Q *The celiac and superior and inferior mesenteric ganglia are not sympathetic trunk ganglia. What kind of ganglia are they?*

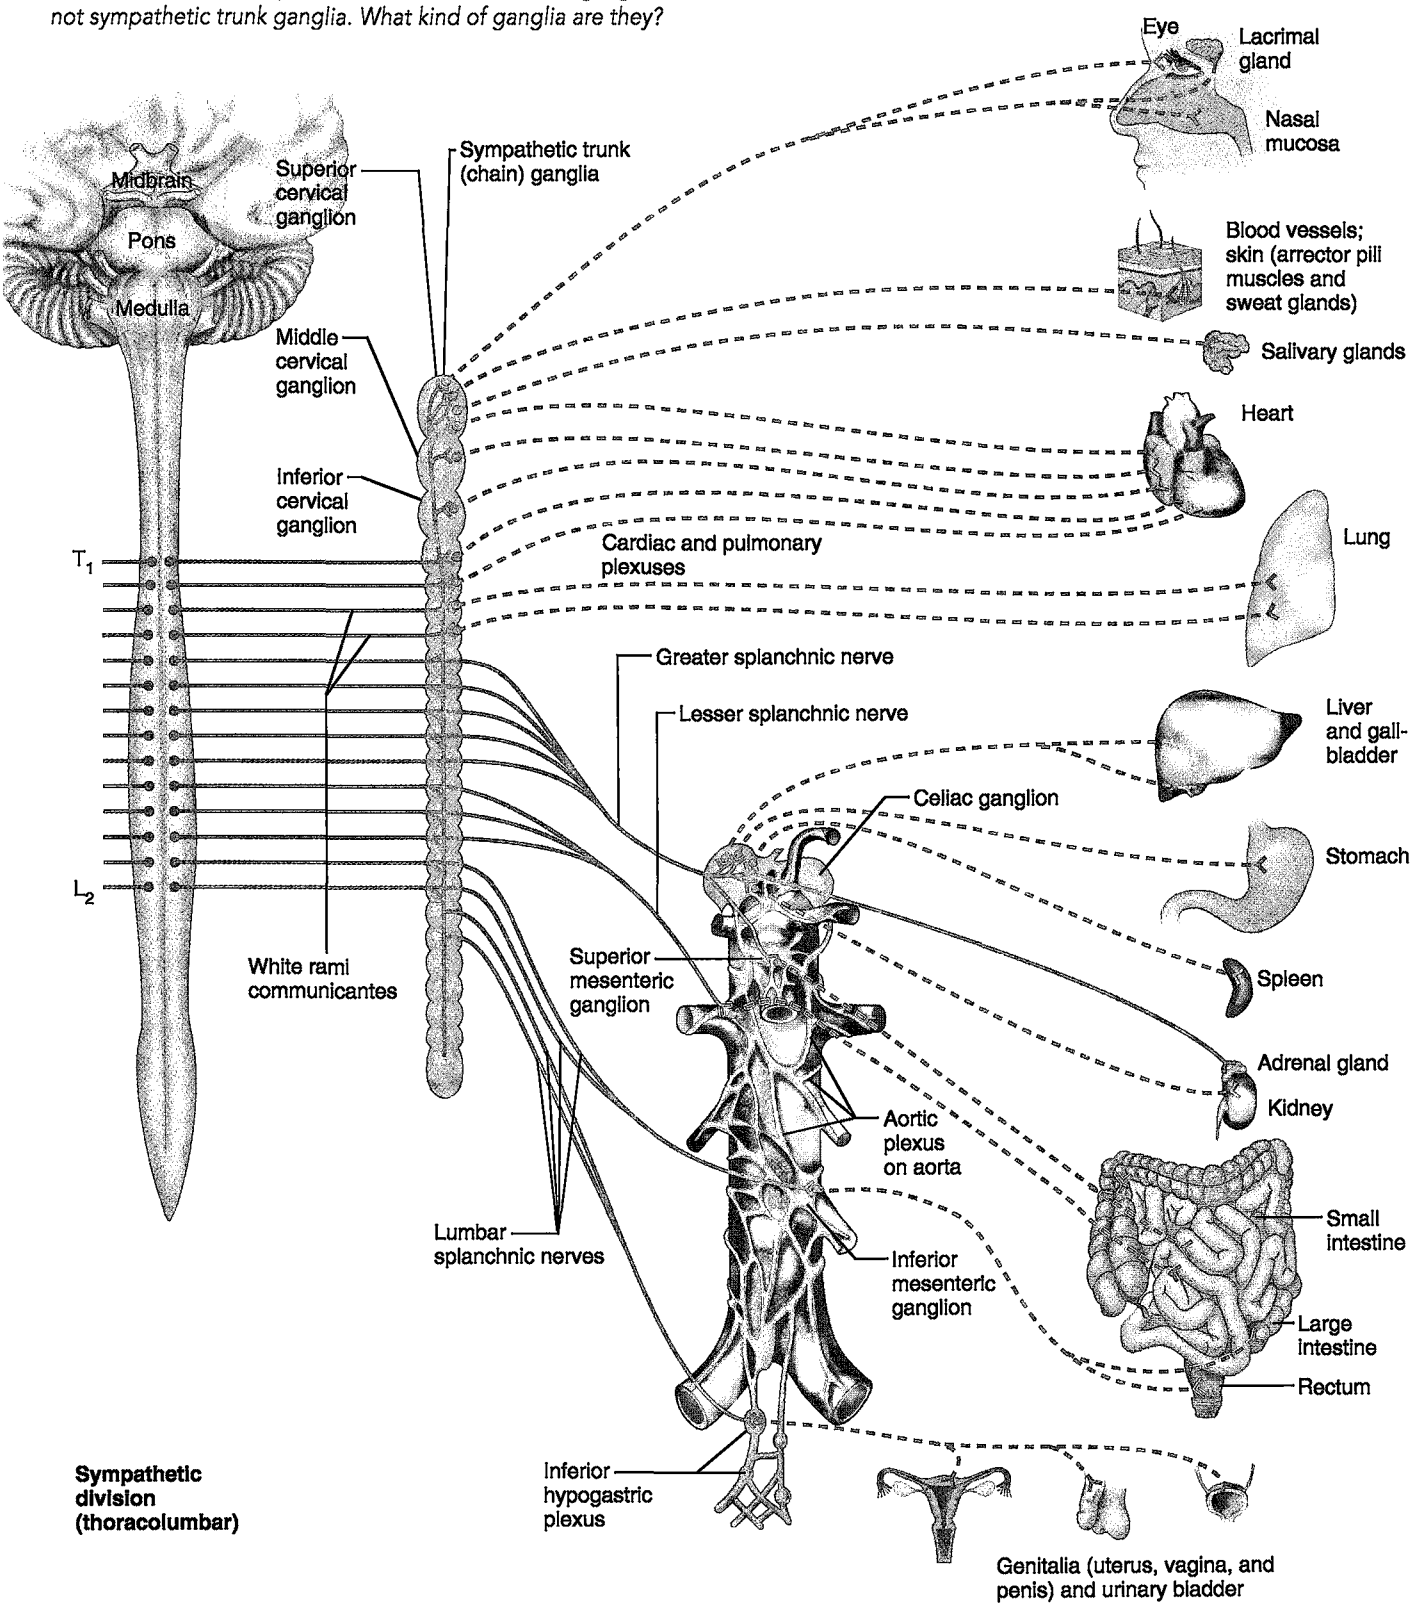

FIGURE 14.5 **Sympathetic (thoracolumbar) division of the ANS.** Solid lines indicate preganglionic fibers; dashed lines indicate postganglionic fibers. Sympathetic innervation to peripheral structures (blood vessels, glands, and arrector pili muscles) is shown only in the cervical area, but occurs in all areas. The least thoracic and sacral splanchnic nerves are not shown.

A *Collateral (prevertebral) ganglia.*

Q *On what basis are the rami communicantes distinguished as gray or white?*

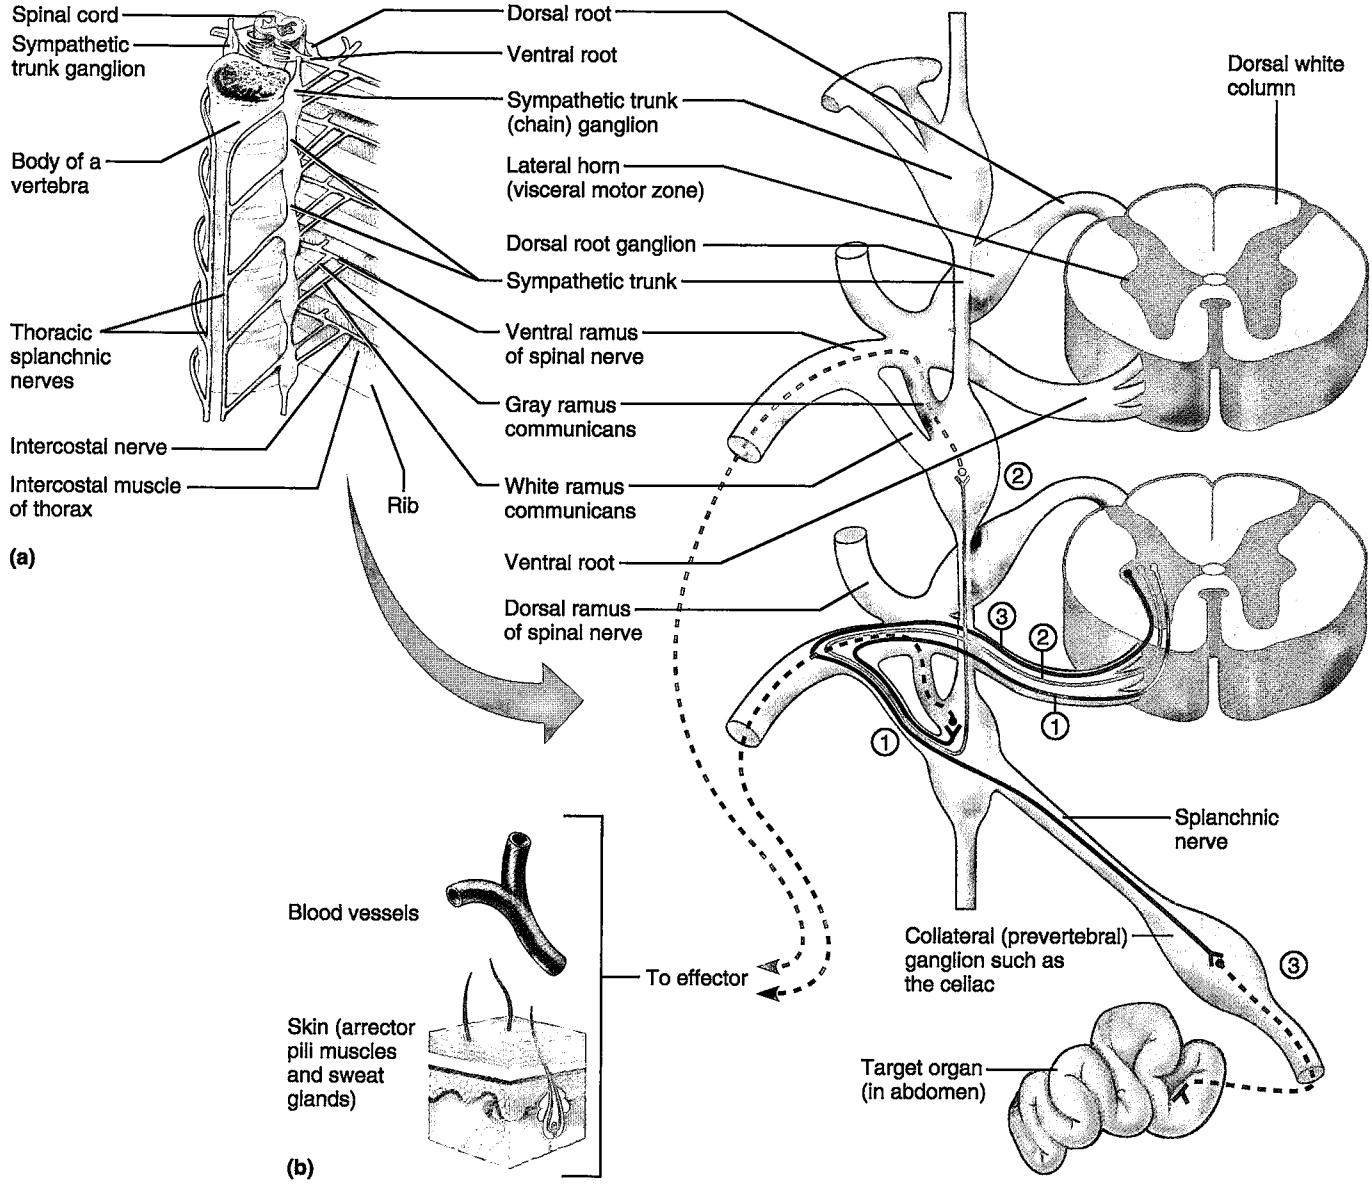

FIGURE 14.6 **Sympathetic trunks and pathways. (a)** Diagram of the left sympathetic trunk in the posterior thorax, along the side of the vertebral column. **(b)** Three sympathetic pathways. ① Synapse in a sympathetic trunk (chain) ganglion at same level (red). ② Synapse in a sympathetic trunk ganglion at a different level (green). ③ Synapse in a collateral (prevertebral) ganglion anterior to the vertebral column (purple).

Regardless of where the synapse occurs, all sympathetic ganglia are close to the spinal cord, and their postganglionic fibers are typically much longer than their preganglionic fibers. Recall that the opposite condition exists in the parasympathetic division, an anatomical distinction that is functionally important.

A The gray rami are unmyelinated. The white rami are myelinated, which gives them a distinguishing white color.

Pathways with Synapses in Trunk Ganglia

When synapses are made in sympathetic trunk ganglia, the postganglionic axons enter the ventral (or dorsal) ramus of the adjoining spinal nerves by way

of communicating branches called **gray rami communicantes** (Figure 14.6). From there they travel via branches of the rami to their effectors, including sweat glands and arrector pili muscles of the skin. Anywhere along their path, the postganglionic axons may transfer over to nearby blood vessels and innervate the vascular smooth muscle all the way to their final branches.

Notice that the naming of the rami communicantes as *white* or *gray* reflects their appearance, revealing whether or not their fibers are myelinated (and has *no* relationship to the white and gray matter of the CNS). Preganglionic fibers composing the white rami are myelinated. Postganglionic axons forming the gray rami are not.

The white rami, which carry preganglionic axons to the sympathetic trunks, are found only in the T_1–L_2 cord segments, regions of sympathetic outflow. However, gray rami carrying postganglionic fibers headed for the periphery issue from *every* trunk ganglion from the cervical to the sacral region, allowing sympathetic output to reach all parts of the body. Because parasympathetic fibers never run in spinal nerves, *rami communicantes are associated only with the sympathetic division.*

Pathways to the Head Sympathetic preganglionic fibers serving the head emerge from spinal cord segments T_1–T_4 and ascend the sympathetic trunk to synapse with ganglionic neurons in the **superior cervical ganglion.** This ganglion contributes sympathetic fibers that run in several cranial nerves and with the upper three or four cervical spinal nerves. Besides serving the skin and blood vessels of the head, its fibers stimulate the dilator muscles of the irises of the eyes, inhibit the nasal and salivary glands (the reason your mouth goes dry when you are scared), and innervate the smooth (tarsal) muscle that lifts the upper eyelid. The superior cervical ganglion also sends direct branches to the heart.

Pathways to the Thorax Sympathetic preganglionic fibers innervating the thoracic organs originate at T_1–T_6. From there the preganglionic fibers run to synapse in the cervical trunk ganglia. Postganglionic fibers emerging from the **middle** and **inferior cervical ganglia** enter cervical nerves C_4–C_8. Some of these fibers innervate the heart via the cardiac plexus, and some innervate the thyroid gland, but most serve the skin. Additionally, some T_1–T_6 preganglionic fibers synapse in the nearest trunk ganglion, and the postganglionic fibers pass directly to the organ served. Fibers to the heart, aorta, lungs, and esophagus take this direct route. Along the way, they run into the plexuses associated with those organs. Sympathetic innervation by spinal cord segment is summarized in Table 14.2.

TABLE 14.2 Segmental Sympathetic Supplies

SPINAL CORD SEGMENT	ORGANS SERVED
T_1–T_5	Head and neck, heart
T_2–T_4	Bronchi and lungs
T_2–T_5	Upper limb
T_5–T_6	Esophagus
T_6–T_{10}	Stomach, spleen, pancreas
T_7–T_9	Liver
T_9–T_{10}	Small intestine
T_{10}–L_1	Kidney, reproductive organs (uterus, testis, ovary, etc.)
T_{10}–L_2	Lower limb
T_{11}–L_2	Large intestine, ureter, urinary bladder

Pathways with Synapses in Collateral Ganglia

The preganglionic fibers from T_5 down synapse in collateral ganglia; thus these fibers enter and leave the sympathetic trunks without synapsing. They form several nerves called splanchnic nerves, including the thoracic **splanchnic nerves** (greater, lesser, and least) and the **lumbar** and **sacral splanchnic nerves.** The splanchnic nerves contribute to a number of interweaving nerve plexuses known collectively as the **abdominal aortic plexus** (a-or'tik), which clings to the surface of the abdominal aorta (Figure 14.5). This complex plexus contains several ganglia that together serve the abdominopelvic viscera (*splanchni* = viscera). From superior to inferior, the most important of these ganglia (and related subplexuses) are the **celiac, superior mesenteric, inferior mesenteric,** and **inferior hypogastric,** named for the arteries with which they most closely associate. Postganglionic fibers issuing from these ganglia generally travel to their target organs in the company of the arteries serving these organs.

Pathways to the Abdomen Sympathetic innervation of the abdomen is via preganglionic fibers from T_5 to L_2, which travel in the thoracic *splanchnic nerves* to synapse mainly at the celiac and superior mesenteric ganglia. Postganglionic fibers issuing from these ganglia serve the stomach, intestines (except the distal half of the large intestine), liver, spleen, and kidneys.

Pathways to the Pelvis Preganglionic fibers innervating the pelvis originate from T_{10} to L_2 and then descend in the sympathetic trunk to the lumbar and sacral trunk ganglia. Some fibers synapse there, but most go directly out from the cord via the

Q *According to the figure legend, the afferent neuron shown in this diagram reaches the CNS via a spinal nerve. How would you know that if it was not mentioned?*

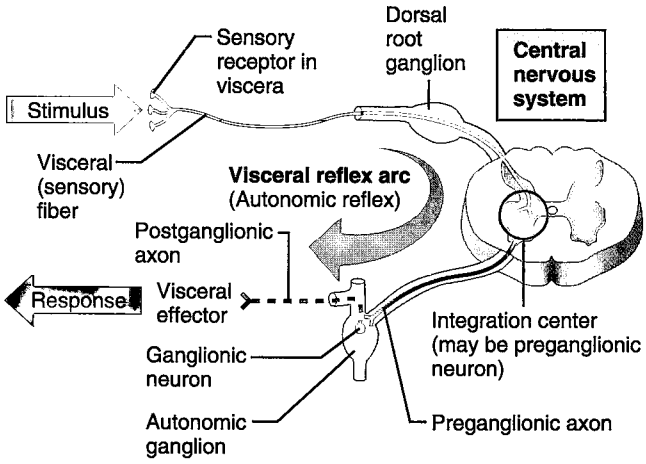

FIGURE 14.7 **Visceral reflexes.** Visceral reflexes have the same elements as somatic reflexes, but the efferent response occurs over a two-motor-neuron efferent pathway. The integration center may involve a dorsal horn interneuron, or it may just be a synapse with a preganglionic neuron (as shown). The visceral afferent fibers are found both in spinal nerves (as depicted here) and in autonomic nerves.

lumbar and *sacral splanchnic nerves,* which send the bulk of their fibers to the inferior mesenteric and inferior hypogastric ganglia. From these ganglia issue postganglionic fibers serving the distal half of the large intestine, the urinary bladder, and the reproductive organs. For the most part, sympathetic fibers *inhibit* the activity of the muscles and glands in these visceral organs.

Pathways with Synapses in the Adrenal Medulla

Some fibers traveling in the thoracic splanchnic nerves pass through the celiac ganglion without synapsing and terminate by synapsing with the hormone-producing medullary cells of the adrenal gland (Figure 14.5). When stimulated by preganglionic fibers, the medullary cells secrete NE and *epinephrine* (also called *noradrenaline* and *adrenaline,* respectively) into the blood, producing the excitatory effects we have all felt as a "surge of adrenaline." Embryologically, sympathetic ganglia and the adrenal medulla arise from the same tissue. For this reason, the adrenal medulla is sometimes viewed as a "misplaced" sympathetic ganglion, and its hormone-releasing cells, although lacking nerve processes, are considered equivalent to ganglionic sympathetic neurons.

Visceral Reflexes

Because most anatomists consider the ANS to be a visceral motor system, the presence of sensory fibers (mostly visceral pain afferents) is often overlooked. However, **visceral sensory neurons,** which send information concerning chemical changes, stretch, and irritation of the viscera, are the first link in autonomic reflexes. **Visceral reflex arcs** have essentially the same components as somatic reflex arcs—receptor, sensory neuron, integration center, motor neuron, effector—except that a visceral reflex arc has *two* neurons in its motor component (Figure 14.7).

Nearly all the sympathetic and parasympathetic fibers described thus far are accompanied by afferent fibers conducting sensory impulses from glands or muscles. Thus, peripheral processes of visceral sensory neurons are found in cranial nerves VII, IX, and X, splanchnic nerves, and the sympathetic trunk, as well as in spinal nerves. Like sensory neurons serving somatic structures (skeletal muscles and skin), the cell bodies of visceral sensory neurons are located either in the sensory ganglia of associated cranial nerves or in dorsal root ganglia of the spinal cord. Visceral sensory neurons are also found in sympathetic ganglia where preganglionic neurons synapse. Furthermore, complete three-neuron reflex arcs (with sensory, inter-, and motor neurons) exist entirely within the walls of the gastrointestinal tract. Neurons composing these reflex arcs make up the *enteric nervous system,* which plays an important role in controlling gastrointestinal tract activity. We will discuss the enteric nervous system in more detail in Chapter 23.

The fact that visceral pain afferents travel along the same pathways as somatic pain fibers helps explain the phenomenon of **referred pain,** in which pain stimuli arising in the viscera are perceived as somatic in origin. For example, a heart attack may produce a sensation of pain that radiates to the superior thoracic wall and along the medial aspect of the left arm. Because the same spinal segments (T_1–T_5) innervate both the heart and the regions to which pain signals from heart tissue are referred, the brain interprets most such inputs as coming from the more common somatic pathway. Cutaneous areas to which visceral pain is commonly referred are shown in Figure 14.8. (Somatic and visceral pain are described in more detail in *A Closer Look* in Chapter 13.)

A The visceral afferent fiber enters the spinal cord via a dorsal root ganglion, found only on the dorsal root of spinal nerves.

ANS Physiology

Neurotransmitters and Receptors

Acetylcholine and *norepinephrine* are the major neurotransmitters released by ANS neurons. ACh, the same neurotransmitter secreted by somatic motor neurons, is released by (1) all ANS preganglionic axons and (2) all parasympathetic postganglionic axons at synapses with their effectors. ACh-releasing fibers are called **cholinergic fibers** (ko"lin-er'jik).

In contrast, most sympathetic postganglionic axons release NE and are classified as **adrenergic fibers** (ad"ren-er'jik). Some exceptions are sympathetic postganglionic fibers innervating sweat glands and some blood vessels in skeletal muscles; these fibers secrete ACh.

Unfortunately for memorization purposes, the effects of ACh and NE on their effectors are not consistently either excitation or inhibition. The response of visceral effectors to these neurotransmitters depends not only on the neurotransmitter but also on the receptor to which it attaches. The two or more kinds of receptors for each autonomic neurotransmitter allows it to exert different effects (activation or inhibition) at different body targets (Table 14.3).

Cholinergic Receptors

The two types of receptors that bind ACh are named for drugs that bind to them and mimic acetylcholine's effects. The first of these receptors identified were the **nicotinic receptors** (nik"o-tin'ik). A mushroom poison, *muscarine* (mus'kah-rin), activates a different set of ACh receptors, named **muscarinic receptors.** All ACh receptors are either nicotinic or muscarinic.

Nicotinic receptors are found on (1) motor end plates of skeletal muscle cells (which, however, are somatic and not autonomic targets), (2) *all* ganglionic neurons, both sympathetic and parasympathetic, and (3) the hormone-producing cells of the adrenal medulla. Just as at the motor end plate of skeletal muscle (examined in Chapter 9), ACh binding to any nicotinic receptor directly opens ion channels, depolarizing the postsynaptic cell. Thus, the effect of ACh binding to nicotinic receptors anywhere is *always* stimulatory.

Muscarinic receptors occur on all effector cells stimulated by postganglionic cholinergic fibers—that is, all parasympathetic target organs and a few sympathetic targets, such as eccrine sweat glands and some blood vessels of skeletal muscles. The effect of ACh binding to muscarinic receptors can be either inhibitory or stimulatory, depending on the subclass of muscarinic receptor found on the target organ. For example, binding of ACh to cardiac muscle receptors slows heart activity, whereas ACh binding to receptors on smooth muscle of the gastrointestinal tract increases its motility.

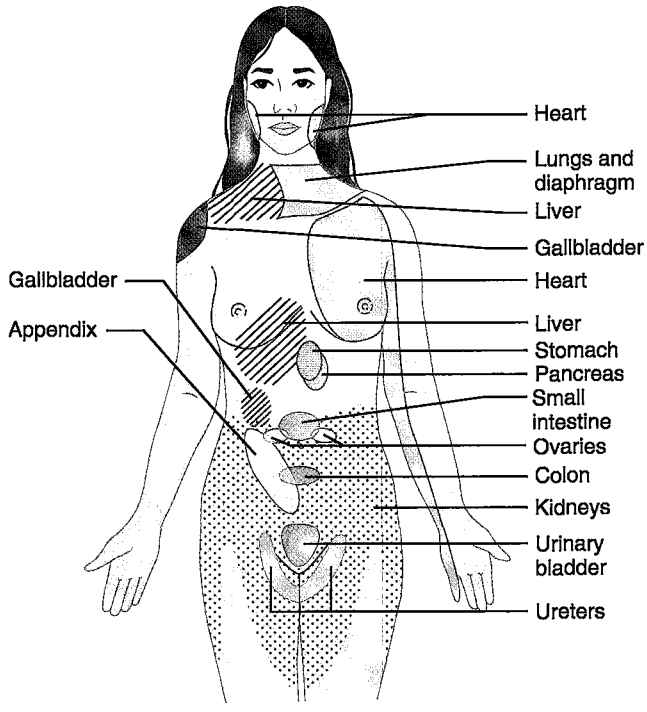

FIGURE 14.8 **Referred pain.** Anterior cutaneous areas to which pain from certain visceral organs is referred.

Adrenergic Receptors

There are also two major classes of adrenergic (NE-binding) receptors: **alpha** (α) and **beta** (β). These receptors are further divided into subclasses (α_1 and α_2; β_1, β_2, and β_3). Organs that respond to NE (or epinephrine) have one or more of these receptor subtypes. NE or epinephrine can have either excitatory or inhibitory effects on target organs depending on which subclass of receptor predominates in that organ. For example, binding of NE to the β_1 receptors of cardiac muscle prods the heart into more vigorous activity, whereas epinephrine binding to β_2 receptors in bronchiole smooth muscle causes it to relax, dilating the bronchiole. An overview of the locations and effects of these receptor subclasses is provided in Table 14.3.

The Effects of Drugs

Knowing the locations of the cholinergic and adrenergic receptor subtypes allows specific drugs to be prescribed to obtain the desired inhibitory or stimulatory effects on selected target organs. For example, atropine, an anticholinergic drug that blocks muscarinic ACh receptors, is routinely administered before surgery to prevent salivation and to dry up respiratory system secretions. It is also used by ophthalmologists to dilate the pupils for eye examination.

TABLE 14.3 Cholinergic and Adrenergic Receptors

NEUROTRANSMITTER	RECEPTOR TYPE	MAJOR LOCATIONS*	EFFECT OF BINDING
Acetylcholine	**Cholinergic**		
	Nicotinic	All ganglionic neurons; adrenal medullary cells (also neuromuscular junctions of skeletal muscle)	Excitation
	Muscarinic	All parasympathetic target organs	Excitation in most cases; inhibition of cardiac muscle
		Limited sympathetic targets:	
		■ Eccrine sweat glands	Activation
		■ Blood vessels in skeletal muscles	Vasodilation (may not occur in humans)
Norepinephrine (and epinephrine released by adrenal medulla)	**Adrenergic**		
	β_1	Heart predominantly, but also kidneys and adipose tissue	Increases heart rate and strength; stimulates renin release by kidneys
	β_2	Lungs and most other sympathetic target organs; abundant on blood vessels serving the heart, liver and skeletal muscle	Effects mostly inhibitory; dilates blood vessels and bronchioles; relaxes smooth muscle walls of digestive and urinary visceral organs; relaxes uterus
	β_3	Adipose tissue	Stimulates lipolysis by fat cells
	α_1	Most importantly blood vessels serving the skin, mucosae, abdominal viscera, kidneys, and salivary glands; also, virtually all sympathetic target organs except heart	Constricts blood vessels and visceral organ sphincters; dilates pupils of the eyes
	α_2	Membrane of adrenergic axon terminals; pancreas; blood platelets	Inhibits NE release from adrenergic terminals; inhibits insulin secretion by pancreas; promotes blood clotting

*Note that all of these receptor subtypes are also found in the CNS.

The anticholinesterase drug *neostigmine* inhibits acetylcholinesterase, thus preventing enzymatic breakdown of ACh and allowing it to accumulate in the synapses. This drug is used to treat myasthenia gravis, a condition in which skeletal muscle activity is impaired for lack of ACh stimulation.

As described in Chapter 11, NE is one of our "feeling good" neurotransmitters, and drugs that prolong the activity of NE on the postsynaptic membrane help to relieve depression. Hundreds of over-the-counter drugs used to treat colds, coughs, allergies, and nasal congestion contain sympathomimetics (phenylephrine and others), sympathetic-mimicking drugs that stimulate α-adrenergic receptors. Much pharmaceutical research is directed toward finding drugs that affect only one subclass of receptor without upsetting the whole adrenergic or cholinergic system. An important breakthrough was finding drugs that mainly activate β_2 receptors. People with asthma use such β_2 activators to dilate their lung bronchioles without activating β_1 receptors, which would increase their heart rate. Selected drug classes that influence ANS activity are summarized in Table 14.4.

Interactions of the Autonomic Divisions

As mentioned earlier, most visceral organs receive *dual innervation*. Normally, both ANS divisions are partially active, producing a dynamic antagonism that allows visceral activity to be precisely controlled. However, one division or the other usually exerts the predominant effects in given circumstances, and in a few cases, the two divisions actually cooperate with each other. The major effects of the two divisions are summarized in Table 14.5.

Antagonistic Interactions

Antagonistic effects, described earlier, are most clearly seen on the activity of the heart, respiratory system, and gastrointestinal organs. In a fight-or-flight situation, the sympathetic division increases heart rate, dilates airways, and inhibits digestion and elimination. When the emergency is over, the parasympathetic division restores heart rate and airway diameter to resting levels and then attends to processes that refuel body cells and discard wastes.

TABLE 14.4 Selected Drug Classes That Influence the Activity of the Autonomic Nervous System

DRUG CLASS	RECEPTOR BOUND	EFFECTS	EXAMPLE	CLINICAL USE
Nicotinic agents (little therapeutic value, but important because of presence of nicotine in tobacco)	Nicotinic ACh receptors on all ganglionic neurons and in CNS	Typically stimulation of sympathetic effects; heart rhythm becomes less regular; blood pressure increases	Nicotine	Used in smoking cessation products
Parasympathomimetic agents (muscarinic agents)	Muscarinic ACh receptors	Mimics effects of ACh, enhances PNS effects	Pilocarpine	Glaucoma (opens aqueous humor drainage pores)
			Bethanechol	Difficulty urinating (increases bladder contraction)
Acetylcholinesterase inhibitors	None; binds to the enzyme (AChE) that degrades ACh	Indirect effect at all ACh receptors; prolongs the effect of ACh	Neostigmine	Myasthenia gravis, (increases availability of ACh)
			Sarin	Used as chemical warfare agent (similar to widely used insecticides)
Sympathomimetic agents	Adrenergic receptors	Enhances sympathetic activity by increasing NE release or binding to adrenergic receptors	Albuterol (Ventolin)	Asthma (dilates bronchioles by binding to β_2 receptors)
			Phenylephrine	Colds (nasal decongestant, binds to α_1 receptors)
Sympatholytic agents	Adrenergic receptors	Decreases sympathetic activity by blocking adrenergic receptors or inhibiting NE release	Propranolol	Hypertension (member of a class of drugs called *β blockers* that decrease heart rate and blood pressure)

Sympathetic and Parasympathetic Tone

Although we have described the parasympathetic division as the "resting and digesting" division, the sympathetic division is the major actor in controlling blood pressure, even at rest. With few exceptions, the vascular system is entirely innervated by sympathetic fibers that keep the blood vessels in a continual state of partial constriction called **sympathetic** or **vasomotor tone.** When a higher blood pressure is needed to maintain blood flow, the sympathetic fibers fire more rapidly, causing blood vessels to constrict and blood pressure to rise. When blood pressure is to be decreased, the vessels are prompted to dilate. *Alpha-blocker drugs* that interfere with the activity of these **vasomotor fibers** are sometimes used to treat hypertension. During circulatory shock (inadequate blood delivery to body tissues), or when more blood is needed to meet the increased needs of working skeletal muscles, blood vessels serving the skin and abdominal viscera are strongly constricted. This blood "shunting" helps maintain circulation to vital organs or enhance blood delivery to skeletal muscles.

On the other hand, parasympathetic effects normally dominate the heart and the smooth muscle of digestive and urinary tract organs. Thus, these organs exhibit **parasympathetic tone.** The parasympathetic division slows the heart and dictates the normal activity levels of the digestive and urinary tracts. However, the sympathetic division can override these parasympathetic effects during times of stress. Drugs that block parasympathetic responses increase heart rate and cause fecal and urinary retention. Except for the adrenal glands and sweat glands of the skin, most glands are activated by parasympathetic fibers.

Cooperative Effects

The best example of cooperative ANS effects is seen in controls of the external genitalia. Parasympathetic stimulation causes vasodilation of blood vessels in the external genitalia and is responsible for erection of the male penis or female clitoris during sexual excitement. (This may explain why sexual performance is sometimes impaired when people

TABLE 14.5 Effects of the Parasympathetic and Sympathetic Divisions on Various Organs

TARGET ORGAN OR SYSTEM	PARASYMPATHETIC EFFECTS	SYMPATHETIC EFFECTS
Eye (iris)	Stimulates sphincter pupillae muscles; constricts pupils	Stimulates dilator pupillae muscles; dilates pupils
Eye (ciliary muscle)	Stimulates muscles, which results in bulging of the lens for close vision	Weakly inhibits muscles, which results in flattening of the lens for far vision
Glands (nasal, lacrimal, gastric, pancreas)	Stimulates secretory activity	Inhibits secretory activity; causes vasoconstriction of blood vessels supplying the glands
Salivary glands	Stimulates secretion of watery saliva	Stimulates secretion of thick, viscous saliva
Sweat glands	No effect (no innervation)	Stimulates copious sweating (cholinergic fibers)
Adrenal medulla	No effect (no innervation)	Stimulates medulla cells to secrete epinephrine and norepinephrine
Arrector pili muscles attached to hair follicles	No effect (no innervation)	Stimulates to contract (erects hairs and produces "goosebumps")
Heart muscle	Decreases rate; slows heart	Increases rate and force of heartbeat
Heart: coronary blood vessels	Weakly dilates coronary vessels	Causes vasodilation*
Bladder/urethra	Causes contraction of smooth muscle of bladder wall; relaxes urethral sphincter; promotes voiding	Causes relaxation of smooth muscle of bladder wall; constricts urethral sphincter; inhibits voiding
Lungs	Constricts bronchioles	Dilates bronchioles*
Digestive tract organs	Increases motility (peristalsis) and amount of secretion by digestive organs; relaxes sphincters to allow movement of foodstuffs along tract	Decreases activity of glands and muscles of digestive system and constricts sphincters (e.g., anal sphincter)
Liver	No effect (no innervation)	Stimulates release of glucose to blood*
Gallbladder	Excites (gallbladder contracts to expel bile)	Inhibits (gallbladder is relaxed)
Kidney	No effect (no innervation)	Causes vasoconstriction; decreases urine output; promotes renin release
Penis	Causes erection (vasodilation)	Causes ejaculation
Vagina/clitoris	Causes erection (vasodilation) of clitoris	Causes contraction of vagina; increases mucus secretion
Blood vessels	Little or no effect	Constricts most vessels and increases blood pressure; constricts vessels of abdominal viscera and skin to divert blood to muscles, brain, and heart when necessary; NE constricts most vessels when necessary; epinephrine dilates vessels of the skeletal muscles during exercise*
Blood coagulation	No effect (no innervation)	Increases coagulation*
Cellular metabolism	No effect (no innervation)	Increases metabolic rate*
Adipose tissue	No effect (no innervation)	Stimulates lipolysis (fat breakdown)*

*Effects are mediated by epinephrine release into the bloodstream from the adrenal medulla.

are anxious or upset and the sympathetic division is in charge.) Sympathetic stimulation then causes ejaculation of semen by the penis or reflex contractions of a female's vagina.

Unique Roles of the Sympathetic Division

The adrenal medulla, sweat glands and arrector pili muscles of the skin, the kidneys, and most blood vessels receive only sympathetic fibers. It is easy to remember that the sympathetic system innervates these structures because most of us sweat under stress, our scalp "prickles" during fear, and our blood pressure skyrockets (from widespread vasoconstriction) when we get excited. We have already described how sympathetic control of blood vessels regulates blood pressure and shunting of blood in the vascular system. We will now mention several other uniquely sympathetic functions.

Thermoregulatory Responses to Heat The sympathetic division mediates reflexes that regulate body temperature. For example, applying heat to the skin causes reflexive dilation of blood vessels in that area. When systemic body temperature is elevated, sympathetic nerves cause the skin's blood vessels to dilate, allowing the skin to become flushed with warm blood, and activate the sweat glands to help cool the body. When body temperature falls, skin blood vessels are constricted, and, as a result, blood is restricted to deeper, more vital organs.

Release of Renin from the Kidneys Sympathetic impulses stimulate the kidneys to release renin, an enzyme that promotes an increase in blood pressure. This renin-angiotensin mechanism is described in Chapter 25.

Metabolic Effects Through both direct neural stimulation and release of adrenal medullary hormones, the sympathetic division promotes a number of metabolic effects not reversed by parasympathetic activity. It (1) increases the metabolic rate of body cells; (2) raises blood glucose levels; and (3) mobilizes fats for use as fuels. These medullary hormones also cause skeletal muscle to contract more strongly and quickly. As a side effect, muscle spindles are stimulated more often and, consequently, nerve impulses traveling to the muscles occur more synchronously. These neutral bursts, which put muscle contractions on a "hair trigger," are great if you have to make a quick jump or run, but they can be embarrassing or even disabling to the nervous musician or surgeon.

Localized Versus Diffuse Effects

In the parasympathetic division, one preganglionic neuron synapses with one (or at most a few) ganglionic neurons. Additionally, all parasympathetic fibers release ACh, which is quickly destroyed (hydrolyzed) by acetylcholinesterase. Consequently, the parasympathetic division exerts short-lived, highly localized control over its effectors. In contrast, preganglionic sympathetic axons branch profusely as they enter the sympathetic trunk, and they synapse with ganglionic neurons at several levels. Thus, when the sympathetic division is activated, it responds in a diffuse and highly interconnected way. Indeed, the literal translation of sympathetic (*sym* = together; *pathos* = feeling) relates to the bodywide mobilization this division provokes. Nevertheless, parts of the sympathetic nervous system can be activated individually. For example, just because your eye pupils dilate in dim light doesn't necessarily mean that your heart rate speeds up.

Effects produced by sympathetic activation are much longer lasting than parasympathetic effects. In contrast to the parasympathetic system's ACh, NE is inactivated more slowly because it must be taken back up into the presynaptic ending before being hydrolyzed (or stored). More importantly, NE and epinephrine are secreted into the blood by adrenal medullary cells when the sympathetic division is mobilized. Although epinephrine is more potent at increasing heart rate and raising blood glucose levels and metabolic rate, these hormones have essentially the same effects as NE released by sympathetic neurons. In fact, circulating adrenal medullary hormones produce 25–50% of all the sympathetic effects acting on the body at a given time. These effects continue for several minutes until the hormones are destroyed by the liver. Thus, although sympathetic nerve impulses act only briefly, the hormonal effects they provoke linger. The widespread and prolonged effect of sympathetic activation helps explain why we need time to "come down" after an extremely stressful experience.

Control of Autonomic Functioning

Although the ANS is not usually considered to be under voluntary control, its activity *is* regulated by CNS controls in the spinal cord, brain stem, hypothalamus, and cerebral cortex (Figure 14.9). In general, the

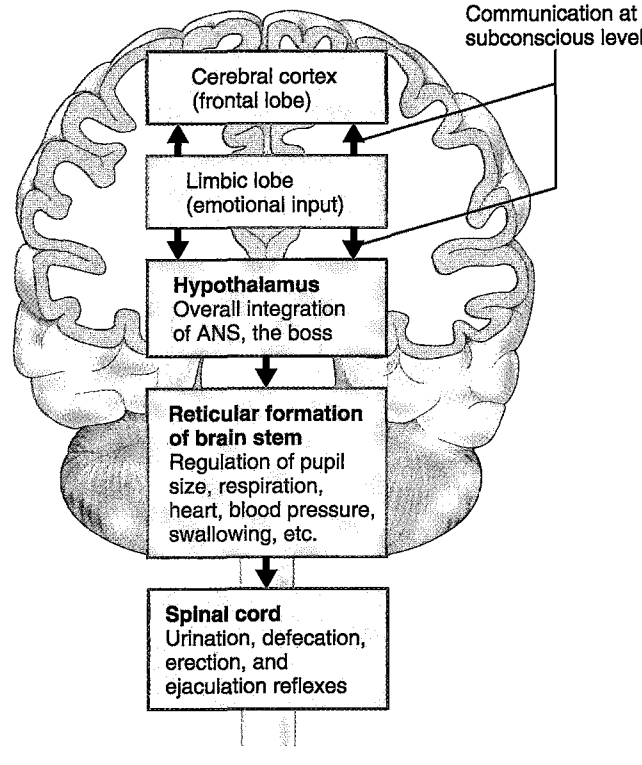

FIGURE 14.9 **Levels of ANS control.** The hypothalamus stands at the top of the control hierarchy as the integrator of ANS activity. However, subconscious cerebral inputs via limbic lobe connections influence hypothalamic functioning.

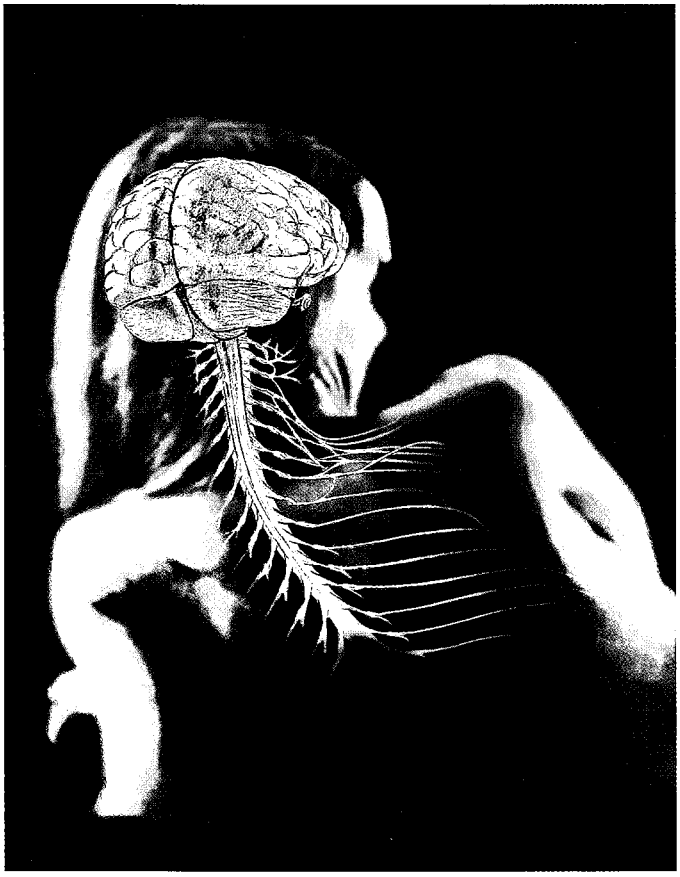
SYSTEM CONNECTIONS: Homeostatic Interrelationships Between the Nervous System and Other Body Systems



Integumentary System

- Sympathetic division of the ANS regulates sweat glands and blood vessels of skin (therefore heat loss/retention)
- Skin serves as heat loss surface

Skeletal System

- Nerves innervate bones and joints, providing for pain and joint sense
- Bones serve as depot for calcium needed for neural function; skeletal system protects CNS structures

Muscular System

- Somatic division of nervous system activates skeletal muscles; maintains muscle health
- Skeletal muscles are the effectors of the somatic division

Endocrine System

- Sympathetic division of the ANS activates the adrenal medulla; hypothalamus helps regulate the activity of the anterior pituitary gland and produces the two posterior pituitary hormones
- Hormones influence neuronal metabolism

Cardiovascular System

- ANS helps regulate heart rate and blood pressure
- Cardiovascular system provides blood containing oxygen and nutrients to the nervous system and carries away wastes

Lymphatic System/Immunity

- Nerves innervate lymphoid organs; the brain plays a role in regulating immune function
- Lymphatic vessels carry away leaked tissue fluids from tissues surrounding nervous system structures; immune elements protect all body organs from pathogens (CNS has additional mechanisms as well)

Respiratory System

- Nervous system initiates and regulates respiratory rhythm and depth
- Respiratory system provides life-sustaining oxygen; disposes of carbon dioxide

Digestive System

- ANS (particularly the parasympathetic division) regulates digestive motility and glandular activity
- Digestive system provides nutrients needed for neuronal health

Urinary System

- ANS regulates bladder emptying and renal blood pressure
- Kidneys help to dispose of metabolic wastes and maintain proper electrolyte composition and pH of blood for neural functioning

Reproductive System

- ANS regulates sexual erection and ejaculation in males; erection of the clitoris in females
- Testosterone causes masculinization of the brain and underlies sex drive and aggressive behavior

THE NERVOUS SYSTEM and Interrelationships with the Muscular, Respiratory, and Digestive Systems

The nervous system pokes its figurative nose into the activities of virtually every organ system of the body. Hence, trying to choose the most significant interactions comes pretty close to a lesson in futility. Which is more important: digestion, elimination of wastes, or motility? Your answer probably depends on whether you are hungry or need to

make a "pit stop" at the bathroom when you read this. Since neural interactions with several other systems are thoroughly plumbed in chapters to come, here we will look at the all-important interactions between the nervous system and the muscular, respiratory, and digestive systems.

Muscular System

Most simply said, the muscular system would cease to function without the nervous system. Unlike visceral or cardiac muscles, both of which have other controlling systems, somatic motor fibers are *it* for skeletal muscle activation and regulation. Somatic nerve fibers "tell" skeletal muscles not only when to contract but also how strongly. Additionally, as the nervous system makes its initial synapses with skeletal muscle fibers, it determines their fate as fast or slow fibers, which forever after affects our potential for muscle speed and endurance. The interactions of the various brain regions (basal nuclei, cerebellum, premotor cortex, etc.) and inputs of stretch receptors also determine our grace—how smooth and coordinated we are. Nonetheless, keep in mind that as long as the skeletal muscle effector cells are healthy, they help determine the viability of the neurons synapsing with them. The relationship is truly synergistic.

Respiratory System

Another system that depends entirely on the nervous system for its function is the respiratory system, which continuously refreshes the blood with oxygen and unloads the carbon dioxide waste to the sea of air that surrounds us. Neural centers in the medulla and pons both initiate and maintain the tidelike rhythm of air flushing into and out of our lungs by activating skeletal muscles that change the volume (thus the gas pressure) within the lungs. Peripheral receptors supply information about gas concentrations, lung stretch and skeletal muscle activity to these CNS respiratory centers.

Digestive System

Although the digestive system responds to many different types of controls—for example, hormones, local pH, and irritating chemicals—the parasympathetic nervous system is crucial to its normal functioning. Without the parasympathetic inputs, sympathetic neural activity, which inhibits normal digestion would be unopposed. So important are parasympathetic controls that some of the parasympathetic neurons are actually located in the walls of the digestive organs, in what are called intrinsic plexuses. Thus, even if all extrinsic controls are severed, the intrinsic mechanisms can still maintain this crucial body function. The role the digestive system plays for the nervous system is the same one it offers to all body systems—it sees that ingested foodstuff gets digested and loaded into the blood for cell use.

CLINICAL CONNECTIONS

Nervous System

Case study: On arrival at Holyoke Hospital, Jimmy Chin, a 10-year-old boy, is immobilized on a rigid stretcher so that he is unable to move his head or trunk. The paramedics report that when they found him some 50 feet from the bus, he was awake and alert, but crying and complaining that he couldn't "get up to find his mom" and that he had a "wicked headache." He has severe bruises on his upper back and head, and lacerations of his back and scalp. His blood pressure is low, body temperature is below normal, lower limbs are paralyzed, and he is insensitive to painful stimuli below the nipples. Although still alert on arrival, Jimmy soon begins to drift in and out of unconsciousness.

Jimmy is immediately scheduled for a CT scan, an operating room is reserved, and an intravenous infusion of dexamethasone, an anti-inflammatory steroid, is started.

Relative to Jimmy's condition:

1. Why were his head and torso immobilized for transport to the hospital?
2. What do his worsening neurological signs (drowsiness, incoherence, etc.) probably indicate? (Relate this to the type of surgery that will be performed.)
3. Why was dexamethasone ordered?
4. Assuming that Jimmy's sensory and motor deficits are due to a spinal cord injury, at what level do you expect to find a spinal cord lesion?
5. Two days after his surgery, Jimmy is alert and his MRI scan shows no residual brain injury, but pronounced swelling and damage to the spinal cord at T_4. On physical examination, Jimmy shows no reflex activity below the level of the spinal cord injury. His blood pressure is still low. Why are there no reflexes in his lower limbs and abdomen?
6. Over the next few days, his reflexes return in his lower limbs and become exaggerated. He is incontinent. Why is Jimmy hyperreflexive and incontinent?

On one occasion, Jimmy complains of a massive headache and his blood pressure is way above normal. On examination, he is sweating intensely above the nipples but has cold, clammy skin below the nipple and his heart rate is very slow.

7. What is this condition called and what precipitates it?
8. How does Jimmy's excessively high blood pressure put him at risk?

(Answers in Appendix G)

hypothalamus is the integrative center at the top of the ANS control hierarchy. From there, orders flow to lower and lower CNS centers for execution. Although the cerebral cortex may modify the workings of the ANS, it does so at the subconscious level and by acting through limbic system structures on hypothalamic centers.

Brain Stem and Spinal Cord Controls

The hypothalamus is the "boss," but the brain stem reticular formation appears to exert the most *direct* influence over autonomic functions. For example, certain motor centers in the ventrolateral medulla (*cardiac* and *vasomotor centers*) reflexively regulate heart rate and blood vessel diameter. Other medullary regions oversee gastrointestinal activities. Most sensory impulses involved in eliciting these autonomic reflexes reach the brain stem via vagus nerve afferents. Although not considered part of the ANS, the medulla and pons also contain respiratory centers that mediate involuntary control of respiration and receive inputs from the hypothalamus. Midbrain centers *(oculomotor nuclei)* control the muscles concerned with pupil diameter and lens focus. Defecation and micturition reflexes that promote emptying of the rectum and bladder are integrated at the spinal cord level but are subject to conscious inhibition. All of these autonomic reflexes are described in later chapters in relation to the organ systems they serve.

Hypothalamic Controls

As noted, the main integration center of the autonomic nervous system is the hypothalamus. In general, anterior hypothalamic regions direct parasympathetic functions, whereas posterior areas direct sympathetic functions. These centers exert their effects both directly and via relays through the *reticular formation,* which in turn influences the preganglionic motor neurons in the brain stem and spinal cord (Figure 14.9). The hypothalamus contains centers that coordinate heart activity, blood pressure, body temperature, water balance, and endocrine activity. It also contains centers that mediate various emotional states (rage, pleasure) and biological drives (thirst, hunger, sex).

Via its associations with the periaqueductal gray matter and the amygdala, the hypothalamus also mediates our reactions to fear. Emotional responses of the limbic system of the cerebrum to danger and stress signal the hypothalamus to activate the sympathetic system to fight-or-flight status. Thus, the hypothalamus serves as the keystone of the emotional and visceral brain, and through its centers emotions influence ANS functioning and behavior.

Cortical Controls

It was originally believed that the ANS is not subject to voluntary controls. However, we have all had occasions when remembering a frightening event made our heart race (sympathetic response) or just the thought of a favorite food, pecan pie for example, made our mouth water (a parasympathetic response). These inputs converge on the hypothalamus through its connections to the limbic lobe.

Additionally, studies have shown that voluntary cortical control of visceral activities is possible—a capability untapped by most people.

Influence of Biofeedback on Autonomic Function

During **biofeedback training,** subjects are connected to monitoring devices that provide an awareness of what is happening in their body. This awareness is called **biofeedback.** The devices detect and amplify changes in physiological processes such as heart rate and blood pressure, and these data are "fed back" in the form of flashing lights or audible tones. Subjects are asked to try to alter or control some "involuntary" function by concentrating on calming, pleasant thoughts. The monitor allows them to identify changes in the desired direction, so they can recognize the feelings associated with these changes and learn to produce the changes at will.

Biofeedback techniques have been successful in helping individuals plagued by migraine headaches. They are also used by cardiac patients to manage stress and reduce their risk of heart attack. However, biofeedback training is time-consuming and often frustrating, and the training equipment is expensive and difficult to use.

Homeostatic Imbalances of the ANS

Because the ANS is involved in nearly every important process that goes on in the body, it is not surprising that abnormalities of autonomic functioning can have far-reaching effects and threaten life itself. Most autonomic disorders reflect exaggerated or deficient controls of smooth muscle activity. Of these, the most devastating involve blood vessels and include conditions such as hypertension, Raynaud's disease, and autonomic dysreflexia.

Hypertension, or high blood pressure, may result from an overactive sympathetic vasoconstrictor response promoted by continuous high levels of stress. Hypertension is always serious because it increases the workload on the heart, which may precipitate heart disease, and increases the wear and tear on artery walls. Stress-induced hypertension can be treated with adrenergic receptor–blocking drugs.

Raynaud's disease is characterized by intermittent attacks causing the skin of the fingers and toes to become pale, then cyanotic and painful. Commonly provoked by exposure to cold or emotional stress, it is an exaggerated vasoconstriction response. The severity of this disease ranges from merely uncomfortable to such severe blood vessel constriction that ischemia and gangrene (tissue death) results. Vasodilators (for example, adrenergic blockers) usually suffice, but to treat very severe cases, preganglionic sympathetic fibers serving the affected regions are severed (a procedure called *sympathectomy*). The involved vessels then dilate, reestablishing adequate blood delivery to the region.

Autonomic dysreflexia is a life-threatening condition involving uncontrolled activation of autonomic neurons. It occurs in a majority of individuals with quadriplegia and in others with spinal cord injuries above the T_6 level, usually in the first year after injury. The usual trigger is a painful stimulus to the skin or overfilling of a visceral organ, such as the bladder. Arterial blood pressure skyrockets to life-threatening levels, which may rupture a blood vessel in the brain, precipitating stroke. This may be accompanied by a headache, flushed face, sweating above the level of the injury, and cold, clammy skin below. The precise mechanism of autonomic dysreflexia is not yet clear.

Developmental Aspects of the ANS

ANS preganglionic neurons derive from the embryonic *neural tube*, as do somatic motor neurons. ANS structures in the PNS—ganglionic neurons, the adrenal medulla, and all autonomic ganglia—derive from the *neural crest* (along with all sensory neurons). Neural crest cells reach their ultimate destinations by migrating along growing axons. Forming ganglia receive axons from preganglionic neurons in the cord or brain and send their axons to synapse with their effector cells in the body periphery. This process depends upon the presence of **nerve growth factor,** and is guided by a number of signaling chemicals similar to those acting in the CNS.

During youth, impairments of ANS function are usually due to injuries to the spinal cord or autonomic nerves. In old age the efficiency of the ANS begins to decline. At least part of the problem appears to be due to structural changes (bloating) of some preganglionic axon terminals, which become congested with neurofilaments.

Many elderly people complain of constipation (a result of reduced gastrointestinal tract motility), and of dry eyes and frequent eye infections (both a result of a diminished ability to form tears). Additionally, when they stand up they may have fainting episodes due to **orthostatic hypotension** (*ortho* = straight; *stat* = standing), a form of low blood pressure that occurs because the aging pressure receptors respond less to changes in blood pressure following changes in position, and because of slowed responses by aging sympathetic vasoconstrictor centers. These problems are distressing, but not usually life threatening, and most can be managed by lifestyle changes or artificial aids. For example, changing position slowly gives the sympathetic nervous system time to adjust the blood pressure; and eye drops (artificial tears) are available for the dry-eye problem.

▪ ▪ ▪

In this chapter, we have described the structure and function of the ANS, one arm of the motor division of the peripheral nervous system. Because virtually every organ system still to be considered depends on autonomic controls, you will be hearing more about the ANS in chapters that follow. Now that we have explored most of the nervous system, this is a good time to examine how it interacts with the rest of the body as summarized in the *Making Connections* feature, pp. 548–549.

Related Clinical Terms

Atonic bladder (ah-ton'ik; *a* = without; *ton* = tone, tension) A condition in which the urinary bladder becomes flaccid and overfills, allowing urine to dribble through the sphincters; results from temporary loss of the micturition reflex following spinal cord injury.

Horner's syndrome A condition due to damage to the superior sympathetic trunk on one side of the body; the affected person exhibits drooping of the upper eyelid (ptosis) and constricted pupil, and does not sweat on the affected side of the head.

Vagotomy (va-got'o-me) Cutting or severing of the vagus nerve to decrease secretion of gastric juice in those with peptic ulcers that do not respond to medication.

Vasovagal syncope Vasovagal syncope, also called *neurocardiogenic syncope,* is the most common cause of fainting. Although it may be provoked by emotional stress, pain, or dehydration, it typically occurs during prolonged standing. Fainting is due to a drop in blood pressure, which decreases blood flow to the brain and results in loss of consciousness.

Chapter Summary

Media study tools that could provide you additional help in reviewing specific key topics of Chapter 14 are referenced below.

IP = *InterActive Physiology*

1. The autonomic nervous system (ANS) is the motor division of the PNS that controls visceral activities, with the goal of maintaining internal homeostasis.

Introduction (pp. 533–535)

Comparison of the Somatic and Autonomic Nervous Systems (pp. 533–535)

1. The somatic (voluntary) nervous system provides motor fibers to skeletal muscles. The autonomic (involuntary or visceral motor) nervous system provides motor fibers to smooth and cardiac muscles and glands.

2. In the somatic division, a single motor neuron forms the efferent pathway from the CNS to the effectors. The efferent pathway of the autonomic division consists of a two-neuron chain: the preganglionic neuron in the CNS and the ganglionic neuron in a ganglion.

3. Acetylcholine, the neurotransmitter of somatic motor neurons, is stimulatory to skeletal muscle fibers. Neurotransmitters released by autonomic motor neurons (acetylcholine and norepinephrine) may cause excitation or inhibition.

IP Nervous System II; Topic: Synaptic Transmission, pp. 8–11.

ANS Divisions (p. 535)

4. The ANS consists of two divisions, the parasympathetic and sympathetic, which normally exert antagonistic effects on many of the same target organs.

5. The parasympathetic division (the resting-digesting system) conserves body energy and maintains body activities at basal levels.

6. Parasympathetic effects include pupillary constriction, glandular secretion, increased digestive tract motility, and smooth muscle activity leading to elimination of feces and urine.

7. The sympathetic division prepares the body for activity and is called the fight-or-flight system.

8. Sympathetic responses include dilated pupils, increased heart rate, increased blood pressure, dilation of the bronchioles of the lungs, increased blood glucose levels, and sweating. During exercise, sympathetic vasoconstriction shunts blood from the skin and digestive viscera to the heart, brain, and skeletal muscles.

ANS Anatomy (pp. 535–543)

Parasympathetic (Craniosacral) Division (pp. 536–538)

1. Parasympathetic preganglionic neurons arise from the brain stem and from the sacral (S_2–S_4) region of the cord.

2. Preganglionic fibers synapse with ganglionic neurons in terminal ganglia located in (intramural ganglia) or close to their effector organs. Preganglionic fibers are long; postganglionic fibers are short.

3. Cranial fibers arise in the brain stem nuclei of cranial nerves III, VII, IX, and X and synapse in ganglia of the head, thorax, and abdomen. The vagus nerves serve virtually all organs of the thoracic and abdominal cavities.

4. Sacral fibers (S_2–S_4) issue from the lateral region of the cord and form pelvic splanchnic nerves that innervate the pelvic viscera. The preganglionic axons do not travel within rami communicantes or spinal nerves.

Sympathetic (Thoracolumbar) Division (pp. 538–542)

5. Preganglionic sympathetic neurons arise from the lateral horn of the spinal cord from the level of T_1 to L_2.

6. Preganglionic axons leave the cord via white rami communicantes and enter the sympathetic trunk (chain) ganglia in the sympathetic trunk. An axon may synapse in a trunk ganglion at the same or at a different level, or it may issue from the sympathetic trunk without synapsing. Preganglionic fibers are short; postganglionic fibers are long.

7. When the synapse occurs in a trunk ganglion, the postganglionic fiber may enter the spinal nerve ramus via the gray ramus communicans to travel to the body periphery. Postganglionic fibers issuing from the cervical ganglia also serve visceral organs and blood vessels of the head, neck, and thorax.

8. When synapses do not occur in the trunk ganglia, the preganglionic fibers form splanchnic nerves (thoracic, lumbar, and sacral). Most splanchnic nerve fibers synapse in collateral ganglia, and the postganglionic fibers serve the abdominal viscera. Some splanchnic nerve fibers synapse with cells of the adrenal medulla.

Visceral Reflexes (p. 542)

9. Visceral reflex arcs have the same components as somatic reflexes.

10. Cell bodies of visceral sensory neurons are located in dorsal root ganglia, sensory ganglia of cranial nerves, or autonomic ganglia. Visceral afferents are found in spinal nerves and in virtually all autonomic nerves.

ANS Physiology (pp. 543–547, 550)

Neurotransmitters and Receptors (p. 543)

1. Two major neurotransmitters, acetylcholine (ACh) and norepinephrine (NE), are released by autonomic motor neurons. On the basis of the neurotransmitter released, the fibers are classified as cholinergic or adrenergic.

2. ACh is released by all preganglionic fibers and all parasympathetic postganglionic fibers. NE is released by all sympathetic postganglionic fibers except those serving the sweat glands of the skin, and some blood vessels within skeletal muscles.

3. Neurotransmitter effects depend on the receptors to which the transmitter binds. Cholinergic (ACh) receptors are classified as nicotinic or muscarinic. Adrenergic (NE) receptors are classified as α_1 or α_2, or β_1, β_2, or β_3.

IP Nervous System II; Topic: Synaptic Transmission, pp. 8–11, 14.

The Effects of Drugs (pp. 543–544)

4. Drugs that mimic, enhance, or inhibit the action of ANS neurotransmitters are used to treat conditions caused by excessive, inadequate, or inappropriate ANS functioning. Some drugs bind with only one receptor subtype, allowing specific ANS-mediated activities to be enhanced or blocked.

Interactions of the Autonomic Divisions (pp. 544–547)

5. Most visceral organs are innervated by both divisions; they interact in various ways but usually exert a dynamic antagonism. Antagonistic interactions mainly involve the heart, respiratory system, and gastrointestinal organs. Sympathetic activity increases heart and respiratory system activity and depresses gastrointestinal activity. Parasympathetic activity reverses these effects.

6. Most blood vessels are innervated only by sympathetic fibers and exhibit vasomotor tone. Parasympathetic activity dominates the heart and muscles of the gastrointestinal tract (which normally exhibit parasympathetic tone) and glands.

7. The two ANS divisions exert cooperative effects on the external genitalia.

8. Roles unique to the sympathetic division are blood pressure regulation, shunting of blood in the vascular system, thermoregulatory responses, stimulation of renin release by the kidneys, and metabolic effects.

9. Activation of the sympathetic division can cause widespread, long-lasting mobilization of the fight-or-flight response. Parasympathetic effects are highly localized and short lived.

Control of Autonomic Functioning (pp. 547, 550)

10. Autonomic function is controlled at several levels: (1) Reflex activity is mediated by the spinal cord and brain stem (particularly medullary) centers; (2) hypothalamic integration centers interact with both higher and lower centers to orchestrate autonomic, somatic, and endocrine responses; and (3) cortical centers influence autonomic functioning via connections with the limbic system; conscious controls of autonomic function are rare but possible, as illustrated by biofeedback training.

Homeostatic Imbalances of the ANS (pp. 550–551)

1. Most autonomic disorders reflect problems with smooth muscle control. Abnormalities in vascular control, such as occur in hypertension, Raynaud's disease, and autonomic dysreflexia, are most devastating.

Developmental Aspects of the ANS (p. 551)

1. Preganglionic neurons develop from the neural tube; ganglionic neurons develop from the embryonic neural crest.

2. The efficiency of the autonomic nervous system declines in old age, as reflected by decreased glandular secretory activity, decreased gastrointestinal motility, and slowed sympathetic vasomotor responses to changes in position.

Review Questions

Multiple Choice/Matching

(Some questions have more than one correct answer. Select the best answer or answers from the choices given.)

1. All of the following characterize the ANS except (a) two-neuron efferent chain, (b) presence of nerve cell bodies in the CNS, (c) presence of nerve cell bodies in the ganglia, (d) innervation of skeletal muscles.

2. Relate each of the following terms or phrases to either the sympathetic (S) or parasympathetic (P) division of the autonomic nervous system:

____ (1) short preganglionic, long postganglionic fibers
____ (2) intramural ganglia
____ (3) craniosacral outflow
____ (4) adrenergic fibers
____ (5) cervical ganglia
____ (6) otic and ciliary ganglia
____ (7) generally short duration action
____ (8) increases heart rate and blood pressure
____ (9) increases gastric motility and secretion of lacrimal, salivary, and digestive juices
____ (10) innervates blood vessels
____ (11) most active when you are swinging in a hammock
____ (12) active when you are running in the Boston Marathon

3. Preganglionic neurons develop from (a) neural crest cells, (b) neural tube cells, (c) alar plate cells, (d) endoderm.

4. The white rami communicantes contain what kind of fibers? (a) preganglionic parasympathetic, (b) postganglionic parasympathetic, (c) preganglionic sympathetic, (d) postganglionic sympathetic.

5. Prevertebral sympathetic ganglia are involved with the innervation of the (a) abdominal organs, (b) thoracic organs, (c) head, (d) arrector pili, (e) all of these.

Short Answer Essay Questions

6. Briefly explain why the following terms are sometimes used to refer to the autonomic nervous system: involuntary nervous system and emotional-visceral system.

7. Describe the anatomical relationship of the white and gray rami to the spinal nerve, and indicate the kind of fibers found in each ramus type.

8. Indicate the results of sympathetic activation of the following structures: sweat glands, eye pupils, adrenal medulla, heart, lungs, liver, blood vessels of vigorously working skeletal muscles, blood vessels of digestive viscera, salivary glands.

9. Which of the effects listed in response to question 8 would be reversed by parasympathetic activity?

10. Which ANS fibers release acetylcholine? Which release norepinephrine?

11. Describe the meaning and importance of sympathetic tone and parasympathetic tone.

12. List the receptor subtypes for ACh and NE, and indicate the major sites where each type is found.

13. What area of the brain is most directly involved in mediating autonomic reflexes?

14. Describe the importance of the hypothalamus in controlling the autonomic nervous system.

15. Describe the basis and uses of biofeedback training.

16. What manifestations of decreased autonomic nervous system efficiency are seen in elderly individuals?

17. Ganglionic neurons were initially called postganglionic neurons. Why is this a misnomer?

Critical Thinking and Clinical Application Questions

1. Mr. Johnson has been suffering from functional urinary retention and a hypoactive urinary bladder. Bethanechol, a drug that mimics acetylcholine's autonomic effects, is prescribed to manage his problem. First explain the rationale for prescribing bethanechol, and then predict which of the following adverse effects Mr. Johnson might experience while taking this drug (select all that apply): dizziness, low blood pressure, deficient tear formation, wheezing, increased mucus production in bronchi, deficient salivation, diarrhea, cramping, excessive sweating, undesirable erection of penis.

2. Mr. Jake was admitted to the hospital with excruciating pain in his left shoulder and arm. He was found to have suffered a heart attack. Explain the phenomenon of referred pain as exhibited by Mr. Jake.

3. A 32-year-old woman complains that she has been experiencing aching pains in the medial two fingers of both hands and that during such episodes, the fingers become blanched and then blue. Her history is taken, and it is noted that she is a heavy smoker. The physician advises her that she must stop smoking and states that he will not prescribe any medication until she has discontinued smoking for a month. What is this woman's problem, and why was she told to stop smoking?

4. Tiffany, a 21-year-old college student, had been having trouble sleeping, crying frequently, and having recurrent thoughts of suicide. She was prescribed an antidepressant. Like many such drugs, this antidepressant has anticholinergic side effects. What side effects might Tiffany experience in the first week of treatment?

5. As the aroma of freshly brewed coffee drifted by dozing Henry's nose, his mouth started to water and his stomach began to rumble. Explain his reactions in terms of ANS activity.

6. Which clinical condition has the classic signs of blue fingertips that later turn red?

CHAPTER

The Special Senses

The Eye and Vision (pp. 556–578)

1. Describe the structure and function of accessory eye structures, eye layers, the lens, and humors of the eye.
2. Trace the pathway of light through the eye to the retina, and explain how light is focused for distant and close vision.
3. Describe the events involved in the stimulation of photoreceptors by light, and compare and contrast the roles of rods and cones in vision.
4. Note the cause and consequences of astigmatism, cataract, glaucoma, hyperopia, myopia, presbyopia, and color blindness.
5. Compare and contrast light and dark adaptation.
6. Trace the visual pathway to the visual cortex, and briefly describe the steps in visual processing.

The Chemical Senses: Taste and Smell (pp. 578–583)

7. Describe the location, structure, and afferent pathways of taste and smell receptors, and explain how these receptors are activated.

The Ear: Hearing and Balance (pp. 583–598)

8. Describe the structure and general function of the outer, middle, and internal ears.
9. Describe the sound conduction pathway to the fluids of the internal ear, and follow the auditory pathway from the spiral organ (of Corti) to the temporal cortex.
10. Explain how one is able to differentiate pitch and loudness and localize the source of sounds.
11. Explain how the balance organs of the semicircular canals and the vestibule help maintain dynamic and static equilibrium.
12. List possible causes and symptoms of otitis media, deafness, Ménière's syndrome, and motion sickness.

Developmental Aspects of the Special Senses (pp. 598–599)

13. List changes that occur in the special sense organs with aging.

People are responsive creatures. The aroma of freshly baked bread makes our mouths water. A sudden clap of thunder makes us jump. These stimuli and many others continually greet us and are interpreted by our nervous systems.

We are usually told that we have five senses: touch, taste, smell, sight, and hearing. Actually, touch reflects the activity of the general senses that we considered in Chapter 13. The other four traditional senses—*smell, taste, sight,* and *hearing*—are called **special senses.** Receptors for a fifth special sense, *equilibrium,* are housed in the ear, along with the organ of hearing. In contrast to the widely distributed general receptors (most of which are modified nerve endings of sensory neurons), the **special sensory receptors** are distinct *receptor cells.* These receptor cells are confined to the head region and are highly localized, either housed within complex sensory organs (eyes and ears) or in distinct epithelial structures (taste buds and olfactory epithelium).

This chapter considers the functional anatomy of each of the five special senses. But keep in mind that our perceptions of sensory inputs are overlapping. What we finally experience—our "feel" of the world—is a blending of stimulus effects.

The Eye and Vision

15

Vision is our dominant sense: Some 70% of all the sensory receptors in the body are in the eyes, and nearly half of the cerebral cortex is involved in some aspect of visual processing.

The adult **eye** is a sphere with a diameter of about 2.5 cm (1 inch). Only the anterior one-sixth of the eye's surface is visible (Figure 15.1); the rest is enclosed and protected by a cushion of fat and the walls of the bony orbit. The fat pad occupies nearly all of the orbit not occupied by the eye itself. The eye is a complex structure and only a small portion of its tissues are actually involved in photoreception. Before turning our attention to the eye itself, let us consider the accessory structures that protect it or aid its functioning.

Accessory Structures of the Eye

The **accessory structures** of the eye include the eyebrows, eyelids, conjunctiva, lacrimal apparatus, and extrinsic eye muscles.

Eyebrows

The **eyebrows** are short, coarse hairs that overlie the supraorbital margins of the skull (Figure 15.1). They help shade the eyes from sunlight and prevent perspiration trickling down the forehead from reaching the eyes. Deep to the skin of the eyebrows are parts of the orbicularis oculi and corrugator muscles. Contraction of the orbicularis muscle depresses the eyebrow, whereas the corrugator moves the eyebrow medially.

Eyelids

Anteriorly, the eyes are protected by the mobile **eyelids** or **palpebrae** (pal'pĕ-bre). The eyelids are separated by the **palpebral fissure** ("eyelid slit") and meet at the medial and lateral angles of the eye—the **medial** and **lateral commissures (canthi),** respectively (Figure 15.1a). The medial canthus sports a fleshy elevation called the **lacrimal caruncle** (kar'ung-kl; "a bit of flesh"). The caruncle contains sebaceous and sweat glands and produces the whitish, oily secretion (fancifully called the Sandman's eyesand) that sometimes collects at the medial canthus, especially during sleep. In most Asian peoples, a vertical fold of skin called the *epicanthic fold* commonly appears on both sides of the nose and sometimes covers the medial commissure.

The eyelids are thin, skin-covered folds supported internally by connective tissue sheets called **tarsal plates** (Figure 15.1b). The tarsal plates also anchor the orbicularis oculi and **levator palpebrae superioris** muscles that run within the eyelid. The orbicularis muscle encircles the eye; when it contracts, the eye closes. Of the two eyelids, the larger, upper one is much more mobile, mainly because of the levator palpebrae superioris muscle, which raises that eyelid to open the eye. The eyelid muscles are activated reflexively to cause blinking every 3–7 seconds and to protect the eye when it is threatened by foreign objects. Reflex blinking helps prevent drying of the eyes because each time we blink, accessory structure secretions (oil, mucus, and saline solution) are spread across the eyeball surface.

Projecting from the free margin of each eyelid are the **eyelashes.** The follicles of the eyelash hairs are richly innervated by nerve endings (hair follicle receptors), and anything that touches the eyelashes (even a puff of air) triggers reflex blinking.

Several types of glands are associated with the eyelids. The **tarsal glands** (*Meibomian glands;* mi-bo'me-an) are embedded in the tarsal plates (see Figure 15.1b), and their ducts open at the eyelid edge just posterior to the eyelashes. These modified sebaceous glands produce an oily secretion that lubricates the eyelid and the eye and prevents the eyelids from sticking together. Associated with the eyelash follicles are a number of smaller, more typical sebaceous glands, and modified sweat glands called *ciliary glands* lie between the hair follicles (*cilium* = eyelash).

HOMEOSTATIC IMBALANCE

Infection of a tarsal gland results in an unsightly cyst called a *chalazion* (kah-la'ze-on; "swelling"). Inflammation of any of the smaller glands is called a *sty.*

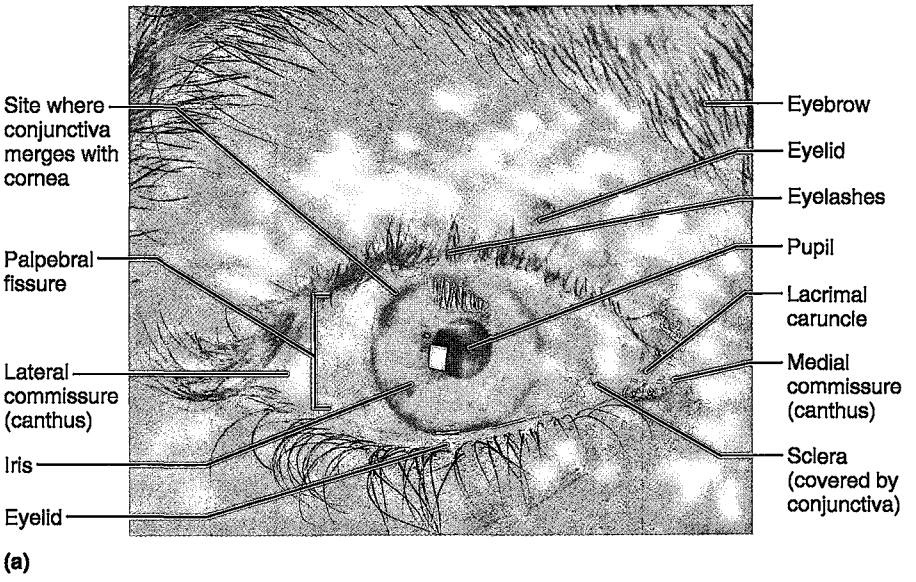

FIGURE 15.1 **The eye and associated accessory structures.** **(a)** Surface anatomy of the right eye. The eyelids are open more widely than normal to show the entire iris. **(b)** Lateral view; some structures are shown in sagittal section.

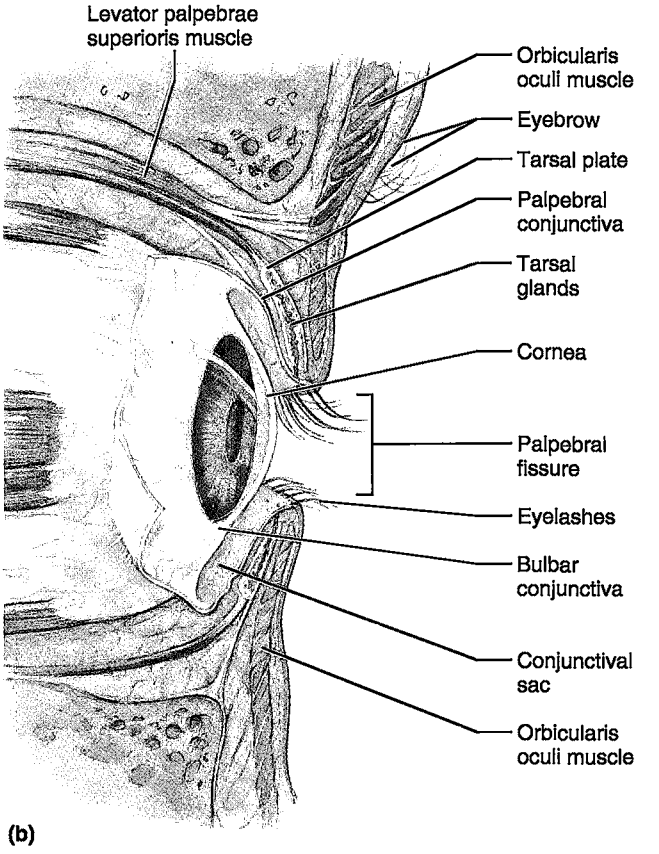
Conjunctiva

The **conjunctiva** (kon"junk-ti'vah; "joined together") is a transparent mucous membrane. It lines the eyelids as the **palpebral conjunctiva** and reflects (folds back) over the anterior surface of the eyeball as the **bulbar conjunctiva** (see Figure 15.1b). The latter covers only the white of the eye, not the cornea (the clear "window" over the iris and pupil). The bulbar conjunctiva is very thin, and blood vessels are clearly visible beneath it. (They are even more visible in irritated "bloodshot" eyes.) When the eye is closed, a slitlike space occurs between the conjunctiva-covered eyeball and eyelids. This so-called **conjunctival sac** is where a contact lens lies, and eye medications are often administered into its inferior recess. The major function of the conjunctiva is to produce a lubricating mucus that prevents the eyes from drying out.

HOMEOSTATIC IMBALANCE

Inflammation of the conjunctiva, called *conjunctivitis*, results in reddened, irritated eyes. *Pinkeye*, a conjunctival infection caused by bacteria or viruses, is highly contagious. ●



Lacrimal Apparatus

The **lacrimal apparatus** (lak'rĭ-mal; "tear") consists of the lacrimal gland and the ducts that drain excess lacrimal secretions into the nasal cavity (Figure 15.2). The **lacrimal gland** lies in the orbit above the lateral end of the eye and is visible through the conjunctiva when the lid is everted. It continually releases a dilute saline solution called **lacrimal secretion**—or, more commonly, **tears**—into the superior part of the conjunctival sac through several small excretory ducts. Blinking spreads the tears downward and across the eyeball to the medial commissure, where they enter the paired **lacrimal canaliculi** via two tiny openings called **lacrimal puncta** (literally, "prick points"), visible as tiny red dots on the medial margin of each eyelid. From the lacrimal canaliculi, the tears drain into the **lacrimal sac** and then into the **nasolacrimal duct,** which empties into the nasal cavity at the inferior nasal meatus.

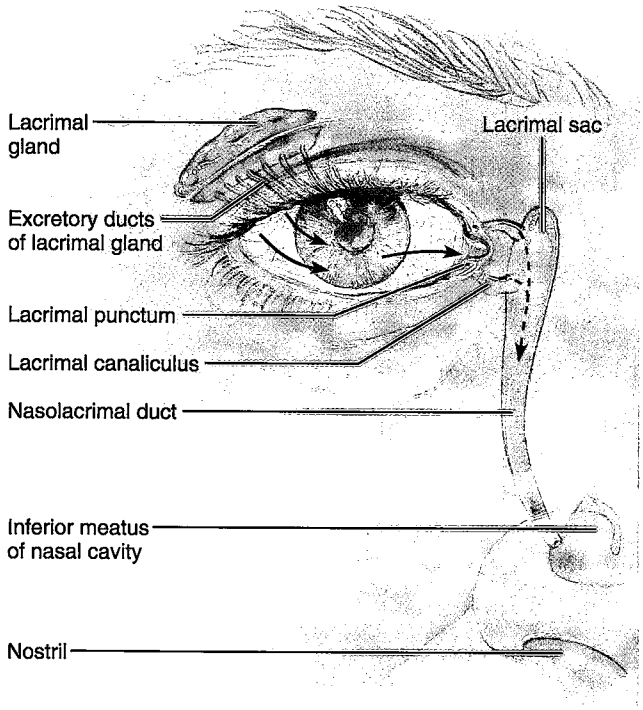


FIGURE 15.2 **The lacrimal apparatus.** Arrows indicate the direction of flow of lacrimal fluid (tears) after its secretion by the lacrimal gland.

Lacrimal fluid contains mucus, antibodies, and **lysozyme,** an enzyme that destroys bacteria. Thus, it cleanses and protects the eye surface as it moistens and lubricates it. When lacrimal secretion increases substantially, tears spill over the eyelids and fill the nasal cavities, causing congestion and the "sniffles." This happens when the eyes are irritated and when we are emotionally upset. In the case of eye irritation, enhanced tearing serves to wash away or dilute the irritating substance. The importance of emotionally induced tears is poorly understood.

HOMEOSTATIC IMBALANCE

Because the nasal cavity mucosa is continuous with that of the lacrimal duct system, a cold or nasal inflammation often causes the lacrimal mucosa to become inflamed and swell. This constricts the ducts and prevents tears from draining from the eye surface, causing "watery" eyes.

Extrinsic Eye Muscles

The movement of each eyeball is controlled by six straplike **extrinsic eye muscles,** which originate from the bony orbit and insert into the outer surface of the eyeball (Figure 15.3). These muscles allow the eyes to follow a moving object, and provide external "guy-wires" that help to maintain the shape of the eyeball and hold it in the orbit.

The four *rectus muscles* originate from a common tendinous ring, the **annular ring,** at the back of the orbit and run straight to their insertion on the eyeball. Their locations and the movements that they promote are clearly indicated by their names: **superior, inferior, lateral,** and **medial rectus muscles.** The actions of the two *oblique muscles* are less easy to deduce because they take rather strange paths through the orbit. They move the eye in the vertical plane when the eyeball is already turned medially by the rectus muscle. The **superior oblique muscle** originates in common with the rectus muscles, runs along the medial wall of the orbit, and then makes a right-angle turn and passes through a fibrocartilaginous loop suspended from the frontal bone called the **trochlea** (trok'le-ah; "pulley") before inserting on the superolateral aspect of the eyeball. It rotates the eye downward and somewhat laterally. The **inferior oblique muscle** originates from the medial orbit surface and runs laterally and obliquely to insert on the inferolateral eye surface. It rotates the eye up and laterally.

The four rectus muscles would seem to provide all the eye movements we require—medial, lateral, superior, and inferior—so why the two oblique muscles? The simplest way to answer this question is to point out that the superior and inferior recti cannot elevate or depress the eye *without also turning it medially* because they approach the eye from a posteromedial direction. For an eye to be *directly* elevated or depressed, the lateral pull of the oblique muscles is necessary to cancel the medial pull of the superior and inferior recti.

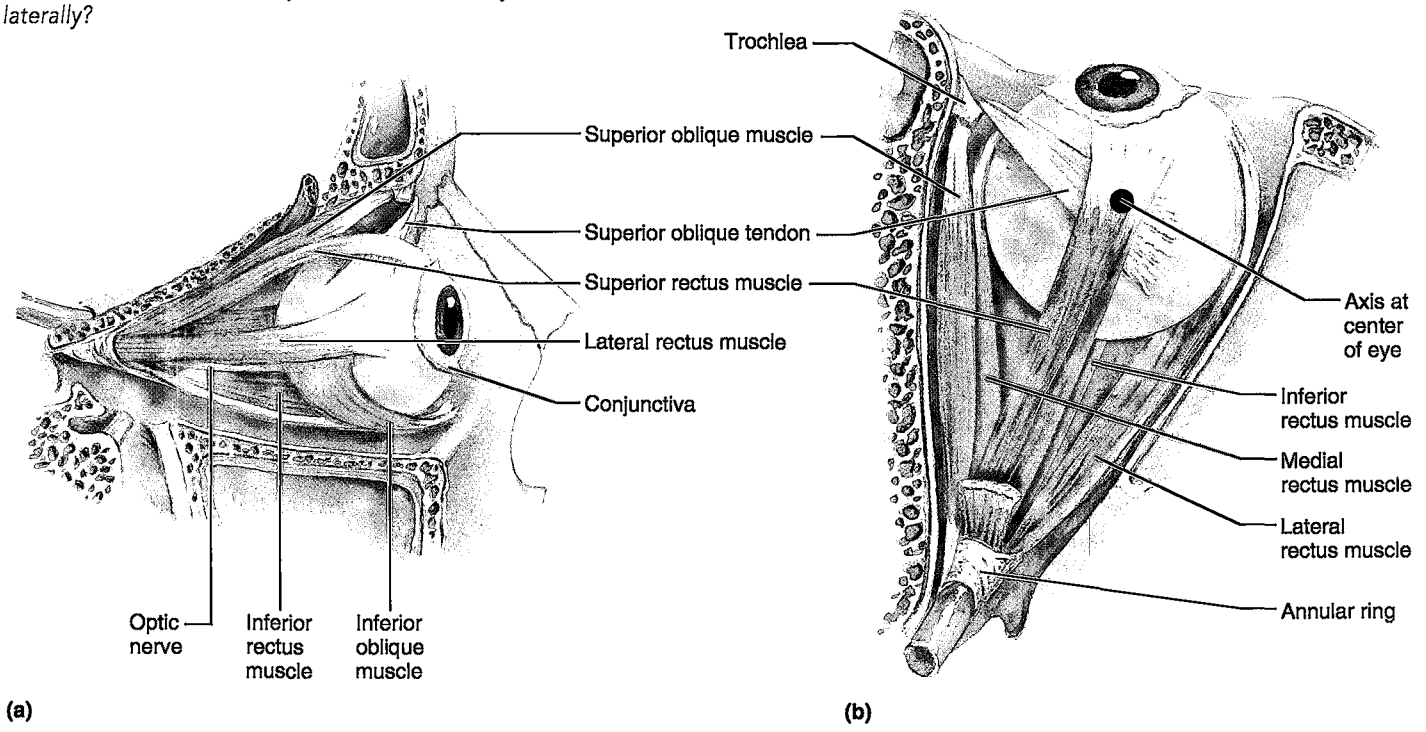
Except for the lateral rectus and superior oblique muscles, which are innervated respectively by the *abducens* and *trochlear nerves,* all extrinsic eye muscles are served by the *oculomotor nerves.* The actions and nerve supply of these muscles are summarized in Figure 15.3c. The courses of the associated cranial nerves are illustrated in Table 13.2.

The extrinsic eye muscles are among the most precisely and rapidly controlled skeletal muscles in the entire body. This reflects their high axon-to-muscle-fiber ratio: The motor units of these muscles contain only 8 to 12 muscle cells and in some cases as few as two or three.

HOMEOSTATIC IMBALANCE

When movements of the external muscles of the two eyes are not perfectly coordinated, a person cannot properly focus the images of the same area of the visual field from each eye and so sees two images instead of one. This condition is called **diplopia**

Q *Which three extrinsic eye muscles turn the eyeball laterally?*



Name	Action	Controlling cranial nerve
Lateral rectus	Moves eye laterally	VI (abducens)
Medial rectus	Moves eye medially	III (oculomotor)
Superior rectus	Elevates eye and turns it medially	III (oculomotor)
Inferior rectus	Depresses eye and turns it medially	III (oculomotor)
Inferior oblique	Elevates eye and turns it laterally	III (oculomotor)
Superior oblique	Depresses eye and turns it laterally	IV (trochlear)

(c)

(c) Summary of innervating cranial nerves and muscle actions.

(dĭ-plo'pe-ah), or *double vision.* It can result from paralysis or weakness of certain extrinsic muscles, or it may be a temporary consequence of acute alcohol intoxication.

Congenital weakness of the external eye muscles may cause **strabismus** (strah-biz'mus; "cross-eyed"), a condition in which the affected eye rotates medially or laterally. To compensate, the eyes may alternate in focusing on objects. In other cases, only the controllable eye is used, and the brain begins to disregard inputs from the deviant eye, which then becomes functionally blind. Strabismus is treated either with eye exercises to strengthen the weak muscles or by temporarily placing a patch on the stronger eye, which forces the child to use the weaker eye. Surgery is needed for unyielding conditions. ●

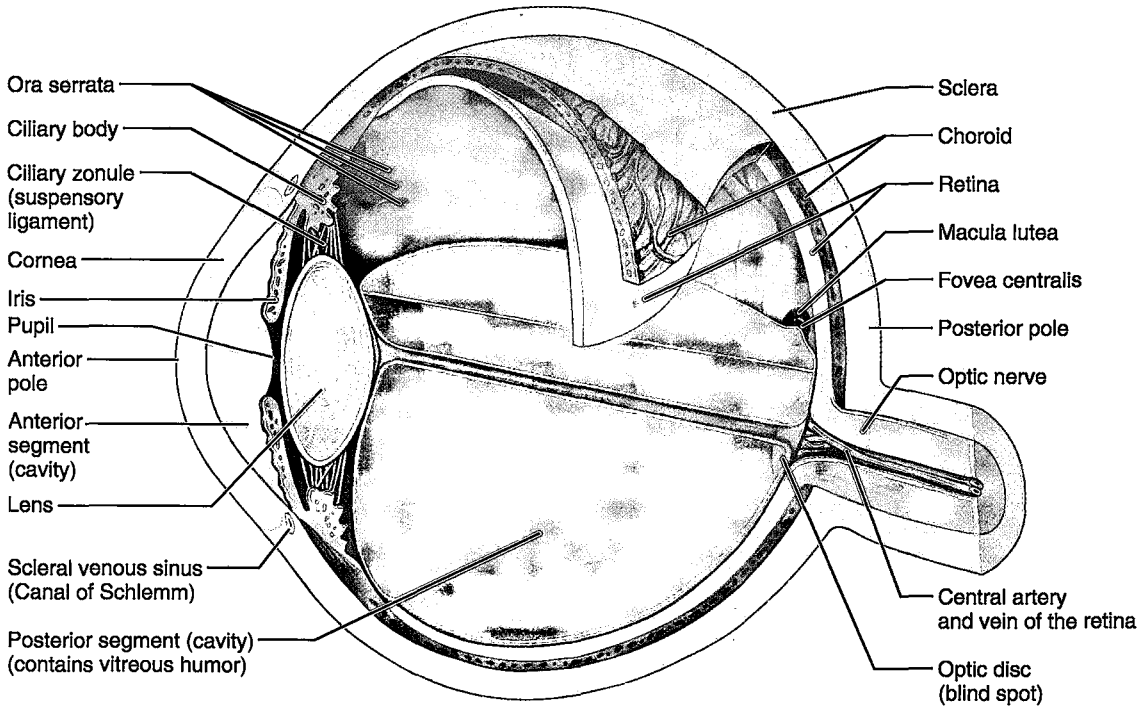
A The lateral rectus and the superior and inferior obliques.

Structure of the Eyeball

The eye itself, commonly called the **eyeball,** is a slightly irregular hollow sphere (Figure 15.4). Because the eyeball is shaped roughly like the globe of the earth, it is said to have poles. Its most anterior point is the **anterior pole;** its most posterior point, the **posterior pole.** Its wall is composed of three layers (formerly called tunics): the fibrous, vascular, and sensory layers. Its internal cavity is filled with fluids called *humors* that help to maintain its shape. The lens, the adjustable focusing apparatus of the eye, is supported vertically within the internal cavity, dividing it into *anterior* and *posterior segments,* or *cavities.*

Layers Forming the Wall of the Eyeball

The Fibrous Layer The outermost coat of the eye, the **fibrous layer,** is composed of dense avascular



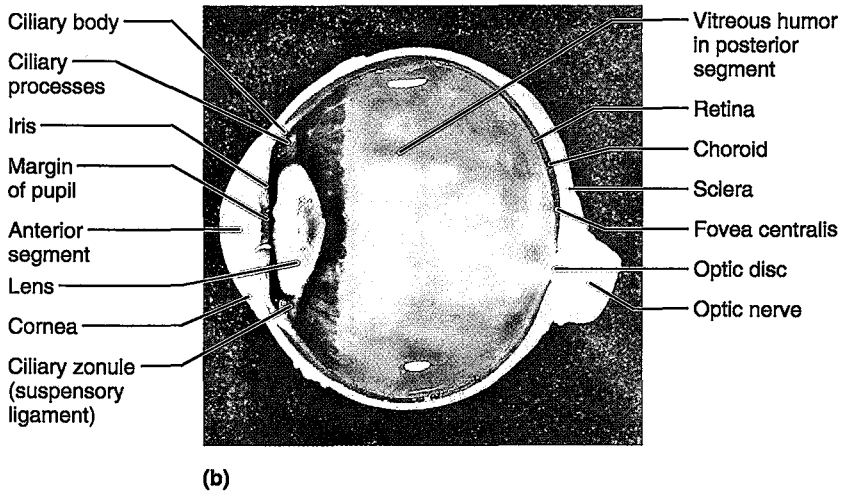


FIGURE 15.4 **Internal structure of the eye (sagittal section). (a)** Diagrammatic view. The vitreous humor is illustrated only in the bottom half of the eyeball. **(b)** Photograph of the human eye.

connective tissue. It has two obviously different regions: the sclera and the cornea. The **sclera** (skle'rah), forming the posterior portion and the bulk of the fibrous layer, is glistening white and opaque. Seen anteriorly as the "white of the eye," the tough, tendonlike sclera (*sclera* = hard) protects and shapes the eyeball and provides a sturdy anchoring site for the extrinsic eye muscles. Posteriorly, where the sclera is pierced by the optic nerve, it is continuous with the dura mater of the brain. The anterior sixth of the fibrous layer is modified to form the transparent **cornea,** which bulges anteriorly from its junction with the sclera. The crystal-clear cornea forms a window that lets light enter the eye, and is a major part of the light-bending apparatus of the eye.

The cornea is covered by epithelial sheets on both faces. The external sheet, a stratified squamous epithelium that helps protect the cornea from abrasion, merges with the bulbar conjunctiva at the sclera-cornea junction. Epithelial cells that continually renew the cornea are located here. The deep *corneal endothelium,* composed of simple squamous epithelium, lines the inner face of the cornea. Its cells have active sodium pumps that maintain the clarity of the cornea by keeping the water content of the cornea low.

The cornea is well supplied with nerve endings, most of which are pain receptors. (For this reason, some people can never adjust to wearing contact lenses.) When the cornea is touched, blinking and increased tearing occur reflexively. Even so, the cornea is the most exposed part of the eye and is very vulnerable to damage from dust, slivers, and the like. Luckily, its capacity for regeneration and repair is extraordinary. Furthermore, the cornea is the only tissue in the body that can be transplanted from one person to another with little or no possibility of rejection. Because it has no blood vessels, it is beyond the reach of the immune system.

The Vascular Layer (Uvea) The **vascular layer,** or middle coat of the eyeball, is also called the **uvea** (u've-ah; "grape"). The pigmented uvea has three regions: choroid, ciliary body, and iris (see Figure 15.4).

The **choroid** is a highly vascular, dark brown membrane (*choroids* = membranelike) that forms the posterior five-sixths of the uvea. Its blood vessels provide nutrition to all eye layers. Its brown pigment, produced by melanocytes, helps absorb light, preventing it from scattering and reflecting within the eye (which would cause visual confusion). The choroid is incomplete posteriorly where the optic nerve leaves the eye. Anteriorly, it becomes the **ciliary body,** a thickened ring of tissue that encircles the lens. The ciliary body consists chiefly of interlacing smooth muscle bundles called **ciliary muscles,** which are important in controlling lens shape. Near the lens, its posterior surface is thrown into radiating folds called **ciliary processes,** which contain the capillaries that secrete the fluid that fills the cavity of the anterior segment of the eyeball. The **ciliary zonule** *(suspensory ligament)* extends from the ciliary processes to the lens; this halo of fine fibers encircles and helps hold the lens in its upright position in the eye.

The **iris,** the visible colored part of the eye, is the most anterior portion of the uvea. Shaped like a flattened doughnut, it lies between the cornea and the lens and is continuous with the ciliary body posteriorly. Its round central opening, the **pupil,** allows light to enter the eye. The iris is made up of two smooth muscle layers with bunches of sticky elastic fibers that congeal into a random pattern before birth. Its muscle fibers allow it to act as a reflexively activated diaphragm to vary pupil size (Figure 15.5). In close vision and bright light, the *sphincter pupillae* (circular muscles) contract and the pupil constricts. In distant vision and dim light, the *dilator pupillae* (radial muscles) contract and the pupil dilates, allowing more light to enter the eye. Pupillary dilation and constriction are controlled by sympathetic and parasympathetic fibers, respectively.

Changes in pupil size may also reflect our interests and emotional reactions to what we are seeing.

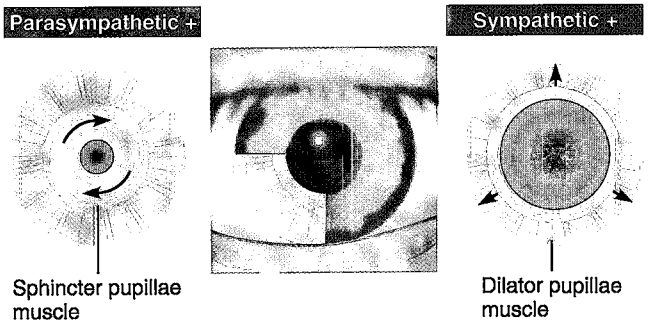

FIGURE 15.5 **Pupil dilation and constriction, anterior view.** Activation of parasympathetic fibers to sphincter pupillae (circular) muscles of the iris causes them to contract, decreasing pupil size. Activation of sympathetic fibers to dilator pupillae (radial) muscles of the iris causes them to contract, increasing pupil size.

Pupil dilation often occurs when the subject matter is appealing, in response to fear, and during problem solving. (Computing your taxes should make your pupils get bigger and bigger.) On the other hand, boredom or subject matter that is personally repulsive causes pupil constriction.

Although irises come in different colors (*iris* = rainbow), they contain only brown pigment. When they have a lot of pigment, the eyes appear brown or black. If the amount of pigment is small and restricted to the posterior surface of the iris, the shorter wavelengths of light are scattered from the unpigmented parts, and the eyes appear blue, green, or gray. Most newborn babies' eyes are slate gray or blue because their iris pigment is not yet developed.

The Inner Layer (Retina) The innermost layer of the eyeball is the delicate, two-layered **retina** (ret'ĭ-nah). Its outer **pigmented layer,** a single-cell-thick lining, abuts the choroid, and extends anteriorly to cover the ciliary body and the posterior face of the iris. These pigmented epithelial cells, like those of the choroid, absorb light and prevent it from scattering in the eye. They also act as phagocytes to remove dead or damaged photoreceptor cells, and store vitamin A needed by the photoreceptor cells. The transparent inner **neural layer** extends anteriorly to the posterior margin of the ciliary body. This junction is called the **ora serrata,** literally, the saw-toothed margin (see Figure 15.4). Originating as an outpocketing of the brain, the retina contains millions of photoreceptors that transduce light energy, other neurons involved in the processing of light stimuli, and glia. Although the pigmented and neural layers are very close together, they are not fused. Only the neural layer of the retina plays a direct role in vision.

From posterior to anterior, the neural layer is composed of three main types of neurons: **photoreceptors,**

Q *Which retinal cells are the output cells?*

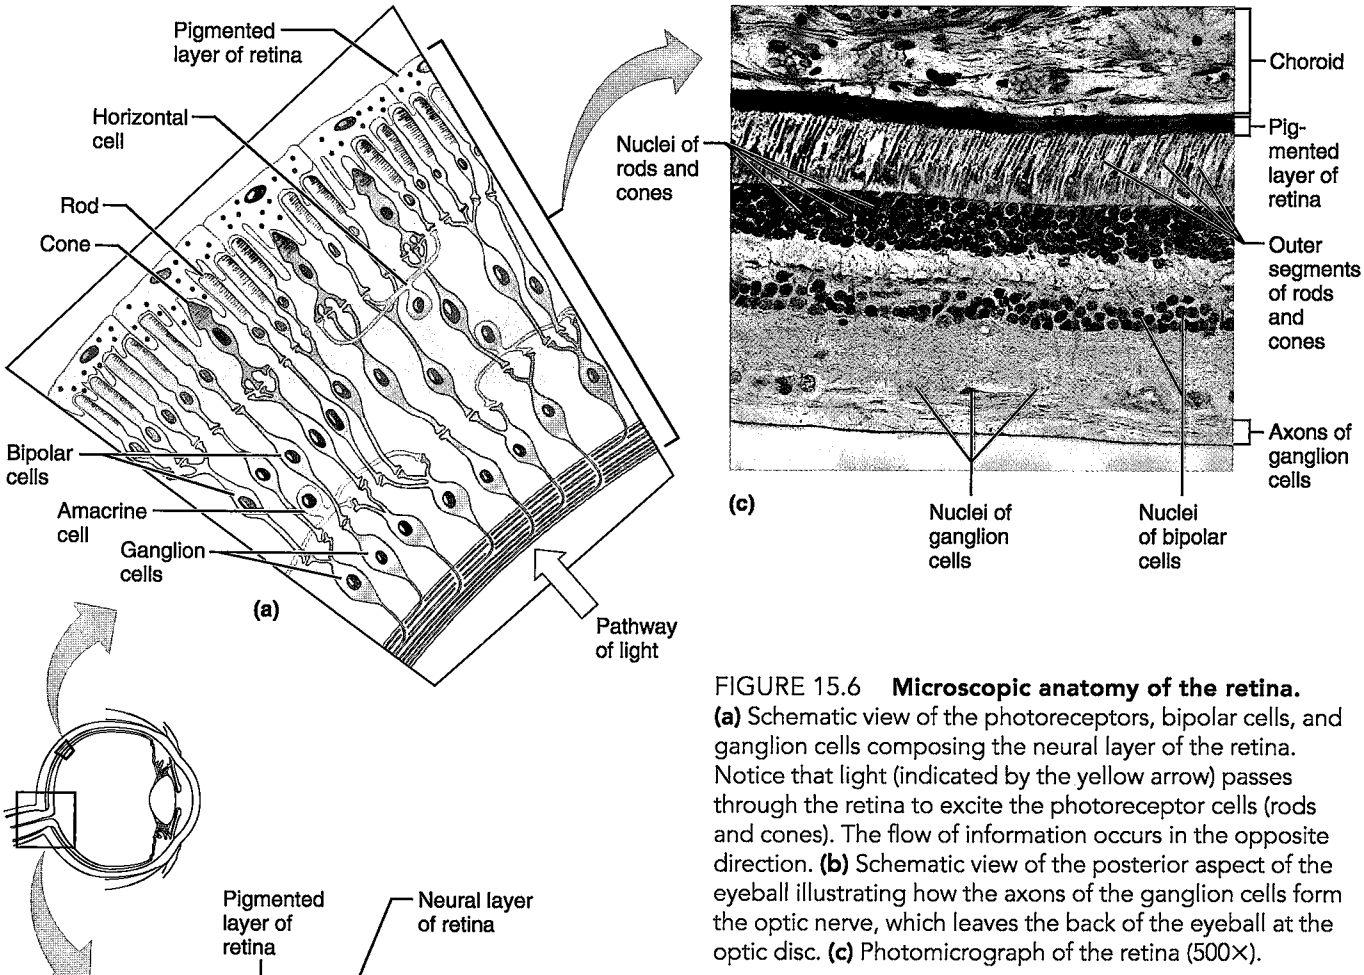

FIGURE 15.6 **Microscopic anatomy of the retina.** **(a)** Schematic view of the photoreceptors, bipolar cells, and ganglion cells composing the neural layer of the retina. Notice that light (indicated by the yellow arrow) passes through the retina to excite the photoreceptor cells (rods and cones). The flow of information occurs in the opposite direction. **(b)** Schematic view of the posterior aspect of the eyeball illustrating how the axons of the ganglion cells form the optic nerve, which leaves the back of the eyeball at the optic disc. **(c)** Photomicrograph of the retina (500×).

15

bipolar cells, and **ganglion cells** (Figure 15.6). Signals are produced in response to light and spread from the photoreceptors (abutting the pigmented layer) to the bipolar neurons and then to the innermost ganglion cells, where action potentials are generated. The ganglion cell axons make a right-angle turn at the inner face of the retina, then leave the posterior aspect of the eye as the thick optic nerve. The retina also contains other types of neurons—horizontal cells and amacrine cells—which play a role in visual processing. The **optic disc,** where the optic nerve exits the eye, is a weak spot in the **fundus** (posterior wall) of the eye

A Ganglion cells.

because it is not reinforced by the sclera. The optic disc is also called the **blind spot** because it lacks photoreceptors, so light focused on it cannot be seen. Nonetheless, we do not usually notice these gaps in our vision because the brain uses a sophisticated process called *filling in* to deal with absence of input.

The quarter-billion photoreceptors found in the neural retinas are of two types: rods and cones. The more numerous **rods** are our dim-light and peripheral vision receptors. They are far more sensitive to light than cones are, but they do not provide either sharp images or color vision. This is why colors are indistinct and edges of objects appear fuzzy in dim light and at the edges of our visual field. **Cones,** by contrast, operate in bright light and provide high-acuity color vision. Lateral to the blind spot of each eye, and located precisely at the eye's posterior pole, is an oval region called the **macula lutea** (mak'u-lah lu'te-ah; "yellow spot") with a minute (0.4 mm) pit in its center called the **fovea centralis** (see Figure 15.4). In this region, the retinal structures abutting the vitreous humor are displaced to the sides. This allows light to pass almost directly to the photoreceptors rather than through several retinal layers, greatly enhancing visual acuity. The fovea contains only cones; the macula contains mostly cones; and from the edge of the macula toward the retina periphery, cone density declines gradually. The retina periphery contains mostly rods, which continuously decrease in density from there to the macula. Only the foveae (plural of fovea) have a sufficient cone density to provide detailed color vision, so anything we wish to view critically is focused on the foveae. Because each fovea is only about the size of the head of a pin, not more than a thousandth of the entire visual field is in *hard focus* (foveal focus) at a given moment. Consequently, for us to visually comprehend a scene that is rapidly changing (as when we drive in traffic), our eyes must flick rapidly back and forth to provide the foveae with images of different parts of the visual field.

The neural retina receives its blood supply from two sources. The outer third (containing photoreceptors) is supplied by vessels in the choroid. The inner two-thirds is served by the **central artery** and **central vein of the retina,** which enter and leave the eye through the center of the optic nerve. Radiating outward from the optic disc, these vessels give rise to a rich vascular network that is clearly seen when the eyeball interior is examined with an ophthalmoscope (Figure 15.7). The fundus of the eye is the only place in the body where small blood vessels can be observed directly in a living person.

HOMEOSTATIC IMBALANCE

The pattern of vascularization of the retina makes it susceptible to *retinal detachment.* This condition, in which the pigmented and neural layers separate (detach) and allow the jellylike vitreous humor to seep between them, can cause permanent blindness because it deprives the photoreceptors of their nutrient source. It usually happens when the retina is torn during a traumatic blow to the head or when the head stops moving suddenly and then is jerked in the opposite direction (as in bungee jumping). The symptom that victims most often describe is "a curtain being drawn across the eye," but some people see sootlike spots or light flashes. If diagnosed early, it is often possible to reattach the retina with a laser before photoreceptor damage becomes permanent.

Q *Which of the areas shown here would have the highest cone density?*

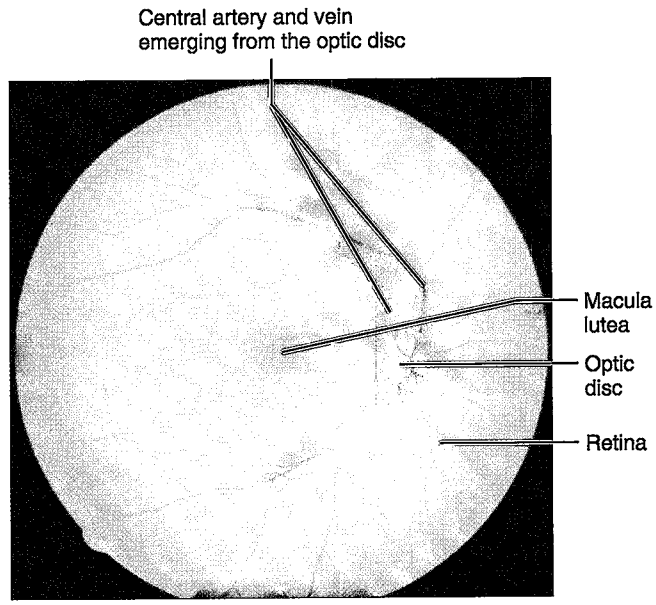

FIGURE 15.7 **Part of the posterior wall (fundus) of the right eye as seen with an ophthalmoscope.** Note the optic disc from which the retinal blood vessels radiate.

Internal Chambers and Fluids

As noted earlier, the lens and its halolike ciliary zonule divide the eye into two segments, the anterior segment in front of the lens and the larger posterior segment behind it (Figure 15.4a). The **posterior segment** (cavity) is filled with a clear gel called **vitreous humor** (*vitre* = glassy) that binds tremendous amounts of water. Vitreous humor (1) transmits light, (2) supports the posterior surface of the lens and holds the neural retina firmly against the pigmented layer, and (3) contributes to intraocular pressure,

A The macula lutea.

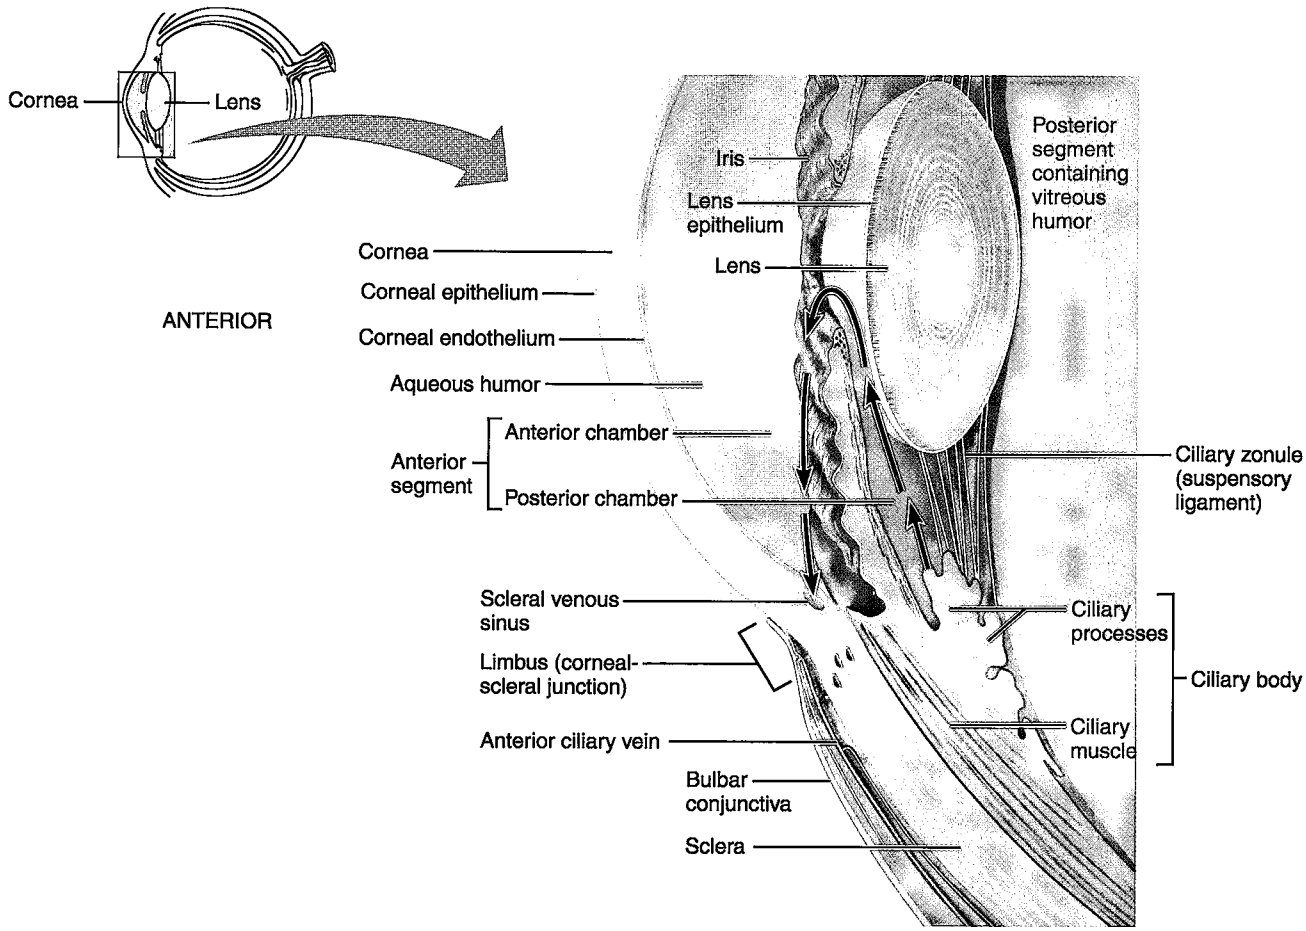

FIGURE 15.8 **Circulation of aqueous humor.** The anterior segment in front of the lens is incompletely divided into anterior and posterior chambers, which are continuous through the pupil. Aqueous humor fills the chambers and diffuses freely through the vitreous humor in the posterior segment. It is formed by filtration from capillaries in the ciliary processes and is reabsorbed into the venous blood by the scleral venous sinus. The arrows indicate the circulation pathway.

helping to counteract the pulling force of the extrinsic eye muscles.

The **anterior segment** (cavity) is partially subdivided by the iris into the **anterior chamber** (between the cornea and the iris) and the **posterior chamber** (between the iris and the lens) (Figure 15.8). The *entire* anterior segment is filled with **aqueous humor,** a clear fluid similar in composition to blood plasma. Unlike the vitreous humor, which forms in the embryo and lasts for a lifetime, aqueous humor forms and drains continually and is in constant motion. It filters from the capillaries of the ciliary processes into the posterior chamber and a portion of it freely diffuses through the vitreous humor in the posterior segment while the remainder flows into the anterior segment. After flowing through the pupil into the anterior chamber, it drains into the venous blood via the **scleral venous sinus** *(canal of Schlemm),* an unusual venous channel that encircles the eye in the angle at the sclera-cornea junction. Normally, aqueous humor is produced and drained at the same rate, maintaining a constant intraocular pressure of about 16 mm Hg, which helps to support the eyeball internally. Aqueous humor supplies nutrients and oxygen to the lens and cornea and to some cells of the retina, and it carries away their metabolic wastes.

HOMEOSTATIC IMBALANCE

If the drainage of aqueous humor is blocked, fluid backs up like in a clogged sink. Pressure within the eye may increase to dangerous levels and compress the retina and optic nerve—a condition called **glaucoma** (glaw-ko'mah). The eventual result is blindness (*glaucoma* = vision growing gray) unless the condition is detected early. Unfortunately, many forms of glaucoma steal sight so slowly and painlessly that people

do not realize they have a problem until the damage is done. Late signs include seeing halos around lights and blurred vision. The glaucoma examination is simple. The intraocular pressure is determined by directing a puff of air at the cornea and measuring the amount of corneal deformation it causes. This exam should be done yearly after the age of 40. The most common treatment is eye drops that increase the rate of aqueous humor drainage or decrease its production. Laser therapy or surgery can also be used. ●

Lens

The **lens** is a biconvex, transparent, flexible structure that can change shape to allow precise focusing of light on the retina. It is enclosed in a thin, elastic capsule and held in place just posterior to the iris by the ciliary zonule (Figure 15.8). Like the cornea, the lens is avascular; blood vessels interfere with transparency.

The lens has two regions: the **lens epithelium** and the lens fibers. The lens epithelium, confined to the anterior lens surface, consists of cuboidal cells that eventually differentiate into the **lens fibers** that form the bulk of the lens. The lens fibers, which are packed tightly together like the layers in an onion, contain no nuclei and few organelles. They do, however, contain transparent, precisely folded proteins called **crystallins** that form the body of the lens. Since new lens fibers are continually added, the lens enlarges throughout life, becoming denser, more convex, and less elastic, all of which gradually impair its ability to focus light properly.

HOMEOSTATIC IMBALANCE

A **cataract** ("waterfall") is a clouding of the lens that causes the world to appear distorted, as if seen through frosted glass (Figure 15.9). Some cataracts are congenital, but most result from age-related hardening and thickening of the lens or are a secondary consequence of diabetes mellitus. Heavy smoking and frequent exposure to intense sunlight increase the risk for cataracts, whereas long-term dietary supplementation with vitamin C may decrease the risk. Whatever the promoting factors, the *direct* cause of cataracts seems to be inadequate delivery of nutrients to the deeper lens fibers. The metabolic changes that result promote clumping of the crystallin proteins. Fortunately, the offending lens can be surgically removed and an artificial lens implanted to save the patient's sight. ●

Physiology of Vision

Overview: Light and Optics

To really comprehend the function of the eye as a photoreceptor organ, we need to have some understanding of the properties of light.

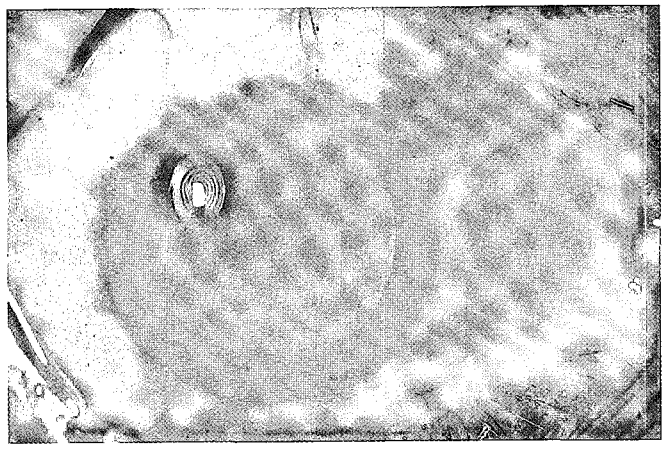

FIGURE 15.9 **Photograph of a cataract due to a clouded lens.**

Wavelength and Color **Electromagnetic radiation** includes all energy waves, from long radio waves (with wavelengths measured in meters) to very short gamma (γ) waves and X rays with wavelengths of 1 nm and less. Our eyes respond to the part of the spectrum called **visible light,** which has a wavelength range of approximately 400–700 nm (Figure 15.10a). (1 nm = 10^{-9} m, or one-billionth of a meter.) Visible light travels in the form of waves, and its wavelengths can be measured very accurately. However, light can also be envisioned as small particles or packets of energy called **photons** or **quanta.** Attempts to reconcile these two findings have led to the present concept of light as packets of energy (photons) traveling in a wavelike fashion at very high speeds (300,000 km/s or about 186,000 mi/s). Thus, light can be thought of as a vibration of pure energy ("a bright wiggle") rather than a material substance.

When visible light passes through a prism, each of its component waves bends to a different degree, so that the beam of light is dispersed and a **visible spectrum,** or band of colors, is seen (Figure 15.10b). (In the same manner, the rainbow seen during a summer shower represents the collective prismatic effects of all the tiny water droplets suspended in air.) Red wavelengths are the longest and have the lowest energy, whereas the violet wavelengths are the shortest and most energetic. Objects have color because they absorb some wavelengths and reflect others. Things that look white reflect all wavelengths of light, whereas black objects absorb them all. A red apple reflects mostly red light; grass reflects more of the green.

Refraction and Lenses Light travels in straight lines and is easily blocked by any nontransparent object. Like sound, light can reflect, or bounce, off a surface. **Reflection** of light by objects

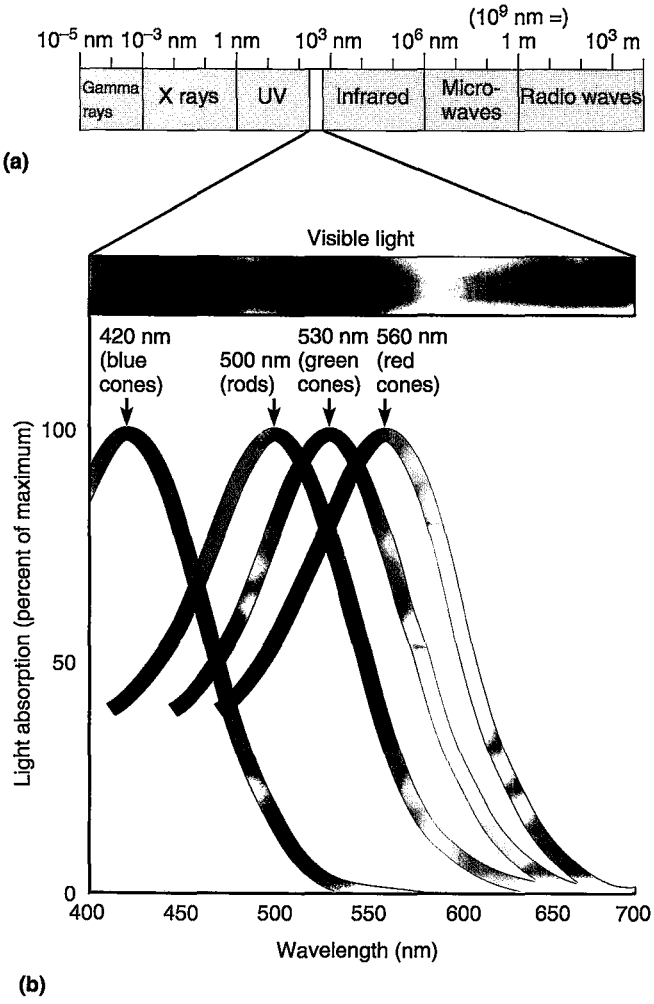

FIGURE 15.10 **The electromagnetic spectrum and photoreceptor sensitivities. (a)** The electromagnetic spectrum extends from the very short gamma waves to the long radio waves. The wavelengths of the electromagnetic spectrum are indicated in nanometers. The spectrum of visible light constitutes only a small portion of this energy range. **(b)** Sensitivities of rods and the three cone types to the different wavelengths of the visible spectrum.

in our environment accounts for most of the light reaching our eyes.

When light is traveling in a given medium, its speed is constant. But when it passes from one transparent medium into another with a different density, its speed changes. Light speeds up as it passes into a less dense medium and slows as it passes into a denser medium. Because of these changes in speed, bending or **refraction** of a light ray occurs when it meets the surface of a different medium at an oblique angle rather than at a right angle (perpendicular). The greater the incident angle, the greater the amount of bending. Figure 15.11 demonstrates the consequence of light refraction when a spoon is placed in a half-full glass of water: The spoon appears to break at the air-water interface.

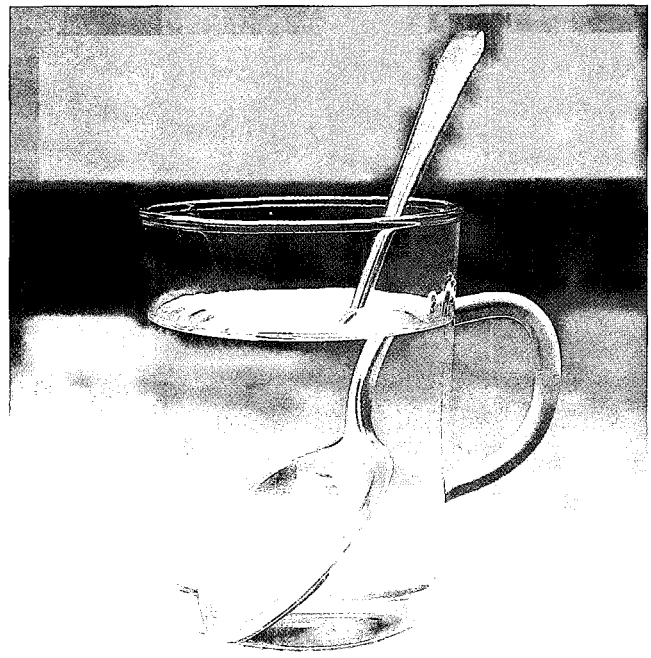

FIGURE 15.11 **A spoon standing in a glass of water appears to be broken at the water-air interface.** This phenomenon occurs because light is bent toward the perpendicular when it travels from a less dense to a more dense medium (air to water in this example).

