift, gullies and rivers emerged with the down cutting and the loess deposited on the plantation surface. Then after, with coming of the relative stable period, lateral erosion broadened the space of riverbed; meanwhile, as the result of the washout or pullout to the front of the bank slope by running water, the small landslides of the early loess on the plantation came into being. With the next cycle of tectonic uplift, the rivers cut down again to form a new narrow riverbed within the primary one, and then the highest terraces were formed and received the loess deposit. With continuous down cutting, the bank walls became higher and steeper, where V-shaped deep gully appeared and small landslides or collapses of the loess on the top of the terrace occurred. As tectonic movement tends to be stable, the lateral erosion worked again, and then the highest terrace retrogressed backward by the erosion, at the same time, large-scale landslides turned out on the top of the terrace. With multi-level terraces emerging by intermittent uplift, the centralized occurrences of large-scale and small-scale landslides turned out periodically. The whole cycle processes was shown in Fig.11.

## Conclusion

Landslides, in loess plateau, mainly occurred on the terraces along the erosion sides of the rivers and their tributaries. There are significant relations among the tectonic movements, the river terraces, and the landslides. During stable tectonic period, the rivers took the lateral erosion mainly and the river channels were widened, large-scale landslides on the terraces occurred. During the period of tectonic uplift, rivers eroded vertically, terraces of the next level began to come into being, small loess landsides and collapse occurred dominantly. Therefore, the landslides in loess region occurred periodically controlled by the tectonic movement.

**Key words:** Coal gangue hill；High fill slope；Self-drilling type hollow bolt；Construction；Safety factor

**Abstract.** In the reinforcement of coal gangue slope treatment, it is difficult for hole and construction with traditional method, self-drilling anchor method was adopted, Slope stability safety factor was calculated with slope stability analysis software under coal gangue slope and self drilled anchor reinforcement coal gangue slope, and finally the anchor pipe processing technology, construction methods and the production of grouting process and framework were introduced, which provided the practice for similar engineering.

## Intorduction

As a new construction technology, self-drilling hollow anchor bar has been gradually promoted and applied in the slope reinforcement engineering in recent years. Integrating drilling, grouting and anchoring, it is an advanced anchoring system and overcomes easy-to-hole collapse and hard-to-pore-forming problems in the anchor bar construction in extremely loose and broken soil-rock mass. Combined with successful comprehensive application of network-attached grouting, drain hole and various support measures, the grouting effects under complicated geological conditions can be guaranteed. On the basis of engineering practice, this paper carried out the calculation and analysis on the self-drilling hollow anchor bar-reinforced coal gangue slope and then gave specific construction technology, providing reference for similar engineering.

## Engineering background

The proposed field is one western modern artificially accumulated slag platform and its terrain is smooth, with small ground elevation difference. It is a new factory district of coal gasification and supporting project of one Coal Industry Group. After site formation, 2 platforms are formed and the elevation difference between two platforms is about 20 meters, belonging to soil slope. Due to the changes of terrain, one fill embankment slope and one site slope of excavation are formed. Because the up and down devices of the slope are far from the side slope, the normal production activities in the factory district can be free from the destroy of the side slope. Considering the elevation of soil slope, its security level is defined as the second level. It needs reinforcement and protection processing to guarantee security. The project work life of the side slope is 50 years.

## Geological conditions

According to the analysis results of drilling, in-situ test and consolidation test, in the field 46.5m exploration depth range, the stratum is divided into 8 engineering geology unit layers according to genetic type, lithological characters and engineering geologic characters. Details are described as follows. ① layer (Q4ml): strong-weathered sandstone and coal gangue. In the drilling process, hole collapse and leakage are common. Its mean layer thickness is 7.2m. ② layer (Q4ml): strong-weathered sandstone and coal gangue, with mean layer thickness of 8.03m. ③ layer (Q2dl):

silty clay, with mean layer thickness of 4.92m. ④ layer (Q2d1): silty clay, with mean layer thickness of 5.17m. ⑤ layer (Q2d1): silty clay, with mean layer thickness of 5.73m. ⑥layer (Q2d1): pebble, with mean layer thickness of 1.89m. ⑦ layer (T): mudstone, with mean layer thickness of 5.86m. ⑧layer (T) with mean layer thickness of 2.18m. ⑨ layer (T): soft rock, with mean layer thickness of 3.50m.

**Coal gangue slope reinforcement stability calculation of self-drilling hollow anchor**

Known from the results of scene geological exploration and exploration report, this slope belongs to high slope, with about 75°slope angle. It is possible for landslide. Bishop Simplified and Janbu Simplified in slide software are used for stability calculation.

Before the slope reinforcement, stability coefficient calculated by Bishop Simplified is 0.491, shown as Figure 1 and that by Janbu Simplified is 0.459, shown as Figure 2. Through calculation, it is obvious to see this slope is unstable and its stability coefficient is less than 1. Thus, it needs reinforcement processing.

Through analysis, the anchor bar is adopted for reinforcement processing plan of the slope. The hollow anchor bar is selected and its extreme tension bearing capacity is no less than 220kN/ piece. The included angle between it and horizontal direction is 20°, shown as Figure 3. After the calculation, it is known that this slope is stable, with stability coefficient calculated by Bishop Simplified of 1.261 (Figure 4) and stability coefficient calculated by Janbu Simplified of 1.062 (Figure5). The calculation results show it is safe.

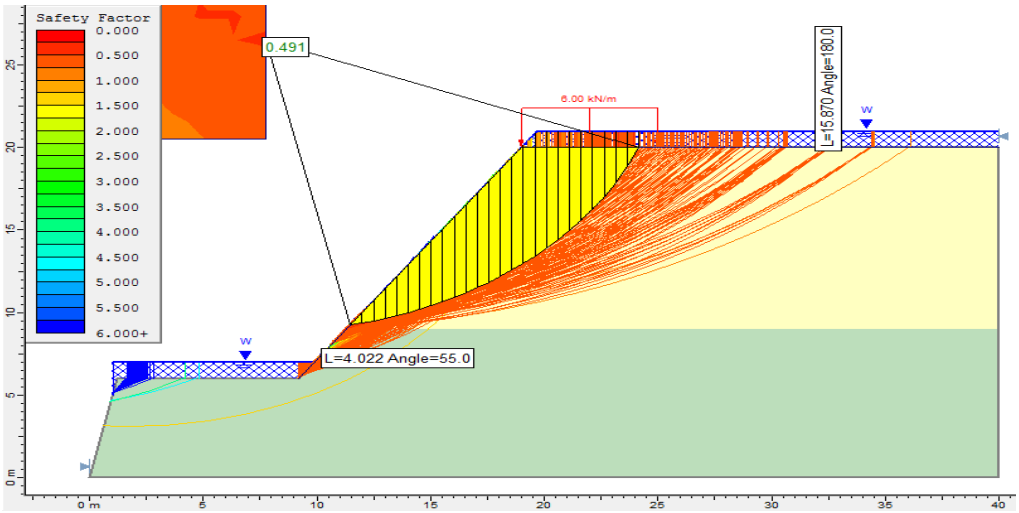

Fig.1 Calculating results of Bishop method

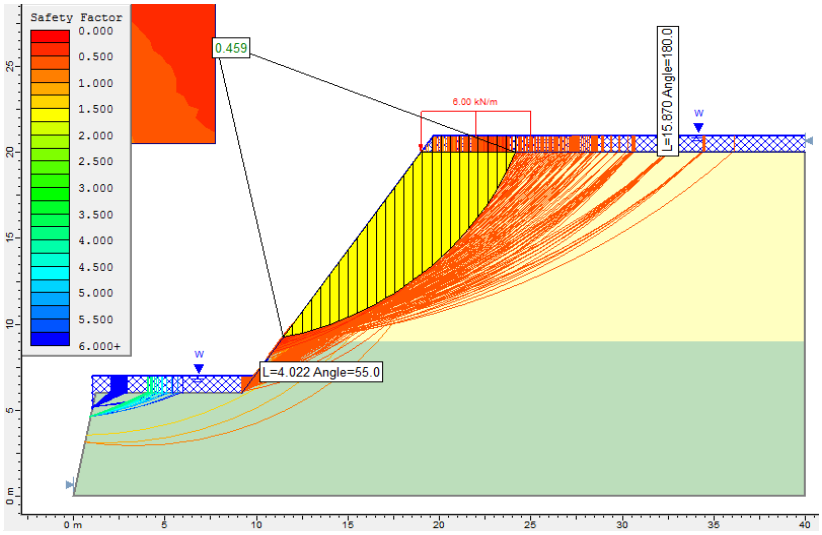

Fig.2 Calculating results of Janbu method

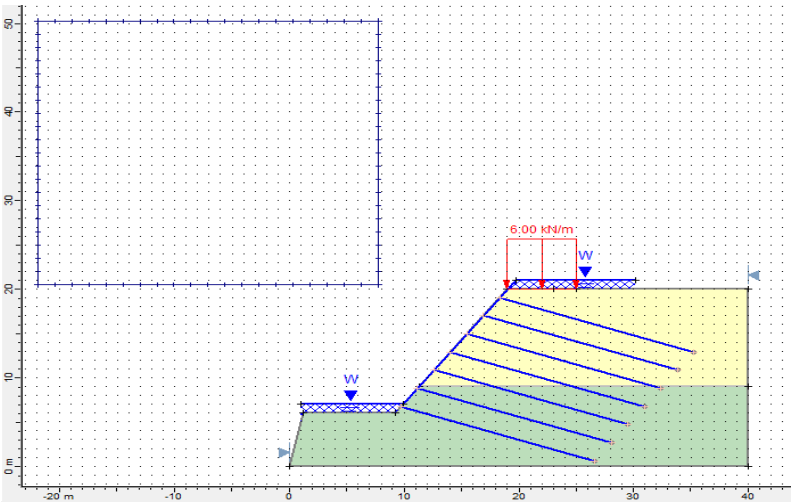

Fig.3 Reinforced slope analysis model

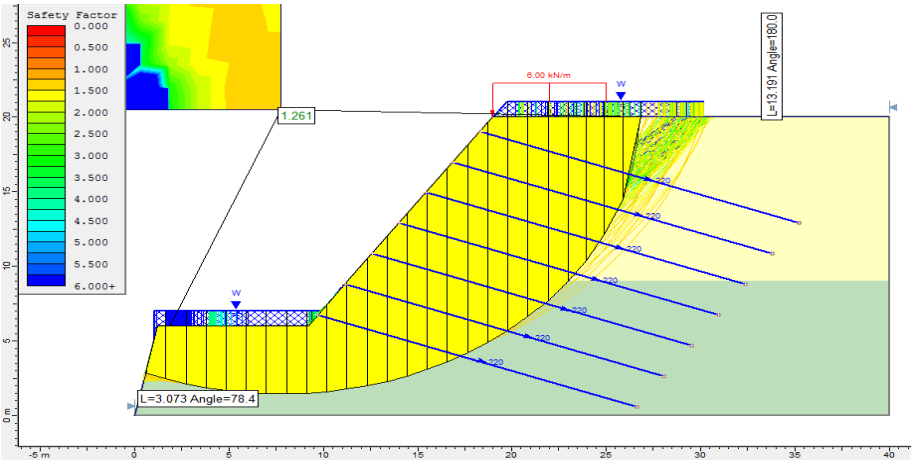

Fig.4 Calculating results of Bishop method with self-drilling hollow anchor

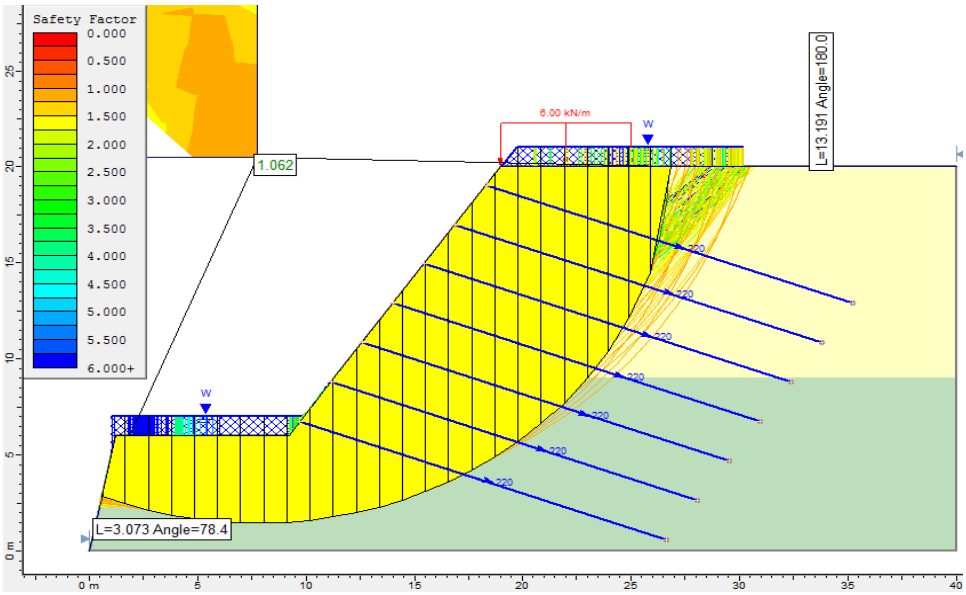

Fig.5 Calculating results of Janbu method with self-drilling hollow anchor

**Major construction technology**

### 5.1 Installation of self-drilling hollow anchor

(1) Excavate the contour line along arch and mark the position of anchor bar according to toroidal spacing. (2) Check anchor bar and whether foreign matter blocks the water pore of the drill and clean it. Connect the drill with anchor bar and anchor bar with drill pipe connection set. (3) Aim anchor bar at the anchor eye and wind or water shall be firstly provided by the hammerdrill. Then drill. (4) After the designed depth is reached, water or high-pressure blast washes the holes to check whether the hole is unblocked. Then discharge the drill pipe connection set. The exposed porthole of anchor bar is 10cm~15cm long. (5) Press the stop-grouting plug from the exposed end of anchor bar into the porthole about 30cm. If the anchor bar needs lengthening, connect the anchor bar in the connecting hole of anchor bar connection set with another anchor bar. Then keep drilling until it reaches the designed depth.

### 5.2 Grouting of self-drilling hollow anchor

(1) Make preparations and check whether the equipment is ready and the materials meet the requirements. Quickly connect the anchor, grout line and pump with quick coupling. (2) Open the pump and grout. The whole process shall be continuous and non-stop and complete at one single time. Stop pumping until the grout flows out from the edge of porthole cap or the pressure meter reaches the design value. (3) After completing the grouting of one piece of anchor bar, the coupling between the grouting flexible pipe and anchor bar. Clean and install another anchor bar and then grout. (4) In the grouting process, quick coupling shall be timely cleaned and the continuity of the grouting process shall be guaranteed. After completing the whole grouting process, timely clean and maintain the pump.

### 5.3 Treatment measures of coal gangue slope

#### 5.3.1 Drainage design

On the basis of the overall plan of landslide preventive treatment, drainage engineering design adopts the plan in consideration of the surface drainage, subsurface drainage or both. Drainage ditch and intercepting drain are set around and drainage system is set on the slope body, forming spatial three-dimensional drainage system.

### 5.3.2 Ecological restoration engineering

Coal gangue slope engineering has serious influences on the environment. Thus, ecological restoration shall be carried out. At present, the most commonly-used method is slope vegetation protection technology. The water-retaining property of coal gangue slope is poor and lacks nutrition, which is not beneficial to the vegetation growth. Thus, the layered compacted coal gangue slope is designed to be covered with mellow soil of 800mm. Shrubbery and grasses with dry resistance, developed root system and strong growth ability are planted. The planting season is spring.

## Conclusion

Self-drilling hollow anchor bar adopts thick-walled seamless steel pipe, surface thread forming process and complicated and refined parts to realize the integration of drilling, grouting and anchoring. By no aid of casing pipe wall protection and pre-grouting mortar and other special means, anchor eye can be formed quickly and the hollow rod grouting is used to guarantee the anchoring effect. In the coal gangue high fill slope treatment, self-drilling hollow anchor bar construction technology is adopts, which not only overcomes easy-to-hole collapse and hard-to-pore-forming problems in the anchor bar construction in extremely loose and broken soil-rock mass, but also achieves sound engineering benefit.

## Acknowledgments

This research had been financed by National Natural Science Foundation of China(51004049,41202246); Foundation for University Key Teacher of Henan province(2010GGJS-129); 2010 Natural Science Research Program of Henan Province Department of Education (2010a480002); the sincere gratitude were given to them!

**Keywords:** Slope, Hot and Rainy, Phase of Deformation, Unloading Loose

**Abstract**. The appearance and development of deformation and loss of stability in the slope of cut is closely related with such interior causes as the qualities of layer rocks. Some external incentives like meteorological conditions, hydrology and process of construction are the main factors leading to the deformation of slope and its development. Three problems of deformation of slope, which is one of the common geographical hazards. The thesis, making an analysis of the geographical environment, the process of deformation and mechanism of destruction on slope of the right cut in Guangle Road K142+320～K142+740, reveals the key factors of deformation and damages of slope and proposes a reasonable realignment methods about slopes, which has achieved a good engineering effect and set a good example for the other similar slopes to be strengthened and improved.

## Introduction

The appearance and development of deformation and loss of stability in the slope of cut is closely related with such interior causes as the qualities of layer rocks. Some external incentives like meteorological conditions, hydrology and process of construction are the main factors leading to the deformation of slope and its development. With a shifting tendency to building more highways in mountain areas, under the conditions of complicated topography, ground features and geographical hydrology, highway construction is facing to a variety of slope problems and the deformation and damages of slope in cut is always one of the crucial factors that exert many influences on the highway construction and normal operation later. The problem of deformation of slope under complicated geographical conditions in rainy and hot areas has become one of the common geographical hazards in highway construction in mountain and hilly areas,

The thesis, taking the improvement of slope of right cut on Guangle Road K142+320～K142+740 as the example, gives a detailed introduction to the analysis of mechanism of deformation and process of improving design under the conditions of complicated geographical environment , high temperature and many rains, especially the process control in the period of slope improvement , which offers some experience to the hazard of slope deformation in the same type.

## The condition of slope and geographical environments in the project

### 1.1 the condition of slope

A section of highway K142+320～K142+740 is located in Shanghuang village, Shakou county, the city of Yingde, Guangdong Province. The slope, extending along the one side of a hill, is an excavated slope with a height of 29.34m ,the original slope rate of 1:1.25 in the design and an arch framework to protect it. Early in 2012, slope began to be excavated, and the method of protecting in unison after excavation is employed. In the period of rainy season from May to July in 2012, because of continuous rains, before the work of protection, the sliding and collapsing of rocks and soils happens on the surface of slope, and develops into the back and two sides, which brings the dangers into the slope of the possibility of loss of stability as a whole that is a threaten to the safety of the iron tower on the top of the slope.

Figure 1 Slope construction and its deformation

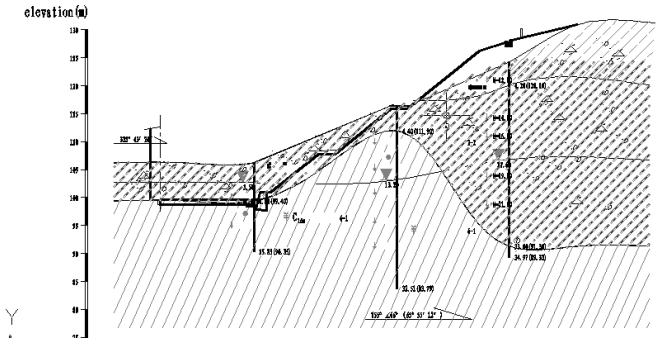

Figure 2 Typical geographical profile of the slope

**1.2 geographical environments in the project**

**1) Meteorology and hydrology**

This area is seated on tropical and sub-tropical monsoon zone. Influenced by the monsoon, it is warm and humid with an abundant waterfall. The summer is wet and hot with many typhoons and storms, but the winter is dry with cold air. In the rainy season from April to August, the waterfall covers the 70% of the yearly waterfall, but in the dry season from October to the next February, about 16%. According to the observation materials of waterfalls during 47 years in the station of Yingde Beijiang, the maximum waterfall in one hour is 320mm and the average waterfall in many years is 1982.4mm. The average temperature is about 20.9℃ in a year with an extreme high temperature 40.12℃. The average evaporation is 1666.7 mm in a year. The stereoscopic climate is distinct and the severe weather, rainstorm in particular, is frequent, which often happens from April to August.

There is no developed gully on the site. At present, ponding can be seen in the lower part of excavated zone. In the rainy season, little ground water, controlled by the rain, can be observed on the foot of slope.

**2）Topography and terrain**

The overall topography on site is shallow hill landform. Micro-

topography is shallow-hill slope, which is relatively mild with the slope of 10°～15°,ground elevation 100.3～118.6m and relative elevation difference 18.3m. It is straight alongside the longitudinal line, on several places of which exists gullies.

**3) Stratum lithology**

According to what the outdoor survey and misering of the topography revealed, exposed stratum lithology in cutting zones is mainly composed of powder slay of Q4dl and Q1el, while subterrane C1ds shale under charcoals. Its features and distribution are separately described as follows:

**(1) Q4dl:** light yellow, hard plastic, poor viscous, non-uniform, containing a small quantity of crushed stone, complicated components in each stratum, and 20%-30% of which are broken rubble with graits. It appears only at the top of the side slope, thickness of each stratum is not uniform, 4.20～10.80m.

**(2) Q2el:** reddish brown or taupe, local part being yellow, hard plastic, after weathering of shale being residual soil, inside which the structure is still visible, the rock core of which mainly comprises powder clay granule, and local part of which mixes weathered broken rubble, ordinary viscosity and 20%-30% of which are broken rubble with graits. It appears all along the slope, and thickness is 0.80～28.80m.

**(3) C1ds**

Weathered shale: taupe or reddish brown, earth structure, flaked formation, mineral components being mainly composed of clay, earth is viscous, weathering is strong, rock core appears like soil column, original rock structure is apparently clear, soft rock property so that it is of easy decomposition when encountering with water. It appears all along the slope, and buried depth, 0.80～33.00m, and stratum thickness are not uniform

Medium weathered shale: offwhite, aphanitic structure, stratified structure, joint crack greatly developed, flaked core and a little stumpy columns. It appears only 45.13m right from K142+640.

**4) Hydrogeology**

According to components of stratum rock and storage of underground water in this zone, the underground water on site can be divided into two kinds: pore phreatic water in loose rock mass and the weathered basement rock strip fracture water.

**An analysis of the mechanism of slope deformation**

**2,1 The qualities of material structures on the slope**

The upper part of the slope is mainly made up of powder-like clay from incomplete slopes, with the changing thickness of 0.8~28.8m, uneven distribution, great variation and lose structure. The rest part is all the weathering shale that under the influence of the structure is rather broken with many dense cracks among jointing and the space of the cracks range from 5cm to 20cm, so the rocks possesses the qualities of broken stones. Because the shale is mainly made up of clay minerals, full of the elements of montmorillonite and Kaolin, the wholly weathered shale and its weathered products also own the features of high liquid limit soiland can swell a little. Under the normal conditions, the performance of the project is OK, but many times of alternative of dryness and wetness, mechanical properties drop quickly. Meanwhile, the weathered shale with the qualities of broken rocks makes the passage of the penetration, evaporation and drainage of the rain smooth. So sliding and deformation is easy to be into existence in a depth that can be influenced by meteorology. The bottom of the slope is made up of uncomforted contact layer limestone with an uneven surface that changes a lot and is distributed in parts [3,4].

**2.2 slope construction and the history and features of deformation**

Excavation of the slope began in early 2012, and went into Phase-II in May, which was about 10m to the designed roadbed and the framework protection was out of operation. The slope is almost uncovered. The rainy season brings frequent and massive rains. To July of 2012, during the period of continuous rainfalls, sliding and collapsing happens on the part of slope K142+480, with a 30m wide , 11.5m tall and 30m thick body of sliding and collapsing. The sliding surface is an arc. The 30cm cracking and dropping happens close to the top of the slope was cut in a swollen shape of about 5- 10cm. The deformation of sliding and collapsing was formed many times and the scale of deformation tended to extend to the back and two sides of the slope. At the same time, there are many cases of sliding and collapsing on the surface of first-class slope that is adjacent to the deformed slope, whose deformation has obvious destructive features of soil-like slope. The development of deformations of rocks will have a heavy damage on the middle of the slope and the safety of electricity tower on the top of it.

In September, 2012, to avoid the above damages, an emergent improvement was operated: piles with three lines of steel pipes were cast on the top of the slope, in the front of the tower. After the improvement, the tendency to develop into the back is controlled. According to the detailed situation on site, by a comprehensive analysis, the surface of the slope is adopted the anchor-sticks grid beam to consolidate., and the first-class slope is placed the anti-sliding to support and defend with a foot-fixed defending wall. According to the adjusted design plan, the construction side completed the third-class and second-class slope anchor-sticks grid beam and anti-sliding pile on the first-class platform and defending wall from October 0f 2012 to May 0f 2013. Because of the coming of the rainy season and the frequent rainfalls, protection cannot be conducted in time, the surface of the first-class slope after being excavated appears the sliding of the rocks and it is hard to take a shape of slope. But the wholly stability is under control with no sign of a wholly stability and crack as a whole.

**Figure 3 Deformations before protection methods taken in july,2012**

**Figure 4 Scene of carrying out protections in july 2013**

**2.3 An analysis of deformation mechanism and influential factors**

The slope is mainly made up of the weathered shale and its weathered products. The rocks of the slope are controlled by the structure and weathering factors, which have dense joint cracks and broken rocks, classified into the category of broken rocks. The deformation of slopes can de divided into two phases according to the construction and process of deformation: Phase I is the superficial problems, which include the areas influenced by the excavation, or excavated unloading loose areas. Phase I can also be the deformation of rocks in the depth influenced by the meteorological conditions. Both of these are called the superficial deformation of slope Phase. Phase II is the wholly sliding and loss of stability of the whole slope, in which the deeper sliding caome into existence. Analysis is as follows respectively:

**1) Phase I----the superficial deformation of the slope**

According to the above analysis, because at the beginning of the excavation, there is no protection and the surface of the slope is exposed, it is easy for the rainfalls to penetrate into it and for the ground water to evaporate and drain. The stability of the slope is controlled by the geographical conditions, materialistic structures and rainfalls. On the basis of that the slope is mainly made up of weathered shale and its weathered products, the deformation macroscopically bears the features of destructive points in soil-like slope deformation----- the potential sliding surface is arc, and microscopically of cracks alongside the joints, and zigzag- like or stair-like layer, because of the control of the structural joint cracks and layers. If we take into the consideration the common existence of the massive rainfalls, strong sunshine, heavy evaporation, a tense alternatives of dryness and wetness on the superficial rocks, and a quick loss of rigid index of the meteorologically influenced rocks, the deformation often happens in a depth influenced by the meteorological conditions. In a word, the areas of deformation of the slope is mainly located in the areas influenced by the excavation, often 3-5m from the excavating ling. The features of deformation on this Phase are as follows: 1. the tensioning crack is often on the surface of the slope or near to the mouth line of the slope. 2. the cutting mouth is at the foot of the slope and the first-class surface of the slope. The preliminary deformation of the slope and the first-class slope deformation operated by anti-sliding piles are in such Phase.

**2) Phase II -----the formation of the deeper sliding and the wholly loss of stability**

Besides the influential factors in Phase I, the deformation of slope in Phase II has its own characteristics. With accumulation of the deformations, the areas of deformation must be extended in the width and broadness. Without the restriction and support in the superficial skidding soil, the depth of the deformation must be further developed. The enlargement and development of the deformation must result in that deformation is aggravated in the deep and back------a wholly loss of stability of the slope. The corresponding deformation features in this phase is: 1. the tensioning cracks and sliding appear in far back. 2. swell and deformation appears at the foot of the slope and

roadbed. 3. the depth of the deformation is over 5m, bigger than Phase I in the terns of the scale. If no effective consolidation is conducted, this phase is also the ultimate tendency of the deformation of the slopes.

**An analysis of the stability**

**3.1 Calculating method**

In recent days, the methods of calculating the stability of the slope can be categorized into 3[5]: limit balanced analysis,2 data analysis, 3. Probability theory. The limit balanced analysis is often employed and is also the most mature.

On the basis of the above analysis, blended with the soil-like sliding features of the deformation of the slope, according to the limit balanced theory and taking into account the loose structure of the weathered shale, the author adopts the arc sliding method to mimic the on-site situation and fold-line sliding theory to repeatedly perform the process of the deformation of the slope under the help of the figures from the survey to make an analysis of its deformation and tendencies.

**3.2 Soil Parameter**

The value of soil parameter was confirmed synthesizable by depending on geological survey reports and combining regional experience and back analysis cases. Below is the soil parameter lists of the slope in details.

**Sheet 1 The soil parameter lists of the slope**

| Name of the Geotechnical | density | | C(KPa) | | φ(°) | |
|---|---|---|---|---|---|---|
| | Degree of natural | Degree of saturation | Degree of Natural | Degree of saturation | Degree of Natural | Degree of saturation |
| Silty clay | 1.88 | 2.00 | 25.07 | 23.82 | 14.83 | 15.32 |
| Completely weathered shale | 1.96 | 2.15 | 22.98 | 26.98 | 15.87 | 15.08 |

**3.3 Computational analysis**

According to the excavation of the slope, in view of the slope deformation,model analysis was used under the continuos rain circumstance.In July 2012,the slope K142+480,stability coefficient of the section Fs=0.927 (superficial sliding) ~0.974 (deeper sliding). The slope is in poor stability and geotechnical landslide would be induced by continuous rainstorm.Refer to figure 5.

Simulation analysis of the overall slope stability after protection based on the adjusted protection schemes according to the design, and the stability coefficient Fs=1.569 (K142+480 section，under the continuous rainstorm circumstance)of rock slope after retaining wall was set. Refer to figure 6.

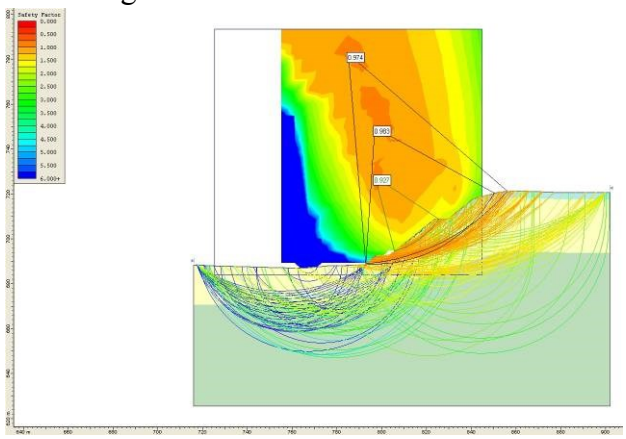

**Figure 5 Stability analysis of slope deformation(sectionK142+480 satus in July 2012)**

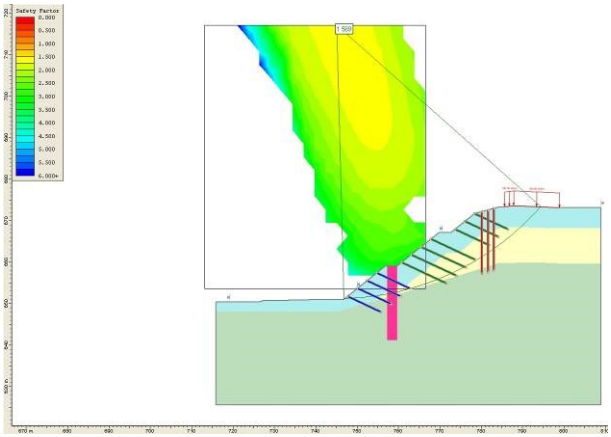

**Figure 6 Stability analysis of slope retaining structure**

According to the results of model analysis,the overall stability of the slope in the sliding surface was analyzed by polygon method. And K142+480 is taken as example:

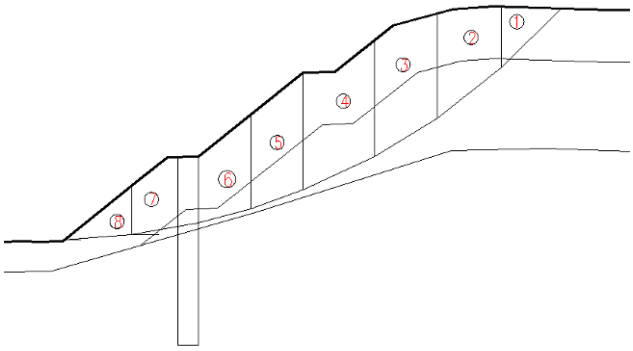

**Figure 7 Slice graph of the overall stability analysis of the slope (K142+480)**

Profile surplus sliding force under natural condition T=268.61kN, under continuos rain circumstance T=391.07kN; downslide force of designed retaining wall under continuos rain :805.83kN/km

**Improvement plan**

This slope has two features as follows:

**(1)** The geographical condition of the slope is complicated. The rocks have some unique qualities, like high limit of liquid and weak expansible ness, and at the same own the features of broken-stone soil and broken rocks. So its mold of destruction is controlled by the above features, which have the different destructive mold in different phases, especially in the later period when the situation is more complicated and the destructive mold is more various.

According to it, the general design plan of consolidating the slope adopts the phase-control and installment operation. That is to say, a preliminary and temporary method of placing steel pipe piles and casting to prevent the deformation from developing into the back, and the following method of taking anti-sliding piles as the main supporting structure to control the deep sliding and deformation. Anchor-sticks grid beam blended with planting grass on the surface of the slope controls the superficial deformation of the rocks in the slope.

**4.1 Improvement design plan in emergency**

To avoid that the deformation developed into the back and guarantee the safety of the tower before conducting the consolidating methods, placing steel pipe piles to support and enhancement of casting in the soil on the top of the slope through the holes of the piles, which improves the external environment of the slope, controls the speed of the deformation and create the conditions for the operation of the improvement methods.

Steel pipe piles placed on the inside of the intercepting dike on the top of the slpoe are arranged rectangularly in 3 rows, with 1.5m distance. The pipe pile's bore diameter is 130mm, with a steel tube(108mm*6mm) in it to be poured into cement mortar, Refer to figure 8.

**4.2 Treatment of the sliding slopes**

In accordance with the excavation condition of the side slope, and in combination with the features of the construction, the ratio of the consolidated part of the slope still abide by 1:1.25, the stepped height 8m. The dome of the side slope shall be consolidated by anchor lattice beam, with greenbelt in lattice, 3m between anchors. 1Φ32 anchors, whose bore diameter is 90mm, shall be adopted to be poured into M30 cement mortar. 3m C15 flag concrete barricade, with 1.2m top width and 3.0m wall height, is placed at the foot of Level one slope. Slide-resistance pile is placed at Level one platform to support the deep sliding down force. The slide-resistance pile is 1.5m*2.0m in section, 18m length, 6m in between, poured into by C30 concrete, placed in the K142+480-K142+580 at the higher part of the side slope of the tower area. See figure 9.

With the superficial rocks weathered and badly loose, collapsing appears on the firs-step slope because of the continuous rainfalls. The consolidation includes: removing the skidding soil from the surface, restoring surface of the slope by filling plant growth bags, casting the framework and afforesting the slope.

Drainage- intercepting system takes into consideration the interception and diversion of the surface precipitation to prevent rainwater permeating into the slope as well as the enhancement of the white-out of the underground water in the interior of the side slope. 60cm*60cm trapezoid catch water is placed at the outer edge of the side slope, and 40cm *40cm rectangular catch water is placed at the platform to divert the surface rainwater. The catch water is constructed by M7.5 mortar rubble. Level one and level three side slope is set with oblique outlet holes, and the holes' bore diameter are 110mm withΦ100 drainage pipes, 15m length and 12m in between. See figure9.

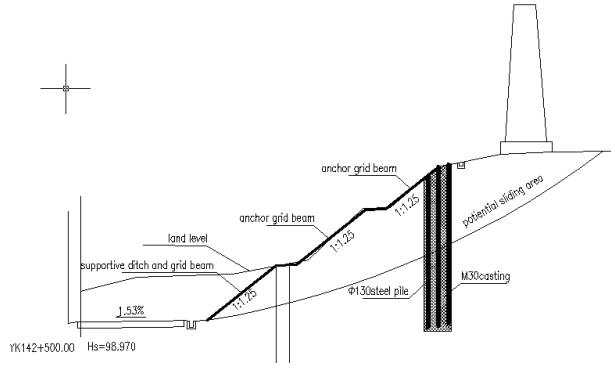

**Figure 8 Section Design of Section in Emergency**

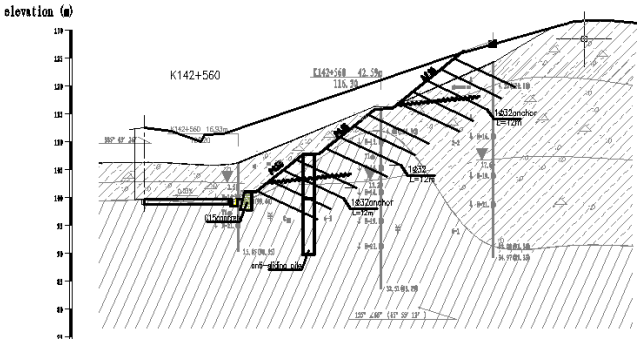

**Figure 9 Slope-consolidation section design (K142+560)**

## Conclusion

The slope on the right cut of Guangle Road K142+320～K142+740 located in a hot and rainy area with a complicated geographical conditions, is a mixed slope controlled by many kinds of factors. The author employs the limit balanced theory to analyze its stability on the basis of make a full analysis of its deformation mechanism and influential factors. According to its features, the consolidation of the slope adopts the ideas of phase-control and comprehensive methods mixed a lot of approaches to harness the slope. In the process of it, the whole slope remained stable and the tower on the top of it ran well, which realize the design ideas.

A successful harness of a slope must meet such requirements as "safety, economic, and environmentally-friendly". From the above analysis, it is known that, the deformation after the excavation is a constantly accumulated process and people's recognition of its deformation mechanism is a gradually deeper and deeper process. On the basis of strengthening the phase-control, timely adjusting with the change of the external condition (like the weather, the adjustment of the order of construction),according to the different phase of the deformation, a targeted improvement and a suitable time for consolidation are crucial to an effective improvement.

**Key words:** Two-dimensional landslide model, least squares support vector machine (LS-SVM), Predictive control.

**Abstract.** Two-dimensional landslide model system is an important experimental platform for studying geological disaster, landslide behavior in different conditions are achieved by controlling the hydraulic pump drive model platform uplifting cabinet inclination. During the process of automation transformation of the two-dimensional landslide model system, control system based on computer is used to achieve a smooth lifting and precise angle of landslide model platform. Thanks to predictive control algorithm of least squares support vector machine (LS-SVM) model used in this paper, random real-time change of equivalent load applied on the hydraulic cylinder system effectively solved. The control system of the two-dimensional landslide model effectively eliminated crawling effect and pulse lifting in the condition of low speed and high load conditions of hydraulic system.

## Introduction

Our nation is one of the countries where the geological disaster happens frequently, such as landslide and debris flow. According to the various geological disasters derived from the Chinese investigations, landslide is as high as 68% in the proportion. Landslide disaster has caused huge losses to human life and property, which has brought the serious influence to the engineering construction[1~2] as well. The landslide slope stability is its natural adjustment, what influence the steady state effect factors are natural and human activities. One of the effective ways to study geological disasters of landslide gets through the landslide model design specific [3]. Model test of landslide belongs to the category of geomechanical model test. At present, the structure model test is the resource of the theory. The geomechanical model test commonly used in domestic and overseas are mainly made of framework model test and centrifugal model test. Frame type model test adopt the similarity model materials and the criteria in the framework by making model in normal gravity, and measure its deformation, stress and other factors in the model satisfying the boundary conditions of similar cases, and then reveal the formation mechanism of the landslide prototype[4]. The two-dimensional model realize the different characteristics in different dip angle by loading in consistent original soil and sand in the landslide box like actual study and lift a certain angle. The hydraulic system is the mainly lifting device of the landslide model. Because of the landslide model experiment box's large size and load and the random

changes of the center of gravity in the actual process, how to realize the exact stationary angle control of landslide model experiment box is the key of the landslide experimental case research.

## Mechanics Analysis Model of 2D Landslide

### 1.1 Landslide Experimental Platform

The landslide model test is destructive test, testing platform lifting control system can ensure the final break of uplift movements of the landslide model, which reveals the deformation characteristics of landslide and calculates the stability coefficient. As shown in figure 1, we can observe the two dimensional landslide model experiment platform.

Testbed frame is 8 meters length, 2 meters width and 5 meters high. The designing capacity is 700 *kN*, which lifted one end supported by a hydraulic cylinder designed to load 25*t*, the platform maximum tilt angle is 25*°*. The platform can install the water test system, non-contact measurement system of displacement field and multi physical quantity testing system (including water, soil pressure and displacement), the upper part of the platform roof installed artificial rainfall system. The test bench is a large comprehensive test platform which can simulate a variety of slope boundary conditions and multi physical quantity measured. The test platform of landslide is under the condition of rainfall and reservoir water, where the experiment box has sediment debris of the simulated landslide and the water of simulated rainfall.

Fig.1 Appearance and interior photos of two-dimensional landslide experiment platform

### 1.2 Landslide experimental platform lifting device

The hydraulic landslide control system transforms automatically mainly based on the original manual hydraulic control. Using a hydraulic cylinder supports one end of the landslide model, the stretch and shrinker of hydraulic cylinder control the inclined angle of the landslide model experiment box, the principle has been shown in figure 2. In order to provide the enough support moment, the hydraulic cylinder has a larger sectional area, so the flow of the solenoid valve should be improved accordingly, if the flow is too low, the speed of the hydraulic cylinder lifting may be very slow. We can control the elevation angle in a certain range, but the large section hydraulic cylinder will appear crawl phenomenon when it is in the low great pressure, thus causing pulsating torque when the hydraulic pressure lifting the landslide model box, and the pulsating torque will affect the landslide model experiment. The lifting speed cannot be too slow, and the accuracy of lifting angle measurement should be controlled, so it is necessary to analyze the movement and force of experimental model during uplift process. In figure 2, *BC* segment refers to hydraulic support device, *A* is the hinge, *G (x, y)* stands for the center of gravity of the sand, the rainfall and walls are simulated in the model. *L*, *H* is respectively defined as the high and long of the landslide model body.

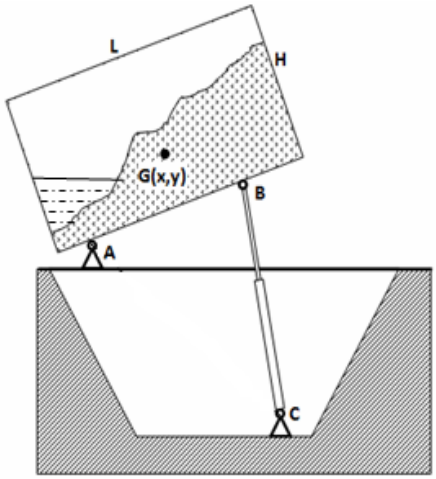

Fig.2 Motion control diagram of landslide experiment platform

**The motorial analysis of 2D landslide model**

**2.1 The geometric relation model in the process of model's movements**

From the analysis of landslide model diagram in figure 2, a schematic diagram model of uplift has shown in figure 3. *BC* refers to hydraulic support device, *A* is the rotating hinge of landslide model in the uplifting process, *F* stands for the lifting force of the hydraulic support device; *G* makes up the monolithic gravity of the model; *AG* is the cables between fulcrum *A* and model's center of gravity. The $\alpha_1$ is the intersection angle between *AC* and the horizontal, which will not change in the lifting process. The $\alpha_2$ is the intersection angle between *AG* and the direction of the box body length will not change as well. The $\alpha$ is the intersection angle between the landslide model and horizontal, changing according to the length of *BC* in the lifting process. The $\beta_1$ is the intersection angle between *BC* and the horizontal will change in the lifting process. The $\beta_2$ is the intersection angle between the length of box body and *BC* will change in the lifting process.

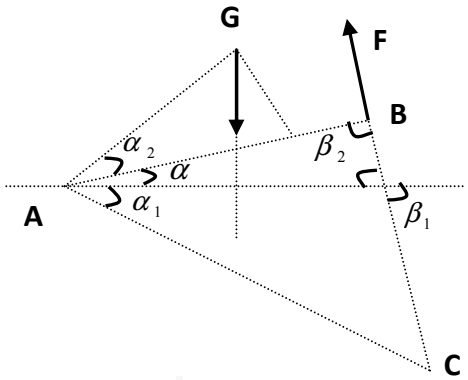

Fig.3 Sketch map of landslide model uplift movement

$$L_{BC}=\sqrt{L_{\mathrm{AB}}^2+L_{AC}^2-2L_{AB}L_{AC}\cos(\alpha+\alpha_1)} \quad .(1)$$

$L_{AB}$, $L_{BC}$ and $L_{AC}$ are the length *AB*, *BC* and *AC*. Known by the law of cosines variant:

$$\beta_2=arc\cos\left(\frac{2L_{AB}^2-2L_{AB}L_{AC}\cos(\alpha+\alpha_1)}{2L_{AB}\sqrt{L_{\mathrm{AB}}^2+L_{AC}^2-2L_{AB}L_{AC}\cos(\alpha+\alpha_1)}}\right) \quad .(2)$$

So we can get the moment that landslide model box gravity gives to fulcrum *A* in the lifting process:

$$T_1=G\times L_{AG}\times\cos(\alpha+\alpha_2) \quad .(3)$$

**2.2 Mechanical analysis in lifting process**

Hydraulic support force relative to the fulcrum of torque for the *A*:

$$T_2=F\times L_{AB}\times\sin(180-\alpha-\beta_2)\times\cos(\alpha) \quad .(4)$$

According to the moment balance:

$$F=\frac{GL_{AG}\cos(\alpha+\alpha_2)}{\sin(180-\alpha-\beta_2)L_{AB}\cos(\alpha)} \quad .(5)$$

Putting (1), (2) into (5) can get F that is the function of angle $\alpha$.

The lifting force is mainly provided by the hydraulic device, the control system adopts the original hydraulic system which provided oil to solenoid valve using a constant current hydraulic

cylinder, the export of solenoid valve is the hydraulic cylinder, considering the whole process of lifting, supposing the entrance constant pressure of hydraulic valve is $P_0$, so the valve flow is:

$$Q = \mu S(\frac{2(P_0 - \frac{F}{S})}{\rho})^{\frac{1}{2}} \tag{6}$$

The $S$ stands for the cylinder section area; $dl$ is the changed length of $BC$ in the lifting process:

$$dl = \frac{Q \times dt}{S} \tag{7}$$

During the lifting process of $BC$, according to (1), the support length differential coefficient of the hydraulic cylinder is:

$$dl = \frac{L_{AB}L_{AC}\sin(\alpha_1 + \alpha) \times d\alpha}{\sqrt{L^2{}_{AB} + L^2{}_{AC} - 2L_{AB}L_{AC}\cos(\alpha_1 + \alpha)}} \tag{8}$$

According to (7), (8):

$$\frac{d\alpha}{dt} = \frac{Q\sqrt{L^2{}_{AB} + L^2{}_{AC} - 2L_{AB}L_{AC}\cos(\alpha_1 + \alpha)}}{L_{AB}L_{AC}\sin(\alpha_1 + \alpha)S} \tag{9}$$

The $dt$ is the open time of valve. According to (5), the $F$ is the only variable in $Q$, and it is a function about $a$, if the center of gravity does not change in the lifting process, the $a$ is the only variable on the right side of (9). It is very difficult to seek the expression of a directly with the change of open time. From the above analysis:

(1) During the lifting process of model box, if the center of gravity of the box body does not change, the $\alpha_2$ and the $L_{AG}$ would not change; and we can get it in the lifting process by measuring α and solenoid valve opening time, and then get the $\alpha_2$ and the $L_{AG}$ of the box body's center of gravity by calculating;

(2) In the condition that the center of gravity of the landslide model body does not change, the tilt angle of landslide model can be controlled accurately by controlling the hydraulic cylinder valve open time.

According to the analysis of equation (9) can get the relationship between electromagnetic valve opening time and the angle of the landslide body. But in the process of time landslide experiment, due to the artificial rainfall added in the landslide experimental box, it causes the sand in the box containing water, and there is a lot of ponding in the box body. In the lifting process ,the the center of gravity of rain ponding is changing in real time, rain water in real time changes, and because of the change of elevation angle, both soil water flow and mudflow will cause the change of gravity center G. Changeable factors associated with water, soil water and soil factors such as landslide movement. Therefore, in order to realize

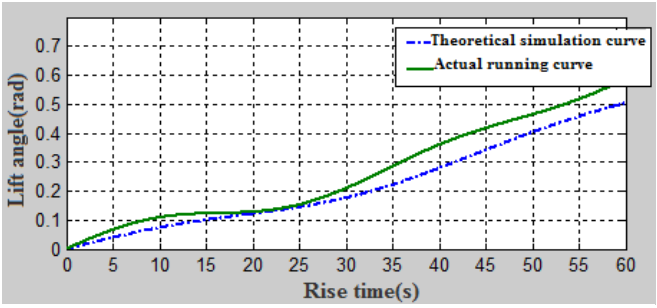

Fig.4 Lifting curve comparison of landslide model experiment box

the precisely control of box body's lifting angle by opening valve flow, we need acquire control system model of the entire landslide experimental box in real-time online. As shown in the figure 4, we can see the theoretic simulation curve and the actual running curve. Due to the parameters changes of the center of gravity in the lifting process, there is a big error between them.

## Control system modeling and predictive control

### 3.1 Support vector machine model

For the two landslide model experiment box, because of the constant changes of the center of gravity in the lifting process , and its changes are unpredictable, so it is a must to know the center of gravity parameters of the current model if want to obtain accurate angle control. This paper realizes to model the current model experiment box during lifting process in real-time by basing on the method of support vector machine rolling window regression modeling ,adopt the predictive control method to realize the control of the accurate angle. Support vector machine control technology is based on the object input and output, the prediction model of the principle of support vector regression direct nonlinear belongs to the nonlinear predictive control，which include predictive model, rolling optimization, feedback correction of basic characteristics[5~7]. The predictive control is a kind of optimal control algorithm, it determines the control effect in the future by optimizing a performance indicator, the index expect the model's predicted output as far as possible approaches to the reference trajectory, the characteristic index system related to behavior in the future[8]. The process of optimization is a rolling optimization in finite time, in every sampling time, the optimization performance index only refers to the limited time from the moment to the future , and in the next sampling time, the optimization period of time also brings forward[9]. Therefore the rolling optimization performance is: online optimization with the elapse of time, each moment repeated times without number; the optimization goal only care about dynamic performance prediction in the time domain system. In the predictive control, the optimization is not an off-line, it is repeated online, this is the fundamental point that the prediction controls is different from the traditional optimal control[10~12].

Suykens and Vandewalb proposed the least squares support vector machine (least-square SVM), the optimized index adopts the square, restrain equation only and have no inequality of C-SVM, then push out a series of different restrainable equations instead the quadratic programming problem[13~14]. The problem is expressed as:

$$\begin{aligned} &\min_{\omega,b,\xi,\rho} \frac{1}{2}\|\omega\|^2+\frac{1}{2}r\sum_{i=1}^{l}\xi_i^2 \\ &s.t. \quad \mathrm{y}_i\left(\omega^T\varphi\left(X_i\right)+b\right)=1-\xi_i \\ &i=1,...,l \end{aligned} \tag{10}$$

In the formula, the r is the regularization parameter.

Linear equation group can be obtained:

$$\begin{bmatrix} 0 & y^T \\ y & Q+r^{-1}I \end{bmatrix}_{(l+1)\times(l+1)} \begin{bmatrix} b \\ a \end{bmatrix} = \begin{bmatrix} 0 \\ e \end{bmatrix} \tag{11}$$

Kernel function adopts the RBF kernel function:

$$K\left(x,x_i\right)=\exp\left(-\left\|x_k-x_i\right\|^2/2\sigma^2\right) \tag{12}$$

The $\sigma$ is the RBF kernel parameters in the formula. In the condition where have no prior knowledge of the problem, the model trained by this kind of kernel function have a superior overall performance than other kernel and model. The $a$ and the $b$ can be solved via the least square method, the result of the application of LS-SVM to nonlinear regression functions is:

$$f(\mathrm{x}) = \sum_{i=1}^{l} a_i K(\mathrm{x}, \mathrm{x}_i) + \mathrm{b} \qquad .(13)$$

The prediction results can be measured by the error indicators: equal coefficient:

$$EC = 1 - \frac{\sqrt{\sum_t \left[T_{pred}(t) - T_{real}(t)\right]^2}}{\sqrt{\sum_t T_{pred}(t)^2} + \sqrt{\sum_t T_{real}(t)^2}} \qquad .(14)$$

The $EC$ express the fit between the prediction value and the real value, in general the fit is great if it is more than 0.90. The biggest advantage of least squares support vector machine is that can significantly improve the training speed of the standard support vector machine, simplify the computation complexity[15]. Adopt the means of literature [14] which proposed a rolling window algorithm, read a tilt sensor results in short-time interval, and regard it as the new sample into the predictive control algorithm model. During the comparative experiment process of support vector machine model, adopt the function theory analysis in it ,and use the numerical analysis method to obtain the needed time of required control angle ,then get a group of direct flow control angle data, the error between the actual setting angle and lifting angle is the direct control error, the support vector machine modeling error is between the setting control error of inclined angle and the error of inclined angle after prediction control, as shown in figure 5.

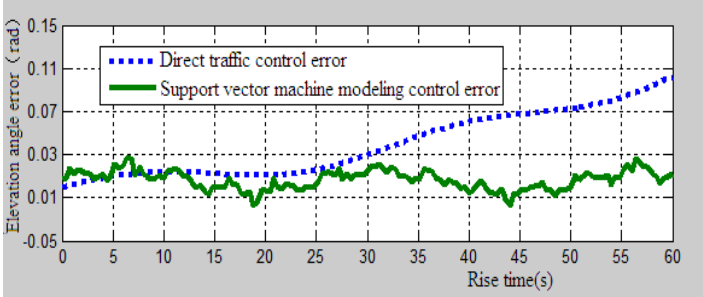

Fig.5 Inclination error curve comparison of landslide model experiment

**Summary**

The two - dimensional experimental box of landslide requires great puissance, because of the large area of hydraulic cylinder, we adopt the original circuit and hydraulic system in order to avoid the influence of the load which gave by the lifting process of the landslide model experiment in slow speed creeping. It needs adopt the control valve with large flow, the large flow makes the control of angle become the main problem in the control system, at the same time, because of the ponding water level's changes of simulated rainfall in the lifting process, the soil water content's transfusion makes the control object is a nonlinear dynamic system. This paper adopt the predictive control method of the support vector machine model as the two experimental box landslide model lift angle control algorithm, it effectively solves the title angle problem brought by the changes of box body in the actual operation. And programming the control software runs on the host computer. The system has been running for more than 2 years, the actual operation shows that the system can effectively control the landslide model lifting angle.

**Keywords:** earth dam; Uncertainty analysis; monitoring.

**Abstract.** Monte Carlo simulation provides a probabilistic method to evaluate the physical behavior of earth dam. Therefore, the behavior could be got in a more realistic manner. Based on the theory, an innovative software program code is developed by combining the Monte Carlo and finite difference methods to predict the performance of earth dams after impounding. In order to assess the efficiency of the method, the case study of earth dam, located at Southeast of China, has been studied in detail. The performance of this dam is predicted and compared with the field monitoring by using the monitoring data. The results shows the robustness of the proposed method.

## Introduction

Dams provide significant social and economic benefits, however risks made by the unstable dams could threat the life and property of the people who live in the downstream area. The safety assessment of a dam is a complex problem that needs to be analyzed and evaluated comprehensively by using different methods. Therefore, it is required to analyze the monitoring information, which is a key subject in the field of dam engineering. A typical dam contains various types of piezometers as total stress cells, settlement devices, triaxial deformation tubes, inclinometers and extensometers, all are installed during construction [1]. These sensors face uncertain inputs, which are originated from the physical uncertainties and human errors. It can be expected that the combination of these unknown parameters leads to an unreliable design [2]. Uncertainty analysis by mathematical and statistical softwares can be then used to evaluate the risks. Other uncertain events affecting dam's behavior and then its modeling are water inflow, reservoir level, earthquake magnitude and etc. They are used as input to the uncertain models, leading to probability distribution of response values (deformation, stresses, etc.). These consequences are expressed as the probability of occurrence functions. In this process, dam safety can be then assessed by mathematical models using the monitoring data [3].

Monte Carlo simulation is a very useful method for modeling the problems with uncertainty in the inputs data. This simulation method is based on input parameters those reflect the probability density function (PDF) of every parameter. Thus, the repetitive calculations take into account the randomly selected combinations of the inputs, generating a PDF or cumulative density function(CDF) for the outputs. Based on these CDFs, a risk level representing the high end (e.g. 95%), central tendency (median or mean), or any other desired level of probability can be obtained [4].

## Methodology

Dam behavior is conventionally evaluated by models of deformation, seepage, stress, and crack opening by using the complex and nonlinear functions. As the consequences of dam failure are serious, monitoring the behavior of dams is needed in the early stages of the impounding. It is also important to validate the assumptions made at the design step, particularly to control seepage phenomenon. Therefore, long-term monitoring of dam performance and regular measurements are improved during the operation period to ensure that the dam structure is functioning well. If the results of monitoring are in good consistency with the model estimations, it shows that the method of analysis has been carried out in a practical manner.

Monte Carlo and other probabilistic analytical techniques are relatively straightforward when applied to a case with parameter variability, the natural heterogeneity of a system and also parameter

uncertainty. On the other hand, model uncertainty represents a lack of knowledge concerning variables and their interactions to each other and thus constitutes uncertainty about whether a model approximates a real-world process or not. In brief, the Monte Carlo simulation is a numerical method to solve problems through stochastic simulation, and in this research the framework of study can be explained as follows: (1) The values of each stochastic variable are generated. The generations are based on the lognormal distribution for permeability variable and the normal distribution for density of foundation soil. (2) The pore pressures are obtained by using the finite difference model. (3) The steps described in points (1) and(2) are repeated until a statistically valid numbers of pore pressures are obtained. (4) The statistics of pore pressures are obtained like the mean, variance, CDFs and PDFs. (5) Finally, the results of Monte Carlo finite difference simulation and those of the monitoring are compared to figure out how the predication is correlated with the real observations.

## Case study

In order to implement the new concept, a case study of earth dam has been considered, which is vital for the life of people and ecology in its area. This dam is located in Shandong province of China.

In this study, only the data of piezometers are used, then the pore water pressure is utilized to demonstrate the capability of the proposed method. There are some hypotheses. First, soil properties are considered to be random variables in the Monte Carlo simulation process along with repetitive numerical analysis. As already discussed the lognormal distribution is assumed for the permeability random variable and normal distribution for the density of foundation soil. Finally, vertical coefficient of permeability, Ky, is taken as random variable and the permeability ratio, Kx/Ky is assumed to be 9. A summary of the field data including the coefficients of permeability and density is presented in Table 1.

In this case study, the piping event is considered the most serious failure mode of the dam. To evaluate the dam safety, 16 locations are considered to monitor the pore pressures. Some piezometers do not work well because of the bad installation. Considering the length of the dam, physical facts and boundary conditions, only some of them can be taken into account. To find the safety measure in the piping failure mode, the most of the evaluations are focused in the downstream area and near the drains. Therefore, 13 piezometers (as shown in Fig. 1) are considered and the summary of the monitoring results are presented in Fig. 2 shows the observed CDFs for all of the monitoring sites.

Table 1 Value of used parameters

| | Specifications | Maximum | Minimum | Average | Standard deviation | Coefficient of variation |
|---|---|---|---|---|---|---|
| Coefficient of permeability (cm/s) | First layer | 0.0072 | $1.540\times10^{-6}$ | $6.210\times10^{-4}$ | $13.6\times10^{-4}$ | 220 |
| | Second layer | 0.0031 | $1.540\times10^{-6}$ | $3.870\times10^{-4}$ | $7.22\times10^{-4}$ | 187 |
| | Third layer | 0.0032 | $1.5840\times10^{-6}$ | $5.270\times10^{-4}$ | $7.51\times10^{-4}$ | 167 |
| Saturated density (kN/m3) | | 18.4 | 14 | 15.38 | 0.77 | 5 |

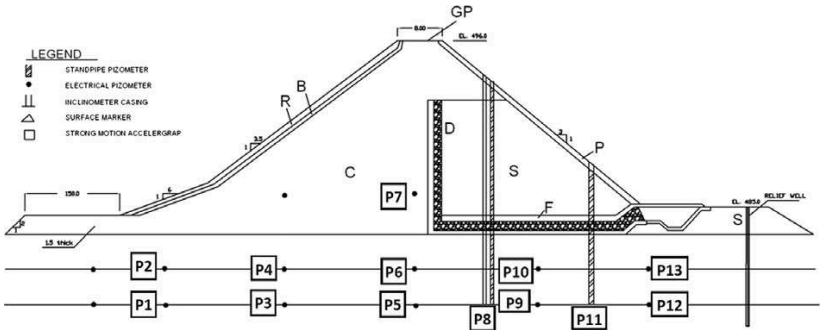

Fig. 1. The locations of the monitoring instruments in cross-section of earth dam

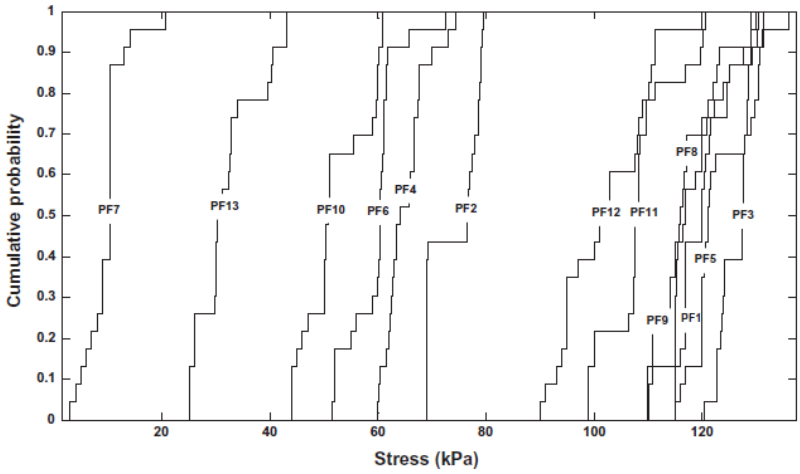

Fig. 2. The CDFs of the monitoring data at all points.

## Calculations by Monte Carlo finite difference method

In order to get an acceptable simulation, a large number of samples should be first produced. Nowak and Collins presented the required number of random samples as

$$N = \frac{1 - P_f}{(CoV)^2 P_f} \quad (1)$$

where Pf is the approximate failure probability and COV is the coefficient of variation. By using Eq. (1), if the failure probability and COV is considered $10^{-4}$ and 2, respectively, the required number of samples should be around 2750. Therefore, in this study, 2750 simulations were performed. In a precise study, the convergence of the statistics should be tested by performing a multiple number of samples. The finite difference grids of earth dam, modeled with FLAC is presented in Fig. 3. Because the dam's geometry is somewhat regular, the most elements are modeled as rectangular, to reduce the calculation time and the complexity of model.

The results of Monte Carlo simulation by using the new code are given in Fig.4. If the coefficient of variation is less than 10%, in this research it is assumed an appropriate output data. These predictions are useful in determining the critical points. The efficiency of the developed algorithm can be now assessed by comparing the observed results (Fig. 4) and those obtained by using the new method (Fig.4). Of course, due to some installation problem with piezometers, in some points (like in P7 and P13) a few errors are reported. Nevertheless, the general outputs indicate a very good fitness, indicating the effectiveness of the developed model in handling this problem and it will be shown by using a statistical test.

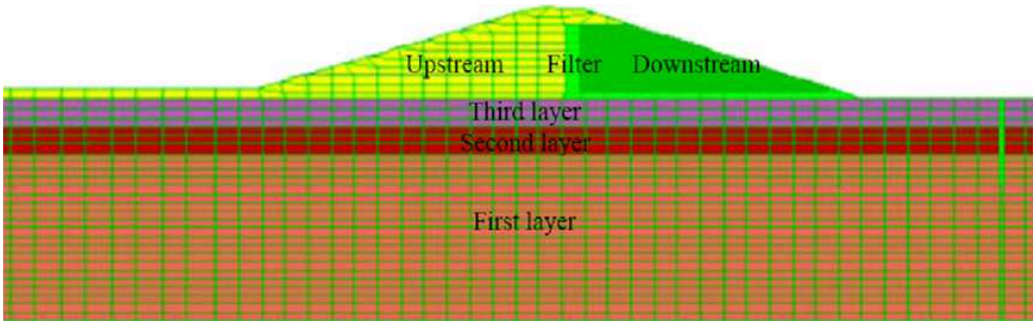

Fig. 3. The finite difference model of earth dam, modeled with FLAC.

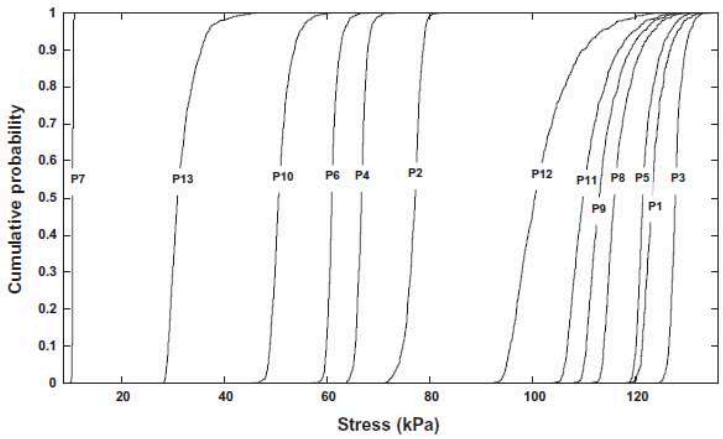

Fig. 4. The simulation results of the CDFs in all points

## Conclusions

There is a growing tendency to assess the safety levels of the dams, either under design or under operation. The risk of dam behavior is however a complex problem and cannot be evaluated just by the observed data. Considering the advantages of the probabilistic finite difference analyses, a new model was applied to predict the behavior of a dam during its impounding stage. According to the results, the predictions were in good fitness with the monitoring outputs. This concept of applying Monte Carlo simulation with a finite difference model resulted in interesting outcomes. However its performance depends on the simulation framework, the nature of the inputs, the nature of the loading conditions, the evidence used to characterize the distribution of the inputs and the extent to which the varied inputs can be considered independent. It is desired by using this method, the risk of dam failure to be reduced and decision-makers could better manage the uncertainties.

**Key words:** Rock specimen; Mechanical test; Point load; Uniaxial compressive strength

**Abstract**：Test point load test requires relatively small load, its instrument is portable, it can be easily applied to on-site testing,which may pave the way for the development of the fieldstrength of rock mechanics test, widely promoted in engineering construction, has a large space for development. When selecting the uniform rock do the load and saturation points uniaxial compression test respectively, and comparing the analysis of the two trials correlation between the results obtained by the method, the results showed that: point load test as a qualitative and semi-quantitative indicators are needed to meet the requiement of project, but if we put it as a fully quantitative indicators ,which will lead to large errors,and even lead to sweeping errors.

## Introduction

The mechanical strength of rock is an important parameter for rock engineering designing, constructing, its accuracy directly affects the security and stability of the construction and operation, as well as the economic rationality of construction[1-5]. The test load is relatively small and the instrument is portable in the point load test, which can be applied to field test. But the result is diversity, the accuracy is highly dependent on the number of test and related empirical formulas[6-9]. Point load test is mainly used for the estimation of rock uniaxial compressive strength or tensile strength, and classification of rock. Study on the correlation between rock point load strength and uniaxial compressive strength, many domestic and foreign scholars have done some research work. The results show that the Rc and $Is_{(50)}$of rocks have good correlation, and the table 1 lists some representative achievements.

## point load test instruments and methods

### 2.1 test instrument

Rocky Point Load Test uses SD-1 type of rock digita l point load tester, shown in Figure 1.

### 2.2 Test method and steps

（1）To ensure the same set of samples has a better uniformity, we take the rock samples into groups and each groups should not be less than 10.

（2）The samples can be,core samples, regular or irregular rock samples, which have different shapes for the corresponding size requirements. Test specimen shape and dimensions of the point load shown in Figure 2.

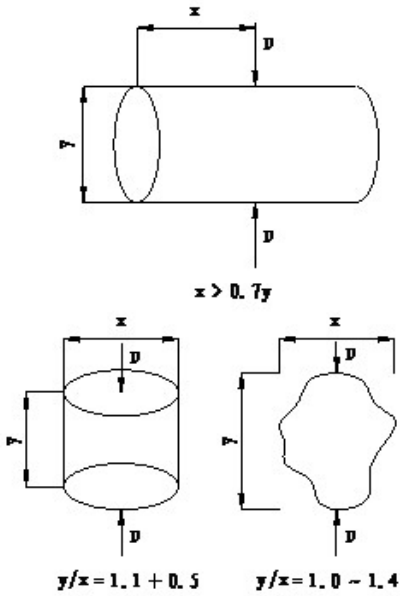

**Fig.2 The requirements of size for different shape specimens**

（3）To describe the rock lithology, we focus on structural characteristics of its structure, such as grain thickness, arrangement and joints, bedding and other developmental characteristic and degree of weathering, etc.

（4）When measuring the strength of the surface structure, we should ensure the two load connection point in the same structural level and uniform the applied load, the rate per second 0.05-0.1MPa.

### 2.3 Test documentation

The failure load of rock point load test is calculated in accordance with the formula (1) :

$$P = C \cdot F \tag{1}$$

The failure of specimens area and the equivalent circle diameter are calculated according to (2)(3):

$$A_f = D \cdot W_f \tag{2}$$

$$D_e^2 = 4A_f \cdot W_f / \pi \tag{3}$$

Rock point load strength formulaed according to (4), (5) .

$$I_s = P / D_e^2 \tag{4}$$

(Is as the unmodified point load strength index (MPa).)

$$I_{s(50)} = I_s \cdot F \tag{5}$$

$$F = \sqrt{\frac{D_e}{50}} \quad (6)$$

At the process of measuring data , deleting the maximum and minimum value, and then listing the rest of the measured value of the arithmetic mean value as the strength of rock point load test group.

**test results analysis**

In order to reduce the influence of rock heterogeneity, the test samples of point load strength and saturated uniaxial compressive strength have used homogeneous processing. We selected some typical magmatic rocks, sedimentary rocks and metamorphic rocks as the research samples, which with high, medium and low strength, as the research object.

The typical saturated uniaxial compression test curve of testing samples is shown in Figure 4.

The test results as shown in table 3. A set of experimental results of table rock point load strength and compressive strength of saturated average are listed, at the process of choosing data we take out a maximum and a minimum, and average value.

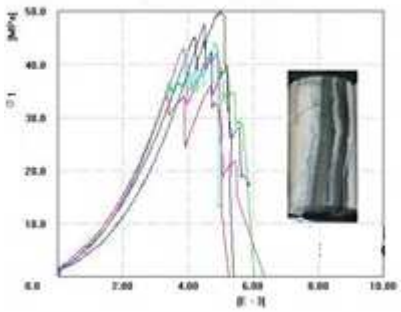

**Fig.3 The typical curves of uniaxial tests**

**Table 3 The results of tests and some parameters**

| types | names | $Is_{(50)}$(MPa) | Rc(MPa) |
|---|---|---|---|
| pyrogenic rock | granite | 9.99 | 198 |
| sedimentary rock | malmstone | 2.34 | 64.2 |
| metamorphic rock | marble | 4.29 | 175 |
| The green schist and marble interbed | Parallel to the bedding | 2.88 | 44.2 |
| | Vertical bedding | 3.73 | 68.8 |

Compared Fig.4 and Table3, the test samples adopted in both homogeneous sample and samples containing bedding rock both have good uniformity, so the same lithologic sample test results is comparable. Combined the domestic and foreign research results with the test results, a comprehensive analysis of different rock can be obtained, through the origin or not after the slope change range linear formula fitting the origin is very wide,nonlinear regression fitting parameters based on amplitude is also larger, with a unified formula ,to accurately summarize rock Rc and $Is_{(50)}$ relationship is difficult to achieve.

**Conclusion**

Point load strength test is a simple, fast speed, low-cost test, the sample size required can be the low and high-volume repeat tests, etc. This method has a good prospect for development and application. The current procedures and specifications of point load strength test on the discussion and provisions still defect, in practical geotechnical applications, it often can not be completely in accordance with standards and regulations to carry out the provisions. The shape and dimensions of the sample, lithology and structure factors directly affect the Rc and $Is_{(50)}$ the relationship. For the

different types of rocks ,whether linear or non-linear equation functions were fitted intensity interval value or whether it is different lithology types segmented partitions individually fitted, it is difficult to reunificate with one or several sub-partition function formula which can accurately describe the Rc and $Is_{(50)}$ related laws of all the rocks . Point load strength index and its conversion saturated uniaxial compressive strength value as the initial classification of rocks, and rock weathering zone or a selected point in the planning and engineering exploration and feasibility study initially estimated half of the compressive strength of rock quantitative indicators, the superiority of its fast economic and other test methods are incomparable. However, due to its accuracy is not enough, in practical the test data engineering are not using point load method to design, should be indoors, on-site testing machines the results obtained mainly in reliable comparative information for the next scene to do a small part of the point load test data, but in major projects or the best method used in all of rock testing machine to test the compressive strength of rock.

**Keywords:** Cretaceous formation. Artificially frozen soil. Elastic modulus. Specific heat.

**Abstract.** Through the test of artificial frozen soil of cretaceous formation soil sample, study the mechanical properties and thermophysical properties of cretaceous formation artificial frozen soil with different soil properties and subzero temperatures. Results indicate that, uniaxial compressive strength of artificial frozen soil of cretaceous formation soil sample linearly increases accompanied with drop in temperature, with identical soil properties and water content; with decreasing temperature, elastic modulus increases and Poisson's ratio decreases, in the case of the identical soil and ambient temperature; with decreasing temperature specific heat of artificial frozen soil decreases and thermal conductivity increases.

## Introduction

Artificial ground freezing, freezing method for short, have applied in China more than 40 years. Coal industry have built up a more perfect test system of frozen soil frozen soil and thermophysical properties. The result of test can directly and reliably guide the frozen design and construction [1-4].

## Elastic Modulus of Cretaceous Formation Frozen Soil

**Test Preparation.** Considering the representative soil sample, it different test point in cretaceous formation, and collect undisturbed soil and remoulded soil during Ling-dong Mine's excavation.

**Collection of Undisturbed Soil Sample.** Undisturbed soil means the sample's physical properties, as particle, water content, density, cementation, structure, remain unchanged.

Process of Undisturbed soil collection, including selection of collection devices, collection, field identification of sample, package storage and transportation of sample, referring to the Standard system of PRC, Technical standard for sampling of undisturbed soils.

Soil sampler. Φ89 penetration soil sampler, it met standard requirements. Field drilling meets depth requirement, Using rotary.

The sample field inspection and process need be done after the sample collection, as shown in Fig. 1 and Fig. 2. Package and transport the samples to laboratory.

Fig. 1. Sample process

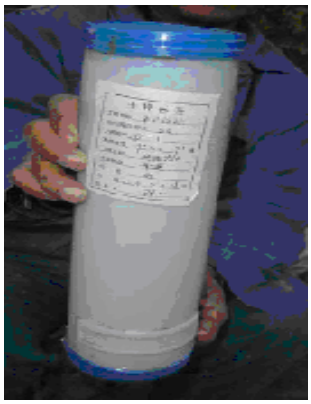

Fig. 2. Sample tag

**Collection and Process of Remoulded Soil Sample.** Remoulded soil sample means sample's physical properties, as particle, water content, density, cementation, and structure, changed after preparation.

The collection package transport and process reference to Artificial frozen soil physics mechanics performance test-Part 1: Artificial frozen soil experiment sample and specimen preparation method (MT/T 593.1).

According to requirement, it collect sample from undisturbed soil layer when shaft excavation reach preset position. In lab, under room temperature, it record sample's color, smell, other and so on, then test the water content and density of representative samples. Soil sample chops, and dry at 105~110°C with constant temperature, then cool to room temperature in the dryer. Chop the dry cool sample, sieve through 2mm standard soil screen. In the experiment, In accordance with the design requirements of moisture, water added to dry soil, stirred uniformly, sealed and put in moist chamber for more than 24h.

**Main Experiment Device.** In the experiment of this paper, uniaxial strength test include making sample, constant temperature maintenance and loading. Madding sample need compaction Jane, cutting ring, cut disc, oven, moist chamber, dryer, wooden mallet, rubber plate, aquarium, modification knife, hacksaw, Vaseline, wrap, plastic bags, sample tags and other containers. Constant temperature maintenance uses high accuracy XT5402 incubator, Meeting the temperature requirements of 0 ~ 60°C. The loading device include MTS-815 digital hydraulic servo machine, LC-127D road material strength machine, and CSS-1120 electronic multifunction machine.

**Test Method and Process.**

**Preparation of Soil Sample**. The test use remoulded soil sample. The sample meet requirements of Standard for soil test method- GB/T50123-1999. Put soil into dryer after screen. During the test, set ingredients in accordance with the required amount of soil moisture.

The sample prepared with pressure by layers. According to Volume, dry density, water content, it could calculate the mass of wet soil of each sample required. Divide the wet soil into 5 parts and press them into container by layer. In the test, a Φ60mm×H120mm ferruginous Cylinder with 5 loop lines is used to make sure same thickness of every layer. Difference between the measured value of density and theoretical value no more than 0.01g/cm3, water content no more than ±1%. The sample uniformity mainly presented in uniformity of density and water content, and the requirement of density and water content will decrease the discreteness of result.

**Test procedure**. There are four procedures in the frozen soil uniaxial compression test, which are develop hardware, constant temperature, lading and data acquisition.

Develop hardware and constant temperature: Configure the soil contains the water content that experimental designed, and put them in the clay for 24h, then in the sand soil for 6~8h. Coat a thin layer Vaseline in the brass test modes, and put the soil into the test modes delimitative, at last sand the test modes into the refrigerator. It is time to dismantle the test modes when they are frozen, Measuring soil sample size and weighed and recorded, and sand into thermostat for 24~48h after the test modes are Waterproofed

Lading: the frozen soil uniaxial compression test applies the way of controlling the strain rate, the loading rates of test machine are 1, 8, 1mm/min when the temperature are -5, -10, -15°C, and the strain rate are 0.013333, 0.106667, 0.013333%/s, the Temperature fluctuation range controls in ±0.2°C.

Data acquisition: Displacement sensors record the soil displacement, and loading sensors record the soil loads, sanding the results in the design documents which can be calculated as the stress-strain curve.

**Test Results**. The test results are shown in Table 1.

## Cretaceous System Stratum Frozen Soil Thermo-physical Properties

Table 1 Test of soil mechanical properties

| NO. | Temperature (°C) | Clay samples | | | Mudstone single axis compressive strength |
|---|---|---|---|---|---|
| | | Single axis compressive strength | Elastic modulus | Poisson's ratio | |
| 1 | -5 | 1.38MPa | 69MPa | 0.36 | 2.34MPa |
| 2 | -10 | 2.06MPa | 98MPa | 0.29 | 4.07MPa |
| 3 | -15 | 3.14MPa | 201MPa | 0.23 | 6.11MPa |

Frozen soil is a plurality mixture which contains Mineral particles, ice, unfrozen water and gas, there is a big difference between frozen and unfrozen soil, which directed by the water difference phase state or changing phase state. The main index of thermo-physical properties are specific heat, coefficient of heat transmission, temperature transfer coefficient, thermal capacity, latent heat of phase change. Specific heat capacity per unit of mass (λ) is called the per unit area soil conduct the temperature when the temperature gradient is 1°C /m in the direction of heat flow. It reflects the frozen soil conducting heat property. Soil thermal diffusivity is an index of the ability to change their temperature when the nearby soil's temperature is changing. It is a Basic indicator of study the process of unstable heat conduction. The soil heat capacity is the total heat of soil send out per volume when the temperature change range from initial temperature to frozen temperature. Latent heat of phase change is a sending out heat of water or a liquid change from liquid-state to Solid-state under a temperature state.

The test results are shown in Table 2. The frozen temperature of clay and mudstone are -0.56, -1.72°C.

Table 2 Specific heat of soil samples

| NO. | Temperature (°C) | Fine sand coefficient of heat transmission (w/(m·K)) | Clay samples | | Mudstone samples (kJ/(kg·K)) | |
|---|---|---|---|---|---|---|
| | | | Specific heat (kJ/(kg·K)) | Coefficient of heat transmission (w/(m·K)) | Specific heat (kJ/(kg·K)) | Coefficient of heat transmission (w/(m·K)) |
| 1 | -5 | 2.977 | 1.132 | 1.727 | 0.982 | 1.936 |
| 2 | -10 | 3.163 | 1.089 | 1.796 | 0.967 | 1.983 |
| 3 | -15 | 3.536 | 1.066 | 1.821 | 0.935 | 2.105 |

## Conclusion

Here are the main conclusions of cretaceous System stratum frozen soil Mechanical properties and thermal physical characteristics under the different properties of soil and temperature through a range of cretaceous System man-made frozen tests.

The single axis compressive strength of cretaceous System man-made frozen soil linearly increase with the temperature decreases under the same properties of soil and moisture content, The calculation ,σ-frozen soil short single axis compressive strength, MPa; a and b-the constants of soil property; θ-frozen temperature, °C.

The elastic modulus of cretaceous System man-made frozen soil increase with the temperature decrease under the same properties of soil and temperature. The Poisson's ratio decrease with the temperature decrease.

The specific heat of cretaceous System man-made frozen soil decrease with the temperature decrease. The coefficient of heat transmission increase with the temperature decrease.

**Keywords:** Coordinate transformation; surface morphology; fractal;

**Abstract.** The mechanics characteristics of the rock are mainly subjected by the joint and the fractures of the rock mass. For the joint, the surface morphology is especially the dominant influence factor. In order to describe the nature physics of rock surface, the surface morphology embarked on a fractured granite rock is described. And use the fractal dimension to calculate the volume of covering rock fracture surface, the relationship between fractal dimension and physical characteristics of rock surface.

## Introduction

Granite is a fractured rock. Deep underground of the granite tend to be able to form a complex fracture network, resulting in a huge seepage system. The fissures and groundwater seepage stress each other, which affects the safety of the role of deep nuclear waste disposal. However, getting the measured value is somewhat difficult. Complex fracture surface is rough surface, you want to use or evaluate the measured data to express the need for a fractured face every part of the fracture surface were measured. If you insist on using the method of measurement to express an artificial fracture surface, the workload is far too large. The actual measurement operation projects will encounter many unexpected trouble. It is difficult to measure the rough rock surface in a point of the projection height and the slope of the projection, followed by the desired distance between any two levels of access is also easy to do accurately, the common measurement tool furthermore error often can't be ignored. Statistical methods are complex and have a degree of objectivity; the results of statistical methods may be affected by the measuring instrument to measure the actual operation of the measurement accuracy. Therefore, many scholars began to characterize the surface morphology of exposure to the joint surface is different from the statistical methods. So far, it has reason to believe that the rock fracture surface morphology is very exploring, and has been getting many meaningful results [1-4].

Fractal methods have been applied to joints and fissures. Fractal dimension approach is still immature, through the tireless efforts of scholars have found that if the fractal dimension of the surface and the slope of the bosses will be able to combine, it will be more objective characterization of the physical characteristics of the rock surface .

Currently there are four kinds of methods for measuring. Fractal measurement of fracture surfaces, respectively perimeter-area relationship method (Kojima law-silt island method), bit -shaped cross-section method (Profile or Vertical section method), power-law spectrum method and self- affine fractal methods, but these methods are difficult to accurately express the rough section anisotropy and local features on the spatial distribution [5]. Calculation methods currently used to estimate the fractal dimension of real rock section, the most representative is triangular prism surface area method [6] , covering projection method [7,8] , covering cube method [9] as well as used herein, the volume of new overlay method. Because you can't change the nature of the approximate calculation of the fractal dimension, it is still not perfect with many errors, but the method of fractal geometry to the study of surface topography of rock brings new ideas and breakthroughs [10-13].

## Coordinate transformations

Normally, the test data is measured to obtain the coordinate conversion, which is not required. The calculation of the average value will not be affected. But in the study of rock surface morphology characteristics, often resulting scan data directly are not suitable for direct calculation. It requires some processing. Among these treatments, the method often requires the use of coordinate transformation, the transformed position of the original data to another new coordinate system to form a new set of position data. The new coordinate system is more conducive to our calculation processing of data can be analyzed better explored. Coordinate conversion process is actually a variation of the method of the coordinate system. The key is not how to calculate mathematical knowledge, but rather the transformation of the original scan data into what kind of a new coordinate system.

Then point to the distance formula based on surface scan data to transforming the old coordinate the new coordinates, we get the scan data of rock samples in the new coordinate system. The 99 data points are show Fig.1. The points that need to be transformed are show in Fig.2.

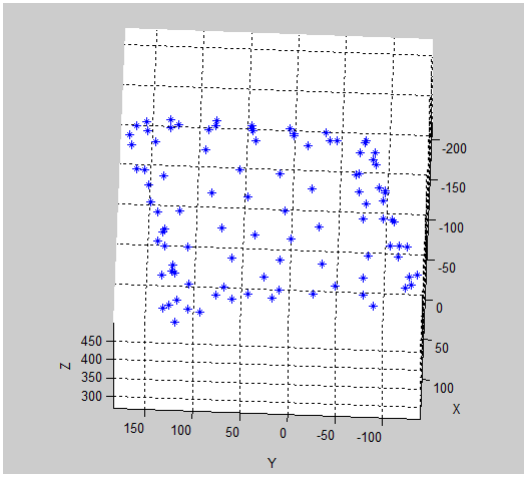

Fig.1. 99 Figure bit data

Fig.2. 29 points to be converted

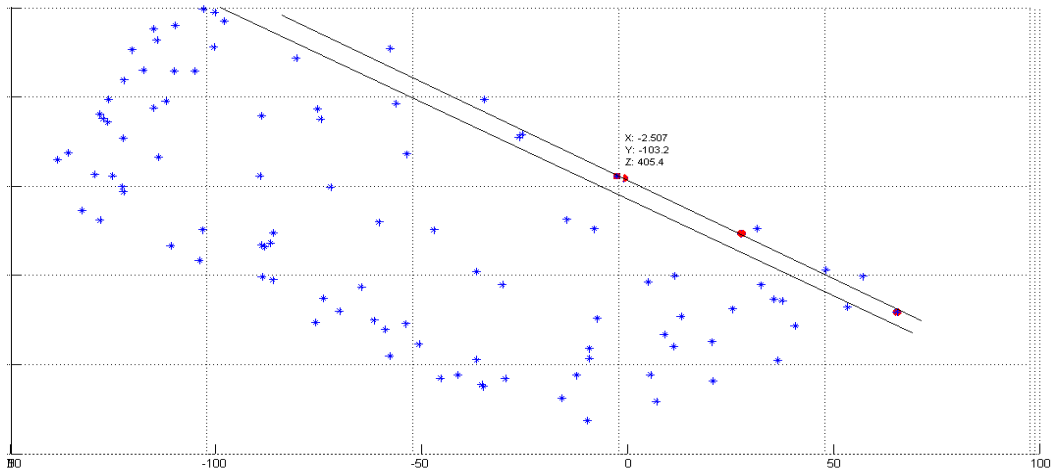

Fig.3. Select the datum

The method of this paper is easy to understand. First, establish benchmarks 3:00 X-Y plane. Select three data points XY plane parallel surfaces in red dots data. The three points are show in Fig.3. They are,

No. 48 data point (0.5797 14101 404.3);

No. 36 data point (66.76 121.6 329.3);

No. 89 data point (-2.507 -103.2 405.4);

Calculate the plane,

$$X - 0.0087Y + 0.88Z - 357 = 0 \tag{1}$$

Easily calculated parallel to the plane and has No. 17 data point (-85.79 -95.13 373.6)

For the new datum,

$$X - 0.0087Y + 0.88Z - 243.8 = 0 \tag{2}$$

The second step, seeking X_Z datum, as over

No. 19 (-130.8 147.4 386.2)

No. 26 (-11 124 294)

With two data points and vertical X_Y, it gets that

$$X + 9.237Y - 1.045Z - 827.18 = 0 \tag{3}$$

Readily calculated parallel to the surface and the data points over the 17th plane,

$$X + 9.237Y - 1.045Z + 1355 = 0 \tag{4}$$

The third step, seeking Y_Z datum,

Over 17 data points and perpendicular to the first two faces, it gets that

$$X - 0.2371Y - 1.1387Z + 488.689 = 0 \tag{5}$$

## Fractal

Classing the definition prism (see Fig.4), the bottom surface of the upper and lower triangular or quadrangular, the remaining faces are quadrilateral, and the quadrilateral are parallel to each of the two mutually adjacent common sides, surrounded by the surface of the polyhedron.

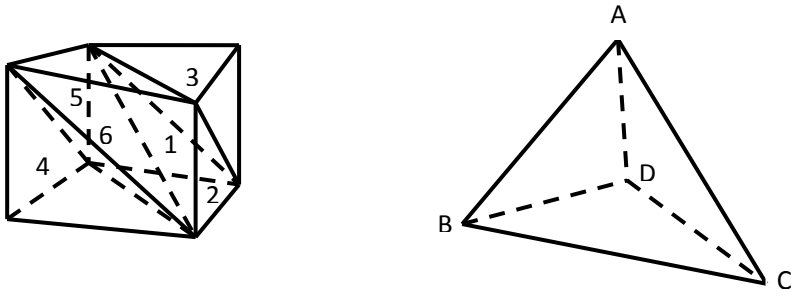

Fig.4. Schematic splitting prism class

Any class prism can be divided into six arbitrary tetrahedrons; accumulating six tetrahedral volumes can be obtained at any volume class prism. Volume formula for an arbitrary tetrahedron

$$V = \frac{1}{6}\begin{vmatrix} 1 & 1 & 1 & 1 \\ x_1 & x_2 & x_3 & x_4 \\ y_1 & y_2 & y_3 & y_4 \\ z_1 & z_2 & z_3 & z_4 \end{vmatrix} \tag{6}$$

Where (x1, y1, z1), (x2, y2, z2) (x3, y3, z3) (x4, y4, z4). Coordinate values are arbitrary tetrahedron of four vertices A, B, C and D.

Changing observation scales covering recalculated to cover the entire surface roughness required total, if the rough surface fractal nature. According to fractal theory, the following relationship is,

$$N(\delta) \sim c\delta^{-s} \tag{7}$$

S is called the fractal dimension, c is the volume per unit $R^3$. Calculated at different scales corresponding to the total volume of coverage, you can get a logarithmic scale with the total relationship, thereby calculating the fractal dimension.

## Conclusions

Scanning data often can't be directly used, the need for coordinate transformation in order to fit the required research, coordinate transformation explored in this paper is based on the selected plane carried, can fit to calculate the fractal dimension, with the presentation of the practical aspects of rock surface topography.

Volume covering method shows a good linear relationship with the volume. The method describing rough surface is feasible. Volume covering method directly adopt the laser scanner elevation data to calculate without regard to whether the scanning errors and other problems caused by the pitch, effectively avoiding the interpolation error.

# Study on control technology of slope in mountainous areas of southwest China under complex geological conditions

Wei Yang[1 2, a], Haiping Li[1 2, b]

[1]China Merchants Chongqing Communications Research & Design Institute Co., Ltd., Chongqing 400067, China

[2]National Engineering & Research Center for Highways in Mountain Area, Chongqing 400067, China

[a]dlyangwei@cmhk.com, [b]lihaiping@cmhk.com

**Keywords:** slope; deformation; geological structure; cataclastic rock; construction control

**Abstract.** Deformation process of slope has been controlled by a variety of factors due to the unique geological, hydrological and meteorological conditions. And southwest mountain areas of China has been become high incidence areas of slope diseases during highway construction and operation. According to Wendu Road K55+590 ~ K55+670 left slope engineering geological environment, the deformation process and mechanism analysis, The key factor of the slope deforming destruction is proposed. the appropriate engineering treatments and the construction control measures are also proposed based on analysis.

## Introduction

Deformation process of cutting slope is controlled by a variety of factors in addition to its internal geological control factors during the high grade highway construction and operation, but the external agency is the key factors affacting ing the development of slope deformation[1, 2]. Take the left side slope of the second grade highway Wenshan to Dulong（K55+590~K55+670）reconstruction project as an example, the detail introduction about slope deformation and treatment process under the complex geological condition southwest mountainous area is provided, especially the control process during the implementation of slope treatment. It provides some experiences for slope disease treatment for similar area or similar conditions.

## Characteristic and geological environment of the slope

**Characteristic of the slope.** Original design height of slope is 22.5m, slope ratio is 1:0.75, each grade heights is 10m. The slope collapsed several times during the construction, then slope ratio was adjusted to 1:1.5, and the total height of slope reached 32.5m. The excavation reached the design elevation in April of 2010. Tensile cracks appeared on the three-stage of the left side slope mouth and first-order platform after several days of continuous rain. And anterior border of slope extendeded outward significantly, soil and rock of first-order side slope collapsed partly. The stability of slope is bad and instability phenomenon appeared. Huge security risk is formed for highway construction and traffic and normal construction of roadbed is seriously affected. The complete picture and cross-section of the slope was shown in fig.1 and fig.2.

Fig.1 Slope construction and deformation

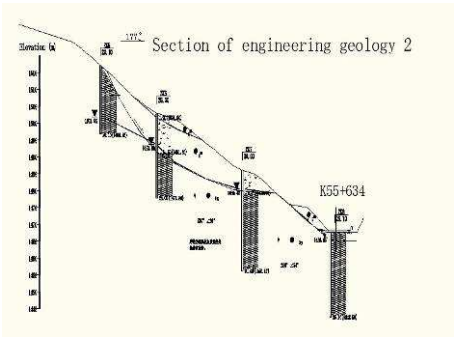

Fig.2 Typical geological cross-section of the slope

**Geological environment of the slope.** The slope located at a transitional zone between a temperate climate and tropical monsoon climate of Nanpan river, with warm, dampness climate, rainy in general. The annual maximum temperature is 22.9℃, minimum temperature is 6.3℃, and the average temperature is 16.7℃. The average annul precipitation was 1366.13mm.The rainy season is from June to September, dry season is from December to the next April. A v-shaped gully developed in southwestern and northern areas near the slope, there is flood flowing through during the rainy season, and with no large surface water near the site. Regional landform unit of the slope belongs to denuded low-middling mountain areas, the slope is located in anterior mid-part of the southern slope, and the nature slope is about 20°to 30°. There formed a three-stage cut slope with 36m heigh and 33°~53° grade. Its main formation lithology consists of the quaternary eluvial slope wash of gravelly silty clay(Qel+dl), Pojiao group argillaceous shale of lower devonian system(D1p), and carbonaceous shale [3]. The slope is located in the "Wenshan Yangliu well broom-like structure "influence zone. The seismic peak ground acceleration is 0.05g, the reflection of characteristic period of ground motion is 0.35s, the basic seismic intensity is six degree. Influenced by two compresso-shear fault belt, the rock secondary folds of the slope developed well, the jointed and fractured of bedrock developed and rock is broken. Based on lithologic combination and groundwater storage, the site groundwater is mainly consists of the loosened rocks pore-water of quaternary and the weathering mesh fissure water in bedrock.

## Deformation and failure mechanism of slope

**Structural characteristic of the slope.** The main formation lithology consists of the quaternary eluvial slope wash of gravelly silty clay (Qel+dl), pojiao group argillaceous shale of lower Devonian system(D1p),and carbonaceous shale. The quaternary eluvial slope wash composed of silty clay, brown red, brown yellow, little humid, hard plastic and mixed with strong weathering brecciated shale ,the thickness is about 1.00, Pojiao group of lower Devonian system composed of argillaceous shale and carbonaceous shale, the characteristics of argillaceous shale are yellow, shale structure and thin-bedded construction; the characteristics of carbonaceous shale are dark grey, black, compact structure and thin-bedded construction. The rock-formation attitude is 230°∠24°, the rock trend to be larger angles with left side artificial slope of the planned road, which belongs to tangential slope, and the attitude of rock formation is favorable for slope stability. Due to the influences of structure, there are crashed rock structures, and with intensive developed joint fissures. the main distance is about 5cm～20cm.The rock has the characteristics of gravel soil, because of argillaceous shale and carbonaceous shale mainly contain clay mineral, rich smectite and kaolin, completely decomposed shale and its weathered products has the character of high liquid limit soil, dry shrinkage and wet expansion characteristics, under normal circumstances the engineering performance is available, but after several alternation of drying and wetting its mechanical properties decrease, because of weathered rock mass has the character of cataclasite, so it's easy for rainwater infiltration ,evaporation and discharge. The slip and deformation problem is easy to occur within atmosphere influence depth (According to the local data, generally about 3m).

**The slope construction.** Original design height is 22.5m, slope ratio is 1:0.75 and each grade heights is 10m. Slope construction began in October 2009, during the construction, the slope collapsed several times, after clear away earthwork, the slope ratio was adjusted to 1.5, and the total height of slope is 32.5m. In mid-April 2010, the cutting excavation reached the design of pavement elevation, The basic shape of the cutting excavation formed. After several days of continuous rain, tensile cracks appeared on the three-stage of the out side slope groove and first-order platform; in the next several days, crack increased and became broad, the lower part of the secondary slope and near the toe of slope zone appeared phenomenon of obvious dilatancy, linear creep circumstances occurred in toe of the slope and middle lower part of secondary slope, part rock soil of first stage slope appeared slip and slump phenomenon. the stability of slope is very low and very easily distorted, under condition of continuous rainfall or Improper clear away earthwork, slope issue has become a engineering landslide problem. The slope deformation was shown as two independent rock and soil deformation and instability situation, which called: H1, H2 landslide.

**analysis of deformation mechanism.** The main material components of slope were completely decomposed shale and its weathered products, controlled by structure and weathering factors, joint fissures of the slope rock mass intensive developed and rock structures are crashed, it belongs to the category of cataclastic rock mass. On the basis of the failure mode controlled by preferred structure planes, and has the gravelly soil type slope failure characteristics at the same time. Based on slope construction and slope deformation process, the deformation of slope was clearly divided into two phases: Phase One is the problem of shallow surface, mainly scope of slope excavation or called slope excavation unloading and relaxation range. And also has the atmosphere influence depth of rock and soil deformation phase--called the shallow surface of slope deformation phase; Phase two is the formation of deep sliding surface, the instability phase of whole sliding slope[4].

## Analysis of stability for the Slope

**Calculation method.** The current calculating method of the stability of the landslide is mainly divided into three categories [5]: limit equilibrium analysis method, digital analysis method, and probability method. Limit equilibrium method is the ripest, and most widely used calculating method in engineering. Combined with the slope characteristics of the disease, based on the limit equilibrium theory, meanwhile taking the weathering rock mass structure is loose and the slope deformation has characteristics of soil landslide into account. We used the circular sliding method analyze the present model situations, and at the same time combined with the survey data we used the sliding broken line method inverse the slope deformation process, simulation and analysis of its deformation, and predicts the future trend of deformation.

**Parameters of rock or soils.** Geotechnical parameter was comprehensive determined by the basis of the geological survey report and combined with regional experiences and back analysis. See table 1 for specific parameters of slope geotechnical parameters [4].

Table 1 Slope geotechnical parameters

| Rock Name | Density(kN/m$^3$) | | C(kPa) | | φ(°) | |
|---|---|---|---|---|---|---|
| | natural | saturate | natural | saturate | natural | saturate |
| completely weathered shale | 22.5 | 23.00 | 8.5 | 7.5 | 24.0 | 23.5 |
| strongly weathered shale | 23.5 | 24.0 | 31.5 | 30.0 | 28.0 | 27.5 |

**Calculation results.** According to slope excavation situation, and in the light of progress on simulation analysis of slope deformation under continuous rainfall condition, in April 2010, section stability coefficient of the slope (K55+634) is Fs=0.953[4], the slope stability is poor, and the sliding instability phenomenon of rock soil will happen under continual heavy rainfall, The calculation results were represented in figure 3. According to the results of simulation analysis, analyzed the overall stability by using the sliding broken line method along with slipping surface. Still used the section (K55+634) as example, the strip of calculation was shown as figure 4.

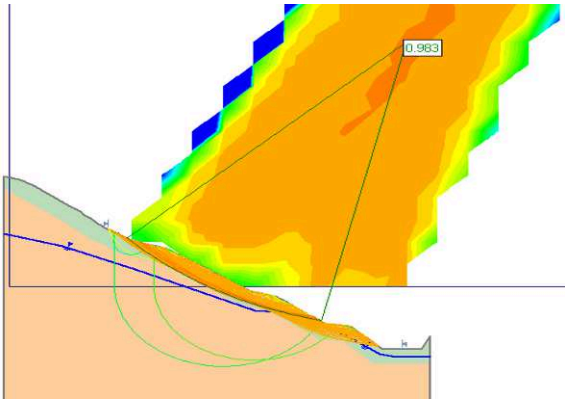

Fig.3 Stability analysis of the slope deformation (the section K55+634 in April 2010)

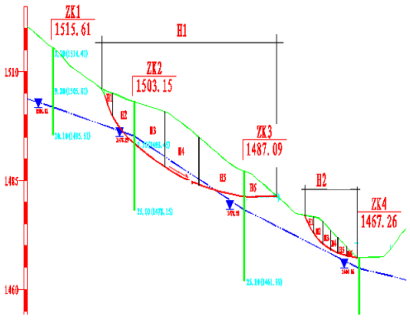

Fig.4 Slice of stability analysis of overall slope (the section K55+634 in April 2010)

Under natural condition the stability coefficient of residual sliding force of slope H1 was Fs=1.05, the residual sliding force is T=1345.95kN, under continuous rainfall condition the stability coefficient is Fs=0.975, the residual sliding force is T=1635.90kN, the landslide H2 was mainly loose rock mass sliding formed, the scale is small, so take the results of the calculation results of the landslide H1.

## Treatment schemes and dynamic design of the slope

Based on the specific characteristics of the slope, considered the bad stability of rock and soil mass of the slope, and the tendency of partial slope sliding, slumping and whole instability, at beginning of slope deformation has used the scheme of purge earthwork for the slope treatment. But after purge earthwork, the slope deformation region continuous extend to trailing edge, and the scale is continually expanding, to avoid further expansion of the slope deformation, this treatment scheme did not reconsider the scheme of purge earthwork. But considering the deformation of surface structure of rock and soil has been completely destroyed, and the loose structure, after saturated with water it is easily slumping under continuous rainfall condition, and it is difficult to add effective support, therefore, used appropriate clearing process for the shallow deformation, the demonstration of reinforcement scheme mainly focus on considering the basis to ensure the overall stability of the slope and taken the stability principle of shallow rock and soil of the slope into account. Used the anti-slide pile as the main supporting engineering, the relative steep slope used hanging net sprayed concrete and closed anchorage to control local deformation of soil slope, the relative gentle slope used the supporting seeping grooves combined with skeleton planting protection ,and assisted with interception and discharge comprehensive treatment.

During the anti-slide pile construction, the process of hole digging appeared extrusion failure and cracking phenomenon at the starting point and the middle parts of the slope, according to the dynamic design principles, steel pipe piles were added in the hierarchical platform for emergency supporting and retaining, at the same time set up temporary back pressure engineering in the lower to ensure the safety of construction, controlling the development rate of slope deformation. After the implementation of emergency measures, main project of the anti-slide pile basically completed. The specific design was shown in figure 5.

Because groundwater is very developed, the rock mass of first stage slope weathering serious, after repeated disturbances, the phenomenon that the poor slope stability, soil slippery and slumping is prominent, and controlled by setting up protective covering retaining wall of the road cut, as shown in figure 6.

After finished the later anti-slide pile construction of slope, the monitoring data shown that the anti-slide pile deformation of the middle of third grade and the fourth grade is large, due to the developed groundwater the first degree appeared severe collapse, to ensure the reinforcement effect, the anchor cable frame beam reinforcement was added to the third grade of slope K55+590-K55+656 and fourth grade of slope K55+608-K55+644, added steel pipe pile retaining to the platform of first

slope and added retaining wall protection to the surface of first slope respectively, as shown in figure 5 and figure 6.

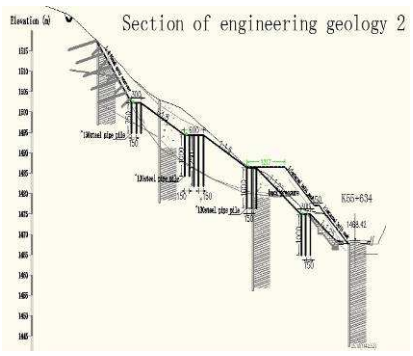

Fig.5 Section design of emergency management

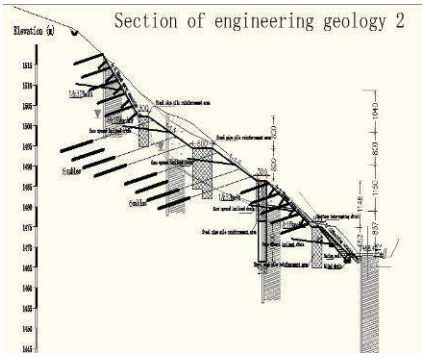

Fig.6 Section design of slope reinforcement （the section K142+560）

After implementation of the above scheme, slope deformation can be effectively controlled; Monitoring data show that, since completed the treatment engineering about 3 years, the various measures of stress and strain are in the design range, slope performances well.

## Conclusions

(1) In southwest mountain area the structure is developed, the rock in fractured zone and its influence zone belong to cataclasite, the slope failure mode on the basis of the controlled preferred combination structure planes, has the gravel soil slope failure characteristic at the same time.

(2) In southwest mountain area, the process of deformation development under complex geological conditions can be divided into two stages, stage one is the problem of shallow surface layer, namely the incidence of slope excavation or called slope excavation unloading relaxation incidence, concurrently with the rock soil mass deformation phase in atomspheric influence depth, stage two is the formation of slip surface, and the whole slope sliding phase.

(3) Adopted the treatment thought of stage control implementation to reinforce the left side slope of Wendu road k55+590~670, and combined with a variety of measures for comprehensive treatment. During slope treatment, the whole slope is stable, the tunnel construction is safe, and the design is realized.

(4) The standard of successful slope treatment is “Safe, economic, and environment-friendly”, the deformation development of slope excavation is a continuously accumulation process, cognition of its deformation mechanism is also a gradually perfected process, strengthen the stage control, with the change of external conditions (Such as weather, adjustment of the construction process and so on), the targeted treatment measures on the slope is proposed, according to the deformation stage, select the appropriate reinforcement time is the key to successful treatment of the slope.

**Keywords:** Dynamic Properties ,Soft Clay , Anisotropic Bounding Surface, UMAT Subroutine.

**Abstract.** This paper presents an improved anisotropic bounding surface model which is based on Wheeler's elastoplastic model (S-CLAY1). The developed model is programmed in ABAQUS software by writing UMAT subroutine, which is integrated in Return Mapping Algorithm. The parameters sensitivity analysis is implemented on plastic modulus. The study shows that the developed anisotropic bounding surface model is capable of describing the dynamic properties of soft clay.

## Introduction

Natural soft clays are generally anisotropic. Most dynamic properties of soft clay are associated with certain preferred orientation in space. Anisotropy of soft clay can be classified into two components, one is inherent anisotropy and the other is stress-induced anisotropy by Casagrande [1]. There have been generally two ways to quantify the anisotropy of soft clay, one is based on micromechanical concept and is called fabric tensor[2,3],the other is based on macroscopic response of soft clay and is named anisotropic tensor[4].

Wheeler[5] proposed an anisotropic elastoplastic model for soft clay from Finland(S-CLAY1). The model is an extension of the critical state model and can describe the change of yield curve inclination with plastic strain.

This paper proposed the new constitutive model of soft clay based on S-CLAY1 model and the bounding surface theory, which is capable of describing anisotropy and dynamic properties of soft clay.

## The anisotropic bounding surface model

### Bounding surface equation of the model

$$F=\frac{3}{2}(\overline{s}_{ij}-\overline{p}\alpha_{ij})(\overline{s}_{ij}-\overline{p}\alpha_{ij})-(M^2-\frac{3}{2}\alpha_{ij}\alpha_{ij})(p_0-\overline{p})\overline{p}=0 \tag{1}$$

where $\overline{s}_{ij}$ and $\overline{p}$ are the mean effective stress and deviatoric stress on bounding surface, respectively, $\alpha_{ij}$ is anisotropic tensor defining the inclination of the yield curve, $M$ is the critical state value of the stress ratio, $p_0$ defines the size of the yield curve.

### Hanrdening laws

The model incorporates two hardening laws. The isotropic hardening law describes change of size of the yield curve, which is assumed to be related to the change of pre-consolidation pressure $P_0$,

$$\dot{p}_0=\frac{v_0}{\lambda-\kappa}p_0\dot{\varepsilon}_v^p \tag{2}$$

where $\lambda$ is the slope of the post-yield compression curve in the $e-\ln p$ plane, $\kappa$ is the slope of elastic swelling lines in the $e-\ln p$ plane, $v_0=1+e_0$, $e_0$ is initial void ratio.

The rotational hardening law describes the change of inclination of the yield curve produced by plastic strain, include plastic volume strain $\varepsilon_v^p$ and plastic deviatoric strain $\bar{\varepsilon}_s^p$

$$\dot{\alpha}_{ij}=\mu[\left(\frac{3s_{ij}}{4p}-\alpha_{ij}\right)<\dot{\varepsilon}_v^p>+\beta\left(\frac{s_{ij}}{3p}-\alpha_{ij}\right)\dot{\bar{\varepsilon}}_s^p] \tag{3}$$

where the soil constant $\beta$ controls the relative effect of plastic deviatoric strains on the rotation of the elliptical surface, the soil constant $\mu$ controls the rate at which the deviatoric fabric tensor heads toward their current target values.

**Mapping rule**

Radial mapping rule has been adopted in the developed mode[6,7].

**Elastic modulus**

Elastic modulus incorporates two components, the elastic shear modulus *G* and the elastic bulk modulus *K*. The elastic shear modulus *G* is related to the elastic bulk modulus *K* by assuming a constant value of Poisson's ratio *v*,

$$K=\frac{v_0}{\kappa}p\ ,\quad G=\frac{3K(1-2v)}{\left[2(1+v)\right]} \tag{4}$$

The relationship between the elastic increments of volumetric and deviatoric strain is

$$\dot{\varepsilon}_v^e=\frac{\dot{p}}{K}\ ,\quad \dot{e}_{ij}^e=\frac{\dot{s}_{ij}}{2G} \tag{5}$$

**Plastic modulus**

The developed model obeys the associated flow rule. Therefore the yield function also serves as the plastic potential function. According to the consistency conditions, the bounding plastic modulus $\bar{K}_p$ is obtained as

$$\bar{K}_p=-\left(\frac{\partial F}{\partial p_0}\dot{p}_0+\frac{\partial F}{\partial \alpha_{ij}}\dot{\alpha}_{ij}\right)/\dot{\Lambda} \tag{6}$$

Where $\Lambda$ is plastic loading index.

The plastic modulus at image stress state in the proposed model is

$$\begin{aligned}\bar{K}_p=&bp\left[\frac{v_0}{\lambda-\kappa}p_0\left(M^2-\frac{3}{2}\alpha_{ij}\alpha_{ij}\right)+3\mu\left(bs_{ij}-p_0\alpha_{ij}\right)\left(\frac{3s_{ij}}{4p}-\alpha_{ij}\right)\right]\\ &\times\left[\left(M^2-\frac{3}{2}\alpha_{kl}\alpha_{kl}\right)(2bp-p_0)-3b\left(s_{kl}-p\alpha_{kl}\right)\alpha_{kl}\right]+3b^2p\mu\beta\\ &\left(bs_{ij}-p_0\alpha_{ij}\right)\left(\frac{s_{ij}}{3p}-\alpha_{ij}\right)\left[6\left(s_{kl}-p\alpha_{kl}\right)\left(s_{kl}-p\alpha_{kl}\right)\right]^{\frac{1}{2}}\end{aligned} \tag{7}$$

The plastic modulus at current stress state in the proposed model is obtained by interpolation method as

$$K_p=\bar{K}_p+\frac{v_0}{\lambda-\kappa}p_A R_{ij}R_{ij}\left(\frac{l}{<r_0-sb>}\right)^W \tag{8}$$

Where $P_A$ is variable related to the value of plastic modulus, $R_{ij}$ is gradient of plastic potential, *s* denote the size of elastic zone, *W* is positive constant[8].

**The parameter sensitivity analysis**

The proposed model involves 9 material parameters. The parameters $\lambda$， $\kappa$， $\nu$， $M$, $p_0$ can be determined in a standard process from triaxial and oedometer tests, bounding surface configurations($W$, $P_A$), these parameters can be determined as proposed by Ling, anisotropic parameters($\beta$， $\mu$) can be determined as proposed by Wheeler. Various value of variable $P_A$ was taken($P_A$=200，$P_A$=2.0E4) to investigate the function of $P_A$.

The required model parameters are listed in Table 1.

Table1. Parameters in simulations of undrained triaxial cyclic test

| $\lambda$ | $\kappa$ | $\nu$ | $M$ | $\mu$ | $\beta$ | $W$ | $p_0$/kpa | $P_A$ |
|---|---|---|---|---|---|---|---|---|
| 0.17 | 0.034 | 0.3 | 1.1 | 15 | 0.6 | 2 | 600 | 200/2.0E4 |

The dynamic load in simulations is the positive and negative alternating load, as shown in Fig.1.

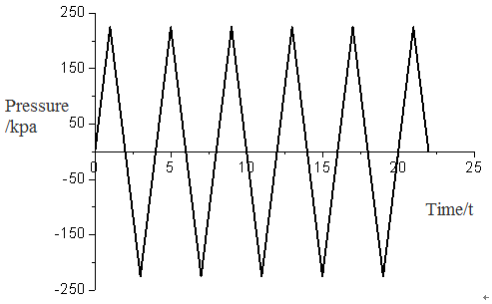

Fig.1 The dynamic load in test

If $P_A$=200，the effective stress path curve and stress-strain curve of soft clay of the simulations are shown as Fig.2 and Fig.3.

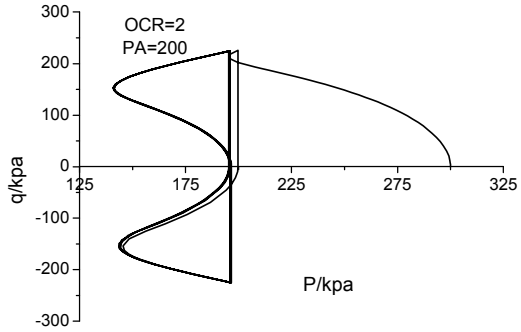

Fig.2. Numerical simulation of the effective stress path of soft clay ($P_A$=200)

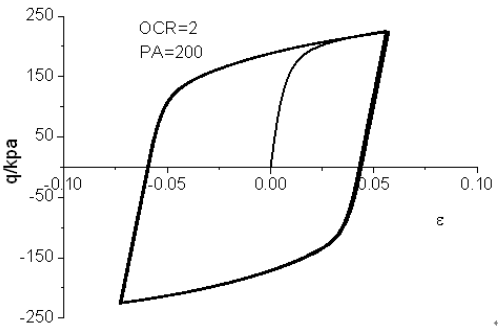

Fig.3. Numerical simulation of the stress-strain of soft clay ($P_A$=200)

Fig.2 and Fig.3 show the results of numerical simulations of undrained triaxial cyclic test on soft clay with $P_A$=200. According to equation (10), the simulation results show the plastic modulus of soft clay is small and the hysteresis loops is large. Larger strain of soft clay is produced compared with the actual deformation of soft clay. So the simulation results do not reproduce the actual dynamic characteristics of the soft clay with $P_A$=200.

If $P_A$=2.0E4，the stress path curve and stress-strain curve of soft clay of simulations are shown as Fig.4 and Fig.5.

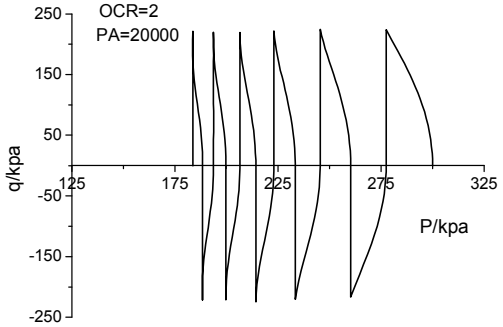

Fig.4. Numerical simulation of the effective stress path of soft clay ($P_A$=2.0E4)

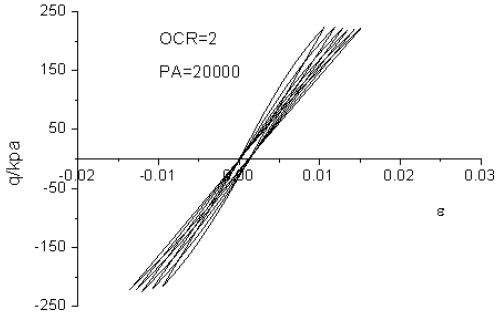

Fig.5. Numerical simulation of the stress-strain of soft clay ($P_A$=2.0E4)

Fig.4 and Fig.5 show the results of numerical simulations of dynamic properties on soft clay with $P_A$=2.0E4. The simulation results show the effective mean stress decrease and inclination increase of hysteresis loops of soft clay. It means the stiffness of soft clay decrease and soft clay become softening. It can be seen the simulation results reasonably agree with practical response behavior of soft clay under dynamic load with $P_A$=2.0E4.

## Conclusions

An anisotropic constitutive model, based on the critical state concept and bounding surface plasticity, has been developed to simulate the dynamic properties of soft clay under cyclic loading. The proposed model is programmed in ABAQUS software by writing UMAT subroutine, which is integrated in Return Mapping Algorithm. The parameter sensitivity analysis is implemented on plastic modulus. The proposed model is suitable to reproduce dynamic behavior of soft clay.

# Construction Methods for Long-span and Bifurcation Tunnel Structure

Chunlei Xin[1,a], Bo Gao[1,b]

[1]Key Laboratory of Transportation Tunnel Engineering, Ministry of Education, Southwest Jiaotong University, Chengdu, Sichuan 610031, China

[a]raymond_xin@qq.com, [b]prgaobo@home.swjtu.edu.cn

**Keywords:** Tunnel Engineering, Long-span Tunnel, Bifurcation Tunnel, Numerical Simulation, Construction Methods.

**Abstract.** Long-span and bifurcation tunnel engineering is not very common in underground engineering field. It is difficult to construct this complicated structure because of numerous influencing factors. In order to find out the optimum construction method for long-span and bifurcation tunnel to guarantee construction security and stabilization of this project, six construction methods were compared and analyzed by using numerical simulation. The results show that: (1) The excavation of confluence segment and small interval tunnel can affect each other but the confluence segment is the crucial part of the whole project. (2) The vertical brace determines the stabilization of surrounding rock and preliminary support in confluence segment. (3) The central concrete between main tunnel and ramp tunnel is the key point to guarantee the construction security and stabilization of small interval tunnel. The above results certainly contribute to research and develop new types of construction methods for long-span and bifurcation tunnel engineering.

## Introduction

Tunnel and underground structures excavation can cause surrounding rock geostress redistribution. Therefore, construction methods of tunnel structures have significant effects on tunnels stabilization and ground subsidence [1]. Normally, tunnel cross-section is divided into several parts to excavate. Thus, different construction procedures can lead to surrounding rock loads acting on tunnel structures in different ways [2]. Ground subsidence and ground buildings destruction may happen after tunnel excavation, especially for the complicated long-span and bifurcation tunnel structures [3]. Therefore, it is of great significant for researching the tunnel structures excavation stabilization. Currently, a great many research results about construction methods mostly base on ordinary tunnel structures [4]. It is quite rare to see the research results about construction methods for long-span and bifurcation tunnel structures. This paper introduces and compares six construction methods for long-span and bifurcation tunnel structures and selects the best one. The key procedure of the best construction method is pointed out and optimized. Finally, the surrounding rock plastic zone and geostress together with preliminary support deformation characteristics are analyzed and the corresponding technical countermeasures are put forward.

## The project background and characteristics

This research bases on the Chongqing Renhechang highway tunnel project and focuses on the bifurcation segment. The bifurcation tunnel ichnography is shown in Fig.1. The bifurcation segment is composed of separation tunnel, small interval tunnel, confluence segment, amplification cavern and main tunnel. The main features of this bifurcation tunnel project are as follows: (1) The fragmentized granite is the main surrounding rock and it has bad self-stabilization; (2) This project is shallow buried tunnel structure, the buried depth of the whole tunnel is approximately 14.2-24.5m; (3) The maximum required ground subsidence is 30mm but it is difficult to achieve because of the complicated construction methods and the poor engineering geologic conditions; (4) The excavation span changes greatly in the construction process. The main tunnel excavation span is 16.23m; the

ramp excavation span is 10.50m; the confluence segment excavation span is 27.80m. The cross-sectional profile of bifurcation tunnel is shown in Fig.2.

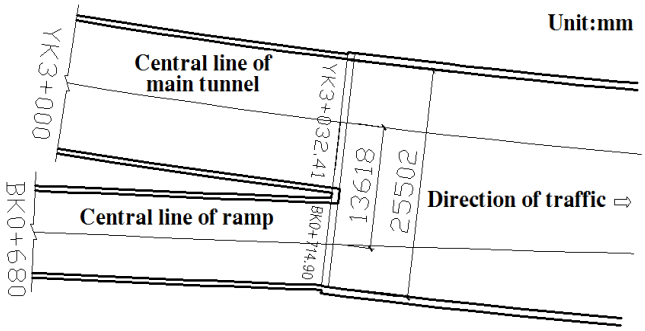

Fig.1 Ichnography of bifurcation tunnel

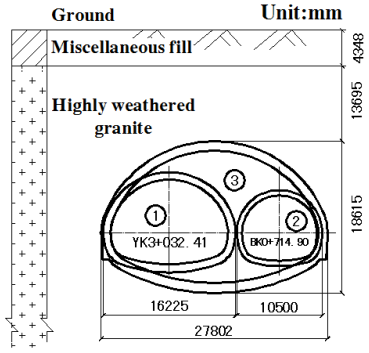

Fig.2 Cross-sectional profile of bifurcation tunnel

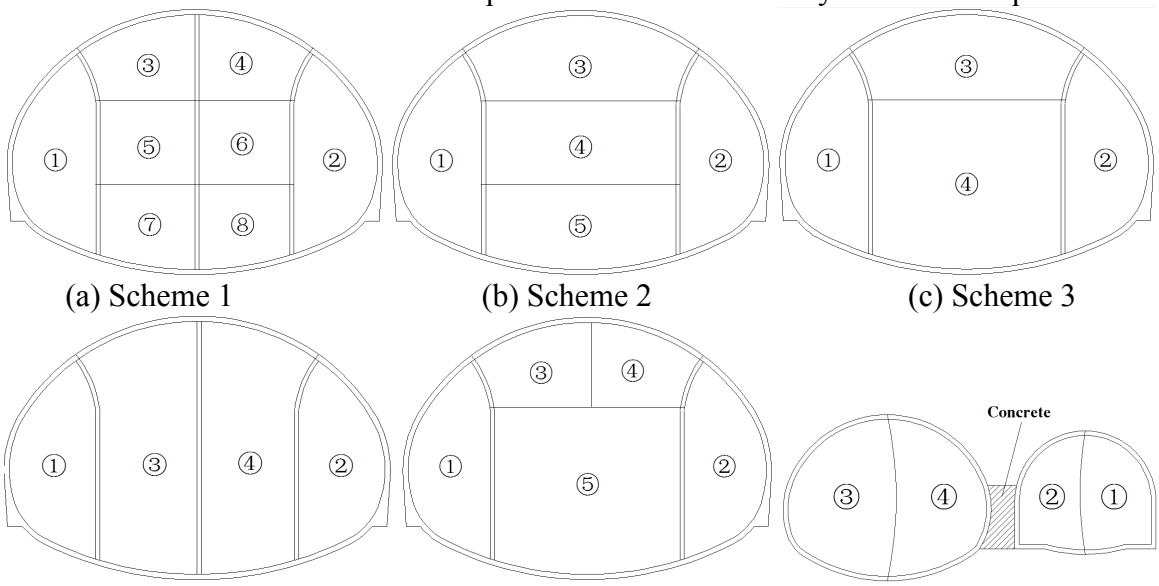
## Comparison and selection for construction methods

Bifurcation segment construction is the emphases and difficulty of this tunnel project. In order to ensure construction security, six construction methods are proposed to optimize. Fig.3 shows these six construction methods and construction procedures are followed by numerical sequence.



(a) Scheme 1 (b) Scheme 2 (c) Scheme 3

(d) Scheme 4 (e) Scheme 5 (f) Scheme 6 (small interval tunnel)

Fig.3 Different construction methods and construction sequence

**3-dimensional numerical model.** The entire numerical model size is X×Y×Z = 300×50×120m$^3$ (shown in Fig.4). Moreover, the scope of small interval separation tunnel is Y=0-25m and the scope of confluence segment is Y=25-50m (shown in Fig.5). The distance between tunnel central point and left or right boundary is more than 3-5 times as long as the tunnel diameter. The upper boundary is ground and the distance between bottom boundary and tunnel central point is 80m. All these boundaries setting can guarantee the accuracy of calculation results. The whole numerical model is comprised of 163600 solid elements and 181818 nodes.

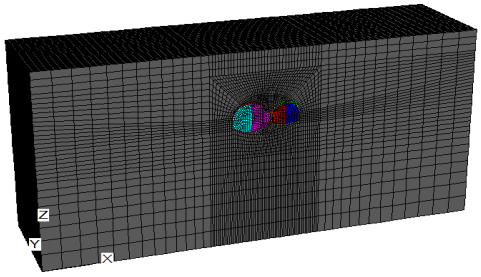


Fig.4 The entire numerical model

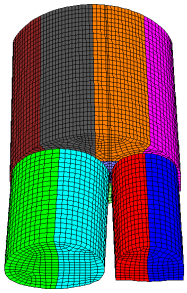

Fig.5 Numerical model of bifurcation segment

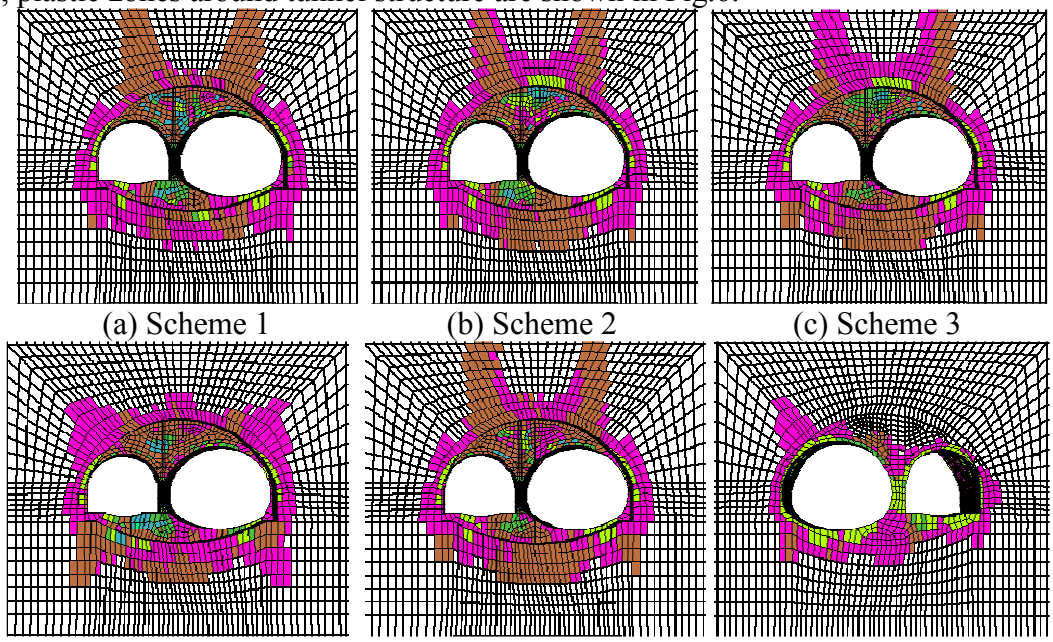
**Calculation parameters.** The physics and mechanics parameters of surrounding rock are listed in Table 1. Where, *B* is bulk modulus, *S* is shear modulus, *F* is friction angle, *C* is cohesive strength and *D* is density.

Table.1 Physics and mechanics parameters of surrounding rock

| Surrounding Rock | *B*/MPa | *S*/MPa | *F*/° | *C*/MPa | *D*/kgm$^{-3}$ |
|---|---|---|---|---|---|
| Miscellaneous fill | 5.6 | 1.23 | 20 | 0.005 | 2000 |
| Highly weathered granite | 1100 | 400 | 25 | 0.1 | 2500 |

## Calculation results analysis and construction method optimization

**Plastic zones of surrounding rock.** The scope and position of surrounding rock plastic zones can be used to evaluate the effects of construction methods. After using different construction methods to excavate, plastic zones around tunnel structure are shown in Fig.6.



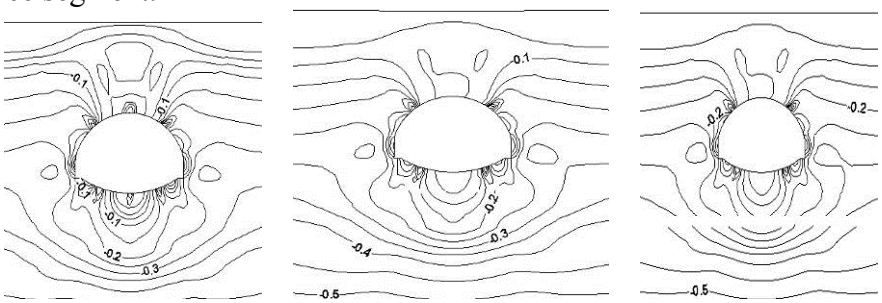
(a) Scheme 1 (b) Scheme 2 (c) Scheme 3

(d) Scheme 4 (e) Scheme 5 (f) Scheme 6 (small interval tunnel)

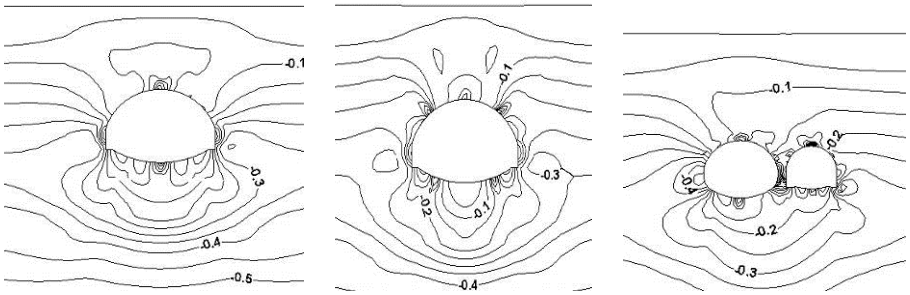
Fig.6 Plastic zones of excavated tunnel by using different construction methods

The plastic zone of scheme 4 is obviously smaller than other schemes, especially at tunnel crown place. But plastic zone on tunnel arch shoulder is approximately 5-6m. However, plastic zones of other schemes are quite similar. There are quite obvious plastic zone belts at crown place of main and ramp tunnel. As for the small interval tunnel, large plastic zone appears on central concrete wall.

**Geostress of surrounding rock**. Fig. 7 is maximum principal stress isolines of surrounding rock around confluence segment.



(a) Scheme 1 (b) Scheme 2 (c) Scheme 3



(d) Scheme 4 (e) Scheme 5 (f) Scheme 6 (small interval tunnel)

Fig.7 Maximum principal stress of tunnel by using different construction methods (Unit: MPa)

Stress concentration appears on tunnel side wall and arch springing, regardless of which method is used. Therefore, it is necessary to strengthen support of these parts during the process of construction. However, stress concentration appears on tunnel crown and invert when scheme 4 is used, because the vertical brace hinders surrounding rock deformation. Moreover, it is quite obvious that stress concentration appears on central concrete of small interval tunnel. It means that tunnel stabilization can be obtained by enlarging scope of central concrete and strengthening advanced support.

**Deformation characters of preliminary support.** Table 2 shows deformation characters of preliminary support when using different construction methods. Although preliminary support deformation largely unaffected by construction methods, the advantage of scheme 4 is obvious.

Table 2 Maximum preliminary support displacement by using different construction methods

| Displacement of prelimenary support | Scheme 1 | Scheme 2 | Scheme 3 | Scheme 4 | Scheme 5 |
|---|---|---|---|---|---|
| Maximun vertical displacement/mm | -37 | -39 | -38 | -32 | -39 |
| Maximun convergence displacement /mm | 11 | 11 | 11 | 10 | 11 |

## Conclusions

The excavation of confluence segment and small interval tunnel can affect each other but the influence of confluence segment excavation plays a dominant role. Scheme 4 is more suitable for confluence segment construction than other schemes, because plastic zone is smaller and geostress is lower than using other schemes. The vertical brace in scheme 4 determines stabilization of surrounding rock and preliminary support. The central concrete between main tunnel and ramp tunnel is the key point to guarantee the construction security and stabilization of small interval tunnel.

**Keywords:** Shield tunnel method; time-varying effect; shrinkage and creep effect; displacement

**Abstract.** In order to survey the time-varying effect on shield tunnel lining structure, rigidity reduce in the Homogeneous Ring Design Theory is introduced. There are three methods to evaluate the rigidity reduction caused by the aging effect. The first is the bending rigidity analysis method, which considers that the bending rigidity changes with the time-dependent stress and strain. The second is the method named the equivalent moment of inertia; the last is aging coefficient method. With the Homogeneous Ring Design Theory, the internal forces and displacement of the shield tunnel segment lining can be calculated. Based on the preliminary results, using the 1st method, the reduced rigidity and the long-time displacement at different instants of time can be calculated. It is found that the concrete shrinkage and creep effect can't be ignored in the segment design. The survey is beneficial to monitor the deformation of tunnel lining, and the maintenance of the segments. It will make the tunnel work steadily and safely during the using period.

## Introduction

With the economy developing, technology improving and urban land decreasing, underground structures are rocketing. The construction of the shield tunnel has stepped into a peak stage in China. Shield tunnel design theories are also developing rapidly. How to make the design model in line with the actual situation is a research hot spot [1].

Shield tunnel lining structure is composed of concrete segment. As we all known, the shrinkage and creep effect is a general characteristic of concrete, which have great influence on the structure. It has both positive aspects and the negative aspects. For the beneficial aspects, in some cases the shrinkage and creep effect is helpful to prevent the formation of crack, reduce the stress concentration phenomena and the temperature stress, etc. For the negative aspects, it will make the structural deformation and flexural deflection increase. In the prestressed concrete, the effect will cause the loss of prestress[2]. So it becomes very necessary to define the degree of the adverse effect to the segment ring structure. The creep and shrinkage of concrete is closely related to the time and environment, and the creep is in connection with load age and the cross section stress. For the reinforced concrete structure, the creep is also influenced by the reinforcement ratio [3].

## Method of the Long-term Stress and Strain Calculation

**Internal force analysis of tunnel lining structure.** As known to all, the stress is a response of the external force. So if we want to make it clear that how the stress and strain will distribute under the long-term load, the first thing we must do is to calculate the inner force on the structure. According to the characteristics of underground structure design in China, the tunnel design model is divided into four kinds: the experience analogy model, the load-structure model, the stratum structure model, the convergence limit model. Among all these models, the load-structure model is the most widely used. For it is featured by less complexity or effort. What's more, it has clear mechanical concepts and clear safety factor evaluation method [4,5,6]. The homogeneous ring method is one representative of the load-structure model, and it is the most commonly used. It defines the lining structure as a uniform circle, and it does not consider the location of the joint. Curved beam element is applied to simulate the lining ring. All of the assumptions make the calculation of the model simpler and more convenient. Not only the method has those advantages, but also the calculation results can meet the

needs of the project. All the characters make the method widespread in the segment design [7]. The inner force of the structure that calculated by the homogeneous ring method can be consulted in the *Tunnel Standard Specification (on Shield tunnel)* [8].

**Long-term stress and strain of eccentrically compressed members.** As the specification above described, the inner force loaded on every section is a combination of bending moment $M$ and axial force $N$. This type of the load effect will make the curved beam element bearing eccentric force. So we consider the tunnel lining structure as an eccentric compression member. The paper titled *the long-term effect of creep and shrinkage of reinforced concrete structures* [9]mainly studies on the calculation of long-term stress and strain in different structure forms bearing different loading forms. The article describes detailedly what effect creep and shrinkage have on the eccentric component. The general idea is that the force of eccentric component separately be treated as a superposition of the axis force and pure bending moment, as shown in Fig.1. We can easily calculate the stress $\sigma(t_0)_N$ , $\sigma(t_0)_M$ and strain $\varepsilon(t_0)_N$ , $\varepsilon(t_0)_M$ for the initial loading times. As to the calculation of the stress and strain with a long-term load, the author established the strain full amount recursive expression which bases on the theory of creep recovery. In the process of analysis and calculation, we can obtain the increment of the stress and strain step by step at the time of $t_i = t_1, t_2, t_3 \cdots\cdots$. The changed value of stress and strain at different times can be calculated at last.

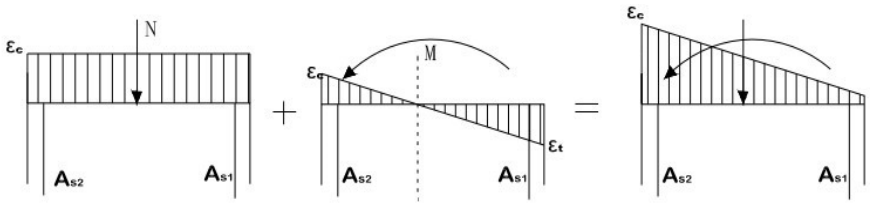

**Fig.1 Strain superposition of section**

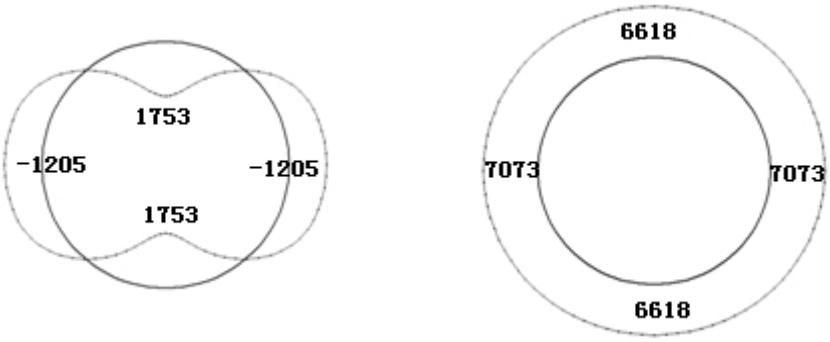
## Example Analysis

**Background and engineering conditions of the project.** Shanghai Yangtze river tunnel project is one of the major infrastructure construction projects in Shanghai or even in China. The design reference period is 100 years. It is designed according to the standard of two-way six-lane highway, and constructed by shield method. The inner diameter of the tunnel is 13.7 meters, outer diameter is 15.0 meters. Each ring is composed of 10 pieces of segments, the width of which is 2 meters. The inside reinforcement area $A_{s1} = 11084mm^2$, $\rho_1 = 0.85\%$, outside $A_{s2} = 5458mm^2$, $\rho_2 = 0.42\%$. In order to validate the bearing capacity and stability of the lining segment to assurance the stress and deformation under construction loads, Tongji University conducted a test on the whole ring with a scale of 1:1. The test applied loads on the model, which simulated the different buried depth and different pressure coefficient. At the same time, the experimenters measured the internal force and bending moment value under various working conditions[10].

**Internal force and deformation based of the lining structure.** The working condition of the structure is as follow. The thickness of earth-fill cover is 29 m, and the coefficient of horizontal pressure is 0.68. As the load and the structure are symmetrical, we can just do mechanical analysis on a quarter of the circle structure. We use straight beam (shell) unit to simulate the segment ring.The strength classes of concrete is C50, whose elastic modulus $E_c = 3.45 \times 10^7 kPa$. According to the computing theory of homogeneous circle model, we obtain the curve of internal force diagram as shown in Fig.2.



a) Bending moment /kN·m b) Axial force /kN

**Fig.2 Internal force based on homogeneous circle theory**

**Time-depend bending rigidity and deformation.** Seeing the results of the internal force, we know that the tunnel structure belongs to the eccentrically compressed members**,** so we can use the analysis method mentioned above to analyze the performance of shield lining under long-term load. According to the principle of minimum stiffness theory and the result of bending moment, the lining structure can be divided into two parts-the positive bending moment part and the negative bending moment part, which differ from the bending rigidity. The rigidity of the section, which accords with the maximum positive bending moment ( $M^{+}_{\max}$ ), is regarded as the rigidity of the positive bending moment part. The rigidity of the section, which accords the corresponding of the minimum negative bending moment ( $M^{-}_{\max}$ ),is regarded as the rigidity of positive bending moment part. Considering the different rigidity we can calculate the corresponding total vertical deformation $\Delta_v$ and total horizontal deformation $\Delta_h$ at the moment of 1 year, 3 years and 10 years. The equivalent rigidity coefficient $\eta^t$ can be obtained comparing the theoretical deformation value with the calculated deformation using different reduction factor values (0.8, 0.7, 0.6……) on the base of the principle of minimum stiffness theory. The results are shown in Table 1. (The relative humidity is 75%).

**Table 1. Total Deformation and Rigidity Coefficient**

| Time | Bending rigidity [$\times 10^{14}$N·mm$^2$] | | $\Delta_v$ [mm] | $\Delta_h$ [mm] | Rigidity coefficient $\eta^t$ |
|---|---|---|---|---|---|
| | $M^{+}_{\max}$ | $M^{-}_{\max}$ | | | |
| $t_0$ | 11.16 | 15.14 | 46.20 | 37.44 | 0.80 |
| t=1 year | 10.11 | 13.77 | 50.75 | 41.56 | 0.74 |
| t=3 years | 9.68 | 13.13 | 52.93 | 43.54 | 0.70 |
| t=10 years | 9.58 | 13.00 | 53.46 | 44.00 | 0.69 |

**Stiffness degradation effect and the deformation analysis.** Based on the results shown in Table 1, the curve of the flexural stiffness and total deformation respectively are shown in Fig.3.

Fig.3 suggests that the cross section rigidity's degenerate, which is the negative impact of shrinkage and creep effect. It shows that the rigidity tends to be basically stable a decade later. In order to take this negative condition into account, we introduce a rigidity reduction factor, whose value is 0.69, in the design of homogeneous ring method. The factor is a comprehensive one, which not only considers the joint's weakening effect on the ring, but also considers the rigidity degradation caused by the shrinkage and creep effect. The displacement diagram shows that the shrinkage creep deformation of shield tunnel lining structure grows rapidly in the first three years and much slowly later. The shrinkage and creep deformation will accomplish in 10 years and remain basically stable then. From the deformation results we find that the increased deformation, which caused by the concrete creep and shrinkage effect, will reach 16.5% of the initial deformation.

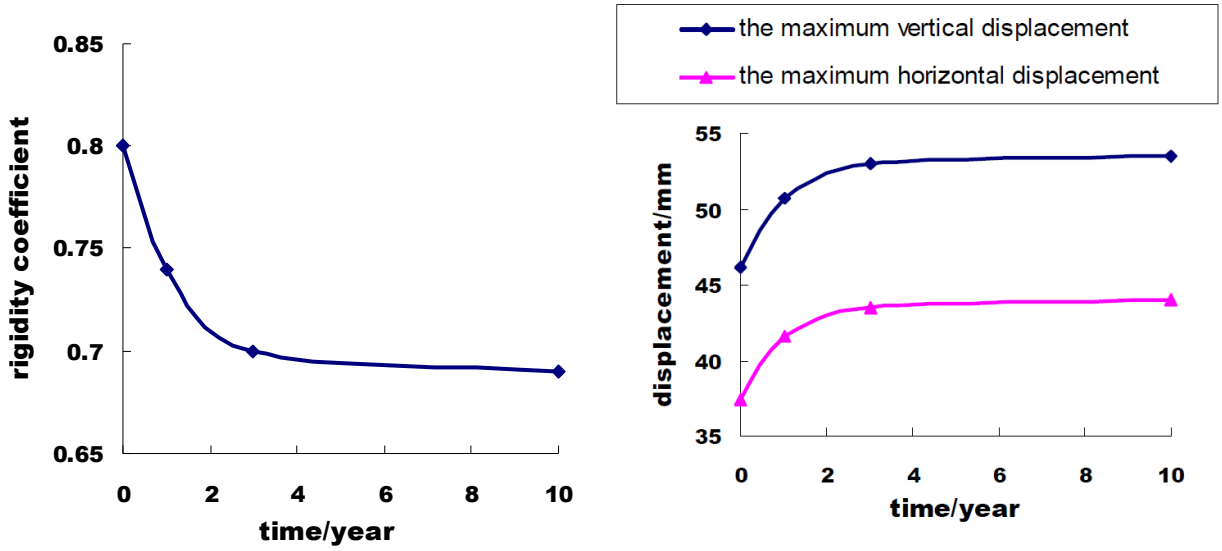


**Fig.3 Changed rigidity and displacements with time**

## Conclusions

1. The concrete shrinkage and creep's influence on segment deformation is large. It is one of the main factors contributing to the increase of the deformation, and can't be ignored in design.

2. The deformation of the first three years will achieve 98.87% to the final deformation. The deformation curve shows that the shrinkage and creep effect has bigger impact on the structure in the first three years. The influence is basically stabilizing later.

3. The shrinkage and creep effect will weaken the rigidity.To match the design result with actual situation up more closely, we recommend using the value of the rigidity at the tenth year in the design of homogeneous ring method.

4. In the first 3 years, we should monitor the deformation of the segment frequently, especially in the vertical and horizontal location. In order to guarantee the tunnel operates safely, measures should be taken to avoid a large displacement.