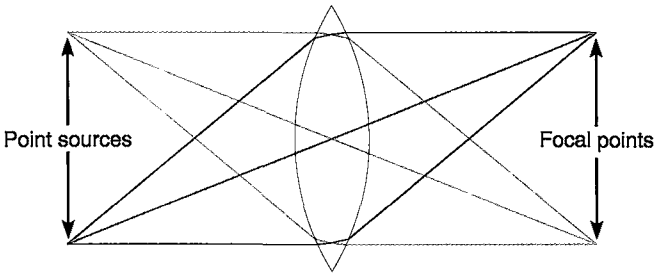
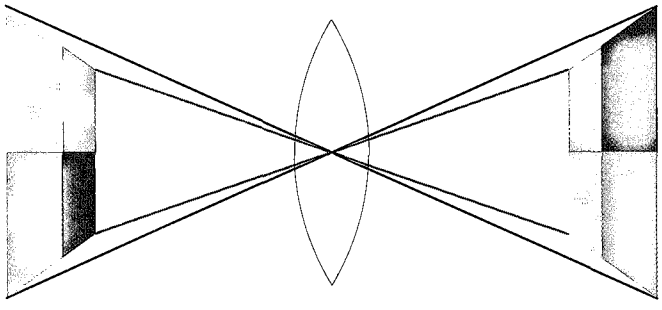
A lens is a transparent object curved on one or both surfaces. Since light hits the curve at an angle, it is refracted. If the lens surface is convex, that is, thickest in the center like a camera lens, the light rays are bent so that they converge (come together) or intersect at a single point called the **focal point** (Figure 15.12). In general, the thicker (more convex) the lens, the more the light is bent and the shorter the focal distance (distance between the lens and focal point). The image formed by a convex lens, called a **real image,** is upside down and reversed from left to right. Concave lenses, which are thicker at the edges than at the center, diverge the light (bend it outward) so that the light rays move away from each other. Consequently, concave lenses prevent light from focusing and extend the focal distance.

Focusing of Light on the Retina

As light passes from air into the eye, it moves sequentially through the cornea, aqueous humor, lens, and vitreous humor, and then passes *through the entire thickness of the neural layer of the retina* to excite the photoreceptors that abut the pigmented layer (see Figures 15.4 and 15.6). During its passage, light is bent three times: as it enters the cornea and on entering and leaving the lens. The refractory power of the humors and cornea is constant. On the



(a)



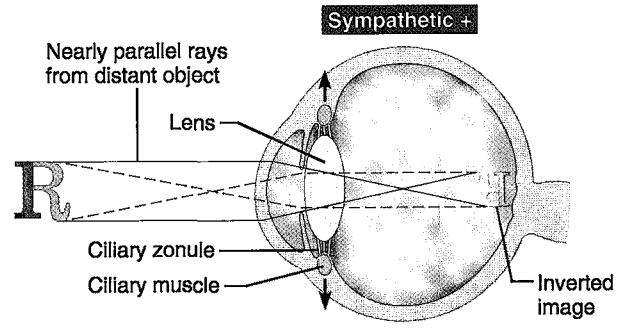
(b)

FIGURE 15.12 **Bending of light points by a convex lens. (a)** How two light points are focused on the opposite side of the lens. **(b)** Formation of an image by a convex lens. Notice that the image is upside down and reversed from right to left.

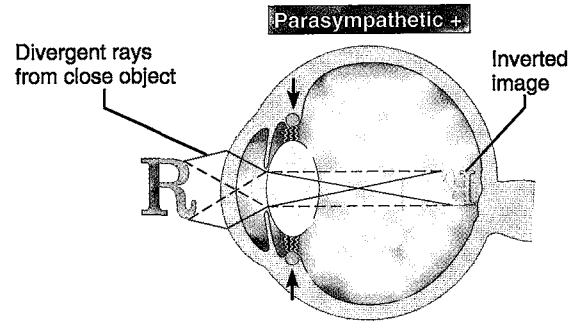
other hand, the lens is highly elastic, and its curvature and light-bending power can be actively changed to allow fine focusing of the image.

Focusing for Distant Vision Our eyes are best adapted ("preset to focus") for distant vision. To look at distant objects, we need only aim our eyeballs so that they are both fixated on the same spot. The **far point of vision** is that distance beyond which no change in lens shape (accommodation) is needed for focusing. For the normal or **emmetropic** (em"ĕ-tro'pik) eye, the far point is 6 m (20 feet).

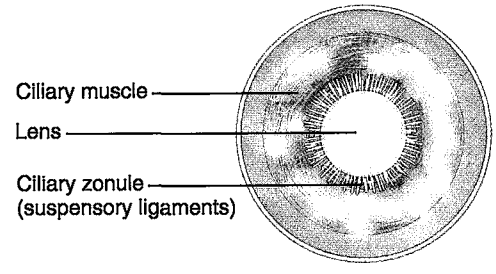
Any object being viewed can be said to consist of many small points, with light radiating outward in all directions from each point. However, because distant objects appear smaller, light from an object at or beyond the far point of vision approaches the eyes as nearly parallel rays and is focused precisely on the retina by the fixed refractory apparatus (cornea and humors) and the at-rest lens (Figure 15.13a). During distant vision, the ciliary muscles are completely relaxed, and the lens (stretched flat by tension in the ciliary zonule) is as thin as it gets. Consequently, the lens is at its lowest refractory power. The ciliary muscles relax when sympathetic input to them increases and parasympathetic decreases.



(a) Lens is flattened for distant vision



(b) Lens bulges for close vision



(c) Anterior segment viewed from behind

FIGURE 15.13 **Focusing for distant and close vision. (a)** For distant vision, the sympathetic nervous system relaxes the ciliary muscle, tightening the ciliary zonule (suspensory ligament) and flattening the lens. Light from distant objects (over 6 m away) approaches as parallel rays and is focused on the retina by the flattened lens. **(b)** For close vision, the parasympathetic nervous system stimulates the ciliary muscle, allowing the ciliary zonule to become less taut and the lens to bulge. Light from close objects (less than 6 m away) tends to diverge and lens convexity must be increased (accommodation) for proper focusing. Notice in both cases that the image formed on the retina is inverted and reversed from left to right (i.e., it is a real image). **(c)** Anterior segment as viewed from within the eye showing the ciliary muscles and ciliary zonule arranged sphincterlike around the lens.

Focusing for Close Vision Light from objects less than 6 m away diverges as it approaches the eyes and it comes to a focal point farther from the lens. Thus, close vision demands that the eye make active

adjustments. To restore focus, three processes—accommodation of the lenses, constriction of the pupils, and convergence of the eyeballs—must occur simultaneously. The signal that induces this trio of reflex responses appears to be a blurring of the retinal image.

1. Accommodation of the lenses. Accommodation is the process that increases the refractory power of the lens. As the ciliary muscles contract, the ciliary body is pulled anteriorly and inward toward the pupil and releases tension in the ciliary zonule. No longer stretched, the elastic lens recoils and bulges, providing the shorter focal length needed to focus the image of a close object on the retina (Figure 15.13b). Contraction of the ciliary muscles is controlled mainly by the parasympathetic fibers of the oculomotor nerves.

The closest point on which we can focus clearly is called the **near point of vision,** and it represents the maximum bulge the lens can achieve. In young adults with emmetropic vision, the near point is 10 cm (4 inches) from the eye. However, it is closer in children and gradually recedes with age, explaining why children can hold their books very close to their faces while many elderly people must hold the newspaper at arm's length. The gradual loss of accommodation with age reflects the lens's decreasing elasticity. In many people over the age of 50, the lens is nonaccommodating, a condition known as **presbyopia** (pres"be-o'pe-ah), literally "old person's vision."

2. Constriction of the pupils. The sphincter pupillae muscles of the iris enhance the effect of accommodation by reducing the size of the pupil (see Figure 15.5) toward 2 mm. This **accommodation pupillary reflex,** mediated by parasympathetic fibers of the oculomotor nerves, prevents the most divergent light rays from entering the eye. Such rays would pass through the extreme edge of the lens and would not be focused properly, and so would cause blurred vision.

3. Convergence of the eyeballs. The visual goal is always to keep the object being viewed focused on the retinal foveae. When we look at distant objects, both eyes are directed either straight ahead or to one side to the same degree, but when we fixate on a close object, our eyes converge. **Convergence,** controlled by somatic motor fibers of the oculomotor nerves, is medial rotation of the eyeballs by the medial rectus muscles so that each is directed toward the object being viewed. The closer that object, the greater the degree of convergence required; when you focus on the tip of your nose, you "go cross-eyed."

Reading or other close work requires almost continuous accommodation, pupillary constriction, and convergence. This is why prolonged periods of reading tire the eye muscles and can result in *eyestrain.* When you read for an extended time, it is helpful to look up and stare into the distance occasionally to relax the intrinsic eye muscles.

HOMEOSTATIC IMBALANCES

Theoretically, visual problems related to refraction could result from a hyperrefractive (overconverging) or hyporefractive (underconverging) lens or from structural abnormalities of the eyeball. In practice, 99% of refractive problems are related to eyeball shape—either too long or too short.

Myopia (mi-o'pe-ah; "short vision") occurs when distant objects are focused not on, but in front of, the retina (Figure 15.14b). Myopic people see close objects without problems because they can focus them on the retina, but distant objects are blurred. The common name for myopia is *nearsightedness.* (Notice that this terminology names the aspect of vision that is *unimpaired.*) Myopia typically results from an eyeball that is too long. Correction has traditionally involved use of concave lenses that diverge the light before it enters the eye, but procedures to flatten the cornea slightly—a 10-minute surgery called *radial keratotomy,* or PRK and LASIK procedures using a laser—have offered other treatment options.

Hyperopia (hy'per-o"pe-ah; "far vision"), or *farsightedness,* occurs when the parallel light rays from distant objects are focused *behind* the retina (Figure 15.14c). Hyperopic individuals can see distant objects perfectly well because their ciliary muscles contract almost continuously to increase the light-bending power of the lens, which moves the focal point forward onto the retina. However, diverging light rays from *nearby* objects are focused so far behind the retina that the lens cannot bring the focal point onto the retina even at its full refractory power. Thus, close objects appear blurry, and convex corrective lenses are needed to converge the light more strongly for close vision. Hyperopia usually results from an eyeball that is too short.

Unequal curvatures in different parts of the cornea or lens lead to blurry images. This refractory problem is **astigmatism** (*astigma* = not a point). Special cylindrically ground lenses, corneal implants, or laser procedures are used to correct this problem. ●

Phototransduction

Once light is focused on the retina, the photoreceptors come into play. First, we will describe the functional anatomy of photoreceptor cells, then the chemistry and response of their visual pigments to

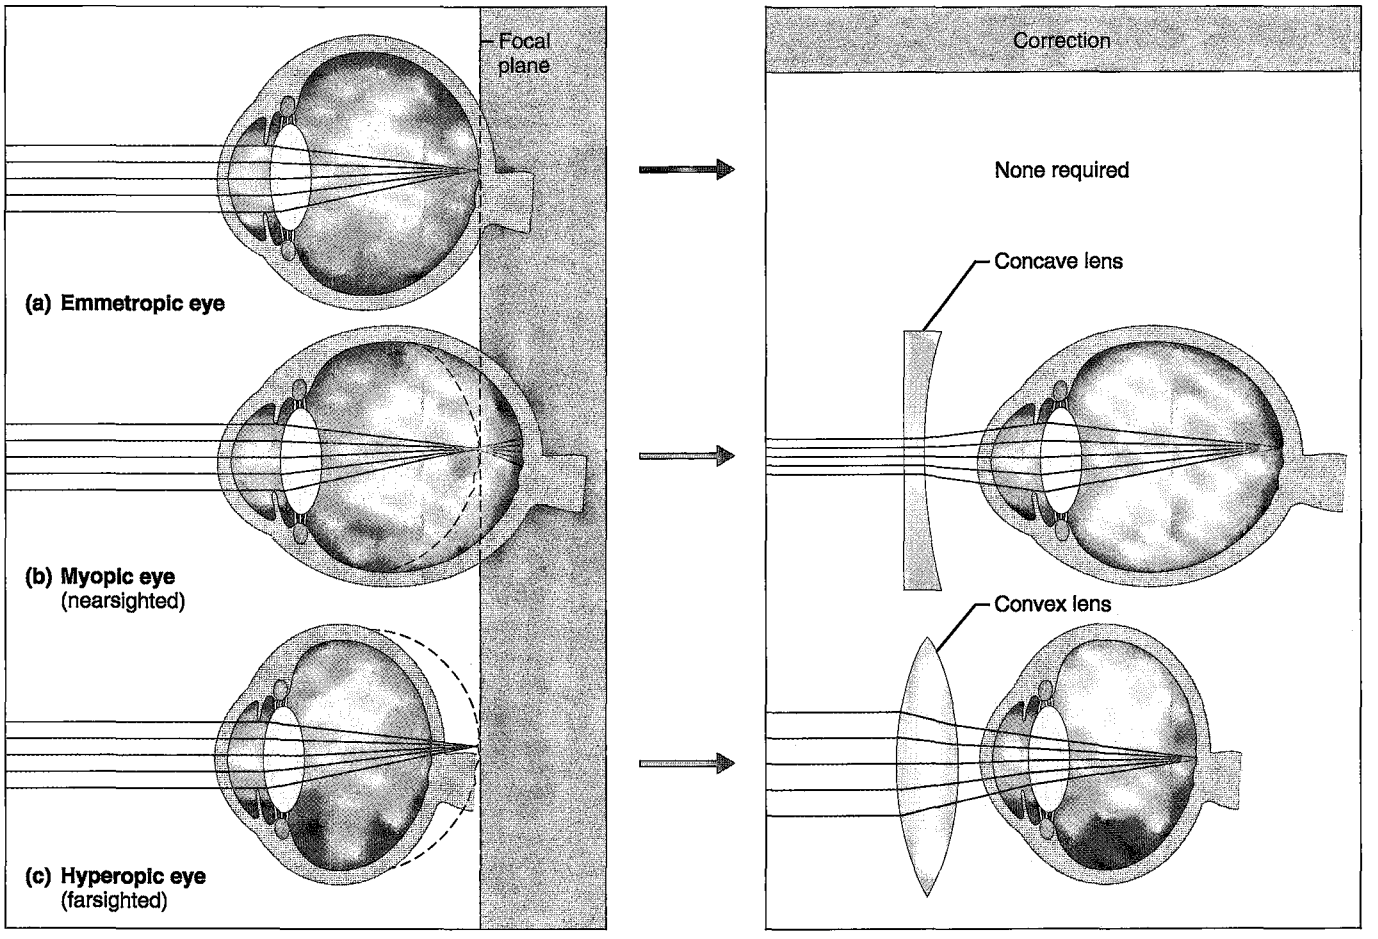


FIGURE 15.14 **Problems of refraction. (a)** In the emmetropic eye, light from both near and distant objects is focused properly on the retina. **(b)** In a myopic eye, light from a distant object comes to a focal point before reaching the retina and then diverges again. **(c)** In the hyperopic eye, light from a near object comes to a focal point behind (past) the retina. (Refractory effect of the cornea is ignored.)

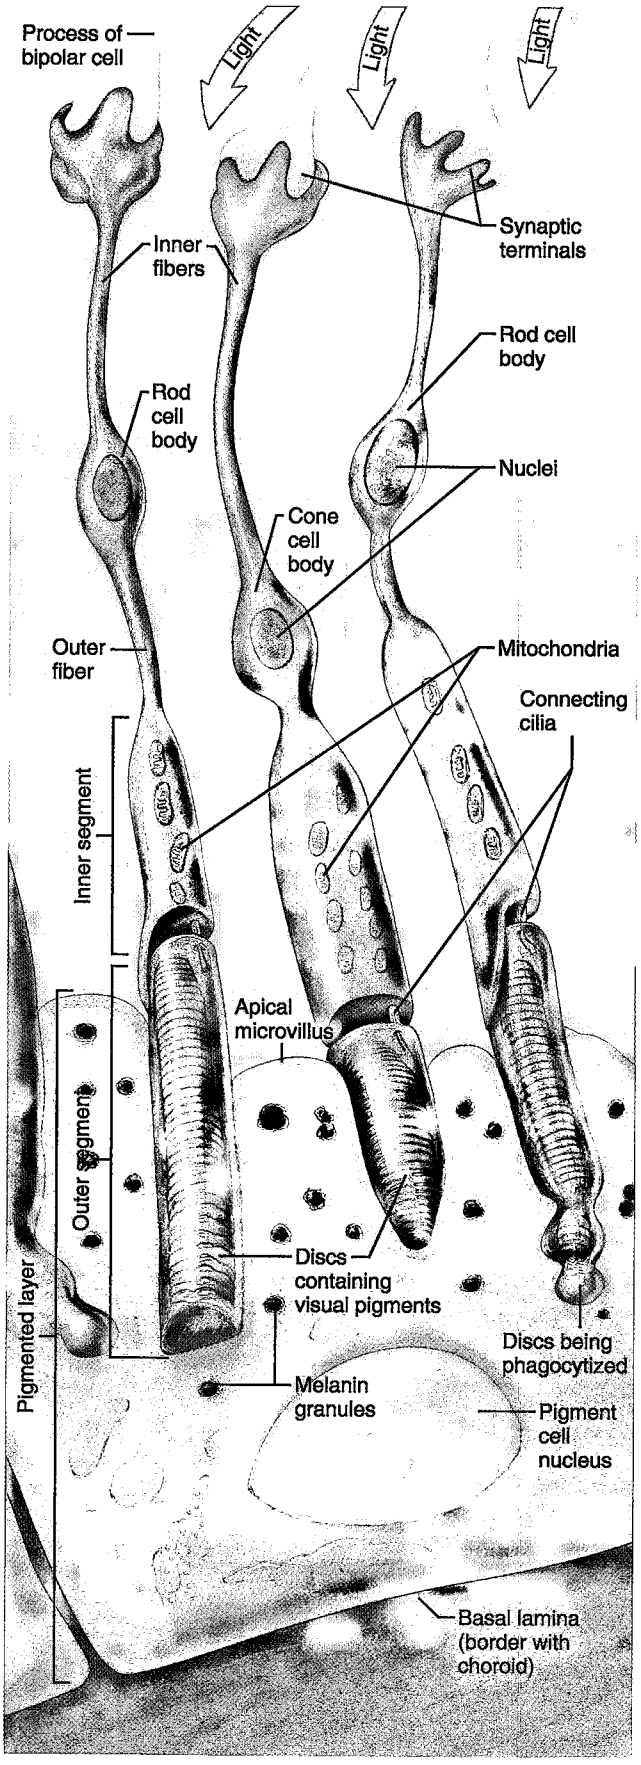
light, and finally, photoreceptor activation and phototransduction. **Phototransduction** is the process by which light energy is converted into a graded receptor potential.

Functional Anatomy of the Photoreceptors

Although photoreceptors are modified neurons, structurally they resemble tall epithelial cells turned upside down with their "tips" immersed in the pigmented layer of the retina (Figure 15.15a). Moving from the pigmented layer into the neural layer, both the rods and cones have an **outer segment** (the receptor region) joined to an **inner segment** by a connecting cilium. The inner segment connects to the *cell body*, which is continuous with an *inner fiber* bearing *synaptic terminals*. The outer segment of the rods is slender and rod shaped (hence their name) and their inner segment connects to the cell body by the *outer fiber*. By contrast, the cones have a short conical outer segment and the inner segment directly joins the cell body.

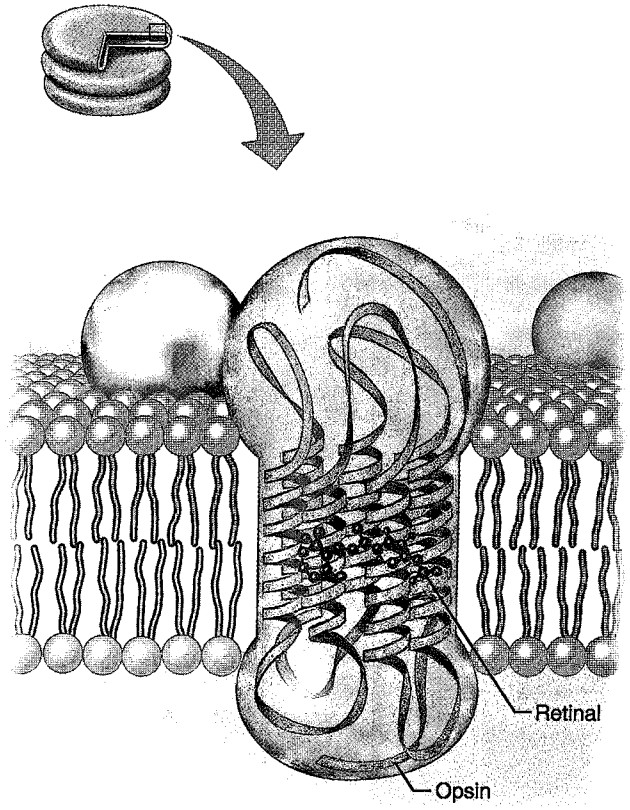
The outer segments contain an elaborate array of **visual pigments (photopigments)** that change shape as they absorb light. These pigments are embedded in areas of the plasma membrane that form discs. Folding the plasma membrane into discs magnifies the surface area available for trapping light (Figure 15.15b). In rods, the discs are discontinuous—stacked like a row of pennies in a coin wrapper. In cones, the disc membranes are continuous with the plasma membrane; thus, the interiors of the cone discs are continuous with the extracellular space.

The photoreceptor cells are highly vulnerable to damage and immediately begin to degenerate if the retina becomes detached. They are also destroyed by intense light, the very energy they are designed to detect. How is it, then, that we do not all gradually go blind? The answer lies in the photoreceptors' unique system for renewing their light-trapping outer segment. In rods, new discs are assembled at the proximal end of the outer segment from materials



(a)

Q *What is the advantage of having the plasma membrane folded into discs in the outer segment?*



(b)

FIGURE 15.15 **Photoreceptors of the retina.**
(a) Diagram of the photoreceptors (rods and cones). The relationship of the outer segments of the photoreceptors to the pigmented layer of the retina is also illustrated.
(b) Diagram of a small section of the membrane of a visual pigment–containing disc of the outer segment of a rod cell. The visual pigments consist of a light-absorbing molecule called retinal bound to an opsin protein. Each type of photoreceptor has a characteristic kind of opsin protein, which affects the absorption spectrum of the retinal. In rods, the pigment-opsin complex is called rhodopsin. Notice that the light-absorbing retinal occupies the core of the rhodopsin molecule.

synthesized in the cell body at the end of each night. As new discs are made, they push the others peripherally. The discs at the tip of the outer segment continually fragment off and are phagocytized by cells of the pigmented layer. The tips of the outer segments of cones are also removed and renewed (but at the end of each day).

A *Because the photopigment is in the membrane, folding the membrane increases the amount of pigment able to catch light.*

Because the rods and each of the three cone types contain unique visual pigments, they absorb different wavelengths of light. Rods and cones also have different thresholds for activation. Rods, for example, (1) are very sensitive (respond to very dim light—a single photon), making them best suited for night vision and peripheral vision, and (2) contain a single kind of visual pigment so their inputs are perceived only in gray tones. Cones (1) need bright light for activation (have low sensitivity), but (2) have one of three different pigments that furnish a vividly colored view of the world.

Rods and cones are also "wired" differently to other retinal neurons. Rods participate in converging pathways, and as many as 100 rods may ultimately feed into each ganglion cell. As a result, rod effects are summated and considered collectively, resulting in vision that is fuzzy and indistinct. (The visual cortex has no way of knowing exactly *which* rods of the large number influencing a particular ganglion cell are actually activated.) In contrast, each cone in the fovea (or at most a few) has a straight-through pathway via its "own personal bipolar cell" to a ganglion cell (see Figure 15.6a). Hence, each cone essentially has its own "labeled line" to the higher visual centers. This accounts for the detailed, high-resolution views of very small areas of the visual field provided by cones.

Because rods are absent from the foveae and cones do not respond to low-intensity light, we see dimly lit objects best when we do not look at them directly, and recognize them best when they move. If you doubt this, go out into your backyard on a moonlit evening and see how much you can actually discriminate.

The Chemistry of Visual Pigments How does light affect the photoreceptors so that it is ultimately translated into electrical signals? The key is a light-absorbing molecule called **retinal** that combines with proteins called **opsins** to form four types of visual pigments. Depending on the type of opsin to which it is bound, retinal preferentially absorbs different wavelengths of the visible spectrum. Retinal is chemically related to vitamin A and is made from it. The liver stores vitamin A and releases it as needed by the photoreceptors to make their visual pigments. The cells of the pigmented layer of the retina absorb vitamin A from the blood and serve as the local vitamin A depot for the rods and cones.

Retinal can assume a variety of distinct three-dimensional forms, each form called an isomer. When bound to opsin, retinal has a bent, or kinked, shape called the **11-*cis* isomer** (Figure 15.16). However, when the pigment is struck by light and absorbs photons, retinal twists and snaps into a new configuration, its **all-*trans* isomer,** which causes opsin to

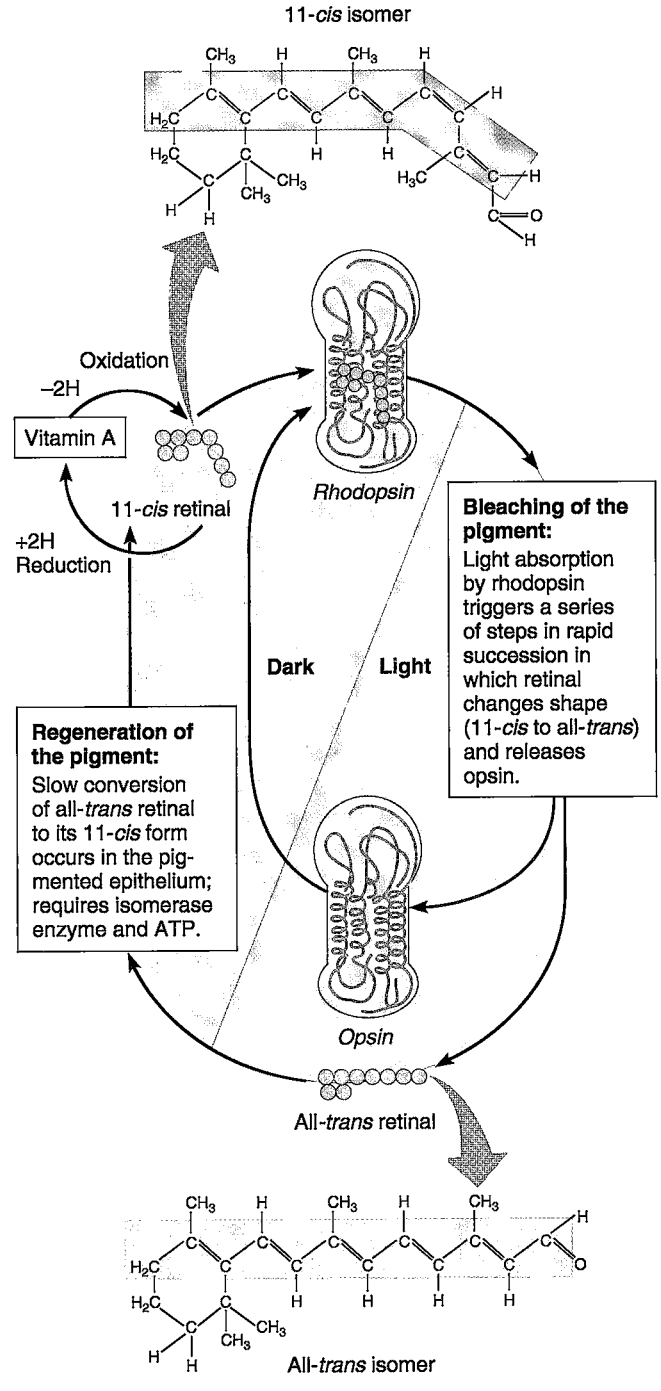


FIGURE 15.16 **Sequence of chemical events in the formation and breakdown of rhodopsin.** When struck by light, rhodopsin breaks down and is converted to its precursors via a number of intermediate steps. Absorption of light converts 11-*cis* retinal to all-*trans* retinal, an event that is responsible for transduction of the light stimulus and which bleaches the pigment. Eventually, all-*trans* retinal separates from opsin. The 11-*cis* retinal is regenerated in energy (ATP)-requiring reactions by enzymatic action from all-*trans* retinal or from vitamin A and recombined with opsin to form rhodopsin.

change shape and assume its activated form. This is the *only* light-dependent stage, and this simple photochemical event initiates a whole chain of chemical and electrical reactions in rods and cones that ultimately causes electrical impulses to be transmitted along the optic nerve.

Stimulation of the Photoreceptors

1. Excitation of rods. The visual pigment of rods is a deep purple pigment called **rhodopsin** (ro-dop'sin; *rhodo* = rose, *opsis* = vision). (Do you suppose the person who coined the expression "looking at the world through rose-colored glasses" knew the meaning of "rhodopsin"?) Rhodopsin molecules are arranged in a single layer in the membranes of each of the thousands of discs in the rods' outer segments (see Figure 15.15b).

Rhodopsin forms and accumulates in the dark in the sequence of reactions shown on the left side of Figure 15.16. As illustrated, vitamin A is oxidized (and isomerized) to the 11-*cis* retinal form and then combined with opsin to form rhodopsin. When rhodopsin absorbs light, retinal changes shape to its all-*trans* isomer, and the retinal-opsin combination breaks down, allowing retinal and opsin to separate. This breakdown is known as the **bleaching of the pigment.** Actually, the story is a good deal more complex than this, and the breakdown of rhodopsin that triggers the transduction process involves a rapid cascade of intermediate steps (right side of Figure 15.16) that takes just a few milliseconds. Once the light-struck all-*trans* retinal detaches from opsin, it is reconverted by enzymes within the pigmented epithelium to its 11-*cis* isomer in an ATP-requiring process. Then, retinal heads "homeward" again to the photoreceptor cells' outer segments. Rhodopsin is regenerated when 11-*cis* retinal is rejoined to opsin.

2. Excitation of cones. The breakdown and regeneration of visual pigments in cones is essentially the same as for rhodopsin. However, cones are about a hundred times less sensitive than rods, which means that it takes higher-intensity (brighter) light to activate cones.

Visual pigments of the three types of cones, like those of rods, are a combination of retinal and opsins. However, the cone opsins differ both from the opsin of the rods and from one another. The naming of cones reflects the colors (that is, wavelengths) of light that each cone variety absorbs best. The blue cones respond maximally to wavelengths around 420 nm, the green cones to wavelengths of 530 nm, and the red cones to wavelengths at or close to 560 nm (see Figure 15.10b). However, their absorption spectra overlap, and perception of intermediate hues, such as orange, yellow, and purple, results from differential activation of more than one type of cone at the same time. For example, yellow light stimulates both red and green cone receptors, but if the red cones are stimulated more strongly than the green cones, we see orange instead of yellow. When all cones are stimulated equally, we see white.

HOMEOSTATIC IMBALANCE

Color blindness is due to a congenital lack of one or more of the cone types. Inherited as an X-linked condition, it is far more common in males than in females. As many as 8–10% of males have some form of color blindness. The most common type is red-green color blindness, resulting from a deficit or absolute absence of either red or green cones. Red and green are seen as the same color—either red or green, depending on the cone type present. Many color-blind people are unaware of their condition because they have learned to rely on other cues—such as differences in intensities of the same color—to distinguish something green from something red, such as traffic signals.

Light Transduction Reactions

How is the capture of light by visual pigments that we've just described converted into an electrical event, that is, a change in membrane potential? In the dark, **cyclic GMP (cGMP)** binds to cation channels in the outer segments, holding them open. Consequently, Na^+ and Ca^{2+} continually enter the outer segment, producing a *dark current* that maintains a transmembrane potential (a *dark potential*) of about −40 mV. This depolarizing current keeps the Ca^{2+} channels *at the photoreceptor synaptic terminals* open. Thus, in the dark there is continuous neurotransmitter (glutamate) release by the photoreceptors at their synapses with the bipolar cells (Figure 15.17a).

When light triggers pigment breakdown, the net effect is to "turn off" cation entry. That is, an enzymatic cascade occurs that ultimately destroys the cGMP that keeps the channels open in the dark. In this process, described in more detail in Figure 15.18, light-activated rhodopsin (metarhodopsin II) activates a G protein called **transducin.** Transducin, in turn, activates *PDE (phosphodiesterase),* the enzyme that breaks down cGMP, and the cation channels close. Cation influx in the outer segment now decreases dramatically but potassium channels in the inner segment remain open, so the photoreceptors develop a *hyperpolarizing receptor potential* (−70 mV) that inhibits their release of neurotransmitter (Figure 15.17b). This is bewildering, to say the least. Here we have receptors built to detect light that depolarize in the dark and hyperpolarize when exposed to light! Nevertheless, turning off neurotransmitter release

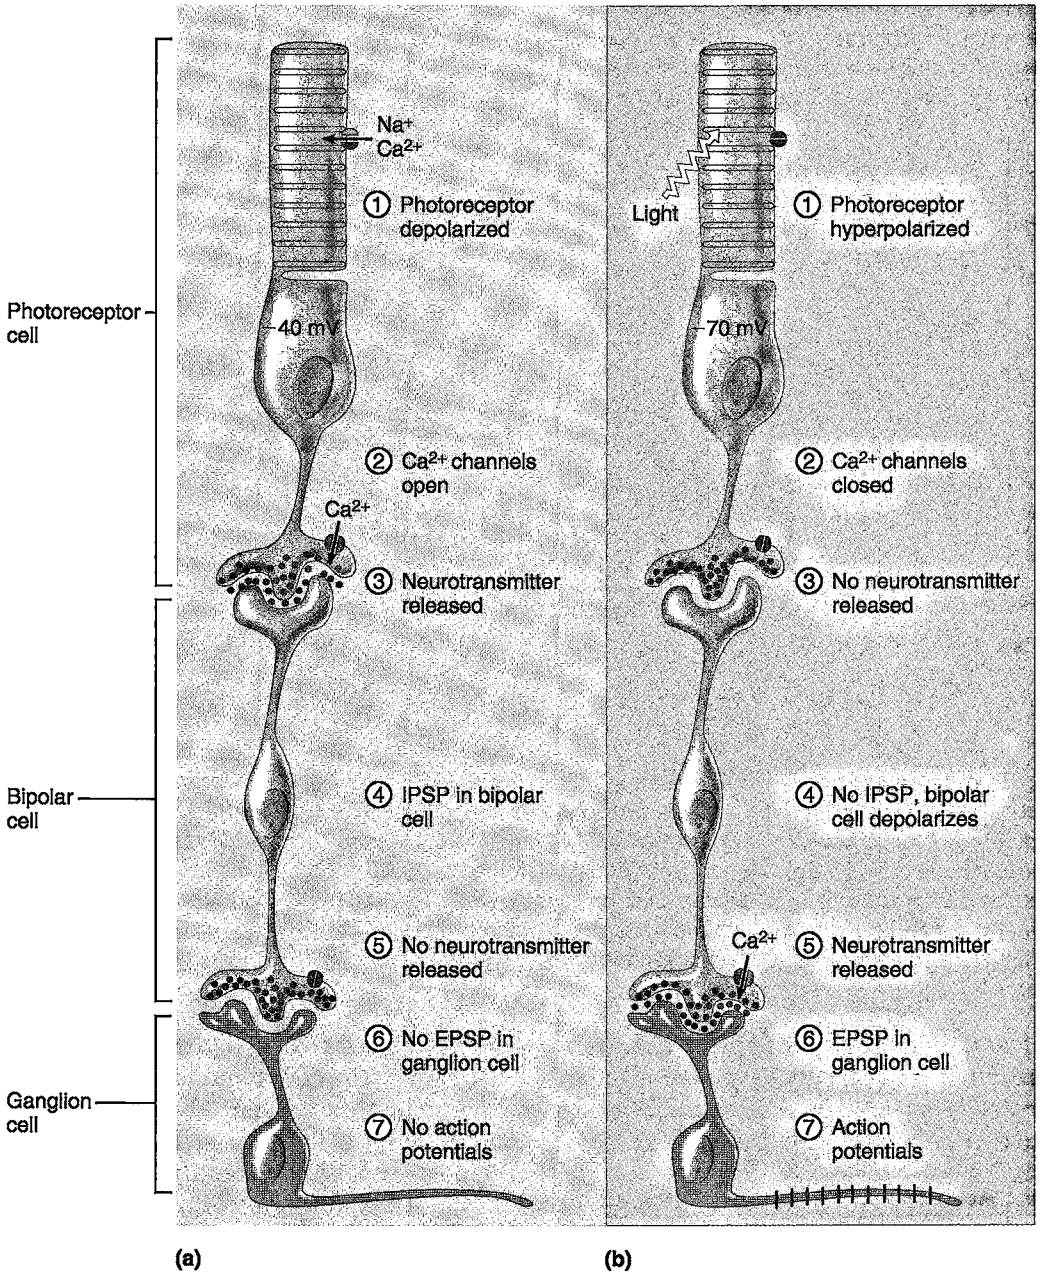

FIGURE 15.17 **Signal transmission in the retina. (a)** In the dark, ① photoreceptors are depolarized to about −40 mV by a continuous influx of cations through cGMP-gated channels. ② In the synaptic terminals of the photoreceptors, voltage-gated Ca^{2+} channels opened by depolarization cause ③ continuous release of neurotransmitter. ④ This neurotransmitter hyperpolarizes the bipolar cells (by producing inhibitory postsynaptic potentials, IPSPs), and ⑤ inhibits release of their neurotransmitter. Signal transmission stops at this point. ⑥ There are no excitatory postsynaptic potentials (EPSPs) in the ganglion cells, and ⑦ no action potentials are generated. **(b)** ① Light causes the photoreceptors to hyperpolarize, ② closing the Ca^{2+} channels in the synaptic terminals, and ③ inhibiting neurotransmitter release. ④ In the absence of IPSPs, the bipolar cell is disinhibited. It depolarizes and ⑤ releases neurotransmitter, which ⑥ depolarizes the ganglion cell (EPSPs). ⑦ Action potentials are generated and propagate along the optic nerve.

by hyperpolarization conveys information as effectively as depolarization.

The photoreceptors do not generate action potentials and neither do the bipolar cells that lie between them and the ganglion cells. The ganglion cells do, however, generate action potentials, which is consistent with their function as the output neurons of the retina. In all other cases, only local currents (graded potentials) are produced. This is not surprising if you remember that the primary function of action potentials

Q *Assume that everything is proceeding normally in the scheme illustrated, but then a metabolic poison that interferes with the Na^+-K^+ pump is introduced. What would happen and why?*

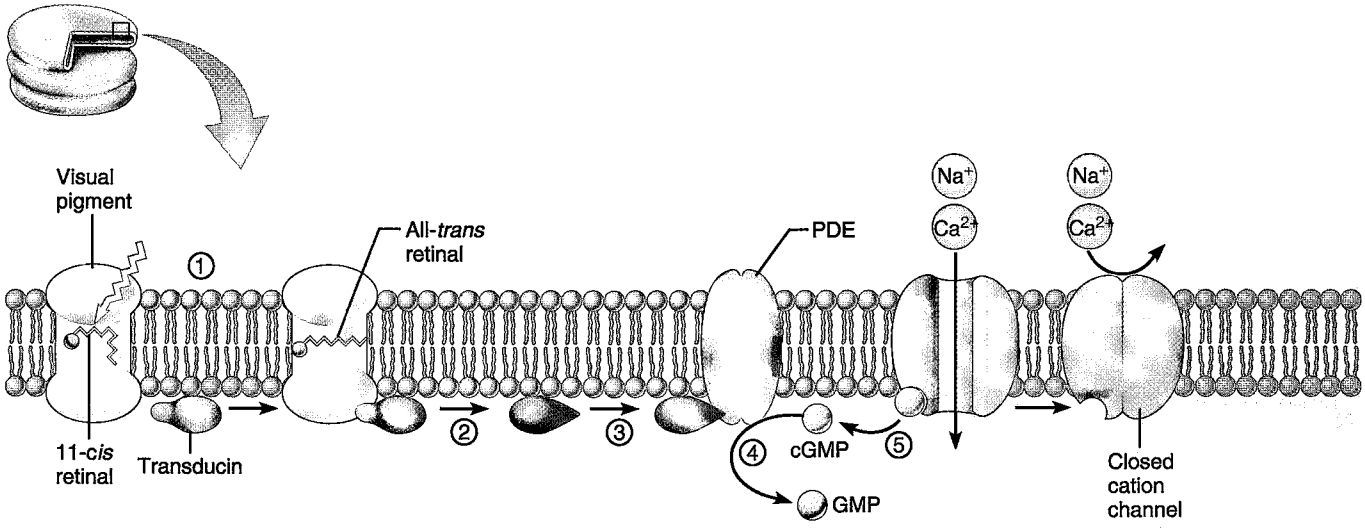

FIGURE 15.18 **Events of phototransduction.** A portion of photoreceptor disc membrane showing the events in phototransduction. ① Light (photons) isomerizes retinal to its all-*trans* form, activating the visual pigment, which in turn ② activates transducin (G protein). ③ Transducin activates the enzyme phosphodiesterase (PDE), which ④ converts cGMP into GMP. ⑤ As the concentration of cGMP falls, cGMP-gated cation channels close, leading to the hyperpolarization of the photoreceptor. The G protein conversion of GTP to GDP has been omitted for clarity. For simplicity, the cGMP-gated channels are shown on the same membrane as the visual pigment instead of in the plasma membrane.

15

is to carry information rapidly over long distances. Retinal cells are small cells that are very close together, so graded potentials can serve quite adequately as signals to regulate neurotransmitter release.

Light and Dark Adaptation Rhodopsin is amazingly sensitive; even starlight causes some of the molecules to become bleached. As long as the light is low intensity, relatively little rhodopsin is bleached and the retina continues to respond to light stimuli. However, in high-intensity light there is wholesale bleaching of the pigment, and rhodopsin is bleached as fast as it is re-formed. At this point, the rods are nonfunctional, but cones still respond. Hence, retinal sensitivity automatically adjusts to the amount of light present.

Light adaptation occurs when we move from darkness into bright light, as when leaving a movie matinee. We are momentarily dazzled—all we see is white light—because the sensitivity of the retina is still "set" for dim light. Both rods and cones are strongly stimulated, and large amounts of the visual pigments are broken down almost instantaneously, producing a flood of signals that accounts for the glare. Under such conditions, compensations occur. The rod system essentially turns off, while the cone system and other retinal neurons rapidly adapt, so that retinal sensitivity decreases dramatically. Within about 60 seconds, the cones, initially overexcited by the bright light, are sufficiently desensitized to take over. Visual acuity and color vision continue to improve over the next 5–10 minutes. Thus, during light adaptation, retinal sensitivity (rod function) is lost, but visual acuity (the ability to resolve detail) is gained.

Dark adaptation, essentially the reverse of light adaptation, occurs when we go from a well-lit area into a dark one. Initially, we see nothing but velvety blackness because (1) our cones stop functioning in low-intensity light, and (2) our rod pigments have been bleached out by the bright light, and the rods are still turned off. But once we are in the dark, rhodopsin accumulates and retinal sensitivity increases. Dark adaptation is much slower than light adaptation and can go on for hours. However, there

A The whole process will come to a halt because excitation depends on having the proper ionic concentrations on the two sides of the membrane.

is usually enough rhodopsin within 20–30 minutes to allow adequate dim-light vision.

During these adaptations, reflexive changes also occur in pupil size. Bright light shining in one or both eyes causes both pupils to constrict (elicits the *consensual* and *pupillary light reflexes*). These pupillary reflexes are mediated by the pretectal nucleus of the midbrain and by parasympathetic fibers. In dim light, the pupils dilate, allowing more light to enter the eye interior.

HOMEOSTATIC IMBALANCE

Night blindness, or *nyctalopia* (nic"tă-lo'pe-uh), is a condition in which rod function is seriously hampered, impairing one's ability to drive safely at night. In countries where malnutrition is common, the most common cause of night blindness is prolonged vitamin A deficiency, which leads to rod degeneration. Vitamin A supplements restore function if they are administered early. In countries where nutrition isn't a problem, a group of degenerative retinal diseases called *retinitis pigmentosa,* in which rods are selectively destroyed, are the most common causes of night blindness. Retinitis pigmentosa is a result of the pigment epithelial cells being unable to recycle the tips of the rods as they get sloughed off. ●

The Visual Pathway to the Brain

As described earlier, the axons of the retinal ganglion cells issue from the back of the eyeballs in the **optic nerves** (Figure 15.19). At the X-shaped **optic chiasma** (*chiasm* = cross), fibers from the medial aspect of each eye cross over to the opposite side and then continue on via the **optic tracts.** Thus, each optic tract (1) contains fibers from the lateral (temporal) aspect of the eye on the same side and fibers from the medial (nasal) aspect of the opposite eye, and (2) carries all the information from the same half of the visual field. Notice that, because the lens system of each eye reverses all images, the medial half of each retina receives light rays from the *temporal* (lateralmost) part of the visual field (that is, from the far left or far right rather than from straight ahead), and the lateral half of each retina receives an image of the *nasal* (central) part of the visual field. Consequently, the left optic tract carries (and sends on) a complete representation of the right half of the visual field, and the opposite is true for the right optic tract.

The paired optic tracts sweep posteriorly around the hypothalamus and send most of their axons to synapse with neurons in the **lateral geniculate body** of the thalamus, which maintains the fiber separation established at the chiasma, but balances and combines the retinal input for delivery to the visual cortex. Axons of the thalamic neurons project through the internal capsule to form the **optic radiation** of fibers in the cerebral white matter. These fibers project to the **primary visual cortex** in the occipital lobes, where conscious perception of visual images (seeing) occurs.

Some nerve fibers in the optic tracts send branches to the midbrain. These fibers end in the **superior colliculi,** visual reflex centers controlling the extrinsic muscles of the eyes. A small subset of neurons donating fibers to the visual pathway contain the visual pigment *melanopsin,* dubbed the circadian pigment, and respond directly to light stimuli independent of vision. These project to the **pretectal nuclei,** which mediate pupillary light reflexes, and to the **suprachiasmatic nucleus** of the hypothalamus, which functions as the "timer" to set our daily biorhythms.

Notice that although both eyes are set anteriorly and look in approximately the same direction, their visual fields, each about 170 degrees, overlap to a considerable extent, and each eye sees a slightly different view (see Figure 15.19). Cortical "fusion" of the slightly different images delivered by the two eyes provides us with **depth perception,** an accurate means of locating objects in space. This faculty is also called **three-dimensional vision.** In contrast, many animals (pigeons, rabbits, and others) have *panoramic vision.* Their eyes are placed more laterally on the head, so that the visual fields overlap very little, and crossover of the optic nerve fibers is almost complete. Consequently, each visual cortex receives input principally from a single eye and a totally different visual field.

Depth perception depends on the two eyes working together. If only one eye is used, depth perception is lost, and the person must learn to judge an object's position based on learned cues (for example, nearer objects appear larger, and parallel lines converge with distance).

HOMEOSTATIC IMBALANCE

The relationships described above explain patterns of blindness that follow damage to different visual structures. Loss of an eye or destruction of one optic nerve eliminates true depth perception, and peripheral vision is lost on the side of damage. For example, if the "left eye" in Figure 15.19 was lost in a hunting accident, nothing would be seen in the visual field area colored yellow in that figure. If neural destruction occurs beyond the optic chiasma—in an optic tract, the thalamus, or visual cortex—then part or all of the opposite half of the visual field is lost. For example, a stroke affecting the left visual cortex leads to blindness in the right half of the visual field, but since the right (undamaged) visual cortex still receives inputs from both eyes, depth perception in the remaining half of the visual field is retained. ●

Q *Where on the retina of the right eye would light from an object in the nasal portion of its visual field be projected?*

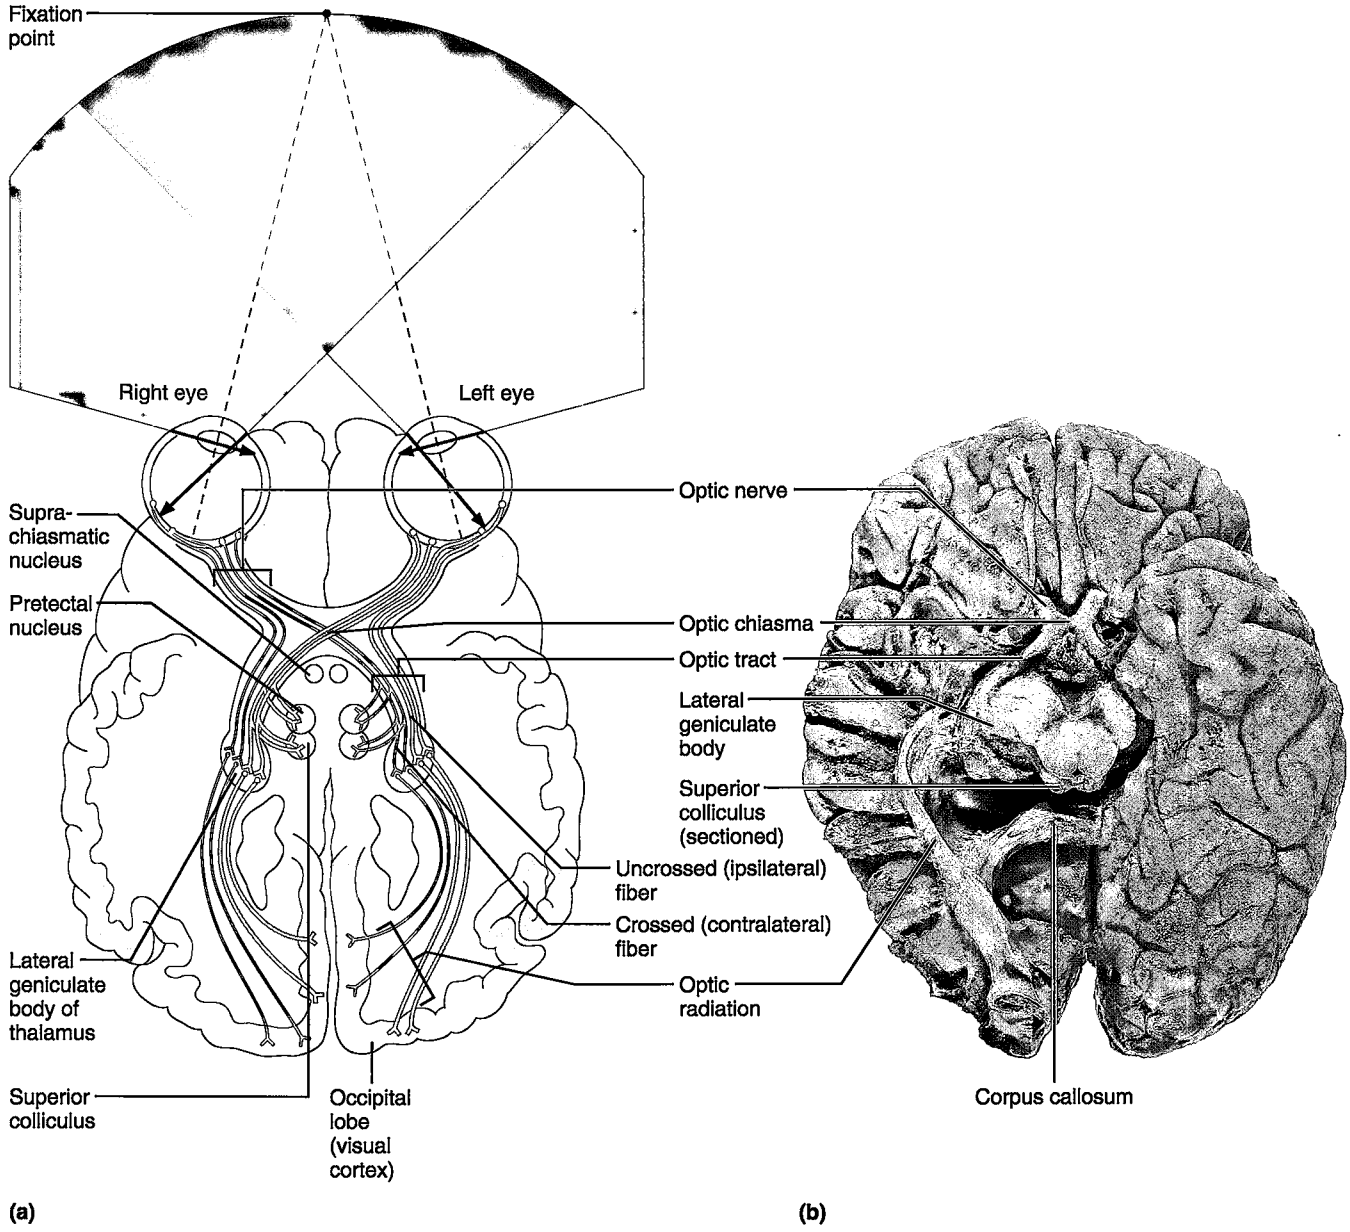

FIGURE 15.19 **Visual fields of the eyes and visual pathway to the brain, inferior view. (a)** Diagram. **(b)** Photograph of human brain. The right side has been dissected to reveal internal structures. In (a) notice that the visual fields of the two eyes overlap considerably. Also notice the retinal sites at which a real image would be focused when both eyes are fixated on a close, pointlike object. The full lateral extension of the visual fields is not illustrated here.

Visual Processing

How does information received by the rods and cones become vision? In the past few years, a tremendous amount of research has been devoted to this question. Some of the more basic information that has come out of these studies is presented here.

Retinal Processing The retinal ganglion cells generate action potentials at a fairly steady rate (20–30 per second), even in the dark. Surprisingly, illuminating the entire retina evenly has no effect on

A *On the temporal portion of the retina.*

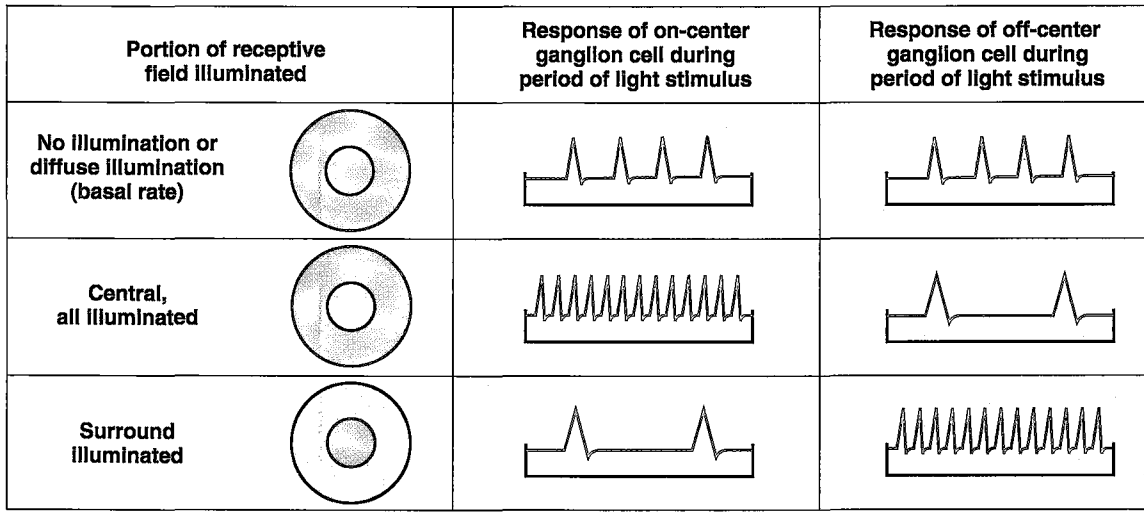

FIGURE 15.20 **Responses of on-center and off-center retinal ganglion cells to different types of illumination.** Intermediate amounts of illumination of the central and surround regions lead to intermediate rates of impulse transmission.

that basal rate. However, the activity of individual ganglion cells changes dramatically when a tiny spot of light falls just on certain portions of their receptive field. The *receptive field* of a ganglion cell consists of the area of the retina that, when stimulated, influences the activity of that ganglion cell (via the rods or cones that funnel their impulses to it).

When researchers mapped the receptive fields of ganglion cells receiving inputs only from rods, they found two types of doughnut-shaped (circle-within-a-circle) receptive fields (Figure 15.20). These are called **on-center** and **off-center fields,** based on what happens to the ganglion cell when the center of its receptive field is illuminated with a spot of light. Ganglion cells with on-center fields are stimulated (depolarized) by light hitting the field center (the "doughnut hole") and are inhibited by light hitting rods in the periphery (the doughnut itself). The opposite situation occurs in ganglion cells with off-center fields. Equal illumination of "on" and "off" regions causes little change in the basal rate of ganglion cell firing.

The mechanisms of retinal processing as currently understood can be summarized briefly as follows:

1. The action of light on photoreceptors hyperpolarizes them.

2. Bipolar neurons in the "on" regions are excited (depolarize) and excite the associated ganglion cell when the rods feeding into them are illuminated (and hyperpolarized). Bipolar neurons in the "off" regions are inhibited (hyperpolarize) and inhibit the ganglion cell when the rods feeding into them are stimulated. The opposite responses of the bipolar neurons in the "on" versus the "off" regions reflect the fact that they have different receptor types for glutamate.

3. Bipolar neurons receiving signals from cones feed directly into excitatory synapses on ganglion cells. Hence, cone inputs are perceived as sharp and clear (and in color).

4. Bipolar neurons receiving inputs from rods excite amacrine cells via gap junctions. These local integrator neurons modify rod inputs and ultimately direct excitatory inputs to appropriate ganglion cells. Thus, rod inputs are not only summated but are subject to "detours" before reaching the output (ganglion) cells. Together these factors provide a more smeary picture than cone inputs.

5. Inputs are also modified and subjected to lateral inhibition by synaptic (gap junction) contacts with horizontal cells. Inputs from these local integrator cells allow the retina to convert inputs that are points of light into perceptually more meaningful contour information by accentuating bright/dark or color contrasts (edges).

6. Two common varieties of ganglion cells are identified. P cells, the target of cone input, relay information about small nonmoving objects in the center of the visual field—their color and details. M cells, which also receive rod input, respond best to large, moving objects at the edge of the image.

Thalamic Processing The lateral geniculate nuclei (LGN) of the thalamus relay information on movement, segregate the retinal axons in preparation for depth perception, emphasize visual inputs from the cones, and sharpen the contrast information

received from the retina. The separation of signals from the two eyes is relayed accurately to the visual cortex.

Cortical Processing Two types of areas for processing retinal inputs are found in the visual cortex. The *primary visual cortex,* also called the **striate cortex,** is thick with fibers coming in from the LGN. This area contains an accurate topographical map of the retina; the left visual cortex receives input from the right visual field and vice versa. Visual processing here occurs at a relatively basic level, with the processing neurons responding to dark and bright edges (contrast information) and object orientation.

The striate cortex also provides form, color, and motion inputs to *visual association areas* collectively called the **prestriate cortices.** The more anterior prestriate cortices are occipital lobe centers that continue the processing of visual information concerned with form, color, and movement. Functional neuroimaging of humans has revealed that complex visual processing extends well forward into the temporal, parietal, and frontal lobes via two main streams: (1) The "what" processing stream extends through the ventral part of the temporal lobe and specializes in the identification of objects in the visual field. (2) The "where" processing stream takes a dorsal path through the parietal cortex all the way to the postcentral gyrus and uses information from the primary visual cortex to assess the spatial location of objects. Output from both these regions then appears to pass to the frontal cortex, which uses that information to direct activities that, among other things, can guide movements such as reaching for a juicy peach.

15

The Chemical Senses: Taste and Smell

Taste and smell are gritty, primitive senses that alert us to whether that "stuff" nearby (or in our mouth) is to be savored or avoided. The receptors for taste (gustation) and smell (olfaction) are **chemoreceptors** (respond to chemicals in an aqueous solution); they complement each other and respond to different classes of chemicals. Taste receptors are excited by food chemicals dissolved in saliva; smell receptors, by airborne chemicals that dissolve in fluids coating nasal membranes.

The Olfactory Epithelium and the Sense of Smell

Although our olfactory sense (*olfact* = to smell) is far less acute than that of many other animals, the human nose is still no slouch in picking up small differences in odors. Some people capitalize on this ability by becoming wine tasters.

Localization and Structure of Olfactory Receptors

Olfaction detects chemicals *(odorants)* in solution. The organ of smell is a yellow-tinged patch (about 5 cm^2) of pseudostratified epithelium, called the **olfactory epithelium,** located in the roof of the nasal cavity (Figure 15.21). Air entering the nasal cavity must make a hairpin turn to stimulate olfactory receptors before entering the respiratory passageway below, so the human olfactory epithelium is in a poor position for doing its job. (This is why sniffing, which draws more air superiorly across the olfactory epithelium, intensifies the sense of smell.) The olfactory epithelium covers the superior nasal concha on each side of the nasal septum, and contains millions of bowling pin–shaped **olfactory receptor cells.** These are surrounded and cushioned by columnar **supporting cells,** which make up the bulk of the penny-thin epithelial membrane (Figure 15.21). The supporting cells contain a yellow-brown pigment similar to lipofuscin, which gives the olfactory epithelium its yellow hue. At the base of the epithelium lie the short **basal cells.**

The olfactory receptor cells are unusual bipolar neurons. Each has a thin apical dendrite that terminates in a knob from which several long cilia radiate. These **olfactory cilia,** which substantially increase the receptive surface area, typically lie flat on the nasal epithelium and are covered by a coat of thin mucus produced by the supporting cells and by olfactory glands in the underlying connective tissue. This mucus is a solvent that "captures" and dissolves airborne odorants. Unlike other cilia in the body, which beat rapidly and in a coordinated manner, olfactory cilia are largely nonmotile. The slender, unmyelinated axons of the olfactory receptor cells are gathered into small fascicles that collectively form the **filaments of the olfactory nerve** (cranial nerve I). They project superiorly through the openings in the cribriform plate of the ethmoid bone, where they synapse in the overlying olfactory bulbs.

Olfactory receptor cells are unique in that they are one of the few types of *neurons* that undergo noticeable turnover throughout adult life. Their superficial location puts them at risk for damage and their typical life span is 30–60 days, after which they are replaced by differentiation of the basal cells in the olfactory epithelium.

Specificity of the Olfactory Receptors

Smell is difficult to research because any given odor (say, tobacco smoke) may be made up of hundreds of different chemicals. Taste has been neatly packaged

Q *What is the importance of the layer of mucus that coats the olfactory epithelium surface?*

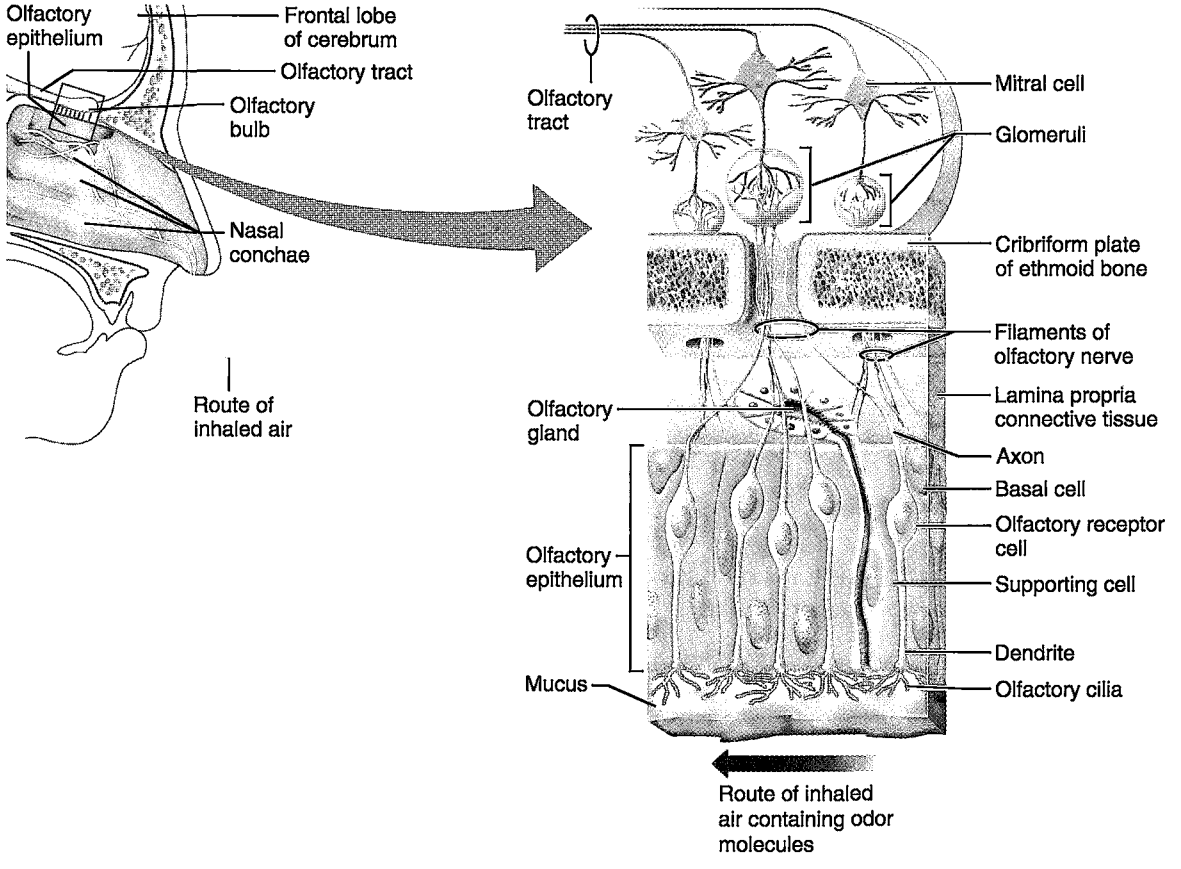

FIGURE 15.21 **Olfactory receptors.** Site of olfactory epithelium in the superior nasal cavity is shown on the left. On the right is an enlarged view of the olfactory epithelium and the course of the fibers (filaments) of the olfactory nerve (I) through the ethmoid bone to synapse in the overlying olfactory bulb. The glomeruli and mitral cells (output cells) within the olfactory bulb are also shown.

into four or five taste qualities, but science has yet to discover any similar means for classifying smell. Humans can distinguish 10,000 or so odors, but research suggests that our olfactory receptors are stimulated by different combinations of a more limited number of olfactory qualities. Most promising in throwing light on this matter are the studies done in the early 1990s suggesting that there are at least 1000 "smell genes" that are active only in the nose. Each such gene encodes a unique receptor protein, and it appears that each of the receptor proteins responds to several different odors and each odor binds to several different receptor types. However, each receptor cell has only one type of receptor protein.

Olfactory neurons are exquisitely sensitive—in some cases, just a few molecules activate them.

A *It serves as a dissolving medium for odor molecules.*

Some of what we call smell is really pain. The nasal cavities contain pain receptors that respond to irritants such as the sharpness of ammonia, the hotness of chili peppers, and the "chill" of menthol. Impulses from these pain receptors reach the central nervous system via afferent fibers of the trigeminal nerves.

Physiology of Smell

Activation of the Olfactory Receptors For us to smell a particular odorant, it must be *volatile*—that is, it must be in the gaseous state as it enters the nasal cavity. Additionally, it must dissolve in the fluid coating the olfactory epithelium. The dissolved odorants stimulate the olfactory receptors by binding to protein receptors in the olfactory cilium membranes and opening cation channels. This leads to a receptor potential and ultimately (assuming threshold

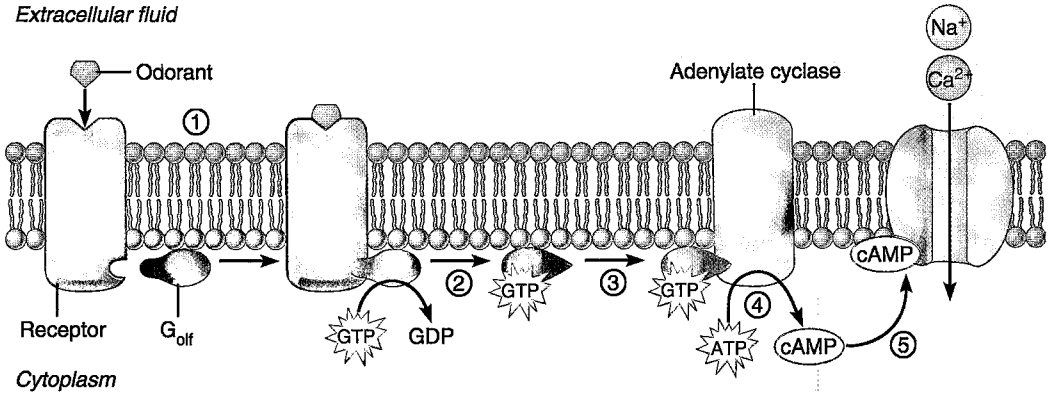

FIGURE 15.22 **Olfactory transduction process.** A portion of olfactory cilium membrane showing the events in olfactory transduction. ① Olfactory transduction occurs when an odorant chemical binds to its receptor. ② The receptor activates G protein (G_{olf}), which ③ activates adenylate cyclase. ④ Adenylate cyclase converts ATP to cAMP, which in turn ⑤ directly opens a cation channel allowing the influx of Na^+ and Ca^{2+}, depolarizing the cell.

stimulation) to an action potential that is conducted to the first relay station in the olfactory bulb.

Mechanism of Smell Transduction Transduction of odorants uses a receptor linked to a G protein (Figure 15.22). The events following odorant binding will be easy for you to remember if you compare them to what you already know: general mechanisms of receptors and G proteins (see Figure 11.22) and phototransduction (Figure 15.18). In olfactory transduction, an odorant binds to a receptor, which activates G protein (G_{olf}), which activates enzymes (adenylate cyclases) that synthesize cyclic AMP as a second messenger. Cyclic AMP acts directly on a plasma membrane cation channel (as in photoreceptors), causing it to open and allowing Na^+ and Ca^{2+} to enter. Na^+ influx leads to depolarization and impulse transmission. Ca^{2+} influx causes the transduction mechanism to adapt, decreasing its response to a sustained stimulus. This *olfactory adaptation* helps explain how a person working in a paper mill or sewage treatment plant can still enjoy lunch!

The Olfactory Pathway

As noted above, axons of the olfactory receptor cells constitute the olfactory nerves that synapse in the overlying **olfactory bulbs,** the distal ends of the olfactory tracts (see Table 13.2). There, the filaments of the olfactory nerves synapse with **mitral cells** (mi'tral), which are second-order neurons, in complex structures called **glomeruli** (glo-mer'u-li; "little balls") (see Figure 15.21). Axons from neurons bearing the same kind of receptor converge on a given type of glomerulus. Hence, each glomerulus represents a "file" that receives only one type of odor signal, and different odors (which would excite a variety of receptor types) would be expected to activate different subsets of glomeruli. The mitral cells refine the signal, amplify it, and then relay it. The olfactory bulbs also house *granule cells,* GABA-releasing cells that inhibit mitral cells (via dendrodendritic synapses), so that only highly excitatory olfactory impulses are transmitted.

When the mitral cells are activated, impulses flow from the olfactory bulbs via the **olfactory tracts** (composed mainly of mitral cell axons) to two main destinations. The first pathway travels to the piriform lobe of the olfactory cortex and the part of the frontal lobe just above the orbit, where smells are consciously interpreted and identified. Each olfactory cortical neuron receives input from up to 100 receptors to analyze. The second pathway flows via the subcortical route to the hypothalamus, amygdala, and other regions of the limbic system, which elicits emotional responses to odors. Smells associated with danger—smoke, cooking gas, or skunk scent—trigger the sympathetic fight-or-flight response. Appetizing odors cause increased salivation and stimulation of the digestive tract, and unpleasant odors can trigger protective reflexes such as sneezing and choking.

Taste Buds and the Sense of Taste

The word *taste* comes from the Latin *taxare,* meaning "to touch, estimate, or judge." When we taste things, we are in fact intimately testing or judging our environment, and the sense of taste is considered by many to be the most pleasurable of the special senses.

Localization and Structure of Taste Buds

The **taste buds,** the sensory receptor organs for taste, are located primarily in the oral cavity. Of our 10,000

Q *Think back to your studies of the cranial nerves as you view Part (a). Sensitivity from which part of the tongue would be most impaired by injury to the glossopharyngeal nerve?*

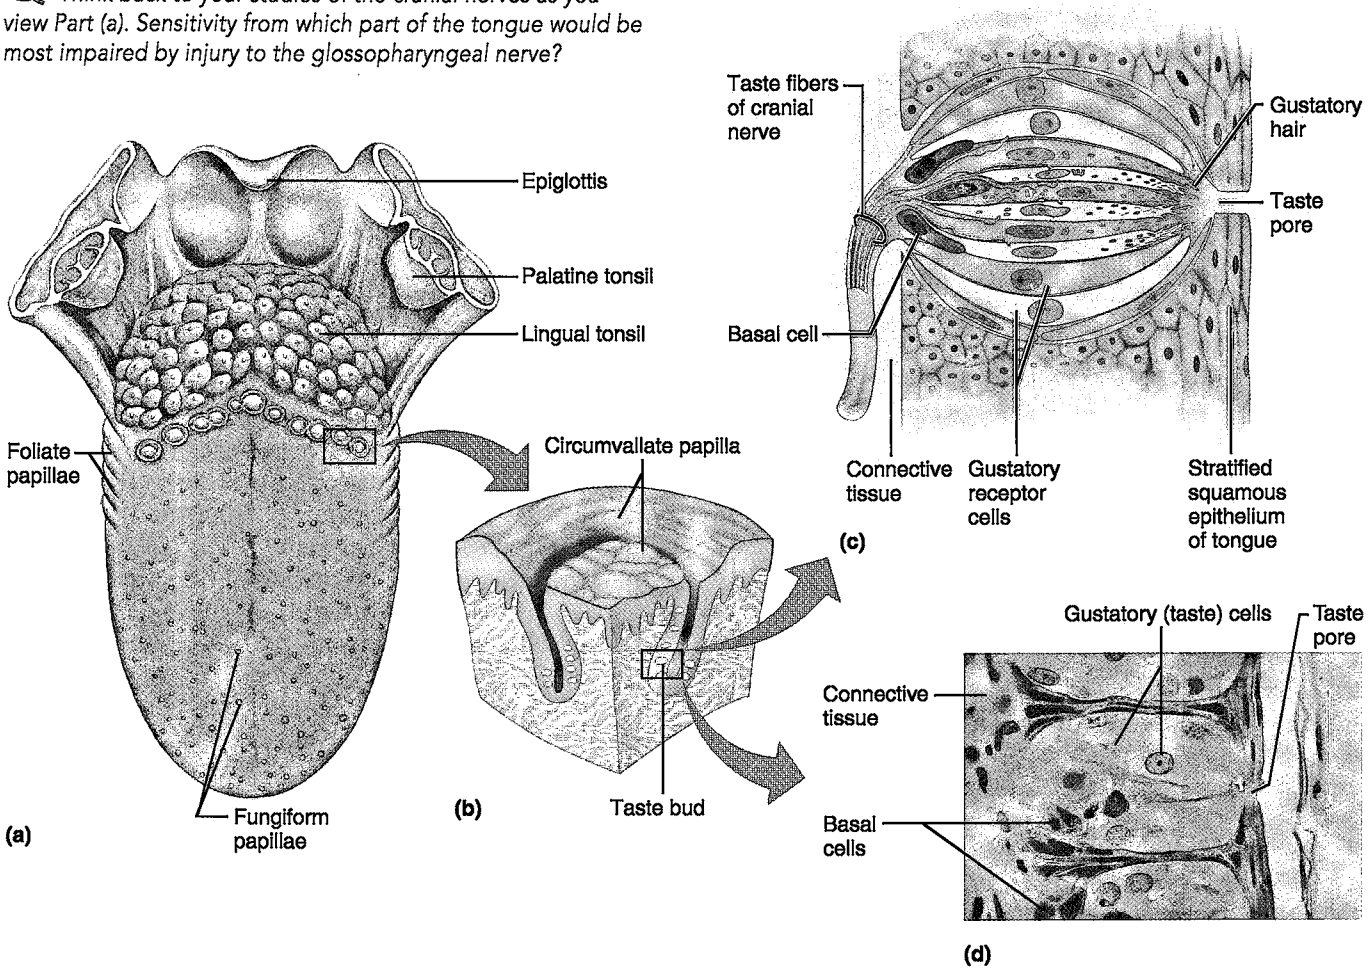

FIGURE 15.23 **Location and structure of taste buds on the tongue. (a)** Taste buds on the tongue are associated with fungiform, foliate, and vallate (circumvallate) papillae, peglike projections of the tongue mucosa. (See *A Brief Atlas of the Human Body*, Figure 62.) **(b)** A sectioned circumvallate papilla shows the positioning of the taste buds in its lateral walls. **(c)** An enlarged view of one taste bud, illustrating gustatory (taste) and basal cells. **(d)** Photomicrograph of a taste bud.

or so taste buds, most are on the tongue. A few taste buds are scattered on the soft palate, inner surface of the cheeks, pharynx, and epiglottis of the larynx, but most are found in **papillae** (pah-pil'e), peglike projections of the tongue mucosa that give the tongue surface a slightly abrasive feel. Taste buds are located mainly on the tops of the mushroom-shaped **fungiform papillae** (fun'jĭ-form) (which are scattered over the entire tongue surface) and in the epithelium of the side walls of the **foliate papillae** and of the large round **circumvallate** (ser"kum-val'āt), or simply **vallate, papillae.** The vallate papillae are the largest and least numerous papillae; 7 to 12 of these form an inverted V at the back of the tongue (see Figure 15.23a).

Each flask-shaped taste bud consists of 50 to 100 *epithelial cells* of two major types: **gustatory**, or **taste cells,** and basal cells (Figure 15.23c). Long microvilli called **gustatory hairs** project from the tips of all gustatory cells and extend through a **taste pore** to the surface of the epithelium, where they are bathed by saliva. The gustatory hairs are the sensitive portions *(receptor membranes)* of the gustatory cells. Coiling intimately around the gustatory cells are sensory dendrites that represent the initial part of the gustatory pathway to the brain. Each afferent fiber receives signals from several receptor cells within the taste bud. Because of their location, taste bud cells are subjected to huge amounts of friction and are routinely burned by hot foods. Luckily, they are among the most dynamic cells in the body, and they are replaced every seven to ten days. The **basal**

∀ Posterior tongue.

15

cells act as stem cells, dividing and differentiating into new gustatory cells.

Basic Taste Sensations

Normally, our taste sensations are complicated mixtures of qualities. However, when taste is tested with pure chemical compounds, taste sensations can all be grouped into one of five basic qualities: *sweet, sour, salty, bitter,* and *umami*. The sweet taste is elicited by many organic substances including sugars, saccharin, alcohols, some amino acids, and some lead salts (such as those found in lead paint). Sour taste is produced by acids, specifically their hydrogen ions (H^+) in solution. Salty taste is produced by metal ions (inorganic salts); table salt (sodium chloride) tastes the "saltiest." The bitter taste is elicited by alkaloids (such as quinine, nicotine, caffeine, morphine, and strychnine) as well as a number of nonalkaloid substances, such as aspirin. Umami (u-mam'e; "delicious"), a new taste discovered by the Japanese, is elicited by the amino acids glutamate and aspartate, which appear to be responsible for the "beef taste" of steak, the characteristic tang of aging cheese, and the flavor of the food additive monosodium glutamate. However, these differences are not absolute: Most taste buds respond to two or more taste qualities, and many substances produce a mixture of the basic taste sensations.

Taste maps that spatially assign sweet receptors to the tip of the tongue, salty and sour receptors to the sides, bitter receptors to the back, and umami receptors to the pharynx are common in the literature. However, researchers have known for years that these mapped areas are misrepresentations, or are dubious at the very least. In reality, there are only slight differences in the localization of specific taste receptors in different regions of the tongue, and all modalities of taste can be elicited from all areas that contain taste buds.

Taste likes and dislikes have homeostatic value. Umami guides the intake of proteins, and a liking for sugar and salt helps satisfy the body's need for carbohydrates and minerals (as well as some amino acids). Many sour, naturally acidic foods (such as oranges, lemons, and tomatoes) are rich sources of vitamin C, an essential vitamin. Because many natural poisons and spoiled foods are bitter, our dislike for bitterness is protective.

Physiology of Taste

Activation of Taste Receptors For a chemical to be tasted it must dissolve in saliva, diffuse into the taste pore, and contact the gustatory hairs. The gustatory cells contain synaptic vesicles, and binding of the food chemical, or *tastant,* to the receptors in the gustatory cell membrane induces a graded depolarizing potential that causes the release of the synaptic vesicle contents, neurotransmitter. Binding of the neurotransmitter to the associated sensory dendrites triggers generator potentials that elicit action potentials in these fibers.

The different gustatory cells have different thresholds for activation. The bitter receptors (in line with their protective nature) detect substances present in minute amounts; the other receptors are less sensitive. Taste receptors adapt rapidly, with partial adaptation in 3–5 seconds and complete adaptation in 1–5 minutes.

Mechanism of Taste Transduction The mechanisms of taste transduction are only partly known—each taste quality has its own special mechanism. However, all of these mechanisms ultimately cause an increase in intracellular Ca^{2+}, which increases neurotransmitter release. Salty taste is due to Na^+ influx through apically located Na^+ channels, which directly depolarizes the gustatory cell. Sour is mediated by H^+, which appears to act on a taste cell in one of three ways—by directly entering the cell through a channel, by opening channels that allow other cations to enter, or by blockade of K^+ channels. Bitter, sweet, and umami responses are mediated by G protein–dependent mechanisms that act via second messengers. Bitter causes Ca^{2+} release from intracellular stores, whereas sweet causes closure of K^+ channels, thereby depolarizing the cell. The G protein that mediates transduction of bitter tastes has recently been identified and named *gustducin.*

The Gustatory Pathway

Afferent fibers carrying taste information from the tongue are found primarily in two cranial nerve pairs. A branch of the **facial nerve** (VII), the *chorda tympani,* transmits impulses from taste receptors in the anterior two-thirds of the tongue, whereas the lingual branch of the **glossopharyngeal nerve** (IX) services the posterior third and the pharynx just behind. Taste impulses from the few taste buds in the epiglottis and the lower pharynx are conducted primarily by the **vagus nerve** (X). These afferent fibers synapse in the **solitary nucleus** of the medulla (Figure 15.24), and from there impulses stream to the thalamus and ultimately to the gustatory cortex in the insula. Fibers also project to the hypothalamus and limbic system structures, regions that determine our appreciation of what we are tasting.

An important role of taste is to trigger reflexes involved in digestion. As taste impulses pass through the solitary nucleus, they initiate reflexes (via synapses with parasympathetic nuclei) that increase saliva secretion into the mouth and gastric juice into the stomach. Saliva contains mucus that moistens food and digestive enzymes that begin the

digestion of starch. Acidic foods are particularly strong stimulants of the salivary reflex. Additionally, when we eat revolting or foul-tasting substances, gagging or even reflexive vomiting may be initiated.

Influence of Other Sensations on Taste

Taste is 80% smell. When the olfactory receptors in the nasal cavity are blocked by nasal congestion (or pinching your nostrils), food is bland. Without smell, our morning coffee would lack its richness and simply taste bitter.

The mouth also contains thermoreceptors, mechanoreceptors, and nociceptors, and the temperature and texture of foods can enhance or detract from their taste. "Hot" foods such as chili peppers actually bring about their pleasurable effects by exciting pain receptors in the mouth.

Homeostatic Imbalances of the Chemical Senses

Most olfactory disorders, or *anosmias* (an-oz'me-ahz; "without smells"), result from head injuries that tear the olfactory nerves, the aftereffects of nasal cavity inflammation, and aging. Brain disorders can distort the sense of smell. Some people have *uncinate fits* (uns'ih-nāt), olfactory hallucinations during which they experience a particular (usually unpleasant) odor, such as rotting meat. Some such cases are undeniably psychological, but many result from irritation of the olfactory pathway by brain surgery or head trauma. *Olfactory auras* experienced by some epileptics just before they have a seizure are transient uncinate fits.

Taste disorders are less common than disorders of smell, in part because the taste receptors are served by three different nerves and thus are less likely to be "put out of business" completely. Causes of taste disorders include upper respiratory tract infections, head injuries, chemicals or medications, or head and neck radiation for cancer treatment. Zinc supplements have been found to help in some cases of radiation-induced taste disorders.

The Ear: Hearing and Balance

At first glance, the machinery for hearing and balance appears very crude. Fluids must be stirred to stimulate the mechanoreceptors of the internal ear. Nevertheless, our hearing apparatus allows us to hear an extraordinary range of sound, and our equilibrium receptors keep the nervous system continually informed of head movements and position. Although the organs serving these two senses are structurally interconnected within the ear, their receptors respond to different stimuli and are activated independently of one another.

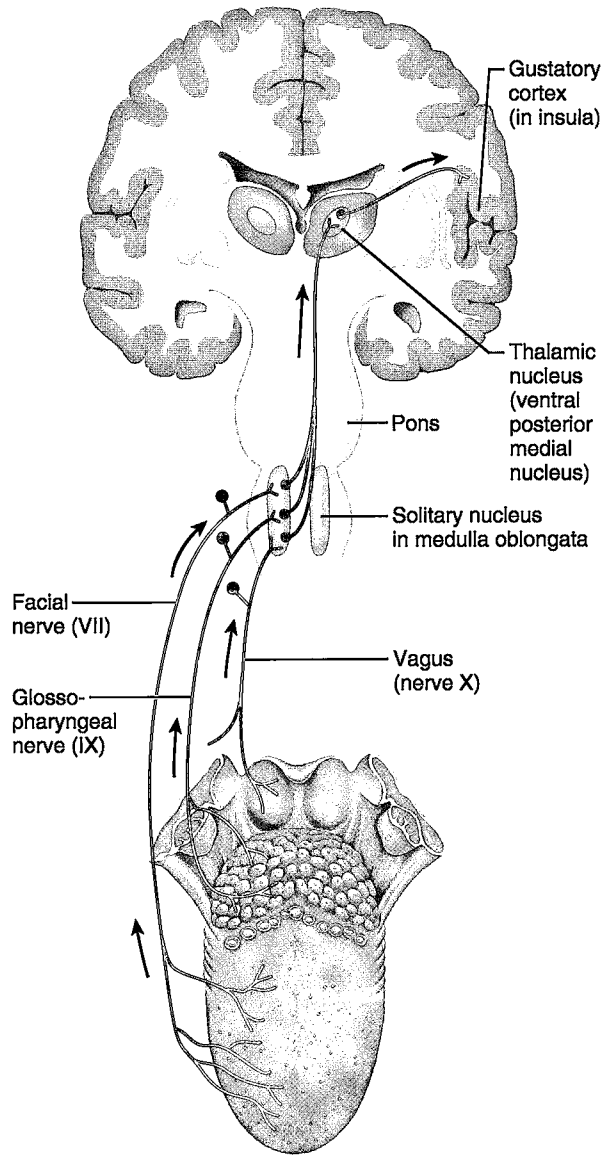

FIGURE 15.24 **The gustatory pathway.** From the taste buds on the tongue and elsewhere, taste impulses travel to the gustatory area of the cerebral cortex.

Structure of the Ear

The ear is divided into three major areas: external ear, middle ear, and internal ear (Figure 15.25). The external and middle ear structures are involved with hearing only and are rather simply engineered. The internal ear functions in both equilibrium and hearing and is extremely complex.

The External (Outer) Ear

The **external (outer) ear** consists of the auricle and the external acoustic meatus. The **auricle,** or **pinna,** is what most people call the ear—the shell-shaped projection surrounding the opening of the external

Q *Besides the bony boundaries, what structure separates the external from the middle ear?*

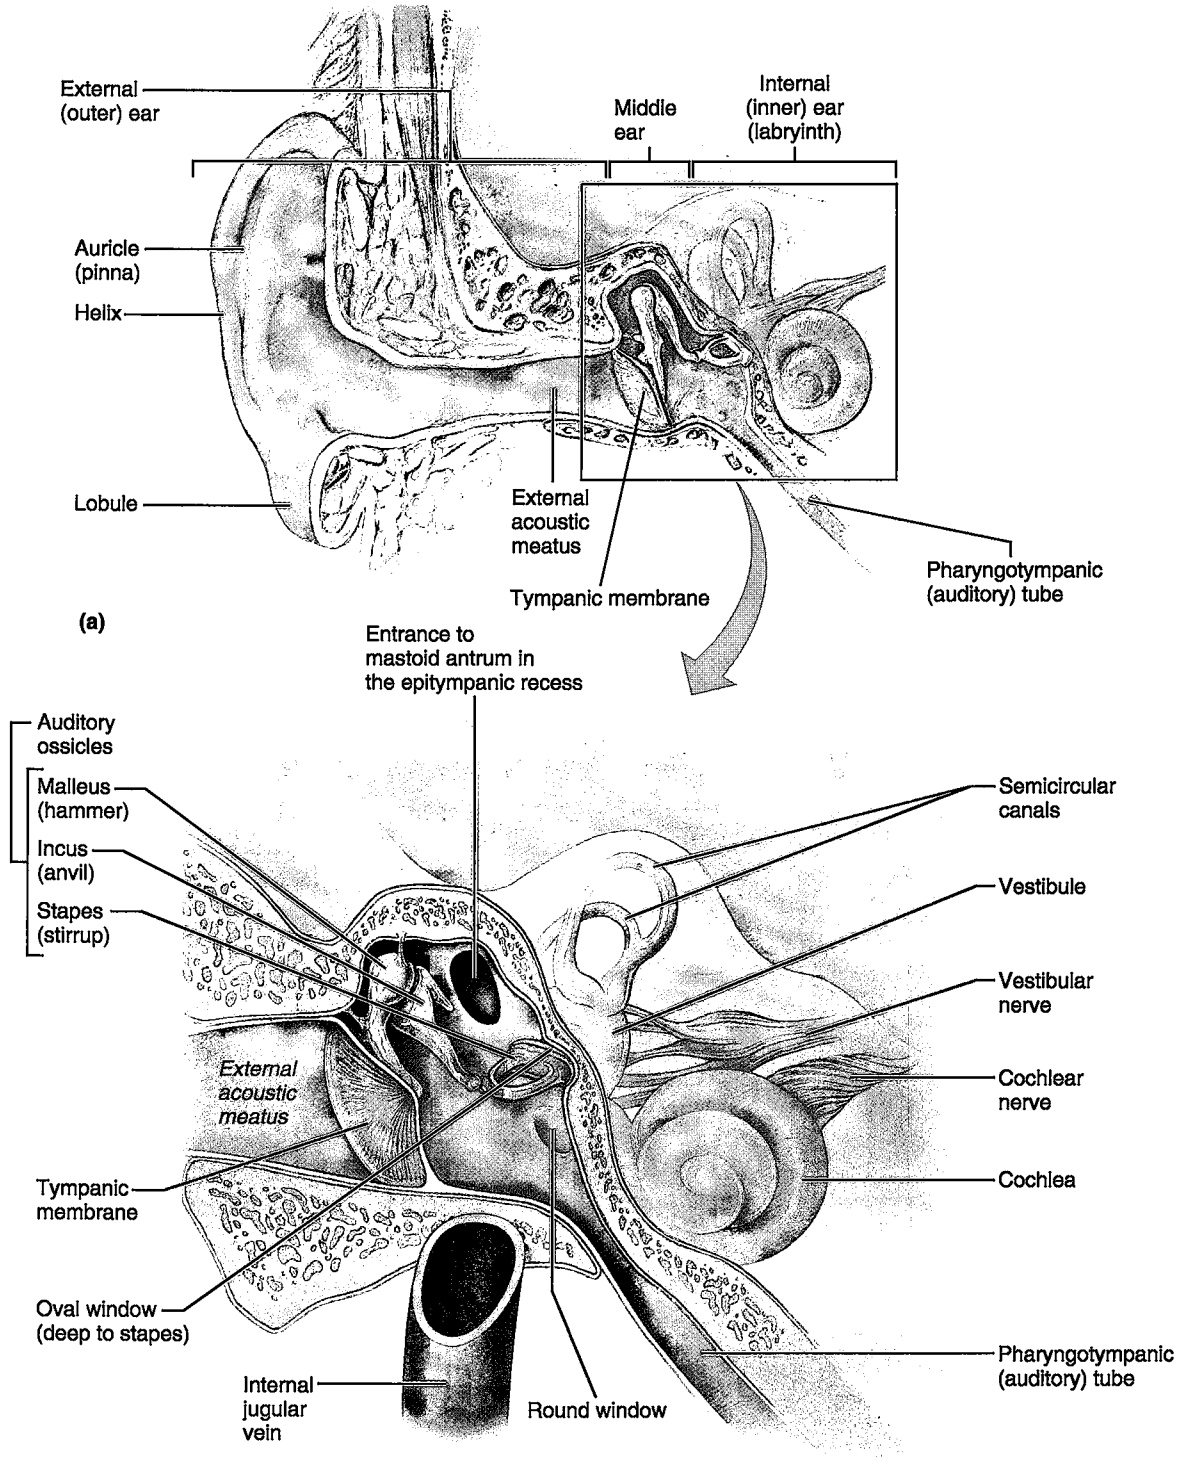

FIGURE 15.25 **Structure of the ear. (a)** The three regions of the ear. **(b)** Enlarged view of the middle and internal ear. Notice that the semicircular canals, vestibule, and cochlea of the internal ear form the bony labyrinth.

A The tympanic membrane.

acoustic meatus. The auricle is composed of elastic cartilage covered with thin skin and an occasional hair. Its rim, the **helix,** is somewhat thicker, and its fleshy, dangling **lobule** ("earlobe") lacks supporting cartilage. The function of the auricle is to direct sound waves into the external acoustic meatus.

The **external acoustic meatus** (auditory canal) is a short, curved tube (about 2.5 cm long by 0.6 cm wide) that extends from the auricle to the eardrum. Near the auricle, its framework is elastic cartilage; the remainder of the canal is carved into the temporal bone. The entire canal is lined with skin bearing hairs, sebaceous glands, and modified apocrine sweat glands called **ceruminous glands** (sĕ-roo'mĭ-nus). These glands secrete yellow-brown waxy **cerumen,** or earwax (*cere* = wax), which provides a sticky trap for foreign bodies and repels insects. In many people, the ear is naturally cleansed as the cerumen dries and then falls out of the external acoustic meatus. (Jaw movements as a person eats, talks, and so on, create an unnoticeable conveyor-belt effect that moves the wax out.) In others, cerumen builds up excessively and becomes compacted, a condition that can impair hearing.

Sound waves entering the external acoustic meatus eventually hit the **tympanic membrane,** or **eardrum** (*tympanum* = drum), the boundary between the outer and middle ears. The eardrum is a thin, translucent, connective tissue membrane, covered by skin on its external face and by a mucosa internally. It is shaped like a flattened cone, with its apex protruding medially into the middle ear. Sound waves make the eardrum vibrate. The eardrum, in turn, transfers the sound energy to the tiny bones of the middle ear and sets them into vibration.

The Middle Ear

The **middle ear,** or **tympanic cavity,** is a small, air-filled, mucosa-lined cavity in the petrous portion of the temporal bone. It is flanked laterally by the eardrum and medially by a bony wall with two openings, the superior **oval (vestibular) window** and the inferior **round (cochlear) window.** Superiorly the tympanic cavity arches upward as the **epitympanic recess,** the "roof" of the middle ear cavity. The **mastoid antrum,** a canal in the posterior wall of the tympanic cavity, allows it to communicate with *mastoid air cells* housed in the mastoid process. The anterior wall of the middle ear abuts the internal carotid artery (the main artery supplying the brain) and contains the opening of the **pharyngotympanic (auditory) tube.** This tube, formerly called the eustachian tube, runs obliquely downward to link the middle ear cavity with the nasopharynx (the superiormost part of the throat), and the mucosa of the middle ear is continuous with that lining the pharynx (throat).

Normally, the pharyngotympanic tube is flattened and closed, but swallowing or yawning opens it briefly to equalize pressure in the middle ear cavity with external air pressure. This is important because the eardrum vibrates freely only if the pressure on both of its surfaces is the same; otherwise sounds are distorted. The ear-popping sensation of the pressures equalizing is familiar to anyone who has flown in an airplane.

HOMEOSTATIC IMBALANCE

Otitis media (me'de-ah), or middle ear inflammation, is a fairly common result of a sore throat, especially in children, whose pharyngotympanic tubes are shorter and run more horizontally. Otitis media is the most frequent cause of hearing loss in children. In acute infectious forms, the eardrum bulges and becomes inflamed and red. Most cases of otitis media are treated with antibiotics. When large amounts of fluid or pus accumulate in the cavity, an emergency *myringotomy* (lancing of the eardrum) may be required to relieve the pressure, and a tiny tube implanted in the eardrum permits pus to drain into the external ear. The tube falls out by itself within the year. ●

The tympanic cavity is spanned by the three smallest bones in the body: the **auditory ossicles** (see Figures 15.25 and 15.26). These bones, named for their shape, are the **malleus** (mal'e-us; "hammer"); the **incus** (ing'kus; "anvil"); and the **stapes**

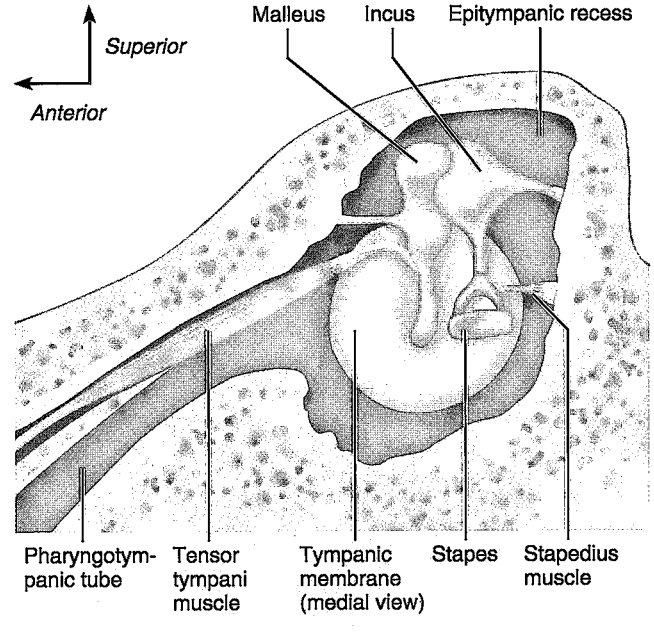

FIGURE 15.26 **The three auditory ossicles in the right middle ear.** Ossicles are seen as if viewed from the oval window looking outward (medial view).

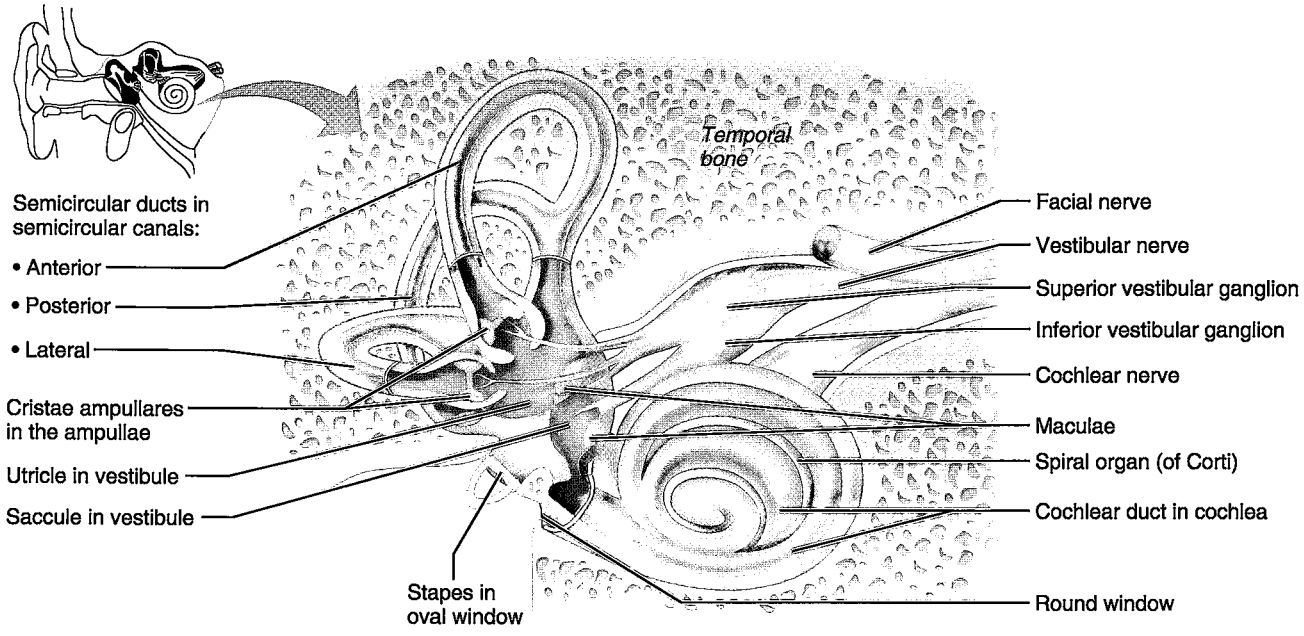

FIGURE 15.27 **Membranous labyrinth of the internal ear.** The membranous labyrinth (blue), is shown in relation to the chambers of the bony labyrinth (orange). The sensory organs for hearing [spiral organ (of Corti)] and equilibrium (maculae and cristae ampullares) are also shown.

(sta'pēz; "stirrup"). The "handle" of the malleus is secured to the eardrum, and the base of the stapes fits into the oval window.

Tiny ligaments suspend the ossicles, and mini synovial joints link them together into a chain that spans the middle ear cavity. The incus articulates with the malleus laterally and the stapes medially. The ossicles transmit the vibratory motion of the eardrum to the oval window, which in turn sets the fluids of the internal ear into motion, eventually exciting the hearing receptors.

Two tiny skeletal muscles are associated with the ossicles (Figure 15.26). The **tensor tympani** (ten'sor tim'pah-ni) arises from the wall of the pharyngotympanic tube and inserts on the malleus. The **stapedius** (stah-pe'de-us) runs from the posterior wall of the middle ear cavity to the stapes. When the ears are assaulted by very loud sounds, these muscles contract reflexively to prevent damage to the hearing receptors. Specifically, the tensor tympani tenses the eardrum by pulling it medially; the stapedius checks vibration of the whole ossicle chain and limits the movement of the stapes in the oval window.

The Internal (Inner) Ear

The **internal (inner) ear** is also called the **labyrinth** ("maze") because of its complicated shape (see Figure 15.25). It lies deep in the temporal bone behind the eye socket and provides a secure site for all of the delicate receptor machinery housed there. The internal ear has two major divisions: the bony labyrinth and the membranous labyrinth. The **bony,** or **osseous, labyrinth** is a system of tortuous channels worming through the bone. Its three regions are the *vestibule,* the *cochlea* (kok'le-ah), and the *semicircular canals.* The views of the bony labyrinth typically seen in textbooks, including this one, are somewhat misleading because we are talking about a *cavity* here. The representation seen in Figure 15.25 can be compared to a plaster of paris cast of the cavity or hollow space inside the bony labyrinth. The **membranous labyrinth** is a continuous series of membranous sacs and ducts contained within the bony labyrinth and (more or less) following its contours (Figure 15.27).

The bony labyrinth is filled with **perilymph,** a fluid similar to cerebrospinal fluid and continuous with it. The membranous labyrinth is suspended in the surrounding perilymph; its interior contains **endolymph,** which is chemically similar to K^+-rich intracellular fluid. These two fluids conduct the sound vibrations involved in hearing and respond to the mechanical forces occurring during changes in body position and acceleration.

The Vestibule The **vestibule** is the central egg-shaped cavity of the bony labyrinth. It lies posterior to the cochlea, anterior to the semicircular canals, and flanks the middle ear medially. In its lateral wall is the oval window. Suspended in its perilymph and united by a small duct are two membranous labyrinth

sacs, the **saccule** and **utricle** (u'tri-kl) (Figure 15.27). The smaller saccule is continuous with the membranous labyrinth extending anteriorly into the cochlea (the *cochlear duct*), whereas the utricle is continuous with the semicircular ducts extending into the semicircular canals posteriorly. The saccule and utricle house equilibrium receptor regions called *maculae* that respond to the pull of gravity and report on changes of head position.

The Semicircular Canals The **semicircular canals** lie posterior and lateral to the vestibule, and each of these canals defines about two-thirds of a circle. The cavities of the bony semicircular canals project from the posterior aspect of the vestibule, each oriented in one of the three planes of space. Accordingly, there is an *anterior, posterior,* and *lateral* semicircular canal in each internal ear. The anterior and posterior canals are oriented at right angles to each other in the vertical plane, whereas the lateral canal lies horizontally (see Figure 15.27). Snaking through each semicircular canal is a corresponding membranous **semicircular duct,** which communicates with the utricle anteriorly. Each of these ducts has an enlarged swelling at one end called an **ampulla,** which houses an equilibrium receptor region called a *crista ampullaris* (literally, crest of the ampulla). These receptors respond to angular (rotational) movements of the head.

The Cochlea The **cochlea,** from the Latin "snail," is a spiral, conical, bony chamber about the size of a split pea. It extends from the anterior part of the vestibule and coils for about 2½ turns around a bony pillar called the **modiolus** (mo-di'o-lus) (Figure 15.28a). Running through its center like a wedge-shaped worm is the membranous **cochlear duct,** which ends blindly at the cochlear apex. The cochlear duct houses the **spiral organ (of Corti),** the receptor organ for hearing (Figures 15.27 and 15.28b). The cochlear duct and the **osseous spiral lamina,** a thin shelflike extension of bone that spirals up the modiolus like the thread on a screw, together divide the cavity of the bony cochlea into three separate chambers or **scalae** (*scala* = ladder). The **scala vestibuli** (ska'lah vĕs-tĭ'bu-li), which lies superior to the cochlear duct, is continuous with the vestibule and abuts the oval window. The middle **scala media** is the cochlear duct itself. The **scala tympani,** which terminates at the round window, is inferior to the cochlear duct. Since the scala media is part of the membranous labyrinth, it is filled with endolymph. The scala vestibuli and the scala tympani, both part of the bony labyrinth, contain perilymph. The perilymph-containing chambers are continuous with each other at the cochlear apex, a region called the **helicotrema** (hel"ĭ-ko-tre'mah; "the hole in the spiral").

The "roof" of the cochlear duct, separating the scala media from the scala vestibuli, is the **vestibular membrane** (see Figure 15.28b). Its external wall, the **stria vascularis,** is composed of an unusual richly vascularized mucosa that secretes endolymph. The "floor" of the cochlear duct is composed of the bony spiral lamina and the flexible, fibrous **basilar membrane,** which supports the spiral organ (of Corti). (We will describe the spiral organ when we discuss the mechanism of hearing.) The basilar membrane, which plays a critical role in sound reception, is narrow and thick near the oval window and gradually widens and thins as it approaches the cochlear apex. The *cochlear nerve,* a division of the *vestibulocochlear* (eighth cranial) *nerve,* runs from the spiral organ through the modiolus on its way to the brain.

Physiology of Hearing

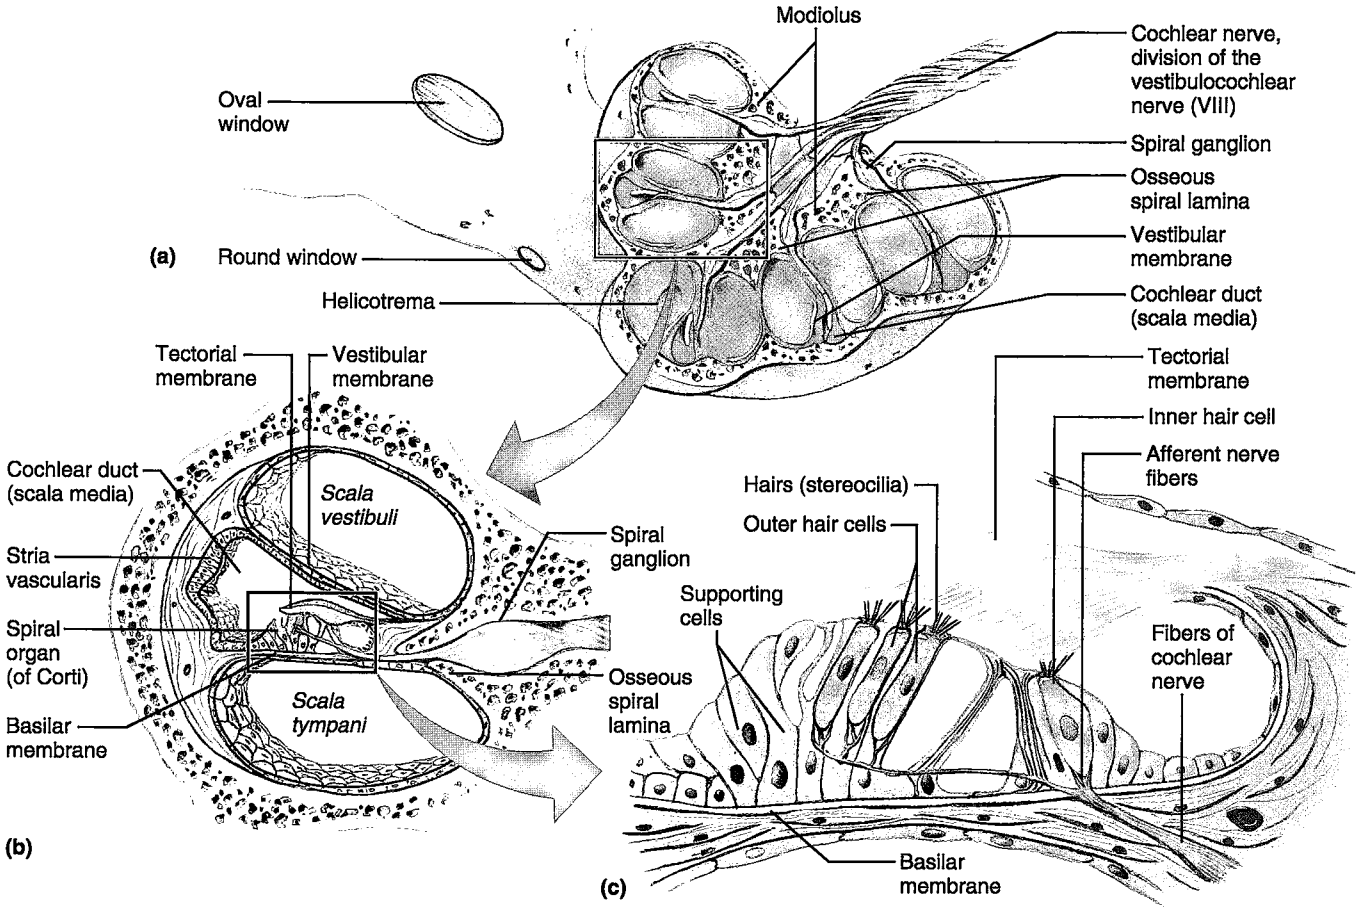
The mechanics of human hearing can be summed up in a single sprawling sentence: Sounds set up vibrations in air that beat against the eardrum that pushes a chain of tiny bones that press fluid in the internal ear against membranes that set up shearing forces that pull on the tiny hair cells that stimulate nearby neurons that give rise to impulses that travel to the brain, which interprets them—and you hear. Before we unravel this intriguing sequence, let us describe sound, the stimulus for hearing.

Overview: Properties of Sound

Light can be transmitted through a vacuum (for instance, outer space), but sound depends on an *elastic* medium for its transmission. Sound also travels much more slowly than light. Its speed in dry air is only about 331 m/s (0.2 mi/s), as opposed to the about 300,000 km/s (186,000 mi/s) of light. A lightning flash is almost instantly visible, but the sound it creates (thunder) reaches our ears much more slowly. (For each second between the lightning bolt and the roll of thunder, the storm is 1/5 mile farther away.) The speed of sound is constant in a given medium. It is greatest in solids and lowest in gases, including air.

Sound is a pressure disturbance—alternating areas of high and low pressure—produced by a vibrating object and propagated by the molecules of the medium. Consider a sound arising from a vibrating tuning fork (Figure 15.29a). If the tuning fork is struck on the left, its prongs will move first to the right, creating an area of high pressure by compressing the air molecules there. Then, as the prongs rebound to the left, the air on the left will be compressed, and the region on the right will be a rarefied, or low-pressure, area (since most of its air molecules

Q *Which scala contains endolymph?*



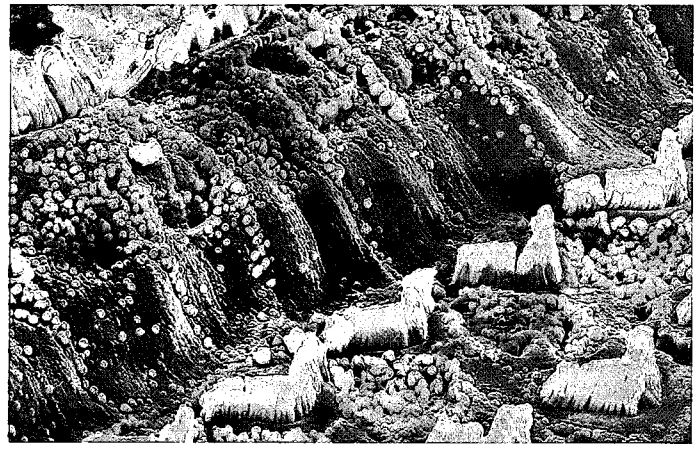


FIGURE 15.28 **Anatomy of the cochlea. (a)** A section through the cochlea (superior half removed). have been pushed farther to the right). As the fork vibrates alternately from right to left, it produces a series of compressions and rarefactions, collectively called a *sound wave,* which moves outward in all directions (Figure 15.29b). However, the individual air molecules just vibrate back and forth for short distances as they bump other molecules and rebound. Because the outward-moving molecules give up kinetic energy to the molecules they bump, energy is always transferred in the direction the sound wave is traveling. Thus, with time and distance, the energy of the wave declines, and the sound dies a natural death.

We can illustrate a sound wave as an S-shaped curve, or *sine wave,* in which the compressed areas are crests and the rarefied areas are troughs (Figure

A The scala media.

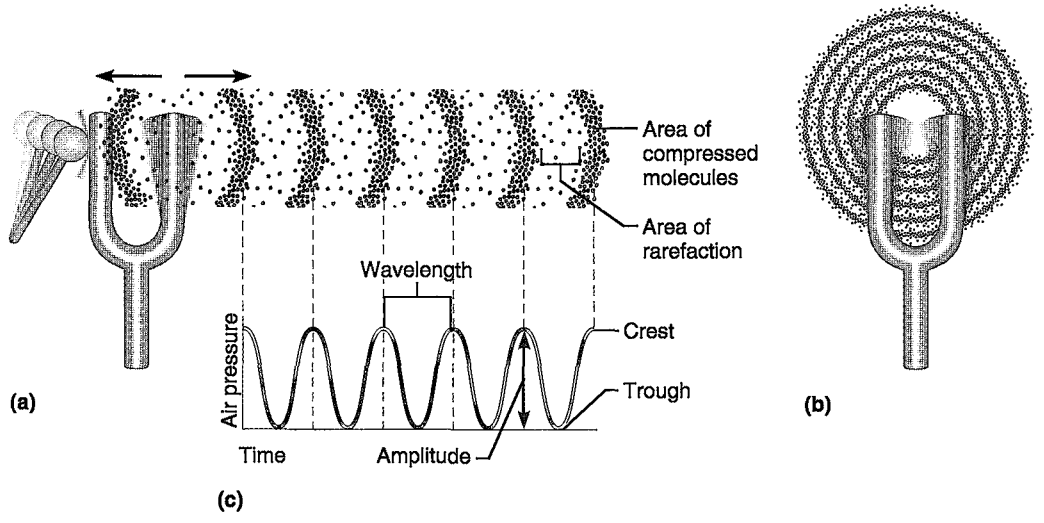

FIGURE 15.29 **Sound: source and propagation.** The source of sound is a vibrating object. **(a)** A tuning fork is struck on the left with a mallet. Its tines move to the right, compressing the air molecules in that region. (The tine movement is shown on the right side only and is exaggerated.) Then the tines move in the opposite direction, compressing the air there and leaving a rarefied area to the right side of the tuning fork. **(b)** In this way, sound waves, consisting of alternate areas of compression and rarefaction, are set up and radiate outward in all directions from the sound source. **(c)** The sound wave may be depicted as a sine wave. The peaks of the wave represent areas of high pressure (compressed areas), and the troughs represent areas of low pressure (rarefied areas). For any tone, the distance between two corresponding points on the wave (two crests or two troughs) is called the wavelength. The height (amplitude) of the crests is related to the energy, or intensity, of the sound wave.

15.29c). Sound can be described in terms of two physical properties inferred from this sine wave graph: frequency and amplitude.

Frequency is defined as the number of waves that pass a given point in a given time. The sine wave of a pure tone is *periodic;* that is, its crests and troughs repeat at definite distances. The distance between two consecutive crests (or troughs) is called the **wavelength** of the sound and is constant for a particular tone. The shorter the wavelength, the higher the frequency of the sound (Figure 15.30a).

The frequency range of human hearing is from 20 to 20,000 waves per second, or *hertz (Hz)*. Our ears are most sensitive to frequencies between 1500 and 4000 Hz and, in that range, we can distinguish frequencies differing by only 2–3 Hz. We perceive different sound frequencies as differences in **pitch:** The higher the frequency, the higher the pitch. A tuning fork produces a *tone,* a pure (but bland) sound with a single frequency, but most sounds are mixtures of several frequencies. It is this characteristic of sound, called **quality,** that enables us to distinguish between the same musical note—say, high C—sung by a soprano and played on a piano or clarinet, and that provides the richness and complexity of sounds (and music) that we hear.

The **amplitude,** or height, of the sine wave crests reveals a sound's intensity, which is related to its energy, or the pressure differences between its compressed and rarefied areas (Figure 15.30b).

Loudness refers to our subjective interpretation of sound intensity. Because we can hear such an enormous range of intensities, from the proverbial pin drop to a steam whistle 10 million times as intense, sound intensity (and loudness) is measured in logarithmic units called **decibels (dB)** (des'ĭ-belz). On a clinical audiometer, the decibel scale is arbitrarily set to begin at 0 dB, which is the threshold of hearing (barely audible sound) for normal ears. Each 10-dB increase represents a tenfold increase in sound intensity. A sound of 10 dB has 10 times more energy than one of 0 dB, and a 20-dB sound has 100 times (10 × 10) more energy than one of 0 dB. However, the same 10-dB increase represents only a twofold increase in loudness. In other words, most people would report that a 20-dB sound seems about twice as loud as a 10-dB sound. The normal range of hearing (from barely audible to the loudest sound we can process without excruciating pain) extends over a range of 120 dB. (The threshold of pain is 130 dB.)

Severe hearing loss occurs with frequent or prolonged exposure to sounds with intensities greater than 90 dB, and in the U.S., employees exposed to occupational noise over that range must wear ear (hearing) protection. This figure becomes more meaningful when you realize that a normal conversation is in the 50-dB range, a noisy restaurant has 70-dB levels, and amplified rock music is 120 dB or more, far above the 90-dB danger zone.

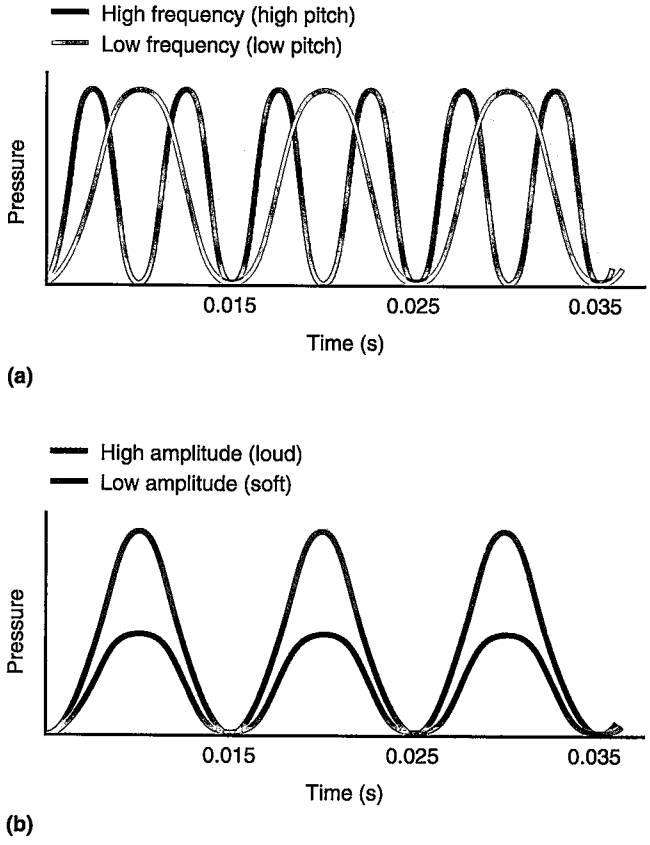

FIGURE 15.30 **Frequency and amplitude of sound waves. (a)** The wave shown in red has a shorter wavelength, and thus a greater frequency, than that shown in blue. The frequency of sound is perceived as pitch. **(b)** The wave shown in purple has a greater amplitude (intensity) than that shown in green and is perceived as being louder.

Transmission of Sound to the Internal Ear

Hearing occurs when the auditory area of the temporal lobe cortex is stimulated. However, before this can happen, sound waves must be propagated through air, membranes, bones, and fluids to reach and stimulate receptor cells in the spiral organ (of Corti) (Figure 15.31).

Airborne sound entering the external acoustic meatus strikes the tympanic membrane and sets it vibrating at the same frequency. The greater the intensity, the farther the membrane is displaced in its vibratory motion. The motion of the tympanic membrane is amplified and transferred to the oval window by the ossicle lever system, which acts much like a hydraulic press or piston to transfer the same total force hitting the eardrum to the oval window. Because the tympanic membrane is 17–20 times larger than the oval window, the pressure (force per unit area) actually exerted on the oval window is about 20 times that on the tympanic membrane. This increased pressure overcomes the stiffness and inertia of cochlear fluid and sets it into wave motion. This situation can be roughly compared to the difference in pressure relayed to the floor by the broad rubber heels of a man's shoes and a woman's tiny spike heels. The man's weight—say, 70 kg (about 150 pounds)—is spread over several square inches, and his heels will not make dents in a pliable vinyl floor. But spike heels will concentrate the same 70-kg force in an area of about 2.5 cm^2 (1 square inch) and *will* dent the floor.

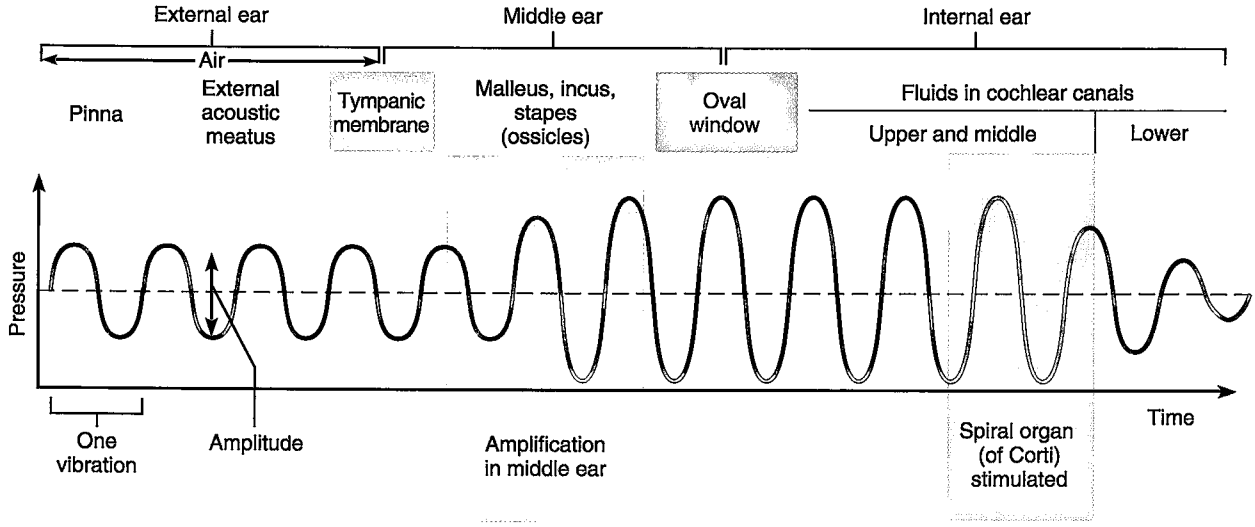

FIGURE 15.31 **Route of sound waves through the ear.** To excite the hair cells in the spiral organ (of Corti) in the internal ear, sound wave vibrations must pass through air, membranes, bones, and fluids. Note that the amplification of pressure in the middle ear is actually much larger than shown here.

Resonance of the Basilar Membrane

As the stapes rocks back and forth against the oval window, it sets the perilymph in the scala vestibuli into a similar back-and-forth motion, and a pressure wave travels through the perilymph from the basal end toward the helicotrema, much as a piece of rope held horizontally can be set into wave motion by movements initiated at one end. Sounds of very low frequency (below 20 Hz) create pressure waves that take the complete route through the cochlea—up the scala vestibuli, around the helicotrema, and back toward the round window through the scala tympani (Figure 15.32a). Such sounds do not activate the spiral organ (are below the threshold of hearing). But sounds of higher frequency (and shorter wavelengths) create pressure waves that take a "shortcut" and are transmitted through the cochlear duct into the perilymph of the scala tympani. Fluids are incompressible. Think of what happens when you sit on a water bed—you sit "here" and it bulges over "there." Thus, each time the fluid adjacent to the oval window is forced medially by the stapes, the membrane of the round window bulges laterally into the middle ear cavity and acts as a pressure valve.

As a pressure wave descends through the flexible cochlear duct, it sets the entire basilar membrane into vibration. Maximal displacement of the membrane occurs where the fibers of the basilar membranes are "tuned" to a particular sound frequency (Figure 15.32b). (This characteristic of many natural substances is called *resonance.*) The fibers of the basilar membrane span its width like the strings of a harp. The fibers near the oval window (cochlear base) are short and stiff, and they resonate in response to high-frequency pressure waves (Figure 15.32b). The longer, more floppy basilar membrane fibers near the cochlear apex resonate in time with lower-frequency pressure waves. Thus, sound signals are mechanically processed by the resonance of the basilar membrane, before ever reaching the receptors.

Excitation of Hair Cells in the Spiral Organ

The spiral organ (of Corti), which rests atop the basilar membrane, is composed of supporting cells and hearing receptor cells called *cochlear hair cells.* The hair cells are arranged functionally—specifically, one row of **inner hair cells** and three rows of **outer hair cells**—sandwiched between the tectorial and basilar membranes. Afferent fibers of the **cochlear nerve** [a division of the vestibulocochlear nerve (VIII)] are coiled about the bases of the hair cells. The hair cells have numerous *stereocilia* (actually long microvilli) and a single *kinocilium* (a true cilium) protruding from their apices. The "hairs" (stereocilia) of the hair cells are stiffened by actin filaments and linked

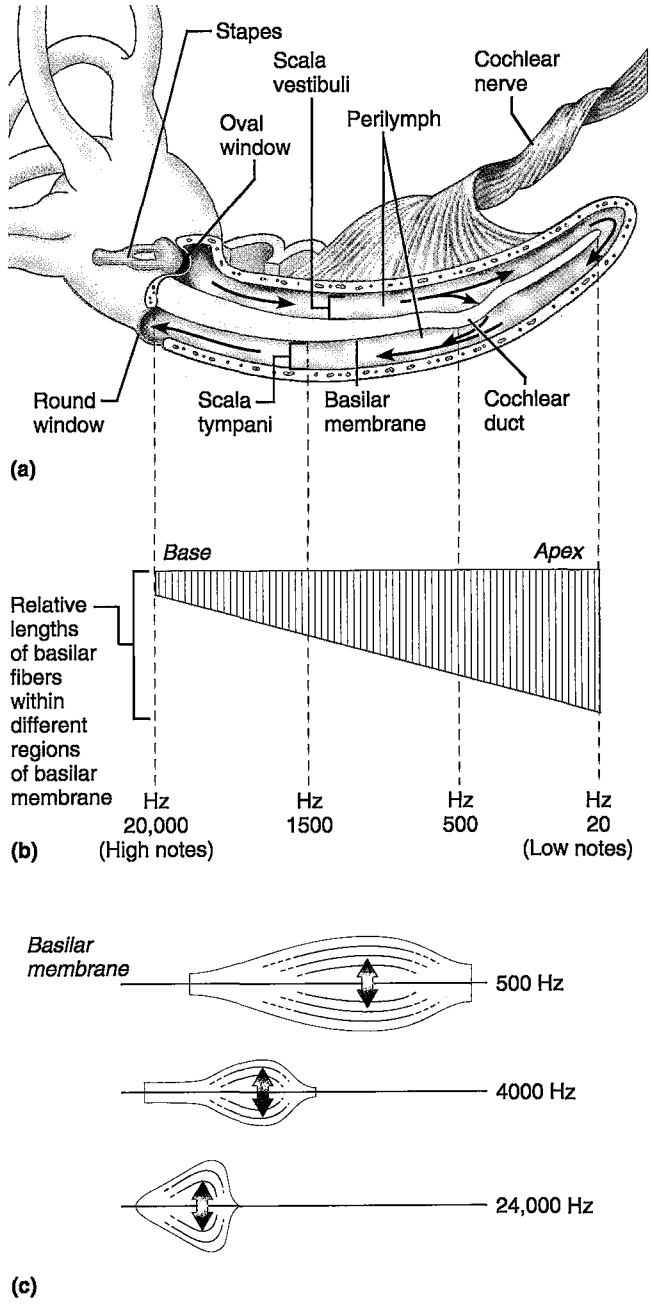

FIGURE 15.32 **Resonance of the basilar membrane and activation of the cochlear hair cells. (a)** The cochlea is depicted as if uncoiled. Sound waves with frequencies below the level of hearing travel through the helicotrema without exciting hair cells. Higher-frequency sounds result in pressure waves that penetrate through the cochlear duct, setting up vibrations in the basilar membrane. The basilar membrane vibrates maximally in specific areas corresponding to specific frequencies of sound. **(b)** Fibers span the width of the basilar membrane. These fibers vary in length and stiffness, being shorter and stiffer near the base of the membrane and longer and floppier near its apex. The stiffness of the fibers "tunes" specific regions of the basilar membrane to vibrate at specific frequencies. **(c)** Different frequencies of pressure waves in the cochlea cause specific places along the basilar membrane to vibrate, stimulating particular hair cells and sensory neurons. The differential stimulation of hair cells is perceived in the brain as sound of a certain pitch.

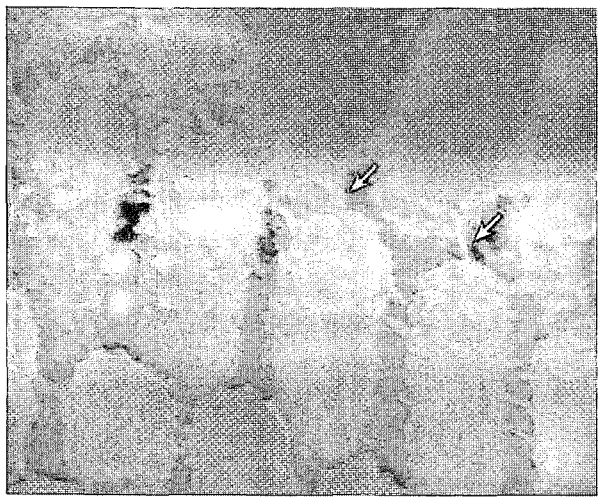

FIGURE 15.33 **Photo of cochlear hair cells with their precise arrays of stereocilia.** White arrows point to tip-links.

together by fine fibers called *tip-links* (Figure 15.33). They protrude into the K^+-rich endolymph, and the longest of them are enmeshed in the overlying, stiff gel-like **tectorial membrane** (see Figure 15.28c).

Transduction of sound stimuli occurs after the trapped stereocilia of the hair cells are "tweaked" or deflected by localized movements of the basilar membrane. Bending the cilia toward the tallest cilium (the kinocilium) puts tension on the tip-links, which in turn opens cation channels in the adjacent shorter stereocilia. This results in an inward K^+ (and Ca^{2+}) current and a graded depolarization (receptor potential). Bending the cilia away from the tallest cilium relaxes the tip-links, closes the mechanically gated ion channels, and allows repolarization and even a graded hyperpolarization. Depolarization increases intracellular Ca^{2+} and so increases the hair cells' release of neurotransmitter (glutamate), which causes the afferent cochlear fibers to transmit a faster stream of impulses to the brain for auditory interpretation. Hyperpolarization produces the exact opposite effect. As you might guess, activation of the hair cells occurs at points of vigorous basilar membrane vibration.

The outer hair cells, more numerous than the inner hair cells, send little information to the brain. Instead, they act on the basilar membrane itself. When outer hair cells depolarize and hyperpolarize as the basilar membrane moves, they contract and stretch in a type of cellular boogie called *fast motility.* Their strange behavior changes the stiffness of the basilar membrane, which alters its motion and amplifies the responsiveness of the inner hair cells—kind of a cochlear tuning. Outer hair cell mobility is also responsible for producing ear sounds *(otoacoustic emissions)* that are so audible in some people that they can actually be heard by others. In clinical pediatrics, the ability to detect a stimulated otoacoustic emission has proven a quick, inexpensive way to screen newborns for hearing defects.

The vast majority of the sensory fibers of the spiral ganglia (90–95%) service the inner hair cells, which shoulder nearly the entire responsibility for sending auditory messages to the brain. By contrast, most fibers coiling around the outer hair cells are *efferent* fibers that convey messages from brain to ear. What is the brain "telling" the outer hair cells? Loud sounds activate a feedback loop from the brain stem to the outer hair cells that dampens the motion of the outer hair cells and causes the sound energy to be spread over a wider area of the basilar membrane. This may help protect the inner hair cells from damage by loud noise.

The Auditory Pathway to the Brain

The ascending auditory pathways to the brain involve several brain stem nuclei, but here we will stress only the major way stations. Impulses generated in the cochlea pass through the **spiral ganglion,** where the auditory bipolar neurons reside, and along the afferent fibers of the cochlear nerve to the **cochlear nuclei** of the medulla (Figure 15.34). From

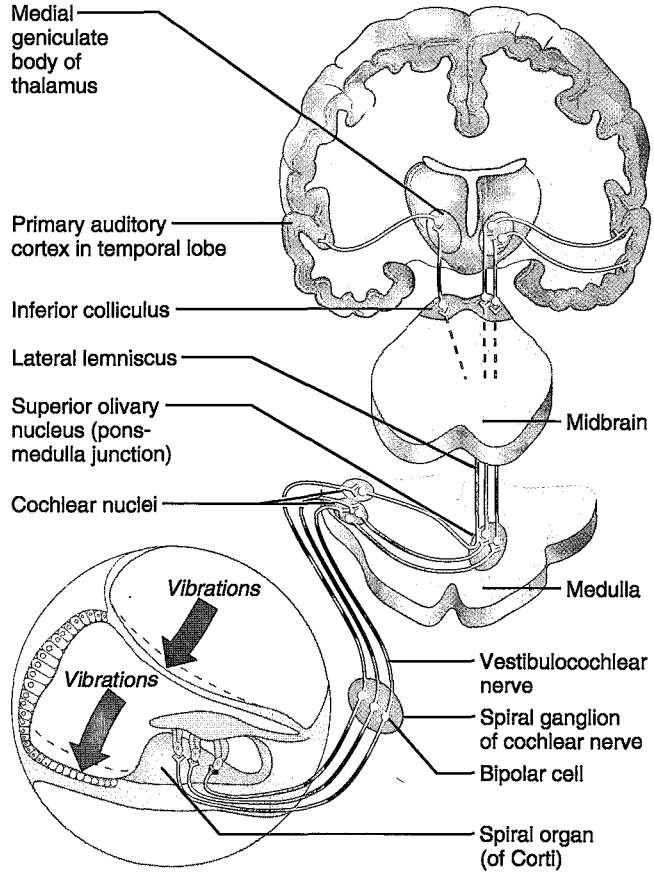

FIGURE 15.34 **Simplified diagram of the auditory pathway to the auditory cortex of the brain.** For clarity, only the pathway from the right ear is illustrated.

there, impulses are sent on to the **superior olivary nucleus** and then via the **lateral lemniscal tract** to the **inferior colliculus** (auditory reflex center in the midbrain) and the **auditory cortex** (which provides for conscious awareness of sound) in the temporal lobe. Relays also communicate with the **medial geniculate body** of the thalamus and the **superior colliculus** of the midbrain. The colliculi act together to initiate auditory reflexes to sound, such as the startle reflex and head turning. The auditory pathway is unusual in that not all of the fibers from each ear decussate (cross over); therefore each auditory cortex receives impulses from both ears.

Auditory Processing

If you are at a Broadway musical, the sound of the instruments, the actors' voices, rustling of clothing, and closing of doors are all intermingled in your sound awareness. Yet, the auditory cortex can distinguish the separate parts of this auditory jumble. Whenever the difference between sound wavelengths is sufficient for discrimination, you hear two separate and distinct tones. In fact, the analytic powers of the auditory cortex are so great that we are able to pick single instruments out of a whole orchestra.

Cortical processing of sound stimuli is complex. For example, certain cortical cells depolarize at the beginning of a particular tone, and others depolarize when the tone ends. Some cortical cells depolarize continuously, and others appear to have high thresholds (low sensitivity), and so on. Here we will concentrate on the more straightforward aspects of cortical perception of pitch, loudness, and sound location.

Perception of Pitch As explained, hair cells in different positions along the length of the basilar membrane are activated by sound waves of different frequencies, and impulses from specific hair cells are interpreted as specific pitches. When the sound is composed of tones of many frequencies, several populations of cochlear hair cells and cortical cells are activated simultaneously, resulting in the perception of multiple tones.

Detection of Loudness Louder sounds cause larger movements of the tympanic membrane, auditory ossicles, and oval window, and pressure waves of greater amplitude in the fluid of the cochlea. This in turn causes larger movements of the basilar membrane, larger deflections of the hairs on the hair cells, and larger graded potentials of the hair cells. As a result, more neurotransmitter is released and action potentials are generated more frequently. The brain interprets this as increased loudness. In addition, as the release of neurotransmitter increases, more of the ten or so bipolar cells connected to a given hair cell are recruited to fire action potentials.

Localization of Sound Several brain stem nuclei (most importantly the superior olivary nuclei) help us localize a sound's source in space by means of two cues: the *relative intensity* and the *relative timing* of sound waves reaching the two ears. If the sound source is directly in front, in back, or over the midline of the head, the intensity and timing cues are the same for both ears. However, when sound comes from one side, the receptors of the nearer ear are activated slightly earlier and more vigorously (because of the greater intensity of the sound waves entering that ear).

Homeostatic Imbalances of Hearing

Deafness

Any hearing loss, no matter how slight, is **deafness** of some sort. Deafness is classified as conduction or sensorineural deafness, according to its cause.

Conduction deafness occurs when something hampers sound conduction to the fluids of the internal ear, for example, impacted earwax blocking the external acoustic meatus or a *perforated (ruptured)* eardrum, which prevents sound conduction from the eardrum to the ossicles. But the most common causes of conduction deafness are middle ear inflammations (otitis media) and **otosclerosis** (o"to-sklĕ-ro'sis) of the ossicles. Otosclerosis ("hardening of the ear") occurs when overgrowth of bony tissue fuses the stapes foot plate to the oval window or welds the ossicles to one another. In such cases, sound is conducted to the receptors of that ear through vibrations of the skull bones, which is far less satisfactory. Otosclerosis is treated surgically.

Sensorineural deafness results from damage to neural structures at any point from the cochlear hair cells to and including the auditory cortical cells. This type of deafness typically results from the gradual loss of the hair cells throughout life. These cells can also be destroyed at an earlier age by a single explosively loud noise or prolonged exposure to high-intensity sounds, such as rock bands or airport noise, which literally tears off their cilia. Degeneration of the cochlear nerve, cerebral infarcts, and tumors in the auditory cortex are other causes. For congenital defects or age- or noise-related cochlear damage, cochlear implants (devices that convert sound energy into electrical signals) can be inserted into a drilled recess in the temporal bone. The original cochlear implants made human voices sound tinny and robotlike, but modern versions are so effective that even children born deaf can hear well enough to learn to speak well.

Tinnitus

Tinnitus (tĭ-ni'tus) is a ringing or clicking sound in the ears in the absence of auditory stimuli. It is more a symptom of pathology than a disease. For example, tinnitus is one of the first symptoms of cochlear nerve degeneration. It may also result from inflammation of the middle or internal ears and is a side effect of some medications, such as aspirin. Recent evidence suggests that tinnitus is analogous to phantom limb pain; that is, it is "phantom cochlear noise" caused by destruction of some neurons of the auditory pathway and the subsequent ingrowth of nearby neurons whose signals are interpreted as noise by the CNS.

Ménière's Syndrome

Classic **Ménière's syndrome** (men"ĕ-ār'z) is a labyrinth disorder that seems to affect all three parts of the internal ear. The afflicted person has repeated attacks of vertigo, nausea, and vomiting. Balance is so disturbed that standing erect is nearly impossible. A "howling" tinnitus is common, so hearing is impaired (and ultimately lost) as well. The cause is uncertain, but it may result from distortion of the membranous labyrinth by excessive endolymph accumulation, or rupture of membranes which allows the perilymph and endolymph to mix. Mild cases can usually be managed by antimotion drugs or a low-salt diet and diuretics to decrease endolymph fluid volume. In severe cases, draining the excess endolymph from the internal ear may help. A last resort is removal of the entire malfunctioning labyrinth, which is usually deferred until hearing loss is complete.

Mechanisms of Equilibrium and Orientation

The equilibrium sense is not easy to describe because it does not "see," "hear," or "feel," but responds (frequently without our awareness) to various head movements. Furthermore, this sense depends not only on inputs from the internal ear but also on vision and on information from stretch receptors of muscles and tendons. Under normal conditions the equilibrium receptors in the semicircular canals and vestibule, collectively called the **vestibular apparatus,** send signals to the brain that initiate reflexes needed to make the simplest changes in position as well as to serve a tennis ball precisely to the right spot (your opponent's backhand). The equilibrium receptors of the internal ear can be divided into two functional arms, with the receptors in the vestibule and semicircular canals monitoring **static** and **dynamic equilibrium,** respectively.

The Maculae and Static Equilibrium

The sensory receptors for static equilibrium are the **maculae** (mak'u-le; "spots"), one in each saccule wall and one in each utricle wall. These receptors monitor the position of the head in space, and in so doing, they play a key role in control of posture. They respond to *linear* acceleration forces, that is, straight-line changes in speed and direction, but not to rotation.

Anatomy of the Maculae Each macula is a flat epithelial patch containing **hair cells** whose structure and function are basically the same as the hair cells of the cochlea. These scattered receptor cells are surrounded by **supporting cells** (Figure 15.35). The "hairs" of the hair cells are embedded in the overlying **otolithic membrane** (o'to-lith-ik), a jellylike mass studded with tiny stones (calcium carbonate

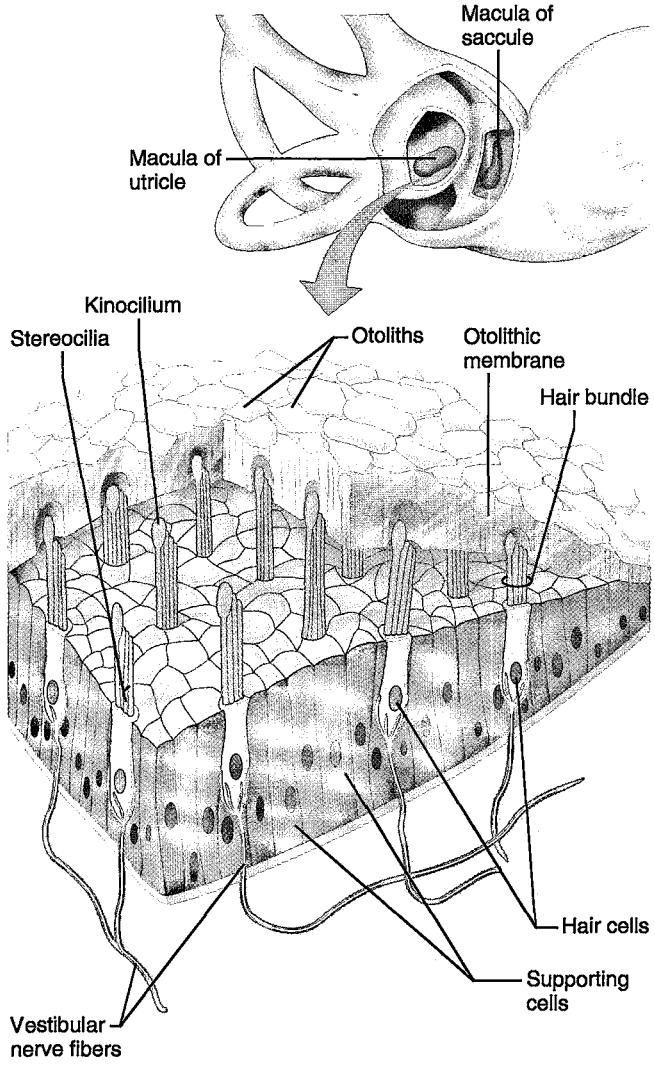

FIGURE 15.35 **Structure of a macula.** The "hairs" of the receptor cells of a macula project into the gelatinous otolithic membrane. Vestibular nerve fibers surround the base of the hair cells.

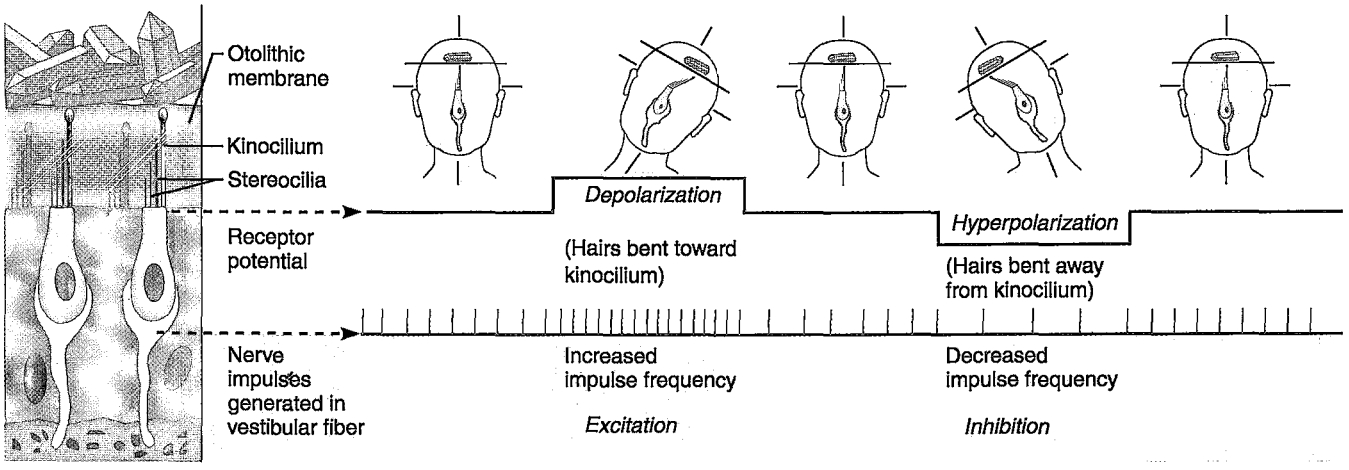

FIGURE 15.36 **The effect of gravitational pull on a macula receptor cell in the utricle.** When movement of the otolithic membrane bends the hair cells in the direction of the kinocilium, the vestibular nerve fibers depolarize and generate action potentials more rapidly. When the hairs are bent in the direction away from the kinocilium, the hair cells become hyperpolarized, and the nerve fibers send impulses at a reduced rate (i.e., below the resting rate of discharge).

crystals) called **otoliths** ("ear stones"). The otoliths, though small, are dense and they increase the membrane's weight and its inertia (resistance to change in motion). In the utricle, the macula is horizontal (Figure 15.35), and the hairs are vertically oriented when the head is upright. Thus, the utricular maculae respond best to acceleration in the horizontal plane and tilting the head to the side, because vertical (up-down) movements do not displace their horizontal otolithic membrane. In the saccule, the macula is nearly vertical, and the hairs protrude horizontally into the otolithic membrane. The saccular maculae respond best to vertical movements, such as the sudden acceleration of an elevator. The hair cells synapse with fibers of the **vestibular nerve,** whose endings coil around their bases. [Like the cochlear nerve, the vestibular nerve is a subdivision of the vestibulocochlear nerve (VIII)]. The cell bodies of the sensory neurons are located in the nearby **superior** and **inferior vestibular ganglia** (Figure 15.27).

Activating Maculae Receptors Let's look more closely at the happenings in the maculae that lead to sensory transduction. When your head starts or stops moving in a linear direction, inertia causes the otolithic membrane to slide backward or forward like a greased plate over the hair cells, bending the hairs. For example, when you start to run, the otolithic membranes of the utricle maculae lag behind, bending the hairs backward. When you suddenly stop, the otolithic membrane slides abruptly forward (just as you slide forward in your car when you brake), bending the hair cells forward. Likewise, when you nod your head or fall, the otoliths roll inferiorly, bending the hairs of the maculae in the saccules. The hair cells release neurotransmitter continuously but movement of their hairs modifies the amount they release. When the hairs are bent *toward the kinocilium,* the hair cells depolarize, stepping up their pace of neurotransmitter release, and a faster stream of impulses travels up the vestibular nerve to the brain (Figure 15.36). When the hairs are bent in the opposite direction, the receptors hyperpolarize, and neurotransmitter release and impulse generation decline. In either case, the brain is informed of the changing position of the head in space.

It is important to understand that the maculae respond *only to changes* in acceleration or velocity of head movement. Because the hair cells adapt quickly (resuming their basal level of neurotransmitter release), they do not report on unchanging head positions. Thus, the maculae help us to maintain normal head position with respect to gravity. They also contribute to dynamic equilibrium by responding to changes in linear acceleration.

The Crista Ampullaris and Dynamic Equilibrium

The receptor for dynamic equilibrium, called the **crista ampullaris,** or simply *crista,* is a minute elevation in the ampulla of each semicircular canal (see Figure 15.27). Like the maculae, the cristae are excited by head movement (acceleration and deceleration), but in this case the major stimuli are rotatory (angular) movements. When you twirl on the dance floor or suffer through a rough boat ride, these gyroscope-like receptors are working overtime. Since the semicircular canals are located in all three planes of space, all rotatory movements of the head disturb one or another *pair* of cristae (one in each ear).

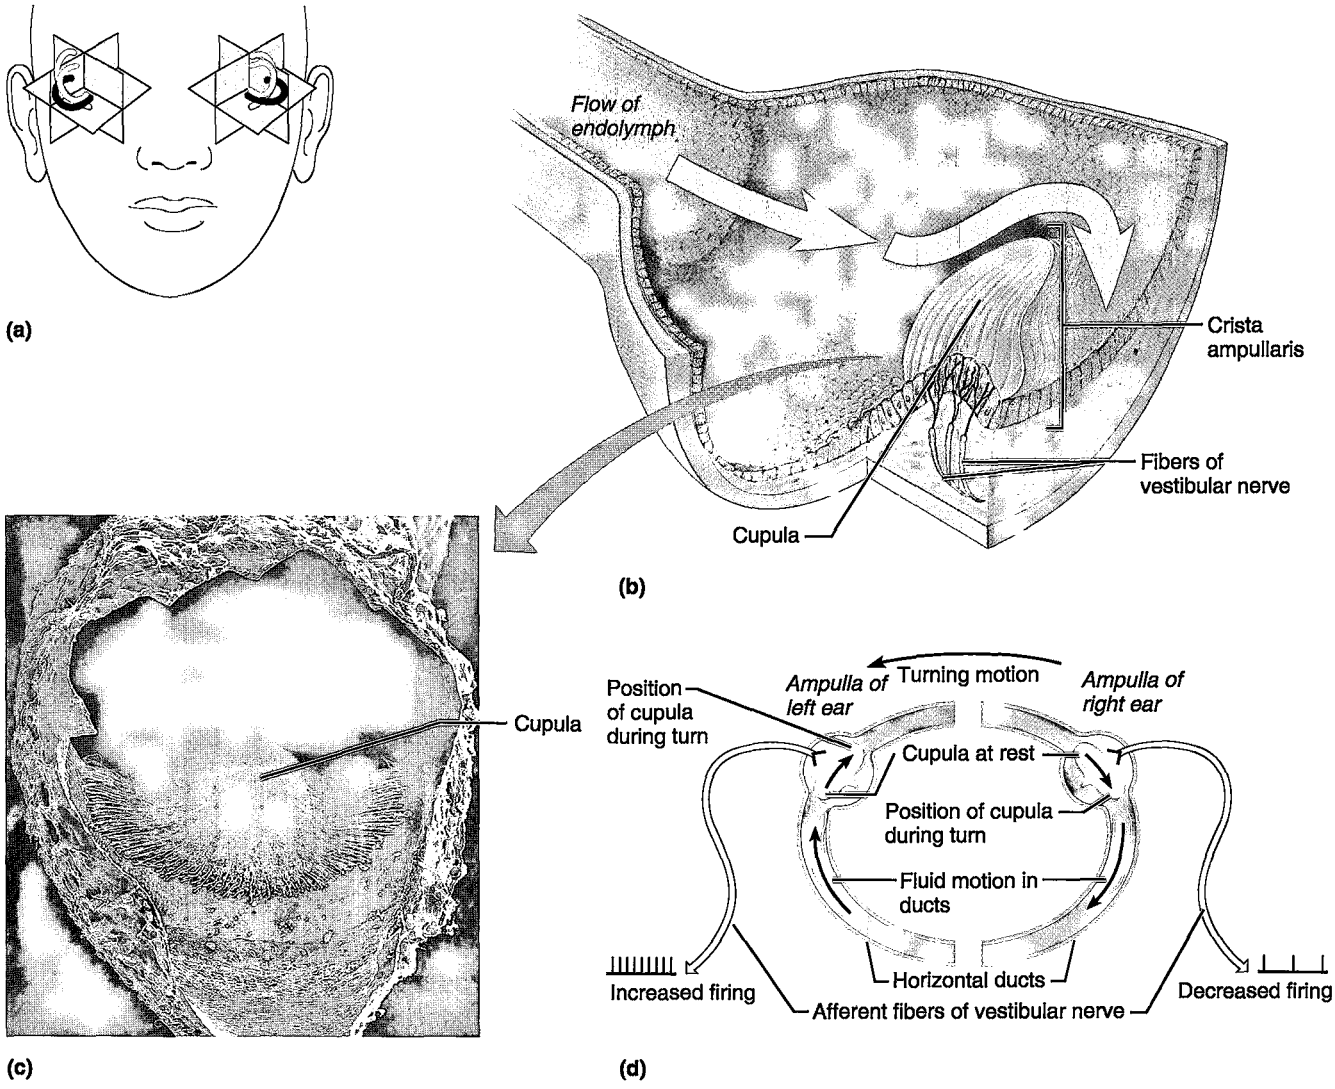

FIGURE 15.37 **Location and structure of a crista ampullaris. (a)** Location of the semicircular canals within the temporal bones of the skull. **(b)** The ampulla of a semicircular duct has been sectioned to show the position of a crista ampullaris receptor. **(c)** Scanning electron micrograph of a crista ampullaris (1000×). **(d)** View of the horizontal ducts from above shows how paired semicircular canals work together to provide bilateral information on rotatory head movement. Notice that the cupula bends in the direction of fluid flow, which is opposite to the direction of head movement.

Anatomy of the Crista Ampullaris Each crista is composed of supporting cells and hair cells. These hair cells, like all those of the internal ear, have stereocilia plus one kinocilium that project into a gel-like mass. In this case, the gelled mass is a **cupula** (ku'pu-lah), which resembles a pointed cap (Figure 15.37b and c). The cupula is a delicate, loosely organized network of gelatinous strands that radiate outward to contact the "hairs" of each hair cell. Dendrites of vestibular nerve fibers encircle the base of the hair cells.

Activating Crista Ampullaris Receptors The cristae respond to *changes* in the velocity of rotatory movements of the head. Because of its inertia, the endolymph in the semicircular ducts moves briefly in the direction *opposite* the body's rotation, deforming the crista in the duct. As the hairs are bent, the hair cells depolarize and impulses reach the brain at a faster rate. Bending the cilia in the opposite direction causes hyperpolarization and reduces impulse generation. Because the axes of the hair cells in the complementary semicircular ducts are opposite, rotation in a given direction causes depolarization of the receptors in one ampulla of the pair, and hyperpolarization of the receptors in the other (Figure 15.37d).

If the body continues to rotate at a constant rate, the endolymph eventually comes to rest—it moves along at the same speed as the body and stimulation of the hair cells ends. Consequently, if

we are blindfolded, we cannot tell whether we are moving at a constant speed or not moving at all after the first few seconds of rotation. However, when we suddenly stop moving, the endolymph keeps on going, in effect reversing its direction within the canal. This sudden reversal in the direction of hair bending results in membrane voltage changes in the receptor cells and modifies the rate of impulse transmission, which tells the brain that we have slowed or stopped.

The key point to remember when considering both types of equilibrium receptors is that the rigid bony labyrinth moves with the body, while the fluids (and gels) within the membranous labyrinth are free to move at various rates, depending on the forces (gravity, acceleration, and so on) acting on them.

Impulses transmitted from the semicircular canals are particularly important to reflex movements of the eyes. **Vestibular nystagmus** is a complex of rather strange eye movements that occurs during and immediately after rotation. As you rotate, your eyes slowly drift in the opposite direction, as though fixed on some object in the environment. This reaction relates to the backflow of endolymph in the semicircular canals. Then, because of CNS compensating mechanisms, the eyes jump rapidly toward the direction of rotation to establish a new fixation point. These alternating eye movements continue until the endolymph comes to rest. When you stop rotating, at first your eyes continue to move in the direction of the previous spin, and then they jerk rapidly in the opposite direction. This sudden change is caused by the change in the direction in which the cristae are bent after you stop. Nystagmus is often accompanied by vertigo.

The Equilibrium Pathway to the Brain

Our responses to body imbalance, such as during stumbling, must be fast and reflexive. By the time we "thought about" correcting our fall, we would already be on the ground. Hence, information from the balance receptors goes directly to reflex centers in the brain stem, rather than to the cerebral cortex as with the other special senses. However, the nerve pathways connecting the vestibular apparatus with the brain are complex and poorly traced. The transmission sequence begins when the hair cells in the vestibular apparatus are activated. As depicted in Figure 15.38, impulses travel initially to one of two destinations: the **vestibular nuclear complex** in the brain stem or the **cerebellum.** The vestibular nuclei, the major integrative center for balance, also receive inputs from the visual and somatic receptors, particularly from proprioceptors in neck muscles that report on the position of the head. They integrate this information and then send commands to brain stem motor centers that control the extrinsic eye muscles (cranial nerve nuclei III, IV, and VI) and reflex movements of the neck, limb, and trunk muscles (via the vestibulospinal tracts). The ensuing reflex movements of the eyes and body allow us to remain focused on the visual field and to quickly adjust our body position to maintain or regain balance.

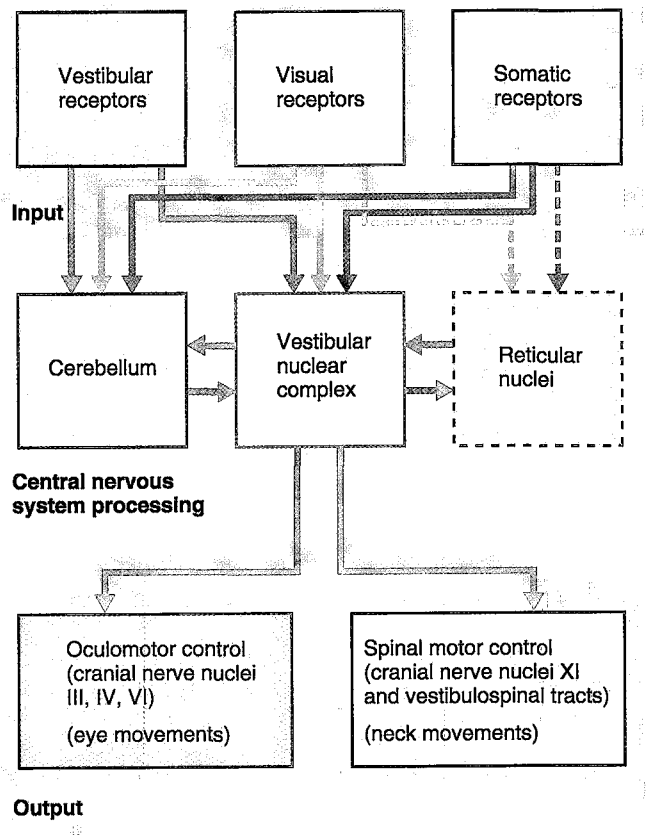

FIGURE 15.38 **Pathways of the balance and orientation system.** The three modes of input—vestibular, visual, and somatic (skin, muscle, and joint) receptors—transmit impulses to two major processing areas: the vestibular nuclei of the brain stem and the cerebellum. (The pathways to and the precise function of the reticular nuclei are unclear.) After vestibular nuclear processing, impulses are sent to one of two major output regions—areas controlling eye movements (oculomotor control) or those controlling the skeletal muscles of the neck (spinal motor control).

The cerebellum also integrates inputs from the eyes and somatic receptors (as well as from the cerebrum). It coordinates skeletal muscle activity and regulates muscle tone so that head position, posture, and balance are maintained, often in the face of rapidly changing inputs. Its "specialty" is fine control of delicate postural movements and timing. Inputs from the eyes and somatic receptors also reach the reticular nuclei, but their precise function in equilibrium is unclear.

Notice that the vestibular apparatus does *not automatically compensate* for forces acting on the body. Its job is to send warning signals to the central nervous system, which initiates the appropriate compensations

(righting) to keep your body balanced, your weight evenly distributed, and your eyes focused on what you were looking at when the disturbance occurred.

HOMEOSTATIC IMBALANCE

Responses to equilibrium signals are totally reflexive, and usually we are aware of vestibular apparatus activity only when its functioning is impaired. Equilibrium problems are usually obvious and unpleasant. Nausea, dizziness, and loss of balance are common and there may be nystagmus in the absence of rotational stimuli.

Motion sickness has been difficult to explain, but it appears to be due to sensory input mismatch. For example, if you are inside a ship during a storm, visual inputs indicate that your body is fixed with reference to a stationary environment (your cabin). But as the ship is tossed about by the rough seas, your vestibular apparatus detects movement and sends impulses that disagree with the visual information. The brain thus receives conflicting information, and its "confusion" somehow leads to motion sickness. Warning signals, which precede nausea and vomiting, include excessive salivation, pallor, rapid deep breathing, and profuse sweating. Removal of the stimulus usually ends the symptoms. Over-the-counter antimotion drugs, such as meclizine (Bonine), depress vestibular inputs and help alleviate the symptoms. They are most effective when taken "before the fact." Scopolamine-containing timed-release skin patches are also used to head off motion sickness.

Developmental Aspects of the Special Senses

Taste and Smell

All the special senses are functional, to a greater or lesser degree, at birth. Smell and taste are sharp, and infants relish food that adults consider bland or tasteless. Some researchers claim that smell is just as important as touch in guiding newborn infants to their mother's breast. However, very young children seem indifferent to odors and can play happily with their own feces.

There are few problems with the chemical senses during childhood and young adulthood. Women generally have a more acute sense of smell than men, and nonsmokers have a sharper sense of smell than smokers. Beginning in the fourth decade of life, our ability to taste and smell declines due to the gradual loss of receptors, which are replaced more slowly than in younger people. More than half of people over the age of 65 years have serious problems detecting odors, which may explain their tendency to douse themselves with large amounts of cologne, or their inattention to formerly disagreeable odors. Additionally, their sense of taste is poor. This along with the decline in the sense of smell makes food taste bland and results in loss of appetite.

Vision

By the fourth week of development, the beginnings of the eyes are seen in the **optic vesicles** that protrude from the diencephalon (see Figure 12.2c on p. 432). Soon these hollow vesicles indent to form double-layered **optic cups,** and their stalks form the optic nerves and provide a pathway for blood vessels to reach the eye interior. Once an optic vesicle reaches the overlying surface ectoderm, it induces the ectoderm to thicken and then form a **lens vesicle** that pinches off into the cavity of the optic cup, where it becomes the lens. The lining (internal layer) of the optic cup becomes the neural retina, and the outer layer forms the pigmented layer of the retina. The rest of the eye tissues and the vitreous humor are formed by mesenchymal cells derived from the mesoderm that surrounds the optic cup.

In the darkness of the uterus, the fetus cannot see. Nonetheless, even before the light-sensitive portions of the photoreceptors develop, the central nervous system connections have been made and are functional. During infancy, synaptic connections are fine-tuned, and the typical cortical fields that allow binocular vision are established.

HOMEOSTATIC IMBALANCE

Congenital problems of the eyes are relatively uncommon, but their incidence is dramatically increased by certain maternal infections, particularly rubella (German measles), occurring during the critical first three months of pregnancy. Common rubella sequels include blindness and cataracts.

As a rule, vision is the only special sense not fully functional at birth. Because the eyeballs are foreshortened, most babies are hyperopic. The newborn infant sees only in gray tones, eye movements are uncoordinated, and often only one eye at a time is used. The lacrimal glands are not completely developed until about two weeks after birth, so babies are tearless for this period, even though they may cry lustily. By 5 months, infants can follow moving objects with their eyes, but visual acuity is still poor (20/200). By the age of 5 years, depth perception is present and color vision is well developed. Because the eyeball has grown, visual acuity has improved to about 20/30, providing a readiness to begin reading. By first grade, the initial hyperopia has usually been replaced by emmetropia, and the eye reaches its adult size at 8–9 years of age. Emmetropia usually continues until presbyopia begins to set in around age 40 owing to decreasing lens elasticity.

With age, the lens loses its crystal clarity and discolors. As a result, it begins to scatter light, causing a glare that is distressing when driving at night. The dilator pupillae muscles become less efficient, so the pupils stay partly constricted. These two changes together decrease the amount of light reaching the retina, and visual acuity is dramatically lower in people over 70. In addition, the lacrimal glands are less active and the eyes tend to be dry and more susceptible to infection. Elderly persons are also at risk for certain conditions that cause blindness, such as macular degeneration, glaucoma, cataracts, arteriosclerosis, and diabetes mellitus.

Hearing and Balance

Development of the ear begins in the three-week embryo. The internal ears develop first, from thickenings of the surface ectoderm called the **otic placodes** (o'tik), which lie lateral to the hindbrain on each side. The otic placode invaginates, forming the **otic pit** and then the **otic vesicle,** which detaches from the surface epithelium. The otic vesicle develops into the membranous labyrinth. The surrounding mesenchyme forms the bony labyrinth.

The middle ear cavity and pharyngotympanic tube of the middle ear develop from **pharyngeal pouches,** lateral outpocketings of the endoderm lining the pharynx. The auditory ossicles develop from neural crest cells.

The external acoustic meatus and external face of the tympanic membrane of the external ear differentiate from the **branchial groove** (brang'ke-al), an indentation of the surface ectoderm, and the auricle develops from swellings of the surrounding tissue.

Newborn infants can hear, but early responses to sound are mostly reflexive—for example, crying and clenching the eyelids in response to a startling noise. By the fourth month, infants will turn to the voices of family members. Critical listening begins as toddlers increase their vocabulary, and good language skills are closely tied to the ability to hear well.

HOMEOSTATIC IMBALANCE

Congenital abnormalities of the ears are fairly common. Examples include partly or completely missing pinnae and closed or absent external acoustic meatuses. Maternal rubella during the first trimester commonly results in sensorineural deafness.

Except for ear inflammations, mostly due to infections, few problems affect the ears during childhood and adult life. By the 60s, however, deterioration of the spiral organ becomes noticeable. We are born with approximately 40,000 hair cells, but their number decreases when they are damaged or destroyed by loud noises, disease, or drugs. The hair cells *are* replaced, but at such a slow rate that there really is no functional regeneration. It is estimated that if we were to live 140 years, we would have lost all of our hearing receptors.

The ability to hear high-pitched sounds leaves us first. This condition, called **presbycusis** (pres"bĭ-ku'sis), is a type of sensorineural deafness. Although presbycusis is considered a disability of old age, it is becoming much more common in younger people as our world grows noisier. Since noise is a stressor, one of its physiological consequences is vasoconstriction, and when delivery of blood to the ear is reduced, the ear becomes even more sensitive to the damaging effects of noise.

■ ■ ■

Our abilities to see, hear, taste, and smell—and some of our responses to the effects of gravity—are largely the work of our brain. However, as we have discovered in this, the last of the nervous system chapters, the large and often elaborate sensory receptor organs that serve the special senses are works of art in and of themselves.

The final chapter of this unit describes how the body's functions are controlled by chemicals called hormones in a manner quite different from what we have described for neural control.

Related Clinical Terms

Ageusia (ah-gu'ze-ah) Loss or impairment of the taste sense.

Age-related macular degeneration (ARMD) Progressive deterioration of the retina that affects the macula lutea and leads to loss of central vision; the main cause of vision loss in those over age 65. Early stages and mild forms involve the buildup of pigments in the macula and impaired functioning of the pigmented epithelium. Continued accumulation of pigment leads to the "dry" form of ARMD, in which many pigment epithelial cells and macular photoreceptors die. Less common is the "wet" form in which an overgrowth of new blood vessels invades the retina from the choroid. Leakage of blood and fluids from these vessels causes scarring and detachment of the retina. The cause is unknown and ARMD is largely untreatable, although laser treatment can destroy some of the growing vessels in the "wet" form.

Blepharitis (blef"ah-ri'tis; *blephar* = eyelash; *itis* = inflammation) Inflammation of the margins of the eyelids.

Enucleation (e-nu"kle-a'shun) Surgical removal of an eyeball.

Exophthalmos (ek"sof-thal'mos; *exo* = out; *phthalmo* = the eye) Anteriorly bulging eyeballs; this condition is seen in some cases of hyperthyroidism.

Labyrinthitis Inflammation of the labyrinth.

Ophthalmology (of"thal-mol'o-je) The science that studies the eye and eye diseases. An ophthalmologist is a medical doctor who specializes in treating eye disorders.

Optometrist A licensed nonphysician who measures vision and prescribes corrective lenses.

Otalgia (o-tal'je-ah; *algia* = pain) Earache.

Otitis externa Inflammation and infection of the external acoustic meatus, caused by bacteria or fungi that enter the canal from outside, especially when the canal is moist (e.g., after swimming).

Papilledema (pap"il-ĕ-de'mah; *papill* = nipple; *edema* = swelling) Protrusion of the optic disc into the eyeball, which can be observed by ophthalmoscopic examination; caused by conditions that increase intracranial pressure.

Scotoma (sko-to'mah; *scoot* = darkness) A blind spot other than the normal (optic disc) blind spot; many causes, including the presence of a brain tumor pressing on fibers of the visual pathway, and stroke.

Trachoma (trah-ko'mah; *trach* = rough) A highly contagious bacterial (chlamydial) infection of the conjunctiva and cornea. Common worldwide, it blinds millions of people in poor countries of Africa and Asia; treated with eye ointments containing antibiotic drugs.

Weber's test Hearing test during which a sounding tuning fork is held to the forehead. In those with normal hearing, the tone is heard equally in both ears. The tone will be heard best in the "good" ear if sensorineural deafness is present, and in the "bad" ear if conduction deafness is present.

Chapter Summary

The Eye and Vision (pp. 556–578)

1. The eye is enclosed in the bony orbit and cushioned by fat.

Accessory Structures of the Eye (pp. 556–559)

2. Eyebrows help to shade and protect the eyes.

3. Eyelids protect and lubricate the eyes by reflex blinking. Within the eyelids are the orbicularis oculi and levator palpebrae muscles, and modified sebaceous and sweat glands.

4. The conjunctiva is a mucosa that lines the eyelids and covers the anterior eyeball surface. Its mucus lubricates the eyeball surface.

5. The lacrimal apparatus consists of the lacrimal gland (which produces a saline solution containing mucus, lysozyme, and antibodies), the lacrimal canaliculi, the lacrimal sac, and the nasolacrimal duct.

6. The extrinsic eye muscles (superior, inferior, lateral, and medial rectus and superior and inferior oblique) move the eyeballs.

Structure of the Eyeball (pp. 559–565)

7. The wall of the eyeball is made up of three layers. The outermost fibrous layer consists of the sclera and the cornea. The sclera protects the eye and gives it shape; the cornea allows light to enter the eye.

8. The middle, pigmented vascular layer (uvea) consists of the choroid, the ciliary body, and the iris. The choroid provides nutrients to the eye and prevents light scattering within the eye. The ciliary muscles of the ciliary body control lens shape; the iris controls the size of the pupil.

9. The sensory layer, or retina, consists of an outer pigmented layer and an inner neural layer. The neural layer contains photoreceptors (rods and cones), bipolar cells, and ganglion cells. Ganglion cell axons form the optic nerve, which exits via the optic disc ("blind spot").

10. The outer segments of the photoreceptors contain the light-absorbing pigment in membrane-bounded discs.

11. The posterior segment of the eyeball, behind the lens, contains vitreous humor, which helps support the eyeball and keep the retina in place. The anterior segment, anterior to the lens, is filled with aqueous humor, formed by capillaries in the ciliary processes and drained into the scleral venous sinus. Aqueous humor is a major factor in maintaining intraocular pressure.

12. The biconvex lens is suspended within the eye by the ciliary zonule attached to the ciliary body. It is the only adjustable refractory structure of the eye.

Physiology of Vision (pp. 565–578)

13. Light is made up of those wavelengths of the electromagnetic spectrum that excite the photoreceptors.

14. Light is refracted (bent) when passing from one transparent medium to another of different density. Concave lenses disperse light; convex lenses converge light and bring its rays to a focal point. The greater the lens curvature, the more light bends.

15. As light passes through the eye, it is bent by the cornea and the lens and focused on the retina. The cornea accounts for most of the refraction, but the lens allows active focusing for different distances.

16. Focusing for distance vision requires no special movements of the eye structures. Focusing for close-up vision requires accommodation (bulging of the lens), pupillary constriction, and convergence of the eyeballs. All three reflexes are controlled by cranial nerve III.

17. Refractory problems include presbyopia, myopia, hyperopia, and astigmatism.

18. Rods respond to low-intensity light and provide night and peripheral vision. Cones are bright-light, high-discrimination receptors that provide for color vision. Anything that must be viewed precisely is focused on the cone-rich fovea centralis.

19. The light-absorbing molecule retinal is combined with various opsins in the visual pigments. When struck by light, retinal changes shape (11-*cis* to all-*trans*) and activates opsin. Activated opsin activates transducin (a G protein) which in turn activates PDE, an enzyme that breaks down cGMP, allowing the cation channels to close. This results in hyperpolarization of the receptor cells and inhibits their release of neurotransmitter.

20. Rod visual pigment, rhodopsin, is a combination of retinal and opsin. The light-triggered changes in retinal cause hyperpolarization of the rods. Photoreceptors and bipolar cells generate graded potentials only; action potentials are generated by the ganglion cells.

21. The three types of cones all contain retinal, but each has a different type of opsin. Each cone type responds maximally to one color of light: red, blue, or green. The chemistry of cone function is similar to that of rods.

22. During light adaptation, photopigments are bleached and rods are inactivated; then, as cones decrease their light sensitivity, high-acuity vision ensues. In dark adaptation, cones cease functioning, and visual acuity decreases; rod function begins when sufficient rhodopsin has accumulated.

23. The visual pathway to the brain begins with the optic nerve fibers (ganglion cell axons) from the retina. At the optic chiasma, fibers from the medial half of each retina cross over and continue on in the optic tracts to the thalamus. Thalamic neurons project to the visual cortex via the optic radiation. Fibers also project from the retina to the midbrain pretectal nuclei and the superior colliculi, and to the suprachiasmatic nucleus of the hypothalamus.

24. Each eye receives a slightly different view of the visual field. These views are fused by the visual cortices to provide for depth perception.

25. Retinal processing involves the selective destruction of inputs so as to emphasize bright/dark or color contrasts (edges). (The horizontal cells and amacrine cells are local integrator cells of the retina that modify and process inputs to the ganglion cells.) Thalamic processing subserves high-acuity color vision and depth perception. Cortical processing involves neurons of the striate (primary) cortex, which receive inputs from the retinal ganglion cells, and neurons of the prestriate (association) cortices, which receive inputs from striate cortical cells and mostly integrate inputs concerned with color, form, and movement. Visual processing also proceeds anteriorly in the "what" and "where" processing streams via the temporal and parietal lobes, respectively.

The Chemical Senses: Taste and Smell (pp. 578–583)

The Olfactory Epithelium and the Sense of Smell (pp. 578–580)

1. The olfactory epithelium is located in the roof of the nasal cavity. The receptor cells are ciliated bipolar neurons. Their axons are the filaments of the olfactory nerve (cranial nerve I).

2. Individual olfactory neurons show a range of responsiveness to different chemicals. Olfactory cells bearing the same odorant receptors synapse in the same glomerulus type.

3. Olfactory neurons are excited by volatile chemicals that bind to receptors in the olfactory cilia.

4. Action potentials of the olfactory nerve filaments are transmitted to the olfactory bulb where the filaments synapse with mitral cells. The mitral cells send impulses via the olfactory tract to the olfactory cortex. Fibers carrying impulses from the olfactory receptors also project to the limbic system.

Taste Buds and the Sense of Taste (pp. 580–583)

5. The taste buds are scattered in the oral cavity and pharynx but are most abundant on the tongue papillae.

6. Gustatory cells, the epithelial receptor cells of the taste buds, have gustatory hairs (microvilli) that serve as the receptor regions. The gustatory cells are excited by the binding of tastants (food chemicals) to receptors on their microvilli.

7. The five basic taste qualities are sweet, sour, salty, bitter, and umami.

8. The taste sense is served by cranial nerves VII, IX, and X, which send impulses to the solitary nucleus of the medulla. From there, impulses are sent to the thalamus and the taste cortex.

Homeostatic Imbalances of the Chemical Senses (p. 583)

9. Most chemical sense dysfunctions are olfactory disorders (anosmias). Common causes are nasal damage or obstruction.

The Ear: Hearing and Balance (pp. 583–598)

Structure of the Ear (pp. 583–587)

1. The auricle and external acoustic meatus compose the external ear. The tympanic membrane, the boundary between the outer and middle ears, transmits sound waves to the middle ear.

2. The middle ear is a small chamber within the temporal bone, connected by the pharyngotympanic tube to the nasopharynx. The ossicles, which help to amplify sound, span the middle ear cavity and transmit sound vibrations from the eardrum to the oval window.

3. The internal ear consists of the bony labyrinth, within which the membranous labyrinth is suspended. The bony labyrinth chambers contain perilymph; the membranous labyrinth ducts and sacs contain endolymph.

4. The vestibule contains the saccule and utricle. The semicircular canals extend posteriorly from the vestibule in three planes. They contain the semicircular ducts.

5. The cochlea houses the cochlear duct (scala media), containing the spiral organ (of Corti), the receptor organ for hearing. Within the cochlear duct, the hair (receptor) cells rest on the basilar membrane, and their hairs project into the gelatinous tectorial membrane.

Physiology of Hearing (pp. 587–593)

6. Sound originates from a vibrating object and travels in waves consisting of alternating areas of compression and rarefaction of the medium.

7. The distance from crest to crest on a sine wave is the sound's wavelength; the shorter the wavelength, the higher the frequency (measured in hertz). Frequency is perceived as pitch.

8. The amplitude of sound is the height of the peaks of the sine wave, which reflect the sound's intensity. Sound intensity is measured in decibels. Intensity is perceived as loudness.

9. Sound passing through the external acoustic meatus sets the eardrum into vibration at the same frequency. The ossicles amplify and deliver the vibrations to the oval window.

10. Pressure waves in cochlear fluids set specific locations on the basilar membrane into resonance. At points of maximal membrane vibration, the hair cells of the spiral organ are alternately depolarized and hyperpolarized by the vibratory motion. Movements of the stereocilia toward the kinocilium depolarize the hair cells and increase the rate of impulse generation in the auditory nerve fibers. Movements away from the kinocilium have the opposite effect. High-frequency sounds stimulate hair cells near the oval window; low-frequency sounds stimulate hair cells near the apex. Most auditory inputs are sent to the brain by inner hair cells. Outer hair cells amplify responsiveness of the inner hair cells.

11. Impulses generated along the cochlear nerve travel to the cochlear nuclei of the medulla and from there through several brain stem nuclei to the medial geniculate body of the thalamus and then the auditory cortex. Each auditory cortex receives impulses from both ears.

12. Auditory processing is analytic; each tone is perceived separately. Perception of pitch is related to the position of the excited hair cells along the basilar membrane. Intensity perception reflects the fact that as sound intensity increases, basilar membrane mobility is increased and the frequency of impulse transmission to the cortex is enhanced. Cues for sound localization include the intensity and timing of sound arriving at each ear.

Homeostatic Imbalances of Hearing (pp. 593–594)

13. Conduction deafness results from interference with conduction of sound vibrations to the fluids of the internal ear. Sensorineural deafness reflects damage to neural structures.

14. Tinnitus is an early sign of sensorineural deafness; it may also result from the use of certain drugs.

15. Ménière's syndrome is a disorder of the membranous labyrinth. Symptoms include tinnitus, deafness, and vertigo. Excessive endolymph accumulation is the suspected cause.

Mechanisms of Equilibrium and Orientation (pp. 594–598)

16. The equilibrium receptor regions of the internal ear are called the vestibular apparatus.

17. The receptors for static equilibrium are the maculae of the saccule and utricle. A macula consists of hair cells with stereocilia and a kinocilium embedded in an overlying otolithic membrane. Linear movements cause the otolithic membrane to move, pulling on the hair cells and changing the rate of impulse generation in the vestibular nerve fibers.

18. The dynamic equilibrium receptor, the crista ampullaris within each semicircular duct, responds to angular or rotatory movements in one plane. It consists of a tuft of hair cells whose microvilli are embedded in the gelatinous cupula. Rotatory movements cause the endolymph to flow in the opposite direction, bending the cupula and either exciting or inhibiting the hair cells.

19. Impulses from the vestibular apparatus are sent via vestibular nerve fibers mainly to the vestibular complex of the brain stem and the cerebellum. These centers initiate responses that fix the eyes on objects and activate muscles to maintain balance.

Developmental Aspects of the Special Senses (pp. 598–599)

Taste and Smell (pp. 598)

1. The chemical senses are sharpest at birth and gradually decline with age as replacement of the receptor cells becomes more sluggish.

Vision (pp. 598–599)

2. Congenital eye problems are uncommon, but maternal rubella can cause blindness.

3. The eye starts as an optic vesicle, an outpocketing of the diencephalon that invaginates to form the optic cup, which becomes the retina. Overlying ectoderm folds to form the lens vesicle, which gives rise to the lens. The remaining eye tissues and the accessory structures are formed by mesenchyme.

4. The eye is foreshortened at birth and reaches adult size at the age of 8–9 years. Depth perception and color vision develop during early childhood.

5. With age, the lens loses its elasticity and clarity, there is a decline in the ability of the iris to dilate, and visual acuity decreases. The elderly are at risk for eye problems resulting from dry eyes and disease.

Hearing and Balance (pp. 599)

6. The membranous labyrinth develops from the otic placode, an ectodermal thickening lateral to the hindbrain. Mesenchyme forms the surrounding bony structures. Pharyngeal pouch endoderm, in conjunction with mesenchyme, forms most middle ear structures; the external ear is formed largely by ectoderm.

7. Congenital ear problems are fairly common. Maternal rubella can cause deafness.

8. Response to sound in infants is reflexive. By 5 months, an infant can locate sound. Critical listening develops in toddlers.

9. Deterioration of the spiral organ (of Corti) occurs throughout life as noise, disease, and drugs destroy cochlear hair cells. Age-related loss of hearing (presbycusis) occurs in the 60s and 70s.

15

Review Questions

Multiple Choice/Matching

(Some questions have more than one correct answer. Select the best answer or answers from the choices given.)

1. The accessory glands that produce an oily secretion are the (a) conjunctiva, (b) lacrimal glands, (c) tarsal glands.

2. The portion of the fibrous layer that is white and opaque is the (a) choroid, (b) cornea, (c) retina, (d) sclera.

3. Which sequence best describes a normal route for the flow of tears from the eyes into the nasal cavity? (a) lacrimal canaliculi, nasolacrimal ducts, nasal cavity; (b) lacrimal ducts, lacrimal canaliculi, nasolacrimal ducts; (c) nasolacrimal ducts, lacrimal canaliculi, lacrimal sacs.

4. Four refractory media of the eye, listed in the sequence in which they refract light, are (a) vitreous humor, lens, aqueous humor, cornea; (b) cornea, aqueous humor, lens, vitreous humor; (c) cornea, vitreous humor, lens, aqueous humor; (d) lens, aqueous humor, cornea, vitreous humor.

5. Damage to the medial recti muscles would probably affect (a) accommodation, (b) refraction, (c) convergence, (d) pupil constriction.

6. The phenomenon of light adaptation is best explained by the fact that (a) rhodopsin does not function in dim light, (b) rhodopsin breakdown occurs slowly, (c) rods exposed to intense light need time to generate rhodopsin, (d) cones are stimulated to function by bright light.

7. Blockage of the scleral venous sinus might result in (a) a sty, (b) glaucoma, (c) conjunctivitis, (d) a cataract.

8. Nearsightedness is more properly called (a) myopia, (b) hyperopia, (c) presbyopia, (d) emmetropia.

9. Of the neurons in the retina, the axons of which of these form the optic nerve? (a) bipolar neurons, (b) ganglion cells, (c) cone cells, (d) horizontal cells.

10. Which sequence of reactions occurs when a person looks at a distant object? (a) pupils constrict, ciliary zonule (suspensory ligament) relaxes, lenses become less convex; (b) pupils dilate, ciliary zonule becomes taut, lenses become less convex; (c) pupils dilate, ciliary zonule becomes taut, lenses become more convex; (d) pupils constrict, ciliary zonule relaxes, lenses become more convex.

11. During embryonic development, the lens of the eye forms (a) as part of the choroid coat, (b) from the surface ectoderm overlying the optic cup, (c) as part of the sclera, (d) from mesodermal tissue.

12. The blind spot of the eye is (a) where more rods than cones are found, (b) where the macula lutea is located, (c) where only cones occur, (d) where the optic nerve leaves the eye.

13. Olfactory tract damage would probably affect your ability to (a) see, (b) hear, (c) feel pain, (d) smell.

14. Sensory impulses transmitted over the facial, glossopharyngeal, and vagus nerves are involved in the sensation of (a) taste, (b) touch, (c) equilibrium, (d) smell.

15. Taste buds are found on the (a) anterior part of the tongue, (b) posterior part of the tongue, (c) palate, (d) all of these.

16. Gustatory cells are stimulated by (a) movement of otoliths, (b) stretch, (c) substances in solution, (d) photons of light.

17. Cells in the olfactory bulb that act as local "integrators" of olfactory inputs are the (a) hair cells, (b) granule cells, (c) basal cells, (d) mitral cells, (e) supporting cells.

18. Olfactory nerve filaments are found (a) in the optic bulbs, (b) passing through the cribriform plate of the ethmoid bone, (c) in the optic tracts, (d) in the olfactory cortex.

19. Conduction of sound from the middle ear to the internal ear occurs via vibration of the (a) malleus against the tympanic membrane, (b) stapes in the oval window, (c) incus in the round window, (d) stapes against the tympanic membrane.

20. The transmission of sound vibrations through the internal ear occurs chiefly through (a) nerve fibers, (b) air, (c) fluid, (d) bone.

21. Which of the following statements does not correctly describe the spiral organ (of Corti)? (a) sounds of high frequency stimulate hair cells at the basal end, (b) the "hairs" of the receptor cells are embedded in the tectorial membrane, (c) the basilar membrane acts as a resonator, (d) the more numerous outer hair cells are largely responsible for our perception of sound.

22. Pitch is to frequency of sound as loudness is to (a) quality, (b) intensity, (c) overtones, (d) all of these.

23. The structure that allows pressure in the middle ear to be equalized with atmospheric pressure is the (a) pinna, (b) pharyngotympanic tube, (c) tympanic membrane, (d) oval window.

24. Which of the following is important in maintaining the balance of the body? (a) visual cues, (b) semicircular canals, (c) the saccule, (d) proprioceptors, (e) all of these.

25. Static equilibrium receptors that report the position of the head in space relative to the pull of gravity are (a) spiral organ, (b) maculae, (c) cristae ampullares, (d) otoliths.

26. Which of the following is *not* a possible cause of conduction deafness? (a) impacted cerumen, (b) middle ear infection, (c) cochlear nerve degeneration, (d) otosclerosis.

27. Which of the following are intrinsic eye muscles? (a) superior rectus, (b) orbicularis oculi, (c) smooth muscles of the iris and ciliary body, (d) levator palpebrae superioris.

28. Which lies closest to the exact posterior pole of the eye? (a) optic nerve, (b) optic disc, (c) macula lutea, (d) point of entry of central artery into the eye.

29. Otoliths (ear stones) are (a) a cause of deafness, (b) a type of hearing aid, (c) important in equilibrium, (d) the rock-hard petrous temporal bones.

Short Answer Essay Questions

30. Name the five primary taste qualities and the cranial nerves that serve the sense of taste.

31. Where are the olfactory receptors, and why is that site poorly suited for their job?

32. Why do you often have to blow your nose after crying?

33. How do rods and cones differ functionally?

34. Where is the fovea centralis, and why is it important?

35. Describe the response of rhodopsin to light stimuli. What is the outcome of this cascade of events?

36. Since there are only three types of cones, how can you explain the fact that we see many more colors?

37. Describe the effect of aging on the special sense organs.

38. Each olfactory cell responds to a single odorant molecule. True or false? Explain your choice.

Critical Thinking and Clinical Application Questions

1. During an ophthalmoscopic examination, Mrs. James was found to have bilateral papilledema. Further investigation indicated that this condition resulted from a rapidly growing intracranial tumor. First, define papilledema. Then, explain its presence in terms of Mrs. James's diagnosis.

2. Sally, a 9-year-old girl, told the clinic physician that her "ear lump hurt" and she kept "getting dizzy and falling down." As she told her story, she pointed to her mastoid process. An otoscopic examination of the external acoustic meatus revealed a red, swollen eardrum, and her throat was inflamed. Her condition was described as mastoiditis with secondary labyrinthitis (inflammation of the labyrinth). Describe the most likely route of infection and the infected structures in Sally's case. Also explain the cause of her dizziness and falling.

3. Mr. Gaspe appeared at the eye clinic complaining of a chip of wood in his eye. No foreign body was found, but the conjunctiva was obviously inflamed. What name is given to this inflammatory condition, and where would you look for a foreign body that has been floating around on the eye surface for a while?

4. Mrs. Orlando has been noticing flashes of light and tiny specks in her right visual field. When she begins to see a "veil" floating before her right eye, she makes an appointment to see the eye doctor. What is your diagnosis? Is the condition serious? Explain.

5. David Norris, an engineering student, has been working in a disco to earn money to pay for his education. After about eight months, he notices that he is having problems hearing high-pitched tones. What is the cause-and-effect relationship here?

6. Assume that a tumor in the pituitary gland or hypothalamus is protruding inferiorly and compressing the optic chiasma. What could be the visual outcome?

7. Four-year-old Gary Zammer is brought to the ophthalmologist for a routine checkup on his vision. Gary is an albino. How do you think albinism affects vision?

8. Right before Jan, a senior citizen, had a large plug of earwax cleaned from her ear, she developed a constant howling sound in her ear that would not stop. It was very annoying and stressful, and she had to go to counseling to learn how to live with this awful noise. What was her condition called?

9. During an anatomy and physiology lab exercise designed to teach the use of the ophthalmoscope, you notice that your lab partner has difficulty seeing objects in the darkened room. Upon examining her retina through the ophthalmoscope, you observe streaks and patches of dark pigmentation at the back of the eye. What might this condition be?

10. Henri, a chef in a five-star French restaurant, has been diagnosed with leukemia. He is about to undergo chemotherapy, which will kill rapidly dividing cells in his body. He needs to continue working between bouts of chemotherapy. What consequences of chemotherapy would you predict that might affect his job as a chef?

CHAPTER 17

The Endocrine System

1. Indicate important differences between hormonal and neural controls of body functioning.

The Endocrine System: An Overview (pp. 605–606)

2. List the major endocrine organs, and describe their body locations.
3. Distinguish between hormones, paracrines, and autocrines.

Hormones (pp. 606–612)

4. Describe how hormones are classified chemically.
5. Describe the two major mechanisms by which hormones bring about their effects on their target tissues.
6. List three kinds of interaction of different hormones acting on the same target cell.
7. Explain how hormone release is regulated.

Major Endocrine Organs (pp. 612–636)

8. Describe structural and functional relationships between the hypothalamus and the pituitary gland.
9. List and describe the chief effects of adenohypophyseal hormones.
10. Discuss the structure of the neurohypophysis, and describe the effects of the two hormones it releases.
11. Describe important effects of the two groups of hormones produced by the thyroid gland. Follow the process of thyroxine formation and release.
12. Indicate general functions of parathyroid hormone.
13. List hormones produced by the adrenal gland, and cite their physiological effects.
14. Compare and contrast the effects of the two major pancreatic hormones.
15. Describe the functional roles of hormones of the testes and ovaries.
16. Briefly describe the importance of thymic and pineal hormones.

Other Hormone-Producing Structures (p. 636–638)

17. Name a hormone produced by the heart, and localize enteroendocrine cells.
18. Briefly explain the hormonal functions of the placenta, kidney, skin, and adipose tissue.

Developmental Aspects of the Endocrine System (p. 639)

19. Describe the effects of aging on endocrine system functioning.

You don't have to watch *CSI* to experience action-packed drama. Molecules and cells inside your body have dynamic adventures on microscopic levels all the time. For instance, when insulin molecules, carried passively along in the blood, attach to protein receptors of nearby cells, the response is dramatic: Glucose molecules begin to disappear from the blood into the cells, and cellular activity accelerates. Such is the power of the second great control system of the body, the **endocrine system,** which interacts with the nervous system to coordinate and integrate the activity of body cells.

The means of control and the speed of the endocrine system are very different from those of the nervous system, however. The nervous system regulates the activity of muscles and glands via electrochemical impulses delivered by neurons, and those organs respond within milliseconds. The endocrine system influences metabolic activity by means of **hormones** (*hormon* = to excite), which are chemical messengers released into the blood to be transported throughout the body. Binding of a hormone to cellular receptors initiates responses that typically occur after a lag period of seconds or even days. But, once initiated, those responses tend to be much more prolonged than those induced by the nervous system.

Hormonal targets ultimately include most cells of the body, and hormones have widespread and diverse effects. The major processes controlled and integrated by these "mighty molecules" are reproduction; growth and development; mobilization of body defenses; maintenance of electrolyte, water, and nutrient balance of the blood; and regulation of cellular metabolism and energy balance. As you can see, the endocrine system orchestrates processes that go on for relatively long periods, in some instances continuously. The scientific study of hormones and the endocrine organs is called **endocrinology.**

The Endocrine System: An Overview

Compared with other organs of the body, those of the endocrine system are small and unimpressive. Indeed, to collect 1 kg (2.2 lb) of hormone-producing tissue, you would need to collect *all* the endocrine tissue from eight or nine adults! In addition, the anatomical continuity typical of most organ systems does not exist in the endocrine system. Instead, endocrine organs are widely scattered about the body.

As explained in Chapter 4, there are two kinds of glands. *Exocrine glands* produce nonhormonal substances, such as sweat and saliva, and have ducts through which these substances are routed to a membrane surface. **Endocrine glands,** also called *ductless glands,* produce hormones and lack ducts. They release their hormones into the surrounding tissue fluid (*endo* = within; *crine* = to secrete), and they typically have a rich vascular and lymphatic drainage that receives their hormones. Most of the hormone-producing cells in endocrine glands are arranged in cords and branching networks—a situation that maximizes contact between them and the capillaries surrounding them.

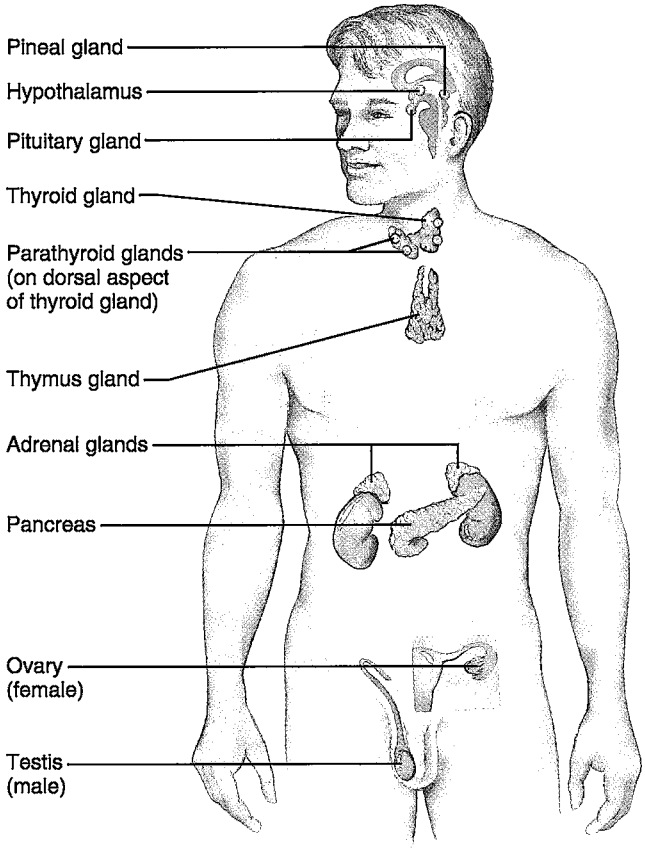

FIGURE 16.1 **Location of the major endocrine organs of the body.**

The endocrine glands include the pituitary, thyroid, parathyroid, adrenal, pineal, and thymus glands (Figure 16.1). The hypothalamus, along with its neural functions, produces and releases hormones, so we can consider the hypothalamus a **neuroendocrine organ.** In addition, several organs contain discrete areas of endocrine tissue and produce hormones as well as exocrine products. Such organs, which include the pancreas and gonads (ovaries and testes), are also major endocrine glands.

Besides the major endocrine organs, various other tissues and organs produce hormones. For example, adipose cells release leptin, and pockets of hormone-producing cells are found in the walls of the small intestine, stomach, kidneys, and heart—organs whose chief functions have little to do with

hormone production. These other hormone-producing structures are described on pp. 636–638.

Although some physiologists include local chemical messengers—autocrines and paracrines—as part of the realm of the endocrine system, that is not the consensus. Hormones are long-distance chemical signals that travel in blood or lymph throughout the body. **Autocrines** are chemicals that exert their effects on the same cells that secrete them. For example, certain prostaglandins released by smooth muscle cells cause those smooth muscle cells to contract. **Paracrines** also act locally but affect cell types other than those releasing the paracrine chemicals. For example, somatostatin released by one population of pancreatic cells inhibits the release of insulin by a different population of pancreatic cells.

HOMEOSTATIC IMBALANCE

Certain tumor cells, such as those of some cancers of the lung or pancreas, synthesize hormones identical to those made in normal endocrine glands. However, they do so in an excessive and uncontrolled fashion leading to problems due to hormone-mediated pathology.

Hormones

The Chemistry of Hormones

Hormones are chemical substances, secreted by cells into the extracellular fluids, that regulate the metabolic function of other cells in the body. Although a large variety of hormones are produced, nearly all of them can be classified chemically as either amino acid based or steroids.

Most hormones are **amino acid based.** Molecular size varies widely in this group—from simple amino acid derivatives (which include amines and thyroxine constructed from the amino acid tyrosine), to peptides (short chains of amino acids), to proteins (long polymers of amino acids). The **steroids** are synthesized from cholesterol. Of the hormones produced by the major endocrine organs, only gonadal and adrenocortical hormones are steroids.

If we also consider the **eicosanoids** (i-ko'să-noyds), which include *leukotrienes* and *prostaglandins,* we must add a third chemical class. These biologically active lipids (made from arachidonic acid) are released by nearly all cell membranes. Leukotrienes are signaling chemicals that mediate inflammation and some allergic reactions. Prostaglandins have multiple targets and effects, ranging from raising blood pressure and increasing the expulsive uterine contractions of birth to enhancing blood clotting, pain, and inflammation. Because the effects of eicosanoids are typically highly localized, affecting only nearby cells, they generally act as paracrines and autocrines and do not fit the definition of the true *hormones,* which influence distant targets. Hence, this class of hormonelike chemicals will not be considered here. Instead, their important effects are considered in later chapters as appropriate.

Mechanisms of Hormone Action

Even though all major hormones circulate to virtually all tissues, a given hormone influences the activity of only certain tissue cells, referred to as its **target cells.** Hormones bring about their characteristic effects on target cells by *altering* cell activity; that is, they increase or decrease the rates of normal cellular processes. The precise response depends on the target cell type. For example, when the hormone epinephrine binds to certain smooth muscle cells in blood vessel walls, it stimulates them to contract. Epinephrine binding to cells other than muscle cells may have a different effect, but it does *not* cause those cells to contract.

A hormonal stimulus typically produces one or more of the following changes:

1. Alters plasma membrane permeability or membrane potential, or both, by opening or closing ion channels
2. Stimulates synthesis of proteins or regulatory molecules such as enzymes within the cell
3. Activates or deactivates enzymes
4. Induces secretory activity
5. Stimulates mitosis

Two main mechanisms account for how a hormone communicates with its target cell, that is, how hormone receptor binding is harnessed to the intracellular machinery needed for hormone action. The mechanism used depends on the chemical nature of the hormone and the cellular location of the receptor. *Water-soluble hormones* (all amino acid–based hormones except thyroid hormone) act on *receptors in the plasma membrane* coupled via regulatory molecules called G proteins to one or more intracellular second messengers which mediate the target cell's response. *Lipid-soluble hormones* (steroid and thyroid hormones) act on *intracellular receptors,* directly activating genes. This will be easy for you to remember if you think about *why* this must be so: Receptors for water-soluble hormones must be in the plasma membrane since these hormones *cannot* enter the cell; receptors for lipid-soluble steroid and thyroid hormones are inside the cell because these hormones *can* enter the cell. Of course, things are not quite that clear-cut. Recent research has shown that steroid hormones exert some of their more immediate effects via plasma membrane receptors, and the second messengers of some hydrophilic hormones can turn genes on.

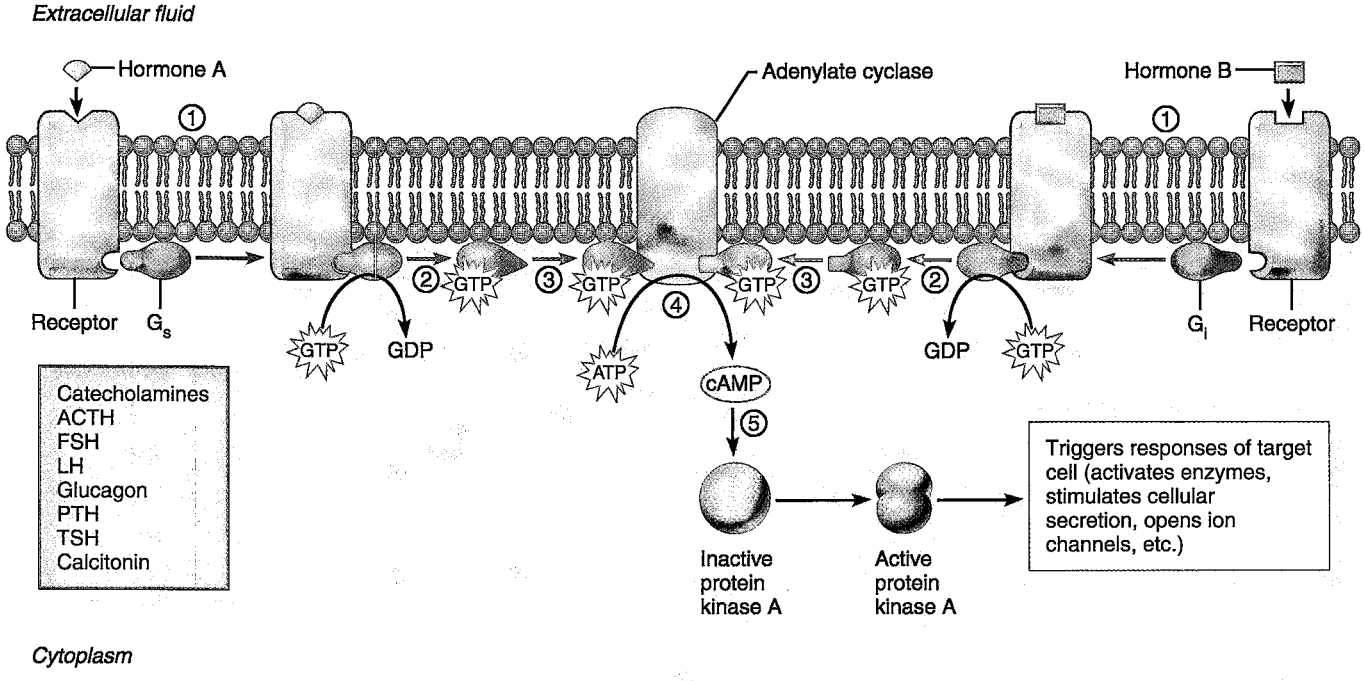

FIGURE 16.2 **Cyclic AMP second-messenger mechanism of amino acid–based hormones.** Mechanisms that generate cyclic AMP by activation of adenylate cyclase are mediated by G_s proteins, which are activated when a hormone (the first messenger, A in this case) binds to plasma membrane receptors (①–③ on left of effector enzyme, green arrows). Cyclic AMP (the second messenger, ④) acts intracellularly to activate protein kinase A enzymes (⑤) that mediate the cell's responses to the hormone. Notice that not all hormones provoke the activation of the effector enzyme. As depicted on the right, binding of hormone B to a membrane receptor is inhibitory because it activates a different G protein (G_i, ①–③ on right of effector enzyme, red arrows). Examples of hormones that act through these mechanisms are listed.

Plasma Membrane Receptors and Second-Messenger Systems

With the exception of thyroid hormone, all amino acid–based hormones exert their signaling effects through intracellular **second messengers** generated when a hormone binds to a receptor on the plasma membrane. You are already familiar with one of these second messengers, **cyclic AMP,** which is used by neurotransmitters (Chapter 11) and olfactory and gustatory receptors (Chapter 15).

The Cyclic AMP Signaling Mechanism As you recall, this mechanism involves the interaction of three plasma membrane components to determine intracellular levels of cyclic AMP (cAMP)—a hormone receptor, a signal transducer (a G protein), and an effector enzyme (adenylate cyclase).

① The hormone, acting as the **first messenger,** binds to its receptor (Figure 16.2).

② Hormone binding causes the receptor to change shape, allowing it to bind a nearby inactive **G protein.** The G protein is activated as the guanosine diphosphate (GDP) bound to it is displaced by the high-energy compound *guanosine triphosphate (GTP).* The G protein behaves like a light switch; it is "off" when GDP is bound to it, and "on" when GTP is bound.

③ The activated G protein (moving along the membrane) binds to the effector enzyme **adenylate cyclase.** Some G proteins (G_s) *stimulate* adenylate cyclase (left side of Figure 16.2); others (G_i) *inhibit* adenylate cyclase (right side of Figure 16.2). Eventually, the GTP bound to the G protein is hydrolyzed to GDP and the G protein becomes inactive once again. (The G protein possesses GTPase activity and cleaves the terminal phosphate group off GTP in much the same way that ATPase enzymes hydrolyze ATP.)

④ If activated, adenylate cyclase generates the second-messenger cAMP from ATP.

⑤ cAMP, which is free to diffuse throughout the cell, triggers a cascade of chemical reactions beginning with the activation of *protein kinase A.* **Protein kinases** are enzymes that *phosphorylate* (add a phosphate group to) various proteins, many of which are other enzymes. Because phosphorylation activates some of these proteins and inhibits others, a variety of reactions may occur in the same target cell at the same time.

Which of the membrane proteins acts as the signal transducer in Figures 16.2 and 16.3? Why are reactions initiated by second-messenger mechanisms called cascades?

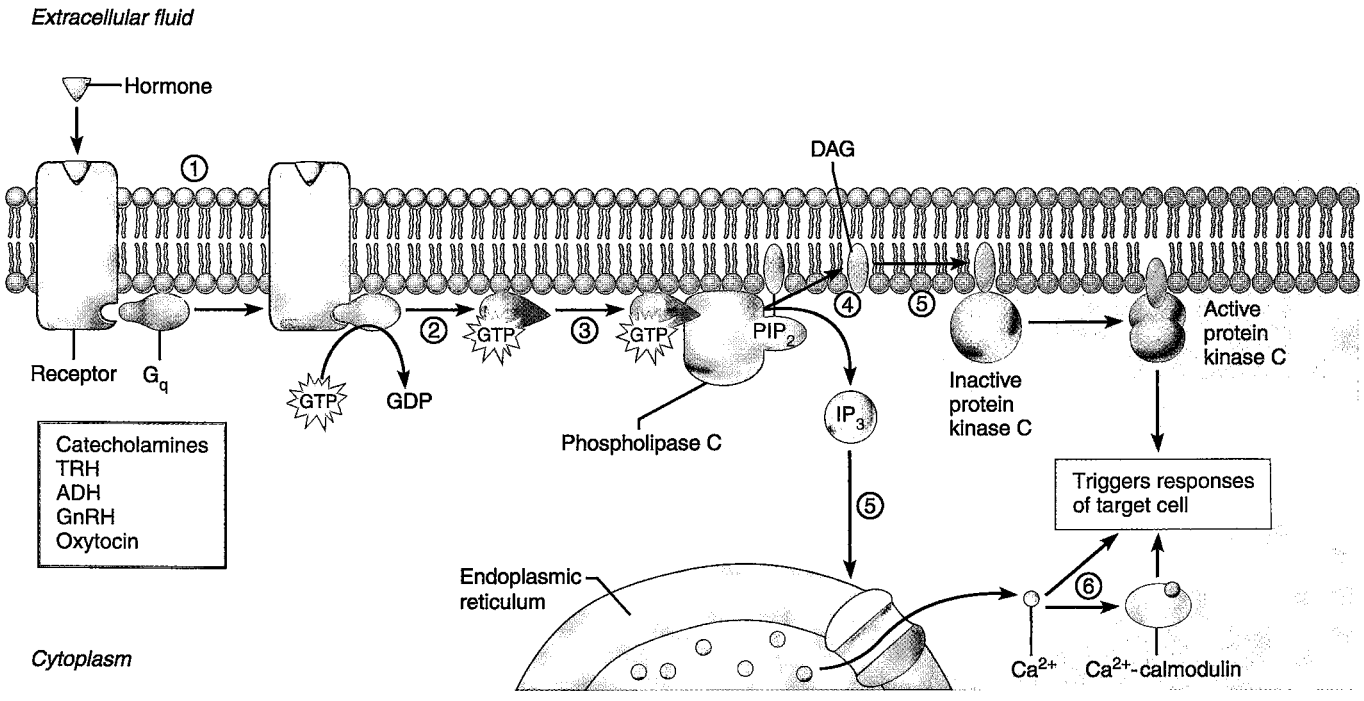

FIGURE 16.3 **PIP second-messenger mechanism of amino acid–based hormones.** Some G protein–coupled receptors use DAG, IP_3, and Ca^{2+} as intracellular messengers. ①–③ The activated G protein (G_q) stimulates the effector molecule, phospholipase C, to ④ cleave PIP_2 into two fragments—diacylglycerol (DAG) and inositol triphosphate (IP_3), which act as intracellular second messengers to ⑤ activate protein kinases and increase the cytoplasmic concentration of Ca^{2+}. ⑥ Ca^{2+} also acts as a second messenger to modify the activity of cellular proteins. Examples of hormones that act through these mechanisms are listed.

This type of intracellular enzymatic cascade has a huge amplification effect. Each activated adenylate cyclase generates large numbers of cAMP molecules, and a single kinase enzyme can catalyze hundreds of reactions. Hence, as the reaction cascades through one enzyme intermediate after another, the number of product molecules increases dramatically at each step. Theoretically, receptor binding of a single hormone molecule could generate millions of final product molecules!

The sequence of reactions set into motion by cAMP depends on the type of target cell, the specific protein kinases it contains, and the substrates within that cell available for phosphorylation by the protein kinase. For example, in thyroid cells, binding of thyroid-stimulating hormone promotes synthesis of the thyroid hormone thyroxine; in bone and muscle cells, binding of growth hormone activates anabolic reactions in which amino acids are built into tissue proteins. Since some G proteins inhibit rather than activate adenylate cyclase, thereby reducing the cytoplasmic concentration of cAMP, even slight changes in levels of antagonistic hormones can influence a target cell's activity.

Because cAMP is rapidly degraded by the intracellular enzyme **phosphodiesterase,** its action persists only briefly. While at first glance this may appear to be a problem, it is quite the opposite. Because of the amplification effect, most hormones need to be present only briefly to cause the desired results. Continued production of hormones then prompts continued cellular activity; no extracellular controls are necessary to stop the activity.

The PIP-Calcium Signal Mechanism Although cyclic AMP is the activating second messenger in some tissues for at least ten amino acid–based hormones, some of the same hormones (e.g.,

A The signal transducer is the G protein(s). Because each step in the pathway has a huge amplification effect and the number of product molecules increases dramatically at each step, a single signal has a cascade effect.

epinephrine) act through a different second-messenger system in other tissues. In one such mechanism, called the PIP-calcium signal mechanism, intracellular calcium ions act as the final mediator. Let's follow this process (Figure 16.3).

① Hormone binding to the receptor causes it to change shape.

② The receptor binds the G protein, which is activated as GTP binds, displacing GDP.

③ The activated G protein (G_q) then binds to and activates membrane-bound **phospholipase C** (the effector enzyme).

④ Phospholipase C splits a plasma-membrane phospholipid called **PIP_2** (**p**hosphatidyl **i**nositol bis**p**hosphate) into **diacylglycerol (DAG)** and **inositol triphosphate (IP_3).** Both these molecules act as second messengers.

⑤ DAG activates *protein kinase C*, and IP_3 triggers the release of Ca^{2+} from the endoplasmic reticulum and other intracellular storage sites.

⑥ The liberated Ca^{2+} takes on a second-messenger role, either by directly altering the activity of specific enzymes and plasma membrane Ca^{2+} channels or by binding to the intracellular regulatory protein **calmodulin.** Once Ca^{2+} binds to calmodulin, enzymes are activated that amplify the cellular response.

Other Signaling Mechanisms Examples of hormones known to act on their target cells via G protein receptors and the cAMP or PIP mechanisms are listed in Figures 16.2 and 16.3. Other hormones that bind plasma membrane receptors act on their target cells through different (and in some cases, unknown) mechanisms. For example, cyclic guanosine monophosphate (cGMP) is a second messenger for selected hormones. Insulin (and other growth factors) appear to work without second messengers. The insulin receptor is a *tyrosine kinase* enzyme that is activated by autophosphorylation (addition of phosphate to several of its own tyrosines) when insulin binds. The activated insulin receptor provides docking sites for intracellular *relay proteins* that, in turn, initiate a series of protein phosphorylations that trigger specific cell responses. In certain instances, any of the second messengers mentioned—and the hormone receptor itself—can cause changes in intracellular Ca^{2+} levels.

Intracellular Receptors and Direct Gene Activation

Being lipid soluble, steroid hormones (and, strangely, thyroid hormone, a small iodinated amine) diffuse into their target cells where they bind to an intracellular receptor that is activated by the coupling (Figure 16.4). The activated hormone-receptor

Q *What is the crucial difference between the signaling mechanism depicted here and those shown in Figures 16.2 and 16.3?*

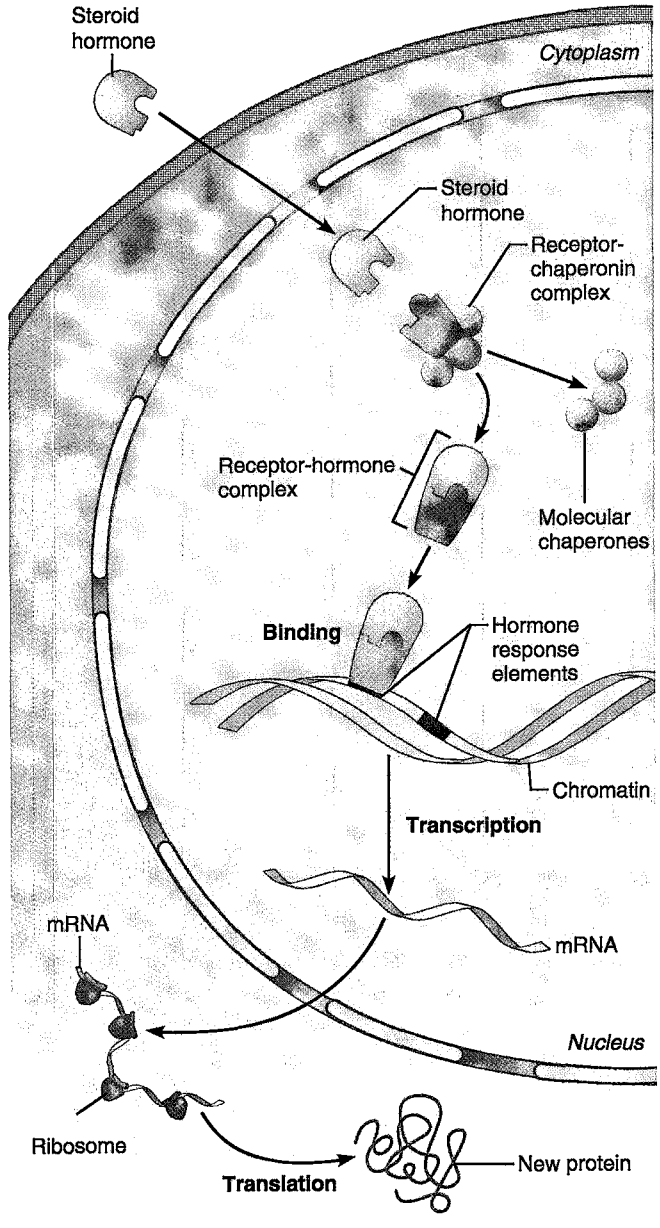

FIGURE 16.4 **Direct gene activation mechanism of steroid hormones.** A lipid-soluble hormone (steroid or thyroid hormone) diffuses through the plasma membrane of the target cell and binds to a receptor-chaperonin complex in the nucleus. Once hormone is bound, the chaperonin dissociates from the receptor and the hormone-receptor complex binds to a specific sequence on the DNA, initiating transcription of a certain gene. The messenger RNA formed migrates into the cytoplasm, where it directs synthesis of a specific protein.

A *Here, the hormone can enter the cell (because it is soluble in the plasma membrane lipids) and directly stimulates the desired effect by acting on DNA to cause transcription. In the Figures 16.2 and 16.3 mechanisms, the hormone cannot enter the cell because it is insoluble in membrane lipids.*

complex then makes its way to the nuclear chromatin, where the hormone receptor binds to a region of DNA (a *hormone response element*) specific for it. (The exception to these generalizations is that thyroid hormone receptors are always bound to DNA even in the absence of thyroid hormone.) This interaction "turns on" a gene, that is, prompts transcription of DNA to produce a messenger RNA (mRNA). The mRNA is then translated on the cytoplasmic ribosomes, producing specific protein molecules. These proteins include enzymes that promote the metabolic activities induced by that particular hormone and, in some cases, promote synthesis of either structural proteins or proteins to be exported from the target cell.

In the absence of hormone, the receptors are bound up in receptor-chaperonin complexes, associations that seem to keep the receptors from binding to DNA and perhaps protect them from proteolysis. (Check back to Chapter 2, pp. 52–53, if your recall of molecular chaperones needs a jog.) When the hormone *is* present, the complex dissociates, which allows it to bind to DNA and influence transcription.

Target Cell Specificity

In order for a target cell to respond to a hormone, the cell must have *specific* protein receptors on its plasma membrane or in its interior to which that hormone can bind. For example, receptors for adrenocorticotropic hormone (ACTH) are normally found only on certain cells of the adrenal cortex. By contrast, thyroxine is the principal hormone stimulating cellular metabolism, and nearly all body cells have thyroxine receptors.

A hormone receptor responds to hormone binding by prompting the cell to perform, or turn on, some gene-determined "preprogrammed" function. Hence, hormones are molecular triggers rather than informational molecules. Although binding of a hormone to a receptor is the crucial first step, target cell activation by hormone-receptor interaction depends equally on three factors: (1) blood levels of the hormone, (2) relative numbers of receptors for that hormone on or in the target cells, and (3) *affinity* (strength) of the bond between the hormone and the receptor. All three factors change rapidly in response to various stimuli and changes within the body. As a rule, for a given level of hormone in the blood, a large number of high-affinity receptors produces a pronounced hormonal effect, and a smaller number of low-affinity receptors results in reduced target cell response or outright endocrine dysfunction.

Receptors are dynamic structures. In some instances, target cells form more receptors in response to rising blood levels of the specific hormones to which they respond, a phenomenon called **up-regulation.** In other cases, prolonged exposure to high hormone concentrations desensitizes the target cells, so that they respond less vigorously to hormonal stimulation. This **down-regulation** involves loss of receptors and prevents the target cells from overreacting to persistently high hormone levels. Hormones influence the number and affinity not only of their own receptors but also of receptors that respond to other hormones. For example, progesterone induces a loss of estrogen receptors in the uterus, thus antagonizing estrogen's actions. On the other hand, estrogen causes the same cells to produce more progesterone receptors, enhancing their ability to respond to progesterone.

Half-Life, Onset, and Duration of Hormone Activity

Hormones are potent chemicals, and they exert profound effects on their target organs at very low concentrations. Hormones circulate in the blood in two forms—free or bound to a protein carrier. In general, lipid-soluble hormones (steroids and thyroid hormone) travel in the bloodstream attached to plasma proteins. Most others circulate unencumbered by carriers. The concentration of a circulating hormone in blood at any time reflects (1) its rate of release, and (2) the speed at which it is inactivated and removed from the body. Some hormones are rapidly degraded by enzymes in their target cells, but most are removed from the blood by the kidneys or liver, and their breakdown products are excreted from the body in urine or, to a lesser extent, in feces. As a result, the length of time for a hormone's blood level to be decreased by half, referred to as its **half-life,** varies from a fraction of a minute to a week, with the water-soluble hormones exhibiting the shortest half-lives.

The time required for hormone effects to appear also varies greatly. Some hormones provoke target organ responses almost immediately, while others, particularly the steroid hormones, require hours to days before their effects are seen. Additionally, some hormones are secreted in a relatively inactive form and must be activated in the target cells.

The duration of hormone action is limited, ranging from 10 seconds to several hours, depending on the hormone. Effects may disappear rapidly as blood levels drop, or they may persist for hours after very low hormone levels have been reached. Because of these many variations, hormonal blood levels must be precisely and individually controlled to meet the continuously changing needs of the body.

Interaction of Hormones at Target Cells

Understanding hormonal effects is a bit more complicated than you might expect because multiple hormones may act on the same target cells at the same time and in many cases the result of such an interaction is not predictable even when you know the effects of the individual hormones. Here we will look at three types of hormone interaction—permissiveness, synergism, and antagonism.

Permissiveness is the situation when one hormone cannot exert its full effects without another hormone being present. For example, the development of the reproductive system is largely regulated by reproductive system hormones, as we might expect. However, thyroid hormone is necessary (has a permissive effect) for normal *timely* development of reproductive structures; without thyroid hormone, reproductive system development is delayed.

Synergism of hormones occurs in situations where more than one hormone produces the same effects at the target cell and their combined effects are amplified. For example, both glucagon (produced by the pancreas) and epinephrine cause the liver to release glucose to the blood; when they act together, the amount of glucose released is about 150% of what is released when each hormone acts alone.

When one hormone opposes the action of another hormone, the interaction is called **antagonism.** For example, insulin, which lowers blood glucose levels, is antagonized by the action of glucagon, which acts to raise blood glucose levels. Antagonists may compete for the same receptors, act through different metabolic pathways, or even, as noted in the progesterone-estrogen interaction at the uterus, cause down-regulation of the receptors for the antagonistic hormone.

Control of Hormone Release

The synthesis and release of most hormones are regulated by some type of **negative feedback system** (see Chapter 1). In such a system, hormone secretion is triggered by some internal or external stimulus. As hormone levels rise, they cause target organ effects and inhibit further hormone release. As a result, blood levels of many hormones vary only within a narrow range.

Endocrine Gland Stimuli

Endocrine glands are stimulated to manufacture and release their hormones by three major types of stimuli: *humoral* (hu'mer-ul), *neural*, and *hormonal.*

Humoral Stimuli Some endocrine glands secrete their hormones in direct response to changing blood levels of certain critical ions and nutrients. These stimuli are called *humoral stimuli* to distinguish them from hormonal stimuli, which are also blood-borne chemicals. The term *humoral* harks back to the ancient use of the term *humor* to refer to various body fluids (blood, bile, and others). This is the simplest of the endocrine control systems. For example, cells of the parathyroid glands monitor blood Ca^{2+} levels, and when they detect a decline from normal values, they secrete parathyroid hormone (PTH). Because PTH acts by several routes to reverse that decline, blood Ca^{2+} levels soon rise, ending the initiative for PTH release (Figure 16.5a). Other hormones released in response to humoral stimuli include insulin, produced by the pancreas, and aldosterone, one of the adrenal cortex hormones.

Neural Stimuli In a few cases, nerve fibers stimulate hormone release. The classic example of neural stimuli is sympathetic nervous system stimulation of the adrenal medulla to release catecholamines (norepinephrine and epinephrine) during periods of stress (Figure 16.5b).

Hormonal Stimuli Finally, many endocrine glands release their hormones in response to hormones produced by other endocrine organs, and the stimuli in these cases are called hormonal stimuli. For example, release of most anterior pituitary hormones is regulated by releasing and inhibiting hormones produced by the hypothalamus, and many anterior pituitary hormones in turn stimulate other endocrine organs to release their hormones (Figure 16.5c). As blood levels of the hormones produced by the final target glands increase, they inhibit the release of anterior pituitary hormones and thus their own release. This hypothalamic-pituitary-target endocrine organ feedback loop lies at the very core of endocrinology, and it will come up many times in this chapter. Hormonal stimuli promote rhythmic hormone release, with hormone blood levels rising and falling in a specific pattern.

Although these three mechanisms typify most systems that control hormone release, they are by no means all-inclusive or mutually exclusive, and some endocrine organs respond to multiple stimuli.

Nervous System Modulation

Both "turn-on" factors (hormonal, humoral, and neural stimuli) and "turn-off" factors (feedback inhibition and others) may be modified by the nervous system. Without this added safeguard, endocrine system activity would be strictly mechanical, much like a household thermostat. A thermostat can maintain the temperature at or around its set value, but it cannot sense that your grandmother visiting from Florida feels cold at that temperature and reset

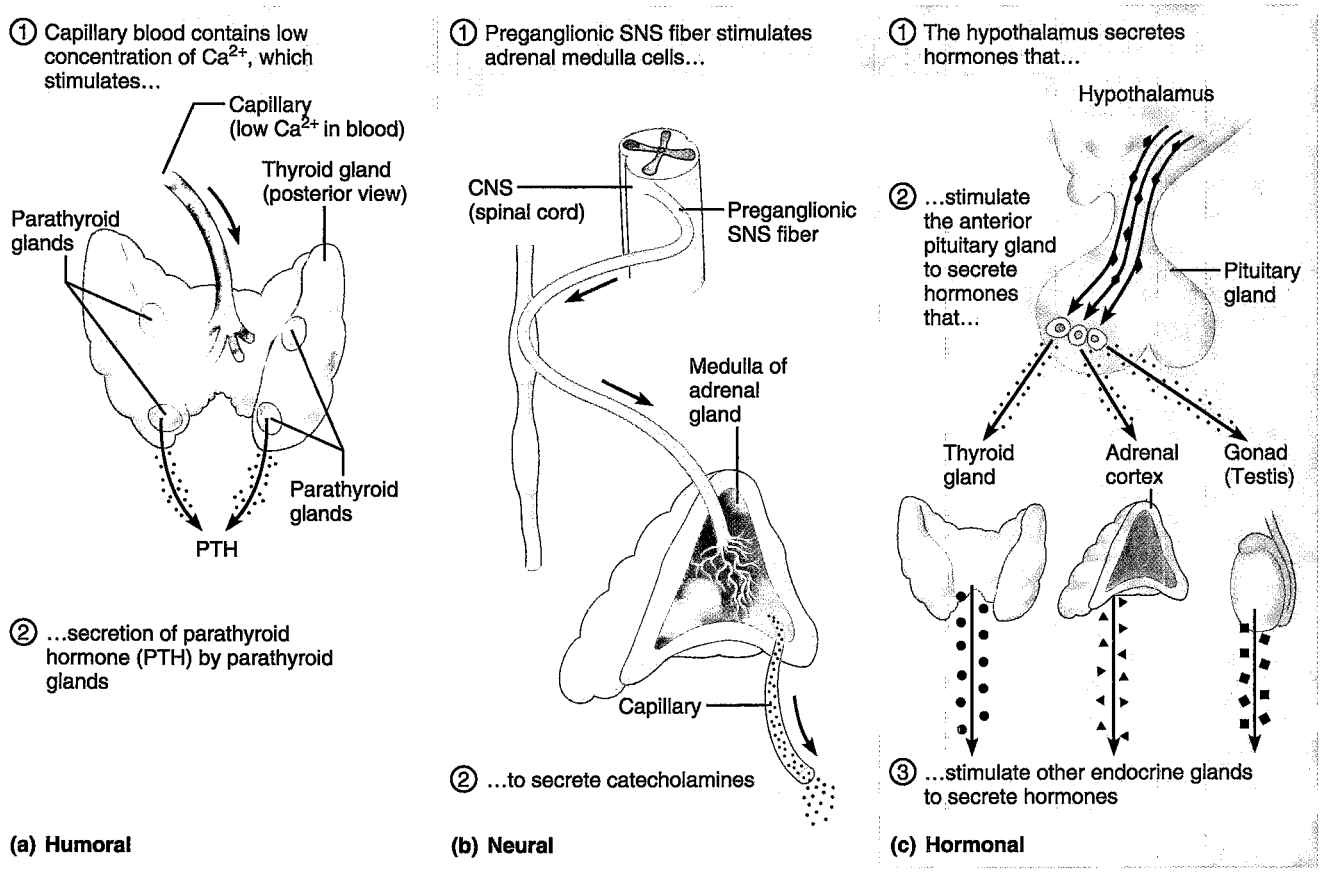

FIGURE 16.5 **Three types of endocrine gland stimuli. (a)** Humoral stimulus: Low blood calcium levels trigger parathyroid hormone release from the parathyroid glands, which causes blood Ca^{2+} levels to rise by stimulating release of Ca^{2+} from bone. **(b)** Neural stimulus: The stimulation of adrenal medullary cells by sympathetic nervous system (SNS) fibers triggers the release of catecholamines to the blood. **(c)** Hormonal stimulus: Hormones released by the hypothalamus stimulate the anterior pituitary to release hormones that stimulate other endocrine organs to secrete hormones.

itself accordingly. *You* must make that adjustment. In your body, it is the nervous system that makes certain adjustments to maintain homeostasis by overriding normal endocrine controls. For example, the action of insulin and several other hormones normally keeps blood glucose levels in the range of 90–110 mg/100 ml of blood. However, when the body is under severe stress, blood glucose levels rise because the hypothalamus and sympathetic nervous system centers are strongly activated. This ensures that body cells have sufficient fuel for the more vigorous activity required during such periods.

Major Endocrine Organs

The Pituitary Gland (Hypophysis)

Securely seated in the sella turcica of the sphenoid bone, the tiny **pituitary gland,** or **hypophysis** (hi-pof'ĭ-sis; "to grow under"), secretes at least nine hormones. Usually said to be the size and shape of a pea, this gland is more accurately described as a pea on a stalk. Its stalk, the funnel-shaped **infundibulum,** connects the gland to the hypothalamus superiorly (Figure 16.1). In humans, the pituitary gland has two major lobes; one is neural tissue and the other glandular. The **posterior pituitary** (lobe) (Figure 16.6) is composed largely of pituicytes (glia-like supporting cells) and nerve fibers. It releases **neurohormones** (hormones secreted by neurons) received ready-made from the hypothalamus. Thus, this lobe is a hormone-storage area and not a true endocrine gland in the precise sense. The posterior lobe plus the infundibulum make up the region called the **neurohypophysis** (nu"ro-hi-pof'ĭ-sis), a term commonly used (incorrectly) to indicate the posterior lobe alone. The **anterior pituitary** (lobe), or **adenohypophysis** (ad"ĕ-no-hi-pof'ĭ-sis), is composed of glandular tissue (*adeno* = gland), and it manufactures and releases a number of hormones (Table 16.1 on pp. 618–619).

Q *What do you think is the advantage of having the hypophyseal portal system as compared to having the usual arrangement of blood vessels?*

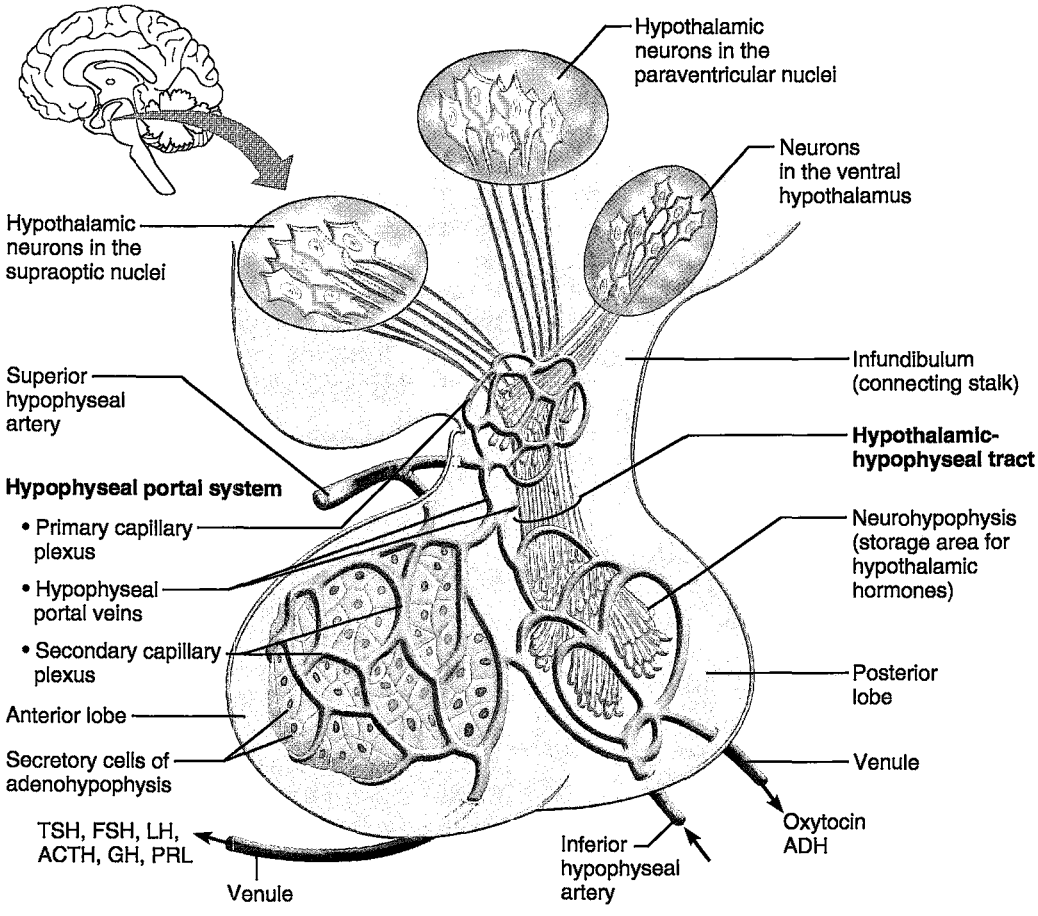

FIGURE 16.6 **Relationships of the pituitary gland and hypothalamus.** Hypothalamic neurons in the supraoptic and paraventricular nuclei synthesize ADH and oxytocin, which are transported along the hypothalamic-hypophyseal tract to the neurohypophysis for storage. Neurons in the ventral hypothalamus have short axons that discharge releasing and inhibiting hormones to the capillaries of the hypophyseal portal system, which runs to the adenohypophysis. These hormones influence the adenohypophyseal secretory cells to release (or not release) their hormones.

Arterial blood is delivered to the pituitary via hypophyseal branches of the internal carotid arteries. The veins leaving the pituitary drain into the dural sinuses.

Pituitary-Hypothalamic Relationships

The contrasting histology of the two pituitary lobes reflects the dual origin of this tiny gland. The posterior lobe is actually part of the brain. It derives from a downgrowth of hypothalamic tissue and maintains its neural connection with the hypothalamus via a nerve bundle called the **hypothalamic-hypophyseal tract,** which runs through the infundibulum (Figure 16.6). This tract arises from neurons in the **supraoptic** and **paraventricular nuclei** of the hypothalamus. These neurosecretory cells synthesize two neurohormones and transport them along their axons to the posterior pituitary. Oxytocin (ok"sĭ-to'sin) is made primarily by the paraventricular neurons, and antidiuretic hormone (ADH) primarily by the supraoptic neurons. When these hypothalamic neurons fire, they release the stored hormones into a capillary bed in the posterior pituitary for distribution throughout the body.

The glandular anterior lobe originates from a superior outpocketing of the oral mucosa (*Rathke's*

∀ *The portal system allows releasing and inhibiting hormones from the hypothalamus to reach the anterior pituitary more quickly than they would otherwise. They are also less diluted, so they can be released in smaller quantities.*

pouch) and is formed from epithelial tissue. After touching the posterior lobe, the anterior lobe loses its connection with the oral mucosa and adheres to the neurohypophysis. There is no direct neural connection between the anterior lobe and hypothalamus, but there is a vascular connection. Specifically, the **primary capillary plexus** in the infundibulum communicates inferiorly via the small **hypophyseal portal veins** with a **secondary capillary plexus** in the anterior lobe. The primary and secondary capillary plexuses and the intervening hypophyseal portal veins make up the **hypophyseal portal system*** (Figure 16.6). Via this portal system, **releasing** and **inhibiting hormones** secreted by neurons in the ventral hypothalamus circulate to the adenohypophysis, where they regulate secretion of its hormones. All these hypothalamic regulatory hormones are amino acid based, but they vary in size from a single amine to peptides to proteins.

Adenohypophyseal Hormones

Although the adenohypophysis has traditionally been called the "master endocrine gland" because of its numerous hormonal products, many of which regulate the activity of other endocrine glands, it has in recent years been dethroned by the hypothalamus, which is now known to control anterior pituitary activity. Researchers have identified six distinct adenohypophyseal hormones, all of them proteins (Table 16.1). In addition, a large molecule with the tongue-twisting name **pro-opiomelanocortin (POMC)** (pro"o"pe-o-mah-lan'o-kor"tin) has been isolated from the anterior pituitary. POMC is a *prohormone*, that is, a large precursor molecule that can be split enzymatically into one or more active hormones. POMC is the source of adrenocorticotropic hormone, two natural opiates (an enkephalin and a beta endorphin, described in Chapter 11), and *melanocyte-stimulating hormone (MSH)*. In amphibians, reptiles, and other animals MSH stimulates melanocytes to increase synthesis of melanin pigment, but this is not an important function of MSH in humans. In humans and other animals, MSH is a CNS neurotransmitter involved in the control of appetite. Although low levels of MSH are found in plasma, its role in the periphery is not yet well understood.

When the adenohypophysis receives an appropriate chemical stimulus from the hypothalamus, one or more of its hormones are released by certain of its cells. Although many different hormones pass from the hypothalamus to the anterior lobe, each target cell in the anterior lobe distinguishes the messages directed to it and responds in kind—secreting the proper hormone in response to specific releasing hormones, and shutting off hormone release in response to specific inhibiting hormones. In general, the hypothalamic releasing hormones are more important than the inhibiting hormones as regulatory factors, because only very little hormone is stored by secretory cells of the anterior lobe.

Four of the six anterior pituitary hormones—thyroid-stimulating hormone, adrenocorticotropic hormone, follicle-stimulating hormone, and luteinizing hormone—are **tropins** or **tropic hormones** (*tropi* = turn on, change), which are hormones that regulate the secretory action of other endocrine glands. Except for growth hormone, all affect their target cells via a cyclic AMP second-messenger system.

Growth Hormone **Growth hormone (GH)** is produced by cells called **somatotrophs** of the anterior lobe (Figure 16.7). Although GH stimulates most body cells to increase in size and divide, its major targets are the bones and skeletal muscles. Stimulation of the epiphyseal plate leads to long bone growth; stimulation of skeletal muscles promotes increased muscle mass.

Essentially an anabolic (tissue-building) hormone, GH promotes protein synthesis, and it encourages the use of fats for fuel, thus conserving glucose. Most growth-promoting effects of GH are mediated indirectly by **insulin-like growth factors (IGFs)**, also known as **somatomedins** (so"mah-to-me'dinz), a family of growth-promoting proteins produced by the liver, skeletal muscle, bone, and other tissues. Specifically, IGFs (1) stimulate uptake of amino acids from the blood and their incorporation into cellular proteins throughout the body; and (2) stimulate uptake of sulfur (needed for the synthesis of chondroitin sulfate) into cartilage matrix. Acting directly, GH mobilizes fats from fat depots for transport to cells, increasing blood levels of fatty acids. It also decreases the rate of glucose uptake and metabolism. In the liver, it encourages glycogen breakdown and release of glucose to the blood. The elevation in blood glucose levels that occurs as a result of this *glucose sparing* is called the *diabetogenic effect* of GH, because it mimics the high blood glucose levels typical of diabetes mellitus.

Secretion of GH is regulated chiefly by two hypothalamic hormones with antagonistic effects. **Growth hormone–releasing hormone (GHRH)** stimulates GH release, while **growth hormone–inhibiting hormone (GHIH)**, also called **somatostatin** (so"mah-to-stat'in), inhibits it. GHIH release is (presumably) triggered by the feedback of GH and IGFs. Rising levels of GH also feed back to inhibit its own release. As indicated in Table 16.1, a number of

*A portal system is an unusual arrangement of blood vessels in which a capillary bed feeds into veins, which in turn feed into another capillary bed.

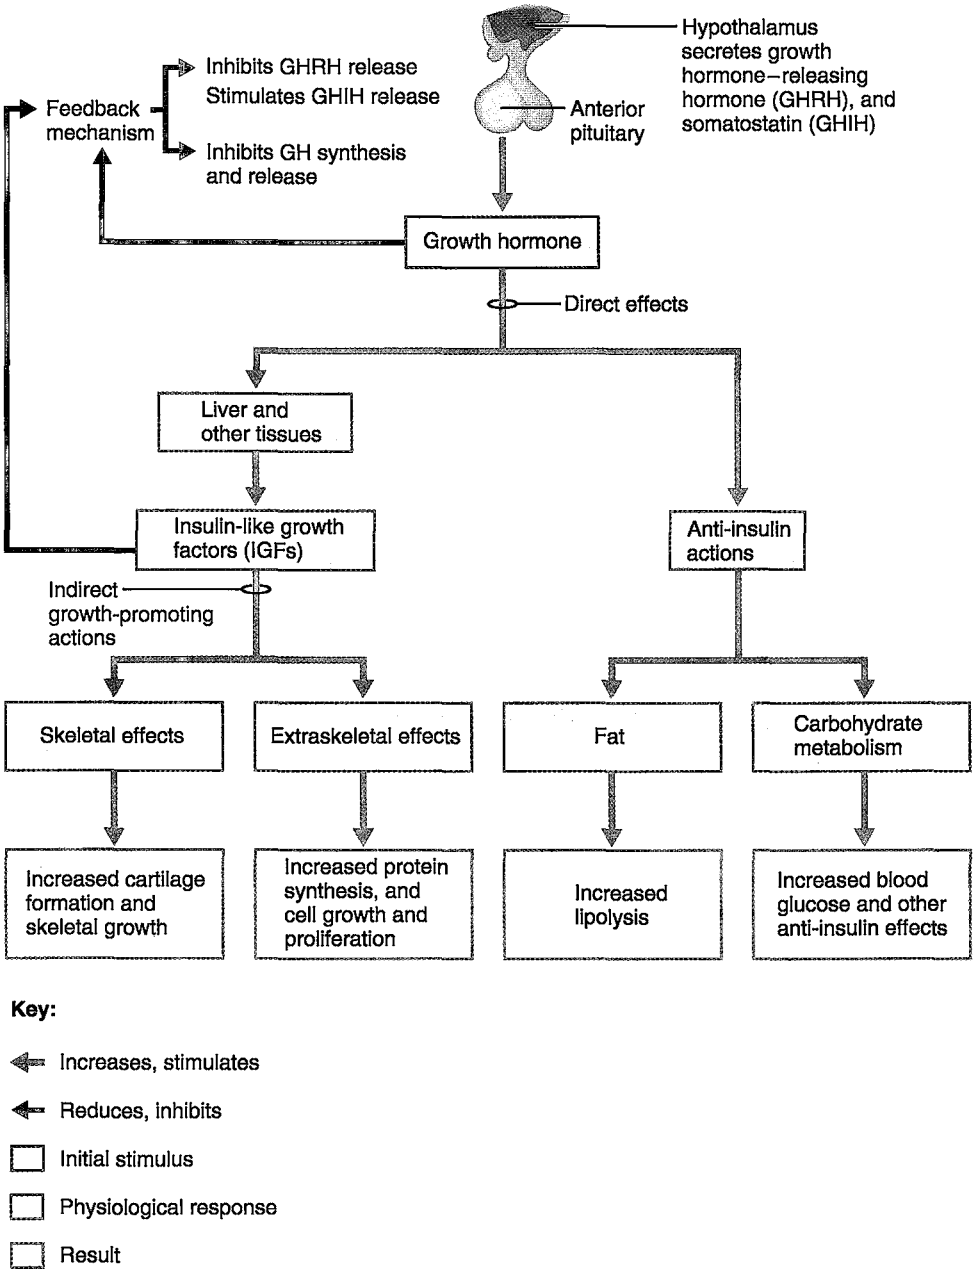

FIGURE 16.7 **Metabolic actions of growth hormone (GH).** The direct actions of GH on target cells stimulate liver, skeletal muscle, bone, and cartilage cells to produce and release insulin-like growth factors, which mediate the indirect, largely anabolic effects of GH. GH acts directly on other tissue cells to promote fat breakdown (lipolysis) and release from adipose tissues and to hinder glucose uptake from the blood by tissue cells. (Because these actions antagonize those of the pancreatic hormone insulin, they are referred to as anti-insulin or glucose-sparing actions.) Elevated levels of GH and IGF feed back to promote GHIH release (and depress GHRH release) by the hypothalamus and to inhibit GH release by the anterior pituitary gland.

secondary triggers also influence GH release. Typically, GH secretion has a daily cycle, with the highest levels occurring during evening sleep, but the total amount secreted daily peaks during adolescence and then declines with age.

Besides inhibiting growth hormone secretion, GHIH blocks the release of thyroid-stimulating hormone. GHIH is also produced in various locations in the gut, where it inhibits the release of virtually all gastrointestinal and pancreatic secretions—both endocrine and exocrine.

HOMEOSTATIC IMBALANCE

Both hypersecretion and hyposecretion of GH may result in structural abnormalities. Hypersecretion in children results in **gigantism** as the still-active epiphyseal (growth) plates are targeted by GH. The person becomes abnormally tall, often reaching a height of 2.4 m (8 feet), but has relatively normal body proportions. If excessive amounts of GH are secreted after the epiphyseal plates have closed, **acromegaly** (ak"ro-meg'ah-le) results. Literally translated as "enlarged extremities," this condition is characterized by overgrowth of bony areas still responsive to GH, namely bones of the hands, feet, and face. Hypersecretion usually results from an adenohypophyseal tumor that churns out excessive amounts of GH and the usual treatment is surgical removal of the tumor; however, anatomical changes that have already occurred are not reversible.

Hyposecretion of GH in adults usually causes no problems. GH deficiency in children results in slowed long bone growth, a condition called **pituitary dwarfism.** Such individuals attain a maximum height of 1.2 m (4 feet), but usually have fairly normal body proportions. Lack of GH is often accompanied by deficiencies of other adenohypophyseal hormones, and if thyroid-stimulating hormone and gonadotropins are lacking, the individual will be malproportioned and will fail to mature sexually as well. Fortunately, human GH is produced commercially by genetic engineering techniques and when pituitary dwarfism is diagnosed before puberty, growth hormone replacement therapy can promote nearly normal somatic growth.

The availability of synthetic GH also has a downside. Athletes and the elderly have been tempted to use GH for its body-building properties, and some parents have used GH in an attempt to give their children additional height. However, while muscle mass increases, there is no evidence for an increase in muscle strength in either athletes or the elderly, and only minimal increases in stature occur in normal children. Moreover, taking GH can lead to fluid retention, joint and muscle pain, diabetes, and may promote cancer. ●

Thyroid-Stimulating Hormone **Thyroid-stimulating hormone (TSH),** or **thyrotropin,** is a tropic hormone that stimulates normal development and secretory activity of the thyroid gland. TSH release from cells of the anterior pituitary called **thyrotrophs** is triggered by the hypothalamic peptide **thyrotropin-releasing hormone (TRH).** Rising blood levels of thyroid hormones act on both the pituitary and the hypothalamus to inhibit TSH secretion. The hypothalamus, in response, releases GHIH, which reinforces the blockade of TSH release.

Adrenocorticotropic Hormone **Adrenocorticotropic hormone (ACTH)** (ah-dre"no-kor"tĭ-kotrōp'ik), or **corticotropin,** is secreted by the **corticotrophs** of the adenohypophysis. ACTH stimulates the adrenal cortex to release corticosteroid hormones, most importantly glucocorticoids that help the body to resist stressors. ACTH release, elicited by hypothalamic **corticotropin-releasing hormone (CRH),** has a daily rhythm, with levels peaking in the morning, shortly before awakening. Rising levels of glucocorticoids feed back and block secretion of CRH and consequently ACTH release. Internal and external factors that alter the normal ACTH rhythm by triggering CRH release include fever, hypoglycemia, and stressors of all types.

Gonadotropins **Follicle-stimulating hormone (FSH)** and **luteinizing hormone (LH)** (lu'te-inīz"ing), referred to collectively as **gonadotropins,** regulate the function of the gonads (ovaries and testes). In both sexes, FSH stimulates gamete (sperm or egg) production and LH promotes production of gonadal hormones. In females, LH works with FSH to cause maturation of an egg-containing ovarian follicle. LH then independently triggers ovulation and promotes synthesis and release of ovarian hormones. In males, LH stimulates the interstitial cells of the testes to produce the male hormone testosterone.

Gonadotropins are virtually absent from the blood of prepubertal boys and girls. During puberty, the **gonadotrophs** of the adenohypophysis are activated and gonadotropin levels begin to rise, causing the gonads to mature. In both sexes, gonadotropin release by the adenohypophysis is prompted by **gonadotropin-releasing hormone (GnRH)** produced by the hypothalamus. Gonadal hormones, produced in response to the gonadotropins, feed back to suppress FSH and LH release.

Prolactin **Prolactin (PRL)** is a protein hormone structurally similar to GH. Produced by the **lactotrophs,** PRL stimulates the gonads of some animals (other than humans) and is considered a gonadotropin by some researchers. Its only well-documented effect in humans is to stimulate milk production by the breasts (*pro* = for; *lact* = milk). The role of prolactin in males is not well understood.

As with GH, PRL release is controlled by hypothalamic releasing and inhibiting hormones, but in this case it is the inhibitory hormone that plays the dominant role. **Prolactin-inhibiting hormone (PIH),** now known to be *dopamine (DA),* prevents prolactin secretion. Decreased PIH secretion leads to a surge in PRL release. The exact nature of **prolactin-releasing hormone (PRH)** is unknown, but it may be a combination of several releasing factors. In females, prolactin levels rise and fall in rhythm with estrogen blood levels. Estrogen stimulates prolactin release, both directly and indirectly. A brief rise in prolactin levels just before the menstrual period partially accounts for the breast swelling and tenderness some women experience at that time, but because this PRL stimulation is so brief, the breasts do not produce milk. In pregnant women, PRL blood levels rise dramatically toward the end of pregnancy, and milk production becomes possible. After birth, the infant's suckling stimulates PRH release in the mother, encouraging continued milk production and availability.

HOMEOSTATIC IMBALANCE

Hypersecretion of prolactin is more common than hyposecretion (which is not a problem in anyone except women who choose to nurse). In fact, hyperprolactinemia is the most frequent abnormality of

adenohypophyseal tumors. Clinical signs include inappropriate lactation, lack of menses, infertility in females, and breast enlargement and impotence in males.

The Posterior Pituitary and Hypothalamic Hormones

The posterior pituitary, made largely of the axons of hypothalamic neurons, stores antidiuretic hormone (ADH) and oxytocin that have been synthesized and forwarded by hypothalamic neurons of the supraoptic and paraventricular nuclei. These hormones are later released "on demand" in response to nerve impulses from the same hypothalamic neurons.

ADH and oxytocin, each composed of nine amino acids, are almost identical. They differ in only two amino acids, and yet they have dramatically different physiological effects (Table 16.1). ADH influences body water balance, and oxytocin stimulates contraction of smooth muscle, particularly that of the uterus and breasts.

Oxytocin A strong stimulant of uterine contraction, **oxytocin** is released in significantly higher amounts during childbirth (*ocytocia* = childbirth) and in nursing women. The number of oxytocin receptors in the uterus peaks near the end of pregnancy, and uterine smooth muscle becomes more and more sensitive to the hormone's stimulatory effects. Stretching of the uterus and cervix as birth nears dispatches afferent impulses to the hypothalamus, which responds by synthesizing oxytocin and triggering its release from the neurohypophysis. Oxytocin acts via the PIP-Ca^{2+} second-messenger system to mobilize Ca^{2+}, allowing stronger contractions. As blood levels of oxytocin rise, the expulsive contractions of labor gain momentum and finally end in birth.

Oxytocin also acts as the hormonal trigger for milk ejection (the "letdown" reflex) in women whose breasts are producing milk in response to prolactin. Suckling causes a reflex-initiated release of oxytocin, which targets specialized myoepithelial cells surrounding the milk-producing glands. As these cells contract, milk is forced from the breast into the infant's mouth. Both of these mechanisms are *positive feedback mechanisms* and are described in more detail in Chapter 28.

Both natural and synthetic oxytocic drugs are used to induce labor or to hasten normal labor that is progressing slowly. Less frequently, oxytocics are used to stop postpartum bleeding (by compressing ruptured blood vessels at the placental site) and to stimulate the milk ejection reflex.