**Keywords:** Tunnel in south China; Health diagnosis; Post-earthquake; Analytical hierarchy process

**Abstract:** In order to evaluate the health condition of the tunnel in South China and give advices on reinforcement and maintenance scheme, a post-earthquake health diagnosis method is presented. After a comprehensive investigation on failure modes of tunnel, a four-level ranking method and a index system for post-earthquake health diagnosis of highway tunnel are proposed. Besides, analytical hierarchy process (AHP) is introduced into for determining the post-earthquake health diagnosis mode. Case study manifests the validity of the proposed method, which can provide valuable guide to the post-earthquake health diagnosis and relief work.

## Introduction

Many tunnels have been built across the mountains in south of China, and would be important lifeline if earthquake happens for its outstanding aseismatic performance. However, some damage appearances are also found in some tunnels after earthquake [1, 2]. In order to avoid hidden danger, it is necessary to provide a valid post- earthquake health diagnosis method for tunnel.

The health condition of those tunnels in the region of South China is affected by high temperature, heavy precipitation and special geology and geomorphology. However, there is no diagnosis method on post-earthquake health diagnosis for these tunnesls. In this paper, an analytical hierarchy process (AHP) based health diagnosis method is established, in which the index limits were decided by norms and engineering experience.

## AHP for post-earthquake health diagnosis of tunnel

The procedure of health diagnosis method for tunnel in South China is presented in Fig. 1, which is based on AHP method. The key steps are consisted of construction of hierarchy analysis, determination of index weight, redistribution of index weight, comprehensive grading and health level judgment.

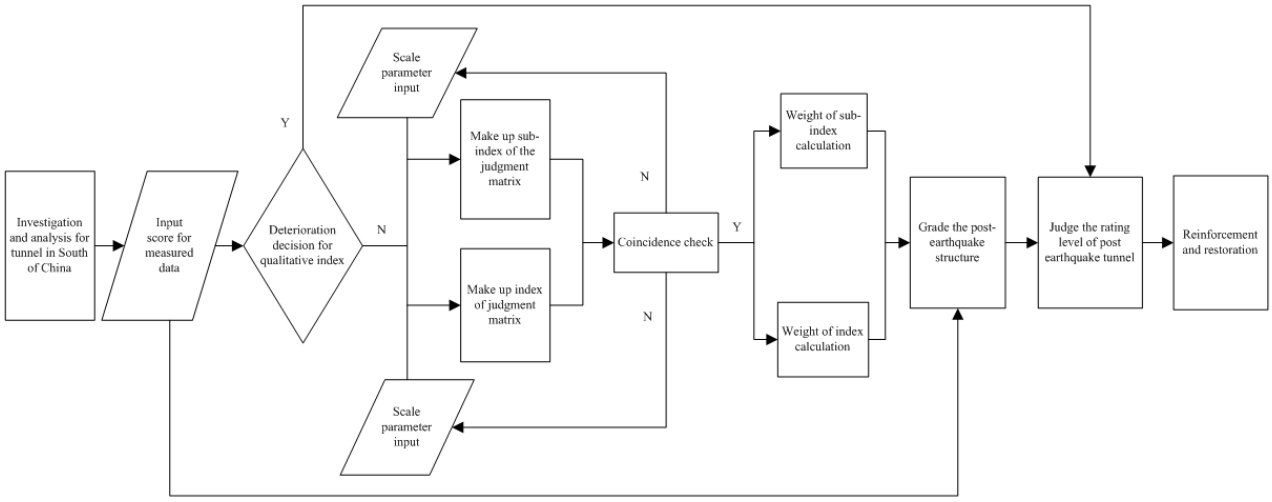

Fig. 1 Procedure of the health diagnosis

## 2.1 Hierarchy analysis structure

According to the tunnel characteristics in South China, an AHP structure is established, in Fig. 2. It is composed of four levels: the target, the index level; the sub index level, scheme level.

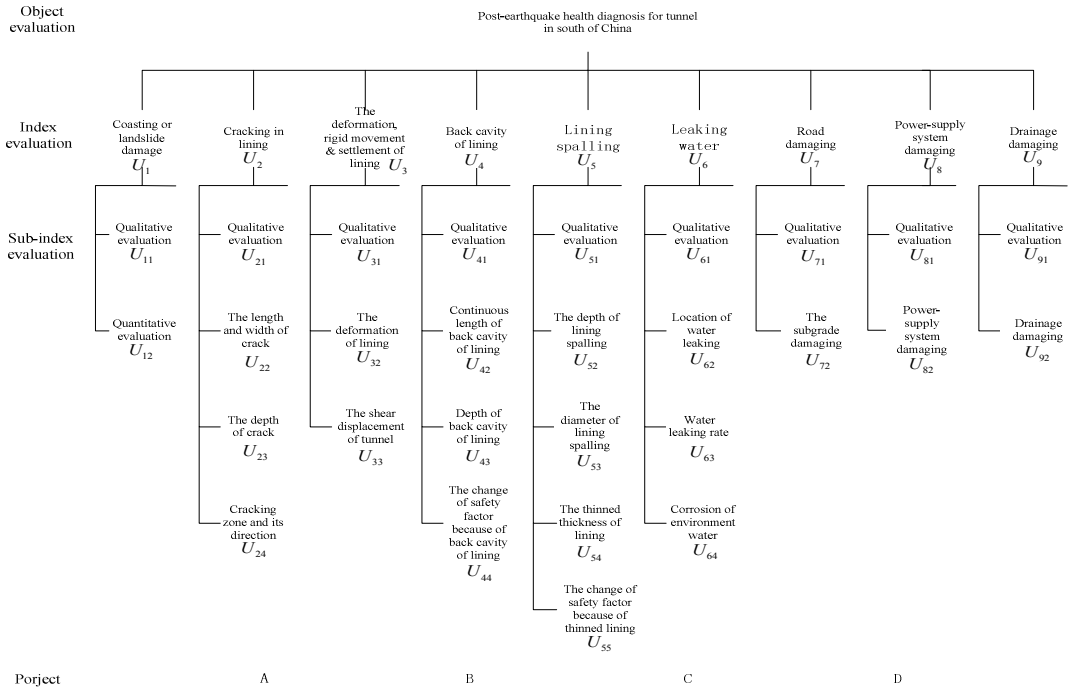

Fig. 2 Analytical hierarchy structure

## 2.2. Index weight

Index weight and sub index weight can be achieved by formulating judgment matrix, calculating its max eigenvalue and the corresponding eigenvector. The judgment matrix can be developed through comparison of each element in the same level and decision of the importance relative to superior level using scaling method. Now, the 10/10~18/2 scaling method is adopted to construct the judgment matrix [3].

$$A=\begin{bmatrix} W_1/W_1 & W_1/W_2 & \cdots & W_1/W_n \\ W_2/W_1 & W_2/W_2 & \cdots & W_2/W_n \\ \vdots & \vdots & \ddots & \vdots \\ W_n/W_1 & W_n/W_2 & \cdots & W_n/W_n \end{bmatrix} \quad (1)$$

Post-multiply the weight W by matrix A and the weight W of each element in matrix A can be derived

$$AW = nW \tag{2}$$

Where, $n$ is the matrix order. The maximum of the eigenvalue in Eqn. (2) is $\lambda_{max}=n$ except that all the other eigenvalues equal zero. In order to guarantee the rationality of the health diagnosis result, the consistence of judgment matrix A should be checked, which can be realized by introducing random consistence ratio CR.

$$CR = CI / RI \tag{3}$$

Where, $CI$ is the index for matrix consistence judgment, $CI = (\lambda_{\max} - n)/(n-1)$, $\lambda_{\max}$ is the maximum of all eigenvalues, $n$ is the order of judgment matrix; $RI$ is the average random consistence index of the same level, as shown in Table 1.

Table 1 Random consistency index

| n | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9 |
|---|---|---|---|---|---|---|---|---|---|
| RI | 0.00 | 0.00 | 0.58 | 0.90 | 0.12 | 1.24 | 1.32 | 1.41 | 1.45 |

According to the investigation conducted by Huang[4], the index weight and sub index weights are proposed as follows.

(1) Index weight

$$W = (W_{u1} \quad W_{u2} \quad W_{u3} \quad W_{u4} \quad W_{u5} \quad W_{u6} \quad W_{u7} \quad W_{u8} \quad W_{u9})$$
$$= (0.0715 \quad 0.2860 \quad 0.1907 \quad 0.0715 \quad 0.0715 \quad 0.1226 \quad 0.1226 \quad 0.0318 \quad 0.0318)$$

(2) Sub index weight

Coasting or landslide damage: $W_{u1} = (W_{u11} \quad W_{u12}) = (0.5000 \quad 0.5000)$

Cracking in lining: $W_{u2} = (W_{u21} \quad W_{u22} \quad W_{u23} \quad W_{u24}) = (0.2000 \quad 0.3000 \quad 0.2000 \quad 0.3000)$

The deformation, rigid movement & settlement of lining:

$W_{u3} = (W_{u31} \quad W_{u32} \quad W_{u33}) = (0.3333 \quad 0.3333 \quad 0.3333)$

Back cavity of lining: $W_{u4} = (W_{u41} \quad W_{u42} \quad W_{u43} \quad W_{u44}) = (0.2222 \quad 0.3332 \quad 0.2222 \quad 0.2224)$

Lining spalling: $W_{u5} = (W_{u51} \quad W_{u52} \quad W_{u53} \quad W_{u54} \quad W_{u55}) = (0.1666 \quad 0.2498 \quad 0.2498 \quad 0.1669 \quad 0.1669)$

Leaking water: $W_{u6} = (W_{u61} \quad W_{u62} \quad W_{u63} \quad W_{u64}) = (0.2999 \quad 0.2999 \quad 0.2001 \quad 0.2001)$

Road damaging: $W_{u7} = (W_{u71} \quad W_{u72}) = (0.4000 \quad 0.6000)$

Power-supply system damaging: $W_{u8} = (W_{u81} \quad W_{u82}) = (0.4000 \quad 0.6000)$

Drainage damaging: $W_{u9} = (W_{u91} \quad W_{u92}) = (0.4000 \quad 0.6000)$

### 2.3. Redistribution of index weight

In consideration of labor and equipment, some judgment indexes cannot be obtained. Accordingly, their weights have to be eliminated; that is to say the index weight should be redistributed as follow.

$$W_{ij} = W_{ij} / \sum_{j=1}^{n} W_{ij} \tag{5}$$

### 2.4. Total score with multi-index and evaluation of health level

The total score is acquired by adding each element multiplied by its index weight:

$$S_{sum} = \sum_{i=1}^{n} \sum_{j=1}^{m_i} W_i \times W_{ij} \times S_{ij} \tag{6}$$

Where, $S_{sum}$ is the total score; $n$ is the number of index; $m_i$ is the number of sub index for each index; $W_i$ is the index weight; $W_{ij}$ is the sub index weight; $S_{ij}$ is the score of sub index.

The sub index grading rules are that the range of $S_{ij}$ is from 1 to 4 for the four conditions: extremely serious condition, serious condition, relative serious and ordinary condition. When the sub index $U_{ij}$ cannot be obtained, $S_{ij}$ is 0. The total score $S_{sum}$ is directly set to be 1 when a tunnel is evaluated to in extremely serious condition by those qualitative indexes.

The health level can be determined according to the value of $S_{sum}$, *as* shown in Table 2.

Table 2 Health level according to $S_{sum}$

| Level | Extremely serious | serious | relatively serious | Ordinary |
|---|---|---|---|---|
| $S_{sum}$ | $1.0 \le S_{sum} \le 1.5$ | $1.5 < S_{sum} \le 2.5$ | $2.5 < S_{sum} \le 3.5$ | $3.5 < S_{sum} \le 4.0$ |

## Health classification

Four-level health classification (shown in Table 3) is adopted with considering of characteristics of tunnel in South China.

Table 3 Four-level health classification

| Level | Conclusion |
|---|---|
| A (extremely serious) | Damage condition is extremely serious. Tunnel should be stopped and reconstructed immediately. |
| B (serious) | Damage condition is serious. Tunnel may be removed or reconstructed according to its importance and service demand. |
| C (relatively serious) | Damage condition is relatively serious Tunnel can be is improved by rehabilitation |
| D (ordinary) | Damage condition is relatively minor. Tunnel can serve normally after rehabilitation. |

Health diagnosis should be conducted according to indexes. There are 9 indexes in the first floor, including coasting or landslide damage, cracking in lining, the deformation & rigid movement & settlement of lining, back cavity of lining, lining spalling, leaking water, road damaging, power-supply system damaging, drainage damaging, as shown in Fig.2. Among these indexes, the universal diagnosis indexes consist of lining crack width and length, lining thickness, lining deformation, displacement, sedimentation, lining back cavity, qualitative evaluation of lining delamination or spalling, quantitative evaluation of lining cross-section strength degradation, lining delamination or spalling, qualitative evaluation of leakage, water intrusion, water and sand emission on road surface[5, 6]. Meanwhile, with regard to the characteristics of tunnel in South China and its destruction mode after earthquake, special diagnosis indexes including qualitative and quantitative evaluation of entrance landslip and collapse, the deformation & rigid movement & settlement of lining, the shear displacement of tunnel, depth of back cavity of lining, the change of safety factor because of back cavity of lining, the thinned thickness of lining, the change of safety factor because of thinned lining, location of water leaking, location of water leaking, leakage flow rate, corrosion of environment water, qualitative evaluation of road damaging, quantitative evaluation of the subgrade damaging, qualitative and quantitative evaluation of power-supply system damaging, are added.

## Indexes and standards of characteristic diagnosis

The indexes and corresponding limits of diagnosis are as follows. For the index of entrance landslip and collapse, its evaluation index and standard can be achieved by statistics data of the cases including entrance landslip and rock collapse[5]. For the lining crack index, the crack depth evaluation index can be defined as the ratio k of crack depth[6]. Meanwhile the influences of lining thickness and the crack position and trend on the structure health should be considered during the establishment of evaluation index[7]. For the ultimate capacity index after earthquake, its evaluation index can be calculated through tunnel experiment data[8]. For the index of lining deformation, displacement, sediment, the evaluation index of lining displacement rate and shear displacement can be obtained depending on the related trade norm and model experiment[7]. For the lining back cavity index, the evaluation index of continuous length of back cavity of lining and cavity depth can be

determined depending on the related trade norm[9] and model experiment[10]. For the leakage index after earthquake, the evaluation index of leakage position can be determined through relevant studies[7], and the leakage flow rate index can be determined according to the Construction Industry Research and Information Association[11]. For road damage index, qualitative evaluation index can be acquired in reference with the emission of water and sand on the road surface[12] and qualitative evaluation of roadbed[13]. While the quantitative evaluation index can be determined based on *The restore guide for post-earthquake road in Wen Chuan* [14]. For the power supply and drainage index, the power supply evaluation index can be determined by the drop of rated voltage, and the sediment index[15] can be determined from the drainage index.

## Case study

Using the proposed diagnosis method, the Wendou highway tunnel survived from the Wenchuan earthquake was selected and evaluated. The health index marks are listed in Table 5.

Table 5 Grade for the health diagnosis parameters of Du-Wen highway tunnel

| Characteristic of earthquake damage [16] | | | Health index mark | | | | | |
|---|---|---|---|---|---|---|---|---|
| Dujiangyan head tunnel entrance | Wenchuan head tunnel entrance | Tunnel body | | | | | | |
| The shotcrete on side and face upward slope cracks, the crack width is about 30~100mm, (has not been construction) | The original entrance slope was strengthened with vertical anchor beams. The protection structures were not damaged seriously，but the vertical beam and the ground cracked generally. The right part without strengthening collapsed locally. | The lining cracks a lot which were mainly transversal and circular. The crack width is about 10~20mm, and some cracks were crisscrossed. The construction joints cracked, and its width were about 5~30mm. The inverse arch and filled part cracked and dislocated a lot. One inverse arch and filled part in the left and right tunnel respectively bugled and cracked, whose length reached 60m and the hump height was about 60cm | $S_{11}$ 2 | $S_{41}$ 0 | $S_{61}$ 0 | | | |
| | | | $S_{12}$ 0 | $S_{42}$ 0 | $S_{62}$ 0 | | | |
| | | | $S_{21}$ 2 | $S_{43}$ 0 | $S_{63}$ 0 | | | |
| | | | $S_{22}$ 1 | $S_{44}$ 0 | $S_{64}$ 0 | | | |
| | | | $S_{23}$ 0 | $S_{51}$ 0 | $S_{71}$ 2 | | | |
| | | | $S_{24}$ 1 | $S_{52}$ 0 | $S_{72}$ 1 | | | |
| | | | $S_{31}$ 1 | $S_{53}$ 0 | $S_{81}$ 0 | | | |
| | | | $S_{32}$ 2 | $S_{54}$ 0 | $S_{82}$ 0 | | | |
| | | | $S_{33}$ 1 | $S_{55}$ 0 | $S_{91}$ 0 | | | |
| | | | | | $S_{92}$ 0 | | | |

Substitute the each of the index mark $S_{ij}$ into equation(6), then the tunnel health condition mark can be calculated, as shown in Table 6.

Table 6 Health diagnosis for the post-earthquake Du-Wen highway tunnel

| Information about Douwen highway[16] | | The health diagnosis for tunnel in South China | | |
|---|---|---|---|---|
| Start and end stake number | Earthquake damage degree | Comprehensive mark | Evaluation level | Health evaluation |
| K13+385~K17+445（right line） | Serious damage | 1.43 | B | Serious |

The tunnel damage condition in Table5 are concluded from the field studies carried out by the authors and the documents given by Road Design Institution of Sichuan and Communications Design Institute of Sichuan. The evaluation results diagnosed by the health diagnosis for tunnel in South China coincides with the results given documents mentioned.

## Conclusion

The post-earthquake diagnosis indexes are established in consideration of the characteristics of the tunnel in South China. Using the AHP method, the comprehensive post-earthquake evaluation for highway tunnel in South China can be appropriately done. The traditional AHP method is improved by judging the stop factor to give the conclusion and redistributing the weight, which can fit the practical condition for the post-earthquake diagnosis of tunnel in South China. The evaluation results of Duwen highway tunnel diagnosed coincides with the results given by some survey documentations. The example shows that the proposed method can provide valuable information and advice for relief work.

# Numerical Analysis of Construction Method in Shallow-buried Large-section Loess Tunnel

Zhijie Sun[1, a]

Shanxi Key Laboratory of Highway Construction & Maintenance Technology in Loess Region, Key Lab of Highway Construction & Maintenance Technology in Loess Region, Shanxi Transportation Research Institute, Shanxi, Taiyuan, 030006

[a]chinasunzhijie@163.com

**Keywords:** Loess tunnel; Large-section; Construction Method; Deformation; Plastic Zone.

**Abstract.** To research the deformation regularity of large section loess tunnel in construction procession with different construction methods, 3D Numerical Simulation is applied and the large-section loess tunnel of highway is taken as an example. Comparing deformation regularity of surrounding rock in three types of construction method conditions, the research results show that: The CRD method takes precedence in the condition of the convergence of surrounding rock is large. The both sides heading method takes precedence in the condition of ground surface settlement is large.

## Introduction

Because of the large span highway tunnel's large cross section, the support structure will be under greater pressure of surrounding rock, which under the influence of more complex load condition and many other factors such as many processes interact during construction, repeated disturbance of surrounding rock and lining of supporting non-simultaneous construction. Which easily lead to surrounding rock collapse and tunnel lining crack. So the construction technology of highway tunnel with large cross section in a major research project shall be implemented at home and abroad.

Because of Bearing capacity of loess layer its own, while tunnel excavating can lead to large deformation easily, particularly when you first entered the cave complex geological condition of shallow-buried portal section not only, most of the time, with shallow, bias and other problems, which brought much risk to the construction safety[1,2].

According to the current construction techniques, excavation of tunnel with large cross section the choice of method is as follows: benching stepping method, CRD method, both sides heading method. This paper discusses the three types of whole process simulation of excavation scheme for construction, during excavation of tunnel surrounding rock deformation studies to find optimal construction method.

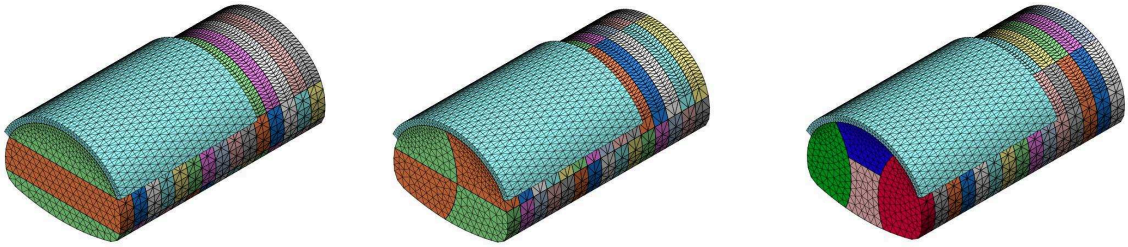
## Engineering Example

Tunnel stratum is the fourth group of upper Pleistocene Malan silt ($Q_{3m}$), In the lower strata is the fourth middle Pleistocene Lishi silty clay ($Q_{2l}$). The lower part of the Pleistocene Lishi is in the fourth group (Q2l) silty clay. The tunnel passes through the bottom of silty clay($Q_{2l}$). The

surrounding rock is classified as class V and class VI by Chinese national standard. The entrance of tunnel placed in the v-class surrounding rock on the hillside slopes in poor geological conditions, which stratum is Lishi loess and Quaternary group, Malan group recent deposits. The stability of surrounding rock is very poor, the construction is difficult and the design uses a pair of side wall heading method.

## Numerical Modeling

Plate elements simulate primary support of sprayed concrete. Solid elements simulate surrounding rocks and reinforced area. Beam elements simulate bolts. The numerical models with different construction methods are as follow in Fig.1.



(a)Benching stepping method (b)CRD method (c) Both side heading method

Fig.1 Three-dimensional simulation model

The constitutive model for rock and reinforced rock are all Mohr-Coulomb models. The primary support of sprayed concrete is elastic material. All material parameters are shown in Tab.1[3,4].

Tab.1 Material Parameters in Model

| Material | Modulus(GPa) | Poisson's | Density ($kg/m^3$) | Cohesive(kPa) | Internal friction angle($^o$) |
|---|---|---|---|---|---|
| Class Ⅴ Rock | 0.15 | 0.3 | 2120 | 91.8 | 35.24 |
| Reinforced Rock | 1 | 0.25 | 2300 | 200 | 45 |
| Primary Support | 27.4 | 0.2 | 2332.84 | — | — |

## Analysis Results

In order to simulate the clearance displacement regularity of surrounding rock with different construction methods, the displacement of the key points with the key parts of the different working conditions were monitored through the whole construction process.

The key points of tunnel section are as follow in Fig.2, in which the point A, B, D is vertical displacement points and the point B, C are horizontal displacement point.

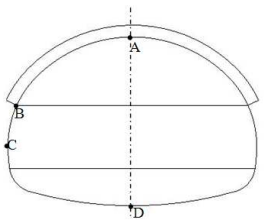


Fig. 2 The key displacement points diagram

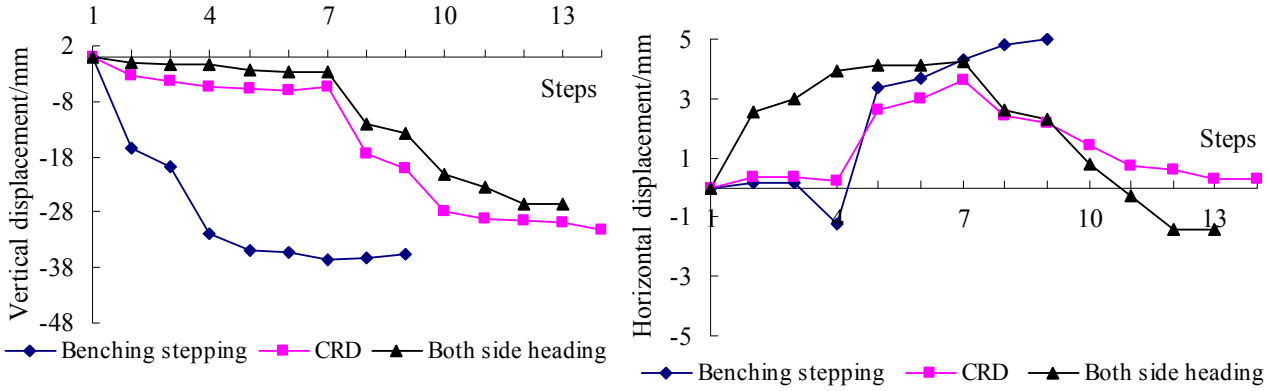
The vertical displacement and horizontal displacement curves through the whole construction process of key points with surrounding rock through the whole construction process in different

construction methods are shown in Fig.3. The position value means surrounding rock settlement, while the negative value means surrounding rock uplift.



(a) Vertical displacement of point A (b) Horizontal displacement of point C

Fig. 3 The displacement curves through the whole construction process

As shown in Fig.3(a), in the construction of benching stepping method, vault subsidence caused by excavating is growing fast, arch settlement occurs most before primary support. The vault subsidence caused by upper bench construction accounts for 46 percent of total settlement value.

As shown in Fig.3(a), in the construction of CRD method, vault subsidence caused by left side heading excavating is very small, while right upper side heading excavating it growing fast. After right lower side heading supported, the arch settlement tended to be stable. The vault subsidence caused by right side heading construction accounts for 37 percent of total settlement value.

As shown in Fig.3(a), in the construction of both sides heading method, vault subsidence caused by both sides heading excavating is very small, while middle upper side heading excavating it growing fast. After middle lower side heading supported, the arch settlement tended to be stable. The vault subsidence caused by middle side heading construction accounts for 55 percent of total settlement value.

The value of vault subsidence in the construction of both sides heading method is minimum, benching stepping method is maximum.

As shown in Fig.3(b), the regularity of horizontal displacement between CRD method and two-side heading method is similar, both are increase at first and reduce at last. Because of the level of the binding to support the surrounding rock, the horizontal displacement of CRD method is minimum. Because of a free surface is large caused by excavation for bench method, the horizontal displacement of benching stepping method is maximum.

The ground settlement curves in different construction methods are shown in Fig.4.

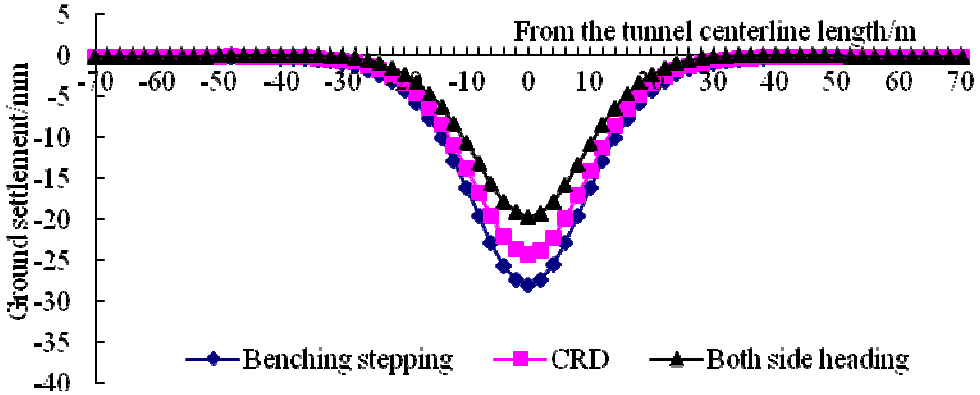


Fig. 4 The ground settlement curves in different construction methods

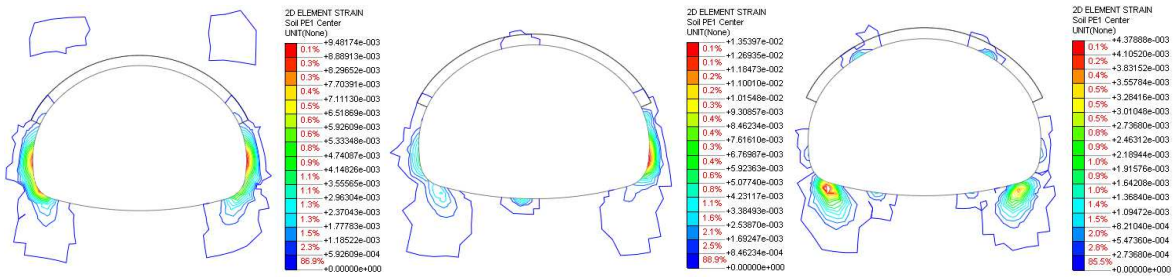
As shown in Fig.4, the max ground settlement with benching stepping method is 28mm, it decreases 24mm with CRD method, it decreases 20mm with both side heading method.

So while ground surface settlement is large, the both sides heading method takes precedence compare with the other two construction methods.

The final plastic zones in different construction methods are shown in Fig.5.



(a)Benching stepping method (b)CRD method (c) Both side heading method

Fig. 5 The plastic zone in different construction methods

As shown in Fig.5(a), in the construction of benching stepping method, the plastic zone occurred around from arch corner to wall side, also vault occurred. The surrounding rock's maximum plastic strain occurred in wall side. As shown in Fig.5(b), in the construction of CRD method, the main plastic zone occurred around from arch corner to wall side, also invert occurred. The surrounding rock's maximum plastic strain occurred in right wall side which construction later. As shown in Fig.5(c), in the construction of both sides heading method, the main plastic zone occurred around invert, stress concentrations appeared small plastic zone. The surrounding rock's maximum plastic strain occurred in both sides invert.

## Conclusions

Comparing deformation regularity and plastic zone of surrounding rock in three types of construction method conditions, the research results show that. The CRD method takes precedence in the condition of the convergence of surrounding rock is large. The both sides heading method takes precedence in the condition of ground surface settlement is large.

# Numerical Simulation of Effect of Foundation Pit Excavation on Underlain Shield Tunnel

Wei Gang*, Hu Ling-wei, Chen Kai-lei

Department of Civil Engineering, Zhejiang University City College, Hangzhou 310015, China

weig@zucc.edu.cn (*Corresponding author)

**Keywords:** foundation pit excavation; shield tunnel; finite element method; uplift

**Abstract:** In the background of a foundation pit excavation project on Yanan Road in Hangzhou City, this study simulated the excavation of foundation pit above an underground tunnel using 3D MIDAS/GTS software. The combined action of foundation pit, ground and tunnel were considered. The influence of foundation pit excavation on the deformation of underlain shield tunnel was evaluated and simulations were carried out on the effectiveness of different strengthening and control approaches. Results from the research showed that during the stages of piling and ground strengthening, settlement occurred at the tunnel; with the excavation of foundation pit, uplift deformation at the bottom of the foundation pit and the tunnel increased; with stricter strengthening and control techniques employed, the magnitude of uplift at the tunnel and bottom of the foundation pit reduced, suggesting that various control procedures were effective to some extent.

## Introduction

As the arterial traffic in modern cities, the safety of subways is significant. However, with the development of the city, subway tunnels would be inevitably affected by underground construction during service period. The excavation and unloading of the foundation pit and dewatering measure would apply vertical and horizontal displacement on the underlain shield tunnel, causing significant disturbance. On the other hand, there is strict limit on the deformation of subway tunnels. In Shanghai for example, the maximum displacement in normal condition shall not exceed 20 mm; the radius of curvature of deformation shall be bigger than 15000 m; the relative deflection shall not exceed 1/2500 [1]. Therefore, it is significant to investigate the influence of foundation pit excavation on the underlain tunnel. A number of studies had been conducted in recent years regarding this issue and the key methodologies include: actual measuring and analysis [2], empirical modelling [3], analytic solution modelling [4] and finite element simulation [5-7] etc. However, the majority of current studies focused on the geological conditions in Shanghai, studies based on the geological conditions in Hangzhou are rare.

This study simulated the excavation of foundation pit above an underground tunnel using 3D MIDAS/GTS software. The influence of foundation pit excavation on the deformation of underlain shield tunnel and the effectiveness of different strengthening and control approaches were evaluated.

## Project summary

This study used an underground pedestrian crosswalk as in Hangzhou as the background. The plan of the foundation pit appeared to be a ‘Z’ shape. The main channel was located in west-east direction with 30 m in length, 10 m in width and 3.8 m in height. The main body of the crosswalk was constructed using box concrete structure. The section of Hangzhou Subway line 1 between Hubin Station and Longxiangqiao Station lay right under the underground crosswalk in a square cross position. The clear distance between the excavation surface of the foundation pit and the tunnel was 8.1 m. Open cut method was used to construct the crosswalk by dividing large foundation pit to small ones. The relative positions of the crosswalk and surround area were given in Figure 1. This study investigated a small foundation pit located at the east side at stage one of the project.

The distribution of rock and soil layer in construction area was: ①1 miscellaneous fill, ①2 plain fill, ②2 silty clay, ②3 sandy silt, ③1 mud and muddy clay, ③2 muddy clay mixed with silt, ③3 muddy and silty clay mixed with silt, ④ silty clay, ⑤1 muddy and silty clay, ⑤2 (muddy) silty clay, ⑥1 silty clay, ⑥2 clay. Based on the actual excavation depth and distribution of ground condition, the western part of the excavation surface was sandy clay and the eastern part muddy clay. The sectional view of the foundation pit was shown in Figure 2.

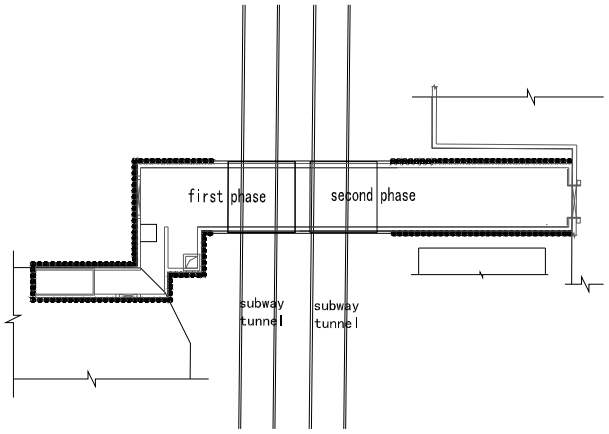

**Fig.1 Plan view of foundation pit and tunnel showing relative positions**

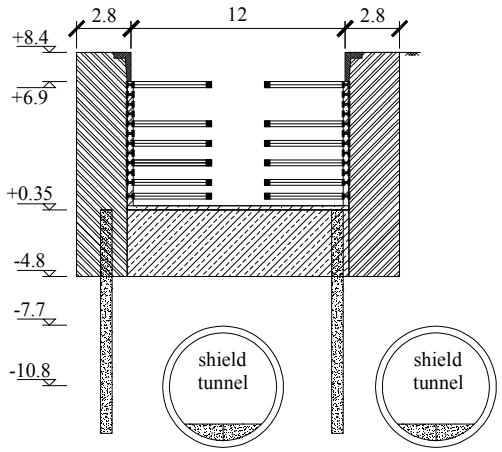

**Fig.2 Sectional view of foundation pit**

The exterior protective structure of the foundation pit consisted of four rows of Φ800@600 high-pressure jet grouting piles. Portal uplift piles with a dimension of Φ600@1500 were bored and grouted using C30 concrete. Steel circuit purlins and steel supports were used as support system. The steel had an 'H' section with a dimension of 300×300×10×15 mm. A total of 6 steel supports were constructed and layered excavation was adopted.

## 3D finite element simulations

### Model establishment and calculation of parameters

The foundation pit had a length in south-north direction of 12 m, a width in west-east direction of 11.4 m and a depth of 8 m. The four rows of high-pressure jet grouting piles with a diameter of 800 mm was replaced by walls (called sidewalls) with a thickness of 2600 mm during simulation. The side wall was 17.2 m in length, 16.6 m in width and 13.2 m in depth. The bored and grouted piles with 600 mm in diameter were replaced by walls (called uplift piles) with 600 mm in thickness and 12 m in length. The steel supports was converted to solid columns with a specific weight of 10.2 $kN \cdot m^{-3}$ and an elastic modulus of 26 GPa. The sidewalls, uplift piles and steel supports were modelled by solid elements and linear elastic materials. The strengthened ground located underneath the excavating ground was modelled by solid elements and Mohr-Coulomb constitutional model with a thickness of 5.2 m, a length of 12 m and a width of 11.4 m. Plane plate elements and linear elastic material were used for the bottom. The bottom was modelled by C15 concrete with a thickness of 0.1 m.

The shield tunnel was modelled with plane plate elements and linear elastic material with a wall-thickness of 0.35 m and an outer diameter of 6.2 m. The depth of the axis of the tunnel was 19.2 m. C50 concrete was used to model the tunnel. To simplify the simulation process, the ground was defined as homogeneous soil and modelled with solid elements and Mohr-Coulomb constitutional model. The parameters were calculated using the weighted average value of each layer. The physical and mechanical parameters of each material were listed in Table 1.

**Table 1 Physical and mechanical parameters for materials**

| | Elastic modulus (MPa) | Poisson's ratio | Specific weight (kN/m$^{3)}$ | Cohesion (kPa) | Angle of friction (º) | $K_0$ |
|---|---|---|---|---|---|---|
| Ground | 24 | 0.33 | 18.9 | 17 | 18 | 0.53 |
| Strengthen ground | 200 | 0.2 | 20 | 30 | 40 | 1 |
| Sidewalls | 10000 | 0.2 | 23 | | | 1 |
| Uplift piles | 30000 | 0.2 | 25 | | | 1.5 |
| Steel supports (original) | 200000 | 0.3 | 78.5 | | | 1.5 |
| Steel supports (converted) | 26000 | 0.3 | 10.2 | | | 1.5 |
| Tunnel | 34500 | 0.2 | 25 | | | |
| Bottom | 22000 | 0.2 | 25 | | | |

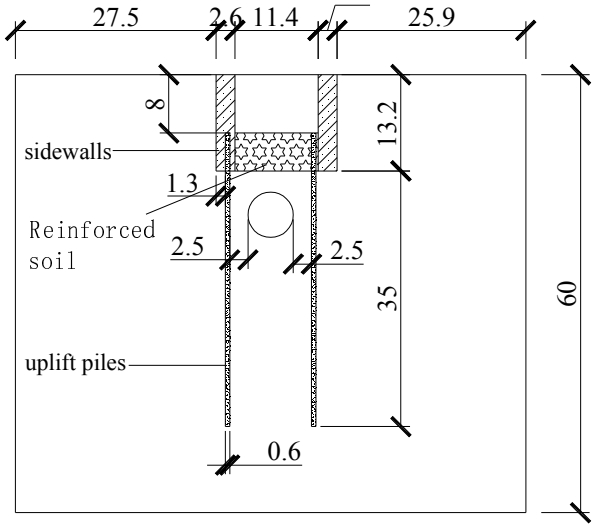

**Fig.3 Longitudinal section diagram of foundation pit**

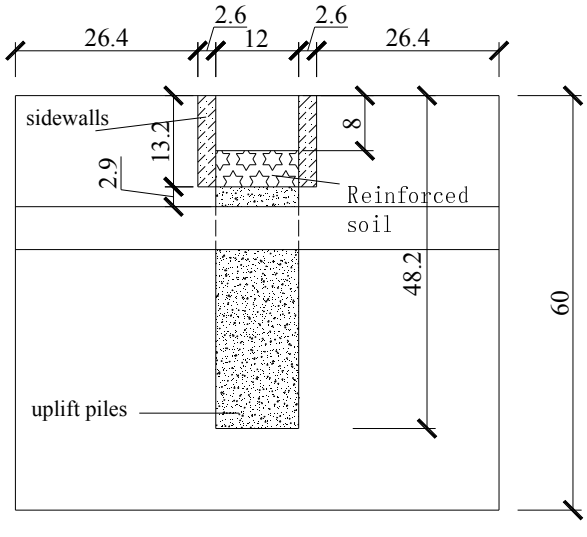

**Fig.4 Horizontal section diagram of foundation pit**

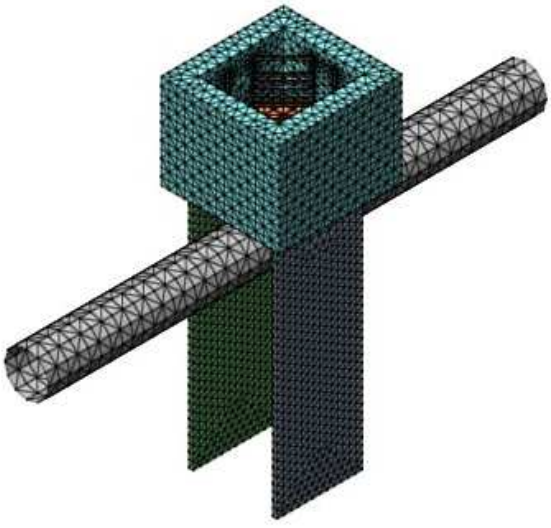

**Fig.5 Models of foundation pit and tunnel**

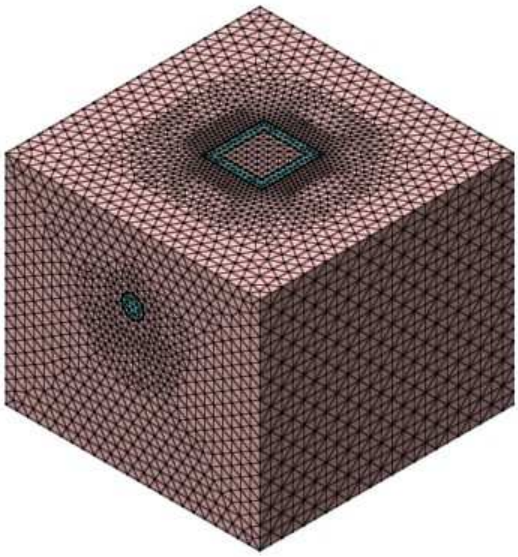

**Fig.6 Overall models**

The model had a length of 70 m in horizontal direction, 70 m in longitudinal direction and 60 m in vertical direction. The longitudinal section and horizontal section of the foundation pit and tunnel was shown in Figures 3 to 4. The meshing of the model was demonstrated in Figures 5 and 6.

**Simulation of excavation process of foundation pit**

The study assumed: (1) The permeation effect of underground water was ignored and the deformation of ground was irrelevant with time; (2) the ground was a homogenous and continuous elasto-plastic material which obeys Mohr-Coulomb yield criterion; (3) Perfect contact existed

between the tunnel, sidewalls, uplift piles and bottom of the foundation pit and the surrounding ground; no slipping or separation occurred during deformation; (4) it was assumed that the deformation of tunnel was zero before the excavation of foundation pit; only the additional deformation of tunnel due to excavation of foundation pit was studied.

Simulation procedures: (1) activate the ground, apply boundary conditions and self-loads, zero clearing the displacement; (2) start the excavation of tunnel ground after the initial stress state was acquired; (3) generate the tunnel and zero clearing the displacement; (4) modify the element attributes for sidewalls and uplift piles; (5) modify the element attributes of strengthened ground; (6) excavate the ground; (7) modify the element attributes of steel supports; (8) generate the bottom.

A total of 6 different excavating manners, and strengthening and control techniques were simulated in ascending order of stricter strengthening and control techniques employed to simulate the effect of different excavation techniques on the tunnel. Setting the actual construction condition as standard, the detailed simulation plan is given in Table 2.

**Table 2 Plan of different excavation, strengthening and control techniques**

| Condition | Detailed plan |
|---|---|
| Condition 1 | One excavation, one support, no uplift pile, no ground strengthening |
| Condition 2 | One excavation, one support, uplift piles, no ground strengthening |
| Condition 3 | One excavation, one support, uplift piles, ground strengthening |
| Condition 4 | Two excavations, four supports, uplift piles, ground strengthening |
| Condition 5 | Three excavations, six supports, uplift piles, ground strengthening (standard condition) |
| Condition 6 | Three excavations, six supports, uplift piles, ground strengthening, distributed load of 20 kPa applied temporarily on the bottom |

## Results of finite element simulation

### Analysis of standard working condition (condition 5)

The excavation of foundation pit was achieved via 6 stages during simulation: (1) construct the sidewalls and uplift piles; (2) strengthen the ground at pit bottom; (3) excavate the first layer of ground and setup the first and second steel support; (4) excavate the second layer of the ground and setup the third and fourth steel support; (5) excavate the second layer of the ground (until the bottom is reached), and setup the fifth and sixth steel support; (6) construct the bottom.

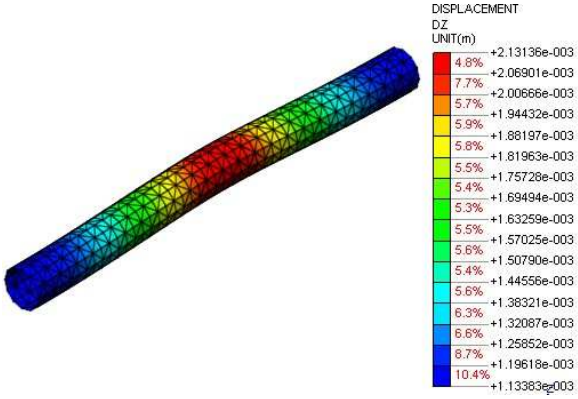

Fig.7 Vertical displacement diagram of tunnel

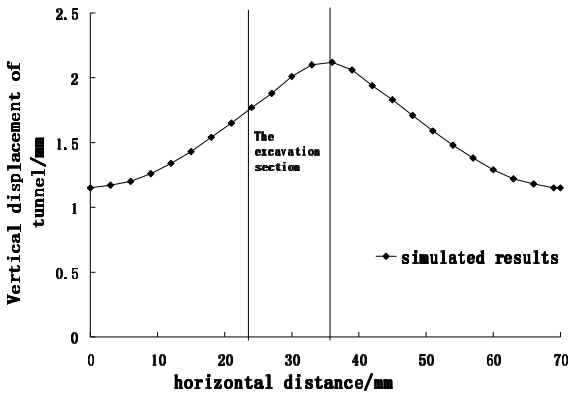

Fig.8 Vertical displacements at each point of tunnel

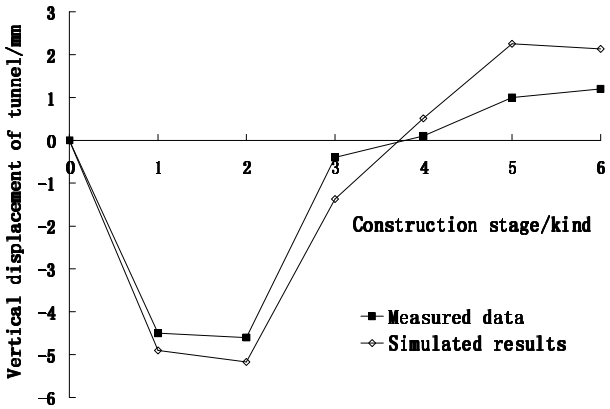

**Fig.9 Maximum vertical displacements for tunnel in different construction stages**

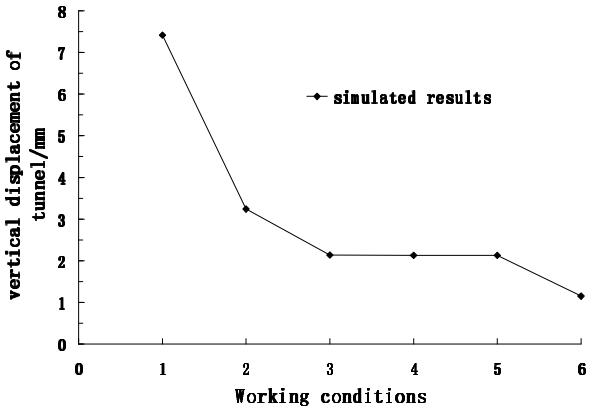

**Fig.10 Ultimate vertical displacement of tunnel under different conditions**

Figure 7 shows the ultimate vertical deformation of tunnel in standard condition. Figure 8 shows the vertical displacement of each point at tunnel in standard condition with a positive value representing humping. The position of foundation pit in the figure ranged from 29 m to 41 m. It can be seen from the figure that the vertical displacement of tunnel appeared to be normal distribution where the maximum uplift located in the middle of the foundation pit; the vertical uplift reduced with the increase of distance to the foundation pit centre; the overall uplift exceeded 1 mm, suggesting that the excavation of foundation pit affected the underneath shield tunnel in a large range.

Figure 9 shows the maximum vertical displacements for tunnel in different construction stages, wherein the negative value in Y coordinate represents settlement and positive value represents uplift. It can be seen from the diagram that: (1) the results from finite element analysis matched favourably with the measured value. Although there were discrepancies in value, the trends were extremely close, which suggests that the simulation was reliable; (2) settlement occurred at the stages of piling and ground strengthening led by downward force induced by the friction between the pile and ground during piling. The measured maximum settlement of tunnel during piling was -4.6 mm and the simulated value was -5.17 mm, which was very close to the measured value; (3) uplift occurred at the tunnel after the excavation of foundation pit. The reason for uplift is that the tunnel floated when the applied pressure reduced due to the excavation. Uplift reached the peak when the excavation was completed (at the fifth construction stage). The value of uplift reduced slightly when the bottom was cast, suggesting that casting the bottom reduces the amount of uplift. The simulated maximum vertical uplift was 2.13 mm which was slightly larger than the measured value, 1.2 mm; (4) Qi [8] discovered the trend of first settlement then uplift during piling and excavation of foundation pit, which matches the findings of this study.

**Analysis of impact factors**

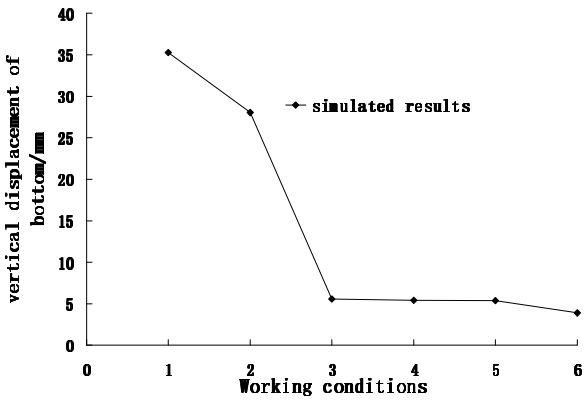

**Fig.11 Ultimate vertical displacement of bottom under different conditions**

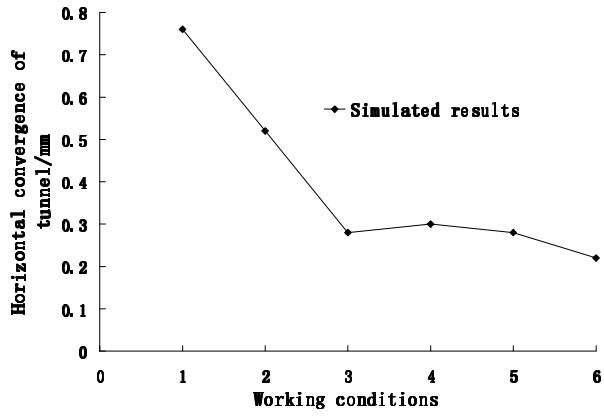

**Fig.12 Ultimate horizontal convergence of tunnel in different conditions**

Figures 10 and 11 demonstrate the ultimate vertical displacement of tunnel and bottom under different conditions with positive value being upward displacement. As shown in the figures: (1) the maximum uplift in the tunnel was 7.42 mm which was smaller than the alarm value (10 mm). This suggests that the effect of excavation of foundation pit on the tunnel is not significant due to the fact that the ground cover above the tunnel was thick (16.1 m) and the distance of excavation surface of foundation pit from the top of the tunnel was large (8.1 m), resulting to a large pressure, and thus, the unloading effect of excavation was not significant; (2) with stricter strengthening and control techniques, the ultimate uplift of tunnel and bottom reduced; (3) the descending rate of the curve was fast in the first three conditions which suggests that the uplift of tunnel and bottom could be significantly reduced with the employment of uplift piles and strengthening of pit bottom ground; (4) the variation of curve in the last three conditions was smooth which suggests that steel supports, layered excavation and temporary load had a certain level of effect on controlling the uplift of tunnel of bottom, but not obvious; (5) in conclusion, multiple strengthening and control techniques can be used to effectively control the floating of tunnel and pit bottom ground when excavating foundation pit on top of an existing shield tunnel.

Figure 12 showed the ultimate horizontal convergence of tunnel in different conditions with positive value being inward converge. It can be seen from the figure that: (1) the excavation of foundation pit reduced the pressure above the tunnel but the horizontal pressure remained the same. Therefore the convergence deformation of tunnel shifted from 'horizontally tension and vertically compression' to 'horizontally compression and vertically tension', suggesting that the additional horizontal convergence was inward (positive value); (2) the horizontal convergence value was small for tunnel with a maximum value of 0.76 mm. The amount reduced with stricter strengthening and control techniques which shows that the techniques had certain effect on convergence control.

## Conclusions

This study used MIDAS/GTS software to conduct 3D finite element simulations to analyse the deformation of existing tunnel using a foundation pit project on Yanan Road in Hangzhou City as background. The efficiency of different strengthening and control techniques was simulated using the software to provide support for similar projects.

The following conclusions were drawn: (1) the tunnel first settled then uplifted during piling and excavation stages. The excavation of foundation pit affected the underneath shield tunnel by a great range: the vertical displacement of the tunnel appeared to be normal distribution with maximum value of humping located at the middle of the pit. With the increase in distance to the centre of the pit, the amount of vertical uplift reduced; (2) with stricter strengthening and control techniques, the uplift in the tunnel and bottom reduced, suggesting that uplift piles, strengthening of pit bottom ground, layered excavation, steel support and surcharge had certain effect on controlling the deformation of tunnel and bottom and the effect was more obvious for uplift piles, ground strengthening and surcharge. Optimisation of project plan could be carried out using finite element analysis in actual constructions.

**Keywords:** karst area, water inrush( gushing),tunnel, geological environment

**Abstract.** According to Pingyang tunnel karst complex groundwater environment ， This paper carried out thorough theoretical analysis and field observation from Pingyang tunnel stratum rock properties, engineering geology, hydrogeology, the surrounding patch, runoff and drainage and the changes of surface water environment, as well as tunnel excavating. The complex formation mechanism has given in the Pingyang tunnel karst water . Some effective references had put forward for the engineering treatment, provided some valuable references for other similar underground engineering construction.

## Introduction

According to incomplete statistics[1], the tunnels were previously built 1992 in China. There are 80% water inrush disaster in construction. There are more than 30% cases of large water. The total water amount exceeds10000$m^3$/d. A lot of water inrush tunnel is not only affecting the project construction and the project progress. But the extensive and profound impact on the ecological environment closely related, including water environment, soil environment, biological habitat environment etc[2].

Influence factors of karst water movement is more complex. Hydrogeological conditions are mostly related to the incomplete quantitative, even the random, fuzzy, it is difficult to use a deterministic model to describe. karst system open, Among the various factors in the system is through interaction. Therefore this article from the karst area of Chongqing Pingyang tunnel excavation were analyzed by the surrounding water environment change.

## Project background

Pingyang tunnel is located in Xiushan County of Chongqing, For double hole four lane highway tunnel, the separation arrangement form according to the uplink and downlink. Tunnel left and right two hole axis maximum distance is 16.5 ~ 43.5m. Tunnel import and export section are restricted by terrain to small spacing tunnels. Tunnel right line is full-length 3315m, Tunnel left line is full-length 3309.949m, the maximum depth is 400m in the middle.

The tunnel site exposed strata mainly carbonate sedimentary, sandwiched between the small continental sedimentary clastic rock. Tunnel exposed strata mainly sedimentary carbonate sedimentary, sandwiched between the small continental sedimentary clastic rock. Fracture is more developed. That development mainly individual form,such as karst fissure, Karst depression, stone bud, karren, solution groove, sinkholes, Karst funnel, Karst valley.The Karst in underground karst mainly forms were karst fissures, karst cavities and underground rivers. In addition, the Pingyang tunnel is passing through the Pingyanggai syncline, in Figure 1.The syncline core formed some longitudinally underground rivers. Existing underground river and cave provided space and favorable remotion channels for groundwater runoff, occurrence and tunnel water irrush(gushing). In general, the main tunnel adverse geological phenomena were weak interlayer and karst.

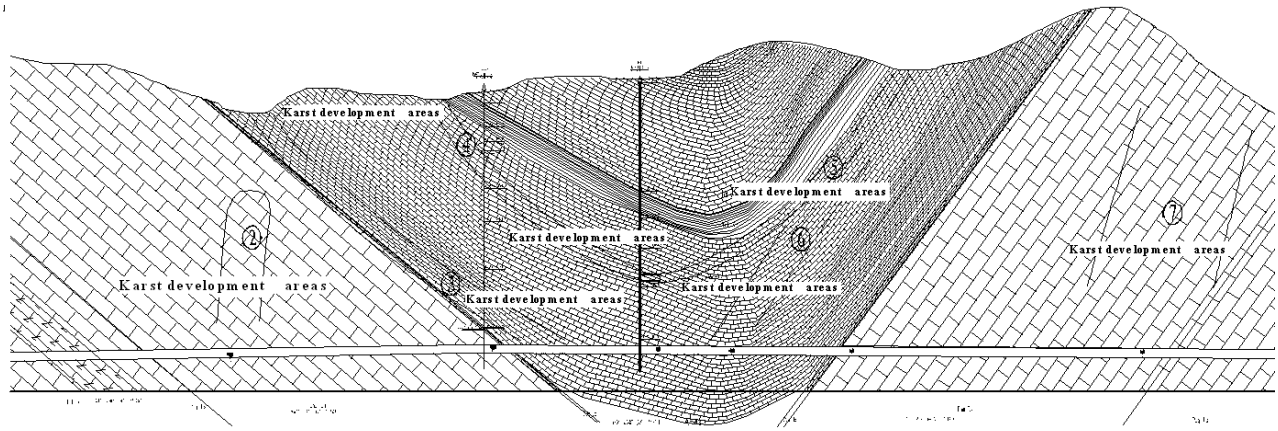

Fig. 1 The left tunnel engineering geological profile

**Pingyang tunnel karst development mechanism**

3.1 The shape and characteristics of karst development

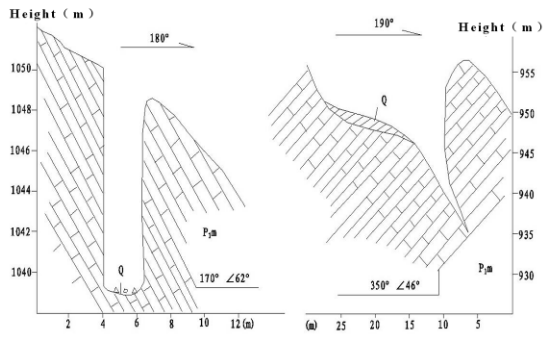

Fig. 2 Sinkholes and funnel section

The tunnel site karren, solution groove, stone teeth can be seen everywhere on the surface. The karst depression, sinkholes or funnel and cave in this area only survey to 234, sinkholes or funnel has 116. Sinkholes hole was circular or ellipse, 3-8m in diameter, general development depth 5-15m, A few depth can not see the bottom, bottom filling clay gravel, main silt, shaft shape less(See Figure 2). Most of them distributed in valley or depression, funnel in the slope zone. That often affected by topography were saucer shaped funnel inclined. Mainly affected by Stratum, terrain and crack control level development, depth in 1-3m.

3.2 Karst development law

There are four levels of planation surface in this region development. The elevation is a large class of mountain stage1200-1300m, 900-1100m and 700-800m mountain basin stage, 400-500m canyon stage.

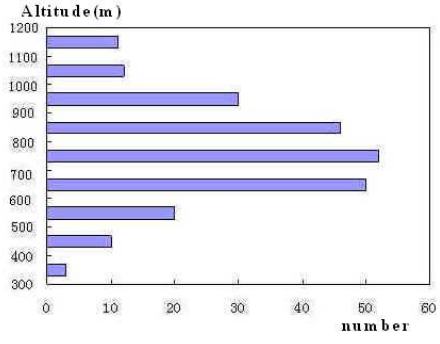

Fig. 3 Karst form distribution

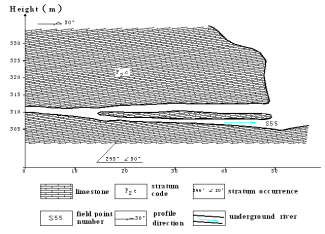
Due to karst development change has closely related to the crustal rise, pause and karst water, the different karst development period with different karst morphology, A layer characteristics formed karst forms in the region, statistics of Pingyang cover area karst depression, sinkholes, caves funnel, as shown in Figure 3. The karst individual form concentrated in three, four and five grade in the karst surface. At the same time, when the crust rise and the pause time interval frequent, At the same time also has a characteristic of karst layer.

3.2.2 Inhomogeneity of karst development

That has inhomogeneity of karst development in this region. In the plane, Karst surface are concentration developed in the lower planation areas of valley and depression. And valley and depression concentrated in the central development part or underground cave distribution development section.Karst individual form number was less in the slope zone, scale small. From the structural point view, Karst centralized development in anticline， syncline core ， fracture zone and the rock faces change belt near. From the view of karst development stratum, large depressions seen area, sinkholes, karst caves, ect. that Karst individual form in the lower Permian, Dazhi group and Changxin group of Permian and Maokou group of Permian distribution area can be seen everywhere, As shown in Figure 4. While in other strata distribution area, Karst individual form relatively less and small.



According to field investigation, the depression, sinkholes, funnel, cave Developed in the $T_{1d+j}$ formation reached to 46. The average surface karst rate K=3.2, P1m thick layer limestone reached to 75, K=6.82. $P_{2c}$ K=6.3, $P_{2w}$ K=2.8, $P_{1q}$ stratum k＝1.7, At the same time, both sides of tunnel line in the range of 2km ,the average surface karst rate was as high as K=5.8. But in this range, concentrated in Pingyanggai syncline core that fully reflect the inhomog- eneity of the karst development.

Fig. 4 Longdong underground river discharge geological profile

3.2.3 Karst development to the deep

Karst development characteristics that is karst sharply to the deep crust development. In the new tectonic movement under the action, large area of intermittent intense crustal rising, the base level of erosion and erosion datum also cut down sharply, but the cutting speed of the former quicker than the latter. The formation of deep high gorge, the karst ground cutting must be reduced to fragments, the modern karst landform formatted.

Groundwater to meet the falling drainage datum plane, sharply to deep runoff, the vadose zone with gradual thickening. Leading to erosion gully region, Trough valley set the depression that stacked sinkholes, funnel phenomenon everywhere, full description of the karst development in succession and to the deep features. At the same time, part of the underground river or karst springs cave pipeline in order to adapt to different periods base level of erosion that led to multilayer cave. That is real reflection the karst development to depth. As developed in the solution crack cave spring at Runxi town Shiban village Chayuan. The spring of early discharge is its left side cave. With the crustal uplifting, groundwater along the advantages water flowing fracture corrosion cut. The intermittent spring discharge point formatted as shown in Figure 5.

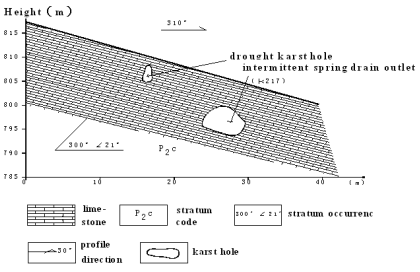


Fig. 5 Intermittent spring discharge geological profile

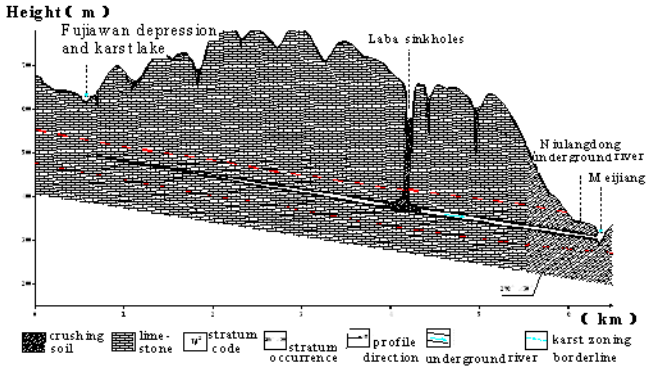
3.2.4 Karst development vertical zonality

Since the quaternary period, Because the region is a large area crust intermittent uplift. The rate of karst development is less than crustal rise speed. This caused the pattern of karst development with

the increasing depth decreased, karst water alternating cycle severe, karst very development, karst cave large scale, a number of. But in the underground depths, groundwater movement is very slow. Only developed some dissolved pore and karst crack. The vertical zonation of karst development has been formatted, from the surface to the underground can be divided into three zones ( see Figure 6).

(1)Vertical hole gap band (vadose zone): Located in the zone between below the surface to water table. Vertical karst caves are well developed, Include sinkholes, shaft, funnel and soluble gap etc.

(2)Horizontal pipe band (including seasonal fluctuation zone and saturated zone): Karst pipeline horizontal direction is very developed, including the cave and underground river, Groundwater in the cave passage runoff to the nearby drainage datum surface.



(3)Deep pore zone (deep circulation zone): this band only developed a small dissolved pore and gap. In the meantime the groundwater slowly flow to discharge area or rarely influenced by the drainage area. This region buried depth different, In the valley, general 10 meters to tens meters. In the mountains can be hundreds of metres deep.

Fig.6 Fujiawan depression and karst lake

3.2.5 Recharge, runoff, discharge and dynamic characteristics of karst water

Karst water is mainly recharged by rain in this area. Some local sections mutually transformated between surface water and groundwater. Atmospheric precipitation intensity recharge of groundwater level is mainly controlled by three factors as following in this area. The first is the intensity of karst development. Due to rainfall infiltration groundwater recharge is realized through the rock inside the cave. Especially the development of karst in vertical valley, depression area, is not only in the terrain conducive to precipitation collected, but after the rain quickly into different sizes of sinkholes, funnels. Therefore, the development of karst, the infiltration recharge amount is higher. The second is limited in fissures that controlled by fracture development direction, the overall present reticular runoff.

According to the groundwater discharge point exposed position can be divided into different overflow, drop and water blocking type excretion and other categories. Drop discharge refers to the distribution in the slope gully in the discharge point. These springs are mostly occurred in the structural fracture or weathering fissure groundwater. Because limited water bearing fractured size, The occurrence water is also very limited, In favorable slope or valley edge collection and excretion. Water blocking type and overflow type excretion is that part of the underground river, spring in the valley on both sides of the steep excretion. Discharge point is generally higher than the water surface 5-10m, This difference is due to the distribution of water resisting layer resistance effect or controlled by the base level of erosion . As mentioned before Niulangdong, Longdong underground river were overflow type. Water blocking type excretion refers to the groundwater to downward flow discharge process by lower non soluble rock resisted that forced runoff to cause by cutting terrain excreted springs, rivers on the earth's surface. Such as investigated rock doorway, water cave, Shendong rock underground river and ash soil, Miaolongtang spring point is the best proof.

3.3 The dynamic change characteristics of the karst water

Atmospheric precipitation to surface infiltration or punctate perfusion method into the underground, A linear relation between the groundwater dynamic change and rainfall variability. Such as the investigation on Pingyanggei preliminary prospecting hole (ZK48-1) water table were randomly observed. In the sunny half months later, drilling water depth is 110m, If reduced the level of 8-15 hours, The water level immediately rises to 70m, that fully reflects the correlation. Generally , the karst water recharge area has relatively larger, the underground runoff path lengther, the pressure gradient smaller, The underground river more development. When discharge point and local erosional surface height difference is small, groundwater discharge point flow and the water level variation is small; otherwise.

## Conclusion

(1)Pingyanggai syncline core formed longitudinally some underground rivers , these underground river and cave existed，to groundwater runoff，to occurre and tunnel water inrush provides space and good migration channel. Weak intercalation distribution when the tunnel after excavation, under the action of surrounding rock prone to fall in, subsidence, collapse and other.

(2)According to the occurrence of karst groundwater migration space，karst water excretion point size，The karst development intensity and strata water abundance，the characteristics of groundwater movement that the karst water divide into water abundant karst conduit water system, Content rich water karst gap and karst cave water system, water second abundant Karst fissure water system, and discusses three major systems distribution of 42 groundwater water points. At same time development, recharge, runoff, discharge characteristics and its relationship with tunnel were carried out.

(3)Most of tunnel section in the strongly developed karst belt that groundwater recharge runoff and deep circulation zone. Therefore, encounter water gushing and mud brust are the main site of K38+420 , K39+ 050,K39+175～K39+350,K39+425,K39+965. This should become the focus of prediction water gushing in construction stage. In case of a stock like water and muddy, flow not reduction, It should take drainage or other control measures.

（4）Tunnel Excavation would formated large catchment channel that will cause both sides of tunnel the large range of surface water omission and underground water level to reduce.

**Keywords:** Shield method, Prefabricated, Metro station, Joint, Standardize

**Abstract.** Confronting with the difficulties of the construction metro station in the Northeast of China, a new idea of shield method combined prefabricated method is put forward. In the paper the research status of the underground engineering precast assembly technology was analyzed and classified firstly. The method of single round interval shield combined with open-cut(or covered excavation) prefabricated sections and on the basis of shield tunnel to build single arch station is especially worth studying and promotion. Then the key prefabricate theory needing to deal with such as how to calculating the spring stiffness and so forth of the calculating model. The key technology such as joint formation, waterproof and the other of shield method combined with prefabricated method was discussed.

## Introduction

During the construction of the Metro Station, the Risk of the shallow mining method is much high. The time of cast-in-place on the basis of the method of open cutting is long and will bring about many difficulties for the traffic. In winter of the Northeast China, the method of cast concrete is difficulty also. Using prefabricated part will not only insure the good quality of the concrete, but also reduce some technology. Meanwhile, it will improve the environment and lower the construction cost.

More and more metro tunnel takes shield method during the construction. For the sake of reducing the mutual interference between station and space interval shield construction, improving the once forward distance of the shield and reducing the abandoned segment and the construction cost, combining with shield tunneling method is a good idea.

So the metro station constructed by shield tunneling method combined with prefabricated method has extensive application prospects.

## Research Status of the Underground Engineering Precast Assembly Technology

### 1.1 Foreign Application Status of the Prefabricated

In foreign the underground engineering precast assembly technology has obtained the certain development and pre-engineer's standardization is one of the underground engineering's principal characters, but it is mainly applied to the open cut metro tunnel[1,2]. For example, Toshkent Shahri city of UZ adopted widespread rectangular "into sections lining structure" in the 1970s, Rotterdam city of Netherlands adopted "shell type tunnel" in Metro East-West Line, Sendai Subway of Japan used prefabricated double span box structure and single span structure of prefabricated rectangle in double-lane vehicular tunnel and large precast arched concrete with its maximum span is 12m in Expansion Project of road by Japan alliance with France. Etc.

The Former Soviet Union has some applied cases about the metro station's prefabricated method[3,4], such as multilayer single arch metro station made of big block fabricated member in Minsk city of Belarus. In Russia the first double-deck interchange station was built on the principle of

the single arch structure and its characteristic, thus is Olympic Green Station. In addition, The Soviet Union has the cases of prefabricated members in shaft and the place between shaft and gallery.

### 1.2 Application Status of the Prefabricated Metro Station of Our Country

Research and application about underground fabricated of our country is not too much. The fabricated technology about underground engineering is mainly used in the metro tunnel constructed by shield and mainly round structure.

During the construction of long tunnel we also have taken the technology of precast slab and template, inverted arch and padding poured by RCC so as to accelerate progress and improve the quality of the inverted arch and the padding concrete[5]. In the construction of the Qinling Tunnel(18.4Km), inverted arch was made of precast unit and abutment wall of cast-in-situ[6].

Compare with the foreign metro station's prefabricated unit research and the successful applications, the study of the metro station's prefabricated unit is in its infancy.

## Research Status of Building the Station Combined with Shield Method

In foreign, countries such as Former Soviet Union[7-10], Japan[11-13], Germany[14] and so forth have studied the method of building metro station combined with shield. Three methods of building the station combined with shield are as follows:

### 1.3 Enlarging the Station on the Basis of Full Diameter Shield

(1)Shield combined with cross aisle to build station

The station was made by two or three parallel circular tunnels with the help of cross aisle and the difficulty is cross aisle's design and construction.

(2) Method of shield combined with semi-shield(roof shield) to build station

In this way both sides of the tunnel was built parallel with two shields. Under cover of one semi-shield the office station was built later which was an island platform typical.

(3)Method of shield combined with mining method or open cut method to build station

### 1.4 On the Basis of Space Interval Shield to Enlarge the Station

Fist the vehicular tunnel was cut-through by the interval shield(OD 5.5m), then the segment on the side of near the platform was removed to enlarge the station. With this method the stations were spread in Russia Saint Petersburg city(about 10 ) which was called three arch wall column station.

(1)Single round shield combined with semi-shield to construction closed platform station

(2)Single round shield combined with open cut method(covered excavation) to construction column station

### 1.5 Single Arch Station

The station was constructed based on the shield tunnel which means through both sides of the travelling tunnel finished by shield filled with concrete as the base of arch abutment to enlarge the station. There are some successful examples of this type of station in the Former Soviet Union.

In China about the project in construction or the planned in Beijing metro, Guangzhou line 1 and 5, Chengdu line 1, professor Weining Liu of BJTU and professor Chuan He of SWJTU each leads his team having done some research on the designing and construction methods of combining with shield to building the station. They also have acquired some good effects[15-20]. The main idea is that the shield transits the station first, removing or keeping part segment to open door providing the condition of loading and unloading, which is using the method of undermining or open cutting cast-in-place. Make a general survey of the method of combining with shield to build the station, it is mainly in research stage of numerical simulation and similar model test and special segment, but no project example and mainly is cast-in-situ station combining with shield and Open Cut(NATM).

In view of our technology and economic capability and applications, the method of single round interval shield combining with open-cut(or covered excavation) prefabricated sections and on the

basis of shield tunnel to build single arch station is especially worth studying and promoting. The shield tunnel is used as the lane and the structure can be prefabricated entirely or partly of the former method which fits the large span station. Of the latter method the arch foundation needs cast-in-site which fits the smaller station.

## the Principle Design Philosophy of Prefabricating

At present, there are many studies of shield tunnel's prefabricated lining. Japan is active in the field of technology about shield method and has published a great quantity papers of numerical calculation[21]. Many domestic experts and scholar have studied in this field in recent years and have achieved some consequence[22-27].

The same point of these model patterns is simulating the property of joint by spring. Now the model pattern can simulate longitudinal joint, girth joint, bedding joint and so forth simultaneously.

Making a general survey of the study history of segment joint, the joint models develop is shown in fig. 1.

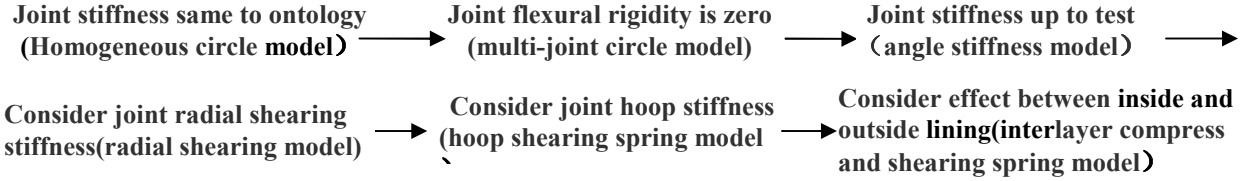

**Fig.1 The Development of the Joint Model**

These types of model are on behalf of the prefabricated lining tunnel's trend probably, although are flaws such as how to think the stiffness of spring and how to simplify the calculating method to improve the efficiency and so forth.

For our country there is no use of the station's prefabricating, and only papers[28-30] are about analyzing the standard section of station. In these papers longitudinal rigidity was not considered and related joint' tectonic pattern and model test of waterproof project was lack, but also there were no further analysis for the detailed dimension and prestressed constructions of rib shape. These also have no discussed the staircase and related gallery's joint which is changed in structural section. In addition, with regard to open cut prefabricated station the anti-seismic is needed to study to analyze the character in earthquake.

## Key of the Prefabricated Method

There are defects of prefabricated concrete structure such as complex structure of joint, low integration, a poor performance in earthquake of joint etc. from the existing project, in the development of the large precast technology; the following for topics need to be resolve.

### 1.6 Study of the Component's Standardization

Prefabricating and Standardization is closely connected. If the components of the metro is standardized or not is the precondition of the component of prefabricated and is also related with benefit. Achieving the standardization means achieving the scale of production and benefit model change. For example, the machine determines the basic configuration in shield tunnel construction. The round section gives the quite advantage of components standardization. So the technology of circular precast segments develops rapidly. For the open cut metro station, the section is mainly rectangular or arched. But how to divide the components is one key of making the components standardized to use the prefabricated parts.

### 1.7 Precast Construction Type to Choose and Structural Parts to Divide

Judging from the application examples there are four types of the prefabricated structural element, that is two types of Rectangular frame and two arch structure also, as fig. 2 shows.

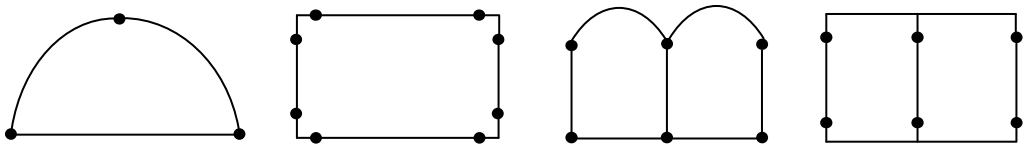

**Fig. 2 Structure Form and Connector Station Sketch Map**

For type (a) and (b), base slab can be adopt when the span is lesser and when the span is larger the slab should be made to inverted arch. For type (c) and (d), base slab can be adopt because of the mid-board can decrease the slab' span.

After the form has been determined, the components' division not only the structure rational condition but also the probability of the components' manufacture and assembling should be considered. Prefabricated parts should be request light for manufacture and assembling. Besides, reducing the types of components so as to scale manufacture is important principle for the components' division. The way of common division is shown in fig.2 and the joint is located at the part of smallest bending moment.

**1.8** Joint Formation and Waterproof

Joint formation and waterproof work is one of the key to the component prefabricated which will affect the service environment and durability.

*5.3.1 Joint Formation*

Like the joint of segment, according to the joint property it can be divided into rigid joint and flexible joint; according to the function it can be divided into longitudinal joint and transverse joint. Longitudinal joint and transverse joint can be in one type and different. Judging from the adopting joint, it probably has the following types:

(1) using concrete joint cast-in-place

It is a simple, economic, reliable and perfect rigidity that can be used in longitudinal direction and transverse direction.

(2) using bolted joint with prestressed tighten

The type of it is similar to concrete segment joint except the prestressed is taken place by push of jack. It is flexible and through PN BW installed between the components to sealing up.

(3) using joint with commercial bolt

It is simple in structure and construction which is major applied to fabricated segment. It can be adapt to a certain error because of its reservation bolt hole is 5-10mm larger than bolt. Besides, bolt hole can be reserved in component in order to assembling conveniently.

(4) using joggle fastener itself

This type of joint is so much that has broad development prospects.

(5) the others type

There are mainly embedded steel plate joints and curved bar bolt joint etc.

The joint should meet the following conditions: has the function of resisting shear; has the function of water proofing requested; connected and located easily; has certain popularity and durability.

According to the above request, the form of transverse joint should be selected commercial bolt with handspike in metro and station' prefabricated part. The joint is simple in structure and construction convenient to save cost. Besides, joggle joint can be selected to joggle the prefabricated part. The joggle joint also can guarantee the accurate position of the flank wall and roof and baseboard without its complex structure.

*5.3.2 Waterproof of joint*

The main reason of leakage for the prefabricated part is its environment, structure, sealing material, construction and etc. Section waterproof can be selected waterproof concrete to sealing itself for its prefabrication can ensure is quality. It is important for the joint sealing because of the main leakage comes from joint and seam. Waterproof process in plane joint is probably pasting rubber waterstop on the side of the wall rock and setting up ring washer in bolt and grouting.

1.9 manufacture and install of component

Success or failure of component is in supervision. Strict and good management specifically manifested in the manufacture and installation work for these reasons the two segments should be pay great attention.

For the manufacture of component, the principle is production precision. In order to guarantee the precision the template should be designed carefully. The other key point is the installation work in engineer especially the effect of waterproof.

**Summarize**

Shield tunneling method combined with prefabricated method to build station is a systematic project. Something such as how to connect segment with prefabricated part, waterproof property of clip ring joint with station's structure and earthquake resistant capability and durability and so forth should be worth studied deeply. Preliminary studies and application should be taken as soon as possible in some good conditions so as to put forward the development of its technology.

# Pre-stressed Reinforcement and Security Analysis of Tunnel Lining with Dislocation and Cracks

Jingwei Zhang[1,a]

[1]Civil Engineering School, Southwest Jiaotong University, Chengdu 610031, Sichuan, China

[a]496521718@qq.com

**Keywords:** Tunnel lining, lining split, pre-stressed reinforcement, numerical simulation, security analysis.

**Abstract.** Security of secondary lining is of utmost importance to tunnel engineering quality as the main bearing structure and the last water-prevent line for rock types I, II, III. Tunnel lining with dislocation and cracks is one of the most serious defects to secondary lining. Based on the case of Goujiagou tunnel, the potential threat is listed. The pre-stressed regulation scheme is designed, and the parameters are determined. The loose surrounding rock pressure on lining is calculated by P's theory. Based on the results, the numerical simulation model is build by means of FES code ANSYS; and the internal pressure before and after the reinforcement is analyzed. According to the above-mentioned research results, this paper calculated the safety factor, and checked the structure strength. Research results indicate that the regulation design is feasible and the pre-stressed parameters are appropriate. The results will provide reference to design for dislocation and cracks of tunnel lining.

## Introduction

With the time goes by, there will be all kinds of defects of existing tunnel. The lining breach which will leads to water leakage of tunnel and lining collapse is one of the main defects of hidden troubles. It will have some impact on using performance of tunnel directly, even though driving safety and useful life. We should pay more attention to treatment of tunnel lining with dislocation and cracks. Because this defect frequently proves surrounding rock pressure had redistributed and there are some other defects.

Since the 1960s, many experts did the research work in this filed and got a lot of research achievements. Among them, Zhi-xiong Qian created finite element model, calculated structure security and finally recommended treating method according to detection results [3]. Yong Wang used engineering criterion to analysis safety factor of liner sections [4]. Ting-jin Liu created finite element model for cavity behind primary lining, and investigated the influence of cavity on bearing capability [1]. Yong-hua Liu used load-structure model and statistical parameter to discuss structure security with vault cavity lining thickness and cracks [5].

This paper mainly discussed the research and analysis on regulation scheme and the parameters of pre-stressed resin anchored bolt, and the structure security during construction which based on practical engineering.

## Engineering Situation

This is a double-track railway tunnel in speed of 160km/h mixed passenger and freight. Most of surrounding rock isⅣ and other is Ⅴ.The rock type is mudstone and sandstone.

There are two longitudinal symmetrical concrete cracks on the arch crown in the section of 9m (K0+435～+444) of tunnel body, and the pressure replacement of right wall occurred due to geological conditions and construction methods etc. The results of detection indicate that left obviously(crack of high slump concrete),right hidden; the left longitudinal crack width is 15mm,depth is about 20mm,and there are different period cement slurry at both ends of cracks; the other crack width

is about 2mm since 0.5m below long span of K+438.5 to lower mileage, and the angle between cross section is 30 extending to right haunch circular construction joint, and it cross to the left arch crown crack, which almost make the lining under dangerous ,and cantilever fracture may be occurred any time.

## Pre-stressed Reinforcement Scheme

The main reasons of the left arch crown longitudinal crack are as follows:

1) There are two intermittent joint both left and right (K0+435～+444) .2) The collapse pressure due to cavity behind liner of left arch crown.3) Additional load on structure because of slight expansion of mudstone .

Based on the above-mentioned reasons and existing engineering experience, the pre-stressed reinforcement scheme was designed. Fig. 1 shows the design of regulation measure.

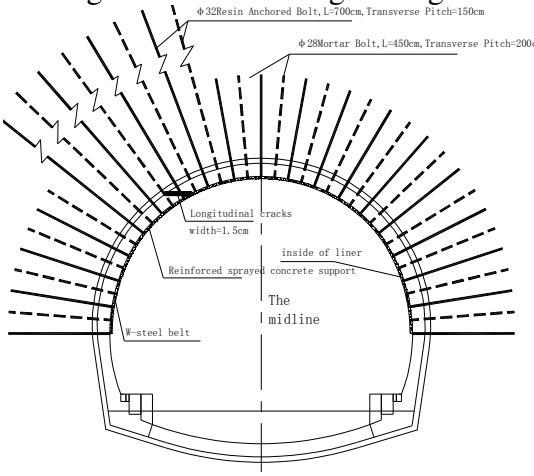

Fig. 1 Design of regulation measure

1) Decorating two rows of pre-stressed Φ32resin anchored bolt up and down along the direction of crack on left lining. The spacing of tangential and longitudinal is 1.5m; then applying 200KN pre-stressed on the anchored bolt to strengthen the liner.2) Decorating W-steel belt and longitudinal decoration is 1.5m above maximum span. Expecting using drill nail or shorter anchor to fixed W-steel belt within the scope of crack 2.5m up and down; others using 4.5m Φ28mechanical anchor bolt and the space is 2m.3) Laying Φ6,10cm×10cm steel fabric in area of W-steel belt.4) Spraying polypropylene fiber concrete and the depth is 8cm.

## Determination of Reasonable Parameters

**Calculation Pattern.** This paper adopts the pattern of conventional load - structure to calculate. The formation and lining function is considered as formation spring without pulling; the force transmission between the primary and second lining is considered as composite beam; the connection of spring is compression or tension in calculation, and broken phase method is adopted in the process.

**Physical and Mechanical Parameters.** The surrounding rock class is V in disease section. Table. 1 shows physical and mechanical parameters of surrounding rock and structure.

Table. 1 Physical and mechanical indexes of surrounding rock and structure

| Structural style | E(GPa) | ν | γ(KN/m$^3$) | Φ ($^o$) | K(MPa) |
|---|---|---|---|---|---|
| Intense weathering mudstone | 2.0 | 0.40 | 22 | 46 | 300 |
| Moderate weathering mudstone | 6.0 | 0.33 | 23 | 55 | 400 |
| C25 concrete | 29.5 | 0.20 | 23 | / | / |

**Calculation Model.** This is a deep tunnel and the depth is 36.95m; the excavation width is 12.98m.According to《Code for design on tunnel of railway》and P's theory to calculate the loose rock pressure:

$$q_1 = \gamma b = \frac{\gamma a_1}{f} \tag{1}$$

$$e_1 = \gamma b tg^2(45° - \frac{\varphi}{2}) \tag{2}$$

$$e_2 = \gamma(b+h)tg^2(45° - \frac{\varphi}{2}) \tag{3}$$

Where b is the maximum height of natural balance arch; $a_1$ is the biggest span arch of natural balance, and $a_1 = a + htg(45° - \frac{\varphi}{2})$ ; $f$ is P's coefficient.

This paper used beam element to simulate second liner, and spring element to the foundation. The left crack is replaced by hinge joint. Fig. 2 a) shows the calculation model before reinforcement and b) shows the calculation model after reinforcement. Fig. 2 shows the calculation model of structure.

**Calculation Results**. Fig.3 shows the axial force in original state, and Fig.4 shows the bending moment in original state; Fig. 5 shows the axial force in reinforcement state, and Fig.6 shows the bending moment in reinforcement state.

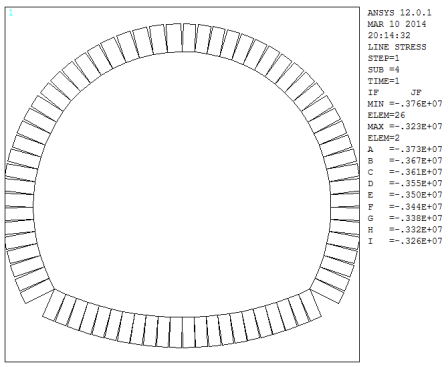

Fig. 3 The axial force in original state (N)

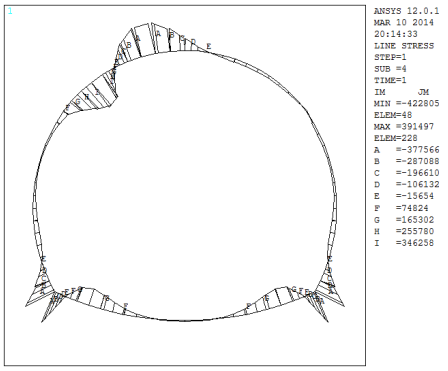

Fig. 4 The bending moment in original state (N.m)

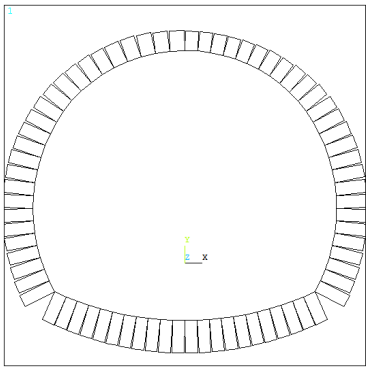

Fig. 5 The axial force in reinforcement state (N)

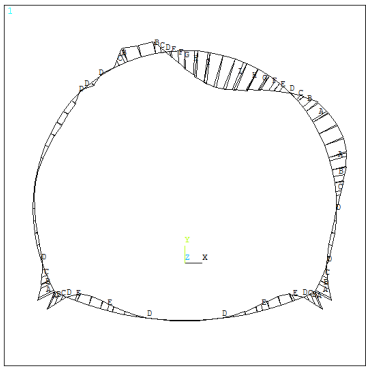

Fig. 6 The bending moment in reinforcement state (N.m)

## Evaluation of Structure Security

Based on the above-mentioned research results, the security factor of control lining section was calculated to evaluate the structure strength by comparing difference between the two states. According to the 《Code for Design of Road Tunnel》 (JTJ D70 -2004) and theory of failure stage, the eccentric compression concrete strength calculation are as follows.

$$K = N_L / N \geq K_P \tag{4}$$

When controlled by the compressive strength. $e = M / N \leq 0.2h$:

$$N_L = \varphi \alpha R_a bh \tag{5}$$

Where $\varphi$ is the coefficient of vertical component, $R_a$ is the ultimate compressive strength of concrete, $\alpha$ is the eccentricity influence coefficient of the axial force, and $\alpha = 1 - 1.5 \cdot e / h$, $b$ is the breadth of section, $h$ is the thickness of section.

When controlled by the tensile strength. $e = M / N \geq 0.2h$:

$$N_L = \varphi \frac{1.75 R_l bh}{\frac{6e}{h} - 1} \tag{6}$$

Where $R_l$ is the ultimate tensile strength of concrete.

Table. 2 shows the security coefficient of control sections before regulation and Table.3 shows the security coefficient of control sections after regulation. Fig. 7 shows the tendency and contrasting relations of the structure security between original and reinforcement state.

Table. 2 Security coefficient of control sections before regulation

| Location | Bending Moment (N·m) | Axial Force (N) | Eccentric Distance $e_0$ (m) | Safety Factor | Note |
|---|---|---|---|---|---|
| Left Arch Crown | -445249 | -3.38E+06 | 0.132 | 1.6 | N |
| Left Arch Haunch | 328814 | -3.46E+06 | 0.095 | 2.1 | Y |
| Side Wall | -445249 | -3.93E+06 | 0.113 | 1.6 | N |
| Inverted Arch | 156800 | -3.77E+06 | 0.042 | 2.5 | Y |

Table. 3 Security coefficient of control sections after regulation

| Location | Bending Moment (N·m) | Axial Force (N) | Eccentric Distance $e_0$ (m) | Safety Factor | Note |
|---|---|---|---|---|---|
| Left Arch Crown | 1.91E+05 | -6.90E+05 | 0.276 | 2.0 | Y |
| Left Arch Haunch | -2.32E+05 | -1.62E+06 | 0.144 | 4.3 | Y |

| Location | Bending Moment (N·m) | Axial Force (N) | Eccentric Distance $e_0$ (m) | Safety Factor | Note |
|---|---|---|---|---|---|
| Side Wall | -2.13E+05 | -1.83E+06 | 0.117 | 4.5 | Y |
| Inverted Arch | 1.05E+05 | -1.72E+06 | 0.061 | 6.1 | Y |

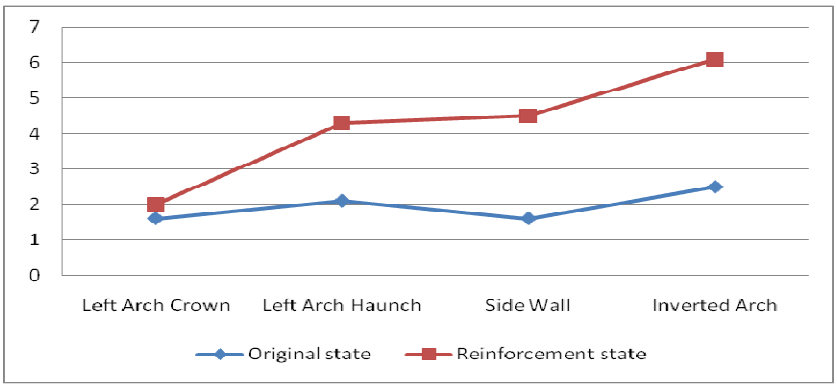

Fig. 7 Security coefficient of structure compared with original and reinforcement state

## Conclusions

The lining cracks result in stress concentration significantly especially the 149 point, and the structure strength greatly reduced. Especially the left arch security coefficient is lower than the standard value 2; at the same time, it results in surrounding rock pressure distribution. The stress concentration of other control nodes also obviously. The security margin of structure is low. Cantilever fracture may occur at any time, and it is unpredictable.

The area of stress concentration moving to the right arch that lining is in good condition and also reinforced, after using 200KN pre-stressed resin anchored bolt and reinforcement measure. Based on the above-mentioned research results, the control section security coefficient has obviously improved than original state, and the security factor of several key nodes meets the specification values. It indicates that pre-stressed reinforcement scheme is feasible, and 200KN parameter selection is appropriate.

**Keywords:** Layout Mode, Measurement Area, DIALux, Range of Light Effects, Tunnel Lighting Experiment .

**Abstract.** Based on the measured data of the tunnel lighting, this paper is focusing on the arrangement of measured points in the experiment of tunnel lighting. Through the way of changing the location of measured area and the arrangement of measured points, comparing the simulation from the software DIALUX and the actual measurement in a repetitive region, the best position of measured area and the corresponding layout mode can be found. Analysis shows that, the larger the lamp distance is, the more similar the experiment and simulation results are. Before the experiment, the analysis of the light distribution curve is required, then, the simulation of software can help to find out the best position of lamp interval, measured area and layout mode, in order to ensure the authenticity of the results and to avoid too large or too small lighting evaluation, layout mode must include the maximum measured points and the minimum measured point.

## Introduction

In recent years, the number of tunnels is increasing year by year, traffic safety problems have become increasingly prominent. In the process of a driver passing across the tunnel by car, traffic safety and the tunnel lighting environment are closely related, Reasonable evaluation of traffic lighting environment have important meaning for enhancing the quality of lighting, ensuring traffic safety, conserving energy, protecting environment, maintaining and improving lighting facilities.

Currently, traffic lighting environment evaluation mainly adopt the method of static measurements of the tunnel lighting parameters; luminance or illumination parameters are the most commonly used parameters [1]. Although with the advancement of technology, measurement tool constantly upgrading [2], the measurements are always measured using the method of drawing line and getting points in the measured area[3] to get illuminance or luminance of each points to evaluate the quality of lighting. For the layout measured point, the distribution is disposed generally rectangular, square etc; according to different requirements of measurement and evaluation, the rational design for the density and location of the points is required.

Due to the high tunnel lighting requirements, the way of reflecting inside of the tunnel is complex [4], and how to choose the right way of distribution, lighting measurement, tunnel lighting quality evaluation, is not explicitly given in the specification. How to choose a rational way of distributing the measured points in a limited area, realistically reflect the actual lighting situation, and provide a reference for tunnel lighting illumination measurement experiment is the main task of this paper. In this paper, DIALux software is used to model and analysis the actual tunnel lighting environment, and carry out the research for tunnel lighting illuminance measurement experiment of measured points distribution, thus finding a suitable distribution of measured points by comparing.

## Tunnel Lighting Evaluation

### 2.1 The Index of Tunnel Lighting Evaluation

The index of highway tunnel generally includes the luminance (illuminance), glare restriction, induction etc, where glare and induction have clear rules in the specification, and the brightness (average brightness, uniformity, luminance range etc.) affect the driver's visual contrast sensitivity and luminance contrast of the road object relative to the visual background, so this paper selects the brightness as a basic index to evaluate the quality of tunnel lighting. Related information shows: selecting the appropriate brightness index do good for improving RP (revealing power) [5], which is conducive to driving safety.

For the highway tunnel in which traffic flow have a larger proportion of motor vehicle, direction and distance of driver's observation is relatively fixed, and the layout of the environment presents a unified, so the road luminance and illuminance distribution in the field of view is corresponding[6]; Also in the actual measurement process, the measurement of illuminance measurements is more convenient and easy in operation compared with the luminance measurements. therefore this paper selects illumination as the research target to evaluate the quality of tunnel lighting.

### 2.2The Method of Tunnel Lighting Measurement

Tunnel lighting evaluation changes with the method of measurement and distribution of measured points; based on the measurement of illuminance and distribution of measured points, this paper mainly introduces the two ways of the illuminance measurement: the center point method which regard the center point of rectangle grid as the basic point; the four-point method which regard the four vertices of rectangle grid as the basic points. According to the different distribution of measured points, in Fig.2-1, 2-2, the calculation formula[1] of corresponding average illuminance is as follows:

$$E_{hav} = \frac{1}{4MN}(\sum E_{\theta} + 2\sum E_0 + 4\sum E) \tag{1}$$

$$E_{hav} = \frac{1}{MN}(\sum E) \tag{2}$$

Where:

$E_{hav}$ —The average horizontal illuminance; Unit: lx; M /N—The number of vertical / transverse grid

$E_0$ —The measured illuminance of four vertices in measured area; Unit: lx;

$E_{\theta}$ —Except $E_0$， the measured illuminance of four outer edges； Unit: lx;

E—The measured illuminance inside of the four outer edges; Unit: lx;

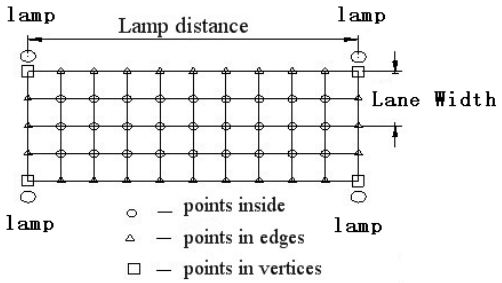

**Fig.2-1 Layout mode of the four point method**

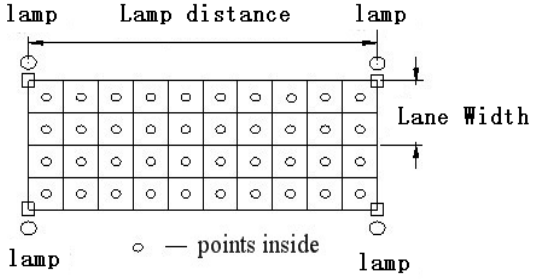

**Fig.2-2 Layout mode of the center point method**

Calculation of the tunnel illumination uniformity:

$$U_1 = E_{\min} / E_{\max} \tag{3}$$

$$U_2 = E_{\min} / E_{hav} \tag{4}$$

Where:

$U_1$ —Illumination uniformity (range); $U_2$ —Illumination uniformity (average deviation);

$E_{\min}$ —Minimum illumination; Unit : 1x; $E_{\max}$ —Maximum illumination; Unit: 1x;

$E_{hav}$ —average illumination； Unit: 1x.

## Evaluation of DIALux Simulation Results Based on the Measured Data

### 3.1 Overview of Physical Measurement

Physical measurements are carried out in the only 1:1 entity tunnel in China located in " Key Laboratory of Tunnel Construction & Maintenance Technology, Ministry of Communications, PRC, " of CCRDI: Tunnel length 200m, width 10m, height 7.15m. Adopting parameters is shown in Table 3.1:

**Table 3.1 Adopting tunnel parameters**

| | |
|---|---|
| Reflection coefficient of tunnel wall | Wall/0.3 , ceiling /0.1, pavemen/0.3 |
| Lamp distance /m | 3、4、5、6、7 |
| Lamp height /m | 5 |
| Sidewall height /m | 5 |

Physical measurements adopt the four-point method which the distance between two points is 1m ×1m, the measured data, test the reliability of the results of the simulation software.

### 3.2 Overview of Software Simulation

DIALux is a professional lighting calculation software developed by the German software company, which can carry out simulation and calculation of lighting design, and has wide support of lamp parameters. Due to its calculations is carried out in strict accordance with CIE140, and built Europe and America standard road values[7], in order to get appropriate parameter modification in the simulation process, and achieve the best effect of simulation, it is necessary to test Lamp light intensity.

### 3.3 Comparison of Analytical Results

In the same location of entity tunnel and simulated tunnel, their illumination indicator parameters are Comparative analysis using the four-point method. In view of the large number of illumination analysis indicators. This paper uses the Origin software to draw and analysis relevant data, as shown in Fig.3-1,

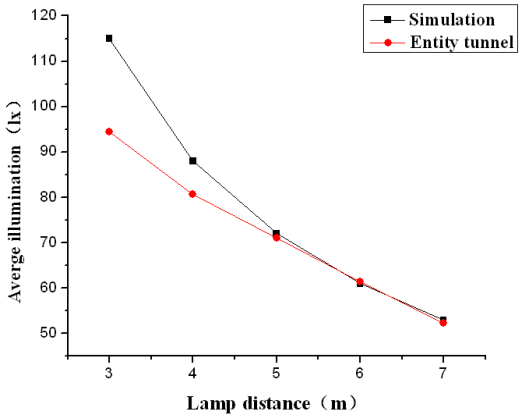

**Fig.3-1 The contrast of average illuminance between entity tunnel and simulation model in different lamp distance**

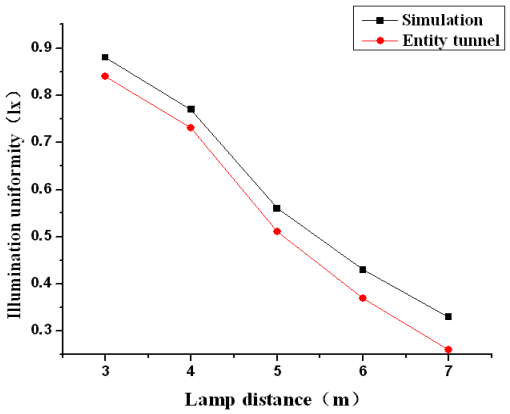

**Fig.3-2 The contrast of illumination uniformity($U_1$) between entity tunnel and simulation model in different lamp distance**

Fig.3-1 shows that the analog value calculated by the simulation model are gradually equal to the measured value of the entity tunnel with the decrease of the lamp distance. And Fig.3-2 show that with the decrease of the lamp distance, the illumination uniformity increase, furthermore the analog value become more and more close to the measured value.

From the comparison above we found that, due to the differences between the reality and ideal experimental conditions, the analog value had some deviation with the measured value, however, they had the same trends with the lamp distance change and their deviation are getting smaller. It is say that we can simplify the evaluation method of measuring the road tunnel lighting quality, and in this method we can had a reasonable assessment to the tunnel lighting.

## Study for Distribution of the Measured Point Based on the DIALux

### Introduction of the Simulation Analysis

Based on the theory above we use the DIALux to analysis the simulation model in this paper, in order to analysis the lighting situation for the entity tunnel.

Ideal parameters was adopted to built the simulation model, and the lamp parameter was based on the LED which was verified by appropriate tool.

The basic rule for layout the measuring point is: the point must be in the lateral lane and between the two vertical lamps; the area for measure should be convenient for the post-processing. According to different circumstances, the pattern of point layout is changed as follows: l×w — 0.5m×0.5m,0.5m×1m,1m×1m,1m×0.5m; Meanwhile translate the measurement area: the spacing area between two lamps is translated to half area on each side. The region of Horizontal line where the midpoint between lamps is the reference position: i.e 0m, and the others is by shift, the largest shift is half the lights spacing. The simulation model is shown in Fig.4-1:

**Fig.4-1 Simulation model**

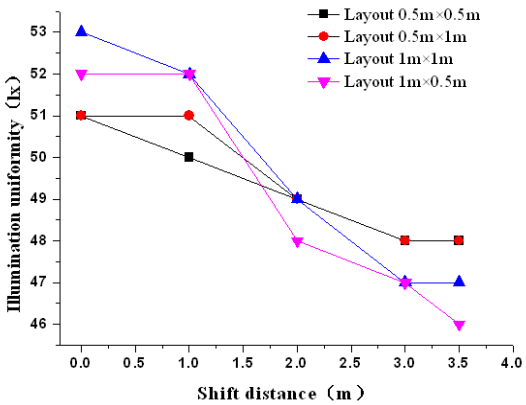

**Fig.4-2 Under different ways of layout, the trend of the average illumination varies with the shift**

### Measurement Position, Layout Can Influence the Calculation Result

The calculation results of Lamps spacing 7m is shown in Fig.4-2, 4-3:

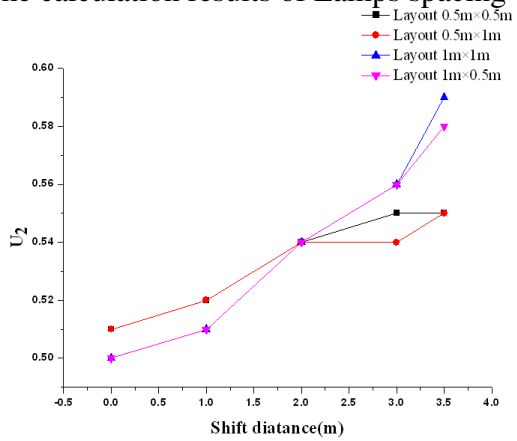

**Fig.4-3 Under different ways of layout, the trend of illumination uniformity ($U_2$) varies with the shift**

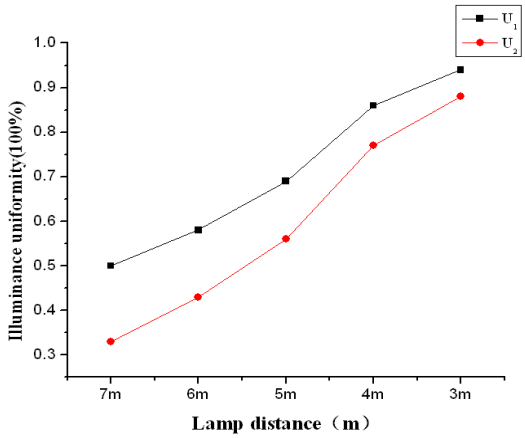

**Fig.4-4 The trend of $U_1$ and $U_2$ as the lamps spacing change**

Diagram result shows that: with the change of measurement region, the average value has a diminishing trend, but $U_2$ increases, the range is 0.08. Meanwhile axial spacing is 1m, whose value is greater than the axial spacing is 0.5m, and the average measurement value of the square layout way with 0.5m×0.5m changes least. which demonstrates more intensive distribution, more effective of the data. From the fig.4-2, 4-3, whether the average or mean difference, they both intersect in the 2m shift. Therefore, under the parameter of this tunnel, measurement area which shift 2m is more reasonable.

**The Impact of Measurement Lamp Spacing**

The Fig.4-4 shows that： with the decrease in lamp spacing, the illuminance uniformity increases, illuminance uniformity increases gradually, and with the illuminance uniformity increase, the measurement point can be appropriately reduced, select 1m×1m points layout may be a better choice.

For the simulation of the other lamps spacing, the measured value change trends are similar to that of 7m, the extremum value is almost not change, the average is changed more, and their change magnitude is different.

**The Impact of Lamps Distribution Curve**

From the measurement data, the lamp distribution curve is asymmetric, which is reflected on the longitudinal points, and the value is asymmetrical, which similar to the distribution of the actual measurement data. The maximum point of the simulated data is below the horizontal lamps and the minimum point is mainly on the weakness side of the axial lamp distribution curve. Therefore, in the case that lamp spacing is 5m, 6m and 7m, the layout average value is minimum without arrange the measurement points below the lamp, and it will low rating the tunnel lighting. On the contrary the layout average value is maximum when arrange measurement points include the points below the lamp, and that will overestimate the road lighting. Therefore, in order to find minimum value, the lamp distribution curve should be considered when arrange the meansurement points to ensure the evaluation data is accurate.

**Conclusions**

Through the comparison of software simulation and the real value, we concluded as follows:

(1) More dense the measurement points, more useful the result in evaluate the tunnel lighting quality.

(2) The best measurement layout of different lamp spacing is different, the smaller lamp spacing, the higher uniformity, the measurement points can decreased appropriately;

(3) Due to the nature of the lamp, the location and layout should consider the lamp distribution curve: the measurement region should contain the maximum and minimum values;

(4) Due to the lamps and design factors of the actual tunnel, we should make software simulation of the entity tunnel, and find the appropriate regions and layout under the different lamps spacing, type and actual tunnels, so that we can have a reasonable evaluation of tunnel lighting.

# Study of Life Safety on the Fire Accidents in the Subway Station

Hua Xie[a], Yanying Xu, Xu Zhang and Jian Chen

School of Safety Engineering, Shenyang Aerospace University, Shenyang 110136, China

[a]email: tedalanchong@163.com

**Keywords:** Life safety, Fire accidents, Subway station.

**Abstract.** Subway station fire can easily cause many calamities that lead to a large amount of social and public problems, because the smoke spread moves in the same direction as the personnel evacuation. Therefore, life safety issues caused by the subway station fire and relevant investigation should be comprehensively taken into account in the fire safety design in order to minimize the fire accident loss. Here previously reported fire accidents in the subway station are reviewed in detail and some research on the life safety of the subway station fire are presented, which could be helpful for the accident prevention and provide guidance to future study on the safety design in the subway station fire.

## Introduction

With the rapid development of economy in China, the urban transportation system faces new opportunities as well as challenges [1, 2]. The subway is one of the most common vehicles and also bears heavy work of transiting large passenger progressively. So, amount of subway stations are built in order to meet the demand of the city development. In the event of subway fire, a lot of smoke are produced and rapidly spread to overall subway stations because of stack effect and space limitation. In particular, the smoke spread direction mostly coincides with the evacuation path of the passenger, which could reduce passengers' visibility and result in the mishaps caused by the asphyxiation and stampede. Large amounts of statistical data show that calamitous fires in the subway station can usually cause heavy fatalities [3]. Additionally, the arson, terrorism attack and other accidental fire may also give rise to the disaster since there are a large number of passengers in the subway station every day.

Emergency evacuation in the subway station fire is very difficult due to the complexity of the smoke spread, the twists and turns of the evacuation route, the dense and chaos of the passengers. Therefore, study of life safety on the fire accidents in the subway station has attracted much attention and becomes an interesting topic in the field. Currently, the reported investigations focus on the evacuation time and human behavior [4], which is limited by the data collection of survivors in the tragedy. In recent years, more and more attentions have been paid to the establishment and development of evacuation models with the fast development of the electron technology, which marks that the fire life safety enter into a new stage of the performance-based design. FDS+Evac is one of the most common evacuation softwares that is developed by VTT Technical Research Center of Finland and National Institute of Standards and Technology (NIST) together [5]. This software has been widely used to investigate life safety issues caused by the subway station fire for offering the theoretical guidance of safety study on further the urban transportation. King's Cross (1987), Zürich (1991), Daegu (2003) and Burnley (2007) have been present in this work, some accidents have been discussed in brief and the suggestion has been provided in order to avoid this type of calamity happen again.

## Fire Accidents

The study on fire accidents in the subway station can provide meritorious information to life safety in the subway station fire, which is used to improve safety design to prevent similar miseries in the future.

The three well known fire subway accidents (King's Cross, Zürich and Daegu) are selected and introduced because they associate with human behavior in fire [6]. All these accidents have a significant impact on life safety, which also urge people to more think about the safety practice in the subway.

**King's Cross, 1987.** On November 18, 1987, a fire accident happened in one escalator at the King's Cross subway station in London, UK [7]. A passenger set fire to a mixture of detritus and dust under the escalator and thus led to the fire. The fire spread quickly to the major ticketing hall on the top of the escalator, where smoke gathered and resulted in a flashover in the end. The fire brigade arrived at the King's Cross subway station after 15 minutes. At the moment, the flashover had already turned into the combustion, so firefighters mainly rescued the passengers trapped in the fire instead of putting out the subway station fire. At last, this fire accident led to 31 fatalities and some others injured [7].

The fire incident at the King's Cross subway station is a typical case, which explained how to escape at a subway station by applying the role-rule model and illustrated the behavior characteristics in the fire [6].

**Zürich, 1991.** On April 16, 1991, a fire started on a subway train in Zürich, Switzerland [8]. The fire accident was due to the arson, which was firstly found by a staff member of the subway station and a conductor in the other train. However, both of them did not report this emergency situation to the subway driver. Then, the subway was forced to stop in the middle of the 1.2 kilometers long Hirschengraben tunnel since a passenger drew the emergency break of the subway. Finally, no casualties and injuries were fortunately reported in this fire accident even if the fire was not stamped out immediately.

The Zürich subway fire [8] is also the other example that can be deciphered by using the human behavior theories.

**Daegu, 2003.** On 18 February 2003, a mentally ill patient ignited a subway train with the gasoline at Jungangno Station in Daegu, South Korea. The fire spread rapidly to all carriages within 60 seconds on account of the flammability of interior materials in the subway. Two trains were burnt down in the fire, which led to 192 fatalities and 148 injuries because the overall subway station was quickly filled with smoke [9].

The fire accident of the Daegu subway station emphasized the importance of life safety design in subway station fire and the necessity of improving smoke control system so as to retain a safe evacuation passageway. A rational and potential way that study life safety issue is to simulate the evacuation behavior of human in the subway station by applying the computer models. Such method may avoid real crowd evacuation experiment in the subway station and ensure the safety of passengers.

## Human Behaviors in Fires

A discussion about human evacuation behavior in the fire accident of the subway station should be carried through, which can provide helpful information for the life safety design of the subway station.

Canter et al. developed the behavior sequence model [10], which contributed to explaining the human behavior in the fire, as shown in Fig.1. The model is established on the basis of the systematic research of the human behavior in a variety of fires, which include household, multiple occupancy and hospital fires. Needed information was collected through talking with survivors of the fires about the escape behaviors taken. Among these behaviors, how to discover the fire and get out of the fire was the research emphasis.

Fig. 1 shows that the human escape behavior in a fire accident may be divided into three different stages, which is the interpret stage, prepare stage and act stage, respectively. Each stage is constituted with a series of behavior sequence, which is a sequence of the spontaneous behavior that human takes in the fire accident. In addition, this figure also proves that the potential behavior of human in the fire

becomes diversity due to the behavior sequence opened up, which can afford a more businesslike evacuation planning [10].

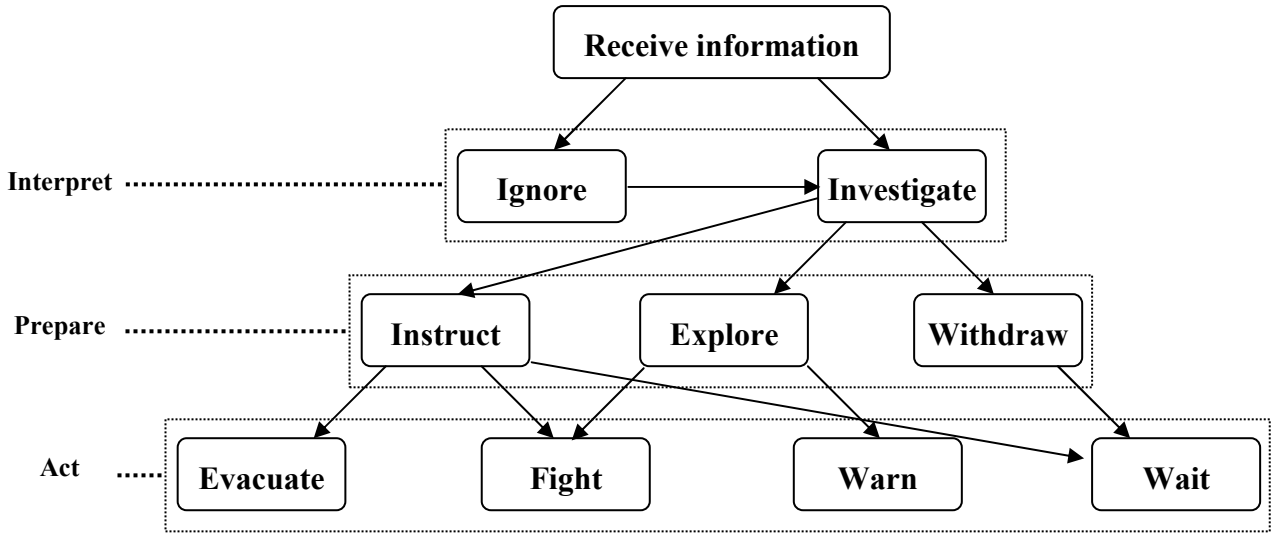

Fig. 1. The behavior sequence model developed by Canter et al. [10], which is helpful for understanding the human behavior in a fire.

In the fire initial stage, the information about the fire is lacking. So, the human behavior is indeterminate because people can not obtain the information needed. That is to say, once persons get enough information for the fire, they can take reasonable action. When people get the original fire cue, they could ignore or investigate the information and then search others information. Therefore, the interpretation stage is the same to all evacuation processes of the fire accident, which could be helpful for reducing the total evacuation time [6].

## Effect of Smoke on Human Behaviors

Smoke spread in the subway station has been investigated, but there has been still a lack of research on the effect of smoke on human behaviors in the subway fire. It is well known that the human behavior in the smoke is different from the in the smokeless environments. In other words, the greater the smoke density is, the lower the visibility of persons is, the longer the evacuation time is and the more dangerous life safety is. Additionally, many toxic gases generated in the fire has also the irritation of human eyes, people can not thus open their eyes, which leads to the extension of the evacuation time [6]. Therefore, study of effect of smoke on human behaviors should be very necessary for the life safety design in the fire accident.

## Summary

People do not pay close attention to the life safety when they travel convenience with the subway. Therefore, the fire accident in the subway station makes it necessary for any countries to re-examine their safety design towards the life safety, which should be tried from the emergency evacuation behaviors of persons.

Additionally, it should be noted that the unreasonable design of the subway path would aggravate fire accidents, and make the subway station more easily to the disaster happens. Smoke control is also an important effect factor subway fire accident becoming calamity. Great effort have been made to carry out the research on the human evacuation behavior in fires by some models, future investigation should thus devote to integrate existing evacuation models with future theoretical framework, which contributes to the rapid development of the urban transportation system.

# Study on Emergency Evacuation in the Subway Fire Accidents

Hua Xie[a], Yanying Xu, Xu Zhang and Jian Chen

School of Safety Engineering, Shenyang Aerospace University, Shenyang 110136, China

[a]email: tedalanchong@163.com

**Keywords:** Emergency evacuation, Fire accidents, Subway.

**Abstract.** The fire accident is a substantial risk in the subway due to the complexity of the underground construction confined space, which can cause a large number of human fatalities. Therefore, some effort should be made to promote the public security in subway fire accidents. Among of them, the establishment of emergency evacuation plan is very important in fire safety design and should be paid enough attention because it can provide beneficial help to life safety. The evacuation strategy including the evacuation route and evacuation safety zone are detailedly discussed in this paper, which lays the foundation for future studies of safe evacuation in the subway fire accidents.

## Introduction

In recent years, the subway construction in Mainland China has obtained the unprecedented development [1, 2]. By the end of 2009, the total length of the subway lines were 950 km, which can be used to the transportation in Chinese Mainland. Additionally, a number of cities (for example, Beijing, Shanghai, Guangzhou, Tianjin, Chongqing, Shenyang, Xian, Chengdu, Nanjing, Hangzhou, Suzhou and Dalian) are building subway lines, which the overall length reaches 1154 km. And then, others cities (such as Qingdao, Shijiazhuang, Jinan, Changsha, Hefei, Kunming, Lanzhou, Fuzhou, Ningbo, Xiamen, Dongguan, Urumqi, Nanning, Taiyuan, Yantai, Wuxi, Zhengzhou, and Guiyang) are planning them. As of August 20, 2009, the total plan length of the subway construction is 2260 km and the total investment budget is 882.003 billion RMB. By 2015, the overall length of the subway lines will extend to 4189 km in Chinese Mainland [3]. Therefore, the emergency evacuation in the subway fire accidents has attracted more and more attentions because it has the relation with the life safety of people. Currently, the computer simulation method is one of the most commonly used measures and is able to model the safe evacuation behavior in the subway fire during the subway design. Shi et al established the safety evacuation strategy by applying the agent-based model on the basis of the experimental data, which results will contribute to the study on the safety design of the subway evacuation [3].

It is well known that the smoke is the most dangerous factor in the fire accident and not flame and high temperature. Many substances in the fire smoke have highly toxic and irritating effects. Among of them, carbon monoxide (CO) is the most dangerous, which can cause carbon monoxide poisoning and the additive effects of hydrogen cyanide (HCN) and phosgene ($COCl_2$). The inhalation of the fire smoke also can result in incapacitation and loss of consciousness. In addition, sulfur oxides ($SO_x$), hydrogen chloride (HCl) and hydrogen fluoride (HF) when wet may transform into sulfuric, hydrochloric and hydrofluoric acid, which has strong corrosion resistance to the human body and material [4]. It should be noted that smoke can reduce the visibility and prevent people get out of the fire safely. In fact, the poor visibility caused by the dense smoke is a hinder to emergency evacuation and fire escape, which can lead to death by suffocation [5]. Therefore, the smoke flow should be taken into account in the investigation of emergency evacuation in the subway fire accidents. Both the subway evacuation strategy and related research progress in the fire accident have been discussed in the present work, and the recommendation has been provided to give some reference about the safety design of the subway.

## Research Progress

With the rapid development of the economy, the evacuation capability designed according to the previously predicted passenger traffic volume can not meet the requirement of the evacuation once the subway fire is really, which hinders the personnel safe escape. Many subway fire accidents around the world have shown that the errors of the emergency evacuation strategies will lead to a large number of casualties [2]. Therefore, the establishment of the emergency evacuation plan has been paid much attention because it is a critical question that we must think about in the design of the subway safety. The influence of some factors has also been analyzed and discussed, which focuses more on the behavioral and psychological characteristics of passengers in the subway, the evacuation plan and evacuation time, etc.

The behavior characteristics of passengers in emergency circumstances of Chinese subway have been investigated by He et al [6]. The organization question of the subway operation has also been researched under the circumstances of unexpected excessive passenger flows [7]. In addition, the traffic congestion characteristics at the floor stairs of the subway station have been studied in the evening peak hours [8].

With the progress of electronic science and technology, the computer is widely used to explore the evacuations behavior in the subway fire accident. For example, Helbing et al. quantified the passenger psychological response and obtained some typical passenger evacuation behaviors on the basis of the social force model [9]. Up to now, more than 20 kinds of the evacuation models have been established based on the modeling framework of the network model, fine grid model and continuous vector model. These proposed models are also segmented into different types in accordance with the practical application of the subway evacuation, such as modeling type, risk assessment type and optimization type [10]. Li et al. applied the evacuation modeling to evaluate the harm of smoke diffusion on life safety when the subway interchange station fired [11]. They concluded that fire smoke would impede the evacuation process, extends the evacuation time and obviously influence physical and psychological state, which ultimately results in a large number of deaths in the subway fire accident.

It should be noted that the subway in some countries are constructed in different eras, which results in the difference of the emergency evacuation strategy between the different countries. Therefore, the emergency evacuation strategy is not universal for the subway of different countries, which should be formulated on the basis of different standards and the actual situation in different countries.

Currently, most of the investigation work reported focus mainly on the crowd evacuation behavior of different buildings. Little attention is given to the subway evacuation strategy, especially the subway of Mainland China. Consequently, a systematic study of the emergency evacuation strategy about China subway is very necessary and helpful for guiding the life safety design of the subway in China. However, how to unify and optimize the safe and economic project is still an urgent issue, which results from the lack of understanding of establishing the evacuation strategy and the limit of applying of appropriate engineering calculation [3].

## Subway Evacuation Strategy

A comparison study found that the evacuation situation in the subway and building had many similarities, but there were also significant difference that needs to be carefully taken into account during designing and constructing the subway. Additionally, many research results about human behaviors in the fire accident may also be applied to the study of the evacuation strategy in the subway fire.

Subway evacuation strategy should comprehensively think over many aspects, such as the geometrical construction of the subway station, the location of a fire, the passenger flow volume, the evacuation route, the evacuation safety zone, and effective evacuation time, etc. The evacuation route and the evacuation safety zone are detailedly discussed in the establishment of emergency evacuation strategy in this work.

**Evacuation Route.** When the subway station fires and people are evacuated, the main escape passages include the platform screen door, the automatic gate, the train door, the escalator and staircase, the entrance and exit passages, the side door These passages with the state of emergency are different from their normal operation state, which is referred to as the emergency evacuation state of the passage [3].

- Opening strategy of the platform screen door. When a fire happens in the subway, the platform screen door and train door should be completely opened for the emergency evacuation of the passenger. However, when the subway train is the emergency shut down and the location of the train door is not in the correct position, the emergency exit of the platform screen door should be opened for the emergency evacuation of the passenger. Such is able to effectively reduce personnel casualties.
- Escalator operating strategy. When the fire happens and the passenger is evacuated, all the upward escalators from the platform to the station hall should be kept in upward operating state. In this case, the downward escalators have two emergency strategies that can be carried out. One strategy is to turn the downward escalators to the upward escalators, another strategy is to stop the downward escalators and use it as the fixed staircase, both of which help the passenger emergency evacuation. However, once the fire in one escalator, and then this escalator can not be applied for the passenger evacuation.
- Automatic gate strategy. And when the fire happens, all the automatic gates should be opened for the emergency evacuation of the passenger, which contain the entire entrance and exit automatic gates.
- Entrance or exit passage strategy. If the subway fire breaks out in an entrance or exit passage, then this access will not be applied to evacuate urgently since the passageway has been very dangerous.

**Evacuation Safety Zone.** When a fire breaks out, the identification of the evacuation safety zone is determined on the availability of the smoke control and exhaust system. The smoke removing system can be applied to efficaciously prevent the smoke from spreading the upper storey and prolong survival time for the various subway platform fires. Under this circumstance, the upper storey of the subway platform is able to be regarded as the evacuation safety zone. It should be noted that the upper storey of the subway platform may not be the storey of the station hall, which could be the storey of the passage or equipment.

When a fire happens in the station hall of the subway station, the storey of the station hall may not always be the evacuation safety zone, which mainly depends on whether or not the smoke control system on the storey of the station hall can efficiently prevent the smoke spreading. Under normal conditions, the evacuation safety zone in a fire of the station hall is the entrance and exit of the station hall.

## Future Prospects

With the improvement of people security awareness, the subway safety has aroused general concern of the society. Therefore, How to ensure the safety of the subway travel is very important and becomes a safety topic. In this paper, the research progress about the emergency evacuation of the subway fire has been reviewed, and the evacuation strategy (includes the evacuation route and the evacuation safety zone) is discussed on the basis of the behavior characteristics of passengers, which can be helpful for the safety design of the subway construction.

In addition, up to now, the emergency evacuation behavior of the disabled people is paid little attention, these efforts should be thus strengthened in order to meet the requirements of travel and safety of the disabled people, which is also a future research direction about the life safety of the subway. All these investigation are for the life safety of human, when the subway offers great convenience to people.

**Keywords:** Urban traffic link tunnel, Fire smoke, Semi-transverse ventilation, numerical simulation.

**Abstract.** Fire simulation software (FDS) was employed to simulate the fire smoke movement of urban traffic link tunnel (UTLT) under the semi-transverse ventilation. Numerical simulation and theoretical analysis were used to analyze the fire smoke movement in three fire scenarios. The analytical results show that: semi-transverse ventilation can effectively control the spread of fire smoke. When the exhaust air rate is certain, the exhaust port interval of 20 m and 50 m has little effect on function of smoke control. The research results provide references for the design of smoke control measures in UTLT.

## Introduction

Most UTLT made up of a main circular tunnel and some connective tunnels are built in underground space of downtown area [1]. UTLT often linked to the underground parking lot and business district is different from regular tunnels. The multiple points of entry and exit, high traffic and narrow section are its most striking feature. Therefore, it's a possibility for a fire. The fire smoke in circular tunnel spreads quickly with great potential fire and harm hazard [2, 3].

So far, the research has focused on longitudinal ventilation and transverse ventilation in UTLT fire that draws most attention from many scholars at home or abroad [4-6]. Until recently, there is little information available in literature about the effect on smoke management and movement under semi-transverse ventilation. In this paper, UTLT has been taken as a research subject. Three fire scenarios are presented and simulated by FDS. Through theoretical and numerical methods, the impacts of exhaust port interval and semi-transverse ventilation on smoke movement are analyzed. The results of the research can provide reference for design of fire control in UTLT under semi-transverse ventilation.

## Model of UTLT

**UTLT Description.** UTLT taken as a research subject runs 2400 m under the municipal road. Each side of UTLT is about 600 m with 4 m high and 8 m wide. The main tunnel with one-way counterclockwise is two lanes. The 560 m long exit ramps is about 4 meters high and 4 m wide.

**Fire Model of UTLT.**

(1) Model of FDS.

In this paper, UTLT has been taken as a research subject. According to the design size, the fire model of UTLT is built by the FDS software, as shown in Fig.1.

(2) Heat Release Rate.

Based on functions and features of UTLT, the frequency of fire is considered once in the same time because it allows only sedan car to drive and it is closed for other cars to traffic. The heat release rate is $t^2$ growth pattern and the maximum is 20MW. This is equivalent to the heat release rate of 3-4 cars ignited.

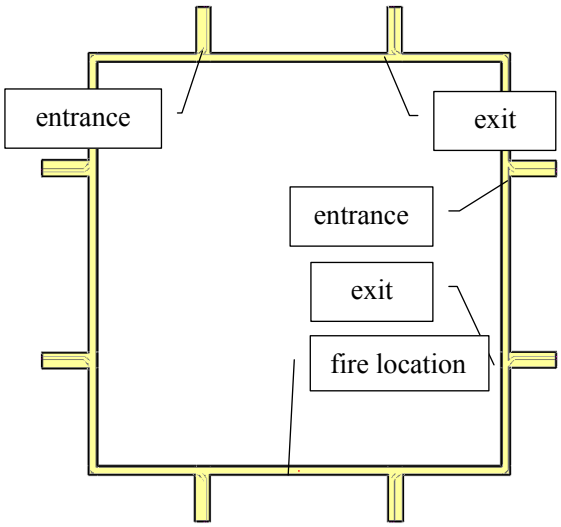

Fig.1 FDS model of UTLT

(3) Smoke Management System.

The size of fire source is 2.0m x 2.0m x 2.0m situated in central tunnel. The exits of UTLT are considered as natural ventilation openings. The simulation time is 1200s.

The smoke zone is set up on every 100 m in main circular tunnel. The exhaust port can be set on request under the semi-transverse ventilation. Smoke screen is 0.5 m high. According to the specification requirements [7], interval of emergency evacuation path is 250-300 m. Therefore, 300 m range is managed as smoke prevention and exhaust area which contains burning smoke zone and its two adjacent sites. The smoke management system works properly when the fire happens. According to the < Specifications for Design of Ventilation and Lighting of Highway Tunnel >, exhaust air rate is 12 air changes per hour determined by way of the specification.

**Scenarios Design.** In order to research the influence of exhaust port and semi-transverse ventilation on the fire smoke movement, three fire scenarios are presented and simulated by FDS, as defined in Table 1.

Table 1 List of fire scenarios

| fire scenarios No. | exhaust port interval (m) | semi-transverse ventilation system |
|---|---|---|
| A | - | failure |
| B | 50 | normal |
| C | 25 | normal |

## Analysis of Simulation Results

**Simulation Results of Fire Scenarios A**. Semi-transverse ventilation system has been failure in fire scenario A. The simulation results indicate that the fire smoke can spread out of the smoke prevention and exhaust area at 290s. The total distance of fire spread can reach 865 m in the range of main circular tunnel at 1200s, as shown in Fig.2. The temperatures exceed 60 ℃ at right-and-left distance of 150m to fire location at 1140s. The poor visibility at right-and-left distance of 150m to fire location can only be 10 meters at 335s.

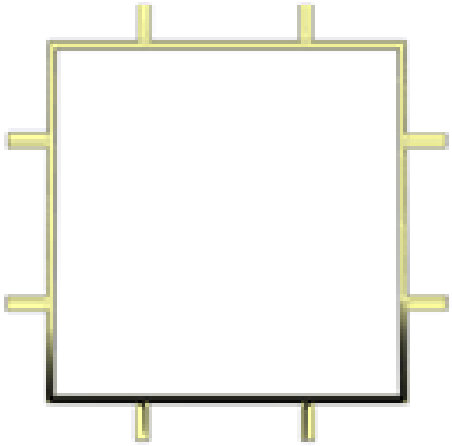

Fig.2 Smoke spread pattern at 1200s

**Simulation Results of Fire Scenarios B.** It is two exhaust ports in one smoke zone interval of 50 m in fire scenario B. The simulation results indicate that the fire smoke can spread out of the smoke prevention and exhaust area at 410s. The total distance of fire spread can reach 430 m at 1200s. The temperatures are always below 60 ℃ at right-and-left distance of 150m to fire location within a period of 1200s. The poor visibility at right-and-left distance of 150m to fire location can only be 10 meters at 583s. The distribution of visibility field on the height of 2 m at 900s is presented, as shown in Fig.3.

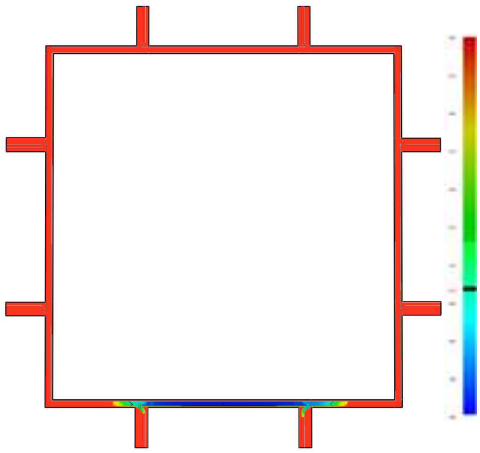

Fig.3 The distribution of visibility field on the height of 2m at 900s

**Simulation Results of Fire Scenarios C.** The exhaust air rate is 12 air changes per hour determined by way of the specification. It is four exhaust ports in one smoke zone interval of 25 m in fire scenario C. From simulation results, the fire smoke can spread out of the smoke prevention and exhaust area at 410s. The total distance of fire spread can reach 425 m at 1200s, as shown in Fig.4. The temperatures are always below 60 ℃ at right-and-left distance of 150m to fire location within a period of 1200s.

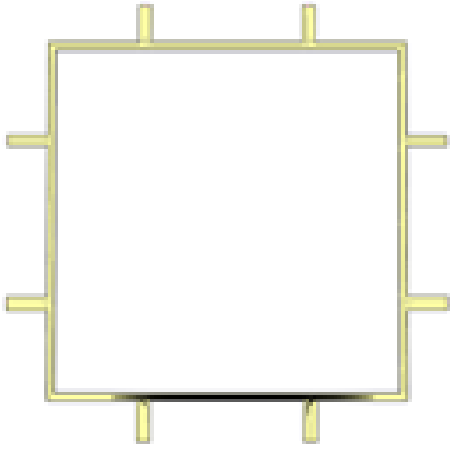

Fig.4 Smoke spread pattern at 1200s

**Influence of Semi-transverse Ventilation System on Simulation Results.** Table 2 describes the distance of smoke spread in scenario A and B. Comparison of the results, when semi-transverse ventilation system operates properly, distance of smoke spread can be as short as about 435 m. The temperature variety curve at 90m is presented as shown in Fig.5. When semi-transverse ventilation system fails, temperatures in the same place are higher than in normal conditions. Because the hot smoke with large amount of heat is being taken out by semi-transverse ventilation system. Semi-transverse ventilation system has a significant effect on smoke control, improvement of visibility and reduction of temperature.

Table 2 Distance of smoke spread in scenario A and B

| fire scenarios No. | distance of fire spread in left side(m) | distance of fire spread in right side(m) | Total distance of fire spread(m) |
|---|---|---|---|
| A | 405 | 460 | 865 |
| B | 195 | 240 | 435 |

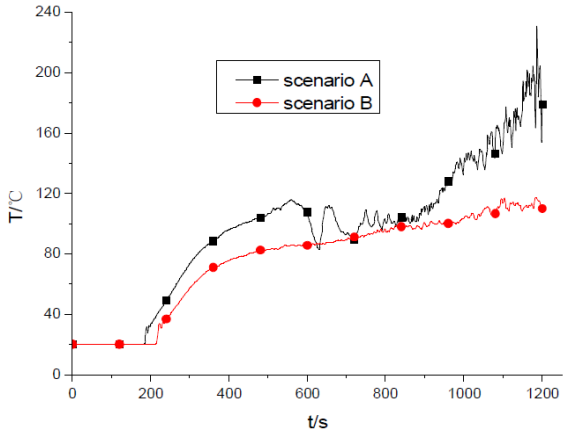

Fig.5 Temperature variety curve at 90m from fire source

**Influence of Exhaust Port Interval on Simulation Results.** Table 3 lists the distance of smoke spread in scenario B and C under the semi-transverse ventilation. The temperature variety curve at 90m is presented as shown in Fig.6. The exhaust port interval has a less influence on smoke control.

Table 3 Distance of smoke spread in scenario B and C

| fire scenarios No. | distance of fire spread in left side(m) | distance of fire spread in right side(m) | Total distance of fire spread(m) |
|---|---|---|---|
| B | 195 | 240 | 435 |
| C | 195 | 235 | 430 |

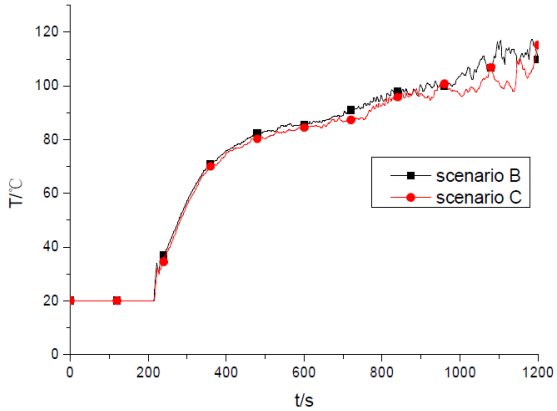

Fig.6 Temperature variety curve at 90m from fire source

## Conclusions

In this paper, UTLT has been taken as a research subject. Three fire scenarios are presented and simulated by FDS. Through the analysis of distance of smoke spread, visibility and temperature, this paper draws the following conclusions:

(1) When semi-transverse ventilation system operates properly, distance of smoke spread can be as short as about 435 m. Semi-transverse ventilation system has a significant effect on smoke control, improvement of visibility and reduction of temperature.

(2) When the exhaust air rate is certain, the exhaust port interval under the semi-transverse ventilation has a less influence on smoke control.

In order to ensure that semi-transverse ventilation system operates properly, it must be periodic examine and maintenance. The settings for exhaust port should be made as economy as possible.

Institute of Rock and Soil Mechanics, Chinese Academy of Sciences, Wuhan 430071, P. R. China

**Keywords**：Baihetan hydropowerstation, regional stress, distribution rules, regression analysis.

**Abstract.** According to the analysis results about the distribution rules of tectonic regional stress in China mainland, the distribution rules of tectonic regional stress in Chuandian and the tectonic movement of Baihetan , the distribution rules of regional stress in Baihetan were preliminary analysed. Based on measured results of geostress and the statistical analysis of the measured results about the geostress of the shallow crustal magmatic in China mainland,the distribution rules of regional stress in underground powerhouse at the right bank of Baihetan hydropower station were studied. In general,the maximum and the minimum horizontal principal stresses and the vertical stresses increase linear with depth . In dam abutment $\sigma_H > \sigma_h > \sigma_v$ .while in the underground powerhouse $\sigma_H > \sigma_v > \sigma_h$ .Based on the measured results of geostress,the dispersed point charts of the ratio among the maximum horizontal stress ,the minimum horizontal stress and the vertical stress with depth in China were established, using the method from the statistical analysis of measured results about the shallow crustal geostress in China mainland and the corresponding regression analysis was studied.

## Introduction

Rock stress is an important factor in rock mass stability and engineering operations, and the geostress is one of the most important fundamental factors that influence the stability of many projects such as underground caverns . The stress field has complicated origin and is influenced by many factors. In recent decades, geostress data measurement and theoretical analysis show that the formation of geostress is related to many kinds of geodynamic processes, among which the movement and extrusion of crustal plate and gravity are the main factors constituting the geostress.In-situ test of the geostress is the most direct method to provide regional geostress data. However, due to high cost, space restriction, geological conditions complexity and so on, the in-situ test is not suitable for a large number of measurements. In addition, the test result of geostress of each point can only reflect the characteristics of local ground stress, which results in the high discreteness of test results[1].Therefore, based on the measured data of ground stress field, geological conditions and the effective mathematical-mechanical inversion methods, the ground stress field can be obtained more accurately. This method has wide application and used widely in engineering to analysis the distribution of ground stress field.

Our country is located in the eastern part of the Eurasian plate. Due to the subduction of the Pacific plate in the east, the push of the Philippine Sea Plate in the southeast and the collision of the Indian plate in the west, the new tectonic movement in the region is particularly active. Especially, since nearly 45 Ma, the strong collision and squeezing resulted from the movement of Indian subcontinent to the Asian continent have changed the topography of western China greatly. With the Indian plate moving northward continuously, Himalayas and Tibetan Plateau uplift rapidly since the middle Miocene(16~10Ma), which generate combined extrusion to the surroundings[2].Because the Chinese mainland is controlled by the interaction of surrounding plates ,the maximum principal

stress decreases from west to east, and tectonic activity is intense in the west, while relatively weak in the east[3].In present, the strike of the maximum principal stress axes in China mainland is distributed radially in generally toward the center of the Tibetan Plateau[4],from west to east, which is rotating clockwise gradually from the direction of nearly NS to the directions of NNE, NE, NEE, and SE; the horizontal stress is dominated in the tectonic stress field, while the maximum and minimum principal stress axes are nearly horizontal. The direction of the maximum principal stress appears obvious regional characteristic, which can be roughly divided into the west region, the north and northeast China region, the south part and Sichuan-Yunnan region [5].

Baihetan hydropower station is constructed on the east of the Sichuan-Yunnan rhombic block, the geostress field is not only influenced by the tectonic movement of itself, but also influenced by the geostress field of china and Sichuan-Yunnan area. Therefore, the geostress field distribution in the engineering site of Baihetan hydropower station can be fitted effectively according to the statistical regularity of stress field and the test results of Baihetan hydropower station. In this paper, the distribution rules of the regional stress in underground powerhouse at the right bank of Baihetan hydropower station will be researched using the method of regression fitting, based on the China regional tectonic stress analysis results and the measured data.

## The analysis about the geological tectonic origin of Baihetan regional stress

Baihetan hydropower station is constructed within the downstream of Jinshariver which links Qiaojia County of Yunnan Province and Ningnan County of Sichuan Province. The Ningnan area is located in the east of the Chuandian rhombic block, where the geostress field is not only influenced by the plate movement but also influenced by the faults in the surrounding area of the Sichuan-Yunnan. In addition, the tectonic movement of the Baihetan area makes the geostress field more complicated .Underground powerhouse cavern group are located within the mountain valley area with strong earthquake activities, where the basic earthquake intensity is Ⅷ degree. The topography of engineering area is complicated, which has higher regional stress , complex geological conditions, developed F14, F16 and F-17 faults, various faulting belts, columnar joints and other adverse geological structures.

**Statistics and analysis of the measured geostress of the shallow crust magmatite in China mainland.**The basement of Baihetan Hydropower Plant is mainly the Emei Mountain Basalt of Permian system, which is typical spray-type magmatic rock.Jingfeng[5] collected the measured geostress from more than 400 drill holes, according to the “in-situ stress field data compiled in the world”[6]by Chen Pengnian, “studies of Chinese mainland crustal stress environment”[7] by XieFuren and other published books and papers . The measured range involves almost the whole area of Chinese mainland. Based on the lithology of the underground powerhouse area in Baihetan right bank, he studied the distribution rule of the geostress field of the shallow magmatic rocks in China mainland by statistical method. Stress relieving methods and hydro-fracturing methods are the primary test methods, while a small number of caving methods is adopted. The distribution of the shallow magmatic rocks with depth in china mainland is shown in Figure 1.As shown in Figure 1, the magnitude of the vertical stress has a linear relation with the buried depth in general .The relationship can be fitted with linear regression method and the fitting formula is shown as Equation (1).

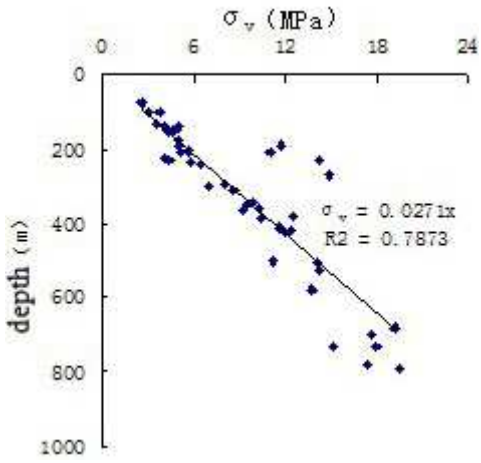

Fig.1.Curve of magmatite's $\sigma_v$ vs. depth in China

$$\sigma_v = 0.0271H \qquad (R^2 = 0.7201) \tag{1}$$

Where $H$ is buried depth, $R$ is linear relative coefficient

The distribution of the maximum and the minimum horizontal principal stresses with depth in the shallow magmatic rocks in China mainland are shown in Figure 2.which shows that the maximum and the minimum horizontal principal stresses has a linear relation with the buried depth in general. The linear regression fitting is adopted, and the fitting formula is shown as Equation (2).