Until recently, oxytocin's role in males and nonpregnant, nonlactating females was unknown, but new studies reveal that this potent peptide plays a role in sexual arousal and orgasm when the body is already primed for reproduction by sex hormones. Then, it may be responsible for the feeling of sexual satisfaction that results from that interaction. In nonsexual relationships, it is thought to promote nurturing and affectionate behavior, that is, it acts as a "cuddle hormone."

Antidiuretic Hormone *Diuresis* (di"u-re'sis) is urine production. Thus, an *antidiuretic* is a substance that inhibits or prevents urine formation. **Antidiuretic hormone (ADH)** prevents wide swings in water balance, helping the body avoid dehydration and water overload. Hypothalamic neurons, called *osmoreceptors,* continually monitor the solute concentration (and thus the water concentration) of the blood. When solutes threaten to become too concentrated (as might follow excessive perspiration or inadequate fluid intake), the osmoreceptors transmit excitatory impulses to the hypothalamic neurons, which synthesize and release ADH. Liberated into the blood by the neurohypophysis, ADH targets the kidney tubules via cAMP. The tubule cells respond by reabsorbing more water from the forming urine and returning it to the bloodstream. As a result, less urine is produced and blood volume increases. As the solute concentration of the blood declines, the osmoreceptors stop depolarizing, effectively ending ADH release. Other stimuli triggering ADH release include pain, low blood pressure, and such drugs as nicotine, morphine, and barbiturates.

Drinking alcoholic beverages inhibits ADH secretion and causes copious urine output. The dry mouth and intense thirst of the "morning after" reflect this dehydrating effect of alcohol. As might be expected, ADH release is also inhibited by drinking excessive amounts of water. *Diuretic drugs* antagonize the effects of ADH and cause water to be flushed from the body. These drugs are used to manage some cases of hypertension and the edema (water retention in tissues) typical of congestive heart failure.

At high blood concentrations, ADH causes vasoconstriction, primarily of the visceral blood vessels, a response that indicates targeting of different receptors found on vascular smooth muscle. Under certain conditions, such as severe blood loss, exceptionally large amounts of ADH are released, causing a rise in blood pressure. The alternative name for this hormone, **vasopressin,** reflects this particular effect.

HOMEOSTATIC IMBALANCE

One result of ADH deficiency is **diabetes insipidus,** a syndrome marked by the output of huge amounts of urine and intense thirst. The name of this condition (*diabetes* = overflow; *insipidus* = tasteless)

TABLE 16.1 Pituitary Hormones: Summary of Regulation and Effects

HORMONE (CHEMICAL STRUCTURE AND CELL TYPE)	REGULATION OF RELEASE	TARGET ORGAN AND EFFECTS	EFFECTS OF HYPOSECRETION ↓ AND HYPERSECRETION ↑
ANTERIOR PITUITARY HORMONES			
Growth hormone (GH) (Protein, somatotroph)	**Stimulated** by GHRH* release, which is triggered by low blood levels of GH as well as by a number of secondary triggers including hypoglycemia, increases in blood levels of amino acids, low levels of fatty acids, exercise, other types of stressors, and estrogens **Inhibited** by feedback inhibition exerted by GH and IGFs, and by hyperglycemia, hyperlipidemia, obesity, and emotional deprivation via either increased GHIH* (somatostatin) or decreased GHRH* release	 Liver, muscle, bone, cartilage, and other tissues: anabolic hormone; stimulates somatic growth; mobilizes fats; spares glucose Most effects mediated indirectly by IGFs	↓ Pituitary dwarfism in children ↑ Gigantism in children; acromegaly in adults
Thyroid-stimulating hormone (TSH) (Glycoprotein, thyrotroph)	**Stimulated** by TRH* and indirectly by pregnancy and (in infants) cold temperature **Inhibited** by feedback inhibition exerted by thyroid hormones on anterior pituitary and hypothalamus and by GHIH*	 Thyroid gland: stimulates thyroid gland to release thyroid hormone	↓ Cretinism in children; myxedema in adults ↑ Hyperthyroidism; effects similar to those of Graves' disease, in which antibodies mimic TSH
Adrenocorticotropic hormone (ACTH) (Polypeptide of 39 amino acids, corticotroph)	**Stimulated** by CRH*; stimuli that increase CRH release include fever, hypoglycemia, and other stressors **Inhibited** by feedback inhibition exerted by glucocorticoids	 Adrenal cortex: promotes release of glucocorticoids and androgens (mineralocorticoids to a lesser extent)	↓ Rare ↑ Cushing's disease
Follicle-stimulating hormone (FSH) (Glycoprotein, gonadotroph)	**Stimulated** by GnRH* **Inhibited** by feedback inhibition exerted by inhibin, and estrogen in females and testosterone in males	 Ovaries and testes: in females, stimulates ovarian follicle maturation and estrogen production; in males, stimulates sperm production	↓ Failure of sexual maturation ↑ No important effects

distinguishes it from diabetes mellitus (*mel* = honey), in which insulin deficiency causes large amounts of blood glucose to be lost in the urine. At one time, urine was tasted to determine which type of diabetes the patient was suffering from.

Diabetes insipidus can be caused by a blow to the head that damages the hypothalamus or the posterior pituitary. In either case, ADH release is deficient. Though inconvenient, the condition is not serious when the thirst center is operating

TABLE 16.1 *(continued)*

HORMONE (CHEMICAL STRUCTURE AND CELL TYPE)	REGULATION OF RELEASE	TARGET ORGAN AND EFFECTS	EFFECTS OF HYPOSECRETION ↓ AND HYPERSECRETION ↑
Luteinizing hormone (LH) (Glycoprotein, gonadotroph)	**Stimulated** by GnRH* **Inhibited** by feedback inhibition exerted by estrogen and progesterone in females and testosterone in males	 Ovaries and testes: in females, triggers ovulation and stimulates ovarian production of estrogen and progesterone; in males, promotes testosterone production	As for FSH
Prolactin (PRL) (Protein, lactotroph)	**Stimulated** by decreased PIH* and increased PRH*; release enhanced by estrogens, birth control pills, breast-feeding, and dopamine-blocking drugs **Inhibited** by PIH* (dopamine)	 Breast secretory tissue: promotes lactation	↓ Poor milk production in nursing women ↑ Inappropriate milk production (galactorrhea); cessation of menses in females; impotence and breast enlargement (gynecomastia) in males
 **POSTERIOR PITUITARY HORMONES (MADE BY HYPOTHALAMIC NEURONS AND STORED IN POSTERIOR PITUITARY)**			
Oxytocin (Peptide mostly from neurons in paraventricular nucleus of hypothalamus)	**Stimulated** by impulses from hypothalamic neurons in response to cervical/uterine stretching and suckling of infant at breast **Inhibited** by lack of appropriate neural stimuli	 Uterus: stimulates uterine contractions; initiates labor; breast: initiates milk ejection	Unknown
Antidiuretic hormone (ADH) or **vasopressin** (Peptide, mostly from neurons in supraoptic nucleus of hypothalamus)	**Stimulated** by impulses from hypothalamic neurons in response to increased osmolality of blood or decreased blood volume; also stimulated by pain, some drugs, low blood pressure **Inhibited** by adequate hydration of the body and by alcohol	 Kidneys: stimulates kidney tubule cells to reabsorb water	↓ Diabetes insipidus ↑ Syndrome of inappropriate ADH secretion (SIADH)

*Indicates hypothalamic releasing and inhibiting hormones: GHRH = growth hormone–releasing hormone; GHIH = growth hormone–inhibiting hormone; TRH = thyrotropin-releasing hormone; CRH = corticotropin-releasing hormone; GnRH = gonadotropin-releasing hormone; PRH = prolactin-releasing hormone; PIH = prolactin-inhibiting hormone

properly and the person drinks enough water to prevent dehydration. However, it can be life threatening in unconscious or comatose patients, so accident victims with head trauma must be carefully monitored.

Hypersecretion of ADH occurs in children with meningitis, may follow neurosurgery or hypothalamic injury, or results from ectopic ADH secretion by cancer cells (particularly pulmonary cancers). It also may occur after general anesthesia or administration

Q *Which of the cell populations shown in view (b) produces calcitonin?*

of certain drugs. The resulting condition, *syndrome of inappropriate ADH secretion (SIADH),* is marked by retention of fluid, headache and disorientation due to brain edema, weight gain, and hypo-osmolarity of the blood. SIADH management requires fluid restriction and careful monitoring of blood sodium levels. ◉

The Thyroid Gland

Location and Structure

The butterfly-shaped **thyroid gland** is located in the anterior neck, on the trachea just inferior to the larynx (Figures 16.1 and 16.8a). Its two lateral *lobes* are connected by a median tissue mass called the *isthmus.* The thyroid gland is the largest pure endocrine gland in the body. Its prodigious blood supply (from the *superior* and *inferior thyroid arteries*) makes thyroid surgery a painstaking (and bloody) endeavor.

Internally, the gland is composed of hollow, spherical **follicles** (Figure 16.8b). The walls of each follicle are formed largely by cuboidal or squamous epithelial cells called *follicle cells,* which produce the glycoprotein **thyroglobulin** (thi″ro-glob′u-lin). The central cavity, or lumen, of the follicle stores **colloid,** an amber-colored, sticky material consisting of thyroglobulin molecules with attached iodine atoms. *Thyroid hormone* is derived from this iodinated thyroglobulin. The *parafollicular cells,* another population of endocrine cells in the thyroid gland, produce *calcitonin,* an entirely different hormone. The parafollicular cells lie in the follicular epithelium but protrude into the soft connective tissue that separates and surrounds the thyroid follicles.

Thyroid Hormone

Often referred to as the body's major metabolic hormone, **thyroid hormone (TH)** is actually two iodine-containing amine hormones, **thyroxine** (thi-rok′sin),

A The parafollicular cells.

TABLE 16.2 Major Effects of Thyroid Hormone (T_4 and T_3) in the Body

PROCESS OR SYSTEM AFFECTED	NORMAL PHYSIOLOGICAL EFFECTS	EFFECTS OF HYPOSECRETION	EFFECTS OF HYPERSECRETION
Basal metabolic rate (BMR)/ temperature regulation	Promotes normal oxygen use and BMR; calorigenesis; enhances effects of sympathetic nervous system	BMR below normal; decreased body temperature and cold intolerance; decreased appetite; weight gain; reduced sensitivity to catecholamines	BMR above normal; increased body temperature and heat intolerance; increased appetite; weight loss
Carbohydrate/lipid/protein metabolism	Promotes glucose catabolism; mobilizes fats; essential for protein synthesis; enhances liver's synthesis of cholesterol	Decreased glucose metabolism; elevated cholesterol/ triglyceride levels in blood; decreased protein synthesis; edema	Enhanced catabolism of glucose, proteins, and fats; weight loss; loss of muscle mass
Nervous system	Promotes normal development of nervous system in fetus and infant; promotes normal adult nervous system function	In infant, slowed/deficient brain development, retardation; in adult, mental dulling, depression, paresthesias, memory impairment, hypoactive reflexes	Irritability, restlessness, insomnia, personality changes, exophthalmos (in Graves' disease)
Cardiovascular system	Promotes normal functioning of the heart	Decreased efficiency of pumping action of the heart; low heart rate and blood pressure	Increased sensitivity to catecholamines leads to rapid heart rate and possible palpitations; high blood pressure; if prolonged, heart failure
Muscular system	Promotes normal muscular development and function	Sluggish muscle action; muscle cramps; myalgia	Muscle atrophy and weakness
Skeletal system	Promotes normal growth and maturation of the skeleton	In child, growth retardation, skeletal stunting and retention of child's body proportions; in adult, joint pain	In child, excessive skeletal growth initially, followed by early epiphyseal closure and short stature; in adult, demineralization of skeleton
Gastrointestinal system	Promotes normal GI motility and tone; increases secretion of digestive juices	Depressed GI motility, tone, and secretory activity; constipation	Excessive GI motility; diarrhea; loss of appetite
Reproductive system	Promotes normal female reproductive ability and lactation	Depressed ovarian function; sterility; depressed lactation	In females, depressed ovarian function; in males, impotence
Integumentary system	Promotes normal hydration and secretory activity of skin	Skin pale, thick, and dry; facial edema; hair coarse and thick	Skin flushed, thin, and moist; hair fine and soft; nails soft and thin

or T_4, and **triiodothyronine** (tri"i-o"do-thi'ro-nēn), or T_3. T_4 is the major hormone secreted by the thyroid follicles; most T_3 is formed at the target tissues by conversion of T_4 to T_3. Very much like one another, the hormones are constructed from two linked tyrosine amino acids. The principal difference is that T_4 has four bound iodine atoms, and T_3 has three (thus, T_4 and T_3).

Except for the adult brain, spleen, testes, uterus, and the thyroid gland itself, TH affects virtually every cell in the body (Table 16.2). By stimulating enzymes concerned with glucose oxidation, it increases basal metabolic rate and body heat production; this is known as the hormone's **calorigenic effect** (*calorigenic* = heat producing). Because TH provokes an increase in the number of adrenergic receptors in blood vessels, it plays an important role in maintaining blood pressure. Additionally, it is an important regulator of tissue growth and development. It is especially critical for normal skeletal and nervous system development and maturation and for reproductive capabilities.

Synthesis Thyroid hormone synthesis involves six interrelated processes that begin when TSH secreted by the anterior pituitary binds to follicle cell receptors. The following numbers correspond to steps 1–6 in Figure 16.9:

① **Formation and storage of thyroglobulin.** After being synthesized on the ribosomes, thyroglobulin is

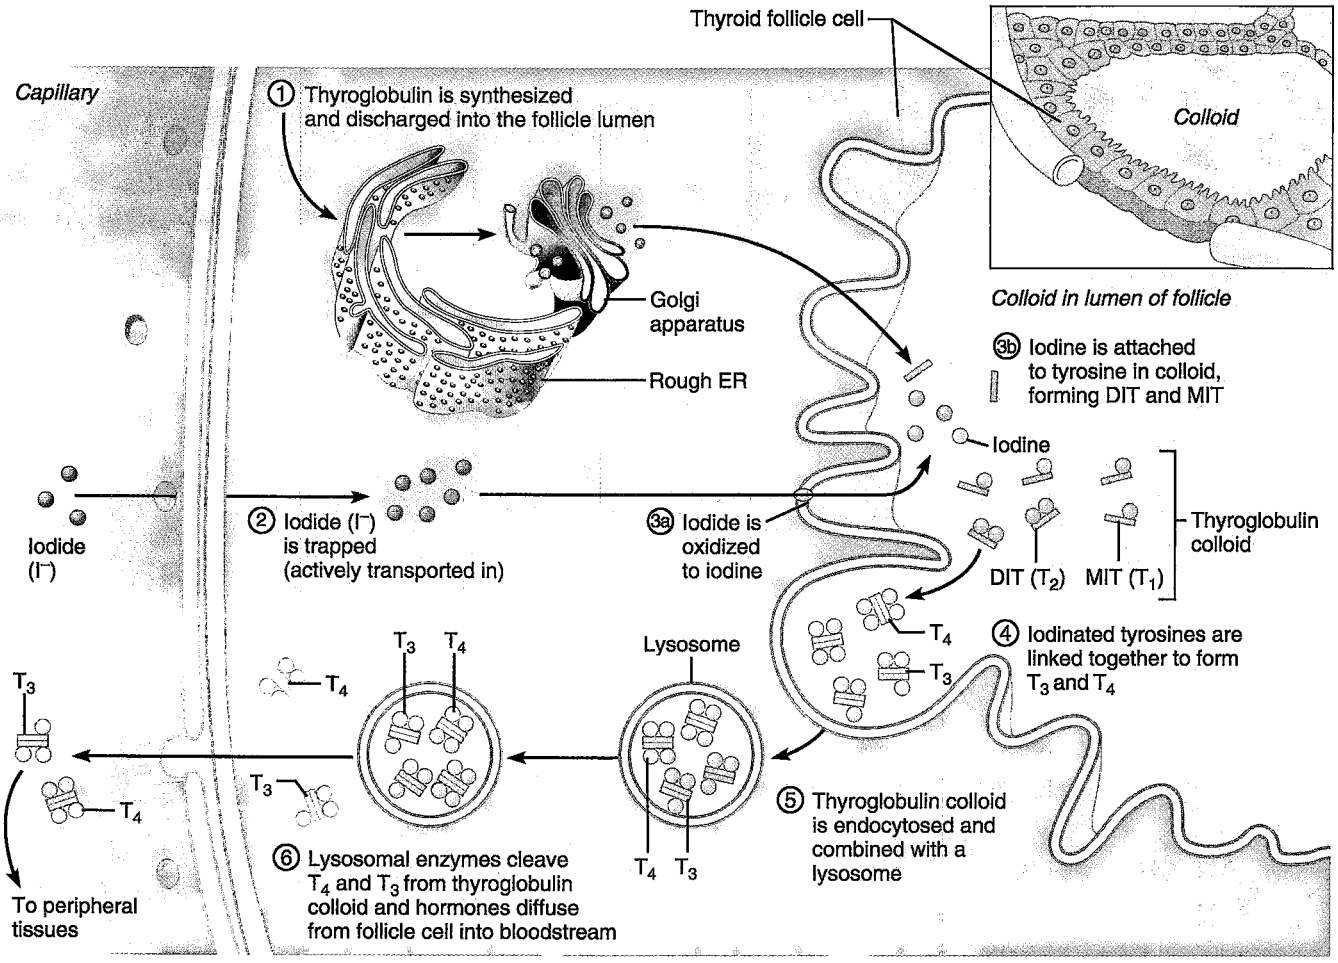

FIGURE 16.9 **Synthesis of thyroid hormone.** Binding of TSH to follicle cell receptors (not illustrated) stimulates synthesis of the thyroglobulin colloid and the release of thyroxine (T_4) and triiodothyronine (T_3) from the cell in the six steps illustrated here. (Only a few of the thyroglobulins in the colloid are illustrated. The rest of the colloid is represented by the unstructured yellow substance.)

transported to the Golgi apparatus, where sugar residues are attached and the molecules are packed into vesicles. These transport vesicles move to the apex of the follicle cell, where their contents are discharged into the follicle lumen and become part of the stored colloid.

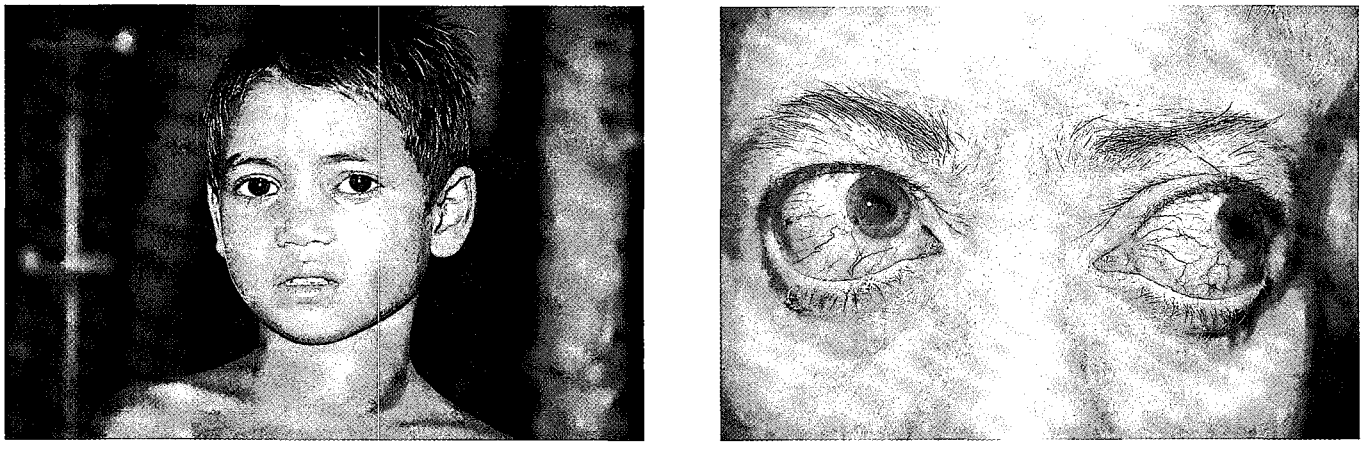
② **Iodide trapping.** To produce the functional iodinated hormones, the follicle cells must accumulate iodides (anions of iodine, I^-) from the blood. Because the intracellular concentration of I^- is over 30 times higher than that in blood, iodide trapping depends on active transport. Once trapped inside the follicle cell, iodide then moves into the follicle lumen by facilitated diffusion.

③ **Oxidation to iodine and iodination.** At the border of the follicle cell and colloid, iodides are oxidized (by removal of electrons) and converted to iodine (I_2). Once formed, iodine is attached to tyrosine amino acids that form part of the thyroglobulin colloid. This iodination reaction occurs at the junction of the follicle cell apex and the colloid and is mediated by peroxidase enzymes. Attachment of one iodine to a tyrosine produces **monoiodotyrosine (MIT or T_1)**; attachment of two iodines produces **diiodotyrosine (DIT or T_2)**.

④ **Coupling of T_2 and T_1.** Next, enzymes in the colloid link T_1 and T_2 together. Two linked DITs result in T_4; coupling of MIT and DIT produces T_3. At this point, the hormones are still part of the thyroglobulin colloid.

⑤ **Colloid endocytosis.** Hormone secretion requires that the follicle cells reclaim iodinated thyroglobulin by endocytosis and combine the vesicles with lysosomes.

⑥ **Cleavage of the hormones for release.** In the lysosomes, the hormones are cleaved out of the colloid by lysosomal enzymes. The hormones then diffuse from the follicle cells into the bloodstream. The



(a) (b)

FIGURE 16.10 **Thyroid disorders. (a)** An enlarged thyroid (goiter) of a Bangladeshi boy. **(b)** Exophthalmos of Graves' disease.

main hormonal product secreted is T_4. Some T_4 is converted to T_3 before secretion, but most T_3 is generated in the peripheral tissues.

Although we have followed TH synthesis from beginning to end (secretion), the *initial response* to TSH binding is secretion of thyroid hormone. Then more colloid is synthesized to "restock" the follicle lumen. As a general rule, TSH levels are lower during the day, peak just before sleep, and remain high during the night.

The thyroid gland is unique among the endocrine glands in its ability to store its hormone extracellularly and in large quantities. In the normal thyroid gland, the amount of stored colloid remains relatively constant and is sufficient to provide normal levels of hormone release for two to three months.

Transport and Regulation Most released T_4 and T_3 immediately binds to transport proteins, most importantly *thyroxine-binding globulins (TBGs)* produced by the liver. Both T_4 and T_3 bind to target tissue receptors, but T_3 binds much more avidly and is about ten times more active. Most peripheral tissues have the enzymes needed to convert T_4 to T_3, a process that entails enzymatic removal of one iodine atom.

Several mechanisms of TH activity probably exist. However, what we know for sure is that, like steroids, TH enters a target cell and binds to intracellular receptors within the cell's nucleus and initiates transcription of mRNA.

Falling TH blood levels trigger release of *thyroid-stimulating hormone (TSH)*, and ultimately of more TH. Rising TH levels feed back to inhibit the hypothalamic-adenohypophyseal axis, temporarily shutting off the stimulus for TSH release. Conditions that increase body energy requirements, such as pregnancy and exposure of infants to cold, stimulate the hypothalamus to secrete *thyrotropin-releasing hormone (TRH)*, which triggers TSH release, and in such instances, TRH overcomes the negative feedback controls. As the thyroid gland releases larger amounts of thyroid hormones, body metabolism and heat production are enhanced. Factors that inhibit TSH release include somatostatin, and rising levels of glucocorticoids. Excessively high blood iodide concentrations inhibit TH release.

HOMEOSTATIC IMBALANCE

Both overactivity and underactivity of the thyroid gland can cause severe metabolic disturbances. Hypothyroid disorders may result from some thyroid gland defect or secondarily from inadequate TSH or TRH release. They also occur when the thyroid gland is removed surgically and when dietary iodine is inadequate.

In adults, the full-blown hypothyroid syndrome is called **myxedema** (mik"sĕ-de'mah; "mucous swelling"). Symptoms include a low metabolic rate; feeling chilled; constipation; thick, dry skin and puffy eyes; edema; lethargy; and mental sluggishness (but not mental retardation). If myxedema results from lack of iodine, the thyroid gland enlarges and protrudes, a condition called **endemic** (en-dem'ik), or *colloidal*, **goiter** (Figure 16.10a). The follicle cells produce colloid but cannot iodinate it or make functional hormones. The pituitary gland secretes increasing amounts of TSH in a futile attempt to stimulate the thyroid to produce TH, but the only result is that the follicles accumulate more and more *unusable* colloid. Untreated, the thyroid cells eventually "burn out" from frantic activity, and the gland atrophies. Before the marketing of iodized salt, parts

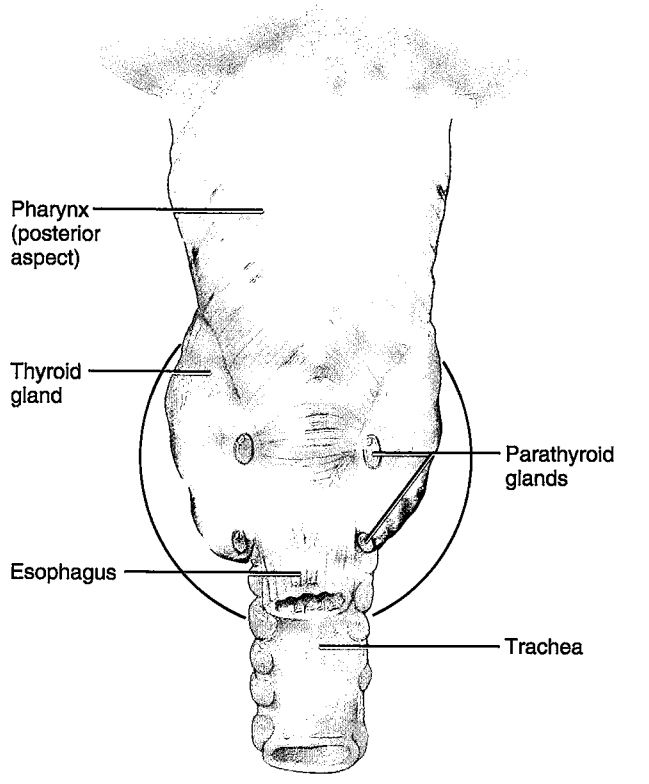


FIGURE 16.11 **The parathyroid glands. (a)** Location of the parathyroid glands on the posterior aspect of the thyroid gland. These tiny glands may be more inconspicuous than depicted. **(b)** Micrograph of a section of the parathyroid gland (1500×).

of the midwestern United States were called the "goiter belt." Because these areas had iodine-poor soil and no access to iodine-rich shellfish, goiters were common there. Depending on the cause, myxedema can be reversed by iodine supplements or hormone replacement therapy.

Like many other hormones, the important effects of TH depend on one's age and development. Severe hypothyroidism in infants is called **cretinism** (kre'tĭ-nizm). The child is mentally retarded and has a short, disproportionately sized body and a thick tongue and neck. Cretinism may reflect a genetic deficiency of the fetal thyroid gland or maternal factors, such as lack of dietary iodine. It is preventable by thyroid hormone replacement therapy if diagnosed early enough, but once developmental abnormalities and mental retardation appear, they are not reversible.

The most common (and puzzling) hyperthyroid pathology is **Graves' disease.** Because the serum of patients with this condition often contains abnormal antibodies that mimic TSH and continuously stimulate TH release, Graves' disease is believed to be an autoimmune disease. Typical symptoms include an elevated metabolic rate; sweating; rapid, irregular heartbeat; nervousness; and weight loss despite adequate food intake. *Exophthalmos,* protrusion of the eyeballs, may occur if the tissue behind the eyes becomes edematous and then fibrous (Figure 16.10b). Treatments include surgical removal of the thyroid gland or ingestion of radioactive iodine (^{131}I), which selectively destroys the most active thyroid cells. ●

Calcitonin

Calcitonin is a polypeptide hormone produced by the **parafollicular,** or **C, cells** of the thyroid gland. Because its most important effect is to lower blood Ca^{2+} levels, calcitonin is a direct antagonist of parathyroid hormone, produced by the parathyroid glands. Calcitonin targets the skeleton, where it (1) inhibits osteoclast activity and hence bone resorption and release of Ca^{2+} from the bony matrix and (2) stimulates Ca^{2+} uptake and incorporation into bone matrix. Thus, calcitonin has a bone-sparing effect.

Excessive blood levels of Ca^{2+} (approximately 20% above normal) act as a humoral stimulus for calcitonin release, whereas declining blood Ca^{2+} levels inhibit C cell secretory activity. Calcitonin regulation of blood Ca^{2+} levels is short lived but extremely rapid.

Calcitonin appears to be important only in childhood, when the skeleton grows quickly and the bones are changing dramatically in mass, size, and shape. In adults, it is at best a weak hypocalcemic agent.

The Parathyroid Glands

The tiny, yellow-brown **parathyroid glands** are nearly hidden from view in the posterior aspect of the thyroid gland (Figure 16.11a). There are usually four of these glands, but the precise number varies from one individual to another. As many as eight have been reported, and some may be located in other regions of the neck or even in the thorax. The parathyroid's glandular cells are arranged in thick,

branching cords containing scattered *oxyphil cells* and large numbers of smaller **chief cells** (Figure 16.11b). The chief cells secrete PTH. The function of the oxyphil cells is unclear.

Discovery of the parathyroid glands was accidental. Years ago, surgeons were baffled by the observation that while most patients recovered uneventfully after partial (or even total) thyroid gland removal, others suffered uncontrolled muscle spasms and severe pain, and subsequently died. It was only after several such tragic deaths that the parathyroid glands were discovered and their hormonal function, quite different from that of the thyroid gland hormones, became known.

Parathyroid hormone (PTH), or **parathormone,** the protein hormone of these glands, is the single most important hormone controlling the calcium balance of the blood. PTH release is triggered by falling blood Ca^{2+} levels and inhibited by hypercalcemia. PTH increases Ca^{2+} levels in blood by stimulating three target organs: the skeleton (which contains considerable amounts of calcium salts in its matrix), the kidneys, and the intestine (Figure 16.12).

PTH release (1) stimulates osteoclasts (bone-resorbing cells) to digest some of the bony matrix and release ionic calcium and phosphates to the blood; (2) enhances reabsorption of Ca^{2+} (and excretion of PO_4^{3-}) by the kidneys; and (3) increases absorption of Ca^{2+} by the intestinal mucosal cells. PTH's effect on calcium absorption by the intestine is indirect via its effect on vitamin D activation. Vitamin D is required for absorption of Ca^{2+} from ingested food, but the form in which the vitamin is ingested or produced by the skin is inactive. For vitamin D to exert its physiological effects, it must first be converted by the kidneys to its active vitamin D_3 form, *calcitriol* (1,25-dihydroxycholecalciferol), a transformation stimulated by PTH.

Because plasma calcium ion homeostasis is essential for so many functions, including transmission of nerve impulses, muscle contraction, and blood clotting, precise control of Ca^{2+} levels is critical.

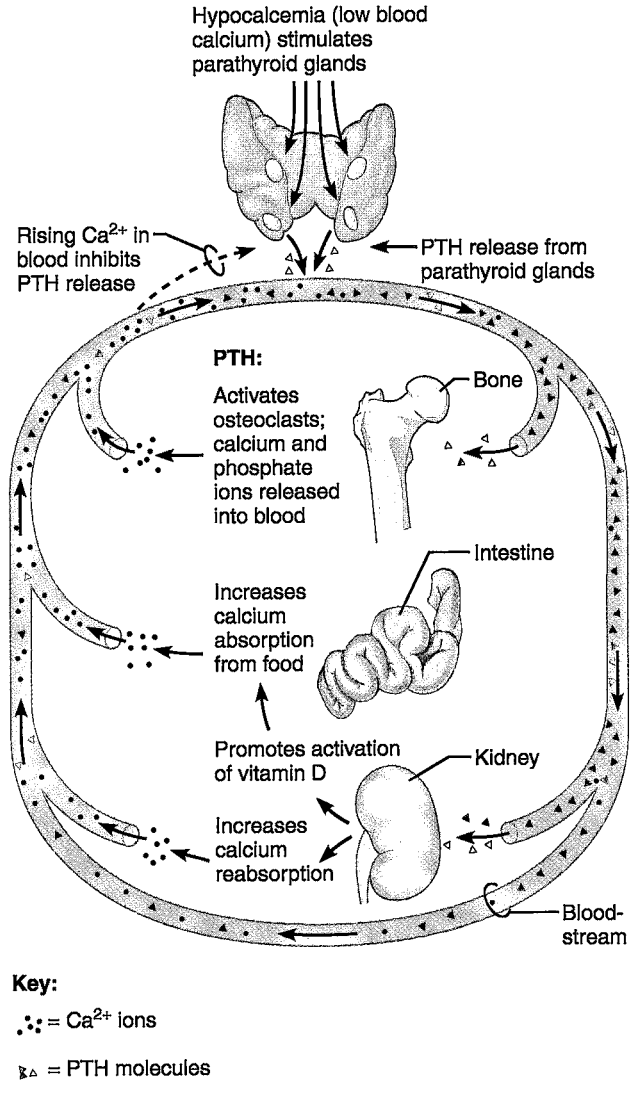

FIGURE 16.12 **Effect of parathyroid hormone on bone, the intestine, and the kidneys.** The effect on the intestine is indirect via activated vitamin D.

HOMEOSTATIC IMBALANCE

Hyperparathyroidism is rare and usually the result of a parathyroid gland tumor. When it occurs, calcium is leached from the bones, and the bones soften and deform as their mineral salts are replaced by fibrous connective tissue. In *osteitis fibrosa cystica*, a severe example of this disorder, the bones have a moth-eaten appearance on X rays and tend to fracture spontaneously. The resulting abnormally elevated blood Ca^{2+} level (hypercalcemia) has many outcomes, but the two most notable are (1) depression of the nervous system, which leads to abnormal reflexes and weakness of the skeletal muscles, and (2) formation of kidney stones as excess calcium salts precipitate in the kidney tubules. Calcium deposits may also form in soft tissues throughout the body and severely impair vital organ functioning, a condition called *metastatic calcification*.

Hypoparathyroidism, or PTH deficiency, most often follows parathyroid gland trauma or removal during thyroid surgery. However, an extended deficiency of dietary magnesium (required for PTH secretion) can cause functional hypoparathyroidism. The resulting hypocalcemia increases the excitability of neurons and accounts for the classical symptoms of *tetany* such as loss of sensation, muscle twitches, and convulsions. Untreated, the symptoms progress to respiratory paralysis and death. ●

Q *Suppose your lab professor springs a "pop" quiz and has adrenal cortical tissue under the microscope for identification. What information about the cell arrangements would help you in this quiz?*

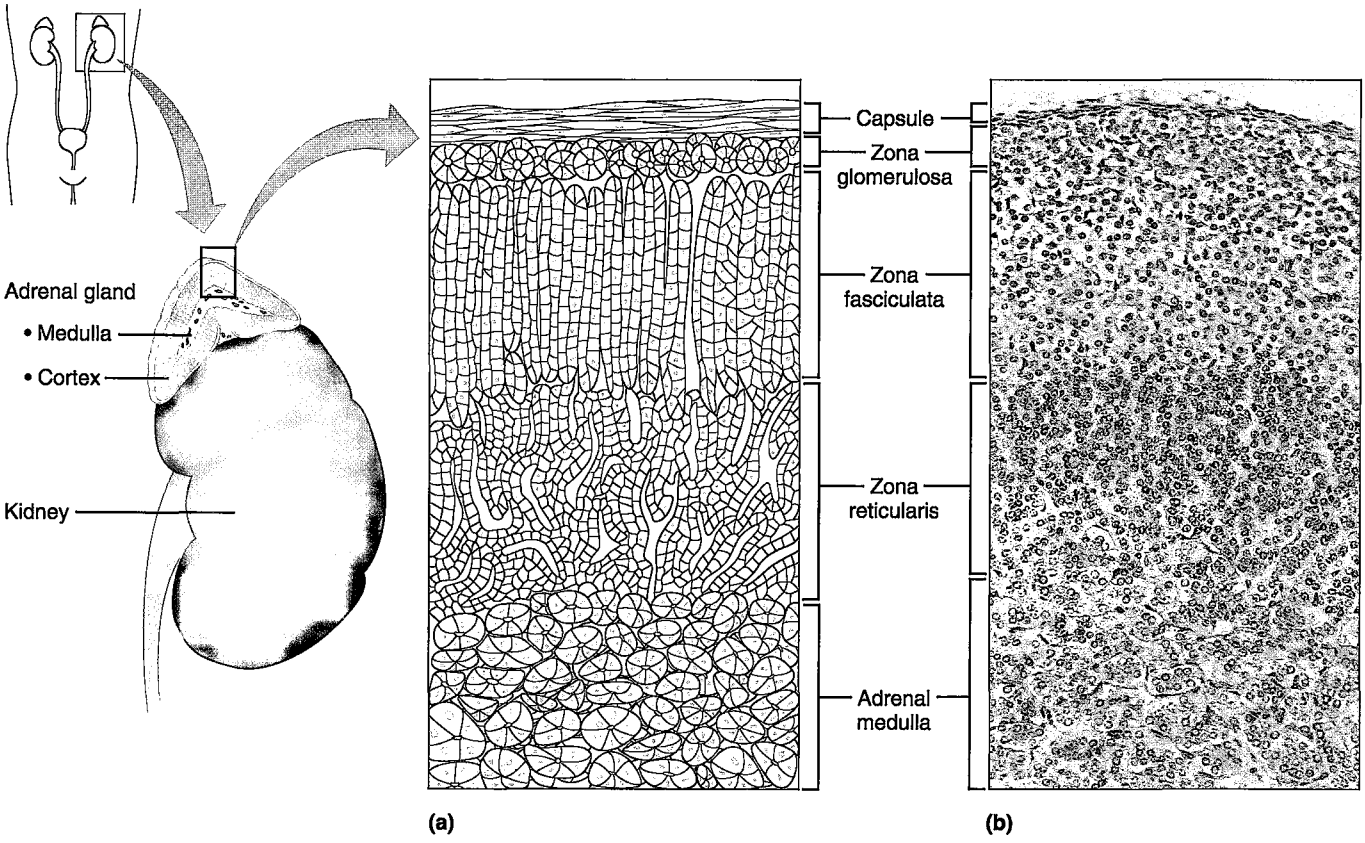

FIGURE 16.13 **Microscopic structure of the adrenal gland. (a)** Diagram and **(b)** photomicrograph of the zona glomerulosa, zona fasciculata, and zona reticularis of the adrenal cortex, and part of the adrenal medulla (200×).

The Adrenal (Suprarenal) Glands

The paired **adrenal glands** are pyramid-shaped organs perched atop the kidneys (*ad* = near; *renal* = kidney), where they are enclosed in a fibrous capsule and a cushion of fat (see Figures 16.1 and 16.13). They are also often referred to as the **suprarenal glands** (*supra* = above).

Each adrenal gland is structurally and functionally two endocrine glands. The inner **adrenal medulla,** more like a knot of nervous tissue than a gland, is part of the sympathetic nervous system. The outer **adrenal cortex,** encapsulating the medullary region and forming the bulk of the gland, is glandular tissue derived from embryonic mesoderm. Each region produces its own set of hormones (Table 16.3), but all adrenal hormones help us cope with stressful situations.

A Zona glomerulosa cells are in clusters, zona fasciculata cells are in parallel cords, and zona reticularis cells have a netlike arrangement.

The Adrenal Cortex

Well over two dozen steroid hormones, collectively called **corticosteroids,** are synthesized from cholesterol by the adrenal cortex. The pathway is multistep and involves varying intermediates depending on the hormone being formed. Unlike the amino acid–based hormones, steroid hormones are not stored in cells. Therefore, their rate of release in response to stimulation depends on their rate of synthesis. The structures of several corticosteroids are illustrated in Table 16.3.

The large, lipid-laden cortical cells are arranged in three layers or zones (Figure 16.13). The cell clusters forming the superficial **zona glomerulosa** (zo'nah glo-mer"u-lo'sah) produce mineralocorticoids, hormones that help control the balance of minerals and water in the blood. The principal products of the middle **zona fasciculata** (fah-sik"u-la'tah) cells, arranged in more or less linear cords, are the metabolic hormones called glucocorticoids. The cells of the innermost **zona reticularis** (rĕ-tik'u-lar-is), abutting the adrenal medulla, have a netlike arrangement. These cells mainly produce

TABLE 16.3 Adrenal Gland Hormones: Summary of Regulation and Effects

HORMONE, STRUCTURE	REGULATION OF OF RELEASE	TARGET ORGAN AND EFFECTS	EFFECTS OF HYPERSECRETION ↑ AND HYPOSECRETION ↓
ADRENOCORTICAL HORMONES			
Mineralocorticoids (chiefly aldosterone)  Aldosterone	Stimulated by renin-angiotensin mechanism (activated by decreasing blood volume or blood pressure), elevated K^+ or low Na^+ blood levels, and ACTH (minor influence); inhibited by increased blood volume and pressure, increased Na^+ and decreased K^+ blood levels	Kidneys: increase blood levels of Na^+ and decrease blood levels of K^+; since water reabsorption accompanies sodium retention, blood volume and blood pressure rise	↑ Aldosteronism ↓ Addison's disease
Glucocorticoids (chiefly cortisol)  Cortisol	Stimulated by ACTH; inhibited by feedback inhibition exerted by cortisol	Body cells: promote gluconeogenesis and hyperglycemia; mobilize fats for energy metabolism; stimulate protein catabolism; assist body to resist stressors; depress inflammatory and immune responses	↑ Cushing's syndrome ↓ Addison's disease
Gonadocorticoids (chiefly androgens, converted to testosterone or estrogens after release)  Testosterone	Stimulated by ACTH; mechanism of inhibition incompletely understood, but feedback inhibition not seen	Insignificant effects in males; responsible for female libido; development of pubic and axillary hair in females; source of estrogen after menopause	↑ Virilization of females (adrenogenital syndrome) ↓ No effects known
ADRENAL MEDULLARY HORMONES			
Catecholamines (epinephrine and norepinephrine)  Epinephrine	Stimulated by preganglionic fibers of the sympathetic nervous system	Sympathetic nervous system target organs: effects mimic sympathetic nervous system activation; increase heart rate and metabolic rate; increase blood pressure by promoting vasoconstriction	↑ Prolonged fight-or-flight response; hypertension ↓ Unimportant

small amounts of adrenal sex hormones, or gonadocorticoids. Note, however, that the two innermost layers of the adrenal cortex share production of glucocorticoids and gonadocorticoids, although each layer is the predominant producer of one type.

Mineralocorticoids The essential function of **mineralocorticoids** is regulation of the electrolyte (mineral salt) concentrations in extracellular fluids, particularly of Na^+ and K^+. The single most abundant cation in extracellular fluid is Na^+, and although this ion is vital to homeostasis, excessive sodium intake and retention may promote high blood pressure (hypertension) in susceptible individuals. Although there are several mineralocorticoids, **aldosterone** (al-dos'ter-ōn) is the most potent and

Q In controlling blood pressure, how do the response times compare for this hormonal mechanism and the action of sympathetic nerves?

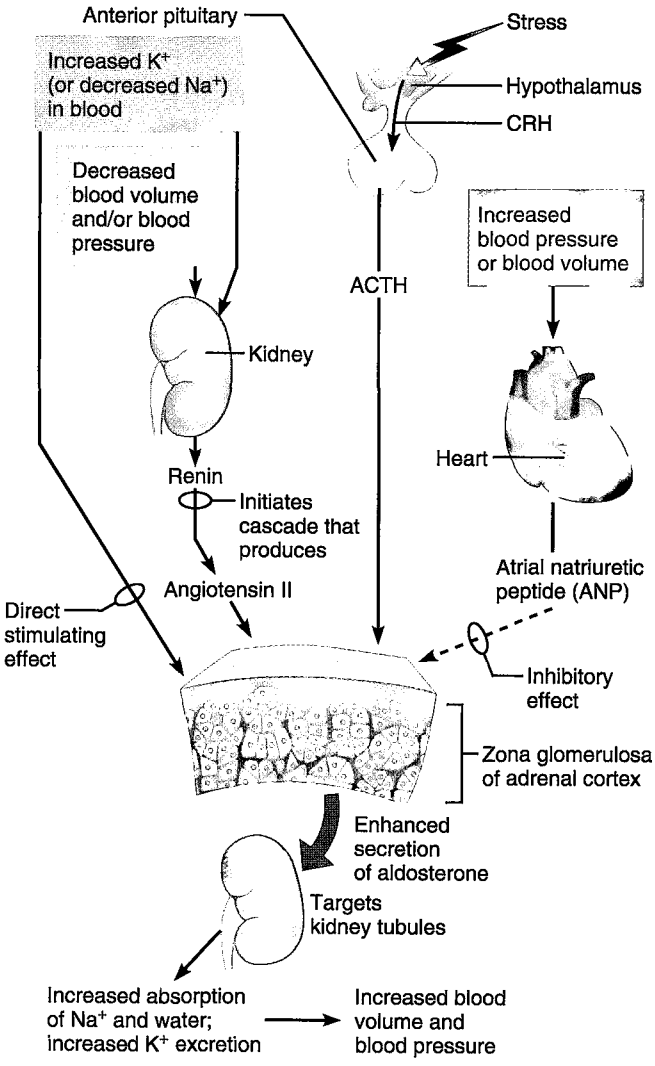

FIGURE 16.14 **Major mechanisms controlling aldosterone release from the adrenal cortex.**

accounts for more than 95% of the mineralocorticoids produced. As you might guess, maintaining sodium ion balance is aldosterone's primary job.

Aldosterone reduces excretion of Na^+ from the body. Its primary target is the distal parts of the kidney tubules, where it stimulates Na^+ reabsorption from the forming urine and its return to the bloodstream. Aldosterone also enhances Na^+ reabsorption from perspiration, saliva, and gastric juice. The mechanism of aldosterone activity involves the synthesis and activation of proteins required for Na^+ transport such as Na^+-K^+ ATPase, the sodium pump that exchanges K^+ for Na^+.

Regulation of a number of other ions, including K^+, H^+, HCO_3^- (bicarbonate), and Cl^- (chloride), is coupled to that of Na^+; and where Na^+ goes, water follows—an event that leads to changes in blood volume and blood pressure. Hence, Na^+ regulation is crucial to overall body homeostasis. Briefly, aldosterone's effects on the renal tubules cause sodium and water retention accompanied by elimination of K^+ and, in some instances, alterations in the acid-base balance of the blood (by H^+ excretion). Because aldosterone's regulatory effects are brief (lasting approximately 20 minutes), plasma electrolyte balance can be precisely controlled and modified continuously.

Although this discussion represents the major roles of bloodborne aldosterone produced by the adrenal cortex, aldosterone is also secreted by cardiovascular organs, where it is a paracrine and plays a completely different role in cardiac regulation.

Aldosterone secretion is stimulated by rising blood levels of K^+, low blood levels of Na^+, and decreasing blood volume and blood pressure. The reverse conditions inhibit aldosterone secretion. Four mechanisms regulate aldosterone secretion (Figure 16.14); these mechanisms are described next.

1. The renin-angiotensin mechanism (re'nin an"je-o-ten'sin). The renin-angiotensin mechanism, the major regulator of aldosterone release, influences both blood volume and blood pressure. Specialized cells of the *juxtaglomerular apparatus* in the kidneys become excited when blood pressure (or blood volume) declines. These cells respond by releasing **renin** into the blood. Renin cleaves off part of the plasma protein **angiotensinogen** (an"je-o-ten'sin-o-gen), triggering an enzymatic cascade leading to the formation of **angiotensin II,** a potent stimulator of aldosterone release by the glomerulosa cells. However, the renin-angiotensin mechanism does much more than trigger aldosterone release, and all of its effects are ultimately involved in raising the blood pressure. These additional effects are described in detail in Chapters 25 and 26.

2. Plasma concentrations of potassium and sodium ions. Fluctuating blood levels of K^+ directly influence the zona glomerulosa cells. Increased K^+ stimulates, whereas decreased K^+ inhibits aldosterone release. Large decreases in Na^+ directly cause a slight increase in aldosterone release.

3. ACTH. Under normal circumstances, ACTH released by the anterior pituitary has little or no effect on aldosterone release. However, when a person is severely stressed, the hypothalamus secretes more corticotropin-releasing hormone (CRH), and the rise in ACTH blood levels that follows steps up the rate

A The hormonal response is much slower because the "messengers" are bloodborne hormones instead of nerve impulses and neurotransmitters.

of aldosterone secretion to a small extent. The increase in blood volume and blood pressure that results helps ensure adequate delivery of nutrients and respiratory gases during the stressful period.

4. Atrial natriuretic peptide (ANP). Atrial natriuretic peptide, a hormone secreted by the heart when blood pressure rises, fine-tunes blood pressure and sodium-water balance of the body. Its major effect is to inhibit the renin-angiotensin mechanism: It blocks renin and aldosterone secretion and inhibits other angiotensin-induced mechanisms that enhance water and Na^+ reabsorption. Consequently, ANP's overall influence is to decrease blood pressure by allowing Na^+ (and water) to flow out of the body in urine (*natriuretic* = producing salty urine).

HOMEOSTATIC IMBALANCE

Hypersecretion of aldosterone, a condition called *aldosteronism,* typically results from adrenal neoplasms. Two major sets of problems result: (1) hypertension and edema due to excessive Na^+ and water retention and (2) accelerated excretion of potassium ions. If K^+ loss is extreme, neurons become nonresponsive and muscle weakness (and eventually paralysis) occurs. *Addison's disease,* a hyposecretory disease of the adrenal cortex, generally involves a deficient output of both mineralocorticoids and glucocorticoids, as described shortly.

Glucocorticoids Essential to life, the **glucocorticoids** influence the energy metabolism of most body cells and help us to resist stressors. Under normal circumstances, they help the body adapt to intermittent food intake by keeping blood glucose levels fairly constant, and maintain blood pressure by increasing the action of vasoconstrictors. However, severe stress due to hemorrhage, infection, or physical or emotional trauma evokes a dramatically higher output of glucocorticoids, which helps the body negotiate the crisis. Glucocorticoid hormones include **cortisol (hydrocortisone)** (see Table 16.3), **cortisone,** and **corticosterone,** but only cortisol is secreted in significant amounts in humans. As for all steroid hormones, the basic mechanism of glucocorticoid activity on target cells is to modify gene activity.

Glucocorticoid secretion is regulated by negative feedback. Cortisol release is promoted by ACTH, triggered in turn by the hypothalamic releasing hormone CRH. Rising cortisol levels feed back to act on both the hypothalamus and the anterior pituitary, preventing CRH release and shutting off ACTH and cortisol secretion. Cortisol secretory bursts, driven by patterns of eating and activity, occur in a definite pattern throughout the day and night. Cortisol blood levels peak shortly before we arise in the morning. The lowest levels occur in the evening just before and shortly after we fall asleep. The normal cortisol rhythm is interrupted by acute stress of any variety as the sympathetic nervous system overrides the (usually) inhibitory effects of elevated cortisol levels and triggers CRH release. The resulting increase in ACTH blood levels causes an outpouring of cortisol from the adrenal cortex.

Stress results in a dramatic rise in blood levels of glucose, fatty acids, and amino acids, all provoked by cortisol. Cortisol's prime metabolic effect is to provoke *gluconeogenesis,* that is, the formation of glucose from fats and proteins. In order to "save" glucose for the brain, cortisol mobilizes fatty acids from adipose tissue and encourages their increased use for energy. Under cortisol's influence, stored proteins are broken down to provide building blocks for repair or for making enzymes to be used in metabolic processes. Cortisol enhances epinephrine's vasoconstrictive effects, and the rise in blood pressure and circulatory efficiency that results helps ensure that these nutrients are quickly distributed to the cells.

Although *ideal amounts of glucocorticoids promote normal function,* significant anti-inflammatory and anti-immune effects are associated with cortisol excess. Excessive levels of glucocorticoids (1) depress cartilage and bone formation, (2) inhibit inflammation by decreasing the release of inflammatory chemicals and preventing vasodilation, (3) depress the immune system, and (4) promote changes in cardiovascular, neural, and gastrointestinal function. Recognition of the effects of glucocorticoid hypersecretion has led to widespread use of glucocorticoid drugs to control symptoms of many chronic inflammatory disorders, such as rheumatoid arthritis or allergic responses. However, these potent drugs are a double-edged sword. Although they relieve some of the symptoms of these disorders, they also cause the undesirable effects of excessive levels of these hormones.

HOMEOSTATIC IMBALANCE

The pathology of glucocorticoid excess, **Cushing's syndrome,** may be caused by an ACTH-releasing pituitary tumor (in which case, it is called **Cushing's disease**); by an ACTH-releasing malignancy of the lungs, pancreas, or kidneys; or by a tumor of the adrenal cortex. However, it most often results from the clinical administration of pharmacological doses (doses higher than those found in the body) of glucocorticoid drugs. The syndrome is characterized by persistent hyperglycemia *(steroid diabetes),* dramatic losses in muscle and bone protein, and water and salt retention, leading to hypertension and edema. The so-called *cushingoid signs* (Figure 16.15) include a swollen "moon" face, redistribution of fat to the abdomen and the posterior neck (causing a "buffalo hump"), a tendency to bruise, and poor wound

(a) (b)

FIGURE 16.15 **A patient (a) before and (b) during Cushing's disease.** In (b), the characteristic "buffalo hump" of fat on the upper back is indicated by a white arrow.

16

healing. Because of enhanced anti-inflammatory effects, infections may become overwhelmingly severe before producing recognizable symptoms. Eventually, muscles weaken and spontaneous fractures force the person to become bedridden. The only treatment is removal of the cause—be it surgical removal of the offending tumor or discontinuation of the drug.

Addison's disease, the major hyposecretory disorder of the adrenal cortex, usually involves deficits in both glucocorticoids and mineralocorticoids. Its victims tend to lose weight; their plasma glucose and sodium levels drop and potassium levels rise. Severe dehydration and hypotension are common. Corticosteroid replacement therapy at physiological doses (doses typical of those normally found in the body) is the usual treatment. ●

Gonadocorticoids (Sex Hormones) The bulk of the **gonadocorticoids** secreted by the adrenal cortex are weak **androgens,** or male sex hormones, such as *androstenedione* and *dehydroepiandrosterone (DHEA)*. These are converted to the more potent male hormone, *testosterone,* in the tissue cells or to estrogens (female sex homones) in females (see Table 16.3). The adrenal cortex also makes small amounts of female hormones (estradiol and other estrogens). The amount of gonadocorticoids produced by the adrenal cortex is insignificant compared with the amounts made by the gonads during late puberty and adulthood. The exact role of the adrenal sex hormones is still in question, but because adrenal androgen levels rise continuously between the ages of 7 and 13 in both boys and girls, it is assumed that these hormones contribute to the onset of puberty and the appearance of axillary and pubic hair during that time. In adult women adrenal androgens are thought to be responsible for the sex drive, and they may account for the estrogens produced after menopause when ovarian estrogens are no longer produced. Control of gonadocorticoid secretion is not completely understood. Release seems to be stimulated by ACTH, but the gonadocorticoids do not appear to exert feedback inhibition on ACTH release.

HOMEOSTATIC IMBALANCE

Since androgens predominate, hypersecretion of gonadocorticoids causes *adrenogenital syndrome* (masculinization). In adult males, these effects of elevated gonadocorticoid levels may be obscured, since testicular testosterone has already produced virilization; but in prepubertal males and in females, the results can be dramatic. In the young man, maturation of the reproductive organs and appearance of the secondary sex characteristics occur rapidly, and the sex drive emerges with a vengeance. Females develop a beard

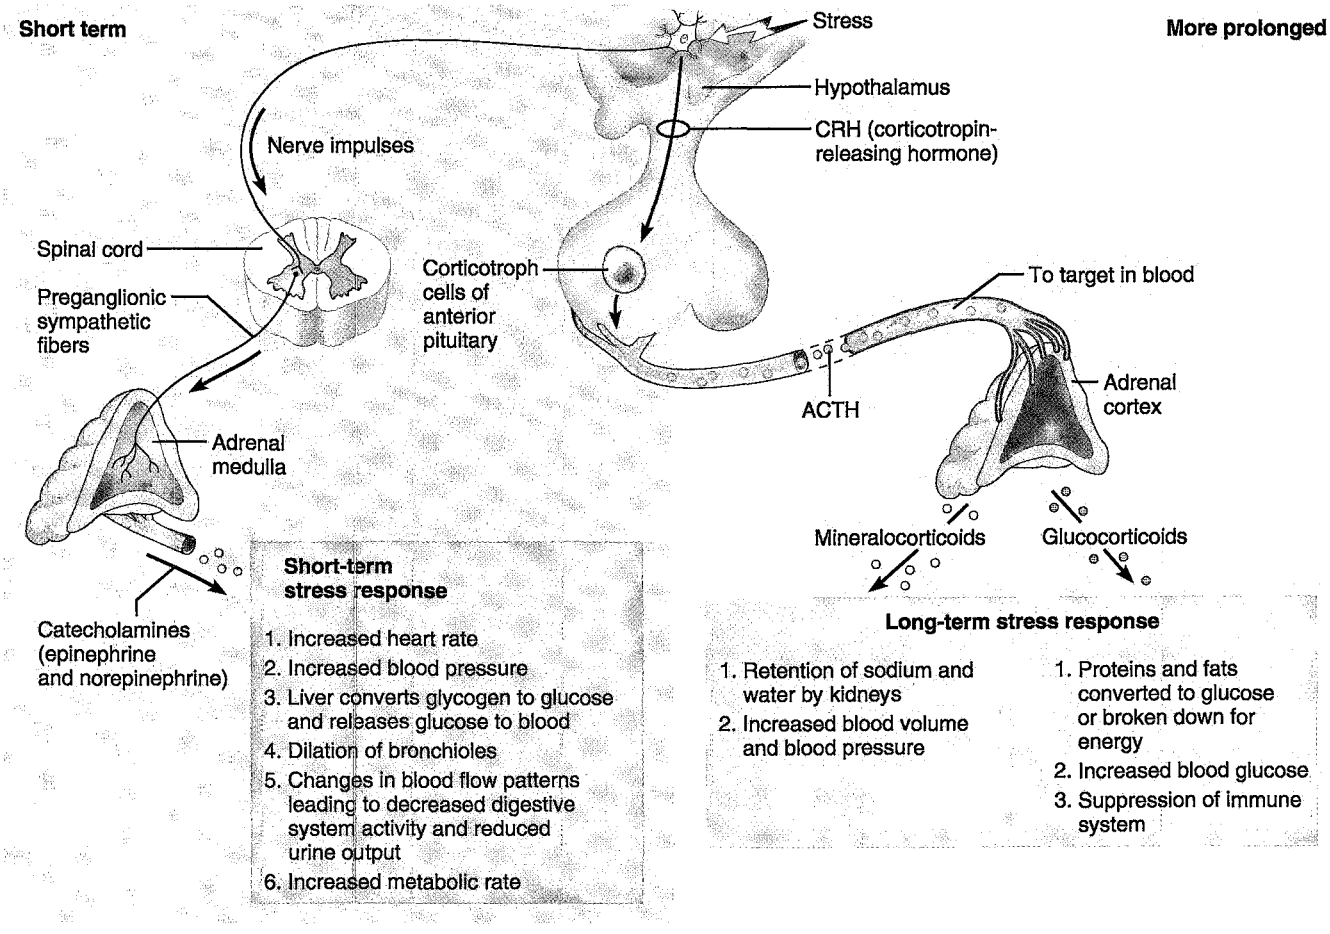

FIGURE 16.16 **Stress and the adrenal gland.** Stressful stimuli cause the hypothalamus to activate the adrenal medulla via sympathetic nerve impulses and the adrenal cortex via hormonal signals. The medulla mediates short-term responses to stress by secreting epinephrine and norepinephrine. The cortex controls more prolonged responses by secreting steroid hormones.

and a masculine pattern of body hair distribution, and the clitoris grows to resemble a small penis. ●

The Adrenal Medulla

Because it is discussed in Chapter 14 as part of the autonomic nervous system, the adrenal medulla is covered only briefly here. Its spherical **chromaffin cells** (kro-maf'in), which crowd around blood-filled capillaries and sinusoids, are modified ganglionic sympathetic neurons that synthesize the *catecholamines* **epinephrine** and **norepinephrine (NE)** via a molecular sequence from tyrosine to dopamine to NE to epinephrine (see Figure 11.21).

When the body is activated to fight-or-flight status by some short-term stressor, the sympathetic nervous system is mobilized: Blood glucose levels rise, blood vessels constrict and the heart beats faster (together raising the blood pressure), blood is diverted from temporarily nonessential organs to the heart and skeletal muscles, and preganglionic sympathetic nerve endings weaving through the adrenal medulla signal for release of catecholamines, which reinforce and prolong the fight-or-flight response.

Unequal amounts of the two hormones are stored and released; approximately 80% is epinephrine and 20% norepinephrine. With a few exceptions, the two hormones exert the same effects (Table 14.3, p. 544). Epinephrine is the more potent stimulator of metabolic activities, bronchial dilation, and increased blood flow to skeletal muscles and the heart, but norepinephrine has the greater influence on peripheral vasoconstriction and blood pressure. Epinephrine is used clinically as a heart stimulant and to dilate the bronchioles during acute asthmatic attacks.

Unlike the adrenocortical hormones, which promote long-lasting body responses to stressors, catecholamines cause fairly brief responses. The interrelationships of the adrenal hormones and the hypothalamus, the "director" of the stress response, are depicted in Figure 16.16.

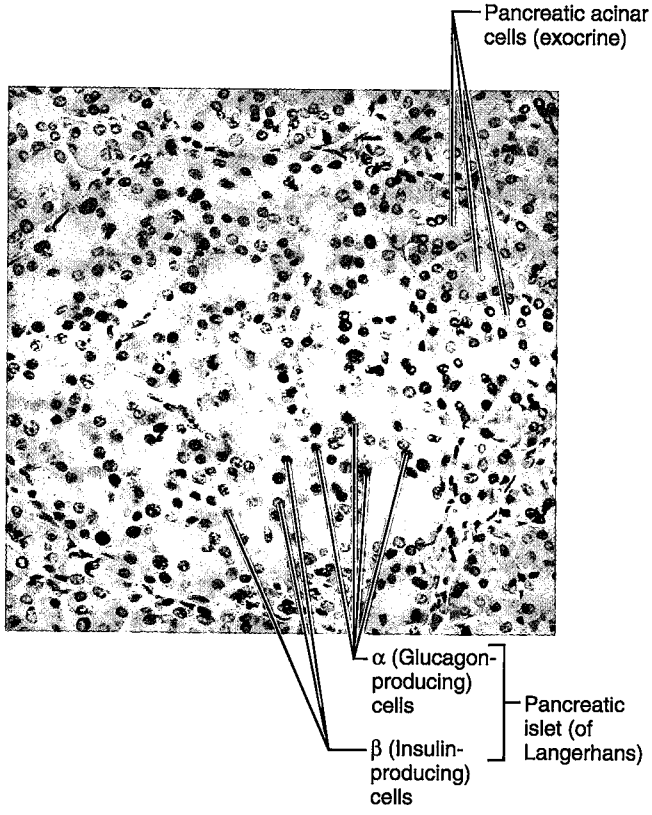

FIGURE 16.17 **Photomicrograph of pancreatic tissue, differentially stained.** A pancreatic islet is surrounded by blue-gray acinar cells, which produce the exocrine product (enzyme-rich pancreatic juice). In this preparation, the β cells of the islets that produce insulin are stained pale pink, and the α cells that produce glucagon are stained bright pink (150×).

16

HOMEOSTATIC IMBALANCE

Because hormones of the adrenal medulla merely intensify activities set into motion by the sympathetic nervous system neurons, a deficiency of these hormones is not a problem. Unlike glucocorticoids, adrenal catecholamines are not essential for life. However, hypersecretion of catecholamines, sometimes arising from a chromaffin cell tumor called a *pheochromocytoma* (fe-o-kro"mo-si-to'mah), produces symptoms of uncontrolled sympathetic nervous system activity—hyperglycemia, increased metabolic rate, rapid heartbeat and palpitations, hypertension, intense nervousness, and sweating. ●

The Pancreas

Located partially behind the stomach in the abdomen, the soft, triangular **pancreas** is a mixed gland composed of both endocrine and exocrine gland cells (Figure 16.1). Along with the thyroid and parathyroids, it develops as an outpocketing of the epithelial lining of the gastrointestinal tract. *Acinar cells,* forming the bulk of the gland, produce an enzyme-rich juice that is ducted into the small intestine during food digestion.

Scattered among the acinar cells are approximately a million **pancreatic islets** (also called **islets of Langerhans**), tiny cell clusters that produce pancreatic hormones (Figure 16.17). The islets contain two major populations of hormone-producing cells, the glucagon-synthesizing **alpha (α) cells** and the more numerous insulin-producing **beta (β) cells.** These cells act as tiny fuel sensors, secreting glucagon and insulin appropriately during the fasting and fed states. Thus insulin and glucagon are intimately but independently involved in the regulation of blood glucose levels. Their effects are antagonistic: Insulin is a *hypoglycemic* hormone, whereas glucagon is a *hyperglycemic* hormone (Figure 16.18). Some islet cells also synthesize other peptides in small amounts. These include *somatostatin, pancreatic polypeptide (PP),* and others. However, these will not be dealt with here.

Glucagon

Glucagon (gloo'kah-gon), a 29-amino-acid polypeptide, is an extremely potent hyperglycemic agent. One molecule of this hormone can cause the release of 100 million molecules of glucose into the blood! The major target of glucagon is the liver, where it promotes the following actions (Figure 16.18):

1. Breakdown of glycogen to glucose (*glycogenolysis*)
2. Synthesis of glucose from lactic acid and from noncarbohydrate molecules (*gluconeogenesis*)
3. Release of glucose to the blood by liver cells, which causes blood glucose levels to rise

A secondary effect is a fall in the amino acid concentration in the blood as the liver cells sequester these molecules to make new glucose molecules.

Secretion of glucagon by the alpha cells is prompted by humoral stimuli, mainly falling blood glucose levels. However, sympathetic nervous system stimulation and rising amino acid levels (as might follow a protein-rich meal) are also stimulatory. Glucagon release is suppressed by rising blood glucose levels, insulin, and somatostatin.

Insulin

Insulin is a small (51-amino-acid) protein consisting of two amino acid chains linked by disulfide (–S–S–) bonds. It is synthesized as part of a larger polypeptide chain called **proinsulin.** The middle portion of this chain is then excised by enzymes, releasing functional insulin. This "clipping" process occurs in the secretory vesicles just before insulin is released from the beta cell.

Insulin's effects are most obvious when we have just eaten. Its main effect is to lower blood glucose

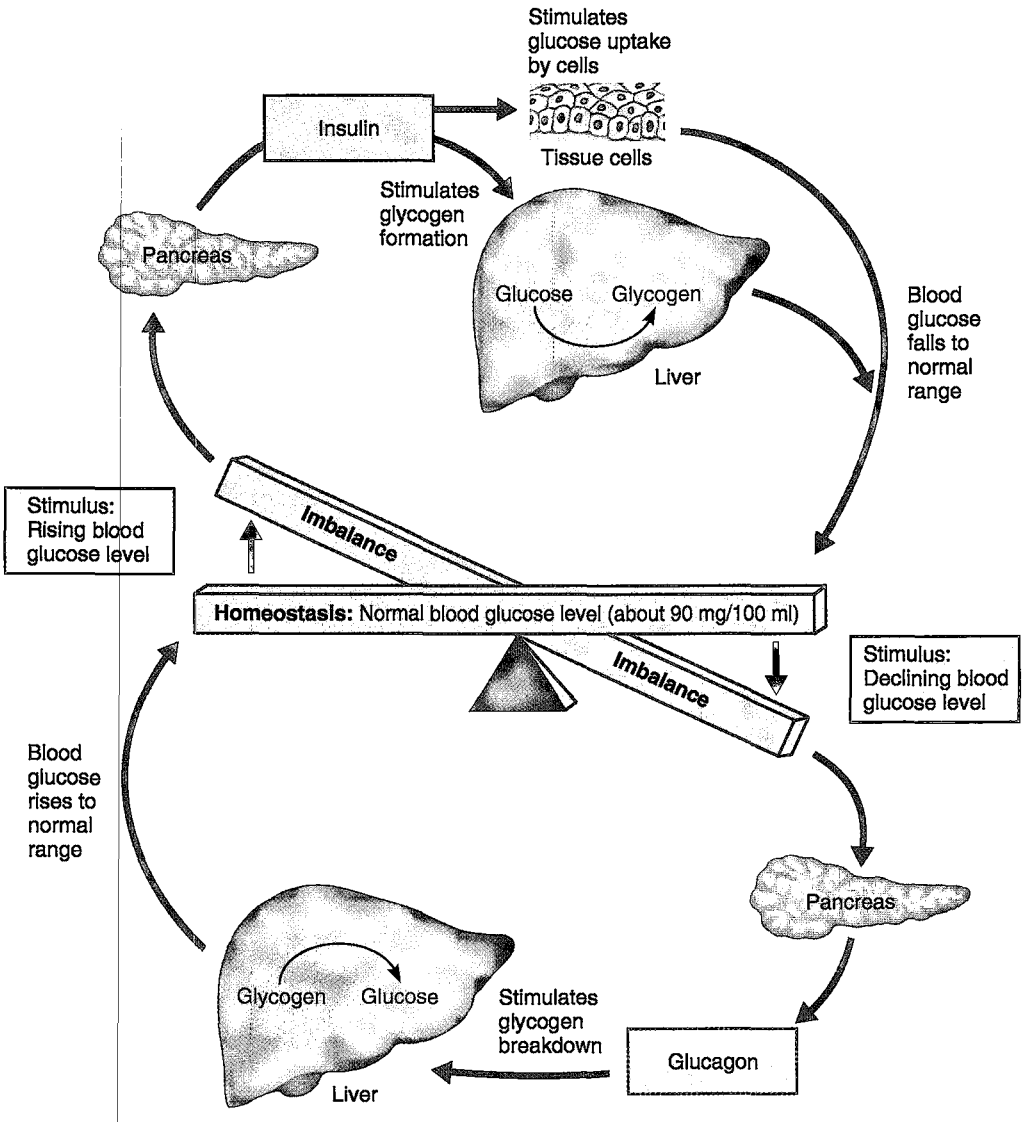

FIGURE 16.18 **Regulation of blood glucose levels by insulin and glucagon.** When blood glucose levels are high, the pancreas releases the hypoglycemic hormone insulin, which stimulates glucose uptake by cells and glycogen formation in the liver, so that blood glucose levels are lowered. When blood glucose levels are low, the pancreas releases the hyperglycemic hormone glucagon, which stimulates glycogen breakdown and thereby increases the amount of blood glucose.

levels (Figure 16.18), but it also influences protein and fat metabolism. Circulating insulin lowers blood glucose levels by enhancing membrane transport of glucose (and other simple sugars) into body cells, especially muscle and fat cells. (It does *not* accelerate glucose entry into liver, kidney, and brain* tissue, all of which have easy access to blood glucose regardless of insulin levels.) Insulin inhibits the breakdown of glycogen to glucose and the conversion of amino acids or fats to glucose; thus, it counters any metabolic activity that would increase plasma levels of glucose. At the cellular level, insulin activates its receptor (a tyrosine kinase enzyme), which phosphorylates specific proteins, beginning the cascade that leads to increased glucose uptake and insulin's other effects.

After glucose enters a target cell, insulin binding triggers enzymatic activities that

1. Catalyze the oxidation of glucose for ATP production
2. Join glucose molecules together to form glycogen
3. Convert glucose to fat (particularly in adipose tissue)

*However, insulin does have important roles in the brain. It participates in neuronal development, feeding behavior, and learning and memory.

As a rule, energy needs are met first, followed by glycogen formation. Finally, if excess glucose is still available, it is converted to fat. Insulin also stimulates amino acid uptake and protein synthesis in muscle tissue. In summary, insulin sweeps glucose out of the blood, causing it to be used for energy or converted to other forms (glycogen or fats), and it promotes protein synthesis and fat storage.

Pancreatic beta cells are stimulated to secrete insulin chiefly by elevated blood glucose levels, but rising plasma levels of amino acids and fatty acids, and release of acetylcholine by parasympathetic nerve fibers, also trigger insulin release. As body cells take up glucose and other nutrients, and plasma levels of these substances drop, insulin secretion is suppressed. Other hormones also influence insulin release. For example, any hyperglycemic hormone (such as glucagon, epinephrine, growth hormone, thyroxine, or glucocorticoids) called into action as blood glucose levels drop indirectly stimulates insulin release by promoting glucose entry into the bloodstream. Somatostatin depresses insulin release. Thus, blood glucose levels represent a balance of humoral and hormonal influences. Insulin and (indirectly) somatostatin are the hypoglycemic factors that counterbalance the many hyperglycemic hormones.

16

HOMEOSTATIC IMBALANCE

Diabetes mellitus (DM) results from either hyposecretion or hypoactivity of insulin. When insulin is absent or deficient, blood glucose levels remain high after a meal because glucose is unable to enter most tissue cells. Ordinarily, when blood glucose levels rise, hyperglycemic hormones are not released, but when hyperglycemia becomes excessive, the person begins to feel nauseated, which precipitates the fight-or-flight response. This results, inappropriately, in all the reactions that normally occur in the hypoglycemic (fasting) state to make glucose available—that is, glycogenolysis, lipolysis (breakdown of fat), and gluconeogenesis. Thus, the already high blood glucose levels soar even higher, and excesses of glucose begin to be lost from the body in the urine *(glycosuria)*.

When sugars cannot be used as cellular fuel, more fats are mobilized, resulting in high fatty acid levels in the blood, a condition called lipidemia or lipemia. In severe cases of diabetes mellitus, blood levels of fatty acids and their metabolites (acetoacetic acid, acetone, and others) rise dramatically. The fatty acid metabolites, collectively called **ketones** (ke'tōnz) or **ketone bodies,** are organic acids. When they accumulate in the blood, the blood pH drops, resulting in **ketoacidosis,** and ketone bodies begin to spill into the urine *(ketonuria)*. Severe ketoacidosis is life threatening. The nervous system responds by initiating rapid deep breathing (hyperpnea) to blow off carbon dioxide from the blood and increase blood pH. (The physiological basis of this mechanism is explained in Chapter 22.) If untreated, ketoacidosis disrupts heart activity and oxygen transport, and severe depression of the nervous system leads to coma and death.

The three cardinal signs of diabetes mellitus are polyuria, polydipsia, and polyphagia. The excessive glucose in the kidney filtrate acts as an osmotic diuretic (that is, it inhibits water reabsorption by the kidney tubules), resulting in **polyuria,** a huge urine output that leads to decreased blood volume and dehydration. Serious electrolyte losses also occur as the body rids itself of excess ketone bodies. Ketone bodies are negatively charged and carry positive ions out with them; as a result, sodium and potassium ions are also lost from the body. Because of the electrolyte imbalance, the person gets abdominal pains and may vomit, and the stress reaction spirals even higher. Dehydration stimulates hypothalamic thirst centers, causing **polydipsia,** or excessive thirst. The final sign, **polyphagia,** refers to excessive hunger and food consumption, a sign that the person is "starving in the land of plenty." Although plenty of glucose is available, it cannot be used, and the body starts to utilize its fat and protein stores for energy metabolism. Figure 16.19 summarizes the consequences of insulin deficiency. DM is discussed in greater detail in *A Closer Look* on pp. 636–637.

Hyperinsulinism, or excessive insulin secretion, results in low blood glucose levels, or **hypoglycemia.** This condition triggers the release of hyperglycemic hormones, which cause anxiety, nervousness, tremors, and weakness. Insufficient glucose delivery to the brain causes disorientation, progressing to convulsions, unconsciousness, and even death. In rare cases, hyperinsulinism results from an islet cell tumor. More commonly, it is caused by an overdose of insulin and is easily treated by ingesting some sugar. ●

The Gonads

The male and female **gonads** (see Figure 16.1) produce steroid sex hormones, identical to those produced by adrenal cortical cells. The major distinction is the source and relative amounts produced. The paired *ovaries* are small, oval organs located in the female's abdominopelvic cavity. Besides producing ova, or eggs, the ovaries produce several hormones, most importantly **estrogens** and **progesterone** (pro-jes'té-rōn). Alone, the estrogens are

Organs/tissue involved	Organ/tissue responses to insulin deficiency	Resulting conditions:		Signs and symptoms
		In blood	In urine	
	Decreased glucose uptake and utilization	Hyperglycemia	Glycosuria	Polyuria (and dehydration, soft eyeballs)
	Glycogenolysis		Osmotic diuresis	Polydipsia (and fatigue, weight loss)
	Protein catabolism and gluconeogenesis			Polyphagia
	Lipolysis and ketogenesis	Lipidemia and ketoacidosis	Ketonuria	Acetone breath
				Hyperpnea
			Loss of Na^+, K^+; electrolyte and acid-base imbalances	Nausea/vomiting/ abdominal pain
				Cardiac irregularities
				Central nervous system depression; coma
= Muscle = Adipose tissue = Liver				

FIGURE 16.19 **Symptomatic results of insulin deficit (diabetes mellitus).**

responsible for maturation of the reproductive organs and the appearance of the secondary sex characteristics of females at puberty. Acting with progesterone, estrogens promote breast development and cyclic changes in the uterine mucosa (the menstrual cycle).

The male *testes*, located in an extra-abdominal skin pouch called the scrotum, produce sperm and male sex hormones, primarily **testosterone** (testos'té-rōn). During puberty, testosterone initiates the maturation of the male reproductive organs and the appearance of secondary sex characteristics and sex drive. In addition, testosterone is necessary for normal sperm production and maintains the reproductive organs in their mature functional state in adult males.

The release of gonadal hormones is regulated by gonadotropins, as described earlier. We will discuss the roles of the gonadal, placental, and gonadotropic hormones in detail in Chapters 27 and 28, where we consider the reproductive system and pregnancy.

The Pineal Gland

The tiny, pine cone–shaped **pineal gland** hangs from the roof of the third ventricle in the diencephalon (see Figure 16.1). Its secretory cells, called **pinealocytes,** are arranged in compact cords and clusters. Lying between pinealocytes in adults are dense particles containing calcium salts ("brain-sand" or "pineal sand"). These salts are radiopaque; hence, the pineal gland is a handy landmark for determining brain orientation in X rays.

The endocrine function of the pineal gland is still somewhat of a mystery. Although many peptides and amines have been isolated from this minute gland, its only major secretory product is **melatonin** (mel"ah-to'nin), a powerful antioxidant and amine hormone derived from serotonin. Melatonin concentrations in the blood rise and fall in a diurnal (daily) cycle. Peak levels occur during the night and make us drowsy; lowest levels occur around noon.

The pineal gland indirectly receives input from the visual pathways (retina → suprachiasmatic nucleus of hypothalamus → superior cervical ganglion → pineal gland) concerning the intensity and duration of daylight. In some animals, mating behavior and gonadal size vary with changes in the relative lengths of light and dark periods, and melatonin mediates these effects. In children, melatonin may have an antigonadotropic effect, that is, it may inhibit precocious (too early) sexual maturation and thus affect the timing of puberty.

The *suprachiasmatic nucleus* of the hypothalamus, an area referred to as our "biological clock," is richly supplied with melatonin receptors, and exposure to bright light (known to suppress melatonin secretion) can reset the clock timing. Hence, changing melatonin levels may also be a means by which the day/night cycles influence physiological processes

A CLOSER LOOK

Sweet Revenge: Can Biotechnology Tame the DM Monster?

Few medical breakthroughs have been as electrifying as the discovery of insulin in 1921, an event that changed diabetes mellitus from a death sentence to a survivable disease. Nonetheless, DM is still a huge health problem: Determining blood glucose levels accurately and maintaining desirable levels sorely challenge our present biotechnology. Let's take a closer look at the characteristics and challenges of type 1 and type 2, the major forms of diabetes mellitus.

More than 1 million Americans have **type 1 diabetes mellitus,** formerly called *insulin-dependent diabetes mellitus (IDDM).* Symptoms appear suddenly, usually before age 15. However, a long asymptomatic period during which the beta cells are systemically destroyed by an autoimmune response precedes these symptoms.

Type 1 diabetes susceptibility genes have been localized on several chromosomes, indicating that type 1 diabetes is an example of a multigene autoimmune response. However, some investigators believe that *molecular mimicry* is at least part of the problem: Some foreign substance (for example, a virus) has entered the body and is so similar to certain self (beta cell) proteins that the immune system attacks the beta cells as well as the invader.

Indeed, elegant studies on certain strains of diabetic mice, stressed by infections or other irritants, demonstrated that they produced increasing amounts of a particular stress protein (heat shock protein 60) and also churned out antibodies against that stress protein. When fragments of the stress protein called p277 were injected into other mice showing early signs of diabetes, the beta cells were spared from the autoimmune attack. This study was extended to newly diagnosed human diabetic subjects, who received the fragment as a drug called DiaPep277. By the end of the study, those receiving DiaPep277 hardly needed outside insulin while those receiving the placebo needed an increasing amount as time went on.

Type 1 diabetics totally lack insulin activity, and their disease is difficult to control. Typically they develop long-term vascular and neural problems. The lipidemia and high blood cholesterol levels typical of the disease can lead to severe vascular complications including atherosclerosis, strokes, heart attacks, renal shutdown, gangrene, and blindness. Consequences of neuropathies include loss of sensation, impaired bladder function, and impotence. Female type 1 diabetics also tend to have lumpy breasts and to undergo premature menopause, which increases their risk for cardiac problems. Some diabetics can delay renal damage by taking drugs to manage high blood pressure.

Previously, the protocol was insulin injections once or twice daily to manage ketoacidosis and, to a lesser extent, hyperglycemia. Currently, more frequent insulin injections (up to four times daily, or better yet, by a continuous infusion pump) are recommended to reduce vascular and renal complications. Add a glucose sensor and a small computer to an insulin pump and you could have an artificial pancreas that would dispense insulin as needed. Such devices are being tested, but problems with glucose sensing and calculating the amount of insulin to dispense have so far confined such devices to the laboratory. A number of alternative insulin delivery methods are also in clinical trials, including insulin mist inhalers and insulin patches.

Pancreatic islet cell transplants have become increasingly successful in helping type 1 diabetics, with 84% of patients needing no injected insulin after three years. The need for long-term immunosuppression, however, limits this treatment to only those diabetics who cannot control their blood glucose by any other means.

Over 90% of known DM cases are **type 2 diabetes mellitus,** formerly called *non-insulin-dependent*

that show rhythmic variations, such as body temperature, sleep, and appetite.

The Thymus

Located deep to the sternum in the thorax is the lobulated **thymus gland.** Large and conspicuous in infants and children, the thymus diminishes in size throughout adulthood. By old age, it is composed largely of adipose and fibrous connective tissues.

The major hormonal product of the thymic epithelial cells is a family of peptide hormones, including **thymopoietins, thymic factor,** and **thymosins** (thi'mo-sinz), which appear to be essential for the normal development of *T lymphocytes* and the immune response. Thymic hormones are described in Chapter 21 with the discussion of the immune system.

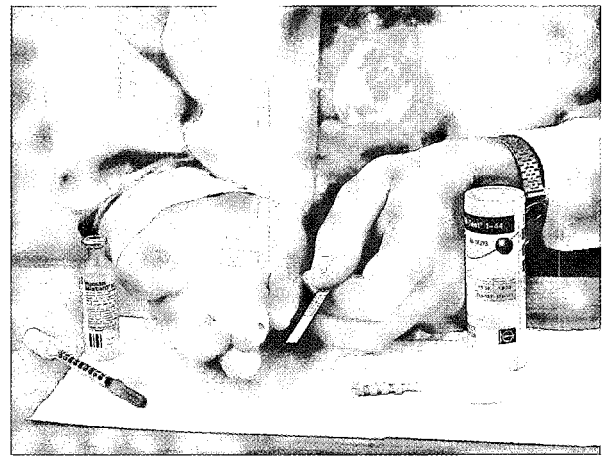
Other Hormone-Producing Structures

Other hormone-producing cells occur in various organs of the body, including the following (see Table 16.4):

diabetes mellitus (NIDDM), which grows increasingly common with age. About 12 million people in the U.S. have been diagnosed with type 2 diabetes, and roughly half as many are believed to be undiagnosed victims. Although ketoacidosis is not a major problem for type 2 diabetics, they are at risk for the same complications as type 1 diabetics—heart disease, amputations, kidney failure, and blindness.

Heredity or a familial predisposition is particularly striking in this diabetic group. An estimated 25–30% of Americans carry a gene that predisposes them to type 2 diabetes, with nonwhites affected to a much greater extent. If an identical twin has type 2 diabetes mellitus, the probability that the other twin will have the disease is 100%. Most type 2 diabetics produce insulin, but for some reason the insulin receptors are unable to respond to it, a phenomenon called **insulin resistance.** Mutations in any one of several genes could lead to insulin resistance. For example, a particular mutation in the PC-1 membrane protein gene causes PC-1 to interact more strongly with the insulin receptor, preventing receptor activation.

Lifestyle factors also play a role: Type 2 diabetics are almost always overweight and sedentary. Adipose cells of obese people overproduce a number of hormonelike chemicals including *tumor necrosis factor alpha* and *adiponectin*, which may alter the enzymatic cascade triggered by insulin binding. The Diabetes Prevention Program, a major clinical trial, showed that weight loss and regular exercise can lower the risk of type 2 diabetes dramatically, even for people at high risk.



In many cases type 2 diabetes can be managed solely by exercise, weight loss, and a healthy diet. Some type 2 diabetics also benefit from oral medications that enhance insulin release [like tolbutamide (Orinase), which has been around for decades]. Other medications are *insulin resistance reducers*, such as rosiglitazone (Avandia). If the disease is not controlled, however, most type 2 diabetics must eventually inject insulin (today manufactured by recombinant DNA techniques or produced by animals, usually pigs). Today nearly all pharmaceutical companies are vying to find *the* drug to treat type 2 diabetes—not only to conquer insulin resistance but also to decrease the neurological and vascular consequences of the disease.

The race is also on to find an easier, preferably bloodless, method of measuring blood glucose. Promising products include the following:

- GlucoWatch, worn like a wristwatch, which uses a mild electric current to extract glucose painlessly onto a transdermal pad. It is approved for use in the U.S. for supplemental but not primary use, because its accuracy is limited.
- Diasensor, a printer-sized device approved in Europe, which shines an infrared beam on the skin to measure blood glucose.
- A battery-operated device that bombards skin pores with ultrasound shock waves, enlarging them so that insulin's large molecules can be absorbed from a transdermal patch.

Biotechnology is on the threshold of taking on the monster and looks like a good bet to win that battle soon. ■

16

1. Heart. The atria contain some specialized cardiac muscle cells that secrete **atrial natriuretic peptide.** By signaling the kidneys to increase their production of salty urine and by inhibiting aldosterone release by the adrenal cortex, ANP reduces blood volume, blood pressure, and blood sodium concentration (see Figure 16.14).

2. Gastrointestinal tract. *Enteroendocrine cells* are hormone-secreting cells sprinkled in the mucosa of the gastrointestinal (GI) tract. These scattered cells release several peptide hormones that help regulate a wide variety of digestive functions, some of which are summarized in Table 16.4. Enteroendocrine cells also release amines such as serotonin, which act as paracrines, diffusing to and influencing nearby target cells without first entering the bloodstream. Because they are similar in certain ways to neurons and many of their hormones and paracrines are chemically identical to neurotransmitters, enteroendocrine cells are sometimes referred to as *paraneurons.*

3. Placenta. Besides sustaining the fetus during pregnancy, the placenta secretes several steroid and protein hormones that influence the course of pregnancy. Placental hormones include estrogens and progesterone (hormones more often associated with the ovary), and human chorionic gonadotropin (hCG).

TABLE 16.4 Selected Examples of Hormones Produced by Organs Other Than the Major Endocrine Organs

SOURCE	HORMONE	CHEMICAL COMPOSITION	TRIGGER	TARGET ORGAN AND EFFECTS
GI tract mucosa				
▪ Stomach	Gastrin	Peptide	Secreted in response to food	Stomach: stimulates glands to release hydrochloric acid (HCl)
▪ Duodenum of small intestine	Intestinal gastrin	Peptide	Secreted in response to food, especially fats	Stomach: stimulates HCl secretion and gastrointestinal tract motility
▪ Duodenum	Secretin	Peptide	Secreted in response to food	Pancreas and liver: stimulates release of bicarbonate-rich juice; stomach: inhibits secretory activity
▪ Duodenum	Cholecystokinin (CCK)	Peptide	Secreted in response to food	Pancreas: stimulates release of enzyme-rich juice; gallbladder: stimulates expulsion of stored bile; sphincter of Oddi: causes sphincter to relax, allowing bile and pancreatic juice to enter duodenum
Kidney	Erythropoietin (EPO)	Glycoprotein	Secreted in response to hypoxia	Bone marrow: stimulates production of red blood cells
Kidney	Renin	Peptide	Secreted in response to low blood pressure or plasma volume, or sympathetic stimulation	Initiates renin-angiotensin mechanism of aldosterone release; returns blood pressure to normal
Skin (epidermal cells)	Cholecalciferol (provitamin D_3)	Steroid	Activated by the kidneys to active vitamin D_3 (calcitriol) in response to parathyroid hormone	Intestine: stimulates active transport of dietary calcium across intestinal cell membranes
Heart (atria)	Atrial natriuretic peptide	Peptide	Secreted in response to stretching of atria (by rising blood pressure)	Kidney: inhibits sodium ion reabsorption and renin release; adrenal cortex: inhibits secretion of aldosterone; decreases blood pressure
Adipose tissue	Leptin	Peptide	Secretion proportional to fat stores; increased by nutrient uptake	Brain: suppresses appetite; increases energy expenditure
Adipose tissue	Resistin	Peptide	Unknown	Fat, muscle, liver: antagonizes insulin's action on liver cells

4. Kidneys. Interstitial cells in the kidneys secrete **erythropoietin** (ĕ-rith"ro-poi'ĕ-tin; "red-maker"), a protein hormone that signals the bone marrow to increase production of red blood cells. The kidneys also release *renin*, the hormone that initiates the renin-angiotensin mechanism of aldosterone release described earlier.

5. Skin. The skin produces **cholecalciferol,** an inactive form of vitamin D_3, when modified cholesterol molecules in epidermal cells are exposed to ultraviolet radiation. This compound then enters the blood via the dermal capillaries, is modified in the liver, and becomes fully activated in the kidneys. The active form of vitamin D_3, **calcitriol,** is an essential regulator of the carrier system that intestinal cells use to absorb Ca^{2+} from ingested food. Without this vitamin, the bones become weak and soft.

6. Adipose tissue. Adipose cells release **leptin** following their uptake of glucose, which they store as fat. As described in Chapter 24, leptin binds to CNS neurons concerned with appetite control, producing a sensation of satiety, and appears to stimulate increased energy expenditure. *Resistin*, also secreted by adipose cells, is an insulin antagonist.

Developmental Aspects of the Endocrine System

Hormone-producing glands arise from all three embryonic germ layers. Endocrine glands derived from mesoderm produce steroid hormones. All others produce amines, peptides, or protein hormones.

Though not usually considered important when describing hormone effectiveness, exposure to many pesticides, industrial chemicals, arsenic, dioxin, and other soil and water pollutants has been shown to disrupt endocrine function. Thus far, sex hormones, thyroid hormone, and glucocorticoids have proved vulnerable to the effects of such pollutants. Interference with glucocorticoids, which turn on many genes that may suppress cancer, may help to explain the high cancer rates in certain areas of the country.

Barring exposure to environmental pollutants, and hypersecretory and hyposecretory disorders, most endocrine organs operate smoothly throughout life until old age. Aging may bring about changes in the rates of hormone secretion, breakdown, and excretion, or in the sensitivity of target cell receptors. Endocrine functioning in the elderly is difficult to research, however, because it is frequently altered by the chronic illnesses common in that age group.

Structural changes in the anterior pituitary occur with age; the amount of connective tissue increases, vascularization decreases, and the number of hormone-secreting cells declines. This may or may not affect hormone production. In women, for example, blood levels and the release rhythm of ACTH remain constant, but levels of gonadotropins increase with age. GH levels decline in both sexes, which partially explains muscle atrophy in old age.

The adrenal gland also shows structural changes with age, but normal controls of cortisol appear to persist as long as a person is healthy and not stressed. Chronic stress, on the other hand, drives up blood levels of cortisol and appears to contribute to hippocampal (and memory) deterioration. Plasma levels of aldosterone are reduced by half in old age; however, this may reflect a decline in renin release by the kidneys, which become less responsive to renin-evoking stimuli. No age-related differences have been found in the release of catecholamines by the adrenal medulla.

The gonads, particularly the ovaries, undergo significant changes with age. In late middle age, the ovaries decrease in size and weight, and they become unresponsive to gonadotropins. As female hormone production declines dramatically, the ability to bear children ends, and problems associated with estrogen deficiency, such as arteriosclerosis and osteoporosis, begin to occur. Testosterone production by the testes also wanes with age, but this effect usually is not seen until very old age.

Glucose tolerance (the ability to dispose of a glucose load effectively) begins to deteriorate as early as the fourth decade of life. Blood glucose levels rise higher and return to resting levels more slowly in the elderly than in young adults. The fact that near-normal amounts of insulin continue to be secreted by the islet cells leads researchers to conclude that decreasing glucose tolerance with age may reflect declining receptor sensitivity to insulin (pre–type 2 diabetes).

Thyroid hormone synthesis and release diminish somewhat with age. Typically, the follicles are loaded with colloid in the elderly, and fibrosis of the gland occurs. Basal metabolic rate declines with age. Mild hypothyroidism is only one cause of this decline. The increase in body fat relative to muscle is equally important, because muscle tissue is more active metabolically than fat.

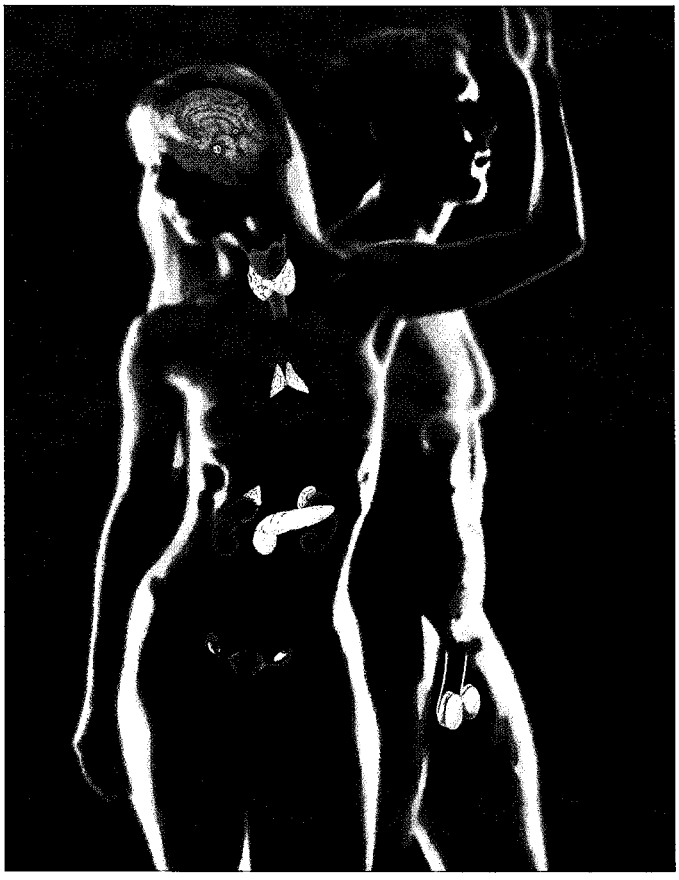
The parathyroid glands change little with age, and PTH levels remain fairly normal throughout life. Estrogens protect women against the demineralizing effects of PTH, but estrogen production wanes after menopause, leaving older women vulnerable to the bone-demineralizing effects of PTH and osteoporosis.

■ ■ ■

In this chapter, we have covered the general mechanisms of hormone action and have provided an overview of the major endocrine organs, their chief targets, and their most important physiological effects, as summarized in *Making Connections* on p. 640. However, every one of the hormones discussed here comes up in at least one other chapter, where its actions are described as part of the functional framework of a particular organ system. For example, the effects of PTH and calcitonin on bone mineralization are described in Chapter 6 along with the discussion of bone remodeling.

MAKING CONNECTIONS

SYSTEM CONNECTIONS: Homeostatic Interrelationships Between the Endocrine System and Other Body Systems



Integumentary System

- Androgens cause activation of sebaceous glands; estrogen increases skin hydration
- Skin produces cholecalciferol (provitamin D)

Skeletal System

- PTH and calcitonin regulate calcium blood levels; growth hormone, T_3, T_4, and sex hormones are necessary for normal skeletal development
- The skeleton provides some protection to endocrine organs, especially to those in the brain, chest, and pelvis

Muscular System

- Growth hormone is essential for normal muscular development; other hormones (thyroxine and catecholamines) influence muscle metabolism
- Muscular system mechanically protects some endocrine glands; muscular activity elicits catecholamine release

Nervous System

- Many hormones (growth hormone, thyroxine, sex hormones) influence normal maturation and function of the nervous system
- Hypothalamus controls anterior pituitary function and produces two hormones

Cardiovascular System

- Several hormones influence blood volume, blood pressure, and heart contractility; erythropoietin stimulates red blood cell production
- Blood is the main transport medium of hormones; heart produces atrial natriuretic peptide

Lymphatic System/Immunity

- Lymphocytes "programmed" by thymic hormones seed the lymph nodes; glucocorticoids depress the immune response and inflammation
- Chemical messengers of the immune system stimulate the release of cortisol and ACTH; lymph provides a route for transport of hormones

Respiratory System

- Epinephrine influences ventilation (dilates bronchioles)
- Respiratory system provides oxygen; disposes of carbon dioxide; converting enzyme in lungs converts angiotensin I to angiotensin II

Digestive System

- GI hormones and paracrines influence GI function; activated vitamin D necessary for absorption of calcium from diet; catecholamines influence digestive motility and secretory activity
- Digestive system provides nutrients to endocrine organs

Urinary System

- Aldosterone and ADH influence renal function; erythropoietin released by kidneys influences red blood cell formation
- Kidneys activate vitamin D (considered a hormone)

Reproductive System

- Hypothalamic, anterior pituitary, and gonadal hormones direct reproductive system development and function; oxytocin and prolactin involved in birth and breast-feeding
- Gonadal hormones feed back to influence endocrine system function

CLOSER CONNECTIONS

THE ENDOCRINE SYSTEM and Interrelationships with the Nervous and Reproductive Systems

Like most body systems, the endocrine system performs many functions that benefit the body as a whole. For example, without insulin, thyroxine, and various other metabolic hormones, body cells would be unable to get or use glucose, and would die. Likewise, total body growth is beholden to the endocrine system, which coordinates the growth spurts with increases in skeletal and muscular mass so that we don't look out of proportion most of the time. But the interactions that are most noticeable and crucial are those that the endocrine system has with the nervous and the reproductive systems, and they begin before birth.

Nervous System

The influence of hormones on behavior is striking. While we are still in the wet darkness of our mother's uterus, testosterone—or lack of it—is determining the "sex" of our brain. If testosterone is produced by the exceedingly tiny male testes, then certain areas of the brain enlarge, develop large numbers of androgen receptors, and thereafter determine the so-called masculine aspects of behavior (aggressiveness, etc.). Conversely, in the absence of testosterone, the brain is feminized. At puberty, Mom and Dad's "little angels," driven by raging hormones, turn into strangers. The surge of androgens—produced first by the adrenal cortices, and then by the maturing gonads—produces an often thoughtless aggressiveness and galloping sex drive, typically long before the cognitive abilities of the brain can rein them in.

Neural involvement in hormonal affairs is no less striking. Not only is the hypothalamus an endocrine organ in its own right, it also effectively regulates the bulk of hormonal activity via its hormonal or neural controls of the pituitary and adrenal medulla. And that's just on a normal day. The effects of trauma on the hypothalamic-pituitary axis can be far-reaching. Lack of loving care to a newborn baby results in failure to thrive; exceptionally vigorous athletic training in the pubertal female can result in bone wasting and infertility. The shadow the nervous system casts over the endocrine system is long indeed.

Reproductive System

The reproductive system is totally dependent on hormones to "order up the right organs" to match our genetic sex. Testosterone secretion by the testes of male embryos directs formation of the male reproductive tract and external genitalia. Without testosterone, female structures develop—regardless of gonadal sex. The next crucial period is puberty, when gonadal sex hormone production rises and steers maturation of the reproductive organs, bringing them to their adult structure and function. Without these hormonal signals, the reproductive organs remain childlike and the person cannot produce offspring. Pregnancy invites more endocrine system interactions with the reproductive system. The placenta, a temporary endocrine organ, churns out estrogens and progesterone, which help maintain the pregnancy and prepare the mother's breasts for lactation, as well as a number of other hormones that influence maternal metabolism. During and after birth, oxytocin and prolactin take center stage to promote labor and delivery, and then milk production and ejection. Other than feedback inhibition exerted by its sex hormones on the hypothalamic-pituitary axis, the influence of reproductive organs on the endocrine system is negligible.

CLINICAL CONNECTIONS

Endocrine System

Case study: We have a new patient to consider today. Mr. Gutteman, a 70-year-old male, was brought into the ER in a comatose state and has yet to come out of it. It is obvious that he suffered severe head trauma—his scalp was badly lacerated, and he has an impacted skull fracture. His initial lab tests (blood and urine) were within normal limits. His fracture was repaired and the following orders (and others) were given:

- Check qh (every hour) and record: spontaneous behavior, level of responsiveness to stimulation, movements, pupil size and reaction to light, speech, and vital signs.
- Turn patient q4h and maintain meticulous skin care and dryness.

1. Explain the rationale behind these orders.

On the second day of his hospitalization, the aide reports that Mr. Gutteman is breathing irregularly, his skin is dry and flaccid, and that she has emptied his urine reservoir several times during the day. Upon receiving this information, the physician ordered

- Blood and urine tests for presence of glucose and ketones
- Strict I&O (fluid intake and output recording)

Mr. Gutteman is found to be losing huge amounts of water in urine and the volume lost is being routinely replaced (via IV line). Mr. Gutteman's blood and urine tests are negative for glucose and ketones.

Relative to these findings:

2. What would you say Mr. Gutteman's hormonal problem is and what do you think caused it?
3. Is it life threatening? (Explain your answer.)

(Answers in Appendix G)

Related Clinical Terms

Hirsutism (her'soot-izm; *hirsut* = hairy, rough) Excessive hair growth; usually refers to this phenomenon in women and reflects excessive androgen production.

Hypophysectomy (hi-pof"i-sek'to-me) Surgical removal of the pituitary gland.

Prolactinoma (pro-lak"tĭ-no'mah; *oma* = tumor) The most common type (30–40% or more) of pituitary gland tumor; evidenced by hypersecretion of prolactin and menstrual disturbances in women.

Psychosocial dwarfism Dwarfism (and failure to thrive) resulting from stress and emotional disorders that suppress hypothalamic release of growth hormone–releasing hormone and thus anterior pituitary secretion of growth hormone.

Thyroid storm (thyroid crisis) A sudden and dangerous increase in all of the symptoms of hyperthyroidism due to excessive amounts of circulating TH. Symptoms of this hypermetabolic state include fever, rapid heart rate, high blood pressure, dehydration, nervousness, and tremors. Precipitating factors include stressful situations, excessive intake of TH supplements, and trauma.

Chapter Summary

Media study tools that could provide you additional help in reviewing specific key topics of Chapter 16 are referenced below. IP = *InterActive Physiology*

1. The nervous and endocrine systems are the major controlling systems of the body. The nervous system exerts rapid controls via nerve impulses; the endocrine system's effects are mediated by hormones and are more prolonged.

2. Hormonally regulated processes include reproduction; growth and development; mobilization of body defenses; maintaining electrolyte, water, and nutrient balance; and regulating cellular metabolism and energy balance.

The Endocrine System: An Overview (pp. 605–606)

16

1. Endocrine organs are ductless, well-vascularized glands that release hormones directly into the blood or lymph. They are small and widely separated in the body.

2. The major endocrine organs are the pituitary, thyroid, parathyroid, adrenal, pineal, and thymus glands, as well as the pancreas and gonads. The hypothalamus is a neuroendocrine organ.

3. Local chemical messengers, not generally considered part of the endocrine system, include autocrines, which act on the cells that secrete them, and paracrines, which act on a different cell type nearby.

IP Endocrine System; Topic: Endocrine System Review, p. 3.

Hormones (pp. 606–612)

The Chemistry of Hormones (p. 606)

1. Most hormones are steroids or amino acid based.

IP Endocrine System; Topic: Biochemistry, Secretion, and Transport of Hormones, p. 3.

Mechanisms of Hormone Action (pp. 606–610)

2. Hormones alter cell activity by stimulating or inhibiting characteristic cellular processes of their target cells.

3. Cell responses to hormone stimulation may involve changes in membrane permeability; enzyme synthesis, activation, or inhibition; secretory activity; gene activation; and mitosis.

4. Second-messenger mechanisms employing intracellular messengers and transduced by G proteins are a common means by which amino acid–based hormones interact with their target cells. In the cyclic AMP system, the hormone binds to a plasma membrane receptor that couples to a G protein. When the G protein is activated it, in turn, couples to adenylate cyclase, which catalyzes the synthesis of cyclic AMP from ATP. Cyclic AMP initiates reactions that activate protein kinases and other enzymes, leading to cellular response. The PIP-calcium signal mechanism, involving phosphatidyl inositol, is another important second-messenger system. Other second messengers are cyclic GMP and calcium.

IP Endocrine System; Topic: The Actions of Hormones on Target Cells, pp. 3–7.

5. Steroid hormones (and thyroid hormone) enter their target cells and effect responses by activating DNA, which initiates messenger RNA formation leading to protein synthesis.

Target Cell Specificity (p. 610)

6. The ability of a target cell to respond to a hormone depends on the presence of receptors, within the cell or on its plasma membrane, to which the hormone can bind.

7. Hormone receptors are dynamic structures. Changes in number and sensitivity of hormone receptors may occur in response to high or low levels of stimulating hormones.

IP Endocrine System; Topic: The Actions of Hormones on Target Cells, p. 3.

Half-Life, Onset, and Duration of Hormone Activity (p. 610)

8. Blood levels of hormones reflect a balance between secretion and degradation/excretion. The liver and kidneys are the major organs that degrade hormones; breakdown products are excreted in urine and feces.

9. Hormone half-life and duration of activity are limited and vary from hormone to hormone.

Interaction of Hormones at Target Cells (p. 611)

10. Permissiveness is the situation in which a hormone cannot exert its full effects without the presence of another hormone.

11. Synergism occurs when two or more hormones produce the same effects in a target cell and their results are amplified.

12. Antagonism occurs when a hormone opposes or reverses the effect of another hormone.

Control of Hormone Release (pp. 611–612)

13. Endocrine organs are activated to release their hormones by humoral, neural, or hormonal stimuli. Negative

feedback is important in regulating hormone levels in the blood.

14. The nervous system, acting through hypothalamic controls, can in certain cases override or modulate hormonal effects.

Endocrine System; Topic: The Hypothalamic–Pituitary Axis, pp. 4 and 5.

Major Endocrine Organs (pp. 612–636)

The Pituitary Gland (Hypophysis) (pp. 612–620)

1. The pituitary gland hangs from the base of the brain by a stalk and is enclosed by bone. It consists of a hormone-producing glandular portion (anterior pituitary) and a neural portion (posterior pituitary), which is an extension of the hypothalamus.

2. The hypothalamus (a) regulates the hormonal output of the anterior pituitary via releasing and inhibiting hormones and (b) synthesizes two hormones that it exports to the posterior pituitary for storage and later release.

3. Four of the six adenohypophyseal hormones are tropic hormones that regulate the function of other endocrine organs. Most anterior pituitary hormones exhibit a diurnal rhythm of release, which is subject to modification by stimuli influencing the hypothalamus.

4. Growth hormone (GH) is an anabolic hormone that stimulates growth of all body tissues but especially skeletal muscle and bone. It may act directly, or indirectly via insulin-like growth factors (IGFs). GH mobilizes fats, stimulates protein synthesis, and inhibits glucose uptake and metabolism. Secretion is regulated by growth hormone–releasing hormone (GHRH) and growth hormone–inhibiting hormone (GHIH), or somatostatin. Hypersecretion causes gigantism in children and acromegaly in adults; hyposecretion in children causes pituitary dwarfism.

5. Thyroid-stimulating hormone (TSH) promotes normal development and activity of the thyroid gland. Thyrotropin-releasing hormone (TRH) stimulates its release; negative feedback of thyroid hormone inhibits it.

6. Adrenocorticotropic hormone (ACTH) stimulates the adrenal cortex to release corticosteroids. ACTH release is triggered by corticotropin-releasing hormone (CRH) and inhibited by rising glucocorticoid levels.

7. The gonadotropins—follicle-stimulating hormone (FSH) and luteinizing hormone (LH)—regulate the functions of the gonads in both sexes. FSH stimulates sex cell production; LH stimulates gonadal hormone production. Gonadotropin levels rise in response to gonadotropin-releasing hormone (GnRH). Negative feedback of gonadal hormones inhibits gonadotropin release.

8. Prolactin (PRL) promotes milk production in humans. Its secretion is prompted by prolactin-releasing hormone (PRH) and inhibited by prolactin-inhibiting hormone (PIH).

9. The neurohypophysis stores and releases two hypothalamic hormones, oxytocin and antidiuretic hormone (ADH).

10. Oxytocin stimulates powerful uterine contractions, which trigger labor and delivery of an infant, and milk ejection in nursing women. Its release is mediated reflexively by the hypothalamus and represents a positive feedback mechanism.

11. Antidiuretic hormone stimulates the kidney tubules to reabsorb and conserve water, resulting in small volumes of highly concentrated urine and decreased plasma osmolality. ADH is released in response to high solute concentrations in the blood and inhibited by low solute concentrations in the blood. Hyposecretion results in diabetes insipidus.

The Thyroid Gland (pp. 620–624)

12. The thyroid gland is located in the anterior throat. Thyroid follicles store colloid containing thyroglobulin, a glycoprotein from which thyroid hormone is derived.

13. Thyroid hormone (TH) includes thyroxine (T_4) and triiodothyronine (T_3), which increase the rate of cellular metabolism. Consequently, oxygen use and heat production rise.

14. Secretion of thyroid hormone, prompted by TSH, requires reuptake of the stored colloid by the follicle cells and splitting of the hormones from the colloid for release. Rising levels of thyroid hormone feed back to inhibit the pituitary and hypothalamus.

15. Most T_4 is converted to T_3 (the more active form) in the target tissues. These hormones act by turning on gene transcription and protein synthesis.

16. Graves' disease is the most common cause of hyperthyroidism; hyposecretion causes cretinism in infants and myxedema in adults.

17. Calcitonin, produced by the parafollicular (C) cells of the thyroid gland in response to rising blood calcium levels, depresses blood calcium levels by inhibiting bone matrix resorption and enhancing calcium deposit in bone.

Endocrine System; Topic: The Hypothalamic–Pituitary Axis, p. 6.

The Parathyroid Glands (pp. 624–625)

18. The parathyroid glands, located on the dorsal aspect of the thyroid gland, secrete parathyroid hormone (PTH), which causes an increase in blood calcium levels by targeting bone, the intestine, and the kidneys. PTH is the antagonist of calcitonin.

19. PTH release is triggered by falling blood calcium levels and is inhibited by rising blood calcium levels.

20. Hyperparathyroidism results in hypercalcemia and all its effects and in extreme bone wasting. Hypoparathyroidism leads to hypocalcemia, evidenced by tetany and respiratory paralysis.

The Adrenal (Suprarenal) Glands (pp. 626–632)

21. The paired adrenal (suprarenal) glands sit atop the kidneys. Each adrenal gland has two functional portions, the cortex and the medulla.

22. Three groups of steroid hormones are produced by the cortex from cholesterol.

23. Mineralocorticoids (primarily aldosterone) regulate sodium ion reabsorption and potassium ion excretion by the kidneys. Sodium ion reabsorption leads to water reabsorption, and increases in blood volume and blood pressure. Release of aldosterone is stimulated by the renin-angiotensin mechanism, rising potassium ion or falling sodium levels in the blood, and ACTH. Atrial natriuretic peptide inhibits aldosterone release.

24. Glucocorticoids (primarily cortisol) are important metabolic hormones that help the body resist stressors by increasing blood glucose, fatty acid and amino acid levels, and blood pressure. High levels of glucocorticoids depress the immune system and the inflammatory response. ACTH is the major stimulus for glucocorticoid release.

25. Gonadocorticoids (mainly androgens) are produced in small amounts throughout life.

26. Hypoactivity of the adrenal cortex results in Addison's disease. Hypersecretion can result in aldosteronism, Cushing's syndrome, and adrenogenital syndrome.

27. The adrenal medulla produces catecholamines (epinephrine and norepinephrine) in response to sympathetic nervous system stimulation. Its catecholamines enhance and prolong the fight-or-flight response to short-term stressors. Hypersecretion leads to symptoms typical of sympathetic nervous system overactivity.

IP Endocrine System; Topic: Response to Stress, pp. 5–8.

The Pancreas (pp. 632–634)

28. The pancreas, located in the abdomen close to the stomach, is both an exocrine and an endocrine gland. The endocrine portion (pancreatic islets) releases insulin and glucagon and smaller amounts of other hormones to the blood.

29. Glucagon, released by alpha (α) cells when blood levels of glucose are low, stimulates the liver to release glucose to the blood.

30. Insulin is released by beta (β) cells when blood levels of glucose (and amino acids) are rising. It increases the rate of glucose uptake and metabolism by most body cells. Hyposecretion of insulin results in diabetes mellitus; cardinal signs are polyuria, polydipsia, and polyphagia.

IP Endocrine System; Topic: The Actions of Hormones on Target Cells, pp. 5 and 8.

The Gonads (pp. 634–635)

31. The ovaries of the female, located in the pelvic cavity, release two main hormones. Secretion of estrogens by the ovarian follicles begins at puberty under the influence of FSH. Estrogens stimulate maturation of the female reproductive system and development of the secondary sex characteristics. Progesterone is released in response to high blood levels of LH. It works with estrogens in establishing the menstrual cycle.

32. The testes of the male begin to produce testosterone at puberty in response to LH. Testosterone promotes maturation of the male reproductive organs, development of secondary sex characteristics, and production of sperm by the testes.

The Pineal Gland (pp. 635–636)

33. The pineal gland is located in the diencephalon. Its primary hormone is melatonin, which influences daily rhythms and may have an antigonadotropic effect in humans.

The Thymus (p. 636)

34. The thymus gland, located in the upper thorax, declines in size and function with age. Its hormones, thymosins, thymic factor, and thymopoietins, are important to the normal development of the immune response.

Other Hormone-Producing Structures (pp. 636–638)

1. Many body organs not normally considered endocrine organs contain isolated cell clusters that secrete hormones. Examples include the heart (atrial natriuretic peptide); gastrointestinal tract organs (gastrin, secretin, and others); the placenta (hormones of pregnancy—estrogen, progesterone, and others); the kidneys (erythropoietin and renin); skin (cholecalciferol); and adipose tissue (leptin and resistin).

Developmental Aspects of the Endocrine System (p. 639)

1. Endocrine glands derive from all three germ layers. Those derived from mesoderm produce steroidal hormones; the others produce the amino acid–based hormones.

2. The natural decrease in function of the female's ovaries during late middle age results in menopause.

3. The efficiency of all endocrine glands seems to decrease gradually as aging occurs. This leads to a generalized increase in the incidence of diabetes mellitus and a lower metabolic rate.

Review Questions

Multiple Choice/Matching

(Some questions have more than one correct answer. Select the best answer or answers from the choices given.)

1. The major stimulus for release of parathyroid hormone is (a) hormonal, (b) humoral, (c) neural.

2. The anterior pituitary secretes all but (a) antidiuretic hormone, (b) growth hormone, (c) gonadotropins, (d) TSH.

3. A hormone not involved in glucose metabolism is (a) glucagon, (b) cortisone, (c) aldosterone, (d) insulin.

4. Parathyroid hormone (a) increases bone formation and lowers blood calcium levels, (b) increases calcium excretion from the body, (c) decreases calcium absorption from the gut, (d) demineralizes bone and raises blood calcium levels.

5. Choose from the following key to identify the hormones described.

Key: **(a)** aldosterone **(e)** oxytocin
(b) antidiuretic hormone **(f)** prolactin
(c) growth hormone **(g)** T_4 and T_3
(d) luteinizing hormone **(h)** TSH

____ **1.** important anabolic hormone; many of its effects mediated by IGFs
____ **2.** involved in water balance; cause the kidneys to conserve water (two choices)
____ **3.** stimulates milk production
____ **4.** tropic hormone that stimulates the gonads to secrete sex hormones
____ **5.** increases uterine contractions during birth
____ **6.** major metabolic hormone(s) of the body
____ **7.** causes reabsorption of sodium ions by the kidneys
____ **8.** tropic hormone that stimulates the thyroid gland to secrete thyroid hormone
____ **9.** secreted by the neurohypophysis (two choices)
____ **10.** the only steroid hormone in the list

6. A hypodermic injection of epinephrine would (a) increase heart rate, increase blood pressure, dilate the bronchi of the lungs, and increase peristalsis, (b) decrease heart rate, decrease blood pressure, constrict the bronchi, and increase peristalsis, (c) decrease heart rate, increase blood pressure, constrict the bronchi, and decrease peristalsis, (d) increase heart rate, increase blood pressure, dilate the bronchi, and decrease peristalsis.

7. Testosterone is to the male as what hormone is to the female? (a) luteinizing hormone, (b) progesterone, (c) estrogen, (d) prolactin.

8. If anterior pituitary secretion is deficient in a growing child, the child will (a) develop acromegaly, (b) become a dwarf but have fairly normal body proportions, (c) mature

sexually at an earlier than normal age, (d) be in constant danger of becoming dehydrated.

9. If there is adequate carbohydrate intake, secretion of insulin results in (a) lower blood glucose levels, (b) increased cell utilization of glucose, (c) storage of glycogen, (d) all of these.

10. Hormones (a) are produced by exocrine glands, (b) are carried to all parts of the body in blood, (c) remain at constant concentration in the blood, (d) affect only non-hormone-producing organs.

11. Some hormones act by (a) increasing the synthesis of enzymes, (b) converting an inactive enzyme into an active enzyme, (c) affecting only specific target organs, (d) all of these.

12. Absence of thyroxine would result in (a) increased heart rate and increased force of heart contraction, (b) depression of the CNS and lethargy, (c) exophthalmos, (d) high metabolic rate.

13. Chromaffin cells are found in the (a) parathyroid gland, (b) anterior pituitary gland, (c) adrenal gland, (d) pineal gland.

14. Atrial natriuretic peptide secreted by the heart has exactly the opposite function of this hormone secreted by the zona glomerulosa: (a) antidiuretic hormone, (b) epinephrine, (c) calcitonin, (d) aldosterone, (e) androgens.

Short Answer Essay Questions

15. Define hormone.

16. Which type of hormone receptor—plasma membrane bound or intracellular—would be expected to provide the most long-lived response to hormone binding and why?

17. (a) Describe the body location of each of the following endocrine organs: anterior pituitary, pineal gland, pancreas, ovaries, testes, and adrenal glands. (b) List the hormones produced by each organ.

18. Name two endocrine glands (or regions) that are important in the stress response, and explain why they are important.

19. The anterior pituitary is often referred to as the master endocrine organ, but it, too, has a "master." What controls the release of anterior pituitary hormones?

20. The posterior pituitary is not really an endocrine gland. Why not? What is it?

21. A colloidal, or endemic, goiter is not really the result of malfunction of the thyroid gland. What does cause it?

22. List some problems that elderly people might have as a result of decreasing hormone production.

23. Name a hormone secreted by a muscle cell and two hormones secreted by neurons.

24. How are the hyperglycemia and lipidemia of insulin deficiency linked?

Critical Thinking and Clinical Application Questions

1. Richard Neis had symptoms of excessive secretion of PTH (high blood calcium levels), and his physicians were certain he had a parathyroid gland tumor. Yet when surgery was performed on his neck, the surgeon could not find the parathyroid glands at all. Where should the surgeon look next to find the tumorous parathyroid gland?

2. Mary Morgan has just been brought into the emergency room of City General Hospital. She is perspiring profusely and is breathing rapidly and irregularly. Her breath smells like acetone (sweet and fruity), and her blood glucose tests out at 650 mg/100 ml of blood. She is in acidosis. What hormone drug should be administered, and why?

3. Johnny, a 5-year-old boy, has been growing by leaps and bounds; his height is 100% above normal for his age. He has been complaining of headaches and vision problems. A CT scan reveals a large pituitary tumor. (a) What hormone is being secreted in excess? (b) What condition will Johnny exhibit if corrective measures are not taken? (c) What is the probable cause of his headaches and visual problems?

4. Sean, a 42-year-old single father, goes to his physician complaining of nausea and chronic fatigue. He reports having felt fatigued and listless for about half a year, but he had attributed this to stress. He has lost considerable weight and, strangely, his skin has a healthy tan, even though he spends long hours at work and rarely ventures outside. His doctor finds very low blood pressure and a rapid, weak pulse. Blood tests show that Sean does not have anemia, but his plasma glucose, cortisol, and Na^+ are low, and his plasma K^+ is high. His doctor orders an ACTH stimulation test, in which Sean's secretion of cortisol is measured after he is given a synthetic form of ACTH. (a) What would account for Sean's low plasma Na^+ and high plasma K^+? (b) What is the reason for doing an ACTH stimulation test? (c) What gland is primarily affected if ACTH *does not* cause a normal elevation of cortisol secretion? What is this abnormality called? (d) What gland is primarily affected if ACTH *does* cause an elevation of cortisol secretion?

5. Roger Proulx has severe arthritis and has been taking prednisone (a glucocorticoid) for two months. He isn't feeling well, complains of repeated "colds," and is extremely "puffy" (edematous). Explain the reason for these symptoms.

CHAPTER

Blood

Overview: Blood Composition and Functions (pp. 647–648)

1. Describe the composition and physical characteristics of whole blood. Explain why it is classified as a connective tissue.
2. List six functions of blood.

Blood Plasma (pp. 648–649)

3. Discuss the composition and functions of plasma.

Formed Elements (pp. 649–662)

4. Describe the structure, function, and production of erythrocytes.
5. Describe the chemical makeup of hemoglobin.
6. List the classes, structural characteristics, and functions of leukocytes. Also describe leukocyte genesis.
7. Describe the structure and function of platelets.
8. Give examples of disorders caused by abnormalities of each of the formed elements. Explain the mechanism of each disorder.

Hemostasis (pp. 663–668)

9. Describe the process of hemostasis. List factors that limit clot formation and prevent undesirable clotting.
10. Give examples of hemostatic disorders. Indicate the cause of each condition.

Transfusion and Blood Replacement (pp. 668–671)

11. Describe the ABO and Rh blood groups. Explain the basis of transfusion reactions.
12. Describe fluids used to replace blood volume and the circumstances for their use.

Diagnostic Blood Tests (pp. 671–672)

13. Explain the diagnostic importance of blood testing.

Developmental Aspects of Blood (pp. 672–673)

14. Describe changes in the sites of blood production and in the type of hemoglobin produced after birth.
15. Name some blood disorders that become more common with age.

Blood is the river of life that surges within us, transporting nearly everything that must be carried from one place to another. Long before modern medicine, blood was viewed as magical—an elixir that held the mystical force of life—because when it drained from the body, life departed as well. Today, centuries later, blood still has enormous importance in the practice of medicine. Clinicians examine it more often than any other tissue when trying to determine the cause of disease in their patients.

In this chapter, we describe the composition and functions of this life-sustaining fluid that serves as a transport "vehicle" for the organs of the cardiovascular system. To get started, we need a brief overview of blood circulation, which is initiated by the pumping action of the heart. Blood exits the *heart* via *arteries*, which branch repeatedly until they become tiny *capillaries*. By diffusing across the capillary walls, oxygen and nutrients leave the blood and enter the body tissues, and carbon dioxide and wastes move from the tissues to the bloodstream. As oxygen-deficient blood leaves the capillary beds, it flows into *veins*, which return it to the heart. The returning blood then flows from the heart to the lungs, where it picks up oxygen and then returns to the heart to be pumped throughout the body once again. Now let us look more closely at the nature of blood.

Overview: Blood Composition and Functions

Components

Blood is the only fluid tissue in the body. Although blood appears to be a thick, homogeneous liquid, the microscope reveals that it has both cellular and liquid components. Blood is a specialized type of connective tissue in which living blood cells, the *formed elements*, are suspended in a nonliving fluid matrix called *plasma* (plaz'mah). The collagen and elastic fibers typical of other connective tissues are absent from blood, but dissolved fibrous proteins become visible as fibrin strands during blood clotting.

If a sample of blood is spun in a centrifuge, the heavier formed elements are packed down by centrifugal force and the less dense plasma remains at the top (Figure 17.1). Most of the reddish mass at the bottom of the tube is *erythrocytes* (ĕ-rith'ro-sīts; *erythro* = red), the red blood cells that transport oxygen. A thin, whitish layer called the **buffy coat** is present at the erythrocyte-plasma junction. This layer contains *leukocytes* (*leuko* = white), the white blood cells that act in various ways to protect the body, and *platelets*, cell fragments that help stop bleeding. Erythrocytes normally constitute about 45% of the total volume of a blood sample, a percentage known as the **hematocrit** (he-mat'o-krit;

Q *Which of the percentages given in this figure represents the measurement called the hematocrit?*

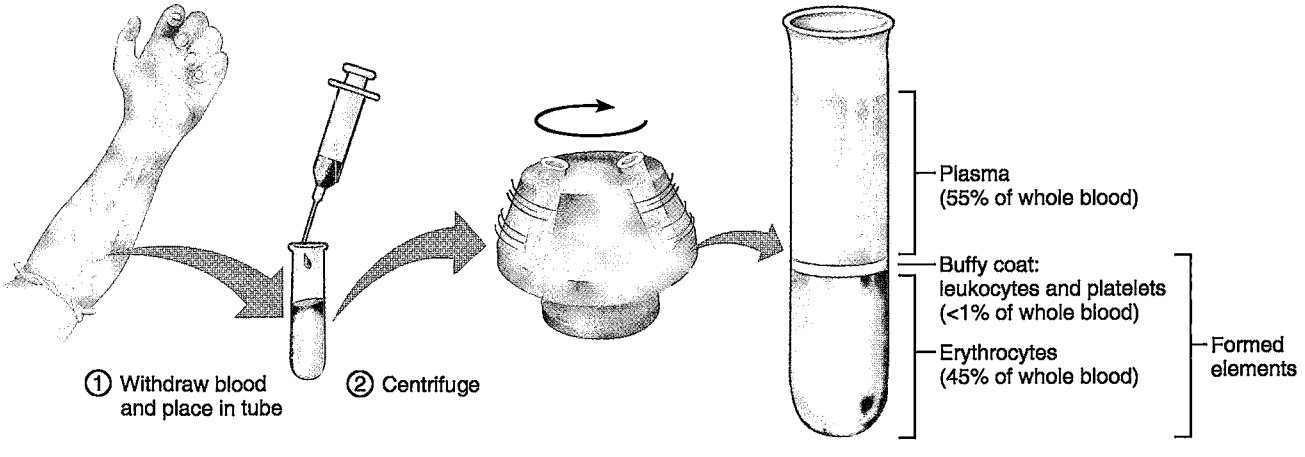

FIGURE 17.1 **The major components of whole blood.** When a blood sample is centrifuged, it separates into layers, the heaviest particles (erythrocytes) moving to the bottom of the test tube. The least dense component is plasma, which is the top layer.

A 45%, the percentage of the erythrocytes.

"blood fraction"). Normal hematocrit values vary. In healthy males the norm is 47% ± 5%; in females it is 42% ± 5%. Leukocytes and platelets contribute less than 1% of blood volume. Plasma makes up most of the remaining 55% of whole blood.

Physical Characteristics and Volume

Blood is a sticky, opaque fluid with a characteristic metallic taste. As children, we discover its saltiness the first time we stick a cut finger into our mouth. Depending on the amount of oxygen it is carrying, the color of blood varies from scarlet (oxygen rich) to dark red (oxygen poor). Blood is more dense than water and about five times more viscous, largely because of its formed elements. Blood is slightly alkaline, with a pH between 7.35 and 7.45, and its temperature (38°C or 100.4°F) is always slightly higher than body temperature.

Blood accounts for approximately 8% of body weight. Its average volume in healthy adult males is 5–6 L (about 1.5 gallons), somewhat greater than in healthy adult females (4–5 L).

Functions

Blood performs a number of functions, all concerned in one way or another with substance distribution, regulating blood levels of particular substances, or body protection.

Distribution

Distribution functions of blood include

- Delivering oxygen from the lungs and nutrients from the digestive tract to all body cells.
- Transporting metabolic waste products from cells to elimination sites (to the lungs for elimination of carbon dioxide, and to the kidneys for disposal of nitrogenous wastes in urine).
- Transporting hormones from the endocrine organs to their target organs.

Regulation

Regulatory functions of blood include

- Maintaining appropriate body temperature by absorbing and distributing heat throughout the body and to the skin surface to encourage heat loss.
- Maintaining normal pH in body tissues. Many blood proteins and other bloodborne solutes act as buffers to prevent excessive or abrupt changes in blood pH that could jeopardize normal cell activities. Additionally, blood acts as the reservoir for the body's "alkaline reserve" of bicarbonate atoms.
- Maintaining adequate fluid volume in the circulatory system. Salts (sodium chloride and others) and blood proteins act to prevent excessive fluid loss from the bloodstream into the tissue spaces. As a result, the fluid volume in the blood vessels remains ample to support efficient blood circulation to all parts of the body.

Protection

Protective functions of blood include

- Preventing blood loss. When a blood vessel is damaged, platelets and plasma proteins initiate clot formation, halting blood loss.
- Preventing infection. Drifting along in blood are antibodies, complement proteins, and white blood cells, all of which help defend the body against foreign invaders such as bacteria and viruses.

Blood Plasma

Blood **plasma** is a straw-colored, sticky fluid (see Figure 17.1). Although it is mostly water (about 90%), plasma contains over 100 different dissolved solutes, including nutrients, gases, hormones, wastes and products of cell activity, ions, and proteins. Table 17.1 summarizes the major plasma components.

Plasma proteins, accounting for about 8% by weight of plasma volume, are the most abundant plasma solutes. Except for hormones and gamma globulins, most plasma proteins are produced by the liver. Plasma proteins serve a variety of functions, but they are *not* taken up by cells to be used as fuels or metabolic nutrients as are most other plasma solutes, such as glucose, fatty acids, and amino acids. **Albumin** (al-bu'min) accounts for some 60% of plasma protein. It acts as a carrier to shuttle certain molecules through the circulation, is an important blood buffer, and is the major blood protein contributing to the plasma osmotic pressure (the pressure that helps to keep water in the bloodstream). (Sodium ions are the other major solute contributing to blood osmotic pressure.)

The makeup of plasma varies continuously as cells remove or add substances to the blood. However, assuming a healthy diet, plasma composition is kept relatively constant by various homeostatic mechanisms. For example, when blood protein levels drop undesirably, the liver makes more proteins; and when the blood starts to become too acidic (acidosis), both the respiratory system and the kidneys are called into action to restore plasma's normal, slightly alkaline pH. Body organs make dozens of adjustments, day in and day out, to maintain the many plasma solutes at life-sustaining levels. In addition to transporting various solutes around the

TABLE 17.1 Composition of Plasma

CONSTITUENT	DESCRIPTION AND IMPORTANCE
Water	90% of plasma volume; dissolving and suspending medium for solutes of blood; absorbs heat
Solutes	
Plasma proteins	8% (by weight) of plasma volume; all contribute to osmotic pressure, maintaining water balance in blood and tissues; all have other functions (transport, enzymatic, etc.)
▪ Albumin	60% of plasma proteins; produced by liver; main contributor to osmotic pressure
▪ Globulins	36% of plasma proteins
alpha, beta	Produced by liver; mostly transport proteins that bind to lipids, metal ions, and fat-soluble vitamins
gamma	Antibodies released by plasma cells during immune response
▪ Fibrinogen	4% of plasma proteins; produced by liver; forms fibrin threads of blood clot
Nonprotein nitrogenous substances	By-products of cellular metabolism, such as urea, uric acid, creatinine, and ammonium salts
Nutrients (organic)	Materials absorbed from digestive tract and transported for use throughout body; include glucose and other simple carbohydrates, amino acids (digestion products of proteins), fatty acids, glycerol and triglycerides (fat products), cholesterol, and vitamins
Electrolytes	Cations include sodium, potassium, calcium, magnesium; anions include chloride, phosphate, sulfate, and bicarbonate; help to maintain plasma osmotic pressure and normal blood pH
Respiratory gases	Oxygen and carbon dioxide; oxygen mostly bound to hemoglobin inside RBCs; carbon dioxide transported bound to hemoglobin in RBCs or dissolved in plasma as bicarbonate ion or CO_2
Hormones	Steroid and thyroid hormones carried by plasma proteins

body, plasma distributes heat (a by-product of cellular metabolism) throughout the body.

Formed Elements

The **formed elements** of blood, *erythrocytes, leukocytes,* and *platelets,* have some unusual features. (1) Two of the three are not even true cells: Erythrocytes have no nuclei or organelles, and platelets are cell fragments. Only leukocytes are complete cells. (2) Most of the formed elements survive in the blood-

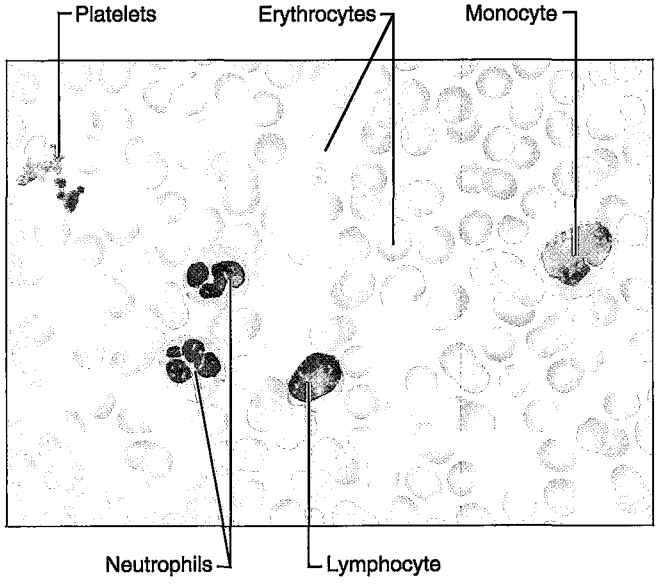

FIGURE 17.2 **Photomicrograph of a human blood smear stained with Wright's stain.**

stream for only a few days. (3) Most blood cells do not divide. Instead, they are continuously renewed by division of cells in bone marrow, where they originate.

If you examine a stained smear of human blood under the light microscope, you will see disc-shaped red blood cells, a variety of gaudily stained spherical white blood cells, and some scattered platelets that look like debris (Figure 17.2). Erythrocytes vastly outnumber the other types of formed elements. Table 17.2 on p. 658 summarizes the important characteristics of the formed elements.

Erythrocytes

Structural Characteristics

Erythrocytes or **red blood cells (RBCs)** are small cells, about 7.5 μm in diameter. Shaped like biconcave discs—flattened discs with depressed centers (Figure 17.3)—they appear lighter in color at their thin centers than at their edges. Consequently, erythrocytes look like miniature doughnuts when viewed with a microscope. Mature erythrocytes are bound by a plasma membrane, but lack a nucleus (are *anucleate*) and have essentially no organelles. In fact, they are little more than "bags" of *hemoglobin (Hb),* the RBC protein that functions in gas transport. Other proteins are present, such as antioxidant enzymes that rid the body of harmful oxygen radicals, but most function mainly to maintain the plasma membrane or promote changes in RBC shape. For example, the biconcave shape of an erythrocyte is maintained by a network of proteins, especially one called *spectrin,* attached to the cytoplasmic face of its plasma membrane. Because the spectrin net is deformable, it gives

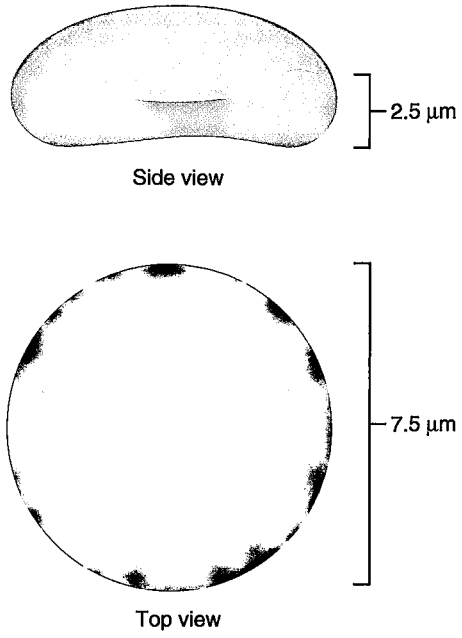

FIGURE 17.3 **Structure of erythrocytes.** Cut side view above; a superficial surface view below. Notice the distinctive biconcave shape.

erythrocytes flexibility to change shape as necessary—to twist, turn, and become cup-shaped as they are carried passively through capillaries with diameters smaller than themselves—and then to resume their biconcave shape.

The erythrocyte is a superb example of complementarity of structure and function. It picks up oxygen in the capillary beds of the lungs and releases it to tissue cells across other capillaries throughout the body. It also transports some 20% of the carbon dioxide released by tissue cells back to the lungs. Each erythrocyte structural characteristic contributes to its gas transport functions: (1) Its small size and biconcave shape provide a huge surface area relative to volume (about 30% more surface area than comparable spherical cells). Because no point within its cytoplasm is far from the surface, the biconcave disc shape is ideally suited for gas exchange. (2) Discounting water content, an erythrocyte is over 97% hemoglobin, the molecule that binds to and transports respiratory gases. (3) Because erythrocytes lack mitochondria and generate ATP by anaerobic mechanisms, they do not consume any of the oxygen they are transporting, making them very efficient oxygen transporters indeed.

Erythrocytes are the major factor contributing to blood viscosity. Women typically have a lower red blood cell count than men [4.3–5.2 million cells per microliter (1 μl = 1 mm^3) of blood versus 5.1–5.8 million cells/μl respectively]. When the number of red blood cells increases beyond the normal range, blood viscosity rises and blood flows more slowly. Similarly, as the number of red blood cells drops below the lower end of the range, the blood thins and flows more rapidly.

Function

Erythrocytes are completely dedicated to their job of respiratory gas (oxygen and carbon dioxide) transport. **Hemoglobin,** the protein that makes red blood cells red, binds easily and reversibly with oxygen, and most oxygen carried in blood is bound to hemoglobin. Normal values for hemoglobin are 14–20 grams per 100 milliliters of blood (g/100 ml) in infants, 13–18 g/100 ml in adult males, and 12–16 g/100 ml in adult females.

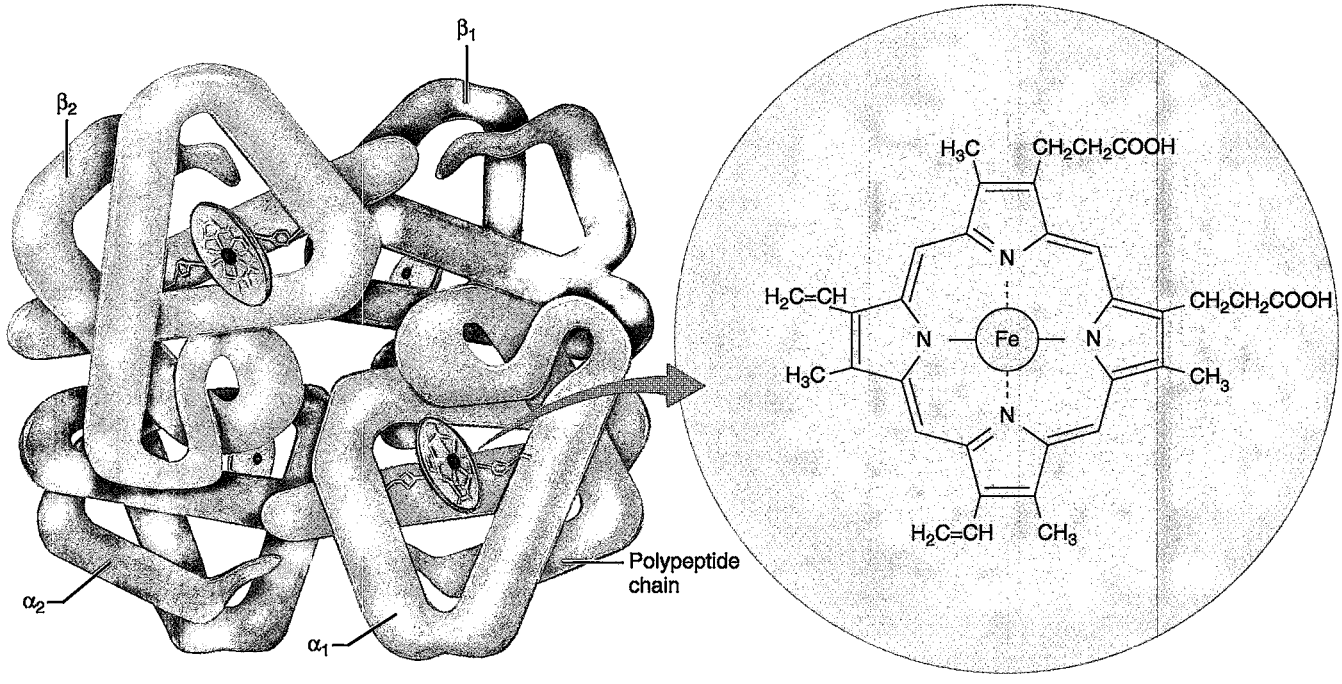
Hemoglobin is made up of the protein **globin** bound to the red **heme** pigment. Globin consists of four polypeptide chains—two alpha (α) and two beta (β)—each bound to a ringlike heme group. Each heme group bears an atom of iron set like a jewel in its center (Figure 17.4). Since each iron atom can combine reversibly with one molecule of oxygen, a hemoglobin molecule can transport four molecules of oxygen. A single red blood cell contains about 250 million hemoglobin molecules, so each of these tiny cells can scoop up about 1 billion molecules of oxygen!

The fact that hemoglobin is contained in erythrocytes, rather than existing free in plasma, prevents it (1) from breaking into fragments that would leak out of the bloodstream (through the rather porous capillary membranes) and (2) from contributing to blood viscosity and osmotic pressure.

Oxygen loading occurs in the lungs, and the direction of transport is from lungs to tissue cells. As oxygen-deficient blood moves through the lungs, oxygen diffuses from the air sacs of the lungs into the blood and then into the erythrocytes, where it binds to hemoglobin. When oxygen binds to iron, the hemoglobin, now called **oxyhemoglobin,** assumes a new three-dimensional shape and becomes ruby red. In the tissues, the process is reversed. Oxygen detaches from iron, hemoglobin resumes its former shape, and the resulting **deoxyhemoglobin,** or *reduced hemoglobin,* becomes dark red. The released oxygen diffuses from the blood into the tissue fluid and then into the tissue cells.

About 20% of the carbon dioxide transported in the blood combines with hemoglobin, but it binds to globin's amino acids rather than to the heme group. This formation of **carbaminohemoglobin** (kar-bam″ĭ-no-he″mo-glo′bin) occurs more readily when hemoglobin is in the reduced state (dissociated from oxygen). Carbon dioxide loading occurs in the tissues, and the direction of transport is from tissues to lungs, where carbon dioxide is eliminated from the body. The mechanisms of loading and unloading these respiratory gases are described in Chapter 22.

Q *How many molecules of oxygen can a hemoglobin molecule transport?*



(a) Hemoglobin **(b) Iron-containing heme group**

FIGURE 17.4 **Structure of hemoglobin. (a)** Hemoglobin is composed of the protein globin bound to the iron-containing heme pigments. Each globin molecule has four polypeptide chains: two alpha (α) chains and two beta (β) chains. Each chain is complexed with a heme group, shown as a circular green structure with iron at its center. **(b)** Structure of a heme group.

Production of Erythrocytes

Blood cell formation is referred to as **hematopoiesis** (hem"ah-to-poi-e'sis), or **hemopoiesis** (*hemo, hemato* = blood; *poiesis* = to make). This process occurs in the **red bone marrow,** which is composed largely of a soft network of reticular connective tissue bordering on wide blood capillaries called *blood sinusoids.* Within this network are immature blood cells, macrophages, fat cells, and *reticular cells* (which secrete the fibers). In adults, red marrow is found chiefly in the bones of the axial skeleton and girdles, and in the proximal epiphyses of the humerus and femur. Each type of blood cell is produced in different numbers in response to changing body needs and different regulatory factors. As they mature, they migrate through the thin walls of the sinusoids to enter the bloodstream. On average, the marrow turns out an ounce of new blood containing some 100 billion new cells each and every day.

A Four O_2 per hemoglobin molecule.

Although the various formed elements have different functions, there are similarities in their life histories. All arise from the same type of *stem cell,* the pleuripotent **hematopoietic stem cell,** or **hemocytoblast** (*cyte* = cell, *blast* = bud), which resides in the red bone marrow. However, their maturation pathways differ; and once a cell is *committed* to a specific blood cell pathway, it cannot change. This commitment is signaled by the appearance of membrane surface receptors that respond to specific hormones or growth factors, which in turn "push" the cell toward further specialization.

Erythrocyte production, or **erythropoiesis** (ĕ-rith"ro-poi-e'sis) begins when a hemocytoblast descendant called a **myeloid stem cell** is transformed into a **proerythroblast** (Figure 17.5). Proerythroblasts, in turn, give rise to the **early (basophilic) erythroblasts** that produce huge numbers of ribosomes. During these first two phases, the cells divide many times. Hemoglobin synthesis and iron accumulation occur as the early erythroblast is transformed into a **late erythroblast** and then a

Q *What does the term "committed cell" refer to?*

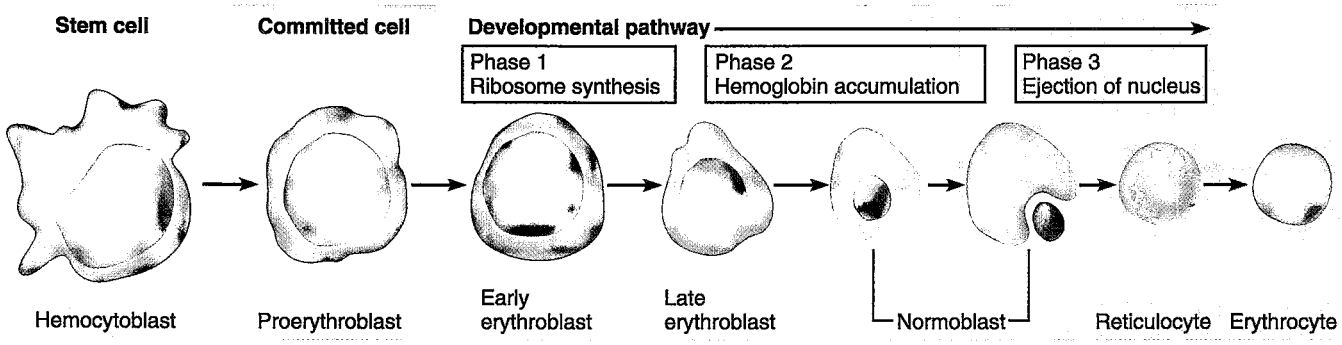


FIGURE 17.5 **Erythropoiesis: genesis of red blood cells.** Erythropoiesis is a sequence involving proliferation and differentiation of committed red marrow cells through the erythroblast and normoblast stages to the reticulocytes that are released into the bloodstream, and finally become erythrocytes. (The myeloid stem cell, the phase intermediate between the hemocytoblast and the proerythroblast, is not illustrated.)

normoblast. The "color" of the cell cytoplasm changes as the blue-staining ribosomes become masked by the pink color of hemoglobin. When a normoblast has accumulated almost all of its hemoglobin, it ejects most of its organelles. Additionally, its nuclear functions end and its nucleus degenerates and is pinched off, allowing the cell to collapse inward and assume the biconcave shape. The result is the **reticulocyte** (essentially a young erythrocyte), so named because it still contains a scant *reticulum* (network) of clumped ribosomes. The entire process from hemocytoblast to reticulocyte takes about 15 days. The reticulocytes, filled almost to bursting with hemoglobin, enter the bloodstream to begin their task of oxygen transport. Usually they become fully mature erythrocytes within two days of release as their ribosomes are degraded by intracellular enzymes. Reticulocytes account for 1–2% of all erythrocytes in the blood of healthy people. **Reticulocyte counts** provide a rough index of the *rate* of RBC formation—reticulocyte counts below or above this percentage range indicate abnormal rates of erythrocyte formation.

Regulation and Requirements for Erythropoiesis

The number of circulating erythrocytes in a given individual is remarkably constant and reflects a balance between red blood cell production and destruction. This balance is important because too few erythrocytes leads to tissue hypoxia (oxygen deprivation), whereas too many makes the blood undesirably viscous. To ensure that the number of erythrocytes in blood remains within the homeostatic range, new cells are produced at the incredibly rapid rate of more than 2 million per second in healthy people. This process is controlled hormonally and depends on adequate supplies of iron, amino acids, and certain B vitamins.

Hormonal Controls The direct stimulus for erythrocyte formation is provided by **erythropoietin (EPO)**, a glycoprotein hormone. Normally, a small amount of EPO circulates in the blood at all times and sustains red blood cell production at a basal rate (Figure 17.6). Although the liver produces some, the kidneys play the major role in EPO production. When certain kidney cells become hypoxic (i.e., have inadequate oxygen), they accelerate their release of erythropoietin. The drop in normal blood oxygen levels that triggers EPO formation can result from

1. Reduced numbers of red blood cells due to hemorrhage or excessive RBC destruction
2. Insufficient hemoglobin per RBC (as in iron deficiency)
3. Reduced availability of oxygen, as might occur at high altitudes or during pneumonia

Conversely, too many erythrocytes or excessive oxygen in the bloodstream depresses erythropoietin production. The easily missed point is that it is *not* the number of erythrocytes in blood that controls the rate of erythropoiesis. Control is based on their ability to transport enough oxygen to meet tissue demands.

Bloodborne erythropoietin stimulates red marrow cells that *are already committed* to becoming erythrocytes, causing them to mature more rapidly.

A committed cell is a blood cell precursor whose path of specialization is determined. For example, the proerythroblast can only become an erythrocyte, not one of the leukocytes.

Q *How does blood doping, practiced by some athletes (see p. 656), affect the negative feedback cycle outlined here?*

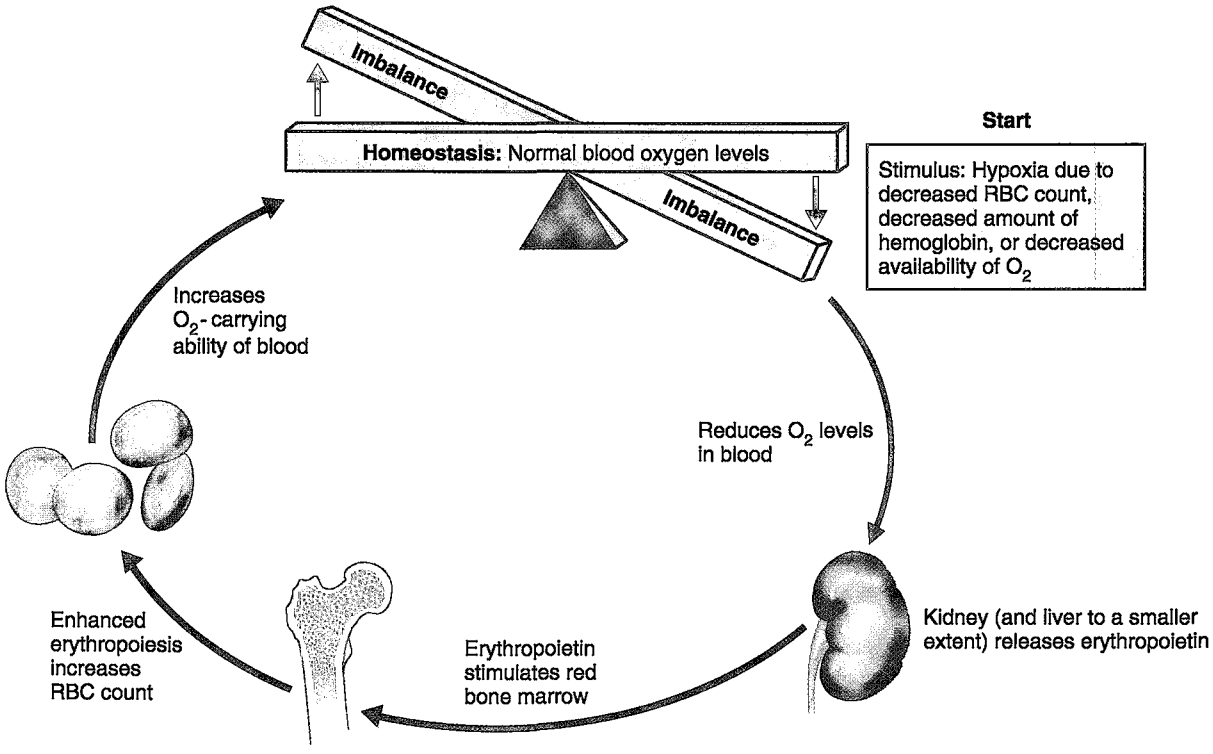

FIGURE 17.6 **Erythropoietin mechanism for regulating erythropoiesis.** Notice that increased erythropoietin release occurs when oxygen levels in the blood become inadequate to support normal cellular activity, whatever the cause.

One to two days after erythropoietin levels rise in the blood, a marked increase in the rate of reticulocyte release (and hence reticulocyte count) occurs. Notice that hypoxia (oxygen deficit) does not activate the bone marrow directly. Instead it stimulates the kidneys, which in turn provide the hormonal stimulus that activates the bone marrow.

HOMEOSTATIC IMBALANCE

Renal dialysis patients whose kidneys have failed produce too little EPO to support normal erythropoiesis. Consequently, they routinely have red blood cell counts less than half that of healthy individuals. Genetically engineered (recombinant) EPO has helped such patients immeasurably and has also become a substance of abuse in athletes—particularly in professional bike racers and marathon runners seeking increased stamina and performance. However, the consequences can be deadly. By injecting EPO, healthy athletes increase their normal hematocrit from 45% to as much as 65%. Then, with the dehydration that occurs in a long race, the blood concentrates even further, becoming a thick, sticky "sludge" that can cause clotting, stroke, and even heart failure. ●

The male sex hormone *testosterone* also enhances EPO production by the kidneys. Because female sex hormones do not have similar stimulatory effects, testosterone may be at least partially responsible for the higher RBC counts and hemoglobin levels seen in males. Also, a wide variety of chemicals released by leukocytes, platelets, and even reticular cells stimulates bursts of RBC production.

Dietary Requirements The raw materials required for erythropoiesis include the usual nutrients and structural materials—amino acids, lipids, and carbohydrates. Iron is essential for hemoglobin synthesis. Iron is available from the diet, and its absorption into the bloodstream is precisely controlled by

A *Blood doping, which increases the number of RBCs in the circulation and thus increases the amount of oxygen being transported, would inhibit erythropoietin release by ending the stimulus for its formation.*

Q *How would you expect blood levels of bilirubin to change in a person that has severe liver disease?*

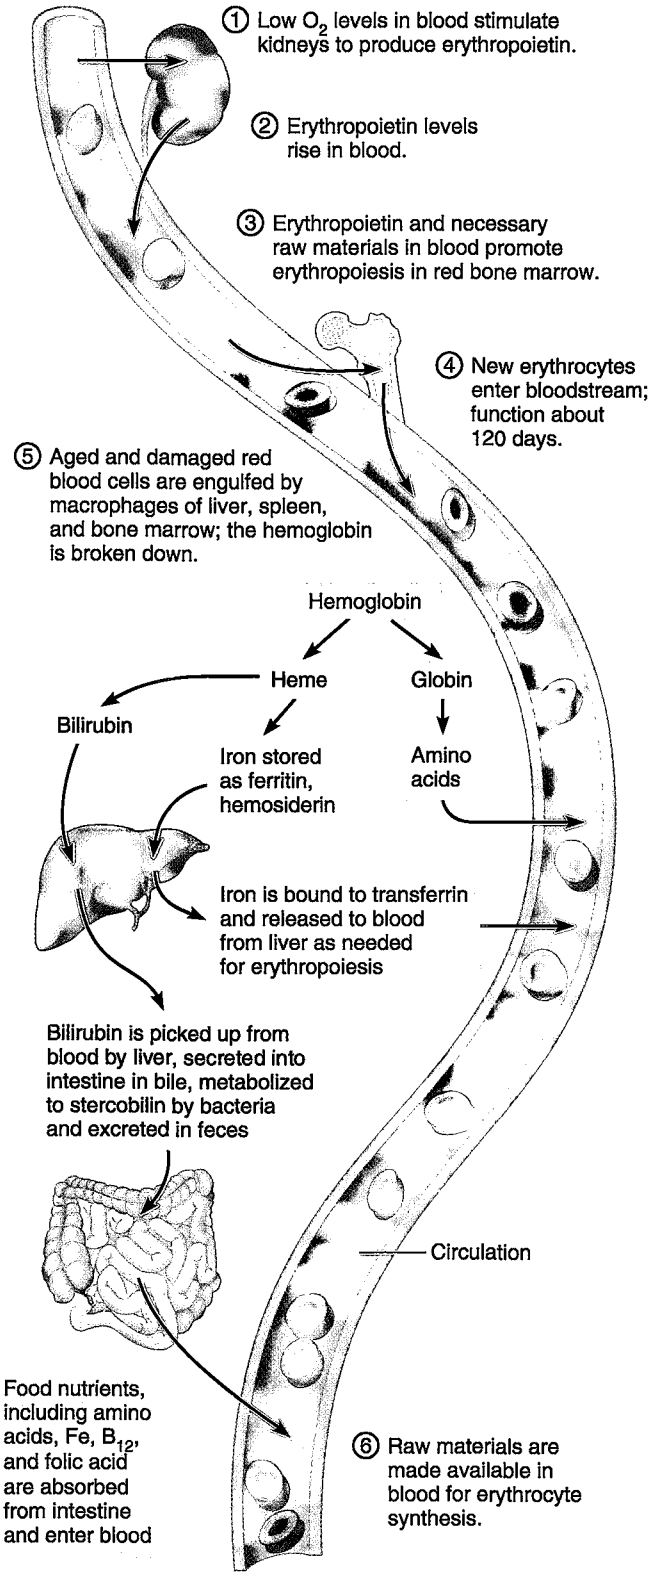

FIGURE 17.7 **Life cycle of red blood cells.**

intestinal cells in response to changing body stores of iron.

Approximately 65% of the body's iron supply (about 4000 mg) is in hemoglobin. Most of the remainder is stored in the liver, spleen, and (to a much lesser extent) bone marrow. Because free iron ions (Fe^{2+}, Fe^{3+}) are toxic, iron is stored inside cells as protein-iron complexes such as **ferritin** (fer'ĭ-tin) and **hemosiderin** (he"mo-sid'er-in). In blood, iron is transported loosely bound to a transport protein called **transferrin,** and developing erythrocytes take up iron as needed to form hemoglobin (Figure 17.7). Small amounts of iron are lost each day in feces, urine, and perspiration. The average daily loss of iron is 1.7 mg in women and 0.9 mg in men. In women, the menstrual flow accounts for the additional losses.

Two B-complex vitamins—vitamin B_{12} and folic acid—are necessary for normal DNA synthesis. Thus, even slight deficits jeopardize rapidly dividing cell populations, such as developing erythrocytes.

Fate and Destruction of Erythrocytes

The anucleate condition of erythrocytes carries with it some important limitations. Red blood cells are unable to synthesize new proteins, to grow, or to divide. Erythrocytes become "old" as they lose their flexibility and become increasingly rigid and fragile, and their contained hemoglobin begins to degenerate. Red blood cells have a useful life span of 100 to 120 days, after which they become trapped and fragment in smaller circulatory channels, particularly in those of the spleen. For this reason, the spleen is sometimes called the "red blood cell graveyard."

Dying erythrocytes are engulfed and destroyed by macrophages. The heme of their hemoglobin is split off from globin. Its core of iron is salvaged, bound to protein (as ferritin or hemosiderin), and stored for reuse. The balance of the heme group is degraded to **bilirubin** (bil"i-roo'bin), a yellow pigment that is released to the blood and binds to albumin for transport (Figure 17.7). Bilirubin is picked up by liver cells, which in turn secrete it (in bile) into the intestine, where it is metabolized to *urobilinogen.* Most of this degraded pigment leaves the body in feces, as a brown pigment called *stercobilin.* The protein (globin) part of hemoglobin is metabolized or broken down to amino acids, which are released to the circulation. Disposal of hemoglobin spilled from red blood cells to the blood (as occurs in sickle-cell anemia or hemorrhagic anemia) takes a similar but much more rapid course to avoid toxic buildup of

A *It would increase because the liver's processing functions are impaired.*

iron in blood. Released hemoglobin is captured by the plasma protein *haptoglobin* and the complex is phagocytized by macrophages.

Erythrocyte Disorders

Most erythrocyte disorders can be classified as anemias or polycythemias. The many varieties and causes of these conditions are described next.

Anemias **Anemia** (ah-ne'me-ah; "lacking blood") is a condition in which the blood has abnormally low oxygen-carrying capacity. It is a *sign* of some disorder rather than a disease in and of itself. Its hallmark is blood oxygen levels that are inadequate to support normal metabolism. Anemic individuals are fatigued, often pale, short of breath, and chilly. Common causes of anemia include the following:

1. An insufficient number of red blood cells. Conditions that reduce the red blood cell count include blood loss, excessive RBC destruction, and bone marrow failure.

Hemorrhagic anemias (hem"o-raj'ik) result from blood loss. In acute hemorrhagic anemia, blood loss is rapid (as might follow a severe stab wound); it is treated by blood replacement. Slight but persistent blood loss (due to hemorrhoids or an undiagnosed bleeding ulcer, for example) causes chronic hemorrhagic anemia. Once the primary problem is resolved, normal erythropoietic mechanisms replace the deficient blood cells.

In *hemolytic anemias* (he"mo-lit'ik), erythrocytes rupture, or lyse, prematurely. Hemoglobin abnormalities, transfusion of mismatched blood, and certain bacterial and parasitic infections are possible causes.

Aplastic anemia may result from destruction or inhibition of the red marrow by certain drugs and chemicals, ionizing radiation, or viruses. In most cases, the cause is unknown. Because marrow destruction impairs formation of *all* formed elements, anemia is just one of its signs. Defects in blood clotting and immunity are also present. Blood transfusions provide a stopgap treatment until bone marrow transplants or transfusion of umbilical blood, which contains stem cells, can be done.

2. Low hemoglobin content. When hemoglobin molecules are normal, but erythrocytes contain fewer than the usual number, a nutritional anemia is always suspected.

Iron-deficiency anemia is generally a secondary result of hemorrhagic anemias, but it also results from inadequate intake of iron-containing foods and impaired iron absorption. The erythrocytes produced, called **microcytes,** are small and pale. The obvious treatment is iron supplements, but if chronic hemorrhage is the cause, blood transfusions may also be needed.

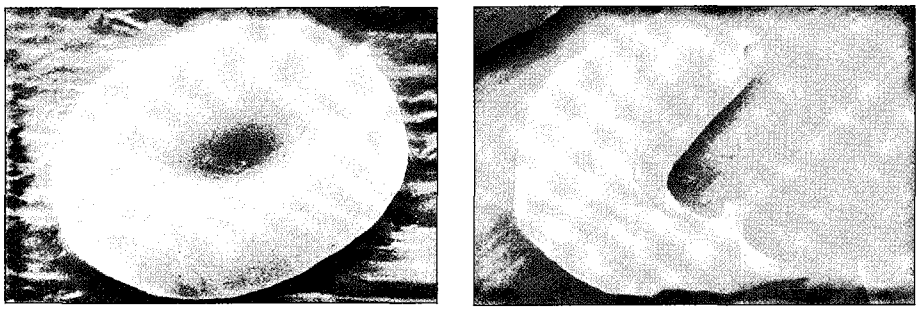
When athletes exercise vigorously, their blood volume expands and can increase by as much as 35% over time. Since this in effect dilutes the blood components, a test for the iron content of the blood at such times would indicate iron-deficiency anemia. However, this iron deficiency illusion, called **athlete's anemia,** is reversed as blood components return to physiological levels within a week or so after resuming a normal level of activity.

Pernicious anemia is due to a deficiency of vitamin B_{12}. Because meats, poultry, and fish provide ample amounts of the vitamin, diet is rarely the problem except for strict vegetarians. A substance called **intrinsic factor,** produced by the stomach mucosa, must be present for vitamin B_{12} to be absorbed by intestinal cells. In most cases of pernicious anemia, intrinsic factor is deficient. Consequently, the developing erythrocytes grow but do not divide, and large, pale cells called **macrocytes** result. Pernicious anemia, an autoimmune disease in which the stomach mucosa atrophies, most often affects the elderly. Treatment involves regular intramuscular injections of vitamin B_{12} or application of a B_{12}-containing gel (Nascobal) to the nasal lining once a week.

3. Abnormal hemoglobin. Production of abnormal hemoglobin usually has a genetic basis. Two such examples, thalassemia and sickle-cell anemia, can be serious, incurable, and sometimes fatal diseases. In both diseases the globin part of hemoglobin is abnormal and the erythrocytes produced are fragile and rupture prematurely.

Thalassemias (thal"ah-se'me-ahs; "sea blood") are typically seen in people of Mediterranean ancestry, such as Greeks and Italians. One of the globin chains is absent or faulty, and the erythrocytes are thin, delicate, and deficient in hemoglobin. There are many subtypes of thalassemia, classified according to which hemoglobin chain is affected and where, ranging in severity from mild to so severe that monthly blood transfusion is required.

In **sickle-cell anemia,** the havoc caused by the abnormal hemoglobin, *hemoglobin S (HbS),* results from a change in just *one* of the 287 amino acids in a beta chain of the globin molecule! This alteration causes the beta chains to link together under low-oxygen conditions, forming stiff rods so that hemoglobin S becomes spiky and sharp. This, in turn, causes the red blood cells to become crescent shaped (Figure 17.8) when they unload oxygen molecules or when the oxygen content of the blood is lower than normal, as during vigorous exercise and other activities that increase metabolic rate. The stiff, deformed erythrocytes rupture easily and tend to dam up in small blood vessels. These events interfere with oxygen delivery, leaving the victims gasping for air and



(a) (b)

FIGURE 17.8 **Comparison of (a) a normal erythrocyte to (b) a sickled erythrocyte.** (6700×)

in extreme pain. Bone and chest pain are particularly severe; infection and stroke are common sequels. Blood transfusion is still the standard treatment for an acute sickle-cell crisis, but preliminary results using inhaled nitric oxide to dilate blood vessels are promising.

Sickle-cell anemia occurs chiefly in black people who live in the malaria belt of Africa and among their descendants. It strikes nearly one of every 400 black newborns in the United States. Globally, 300–500 million people are infected with malaria and more than a million die each year. Apparently, the gene that causes sickling of red blood cells also causes erythrocytes infected by the malaria-causing parasite to stick to capillary walls. Then, during oxygen deficit, these abnormal erythrocytes lose potassium, an essential ingredient for survival of the parasite. Thus, individuals with the sickle-cell gene have a better chance of surviving in regions where malaria is prevalent. Only those carrying two copies of the defective gene have sickle-cell anemia. Those carrying only one sickling gene have sickle-cell trait; they generally do not display the symptoms, but can transmit the gene to their offspring.

Since fetal hemoglobin (HbF) does not "sickle," even in those destined to have sickle-cell anemia, investigators have been looking for ways to switch the fetal hemoglobin gene back on. *Hydroxyurea,* a drug used to treat chronic leukemia, does just that. This drug dramatically reduces the excruciating pain and overall severity and complications of sickle-cell anemia (by 50%). A number of other approaches are now being tested, including oral arginine to stimulate nitric oxide production and dilate blood vessels, bone marrow transplants, and gene therapy using a small portion of the HIV virus as a vector to deliver therapeutic beta A globin genes for synthesizing normal beta chains.

Polycythemia **Polycythemia** (pol"e-si-the'me-ah; "many blood cells") is an abnormal excess of erythrocytes that increases blood viscosity, causing it to sludge, or flow sluggishly. *Polycythemia vera,* a bone marrow cancer, is characterized by dizziness and an exceptionally high RBC count (8–11 million cells/μl). The hematocrit may be as high as 80% and blood volume may double, causing the vascular system to become engorged with blood and severely impairing circulation.

Secondary polycythemias result when less oxygen is available or EPO production increases. The secondary polycythemia that appears in individuals living at high altitudes is a normal physiological response to the reduced atmospheric pressure and lower oxygen content of the air in such areas. RBC counts of 6–8 million/μl are common in such people. Severe polycythemia is treated by blood dilution, that is, removing some blood and replacing it with saline.

Blood doping, practiced by some athletes competing in aerobic events, is artificially induced polycythemia. Some of the athlete's red blood cells are drawn off and then reinjected a few days before the event. Because the erythropoietin mechanism is triggered shortly after blood removal, the erythrocytes are quickly replaced. Then, when the stored blood is reinfused, a temporary polycythemia results. Since red blood cells carry oxygen, the additional infusion should translate into increased oxygen-carrying capacity due to a higher hematocrit, and hence greater endurance and speed. Other than problems that might derive from increased blood viscosity, such as temporary high blood pressure or reduced blood delivery to body tissues, blood doping seems to work. However, the practice is considered unethical and has been banned from the Olympic Games.

Leukocytes

General Structural and Functional Characteristics

Leukocytes (*leuko* = white), or **white blood cells (WBCs),** are the only formed elements that are complete cells, with nuclei and the usual organelles. Accounting for less than 1% of total blood volume, leukocytes are far less numerous than red blood cells. On average, there are 4800–10,800 WBCs/μl (mm^3) of blood.

Leukocytes are crucial to our defense against disease. They form a mobile army that helps protect the body from damage by bacteria, viruses, parasites, toxins, and tumor cells. As such, they have some special functional characteristics. Red blood cells are confined to the bloodstream, and they carry out their functions in the blood. But white blood cells are able to slip out of the capillary blood vessels—a process called **diapedesis** (di"ah-pĕ-de'sis; "leaping across")—and the circulatory system is simply their means of transport to areas of the body (mostly loose connective tissues or lymphoid tissues) where they are needed to mount inflammatory or immune responses. As explained in more detail in Chapter 21, the signals that prompt WBCs to leave the bloodstream at specific locations are adhesion molecules *(selectins)* displayed by endothelial cells forming the capillary walls at sites of inflammation. Once out of the bloodstream, leukocytes move through the tissue spaces by **amoeboid motion** (they form flowing cytoplasmic extensions that move them along). By following the chemical trail of molecules released by damaged cells or other leukocytes, a phenomenon called **positive chemotaxis,** they can pinpoint areas of tissue damage and infection and gather there in large numbers to destroy foreign substances or dead cells.

Whenever white blood cells are mobilized for action, the body speeds up their production and twice the normal number may appear in the blood within a few hours. A *white blood cell count* of over 11,000 cells/μl is **leukocytosis.** This condition is a normal homeostatic response to an infection in the body.

Leukocytes are grouped into two major categories on the basis of structural and chemical characteristics: *Granulocytes* contain obvious membrane-bound cytoplasmic granules; *agranulocytes* lack obvious granules. General information about the various leukocytes is provided next. More details appear in Figure 17.9 and Table 17.2.

Students are often asked to list the leukocytes in order from most abundant to least abundant. The following phrase may help you with this task: Never **l**et **m**onkeys **e**at **b**ananas (neutrophils, lymphocytes, monocytes, eosinophils, basophils).

Granulocytes

Granulocytes (gran'u-lo-sīts), which include neutrophils, basophils, and eosinophils, are all roughly spherical in shape. They are larger and much shorter lived (in most cases) than erythrocytes. They characteristically have lobed nuclei (rounded nuclear masses connected by thinner strands of nuclear material), and their membrane-bound cytoplasmic granules stain quite specifically with Wright's stain. Functionally, all granulocytes are phagocytes to a greater or lesser degree.

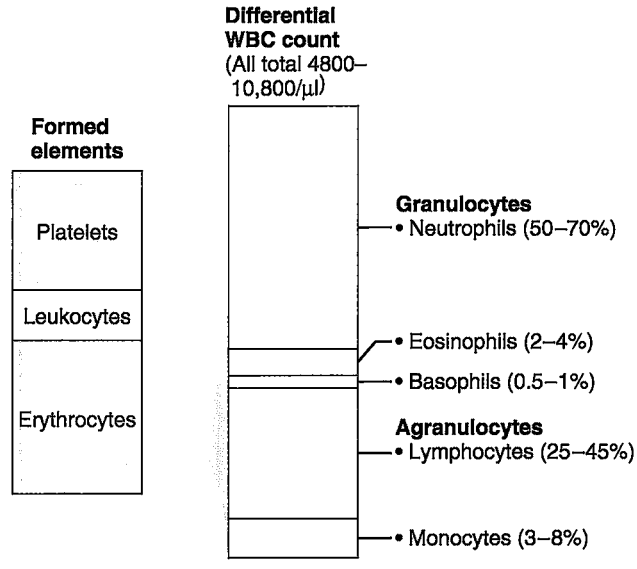


FIGURE 17.9 **Types and relative percentages of leukocytes in normal blood.** (The relationship of the formed elements in the left column is not shown to scale because erythrocytes comprise nearly 98% of the formed elements whereas leukocytes and platelets together account for the remaining 2+%.)

Neutrophils **Neutrophils** (nu'tro-filz), the most numerous of the white blood cells, account for 50–70% of the WBC population. Neutrophils are about twice as large as erythrocytes.

The neutrophil cytoplasm stains pale lilac and contains very fine granules (of two varieties) that are difficult to see (see Table 17.2 and Figure 17.10a). They are called neutrophils (literally, "neutral-loving") because their granules take up both *basic* (blue) and *acidic* (red) *dyes*. Together, the two types of granules give the cytoplasm a lilac color. Some of these granules contain hydrolytic enzymes, and are regarded as lysosomes. Others, especially the smaller granules, contain a potent "brew" of antimicrobial proteins, called **defensins.** Neutrophil nuclei consist of three to six lobes. Because of this nuclear variability, they are often called **polymorphonuclear leukocytes (PMNs)** or simply **polys** (*polymorphonuclear* = many shapes of the nucleus). (However, some authorities use this term to refer to all granulocytes.)

Neutrophils are chemically attracted to sites of inflammation and are active phagocytes. They are especially partial to bacteria and some fungi, and bacterial killing is promoted by a process called a respiratory burst. In the **respiratory burst,** oxygen is actively metabolized to produce potent germ-killer oxidizing substances such as bleach and hydrogen peroxide, and defensin-mediated lysis occurs. It appears that when the granules containing defensins are merged with a microbe-containing phagosome, the defensins form peptide "spears" that pierce holes

TABLE 17.2 Summary of Formed Elements of the Blood

CELL TYPE	ILLUSTRATION	DESCRIPTION*	CELLS/μl (mm^3) OF BLOOD	DURATION OF DEVELOPMENT (D) AND LIFE SPAN (LS)	FUNCTION
Erythrocytes (red blood cells, RBCs)		Biconcave, anucleate disc; salmon-colored; diameter 7–8 μm	4–6 million	D: about 15 days LS: 100–120 days	Transport oxygen and carbon dioxide
Leukocytes (white blood cells, WBCs)		Spherical, nucleated cells	4800–10,800		
Granulocytes					
▪ Neutrophil		Nucleus multilobed; inconspicuous cytoplasmic granules; diameter 10–12 μm	3000–7000	D: about 14 days LS: 6 hours to a few days	Phagocytize bacteria
▪ Eosinophil		Nucleus bilobed; red cytoplasmic granules; diameter 10–14 μm	100–400	D: about 14 days LS: about 5 days	Kill parasitic worms; inactivate some inflammatory chemicals of allergy
▪ Basophil		Nucleus lobed; large purplish-black cytoplasmic granules; diameter 10–14 μm	20–50	D: 1–7 days LS: a few hours to a few days	Release histamine and other mediators of inflammation; contain heparin, an anticoagulant
Agranulocytes					
▪ Lymphocyte		Nucleus spherical or indented; pale blue cytoplasm; diameter 5–17 μm	1500–3000	D: days to weeks LS: hours to years	Mount immune response by direct cell attack or via antibodies
▪ Monocyte		Nucleus U or kidney shaped; gray-blue cytoplasm; diameter 14–24 μm	100–700	D: 2–3 days LS: months	Phagocytosis; develop into macrophages in the tissues
Platelets		Discoid cytoplasmic fragments containing granules; stain deep purple; diameter 2–4 μm	150,000–400,000	D: 4–5 days LS: 5–10 days	Seal small tears in blood vessels; instrumental in blood clotting

*Appearance when stained with Wright's stain.

17

in the membrane of the ingested "foe." Neutrophils are our body's bacteria slayers, and their numbers increase explosively during acute bacterial infections such as meningitis and appendicitis.

Eosinophils **Eosinophils** (e"o-sin'o-filz) account for 2–4% of all leukocytes and are approximately the size of neutrophils. Their deep red nucleus usually resembles an old-fashioned telephone receiver; that is, it has two lobes connected by a broad band of nuclear material (see Table 17.2 and Figure 17.10b). Large, coarse granules that stain from brick red to crimson with acid (eosin) dyes pack the cytoplasm. These granules are lysosome-like and filled with a unique variety of digestive enzymes. However, unlike typical lysosomes, they lack enzymes that specifically digest bacteria.

The most important role of eosinophils is to lead the counterattack against parasitic worms, such as flatworms (tapeworms and flukes) and roundworms (pinworms and hookworms) that are too large to be phagocytized. These worms are ingested in food

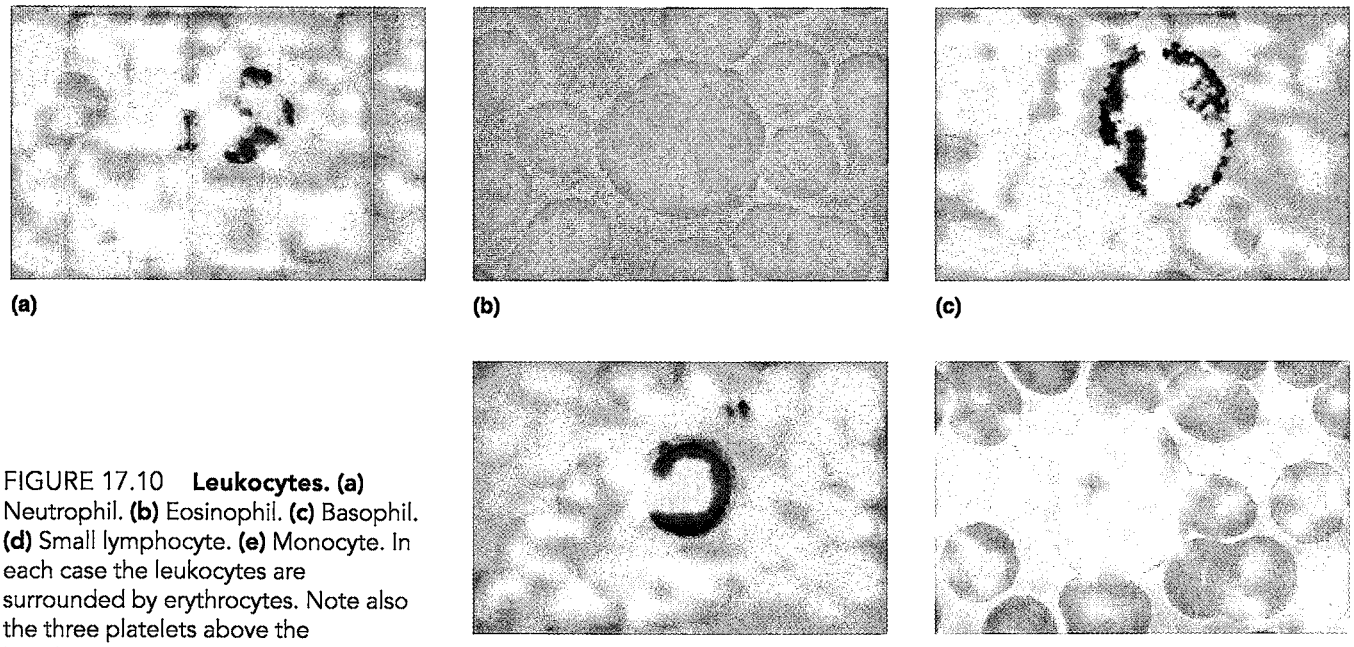

FIGURE 17.10 **Leukocytes. (a)** Neutrophil. **(b)** Eosinophil. **(c)** Basophil. **(d)** Small lymphocyte. **(e)** Monocyte. In each case the leukocytes are surrounded by erythrocytes. Note also the three platelets above the lymphocyte in (d). (All 1600×)

(especially raw fish) or invade the body via the skin and then typically burrow into the intestinal or respiratory mucosae. Eosinophils reside in the loose connective tissues at the same body sites, and when a parasitic worm "prey" is encountered, they gather around and release the enzymes from their cytoplasmic granules onto the parasite's surface, digesting it away. Eosinophils may also lessen the severity of allergies by inactivating certain inflammatory chemicals released during allergic reactions.

Basophils **Basophils** are the rarest white blood cells, averaging only 0.5–1% of the leukocyte population. Their cytoplasm contains large, coarse, histamine-containing granules that have an affinity for the basic dyes (*basophil* = "base loving") and stain purplish-black. *Histamine* is an inflammatory chemical that acts as a vasodilator (makes blood vessels dilate) and attracts other white blood cells to the inflamed site; drugs called antihistamines counter this effect. The deep purple nucleus is generally U or S shaped with two or three conspicuous constrictions.

Granulated cells similar to basophils, called *mast cells*, are found in connective tissues. Although mast cell nuclei tend to be more oval than lobed, the cells are similar microscopically, and both cell types bind to a particular antibody (immunoglobulin E) that causes the cells to release histamine. However, they arise from different cell lines.

Agranulocytes

The **agranulocytes** include lymphocytes and monocytes, WBCs that lack *visible* cytoplasmic granules. Although they are similar structurally, they are functionally distinct and unrelated cell types. Their nuclei are typically spherical or kidney shaped.

Lymphocytes **Lymphocytes,** accounting for 25% or more of the WBC population, are the second most numerous leukocytes in the blood. When stained, a typical lymphocyte has a large, dark-purple nucleus that occupies most of the cell volume. The nucleus is usually spherical but may be slightly indented, and it is surrounded by a thin rim of pale-blue cytoplasm (see Table 17.2 and Figure 17.10d). Lymphocyte diameter ranges from 5 to 17 μm, but they are often classified according to size as small (5–8 μm), medium (10–12 μm), and large (14–17 μm).

Although large numbers of lymphocytes exist in the body, only a small proportion of them (mostly the small lymphocytes) is found in the bloodstream. In fact, lymphocytes are so called because most are firmly enmeshed in lymphoid tissues (lymph nodes, spleen, etc.), where they play a crucial role in immunity. **T lymphocytes (T cells)** function in the immune response by acting directly against virus-infected cells and tumor cells. **B lymphocytes (B cells)** give rise to *plasma cells*, which produce **antibodies** (immunoglobulins) that are released to the blood. (B and T lymphocyte functions are described in Chapter 21.)

Monocytes **Monocytes,** which account for 3–8% of WBCs, have an average diameter of 18 μm and are the largest leukocytes. They have abundant pale-blue cytoplasm and a darkly staining purple nucleus, which is distinctively U or kidney shaped (see Table 17.2 and Figure 17.10e). When circulating monocytes leave the bloodstream and enter the tissues,

they differentiate into highly mobile **macrophages** with prodigious appetites. Macrophages are actively phagocytic, and they are crucial in the body's defense against viruses, certain intracellular bacterial parasites, and *chronic* infections such as tuberculosis. As explained in Chapter 21, macrophages are also important in activating lymphocytes to mount the immune response.

Production and Life Span of Leukocytes

Like erythropoiesis, **leukopoiesis,** or the production of white blood cells, is stimulated by chemical messengers. These messengers, which can act either as paracrines or hormones, are glycoproteins that fall into two families of hematopoietic factors, **interleukins** and **colony-stimulating factors,** or **CSFs.** The interleukins are numbered (e.g., IL-3, IL-5), whereas most CSFs are named for the leukocyte population they stimulate—thus *granulocyte-CSF (G-CSF)* stimulates production of granulocytes. Hematopoietic factors, released by supporting cells of the bone marrow and mature WBCs, not only prompt the white blood cell precursors to divide and mature, but also enhance the protective potency of mature leukocytes.

Many of the hematopoietic hormones (EPO and several of the CSFs) are used clinically to stimulate the bone marrow of cancer patients who are receiving chemotherapy (which suppresses the marrow) and of those who have received marrow transplants, and to beef up the protective responses of AIDS patients.

Figure 17.11 shows the pathways of leukocyte differentiation. An early branching of the pathway divides the **lymphoid stem cells,** which produce lymphocytes, from the **myeloid stem cells,** which give rise to all other formed elements. In each granulocyte line, the committed cells, called **myeloblasts** (mi'ĕ-lo-blasts"), accumulate lysosomes, becoming **promyelocytes.** The distinctive granules of each granulocyte type appear next in the **myelocyte** stage and then cell division stops. In the subsequent stage, the nuclei arc, producing the **band cell** stage. Just before granulocytes leave the marrow and enter the circulation, their nuclei constrict, beginning the process of nuclear segmentation. The bone marrow stores mature granulocytes and usually contains about ten times more granulocytes than are found in the blood. The normal ratio of granulocytes to erythrocytes produced is about 3:1, which reflects the much shorter life span (0.5 to 9.0 days) of the granulocytes, most of which die combating invading microorganisms.

Despite their similar appearances, the two types of agranulocytes have very different lineages. Monocytes diverge from a myeloblast that can become either a neutrophil or a monocyte. Cells following the monocyte line pass through the **promonocyte** stage (see Figure 17.11) before leaving the bone marrow and becoming monocytes. Lymphocytes derive from the lymphoid stem cell and progress through the **lymphoblast** and **prolymphocyte** stages. The prolymphocytes leave the bone marrow and travel to the lymphoid tissues, where their further differentiation occurs (as described in Chapter 21). Monocytes may live for several months, whereas the life span of lymphocytes varies from a few days to decades.

Leukocyte Disorders

Overproduction of abnormal leukocytes occurs in leukemia and infectious mononucleosis. At the opposite pole, **leukopenia** (loo"ko-pe'ne-ah) is an abnormally low white blood cell count (*penia* = poverty), commonly induced by drugs, particularly glucocorticoids and anticancer agents.

Leukemias The term *leukemia,* literally "white blood," refers to a group of cancerous conditions involving white blood cells. As a rule, the renegade leukocytes are members of a single *clone* (descendants of a single cell) that remain unspecialized and proliferate out of control, impairing normal bone marrow function. The leukemias are named according to the abnormal cell type primarily involved. For example, *myelocytic leukemia* involves myeloblast descendants, whereas *lymphocytic leukemia* involves the lymphocytes. Leukemia is *acute* (quickly advancing) if it derives from blast-type cells like lymphoblasts, and *chronic* (slowly advancing) if it involves proliferation of later cell stages like myelocytes. The more serious acute forms primarily affect children. Chronic leukemia is seen more often in elderly people. Without therapy, all leukemias are fatal; only the time course differs.

In all leukemias, the bone marrow becomes almost totally occupied by cancerous leukocytes and immature WBCs flood into the bloodstream. Because the other blood cell lines are crowded out, severe anemia and bleeding problems also result. Other symptoms include fever, weight loss, and bone pain. Although tremendous numbers of leukocytes are produced, they are nonfunctional and cannot defend the body in the usual way. The most common causes of death are internal hemorrhage and overwhelming infections.

FIGURE 17.11 **Leukocyte formation.** Leukocytes arise from ancestral stem cells called hemocytoblasts. **(a–c)** Granular leukocytes develop via a sequence involving myeloblasts. **(d–e)** Monocytes, like granular leukocytes, are progeny of the myeloid stem cell and diverge from a myeloblast that can become either a neutrophil or a monocyte. Only lymphocytes arise via the lymphoid stem cell line.

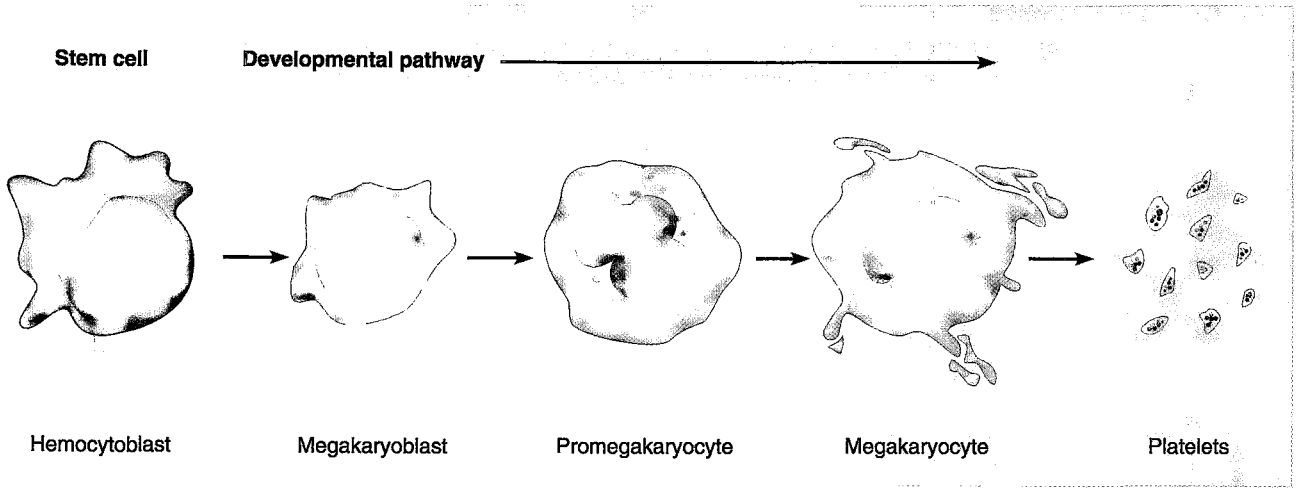

FIGURE 17.12 **Genesis of platelets.** The hemocytoblast gives rise to cells that undergo several mitotic divisions unaccompanied by cytoplasmic division to produce megakaryocytes. The cytoplasm of the megakaryocyte becomes compartmentalized by membranes, and the plasma membrane then fragments, liberating the platelets. (Intermediate stages between the hemocytoblast and megakaryoblast are not illustrated.)

Irradiation and administration of antileukemic drugs to destroy the rapidly dividing cells have successfully induced remissions (symptom-free periods) lasting from months to years. Bone marrow or umbilical cord blood transplants are used in selected patients when compatible donors are available.

Infectious Mononucleosis Once called the kissing disease, *infectious mononucleosis* is a highly contagious viral disease most often seen in young adults. Caused by the Epstein-Barr virus, its hallmark is excessive numbers of agranulocytes, many of which are atypical. The affected individual complains of being tired and achy, and has a chronic sore throat and a low-grade fever. There is no cure, but with rest the condition typically runs its course to recovery in a few weeks.

17

Platelets

Platelets are not cells in the strict sense. About one-fourth the diameter of a lymphocyte, they are cytoplasmic fragments of extraordinarily large cells (up to 60 μm in diameter) called **megakaryocytes** (meg"ah-kar'e-o-sītz). In blood smears, each platelet exhibits a blue-staining outer region and an inner area containing granules that stain purple. The granules contain an impressive array of chemicals that act in the clotting process, including serotonin, Ca^{2+}, a variety of enzymes, ADP, and platelet-derived growth factor (PDGF).

Platelets are essential for the clotting process that occurs in plasma when blood vessels are ruptured or their lining is injured. By sticking to the damaged site, platelets form a temporary plug that helps seal the break. (This mechanism is explained shortly.) Because platelets are anucleate, they age quickly and degenerate in about ten days if they are not involved in clotting. In the meantime, they circulate freely, kept mobile but inactive by molecules (nitric oxide, prostacyclin) secreted by endothelial cells lining the blood vessels.

Platelet formation is regulated by a hormone called **thrombopoietin.** Their immediate ancestral cells, the megakaryocytes, are progeny of the hemocytoblast and the myeloid stem cell, but their formation is quite unusual (Figure 17.12). In this line, repeated mitoses of the **megakaryoblast** occur, but cytokinesis does not. The final result is the megakaryocyte (literally "big nucleus cell"), a bizarre cell with a huge, multilobed nucleus and a large cytoplasmic mass. When formed, the megakaryocyte presses up against a sinusoid (the specialized type of capillary in the marrow) and sends cytoplasmic extensions through the sinusoid wall into the bloodstream. These extensions rupture, releasing the platelet fragments like stamps being torn from a sheet of postage stamps and seeding the blood with platelets. The plasma membranes associated with each fragment quickly seal around the cytoplasm to form the grainy, roughly disc-shaped platelets (see Table 17.2), each with a diameter of 2–4 μm. Each cubic millimeter of blood contains between 150,000 and 400,000 of the tiny platelets.

TABLE 17.3 Blood Clotting Factors (Procoagulants)

FACTOR NUMBER	FACTOR NAME	NATURE/ORIGIN	FUNCTION OR PATHWAY
I	Fibrinogen	Plasma protein; synthesized by liver	Common pathway; converted to fibrin, insoluble weblike substance of clot
II	Prothrombin	Plasma protein; synthesized by liver; formation requires vitamin K	Common pathway; converted to thrombin, which enzymatically converts fibrinogen to fibrin
III	Tissue factor (TF) or tissue thromboplastin	Glycoprotein in plasma membrane of cells underneath the endothelium	Activates extrinsic pathway
IV	Calcium ions (Ca^{2+})	Inorganic ion present in plasma; acquired from diet or released from bone	Needed for essentially all stages of coagulation process
V	Proaccelerin, labile factor, or platelet accelerator	Plasma protein; synthesized in liver; also released by platelets	Common pathway
VI	Number no longer used; substance now believed to be same as factor V		
VII	Proconvertin or convertin	Plasma protein; synthesized in liver in process that requires vitamin K	Both extrinsic and intrinsic mechanisms
VIII	Antihemophilic factor (AHF)	Plasma protein synthesized in liver; deficiency causes hemophilia A	Intrinsic mechanism
IX	Plasma thromboplastin component (PTC) or Christmas factor	Plasma protein; synthesized in liver; deficiency results in hemophilia B; synthesis requires vitamin K	Intrinsic mechanism
X	Stuart factor, Stuart-Prower factor, or thrombokinase	Plasma protein; synthesized in liver; synthesis requires vitamin K	Common pathway
XI	Plasma thromboplastin antecedent (PTA)	Plasma protein; synthesized in liver; deficiency results in hemophilia C	Intrinsic mechanism
XII	Hageman factor, glass factor	Plasma protein; synthesized in liver; activated by negatively charged surfaces (e.g., glass)	Intrinsic mechanism; activates plasmin; initiates clotting in vitro; activation initiates inflammation
XIII	Fibrin stabilizing factor (FSF)	Plasma protein; synthesized in liver and bone marrow	Cross-links fibrin, forming a strong, stable clot

Hemostasis

Normally, blood flows smoothly past the intact blood vessel lining (endothelium). But if a blood vessel wall breaks, a whole series of reactions is set in motion to accomplish **hemostasis** (he″mo-sta′sis), or stoppage of bleeding (*stasis* = halting). Without this plug-the-hole defensive reaction, we would quickly bleed out our entire blood volume from even the smallest cuts.

The hemostasis response, which is fast, localized, and carefully controlled, involves many blood coagulation factors (Table 17.3) normally present in plasma as well as some substances that are released by platelets and injured tissue cells. During hemostasis, three steps occur in rapid sequence: (1) vascular spasms, (2) platelet plug formation, and (3) coagulation, or blood clotting (Figure 17.13a). Blood loss at the site is permanently prevented when fibrous tissue grows into the clot and seals the hole in the blood vessel.

Vascular Spasms

The immediate response to blood vessel injury is constriction of the damaged blood vessel (vasoconstriction). Factors that trigger this **vascular spasm** include direct injury to vascular smooth muscle, chemicals released by endothelial cells and platelets, and reflexes initiated by local pain receptors. The spasm mechanism becomes more and more efficient as the amount of tissue damage increases, and is

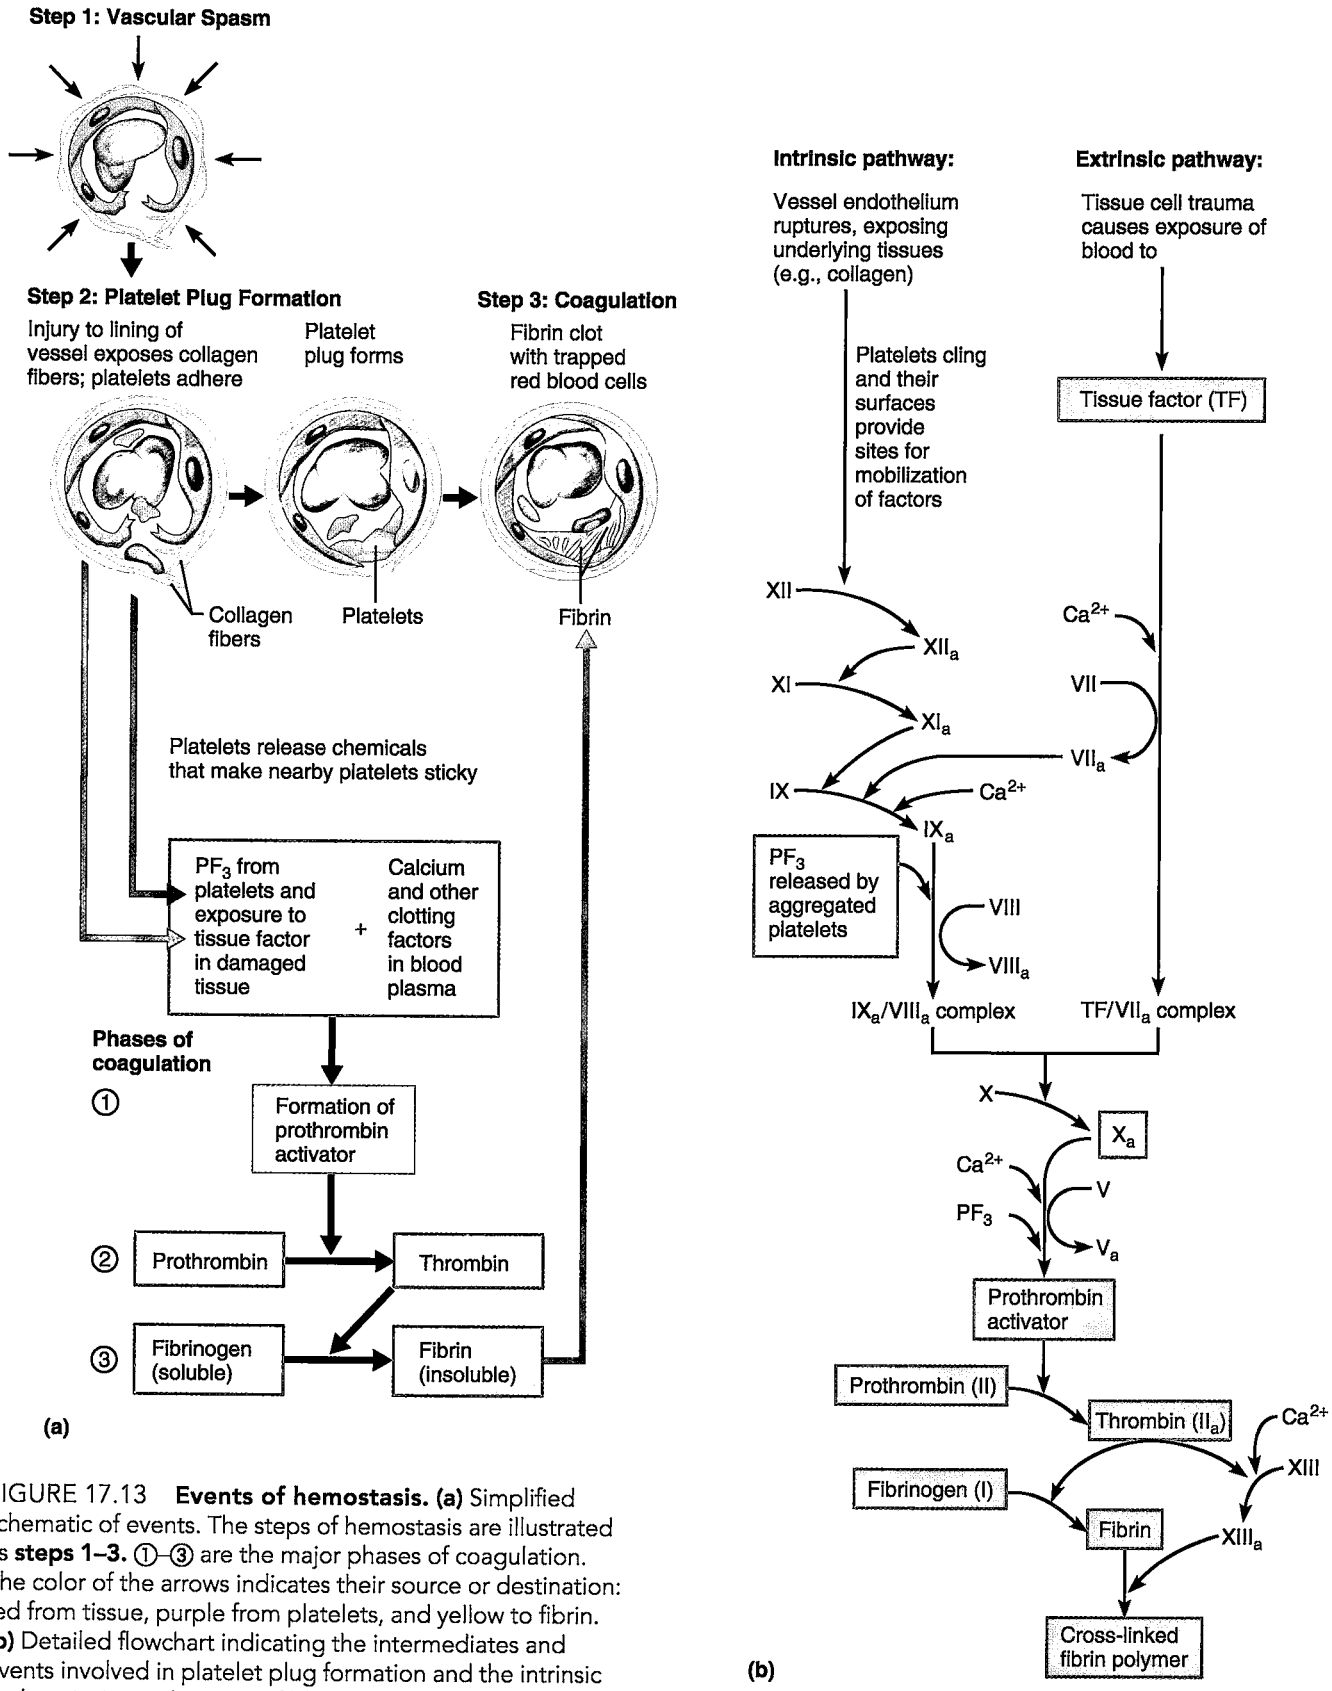

FIGURE 17.13 **Events of hemostasis. (a)** Simplified schematic of events. The steps of hemostasis are illustrated as **steps 1–3.** ①–③ are the major phases of coagulation. The color of the arrows indicates their source or destination: red from tissue, purple from platelets, and yellow to fibrin. **(b)** Detailed flowchart indicating the intermediates and events involved in platelet plug formation and the intrinsic and extrinsic mechanisms of blood clotting (coagulation). (The subscript "a" indicates the activated procoagulant.)

most effective in the smaller blood vessels. The value of the spasm response is obvious: A strongly constricted artery can significantly reduce blood loss for 20–30 minutes, allowing time for platelet plug formation and blood clotting to occur.

Platelet Plug Formation

Platelets play a key role in hemostasis by forming a plug that temporarily seals the break in the vessel wall. They also help to orchestrate subsequent events that lead to blood clot formation. These events are shown in simplified form in Figure 17.13a.

As a rule, platelets do not stick to each other or to the smooth endothelial linings of blood vessels. However, when the endothelium is damaged and underlying collagen fibers are exposed, platelets, with the help of a large plasma protein called von Willebrand factor (VWF) synthesized by endothelial cells, adhere tenaciously to the collagen fibers and undergo some remarkable changes. They swell, form spiked processes, and become sticky.

Once attached, the platelets are activated and their granules begin to break down and release several chemicals. Some, like **serotonin,** enhance the vascular spasm. Others, like **adenosine diphosphate (ADP),** are potent aggregating agents that attract more platelets to the area and cause them to release their contents. **Thromboxane A_2** (throm-boks'ān), a short-lived prostaglandin derivative that is generated and released, stimulates both events.

Thus, a positive feedback cycle that activates and attracts greater and greater numbers of platelets to the area begins and, within one minute, a platelet plug is built up, which further reduces blood loss. Limiting the platelet plug to the immediate area where it is needed is the task of **prostacyclin** (also called *PGI_2*), a prostaglandin produced by intact endothelial cells that is a strong inhibitor of platelet aggregation. Platelet plugs are loosely knit, but when reinforced by fibrin threads to act as a "molecular glue" for the aggregated platelets, they are quite effective in sealing the small tears in a blood vessel that occur with normal activity. Once the platelet plug is formed, the next stage, coagulation, comes into play.

Coagulation

Coagulation or **blood clotting** (Figure 17.13a), during which blood is transformed from a liquid to a gel, is a multistep process that leads to its critically important last three phases:

① A complex substance called *prothrombin activator* is formed.

② Prothrombin activator converts a plasma protein called *prothrombin* into *thrombin,* an enzyme.

③ Thrombin catalyzes the joining of *fibrinogen* molecules present in plasma to a *fibrin mesh,* which traps blood cells and effectively seals the hole until the blood vessel can be permanently repaired.

The complete coagulation process is much more complicated, however. Over 30 different substances are involved. Factors that enhance clot formation are called **clotting factors** or **procoagulants.** Although vitamin K is not directly involved in coagulation, this fat-soluble vitamin is required for the synthesis of four of the procoagulants made by the liver (see Table 17.3). Factors that inhibit clotting are called **anticoagulants.** Whether or not blood clots depends on a delicate balance between these two groups of factors. Normally, anticoagulants dominate and clotting is prevented; but when a vessel is ruptured, procoagulant activity in that area increases dramatically and clot formation begins. The procoagulants are numbered I to XIII (Table 17.3) according to the order of their discovery; hence the numerical order does *not* reflect the reaction sequence. Tissue factor (III) and Ca^{2+} (IV) are usually indicated by their names, rather than by numerals. Most of these factors are plasma proteins made by the liver that circulate in an inactive form in blood until mobilized.

Phase 1: Two Pathways to Prothrombin Activator

Clotting may be initiated by either the **intrinsic** or the **extrinsic pathway** (Figure 17.13b), and in the body both pathways are usually triggered by the same tissue-damaging events. Clotting of blood outside the body (such as in a test tube) is initiated *only* by the intrinsic mechanism. Let's examine the "why" of these differences.

Pivotal components in both mechanisms are negatively charged membranes, particularly those on platelets containing phosphatidylserine, also known as **PF_3** (platelet factor 3). Many intermediates of both pathways can be activated only in the presence of PF_3. In the slower intrinsic pathway, all factors needed for clotting are present in (intrinsic to) the blood. By contrast, when blood is exposed to an additional factor in tissues underneath the damaged endothelium called **tissue factor (TF), factor III,** or **tissue thromboplastin,** the "shortcut" extrinsic mechanism, which bypasses several steps of the intrinsic pathway, is triggered.

Each pathway requires ionic calcium and involves the activation of a *series* of procoagulants, each functioning as an enzyme to activate the next procoagulant in the sequence. The intermediate steps of each pathway *cascade* toward a common intermediate, factor X (Figure 17.13b). Once factor X has been activated, it complexes with calcium ions, PF_3, and factor V to form **prothrombin activator.**

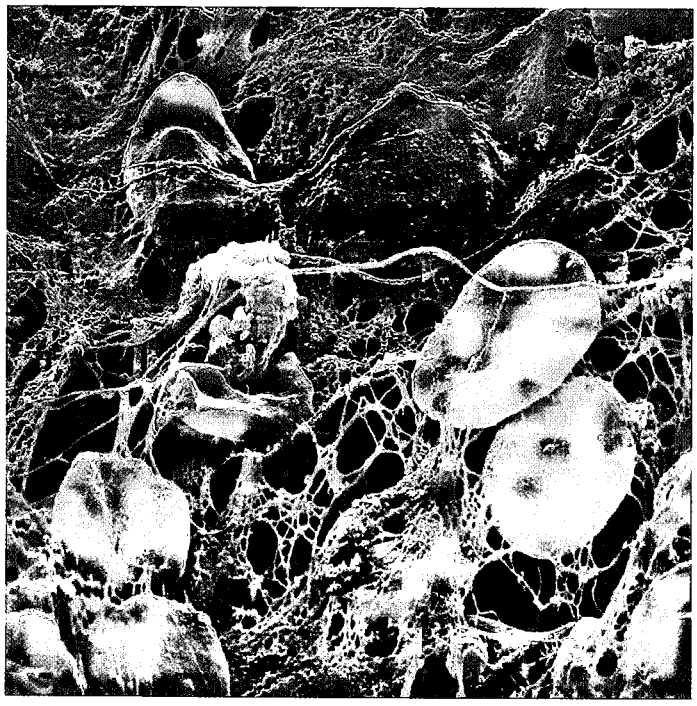

FIGURE 17.14 **Scanning electron micrograph of erythrocytes trapped in a fibrin mesh.** (3000×)

This is usually the slowest step of the blood clotting process, but once prothrombin activator is present, the clot forms in 10 to 15 seconds.

Phase 2: Common Pathway to Thrombin

Prothrombin activator catalyzes the transformation of the plasma protein **prothrombin** to the active enzyme **thrombin.**

Phase 3: Common Pathway to the Fibrin Mesh

Thrombin catalyzes the polymerization of **fibrinogen** (another plasma protein made by the liver). As the fibrinogen molecules are aligned into long, hairlike, insoluble **fibrin** strands, they glue the platelets together and make a web that forms the structural basis of the clot. In the presence of fibrin, plasma becomes gel-like and traps formed elements that try to pass through it (Figure 17.14).

In the presence of calcium ions, thrombin also activates **factor XIII (fibrin stabilizing factor),** a cross-linking enzyme that binds the fibrin strands tightly together and strengthens and stabilizes the clot. Clot formation is normally complete within 3 to 6 minutes after blood vessel damage. Because the extrinsic pathway involves fewer steps it is more rapid than the intrinsic pathway; in cases of severe tissue trauma it can promote clot formation within 15 seconds.

Clot Retraction and Repair

Within 30 to 60 minutes, the clot is stabilized further by a platelet-induced process called **clot retraction.** Platelets contain contractile proteins (actin and myosin), and they contract in much the same manner as muscle cells. As the platelets contract, they pull on the surrounding fibrin strands, squeezing **serum** (plasma minus the clotting proteins) from the mass, compacting the clot and drawing the ruptured edges of the blood vessel more closely together. Even as clot retraction is occurring, vessel healing is taking place. **Platelet-derived growth factor (PDGF)** released by platelet degranulation stimulates smooth muscle cells and fibroblasts to divide and rebuild the wall. As fibroblasts form a connective tissue patch in the injured area, endothelial cells, stimulated by vascular endothelial growth factor (VEGF), multiply and restore the endothelial lining.

Fibrinolysis

A clot is not a permanent solution to blood vessel injury, and a process called **fibrinolysis** removes unneeded clots when healing has occurred. Because small clots are formed continually in vessels throughout the body, this cleanup detail is crucial. Without fibrinolysis, blood vessels would gradually become completely blocked.

The critical natural "clot buster" is a fibrin-digesting enzyme called **plasmin,** which is produced when the plasma protein **plasminogen** is activated. Large amounts of plasminogen are incorporated into a forming clot, where it remains inactive until appropriate signals reach it. The presence of a clot in and around the blood vessel causes the endothelial cells to secrete **tissue plasminogen activator (tPA).** Activated factor XII and thrombin released during clotting also serve as plasminogen activators. As a result, most plasmin activity is confined to the clot, and any plasmin that strays into the plasma is quickly destroyed by circulating enzymes. Fibrinolysis begins within two days and continues slowly over several days until the clot is finally dissolved.

Factors Limiting Clot Growth or Formation

Factors Limiting Normal Clot Growth

Once the clotting cascade has begun, it continues until a clot is formed. Normally, two homeostatic mechanisms prevent clots from becoming unnecessarily large: (1) swift removal of clotting factors, and (2) inhibition of activated clotting factors. For clotting to occur in the first place, the concentration of activated procoagulants must reach certain critical

levels. Clot formation in rapidly moving blood is usually curbed because the activated clotting factors are diluted and washed away. For the same reasons, further growth of a forming clot is hindered when it contacts blood flowing normally.

Other mechanisms block the final step in which fibrinogen is polymerized into fibrin by restricting thrombin to the clot or by inactivating it if it escapes into the general circulation. As a clot forms, almost all of the thrombin produced is bound onto the fibrin threads. This is an important safeguard because thrombin also exerts positive feedback effects on the coagulation process prior to the common pathway. Not only does it speed up the production of prothrombin activator by acting indirectly through factor V, but it also accelerates the earliest steps of the intrinsic pathway by activating platelets. Thus, fibrin effectively acts as an anticoagulant to prevent enlargement of the clot and prevents thrombin from acting elsewhere. Thrombin not bound to fibrin is quickly inactivated by **antithrombin III,** a protein present in plasma. Antithrombin III and **protein C,** another protein produced in the liver, also inhibit the activity of other intrinsic pathway procoagulants.

Heparin, the natural anticoagulant contained in basophil and mast cell granules, is also found on the surface of endothelial cells. It inhibits thrombin by enhancing the activity of antithrombin III. Like most other clotting inhibitors, heparin also inhibits the intrinsic pathway.

Factors Preventing Undesirable Clotting

As long as the endothelium is smooth and intact, platelets are prevented from clinging and piling up. Also, antithrombic substances—nitric oxide and prostacyclin—secreted by the endothelial cells normally prevent platelet adhesion. Additionally, it has been found that vitamin E quinone, a molecule formed in the body when vitamin E reacts with oxygen, is a potent anticoagulant.

Disorders of Hemostasis

Blood clotting is one of nature's most elegant creations, but it sometimes goes awry. The two major disorders of hemostasis are at opposite poles. **Thromboembolic disorders** result from conditions that cause undesirable clot formation. **Bleeding disorders** arise from abnormalities that prevent normal clot formation. **Disseminated intravascular coagulation (DIC)** involves both wide spread clotting and severe bleeding.

Thromboembolic Conditions

Despite the body's many safeguards, undesirable intravascular clotting, called "hemostasis in the wrong place" by some, sometimes occurs. A clot that develops and persists in an *unbroken* blood vessel is called a **thrombus.** If the thrombus is large enough, it may block circulation to the cells beyond the occlusion and lead to death of those tissues. For example, if the blockage occurs in the coronary circulation of the heart (coronary thrombosis), the consequences may be death of heart muscle and a fatal heart attack. If the thrombus breaks away from the vessel wall and floats freely in the bloodstream, it becomes an **embolus** (plural: *emboli*). An embolus ("wedge") is usually no problem until it encounters a blood vessel too narrow for it to pass through; then it becomes an **embolism,** obstructing the vessel. For example, emboli that become trapped in the lungs (pulmonary embolisms) dangerously impair the ability of the body to obtain oxygen. A cerebral embolism may cause a stroke. Drugs that dissolve blood clots (such as tPA) and innovative medical techniques for removing clots are described in *A Closer Look* in Chapter 19.

Conditions that roughen the vessel endothelium, such as atherosclerosis or inflammation, cause thromboembolic disease by allowing platelets to gain a foothold. Slowly flowing blood or blood stasis is another risk factor, particularly in bedridden patients and those taking a long flight in economy-class seats. In this case, clotting factors are *not* washed away as usual and accumulate so that clot formation finally becomes possible.

A number of drugs, most importantly aspirin, heparin, and warfarin, are used clinically to prevent undesirable clotting in patients at risk for heart attack or stroke. **Aspirin** is an antiprostaglandin drug that inhibits thromboxane A_2 formation (hence, it blocks platelet aggregation and platelet plug formation). Clinical studies of men taking low-dose aspirin (one aspirin every two days) over several years demonstrated a 50% reduction in incidence of heart attack. Heparin (see above) is also prescribed as an anticoagulant drug, as is warfarin, an ingredient in rat poison. Administered in injectable form, heparin is the anticoagulant most used clinically (i.e., for preoperative and postoperative cardiac patients and for those receiving blood transfusions). Taken orally, **warfarin** (Coumadin) is a mainstay in the treatment of those prone to atrial fibrillation, a condition in which blood pools in the heart, to reduce the risk of stroke. It works via a different mechanism than heparin; it interferes with the action of vitamin K in the production of some procoagulants (see Impaired Liver Function below).

Disseminated Intravascular Coagulation

DIC is a situation in which widespread clotting occurs in intact blood vessels and the residual blood becomes unable to clot. Blockage of blood flow accompanied by severe bleeding follows. DIC is

most commonly encountered as a complication of pregnancy or a result of septicemia or incompatible blood transfusions.

Bleeding Disorders

Anything that interferes with the clotting mechanism can result in abnormal bleeding. The most common causes are platelet deficiency (thrombocytopenia) and deficits of some procoagulants, which can result from impaired liver function or certain genetic conditions.

Thrombocytopenia A condition in which the number of circulating platelets is deficient, **thrombocytopenia** (throm"bo-si"to-pe'ne-ah) causes spontaneous bleeding from small blood vessels all over the body. Even normal movement leads to widespread hemorrhage, evidenced by many small purplish blotches, called *petechiae* (pe-te'ke-e), on the skin. Thrombocytopenia can arise from any condition that suppresses or destroys the bone marrow, such as bone marrow malignancy, exposure to ionizing radiation, or certain drugs. A platelet count of under 50,000/μl of blood is usually diagnostic for this condition. Transfusions of concentrated platelets provide temporary relief from bleeding.

Impaired Liver Function When the liver is unable to synthesize its usual supply of procoagulants, abnormal, and often severe, bleeding occurs. The causes can range from an easily resolved vitamin K deficiency (common in newborns and after taking systemic antibiotics) to nearly total impairment of liver function (as in hepatitis or cirrhosis). Vitamin K is required by the liver cells for production of the clotting factors, and because vitamin K is produced by bacteria that reside in the intestines, dietary deficiencies are rarely a problem. However, vitamin K deficiency can occur if fat absorption is impaired, because vitamin K is a fat-soluble vitamin that is absorbed into the blood along with fats. In liver disease, the nonfunctional liver cells fail to produce not only the procoagulants but also bile, which is required for fat and vitamin K absorption.

Hemophilias The term **hemophilia** refers to several different hereditary bleeding disorders that have similar signs and symptoms. *Hemophilia A,* or *classical hemophilia,* results from a deficiency of **factor VIII (antihemophilic factor).** It accounts for 77% of cases. *Hemophilia B* results from a deficiency of factor IX. Both types are X-linked conditions occurring primarily in males. *Hemophilia C,* a less severe form of hemophilia seen in both sexes, is due to a lack of factor XI. The relative mildness of this form, as compared to the A and B forms, reflects the fact that the procoagulant (factor IX) that factor XI activates may also be activated by factor VII (see Figure 17.13b).

Symptoms of hemophilia begin early in life; even minor tissue trauma causes prolonged bleeding into tissues that can be life threatening. Commonly, the person's joints become seriously disabled and painful because of repeated bleeding into the joint cavities after exercise or trauma. Hemophilias are managed clinically by transfusions of fresh plasma or injections of the appropriate purified clotting factor. These therapies provide relief for several days but are expensive and inconvenient. In addition, the dependence of hemophiliacs on blood transfusions or factor injections has caused other problems. In the past, many became infected by the hepatitis virus and, beginning in the early 1980s, by HIV, a blood-transmitted virus that depresses the immune system and causes AIDS. (See Chapter 21.) New infections are now avoided as a result of new testing methods for HIV, availability of genetically engineered factor VIII, and hepatitis vaccines.

Transfusion and Blood Replacement

The human cardiovascular system is designed to minimize the effects of blood loss by (1) reducing the volume of the affected blood vessels, and (2) stepping up the production of red blood cells. However, the body can compensate for only so much blood loss. Losses of 15–30% cause pallor and weakness. Loss of more than 30% of blood volume results in severe shock, which can be fatal.

Transfusion of Red Blood Cells

Whole blood transfusions are routine when blood loss is rapid and substantial. In all other cases, infusions of **packed red cells** (whole blood from which most of the plasma has been removed) are preferred for restoring oxygen-carrying capacity. The usual blood bank procedure involves collecting blood from a donor and then mixing it with an anticoagulant, such as certain citrate or oxalate salts, which prevents clotting by binding with calcium ions. The shelf life of the collected blood at 4°C is about 35 days. Because blood is such a valuable commodity, it is most often separated into its component parts so that each component can be used when and where it is needed.

Human Blood Groups

People have different blood types and transfusion of incompatible blood can be fatal. RBC plasma membranes, like those of all body cells, bear highly specific

TABLE 17.4 ABO Blood Groups

BLOOD GROUP	FREQUENCY (% U.S. POPULATION) WHITE	BLACK	ASIAN	NATIVE AMERICAN	RBC ANTIGENS (AGGLUTINOGENS)	ILLUSTRATION	PLASMA ANTIBODIES (AGGLUTININS)	BLOOD THAT CAN BE RECEIVED
AB	4	4	5	<1	A B		None	A, B, AB, O (Universal recipient)
B	11	20	27	4	B		Anti-A (a)	B, O
A	40	27	28	16	A		Anti-B (b)	A, O
O	45	49	40	79	None		Anti-A (a) Anti-B (b)	O (Universal donor)

glycoproteins (antigens) at their external surfaces, which identify each of us as unique from all others. One person's RBC proteins may be recognized as foreign if transfused into someone with a different red blood cell type, and the transfused cells may be agglutinated (clumped together) and destroyed. Since these RBC antigens promote agglutination, they are more specifically called **agglutinogens** (ag"loo-tin'o-jenz).

At least 30 varieties of naturally occurring RBC antigens are common in humans. Besides these, perhaps 100 others occur in individual families ("private antigens") rather than in the general population. The presence or absence of each antigen allows each person's blood cells to be classified into several different blood groups. Antigens determining the ABO and Rh blood groups cause vigorous transfusion reactions (in which the foreign erythrocytes are destroyed) when they are improperly transfused. Thus, blood typing for these antigens is *always* done before blood is transfused. Other antigens (such as the MNS, Duffy, Kell, and Lewis factors) are mainly of legal or academic importance. Because these factors cause weak or no transfusion reactions, blood is not specifically typed for them unless the person is expected to need several transfusions, in which case the many weak transfusion reactions could have cumulative effects. Only the ABO and Rh blood groups are described here.

ABO Blood Groups As shown in Table 17.4, the **ABO blood groups** are based on the presence or absence of two agglutinogens, type A and type B. Depending on which of these a person inherits, his or her ABO blood group will be one of the following: A, B, AB, or O. The O blood group, which has neither agglutinogen, is the most common ABO blood group in white, black, Asian, and Native Americans; AB, with both antigens, is least prevalent. The presence of either the A or the B agglutinogen results in group A or B, respectively.

Unique to the ABO blood groups is the presence in the plasma of *preformed antibodies* called **agglutinins.** The agglutinins act against RBCs carrying ABO antigens that are *not* present on a person's own red blood cells. A newborn lacks these antibodies, but they begin to appear in the plasma within two months and reach adult levels between 8 and 10 years of age. As indicated in Table 17.4, a person with neither the A nor the B antigen (group O) possesses both anti-A and anti-B antibodies, also called *a* and *b agglutinins* respectively. Those with group A blood have anti-B antibodies, while those with group B have anti-A antibodies. Neither antibody is produced by AB individuals.

Rh Blood Groups There are 45 different types of Rh agglutinogens, each of which is called an **Rh factor.** Only three of these, the C, D, and E antigens,

are fairly common. The Rh blood typing system is so named because one Rh antigen (agglutinogen D) was originally identified in *rhesus* monkeys. Later, the same antigen was discovered in humans. Most Americans (about 85%) are Rh^+ (Rh positive), meaning that their RBCs carry the D antigen. As a rule, a person's ABO and Rh blood groups are reported together, for example, O^+, A^-, and so on.

Unlike the ABO system antibodies, anti-Rh antibodies are not spontaneously formed in the blood of Rh^- (Rh negative) individuals. However, if an Rh^- person receives Rh^+ blood, the immune system becomes sensitized and begins producing anti-Rh antibodies against the foreign antigen soon after the transfusion. Hemolysis does not occur after the first such transfusion because it takes time for the body to react and start making antibodies. But the second time, and every time thereafter, a typical transfusion reaction occurs in which the recipient's antibodies attack and rupture the donor RBCs.

HOMEOSTATIC IMBALANCE

An important problem related to the Rh factor occurs in pregnant Rh^- women who are carrying Rh^+ babies. The first such pregnancy usually results in the delivery of a healthy baby. But, when bleeding occurs as the placenta detaches from the uterus, the mother may be sensitized by her baby's Rh^+ antigens that pass into her bloodstream. If so, she will form anti-Rh antibodies unless treated with RhoGAM before or shortly after she has given birth. (The same precautions are taken in women who have miscarried or aborted the fetus.) RhoGAM is a serum containing anti-Rh agglutinins. Because it agglutinates the Rh factor, it blocks the mother's immune response and prevents her sensitization. If the mother is not treated and becomes pregnant again with an Rh^+ baby, her antibodies will cross through the placenta and destroy the baby's RBCs, producing a condition known as **hemolytic disease of the newborn,** or **erythroblastosis fetalis.** The baby becomes anemic and hypoxic. In severe cases, brain damage and even death may result unless transfusions are done *before* birth to provide the fetus with more erythrocytes for oxygen transport. Additionally, one or two *exchange transfusions* (see Related Clinical Terms, p. 673) are done after birth. The baby's Rh^+ blood is removed, and Rh^- blood is infused. Within six weeks, the transfused Rh^- erythrocytes have been broken down and replaced with the baby's own Rh^+ cells. ●

Transfusion Reactions: Agglutination and Hemolysis

When mismatched blood is infused, a **transfusion reaction** occurs in which the donor's red blood cells are attacked by the recipient's plasma agglutinins. (Note that the donor's plasma antibodies may also be agglutinating the host's RBCs, but they are so diluted in the recipient's circulation that this does not usually present a serious problem.)

The initial event, agglutination of the foreign red blood cells, clogs small blood vessels throughout the body. During the next few hours, the clumped red blood cells begin to rupture or are destroyed by phagocytes, and their hemoglobin is released into the bloodstream. (When the transfusion reaction is exceptionally severe, the RBCs are lysed almost immediately.) These events lead to two easily recognized problems: (1) The oxygen-carrying capability of the transfused blood cells is disrupted, and (2) the clumping of red blood cells in small vessels hinders blood flow to tissues beyond those points. Less apparent, but more devastating, is the consequence of hemoglobin escaping into the bloodstream. Circulating hemoglobin passes freely into the kidney tubules, causing cell death and renal shutdown. If shutdown is complete (acute renal failure), the person may die.

Transfusion reactions can also cause fever, chills, low blood pressure, rapid heartbeat, nausea, vomiting, and general toxicity; but in the absence of renal shutdown, these reactions are rarely lethal. Treatment of transfusion reactions is directed toward preventing kidney damage by administering fluid and diuretics to increase urine output, diluting and washing out the hemoglobin.

As indicated in Table 17.4, group O red blood cells bear neither the A nor the B antigen; thus, theoretically this blood group is the **universal donor.** Indeed, some laboratories are developing methods to enzymatically convert other blood types to type O by clipping off the extra (A- or B-specific) sugar residue. Since group AB plasma is devoid of antibodies to both A and B antigens, group AB people are theoretically **universal recipients** and can receive blood transfusions from any of the ABO groups. However, these classifications are misleading, because they do not take into account the other agglutinogens in blood that can trigger transfusion reactions.

Because pooled blood transfusions carry the risk of transfusion reactions and transmission of life-threatening infections (particularly with HIV), public interest in **autologous transfusions** has risen. Autologous (*auto* = self) transfusions are particularly sought by those considering elective surgery when they are in no immediate danger. The patient *predonates* his or her own blood, and it is stored and immediately available if needed during or after the operation. Iron supplements are given, and as long as the patient's preoperative hematocrit is at least 30%, one unit (400–500 ml) of blood can be collected every 4 days, with the last unit taken 72 hours prior to surgery.

Blood Typing

The importance of determining the blood group of both the donor and the recipient *before* blood is transfused is glaringly obvious. The general procedure for determining ABO blood type is briefly outlined in Figure 17.15. Because it is critical that blood groups be compatible, cross matching is also done. *Cross matching* tests for agglutination of donor RBCs by the recipient's serum, and of the recipient's RBCs by the donor serum. Typing for the Rh factors is done in the same manner as ABO blood typing.

Restoring Blood Volume

When a patient's blood volume is so low that death from shock is imminent, there may not be time to type blood, or appropriate whole blood may be unavailable. Such emergencies demand that blood *volume* be replaced immediately to restore adequate circulation.

Fundamentally, blood consists of proteins and cells suspended in a salt solution. Replacing lost blood volume essentially consists of replacing that isotonic salt solution. *Normal saline* or a *multiple electrolyte solution* that mimics the electrolyte composition of plasma (for example, *Ringer's solution*) are the preferred choices. You might think that it would be important to add materials to mimic the osmotic properties of albumin in blood, and indeed this has been widely practiced. However, studies have shown that **plasma expanders** such as *purified human serum albumin, hetastarch,* and *dextran* provide no benefits over much cheaper electrolyte solutions and are associated with significant complications of their own. Volume replacement restores adequate circulation but cannot, of course, replace the oxygen-carrying capacity of the lost red blood cells. Research on ways to replace that capability is ongoing, as described in *A Closer Look* on pp. 672–673.

Diagnostic Blood Tests

A laboratory examination of blood yields information that can be used to evaluate a person's current state of health. For example, in some anemias, the blood is pale and yields a low hematocrit. A high fat content *(lipidemia)* gives blood plasma a yellowish hue and forecasts possible problems in those with heart disease. How well a diabetic is controlling diet and blood sugar levels is routinely determined by blood glucose tests. Infections are signaled by leukocytosis and, if severe, larger than normal buffy coats in the hematocrit.

Microscopic studies of blood can reveal variations in the size and shape of erythrocytes that predict iron deficiency or pernicious anemia. Furthermore, a determination of the relative proportion of individual leukocyte types, a **differential white blood cell count,** is a valuable diagnostic tool. For example, a high eosinophil count may indicate a parasitic infection or an allergic response somewhere in the body.

A number of tests provide information on the status of the hemostasis system. The amount of prothrombin present in blood is assessed by determining the **prothrombin time,** and a **platelet count** is done when thrombocytopenia is suspected.

Two batteries of tests—a SMAC (SMA20, CHEM-20, or similar series) and a **complete blood count (CBC)**—are routinely ordered during physical

Q *Is an agglutinin a plasma membrane glycoprotein or an antibody in the plasma?*

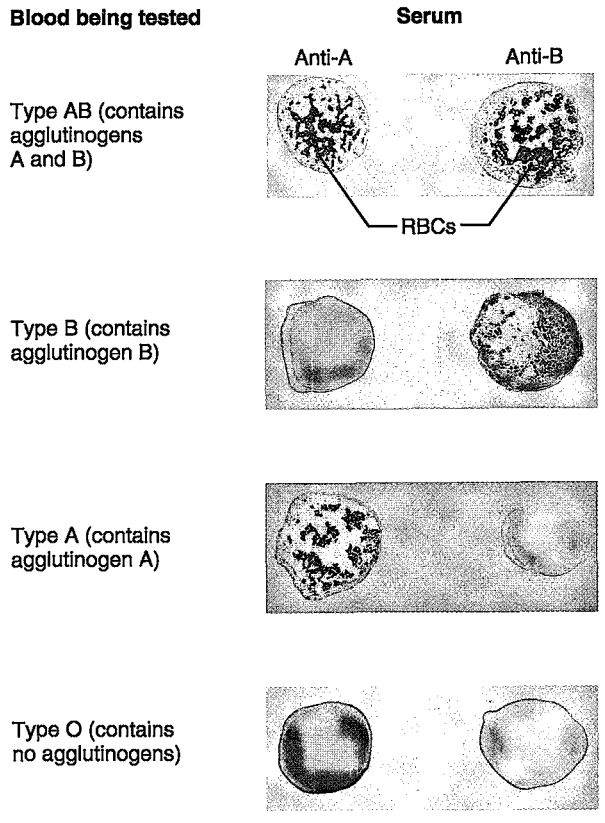

FIGURE 17.15 **Blood typing of ABO blood types.** When serum containing anti-A or anti-B agglutinins is added to a blood sample diluted with saline, agglutination will occur between the agglutinin and the corresponding agglutinogen (A or B). As illustrated, agglutination occurs with both sera in blood group AB, with anti-B serum in blood group B, with anti-A serum in blood group A, and with neither serum in blood group O.

A *An agglutinin is a plasma antibody.*

A CLOSER LOOK

Concocting Blood: Artificial Blood Substitutes

The term "blood substitute" is somewhat misleading. Blood has many components and plays such a wide variety of roles—from fighting infection to transporting oxygen—that no single artificial substitute yet engineered can fulfill all those functions. However, substitute liquids are available that can transport oxygen from the lungs through the body and can "stretch" a limited blood supply, while sidestepping transfusion reactions. An important benefit of these blood substitutes is that the recipient is not at risk for transmission of bloodborne disease factors.

Modified Hemoglobin

Let's pretend to be biomedical engineers for a moment. If you wanted a substance to transport oxygen in the blood, what would you use? Like many researchers, you'd probably start with hemoglobin, the blood's own oxygen carrier. You could obtain hemoglobin from human red blood cells too old for transfusion, from readily available cow blood, or by genetic engineering. Unfortunately, hemoglobin by itself is unusable—it spontaneously splits in half in the plasma, and is rapidly cleared by the kidneys (which can lead to renal shutdown). Chemically linking hemoglobin subunits together so that they don't come apart or tying hemoglobin molecules together into long chains reduces clearance by the kidneys. Some types of these hemoglobin chains can stay in the blood for as long as 24 hours.

Another problem with free human hemoglobin is that it binds oxygen much more tightly (has a higher affinity) than hemoglobin contained inside a red blood cell, only reluctantly giving up oxygen to needy tissues. Cow hemoglobin, on the other hand, naturally binds oxygen less tightly. This solution has its own problems: the possible transmission of mad cow disease and the risk of immune reactions. Nevertheless, a cow-based product is licensed for use in South Africa where the high prevalence of HIV has made collecting uninfected blood extremely difficult. It's also possible to modify the hemoglobin with chemicals (such as pyridoxal phosphate) which mimic chemicals that lower oxygen affinity in the normal red blood cell. Hemoglobin's affinity for oxygen can also be lowered by genetically engineering its oxygen binding pocket. Each of these modified hemoglobins has undergone clinical trials with varying degrees of success.

A common problem in these trials is an increase in blood pressure when the hemoglobin compound is infused into the patient's blood. Blood vessels are normally held in a relaxed state by the action of the chemical messenger nitric oxide. Hemoglobin mops up nitric oxide, causing blood vessels to constrict and blood pressure to rise. Normally, hemoglobin in red blood cells is too far away from the source of nitric oxide to mop up much of it. The small free hemoglobin chains, however, slip close to the walls of the blood vessel where the concentration of nitric oxide is very high, and so absorb it in large quantities.

A miniature artificial cell (called a liposome) enclosing our modified hemoglobin would keep it away from blood vessel walls. Unfortunately, liposomes are cleared very rapidly by macrophages of the immune system.

examinations and before hospital admissions. SMAC is a blood *chemistry* profile. The CBC includes counts of the different types of formed elements, a hematocrit, measurements of hemoglobin content, and size of RBCs. Together these tests provide a comprehensive picture of one's general health status in relation to normal blood values.

A listing of the normal values for selected blood tests is provided in Appendix F.

Developmental Aspects of Blood

Early in fetal development there are many sites of blood cell formation—the fetal yolk sac, liver, and spleen, among others—but by the seventh month, the red marrow has become the primary hematopoietic area and remains so (barring serious illness) throughout life. If there is a severe need for blood cell production, however, the liver and the spleen may resume their fetal blood-forming roles. Additionally, inactive yellow bone marrow regions (essentially fatty tissue) may reconvert to active red marrow.

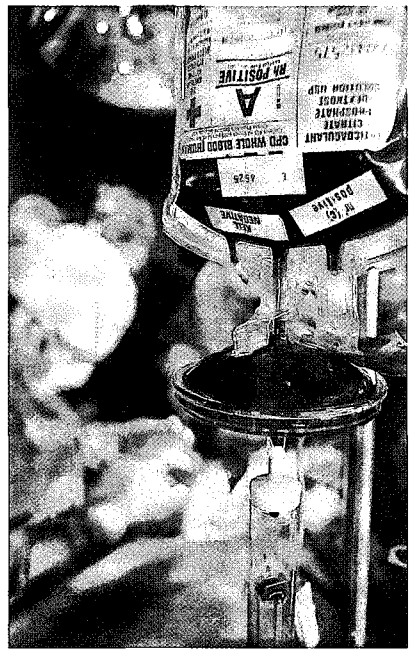
Blood cells develop from collections of mesenchymal cells, called *blood islands*, derived from the mesoderm germ layer. The fetus forms a unique hemoglobin, **hemoglobin F**, that has a higher affinity for oxygen than does adult hemoglobin (hemoglobin A). It contains two alpha and two gamma (γ) polypeptide chains per globin molecule, instead of the paired alpha and beta chains typical of hemoglobin A. After birth, fetal erythrocytes carrying hemoglobin F are rapidly destroyed by the liver, and the baby's erythroblasts begin producing hemoglobin A.

The most common blood diseases that appear during aging are chronic leukemias, anemias, and clotting disorders. However, these and most other age-related blood disorders are usually precipitated by disorders of the heart, blood vessels, or immune system. For example, the increased incidence of leukemias in old age is believed to result from the waning efficiency of the immune system, and abnormal thrombus and embolus formation reflects the

Instead, we could make the hemoglobin itself physically bigger by tying on long chains of polyethylene glycol (PEG). Think of it as hemoglobin floating down a river in a big inner tube, bouncing off the banks. Such a molecule is currently undergoing clinical trials and appears not to have the hypertensive effects seen with other modified hemoglobins.

And Now for Something Completely Different . . .

Some engineers have asked, "If hemoglobin has all of these problems, why use it? If you want a product with long shelf life, no biological contamination, and available in industrial quantities, why not use industrial chemistry?" Enter perfluorinated hydrocarbon chains (PFCs). These compounds, chemically similar to Teflon used in nonstick cookware, can hold large amounts of dissolved oxygen, much more than plasma. In the 1960s, researchers were amazed to discover that they could fully immerse mice for up to 30 minutes in liquid PFCs. (Mice happily breathing liquid PFCs rather than air led researchers to try ventilating humans with PFCs. Premature newborns who would ordinarily be breathing amniotic fluid are



obvious candidates, but liquid ventilation of adults with severe lung dysfunction is also currently in clinical trials.)

As artificial blood, PFCs have a serious shortcoming—they don't dissolve in plasma. Combining detergent and phospholipids with PFCs produces an emulsion of small droplets that can be suspended in the watery plasma. In order to load sufficient amounts of oxygen into PFCs, patients must breathe 70–100% oxygen by mask. The developers claim that oxygen transported by PFCs is used more easily by the body tissues because the slippery particles are much smaller than erythrocytes and glide through the capillaries at a faster rate. PFCs are cleared from the circulation and stored in the spleen and liver until they are exhaled as vapor by the lungs over several days. Side effects include hypertension, loss of gastric motility, and flu-like symptoms. Currently, one PFC is approved in the U.S. for use during cardiac catheterization.

Because each of these blood substitutes has both advantages and disadvantages, it's unlikely that we will soon come up with one universal blood substitute. Rather, it will be a matter of choosing the substitute that best fits the patient's clinical needs. Although the FDA has encouraged the development of artificial blood for over 30 years, no product, including those described above, has been approved in the U.S. for anything but experimental use in humans. Blood still remains a priceless commodity, and its beautiful complexity has yet to be replaced by modern medical technology. ■

progress of atherosclerosis, which roughens the blood vessel walls.

■ ■ ■

Because blood serves as the vehicle that the cardiovascular system uses to transport substances throughout the body, it could be considered the servant of the cardiovascular system. On the other hand, without blood, the normal functions of the heart and blood vessels are impossible. So perhaps the organs of the cardiovascular system, described in Chapters 18 and 19, are subservient to blood. The point of this circular thinking is that blood and the cardiovascular system organs are vitally intertwined in their common functions—to see that nutrients, oxygen, and other vital substances reach all tissue cells of the body and to relieve the cells of their wastes.

Related Clinical Terms

Blood chemistry tests Chemical analysis of substances in the blood, e.g., glucose, iron, or calcium determinations, protein tests, bilirubin content, and pH.

Blood fraction Any one of the components of whole blood that has been separated out from the other blood components, such as platelets or clotting factors.

Bone marrow biopsy A sample of red bone marrow is obtained by needle aspiration (typically from the anterior or posterior iliac crest), and is examined to diagnose disorders of blood-cell formation, leukemia, various marrow infections, and anemias resulting from damage to or failure of the marrow.

Exchange transfusion A technique of alternating removal of patient's blood and infusion of donor blood until a large fraction of the patient's blood has been replaced; used to treat fetal blood incompatibilities and poisoning victims.

Hematology (hem"ah-tol'o-je) Study of blood.

Hematoma (hem"ah-to'mah) Accumulated, clotted blood in the tissues usually resulting from injury; visible as "black and blue" marks or bruises; eventually absorbed naturally unless infections develop.

Hemochromatosis (he"mo-kro"mah-to'sis) An inherited disorder of iron overload in which the intestine absorbs too much iron from the diet. The iron builds up in body tissues, where it oxidizes to form compounds that poison those organs (especially joints, liver, and pancreas).

Myeloproliferative disorder All-inclusive term for a group of proliferative disorders including leukoerythroblastic anemia involving fibrosis of the bone marrow, polycythemia vera, and leukemia.

Plasmapheresis (plaz"mah-fe-re'sis) A process in which plasma is removed, separated from formed elements, and the formed elements are returned to the patient or donor. Most important application is removal of antibodies or immune complexes from the blood of individuals with autoimmune disorders (multiple sclerosis, myasthenia gravis, and others). Also used by blood banks to collect plasma for burn victims and for obtaining plasma components for therapeutic use.

Septicemia (sep"ti-se'me-ah; *septos* = rotten) Situation of excessive and harmful levels of bacteria or their toxins in the blood; also called blood poisoning.

Chapter Summary

Media study tools that could provide you additional help in reviewing specific key topics of Chapter 17 are referenced below. IP = *InterActive Physiology*

Overview: Blood Composition and Functions (pp. 647–648)

Components (pp. 647–648)

1. Blood is composed of formed elements and plasma. The hematocrit is a measure of one formed element, erythrocytes, as a percentage of total blood volume.

Physical Characteristics and Volume (p. 648)

2. Blood is a viscous, slightly alkaline fluid representing about 8% of total body weight. Blood volume of a normal adult is about 5 L.

Functions (p. 648)

3. Distribution functions include delivery of oxygen and nutrients to body tissues, removal of metabolic wastes, and transport of hormones.

4. Regulation functions are maintenance of body temperature, of constant blood pH, and of adequate fluid volume.

5. Protective functions include hemostasis and prevention of infection.

Blood Plasma (pp. 648–649)

1. Plasma is a straw-colored, viscous fluid and is 90% water. The remaining 10% is solutes, such as nutrients, respiratory gases, salts, hormones, and proteins. Plasma makes up 55% of whole blood.

2. Plasma proteins, most made by the liver, include albumin, globulins, and fibrinogen. Albumin is an important blood buffer and contributes to the osmotic pressure of blood.

Formed Elements (pp. 649–662)

1. Formed elements, accounting for 45% of whole blood, are erythrocytes, leukocytes, and platelets. All formed elements arise from hemocytoblasts in red bone marrow.

Erythrocytes (pp. 649–656)

2. Erythrocytes (red blood cells) are small, biconcave cells containing large amounts of hemoglobin. They have no nucleus and few organelles. Spectrin allows the cells to change shape as they pass through tiny capillaries.

3. Oxygen transport is the major function of erythrocytes. In the lungs, oxygen binds to iron atoms in hemoglobin molecules, producing oxyhemoglobin. In body tissues, oxygen dissociates from iron, producing deoxyhemoglobin.

4. Red blood cells begin as hemocytoblasts and, through erythropoiesis, proceed from the proerythroblast (committed cell) stage to the erythroblast (early and late), normoblast, and reticulocyte stages. During this process, hemoglobin accumulates and the organelles and nucleus are extruded. Differentiation of reticulocytes is completed in the bloodstream.

5. Erythropoietin and testosterone enhance erythropoiesis.

6. Iron, vitamin B_{12}, and folic acid are essential for production of hemoglobin.

7. Red blood cells have a life span of approximately 120 days. Old and damaged erythrocytes are removed from the circulation by macrophages of the liver and spleen. Released iron from hemoglobin is stored as ferritin or hemosiderin to be reused. The balance of the heme group is degraded to bilirubin and secreted in bile. Amino acids of globin are metabolized or recycled.

IP Respiratory System; Topic: Gas Transport, pp. 3–5, 11–17.

8. Erythrocyte disorders include anemias and polycythemia.

Leukocytes (pp. 656–662)

9. Leukocytes are white blood cells. All are nucleated, and all have crucial roles in defending against disease. Two main categories exist: granulocytes and agranulocytes.

10. Granulocytes include neutrophils, basophils, and eosinophils. Basophils contain histamine, which enhances migration of leukocytes to inflammatory sites and promotes vasodilation. Neutrophils are active phagocytes. Eosinophils attack parasitic worms and their numbers increase during allergic reactions.

11. Agranulocytes have crucial roles in immunity. They include lymphocytes, the "immune cells," and monocytes which differentiate into macrophages.

12. Leukopoiesis is directed by colony-stimulating factors and interleukins released by supporting cells of the bone marrow and mature WBCs.

13. Leukocyte disorders include leukemias and infectious mononucleosis.

Platelets (p. 662)

14. Platelets are fragments of large, multinucleate megakaryocytes formed in red marrow. When a blood vessel is damaged, platelets form a plug to help prevent blood loss and play a central role in the clotting cascade.

Hemostasis (pp. 663–668)

1. Hemostasis is prevention of blood loss. The three major phases of hemostasis are vascular spasms, platelet plug formation, and blood coagulation.

Vascular Spasms and Platelet Plug Formation (pp. 663–665)

2. Spasms of smooth muscle in blood vessel walls and accumulation of platelets (platelet plug) at the site of vessel injury provide a temporary means of stopping or slowing blood loss until coagulation occurs.

Coagulation (pp. 665–666)

3. Coagulation of blood may be initiated by either the intrinsic or the extrinsic pathway. Platelet phospholipid (PF_3) is crucial to both pathways. Tissue factor (thromboplastin) exposed by tissue injury allows the extrinsic pathway to bypass many steps of the intrinsic pathway. A series of activated procoagulants oversees the intermediate steps of each cascade. The pathways converge as prothrombin is converted to thrombin.

Clot Retraction and Repair (p. 666)

4. After a clot is formed, clot retraction occurs. Serum is squeezed out and the ruptured vessel edges are drawn together. The vessel is repaired by smooth muscle, connective tissue, and endothelial cell proliferation and migration.

Fibrinolysis (p. 666)

5. When healing is complete, clot digestion (fibrinolysis) occurs.

Factors Limiting Clot Growth or Formation (pp. 666–667)

6. Abnormal expansion of clots is prevented by removal of coagulation factors in contact with rapidly flowing blood and by inhibition of activated blood factors. Prostacyclin (PGI_2) and nitric oxide secreted by the endothelial cells help prevent undesirable (unnecessary) clotting.

Disorders of Hemostasis (pp. 667–668)

7. Thromboembolytic disorders involve undesirable clot formation, which can occlude vessels. DIC is a condition of bodywide clotting in undamaged blood vessels and subsequent hemorrhages.

8. Thrombocytopenia, a deficit of platelets, causes spontaneous bleeding from small blood vessels. Hemophilia is caused by a genetic deficiency of certain coagulation factors. Liver disease can also cause bleeding disorders because many coagulation proteins are formed by the liver.

Transfusion and Blood Replacement (pp. 668–671)

Transfusion of Red Blood Cells (pp. 668–671)

1. Whole blood transfusions are given to replace severe and rapid blood loss. Packed RBCs are given to replace lost O_2-carrying capacity.

2. Blood group is based on agglutinogens (antigens) present on red blood cell membranes.

3. When mismatched blood is transfused, the recipient's agglutinins (plasma antibodies) clump the foreign RBCs; the clumped cells are then lysed. Blood vessels may be blocked by clumped RBCs. Released hemoglobin may precipitate in the kidney tubules, causing renal shutdown.

4. Before whole blood can be transfused, it must be typed and cross matched so that transfusion reactions are avoided. The most important blood groups for which blood must be typed are the ABO and Rh groups.

Restoring Blood Volume (p. 671)

5. Plasma volume can be replaced with balanced electrolyte solutions, and these are generally preferred over plasma expanders.

Diagnostic Blood Tests (pp. 671–672)

1. Diagnostic blood tests can provide large amounts of information about the current status of the blood and of the body as a whole.

Developmental Aspects of Blood (pp. 672–673)

1. Fetal hematopoietic sites include the yolk sac, liver, and spleen. By the seventh month of development, the red bone marrow is the primary blood-forming site.

2. Blood cells develop from blood islands derived from mesoderm. Fetal blood contains hemoglobin F. After birth, hemoglobin A is formed.

3. The major blood-related problems associated with aging are leukemia, anemia, and thromboembolytic disease.

Review Questions

Multiple Choice/Matching

(Some questions have more than one correct answer. Select the best answer or answers from the choices given.)

1. The blood volume in an adult averages approximately (a) 1 L, (b) 3 L, (c) 5 L, (d) 7 L.

2. The hormonal stimulus that prompts red blood cell formation is (a) serotonin, (b) heparin, (c) erythropoietin, (d) thrombopoietin.

3. All of the following are true of RBCs except (a) biconcave disc shape, (b) life span of approximately 120 days, (c) contain hemoglobin, (d) contain nuclei.

4. The most numerous WBC is the (a) eosinophil, (b) neutrophil, (c) monocyte, (d) lymphocyte.

5. Blood proteins play an important part in (a) blood clotting, (b) immunity, (c) maintenance of blood volume, (d) all of the above.

6. The white blood cell that releases histamine and other inflammatory chemicals is the (a) basophil, (b) neutrophil, (c) monocyte, (d) eosinophil.

7. The blood cell that can become an antibody-secreting cell is the (a) lymphocyte, (b) megakaryocyte, (c) neutrophil, (d) basophil.

8. Which of the following does not promote multiple steps in the clotting pathway? (a) PF_3, (b) factor XI, (c) thrombin, (d) Ca^{2+}.

9. The normal pH of the blood is about (a) 8.4, (b) 7.8, (c) 7.4, (d) 4.7.

10. Suppose your blood was found to be AB positive. This means that (a) agglutinogens A and B are present on your red blood cells, (b) there are no anti-A or anti-B agglutinins in your plasma, (c) your blood is Rh^+, (d) all of the above.

Short Answer Essay Questions

11. (a) Define formed elements and list their three major categories. (b) Which is least numerous? (c) Which comprise(s) the buffy coat in a hematocrit tube?

12. Discuss hemoglobin relative to its chemical structure, its function, and the color changes it undergoes during loading and unloading of oxygen.

13. If you had a high hematocrit, would you expect your hemoglobin determination to be low or high? Why?

14. What nutrients are needed for erythropoiesis?

15. (a) Describe the process of erythropoiesis. (b) What name is given to the immature cell type released to the circulation? (c) How does it differ from a mature erythrocyte?

16. Besides the ability to move by amoeboid motion, what other physiological attributes contribute to the function of white blood cells in the body?

17. (a) If you had a severe infection, would you expect your WBC count to be closest to 5000, 10,000, or 15,000/μl? (b) What is this condition called?

18. (a) Describe the appearance of platelets and state their major function. (b) Why should platelets not be called "cells"?

19. (a) Define hemostasis. (b) List the three major steps of coagulation. Explain what initiates each step and what the step accomplishes. (c) In what general way do the intrinsic and extrinsic mechanisms of clotting differ? (d) What ion is essential to virtually all stages of coagulation?

20. (a) Define fibrinolysis. (b) What is the importance of this process?

21. (a) How is clot overgrowth usually prevented? (b) List two conditions that may lead to unnecessary (and undesirable) clot formation.

22. How can liver dysfunction cause bleeding disorders?

23. (a) What is a transfusion reaction and why does it happen? (b) What are its possible consequences?

24. How can poor nutrition lead to anemia?

25. What blood-related problems are most common in the aged?

Critical Thinking and Clinical Application Questions

1. Cancer patients being treated with chemotherapeutic drugs designed to destroy rapidly dividing cells are monitored closely for changes in their red and white blood counts. Why so?

2. Mary Healy, a young woman with severe vaginal bleeding, is admitted to the emergency room. She is three months pregnant, and the physician is concerned about the volume of blood she is losing. (a) What type of transfusion will probably be given to this patient? (b) What blood tests will be performed before starting the transfusion?

3. Alan Forsythe, a middle-aged college professor from Boston, is in the Swiss Alps studying astronomy during his sabbatical leave. He has been there for two days and plans to stay the entire year. However, he notices that he is short of breath when he walks up steps and tires easily with any physical activity. His symptoms gradually disappear, and after two months he feels fine. Upon returning to the United States, he has a complete physical exam and is told that his erythrocyte count is higher than normal. (a) Attempt to explain this finding. (b) Will his RBC count remain at this higher-than-normal level? Why or why not?