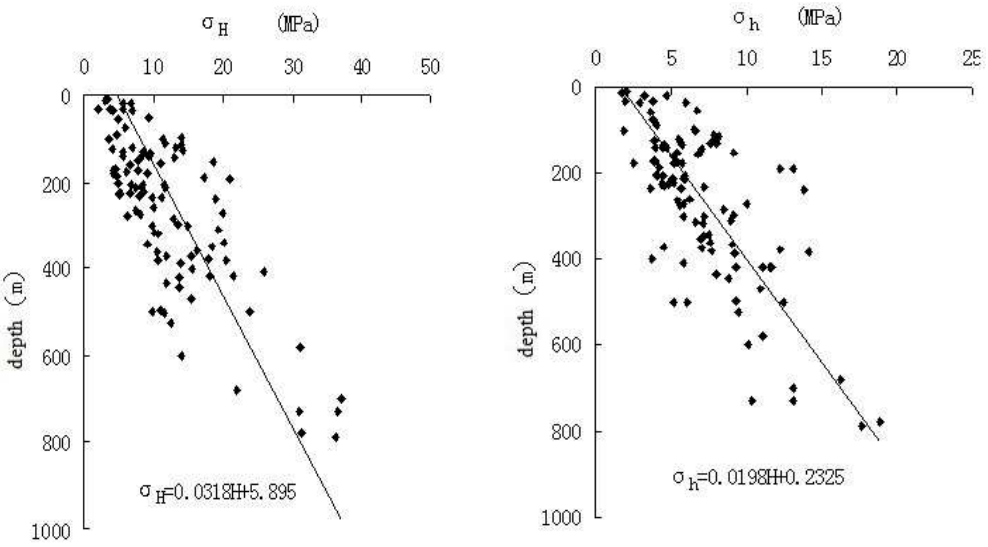

Fig.2. Curve of magmatite' horizontal principal stress vs.depth in China

$$\begin{cases} \sigma_H = 0.0318H + 5.895 & (R^2 = 0.7111) \\ \sigma_h = 0.0198\ H + 0.2325 & (R^2 = 0.5534) \end{cases} \tag{2}$$

**The study on the modern tectonic stress field in Sichuan-Yunnan region.** Sichuan-Yunnan region is one of the four tectonic stress areas in China, located in the southeastern edge of Qinghai-Tibet plateau, which is the edge of the interaction converge contact zone between the Eurasian plate and Indian plate. As the strong earthquake activity area in China, its tectonic stress field is relatively complicated. The direction of the principal compressive stress has great change,

where the direction of the principal compressive stress rotates clockwise from north to south[8].In Longmenshan fault zone ,Xianhuihe fault zone, and the north area, the direction of the principal compressive stress of geologic structure stress field is nearly east-west; In Sichuan-Yunnan rhombic block, the principal compressive stress directs between north and north-west[9]; in the east of Sichuan-Yunnan rhombic block, the direction of the principal compressive stress appears mainly north- west; while in the west of Sichuan and Yunnan rhombic block, the principal compressive stress directs between north and north- east.

By the mechanism of the inversion of focal, Cui classified the tectonic stress field of China mainland into 3 zones[10], which is southwestern Yunnan stress zone, Sichuan-Yunnan stress zone and Mabian-Zhaotong stress zone. In southwestern Yunnan stress zone, the distribution orientation of the maximum horizontal principal stress is mainly NNE - SSW trending ( azimuth angle20°);in Sichuan-Yunnan stress area, the distribution orientation of the maximum horizontal principal stress is mainly NNW-SSE trending(azimuth angle340°)； in Mabian-Zhaotong stress area， the distribution orientation of the maximum horizontal principal stress is mainly NWW-SEE trending. In general, in the Sichuan-Yunnan region the direction of the maximum principal stress of the three stress zones appears the characteristic of the rotation clockwise from east to west.

**The analysis of Baihetan regional tectonic movement.** Since the basalt eruption of Permian Emeishan, the project area of Baihetan hydropower had experienced mainly Himalayan movement and Yanshan movement .After the basalt eruption ,the geological evolution history of this area is divided into Himalayan period and Yanshan period. There are Sichuan movement, Himalayan movement and the Neotectonic movement in Himalayan period, in which the latter two geological tectonic movements are the main affecting factors for the formation of the geostress field in Baihetan dam area.

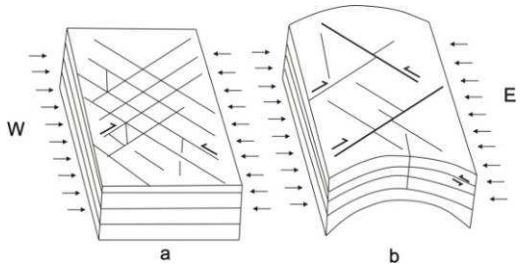

Fig.3.Sketch map of the direction of development and movement of fault in Stage of Yanshan

Formed in the late Yanshan period, the fault structures in Baihetan hydropower station dam area include four groups of faults, which are N60 º W, N20 º W, N40 º E and near NS faults. Under the nearly east-west extrusion stress field, the NW trending faults mainly acted as left-lateral slippage, while the NE trending faults acted as right slippage(Fig. 3 b), and the near NS trending faults acted as reverse faults. In the Xishan period, the Himalayan Indian Plate squeezed the Chinese continental plate along the NNE trending , where the main features of the tectonic stress field were nearly horizontal NS shortening and EW extension. The dam site area did not form a new fault system, and mainly the pre-existing four group faults moved again. In this period, the NW trending faults mainly acted as right-lateral slippage, while the NE trending faults acted as left-lateral slippage, and the NS trending faults mainly acted as normal faults. Neotectonic movement refers to the tectonic movement after the Sichuan-Yunnan rhombic block formation (about 5 Ma).In this period, the Tibetan plateau extrused eastward, leading to the separation of Sichuan-Yunnan rhombic block Yangzi landmass, with the movement to the south and clockwise rotation. Based on the earthquake mechanism, the measured stress condition in-situ and the distribution rule of the present tectonic stress field in southwestern China, the basement of Baihetan hydropower station is located in the east of the Sichuan-Yunnan rhombic block. Due to the Indian plate pushing northward, the crust in China is shortened in the north-south direction and extended in the south-west direction. The lithosphere substance of the Tibetan plateau is extruded to the east, which forms a NWW trending

compressive stress field in Xichang-Ningnan area. Therefore, according to the analysis of Baihetan regional tectonic movement, the principal compressive stress direction is NW-NWW trending [11].

**The analysis of the measured geostress in the right bank of Baihetan hydropower station**

In order to measure the accurate magnitude and the direction of the geostress field in the Hydropower Station, 8 drill holes are distributed in the slope of the right side bank, while 6 in the plant area , as shown in Fig 4.

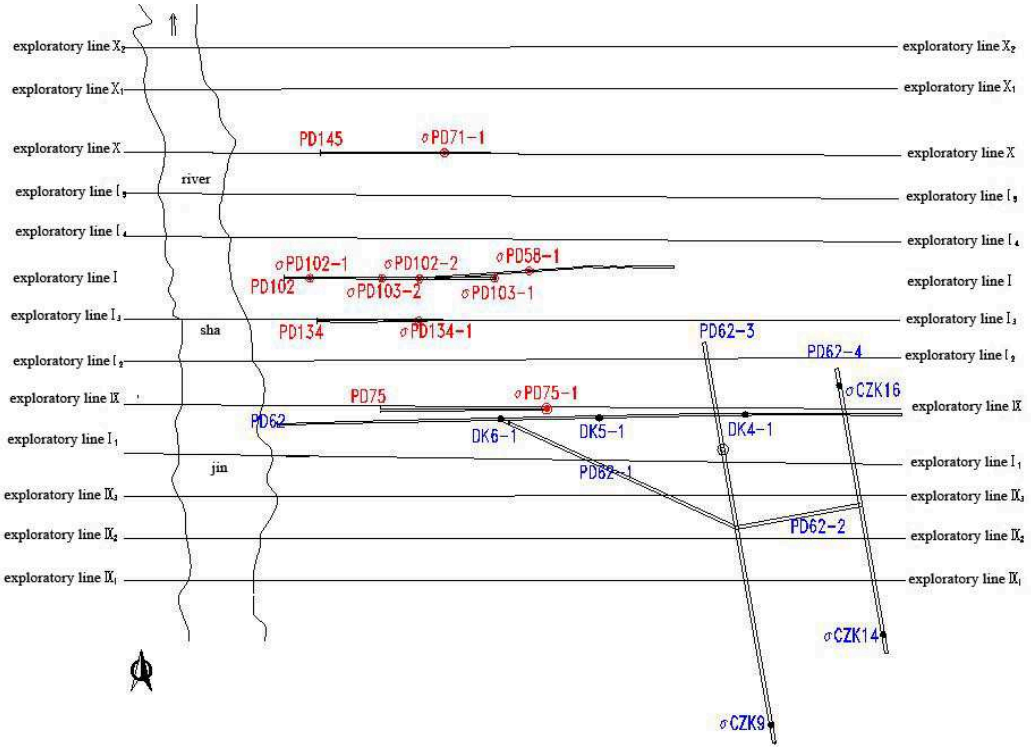

Fig.4.Sketch map of measuring points

From the test results, the value range of the maximum principal stresses of the slope at the right bank is approximately 3.8～14.2MPa, with the average of 8.7MPa. The main direction is NNE trending, with a few direction being NNW and NW and the average value being about N7°E, the dips being given priority to gently dips with a small amount being nearly level. The value range of the minimum principal stresses is 3.5~6.0MPa, with the direction being NWW trending and the dips changing greatly. In the factory of the right bank, the value range of the maximum principal stresses is19.2~24.6Mpa, with the average value being 21.8Mpa, the main direction being NEE trending, and the dips being nearly level. The value range of the minimum principal stresses is 5.2~11.5MPa, giving priority to NNW trending, and the dips are middle steep. There is large deflection between the direction of the measured principal stress and regional structure analysis. According to the current preliminary analysis, the main reasons are the river erosion, the geological movement of bank slope and so on.

**The deduction analysis of the stress field in the engineering area based on the statistics of the measured data**

**Regression fitting of the measured geostress.** The geostress field of the engineering area can be denoted by the three orthogonal principal stresses .The direction of $\sigma_2$ is nearly vertical, which can be expressed by $\sigma_v$;The direction of $\sigma_1$ and the minimum principal stress $\sigma_3$ are nearly horizontal, which can be expressed by $\sigma_H$ and $\sigma_h$ separately. Based on the measured geostress data of Baihetan hydropower station area and the distribution rule of the geostress field of the shallow magmatic rocks in China mainland, the distribution rule of the geostress field of the underground

powerhouse at the right bank of Baihetan hydropower station is studied by the method of linear regression fitting without considering the maximum and minimum horizontal principal stress direction, which is shown in figure 5.

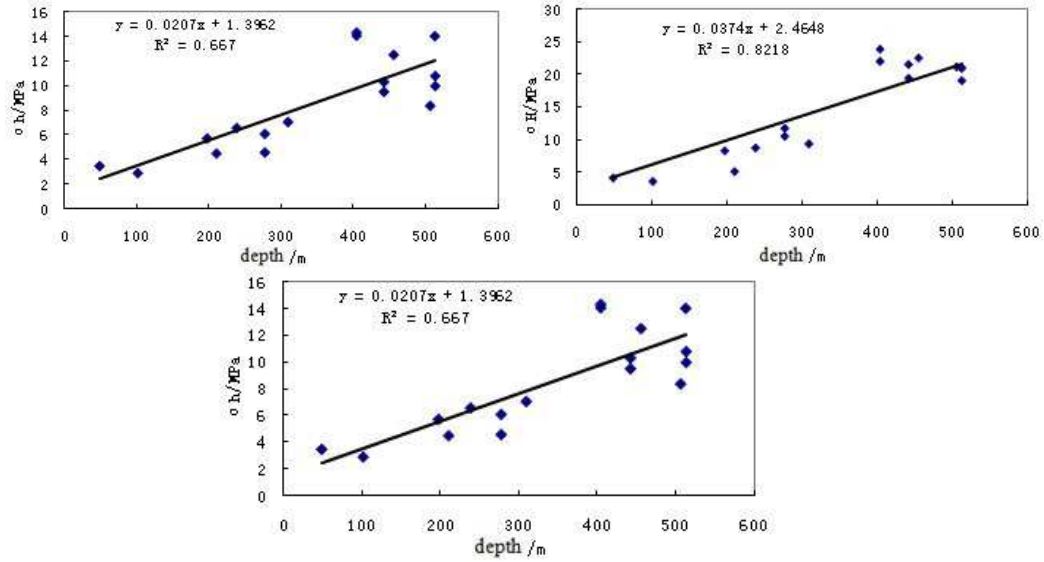

Fig.5. Curve of the verticalstresses,the maximum and minimum horizontal principal stress vs.depth in underground powerhouse of the right bank of Baihetan hydropower station

As shown in fig 5 , in generally, $\sigma_v$ , $\sigma_H$ and $\sigma_h$ increase with the burial depth, scatters change within a near parallel band. $\sigma_v$ , $\sigma_H$ and $\sigma_h$ show the linear relationship with the buried depth, and the result of the linear regression fitting formula is following Equation (3)

$$\begin{cases} \sigma_v = 0.0254H & (R^2 = 0.708) \\ \sigma_H = 0.0374H + 2.4648 & (R^2 = 0.822) \\ \sigma_h = 0.0207H + 1.3962 & (R^2 = 0.667) \end{cases} \quad (3)$$

In the depth range of the test, the change trend of the geostress with depth of the underground powerhouse area at the right bank of Baihetan hydropower station is similar to the statistic distribution of the stress of the shallow continental in China, while there are some errors in the magnitude. This is because that it is affected by the factors such as geomorphology, rock weathering and so on.

**The analysis of the measured geostress and the verification of fitted stress.** The change laws of the average lateral pressure coefficient $(\sigma_H + \sigma_h)/2\sigma_v$ , lateral pressure coefficient $\sigma_H/\sigma_v$ and $\sigma_h/\sigma_v$ with buried depth at the right bank of Baihetan hydropower station can reflect properly the differences of horizontal stress and the role of the horizontal tectonic stress, and also can be applied to the practical engineering more conveniently. The comparison between the measured stress and the principal stress obtained by fitting formula(3) is shown in table 1,and the profile of $\sigma_H/\sigma_v$ , $\sigma_h/\sigma_v$ and $(\sigma_H + \sigma_h)/2\sigma_v$ with buried depth are shown in figure 6.

Figure 5 and 6 illustrate that , in the depth range (48~309m) at right bank slope, the value range of the vertical stresses $\sigma_v$ is about1.22~7.85MPa ,the value range of the maximum horizontal principal stresses $\sigma_H$ being about4.26~14.02MPa, the value range of the minimum horizontal principal stresses $\sigma_h$ being about 2.39~7.79MPa. The ratio of the average horizontal principal stress and the vertical stress $(\sigma_H + \sigma_h)/2\sigma_v$ is about 1.42~2.73,and the ratio of the maximum horizontal

principal stress and the vertical stress $\sigma_H/\sigma_v$ is about 1.79~3.49,that is to say, the lateral pressure coefficient of the maximum horizontal principal stress direction is about 1.79~3.49,andthe ratio of the minimum horizontal principal stress and vertical stress $\sigma_h/\sigma_v$ is about 0.99~1.96, that is to say, the lateral pressure coefficient of the minimum horizontal principal stress direction is about 0.99~1.96. Generally, the horizontal stress of the abutment area stress field in shallow ground of the earth crust dominate ,the numerical size of the above three stresses is $\sigma_H > \sigma_h > \sigma_v$. In the depth range of the underground powerhouse in right bank (404～513m), the value range of the vertical stresses $\sigma_v$ is about 10.3~13MPa ,the value range of the maximum horizontal principal stresses being $\sigma_H$ about 17.57~21.65MPa, the value range of the minimum horizontal principal stresses $\sigma_h$ being about 9.76~12MPa.The ratio of the average horizontal principal stress and vertical stress $(\sigma_H+\sigma_h)/2\sigma_v$ is about 1.29~1.33,the ratio of the maximum horizontal principal stress and vertical stress $\sigma_H/\sigma_v$ is about 1.66~1.71,that is to say, the lateral pressure coefficient of the maximum horizontal principal stress direction is about1.66~1.71 ,and the ratio of the minimum horizontal principal stress and vertical stress $\sigma_h/\sigma_v$ is about0.92~0.95, that is to say, the lateral pressure coefficient of the minimum horizontal principal stress direction is about 0.92~0.95. generally, the numerical size of the above three stresses is $\sigma_H > \sigma_h > \sigma_v$.

From Table 1, when the depth is less than 100m, the stress value obtained by fitting formula (3) appears a large jump, which is not consistent with the actual condition .This is because the geostress in the shallow rock stress field is mainly affected by the poisson effect and rock weathering .Therefore, fitting formula (3) must be modified. The method of piecewise fitting is adopted, and the result is shown as equation(4).

Table1. Comparison between measured stresses and stresses got in the fitting analysis

| Location | Drilling | The depth of gallery (m) | Altitude (m) | Burial depth (m) | $\sigma_H$(MPa) | | $\sigma_h$(MPa) | | $\sigma_v$(MPa) | |

## Conclusions

By analyzing the distribution of the geostress field in Chinese mainland, Sichuan-Yunnan region and the tectonic movement of Baihetan area, preliminarily conclude the direction of the principal compressive stress field of the underground powerhouse area in Baihetan hydropower station is concluded preliminarily as NW ~ NWW trending. Based on the geostress measurement, the method of the statistical analysis about the measured data of the shallow crustal geostress in China mainland is adopted. The regression formulas of the distribution law of the geostress with depth at the right bank underground powerhouse area are fitted .Then the fitting result is analyzed, and the distribution law of the geostress field in the right bank underground powerhouse of Baihetan hydropower station is studied:

(1) In the right bank slope area, the average direction of the maximum principal stresses is about N7 ° E trending, the dips being given priority to gently dips, a small amount being nearly level; The direction of the minimum principal stresses is NWW trending, the dips changing greatly in the right bank factory. The main direction of the maximum principal stresses is NEE trending, the dips being nearly level, while the main direction of the minimum principal stresses is NNW trending,the dips being middle steep.

(2) $\sigma_v$, $\sigma_H$ and $\sigma_h$ generally present the linear relationships with buried depth generally, which is similar to the distribution of the stress at the shallow continental in China, but there are some errors in magnitude. The numerical size of the above three stresses is $\sigma_H > \sigma_h > \sigma_v$ in the dam abutment ,while $\sigma_H > \sigma_v > \sigma_h$ in the underground powerhouse .

(3) In the right bank slope area, the change range of $(\sigma_H + \sigma_h)/2\sigma_v$, $\sigma_H/\sigma_v$ and $\sigma_h/\sigma_v$ are large in the shallow area, and decrease rapidly with the increase of buried depth. In the depth range of the right bank underground powerhouse(404～513m),the value of $(\sigma_H + \sigma_h)/2\sigma_v$, $\sigma_H/\sigma_v$, and $\sigma_h/\sigma_v$ is smaller.

**Keywords:** Urban Tunnel, Shallow-underground Cut Method, Blasting Construction, CD Method, Bench Method with Reserved Core Soil.

**Abstract.** The construction method requires careful consideration in order to reduce impact of tunnel on the surface of the building in the city. It can have great significance in choosing appropriate blasting excavation method for the poor surrounding rock conditions and complicated ground constructions of shallow buried tunnel. This paper combines the Guanhui urban railway transport projects which the shallow buried tunnel through the dense residential areas, research on the influence of CD method and bench method with reserved core soil when use blasting excavation method on the surface buildings by finite element method. The suitability of two kinds of blasting excavation method in the urban shallow tunnels is analyzed and compared, eventually determine the CD method with blasting excavation is more suitable for the urban shallow tunnel construction, it provides reference and suggestion for future similar construction methods that tunnel construction under the city.

## Introduction

With the development of the national economic, a large number of various types of city tunnel have been constructed, its environment is usually complex such as the buried depth is shallow, too many surface buildings, road facilities and underground pipeline planted densely, it is inevitable to impact the surrounding environment during tunnel construction[1]. Take the mechanical excavation can effective reduce the impact of urban tunnel construction on the environment. But due to the high cost, slow construction progress, narrow working space, blasting excavation is usually chosen in the city shallow tunnel[2].

Seismic effect is an important factor affecting the safety of blasting during the city tunnel blasting excavation. The harm of excavation vibration of underground structures on the ground facilities, especially on the urban surface buildings has attracted the attention of engineering field, domestic and foreign researchers have done a lot of research on this. Glenn gets the relationship between blasting vibration frequency and structural damage degree by the study[3]. Shibo Liu put forward that by the blasting construction environment more and more complex, the resident reaction near the blast area response more strongly[4]. Shigen Fu analysis the seismic effect of blasting vibration principle and point out the blasting vibration velocity is an important quantity that leads to destruction of building structure, it can also make normal work of buildings affected[5]. From the existing research results, the research for the influence of blasting construction on the surrounding environment have achieved certain results, but the choice of blasting construction method has no definite conclusion when shallow buried tunnel underpass densely populated areas.

This paper is based on the Guanhui urban railway transport projects which the shallow buried tunnel through the dense residential areas as the research background, combined with the actual engineering environment and use numerical simulation method to analyze the vibration velocity and surface subsidence of the adjacent buildings above the tunnel what are caused by CD method or bench method with reserved core soil. This paper analyzes the suitability of construction method when the tunnel through the dense residential areas, and provide reference and recommendations for similar engineering.

## Research Background

**Safety Criteria of Blasting Vibration.** According to the relevant provisions of China *Blasting Safety Regulations*[6], the safety velocity of blasting vibration is determined as $V$=2cm/s, combined with the actual geological conditions and surface structures of the Guanhui urban railway transport projects, specified the safe and permitted standard value of blasting vibration is 1.5cm/s for the V~VI class surrounding rock.

**Construction Method Introduction.** Depending on the nature of each segment surrounding rock of Guanhui urban railway, mainly choose CD method and bench method with reserved core soil for the V~VI class surrounding rock.

**Bench Method with Reserved Core Soil.** Using circular excavation with reserved core soil can reduce the amount of one-off surrounding rock excavation and prevent squeezing out the tunnel face in the city shallow buried tunnel, the excavation method is as: reserved the core soil platform in upper heading curved section → primary support → excavate the central core soil → excavate the lower bench → carry out combined bolting and shotcrete for the side wall → concrete filling the secondary lining and inverted arch. Combining with actual situation of engineering, the longitudinal size of core soil should be more than 4m, the area of core soil should be more than half of the upper section.

**Middle-wall Method (CD Method).** CD method is mainly used in the rock mass which the geological conditions is poor and the steady ability is low, it also applies to underground engineering construction when surface subsidence must be strictly controlled. The excavation method is as: excavate one side of the tunne → construct the temporary middle-wall → after a certain distance in advance excavation side, partially excavate the other side of the tunnel. To support each part after the excavation so making each part to be an independent closed structure.

**The Determination of Blasting Load.** This paper assumes that blasting load on the excavation boundary surface and face of tunnel by the triangular load method. Taking rise time as 0.012s and time of descent segment as 0.100s on the basis of numerous investigations. Total duration of the simulation takes 2.0s in order to understand the situation of surrounding rock-supporting system after the blasting load.

The peak stress $P_{\max}$ of blasting load uses the following empirical formula to solve:

$$P_{\max} = \frac{139.97}{Z} + \frac{844.81}{Z^2} + \frac{2154}{Z^3} - 0.8034 \,(\text{kPa}) \tag{1}$$

$$Z = R^* / Q^{1/3} \tag{2}$$

where, $Z$ = reduced distance; $R^*$ = the distance from explosion center to the load acting surface (m); and $Q$ = explosive charge (kg), take the total explosive charge when simultaneous blasting, take the maximum period of explosive charge when segmented blasting.

## The Establishment of the Finite Element Model

**Project Profile.** The Guanhui urban railway transport projects in close proximity to above many important ground buildings and underground pipelines clouds. Most foundation of the ground building above tunnel are natural foundation and man-power hole pile foundation, Most building are the framework structure and masonry structure. It is strict with the ground surface settlement when the section tunnel passes through large area of residential areas and factory. Tunnel sits mostly on completely-weathered migmatitic gneiss, it is belongs to the urban shallow tunnel that the minimum thickness of covering soil on the vault is only 8m.

**Establishment of the Model.** In this calculation, the surrounding rock is simulated by using the bilinear elastic-plastic model, sprayed concrete and middle wall is simulated by using the elastic model. The blasting load value of CD method and bench method are both 1.2MPa on the basis of the f Eq. 1 to Eq. 2. Apply the no reflection boundary in the X, Y and Z considering that seismic wave reflects at the boundary will affect the accuracy of the results during the blasting process, at the same time, enlarge the model appropriately in order to a better research on the change rules of surface

velocity during blasting excavation. Specific size is as follows: Z = 76m, X = 80m, Y = 61.45m, the finite element model as shown in fig. 1.

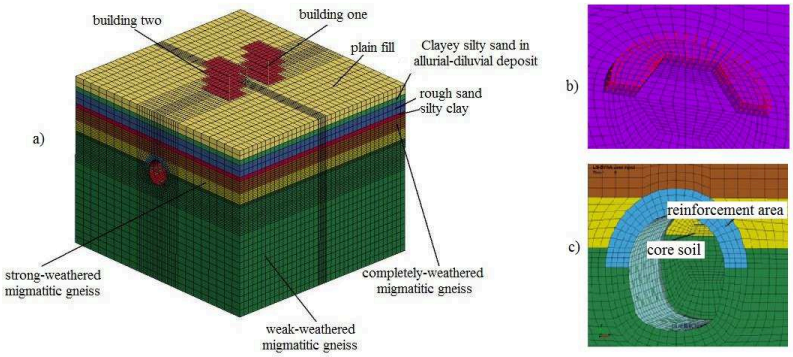

Figure 1. Schematic diagram of the finite element model where they act as valves: a) Full finite element model; b) Bench method; c) CD method with reserved core soil

The selection of surrounding rock parameters is according to the 7 section field test and support parameters refer to Dongguan other similar projects and relevant codes.

Table 1. The parameter of numerical simulation.

| Designation | Elasticity modulus(Pa) | Poisson's ratio | Yield strength(Pa) | Failure strain | Density(kg/m³) |
|---|---|---|---|---|---|
| Weak-weathered migmatitic gneiss | 1e9 | 0.28 | 1e6 | 0.02 | 2500 |
| Strong-weathered migmatitic gneiss | 0.4e9 | 0.32 | 0.8e6 | 0.02 | 2300 |
| Completely-weathered migmatitic gneiss | 0.1e9 | 0.33 | 0.5e6 | 0.02 | 2200 |
| Silty clay | 0.26e9 | 0.35 | 0.2e6 | 0.02 | 1950 |
| Rough sand | 0.20e9 | 0.35 | 0.5e6 | 0.02 | 1900 |
| Clayed silty sand in allurial-diluvial deposit | 0.14e9 | 0.36 | 0.1e6 | 0.02 | 1850 |
| Plain fill | 0.05e9 | 0.37 | 5e4 | 0.02 | 1800 |
| Sprayed concrete | 2.8e10 | 0.2 | - | - | 2300 |
| Middle wall | 2.8e10 | 0.2 | - | - | 2500 |

This paper simulates four conditions as shown in Table 2. Furthermore, tunnel vault and settlement of ground surface are monitored as follows: every 2m to set up a monitoring site in the tunnel axial direction and the horizontal direction of tunnel face.

Table 2. Calculated work condition.

| Work condition | Construction method | Blasting excavation position | Surface condition |
|---|---|---|---|
| 1 | Bench method with reserved core soil | The upper arc heading | No buildings |
| 2 | Bench method with reserved core soil | The upper arc heading | Buildings |
| 3 | CD method | The upper left section | No buildings |
| 4 | CD method | The upper left section | Buildings |

**The Analyses of the Results of Model Calculation**

With the help of computer simulation, get the influence of different blasting excavation methods on the tunnel and surface building by the $V_{ymax}$ change curve of tunnel horizontal and longitudinal monitoring sites. Set monitoring site as the origin, the abscissa negative value of X direction indicates

the left side of the origin, the positive value indicates the right side, the abscissa negative value of Z direction indicates the front of tunnel face, the positive value indicates behind tunnel face.

**The Analysis of Work Condition 1 and 2.** Fig. 2 shows each monitoring site $V_{ymax}$ change curve of X direction in work condition 1 and 2. Fig. 3 shows each monitoring site $V_{ymax}$ change curve of Z direction in the work condition.

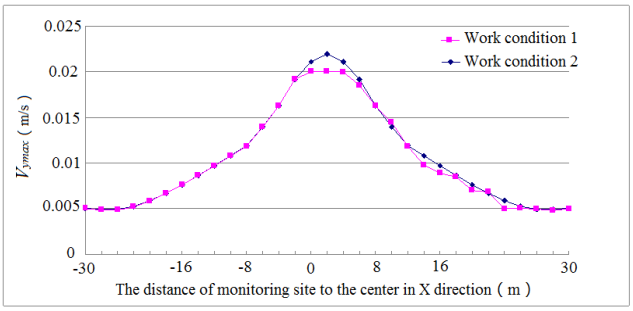

Figure 2. Comparison of work condition 1 and 2 monitoring site in the X direction

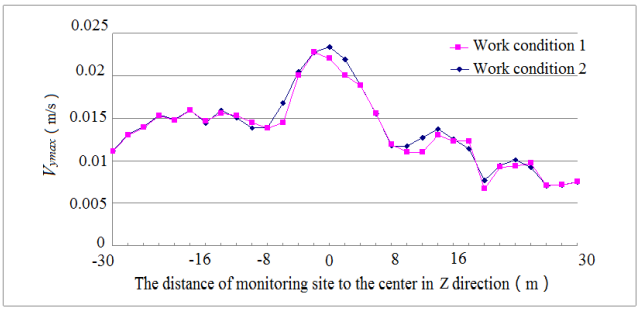

Figure 3. Comparison of work condition 1 and 2 monitoring site in the Z direction

As shown in Fig. 2, the maximum vertical velocity $V_{ymax}$ of the working condition 1 and 2 have appeared in the upper part position of tunnel face (X = 0) what are 2.19 cm/s and 2.04 cm/s. Contrast work condition 1 with 2: 1. Both the change rule of $V_{ymax}$ curve are consistent: $V_{ymax}$ gradually decreases with the increase of distance from the center and its ratio of decline tends to slow, $V_{ymax}$ changes gradually stable and show a converging trend when the distance is about 22m from the center. The result shows that effects of blasting no longer increase when the horizontal distance from the center of the tunnel excavation over 22m and that is the range of influence by bench method with reserved core soil. 2. Surface velocity appeared certain reduced because of the existence of the building structure (cylinder nodes at X = 0m and X = 13.75m) and performance more obvious but varied little near the X = 0 m and X = 12.

As shown in Fig. 3, the maximum vertical velocity $V_{ymax}$ of the working condition 1 and 2 have appeared in the front of tunnel face what are 2.34 cm/s and 2.27 cm/s. Contrast work condition 1 with 2: 1. Both the change rule of $V_{ymax}$ curve is consistent: The velocity attenuates quickly within the range of 10m in front of tunnel face to 6m behind tunnel face and finally decreased about 50%. Velocity remained unchanged during 10m-24m in front of tunnel face and 6-16m behind tunnel face. 2. The velocity in front of tunnel face is always greater than that behind tunnel face and the influence of blasting vibration in front of tunnel face is also bigger in the same distance from center position.3. Surface velocity appeared certain reduced because of the existence of the building structure (cylinder nodes at Z = -8m, Z = 0m, Z = 10m and Z = 18m).

**The Analysis of Work Condition 3 and 4.** Fig. 4 shows each monitoring site $V_{ymax}$ change curve of X direction in work condition 3 and 4. Fig. 5 shows each monitoring site $V_{ymax}$ change curve of Z direction in the work condition.

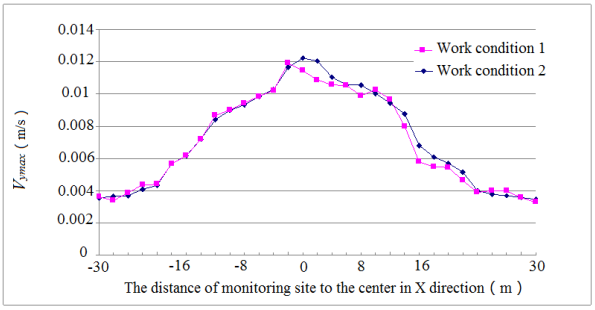

Figure 4. Comparison of work condition 3 and 4 monitoring site in the X direction

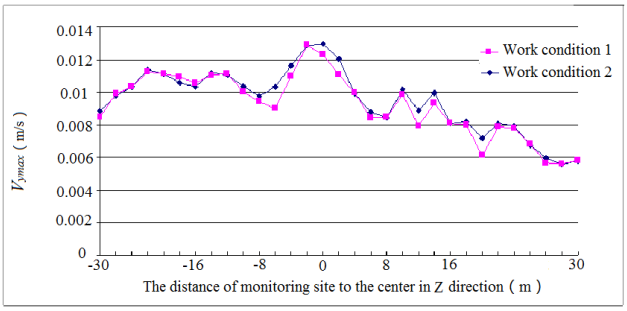

Figure 5. Comparison of work condition 3 and 4 monitoring site in the Z direction

As shown in Fig. 4, the maximum vertical velocity $V_{ymax}$ of the working condition 3 and 4 have appeared near the center point what are 1.226 cm/s and 1.245 cm/s. Contrast work condition 3 with 4: 1. Both the change rule of $V_{ymax}$ curve are consistent: $V_{ymax}$ gradually decreases with the increase of

distance from the center and its ratio of decline tends to slow, $V_{ymax}$ changes gradually stable and show a converging trend when the distance is about 22m from the center. The result shows that the influence of blasting excavation is very weak when the horizontal distance from the center of the tunnel excavation over 22m. 2. Surface velocity appeared certain reduced because of the existence of the building structure (cylinder nodes at X = 0m and X = 13.75m) and performance more obvious but varied little near the X = 0 m and X = 12.

As shown in Fig. 5, the maximum vertical velocity $V_{ymax}$ of the working condition 3 and 4 have appeared near the center point what are 1.296 cm/s and 1.287 cm/s. Contrast work condition 3 with 4: 1. Both the change rule of $V_{ymax}$ curve are consistent: The velocity attenuates quickly within the range of 8m in front of tunnel face to 4m behind tunnel face and finally decreased about 30%. Velocity remained unchanged during 8m-26m in front of tunnel face and 4-22m behind tunnel face. 2. The velocity in front of tunnel face is always greater than that behind tunnel face and the influence of blasting vibration in front of tunnel face is also bigger in the same distance from center position. 3. Surface velocity appeared certain reduced because of the existence of the building structure (cylinder nodes at Z = -8m, Z = 0m, Z = 10m and Z = 18m).

**The analysis of work condition 1 and 3.** By comparing the pictures above, the general regularity of the vibration velocity of CD method and bench method are the same, the maximum velocity appears on the surface near the tunnel face. From the vibration velocity values, bench method is much higher than that of CD method and the biggest value difference reached about 1 cm/s. This is mainly due to the area of excavation section of bench method is bigger and explosive payload is more compared with CD method.

## Conclusion

This paper simulates the different blasting construction methods when shallow buried tunnel underpassing densely populated areas by numerical analysis, analysis different blasting construction methods on the impact of tunnel and surface buildings and come to the conclusions as follows:

1. By contrasting two kinds of blasting excavation method, the surface vibration velocity attenuation regularity consistent. But the vibration velocity caused by bench method is significantly higher, the area of excavation section is bigger and explosive payload is more compared with CD method. Given the facts, the bench method is much better than CD method when buried tunnel underpassing densely populated areas.

2. The vibration velocity of the excavation section caused by two methods gradually decreases with the increase of distance from the center, the influence of blasting is no longer increasing when the horizontal distance from the center is more than 22m, the tow methods show similar laws.

3. The extreme value of tunnel longitudinal vibration velocity both appear in the front of tunnel face at the same position from the center point. The range of influence by bench method on the rear is about 18m and that is about 24m caused by CD method. Although the influence range of CD method is greater, but the value has been far less than the control value.

4. During the process of two kinds of blasting construction methods, surface velocity appeared certain reduced because of the existence of the building structure, but the magnitude and range of influence are small.

**Keywords:** monitoring measurement; stress release; numerical simulation; underpass.

**Abstract.** Based on the dynamic monitoring project of one underpass in Dalian, this paper tries to validate the control effect of the ground settlement on the stability of tunnel surrounding rocks during construction of underground passage under urban arterial road by means of analyzing the vertical ground settlement curves, convergence curves of tunnel inner perimeter and vault displacement curves. With the numerical calculation tool of the software FLAC, it also analyzes the construction of XS- 2 # cross-section which was in the south side of the whole construction section at different stages by adopting the plane-strain model. Therefore, we can get the influence curves of ground settlement under different construction stages with considering the release of stress. The simulation results are basically consistent with the measured data, which has a great significance for the subsequent design and construction of underground projects with similar geological conditions.

## Introduction

In consequence of the losses of the stratum and changes in groundwater levels during excavation of underground tunnel, formation stress of a certain range of cavern excavation area is adjusted and changed from the cavern invading to deep geological formations, resulting in the subsidence and displacement of ground surface and buildings [1]. When the surface movement and deformation exceed a certain limit, it will affect safety and proper usage of the tunnel and the ground buildings. Therefore, it requires more stringent for the design and construction of the tunnel and the control on the surrounding environment [2].Based on the dynamic monitoring project of one underpass in Dalian, the field measurements and numerical simulation analysis which are two different means are used to investigate the influence on surface subsidence and crown settlement in various stages of construction. This dynamic information is an important reference data of information construction to guide the construction progress and ensure the safety and efficiency of construction.

## Project Overview

The project is located in interchange of Wuhui Road and Zhongshan Road, which is the rare city underground without effect of traffic during construction. And shallow mining method is adopted for the main channel Construction. The Underpass passes through Zhongshan Road and Wuhui Road.

Engineering site belongs to gentle slope belt, and the ground level changes from 25.76 m to 26.98 m. As the survey data is shown, the top-down of site strata: plain fill (layer thickness is 3.4-5.4m), silty clay (layer thickness is 1.6-4.0 m), sidewall rock (layer thickness is 2.0-2.6m), and bed rock which is mainly strongly weathered lime stone. It is only a small amount of groundwater in the drilling depth, and the main source is atmospheric precipitation.

## Construction Monitoring Program

According to the project monitoring program, the main monitoring content includes: Surface subsidence monitoring, crown settlement monitoring and clearance convergence monitoring.

Three survey lines of surface subsidence monitoring were located along the Zhongshan road: XN - 1#, XN - 2#, XN – 3 are located on both sides of road and pat respectively and the interval is 5m.Three survey lines of Wuhui Road were established : XS -1#, XS- 2#, XS - 3#, which are consistent with the north side. Each survey line from the west to the east is arranged five measuring points (as shown in Figure1); Convergence clearance section is for each surface subsidence monitoring sections below and a total of six monitoring sections and each section has three survey lines (as shown in Figure 2); Vault subsidence monitoring puts clearance convergence points as the monitoring points and each section sets up one monitoring point.

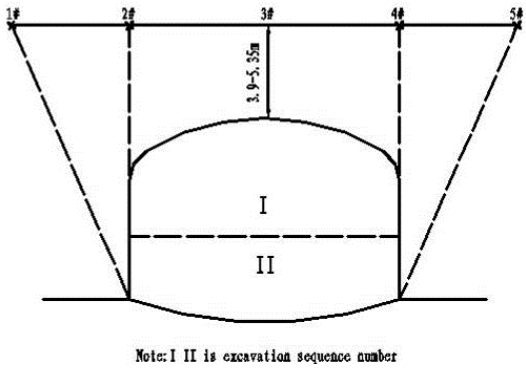

**Fig. 1** Surface Subsidence Monitoring of Cross-section Diagram

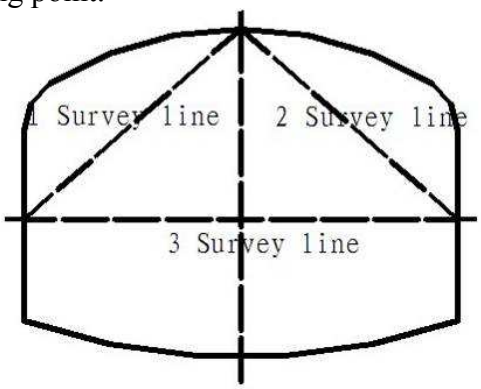

**Fig. 2** The Diagram of Deformation Monitoring Convergence

## The Analysis of Construction Monitoring Data

**The Analysis of Longitudinal Settlement.** The underpass project taskes the excavation foundation pit of Hope Square as the center. Then it is excavated in both sides of the direction and the construction period of three months in the cave. Surface subsidence monitoring uses six monitoring sections which located north and south and the monitoring frequency is once a day. Choose two of the six lines, the monitoring results are shown in Figure 3.

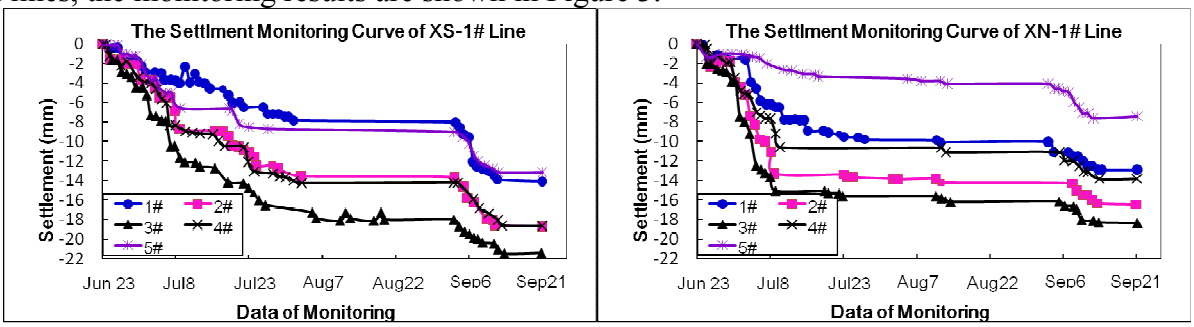

**Fig. 3** Longitudinal Monitoring of Ground Subsidence Curves

By the curves of monitoring in Figure 3 and combining the construction site conditions, we pair the data of inspection to analyze as follows:

(1) Owing to the sudden release of the stress, surrounding rock generates unbalanced force in the initial excavation of the tunnel, resulting in a larger surface subsidence ( of the total settlement amount of 50%~ 80% ) and rapid sedimentation rate(maximum sedimentation of 2. 6mm/d) at this stage, moreover, the sedimentation rate with long duration is greater than zero. With the completion of stress redistribution and the initial support system, pavement settling tends to zero.

(2) Since the cross-section roof surrounding are plain fill with poor uniformity and high compression , resulting in a sudden increase in road subsidence ,it have brought a safety hazard to underground construction and road traffic.

(3) The second step of the excavation is from mid-July 2009 to early August 2009,and vertical ground subsidence curve shows the second step of the excavation of the tunnel surrounding rock has a significant impact on stability , resulting in 10 ~ 12mm ground subsidence.

**The Data Analysis of Clearance Convergence.** Tunnel displacement monitoring data can better reflect the surrounding conditions (including rock lithology and disturbance), so by dynamically monitoring the displacement of the tunnel, the state of the tunnel deformation can be understood to determine the stability of surrounding rock. The monitoring result of XS-1 # headroom displacement is shown in Figure 4 and Figure 5.

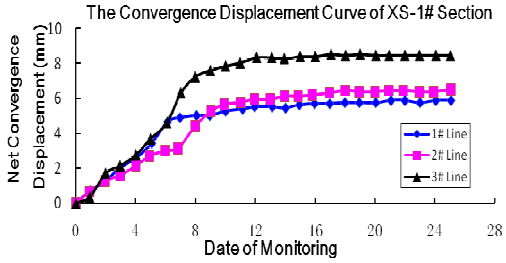

**Fig. 4** XS-1 # Cross-section Convergence Curve

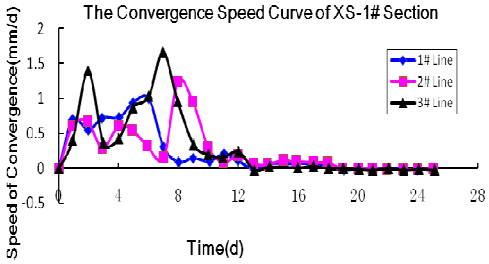

**Fig. 5** XS-1 # Cross-section Convergence Rate Curve

The convergence monitoring data curve shows that it has three stages:

The first phase (after excavation 10d) is increased dramatically Stage: the convergence rate is three times of average rate throughout the monitoring period and convergence reaches more than 80% of a cumulative amount of convergence.

The second phase (after excavation 11 ~ 20d) is slow growth phase: the cumulative amount of convergence grows slowly and convergence rate is only 25 to 30% of average convergence rate .Surrounding rock deformation has not yet reached a steady state.

The third phase (after excavation 21 ~ 26d) is stabilization phase : When the convergence rate with continuous 3 ~ 5 d is zero and convergence is no longer growing ,it can be considered as a steady state and can be secondary lining construction.

**The Data Analysis of Vault Subsidence**. Since vault subsidence monitoring as a reflection of overlying soil is an important cave monitoring project. It can timely reflect of cave excavation and support for overlying soil disturbances. Vault subsidence monitoring curve of sections XS-2 # # is shown in Figure 6.

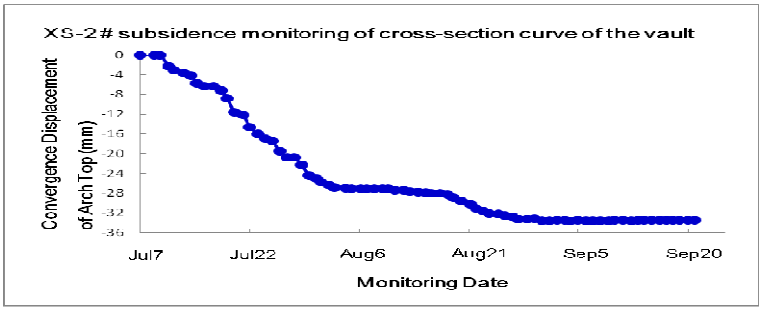

**Fig. 6** XS-2 # Subsidence Monitoring of Cross-section Curve of The Vault

As can be seen from the figure 6, vault subsidence and the ground settlement almost simultaneously generate and the impact factor is basically the same. Vault final subsidence is (33.6mm) slightly larger than the maximum surface subsidence (32.4mm), which is due to the overburden excavation makes overlying soil produce a certain amount of Ta areas resulting in vault settlement slightly larger than the amount of surface subsidence.

## Numerical Simulation of Cross Section XS-2# Excavation

In order to further verify that the observed results in construction site, it is analyzed using numerical simulation method for the deformation of tunnel surrounding rock. According to the prospecting data and actual excavation, the numerical simulation for XS–2# section by adopting plane strain model is carried out based on the numerical simulation software–FLAC2D. In order to simulate the excavation

space effect on changes in the surrounding rock stress better, the stress release method is adopted for numerical simulation of the whole process of excavation.

Stress release method, which is also called Reverse Stress method or Reverse Stress Release method ,was first put forward by Duncan and Dunlop (in 1969)[3]. The excavation of tunnel engineering problem is analyzed by De-an Zhao[4], Zhe Hao[5], Qing-an Hu[6], Linsheng Xu[7] and so on, who adopted the method removing unit to produce the node force vector of release load to extract equivalent load vector for the release, respectively.

**Calculation Model.** Due to the channel length is greater than the height and width of its cross section, the plane strain model is adopted to analyze to simplify the calculation. The balance of the accuracy of the calculation and calculation for engineering should be considered to determine the calculation area. In order to guarantee the reliable data, the distance between the edge of the area calculation model and the perimeter of the tunnel should be greater than three times of the largest span tunnel. At the same time, the error caused by the size of the calculation area can be ignored. Therefore the size of the model can be taken as 64X39m. The FLAC Lagrange finite difference method is adopted in the numerical simulation. Calculation model is established by using Mohr - Coulomb criterion as the yield criterion of soil, as is shown in figure 7.

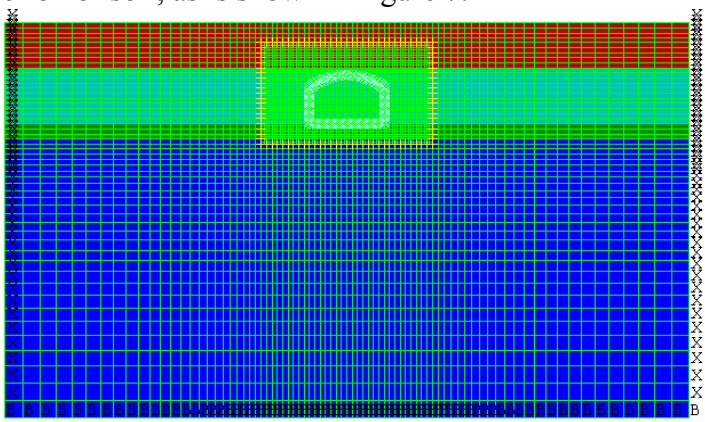

**Fig. 7** Model of Cross Section XS-2#

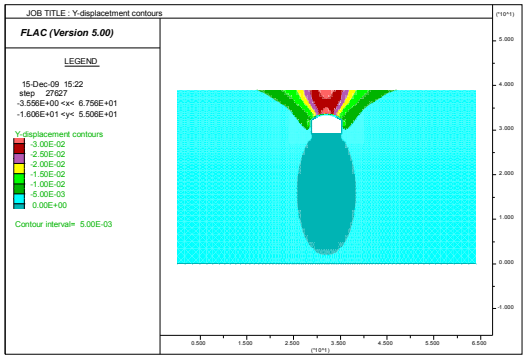

**Fig. 8** The Displacement Fringe of cross section XS-2#

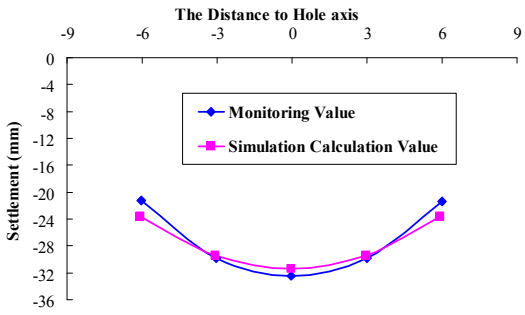

**Fig. 9** The calculated results of surface settlement trough curve compared with the monitoring of cross section XS-2#

**The Analysis of Simulation Results.** From the simulation results, stability of tunnel can be guaranteed during being excavated under the condition of the existing supporting, we can draw the following conclusions through calculation:

(1) The vertical displacement contours of the section XS-2# is shown in figure 8 and the largest vertical displacement of the section is occurred in the vault (32.6 mm), which is consistent with vault subsidence of field monitoring (33.3 mm).

(2) From figure 9, the calculated results of surface settlement trough curve compared with the monitoring of cross section XS-2#, we can conclude that the two curves are similar to normal

distribution curve. and is basically consistent with each other either on the change law or on the maximum which makes clear that FLAC finite difference method will reflect the excavation affect the ground settlement better.

(3) Although the ground last subsidence of tunnel axis in both the detection result and numerical simulation result are larger than the vigilance values 30 mm, surrounding rock is still keep the steady state and do not undergo plastic yield.

## Conclusion

Through the analysis of the field monitoring data about one of the underground tunnel engineering in Dalian and combining with the finite difference numerical in software–FLAC, the stress release method is adopted to XS–2# section for numerical simulation of the excavation.

Therefore, through the comparison of field monitoring and the results of numerical simulation we can draw the following conclusion:

(1) It should highly pay attention to the influence of rainfall on ground settlement during the construction process in rainy season, especially for area with more backfill soil. Meanwhile, the most efficient way to eliminate potential frustrations caused by rainfall should be adopted, such as increasing the frequency of monitoring when rain falls, builders and monitoring personnel is required to be present at all times and pumping-exhaust the accumulated water in the tunnel immediately.

(2) The stress release method can simulate the effect of tunnel excavation space influence on change of surrounding rock stress under the plane strain condition very well. Meanwhile, the best construction simulation period of the secondary lining is given according to the reflect curve of the underlying stress controlling the process of stress release during tunnel excavation.

(3) By comparing the calculation result of numerical simulation software–FLAC with field monitoring data, when the ground last subsidence is slightly larger than the vigilance values 30 mm, it can be proved that surrounding rock might not lose stability either on the observation in the construction site or the convergence of the max unbalance force in the numerical simulation.

# Metro Station Deformation Caused by Deep Foundation Pit Construction

Chunlei Xin[1,a], Bo Gao[1,b]

[1]Key Laboratory of Transportation Tunnel Engineering, Ministry of Education, Southwest Jiaotong University, Chengdu, Sichuan 610031, China

[a]raymond_xin@qq.com, [b]prgaobo@home.swjtu.edu.cn

**Keywords:** Underground Engineering, Deep Foundation Pit, Metro Station, Numerical Simulation, Structural displacement.

**Abstract.** Many excavation and backfill methods can be used to construct a deep foundation pit, but foundation pit construction will undoubtedly affects security of existing metro station. This research based on a transfer station of Chengdu Metro, three-dimensional numerical simulation method was used to analyze the deformation of metro station by changing construction methods of foundation pit. The results show that: (1) Both excavation and backfill methods of foundation pit have a significant effect on connection segments of metro station. (2) The main body of metro station is largely unaffected by foundation pit construction but it has been in the process of subsidence. (3) The more the construction steps of foundation pit are, the more slowly the displacement of metro station changes. The above results certainly contribute to research and develop new types of construction methods for complicated metro station.

## Introduction

It is common that a deep foundation pit engineering is close to a metro station in operation, especially in this extensive development era of urban underground space. The excavation of deep foundation pit can certainly lead to redistribution of geostress field, thereby causing deformation of metro station [1]. However, the structural deformation requirement of operating metro station is quite stringent. Therefore, many deformation control measures must be used in the process of foundation pit excavation [2]. Obviously, it is of great significance to resolve a contradiction between urban construction and existing metro protection [3]. Currently, many scholars have done some research on similar issue but each real project has their own features and solutions [4]. Many construction methods are put forward but they may not be suitable for another projects. This paper bases on Chengdu Metro Chunxilu station project. Numerical simulation method is used to analyze deformation features of metro station by changing excavation and backfill methods of deep foundation pit. Finally, the best foundation pit construction method is put forward for this project.

## Background and features of project

Chunxilu station is a transfer station on Chengdu Metro line two and line three. This project includes two sections, one is No.1 transfer hall and the other is No.2 entrance. The transfer hall is a new construction and the entrance needs to be reformed. According to the design requirements of this transfer station, the relative position between transfer hall and existing entrance is shown in Fig.1. The length of transfer hall is 28.2m, the width is 14.1m and the height is 7.5m. There is a ventilation channel connected with transfer hall and its cross-section dimension is 14.8m×10.3m.

The transfer hall and the ventilation channel are constructed simultaneously by using cut and cover method. Construction procedures include foundation pit excavation, soil reinforcement, lining construction and soil backfill. Each construction procedure can affect the structural deformation of existing metro station. The subsection excavation method is used to excavate transfer hall. Along the vertical direction of transfer hall, the soil mass is divided into two layers to excavate. Meanwhile, the soil mass is divided into four equal parts along the length direction of transfer hall. Bored piles are constructed around the foundation pit before soil mass excavation and steel braces are made

immediately after excavation. After constructing the lining structures, the steel braces are removed and soil mass is backfilled in four equal parts. The excavation method is shown in Fig.2 and Fig.3.

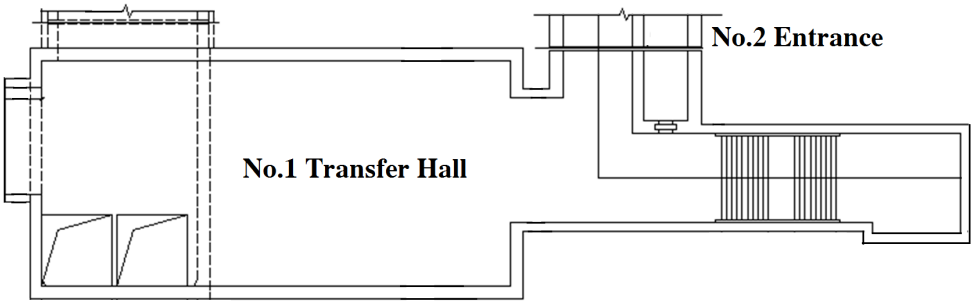

Fig.1 Relative position between transfer hall and existing entrance

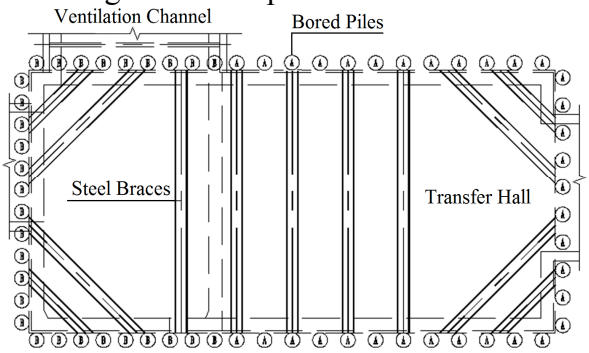

Fig.2 Ichnography of transfer hall excavation

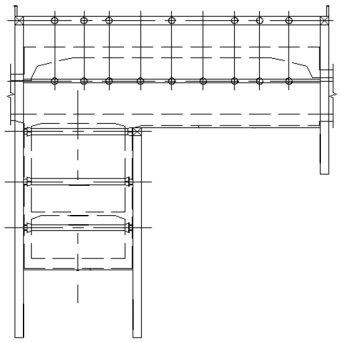

Fig.3 Profile of transfer hall excavation

## General situation of numerical simulation

**3-dimensional numerical model.** According to the tunnel mechanics theory and border theory, the entire numerical model size is X×Y×Z = 65×50×100m$^3$ (shown in Fig.4). Specifically, the model system is composed of existing metro station, civil defense section, passageway section and transfer hall (shown in Fig.5). All these boundaries setting can guarantee the accuracy of calculation results. The whole numerical model is comprised of 207,000 solid elements.

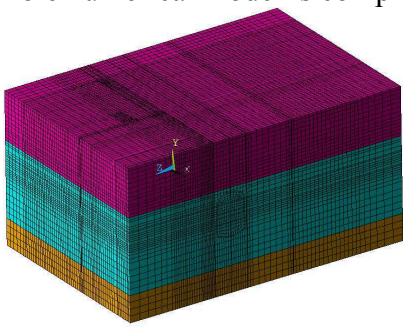

Fig.4 The entire numerical model

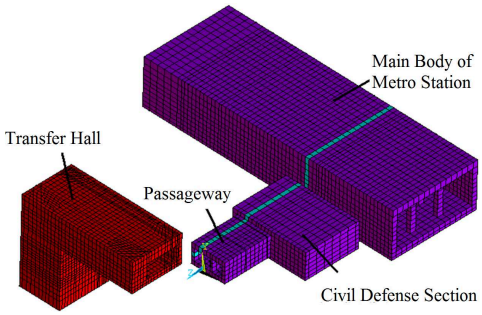

Fig.5 Numerical model of research system

**Calculation parameters.** The physics and mechanics parameters of soil mess and foundation pit are listed in Table 1. Where, $\gamma$ is bulk density, $E$ is elastic modulus, $\mu$ is Poisson's ratio, $C$ is cohesive strength and $\varphi$ is friction angle.

Table.1 Physics and mechanics parameters of model system

| Position | $\gamma/(kNm^{-3})$ | $E/MPa$ | $\mu$ | $C/kPa$ | $\varphi/(°)$ |
|---|---|---|---|---|---|
| Soillayer 1 | 17.3 | 15 | 0.35 | 10 | 21 |
| Soillayer 2 | 20.9 | 50 | 0.35 | 22 | 38 |
| Soillayer 3 | 21.5 | 80 | 0.35 | 15 | 48 |
| Bored piles | 21 | 800 | 0.3 | 100 | 39 |
| Lining | 24 | $3.15\times10^4$ | 0.25 | -- | -- |
| Steel braces | 25 | $8\times10^4$ | 0.2 | -- | -- |

## Analysis of calculation results

**Influence of foundation pit excavation on metro station displacement.** After excavating the foundation pit, the existing metro station displacement nephograms are shown in Fig.6 and Fig.7.

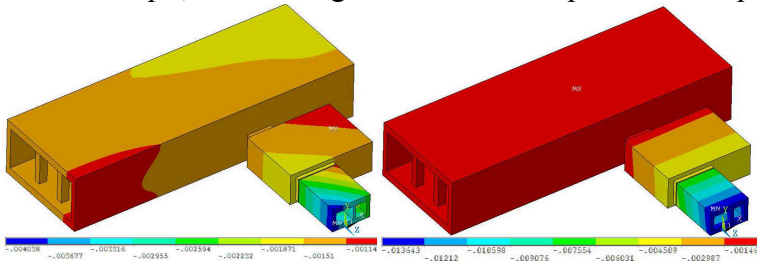

Fig.6 Vertical displacement Fig.7 Horizontal displacement

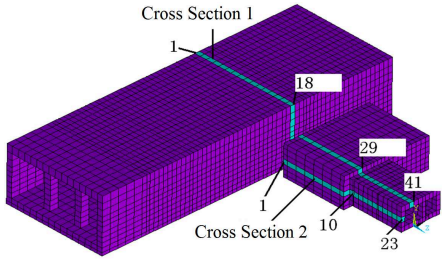

Fig.8 Monitoring sections and spots

The horizontal displacement of existing metro station is larger than vertical displacement. The main body of metro station is largely unaffected by foundation pit excavation. However, foundation pit excavation has a significant effect on both passageway section and civil defense section. The shorter the distance between metro station and foundation pit is, the more obvious the displacement of metro station is.

In order to further study on displacement features of metro station, monitoring spots are chosen to analyze the vertical and horizontal displacement separately (shown in Fig.8).

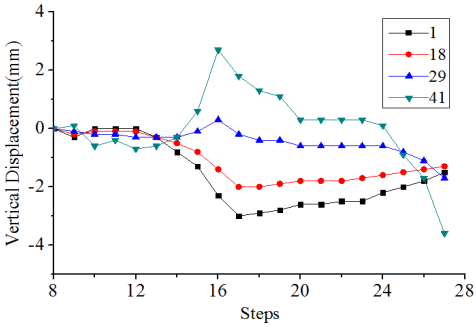

Fig.9 Vertical displacement of monitoring spots

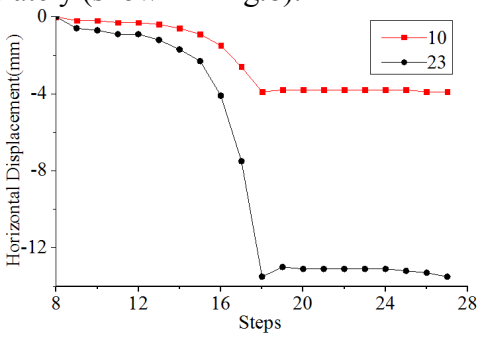

Fig.10 Horizontal displacement of monitoring spots

Fig.9 shows that a bulge phenomenon happens in passageway and civil defense section in the process of foundation pit excavation. Moreover, the shorter the distance between metro station and foundation pit is, the more obvious the upheaval is. The main body of metro station has been in the process of subsidence. Fig. 10 shows that the horizontal displacement mainly happens in the process of foundation pit excavation.

**Influence of excavation methods on metro station displacement**. Fig. 11 and Fig.12 show the vertical and horizontal displacement curves with different excavation methods separately.

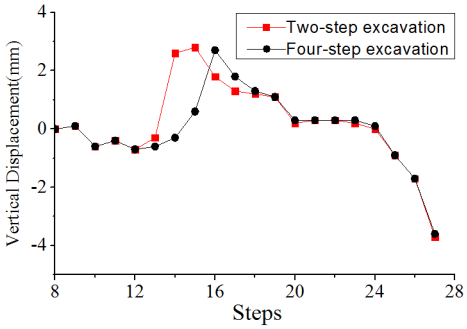

Fig.11 Vertical displacement of metro station with different excavation methods

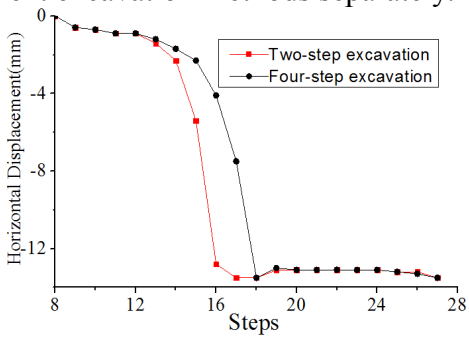

Fig.12 Horizontal displacement of metro station with different excavation methods

The final displacement of metro station is largely unaffected by different excavation methods of foundation pit. The major influence of excavation methods on metro station displacement is in the process of excavation. The more the excavation steps of foundation pit are, the more slowly the displacement of metro station changes. Thus, the metro station is not vulnerable to large displacement.

**Influence of backfill methods on metro station displacement.** Fig. 13 and Fig.14 show the vertical and horizontal displacement curves with different backfill methods separately.

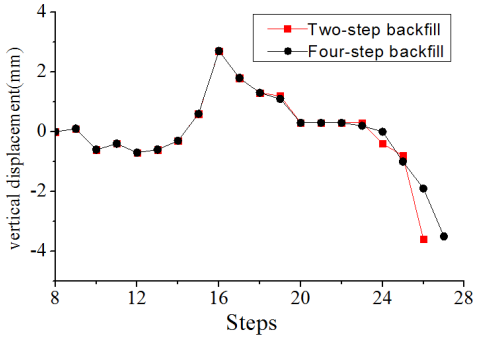

Fig.13 Vertical displacement of metro station with different backfill methods

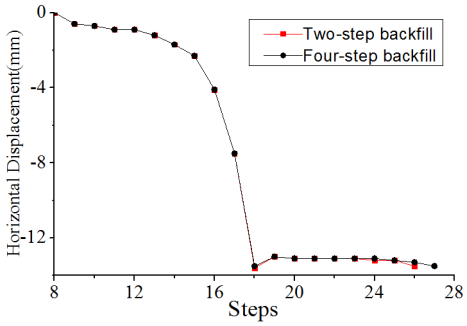

Fig.14 Horizontal displacement of metro station with different backfill methods

The final vertical displacement of metro station is not affected by backfill methods of foundation pit and backfill methods merely affect the subsidence velocity of metro station. When using four-step backfill method, the subsidence velocity is slower than using two-step backfill method. Moreover, the more slowly the displacement of metro station changes, the more secure the metro station is. Since the horizontal displacement is mainly determined by foundation pit excavation methods, backfill methods have little effect on horizontal displacement of metro station.

## Conclusions

Both excavation and backfill methods of foundation pit have significant effects on connection segments such as passageway section and civil defense section. However, the main body of metro station is largely unaffected by foundation pit construction but it has been in the process of subsidence. The shorter the distance between metro station and foundation pit is, the more obvious the displacement of metro station is. The more the construction steps of foundation pit are, the more slowly the displacement of metro station changes.

## Acknowledgments

The research was funded by the National Natural Science Foundation of China (No. 51178398).The authors also gratefully acknowledge the financial provided by Southwest Jiaotong University and China Scholarship Council.

**Keywords:** rail transit, new technology, shallow mining method, new construction equipment, risk source;

**Abstract.** Combining with the practical engineering case, the paper summarizes the shallow mining method construction mechanism, construction methods and auxiliary technology. Aiming at the problems in the shield construction, the paper introduces the shield machine equipment's latest comprehensive construction and technology, especially the shield technology dealing with the conglomerate stratum where the water and boulders is rich. It fills the domestic blank; Deep grouting and pipe roof reinforcement technology are aimed at the specific sources of risk; Whole cross-section of pallet trucks, electric vehicles, automatic metering and other new equipment have been widely applied to the construction site.

## Introduction

Now the development of urbanization is in high-speed in China, as a key part of urban transportation , rail transit, which has the merits of large capacity, punctuality, shortcut, safety and high efficiency, low carbon environmental protection, etc. is the focus of the big cities' development in the current and future. The rail lines, often along the main roads in the cities, inevitably will through a lot of underground pipelines, lakes and the surrounding building structures. So it constitutes a potential threat that the track traffic construction exerts negative influences on nearby existing architectural environment. On the other hand, the lines, which are often difficult to avoid water-rich sand pebbles, silty sand stratum and other undesirable formation, tend to restrict its construction. Together with the emerging of new technologies, equipments and processes, the rapid development of the theory about the design of rail transit construction brings the fast-developing track traffic.

## The rapid development of shallow mining method

In 1948, L.V.Rabcewicz, an Austrian expert, designed the safe and economic tunnel excavation method and support structure basing on the use of new building materials. And a theory named "New Austrian Tunnel Construction Method" was formed in 1963, or "New Austrian Tunneling Method" (NATM) for short[1]. In the 1980s, the principle of NATM was first used to study and test the shallow mining method in the loess stratum near the portal of the double-line tunnel in Jundushan railway. Then this new technology was successfully applied in the return section building of Fuxingmen subway in Beijing in 1986. The shallow mining method was widely introduced in Beijing subway Fu-Ba line in the 1990s, resulting in the construction of the Metro section of 13.5 km approximately and 4 underground digging stations, including Xi'dan, Tian'anmen West, Wangfujing and Dong'dan[2]. It created a set of new technologies, processes and methods about underground excavation construction of urban metro works that the successful construction of Fu-Ba line enriched and developed the shallow mining method.

Due to the different excavation methods, the shallow mining method can be divided into a number of specific construction methods, such as the full-face method, the positive step method, the method of circular excavation with core soil, the single side heading method, the double side heading method,

the center diaphragm method, the cross diaphragm method, the center drift method, the side drift method, the column-hole method, etc. According to the geological and hydrological conditions, the size and shape of the cross-section, the length of the tunnel, the engineering support form, the buried depth, the construction technology and equipment, the project duration and other factors, underground construction projects have a variety of construction methods. Especially the new technology of "one-time supporting arches covered cut and reverse approach", it is shown in Fig 1 that research of " one-time supporting arches" has formed new technology of design and construction. It has obtained the national invention patent, and realized the new breakthrough of underground construction methods of underground engineering[3].

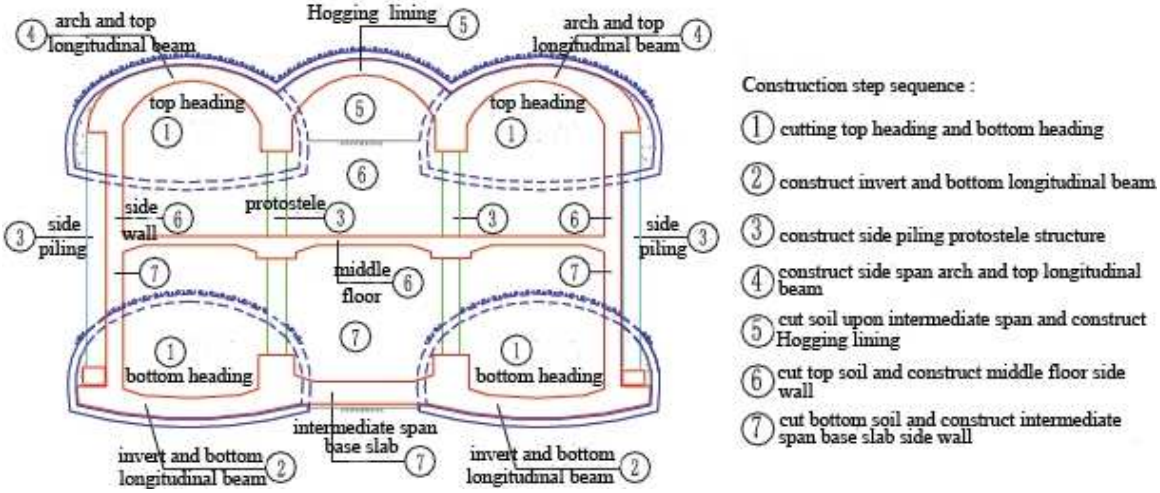

Fig.1 One-time supporting arches covered cut and reverse approach

**The extensive use of Shield Technology**

The construction technology of shield in China was first used in the late 50's of twentieth Century. In the year of 1957, Beijing constructed its city sewer by hand dug type shield diameter of 2.0m and 2.6m, systemic and comprehensive shield test was started in Shanghai Tang'qiao in 1963. In the year of 1996, the subway line 8 introduced knife type shield, and the shield construction technology was first substantively used in subway engineering in Beijing. After entering 21st century, with the large-scale construction of rail transit, the shield construction technology has been widely used and developed indifferent depth of shallow buried stratum. Taking the construction of Beijing subway as an example, since the shield construction of subway line 5 in 2000, subway line 5, line 4, line 10, airport Line, line 9, Daxing line, line 6, line 8, Yizhuang lines have started construction. At present, the new lines under construction such as line 6 (phase two), line 7, line 14, Changping line (phase two) and line 16 extensively used earth pressure balance shield technology to construct tunnel, for example, the 7 intervals of line 6 (phase two) are all constructed by shield method. The upcoming construction of subway line 8 phase three, line 6 west extension, line 3, line 12, line 17 and Yanfang line north extension section will extensively use shield technology to construct interval tunnel[4].

Shield construction technology is a tunnel construction method of high degree of mechanization and automation, its basic working principle is a cylinder of steel component along the tunnel axis forward while to dig soil. The shell of the cylinder components is shield, it plays a role of temporary support in the unlined tunnel bearing the soil pressure, and sometimes it bears the pressure of underground water and keeps the underground water outside. Mining, row soil and lining operations work under the cover of a shield.

Shield construction consists of 3 parts, they are stabilizing the excavation face, mining and rowing soil, lining (backwall grouting). Shield machine is made up of excavation system, propulsion system, soil system, the segment assembling system, hydraulic, electrical, control systems, attitude control device, guide system, the grouting device, rear trolley, centralized lubrication device, advanced drilling and grouting, articulated device, ventilation, muck improvement device and some other

important devices such as shield shell, stabilizer and entry gate. Shield machines used in subway construction are mainly imported from Japan and Germany, domestic equipments and equipments imported from other countries are less. With the development of domestic shield, shield (such as railway equipment and railway heavy) has begun the application in the subway. And this percentage will be further improved in the subway shield tunnel construction in the future; it is expected to become the mainstream of subway construction equipment in the future.

Shield construction is divided into air, mud, earth pressure balance of different types according to different soil and working mode. Shield construction has many characteristics such as high degree of automation, saving manpower, fast speed of construction, excavate at once, and not affected by climate, can control the ground settlement, reduce the impact on ground buildings, the underwater excavation does not affect the water transport, in the tunnel under the condition of long, large buried depth, shield in subway construction is more economic and reasonable. As the optimization of cutter head, the update of soil improvement method and modified agent, especially the appearance of real-time information management system of shield construction, shield technology will be widely used in railway construction[5].Under the shield of Beijing subway line 9 in Yuyuantan east lake project, a large diameter high-strength boulder-rich conglomerate formation is very difficult water-rich, through scientific research, exploration summary, under the successful wear, to fill the domestic blank.

**Over-seat single-track Transit Systems**

Straddled-type monorail refers to the single track to support, keep stability and guide, the car ride on track beam of the railway. In China, the Chongqing metro line two was first imported from Japan, from opening the trial operation in 2004; it has been running 19 km. In the near future, Chongqing will build two city backbone lines and two branch lines, the newly built lines will be totally 100km. The city of Beijing will also start the two straddle type monorail, the length will be approximately 60 km, and the two lines will be in the form of the viaduct. Straddled-type monorail is characterized by strong adaptability, low noise, small turning radius and strong climbing ability[6]. Similar to the "air train", the speed of straddled-type monorail can reach 60 kilometers per hour, and it is especially suitable for the ground and elevated city rail transit line. Straddled-type monorail, for example, the use of special track will not cause derailment; the use of air springs and rubber wheel makes passengers feel superior; Powered by electricity does not produce air pollution; low noise and low vibration; it has simple structure and short construction period, saving construction and repair cost[7].

**The methods for ground reinforcement and supporting surrounding rock are keeping update**

In recent years, the traditional ground reinforcement and rock support of grouting, pipe roof, advanced small catheter reinforcement, anchors and other methods in terms of technology, construction methods, equipment, etc. have made great strides[8].

Grouting generally pre-grout proceeding from the vertical face of soil, mainly static pressure grouting, chemical grouting and fracture grouting, respectively, for sand and gravel, sand and silt soil of different porosity strata; from the grouting way of advancing and retreating deep grouting technology. In addition to the tunnel excavation grouting can be carried from the ground, but also horizontally or diagonally levels grouting from the tunnel face and vault Excavation outside. In terms of grouting materials, in addition to general grout, modified silicate slurry, there are some expansion of the slurry, the slurry as TGRM, no shrinkage slurry, WSS and ultrafine grout slurry, MS slurry and so on. In particular, in recent years, the construction of the subway emerging deep drilling equipment by injecting grouting process improvement, process optimization grouting, grouting equipment improvements and slurry flow and pressure control, well played strata reinforcement, sealing effect, substantially increased the risk of various types of subway construction safety management and control source are shown in Fig 2.

Fig.2 Grouting slurry injection volume and pressure dual control

Fig.3 Pneumatic down the hole hammers managed drilling pipe shed construction

General methods for bassoon shed construction: before the tunnel excavation, using horizontal drilling rigs in the arch area drill horizontal according to holes, spacing and depth by design, bury pipe with pre-drilled hole wall and pre-drilled through the wall hole injecting grout to reinforce and increase the stiffness of the soil pipe so that to perform an arch tunnel umbrella steel shed. The structure itself is a shear behavior, which can effectively carry partial load of overlying soft soil, and so was reinforced soil shear strength has dramatically increased, resulting in tunnel excavation has started but the arch support did not construct or not play a role in the casing body to provide the required support force, to reduce or eliminate the pipeline near ground subsidence and deformation caused by tunneling, tunneling to ensure safety. Mature engineering methods are: aqueous drilling method, pneumatic hammer drilling method and hosting DTH drilling method (for the heart with pipe DTH) and so on. As shown in Fig 3, to solve pipe roof power in large-size pebble layer and other issues, from the impact of the power drill, impact configure and slag, and other aspects of the drill torque constantly update and improve the pneumatic DTH drilling method as custodian double drill large diameter wind slagging DTH drilling hosting new technology, to achieve a structure of 50m long bassoon studio in large-size sand and gravel formations.

Advanced small catheter is a kind of process during bored tunnel of tunneling excavation, mainly for handling formation fracture zone, ultra-shallow construction support, arch safety. Small catheter tip tapering to be easy inserted and hit and prevent slurry to kick ahead. The middle of a small catheter should be diamonded grout vent hole with φ6 ~ 8mm, which was plum-shaped layout[9]. Currently advanced small pipes are mainly water gas pipes with outside diameter φ32mm, wall thickness 3.25mm, tube length 2 ~ 4.0m, different strata using ultra-fine grout or cement-silicate double slurry, strictly control the pressure of grouting process, grouting amount and gelling time and other parameters, all these measures achieved good results. according to the different strata ,when setting a small catheter ,we can choose to set it in front of shotcrete or after shotcrete , Methods for setting up small catheter have fight the rig method, blowpipe law, hammering method and wind pipe jacking method. Advanced small pipes have advantages such as obvious initial support effect, good construction and high security; it can greatly improve the safety of Shallow mining method[10].

**Establishing real-time monitoring system for construction information**

Monitoring of the construction process has not only the construction monitoring but also the introduced the third-party monitoring. Construction Monitoring is mainly construction units monitor all the construction process monitoring project. Third-party monitoring is a third-party monitories part of the construction monitoring project, the frequency of this kind monitoring is generally lower than the construction monitoring. In recent years, management at all levels attached great importance to the monitoring and management during construction process and the control of the work surface, put a lot of manpower, material resources, in the establishment of network platform system. It has played a good role in the construction of the security risk management process. For example, the establishment and operation of Beijing city track traffic engineering construction security monitoring system can effectively implement the risk management and control, reduce the frequency and the probability of risk source induced accidents[11].

In addition, Building information modeling (BIM) technology is introduced into the construction of subway engineering, exploring the implementation mechanism and mode of action of technology

of building information modeling in the subway construction management. Turning the traditional 2D static design drawings into the text for computer manipulation of virtual procedures, through the system platform can effectively integrate information of the project construction which realize the three-dimensional size of real (3D) method of construction simulation and construction progress of image interactive display organic combination ( 4D), and contribute to correct all kinds of display the complex construction information and guidance for construction security through environmental risk source give full play to the role of information model[12].

**Special risk source engineering process technology**

Subway line in city, which is inevitable that among housing, building and foundation of buildings and roads, pipelines, subway, railway and other structures near, side wear or wear, namely the proximity between the building (structure). In order to ensure the construction safety of Metro and the adjacent buildings safety, generally taken in isolation or protection way for scientific disposition. Approaching construction of buildings should be detailed investigation of engineering conditions, geological conditions, both the current situation and structure safety requirements, and implementation plan protection measures for analysis and prediction, on the basis of the investigation; the construction process by monitoring feedback to guide construction and ensure the safety of existing structures.

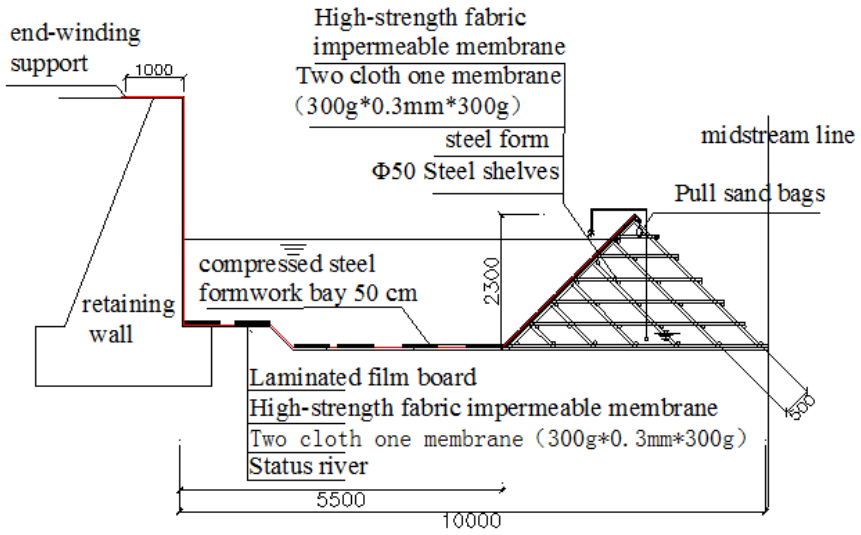

Fig.4 Pile cofferdam

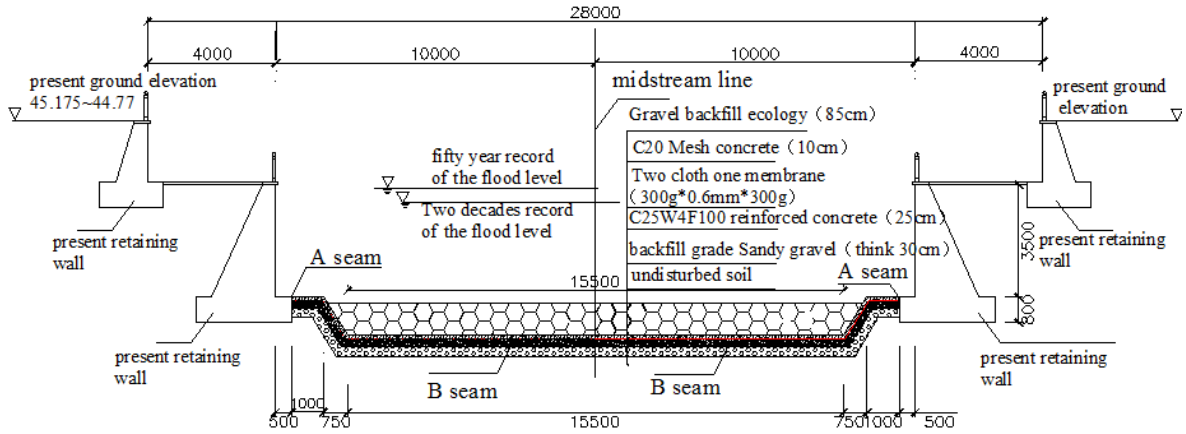

Fig.5 Two cloth of a film with reinforced concrete rigid flexible and economic structure

In recent years, in Hangzhou, Tianjin, Beijing and many, the construction of subway line under construction in rivers and lakes in the accident, causing huge losses, therefore, formation reinforcement of the tunnel pass below the rivers and the reinforcement technology is concerning. At present, from the construction management and technical measures have some new progress, such as

pre grouting and freezing of the soil reinforcement, can significantly improve the safety of excavation construction of Shield Crossing Rivers, As shown in Fig 4, the use of new technology of river diversion pile cofferdam construction is simple, detachable, material recycling, short time limit and no pollution to the river; As shown in Fig 5, new technology channel seepage "two Cloth one Membrane" is better than the reinforced concrete rigid flexible and economic structure seepage, with higher properties; stronger resistance to deformation, little affect the river ecological.

**Special equipment in Metro Construction**

Subway construction mostly is underground construction. The project safety, personnel safety and environmental protection have become the focus of the industry gradually. To this end, around quickly closed, low pollution, the respect such as mechanical operation appeared a lot of new type of special equipment.

As shown in Fig 6, The formwork jumbo for standard tunnel should be combined with the characteristics of linear engineering design to power driven walking mechanism to drive the trolley running tunnel concrete molding, the use of cylinder and screw jack adjustment in place and the template die machine; formwork jumbo in shallow tunnel large amount of use, has the advantages of safety, convenience, high work efficiency[13]. Tunnel primary support structure in the construction process according to the mixing ratio of cement, sand, gravel, accelerating agent, according to the proportion of weighing mixing can be used only for the spraying operation. Through the design of metering, automatic lifting, stirring devices to achieve the shotcrete material automatic metering, mixing, As shown in Fig 7, namely the development of automatic metering mixing device for mixing concrete, high efficiency, low dust, to ensure that the excavation work quickly closed, improve the construction risk controllability.

Fig.6 Formwork jumbo

Fig.7 Automatic metering and mixing equipment

In addition, with the improvement of mechanization operation level, many small jobs independent research and development of new machinery and equipment appeared in the cave. Excavation operations tunneling machine to improve the high-risk mechanized tunneling earthmoving operations, as shown in Fig 8, efficiency and operational safety improved significantly; As shown in Fig 9, construction materials hole transport vehicles with electric vehicles relative to gasoline or diesel fuel, greatly reducing air pollution; multi-hole guide the beginning of the formation of branched structures need to be rid of jobs, high-power hydraulic shears, avoiding artificial rid of security risks, but also significantly improve the effectiveness.

Fig.8 Tunneling machine

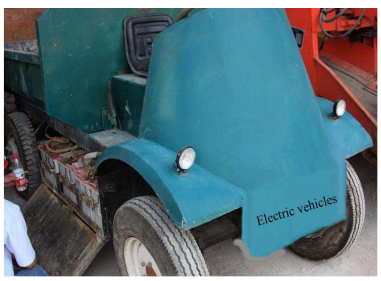

Fig.9 Electric vehicles

## Conclusion

With the development of urbanization, urban land space getting smaller and smaller, environmental conditions getting more complex, the construction of rail transit is growing more difficult, more and more high risk, and construction method, technology, process, equipment, etc are required innovating to adapt to the needs of social development.

**Keywords:** Shield tunnel; Equivalent circle zone; Ground settlement; Numbering analysis; Back analysis

**Abstract.** Through the analysis of 'gap parameter' and ground movement pattern in shield tunnel, this paper researched and corrected the model of 'equivalent circle zone' proposed by predecessors. The 'equivalent circle zone', which is a comprehensive reflection of shield gap, grouting filling and stratum perturbation, is considered to be unequal thickness in this paper. With the measured data of practical shield tunneling, the unknown parameters of corrected 'equivalent circle model' can be obtained by back analysis through numbering analysis. The back analysis of Shen Zhen line-5 is carried out to validate the rationality of the method proposed in this paper. Research shows that: the corrected model can reflect the feature and values of ground settlement more factually than the previous model and can offer a reference to predict ground deformation during shield tunneling.

## Introduction

It is unavailable to disturb the stratum in shield tunneling, so predicting and controlling the ground settlement effectively are always a research hotspot in tunnel community. The factors, such as soil conditions, construction technology and workmanship parameters are hard to be analyzed quantitatively. So, how to reflect the influence of those factors on the ground settlement is an important problem to be resolved.

Researches on the ground settlement of shield tunneling are as follows: Perk (1969) [1] imposed the famous perk formula to predict the ground settlement, this theory assumes that the volume of curve of ground settlement is equal to the volume of ground loss; Rowe& Kack (1983) [2] proposed the concept of 'gap parameter ' to reflect the ground loss caused by overbreak of shield cutter, deformation of excavation face and the gaps between the shield shell and soil layer; Zhu Zhonglong (2001) [3] performed a formula to calculate the settlement on the vertical section based on the theory of stochastic medium; Wang Huihui (2001) [4] predict the trend of ground movement using the method of neural network. ; Wei Gang (2006) derived a ground deformation formula based on the Mindlin solution of elastic mechanics. These researches based on analytical method, stochastic medium and neural network have strict theoretical basis, but cannot consider the influence of workmanship and the nonlinear character of soil.

Compared with theoretical studies, numerical modeling provides a convenient, economical approach to study the settlement of ground. Based on the model of 'equivalent circle zone' proposed by Zhang Yun (2002) [5], this paper carried out a numbering model to analysis the ground settlement. The corrected 'equivalent circle zone' are proposed in numbering analysis. Based on actual project, ground settlement predicted by this method is been compared with actual measured data.

### ‘Gap parameter’ and movement model of ground

Shield tunneling is a complex mechanic process. Overbreak of shield cutter, deformation of excavation face, gaps between the shield machine and soil, and workmanship are most important factors to induce the ground settlement, Rowe & Kack (1983) proposed ‘gap parameter’ to equivalent the impact of these factors. The ‘gap parameter’ is:

$$g = G_p + U_{3D} + w \tag{1}$$

Where, $g$ means the ‘gap parameter’; $G_p$ is the physical gap; $U_{3D}$ is the elastoplastic deformation of excavation face; $w$ means the level of workmanship.

Shield gap will induce ground movement. For the flowing reasons: (*i*) shield machine in construction usually keep the posture of pitching up to avoid bowing down; (*ii*) the gravity of shield machine and segments applied on the soil layer below the tunnel. So the movement model of soil around segment is unevenly factually. Lee (1992) proposed unevenly movement model of ground. Lee’ theory is consistent with the case in practical tunneling and has been applied extensively.

### Numbering method

**Corrected equivalent circle zone.** The shield gap, ground movement and distribution pattern of synchronous grouting are hard to be analyzed quantified in numbering simulation. To address this issue, Zhang Yun (2002) presented the concept of ‘equivalent circle zone’, as shown in Fig. 1. The factors above are generalized to be an orbicular ‘equivalent circle zone’ which distribute evenly around the segment. The ‘equivalent circle zone’ can be reflected by three parameters: Young’ modulus $E$, Poisson's ratio $u$ and thickness $\Delta$. With the measured data, these parameters above can be obtained by back analysis.

Through the analysis of ‘Gap parameter’ and movement model of ground above, the distribution forms of shield gap and movement of ground, which are closely related to the shape and distribution pattern of ‘equivalent circle zone’, are unevenly back around the segment. So, the distribution pattern of ‘equivalent circle zone’ is uniform actually too, and its’ shape is not a ring strictly. Based on these cognitions, this paper present a model of corrected ‘equivalent circle zone’, as shown in Fig. 2. In this model, the displacement of soil upper the tunnel is largest under gravity, while the soil below the tunnel is smallest with little resilience deformation of ground.

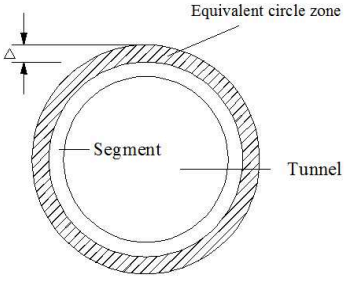

Fig. 1 Model of “Equivalent circle zone”

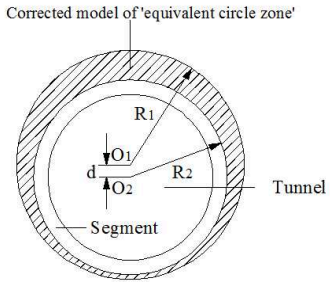

Fig. 2 Corrected model of “Equivalent circle zone”

In Fig. 2, $R_2$ is the outside diameter of segment. To reflect the scope and changes of thickness of corrected ‘equivalent circle zone’, two parameters are introduced as following: $R_1$ and $d$. Among these two parameters, $R_1$ is the radius of equivalent circle zone, which can reflect the scope of corrected ‘equivalent circle zone’; d is the distance from the center of equivalent circle zone to the center of shield tunnel, which can reflect the changes of thickness.

**The method of back-analysis.** In numbering analysis using the model proposed in this paper, there are four parameters to be assured: $R_1$, $d$, $u$ and $E$. To determine the values of above four parameters, the optimized back analysis are used in this paper according to the measured data, and the objective function for these unknown parameters is shown as follows:

$$J(x)=\sum_{j=1}^{D}\sum_{i=1}^{N}[u_{ij}(x_i)+u(x_i)'_{ij}]^2 \tag{2}$$

where, $u_{ij}(x_{ij})$ and $u_{ij}(x_{ij})'$ mean the settlement of monitoring point $i$ after the excavation stage $j$, respectively; $x_k$ denote parameter vector $x_k=[R_1,d,E]$. The value range of $x_k$ is shown as follows:

$$R_2 \le R_1 \le R_2+0.2;\quad 0\le d\le 2(R_2-R_1);\quad E_{\text{soil}}\le E\le E_{cement};\quad 0\le u\le 0.5 \tag{3}$$

where, $E_{soil}$ and $E_{cement}$ denote the Young' modulus of soil and cement respectively. In back analysis, the objective function *J(x)* is a complex functions with high nonlinearity and the method of 'corrected Powell' is employed to back-analyze the unknown parameter vector $x_k$.

## Numbering analysis of practical shield tunnel

**General situation of practical tunnel.** Numbering analysis is conducted based on project of Shen Zhen line-5. The metro tunnel between Qian Haiwan station and Lin Hai station was constructed by shield method. Designed inner-diameter of segment is 5.8m, thickness of segment is 0.36m, strength of segment is C50, value of 'gap parameter' is 8.5cm. The stratums from top to bottom are artificial fill-back, clay, silt clay and sand, hard clay and sand. The mechanical parameters of stratums and segments are shown in Table 1.

Table 1 The mechanical parameters of soil and segment material

| Materials | $E_0(M\text{pa})$ | Poisson's ratio | Unit weight (KN/m$^3$) | Cohesion (kPa) | Friction (°) |
|---|---|---|---|---|---|
| Artificial fill-back | 3.1 | 0.3 | 18.0 | 16.0 | 11.0 |
| Clay | 8.5 | 0.32 | 19.5 | 31.0 | 15.0 |
| Silt clay and sand | 11.6 | 0.32 | 19.5 | 32.1 | 16.5 |
| Hard clay and sand | 20.0 | 0.3 | 21.0 | 33.4 | 20.0 |
| Segment | 30000 | 0.2 | - | - | - |

**Numbering modeling.** A three-dimension numbering model is carried out by Flac3D to analyze the ground settlement in tunneling. The results obtained this method will be compared with the results obtained by Zhang Yun' model and Perk formula. Numbering model and grid mesh is shown in Fig. 3. The sizes of model are as follows: horizontal width 25m, high 32m and with a longitudinal length of 30m. The displacements are constrained in vertical direction at the bottom, while the zero displacements are imposed at the later boundary. The soil behavior is described to be an elastic-plastic model based on Mohr-Coulomb criterion.

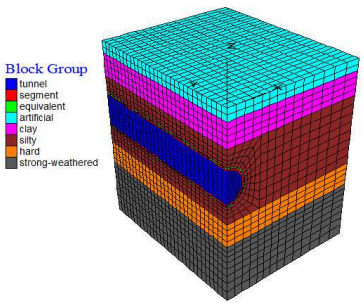

Fig. 3 Numbering model and grid mesh

**Result of analysis.** According to the back analysis, the parameters' value of corrected 'equivalent circle zone' are as follows: $R_1$=3.112m, d=4.6cm, u=0.21, E=1.58Mpa. To compare the results, this paper also carry out the back analysis using the method of 'equivalent circle zone', and the values of parameters are as follows: E=1.46MPa, u=0.21，and $\Delta$=12.4cm .

The results of ground settlement on tunnel' cross-section is shown in Fig. 4. As can be seen, the settlement curves obtained through the corrected 'equivalent circle zone' proposed is the most consistent with the measured data compared with other methods. The result of "equivalent circle zone" is larger than measured data, which means that the distribution pattern of equivalent circle of zone has an important influence to ground settlement. The result of Perk formula is the largest, that's because Perk formula hasn't consider the elimination of synchronous grouting to the shield gap in calculation; The changes of ground settlement curves on tunnel' longitudinal-section in Fig. 5. Because the deformation of the excavation face' soil caused by the supporting force applied on the working face, the ground located at about two-diameter in front of the shield machine occurred uplift deformation, the maximum value of uplift is about 0.25cm. Measured data of ground settlement is very consistent with the calculation data, which verified the rationality of the method proposed in this paper.

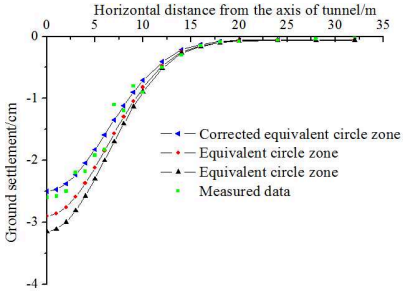

Fig. 4 Ground settlement curves on cross-section

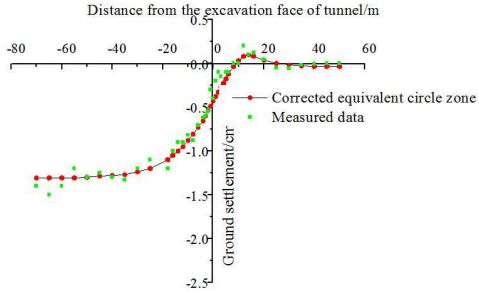

Fig. 5 Ground settlement curves on longitudinal-section

## Conclusion

In this paper, a model of corrected 'equivalent circle zone' is proposed to predict the ground settlement. Some conclusions are drawn as flows:(1) The distribution forms of shield gap and movement of ground are closely related to the shape and distribution pattern of 'equivalent circle zone', and its' distribution pattern back around the segment is unevenly;(2) In numbering analysis, the distribution pattern of equivalent circle of zone has an important influence to ground settlement. The results of ground settlement obtained by using the method proposed in this paper are very consistent with measured data, which verified the rationality of the method proposed in this paper.

**Keywords:** Numerical simulation; Tunnel intersection; Vault settlement; Reinforcement measure

**Abstract.** A position conflict exists between Harbin Urban Rail Transit Line No.1 and the branch tunnel of "7381" civil air defense tunnel. Intense tunnel interaction occurs when Line No.1 is perpendicularly tunneled across the branch tunnel. The investigation of the interaction is necessary. A 3D numerical simulation is established using FLAC$^{3D}$ and the vault deformation around the tunnel intersection is analyzed. The vault settlement of Line No.1 increases by 1.4 times during crosswise tunneling, while the vault settlement of branch tunnel increases 21.0mm in addition. The affected region of the tunnel intersection is further revealed. The affected length of the vault of Line No.1 and branch tunnel is 7.5 times the diameter and 6 times the width respectively. In combination with monitoring data, the reinforcement effect is studied at last. Both the vault settlement and surface settlement are well controlled in the tunnel intersection.

## Introduction

As the development of urban cities in China, underground tunnels for various purposes appear and experience rapid expansion. Meanwhile, the phenomenon of overlapped tunnels frequently occurs[1,2]. In the recent years, the issues related to overlapped tunnels arouse the attention of many researchers as the potential danger remains uncertain and the ground deformation is complicated. For the purpose of structure protection, the influence of a new bored tunnel on an existing tunnel is widely studied in the overlapped region[3,4]. Through in-situ monitoring, Zhang et al.[5] revealed the ground movement induced by the construction of overlapped tunnels using shallow buried-tunnelling method. Huang[6] obtained the values of surface deformation induced by excavation and water drawdown respectively on the basis of numerical results of overlapped tunnels. The complicated procedures of staged excavation were simulated in FLAC$^{3D}$. Liu et al. [7] analyzed the vault settlement of the existing tunnel under different excavation sequences. However, a new bored tunnel is either excavated beyond an existing tunnel, or excavated beneath an existing tunnel in these researches about overlapped tunnels. The overlapped situation that a new bored tunnel is excavated across an existing tunnel at same buried depth is rarely encountered. For the related study is insufficient, many risks exist during the crossing construction. This paper takes the tunnel section from the Ammeter Factory Station to Coast Park Station in Harbin Urban Rail Transit Line No.1 as background. Through 3D numerical simulation, the influence of the tunnel intersection on vault settlement is analyzed, and the affected value and region of vault settlement are both discovered. Furthermore, the feasibility of corresponding supporting measures is certified. The results of this paper have guiding significance for the design of other similar tunnel construction.

## Engineering Situation

The Ammeter Factory Station to Coast Park Station in Harbin Urban Rail Transit Line No.1 lay beneath at the west side of Xizhimen Street. Line No.1 consists of two single circular tunnels with an average diameter of 6.5m. The buried depth is about 14.0m~17.0m. The start-end mileage of tunnel section is CK6+129.4~CK7+116.5. Shallow buried-tunnelling method is adopted in the construction. And the typical cross section of the single circular tunnel is excavated by benching tunneling method. Before the excavation of metro tunnel, a civil air defense tunnel ("7381" Tunnel) which has been constructed in earlier years already exists underground. The paper abbreviates the civil air defense tunnel to *CAD* tunnel in the following sections. The No.1, No.2 and No.3 branch tunnel of the *CAD* tunnel has a geographical location conflict with the metro line abovementioned. The branch tunnel and Line No.1 perpendicularly intersects. The plan of overlapped intersection is presented in Fig.1. Fig.2 indicates the profile of tunnel intersection.

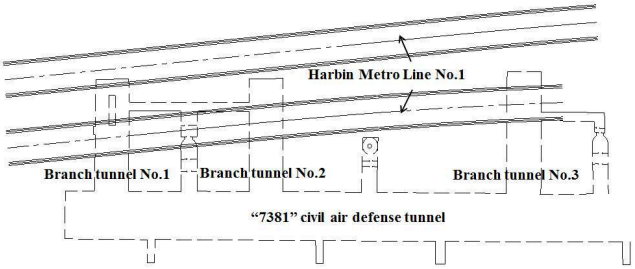

**Fig.1** Plan sketch of tunnel intersection

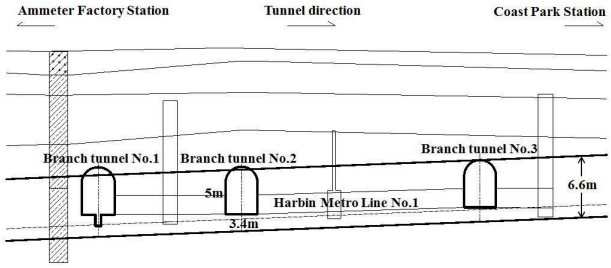

**Fig.2** Profile diagram of tunnel intersection

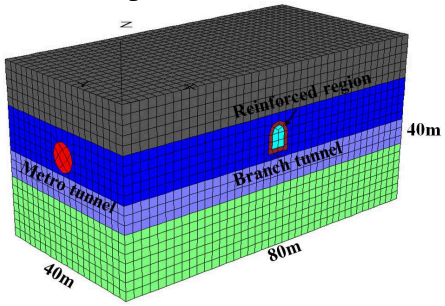
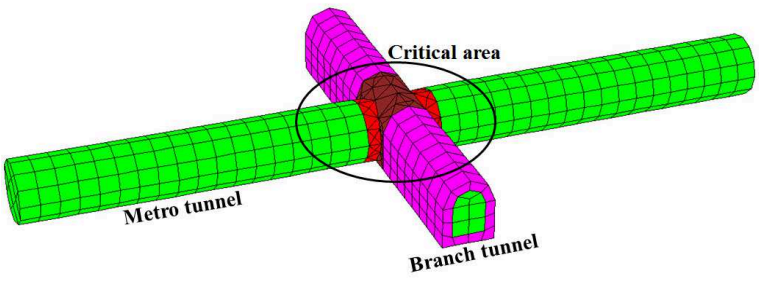
## Numerical Simulation

**Engineering Simplification.** The proposed up line of metro tunnel intersects almost perpendicularly with the branch tunnel No.1, branch tunnel No.2 and branch tunnel No.3 of the civil air defense tunnel in spatial terms. During the construction crossing each branch tunnel, the soil is greatly disturbed and the stress of soil is complicated around tunnel intersection. Accidents may occur and the existed *CAD* tunnel will be damaged if not taking the right supporting way. Considering the engineering conditions that the up line tunnel excavated across three branch tunnels are similar, the research can be simplified as a problem that the up line is excavated across one branch tunnel. The following analysis is conducted on the basis of this typical condition and vault settlement induced by excavation is analyzed using FLAC$^{3D}$.

**FLAC$^{3D}$ Model.** The numerical model of the tunnel intersection is shown in Fig.3. The whole model consists of 18036 elements and 18748 grid points. As Fig.3 shown, the length of the model in x, y, z direction is 80m, 40m and 40m respectively. The metro tunnel is a single circular tunnel with the diameter of 6.6m and the height and width of the branch tunnel is 5m and 3.4m respectively. The Mohr-Coulomb elasto-plastic constitutive model is employed for the soil in this analysis. Pre-grouting and concrete lining of the tunnels are simply modeled by shell element. According to the geotechnical investigation report between Ammeter Factory Station and Coast Park Station, the mechanic parameters of soil and shell elements are given in Table 1 and Table 2.



(a) Global mesh model



(b) Internal tunnel intersection

**Fig.3** Finite difference model

**Table 1** Mechanic parameters of soil

| Soil Type | $\gamma$ (kN/m$^3$) | $E$ (MPa) | $C$ (kPa) | $\varphi$ ($^o$) |
|---|---|---|---|---|
| Silty clay | 18.4 | 33.6 | 63 | 10.7 |
| Silty clay | 18.9 | 36.0 | 66 | 15.0 |
| Medium sand | 18.9 | 45.6 | 6 | 28.7 |
| Reinforced soil | 20.0 | 72.0 | 300 | 50.0 |

**Table 2** Parameters of shell elements

| Shell Type | $E$ (MPa) | $d$ (m) | $v$ |
|---|---|---|---|
| Branch tunnel | 120 | 0.3 | 0.25 |
| Reinforced branch tunnel | 200 | 0.6 | 0.25 |
| Metro tunnel | 500 | 0.3 | 0.25 |
| Reinforced metro tunnel | 600 | 0.6 | 0.25 |

**Sequences of simulation.** Step1: Obtain initial stress field under gravity; Step2: Excavate and support the branch tunnel; Step3: Excavate and support the metro tunnel when tunnel intersection is unreinforced; Step4: Excavate and support the metro tunnel when tunnel intersection is reinforced.

## Result Analysis

**Vault settlement without reinforced measures.** Vault settlement around the intersection of the metro tunnel and branch tunnel is the research emphasis in this paper. First, we assume that no reinforced measures are adopted in the intersection. The metro tunnel is excavated according to benching tunneling method. After calculation of FLAC$^{3D}$, the vault settlement curves of metro tunnel and branch tunnel are shown in Fig.4 and Fig.5 respectively. As Fig.4 shown, the settlement curve performs like V-shape which consists of two parabolas. The maximum vault settlement is 21.0mm which occurs at the crossing point of metro tunnel and branch tunnel (X=40m). Vault settlement gradually decreases to 15.1mm from the center to the edge in X direction. The maximum differential settlement is 0.45mm/m. The reason for increasing settlement is great stress concentration around tunnel intersection. In Fig.4, the vault settlement curve induced by individual excavation of metro tunnel is also presented so that the tunnel interaction can be clearly revealed. The vault settlement is basically uniform and there won't be any great differential settlement. However, due to the existence of branch tunnel, vault settlement around the tunnel intersection is obviously larger. The affected region reaches from X=15m to X=65m. This length equals to 7.5 times the diameter of metro tunnel.

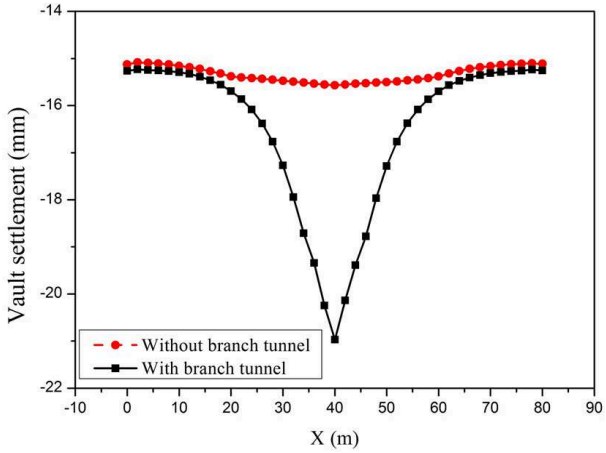


**Fig.4** Vault settlement of metro tunnel

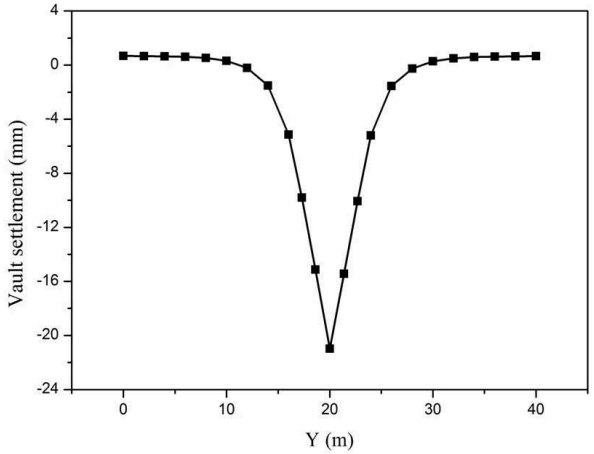

**Fig.5** Vault settlement of branch tunnel

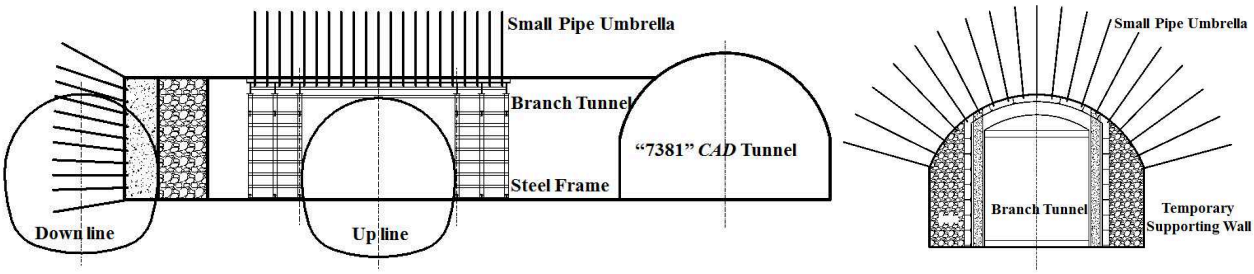
As Fig.5 shown, a similar V-shape settlement curve of branch tunnel is induced by the tunneling of metro tunnel. The position where maximum vault settlement occurs is the same as metro tunnel. However, the vault settlement almost drops to 0 at the edge of branch tunnel. The maximum different settlement is 2.92mm/m which is much larger than metro tunnel. Thus the branch tunnel is more dangerous than metro tunnel during the crossed tunneling. The affected region of branch tunnel during tunneling reaches from Y=10m to Y=30m. This length equals to 6 times of the width of branch tunnel. Therefore, the affected region in the tunnel intersection is very big in both metro tunnel and branch tunnel. For reducing vault settlement around the tunnel intersection, the surrounding soil needed to be mainly reinforced.

**Reinforced measures and analysis.** As above mentioned, the tunneling will lead great vault settlement around the tunnel intersection and cracks may occur. Therefore, before the excavation of up line, pipe umbrella grouting is employed behind the lining of branch tunnel around the intersection. After grouting, I-steel (I45b) frame is installed inside the branch tunnel at the up line location to reinforce the intersection. I22a steel is used in the junctions of steel frame at the vault, sidewall and inverted arch part. The distance between two steel frames in the longitudinal direction is 0.5m. In addition, for the uncompacted places between steel frame and lining of branch tunnel, steel plates are employed to pad and weld the gaps. What's more, double-layer welding steel net ($\Phi$6.5@150×150) and C20 shotcrete are employed at the gap of the vault and inverted arch of steel frame. Detailed reinforced measures of branch tunnel No.1 is shown in Fig.6.



(a) Longitudinal view (b) Transverse view

**Fig.6** Reinforced scheme diagram

According to the practical supporting condition, soil parameters of the reinforced region and shell element are updated to the value in Table 2 at a 12m range of tunnel intersection in both transverse and longitudinal direction (X=34m~X=46m, Y=14m~Y=26m). For the lack of relevant date of grouting and steel reinforcement, the parameters in Table 2 are quoted from the paper of Queiroz[8]. After the calculation under reinforced measures, vault settlement curves of metro tunnel and branch tunnel are drawn in Fig.7 and Fig.8 respectively. The numericla results are similar to the monitoring data. As Fig.7 shown, the previous maximum vault settlement drops to 13.2mm after reinforcement. And the vault settlement in the reinforcement region is even smaller than other region. In Fig.8, the vault settlement of branch tunnel also decreases after reinforcement. All the final settlement stabilizes in a safe range. Thus, the reinforced measures are effective for the safety of the tunnel intersection.

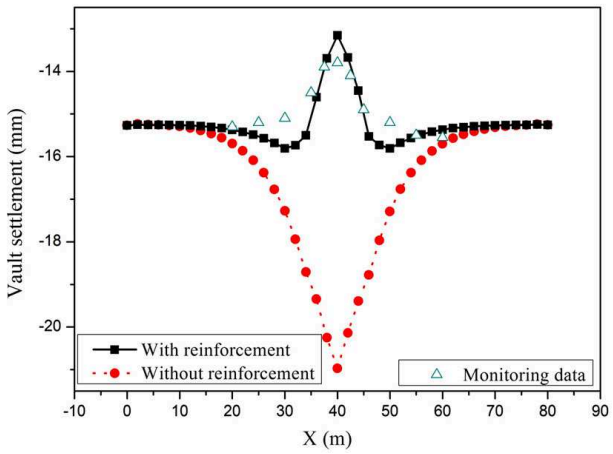


**Fig.7** Reinforcement effect on vault settlement of metro tunnel

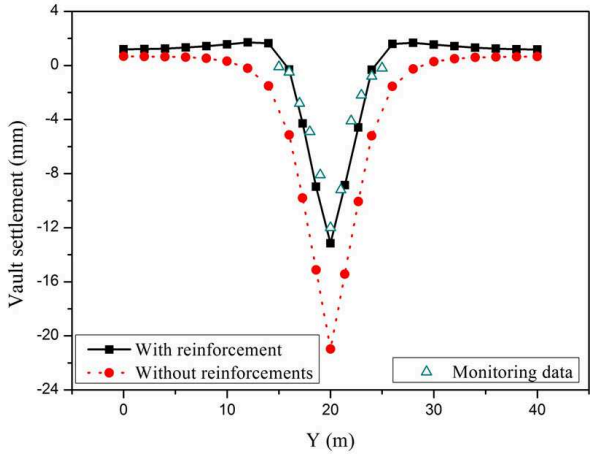

**Fig.8** Reinforcement effect on vault settlement of branch tunnel

Besides, the surface settlement is investigated. The surface settlement curve right above the axis of metro tunnel is drawn in Fig.9. Before reinforcement, the settlement curve fits the gauss distribution. After reinforcement, the maximum surface settlement changes from 6.1mm to 3.1mm. The decline degree in settlement reached to 50%. The surface settlement in the reinforcement region obviously reduces and the entire settlement becomes more even. Fig.10 shows the surface sttlement right above

the axis of branch tunnel. The entire surface settlement has also been reduced by reinforcement. From the view of surface settlement, the reinforced measures are still effective and needed.

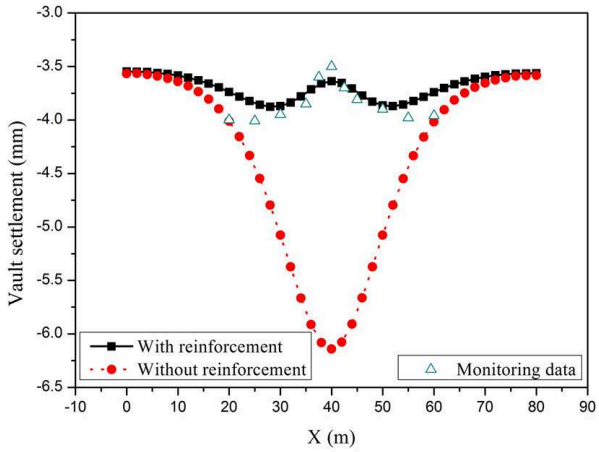

**Fig.9** Reinforcement effect on surface settlement right above axis of metro tunnel

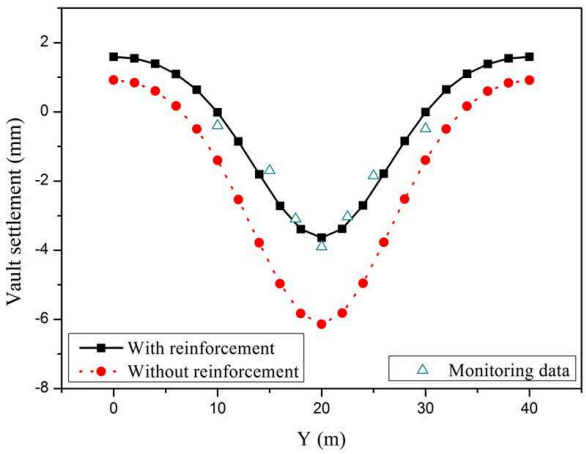

**Fig.10** Reinforcement effect on surface settlement right above axis of branch tunnel

## Conclusions

A numerical simulation of crosswise tunneling is conducted by FLAC$^{3D}$ in this paper. The following conclusions can be drawn:

(1) Without any reinforced measures, the vault settlement in the tunnel intersection will increase significantly during the metro tunneling across the branch tunnel.

(2) Due to existence of branch tunnel, a large region of vault will be affected in the tunnel intersection. The length of affected region of metro tunnel is 7.5 times diameter and the length of affected region of branch tunnel is 6 times width.

(3) Reinforced measures including grouting, steel frame and shotcrete decrease the vault settlement and ground settlement effectively in the tunnel intersection. The reinforcing method employed in the construction is the reference to other similar engineering.

From the conclusions mentioned above, an existing tunnel has significant influence on vault settlement during a new tunnel excavated across. Detailed research need to be conducted in the future.

**Keywords:** shield machine, main drive sealing, fracture failure, installation forms, platen method

**Abstract.** Due to poor bonding of a shield machine main drive leading to seal failure sealing fracture failure occurs, the proposed installation forms of adhesive sealing method is replaced by platen method, and seal material NBR replaced by a fluorine rubber, so that the combination of the housing seal is more reliable, avoiding the fracture caused by discontinuity of local sealing. Construction process increases the injection of three different oils enhancing the sealing effect. Through the application of practical project, no failure appears after sealing transformation.

## Introduction

Shield machine main drive system called Shield "heart", the main drive sealing is the "heart of the diaphragm", and so the main drive sealing crucial role. On the one hand, Complete and reliable main drive seal through the lubrication grease injection and maintain a certain pressure, provide a good working environment for the main drive bearing; on the other hand, grease with a certain pressure to force out the shield machine kokura side, can effectively prevent silt soil compartment into the main drive inside, causing parts to wear out and fail. While the shield machine main drive seal forms a seal with other mechanical devices are basically the same, but because of the shield tunneling machine in the underground construction, the sealing system cannot be replaced in the tunnel cave interior, if the seal is damaged due to the construction of the gap is too big or worn and other problems caused by the main bearing gear oil leak or silt particles into the gearbox, causing damage to the main bearings or gears, resulting in paralysis of the shield machine, very serious economic losses immeasurable impact and will shield project. Shield Construction of such incidents occurred both at home and abroad, such as: 2007 send in East Gas Pipeline crossing the river to the 360m tunnel shield construction, the shield machine cutter head main bearing oil seal oil pressure drops, the inspection shield structure cutter head pressure plate bolt main bearing seal all broken, deformed outward pressure plate, dual-sealed damaged and must be repaired in order to continue the excavation. The final choice of methods for slurry pipeline from TBM cutter heading to face pressure injection of modified mud on the heading face for closure sealing, maintenance personnel with pressure for entrance, replace the seal and the pressure plate. The direct cost of 179,000 Yuan is needed to repair it with a time of 13 days [1]. Another example: in 2010 a company in the construction of Beijing metro line in a bid to promote the use of the shield machine in the process due to seal wear, a lot of sediment into the main drive gear box, resulting in paralysis of the shield machine. Approach is to clean up the soil positions, removal of the main drive motor reducer, the seal cavity clean sediment, unable to disassemble the main drive, it cannot replace the main drive seal, before finally taking a Kokura face seal bulkhead installation and continued into the seal grease to make the completion of the tunnel shield machine construction, maintenance took a month or so. After completion of the shield tunneling machine construction receives disintegration, the main driver for almost scrapped eventually is replaced as a whole, huge economic loss.

Causes of these accidents are due to the main drive seal design, installation, and use of the material, resulting in the main drive seal due to the presence of certain defects or maintenance is not

in place. The units used a shield machine for some period after the completion of tunneling construction, repair and maintenance base for the maintenance process; we found broken main drive seal failure problem occurs. After we analyze the reasons for breaking the seal on the main drive seal a technical research to improve and achieved good effect in the subsequent construction of the shield to avoid the risk of seal failure because the main drive and cause serious accidents shield machine.

## The main drive seal design of shield machine

**The main drive sealed design of factory.** The current domestic market of shield machine brand is more, but the form of main drive seal is very much the same. Seal structure of the design shall ensure that the sealing lip has a good follow, keep the best contact Angle with the axis of rotation. Ensuring dynamic sealing effect while reducing the contact area of the seal, reducing friction and heat sealing lip wear to the maximum extent, so that it can be used for pressure conditions (such as EPB working condition)[2][3]. EPB shield machine main drive seal is generally divided into the inner periphery seal and the outer periphery seal, both are combined seal, respectively combined by lip seals and seal combination VD. Lip seals are Multi-lip seal with the effect of static, dynamic, self-sealing effect and better toughness. VD seal is a seal-ring side of the V formed by the thick lip, VD ring is applicable to the axis of rotation dynamic seal, the sealing lip has good mobility and adaptability, can compensate the larger tolerance and angular deviation[4].

The shield machine original factory design of main drive seal form is shown in figure 1, The inner periphery and the outer periphery seal sealing lip seals are combined by one Multi-lip seal (hereinafter referred to as lip seal) three VD seals. The materials used in making the VD seal of shield machine Lord drive seal is nitrile butadiene rubber ,called NBR. The surface roughness Ra of the seal is 3.2μm, the roughness Ra of the metal surface which is in contact with the lip is 1.6μm.

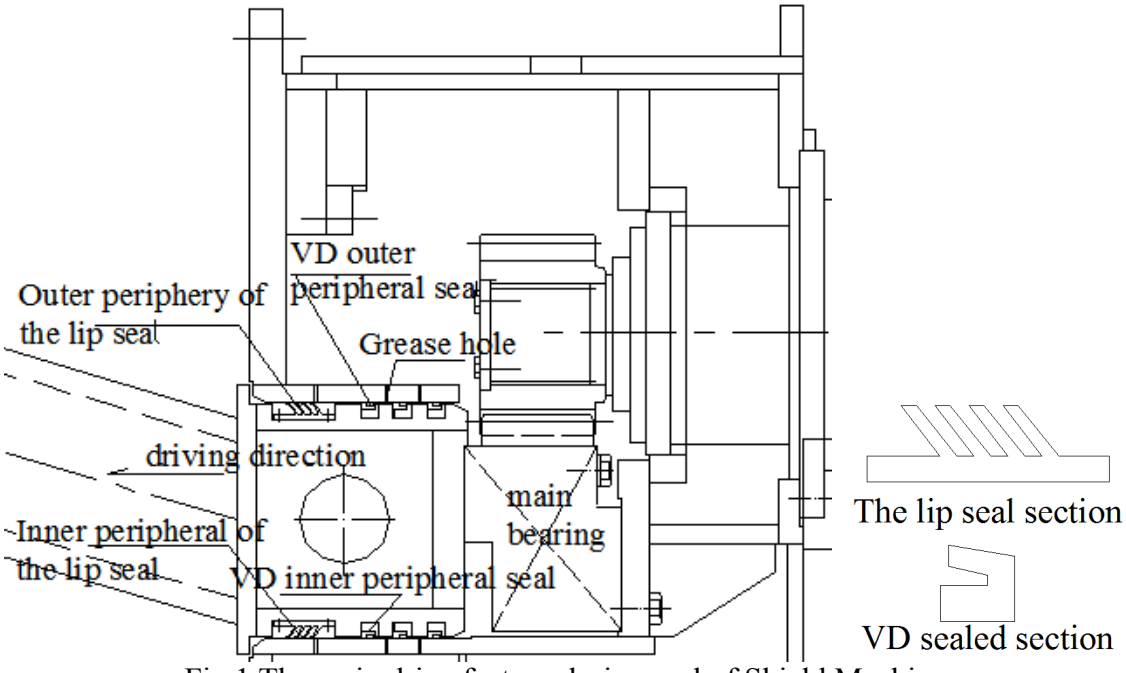

Fig.1 The main drive factory design seal of Shield Machine

**The installation of the main drive seal.**

(1)The installation form of the lip seal

The form of lip seal is circular, LORD Corporation LORD produced using 305 two-component epoxy adhesive bonding with the metal mounting surface plate bolts tightened before use, after the installation is complete, the top spot of the platen bolts fixed to prevent bolts loose. Figure 2: The lip seal installation.

Fig.2 The lip seal installation

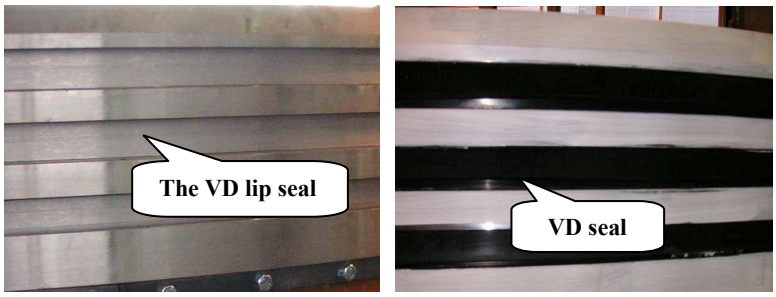

Fig.3 VD the lip seal installation

(2)The installation form of the VD seal

The form of the VD seal is band, the Joint use instant dry adhesive , then embedded it into the drive seal groove, and before embedding seal groove in metal groove, daub a two-component epoxy Lord LORD305 adhesive. Adhesive solidifying time is around 24 hours. As shown in figure 3: VD the lip seal installation.

**The working principle of main drive seal.** Using concentrated lubrication equipment inject EP0 lubricating grease in the cavity between the two sealing，Design the outer periphery of each cavity injection volume was 20ml/min, within weeks of each chamber is 16ml/min, a total consumption of about 2000ml / m when the shield tunneling was working. VD seal may remain in the cavity to produce a lubricating grease pressure when the pressure exceeds a certain range of a forward cavity grease leakage, while the former can ensure that the grease lubrication of the cavity does not flow. Lubricants grease injection device with a certain pressure to squeeze a steady stream to the main drive end face plate and spacer transfer surface soil positions to prevent silt soil compartment under the action of earth pressure inside the sealed into the main drive, which in turn has to the sealing effect.

## The problems of Shield Machine Main Drive Sealing

**The general situation of shield tunneling construction.** In the second phase of Beijing Metro Line 10, Chedaogou Station to Changchun Bridge Station tunnel section is located in Haidian District, Beijing. This tunnel section runs north-south. The length of the right line tunnel is 749.374m and the length of the left line tunnel is 742.44m. Interval line profile design average grade is 14.47 ‰. The thickness of covering soil is 10～12m. The section of shield tunnel crossing strata is mainly composed of sandy pebble with size of 20 ~ 40 mm. Maximum particle size is not less than 170 mm and particle size is greater than 20 mm pebble accounted for over 60% of the total mass.

The main technical parameters of shield machine in the process of tunneling construction include, the upside soil pressure is 40~50KPa, the knife rotating speed is 1.4 rpm, the cutter torque is about 2850kN·m (50%), the total thrust is about 20000kN, the advance rate is between 40~60mm/min.

**The problems of Shield Machine Main Drive Sealing.** After completion of the above construction, we found that the Shield Machine Main Drive Sealing appeared the following two issues when we repaired shield machine. One is the VD sealing fracture failure. Second, the lip seal and seal liner worn metal surface.

(1) The VD sealing fracture failure

The VD sealing fracture failure as shown in figure 4, the third DVD sealed fracture length of about 10 cm. The reason of fracture is the VD sealing installed in the form of adhesive. Local bonding strength is not uniform. While seals and sealing bushing sliding relative rotation, sealing bushing to seal tangential tensile force along the circumferential direction. Seal bonding strength with low position under the action of tensile force does cause gradual sealing glue. And then to form stress concentration. Eventually lead to seal fracture failure.

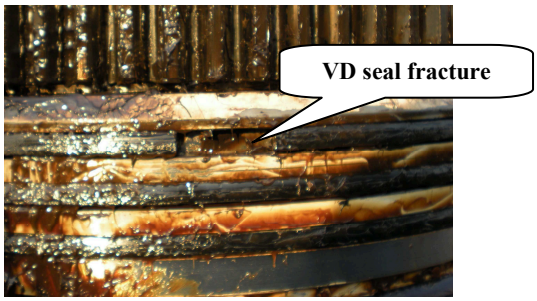

Fig.4 VD seal fracture

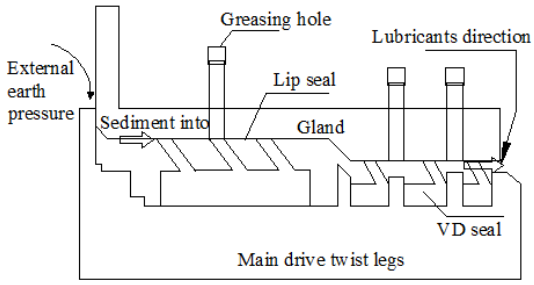

Figure.5 Diagram of sand invasion after VD seal fracture

The VD sealing fracture failure consequence is the grease inside the sealed cavity leakage to the big gear system and bearings in the box due to the loss of seal block. At the same time due to loss of pressure seal back and front-end existing earth pressure, resulting the mud invasion led to the lip seal wear and then the failure, as shown in figure 5. But also can make the lubricating oil consumption increase. By measuring, in the later stages lubricating grease for construction usage increased about 1000 ml/m compared with the previous. More serious is that mud into the large gear box and main bearing lead to wear retarding mechanism of Shield Machine Main Drive. Fortunately, due to the interval in short driving distance has not caused serious failure of shield machine downtime.

(2) Lip seal and the sealing bushing wear

Lip seal wear. After the collapse of the main driver, we check found lip seal four lip all have different degree of abnormal wear. Especially the lip seal the outside piece, due to the direct contact with the mud, the wear is most serious. In the process of shield tunneling in normal, the knife rotating speed is 1.4 rpm, peripheral lip seal linear velocity $V=2\pi rn/60=0.23m/s$, the temperature can reach 50℃, and cannot ensure that the lubricating oil supply is adequate, the seal is easy to wear. As shown in figure 6 was the state of the lip seal maintenance after the excavation of shield machine is about 1.5 km. The first and second sealing lip has damage failure. If promote longer distance will have serious consequences as shield machine downtime.

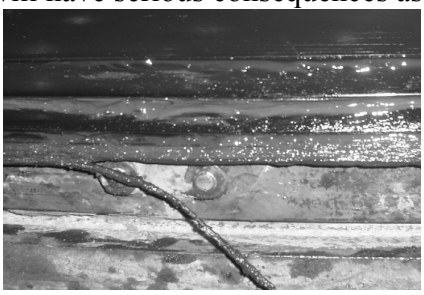

Fig.6 The lip seal wear

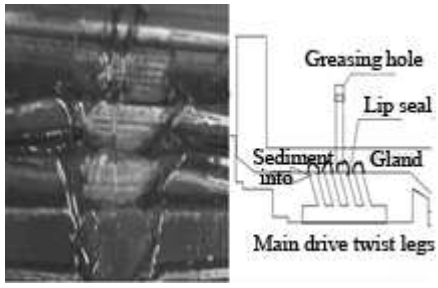

Fig.7 Gland sealing position corresponding to the wear of the lip

According to the design requirements, for the reason of sealing bushing wear, the amount of compression of the sealing lip is 7mm, to ensure the reliability of the seal. Shield machine in use after a certain period of time, as a result of the main bearing sealing lip and mud -normally the first sealing lip only direct contact with mud-and sealing bushing relative rotating slide for a long time. Lip seal in grinding out a liner circumferential direction of the bushing about 3~5 mm groove(The depth of the groove mark according to the length of the run time and external when excavating soil storehouse to the pressure of the sealing lip)[5]. In a sealed bushing and sealing lip seal and VD sealing contact position there are varying degrees of wear. As shown in figure 7.

Because this kind of wear and tear of the clearance groove will reduce the main bearing sealing lip seal performance and accelerated wear of the sealing lip. Although there is continuous lubricating grease filling, when the wear reaches a certain degree, amount of compression seal cannot compensate for wear. Still can cause the main bearing seal chamber lubricating grease in the body can't establish a certain pressure, lead to external mud invasion, causing the main driving gear,

main bearing roller, roller and cage damage[5]. If you do not eliminate the dangers caused by the groove marks, even change the new seal, due to the uneven groove mark, lip and fitting clearance of bushing cannot meet the design requirements, the sealing effect is also not ideal. So you need to repair or replace the seal.

## Retrofit scheme of main drive sealing

According to the analysis of the above problems, wear and tear of VD seal and wear of sealing bush can lead to serious consequences, in order to avoid the problems and enhance the reliability of sealing, it is essential to improve the material and installation form of the three seal.

**Material improvement of the three seal.** As the three seal is near the gear box, the temperature of the seal is high when the main drive is running and, the maximum can reach 60℃, the seal prone to accelerated aging and the binder may fail in the environment. The solution is to change the material of the three seal outside and inside, replace Nitrile butadiene rubber with Synthetic rubber containing fluorine. Fluorine rubber has excellent properties such as high temperature resistant performance, corrosion resistance, hot water resistance and hot steam resistance[6]. Characteristics of various rubbers are shown in Table 1.

Table 1 Characteristics of various rubber sheets

| Varieties / Characteristic | | Natural rubber | Styrene buta-diene | Nitrile buta-diene | Butyl chloride | silicone | Fluorine rubber |
|---|---|---|---|---|---|---|---|
| operating temperature | Min | -50 | -40 | -25 | -35 | -60 | -15 |
| | Max | 80 | 100 | 130 | 130 | 280 | 250 |
| hardness | | 20-90 | 30-90 | 30-90 | 30-90 | 10-80 | 60-90 |
| tensile strength MPa | | 10-30 | 10-25 | 8-25 | 10-25 | 6-11 | 8-20 |
| Tear resistence KN/m | | 30-100 | 20-70 | 20-80 | 20-80 | 10-35 | 15-60 |

**Modification installation form of VD seal.** Most seal fractures are caused by bad bonding and local uneven stress change the installation from Cementation method to platen method. Process plate according to the mounting surface radian inside and outside the main drive sealing; reorder the VD seal with crimping edges. The seal plate is annular after installation, then, fixes the plate with bolt. The seal renderings are shown in Fig. 8.

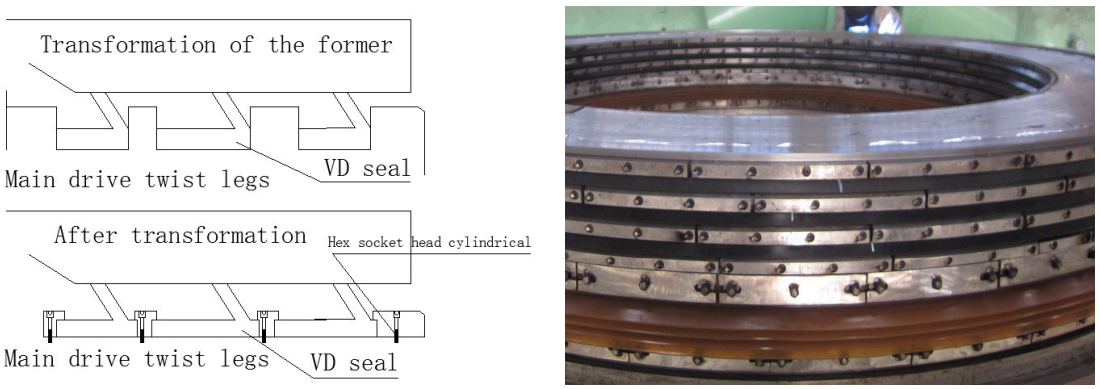

Fig.8 Seal after renovation renderings

Transformation process and main points:

(1) Process the bracket by vertical lathe machine, then, drill and thread at the design location. Process plate is according to the surface radian of the processed bracket and drill.

(2) The bolts must be new ones, totally 832. The bolt strength grade 8.8.

(3) Coat the surface of VD seal uniformly with cementing agent in case the grease reflows from the mounting surface gap.

(4) The pressure of bolt must be uniform when install the plate in case the plate deformed.

(5) Weld the connection point of bolt and plate after tightening the bolt in case the Screwed off. In the process of welding, care must be taken not to make the high temperature welding slag welding with seal and damage the sealing. In order to prevent failures, fireproof cloth must be used to protect the seal, preventing the contact of welding rod and seal.

**The application effect after the transformation of the main drive seal**

After the transformation of the main drive seal, this shield machine was used in the sixth engineering contract section of Beijing metro line 9, between Diaoyutai East station to Baishiqiao South station, and switched to the construction of 404 meters along the right line after tunneling a distance of 651 meters to Baishiqiao South station along the left line, total 1.05km in distance. Geological conditions across the range: pebble and conglomerate layers, partially mixed with fine sand and silt. The state of the shield machine, whose main technical parameters: the rotation speed of the disk cutters was 1.4rpm, tunneling speed was about 50mm/min, the cutter head torque about 60% (about 3462kN.m), was relatively stable.

During the excavation of the 1.05 km-long project, through continuous monitoring on lubricating oil, the consumption of lubricating oil was about 2.20 ml/m and pressure and consumption of lubricating oil were kept within the threshold set by the design. After the tunnel was completed, when the main drive seal was dismantled and checked again, no rupture phenomenon of inner and outer VD seal had been discovered. It was not found looseness occurred or Silt invaded when checking the seal plate at the same time. Figure 9：The wear of the contact place between the sealing lip and cartridge decreased and was about 0.6 ~ 0.8mm.

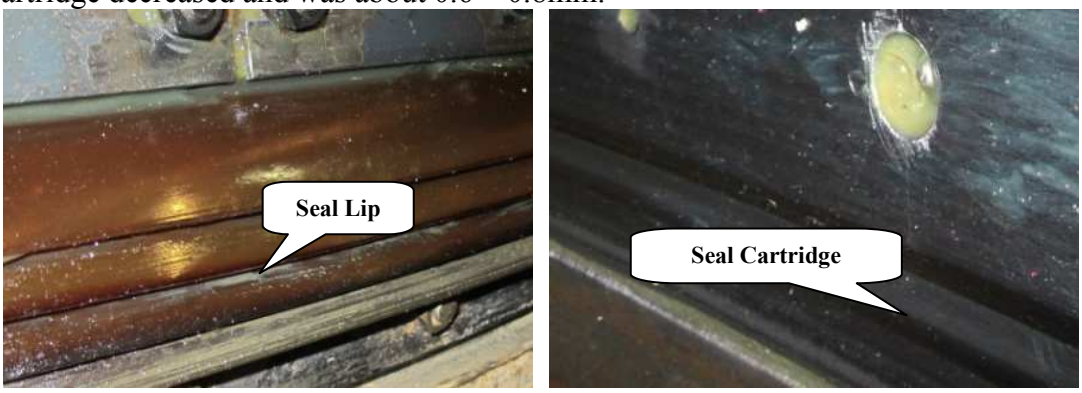

Fig.9 Main drive seal using renderings

**Conclusion**

After the technical reconstruction of the main drive seal, shield machine with favorable effects did not fracture again; Roughness Ra value, elasticity and other properties of the fluorine rubber seal complied with the design requirements, and its high-temperature aging performance had increased compared with nitrile butadiene rubber. This ensured that the shield machine was reliable in underground construction.

The pressure plate type, the installation form of this main drive seal, made the combination of seal and shell more reliable, avoiding failure caused by the seal fracture owing to local uneven stress. After modification, through the engineering application test, it achieved the desired effect of modification technology research of the seal, accumulated rich experience for the design and manufacture of shield machine.

At the same time, we should draw lessons from the main drive seal system of shield machine of other brands, such as main drive sealing system of NFM shield, which is injected three kinds of oil to achieve the purpose of sealing and lubrication and designed mechanical labyrinth seal in the side of soil storehouse to further enhance the sealing effect, consists of five lip seals specially designed.

In the course of excavation, the monitoring of lubricating grease should be strengthened, including consumption, oil pressure, etc. to enhance the ability to predict failures.

In short, shield tunneling will be more and more safe and reliable with continuous improvement and innovation of the technical performance of shield equipment; shield equipments are also easier to maintain; this tunneling technology will be continually applied to various fields in underground engineering construction.

**Keywords:** metro; environmental vibration; vibration measurement; vibration mitigation measuremen

**Abstract.** With the rapid development of metro, the vibration induced by metro is the more and more common and widely concerned. In this paper, test and analysis of vibration induced by metro is discussed, and the five aspects of the research status at home and abroad are emphasized, which are the analysis of the vibration causes, the analysis of vibration influence, the summary of vibration test technology, the analysis of the relevant theoretical results and the analysis of vibration reduction application measures. This paper will provide the theory basis and the practice reference for the vibration design of environmental vibration induced by metro.

## Introduction

Since twentieth Century 60-70 years, the world economy rapidly develops, the number of vehicles sharply increase, which led traffic conditions to more and more worsening[1]. Metro become aware of an effective way to solve the traffic problems, which has a lot of advantages such as saving land, large transport capacity, stable running time, small investment, safety and environmental protection.

With the rapid development of metro, while bringing a lot of convenience to people, it also causes a lot of problems. Usually, the subway traffic throughout the city downtown area, its impact on the surrounding environment can not be ignored. Among the complaints about the metro, the vibration induced by metro is the most common and most widely concerned. Because vibration induced by metro is long-term and repetitive, may cause the shedding and cracking of decorations, deformation or subsidence of foundation, thus it will affect the safety of buildings and service life; vibration will affect physiology and life[2]; in addition, it is bound to affect the normal operation of precision instrument[3]. As in Czech, some of masonry structures near rail cracked, which is caused by vibration of the vehicle through them, and in some place the ancient church collapsed because of the expanding crack[4]; some walls of the Guta lie in China Xi'an city and many pagodas of Beijing have different degree damage by the traffic vibration[5]; the some tile murals of Beijing Metro Line 2 falled off which is caused by vibration not only affect the appearance but also affect traffic safety in certain degree[6].

## Analysis of the causes of vibration induced by metro

In the metro system, the train is due to interact between the wheel and rail, the vibration energy is produced; it is transferred to the tunnel hrough the bed, then the vibration of the tunnel and surrounding rock is caused; the vibration is transferred to the foundation near the building through the surrounding soil and rock, further it will transfer along the column, beam, wall and floor; at last the vibration of people and equipment lieing on the floor is caused[7].

The vibration induced by metro mainly experiences 3 stages, vibration source, propagation in the medium and the environment vibration, which constitute a system including of train-support structure- soil - building - people. The vibration system is composed of the source, propagation path and the vibrating body, the vibration source is mainly composed of a train, rail supporting structure and fundation, the important affecting factors include of characteristics of vehicle types, marshalling,

dynamic characteristics, speed, bearing structure and its foundation; the propagation path, namely, ground and underground soil, including bearing structure foundation soil interaction, the upper and the building, vibration in soil spread; vibration bodys include of building, equipment and people[8].

From the metro vibration process, while the train moves as a certain speed, there are a lot of causes of vibration induced as the following [7,9]: 1) the wavefront of moving loads; 2) the discrete support sleeper or fastener; 3) the change of track stiffness caused by changing stiffness of subgrade; 4) the cyclic loading of trains; 5) the collision impact force while train moves through rail joint or switch; 6) the continuous irregularity generated by eccentric wheels; 7) the uneven pulse irregularity caused by wheel tread wear; 8) the deformation of embankment system under wheel pressures; 9) the horizontal gap between wheel and axle deformation. Among these the train's wheel pressure is the main reason.

**Analysis of the influence of vibration induced by metro**

1) vibration impact on the structural safety

Compared to the earthquake and explosion that can cause severe damage, the impact of metro vibration on the building is not due to get instant results, because its vibration energy is smaller, but as the result of long-term accumulation, the dynamic fatigue and stress concentration will be caused, which will mainly be appearance of structure and function loss, damage and short service life.

2) vibration impact on the use of instrument

Precision instruments have high requirements for storage and use, every type of equipment has its own normal indicators of control. While the value of the vibration transfered by the running subway exceeds its allowable indicators, the work system and dense instrument will swing or tremble, which leads to cause error of measurement system. Serious when causing the precision instrument failure, or even destroy, more serious condition is that the instrument can't be used. So, when the subway line is planned, it must be inspected whether there are precision instruments where the line runs through, it must take reasonable measures to avoid causing immeasurable loss.

3) vibration impact on human life

Vibration impact on people's daily life is very extensive, especially the large noise is often accompanied by vibration. So the vibration mainly generate interference and influence for people's life, work, study and rest, the main performance is unable to efficiently concentrate, to study or work.

4) vibration impact on human health

The long time metro vibration will have great effects on the human body and psychological reaction, including of impaired visual sense, vomiting, fainting, heart sick, nervous disorders and limb activity decreases. The impact on psychology is that people sometimes feel fear, pain, sensitivity, insomnia and nightmares. It is visible that the long-term vibration impact on human daily life can not be ignored.

**Summary of metro vibration testing technology**

At present, there are contact and non-contact vibration test methods, contact test method is more common. The former has two types: one is magnetoelectric speed sensor, its working principle is when the magnetic flux changes through a coil, the electromotive force will be produced, velocity output electromotive force and the coil is proportional; the other is piezoelectric acceleration sensor, its working principle is using certain substances such as piezoelectric effect of quartz crystal, while the accelerometer vibrates, the force of the mass on the piezoelectric elements will change, when the measured vibration frequency is much lower than the natural frequency of the accelerometer, the change of force and the measured acceleration is proportional.

The data extracted by piezoelectric acceleration sensor is more intuitive, more convenient. But this method can not realize long distance real time monitoring, there are some shortcomings such as the piezoelectric sensor is still the traditional connection mode, when the number of measuring point is more, the test operation time will be in short [10]; and like that only one sensor can be arranged in a cross section, which can only measure the parameters of a specific section of real-time monitoring,

but the long distance real-time changes of the parameters along the line is in need; moreover the data processing must be carried on after the end of the test, which can not monitor in real time.

The development of science and technology provides the possibility for solving the above defects, the distributed optical fiber sensing technology with its unique advantage is particularly worthy of esteem[11]: it can realize remote measurement and monitoring; it can carry on the long distance test, it has high performance ratio; the optical fiber can all become sensitive element, which can acquire the distribution information of measured the sensing area in real time; it can process data in real time, and it can achieve truly real-time monitoring, timely finding and solving the potential problems and harm.

## Analysis of related theoretical results of metro vibration

There are many relevant theories about metro vibration, which mainly consists of the theoretical analysis method, the experimental method, and the numerical calculating method.

The theoretical analysis method is an analytic method, which directes mainly against the train load, the rule of vibration transmission, vibration prediction and affecting of the buildings and so on.

But the theoretical analysis method has its limitations, it is difficult to meet the harsh application environment, so numerical finite element method, boundary element method and the two mixed method are widely applied. Among them, the finite element method is a kind of modern computational methods with the development of computer technology and the rapid development of the solution domain. Boundary element method is more suitable for the infinite medium, and it is not suitable for study on vibration problems with irregular shape, therefore, usually the finite element and boundary element are jointed to use[12].

The experimental method obtains data through tests, analyzes vibration propagation and environmental impact through the data. So the conclusion is more direct, more reliable[13].

## Application and analysis of reducing vibration measures

1) controlling vibration source measures

The vibration source is track structure, the elastic support is instead of rigid links to reduce energy transfer. There are many research results and engineering practice case, as shown in Table 1 [14].

Table 1 Comparison of several common rail structure

| Structure / Project | III track absorber fasteners | LORD fasteners | Vanguard fasteners | Elastic holistic beds | Rubber floating slab | Steel floating slab | Ladder track system |
|---|---|---|---|---|---|---|---|
| Damping [db] | **≤8** | **≤8** | **≥12** | **8~12** | **10~18** | **≥25** | ≥20 |
| Cost [mil./km] | **1.2** | **1.2** | **7** | **1** | **7.5** | **10** | 6.3 |
| Service-life[year] | **10** | **30** | **50** | **30** | **50** | **Long** | Long |
| Maneuverability | Mature technology | Mature technology | High precision | complex processes | Cast in situ | High precision | Uneasily control |

2) controlling vibration transmission measures

Vibration spreads through tunnel wall and soil, the control measures mainly barrier the vibration transmission through them. Cutting vibration propagation can be employed to optimize the roadbed, bridge, tunnel, soil structure and increase the strata thickness, commonly the most used methods include excavation damping ditch and setting the isolation wall and the isolation barrier [15].

3) vibration receptors control measures

The building installation damper is one of the most common measures, the components and materials of vibration isolation commonly used are steel springs, air springs, rubber, liquid spring, cork and felt. Among all, the most widely used is metal rubber composite shock absorber.

During the choice of building materials, it is necessary to choose some greater rigidity material, such as while selecting the materials of the ground, the hard materials can be chosen, such as cement floor and terrazzo floor, which have good vibration reduction effect.

**Summary**

In this paper, test and analysis of vibration induced by metro is discussed, and the five aspects of the research of home and abroad are emphasized, which are the analysis of the vibration causes, the analysis of vibration influence, the summary of vibration test technology, the analysis of the relevant theoretical results and the analysis of vibration reduction measures. This paper will provide the theory basis and the practice reference for the vibration design of environmental vibration induced by metro.

# Stability Analysis of Wall Structure which its Depth is over thousand m

Yinghao Wang[1,a] Xiaochen Fu [1,b] Xiaohong Jing[1,c]

[1]The school of Architecture and Civil Engineering, Inner Mongolia University of Science & Technology, Baotou 014010, China

[a]wyh1978@sina.com, [b] 461329321@qq.com, [c] 790540500@qq.com

**Key words:** concrete; wall structure; deformation coordination; strength check

**Abstract:** According to the monitoring result of wall structure which its depth is over thousand, analyzed the strain of inner and outer edges of concrete and inner steel; Neglect construction factors, by comparing the strain of inner concrete and inner steel, it shows that their deformation is consistently; Using the average strain of inner and outer edges of concrete to check strength adopting method of concrete structure design code, shows that they can meet the requirement.

## Introduction

In China, after decades of development of coal industry, shallow resources both in quantity and quality appear degradation trends. The forecast shows that by 2020 China's key coal mining depth will reach an average of 1200 m.

Shaft is important thoroughfare of mine underground engineering contact with the ground, and it is first built in mine construction. But deep engineering confronts complex stress, temperature and seepage, there was no theoretical formula on wall design with super km; According to current "Code for design of coal mine shaft and chamber" [1], 1200 m deep shaft design shows that both concrete strength and thickness of the wall is greater than the real results or appears failure. But in reality face similar projects using engineering analogy method. There is no theoretical basis of its security. So the super km wall stability analysis has practical significance.

## Project profile

This mine lays Hebei province. The wellbore diameter is 8.0 m; its depth is 1340 m. From top to bottom, wellbore cut across the Cenozoic quaternary strata, tertiary alluvium with189 m, Mesozoic Triassic strata with 331 m, the upper Permian series of strata with 840m; Bedrock section full of mudstone and powder, fine, medium and thick sandstone. Under - 1100 m, wall structure is single-layer steel concrete which concrete strength grade is C60; - 1100~1200 m, wall thickness is 80 cm; under -1200 m is 90 cm.

## Monitoring program

According to the progress of the project, the whole monitoring is divided into two levels: first level located at - 1208 m, the second level is located at - 1306 m.

The selected principles of measured vertical position: (1) can monitor deformation of different lithology. (2)According to the requirement of the design institute， near the horsehead (-1309 m) set up a monitoring level.

The selected principles of measured plan position: (1) to avoid all kinds of conflicts such as with sinking equipment layout, the permanent equipment and guide. (2) Measuring point layout accord with suitable density, focused, avoid duplication and reduce cost.

Tests include: radial, tangential and vertical strain of concrete in outer margin; tangential and vertical strain in inner margin; stress changes of circular and longitudinal reinforcement in outer margin.

Monitoring equipment include vibrating sensor, multi-point measurement system by microcomputer control, vibrating concrete strain meter, reinforcement meter and soil pressure box.

First level sensors were embedded in a vertical wellbore 1208 m deep. The basic on behalf of the wellbore wall force and deformation of shaft wall, and the first level of embedding location in northeast, north to west 58° and east to south75°, a total of 27 sensor, there are 26 normal work, have the effect of 21 sensors, reflect the mechanical response characteristics of borehole wall lasted 288 days. This paper only analyzes monitoring results of the first level.

### Average strain analysis on outer margin concrete

Outer margin strain includes hoop strain, vertical strain and radial strain; the average strain varying with time as shown in figure 2.1.

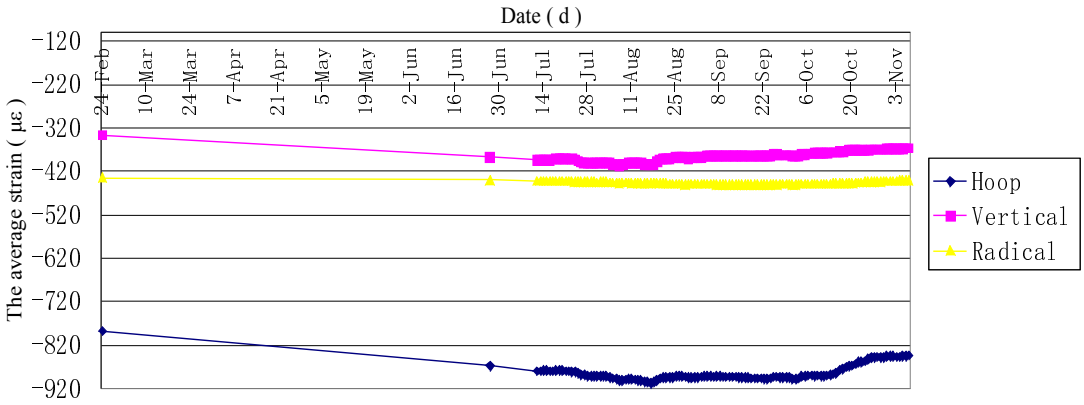

**Fig.2.1 The average strain of outer margin concrete**

The figure 2.1 shows that concrete strain has the following features:

(1)Overall, hoop strain is the largest, the second is vertical strain and radial strain is minimum, shows that the maximum principal stress appear in hoop; the minimum principal stress appear in radial; their strain increase all the time, show the obvious creep properties;

(2)Deformation of inner margin basically includes instantaneous deformation and creep deformation; creep deformation is divided into decay creep and steady creep stage; On June 27, begin to construct horsehead (-1309 m); because the influence of the construction, the vertical and hoop deformation of outer margin show the obvious phenomenon of load shedding after middle of August.

### Average strain analysis on inner margin concrete

Outer margin strain includes hoop strain and vertical strain; the average strain varying with time as shown in figure 2.2.

The figure 2.2 shows that concrete strain has the following features:

(1)Because taking no reinforcement measures around the borehole wall, so the radial strain near the zero (even producing strain, relative to the ring and vertical should be very small and negligible), then only monitor the ring and vertical strain; Overall, the ring strain is greater than the vertical strain; they increase all the time, show the obvious creep properties;

(2) Two direction deformation basically includes instantaneous deformation and creep deformation, creep deformation is divided into decay creep and steady creep stage; the vertical and hoop

deformation of inner margin show the obvious phenomenon of load shedding after middle of August.

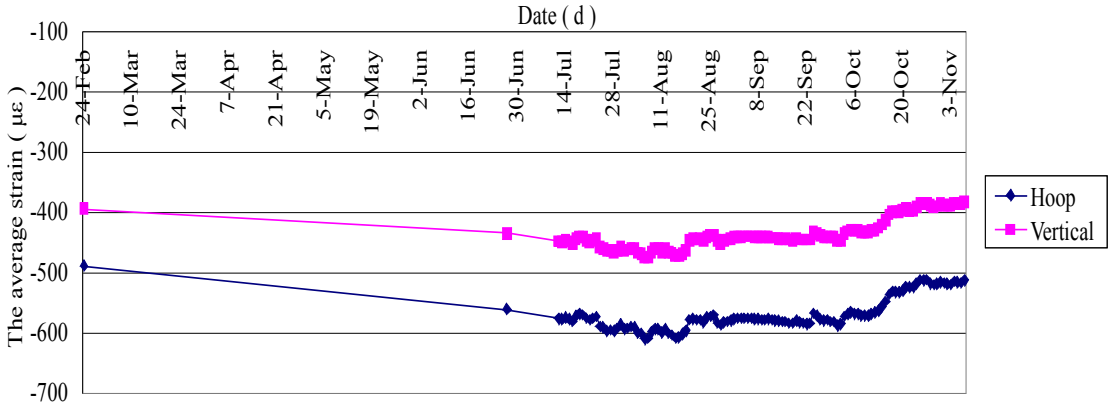

**Fig.2.2 The average strain of inner margin concrete**

**Average stress analysis on inner margin reinforcing bar**

Inner margin reinforcing bar stress directions include the ring and the vertical; The average stress varying with time as shown in figure 2.3.

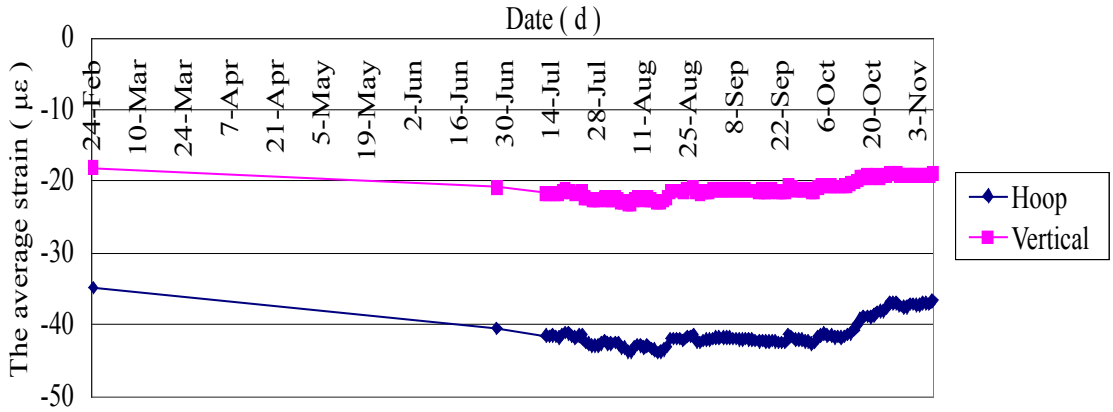

**Fig.2.3 The average stress of inner margin reinforcing bar**

The figure 2.3 shows that inner margin reinforcing bar has the following features:

(1) For inner margin reinforcing bar stress include the ring and the vertical, its increasing regularities is same as the concretes either outer margin or inner margin;

(2) Around the steel bar and concrete strain should be coordinated: reinforced elastic modulus E is 2.0 x $10^5$ MPa, the maximum hoop strain of steel was - 576.69με, the average strain was - 541.96με, compare with the inner margin concrete strain, reach to the maximum - 608.30με,same to the average -568.01με ; the maximum vertical strain of steel was -305.31με, the average strain was - 276.77με; compare with the inner margin concrete strain, either maximum - 474.68με or average -434.61με, has a gap.

**Stability judgment on borehole wall**

Due to the depth is much greater than the thickness, inner or outer radius, and monitoring the wall rock deformation with time change is main target, therefore can be considered as a plane strain problem.

According to the average concrete strain of inner and outer margin, to calculate the average stress using the generalized Hooke's law [2], the result was shown in table 2.1.

**Table 2.1 Three dimensional stress average value of inner and outer edge concrete**

| location | hoop stress $\sigma_1$ （MPa） | vertical stress $\sigma_2$ （MPa） | radial stress $\sigma_3$ （MPa） |
|---|---|---|---|
| Inner margin | 24.56 | 20.56 | 0 |
| Outer margin | 39.47 | 32.58 | 29.21 |

**Stability judgment on outer margin**

By the calculation rules on strength of concrete under multi-axial stress state which comes from the current code for design of concrete structure [3], the stress ratio of $\sigma_2 / \sigma_1 = 0.84$, find concrete compressive strength increase coefficient is 1.2; C60 concrete compressive strength design value is 27.5 MPa, the $\sigma_1 = 24.56 < 27.5 \times 1.2 = 33$MPa, so meet the strength requirements of concrete.

**Stability judgment on inner margin**

By the calculation rules on strength of concrete under multi-axial stress state which comes from the current code for design of concrete structure, the stress ratio of $\sigma_2/\sigma_1 = 0.83$, $\sigma_3/\sigma_1 = 0.74$, find concrete compressive strength increase coefficient is 3.0; C60 concrete compressive strength design value is 27.5 MPa, the $\sigma_1 = 39.47 < 27.5 \times 3 = 82.5$MPa, so meet the strength requirements of concrete.

**Conclusions**

(1) By average strain on inner and outer margin concrete, the hoop strain is the largest, vertical strain is second and radial strain is the smallest. So the maximum and minimum principal stress direction is hoop and radial.

(2)The gap between the hoop strain of concrete and steel is smaller, shows that their deformation is coordinated; Due to the horsehead construction factors, the gap between the vertical strain of concrete and steel is greater, but their stress direction is the same. Therefore, regardless of construction factors, steel and concrete strain is coordinated;

(3) Based on three position concrete strain average of outer and inner margin, to calculate three principal stress direction strain average, then using the generalized Hooke's law to calculate the principal stress, at last using the first rule of strength to check concrete strength, meet the strength requirements.

**Keywords:** Railway tunnel, tunnel portal, loose rockmass, four bench cut method, pipe roof protection, friction pile

**Abstract.** This paper mainly deals with the structural design of high speed railway tunnel and its driving method in abrupt slope with loose rockmass, meanwhile summarizes the connection between tunnel portal and bridge abutment in loose rockmass according to complicated landform and geology. The anti-slide piles are adopted to retain the stability of abrupt slope near the tunnel portal. In order to eliminate the risk and cost in tunnel construction, four bench cut method is invented to satisfy the safe excavation of loose rockmass in the tunnel. Composite fiber rockbolt is also employed to keep the stability of working face while driving the tunnel. The innovative tunneling method presented in the paper can be applied to guide the rational design and economical construction of high speed railway tunnels in loose surrounding rock under harsh geological conditions.

## Introduction

The land in southwestern China teems with high mountains with harsh landform and geology [1]. So a great amount of tough technical problems may be encountered when designing and building transportation lines such as expressways and high speed railways [2]. In order to expedite the social and economic development of western China, a new railway line entitled as Chengdu-Lanzhou railway is now concurrently under construction in Sichuan and Gansu province of China, its whole line is 457.59km long, in which tunnels and bridges account for 86.06% of its total length. The average altitude of the railway line in these regions ranges from 500m to 1800m. The longest tunnel is called Ping'an tunnel with an entire length of 28km. Since the most lands in Southwestern China is covered by mountains, so there are countless valleys and slopes in this terrain. Another tough problem is that the region had been struck by the magnitude 8 seism that took place in 2008. This shows that most slopes and precipices are very weak and its rockmass haven been loosened by the seism, especially rockmass in shallow layer of mountain slopes. If tunnels are designed to pass through the mountains in transportation lines at this terrain, the connection between tunnels and bridges in the same line still becomes another key problem. This paper focuses on the design and connection of tunnel portal and bridge in steep slopes, meanwhile, dissect the construction method for tunnels in abrupt slope with loose rockmass. According to the planning of the Chengdu–Lanzhou railway line, it consists of two main lines, i.e., right line and left one. One typical of its tunnels is named Mao Xian tunnel, it is 9910m long, its two exit portals lie on a steep slope of a mountain and its aerial view is depicted in Fig.1.

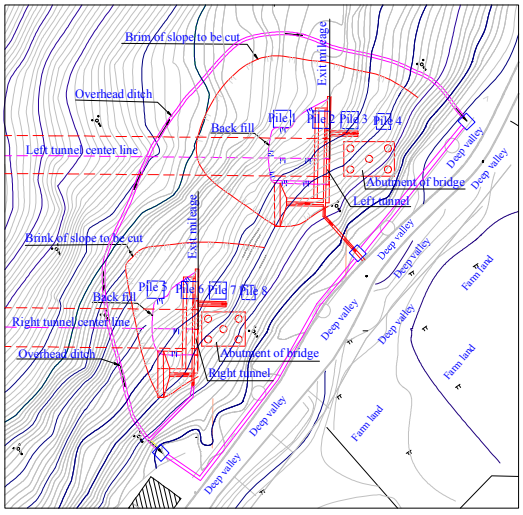

Fig.1 Aerial view of railway tunnel

It is seen from Fig.1 that the landform of the slope exists in oblique form; its inclination angle reaches 36°. The two tunnels pass through the mountain with an angel of 22° against the contour line of the slope. Since the slope of the mountain exists in curved surface, so the mileage of the tunnel portal is different from each other. The exit mileage of left portal is greater than that of the right one. So there is 10 meters distance between left portal and right one. According to the general extension of Chengdu–Lanzhou railway line, two bridges will be upbuilt to concatenate the tunnel portals, as there is much less place to lay the bridge in front of the portals, so the bridges and their abutments must be placed closely to the portals and the detailed location of the bridge abutments are also shown in Fig.1.

## Geological Condition of the Tunnel Portals

It has been testified that geological condition of slope and lithology of surrounding rock always essentially affect the design and selection of tunnel structure and its tunneling method [3, 4]. In order to effectuate rational and economical design of the tunnel, reconnaissance and survey on the geological conditions of the slope have been carried out in advance. The obtained results show that the surrounding rock lithology falls into two types, namely the Quaternary period and the Triassic system. The surface layer of the slope mainly consists of gravel soil ($Q_4^{dl+col}$) and sandy gray ($Q_4^{dl+col}$), but the lower strata comprises phyllite with embedded sandstone ($T_3^x$). The obtained physical and mechanical parameters are listed in Table 1.

Table 1 Physical and mechanical parameters of surrounding rock

| Surrounding rock | Density/(g/cm$^3$) | Cohesion/(kPa) | Internal friction/(°) | Load bearing capacity (kPa) |
|---|---|---|---|---|
| Gravel soil ($Q_4$) | 2.10 | 8.0 | 40.0 | 250 |
| Sandy clay ($Q_4$) | 1.95 | 13.0 | 18.0 | 150 |
| Phyllite ($T_3^x$) | 2.20 | 20.0 | 25.0 | 300 |

It's deduced from Table 1 that both sandy clay and phyllite possess low shear strength. This connotes that if the loose surrounding rock is not treated, then it easily collapses during tunneling. According to the basic load bearing capacity of surrounding rock, the front and side slope around tunnel portals should be also enhanced. Thus it is deduced that before building tunnels and bridges in the railway line, subsidiary measures must be taken to augment the strength of surrounding rock and slope [5, 6].

## Tunnel Portal and Its Design

According to the designed velocity of passenger train in this new railway line, its travelling speed reaches 200km/h. meanwhile, in view of the line extension; two separated tunnels must be built at this site, namely the right tunnel and the left one in its corresponding line. The clear spacing between the two tunnel center lines is set within 30m. Fig.1 additionally shows that the exit mileage of right tunnel is 10m smaller than that of the left one. Concurrently, in consideration of the oblique slope, bench portal is employed to satisfy the abrupt slope of the mountain [4]. Bench portal may readily consort with its inclined landform, thus they are applied to the separated tunnels. In addition to the tunnel portal, there are two railway bridges in front of them so that rail tracks on the bridges can be linked with those in the tunnels. Moreover, since a deep valley exists in front of the portals, in order to diminish the influence of flood and solifluction on the bridge piers in the valley where there is a heavy rainfall, thus bridge piers must be laid near the portals. So their abutments and piers will occupy the patch where tunnel portals stand. The relationship between tunnel portals and bridge abutments is still plotted in Fig.1. The four red rectangles in front of portals in Fig.1 illustrate the concrete location of bridge abutments in the railway line. The designed portals and abutments of bridges are concisely illustrated in Fig.2 and Fig.3 respectively. In order to ensure the stability of left slope with higher height, four anti-slide piles with depth of 30m are placed at each left side of the slope by means of finite element analysis, so there are 8 anti-slide piles altogether placed in the left slopes. In addition, prestressed tensile cables are set in the surrounding rock so as to exalt the stability of slopes during

tunneling and future operation of the bored railway tunnels [5, 6]. Fig.2 also shows the relationship between left tunnel and right one. Since the exit mileage of left tunnel is longer in comparison with that of the right tunnel, so the transection of right tunnel is shown in Fig.2. However, the transection of right tunnel is not picturized in Fig.3.

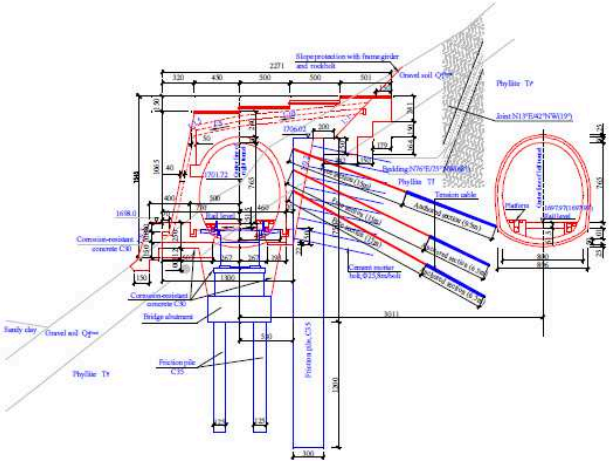

Fig.2 Front view of right tunnel portal (Unit: cm)

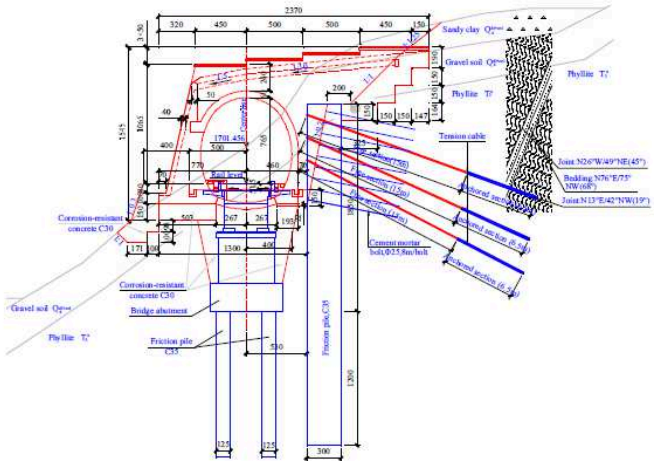

Fig.3 Front view of left tunnel portal (Unit: cm)

**Tunneling Process and Its Design**

In order to eliminate ground settlement and abrupt collapse generated by excavation of the tunnels and their portals, the key task is to choose feasible and economical tunneling procedure before excavation. According to the geological condition of surrounding rock, the slope and surrounding rock must be treated in advance; therefore, friction piles and pipe roof protection have been implemented. Only the treatment and reinforcement of surrounding rock have been accomplished begins the excavation of tunnel portals. The treatment scheme is picturized in Fig.4. Since the surrounding rock in the front working face is loose, if full face cut method is used then collapse may easily occurs during tunneling, this does not only affect the safety of working staff, but thwart the construction progress as well. Therefore partial excavation is considered [4, 5]. Furthermore, composite fiber rockbolt is applied to fortify the strength and stability of working face [6]. The application of fiber rockbolt is conducted in terms of 1bolt/m$^2$. Its length reaches 5m in front of working face. The detained layout and distribution of fiber rockbolt in working face is clearly depictured in Fig.4.

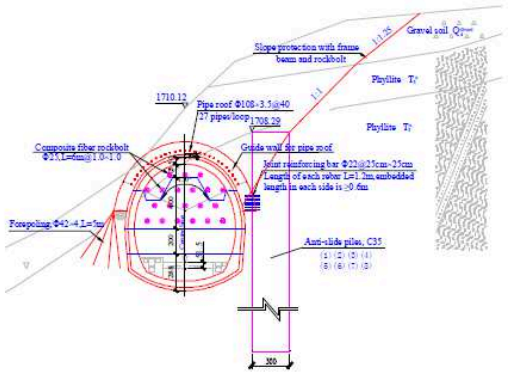

Fig.4 Ground treatment for tunnel portals (Unit: cm)

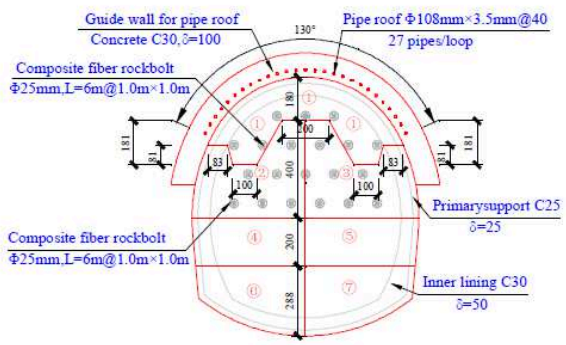

Fig.5 Four bench cut method (Unit: cm)

On the basis of the loose surrounding rock and its mechanical parameters, four bench cut method is proposed, according to this tunneling method, the whole working face of the tunnel including its portal is divided into four drifts, and in order to banish the mutual disturbance on excavation of loose rock in each working face, a short distance of about 7m to 8m must be maintained among them. The

tunneling procedures for the bored tunnels are explicitly depicted in detail in Fig.5 and Fig.6 separately. Fig.5 shows the division of working face in the tunnel, and Fig.6 illustrates the longitudinal profile of the tunneling method.

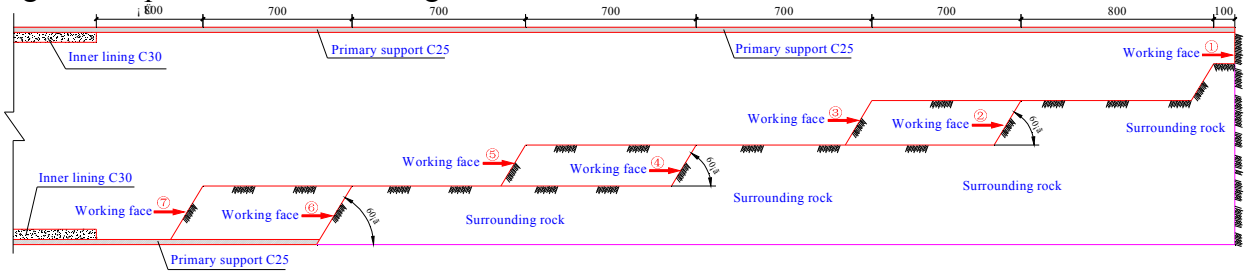

Fig.6 Profile of four bench cut method (Unit: cm)

The numbers circumscribed with red-hued circles in Fig.5 and Fig.6 betokens the principal driving steps in loose surrounding rock. According to this method, primary support must be established in time because it is used to resist all rock pressure or soil thrust during tunneling and long-term operation. The permanent reinforced beton lining must be cast in time when the fourth bench has been bored. The minimum distance must be kept within 7m between every two working faces.

## Conclusions

If drill and blast method is used to bore railway tunnel in steep slope with loose rockmass in mountainous area, four bench cut method (FBCM) is effective in reducing construction risk and cost in comparison with such tunneling methods as center diaphragm method (CD method), cross diaphragm method (CRD method) and two side drift method. In order to abate the collapse of surrounding rock during tunneling, composite fiber rockbolt is a useful mean to enhance the stability of working face. With respect to inclined slope, anti-slide piles are also efficient in retaining its stability. If loose soil and rockmass is treated with rational technical measures, then abutment of bridge in railway line can be closely laid to the tunnel portal. The method presented in this paper is a useful one to guide the design and construction of high speed railway tunnels in complex strata.

# Numerical Simulation for Construction Process Large-span Flat Tunnel Under the Condition of Shallow Buried

JunJie Li[1, a], Li Tuo[1,b] GuanJun Zhang[1,c]

[1] College of architecture and civil engineering, Xihua University, China

[a]18903911619@163.com, [b] 13980883865@163.com, [c] 15208214048@163.com

**Keywords:** numerical simulation; shall large span tunnel; benching with a small pilot tunnel tunneling method; surrounding; rock deformation; construction method

**Abstract.** The thesis takes a three-lane tunnel construction in Zhejiang as an example. Simulating the course of dynamic construction of large- span tunnel on geology condition of four- grade rock mass and shallow buried by FLAC 3D software ,it carries out comparative and stress situation in the runnel surrounding rocks .Getting the displacement and stress changes rule of the construction by using benching with a small pilot tunnel tunneling method can guide the construction scientifically.

## Introduction

Along with the increasing traffic demand and the continuous development of tunnel construction technology, there are more and more large-span tunnel engineering. Large-span tunnel has a flat shape, the characteristics of large span, so it is easy to affect the stability of surrounding rock in the process of construction. At the same time, Large-span tunnel's surrounding rock stress will be converged more easily, relaxation pressure will be bigger, the bearing capacity of the supporting structure will be relatively smaller. Large span tunnel out of hole construction must be not only ensure the construction safety, but also guarantee the progress of construction because great potential risk exist [1]. So it is necessary to do research on large-span flat tunnel under the condition of shallow buried way out of the hole.

## Project summary

The tunnel is a separated tunnel in Zhejiang , in accordance with the level of highway and urban road design standard, speed of 60 km/h, the width of 14.5 m, clear height of 5.0 m. Left hole is 646 meters long and right hole is 699 m long. Hole right out of the mouth of the cave is hilly slope landforms, weak rock weathering, through strong breeze ~ rock tunnel,as the same time the tunnel was buried of depth above 20 m, groundwater activity is stronger.There are drench and dripping water When it is excavated,The surrounding rock belongs to the Ⅳ level which stability is poor. This paper, by using FLAC 3D program , simulate for benching with a small pilot tunnel tunneling method through numerical analysis method.

## Finite element model and calculation parameters

Modeling selection scope is the inverted arch tunnel to the lower tunnel below 50 m, length of 129.1m, width at 149m,tunnel length 80 m.Model boundary condition are as follows: the bottom adopt displacement boundary conditions,both of the vertical and horizontal displacement are imposed constraint, the horizontal displacement lateral is imposed constraint, only the top for the free surface, not imposed any constraint.

The early bolting shotcrete primary support (thickness 20 cm) ,bolting and steel arch shelf are converted into the shotcrete in Stiffness contribution way in modeling[1].The surrounding rock used Mohr coulomb model ,according to geological exploration data,surrounding rock and supporting material parameters such as Table 1, calculation model is shown in Fig. 1.

Considering time and space effect, the construction process simulation of tunnel excavation release stress by 30%, 70% after tunnel primary support and the stress release. By only considering the stability of surrounding rock in the construction process, so it is simulated without the second lining[1].

Table 1 Model parameters

| | ρ/kg/m³ | E /GPa | μ | c /MPa | ϕ /° |
|---|---|---|---|---|---|
| Ⅳ | 2200 | 5 | 0.3 | 0.5 | 35 |
| Ⅲ | 2400 | 15 | 0.25 | 1.2 | 45 |
| Primary lining | 2500 | 21 | 0.2 | | |

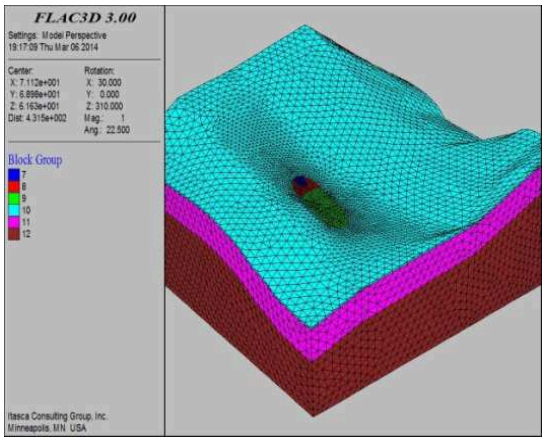

Fig. 1 Numerical simulation mode

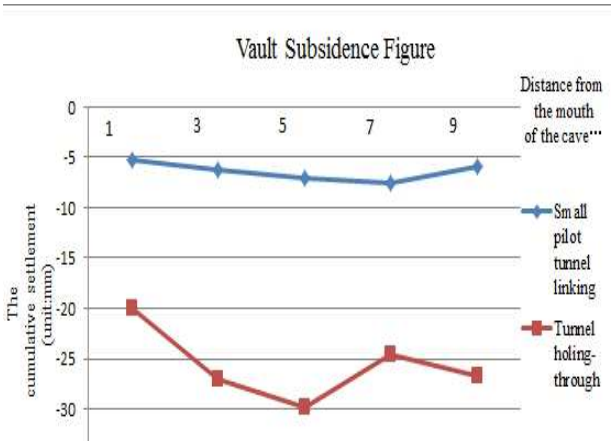

Fig.2 Vault subsidence (unit: mm)

**The analysis of numerical simulation results**

FLAC 3D software was used to calculate respectively the stress and displacement of surrounding rock and supporting structure in excavation process to get the stress and strain rules of surrounding rock when up and down the steps small pilot tunnel method applied.

As shown in figure 2,the surface range,vertical displacement and the vertical stress of surrounding rock of small pilot tunnel excavation are smaller,especially the data section of the surface subsidence after small pilot tunnel breakthrough is 2mm while the total settlement after the tunnel is 29.5mm,which shows that up and down the steps of small pilot tunnel method is a relatively safe method of out of the hold,which caused the relatively small disturbance to surrounding rock during construction.

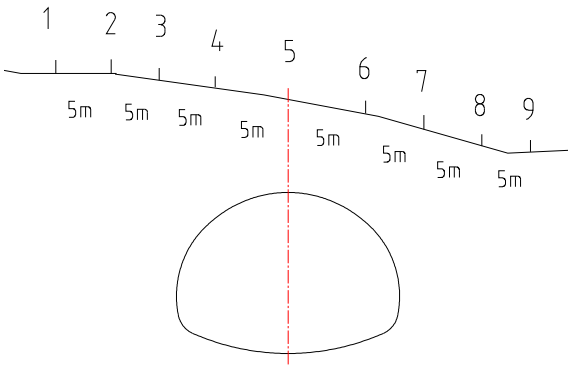

Fig. 3 The settlement measurement point of the surface

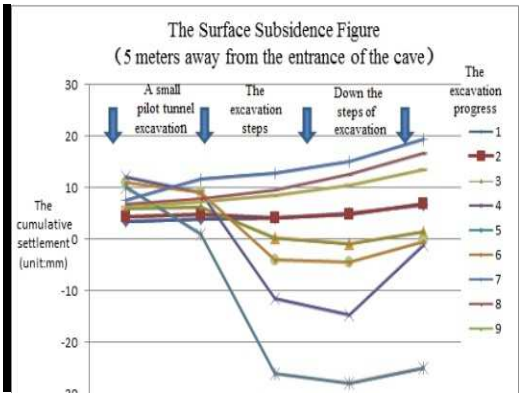

Fig. 4 Surface subsidence (5 meters away from the mouth of the cave) (unit: mm)

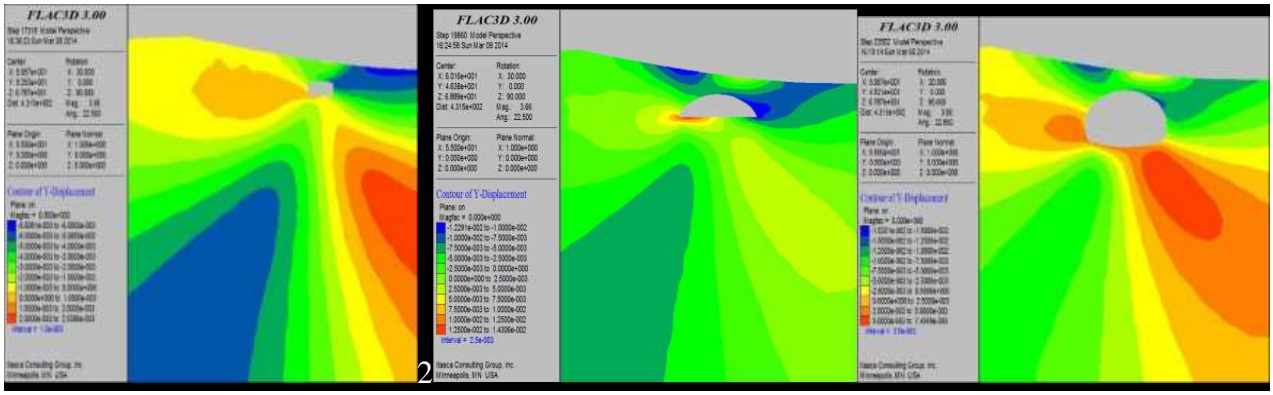
We can learn from figure 4 that the impact of small pilot tunnel excavation to ground surface settlement is small, but deformation increases significantly after step excavation. This is due to the large span on the steps which result in the stress concentration and cause settlement increases. The subsidence area is stable after supporting in bottom bench excavation, which states that the tunnel supporting closed loop can greatly improve the stability of surrounding rock.



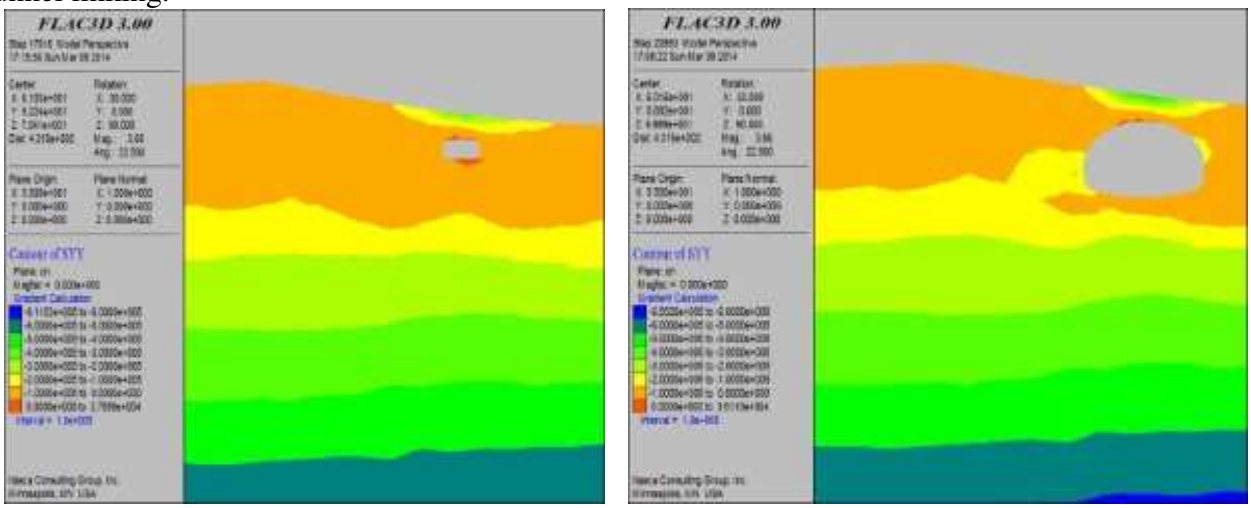
a) Small pilot tunnel linking b） Linking up the stairs c） Down the steps through

Fig. 5Hoeizontal deformation of surrounding rock
(5 meters away from the mouth of the cave) (unit: mm)

Fig.5 shows that sidewall astringed after small pilot tunnel linking, deep side of the arch foot parts astringed inward 2.54 mm, shallow buried side arch of astringed outward 6.6 mm, as shown in figure 6 a.Due to bias, after the up and down the steps through, the most obvious convergence is in deep side arch on shallow buried and side inverted arch and the largest amount of convergence is 7.5 mm.

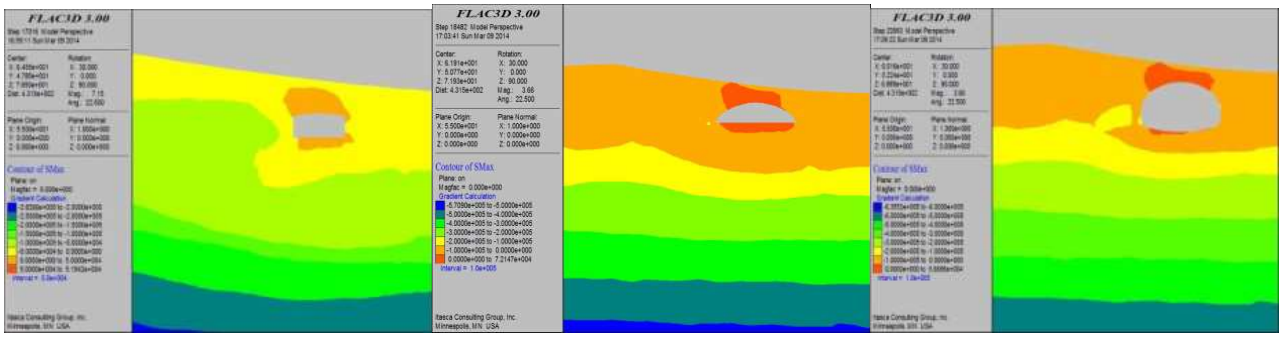
Select 5 meters away from the mouth of the cave, buried depth of 6.9 meters of cross section to study.

Fig.6 shows that a small pilot tunnel excavation area is lesser, the disturbance of surrounding rock after excavation is smaller, the surrounding rock mass stress concentration phenomenon is not obvious. All excavation complied caused stress redistribution, the arch foot of surrounding rock exhibited obvious stress concentration phenomenon after up and down the steps excavation,local failure may occur in the practical construction this part, hence the construction of the arch foot foot bolt lock should be strengthened. The maximum vertical stress should be in the vicinity of a wall after tunnel linking.



a) Small pilot tunnel linking b) Down the steps through

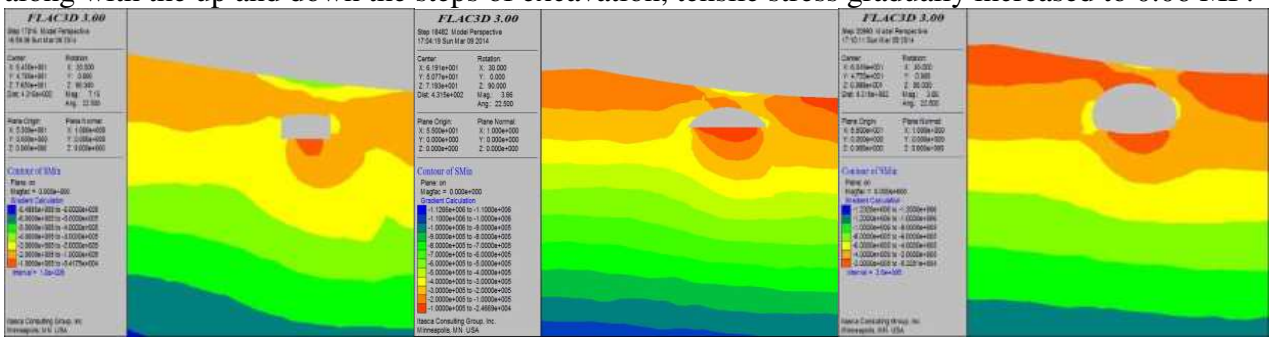
Fig.6 The stress cloud of surrounding rock (unit: kN / ㎡)



a) Small pilot tunnel linking b） Linking up the stairs c） Down the steps through

Fig.7 The first principal stress of surrounding rock (unit: kN/㎡)

Fig.7 shows that 0.05MP tensile stress produced on the top after small pilot tunnel excavation, along with the up and down the steps of excavation, tensile stress gradually increased to 0.06 MP.



a) Small pilot tunnel linking b） Linking up the stairs c） Down the steps through

Fig.8 The third principal stress of surrounding rock (unit: kN/㎡)

Fig.8 shows that the third principal stress are mainly as follows:due to the influence of the bias effect,after small pilot tunnel breakthrough,surrounding rock stress distributed asymmetry, main stress direction from deep side to shallow buried side.Along with the excavation, on both sides of the arch waist has emerged the phenomenon of stress concentration, reached 0.04 MP and deep side stress concentration range is larger than shallow buried side, covering the arch foot position.so construction quality of lock foot bolt should be noticed during construction.

## Conclusion

The tunnel in Zhejiang province is simulated by using the FLAC 3 d software, there are some conclusions through analyzing stress ,displacement of surrounding rock and surface settlement of shall large span tunnel on condition of shallow buried .

1）Under the condition of shallow buried shall large span tunnel, the impact on surrounding rocks is little by using benching with a small pilot tunnel tunneling method, the rock surface range , vertical displacement and the vertical stress of surrounding rock are relatively small, relatively safe.so it is a good method .

2）The surrounding rock pressure will redistribute when a small pilot tunnel and up the step are excavated,there is tensile stress in the top of the tunnel , arch foot of deep-buried and arch arch crown of shallow-buried have a phenomenon of compressive stress concentration of different levels. Feet-lock bolt is paid special attention to strengthen the construction because the rocks near the feet-lock bolt may be failure

3）The benching with a small pilot tunnel tunneling method is better than others at construction resource utilization, schedule, the construction difficulty , process transformation and cost if the surrounding rock is better,and it can ensure the efficiency of the construction, speed and and safety .

4）The crown settlement and peripheral convergence change completely in the process of excavation, it needs to strengthen the monitoring , the real-time data from the monitoring guide the construction of scientifically

Supported by the Innovation Found of Postgraduate Xi Hua University

**Keywords:** tunnel engineering, separated tunnel, secondary lining, FEM numerical simulation, strain on-site monitoring

**Abstract.** Safety of secondary lining is of utmost importance to tunnel engineering quality as the main load-bearing structure and the last waterproof line of rock tunnel under type III. The comparative study of strain state results from FEM numerical simulation and on-site monitoring in Yunnan Tianxin Tunnel was conducted to obtain the stress regularity of tunnel lining. The results showed that except vault, the strain states of secondary lining obtained by numerical simulation and on-site monitoring were consistent. The strain value of on-site monitoring was approximately 60%~70% to the simulation value. And the strain value of right side was greater than the value of the corresponding location on the left side. It's noticed that high strain were found in tunnel haunch and arch springing. Great attention should be paid to arch springing for the largest strain value. The strain monitoring value of vault (309.83με~327.23με) has been detected larger than simulation value (209.37με), which matches well the crack phenomenon of vault. Therefore it's significant to focus on the long-term monitoring of vault. The defects of single on-site monitoring method such as poor predictability were made up effectively by comparative study. The results achieved can be recommended for similar projects.

## Introduction

With the increasing development of economy, more and more highway tunnels are constructed [1]. Nowadays composite lining structure is prevailing of the high-grade highway tunnel construction, which consisted of primary support, secondary lining and the waterproof layer between them [2]. For rock tunnel under type III, safety of secondary lining is of utmost influence on tunnel engineering quality as the main load-bearing structure and the last waterproof line of tunnel. Thus the stress monitoring and analysis of secondary lining are of great significance for the tunnel [3]. As an important part of NATM, tunnel monitoring measurement plays a vital role in guaranteeing the construction safety, optimizing the support structure and reducing the materials consumption. However the limited results and poor predictability can be obtained from on-site monitoring owing to the restricted field condition and measuring method, measurement error and data deficient [4-7]. FEM numerical simulation is widely employed as aid in tunnel monitoring measurement result from the merits of perceptual intuition, fast, economical and experiment repeatedly [6,8]. The combination of the FEM numerical simulation and on-site monitoring is beneficial to understand the stress regularity of secondary lining in construction process comprehensively, and also the defects of single on-site monitoring method such as poor predictability can be made up effectively [7,9]. It's therefore significant for the combination method in realizing tunnel information construction.

In this study, taking Yunnan Tianxin Tunnel as the research object, FEM numerical simulation and long-term on-site monitoring of secondary lining strain were conducted. And the stress state of

secondary lining was analyzed through the comparative study which can be recommended for similar projects.

**Tianxin Tunnel Engineering Situation**

TianXin Tunnel is a two-tube, two-lane separated tunnel which is the control project of Yunnan Yi Egao second-class highway. Its beginning and ending stake numbers are shown as follows: Left K47+100~K49+220 (total 2120 meters); Right K47+073~K49+345 (total 2272 meters). The maximum buried depth of tunnel is 257meters. And the midlines distance between left range and right range is 30meters approximately. The tunnel is located in medium low mountain gentle slope area that makes a shallow cut, outcropping Mesozoic "red rock", with 1500~1900 meters above sea level and the relative height difference of 100~500 meters. With accordance of summit levels the mountaintop is rounded. And the slope gradient is about 20 degrees with shape "V" valleys. The lithological characters of the tunnel area are mainly mud rock, mingled with sandstone, argillaceous sandstone and conglomerate. The tunnel mainly passes through the class IV and V surrounding rock. The supporting structure of the tunnel designed by NATM is composed of primary lining and secondary lining. And inner contour is designed to the single-center circle curved wall lining structure of which radius is 5.5 meters with 11 meters wide and 7.10 meters high, as shown in Fig.1.

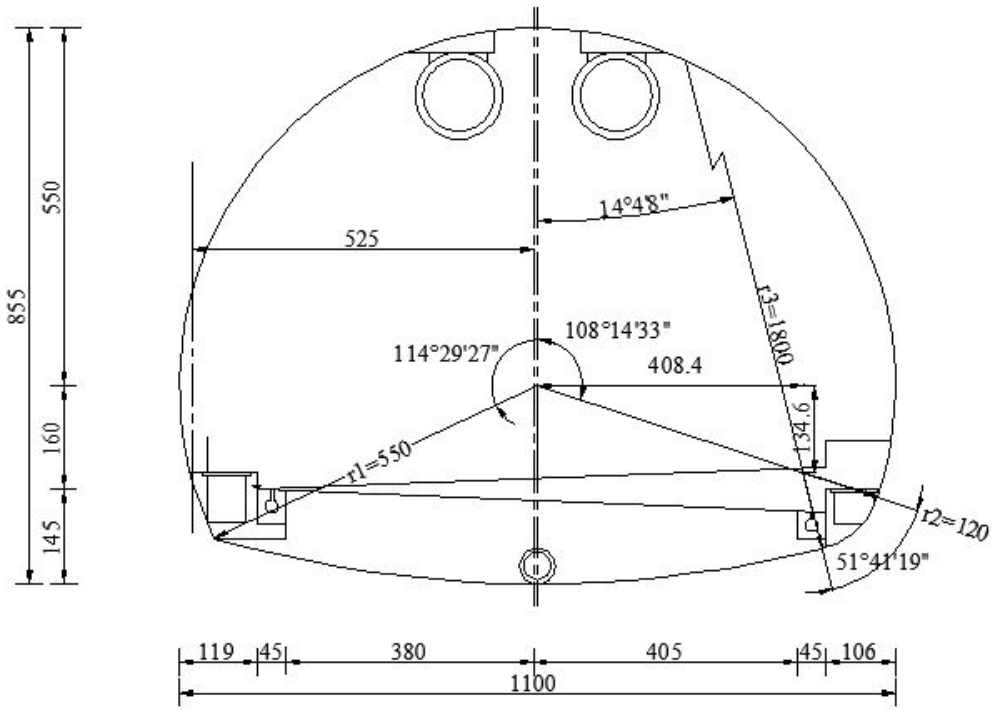

Fig.1 Inner contour drawing of the tunnel (unit: cm)

**Finite Element Model of Tunnel Structure**

The FEM numerical simulation and analysis on secondary lining strain state of right Section K47+808 were conducted by using ANSYS FEM analysis software in this part.

**Ansys Finite Element Model and Simplification.** Right section K47+808 that using type S5b composite lining structure is located in class IV (type III) surrounding rock with about 158.2 m burial depth. Its primary lining and secondary lining thickness are 25 cm and 50 cm respectively. The plane strain model of elastic theory was built in which element Plane42, Beam3 and Link1 simulated the surrounding rock and primary lining, secondary lining and anchor separately. Utilizing the method of improving the rock mechanical parameters of reinforcement area of which reinforcement range was 3.5 m (the length of anchor bolt) simulated the supporting effect of advanced small pipe, steel mesh reinforcement and structural steel support [10]. Based on Saint Venant's principle, the left and right

calculating boundary was 5 times the width of the tunnel, and the lower and upper calculating boundary was 3 times and 2 times the height of the tunnel respectively. Meanwhile the vertical uniform loads (3350.41kPa) were applied to the upper boundary. The benching tunneling method was simulated by the technique of "birth and death of element". The stress releasing was simulated by the method of applying virtual support force to release the stress step by step [11]. The coefficient of stress releasing was 0.6 when the primary lining was built. After secondary lining built, the stress released entirely. The FEM computation model and mesh generation were presented in Fig.2.

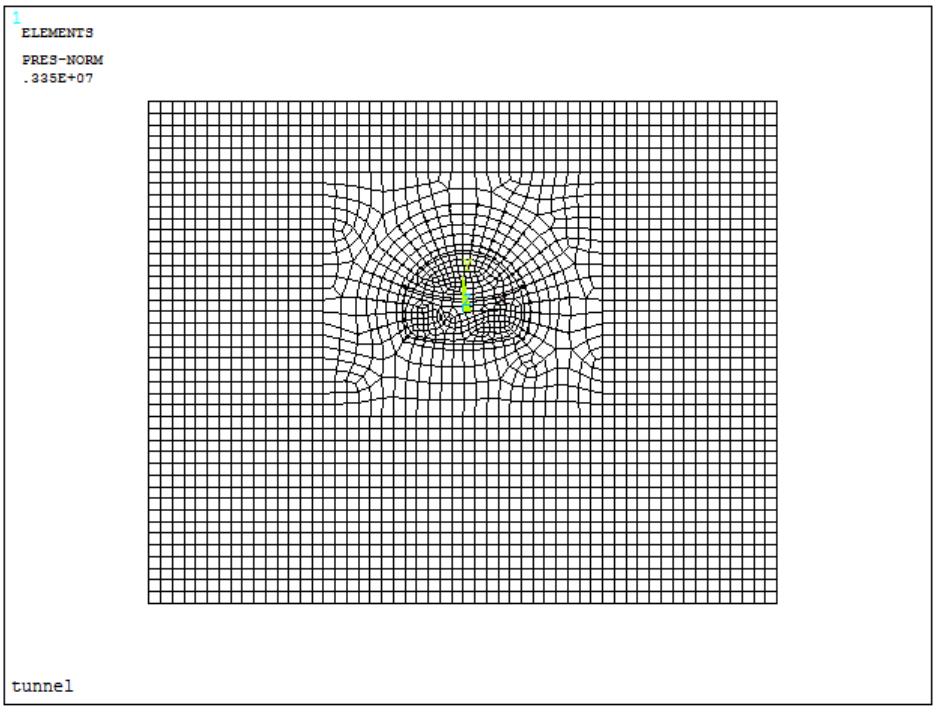

Fig.2 The FEM computation model and mesh generation

**The Parameters of Tunnel Model.** According to Code for Design of Road Tunnel (JTG D70-2004) [2], Code for Design of Concrete Structures (GB 50010-2010) [12] and Technical Regulations for Hollow Bolt (TB/T 3209-2008) [13], the material parameters of surrounding rock, support structure and anchor bolt were selected in Table 1.

Table 1 The parameters of materials in computation model

| Materials | Elastic Modulus E[GPa] | Poisson Ratio μ | Density γ[kN/m$^3$] | Cohesion c[MPa] | Frictional Angle φ[$^o$] |
|---|---|---|---|---|---|
| Surrounding rock(IV) | 6 | 0.35 | 23 | 0.7 | 39 |
| Reinforcing ring(III) | 10 | 0.3 | 25 | 1.5 | 50 |
| Primary lining | 28 | 0.2 | 25 | - | - |
| Anchor bolt | 206 | 0.3 | 78.5 | - | - |
| Secondary lining | 28 | 0.2 | 25 | - | - |

**Analysis of Strain Simulation Results.** The simulated secondary lining axial strain of Tianxin Tunnel right Section K47+808 was shown in Fig.3.

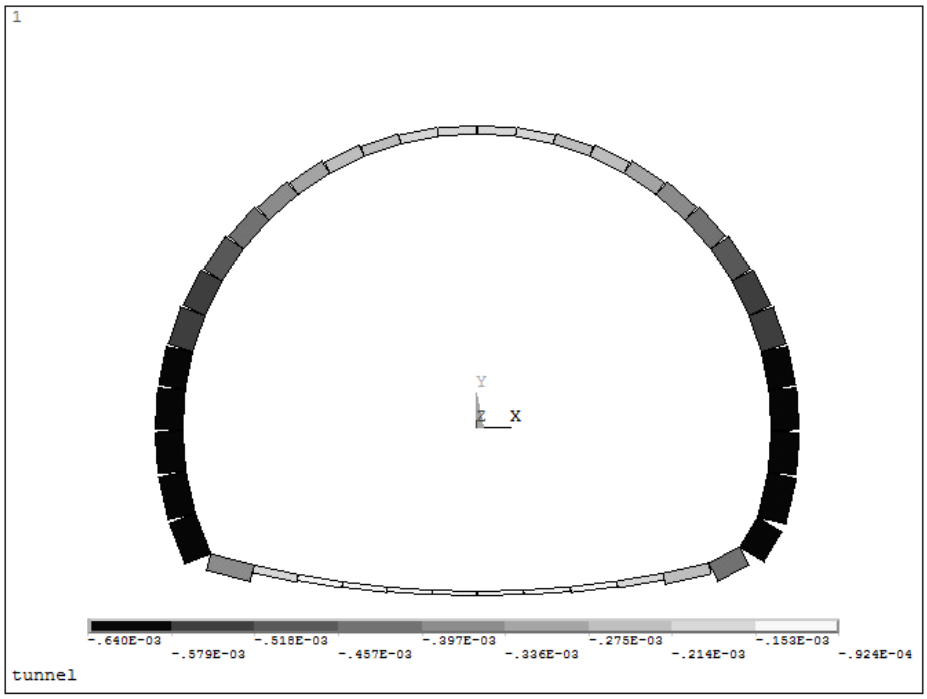

Fig.3 Axial strain of the secondary lining on Section K47+808 (unit: με)

It was observed from the simulation result that the secondary lining strain of this section was compression strain and the strain value of right side was greater than the value of the corresponding location on the left side. The strain gradually increased from vault to arch springing. It was noticed that high and low strain values were found in the position from haunch to arch springing and the inverted arch respectively. The strain varied from 92.40 με to 639.87 με. The minimum strain (92.40 με) occurred in the middle of inverted arch (element 5810) and the maximum strain (639.87 με) occurred in right arch springing (element 5841). The strain (613.50 με) of left arch springing (element 5827) was also large. The values of haunches, spandrels and vault were 483.15 με (left haunch), 522.42 με (right haunch), 373.29 με (left spandrel), 441.77 με (right spandrel) and 209.37 με (vault) separately. Great attention should be paid to the position from haunch to arch springing after secondary lining built.

## Tunnel Monitoring Scheme

For the purpose of monitoring the secondary lining stress state of Tianxin Tunnel for long time, 10 representative sections were respectively selected in the left and right holes according to the progress and defect of the project. The spacing of sections was 20 meters. The monitoring mileage of left hole were K47+770, K47+790, K47+810, K47+830, K47+850, K47+870, K47+890, K47+910, K47+830, K47+950 and the monitoring mileage of right hole were K47+810, K47+830, K47+850, K47+870, K47+890, K47+910, K47+930, K47+950, K47+970, K47+990. Based on the strain distribution of the numerical simulation, the embedded FBG strain sensors were installed on the secondary lining main reinforcement of the sections above, as shown in Fig.4.

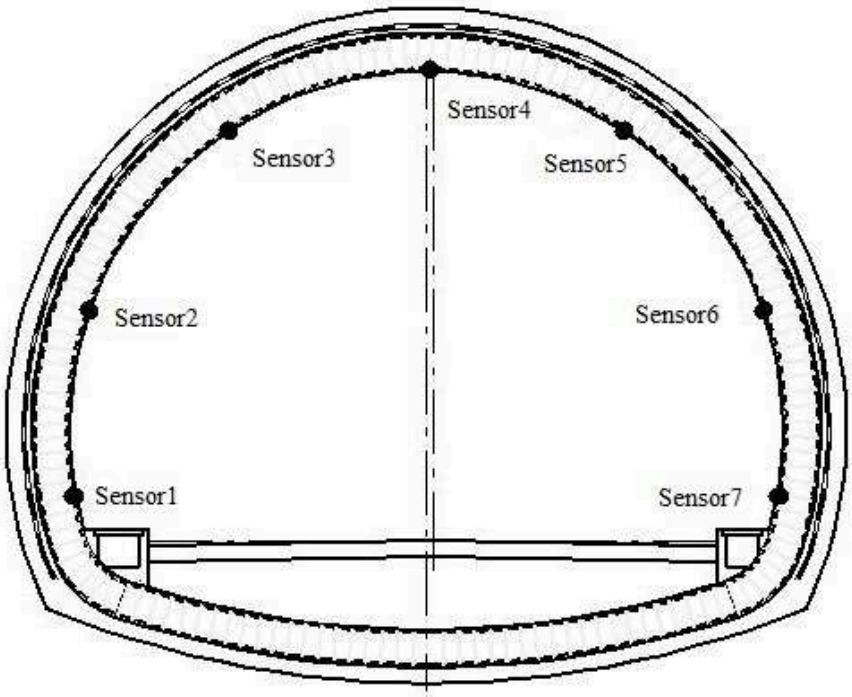

Fig.4 Layout of the strain monitoring point in secondary lining

The embedded FBG strain sensors were installed from August 1, 2011 to April 29, 2012. The collection frequency of the strain data was provided in Table 2.

Table 2 Collection frequency of the strain data

| Measurement Item | Instrument Equipment | Collection Frequency | | | |
|---|---|---|---|---|---|
| | | 1-15d | 16-30d | 30-90d | >90d |
| Strain of Secondary lining | The Embedded FBG Strain Sensor | 1time/d | 1time/2d | 1-2times/7d | 1-3times/30d |

The strain formula of the embedded FBG strain sensor used in monitoring was as follows:

$$\varepsilon = K * \left[ \lambda_1 - \frac{(\lambda_{t1} - \lambda_{t0}) * K_t}{K_w} - \lambda_0 \right] \tag{1}$$

Eq.(1), $K$ was the strain sensing coefficient of FBG strain sensor( $\mu m / nm$ ); $K_t$ was the temperature sensing coefficient of FBG strain sensor( $C / nm$ ); $\lambda_1$ was the current wavelength of FBG strain sensor( $nm$ ); $\lambda_0$ was the initial wavelength of FBG strain sensor( $nm$ ); $K_w$ was the temperature sensing coefficient of FBG temperature sensor( $C / nm$ ); $\lambda_{t1}$ was the current wavelength of FBG temperature sensor( $nm$ ); $\lambda_{t0}$ was the initial wavelength of FBG temperature sensor( $nm$ ).

**Analysis of Strain Monitoring Data**

Strain monitoring of secondary lining had been conducted on right Section K47+808 for sixteen months. The variation of secondary lining strain on time was presented in Fig.5.

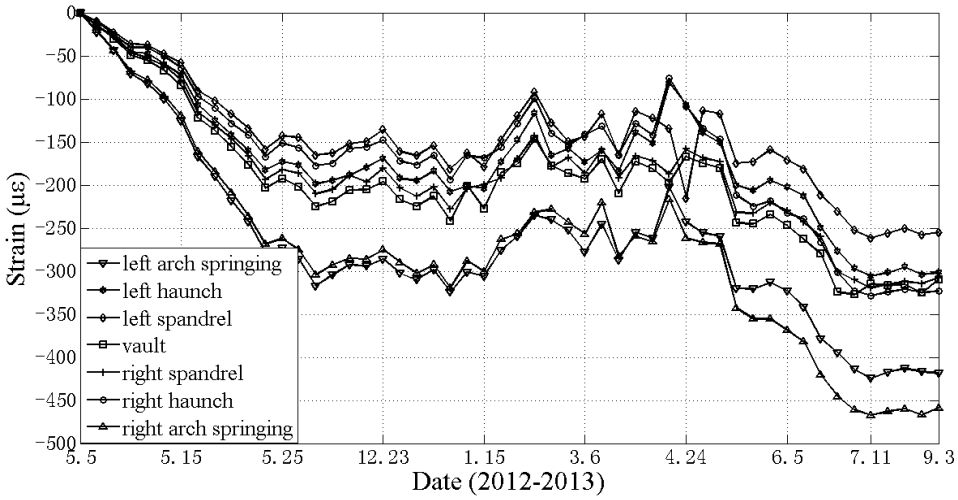

Fig.5 The space-time diagram of secondary lining strain on right Section K47+808 of Tianxin Tunnel

The monitoring results showed that the stress of secondary lining was asymmetric compression state. And the strain of right side was greater than the value of the corresponding location on the left side. The arch springing value was larger than haunch and spandrel. During June 2013 to September 2013, the monitored strain value of secondary lining had been basically stable. The maximum strain reached to 472.44 με occurred in the right arch springing, which was in the range of the safety variation. The stress state of right section K47+808 was in line with the stress regularity of tunnel secondary lining. Great attention should be paid to the changes in arch springing of secondary lining due to its greater strain monitoring value.

According to the buried position of embedded FBG strain sensors on right section K47+808, the simulated strain value of corresponding position on the finite element model was selected to be analyzed compared to monitoring value, as listed in Table 3.

Table 3 Comparison of the on-site strain monitoring data and simulation results on right Section K47+808 of Tianxin Tunnel

| Positions | Strain Variation Range of Monitoring Stable Value (2013.6~2013.9) | Strain Simulation Value |
|---|---|---|
| left arch springing | -424.27με~-413.08με | -613.50με |
| left haunch | -306.07με~-294.88με | -483.15με |
| left spandrel | -261.66με~-250.47με | -373.29με |
| vault | -327.23με~-309.83με | -209.37με |
| right spandrel | -319.73με~-307.78με | -441.77με |
| right haunch | -328.61με~-320.84με | -522.42με |
| right arch springing | -467.31με~-458.78με | -639.87με |

Comparison of monitoring data with simulation results showed that except vault the simulation results coincided with the monitoring data quite well. However the strain value of on-site monitoring was smaller than simulation results and was approximately 60%~70% to the simulated value. This is mainly because the on-site strain monitoring of this section started with the sixth measurement value (May 5, 2012) and the monitoring value later was based on it. The whole strain of secondary lining couldn't be measured, which resulted in smaller monitoring value. The strain monitoring value of

vault had been detected larger than simulation value, which matched well the crack phenomenon of vault on this section. Therefore it's significant to focus on the long-term monitoring of vault.

## Conclusions

The comparative study of strain states resulted from FEM numerical simulation and on-site monitoring on right section K47+808 of Tianxin Tunnel was conducted. The results showed that:

(1)Except vault, the strain states of secondary lining obtained by numerical simulation and on-site monitoring were consistent. The strain value of on-site monitoring was approximately 60%~70% to the simulated value. The stress of secondary lining was asymmetric compression state. And the strain value of right side was greater than the value of the corresponding location on the left side. It's noticed that high strain was found in tunnel haunch and arch springing. Great attention should be paid to arch springing for the largest strain value.

(2)The strain monitoring value of vault (309.83 με~327.23 με) has been detected larger than simulation value (209.37 με), which matches well the crack phenomenon of vault. Therefore it's significant to focus on the long-term monitoring of vault. The defects of single on-site monitoring method such as poor predictability were made up effectively by comparative study, which proved that this method was effective in the process of tunnel construction.

**Keywords:** MIDAS GTS,deep foundation pit,analogue simulation, retaining structure,Tianjin Subway

**Abstract.** On the basis of hydrogeology data,Mohr-Coulomb constitutive model in software MIDAS GTS was employed to simulate excavation deep foundation pit in Qingnian Road station of Tianjin subway line 2 after each excavation step of different construction procedures.It is positive scinentifcity for simulating excavation pit ahead of time and predicting its deformation and displacement characteristics in the foundation pit,and it is significant for the timely revision of the schemes in the next construction process.

## Introduction

With the development of economy of China,subway plays a vital role in overall arrangement of a city,such as city planning,traffic,economy and environment and so on.The primay task in constructing subway is to maintain the stability of enclosure structure of subway station.Deep excavation is fundamental basis of subway station.To ensure its security is significant economic and social benefit. The excavation of the subway station has great influence on the surrounding environment,which may affect the safety of the adjacent constructions and the underground pipelines.Moreover water gushing and collapse accidents may occur when shield tunneling entering or leaving the well.In order to avoid or mitigate these harmful effects,it is necessary to study the variation laws of the stress and deformation of supporting system and the ground surface during the excavation.

## The General Situation of the Project

The QingNian Road station of Tianjin subway line 2 is located near a junction of Huanghe Avenue,Qingnian road and Yuci road in Nankai district, Tianjin. The station start stop mileage is DK7+931.203～DK8+122.803, the mileage of the station center is DK8+022.003.The length of Qingnian station is 191.600m, the main structure is double-story and double-span frame structure (island style), the length of deep foundation pit of the station is 191.600m,the width of the standard section is 21.00m,the depth of the standard section is 16.000m. Retaining structure of foundation pit is diaphragm wall with reinforcement concrete and steel struts,the width of diaphragm wall is 0.8m. the standard width of the diaphragm wall is 6m, Adjusted the width according to external situational changed, the joint of continuous wall is aligned with the induction joint. Constructed the reinforcement concrete top beam and the size of beam section is $b \times h$=1.0m×0.8m. The main station steel strut is φ 600 × 14 steel pipe, the steel struts are assembled on site according to the width of the foundation pit and the deviation of center line must be less than 20mm, The steel struts moving end and fixing end are required to meet the force and setted the jack to support the pre axial force in the steel side.The parameters of strata are shown in Table 1 and the parameters of supporting measures are shown in Table 2.

Table 1.Parameters of strata

| Stratigraphics | Elastic modulus /kpa | Poisson ratio | Weight /( $KN \cdot m^{-3}$ ) | Cohesion /kpa | Frictional angle /( ° ) | Initial stress parameter $K_0$ |
|---|---|---|---|---|---|---|
| Filling soil | 5000 | 0.42 | 20 | 15 | 15 | 0.63 |
| Silty clay | 18000 | 0.36 | 20 | 9 | 9 | 0.42 |
| Mud limestone | 500000 | 0.24 | 28 | 300 | 36 | 0.36 |

Table 2.Parameters of supporting measures

| Title | Elastic modulus /Mpa | Poisson ratio | Weight /( $KN \cdot m^{-3}$ ) | Section types |
|---|---|---|---|---|
| Diaphragm wall | 30000 | 0.2 | 25 | 0.8m thickness |
| Reinforced concrete support | 30000 | 0.2 | 25 | 0.8m width, 1.0m height, square |
| Steel support | 200000 | 0.25 | 78 | 0.6m diameter，pipe wall thickness 0.012m ，pipe |

**The excavation procedures**.The foundation pit is excavated from top to bottom and the main station foundation pit excavation is divided into 5 layers, the excavation procedures are as follows:

Step 1, analyzing initial earth stress, earthwork excavation began in the consolidation settlement of soil under the action of self weight in the construction;

Step 2,diaphragm wall construction;

Step 3,diaphragm wall construction and concreted the first reinforced concrete support;

Step 4,Excavated 4.8 meters below the surface and constructed the second steel support;

Step 5,Excavated 8.8 meters below the surface and constructed the third steel support;

Step 6,Excavated 12.8 meters below the surface and constructed the fourth steel support;

Step 7,Excavated to the bottom of the pit (16.0 meters below the surface) ,as is shown in Fig.1.

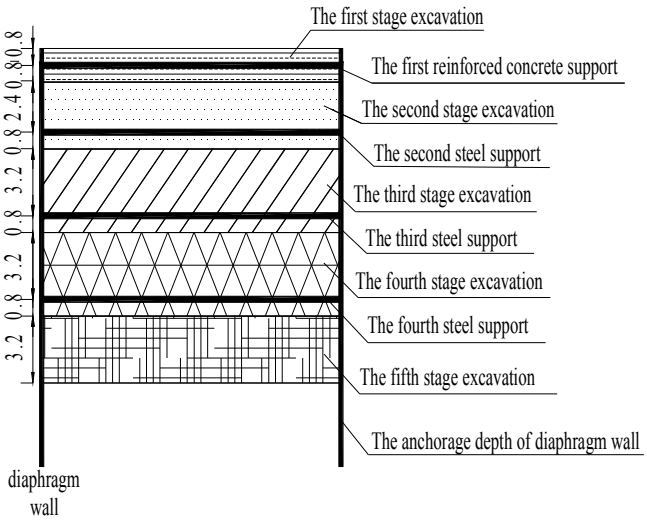

Fig.1 Schematic diagram of excavation sections

Fig.2 Schematic diagram of excavation sections in midas gts

Then established the model of schematic diagram of excavation by using Mohr-Coulomb constitutive model in software Midas (As is shown in Fig.2).

The grade of deformation-control foundation pit:

1.The safety grade of the main station foundation pit support structure is the first degree.

2.The Maximum ground surface settlement≤0.1%H.

3.The horizontal shifting of the diaphragm wall $\delta_h \leq 0.14\%H$， and $\delta_h \leq 30mm$ .

**Basic assumptions.**Being satisfied with the conditions of the calculation accuracy and making correct conclusions, basic assumptions to simplify the calculation are as follows:

1.The materials are homogeneous and isotropic,
2.The soil is considered as the perfect elastic-plastic material,
3.Ignores the stiffness change caused by diaphragm wall segmental construction,
4.Steel and concrete supports are considered as linear elastic materials.

**Analysis of numerical results.**

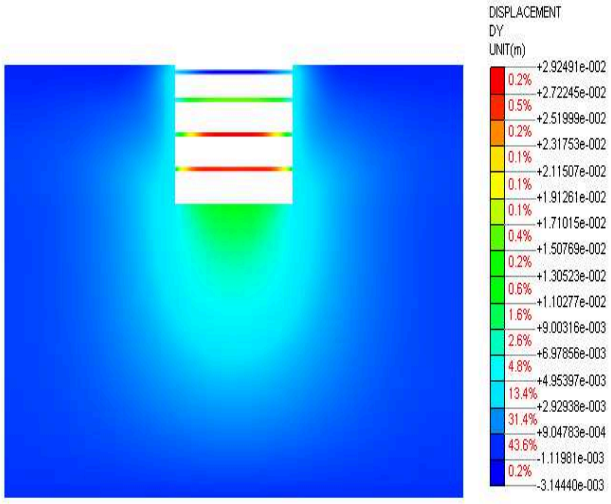

Fig.3 Displacements in *y* direction

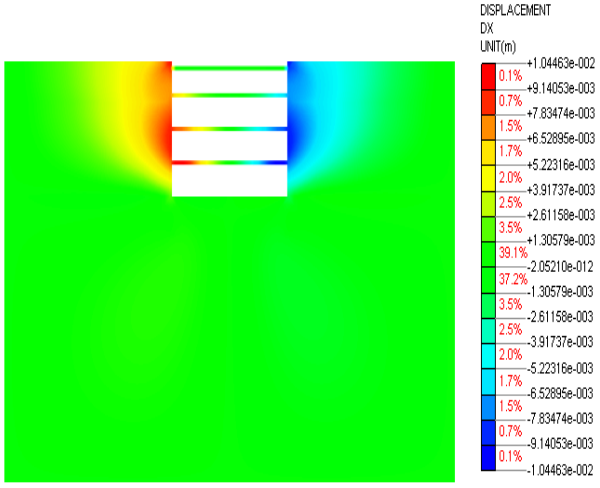

Fig.4 Displacements in *x* direction

As is shown in Fig3.The maximum of uplift of the bottom of foundation pit is 11.8mm where occurs in the central regions of the bottom of foundation pit.The maximum of uplift of the top of foundation pit is 4.8mm. The figures are less than the specified value of the grade of deformation-control foundation pit ,so that the excavation process is safe and reliable.

As is shown in Fig4.The maximum of horizontal deformation of the diaphragm wall is 9.13mm, The figures are less than the specified value of the grade of deformation-control foundation pit ($\delta h \leq 0.14\%H=22.4mm$ and $\leq 30mm$) .Along with the increase of the depth of excavation, horizontal displacement of steel support restraint decreases gradually. Therefore, in the process of excavation, it's need to increase the other auxiliary supporting structures.

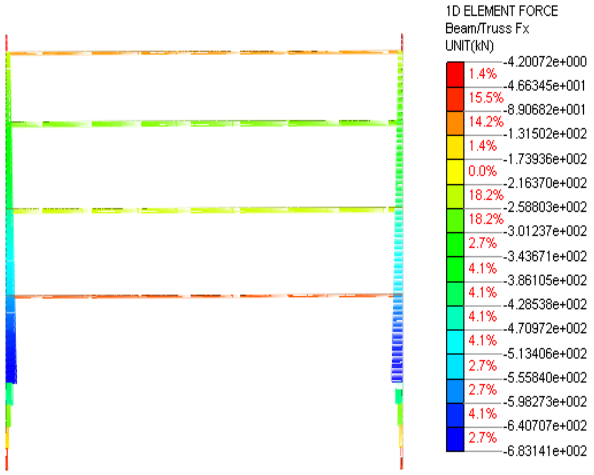

Fig.5 Axial force of retaining structure

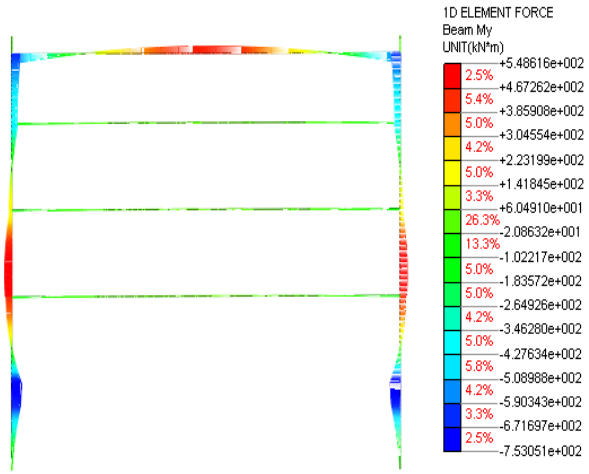

Fig.6 Bending moment of retaining structure

The axial force of the diaphragm wall increases along with the depth of excavation according to the *x* direction of axis of the retaining structure of foundation pit(as is shown in Fig.5) and the maximum of axial force is $6.67*10^2 KN$. While with anchorage depth of the diaphragm wall (4 metres) increases the axial force goes down.The axial force of the first,second and the third supports are high and the forth support is low for the strength of lower layer of soil is more higher.

For the first reinforced concrete support,the diaphragm wall can be considered to a beam structure.As is shown in Fig.6,the bending moment of the upper part and lower part of the wall is

$6.41*10^2 KN•m$ and $5.33*10^2 KN•m$， the maximum bending moment is $7.53*10^2 KN•m$ at the bottom of the deep foundation pit. The first reinforced concrete support can be considered as two fixed ends beam , the maximum bending moment of the first reinforced concrete support are $4.56*10^2 KN•m$ and $6.61*10^2 KN•m$ at the fixed ends and the middle of the support.The bending moment of three steel supports are very small.

Through the numerical simulation analysis of the excavation deep foundation pit in Qingnian Road station of Tianjin subway Line 2, the design of retaining structure of the deep foundation pit is safe and reliable, the construction of the layer-step method excavation is safe and feasible. The foundation pit is stable, numerical simulation can predict the displacement and internal force of important parts of retaining structure of the deep foundation pit which can guide the correction of foundation pit scheme.As for the foundation pit, soil is the main source of load, and a part of the support system , the deformation of supporting structure not only influences the stability of foundation pit, also can make the load and the distribution of soil are changed; as the foundation of inner soil have been digging pit, which reduces the supporting role of inner soil continuous wall.

## Conclusions

Deep foundation pit of subway station is a systematic project, due to the complexity of the soil medium and timeliness, and the diversity of the support and the environment, so the use of numerical simulation of the finite element method can more fully from the space, time, reflecting a variety of factors on the supporting structure and surrounding soil stress and displacement effects.By using Mohr-Coulomb constitutive model in software Midas,the numerical simulation was carried out to research the deep excavation of subway station in Qingnian Road station of Tianjin subway line 2. Analysed the deformation of foundation pit which includes the displacement of supporting structure,the deformation of soil in the pit and near the pit, the internal force of the retaining structure with struts .And the theoretical basis and guidance are provided to actual engineering and these can contribute to improve the structutre design and construction level and safety.Valuable design,construction and scientific research experiences are accumulated and provided to the similar engineering.

The excavation of foundation pit has obvious spatial effect, exposure time after excavation has great influence to the deformation of foundation pit. The construction procedures of foundation pit excavation should be reasonably arranged by the principle of “the first support then slotting,the first support then excavation,excavates layer by layer, avoid excessive excavation”.

**Keywords:** POINT LOAD; REBOUND; TUNNEL SURROUNDING ROCK; ROCK CLASSIFICATION; MATLAB TECHNOLOGY.

**Abstract.** The point load test and rebound tests were part of a simple rock testing methods, which together with a user-friendly, work environment characterized by less demanding test, so test the application of rock in the tunnel are very broad. Obtained by these two tests of rock uniaxial compressive strength Rc saturation level for the characterization of rock hard quantitative indicators, in the rock classification has a high status. With the computer technology in tunnel works in the field of application that can batch test data to establish the tunnel surrounding rock classification system. Article is based on two kinds of test in the same tunnel project in contrast to the use, through the rock classification system to analyze and evaluate both.

## Introduction

Tunnel is one kind of chamber architecture built in rock mass which has stress history and tectonic signs. Thus, correct classification on the rock level is related to tunnel design, construction program, construction costs, etc.. In recent decades, tunnel surrounding rock classification is regarded as one of the most important research contents in tunnel technique all over the world. In China, the classification should be a combination of qualitative and quantitative methods, so rock grading sections are generally determined by field experience. Undoubtedly, various tests in the surrounding rock mass must be accurate enough so that the consistent results of field observations and field test can finally judge the level of surrounding rock. The main index like $R_c$(rock uniaxial saturated compressive saturated compressive strength), however, can greatly influence the result of level classification. Indeed, this kind of indexes need combination of unified factors and artificial intelligence system[1-2], and point load test and rebound test offer the possibility for $R_c$ as an example.

## The Theory of Reflecting the Rock Mass by $R_c$

By the standard of Engineering classification of rock mass(GB50218-94, China), there has the following correspondence between rock uniaxial compressive strength and rock hardness divided qualitatively in Table 1.

**Table 1 The corresponding relationship between Rc and qualitative division of rock hard degree**

| *Rc* [MPa] | >60 | 60~30 | 30~15 | 15~5 | <5 |
|---|---|---|---|---|---|
| Rigidity | Hard Rock | Subhard Rock | Subsoft Rock | Soft Rock | Extremely Soft Rock |

Commonly used index BQ represents the basic quality of rock, and it is determined by rock uniaxial compressive strength and rock mass integrity index. Their relationship is shown as Eq. 1.

$$BQ = 90 + 3R_C + 250K_V \quad (1)$$

(Restrictions: when $R_C > 90K_V + 30$, $R_C = 90K_V + 30$, and when $K_V > 0.04R_C + 0.4$, $K_V = 0.04R_C + 0.4$)

## The Achievement of $R_c$ Value in Grading System for Tunnel Surrounding Rock

Based on the MATLAB technology, grading system for tunnel surrounding rock relying on GB50218-94 can be built. There are qualitative classification, quantitative classification and BQ correction three modules step by step in order to establish the ultimate level of the rock mass and guide engineering[3-5]. Combined with point load test data and rebound test data, field parameters analysis opens up a path to get $R_c$ and BQ at the investigation stage.

Point load test data needs to entry D[cm], L[cm], P[kN] as the format at the input, and the data of single test block forms a row. Files at the input must be EXCEL format so that they can form tabular database. On the other hand, rebound test data needs to enter two tables at the input, namely rebound value table and bulk density data table. In the rebound value table, rebound number N [no unit] and modified angle · [°] are input as the column, while a single measurement point data forms a row. In the bulk density data table, the mass m [g] and the volume V [$cm^3$] of single test block are input as the column, while a single test block data forms a row. Naturally, the two tables are EXCEL file format at the input.

After multi-step formula calculations, the core program of point load data processing module formed a principal formula, which is in an unprecedented way. The $R_c$ of a single test block is obtained as Eq. 2 and Eq. 3:

$$R_c[\mathrm{MPa}] = 22.82I_{s(50)}^{0.75} = 58.5 \cdot \frac{P[\mathrm{kN}]^{0.75}}{D[\mathrm{cm}]^{0.375} L[\mathrm{cm}]^{0.375}} \quad (2)$$

And then the values for each row are averaged and output[6].Similarly, the rebound data processing module core program is the following formula:

$$R_c[\mathrm{MPa}] = 10^{0.0088\bar{N}\cdot\gamma+1.01}, \gamma = \frac{m}{V} \quad (3)$$

Here $\bar{N}$ is the average of $\Delta N_\alpha$ (rebound correction value). In practical engineering, the rebound hammer frequently can not be kept horizontal test situation. Thus, ±15°, ±30°,±45°,±60°, ±90° angles are chosen in actual use. Different rebound test angle correction of internal procedures formulas are shown in Table 2.

**Table 2 The use of rebound correction formula for different testing angles**

| Angle | Correction formula |
|---|---|
| 90° | $\Delta N_\alpha = -0.0012N^2 + 0.1725N - 8.975$ |
| 60° | $\Delta N_\alpha = -0.0003N^2 - 0.0289N + 3.64$ |
| 45° | $\Delta N_\alpha = 0.05N - 5$ |
| 30° | $\Delta N_\alpha = 0.05N - 4$ |
| 15° | $\Delta N_\alpha = -0.0005N^2 + 0.055N - 2.4$ |
| −15° | $\Delta N_\alpha = -0.0003N^2 + 0.0005N + 1.395$ |
| −30° | $\Delta N_\alpha = -0.0005N^2 - 0.0162N + 2.294$ |
| −45° | $\Delta N_\alpha = -0.0003N^2 - 0.0289N + 3.64$ |
| −60° | $\Delta N_\alpha = 0.05N + 4.5$ |
| −90° | $\Delta N_\alpha = 0.05N + 5$ |

In the system, weight options are set up rock hardness qualitative survey, as shown in Table 3.

**Table 3 Qualitative survey of the rock hard degree**

| Qualitative survey of the rock hard degree | |
|---|---|
| Hammering sound | 1. Crisp; 2. Subcrisp; 3. Uncrisp; 4. Dumb; |
| Reboundstrength | 1. Rebound; 2. Slight rebound; 3. None; |
| Hand touchfeeling | 1. Shock hand; 2. Slightly shock hand; 3. Not shock the hand |
| Degree ofcrushed difficulty | 1. Hard to crush; 2. Difficult to crush; 3. Sub-Easily crushed; 4. Easily crushed; 5. Can be crushed by hands |
| Water reaction | 1. None; 2. Slight water reaction; 3. Nails can carve prints; 4. Hand can break apart; 5. Can be shaped into groups |

So, as long as the intuitive investigation ends, operator of the system can add the option values have been selected[7], then the range of $R_c$ can be got. The setting is:

(1)When the sum is in the range of 0-6, $R_c$ >60;

(2)When the sum is in the range of 7-11, 30< $R_c$ <60;

(3)When the sum is in the range of 12-15, 15< $R_c$ <30;

(4)When the sum is in the range of 16-18, $R_c$ <5.

This structure is characterized in that large quantities of data can be done in one process[8]. As Matlab program is relatively simple and operation time is very short, computational efficiency can be greatly improved[9]. Meanwhile, the structure takes into the condition that only one kind of the two test can be obtained when the other one does not have a case[10]. But when both tests have been carried out, there has a comparison module. Module interface is shown in Fig.1.

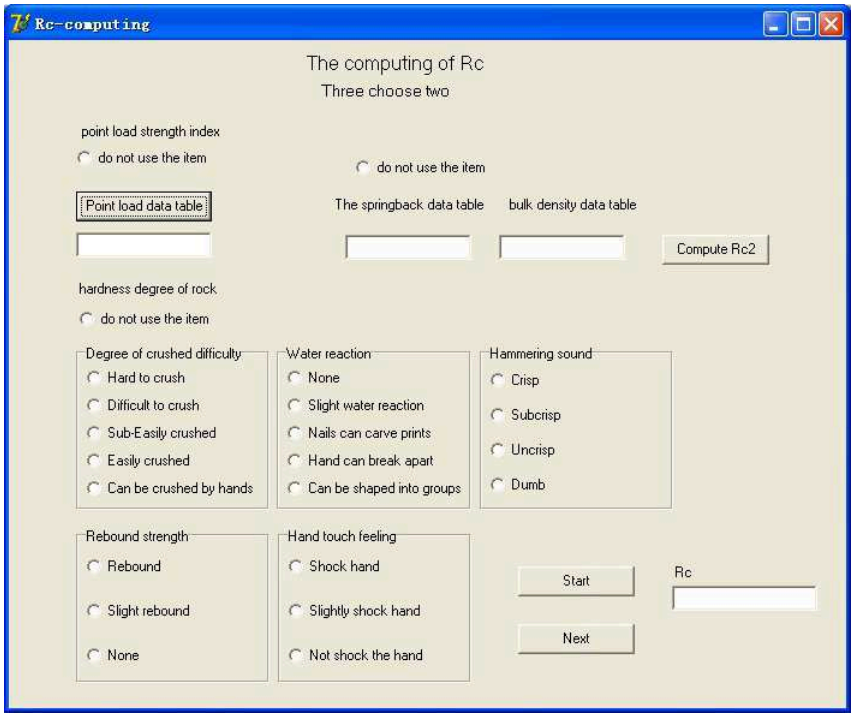

**Fig.1 The interface of Rc value determination in Matlab tunnel surrounding rock classification system**

## Comparison of the Two Tests in Actual Projects

**Changbanpo Tunnel in Jingyu County, Jilin Province, China.** Changbanpo tunnel is located at the west side of Yanping village, Sandaohu township, Jingyu county in Jilin province of China, which belongs to two-lane separate tunnel from west to east. The surrounding rock is mainly brown

and gray, weak andesite. Joints and fractures mostly exist in a fault zone in the RK248 +593-565 section that will be discussed here. Overall, the rock here is cracked structure and poor stability. Fig.2 is the scene photo of tunnel surrounding rock graphed during the tunneling process, which needs accurate and step-by-step rock classification.

**Fig.2 The broken rock mass of Changbanpo tunnel**

Table 4 is the result of tunnel analyze using the grading system for three times.

**Table 4 The rock classification results of Changbanpo tunnel RK248+593-565 bid section**

| Section | $R_C$ value(point load test) | $R_C$ value(rebound test) | Difference | Relative error | Final rock classification |
|---|---|---|---|---|---|
| RK248+590.6 | 20.79MPa | 22MPa | 1.21MPa | 5.82% | IV |
| RK248+588.2 | 26.82MPa | 27MPa | 0.18MPa | 0.67% | IV |
| RK248+576.3 | 28.19MPa | 30MPa | 1.81MPa | 6.42% | IV |

**Liuhuangqian Tunnel in Anhui Province, China.** Liuhuangqian tunnel is in southwestern Anhui province, and the tunnel is an important component of the Xizong highway in Anhui province. The ZK47+355-267 section being analyzed lies on the Meizi checkpoint. The surrounding rock here is subhard rock, and hammering sound is crisp, and hands have shocked feeling. The structure is between crack blocks and thick layers.

Table 5 is the result of tunnel analyze using the grading system for four times.

**Table 5 The rock classification results of Meiziguan tunnel ZK47+355-267 bid section**

| Section | $R_C$ value (point load test) | $R_C$ value (rebound test) | Difference | Relative error | Final rock classification |
|---|---|---|---|---|---|
| ZK47+355 | 56.35MPa | 42MPa | 14.35MPa | 25.47% | III |
| ZK47+325 | 67.98MPa | 61MPa | 6.98MPa | 10.27% | III |
| ZK47+287 | 57.23MPa | 45MPa | 12.23MPa | 21.37% | III |
| ZK47+267 | 76.49MPa | 70MPa | 6.49MPa | 8.48% | III |

From the above two examples of engineering analysis, it can be shown that $R_c$ reflects the rock rigidity[11]. It has obvious correlation between point load test and rebound test. However, there are some other features of the two tests:

(1)The difference and relative error between the two tests become larger when the rock is harder. Inversely, the difference and relative error between the two tests become smaller when the rock is softer. This maybe because there are larger difference between rock strength and structural plane strength in hard rock.

(2)When the rock is hard, the point load test data is more often larger than the rebound test data. When the rock is soft, the point load test data is more often smaller than the rebound test data. The reasons may be these: first, the risk of point load test obtaining in a weak rock structure is less than the risk of rebound test obtaining in a weak rock structure; second, if the rock hardness is poor, rebound hammer is not sensitive to the value of 10 or less, then rebound hammer will get no data, and the operator will often classify this condition as a test failure condition, thus smaller number will may be filtered.

(3)Compared to rebound test, point load test data can obtain more significant figures, the results are more accurate.

In summary, the point load test and rebound test effectively reflect the degree of rock hardness. If more precision is required, point load test can be chosen. But the rebound test is convenient and needs lower time and space condition, thus it can be considered using rebound test instead of point load test (especially in soft rock).

## Conclusion

In view of the above described, the following conclusions can be maked:

(1)Quick surrounding rock classification can not be ignored in tunnel construction. The using of computer software technology and artificial intelligence system is necessary so that the efficiency of grading will be effectively improved.

(2)The rock uniaxial compressive strength Rc is an important parameter in the tunnel surrounding rock classification. Through the point load test data and rebound test can meet the engineering requirements because of their own advantages. In the actual project, they can be chosen under the circumstances or combined in AI system.

**Keywords:** ground explosion; shallow buried structure; dynamic response

**Abstract.** Simulating and analyzing the dynamic response of the shallow underground structure under the ground explosions by LS-DYNA. The results show that the ground shock under ground explosions contains two different forms, one is direct impact ground shock and the other is indirect impact ground shock; with the increasing of depth, the ground shock decreases. The effective stress of the upper part of the roof is larger than other parts of the shallow underground structure; the effective strain of the corner of the roof is larger than other parts of the shallow underground structure.

## Introduction

Because of the underground structures (such as subway station, underground passage) are crowded and not easy evacuation, they often become the first choice for the terrorist attack[1]. Once the terrorist attack occurring, it is difficult to measure the serious consequences, so improving the ability of physical protection of underground structures is extremely important.

The ground shock under ground explosions contains two different forms, one is direct impact ground shock and the other is indirect impact ground shock. When designing the underground protective structure, it mainly considers the load causing by the ground shock. This paper simulated and analyzed the distribution of the wave field and the dynamic response of the shallow underground structure under ground explosion by using finite element software LS-DYNA. The research achievements on the issue at home and abroad are as follow. Junyu Fan[2] analyzed the wave field distribution of the shallow ground under the ground explosion; simulated the load distribution of the shallow buried underground structure, when the dynamite did not hit the structure directly. Jinchun Liu[3] putted forward the practical calculation method of the impact induced wave in soil, they analyzes the experimental data and the results of numerical simulation of the explosive induced wave under the contact explosion. Literature [4] putted forward the calculation method of ground motion parameters of the shallow surface shock induced by explosives, when the ground and the soil is given for homogeneous medium.

## The calculation model and material model

### The calculation model

The calculation model is shown in Fig1, the size of the explosives is 0.4 m * 0.4 m * 0.4 m, the charge is 104.3kg.The distance between the structure and the explosive is h = 3.5 m. The thickness of the air layer in the calculation model is 0.9 m, the thickness of soil layer is 8 m, the structure in the model is reinforced concrete structure, the strength grade of concrete is C30, the steel strength grade is HRB300,the height of structure is h = 4.1m, the span is L=7 m, the thickness of the roof is h1 = 0.5 m, the thickness of the bottom is h2 = 0.5 m, the thickness of the side wall is h3 = 0.5 m.

In this paper, the model of finite element analysis used a quarter model, the attribute of the unit are SOLIDE164, the boundary adopted no reflection boundary.

This paper will be divided into two kinds of working condition. One is without underground structures; it is mainly used to study the field distribution of the explosion shock wave under the ground explosions. The grid of the explosive and the air, the solid are meshing into Euler grid in the model. The algorithm used multiple material ALE algorithms; this algorithm allows the same grid

contains different materials. The other condition has the underground structure; it is mainly used to study the dynamic response of underground structures under ground explosions. The grid of the explosive and the air, the solid are meshing into Euler grid in the model. The grid of the reinforced concrete structure is divided into Lagrange; it used the algorithm of fluid-structure interaction. Finite element model and the meshing of the model is shown in Fig2.

The unit system adopts cm, g, us in this article.

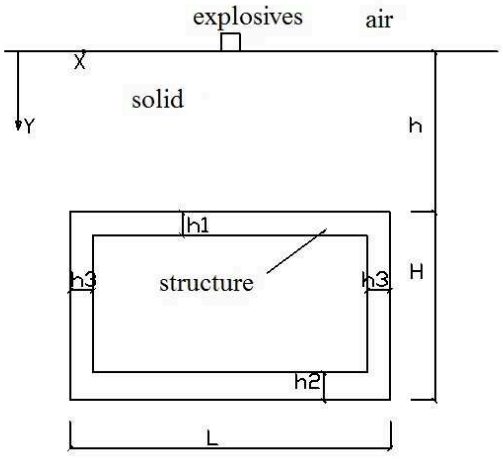

Fig1.The calculation model

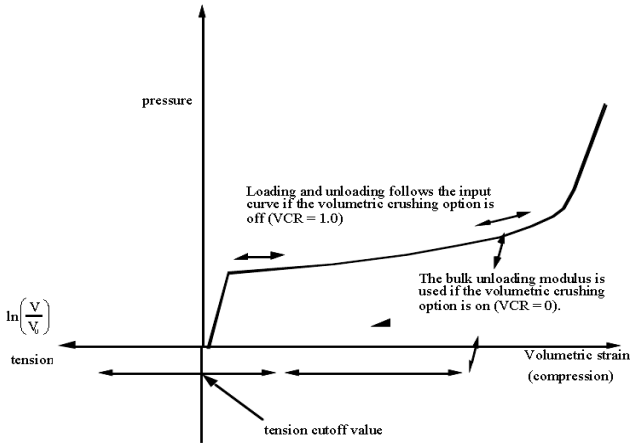

Fig3.The relationship

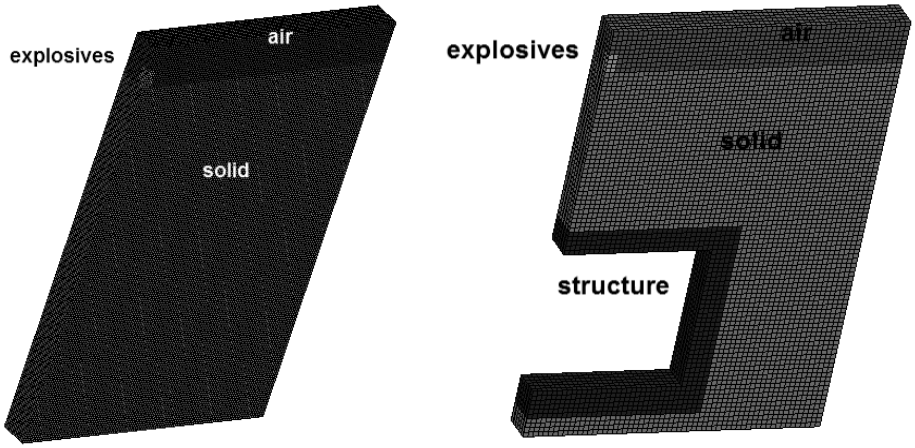

Fig2. The finite element model and the meshing

**The model and parameters of material**

(1)The material model and parameters of the air

In this paper, the air was described by material model of * MAT_NULL and state equation of LINEAR_POLYNOMIAL. This article takes:

$C_0 = -1E-6, C_1 = C_2 = C_3 = C_6 = 0, C_4 = C_5 = 0.4, V_0 = 1.0\ E_0 = 0.25E-5$

(2) The material model and parameters of the explosive

In this paper, explosives was described by material model of *MAT_HIGH_EXPLOSIVE_BURN and the state equation of JWL. The value of material parameters are shown in Table1.

Table1.parameters of JWL and*MAT_HIGH_EXPLOSIVE_BURN

| A | B | R1 | R2 | ω | E0 | V0 | R | D | PCJ | BE-TA | K | G | SI-GY |
|---|---|---|---|---|---|---|---|---|---|---|---|---|---|
| 3.737 | $7.33e^{-2}$ | 4.15 | 0.95 | 0.3 | 0.043 | 1.0 | 1.63 | 0.693 | 0.21 | 0 | 0 | 0 | 0 |

(3)The material model and parameters of the soil

In this paper, soil was described by material model of *MAT_SOIL_AND_FOAM, the relationship between pressure and volume strain is shown in Fig3.the values of material parameter are shown in Table2.

Table2.The parameters of the soil

| R0 | G | BULK | A0 | A1 | A2 | PC | VCR | REF |
|---|---|---|---|---|---|---|---|---|
| 1.8 | $6.4E^{-4}$ | 0.3 | $3.4E^{-13}$ | $7E^{-7}$ | 0.3 | $-6.9E^{8}$ | 0 | 0 |

(4) The material model of the structure

This article used the * MAT_BRITTLE_DAMAGE to describe the reinforced concrete. This kind of material contains the option of reinforcement ratio. It is a composite material of concrete and steel. The value of parameter is: density $\rho$=2.5, Poisson's ratio $\nu$=0.2, elastic modulus E=0.3, reinforcement of volume percentage is 0.02, the yield stress of reinforced is 0.003.

**The results and analysis of calculation**

**The ground shock under ground explosions**

Fig 4 is the propagation of stress wave with time under the ground contact explosion. We can see the ground shock of the shallow ground can be divided into direct impact and indirect impact in the figure. In Fig5, indirect impact almost has no effect on cell c, At the moment, the value of angle $\beta$ is about 61° ($\beta$ is the angle between radial of blasting center and the plumb line of the ground). Below the surfer of ground, when $\beta$ is between 0°to 61°, compression wave is mainly caused by direct impact shock. The area is called central region. When the value of $\beta$ is about between 61°to 90°, compression wave is a mixture of direct and indirect wave. The region is called surface region. The result is in accordance with the conclusion of literature [5].

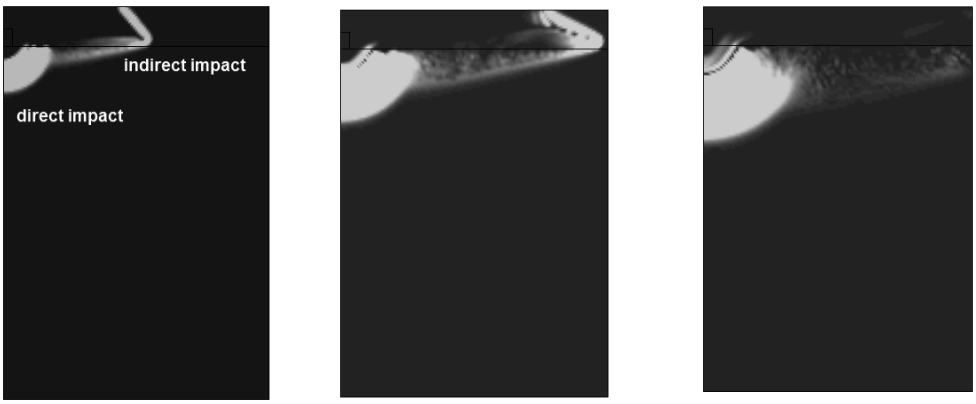

Fig4.The propagation of stress wave

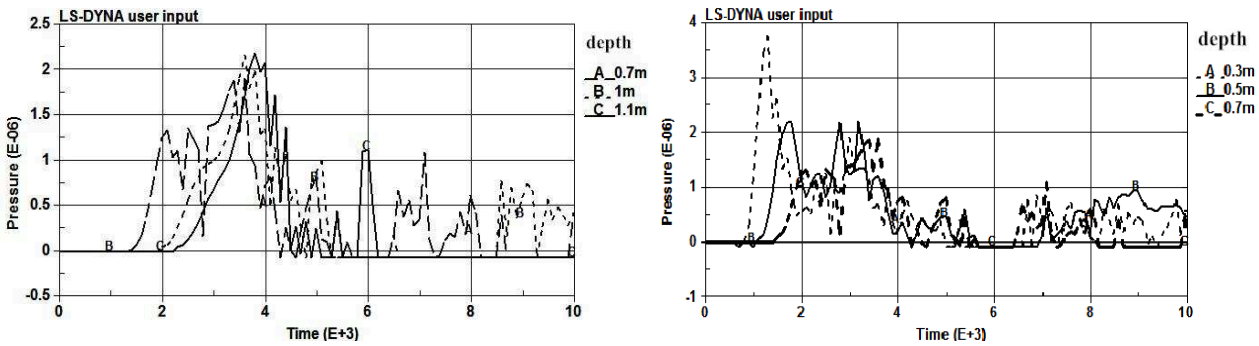

Fig5.The horizontal distance to the explosion center is 2m

In the surface region, the cell has two pressure peaks, showing in Fig5. At the first time, pressure peak was caused by the indirect impact; the second was caused by the direct impact. With the increasing of the depth, the values of two peaks are reducing. With the increasing of the depth, the

effect of indirectly impact is diminishing. Cell B in the figure, the values of two peaks are equal. At the moment, the value of angle β is about77°. When the beta is greater than 77°, indirectly impact played the leading role, namely the value of the first peak is greater than the second peak. The area is called near surface region. When β between 61°to 77°, the directly impact played the leading role, namely the value of the first peak is less than the second peak, the area is called the surface area. The result is in accordance with the literature [5].

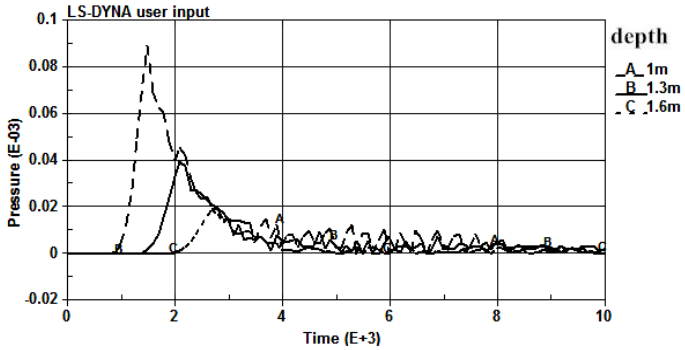

Fig6.The horizontal distance to the explosion center is 0m

In the central region, we can see in figure 6, with the increasing of depth, the value of overpressure decreasing, and the rising time increasing.

To sum up: 1.The ground explosion will cause the ground impact .The ground shock of the shallow ground can be divided into direct impact and indirect impact.

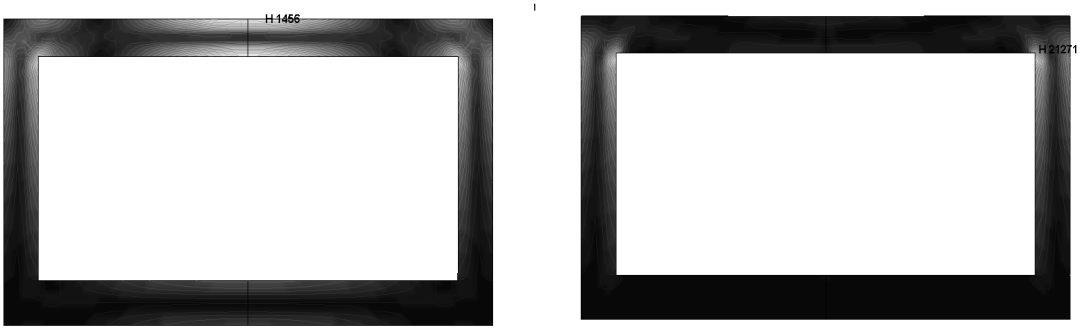
2. When β≤61°, it is called the central region. In the region, compression wave is mainly caused by direct impact shock. When 61°≤β≤77°, it is called the near surface region . In the region, compression wave is a mixture of direct and indirect wave; the directly impact played the leading role. When 77°≤β≤90°,It is called the surface region . In the region, compression wave is a mixture of direct and indirect wave; the indirectly impact played the leading role.

3. With the increasing of depth, directly and indirectly impact shocks were decreasing.

## The load-bearing characteristics of the shallow buried underground

In this article, the explosive hit structure directly. Structure is in the region of the β≤61°, where the directly impact played the leading role on the structure. In Fig 8, 9, we can see that the effective stress of the upper part is larger than other parts of the shallow underground structure; the effective strain of the corner of is larger than other parts .The destruction of the structure starts from the central and the corner of the roof.

Figure 7, 8 for biggest moment of the effective stress and effective strain, respectively, unit # 1456 has the maximum effective stress, the value is 0.35 Mpa; unit # 21271 has the maximum effective strain, the value is 8.49e-6. The effective strain is less than 0.025, the structure has not cracked, and it was not destroyed.



## Conclusions

This paper studies the form of propagating and the classification of compression wave, and dynamic response of underground structures under the ground contact explosion by LS-DYNA. The conclusion is as follows:

(1) The compression wave field under the contact explosion is divided into three regions. They are the central region $0°\leq\beta\leq61°$, the surface area $61°\leq\beta\leq77°$, the shallow surface region $77°\leq\beta\leq90°$.

(2) The directly impact has mainly effect on central region, the directly impact and the indirect impact has the effect on the surface area and the shallow surface area. The directly impact played the leading role on the surface area, the indirectly impact played the leading role on the shallow surface area

(3) In the shallow buried underground structure, the peak of effective stress appears in the central of roof, the peak of effective strain appears in the corner of the roof. In the condition, the structure has not cracked, not destructed.

**Key Words:**Tunnel construction; Monthitoring and Measurement; Control standards; Surrounding rock stability

**Abstract:**Tunnel monthitoring reference value is an important indicator to determine the stability of surrounding rock. Existing tunnel specification vault settlement and surrounding convergence gives some guidance views, But in the actual project also found a number of problems, And no indication of surface displacement control reference value specification in. Based on the analysis of relevant norms, In practical engineering, for example, Monthitoring and Measurement standards for construction tunnel some meaningful discussion.

Design and construction of highway tunnels are increasingly using NATM. In order to grasp the extent of the construction of rock stability and support force, Dynamic mechanical deformation or information, To determine the design, construction, safety and economy, After the tunnel excavation site shall be in accordance with the design requirements and the actual situation of immediate distribution and monthitoring, Feedback so as to achieve the design, construction instructional purposes. But control standards is not an easy thing to determine, There is no uniform standard at home and abroad, Although the current specification gives some guiding opinions for surrounding tunnel displacement and vault settlement,there are also some problems, so individual scholars have done some researches on surface subsidence control standards for some particular projects.

This paper focuses on monthitoring and measuring the surrounding tunnel displacement and vault settlement as well as surface subsidence control standards,for the purpose to throw away a brick in order to get a gem.

## Existing tunnel monthitoring measurement control standards specification

### 1.1 The projects must be measured in existing tunnel measurements norms

The projects must be measured are current measurement to ensure the stability of surrounding rock in the design and construction.Then by judge the stability of the rock to guide design and construction. Such kind of tests are simple, low cost, high reliability, but it plays a vital role in monthitoring rock stability and guiding the design and construction.

Table 1 Tunnel site monthitoring measurements will test the project

| No. | Project Name | Methods and Tools | Arrange | Test accuracy | Measurement interval | | | |
|---|---|---|---|---|---|---|---|---|
| | | | | | 1 ～ 15[d] | 16[d] ～ 1[month] | 1 ～ 3[month] | ＞ 3[month] |
| 1 | Inside, outside observation | Field bservations, geological ompass | After the initial excavation and shoring | | After blasting each | | | |
| 2 | Peripheral displacement | the various types of convergence | Each 5 ~ 50[m] a cross-section, each section of the measured points 2-3 | 0.1[mm] | 1 to 2 times / [d] | 1times / 2[d] | 1 to 2 times / [week] | 1 to 2 times / [month] |
| 3 | Vault settlement | Method of leveling, level, ruler, etc. | Each 5 ~ 50[m] a section | 0.1[mm] | 1 to 2 times / [d] | 1times / 2[d] | 1 to 2 times / [week] | 1 to 2 times / [month] |
| 4 | Surface subsidence | Method of leveling, level, ruler, etc. | Hole section, Shallow segment(h0≤2b) | 0.5[mm] | Before and after the excavation face distance measurement section <2b, the 1 or 2 times / [d] | | | |
| | | | | | Before and after the excavation face distance measurement section <5b, the 1/2 ~ 3[d] | | | |
| | | | | | Excavation face from the front and rear sections measuring> 5b, the 1/3 ~ 7[d] | | | |

Note: b——Tunnel excavation width.

$h_0$——Tunnel depth.

**1.2 Existing Monthitoring and Measurement tunnel specification control standards**

Measured displacement value should not exceed the limits of the tunnel displacement, then must be constructed follow the requirements in Table 2 of displacement management level. Under normal circumstances, it is better to set the designed tunnel reserved deformation as the ultimate displacement. The tunnel excavation contour should be reserved for the deformation according to the requirement, if there is no such a requirement, Table 3 is a reference, and the adjustments could be made based on monthitoring and measurement information.

Table 2 Displacement management level

| Management Level | Management displacement [mm] | Construction Status |
|---|---|---|
| Ⅲ | $U<(U_0/3)$ | Construction may be normal |
| Ⅱ | $(U_0/3)\leq U\leq(2U_0/3)$ | Should strengthen support |
| Ⅰ | $U>(2U_0/3)$ | Special measures should be taken |

Note: U—Measured displacement value;

U0—Design limits displacement value.

Table 3 Outlines reserved deformation of excavation

| Rock level | Set aside the amount of deformation [mm] | | Rock level | Set aside the amount of deformation [mm] | |
|---|---|---|---|---|---|
| Ⅰ | Two lanes | — | Ⅳ | Two lanes | 50～80 |
| | Three lanes | — | | Three lanes | 80～120 |
| Ⅱ | Two lanes | — | Ⅴ | Two lanes | 80～120 |
| | Three lanes | 10～50 | | Three lanes | 100～150 |
| Ⅲ | Two lanes | 20～50 | Ⅵ | Two lanes | Field measurements to determine |
| | Three lanes | 50～80 | | Three lanes | |

According to the Specification, to determine whether the tunnel ceiling unstable or failure,the maximum displacement value is a standard, the upper limit of construction management control standard is the 2/3 of the ultimate displacement in the displacement level management table .

### 1.3 Discussion control standards

In the monthitoring and measurement, it is not proper to tell whether the tunnel is relatively unstable or failure occur to compare the measured maximum displacement with limit displacement . The reasons are:

（1）In the tunnel excavation process it is hard to precise the limit displacement due to the engineering geological conditions, environmental conditions, Excavation method, complex support forms of tunnel and underground. So the comparison of measured maximum displacement with ultimate displacement is difficult to operate.

（2）Design drawings or related specification has the deformation of the initial reservation tunnel support.In order to ensure the secondary lining support space can't be invaded by the surrounding rocks and initial support and to ensure the accurately of tunnel construction clearance after the secondary lining, you can take the designed reserved deformation as the ultimate displacement and control it and can not guarantee that whether the tunnel will be destroyed when the secondary lining support space being invaded.In the actual project, The surrounding rocks have already damaged although the measured displacements are far from the limit displacements.(table 4 for reference)

（3）Specifications did not clearly pointed out in the end is the ultimate displacement vault settlement or the surrounding convergence displacement is controlled vault settlement is based on the convergence or in the surrounding displacement control based norms seem vague, actually vault settlement and surrounding convergence displacement is not the same (see Table 4).

（4）There is no value of the reference surface displacement control in the specification, it is difficult to guide the construction of the actual project.

Table 4 Den Cao Tang pond tunnel section measured maximum displacement

| Section Stake | Rock level | Vault settlement [mm] | Surrounding convergence [mm] | Ultimate displacement [mm] | Remark |
|---|---|---|---|---|---|
| K4+334[mid] | VI | 4.39 | 5.36 | 200 | Appear mud |
| K4+403[mid] | VI | 15.76 | 29.76 | 200 | Cracking vault |

| YK4+339 | V | 30.89 | 31.93 | 180 | |
| ZK4+225 | VI | 20.02 | 26.06 | 200 | Vault cracking and seepage |
| The first platform（exit）surface | | 208.68 | | Reference value specification does not surface displacement | Severe ground subsidence, the emergence of local slump, some cross beam broken, damaged or deformed serious anchorage |
| The second platform（exit）surface | | 248.14 | | | |
| The third platform（exit）surface | | 89.11 | | | |
| The fourth platform（exit）surface | | 255.81 | | | |

### The domestic and foreign relevant specifications to determine deformation standards

（1）Relevant normative standards in France

France M.Louis proposed maximum allowable displacement increases with increasing depth, the depth of about 1/1000. Tunnel displacement reference values established by the French Ministry of Industry Table 5 (tunnel section 50 ~ 100 ㎡). The reference value can be used as a reference displacement reference primary election, it is more important is to rely on engineering experience accumulation.

Table 5 French crown and surface subsidence of different allowable depth

| Tunnel depth/[m] | Inside the vault allowed to settlement/[mm] | | Allow the surface to settlement/[mm] | |
|---|---|---|---|---|
| | Hard Rock | Soft Rock | Hard Rock | Soft Rock |
| 10~50 | 10~20 | 20~50 | 10~20 | 20~50 |
| 50~100 | 20~60 | 100~200 | 20~60 | 150~300 |
| 100~500 | 50~100 | | 50~100 | 200~400 |
| 500~750 | 40~120 | 200~400 | 40~120 | 300~600 |

Can be seen from Table 5,①This standard takes the conditions of rock and effects of the depth into account, without considering the impact of the shape of the tunnel excavation;② soft rock allowed more vault settlement than hard rock when buried in the same depth;③ under the same condition of surrounding rocks, allowing vault settlement increases with depth .

（2）Japan related normative standards

A Japanese company proposed to determine the threshold of vault sinking according to rock compressive strength, as shown in Table 6. Analysis can be obtained from the table. It considered the effect of the strength of the rock and the requirements of the different levels of alert, but it did not consider the effect of tunnel depth and the shape of the tunnel. Similarly, the lower the alert level, the lower the compressive strength, the greater the allowable vault settlement; while at the same compressive strength, the higher alert level, the smaller the allowable vault settlement.

Japan《NATM construction design draft guidelines》made in accordance with the value of the total displacement monthitoring (or monthitoring the displacement has been estimated based on the final displacement value) to typed the rocks, and then, in accordance with the rock category to determine the appropriate support systems. The relationship of Clearance change value and rock categories are shown in Table 7. In-depth analysis of the table shows, ① It considered the impact of two factors :that is the tunnel span and the rock categories , without considering the impact of the depth of tunnel; ② With the same span, the worse the rock, the greater Clearance change value allowed ; ③ rock under the same conditions, the greater the span, the greater the Clearance change value allowed.

Table 6 Vault subsidence

| Alert level | Uniaxial compressive strength(MPa)/Settlement/cm | | |
|---|---|---|---|
| | Rc＞100 | Rc=5~100 | Rc=0.5~5 |
| Ⅰ | 0.3~0.5 | 0.5~1 | 1~3 |
| Ⅱ | 1~1.5 | 1.5~4 | 4~9 |
| Ⅲ | 3~4 | 4~11 | 11~27 |

Table 7 Clearance change and the relationship between the rock category

| Rock type | The value of clean air/mm | |
|---|---|---|
| | Single line | Double line |
| Ⅰ~Ⅱ | ＞75 | ＞150 |
| Ⅱ~Ⅲ | 25~75 | 50~150 |
| Ⅲ~Ⅴ | ＜25 | ＜50 |

(3) The country of the relevant norms or regulations

To determine whether the tunnel is relatively unstable or failure occurs,you can judge it by comparison of the measured maximum displacement with the limit displacement as well as according to the displacement rate of change or the trend rate of displacement to judge.

To determine according to the displacement rate of change:

(1) the rapid growth phase of deformation: the deformation rate is greater than 1.0mm / d ;

(2) slow growth stages of deformation: the strain rate 1 ~ 0.2mm / d ;

(3) stable phases: the deformation rate of less than 0.2mm / d

The above strain rate deformation clearance standards are measurements for general tunnels Clearance change and vaults settlement. If it is for measuring high stress, karst, swelling, squeezing rock, etc, you should make specific standards for determining the specific circumstances.

To determine according to the trend rate of displacement:

Since the rheological properties of rock, rock deformation before damaged is a curve process which can be divided into three stages:

(1) Basically stable region: the main indicator is the displacement rate gradually decreased, namely: $\frac{d^2u}{dt^2} < 0$ ,rock are stable .

(2) Transition zone: displacement rate remains unchanged, namely $\frac{d^2u}{dt^2} = 0$ , Showing that the rocks are becoming unstable, need to warn, to strengthen support systems.

(3) Damage zone: displacement rate gradually increases, namely $\frac{d^2u}{dt^2} > 0$ , Showing that the rock in danger, must immediately stop construction, to take effective measures to control the deformation.

《Technical Specification for monthitoring and measuring the tunnel railway TB 10121-2007》 take the allowed relative displacement values to determine the ultimate displacement.

Further analysis to regulate shows that: ① The table considers the two factors:tunnel depth and rock types.Didn't consider the size of the span of the tunnel or excavated cross-section; ② rock under the same conditions, the greater the depth, the larger relative convergence allowed; ③ the same depth, the worse rock conditions , the greater the relative convergence allowed.

（4）Compare domestic and foreign relevant provisions of the subway project

In Beijing, Guangzhou, according to local experience, we recommend the appropriate monthitoring and control standard for subway construction.See Table 8 Table 9 Table 10.

Table 8 Beijing subway shield law, construction law Shallow control reference monthitor

| Method | Monthitoring Project | | Reference value/[mm] | Average and maximum displacement speed control value/([mm]/[d]) |
|---|---|---|---|---|
| Shield | Surface subsidence | | 20 | Average value of 1, a maximum of 3 |
| | Vault settlement | | 20 | Average value of 1, a maximum of 3 |
| Shallow law | Surface subsidence | Interval | 30 | Average value of 2, a maximum of 5 |
| | | Workshop | 60 | |
| | Arch bottom bulge | Interval | 10 | |
| | | Workshop | 10 | |
| | Vault settlement | Interval | 60 | Average value of 2, a maximum of 5 |
| | | Workshop | 120 | |
| | Horizontal convergence | Interval | 20 | Average value of 2, a maximum of 3 |
| | | Workshop | 20 | |

Table 9 Guangzhou subway construction baseline monthitoring and control

| Monthitoring Project | Reference value/[mm] | Control reference |

Table10 Monthitoring benchmarking countries, both inside and outside the subway project deformation

| Standard | Ground largest settlement/[mm] | Ground subsidence trough curvature inflection | Formation loss coefficient/% | Inside Sidewall horizontal convergence/[mm] | Inside the dome settlement/[mm] |
|---|---|---|---|---|---|
| Japan, France, Germany, comprehensive specification | 50 | 1/300 | 5 | 20~40 | 75~229 |
| Our management standards | 30 | 1/500 | 5 | 20 | 50 |

**Explore the tunnel deformation monthitoring measurement control standards**

Tunnel monthitoring deformation control benchmark are an important part of the tunnel construction risk assessment,and it is also the premise of monthitoring the risk ,besides it is the maximum allowable value to ensure the safety of monthitored object. During monthitoring process, once the monthitoring data exceeds the reference value control, monthitoring department must mark it out in the monthitoring reports prominently and call the police, and do research and analysis jointly with the relevant departments , the reference value can be adjusted to control if necessary. Generally according to the following principles to determine the control reference:①should meet requirements of existing regulations related to design and construction, specifications and guidelines. jointly determined by the construction, design, supervision, construction and other related departments ,then being included in monthitoring programs. ③The monthitoring and control ling reference value should ensure the safety and normal use of the tunnel adjacent structures and to consider the requirements proposed by the competent authorities of the neighboring structures.④monthitoring and control reference value should have the feasibility of construction projects, to meet the premise of safety, you should consider increasing the speed of construction and reducing construction costs.⑤some monthitoring projects whose baseline values is not yet clearly defined at present, the monthitoring data can be reference to similar projects abroad.⑥to analyze the stability of the surrounding rock and supporting structure condition and the safety of the surrounding environment, you should correct the predetermined allowable displacement according to specific engineering field monthitoring results and engineering experience.

**Conclusion**

During the construction phase of the tunnel, in order to measure the Changes of surrounding rock (Such as surface subsidence, vault settlement, circumference displacement and so on) and the working state of the supporting structure ,we often use the total station, level meter, instrument and so on .Timely provide the information like the stability of rock degree and reliability and safety of the supporting structure,to anticipate accidents and danger, as the basis for adjustment and modificator of support design.To settle down the time for the second lining construction according to the measured results in the Composite lining,to monthitor the surrounding rock displacement of retaining structure of prestress shall not exceed the design standard.Therefore, it is very important to determine the reference value of monthitoring and measurement. The paper analyzed the existing tunnel monthitoring measurement specification, domestic and foreign relevant specifications, and some practical engineering projects, aiming to throw away a brick in order to get a gem.

**Keywords:** subway.concrete; cracking. construction quality.

**Abstract.** The control of concrete cracking is a complicated and difficult problem for civil engineering. It is more difficult to control the cracking of the concrete poured in the winter. Thorough the analysis of the construction of the Shijiazhuang subway in winter, several methods are integrally applied. Frost proof and decreasing the temperature stress of concrete is considered together. The construction quality of the concrete arrive a satisfied level and the cracking of the concrete is successfully handled.

## Introduction

Concrete crack control has long been a complicated and difficult subject in both engineering and academic circles. To solve this difficult problem, engineering technologists and researchers of many institutions have carried on long-term and large amount research and exploration work on construction technology, concrete admixtures, concrete mixture ratio, raw materials for concrete and many other aspects and made many achievements and gained valuable experience]. HanSufang and others] put forward that the comprehensive measure combining prevention, release and resistance, as well as the method combining design, material and construction should be adopted to control the concrete crack. However, concrete crack control is a complicated system problem and when it comes to the specific measure to control the crack, and different scientists hold different academic and technical opinions]. Especially, since the late 90s of last century, with the updating national cement standard, concrete products have developed towards high fineness and strength with fast growing speed, and early strength grinding aid, which has brought more serious problem to concrete crack control [1-2].

## Mechanism of concrete crack

The early cracks on concrete with large volume appear mainly due to the thermal shrinkage caused by hydration heat, as well as drying shrinkage, plastic shrinkage and autogenous shrinkage. Plastic shrinkage control is relatively simple that is to say common construction measures can better avoid it, but to avoid other kinds of shrinkage, research on mechanism is needed to get the countermeasures.

The greater the volume of concrete, especially in the subway station construction, the more difficult the diffusion of the heat produced by hydration of cement, the higher the temperature, and the greater the volume change caused. The most fundamental reason led to the crack is the large volume change caused by risen temperature due to the hydration. The adiabatic risen temperature inside the concrete caused by concrete hydration heat is Eq. 1 [3-6]:

$$T_{max} = \frac{W \cdot Q}{\gamma_h \cdot C} \tag{1}$$

In the formula: $T_{max}$ -- The highest adiabatic risen temperature (℃)

Q-- hydration heat （KJ/kg）

$\gamma_h$ -- density of concrete （Kg/m3）

C-- specific heat of concrete (KJ/(kg. ℃))

Thus, the adiabatic temperature produced by the concrete can rise highly, and when the environment temperature change is great and subway station wallboards of large volume adopts temperature control measures rather than computing according to thermal engineering, the difference between inside and outside temperature of concrete will rise and be more than 25 ℃, which will generate considerable temperature stresses (cause cold shrinkage) leading to the crack. At the same time, the risen temperature of concrete also accelerates the evaporation on concrete surface, leading to drying shrinkage.

The interior of large volume concrete has free water, bound water, combined water,interlayer water and a variety of forms of water, and they have different losing processes of internal and external moisture gradient. In early period, first, big pores and big capillary pores lose water, but the loss of this kind of water will not cause shrinkage. Then, pores with radius less than 1000A start to lose water. The kind of water loss will generate shrinkage due to capillary pressure. After losing some water, concave surface will be formed in the capillary pore. Capillary pore pressure formula of single pore is Eq. 2:

$$P=2\sigma/r \tag{2}$$

In the formula, $\sigma$ represents the surface tension, the lower temperature of surroundings, the smaller the radius of the concave surface, the greater the capillary pressure. The relation among capillary pressure, surface tension and relative environment humidity is determined by the following type Eq. 3:

$$P=2\sigma/r=1300\ln(1/\phi) \tag{3}$$

In the formula, $\phi$ represents relative humidity and pores distribute randomly to all directions inside concrete, leading to the shrinkage of all directions inside concrete due to the pressure. As the humidity lowers further (less than 60%), the water adsorbed on the surface of hydrated calcium silicate gel will evaporate, leading to the closer distance between the gel and finally the irreversible shrinkage. When the humidity is reduced to 45%, the interlayer water of hydrated calcium silicate gel structure will lose, and the loss of this kind of water will cause great and irreversible shrinkage of concrete.

Table 1 Concrete materials proportion

| *No.* | *Structure position* | *Concrete number* | *Cement content kg/m³* | *Sand content kg/m³* | *Stone content kg/m³* | *Water kg/m³* |
|---|---|---|---|---|---|---|
| 1 | Station flank | $C_{40}$ | 310 | 773 | 1082 | 165 |
| 2 | Station flank | $C_{40}$ | 281 | 832 | 1018 | 170 |
| 3 | Station flank | $C_{40}$ | 362 | 713 | 1069 | 180 |
| 4 | Station flank | $C_{40}$ | 330 | 713 | 1069 | 180 |
| 5 | Station roof | $C_{40}$ | 340 | 720 | 1079 | 180 |

Concrete autogenous shrinkage mechanism is quite complex, and mature theory has not been formed yet. By so far, capillary tension theory is accepted widely. According to the definition, autogenous shrinkage presents more obviously in high performance concrete with low water-binder, because the gel material that do not hydrate needs water to continue the hydration process, and when there is no water or the water consumption rate is faster than the outside water migration rate, moisture migration inside concrete will occur and concave surface be formed inside pores. The

formation of this kind of concave surface will generate tension inside concrete, resulting in shrinkage and this kind of shrinkage is autogenous shrinkage.

## Practical project analysis

Shijiazhuang subway line No.1 has a total length of 22.14km, 7028m of which adopts mine construction method, 749m open digging method and the rest shield driven method. We research the subway station constructed in winter, detailed summary the concrete crack situation of the subway station constructed in winter, select 5 typical stations to describe, and the concrete construction materials proportion of the investigated stations is on Table 1. After the concrete cracks were found in former sections, we have adopted appropriate and adjusted the materials proportion reasonably, and then continue to observe concrete construction of the later sections.

## The generation reason and control analysis of concrete crack

The concrete crack factors influenced by the subway construction in winter are quite complicated, involving design, material, construction craft and many others. Therefore, we comprehensively analyze the concrete crack problem of the subway stations and the main reasons are as follows:

Both the floor and roof of the subway station are commonly of large volume. The thickness of flank is 600 mm, and if the lateral widened part is considered, the thickness is about 700 ~ 800 mm. The hydration heat of concrete causes the appearance of the cracks. Wind resistance, heat preservation, stove or steam anti-freezing measures are adopted. Site concrete after pouring concrete has been in a state of normal temperature, about 10 ℃, and the early strength of concrete develops very fast. Under such circumstance, the relatively dry condition in shed is harmful to the moisture retention and maintenance. The initial setting time of concrete of the two sections poured in December 2006 is about 5 hours, the concrete hydration hardening speed is quite fast, and the hydration heat is quite concentrated. The initial setting time of concrete poured between January and March, 2007 is about 11 hours, which is conducive to the delay of the concrete heat release speed and can lower the concrete hydration heat peak.

Due to the vertical flank concrete structure, on the one hand, it is difficult to reserve the moisture and maintain. After removing from the mold, the moisture loses quickly, further speeding up the drying shrinkage and autogenous shrinkage of concrete. The dosage of crack-resistance waterproofing agent needs to be increased, by raising the limit expansion ratio of concrete to eliminate the shrinkage influence brought by the negative maintenance conditions. On the other hand, the flank concrete is restricted by the foundation concrete, and shrinkage stress is not easy to release. When comprehensive value of the temperature shrinkage stress caused by concrete hydration heat, the autogenous shrinkage stress and drying shrinkage stress by concrete early strength and other shrinkage stresses exceeds the tensile strength of concrete, the concrete can produce cracks. However, the early tensile strength of concrete is very low. About 3 days or so, the expansion value of the compensation shrinkage concrete is not high, less than 1.5 x 10-4, which can only compensate the early drying shrinkage and autogenous shrinkage of concrete, and if there is a large temperature stress at this point, it is impossible to completely compensate. The thermal expansion coefficient of concrete is about one over one hundred thousand. According to the theory of linear expansion, the reduction of every 10 ℃ will produce 1 x 10-4 shrinkage value. The wall structure is different form the floor structure, after removing from the mold, the heat loses quite fast, and in a very short period of time to environment temperature inside the shed can be reached. Considering the temperature measuring situation of the project, the difference between the environment and the internal concrete temperature is about 40 ℃, temperature shrinkage 4 x 10-4, and the ultimate tensile strain rate of concrete only 2.5 x 10-4. Therefore, concrete crack problem of this project is mainly caused by the temperature stress.

According to theoretical analysis, experiment and practice experience, the following measures are adopted in the subsequent subway construction in winter: reduce the cement dosage appropriately, in order to reduce the amount of hydration heat; increase the fly-ash dosage appropriately; adjust the

CSA crack-resistance waterproofing agent dosage from 9% to 11%, in order to increase the expansion of the concrete; fully retard, retarding the setting time of concrete from 5 hours to 11 hours, to slow the rate of hydration heat. Through the implementation of the above countermeasures, the highest temperature inside the concrete is controlled to 35 ℃, environment and the internal concrete temperature lower to 25 ℃, so that no crack is found in the concreted constructed in January to march 2007.

**Winter construction suggestions on Shijiazhuang subway station concrete**

Try to reduce the dosage of cement, but the minimum dosage of silicate cement should not be less than 300 kg/m3; Water cement ratio should be controlled in 0.45, not higher than 0.55. Secondary fly ash dosage should be increased, generally between 15% to 30%; Add high efficiency water reducing agent, or compound admixture with high efficiency water reducing function, retarder, and etc; Appropriately choose silicate cement of strength grade 42.5, with area of no more than 350 m2 / kg, the measured C3A content of cement should not be more than 5%;The anti-cracking water-proofing agent used should accord with JC476-2001 and JC474-1999, and higher technical requirements should be put forward (7 d limit inflation rate in water should not be less than 0.030%, 7 d in water turning to dry air 21 d limit inflation rate not less than - 0.010%, exudation rate not more than 50%, penetration height ratio not more than 35%).

**Conclusion**

Although adding anti-cracking water-proofing agent is an effective method to control concrete crack, but it is not a panacea. The concrete crack control is a complicated system problem, to solve which comprehensive measures are needed. Especially for the winter construction of large volume and long line concrete, in order to prevent concrete from enduring the cold , heat preservation, heat storage and adding mixed antifreeze and other measures should be adopted, to help concrete set and harden as soon as possible, which is construction standard requirements in winter. However, from the perspective favorable to crack control, hydration heat release process of concrete should be slowed down, so as to decrease the difference between the highest temperature inside the concrete and the environment temperature. Antifreeze and reducing the temperature stress of concrete must be considered coordinately to ensure that the quality control of concrete can reach the satisfactory level.

**Keywords:** Shield Construction; Spiral Conveyor Spewing; Response Measures

**Abstract.** Spiral conveyor spewing is a serious danger when the shield tunneling machine crosses water-rich sand stratum. It will lead to the malfunction of dregs discharging and the failure of soil pressure's effective control. It will be a chief reason to influence construction progress and even cause secondary disaster, which led to the serious destroy of the survival environment, such as ground collapse, water leakage in the tunnel. The danger of spiral conveyor spewing and the countermeasures and the method of the project can be stated by the construction experience in some sections, in order to give some suggestion and references to similar engineering.

## Introduction

The stratum is made of grain filling soil, silty clay and fine sand, coarse sand, gravel, sand and gravel in order from top to bottom, see Pig1. According to the exploration report the shield machine is in the gravel sand and gravel stratum [1].

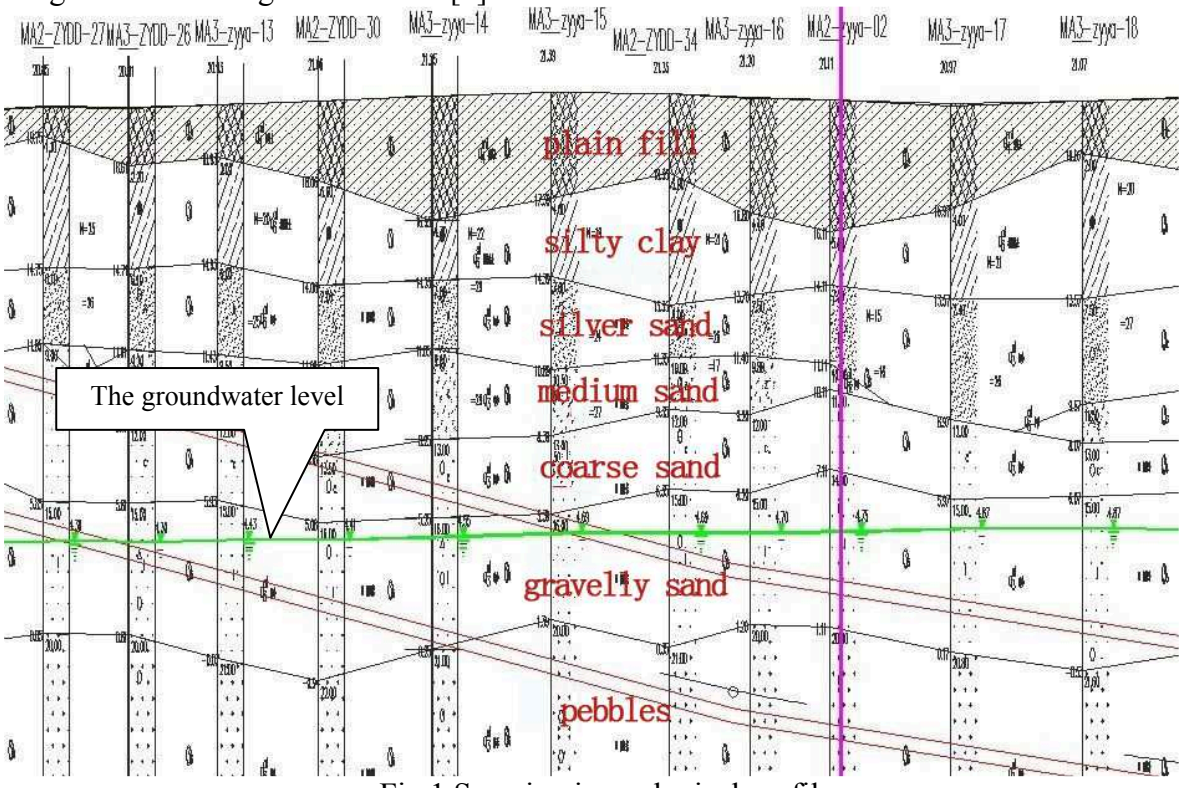

Fig.1 Spewing in geological profile

Gravelly sand: saturated, moderate density, good permeability. Its mechanical properties have obvious thixotropy and liquidity. Its penetration is medium. Under the dynamic water pressure, it has the possibility of soil flowing or piping. On the basis of the Technical Manual on Municipal Soft soil underground construction (in 1990, compiled by Shanghai municipal engineering), the

flowing sand is easy to be caused in gravelly sand layer. Circular gravel: saturated, moderate density, mixed grain size, poor uniformity. The largest diameter of the circular gravel can be 4cm~5cm. The lithological composition in this layer is complicated, it is mainly composed of quartz and sandstone, a little siliceous rock. Roundness of round gravel is better, most of them are sub round ~ round. Permeability is good in this layer. It is rich in water and has high hydraulic permeability. These traits can also cause water gushing and bursting during the construction, thus influencing directly on the safety of construction. The stability of the surrounding rock is poor, so it is easy to collapse and easy to be damaged. Above the underground water level 4.70m is the whole section water rich sand layer.

## The Harm Caused by Spewing and the Mechanism of It

**The Harm Caused by Spewing.** Firstly, a lot of mud is squirted from the screw machine's slag notch, see Pig 2 and Pig 3. It seriously affect construction environment in the connection bridge area and even affect the shield tail and the whole car. So the screw machine must be stopped to clean the waste residue. The waste residue cleaning is time-consuming by manpower. Secondly, when the shield machine stops driving, slag notch of the screw machine is closed, the mud in the soil bin quickly fill the whole screw machine. Once the gate is started again, another spewing will happen, this will form a vicious circle. Then the diving speed should be slow down. It will take a long time to clean the muck. These will seriously influence Shield construction progress. Lastly, due to the uncontrollable quantity of soil slag in the process of spewing, it is difficult to establish the real earth pressure balance. So the perturbation to the stratum will be dramatic and even cause secondary quality accidents, such as surface subsidence [2].

Fig.2 The segment assembling area construction environment after spewing

Fig.3 Construction environment trolley region after spewing

**Spewing Mechanism.** The mechanism of EPB shield tunneling (Pig 4) stabilization is that sand which is left over after the process of cutter cutting is filled with soil warehouses, equilibrating pressure between earth in the soil warehouses and out of the soil warehouses; in the process of digging, screw conveyor is for adjusting speed and amount of excavated soil, equilibrating amount between entering soil and excavated soil, which can ensure stabilization of shield tunneling. If excavation surface exists high pore pressure and permeability coefficient is high, muck at excavation surface will become thin with tremendous mobility [3-7].