4. A young child is diagnosed as having acute lymphocytic leukemia. Her parents cannot understand why infection is a major problem for Janie when her WBC count is so high. Can you provide an explanation for Janie's parents?

5. Mrs. Ryan, a middle-aged woman, appears at the clinic complaining of multiple small hemorrhagic spots in her skin and severe nosebleeds. While taking her history, the nurse notes that Mrs. Ryan works as a rubber glue applicator at a local factory. Rubber glue contains benzene, which is known to be toxic to red marrow. Using your knowledge of physiology, explain the connection between the bleeding problems and benzene.

6. A reticulocyte count indicated that 5% of Tyler's red blood cells were reticulocytes. His blood test also indicated he had polycythemia and a hematocrit of 65%. Explain the connection between these three facts.

7. In 1998, the U.S. Food and Drug Administration approved the nation's first commercial surgical glue to control bleeding during certain surgeries. Called Tisseel, it forms a flexible mesh over an oozing blood vessel to help stem bleeding within five minutes. This sealant is made from two blood proteins that naturally cause blood to clot when they latch together. Name these proteins.

8. Jenny, a healthy young woman, had a battery of tests during a physical for a new job. Her RBC count was at the higher end of the normal range at that time, but four weeks later it was substantially elevated beyond that. When asked if any circumstances had changed in her life, she admitted to taking up smoking. How might her new habit explain her higher RBC count?

9. Mr. Chu has been scheduled for surgery to have his arthritic hip replaced. His surgeon tells him he must switch from aspirin to acetaminophen for pain control before his surgery. Why?

CHAPTER 18

The Cardiovascular System: The Heart

Heart Anatomy (pp. 678–689)

1. Describe the size, shape, location, and orientation of the heart in the thorax.
2. Name the coverings of the heart.
3. Describe the structure and function of each of the three layers of the heart wall.
4. Describe the structure and functions of the four heart chambers. Name each chamber and provide the name and general route of its associated great vessel(s).
5. Trace the pathway of blood through the heart.
6. Name the major branches and describe the distribution of the coronary arteries.
7. Name the heart valves and describe their location, function, and mechanism of operation.

Properties of Cardiac Muscle Fibers (pp. 689–692)

8. Describe the structural and functional properties of cardiac muscle, and explain how it differs from skeletal muscle.
9. Briefly describe the events of cardiac muscle cell contraction.

Heart Physiology (pp. 692–705)

10. Name the components of the conduction system of the heart, and trace the conduction pathway.
11. Draw a diagram of a normal electrocardiogram tracing; name the individual waves and intervals, and indicate what each represents. Name some abnormalities that can be detected on an ECG tracing.
12. Describe the timing and events of the cardiac cycle.
13. Describe normal heart sounds, and explain how heart murmurs differ.
14. Name and explain the effects of various factors regulating stroke volume and heart rate.
15. Explain the role of the autonomic nervous system in regulating cardiac output.

Developmental Aspects of the Heart (pp. 705–709)

16. Describe fetal heart formation, and indicate how the fetal heart differs from the adult heart.
17. Provide examples of age-related changes in heart function.

The ceaselessly beating heart in the chest has intrigued people for centuries. The ancient Greeks believed the heart was the seat of intelligence. Others thought it was the source of emotions. While these theories have proved false, we do know that emotions affect heart rate. When your heart pounds or occasionally skips a beat, you become acutely aware of how much you depend on this dynamic organ for your very life.

Despite its vital importance, the heart does not work alone. Indeed, it is part of the cardiovascular system, which also includes the miles of blood vessels that run through the body. Day and night, tissue cells take in nutrients and oxygen and excrete wastes. Because cells can make such exchanges only with their immediate environment, some means of changing and renewing that environment is necessary to ensure a continual supply of nutrients and to prevent a buildup of wastes. The cardiovascular system provides the transport system "hardware" that keeps blood continuously circulating to fulfill this critical homeostatic need.

Stripped of its romantic cloak, the **heart** is no more than the transport system pump; the hollow blood vessels are the delivery routes. Using blood as the transport medium, the heart continually propels oxygen, nutrients, wastes, and many other substances into the interconnecting blood vessels that service body cells. Blood and blood vessels are considered separately in Chapters 17 and 19, respectively. This chapter focuses on the structure and function of the heart.

Heart Anatomy

Size, Location, and Orientation

18

The modest size and weight of the heart belie its incredible strength and endurance. About the size of a fist, the hollow, cone-shaped heart (Figure 18.1) has a mass of between 250 and 350 grams—less than a pound.

Snugly enclosed within the **mediastinum** (me"de-ah-sti'num), the medial cavity of the thorax, the heart extends obliquely for 12 to 14 cm (about 5 inches) from the second rib to the fifth intercostal space (Figure 18.1). As it rests on the superior surface of the diaphragm, the heart lies anterior to the vertebral column and posterior to the sternum. The lungs flank the heart laterally and partially obscure it. Approximately two-thirds of its mass lies to the left of the midsternal line; the balance projects to the right. Its broad, flat **base,** or posterior surface, is about 9 cm (3.5 in) wide and directed toward the right shoulder. Its **apex** points inferiorly toward the left hip. If you press your fingers between the fifth and sixth ribs just below the left nipple, you can easily feel your heart beating where the apex contacts the chest wall. Hence, this site is referred to as the **point of maximal intensity (PMI).**

Coverings of the Heart

The heart is enclosed in a double-walled sac called the **pericardium** (per"ĭ-kar'de-um; *peri* = around, *cardi* = heart) (Figure 18.2). The loosely fitting superficial part of this sac is the **fibrous pericardium.** This tough, dense connective tissue layer (1) protects the heart, (2) anchors it to surrounding structures, and (3) prevents overfilling of the heart with blood.

Deep to the fibrous pericardium is the **serous pericardium,** a thin, slippery, two-layer serous membrane. Its **parietal layer** lines the internal surface of the fibrous pericardium. At the superior margin of the heart, the parietal layer attaches to the large arteries exiting the heart, and then turns inferiorly and continues over the external heart surface as the **visceral layer,** also called the **epicardium** ("upon the heart"), which is an integral part of the heart wall.

Between the parietal and visceral layers is the slitlike **pericardial cavity,** which contains a film of serous fluid. The serous membranes, lubricated by the fluid, glide smoothly past one another during heart activity, allowing the mobile heart to work in a relatively friction-free environment.

HOMEOSTATIC IMBALANCE

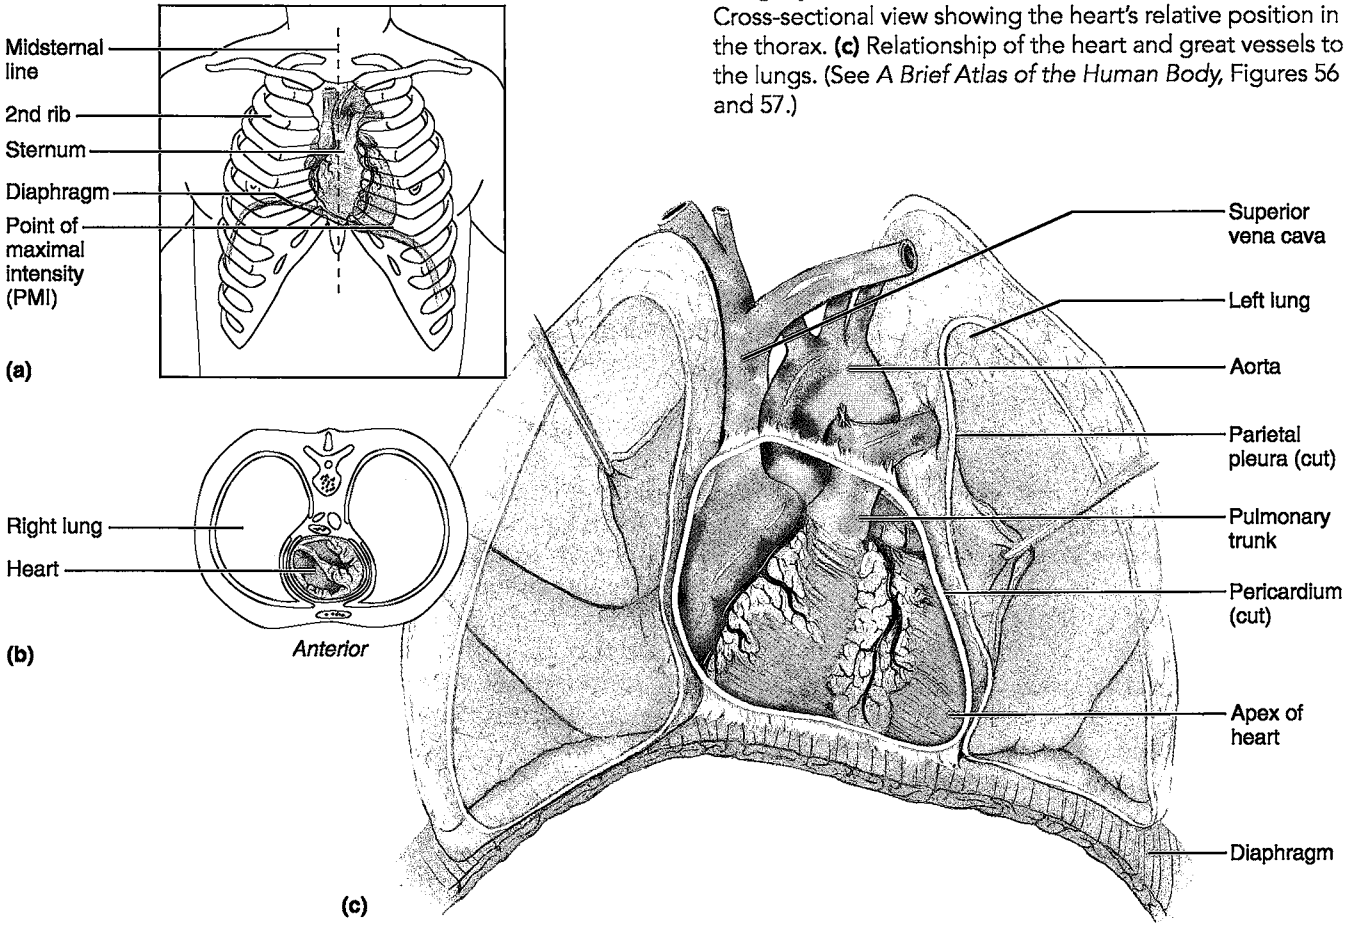
Pericarditis, inflammation of the pericardium, roughens the serous membrane surfaces. Consequently, as the beating heart rubs against its pericardial sac, it creates a creaking sound *(pericardial friction rub)* that can be heard with a stethoscope. Pericarditis is characterized by pain deep to the sternum. Over time, it may lead to adhesions in which the visceral and parietal pericardia stick together and impede heart activity. In severe cases, the situation changes and *large* amounts of inflammatory fluid seep into the pericardial cavity. This excess fluid compresses the heart, limiting its ability to pump blood. This condition in which the heart is compressed by fluid is called *cardiac tamponade* (tam"pŏ-nād'), literally, "heart plug." Physicians treat it by inserting a syringe into the pericardial cavity and draining off the excess fluid.

Layers of the Heart Wall

The heart wall, richly supplied with blood vessels, is composed of three layers (Figure 18.2).

Q *The title for this figure points out that the heart is in the mediastinum. Just what is the mediastinum?*

FIGURE 18.1 **Location of the heart in the mediastinum. (a)** Relationship of the heart to the sternum, ribs, and diaphragm in a person who is lying down (the heart is slightly inferior to this position in a standing person). **(b)** Cross-sectional view showing the heart's relative position in the thorax. **(c)** Relationship of the heart and great vessels to the lungs. (See *A Brief Atlas of the Human Body,* Figures 56 and 57.)



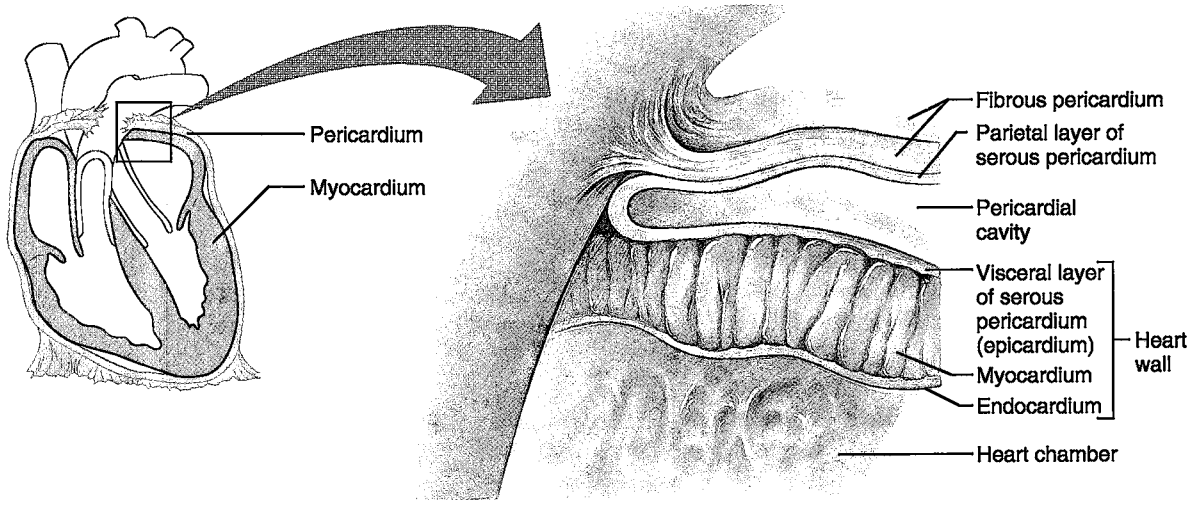


FIGURE 18.2 **The pericardial layers and layers of the heart wall.**

A *The medial cavity of the thorax within which the heart, great vessels, and trachea are found.*

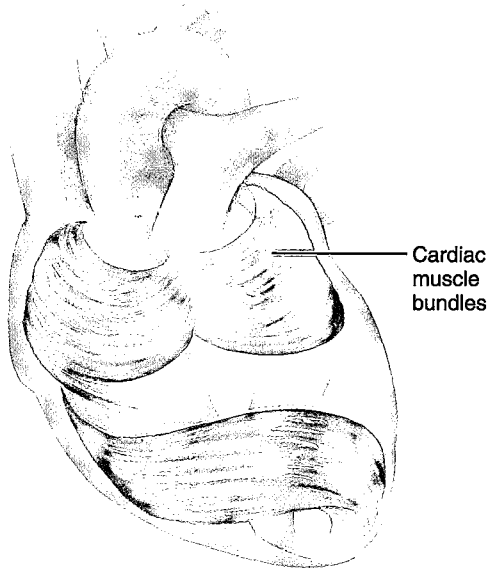

FIGURE 18.3 **The circular and spiral arrangement of cardiac muscle bundles in the myocardium of the heart.**

The superficial *epicardium* is the visceral layer of the serous pericardium. It is often infiltrated with fat, especially in older people.

The middle layer, the **myocardium** ("muscle heart"), is composed mainly of cardiac muscle and forms the bulk of the heart. It is the layer that contracts. In this layer, the branching cardiac muscle cells are tethered to one another by crisscrossing connective tissue fibers and arranged in spiral or circular *bundles* (Figure 18.3). These interlacing bundles effectively link all parts of the heart together. The connective tissue fibers form a dense network, the **fibrous skeleton of the heart,** that reinforces the myocardium internally and anchors the cardiac muscle fibers. This network of collagen and elastin fibers is thicker in some areas than others. For example, it constructs ropelike rings that provide additional support where the great vessels issue from the heart and around the heart valves (see Figure 18.8a, p. 687). Without this support, the vessels and valves might eventually become stretched because of the continuous stress of blood pulsing through them. Additionally, because connective tissue is not electrically excitable, the fibrous skeleton limits the direct spread of action potentials across the heart to specific pathways.

The third layer, the **endocardium** ("inside the heart"), is a glistening white sheet of endothelium (squamous epithelium) resting on a thin connective tissue layer. Located on the inner myocardial surface, it lines the heart chambers and covers the fibrous skeleton of the valves. The endocardium is continuous with the endothelial linings of the blood vessels leaving and entering the heart.

Chambers and Associated Great Vessels

The heart has four chambers (Figure 18.4e)—two superior **atria** (a′tre-ah) and two inferior **ventricles** (ven′trĭ-klz). The internal partition that divides the heart longitudinally is called the **interatrial septum** where it separates the atria, and the **interventricular septum** where it separates the ventricles. The right ventricle forms most of the anterior surface of the heart. The left ventricle dominates the inferoposterior aspect of the heart and forms the heart apex. Two grooves visible on the heart surface indicate the boundaries of its four chambers and carry the blood vessels supplying the myocardium. The **coronary sulcus** (Figure 18.4b, d), or *atrioventricular groove*, encircles the junction of the atria and ventricles like a crown (*corona* = crown). The **anterior interventricular sulcus,** cradling the anterior interventricular artery, marks the anterior position of the septum separating the right and left ventricles. It continues as the **posterior interventricular sulcus,** which provides a similar landmark on the heart's posteroinferior surface.

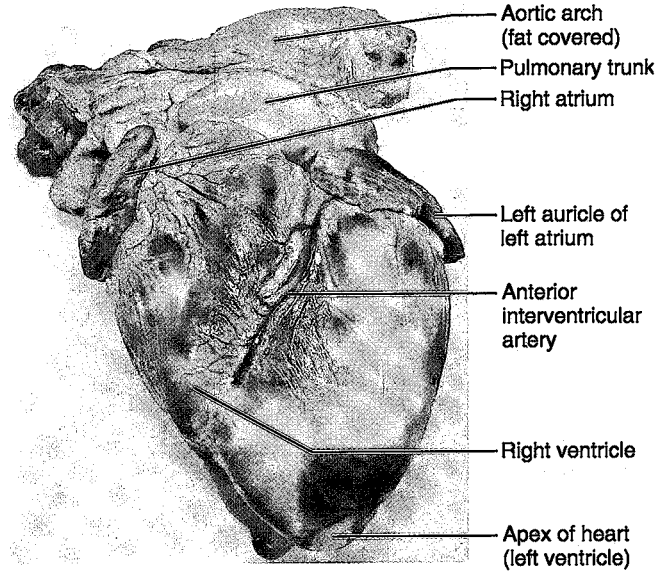
Atria: The Receiving Chambers

Except for small, wrinkled, protruding appendages called **auricles** (or′ĭ-klz; *auricle* = little ear), which increase the atrial volume somewhat, the right and left atria are remarkably free of distinguishing surface features. Internally, the right atrium has two basic parts (Figure 18.4c): a smooth-walled posterior part and an anterior portion in which the walls are ridged by bundles of muscle tissue. Because these bundles look like the teeth of a comb, these muscle bundles are called **pectinate muscles** (*pectin* = comb). The posterior and anterior regions of the right atrium are separated by a C-shaped ridge called the *crista terminalis* ("terminal crest"). In contrast, the left atrium is mostly smooth and undistinguished internally. The interatrial septum bears a shallow depression, the **fossa ovalis** (o-vă′lis), that marks the spot where an opening, the *foramen ovale,* existed in the fetal heart (Figure 18.4c,e).

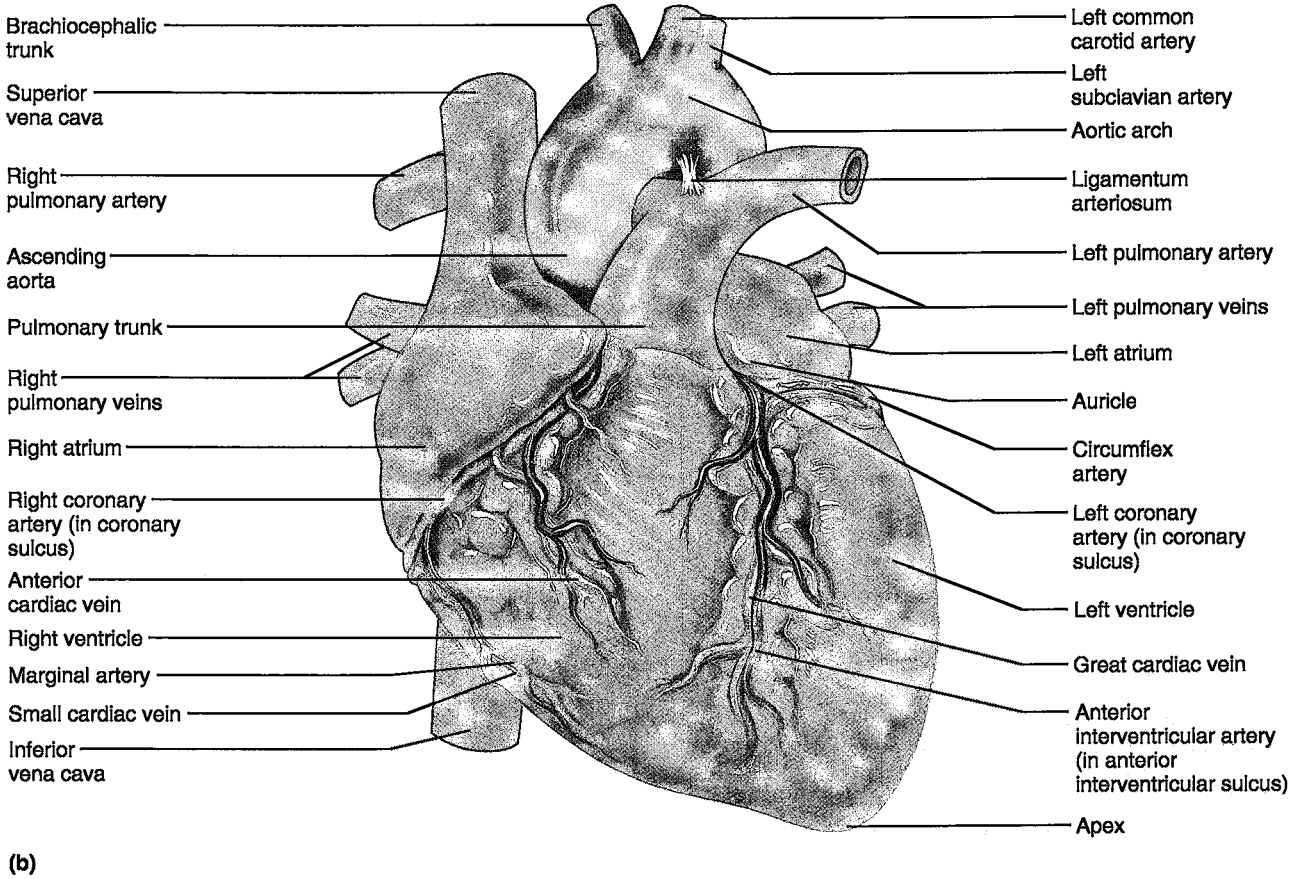
Functionally, the atria are receiving chambers for blood returning to the heart from the circulation (*atrium* = entryway). Because they need contract only minimally to push blood "downstairs" into the ventricles, the atria are relatively small, thin-walled chambers. As a rule, they contribute little to the propulsive pumping activity of the heart.

Which heart chamber has the thickest walls? What is the significance of this structural difference?

FIGURE 18.4 **Gross anatomy of the heart.** In diagrammatic views, vessels transporting oxygen-rich blood are red; those transporting oxygen-poor blood are blue. **(a)** Photograph of anterior aspect (pericardium removed). **(b)** Anterior view. (See *A Brief Atlas of the Human Body*, Figure 57.)

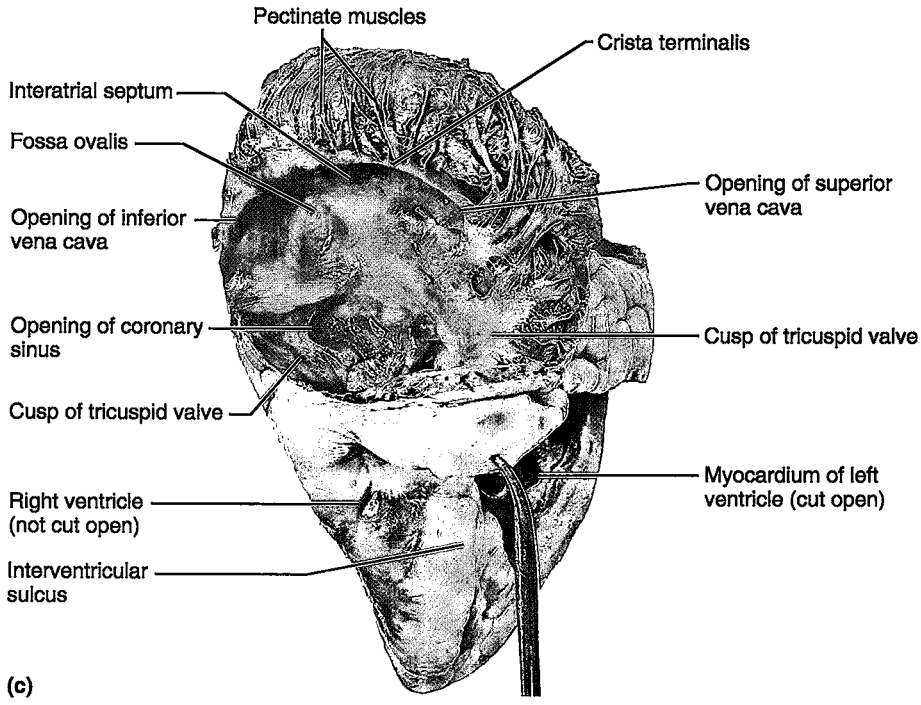


(a)



(b)

A Left ventricle. It's the systemic pump that has to pump blood through the entire systemic circulation against high resistance.



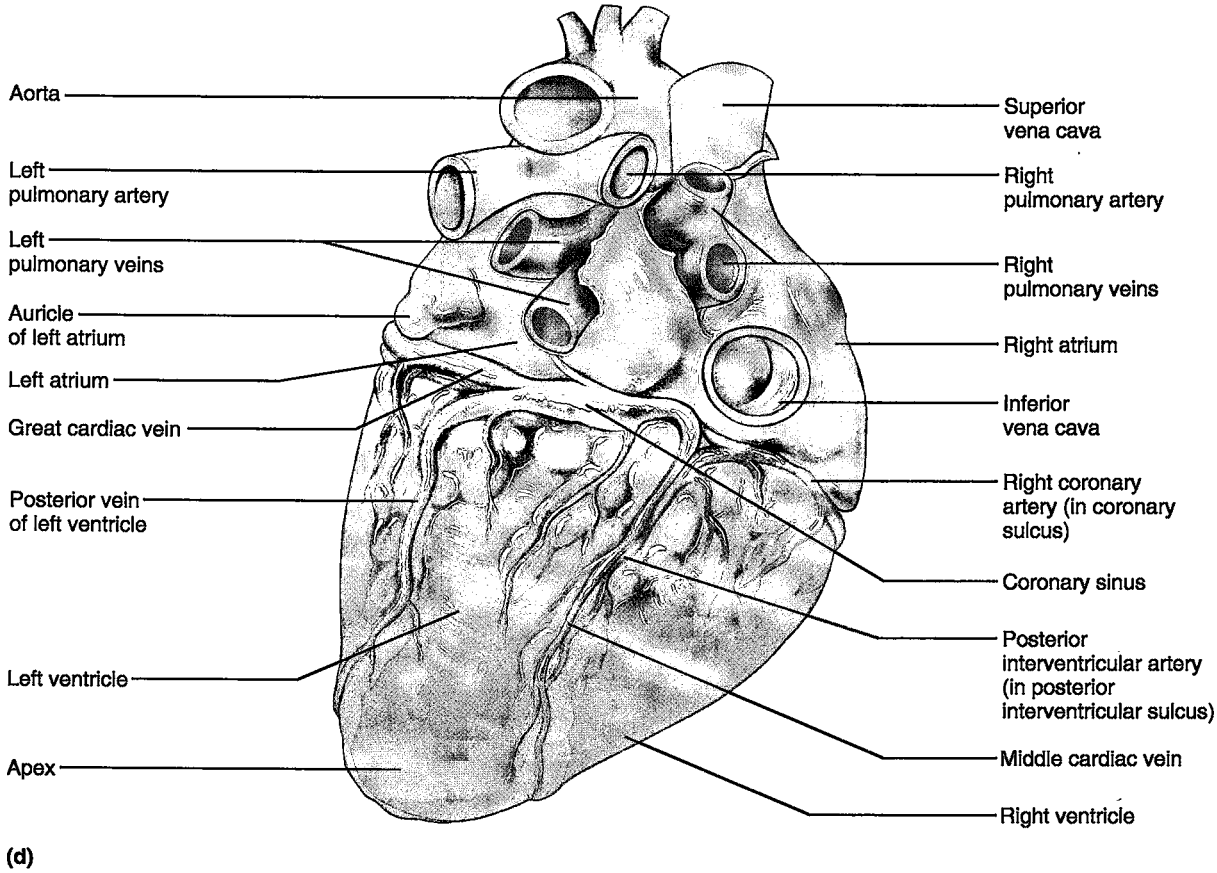


FIGURE 18.4 *(continued)* **Gross anatomy of the heart. (c)** Right anterior view of the internal aspect of the right atrium. The anterior wall of the atrium has been opened and folded superiorly. **(d)** Posterior surface view. (See *A Brief Atlas of the Human Body*, Figure 59.)

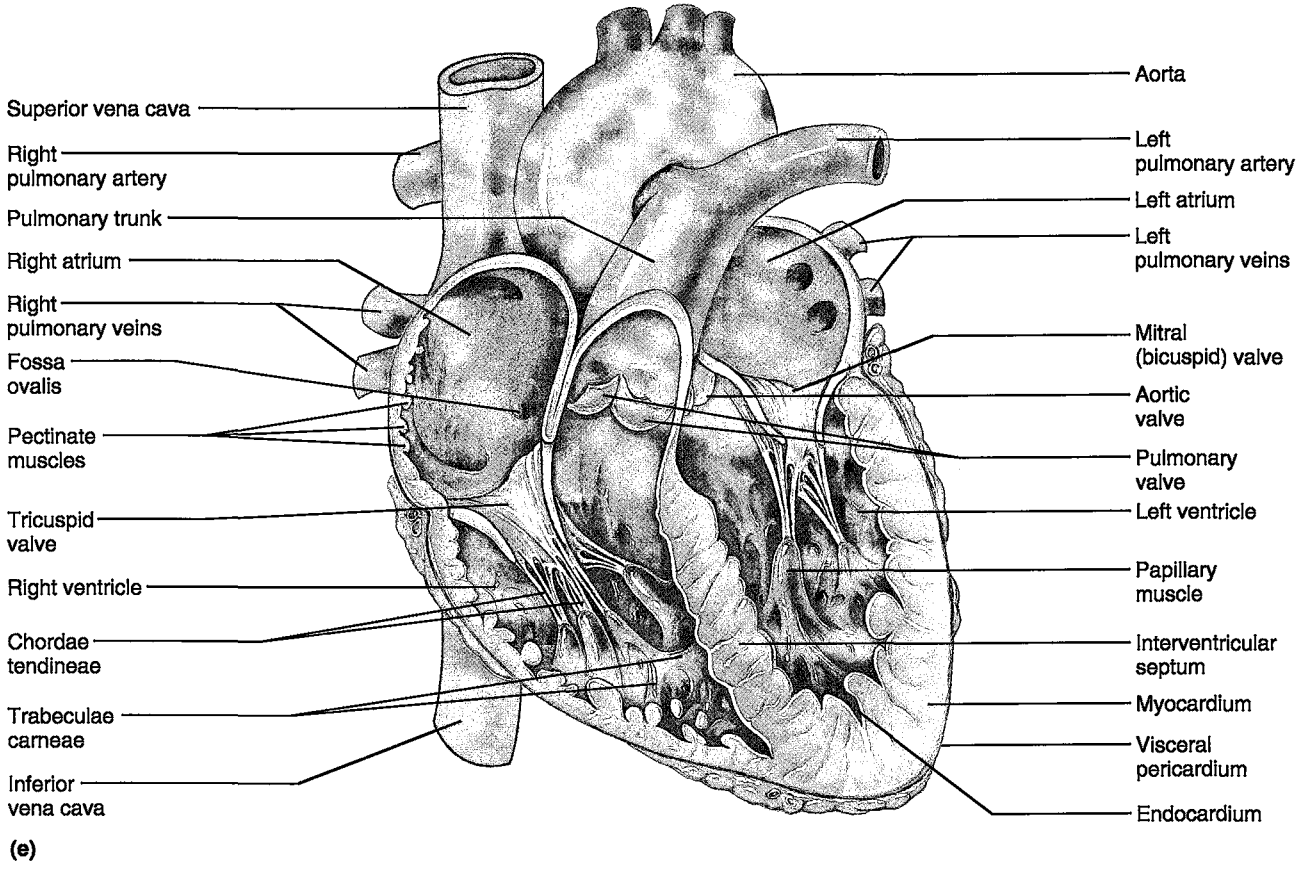


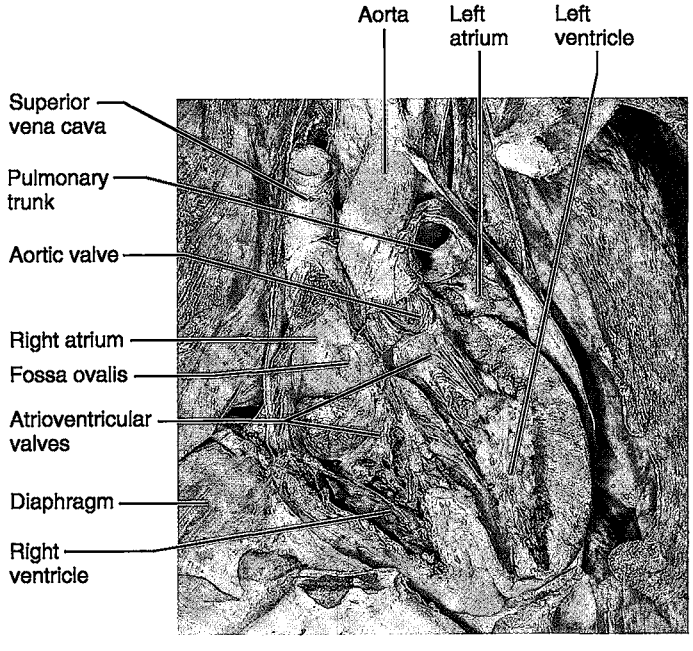
(e)

Blood enters the *right atrium* via three veins (Figure 18.4c–e): (1) The **superior vena cava** returns blood from body regions superior to the diaphragm; (2) the **inferior vena cava** returns blood from body areas below the diaphragm; and (3) the **coronary sinus** collects blood draining from the myocardium. Four **pulmonary veins** enter the *left atrium*, which makes up most of the heart's base. These veins, which transport blood from the lungs back to the heart, are best seen in a posterior view (Figure 18.4d).

Ventricles: The Discharging Chambers

Together the ventricles (*ventr* = underside) make up most of the volume of the heart. As already mentioned, the right ventricle forms most of the heart's anterior surface and the left ventricle dominates its posteroinferior surface. Marking the internal walls of the ventricular chambers are irregular ridges of muscle called **trabeculae carneae** (trah-bek'u-le kar'ne-e; "crossbars of flesh"). Still other muscle bundles, the conelike **papillary muscles,** which play a role in valve function, project into the ventricular cavity.

The ventricles are the discharging chambers or actual pumps of the heart (the difference in function



(f)

FIGURE 18.4 *(continued)* **Gross anatomy of the heart. (e)** Frontal section showing interior chambers and valves. **(f)** Photograph of a cadaver heart comparable to diagrammatic view of Figure 18.4e but with part of the pulmonary trunk removed.

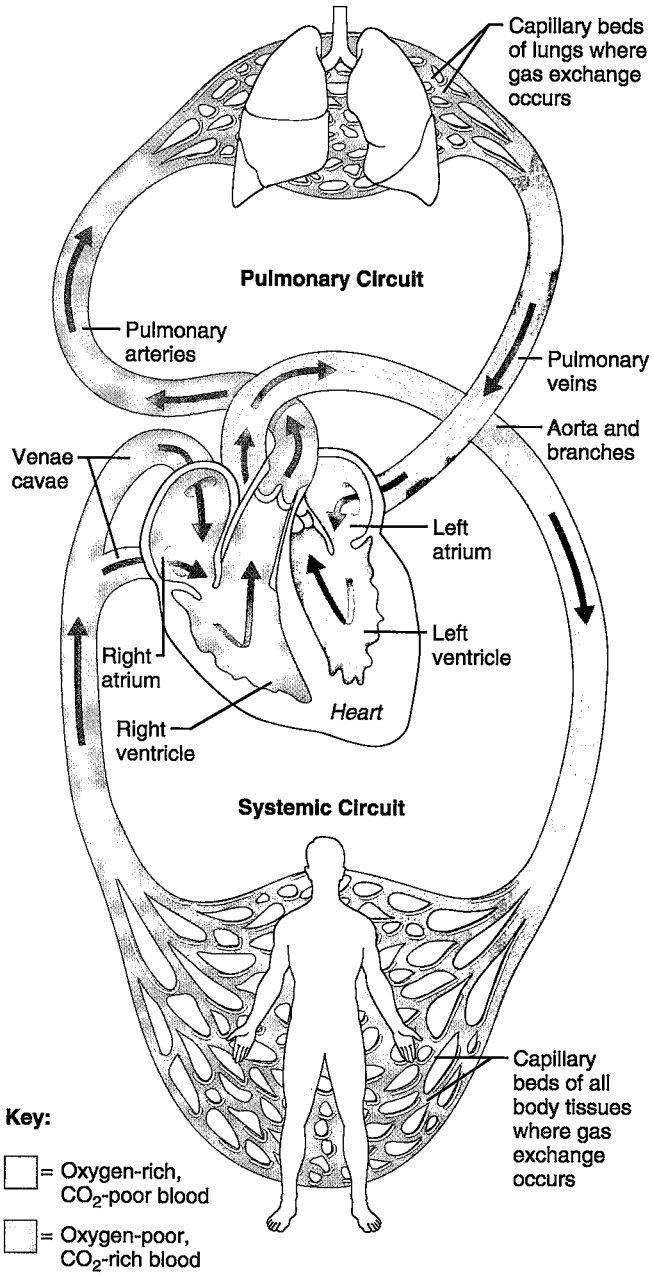


FIGURE 18.5 **The systemic and pulmonary circuits.** The right side of the heart pumps blood through the pulmonary circuit* (to the lungs and back to the left side of the heart). The left side of the heart pumps blood via the systemic circuit to all body tissues and back to the right side of the heart. Blood flowing through the pulmonary circuit gains oxygen and loses carbon dioxide, indicated by the color change from blue to red. Blood flowing through the systemic circuit loses oxygen and picks up carbon dioxide (red to blue color change).

*For simplicity, the actual number of two pulmonary arteries and four pulmonary veins has been reduced to one each.

between atria and ventricles is reflected in the much more massive ventricular walls; Figure 18.4e). When the ventricles contract, blood is propelled out of the heart into the circulation. The right ventricle pumps blood into the **pulmonary trunk,** which routes the blood to the lungs where gas exchange occurs. The left ventricle ejects blood into the **aorta** (a-or'tah), the largest artery in the body.

Pathway of Blood Through the Heart

Until the sixteenth century, it was believed that blood moved from one side of the heart to the other by seeping through pores in the septum. We now know that the heart passages open not from one side to the other but vertically and that the heart is actually two side-by-side pumps, each serving a separate blood circuit (Figure 18.5). The blood vessels that carry blood to and from the lungs form the **pulmonary circuit** (*pulmonos* = lung), which serves gas exchange. The blood vessels that carry the functional blood supply to and from all body tissues constitute the **systemic circuit.**

The right side of the heart is the *pulmonary circuit pump.* Blood returning from the body is relatively oxygen-poor and carbon dioxide–rich. It enters the right atrium and passes into the right ventricle, which pumps it to the lungs via the pulmonary trunk (Figure 18.4e). In the lungs, the blood unloads carbon dioxide and picks up oxygen. The freshly oxygenated blood is carried by the pulmonary veins back to the left side of the heart. Notice how unique this circulation is. Typically, we think of veins as vessels that carry blood that is relatively oxygen-poor to the heart and arteries as transporters of oxygen-rich blood from the heart to the rest of the body. Exactly the opposite condition exists in the pulmonary circuit.

The left side of the heart is the *systemic circuit pump.* Freshly oxygenated blood leaving the lungs is returned to the left atrium and passes into the left ventricle, which pumps it into the aorta. From there the blood is transported via smaller systemic arteries to the body tissues, where gases and nutrients are exchanged across the capillary walls. Then the blood, once again loaded with carbon dioxide and depleted of oxygen, returns through the systemic veins to the right side of the heart, where it enters the right atrium through the superior and inferior venae cavae. This cycle repeats itself continuously.

Although equal volumes of blood are pumped to the pulmonary and systemic circuits at any moment, the two ventricles have very unequal workloads. The pulmonary circuit, served by the right ventricle, is a

short, low-pressure circulation, whereas the systemic circuit, associated with the left ventricle, takes a long pathway through the entire body and encounters about five times as much friction, or resistance to blood flow. This functional difference is revealed in the anatomy of the two ventricles (Figures 18.4e and 18.6). The walls of the left ventricle are three times as thick as those of the right ventricle, and its cavity is nearly circular. The right ventricular cavity is flattened into a crescent shape that partially encloses the left ventricle, much the way a hand might loosely grasp a clenched fist. Consequently, the left ventricle can generate much more pressure than the right and is a far more powerful pump.

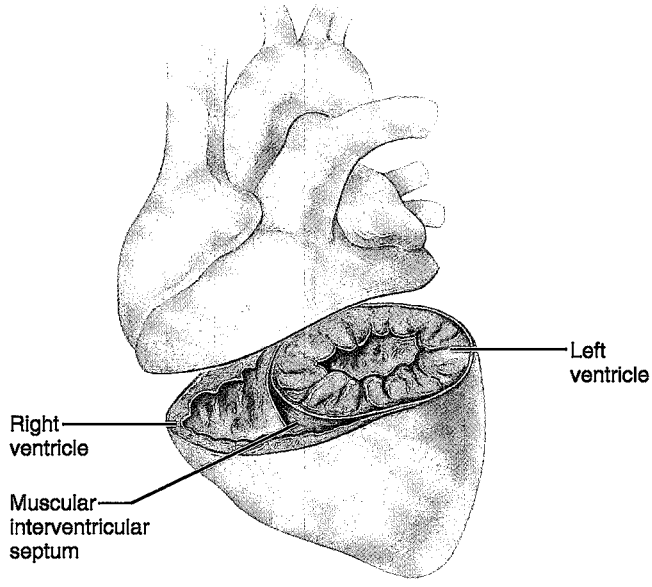

FIGURE 18.6 **Anatomical differences in right and left ventricles.** The left ventricle has a thicker wall and its cavity is basically circular; the right ventricle cavity is crescent shaped and wraps around the left ventricle.

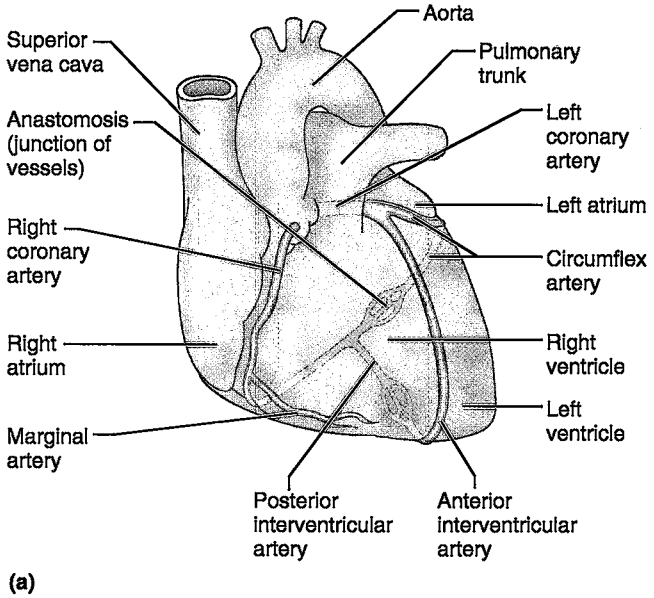
Coronary Circulation

Although the heart is more or less continuously filled with blood, this blood provides little nourishment to heart tissue. (The myocardium is too thick to make diffusion a practical means of nutrient delivery.) The **coronary circulation,** the functional blood supply of the heart, is the shortest circulation in the body. The arterial supply of the coronary circulation is provided by the *right* and *left coronary arteries,* both arising from the base of the aorta and encircling the heart in the coronary sulcus (Figure 18.7a). The **left coronary artery** runs toward the left side of the heart and then divides into its major branches: the **anterior interventricular artery** (also known clinically as the *left anterior descending artery*), which follows the anterior interventricular sulcus and supplies blood to the interventricular septum and anterior walls of both ventricles; and the **circumflex artery,** which supplies the left atrium and the posterior walls of the left ventricle.

The **right coronary artery** courses to the right side of the heart, where it also divides into two



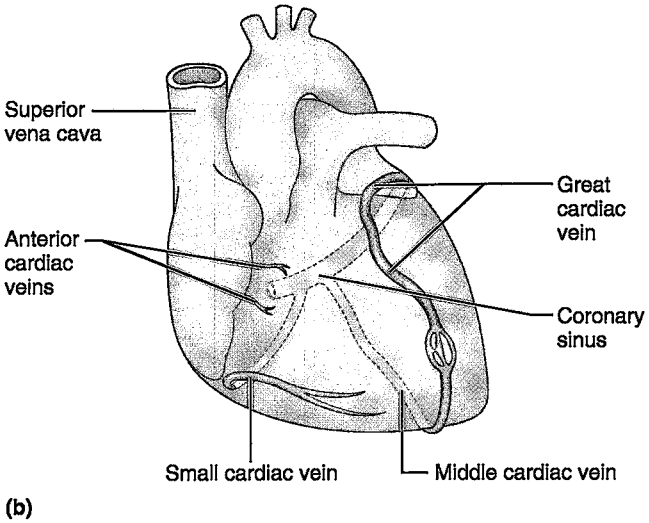


FIGURE 18.7 **Coronary circulation. (a)** The main coronary arteries. **(b)** The major cardiac veins. (In both drawings, lighter-tinted vessels are more posterior in the heart.)

branches: the **marginal artery,** which serves the myocardium of the lateral right side of the heart, and the **posterior interventricular artery,** which runs to the heart apex and supplies the posterior ventricular walls. Near the apex of the heart, this artery merges (anastomoses) with the anterior interventricular artery. Together the branches of the right coronary artery supply the right atrium and nearly all the right ventricle.

The arterial supply of the heart varies considerably. For example, in 15% of people, the left coronary artery gives rise to *both* the anterior and posterior interventricular arteries; in about 4% of people, a single coronary artery supplies the whole heart. Additionally, there may be both right and left marginal arteries. There are many anastomoses among the coronary arterial branches. These fusing networks provide additional *(collateral)* routes for blood delivery to the heart muscle, but are not robust enough to supply adequate nutrition when a coronary artery is suddenly occluded. Complete blockage leads to tissue death and heart attack.

The coronary arteries provide an intermittent, pulsating blood flow to the myocardium. These vessels and their main branches lie in the epicardium and send branches inward to nourish the myocardium. They deliver blood when the heart is relaxed, but are fairly ineffective when the ventricles are contracting because they are compressed by the contracting myocardium. Although the heart represents only about 1/200 of the body's weight, it requires about 1/20 of the body's blood supply. As might be expected, the left ventricle receives the most plentiful blood supply.

After passing through the capillary beds of the myocardium, the venous blood is collected by the **cardiac veins,** whose paths roughly follow those of the coronary arteries. These veins join together to form an enlarged vessel called the **coronary sinus,** which empties the blood into the right atrium. The coronary sinus is obvious on the posterior aspect of the heart (Figure 18.7b). The sinus has three large tributaries: the **great cardiac vein** in the anterior interventricular sulcus; the **middle cardiac vein** in the posterior interventricular sulcus; and the **small cardiac vein,** running along the heart's right inferior margin. Additionally, several **anterior cardiac veins** empty directly into the right atrium anteriorly.

HOMEOSTATIC IMBALANCE

Blockage of the coronary arterial circulation can be serious and sometimes fatal. **Angina pectoris** (an-ji'nah pek'tor-is; "choked chest") is thoracic pain caused by a fleeting deficiency in blood delivery to the myocardium. It may result from stress-induced spasms of the coronary arteries or from increased physical demands on the heart. The myocardial cells are weakened by the temporary lack of oxygen but do not die. Far more serious is prolonged coronary blockage, which can lead to a **myocardial infarction (MI),** commonly called a **heart attack** (see *A Closer Look* on pp. 706–707). Because adult cardiac muscle is essentially amitotic, most areas of cell death are repaired with noncontractile scar tissue. Whether or not a person survives a myocardial infarction depends on the extent and location of the damage. Damage to the left ventricle, which is the systemic pump, is most serious. ●

Heart Valves

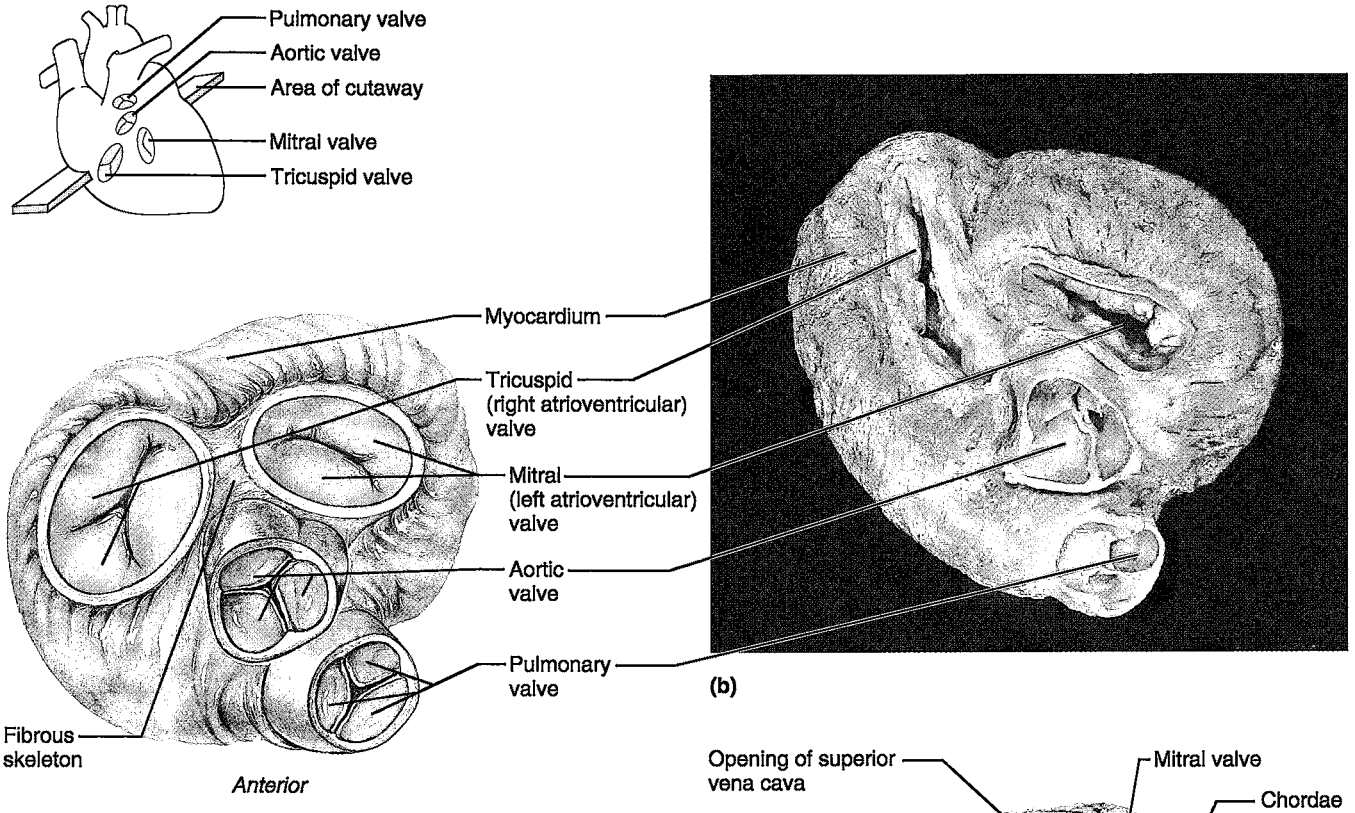
Blood flows through the heart in one direction: from atria to ventricles and out the great arteries leaving the superior aspect of the heart. This one-way traffic is enforced by four valves (Figures 18.4e and 18.8) that open and close in response to differences in blood pressure on their two sides.

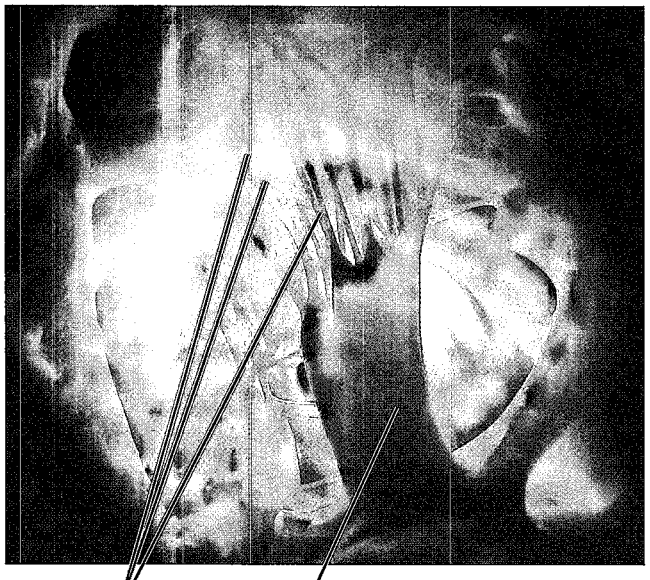
Atrioventricular Valves

The two **atrioventricular (AV) valves,** one located at each atrial-ventricular junction, prevent backflow into the atria when the ventricles are contracting. The right AV valve, the **tricuspid valve** (tri-kus'pid), has three flexible cusps (flaps of endocardium reinforced by connective tissue cores). The left AV valve, with two flaps, is called the **mitral valve** (mi'tral) because of its resemblance to the two-sided bishop's miter or hat. It is sometimes called the *bicuspid valve*. Attached to each AV valve flap are tiny white collagen cords called **chordae tendineae** (kor'de ten"dĭ'ne-e; "tendonous cords"), "heart strings" which anchor the cusps to the papillary muscles protruding from the ventricular walls.

When the heart is completely relaxed, the AV valve flaps hang limply into the ventricular chambers below and blood flows into the atria and then through the open AV valves into the ventricles. When the ventricles contract, compressing the blood in their chambers, the intraventricular pressure rises, forcing the blood superiorly against the valve flaps. As a result, the flap edges meet, closing the valve (Figure 18.9). The chordae tendineae and the papillary muscles serve as guy-wires to anchor the valve flaps in their *closed* position. If the cusps were not anchored in this manner, they would be blown upward into the atria, in the same way an umbrella is blown inside out by a gusty wind. The papillary muscles contract *before* the other ventricular musculature so that they take up the slack on the chordae tendineae before the full force of ventricular contraction hurls the blood against the AV valve flaps.

Q *What is the function of the papillary muscles and chordae tendineae?*





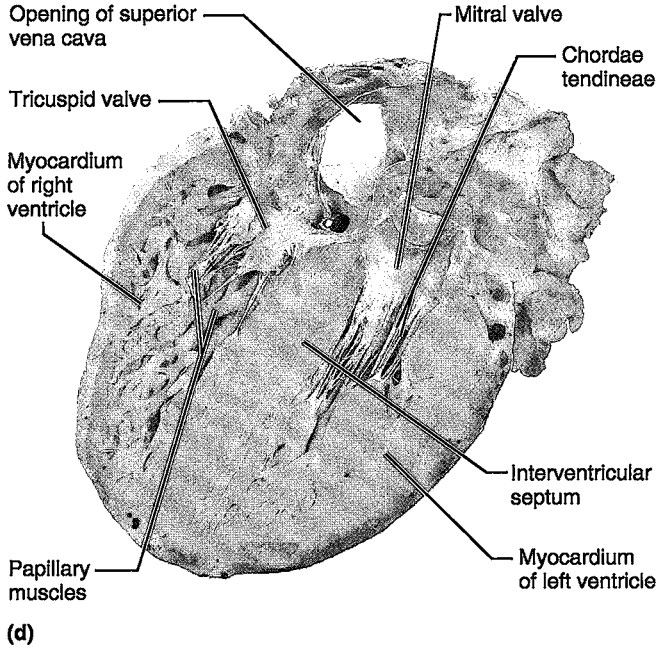


FIGURE 18.8 **Heart valves. (a)** Superior view of the two sets of heart valves (atria removed). The paired atrioventricular valves are located between atria and ventricles; the two semilunar valves are located at the junction of the ventricles and the arteries issuing from them. **(b)** Photograph of the heart valves, superior view. **(c)** Photograph of the tricuspid valve. This bottom-to-top view begins in the right ventricle and faces toward the right atrium. **(d)** Coronal section of the heart. (See *A Brief Atlas of the Human Body,* Figures 58 and 60.)

A *They keep the AV valve flaps from everting into the atria as the ventricles contract.*

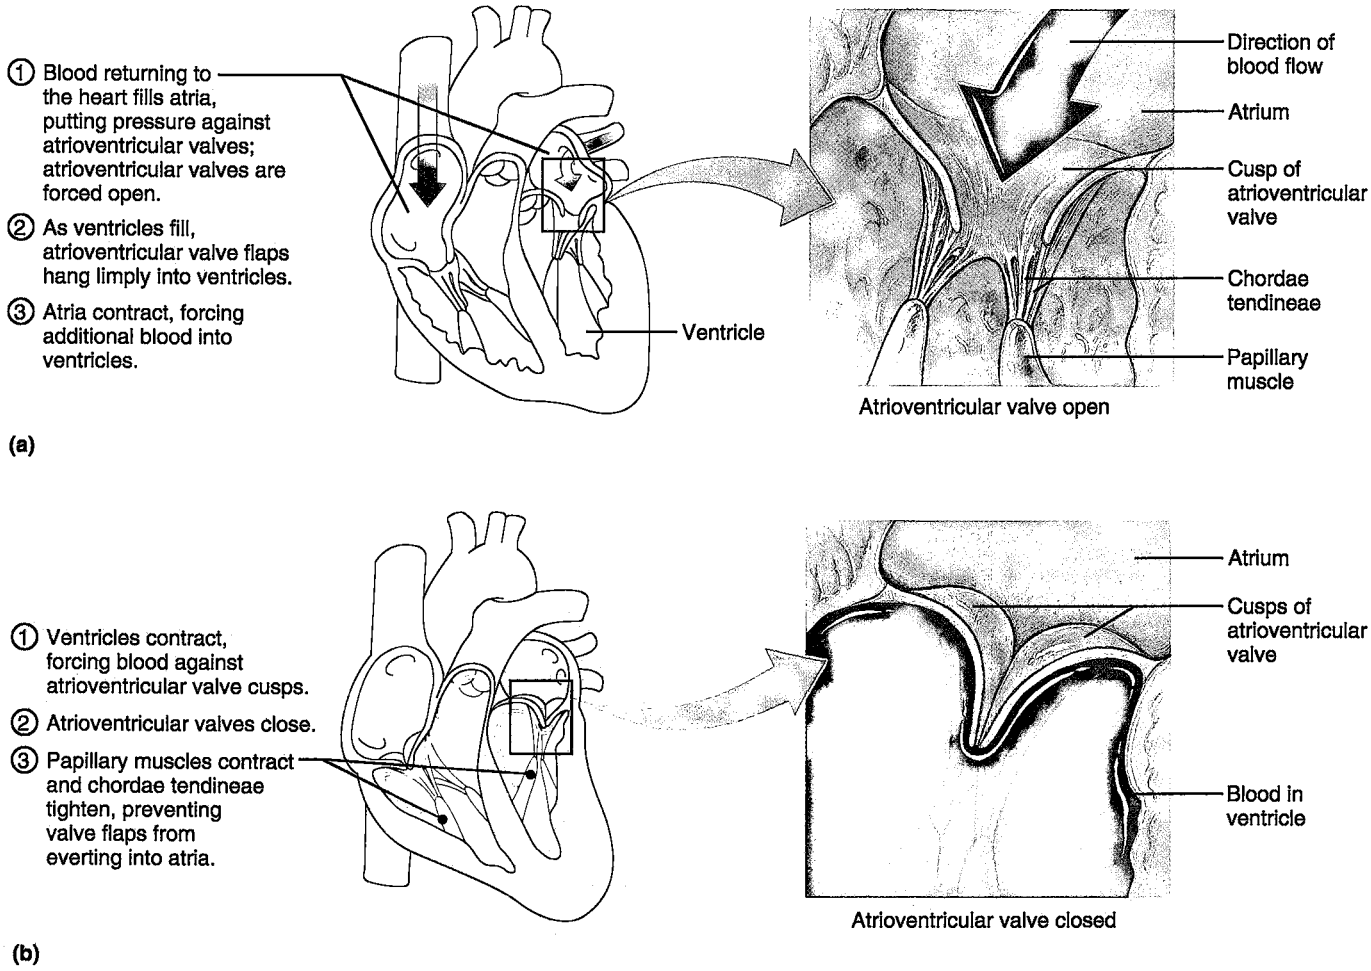

FIGURE 18.9 **The atrioventricular valves. (a)** The valves open when the blood pressure exerted on their atrial side is greater than that exerted on their ventricular side. **(b)** The valves are forced closed when the ventricles contract and intraventricular pressure rises, moving the contained blood superiorly. The action of the papillary muscles and chordae tendineae keeps the valve flaps closed.

Semilunar Valves

The **aortic** and **pulmonary (semilunar, SL) valves** guard the bases of the large arteries issuing from the ventricles (aorta and pulmonary trunk, respectively) and prevent backflow into the associated ventricles. Each SL valve is fashioned from three pocketlike cusps, each shaped roughly like a crescent moon (*semilunar* = half-moon). Like the AV valves, the SL valves open and close in response to differences in pressure. In the SL case, when the ventricles are contracting and intraventricular pressure *rises above* the pressure in the aorta and pulmonary trunk, the SL valves are forced open and their cusps flatten against the arterial walls as the blood rushes past them (Figure 18.10). When the ventricles relax, and the blood (no longer propelled forward by the pressure of ventricular contraction) flows backward toward the heart, it fills the cusps and closes the valves.

We complete the valve story by mentioning what seems to be an important omission—there are no valves guarding the entrances of the venae cavae and pulmonary veins into the right and left atria, respectively. Small amounts of blood *do* spurt back into these vessels during atrial contraction, but backflow is minimal because of the inertia of the blood and because as it contracts, the atrial myocardium compresses (and collapses) these venous entry points.

HOMEOSTATIC IMBALANCE

Heart valves are simple devices, and the heart—like any mechanical pump—can function with "leaky" valves as long as the impairment is not too great. However, severe valve deformities can seriously hamper cardiac function. An *incompetent valve* forces the heart to repump the same blood over and over because the valve does not close properly and

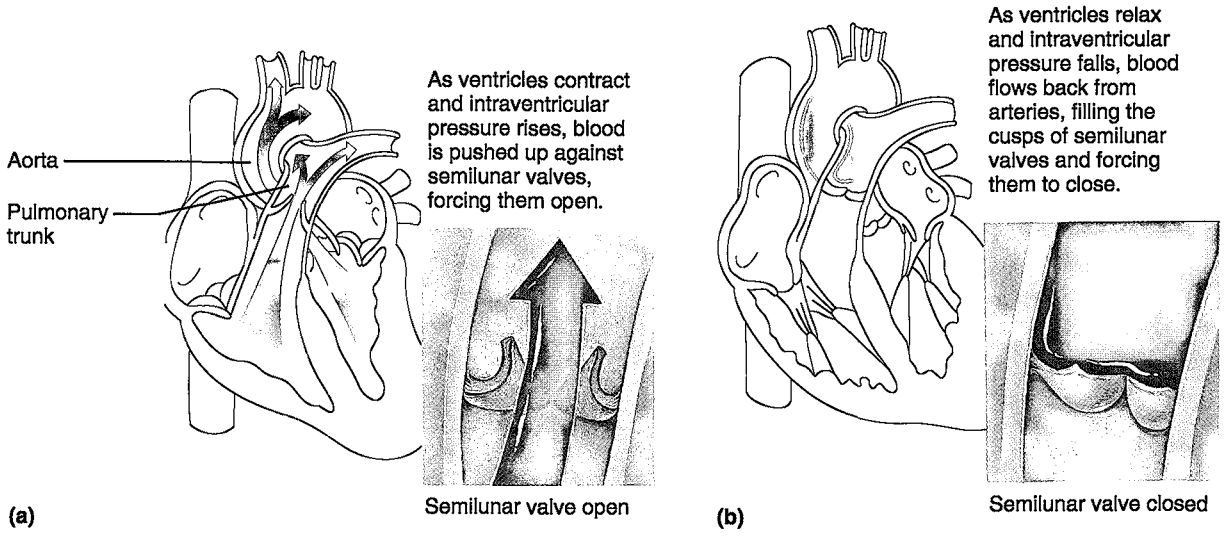

FIGURE 18.10 **The semilunar valves. (a)** During ventricular contraction, the valves are open. **(b)** When the ventricles relax, the backflowing blood closes the valves.

blood backflows. In valvular *stenosis* ("narrowing"), the valve flaps become stiff (typically because of scar tissue formation following endocarditis or calcium salt deposit) and constrict the opening. This stiffness compels the heart to contract more forcibly than normal. In both instances, the heart's workload increases and, ultimately, the heart may be severely weakened. Under such conditions, the faulty valve (most often the mitral valve) is replaced with a mechanical valve, a pig heart valve chemically treated to prevent rejection, or cryopreserved valves from human cadavers. Heart valves tissue-engineered from a patient's own cells grown on a biodegradable scaffold are being developed.

Properties of Cardiac Muscle Fibers

Although similar to skeletal muscle, cardiac muscle displays some special anatomical features that reflect its unique blood-pumping role.

Microscopic Anatomy

Cardiac muscle, like skeletal muscle, is striated, and it contracts by the sliding filament mechanism. However, in contrast to the long, cylindrical, multinucleate skeletal muscle fibers, cardiac cells are short, fat, branched, and interconnected. Each fiber contains one or at most two large, pale, *centrally* located nuclei (Figure 18.11a). The intercellular spaces are filled with a loose connective tissue matrix (the *endomysium*) containing numerous capillaries. This delicate matrix is connected to the fibrous skeleton, which acts both as a tendon and as an insertion, giving the cardiac cells something to pull or exert their force against.

Skeletal muscle fibers are independent of one another both structurally and functionally. By contrast, the plasma membranes of adjacent cardiac cells interlock like the ribs of two sheets of corrugated cardboard at dark-staining junctions called **intercalated discs** (in-ter'kah-la"ted; *intercala* = insert) (Figure 18.11b). These discs contain anchoring *desmosomes* and *gap junctions* (cell junctions discussed in Chapter 3). The desmosomes prevent adjacent cells from separating during contraction, and the gap junctions allow ions to pass from cell to cell, transmitting current across the entire heart. Because cardiac cells are electrically coupled by the gap junctions, the myocardium *behaves* as a single coordinated unit, or **functional syncytium.**

Large mitochondria account for 25–35% of the volume of cardiac cells (compared with only 2% in skeletal muscle) and give cardiac cells a high resistance to fatigue. Most of the remaining volume is occupied by myofibrils composed of fairly typical sarcomeres. The sarcomeres have Z discs, A bands, and I bands that reflect the arrangement of the thick (myosin) and thin (actin) filaments composing them. However, in contrast to what is seen in skeletal muscle, the myofibrils of cardiac muscle cells vary greatly in diameter and branch extensively, accommodating the abundant mitochondria that lie between them. This produces a banding pattern less dramatic than that seen in skeletal muscle.

The system for delivering Ca^{2+} is less elaborate in cardiac muscle cells. The T tubules are wider and fewer than in skeletal muscle and they enter the cells once per sarcomere at the Z discs. (Remember that T

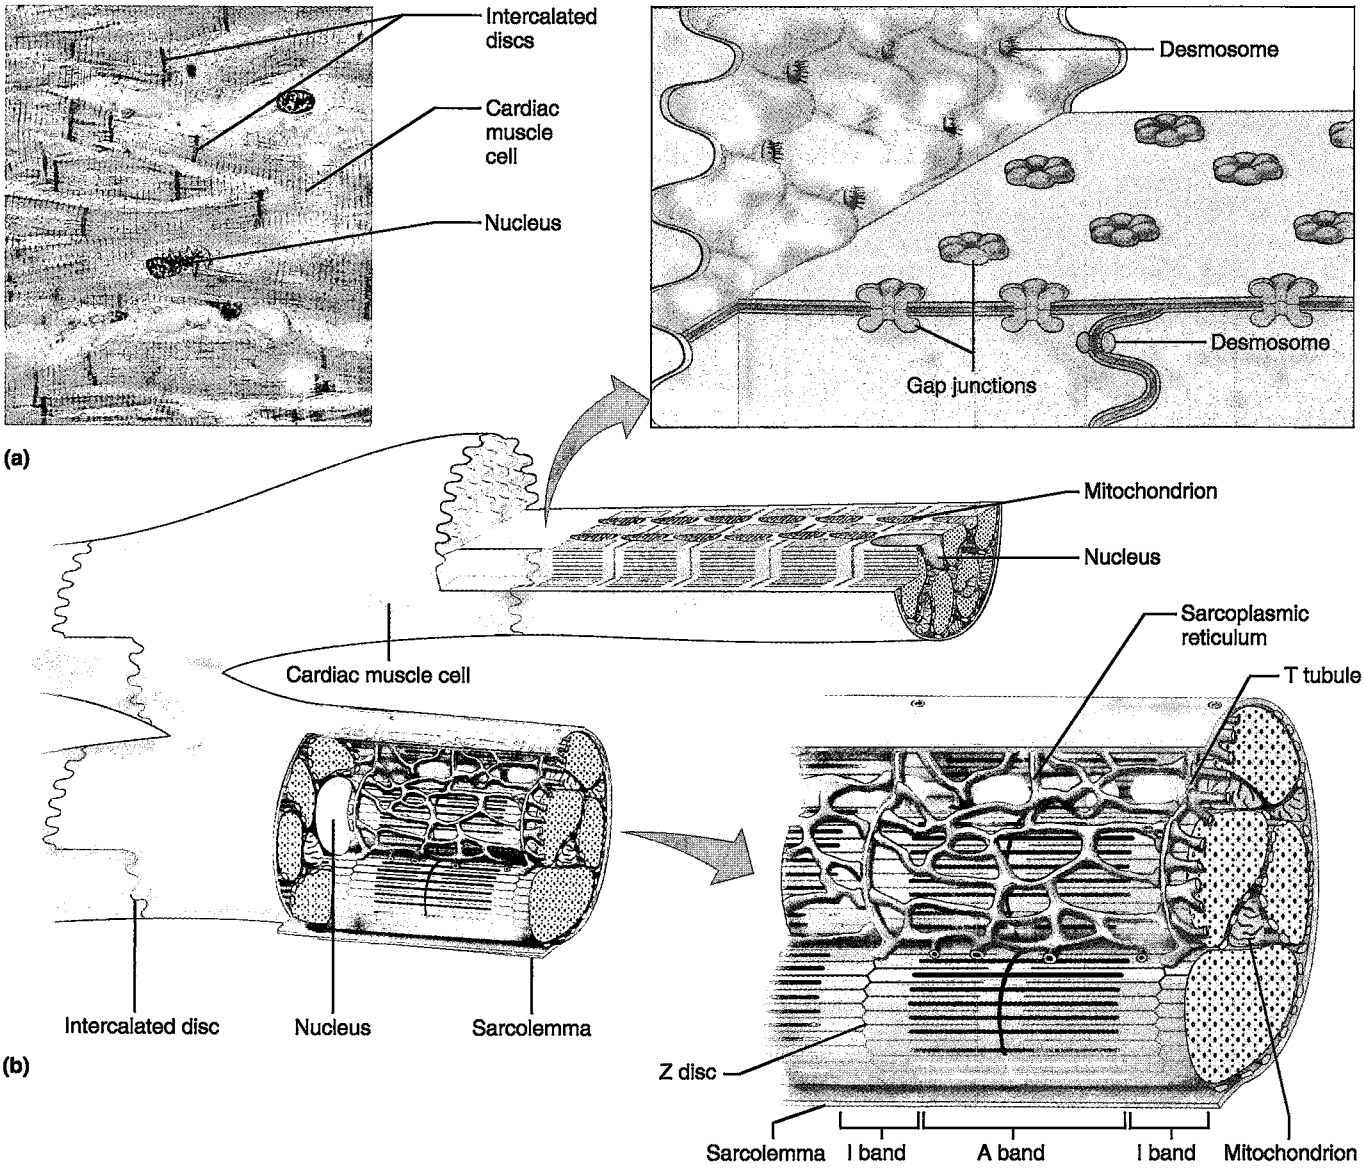

FIGURE 18.11 **Microscopic anatomy of cardiac muscle. (a)** Photomicrograph of cardiac muscle (700×). Notice that the cardiac muscle cells are short, branched, and striated. The dark-staining areas are intercalated discs, or junctions, between adjacent cells. **(b)** Cardiac cell relationships at the intercalated discs and relationships of cell components.

tubules are invaginations of the sarcolemma. In skeletal muscle, the T tubules invaginate twice per sarcomere, at the A-I junctions.) The cardiac sarcoplasmic reticulum is simpler and lacks the large terminal cisternae seen in skeletal muscle. Hence, no *triads* are seen in cardiac muscle fibers.

Mechanism and Events of Contraction

Although heart muscle and skeletal muscle are contractile tissues, they have some fundamental differences:

1. Means of stimulation. Each skeletal muscle fiber must be stimulated to contract by a nerve ending, but some cardiac muscle cells are self-excitable and can initiate their own depolarization, and that of the rest of the heart, in a spontaneous and rhythmic way. This property, called **automaticity,** or **autorhythmicity,** is described in the next section.

2. Organ versus motor unit contraction. In skeletal muscle, all cells of a given motor unit (but not necessarily all motor units of the muscle) are stimulated and contract at the same time. Impulses do not spread from cell to cell. In cardiac muscle, the heart either contracts as a unit or doesn't contract at all.

This is ensured by the transmission of the depolarization wave across the heart from cell to cell via ion passage through gap junctions, which tie all cardiac muscle cells together into a single contractile unit.

3. Length of absolute refractory period. The absolute refractory period (the inexcitable period when Na^+ channels are still open or inactivated) lasts approximately 250 ms in cardiac muscle cells, nearly as long as the contraction (Figure 18.12a). Contrast this to the refractory periods of 1–2 ms in skeletal muscle fibers, in which contractions last 15–100 ms. The long cardiac refractory period normally prevents tetanic contractions, which would stop the heart's pumping action.

Having probed their major differences, let's now look at cardiac and skeletal muscle similarities. As with skeletal muscle, cardiac muscle contraction is triggered by action potentials that sweep across cell membranes. Although about 1% of cardiac fibers are *autorhythmic* ("self-rhythm") and have the special ability to depolarize spontaneously and thus pace the heart, the bulk of heart muscle is composed of *contractile muscle fibers* responsible for the heart's pumping activity. In these contractile cells, the sequence of electrical events is similar to that in skeletal muscle fibers:

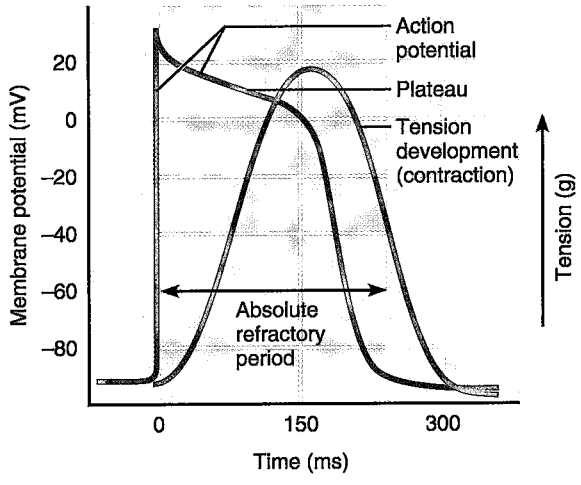
1. Depolarization opens a few **voltage-gated fast Na^+ channels** in the sarcolemma allowing extracellular Na^+ to enter. This initiates a positive feedback cycle that causes the rising phase of the action potential (and reversal of the membrane potential from −90 mV to nearly +30 mV; see Figure 18.12). The period of increased Na^+ permeability is very brief, because the sodium channels are quickly inactivated and the Na^+ influx stops.

2. Transmission of the depolarization wave down the T tubules (ultimately) causes the sarcoplasmic reticulum (SR) to release Ca^{2+} into the sarcoplasm.

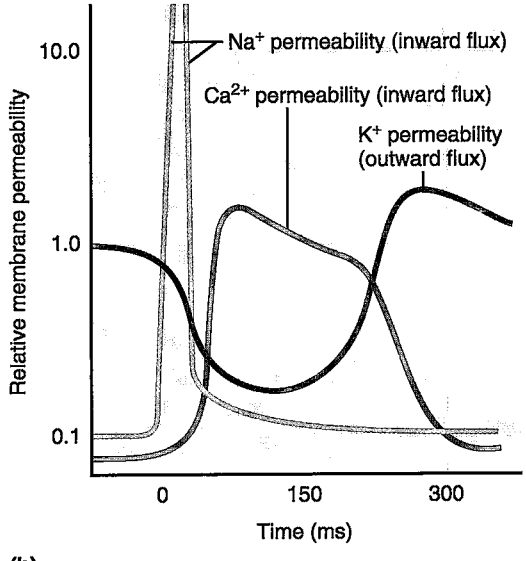
3. Excitation-contraction coupling occurs as Ca^{2+} provides the signal (via troponin binding) for cross bridge activation and couples the depolarization wave to the sliding of the myofilaments.

Although these three steps are common to both skeletal and cardiac muscle cells (see Figure 9.10), how the SR is stimulated to release Ca^{2+} differs in the two muscle types. Let's take a look.

Some 10–20% of the Ca^{2+} needed for the calcium pulse that triggers contraction enters the cardiac cells from the extracellular space. Once inside, it stimulates the SR to release the other 80% of the Ca^{2+} needed. Ca^{2+} is barred from entering nonstimulated cardiac fibers, but when Na^+-dependent membrane depolarization occurs, the voltage change *also* opens channels that allow Ca^{2+} entry from the extracellular space. These channels are called **slow**



(a)



(b)

FIGURE 18.12 **Changes in membrane potential and permeability during action potentials of contractile cardiac muscle cells. (a)** Relationship between the action potential, period of contraction, and absolute refractory period in a single ventricular cell. (The tracing for an atrial contractile cell is similar but the plateau phase is shorter.) **(b)** Membrane permeability changes during the action potential. (The Na^+ permeability rises to a point off the scale during the action potential spike.)

Ca^{2+} channels because their opening is delayed a bit (Figure 18.12b). The local influxes of Ca^{2+} through these channels trigger opening of nearby Ca^{2+}-sensitive channels in the SR tubules, which liberate bursts of Ca^{2+} ("calcium sparks") that dramatically increase the intracellular Ca^{2+} concentration.

Although Na^+ permeability has plummeted to its resting levels and repolarization has begun by this point, the calcium surge across the sarcolemma prolongs the depolarization potential briefly, producing

a **plateau** in the action potential tracing (Figure 18.12a). At the same time, K^+ permeability decreases, which also prolongs the plateau and prevents rapid repolarization. As long as Ca^{2+} is entering, the cells continue to contract. Notice in Figure 18.12a that muscle tension develops during the plateau, and peaks just after the plateau ends. Notice also that the duration of the action potential and contractile phase is much greater in cardiac muscle than in skeletal muscle. In skeletal muscle, the action potential typically lasts 1–2 ms and the contraction (for a single stimulus) 15–100 ms. In cardiac muscle, the action potential lasts 200 ms or more (because of the plateau), and tension development persists for 200 ms or more, providing the sustained contraction needed to eject blood from the heart.

After about 200 ms, the slope of the action potential tracing falls rapidly. This results from closure of Ca^{2+} channels and opening of voltage-gated K^+ channels, which allows a rapid loss of potassium from the cell that restores the resting membrane potential. During repolarization, Ca^{2+} is pumped back into the SR and the extracellular space.

Energy Requirements

Cardiac muscle has more mitochondria than skeletal muscle does, reflecting its greater dependence on oxygen for its energy metabolism. Unlike skeletal muscle, which can contract for prolonged periods, even during oxygen deficits, by carrying out anaerobic respiration, the heart relies almost exclusively on aerobic respiration. Hence, cardiac muscle cannot incur much of an oxygen debt and still operate effectively.

Both types of muscle tissue use multiple fuel molecules, including glucose and fatty acids. But cardiac muscle is much more adaptable and readily switches metabolic pathways to use whatever nutrient supply is available, including lactic acid generated by skeletal muscle activity. Thus, the real danger of an inadequate blood supply to the myocardium is lack of oxygen, not of nutrient fuels.

HOMEOSTATIC IMBALANCE

When a region of heart muscle is deprived of blood (is ischemic), the oxygen-starved cells begin to metabolize anaerobically, producing lactic acid. The rising H^+ level that results hinders the cardiac cells' ability to produce the ATP they need to pump Ca^{2+} into the extracellular fluid. The resulting increase in intracellular H^+ and Ca^{2+} levels causes the gap junctions (which are usually open) to close, electrically isolating the damaged cells and forcing generated action potentials to find alternate routes to the cardiac cells beyond them. If the ischemic area is large, the pumping activity of the heart as a whole may be severely impaired, leading to a heart attack. ●

Heart Physiology

Electrical Events

The ability of cardiac muscle to depolarize and contract is intrinsic; that is, it is a property of heart muscle and does not depend on the nervous system. Even if all nerve connections to the heart are severed, the heart continues to beat rhythmically, as demonstrated by transplanted hearts. Nevertheless, the healthy heart is amply supplied with autonomic nerve fibers that can alter the basic rhythm of heart activity set by intrinsic factors.

Setting the Basic Rhythm: The Intrinsic Conduction System

The independent, but coordinated, activity of the heart is a function of (1) the presence of gap junctions, and (2) the activity of the heart's "in-house" conduction system. The latter, called the **intrinsic cardiac conduction system,** consists of noncontractile cardiac cells specialized to initiate and distribute impulses throughout the heart, so that it depolarizes and contracts in an orderly, sequential manner. Thus, the heart beats as a coordinated unit. Let's look at how this system works.

Action Potential Initiation by Autorhythmic Cells

Unlike unstimulated contractile cells of the heart (and neurons and skeletal muscle fibers), the **autorhythmic cells** making up the intrinsic conduction system do *not* maintain a stable resting membrane potential. Instead, they have an *unstable resting potential* that continuously depolarizes, drifting slowly toward threshold. These spontaneously changing membrane potentials, called **pacemaker potentials** or **prepotentials,** initiate the action potentials that spread throughout the heart to trigger its rhythmic contractions (Figure 18.13). The pacemaker potential is due to the special properties of the ion channels in the sarcolemma. In these cells, hyperpolarization at the end of an action potential leads to both closing of K^+ channels and opening of slow Na^+ channels. The Na^+ influx alters the balance between K^+ loss and Na^+ entry, and the membrane interior becomes less and less negative (more positive). Ultimately, at threshold (approximately −40 mV), **Ca^{2+} channels** open, allowing explosive entry of Ca^{2+} from the extracellular space. Thus, in autorhythmic cells, it is the influx of Ca^{2+} (rather than Na^+) that produces the rising phase of the action potential and reverses the membrane potential.

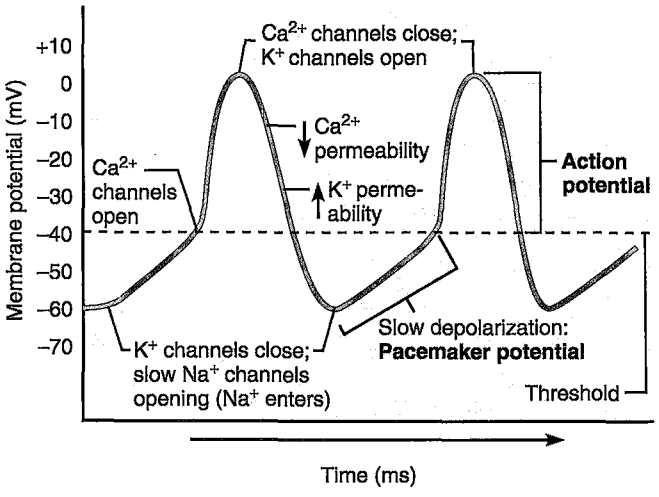


FIGURE 18.13 **Pacemaker and action potentials of autorhythmic cells of the heart.**

As in other excitable cells, the falling phase of the action potential and repolarization reflect increased K^+ permeability and efflux from the cell. Once repolarization is complete, K^+ channels close, K^+ permeability declines, and the slow depolarization to threshold begins again.

Sequence of Excitation Autorhythmic cardiac cells are found in the following areas (Figure 18.14): sinoatrial (si"no-a'tre-al) node, atrioventricular node, atrioventricular bundle, right and left bundle branches, and ventricular walls (as Purkinje fibers). Impulses pass across the heart in the same order.

① **Sinoatrial node.** The crescent-shaped sinoatrial (SA) node is located in the right atrial wall, just inferior to the entrance of the superior vena cava. A minute cell mass with a mammoth job, the SA node typically generates impulses about 75 times every minute. (However, its inherent rate in the absence of extrinsic neural and hormonal factors is closer to 100 times per minute.) Because no other region of the conduction system or the myocardium has a faster depolarization rate, the SA sets the pace for the heart as a whole. Hence, it is the heart's **pacemaker,** and its characteristic rhythm, called **sinus rhythm,** determines heart rate.

② **Atrioventricular node.** From the SA node, the depolarization wave spreads via gap junctions throughout the atria and via the *internodal pathway* to the atrioventricular (AV) node, located in the inferior portion of the interatrial septum immediately above the tricuspid valve. At the AV node, the impulse is delayed for about 0.1 s, allowing the atria to respond and complete their contraction before the ventricles contract. This delay reflects the smaller diameter of the fibers here and the fact that they have fewer gap junctions for current flow. Thus, the AV node conducts impulses more slowly than other parts of the system, just as traffic slows when cars are forced to merge into two lanes from four. Once through the AV node, the signaling impulse passes rapidly through the rest of the system.

③ **Atrioventricular bundle.** From the AV node, the impulse sweeps to the atrioventricular (AV) bundle (also called the **bundle of His**) in the superior part of the interventricular septum. Although the atria and ventricles abut each other, they are *not* connected by gap junctions. The AV bundle is the *only* electrical connection between them. The balance of the AV junction is insulated by the nonconducting fibrous skeleton of the heart.

④ **Right and left bundle branches.** The AV bundle persists only briefly before splitting into two pathways—the right and left bundle branches, which course along the interventricular septum toward the heart apex.

⑤ **Purkinje fibers.** Essentially long strands of barrel-shaped cells with few myofibrils, the Purkinje (pur-kin'je) fibers complete the pathway through the interventricular septum, penetrate into the heart apex, and then turn superiorly into the ventricular walls. The bundle branches excite the septal cells, but the bulk of ventricular depolarization depends on the large Purkinje fibers and, ultimately, on cell-to-cell transmission of the impulse via gap junctions between the ventricular muscle cells. Because the left ventricle is much larger than the right, the Purkinje network is more elaborate in that side of the heart.

Interestingly, the Purkinje fibers directly supply the papillary muscles, which are excited to contract before the rest of the ventricular muscles. As mentioned, the papillary muscles are already tightening the chordae tendineae before the full force of the ventricular contraction pushes blood against the AV valve flaps.

The total time between initiation of an impulse by the SA node and depolarization of the last of the ventricular muscle cells is approximately 0.22 s (220 ms) in a healthy human heart.

Ventricular contraction almost immediately follows the ventricular depolarization wave. A wringing contraction begins at the heart apex and moves toward the atria, following the direction of the excitation wave through the ventricle walls. This ejects some of the contained blood *superiorly* into the large arteries leaving the ventricles.

The various autorhythmic cardiac cells have different rates of spontaneous depolarization. Although the SA node normally drives the heart at a rate of 75 beats per minute, the AV node depolarizes only about 50 times per minute, the AV bundle and the Purkinje fibers (though they conduct very rapidly) depolarize at the rate of only about 30 times per minute. However,

Q *What ionic event produces the plateau in the AP of the contractile muscle cells?*

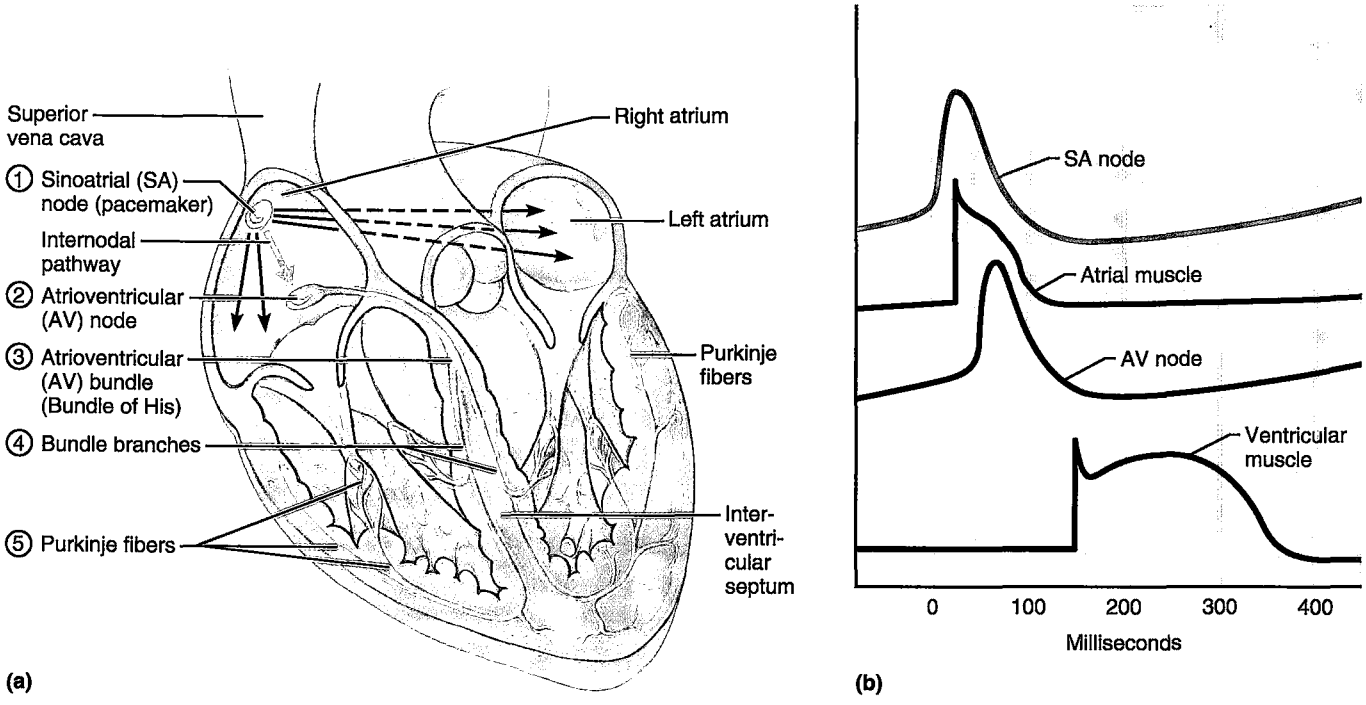

FIGURE 18.14 **Cardiac intrinsic conduction system and action potential succession during one heartbeat. (a)** The depolarization wave initiated by the SA node passes successively through the atrial myocardium to the AV node, the AV bundle, the right and left bundle branches, and the Purkinje fibers in the ventricular myocardium. **(b)** Comparison of the tracings of membrane potentials generated at various locations in the heart is shown from top to bottom beginning with the pacemaker potential generated by the SA node and ending with an action potential (with a broad plateau) typical of the contractile cardiac cells of the ventricles.

these slower "pacemakers" cannot dominate the heart unless faster pacemakers become nonfunctional.

The cardiac conduction system coordinates and synchronizes heart activity. Without it, the impulse would travel much more slowly through the myocardium—at the rate of 0.3 to 0.5 m/s as opposed to several meters per second in most parts of the conduction system. This slower rate would allow some muscle fibers to contract well before others, resulting in reduced pumping effectiveness.

HOMEOSTATIC IMBALANCE

Defects in the intrinsic conduction system can cause irregular heart rhythms, or **arrhythmias** (ah-rith'me-ahz), uncoordinated atrial and ventricular contractions, and even **fibrillation,** a condition of rapid and irregular or out-of-phase contractions in which control of heart rhythm is taken away from the SA node by rapid activity in other heart regions. The heart in fibrillation has been compared with a squirming bag of worms. Fibrillating ventricles are useless as pumps; and unless the heart is defibrillated quickly, circulation stops and brain death occurs. Defibrillation is accomplished by electrically shocking the heart, which interrupts its chaotic twitching by depolarizing the entire myocardium. The hope is that "with the slate wiped clean" the SA node will begin to function normally and sinus rhythm will be reestablished. Implantable cardioverter defibrillators (ICDs) are now available that continually monitor heart rhythms and can slow an abnormally fast heart rate or emit an electrical shock if the heart begins to fibrillate.

A defective SA node may have several consequences. An **ectopic focus** (ek-top'ik), which is an abnormal pacemaker, may appear and take over the pacing of heart rate, or the AV node may become the pacemaker. The pace set by the AV node **(junctional rhythm)** is 40 to 60 beats per minute, slower than sinus rhythm but still adequate to maintain circulation. Occasionally, ectopic pacemakers appear even when the SA node is operating normally. A small region of the heart becomes hyperexcitable, sometimes

A Calcium entry

as a result of too much caffeine (several cups of coffee) or nicotine (excessive smoking), and generates impulses more quickly than the SA node. This leads to a *premature contraction* or **extrasystole** (ek"strah-sis'to-le) before the SA node initiates the next contraction. Then, because the heart has a longer time for filling, the next (normal) contraction is felt as a thud. As you might guess, premature *ventricular* contractions (PVCs) are most problematic.

Because the only route for impulse transmission from atria to ventricles is through the AV node, any damage to the AV node, referred to as a **heart block,** interferes with the ability of the ventricles to receive pacing impulses. In total heart block no impulses get through and the ventricles beat at their intrinsic rate, which is too slow to maintain adequate circulation. In partial heart block, only some of the atrial impulses reach the ventricles. In both cases, pacemakers are used to recouple the atria to the ventricles as necessary. These programmable devices speed up in response to increased physical activity just as a normal heart would, and many can send diagnostic information to the patient's doctor via the telephone. ●

Modifying the Basic Rhythm: Extrinsic Innervation of the Heart

Although the basic heart rate is set by the intrinsic conduction system, fibers of the autonomic nervous system modify the marchlike beat and introduce a subtle variability from one beat to the next. The sympathetic nervous system (the "accelerator") increases both the rate and the force of heartbeat; parasympathetic activation (the "brakes") slows the heart. These neural controls are explained later. Here we discuss the anatomy of the nerve supply to the heart.

The cardiac centers are located in the medulla oblongata. The **cardioacceleratory center** projects to sympathetic neurons in the T_1–T_5 level of the spinal cord. These preganglionic neurons, in turn, synapse with ganglionic neurons in the cervical and upper thoracic sympathetic trunk (Figure 18.15). From there, postganglionic fibers run through the cardiac plexus to the heart where they innervate the SA and AV nodes, heart muscle, and the coronary arteries. The **cardioinhibitory center** sends impulses to the parasympathetic dorsal vagus nucleus in the medulla, which in turn sends inhibitory impulses to the heart via branches of the vagus nerves. Most parasympathetic ganglionic motor neurons lie in ganglia in the heart wall and their fibers project most heavily to the SA and AV nodes.

Electrocardiography

The electrical currents generated in and transmitted through the heart spread throughout the body and can be detected with an **electrocardiograph.** A graphic record of heart activity is called an **electrocardiogram** (**ECG** or **EKG;** *kardio* is Greek for "heart"). An ECG is a composite of all the action potentials generated by nodal and contractile cells at a given time and *not,* as sometimes assumed, a tracing of a single action potential. Recording electrodes (leads) are positioned at various sites on the body surface; typically in a clinical setting, 12 leads are used. Three are bipolar leads that measure the voltage difference either between the arms or between an arm and a leg, and nine are unipolar leads. Together the 12 leads provide a fairly comprehensive picture of the heart's electrical activity.

A typical ECG has three distinguishable waves or *deflections* (Figure 18.16). The first, the small **P wave,** lasts about 0.08 s and results from movement of the depolarization wave from the SA node through the atria. Approximately 0.1 s after the P wave begins, the atria contract.

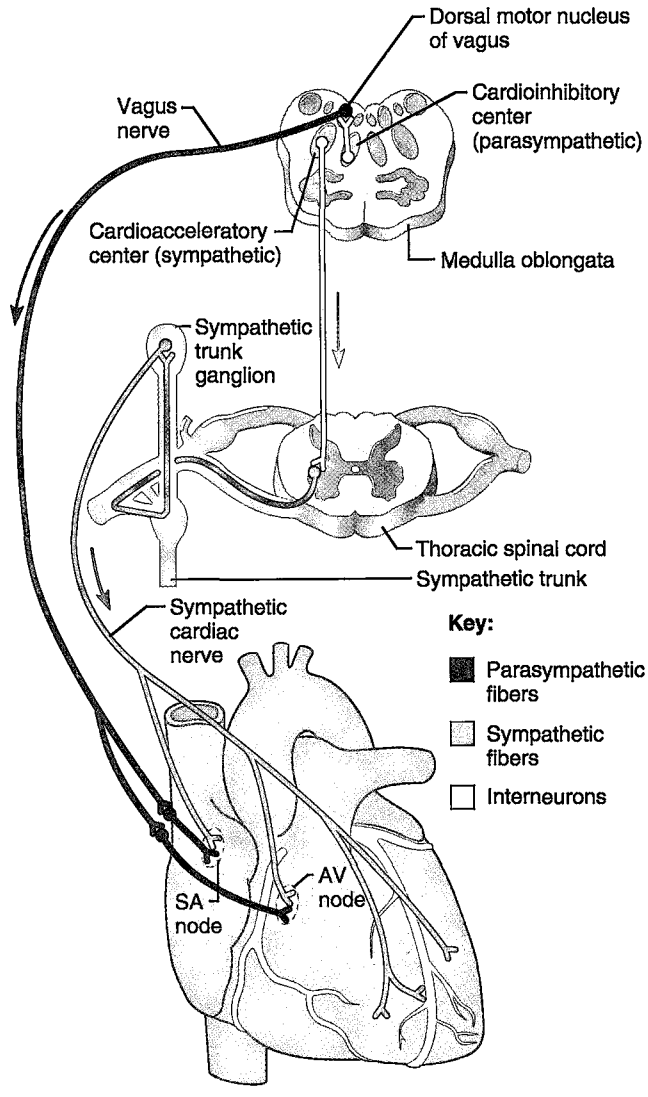

FIGURE 18.15 **Autonomic innervation of the heart.**

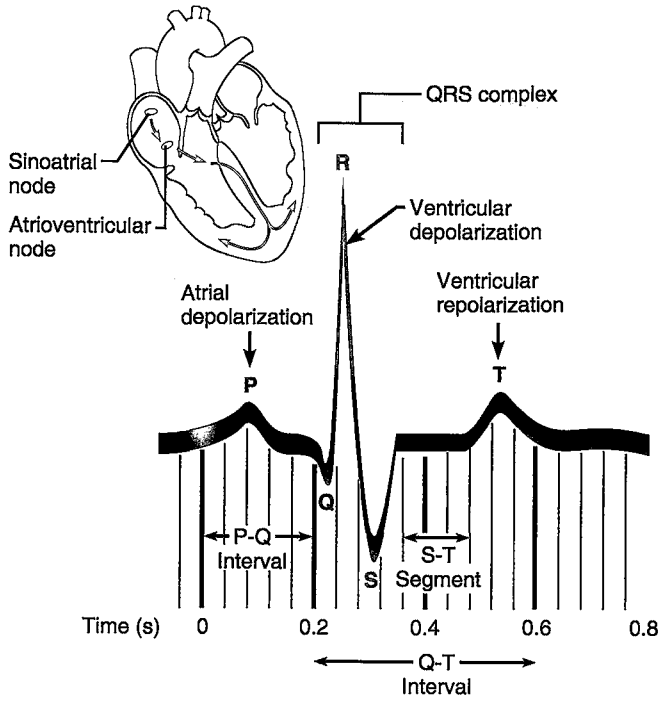

FIGURE 18.16 **An electrocardiogram tracing (lead I).** The three normally recognizable deflections (waves) and the important intervals are labeled.

Q *Knowing that ventricular contraction follows the pattern of ventricular excitation, describe the path you expect the contraction wave to follow across the ventricles.*

The large **QRS complex** results from ventricular depolarization and precedes ventricular contraction. It has a complicated shape because the paths of the depolarization waves through the ventricular walls change continuously, producing corresponding changes in current direction. Additionally, the time required for each ventricle to depolarize depends on its size relative to the other ventricle. Average duration of the QRS complex is 0.08 s.

The **T wave** is caused by ventricular repolarization and typically lasts about 0.16 s. Repolarization is slower than depolarization, so the T wave is more spread out and has a lower amplitude (height) than the QRS wave. Because atrial repolarization takes place during the period of ventricular excitation, the wave representing atrial repolarization is normally obscured by the large QRS complex being recorded at the same time.

The **P-Q interval** is the time (about 0.16 s) from the beginning of atrial excitation to the beginning of ventricular excitation. Sometimes called the **P-R interval** because the Q wave tends to be very small, it includes atrial depolarization (and contraction) as well as the passage of the depolarization wave through the rest of the conduction system. During the **S-T segment** of the ECG, when the action potential is in its plateau phase, the entire ventricular myocardium is depolarized. The **Q-T interval,** lasting about 0.38 s, is the period from the beginning of ventricular depolarization through ventricular repolarization. The relationship of the parts of an ECG to movement of the action potential over the heart is illustrated in Figure 18.17.

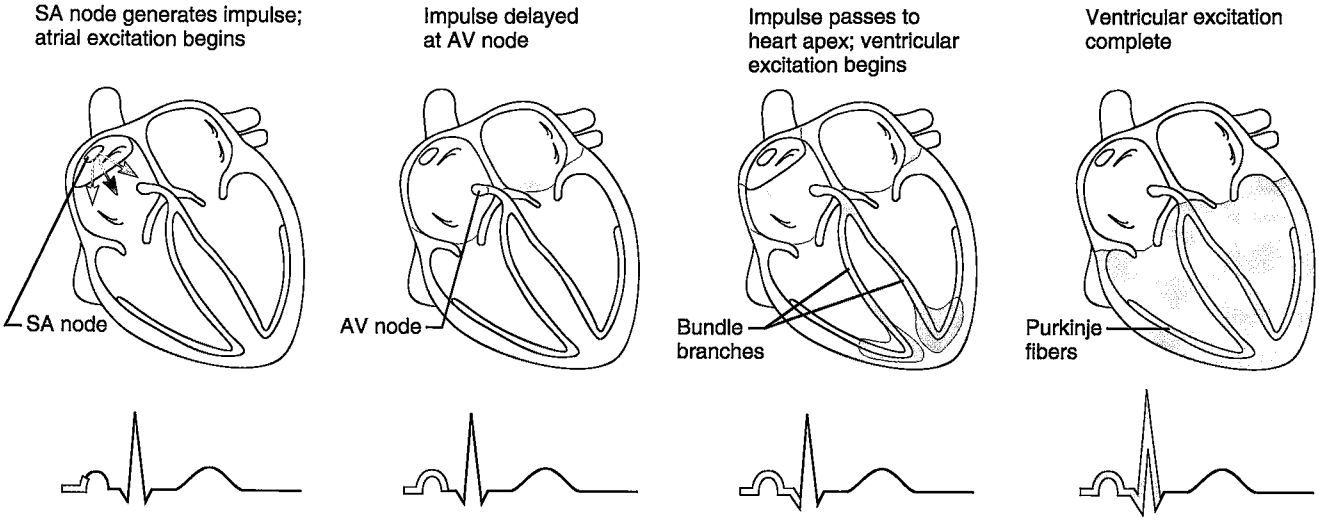

FIGURE 18.17 **The sequence of excitation of the heart related to the deflection waves of an ECG tracing.**

A *From the apex of the heart superiorly toward the atria.*

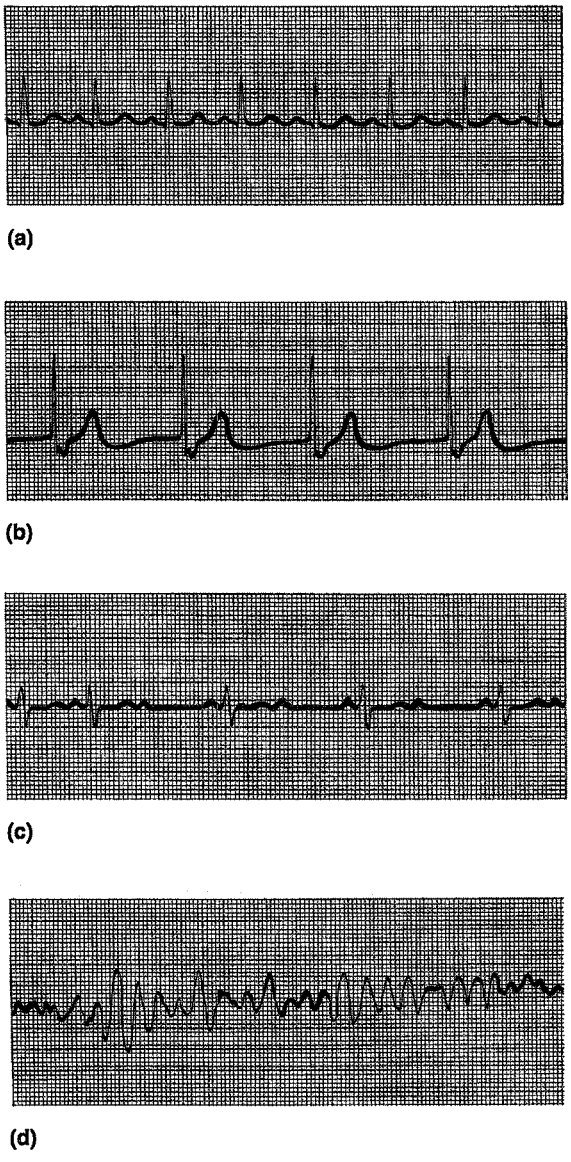

FIGURE 18.18 **Normal and abnormal ECG tracings.** **(a)** Normal sinus rhythm. **(b)** Junctional rhythm. The SA node is nonfunctional, P waves are absent, and heart rate is paced by the AV node at 40–60 beats/min. **(c)** Second-degree heart block. Some P waves are not conducted through the AV node; hence more P than QRS waves are seen. In this tracing, the ratio of P waves to QRS waves is mostly 2:1. In total (third degree) heart block, there is no whole number ratio between P and QRS waves, and the ventricles are no longer paced by the SA node. **(d)** Ventricular fibrillation. These chaotic, grossly irregular ECG deflections are seen in acute heart attack and electrical shock.

In a healthy heart, the size, duration, and timing of the deflection waves tend to be consistent. Thus, changes in the pattern or timing of the ECG may reveal a diseased or damaged heart or problems with the heart's conduction system (Figure 18.18). For example, an enlarged R wave hints of enlarged ventricles, an S-T segment that is elevated or depressed indicates cardiac ischemia, and a prolonged Q-T interval reveals a repolarization abnormality that increases the risk of ventricular arrhythmias.

Heart Sounds

During each heartbeat, two sounds can be distinguished when the thorax is auscultated (listened to) with a stethoscope. These **heart sounds,** often described as lub-dup, are associated with closing of heart valves. (The timing of heart sounds in the cardiac cycle is shown in Figure 18.20a.)

The basic rhythm of the heart sounds is lub-dup, pause, lub-dup, pause, and so on, with the pause indicating the quiescent period. The first sound, which occurs as the AV valves close, signifies the point when ventricular pressure rises above atrial pressure (the beginning of ventricular systole, discussed in the next section). The first sound tends to be louder, longer, and more resonant than the second, which is a short, sharp sound heard as the SL valves snap shut at the beginning of ventricular relaxation (diastole). Because the mitral valve closes slightly before the tricuspid valve does, and the aortic SL valve generally snaps shut just before the pulmonary valve, it is possible to distinguish the individual valve sounds by auscultating four specific regions of the thorax (Figure 18.19). Notice that these four points, while

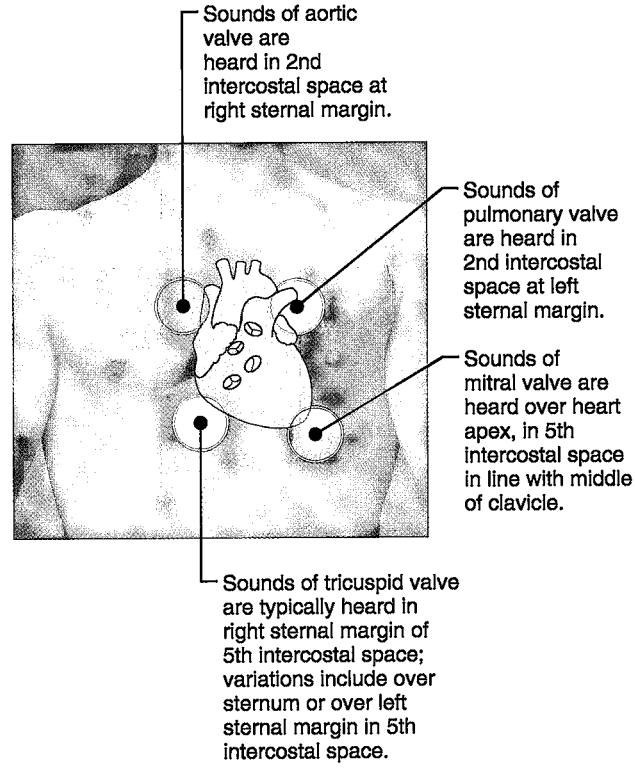

FIGURE 18.19 **Areas of the thoracic surface where the heart sounds can be best detected.**

not directly superficial to the valves (because the sounds take oblique paths to reach the chest wall), do handily define the four corners of the normal heart. Knowing normal heart size and location is essential for recognizing an enlarged (and often diseased) heart.

HOMEOSTATIC IMBALANCE

Abnormal heart sounds are called **heart murmurs.** Blood flows silently as long as the flow is smooth and uninterrupted. If it strikes obstructions, however, its flow becomes turbulent and generates heart murmurs that can be heard with a stethoscope. Heart murmurs are fairly common in young children (and some elderly people) with perfectly healthy hearts, probably because their heart walls are relatively thin and vibrate with rushing blood. Most often, however, murmurs indicate valve problems. If a valve is *incompetent,* a swishing sound is heard as the blood backflows or regurgitates through the partially open valve, *after* the valve has (supposedly) closed. A stenotic valve, in which the valvular opening is narrowed, restricts blood flow *through* the valve. In a stenotic aortic valve, for instance, a high-pitched sound or click can be detected when the valve should be wide open during systole, but is not. ●

Mechanical Events: The Cardiac Cycle

The heart undergoes some dramatic writhing movements as it alternately contracts, forcing blood out of its chambers, and then relaxes, allowing its chambers to refill with blood. The terms **systole** (sis'to-le) and **diastole** (di-as'to-le) refer respectively to these *contraction* and *relaxation* periods. The **cardiac cycle** includes *all* events associated with the blood flow through the heart during one complete heartbeat, that is, atrial systole and diastole followed by ventricular systole and diastole. These mechanical events always *follow* the electrical events seen in the ECG.

The cardiac cycle is marked by a succession of pressure and blood volume changes in the heart. Because blood circulates endlessly, we must choose an arbitrary starting point for one turn of the cardiac cycle. As shown in Figure 18.20, which outlines what happens in the left side of the heart, we begin our explanation with the heart in total relaxation: Atria and ventricles are quiet, and it is mid-to-late diastole.

① **Ventricular filling: mid-to-late diastole.** Pressure in the heart is low, blood returning from the circulation is flowing passively through the atria and the open AV valves into the ventricles, and the aortic and pulmonary valves are closed. Approximately 80% of ventricular filling occurs during this period, and the AV valve flaps begin to drift toward the closed position. (The remaining 20% is delivered to the ventricles when the atria contract toward the end of this phase.) Now the stage is set for atrial systole. Following depolarization (P wave of ECG), the atria contract, compressing the blood in their chambers. This causes a sudden slight rise in atrial pressure, which propels residual blood out of the atria into the ventricles. At this point the ventricles are in the last part of their diastole and have the maximum volume of blood they will contain in the cycle, a volume called the *end diastolic volume (EDV).* Then the atria relax and the ventricles depolarize (QRS complex). Atrial diastole persists through the rest of the cycle.

② **Ventricular systole.** As the atria relax, the ventricles begin contracting. Their walls close in on the blood in their chambers, and ventricular pressure rises rapidly and sharply, closing the AV valves. Because, for a split second, the ventricles are completely closed chambers and blood volume in the chambers remains constant, this is called the **isovolumetric contraction phase** (i"so-vol"u-met'rik). Ventricular pressure continues to rise and when it finally exceeds the pressure in the large arteries issuing from the ventricles, the isovolumetric stage ends as the SL valves are forced open and blood is expelled from the ventricles into the aorta and pulmonary trunk. During this **ventricular ejection phase,** the pressure in the aorta normally reaches about 120 mm Hg.

③ **Isovolumetric relaxation: early diastole.** During this brief phase following the T wave, the ventricles relax. Because the blood remaining in their chambers, referred to as the *end systolic volume (ESV),* is no longer compressed, ventricular pressure drops rapidly and blood in the aorta and pulmonary trunk backflows toward the heart, closing the SL valves. Closure of the aortic valve causes a brief rise in aortic pressure as backflowing blood rebounds off the closed valve cusps, an event beginning at the **dicrotic notch.** Once again the ventricles are totally closed chambers.

All during ventricular systole, the atria have been in diastole; they have been filling with blood and the intra-atrial pressure has been rising. When blood pressure on the atrial side of the AV valves exceeds that in the ventricles, the AV valves are forced open and ventricular filling, phase 1, begins again. Atrial pressure drops to its lowest point and ventricular pressure begins to rise, completing the cycle.

Assuming the average heart beats 75 times each minute, the length of the cardiac cycle is about 0.8 s, with atrial systole accounting for 0.1 s and ventricular systole 0.3 s. The remaining 0.4 s is a period of total heart relaxation, the **quiescent period.**

Notice two important points: (1) blood flow through the heart is controlled entirely by pressure

Q *Are the ventricular cardiac cells in isotonic or isometric contraction during phase 2a of part (b)?*

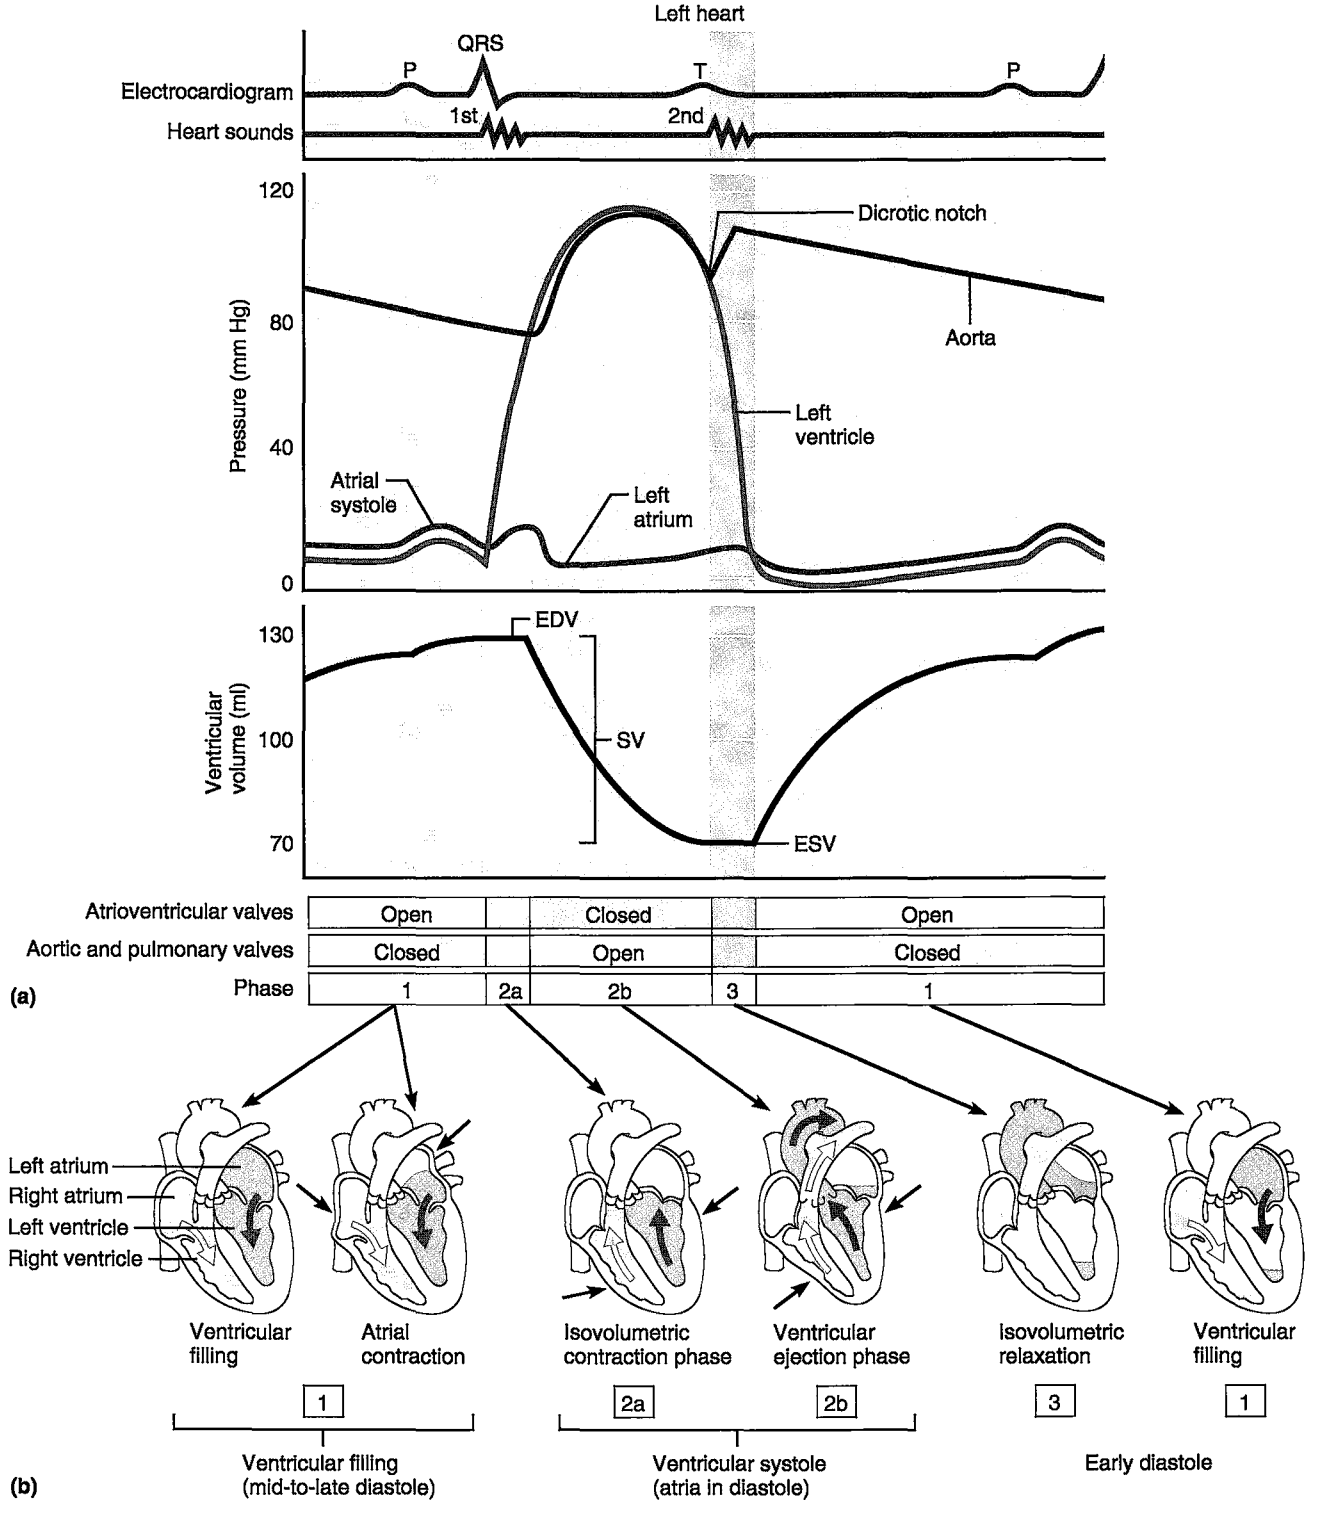

FIGURE 18.20 **Summary of events during the cardiac cycle. (a)** An ECG tracing correlated with graphs of pressure and volume changes in the left side of the heart. Pressures are lower in the right side of the heart. Timing of heart sounds is also indicated. **(b)** Events of phases 1 through 3 of the cardiac cycle.

A They are contracting isometrically until ventricular pressure rises above the pressure in the aorta.

changes and (2) blood flows down a pressure gradient through any available opening. The pressure changes, in turn, reflect the alternating contraction and relaxation of the myocardium and cause the heart valves to open, which keeps blood flowing in the forward direction.

The situation in the right side of the heart is essentially the same as in the left side *except* for pressure. The pulmonary circulation is a low-pressure circulation as evidenced by the much thinner myocardium of its right ventricle. Hence, typical systolic and diastolic pressures for the pulmonary artery are 24 and 8 mm Hg as compared to systemic aortic pressures of 120 and 80 mm Hg, respectively. However, the two sides of the heart eject the same blood volume with each heartbeat.

Cardiac Output

Cardiac output (CO) is the amount of blood pumped out by *each* ventricle in 1 minute. It is the product of heart rate (HR) and stroke volume (SV). **Stroke volume** is defined as the volume of blood pumped out by one ventricle with each beat. In general, stroke volume is correlated with the force of ventricular contraction.

Using normal resting values for heart rate (75 beats/min) and stroke volume (70 ml/beat), the average adult cardiac output can be computed:

$$CO = HR \times SV = \frac{75 \text{ beats}}{\text{min}} \times \frac{70 \text{ ml}}{\text{beat}}$$
$$= \frac{5250 \text{ ml}}{\text{min}} = \frac{5.25 \text{ L}}{\text{min}}$$

The normal adult blood volume is about 5 L (a little more than 1 gallon). Thus, the entire blood supply passes through each side of the heart once each minute. Notice that cardiac output varies directly with SV and HR. Thus CO increases when the stroke volume increases or the heart beats faster or both, and decreases when either or both of these factors decrease.

Cardiac output is highly variable and increases markedly in response to special demands, such as running to catch a bus. The difference between resting and maximal CO is referred to as **cardiac reserve.** In nonathletic people, cardiac reserve is typically four to five times resting CO (20–25 L/min), but CO in trained athletes during competition may reach 35 L/min (seven times resting). To understand how the heart accomplishes such tremendous increases in output, let's look at how stroke volume and heart rate are regulated.

Regulation of Stroke Volume

Essentially, SV represents the difference between **end diastolic volume (EDV),** the amount of blood that collects in a ventricle during diastole, and **end systolic volume (ESV),** the volume of blood remaining in a ventricle *after* it has contracted. The EDV, determined by how long ventricular diastole lasts and by venous pressure (an increase in either factor *raises* EDV), is normally about 120 ml. The ESV, determined by arterial blood pressure (the higher the pressure the higher the ESV) and the force of ventricular contraction, is approximately 50 ml. Thus, to figure normal stroke volume, these values are simply plugged into this equation:

$$SV = EDV - ESV = \frac{120 \text{ ml}}{\text{beat}} - \frac{50 \text{ ml}}{\text{beat}} = \frac{70 \text{ ml}}{\text{beat}}$$

Hence, with each beat, each ventricle pumps out about 70 ml of blood, which is about 60% of the blood in its chambers.

So what is important here—how do we make sense out of this alphabet soup (SV, ESV, EDV)? Although many factors affect SV by causing changes in EDV or ESV, the three most important are *preload, contractility,* and *afterload.* As described in detail next, preload affects EDV, whereas contractility and afterload affect the ESV.

Preload: Degree of Stretch of Heart Muscle

According to the **Frank-Starling law of the heart,** the critical factor controlling SV is the **preload,** which is the degree to which cardiac muscle cells are stretched just before they contract (Figure 18.21a). Recall that at an *optimal length* of muscle fibers (and sarcomeres) (1) the maximum number of active cross bridge attachments is possible between actin and myosin, and (2) the force of contraction is maximal. Cardiac muscle, like skeletal muscle, exhibits a *length-tension relationship.* Resting skeletal muscle fibers are kept at or near optimal length for developing maximal tension while resting cardiac cells are normally *shorter* than optimal length. Therefore, stretching cardiac cells can produce dramatic increases in contractile force. The most important factor stretching cardiac muscle is the amount of blood returning to the heart and distending its ventricles, called **venous return.**

Anything that increases the volume or speed of venous return, such as a slow heart rate or exercise, increases EDV and, consequently, SV and contraction force. A slow heartbeat allows more time for ventricular filling. Exercise speeds venous return because of an increased heart rate and the squeezing action of the skeletal muscles on the veins returning blood to the heart. During vigorous exercise, SV may double as a result of these factors. Conversely, low venous return, such as might result from severe blood loss or an extremely rapid heart rate, decreases EDV, causing the heart to beat less forcefully and the SV to drop (see Figure 18.23 on p. 703).

Q *What problem might ensue relative to cardiac output if the heart beats far too rapidly for an extended period, that is, if tachycardia occurs? Why?*

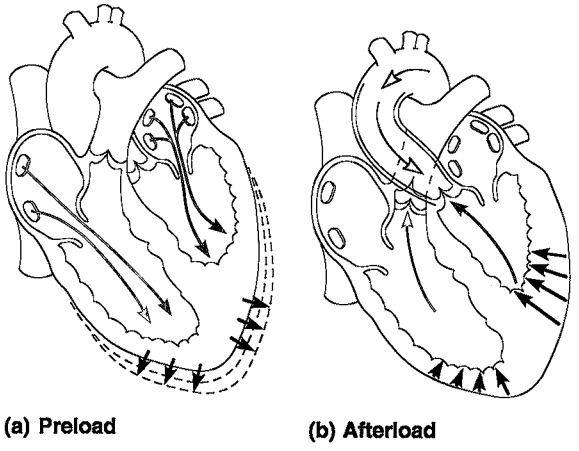

FIGURE 18.21 **Preload and afterload influence stroke volume. (a)** Preload is proportional to the amount of ventricular myocardial fiber stretch (chamber blood volume) just before systole. **(b)** Afterload is the pressure that the ventricles must overcome to force open the aortic and pulmonary valves. Black arrows indicate the direction the ventricular walls are moving.