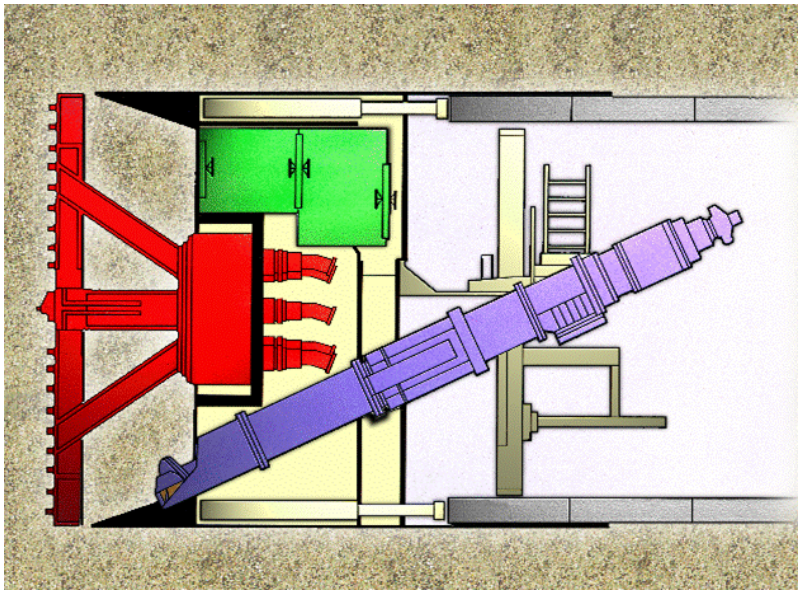

Fig.4 EPB Shield Tunneling

Water body under high pressure which flows soil warehouses and spiral conveyor collects, which will increase pressure in the soil warehouses and back brake of spiral conveyor, cutter torque, and slow down driving speed. When the gate is open, pressure in the soil warehouses decreases; while the gate is closed, water in the strata is soon filled with the soil warehouses, as a result, earth pressure will increase and mud water spurts after opening screw conveyor, which causes that shield fails to work [8-10].

## Reason Analysis

- This location is negative terrain which is easy to collect surface water, and silty clay under plain fill as water-resisting layer, as a concave shape, it is easy to collect the groundwater. If the perched groundwater of plain fill leakage occurs through silty clay, spewing may arise.
- Survey data indicate that, in this section, the plain fill of MA2-ZYDD34 hole, MA3-zyya2 hole, MA2-zyya2 hole and MA3-zyya17 hole is loose, with the clay, sand and a small amount of gravel. This plain fill backfill recently, the permeability and water storage performance in this section are relatively well. It is Easy to form the upper perched water and generate spewing conditions.

- There are drainage pipes above the shield axis surface buried in the region. If the pipes leak, sewage will be gathered in the plain fill, it will be another water leakage conditions. In the process of construction, the tunnel operators can smell peculiar smell which indicates that between spewing water and surface water connections exist.
- Silty clay as water-resisting layer, if it is not serious disturbance or destruction, the leakage will be very weak. In ordinary it can not constitute the spewing conditions, but the exploration drilling penetrates water-resisting layer. If the sealing is not good, it will become a juncture of the perched water and the lower part of the phreatic water. After a certain period of time, there will be form the funnel-like pressure water between the silty clay and phreatic water, the pressure formed by the pressure water acting on the top of the shield. After a certain disturbance in the shield machine construction process, spewing will occur.

**The Countermeasures**

During shield construction process, if the spewing is not treated in a timely and appropriate manner, the water or mud gush was easy to happen. sandy soil around excavation surface and shield tunnel segment will be taken out. These easily lead to construction accidents, such as ground collapse, the seepage of shield tunnel.

Effective measures should be taken to eliminate the spewing as soon as possible, in order to avoid these construction accidents. Construction control measures are listed as following:

- Inject the polymer materials into soil bin after the field engineer testing. Strengthen the workability of residue. Then inject Polymer solution into soil bin after been mixed in the bentonite tank.
- Innovate screw machine slag not, in order to avoid a lot of water and soil flow from belt conveyor. Then the artificial cleaning time will be reduced and ergonomics will be improved.
- To strengthen the surface subsidence monitoring, 24 hours on duty.
- optimize tunneling parameters，adopt the mode of high earth pressure, high thrust tunneling.
- Before tunneling, we should inject polymer into soil bin，then start the cutter. After mixing muck and high-molecular polymer up, the shield machine works again.
- Stop using foaming agent during the tunnel digging. Just use it occasionally in order to avoid the pipe block.
- Do the second grouting in the area which is about the tenth ring around the gushing area to block the water behind shield machine flowing into the soil bin(Fig 5).
- Add a circle of bubbles and the quilt to the outer surface of segment which is assembled in the subsequent steps, to stop the rear water(Fig6).

Fig.5 Secondary grouting

Fig.6 Add a circle of Quilts and foam

## Conclusions

These measures can successfully govern the gushing of screw machine and make the shield machine bail out as soon as possible. Many harmful factors are caused by screw machine spewing, but now quite limited measures can be taken to solve this problem. So we can only try to avoid it in the shield construction. Try to avoid rainwater and sewage pipe lines in the planning the subway route. In the stratum where the spewing easily happens, shield machine should go through as soon as possible. Machines should not stay a long time for the hidden danger increasing.

**Key words:** grey system; GM (1, 1);deformation; non-equal time-interval

**Abstract:** The thesis develops an non-equal time-interval GM (1, 1) model to forecast the deformation of the tunnel surrounding rock. A program is compiled via MATLAB 7.1 platform to implement the model. With the assistance of the program and the monitoring record of the convergence, the deformation is predicted and the error is analyzed. The numerical results indicate that the non-equal time-interval GM (1, 1) model does well in predicting the deformation of tunnel surrounding rock and is worthy to put into use in tunnel engineering.

## Introduction

As is well known, it is difficult to measure or forecast the deformation in tunnel engineering due to unknown of rock formation condition, rock attitude, different geologic progress. In addition, excavation sequence and method, supporting time and method, supporting rigidity etc, also have effects on the stability of the surrounding rock[1]. Thus make the tunneling progress a grey system [2-4] . In order to avoid injured and master the behavior of the rock, develop a effective model to exactly predict the deformation may be necessary.

At present, there are many methods to forecast rock deformation such as regression analysis model, data smoothing processing, time series model, grey model, artificial neural network model, etc. Among these models, the grey system model is widely used in projects and does a good performance with few amount of monitoring data[5-6].

The target of the grey model is a differential equation according to a few data. The demand is the utilizing, developing and processing of the dynamic information.

The primary research object is intrinsic grey system which need a discrete function to simulate the behavior characteristics of grey system. The main task of the grey system is to establish a differential equation dynamic model with discrete sequence, which is known as the grey model GM. [7]

GM(1,1) model is the core content of the grey model, its prerequisite is the equality of the sample period time distance and its main means to processing is to rule the original data to find the relationship.[8] The most commonly methods used is additive. This approach is called number generation.

Generally, the original sequence $x(i)$ shows no regularity but considerable randomness. After its implementation of the accumulated generating:

$$x^{(1)}(i) = \sum_{k=1}^{i} x^{(0)}(k) \tag{1}$$

the new sequence series $x^{(1)}(i)$ can weaken the randomness of the data and make it shows significant feature regularity. Taking the new series $x^{(1)}(i)$ into the grey model GM and then the model was conducted to inverse operation to restore the original sequence.

As we can see, in this process, the time distance are equal. This type of grey system is called equal time-interval grey model. But in the observe progress, because of the weather and construction order and other factors, the sample period time distance are not easy to keep equal.

For a number of issues in many fields, due to changes in conditions or influence of various factors, the time distance is unequal so that it would resulted in large error when use such models. Therefore, constructing an non-equal time-interval grey model has some real needs and theoretical significance.[9]

In view of this, this paper use the non-equal time-interval GM(1,1) model to forecast the convergence of the surrounding rock combining with the data measured from Zhangzhuo expressway Linli tunnel project and confirm the reliability and validity of the model[8].

**Modeling GM (1, 1)**

Based on the time series $t(i)$, a grey progress's original sequence $x_0^{(0)}(i)$ meets the condition:

(1) $t(i)-t(i-1)>0$;

(2) $\exists i, j \in [1,n]$,

$t(i)-t(i-1) \neq t(j)-t(j-1)$ ,

where $1 \le i \le n$, we call it non-equal time-interval grey progress.

Set $\Delta t = t(i)-t(i-1)$, when $\Delta t$ is small, we can construct a new set of time series $t_n(i)$.

$$t_n(i) = b_0 + b_1(i) \tag{2}$$

where $i \in N, b_0, b_1$ are constant.

As we can see $t_n(i)$ and $t(i)$ are very close.

$$\text{Set} \quad \sum_{i=1}^{n}[t_n(i)-t(i)]^2 = \min \tag{3}$$

By Lagrange interpolation principle, we can conclude that:

$$x_1^{(0)}(i) = x_0^{(0)}(i) + \frac{[x_0^{(0)}(i+1)-x_0^{(0)}(i)][t_n(i)-t(i)]}{t(i+1)-t(i)} \tag{4}$$

Throw formula (4), we can get a new series sequence $x_1^{(0)}(i)$ related to $t_n(i)$. The new series is liner and satisfied with the GM (1, 1) model.

According to the principle of least squares and (1),(2),(3),it can be deduced that:

$$\left.\begin{aligned} b_0 &= \frac{\sum t_n(i)}{n} - \frac{b_1 \sum i}{n} \\ b_1 &= \frac{n\sum i t_n(i) - \sum i \cdot \sum t_n(i)}{n\sum t_i^2 - \sum i^2} \end{aligned}\right\} \tag{5}$$

$$\frac{dx^{(1)}(i)}{di} + a_1 x_1^{(1)}(i) = a_2 \tag{6}$$

$$\text{Set} \quad B = \begin{bmatrix} -[x_1^{(1)}(1)+x_1^{(1)}(2)]/2 & 1 \\ -[x_1^{(1)}(2)+x_1^{(1)}(3)]/2 & 1 \\ \cdots & \cdots \\ -[x_1^{(1)}(n-1)+x_1^{(1)}(n)]/2 & 1 \end{bmatrix}$$

Then $a_1$ and $a_2$ meets:

$$[a_1 a_2]^T = (B^T B)^{-1} B^T y^n \tag{7}$$

Thus, we can have the following equation:

$$x^{(1)}(k) = (x^{(0)}(1) - \frac{a_2}{a_1}) e^{a_1(1-k)} + \frac{a_2}{a_1} \tag{8}$$

The equation (8) is an equal time interval grey model. After taking formula (2) into (8) we can draw the non-equal time-interval GM (1, 1) model responsive equation as:

$$x_0^{(1)}(t) = [x^{(0)}(1) - \frac{a_2}{a_1}] e^{a_1(1-\frac{t-b_0}{b_1})} + \frac{a_2}{a_1} \tag{9}$$

Calculate the value of each point in $x_0^{(1)}(t)$ and regressive reduction to get the fitted value related to the original data. The reduction formula for generating is:

$$\hat{x}_0^{(0)}(t) = \frac{(x_1^{(0)}(1) - \frac{a_2}{a_1})(1 - e^{a_1}) e^{a_1(b_0 + b_1 - t)}}{b_1} \tag{10}$$

**Model accuracy test**

(1) Residual test

Absolute error of the prediction is:

$$\varepsilon^{(0)}(k) = X^{(0)}(k) - \hat{X}^{(0)}(k) \text{ ,k=1,2,…,n} \tag{11}$$

The relative error of prediction is:

$$q = \left| \frac{\varepsilon^{(0)}(k)}{X^{(0)}(k)} \right| \times 100\% \tag{12}$$

(2) Posterior error test

$$S_1 = \frac{1}{n} \sum_{k=1}^{n} [x^{(0)}(k) - \bar{x}]^2 \quad \bar{x} = \frac{1}{n} \sum_{k=1}^{n} x^{(0)}(k)$$

$$S_2 = \frac{1}{n} \sum_{k=1}^{n} [\varepsilon^{(0)}(k) - \bar{\varepsilon}]^2 \quad \bar{\varepsilon} = \frac{1}{n} \sum_{k=1}^{n} \varepsilon^{(0)}(k)$$

The posteriori error ratio is:

$$c = S_2 / S_1 \tag{13}$$

Small error probability is:

$$p = p\{|\varepsilon(k) - \bar{\varepsilon}| < 0.6745 S_1\} \tag{14}$$

**Table 1 Accuracy class reference table**

| | posteriori error ratio C | Small error probability P | Result |
|---|---|---|---|
| Ⅰ | c≤0.35 | P≥0.95 | Excellent |
| Ⅱ | c≤0.50 | P≤0.95 | Good |
| Ⅲ | c≤0.65 | P≤0.80 | Pass |
| Ⅳ | c＞0.65 | P＜0.70 | Fail |

According to the descending order of P and C, the prediction accuracy can be divided into four categories as the Table1 shows.

## Engineering practice

The model developed above was used to predict the convergence of the surrounding rock in Linli tunnel, Zhangzhuo expressway engineering. The data was measured by JSS30A type digital device. The method to note the record is to read three value each time, the final record is the average of the three reading records. Because of the construction and human factors, the records were noted in non-equal time distance. In order to improve the prediction accuracy, the record was intercepted; the middle section was used to the prediction. The prediction program was compiled via MATLAB 7.1 platform.

Table 2 is the YK79+010-section convergence monitoring records after temperature correction. Table 3 is the contrast of monitoring and predicted value.

| **Relative error/%** | **0.92** | **0.68** | **0.89** | **0.66** | **0.31** | **0.43** | **0.39** | **0.39** | **0.36** | **0.41** | **0.21** |

The non-equal time-interval GM (1, 1) model responsive equation is

$$\hat{x}_0^{(0)}(t) = (7.235 - \frac{7.1508}{-0.0053})(1 - e^{-0.0053})e^{-0.0053(1-t)}$$

Absolute percentage error is 0.041786%; posteriori error ratio $c = 0.136734$ ; small error probability P=0.9545; excellent rate for Ⅰ.

The results indicate that the non-equal time-interval GM (1, 1) model is considered exactly accurate. The predicted value coincides perfectly with the measured data.

## Conclusions

1.This article developed an non-equal time-interval GM(1,1) model, predicted the convergence of the surrounding rock in Linli tunneling engineering with a small amount of data, provided a theoretical basis on deformation prediction.

2. The accuracy test of the model shows the excellent rate for, I ,which ensure the predicted value reliable and truthful.

3. With the utilizing of measured data and MATLAB 7.1 platform, the paper demonstrated the rationality of taking tunnel deformation as a grey model and the feasibility of using the model to forecast the value.

4. The engineering example confirmed that the non-equal time-interval GM (1,1) model shows a good performance in short time distance. However, the model is in an exponential form, when the time distance become longer, its predictive ability remains further proof.

**Keywords:** shallow tunnel, surrounding rock pressure, limit analysis

**Abstract.** The upper bound method of limit analysis is used for surrounding pressure calculation of shallow tunnel. Two rigid-block translational collapse mechanisms are assumed for shallow tunnel and the corresponding formulas are deduced. The earth pressure of shallow tunnel has been transformed into a mathematic optimization problem, we can get optimization solutions for the surrounding rock pressure by corresponding calculating program. It is concluded that the upper bound method of limit analysis is a feasible approach for the determination of surrounding pressures on shallow tunnel.

## Introduction

As the tunnel designing, the core problem is how to determine the reasonable supporting parameters of tunnel surrounding rock, and the failure modes are determined by the supporting parameters of tunnel surrounding rock failure mode,so the research is of great significance for the structural design of tunnel. Because of the model test uses the real material in reality, it can reflect the spatial relationship between geological structure and engineering structure at the basic principle in similar conditions, so it more intuitively reflects the overall characteristics of geotechnical engineering mechanics, deformation and failure characteristics.

## The collapse mechanism of shallow buried tunnel surrounding rock

There are many factors influencing the surrounding rock pressure of shallow tunnel, we only consider the surface as level here, and it simplified as a plane strain problem, and we make the following Basic assumption:

(1) The tunnel with circular cross section is simplified as a rectangular section which highs H, span of 2b, and H and 2b are diameter, irregular shaped section can also be simplified to rectangle, to do so doesn't lose generality. (2) We suppose the surrounding rock of tunnel is elastic perfectly plasticity body, the c-material obeys the Mohr Coulomb yield criterion. (3) The overburden thickness of tunnel is h, the subjected uniform supporting force of tunnel roof is q, the horizontal uniform supporting force of side wall is e, e=Kq, K is parameters.(4) The side walls moving inwards is allowed in the deformation of the tunnel mode, the vertical of roof moves downward. At the same time, the movement of side wall and roof dosn't affect from each other, the support structure may be appropriate to move in order to adapt to the deformation of surrounding rock, and the mutual friction of surrounding rock in the deformation process of mutual is ignored.

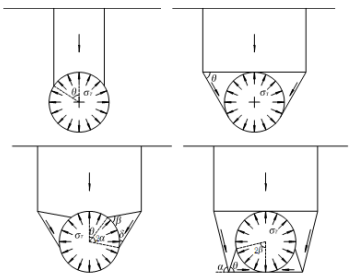

Fig.1 Collapse mechanisms of shallow tunnel in cohesive material

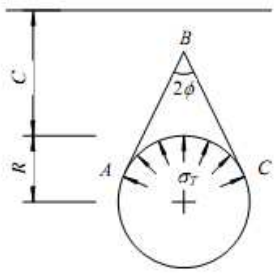

Fig.2 Collapse mechanism of shallow tunnel in cohesionless material

Formulating a suitable structure of shallow tunnel surrounding rock failure mode is the key to calculate the surrounding rock pressure by upper bound method, usually through the analysis of engineering example, model test or numerical calculation methods. Usually collapse mechanism includs rigid block rotation and translation, translation and rotation combined form. In practical application, the translational collapse mechanism is the one most commonly used [1]. Figure 1 is the four kinds of failure modes of [2] clay of shallow buried tunnel proposed by Davis E H. Figure 2 is a cohesionless soil and shallow buried tunnel surrounding rock collapse mechanism proposed byAtkinson J H and Potts DM[3].

Collapse mechanism that figure1 and figure2 showing basicly reflects the main collapse forms of cohesive and cohesionless soil about shallow buried tunnel, but still rough. Therefore,to the shallow buried tunnel constructed by the new Austrian Tunneling Method, the C-φ materials as surrounding rock, two kinds of collapse mechanism is presented in Figure3, shown in Figure4 (based on the mode A and mode B) in translational mode, and assuming that the tunnel roof and side wall support force are uniformly distributed, but it's not the same.

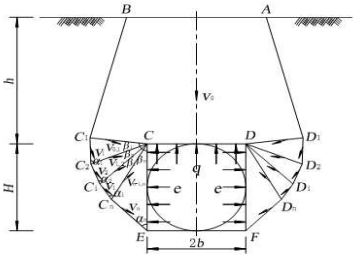

Fig.3 Collapse mechanism A

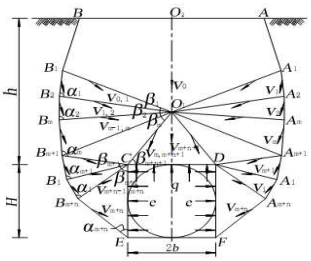

Fig.4 Collapse mechanism B

According to the associated flow rule, speed rigid slider between discontinuous velocity vector line and discontinuous line is the angle $\varphi$, and the velocity vector should satisfy the vector closure, then can get the tunnel overall buckling collapse mechanism A the corresponding velocity field as shown in figure5. The velocity of the roof above the wedge $ABC_1CDD_1$ is $\nu_0$, vertical downward. Speed at the side wall of the triangular block from top to bottom is $\nu_0$ in turn, their relative speed is $\nu_1 \cdots \nu_i \cdots \nu_n$, the relative velocity in each triangular shape followed and the determined by the angle $\alpha_1 \cdots \alpha_i \cdots \alpha_n$ and $\beta_1 \cdots \beta_i \cdots \beta_n$ , (Fig. 3).

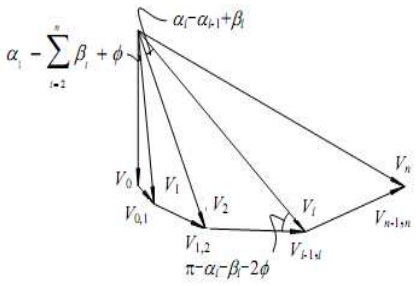

Fig.5 Velocity field for collapse mechanism A

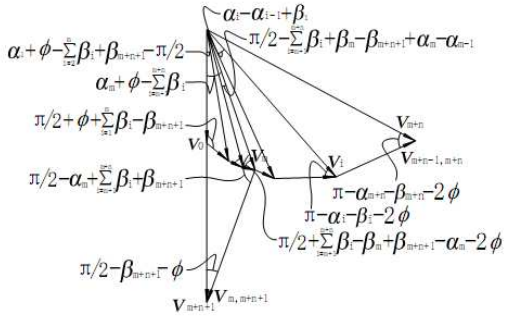

Fig.6 Velocity field for collapse mechanism B

The velocity field figure 6 for the collapse mechanism to the corresponding B. The velocity of the wedge $AO_2BB_1O_1A_1$ is $\nu_0$, vertical downward. The wall above the speed of the triangular block from top to bottom $\nu_1 \cdots \nu_{m-1}$ in turn, the relative velocity between the order, quadrilateral slider velocity $B_mB_{m+1}CO_1$ between side wall and roof top is $\nu_m$ ,form and collapse mechanisms of side wall is similar to the A slider, slider velocity from top to bottom $\nu_{m+1} \cdots \nu_i \cdots \nu_{2,m+n}$ in turn, roof top triangle slider $CDO_1$ velocity is $\nu_{m+n+1}$, direction vertical downward, and the relative speed of slide $B_mB_{m+1}CO_1$ is $\nu_{m,m+n+1}$. The collapse mechanism is determined by $\alpha_1 \cdots \alpha_i \cdots \alpha_{m+n}$ and $\beta_1 \cdots \beta_i \cdots \beta_{m+n}, \beta_{m+n+1}$ (Fig. 4).

**Maximum limit analysis method**

Maximum limit analysis theorem can be stated as:to the plasticity strain rate field $\dot{\varepsilon}_{ij}^{*}$ and velocity field $v_i^{*}$ of arbitrary movement permit, the limit load $F_i$ determined by the virtual power equation (1) is same or greater than the limit load of the real $F$ [4]:

$$\int_S F_i v_i^{*}\,\mathrm{d}S+\int_A \gamma_i v_i^{*}\,\mathrm{d}A=\int_A \sigma_{ij}\dot{\varepsilon}_{ij}^{*}\,\mathrm{d}A+\int_{S_D}(\tau-\sigma_n\tan\phi)\Delta v_i^{*}\,\mathrm{d}S \qquad (1)$$

The limit load in type (1)is the load prompting system damage. Assuming the material obeys the Mohr Coulomb yield criterion and associated flow rule [4], for two-dimensional problems, velocity discontinuity lines as power dissipation is:

$$D=cv\cos\phi \qquad (2)$$

**Mechanical calculation**

Mechanical calculation according to the collapse mechanism A. The calculation of velocity field to movement permission. According to the permissive condition that rigid sliding should meet, The velocity vector should meet the closure conditions[4] , According to figure 3 , figure 5,each velocity should satisfy the following recurrence relationseach:

$$v_1=\frac{\sin\left(\sum_{i=1}^{n}\beta_i+\phi\right)}{\sin(\pi-\alpha_1-\beta_1-2\phi)}v_0 \qquad (3)$$

$$v_{0,1}=\frac{\sin\left(\alpha_1-\sum_{i=2}^{n}\beta_i+\phi\right)}{\sin(\pi-\alpha_1-\beta_1-2\phi)}v_0 \qquad (4)$$

$$v_{i+1}=\frac{\sin(\alpha_i+2\phi)}{\sin(\pi-\alpha_{i+1}-\beta_{i+1}-2\phi)}v_i \quad (i=1,\cdots,n-1) \qquad (5)$$

$$v_{i,i+1}=\frac{\sin(\alpha_{i+1}-\alpha_i+\beta_{i+1})}{\sin(\pi-\alpha_{i+1}-\beta_{i+1}-2\phi)}v_i \quad (i=1,\cdots,n-1) \qquad (6)$$

The calculation of the gravitational power. As it is shown in Figure 3,when the shallow buried tunnel suffers destruction , gravity power is equal to all rigid blocks' gravity power.So,we need calculate the rigid block area and their speed in the vertical direction component.The recursive relations of each velocity discontinuity length are as follows：

$$BC_1=\frac{1}{\cos\phi}\left(h-CC_i\cdot\cos\sum_{j=1}^{i}\beta_j\right) \qquad (7)$$

$$CC_i=\frac{\sin\alpha_i}{\sin(\pi-\alpha_1-\beta_i)}CC_{i+1} \quad (i=1,\cdots,n-1) \qquad (8)$$

$$CC_{i+1}=\frac{\sin\beta_i}{\sin(\pi-\alpha_i-\beta_i)}CC_{i+1} \quad (i=1,\cdots,n-1) \qquad (9)$$

$$CC_n=\frac{\sin\alpha_n}{\sin(\pi-\alpha_n-\beta_n)}CE \quad (i=1,\cdots,n-1) \qquad (10)$$

$$C_nE=\frac{\sin\beta_n}{\sin(\pi-\alpha_n-\beta_n)}CE \quad (i=1,\cdots,n-1) \qquad (11)$$

Each rigid block area respectively is as follows：

$$\Delta CC_iC_{i+1}=\frac{1}{2}CC_i\cdot C_iC_{i+1}\cdot\sin(\pi-\alpha_i-\beta_i) \quad (i=1,\cdots,n-1) \qquad (12)$$

$$\Delta CC_nE=\frac{1}{2}CC_n\cdot C_nE\cdot\sin(\pi-\alpha_n-\beta_n) \qquad (13)$$

$$\frac{1}{2}\square ABC_1CDD_1=\frac{1}{2}BC_1\cdot CC_1\cdot\sin\left(\sum_{i=1}^{n}\beta_j-\phi_n\right)+\frac{1}{2}\left[2b+CC_1\cdot\cos\left(\sum_{i=1}^{n}\beta_i-\frac{\pi}{2}\right)-BC_1\sin\phi\right] \quad (14)$$

According to equation (3) - (14) and the rigid block velocity vector together with the vertical angle,we can get half of the failure mode of gravity power called $P_\gamma$:

$$\int_S P_\gamma=\int_A\gamma_i v_i^*\,\mathrm{d}A=\frac{1}{2}\square ABC_1CDD_1\cdot\gamma v_0+\frac{1}{2}\Delta CC_nE\cdot\gamma v_n\cdot\cos(\alpha_n+\phi)+\gamma\cdot\sum_{i=1}^{n-1}\left[\Delta CC_1C_{i+1}\cdot v_0\cdot\cos(\alpha_i+\phi)-\sum_{j=i+1}^{n}\beta_j\right]\frac{n!}{r!(n-r)!} \quad (15)$$

The calculation of dissipation power. The dissipation power can be calculated according to equation (2), half of the total power dissipation called Pe also can be calculated according to the following equation:

$$\int_S P_e=\int_{S_D}(\tau-\sigma_n\tan\phi)\Delta v_t^*\,\mathrm{d}s=c\cdot\cos\phi\left[\sum_{i=1}^{n-1}\left(C_iC_{i+1}\cdot v_i+CC_i\cdot v_{i-1,i}\right)+BC_1\cdot v_0+C_nE\cdot v_n\right] \quad (16)$$

The calculation of Supporting force power. The power of vertical supporting force of tunnel roof called q and horizontal side wall supporting force called e can be calculated as following:

$$P_T=\int_S F_i v_i^* dS=-bqv_0-HKqv_n\cdot\sin(\alpha_n+\phi) \quad (17)$$

The calculation of support reaction force. Throug feding equation (15)-(17) into equation (1),we can get the tunnel roof vertical support reaction called q:

$$q=\frac{p_\gamma-p_c}{bv_0+HK\cdot\sin(\alpha_n+\phi)v_n} \quad (18)$$

The optimization of the upper limit solution to surrounding rock pressure. For the collapse mechanism A,assuming that the tunnel side wall of the triangle number is n,so we can determine its shape according to a group of angle $\alpha_1\cdots\alpha_i\cdots\alpha_n$ and $\beta_1\cdots\beta_i\cdots\beta_n$, correspond to an upper bound solution called Q at the same time ,that is $q=f(\alpha_1,\cdots,\alpha_i,\cdots,\alpha_n,\beta_1,\cdots,\beta_i,\cdots,\beta_n,)$. According to the upper bound theorem, maximum q that meet the licensing conditions is corresponding to an optimal solution to this collapse mechanism. So the problem changes:On condition of meeting physical constraint conditions,seek the maximum value of the objective function. From Figure 4,the angle between the velocity vector must be positive.Then, the constraints to collapse mechanism called A are as bellow:

$$\begin{cases}\alpha_1-\sum_{i=2}^{n}\beta_i+\phi>0\\ \pi-\alpha_i-\beta_i-2\phi>0 \quad (Among\ them\ i=1,\cdots,n)\\ \alpha_i-\alpha_{i-1}-\beta_i>0 \quad (Among\ them\ i=1,\cdots,n)\end{cases} \quad (19)$$

As for the failure mode of B,according to the above steps we can calculate each speed recursive relationship.

## Conclusions

(1) The objective function and constraint conditions of the upper bound method of limit analysis for surrounding rock pressure are get by two collapse mechanisms of shallow tunnel. after that optimization solutions for the surrounding rock pressure can be gotten by corresponding calculating program and an optimization method. (2) For the upper bound method of limit analysis, we need to determine K value of the ratio of the level of uniform support reaction force e and the vertical uniform supporting reaction force q. We should choose multiple K values in practical application so it can get a set of e and q , and then them are checked as structure load. (3) It may form a sliding surface through the earth's surface after Shallow tunnel wre excavated and leading to produce a wide range of plastic area. It is concluded that the upper bound method of limit analysis is a feasible approach for the determination of surrounding rock pressures on shallow tunnel.

**Keywords:** Subway tunnel; Environment vibration; Frequency-domain method; Rail pad; Frequency-dependent stiffness.

**Abstract:** Based on Vehicle-Track Coupling Dynamics and the spectrum analysis technique of the Finite Element Method, a frequency-domain method of environment vibration due to subway is put forward and frequency-range distribution of ground acceleration is discussed. Compared with the measured data, the result shows that after considering frequency-dependent stiffness of rail pad, the error is less than 0.3dB in the frequency range of 0-30 Hz, but it is up to 11.8 dB in the frequency range of 50-100 Hz. And the frequency-domain distribution of ground vibration changes too. Thus, the frequency-dependent stiffness of rail pads is not negligible in the prediction of environment vibration generated by subway.

## Introduction

The vibration and noise induced by subway recently troubles people a lot. To reduce their influence, the vibroisolating material is adopted such as the rail pad, the damping pad under track sleepers or beds and so on. In this paper, the rail pad generally made of viscoelastic rubber material is focused on.

In the past, the stiffness was treated as a constant when dynamic characteristics was analysed. However, the viscoelastic material's dynamic constitutive behavior relies on frequency, temperature and amplitude. So its dynamic performance changes with the frequency. And the wheel-rail force has a wide frequency band. Therefore it's not reasonable to treat the stiffness as a constant.

According to Vehicle-Track Coupling Dynamics and Finite Element Method, the random vibration response of subway system in which the viscoelastic material's stiffness changes with frequency is analysed.

## The Frequency-domain Method of Environment Vibration due to Subway

First, the spectrum of the dynamic random load acting on the fastening system is achieved. Then it's processed to be the linear load which acts on the two dimensional finite element model of the tunnel and foundation. Through the direct integral method of finite element model, the environment vibration level around the subway tunnel can be calculated.

### 1.1 The spectrum feature of the force acting on the subway fastening system

#### 1.1.1 Vehicle-track coupling dynamic model [1]

**(1)Vehicle model**

Subway car can be simplified as a half vehicle system with doubled suspension systems. It has ten freedom degrees including the vertical and nodding motion of the vehicle and the bogies, and the vertical motion of the wheelsets.

**(2)Track model**

The subway common track structure is the monolithic track bed with short sleepers embedded, which is composed of rail, fastener, perforated concrete sleeper and concrete ballastless track bed.

For the sleeper is encastred into the track bed and the mass of the base is big, the vibration mainly reflects on the rail. Thus, the rail is simplified as an Euler beam supported by discrete points.

**1.1.2 The amplitude spectrum of the fastening force**

The vehicle-track vertical system is simplified as a linear spring-damper system. And the response spectrum of freedom degrees is achieved by the classic analysis method of linear random vibration. The specific calculation steps are as follows.

The vibration differential equation of Vehicle-Track Coupling Dynamic System is expressed below.

$$[M]\{\ddot{q}\}+[C]\{\dot{q}\}+[K]\{q\}=\{Q\}=\left[K_f\right][Z_0] \tag{1}$$

Where: $[M]$ is the mass matrix of the system; $[C]$ is the damping matrix of the system; $[K]$ is the stiffness matrix of the system; $[K_f]$ is the transformation matrix of the system; $\{Q\}$ is the generalized force vector of the system; $\{q\}$ is the generalized displacement vector of the system; $\{Z_0\}$ is the irregular displacement vector.

If $\{Z_0\}=[I]e^{-j\omega t}$, then $[q]=[H(\omega)]\ e^{-j\omega t}$. $[H(\omega)]$ can be solved by Eq. (1).

$$(-\omega^2[M]+i\omega[C]+[K])[H(\omega)]=\left[K_f\right][I] \tag{2}$$

The transfer function considering the frequency-dependent stiffness can be solved by Eq. (2).

$$(-\omega^2[M]+i\omega[C_\omega]+[K_\omega])[H(\omega)]=\left[K_f\right][I] \tag{3}$$

The relationship between the input and output power density function is achieved by random vibration theory and the transfer function:

$$[S_{out}(\omega)]=\left[H^*(\omega)\right][S_{in}(\omega)][H(\omega)]^T \tag{4}$$

Where: $[H(\omega)]$ is the vibration transfer function matrix of the system; $[H^*(\omega)]$ is the conjugate function matrix of $[H(\omega)]$; $[H(\omega)]^T$ is the transposed matrix of $[H(\omega)]$. To simplify the power spectrum of the output response, the transfer function matrix of the single input-output system with multiple degrees of freedom is put forward.

$$[H_s(\omega)]=[H_1(\omega)]e^{-j\omega\tau_1}+[H_2(\omega)]e^{-j\omega\tau_2}\quad\cdots+[H_n(\omega)]e^{-j\omega\tau_n} \tag{5}$$

Where: $[H_s(\omega)]$ is the transfer function matrix of the response of all freedom degrees in the system with the excitation of n wheelsets.

$$\tau_1=0\qquad\tau_i=\Delta l/v \tag{6}$$

Where: $\Delta l$ is the distance between the first wheelset and the $i$th wheelset (m); $v$ is the speed of the vehicle (m/s).

Then the response power spectral density of different freedom degrees is achieved by calculating the transfer function matrix $[H_s(\omega)]$.

$$S_{qi}(\omega)=\left|H_s(\omega)\right|^2 S_{11}(\omega) \tag{7}$$

$$\ddot{S}_{qi}(\omega)=\omega^4 S_{qi}(\omega) \tag{8}$$

Where: $S_{qi}(\omega)$ is the power spectral density of the displacement response of the $i$th freedom degree; $\ddot{S}_{qi}(\omega)$ is the power spectral density of the acceleration response of the ith degree of freedom; $S_{11}(\omega)$ is the power spectrum density of the track irregularity under the wheelset 1; $H_{s(i,1)}(\omega)$ is the transfer function matrix of the frequency response of the $i$th freedom degree.

Assuming the vehicle speed is 80 km/h and the track irregularity comes from the fifth grade track irregularity PSD of U.S. railways (wavelength ranging from 0.1 to 100 meters), the power spectral density amplitude spectrum of the force acting on the fastener whose stiffness is 40 or 50 kN/mm is shown in Fig. 1.

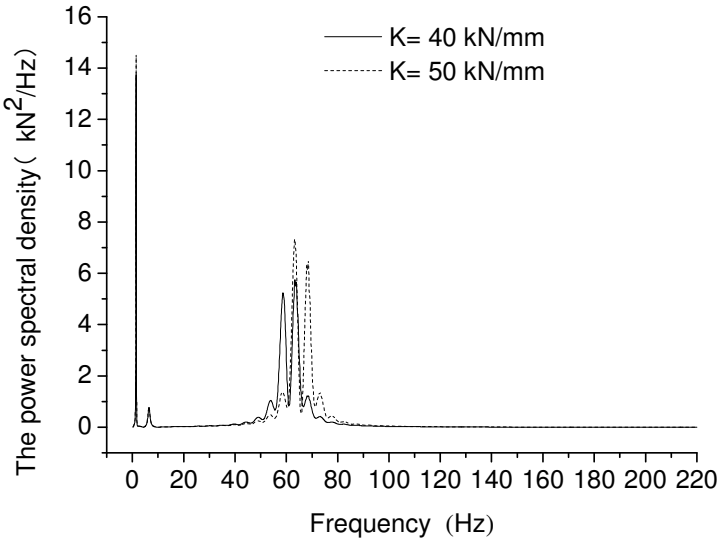

Fig. 1 The power spectral density of the force acting on the fastener

As shown in Fig. 1, the frequency-domain distribution and the amplitude of the dynamic random load change with the fastener stiffness. And the dynamic load is especially sensitive to the fastener stiffness changing. Thus, the frequency-dependent stiffness must be taken into consideration in the analysis of wheel-rail dynamic system.

Usually, the stiffness of rail pad increases with the frequencies raising. But it's a pity few researchers study the frequency-dependent stiffness of rail pads. Some research conclusions show the stiffness was linear with the frequency under the logarithmic coordinate, to see the Eq. (9). The approximate frequency-stiffness curve of the rail pads in the test line can be given based on the Eq. (9) when treating $f$ as 4 Hz and taking $K$ as 40kN/mm.

$$\log_{10}^{y} = 0.1306(\log_{10}^{x} - \log_{10}^{f}) + \log_{10}^{K} \tag{9}$$

Based on the above analysis and the frequency-dependent stiffness of the rail pad being 40kN/mm at 4 Hz. Then the spectrum of the dynamic random load is shown in Fig. 3 after considering the frequency–dependent stiffness of rail pad.

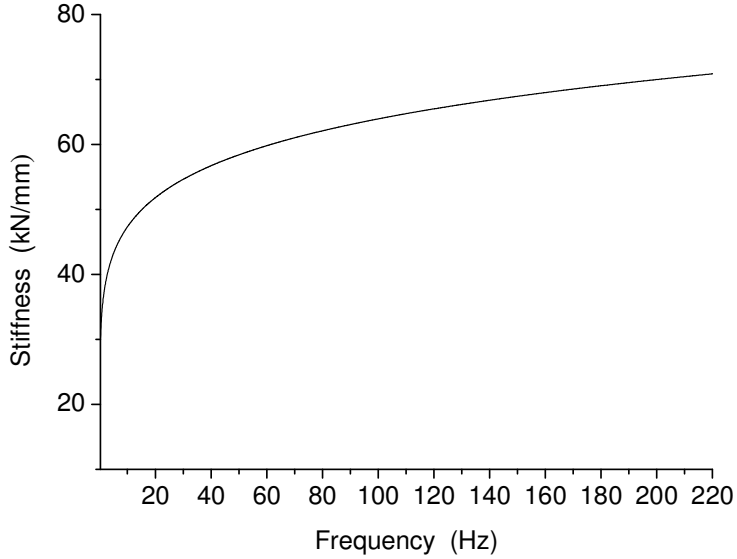

Fig. 2 The relationship between the stiffness of rail pad named **DT VI 2** and the frequencies based on the tested fitting curve

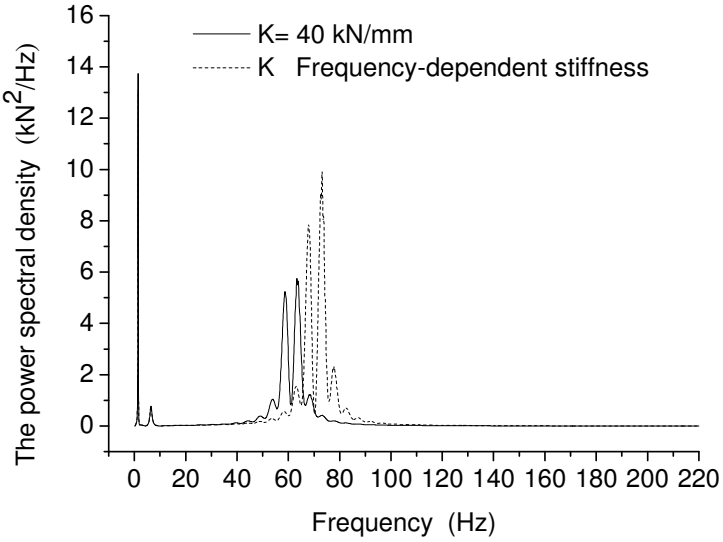

Fig. 3 The dynamic random load acting on the fastener whether considering the frequency-dependent stiffness of the rail pad

### 1.1.3 The simulation of the equivalent linear load about the force acting on the subway fastener

The dynamic random load acting on the subway fastener should be processed to be equivalent linear load so that the subway tunnel can be simplified as the two-dimensional tunnel-foundation model to solve. The Ref. [2] puts forward an equivalent linear load formula(Eq. (10)) whose calculation accurancy depends on $K_0$. But $K_0$ ranges from 0.6 to 0.9, so the calculation error is a little large and the fastener's stiffness and the fastener spacing are not considered.

$$L_F(t) = K_0 \cdot \frac{P(t) N_b n_w}{L_{car}} \tag{10}$$

Where: $L_F(t)$ is the linear load evenly distributed along the center line of the track (kN/m); $P(t)$ is the measured vertical load acting on the rail(kN); $N_b$ is the number of the bogies of one vehicle ($N_b$=2); $n_w$ is the number of the wheelsets of one bogie ($n_w$=2); $L$ is the length of one carriage ($L$=22.1m).

The noise and vibration evaluation ideas put forward by the Federal Railroad Administration in 2006 introduced the concept of force density. The force density means the traffic load per meter(N/m) which is averaged in the length of one car. The result will be treated as the equivalent linear load. According to the static calculation, it's found one wheel force can be supported by at least 3 fasteners whose spacing is about 1 meter. In one meter range, the equivalent uniformly distributed load seems the ratio between $P(t)$ (the fastener force) and $d$(the fastener spacing). In this method, the fastener's stiffness can be taken into consideration, to see Eq. (11).

$$F(t)=\frac{2P(t)N_b n_w}{L} \tag{11}$$

Where: $F(t)$ is the linear load evenly distributed along the center line of the track; $P(t)$ is the fastening force.

Because of the symmetry, half of the tunnel structure and load ($F(t)$/2) are analysed in this paper. So the equivalent load of the amplitude of the spectrum by Eq. (11) is used in this paper to study on the influence of the stiffness of the fastener.

### 1.2 The finite element model of the tunnel and foundation

#### 1.2.1 The model parameters and boundary conditions

Researches show that the precision of the dynamic calculation will be sufficient when the width of the soil model is 15 times the width of the tunnel diameter and the depth is 7 times the depth of the tunnel depth[3,4]. At the test site, the diameter is 6.2 meters and the depth is 6 meters.So the model is made 100 meters wide and 50 meters deep.

Moreover, the minimum size of the soil layer should be 1/12 times the stratigraphic shear wavelength to obtain sufficient accurancy($\lambda_s=C_s/f$). For the vibration frequency range which has great effect on the human body is 1-80 Hz and the shear wave velocity is shown in Table 1, the minimum size of the soil layer is at least 0.2 meter.

A horizontal displacement constraint is applied at the axis of symmetry and fixed constraint is applied on the bottom. To guarantee precision, the free boundary is applied in the far-field region .

#### 1.2.2 The dynamic parameters of the soil layer

**(1)The dynamic shear modulus**

The Martin-Davidenkov Model can be used to compute the dynamic shear modulus in Eq. (12).

$$\frac{G_d}{G_{\max}}=1-\left[\frac{\left(\frac{\gamma_a}{\gamma_0}\right)^{2B}}{1+\left(\frac{\gamma_a}{\gamma_0}\right)^{2B}}\right]^A \tag{12}$$

$$G_{\max}=x\rho V_s^y \tag{13}$$

Where: $G_{max}$ depends on Eq. (13); $G_{max}$ is the maximum dynamic shear modulus; $G_d$ is the dynamic shear modulus; $\gamma_0$, $A$ and $B$ ($\gamma_a=10^{-5}$) is shown in the Ref. [5]; $x$ and $y$ is the curve fitting constants whose values are suggested in Ref. [6] and [7]. To clay soil: $x$=20.9, $y$=1.28; To sand: $x$=30.0, $y$=1.29.

The relationship between shear modulus and elasticity modulus is shown in Eq. (14).

$$E_d=2G_d(1+\mu) \tag{14}$$

**(2)The dynamic damping**

The dynamic damping ratio D is calculated according to Eq. (15) where $\varphi$ and $D_{\max}$ come from Ref. [5]. In the finite element model, rayleigh damping matrix is adopted. The proportional damping coefficient $\alpha$, $\beta$ is calculated assuming $f_1$ and $f_2$ is 10 and 80 Hz respectively.

$$D = D_{\max}(1-\frac{G}{G_{\max}})^{\varphi} \tag{15}$$

Table 1 Soil Parameters

| Soil category | The thickness of soil layer (m) | Density (kg/m$^3$) | Shear wave velocity(m/s) | Dynamic modulus (MPa) | Damping ratio | Poisson's ratio |
|---|---|---|---|---|---|---|
| Silty clay | 12.5 | 1740 | 190 | 75.0 | 0.01 | 0.3 |
| Silty-fine sand | 30 | 1860 | 340 | 250.3 | 0.014 | 0.3 |

**Analysis of the Results**

**2.1 The test site of Nanjing subway in tunnel**

Nanjing Metro Line 1 begins from Bridge Maigao and ends to China Pharmaceutical University. It's 39.7 kilometres long. There are 27 stations along it. The subway train are marshaled by six Vehicle A whose highest speed is 80 km/h. The test site between the Station Zhongsheng and the Station Xiaoxing is so spacious that the background vibration is very small. In addition, the soil layer is obviously divided into two layers where the upper layer is silty clay and the lower layer is silty-fine sand.

The track structure consists of 60kg/m rail, Fastener DT VI2(shown in Fig. 4) and the monolithic concrete bed. The static stiffness of the fastening system is composed of the fastening element stiffness $K_c$ and the rail pad stiffness $K_p$. The static stiffness $K$ is 30kN/mm. But $K_c$ is only 0.5~1.2kN/mm. So $K_p$ is approximately equal to $K$. Moreover, the dynamic and static stiffness ratio of the Fastener DT VI2 is 1.2-1.4 at the frequency of 4 Hz. So the dynamic stiffness is about 36kN/mm~42kN/mm. The value was set as 40kN/mm at 4 Hz.

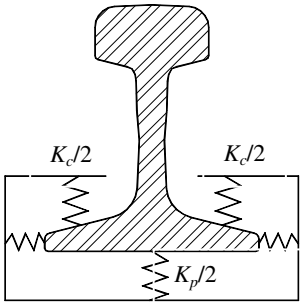

Fig. 4 The mechanical model of the fastener

**2.2 The influence of frequency-dependent stiffness of rail pads on environment vibration**

Under the condition: the speed-80km/h, $K$-40kN/mm and the irregularity-the fifth grade track irregularity PSD of U.S. railways. The vertical ground vibration acceleration in 1/3 octave at the position 5m away from the tunnel center is extracted to compare with the measured data.

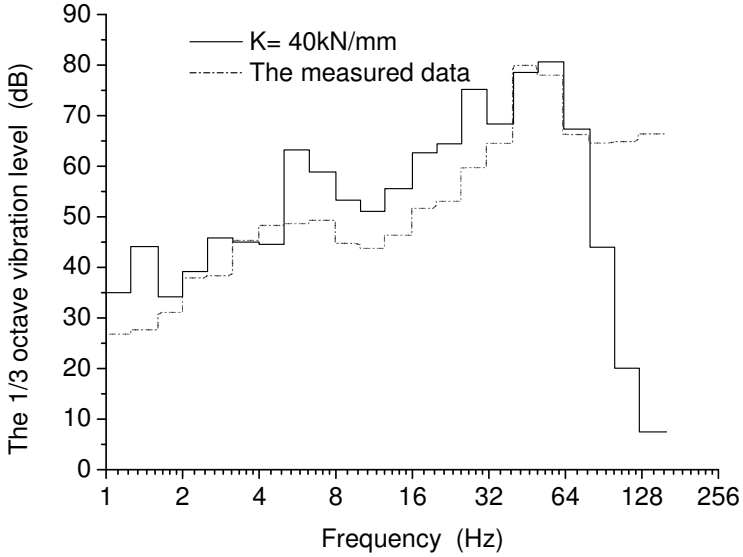

Fig. 5 The comparison of the measured data and the results with *K* being 40kN/mm

Compared with the measured data, they agree well on the whole. And the gaps between them are 1.3dB and 2.6dB at the center frequency 50 Hz and 63 Hz. But the gaps are 7-14 dB at the center frequency 1.6 Hz and 6.3-31.5 Hz.

For the load peak calculated from the fifth grade track irregularity PSD of U.S. railways appears at 1.6 Hz and 6.3 Hz. It means the actual irregularity of the track is different from the fifth grade track irregularity PSD of U.S. railways at the wavelength $V/f$=50m and 12.7m.

In conclusion, the method put forward in this paper agrees with the measured data well.

**2.3 The influence of frequency-dependent stiffness of rail pads on environment vibration**

The environmental vibration is calculated according to whether taking the frequency-dependent stiffness into consideration. Compare their 1/3 octave vibration level as follows.

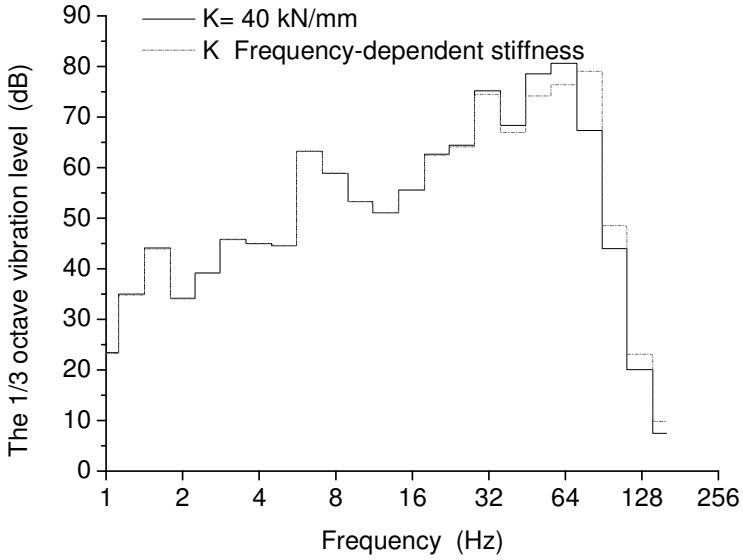

Fig. 6 The result of K being 40kN/mm and the frequency- dependent stiffness

As shown in Fig. 6, the difference of the response in the low frequency range can be ignored. In the range of frequency less than 30 Hz, the difference is less than 0.3dB. But the difference is a little large

when the frequency is more than 30 Hz. And the gap is up to 11.8dB at 80 Hz. The gap decreases when the frequency is more than 80 Hz. Given all these, the frequency-dependent stiffness of rail pads in the analysis of environmental vibration induced by subway must be considered, especially in the project where a lot of rubber material is used.

## Conclusions and Suggestions

**(1)** The calculated results agree with the measured data well, so the calculation model and the selection of parameters are reasonable. The accurancy and the efficiency of frequency-domain solution are high.

**(2)** By comparing the 1/3 octave vibration level of vertical ground acceleration after considering the frequency-dependent stiffness of rail pad, the result shows:

The gap is less than 0.3dB in the center frequency range of 0-30 Hz;

The maximum gap is 11.3dB at the center frequency more than 30 Hz and the frequency-domain distribution also changes;

In a word, if the frequency-dependent stiffness of rail pads in wheel-rail dynamic system is ignored, the prediction accurancy of environment vibration in the frequency domain is hard to ensure.

# Tunnel collapse treatment technique Research in Xinjiang Tianshan high-altitude, low-temperature Mountain

ZHU Chun-sheng[1],YANG Xiao-hua[1]

(Key laboratory for Special Area Highway Engineering of Ministry of Education,

Chang'an University,Xi'an 710064,China)

**Keywords:** Tunnel Collapse Treatment technique

**Abstract:** Based on YuXiMoLeGai tunnel in G217 Cholma to the Nalati highway, aiming at the outlet section of K723+911~K723+919 collapse, through model experiment and numerical calculation combined with on-site measurement, the article studies tunnel collapse treatment technique and technical effect in xinjiang tianshan mountains in the geological conditions of high altitude, low temperature, crushing of rock mass and rock rich in water. The results show that after the CRD method, expanding the scope of the grouting construction, increasing the number of small duct grouting lock foot, strengthening methods of supporting parameters are adopted, vault subsidence deformation rate is 0.4-1.5 mm/d, peripheral convergence deformation rate is 0.5-2.2 mm/d, stress the most unfavorable right hance monthly increase in stress and strain amplitude is 3.97% and 2.35% respectively.The treatment controls the land slide body deformation and stress well.

## 0 Introduction

Along with the accelerating of the construction of the highway transportation in Xinjiang , Urumqi-WeiLi,WenSu-ZhaoSu highway project through the Tianshan mountains will be on the agenda step by step.The highway tunnels will grow up to be project control engineering.

At present, the number of highway tunnel operation in Xinjiang is not much, mainly along the highway such as G30, G217 in the TianShan mountains. In such a complex environment with high altitude, low temperature, crushing rock and rich groundwater, it is less experience to build a road tunnel in Xinjiang even no reliable reference in domestic. The operated SaiLiMuHu tunnel in G30 line built alongside lake has encountered water gushing in its build progress. The project targetly studied the tunnel waterproof material and system. Haxilegen tunnel in G217 line studied the segregation and void treatment technology for dealing with lining seepage, local deformation, cracking and other diseases. The tunnel old G217 was built through Tianshan mountains scrapped soon due to improper collapse treatment coursed forming hollow water into ice frozen. Visibly, recent research focuses on the tunnel waterproof and drainage system, percolating water treatment technology,but it is less for collapse treatment technology research.

In 2009, the reconstruction of G217 Yuximolegai tunnel. Along the full tunnel especially the K723 + 600 ~ K724 + 038 period is surronded by broken rock and rich water, which brought great difficulties to the project. This paper takes K723 + 911 ~ + 919 section of collapse as support, studies tunnel collapes treatment technology in Tianshan mountain in Xinjiang high altitude, cold mountain. This paper can provide technical support for the project land slide treatment and engineering experiences to the construction of highway tunnel in the Tianshan mountains.

## 1 The geological conditions and the land slide

### 1.1 The geological conditions

The exit of Yuximolegai tunnel through 385m fault fracture zone, which is compression and scissor fault derived from Awulela bruchfalten zone, distributed at the top of Yuximolegai. Tunnel cave itself is developed through the formation of joints, groundwater flow, moderate water-rich area. Tunnel entrance is mileage of K722 +095, entrance elevation is about 3200m,and the exit mileage of K724 +038, exit elevation is about 3230m, throughing fault fracture zone at K723 +600 ~ K724 +038, the total length of the tunnel is 1943m. K723 +910 ~ K723 +940 section of tunnel hole body is Ⅴ grade rock, weathered seriously, extremely broken, wet, integrity is poor. The segment with strong chlorite schist ~ weak weathered, soft, easy to soften water, rock Ⅴ grade level. At which K723 +911 chlorite schist right tunnel face by softening effect of groundwater is extremely weak broken.

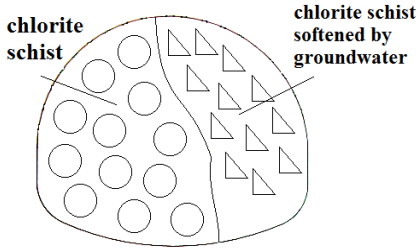

Figure 1 K723 + 911 geology sketch

1.2 Original construction plan and landslides case

The method of large section tunnel construction is in accordance with the usual "three-step seven-step excavation" construction way, and method of pre-grouting small pipe supporting to against rock weak and rich in water. Flault fracture zone segment is Ⅴ Grade Rock , the main support parameters shown in Table 1:

Table 1 The main supporting parameters

| Rock type | Bolt | The grid steel frame | Steel mesh | Shotcrete thickness | Second lining thickness |
|---|---|---|---|---|---|
| V grade | The arch of 120°φ42×3.5， l=3.0m advance grouting pipe, ring distance 0.4m ， side wall hollow grouting anchor diameterφ25，L=3.5，ring, vertical spacing of 1.0×0.5m, plum blossoms. | The 0.5m/ pin spacing | Full set HPB235 phi 6 steel mesh, mesh of 15 x 15cm | 25cm C25 | 50cm C30, S8 Reinforced concrete ， The main reinforcement spacing:20cm |

According to on-site monitoring and measuring, the vault cumulative subsidence curves (Fig. 2) of K723 +911 section from 27 th to 29th of July sedimentation rate accelerated. So at 2:00 on the 29th, at the right side of arch start peeling off and cracking at exit of K723 +911 ~ K723 +919 Yuximolegai tunnel, after that a small amount of sprayed concrete block out. At 5:00 pm, the part sprayed concrete falling off the block, 5:36 ection landslided at the right location demi, the landslides amount of 200 ~ 300m$^3$. Subsequently, landslides off the block has been continued, about 8:00 am, the collapse of the cavity has a small amount of water gushing, 8:50 emerged a large landslide, collapse the entire body will be closed tunnel section, landslides volume 600 m3 ~ 700m3. 9:15 slump continued with plenty of water gushing cavity (Figure 3).

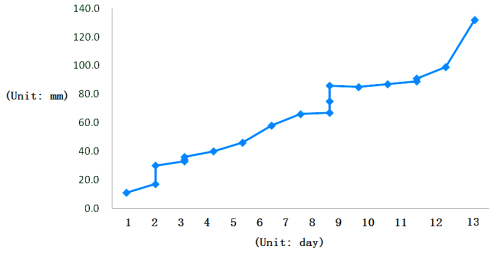

Figure 2 K723 + 911 section of soil slip before vault settlement curve

Figure 3 Tunnel K723 + 911 ~ + 919 section of land slide K723 and running water

According to the engineering geological conditions and soil slip situation description, watering, broken surrounding rock are the major causes of soil slip, the construction plan did not meet the requirements of practical engineering in construction may be a fall-in internal cause. To carry out the groundwater seepage field analysis and broken effect on lining structure stress analysis of surrounding rock is the main research content of this article.

## 2 Numerical analysis of groundwater seepage field changes

The Thermal Seepage model is established (temperature) module adopting the software ADINA, grouting water plugging the water-resisting layer model, the mountain rock using four-node isoparametric plane entity unit (2D - Conduction) Seepage material (Seepage) definition.

Table 2 Geotechnical permeable classification table

| Permeability grade | Standard | | The character of rock mass |
|---|---|---|---|
| | k（cm/s） | q（Lu） | |
| Extremely permeable | K<10-6 | q<0.1 | The intact rock, rock mass containing equivalent opening <0.025mm fracture |
| Medium permeability | 10-4≤K＜10-2 | 10≤q＜100 | Rock containing equivalent opening 0.1-0.5mm fracture |

Take K724 K723 + 500 - + 500 tunnel profile for calculating object (range of about 700 m × 600 m), the water-bearing media of the tunnel area is strong to the weak chlorite schist, soft, easy under the influence of water softening, joint fissure development, crushing of rock mass, see table 2 for rock and soil permeability scale, permeability coefficient $8\times10^{-3}$ cm/s, the grouting body permeability coefficient of $1\times10^{-8}$ cm/s, failure to take 30 kN/m$^3$. A small amount of breccia layers of mountain surface is neglected.

Seepage head pressure and the results of equipotential line distribution, the analysis results are as follows:

Atmospheric precipitation and snow melt water infiltration through strata cranny migration within the mountain, general mountain gradually loss from the left ridge to the right. K723 + 911 in 42.5% of the total water area, the minimum head appeared near the tunnel, as shown in figure 4, head pressure are uniformly distribution of equipotential line and seepage field in the condition of basically stable.

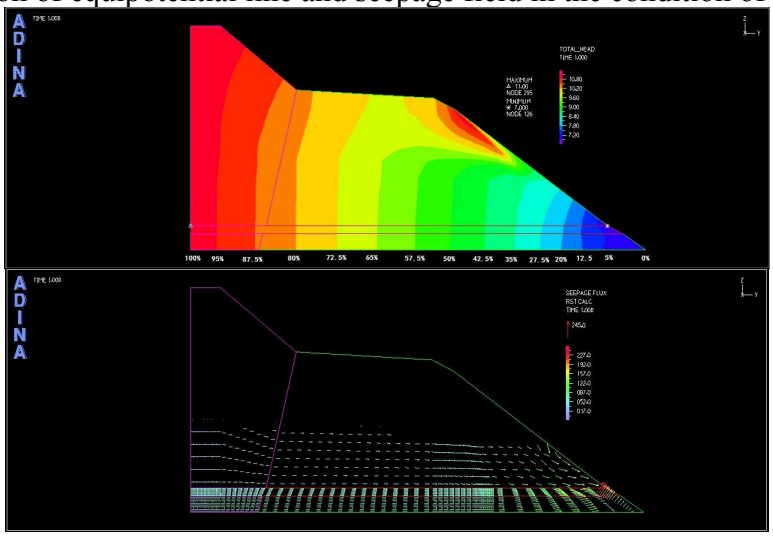

Figure 4 Initial seepage water head distribution and flow distribution

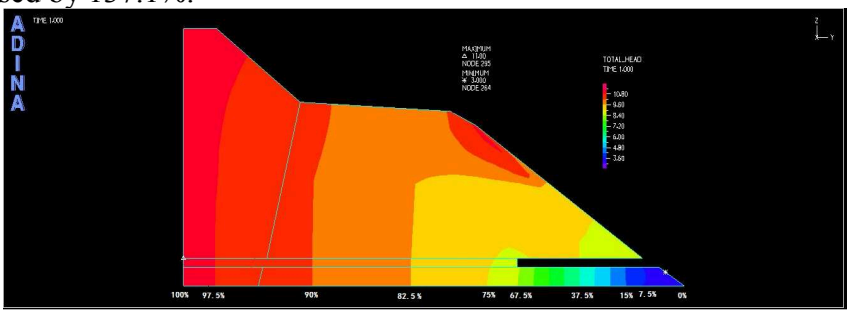
After tunnel cavern excavation, groundwater seepage field of mountain change, as shown in figure 5, constraints K723 + 911 in 67.5% head pressure area, before the excavation increased 58.8%; Tunnel excavation constraints to exit, head pressure distribution of equipotential line more tightly, change is more compact, 240m from K723 +911 to the exit,water head pressure decreased from 67.5% to 0%, that of tunnel excavation change mountain of groundwater seepage field distribution, exacerbating the groundwater flocked to the trend of the tunnel. Constraints value maximum seepage line, seepage flow maximum velocity of 581.0 m/d, a mountain of initial seepage field maximum flow velocity of 245.0 m/d increased by 137.1%.



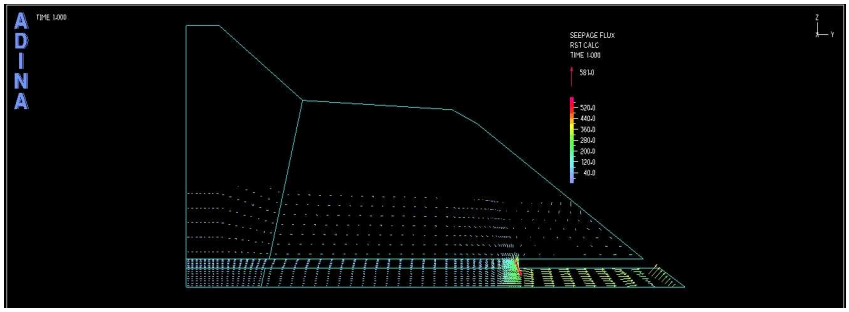


Figure 5 Tunnel after excavation of the seepage water head distribution and flow distribution

Grouting to the surrounding rock within 10M of Constraints, groundwater seepage velocity is less than 0.04 m/d in scope of grouting, water inflow fell dramatically, but through the calculation results can be seen, the groundwater in the grouting body water-resisting layer below a lot of concentration.

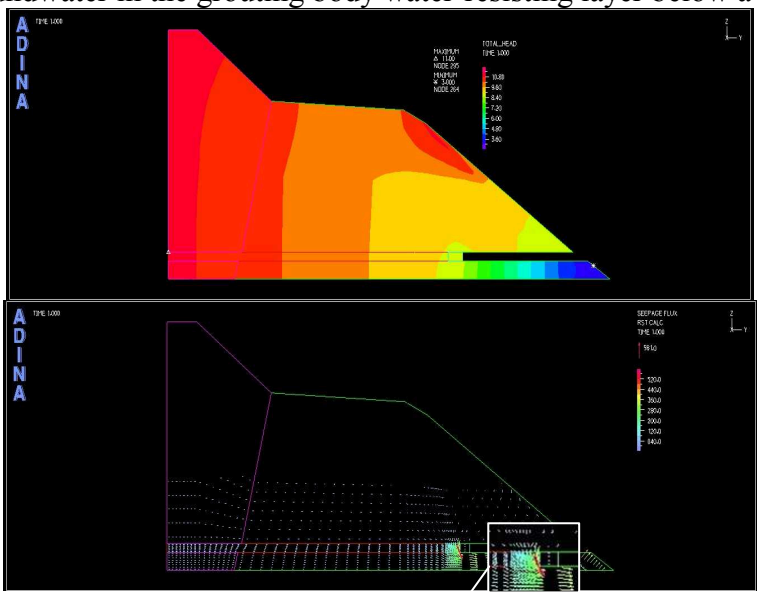

Figure6 After grouting seepage water head distribution and flow distribution

Analysis showed that: firstly, mountain tunnel excavation leads to groundwater seepage field change, in the role of head pressure, ground water to the tunnel portal area where and gushed out; Secondly, after grouting water plugging, grouting body can form good sealing effect, but the groundwater along the grouting water-resisting layer formed by the peripheral (below), suggest that area should be increased when water plugging grouting to ensure sealing ability of water-resisting layer or set drainage tunnel drainage facilities such as channel.

**3 Land slide tunnel lining stress model experiment and the simulation analysis**

3.1 Model experiment

3.1.1 Parameter Settings

The PYD - 50 three to plane strain loading geomechanics model experiment device for horizontal loading experiment, the model size is 70 cm X 50 cm × 20 cm. Barite powder：quartz sand：gypsum model: water = 1:1:0. 27:0. 45 simulate weakly weathered limestone (equivalent to Ⅴ class rock),with angle of internal friction for 19 °,cohesive for 0.09MPa, the elastic modulus of 210 MPa, poisson's ratio of 0.35. the water: dosage of gypsum=1:1 simulate model of concrete material, the modulus of elasticity of 3.5 GPa.

In order to simulate K723 + 911 geological situation, using the quartz sand simulating soften chlorite schist of the right constraints. Considering the original construction scheme adopt the arch of 120 ° grouting failed to effectively curb the abuse of the surrounding rock collapse, the experiment adopt whole grouting scheme.

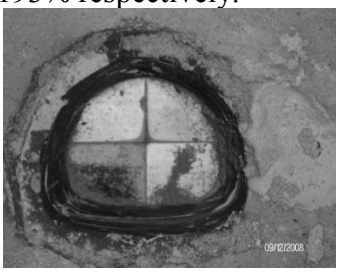
The experiment simulate in-situ stress on the tunnel structure in the way of loading step by step,observating and recording pressure of surrounding rock and lining structure of tangential stress changes. Experimenting process includes two stages: the first stage starts from the experiment load to tunnel lining to crack limit load condition. Crushed surrounding rock of tunnel on the right side make lining structure be under non-uniform pressure of surrounding rock, observating and recording lining disease occurrence and distribution characteristics.The second stage, after whole grouting scheme, the lining structure eventually achieve full damage state by the ground stress

Table 2 The parameter value selection

| Media type | E(GPa) | \μ | φ（°） | C（MPa） |
|---|---|---|---|---|
| Rock | 1.5 | 0.35 | 24 | 0.1 |
| Shotcrete | 30 | 0.167 | / | / |
| Second lining | 30 | 0.167 | / | / |
| Soften rock | 0.15 | 0.35 | 22 | 0.01 |
| Grouting reinforcement | 30 | 0.167 | / | / |

3.1.2Model experimental results

As shown in figure 8,analysising from the characteristics of time: before grouting, left arch feet first crack and extending to the left side-wall, then right hance and side-wall occurs serious cracks, the last is the left hance disease. Analysising from characteristics of location: affected by crushed on the right side of the weak surrounding rock, the lining of the diseases are mainly distributed in the upper half of the arch ring. Measured stress on the left arch foot is the most serious, the tensile stress is 3.36 Mpa. secondly, tensile stress is 1.79 Mpa at right side of the wall and right hance compressive stress is 1.09 MPa. That crushed surrounding rock of tunnel on the right side of distribution of weak bias effect, making the left arch foot force the most unfavorable, and drive the arch ring right side to produce torque, which does not favor the structure safety. After grouting, from the time characteristics: left arch and left foot arch waist firstly crack, gradually extending upward to the vault and downward to the inverted arch, eventually crack at the vaul. From the spatial characteristics: the distribution of diseases from main upper arch ring transferring to the left arch ring.Diease in the second quadrant area inclouding vaule and left arch waist is most serious. Comparison with before and after grouting to load the plane x, y, - x, -y four direction stress as followe: except the y direction stress changing from tensile to compressive, the other three direction of the lining under stress value increased by 193%, 193% and 193% respectively.



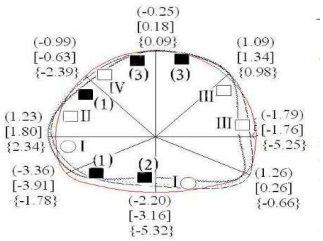


Figure 7 Experimental model Figure 8 Lining structure distribution of tangential stress and disease

3.2 The simulation analysis

3.2.1 Timulation model

Using ANSYS finite element software, the calculating model with four node isoparametric plane entity unit (PLANE42) simulates the surrounding rock (including grouting period).Two node isoparametric plane beam element (BEAM3) simulates the initial supporting structure.Four node isoparametric plane entity unit (PLANE42) simulates of the secondary lining.The parameter value is according to table 1, by adjusting the parameters of surrounding rock modulus to simulate grouting measures.

3.2.2 the simulation analysis results

The simulation calculation shows that:before grouting,arch feet lining under negative bending moment is maximum（4.459 kN） and maximum axial force distribution on the left arch foot 649.37 kN. From the overall, the upper arch ring under high axial force，which in vault and arch waist is 585.36kN. After grouting, bending moment and axial force distribution are reduced, the bending moment of the right side wall reduce from 1.159 kN close to zero, on the right side of the wall axial force is 439.114 kN, decreased by 32.4% before the grouting. After grouting, moment extremum at arch feet increase by about 92%.Bending moment of the inverted arch extreme value increase by about 115%, sidewall axial force extreme value increase by about 36%.

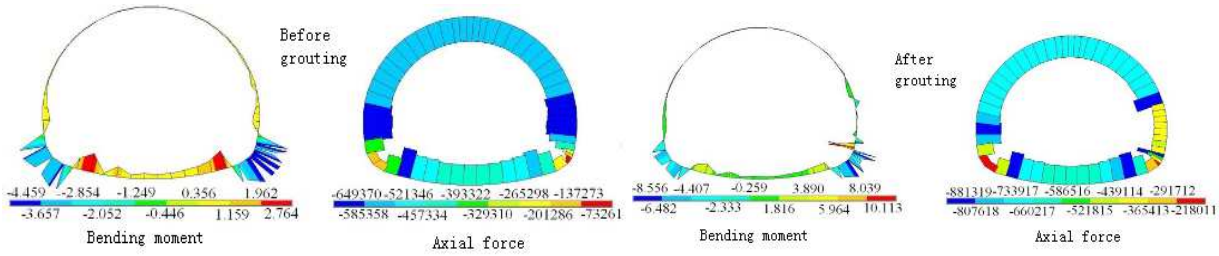

Figure 9Lining bending moment (unit kN, m) and axial force (unit: N)

3.3 Comprehensive analysis

Comprehense model experiment and finite element calculation, analysis results are as follows:

First is the mechanical properties: in experiment，stress on ±x, ±y directions of arch ring plane increase by 1.0 to 2.0 times, which is consistent with the simulation calculation results： the bending moment and axial force of lining reflected by 0.3 to 1.0 times.It suggests that increase scope such as the whole grouting is to improve the force distribution of arch ring, and improve the lining structure stress performance.

Secondly, disease characteristics, as shown in table 4, in the experiment model, the tunnel arch waist and sidewall inherit the maximum axial force that influence the safety of the structure. It is suggested that in addition to the supporting parameters improve lining.Adding beam to improve horizontal and vertical resistance is necessary.

Table 4 Results contrast

| | Model test | Simulation analysis |
|---|---|---|
| Arch half amplitude | Before grouting, large area crack | Bear huge axial force on the half range |
| The left half ring | after grouting, large area crack | On the left side wall bear huge axial force |
| The arch foot | Before and after the left arch foot grouting are the first to crack | Arch subjected to a great moment |

Thirdly, after grouting,by bias effect of surrounding rock, arch feet especially on the left become adverse stress area.It is suggested besides improving constraints in weak rock,reinforcement measures should also pay attention to the measures such as anchor pipe with lock foot.

4. The cause analysis and treatment plan

4.1 Collapse cause analysis as following

(1) Hydrogeological: tunnel site in central area of rock joints and fissures is developed, connective and of rich groundwater groundwater.On the right side of tunnel face at K723 + 911,chlorite schist in water is softened serious, the stability of surrounding rock capacity reductions beyond lining bearing expectations, which is the direct cause of land slide.

(2) Reinforcement measures: collapse section surrounding rock is main of strong weathering chlorite schist.Integrity is poorer.The lack of stability to of surrouding rock make support bear a huge pressure cause arch feet, arch waist buckling deformation. Fault zone pre-reinforcement take arch department 120 ° setting 3.0 m long lead small duct grouting measures parameters is too low to control the deformation of the surrounding rock.

**4.2 Treatment scheme**

(1)Adopting the advanced small pipe grouting is to reinforce stratum.Using Φ42 cm 3.5 m lone small duct grouting forepole, along the upper half arch ring, ranging from the original plan 120 ° to 150 °, improve the ability of the surrounding rock stability.

(2) For hance and sidewall are greatly under axial force, the CRD method is suggested to adopte, to establish the relation between beam, increasing the bearing capacity, hance, sidewall bearing.

(3) The grid steel frame adopts Φ42 small duct grouting (length of 3 m) lock foot which set two each nodes.

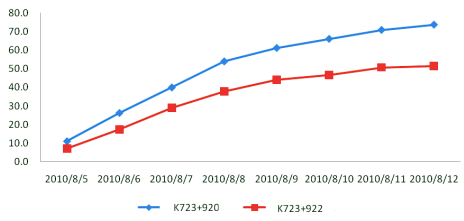
(4) The primary support use C25 Sprayed concrete thickness changed from 25 cm to 30 cm.

(5) The second lining:encryption lining steel ring space, which changed from 20 cm to 15 cm.

4.3 Site measurement

(1) K723 + 920 vault subsidence curve and peripheral convergence curves are as shown in figure 10 and 11: vault subsidence deformation rate is 0.4 -- 1.5 mm/d, peripheral convergence deformation rate

is 0.5 -- 2.2 mm/d.It indicates that after the treatment land slide body tends to be stable, not continues to expand.



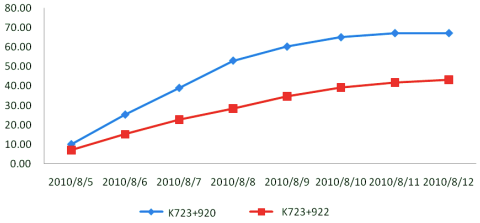


Figure 10 K723+ 920 vault subsidence curve Figure 11 K723 + 920 peripheral convergence curves

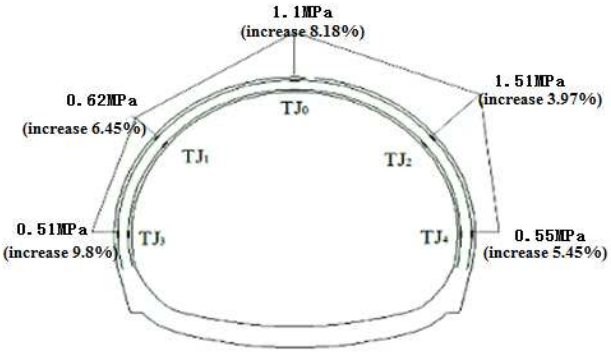
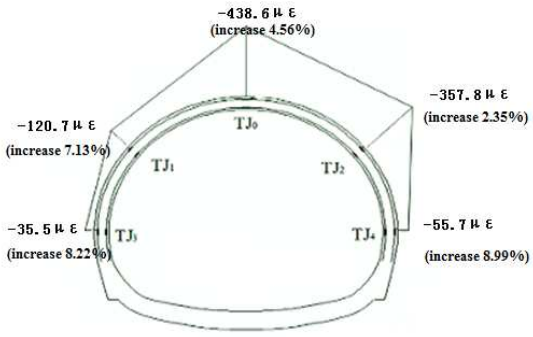
(2)The lining stress and strain comparison no August and September are as shown in figure 12. The stress and strain monthly increase rate were 3.97% and 2.35% respectively at the right hance which is seriously pressed.It indicates the treatment make the land slide body deformation and stress get better control, treatment scheme is reasonable.





A: distribution and changes of pressure B: the distribution and variation of strain (negative tension)

Figure 14 K723+915 section two lining stress, strain distribution

## 5 Conclusion

(1)The tianshan mountain area affected by the snow melt water and atmospheric precipitation.The groundwater is relatively rich. Excavation make groundwater seepage field change and the groundwater collecting at the tunnel face cause water disease.Grouting have good water plugging effect, but should be combined with hydrology geology determine reasonable grouting scope to ensure the sealing ability of water-resisting layer.

(2) The ground water make the right crushed rock soften cause bias.Experiment shows the arch foot force is disadvantageous, in addition to improve grouting range，treatment should also pay attention to complementary with anchor pipe and lock foot.

(3) The model experiment and simulation analysis results shows：In the arch ring plane ±x, ±y principal directions except the y direction, the other three direction of the lining under stress value increased by 193%, 90% and142% respectively. Whole grouting measures can obviously improve the arch ring stress, improve safety lining structure.

(4)By adopting CRD construction scheme for the soil slip K723 + 919, expanding the scope of the grouting construction to 150 °, and adding small duct grouting lock foot, strengthen lining supporting parametersm, tunnel collapse is controlled in the normal range. Treatment scheme is reasonable with vault subsidence deformation rate is 0.4 -- 1.5 mm/d, peripheral convergence deformation rate is 0.5 -- 2.2 mm/d

# Tunnel lining microstructure and mechanical properties of evolutionary analysis

Yundong Ma[1, a], Shuang Liang[1,b]

[1]Dalian Jiaotong University, Dalian, Liaoning,China

[a] yundongma@126.com, [b]liangsflai@126.com

**Keywords:** Tunnels, Mesoscopic Model, Strain, Fracture.

**Abstract.** For the tunnel lining microstructure, mechanical properties evolve analyzed. This paper have established and meshed microstructural model and got the situation under its force structure loads, the cracking strain as a criterion for its application fracture criterion to get a good cracking and expansion of the tunnel lining meso model. The results of the case under the macrostructure of the model compared with the microstructure results can get the adventage of the microstructure in using tunnel lining.

## Introduction

In the course of the tunnel lining mainly by internal stress of the mountain came load, temperature and humidity changes caused. Temperature and humidity are the main factors that cause cracking and failure of the tunnel lining. Any strength suffered a load of tunnels are lower than the fracture failure of the concrete lining, The failure of tunnel lining is due to repeated loads of concrete damage, lower intensity, thus causing cracks to appear concrete lining failure[1].

At present, China is taking most of the tunnel concrete lining macro model to analyze the forces. Due to increase the degree of importance of tunnel security, this macro model is no longer able to meet the demand for the safety of the tunnel, concrete lining microstructure model can better analyze the real force, the improved security[2].

## Concrete microstructural model's establish

Concrete on Meso usually seen as a composite consisting of coarse aggregate, cement mortar and interface consists of a three-phase medium. Research shows that two-dimensional numerical simulation method is a static circular aggregate distributed simulation method, which have high efficiency and good usability. Table 1 is a microscopic model properties of various materials and concrete materials.

Table 1 Material parameters

| Material | Modulus of elasticity$(GPa)$ | Poisson's ratio | Bulk density$(kN/m^3)$ |
|---|---|---|---|
| Aggregate | 50 | 0.2 | 27 |
| Curing cement morta | 25 | 0.2 | 21 |
| Bonding interface | 22 | 0.2 | 21 |
| Concrete | 28 | 0.2 | 21 |

In this paper,with the aid of Fuller proposed maximum density ideal grading curve, taking the Monte Carlo method, using a formula Guevara text, making three-dimensional model into a two-dimensional plane of concrete conduct. Using the random aggregate model to do the stress of the tunnel under the effect of load analysis.Figure 1 is a micromechanical model of tunnel.

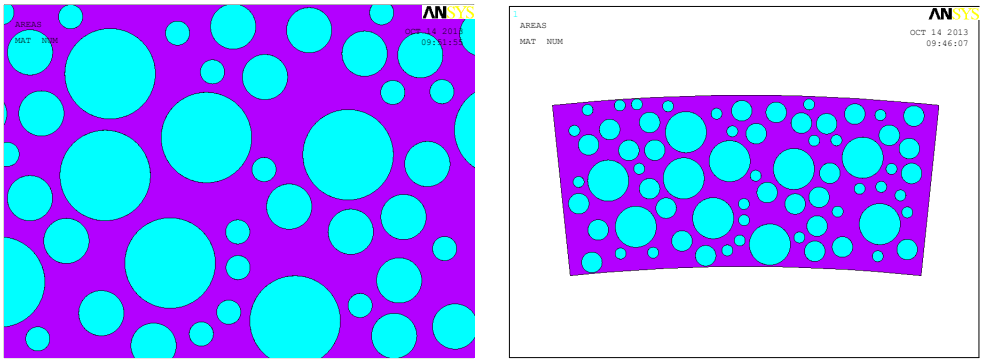

Fig.1 A micromechanical model of tunnel lining concrete

According to the properties of various materials to mesh[3], mesh diagram is shown in Fig.2:

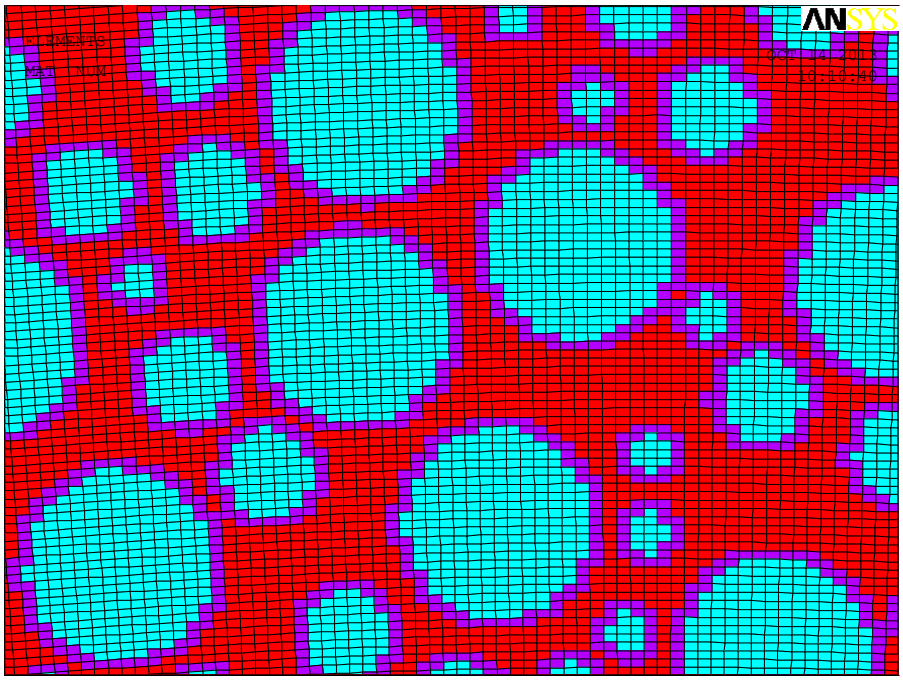

Fig.2 Meshing figure

**The establishment of a fracture criterion**

Based on the concrete mesoscopic mechanics method is to continuum mechanics, damage mechanics and computational mechanics to analyze the combination of meso-scale deformation, damage and failure process. Basic idea is to regard concrete as aggregate, cement mortar and curing of the interface between the three-phase heterogeneous composite material, choose the appropriate concrete mesoscopic structure model, considering the aggregate unit, curing cement mortar and interface materials mechanical properties of different units, as well as the failure criterion and simple tension and compression damage model reflect the stiffness degradation, using finite element method (fem) simulation of concrete crack propagation process of the specimens and the failure pattern, intuitively reflect the damage fracture failure mechanism of the specimens.

Concrete is a kind of quasi brittle material, after carrying on the macroscopic stress-strain curve of nonlinear because of micro crack initiation and extension, and is not caused by the plastic deformation. Therefore, can be described by elastic constitutive relation of damage mechanics and mechanical properties of concrete mesoscopic unit of each phase. Damaged material constitutive relation by the relationship between the nominal stress $\sigma$ and the strain $\varepsilon$ nondestructive material

$$E = E_0(1-D)\ \sigma = E\varepsilon\ (0 \le D \le 1) \tag{1}$$

$E_0$ is the initial elastic modulus in formula, $E$ is modulus of elasticity after injury,D isdamage variable. This paper argues that when the unit of the maximum tensile stress reaches its limit value of the given when the cell starts tensile damage. This article uses the double line damage evolution model, the equation asbelow and stress strain graph as Fig.3

$$D=\begin{cases} 0 & \varepsilon_{\max}<\varepsilon_0 \\ 1-\dfrac{\eta-\lambda}{\eta-1}\dfrac{\varepsilon_0}{\varepsilon_{\max}}+\dfrac{1-\lambda}{\eta-1} & \varepsilon_0<\varepsilon_{\max}\le\varepsilon_r \\ 1-\lambda\dfrac{\varepsilon_0}{\varepsilon_{\max}} & \varepsilon_r<\varepsilon_{\max}\le\varepsilon_u \\ 1 & \varepsilon_{\max}>\varepsilon_u \end{cases} \tag{2}$$

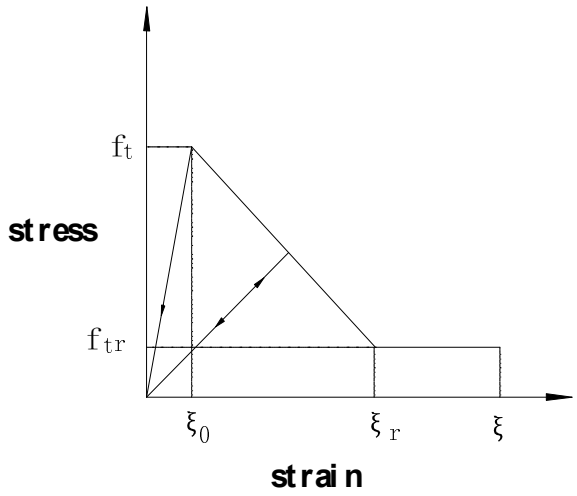

Fig.3 Double broken line model of concrete meet each phase

$f_t$ is the tensile strength of concrete material in; $f_{tr}$ for each phase damage unit tensile residual strength, $f_{tr}=\lambda f_t$, $\lambda$ is residual strength coefficient, $0\le\lambda\le1$; $\varepsilon_0$ as a unit stress reaches tensile strength of the principal tensile strain; $\varepsilon_r$ with tensile residual strength of the corresponding residual strain, $\varepsilon_r=\eta\varepsilon_0$, $\eta$ for residual strain coefficient, for concrete material in general scope of $1<\eta\le5$; $\varepsilon_u$ as the ultimate tensile strain, $\varepsilon_u=\xi\varepsilon_0$, $\xi$ as the ultimate strain coefficient, $\xi>\eta$; $\varepsilon_{\max}$ as a unit in the maximum principal tensile strain loading history[4].

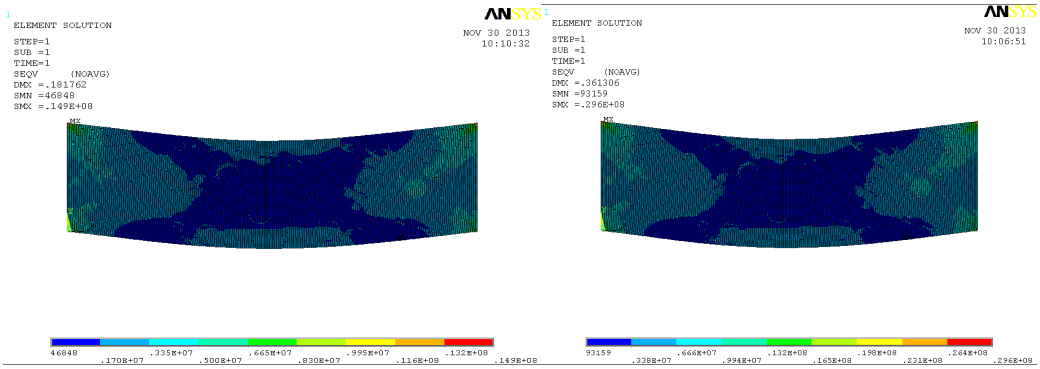
Fracture criterion is measured by strain, due to the micromechanical model is a combination of three kinds of materials, so using three different critical strain. This article take the fracture strain of the aggregate is 0.002, the fracture strain of the slurry was 0.0012, the interface fracture strain of 0.001. And macroscopic model is a kind of material, the fracture strain value through weighted arithmetic is 0.0015.

**The mesoscopic model and macroscopic model for comparative analysis**

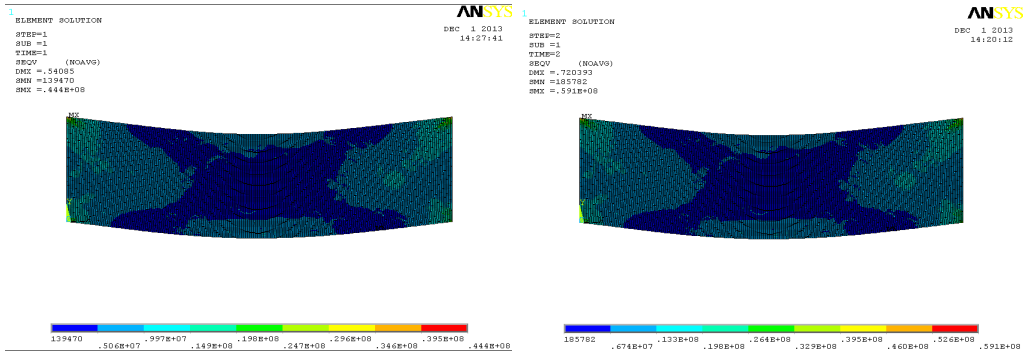
Because the model of the tunnel is very big, the whole model of mesoscopic models are used to analysis, has a high requirement on the computer, and will take a long time to operations, so we take the part of the largest stress tunnel is analyzed, namely the top of the tunnel. Due to the tunnel radius is big, can take the top analysis similar to rectangle concrete blocks, so this article simulated by rectangular concrete blocks.

This article selects 2000 mm long and 600 mm high concrete two-dimensional model as an example for analysis. In this model distribute with uniformly load, load is increased, Until the concrete bear not the fracture load. Fig.4 is the micromechanical model of concrete at various stages

in the process of gradually loading, strain and fracture in the diagram in (a) - (d) the load is increased, it is concluded that the stress at the same time also has been increased.



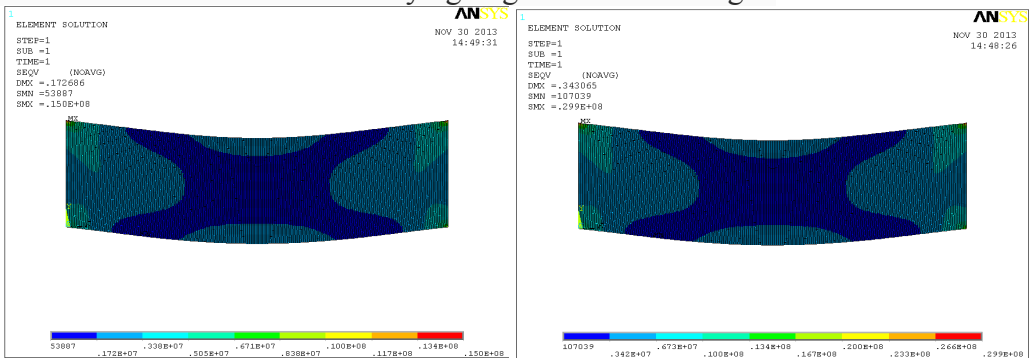
(a) Load for $1\times10^8\,N$ stress nephogram (b) Load for $2\times10^8\,N$ stress nephogram



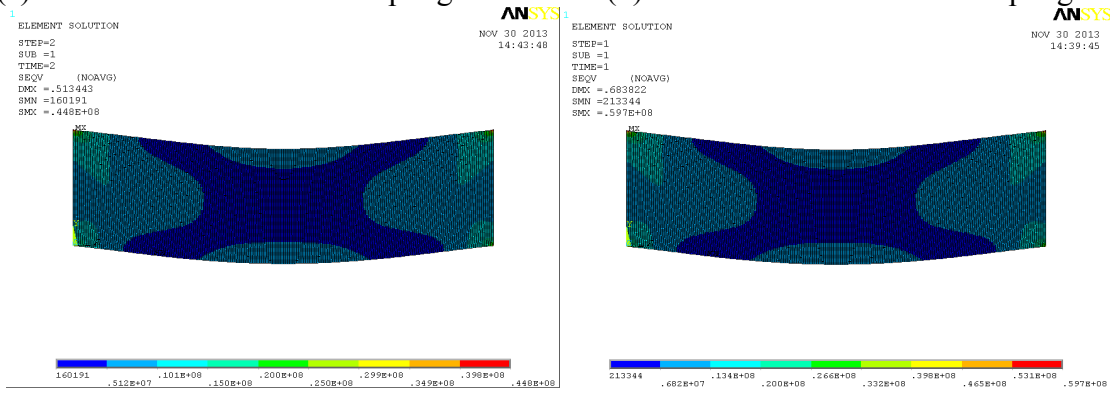
(c) Load for $3\times10^8\,N$ stress nephogram (d) Load for $4\times10^8\,N$ stress nephogram

Fig.4 Mesoscopic model the forces of the concrete loading

Compared to concrete mesoscopic model, macroscopic model is as the same material of the concrete under the same load should be trying to get as shown in fig.5:



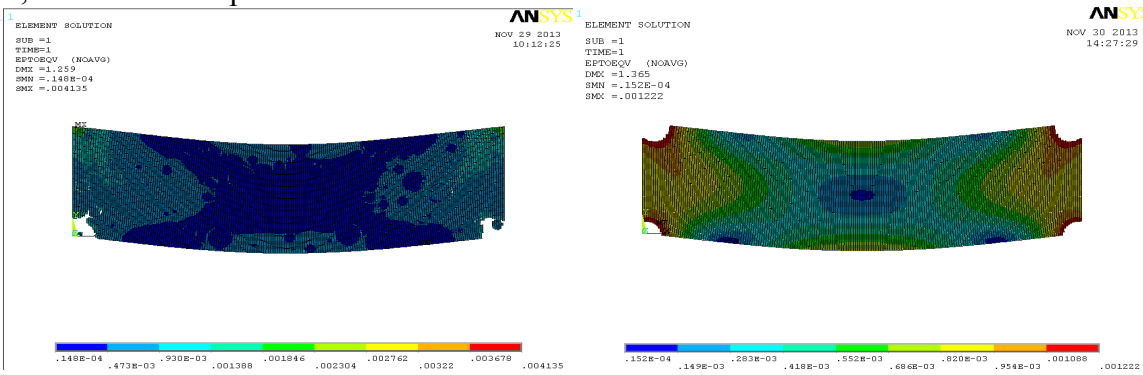
(a) Load for $1\times10^8\,N$ stress nephogram (b) Load for $2\times10^8\,N$ stress nephogram



(c) Load for $3\times10^8\,N$ stress nephogram (d) Load for $4\times10^8\,N$ stress nephogram

Fig.5 Macromodel the forces of the concrete loading

Fig.6 is application of a fracture criterion of crack, (a) is a mesoscopic mechanics model of concrete fracture diagram, it can be seen that the fracture of concrete is not regular, accord with the actual situation. (b) is the model of concrete as the same kind of material, this case model is completely symmetrical, although on the mechanics analysis is set up, but with the actual situation is different, so the mesoscopic model is more accurate.



(a) The fracture in mesoscopic mechanics model (b) The fracture in macroscopic mechanics model

Fig.6 The comparison of concrete fracture

Figure 7 is the two forms of concrete strain increases with the load together, although looks gap is not very big, but because of the fracture strain of the concrete as the same kind of material is bigger than the actual, so have led some to achieve the ultimate strain unit without failure, lead to error will be larger and larger

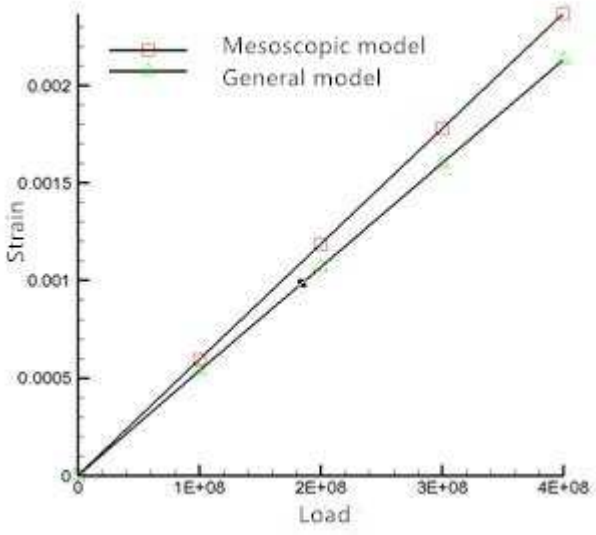


Fig.7 Under various stages of the loading strain contrast.

## Conclusions

Through the above analysis and comparison, in the process of load increasing, the difference between the two models are gradually revealed. We can see from fig.4 to fig.6 mesoscopic model is more close to reality, because the concrete itself is uneven, but the latter obvious symmetry is clearly is inconsistent with the actual, the micromechanical model of crack position is consistent with the actual situation. Two models are begin when load for cracks, but the position of the cracks, and extend the degree are different, micromechanical model of crack is more close to actual. Mesoscopic model the crack propagation of concrete in the trend of faster and faster, and the macro model belongs to a steady state, is at odds with the theory of what we know.

To sum up, Mesoscopic model is more accurate compared to the macroscopic model in the analysis of the mechanical properties, the micromechanics of concrete will be our future development direction.

# BIM technology Used in underground subway station planning simulation

Hongke Pu[1, a*], Qingchao Wei[1,b]

[1] School of Civil Engineering, Beijing Jiaotong University, Beijing 100044, China

[a]peakhill@163.com, [b]qcwei@bjtu.edu.cn

**Keywords:** BIM technology, underground station, planning, cooperative design, cost.

**Abstract.** This paper studied the underground subway station planning depend on BIM technology. The existing 3D buildings' information was processed by computer technology. Using the information and planning based on constraints on the space station, the simulation of the actual situation in 3D view way constantly, adjust planning position, compare each project calculation cost, obtain the optimal line position. We can carry cooperative design plan the subway station by the restrictive conditions and achieve the optimal line layout.

## BIM technology Introduction

BIM is a Building Information Model, a combination of all of the geometry Model Information, functional requirements and component performance, will be a construction project throughout the life cycle with information including the construction schedule, construction, maintenance and management of the process of information [1]. The simulation with the real information of building digital information integration of all kinds of information related to project data model is a detail expression of relevant information about the project. Building information model is a direct application of digital technology in architectural project, but it is also a kind of application to the design, construction, management of the digital method. This method supports the construction project integrated management environment, can significantly improve efficiency and reduce risk in the process of its life[2,3].

BIM is using digital technology to the process of the construction project design, construction, operation and its process results is an information rich multi-dimensional project model - named the BIM model. Different cooperated parties use different software to solve their problems to complete the project construction and operation method of work is a production line, with information creation, management and share。 The purpose of BIM is to make the information on this production line coherence, error elimination, increased efficiency in advance.

Through the analysis of the BIM overall solution in traffic planning, project cost control, data sharing on the application of multiple directions, successfully overcome people and traffic with pedestrian safety problems that may arise, collaborative underground space, and with the perfect blend of the whole region.

## BIM application in underground engineering

Domestic well-known experts and scholars in the field of underground space make "ideas and technology leading the urban underground space in the future the development" as the theme, put forward the concept and technology direction of the development and utilization of urban underground space[4]. Though the construction of urban underground space in China has made rapid development, there are larger gap between our cities and the development and utilization of historic, economic strength of the city in the developed countries.

Therefore, urban underground space development and utilization in our country is facing the huge opportunity and challenge situation, need to lead the future development of urban underground space in China with advanced ideas and technology. First is in terms of concept, to promote resource

conservation and environment friendly urban construction as the basis, comprehensive exploitation and utilization should be forward-looking strategic planning, integration of underground space on the ground, strengthen the modernization of urban underground space atmosphere, improve the quality of internal environment. According to different area can adhere to the principle of focus, in view of the underground space of rail transit around development can adopt flexible planning. Second, in terms of technology research and application, study ways to establish urban underground space building integrated design methods and standards. Strengthen the urban underground construction comprehensive disaster prevention technology research. System of urban underground space construction standards, perfect the relevant standard specification. Internal environment protection technology measures were put forward. Strengthen research and development of urban underground construction management information platform based on BIM technology. To strengthen all kinds of construction technology research and popularize advanced technology.

Using BIM technology in civil engineering, construction and management of underground space, realize the underground engineering design, plan approval, construction, daily management full cycle of information, intellectualization. It is important to promote construction of underground space development and utilization, and management level, and it is the modern city construction management direction.

The characteristics of underground space: the poor geological conditions, surrounding environment complex, shallow buried structure, the stability of surrounding rock. Urban underground engineering construction lags behind the urban construction, especially the urban subway projects are often built under the buildings in highly concentrated area, and through a variety of the vicinity of the pipeline under the road in the city. Construction often causes ground deformation and surface subsidence. The inherent deformation and settlement of neighbor buildings and facilities damage cannot be ignored. Urban underground pipe network facilities, street, parking and other structures with influence each other, restrict each other, it may create many special problems in design and construction technology.

BIM technology can provide better solutions [5] on the collision coordination management with other buildings and pipelines, quantity control, performance analysis, and design efficiency.

## Subway station planning and BIM Technology

Underground station layout, especially under the environment of existing structures should follow certain principles [6].

- Station hall layer partition should be arranged clear, management room and equipment room should meet the technological requirements of each system.
- Determine platform type based on alignments and transfer requirements.
- Station entrances should be set on the road outside red line or surrounding the city square, and consider the transfer and connection with other traffic.

The station layout needs to analyze the influencing factors, and determines the boundary conditions. The surrounding environment; Building demolition and pipeline moving conditions; The construction method; Traffic source; The conditions of the comprehensive development.

After determining the limiting conditions and influence factors, plan the location of the space station. Station surrounding by existing facilities such as shopping malls, residential, roads, parks, power pipe trench, fire pipeline, rain water pipe, water pipe, gas pipe, communications net, heat pipe network, need to be considered in space layout, whether the construction is convenient, and save on economy. Collaborative design is very important in the design of underground station. Collision detection is the key to the collaborative design, including hard collisions and soft collision. Hard collision is direct contact. Soft collision is two entity's distance within limits. In this case, BIM technology combined with related 3D software can efficiently deal with this kind of problem. Calculated the corresponding project cost: earth quantity, demolition costs etc.

Station planning process as follows:

- Through the existing conditions of information processing, extraction size, location and other specific information and data from pipes, facilities, buildings, etc., save to the database.
- On drawing software AutoCAD and REVIT for secondary development, stereo display all information.
- According to the principle, design specification and input constraints, design program for the station planning.
- If do not conform to the requirements, repeat last step, to achieve the optimal design scheme.

## Case analysis

FaTou station of one metro line no.7 is taken as an example to analyze application of BIM technology. The metro line is near to parks, schools, community (Fig. 1). Follow is the case of FaTou station planning analysis.

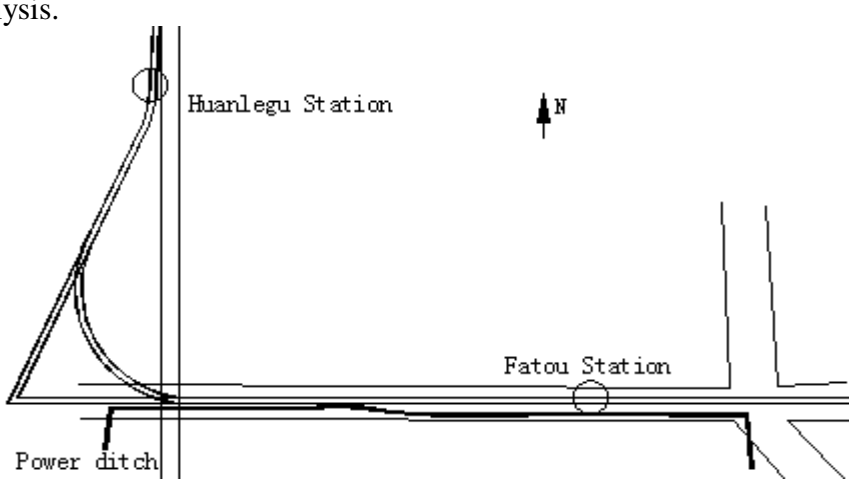

Fig. 1 Fatou station planning position

- **Status**

Road and traffic status: the station site in FaTou south road on the east side with FaTou road intersection. The station has JinFa stance on the east side road and vertical FaTou road intersection. The road traffic flow is not big.

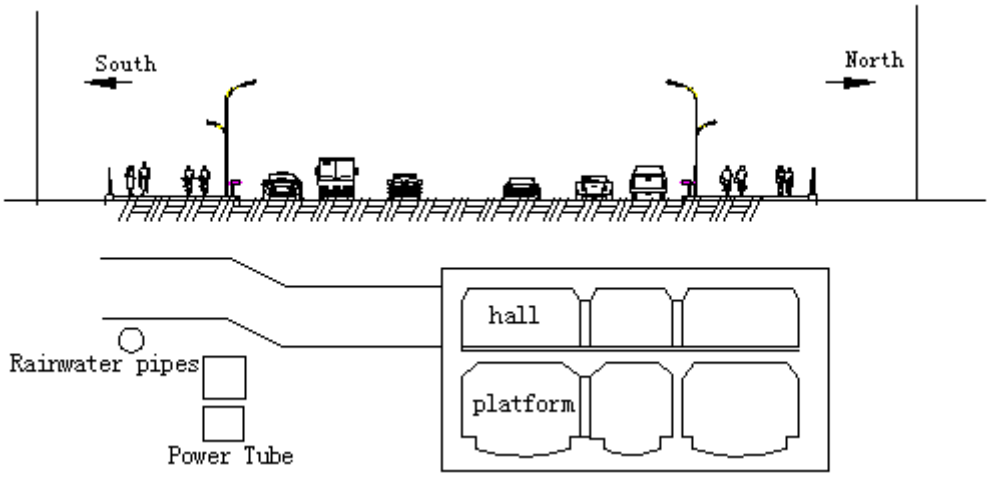

Fig. 2 Section of pipe, road and station

Present situation of underground pipeline: pipeline lays under the road, near the rain water, telecommunications, electricity, water pipes, etc. FaTou south road under rain sewage, electricity pipeline,(Fig 2).

- **Analysis**

Line main control points: One is residential buildings located on FaTou south road on the west road corner. Another is along the south road of FaTou buried two parallel power channel. FaTou station is located in influence scope of the power channel. Because power trench has many ground manholes, the left hand lane and Fatou line station at the top of the heat pipe can not be achieved through the ditch. If pass from the bottom, then the requirements of the line as a whole buried deeper and the part of heat pipe near Fatou local station needs to be moved. To solve above problems focus on the line flat position, Fatou station's selection need to be optimize and to choose.

1. Set the corner radius of the curve R350m, line and station are located beneath the power trench, the left side of the center line distance to residential 10.5m, requires diversion of large power line, entrances lift height is large, poor conditions

2. Move the Fatou South line southward 5m, subway line and FaTou station deviate power pipe trench. FaTou station stands below the part position in the south planning green space, add a set of R1200m curve. The center of the left line distance to apartment can be adjusted to 21m. Due to adjust line to the power line south, the line needs to pass two times through power trench. After adjusting for the underground station, two layers of island platform station along the west. Station has three channels, three entrances, and two sets of four wind pavilion, northwest three entrances in FaTou south road. Construction of open-cut method is simple, is easy to carry out.

3. Move FaTou south route northwest 20m, the line and FaTou station deviate power line range, reduce the construction's change and impact on the pipeline. But due to the line moving north, FaTou station is within the scope of residential land, and the circular curve radius is adjusted to R300m, adjust center line of left subway line distance to house boundary to 8m. The station is close to the north of FaTou south road red line. Construction of open-cut method is simple, is easy to carry out.

After several adjustments and comprehensive evaluation, get the optimal solution.

## Summary

Through the analysis of the underground station, using BIM technology, combining with computer automated processing, convenient man-machine interaction, collaborative design with the original facilities and building, choose the right station and line and put forward the optimal solution. In urban rail line planning, using BIM in the whole line network planning, automation line network planning, adjustment, it will improve efficiency and save cost.

# Comfortable Quality Analysis of Subway Station Vibration Induced by Multiple Trains

Bingqing Zhang[1,a*]

[1]Key Laboratory of Road and Traffic Engineering of Ministry of Education, Tongji University, 4800 Caoan Road, Shanghai, China

[a]zhangbingqingjane@gmail.com

**Keywords:** multiple trains; subway; comfortable quality of vibration

**Abstract.** With more and more subway lines in cities, people have pay much attention to the comfortable quality of subway vibration, especially in transfer stations or stations that have more than one line which platform and floor have much violent vibration. The paper bases on a subway station with multiple trains, builds the finite model, puts measured wheel-rail force as the load and gets the dynamic responses. Then it accords conventional international standard of comfortable quality which uses weighted root mean square acceleration as index to evaluate the comfortable quality of platform and floor or other areas. The result shows: The station could meet the requirement of comfortable quality.

## Introduction

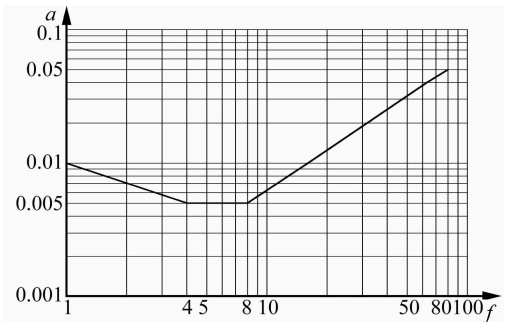
With the fast development of urban railroad transportation and the need of city traffic network, the phenomenon of more than one line goes through a station is more and more. Multiple trains' operations must have much stronger influence on the station's vibration, especially the people who are on the platform. The noise and vibration induced by trains could beyond people's comfortable field and do harm to people's health [1,2]. So, it's necessary to evaluate the comfortable quality of vibration when multiple trains run at the same time.

## Evaluation method of vibration comfortable quality

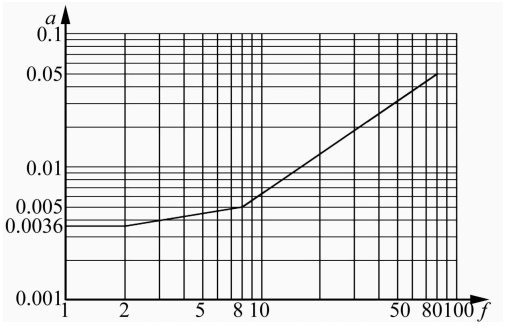
### Existing research and specification

There are many factors relate to body comfortable quality, such as vibration frequency, direction, exposure time, distance , human posture and so on. The vibration ergonomics expert Griffin[3-6] have done a series of indoor test in the field and made a lot of contribution. Domestic scholar have done some theoretical researches, put forward some evaluation methods and put them into engineer practice[7-12].But now there is still no mature and global standard or method at home and abroad.

The paper accords to the methods in ISO10137:2007[13], it includes base evaluation method and additional evaluation method. When ACC PEAK/weighted root mean square acceleration value<6, using weighted root mean square acceleration value as the evaluation index, the value is compared with the multiplied base curve. When ACC PEAK/weighted root mean square acceleration value>6, using vibration dose as the evaluation index in order to consider the influence of load impact effect on the vibration comfort. Then the value is compared with the multiplied base curve. The base curve is shown in Fig.1, for the continuous and intermittent vibration, the multiplying factors are shown in Table 1.



(a)Building vibration Z-axis base curve for acceleration (foot-to-head vibration direction)



(b) Building vibration combined direction(x-, y-,z- axis) acceleration base curve

Fig.1 Vibration acceleration base curves

Tab.1 Multiplying factors in the standard of ISO10137:2007

| Place | Time | Multiplying factors |
|---|---|---|
| Critical working areas（e.g. some hospital operating-theatres, some precision laboratories, etc） | Day | 1 |
| | Night | 1 |
| Residential(e.g. flats, homes, hospitals) | Day | 2~4 |
| | Night | 1.4 |
| Quiet office, open plan | Day | 2 |
| | Night | 2 |
| General office (e.g. schools, offices) | Day | 4 |
| | Night | 4 |
| Workshops | Day | 8 |
| | Night | 8 |

## The calculation method

According to former evaluation index and method, the evaluation can be divided into the following steps:

(1) Determine working environment, which determine the multiplying factor;

(2) Build the finite model, get acceleration-time curve of measuring points;

(3) Transfer time value to frequency-domain value of acceleration with the use of Fourier Transform, get the root mean square acceleration values of 1/3 octave;

(4) Get the weighted root mean square acceleration values as the weight coefficient (specific coefficients and ways according to ISO2631[14]);

(5) Calculate the value of ACC PEAK/weighted root mean square acceleration value, in order to make sure choose base evaluation method or additional evaluation method;

(6) Compare the weighted root mean square acceleration values or vibration does with the multiplied base curve, then evaluate the comfort degree of different areas in the station.

## The calculation model of station

The station with a single pole and double spans structure. It has station hall floor, ground floor first floor and second floor, three floors in total. The elevation of station hall floor is -2.5m, the elevations of platforms are -9.5m and -17.7m. On the left side and right side of ground floor first floor and second floor are line 4, the left, right line and line 6, the left, right line, 4 lines in total. The cross section of station is shown in Fig.2, the calculation model is shown in Fig.3.

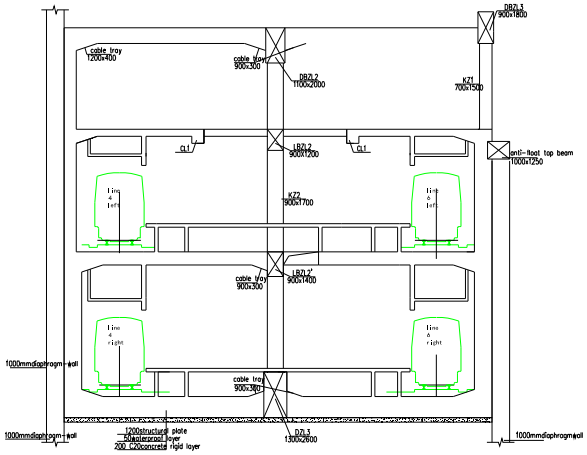


Fig.2 The cross section of station

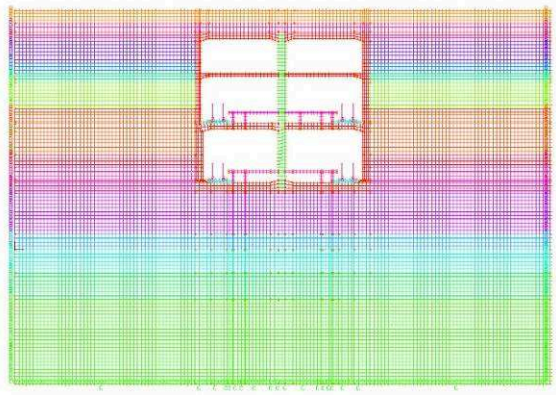

Fig.3 The finite calculation model of station

## Acceleration calculation and comfortable quality evaluation

The object in the paper is a subway station, which belongs to noisy regions with dense population. So, it regards the station as the 4th kind place is enough according to Tab.1, makes the multiplying factor as 4.0, then the limit acceleration should be: only consider vertical vibration is $4\times5.0\times10^{-3}=2.0\times10^{-2}$ m/s$^2$; consider three directions' vibration is $4\times3.6\times10^{-3}=1.44\times10^{-2}$ m/s$^2$. Because the influence of train's vibration on environment mainly in the vertical direction, so following analysis only consider vertical vibration, which means $2.0\times10^{-2}$ m/s$^2$ is the evaluation standard.

It needs to evaluate the comfortable quality of station hall and two platforms respectively. During modelling, it regards station structure as train-station structure and uses structure-load model which puts measured wheel-rail force on the foundation bed as external force. The wheel rail force-time curve is shown as Fig.4. According to the condition of trains' running, it have two most dangerous conditions, first condition is that: Line 4 left and right trains go through at the same time, no trains of Line 6; second condition is that: Line 4 and Line 6 left and right trains go through at the same time. The distribution of the measured points in station hall floor and platforms is shown in Fig.5.

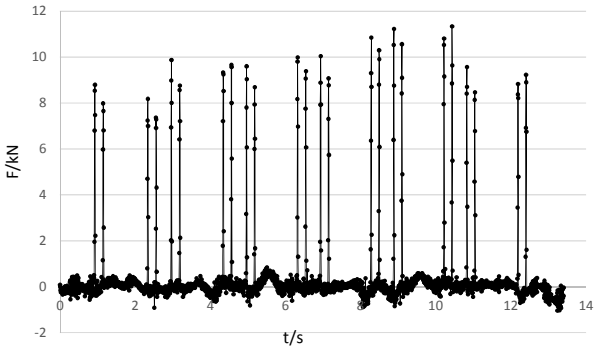

Fig.4 The wheel rail force-time curve

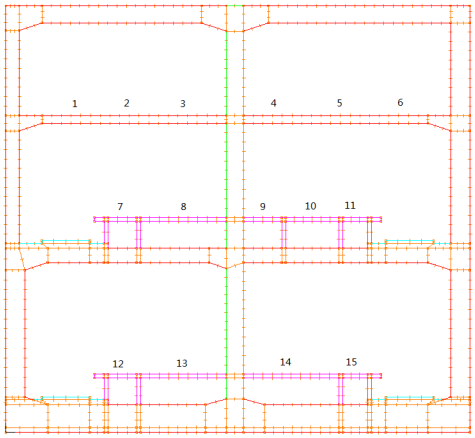

Fig.5 Distribution of the measured points

Through the calculation of 2 conditions, it can get acceleration-time curve of measuring points, as shown in Fig.6,7,8,9(only list several points);then transfer time value to frequency-domain value of acceleration with the use of Fourier Transform, finally get the weighed root mean square acceleration values with the method in ISO2631.

**Station hall floor**

*Condition 1*

In the condition 1, the acceleration- time curve of point 2 is shown in Fig.6, the weighed root mean square acceleration values $a_w$ of every point in station hall floor are in Table 2.

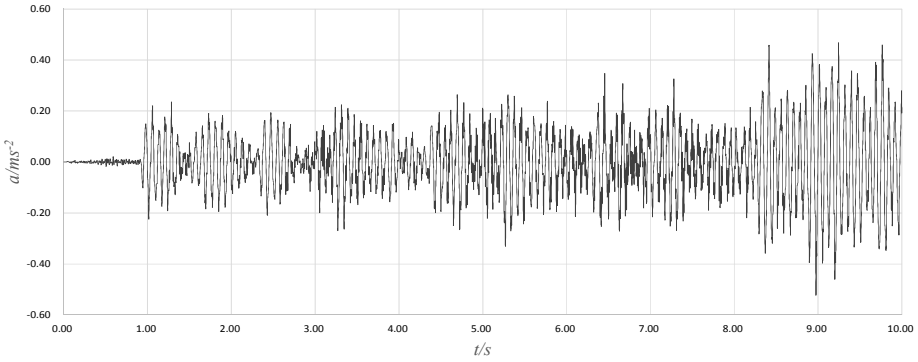

Fig.6 The acceleration- time curve of point 2 in condition 1

Table 2 The weighed root mean square acceleration values of every point $a_w$

| Node number | 1 | 2 | 3 | 4 | 5 | 6 |
|---|---|---|---|---|---|---|
| $a_w$/mm.s$^{-2}$ | 0.098 | 0.100 | 0.063 | 0.212 | 0.200 | 0.054 |

*Condition 2*

In the condition 2, the acceleration- time curve of point 2 is shown in Fig.7, the weighed root mean square acceleration values $a_w$ of every point in station hall floor are in Table 3.

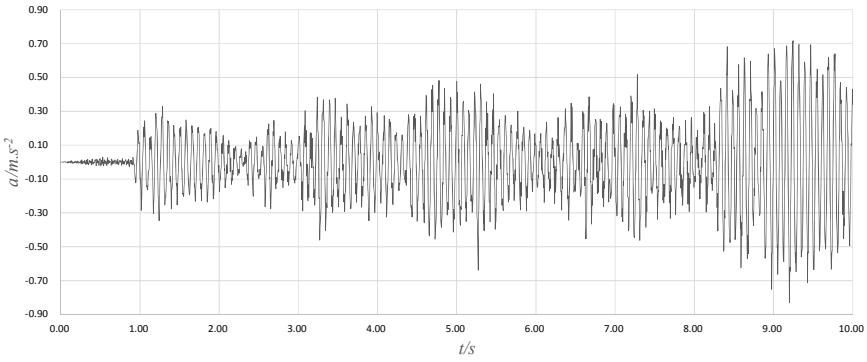

Fig. 7 The acceleration- time curve of point 2 in condition 2

Table 3 The weighed root mean square acceleration values of every point $a_w$

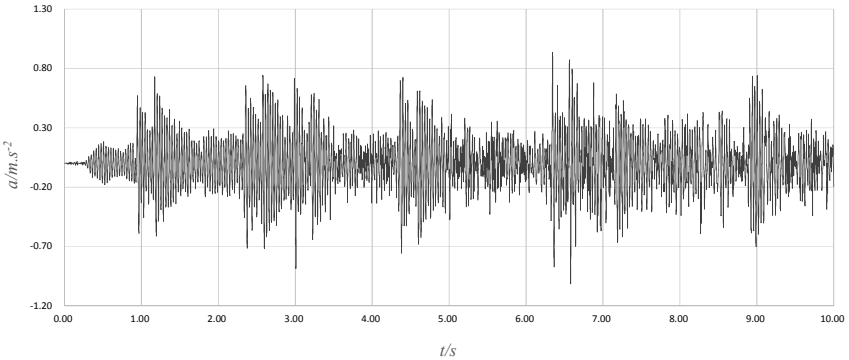
| Node number | 1 | 2 | 3 | 4 | 5 | 6 |
|---|---|---|---|---|---|---|
| $a_w$/mm.s$^{-2}$ | 0.112 | 0.215 | 0.135 | 0.140 | 0.276 | 0.091 |

From Table 2 and Table 3, we can see the maximum of weighed root mean square acceleration values $a_w$ of every point in platform is 0.276mm/s$^2$, which is less than 20 mm/s$^2$, it shows that the station hall floor could meet the need of comfortable quality. At the same time, it shows that condition 2 has much influence on the platform's vibration.

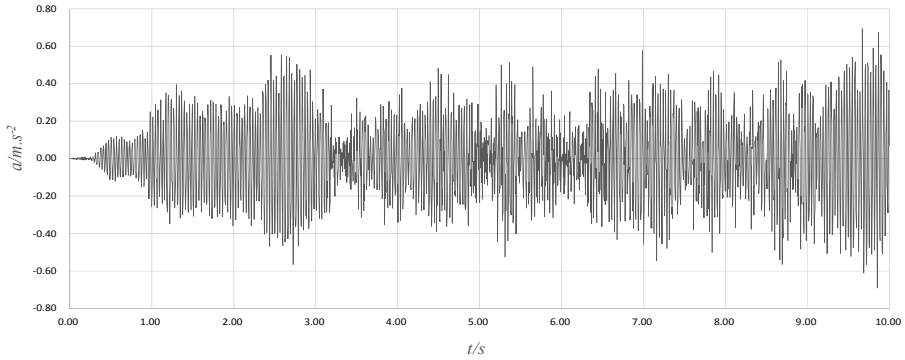
**Platform**

*Condition 1*

In the condition 1, the acceleration- time curves of point 8 and 13 are shown in Fig.8, the weighed root mean square acceleration values $a_w$ of every point in station hall floor are in Table 4.



(a) the acceleration- time curve of point 8 in condition 1



(b) the acceleration- time curve of point 13 in condition 1

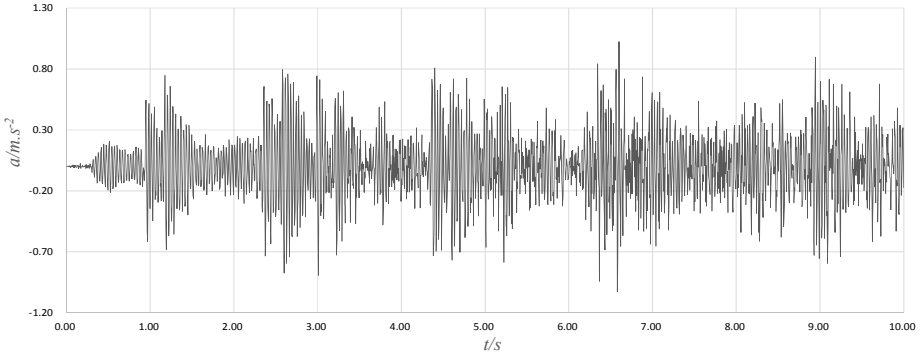
Fig 8. The acceleration- time curves of point 8 and 13 in condition 1

Table 4 The weighed root mean square acceleration values of every point $a_w$

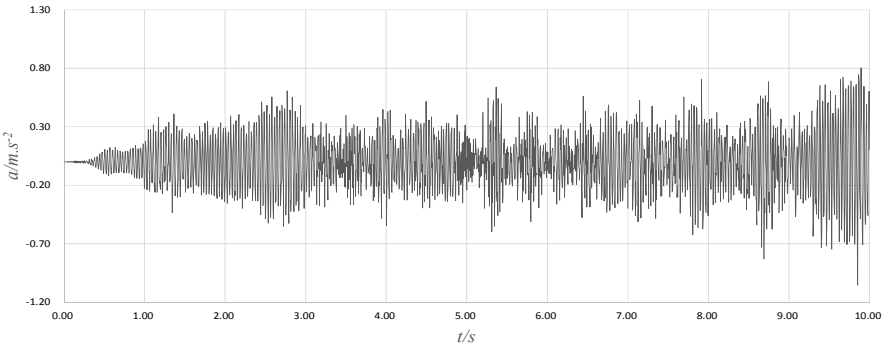
| Node number | 7 | 8 | 9 | 10 | 11 | 12 | 13 | 14 | 15 |
|---|---|---|---|---|---|---|---|---|---|
| $a_w$/mm.s$^{-2}$ | 0.126 | 0.234 | 0.130 | 0.143 | 0.263 | 0.094 | 0.123 | 0.251 | 0.044 |

*Condition 2*

In the condition 2, the acceleration- time curves of point 8 and 13 are shown in Fig.9, the weighed root mean square acceleration values $a_w$ of every point in station hall floor are in Table 5.



(a) the acceleration- time curve of point 8 in condition 2



(b) the acceleration- time curve of point 13 in condition 2

Fig 9. The acceleration- time curves of point 8 and 13 in condition 2

Table 5 The weighed root mean square acceleration values of every point $a_w$

| Node number | 7 | 8 | 9 | 10 | 11 | 12 | 13 | 14 | 15 |
|---|---|---|---|---|---|---|---|---|---|
| $a_w$/mm.s$^{-2}$ | 0.073 | 0.139 | 0.045 | 0.080 | 0.084 | 0.049 | 0.118 | 0.081 | 0.039 |

From Table 4 and Table 5, we can see the maximum of weighed root mean square acceleration values $a_w$ of every point in platform is 0.263mm/s$^2$, which is less than 20 mm/s$^2$, it shows that the platform could meet the need of comfortable quality. At the same time, it shows that condition 1 has much influence on the platform's vibration.

## Conclusions

From the results above, we can see the maximum of weighed root mean square acceleration values $a_w$ of every point in station is 0.276mm/$s^2$, which is less than 20 mm/$s^2$, it shows that the station could meet the need of comfortable quality. Weighed root mean square acceleration values of every point varied differently, and floors don't have much relation with weighed root mean square acceleration values.

The paper gives the way of evaluating comfortable quality of vibration in projects according to ISO10137-2007 and ISO2631-1997, it evaluates the floors' comfortable quality in a station when multiple trains go through. It shows that the station could meet the comfortable quality need of vibration.

# Optimization of tunnel support type through fault zone

Ke Li[1, a,*], Han Guo[2, b,*]

[1]Natinoal Engineering laboratory for highway tunnel construction technology, China Merchants Chongqing Communications Research & Design Institute, China

[2]College of Civil Engineering, Chongqing University, China

[a]nick.88@163.com, [b]brankoilic14@gmail.com, [*]These authors contributed equally to this work

**Keywords:** tunnel, finite element method, fault zone, support type.

**Abstract.** The mechanical properties of tunnel surrounding rock in fault zone is usually quite weak, and the support pressure and displacement are larger than other sections, so the support type in fault zone is a critical issue for tunnel safety. Three types of tunnel support through fault zone were analyzed by finite element method (FEM): ①Reinforced concrete support, ②bolting-shotcreting and reinforced concrete support, ③grouting and reinforced concrete support. The result shows that support stress and surrounding rock displacement with grouting and reinforced concrete support is quite smaller than the other support types.

## Introduction

For mountain tunnel, fault zone is a weak section in construction, because of the weak physical and mechanical properties of surrounding rock mass. After excavation, the displacement of surrounding rock is larger than other sections, which causes larger stress for support structure[1-3], the stability of tunnel rock in fault zone is difficult to be ensured[4].

As the important influence of fault zone on tunnel construction, prediction of the location of fault zone and dynamic response of tunnel in fault zone were investigated by researchers[5,6], which provided theoretical basis for engineering practice. But in actual tunnel engineering through fault zone, the support type is reinforced by experience, the quantitative calculations of typical support results are not conducted in design.

In this paper, three typical tunnel support types are analyzed in a mountain tunnel project through fault zone, the calculation results by 3D-FEM are compared to quantitatively study the effects of the three support types and identify the proper support type.

## Engineering Background

A mountain road tunnel in western China is a double line tunnel penetrating a fault fractured zone. The left line tunnel is chosen as the research tunnel, it is designed as a 3 lane tunnel, its excavation area is 113.93 $m^2$. The length of the tunnel is 1567m and the maximum buried depth of the tunnel is 188.91m. The width of fault zone is 70~360m, the mountain rock is mainly consists of limestone, dolomitic limestone, and sandstone.

## FEM model

To focus on the support effect in fault zone, some assumptions are made in the FEM calculation:
(1) The earth surface is smoothed;
(2) The rock is homogeneous and isotropic except in fault zone;
(3) Only the major fault zone is considered.

A 100m wide, 900m long model is established (see Fig.1), the middle fault zone is 300m long. The bottom is constrained in three directions, the earth surface is free, and the other surfaces are constrained in normal direction. The rock constitutive model is Mohr-Coulomb model. The initial stress is obtained by regression analysis:
Stress in $y$ direction is 1.24 times gravity, normal stress in $x$ direction is 20.4MPa, normal stress in $z$ direction is 22.2MPa, shear stress $\tau_{xy}$ is 0.13MPa, $\tau_{yz}$ is 1.2MPa, $\tau_{xz}$ is 0.33MPa.

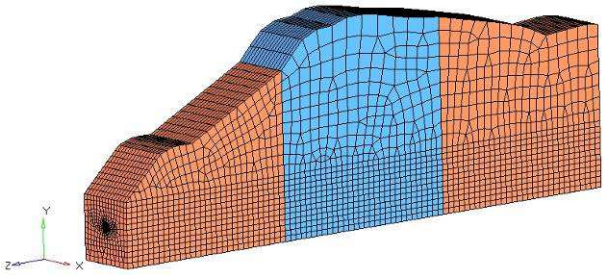

Fig.1 3D-FEM model of tunnel

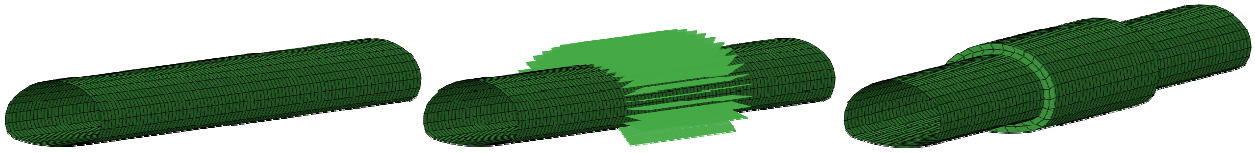
The calculation parameters of rock and structure is shown in Table 1, $t$ is the thickness of support, $E$ is elastic modulus $\mu$ is Possion ratio, $\rho$ is density, $c$ is cohesion, $\varphi$ is frction angle.

Table1 Calculation parameters of FEM tunnel model

| Support structure | | | Rock in fault zone | | | | | Rock out of fault zone | | | | |
|---|---|---|---|---|---|---|---|---|---|---|---|---|
| $t$ | $E$ | $\mu$ | $\rho$ | $E$ | $\mu$ | $c$ | $\varphi$ | $\rho$ | $E$ | $\mu$ | $c$ | $\varphi$ |
| 0.6m | 28 GPa | 0.2 | 2400 kg/m$^3$ | 4.03 GPa | 0.38 | 3.25 MPa | 32° | 2680 kg/m$^3$ | 11.29 GPa | 0.27 | 7.6 MPa | 45.2° |

**Three support types**

Three typical tunnel support types are calculation in FEM model (see Fig.2): ①Reinforced concrete support(type I), ②bolting-shotcreting and reinforced concrete support(type II), ③grouting and reinforced concrete support(type III).



(1) Reinforced concrete support

(2) Bolting-shotcreting and reinforced concrete support

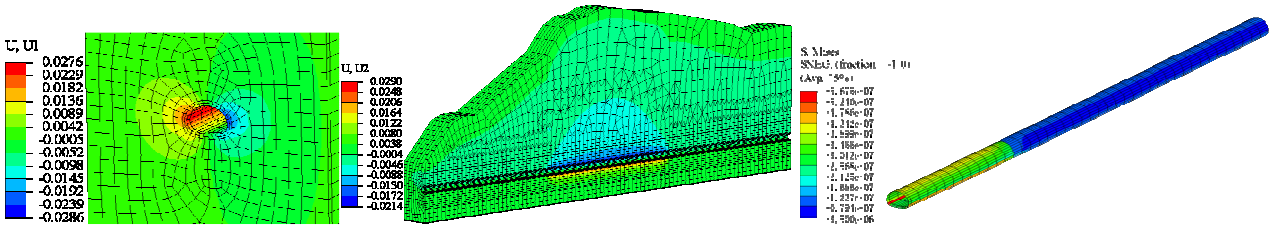
(3) Grouting and reinforced concrete support

Fig.2 Three support types of the tunnel

Other calculation parameters:
(1) Bolt: spacing 0.6m×0.6m, 4m long, diameter 25cm, $E$=206GPa, $\mu$=0.3;
(2) Grout: thickness is 2m, $E$=21GPa, $\mu$=0.24, $c$=3.25MPa, $\varphi$=32°.

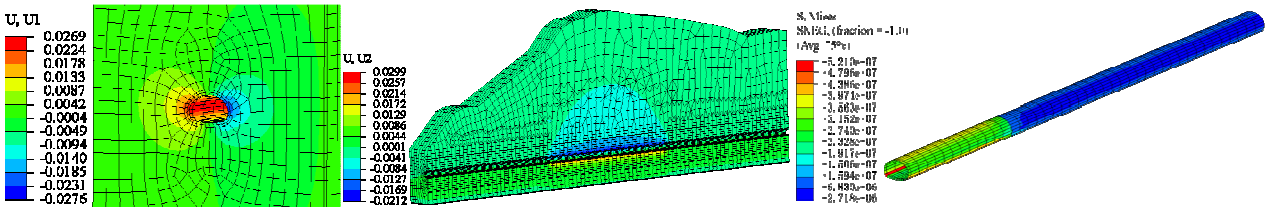
**Comparison of three supporting effects**

**Calculation Results**. The horizontal, vertical displacement of tunnel surrounding rock and the Mises stress of the tunnel support structure with three support types are shown in Fig.3.



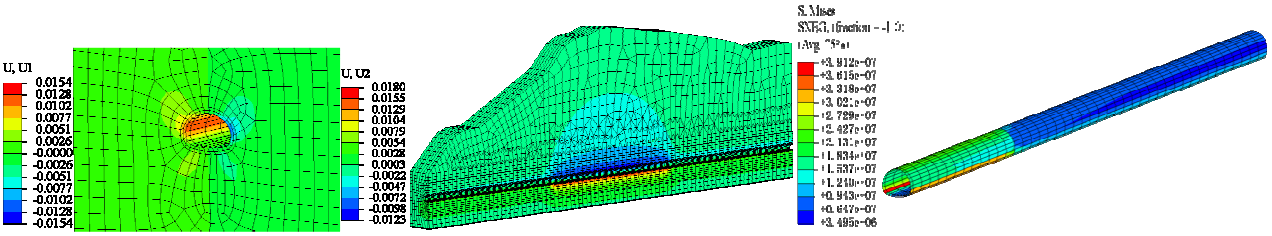
(1) Horizontal displacement (2) Vertical displacement (3) Mises stress of support structure

Fig.3 Calculation result of reinforced concrete support(type I)



(1) Horizontal displacement (2) Vertical displacement (3) Mises stress of support structure

Fig.4 Calculation result of bolting-shotcreting and reinforced concrete support(type II)

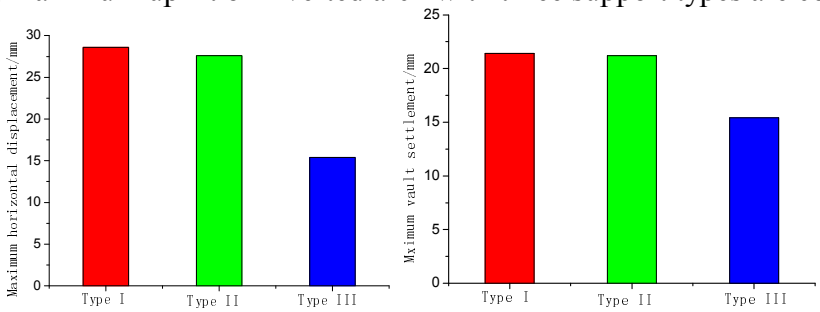


(1) Horizontal displacement (2) Vertical displacement (3) Mises stress of support structure

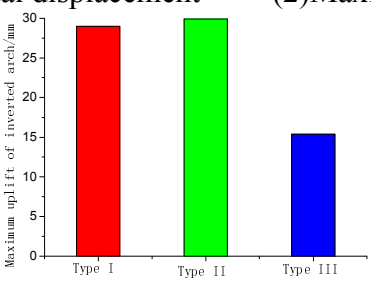
Fig.5 Calculation result of grouting and reinforced concrete support(type III)

It is shown that rock displacement and structure stress in fault zone are much larger than the other sections. The displacment in fault zone is more than 10mm larger than common zone, so the reinforcment of structre is necessary. The maximum stress of structure is at the bottom of side wall, more attention should be paid in design.

**Comparison of results**. The maximum horizontal displacement of surrounding rock, maximum settlement of valt, maximum uplift of inverted arch with three support types are compared in Fig.6.



(1)Maximum horizontal displacement (2)Maximum vault settlement



(3)Maximum uplift of inverted arch

Fig.6 Maximum displacement of surrounding rock with three support types

The comparison of maximum support structure stress is shown in Fig.7.

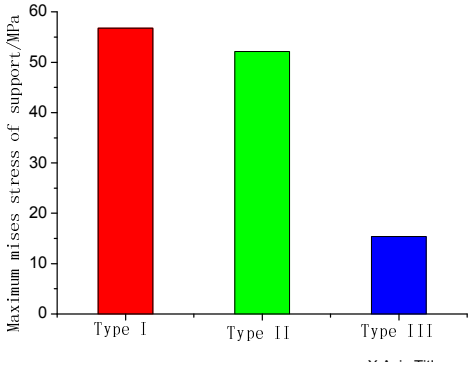


Fig.7 Maximum mises stress of support structure with three support types

The results shows that the displacement of surrounding rock and support stress with support type I is the largest, and the displacement and stress with support type III is the lowest. The maximum horizontal displacement with three support types are 27.6mm, 26.9mm, 15.4mm respectively, and the maximum support structure stress with three support types are 56.75MPa, 52.10MPa, 39.12MPa, respectively.

## Summary

Three tunnel support types in fault zone are compared:①Reinforced concrete support(type I), ②bolting-shotcreting and reinforced concrete support(type II), ③grouting and reinforced concrete support(type III). The FEM calculation shows that the surrounding rock displacment and structure stress with type III is the lowest, on other hands, type III is the most effective tunnel support type for fault zone.

# Force Analysis of the Middle Wall in Multi-arch Tunnel under Central Hole + CRD Method

Li Jun, Wang Zong Lin

School of Transportation Science and Engineering, Harbin Institute of Technology, Harbin 150090, China

hitlij@yeah.net

**Keywords:** Multi-arch Tunnel, Force Analysis, Middle Wall, Mechanical Properties

**Abstract.** arch tunnel construction in the presence of construction mechanics often unclear, the lack of systematic design and construction of the theory can learn. Harbin Clinic Road thesis double-arch tunnel project as the basis, the construction process through its hole + CRD using the finite element simulation analysis and on-site monitoring measurement data processing, engineering arch tunnel song used in the wall study the mechanical properties.

## Introduction

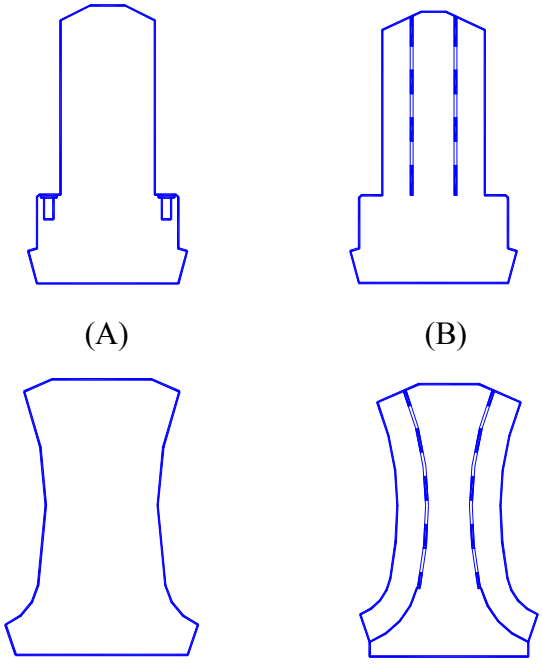
In the design and construction of the arch of the tunnel, is still a lack of effective projects can draw analogies can be, there are more problems, in addition to even itself be perfect arch tunnel structure type, another important factor is the mechanics of the arch tunnel no in-depth study of the characteristics, especially the position of the wall in the arch of the tunnel, the tunnel of this site is the place where stress concentration, the force is very complex, tension, compression, bending, twisting, cutting both, while the wall mechanics behavior and its displacement and settlement indicators directly related to the overall stability of the arch of the tunnel. In subway construction, although open-cut construction method is most convenient, but in the bustling city traffic arteries, intensive commercial construction zone, due to traffic conditions, geographical conditions, open-cut construction can not be implemented, and the cover lid down construction dig dug along the building need traffic relief, to some extent, affect traffic. Therefore, it is necessary to combine the mechanical properties of the actual project arch tunnel in the wall for further analysis, which is an important reference and guidance for total construction of double-arch tunnel.

## Project Overview

Health Road Bridge project is located in Nangang District, Harbin and Xiangfang District, Ha Ping Road starting point for the design and finish of the street through the village, project length of 3500 meters. East-west road red line width of 60m. Associated with the Arboretum area to consider wearing Ha Ping Road tunnel form, Province Forest Botanical Garden and triple road. This project is parallel to the Ring Road, a city main road between the Third Ring Road, Ring Road and the Third Ring Road and 3.5 km spacing are also supporting road between the two loops. After the project is completed effectively triage and Hing, dynamic road traffic coming up with triple road through rural road network formed Street, the main road to form a new system. Tunnel "middle hole + CRD" method of construction, the use of soft soil Shallow Large Span Tunnel and the Urban Design Study hole + CRD method, that is, first excavated in the hole, and then the outside of the two main tunnel excavation has three pilot tunnel , followed successively by the main tunnel excavation inside the left lane of the three guide hole in the wall, and finally has the right line of the main tunnel excavation construction technology on the inside of the walls of the three-hole lead, materials and energy savings, effective control of costs, maximize social, economic efficiency. The construction method for the construction method similar to existing industry or national labor law innovation and development, the formation of patented technologies, and supporting construction method.

**The wall structure type double-arch tunnel**

Arch tunnel's arch tunnel wall is load-bearing force transmission and key parts, is to maintain the overall stability of the central arch of the tunnel, but also anti-drain key positions. In the double-arch tunnel structure, the importance of the wall can be said pivotal. Corresponding to the four double-arch tunnel section type, the structure type also has four walls, the walls are straight overall layered straight in the wall, the whole song in the wall, and three songs in the wall, the basic section type shown in Fig.1. Harbin Clinic Road tunnel wall in the form of a curved wall.Tunnel "middle hole + CRD" method of construction, the use of soft soil Shallow Large Span Tunnel and the Urban Design Study hole + CRD method, that is, first excavated in the hole, and then the outside of the two main tunnel excavation has three pilot tunnel , followed successively by the main tunnel excavation inside the left lane of the three guide hole in the wall, and finally has the right line of the main tunnel excavation construction technology on the inside of the walls of the three-hole lead, materials and energy savings, effective control of costs, maximize social, economic efficiency. The construction method for the construction method similar to existing industry or national labor law innovation and development, the formation of patented technologies, and supporting construction method.



A whole wall directly, B layered straight in the wall,

C whole song in the wall, D three-song in the wall

Figure.1 Basic types of double-arch tunnel wall

**Force process variation in middle wall construction**

Arch tunnel in the wall by the time the two main tunnel construction in all directions repeatedly loads and loads vault over the role of the force is very complex, pressing, pulling, bending, shear are internal forces are constantly changing, mainly five distinct converting the internal forces, shown in Figure 2. (1) before the main tunnel excavation: the guide hole equivalent to one-way tunnel, the walls to withstand the pressure from the main dome of the rock to produce relaxation, belonging axial compression structure, since the wall section is relatively large, at this stage by force is relatively stable. If the tunnel bias exists, the wall is also biased loads role. (2) the right hole before excavation support: excavation hole left, destabilizing the pilot tunnel excavation in rock formation, the whole tunnel produces bias. The walls are eccentric compression structure, this time in the main wall shear

and bending. (3) When the hole is not left right after the cave excavation support: Supporting the right tunnel surrounding rock deformation is suppressed, while the right footing to set the initial support of the top hole on the right side of the wall. At this point, only the left hole in the wall on the same side of the pressure to produce, and bear right tunnel initial support to pass pressure. (4) when the left does not support tunnel excavation: excavation hole left and right holes in the wall to form a bias. Early (5) support on both sides of the main tunnel after the completion of: the left and right holes are formed, the wall is mainly exposed to the vertical force, force and stability. The wall by the force process also closely related to geological factors and construction. If the tunnel overall bias exists, or the side of the main tunnel collapse occurred a great impact, the force will give the wall construction.

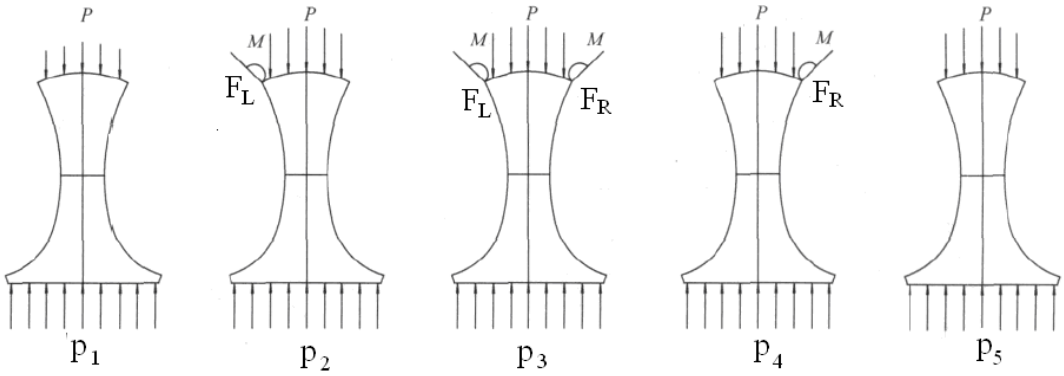


Figure.2 Wall force convert in the construction process

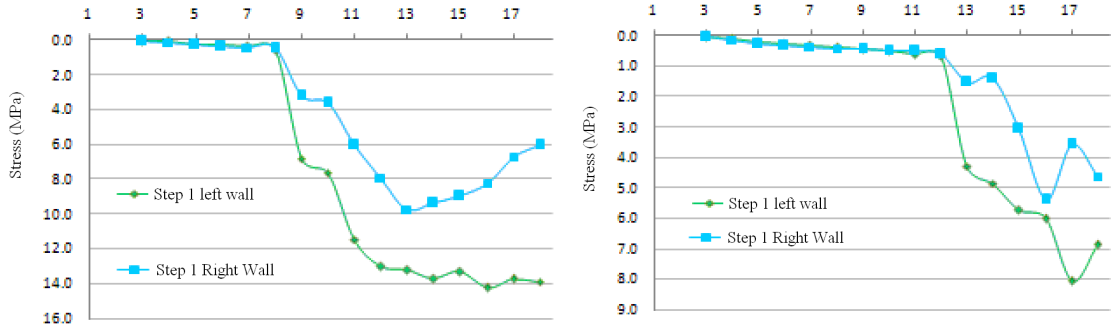
**Middle wall stress analysis**

As an important load-bearing walls in the double-arch tunnel structure, which is closely related to the force in the form of the construction process, the analysis of the wall in both the construction process, the wall construction process with effective stress changes, shown in Figure 4-4 - 7,4-4-8 shown by comparative analysis because the first step of an excavation hole left, then the right excavation hole in the wall left, right uneven stress concentration in the excavation process, the maximum stress 14.2Mpa, and with a significant reduction in stress during the excavation, the final state of total stress contours significant concentration phenomenon (Figure 3). As the excavation process step 2 symmetry, the main form of stress distribution is relatively symmetrical relative terms during the excavation process a maximum stress in the wall of a small 8.1Mpa, and the construction process in the wall left and right small differences, the force uniform and stable (Fig.4).

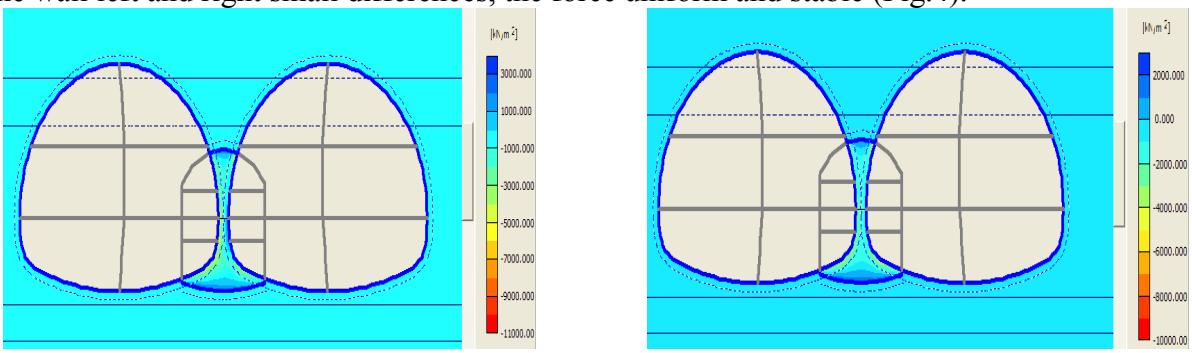


Wall stress in Step 1 Wall stress in Step 1

Figure.3 The results of the wall stress data

Middle wall stress analysis As an important load-bearing walls in the double-arch tunnel structure, which is closely related to the force in the form of the construction process, the analysis of the wall in both the construction process, the wall construction process with effective stress changes, shown in Fig.3 and 4 shown by comparative analysis because the first step of an excavation hole left, then the

right excavation hole in the wall left, right uneven stress concentration in the excavation process, the maximum stress 14.2Mpa, and with a significant reduction in stress during the excavation, the final state of total stress contours significant concentration phenomenon (Fig.3). As the excavation process step 2 symmetry, the main form of stress distribution is relatively symmetrical relative terms during the excavation process a maximum stress in the wall of a small 8.1Mpa, and the construction process in the wall left and right small differences, the force uniform and stable (Fig.4).



Tunnel wall stress in Step 1 Tunnel wall stress in Step 2

Figure.4 Tunnel wall stress

Excavation processes impact on the wall by the force of a large, asymmetrical when excavation process, the wall will withstand the horizontal force and overturning moment, especially in the first cavern while construction is completed, the other side of the cavern cave hair only when the wall will be in the most dangerous state, according to this time the forces should be as the wall design.

## Conclusion

In the process of dismantling temporary support will encounter break the balance of the original architecture of the risks arising from excessive deformation or structural instability, but as long as removal of temporary support scheme selection is reasonable, and strictly control the construction process, the removal of temporary support to strengthen monitoring during the measurement, so that monitoring and feedback to guide the construction, tunneling structure can ensure the temporary removal process does not produce too large deformation, fully able to ensure formation occurred within the scope of the displacement can be controlled. This is mainly due to the loose soil belongs to the medium, not a homogeneous elastic medium, adjustments due to the stress caused by unloading obvious, stress of soil material is mainly due to their own gravitational mass and the accompanying stress field. This shows that the theoretical calculations and underground engineering can not be fully consistent with the actual situation, resulting in major reason for this is because of the complexity of the decision geotechnical conditions. In actual engineering practice, we must pay attention to measurement, based on the actual situation to choose the right parameters and appropriate supporting construction methods.

# Force State of Country Rock and Supporting Structure in Multi-arch Tunnel under Central Hole + CRD Method

Li Jun, Wang Zong Lin, Zhong Jun Fei

School of Transportation Science and Engineering, Harbin Institute of Technology, Harbin 150090, China

hitlij@yeah.net

**Keywords:** Engineering Mechanics, Construction Mechanics, Tunneling, Rock Stress

**Abstract.** The reason situ stress is very complicated, and it is still not very clear question. In this paper, the construction process through practical engineering analysis on a variety of construction methods and steps arch tunnel to study the effects of different excavation methods and deep anchor support large section tunnel under guard by theoretical analysis of surrounding rock stress field, strain field and variation of the displacement field, analysis of different rock excavation methods, supporting stress state characteristics, in order to optimize the choice of tunneling method provides a theoretical basis. Under the conditions all kinds of rock reasonable steps to secure construction methods put forward and lay the foundation for long-term safety arch tunnel.

## Introduction

In the process of tunnel excavation, the surrounding rock, and the walls supporting the force, such as the state of research is necessary. By the beginning of the lining between the support and the soil pressure cells buried early lining, second lining, buried in wall reinforcement meter measured the actual rock, initial support, the walls of the excavation force size , always comparing initial support, second lining, the wall by the condition of the actual force with the theoretical value of the support is within the control of the controllable range of safety analysis of the progress of each step with the various parts of the excavation of the force changes in the analysis that is located in various parts of the rock vaults, arches back (lumbar arch left and right arch waist), invert (invert left and right side invert, invert the bottom) of the rock stress conditions, peri with the dynamic effects of stress in rock excavation face advance to determine the shortest distance between the excavation face the stress of the surrounding rock, excavation for the introduction of the Act, in which the accumulation of geological conditions for construction data, and construction. The use of soft soil Shallow Large Span Tunnel and the Urban Design Study Cave + CRD method, that is, first excavated in the hole, and then has two main tunnel excavation outside the three-hole lead, followed successively by the main tunnel excavation in the left lane the inside wall of the three-hole lead, finally has the right line of the main tunnel excavation by construction technology inside the walls of the three-hole lead, materials and energy savings, effectively control costs and maximize social and economic benefits. The construction method for the construction method similar to existing industry or national labor law innovation and development, the formation of patented technologies, and supporting construction method.

## Rock stress state of the construction process

Refers to the surrounding rock tunnel tunnel certain range, have an impact on the stability of the rock tunnel . From the perspective of mechanical analysis point of view, the boundary should be drawn in rock stress changes caused by tunneling negligible place , or on the border due to the excavation of the tunnel surrounding rock displacement should be zero in this range should be 6 to 10 times the hole diameter on the cross section. In Weak Rock , joints and fissures are well developed , very broken rock was cut , structural deformation and failure of rock face have no effect , so the

characteristics of the rock mass and structure characteristics of the rock is not fundamentally the difference between , for example, soil can be considered as a special kind of severe weathering broken rock . Soil conditions can be classified according to particle size clayey soil, sandy soil, gravel soil . Soil plasticity index greater than 10, becoming clayey soil, which plasticity index greater than 10 and less than or equal to 17 for the powder soil clayey soil, soil plasticity index greater than 17 is clay. Particle size greater than 2mm content does not exceed 50% of the total mass of fine particles and particle size greater than 0.075mm content of more than 50% of the total mass of the soil is sandy soil . Particle size greater than 2mm content of more than 50% of the total mass of soil is gravelly soil . Thus, the mechanical properties of the rock mass is the result of the inevitable effects of many factors , but some rock is rock mechanical properties from the control action , and some rock mechanical properties of structural plane is dominant . Description and determine the level of construction rock The tunnel is the beginning of large-span Shallow silty clay rock lining double, two separate tunnel lining, excavation width of 26.4m, excavation height of 9.812m, the roof covering the soil around 7 ~ 8m. Rock level can be calculated are V-class rock. Construction using the middle hole + CRD construction method, and this method has been optimized to realize that both sides of the hole and the hole while the main tunnel excavation, on both sides of the hole, the pilot tunnel excavation method has under construction excavation.

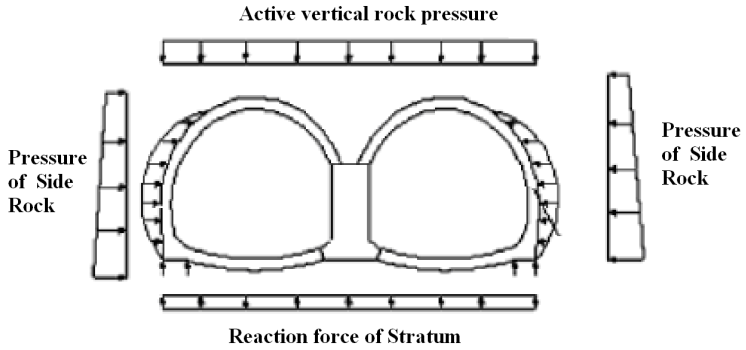

Figure.1 Composite lining rock pressure analysis

When architecture design of the tunnel, there are two computing models, one is the main supporting structure as the bearer, rock deformation from the supporting structure of a constraint, called load - structure model. Another rock was carrying in the body, supporting structure to limit the tunnel rock deformation, supporting structure and surrounding it as a single unit, as co-hosts of the tunnel structure system, called strata - load model. Before the tunnel excavation, rock in the initial stress state, the tunneling induced redistribution of rock stress, and natural rock "arching" form a natural arch. According to the two models can be considered: the arch tunnel in shallow, so to load - structural model to analyze its force. So in the process of double-arch tunnel excavation in rock stress changes are as follows: 1. In the pilot tunnel excavation, the destruction of the initial rock stress state, causing the cavern and initial support deformation stress redistribution, the formation of new stress field - rock secondary stress field. 2. When the right tunnel excavation, rock stress redistribution roof also formed three rock stress state. 3. When the left tunnel excavation, rock stress redistribution roof also formed four rock stress state. 4. Set "second lining", due to some of the deformation front has not completely stopped, so there will still be part of the force, such as residual deformation of rock, and reduce the physical and mechanical properties of rock after construction, etc., still "second lining" to commitments. This "second lining" stress state of the rock should be called double-arch tunnel surrounding rock stress state five times.

**Rock Pressure Calculation**

Calculation of shallow buried even the top of the vertical uniform Jacobsson Arch Tunnel dynamic pressure consists of two parts, namely:

$$q = \gamma H$$
$$q_z = \gamma(H_1 - H) \tag{1}$$

Where: q-tunnel vertically uniform pressure (kN/m$^2$); qz-as between the walls and the sides of the triangular block sandwiched arch weight (kN/m$^2$); γ-rock density (kN/m$^3$); H-tunnel depth, refers to the top of the tunnel to the distance (m) the ground. The role of rock pressure levels on both sides of the tunnel lining is:

$$e_1 = \gamma H \tan^2(45^\circ - \frac{\phi}{2})$$
$$e_2 = \gamma(H + h)\tan^2(45^\circ - \frac{\phi}{2}) \tag{2}$$

Where: e1, e2-tunnel vault and horizontal rock pressure at the bottom; γ-rock density (kN/m3); H-tunnel depth, refers to the top of the tunnel to the distance (m) the ground; h-tunnel excavation height (m); Φ-rock to calculate the friction angle (°).

Rock pressure can be calculated during construction due to rock stress five double-arch tunnel construction process of re-distribution, the more complex nature of the rock, but a lot of changes, human factors, such as excavation and support methods great influence on rock nature, can not be estimated in advance. In theory it should be analyzed to determine the combination of experience, to guide the construction of double-arch tunnel.

**Charged to guard the construction process study the stress state**

Before the body hole tunneling, rock for relatively low-level implementation of advance support to enhance the strength and stability of surrounding rock. Body in the hole tunneling process, also in order to maintain a stable rock, must immediately apply for initial support. Support form the tunnel is: a bolt, steel mesh, shotcrete and steel as the primary support and supplemented necessary to mold build advance support for the secondary lining of reinforced concrete lining composition, initial support and the secondary set between the arch lining waterproof barrier.

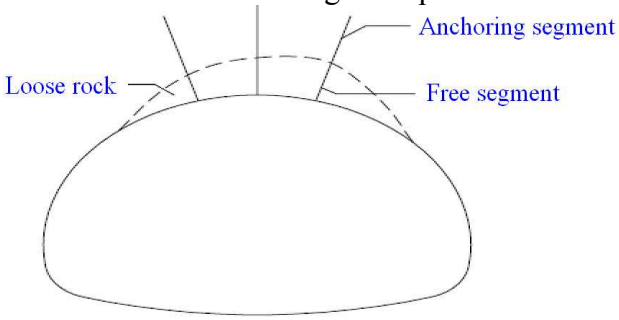

Figure.2 Schematic of rock tunnels bolt action

Through on-site testing of soft soil tunnel anchor stress and statistical analysis to study the effects and mechanisms supporting soft soil tunnel anchor, the following main conclusions: (1) Through the anchor stress test data meta-analysis, found arch compression bolt to the main arch of the foot anchors in tension-based, skirting the foot of the lock bolt has a tensile stress is also compressive stress; locking bolt stress is generally greater than the foot arch anchor stress. In soft soil tunnel system bolting obvious. (2) analysis that the tunnel excavation of shallow tunnels in soft soil arch occurred overall settlement, there is no anchor anchoring section. Deep soft soil tunnel excavation soil mass produce a larger plastic zone, and the system is currently anchor of "short and tight" is not used to set principles through the plastic zone, there was no anchoring segment. In addition, anchor and soil using cement mortar or adhesive roll poor anchoring agent, thus arch tunnel in soft soil anchor system protective role in not charged.

From the analysis of the deformation of soil mechanics state arch tunnel in soft soil anchor system, analysts believe that because the anchor is anchored to the initial support and into the soil, the soil from inside the deformation constraint in the early after applying for support, with respect to the subsequent deformation of the soil, the anchor is stationary, so the big tunnel in soft soil deep loess Shallow tunnels or plastic zone, arch system bolt down by the soil the frictional resistance, which is equivalent to withstand negative skin friction piles, which anchors the arch system pressure.

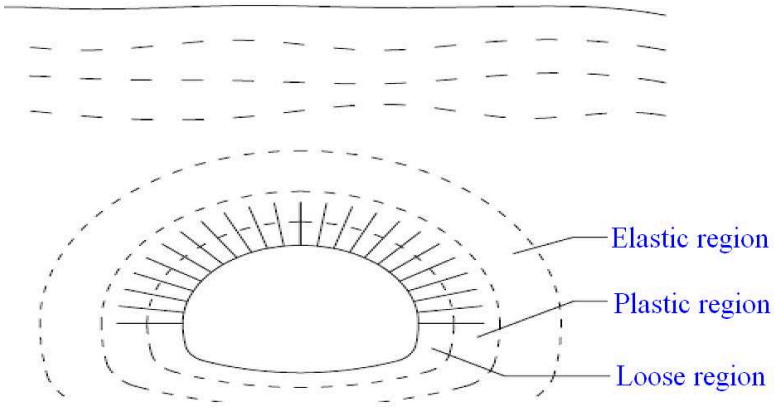

Figure.3 Produces of plastic tunnels in deep loess area

Description and determine the level of construction rock The tunnel is the beginning of large-span Shallow silty clay rock lining double, two separate tunnel lining, excavation width of 26.4m, excavation height of 9.812m, the roof covering the soil around 7 ~ 8m. Rock level can be calculated are V-class rock. Construction using the middle hole + CRD construction method, and this method has been optimized to realize that both sides of hole while the main tunnel excavation, on both sides of the hole, the pilot tunnel excavation method has under construction excavation.

**I-beam gantry study the stress state**

When measured using surface-type strain gauge steel top and bottom flange steel support indirect test strain, then by Hooke's law to calculate the stress test point, and then assume that the steel support in the state without regard to flexible working beam web site shotcrete force, you can get the steel support inverse mechanical method based on the actual internal forces as follows:

$$\sigma_1 = \frac{N}{A} - \frac{M}{I}h$$
$$\sigma_2 = \frac{N}{A} + \frac{M}{I}h \tag{3}$$

$$N = \frac{A(\sigma_1+\sigma_2)}{2}$$
$$M = \frac{I(\sigma_2-\sigma_1)}{2h} \tag{4}$$

wherein: $\sigma_1, \sigma_2$ is the upper beam of I-beam, a lower edge of the test stress (MPa); N is calculated beam axial force (kN), M for the beam bending moment calculated value (kN * m); A is the beam cross-sectional area ($m^2$), I is the moment of inertia beam ($m^4$); h is a surface-type steel beam horizontal strain (X-axis) of the distance (m) meter away.

It is prone to collapse during excavation, so depending on the circumstances when applying for advanced small pipe excavation, excavation contour play reinforcement and soil pipe roof reinforcement area of effect. In the long tube, and a small catheter together, even rock stress relaxation, the initial relaxation small, can effectively achieve the maintenance of rock, rock reinforcement purposes, to provide a reliable guarantee safe excavation. As can be seen from the results of the analysis that the beam erection short, stress increases rapidly, visible beam earlier play

its carrying capacity, can play a role in supporting timely rock. Beam stress lasts about 2-4 months before gradually stabilized, the same description of weak and fractured rock, the rheological properties of the original rock stress release, and verify the correctness of the foregoing analysis. Beam overall state of compression, bending moment is small, in line with the theoretical analysis of the law, but its material properties play a limited, in contrast to shot Crete stress state, the proposed design phase should be appropriately reduced beam model, increasing jet concrete thickness, material properties, and give full play to project cost savings.

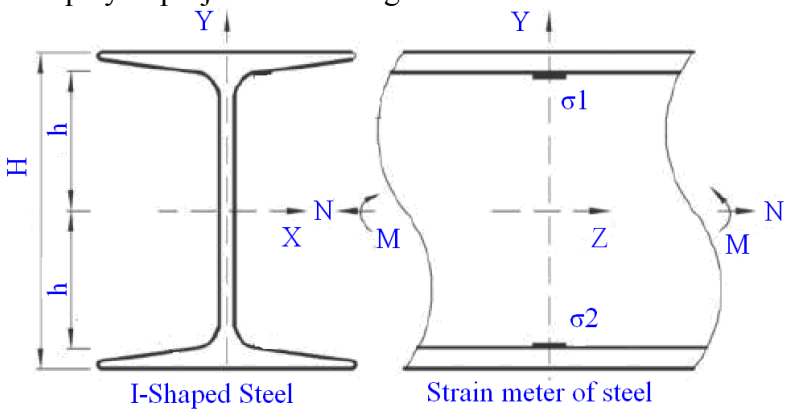

Figure.4 Steel strain gauge layout and internal force calculation icon

## Conclusion

During the design calculation of the external load is considered as rock pressure, ignoring the role of rock reinforcement and self-supporting capability bolt, the calculation model is safer. Through the entire shell of reinforced mesh shelf space calculation shows that steel compression deformation is synchronous, while unit internal forces reinforced curve indicates the middle of the reinforced to withstand a greater load for the main bearing bars. According to the mechanical characteristics of steel lattice shell structures, we arranged some reinforcement strain test section. About ten days or so deformed shell from installing network supporting structure is large, the future network shell and rock interactions stabilize.

**Keywords:** shield machine in shallow soil, airport apron, sedimentation control, soil pressure control, deep splitting grouting

**Abstract.** It is a hard engineering problem for the shield machine passing through the capital airport apron in shallow soft soil. Tunneling parameters were obtained from the 50m simulation test section ahead the apron. The shield machine kept tunneling steady and balanced by optimizing the control technology of soil pressure and grouting. According to the monitoring results, the secondary and repeated grouting technology was applied timely. The deep splitting grouting technology was used when the monitoring value exceeding control standards. The settlement value was effectively controlled.

## Introduction

The shield machine past through the Capital Airport apron in T2 branch line of Beijing Capital International airport. It is a super risk source, on the one hand, to ensure the safety of aircraft taxiing and parking, airport apron surface deformation is very hard to control; On the other hand, the tunneling of shield machine in shallow soil make great disturbance to the surface, it's hard to control the deformation of the surface, which makes construction more hard[1], so effective measures must be taken to ensure the safety and success.

## Engineering situation

**Design overview.** The underground section of the shield interval in T2 branch line need to pass through the Capital Airport apron[2] before reaching the T2 Airport terminal. As shown in Fig.1, the length is 376m. The thickness of the covering soil above the tunnel is 8.6-10.2m, line spacing is 12m, internal diameter of shield tunnel is 5400mm, thickness is 300mm, width is 1200m. Construction used earth pressure balance shield machine[3].

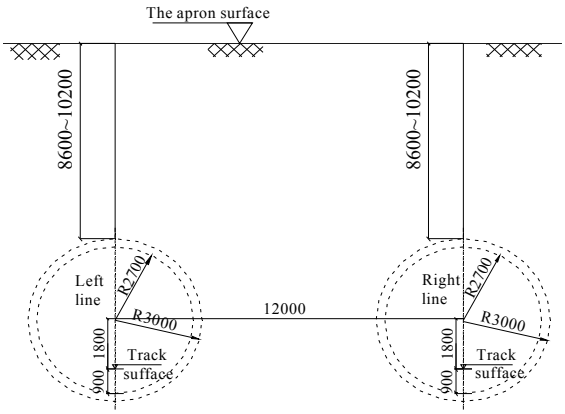

Fig.1 Shield tunnel under apron profile sketch

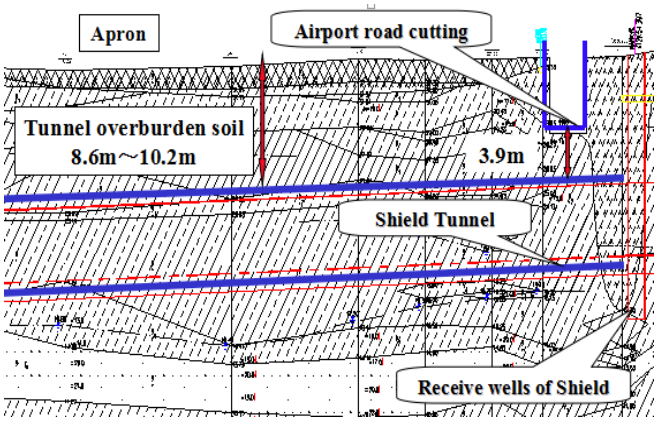

Fig.2 Geological section of shield crossing the apron

**Geological and hydrological conditions.** As shown in Fig.2, the shield machine mainly cross the silty clay④, clay④second layers, some local cross silty sand④third layers, which belong to soft soil layer. The water which tunnel shield crossed involved two layers: The one is perched water, buried depth of groundwater is 3.46-3.80m; The other one is Interlayer diving, buried depth of groundwater is 15.7-19.5m. Water is larger.

## Engineering characteristics

(1)The control of ground subsidence is very strict, which leads the difficult construction. Due to the particularity of the airport apron, especially the plane taxiing area have a high demand to the sedimentation value of surface, the control standard of sedimentation value by airport management department is: the maximum subsidence control values allowed by surface should no more than 20mm, which made it very hard to control the surface sedimentation for double lines shield tunnel crossing.

(2) Covering soil is shallow, which has large disturbance to the formation.

(3) The formation is mainly saturated silty clay, and has a high level of underground water.

## Soil pressure management techniques of tunnel shield excavation

**Working soil pressure setting of tunnel shield.** The soil pressure value could calculate according to "Static soil pressure+ hydraulic pressure+ the reserved pressure" [4], but the static soil pressure value is difficult to determine, under the general, we can make the measured value of the soil pressure gage on excavation face when the shield stop approximately as the target soil pressure set point. According to the calculation and initial tunneling debugging, the target soil set point is 55~70 Kpa.

**Keep excavation surface soil pressure balance.** In order to control surface stability, we must keep formation soil pressure P and soil pressure in the sealed cabin P0 for a dynamic balance by the management of target soil pressure. This balance, can realize by adjust and control the dump soil mass of screw conveyer.

As shown in Fig.3, it is the relationship between excavation surface pressure difference $|P-P|$ and the dump soil mass of screw conveyer when tunneling. It is clear that the value and range of change of soil pressure is an important factor for excavation surface stability. In order to make the screw conveyer dump regularly, and ensure the soil pressure of excavation surface, target of soil

pressure management also contained mud add amount (mud property involved), Jack advancing speed, Cutting knife plate speed control etc. Therefore, the target work pressure management actually is an integrated management of technology. As shown in Fig.4, through the adjustment of soil pressure above, soil pressure stability was realized.

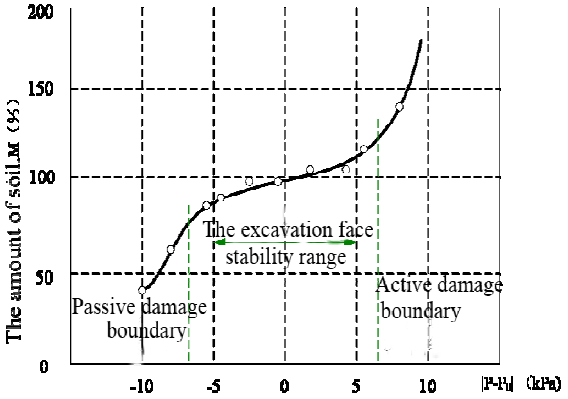

Fig.3 The relationship between pressure change and the amount of soil

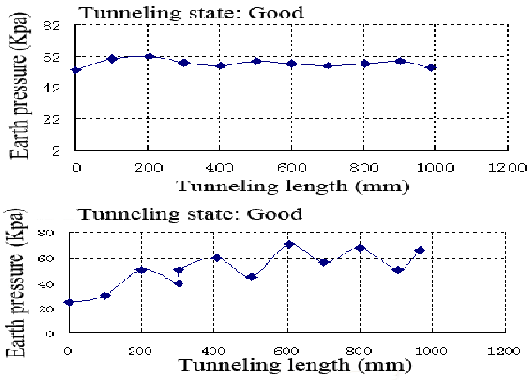

Fig.4 Variation graph of soil pressure in indoor soil which excavating a ring indoor

**The management of excavation soil mass.** Whether there is a balance between excavation soil mass and dump soil mass has a big impaction to excavation surface soil pressure[5]. Fig.5 shows the relationship between excavation soil mass and dump soil mass of one circle when tunneling. As shown in Fig.5, if excavation soil mass bigger than dump soil mass, the soil pressure has a tendency to rise, or the soil pressure has a tendency to reduce.

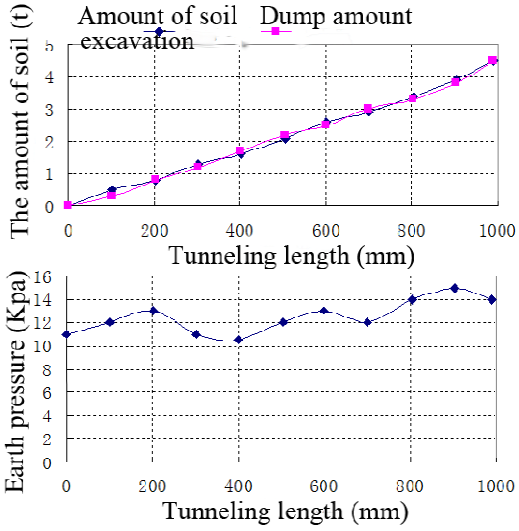

Fig.5 The relationship between the amount of excavated soil, soil volume and soil pressure

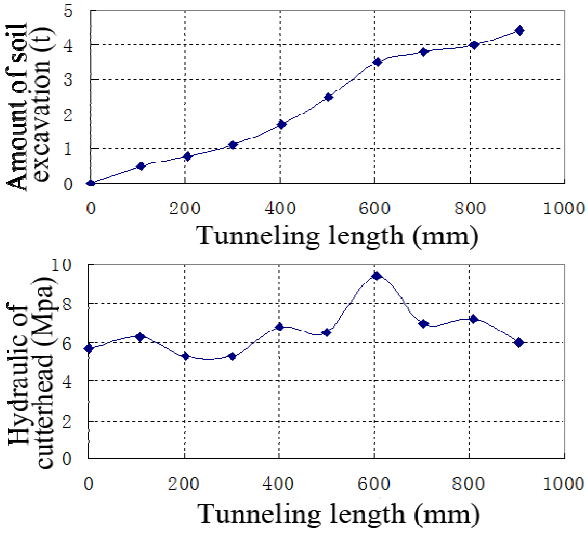

Fig.6 The relationship between excavated soil volume and hydraulic cutter

As shown in Fig.6, the tunnel shield excavation soil mass management requirements is to make the amount of soil digging and dump equal volume of soil Through adjust oil pressure of cutter head and screw conveyer when construction to realize the balance of excavation soil mass and dump soil mass. But these parameters are changing constantly as the shield tunneling, so, it's too hard to make excavation soil mass and dump soil mass strictly equal to each other, there are some fluctuation between them in engineering practice.

### Synchronous grouting and multiple supplement grouting

**Synchronous grouting.** Synchronous grouting use double(A,B) slurry, when the shield advance about 100 mm, send the A and B slurry respectively through the two grouting pumps on the trolley, and intensively mixed in the hybrid tube of the machine head then outpoured by the grouting lines on the shield shell, the synchronous grouting would begin, When pushed over 900 mm then the synchronous grouting completed. After every synchronous grouting the grouting lines should be cleaned by the high pressure water pipe in the head.

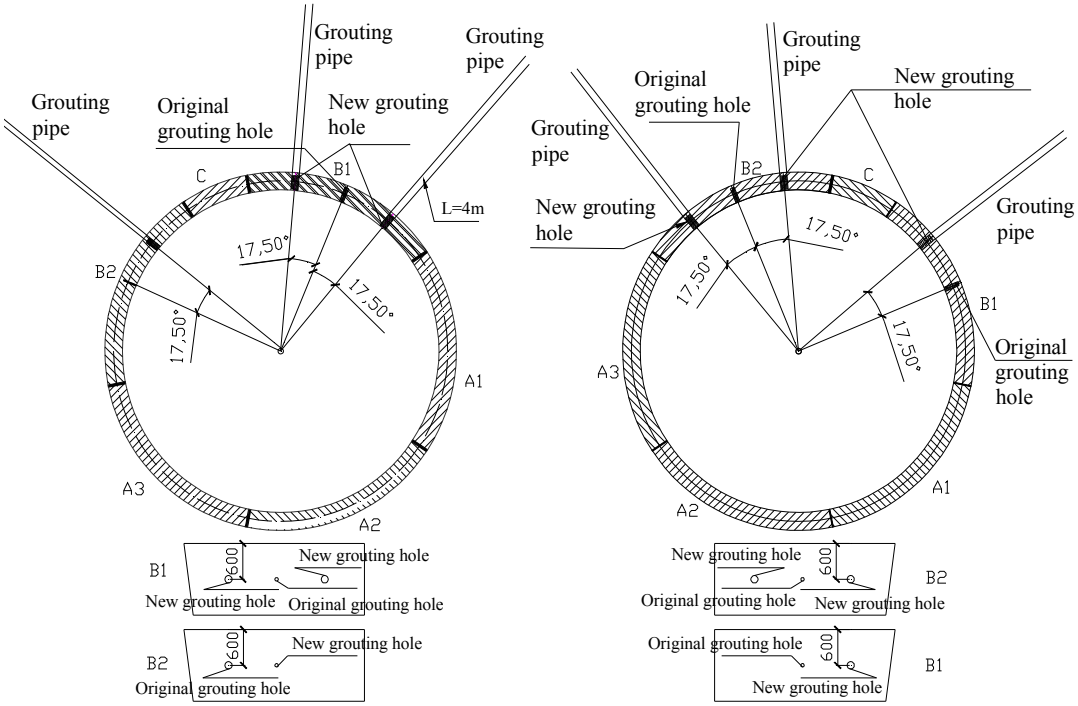
In this engineering, the pressure of the synchronous grouting inlet was chosed 1.1 ~ 1.2 times of static soil pressure, grouting pressure≤0.28Mpa. Synchronous grouting quantity was nearly about 140％ of the theory of clearance, which was 1300L per circle; Synchronous grouting began meanwhile with lining away from shield tail and tunneling, and should complete before one circle driving completed.

**Twice (or more times) grouting.** Twice (or more times) grouting mainly make up for the inadequacy of synchronous grouting, Therefore the slurry property are obviously different from synchronous grouting slurry. The fineness of slurry material should be smaller and fluidity of slurry should be better, it was necessary to adding retarder to prolong the setting time. Meanwhile, in order to increase the strength of slurry, bentonite must be abandoned. The grouting pressure should be some smaller, the time might extend appropriately, which is long time and low pressure. Twice grouting: 700L/2 loop, grouting pressure ≤0.3Mpa；Three times grouting: 500L/2 loop, grouting pressure ≤0.35Mpa.Twice, three times supplement grouting use the injected hole on the 4 ~ 6 slices with loop after the tunnel shield to complete.

### Deep hole fracturing grouting technology inside the tunnel hole

In order to control the surface subsidence value of the airport apron, after the shield machine went through, the deep hole fracturing grouting technology[6] was introduced to compact and split the soil with disturbance, to jacking and strengthen formation a little to ensure the final settlement of apron was controlled within the allowable range.

Specific practices are as follows: reserved grouting hole at its top segment, each loop is 2-3 ones, mainly upward direction, as shown in Fig.7, the depth of grouting in this engineering is 6m; Grouting hole diameter 84 mm. Slurry was double grout and grouting volume and pressure should be adjusted according to monitoring data timely.



Explanation:
1, the new grouting hole locations acrossing the tube sheet steel can be adjusted.
2, the new grouting hole diameter 84mm. Grouting pipe depth is 4m.

The distribution map of the added grouting hole on B1, B2 segment

Fig.7 Schematic diagram of deep hole grouting

**Other technology measures**

1) Before entering the apron 50 meters as the apron simulation period, completely simulated tunneling according to the operation requirement when tunnel shield cross the apron[7], strengthened the monitoring, summarized the construction parameters to provide the basis for the formal construction of crossing the apron.

2) Verify each control point coordinates and elevation in detail, especially on curve and vertical curve, determined shield tunneling line based on design curve deviant and vertical curve modification value and control the tunneling posture of shield machine to avoid deviation.

**Monitoring results**

Based on the data analysis of whole process crossing, and due to limited space, monitoring results of midcourt line which through the right line were chosed was shown in Fig.8.

Monitoring results showed that the maximum subsidence of right line is18 mm, which means taking these effective technical measures ensure the safety of apron when shield machine crossing.

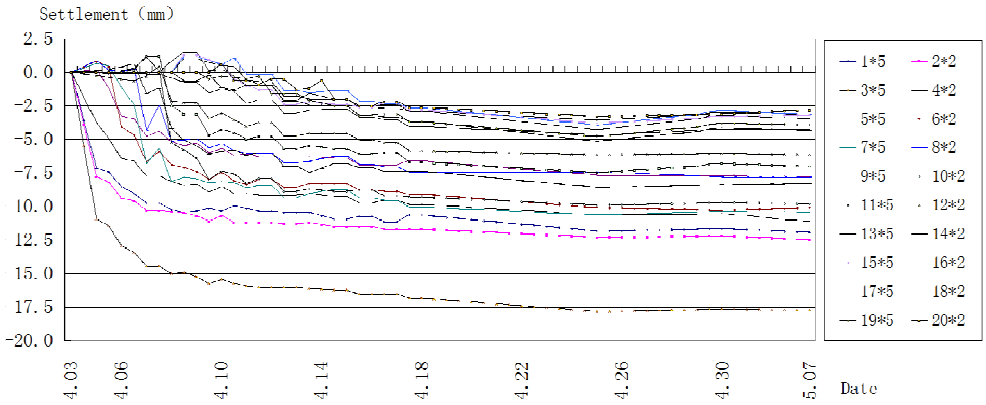


Fig.8 Settlement graph of right tunnel centerline monitoring points

## Conclusion

1) When advanced in shallow overburden soil and saturated silt and silty clay (local of sand layer) , because of the low strength of soil, the stability is poor, formation displacement increases, surface subsidence control is difficult, and airport management requirements of the surface control values is very strict, during the construction process, based on optimizing shield tunneling parameters, taking dynamic soil pressure control technology, secondary grouting technique and deep hole fracturing grouting technology, sedimentation valve was controlled within the target value, to ensure the safety and speed when the shield crossing.

2) Due to the particularity of the airport apron, In order to ensure the safety of the aircraft taxiing and parking, strengthen the construction of monitoring, monitoring data timely feedback operation surface to ensure the safety of apron during the shield crossing.

**Keywords:** subway, scheme, model.

**Abstract.** To choose an appropriate construction scheme for subway, it's feasible to use fuzzy optimization theory and comprehensively consider the security of four construction methods as well as such factors as environmental influence, construction period, construction difficulty and construction cost, etc. to set up a mathematical model for the construction method of subway station. An analysis is made on the impact of group-effect in the excavation construction of pilot tunnel presented in PBA construction method on arch crown settlement and ground surface settlement, and a study is made on the arch crown settlement and ground surface settlement caused by the four construction methods in construction process. In addition, a contrastive analysis is made to draw a conclusion that PBA construction method is the most suitable construction method for Xinbai Square Subway Station in Shijiazhuang.

## The establishment of multi-objective fuzzy model

The establishment of a decision set, that is, a tentative construction scheme for Xinbai Square Subway Station is as follows:

$$D=\{d1，d2，d3，d4\}. \tag{1}$$

In the set, d1 refers to PBA construction method, d2 refers to twin-side heading method, d3 refers to center drift excavation method, and d4 refers to NTR construction method.

The following is the factor set affecting the construction methods for subway:

$$U=\{u1，u2，u3，u4，u5\}. \tag{2}$$

In the set, u1 refers to safety influence; u2 refers to environmental influence; u3 refers to impact of construction duration; u4 refers to impact of construction difficulty; u5 refers to impact of construction cost.

After the above is summed up, the fuzzy optimization matrix R of alternatives for five indicators is shown below:

$$R=\begin{pmatrix} r_{11} & r_{12} & r_{13} & r_{14} \\ r_{21} & r_{22} & r_{23} & r_{24} \\ r_{31} & r_{32} & r_{33} & r_{34} \\ r_{41} & r_{42} & r_{43} & r_{44} \\ r_{51} & r_{52} & r_{53} & r_{54} \end{pmatrix} \tag{3}$$

## Comparison of security

As per field measured data, the final arch crown settlement value of each construction method is extracted for comparison, as shown in Table1.

Table1 Comparison of arch crown settlement

| Construction methods | Final arch crown settlement (mm) |
|---|---|
| PBA construction method | -40.2 |
| Twin-side heading method | -73.9 |
| Center drift excavation method | -68.2 |
| NTR construction method | -11.3 |

The values in Table1 show that NTR can minimize the value of arch crown settlement, and the value of settlement doesn't increase suddenly in each simulated construction procedure. For the sake of safety, among the four construction methods, NTR construction method is the most suitable one for the complex environment of Xinbai Square Subway Station Work, followed by PBA construction method, with twin-side heading method at the bottom.

As for safety influence, NTR construction method is a little better than PBA construction method, rather better than center drift excavation method, and significantly better than twin-side heading method, so the following is worked out:

$$1r = (1r1,\ 1r2,\ 1r3,\ 1r4) = (0.818, 0.429, 0.538, 1). \quad (4)$$

**Comparison of the impact on the surroundings**

Measured value shows that NTR can minimize the value of ground surface settlement upon the completion of construction, the construction method can reduce the value of ground surface settlement to 0.3 and 1.4 in the places ±14m away from the symmetric axis of subway station; When PBA construction method is used, the value of ground surface settlement in each observation point is greater than that when NTR construction method is used, and the value of ground surface settlement is only 187 and 18.6 in the places ±14m away from the symmetric axis of subway station; compared to NTR construction method and PBA construction method, twin-side heading method and center drift excavation method cause a much larger value to ground surface settlement. As per the contrast analysis of the four construction methods, NTR construction method is the best one, while center drift excavation method is the worst one, from the perspective of the impact on the surrounding buildings.

In addition, the size of ground surface settlement can also reflect the impact of construction on underground utilities to a certain degree, that is to say, the smaller the size of ground surface settlement is, the weaker the impact of the settlement on underground utilities will be. Anhydrous operation is essential for PAB construction method, twin-side heading method and center drift excavation method, namely, underground water level must fall below working face. This will cause consolidation and shrinkage to soil void, and very precocious and large-scale deformation and settlement to earth surface, which will produce a particularly great impact on environments. However, NTR construction method includes a perfect waterproof design, which is conducive to soft foundation and water-rich sandy land. Construction precipitation is not available, lest surface subsidence should occur. In conclusion, from the perspective of an impact on environment, NTR construction method is optimal and center drift excavation method is worst.

Environmental impact serves for a qualitative index, and the method for the determination of the relative superiority of qualitative index is adopted. As for environmental impact, NTR construction method is a little better than, rather better than twin-side heading method, and significantly better than center drift excavation method, so the following is worked out:

$$2r = (2r1,\ 2r2,\ 2r3,\ 2r4) = (0.818, 0.538, 0.429, 1). \quad (5)$$

**Comparison of construction difficulty**

When PBA construction method is adopted, heading construction should be implemented in advance; afterwards, in the pilot tunnel, construction should be implemented for fender post, middle column,

floor beam and head beam. However, operating conditions are poor and construction space is small inside the tunnel, so it's very difficult to implement construction. After beam column is completed, vault construction will be implemented. The section size of Shijiazhuang Xinbai Subway Square is very large, which adds to the difficulty of arch crown construction.

In spite of the fairly mature construction technique for twin-side heading method and center drift excavation method, both construction methods adopt partition excavation, and use grill steel frame, wire mesh, and pneumatically placed concrete flexible supporting system to implement construction timely, so that fracture surface should be closed as soon as possible and construction should be simple. However, due to the impact of preliminary bracing and cross strut, before second lining is established, it's necessary to explode preliminary bracing and dismantle cross strut, for stress transformation is needed for the lining. In this process, it's necessary to ensure the safety and stability of preliminary supporting system. If only part of second lining is established, the quality of concrete and waterproofing layer can't be guaranteed. If the full section is established, there will be a great potential safety hazard when preliminary bracing and supporting system is dismantled.

For NTR construction method, construction should be implemented inside steel tube. However, due to the limited space and more joints of reinforcement inside a steel tube, a great many connectors are needed. In the same time, second lining concrete can't be tamped but can only be processed as per pouring sequence and pouring measures in construction process. Also because of the features of NTR construction method, the construction for each of its tube awnings is an independent working plane. During the construction period for tube awnings, in each steel tube there should be separately set ventilation and lighting facilities; in addition, such facilities as transport rail, etc. are needed as well, which adds to the difficulty of engineering construction. Therefore, a conclusion can be drawn that twin-side heading method is the same to center drift excavation method concerning the impact of construction difficulty. Twin-side heading method is a little better than PBA construction method and significantly better than NTR construction method, so the following is worked out:

$$4r = (4r1,\ 4r2,\ 4r3,\ 4r4) = (0.667,\ 1,\ 1,\ 0.333). \tag{6}$$

**Comparison of construction cost and duration**

As a quantitative index, construction cost and duration are represented by determined values. Detailed value of partial costs and construction duration should be offered to the designing institute and construction side. The value of partial costs is shown in Table 2.

Table2 Value of partial costs (unit: ten thousand yuan)

| Partial costs | PBA construction method | Twin-side heading method | Center drift excavation method | NTR |
|---|---|---|---|---|
| Cost of labor | 2058.27 | 1743.63 | 1848.51 | 2932.71 |
| Cost of materials | 11052.8 | 9363.2 | 9926.4 | 15748.48 |
| Cost of construction machinery | 1441.26 | 1220.94 | 1294.38 | 2053.57 |
| Disposal costs | 785 | 665 | 705 | 1118.5 |
| Management cost | 362.67 | 307.23 | 325.71 | 516.75 |
| Total | 15700 | 13300 | 14100 | 22370 |

The time limit for the project will be 32 months for PBA construction method; 30 months for twin-side heading method; 30 months for center drift excavation method; 36 months for NTR construction method.

Both construction cost and construction duration are a quantitative index, and the following is obtained based on the method for the determination of the relative superiority of quantitative index:

3r =(3r1， 3r2，3r3，3r4)=( 0.67, 1 ,1, 0). (7)

5r =(5r1， 5r2，5r3，5r4)=( 0.735, 1 ,0.912, 0). (8)

After the above is summed up, the fuzzy optimization matrix R is worked out:

$$R_{4\times5}=\begin{pmatrix} r_{11} & r_{12} & r_{13} & r_{14} \\ r_{21} & r_{22} & r_{23} & r_{24} \\ r_{31} & r_{32} & r_{33} & r_{34} \\ r_{41} & r_{42} & r_{43} & r_{44} \\ r_{51} & r_{52} & r_{53} & r_{54} \end{pmatrix}=\begin{pmatrix} 0.818 & 0.429 & 0.538 & 1 \\ 0.818 & 0.538 & 0.429 & 1 \\ 0.67 & 1 & 1 & 0 \\ 0.667 & 1 & 1 & 0.333 \\ 0.735 & 1 & 0.78 & 0 \end{pmatrix}. \quad (9)$$

**Calculation of weighted value**

Determine a judgment value for the comparison of each two factors

Create a judgment matrix

e11=1;e12=1; e13=3; e14=5;e15=5.

A judgment matrix is created:

$$E=\begin{pmatrix} e_{11} & \cdots & e_{1m} \\ \vdots & \ddots & \vdots \\ e_{m1} & \cdots & e_{mm} \end{pmatrix}=\begin{pmatrix} 1 & 1 & 3 & 5 & 5 \\ 1 & 1 & 1 & 3 & 5 \\ \frac{1}{3} & 1 & 1 & 1 & 3 \\ \frac{1}{5} & \frac{1}{3} & 1 & 1 & 1 \\ \frac{1}{5} & \frac{1}{5} & \frac{1}{3} & 1 & 1 \end{pmatrix}. \quad (10)$$

**Fuzzy synthetic evaluation system**

The compound operation of weight matrix A and fuzzy relation matrix B works out:

D= A ×R={0.773，0.648，0.645，0.703}. (11)

The computation result shows that NTR construction method, though better than other construction methods in the aspect of settlement control, is inferior to other ones in the aspect of construction duration, construction difficulty and construction cost. The computation result shows that the synthesis score of PBA construction method is 0.773, higher than that of other construction methods, which indicates that PBA construction method is the most suitable method for Xinbai Square Subway Station after such factors as environmental impact, construction duration, construction difficulty and construction cost, etc are taken into overall consideration.

**Keywords:** Railway tunnel, quality defects, regulation classification, project design, treating techniques.

**Abstract.** Quality defects and diseases will happen to railway tunnel after it in operation four to five years later, such as lining split, water leakage and landslide of second lining. Based on the case of Goujiagou tunnel located at Ⅳ surrounding rock with mudstone and sandstone, the regulation for this tunnel is put forward; the causes and characteristics of all kinds of defects are analyzed by studying on the particularity of railway tunnel construction. Based on different extend of injury, the classification of the same type defect is proposed. Research results indicate that the regulation design is feasible and the treating technique is appropriate by using new technology, methods and materials. The results will provide reference to design for the same type tunnel regulation.

## Introduction

Quality defects mainly include lining thickness, imperfect, hollow behind the lining, bad waterproof system and so on; disease mainly include lining split, morphology and seepage which caused by quality defects and other external factors. There is a causal connection between defects and disease, and the former is the cause of the latter. Yinming LU analyzed the classification of tunnel disease and the reasons on the existing tunnel [1]; Xiaojun XIANG determined the different regulation schemes, and introduced the construction technology according to Longquanshan tunnel [2].

These studies are too simple to solve tunnel defects and lacking of creativity so that it could not be able to governance defects timely and effectively. Also regulation should be different because the same defects vary in degree, and research work in this field is not enough. We should improve the treating techniques and adopt new technologies and materials because of the limitation of existing construction in span time.

## Engineering Situation

This is a double-track railway tunnel in speed of 160km/h mixed passenger and freight. Most of surrounding rock isⅣ and other is Ⅴ.The rock type is mudstone and sandstone.

By using ground penetrating radar to identify the causes of detects in further development of nondestructive testing. The biggest density in the section of 105m（K0+000~+105）, 31cavities in arch lining; 2 insufficient lining thickness; 14 less dense of concrete; 6 lining split without seepage; 17 water leakage etc.

## Analysis of Causes of Defects

In terms of this tunnel, there are basically the following several aspects:

**The Geological Reasons**. The tunnel through the hill with denudation and groove valley landform where distribute of powder clay. Some tunnel diseases are caused by the geological reasons which have effect on tunnel lining, such as lining deformation and split. The surrounding rock is poor and loose. Vertical load of loosely pressure on arch will lead to tensile crack along the longitudinal easily;

horizontal strata structure will lead to plastic extrusion and gravity collapsing possibly in loose rock mass; the swelling soil pressure will lead to horizontal cracks on side wall or spandrel etc.

**The Construction Reasons.** This tunnel constructed by means of Center Diaphragms (CD).According to the confirmation with drilling, some cavity behind lining split caused by over-break. Poor quality of compaction of concrete leads to less dense of lining; improper handling measures of waterproof and drainage will lead to expansion joint seepage etc; thus it can be seen that imperfect quality of control system is the main causes of quality defects.

**Underground Water Development.** When there are cavities behind lining, groundwater will be deposited in the formation of cystic fluid, increase the pressure of surrounding rock and lead to lining damage; loosing bearing capacity or happening plastic flow will lead to lining pressure increasing because of surrounding rock mudding or softening in mudstone and sandstone. Rock discontinuities and weak surrounding rock instability because of water will also lead to loss bearing ability of surrounding rock, thus increasing lining pressure. These factors are likely to destroy the structure.

**Other Reasons.** Tunnel lining is prone to be damaged in earthquake, because it belongs to support rigidity, and bending shear capacity is lower. Gas is another cause.

## Regulation Design

### Design Principle.

1）Using general, dynamic design, in line with safe, practical, reliable quality, reasonable economy, the principle of advanced technology

2） Try to use the existing lining structure performance, and repair damage areas timely and efficiently

3） Ensure safety and reduce the impact on line operation

4） Method and the process should be operability and safety

5） All of the empty and imperfect area behind the lining must be grouted

**Design Scheme.** The main reference resources are as follows: 1) investigation data 2) tunnel nondestructive testing report 3) topography, landform and geological conditions 4) completion data 5) related specifications. This paper analyzes the cause of defects and disease. The regulation design is based on the experience of the past. Table. 1 shows the characteristics of the regulation and classification.

Table. 1 The characteristics of the regulation and classification

| Package type | Regulation measure | Suitable objects | Process method | Level |
|---|---|---|---|---|
| Structure reinforcement | Chisel and repair-DCBZT-03 （as shown in Fig.1） | Thickness of plain concrete lining | Break lining --setΦ42Grouting and slurry pipe etc—implant shear rebar--Φ28 mechanical anchor bolt -- Steel fabricΦ6@10×10cm --sprayed Polypropylene fiber concrete support--24h grouting. | I |

W is the width of cracks.

## Controlling Techniques of Construction

**Process of Grouting.** The process of grouting behind lining: according to the area of cavity and not dense, ensure hole location; grouting, observation and spout hole are from low to high to internal surface of cavity; spout hole could also play the role as grouting in sometimes; It is important in process of grouting to determine the length and opening size of notch, and it should be between primary and second to fill in the both lining by the way.

**Polypropylene Fiber Concrete.** The main difficulty of this process is that it should avoid populating railway track and track bed during concrete. So it is important to do the best to protect the structure with open tube and agricultural cloth. Lining Surface should be chiseled before concrete.

## Conclusion

The load model of tunnel structure is changeable. Surrounding rock change with time and development of groundwater and external disturbance; the cause of tunnel disease is various, and the limitation of non-destructive testing with geological radar, such as the limited Survey Line, The strong

interference of steel arch to testing results. For the above reasons, we can't find out the situation of quality defects and disease fully.So we should adjust the design according to the site condition.

There is a large quantity of leakage. The application effect of "combine caulking with draining" in the treatment is good, but it remains to be further tested during the rainy season; the carbon fiber cloth was not adopted,and the reason is that zone of Tension and compression is Not easy to be determined and it is poor durability; the final solution of W-Steel belt combined with sprayed Polypropylene fiber concrete support not only achieved, but also belongs to flexible support;the construction technology of mortar bolt has reference significance for existing railway for the speediness of pore-forming and good effect of grouting.

The research results were adopted in the remaining 11 tunnel.

**Keywords:** Zhengyangmen gate tower; subway vibration; vibration velocity; vibration displacement

**Abstract.** Zhengyangmen gate tower is a national emphasis cultural relic unit along the north-south axis of Beijing, which is above the Beijing metro line 2. Based on dynamic analysis model of gate tower and the position of gate tower and subway, the dynamic response characteristics of gate tower induced by Beijing metro line 2 are calculated, and compared with the in-site vibration test data.

## Introduction

With the development of metro, the vibration caused by subway train has negative effects on people's life, the normal use of equipment, and the safety of buildings, especially the ancient architectures.

The ancient architectures are much fragiler as time passes, and the subway vibration will make it worse. So, the dynamic research of the ancient architectures induced by subway vibration becomes more and more important. The in-site vibration test is widely used to direct the dynamic response of the ancient architectures under the effect of existing subway vibration, and the theory research are not mature.

In this paper, taking Zhengyangmen gate tower (as shown in Fig.1) for example, the dynamic characteristics of gate tower are calculated by theory method.

Fig.1 Zhengyang Men gate tower

**Vibration of subway train**

The dynamic equation is set by the dynamic model of subway train, and the vibration of subway train is calculated by solving the equation (Eq.1).

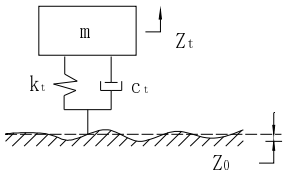

Fig.2 Dynamic model of train

$$m\ddot{Z}(t) + c_t[\dot{Z}(t) - \dot{Z}_0)] + k_t[Z(t) - Z_0)] = 0 \quad (1)$$

where m is 11048kg,$k_t$ is 1050kN·m$^{-1}$,ct is 24000kN·m$^{-1}$.

The vibration displacement and velocity of subway train are shown as Fig.3and Fig.4.

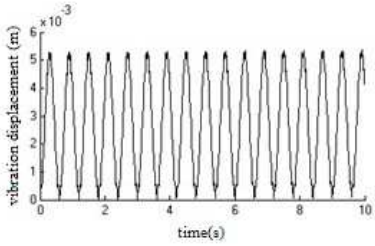

Fig.3 Displacement time history of irregular excitation of train

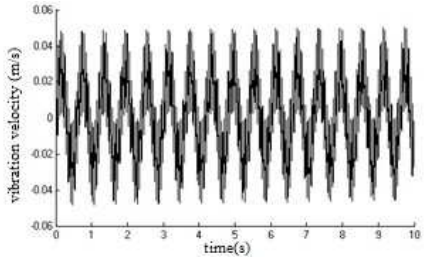

Fig.4 Velocity time history of irregular excitation of train

**Dynamic model of gate tower**

The space coordinate (Fig.5) is set by the position of gate tower and metro line 2, and simplified into2-D plane problem (Fig.6).

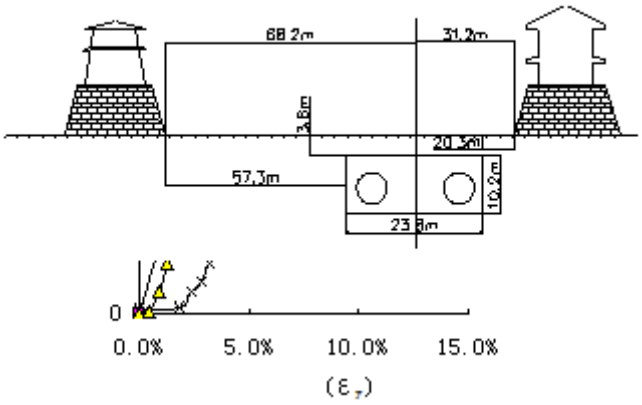

Fig.5 The position of gate tower and metro line 2

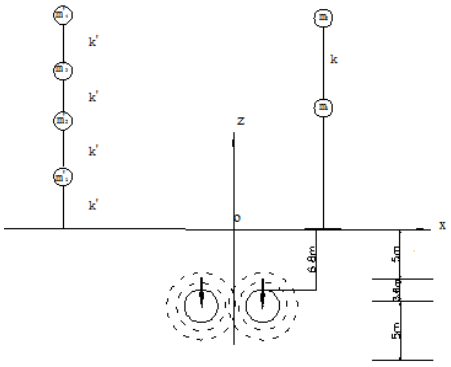

Fig.6 Dynamic model of gate tower under the action of subway

As shown in Fig.6, the propagation distance of the vibration of subway train is short in silt strata, so it is assumed that the propagation route of train vibration is direct and the vibration is spread as wave P. When the vibration reaches the bottom of gate, the direction of propagation can be decomposed into two, one is along X axis and the other is along Z axis.

The dynamic equation of gate tower is set as follow:

$$M\ddot{u} + C\dot{u} + Ku + MI\ddot{u}_p(t) = 0 \quad (2)$$

Where M is mass matrix of gate tower, C is damping matrix of gate tower, K is rigidity matrix of gate tower, I is unit vector, u is the vibration displacement of gate tower, $\ddot{u}_p(t)$is the vibration acceleration of subway train.

## Dynamic response of gate tower

### 3.1 under right tunnel subway train vibration

The dynamic characteristics of gate tower are calculated as follow (Fig.7-Fig.10), when the gate tower is affected by right tunnel subway train vibration.

When the vibration propagates along X axis, the gate tower vibrates along X axis.

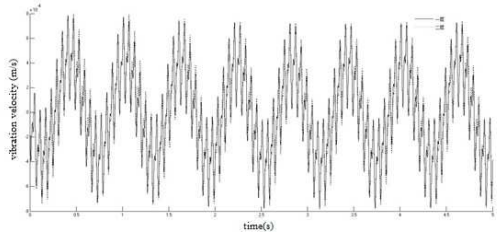

Fig.7 Velocity time history of gate tower along X axis

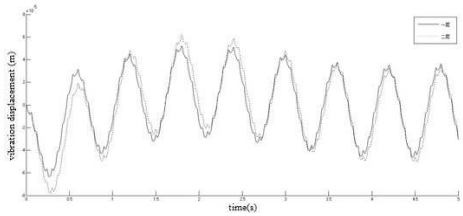

Fig.8 Displacement time history of gate tower along X axis

When the vibration propagates along Z axis, the gate tower vibrates along Z axis.

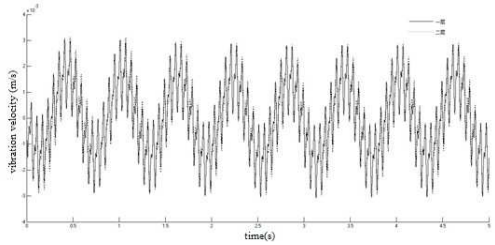

Fig.9 Velocity time history of gate tower along Z axis

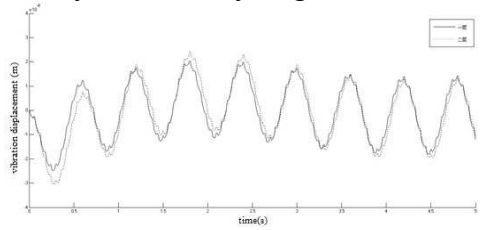

Fig.10 Displacement time history of gate tower along Z axis

### 3.2 under left tunnel subway train vibration

The dynamic characteristics of gate tower are calculated as follow (Fig.11-Fig.14), when the gate tower is affected by left tunnel subway train vibration.

When the vibration propagates along X axis, the gate tower vibrates along X axis.

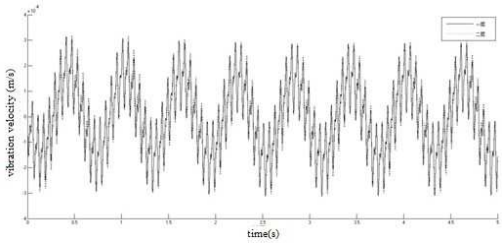

Fig.11 Velocity time history of gate tower along X axis

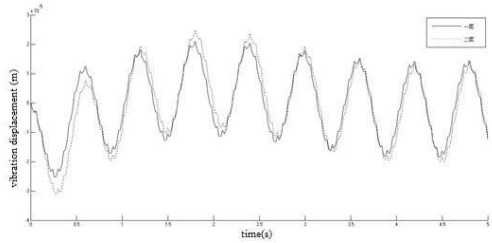

Fig.12 Displacement time history of gate tower along X axis

When the vibration propagates along Z axis, the gate tower vibrates along Z axis.

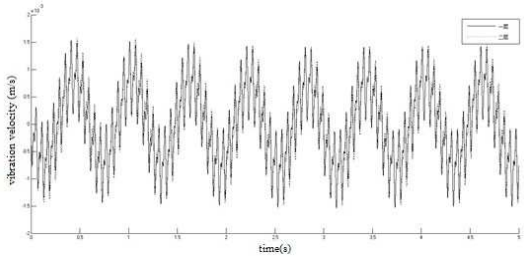

Fig.13 Velocity time history of gate tower along Z axis

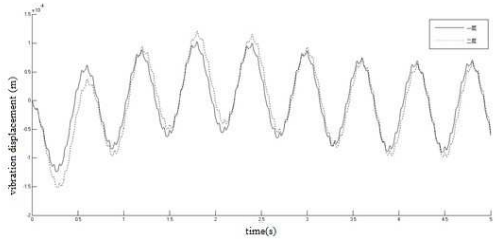

Fig.14 Displacement time history of gate tower along Z axis

### 3.3 under two tunnels subway trains vibration

The dynamic characteristics of gate tower are calculated as follow (Fig.15-Fig.18), when the gate tower is affected both by right and left tunnel subway train vibration.

When the vibration propagates along X axis, the gate tower vibrates along X axis.

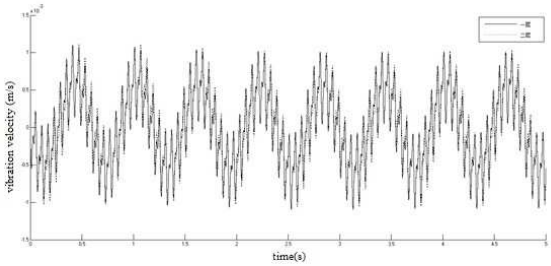

Fig.15 Velocity time history of gate tower along X axis

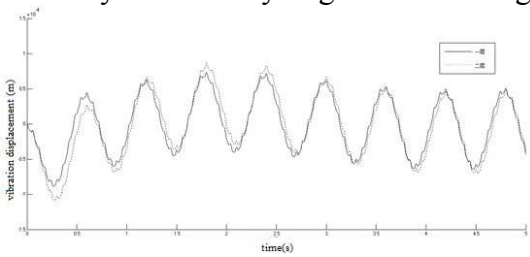

Fig.16 Displacement time history of gate tower along X axis

When the vibration propagates along Z axis, the gate tower vibrates along Z axis.

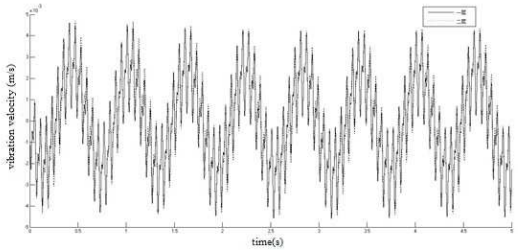

Fig.17 Velocity time history of gate tower along Z axis

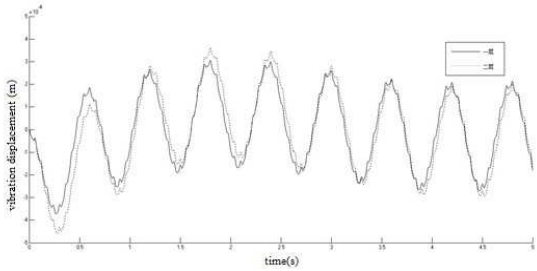

Fig.18 Displacement time history of gate tower along Z axis

### Summary

The vibration velocity of gate tower is analyzed by the spectral analysis method, and spectrogram is shown in Fig.19.

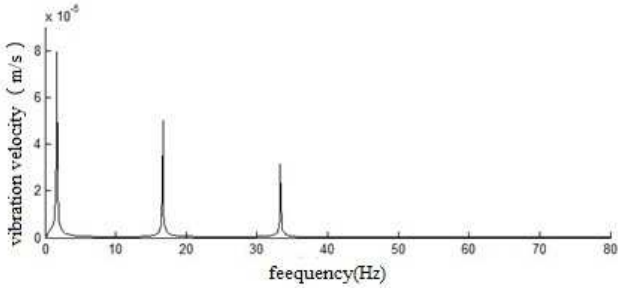

Fig.19 Vibration velocity frequency analysis of gate tower

The dynamic response characteristics of gate tower can be summarized as follow:

(1) The vibration displacement of gate tower increases with height, but the vibration velocity is almost same;

(2) The vibration displacement under the effect of two tunnel subway train is nearly double of one tunnel's, the vibration displacement maximum along X axis is 0.11mm,and the vibration velocity maximum is 1.15mm/s, which are a little bigger than the value of in-site test.

(3) The main vibration frequencies of gate tower are focus in three different frequencies, 1.8-2.1Hz, 15-17Hz, and 32-34Hz, which are same as the in-site test.

**Keywords:**Investigation, Analysis, Existing Railway, Tunnel Disease

**Abstract:** Due to the impactofgeological condition, climate condition, design, construction and other factors, the existing railway tunnelappears some diseases more and more, and even some diseases have serious influence to the normal use of tunnels and traffic safety. To eliminate these dangers, we should understand the typeof diseases and their causes. Based on the existing tunnel disease investigation and analysis,tunnel diseases were classified, the reason of tunnel diseases were analyzed, which can provide a reliable basis for the tunnel disease treatment. The result indicates that railway tunnel diseases include lining water leakage, lining structure disease, lining concrete disease, foundation disease, lining off block and so on. All kinds of diseases of tunnel lining are often interrelated, so the tunnel disease usually is a result of multiple factors.

## Introduction

Nowadays, the tunnel construction and operation scale of China are all at the first place of the world. By the end of 2012, in mainland, 10,100 railway tunnels with a total length of about 7600 km were operating, about 3800 railway tunnels with a total length of about 7300 km were constructing, and 5100 railway tunnels with a total length of about 10800km were planning[1].With the increasing number of tunnels, tunnel diseases become increasingly prominent after tunnel operation, the number of tunnel diseasesis increasing year by year, and some diseases have seriously affected the normal use of the tunnel structure and traffic safety[2][3].

In fact, the tunnel disease exists in the whole process. Some tunnel diseases have been existed before being used[4][5]. The causeof tunnel diseasesis very complex. Different diseases affect tunnel'sservice life differently.Therefore, many scholars have made a lot of researches work on the tunnel disease[6]~[11]. Most of the existing research works are mostly limited to a particular disease and specific engineering conditions, and the understanding of the tunnel disease mechanism is not deep enough. So, the reliability improvement measures and their operabilityare not satisfied.

Based on the existing tunnel disease investigation and analyzed, the author classifies tunnel diseases, and analyzes causes of tunnel disease generation, the result can provide a reliable basis for the tunnel disease treatment.

## Railway Tunnel Diseases Investigation

The range ofdisease survey covers 1995 tunnels, with a total length of 1397 km, all these tunnels are within the scope of jurisdiction of Chengdu Railway Bureau. As it can be seen from the survey results, regardless of their construction period, the number of tunnel with disease is more than 50% of the total number of tunnels, some even up to 100%, as shown in Figure 1.

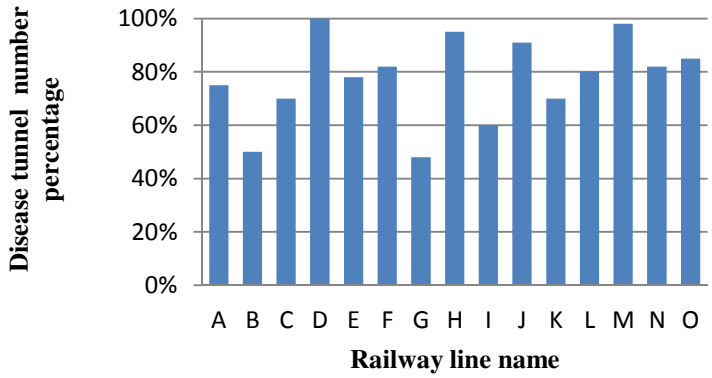

Fig. 1 Proportion of Disease Tunnels' number in Each Railway Line

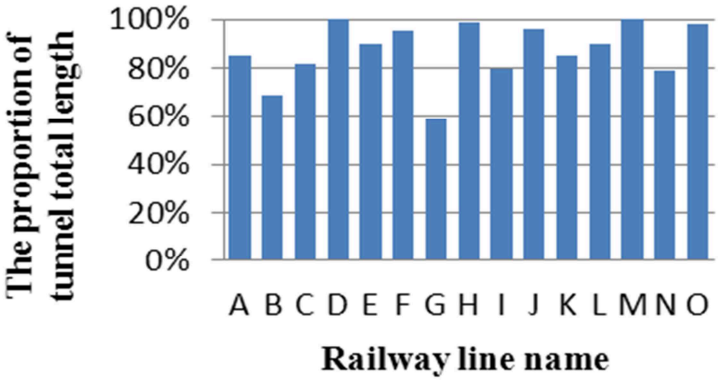

Fig. 2 Proportion of Disease Tunnels' total length in Each Railway Line

In Figures 1 and 2, the abscissa represents the letter name of the line, which are described in Table 1.

Tab. 1 The correspondence between letters and the name of the railway line

| CODE | RAILWAY LINE NAME |
|---|---|
| A | Hukun the first line |
| B | Hukun the second line |
| C | Xiangyu the first line |
| D | Xiangyu the second line |
| E | Baocheng the first line |
| F | Baocheng the second line |
| G | Yuhuai line |
| H | Qiangui line |
| I | Chengkun line |
| J | Chengyu line |
| K | Neiliu line |
| L | Chuanqian line |
| M | Dacheng the first line |
| N | Dacheng the second line |
| O | Dawan line |

Judging from the surrounding rock of diseased tunnel, the worse surrounding rock conditions, the higherfrequency of the tunnel disease occurrence.Conversely, the better rock conditions, the lower frequency of occurrence of disease phenomenon.Generally, the disease phenomenon occurs in IV-class surrounding rock, V-class surrounding grade rock area, accounting for about 83% of the total disease section, as shown in Figure3.

Judging from the type of damage, water leakage and lining cracks are two main types, accounting for about 84% of the total number, followed by facilitiedamage, lining corrosion, arch bottom deformation, as shown in Figure 4.

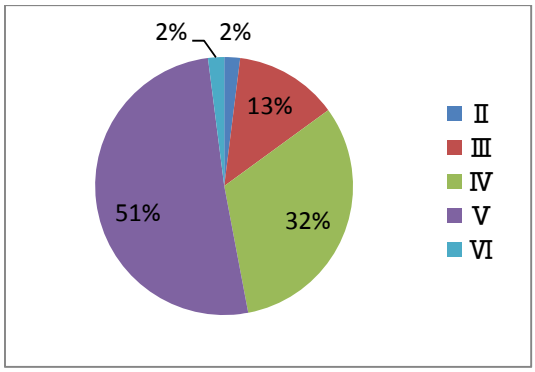

Fig.3 Relationship between Disease Tunnel and Surrounding Rock Grade

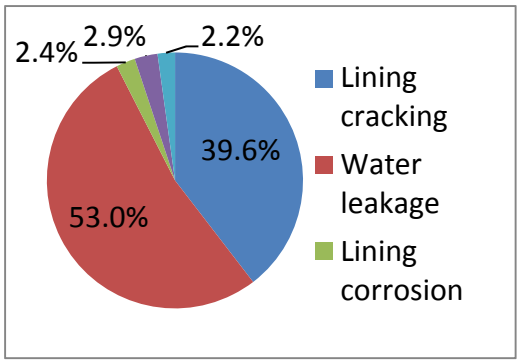

Fig. 4 Proportions of Various Types of Disease

Based on an investigation of 226 tunnels in the range of Shenyang railway Bureau, the tunnel disease can be summed up four types, namely, lining cracks,water leakage and seepage, freezing injury, lining corrosion and so on.The statistic result of tunnel disease characteristic was shown in table 1.

Tab. 1 Statistic of Tunnel Disease Characteristics

| Disease Characteristics | Tunnel Quantity | Diseases Quantity | Total Length/m |
|---|---|---|---|
| Lining Crack | 120 | 894 | 6115 |
| Water Leakage or Seepage | 156 | 1595 | 9061 |
| Freezing Injury | 33 | 109 | 2279 |
| Lining Corrosion | 112 | 722 | 3684 |
| Drainage Facilities Damage | 26 | 69 | 6037 |

## The Typeand Cause of Railway Tunnel Diseases

Study results indicate that China railway tunnel diseasequantity is more, and tunnel disease type is rich, and the cause of tunnel disease is complicated. The railway tunnel disease types include lining water leakage, lining structure disease, lining concrete disease, foundation disease and so on.

The tunnel lining water leakage includes tunnel leaks, gushing water, subsurface flow, lining corrodible water and freezing injuryetc. Underground water from tunnel surrounding rock or earth's surfaceenters the tunnel directly and indirectly by the type of seepage,leakage or drip, which will form lining water leakage disease finally.The chemical composition of underground water from tunnel surrounding rock, including salts, acids and alkalies, which will corrodes lining concrete, the water erosion disease will be formed. In cold region, if underground water or surface water enters the tunnel and freezes into ice, tunnel lining structure will be damaged seriously. In general, tunnel water leakage disease in the non-electrified railways does not directly interfere with traffic and is easily overlooked. However, along with the time growth, the various water damages may cause lining erosion,rail corrosion, sleeper decomposition, subgrade pumping mud. In the electrified railways, it may endanger the traffic. In cold region, it may induce freezing injury or the glazed ice invasion.The tunnel water leakage mainly has five reasons:①tunnel waterproof and drainage system failure; ②outlet pipes formation because of lining concrete density insufficient; ③chemical corrosion of

lining concrete by underground water; ④lining concrete construction defect, including uneven mix of concrete,improper construction methods,etc.⑤lining cracks.

Tunnel lining structural diseases mainly include lining deformation, lining movement and lining crack damage. Deformation of tunnel lining is divided into lateral deformation and vertical deformation, and the lateral deformation is the main deformation. Movement refers to the lining of the tunnel lining whole or part of a rotation (tilt), translation and sink. The movement of lining is divided into vertical movement and lateral movement. The crack of tunnel lining is refers to the lining surface is the result of the deformation of the lining. Tunnel lining crack is usually is visible on the surface of the inner lining, this is the main cause of concrete damage.The main reasons for the formation of tunnel lining structural disease are following severalaspects.First of all is geological impact,it makes rock pressure too large or uneven distribution and even more than lining actual strength and stiffness.The second is the impact of the terrain, the tunnel near the water in the hillside prone to bias, when the roof covering layer is thin, easily leads lining cracking.The third is the impact of groundwater. The fourth is the impact of the lining structure. Because there is difference between actual stress and assumedstress when the tunnel be designed, which may leadthe lining cracking. The fifth is the impact ofconstruction methods and construction qualities. When the tunnel be built in loose rock, the pressure increases, and the lining thickness is not enough, lack of strength, backfill behind the lining not dense, and there will be structural deformation and cracking after tunnel operation. The sixth is the impact of operation and maintenance. The lining strength will be affected by train vibration, soot, steam, etc. which will also produce lining cracks.

Tunnel lining concrete disease is the phenomenon of lining concrete strength decline, concrete lining cracking, corrosion, porosity, surface off or off blocks etc. which is caused by physical or chemical factors. Thereby itwill reduce the durability of structure, and cause other types of diseases, directly reduce the service life of tunnels.Tunnel lining concrete disease mainly damage are as follows. ①Reduce the bearing capacity of lining structure on the same surrounding rock. ② The tunnel clearance area becomes small, the running safety of vehicle be affected③Arch lining off, affecting traffic and personal safety④The crack water Leakage, causing the facilities corrosion, roadbed frost heave. ⑤The bedding and inverted breakage.The main reason for the formation of tunnel lining concrete diseaseismainlyfollowing severalaspects. First,lining concrete subjected to various chemical erosion, such as solubility (or soft) erosion, decomposition (or acid) erosion, salt corrosion, oil erosion and biologyerosion.Second, concrete alkali aggregate reaction products cause swelling of concrete cracking. Third, carbonation or chloride contamination destruction the passive film of reinforced concrete, steel corrosion, concrete smooth muscle bursting, the protective layer and some corners take off. Fourth, concrete micro pores water, at a temperature of alternating positive and negative effects, the formation of ice inflation pressure and fatigue stress combined effects of osmotic pressure, at the role of this fatigue stresses concrete produced denudation outside to the inside, thereby reducing the strength of concrete. Fifth,the lining concrete deformation cracks caused by factors such as temperature, shrinkage, swelling, uneven settlement, etc. reduce the strength and durability of concrete.

Tunnel foundation disease mainly refers to subsidence, cracking, and mud pumping caused by base disease and water leakage. Tunnel foundation diseases easily lead to difficultly maintain the geometric lines, restrict train speed-up and derail in the tunnel seriously.Tunnel foundation disease has three reasons. Firstly, when the base is weak layer, such as weathered bedrock, fracture zone, over break section, it is easily soaked and softens by water because of its low intensity and loose structure. Secondly, cyclic action of the dynamic train loads to the track bedforms mud pumping. Thirdly, the expansion of soft rock usually leads toTunnel foundation diseas.

## Summary

The railway tunnel disease include lining water leakage, lining structure disease, lining concrete disease, foundation disease, lining off block and so on. All kinds of diseases of tunnel lining are often interrelated, which is a result of multiple factors.Lining water leakage is the first class. Lining

structure disease is the second class. Lining concrete disease is the third class. Foundation disease is the fourth class. Moreover, some accident happens occasionally, like landslide squeezing tunnel lining making lining damage, rock cavity where tunnel pass through karst strata, lining collapse, landslide in the opening of the tunnel and rockslide, and is still dangers to traffic.

All kinds of diseases tunnel lining are often interrelated, is a result of multiple factors. Lining Leakage is the first category of disease, the disease is the second largest category of structural lining diseases, diseases of concrete lining is the third largest category of disease, the disease is the fourth largest category of subgrade disease. In addition, landslides caused by squeezing the tunnel lining Lining Crack, tunnel through lava rock formations formed cavity lining collapse, landslides and rockfall at the entrance and other small incidents have also occurred, and endanger traffic safety.

**Key words:** anchor, Nondestructive testing,The research progress, detector.

**Abstract.** As the primary technique to offer safety and productivity improvement s for under-ground project s , rock bolt s have been widely used in t he construction of t raffic and hydro-power stations. The quality of the rock bolt s is of great importance and has been paid a lot of at tention to. This paper reviewed the history of some techniques used for the inspection of rock bolt s and analyzed their t heory and application. It point sout that the t heoretic p roblem is t he primary problem existed in t hese techniques.Nondestructive testing of bolt develops quickly with plenteous accomplishments and experiences.And we state these accomplishments mainly and look into the future.

## Introduction

Anchoring technique is applied widely in large construction projects such as tunnel,mine and slope strengthening now.Anchering technique in geotechnical engineering will reduce support structure weight greatly, save meterial and guaratee construction safety and stability by using fully rock-soil self-strength and self bearing capacity.There is a urgent need of an easy, economical, reliable anchoring quality testing method to meet all kinds anchoring engineer testing requirements further and offer a reliable method for construction quality control and engineer reliability testing in engineering. Drawing testing of anchoring quality with hydraulic jack in our country due to various reasons will desturb anchor solid greatly,which is a destructive method. Applying dynamic testing method is necessary and is important for engineer in remedy of static load testing.

It's hard to discover quality problems and manage accidents due to anchoring imperceptibility. So bolt testing is necessary in anchoring engineering. The improvements of testing quality and result reliability will guarantee the anchoring engineering quality and safety.

There are many problems to solve both in theory and practice in the complicated systems engineering Traditional testing method depends mainly on pulling resistance testing which is suitable for some occasions with many deficiencies. First, it's a destructive testing method with limited sample numbers which may take a part for the whole and can't guarantee anchoring quality. Secondly, its operation is troublesome with high cost. So Non - destructive Testing of Bolt becomes the research point. But it is possible to solve the problem with wave theory because of the theory application widely in rock-soil engineer. Anchor rod body fits elastic rod wave theory on aspects, geometry form, material and stress conditions, so stress wave method can be applied in anchoring quality testing.

## Development states

### Development states abroad

H.F.Thurner[1] proposed ultrasonic testing method in mortar bolt anchoring and trial-produce Bultmer detector in 1988. But there are two problems to solve. Ultrasonic testing is just suitable for short bolt and in simplex anchoring medium due to serious ultrasonic attenuation.And the piezo-electric crystal can make ultrasonic emission into bolt under the strict conditions of bolt end re-machining and polishing on the scene.

Minerals Management Service exploited ultrasonic apparatus in 1990's for bolt strain and length, but it can't evaluate construction quality[2]. It adopted ultrasonic principle and the deficiencies are that it's not suitable for long bolt because of serious ultrasonic attenuation, strict excitation condition can't make quantification evaluation, and bolt end polishing on the scene for better ultrasonic signal is not applicable.

Doctor M．D．[3]Beard in London University made use of Guided Wave Ultrasonic Technique for bolt testing. He got the most ideal Ultrasonic excitation frequency and developed specialized Vibration sensor by analyzing dispersion curves of signal rate, energy rate, attenuation coefficient and taking the influences of rock modulus, Epoxy layer modulus and anchoring quality into consideration.40 kHz is the most ideal low excitation frequency and 2MHz is on the contrary. And the testing is just for 3.0m max combining low excitation frequency and high excitation frequency.

### Development states at home

Non - destructive Testing of Bolt applied to anchoring quality in 1980's and developed quickly in these years. In the end of 1980's, the bolt detector M-7 developed by china academy of rall way sciensces and Institute of technology and methods increased effective testing length by use of mechanical im pact excitation with relative accordant energy.The bolt detector LX 一 10E can make comprehensive analysis with pulling resistance testing, which is developed by Wuhan creative high-tech Co., ltd, and mainly used in anchoring quality testing in slope engineering. The model test using audio frequency stress wave to test anchoring quality and estimate anchoring force by Wang Mingwu studied the non-destructive drawing testing and can make applications of results to practical engineering.

Xu Ming in Chongqing University[4] applied sonic wave technique into non-destructive anchoring engineering integrity testing based on sonic wave principle and estimated bolt integrity by using artificial neural network of non-linear dynamics into the grey system quality testing and acquired certain effects.

Lv Fu[5] raised a new non-destructive bolt testing method based on magnetostrictive guided wave technology in 2010. And developed bolt testing system on the basis of magnetostrictive guided wave testing principle and guided wave characters in bolt.And with the system he accomplished bolt length and deficiency testing experiment in air and concrete structure and realized contactless non-destructive bolt testing by stimulating L(0,1) model guided wave.
And the result indicated that the method can be applied into bolt quality testing with easy process, high detection precision and bolt imperceptibility testing.

Li Yi, Wang Cheng and Liu Haifeng[6] in Taiyuan University of Technology raised anchoring comprehensive parameter dynamic nondestructive testing with laboratory studies and field measurements. The ultimate principle is that the sensor installed on the top of bolt accepts reflected signal from The transient impact load applied to the bolt end and makes signal proceeding and frequency domain analysis to get_essential parameters of effective anchoring length, anchoring quality, working load and ultimate bearing capacity (drawing force) which reflects anchoring characters. And the method meets the requirements of construction quality security detection and support parameter optimization design.

## Existing problems

There are many problems in nondestructive testing in theory, apparatus, signal processing and inversion imaging although many scientific and technical workers preceded much theory researches.

In theory wave propagation law in anchoring, stimulating method of some model wave in favor of anchoring quality testing and effective wave identification and extraction technology are the problems. So many testing workers may handle affairs by experiences in practices.

Wave propagation theories are on the solutions of One-dimensional non-homogeneous wave equation under different boundary and initial conditions. Its results are not important for testing apparatus system design and effective wave application although it decreased mathematical calculation. Taking the testing solution as a one-dimensional project is just based on longitudinal wave propagation in bolt and ignored medium influences. The coupled effect of the bolt, anchoring medium and surrounding rock should be took into consideration for theory application in practice.

In apparatus and software, some manufactures and institutes at home and aboard developed non destructive testing and apparatus depending on small strain foundation pile integrity detection technology with the progress of electronic technique and detection technical[7]. There are many nondestructive detectors such as the multifunction rock anchoring detector of SRB-MATS-P/B/S/P, the mineral anchor cable intrinsic safety type detector of CMSW6(A),the bolt quality detector of LHMG-V8,the bolt detector of MT-1by Wang Mingwu and the portable bolt detector by institute of rock and soil machenics,chinese academy of sciences. However, these detectors have disadvantages of low sampling rate and defection effect.The portable intrinsic safety type non destructive detector based on guided wave by Wang cheng can test effect anchoring length and anchoring force accurately and verdict anchoring quality. It is proved by repetitive tests the detector has application potential in underground coal mine because it meets intrinsic safety anti-explosion requirements with its stable and reliable property. Non destructive detector will be more accurate result, easy operation, perfect function and high effect with science and technology development and researchers study.

## Thoughts and suggestions to solve problems

According above analysis, the problem demanding prompt solution in nondestructive anchoring quality testing is in theory which apparatus and software development problems will be solved on. We should solve the wave equation under cylindrical multi-layer elastic medium model, calculate different guided wave dispersion characteristics and find out deficiency testing model wave so that to solve wave propagation characters theories in anchoring system. Meanwhile we exploit processing and imaging software on the theoretical forward modeling results, extract effect signals specially and remove noise wave, and use joint time frequency analysis for processing and imaging which will work well. Theoretical forward modeling difficulty is great without a doubt. So model test for Theoretical forward modeling will be necessary for anchoring quality sonic wave testing. And the results of model test can checkout theoretical forward modeling results validity as well as remedy theory deficiencies. More useful we can establish standard gallery with a certain model test workload, deal with measured data by using pattern recognition and neural network technique. and this is another solution. In all, model tests benefit for the nondestructive anchoring quality testing.

## Conclusions

Nondestructive anchoring testing has a great progress and also huge development space at home. These nondestructive testing methods have deferent deficiencies and limitations. Thorough analysis and researches in theory and enough engineering practices will ensure a perfect application of the nondestructive anchoring testing. I believe that the technique will promote engineering creation development greatly with its improvement.

**Keywords:** rock parameter, identification, MSVR, PSO.

**Abstract.** An inversion method based on multi-output support vector regression (MSVR) is proposed for identifying the mechanical parameters of surrounding rock. This method considers the surrounding rock as a multi-output system during excavation, and the surveyed rock deformations of each monitoring section as its output. First, perform numerical experiments based on the principle of orthogonal test to obtain the calculated deformation values corresponding to different rock parameter combinations, and use them as the samples for training the model of MSVR as reflecting the nonlinear mapping relationship between rock and its deformations. Second, use the PSO to seek the optimal rock parameters based on measured deformations of rock mass. An example is employed to test the presented inversion method. The results showed that compared with the inversion method based on single-output support vector regression (SSVR), the proposed one is more inclined to reach the global optimization goals and achieve more reliable inversion results due to its consideration of the inherent correlativity among the measured deformations of each monitoring section.

## Introduction

Due to high inhomogeneity of stratum, the rock parameters obtained by means of laboratory or field test are short of representativeness and therefore can't meet the requirements of numerical analysis of underground engineering. The back analysis technique developed in recent decades is regarded as a kind of relatively ideal method to determine the wanted parameters.

Zhao et al. used SVM for geo-material parameters back analysis[1]. Xu et al. developed the joint inversion method of SVM and simulated annealing algorithm (SA) for identifying the rock mechanic parameters of underground grotto of Suofengying Hydraulic Power Plant[2]. Liu et al. successfully identified the three-dimensional elastoplastic model parameters in tunnel engineering by using improved GA-SVR algorithm[3].

However, by far almost all back analysis methods based on SVM employ single output SVM, and this means that the individual regression model should be established for the deformation data of each monitoring point or line. But in fact, during excavation for each monitoring section, usually more than one survey points or lines are set and so more than one array of deformation data are got. In the other words, these data are the outputs corresponding to same monitoring section. So during excavation the surrounding rock is in essence a multi-output system and using MSVR to identify the geo-material parameters maybe be more reasonable and perhaps can lead more ideal results. Based on such consideration, a inversion method based on MSVR is presented in this paper. The method first establishes the MSVR model reflecting the nonlinear mapping relationship between rock and its deformations, then applies PSO to seek the optimal rock parameters. Finally, an inversion example is selected to investigate the method's applicability.

## Multi-output Support Vector Regression

SVM is a new type of general machine learning method proposed by Vapnik in 1990s under the framework of Statistical Learning Theory (SLT)[4]. Based on structural risk minimization principle (SRM), SVM possesses powerful nonlinear mapping and generalization ability, and has become a new hot topic after artificial neutral network (ANN). SVM was initially developed for handling

pattern recognition problem, and later, the SVM for regression was also put forward by Smola and Schoelkopf, also called support vector regression (SVR), which can approximate to any nonlinear function by an arbitrary accuracy and is widely used in practical projects[5].

Soon after that, multi-output support vector regression (MSVR) was proposed by Perez-Cruz[6]. The MSVR provides a new regression algorithm for the problem that the output variable of a system is a vector. Suppose we are given a training data set, $\{x_i, y_i\}$ $(i=1,\ldots,l)$, where $x_i \in R^d$ denotes the space of the input, $y_i \in R^m$ denotes the corresponding output. The object of MVSR is to generate a set of regression functions,

$$f^j(x) = (w^j, x) + b^j, \quad j = 1,\ldots,m \tag{1}$$

to minimize the structural risk. By using a hyper-spherical insensitive zone, the structural risk function can be defined as follows:

$$\min \sum_{j=1}^{m} \left\| w^j \right\|^2 + C \sum_{i=1}^{l} \xi_i \tag{2}$$

subject to

$$\left\| \boldsymbol{y}_i - \boldsymbol{\Phi}^T(x_i)\boldsymbol{w} - \boldsymbol{b} \right\| \le \varepsilon + \xi_i \quad i = 1,\ldots,l \tag{3}$$

where $\xi_i \ge 0$, $\boldsymbol{y}_i = \left(y_i^1, y_i^2, \ldots, y_i^m\right)^T$, $\boldsymbol{w}_i = \left(w_i^1, w_i^2, \ldots, w_i^m\right)^T$, $\boldsymbol{b} = \left(b^1, b^2, \ldots, b^m\right)^T$, and $\boldsymbol{\Phi}(\cdot)$ is a function vector to realize nonlinear transformation to a higher dimensional space.

In order to solve the MSVR, we first introduce the constrains (3) into (2), making use of the Lagrange multipliers, leading to the minimization of

$$L_P = \min \sum_{j=1}^{m} \left\| w^j \right\|^2 + C \sum_{i=1}^{l} \xi_i - \sum_{i=1}^{n} \alpha_i (\varepsilon + \xi_i - \left\| \boldsymbol{y}_i - \boldsymbol{\Phi}^T(x_i)\boldsymbol{w} - \boldsymbol{b} \right\|^2) - \sum_{i=1}^{n} \mu_i \xi_i \tag{4}$$

With respect to $w^j$, $b^j$ and $\xi_i$ and its maximization with respect the Lagrange multipliers, $\alpha_i$ and $\mu_i$. Then using the Karush-Kuhn-Tucker Theorem, the above optimization problem can be converted into solving the following equation system:

$$\begin{bmatrix} \mathrm{K} + \mathrm{D}_{\alpha}^{-1} & 1 \\ \alpha^T \mathrm{K} & \alpha^T 1 \end{bmatrix} \begin{Bmatrix} \beta^j \\ b^j \end{Bmatrix} = \begin{Bmatrix} y^j \\ \alpha^T y^j \end{Bmatrix} \tag{5}$$

**Execution of the Back Analysis Method Based on MSVR**

As in any conventional approach to the displacement back analysis, the objective function,is defined as the sum of absolute value of deviation between the calculated displacement and the measured one of each point or line, and is expressed as the following Eq (6).

$$f = \sum_{i=1}^{n} \left| u_{im} - u_{ic} \right| \tag{6}$$

Where *f* represents objective function value, *n* is the total number of monitoring points (or lines), $u_{im}$ is the measured displacement of the *i*th point (or line), and $u_{ic}$ is the calculated displacement of the *i*th point (or line).

The execution of the inversion method comprises such steps as follows:

(1) Estimate the valuing range of rock mass mechanical parameters to be recognized according to the practical engineering problems and determine the scheme of numerical experiments in line with the principle of orthogonal or uniform experimental design.

(2) Establish a reasonable numerical model of underground engineering. Use the model to calculate the corresponding displacement of key points for each set of tentative geomechanical parameters. Each set of geomechanical parameters and corresponding displacement of key points compose a training example.

(3) Based on the learning examples obtained in the previous step, use PSO[7] for optimal selection of the MSVR model parameters, and establish the MSVR model with best approximation ability.

(4) Substitute MSVR model for the numerical model of underground engineering to calculate the surrounding rock deformations corresponding to every group of parameters, and again, use the PSO to search for optimal rock mass parameters till the inversion results meet the precision requirement are find.

**Verification of the Back Analysis Method**

To verify the back analysis method presented in this paper, a certain deeply buried tunnel is considered. The tunnel's excavation section and arrangement of survey lines are depicted in Figure 1. Suppose the surrounding rock is isotropic and homogeneous, the initial vertical ground stress is $\sigma_y = 2.34\text{MPa}$, lateral pressure coefficient is $\lambda = 0.57$, the elastic modulus is $E = 7\text{GPa}$, Poisson's ratio is $\mu = 0.25$, cohesive stress is $C = 0.6\text{MPa}$, and internal friction angle is $\phi = 30^\circ$. FEM is used to establish the numerical model of the tunnel and Drucker-Prager yield criterion is employed for elastoplastic analysis.

As rock deformation is insensitive to Poisson's ratio, the elastic modulus of surrounding rock, cohesive stress and internal friction angle are selected as the parameters need to be identified. According to related engineering geological data, the valuing ranges of the three parameters are estimated as 20°≤$\varphi$≤40°; 4GPa≤$E$≤9GPa; 0.3MPa≤$C$≤0.9MPa, respectively.

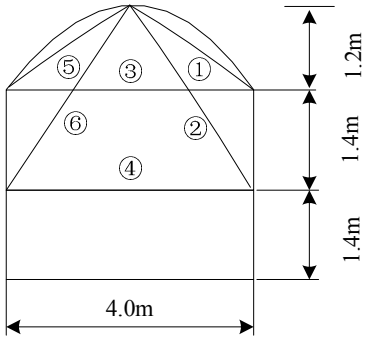

**FIG. 1. Tunnel section and layout of measured lines**

Each parameter is divided into 6 levels as illustrated in Table 1. The orthogonal experiment principle is used to design the learning sample, and there are 36 groups of parameter combination altogether. Uniform design method is used to construct test sample and there are 6 groups of parameter combination. For each group of parameters, use the established finite element model to calculate the corresponding deformation values of survey line 1, 2, 3 and 4 (the calculated values of survey line 1 and 5, 2 and 6 are identical, respectively, due to the symmetrical structure). Each set of geomechanical parameter with its corresponding deformations of the monitoring lines is considered as a training sample.

**Table 1. Factors for tests on orthogonal table and their levels**

| levels | 1 | 2 | 3 | 4 | 5 | 6 |
|---|---|---|---|---|---|---|
| $E$/GPa | 4 | 5 | 6 | 7 | 8 | 9 |
| $C$/MPa | 0.3 | 0.42 | 0.54 | 0.66 | 0.78 | 0.9 |
| $\varphi$/° | 20 | 24 | 28 | 32 | 38 | 40 |

To compare the inversion precision of SSVR and MSVR, suppose the computed deformations of survey line 1, 2, 3 and 4 as measured values corresponding to predetermined parameters, and use the two methods to identify them, respectively. The MSVR model parameters was set as: choosing RBF function as Kernel function, $\sigma = 0.35$, $c = 50$, $\varepsilon_m = 0.006$. For SSVR, to make hypercube and 3-dimensional hyper-sphere have the same volume, the width of insensitive zone is set as $\varepsilon_s = 0.7435\varepsilon_m$, and the other parameters are same as SSVR. The particle swarm optimization

parameters are selected as: acceleration factors $c_1 = 0.5$, $c_2 = 0.5$, $\omega$ applying linear inertia weight, population size $N = 20$ and the maximum iterations $t_{max} = 40$.

The parameters' inversion results are shown in the following table 2 and table 3. It can be seen that compared with standard SSVR, the proposed method using MSVR obviously possesses higher inversion precision. For MSVR, its maximum relative error of inversion parameter is 1.74%, and its final object function is 0.02, while for SSVR, the maximum relative error reaches 9.33%, and the object function is just 0.07. The reason maybe explained by the surrounding rock is regarded as a multi-output system and the inherent correlativity among the measured deformations of different survey lines of the same section is considered when using MSVR.

**Table 2. Result of back analysis**

| | theoretical value | MSVR | | SSVR | |
|---|---|---|---|---|---|
| | | inverse value | relative error % | inverse value | relative error % |
| *E*/GPa | 7.0 | 6.88 | 1.71 | 7.16 | 2.28 |
| *C*/MPa | 0.6 | 0.592 | 1.33 | 0.612 | 2.2 |
| *φ*/° | 30 | 29.7 | 1.0 | 27.2 | 9.33 |

**Table 3. Comparison of back analysis results with measured displacements**

| survey line | 1 | 2 | 3 | 4 | $f$ min |
|---|---|---|---|---|---|
| theoretical value/mm | 1.73 | 3.37 | 3.22 | 5.57 | |
| MSVR/mm | 1.73 | 3.36 | 3.23 | 5.57 | 0.02 |
| SSVR/mm | 1.72 | 3.39 | 3.24 | 5.59 | 0.07 |

## Conclusion

By substituting the multi-output support vector machine (MSVR) for standard singe-output support vector machine (SSVR), a novel inversion method of MSVR is proposed for identifying the mechanical parameters of surrounding rock. An example of back calculating tunnel rock's elastoplastic parameters was employed to test the method's practicality and reliability. The results showed that, compared with the back analysis method based on standard SSVR, the presented method is more inclined to reach the global optimization goals and thus could achieve more reliable inversion results with higher precision.

**Keywords:** motion equation, cutterhead, gauge disc cutter, tunneling machine

**Abstract.** Based on the analysis of movement characteristics of gauge disc cutter in cutterhead of tunneling machine, the motion equation to describe the working behavior of the edge point of gauge disc cutter in tunneling process is deduced by using the method of space coordinate transformation matrix. The motion equation has the advantages of considering more parameters, such as position variables of disc cutter, cutter radius, cutterhead rotating speed and advance speed.

## Introduction

Disc cutter is the main component of tunneling machine, which is also an important and wearing part for breaking rock. Relevant statistics data[1,2] shows that cutter tools are the largest amount of consumables in the boring process of tunneling, and their costs are often one-third of the whole price of the machine. Since the tool life directly determines the number of tool changes and downtime, the operating efficiency and construction costs of the tunneling machine will be affected seriously. Therefore, the kinematics analysis of working edge point for disc cutter of tunneling machine will be helpful to analyze cutter wear and rock breaking mechanism further, which will be the theoretical basis for cutter life prediction and cutterhead design of tunneling machine.

## Movement characteristics of disc cutter

Movement state of disc cutter in cutterhead of tunneling machine can be thought as the synthetic motion of two fixed axis rotations[3,4]. As shown in Fig.1, relative to the frame OAB, the rigid body rotates around the fixed shaft $Z_1$ with angular velocity $\omega_1$, while the fixed shaft $Z_1$ rotates around the fixed axis $Z_2$ with angular velocity $\omega_2$. Taking the framework OAB as a moving reference system, the former moving pattern is relative motion and the latter is implicated motion. When $\angle AOB = 90°$, the rotating rigid body corresponds to a disc cutter of the tunneling flat cutterhead, whose mounting axis $OZ_1$ intersects with rotation center axis $OZ_2$ of the cutterhead. Then the disc cutter advances together with the cutterhead along axis $OZ_2$.

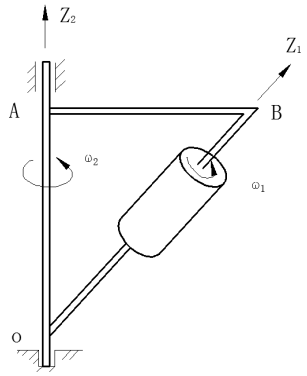

Fig.1 General model of the disc cutter motion

Because the movement state of any edge point of disc cutter affects the degree of cutter wear and rock breaking, it is necessary to study the trajectory equation of any disc cutter edge point for analyzing the rock breaking course, which includes the process from the contacting moment of edge point with rock to the time of its maximum penetration. The process of breaking rock by disc cutter is the aggregate of numerous edge points which break rock through penetrating[5-7].

## Motion equation of working edge point of gauge disc cutter

As discussed earlier, when the disc cutter goes ahead along the excavation axis, it revolves around the central axis of cutterhead and rotates around its mounting shaft at the same time. It is showed that the motion state of disc cutter is three-dimensional. Therefore, spatial kinematic analysis method[8] is suitable to be used to analyze the motion of disc cutter.

The cutters of tunneling machine cutterhead include two styles: inner and gauge disc cutters, as showed in fig.2. The kinematics analysis of working edge point for inner disc cutter in cutterhead of tunneling machine has been finished[9]. So the relatived analysis for gauge disc cutter especially will be carried out as following.

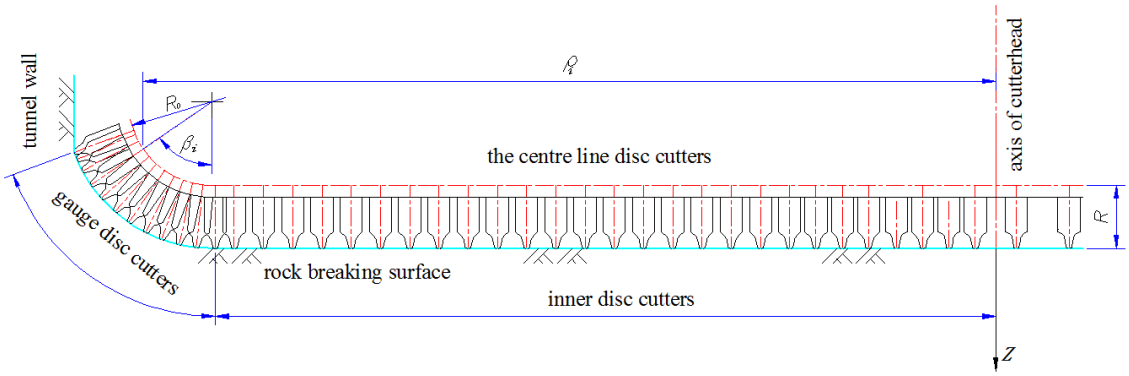

Fig.2 Arrangement of disc cutters on cutterhead of Herrenknecht EPBΦ6280 shield

**Matrix method of spatial coordinate transformation**[8, 10]**.**Spatial coordinate transformation is the coordinate relations of any spatial point $P$ between two spatial systems $o_m x_m y_m z_m$ and $o_n x_n y_n z_n$, as shown in Fig.3. Let coordinate arrays of point $P$ in coordinate system $o_m x_m y_m z_m$ and $o_n x_n y_n z_n$ are $r_m$ (refer with: Eq.1) and $r_n$ (refer with: Eq.2) respectively. The movement of origin $O_n$ in $m$ coordinate system can be expressed by vector $\overrightarrow{O_m O_n}$ with coordinate array $R_m^{(O_n)}$ (refer with: Eq.3).

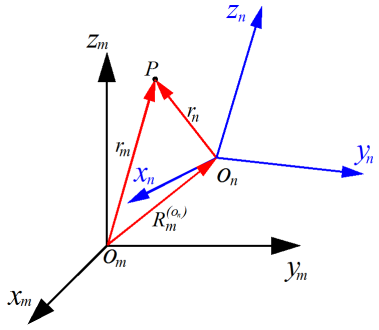

Fig.3 An sketch of coordinate transformation of a spatial point

$$r_m = [x_m, y_m, z_m]^T . \tag{1}$$

$$r_n = [x_n, y_n, z_n]^T . \tag{2}$$

$$R_m^{(O_n)} = \left[x_m^{(O_n)}, y_m^{(O_n)}, z_m^{(O_n)}\right]^T . \tag{3}$$

From point $O_m$, the vector relationship of point $P$ is expressed as Eq.4.

$$\overrightarrow{O_mP} = \overrightarrow{O_mO_n} + \overrightarrow{O_nP}. \tag{4}$$

By coordinate transformation , the Eq.4 becomes Eq.5.

$$r_m = R_m^{(O_n)} + C_{mn} r_n. \tag{5}$$

Wherein $C_{mn}$ is $3 \times 3$ transformation matrix from $n$ coordinate system to $m$ coordinate system. Each matrix element is cosine of the angle corresponding to the two coordinate axes, namely the direction cosine. So matrix $C_{mn}$ is also called the direction cosine matrix, expressed as Eq.6.

$$C_{mn} = \begin{bmatrix} \cos(x_m \hat{} x_n) & \cos(x_m \hat{} y_n) & \cos(x_m \hat{} z_n) \\ \cos(y_m \hat{} x_n) & \cos(y_m \hat{} y_n) & \cos(y_m \hat{} z_n) \\ \cos(z_m \hat{} x_n) & \cos(z_m \hat{} y_n) & \cos(z_m \hat{} z_n) \end{bmatrix}. \tag{6}$$

**Establish trajectory equation of working edge point of gauge disc cutter.**The measurement sensors installed in copy tool can be used to determine the position of cutterhead rotation angle of tunneling machine. When the copy tool is at the bottom the rotation angle is generally defined as zero degree. And then the rotation angle increases from 0° to 360° in a counterclockwise direction viewing from the front of the cutterhead.

Fixed coordinate system *OXYZ*: plane *XOY* is tunnel excavating face which is parallel to the cutterhead plane and *OX* axis is consistent with the position of copy tool when it is at the bottom (i.e. the cutterhead rotation angle is 0° ). Viewing from the rear of cutterhead, rotation angle increases when cutterhead rotates in clockwise, and *OZ* axis is the cutterhead rotation center axis with the excavating direction forward positive, as shown in Fig.4.

Moving coordinate system $o_1xyz$: point $O_1$ is the center of disc cutter; $o_1y$ axis is the mounting shaft of disc cutter and the direction away from the cutterhead center is positive; $o_1z$ axis connects the center of disc cutter and the maximum penetration point of cutter edge and the direction to penetrate rock is positive; the direction of $o_1x$ axis is positive at which the disc cutter rotates forward, as shown in Fig.4.

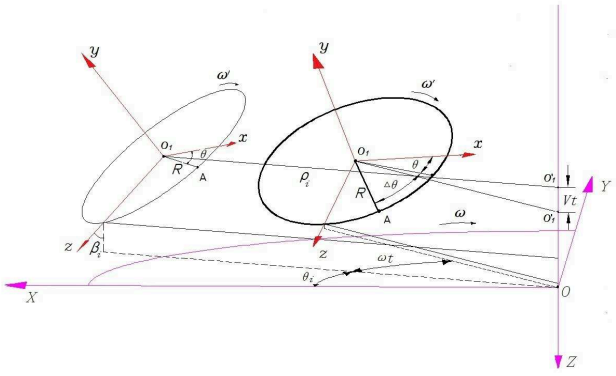

Fig.4 An analytical sketch of the rock-breaking movement of the gauge disc cutter

In fixed coordinate system *OXYZ* shown in fig.3 and fig.4, among all the positional parameters for the number $i$ disc cutter, installation dip $\beta_i$ and gauge installation radius $R_i$ need to be considered besides installation radius $\rho_i$ and polar angle $\theta_i$.

In moving coordinate system $o_1xyz$ showed in fig.4, the polar coordination of working edge point $A$ of gauge disc cutter in plane $xo_1z$ is $(R,\theta)$, in which $R$ is the radius of the disc cutter and $\theta$ is the initial polar angle of working edge point $A$ of gauge disc cutter.

Therefore, the coordinate array of the moving coordinate system origin $O_1$ in the fixed coordinate system can be expressed as Eq.7.

$$r_O^{(O_1)} = \begin{bmatrix} \rho_i \cos\theta_i \\ \rho_i \sin\theta_i \\ -R - R_0(1-\cos\beta_i) \end{bmatrix}. \tag{7}$$

The coordinate array of working edge point $A$ of gauge disc cutter in the moving coordinate system can be expressed as Eq.8.

$$r_{O_1}^{(A)} = \begin{bmatrix} R\cos\theta \\ 0 \\ R\sin\theta \end{bmatrix}. \tag{8}$$

According to the method of spatial coordinate transformation matrix, the point $A$ in the moving coordinate system can be transformed into the fixed coordinate system by two transformation.

(1) Turn dip $\beta_i$ to positive position of disc cutter around negative direction of $o_1x$ axis with the coordinate system origin $O_2$, then the direction cosine matrix $C_{O_2O_1}$ is Eq.9.

$$C_{O_2O_1} = \begin{bmatrix} 1 & 0 & 0 \\ 0 & \cos\beta_i & \sin\beta_i \\ 0 & -\sin\beta_i & \cos\beta_i \end{bmatrix}. \tag{9}$$

（2）Transform the positive position of disc cutter into fixed coordinate system $OXYZ$, then the direction cosine matrix $C_{OO_2}$ is Eq.10.

$$C_{OO_2} = \begin{bmatrix} -\sin\theta_i & \cos\theta_i & 0 \\ \cos\theta_i & \sin\theta_i & 0 \\ 0 & 0 & 1 \end{bmatrix}. \tag{10}$$

After above transformation, the coordinate array of working edge point $A$ of gauge disc cutter at the initial moment in the fixed coordinate system can be expressed as Eq.11.

$$r_O^{(A)} = r_O^{(O_1)} + C_{OO_2} C_{O_2O_1} r_{o_1}^{(A)}. \tag{11}$$

The Eq.7, Eq.8, Eq.9, Eq. 10 are substituted into the equation Eq.11 , Eq.12 can be obtained.

$$\begin{aligned} r_O^{(A)} &= \begin{bmatrix} \rho_i \cos\theta_i \\ \rho_i \sin\theta_i \\ -R - R_0(1-\cos\beta_i) \end{bmatrix} + \begin{bmatrix} -\sin\theta_i & \cos\theta_i & 0 \\ \cos\theta_i & \sin\theta_i & 0 \\ 0 & 0 & 1 \end{bmatrix} \begin{bmatrix} 1 & 0 & 0 \\ 0 & \cos\beta_i & \sin\beta_i \\ 0 & -\sin\beta_i & \cos\beta_i \end{bmatrix} \begin{bmatrix} R\cos\theta \\ 0 \\ R\sin\theta \end{bmatrix} \\ &= \begin{bmatrix} \rho_i \cos\theta_i - R\sin\theta_i\cos\theta + R\sin\beta_i\cos\theta_i\sin\theta \\ \rho_i \sin\theta_i + R\cos\theta_i\cos\theta + R\sin\beta_i\sin\theta_i\sin\theta \\ -R - R_0(1-\cos\beta_i) + R\cos\beta_i\sin\theta \end{bmatrix} \end{aligned}. \tag{12}$$

Then the coordinate of point $A$ at the initial moment in the fixed coordinate system can also be expressed as Eq.13

$$\begin{cases} X_A = \rho_i \cos\theta_i - R\sin\theta_i \cos\theta - R\sin\beta_i \cos\theta_i \sin\theta \\ Y_A = \rho_i \sin\theta_i + R\cos\theta_i \cos\theta - -R\sin\beta_i \sin\theta_i \sin\theta \\ Z_A = -R - R_0(1-\cos\beta_i) + R\cos\beta_i \sin\theta \end{cases}. \tag{13}$$

Let rotation angular velocity of shield cutterhead is $\omega$ and advance speed is $V$, then after time $t$, the cutterhead rotation angle is $\omega t$ and the azimuth of disc cutter becomes ($\theta_i$+$\omega t$), the coordinate array of origin $O_1$ of the moving coordinate system in the fixed coordinate system becomes into Eq.14.

$$r_O^{(O_1)} = \begin{bmatrix} \rho_i \cos(\theta_i + \omega t) \\ \rho_i \sin(\theta_i + \omega t) \\ -R - R_0(1-\cos\beta_i) + Vt \end{bmatrix}. \tag{14}$$

The direction cosine matrix $C_{O_2O_1}$ keeps unchanged, while $C_{OO_2}$ changes to Eq.15.

$$C_{OO_2} = \begin{bmatrix} -\sin(\theta_i + \omega t) & \cos(\theta_i + \omega t) & 0 \\ \cos(\theta_i + \omega t) & \sin(\theta_i + \omega t) & 0 \\ 0 & 0 & 1 \end{bmatrix}. \tag{15}$$

Suppose the rotation of disc cutter is pure rolling, the Eq.16 will be satisfied.

$$(\rho_i + R\sin\beta_i) \cdot \omega t = R \cdot \Delta\theta. \tag{16}$$

After time $t$, rotation angle of gauge disc cutter rolling is Eq.17

$$\Delta\theta = \frac{\rho_i + R\sin\beta_i}{R} \omega t. \tag{17}$$

So after time $t$, the coordinate array of point $A$ in the moving coordinate system becomes Eq.18.

$$r_{O_1}^{(A)} = \begin{bmatrix} R\cos(\theta + \frac{\rho_i + R\sin\beta_i}{R} \omega t) \\ 0 \\ R\sin(\theta + \frac{\rho_i + R\sin\beta_i}{R} \omega t) \end{bmatrix}. \tag{18}$$

And the coordinate array of point $A$ in the fixed coordinate system becomes Eq.19.

$$r_O^{(A)} = \begin{bmatrix} \rho_i \cos(\theta_i + \omega t) - R\sin(\theta_i + \omega t)\cos(\theta + \frac{\rho_i + R\sin\beta_i}{R} \omega t) + R\sin\beta_i \cos(\theta_i + \omega t)\sin(\theta + \frac{\rho_i + R\sin\beta_i}{R} \omega t) \\ \rho_i \sin(\theta_i + \omega t) + R\cos(\theta_i + \omega t)\cos(\theta + \frac{\rho_i + R\sin\beta_i}{R} \omega t) + R\sin\beta_i \sin(\theta_i + \omega t)\sin(\theta + \frac{\rho_i + R\sin\beta_i}{R} \omega t) \\ -R - R_0(1-\cos\beta_i) + Vt + R\cos\beta_i \sin(\theta + \frac{\rho_i + R\sin\beta_i}{R} \omega t) \end{bmatrix}. \tag{19}$$

Thus, at time $t$, the equations of motion parameters of point $A$ in the fixed coordinate system is also represented by the following Eq.20.

$$\begin{cases} X_A = \rho_i \cos(\theta_i + \omega t) - R\sin(\theta_i + \omega t)\cos(\theta + \frac{\rho_i + R\sin\beta_i}{R} \omega t) - R\sin\beta_i \cos(\theta_i + \omega t)\sin(\theta + \frac{\rho_i + R\sin\beta_i}{R} \omega t) \\ Y_A = \rho_i \sin(\theta_i + \omega t) + R\cos(\theta_i + \omega t)\cos(\theta + \frac{\rho_i + R\sin\beta_i}{R} \omega t) - R\sin\beta_i \sin(\theta_i + \omega t)\sin(\theta + \frac{\rho_i + R\sin\beta_i}{R} \omega t) \\ Z_A = -R - R_0(1-\cos\beta_i) + Vt + R\cos\beta_i \sin(\theta + \frac{\rho_i + R\sin\beta_i}{R} \omega t) \end{cases}. \tag{20}$$

When $\beta_i$=0, which means inner disc cutter, the formula (20) will change into the same as the motion equation of inner disc cutter in file [9]. So the motion of inner disc cutter can be thought as a special case of gauge disc cutter.

At last, when all the parameters of $R$, $\rho_i$, $\theta_i$, $\beta_i$, $R_0$, $\theta$, $\omega$ and $V$ are determined, the spatial motion position of working edge point of gauge disc cutter at any time can be calculated accurately.

## Conclusion

On the basis of the analysis of movement characteristics of gauge disc cutter in cutterhead, the motion equation of working edge point of gauge disc cutter is deduced in tunneling process by using the method of space coordinate transformation matrix, which provides theoretical basis for analyzing tool wear and rock breaking mechanism.

**Keywords:**Tunnel fire; Spontaneous combustion; Ambient temperature; Ventilation; Combustibles

**Abstract:**By analyzing the typical fire casesand tunnel fire statistics during 2008 to 2013 in Fujianprovince of China, results shows that the main causesfor the fire were vehicle accidents and spontaneous combustion. By the investigation, there are three approaches to prevent the tunnel fire exposed to different combustibles. For flammable solid, an effective method to prevent fires is to decrease the maximum environment temperature and the product concentration.For flammable liquid, adjusting the ambient temperature and enhancing ventilation can prevent or reduce the fire accidents.For flammable gas, the effective method to prevent the fire is to decrease the fuel density and the ambient temperature.So, for long tunnels or busy tunnels,it must strengthen the management of the vehicles. Moreover, in the hot season and rush hour it should control the ambient temperature inside the tunnels.

## Introduction

In recent years, with the rapid development of the transport industry, tunnels are emerging and the trafficsare increasing.The number and the frequency of vehicles which carrying all kinds of combustible material through tunnel is growing, and also the frequency of tunnel fire is increasing year by year.

According to statistics, the frequency of road tunnel fire is 10 to 17 times per million kilometers, which average frequency is 13.5 times per million kilometers,and the road tunnel fire risk is 20 to 25 times the railway tunnel[1]. Take an example of FujianProvince in China, the special topography as "eight mountains one waterand one field", the total number of expressway tunnels and the total length of single-hole tunnelsare all more than 470 and 470 kms in 2010. With the construction of the highway extending from the coastal areas to the inland mountains, the highway mileage will reach 6,100 kms, and the total length of single-hole tunnels will be more than 1000 kms till2020 inFujianProvince [2]. According to the data of Traffic Police Corps Public Security Bureau of Fujian Province, the highway tunnel accidents caused the number of deaths is nine in 2009 from the whole province, the death toll in 2010 and in 2011 is respectively ten and seven.Until October 2012, the number is six.

## Causes of tunnel fire

Through the typical cases, the various causes to the tunnel fire are as below [3~6]:

**1.1 Traffic accidents.**After vehicle occurred rear-end, scratch, collision (against wall), digression in the tunnel, fires take placed by the overturning derailment or the explosion. For example, the most serious tunnel accident up to nowwas happened in Salang tunnel of Afghanistan in 1982, a truck crashed into a tanker, causing an explosion, and resulting 200 deaths and hundreds of vehicles damaged. And just before author finalized the paper, two tankers carrying hazardous chemicals took rear-end collision in Yanhou tunnel of Shanxi province in China on March 1st, 2014, the front vehicle leaked out methanol, and the methanol caughtfire in the driver's disposal, then the rest vehicles and coal and other flammable goods ignited an explosion inside the tunnel, which caused 31deaths, and 9persons missing. The fire burned for 73 hours, 42 vehicles were damaged.

**1.2 Vehicles and cargo spontaneous combustion.**There are varieties of vehicles through the tunnel, some of them carrying combustible cargo or flammable items, which meet open flame or the road beating or in high temperature environment,then cargo mutual friction was burning or

spontaneous combustion occurred. Take an example: the earliest recorded tunnel accident was in 1949, the truck equipped with carbide and sulfide caught fire in Holland tunnel of New York in U.S.A, large amounts of carbon monoxide and sulfide were produced which led to 66 persons poisoned and 23 vehicles damaged. The tunnel was nearly severely damaged 200 meters.

**1.3 Vehicles own faults.**It was caused by power overheating, electrical circuit overload, short circuit and flash fire, and the wheel, rail, brake friction gave out heat. For example, a large truck caught fire due to friction tire burst in Spa tunnel of Beijing-Zhuhai expressway on March 21st, 2006, which caused tunnel lighting and fire-proofing seriously damaged, and the tunnel was maintained for 11 days before opening to traffic.

**1.4 Tunnels aging and failuresof electrical facilities.**Generally the tunnel useful life is very long. And it is dark, damp, dusty, electric and wiring facilities are easy to be aging and failure, equipment maintenance and overhaul are weak, which easily leads to fires. Such as on September 21st, 1987, the high-voltage wire spit fire in Ikoma Railway tunnel of Japanese, the broken power lines and the traveling train (the front) sparked firesin the tunnel, resulting 49 casualties.

**1.5 Arson.** Such as terrorist activities, take revenge on society, mental illness tolead man-made fires. As Daegu subway fire of Korea in 2003, a man ignited a plastic bottle which contained 2L gasoline, and then thrown to the carriage, resulting the entire cars and the train traveling across on fire, eventually leading to 196 deaths and 147 persons injured.

**1.6 Illegal use of fire.** It was caused by throw fire (cigarettes) and the use of unprotected fire. Such as: combustible gas explosion occurred inDaegu subway construction of Korea in 1995, killing 101 persons on the spot and injuring 143 ones.

**1.7 Other factors.** The earthquake, tornado, outside fire or other external hazards lead to vehicles or facilities in the tunnel on fire. For example in 2008, the train derailed due to Wenchuan earthquake and caught fire in the 109 tunnel of Baocheng railway inChina.

Table 1 shows the cause classification of railway, highway and subway tunnel fires in recent years.

Tab.1 Cause classification of tunnel fires in recent years[4]

| Classification of tunnels | The number of fires | Tunnel facilities spontaneous combustion | Vehicles and cargo ignition | Traffic accidents | Illegal use of fire | Arson | Others |
|---|---|---|---|---|---|---|---|
| Railway tunnels | 16 | 2 | 4 | 7 | 1 | 0 | 2 |
| Highway tunnels | 46 | 0 | 25 | 20 | 1 | 0 | 0 |
| Subway tunnels | 27 | 4 | 11 | 3 | 2 | 6 | 1 |

From Tab.1, for highway tunnels and subway tunnels, vehicle ignition is the main reason, followed by traffic accidents and arson. For railway tunnels, traffic accidents as the leading cause, followed byvehicles ignition. The resultis consistent with the tunnel fire statistics during 2008 to 2013 inFujianwhichwas acquired from Fujian Fire Brigade of China, as shown in Table 2 and Table 3.

Tab.2 Statistics of tunnel fires in Fujian province on January 2008 to May 2013

| Fires types | Number | Proportion |
|---|---|---|
| Failures of electrical facilities | 24 | 19.67% |
| Illegal use of fire | 1 | 0.82% |
| Vehicles and cargo ignition | 17 | 13.93% |
| Arson | 1 | 0.82% |
| Vehicles own faults | 0 | 0.00% |
| Traffic accident | 64 | 52.46% |
| Other | 15 | 12.30% |
| Total | 122 | 100.00% |

Tab.3 Statistics of tunnel fires in Fujian province in 2012

| Fires types | Number | Proportion |
|---|---|---|
| Failures of electrical facilities | 5 | 11.11% |
| Illegal use of fire | 0 | 0.00% |
| Vehicles and cargo ignition | 9 | 20.00% |
| Arson | 1 | 2.22% |
| Vehicles own faults | 2 | 4.44% |
| Traffic accident | 22 | 48.89% |
| Other | 6 | 13.33% |
| Total | 45 | 100.00% |

**Mechanism analyses of tunnel fires**

According to the tunnel fire causes investigation and Fujian tunnel fire statistics, the tunnel fire was mainly caused by trafficaccidents and spontaneous combustion. Due to the causesof traffic accidentsaremore complex, some scholars such as ShenAizhong[5], Kang Xiaolong[7] have studied, and the author would not repeat them again. This article focused on the combustion mechanism of some combustibles lead to vehicles ignition, and using this method to prevent the tunnel fire.

Combined with the types of flammable materials and combustion state, the tunnel fires classificationsare shown in Table 4. Generally, tunnel fires primarily are Class A, Class B and Class C fires. The following details describe these three types of fire burning mechanism.

Tab.4 Classifications for tunnel fires

| Items | Types | Definitions or features |
|---|---|---|
| Classified by the type of combustibles | Class A fire | Caused by carbonaceous solid combustibles such as wood, cotton, paper and so on. |
| | Class B fire | Caused by TypeA, B, C liquids, such as gasoline, diesel, methanol, etc. |
| | Class C fire | Caused by the flammable gases, such as coal gas, natural gas, acetylene, hydrogen, etc. |
| | Class D fire | Caused by flammable reactive metals, such as potassium, sodium, magnesium, aluminum-magnesium alloyand so on. |
| | Class E fire | Refers to the fire burning still live from electrical components and equipments, such as electronic components, electric and electronic wires and cables |
| Classification by burning state | Smoldering combustion | Smoldering fires burning, no flame |
| | Naked flame | The fire burning has a long flame |

**2.1 Flammable solid (Class A fire).**Before solid fuel caught fire, it usually had occurred pyrolysis due to heating, by melting, sublimation, cracking, pyrolysis and other gasification reaction, released flammable gas, which mixed with the oxidizer, and resulted in fire. It formed gas flame first.

At high enoughtemperature, common solid combustibles in the vehicle (such as: wood, coal, plastics, rubber, etc.) would occur pyrolysis and gasification reaction, and release flammable gases. Usually the volatile gases releasingorder is: $H_2O$, $CO_2$, $C_2H_6$, $C_2H_4$, $CH_4$, tar, CO, $H_2$, etc. At last, the productis the porous carbon. Determining how much the amount of carbon depends on fuel types, heating rate and the final temperature of heating. In particular, some solid combustibles rapidly increase alargenumber of flammable gases when the temperature reaches a certain value(flash temperature),such as the flash temperature of woodis 260℃, then the weak spark can ignite them, thus it must strictly monitor the ambient temperature.

In addition, smoldering combustion caused fires in many countries has a large proportion of the total, it should be much concerned. Smoldering is the only gas-solid interface burning, no gas-phase flame. Smoldering temperature is low, slow burning, and involves high levels of CO gas. The plume is explosive and flammable, not easy to discover, but great danger.

Compared with naked flame, smoldering fires' characteristics are: in the small heat strength, it can also occur smoldering.When the heat dissipation conditions are poor, the heat is likely to accumulate, and it would be benefit to spread.Smoldering would spread in low oxygen concentration environment.When the oxidation reaction rate is slow, and the corresponding maximum temperature is low, alsothe spread velocity is very slow.Using short high-speed airflow is difficult to blow smoldering.When the combustion zone expands, it could turn into flame fire.

In short, the maximum temperature and the product concentration in the reaction zone are the key parameters when solid combustible turn into the fire. These analyzes are consistent with scholars' experiment results[8].

**2.2 Flammable liquid (Class B fires).**Before burning, combustible liquids evaporated first, followed by the diffusion of fuel vapor, and mixed air to form a combustible mixture, at last formed the premixed flame or diffusion flame in space somewhere after ignition (the flame is not close to the surface, but in the location of space).

Therefore, the ignition characteristics are related to the evaporation of combustible liquids. And the flash point is an important parameter indicating the evaporation characteristics. Table 5 shows the flashpoint values of flammable goods which vehicles contained in the tunnel. The lower the flash point is, the more easily to be vaporized. From the table, most petroleum products have low flash point, even like diesel fuel, engine oil, etc. They may have a high concentration after a long period.Once within the firingrange, they are in the risk of combustion.

Tab. 5 Flash points of some flammable liquids

| Combustibles' name | Ethanol | N-butanol | Acetone | Petroleum | Engine oil | Cylinder oil | Gasoline | Lubricants |
|---|---|---|---|---|---|---|---|---|
| Flash point (℃) | 10 | 34 | -20 | 30 | 196 | 215 | 10 | 285 |

The morethe combustible liquidis likely to evaporate, the more the vapor concentration easily reaches the ignition ranges, and fire hazard is more danger. The evaporation characteristics are affected by temperature, thus it must monitor the ambient temperature and ventilation, and then the flammable vapors'concentration can't reach the firingrange.

As seen from above, the temperature is still an important factor. In order to prevent or reduce the tunnel fire, it should strengthen monitoring of liquid fuel in high-temperature environment.

**2.3 Flammable gas (Class C fire).** The combustible gas mixed with the oxidant (air or oxygen) in the space, when the mixture concentration reached the firingrange, under certain external conditions the reaction intensely accelerated, and the space instantaneously arriveda high temperature(on fire), then the external conditions called fire condition.It can be expressed asEq. (1):

$$f(T_0, P_0, h, d, u_\infty, T_\infty, x_i) = 0. \quad (1)$$

Where,

$T_0$: initial temperature of the combustible mixture. $P_0$: initial pressure of the combustible gas mixture. h:convective heat transfer coefficient of the system and the environment.d:the characteristic size of the system. $u_\infty$: the relative speed of the system and the environment. $T_\infty$: ambient temperature.$x_i$: ignition distance.

From Eq. (1), when the flammable gas and the system are constant, ambient temperature, wind speed and ignition distance play a vital role in the fire conditions.

In this system, the chemical-reactiongeneration heat and losing heat to environmentalare two main considerations. If the exothermic chemical-reaction plays a dominant role, the system must be on fire.Otherwise it can not be. Thus, the critical condition can be expressed asEq. (2):

$$\frac{VEP_c}{hFR^3T_\infty^4} Q_i k_{oi} X_A \cdot X_B \exp(-\frac{E}{RT_\infty}) = 1. \quad (2)$$

Where,

V - volume of the system, $m^3$

F - surface area of the system, $m^2$

$P_c$ - pressure, Pa

h - convective heat transfer coefficient, $W/(m^2 \cdot K)$

R - universal gas constant, J/(mol·K)

E - activation energy, J/mol

$T_\infty$ - ambient temperature, K

$Q_i$ - the heat of reaction, J/mol

$k_{oi}$- reaction constant

$X_A$, $X_B$- mass percentage of fuel and oxidant (concentration),%.

When $X_A$ and $X_B$ are constant, we can obtain the relationship between critical temperature and critical pressure.When $P_c$ is constant, we can get the relationship between critical ignition temperature and the concentration of combustible gas mixture. When $T_\infty$ is unchanged, we can gain the relationship between critical ignition pressure and the concentration of combustible gas mixture.

From Eq. (2) the firingrange curve can be drawn.And the curve shows that controlling fuel concentration and ambient temperature is an effective way to prevent ignition.

In fact, only one combustible during the burning in the fire is rare. Most of the fires are simultaneously burning several combustible materials.

## Conclusions

Combine the typical fire cases with tunnel fire statistics in Fujian, it shows spontaneous combustion and vehicle accidents are the two main causes.

To analyze the mechanisms of different combustibles leading to the tunnel fire, the following conclusions can be obtained:

(1) For solid combustibles, controlling the maximum environment temperature and the product concentration are the most effective measures to prevent fires.

(2) For the combustibleliquid, adjusting the ambient temperature and enhancingventilation can reduce the incidence of fires.

(3) For the combustible gas, monitoring fuel concentration and ambient temperature are still an effective way to prevent ignition.

## Recommendations

(1) For long tunnels or busy tunnels, it must strengthen the management of the vehicles to reduce the frequency of tunnel fires and the risk of accidents. Such as: set fast and effective equipments to detect inflammable and explosive goods at the tunnel entrances.The vehicles catching large amount or large-scale Class A fire hazard are ban or restricted through the tunnel.Tunnel traffic management department staff should regulate flammable product packing and transport, when the vehicles do not meet the packaging requirements and transport condition, they need to be corrective in the parking lot or go back to repackage and load, and to hang an obvious mark of dangerous cargo.

(2) In the hot season and rush hour it should control the ambient temperature inside the tunnel. Such as: install temperature probes.Once the temperature exceeds the critical value, they would start fans for ventilation.In addition to ventilation, it can also carry out other cooling measures.Under the traffic jam, it should control the number of vehicles entering the tunnel, and keepa requirement safe distance.

# Metro construction safety risk assessment based on the fuzzy AHP and the comprehensive evaluation method

Xin Zheng[1, a], Fenghai Ma[1,b]

[1]College of Civil and Architectural Engineering, Dalian University, Dalian, 116622, China

[a]jasmine150@163.com, [b]xkb@vip.163.com

**Keywords:** Subway construction, Risk management, Risk assessment

**Abstract.** Facing with a variety of risks in the process of the metro construction, the metro construction needs to carry on the risk management. The risk assessment is the main link of the metro project risk management also the foundation of the decision analysis. This paper introduces the basic concept of the subway risk management, as a case study of Changchun No.1 subway construction risk assessment using the fuzzy AHP and the comprehensive evaluation method. The results show that Changchun subway station work sites exist many risk factors and the risk level difference is big. The major attention should be paid to the geological risks, the environment risks and the construction technical risks, while the environment risks and the construction technical risks are the focus of the risk analysis.

## Introduction

The adverse consequences or influence in the process of the subway and the underground engineering construction stands a big chance, whose main types include: economic losses, schedule delays, casualties, environmental impacts and social impacts. The implementation of the subway and underground engineering risk management should be reasonable and feasible to reduce the adverse consequences or adverse effects[1,2].

The project risk management refers to the project participants through risk definition, risk identification, risk estimate, risk evaluation and risk decision-making and control, optimizes the combination of various risk management techniques, the engineering implementation of effective risk control and tracking process properly. The project risk assessment is an important content and step in the process of the risk management. On the basis of project risk identification, with methods of risk assessment, it assesses overall risks of the project. According to the results of the risk assessment, take risk control measures, carry on the effective management of risk, make every stage of the project construction risk reduce to the lowest level[3].

The risk analysis of subway construction has quite a few achievements at the present stage, but still no in accordance with the risk of underground engineering construction to specific analysis. This paper, under the premise of the brief introduction of the risk management, combined with Changchun metro engineering construction, clearly puts forward all kinds of the risk source in Changchun subway construction, and a quantitative classification on the basis of this, the corresponding control measures are put forward.

## Risk Management

**The definition and classification of risk management.** The risk management is the economic unit of the possible risks to predict, identify, assess, analyze, and on this basis to effectively dispose of the risk at the lowest cost to achieve scientific management methods of the largest security .

Risk management is mainly divided into two categories:

(1) Business management risk management mainly study the political, economic, social change, the management risk which all enterprises face.

(2) Insurance risk management mainly regards insurable risk as an object of risk management, puts the insurance management at the core position, security management as a supplementary means.

**The objectives of risk management.** The basic goal of risk management is the minimum economic cost to obtain maximum security benefits. That is the least amount of the risk management to maximize dispersed expenses, transfer, eliminate the risk in order to achieve economic benefits and safeguard people's basic purpose of social stability.

**The content of risk management.** The content of the risk management includes the following four parts:

(1) Risk identification. The risk identification is the first step in project risk management. It refers to identify the principal risks affecting project quality, progress, investment and security objectives successfully achieved.

(2) Risk assessment. Risk assessment is the quantification of the project risk process after risk identification. Risk assessment can be used in an integrated evaluation method, AHP analytic hierarchy process and fuzzy evaluation method, etc.

(3) Risk analysis. Risk analysis is based on the previous work in the process of the project management about the consequences of any events that may occur, in order to determine the probability of the event and the potential impact of the project related to the possible consequences.

(4) Risk Control. Risk control is the use of certain techniques to try to avoid or control risks, eliminate or reduce the risk of loss caused by the incident. Focus on risk control is to eliminate the risk factors and reduce the risk of loss.

## Subway Construction Risk Assessment

Yikuang Street station in Changchun No.1 subway project as an example, uses the AHP and the fuzzy comprehensive evaluation method for the risk assessment, in order to solve possible safety hazards in Changchun subway construction, ensuring the safety of the subway construction.

**Project overview.** Yikuang street station is located at a street intersection of the Yikuang street and the people's street, along the people's street to the north-south layout. The standard segment of the main structure of the station is two-floor cross- island platform, the effective platform length is 118m and the total width of the standard segment is 19.0m. The station floor depth is of 16.0m~19.0m and the roof cases 3.0m ~ 4.35m. The main station and the station interval structure use the open cut method construction. The retaining structure is in the form of bored piles combined with steel support while soil between piles is under the protection of the net-suspended spray concrete. In the main scope of the station underground are many pipelines. The site formation is composed of the quaternary holocene artificial filling soil layer, the quaternary alluvial cohesive soil and sandy soil, the cretaceous mudstone. Two layers of groundwater exist in the interval formation. The foundation pit precipitation method of the main structure uses tube well dewatering.

**Risk identification.** Through access to a large number of the station construction materials, taking the actual needs of the project and the operational risk assessment into account, do the systems analysis. The risk of the Yikuang street station Construction(A) are divided into the geological risk($B_1$), the construction technology risk($B_2$), the environment risks($B_3$). The geological risk($B_1$) has subordinate levels: the poor stability silty clay layer($C_1$); the construction technology risks($B_2$) have subordinate levels: the bored piles construction risks($C_2$), the erection of steel support is not timely($C_3$), the net sprayed concrete and the waterproof mortar is not timely($C_4$), the pit heap dynamic load is too large($C_5$), the winter construction risks($C_6$); the environment risks($B_3$) have subordinate levels: the adjacent buildings($C_7$), the power lines under the precincts of the mainland($C_8$), the venue feedwater supply cast iron DN300($C_9$). According to these three risk factors as the criterion, set up 3-class hierarchy model, use fuzzy analytic hierarchy process(AHP)[4] to the subway station construction risk identification[5,6]. The process is as follows.

(1) Establish hierarchical structure model. As is showed in fig.1.

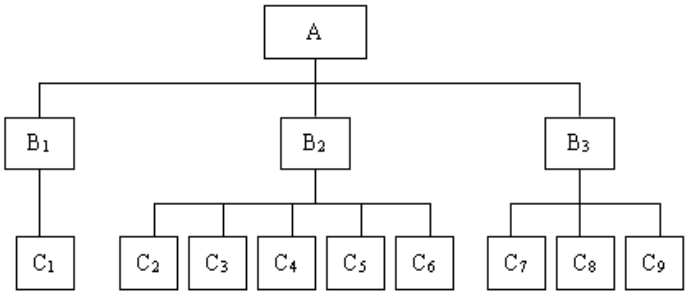

Fig.1 The structure model of hierarchical levels

(2) Priority of judgment matrix. In Yikuang street station construction risk pass class hierarchy model with more than one layer of each element layer elements as a criterion, establish fuzzy preference relation matrix.

$$A^K = (a_{ij}^k)_{n\times n}, k = 1,2,\cdots,m \tag{1}$$

In the above formula, $a_{ij}^k$ stands for the precedence relations coefficient evaluated between the object i and j. When the evaluation object i is better than j, $a_{ij}^k = 1$; when the evaluation object i is the same as j, $a_{ij}^k = 0.5$; when the evaluation object i is worse than j, $a_{ij}^k = 0$. The results of the judgment optimizing the relationship between numerical value is shown in Tab.1, Tab.2 and Tab. 3.

Tab.1 A~$B_{1\text{-}3}$ precedence relations determined matrix

| A | $B_1$ | $B_2$ | $B_3$ |
|---|---|---|---|
| $B_1$ | 0.5 | 0 | 0 |
| $B_2$ | 1 | 0.5 | 0.5 |
| $B_3$ | 1 | 0.5 | 0.5 |

Tab.2 $B_2$~$C_{2\sim6}$ precedence relations determined matrix

| $B_2$ | $C_2$ | $C_3$ | $C_4$ | $C_5$ | $C_6$ |
|---|---|---|---|---|---|
| $C_2$ | 0.5 | 0 | 0 | 0 | 0 |
| $C_3$ | 1 | 0.5 | 0.5 | 0.5 | 1 |
| $C_4$ | 1 | 0.5 | 0.5 | 0.5 | 1 |
| $C_5$ | 1 | 0.5 | 0.5 | 0.5 | 1 |
| $C_6$ | 1 | 0 | 0 | 0 | 0.5 |

Tab.3 $B_3$~$C_{7\sim9}$ precedence relations determined matrix

| $B_3$ | $C_7$ | $C_8$ | $C_9$ |
|---|---|---|---|
| $C_7$ | 0.5 | 1 | 1 |
| $C_8$ | 0 | 0.5 | 0.5 |
| $C_9$ | 0 | 0.5 | 0.5 |

(3) Construction of fuzzy judgment matrix. Numerically transform the above priority of judgment matrix according to the following formula.

$$r_{ij} = \frac{r_i - r_j}{2n} + 0.5 \tag{2}$$

$$R = r_{ij} = \begin{pmatrix} r_{11} & r_{12} & \cdots & r_{1n} \\ r_{21} & r_{22} & \cdots & r_{2n} \\ \cdots & \cdots & \cdots & \cdots \\ r_{n1} & r_{n2} & \cdots & r_{nn} \end{pmatrix} \tag{3}$$

In the above formulas, $r_{ij}$ stands for the relative importance of element i compared with j. You can get fuzzy judgment matrix as $R^{A}_{B_{1-3}}$, $R^{B_1}_{C_1}$, $R^{B_2}_{C_{2-6}}$, $R^{B_3}_{C_{7-9}}$.

$$R^{A}_{B_{1-3}} = \begin{pmatrix} 0.617 & 0.417 & 0.417 \\ 0.417 & 0.667 & 0.667 \\ 0.417 & 0.667 & 0.667 \end{pmatrix} \qquad R^{B_1}_{C_1} = (1)$$

$$R^{B_2}_{C_{2-6}} = \begin{pmatrix} 0.100 & 0.400 & 0.400 & 0.400 & 0.200 \\ 0.400 & 0.700 & 0.700 & 0.700 & 0.300 \\ 0.400 & 0.700 & 0.700 & 0.700 & 0.300 \\ 0.400 & 0.700 & 0.700 & 0.700 & 0.300 \\ 0.200 & 0.500 & 0.500 & 0.500 & 0.300 \end{pmatrix} \qquad R^{B_3}_{C_{7-9}} = \begin{pmatrix} 0.833 & 0.583 & 0.583 \\ 0.583 & 0.333 & 0.333 \\ 0.583 & 0.333 & 0.333 \end{pmatrix}$$

(4) Single -level sorting. Using the square root to calculate Yikuang street station hierarchical structure model, the indicators relative to the upper layer of the criteria weights. The calculation results obtain as follows.