Because the systemic and pulmonary circulations are in series, the intrinsic mechanism just described ensures equal outputs of the two ventricles and proper distribution of blood volume between the two circuits. If one side of the heart suddenly begins to pump more blood than the other, the increased venous return to the opposite ventricle forces that ventricle to pump out an equal volume, thus preventing backup or accumulation of blood in the circulation.

Contractility Although EDV is the major *intrinsic factor* influencing SV, the latter can also be enhanced by *extrinsic factors* that increase heart muscle contractility. **Contractility** is defined as the contractile strength achieved at a given muscle length. Notice that contractility is *independent* of muscle stretch and EDV. An increase in contractility is due to a greater Ca^{2+} influx into the cytoplasm from the extracellular fluid and the SR. Enhanced contractility results in ejection of more blood from the heart (greater SV), hence a lower ESV. Increased sympathetic stimulation increases contractility of the heart. As noted on p. 695, sympathetic fibers serve not only the intrinsic conduction system but the entire heart, and one effect of

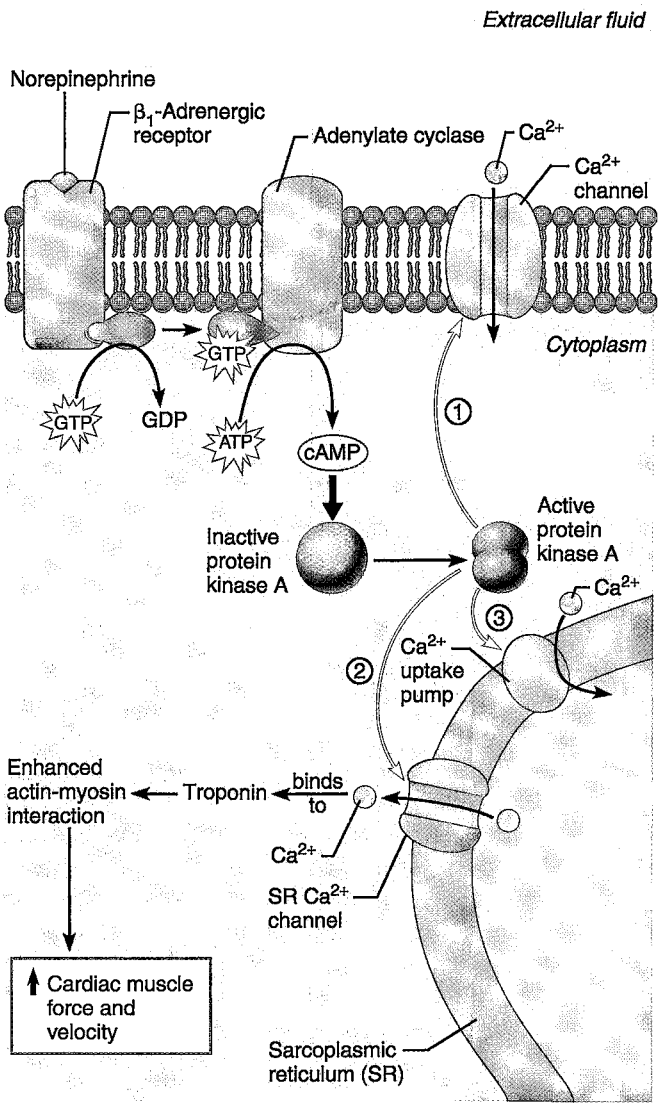

FIGURE 18.22 **Mechanism by which norepinephrine influences heart contractility.** Cyclic AMP activation of protein kinases phosphorylates ① Ca^{2+} channels in the plasma membrane, promoting entry of more Ca^{2+} from the extracellular space; and ② SR Ca^{2+} channels, causing the SR to release more Ca^{2+}. ③ In addition, phosphorylation of SR calcium uptake pumps removes Ca^{2+} more rapidly from the sarcoplasm, thus speeding relaxation and making more Ca^{2+} available for release on the next beat.

norepinephrine or epinephrine binding is to initiate a cyclic AMP second-messenger system that increases Ca^{2+} entry, which in turn promotes more cross bridge binding and enhances ventricular contractility (Figure 18.22).

A battery of other chemicals also influence contractility. For example, contractility is enhanced by Ca^{2+}, by the hormones glucagon, thyroxine, and epinephrine, and by the drug digitalis. Factors that increase contractility are called *positive inotropic agents* (*ino* = muscle, fiber). Those that impair or

▲ *Pathological increase in heart rate results in too little time for ventricular filling. Therefore, CO declines and the heart beats feebly.*

decrease contractility are called *negative inotropic agents,* and include acidosis (excess H^+), rising extracellular K^+ levels, and drugs called calcium channel blockers.

Afterload: Back Pressure Exerted by Arterial Blood The pressure that must be overcome for the ventricles to eject blood is called **afterload.** It is essentially the back pressure exerted on the aortic and pulmonary valves by arterial blood, about 80 mm Hg in the aorta and 8 mm Hg in the pulmonary trunk (Figure 18.21b). In healthy individuals, afterload is not a major determinant of stroke volume because it is relatively constant. However, in those with hypertension (high blood pressure), it is important indeed because it reduces the ability of the ventricles to eject blood. Consequently, more blood remains in the heart after systole, resulting in increased ESV and reduced stroke volume.

Regulation of Heart Rate

Given a healthy cardiovascular system, SV tends to be relatively constant. However, when blood volume drops sharply or when the heart is seriously weakened, SV declines and CO is maintained by increasing HR and contractility. Temporary stressors can also influence HR—and consequently CO—by acting through homeostatic mechanisms induced neurally, chemically, and physically. Factors that increase HR are called *positive chronotropic* (*chrono* = time) factors; those decreasing HR are *negative chronotropic* factors.

Autonomic Nervous System Regulation The most important extrinsic controls affecting heart rate are exerted by the autonomic nervous system. When the sympathetic nervous system is activated by emotional or physical stressors, such as fright, anxiety, or exercise (Figure 18.23), sympathetic nerve fibers release norepinephrine at their cardiac synapses. Norepinephrine binds to β_1-adrenergic receptors in the heart, causing threshold to be reached more quickly and accelerating relaxation. As a result, the pacemaker fires more rapidly and the heart responds by beating faster. Sympathetic stimulation also enhances contractility by enhancing Ca^{2+} entry into the contractile cells as described above and in Figure 18.22. Because ESV falls as a result of this increased contractility, SV does not decline, as it would if only heart *rate* were increased. (Remember, when the heart beats faster, there is less time for ventricular filling and so a lower EDV.)

The parasympathetic division opposes sympathetic effects and effectively reduces heart rate when a stressful situation has passed. Parasympathetic-initiated cardiac responses are mediated by acetylcholine, which hyperpolarizes the membranes of its effector cells by *opening* K^+ channels. Because vagal innervation of the ventricles is sparse, parasympathetic activity has little or no effect on cardiac contractility.

Under resting conditions, both autonomic divisions continuously send impulses to the SA node of the heart, but the *dominant* influence is inhibitory. Thus, the heart is said to exhibit **vagal tone,** and heart rate is generally slower than it would be if the vagal nerves were not innervating it. Cutting the vagal nerves results in an almost immediate increase in heart rate of about 25 beats/min, reflecting the inherent rate (100 beats/min) of the pacemaking SA node.

When either division of the autonomic nervous system is stimulated more strongly by sensory inputs relayed from various parts of the cardiovascular system, the other division is temporarily inhibited. Most such sensory input is generated by *baroreceptors* which respond to changes in systemic blood pressure, as we will discuss in Chapter 19. Another example, the **atrial (Bainbridge) reflex,** is a sympathetic reflex initiated by increased venous return and increased atrial filling. Stretching the atrial walls increases heart rate by stimulating both the SA node and the atrial stretch receptors, which trigger reflexive adjustments that result in increased sympathetic stimulation of the heart.

Because increased CO results in increased systemic blood pressure and vice versa, blood pressure regulation often involves reflexive controls of heart rate. Neural mechanisms that regulate blood pressure are described in more detail in Chapter 19.

Chemical Regulation Chemicals normally present in the blood and other body fluids may influence heart rate, particularly if they become excessive or deficient.

1. Hormones. *Epinephrine,* liberated by the adrenal medulla during sympathetic nervous system activation, produces the same cardiac effects as norepinephrine released by the sympathetic nerves; that is, it enhances heart rate and contractility.

Thyroxine is a thyroid gland hormone that increases metabolic rate and body heat production. When released in large quantities, it causes a slower but more sustained increase in heart rate than that caused by epinephrine. Because thyroxine also *enhances* the effect of epinephrine and norepinephrine on the heart, chronically hyperthyroid individuals may develop a weakened heart.

2. Ions. Physiological relationships between intracellular and extracellular ions must be maintained for normal heart function. Plasma electrolyte imbalances pose real dangers to the heart.

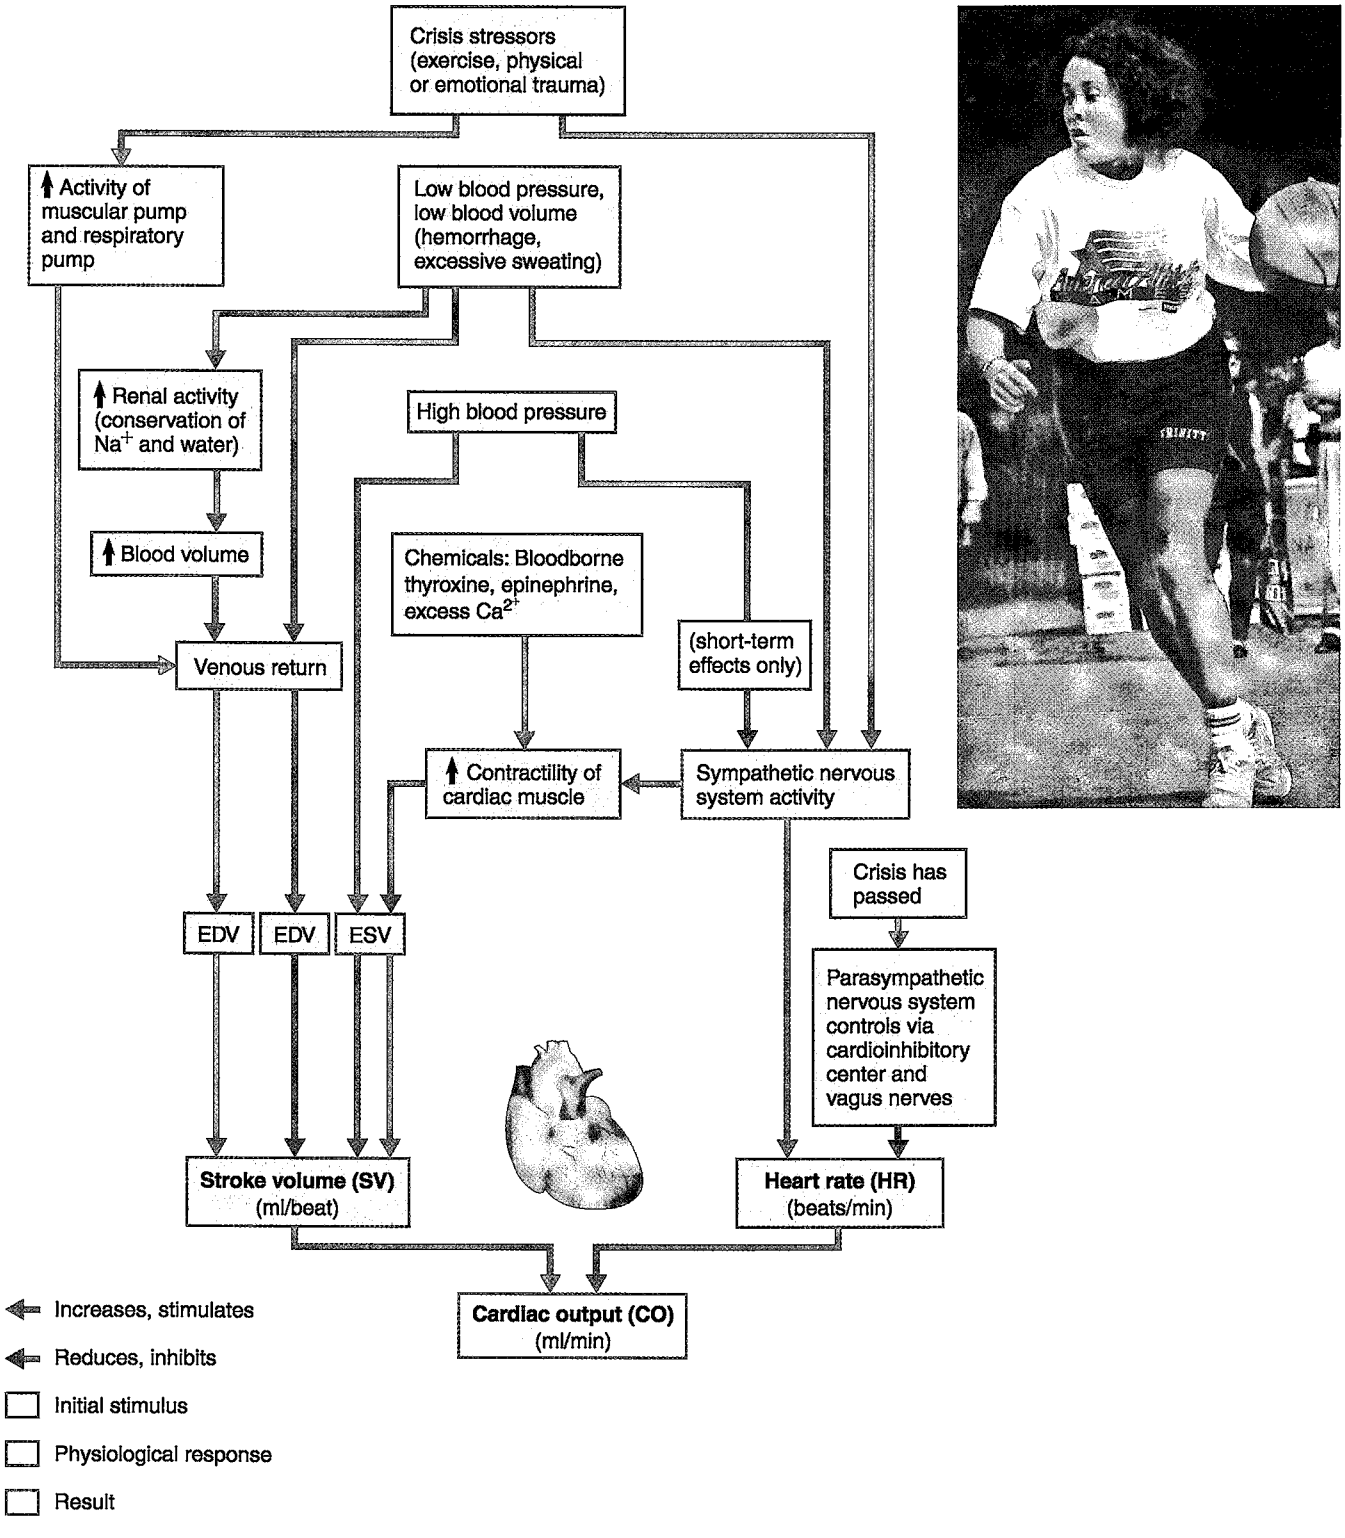

FIGURE 18.23 **Factors involved in regulation of cardiac output.**

HOMEOSTATIC IMBALANCE

Reduced Ca^{2+} blood levels *(hypocalcemia)* depress the heart. Conversely, above-normal levels *(hypercalcemia)* tightly couple the excitation-contraction mechanism and prolong the plateau phase of the action potential. These events dramatically increase heart irritability, which can lead to spastic heart contractions that permit the heart little rest. Many drugs used to treat heart conditions focus on calcium transport into cardiac cells.

High or low blood K^+ levels are particularly dangerous and arise in a number of clinical conditions. Excessive K^+ *(hyperkalemia)* interferes with depolarization by lowering the resting potential, and may lead to heart block and cardiac arrest. *Hypokalemia* is also life threatening, in that the heart beats feebly and arrhythmically.

Other Factors Although less important than neural factors, age, gender, exercise, and body temperature also influence HR. Resting heart rate is fastest in the fetus (140–160 beats/min) and gradually declines throughout life. Average heart rate is faster in females (72–80 beats/min) than in males (64–72 beats/min).

Exercise raises HR by acting through the sympathetic nervous system (Figure 18.23). Exercise also increases systemic blood pressure and routes more blood to the working muscles. However, resting HR in the physically fit tends to be substantially lower than in those who are out of condition, and in trained athletes it may be as slow as 40 beats/min. This apparent paradox is explained below.

Heat increases HR by enhancing the metabolic rate of cardiac cells. This explains the rapid, pounding heartbeat you feel when you have a high fever and also accounts, in part, for the effect of exercise on HR (remember, working muscles generate heat). Cold directly decreases heart rate.

18

HOMEOSTATIC IMBALANCE

Although HR varies with changes in activity, marked and persistent rate changes usually signal cardiovascular disease. **Tachycardia** (take-kar'de-ah; "heart hurry") is an abnormally fast heart rate (more than 100 beats/min) that may result from elevated body temperature, stress, certain drugs, or heart disease. Because tachycardia occasionally promotes fibrillation, persistent tachycardia is considered pathological.

Bradycardia (brade-kar'de-ah; *brady* = slow) is a heart rate slower than 60 beats/min. It may result from low body temperature, certain drugs, or parasympathetic nervous activation. It is a known, and desirable, consequence of endurance training. As physical and cardiovascular conditioning increases, the heart hypertrophies and SV increases; thus, resting heart rate can be lower and still provide the same cardiac output. However, persistent bradycardia in poorly conditioned people may result in grossly inadequate blood circulation to body tissues, and bradycardia is often a warning of brain edema after head trauma.

Homeostatic Imbalance of Cardiac Output

The heart's pumping action ordinarily maintains a balance between cardiac output and venous return. Were this not so, a dangerous damming up of blood (blood congestion) would occur in the veins returning blood to the heart.

When the pumping efficiency (CO) of the heart is so low that blood circulation is inadequate to meet tissue needs, the heart is said to be in **congestive heart failure (CHF).** This progressively worsening condition reflects weakening of the myocardium by various conditions which damage it in different ways. Let's take a look.

1. Coronary atherosclerosis. This condition, essentially a clogging of the coronary vessels with fatty buildup, impairs blood and oxygen delivery to the cardiac cells. The heart becomes increasingly hypoxic and begins to contract ineffectively.

2. Persistent high blood pressure. Normally, pressure in the aorta during diastole is 80 mm Hg, and the left ventricle exerts only slightly over that amount of force to eject blood from its chamber. When aortic diastolic blood pressure rises to 90 mm Hg or more, the myocardium must exert more force to open the aortic valve and pump out the same amount of blood. If this situation of enhanced afterload becomes chronic, the ESV rises and the myocardium hypertrophies. Eventually, the stress takes its toll and the myocardium becomes progressively weaker.

3. Multiple myocardial infarcts. A succession of MIs depresses pumping efficiency because the dead heart cells are replaced by noncontractile fibrous (scar) tissue.

4. Dilated cardiomyopathy (DCM) (kar"de-o-my-ah'path-e). The cause of this condition, in which the ventricles stretch and become flabby and the myocardium deteriorates, is often unknown. Drug toxicity (alcohol, cocaine, excess catecholamines, chemotherapeutic agents), hyperthyroidism, and inflammation of the heart following an infection are implicated in some cases. The heart's attempts to work harder result in increasing levels of Ca^{2+} in the cardiac cells. The Ca^{2+} activates calcineurin, a calcium-sensitive enzyme that initiates a cascade which switches on genes that cause heart enlargement. Because ventricular contractility is

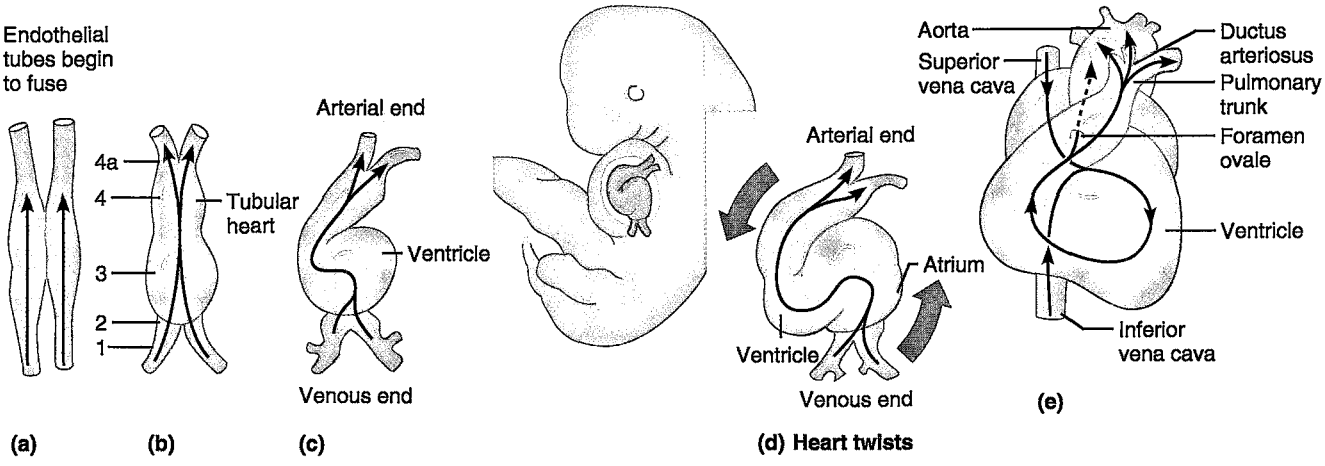

FIGURE 18.24 **Development of the human heart during week 4.** Ventral view, with the cranial direction toward the top of the figures. Arrows show the direction of blood flow. **(a)** Around day 21. **(b)** Day 22: 1 is the sinus venosus; 2, the atrium; 3, the ventricle; 4, the bulbus cordis; and 4a, the truncus arteriosus. **(c)** Day 23. **(d)** Day 24. **(e)** Day 28.

impaired, CO is poor and the condition progressively worsens.

Because the heart is a double pump, each side can initially fail independently of the other. If the left side fails, **pulmonary congestion** occurs. The right side continues to propel blood to the lungs, but the left side does not adequately eject the returning blood into the systemic circulation. Blood vessels in the lungs become engorged with blood, the pressure in them increases, and fluid leaks from the circulation into the lung tissue, causing pulmonary edema. If the congestion is untreated, the person suffocates.

If the right side of the heart fails, **peripheral congestion** occurs. Blood stagnates in body organs, and pooled fluids in the tissue spaces impair the ability of body cells to obtain adequate amounts of nutrients and oxygen and to rid themselves of wastes. The resulting edema is most noticeable in the extremities (feet, ankles, and fingers).

Failure of one side of the heart puts a greater strain on the other side, and ultimately the whole heart fails. A seriously weakened, or *decompensated,* heart is irreparable. Treatment is directed primarily toward (1) removing the excess leaked fluid with *diuretics* (drugs that increase excretion of Na^+ and water by the kidneys), (2) reducing afterload with drugs that drive down blood pressure, and (3) conserving heart energy with digitalis derivatives (which reduce HR). However, heart transplants and other surgical or mechanical remedies to replace damaged heart muscle are providing additional hope for some cardiac patients (see *A Closer Look* on pp. 706–707).

Developmental Aspects of the Heart

The human heart, derived from mesoderm and guided by powerful signaling molecules, begins as two simple endothelial tubes that quickly fuse to form a single chamber or heart tube that is busily pumping blood by the 23rd day of gestation (Figure 18.24). One or two days later, the tube develops four slightly bulged areas that represent the earliest heart chambers. From tail to head, following the direction of blood flow, the four chambers developed by day 25 are the following:

1. **Sinus venosus** (ven-o'sus). This chamber initially receives all the venous blood of the embryo. It will become the smooth-walled part of the right atrium and the coronary sinus. It also gives rise to the sinoatrial node, which takes the "baton" and sets heart rate early in embryonic development.
2. **Atrium.** This embryonic chamber eventually becomes the pectinate muscle-ridged parts of the atria.
3. **Ventricle.** The strongest pumping chamber of the early heart, the ventricle gives rise to the *left* ventricle.
4. **Bulbus cordis.** This chamber, plus its cranial extension, the *truncus arteriosus,* give rise to the pulmonary trunk, the first part of the aorta, and most of the *right* ventricle.

During the next three weeks, the heart "tube" exhibits dramatic contortions as it undergoes rightward looping, and major structural changes convert it into a four-chambered organ capable of acting as a double pump—all without missing a beat! The ventricle moves caudally and the atrium cranially, assuming their adult positions. The heart divides into

A CLOSER LOOK

From "Oh, What a Beautiful Morning" to Heart Boosters, Retreads, and Replacements

Getting up can be hazardous to your health! Even if you are a morning person, your risk of dropping dead from a heart attack is twice as high the first two hours after you climb out of bed as at any other time of the day or night. Plasma levels of stress hormones (epinephrine and others) increase right after you arise, and this makes your platelets stickier.

Some heart attacks strike like a lightning bolt with sudden, crushing chest pain. Others, particularly in women, start more subtly with shortness of breath, nausea, cold sweat, or vague discomfort in the chest, shoulder, jaw, or arm. Several million Americans will suffer a heart attack this year. Perhaps one-third of them will die almost immediately; half will be dead within the year.

But exactly what is a heart attack? Basically, it is an interruption of oxygen delivery to part of the myocardium. This is usually caused by blockage of a coronary artery by a thrombus or embolus, or occasionally by irregular and unexplainable spasms of the coronary vessels. Atherosclerosis of the coronary arteries, known as coronary artery disease (CAD), creates locations where clots can form and block the artery.

At the cellular level, oxygen deprivation, if it lasts long enough, leads to a myocardial infarction (MI), a situation in which heart muscle dies and is (eventually) replaced by scar tissue. Although it was once presumed that the lack of oxygen itself injured the myocardial cells, this is apparently not so. The trouble starts when the ischemic area is reperfused with blood, and lymphocytes and other inflammatory cells congregate in the area. These "immigrants" release cytokines (signaling chemicals) that prod macrophages and neutrophils to release a deluge of free radicals, including superoxide. These toxic substances depress cardiac contractility ("stunned myocardium"), and also appear to cause most of the local tissue damage.

If the heart is not "tipped" into fibrillation, the patient generally survives unless damage to the myocardium is massive. Heart attack victims lucky enough to reach the hospital quickly are routinely treated with tPA or other clot-dissolving drugs, which stop many heart attacks in progress and help prevent loss of viable heart muscle.

The greater the damage to the heart, the less efficiently it pumps blood and the more likely it is that the patient begins a downward spiral toward congestive heart failure and death. So, how do we deal with a damaged heart? Our first line of treatment is drug therapy. The drug strategies for patients in congestive heart failure (p. 705) are useful here. Two classes of blood pressure–lowering drugs, beta-blockers and ACE inhibitors, are particularly important. When norepinephrine (or epinephrine) attaches to beta receptors, heart rate and force increase. Because beta-blockers inhibit this activation by the sympathetic nervous system and successfully prevent increases in blood pressure, they reduce the strain on the heart. ACE (angiotensin-converting enzyme) inhibitors lower blood pressure by preventing the formation of angiotensin II. However, ACE also has a second function—it breaks down chemicals called kinins, particularly bradykinin. Kinins protect the heart from ischemia, and blocking their breakdown improves heart function.

In the future, therapies might be aimed at coaxing the body to repair itself. Although for years the dogma has been that heart muscle does not regenerate, it is now clear that there is some mitotic activity in cardiac muscle throughout life, and limited regeneration of cardiac muscle occurs after an MI. However, this is not enough to recover from "the big one." Since the heart lacks the ability to heal itself, researchers are trying to implant stem cells derived from the patient's own blood or bone marrow into the heart in the hope that they will differentiate into new heart muscle. Clinical trials have shown some improved heart function following stem cell infusion after MI. What's not clear is whether the injected stem cells turn into myocytes or the improvement is due to some other action of the injected cells, or to the procedure itself.

Currently, the gold standard of treatment for a dying heart is heart transplant surgery. Even so, this procedure is riddled with problems. First, an acceptable tissue match must be found. Then, after complicated and traumatic surgery, the heart recipient must take drugs that suppress the immune system to thwart rejection of the donor heart. After about a year of survival, a new type of rejection may develop, in which antibodies attack the inner layer of the coronary vessels, possibly leading to a fatal MI. This rejection does not respond to any known immunosuppressive treatment. Despite the complications, heart transplants are becoming more and more successful and it is now clear that transplanted hearts incorporate muscle and blood vessel cells of the recipient. Over

18

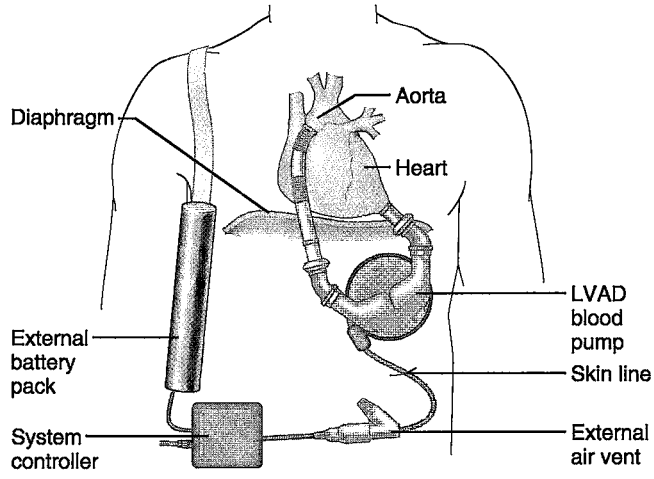
its four definitive chambers (via a number of stages), the midline septum forms, and the bulbus cordis splits into the pulmonary trunk and ascending aorta. After the second month, few changes other than growth occur until birth.

The interatrial septum of the fetal heart is incomplete. The **foramen ovale** (literally, "oval door") connects the two atria and allows blood entering the right heart to bypass the pulmonary circuit and the collapsed, nonfunctional fetal lungs. Another lung bypass, the **ductus arteriosus,** exists between the pulmonary trunk and the aorta. At or shortly after birth, these shunts close, completing the separation between the right and left sides of the heart. In the

three-quarters of transplant patients now survive for 2 years, and half of them survive for more than 12 years.

The severe shortage of donor hearts contrasts with the great demand for them (fully one-third of patients awaiting a heart transplant in North America die without receiving one). This unmet demand has created tremendous pressure to develop alternative treatment procedures:

- **Left ventricular reconstruction.** Small, well-defined areas of damaged heart tissue can be surgically removed from an enlarged left ventricle. The heart, restored to its proper size, can beat more efficiently and with reduced tension on the ventricular wall. Once regarded as a last resort, this treatment is best performed before excessive stretching of the myocardium has done permanent damage.
- **Left ventricular assist devices (LVADs).** These mechanical pumps are implanted into the abdomen, connected to the left ventricle through a hole in the diaphragm, and powered by an external battery carried in a backpack or shoulder holster (see illustration). LVADs take over part of the workload from an ailing heart, giving it the opportunity for rest and recovery. They can be used either to "bridge" a patient waiting for transplant or as a permanently implanted device in those ineligible for transplant. Compared with a 25% survival after one year for patients receiving standard medical therapy alone, about 50% of patients with LVADs survive. The primary problem with these devices is infection around the power tube that passes through the skin. Other problems include device failure, and the tendency for clots to form within the pump.
- **Artificial hearts.** Despite over 40 years of intense development, artificial hearts are not yet ready for prime time. They are so bulky that they are only suitable for large males, and their recipients are susceptible to strokes, infections, and kidney failure. Because of these disappointing results, U.S. regulations presently allow use of an artificial heart only as a lifesaving stopgap measure while the patient awaits a permanent organ transplant.



The HeartMate LVAD

Another surgical treatment is available for a slightly different population of patients with CAD. These are patients who, in spite of conventional medical (and often surgical) treatment, continue to have angina (a sharp squeezing chest pain) on exertion. Often, they are not good candidates for other, more demanding surgical techniques. *Transmyocardial laser revascularization (TMR)* uses a laser to zap 15 to 20 small channels into the wall of the left ventricular myocardium. The procedure seems to work by stimulating the coronary vessels to send more branches into the myocardium. Clinical studies indicate that TMR reduces chest pain and improves blood flow in over 40% of those treated.

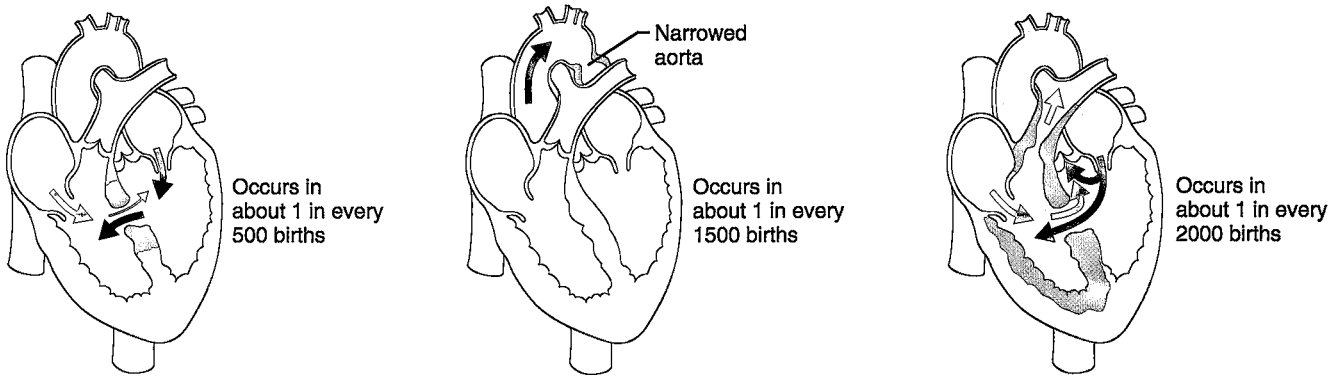
A noninvasive treatment for CAD used in China for the past 20 years, *external enhanced counterpulsation (EECP),* is now being adopted in the West. EECP consists of 35 one-hour sessions. The patient lies down while wearing three inflatable pressure cuffs on the upper and lower thighs and calves. The cuffs inflate sequentially during diastole, starting with those on the calves and moving upward, then deflate during systole. These rhythmic waves of compression push blood toward the heart, increasing cardiac output and coronary perfusion while also relieving cardiac workload. Most patients who finish the seven-week regimen report more energy and less angina. Doctors are not sure why EECP helps; it may stimulate the formation of new blood vessels, the release of growth factors that enhance blood vessel function, or the production of the vasodilator nitric oxide.

Even with all this advanced medical technology, your best bet is still to prevent CAD in the first place by decreasing the risk factors, many of which are related to lifestyle: excess weight, high cholesterol and saturated fat in the diet, smoking, and excess stress. In addition, a diet rich in antioxidant-containing fruits and vegetables is recommended. Some studies link tea drinking—the more the better—with lower cardiovascular mortality. So take care of yourself, relax with a nice cup of tea (chock-full of antioxidants), and let the stress of your anatomy and physiology course wash away! ■

adult heart, the position of the foramen ovale is revealed by the fossa ovalis, and the **ligamentum arteriosum** is the fibrous remnant of the ductus arteriosus (see Figure 18.4b). A more complete description of the fetal and newborn circulation is given in Chapter 28 (see Figure 28.13).

HOMEOSTATIC IMBALANCE

Building a perfect heart is difficult. Each year about 30,000 infants are born in the U.S. with one or more of 30 different **congenital heart defects,** making them the most common of all birth defects. Most congenital heart problems are traceable to environmental



(a) Ventricular septal defect. The superior part of the interventricular septum fails to form; thus, blood mixes between the two ventricles, but because the left ventricle is stronger, more blood is shunted from left to right.

(b) Coarctation of the aorta. A part of the aorta is narrowed, increasing the workload on the left ventricle.

(c) Tetralogy of Fallot. Multiple defects (*tetra* = four): Pulmonary trunk too narrow and pulmonary valve stenosed, resulting in a hypertrophied right ventricle; ventricular septal defect; aorta opens from both ventricles; wall of right ventricle thickened from overwork.

FIGURE 18.25 **Three examples of congenital heart defects.** Purple indicates heart areas where the defects are present.

influences, such as maternal infection or drug intake during month 2 when the major events of heart formation occur.

The most prevalent abnormalities produce two basic kinds of disorders in the newborn. They either (1) lead to mixing of oxygen-poor systemic blood with oxygenated pulmonary blood (so that inadequately oxygenated blood reaches the body tissues) or (2) involve narrowed valves or vessels that greatly increase the workload on the heart. Examples of the first type of defect are *septal defects* (Figure 18.25a) and *patent ductus arteriosus,* in which the connection between the aorta and pulmonary trunk remains open. *Coarctation of the aorta* (Figure 18.25b) is an example of the second type of problem. *Tetralogy of Fallot* (te-tral'o-je ov fal-o'), a serious condition in which the baby becomes cyanotic within minutes of birth, encompasses both types of disorders (Figure 18.25c). Modern surgical techniques can correct most of these heart defects.

In the absence of congenital heart problems, the heart functions admirably throughout a long lifetime for most people. Homeostatic mechanisms are normally so efficient that people rarely notice when the heart is working harder. In people who exercise regularly and vigorously, the heart gradually adapts to the increased demand by increasing in size and becoming a more efficient and more powerful pump. Consequently, SV increases and resting heart rate declines. Aerobic exercise also helps to clear fatty deposits from blood vessel walls throughout the body, thus retarding atherosclerosis and coronary heart disease. Barring some chronic illnesses, this beneficial cardiac response to exercise persists into ripe old age.

The key word on benefiting from exercise is *regularity.* Regular exercise gradually enhances the myocardial endurance and strength. For example, 30 minutes a day of moderately vigorous exercise (brisk walking, biking, or yard work) offers significant health benefits to most adults. However, intermittent vigorous exercise, enjoyed by weekend athletes, may push an unconditioned heart beyond its ability to respond to the unexpected demands and bring on a myocardial infarct.

Because of the incredible amount of work the heart does over the course of a lifetime, certain structural changes are inevitable. These age-related changes affecting the heart include

1. Sclerosis and thickening of valve flaps. This occurs particularly where the stress of blood flow is greatest (mitral valve). Thus, heart murmurs are more common in elderly people.

2. Decline in cardiac reserve. Although the passing years seem to cause few changes in resting heart rate, the aged heart is less able to respond to both sudden and prolonged stressors that demand increased output. Sympathetic control of the heart becomes less efficient (in part because the amount of cAMP produced on stimulation decreases with age). HR gradually becomes more variable and there is a decline in maximum HR. These changes are less of a problem in physically active seniors.

3. Fibrosis of cardiac muscle. As one ages, more and more cardiac cells die and are replaced with

fibrous tissue. As a result, the heart stiffens and its filling in preparation for the next heartbeat is less efficient, resulting in reduced stroke volume. Additionally, the nodes of the heart's conduction system sometimes become fibrosed (scarred) with age, which increases the incidence of arrhythmias and other conduction problems.

4. Atherosclerosis. Although the insidious progress of atherosclerosis begins in childhood, it is accelerated by inactivity, smoking, and stress. The most serious consequences to the heart are hypertensive heart disease and coronary artery occlusion, both of which increase the risk of heart attack and stroke. Although the aging process itself leads to changes in blood vessel walls that result in atherosclerosis, many investigators feel that diet, not aging, is the single most important contributor to cardiovascular disease. There is some agreement that risk is lowered if people consume less animal fat, cholesterol, and salt.

■ ■ ■

The heart is an exquisitely engineered double pump that operates with precision to propel blood into the large arteries leaving its chambers. However, continuous circulation of blood also depends critically on the pressure dynamics in the blood vessels. Chapter 19 considers the structure and function of these vessels and relates this information to the work of the heart to provide a complete picture of cardiovascular functioning.

Related Clinical Terms

Asystole (a-sis'to-le) Situation in which the heart fails to contract.

Cardiac catheterization Diagnostic procedure involving passage of a fine catheter (tubing) through a blood vessel into the heart; blood samples are withdrawn, allowing oxygen content, blood flow, and pressures within the heart to be measured. Findings help to detect valve problems, heart deformities, and other heart malfunctions.

Commotio cordis ("concussion of the heart") Situation in which a relatively mild blow to the chest causes heart failure and sudden death because it occurs during a vulnerable interval (2 ms) when the heart is repolarizing. Explains those rare instances when youngsters drop dead on the playing field after being hit in the chest by a ball.

Cor pulmonale (kor pul-mun-nă'le; *cor* = heart, *pulmo* = lung) A condition of right-sided heart failure resulting from elevated blood pressure in the pulmonary circuit (pulmonary hypertension). Acute cases may develop suddenly due to a pulmonary embolism; chronic cases are usually associated with chronic lung disorders such as emphysema.

Endocarditis (en"do-kar-di'tis) Inflammation of the endocardium, usually confined to the endocardium of the heart valves. Endocarditis often results from infection by bacteria that have entered the bloodstream but may result from fungal infection or an autoimmune response. Drug addicts may develop endocarditis by injecting themselves with contaminated needles.

Heart palpitation A heartbeat that is unusually strong, fast, or irregular so that the person becomes aware of it; may be caused by certain drugs, emotional pressures ("nervous heart"), or heart disorders.

Hypertrophic cardiomyopathy (HCM) The leading cause of sudden death in young athletes, this condition, which is usually inherited, causes the cardiac muscle cells to enlarge, thickening the heart wall. The heart pumps strongly but doesn't relax well during diastole when the heart is filling.

Mitral valve prolapse Valve disorder affecting up to 1% of the population; most often seen in young women. It appears to have a genetic basis resulting in abnormal chordae tendineae or a malfunction of the papillary muscles; one or more of the flaps of the mitral valve become incompetent and billow into the left atrium during ventricular systole, allowing blood regurgitation. Occasionally requires valve replacement surgery.

Myocarditis (mi"o-kar-di'tis; *myo* = muscle, *card* = heart, *itis* = inflammation) Inflammation of the cardiac muscle layer (myocardium) of the heart; sometimes follows an untreated streptococcal infection in children. May weaken the heart and impair its ability to act as an effective pump.

Paroxysmal atrial tachycardia (PAT) Bursts of atrial contractions with little pause between them.

Ventricular tachycardia (VT or V-tac) Rapid ventricular contractions that are not coordinated with atrial activity.

Chapter Summary

Media study tools that could provide you additional help in reviewing specific key topics of Chapter 18 are referenced below.
IP = *InterActive Physiology*

Heart Anatomy (pp. 678–689)

Size, Location, and Orientation (p. 678)

1. The human heart, about the size of a clenched fist, is located obliquely within the mediastinum of the thorax.

Coverings of the Heart (p. 678)

2. The heart is enclosed within a double sac made up of the outer fibrous pericardium and the inner serous pericardium (parietal and visceral layers). The pericardial cavity between the serous layers contains lubricating serous fluid.

Layers of the Heart Wall (pp. 678–680)

3. Layers of the heart wall, from the interior out, are the endocardium, the myocardium (reinforced by a fibrous skeleton), and the epicardium (visceral layer of the serous pericardium).

Chambers and Associated Great Vessels (pp. 680–684)

4. The heart has two superior atria and two inferior ventricles. Functionally, the heart is a double pump.

5. Entering the right atrium are the superior vena cava, the inferior vena cava, and the coronary sinus. Four pulmonary veins enter the left atrium.

6. The right ventricle discharges blood into the pulmonary trunk; the left ventricle pumps blood into the aorta.

Pathway of Blood Through the Heart (pp. 684–685)

7. The right heart is the pulmonary circuit pump. Oxygen-poor systemic blood enters the right atrium, passes into the right ventricle, through the pulmonary trunk to the lungs, and back to the left atrium via the pulmonary veins.

8. The left heart is the systemic circuit pump. Oxygen-laden blood entering the left atrium from the lungs flows into the left ventricle and then into the aorta, which provides the functional supply of all body organs. Systemic veins return the oxygen-depleted blood to the right atrium.

Coronary Circulation (pp. 685–686)

9. The right and left coronary arteries branch from the aorta and via their main branches (anterior and posterior interventricular, marginal, and circumflex arteries) supply the heart itself. Venous blood, collected by the cardiac veins (great, middle, and small), is emptied into the coronary sinus.

10. Blood delivery to the myocardium occurs during heart relaxation.

Heart Valves (pp. 686–689)

11. The atrioventricular valves (tricuspid and mitral) prevent backflow into the atria when the ventricles are contracting; the pulmonary and aortic valves (semilunar valves) prevent backflow into the ventricles when the ventricles are relaxing.

Cardiovascular System; Topic: Anatomy Review: The Heart, pp. 1–8.

Properties of Cardiac Muscle Fibers (pp. 689–692)

Microscopic Anatomy (pp. 689–690)

1. Cardiac muscle cells are branching, striated, generally uninucleate cells. They contain myofibrils consisting of typical sarcomeres.

2. Adjacent cardiac cells are connected by intercalated discs containing desmosomes and gap junctions. The myocardium behaves as a functional syncytium because of electrical coupling provided by gap junctions.

Mechanism and Events of Contraction (pp. 690–692)

3. As in skeletal muscle, the membrane depolarization of contractile myocytes causes opening of sodium channels and sodium entry, which is responsible for the rising phase of the action potential curve. Depolarization also opens slow Ca^{2+} channels; Ca^{2+} entry prolongs the period of depolarization (creates the plateau). The action potential is coupled to sliding of the myofilaments by Ca^{2+} released by the SR and entering from the extracellular space. Compared to skeletal muscle, cardiac muscle has a prolonged refractory period that prevents tetany.

Cardiovascular System; Topic: Cardiac Action Potential, pp. 11–18.

Energy Requirements (p. 692)

4. Cardiac muscle has abundant mitochondria and depends almost entirely on aerobic respiration to form ATP.

Heart Physiology (pp. 692–705)

Electrical Events (pp. 692–697)

1. Certain noncontractile cardiac muscle cells exhibit automaticity and rhythmicity and can independently initiate action potentials. Such cells have an unstable resting potential called a pacemaker potential that gradually depolarizes, drifting toward threshold for firing. These cells compose the intrinsic conduction system of the heart.

2. The conduction system of the heart consists of the SA and AV nodes, the AV bundle and bundle branches, and the Purkinje fibers. This system coordinates the depolarization of the heart and ensures that the heart beats as a unit. The SA node has the fastest rate of spontaneous depolarization and acts as the heart's pacemaker; it sets the sinus rhythm.

3. Defects in the intrinsic conduction system can cause arrhythmias, fibrillation, and heart block.

4. The heart is innervated by the autonomic nervous system. Cardiac centers in the medulla include the cardioacceleratory center, which projects to the T_1–T_5 region of the spinal cord, which in turn projects to the cervical and upper thoracic sympathetic trunk. Postganglionic fibers innervate the SA and AV nodes and the cardiac muscle fibers. The cardioinhibitory center exerts its influence via the parasympathetic vagus nerves (X), which project to the heart wall. Most parasympathetic fibers serve the SA and AV nodes.

5. An electrocardiogram is a graphic representation of the cardiac conduction cycle. The P wave reflects atrial depolarization. The QRS complex indicates ventricular depolarization; the T wave represents ventricular repolarization.

Cardiovascular System; Topic: Intrinsic Conduction System, pp. 1–7; Topic: Cardiac Action Potential, pp. 1–10.

Heart Sounds (pp. 697–698)

6. Normal heart sounds arise chiefly from turbulent blood flow during the closing of heart valves. Abnormal heart sounds, called murmurs, usually reflect valve problems.

Mechanical Events: The Cardiac Cycle (pp. 698–700)

7. A cardiac cycle consists of the events occurring during one heartbeat. During mid-to-late diastole, the ventricles fill and the atria contract. Ventricular systole consists of the isovolumetric contraction phase and the ventricular ejection phase. During early diastole, the ventricles are relaxed and are closed chambers until increasing atrial pressure forces the AV valves open and the cycle begins again. At a normal heart rate of 75 beats/min, a cardiac cycle lasts 0.8 s.

8. Pressure changes promote blood flow and valve opening and closing.

Cardiovascular System; Topic: Cardiac Cycle, pp. 1–19.

Cardiac Output (pp. 700–705)

9. Cardiac output, typically 5 L/min, is the amount of blood pumped out by each ventricle in 1 minute. Stroke volume is the amount of blood pumped out by a ventricle with each contraction. Cardiac output = heart rate × stroke volume.

10. Stroke volume depends to a large extent on the degree of stretch of cardiac muscle by venous return. Approximately 70 ml, it is the difference between end diastolic volume (EDV) and end systolic volume (ESV). Anything that influences heart rate or blood volume influences venous return, hence stroke volume.

11. Activation of the sympathetic nervous system increases heart rate and contractility; parasympathetic activation decreases heart rate but has little effect on contractility. Ordinarily, the heart exhibits vagal tone.

12. Chemical regulation of the heart is effected by hormones (epinephrine and thyroxine) and ions (particularly potassium and calcium). Imbalances in ions severely impair heart activity.

13. Other factors influencing heart rate are age, sex, exercise, and body temperature.

14. Congestive heart failure occurs when the pumping ability of the heart is inadequate to provide normal circulation to meet body needs. Right heart failure leads to systemic edema; left heart failure results in pulmonary edema.

Cardiovascular System; Topic: Cardiac Output, pp. 1–10.

Developmental Aspects of the Heart (pp. 705–709)

1. The heart begins as a simple (mesodermal) tube that is pumping blood by the fourth week of gestation. The fetal heart has two lung bypasses: the foramen ovale and the ductus arteriosus.

2. Congenital heart defects are the most common of all birth defects. The most common of these disorders lead to inadequate oxygenation of blood or increase the workload of the heart.

3. Age-related changes include sclerosis and thickening of the valve flaps, declines in cardiac reserve, fibrosis of cardiac muscle, and atherosclerosis.

4. Risk factors for cardiac disease include dietary factors, excessive stress, cigarette smoking, and lack of exercise.

Review Questions

Multiple Choice/Matching

(Some questions have more than one correct answer. Select the best answer or answers from the choices given.)

1. When the semilunar valves are open, which of the following are occurring? (a) 2, 3, 5, 6, (b) 1, 2, 3, 7, (c) 1, 3, 5, 6, (d) 2, 4, 5, 7.

(1) coronary arteries fill
(2) AV valves are closed
(3) ventricles are in systole
(4) ventricles are in diastole
(5) blood enters aorta
(6) blood enters pulmonary arteries
(7) atria contract

2. The portion of the intrinsic conduction system located in the interventricular septum is the (a) AV node, (b) SA node, (c) AV bundle, (d) Purkinje fibers.

3. An ECG provides information about (a) cardiac output, (b) movement of the excitation wave across the heart, (c) coronary circulation, (d) valve impairment.

4. The sequence of contraction of the heart chambers is (a) random, (b) left chambers followed by right chambers, (c) both atria followed by both ventricles, (d) right atrium, right ventricle, left atrium, left ventricle.

5. The fact that the left ventricular wall is thicker than the right reveals that it (a) pumps a greater volume of blood, (b) pumps blood against greater resistance, (c) expands the thoracic cage, (d) pumps blood through a smaller valve.

6. The chordae tendineae (a) close the atrioventricular valves, (b) prevent the AV valve flaps from everting, (c) contract the papillary muscles, (d) open the semilunar valves.

7. In the heart, which of the following apply? (1) Action potentials are conducted from cell to cell across the myocardium via gap junctions, (2) the SA node sets the pace for the heart as a whole, (3) spontaneous depolarization of cardiac cells can occur in the absence of nerve stimulation, (4) cardiac muscle can continue to contract for long periods in the absence of oxygen. (a) all of the above, (b) 1, 3, 4, (c) 1, 2, 3, (d) 2, 3.

8. The activity of the heart depends on intrinsic properties of cardiac muscle and on neural factors. Thus, (a) vagus nerve stimulation of the heart reduces heart rate, (b) sympathetic nerve stimulation of the heart decreases time available for ventricular filling, (c) sympathetic stimulation of the heart increases its force of contraction, (d) all of the above.

9. Freshly oxygenated blood is first received by the (a) right atrium, (b) left atrium, (c) right ventricle, (d) left ventricle.

Short Answer Essay Questions

10. Describe the location and position of the heart in the body.

11. Describe the pericardium and distinguish between the fibrous and the serous pericardia relative to histological structure and location.

12. Trace one drop of blood from the time it enters the right atrium until it enters the left atrium. What is this circuit called?

13. (a) Describe how heart contraction and relaxation influence coronary blood flow. (b) Name the major branches of the coronary arteries, and note the heart regions served by each.

14. The refractory period of cardiac muscle is much longer than that of skeletal muscle. Why is this a desirable functional property?

15. (a) Name the elements of the intrinsic conduction system of the heart in order, beginning with the pacemaker. (b) What is the important function of this conduction system?

16. Draw a normal ECG pattern. Label and explain the significance of its deflection waves.

17. Define cardiac cycle, and follow the events of one cycle.

18. What is cardiac output, and how is it calculated?

19. Discuss how the Frank-Starling law of the heart helps to explain the influence of venous return on stroke volume.

20. (a) Describe the common function of the foramen ovale and the ductus arteriosus in a fetus. (b) What problems result if these shunts remain patent (open) after birth?

Critical Thinking and Clinical Application Questions

1. A gang member was stabbed in the chest during a street fight. He was cyanotic and unconscious from lack of blood delivery to the brain. The diagnosis was cardiac tamponade. What is cardiac tamponade and how does it cause the observed symptoms?

2. You have been called upon to demonstrate the technique for listening to valve sounds. (a) Explain where you would position your stethoscope to auscultate (1) the aortic valve of a patient with severe aortic valve incompetence and (2) a stenotic mitral valve. (b) During which period(s) would you hear these abnormal valve sounds most clearly? (During atrial diastole, ventricular systole, ventricular diastole, or atrial systole?) (c) What cues would you use to differentiate between an incompetent and a stenosed valve?

3. Florita Santos, a middle-aged woman, is admitted to the coronary care unit with a diagnosis of left ventricular failure resulting from a myocardial infarction. Her history indicated that she was aroused in the middle of the night by severe chest pain. Her skin is pale and cold, and moist sounds are heard over the lower regions of both lungs. Explain how failure of the left ventricle can cause these signs and symptoms.

4. Heather, a newborn baby, needs surgery because she was born with an aorta that arises from the right ventricle and a pulmonary trunk that issues from the left ventricle, a condition called transposition of the great vessels. What are the physiological consequences of this defect?

5. Gabriel, a heroin addict, feels tired, is weak and feverish, and has vague aches and pains. Terrified that he has AIDS, he goes to a doctor and is informed that he is suffering not from AIDS, but from a heart murmur accompanied by endocarditis. What is the most likely way that Gabriel contracted endocarditis?

6. As Cara worked at her dissection, she became frustrated that several of the structures she had to learn about had more than one common name. Provide another name for each of these structures: (a) atrioventricular groove, (b) tricuspid valve, (c) bicuspid valve (give two synonyms), and (d) atrioventricular bundle.

CHAPTER

The Cardiovascular System: Blood Vessels

PART 1: OVERVIEW OF BLOOD VESSEL STRUCTURE AND FUNCTION (pp. 714–723)

1. Describe the three layers that typically form the wall of a blood vessel, and state the function of each.
2. Define vasoconstriction and vasodilation.
3. Compare and contrast the structure and function of the three types of arteries.
4. Describe the structure and function of a capillary bed.
5. Describe the structure and function of veins, and explain how veins differ from arteries.

PART 2: PHYSIOLOGY OF CIRCULATION (pp. 723–742)

6. Define blood flow, blood pressure, and resistance, and explain the relationships between these factors.
7. List and explain the factors that influence blood pressure, and describe how blood pressure is regulated.
8. Define hypertension. Describe its manifestations and consequences.
9. Explain how blood flow is regulated in the body in general and in its specific organs.
10. Outline factors involved in capillary dynamics, and explain the significance of each.
11. Define circulatory shock. List several possible causes.

PART 3: CIRCULATORY PATHWAYS: BLOOD VESSELS OF THE BODY (pp. 742, 744–766)

12. Trace the pathway of blood through the pulmonary circuit, and state the importance of this special circulation.
13. Describe the general functions of the systemic circuit. Name and give the location of the major arteries and veins in the systemic circulation.
14. Describe the structure and special function of the hepatic portal system.

Developmental Aspects of Blood Vessels (p. 743)

15. Explain how blood vessels develop in the fetus.
16. Provide examples of changes that often occur in blood vessels as a person ages.

Although blood vessels are sometimes compared to a system of pipes within which the blood circulates, this analogy is only a starting point. Unlike rigid pipes, blood vessels are dynamic structures that pulsate, constrict, relax, and even proliferate. This chapter examines the structure and function of these important circulatory passageways.

The **blood vessels** of the body form a closed delivery system that begins and ends at the heart. The idea that blood circulates in the body dates back to the 1620s with the inspired experiments of William Harvey, an English physician. Prior to that time, it was thought, as proposed by the ancient Greek physician Galen, that blood moved through the body like an ocean tide, first moving out from the heart and then ebbing back in the same vessels.

PART 1: OVERVIEW OF BLOOD VESSEL STRUCTURE AND FUNCTION

The three major types of blood vessels are *arteries*, *capillaries*, and *veins*. As the heart contracts, it forces blood into the large arteries leaving the ventricles. The blood then moves into successively smaller arteries, finally reaching their smallest branches, the *arterioles* (ar-te're-ōlz; "little arteries"), which feed into the capillary beds of body organs and tissues. Blood drains from the capillaries into *venules* (ven'ūlz), the smallest veins, and then on into larger and larger veins that merge to form the large veins that ultimately empty into the heart. Altogether, the blood vessels in the adult human stretch for about 100,000 km (60,000 miles) through the internal body landscape!

Because **arteries** carry blood *away from* the heart, they are said to "branch," "diverge," or "fork" as they form smaller and smaller divisions. **Veins,** by contrast, carry blood *toward* the heart and so are said to "join," "merge," and "converge" into the successively larger vessels approaching the heart. In the systemic circulation, arteries always carry oxygenated blood and veins always carry oxygen-poor blood. The opposite is true in the pulmonary circulation, where the arteries, still defined as the vessels leading away from the heart, carry oxygen-poor blood to the lungs, and the veins carry oxygen-rich blood from the lungs to the heart. The special umbilical vessels of a fetus also differ in the roles of veins and arteries.

Of all the blood vessels, only the capillaries have intimate contact with tissue cells and directly serve cellular needs. Exchanges between the blood and tissue cells occur primarily through the gossamer-thin capillary walls.

Structure of Blood Vessel Walls

The walls of all blood vessels, except the very smallest, have three distinct layers, or *tunics* ("coverings"), that surround a central blood-containing space, the vessel **lumen** (Figure 19.1).

The innermost tunic is the **tunica intima** (in'tĭ-mah; formerly called the *tunica interna*). The name is easy to remember once you know that this tunic is in *intimate* contact with the blood in the lumen. This tunic contains the *endothelium*, the simple squamous epithelium that lines the lumen of all vessels. The endothelium is a continuation of the endocardial lining of the heart, and its flat cells fit closely together, forming a slick surface that minimizes friction as blood moves through the lumen. In vessels larger than 1 mm in diameter, a *subendothelial layer*, consisting of a basement membrane and loose connective tissue, supports the endothelium.

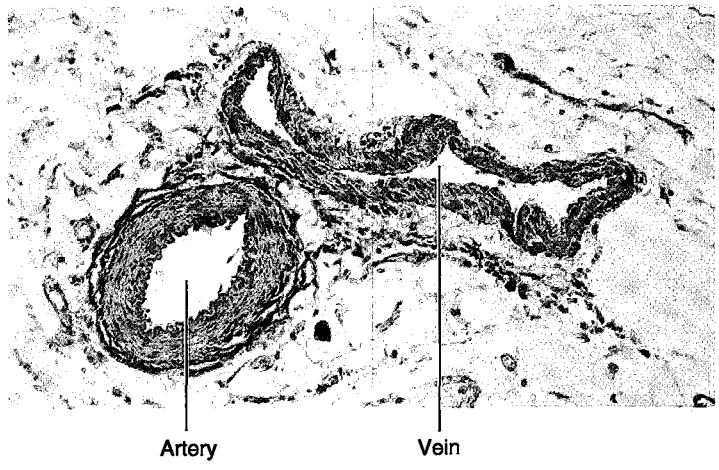
The middle tunic, the **tunica media** (me'de-ah), is mostly circularly arranged smooth muscle cells and sheets of elastin. The activity of the smooth muscle is regulated by sympathetic *vasomotor nerve fibers* of the autonomic nervous system and a whole battery of chemicals. Depending on the body's needs at any given moment, either **vasoconstriction** (reduction in lumen diameter as the smooth muscle contracts) or **vasodilation** (increase in lumen diameter as the smooth muscle relaxes) can be effected. Because small changes in vessel diameter greatly influence blood flow and blood pressure, the activities of the tunica media are critical in regulating circulatory dynamics. Generally, the tunica media is the bulkiest layer in arteries, which bear the chief responsibility for maintaining blood pressure and continuous blood circulation.

The outermost layer of a blood vessel wall, the **tunica externa** (formerly called the *tunica adventitia*; ad"ven-tish'e-ah; "coming from outside"), is composed largely of loosely woven collagen fibers that protect and reinforce the vessel, and anchor it to surrounding structures. The tunica externa is infiltrated with nerve fibers, lymphatic vessels, and, in larger veins, a network of elastin fibers. In larger vessels, the tunica externa contains a system of tiny blood vessels, the **vasa vasorum** (va'sah va-sor'um)—literally, "vessels of the vessels" that nourish the more external tissues of the blood vessel wall. The innermost or luminal portion of the vessel obtains its nutrients directly from blood in the lumen.

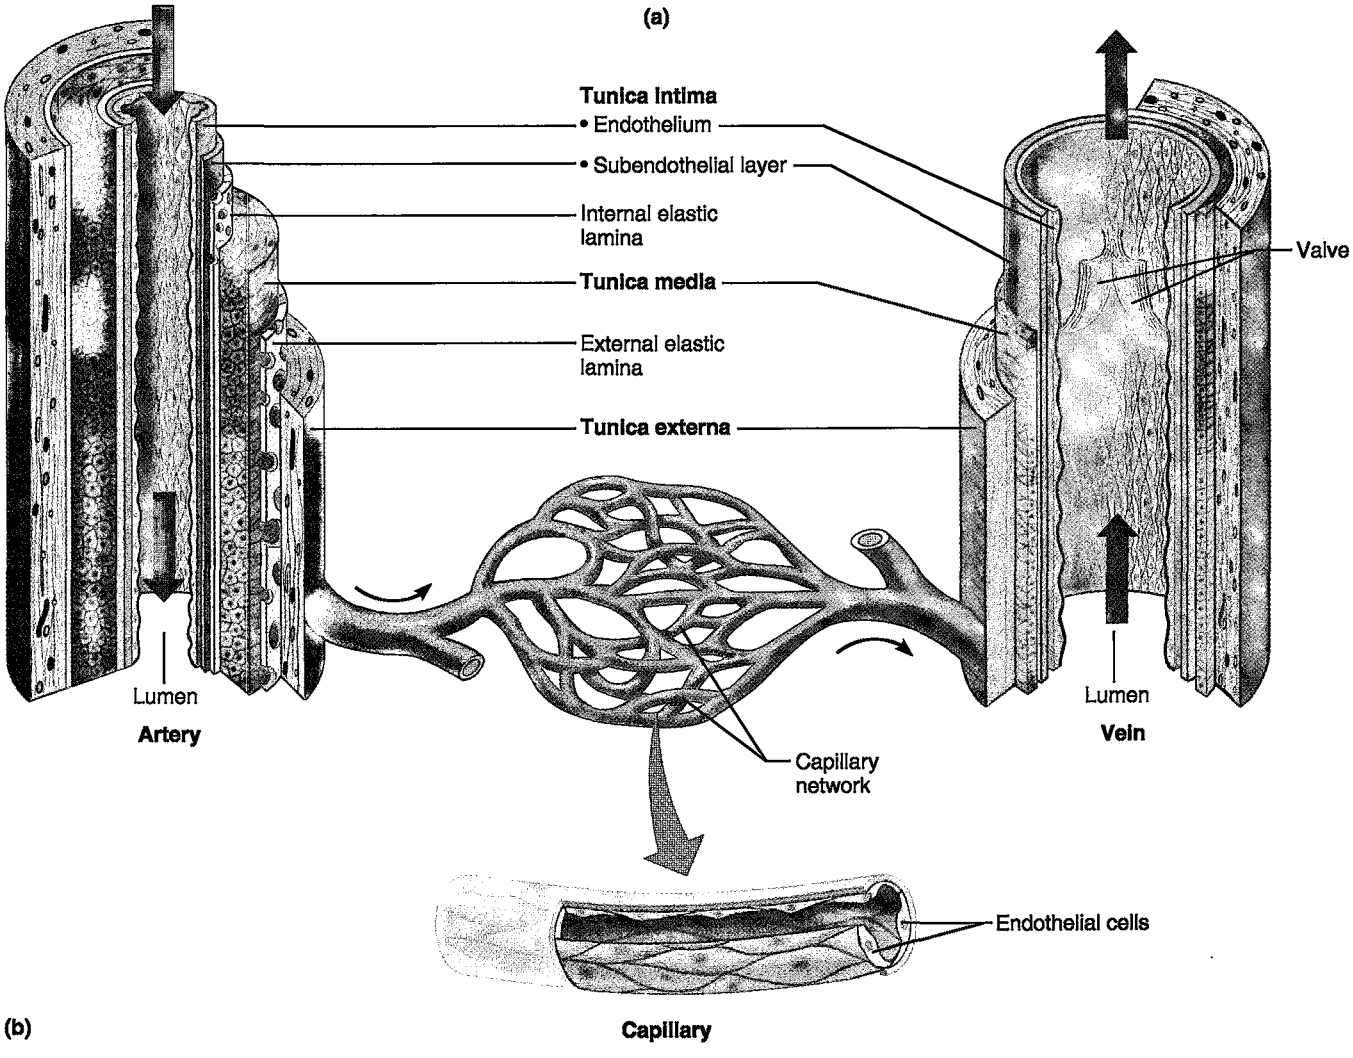
The three vessel types vary in length, diameter, relative wall thickness, and tissue makeup (Table 19.1). The relationship of the various blood vascular channels to one another and to vessels of the lymphatic system (which recovers fluids that leak from the circulation) is summarized in Figure 19.2a.

Q *What is the functional value of having capillaries that consist of a single layer of squamous cells underlain by sparse connective tissue?*

FIGURE 19.1 **Generalized structure of arteries, veins, and capillaries. (a)** Light photomicrograph of a muscular artery and the corresponding vein in cross section (30×). **(b)** The walls of arteries and veins are composed of the tunica intima (endothelium underlain by loose connective tissue), the tunica media (smooth muscle cells and elastic fibers), and the tunica externa (largely collagen fibers). Capillaries are composed of only the endothelium and a basement membrane. The tunica media is thick in arteries and thin in veins, while the tunica externa is thin in arteries and relatively thicker in veins. (See *A Brief Atlas of the Human Body*, Plate 38.)



(a)



(b) Capillary

A Capillaries are the exchange sites. The thinner their walls (the barrier to exchanges), the more rapid and efficient the exchange process.

19

TABLE 19.1 Summary of Blood Vessel Anatomy

VESSEL TYPE/ ILLUSTRATION*	AVERAGE LUMEN DIAMETER (D) AND WALL THICKNESS (T)	RELATIVE TISSUE MAKEUP (Endothelium, Elastic Tissues, Smooth Muscles, Fibrous (Collagenous) Tissues)
 Elastic artery	D : 1.5 cm T : 1.0 mm	
 Muscular artery	D : 6.0 mm T : 1.0 mm	
 Arteriole	D : 37.0 μm T : 6.0 μm	
Capillary	D : 9.0 μm T : 0.5 μm	
 Venule	D : 20.0 μm T : 1.0 μm	
 Vein	D : 5.0 mm T : 0.5 mm	

*Size relationships are not proportional. Smaller vessels are drawn relatively larger so detail can be seen. See column 2 for actual dimensions.

Arterial System

In terms of relative size and function, arteries can be divided into three groups—elastic arteries, muscular arteries, and arterioles.

Elastic (Conducting) Arteries

Elastic arteries are the thick-walled arteries near the heart—the aorta and its major branches. These arteries are the largest in diameter, ranging from 2.5 cm to 1 cm, and the most elastic (Table 19.1). Because their large lumens make them low-resistance pathways that conduct blood from the heart to medium-sized arteries, elastic arteries are sometimes referred to as **conducting arteries** (Figure 19.2a). They contain more elastin than any other vessel type. It is present in all three tunics, but the tunica media contains the most. There the elastin constructs concentric "holey" laminae (sheets) of elastic connective tissue that look like slices of Swiss cheese interspersed between the layers of smooth muscle cells. Although elastic arteries also contain substantial amounts of smooth muscle, they are relatively inactive in vasoconstriction. Thus, in terms of function, they can be visualized as simple elastic tubes.

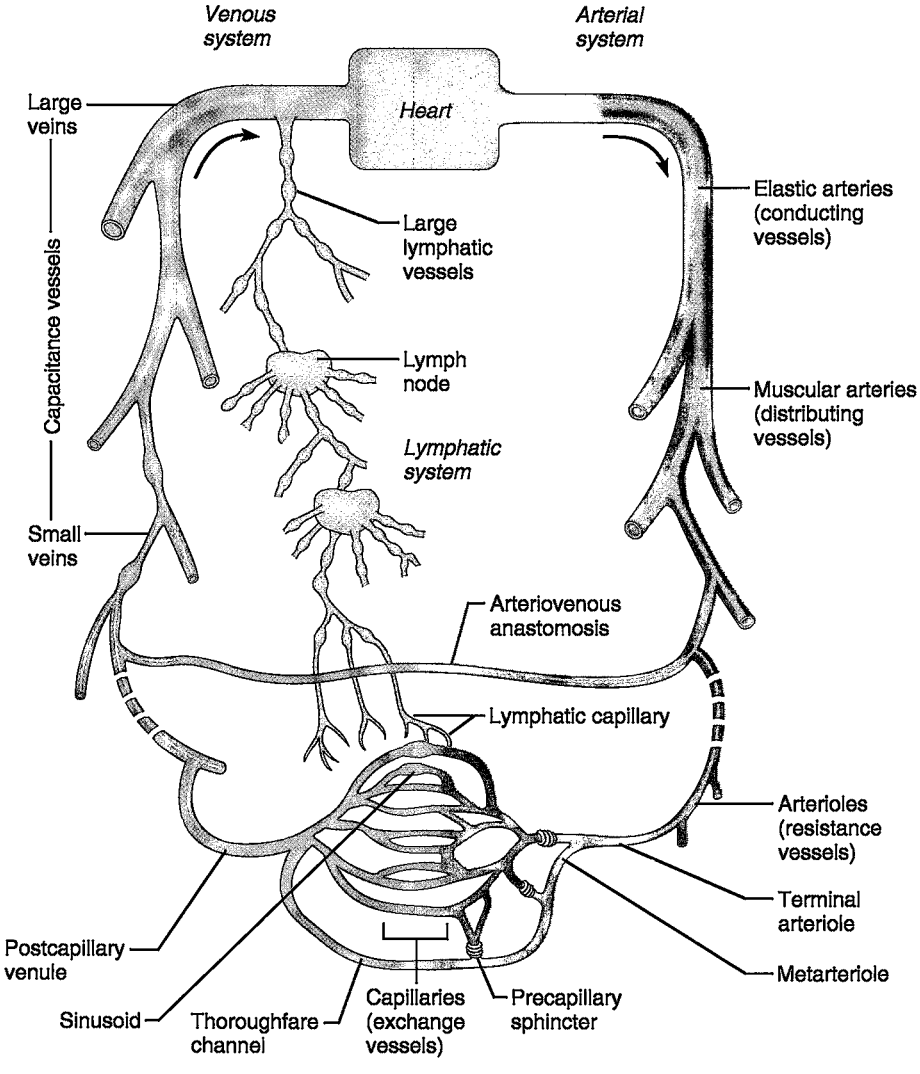
Elastic arteries are pressure reservoirs, expanding and recoiling as blood is ejected from the heart. Consequently, blood flows fairly continuously rather than starting and stopping with the pulsating rhythm of the heartbeat. If the blood vessels become hard and unyielding, as in arteriosclerosis, blood flows more intermittently, similar to the way water flows through a hard rubber garden hose attached to a faucet. When the faucet is on, the high pressure makes the water gush out of the hose. But when the faucet is shut off, the water flow abruptly becomes a trickle and then stops, because the hose walls cannot recoil to keep the water under pressure. Also, without the pressure-smoothing effect of the elastic arteries, the walls of arteries throughout the body experience higher pressures. Battered by high pressures, the arteries eventually weaken and may balloon out or even burst. (These problems are discussed in *A Closer Look* on pp. 718–719.)

Muscular (Distributing) Arteries

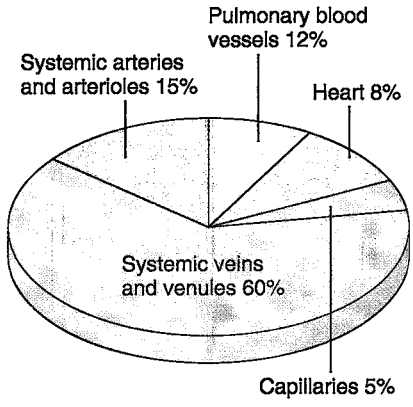
Distally the elastic arteries give way to the **muscular, or distributing, arteries,** which deliver blood to specific body organs and account for most of the named arteries studied in the anatomy laboratory. Their internal diameter ranges from that of a little finger (1 cm) to that of a pencil lead (about 0.3 mm). Proportionately, they have the thickest media of all vessels.

19

Q *Which contains more blood, the systemic or pulmonary circulation? In the systemic circulation, which contains more blood, arteries or veins?*



(a)



(b)

FIGURE 19.2 **Overview of vascular components and blood distribution. (a)** Schematic showing the relationship of vessels of the blood vascular system to one another and to lymphatic vessels. **(b)** Relative proportion of blood volume in the various portions of the cardiovascular system. Pulmonary blood vessels supply the lungs; systemic blood vessels supply the rest of the body.

Their tunica media contains relatively more smooth muscle and less elastic tissue than do elastic arteries (Table 19.1); therefore, they are more active in vasoconstriction and less distensible. In muscular arteries, however, there *is* an *elastic lamina* on each face of the tunica media.

Arterioles

The smallest of the arteries, **arterioles** have a lumen diameter ranging from 0.3 mm down to 10 μm. Larger arterioles have all three tunics, but their tunica media is chiefly smooth muscle with a few scattered elastic fibers. Smaller arterioles, which lead into the capillary beds, are little more than a single layer of smooth muscle cells spiraling around the endothelial lining.

As described shortly, minute-to-minute blood flow into the capillary beds is determined by arteriole diameter, which varies in response to changing neural, hormonal, and local chemical influences. When arterioles constrict, the tissues served are largely bypassed. When arterioles dilate, blood flow into the local capillaries increases dramatically.

(Text continues on p. 720.)

A *The systemic circulation contains more blood and most of that blood is in the veins.*

A CLOSER LOOK

Atherosclerosis? Get Out the Cardiovascular Drāno

When pipes get clogged, it is usually because we've dumped something down the drain that shouldn't be there—a greasy mass or a hairball. Sometimes, pipes get blocked when something is growing inside them (tree roots, for example), trapping the normal sludge coming through (see top photo). In **arteriosclerosis,** the walls of our arteries become thicker and stiffer, and hypertension results. In **atherosclerosis,** the most common form of arteriosclerosis, small, patchy thickenings called *atheromas* form that can intrude into the vessel lumen, making it easy for arterial spasms or a roaming blood clot to close the vessel completely.

Although all blood vessels are susceptible to atherosclerosis, the aorta and the coronary arteries are most often affected. The condition progresses through many stages before the arterial walls actually approach the rigid tube system described in the text, but some of the earlier stages are just as lethal.

Atherosclerosis: Onset and Stages

What triggers this scourge of blood vessels that indirectly causes half of the deaths in the Western world? According to the *response to injury* hypothesis, the initial event is damage to the tunica intima caused by bloodborne chemicals, hypertension, chronic ingestion of contaminants such as arsenic, physical factors such as blows, or viral or bacterial infections. The bacterium *Chlamydia pneumoniae,* known primarily as a cause of sexually transmitted disease; *cytomegalovirus (CMV),* which causes respiratory infections; oral bacteria from infected gums; and even *Helicobacter pylori,* the ulcer-causing bacterium, have all been found in vascular lesions. Indeed, researchers suspect that almost any type of chronic infection—including respiratory, periodontal, and urinary tract problems—could set the stage for atherosclerosis.

Irritation to the endothelium sets off the alarm summoning the immune system and the inflammatory process to repair the damage. If it's a one-time injury, when it's over it's over, but most plaques grow slowly. The plaque gradually enlarges as injured endothelial cells release chemotactic agents and growth (mitosis-inducing) factors, and begin to transport and modify greater amounts of lipids picked up from the blood, particularly low-density lipoproteins (LDLs). LDLs are the type that deliver cholesterol to tissue cells via the bloodstream. When the sequestered LDL becomes oxidized (this seems to be a common event), it not only damages neighboring cells but also acts as a chemotactic agent to attract macrophages. Normally macrophages protect the body by ingesting invading microorganisms and toxic substances including oxidized proteins and lipids. But in a particularly fatty plaque they can become so engorged with the oxidized LDLs in the intima that they are transformed into lipid-laden *foam cells* and lose their scavenging ability.

The macrophages are joined by smooth muscle cells migrating from the tunica media. These also take up lipids and become foam cells. The accumulating foam cells initiate the **fatty streak stage.** The smooth muscle cells also deposit collagen and elastin fibers, thickening the intima and producing fibrous lesions with a core of dead and dying foam cells called **fibrous** or **atherosclerotic plaques.** At first the vessel walls accommodate the growing plaque by expanding outward, but eventually these fatty mounds begin to protrude into the vessel lumen, producing full-blown atherosclerosis (see bottom photo).

Additionally, impaired endothelial function accounts for at least some cases of coronary artery spasms. Healthy endothelial cells release nitric oxide and prostacyclin—chemicals that promote vasodilation and inhibit platelet aggregation. Atherosclerosis impairs release of these vasodilators and antiaggregating factors. Indeed, this may be one cause of the increased thrombus formation in those with atherosclerosis.

If you add another ingredient—*lipoprotein (a)*—to the picture, the disease course accelerates. Lipoprotein (a) is a special LDL found in varying amounts in different people. It delivers cholesterol to sites where tissue is being repaired, such as areas of damaged endothelium. Although it is presumed to assist healing, it backfires when present in excess. Lipoprotein (a) is similar to a common growth factor, and it is thought to promote mitosis of the cells in the vessel wall. Because it resembles plasminogen, it can stand in for it at sites where clots have formed. However, it lacks plasminogen's clot-dissolving ability, so by competing successfully with that clot buster, it may *prevent* disposal of unneeded or undesirable clots.

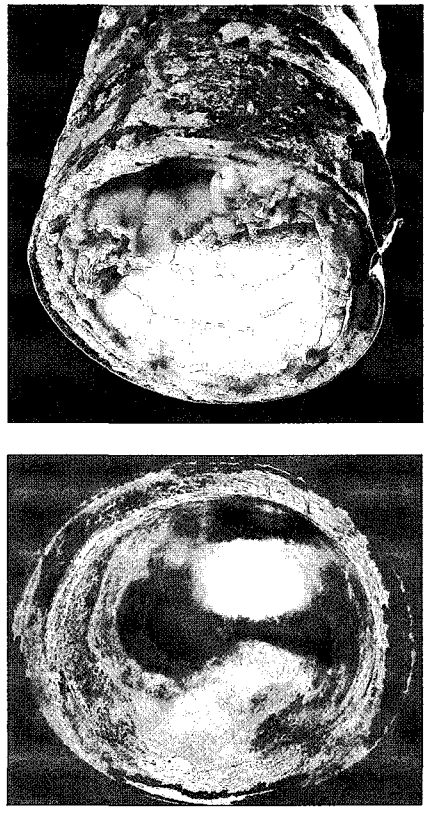
As enlarging plaques hinder diffusion of nutrients from the blood to deeper tissues of the artery wall, smooth muscle cells in the tunica media die and the elastic fibers deteriorate. These elements are replaced by nonelastic scar tissue, and calcium salts are deposited in the lesions, now called **complicated plaques.** These events constrict the vessel and cause the arterial walls to fray and ulcerate, conditions that encourage blood sludging and backup, platelet adhesion, and thrombus formation. The vessels' increased rigidity leads to hypertension. Together, these events increase the risk of myocardial infarcts, strokes, and aneurysms, and are responsible for the pain (angina) that occurs when heart muscle is ischemic.

However, the popular view that most heart attacks are the consequence of severe vessel narrowing and hardening is now being challenged, particularly since some 70% of heart attacks are caused by much smaller obstructions, too small to be seen on an arteriogram or to cause any symptoms in most cases. It now appears that the body's defense system betrays it. The inflammatory process that occurs in the still soft, unstable, cholesterol-rich plaques changes the biology of the vessel wall and makes these vulnerable plaques susceptible to rupture, exploding off fragments that trigger massive clots that can cause lethal heart attacks. The victim appears perfectly healthy until he or she drops dead!

Treatment and Prevention

Although this theory of *vulnerable plaque* has attracted many medical converts, the question of what to do about it remains. Medical centers now test heart patients for elevated levels of cholesterol and C-reactive protein, a marker of inflammation. Electron beam computed tomography (EBCT) scans may be able to identify those at risk for heart attack by detecting calcium deposits in their coronary arteries. New classes of anti-inflammatory and antioxidant drugs are being tested as preventive measures. Even the humble aspirin is gaining new respect; the American Heart Association recommends that people at high risk for heart attack or stroke take one baby aspirin (81 mg) daily. As yet, however, there is no Drāno for clogged vessels.

When your sewer pipes are blocked, you have two choices: dig them up and replace them, or call Roto-Rooter to drill through the obstruction. Stenosis in coronary arteries is treated in much the same way. In *coronary bypass surgery,* veins removed from the legs or small arteries removed from the thoracic cavity are implanted in the heart to restore myocardial circulation. In *balloon angioplasty,* a catheter with a balloon tightly packed into its tip is threaded through the vessels. When the catheter reaches the obstruction, the balloon is inflated to compress the fatty mass against the vessel wall.



Top *A pipe clogged by accumulated deposits.* ***Bottom*** *Atherosclerotic plaques nearly close a human artery.*

Although angioplasty is faster, cheaper, and much less risky than coronary bypass surgery, it has the same major shortcoming: It does nothing to stop the underlying disease, and in time *restenoses* (new blockages) occur in 30–50% of cases. Insertion of *stents,* short metal-mesh tubes that look much like a ziti noodle, into newly dilated vessels has helped solve the restenosis problem. Bursts of radiation to inhibit reclogging of arteries, a procedure called *brachytherapy,* have reduced restenosis by 50–80% in patients tested.

Even more exciting is a gel that is smeared on the area treated by angioplasty to form a translucent film over the wall. Composed of chemicals called *antisense agents,* the gel blocks the function of specific genes that are essential for smooth muscle proliferation. Another technique is to bathe bypass graft vessels in a solution containing DNA segments targeted to limit smooth muscle proliferation after vascular injury. Researchers are also testing nitric oxide (NO) donor drugs, which enhance NO activity. NO inhibits the cell proliferation and migration necessary for plaque formation.

It was hoped that cholesterol-lowering drugs (statins) would act as cardiovascular Drāno and wash the fatty plaques off the walls. They do work to some extent, but a significant part of their action is their unexpected side benefit—anti-inflammatory activity.

When an atheroma ruptures and induces clot formation, *thrombolytic (clot-dissolving) agents* are used. These revolutionary drugs include *tissue plasminogen activator (tPA),* a natural substance produced by genetic engineering techniques. Injecting tPA directly into the heart restores blood flow quickly and puts an early end to many heart attacks in progress. Cardiac patients receiving vessel-opening drugs appear to have a lower incidence of ventricular tachycardia and sudden death following a heart attack.

Of course, it's best to prevent atherosclerosis from progressing in the first place—by quitting smoking, losing weight to reduce blood lipid (triglyceride) levels, eating a healthy diet rich in antioxidants, and exercising regularly to increase blood levels of high-density lipoprotein (HDL, the "good" lipoprotein that removes cholesterol from vessel walls and carries it to the liver for elimination). Americans like their burgers and butter. But if heart disease can be prevented by reversing atherosclerosis, many people with diseased arteries may be willing to trade lifelong habits for a healthy old age! ■

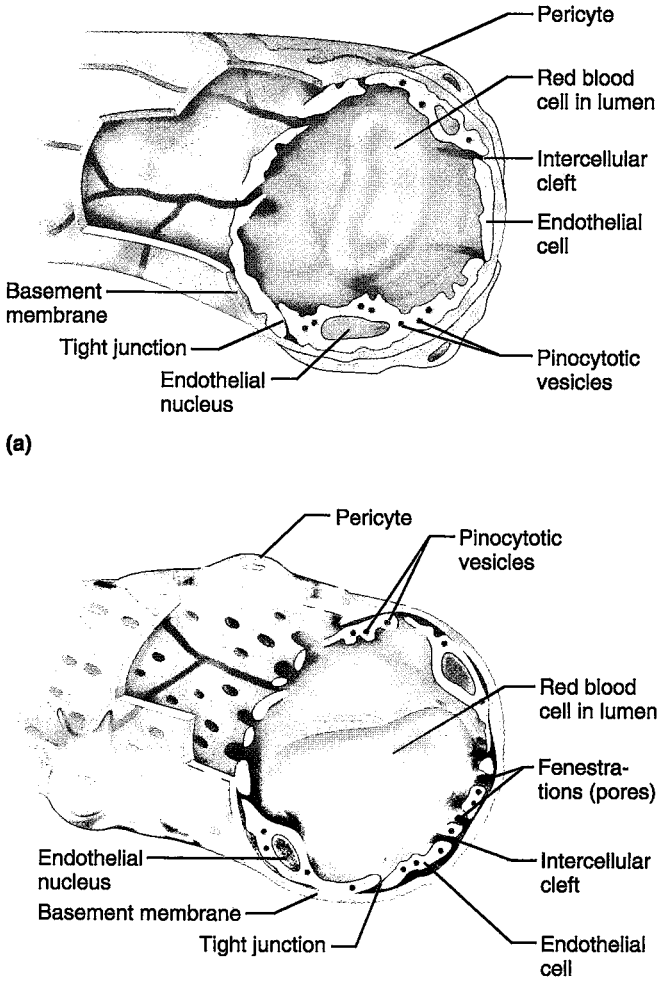


FIGURE 19.3 **Capillary structure.** Three-dimensional views of **(a)** continuous capillary, **(b)** fenestrated capillary, **(c)** sinusoidal capillary. [Note: The basement membrane is incomplete only in (c).]

Capillaries

The microscopic **capillaries** are the smallest blood vessels. Their exceedingly thin walls consist of just a thin tunica intima (see Figure 19.1b). In some cases, one endothelial cell forms the entire circumference of the capillary wall. Here and there along the outer surface of the capillaries are spider-shaped *pericytes*, smooth muscle-like cells that stabilize the capillary wall.

Average capillary length is 1 mm and average lumen diameter is 8–10 μm, just large enough for red blood cells to slip through in single file. Most tissues have a rich capillary supply, but there are exceptions. Tendons and ligaments are poorly vascularized. Cartilage and epithelia lack capillaries, but receive nutrients from blood vessels in nearby connective tissues, and the avascular cornea and lens of the eye receive nutrients from the aqueous humor.

If blood vessels are compared to a system of expressways and roads, the capillaries are the back alleys and driveways that provide direct access to nearly every cell in the body. Given their location and the thinness of their walls, capillaries are ideally suited for their role—exchange of materials (gases, nutrients, hormones, and so on) between the blood and the interstitial fluid (Figure 19.2a and Table 19.1). The mechanisms of these exchanges are described later in this chapter; here we focus on capillary structure.

Types of Capillaries

Structurally, there are three types of capillaries—*continuous*, *fenestrated*, and *sinusoidal*. **Continuous capillaries**, abundant in the skin and muscles, are most common. They are continuous in the sense that their endothelial cells provide an uninterrupted lining, adjacent cells being joined laterally by *tight junctions*. However, these junctions are usually incomplete and leave gaps of unjoined membrane called **intercellular clefts** (Figure 19.3a), which are just large enough to allow limited passage of fluids and small solutes. Typically, the endothelial cell cytoplasm contains numerous pinocytotic vesicles believed to ferry fluids across the capillary wall. However, brain capillaries are unique. There the tight junctions of the continuous capillaries are complete and extend around the entire perimeter of the endothelial cells, constituting the structural basis of the *blood-brain barrier* described in Chapter 12.

Fenestrated capillaries (fen'es-tra-tid) are similar to the continuous variety except that some of the endothelial cells in fenestrated capillaries are riddled with oval *pores*, or *fenestrations* (*fenestra* = window) (Figure 19.3b). The fenestrations are usually covered

by a delicate membrane, or diaphragm (probably condensed basal lamina material), but even so, fenestrated capillaries are much more permeable to fluids and small solutes than continuous capillaries are. Fenestrated capillaries are found wherever active capillary absorption or filtrate formation occurs. For example, fenestrated capillaries in the small intestine receive nutrients from digested food, and those in endocrine organs allow hormones rapid entry into the blood. Fenestrated capillaries with perpetually open pores occur in the kidneys, where rapid filtration of blood plasma is essential.

Sinusoids (si'nŭ-soyds), or **sinusoidal capillaries,** are highly modified, leaky capillaries found only in the liver, bone marrow, lymphoid tissues, and some endocrine organs. Sinusoids have large, irregularly shaped lumens and are usually fenestrated. Their endothelial lining has fewer tight junctions and larger intercellular clefts than ordinary capillaries (Figure 19.3c). These structural adaptations allow large molecules and even blood cells to pass between the blood and surrounding tissues. In the liver, the endothelium of the sinusoids is *discontinuous* and large macrophages called **Kupffer cells,** which remove and destroy any contained bacteria, form part of the lining. In other organs, such as the spleen, phagocytes located just outside the sinusoids stick cytoplasmic extensions through the intercellular clefts into the sinusoidal lumen to get at their "prey." Blood flows sluggishly through the tortuous sinusoid channels, allowing time for it to be modified in various ways.

Capillary Beds

Capillaries do not function independently. Instead they tend to form interweaving networks called **capillary beds.** The flow of blood from an arteriole to a venule—that is, through a capillary bed—is called the **microcirculation.** In most body regions, a capillary bed consists of two types of vessels: (1) a *vascular shunt* (metarteriole–thoroughfare channel), a short vessel that directly connects the arteriole and venule at opposite ends of the bed, and (2) *true capillaries,* the actual *exchange vessels* (Figure 19.4). The **terminal arteriole** feeding the bed leads into a **metarteriole** (a vessel structurally intermediate between an arteriole and a capillary), which is continuous with the **thoroughfare channel** (intermediate between a capillary and a venule). The thoroughfare channel, in turn, joins the **postcapillary venule** that drains the bed.

The **true capillaries** number 10 to 100 per capillary bed, depending on the organ or tissues served. They usually branch off the metarteriole (proximal end of the shunt) and return to the thoroughfare channel (the distal end), but occasionally they spring

Q *Assume the capillary bed depicted is in your calf muscle. Which condition would the bed be in—(a) or (b)—if you were doing calf raises at the gym?*

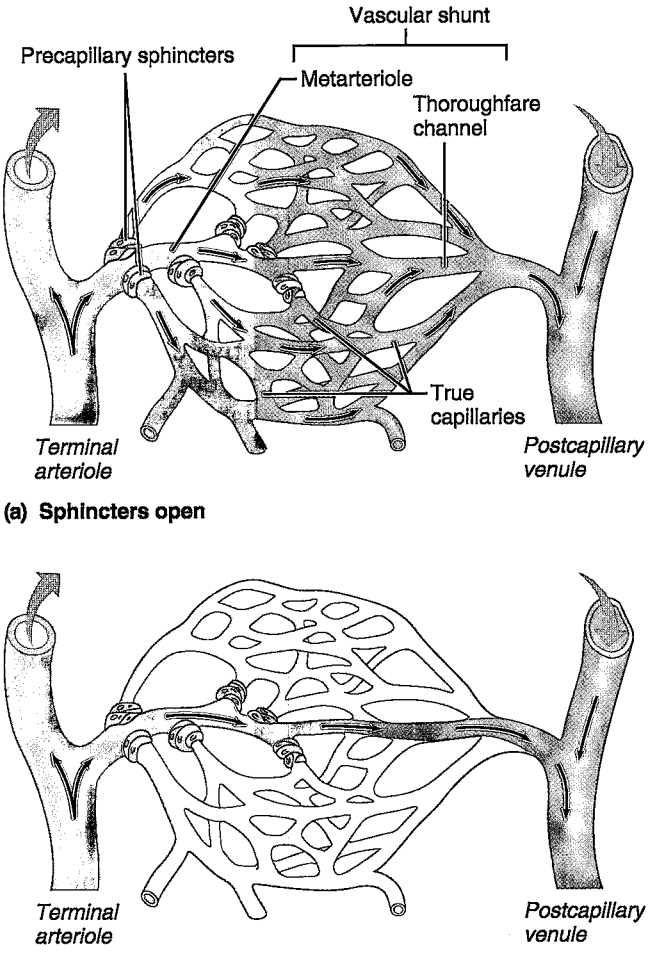

FIGURE 19.4 **Anatomy of a capillary bed.** When precapillary sphincters are constricted, the metarteriole–thoroughfare channel acts as a shunt to bypass the true capillaries.

from the terminal arteriole and empty directly into the venule. A cuff of smooth muscle fibers, called a **precapillary sphincter,** surrounds the root of each true capillary at the metarteriole and acts as a valve to regulate blood flow into the capillary. Blood flowing through a terminal arteriole may go either through the true capillaries or through the shunt. When the precapillary sphincters are relaxed (open), blood flows through the true capillaries and takes part in exchanges with tissue cells. When the

A Condition (a): The true capillaries would be flushed with blood to ensure that the working calf muscles could receive the needed nutrients and dispose of their metabolic wastes.

sphincters are contracted (closed), blood flows through the shunts and bypasses the tissue cells.

The relative amount of blood entering a capillary bed is regulated by local chemical conditions and arteriolar vasomotor nerve fibers. A bed may be flooded with blood or almost completely bypassed, depending on conditions in the body or in that specific organ. For example, suppose you have just eaten and are sitting relaxed, listening to your favorite musical group. Food digestion is going on, and blood is circulating freely through the true capillaries of your gastrointestinal organs to receive the breakdown products of digestion. However, most of these same capillary pathways are closed between meals. To take another example, when you are exercising vigorously blood is rerouted from the digestive organs (food or no food) to the capillary beds of your skeletal muscles where it is more immediately needed. This helps explain why vigorous exercise right after a meal can cause indigestion or abdominal cramps.

Venous System

Blood is carried from the capillary beds toward the heart by veins. Along the route, the diameter of successive venous vessels increases, and their walls gradually thicken as they progress from venules to the larger and larger veins.

Venules

Ranging from 8 to 100 μm in diameter, **venules** are formed when capillaries unite. The smallest venules, the *postcapillary venules*, consist entirely of endothelium around which a few pericytes congregate. They are extremely porous (more like capillaries than veins in this way), and fluid and white blood cells move easily from the bloodstream through their walls. Indeed, a well-recognized sign of an inflamed area is adhesion of white blood cells to the postcapillary venule endothelium, followed by their migration through the wall into the inflamed tissue. The larger venules have one or two layers of smooth muscle cells (a scanty tunica media) and thin externa as well.

Veins

Venules join to form *veins*. Veins usually have three distinct tunics, but their walls are always thinner and their lumens larger than those of corresponding arteries (Figure 19.1 and Table 19.1). Consequently, in the view seen in routine histological preparations, veins are usually collapsed and their lumens appear slitlike. There is relatively little smooth muscle or elastin in the tunica media, which is poorly developed and tends to be thin even in the largest veins. The tunica externa is the heaviest wall layer. Consisting of thick longitudinal bundles of collagen fibers and elastic networks, it is often several times thicker than the tunica media. In the largest veins—the venae cavae, which return blood directly to the heart—the tunica externa is further thickened by longitudinal bands of smooth muscle.

With their large lumens and thin walls, veins can accommodate a fairly large blood volume. Because up to 65% of the body's blood supply is found in the veins at any time, veins are called **capacitance vessels** and **blood reservoirs** (Figure 19.2b). Even so, they are normally only partially filled.

Because the blood pressure in veins is low, the walls of these vessels can be much thinner than arterial walls without danger of bursting. However, the low-pressure condition demands some adaptations to ensure that blood is returned to the heart at the same rate it was pumped into the circulation. The large-diameter lumens of veins (which offer relatively little resistance to blood flow) are one structural adaptation. Another is valves that prevent blood from flowing backward. **Venous valves** are formed from folds of the tunica intima (Figure 19.1), and resemble the semilunar valves of the heart in both structure and function. Venous valves are most abundant in the veins of the limbs, where the upward flow of blood is opposed by gravity. They are absent in veins of the ventral body cavity.

A simple experiment demonstrates the effectiveness of venous valves. Hang one hand by your side until the blood vessels on its dorsal aspect distend with blood. Next place two fingertips against one of the distended veins, and pressing firmly, move the superior finger proximally along the vein and then release that finger. The vein will remain flattened and collapsed, despite the pull of gravity. Finally, remove the distal fingertip and watch the vein refill with blood.

HOMEOSTATIC IMBALANCE

Varicose veins are veins that have become tortuous and dilated because of incompetent (leaky) valves. More than 15% of adults suffer from varicose veins, usually in the lower limbs. Several factors contribute, including heredity and conditions that hinder venous return, such as prolonged standing in one position, obesity, or pregnancy. Both the "potbelly" of an overweight person and the enlarged uterus of a pregnant woman exert downward pressure on vessels of the groin, and restrict return of blood to the heart. Consequently, blood pools in the lower limbs, and with time, the valves weaken and the venous walls stretch and become floppy. Superficial veins, which receive little support from surrounding tissues, are especially susceptible. Another cause of varicose veins is elevated venous pressure. For example,

straining to deliver a baby or have a bowel movement raises intra-abdominal pressure, preventing blood from draining from the veins of the anal canal. The resulting varicosities in the anal veins are called *hemorrhoids* (hem'ŏ-roidz). ●

Venous sinuses, such as the *coronary sinus* of the heart and the *dural sinuses* of the brain, are highly specialized, flattened veins with extremely thin walls composed only of endothelium. They are supported by the tissues that surround them, rather than by any additional tunics. The dural sinuses, which receive cerebrospinal fluid and blood draining from the brain, are reinforced by the tough dura mater that covers the brain surface.

Vascular Anastomoses

Where vascular channels unite, they form **vascular anastomoses** (ah-nas"to-mo'sēz; "coming together"). Most organs receive blood from more than one arterial branch, and arteries supplying the same territory often merge, forming **arterial anastomoses.** These anastomoses provide alternate pathways, called **collateral channels,** for blood to reach a given body region. If one branch is cut or blocked by a clot, the collateral channel can often provide the area with an adequate blood supply. Arterial anastomoses occur around joints, where active movement may hinder blood flow through one channel. They are also common in abdominal organs, the brain, and the heart. Arteries that do not anastomose or that have a poorly developed collateral circulation supply the retina, kidneys, and spleen. If their blood flow is interrupted, cells supplied by such vessels die.

The metarteriole–thoroughfare channel shunts of capillary beds that connect arterioles and venules are examples of **arteriovenous anastomoses.** Veins interconnect much more freely than arteries, and **venous anastomoses** are common. (You may be able to see venous anastomoses through the skin on the dorsum of your hand.) Because venous anastomoses are abundant, occlusion of a vein rarely blocks blood flow or leads to tissue death.

PART 2: PHYSIOLOGY OF CIRCULATION

Have you ever climbed a mountain? Well, get ready to climb a hypothetical mountain as you learn about circulatory dynamics. Like scaling a mountain, tackling blood pressure regulation and other topics of cardiovascular physiology is challenging while you're doing it, and exhilarating when you succeed. Let's begin the climb.

To sustain life, blood must be kept circulating. By now, you are aware that the heart is the pump, the arteries are pressure reservoirs and conduits, the arterioles are resistance vessels that control distribution, the capillaries are exchange sites, and the veins are conduits and blood reservoirs. Now for the dynamics of this system.

Introduction to Blood Flow, Blood Pressure, and Resistance

First we need to define three physiologically important terms—blood flow, blood pressure, and resistance—and examine how these factors relate to the physiology of blood circulation.

Definition of Terms

1. Blood flow is the volume of blood flowing through a vessel, an organ, or the entire circulation in a given period (ml/min). If we consider the entire vascular system, blood flow is equivalent to cardiac output (CO), and under resting conditions, it is relatively constant. At any given moment, however, blood flow through *individual* body organs may vary widely and is intimately related to their immediate needs.

2. Blood pressure (BP), the force per unit area exerted on a vessel wall by the contained blood, is expressed in millimeters of mercury (mm Hg). For example, a blood pressure of 120 mm Hg is equal to the pressure exerted by a column of mercury 120 mm high. Unless stated otherwise, the term *blood pressure* means systemic arterial blood pressure in the largest arteries near the heart. It is the pressure gradient—the *differences* in blood pressure within the vascular system—that provides the driving force that keeps blood moving, always from an area of higher pressure to an area of lower pressure, through the body.

3. Resistance is opposition to flow and is a measure of the amount of friction blood encounters as it passes through the vessels. Because most friction is encountered in the peripheral (systemic) circulation, well away from the heart, we generally use the term **peripheral resistance.** There are three important sources of resistance: blood viscosity, vessel length, and vessel diameter.

▪ ***Blood viscosity.*** *Viscosity* (vis-kos'ĭ-te) is the internal resistance to flow that exists in all fluids and is related to the thickness or "stickiness" of a fluid. The greater the viscosity, the less easily molecules slide past one another and the more difficult it is to get and keep the fluid moving. Because it contains formed elements and plasma proteins, blood is much more viscous than water; hence it flows more slowly under the same conditions. Blood viscosity is

fairly constant, but infrequent conditions such as polycythemia (excessive numbers of red blood cells) can increase blood viscosity and, hence, resistance. On the other hand, if the red blood cell count is low, as in some anemias, blood is less viscous and peripheral resistance declines.

- ***Total blood vessel length.*** The relationship between total blood vessel length and resistance is straightforward: the longer the vessel, the greater the resistance. An extra pound or two of fat requires that miles of small vessels be added to service it. This significantly increases the peripheral resistance.

- ***Blood vessel diameter.*** Because blood viscosity and vessel length are normally unchanging, the influence of these factors can be considered constant in healthy people. Changes in blood vessel diameter are frequent, however, and significantly alter peripheral resistance. How so? The answer lies in principles of fluid flow. Fluid close to the wall of a tube or channel is slowed by friction as it passes along the wall, whereas fluid in the center of the tube flows more freely and faster. You can verify this by watching the flow of water in a river. Water close to the bank hardly seems to move, while that in the middle of the river flows quite rapidly.

In a tube of a given size, the relative speed and position of fluid in the different regions of the tube's cross section remain constant, a phenomenon called *laminar flow* or *streamlining*. The smaller the tube, the greater the friction, because relatively more of the fluid contacts the tube wall, where its movement is impeded. Resistance varies *inversely* with the *fourth power* of the vessel radius (one-half the diameter). This means, for example, that if the radius of a vessel is doubled, the resistance drops to one-sixteenth of its original value ($r^4 = 2 \times 2 \times 2 \times 2 = 16$ and $1/r^4 = 1/16$). Thus, the large arteries close to the heart, which do not change dramatically in diameter, contribute little to peripheral resistance, and the small-diameter arterioles, which can enlarge or constrict in response to neural and chemical controls, are the major determinants of peripheral resistance.

When blood encounters either an abrupt change in the tube size or rough or protruding areas of the tube wall (such as the fatty plaques of atherosclerosis), the smooth laminar blood flow is replaced by *turbulent flow*, that is, irregular fluid motion where blood from the different laminae mixes. Turbulence dramatically increases resistance.

Relationship Between Flow, Pressure, and Resistance

Now that we have defined these terms, let us summarize briefly the relationships between them. Blood flow (F) is *directly* proportional to the difference in blood pressure (ΔP) between two points in the circulation, that is, the blood pressure, or hydrostatic pressure, gradient. Thus, when ΔP increases, blood flow speeds up, and when ΔP decreases, blood flow declines. Blood flow is *inversely* proportional to the peripheral resistance (R) in the systemic circulation; if R increases, blood flow decreases. These relationships are expressed by the formula

$$F = \frac{\Delta P}{R}$$

Of these two factors influencing blood flow, R is far more important than ΔP in influencing local blood flow. This is because when the arterioles serving a particular tissue dilate (thus decreasing the resistance), blood flow to that tissue increases, even though the systemic pressure is unchanged or may actually be falling.

Systemic Blood Pressure

Any fluid driven by a pump through a circuit of closed channels operates under pressure, and the nearer the fluid is to the pump, the greater the pressure exerted on the fluid. The dynamics of blood flow in blood vessels is no exception, and blood flows through the blood vessels along a pressure gradient, always moving from higher- to lower-pressure areas. Fundamentally, *the pumping action of the heart generates blood flow. Pressure results when flow is opposed by resistance.*

As illustrated in Figure 19.5, systemic blood pressure is highest in the aorta and declines throughout the pathway to finally reach 0 mm Hg in the right atrium. The steepest drop in blood pressure occurs in the arterioles, which offer the greatest resistance to blood flow. However, as long as a pressure gradient exists, no matter how small, blood continues to flow until it completes the circuit back to the heart.

Arterial Blood Pressure

Arterial blood pressure reflects two factors: (1) how much the elastic arteries close to the heart can be stretched (their *compliance* or *distensibility*) and (2) the volume of blood forced into them at any time. If the amounts of blood entering and leaving the elastic arteries in a given period were equal, arterial pressure would be constant. Instead, as Figure 19.5 reveals, blood pressure rises and falls in a regular fashion in the elastic arteries near the heart, that is, it is obviously *pulsatile*.

As the left ventricle contracts and expels blood into the aorta, it imparts kinetic energy to the blood, which stretches the elastic aorta as aortic pressure reaches its peak. Indeed, if the aorta were

opened during this period, blood would spurt upward 5 or 6 feet! This pressure peak, called the **systolic pressure** (sis-tah'lik), averages 120 mm Hg in healthy adults. Blood moves forward into the arterial bed because the pressure in the aorta is higher than the pressure in the more distal vessels. During diastole, the aortic valve closes, preventing blood from flowing back into the heart, and the walls of the aorta (and other elastic arteries) recoil, maintaining sufficient pressure to keep the blood flowing forward into the smaller vessels. During this time, aortic pressure drops to its lowest level (approximately 70 to 80 mm Hg in healthy adults), called the **diastolic pressure** (di-as-tah'lik). Thus, you can picture the elastic arteries as pressure reservoirs that operate as auxiliary pumps to keep blood circulating throughout the period of diastole, when the heart is relaxing. Essentially, the volume and energy of blood stored in the elastic arteries during systole are given back during diastole.

The difference between the systolic and diastolic pressures is called the **pulse pressure.** It is felt as a throbbing pulsation in an artery (a *pulse*) during systole, as the elastic arteries are expanded by the blood being forced into them by ventricular contraction. Increased stroke volume and faster blood ejection from the heart (a result of increased contractility) cause *temporary* increases in the pulse pressure. Pulse pressure is chronically increased by arteriosclerosis because the elastic arteries become less stretchy. Because aortic pressure fluctuates up and down with each heartbeat, the important pressure figure to consider is the **mean arterial pressure (MAP);** it is this pressure that propels the blood to the tissues. Because diastole usually lasts longer than systole, the MAP is not simply the value halfway between systolic and diastolic pressures. Instead, it is roughly equal to the diastolic pressure plus one-third of the pulse pressure.

$$\text{MAP} = \text{diastolic pressure} + \frac{\text{pulse pressure}}{3}$$

Thus, for a person with a systolic blood pressure of 120 mm Hg and a diastolic pressure of 80 mm Hg:

$$\text{MAP} = 80 \text{ mm Hg} + \frac{40 \text{ mm Hg}}{3} = 93 \text{ mm Hg}$$

MAP and pulse pressure both decline with increasing distance from the heart. The MAP loses ground to the never-ending friction between the blood and the vessel walls, and the pulse pressure is gradually phased out in the less elastic muscular arteries, where elastic rebound of the vessels ceases to occur. At the end of the arterial tree, blood flow is steady and the pulse pressure has disappeared.

In which class of blood vessels does the greatest drop in blood pressure occur?

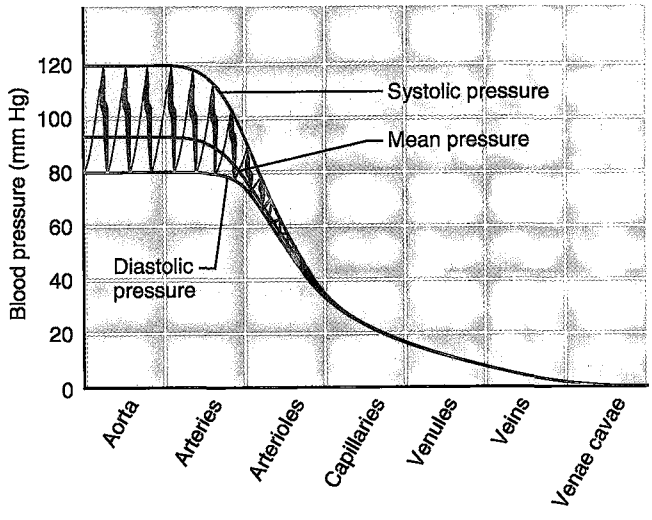

FIGURE 19.5 **Blood pressure in various blood vessels of the systemic circulation.**

Capillary Blood Pressure

As Figure 19.5 shows, by the time blood reaches the capillaries, blood pressure has dropped to approximately 35 mm Hg and by the end of the capillary beds is only around 15 mm Hg. Such low capillary pressures are desirable because (1) capillaries are fragile and high pressures would rupture them, and (2) most capillaries are extremely permeable and thus even the low capillary pressure forces solute-containing fluids (filtrate) out of the bloodstream into the interstitial space. As described later in this chapter, these fluid flows are important for continuously refreshing the interstitial fluid.

Venous Blood Pressure

Unlike arterial pressure, which pulsates with each contraction of the left ventricle, venous blood pressure is steady and changes very little during the cardiac cycle. The pressure gradient in the veins, from venules to the termini of the venae cavae, is only about 15 mm Hg (that from the aorta to the ends of the arterioles is about 60 mm Hg). This pressure difference between arteries and veins becomes very clear when the vessels are cut. If a vein is cut, the blood flows evenly from the wound; a lacerated artery spurts blood. The very low pressure in the

A Arterioles, because this is the site of greatest resistance. Arterioles control the distribution of blood to the tissues by changing their resistance.

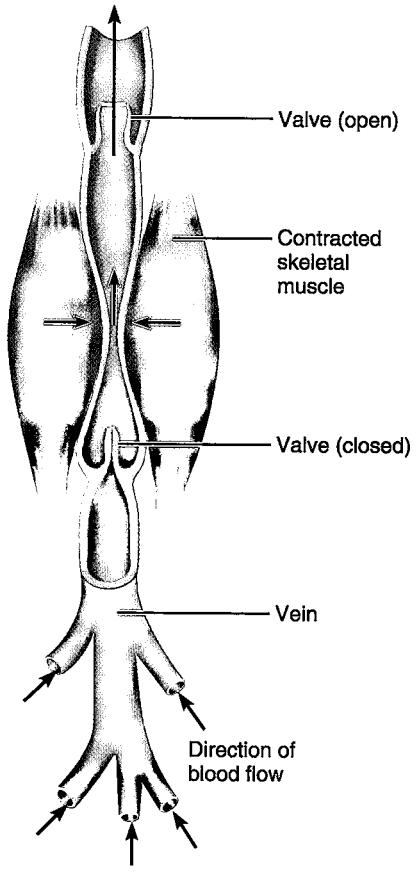

FIGURE 19.6 **The muscular pump.** When contracting skeletal muscles press against a vein, the valves proximal to the area of contraction are forced open and blood is propelled toward the heart. The valves distal to the area of contraction are closed by the backflowing blood.

venous system reflects the cumulative effects of peripheral resistance, which dissipates most of the energy of blood pressure (as heat) during each circuit.

Despite the structural modifications of veins (large lumens and valves), venous pressure is normally too low to promote adequate venous return. Hence, three functional adaptations are critically important to venous return. The first is the **respiratory "pump."** Pressure changes occurring in the ventral body cavity during breathing create the respiratory pump that moves blood up toward the heart. As we inhale, abdominal pressure increases, squeezing the local veins and forcing blood toward the heart. At the same time, the pressure in the chest decreases, allowing thoracic veins to expand and speeding blood entry into the right atrium. The second adaptation is the **muscular "pump."** Skeletal muscle activity, or the so-called muscular pump, is the more important pumping mechanism. As the skeletal muscles surrounding the deep veins contract and relax, they "milk" blood toward the heart, and once blood passes each successive valve, it cannot flow back (Figure 19.6). People who earn their living in "standing professions," such as hairdressers and dentists, often have swollen ankles because blood pools in the feet and legs during prolonged periods of skeletal muscle inactivity. The third adaptation is the layer of smooth muscle around the veins that constricts under sympathetic control, increasing venous return. This is yet another way in which the sympathetic nervous system increases cardiac output.

Maintaining Blood Pressure

Maintaining a steady flow of blood from the heart to the toes is vital for proper organ function. But making sure a person jumping out of bed in the morning does not keel over from inadequate blood flow to the brain requires the finely tuned cooperation of the heart, blood vessels, and kidneys—all supervised by the brain. Central among the homeostatic mechanisms that regulate cardiovascular dynamics are those that maintain blood pressure, principally *cardiac output, peripheral resistance,* and *blood volume.* If we rearrange the formula pertaining to blood flow presented on p. 724, we can see how cardiac output (blood flow of the entire circulation) and peripheral resistance relate to blood pressure.

$$F = \Delta P/R \quad \text{or} \quad CO = \Delta P/R \quad \text{or} \quad \Delta P = CO \times R$$

Because CO depends on blood volume (the heart can't pump out what doesn't enter its chambers), it is clear that blood pressure varies *directly* with CO, *R,* and blood volume. Thus, in theory, a change (increase or decrease) in any of these variables causes a corresponding change in blood pressure. However, what *really* happens in the body is that changes in one variable that threaten blood pressure homeostasis are quickly compensated for by changes in the other variables.

As described in Chapter 18, CO is equal to *stroke volume* (ml/beat) times *heart rate* (beats/min), and normal CO is 5.0 to 5.5 L/min. Figure 19.7 shows the main factors determining cardiac output—venous return and the neural and hormonal controls. Remember that the cardioinhibitory center in the medulla is "in charge" of heart rate most of the time and, via the parasympathetic vagus nerves, maintains the *resting heart rate.* During "resting" periods, stroke volume is controlled mainly by venous return (end diastolic volume). During stress, the cardioacceleratory center takes over, activating the sympathetic nervous system and increasing both heart rate (by acting on the SA node) and stroke volume (by enhancing cardiac muscle contractility, which decreases end systolic volume). The enhanced CO, in turn, results in an increase in MAP.

The following discussion focuses on factors that regulate blood pressure by altering peripheral resistance and blood volume, but a flowchart showing the influence of nearly all other important factors is provided in Figure 19.10 (p. 731).

Short-Term Mechanisms: Neural Controls

The *short-term controls* of blood pressure, mediated by the nervous system and bloodborne chemicals, counteract moment-to-moment fluctuations in blood pressure by altering peripheral resistance (and CO).

Neural controls of peripheral resistance are directed at two main goals: (1) Maintaining adequate MAP by altering blood vessel diameter. (Remember, very small changes in blood vessel diameter cause substantial changes in peripheral resistance, and hence in systemic blood pressure.) Under conditions of low blood volume, all vessels except those supplying the heart and brain are constricted to allow as much blood as possible to flow to those two vital organs. (2) Altering blood distribution to respond to specific demands of various organs. For example, during exercise blood is shunted temporarily from the digestive organs to the skeletal muscles.

Most neural controls operate via reflex arcs involving *baroreceptors* and associated afferent fibers, the vasomotor center of the medulla, vasomotor fibers, and vascular smooth muscle. Occasionally, inputs from *chemoreceptors* and higher brain centers also influence the neural control mechanism.

Role of the Vasomotor Center

The neural center that oversees changes in the diameter of blood vessels is the **vasomotor center,** a cluster of neurons in the medulla. This center plus the cardiac centers described earlier make up the **cardiovascular center** that integrates blood pressure control by altering cardiac output and blood vessel diameter. The vasomotor center transmits impulses at a fairly steady rate along sympathetic efferents called **vasomotor fibers,** which exit from the T_1 through L_2 levels of the spinal cord and run to innervate the smooth muscle of blood vessels, mainly arterioles. As a result, the arterioles are almost always in a state of moderate constriction, called **vasomotor tone.**

The degree of tonic vasoconstriction varies from organ to organ. Generally, arterioles of the skin and digestive viscera receive vasomotor impulses more frequently and tend to be more strongly constricted than those of skeletal muscles. Any increase in sympathetic activity produces generalized vasoconstriction and a rise in blood pressure. Decreased sympathetic activity allows the vascular muscle to relax somewhat and causes blood pressure to decline to basal levels. Most vasomotor fibers release norepinephrine, which is a potent vasoconstrictor. In skeletal muscle, however, some vasomotor fibers release acetylcholine, causing vasodilation. Though they may influence local blood flow, such vasodilator fibers are *not* important to overall regulation of systemic blood pressure.

Vasomotor activity is modified by inputs from (1) baroreceptors (pressure-sensitive mechanoreceptors that respond to changes in arterial pressure and stretch), (2) chemoreceptors (receptors that respond to changes in blood levels of oxygen, carbon dioxide, and H^+), and (3) higher brain centers. Let's take a look.

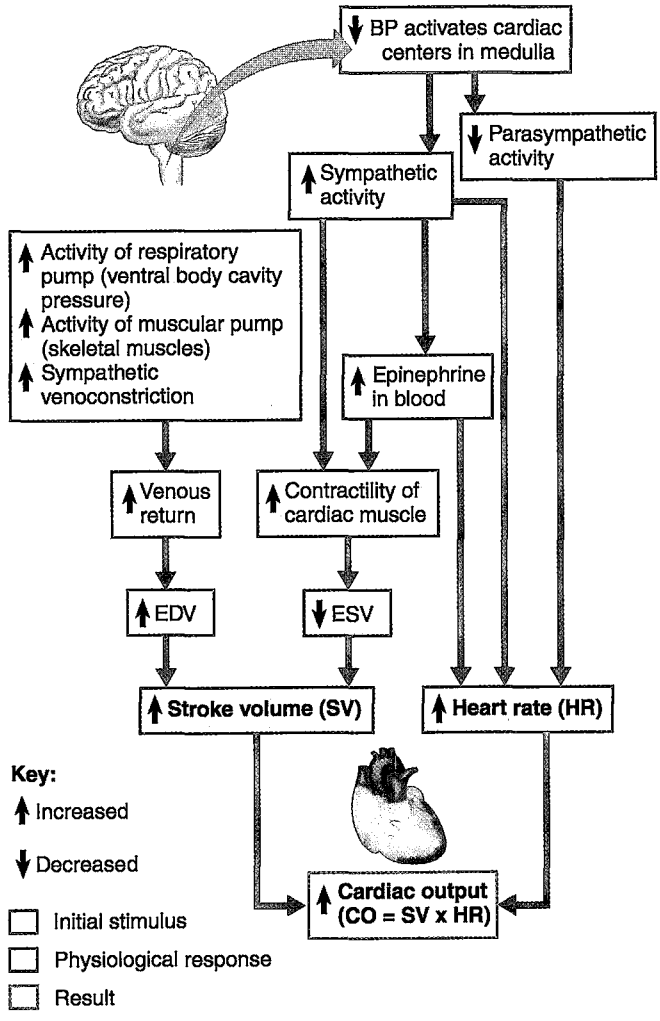

FIGURE 19.7 **Major factors enhancing cardiac output.** (Efferent impulses from cardiac centers travel along autonomic nerves. EDV = end diastolic volume, ESV = end systolic volume.)

Baroreceptor-Initiated Reflexes

When arterial blood pressure rises, it stretches **baroreceptors,** neural receptors located in the *carotid sinuses* (dilations in the internal carotid arteries, which provide the major blood supply to the brain), in the *aortic arch,* and in the walls of nearly every large artery of the neck and thorax. When stretched, baroreceptors send a rapid stream of impulses to the vasomotor center. This input inhibits the vasomotor center, resulting in vasodilation of not only arterioles but also veins, and a decline in blood pressure (Figure 19.8). While dilation of the arterioles substantially reduces peripheral resistance, venodilation shifts blood to the venous reservoirs,

Q *Which part of this feedback loop occurs when you rise from a seated position?*

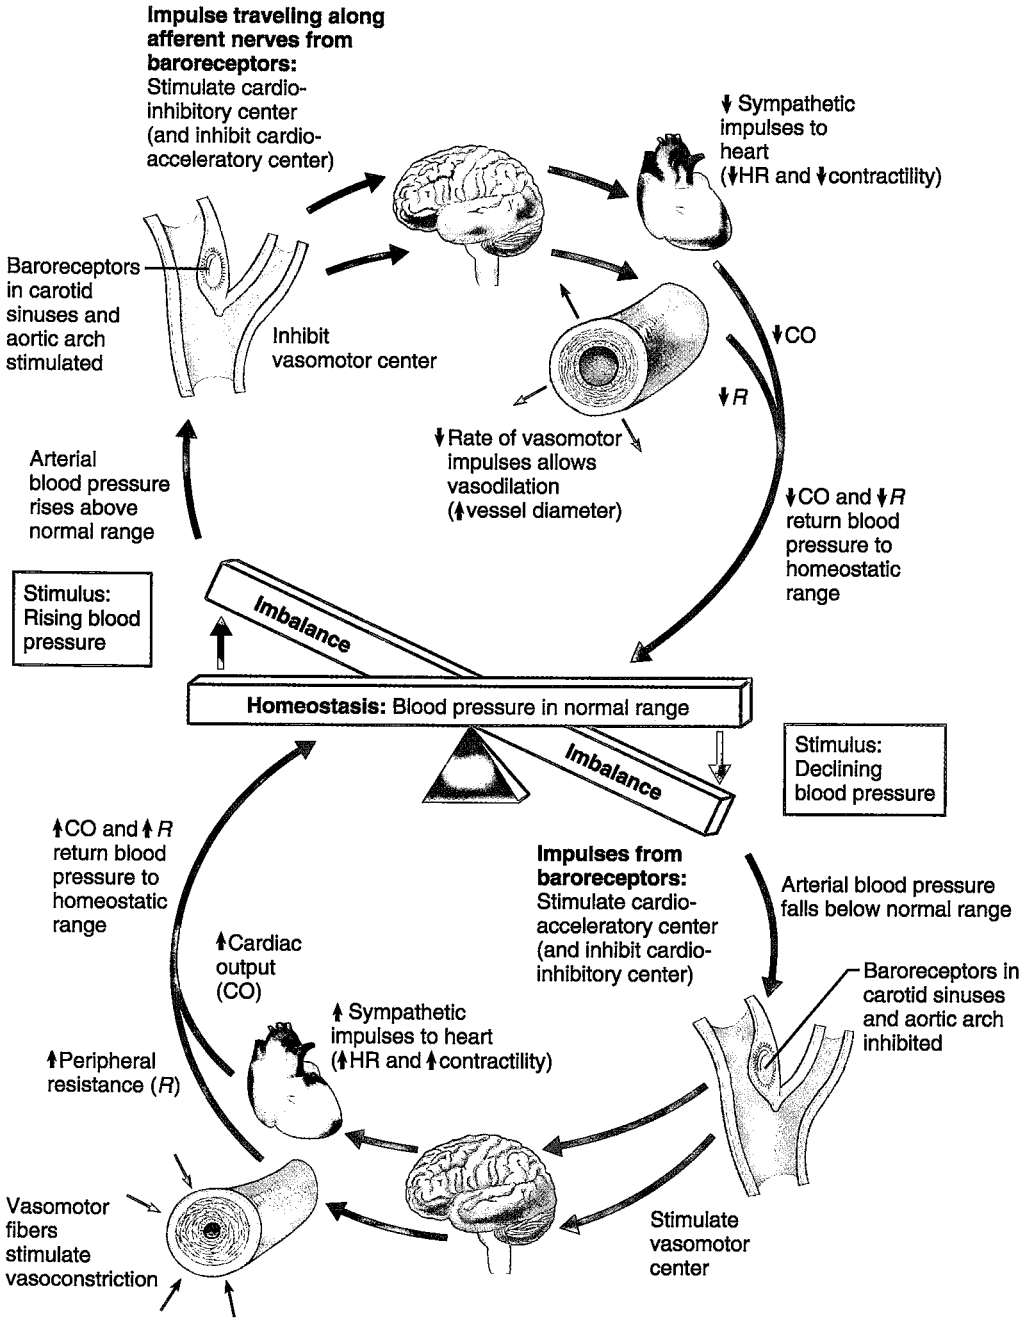

FIGURE 19.8 **Baroreceptor reflexes that help maintain blood pressure homeostasis.** CO = cardiac output; *R* = peripheral resistance; HR = heart rate; BP = blood pressure.

19

A The bottom part of the figure applies because arterial blood pressure initially drops, resulting in stimulation of the vasomotor and cardioaccelerator centers. The result is increased heart rate and vasoconstriction, which increases arterial pressure, restoring homeostasis.

TABLE 19.2 Influence of Selected Hormones on Variables Affecting Blood Pressure

VARIABLE AFFECTING BP	EFFECT ON VARIABLE	HORMONE(S)	SITE OF ACTION	RESULT
Cardiac output	↑(↑ HR and contractility)	Epinephrine and norepinephrine (NE)	Heart (β_1 receptors)	↑ BP
Peripheral resistance	↑ (via vasoconstriction)	Angiotensin II	Arterioles	↑ BP
		Antidiuretic hormone (ADH)	Arterioles	↑ BP
		Epinephrine and NE	Arterioles (α receptors)	↑ BP
	↓ (via vasodilation)	Atrial natriuretic peptide	Arterioles	↓ BP
Blood volume	↓ (salt and water loss)	Atrial natriuretic peptide	Kidney tubule cells	↓ BP
	↑ (salt and water retention)	Aldosterone	Kidney tubule cells	↑ BP
		Cortisol	Kidney tubule cells	↑ BP
	↑ (water retention)	ADH	Kidney tubule cells	↑ BP

causing a decline in both venous return and cardiac output. Afferent impulses from the baroreceptors also reach the cardiac centers, where the impulses stimulate parasympathetic activity and inhibit the cardioacceleratory center, reducing heart rate and contractile force. A decline in MAP initiates reflex vasoconstriction and increases cardiac output, causing blood pressure to rise. Thus, peripheral resistance and cardiac output are regulated in tandem so that changes in blood pressure are minimized.