$\partial^{A}_{B_{1-3}} = [0.222 \;\; 0.389 \;\; 0.389]^{T}$ $\qquad \partial^{B_1}_{C_1} = [1]^{T}$

$\partial^{B_2}_{C_{2-6}} = [0.126 \;\; 0.235 \;\; 0.235 \;\; 0.235 \;\; 0.168]^{T}$ $\qquad \partial^{B_3}_{C_{7-9}} = [0.445 \;\; 0.278 \;\; 0.278]^{T}$

(5) The total level sorting. Synthesized according to the relative weigh, calculate the element C level relative to A weights of hierarchy elements, in order to achieve overall level sorting. The results are shown in Tab.4.

Tab.4 The hierarchy total sort

| Level | $B_1$ | $B_2$ | $B_3$ | $\partial^{A}_{C}$ | Sort |
|---|---|---|---|---|---|
| | 0.222 | 0.389 | 0.389 | | |
| $C_1$ | 1.000 | 0.000 | 0.000 | 0.222 | 1 |
| $C_2$ | 0.000 | 0.126 | 0.000 | 0.049 | 6 |
| $C_3$ | 0.000 | 0.235 | 0.000 | 0.091 | 4 |
| $C_4$ | 0.000 | 0.235 | 0.000 | 0.091 | 4 |
| $C_5$ | 0.000 | 0.235 | 0.000 | 0.091 | 4 |
| $C_6$ | 0.000 | 0.168 | 0.000 | 0.065 | 5 |
| $C_7$ | 0.000 | 0.000 | 0.445 | 0.173 | 2 |
| $C_8$ | 0.000 | 0.000 | 0.278 | 0.108 | 3 |
| $C_9$ | 0.000 | 0.000 | 0.278 | 0.108 | 3 |

Obtained from Tab.4, according to the geological risk, the construction technology risk and the environment risk, the order of importance for the risk factors effected on Changchun Yikuang Street subway station construction is $C_1$, $C_7$, $C_{8,9}$, $C_{3\text{-}5}$, $C_6$, $C_2$.

**Risk Assessment.** Metro station construction risk assessment is on the basis of identifying the source of the metro station construction risk, establishing a model comprehensively considering the risk probability and the risk assessment. According to the relevant risk acceptance criteria and

evaluation standards, evaluating the metro station construction risk, which will provide a scientific basis for the risk response and monitoring, could ensure the metro station project smoothly.

In this paper, Yikuang street station construction risk acceptance criteria and evaluation criteria applied the relevant provisions of grade adopt the rules of the urban rail transit construction risk management of underground engineering (GB50652-2011). Using comprehensive evaluation method, first of all, according to the identified risk factors list the risk questionnaires, then please experienced experts to evaluate the possible risk factors and risk events, and then integrate and conclude that the overall level of risks, the risk classification are shown in Tab.5.

Tab.5 Yikuang street station risk classification

| Risk Type | Risk Factors | Risk events | Risk Level | The overall risk level |
|---|---|---|---|---|
| Geological risk($B_1$) | $C_1$ | Disturbed by the construction of large deformation | Ⅳ | Ⅲ |
| Construction technology risk($B_2$) | $C_2$ | Split between pile, piles intrude into structure limits | Ⅲ | |
| | $C_3$ | Maintenance of structural deformation | Ⅲ | |
| | $C_4$ | Leakage of water | Ⅲ | |
| | $C_5$ | Excessive local deformation | Ⅲ | |
| | $C_6$ | Concrete frostbite , support prestressing loss | Ⅲ | |
| Environment risk($B_3$) | $C_7$ | Settlement deformation | Ⅲ | |
| | $C_8$ | Mechanical construction, easy to break | Ⅱ | |
| | $C_9$ | Subsidence deformation, easy water leakage | Ⅲ | |

## Conclusion

Subway construction technology is now quite mature, but due to the construction market confusion, the expansion of construction scale, resulting in a subway construction is still accident-prone subway construction phase, and targeted to construction risk analysis is quite necessary. Yikuang street station construction risk assessment as an example, assess the construction risks of the every work site in Changchun No.1 subway. The following conclusions can be drawn:

(1) Changchun subway construction risk analysis is focused on the construction technology risk and the environment risks, while the geological risk of the construction risk related to the influence of the environment risks and the construction technology risks is relatively weak.

(2) The supporting process of the foundation pit excavation phase is the main part of the risk of construction technology, taking reasonable support method and strict construction quality control is the key to solve this problem.

(3) On the ground along Changchun subway line existing a mass of buildings and large structures and the underground pipe network are the main factors causing the environment risk.

**Keywords:** Deep Foundation Pit; SMW; Monitoring; deformation; Subway Station.

**Abstract.** The monitoring is carried out for deformation of the soil-mixing-wall structures used in Baijihu subway station. The horizontal displacement of deep soil is obtained, as well as the ground subsidence around the edges of the foundation pit. Their variation rules under the influence of some factors, such as soil excavation and support settings etc, is analyzed. The results show that during the process of SMW construction, it is necessary to monitor the horizontal displacement of deep soil and the ground subsidence around the edges of the foundation pit, especially during the early stage of excavation.

## Introduction

Soil-Mixing-Wall (SMW) construction method is a relatively new flexible retaining technology for deep foundation pit. It have some advantageous characteristic in terms of social and economic efficiency compared with other retaining structures. However, its working mechanism and design theory remains immature yet. Therefore, it's limited from a wide range of applications for deep foundation engineering.[1-2] With the advent of the era of the subway, it is particularly urgent to strengthen the research in the field of how to accurately predict the deformation of SMW retaining structures in deep foundation pit, in order to take measures to control the loading and deformation in the process of design and construction of subway.[3]

In recent years, various kinds of practical methods have been put forward to improve the performance of SWM retaining structures. Osamu et al.[4] introduced the soil-cement mixed wall technique for excavation support and groundwater control. Anderson[5] introduced an innovative retaining wall technique utilizing a deep soil mixed cutoff wall system with an architectural concrete facing. Nicholson et al.[6] presented a design for a new deep mixing method wall system using deep mixing techniques with an array of soil/cement mixed columns arranged in the native soil to creates a gravity block. Kim et al.[7] proposed a novel retaining wall system employing the soil-cement mixing technique which can be applied at urban excavation sites. David et al.[8] described the construction of the cement deep soil mixed wall for the earth retention system.

In this paper, the monitoring is carried out for the horizontal displacement of the maintenance structures in the deep soil, as well as the surrounding ground subsidence, for the Baijiahu station. Meanwhile, the variation of the horizontal displacement in deep soil and the ground subsidence under the influence of some factors, such as soil excavation and support setting etc, is analyzed. As a result, the deformation rules of SMW retaining structures are found when it is applied for the deep foundation pit during the construction of subways stations.

## Overview of the Project and its Monitoring

**Project overview.** Baijiahu station belongs to the south extension of Line 1 of Nanjing subway. It is located in the north from intersection of Ningli Road and Tianyuan Road, near the north-south axial of

Phoenix Port. Baijiahu station is designed as a box-like structure with two layers and three spans lying underground. The first layer underground is the station hall and the second layer is platform, which has an island-like form and a width of 12 m.

The geological conditions in this project is very complicated, which can be described as follows. From top to bottom, ①-1 miscellaneous fill, ③-1b1-2 silty clay (hard-plastic), ③-1c2-3 silty soil (slightly-medium density), ③-2d2-3 silty sand (slightly-medium density), ③-2b2-3 silty clay (plastic), ③-4e silty sand mixed gravel, k1g-1 strong weathered argillaceous conglomerate, k1g-2 moderately weathered argillaceous conglomerate, the based floor located on ③-2d2-3 silty sand.

The open-cut and sequential construction technique is adopted for the main structures. The depth of the foundation pit varies from 14.494m to 14.834m. Thus, φ850@600 cement -soil three-axis mixing piles with interpolation of HN700×300 steel are applied in the retaining structures. According to the depth of excavation and geological data, the interpolation steel is arranged in two ways: two h-shaped steel interpolated with one ignored, and one ore ignored. All of the h-shaped steels will be recycled after the construction of main structures is completed.

The layout of the station is mainly symmetric along the direction in the plane. At the corner of the pit, moderate amount of diagonal braces are set down to stabilize the walls of the foundation pit. The excavation of the pit is symmetrically carried out, layer by layer and segment by segment. The depth of each layer of excavation is about 3m. Before the support and the waist beam are installed, the excavation should be extended down to about 0.3m below them. The supports in the walls of the main foundation is divided into four groups distributing in the vertical direction. The length of vertical intervals between each group are 4.1m , 3.0m and 4.1m, respectively. And the horizontal intervals between each support is 3.5m.

**Monitoring Scheme.** According to some general characteristics of Baijiahu station, such as engineering geology and construction, etc., the plain layout of the monitoring points of the foundation pit is shown in Fig. 1. Herein CX1–CX8 denote the monitoring points for the horizontal displacement of the deep soil; $Z_{1\text{-}1}$–$Z_{6\text{-}4}$ denote the monitoring points for the axial forces in the steel supports; $d_i$ ($i$ = 1–22) denote the monitoring points for the surrounding ground subsidence.

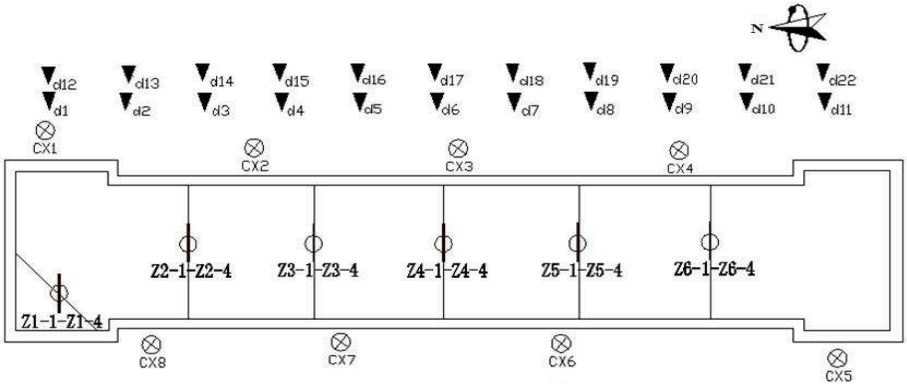

Fig.1 Layout diagram of the monitoring points

The main monitoring points are distributed as follows: In order to measure the horizontal displacement of the deep soil, four monitoring points are set up in the measurement holes on each side of the station's section. And 8 inclinometers are buried in the inclinometers holes, which are drilled by the light drilling rig. Each hole has the depth of 30m, numbered from CX1 to CX8. Twenty-two monitoring points for the surrounding ground subsidence are located on the road near the east of the station. Each monitoring point is numbered as $d_i$ ($i$ = 1–22). In the 6 typical sections of foundation pit, a steel-string type axial force meter is arranged at one end of each steel pipe support in order to monitor the supporting force. There are four support on each typical section. All of the 24 monitoring points are numbered as $Z_{i\text{-}j}$ ($i$ = 1–6, $j$ =1–4), where $i$ represents the No. of sections, and $j$ represents the No. of supports on each section. For example, "$Z_{3\text{-}2}$" represents the second supporting axial force monitoring points from top to bottom in the third section.

## Monitoring Results and Analysis

**Monitoring and analysis of deep soil horizontal displacement.** The whole process of the excavation of the foundation pit can be divided into six steps. In Step 1, the excavation is extended to the location near the first support. In Step 2, the first support is installed and the first layer of the foundation pit is excavated. In Step 3, the second support is installed and the second layer of the foundation pit is excavated. Step 4 and Step 5 can be deduced from this. In Step 6, the main structures of the station is poured, as well as the foundation cushion.

The horizontal displacement of deep soil varies continuously along with the steps. The monitoring results obtained from point CX8 is shown in Fig. 2. In Step 1, the horizontal displacement is relatively small. From Step 2 to Step 3, the maximum horizontal displacement increases rapidly from 3.5mm to 17.7mm. It is mainly resulted from the quick release of the loading during the process of the excavation. And the rate of load releasing is the fastest at the beginning of excavation.

As the first two support is set up timely, the stiffness of the retaining structures becomes higher. As a result, there is no notable variation in the horizontal displacement from Step 3 to Step 4. It is obvious that the first and second support have significant restriction on the horizontal displacement of retaining structures. In Step 6, the maximum horizontal displacement is 29.3mm, which does not exceed the alarm value (30mm). The maximum value occurs at the depth of 10.5 m, about 3/4 depth of the pit.

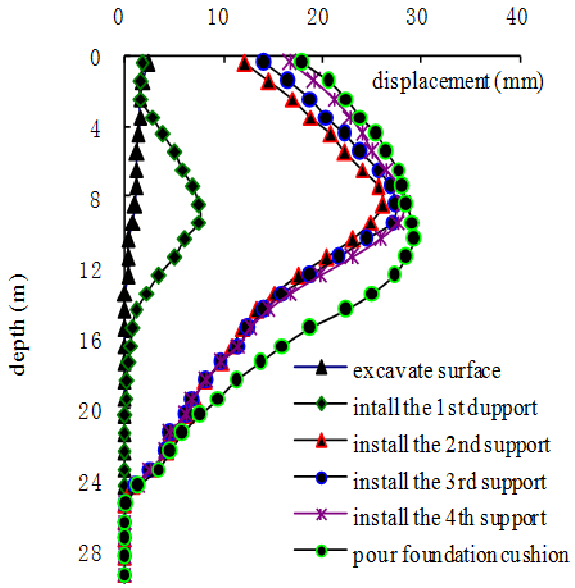

Fig.2 Curves of horizontal displacement of retaining structure in CX8.

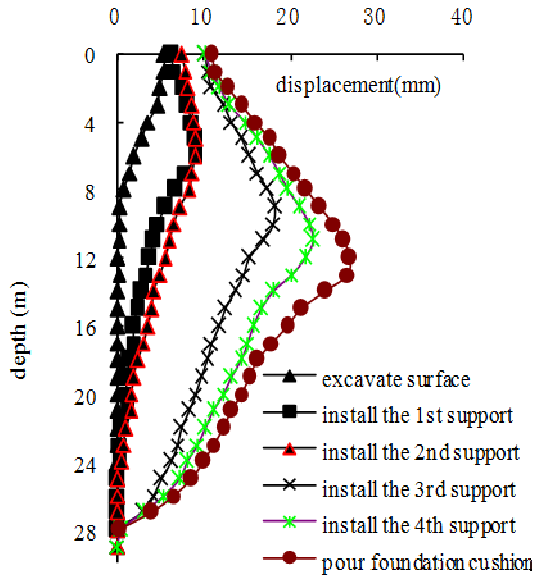

Fig.3 Curves of horizontal displacement of retaining structure in CX2.

The monitoring results obtained from point CX2 is shown in Fig. 3. Its variation tendency is similar with the one in CX8. Only the maximum horizontal displacements at the pile head are slightly different: CX8 is 18.0mm, while CX2 is 10.7mm. It is maybe caused by storing of the steel supports near the west side of CX8 monitoring point. Therefore, during of the process of construction, the heaped load around foundation pit should be strictly controlled. Moreover, the load near the edges of the foundation pit should be reduced as much as possible to minimize the impact on the deformation of the foundation pit. The maximum value of the deep soil's horizontal displacement in CX2, close to the one in CX8, does not exceed the alarm value either. It can be concluded that temporary heaped load has less influence on the maximum value of the deep soil's horizontal displacement.

**Monitoring and analysis of surrounding ground subsidence.** There are no important buildings around the project. The subsidence curves at surface monitoring points ($d_1$–$d_5$) located in a row near the east side of the foundation pit are shown in Fig. 4. As it can be seen from the Fig. 4, the ground subsidence at all monitoring points is relatively small. The maximum occurs at the point $d_4$ with the value of only -3.4mm, where the minus sign denotes the downward subsidence.

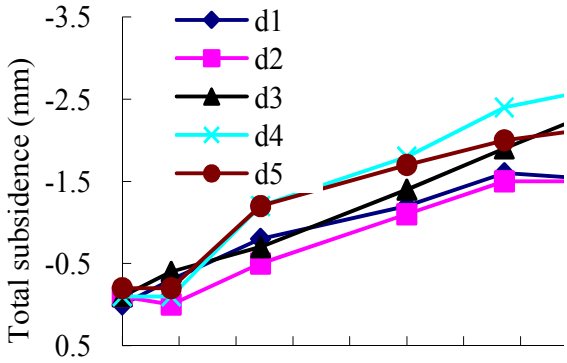

Fig.4 Ground subsidence curves at monitoring points $d_1$-$d_5$.

During the process of SMW construction, the soil is cut and mixed, which cause a relatively small disturbance in the soil around the foundation pit. It is shown from the theoretical analysis that the ground subsidence curves are groove-like. At the monitoring point closer to the edges of the pit, the subsidence is larger, and vice versa. It is shown, from the Fig. 4, that there is a similar developing trend of the subsidence at all monitoring points. The maximum subsidence was detected on October 14th, when the excavation was extended to the location near the forth support. All of the ground subsidence curves can be divided into three stages obviously. In the first stage, the subsidence develops rapidly during the Step 1 of the excavation. The vertical deformation is mainly led by the lateral deformation of the support structures, which accounts for about 34% of the total subsidence. As mentioned above, the fast rate of the subsidence is mainly resulted from the quick deformation of the support structures during the initial process of the excavation. In the second stage, the pre-stressed steel supports provide an enough lateral supporting force to reduce the lateral displacement. Thus, the further subsidence is prevented and the downward subsidence becomes slow. In the third stage, the cushion was poured, and the foundation pit tended to be almost stable. Therefore, the subsidence gradually became stable and slow.

The final total ground subsidence at all monitoring points are listed in Table 1. It can be found that there is an obvious space effect in the around ground subsidence. The ground subsidence at most monitoring points has a trend of downward subsidence. Exceptionally, in the initial process of the excavation, there is slightly rising at the north points $d_1$, $d_2$, $d_{12}$, $d_{13}$, due to the temporarily stacked materials around the foundation pit.

The SMW retaining structures are somewhat flexible. When the excavation is fairly deep, and the soil is relatively soft, a considerable plastic flow would occur in the soil. As the soil near the support structures deviates to the interior and the bottom of the foundation pit, the stresses in the soil behind the retaining walls are released, and the ground subsidence occurs.

Tab. 1 Final total ground subsidence at all monitoring points

| | | | | | | |
|---|---|---|---|---|---|---|
| Monitoring points | $d_1$ | $d_2$ | $d_3$ | $d_4$ | $d_5$ | $d_6$ |
| Subsidence (mm) | -1.5 | -1.5 | -2.5 | -2.7 | -2.2 | -10.2 |
| Monitoring points | $d_7$ | $d_8$ | $d_9$ | $d_{10}$ | $d_{11}$ | $d_{12}$ |
| Subsidence (mm) | -29.7 | -29.9 | -17.4 | -20.7 | -18.7 | -1.2 |
| Monitoring points | $d_{13}$ | $d_{14}$ | $d_{15}$ | $d_{16}$ | $d_{17}$ | $d_{18}$ |
| Subsidence (mm) | -2.9 | -4.1 | -3.4 | -3.3 | -7.0 | -38.9 |
| Monitoring points | $d_{19}$ | $d_{20}$ | $d_{21}$ | $d_{22}$ | | |
| Subsidence (mm) | -79.2 | -21.1 | -19.4 | -14.1 | | |

As it can be seen from Table 1, the subsidence at points $d_{18,}$ $d_{19,}$ $d_{20}$ is relatively large. The underground pipelines around the pit are damaged during the process of construction, which caused the leakage accident occurring in the southeastern section of the foundation pit. As a result, the ground subsidence at the corresponding points around the pit is increased. The subsidence at the monitoring points of $d_{18,}$ $d_{19}$ and $d_{20}$ exceeds the alarming value.

Herein, some measures, such as gravity grouting, dewatering well, are timely taken to prevent the subsidence from increasing. When the sidewalls in the leakage section are poured completely, the dewatering wells stop working. The downward subsidence becomes slower, even has a rising trend with the recovery of groundwater level. Finally, the subsidence is controlled.

## Conclusions

Through monitoring and analysis for the deformation of the SMW structures used in Baijiahu station, it can be concluded that:

(1) The soil-mixing-walls (SMWs) are flexible retaining structures. During the excavation, the maximum value of horizontal displacement appears at about 3/4 depth of the foundation pit.

(2) The axial forces in the support structures vary with the depth of excavation. During the process of excavation of foundation pit, it is necessary to strictly control the preloading around the edges of pit to reduce its influence on the deformation of foundation pit.

(3) During the early stage of excavation, the ground subsidence is obvious (about 34% of the total subsidence), which need strict monitoring. When the pouring of cushion is finished, the ground subsidence around the foundation pit becomes gradually stabilized.

(4) It is necessary to enhance the monitoring during the construction, which will contribute to the quick feedback of construction information. Informational construction is an effective means for the smooth implementation of SMW construction method. It is helpful to promptly find the problem and adopt the optimal countermeasure.

**Keywords:** Small spacing tunnel. Diffusion path.CFD. Treatment program

**Abstract.** Small spacing tunnel due to the special structure form and two tubes are only separated by a thin wall. This structure form is likely to cause secondary pollution, pollution gas discharged into the adjacent tunnel. This phenomenon will lead to increased ventilation system energy consumption. This paper analysis gas diffusion path between two adjacent tunnels, using CFD (Ansys Fluent). To relieve the pollution gases secondary pollution of tunnel portal area, using CFD analyzed gas diffusion path under different circumstances, for opening hole on the top of sunshades, extended of the wall between two adjacent tunnels and other programs, and identify more comprehensive disposal program.

## Introduction [1,2,3]

Due to the special structure form of small spacing tunnel, two tubes are only separated by a thin wall. Two-tubes can't be staggered in the longitudinal direction (refer with: Fig. 1). This structure form is likely to cause secondary pollution pollution gases on tunnel entrance area, reducing the efficiency of the ventilation system.

This article relies on a small spacing tunnel, using CFD software to analyze the gas diffusion path .Based on the analysis results, take appropriate measures to alleviate secondary pollution polluting. Using CFD software analyze the spread of pollution gases under taken different treatments and put forward the corresponding counter measures.

Fig.1 Schematic of small spacing tunnel portal (Sketch map)

## Description of small spacing tunnel

Tunnel with two-tubes
One-way traffic
Six-lane (two-way)
Small spacing with sunshades
Jet fan longitudinal ventilation (normal operation case)

## Numerical simulation model [4,5,6]

Establish the actual tunnel size ratio of 1:1 numerical model.

Using CO as tracer gas.

Viscous model: k-ε

Component transport model

The actual model by using a three-dimensional model of the tunnel 1:1 numerical simulation as following:

Tunnel model length is 20m. Cave sunshades length is 90m.

Tunnel exit section length 100m, width 80m, 50m high cubes simulation outside atmosphere.

In order to simplify the problem, the model made the following assumptions:

1) Made in the tunnel the tracer gas inlet CO with maximum concentration 150ppm.

2) Considered contaminated gas flow rate and concentration at the exit of the tunnel are evenly distributed.

3) Don't consider the impact of motor vehicle pollution in the tunnel gas diffusion.

## Pollution gases diffusion path under original model [5,6]

At the exit of the tunnel ( no wind on the sunshades tunnel exit )， pollution gases diffusion path were simulated, CO concentrations are shown below(refer with: Fig. 2).

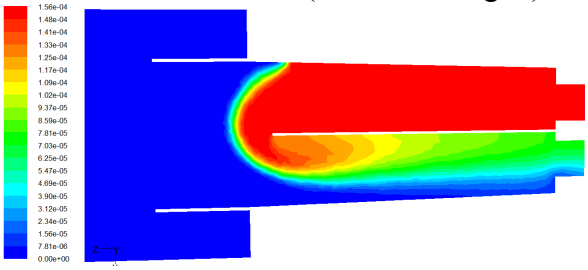

Fig.2 Pollution gases diffusion path near tunnel portal (original model)

As can be seen from the Fig.2, CO concentrations of downstream tunnel entrance is higher. Pollution gas diffusion along the tunnel entrance area into the adjacent tunnel with the piston wind action. It causes pollution gases such secondary pollution between two tubes.

By analyzing the simulation results, CO concentrations of upstream and downstream tunnel entrance tunnel exit were 150ppm, 55.3pmm. Approximately 30% of pollution gases from upstream tunnel come into the downstream tunnel. To reduce secondary pollution between two tubes, it's necessary to take measures to intervene contaminated gas diffusion path. Combined with engineering practice, ready to adopt the following three options: " increase the length of the wall between two tubes", "open holes on top of sunshades " and " increase the length of the wall between two tubes combined with open holes on top of sunshades " .Analyzed pollution gases diffusion path for three scenarios, using CFD software and identify the optimal technology solutions.

## Pollution gases diffusion path under improve model [5,6]

Creat numical simulation models based on on the actual size of the tunnel and analyze pollution gaes diffusion path under different case.The results of pollution gaes diffusion path under three kind of program conditions ,as following:

- **Lengthen the wall between the two tubes**

Under no wind conditions outside, lengthen the wall between the two tubes (Length increased is 20m), CO diffusion path as shown below (refer with: Fig. 3).

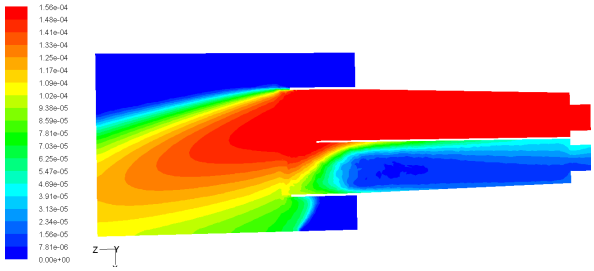

Fig.3 Pollution gases diffusion path near tunnel portal (lengthen the wall between two tubes)

As can be seen from the Fig 3, the concentration of pollutant gases downstream of the tunnel is relatively small and the polluted gas diffusion in the horizontal direction. Compared with the original model, contaminated gas stream to get a better suppression. This is due to the growth in the length of the wall, so that the interaction between two tubes is relatively small.

After analyzing the results of numerical simulation, concentration of CO is 150ppm on tunnel exit portal, and concentration of CO is 23.6ppm on adjacent tunnel entrance. Pollution gases upstream of approximately 15.6% in the tunnel into the downstream tunnel. Compared with the original scheme, polluted gas stream between two tubes has been greatly improved.

- **Open holes on top of tunnel sunshades** [5,6]

Under no wind conditions outside, open holes on top of tunnel sunshades, CO diffusion path as shown below (refer with: Fig. 4).

At the top of sunshades opening size of its opening is 3m × 3m. No wind tunnel exit conditions, the gas stream pollution case sunshades top opening program was simulated, and its CO diffusion path as shown below.

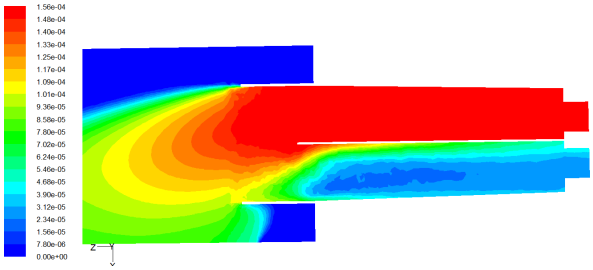

Fig.4 Pollution gases diffusion path near tunnel portal (open holes on top of tunnel sunshades)

As can be seen from the Fig.4, the concentration of CO in the tunnel portal region, respectively, compared with the original plan, the change is significantly. Concentration of pollutant gases and down the tunnel entrances CO were 150ppm, 54.6ppm, and program two gas streams contaminated hole inhibition effect is basically the same.

- **Lengthen the wall between the two tubes combination open holes on top of tunnel sunshades** [5,6]

The scheme 1 and 2 together, namely lengthen the wall and open holes on top of tunnel sunshades.

The tunnel exit windless condition, the scheme 1, 2 combinations of polluted gas stream is used to simulate the CO diffusion path, as shown below (refer with: Fig. 5).

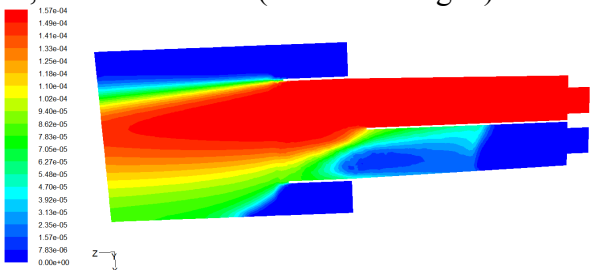

Fig.5 Pollution gases diffusion path near tunnel portal (Combination scheme)

As can be seen from the Fig.5, the concentration of pollutant gases downstream of the tunnel is relatively small, and the polluted gas diffusion in the horizontal direction in the hole. Concentration of pollutant gases and down the tunnel entrances CO were 150ppm, 20ppm. The scheme to curb pollution gas stream is more advantages than the front two schemes.

Above three kinds of schemes to alleviate pollution gas stream is efficiently. which kinds of scheme can be used depending on operation condition.

**Acknowledgements**

In this paper, use the CFD(Ansys Fluent )software to analyze pollution gas diffusion path on the small spacing tunnel portal area, by CO as tracer gas. Through numerical analysis with different intervention programs, we have found the way to control tunnel polluted gas stream of small spacing tunnel and to improve the efficiency of ventilating system.

The tunnel portal also by restricting the tunnel lighting, landscape and other factors, the scheme also needs to integrate various factors. It need achieve the unity of function and landscape.

**Keywords:** foundation pit excavation; tunnel displacement; numerical simulation; protection range

**Abstract.** Taking a foundation pit in Nanjing as the background, a numerical model was established to simulate the dynamic process of foundation excavation by 2D finite element software. The influences of different factors on the displacement of the lateral shield tunnel during the foundation pit excavation are studied. The research indicates: when a foundation pit excavation is needed on the side of a shield tunnel, we should select the area in which the tunnel is buried deeper, control both the excavation volume and the distance between tunnel and pit, and try to avoid the excavation depth close to the buried depth of the tunnel. On the basis of numerical calculation, the protection range of the shield tunnels is determined according to different excavation depth of the foundation pits and different buried depth of the tunnels.

## Introduction

Among the 48 Chinese cities with over 1 million inhabitants, more than 30 cities have carried out preparatory work for rail transit. By 2015, it is predicted that 79 rail transit lines will be built in 22 cities, with a total length of 2259.84km.

With the open of the subway, the areas along the line usually become the gold land for commercial development and residential buildings, which leads to a growing number of foundation pits near the existing subway tunnels. In recent years, the scale of the foundation pits near tunnels has a trend of "deep, big and near"[1]. While the underground space today is getting much tighter, the protection of the surrounding environment has gradually become the dominant controlling factor when referring to the design and construction of foundation pits. The influence of the foundation pit construction on surrounding environment should be controlled within an allowable range. The key point of the foundation pit design is gradually shifted to deformation control[2]. As for subway tunnels, the requirements of Shanghai Metro are as follows: under normal circumstances, the maximum of the structure cannot exceed 20mm; the radius of curvature of the line curve after deformation must be larger than 15000m; the relative bending must be smaller than 1/2500. Under such strict conditions, the influence of the foundation pit excavation on nearby tunnels has become an important issue which attracts a great deal of attention in engineering.

Some research on the calculation of foundation pit has been carried out. Yu Chen[3] and Zhiguo Zhang[4] deducted the calculation method of longitudinal deformation of the tunnel caused by foundation pit excavation by analytical method. By taking time-space effect into consideration, Zhigao Li[5] conduced a practical calculation method of tunnel displacement and deformation. Jiaping Li[6] and Lijuan Zhang[7] analyzed the tunnel deformation caused by foundation pit construction, respectively, with the help of numerical simulation. And they both proposed effective technical measures after analysis. Overall, analytical method cannot take the complexity of the construction border into consideration, while the study is only about the tunnel's longitudinal deformation, instead of cross section deformation. What's more, the deformation of only one or two items can be estimated by the empirical or semi-empirical formulation in which not much factors is contained. The numerical method can comprehensively consider the interaction of soil, surrounding structures and excavation.

However, the soil parameters cannot be selected accurately because it's affected by many factors, which is also the important and difficult part of numerical simulation.

This paper is based on the background of a foundation pit in Nanjing. A numerical model is established to simulate the dynamic process of foundation excavation by 2D finite element software. The influences of different factors on the displacement of the lateral shield tunnel during the foundation pit excavation are studied. On the basis of numerical calculation, the protection range of the shield tunnels is determined in order to provide some reference for similar constructions.

## Analysis about the influence of the foundation pit excavation on shield tunnel

The process of foundation pit excavation is the process of foundation pit unloading. The unloading volume gradually increases during the excavation process. Foundation pit unloading may cause the upward bulge at the bottom of the pit, the lateral deformation of the envelope and the deformation of the soil layer, which leads to the ground settlement and the deformation of the nearby subway tunnel as well[8].

The stress state changes both inside and outside the foundation pit during the excavation. The original earth pressure at rest may turn into active or passive earth pressure, which makes envelope to withstand loads and then deformation occurs. So the displacement field may change and pass to the adjacent tunnels. And as a result, deformation of the tunnel will be developed. As for shield tunnels, partial displacement of the tunnel may cause the tunnel axis deviation, which leads to such problems as the open of the longitudinal joints, the leakage of the longitudinal seams and the cracks in the segments, thus affecting the security of the tunnel structures. The deformation problems of the tunnels caused by deep foundation pit excavation are particularly severe in soft soil areas.

In recent years, there's a growing trend in both size and depth of foundation pit. Engineering practice has shown that the area and the amount of the ground settlement caused by deep large foundation pit are much larger than those of the past narrow pit because of the bigger unloading volume, long construction time and complicated construction condition. Also, the influences on the adjacent subway structures and other municipal facilities are much more sophisticated.

## Establishment of the model

A numerical model is established by 2D Plaxis based on a foundation pit in Nanjing. In order to study the influence laws of the foundation pit on the displacement of the lateral shield tunnel, following factors should be contained in the simulation process: the buried depth h of shield tunnel, the excavation width l, the excavation depth H and the horizontal distance d between tunnel and foundation pit.

In practical engineering, the effect of building foundation pit excavation on existing shield tunnel is a complicated three-dimensional problem. In this engineering, taking the fact into consideration that not only the direction of the length of the pit is consistent with the direction of the tunnel line, but also the length is relatively longer, the problem can be simplified as a plane problem. The cross section which is perpendicular to the tunnel axis is selected. The schematic diagram of the simplified calculation model is shown in Fig.1.

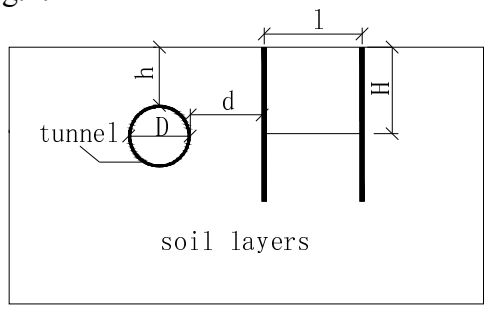

Fig.1 Schematic diagram of simplified calculation model

The width of the model varies with the excavation width and the distance between the tunnel and pit. A distance of two times the excavation width is left on the side of the structures. The depth of the model is 80m. The soil elements obey the elastic-plastic yield criterion of Hardening-soil. The tunnel's segments and the diaphragm walls are simulated by linear elastic plate elements, while the support in the foundation pit is simulated by bolt elements. The insertion ratio of the diaphragm is set as 1:1. The interactions between the segments and the walls with the soil are simulated by setting Goodman contact surface elements on the surfaces of the segments and walls, along with appropriate virtual thickness factor and strength reduction factor. Fully fixed constraints are applied at the bottom of the model. Vertical sliding constraints are applied on both sides. The top of the model is set as a free boundary. The calculation model is shown in Fig.2.

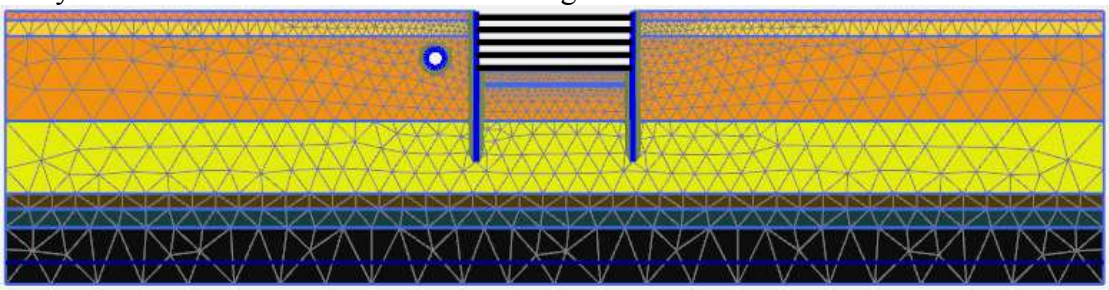

Fig.2 Plaxis model

**Selection of the Parameters**

According to the practical engineering, the outer diameter of the tunnel is 6m, the thickness of the segments is 0.35m. The young's modulus of the concrete used in the segments is 34.5GPa and its density is 2500kg/m$^3$. The segments are viewed as an elastic homogeneous ring, while the parameters of the segments are altered according to the actual situation. The envelope used in the foundation pits of different depth varies, so the equivalent thickness of the diaphragm wall in the model is set different accordingly.

The soil parameters refer to the geological survey report of this engineering, which is shown in Table 1.

Table 1 Soil properties

| Soil layer | $\gamma$[kN/m$^3$] | $c$[kPa] | $\Phi$[°] | $E_s$ [MPa] |
|---|---|---|---|---|
| ① | 18.0 | 16 | 8 | 6.10 |
| ②-2 | 17.9 | 25 | 12 | 3.50 |
| ②-3 | 17.3 | 18 | 9 | 2.95 |
| ③-1 | 18.6 | 5 | 33 | 11.60 |
| ③-2 | 20.7 | 2 | 40 | 16 |
| ④ | 20.0 | 20 | 36 | 15 |
| ⑤-1 | 21.0 | —— | —— | 45 |

**Analysis of the calculation result**

The key point of finite element calculation is to study the law by which the factors affects the displacement when the foundation pit excavation take place near the existing tunnel. In the calculation, the standard values of the factors are set by the following way: the buried depth of shield tunnel h=2D, the excavation width l=50m, the excavation depth H=18m and the horizontal distance between tunnel and foundation pit d=10m. The control variable method is used to find how different factors influenced the displacement of the shield tunnel, which means when one of the factors is under study, the others should be considered as invariable. How these factors influence the tunnel displacement is shown in Fig.3~Fig.6 (the horizontal displacement towards the pit is set as positive value; the vertical displacement upward is set as positive value).

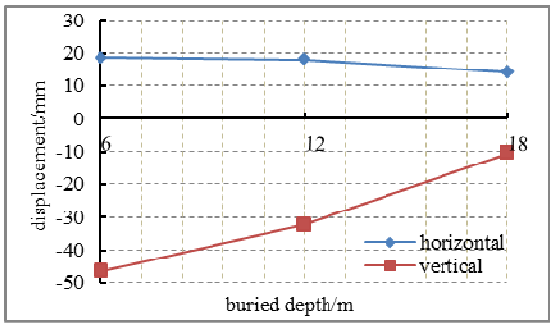

Fig.3 Displacement variation along with buried depth h

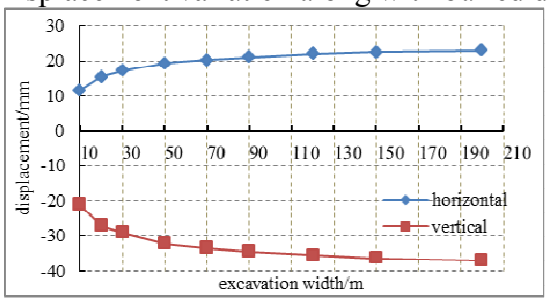

Fig.4 Displacement variation along with excavation width l

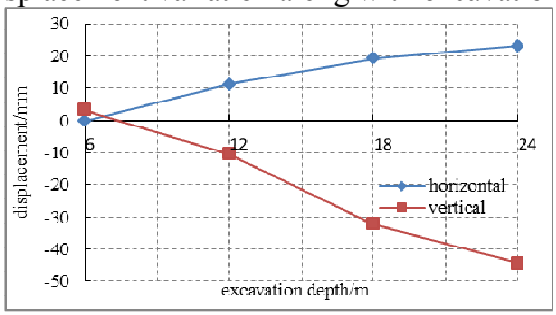

Fig.5 Displacement variation along with excavation depth H

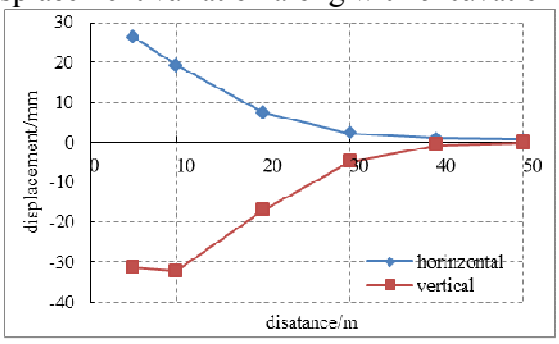

Fig.6 Displacement variation along with the distance between tunnel and pit d

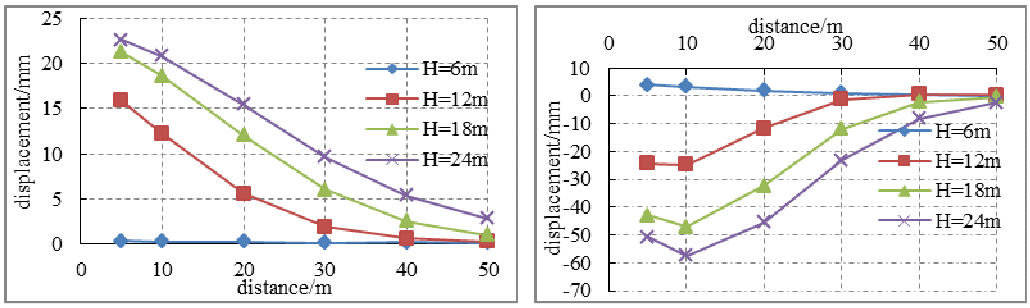
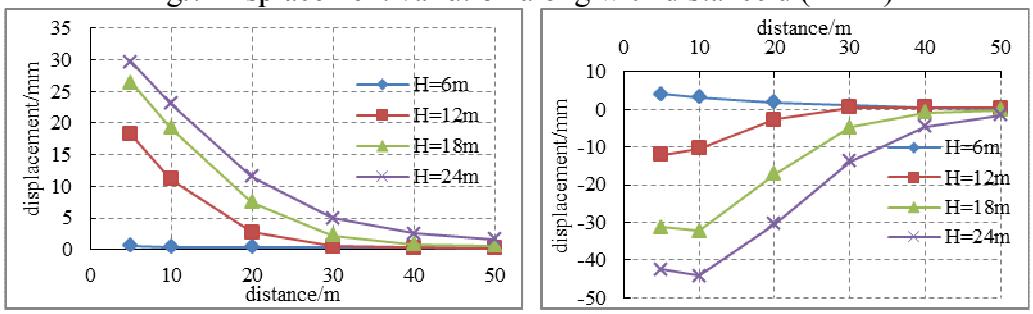
The horizontal and vertical displacement of the tunnel both decrease as the buried depth increases. The tunnel displacement increases with the increasing excavation width. When the excavation reaches 50m, the rate of increase gets smaller and presents a convergence trend. Similarly, the tunnel displacement increases with the increasing excavation depth and the rate of increase has a trend of convergence. As the horizontal distance between the foundation pit and the tunnel gets larger, both the horizontal and the vertical displacement gradually approach 0. But unlike the horizontal displacement which decreases monotonously, the vertical displacement first increases and then decreases. That is because when the tunnel and the foundation pit are too close, the existence of the tunnel hindered the downward development of soil displacement to some extent. The maximum tunnel displacement occurs when the horizontal distance is 10m.

In addition, when the excavation width l is 50m, how the horizontal and vertical displacement of the tunnel varies with the distance between the tunnel and foundation pit d under the circumstance of different buried depth h and excavation depths H is shown in Fig.7~Fig.9.



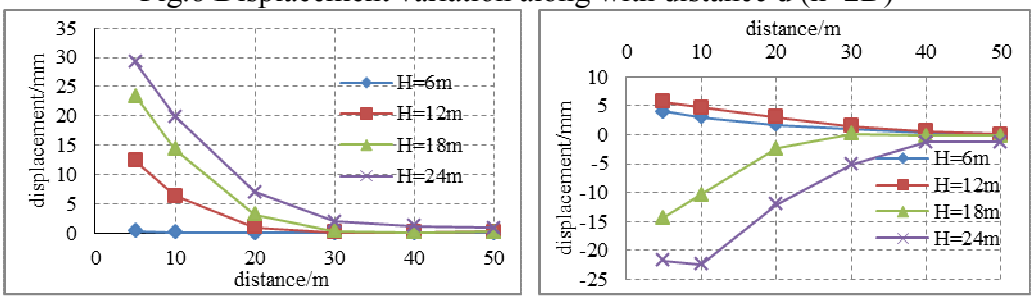
(a) horizontal displacement (b) vertical displacement

Fig.7 Displacement variation along with distance d (h=1D)



(a) horizontal displacement (b) vertical displacement

Fig.8 Displacement variation along with distance d (h=2D)



(a) horizontal displacement (b) vertical displacement

Fig.9 Displacement variation along with distance d (h=3D)

When the settlement of the tunnel occurs, the amount of the horizontal displacement is usually about 36%~59% of that of the vertical displacement. It's worth noting that when the buried depth of the tunnel is close to the excavation depth, the horizontal displacement may be larger than the vertical displacement. As an example, when the excavation depth is 12m and the buried depth is 2D(12m), the amount of the horizontal displacement is 107% of that of the vertical displacement; when the excavation depth is 18m and the buried depth is 3D(18m), the amount of the horizontal displacement is 138% of that of the vertical displacement. The reason for this phenomenon is that where the maximum horizontal displacement of the diaphragm wall takes place happens to meet the buried depth of the tunnel, which makes the horizontal displacement relatively larger.

Specially, when the excavation depth is 6m, the vertical displacement of the tunnel comes in the form as bulge, but by a small amount. When the excavation depth is 12m and the buried depth is 3D, the tunnel may bulge as well.

**Protection range of tunnel**

As we can learn from the calculation result by finite element methods in previous chapter, when the excavation volume is very large, the tunnel displacement cannot meet the requirements of Shanghai Metro. So the control and protection of the foundation pit excavation is necessary on both sides of the tunnel within a certain range. Based on the calculation above, to control the tunnel displacement less than 20mm, the minimum distance between the tunnel and the foundation pit——the protection range of tunnel——is determined according to different excavation depth and buried depth, as is shown in Table 2.

Table 2 Protection range of tunnel

| Excavation depth / Buried depth | 6m | 12m | 18m | 24m |
|---|---|---|---|---|
| 1D | **5m** | **20m** | **30m** | **40m** |
| 2D | **5m** | **5m** | **20m** | **30m** |
| 3D | **5m** | **5m** | **10m** | **20m** |

## Conclusions

The close excavation on the side of the existing tunnel may cause the displacement of the lateral tunnel. Taking a foundation pit in Nanjing as a background, this paper discussed the influence of several factors on the tunnel displacement. The following conclusions can be drawn:

1. As the buried depth increases, both the horizontal and the vertical displacement decrease gradually. Selecting the area in which the tunnel is buried deeper helps to reduce the impact of the excavation on tunnel.

2. The tunnel displacement increases with the excavation width and depth, which represent the excavation volume. When conducting a foundation pit excavation, the excavation volume should be controlled. Dividing the foundation into several areas is a proper way when it comes to a pit of large size, while the specific dividing method remains to be further studied.

3. As the horizontal distance between the foundation pit and the tunnel gets larger, both the horizontal and the vertical displacement gradually approach 0. The horizontal displacement decreases monotonously, while the vertical displacement first increases and then decreases.

4. When the buried depth of the tunnel is close to the excavation depth, where the maximum horizontal displacement of the diaphragm wall takes place happens to meet the buried depth of the tunnel, which makes the horizontal displacement relatively larger. Such circumstance should be avoided as much as possible in engineering.

5. On the basis of numerical calculation, the protection range of the shield tunnels is determined according to different excavation depth of the foundation pits and different buried depth of the tunnels. The excavation within the protection range should be strictly controlled.

**Keywords:** Tunnel deformation analysis, LS-SVM; Markov chain, displacement prediction.

**Abstract.** In order to effectively predict aspects of tunnel deformation, taking effective and timely measures against the problem to ensure the safety of tunnel ,LS-SVM-MC model is proposed . Namely, Markov chain based on LS-SVM corrects the error, and ultimately improves the accuracy of prediction. By the analysis and calculation of deformation prediction of a tunnel , you can find that the method is more in line with the actual situation, showing predictive superiority and a high prediction accuracy.so the method can serve as a new ways of tunnel deformation prediction,some promotional value can be gained in later work.

## Introduction

In tunnel safety monitoring, analysis and processing of tunnel deformation monitoring data is very significant.. Least squares support vector machine (LS - SVM) is an extension of a standard support vector machine, which is different from the conventional method using equality constraints, LS-SVM can convert the SVM quadratic programming problem into solving linear equations ,not only makes a significant reduction in the workload, but also improves the computing speed. Markov chain has nothing to do with the past state, has certain advantages in forecast of the displacement series affected by many factors . In order to make tunnel deformation monitoring work more accurate, text combine these two predictive methods, namely the LS-SVM - Markov chain model is introduced into the tunnel deformation forecast, the results show that the model prediction accuracy is high, can be extended . in engineering practice.

## LS-SVM-MC Model Construction

### The theory of LS-SVM model

while adhering to the principle of structural minimization, in high-dimensional space, dot product operation is replaced by kernel function of the former space, as a result, the calculation can be simplified. LS-SVM[1-2] is a nonlinear, black-box regression method, which is a modified vision of standard SVM regression. The LS-SVM training procedure involves the selection of a kernel parameter, which should be chosen carefully because it defines the structure of the high dimensional feature space, and thus controls the complexity of the solution.

Given the data set $(X_i, Y_i)$ ,i= 1,2,...,1, consider the regression model:

$$y_i = F(x_i) = w^T \varphi(x_i) + b \tag{1}$$

$$\min_{w,b,\varepsilon} J(w,b,\varepsilon) = \frac{1}{2} w^T w + \gamma \frac{1}{2} \sum_{i=1}^{l} \varepsilon_i^2 \tag{2}$$

$$y_i = F(x_i) = w^T \varphi(x_i) + b + \varepsilon_i \tag{3}$$

where $\varepsilon$ is slack variable of error, $b$ is constant deviation and $\gamma$ is referred as the regularization constant. In order to solve this constrained optimization problem, the Lagrangian corresponding to Eq. (2) can be constructed

$$L(w,b,\varepsilon,a) = J(w,e) - \sum_{i=1}^{l} a_i [w^T \varphi(x_i) + b + \varepsilon_i - y_i] \tag{4}$$

Any function satisfying Mercer's condition can be used as the kernel function. And there are three typical kernel functions, they are, Linear Kernel, Polynomial Kernel and Radial Basis Function (RBF) Kernel.

The LS-SVM model can be obtained at a new point $x_i$ by:

$$y(x) = \sum_{i=1}^{l} \alpha_i K(x, x_i) + b \tag{10}$$

.

In addition, Corresponding changes are made through specific issues, in order to derive the best predictive models.

**Markov correction model**

MC is released by Markov in the early 20th century, because of it has strong applicability is actively promoting in various fields [4-6].such as geotechnical, transportation, construction. Namely, the error of between the observed value and the predicted value is divided into several intervals, and each interval is named. For $S_m \quad (m = 1,2,3.....l)$, the state probability of relative error state $S_m$ transfered into state $S_n$ from time step k is

$$P_{mn}^{(k)} = \frac{C_{mn}^{(k)}}{C_m} \qquad (m,n = 1,2,3.....) \tag{11}$$

Where, $C_{mn}^{(k)}$ represents the number that $C_m$ transfers to $C_n$, $C_n$ represents the number of states for the relative error in a number of intervals. But in the calculation of the number of $C_n$. Because they do not know what the future state of development. The last k states need to be eliminated.

The probability of each state will be in statistics, in which the probability is maximum, then the predicted value is in the corresponding state. This paper argues that the midpoint of the range is the most likely relative error of the predicted value. the following formula can be predictive value: of the most probable timing displacement .

$$U(x) = (1+\overline{\Delta})u(x) = \left[1+\frac{(\Delta_U + \Delta_D)}{2}\right]\times u(x) \tag{13}$$

Where(12), $U(x)$ is the final prediction value obtained by the MC model, $u(x)$ is the initial predicted value obtained by LS-SVM. $\Delta_U$, $\Delta_D$ is the upper and lower limits. $\overline{\Delta}$ is The average relative error..

**Project**

To test the LS-SVM-Markov model in tunnel displacement prediction results, a tunnel literature displacement time series of observations of this paper gives are verified. Due to be affected by various factors, the tunnel has a certain displacement,According to accordingly its deformation prediction, LS-SVM --- Markov model makes predictions of a vertical displacement of the measuring point ,and compare with prediction results of the sole LS-SVM. Firslyt, the state transition probability matrix is listed:

$$P(1) = \begin{bmatrix} 0.67 & 0.33 & 0 & 0 \\ 0.01 & 0.84 & 0.15 & 0 \\ 0.02 & 0.18 & 0.74 & 0.06 \\ 0 & 0 & 0.43 & 0.57 \end{bmatrix} \qquad P(2) = \begin{bmatrix} 0.50 & 0.33 & 0.17 & 0 \\ 0.01 & 0.74 & 0.24 & 0.01 \\ 0.04 & 0.3 & 0.58 & 0.08 \\ 0 & 0.14 & 0.57 & 0.29 \end{bmatrix}$$

$$P(3) = \begin{bmatrix} 0.33 & 0.50 & 0.17 & 0 \\ 0 & 0.66 & 0.31 & 0.03 \\ 0.08 & 0.35 & 0.49 & 0.08 \\ 0 & 0.29 & 0.57 & 0.14 \end{bmatrix} \qquad P(4) = \begin{bmatrix} 0.17 & 0.50 & 0.33 & 0 \\ 0 & 0.61 & 0.33 & 0.06 \\ 0.09 & 0.38 & 0.47 & 0.06 \\ 0 & 0.57 & 0.43 & 0 \end{bmatrix}$$

Taking the predicted displacement of 2011/3/, shown in fig. 1. For example, extract the four date values of LS-SVM [3]which is closed to it in order to predict vertical displacement by Markov.

The results is shown in the following table 1.

Table1. COMPARING THE PREDICTION OF LS-SVM AND LS-SVM-MARKOV MODEL

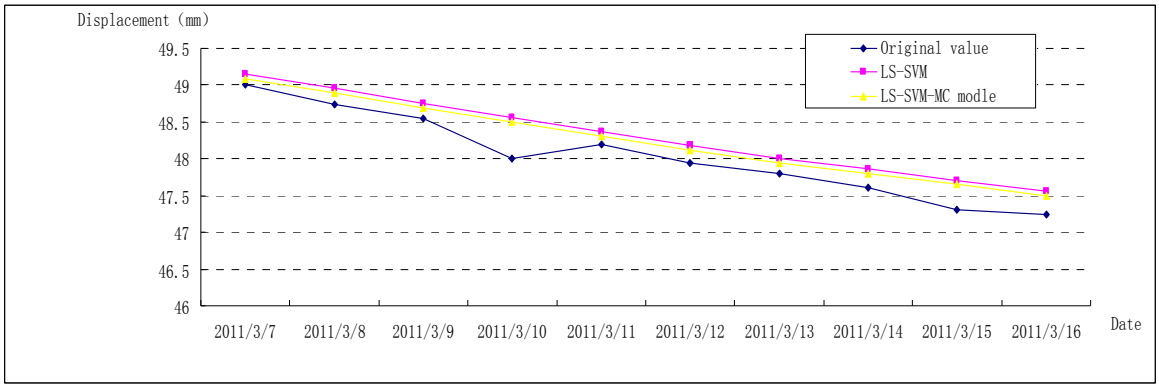

Fig.1 Fitting Curves of LS-SVM and LS-SVM—Markov

## Conclusion

On the basis of tunnel displacement prediction of the LS-SVM, this paper proposes a new method, namely LS-SVM-MC model. Markov chains can furtherly correct data which LS-SVM treated, thereby improving the accuracy and effectiveness. Through this project example, you can know, LS-SVM-Markov model is closer to the actual value than a single LS-SVM model, the tunnel displacement prediction has promotional value.

**Keywords:** room-and-pillar mining; structural parameter optimization; stope stability; numerical simulation

**Abstract.** A mine plans to exploit the low dip thin phosphate deposit by room-and-pillar mining. But a township highway is just above the orebody, and its distance is only 80m, in order to better control the ground pressure in stopes and ensure the operation security, the size of room and pillar must be reasonably designed to maintain the stability of stopes and surrounding rock. The 3D-σ numerical simulation method was applied to analyze the surrounding rock stability in different stope structure parameters. The results show that when holding the size of pointed prop unchanged, the surrounding rock stability would decline with the increase of room width and pillar spacing, for security, the mining plan, the pointed prop is 3×3 m, the stope width and pillar spacing is not more than 9 m, were considered to be one of the optimal. In addition, it is important to emphasize that if the mining depth exceeds 300m, some methods, such as decreasing the spacing of stope and pointed props or increasing the pillar size, need to be taken to avoid the stope instability caused by greater ground pressure.

## Introduction

For underground mine which applied open-stope method, the stope stability is directly related to the safety of the production and ore recovery rate [2-3]. Therefore, to reasonable confirm the stope's structure parameters on span of the room, the pillar size etc, has a very important theoretical and guiding significance to maintain the stability of the overlying rock and ensure the safe, efficient and sustainable production of mining enterprises. Based on the background for underground mining of phosphate rock in Yunnan province, on the basis of rock mechanics parameters, taking the finite element numerical method for simulating analyzing the stability of different stope mining methods is to reach the aim of through the optimization of stope structure parameters to ensure that the purpose of mine safety production and provide theoretical basis for the mine production.

## Engineering situation

The Deng ganshu phosphate ore is monoclinic structure, orebody thickness is 3~4m, dip angle is between 20° and 40 °, ore body part exposed on the surface, and the tendency to extend along nearly 400 meters deep. Formation lithology is relatively single, roof and floor of ore bodies are in thick bedded dolostone, and the difference of rock engineering geological characteristics is not big. The rock has hard dense, high mechanical strength, and good stability. Mining area terrain elevation has not big difference, there are not major surface water bodies; the surface of roadway is relatively dry, water has not the big impact on mining. As the ore body and surface topography is anti-dip occurrence and does not have the open-pit mining conditions, therefore, the room and pillar mining method is determined to use for underground mining of phosphate body. In addition, there is also a village road through the upper part of the phosphate rock body. In order to guarantee the normal production of the mine and highway operation safety, it is necessary to optimize the stope structure parameters when mining the phosphate rock body.

**Establishment of the model**

According to the occurrence conditions of Jinsha phosphate rock and the select principle of drawing boundaries [4-8], combining with the theory of mechanics, a three-dimensional finite element model is built. The Model along the ore body strike direction is 400 m (x direction), cross ore body strike direction is 500 m (z direction), and the vertical direction is 420m (y direction). It is divided more than 299250 nodes and 70,006 20-node three-dimensional isoparametric element units. Using the horizontal displacement constraint the Model, then the bottom is fixed boundary constraints, and the Mohr - Coulomb plastic failure criteria is adopted. The research section of the ore body buried shallow, according to the relevant experience , in-situ stress changes in the shallow levels is relatively complex and horizontal stress is small, so this calculation use $\lambda=\mu/(1-\mu)=0.43$ as the basic calculation scheme. Figure 1 is the resulting grid computing model.

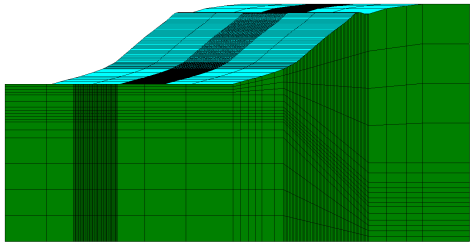

Fig. 1 The result of grid computing model

**Value of rock mass mechanics parameters**

Rock mass is complex organism which is made up of rock and structural plane. Due to the differences of nature and stress conditions, rock breaking can be divided into brittle failure and the plastic failure, its strength characteristics is influenced and controlled by the intensity of the rock and structural plane, rock mass structure factors and so on. Based on this, getting accurate mechanical parameters of rock mass is not realistic, but the follow-up calculation still need to make the accurate solution of the analysis and rock mass mechanics parameters in line with the actual as far as possible. On the basis of the rock mass structure statistical analysis, indoor rock mechanics test, and combining with Hoek Brown - experience formula, it is able to determine rock mass mechanics parameters. Due to the limitation of space, the concrete solving process can refer to reference [9]. Table1 is physical mechanics parameter values of rock mass by reduced and inversed.

Table 1 Physico-mechanical parameters of rock mass

| Rock type | density/g·cm$^{-3}$ | Elastic modulus/GPa | Poiss-on ratio | Tensile strength/MPa | Cohesion /MPa | Internal friction angle/° |
|---|---|---|---|---|---|---|
| orebody | 2.81 | 35.35 | 0.338 | 1.34 | 1.87 | 37.42 |
| direct roof | 2.72 | 27.51 | 0.251 | 0.93 | 1.46 | 38.47 |
| direct floor | 2.72 | 27.51 | 0.251 | 0.93 | 1.46 | 38.47 |
| Indirect roof | 2.74 | 45.22 | 0.305 | 1.74 | 2.25 | 41.35 |
| Indirect floor | 2.74 | 45.22 | 0.305 | 1.34 | 1.87 | 37.42 |

**Determination of analysis methods**

For the mine exploitation used room and pillar methods, the content of the stope structure parameter optimization is rich, if we consider the overall amount of computation together, the calculation is very large and not easy to realize, therefore, the computational study is divided into the following two steps:

The first step: According to the orebody occurrence conditions, on the premise of preliminary determine the point column size, the different room span size affect on the stope stability is analyzed;

The second step: Based on the results of research in the first step, exploring the stability of the roof, pillars, roof and bottom pillar point at different points column spacing, and finally achieving the goal of stope structure parameters optimization.

**Analysis of stope stability of different room span**

Because the ore body of Deng ganshu ore block is thinner, and when the point column is 3 x 3m, the ratio of height to width is close to 1:1, which can fully meet the requirements. Therefore, in the process of simulation, the point column is determined primarily to adopt 3 x 3 m. On this basis, using the following four schemes simulates and analyses mining stope stability of different room spans:

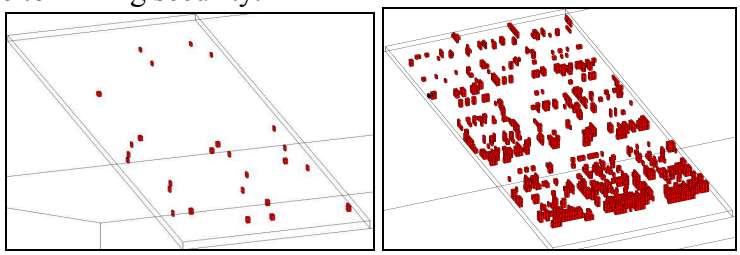
Option one: Point column is 3 × 3m, stope span is 6m; Option two: Point column is 3 × 3m, stope span is 9m;

Option three: Point column is 3 × 3m, stope span is 12m; Option four: Point column is 3 × 3m, stope span is 15m.

The calculation results are analyzed from the aspects of stress distribution, safety factor and plastic zone. Due to the limitation of space, the results are only presented in part. Figure 2, Figure 3, are respectively orebody ceiling and point column plastic layout of part schemes after excavation, Figure 4 is the change curve of safety coefficient of different orebody's roof and point column.

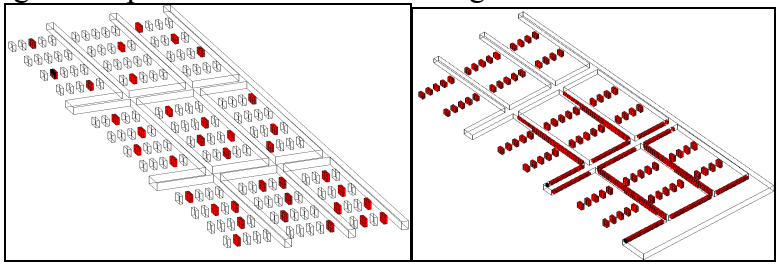
(1)In the aspect of stress distribution, orebody roof in scheme 1 and 2 did not appear tensile stress, but the value in scheme 3 and 4 had reached 1.581 MPa, is greater than the tensile strength of rock mass itself, which can cause large area roof caving. Therefore, the room span should not be too big in the mining process, which should be controlled about 9 m. The point spacing also should not be too big, otherwise, the point column pressure is too big to favor the stope stability.

(2)In plastic zone distribution, when the room span is 12 or 15 m (scheme 3 and 4), the direct roof after orebody mining almost completely access into plastic state (fig.2a), the minimum safety coefficient is less than 1, only 0.984 and 0.963. When the room span is reduced to 9m (scheme 2), the plastic area of direct roof is decreasing obviously (fig.2b). The plastic zone near the excavation body exists in the independent form, and there is no contiguous phenomenon, although the partial failure of direct roof is possible, it won't appear the total collapse, the minimum safety factor of roof increases to 1.173. From scheme 1 to 4, the variation of plastic zone and safety coefficient from point column, pillar, roof and bottom pillar are as same as that of roof (fig.3). Therefore, to control the room span about 9 m is favorable to mining security.



(a) scheme 2 (b) scheme 4

Fig. 2 The plastic zoo distribution range of the roof of different room span



(a) scheme 2 (b) scheme 4

Fig. 3 The plastic zone distribution range of point pillar, roof and bottom pillar of different room span

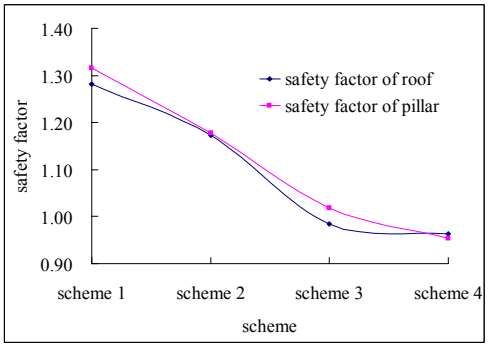


Fig. 4 The safety factor curve of roof and pillar of different schemes

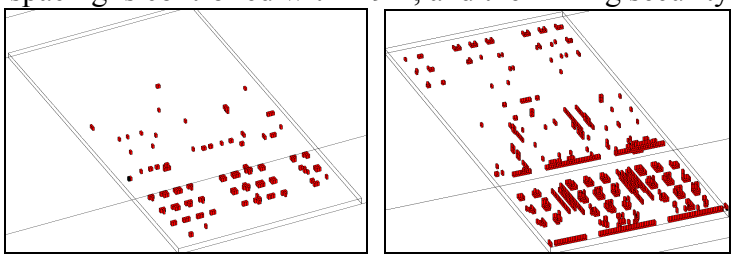
**Stability analysis of different pillar column spaces**

According to the previous calculation results, for Deng ganshu ore block, the ore room span should be controlled about 9 m is reasonable if the point column is reserved 3x3 m. On this basis, using simulation analysis of the following four pillar spacing tries to find out the reasonable numerical value to guide production.

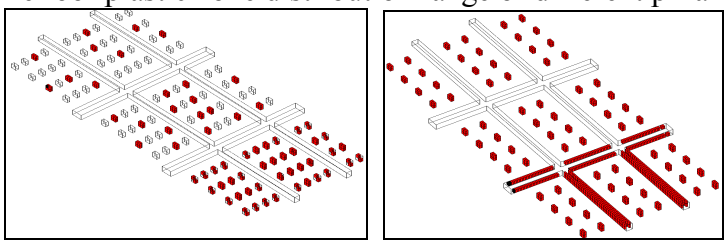
Scheme 5: point column is 3 x 3m, ore room span is 9m, point spacing is 6 m;
Scheme 6: point column is 3 x 3m, ore room span is 9m, point spacing is 9 m;
Scheme 7: point column is 3 x 3m, ore room span is 9m, point spacing is 12 m;
Scheme 8: point column is 3 x 3m, ore room span is 9m, point spacing is 15 m;

From the calculation results of four schemes, three schemes except scheme 5 appeared roof tensile stress. when the pillar spacing exceeds 9 m, the roof tensile stress exceeds the strength of rock mass itself, the stope lacking of stability. In safety factor of the roof, pillar, roof and bottom pillar, the minimum value in scheme 5 and 6 is respectively 1.149 and 1.144, other solutions are less than 1. As well, the distribution of plastic zone is smaller in scheme 5 and 6, better stability (Fig. 5a, Fig. 6a). So, the best point column spacing is controlled within 9m, and the mining security can be guaranteed.



(a)Scheme 5 (b) Scheme 8

Fig. 5 The roof plastic zone distribution range of different pillar spacing



(a) Scheme 5 (b) Scheme 8

Fig. 6 The plastic zone distribution range of point pillar, roof and bottom pillar of different pillar spacing

**The final suggestion and optimization of stope structure parameters**

Due to the limitation of computing grid unit, the simulation only analyzed three sections along the tendency of the orebody, a total of nine stopes' stability, not considered change rule of continuing deep mining of the ore bodies. But through the investigation of the calculation results, it can be found, the mining is deeper, the pressure of the roof, pillar spacing and the roof and bottom pillar is greater;

the plastic zone is wider, the safety factor is smaller. It also shows that the stability of the stope field and the overlying rock is worse. Therefore, if the buried depth of ore body is bigger, stope structure parameters should be adjusted. According to the engineering practice, we recommend:

(1)If the mining depth is less than 200 m, mining can be in accordance with the point column 3 x3 m, ore room span 9 m, pillar column spacing 9 m;

(2)when the mining depth exceeds 200 m, in the premise of maintaining the point column 3x3 m, room span and point column spacing should be decreased (e.g. 6 m), or increase the point column (e.g. 5x5 m), which can continue to ensure mine safety production.

## Conclusions

The result analysis of the 3D-σ numerical simulation technology is shown below:

(1) For shallow mining, if mining point column size is within 3x3m, controlling the room span and point spacing about 9m is more reasonable.

(2)As mining is deeper, the stope structure parameters should adjust, or pillar size still maintain 3x3m, but the room span and the point column spacing is reduced to 6 m, or increase point pillar size, only in this way can we guarantee the stability of the overlying rock mass.

(3)The mining is a dynamic process, blasting damage will reduce continually the mechanical strength of rock mass, therefore, the subsequent production should be based on the actual condition of stope stability, repeated analyses and verifications, in order to achieve the purpose of safe and efficient mining.

**Keywords:** shield tunnel; long-wave irregularity; settlement trough; numerical simulation; control standards

**Abstract.** This paper takes a new shield tunnel as the research object, which intends to cross a section of a high speed railway. Based on design specifications and the existing monitoring data to analyze the change rule of track irregularities, this article proposes the control of wavelength and relevant amplitude in the above case, following the design specifications and long-wave irregularity management demands of high-speed highway. And the controlling values of wavelength and amplitude required are presented with the outcome of the range of the settlement trough, drawn out of the under-crossing process. And it also uses large-scale non-linear finite element analysis software to simulate the high speed railway track deformation in actual constructions, to test whether the deformation meet the requirements of the control standards and deformation law. The results can provide reference for the construction measure when shield tunnel under crosses the high speed railway in the future.

## Introduction

With the rapid progress of China's urbanization, it has the urgent needs to the rapid development of urban transport. In the development of a new round of transportation, the railway will undoubtedly become one of the spotlight。Among these, The safe, fast, efficient, low-carbon quality make the high-speed railway become the object of focus on the development of China's transportation construction.

Meanwhile, the great development of high-speed railway has gradually bring some engineering problems. Domestic and foreign scholars have done a lot of research to explore such issues.[1].Some scholars do research by choosing stratum reinforcement proposal in different geological conditions.Depend on the different geological conditions,Xu [2] made a research to choose the ground reinforcement program.Zhu[3] calculate the surface subsidence by two-dimensional finite element method.

The focus and problems of the research at home and abroad include the following aspects: 1):Most of the study at present is the general railroad, Since the standard of the high-speed railway considerably stricter than the general railroad,we need to be discussed in depth study of the high-speed rail.2): Control indicator is the core of the control standards, the control indicators of the high-speed rail can not meet the needs of the actual operation largely. 3): Most of the current study of the tunnel under-crossing the railway are mostly concentrated in the choice of reinforcement, then prove its feasibility by calculating. But this method can not quantify the value of the specific construction control and has little effect to guide the construction in different backgrounds.

Based on the need to solve the above problems, in this paper, considering the settlement after construction and the settlement after the operations of the high-speed railway. Emphasis on the effects of long-wave irregularity to the high-speed rail, proposed the waveform control indicator to improve the indicator system of tunnel under-crossing high speed railway. Hope to provide a reference to construction of the tunnel under-crossing high speed railway in the future.

## Project overview

The paper do the research about the section of the subway under-crossing high speed railway, the right section of the subway under-crossing the railway with oblique 61 °. The length of Intersection is 33 m. the left section of the subway under-crossing the railway with oblique 64 °. The length of Intersection is 32 m.。

The field area strata including 2.2m of miscellaneous fill soil; The plain fill layer is 0.63m ; The sand and gravel formations is 5.86m; The clayey silt is 2.23m; The following layer is pebble layer. The subway is mainly under-across the gravel layer formation.

## Track irregularity management control indicators of high-speed railway

The high-speed railway roadbed, bridges, rail and other design and construction standards are much higher than the general railroad, The fundamental reason is due to the high-speed railway track must ensure the smoothness of the track lasting stability. Because the train track irregularity increased mainly by vibration, wheel and rail movement. When the smoothness of the track in high stage, The dynamic force in vibration and movement of trains between wheel and rail is relatively small.Traffic safety, stability and comfort can be guaranteed. On the contrary,even when track, roadbed and bridge structure are fully meet the requirements of strength, and the smoothness of the track is poor,vehicle vibration and wheel-rail forces caused by track irregularity will significantly increase under the conditions of high-speed trains is running. It make the smoothness,comfortable and security of the train seriouly deterioration, there may even lead to the train derailment. Therefore, the countries which has developed technology of high-speed railway,for example, Japan and Germany have been established the relatively perfect high-speed rail irregularity management standards that adapt their national conditions. Table 1 is the Japanese Shinkansen irregularity management's value.

With the development of China's high-speed railway undertakings is growing fast, China is also focus on the harm of train track irregularity. At present, the high-speed rail irregularity management standards of China mainly do reference to foreign standards,at the same time, there are many scholars achieved research results in the field of Irregularity Management that adapt our country. Table 2 is a the vertical smoothness of longwave amplitudes management control indicators in different speeds.

Table 1: Japanese Shinkansen management objectives index value

## Irregularity status and analysis

**An existing field trials.** According to the geological conditions of the parameters involved in this article, set the measured data of a high-speed railway foundation testing work sites as an example. [4] Analysis of its regularity.

The test points are in DK1472+052.3 ～ +167.3section. Select32 sections for text,such as DK1623+051,DK1623+57, DK1623+512 and so on. Set the settlement monitoring instrument under the subgrade surface in all types of monitoring section. And planted settlement monitoring instrument in all section of center and the left and right sides of embankment.

**The analysis of irregularity data.** With the train operating speed increased, people focus the attention of high-speed railway irregularity. The researchers found that not only the shortwave irregularity controlled by 10m chord will cause the train shake, Long-wave irregularity also makes the strong resonance of train. This is the "1Hz problem"occurred in Japan and France. Long-wave irregularity caused by tunnel under-crossing high speed railway is the key of this article. Set the magnitude of the irregularity as the function of the mileage. Graphed to facilitate the analysis of its irregularity wavelength, use the irregularity wavelength to contrast with the irregularity management standards.

Use the mileage-irregularity amplitude value chart to represent the subsidence of test cross section in different test section. The chart can use to analysis the irregularity wavelength and amplitude of track,and prepare for propose the control chart of settler waveform. Use the monitoring data of [4] to established coordinate chart by mileage - irregularity amplitude value.The results are Fig 1.

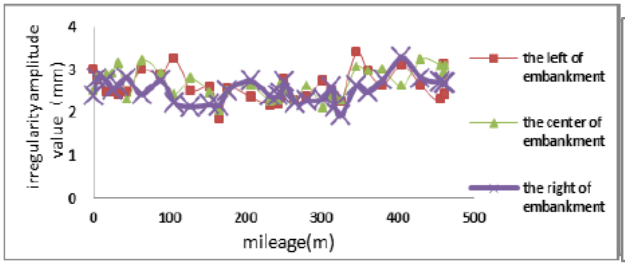

Fig 1: The maximum settlement test by settlement observation pile

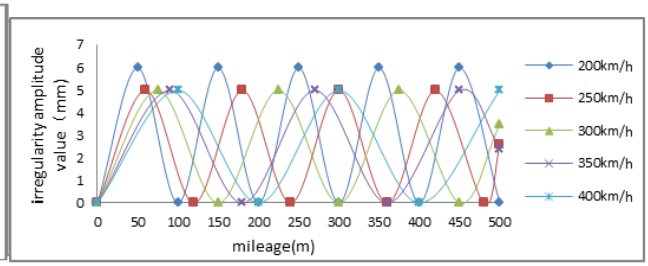

Fig 2: Net operating under standard conditions of comfort settlement irregularity amplitude (comfort standards)

According to Ⅱ class in Table 2,the comfort standard, reserved 5mm as the settlement in the period of train operation by the regulatory requirements. Draw the maximum amplitude chart under the conditions of 200km/h ~ 400km/h controled wavelength.(Fig2)

The sum of the track settlement after constration and the settlement caused by under-crossing high speed railway should less than control standards of high speed railway track amplitude. According to this idea, long wave irregularity control index value caused by tunnel under-crossing high speed railway is the difference value between long wave irregularity control index value of high speed railway with the actual longwave irregularity value of track settlement after constration.

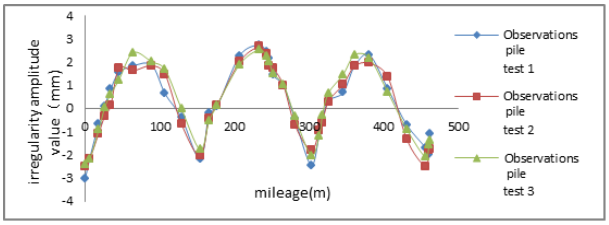

Fig3: Comfortable waveform control standards of under-crossing high speed railway (300km / h)

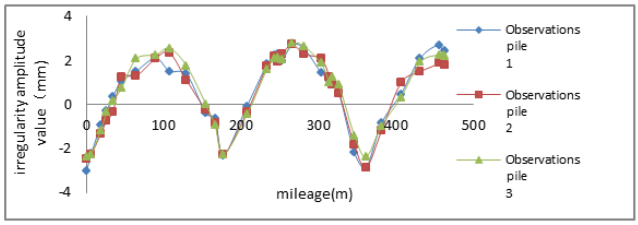

Fig 4: Comfortable waveform control standards of under-crossing high speed railway (350km/h)

And concern about the high speed railway, focus the two situation of 300km/h and 350km/h. The irregularity amplitude of the two speed that deduct the settlement during operation time in Fig 2 subtract the maximum settlement of the observation test pile in figure 1, then obtained the 300km/h

irregularity waveforms in Fig 3. And obtained the 350km/h irregularity waveforms in Fig 4 by the same way.

According to the safety standards of III level in Table 2, and set 5mm settlement for the settlement during train operations. drawing maximum amplitude diagram under the wavelength control conditions by 200km/h ~ 400km/h. (Fig 5).

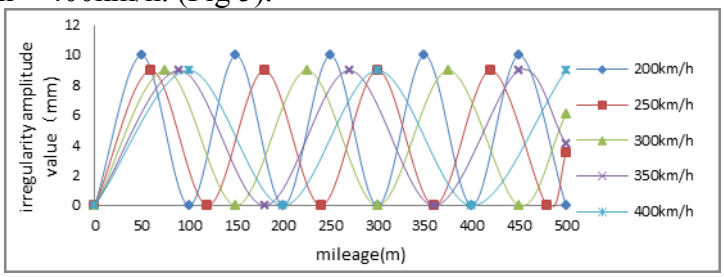

Figure 5: 200 km/h ~ 400km/h, net operating under standard conditions of safety settlement irregularity amplitude(safety standard)

The irregularity amplitude of the two speed that deduct the settlement during operation time in Fig 5 subtract the maximum settlement of the observation test pile in Fig 2,then obtained the 300km/h irregularity waveforms in Fig 6. And obtained the 350km/h irregularity waveforms in Fig 7 by the same way.

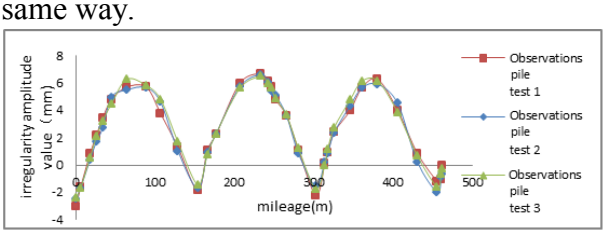

Fig6:Safety waveform control standards of under-crossing high speed railway(300km/h)

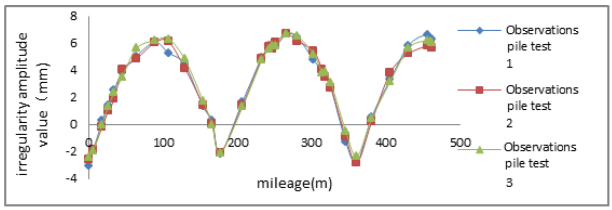

Fig7:Safety waveform control standards of under-crossing high speed railway(350km/h)

Through the analysis above, the minimum cosine waveform can be the control standard for sedimentation trough by tunnel under-crossing high speed railway. Invert the cosine waveform, then the control waveform of sedimentation trough has been created. The control waveform of sedimentation trough is the key indicators by tunnel under-crossing high speed railway.

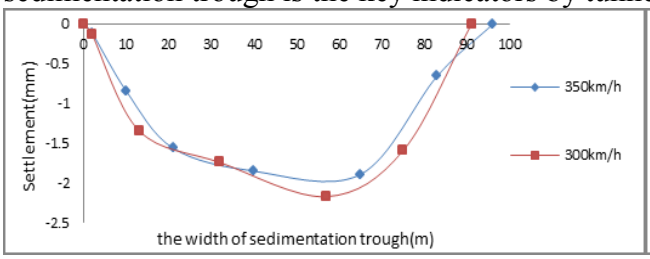

Fig 8:The control waveform of sedimentation tank(comfort standards)

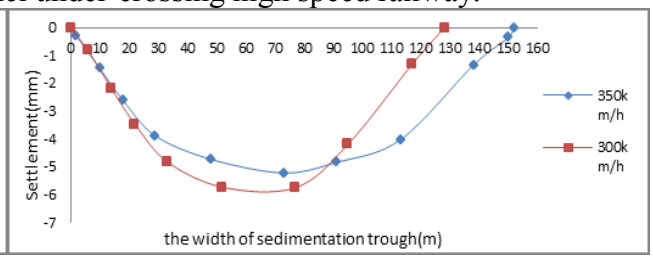

Fig 9:The control waveform of sedimentation trough (safety standard)

According to the comfort standard (Fig 3-4), the control waveform of sedimentation trough by tunnel under-crossing high speed railway gived in Fig 8; According to the safety standard (Fig 6-7), the control waveform of sedimentation trough by tunnel under-crossing high speed railway gived in Fig 9. The waveform control chart of sedimentation trough can define the range of sedimentation trough by tunnel under-crossing high speed railway. Use the width of the settlement trough limited the irregularity management of longwave values. The maximum settlement value of sedimentation trough limited the magnitude of longwave irregularity management. In other words, if you want to meet the comfort requirements of the high-speed railway during operation, the sedimentation trough graph caused by tunnel under-crossing high speed railway must inside the waveform control diagram of sedimentation in fig8.If you want to ensure the safety requirements of high-speed railway,then the sedimentation trough graph caused by tunnel under-crossing high speed railway must inside the waveform control diagram of sedimentation in fig 9.

Long-wave irregularity of the track means that the uneven settlement will cause the vehicle resonance at a specific wavelength . So the sedimentation tank formed by the tunnel under-crossing high-speed railway should be less than or greater than this wavelength range. And because this particular wavelength is longer, in order to make it easy to control, so choose the control targets of settlement trough width less than this particular wavelength. According to this idea, the next Fig 8 to 9 summarized the control waveform of tunnel under-crossing high-speed railway according to the comfort and safety indicators respectively. It has been shown in Table 3.

Table 3:The control indicators of sedimentation trough by tunnel under-crossing high-speed railway

| Category \ v | 300（km/h） | 350（km/h） |
|---|---|---|
| Comfort index | maximum settlement 2.17mm | maximum settlement 2.01mm |
| | The maximum width of the sedimentation tank 91m | The maximum width of the sedimentation tank 96m |
| Safety index | maximum settlement 5.94mm | maximum settlement 5.21mm |
| | The maximum width of the sedimentation tank 126m | The maximum width of the sedimentation tank 149m |

**Numerical simulation of tunnel under-crossing high-speed railway**

Numerical simulation using finite element analysis software, the overall model is shown below in Figure 10. In order to reduce the influence of boundary effects, the model along the tunnel axis (Z direction) taking 78m, vertical (Y direction) taking 36m, a horizontal plane perpendicular to the tunnel direction (X direction) to take 108m. Since the tunnel Oblique under-crossing the high-speed railway, in order to facilitate the calculation of excavation, take the tunnel perpendicular to XOZ plane, and the tunnel has 32.5 degrees to XOZ plane. The track length is 110m. Model boundary conditions are displacement boundary conditions, where the soil and the bottom around the vertical restraint on the free surface of the soil constraints embankment also used two vertical constraints.

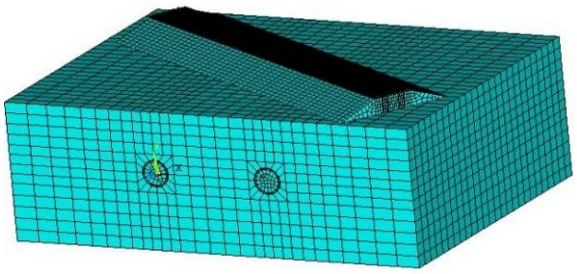

Fig 10: Overall model figure

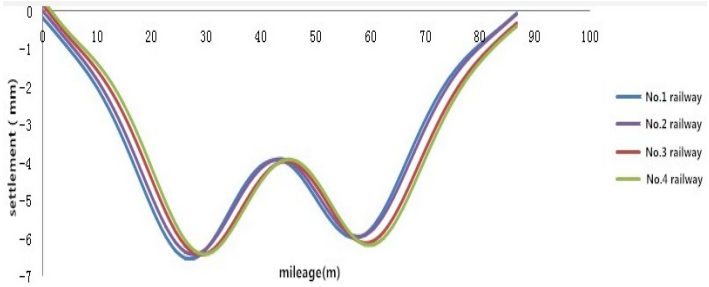

Fig11: 1 to 4 Track sedimentation trough

**The parameters of each material in Numerical simulation.** According to the geological survey report, simplified the soil into layers.The parameter has been shown in Table 4-5.

Table 4:The basic physical and mechanical properties of the foundation soil

| Soil | $\gamma(N/m^3)$ | CohesionC($Pa$) | friction $\varphi$ (°) | Poisson's ratiom | Modulus E(kpa) | Thickness (m) |
|---|---|---|---|---|---|---|
| plain fill soil | $1.85\times10^4$ | $1.5\times10^4$ | 10 | 0.3 | $1.5\times10^7$ | 2 |
| silt soil | $1.90\times10^4$ | $2.2\times10^4$ | 10.2 | 0.3 | $2.5\times10^7$ | 22 |
| pebble | $2\times10^4$ | $1.02\times10^4$ | 18.7 | 0.3 | $6.0\times10^7$ | 12 |
| embankment soil | $1.95\times10^4$ | $6\times10^4$ | 7.4 | 0.3 | $3.0\times10^7$ | 4 |

**Calculation process and the analysis of the results.** Soil, lining, concrete slabs, are using solid elements, use the contact elements between the concrete slab and the embankment soil , the miscellaneous and embankment soil.

Table 5 The parameters of tunnel lining, rails and concrete slab structure

| Name | g(N/m3) | E(kpa) | m | inside diameter (m) | outside diameter(m) | thickness (m) |
|---|---|---|---|---|---|---|
| tunnel lining | $2.5\times10^4$ | $2.76\times\times10^{10}$ | 0.2 | 3 | 3.3 | 0.3 |
| rail | $7.83\times10^4$ | $2.1\times10^{11}$ | 0.3 | — | — | — |
| concrete slab | $2.5\times10^4$ | $2.76\times\times10^{10}$ | 0.2 | — | — | 0.5 |

Tunnel excavation, the disturbed ground has already been completed in this consolidation settlement, the settlement will be cleared during the simulation strata and orbit. The left side of the tunnel has been excavated first, and then the right side of the tunnel . Make a two-dimensional figure of the sedimentation trough accroading to the mileage and settlement results. And the mileage as the X-axis, Y-axis as a settlement. sedimentation trough were drawn 1-4. As shown in Fig 11.

Fig 11 shows that the largest settlement on the 1st rail tunnel under the left side of the under-crossing is caused at the 3rd largest settlement of the track 6.33mm,cause the 4th largest settlement was 6.32 mm.The right side of the rail caused by tunnel under-crossing is 5.88mm; the 2nd largest settlement of the track 5.91mm; the 3rd largest settlement of the track 6.12mm; the 4th largest settlement of 6.15mm.

because of the left side of the tunnel should excavate first,and the sedimentation trough caused by right side of the tunnel excavation will superimpose the sedimentation trough caused by the left side of the tunnel.It will cause top of the left side tunnel greater settlement. The settlement in the left side of the tunnel is 0.2 ~ 0.3mm larger than the settlement in the right side. Formed the largest settlement in the upper left position of the track on the 1st tunnel.

We can judged by the 11 figure that irregularity wavelength caused by lane tunnel is about 86m, therefore, the sedimentation trough caused wavelength must satisfy the control value of long-wave irregularity at 300km / h, 350km / h speed conditions. The lane tunnel caused maximum subsidence is 6.36mm. Basically satisfy the control standards of 300km / h herein,and a little larger than the control standards of 350km / h .

## Conclusions

1.Reference to the National norms long-wave uneven amplitude. Proposed the comfort and safety indicators of tunnel long-wave irregularity and its corresponding limited amplitude under-crossing high-speed railway. Proposed the limited value of respectively.

2. Use the finite element simulations the tunnel under-crossing the railway. The results show that the safty requirements achieved both of the irregularity wavelength control value and amplitude control values.but the comfort requirements is only achieved the irregularity wavelength control value,and the amplitude of the control targets is not achieved . This shows that we need to strictly control the level of construction technology in the construction process. Focusing on the use of support measures to ensure the comfort requirements of high-speed passenger.

**Keywords:** operation tunnel; tunnel portal; defects; mechanics analysis.

**Abstract.** Through the site investigation of defects on a secondary highway tunnel portal in Guizhou Province and survey data, this paper aims to analyze the detection mechanism of all defects. Controlled by bias effect of tunnel portals, the defects of portal lining cracking and leakage are pretty serious. A fully understanding of these mechanisms can help to improve and fine design and construction of tunnel portal, reducing the production of defect.

## Introduction

Surveys [1~3] indicate that dehiscence, deformation, peeling, water leakage and other defects in a substantial proportion of the lining. It will affect traffic, the safety of tunnel and shorter the time of intervals service life. As the complicated natural environment and other factors around the portals, result in the evaluation of the health status of the tunnel a world-class problem. According to the present experience, the defects treatment lack of exact system and scientific research on tunnel defect theories, methods and procedures. This will inevitably lead to unreasonable and wrong defect management programs and measures. Thus, it is necessary to conduct a comprehensive research on defects of tunnel portals. Through site investigation, detection data, this paper will take a tunnel in Guizhou Province as an example to evaluate the health of the portals, and make some suggestions about design, construction and maintenance of the tunnel portal of this kind.

## Project overview and main defects of the tunnel

**Project overview**. A secondary roads tunnel is 656m long. It has two lanes whose width and height are namely 9 and 6.5 meters. The entrance is between K45+862~K45+872, exit is K46+505~K46+518.Tunnel portals are designed with wing wall forms while the hole body support in the form of curved wall. This tunnel construction started in 1991 and opened to traffic in late 1992. Tunnel has simple geological structure, no fault, and rocks clear hierarchy. Near in tunnel entrance, vertical rock weathering is 20m deep, with the weathered rock crushing, unstable joint development. Destruction of rock structures directly lead to a large tunnel structure defects, and even endanger the safe operation of the tunnel. Tunnel have opened to traffic since 1992, there has been a large area of seepage water and some structural cracks and other defects. On export segment structure the problems like settlement deformation, damage cracking appeared in 2003.

**Site survey.** In order to grasp the current situation of the tunnel, ensure the reasonability of management and maintenance of the tunnel defects, we need to carry out a detailed survey on tunnel. Finally, we can make a comprehensive evaluation of the security situation about tunnel. In terms of these factors, following are investigation and analysis on tunnel,(1) The site detailed survey of cracks and water leakage and other defects;(2) Measure the tunnel contour by tunnel laser

profiler;(3) Measure the lining thickness, defects and intensity of lining through high-frequency radar, ultrasonic.Based on site surveys tunnel disease, the main defects are as follows: cracks (As shown in Fig.1), water leakage, the surface of the lining of disease, deform. As shown in Table 1. Defect of the tunnel entrance sketching are shown in Fig.2.

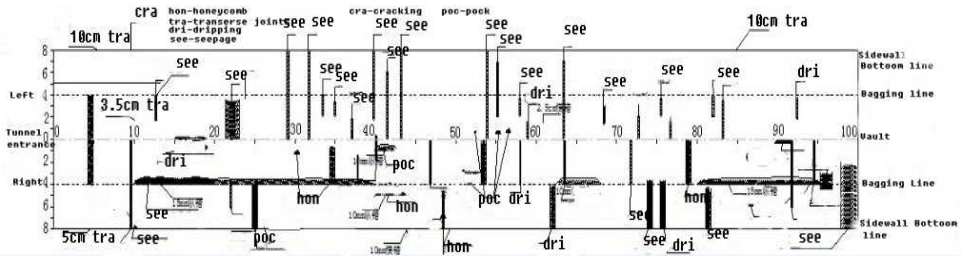

Fig. 1 Cracks on tunnel portal Fig.2 Lining defects sketch

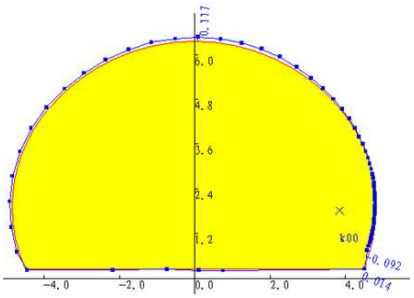
Table1 Statistics tunnel disease site survey

| Types Of Defects | Lining Disease（quantity） | | | Deform | | | | Leakage of water （quantity） | Crack （quantity） |
|---|---|---|---|---|---|---|---|---|---|
| | Honeycomb | Pock | Peel off | Dislocation | | Concave | Convex | | |
| | | | | Transverse | Longitudinal | | | | |
| left | 0 | 0 | 0 | 6 | 8 | 0 | 5 | 119 | 54 |
| right | 49 | 51 | 84 | 56 | 58 | 15 | 35 | 197 | 83 |
| Total | 49 | 51 | 84 | 62 | 64 | 15 | 40 | 316 | 137 |

**Detect of tunnel portal.** Combined tunnel survey data, the completion of the design documents and a comprehensive analysis to detect cross-section of the tunnel contour, The lining section outlines the characteristics of temple tunnel entrance can be inferred in the cross section K45+862 shown in Fig.3 and the reasons are as follows: (1) Section K45+862~K46+072: The overall outline of lining is over break. That is to say, the actual measurement segment is larger than design section on the cross-sectional contour, and has no significant local deformation. (2)Section K46+452~K46+518: lining hasn't significant deformation. But the lining segments are serious due to cracks, because the mold has been built concrete to reinforce lining, the actual measurement segment does not reflect the state before reinforcement.



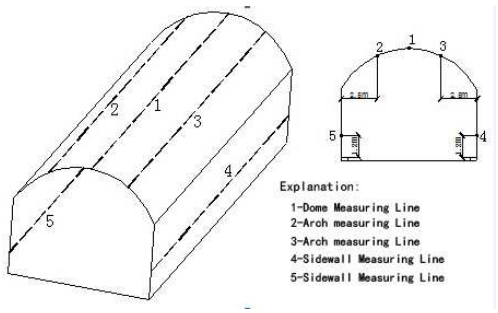


Fig.3 Tunnel transect contour - K45+862 section Fig.4 Schematic geological radar line lay out

**Geological radar detects.** Five survey lines were arranged longitudinally along the tunnel, one arranged on vault; two on arch waist, other two on side walls. Particular arrangements are shown in Fig.4. According to detecting the lining quality on the import and export by geological radar, rebar spacing comply with regulatory requirements completely, and early and secondary lining concrete lining are relatively dense. Due to space limitations, this paper did not attached to specific test data.

**Strength tests of concrete lining.** According rock category lining forms and disease characteristics, strength testing of each section, respectively, use the rebound method, ultrasonic and rebound combined method in strength. Combining with the results of geological radar, strength testing of concrete lining is carried out on the basis of water leakage and crack investigative work in

the tunnel. Taking into account the actual characteristics of the tunnel project, strength testing work to the tunnel treats cross-section as the research object, especially in key positions of export segment, it should be encrypted to ensure the reliability and precision of research.

Rebound method is a basic method of nondestructive testing, which is based on direct hammer rebound values to obtain the concrete surface compressive strength of concrete.

Ultrasound combined rebound method use low-frequency ultrasound measurement instrument and a standard kinetic energy 2.207J 's Hammer to test same area of structure or component through rebound speed of sound and in situ testing. By using of national unity strength curve which has been built up, it can calculate concrete compressive strength of the survey area.

In order to compare the results of measuring strength of different detection methods, the test results of rebound method, ultrasonic and combined rebound method are summarized in Table 2.

Table 2 Strength test results

| Sectional position | Lining concrete strength（M Pa） | | | | |
|---|---|---|---|---|---|
| | Rebound Method | | Ultrasonic combined method | | Comprehensive estimated value |
| | Left wall | Right wall | Left wall | Right wall | |
| K45+862(K000) | 34.2 | 23.9 | 35.4 | 30.4 | 23.9 |

**Causes of defects**

**Influenced by bias effect.** There are 205 defects in the section K45+862~K45+962, in a density of 2.05 per meter. From the number of defects, we can draw that the defects on right side of the tunnel are more severe than that on left. According to the analysis of the geological data, the main reasons are: (1) rock tilted from right to left, causing the right side of the tunnel withstand greater pressure than the left and formed the bias effect; (2) rock groundwater vulnerability in the lining behind the right side of collection, (3) underground tunnel in which the lining has some erosion [4].

**Leakage water.** Surface water is mainly main ditch water from Dashibao Dam, and its exposure position is higher than the entrance; tunnel's exit section go through a length of 100m coal-strata which has been mined largely. Inside the cave, it's filled, semi- filling or unfilled, which could easily lead to the accumulation of groundwater; Lots tunnel entrance near vertical rock weathering a depth of 20m, with the weathered rock crushing, which formed a tunnel seepage water channel; Outlet sections of the tunnel more than 100 meters occurred within the scope of collapse several times; construction unit when the original footage from the outlet end to more than 40 meters, the tunnel arch was larger leaks, the cave was saturated with water after a long plastic state, the body is completely collapse loss of self-supporting capability. These adverse conditions provide the conditions for the production of leakage water; however, the gaps between the lining, improper water-proof measures of arch and side walls on the same lining, cause of leakage water [5].

**Lining cracks of entrance-portal.** There are ring-cracks of the entrance-portal lining. It is in the haunch section which formed an angle of 45° with the plumb line, in a length of about one meter. Both the side has cracks, presenting a symmetrical shape. There are also cracks in the vault. Meanwhile, there is a radial crack on the left, developed tracking the building blocks until the top of the portal. And there are small cracks in the peak of the arch. Portal on the right side there are cracks in development. According tunnel portal near the surface cracks and circumstances, there is a gallery portal segment slipped body, resulting in bias. The side slope in the entrance-portal is stable. Due to the bias effect, there are cracks on the portal and other defects in gallery portal segment.

**Lining cracks of exit-portal.** There are wide cracks in the exit-portal, as is shown in Fig 5, and it also shows that the tunnel has no obvious bias. Exit-portal has an about 13 meters gallery portal. Since gallery portal of lining segments has many cracks, reflecting that the lining has been

damaged. Based on the above analysis, because the upper covering of the gallery portal and the adjacent surrounding rock are poor, therefore, pressure acting on the lining is huge. Moreover, the lining material's strength and thickness is smaller than the original design, making the peak of the arch sink too much, thus, the lining is cracked. The mechanism is shown in Fig 6, the destruction of gallery portal segment and adjacent surrounding rock has grown to the surface.

Fig.5 Cracks on the exit -portal

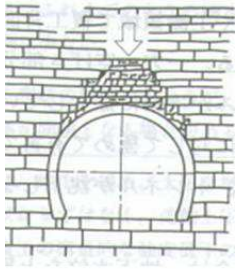

Fig.6 Mountain Temple tunnel portal collapse mechanism

**Conclusions of tunnel health evaluation and Suggestion**

**Cracks and water leakage.** (1) From the point of defects severity, the entrance-portal is more serious than the exit- portal and the right side of tunnel is more severe than the left side;(2) From the point of defects distribution, the defects are mainly in K45+862~K45+962, K46+062~K46+162, K46+362~K46+462, K46+462~K46+518.

**Fracture surface contour of the tunnel and surface deformation.** The actual fracture surface contour of section: K45+862 ~ K46+072 of the tunnel is larger than its design, the outer of lining is in a whole external expansion.

**Tunnel portal and side slope.** (1) Side slopes of the tunnel's entrance and exit are steady;(2) There are cracks in the entrance-portal and gallery portal; grouting slippage massif above the gallery portal: K45+862~K45+872 of the entrance-portal, and behind the lining;(3) Exit-portal has been severely damaged; the lining of its gallery portal has been damaged, cracks have developed to the earth's surface. Grouting and reinforcing the gallery portal:K46+505 ~K46+518 of exit-portal, setting a thick of 20cm concrete arch cover, injecting Epoxy slurry to the cracks.

**Keywords:** risk trend assessment; underground pipeline; set-pair analysis (SPA); partial connection number

**Abstract.** A model of risk trend assessment for metro tunnel crossing underground pipelines is proposed in this paper based on the partial connection number. This paper fully considered the certainty and uncertainty of the index and used "partial connection number method" to analyze the risk developing trend and its sort of metro tunnel crossing underground pipelines. A case study was performed on a metro tunnel engineering of Shenzhen Line 9. The results showed that this model considered the dynamic characteristics of risk, enriching the contents of risk assessment of underground engineering, which can provide a reference for the risk management.

## Introduction

There are a variety of underground pipelines in urban cities, such as gas pipe, water mains, thermal pipeline, cable conduit communication, etc. These guarantee the normal life of the urban residents. Metro lines usually emplace along city arterial road, thus, metro tunnel construction will inevitably pass through a variety of urban underground pipelines. The available risk assessment methods which focus on risk state assessment lack of analysis for risk dynamic trends [1, 2]. Based on the partial connection number of set-pair analysis (SPA), this paper proposes a risk trend analysis method of the metro crossing underground pipeline to comprehensively analyze the development trends of risk, which provides a new way to evaluate the impact of urban metro tunnel on underground pipeline.

## Risk Trend Assessment Model

Set pair analysis is a theoretical method based on identical discrepancy contrary (IDC) analysis proposed by Chinese scholar Keqin Zhao, which made to study theory uncertainty problem. It takes connection number to reflect the uncertainty and uncertainty of systems, and their mutual conversion rule [3]. Connection number is represented by $U$:

$$U = a + bi + cj \tag{1}$$

The letters $a$, $b$ and $c$ are identical degree, discrepancy degree and contrary degree under the studied question of two sets, and $a+b+c=1$. $i$ is discrepancy coefficient, $i \in [-1, 1]$; $j$ is contrary coefficient, $j=-1$. Five-element connection number is an extension of three-unit connection number, expands from $bi$ to get the mathematical expression of five-element connection number:

$$U = a + bi_1 + ci_2 + di_3 + ej \tag{2}$$

**Connection Degree.** After form a set pair with each index and its risk level, calculate the connection number between them. Taking the fuzzy division of risk level standard into account, the formula of fuzzy connection degree is formed. The connection degree between the smaller-better indexes and its risk level standard is:

$$\mu_l = \begin{cases} 1+0i_1+0i_2+\cdots+0i_{K-2}+0j & x_l \le s_1 \\ \dfrac{s_2-x_l}{s_2-s_1}+\dfrac{x_l-s_2}{s_2-s_1}i_1+0i_2+\cdots+0i_{K-2}+0j & s_1 < x_l \le s_2 \\ 0+\dfrac{s_3-x_l}{s_3-s_2}i_1+\dfrac{x_l-s_2}{s_3-s_2}i_2+\cdots+0i_{K-2}+0j & s_2 \le x_l \le s_3 \\ \vdots & \\ 0+0i_1+0i_2+\cdots+\dfrac{s_K-x_l}{s_K-s_{K-1}}i_{K-2}+\dfrac{x_l-s_{K-1}}{s_K-s_{K-1}}j & s_{K-1} < x_l \le s_K \\ 0+0i_1+0i_2+\cdots+0i_{K-2}+1j & x_l > s_K \end{cases} \tag{3}$$

The connection degree between the greater-better indicators and its risk level standard is:

$$\mu_l = \begin{cases} 1+0i_1+0i_2+\cdots+0i_{K-2}+0j & x_l \ge s_1 \\ \dfrac{x_l-s_2}{s_1-s_2}+\dfrac{s_1-x_l}{s_1-s_2}i_1+0i_2+\cdots+0i_{K-2}+0j & s_2 \le x_l < s_1 \\ 0+\dfrac{x_l-s_3}{s_2-s_3}i_1+\dfrac{s_2-x_l}{s_2-s_3}i_2+\cdots+0i_{K-2}+0j & s_3 \le x_l < s_2 \\ \vdots & \\ 0+0i_1+0i_2+\cdots+\dfrac{x_l-s_K}{s_{K-1}-s_K}i_{K-2}+\dfrac{s_{K-1}-x_l}{s_{K-1}-s_K}j & s_K \le x_l < s_{K-1} \\ 0+0i_1+0i_2+\cdots+0i_{K-2}+1j & x_l < s_K \end{cases} \tag{4}$$

**Risk level**. If considering indexes weight, the comprehensive connection degree between index and its risk level can be expressed as:

$$u = \sum_{m=1}^{n}\omega_m a_m + \sum_{m=1}^{n}\omega_m b_{m,1} i_1 + \cdots \sum_{m=1}^{n}\omega_m b_{m,K-2} i_{K-2} + \sum_{m=1}^{n}\omega_m c_m j \,. \tag{5}$$

Wherein $\omega_m$ is the weight of index $m$ ($m$ = 1,2,…$n$).

Evaluate the risk level of factors through confidence.

$$h_k = (f_1 + f_2 + \cdots + f_k) > \lambda \,, \quad k = 1,2,\cdots K \tag{6}$$

Wherein: $f_1 = \sum_{m=1}^{m}\omega_m u_{m1}$ ; $f_2 = \sum_{m=1}^{m}\omega_m u_{m2}$ ; $f_3 = \sum_{m=1}^{m}\omega_m u_{m3}$ ; $f_4 = \sum_{m=1}^{m}\omega_m u_{m4}$ ;… $f_k = \sum_{m=1}^{m}\omega_m u_{mk}$

$\lambda$ is confidence level, when it remains constant, if $h_k > \lambda$ and $h_{k-1} < \lambda$, the risk level is $k$. In general, its value is in a range of [0.50, 0.70].

**Partial connection number.** Partial connection number is an adjoint function reflecting the system's development trends of connection state, which characterizes the strength of risk trends. Partial connection number of five-element connection numbers is defined as follows:

Partial positive connection number:

$$\partial u^+ = \partial a + \partial b i_1 + \partial c i_2 + \partial d i_3 \,. \tag{7}$$

Partial negative connection number:

$$\partial u^- = \partial b^- i_1 + \partial c^- i_2 + \partial d^- i_3 + \partial e^- j \tag{8}$$

Wherein: $\partial a = \dfrac{a}{a+b}, \partial b = \dfrac{b}{b+c}, \partial c = \dfrac{c}{c+d}, \partial d = \dfrac{d}{d+e}; \partial b^- = \dfrac{b}{a+b}, \partial c^- = \dfrac{c}{b+c}, \partial d^- = \dfrac{d}{c+d}, \partial e^- = \dfrac{e}{d+e}$

Partial positive connection number reflects the degree of positive risk trends; Partial negative connection number reflects the degree of risk negative trends. The actual development trend of risk is the synthetic action of positive and negative trends. Therefore, the definition of total partial

connection number is $\partial^{+}_{-}u = \partial u^{+} - \partial u^{-}$. If $\partial^{+}_{-}u > 0$, which means a potential decreasing trend of risk; If $\partial^{+}_{-}u < 0$, it means a potential improving trends of risk; If $\partial^{+}_{-}u = 0$, it means a critical state of system, the system trend may be negative or positive.

## Risk Index System of Metro Construction crossing Underground Pipelines

Stratum settlement by metro tunnel excavation may cause joint pipeline deformation. If the deformation is too large, the damage of the pipeline will be caused, The impact between metro tunnel construction and the adjacent underground pipeline is mutual, which is not only associated with pipeline type, damage condition, pipeline materials and joint type, but also about construction methods, construction technology and management, engineering and hydrogeological conditions[4, 5]. Based on available research achievements and influence of various parties, risk indexes of metro tunnel crossing adjacent underground pipeline are shown in Table 1.The risk index is divided into five levels: level 1(secure), level 2(comparatively secure), level 3(general secure), level 4(comparatively dangerous) and level 5(dangerous).

Table 1 Risk indicators and classification of metro tunnel crossing underground pipelines

| | index layer | Level 1 | Level 2 | Level 3 | Level 4 | Level 5 |
|---|---|---|---|---|---|---|
| underground pipeline situation/$u_1$ | pipeline type/$u_{11}$ | heat-supply pipeline | water supply pipeline | waste pipeline | gas pipeline | cable conduit |
| | pipeline materials/$u_{12}$ | flexible pipe(PVC) | steel pipe | reinforced concrete pipe | concrete pipe | cast-iron pipe |
| | pipeline size/$u_{13}$ | 1800(mm) | 1500(mm) | 1000 (mm) | 500 (mm) | 200 (mm) |
| | joint type/$u_{14}$ | flexible pipe(PVC) | Steel pipe | cast-iron pipe | reinforced concrete pipe | concrete pipe |
| | damage condition/$u_{15}$ | intact | basically intact | general intact | damaged | severely damaged |
| | pipeline depth/$u_{16}$ | 1(m) | 2(m) | 3(m) | 4(m) | 5(m) |
| tunnel engineering conditions /$u_2$ | formation conditions/$u_{21}$ | Ⅵ | Ⅴ | Ⅳ | Ⅲ | Ⅱ, Ⅰ |
| | tunnel depth/$u_{22}$ | 30(m) | 25(m) | 20(m) | 15(m) | 10(m) |
| | tunnel cross-sectional dimension/$u_{23}$ | 6(m) | 9(m) | 12(m) | 15(m) | 18(m) |
| | construction environment/$u_{24}$ | excellent | good | general | poor | bad |
| | level of construction techniques and management/$u_{25}$ | richful similar construction experience,powerful technical force,high management level | comparatively richful similar construction experience,comparatively powerful technical force,comparatively high management level | general richful similar construction experience,general powerful technical force,general high management level | scanty similar construction experience,weak technical force,lower level of management | no similar construction experience,shortage of technical force,poor level of management |
| | construction method/$u_{26}$ | shield,reasonable cross-sectional shape and force conditions,no stress concentration | shield,comparatively reasonable cross-sectional shape and force conditions,no stress concentration | mining,comparatively reasonable cross-sectional shape and force conditions | mining, poor cross-sectional shape and force conditions | open excavation, poor force conditions,large stress concentration |
| | construction time effect/$u_{27}$ | losse | comparatively losse | progressive | tight | grab duration |
| pipelines adjacenct to tunnel/$u_{31}$ | | non-adjacent | comparatively adjacent | adjacent | very adjacent | extremely adjacent |
| security measure/$u_{41}$ | | excellent | good | general | poor | bad |

## Application Example

A tunnel engineering under construction of Shenzhen metro Line 9 crosses multiple urban underground pipelines. Four underground pipelines were selected to investigate their type, material, joint type, depth, damage condition, as well as plane location relation with tunnel. The parameters are shown in Table 2.

Table 2 Pipelines risk parameters

| Index | pipelines parameter | | | |
|---|---|---|---|---|
| | A | B | C | D |
| pipeline type | flexible cable conduit | gas steel pipeline | concrete sewer | steel water supply pipe |
| pipeline materials | PVC | steel | concrete | steel |
| pipeline size | diameter 300(mm) | diameter 400(mm) | diameter 1200(mm) | diameter 1000(mm) |
| pipeline depth | 1.86(m) | 1.31(m) | 3.24(m) | 0.99(m) |
| damage condition | basically intact | basically intact | general intact | basically intact |
| joint type | PVC pipe | steel pipe | concrete pipe | steel pipe |
| surrounding rock level | Ⅳ | Ⅳ | Ⅲ | Ⅲ |
| tunnel depth | 14.25(m) | 13.30(m) | 11.56(m) | 12.60(m) |
| tunnel cross-sectional dimension | 6(m) | 6(m) | 6(m) | 6(m) |
| construction method | shield | shield | mining | shield |
| plane location relation between pipeline and tunnel | pipeline and tunnel parallel /horizontal distance 2.3m | Pipeline and tunnel vertical | pipeline and tunnel intersect | pipeline and tunnel intersect |

The quantitative indexes can be directly put into equation (3) and (4) to solve connection degree. But qualitative indexes must be combined with engineering practice to contrast the value of risk index to risk rating criteria. Expert evaluation method was used to measure coincidence degree between them, respectively assign value: level 1(90 points), level 2(80 points), level 3(70 points), level 4(60 points), level 5 (50 points). the risk parameters value of each pipeline was shown in Table 3.

Table 3 Risk parameters value of pipelines

| index | $u_{11}$ | $u_{12}$ | $u_{13}$(mm) | $u_{14}$ | $u_{15}$ | $u_{16}$(m) | $u_{21}$ | $u_{22}$(m) | $u_{23}$(m) | $u_{24}$ | $u_{25}$ | $u_{26}$ | $u_{27}$ | $u_{31}$ | $u_{41}$ |
|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|
| weight | 0.15 | 0.20 | 0.10 | 0.20 | 0.20 | 0.15 | 0.10 | 0.10 | 0.10 | 0.05 | 0.30 | 0.30 | 0.05 | 0.20 | 0.15 |
| A | 50 | 90 | 300 | 90 | 76 | 1.86 | Ⅳ | 14.25 | 6 | 68 | 85 | 83 | 68 | 56 | 83 |
| B | 60 | 80 | 400 | 80 | 84 | 1.31 | Ⅳ | 13.30 | 6 | 76 | 85 | 83 | 68 | 50 | 84 |
| C | 70 | 60 | 1200 | 50 | 68 | 3.24 | Ⅲ | 11.56 | 6 | 65 | 85 | 69 | 68 | 50 | 76 |
| D | 80 | 80 | 1000 | 80 | 75 | 0.99 | Ⅲ | 12.60 | 6 | 66 | 85 | 77 | 68 | 50 | 79 |

Professional system and Analytic Hierarchy Process (AHP) were used to determine relative importance of index and index weight, as shown in Table 3. Comprehensive connection number for each pipelines are:

$u_A$=0.294+0.300$i_1$+0.082$i_2$+0.163$i_3$+0.160$j$;

$u_B$=0.226+0.405$i_1$+0.048$i_2$+0.099$i_3$+0.222$j$;

$u_C$=0.075+0.149$i_1$+0.258$i_2$+0.227$i_3$+0.291$j$;

$u_D$=0.328+0.471$i_1$+0.133$i_2$+0.055$i_3$+0.014$j$;

According to confidence 0.60, the risk level of pipelines A, B, C and D are “general secure”, “comparatively secure”, “comparatively dangerous” and “comparatively secure”. The order of security is D>B>A>C, minimum risk of D, followed by B and A, the highest risk of pipeline is C. Pipeline C needs intensive monitoring and corresponding control measures during construction.

Put five-element connection number of each pipelines into the formula to solve partial positive and negative connection number, and then make them normalized. According to the definition of five-element connection number, i1,i2,i3∈[-1,1], j=-1. Partial connection number method of proportional parts is applied to discrepancy coefficients.

Discrepancy coefficients of first-order partial positive connection number are:

$i_1=\partial a/(\partial a+\partial b)$, $i_2=\partial b/(\partial b+\partial c)$, $i_3=\partial c/(\partial c+\partial d)$

Discrepancy coefficients of first-order partial negative connection number are:

$i_1=\partial c^-/(\partial b^-+\partial c^-)$, $i_2=\partial d^-/(\partial c^-+\partial d^-)$, $i_3=\partial e^-/(\partial d^-+\partial e^-)$

Calculation results and pipeline risk development trend analysis are shown in Table 4. The total partial connection numbers of pipeline A, B and C are less than zero, the risk trend is positive; the total partial connection numbers of pipeline D is greater than 0, the risk trend is negative. Comparing the total partial connection numbers of each pipeline, the risk trend ranking of them can be determined. The result shows that the trend of D is the best, followed by A and C, B is the worst. Based on the level "comparatively secure", the risk of pipeline B has a significant tendency to the level "general secure".

Table 4 The correlation degree and risk level of pipelines

| | partial positive connection number | $i_1$ | $i_2$ | $i_3$ | $\partial u^+$ | partial negative connection number | $i_1$ | $i_2$ | $i_3$ | $\partial^- u$ | $\partial^+ u$ | risk trend | rank |
|---|---|---|---|---|---|---|---|---|---|---|---|---|---|
| A | $0.234+0.371i_1+0.158i_2+0.238i_3$ | 0.260 | 0.472 | 0.268 | 0.468 | $0.269i_1+0.114i_2+0.354i_3+0.263j$ | 0.201 | 0.510 | 0.288 | 0.478 | -0.0095 | positive | 2 |
| B | $0.190+0.474i_1+0.173i_2+0.163i_3$ | 0.187 | 0.478 | 0.336 | 0.416 | $0.304i_1+0.050i_2+0.319i_3+0.327j$ | 0.094 | 0.571 | 0.335 | 0.491 | -0.0755 | positive | 4 |
| C | $0.200+0.219i_1+0.318i_2+0.262i_3$ | 0.333 | 0.284 | 0.382 | 0.464 | $0.286i_1+0.272i_2+0.201i_3+0.241j$ | 0.335 | 0.291 | 0.374 | 0.491 | -0.0271 | positive | 3 |
| D | $0.152+0.289i_1+0.263i_2+0.296i_3$ | 0.257 | 0.391 | 0.351 | 0.433 | $0.452i_1+0.169i_2+0.224i_3+0.155j$ | 0.217 | 0.456 | 0.327 | 0.404 | 0.0297 | negative | 1 |

## Conclusions

Based on existing research, this paper proposed a risk evaluation index system of metro tunnel construction crossing adjacent underground pipeline. The impact of various aspects is taken into consideration during selecting index, which is more realistic, the assessment result is more reasonable. From the perspective of development, the partial connection number was used to analyze risk trends of metro tunnel crossing underground pipeline in this paper based on the static risk assessment, which comply with the requirements of the project dynamic risk management. Introducing partial connection number of set pair analysis into analysis of risk trends riches the risk assessment content of underground engineering risk assessment.

**Keywords:** Risk measurement; Water inrush; Karst tunnel; Fuzzy comprehensive mathematics; Tanjiaba mountain tunnel.

**Abstract.** The Tanjiaba tunnel lies in Hurongxi highway in Hubei Province. There are some middle karstified soluble rocks and a fish pool above the tunnel. To avoid the disaster of water inrush into the tunnel, risk evaluation is necessary to guide the construction. Fuzzy mathematics model is put forward to distinguish potentially dangerous parts along the tunnel. Use the fuzzy mathematics model differentiated the tunnel into 4 ranks of dangerous parts according to risk index. It is applied in the Tanjiaba tunnel and practice approves that the model are useful.

## Introduction

In the industrial revolution of 18th century, Hneri Fyaol introduced risk management thought into enterprise management field. Until 1950s, risk management is developed to a subject in American and risk management is developed rapidly in western countries. In 1970s, risk analysis was introduced into tunnel and underground projects study by Einstein. H. H. Since 1990s, risk of tunnel construction was paid more attention than ever before for more and more amazing tunnel collapse accidents occurred. Risk analysis came to use rapidly in tunneling engineering. The ITA committee was also paid much attention to tunnel risk analysis and published the book "Guidelines for Tunneling Risk Management" as standard and reference for risk analysis and management for tunneling engineering at 2002.

In China, the fuzzy analysis approach has been used in project by YANG Jian-ping at 1998. In recent years, LIU Dan, BAI Ming-zhou, LI Bing, ZOU Chong-feng and etc have been studied water inrush risk. However, theory on water inrush risk and evaluation is not mature yet now. The main controlling factors need to be refined. Application of fuzzy comprehensive evaluation method must help development of risk analysis technique of water inrush into karst tunnel significantly.

## Risk measurement

## Main controlling factors of water inrush into karst tunnel

**Lithology.** According to lithology, karst aquifers can be grouped into 4 categories: intensively, middle, weekly karstified aquifer and aquifuge of insoluble rocks.

**Groundwater.** Groundwater level (h) is an important factor governing of water inrush into karst tunnel. In the case when $h \geq 60$m above tunnel floor at the time of excavation, water inrush disaster may cause severe damages of property and person safety. If $30 < h \leq 60$m, the severe property damage may be occur but generally the safety of person may not be caused. If $0 < h \leq 30$m, only the construction may be influenced. If there is no drainage in time, collapse may be caused. If $h < 0$, there will be no water inrush.

**Geostructure surface.** The open surfaces such as fault, fracture, joint and migration pathway serve for ground water. The secondary dissolution pipeline mainly formed at surface. Large karst cave systems always following tenso-shear faults, lager fracture, bedding plane and unloading fracture

along the quayside. Practice shows that the structure surface of fracture does more contribute to the cave, pipeline and strong development than bedding plane.

**Occurrence of strata.** Rock karstification is inhibited considerable in case strata occur horizontally as a result of anisotropy of rock body broking infiltration of rain and surface water. Karstification of rocks is limited as well in the case when strata occur vertically, as outcrop area of soluble rock in this case will be the smallest and subsequently function of the feedback loop of karst differentiation discussed by WANG Shitian in 1962 will be significantly limited. The most favorable conditions for kastification would take place when strata occurs 20ºto 60º inclined, for example, in a monocline structure or in the wing parts of a syncline or anticline.

**Ancient denudation (paleoerosion) surface.** The ancient denudation surface consists of discontinuity surface, the continental deposit upon the surface and the dissolution zone under the surface. In China, according to the sort of the continental deposit, ancient denudation surface used to be divided into 3 types which are Fe-Al type, phosphate type and coal type. In the south of China, one of the most popular ancient denudation surfaces of coal type is one at the top of Maokou limestone ($P_{1m}$) and in most areas in south western China a intensively karstified zone with large open cavities had always been recognized in lime stone beds right beneath the denudation surface.

**Landform.** Surficial karst feature is taken as parts of the underground river systems on the ground. Depression, sinkhole (doline) and swallow hole are actual inlets or reliable indicator of trunk or tributary of underground river systems and their water input depends on the surficial catchment area. Karst shaft and swallow hole are located in unsaturated zone. They are formed not only by dissolution but also by gravitational collapse.

**Rainfall.** Groundwater level in karst region fluctuates with time greatly. The amplitudes of fluctuation depend on water recharge amount from surface water. If there is a strong rainfall during construction, the water level will rise rapidly and may reach 100m even more in annual amplitudes in conduits. A high water level increases water inrush risk. While in fissure zone surrounding conduits surfacial water into ground slowly and they obtain little water from unsaturated zone, but much water may receive laterally from conduits and water level here also rises although slowly. When water level in conduits rapidly dropping, water in fissures comes to flow to niebering conduits and this makes water level in conduits drops at a lower rate than rising one.

**Table . 1.** Controlling factors of water inrush

| factor rank | $D_1$ | $D_2$ (m) | $D_3$ | $D_4$ (º) | $D_5$ | $D_6$ |
|---|---|---|---|---|---|---|
| I | strong | >60 | strong | 20－60 | strong | strong |
| II | middle | 30<h<60 | middle | 0<a<20<br>60<a<90 | middle | middle |
| III | weak | 0<h<30 | weak | 0, 90 | weak | weak |

## Fuzzy comprehensive evaluation model

**Determining influence factors.** At first, the influence factors are determined. Secondly, the factor set D is conformed. The D is defined as D={$D_1$，$D_2$，……$D_7$}.

Where, $D_1$－lithology, $D_2$－groundwater, $D_3$－geostructure surface, $D_4$－strata occurrence, $D_5$－paleoerosion surface, $D_6$－landform and $D_7$－rainfall.

**Giving evaluation set.** For the risk of water inrush was divided into 4 ranks, the evaluation set is given as V={$V_1$, $V_2$, $V_3$,$V_4$}. Where, $V_1$ - the risk of rank I, $V_2$ - rank II, $V_3$ - rank III, and $V_4$ - rank IV.

**Forming the mathematical model.** As mentioned above, each factor has 4 index or state sets and is denoted by $V_1$， $V_2$， $V_3$，$V_4$. Where $V_i$＝ {$V_{i1}$，$V_{i2}$，…，$V_{i7}$} (i＝1，2，3，4). Then Table 1 can be expressed by the following matrix V.

$$V = V_{ij}\begin{bmatrix} V_{11} & V_{12} & \cdots & V_{17} \\ V_{21} & V_{22} & \cdots & V_{27} \\ \vdots & \vdots & & \vdots \\ V_{41} & V_{42} & \cdots & V_{47} \end{bmatrix}$$

Where, V is the matrix of the state or index of water inrush risk and it is considered as the mathematical model of water inrush. The row vector of V is called class vectors and the column vector of V is called state vector.

**Determining weight value.** The weight value is the experience of the referee and has greatly fluctuation. The different weight values of the same factor are given by different experts and the weight average is considered as the value of the factor. As each of the factors of the water inrush has different status and function, the weight is different. The weight value of all the factors is defined as A. Where, A =( $a_1$， $a_2$， …， $a_7$).

According to the properties and internal relations of the factors and the weight given by the experts, all the weight is given as following.

Without the aquifer of karst, there is no water inrush. So $D_1$ is regarded as the first important factor and the weight is the maximum, $a_1$=1. The underground water level is the second important factor and $a_2$ is 0.9. $D_3$ and $D_4$ are the factors influence the migration of the water and generally looked as the important factors, ($a_3$, $a_4$)=(0.8, 0.7). $D_5$ is less important than $D_4$, $a_5$=0.6. $D_6$ and $D_7$ are the secondary factors and ($a_6$, $a_7$) = (0.4, 0.2). By substitution of the data obtained into A, A= $1/D_1$+$0.9/D_2$+ $0.8/D_3$+$0.7/D_4$ + $0.6/D_5$+$0.4/D_6$+$0.2/D_7$. Normalized A, then (a1， $a_2$， $a_3$， $a_4$， $a_5$， $a_6$， $a_7$) = (0.22， 0.20， 0.17， 0.15， 0.13， 0.09， 0.04).

The weight value of $D_1$ is the maximum and account for 22%, so petrofabric is the main controlling factor. If add $D_1$ to $D_5$, the sum accounts for 87%, so these 5 factors compose the basic factor of water inrush.

**Model of fuzzy comprehensive evaluation.** To evaluate the risk rank of water inrush, the fuzzy relation is introduced,

$$V = V_{ij}\begin{bmatrix} a_1p_1 & a_2p_1 & \cdots & a_7p_1 \\ a_1p_2 & a_2p_2 & \cdots & a_7p_2 \\ a_1p_3 & a_2p_3 & \cdots & a_7p_3 \\ a_1p_4 & a_2p_4 & \cdots & a_7p_4 \end{bmatrix}$$

Where, V is called the matrix risk rank indices of water inrush.

The value of $p_i$ is given by the experience or the expert. Using the arithmetic progression with the difference of 1/8 and 3/8 which multiplies by 100 correspond to $p_i$, the pi value of water inrush ranks is given in Tab**le 2.**

**Table 2.** The risk rank indices of water inrush

| factor rank | $D_1$ | $D_2$ | $D_3$ | $D_4$ | $D_5$ | $D_6$ | $D_7$ | $P_i$ |
|---|---|---|---|---|---|---|---|---|
| I | 19.25 | 17.5 | 14.875 | 13.125 | 11.375 | 7.875 | 3.5 | 87.5 |
| II | 13.75 | 12.5 | 10.625 | 9.375 | 8.125 | 5.625 | 2.5 | 62.5 |
| III | 8.25 | 7.5 | 6.375 | 5.625 | 4.875 | 3.375 | 1.5 | 37.5 |
| IV | 2.75 | 2.5 | 2.125 | 1.875 | 1.625 | 1.125 | 0.5 | 12.5 |

**Table 3.** Interval of the rank value

| Risk rank | Interval of $P_i$ value |
|---|---|
| I | 75～100 |
| II | 50～ 75 |
| III | 25～50 |
| IV | 0～25 |

According to the factors of the tunnel section, $\sum D_{ij}$ can be obtained. Compare $\sum D_{ij}$ to the interval of the ranks value (Table 3), and then the rank is obtained.

## Engineering Application

**Engineering situation.** In the area mainly lies formation outcrop: Zhengyangzu($K_{2z}^1$). The tunnel passes two pass areas.

**The sample of the risk evaluation.** The interval YK224＋380-YK224＋400 occurs $K_{2z}^{1}$. Underground water level is about 25m above the bottom of tunnel when recharge is sufficient. There is no geostructure and the stratium inclined at about 20º. There is no paleoerosion surface. This part of tunnel route lies beneath a trough valley and the construction take place in rainy while the condition of seepage of the surface water is quite well. The index of water inrush factors and the risk value are given in Ta**ble 4.**

**Table . 4.** The risk index of the rank of water inrush

| factor | $D_1$ | $D_2$ | $D_3$ | $D_4$ | $D_5$ | $D_6$ | $D_7$ | $\sum D_{ij}$ |
|---|---|---|---|---|---|---|---|---|
| state | middle | 0<h<30 | \ | 20－60 | \ | strong | strong | |
| value | 8.25 | 12.5 | 2.125 | 13.125 | 1.625 | 5.625 | 3.5 | 46.75 |

As $\sum D_{ij}$ =46.75, so the risk of this section is rank Ⅲ.

**Verification.** When tunneling, there are a water inflow at YK224＋398. And the results show that there is underground water at the place. Several outflow points occur, the largest outflow of water is about 50m$^3$/h, the hydrops is about 100m (Figure 1), and the construction is iffuluenced by that. The water inflow shows that the risk evaluation model is fit for dividing the water inrush rank.

**Fig. 1.** Hydrops after water inrush when excavation

(1) In this paper, Factors controlling water inrush risk are analyzed and proposed.
(2) With the help of fuzzy mathematic，a fuzzy comprehensive evaluation model for dividing the rank of water inrush into karst tunnel risk has been put forward. The evaluation procedure and criteria are given for evaluation.
(3) Risk evaluation model is used in Tanjiaba tunnel of Hurongxi highway. And the excavation result shows that the model is reasonable and correct.

# Numerical Analysis of Two Structural Schemes of the HK-Zhuhai-Macau Immersed Tunnel

Yajiao Dai[1, a *], Mengjia Zhou[1], Yufei Kong[1], Xiaodong Liu[2] and Zhigang Zhang[2]

[1]Department of Civil Engineering, Tsinghua University, Beijing 100084, China;

[2]CCCC Highway Consultants CO., Ltd., Beijing 100088, China;

[a]daiyajiao@163.com

**Keywords:** Immersed tunnel; FE simulation; Structural design;

**Abstract.** Two structural schemes of the Hong Kong-Zhuhai-Macau Immersed Tunnel were compared. In Scheme 1, the prestressed reinforcing bars were to be cut off after installation. And in Scheme 2, the prestressed reinforcing bars will be kept there as they were after installation. A finite element model for sections E12~E15 was built by using the finite element software PLAXIS with consideration to the construction process and different loading conditions to analyze both schemes. The calculation results show that they both meet the design requirements.

## Introduction

The immersed tunnel of the Hong Kong-Zhuhai-Macao Bridge (or HK-Zhuhai-Macau Immersed Tunnel) is a great project that has attracted worldwide attention. Its is about 6 km in length and most of the tunnel is buried deep in the seabed. The immersed tunnel consists of 33 sections, namely E1~E33, in which E1, E2, E32 and E33 are 135m long and others are 180m in length. Each section contains several segments of 22.5 meters long.

The segments are connected by shear connecters at their joints and the Ω Gasket (Rubber Waterstop) is used for water prevention. Eight or six segments are connected as a whole by prestressed reinforcing bars at both the top and the buttom during the floating transportation and immersing. After being laid onto the foundation trench in the sea, adjacent sections are connected by the GINA Gasket as well as the Ω Gasket and compressed by water pressure. Two designing schemes were proposed during the design and discussion.

Scheme 1(Flexible Design): In the original structural design, all the prestressed reinforcement were to be cut off after installation of the tunnel. In this way, the GINA Gasket at *section joints* (or immersion joints) would be compressed once more and the *segment joints* (or expansion joints) could deform more freely after the relaxation of reinforcement. The Flexible Design allows certain deformation at segment joints to make the tunnel adapted to differential settlement and earthquake.

Scheme 2: The second scheme proposed by CCCC Highway Consultants required prestressed reinforcement be kept during the tunnel's usage period. It was aimed to overcome some disadvantages of the Flexible Design, where flexibility of segment joints would increase the risk of water leakage when considering differential settlement or seismic activity[1]. The original design referred to the famous Oresund Tunnel. However, geological and loading conditions here are more various than that in the Oresund strait. Moreover, cutting off reinforcement would change the internal force of the whole tunnel and the sudden relaxion of the prestress might possibly introduce damage to the structure. So, Scheme 2 was put forward to reserve prestressed reinforcement, the same as they were for transportation. The second scheme tended to tie the eight or six segments in a section more firmly. It still differed from traditional rigid designs since the prestress was not so large.

The main objectives of this paper are to analyse the two structural schemes and to checking out which one is more suitable. A finite element model is made, including four neighbouring segments. Sections in the numerical model include E12S4~E12S8, E13S1~E13S8, E14S1~E14S8, and E15S1~E15S5. Dead loads, live loads, temperature loads and basement unevenness are considered in the calculation.

## The Numerical Model

The calculation is completed in the famous FEM software PLAXIS 3D 2012. Staged construction in the software is used, including excavation, ground improvement, tunnel immersion, rubble filling and long-term muck siltation in the next decades. Figure 1 shows 2D sketches of four main calculation steps. Figure 2 shows the shape of the tunnel's cross section and a side view of the model.

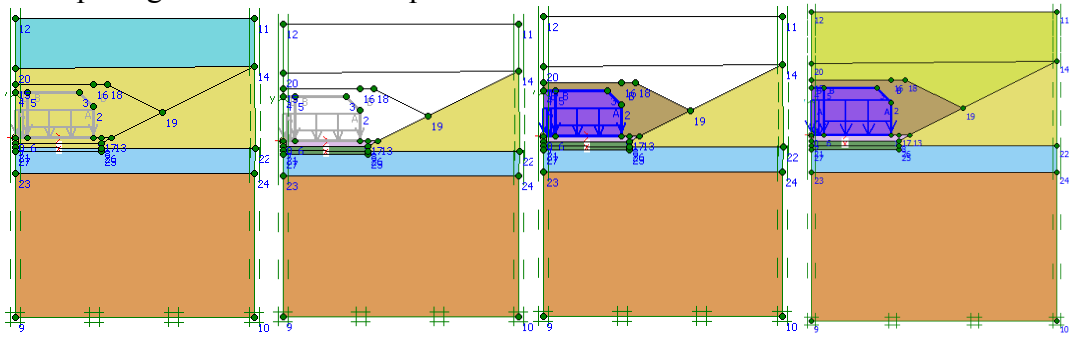

Figure 1. Four main construction steps: 1. inatial phase, 2. excavation and mat layer pavement, 3. tunnel immersion and rubble filling, 4. muck siltation.

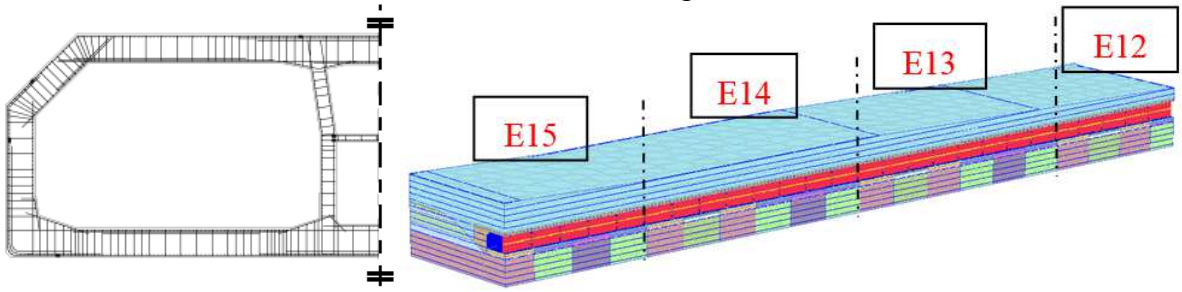

Figure 2. Left: cross section of the tunnel(half), the tunnel is 37.95m in width and 11.45m in height; Right: 3D FE model in PLAXIS.

**Soil Parameters.** According to the geological investigation report, there are mainly four soil layers. Some are excavated first. Before installing the tunnel, soils beyond the tunnel would be replaced by dynamic compacted rubble fill. After tunnel installation, more rubble would be filled in the foundation trench. The Hardening Soil Model [2] is used for soils and soil parameters come from geological reports and experiments. Parameters for HSM are listed in Table 1.

In order to reflect uncertainties in the ground improvement, the unevenness of foundation stiffness is considered in this model. We change the modulus of subsoils manually to let it vary like a sine function within the range of each section (180m). The amplitude of the variation is 30%. The unevenness of muck siltation has also been taken into account. The height of the muck siltation over E14 is 20m and that over E13 changes from 20m-16m linearly.

Table 1. Parameters of soils in Hardening Soil Model

| Number of soil layers | Soil | $\gamma$ (kN.m$^{-3}$) | $c$ (kPa) | $\varphi$ (°) | $E_{50}^{ref}$ (MPa) | $E_{oed}^{ref}$ (MPa) | $E_{ur}^{ref}$ (MPa) | $m$ |
|---|---|---|---|---|---|---|---|---|
| 11 | Muck and mucky soil | 16.2 | 9 | 6 | 2.50 | 1.25 | 7.50 | 0.76 |
| 31 | Clay | 18.1 | 43 | 20 | 9.65 | 4.88 | 28.95 | 0.90 |
| 32 | Clay with sand | 18.5 | 36 | 24 | 15.25 | 7.63 | 45.75 | 0.60 |
| 44 | Medium sand | 20.3 | 0 | 37.8 | 42.42 | 42.42 | 127.3 | 0.60 |
| / | Compacted rubble fill | 20 | 0 | 40 | 100 | 100 | 300 | 0.60 |
| / | Mat layer rubble fill | 20 | 0 | 40 | 10 | 10 | 30 | 0.60 |
| / | Rubble fill over tunnel | 20 | 0 | 40 | 10 | 10 | 30 | 0.60 |
| / | Muck siltation | 15 | 9 | 6 | 2.5 | 1.25 | 7.50 | 0.76 |

Note: the first four soils are in-situ soils; four original layers in Figure1-1 are 11, 31, 32 and 44 from top to buttom.

**Jiont modelling.** It's quite important to model the joints properly. We proposed a method for joint modelling, where the mechanical behavior of segment joints in both schemes can be reflected by changing material properties.

As is shown in Figure 3, an imagined gap of 0.8m is reserved between two segments. Horizontal springs (node-to-node anchors) connect both sides to transmit axial pressure and bending moment (Figure 3-c). These node-to-node anchors are 0.2m long. And they are elasto-plastic in segment joints to allow tension cut-off. There are also some springs connecting vertical and horizontal shear connecters to transmit shear force and allow shear deformation(Figure 3-a,b). As is mentioned above, sections are connected by the GINA Gasket and Ω Gasket. Segments are connected by shear connecters as well as the Ω Gasket at their joints. GINA Gasket used here is *GINA seal TB G-320/370*. The *EA* of each spring is calculated from the GINA Gasket, Ω Gasket or the concret that this spring stands for.

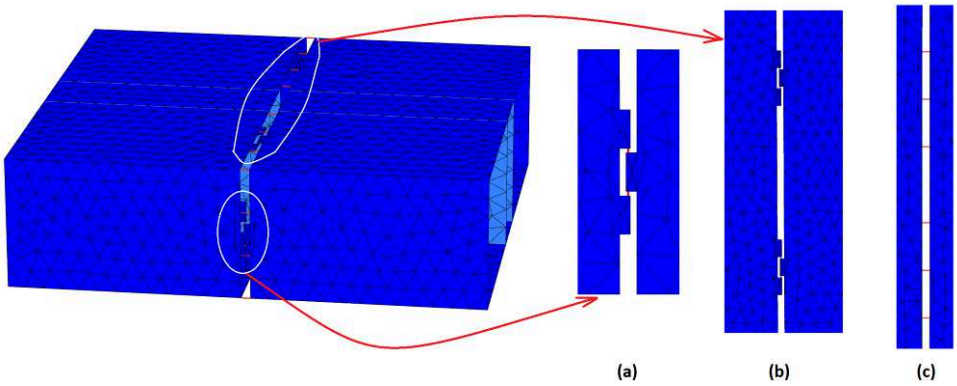

Figure 3. Section joint simulation, (a) vertical shear connecter, (b) horizontal shear connecter, (c) springs to transmit axial pressure and bending moment.

**Loading.** Dead loads of the tunnel include: 1. Self-weight of the structure, 26.023kN/ m³; 2. Dead load of road surfaces and equipments, 30kPa on the floor; 3. Hydrostatic pressure, mean sea level +0.54m is used for determining water pressure on the walls and floors; the axial force induced by water is about 158323kN, considering the relaxion of GINA, it is reduced to 158323*0.6=94994kN; 4. Rubble filling and muck siltation, calculated automatically in the spftware; 5.Concret shrinkage and creep, equivalent to 4.65˚C cooling; 6. Prestress, totally 191578k. Live loads considered here include: 1.Traffic load, 8.4kPa on the floor; 2. Temperature load, ±10˚C.

The loading conditions include: (1) Basic condition: dead loads with out shrinkage and creep, as well as traffic loads; (2) Cooling condition: the basic one with shrinkage and creep and temperature decrease. (3) Warming condition: the basic one with shrinkage and creep and temperature increase. The partial factor of live loads is 0.8.

As the software cannot simulate temperature change directly, an axial force equalling $EA\alpha\Delta t$ is applied to each segment instead. This method is accurate in calculating deformation and joint forces.

## Calculation and Results

The main difference between two design schemes is whether to cut off the prestressed reinforcing bars. The difference should also be expressed in our model. The axial force resulted from prestress and water pressure are simulated by axial load define in the model. If the prestressed bars are cut off, the axial force will change with it.

The axial force in segment joints introduced by prestressing is 191578kN. The axial water pressure for hydraulic compression is 158323kN, which make the prestress reduce a little; as a result, the increment of axial force is 157433kN, and the compressive deformation of GINA is 154mm in hydraulic compression. If the prestress is relaxed in Scheme 1, GINA will be compressed by 2.9mm more. The axial force in segment joints reduces by 176197 kN. Taking into account GINA's relaxion, the axial force at different position is adjusted, shown in Table 2.

Table 2. Initial axial compressive force at different positions before loading

| | Reinforced concrete and segment joints (kN) | Prestressed bars(MPa) | GINA(kN) |
|---|---|---|---|
| Scheme 1: Flexible Design | 191578+157433*0.6 -(190697-14500*0.6)=104041 | -- | (158323+14500)*0.6 =103693.8 |
| Scheme 2: | 191578+157433*0.6=286038 | 1209-5.56*0.6=1205.664 | 158323*0.6=94993.8 |

Table 3. Main results of calculation

| | Max bending moment of segment joints (kN*m) | | Max axial force increment of segment joins (kN) | Max shear force of segment joints (kN) | Max shear force of section joints (kN) | Max opening of section joints (mm) |
|---|---|---|---|---|---|---|
| Scheme 1 | +552512 | -542868 | +95861 | 23816kN | 21234 | 12.6 |
| Loading condition | Basic | Warming | Cooling | Basic | Basic | Cooling |
| Scheme 2 | +749981 | -726393 | +136358 | 28773 | 27940 | 18.0 |
| Loading condition | Warming | Cooling | Cooling | Cooling | Basic | Cooling |

Note: 1.positive bending moment means concret at the top has bigger compressive stress; 2. axial force increment should be added to the axial force in Table 2 to get the total axial force force, tension positive; 3. the opening of section joints is a increment value on the basic of primary compression, around 155mm.

Obviously, the deformation of segment joints in Scheme 2 would be smaller than that in Scheme 1. As worries for Scheme 2 include larger internal forces at segment joints and larger deformation at section joints(GINA Gasket), we list results of joint stress and section joint opening in Table 3.

It can be seen from Table 3 that, for Scheme 2, even though deformation at section joints are bigger that the Flexible Design, the GINA Gasket is still safe for water prevention. The bending moment and axial force in both schemes meets the requirement of structural design.

Due to the axial force provided by prestress, the minimum axial force of segment joins in Scheme 2 is 149680kN. To be conservative, we use the coefficient of friction of concret as 0.3 to estimate the maximun shear capacity: 149680*0.3=44904kN. This is much bigger than the maximum shear force, 28773kN. It is the same with the Flexible Design in Basic and Warming Conditions. However, for the Flexible Design in Cooling condition, where the shear force is 11276kN, the minimum axial force is too small to provide enough friction, so the shear capacity depends on the concret shear connecter, 16000kN. From this perspective, Scheme 2 has more emergency capacity.

## Conclusions

The calculation of static loads presented above shows that, both design schemes can meet the design requirements and have enough capacity. Considering possible risks for cutting prestressed bars off and the fact that Scheme 1(Flexible Design) not being suitable for seismic activities, we recommend Scheme 2 for the Hong Kong-Zhuhai-Macau Immersed Tunnel.

**Keywords:** metro; deformation characteristics; monitoring and measuring; numerical simulation

**Abstract:** Qingdao Metro Line 3 is the first subway line in Shandong province, some tunnels need to cross water-rich sandy layers. At the time of passing through the water-rich sandy layers, how to maximum the deformation characteristics of the tunnel during excavation becomes the critical problem of the design and construction. This paper studies Qingdao Metro Line 3, directs at water-rich sand layer section YK16+382, with the use of on-site monitoring and measuring instruments, analyses the characteristics of ground deformation of the cross section. And we calculated the deformation by Flac3D numerical simulation in YK16+382 cross section, studied the arch and surface subsidence and convergence deformadon variation of convergence. Finally compare site monitoring measurement with numerical computational results and then we can get the convergence of arch and surface subsidence and convergence deformadon, provide theoretical guidance for the actual construction.

## Introduction

Metro as a new means of transport in plays a vital role in easing urban traffic congestion, serve the general public with a safe, convenient, comfortable, clean form of transport. By the end of 2012, including Beijing, Shanghai, Tianjin and other 12 cities have opened metro[1]. Subway tunnel built on the place that has accumulated soil and geological complex, underground pipeline dense, narrow tunnels, heavy traffic, busy shopping center, and the construction and development along the subway tunnel will due to urban vertical deposition. A certain degree of settlement can be regarded as normal phenomenon[2]. But if the settlement amount exceeds a certain limit, it will cause deformation of subway tunnel construction, settlement and displacement on the surrounding environment, even unimaginable accidents. In order to ensure the safety of subway tunnels main structure and surroundings, the subway tunnel construction must be carried out settlement monitoring, timely analysis of the monitoring data and feedback, as well as to forecast future settlement[3-5].

This paper study on the subway project under complex formation in Qingdao Metro line 3, analysis of arch and surface subsidence and convergence deformadon and numerical simulation for the convergence of data, by comparison to get some useful conclusions.

## Project overview

Qingdao metro line 3 first-stage project west since Shinan District Qingdao railway station, to east along Guangxi road, and Taiping road, and Wendeng road, and Hong Kong Road, to municipal government and then turn into Nanjing Road to North, entere Harbin road, and Heilongjiang road, and Wannianquan Road to licun, to west along Jingkou road, and Zhenhua road to end at Qingdao North Station, total length about 25.1km, all for underground line.

Qingdao metro line 3 first-stage project of He-He section is single-hole single lane, the interval is underground excavation, from the Hexi station, through Zhangcunhe, tunnel starting mileage is K16+149.875, ending mileage is the K17+24.969.The tunnel go through the formation of water -rich sand layers, depth 2.5~10.5M,line spacing is 13~36.35m. Hexi station ~ Hedong station tunneling section is single hole single horseshoe-shaped structure that tunnel through the formation of water -rich sand layers, maximum depth of the tunnel is 10.5M.

## Field monitoring and measuring

3.1 Field monitoring data

The major monitoring of He-He interval is arch and surface subsidence and convergence deformadon. Select YK16+382 monitor to study, for example, the monitoring surface subsidence have 6 monitoring stations, arch settlement has 2 monitoring stations, and convergence deformadon has 4 monitoring stations. Monitoring data measured points as shown in table 1 below.

Table 1 The accumulative total settlement of the measuring points

| Number of measuring points | Accumulative total settlement (mm) | Number of measuring points | Accumulative total settlement (mm) |
|---|---|---|---|
| DC02-68 | -5.34 | DC02-71 | -6.76 |
| DC02-69 | -6.55 | DC02-72 | -6.45 |
| DC02-70 | -7.38 | DC02-73 | -4.84 |

3.2 Analysis on ground settlement data

According to monitoring YK12+660 from May 13, 2012 to September 16, 2012, 5 months of monitoring data curves. From figure 2, the largest settlement appear in the measuring points 10DC02-70 between the two tunnel, has a maximum cumulative amount of change of -7.38mm. Axle wire of the right line and peripheral point of the left line measuring points 10DC02-69, 10DC02-71, and 10DC02-72 are slightly less than the settlement of intermediate points, the average settlement is -6.5mm. Measuring points on both sides of the tunnel have the smallest settlement, about -5.3mm and -4.8mm. According to the curve, we can get that the surface begins to subside after tunnel excavation, there might be some rebound .Then subsidence rate become faster, finally plateaued.

Above the tunnel right line YK16+382 cross section,6 points settlement changes at different times are showed in Figure 3 , the data curve is a sedimentation tank. From the line charts we can clearly see that there is maximum surface subsidence above the tunnel centre line, reaching 7-8mm, and diminishingly along the tunnel centre line, the settlement is very small about 10 meters away from the center line. The settlement can basically be ignored. According to the settlement curve we can reveal the excavation sequence of the two tunnels. The right line tunnel excavat early, measuring point 10DC02-69 settled clearly, with the excavation of the left lane, other measuring points also have a significant settlement. Eventually reaches a steady state.

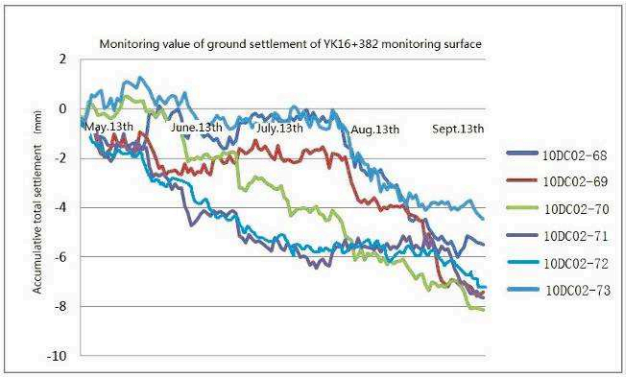

Fig 2 The cumulative curve of ground settlement of YK16+382 section

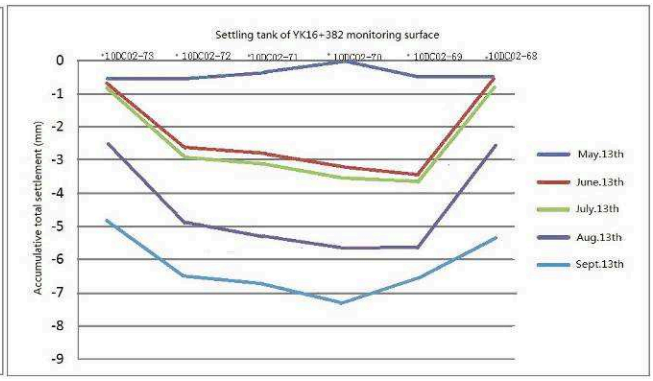

Fig 3 Settling tank analysis of YK16+382 section

**Numerical simulation and comparative analysis of ground settlement**

Numerical simulation is presented using Flac3d. The left and right sides of the model are imposed X-direction horizontal constraint, the front and back sides are imposed Y-direction constraint, the bottom of the model is imposed Z-direction constraint, and all borders are imposed self-weight stress of rock and soil mass. The calculation model is shown in figure 4.

By comparing the curve obtained from measured data with the one obtained from numerical simulation, we obtain the curve shown in figure 6. In the figure, YK16+382 actually measured settling tank is obtained from the latest settlement record in the monitoring data table, and settlement from numerical simulation is obtained after the final settlement is stable. Through the comparison of the curves, at the axes and both sides of the tunnel, the settlement of monitoring surface obtained from numerical simulation can virtually satisfy with the one obtained from actual measurement, however, in the middle of the two tunnels, the actually measured settlement is different from the numerically simulated one. The former is slightly smaller than the later.

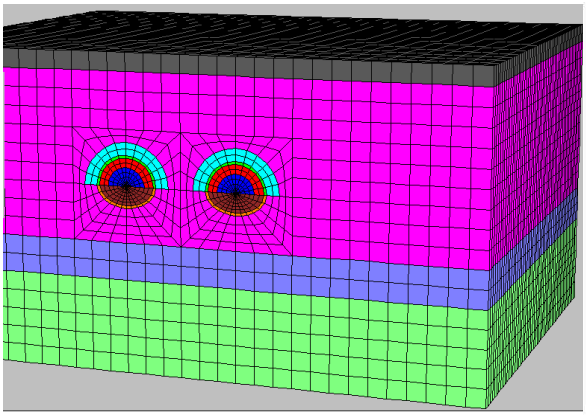

Fig 4 Numerical simulation

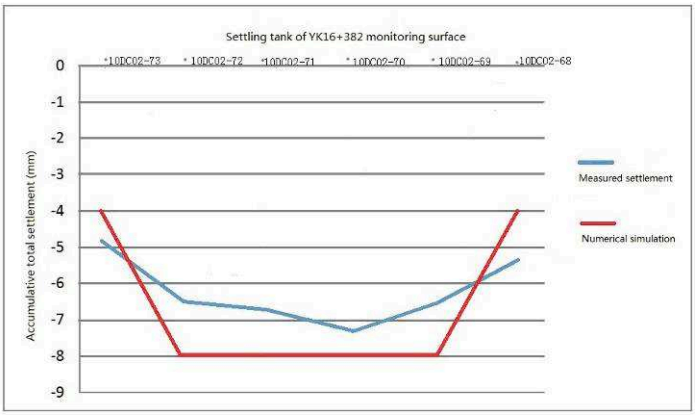

Fig 5 Comparison between actual measurement and numerical simulation of settling tank

The following points can be summarized by comparing the actually measured ground settlement with the numerically simulated one of YK16+382 monitoring surface.

1. The curves of both actually measured ground settlement and numerically simulated one of YK16+382 monitoring surface can virtually satisfy the calculation of settling tank in experience method. The settlement at the tunnel axes and the middle of the two tunnels is large and decreases gradually towards both sides.

2. The reason why the numerically simulated settlement is larger than the actually measured one is that the former is obtained after the layer is finally stable, however, the monitoring surface is monitored within 6 months, when the layer is not stable, which makes the simulation value lager than actual settlement.

## Conclusion

This paper comparatively analyzes the actual measurement and numerical simulation of ground settlement, vault settlement and convergence of the tunnel in watery sand section of Qingdao metro line 3, making the following conclusions and recommendations.

1. The settling tank of Hehe tunnel virtually satisfies the experience method prediction, which means the settlement at tunnel axes is the largest and decreases towards both sides. However, since the distance between the two tunnels is less than 3D (D means the width of the tunnel), there is a superposition to the settlement between the two tunnels. It can be proved by both numerical simulation and actual measurement that after the superposition, the settlement of the layer between the two tunnels is close to the one of tunnel axis.

2. The displacement nephogram of numerical simulation and settlement curve tendency virtually satisfy the monitoring situation in practical engineering. Thus numerical simulation is helpful to site construction and measurement and can provides theoretical and data bases to raise the accuracy and efficiency of ground settlement control.

# Auger Bored Piles Application Works in the Subway

Wu Yang

(Hunan Urban Construetion College ,Xiangtan, 411103 ,China)

**Keywords:** Long spiral; pile; metro; construction applications

**Abstract:** Pile Foundation Construction jobs are usually wet process has contaminated a large, long duration, the pile of inconsistent quality, cost out. And long bored piles to adapt to a variety of complex geological conditions, but not the impact of water table, is widely used in various projects of the foundation engineering, this according to subway construction in Kunming, the application of experience, a brief description length screw pile construction anti-interpolation technology.

## Project profile

Chenggong Station of Kunming Rail Transit is located at the crossing of Caiyunnanlu Road and Liandalu Road, arranged along the Caiyunnan Road. It is an underground double-layer and three-span island station and it is the transfer station of Line 1 and Line 4. It has four entrances, named No.1, 2, 3, 4 respectively, as well as No.1, 2, 3 fire evacuation exits and No.1, 3 air ducts. The east side of the station entrances, air ducts and other ancillary structures will be constructed by using open-cut construction, part of the west side of No.1 2 entrances and No.1 fire evacuation exit will be constructed by using underground tunneling. The building envelope of open-cut ancillary structures adopts a diameter of Φ800@1000～@1100 drilling interval pile + internal bearing support system, local channel adopts using 40C U-bar @ 1000 supporting. There are six types of retaining piles, 800mm in diameter, 5 to 16 meters in length, with a total number of 804 piles, 9,361 linear meters. The project demands a large number of ancillary envelope piles, short period and high construction requirements, traditional wet construction process will lead to long pore-forming period, bring difficulties in slurry wall, cause great pollution and piles unstable, as well as high construction cost. Through projects optimization, the Project Department has selected a long spiral auger to conduct pore-forming. Long spiral auger pumping superfluid concrete inserting steel reinforcement cage technology is evolved from the Japan CIP construction method. It uses a dedicated long spiral auger drill machine to a predetermined depth, continuously injects superfluid concrete through the drill valve until the pile-top, and then inserts the steel reinforcement cage to form the pile. It is a new pile foundation construction method. Superfluid concrete bored pile technology is widely used, because it is not restricted by underground water level, adopting the concrete with low friction coefficient, strong liquidity and good aggregate dispersion, the auger can drill as well as press-grouting concrete, easily to handle and concrete pouring fast, good pile quality and reduce cost. Remarkable results have been achieved. Engineering geological conditions are listed below:

| Table 1: Geological conditions | | | |
|---|---|---|---|
| Level No. | Name of rock-soil | Characteristics of Rock-soil | Thickness of the level |
| 1 | Plain fill | Containing clay, crushed stones; compaction slightly | 2～5.5m |
| 1-2 | Silty clay | Isabelline; grayish yellow; plastic | 1.5～3m |
| 2-2 | Clay | Grayish yellow; grey; plastic | 5m |
| 3-3 | Organic clay | Ash black; plastic | 0.5～5m |
| 4-3 | Organic silt | Black; plastic | 0.5～3m |
| 5-4 | Silt | Grey, dark grey; saturated and dense | 6m |
| 11-3 | Round grave soil | Grey, yellowish-brown; saturated and dense | 0.5～4m |

**Construction process**

Superfluid concrete bored pile uses long spiral auger drill machine to design elevation, after stop drilling as lifting the auger as pressure injecting the superfluid through the concrete holes on the inner pipe bit, continuously injecting until reaches the top of design elevation, then removes the drill pipe and inserts the steel reinforcement cage into pile. When pressing the concrete to the top of the pile, poured concrete should exceed 50cm to the top to ensure the concrete strength of the pile-top. The construction process is as follows:

Leveling the ground → lofting pile → mounting equipment → place steel casing→ drilling machine in position → drill to the design elevation then stop → as lifting the auger as pressure injecting the superfluid through the concrete holes on the inner pipe bit → lift the drill pipe and insert the steel reinforcement cage → pile-forming → pile-top protection.

**Construction scheme**

3.1 Construction technology preparation

According to the survey report of geotechnical engineering, grasp the geological and hydrological conditions; jointly examine the pile foundation construction drawings and other drawings; investigate the underground pipelines, underground structures and adjacent dilapidated buildings around the construction site and adjacent areas, in order to take appropriate measures to secure and protect, thereby ensure the smooth construction of the piles; level the ground, site pay-off, assemble equipments; detect the pile elevation and determine the drilling depth.

3.2 Construction raw materials preparation

The raw materials used in the project must be re-inspected and qualified; use Portland cement and ordinary Portland cement, strength grade is not less than 32.5Mpa, water-cement ratio should be 0.5 to 0.6; stone diameter should be 5 to 16cm; adopt medium sand, clay content$\leqslant$2%; tap water.

3.3 Construction mechanical equipments

Superfluid concrete pile construction should use auger boring machine, depending on the types of pile to select appropriate models and rig drilling parameters. The project uses 2 sets of CFG-32 long auger, the electrical power 200kw, drilling speed 2m/min and 81r/min, 20 piles forming everyday.

3.4 Master operation construction scheme

3.4.1 pore-forming

(1) Re-inspect the pile location before point leading drilling in place, the drill should align the pile points when construct, stabilize the drilling, control the auger drill center and verticality by using leveling instrument and plummet to ensure the drilling steady during the construction, the drilling lower should be 10 to 20cm away from the ground, aligned with the pile location and buried in the ground, making the pile center deviation is less than 10mm required by the specifications and design.

(2) Using wire pendant to measure pile frame verticality during the drilling process, use leveling instrument to measure the level of the chassis to ensure that the drill pipe verticality (≤0.5%), meanwhile, clean the muck beside the hole as rotate the drill to prevent the muck falling when lift the drilling.

(3) When touch underground obstructions or hard formations, slow down the drilling speed to avoid sticking.

(4) Check the drill bit and blade diameter every shift to ensure pile aperture not less than the design value.

(5) Drill to the design depth, rotate 0.5 to 1min, wait for all bottom soil entering leaves and then stop rotating to ensure the thickness of bottom soil less than 10cm.

(6) Directly use the drill pipe to measure the depth of pore, i.e. mark the drill pipe to measure before construction.

3.4.2 Concrete injecting

(1) Drill to the design depth and make all soil into the blades, then lift the drill bits off the bottom of the pore 20 to 30cm to ensure the superfluidity drill discharge to open flexibly.

(2) Inject concrete to bury drill bit 50 to 100cm, then begin to lift the drill. When lift the drill to inject concrete pumping, strictly control the lifting speed, making sure the lifting speed matches the speed of the concrete injecting. Before lifting the drill pipe, the concrete in the drill pipe is required to be above the ground. At the same time, to calculate each pile pumped concrete square volume, adjust the drill speed depending on the lift force that concrete pumping exerts to the drill pipe, ensuring the drill pipe and blades to exert squeezing effect on the concrete, lift the drill as injecting, until reach the design elevation of the pile-top.

3.4.3 Lift steel reinforcement cage making machine

(1) Steel reinforcement cage shall be welded strictly in accordance with the requirements of design drawings, ensure the lap length and welding quality as required, in order to prevent that vibration subsidence leads to the cage sealing off and falling apart.

(2) The Steel cage should be stocked for certain amount before construction. The finished cage must be submitted to the commissioner to inspect and accept. A qualifying signage should be hung on the qualified cage to mark the information such as the cage type, location and length.

(3) The cage production should be arranged on a relatively level area to guarantee the cage straight. During the process, manual tumbling and lifting must strictly protect the steel cage from deformation and sealing off.

(4) Before laying down the steel cage, alignment and centering should be conducted; when lifting the cage, reasonably arrange the lifting point, lift the head of the cage as workers lift the bottom of the cage; in the process of hanging straight, at least two technicians should control and command far away in the vertical direction; prohibit to hit the hole wall to make sure the protective layer of the cage is 70 to100mm; The cage should continuously sink depend on the weight of itself, if the

sinking resistance is too large, remove the steel cage promptly, re-insert into the bore; the reinforcement sink until the exposing part is less than 1m away from the ground, then use the vibrator to press it into the bore, and monitor top of the pile with a level elevation.

**Quality standards**

Test the steel and other raw materials before the construction to ensure the quality in line with national standards; inspect the bores, concrete injecting, the steel reinforcement cage production and installation in the whole construction process; examine the concrete strength and pile quality after the construction; master control project quality should satisfy the standards in Table 2.

Table2: Master control project quality standards

| No | Content | Allowable deviation |
|---|---|---|
| 1 | Space between the main reinforcements of the cage | ±10mm |
| 2 | Pile position | Supporting pile side foundation pit side direction 100mm; vertical foundation pit side direction 150mm; |
| 3 | Bore depth | 0，+300mm |

**Pile foundation detection**

5.1 Pile quality inspection

(1) Superfluid concrete mixing should inspect the raw materials quality, measuring, concrete mixing proportion, admixtures, slump, and concrete strength;

(2) The steel reinforcement cage producing should inspect the reinforce specifications, welding specifications, variety, weld length, weld appearance quality, main reinforcement and stirrups producing deviation;

(3) During the construction, it is required to inspect the hole center location, hole depth, diameter, verticality, the actual position of the steel cage, and fill in the appropriate quality inspection records;

(4) Test the concrete strength grade after pile-forming;

(5) When excavate the pile-top, it is required to inspect the number of piles, position and pile-top appearance quality promptly.

5.2 Pile Integrity Test

Piles will be tested according to *Technical specification for testing of building foundation piles"* (JGJ106-2003). This project uses low strain to test the pile integrity. There are 804 envelope piles in the project and 20% of them, i.e. 17 piles will be tested in accordance with the design and specification.

**Conclusions**

Superfluid concrete pile construction technology is of high degree of mechanization, fast construction progress, economic efficiency; compared with wet pile-forming filling pile, although he concrete filling factor is slightly higher, but in the same geological conditions, it is able to

remove the demand for mud wall, thus the comprehensive cost will be saved 15%～20%. This technology has the function of wall self- protection with pile materials, without any additional measures to protect the wall, basically save the work of mud contamination, mud treatment, and mud outward transport, exerting little effects on the environment; In the process of planting the cage, due to the energy of vibration equipment is small, and the force is exerted in the flow plastic concrete, therefore, it will not produce intense vibration and shock response, and the vibration and noise is fully controlled in the range allowed by construction, thus it can be confirmed that the construction method has less impact on the environment, so it is a environment friendly green construction method. Placed the cage in plain concrete pile is helpful to improve the load-bearing and pullout resistance capacity; simplify the construction program will improve the efficiency and reduce the cost.

The key technology of the steel reinforcement cage piles applied in metro construction has yet to be thorough investigation, research, testing, evaluation and application. Through continuous accumulation, progress and creation, make the technology reach high engineering application level.

**Keywords:** urban rail transit; residential property value; hedonic pricing

**Abstract.** This research investigates the impact of the first metro line (Line 1) in Hangzhou on its station-area residential property values. A hedonic pricing model shows that Line 1 had a statistically significant and positive effect on residential prices in its operation period. Compared with its construction phase, the impact did not change significantly, indicating that metro rail transit had a long-term positive influence on the station-area property values. These findings suggest that such capitalization is likely to lead to high-density and transportation-oriented development. While planning the urban rail transit system, such impact should be fully considered.

## Introduction

There is no doubt that urban rail transit greatly improves the accessibility to urban spatial location, and is convenient for people to travel. A survey in Shanghai showed that in three major factors that have effects on the housing price (along the rail transit, around the large green areas, along the river), along the rail transit is the first factor to consider for 88% of buyers while buying houses [1].

## The literature review

Empirically, urban rail transit plays an important or even a guiding role on urban spatial planning and layout. In theory, most of quantitative researches around the world especially in western developed countries use asset value method. This method is based on the capitalization hypothesis theory that the benefits brought by social infrastructure will be fully reflected in the increasing of the land price or real estate price finally [2]. Existing researches home and abroad, except for a few studies that concluded the impact of rail transit on the surrounding properties is not significant or even negative [3], most studies supported the conclusion of the hypothesis. Knaap et al. (2001) used data on vacant land sales in Washington County, Oregon. They found that plans for light rail investments have positive effects on land values in proposed station areas. These findings suggested that such capitalization is likely to discourage the development of low-density housing in station areas and encourage high-density, transportation-oriented development [4]. Bae (2003) investigated the impact of the construction of a new subway line (Line 5) in Seoul on nearby residential property values. The results showed that distance from a Line 5 subway station had a statistically significant effect on residential prices only prior to the line's opening [5]. Most other studies had shown that urban rail transit stations had positive multiplier effects on property values. And from the city center area to the peripheral zone, the impacts of rail transit on land prices or housing prices gradually expand [1, 2, 6, 7, 8]. Therefore, while planning the urban rail transit system, designers should fully think of such impact.

Metro Line 1 is the first line of the urban rail transit lines construction in Hangzhou, total length 53 km (including xiasha extension) with 34 stations, of which 31 underground stations, 3 elevated stations. It is the main backbone line in Hangzhou rail transit network, connecting the main city zone with the suburb areas. The project started construction on March 28, 2007 and its opening date is November 24, 2012 (excluding xiasha extension). Yang Hong (2010) had examined the effects of Hangzhou Metro Line 1 on house prices, finding that the properties which are less than 500 meters away from the rail station had a significant premium of 9.4%, while those in the 1500 meters range didn't show any increment [8].

Yang's research was during the construction phase of Line 1 and didn't cover the operation period. So studying the multiplier effect on the property of Metro Line 1 in its operation phase is conducive to explore long-term impacts of urban rail transit on its surrounding properties. If the multiplier effect during the operational phase is still significant, urban rail transit can be considered to have a long-term effect on property values, thus leading to a high-density development in station area and thereby affecting the design of urban planning.

In this paper we try to deepen Yang's study to examine the impact on the operation phase, and focus on the residential properties with a distance of 500 meters from Line 1. More important, by comparing with Yang's results, we try to figure out whether the Hangzhou urban rail transit contributes to transportation-oriented development or not.

## Variables selected

The affected area of rail transit on the real estate values is generally limited to a certain area, and Yang's study showed that significantly affected area by Metro Line 1 during the construction phase is in the range of 500 meters. So in order to facilitate comparison, the paper determines the radius of 500 meters from the station as research area. In addition, the impact of rail transit on different types of properties is very different. This paper focuses on the commercial residential houses, which is consistent with Yang's research.

**Variables.** Factors that affect the housing price are complex. In order to control the other variables, and to focus on the rail transit factor, this paper intends to use the common factor controlling method: hedonic pricing method. Hedonic pricing method usually controls factors through three aspects: characteristics of the house and property itself, characteristics of the neighborhood and community, and environmental characteristics (accessibility characteristics). Based on the results of previous researches, as well as the availability of the data, here we choose the average sale price of a residential project (donated as Pr) as the dependent variable. And also we select eight independent variables from the above three aspects, where there are one property characteristic, three accessibility characteristics and four neighborhood characteristics. The definitions of these variables and the expected sign of each variable are shown in Table 1. The major purpose of this paper is to investigate the impact of Line 1 on residential prices, so we list the metro rail transit variable separately from accessibility characteristic vector.

Table1 Quantification and the expected sign of the residential characteristic variables

| Variable | Definition | Unit | Expected sign |
|---|---|---|---|
| Pr | The average price per square meter of a project | yuan/$m^2$ | |
| Metro | Dummy variable, distance from the Line 1 station (less than 0.5Km = 1, otherwise = 0) | | + |
| Age | The average age of residential houses | year | - |
| D_WCBD | Straight-line distance from the traditional CBD Wulin Square | Km | - |
| D_QCBD | Straight-line distance from the new CBD Qianjiang New City | Km | - |
| D_WL | Straight-line distance from the pleasant landscape : West Lake | Km | - |
| BL | The number of bus lines around the project within 1Km | | + |
| SCH | Distance from the nearest primary school | Km | - |
| SCH_Q | Dummy variable, quality of the nearest primary school (very good=3, good=2, ordinary= 1) | | + |

**Data collection and processing.** In this paper, the main city of Hangzhou is chose as research area. The real estate industry in this region is relatively mature. Take project as the basic unit of

analysis, and data sample contains a total of 660 projects in Hangzhou. Use the average transaction prices in April 2014 as housing prices, which are obtained directly from the real estate company. In addition, from a variety of real estate search sites (such as SouFun etc.) we complement the residential own characteristics data, such as the average age of residential project, so that the data is more complete. Use Google Maps to measure the distance variables, including the distance to Hangzhou traditional CBD (Wulin Square), the distance to new CBD (Qianjiang New City), and the straight-line distance to the pleasant landscape West Lake. Before put these variables into the model, we preprocess the data to eliminate abnormal values, and finally get a valid sample of 603 projects.

Conducting all variables correlation analysis before build the model can provide an intuitive point of view to determine the relationship between the sequences. The results show that the correlation coefficient between BL and D_WCBD is statistically significant, with value of -0.786. The correlation coefficient between D_WL and D_WCBD is also significantly, up to 0.756. This phenomenon is not out of expectation. Wulin Square as the traditional CBD, is the center of public transport system, the closer to Wulin Square, the more bus lines. West Lake is near to Wulin Square, so their correlation is high. Therefore here we intend to select variables BL and D_WL into the model rather than selecting D_WCBD to prevent collinearity problems.

## Empirical Analysis

**Model building.** Hedonic pricing model has three forms: logarithmic form, semi-log form and direct form. Because both real variables and dummy variables are in this paper, we choose the semi-log form that in addition to the dummy variables, the other variables are in the form of logarithm. Model equation is expressed as Eq. 1.

$$\text{InPr}=\beta_0+\beta_1\text{Metro}+\beta_2\text{In Age}+\beta_3\text{ In D_QCBD}+\beta_4\text{In D_WL}+\beta_5\text{ BL}+\beta_6\text{ In SCH}+\beta_7\text{SCH_Q}+\varepsilon. \quad (1)$$

OLS is used to estimate the model with all variables entering the regression equation directly. The overall indexes of regression results are shown in Table 2.

Table2 Results of overall indexes

| Model | $R^2$ | Adjusted $R^2$ | Std. Error | F | Sig.F |
|---|---|---|---|---|---|
| 1 | 0.448 | 0.442 | 0.203 | 60.521 | 0.000 |

From Table 2, we can see $R^2$ of the regression is 0.448, indicating that the model has a certain degree of explanatory power. And F statistic value is 60.521, much larger than 2, rejecting the assumption that all variable coefficients in the model are 0, which means the overall regression is statistically significant. The estimation of hedonic pricing model is shown in Table 3.

Table 3 Estimation of hedonic pricing model

| Model | B | Beta | t | Sig. | VIF |
|---|---|---|---|---|---|
| Constant | 10.532* | | 163.259 | 0.000 | |
| InSCH | -0.016 | -0.026 | -0.833 | 0.405 | 1.086 |
| SCH_Q | 0.060* | 0.180 | 5.668 | 0.000 | 1.084 |
| InD_WL | -0.261* | -0.562 | -13.806 | 0.000 | 1.790 |
| InD_QCBD | -0.051* | -0.102 | -3.037 | 0.002 | 1.216 |
| BL | 0.001 | 0.037 | 0.932 | 0.352 | 1.684 |
| InAge | -0.089* | -0.219 | -6.285 | 0.000 | 1.309 |
| Metro | 0.060* | 0.098 | 2.972 | 0.003 | 1.174 |

Note: *donate significant level at 1%.

As we can see from Table 3, VIF values of all variables are less than 10, indicating that there is no significant multi-collinearity. When put D_WCBD variable into the equation, all variable VIF values

are still less than 10, but the VIF values of D_WL and BL increase significantly. So it is reasonable not to put D_WCBD variable into the model.

Comparing the results of this paper with Yang's results, the result is shown in Table 4.

Table 4 Comparison of the results in operation phase (2014) and construction phase (2010)

| Variable | Operation phase (2014.4) | Construction phase (2010.3) |
|---|---|---|
| Constant | 10.532* | |
| InSCH | -0.016 | |
| SCH_Q | 0.060* | |
| InD_WL | -0.261* | -0.340* |
| In D_QCBD | -0.051* | -0.105* |
| BL | 0.001 | |
| InAge | -0.089* | -0.018* |
| Metro | 0.060* | 0.090* |

Note: *donate significant level at 1%.

**Result analysis.** From Table 3 we can see that the coefficient of Metro variable is 0.06, significantly positive and consistent with our expectation, indicating that Line 1 on its operational phase has a positive effect on the surrounding residential prices, with a premium of 6%. The Metro coefficient value (0.06) is almost the same as that of InD_QCBD (-0.051), while smaller than InD_WL coefficient value (-0.261). This suggests that Line 1 plays an important role in guiding residential development in the view of comparison with CBD's impact on poverty values.

Take a closer look at comparison of the results in operation phase (2014) and construction phase (2010) shown in Table 4. Because the selected variables and the samples in the two papers are not the same, the absolute values of the coefficients in the two aren't able to compare. However, the basic condition for a qualified econometric model is its applicability, which means the estimations of different scientific equations on a same issue won't be completely different without any rational reasons. The coefficient signs of D_WL, D_QCBD and Age are the same in the two models, and the difference between these coefficient values are small. So we have reasons to believe that the coefficients of Metro in the two models are comparable. Both Metro variable coefficients are significantly positive, and the values are only of a small gap (0.09 to 0.06). The explanation of this result is as follow.

In construction phase, metro rail transit did not bring substantial convenience to people. But most of commercial houses in Hangzhou are pre-sale, so the value of convenience brought by rail transit for travel had been partly reflected in property prices in advance. In addition, buyers for the investment purpose also contributed to the increase. When it comes to the operation phase, the actual rail transit convenient features appeared. Those people waiting to see the substantial convenience no longer hesitate to purchase, thereby further contributing to transfer the benefit value brought by metro rail transit to property price.

## Conclusions

Metro Line 1 has a significantly positive effect on residential prices in its operation phase (2014). Compared with the impact on its construction phase (2010), there is no significant change, indicating that metro rail transit has a long-term positive influence on the station-area property values. The result is consistent with most previous studies, and contributes to adding evidence to verify the assumption that capitalization of convenience brought by urban rail transit is likely to lead to high-density and transportation-oriented development. So we suggest that while planning the urban rail transit system, such impact should be fully considered.

# Dynamic accumulation damage characteristics of initial cracks for the lining of high-speed railway's tunnel

Xiangqiu Wang[1,a], Bin Cai[2,b]

[1] Dept. of Civil Engineering, Foshan University, Foshan,528000, China

[2]Faculty of Civil Engineering of Guangdong University of technology ,510006，China

[a]tongji_wxq@163.com,[b]864353786@qq.com

**Keywords:** tunnel of high railway, initial damage of lining structure, mechanism of cumulative damage, theory of linear elastic damage

**Abstract:** After have been analysed the initial dynamic cumulative damage mechanism of lining structure of the high speed railway tunnel,the conclusions have been gained that, under the effect of the long-term vibrating load of high speed train, When the damage energy accumulation reached a limit values, the damage zone caused by the initial crack which has been existed in the tunnel lining will be expansed further more. for the more, based on the accumulation damage theory linear elasticity and the analysis method dynamic finite element, The extension characters and calculation method of initail crack in the tunnel lining structures for the high railway have been proposed.

## Introduction

The lining of high speed railway's tunnel belongs to the steel reinforced concrete structure, Inevitably there are initial cracks or defects in the process of tunnel construction, under the effect repeatedly on the vibration loadings of the running train, the initial cracks will be expanded and evoluted,the dynamic damage of tunnel structure will also continue to accumulate and deepen. When the damage is accumulated to a certain extent, it may lead to local failure of tunnel structure and overall instability. The research is very rarely about the dynamic damage mechanism of tunnel structure at home and abroad. The current representative research on the dynamic damage characteristics of tunnel structure mainly includes that the spectral analysis techniques based on the Hilbert-Huang transform had been used to analyse the spectral characters of inputting seismic waves by Wang Zhengzheng etc. in refrences [1,2], according to the principle of energy, the energy responsing equation was derived out under the principle of damage conditions, and based on the damage energy equation the nonlinear seismic responsing characteristics of tunnel structure had been analysed. Based on the theory of fatigue cumulative damage, The train loads of ordinary railway tunnel bed structure fatigue life and damage degree had been studied by Peng Limin, Shi Chenghua etc. in refrences [3]. The method of finite element and the indoor model test had been used to research the vibration responsing characteristics and fatigue life of the tunnel structure for the high-speed railway by Huang Juan etc.in refrences [4],and this study had founded a new researching field on the damage of structural tunnel.

The engineering practice shows that the initial damage exists inevitably in the concrete lining structure of high railway's tunnel because of the particular construction environment. under the effect of the long-term vibrating load of high speed train, the initial damage will be continuously accumulated, leading to mechanical characteristics of tunnel lining structure inevitably becomes cumulative damage weakening. In this paper, based on the concrete damage theory, the evolution regularities of fatigue damage discussed for the initial crack of the high-speed railway tunnel, and

then, the foundation was laid to study on the long-term dynamic stability of the structure of high speed railway's tunnel.

**Dynamic damage mechanism of tunnel structure of high-speed railway**

According to the existing design theory and specifications of railway tunnel, the lining structrue is usually composed by two supportings,and the second lining structure is generally in elastic state. If the initial crack is not exsited in the second lining structure, even though the vibration loads of high-speed train effect for a long-term, the new dynamic crack will theoretically not produce,and the dynamic damage or destruction will not take place in the lining structure.but there are so many of unfavorable factors such as the construction quality problems, the groundwater seepage of surrounding rock induced by the vibration of train, The damage of initial lining, the redistribution of surrounding rock stress and so on,the initial cracks usually exists in the key parts of tunnel such as the roof , the arch waist and other Location. The vibration energy would be accumulated in the initial damage region around those initial cracks,with the long-term effect of high-speed train vibration loads. When the accumulation of damage energy reaches a limit value, It will lead to the stable growth of damage crack, and ultimately leads to the damage destruction of tunnel lining structure.

**Stress intensity factor of initial Damage crack**

The engineering practice shows that the initial cracks of tunnel lining mainly belongs to the tension crack, even though the forms of them are complex and diverse. The growth direction of crack is generally perpendicular to the surface of the lining structure,and the destructive force is also the strongest,So this paper mainly focus on the development law of these cracks. In order to simplify the calculation, the lining structure of high speed railway's tunnel is regarded as the problem of plane strain. for an initial damage crack of tunnel lining structure, the tip of this initial damage crack is regarded as the origin of coordinates to establish a corresponding coordinate system.based on the linear elastic theory, The displacement field around the finite region of crack's tip can be obtained as following as[5]:

$$\left.\begin{aligned} u &= \frac{K_I}{8G}\sqrt{\frac{2r}{\pi}}\left[(2\lambda-1).\cos\frac{\alpha}{2}-\cos\frac{3\alpha}{2}\right] \\ v &= \frac{K_I}{8G}\sqrt{\frac{2r}{\pi}}\left[(2\lambda+1).\sin\frac{\alpha}{2}-\sin\frac{3\alpha}{2}\right] \end{aligned}\right\} \quad (1)$$

In which, $\lambda$ is the elastic coefficient of material, for the problem of plane strain, which equals to $3-4\mu$. $G$ is The shear modulus of the material, $\mu$ is the Poisson's ratio, $K_I$ is the stress intensity factor of crack's tip, r is the distance from the calculation point to the crack's tip.

By the refrence [5], for the equation of [1],suppose to $\alpha=\pi$ ,the vertical displacement near to the crack's tip can be obtained as following as:

$$v = \frac{4(1-\mu^2)}{\sqrt{2\pi}E}K_I\sqrt{r} \quad (2)$$

In which,E is the elastic modulus of material.

When $r \to 0$ ,the tensile stress intensity factor at the tip of initial damage crack can be expressed as following as:

$$K_I = \lim_{r \to 0} \left( \frac{\sqrt{2\pi} E v}{4(1-\mu^2)\sqrt{r}} \right) \quad (3)$$

Because of the stress intensity factor varies with the displacement field of crack's tip, In order to consider the vibration loadings of high-speed train and the dynamic interaction between the surrounding rockmass and the tunnel's structure effect on the stress intensity factors of crack's tip, a model of finite element can be established to simulate the dynamic interaction between the surrounding rockmass and the tunnel's structure,and applying the vibration loadings of high-speed train on the model to analyse the changing regularity of the stress intensity factor for the initial damage crack's tip in different times.

**The propagation criterion for the initial damage crack**

As is mentioned before, When the damage energy accumulation reaches a limit values at the initial crack's tip in the lining structure of tunnel, which caused by the external forces such as the vibration of train and so on.it can be said that if the stress intensity factor at the tip of initial damage crack reach the fracture toughness of concrete,the new expansion will be generated at the initial crack,and the damage degree will be continued until the unstable fracture of concrete lining structure. According to the criterion of fracture mechanics of concrete structure[6], the criteria for crack propagation can be expressed as followings as:

When $K_I < K_{IC}^S$, the crack will not be extended.when $K_{IC}^S \le K_I \le K_{IC}^E$, the crack will be extended steadily.and when $K_I > K_{IC}^E$, the crack will be in the unstable growth stage. Where, $K_{IC}^S$ is the fracture toughness of concrete, $K_{IC}^E$ is the unstable fracture toughness of concrete. These parameters can be obtained by the method of three point bending beam, the splitting test of cube and so on.

**The cumulative damage calculation of tunnel lining structure**

The dynamic loadings caused by the high speed railway's train is a random vibration.the dynamic stress caused by the vibration loadings can be considered to be composed with a number of different amplitude vibration cycles, and the cumulative damage effect caused by the vibration of high speed railway's train can be calculated by the method of numerical integral which based on the linear cumulative damage theory.

Supposing that the crack length of tunnel's lining at some moment is $a_i$,the dynamic stress amplitude is $S_i$, so the amplitude of stress intensity factors can be expressed as:

$$\Delta K_i = C S_i \sqrt{\pi a_i} \quad (4)$$

In which, $C$ is the flexibility coefficient of materail, the increment of crack growth, is also called as $da$ can be obtained by the fatigue damage characteristic curve of tunnel's lining that is $da/dN - \Delta K$ , so we can get $a_{i+1} = a_i + da$ , for the more, if the damage cracks are superposited,which caused by several different amplitude of the vibration cycle ,the dynamic accumulation damage crack can be expressed as followings as:

$$a = a_0 + \sum_{i=1}^{N} (da_i) \quad (5)$$

## Analysis of examples

A high-speed railway's tunnel with composite lining those average thickness of the second lining is 50cm, The straight wall arch was adopted for the section of tunnel, the buried depth of tunnel is 10.6m, the concrete grade of tunnel is C25, there exists an initial crack with depth of 20mm In the part of tunnel's vault Center because of construction reasons. It has known that the fatigue damage curve of tunnel's lining structure can be expressed as $da/dN = 3.2\times10^{-3}.(\Delta K)^{4.23}$, the elastic modulus of concrete lining $E$ equals to $2.55\times10^{4}Mpa$, the poisson's ratio of concrete lining $\mu$ equals to $0.20$, the fracture toughness of concrete lining $K_{IC}^{S}$ equals to $0.348Mpa/m^{1/2}$,and the unstable fracture toughness of Concrete lining $K_{IC}^{E}$ equals to $1.16Mpa/m^{1/2}$.The method of dynamic finite element as shown in the refrence [7] is adopted to analyse the dynamic response characteristics of tunnel's lining structure,and the equations as metioned as before are adopted to analyse the damage characteristics of tunnel's lining structure. The maximum stress intensity factor of tunnel lining arch top position of the initial crack tip, it is also called $K_{\mathrm{Im}ax}$ can be obtained to $0.396Mpa/m^{1/2}$.it is satisfied to the Stable growth conditions of crack.for the more,we can calculate out the fatigue life of tunnel's lining structure is $3.52\times10^{6}$ under the vibration loadings of high-speed train. The calculation results accord with the practical engineering[8].

## Conclusions

The crack of initial damage has enormous influence on the fatigue damage of high-speed railway's tunnel, its impact on the long-term life of tunnel's lining structure can not be ignored. Based on the cumulative damage theory of the linear elastic fracture mechanics and combined with the finite element method which can consider the dynamic interaction between the surrounding rockmass and the lining structure of tunnel, the fatigue cumulative damage characteristics of tunnel's lining structure can be calculated reasonably and its results can satisfied to the practical engineering.

# A Numerical Investigation on Time-Dependent Failure of Tunnels Based on the Long-Term Strength Characteristics of Rocks

Lianchong Li [1, a], Meng Xing [1, b]

[1] School of Civil Engineering, Dalian University of Technology, Dalian 116024, China

**Keywords:** Rock tunnel; Strength degradation; Time-dependent deformation; Numerical simulation

**Abstract.** How to establish the proper rheological model to describe and simulate the relationship between rock mechanic characteristics and time is one of the difficulties in the tunnel long-term stability analysis. In this paper, a numerical model to replicate the time-dependent deformation of rock mass was presented. In the model, the time-dependent deformation is described in terms of degradation of intrinsic physical and mechanical properties of rock and accumulation of mesoscopic damage inside the rock. Based on the model, uniaxial numerical experimentation and tunnel numerical model test are numerically constructed and investigated respectively. The model well reflects the initial creep, steady creep of rock and accelerated creep, which preliminary prove the validity of the proposed model. The results of the tunnel numerical model test show that the displacement curves from the numerical simulation were generally consistent with those from physical model tests. Furthermore, the macroscopic failure modes and local mesoscopic damage evolution of the tunnels were simulated.

## Introduction

The long-term stability is the key to the design of tunnel engineering in rock masses; nevertheless, rheological properties have a variety of adverse effects on the long-term stability of engineering. Previous studies have proved that time-dependent deformations of rock play an important role in the design and construction of tunnels in rock masses with time-dependent strength and deformation properties [1]. In general, when the load reaches the instantaneous strength of the rock (usually refers to the rock uniaxial compressive strength), the rock is destroyed. When load is lower than the instantaneous strength, such as continuous action for a long time, rock damage may also occur due to the rheological effect. So, measuring the stability of permanent and long lived rock engineering should not be in terms of long-term strength rather than the instantaneous intensity as the calculation index of rock strength. In this study, a rheological model based on a simple strength-degradation law was employed in RFPA [2] to study the mechanism of time-dependent deformation and damage evolution of rock tunnels, which was attempted to gain an insight into the long-term stability of rock tunnels.

## The relationship of the rock long-term strength and time

Long-term strength is an important mechanics index of rock rheological mechanics properties. The long-term strength of rock refers to strength with time is reduced, and gradually tend to be a stable convergence value [3]. According to the creep experiment, Chen illustrated the concept of long-term strength of rock, there was a critical strength $f_c$, when the load was less than the $f_c$, deformation was stable creep; when the load was greater than the $f_c$ for accelerating creep, and $f_c$ is the long-term strength of the rock, and pointed out that the long-term stability of the roadway after excavation mainly depended on the long-term strength of surrounding rock [4]. Shao, in terms of the perspective of material mechanical properties degradation over time, carried on the simulation study on characteristics of rock creep [5]. And based on the characteristic of the long-term strength, a series of studies on the long-term stability of tunnels have been widely carried out [6].

In this work, in view of degradation of intrinsic physical and mechanical properties of rock and accumulation of mesoscopic damage inside the rock, the strength degradation model of mesoscopic representative element is employed in the mesoscopic elastic damage model. As is shown in Fig.1, the strength degradation model assumes the strength of the mesoscopic elements degrades with time, and the degradation rate depends on a combination of factors, such as stress, environment, etc., and finally reached a stable long-term strength. The strength degradation model of the mesoscopic representative element can be described as the following equation [7]:

$$f_t = f_\infty + (f_0 - f_\infty)e^{-at} \quad (1)$$

Where $f_0$ is the initial strength of the element; $f_t$ is the element strength at time t; $f_\infty$ is the long-term strength of the element, when $t \to \infty$, $f_t \to f_\infty$; $a$ is the factor of the strength degradation, reacting the speed of intensity attenuation. The values of $f_\infty$ and $a$ depend on the environment factors around rock mass and can be determined by experiments and field calibration. The above model has been achieved in RFPA$^{2D}$, and this work makes use of RFPA$^{2D}$ to conduct corresponding numerical analysis investigations. The introduction of RFPA$^{2D}$ can be found in the literature [8].

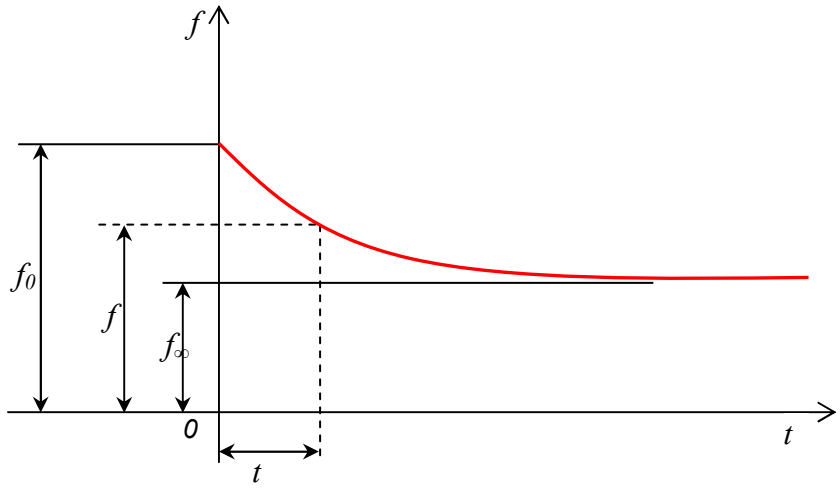

Fig.1 Strength degradation model of mesoscopic representative element

## Model validation and creep damage analysis

**The rock creep numerical experimentation under uniaxial loading.** In the section, characteristics of creep damage of rock under uniaxial loading are analyzed. The literature [9] implemented uniaxial compression creep test of some argillaceous slate, and based on the creep test results under different stress level, the time-dependent behaviors of strength and elasticity modulus of weak rock are discussed. The uniaxial numerical experimentation, based on above the physical experiment, establishes a two-dimensional numerical sample, the mechanical properties of which are of are listed in Table 1. And its geometrical dimension is 50mm×100mm, divided into 125×250, 31250 units. Then numerical samples are applied loads, $P$=5.08MPa, 10.10MPa and 15.82MPa, respectively. The creep curves of physical and numerical experimentations are showed in Fig.2.

Table 1 Parameters employed in uniaxial numerical test

| Parameter | Homogeneity index($m$) | Young's modulus($E$/ MPa) | Compressive strength($\sigma_c$/ MPa) | Tensile strength ($\sigma_t$ /MPa) | Friction angle ($\varphi$/°) |
|---|---|---|---|---|---|
| Rock | 3.5 | 5880 | 108.5 | 10.85 | 45 |
| Parameter | Unit Weight ($\gamma$/ KN·m$^{-3}$) | Poisson's ratio ($\mu$) | Ratio of long-term strength to instantaneous strength | | Coeff. of strength degradation ($a$) |
| Rock | 22.8 | 0.25 | 0.49 | | 0.05 |

As shown in Fig.2, the simulations agree well with the experimental results. And, according to either physical or numerical results, load stress level has great effect on creep properties of rock.

When load stress ($P$=5.08MPa, 10.10MPa) is less than the long-term strength, the creep stage 1 and 2 occur, and in the first phase of the creep, duration is within 75 d with large deformation and the strain rate continues to decay; to stage 2, strain rate keeps on constant with small deformation and duration is very long, specimen without damage, so they belong to the stable creep. When load stress ($P$=15.82MPa) is greater than the long-term strength, the model well reflects the initial creep, steady creep of rock and accelerated creep, and both experimental and numerical simulation results show significantly accelerated creep stage. The strain rate changes acceleration after attenuation firstly, belonging to the unstable creep. Research on the creep properties laws of rock accords with the creep basic laws got by experiment, which preliminary prove the validity of the strength degradation model.

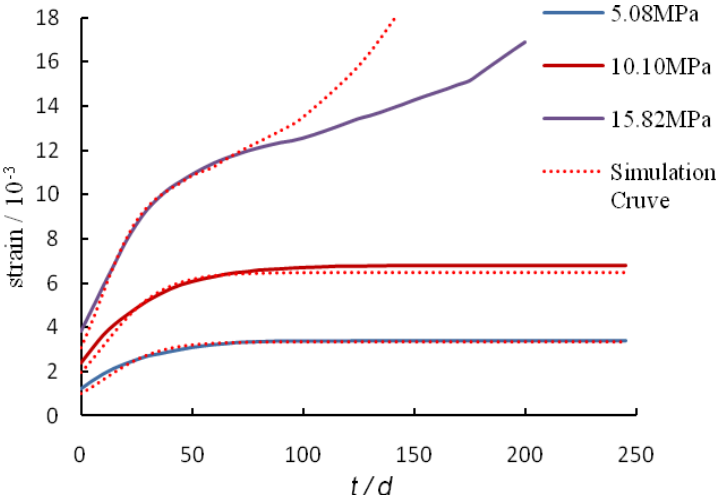

Fig.2 The creep curves of physical and numerical tests under different stress level

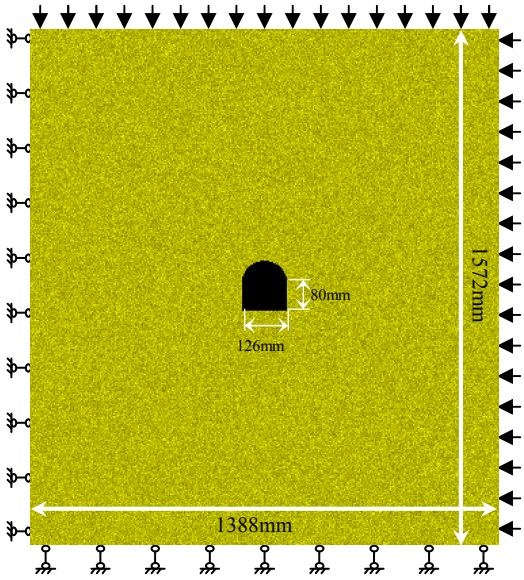

Fig. 3 The numerical simulation model

**Creep damage analysis of rock surrounding tunnel.** As a representative form of rock engineering, tunnel is widely used in mining engineering, traffic engineering, etc., and rheological properties have more adverse impacts on the long-term stability. How to establish the proper rheological model to describe and simulate the relationship between rock mechanics characteristics and time, relevantly describing deformation and failure characteristics of rock mass, have been one of the difficult problems in the tunnel long-term stability analysis [10]. In view of the uniaxial numerical experimentation in the above section, the strength-degradation model was employed to study the mechanism of time-dependent deformation and damage evolution of rock tunnel by the reproducibility of the scale model experimentation.

The literature [11] studied the creep properties of tunnel surrounding rock, not setting lining, after the excavation. The reproducibility of the scale models was examined by comparing the results of model experiments with the numerical analysis. The numerical simulation model and the properties of the trial material are described in Table 2 and Fig. 3 respectively. On the basis of model experiment, the surrounding rock pressure (Vertical: $P$=150KPa, Horizontal: $\lambda P$=52KPa) is defined as $\sigma_o$, and the numerical model are applied loads in sequence, $2\sigma_o$, $3\sigma_o$, $3.5\sigma_o$, by multi-stage loading. Fig. 4 compares displacement of floor heave, roof subsidence and wall convexity under multi-stage loads in the model tests with the displacement in the numerical simulation. From the comparison, we can see that the displacement curves from the numerical simulation shows a good agreement with that in the physical model tests. After the tunnel model is loaded (the excavation of the tunnel, in practice), the tunnel surrounding rock stress occurs redistribution and there will be a rapid initial instantaneous elastic deformation in surrounding rocks at this time. After the experiences of stress redistribution and the initial deformation of tunnel surrounding rock, under the long-term load, the destructions of both of side walls, roof and floor focus on creep, and its creep displacement is slow, with deformation rate lower than the previous stage; this phase is called the transient creep stage.

Table 2 Parameters employed in tunnel numerical model test

| Parameter | Homogeneity index($m$) | Young's modulus($E$/ MPa) | Compressive strength($\sigma_c$/ MPa) | Tensile strength ($\sigma_t$ /MPa) | Friction angle ($\varphi$/°) |
|---|---|---|---|---|---|
| Rock | 3 | 110 | 2.4 | 0.24 | 32 |
| Parameter | Unit Weight ($\gamma$/ KN·m$^{-3}$) | Poisson's ratio ($\mu$) | Ratio of long-term strength to instantaneous strength | | Coeff. of strength degradation ($a$) |
| Rock | 27.2 | 0.44 | 0.7 | | 0.1 |

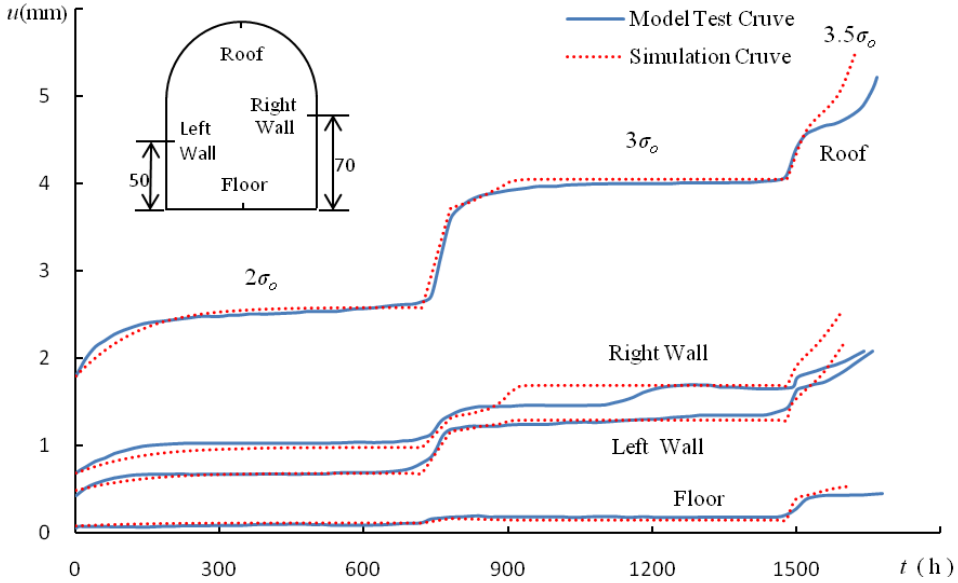

Fig. 4 The displacement curves of model and numerical tests

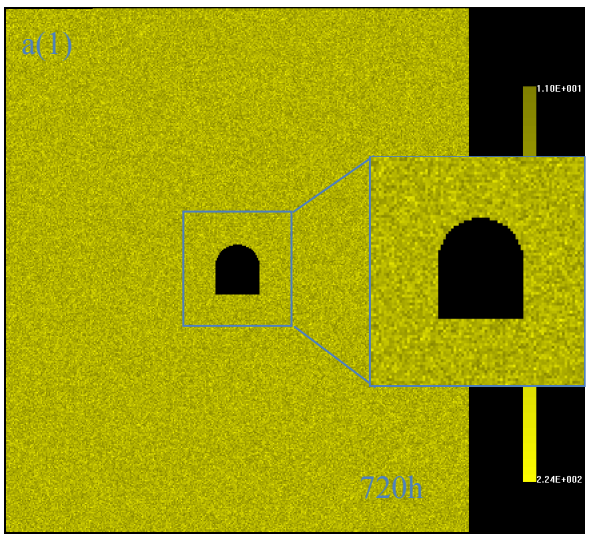
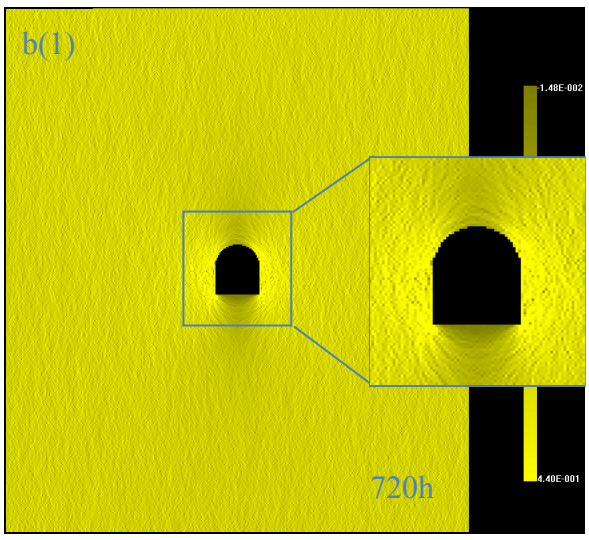
In the numerical simulation, the distribution of failure zone was used to represent the failure pattern of the tunnel. The calculation results are described in Fig. 5. Fig. a and Fig. b, respectively, shows elastic modulus and the maximum stress figures numerically obtained, and the dark elements represent the nucleated flaw. In Fig. b, the elements with lighter shade of grey have relatively higher stresses. During applying the first-stage load, high stress concentration occurs in the two side walls, showed in Fig. b(1); in spite of strength degradation over time, since tunnel surrounding rock suffer less pressure, damage does not occur. Because of second-stage load applied, higher stress concentration occurs and the initial cracks generate in the two side walls, illustrated in Fig. a(2) and Fig. b(2). As time goes on, the rock mass strength attenuates with time constantly and cracks cut-through in the side walls and extend into the tunnel gradually, described in Fig. a(3) and Fig. b(3). Eventually, according to Fig. a(4) and Fig. b(4), under the time and third-stage load, both of side walls generate the overall destruction and cracks extend into two shoulders of the tunnel.





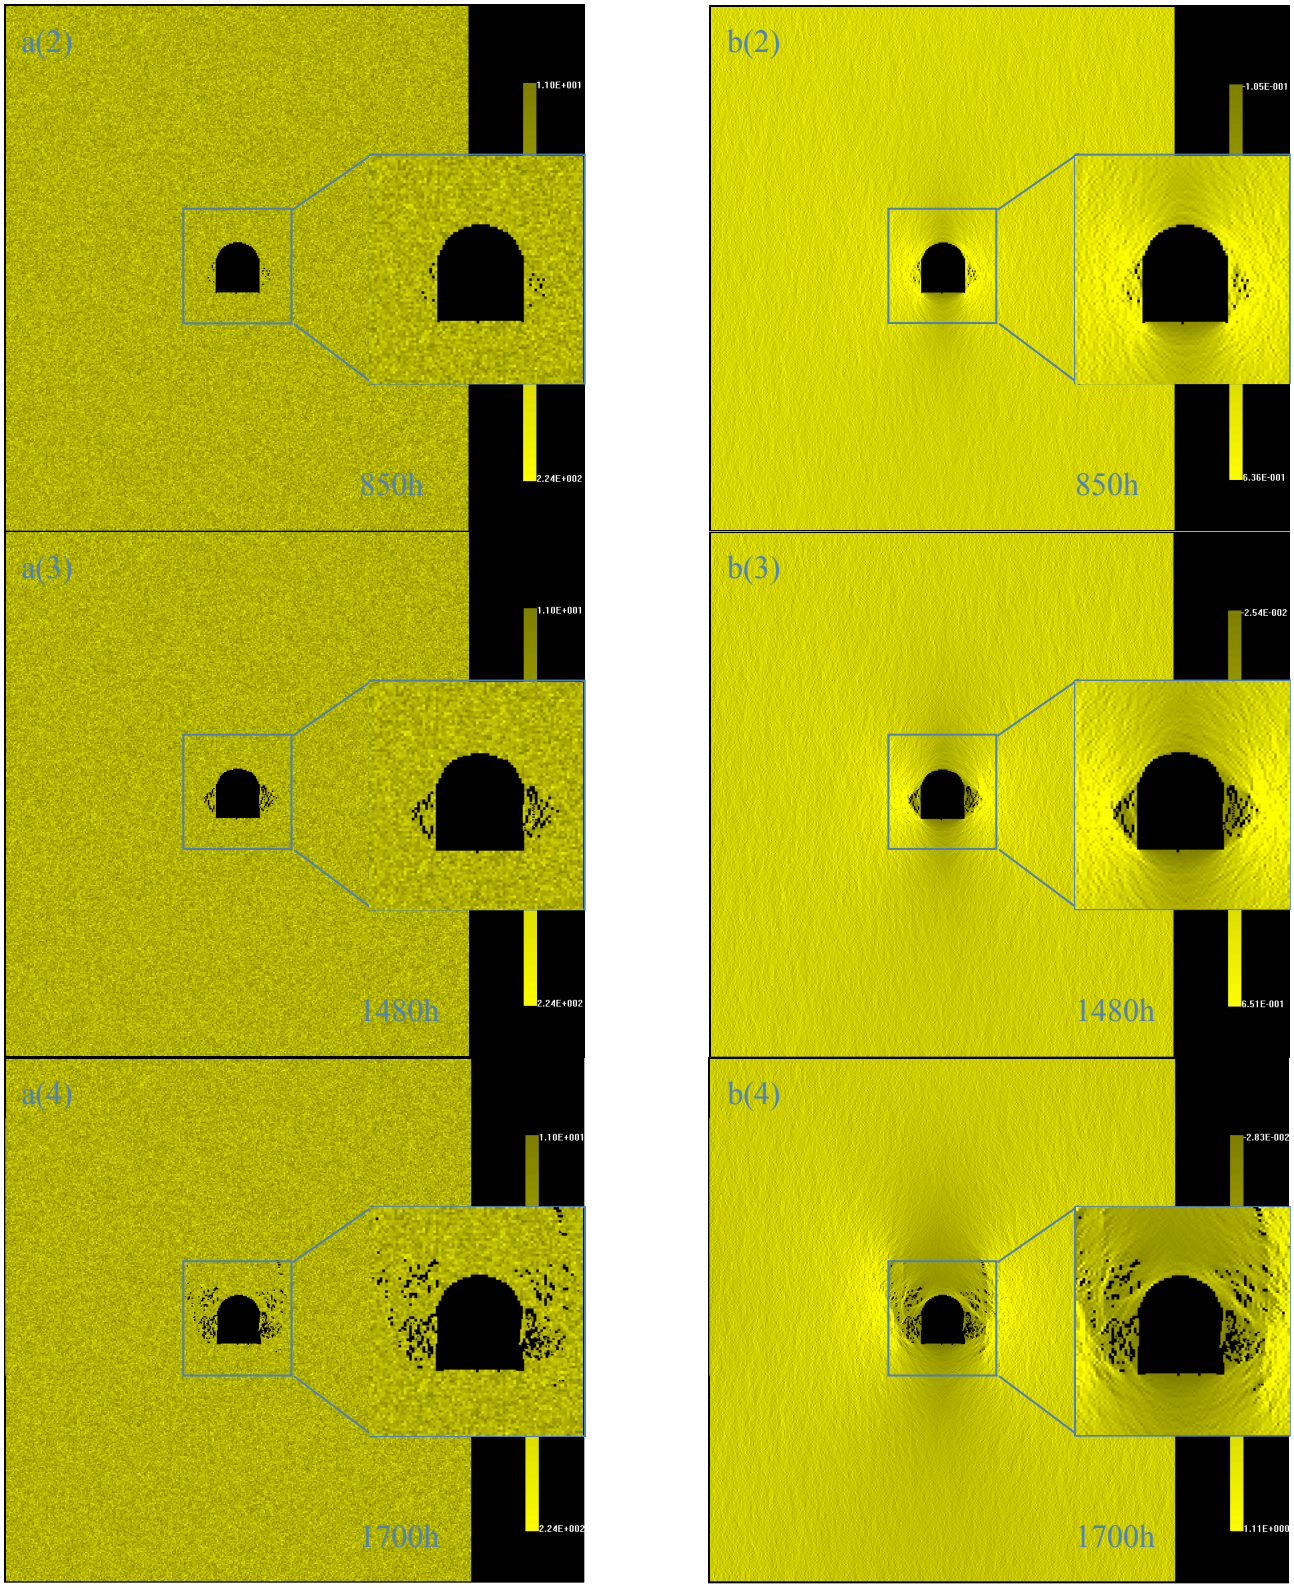


Fig. 5 Numerically obtained time-dependent failure mode of tunnel, (a) failure mode shown with modulus, (b) maximum shear stress evolution

## Conclusions

In this study, a numerical model in an attempt to replicate the time-dependent deformation of heterogeneous rock mass was presented. In the model, the time-dependent deformation is described in terms of degradation of intrinsic physical and mechanical properties of rock and accumulation of mesoscopic damage inside the rock.

Using this model, implemented in the RFPA$^{2D}$, uniaxial numerical experimentation and tunnel numerical model case are numerically constructed and investigated respectively. It is shown that the long-term features of rock mass can be accurately modeled with the proposed approach:

(a) The results of the uniaxial numerical experimentation show that the strain laws agree well with the experimental results and the model well reflects the initial creep, steady creep of rock and accelerated creep. These preliminary prove the validity of the strength degradation model;

(b) In view of the application of the strength-degradation model in the reproducibility of the tunnel scale model experimentation, we can see that the displacement curves from the numerical simulation shows a good agreement with that in the physical model tests. After the tunnel model is loaded, the tunnel surrounding rock stress occur redistribution and there is a rapid initial instantaneous elastic deformation. Then under the long-term load, the destructions of both of side walls, roof and floor focus on creep, with deformation rate lower than the previous stage; this phase is called the transient creep stage. As the rock mass strength attenuates constantly, or environmental factors change, such as load change, the displacement may increase rapidly, and then creep damage occurs.

**Keywords:** Surrounding Rock; Broken rock zone; Elastic-plastic analysis; Multi-point displacement meter;

**Abstract.** The use of the Analysis and calculation with elastic-plastic theory and Deep displacement of surrounding rock measurement determine the distribution range on broken zone of surrounding rock in Cha Zhen tunnel ; it verifies The stability of surrounding rock and the design rationality of bolting parameters ;Providing a theoretical base for the setting on broken zone of surrounding rock supporting parameters.

## Introduction

As the rapid development of highway tunnel construction and the continuous renewal of tunnel construction technology in China, the introduction of various kinds of modern construction machinery possibly makes Blasting excavation replaced by Mechanical excavation. However, drilling and blasting method is still the main method of tunnel excavation in the mountains. In engineering practice, In order to optimize the design scheme, it's essential to minimize the disturbance of rock and drill blasting excavation on the surrounding rocks as much as possible, and to play the bearing capacity of surrounding rock to maximum. In the construction of Cha Zhen Tunnel, it unites the elastic-plastic theory with deep displacement monitoring method to determine the range of the broken zone of surrounding rock ,which offers a more reliable basis in the design of surrounding rock bracing.

In recent years, many scholars have studied a lot on broken zone of surrounding rock. GUO Liang,LI Jun-cai ,who used ground penetrating radar to determining the broken zone about bias tunnel and get the range of the bias tunnel's broken zone(GUO Liang et al.,2011).LI Ning,DUAN Xiaoqiang, Who used The process of tunnel's working face and monitoring data, by using the analysis of plastic theory， acquiring the rock parameters of the real state(LI Ning et al.,2006).

Li Zheng Lin, Wu Ruixiang using bilinear stress injury model and the Stress equivalence principle to obtain the analytical solution of theoretical analysis， and Validated it through projects(Li Zhenglin et al.,2011). Dong Fangting and other scholars put for forward the Detailed method of support theory of Broken Zone of Surrounding Rock Through a large coal mine tunnel testing and laboratory testing(Dong Fangting,2001;GONG Jian-wu,2007).

## Project Overview

Cha Zhen Tunnel, with the total length of 1496m, which is located between Yufeng village and Chazhen village of Xixiang County has one-way two lane.Lithology is mainly moderate and intense weathering metamorphic andesitic basalt, and the surrounding rock is mainly IV class, V class. The main groundwater is bedrock fissure water,structural fissure water， and little layer pore water spread over its surface.

The construction clearance of Cha Zhen Tunnel is: clear width of 10.25m, clear hight of 6.8m. The inside radius of the arch wall of the designing inner contour is 5.0m, of the inverted arch is 15.0m. The biggest excavation line is 12.88m. Construction adopts NATM and Composite lining support. The initial support uses sprayed concrete of C25, steel fabric and hollow grouting anchor rod whose length is 3.5m; the secondary support adopts C30 overall model of reinforced concrete lining and Core-keeping Ring Cut blasting Method.

**Adopt elastic-plastic analysis to determine Broken Zone of Surrounding Rock**

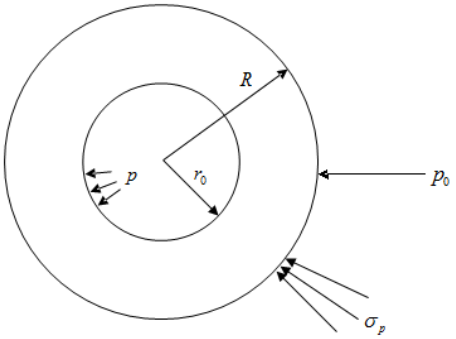

Fig . 1 Elastic-plastic area of tunnel

The method of elastic-plastic mechanics can establish equation on the basis of the character that elastic stress is equal to the plastic stress between the plastic zone and the elastic zone interface(REN Qingwen,2001), and deduce the computational formula of the surrounding rock's radius. It is regarded as axisymmetric problem and assumes that initial ground stress is ,inner pressure is,lateral pressure coefficient is 1, cohesion is,angle of internal friction is,radius stress ishoop stress is,As shown in picture 1, the excavation radius of the tunnel is,the plastic zone's radius is,and the thickness of the broken zone of surrounding rock is:

$$\mathrm{B} = R - r_0 \tag{1}$$

Regardless of the volume strength in the plastic zone, the differential equation of equilibrium of axisymmetric problem is:

$$\frac{\mathrm{d}\sigma_r}{\mathrm{d}r} + \frac{\sigma_r - \sigma_\theta}{r} = 0 \tag{2}$$

The yield criterion adopts Mohr-Coulomb yield criterion:

$$\tau_f = c - \sigma_n \tan\varphi \tag{3}$$

Or it could be expressed as $\sigma_1(1+\sin\varphi) - \sigma_3(1-\sin\varphi) = 2c\cos\varphi$ (4)

When we adopts $\sigma_1, \sigma_2, \sigma_3$ ,($\sigma_1 \geq \sigma_2 \geq \sigma_3$) for principal stress

If $\sigma_1 = \sigma_r, \sigma_3 = \sigma_\theta$, we can acquire the equation (5) and then (6):

$$\sigma_r(1+\sin\varphi) - \sigma_\theta(1-\sin\varphi) = 2c\cos\varphi \tag{5}$$

$$\sigma_\theta = \frac{\sigma_r(1+\sin\varphi)-2c\cos\varphi}{1-\sin\varphi} \tag{6}$$

Put equation(6)into equation (2), and we can reach:

$$\frac{\mathrm{d}\sigma_r}{\mathrm{d}r} - \frac{2\sigma_r\sin\varphi}{r(1-\sin\varphi)} = -\frac{2c\cos\varphi}{r(1-\sin\varphi)} \tag{7}$$

integrate equation (7), and we can get $\sigma_r = c\cot\varphi + c_1 r^{\frac{2\sin\varphi}{1-\sin\varphi}}$, in the boundary condition: $(\sigma_r)_{r=r_0} = -p$, and we can also reach: $c_1 = \frac{-p-c\cot\varphi}{r_0^{\frac{2\sin\varphi}{1-\sin\varphi}}}$, and

$$\sigma_r = c\cot\varphi - (p+c\cot\varphi)(\frac{r}{r_0})^{\frac{2\sin\varphi}{1-\sin\varphi}} \tag{8}$$

Substituting the equation (8) into equation (6), we can get the plastic zone's stress:

$$\sigma_\theta = c\cot\varphi - \frac{1+\sin\varphi}{1-\sin\varphi}(p+c\cot\varphi)(\frac{r}{r_0})^{\frac{2\sin\varphi}{1-\sin\varphi}} \tag{9}$$

In the elastic zone($r \geq R$) according to Lame Answer of elastic mechanics, we can assume that stress at $r=R$ is $\sigma_p$, initial ground stress in the distance is , we can get:

$$\left\{\begin{array}{l}\sigma_r = -\frac{R^2}{r^2}\sigma_p - (1-\frac{R^2}{r^2})p_0 \\ \sigma_\theta = \frac{R^2}{r^2}\sigma_p - (1+\frac{R^2}{r^2})p_0\end{array}\right\} \tag{10}$$

Add the equations of (10) together, we can get: $\sigma_\theta + \sigma_r = -2p_0$, at the same time, this equation can meet the requirement, and then combine it with equation (8) and (9), we can reach:

$$\sigma_r = c\cos\varphi - p_0(1-\sin\varphi) \tag{11}$$

Because of $(\sigma_r)_{r=R} = \sigma_p$, equation(8) is equal to equation(11), and then combine them eliminating , finally we can get Fenner formula to determine the scope of the broken rock zone.

$$\frac{R}{r_0} = [\frac{(c\cot\varphi+p_0)(1-\sin\varphi)}{p+c\cot\varphi}]^{\frac{1-\sin\varphi}{2\sin\varphi}} \tag{12}$$

This paper chooses the tunnel's left hole ZK225+527 as an example. The depth of tunnel is 150m, natural stress ratio =1.This paper assumes $\sigma_h \approx \sigma_v = \sigma_0$, the initial ground stress is caculated as geostatic stress, and $p_0$=3.672, The selection of rock parameters is shown in table1.

Tab . 1 The parameter selection

| rock grade | elasticiy modulus E MPa | Bulk density V KN/m$^3$ | Friction Angle $\varphi$ ° | Cohesive force $c$ MPa |
|---|---|---|---|---|
| Ⅴ | 15 | 24.48 | 31 | 0.67 |

Combined with the tunnel's monitoring measurement data, at the vault of tunnel section ZK225+527, the contact pressure between the surrounding rock and the initial lining at the angle of 45°,90°,135°.is 32.7215 k Pa， 22.7035 k Pa， 24.5672 k Pa .

Put the parameters into the equation(12), the tunnel's excavation radius is $r_0$ =5.0m

$p$ =32.7215 k Pa , we can reach： $R/r_0$ = 1.393，and then B= $R-r_0$ =1.965 m；

$p$ =22.7035 k Pa ， we can reach: $R/r_0$ = 1.399，and then B= $R-r_0$ =1.995 m；

$p$ =24.5672 k Pa ， we can reach： $R/r_0$ = 1.398，and then B= $R-r_0$ =1.990 m.

Above all, we can get the scope of the broken rock zone $1.965 \le B \le 1.995$

**Measure the displacement of the deep surrounding rock to determine the broken rock zone**

Cha Zhen tunnel adopts multiple position extensometer to measure the rock's displacement in different depths, and then according to the displacement measurements and temporal curve we can get displacements measurements within the rocks in different depths. Ideally, the displacement of the deep surrounding rock is more smaller when it is more farther from the excavation contour surface, and it's Generally linear with depth. If there is displacement mutation between adjacent two points, it shows that the surrounding rock's interface exists between these two points. When adjust the supporting parameters it needs anchor stock overstep these points. If the displacement between adjacent two points changes on average and meanwhile there exists larger displacement in the deepest point, it'll show that the surrounding rock's disturbed scope is larger, it's not enough only to adjust the length of anchor stock but needs further comprehensive measures.

This paper chooses the typical section ZK225+527 as the monitoring section, respectively bury three groups of multiple position extensometer at vault and both sides of the arch waist place, each of them has three points respectively monitoring the surrounding rock's displacement at hole's depth of 1m,2m,3m. Multi-point displacement meter embedded graph is shown as picture 2.

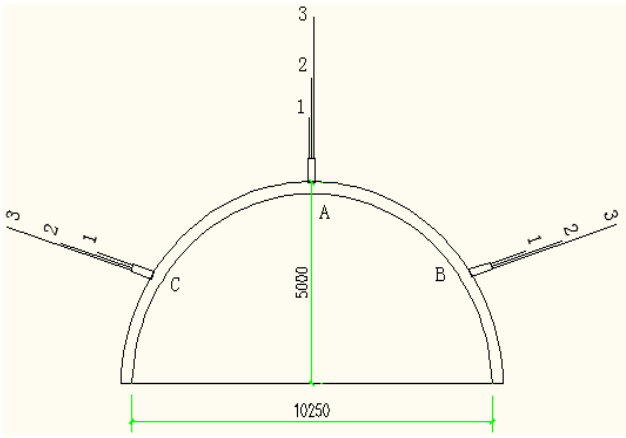

Fig . 2 Multi-point displacement meter embedded graph

This monitoring lasts 60 days, the frequency of the monitoring is twice a day from day1 to day15. once for two days in 16—30days, twice for two weeks in 30—60days, and choose accumulative data of multiple position extensometer as analytic object. The data of multiple position extensometer which is monitored is shown in table2.

Tab . 2 Multi-point displacement meter test results

| Measuring point | | Hole depth m | displacement mm |
|---|---|---|---|
| A | 1 | 1.0 | 23.36 |
| | 2 | 2.0 | 3.31 |
| | 3 | 3.0 | 1.52 |
| B | 1 | 1.0 | 16.98 |
| | 2 | 2.0 | 1.18 |
| | 3 | 3.0 | 0.95 |
| C | 1 | 1.0 | 25.42 |
| | 2 | 2.0 | 2.64 |
| | 3 | 3.0 | 2.20 |

From the table, three groups of displacements tend to be smaller along with the depth,but don't have linear relation. The displacement of point 1 is lager while point 2 and point 3 are smaller, and there is a mutation between point1 and point 2. Above all, we can get the thickness of the broken rock zone :1.0<B<2.0m.

## Conclusions

①Combining the result of elastic-plastic theory with the analysis of the measured data, we can get that the scope of broken rock zone of Cha Zhen tunnel is between 1.9m and 2.0m.Actually, the designed length, which is 3.5m, can meet the needs of practical engineering and ensure the surrounding rock's stability.

②This paper verifies that Elastic plastic formula has high accuracy when it calculates the scope of broken rock zone, especially the tunnel with circular section, but should have higher accuracy for initial ground stress.

③It seems intuitive using multiple position extensometer to monitor the surrounding rock's deformation, but the result is not so accurate because of many disturbing factors and changeable rock conditions. So it should consider theoretical analysis to better determine the scope of broken rock zone.

④The broken rock zone is an important parameter for tunnel's design and construction , and the important parameter to assess the stability of the surrounding rock.Cha Zhen tunnel's using of method which combines theoretical analysis with measurement at the job site lays the foundation for supporting system's optimization and provides a strong guarantee to ensure the safety of tunnel construction .

# Numerical simulation study on three-step method Construction for Neighborhood tunnel

Cai Lingling, Yang Xiuyuan, Guo Ning

Center for Hydrogeology and Environmental geology, CGS , Baoding, Heibei,China

caill00@163.com

**Keywords:** neighborhood tunnel, numerical simulation, stress field, displacement field

**Abstract.** When crossing difficult terrain or extreme regional geological conditions encountered, there are difficulties in laying road routes, the spacing between two adjacent tunnels is limited. Neighborhood tunnel is a form of tunnel structure between separate and arch ones, less affected by the topography. It is more conveniently and easier to control the cost. Surrounding rock deformation mechanism with construction of three-step method is more complex, and therefore a reasonable means of construction technology and support is essential. Taking a certain neighborhood tunnel highway engineering background, aimed to provide guidance for follow-up monitoring and support, we use numerical simulation software FLAC$^{3D}$ on three-step method excavation construction. Rational creep analysis of geotechnical model and calculation parameters is selected. It helps to calculation and analysis the mechanical response of tunnel surrounding rock characteristics and clarify the tendency of displacement and stress fields.

## Introduction

When complex terrain or extreme regional geological conditions encountered, difficulties of laying road routes arise. In this case the construction of the tunnel project, about road width is difficult to form a separate lane distance, requiring the use of neighborhood tunnel or arch tunnel [1]-[2]. Neighborhood Tunnel is a tunnel in the form between separate tunnel and arch tunnel. It is more conveniently and less affected by topography. In recent years, many scholars have carried out research associated with it[3]-[5]. Here we take Shi-Man expressway project which was constructed with three-step method as the example, and analysis of the mechanical response characteristics after excavation by numerical simulation calculation FLAC$^{3D}$ .

## Project profile

Shi-Man Expressway crossing region is located in the Qinba mountainous hinterland, at an altitude between 100 ~ 1596.2m, belonging to mountainous terrain. Route strides over four types of landscapes, as follows: tectonic erosion of the low mountains, tectonic denudation of the hilly, mountain basin tectonic denudation and erosion valley accumulation. The area attributes South Qinling miogeosyncline fold belt on tectonics, complex lithology and fissure karst water groundwater mainly water -based.

## Calculation model and simulation program

### 3.1 Tunnel construction and model selection

The study takes neighborhood tunnel to the highway as the main object. To facilitate the simulation, the three- step method excavation can simplify to four major procedure, as follows: construction in right steps →construction in the upper left and middle right steps →construction in middle left and lower right steps →construction in left steps.

If the country rock condition is complex in engineering practice, it will show various characteristics of composite or overlay after excavation. FLAC$^{3D}$ can simulate the creep properties of the material which is related to the time. But a single model can not reflect the actual deformation.

Burgers model and Mohr-Coulomb model is combined here to be a viscoplastic model (Fig.1), it can better reflect the deformation characteristics of soft rock. Rock in the tunnel appears viscoelastic performance before the yield, and viscoplastic performance after entering the yield, with a clear three-stage creep curve.

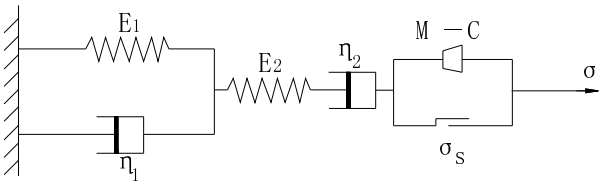

Fig.1 Modified Burgers creep model

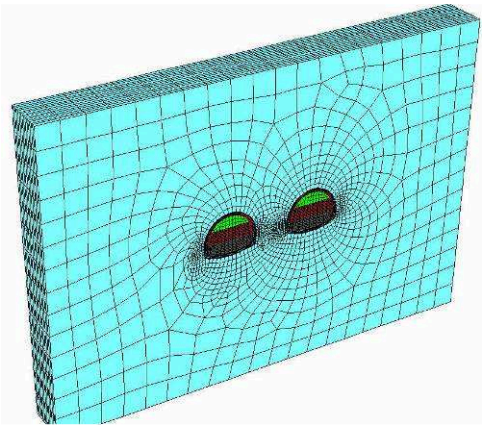

Fig.2 Tunnel model

3.2 Computing model

According to the terrain conditions, the maximum depth of the tunnel is 47m. Due to poor mechanical properties of rock, large rock deformations occur easily. Rock Classification is mostly at level Ⅳ～Ⅴ. By simplifying the geological model, the model boundaries is rather than three times the effective diameter of the neighborhood tunnel, namely the horizontal length of 100m, vertical height of 70m, vertical take 10m that a construction cycle. Model set boundary conditions that limit the model in addition to the five ground surface boundary edge interface, based on the model of the surface terrain conditions under its own weight load stress. Bearing on the bottom plus a fixed model to restrain all degrees of freedom, and in parallel to the sides of the tunnel plus sliding bearings, only restrain degrees of freedom in the X-axis direction. In summary, through the above modeling requirements, a three-dimensional tunnel model (Fig.2) is established, containing 37,335 units and 40,384 nodes.

3.3 Calculation parameters selected

Rock relaxation and destruction after tunnel excavation is a dynamic process, affecting by many factors and complex mechanism of action. Tunneling-induced rock initial stress release and adjusting is finally bound to form elastic and plastic zones in the tunnel. The strength and deformation characteristics of rock within the range will deteriorate. Considering structural surface, interlayer and other uncertainties inside the rock, its mechanical properties are very different from experimental rock mechanical parameters. In order to reflect the deterioration of the mechanical parameters as much as possible, we appropriately reduce the mechanical parameters , the parameters used in the simulation is then reduced : $E_M$＝1.17GPa,$E_K$＝0.98GPa,$\eta_M$＝$16.5\times10^3$GPaS,$\eta_K$＝$4.57\times10^3$GPaS,E＝1.8GPa,μ＝0.3,C＝0.3MPa,Φ＝23º, the tensile strength = 0.32MPa.

## Simulation results

4.1 Analysis of the displacement field

After excavation and initial support in three-step method construction for neighborhood tunnel, the vertical displacement and horizontal displacement field distribution changes (shown in Fig.3). According to the simulation results, when construction in right steps is finished, vault settlement is 2.80mm; when construction in the upper left and middle right steps is finished, vault settlement is 25.49mm; when construction in middle left and lower right steps is finished, vault settlement reaches 36.31mm; when construction in left steps is finished, which means all sections are completed, vault settlement reaches the maximum of 65.77mm.

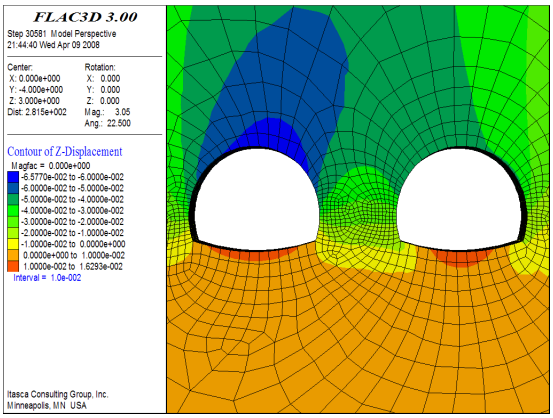

Fig.3a The final Z direction displacement

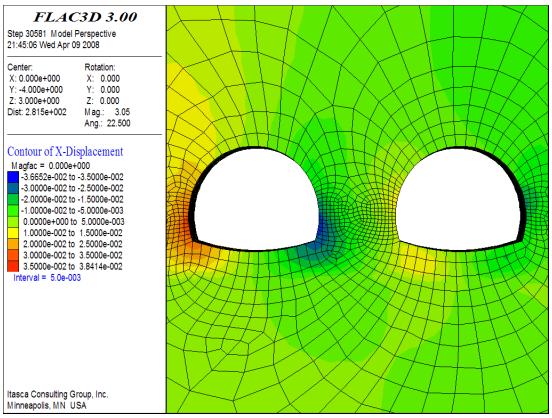

Fig.3b The final X direction displacement

In terms of horizontal displacement, when construction in right steps is finished, the maximum convergence is 0.5mm; when construction in the upper left and middle right steps is finished, the maximum horizontal displacement is 11.39mm, located in the right steps outside the cave wall with horizontal displacement of the inner sidewall of 11.34mm and the inside on the left stepped buttresses maximum horizontal displacement of 7.5mm; when construction in middle left and lower right steps is finished, the maximum horizontal displacement is 17.27mm, located in the right steps outside the cave wall; when construction in left steps is finished, the maximum horizontal displacement gets 38.41mm, located in the left side wall parts.

4.2 Stress field analysis

After excavation and initial support in three-step method construction for neighborhood tunnel, maximum and minimum principal stress distribution changes (shown in Fig.4). According to the simulation results, when construction in right steps is finished, principal stress σ1 maximum compressive stress is 2.70MPa and tensile stress is 0.02MPa, located in the right steps outside the cave wall; principal stress σ3 maximum compressive stress is 0.97MPa and tensile stress is 0.14MPa, having a small amount of the distribution at the top of the arch and the bottom on the steps. When construction in the upper left and middle right steps is finished, principal stress σ1 maximum compressive stress is 9.56MPa and tensile stress is 0MPa, focused on top of the arch of the right hole. When construction in middle left and lower right steps is finished, principal stress σ1 maximum compressive stress is 11.04MPa and tensile stress is 0MPa, located in both arch of two holes, but the maximum value is found in right hole. There also has a small distribution at the right side of the right hole. Principal stress σ3 maximum compressive stress is 1.0MPa and tensile stress is 0.10MPa, located at the bottom of both two hole. When construction in left steps is finished, principal stress σ1 maximum compressive stress is 15.97MPa and tensile stress is 0MPa, principal stress σ3 maximum compressive stress is 1.26MPa and tensile stress is 4.98MPa, concentrated on both sides of the right holes' foot.

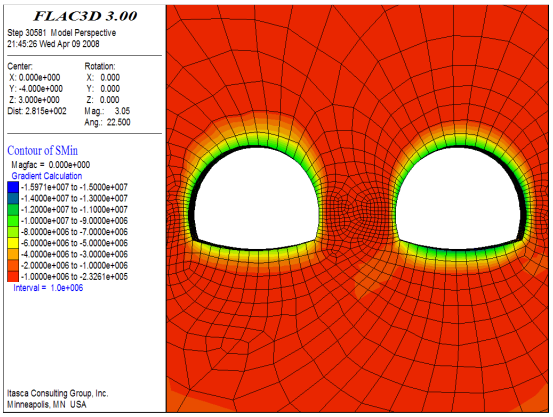

Fig.4a The maximum principal stress

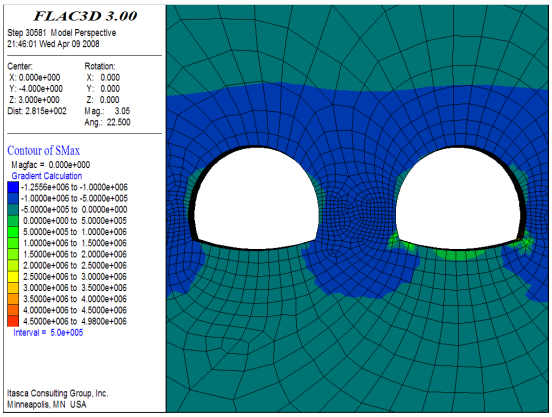

Fig. 4b The minimum principal stress

Neighborhood Tunnel excavation at each step of the maximum displacement and the maximum / minimum principal stress is shown in Table 1.

Table 1 Comparison of the displacement and principal stress

| step | maximum displacement (cm) | | maximum / minimum principal stress (MPa) | | | |
|---|---|---|---|---|---|---|
| | | | $\sigma_1$ | | $\sigma_3$ | |
| | Z | X | press | tense | press | tense |
| 1 | 2.80 | 0.5 | 2.70 | 0.02 | 0.97 | 0.14 |
| 2 | 25.49 | 11.39 | 9.56 | 0 | 1.43 | 0.06 |
| 3 | 36.31 | 17.27 | 11.04 | 0 | 1.00 | 0.10 |
| 4 | 65.77 | 38.41 | 15.97 | 0 | 1.26 | 4.98 |

## Conclusion

It can be learned from numerical simulation on the three-step neighborhood tunnel construction methods, after construction is completed the vault maximum settlement value is up to 65.77mm, the maximum horizontal displacement value is up to 38.41mm (located in the left bottom part of the left hole); principal stress $\sigma_1$ maximum compressive stress is 15.97MPa and tensile stress is 0MPa； σ3 maximum compressive stress is 1.26MPa and maximum tensile stress is 4.98MPa, concentrated on both sides of the arch foot in the right hole. In the excavation and construction, it should be the importance of these parts above-mentioned and strengthen the monitoring and measurement together with lining for the tunnel timely.

**Keywords:** fully mechanized caving face, pressure appearance law, pressure observation, mining roadway

**Abstract.** Taking the first fully mechanized caving face in Xiagou coal mine as research background, through the pressure observation on the scene field of fully mechanized caving face with rock burst danger, this essay reveals the pressure appearance law of coal seams rock burst danger and concludes that the field roof structure of fully roof mining is more conducive to the release of coal rock stress compared to layered mining structure and this method plays a mitigation role on moving pressure shock of coal rock. The fully mechanized caving faces can be explored fast under safety conditions. The research results are of great theoretical and practical significance to the mining production with similar geological conditions.

## Introduction

ZF4401 working face is the first caving fully mechanized caving face in Xiagou coal mine and it is located on the western flank of three down hills in 404 mining area. The non-mining district is on the western end of the face and the three down hills coal pillars are on the eastern end, leaving 2.5~3.5m at the bottom of the face. The inclined length of the face is 186m, and the inclination of its first 77.8m is 25 ° as well as the inclination of its last 108.2m is 7 °.

## Layout of measuring points on the working face

The comprehensive pressure observation on 4401 face was carried out through laying out three key measuring areas to do "three volume" observation. I test area was on the 15, 16 frame, Ⅱ test area was on the 50, 51 frame and III test area was on the 85, 86 frame. At the same time the chart recorder observation was done on the 50 frame [1]. The layout schematic diagram of working surface area is shown in Fig.1.

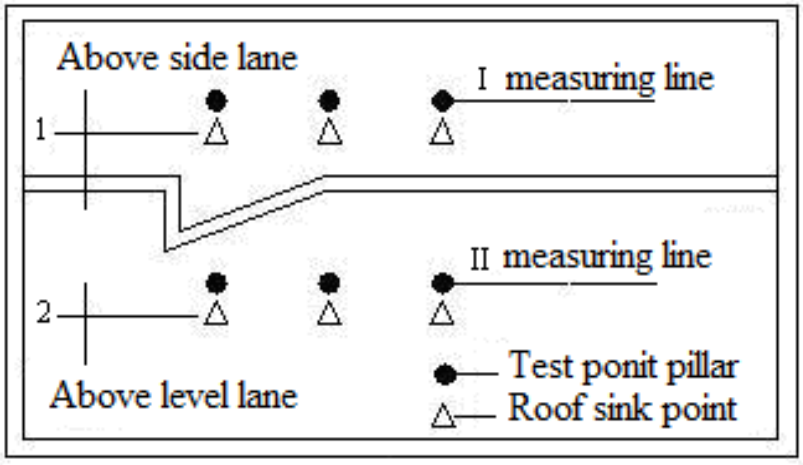

Fig.1 Layout of test areas on the working face

We used the roof dynamic method to observe the pressure distribution law of advanced support. Seven dynamics detectors were laid out in track, the space of which was five meters, as shown in Fig. 2.

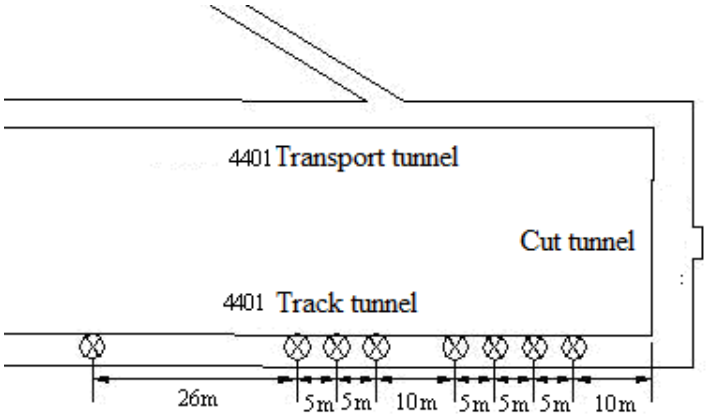

Fig.2 Layout of Roof dynamic detectors

**Initial and periodic pressure**

The push-production of 4401 face began on April 28, 2005. When the above push mining distance reached 20m, the direct roof of 4401 face felled without any water spray on the face and its gob-sides. During the period of direct roof initial collapse, the pressure increase of face frame was not apparent; however, the caving phenomenon of face side and local top coal appeared. But, when the above push mining distance reached 27m, meanwhile when the bellow push mining distance reached 35.5m to the western side of cut hole, the basic top initial pressure in working face began, as shown in Fig.3.

The number of coal cannons before initial pressure increased up to more than 10 times with a modest sense of vibration in the central. The working resistance of support increases were not obvious and some reduced, in which 70~74 frames spelled with the depth of 0.4m, 82~87 frames spelled with the depth of 0.8m, 63~64 frames spelled with the depth of 0.5m and 42～45 frames spelled with the depth of 0.3m.These data showed that the initial pressure was biggest at coal wall[2].

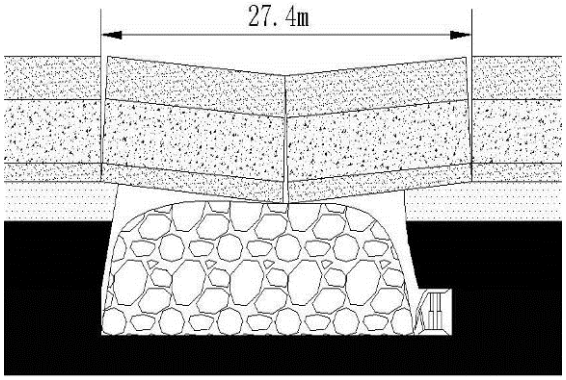

Fig.3 First pressure rock structure on working face

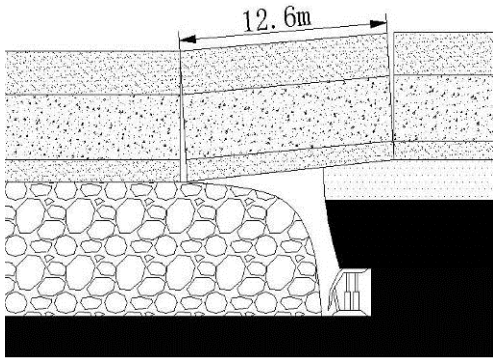

Fig.4 Periodic pressure rock structure on working face

It could be drawn from the comparison and statistics results of support resistance around the appearance of face periodic pressure that the pressure increased little when the face main roof periodic pressure came. The increase range of support resistance was around 4.9MPa on average and the safety valve did not opened, as shown in Fig.4.

**Laws of mining face pressure appearance**

The measured initial supporting force of bracket during the observation was 25.87MPa on average while the design support force was 31.5MPa, which was only 82.1% of rated initial support force. The initial supporting force of bracket during pressure was 26.12MPa on average, which was 82.9% of rated initial support force. The frequency distribution of initial supporting force is shown in Fig. 5.

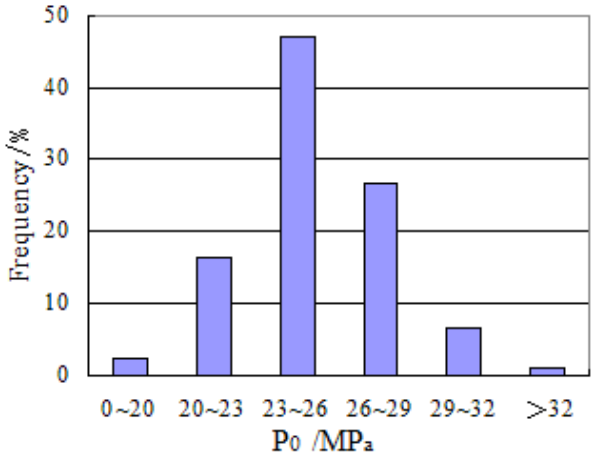

Fig.5 Frequency distribution histogram of initial supporting force ($P_0$)

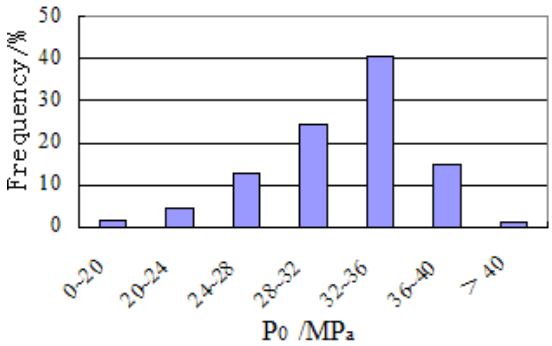

Fig.6 Frequency distribution histogram of working resistance ($P_0$)

Fig.5 shows that the initial supporting force between 23MPa and 26MPa accounted for 46.9%, while the same force between 23MPa and 29MPa accounted for 73.7%. And the conclusion can be drawn from the measured average initial support force and its distribution characteristics that the initial support force of bracket is relatively high so that it can meet the practical requirements.

The measured working resistance of bracket during the observation was 32.7MPa on average while the design working resistance was 38.0MPa, which was only 86.1% of rated working resistance. The working resistance of bracket during pressure was 35.92MPa on average, which was 94.5% of rated working resistance. The frequency distribution of working resistance is shown in Fig. 6.

Fig.6 shows that the working resistance between 24.0MPa and 36.0MPa accounted for 77.8%. The percent of working resistance above 32.0MPa is near 60% while the percent above 28.0MPa exceeds 80.0%.

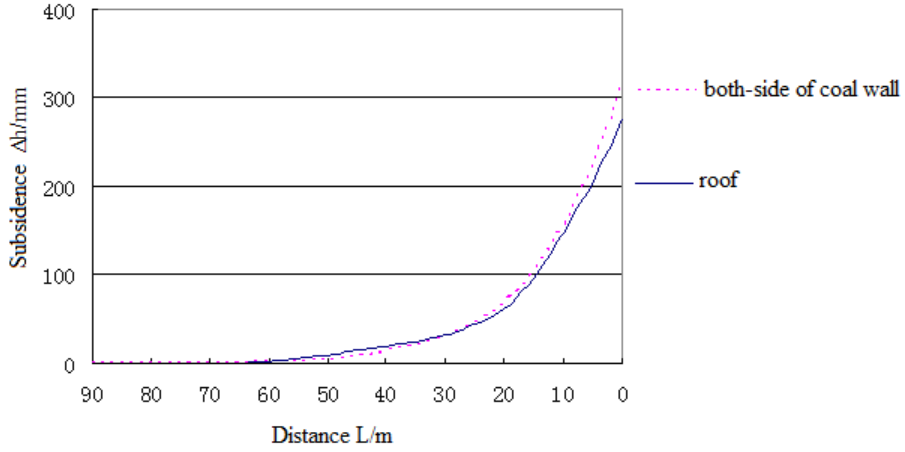

Fig.7 Curve of the relationship between displacement and distance on both-sides of tunnel

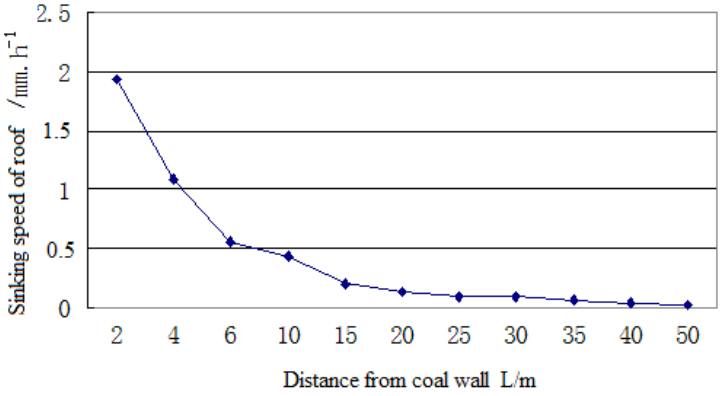

Fig.8 Curve of the relationship between velocity and distance on roof

**Pressure appearance laws of mining tunnel**

We can make the surface displacement curve of surrounding rock and the displacement velocity curve by sorting out the observation data, as shown in Fig.7 and Fig.8. Based on the roadway displacement curve, the mining influence on tunnel can be analyzed [3-4].

From the above analysis, it can be concluded that the pressure appearance of transportation tunnels is significant when the working face advance support distance is 50m; meanwhile the phenomenon of bottom drum and roof local fracture occurs at the advanced support pressure zone. But the moving speed of tunnel sides is faster than the roof subsidence during the coal mining influence stage. The coal body roof outburst distance is between 150mm and 200mm while the lower part distance is between 20mm and 60mm when the mining distance is at the range of 5m to 40m close to the working face export. And the bending deformation of anchor steel appears at the same time. Also from the observation results it can be seen that the design of tunnel support can basically meet the support requirements.

**Conclusions**

•The direct roof of 4401 fully mechanized caving face in Xiagou coal mine belongs to the second kind of roof, the initial caving step distance of which is 11.3m. The initial roof caving step distance of old roof is 27.4m and the periodic pressure step distance is 12.6m on average. So its roof stability is jugged as medium, that is II level and its pressure appearance is obvious.
•The geological mining condition of 4401 working face is stable and the step sink of coal roof will not happen.
•The field roof structure of fully mining is more conducive to the release of coal rock stress compared to layered mining structure and this method plays a mitigation role on moving pressure shock of coal rock.

**Keywords:** roadway; original rock stress; sight instrument; ultrasonic test; bolt support; numerical simulation

**Abstract.** In order to tunnel safely, efficiently and economically, we carried out the study on geostatic stress characters and optimizing bolting support parameters in 2# coalbed of Zijin Colliery. Based on the surveys of geological conditions, original rock stress, broken rock zone measurement and analysis of roadway deformation, characters and mechanism of roadway failure is figured out. According to existent problems, normal support theories were used and a variety of numerical computations were carried out by FLAC$^{3D}$.New support methods of bolt installed vertically in tilted roof and strengthen support of sidewalls and corners of roadway were figured out. Monitoring of convergence meters and roof separation were followed to know effects of new design timely. The research was carried out for 600 meters The monitoring results proved that the optimized support design was viable and the new bolting parameters were reasonable.

## Introduction

Due to the complicated geological conditions and existence of the tectonic stress, rock failure and stress distribution of the roadway[1,2], which is located in tilted strata, present asymmetry. Meanwhile for the existence of soft rocks, the range of broken rock zone is quite wide[3], and traditional symmetrical support is difficult to control rock formation effectively[4]. So many scholars have carried out extensive research on failure mechanism and its support measures[5].

Taking advantage of stress sensor[6] , ultrasonic test[7] and sight instrument[8], the maximum principal stress, thickness of broken rock zone and rock fissures situation of surrounding rock of 2# coalbed in Zijin mine can be got .The reasons of rock deformation and failure is analyzed. On this basis, according to the theory of strengthening sidewall support and corner support[9], the original support design and many optimized support designs are compared and analyzed by FLAC $^{3D}$[10]. In these ways, support problems of 3024 workface can be effectively solved.

## Geological conditions

Zijin Colliery is located in Huozhou city, Shanxi Province, 2# coalbed in Shanxi formation is mainly mined in 3204workface. The coal is mainly made up of semibright coal and durain comes second. The structure is layered and the dip angle of the coalbed is 8°~10°.The coalbed is medium strength ,f<1.5. The joint and stratification are medium developmental. The fracture is uneven and brittle. The striation is black. The thickness of coalbed is 2.04~2.06m. The roof is made up of black mudstone with a thickness of 0.2m, and sometimes becomes to grey sandy mudstone. The joint and stratification are both developmental. The floor is made up of sandy mudstone and the stratification is developmental. , Fig 1.shows rock formation of surrounding rock. The gas emission of 3204 workface is 2.63m$^3$/min. Mine inflow mainly comes from K8 fracture aquifer of sandstone. The estimated normal water inflow during driving is 6m$^3$/h and the maximum water inflow is 15m$^3$/h.

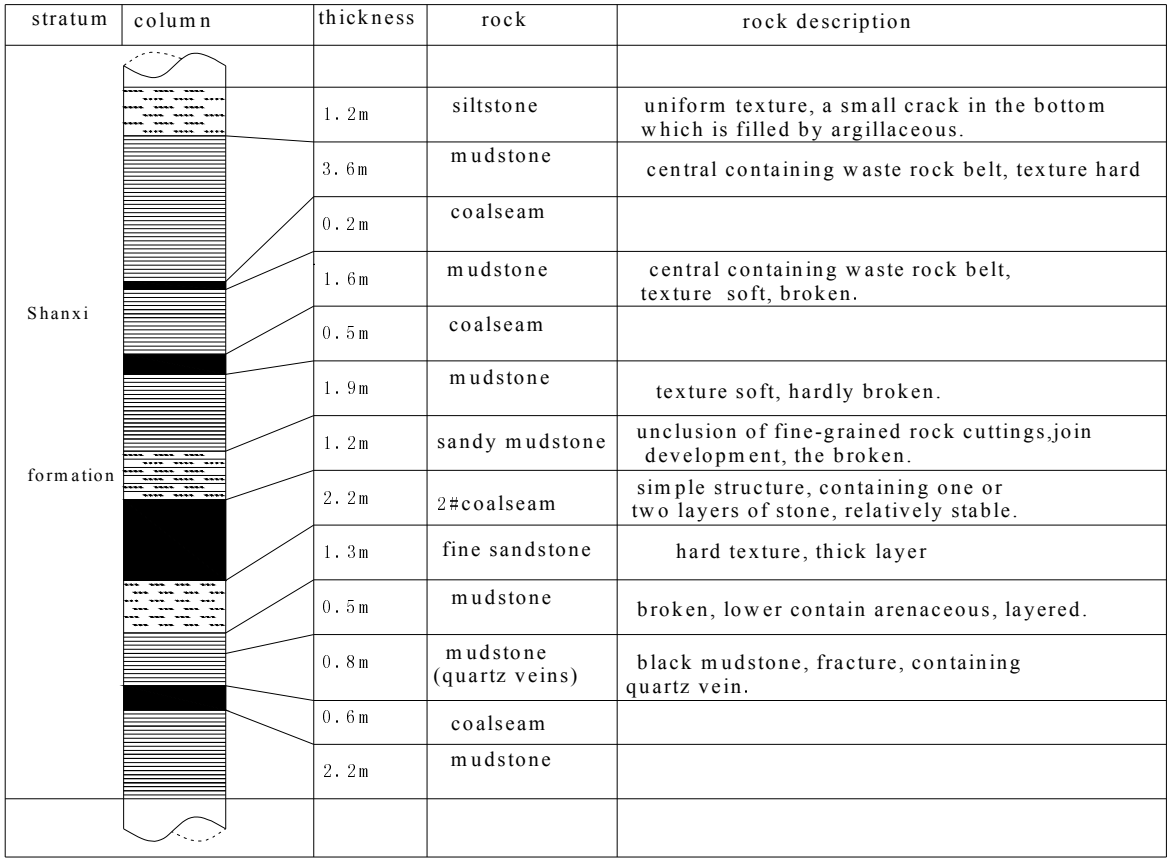

Fig 1 Rock formation of 2# coal bed

**Original rock stress**

Stress relief method was used in our test, the instrument is CSIRO HI stress sensor,which is made in Australia. There were two monitoring position, once is in right sidewall of 3201-1 roadway ,the other is in left sidewall of west airway. There were holes , the length of them were totally 76.6m.Tab 1 shows the parameters and test results.

Tab 1 Parameters of holes and results of original rock stress

| position | rock | azimuth angle [°] | dip angle [°] | length [m] | $\sigma_{hmax}$ [Mpa] | $\sigma_{hmin}$ [Mpa] | $\sigma_v$ [Mpa] | $\sigma_{hmax}/\sigma_v$ |
|---|---|---|---|---|---|---|---|---|
| 3201-1 | siltstone | 95 | 55 | 15.25 | 15.76 | 8.25 | 8.30 | 1.90 |
| | mudstone | 92 | 31 | 15.50 | 9.34 | 0.41 | 8.30 | 1.13 |
| | fine sandstone | 67 | 4 | 15.30 | 20.75 | 6.61 | 8.30 | 2.50 |
| west airway | siltstone | 355 | 45 | 15.45 | 16.00 | 6.87 | 8.05 | 1.99 |
| | mudstone | 355 | 14 | 15.10 | 11.70 | 1.15 | 7.96 | 1.47 |

We come to a conclusion that horizontal stress is major principle rock stress, its azimuth angle is 85º～101º.Horizontal principal stress is greater than vertical stress,it's 1.13 to 2.50 times the level of vertical stress, horizontal principal stress has big effect to north-south roadway, but small to east-west roadway.

**Broken rock zone measurement**

Sight instrument and ultrasonic test were used for broken rock zone measurement. The four pictures in Fig 2 show the result of sight instrument in roof rock. The hole is 2.5 m, probe location was counted by 2.5 minus the number on steel rule. We can see clearly that there is a fracture at 2m in Fig 2(a), its width is about 8mm. When it reached about 1.4 m, shown in Fig 2(b) and Fig 2(c), anther two

fractures appeared. Finally the probe reached nearly to 0.5m, the upper-left wall in the hole dropped out for rock stress. We come to a conclusion that zone of broken rock in roof is 2.0m deep.

(a)2.0m (b)1.45m (c)1.37m (d)0.5m

Fig 2 Roof hole of roadway

We carried out ultrasonic test in order to get more accurate range of broken rock zone. The principle of ultrasonic test is that the wave velocity is different in different kind of rocks. With the development of fractures, its velocity will lower. We chose three positions and there are 14 holes in all. The result shows that the thickness of broken rock is 1.4m~2.2m.

## Characters and mechanism of roadway formation and failure

**Characters.** A survey of roadway formation and failure was done in roadway of 1201 and 3201 workface, we found the failure characters as follows. Fig 11 shows the deformation and failure of roadway.

(1) Surrounding rock was unbroken early days. With the excavation of roadway, it became hardly broken because of the effect of weathering and water supply, bearing capacity of rock reduced badly.

(2) The deformation of right sidewall was larger than left. After a period of time, bulking force results in large deformation in surrounding rock, especially in the lower coal. The deformation of roof and sidewalls was extremely broken near fault

(3) Large deformation of support components occurred. The mesh changed into shape of pocket, most of metallic belts change into waves pattern, wall caving were severe and there's no belt in sidewall support.

(4) Size of roadway shape was definitely changed because of complicated strata and construction. The height of middle roadway enlarges from 2.8m to 3.3 m, while its width enlarges from 4.2m to 4.4m.The height of sidewalls also increase obviously.

**Mechanism.** (1)High horizontal tectonic stress has big effect to north-south roadway.

(2) The coal and its roof is too soft and fractures in rock are fully developed. The existence of fault aggravates bearing capacity of rock.

(3) Force analysis of pre-stressed anchor is shown in Fig 3,when anchor is perpendicular to roof, the effective component force $F_1$ is smaller than $F'$ , while the component force $F_2$ is harm to roof stability.

Fig 4 shows two kinds of shear stress in different sections, when anchor is perpendicular to roof, the section is circular *abcd*, while it is vertically set, the section is elliptical $a'b'c'd'$.With the effect of the same shear force Fs, the maximum of shear stress in circular section is Eq 1, while in elliptical, the value is Eq 2. The dip angle of gently inclined seam is $\theta$=8°~25°, $\tau'_{\max} = 0.99 \sim 0.91\tau_{\max}$ , so setting anchors vertically can enhance shear resistance.

$$\tau_{\max} = \frac{4F_S}{3\pi r^2} \tag{1}$$

$$\tau'_{\max} = \frac{4F_S}{3\pi r^2}\cos\theta \tag{2}$$

(4) The value of torque is 120 N·m , which is too low to blot support in broken roadway. Some pressure gages were lost or destroyed, it also led to low prestress.

(5) Rigidity of meshes are not enough.

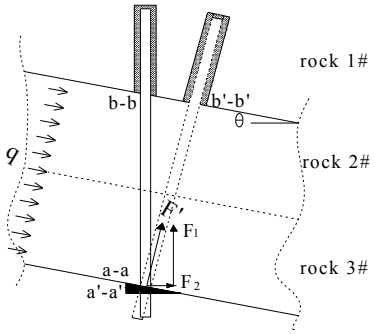

Fig 3 Force analysis of pre-stressed anchor in roof

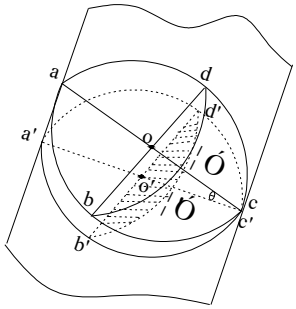

Fig 4 Sketch map of shear stress

**Numerical analysis by FLAC$^{3D}$**

The numerical model is shown in Fig 5. The length, height, width of the model is 30 m, its parameters are all based on field rock formation. Shape of roadway is excavated once, the length of numerical roadway is totally 14.4m with nine times to complete.

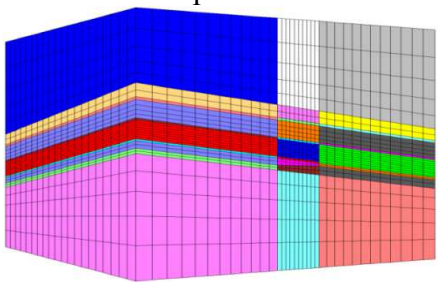

Fig 5 Numerical model of rock stratum

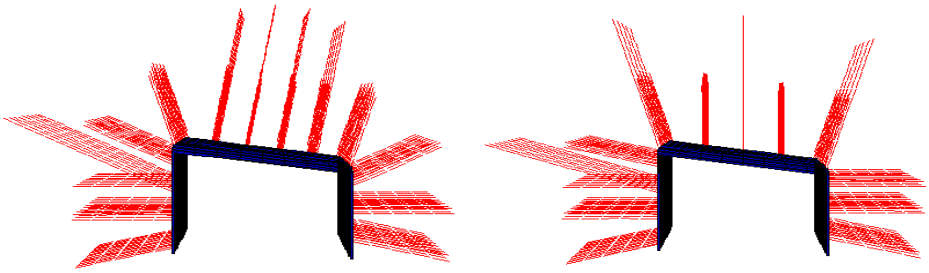
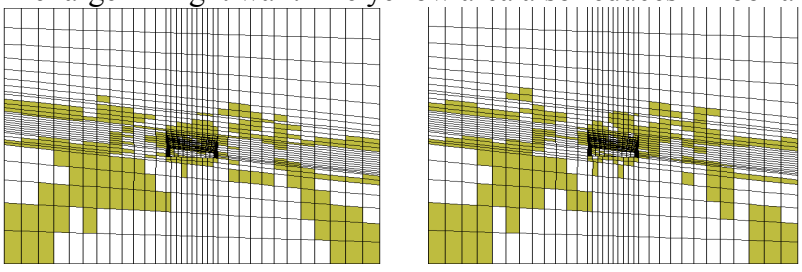
Fig 6 shows two mechanical models of different support designs. The optimized design change 6 anchors into 5 in roof, its new row space is 1000×800mm. We change position of cables and its row space to 1600 m, some of anchors in sidewalls are also changed.



(a) (b)

Fig 6 Mechanical model of different support designs

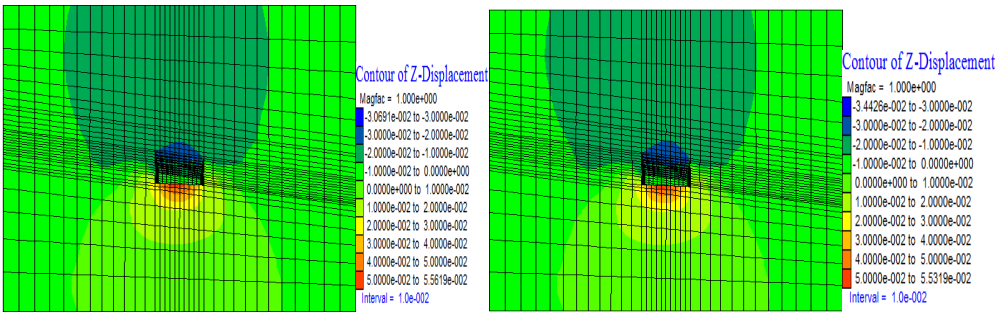
Fig 7 shows plastic zone of different support designs. The yellow area means plastic zone of surrounding rock. Compared Fig 7(b) with Fig 7(a), we can find that yellow area in left sidewall become smaller, while larger in right wall. The yellow area also reduces in roof and floor.



(a) (b)

Fig 7 Plastic zone of different support designs

Displacement of different support designs are shown in Fig 8, the number means z-displacement. The blue area is the maximum of z-displacement



(a) (b)

Fig 8 Displacement diagram of different support designs

The displacement of surrounding rock is shown in Tab 2. In this table, the effect of two designs, including roof, sidewalls and floor is Compared with original design, the displacement of roof increase 0.95%, while displacement of sidewalls and floor decrease all. By increasing the yielding deformation of roof properly, the stress in sidewalls and floor can lower, it do good to stability of roadway.

Tab 2 Displacement of surrounding rock

| supporting design | | roof | left sidewall | right sidewall | floor |
|---|---|---|---|---|---|
| original design | displacement[mm] | 23.912 | 33.531 | 43.141 | 44.248 |
| optimized design | displacement[mm] | 24.138 | 33.326 | 42.181 | 43.998 |
| | variation[%] | 0.95↑ | 0.61↓ | 2.22↓ | 0.56↓ |

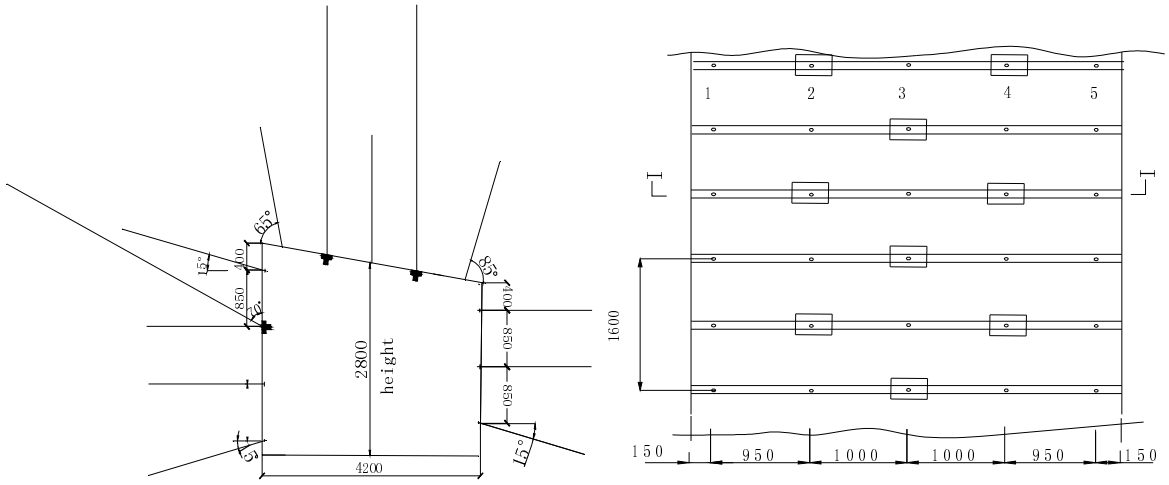
## Control technology of tilted strata roadway

**Optimized support design.** Based on theory of strengthening sidewall support and corner support and theory of anchors set vertical, we determine the final support design with technicists of Zijin colliery after ten designs were completed by FLAC$^{3D}$. Fig 9 shows the optimized settlement of anchors and cables.

(1) Anchors in roof should be set vertically. For roof support, the number of anchors decrease from 6 to 5. Its size is Ø20×2400 mm. Row space changed for 1000×800 mm, the dip angle of anchors in corner is 75°.The cables in roof are Ø 17.8×5400 mm and set vertically, its row space is 2000×800 mm. Fig 9(b) shows the location.

(2)Anchors in sidewalls and corner should be strengthened. Anchors used in sidewalls should be lengthened from 2.0 m to 2.4 m. Its row space is 850×800 mm There are four anchors of Ø20×2400mm in left sidewalls and three in the right side. The first row should be tilted upward 15°in left side. The fourth row anchors in both side are tilted 15°down. The cable is Ø 17.8×4500 mm combined with belt. it's dip angle is 20°.

(3) There is one K2355 resin and one CK 2355 resin for each anchor, and each cable is matched with one CK 2355 resin and two K2355 resin. Gridding of meshes is 150×150 mm. The thickness of tray is 12 mm.



(a) (b)

Fig 9 Optimized support design

**Support effect.** In order to monitor the surface displacement and roof separation of surrounding rock, we chose four sections as shown in Fig 10. Original support design was used for section 2, optimized design was used for section1, 3 and 4. Monitoring work began from Apr 16, 2010 to May 28.It lasted for 43 days, the optimized design was applied to support for 600m.

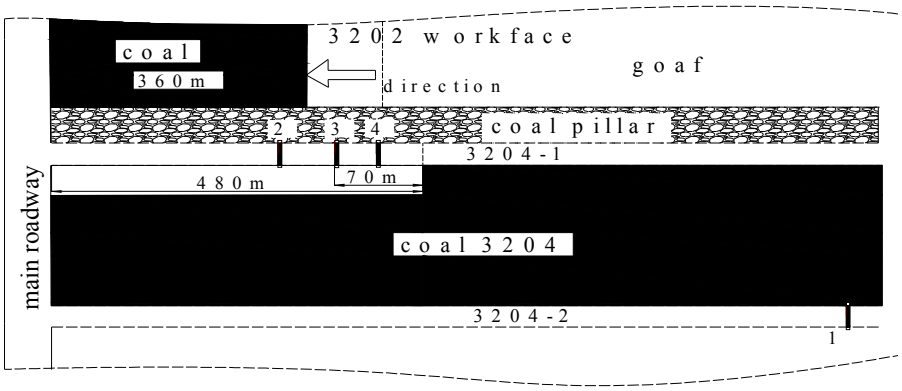


Fig 10 Sketch map of monitoring sections and excavation in 3204 workface

Fig 12 is the optimized support effect of roadway on May.28, 2010.Compared with Fig 11, we can see that deformation and failure of roadway is well controlled. According to monitoring results, the maximum of roof separation is 181mm at section 2, the average separation is 69 mm, it's very close to numerical result. And the average convergence of sidewall is 83mm, and average convergence between roof and floor is 87 mm. All the values are less than original design effect.

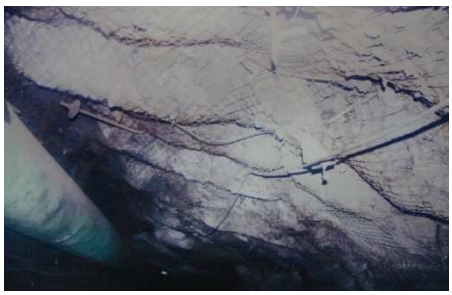

Fig 11 Failure of surrounding rock

Fig 12 Support effect of optimized support

## Conclusions

(1)Horizontal stress is major principle rock stress, its azimuth angle is 85º～101º. It's 1.13 to 2.50 times the level of vertical stress. Horizontal principal stress has big effect to north-south roadway, but small to east-west roadway.

(2)The broken rock zone of roof and two sidewalls in 2# coal seam are both greater than 1.5m, the stability of the roadway is so bad that it's really difficult to control deformation.

(3)Settling anchor and cable vertically can make the prestress of anchor (cable) get more effective, meanwhile horizontal component force with side effect can be reduced.

(4)By these measures, such as lengthening anchor and cable of sidewall, increasing its diameter or intensity, can improve the strength and rigidity of sidewall in coal roadway to restrain roof deformation.

**Keywords:** Crown Settlement; Clearance Convergence; Ground Settlement; Wall Rock; Tunnel

**Abstract.** Based on the railway tunnel engineering, the research on comprehensive technological for the monitoring of tunnel construction is performed. It is shown that the deformation of wall rock would mainly suffer the comprehensive influence of multiple factors like type of the wall rock, construction method and supporting measures, size of the excavated section, etc. through the monitoring of the crown settlement, clearance convergence and ground settlement. The wall rock will be stable within 20d and 40d after the tunnel excavation. And the secondary tunnel lining could be constructed. Numerical simulation method was also adopted to analyze the deformation and stress of the wall rock. It is presented that the construction interval shall not be too long for the stability of wall rock. Therefore, the numerical analysis method and site monitoring method could be used together to achieve more comprehensive and reliable monitoring of tunnel construction.

## Introduction

In recent years, the railway tunnel engineering is gradual developed and the tunnel construction technology is increasingly improvement. New Austrian Tunneling Method has been widely recognized as the most advanced method in the current tunnel construction. However, the technical level of new Austrian Tunneling Method application is still not matured in the design and construction of the mountain tunnel in our country[1], and the site monitoring and measurement especially needs further improvement. Dynamic design and construction based on the site monitoring and measurement have become the development direction for the design and construction of current tunnel engineering[2]. With the basis of one railway tunnel, the clearance convergence and crown settlement of tunnel were measured in this paper. And then the wall rock was evaluated, the influencing factors was analyzed. Last, the effective monitoring technology for railway tunnel construction was also researched.

## Project Overview

The geologicl structure of the tunnel region is relative complicate, and the levels wall rock mainly include level III, level IV, level V and etc. The underground water is also relative sufficient. The construction methods were full face tunnel construction method and benching tunneling method. The monitoring and measurement items mainly included: observation within and outside of cave, clearance change, crown settlement of tunnel and ground settlement. All items were all placed on single test section and the single test section was arranged in lengthwise along the tunnel. The density of observation points at the central line of the tunnel was increased appropriately. Fig 1 is the picture of measurement lines and the measurement points placing the end of line. One test section of the full

face tunnel construction method would have two lines with three points. The benching tunneling method would have three lines and five points.

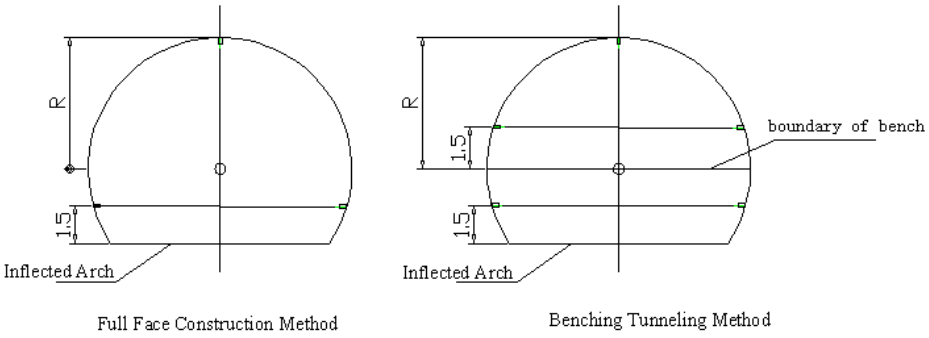

**Fig.1 Arrangement Diagram for the Measurement Lines and Points**

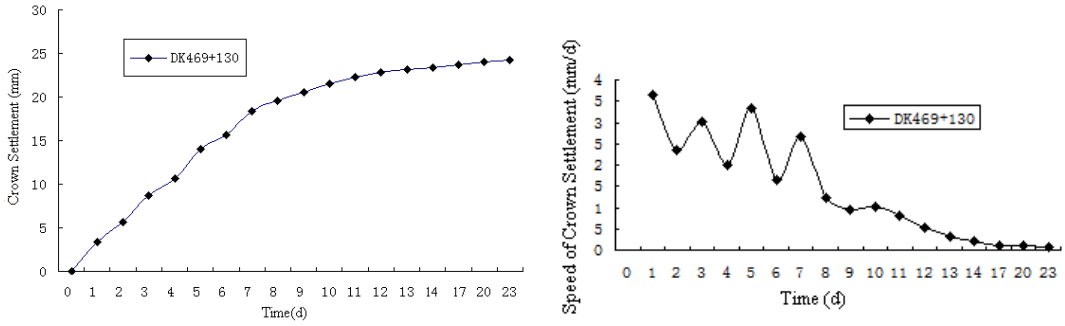
The initial reading data were completed within 24 hours after the excavation and before the excavation of the next cycle. The ending time for the monitoring was the following. After the wall rock stability, the measure frequency was one time per three days for two weeks. The measurement work could be completed if no obvious deformation had been detected. The measurement should be continued if any obvious deformation had been detected. The measurement could only be finished when no obvious deformation had been detected.

## Monitoring Results and Analysis

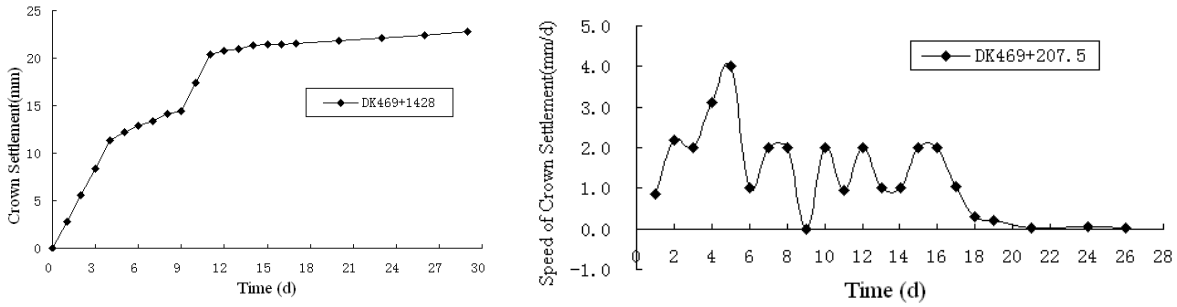
**Crown Settlement.** Fig.2 is the classic crown settlement curve, which is often shown on the exit and entrance of tunnel, class III wall rock, benching tunneling method. It is also named as 'perfect and smooth deformation curve'. The curve was relative smooth. After the excavation, the crown settlement was relatively even, the settlement speed was gradually decreased, and the curve of crown settlement was demonstrated in a logarithm function curve. The settlement speed of the crown is maintained at the level of 0.07mm/d at 16 days and the crown settlement was maintained at 24mm. It was shown that the wall rock was basically stable.



(a) Crown Settlement (b) Crown Settlement Speed

**Fig.2 Perfect and Smooth Deformation Curve**

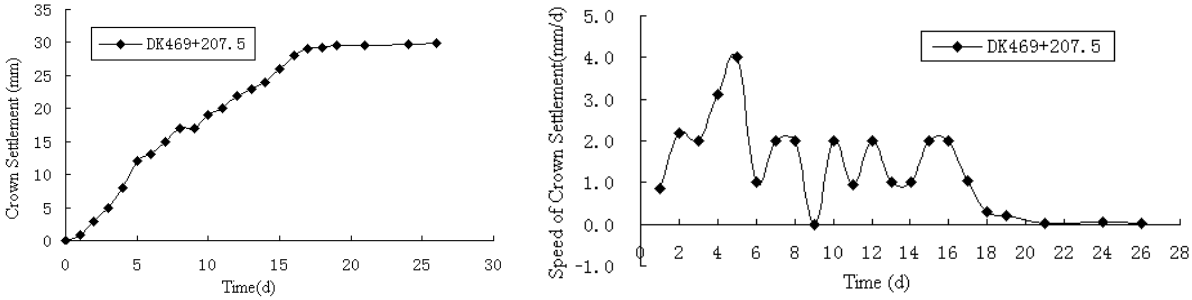
At the exit of the tunnel of class IV wall rock, full face tunnel construction metho,the crown settlement curve demonstrated in the similar shape of 'step' as being shown in Fig.3. This type of curve could be generally divided into four stages: 1) High-speed increasing stage: the time of duration was 4d and the average rate of variation was between 2.5mm/d and 3.0mm/d; 2) Slow increasing stage: the time of duration was 6d, and the average rate of variation was between 0.2mm and 0.8mm/d; 3) Second high-speed increasing stage: the time of duration was 2d, the settling velocity increased quickly and the crown settlement speed was 3mm/d; 4) Gradual stable stage: the time of duration was 17d, and the average rate of variation was 0.1mm/d. The second high-speed increasing stage was occurred because of the influence of the excavation of steps. It is necessary to increase the monitoring and the observation within the cave.



(a) Crown Settlement (b) Crown Settlement Speed

**Fig.3 Deformation Curve Similar to the Shape of Step**

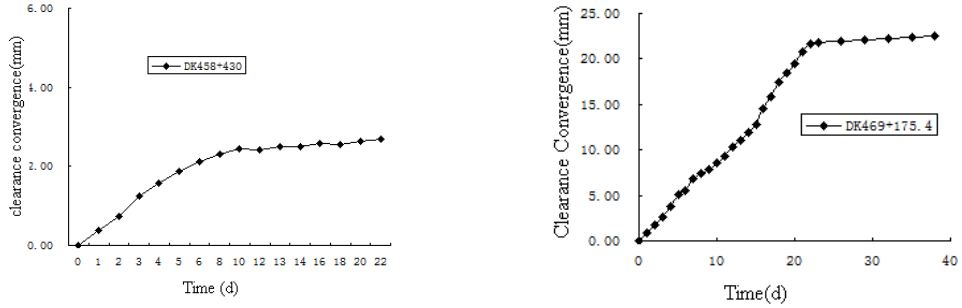
The curve showing in Fig.4 would generally demonstrated in shallow-buried section. The deformation of the crown at the early stage was relative quick. The wall rock was basically stable at the time of 18d. For such curve, it is necessary to strengthen the monitoring and measurement, especially strengthening the monitoring density and observation within cave when the settlement speed was high.



(a) Crown Settlement (b) Crown Settlement Speed

**Fig.4 Deformation Curve in Shallow-buried Section**

**Clearance Convergence.** The classic Clearance Convergence curve is shown on Fig.5. Fig.5(a) is the most common curve with small excavation. The clearance convergence was maintained at 2.6mm after 10 days. Fig.5(b) is shown in some measurement section with big excavation. Due to the influence of the surrounding construction, the convergence speed at the time of 16d was very high. However, the wall rock was not damaged. The wall rock is basically stable at the time of 40d. It should be strengthened the monitoring for the test section with the curve like Fig. 5(d).



(a) Smooth Type (b) Other Type

**Fig.5 Clearance Convergence Curve**

**Ground Settlement.** Eight observation points of ground settlement were placed at each section. Fig.6 was the settlement curve. 1# observation point was located at the center and 4# observation point was located far away from the center. The ground settlement of 1# observation point was greater than that of 4# observation point. They were respectively 4.9mm and 2.7mm. However, the trends of two cuvers were basically same. Both of them had demonstrated slow settlement at the beginning, and the settlement was stopped at the time of 13d.

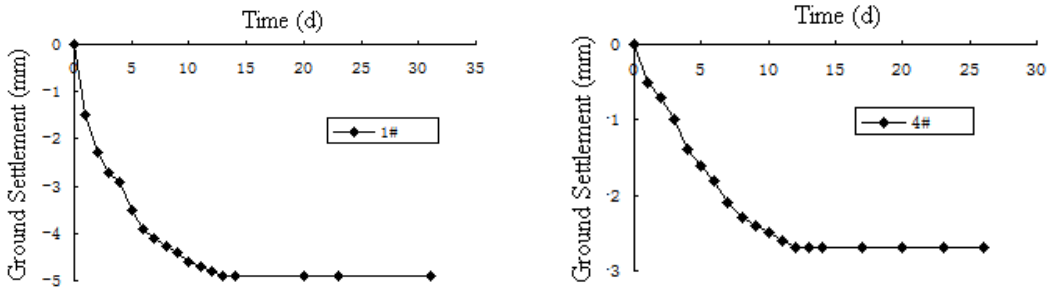


**Fig.6 Ground Settlement Curve**

Above all, the main influencing factors to wall rock deformation included: (1)Wall rock type: along with the decrease of the types of wall rock, the deformation of rock wall would increase and the stable time would also become longer; (2) Construction method and supporting measures: the excavation method and supporting measures of the tunnel construction would directly influence the release of the stress of wall rock; (3) size of the excavation section: the deformation displacement of small excavation section was relative small. Therefore, it is necessary to comprehensively consider the influencing factors of various aspects to effectively guide the tunnel construction.

## Deformation Calculation Analysis of Wall Rock

**Calculation Section.** A classic section locating at class IV wall rock area was as the typical calculation section. And the construction method was benching tunneling method. FE analysis software PLAXIS3D was adopted with M-C constitutive model. According to the construction procedure, the construction could be simplified into three work conditions. They were excavation and supporting of upper steps; excavation and preliminary supporting of sinus and side wall; the excavation and preliminary supporting of inflected arch. The height of tunnel model was 12.9m, the maximum span was about 14.7m, the length was 103m and the burial depth was 100m. The upper border was free border, the left and right border demonstrated lateral displacement, and both the vertical and lateral displacement on the lower border were restricted. The elements were solid[3,4].

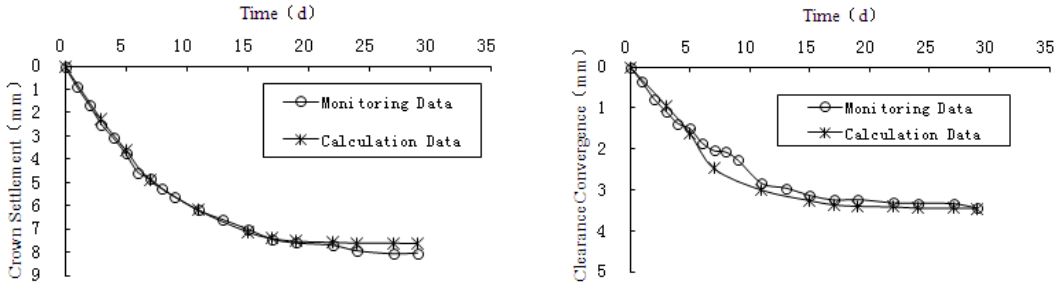
**Material Parameters.** The parameters of the materials selected are shown in Table 1.

**Table 1 Material Parameters**

| Material | Unit Weight | Cohesive force | Friction angle | Expansion angle | Elasticity modulus | Poisson's ratio | Burial Depth or Thickness |
|---|---|---|---|---|---|---|---|
| | $\gamma$ (kN/m$^3$) | c (kPa) | $\varphi$(°) | $\psi$ | E (GPa) | $\nu$ | $H$ (m) |
| Wall Rock | 27 | 10 | 50 | 0 | 80 | 0.25 | 100 |
| Preliminary Supporting | 26 | - | - | - | 40 | 0.2 | 0.27 |

**Calculation Results.** The results showed the excavation and supporting of tunnel changed the stress distribution of the wall rock, and stress concentration appeared at the connection area between the preliminary supporting and wall rock. Therefore, the time interval between the construction of the upper steps and lower steps shall be not too long. Otherwise, the stress concentration would result in the instability of the wall rock.

Fig.7 is the comparison of the calculation results and the actual measured data.



(a) Crown Settlement (b) Clearance Convergence of Upper Step

**Fig.7 Comparison between Actual Measured Data and Calculation Results**

It could be seen from Fig.7 that the trends of the calculation results and the actual measure data are basically similar. The crown settlement calculation result was stabilized at 20d after the construction. The actual measured data was slightly larger than the calculation, which was stabilized at 28d after the construction. It was because that the errors were resulted from the differences between the complicate construction environment and the ideal status of numerical analysis. The clearance convergence calculation value of upper step was slightly higher than the actual measured value, and the wall rock was stable after 25d. Therefore, numerical analysis method could be used to perform forecast for the wall rock in the construction process, and evaluate the safety of wall rock with the site construction monitoring.

## Conclusion