The function of rapidly responding baroreceptors is to protect the circulation against short-term (acute) changes in blood pressure, such as those occurring when you change your posture. For example, blood pressure falls (particularly in the head) when one stands up after reclining. Baroreceptors taking part in the **carotid sinus reflex** protect the blood supply to the brain, whereas those activated in the **aortic reflex** help maintain adequate blood pressure in the systemic circuit as a whole. Baroreceptors are relatively *ineffective* in protecting us against sustained pressure changes, as evidenced by the fact that some people do have chronic hypertension. In such cases, the baroreceptors are "reprogrammed" (adapt) to monitor pressure changes at a higher set point.

Chemoreceptor-Initiated Reflexes

When the oxygen content or pH of the blood drops sharply or the carbon dioxide levels rise, **chemoreceptors** in the aortic arch and large arteries of the neck transmit impulses to the cardioacceleratory center, which then increases cardiac output, and to the vasomotor center, which causes reflex vasoconstriction. The rise in blood pressure that follows speeds the return of blood to the heart and lungs.

The most prominent chemoreceptors are the *carotid* and *aortic bodies* located close by the baroreceptors in the carotid sinus and aortic arch. Because chemoreceptors are more important in regulating respiratory rate than blood pressure, their function is considered in Chapter 22.

Influence of Higher Brain Centers

Reflexes that regulate blood pressure are integrated in the medulla of the brain stem. Although the cerebral cortex and hypothalamus are not involved in routine controls of blood pressure, these higher brain centers can modify arterial pressure via relays to the medullary centers. For example, the fight-or-flight response mediated by the hypothalamus has profound effects on blood pressure. (Even the simple act of speaking can make your blood pressure jump if the person you are talking to makes you anxious.) The hypothalamus also mediates the redistribution of blood flow and other cardiovascular responses that occur during exercise and changes in body temperature.

Short-Term Mechanisms: Hormonal Controls

As we have seen, changing levels of oxygen and carbon dioxide help regulate blood pressure via the chemoreceptor reflexes. Hormones, too, help regulate blood pressure, both in the short term via changes in peripheral resistance and in the long term via changes in blood volume (Table 19.2). Paracrines (local chemicals), on the other hand, primarily serve to match the amount of blood flow to the metabolic need of a particular tissue. In rare instances, massive release of paracrines can affect blood pressure. We will discuss these paracrines later—here we will examine the short-term effects of hormones.

- **Adrenal medulla hormones.** During periods of stress, the adrenal gland releases norepinephrine (NE) and epinephrine to the blood, and both hormones enhance the sympathetic fight-or-flight response. As noted earlier, NE has a vasoconstrictive action. Epinephrine increases cardiac output and promotes generalized vasoconstriction (except in skeletal and cardiac muscle, where it generally causes vasodilation). It is interesting to note that *nicotine*, an important chemical in tobacco and one of the strongest toxins known, causes intense vasoconstriction not only by directly stimulating ganglionic sympathetic neurons but also by prompting release of large amounts of epinephrine and NE.
- **Atrial natriuretic peptide (ANP).** The atria of the heart produce the hormone atrial natriuretic peptide, which causes blood volume and blood pressure to decline. As noted in Chapter 16, ANP antagonizes aldosterone and prods the kidneys to excrete more sodium and water from the body, causing blood volume to drop. It also causes generalized vasodilation.
- **Antidiuretic hormone (ADH, vasopressin).** This hormone is produced by the hypothalamus and stimulates the kidneys to conserve water. It is not usually important in short-term blood pressure regulation, but when blood pressure falls to dangerously low levels (as during severe hemorrhage), much more ADH is released and helps restore arterial pressure by causing intense vasoconstriction.
- **Angiotensin II.** When renal perfusion is inadequate, the kidneys release the hormone renin. Renin acts as an enzyme, ultimately generating angiotensin II (an"je-o-ten'sin), which stimulates intense vasoconstriction, promoting a rapid rise in systemic blood pressure. It also stimulates release of aldosterone and ADH, which act in long-term regulation of blood pressure by enhancing blood volume.

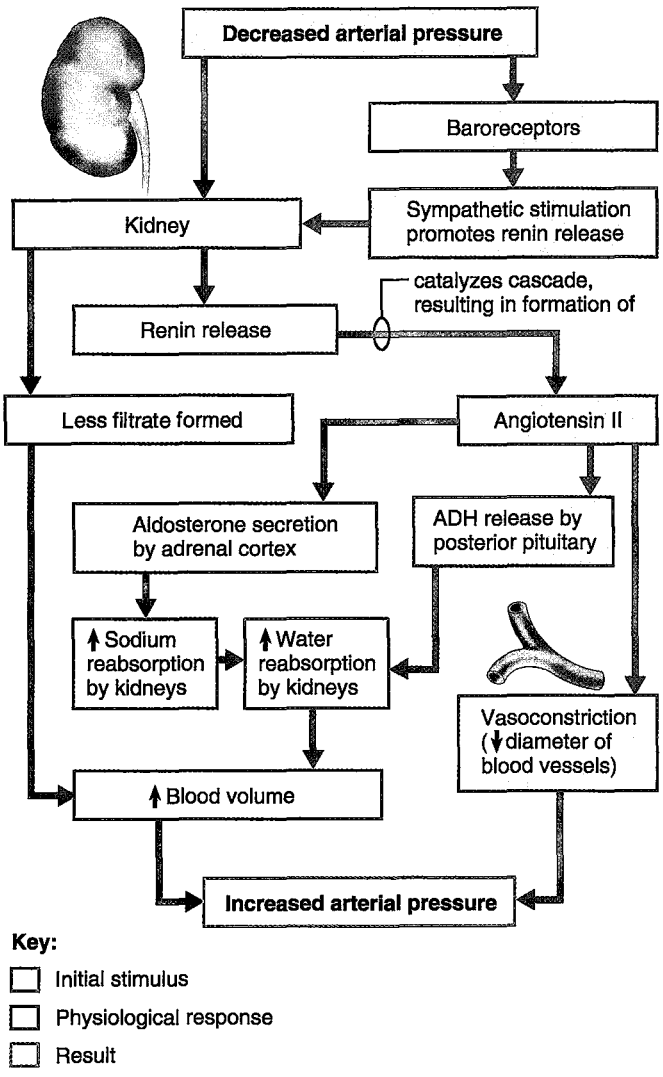

FIGURE 19.9 **Direct and indirect (hormonal) mechanisms for renal control of blood pressure.** Sympathetic nervous system stimulation and action, both part of the more rapidly acting short-term control pathway, also participate in this system by triggering renin release.

Long-Term Mechanisms: Renal Regulation

The long-term controls of blood pressure, mediated by renal mechanisms, counteract fluctuations in blood pressure not by altering peripheral resistance (as in short-term controls) but rather by altering blood volume.

Although baroreceptors respond to short-term changes in blood pressure, they quickly adapt to prolonged or chronic episodes of high or low pressure. This is where the kidneys step in to restore and maintain blood pressure homeostasis by regulating blood volume. Although blood volume varies with age, body size, and sex, renal mechanisms usually maintain it at close to 5 L.

As noted earlier, blood volume is a major determinant of cardiac output (via its influence on venous return, EDV, and stroke volume). An increase in blood volume is followed by a rise in blood pressure, and anything that increases blood volume—such as excessive salt intake, which promotes water retention—raises MAP because of the greater fluid load in the vascular tree. By the same token, decreased blood volume translates to a fall in blood pressure. Blood loss and the garden-variety dehydration that occurs during vigorous exercise are common causes of reduced blood volume. A sudden drop in blood pressure often signals internal bleeding and blood volume too low to support normal circulation.

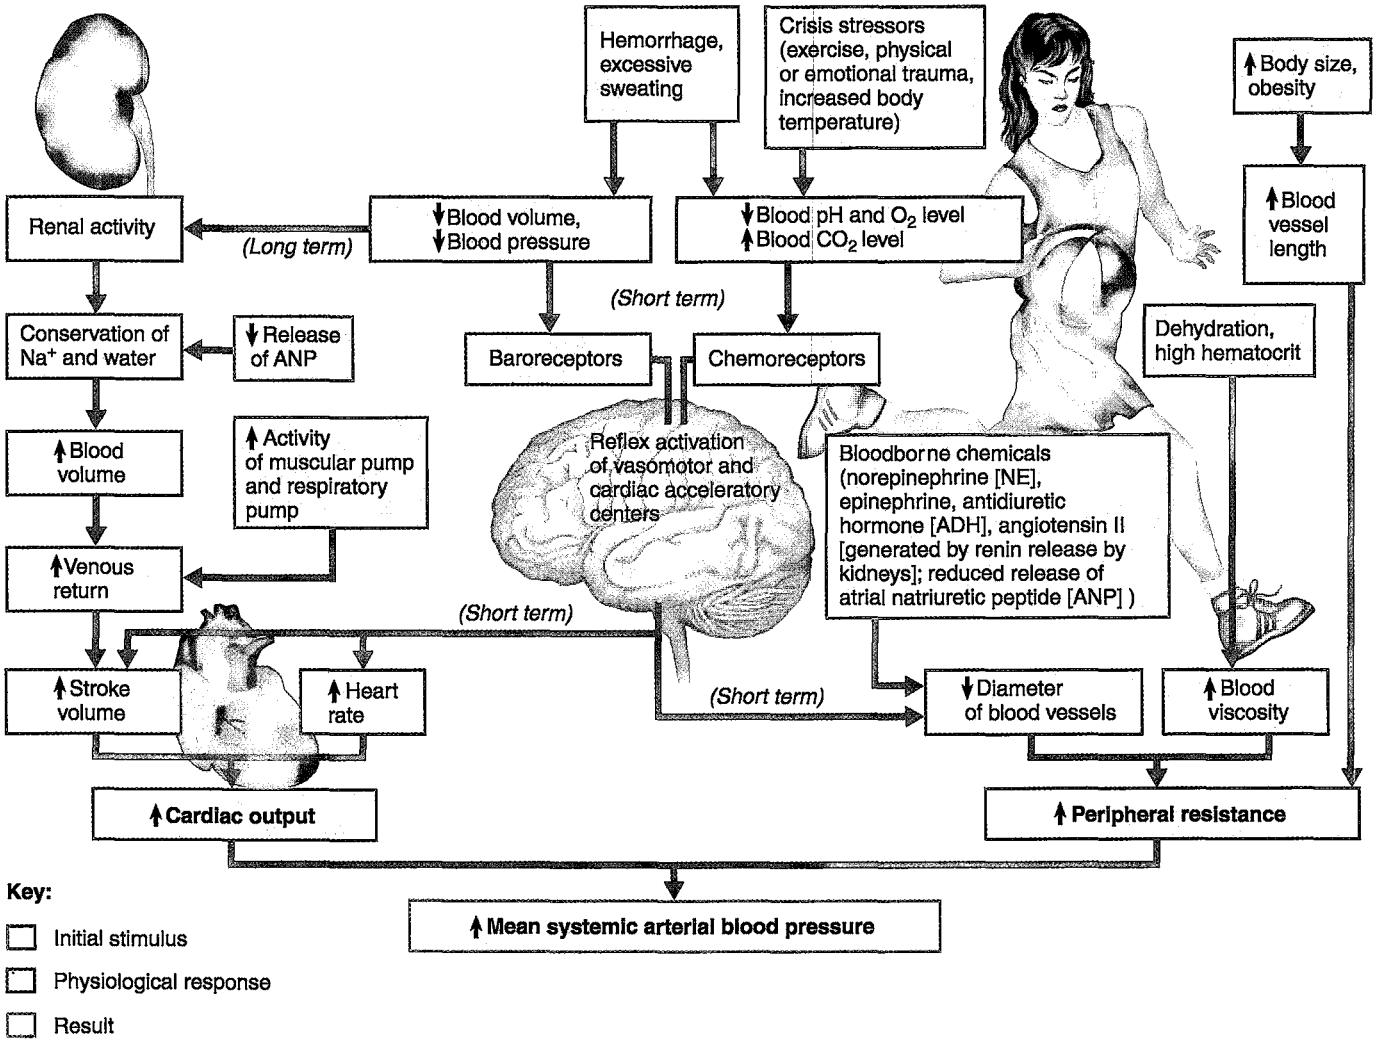

FIGURE 19.10 **Factors causing an increase in MAP.**

However, these assertions—increased blood volume increases BP and decreased blood volume decreases BP—do not tell the whole story because we are dealing with a dynamic system. Increases in blood volume that cause a rise in blood pressure also stimulate the kidneys to eliminate water, which reduces blood volume and consequently blood pressure. Likewise, falling blood volume triggers renal mechanisms that increase blood volume and blood pressure. As you can see, blood pressure can be stabilized or maintained within normal limits only when blood volume is stable.

The kidneys act both directly and indirectly to regulate arterial pressure and provide the major long-term mechanism of blood pressure control. The *direct renal mechanism* alters blood volume independently of hormones. When either blood volume or blood pressure rises, the rate at which fluid filters from the bloodstream into the kidney tubules is speeded up. In such situations, the kidneys cannot process the filtrate rapidly enough, and more of it leaves the body in urine. As a result, blood volume and blood pressure fall. When blood pressure or blood volume is low, water is conserved and returned to the bloodstream, and blood pressure rises (Figures 19.9 and 19.10). As blood volume goes, so goes the arterial blood pressure.

The *indirect renal mechanism* is the **renin-angiotensin mechanism.** When arterial blood pressure declines, the kidneys release the enzymatic hormone *renin* into the blood. Renin triggers a series of reactions that produce angiotensin II, as mentioned previously. *Angiotensin II* is a potent vasoconstrictor, increasing blood pressure by increasing peripheral resistance. It also stimulates the adrenal cortex to secrete **aldosterone,** a hormone that enhances renal reabsorption of sodium, and prods the posterior pituitary to release ADH, which promotes more water reabsorption (Figure 19.9). As sodium moves into the bloodstream, water follows; thus, both blood volume and blood pressure rise.

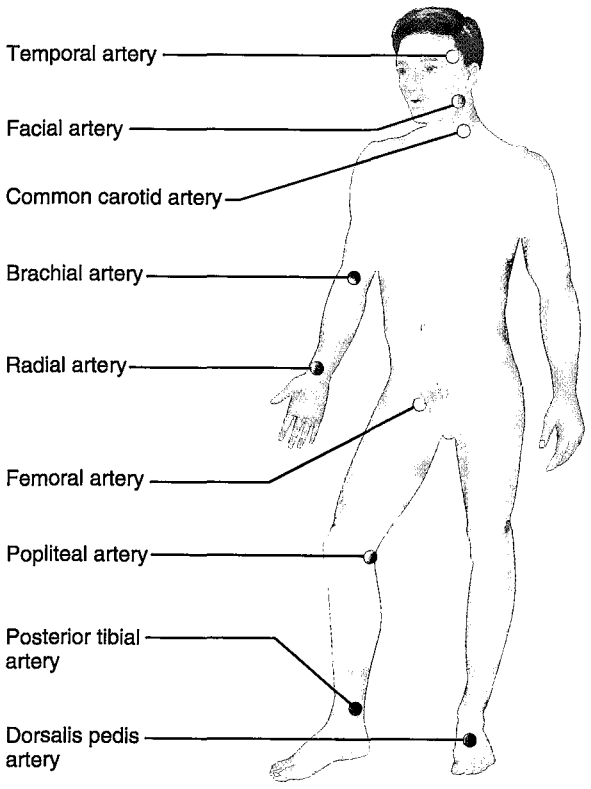

FIGURE 19.11 **Body sites where the pulse is most easily palpated.** (The specific arteries indicated are discussed on pp. 746–757.)

Monitoring Circulatory Efficiency

The efficiency of a person's circulation can be assessed by taking pulse and blood pressure measurements. These measurements, along with measurements of respiratory rate and body temperature, are referred to collectively as the body's **vital signs.** Let's examine how vital signs are determined or measured.

Taking a Pulse

The alternating expansion and recoil of arteries during each cardiac cycle allow us to feel a pressure wave—a **pulse**—that is transmitted through the arterial tree. You can feel a pulse in any artery that lies close to the body surface by compressing the artery against firm tissue, and this provides an easy way to count heart rate. Because it is so accessible, the point where the radial artery surfaces at the wrist, the *radial pulse,* is routinely used to take a pulse measurement, but there are several other clinically important arterial pulse points (Figure 19.11). Because these same points are compressed to stop blood flow into distal tissues during hemorrhage, they are also called **pressure points.** For example, if you seriously lacerate your hand, you can slow or stop the bleeding by compressing the radial or the brachial artery.

Monitoring pulse rate is an easy way to assess the effects of activity, postural changes, and emotions on heart rate. For example, the pulse of a healthy man may be around 66 beats per minute when he is lying down, rise to 70 when he sits up, and rise to 80 when he suddenly stands. During vigorous exercise or emotional upset, pulse rates between 140 and 180 are not unusual because of sympathetic nervous system effects on the heart.

Measuring Blood Pressure

Most often, systemic arterial blood pressure is measured indirectly in the brachial artery of the arm by the **auscultatory method** (aw-skul'tah-to"re). The *blood pressure cuff,* or *sphygmomanometer* (sfig"mo-mah-nom'ĕ-ter; *sphygmo* = pulse), is wrapped snugly around the arm just superior to the elbow and inflated until the cuff pressure exceeds systolic pressure. At this point, blood flow into the arm is stopped and a brachial pulse cannot be felt or heard. As the cuff pressure is gradually reduced, the examiner listens (auscultates) with a stethoscope for sounds in the brachial artery. The pressure read when the first soft tapping sounds are heard (the first point at which a small amount of blood is spurting through the constricted artery) is systolic pressure. As the cuff pressure is reduced further, these sounds, called the *sounds of Korotkoff,* become louder and more distinct, but when the artery is no longer constricted and blood flows freely, the sounds can no longer be heard. The pressure at which the sounds first disappear is the diastolic pressure.

In normal adults at rest, systolic pressure varies between 110 and 140 mm Hg, and diastolic pressure between 70 and 80 mm Hg. Blood pressure also cycles over a 24-hour period, peaking in the morning in response to waxing and waning levels of various hormones (epinephrine, glucocorticoids, and perhaps retinoic acid). These hormones can either bind directly to receptors that control vasoconstriction or increase the number of receptors available.

Extrinsic factors also play a role: Blood pressure varies with age, sex, weight, race, mood, physical activity, posture, and socioeconomic status. What is "normal" for you may not be normal for your grandfather or your neighbor. Nearly all of these variations can be explained in terms of the factors affecting blood pressure discussed earlier.

Alterations in Blood Pressure

Hypotension

Hypotension, or low blood pressure, is a systolic pressure below 100 mm Hg. In many cases, hypotension simply reflects individual variations and is no cause for concern. In fact, low blood pressure is

often associated with long life and an old age free of cardiovascular illness.

HOMEOSTATIC IMBALANCE

Elderly people are prone to *orthostatic hypotension*—temporary low blood pressure and dizziness when they rise suddenly from a reclining or sitting position. Because the aging sympathetic nervous system does not respond as quickly as it once did to postural changes, blood pools briefly in the lower limbs, reducing blood pressure and consequently blood delivery to the brain. Making postural changes slowly to give the nervous system time to adjust usually prevents this problem.

Chronic hypotension may hint at poor nutrition because poorly nourished people are often anemic and have inadequate levels of blood proteins. Because blood viscosity is low, their blood pressure is also lower than normal. Chronic hypotension also warns of Addison's disease (inadequate adrenal cortex function), hypothyroidism, or severe tissue wasting. *Acute hypotension* is one of the most important signs of circulatory shock (p. 740) and a threat to patients undergoing surgery and those in intensive care units. ●

Hypertension

Hypertension, high blood pressure, may be transient or persistent. Transient elevations in systolic pressure occur as normal adaptations during fever, physical exertion, and emotional upset. Persistent hypertension is common in obese people because the total length of their blood vessels is relatively greater than that in thinner individuals.

HOMEOSTATIC IMBALANCE

Chronic hypertension is a common and dangerous disease that warns of increased peripheral resistance. An estimated 30% of people over the age of 50 years are hypertensive. Although this "silent killer" is usually asymptomatic for the first 10 to 20 years, it slowly but surely strains the heart and damages the arteries. Prolonged hypertension is the major cause of heart failure, vascular disease, renal failure, and stroke. Because the heart is forced to pump against greater resistance, it must work harder, and in time the myocardium enlarges. When finally strained beyond its capacity to respond, the heart weakens and its walls become flabby. Hypertension also ravages the blood vessels, accelerating the progress of atherosclerosis (see *A Closer Look* on pp. 718–719). As the vessels become increasingly blocked, blood flow to the tissues becomes inadequate and vascular complications appear in the brain, heart, kidneys, and retinas of the eyes.

Although hypertension and atherosclerosis are often linked, it is often difficult to blame hypertension on any distinct anatomical pathology. Hypertension is defined physiologically as a condition of sustained arterial pressure of 140/90 or higher, and the higher the pressure, the greater the risk for serious cardiovascular problems. As a rule, elevated diastolic pressures are more significant medically, because they always indicate progressive occlusion and/or hardening of the arterial tree.

About 90% of hypertensive people have **primary,** or **essential, hypertension,** in which no underlying cause has been identified. However, the following factors are believed to be involved:

1. Diet. Dietary factors that contribute to hypertension include high intakes of sodium, saturated fat, and cholesterol and deficiencies in certain metal ions (K^+, Ca^{2+}, and Mg^{2+}).
2. Obesity.
3. Age. Clinical signs of the disease usually appear after age 40.
4. Diabetes mellitus.
5. Heredity. Hypertension runs in families. Children of hypertensive parents are twice as likely to develop hypertension as are children of normotensive parents. More blacks than whites are hypertensive, and the course of the disease varies in different population groups.
6. Stress. Particularly at risk are "hot reactors," people whose blood pressure zooms upward during every stressful event.
7. Smoking. Nicotine enhances the sympathetic nervous system's vasoconstrictor effects.

Primary hypertension cannot be cured, but most cases can be controlled by restricting salt, fat, and cholesterol intake, losing weight, stopping smoking, managing stress, and taking antihypertensive drugs. Drugs commonly used are diuretics, beta-blockers, calcium channel blockers, and angiotensin-converting enzyme (ACE) inhibitors. Inhibiting ACE suppresses the renin-angiotensin mechanism.

Secondary hypertension, which accounts for 10% of cases, is due to identifiable disorders, such as obstruction of the renal arteries, kidney disease, arteriosclerosis, and endocrine disorders such as hyperthyroidism and Cushing's disease. Treatment for secondary hypertension is directed toward correcting the causative problem. ●

Blood Flow Through Body Tissues: Tissue Perfusion

Blood flow through body tissues, or **tissue perfusion,** is involved in (1) delivery of oxygen and nutrients to, and removal of wastes from, tissue cells, (2) gas exchange in the lungs, (3) absorption of

Q *Why is blood delivery to the skin vasculature increased during strenuous exercise?*

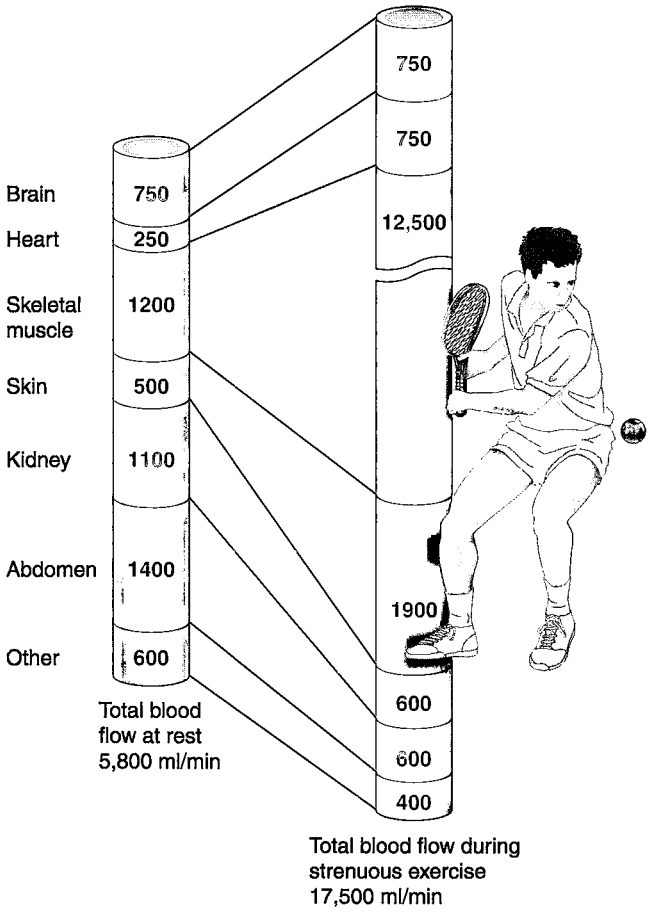

FIGURE 19.12 **Distribution of blood flow at rest and during strenuous exercise.**

nutrients from the digestive tract, and (4) urine formation in the kidneys. The rate of blood flow to each tissue and organ is almost exactly the right amount to provide for proper function—no more, no less. When the body is at rest, the brain receives about 13% of total blood flow, the heart 4%, kidneys 20%, and abdominal organs 24%. Skeletal muscles, which make up almost half of body mass, normally receive about 20% of total blood flow. During exercise, however, nearly all of the increased cardiac output flushes into the skeletal muscles and blood flow to the kidneys and digestive organs is reduced (Figure 19.12).

A *Muscle activity generates heat, which must be dissipated if homeostasis is to be maintained. The skin is the body's heat exchange site.*

Velocity of Blood Flow

Have you ever watched a swift river emptying into a large lake? The water's speed decreases as it enters the lake until it becomes almost imperceptible. This is because the total cross-sectional area of the lake is much larger than that of the river. Velocity in this case is *inversely* related to cross-sectional area. The same thing happens with blood flow inside our blood vessels. As shown in Figure 19.13, the speed or velocity of blood flow changes as blood travels through the systemic circulation. It is fastest in the aorta and other large arteries (the river), slowest in the capillaries (whose large total cross-sectional area make them analogous to the lake), and then picks up speed again in the veins (the river again).

Just as in our analogy of the river and lake, blood flows fastest where the total cross-sectional area is least. As the arterial system branches, the total cross-sectional area of the vascular bed increases, and the velocity of blood flow declines proportionately. Even though the individual branches have smaller lumens, their *combined* cross-sectional areas and thus the volume of blood they can hold are much greater than that of the aorta. For example, the cross-sectional area of the aorta is 2.5 cm^2 but that of all the capillaries is 4500 cm^2. This difference in cross-sectional area results in a fast blood flow in the aorta (40–50 cm/s) and a slow blood flow in the capillaries (about 0.03 cm/s). Slow capillary flow is beneficial because it allows adequate time for exchanges between the blood and tissue cells.

As capillaries combine to form first venules and then veins, total cross-sectional area declines and velocity increases. The cross-sectional area of the venae cavae is 8 cm^2, and the velocity of blood flow varies from 10 to 30 cm/s in those vessels, depending on the activity of the skeletal muscle pump.

Autoregulation: Local Regulation of Blood Flow

Autoregulation is the automatic adjustment of blood flow to each tissue in proportion to the tissue's requirements at any instant. This process is regulated by local conditions and is largely independent of systemic factors. The MAP is the same everywhere in the body and homeostatic mechanisms adjust cardiac output as needed to maintain that constant pressure. Changes in blood flow through individual organs are controlled *intrinsically* by modifying the diameter of local arterioles feeding the capillaries. You can compare blood flow autoregulation to water use in your home. To get water in a sink, or a garden hose, you have to turn on a faucet. Whether you have several taps open or none, the pressure in the main water pipe in the street remains

Q *Does the speed of blood flow vary directly or inversely with the cross-sectional area of the vascular bed?*

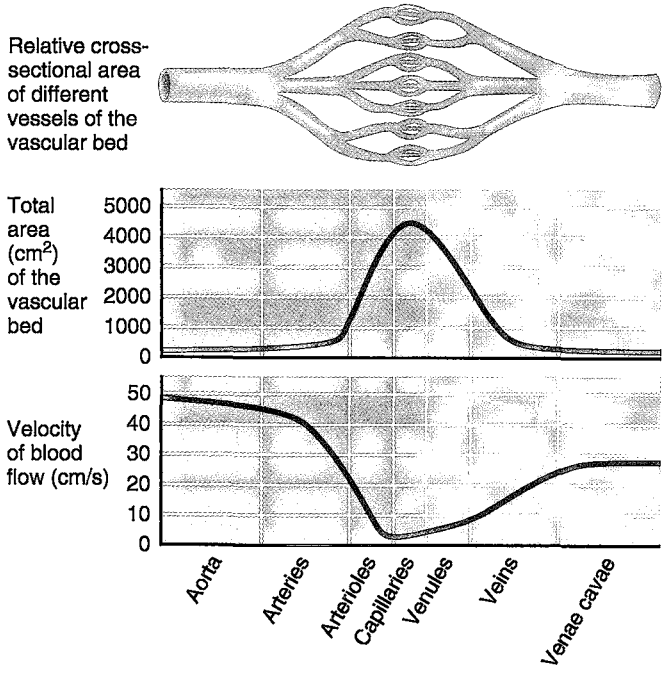

FIGURE 19.13 **Relationship between blood flow velocity and total cross-sectional area in various blood vessels of the systemic circulation.**

relatively constant, as it does in the even larger water lines closer to the pumping station. Similarly, what is happening in the arterioles feeding the capillary beds of a given organ has little effect on pressure in the muscular artery feeding the organ, or in the large elastic arteries. The pumping station is, of course, the heart. The beauty of this system is that as long as the water company (circulatory feedback mechanisms) maintains a relatively constant water pressure (MAP), local demand regulates the amount of fluid (blood) delivered to various areas.

Thus, organs regulate their own blood flows by varying the resistance of their arterioles. As described next, these intrinsic control mechanisms may be classed as *metabolic* or *myogenic* (Figure 19.14).

Metabolic Controls

In most tissues, declining levels of oxygen and nutrients are the strongest stimuli for autoregulation. Certain other substances released by metabolically active tissues (such as K^+, H^+, adenosine, lactic acid, and prostaglandins) also serve as autoregulation stimuli. The relative importance of these factors is not clear. Many of them act directly to relax vascular smooth muscle, but some may act by causing the release of nitric oxide from vascular endothelial cells. **Nitric oxide (NO)** is a powerful vasodilator which acts via a cyclic GMP second-messenger system. NO is quickly destroyed and its potent vasodilator effects are very brief. However, some researchers believe that NO can be transported over longer distances by being bound to chemical buffers in the blood and that it is released where vasodilation is needed. Until recently the sympathetic nervous system was thought to rule blood vessel diameter, but we now know that its primary vascular role is to produce vasoconstriction, and that NO plays the major role in causing vasodilation. The endothelium also releases potent vasoconstrictors, including the family of peptides called **endothelins,** which are among the most potent vasoconstrictors known.

Inflammatory chemicals (such as histamine, kinins, and prostaglandins) released in injury, infection, or allergic reactions also cause vasodilation. The net result of metabolically controlled autoregulation is immediate vasodilation of the arterioles serving the capillary beds of the "needy" tissues, and therefore a temporary increase in blood flow to the area. This is accompanied by relaxation of the precapillary sphincters, which allows blood to surge through the true capillaries and become available to the tissue cells.

Myogenic Controls

Fluctuations in systemic blood pressure would cause problems for individual organs were it not for the **myogenic responses** (*myo* = muscle; *gen* = origin) of vascular smooth muscle. Inadequate blood perfusion through an organ is quickly followed by a decline in the organ's metabolic rate and, if prolonged, organ death. Likewise, excessively high arterial pressure and tissue perfusion can be dangerous because the combination may rupture more fragile blood vessels. Fortunately, vascular smooth muscle prevents these problems by responding directly to passive stretch (increased intravascular pressure) with increased tone, which resists the stretch and causes vasoconstriction. Reduced stretch promotes vasodilation and increases blood flow into the tissue. Hence, the myogenic mechanism keeps tissue perfusion fairly constant despite most variations in systemic pressure.

Generally, both chemical (metabolic) and physical (myogenic) factors determine the final autoregulatory response of a tissue. For example, **reactive hyperemia** (hi"per-e'me-ah) refers to the dramatically increased blood flow into a tissue that occurs

A *Inversely: As cross-sectional area of the vascular bed increases, flow velocity decreases.*

Q *Suppose you were in a bicycle race. What would happen to the smooth muscle in the arterioles supplying your quadriceps femoris muscle? What are the key mechanisms in this case?*

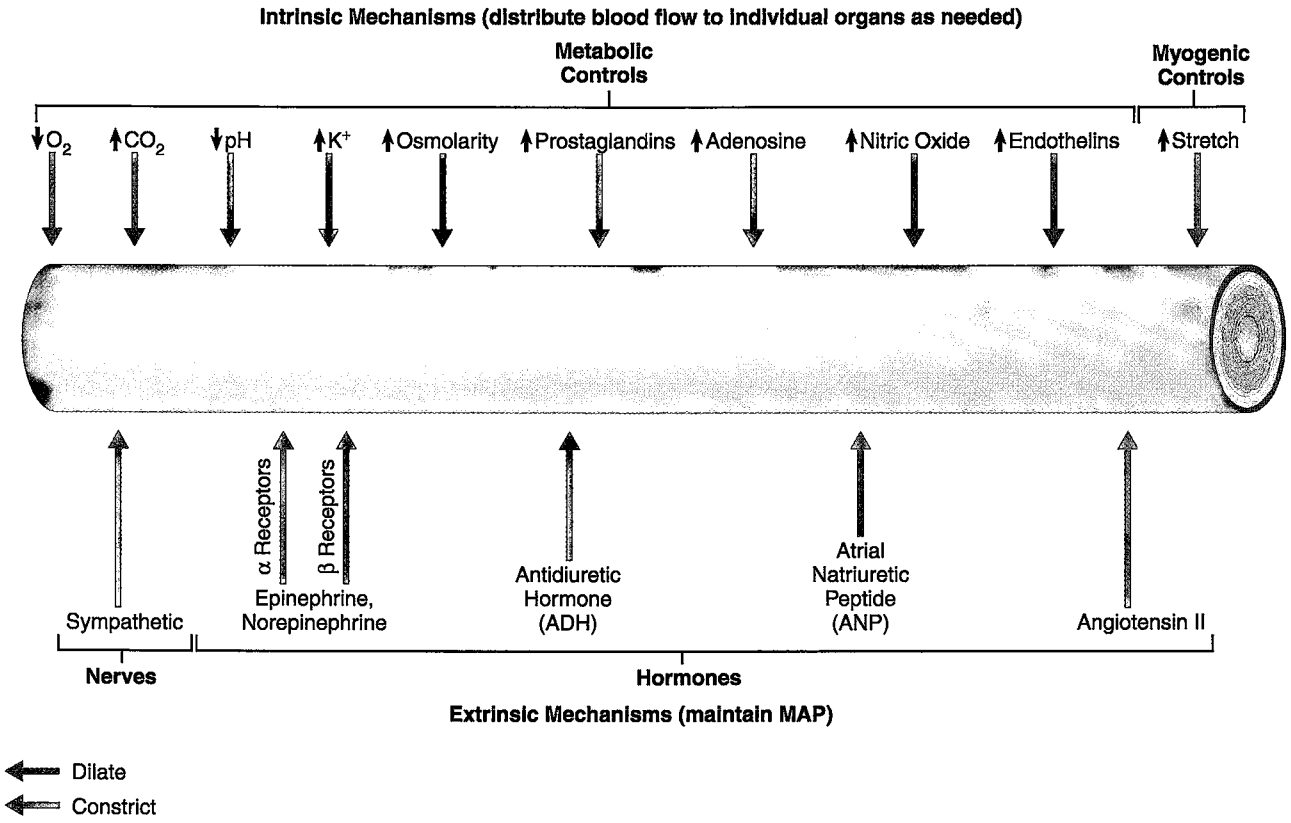

FIGURE 19.14 **Summary of control of arteriolar smooth muscle in the systemic circulation.** Arteriolar smooth muscle is under both intrinsic (local) and extrinsic control. Intrinsic mechanisms (metabolic and myogenic) control the distribution of blood flow to each organ and tissue according to its needs. Extrinsic mechanisms primarily maintain mean arterial pressure (MAP) but also redistribute blood during exercise and thermoregulation. α-Adrenergic receptors (smooth muscle contraction, arteriolar constriction) are located in arterioles supplying most tissues, whereas β-adrenergic receptors (smooth muscle relaxation, arteriolar dilation) are located primarily in arterioles supplying skeletal and heart muscle.

19

after the blood supply to the area has been temporarily blocked. It results both from the myogenic response and from an accumulation of metabolic wastes in the area during occlusion. The various intrinsic (local) and extrinsic controls of arteriolar diameter are summarized in Figure 19.14.

Long-Term Autoregulation

If the nutrient requirements of a tissue are greater than the short-term autoregulatory mechanism can easily supply, a long-term autoregulatory mechanism may evolve over a period of weeks or months to enrich the local blood flow still more. The number of blood vessels in the region increases, and existing vessels enlarge. This phenomenon, called *angiogenesis*, is particularly common in the heart when a coronary vessel is partially occluded. It occurs throughout the body in people who live in high-altitude areas, where the air contains less oxygen.

A *Intrinsic metabolic controls cause arteriolar smooth muscle to relax, dilating the vessel and supplying more O_2 and nutrients. Epinephrine from the adrenal medulla may reinforce these mechanisms via β_2 receptors.*

Blood Flow in Special Areas

Each organ has special requirements and functions that are revealed in its pattern of autoregulation. Autoregulation in the brain, heart, and kidneys is extraordinarily efficient. In those organs, adequate perfusion is maintained even when MAP is fluctuating.

Skeletal Muscles

Blood flow in skeletal muscle varies with fiber type and muscle activity. Generally speaking, capillary density and blood flow is greater in red (slow oxidative) fibers than in white (fast glycolytic) fibers. Resting skeletal muscles receive about 1 L of blood per minute, and only about 25% of their capillaries are open. During such periods, myogenic and general neural mechanisms predominate. When muscles become active, blood flow increases *(hyperemia)* in direct proportion to their greater *metabolic* activity, a phenomenon called **active** or **exercise hyperemia.**

This form of autoregulation occurs almost entirely in response to the decreased oxygen concentration and accumulation of metabolic factors that result from the "revved-up" metabolism of working muscles. However, systemic adjustments mediated by the vasomotor center must also occur to ensure that blood delivery to the muscles is both faster and more abundant. During exercise, sympathetic nervous system activity increases. Norepinephrine released from sympathetic nerve endings causes vasoconstriction of the vessels of blood reservoirs such as those of the digestive viscera and skin, diverting blood away from these regions temporarily and ensuring that more blood reaches the muscles. In skeletal muscles, the sympathetic nervous system and local metabolic controls have opposing effects on arteriolar diameter. During exercise, local controls override sympathetic vasoconstriction. Consequently, blood flow can increase tenfold or more during physical activity (see Figure 19.12), and virtually all capillaries in the active muscles open to accommodate the increased flow.

Epinephrine acting at beta (β) adrenergic receptors and acetylcholine acting at cholinergic receptors were once thought to contribute to arteriolar dilation during exercise. However, these appear to have little physiological importance in the control of human skeletal muscle blood flow. Without question, strenuous exercise is one of the most demanding conditions the cardiovascular system faces. Ultimately, the major factor determining how long muscles can continue to contract vigorously is the ability of the cardiovascular system to deliver adequate oxygen and nutrients and remove waste products.

The Brain

Blood flow to the brain averages 750 ml/min and is maintained at a relatively constant level. The necessity for constant cerebral blood flow becomes crystal clear when one takes into account that neurons are totally intolerant of ischemia.

Although the brain is the most metabolically active organ in the body, it is the least able to store essential nutrients. Cerebral blood flow is regulated by one of the body's most precise autoregulatory systems and is tailored to local neuronal need. Thus, when you make a fist with your right hand, the neurons in the left cerebral motor cortex controlling that movement receive a more abundant blood supply than the adjoining neurons. Brain tissue is exceptionally sensitive to declining pH, and increased blood carbon dioxide levels (resulting in acidic conditions in brain tissue) cause marked vasodilation. Oxygen deficit is a much less potent stimulus for autoregulation. However, very high carbon dioxide levels abolish autoregulatory mechanisms and severely depress brain activity.

Besides metabolic controls, the brain also has a myogenic mechanism that protects it from possibly damaging changes in blood pressure. When MAP declines, cerebral vessels dilate to ensure adequate brain perfusion. When MAP rises, cerebral vessels constrict, protecting the small, more fragile vessels farther along the pathway from rupture due to excessive pressure. Under certain circumstances, such as brain ischemia caused by rising intracranial pressure (as with a brain tumor), the brain (via the medullary cardiovascular centers) regulates its own blood flow by triggering a rise in systemic blood pressure. However, when systemic pressure changes are extreme, the brain becomes vulnerable. Fainting, or *syncope* (sin'cuh-pe; "cutting short"), occurs when MAP falls below 60 mm Hg. Cerebral edema is the usual result of pressures over 160 mm Hg, which dramatically increase brain capillary permeability.

The Skin

Blood flow through the skin (1) supplies nutrients to the cells, (2) aids in body temperature regulation, and (3) provides a blood reservoir. The first function is served by autoregulation in response to the need for oxygen; the second and third require neural intervention. The primary function of the cutaneous circulation is to help maintain body temperature, so we will concentrate on the skin's temperature regulation function here.

Below the skin surface are extensive venous plexuses, through which the blood flow can change from 50 ml/min to as much as 2500 ml/min, depending on body temperature. This capability reflects neural adjustments of blood flow through arterioles and through unique coiled arteriovenous anastomoses. These tiny A-V shunts are located mainly in the fingertips, palms of the hands, toes, soles of the feet, ears, nose, and lips. They are richly supplied with sympathetic nerve endings (a characteristic that sets them apart from the shunts of most other capillary beds), and are controlled by reflexes initiated by temperature receptors or signals from higher CNS centers. The arterioles, in addition, are responsive to metabolic autoregulatory stimuli.

When the skin surface is exposed to heat, or body temperature rises for other reasons (such as vigorous exercise), the hypothalamic "thermostat" signals for reduced vasomotor stimulation of the skin vessels. As a result, warm blood flushes into the capillary beds and heat radiates from the skin surface. Vasodilation of the arterioles is enhanced even more when we sweat, because an enzyme in perspiration acts on a protein present in tissue fluid to produce *bradykinin*, which stimulates the vessel's endothelial cells to release the potent vasodilator NO.

When the ambient temperature is cold and body temperature drops, superficial skin vessels are strongly constricted. Hence, blood almost entirely bypasses the capillaries associated with the arteriovenous anastomoses, diverting the warm blood to the deeper, more vital organs. Paradoxically, the skin may stay quite rosy because some blood gets "trapped" in the superficial capillary loops as the shunts swing into operation; also, the chilled skin cells take up less O_2.

The Lungs

Blood flow through the pulmonary circuit to and from the lungs is unusual in many ways. The pathway is relatively short, and pulmonary arteries and arterioles are structurally like veins and venules. That is, they have thin walls and large lumens. Because resistance to blood flow is low in the pulmonary arterial system, less pressure is needed to propel blood through those vessels. Consequently, arterial pressure in the pulmonary circulation is much lower than in the systemic circulation (24/8 versus 120/80 mm Hg).

Another unusual feature of the pulmonary circulation is that the autoregulatory mechanism is the *opposite* of what is seen in most tissues: Low pulmonary oxygen levels cause vasoconstriction, and high levels promote vasodilation. While this may seem odd, it is perfectly consistent with the gas exchange role of this circulation. When the air sacs of the lungs are flooded with oxygen-rich air, the pulmonary capillaries become flushed with blood and ready to receive the oxygen load. If the air sacs are collapsed or blocked with mucus, the oxygen content in those areas is low, and blood largely bypasses those nonfunctional areas.

The Heart

Movement of blood through the smaller vessels of the coronary circulation is influenced by aortic pressure and by the pumping activity of the ventricles. When the ventricles contract and compress the coronary vessels, blood flow through the myocardium stops. As the heart relaxes, the high aortic pressure forces blood through the coronary circulation. Under normal circumstances, the myoglobin in cardiac cells stores sufficient oxygen to satisfy the cells' oxygen needs during systole. However, an abnormally rapid heartbeat seriously reduces the ability of the myocardium to receive adequate oxygen and nutrients during diastole.

Under resting conditions, blood flow through the heart is about 250 ml/min and is probably controlled by a myogenic mechanism. Consequently, blood flow remains fairly constant despite wide variations (50 to 140 mm Hg) in coronary perfusion pressure. During strenuous exercise, the coronary vessels dilate in response to local accumulation of carbon dioxide (leading to acidosis), and blood flow may increase three to four times (see Figure 19.12). Additionally, any event that decreases the oxygen content of the blood releases vasodilators that adjust the O_2 supply to the O_2 demand. This enhanced blood flow during increased heart activity is important because under resting conditions, cardiac cells use as much as 65% of the oxygen carried to them in blood. (Most other tissue cells use about 25% of the delivered oxygen.) Thus, increasing the blood flow is the only way to make sufficient additional oxygen available to a more vigorously working heart.

Blood Flow Through Capillaries and Capillary Dynamics

Blood flow through capillary networks is slow and intermittent. This phenomenon, called **vasomotion,** reflects the on/off opening and closing of precapillary sphincters in response to local autoregulatory controls.

Capillary Exchange of Respiratory Gases and Nutrients

Oxygen, carbon dioxide, most nutrients, and metabolic wastes pass between the blood and interstitial fluid by diffusion. Recall that in **diffusion,** movement always occurs along a concentration gradient—each substance moving from an area of its higher concentration to an area of its lower concentration. Hence, oxygen and nutrients pass from the blood, where their concentration is fairly high, through the interstitial fluid to the tissue cells. Carbon dioxide and metabolic wastes leave the cells, where their content is higher, and diffuse into the capillary blood. There are four different routes across capillaries for different types of molecules (Figure 19.15). ① Lipid-soluble molecules, such as respiratory gases, diffuse through the lipid bilayer of the endothelial cell plasma membranes. Small water-soluble solutes, such as amino acids and sugars, pass through ② fluid-filled intercellular capillary clefts or ③ fenestrations. ④ Some larger molecules, such as proteins, are actively transported in pinocytotic vesicles or caveolae. As mentioned earlier, capillaries differ in their "leakiness," or permeability. Liver capillaries, for

instance, have large fenestrations that allow even proteins to pass freely, whereas brain capillaries are impermeable to most substances.

Fluid Movements: Bulk Flow

All the while nutrient and gas exchanges are occurring across the capillary walls by diffusion, bulk fluid flows are also going on. Fluid is forced out of the capillaries through the clefts at the arterial end of the bed, but most of it returns to the bloodstream at the venous end. While relatively unimportant to capillary exchange, bulk flow is extremely important in determining the relative fluid volumes in the bloodstream and the extracellular space. (Approximately 20 L of fluid are filtered out of the capillaries each day before being returned to the blood—almost seven times the total plasma volume!) As described next, the *direction and amount* of fluid that flows across the capillary walls reflect the balance between two dynamic and opposing forces—hydrostatic and colloid osmotic pressures (Figure 19.16).

Hydrostatic Pressures **Hydrostatic pressure** is the force exerted by a fluid pressing against a wall. In capillaries, hydrostatic pressure is the same as *capillary blood pressure*—the pressure exerted by blood on the capillary walls. **Capillary hydrostatic pressure (HP_c)** tends to force fluids through the capillary walls (a process called *filtration*), leaving behind cells and most proteins. Because blood pressure drops as blood flows along the length of a capillary bed, HP_c is higher at the arterial end of the bed (35 mm Hg) than at the venous end (17 mm Hg). In theory, blood pressure—which forces fluid out of the capillaries—is opposed by the **interstitial fluid hydrostatic pressure (HP_{if})** acting outside the capillaries and pushing fluid in. Thus, the *net* hydrostatic pressure acting on the capillaries at any point is the difference between HP_c and HP_{if}. However, there is usually very little fluid in the interstitial space, because the lymphatic vessels constantly withdraw it. Although HP_{if} may vary from slightly negative to slightly positive, traditionally it is assumed to be zero. For simplicity, that is the value we use here. The *net effective hydrostatic pressures* at the arterial and venous ends of the capillary bed are essentially equal to HP_c (in other words, to blood pressure) at those locations. This information is summarized in Figure 19.16.

Colloid Osmotic Pressures **Colloid osmotic pressure,** the force opposing hydrostatic pressure, is created by the presence in a fluid of large nondiffusible molecules, such as plasma proteins, that are unable to cross the capillary wall. Such molecules draw water toward themselves; that is, they encourage osmosis whenever the water concentration in their vicinity is lower than it is on the opposite side of the capillary

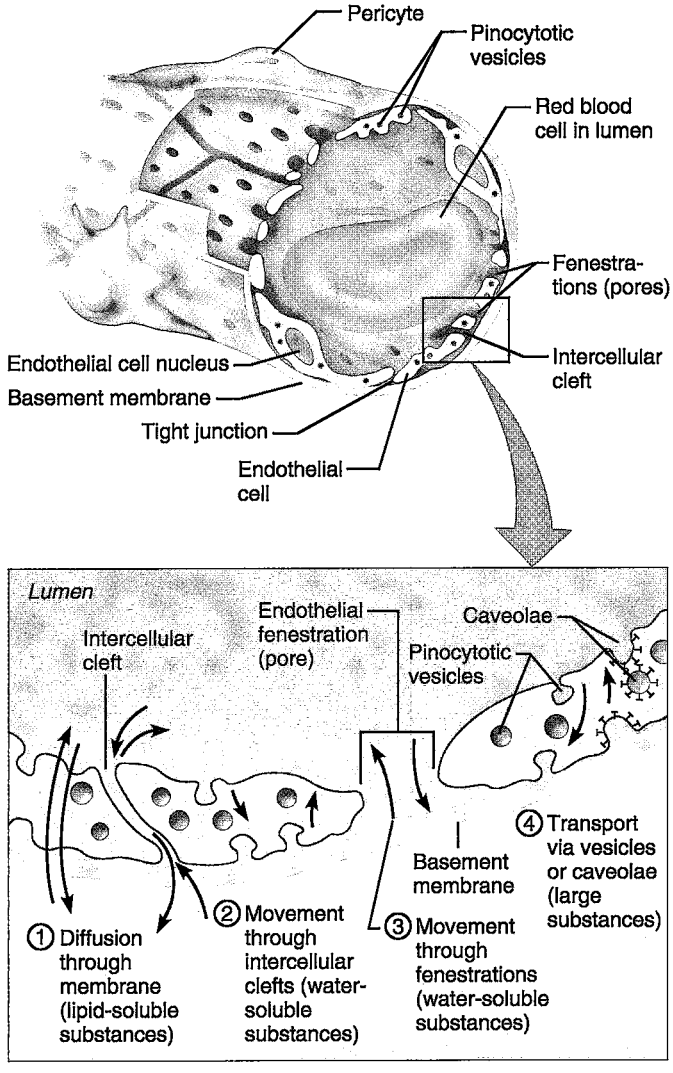

FIGURE 19.15 **Capillary transport mechanisms.** The four possible pathways or routes of transport across the endothelial cell wall of a fenestrated capillary. (The endothelial cell is drawn as if cut in cross section.)

membrane. The abundant plasma proteins in capillary blood (primarily albumin molecules) develop a **capillary colloid osmotic pressure (OP_c),** also called *oncotic pressure,* of approximately 26 mm Hg. Because interstitial fluid contains few proteins, its colloid osmotic pressure **(OP_{if})** is substantially lower—from 0.1 to 5 mm Hg. We use a value of 1 mm Hg for the OP_{if} in Figure 19.16. Unlike HP, OP does not vary significantly from one end of the capillary bed to the other. Thus, in our example, the *net osmotic pressure* that pulls fluid back into the capillary blood is $OP_c - OP_{if} = 26 \text{ mm Hg} - 1 \text{ mm Hg} = 25 \text{ mm Hg}$.

Hydrostatic-Osmotic Pressure Interactions To determine whether there is a net gain or net loss of fluid from the blood, we have to calculate the **net filtration pressure (NFP),** which considers all the forces acting at the capillary bed. At any point along a capillary, fluids

How would fluid flows change if the OP of the interstitial fluid rose dramatically—say because of a severe bacterial infection in the surrounding tissues?

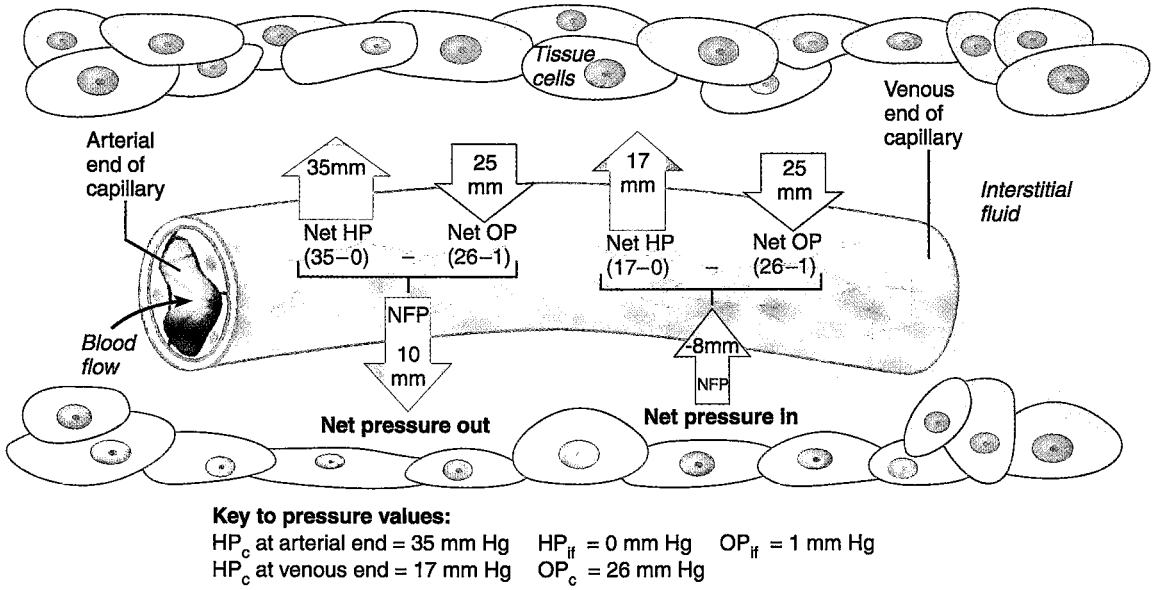

FIGURE 19.16 **Fluid flows at capillaries.** The direction of fluid movement depends on the difference between net hydrostatic pressure (HP), the force that tends to push fluid out of the capillary, and net colloid osmotic pressure (OP), the force that draws fluid back into the capillary. Because HP_{if} is taken to be zero, net HP ($HP_c - HP_{if}$) is equal to the hydrostatic pressure of the blood (HP_c), which varies along the length of the capillary. Net OP ($OP_c - OP_{if}$) reflects the fact that blood has a much higher content of nondiffusible solutes (proteins) than does interstitial fluid. At the arterial end of the capillary bed, net HP forcing fluid outward exceeds OP drawing water inward, resulting in a NFP (net filtration pressure) that promotes a net fluid loss from the capillary: NFP = 10 mm Hg. At the venule end of the bed, HP is overpowered by OP (NFP = −8 mm Hg), and fluid returns to the bloodstream.

will leave the capillary if net HP is greater than net OP, and fluids will enter the capillary if net OP exceeds net HP. As shown in Figure 19.16, hydrostatic forces dominate at the arterial end (all values are mm Hg):

$$\begin{aligned} NFP &= (HP_c - HP_{if}) - (OP_c - OP_{if}) \\ &= (35 - 0) - (26 - 1) \\ &= (35 - 25) = 10 \text{ mm Hg} \end{aligned}$$

Thus, in this example, a pressure of 10 mm Hg (net excess of HP) is forcing fluid out of the capillary. At the other, venous end, osmotic forces dominate:

$$\begin{aligned} NFP &= (17 - 0) - (26 - 1) \\ &= 17 - 25 = -8 \text{ mm Hg} \end{aligned}$$

The negative pressure value we see here indicates that the NFP (due to net excess of OP) is driving fluid *into* the capillary bed (a process called *reabsorption*). Thus, net fluid flow is *out* of the circulation at the arterial ends of capillary beds and *into* the circulation at the venous ends. However, more fluid enters the tissue spaces than is returned to the blood, resulting in a net loss of fluid from the circulation of about 1.5 ml/min. This fluid and any leaked proteins are picked up by the lymphatic vessels and returned to the vascular system, which accounts for the relatively low levels of both fluid and proteins in the interstitial space. Were this not so, this "insignificant" fluid loss would empty your blood vessels of plasma in about 24 hours!

Fluid that would ordinarily reenter the circulation at the venous end of the capillary bed would remain in the tissue spaces, held by the elevated OP of the interstitial fluid.

Circulatory Shock

Circulatory shock is any condition in which blood vessels are inadequately filled and blood cannot circulate normally. This results in inadequate blood flow to meet tissue needs. If the condition persists, cells die and organ damage follows.

The most common form of shock is **hypovolemic shock** (hi"po-vo-le'mik; *hypo* = low, deficient; *volemia* = blood volume), which results from large-scale loss of blood, as might follow acute hemorrhage,

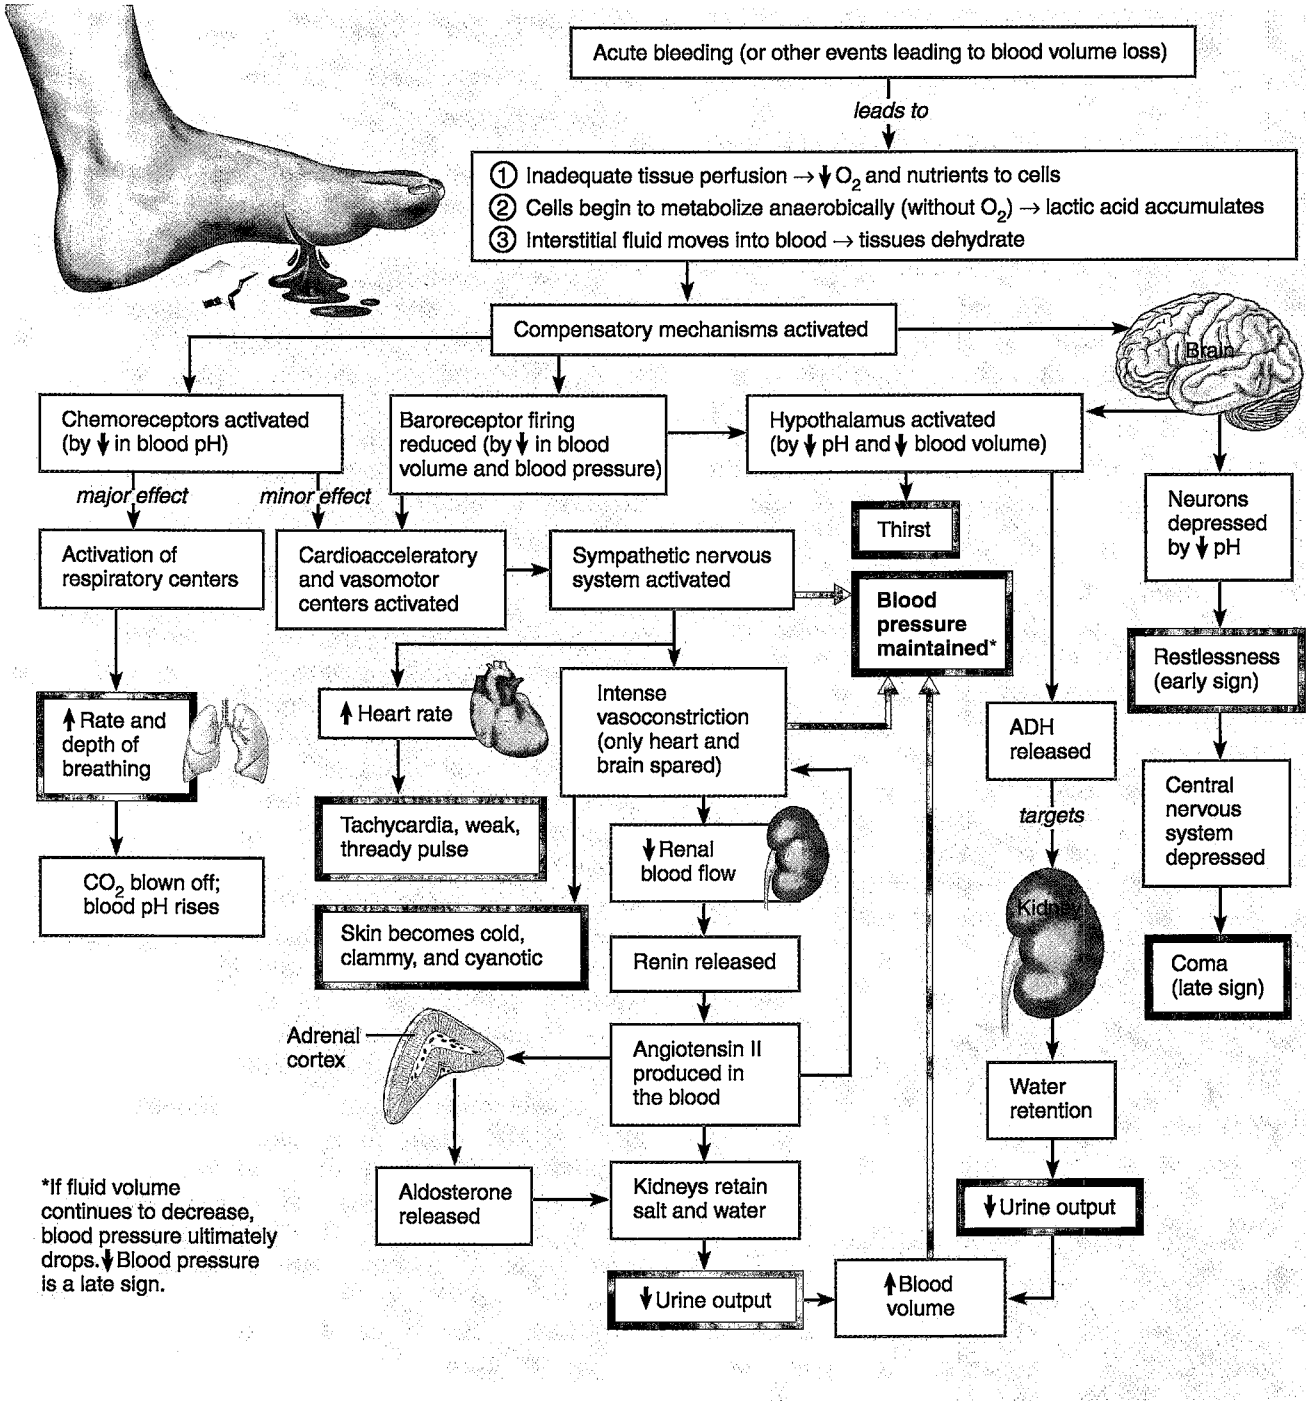

FIGURE 19.17 **Events and signs of compensated (nonprogressive) hypovolemic shock.** (Recognizable clinical signs are shown in *red-bordered boxes.*)

severe vomiting or diarrhea, or extensive burns. If blood volume drops rapidly, heart rate increases in an attempt to correct the problem. Thus, a weak, "thready" pulse is often the first sign of hypovolemic shock. Intense vasoconstriction also occurs, which shifts blood from the various blood reservoirs into the major circulatory channels and enhances venous return. Blood pressure is stable at first, but eventually drops if blood loss continues. A sharp drop in blood pressure is a serious, and late, sign of hypovolemic shock. The key to managing hypovolemic shock is to replace fluid volume as quickly as possible.

Although you have not yet explored all of the body systems that respond to hypovolemic shock, acute bleeding is such a threat to life that it seems important to have a comprehensive flowchart of its recognizable signs and symptoms and an accounting of the body's attempt to restore homeostasis. Figure 19.17

provides such a resource. Study it in part now, and in more detail later once you have studied the remaining body systems.

In **vascular shock,** blood volume is normal, but circulation is poor as a result of an abnormal expansion of the vascular bed caused by extreme vasodilation. The huge drop in peripheral resistance that follows is revealed by rapidly falling blood pressure. The most common causes of vascular shock are loss of vasomotor tone due to anaphylaxis (anaphylactic shock), a systemic allergic reaction in which body-wide vasodilation is triggered by the massive release of histamine; failure of autonomic nervous system regulation (also referred to as *neurogenic shock*); and septicemia *(septic shock),* a severe systemic bacterial infection (bacterial toxins are notorious vasodilators).

Transient vascular shock may occur when you sunbathe for a prolonged time. The heat of the sun on your skin causes cutaneous blood vessels to dilate. Then, if you stand up abruptly, blood pools briefly (because of gravity) in the dilated vessels of your lower limbs rather than returning promptly to the heart. Consequently, your blood pressure falls. The dizziness you feel at this point is a signal that your brain is not receiving enough oxygen.

Cardiogenic shock, or pump failure, occurs when the heart is so inefficient that it cannot sustain adequate circulation. Its usual cause is myocardial damage, as might follow numerous myocardial infarcts.

PART 3: CIRCULATORY PATHWAYS: BLOOD VESSELS OF THE BODY

19 The Two Main Circulations of the Body

When referring to the body's complex network of blood vessels, the term **vascular system** is often used. However, the heart is actually a double pump that serves two distinct circulations, each with its own set of arteries, capillaries, and veins. The *pulmonary circulation* is the short loop that runs from the heart to the lungs and back to the heart. The *systemic circulation* routes blood through a long loop to all parts of the body before returning it to the heart. Both circuits are shown schematically in Table 19.3 on pp. 744–745.

Systemic Arteries and Veins: Differences in Pathways and Courses

Although there are many similarities between the systemic arteries and veins, there are also important differences:

1. Whereas the heart pumps all of its blood into a single systemic artery—the aorta—blood returning to the heart is delivered largely by two terminal systemic veins, the superior and inferior venae cavae. The single exception to this is the blood draining from the myocardium of the heart, which is collected by the cardiac veins and reenters the right atrium via the coronary sinus.

2. All arteries run deep and are well protected by body tissues along most of their course, but both deep and superficial veins exist. Deep veins parallel the course of the systemic arteries, and with a few exceptions, the naming of these veins is identical to that of their companion arteries. Superficial veins run just beneath the skin and are readily seen, especially in the limbs, face, and neck. Because there are no superficial arteries, the names of the superficial veins do not correspond to the names of any of the arteries.

3. Unlike the fairly clear arterial pathways, venous pathways tend to have numerous interconnections, and many veins are represented by not one but two similarly named vessels. As a result, venous pathways are more difficult to follow.

4. In most body regions, there is a similar and predictable arterial supply and venous drainage. However, the venous drainage pattern in at least two important body areas is unique. First, venous blood draining from the brain enters large *dural sinuses* rather than typical veins. Second, blood draining from the digestive organs enters a special subcirculation, the *hepatic portal circulation,* and perfuses through the liver before it reenters the general systemic circulation.

Principal Vessels of the Systemic Circulation

Except for special vessels and shunts of the fetal circulation (described in Chapter 28), the principal arteries and veins of the systemic circulation are described in Tables 19.4 through 19.13.

Notice that by convention, oxygen-rich blood is shown red, while blood that is relatively oxygen-poor is depicted blue, regardless of vessel types. A unique convention used in the schematic flowcharts (pipe

diagrams) that accompany each table is that the vessels that would be closer to the viewer are shown in brighter, more intense colors than those deeper or farther from the viewer—for example, for veins, the darker blue vessels would be closer to the viewer in the body region shown.

Developmental Aspects of the Blood Vessels

The endothelial lining of blood vessels is formed by mesodermal cells, which collect in little masses called **blood islands** throughout the microscopic embryo. These then form fragile sprouting extensions that reach toward one another and toward the forming heart to lay down the rudimentary vascular tubes. Meanwhile, adjacent mesenchymal cells, stimulated by platelet-derived growth factor, surround the endothelial tubes, forming the stabilizing muscular and fibrous coats of the vessel walls. It appears that, in arteries at least, the pattern of vessel branching is orchestrated by vascular endothelial growth factor released by nearby nerves, and forming arteries snuggle closely to those nerves. As noted in Chapter 18, the heart is pumping blood through the rudimentary vascular system by the fourth week of development.

In addition to the fetal shunts that bypass the nonfunctional lungs (the *foramen ovale* and *ductus arteriosus*), other vascular modifications are found in the fetus. A special vessel, the *ductus venosus*, largely bypasses the liver. Also important are the *umbilical vein* and *arteries*, large vessels that circulate blood between the fetal circulation and the placenta where gas and nutrient exchanges occur with the mother's blood (see Chapter 28). Once the fetal circulatory pattern is laid down, few vascular changes occur until birth, when the umbilical vessels and shunts are occluded.

In contrast to congenital heart diseases, congenital vascular problems are rare, and blood vessels are remarkably trouble-free during youth. Vessel formation occurs as needed to support body growth, wound healing, and to rebuild vessels lost each month during a woman's menstrual cycle. As we age, signs of vascular disease begin to appear. In some, the venous valves weaken, and purple, snakelike varicose veins appear. In others, more insidious signs of inefficient circulation appear: tingling in the fingers and toes and cramping of muscles.

Although the degenerative process of atherosclerosis begins in youth, its consequences are rarely apparent until middle to old age, when it may precipitate a myocardial infarct or stroke. Until puberty, the blood vessels of boys and girls look alike, but from puberty to about age 45, women have strikingly less atherosclerosis than men because of the protective effects of estrogen, the beneficial effects of which are well documented. By enhancing nitric oxide production, inhibiting endothelin release, and blocking voltage-gated Ca^{2+} channels, estrogen's effect on blood vessels is to reduce resistance to blood flow. Estrogen also stimulates the liver to produce enzymes that speed up catabolism of LDLs and increase the production of HDLs, thus reducing the risk of atherosclerosis (see *A Closer Look*). Between the ages of 45 and 65, when estrogen production wanes in women, this "gap" between the sexes closes, and males and females above age 65 are equally at risk for cardiovascular disease. You might expect that giving postmenopausal women supplementary estrogen would maintain this protective effect. Surprisingly, clinical trials have shown that this is not the case.

Blood pressure changes with age. In a newborn baby, arterial pressure is about 90/55. Blood pressure rises steadily during childhood to finally reach the adult value (120/80). In old age, normal blood pressure averages 150/90, which is hypertensive in younger people. After age 40, the incidence of hypertension increases dramatically. Unlike atherosclerosis, which is increasingly important in old age, hypertension claims many youthful victims and is the single most important cause of sudden cardiovascular death in men in their early 40s and 50s.

At least some vascular disease is a product of our modern technological culture. "Blessed" with high-protein, lipid-rich diets, empty-calorie snacks, energy-saving devices, and high-stress jobs, many of us are struck down prematurely. Cardiovascular disease can be prevented somewhat by diet modifications, regular aerobic exercise, and eliminating cigarette smoking. Poor diet, lack of exercise, and smoking are probably more detrimental to your blood vessels than aging itself could ever be!

■ ■ ■

Now that we have described the structure and function of blood vessels, our survey of the cardiovascular system is complete. The pump, the plumbing, and the circulating fluid form a dynamic organ system that ceaselessly services every other organ system of the body, as summarized in *Making Connections* on pp. 768–769. However, our study of the *circulatory system* is still unfinished because we have yet to examine the lymphatic system, which acts with the cardiovascular system to ensure continuous circulation and to provide sites from which lymphocytes can police the body and provide for immunity. These are the topics of Chapter 20.

TABLE 19.3 **Pulmonary and Systemic Circulations**

Pulmonary Circulation

The pulmonary circulation (Figure 19.18a) functions only to bring blood into close contact with the alveoli (air sacs) of the lungs so that gases can be exchanged. It does not directly serve the metabolic needs of body tissues.

Oxygen-poor, dark red blood enters the pulmonary circulation as it is pumped from the right ventricle into the large **pulmonary trunk** (Figure 19.18b), which runs diagonally upward for about 8 cm and then divides abruptly to form the **right** and **left pulmonary arteries.** In the lungs, the pulmonary arteries subdivide into the **lobar arteries** (lo'bar) (three in the right lung and two in the left lung), each of which serves one lung lobe. The lobar arteries accompany the main bronchi into the lungs and then branch profusely, forming first arterioles and then the dense networks of **pulmonary capillaries** that surround and cling to the delicate air sacs. It is here that oxygen moves from the alveolar air to the blood and carbon dioxide moves from the blood to the alveolar air. As gases are exchanged and the oxygen content of the blood rises, the blood becomes bright red. The pulmonary capillary beds drain into venules, which join to form the two **pulmonary veins** exiting from each lung. The four pulmonary veins complete the circuit by unloading their precious cargo into the left atrium of the heart. Note that any vessel with the term *pulmonary* or *lobar* in its name is part of the pulmonary circulation. All others are part of the systemic circulation.

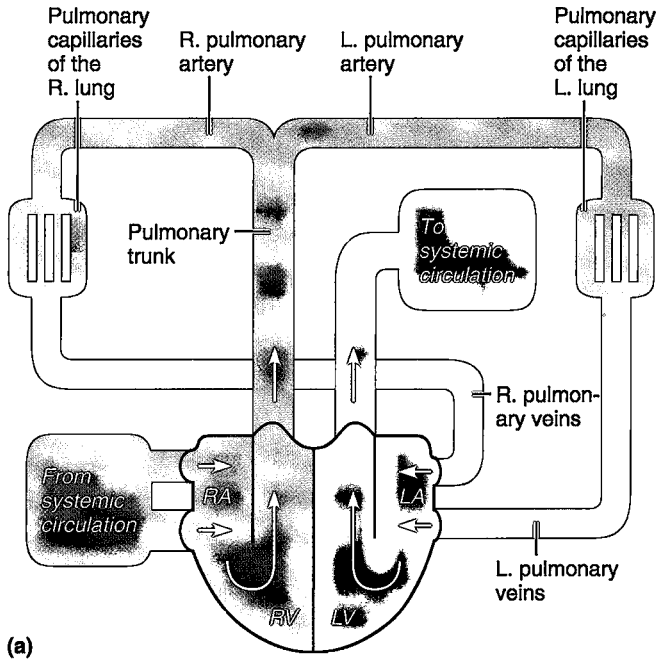

FIGURE 19.18 **Pulmonary circulation. (a)** Schematic flowchart. **(b)** Illustration. The arterial system is shown in blue to indicate that the blood carried is oxygen-poor; the venous drainage is shown in red to indicate that the blood transported is oxygen-rich.

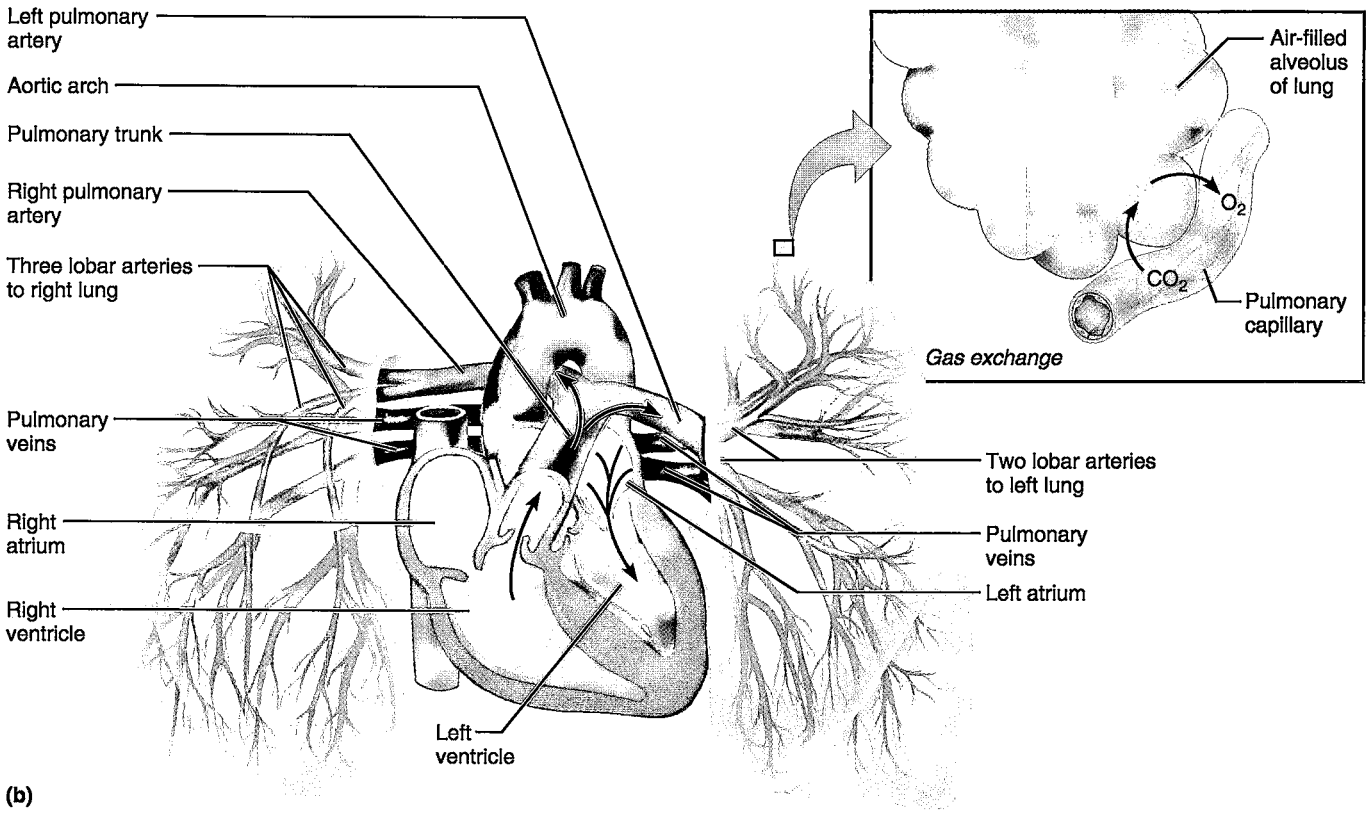

TABLE 19.3 (continued)

Pulmonary arteries carry oxygen-poor, carbon dioxide–rich blood, and pulmonary veins carry oxygen-rich blood.* This is opposite the situation in the systemic circulation, where arteries carry oxygen-rich blood and veins carry carbon dioxide–rich, relatively oxygen-poor blood.

Systemic Circulation

The systemic circulation provides the *functional blood supply* to all body tissues; that is, it delivers oxygen, nutrients, and other needed substances while carrying away carbon dioxide and other metabolic wastes. Freshly oxygenated blood* returning from the pulmonary circuit is pumped out of the left ventricle into the aorta (Figure 19.19). From the aorta, blood can take various routes, because essentially all systemic arteries branch from this single great vessel. The aorta arches upward from the heart and then curves and runs downward along the body midline to its terminus in the pelvis, where it splits to form the two large arteries serving the lower extremities. The branches of the aorta continue to subdivide to produce the arterioles and, finally, the capillaries that ramify through the organs. Venous blood draining from organs inferior to the diaphragm ultimately enters the inferior vena cava.† Except for some coronary and thoracic venous drainage (which enters the azygos system of veins), body regions above the diaphragm are drained by the superior vena cava. The venae cavae empty the carbon dioxide–laden blood into the right atrium of the heart.

Two points concerning the two major circulations must be emphasized: (1) Blood passes from systemic veins to systemic arteries only after first moving through the pulmonary circuit (Figure 19.18a), and (2) although the entire cardiac output of the right ventricle passes through the pulmonary circulation, only a small fraction of the output of the left ventricle flows through any single organ (Figure 19.19). The systemic circulation can be viewed as multiple circulatory channels functioning in parallel to distribute blood to all body organs.

As you examine the tables that follow and locate the various systemic arteries and veins in the illustrations, be aware of cues that make your memorization task easier. In many cases, the name of a vessel reflects the body region traversed (axillary, brachial, femoral, etc.), the organ served (renal, hepatic, gonadal), or the bone followed (vertebral, radial, tibial). Also, notice that arteries and veins tend to run together side by side and, in many places, they also run with nerves. Finally, be alert to the fact that the systemic vessels do not always match on the right and left sides of the body. Thus, while almost all vessels in the head and limbs are bilaterally symmetrical, some of the large, deep vessels of the trunk region are asymmetrical or unpaired.

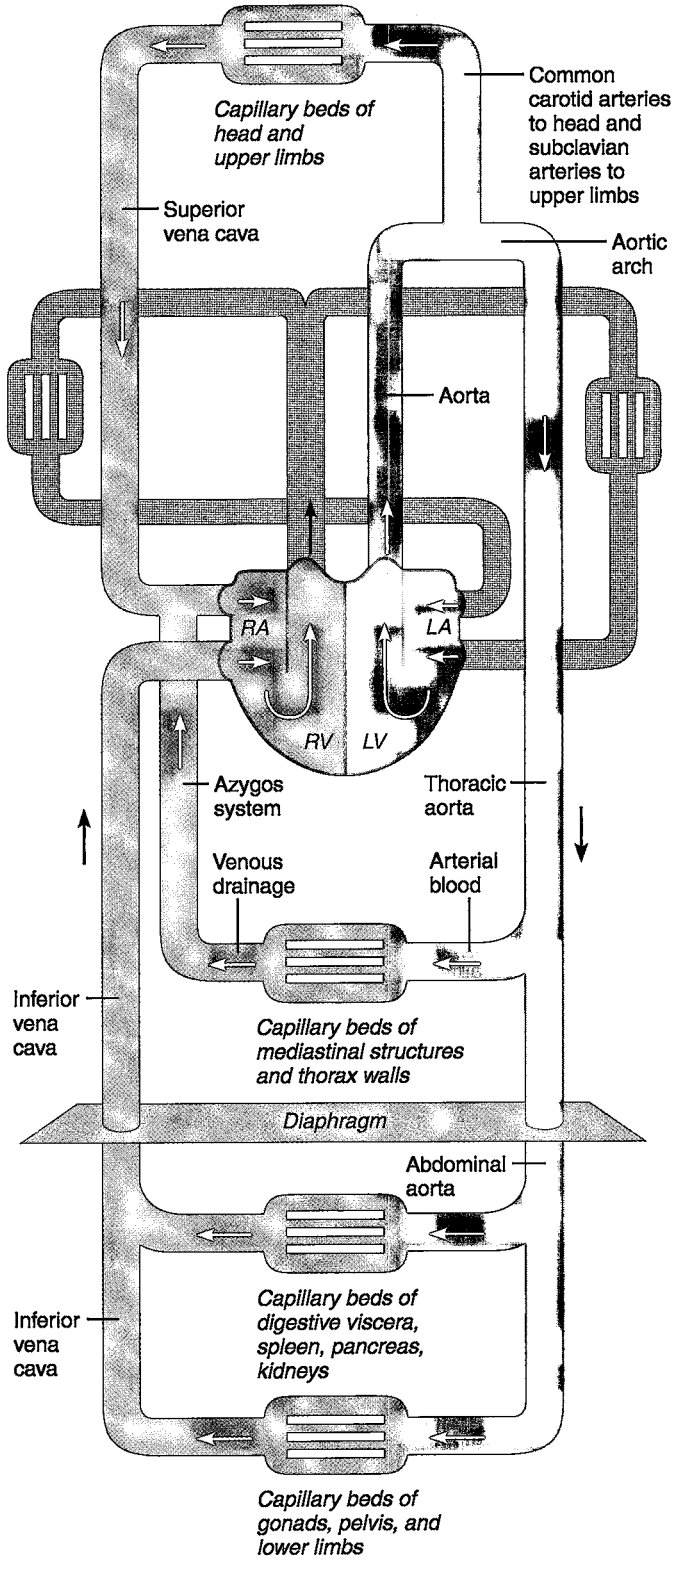

FIGURE 19.19 **Schematic flowchart showing an overview of the systemic circulation.** The pulmonary circulation is shown in gray for comparison.

*By convention, oxygen-rich blood is shown *red* and oxygen-poor blood is shown *blue*.

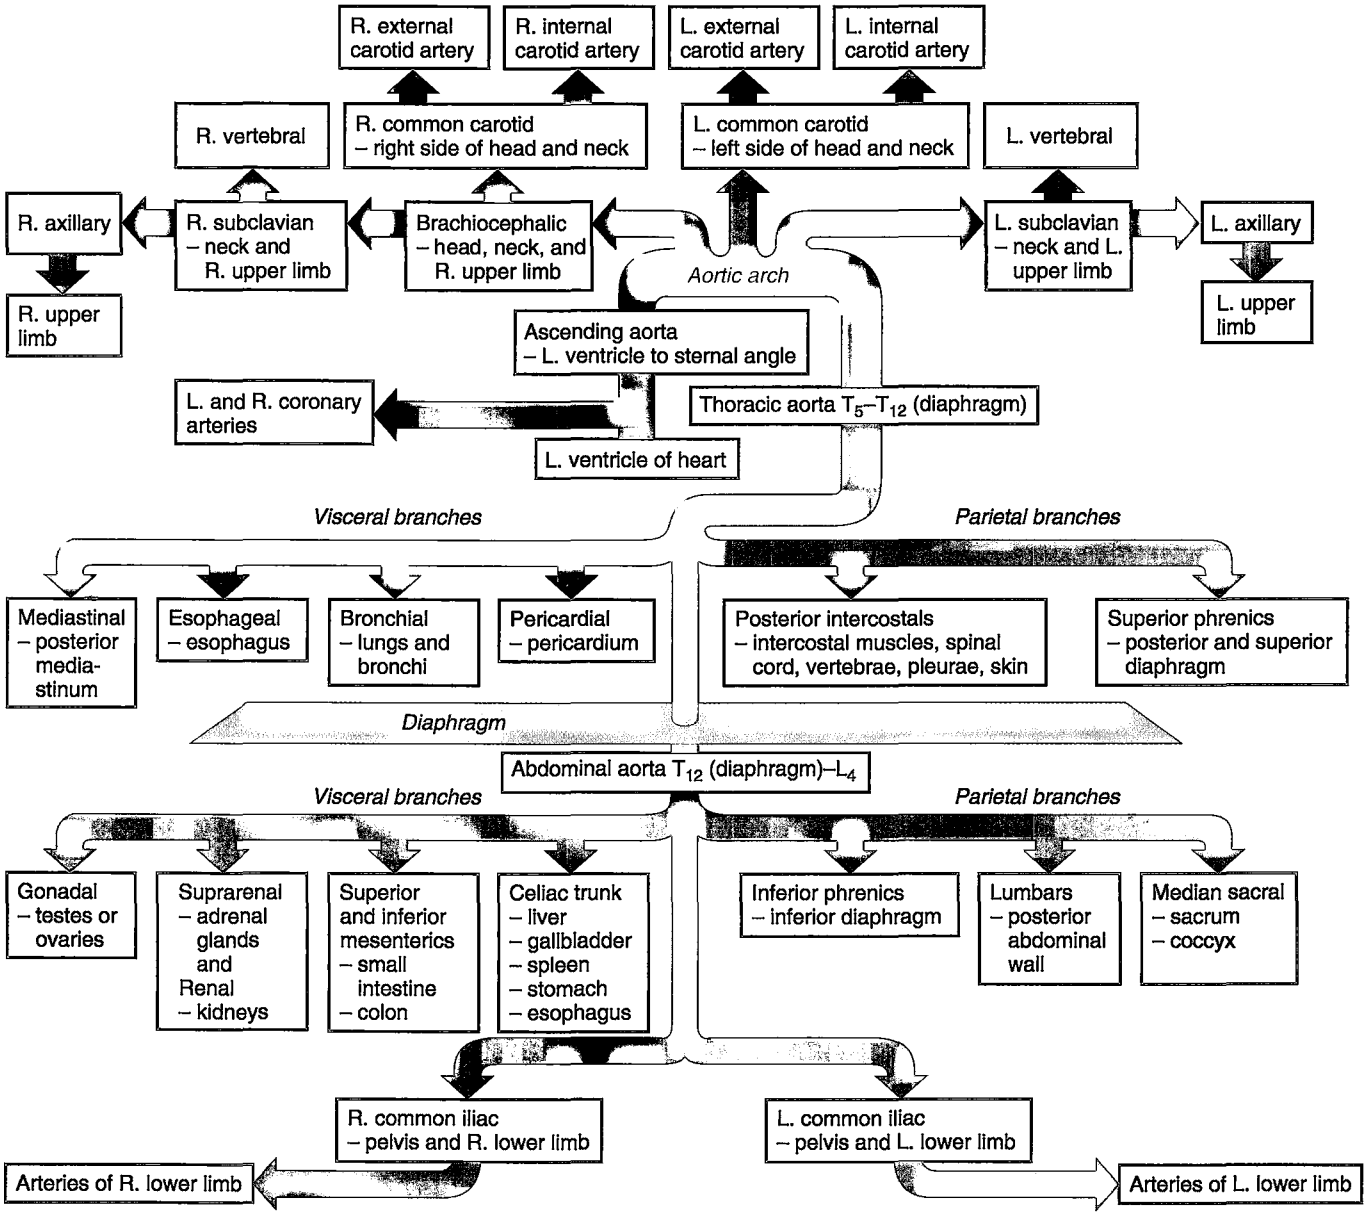
†Venous blood from the digestive viscera passes through the hepatic portal circulation (liver and associated veins) before entering the inferior vena cava.

TABLE 19.4 The Aorta and Major Arteries of the Systemic Circulation

The distribution of the aorta and major arteries of the systemic circulation is diagrammed in flowchart form in Figure 19.20a and illustrated in Figure 19.20b. Fine points about the various vessels arising from the aorta are provided in Tables 19.5 through 19.8.

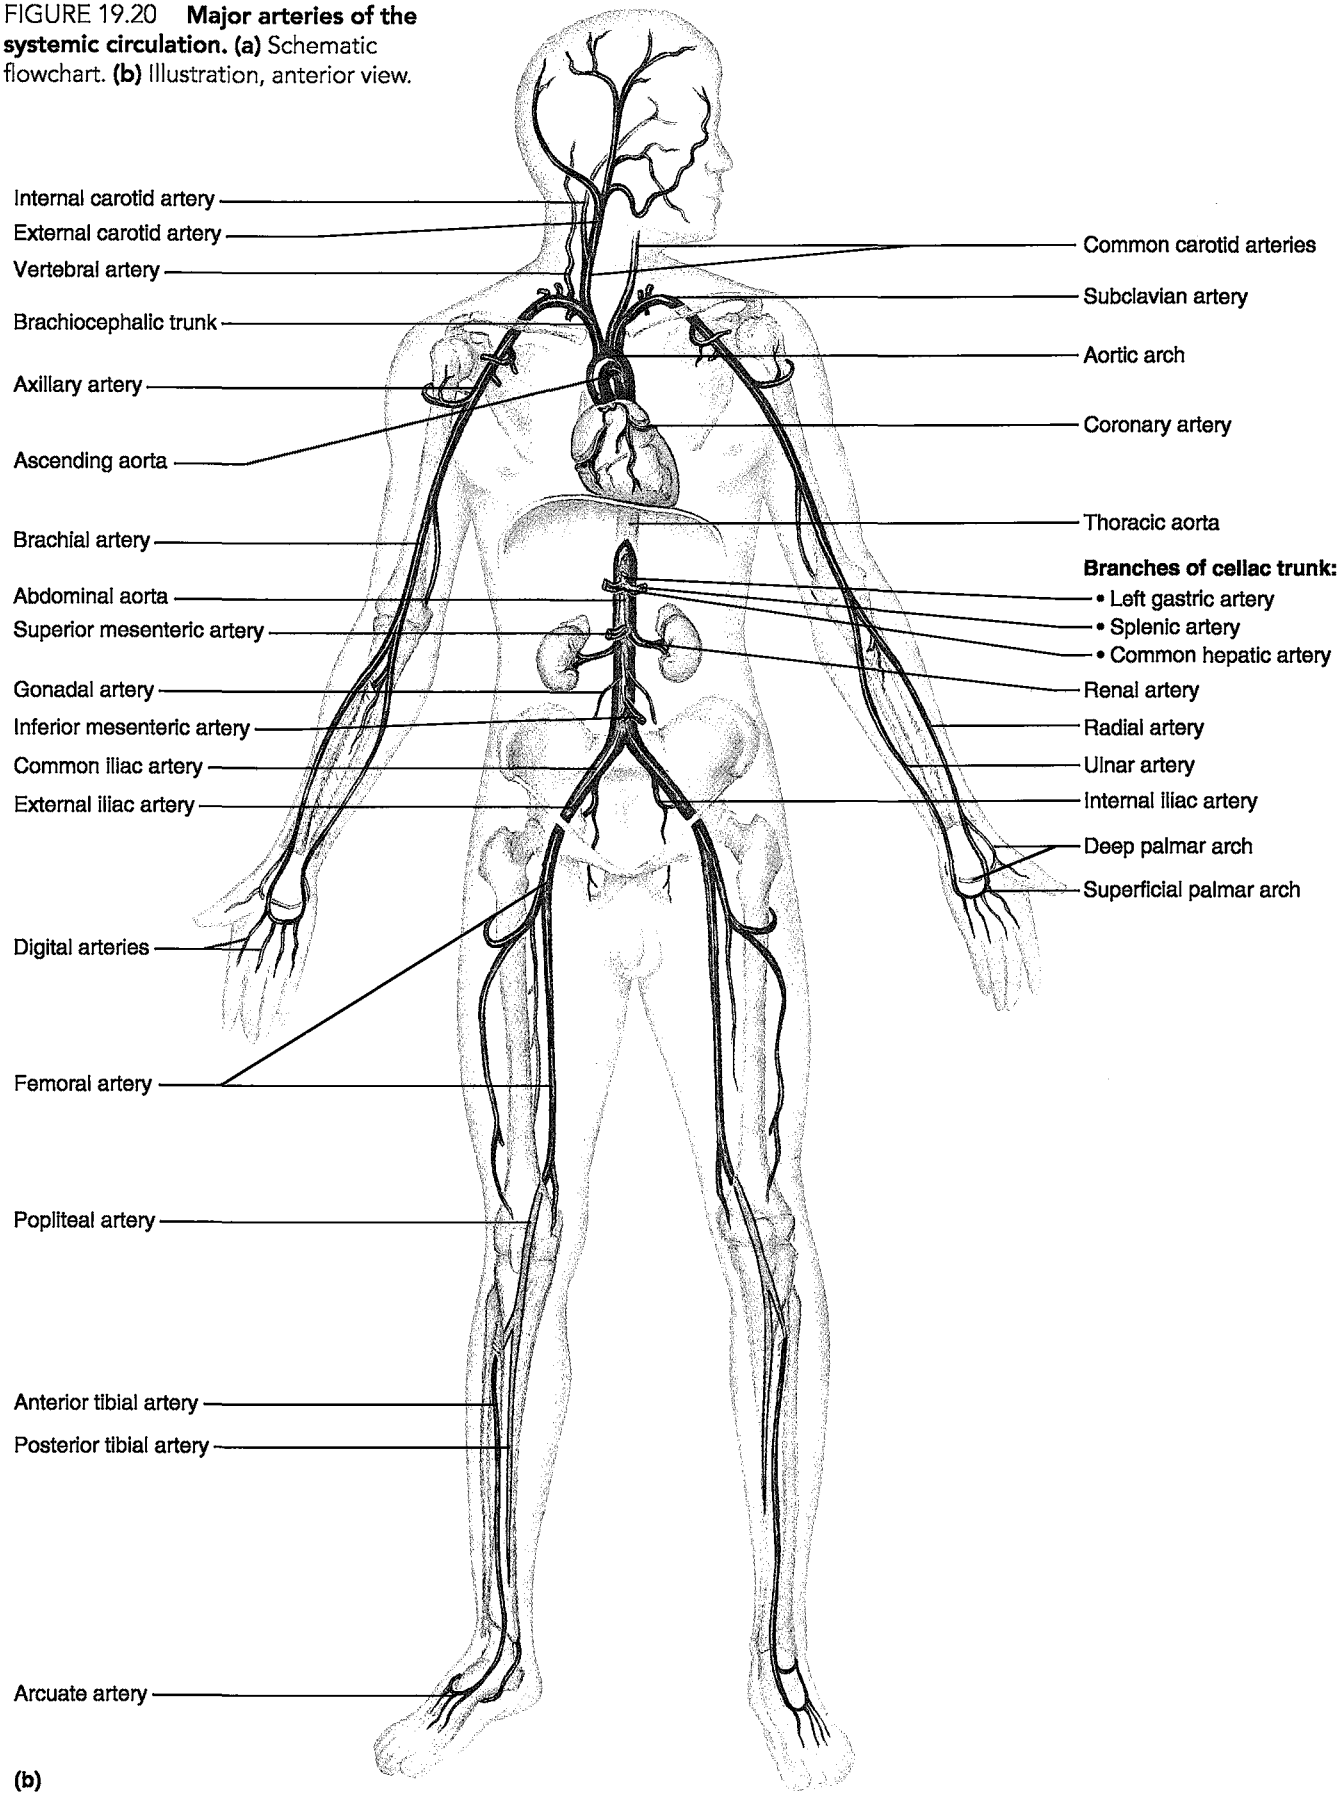
The **aorta** is the largest artery in the body. In adults, the aorta (a-or'tah) is approximately the size of a garden hose where it issues from the left ventricle of the heart. Its internal diameter is 2.5 cm, and its wall is about 2 mm thick. It decreases in size slightly as it runs to its terminus. The aortic valve guards the base of the aorta and prevents backflow of blood during diastole. Opposite each aortic valve cusp is an *aortic sinus*, which contains baroreceptors important in reflex regulation of blood pressure.

Different portions of the aorta are named according to shape or location. The first portion, the **ascending aorta,** runs posteriorly and to the right of the pulmonary trunk. It persists for only about 5 cm before curving to the left as the aortic arch. The only branches of the ascending aorta are the **right** and **left coronary arteries,** which supply the myocardium. The **aortic arch,** deep to the sternum, begins and ends at the sternal angle (T_4 level). Its three major branches (R to L) are: (1) the **brachiocephalic trunk** (bra'ke-o-sĕ-fal"ik; "armhead"), which passes superiorly under the right clavicle and branches into the **right common carotid artery** (kah-rot'id) and the **right subclavian artery,** (2) the **left common carotid artery,** and (3) the **left subclavian artery.** These three vessels provide the arterial supply of the head, neck, upper limbs, and part of the thorax wall. The **thoracic,** or **descending, aorta** runs along the anterior spine from T_5 to T_{12}, sending off numerous small arteries to the thorax wall and viscera before piercing the diaphragm. As it enters the abdominal cavity, it becomes the **abdominal aorta.** This portion supplies the abdominal walls and viscera and ends at the L_4 level, where it splits into the **right** and **left common iliac arteries,** which supply the pelvis and lower limbs.



(a)

FIGURE 19.20 **Major arteries of the systemic circulation. (a)** Schematic flowchart. **(b)** Illustration, anterior view.

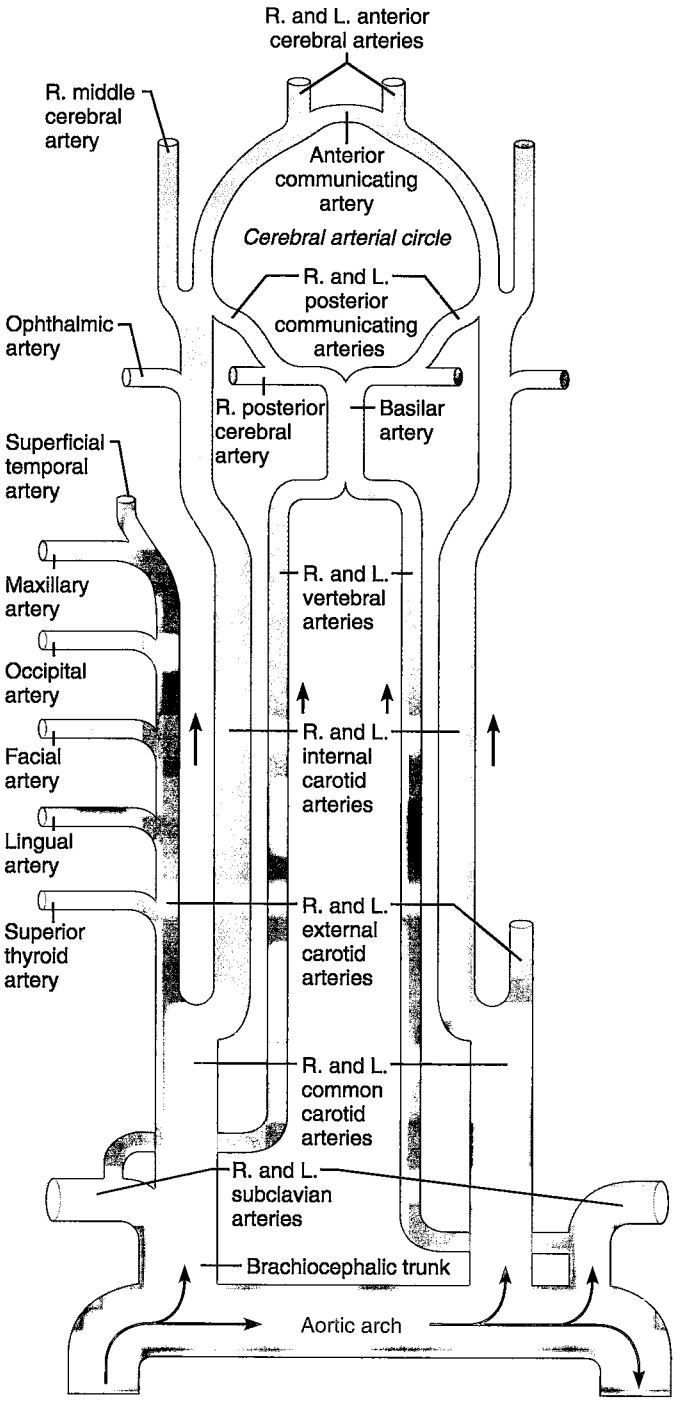


(b)

TABLE 19.5 Arteries of the Head and Neck

Four paired arteries supply the head and neck. These are the common carotid arteries, plus three branches from each subclavian artery: the vertebral arteries, the thyrocervical trunks, and the costocervical trunks (Figure 19.21b). Of these, the common carotid arteries have the broadest distribution (Figure 19.21a).

Each common carotid divides into two major branches (the internal and external carotid arteries). At the division point, each internal carotid artery has a slight dilation, the **carotid sinus,** that contains baroreceptors that assist in reflex blood pressure control. The **carotid bodies,** chemoreceptors involved in the control of respiratory rate, are located close by. Pressing on the neck in the area of the carotid sinuses can cause unconsciousness (*carot* = stupor) because the pressure created mimics high blood pressure, eliciting vasodilation, which interferes with blood delivery to the brain.



(a)

Description and Distribution

Common carotid arteries. The origins of these two arteries differ: The right common carotid artery arises from the brachiocephalic trunk; the left is the second branch of the aortic arch. The common carotid arteries ascend through the lateral neck, and at the superior border of the larynx (the level of the "Adam's apple"), each divides into its two major branches, the *external* and *internal carotid arteries.*

The **external carotid arteries** supply most tissues of the head except for the brain and orbit. As each artery runs superiorly, it sends branches to the thyroid gland and larynx **(superior thyroid artery),** the tongue **(lingual artery),** the skin and muscles of the anterior face **(facial artery),** and the posterior scalp **(occipital artery).** Each external carotid artery terminates by splitting into a **superficial temporal artery,** which supplies the parotid salivary gland and most of the scalp, and a **maxillary artery,** which supplies the upper and lower jaws and chewing muscles, the teeth, and the nasal cavity. A clinically important branch of the maxillary artery is the *middle meningeal artery* (not illustrated). It enters the skull through the foramen spinosum and supplies the inner surface of the parietal bone, squamous region of the temporal bone, and the underlying dura mater.

The larger **internal carotid arteries** supply the orbits and more than 80% of the cerebrum. They assume a deep course and enter the skull through the carotid canals of the temporal bones. Once inside the cranium, each artery gives off one main branch, the ophthalmic artery, and then divides into the anterior and middle cerebral arteries. The **ophthalmic arteries** (of-thal'mik) supply the eyes, orbits, forehead, and nose. Each **anterior cerebral artery** supplies the medial surface of the frontal and parietal lobes of the cerebral hemisphere on its side and also anastomoses with its partner on the opposite side via a short arterial shunt called the **anterior communicating artery** (Figure 19.21d). The **middle cerebral arteries** run in the lateral sulci of their respective cerebral hemispheres and supply the lateral parts of the temporal, parietal, and frontal lobes.

Vertebral arteries. These vessels spring from the subclavian arteries at the root of the neck and ascend through foramina in the transverse processes of the cervical vertebrae to enter the skull through the foramen magnum. En route, they send branches to the vertebrae and cervical spinal cord and to some deep structures of the neck. Within the cranium, the right and left vertebral arteries join to form the **basilar artery** (bas'ĭ-lar),

TABLE 19.5 (continued)

which ascends along the anterior aspect of the brain stem, giving off branches to the cerebellum, pons, and inner ear (Figure 19.21b and d). At the pons-midbrain border, the basilar artery divides into a pair of **posterior cerebral arteries,** which supply the occipital lobes and the inferior parts of the temporal lobes.

Arterial shunts called **posterior communicating arteries** connect the posterior cerebral arteries to the middle cerebral arteries anteriorly. The two posterior and single anterior communicating arteries complete the formation of an arterial anastomosis called the **cerebral arterial circle (circle of Willis)**. This structure encircles the pituitary gland and optic chiasma and unites the brain's anterior and posterior blood supplies. It also equalizes blood pressure in the two brain areas and provides alternate routes for blood to reach the brain tissue if a carotid or vertebral artery becomes occluded.

Thyrocervical and costocervical trunks. These short vessels arise from the subclavian artery just lateral to the vertebral arteries on each side (Figures 19.21b and Figure 19.22). The thyrocervical trunk mainly supplies the thyroid gland, portions of the cervical vertebrae and spinal cord, and some scapular muscles. The costocervical trunk serves deep neck and superior intercostal muscles.

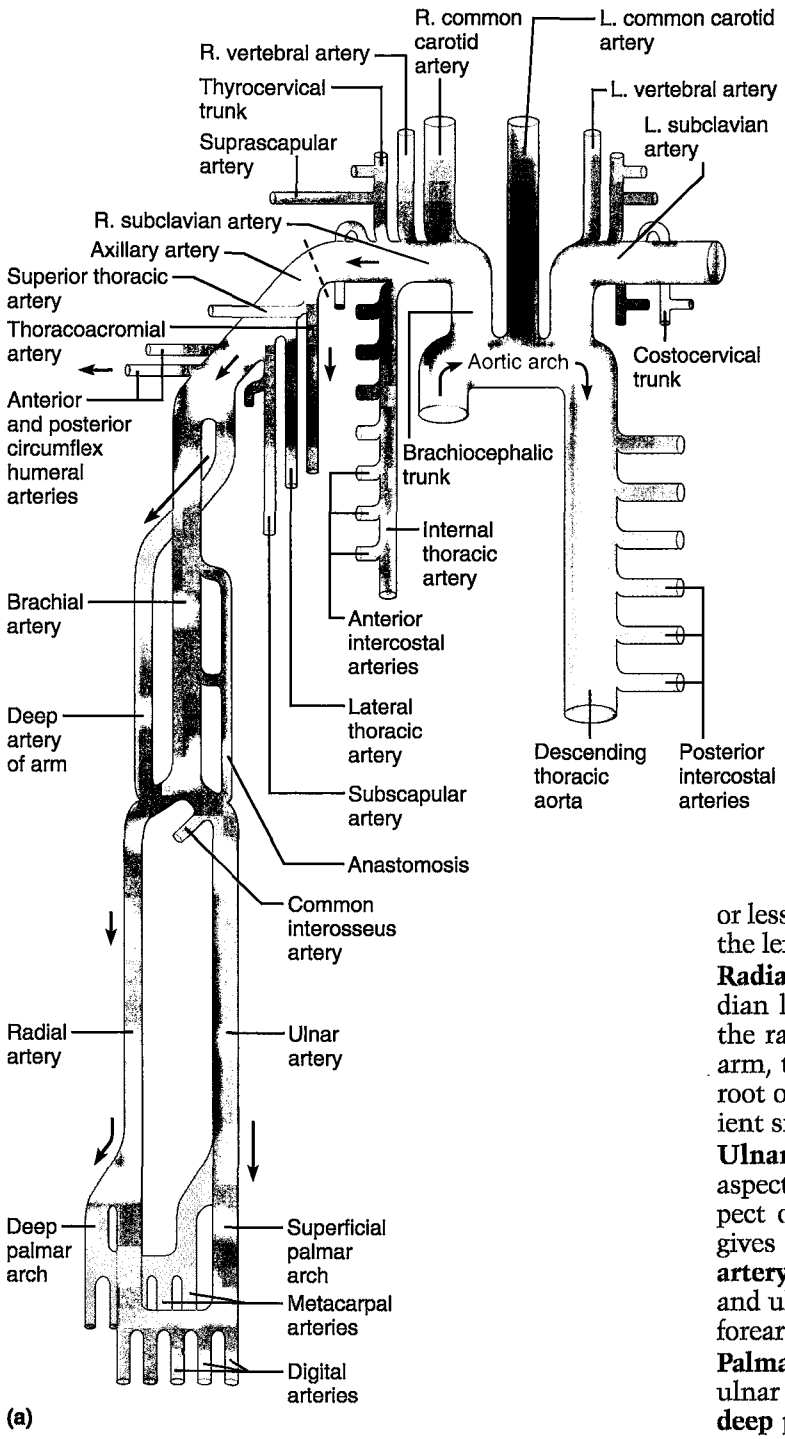
19

TABLE 19.6 Arteries of the Upper Limbs and Thorax

The upper limbs are supplied entirely by arteries arising from the **subclavian arteries** (Figure 19.22a). After giving off branches to the neck, each subclavian artery courses laterally between the clavicle and first rib to enter the axilla, where its name changes to axillary artery. The thorax wall is supplied by an array of vessels that arise either directly from the thoracic aorta or from branches of the subclavian arteries. Most visceral organs of the thorax receive their functional blood supply from small branches issuing from the thoracic aorta. Because these vessels are so small and tend to vary in number (except for the bronchial arteries), they are not illustrated in Figures 19.22a and b, but several of them are listed at the end of this table.



(a)

Description and Distribution

Arteries of the Upper Limb

Axillary artery. As it runs through the axilla accompanied by cords of the brachial plexus, each axillary artery gives off branches to the axilla, chest wall, and shoulder girdle. These branches include the **thoracoacromial artery** (tho"rah-ko-ah-kro'me-al), which supplies the deltoid muscle and pectoral region; the **lateral thoracic artery,** which serves the lateral chest wall and breast; the **subscapular artery** to the scapula, dorsal thorax wall, and part of the latissimus dorsi muscle; and the **anterior** and **posterior circumflex humeral arteries,** which wrap around the humeral neck and help supply the shoulder joint and the deltoid muscle. As the axillary artery emerges from the axilla, it becomes the brachial artery.

Brachial artery. The brachial artery runs down the medial aspect of the humerus and supplies the anterior flexor muscles of the arm. One major branch, the **deep artery of the arm,** serves the posterior triceps brachii muscle. As it nears the elbow, the brachial artery gives off several small branches that contribute to an anastomosis serving the elbow joint and connecting it to the arteries of the forearm. As the brachial artery crosses the anterior midline aspect of the elbow, it provides an easily palpated pulse point (brachial pulse) (see Figure 19.11). Immediately beyond the elbow, the brachial artery splits to form the radial and ulnar arteries, which more or less follow the course of similarly named bones down the length of the anterior forearm.

Radial artery. The radial artery runs from the median line of the cubital fossa to the styloid process of the radius. It supplies the lateral muscles of the forearm, the wrist, and the thumb and index finger. At the root of the thumb, the radial artery provides a convenient site for taking the radial pulse.

Ulnar artery. The ulnar artery supplies the medial aspect of the forearm, fingers 3–5, and the medial aspect of the index finger. Proximally, the ulnar artery gives off a short branch, the **common interosseous artery** (in"ter-os'e-us), which runs between the radius and ulna to serve the deep flexors and extensors of the forearm.

Palmar arches. In the palm, branches of the radial and ulnar arteries anastomose to form the **superficial** and **deep palmar arches.** The **metacarpal arteries** and the

TABLE 19.6 *(continued)*

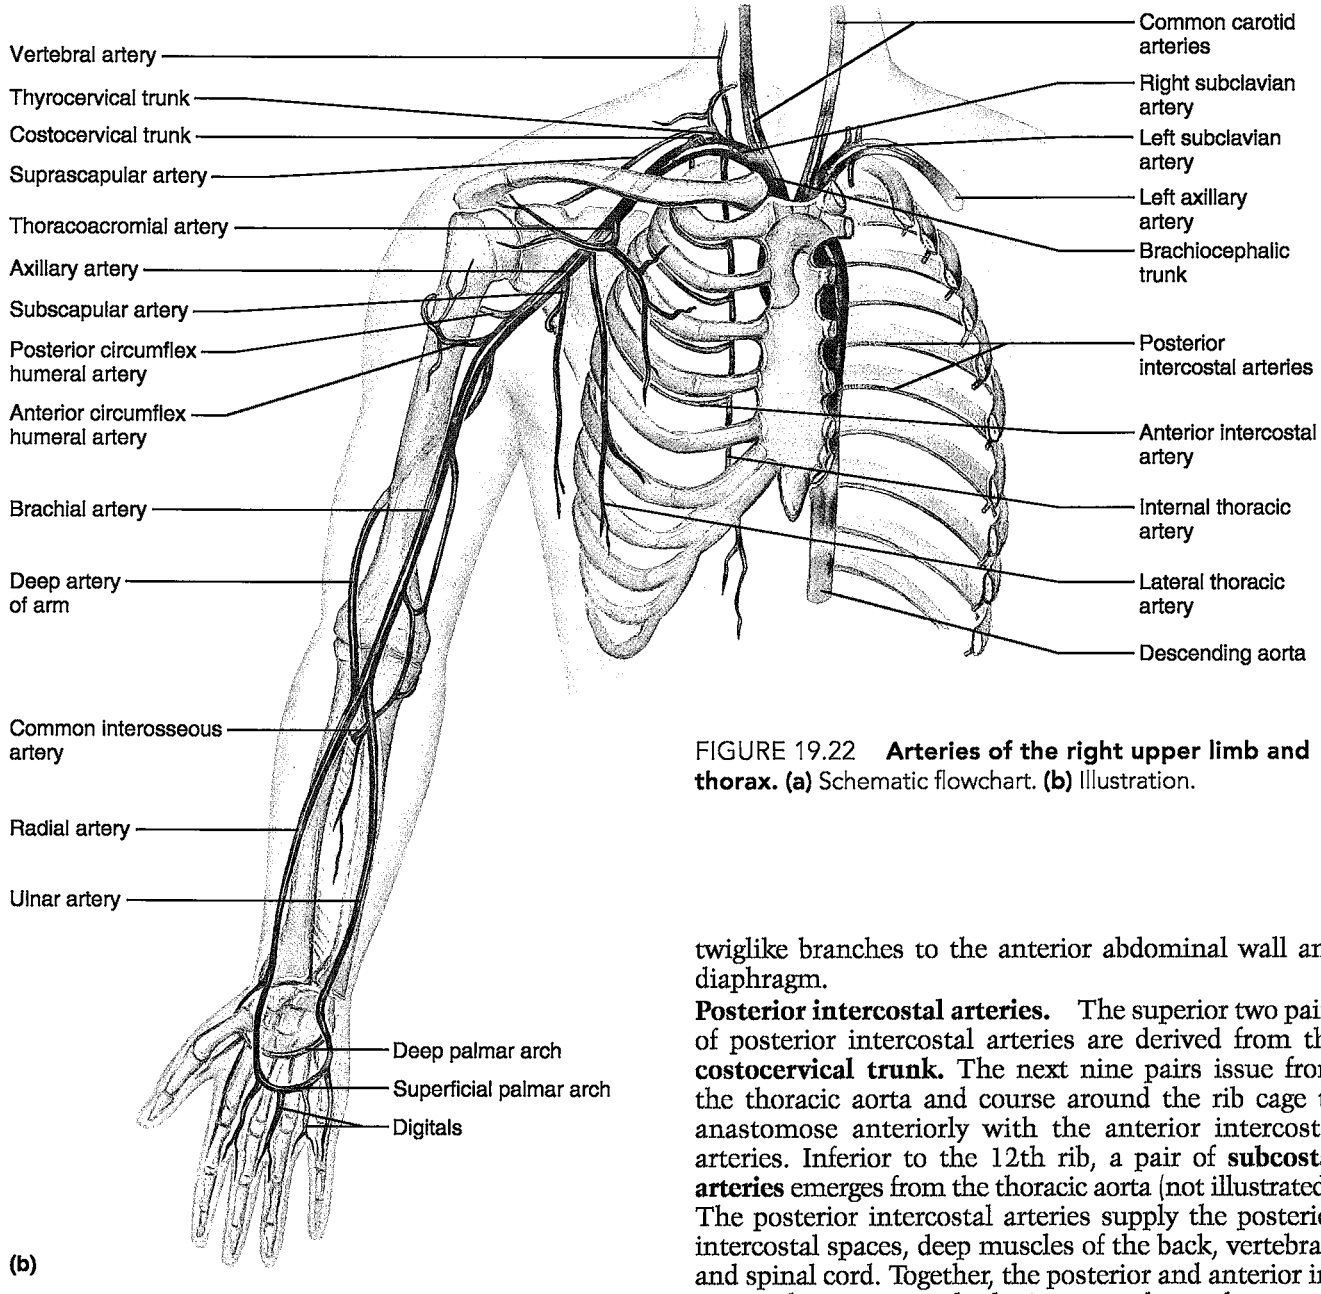


FIGURE 19.22 **Arteries of the right upper limb and thorax. (a)** Schematic flowchart. **(b)** Illustration.

digital arteries that supply the fingers arise from these palmar arches.

Arteries of the Thorax Wall

Internal thoracic arteries. The internal thoracic arteries, also called the mammary arteries, arise from the subclavian arteries and supply blood to most of the anterior thorax wall. Each of these arteries descends lateral to the sternum and gives off **anterior intercostal arteries,** which supply the intercostal spaces anteriorly. The internal thoracic artery also sends superficial branches to the skin and mammary glands and terminates in twiglike branches to the anterior abdominal wall and diaphragm.

Posterior intercostal arteries. The superior two pairs of posterior intercostal arteries are derived from the **costocervical trunk.** The next nine pairs issue from the thoracic aorta and course around the rib cage to anastomose anteriorly with the anterior intercostal arteries. Inferior to the 12th rib, a pair of **subcostal arteries** emerges from the thoracic aorta (not illustrated). The posterior intercostal arteries supply the posterior intercostal spaces, deep muscles of the back, vertebrae, and spinal cord. Together, the posterior and anterior intercostal arteries supply the intercostal muscles.

Superior phrenic arteries. One or more paired superior phrenic arteries serve the posterior superior aspect of the diaphragm surface.

Arteries of the Thoracic Viscera

Pericardial arteries. Several tiny branches supply the posterior pericardium.

Bronchial arteries. Two left and one right bronchial arteries supply systemic (oxygen-rich) blood to the lungs, bronchi, and pleurae.

Esophageal arteries. Four to five esophageal arteries supply the esophagus.

Mediastinal arteries. Many small mediastinal arteries serve the posterior mediastinum.

TABLE 19.7 Arteries of the Abdomen

The arterial supply to the abdominal organs arises from the abdominal aorta (Figure 19.23a). Under resting conditions, about half of the entire arterial flow is found in these vessels. Except for the celiac trunk, the superior and inferior mesenteric arteries, and the median sacral artery, all are paired vessels. These arteries supply the abdominal wall, diaphragm, and visceral organs of the abdominopelvic cavity. The branches are given here in order of their issue.

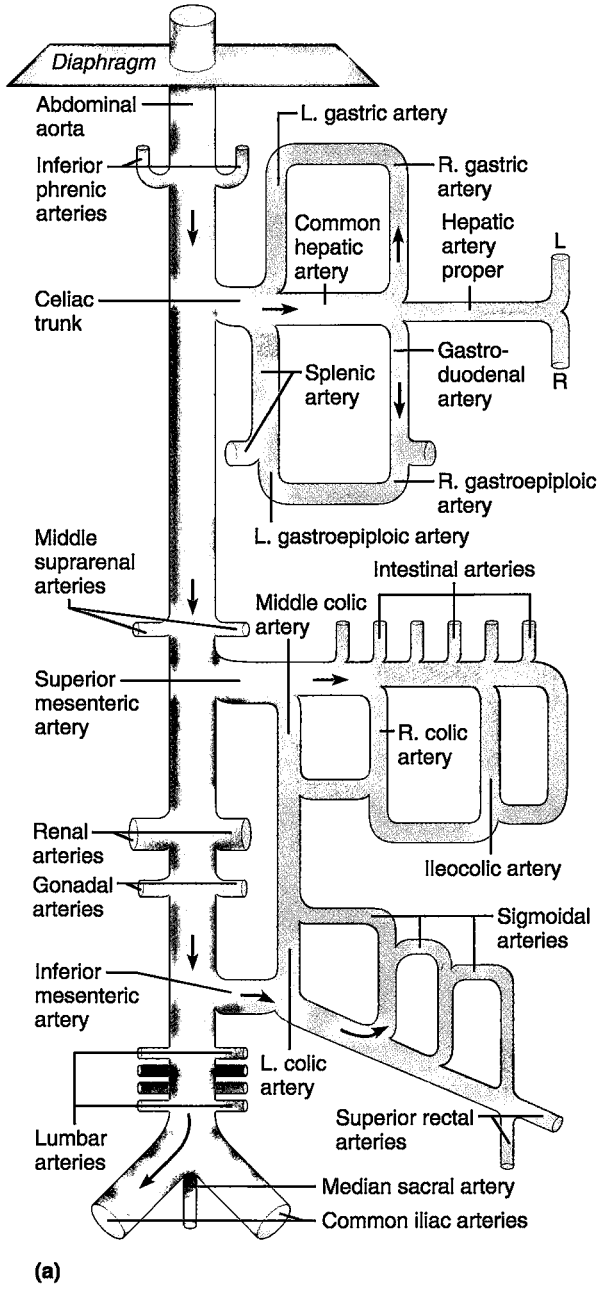

FIGURE 19.23 **Arteries of the abdomen. (a)** Schematic flowchart.

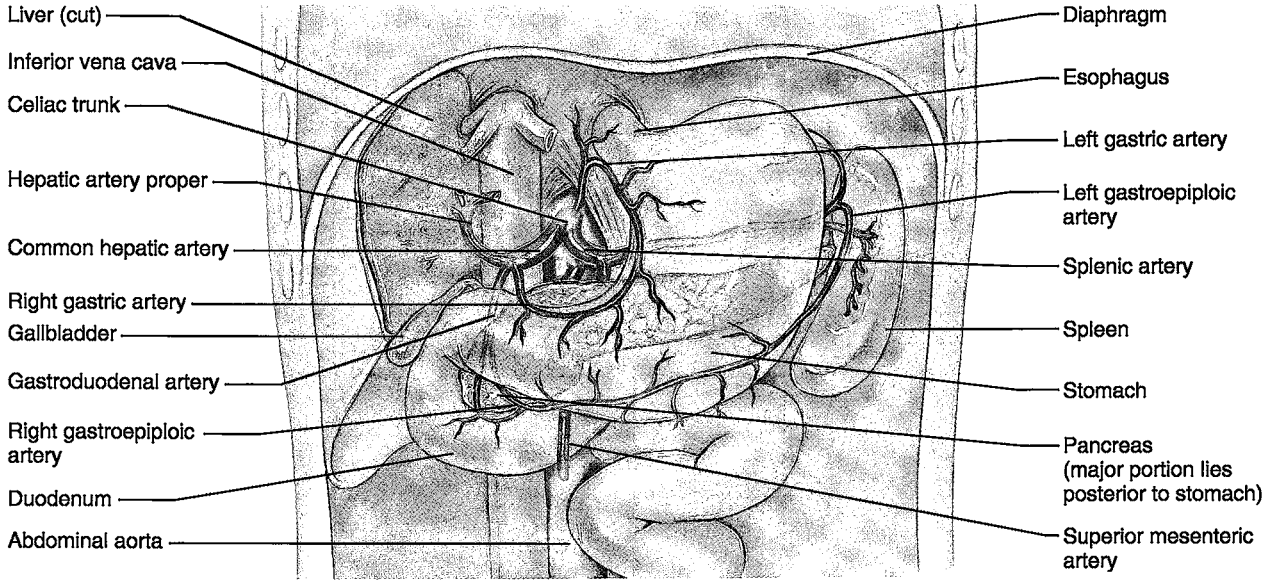
TABLE 19.7 (continued)

Description and Distribution

Inferior phrenic arteries. The inferior phrenics emerge from the aorta at T_{12}, just inferior to the diaphragm. They serve the inferior diaphragm surface.

Celiac trunk. This very large unpaired branch of the abdominal aorta divides almost immediately into three branches: the common hepatic, splenic, and left gastric arteries (Figure 19.23b). The **common hepatic artery** (hĕ-pat'ik) gives off branches to the stomach, duodenum, and pancreas. Where the **gastroduodenal artery** branches off, it becomes the **hepatic artery proper,** which splits into right and left branches that serve the liver. As the **splenic artery** (splen'ik) passes deep to the stomach, it sends branches to the pancreas and stomach and terminates in branches to the spleen. The **left gastric artery** (*gaster* = stomach) supplies part of the stomach and the inferior esophagus. The **right** and **left gastroepiploic arteries** (gas"tro-ep"ĭ-plo'ik), branches of the gastroduodenal and splenic arteries, respectively, serve the greater curvature of the stomach. A **right gastric artery,** which supplies the stomach's lesser curvature, may arise from the common hepatic artery or from the hepatic artery proper.



(b)

FIGURE 19.23 *(continued)* **Arteries of the abdomen. (b)** The celiac trunk and its major branches. To make these arteries visible, the left half of the liver has been removed. (See *A Brief Atlas of the Human Body,* Figure 68.)

TABLE 19.7 **Arteries of the Abdomen** *(continued)*

Superior mesenteric artery (mes-en-ter'ik). This large, unpaired artery arises from the abdominal aorta at the L_1 level immediately below the celiac trunk (Figure 19.23d). It runs deep to the pancreas and then enters the mesentery, where its numerous anastomosing branches serve virtually all of the small intestine via the **intestinal arteries,** and most of the large intestine—the appendix, cecum, ascending colon (via the **ileocolic artery**), and part of the transverse colon (via the **right** and **middle colic arteries**).

Suprarenal arteries (soo"prah-re'nal). The **middle suprarenal arteries** flank the origin of the superior mesenteric artery as they emerge from the abdominal aorta (Figure 19.23c). They supply blood to the adrenal (suprarenal) glands overlying the kidneys. The adrenal glands also receive two sets of branches not illustrated: *superior suprarenal* branches from the nearby inferior phrenic arteries, and *inferior suprarenal* branches from the nearby renal arteries.

Renal arteries. The short but wide renal arteries, right and left, issue from the lateral surfaces of the aorta slightly below the superior mesenteric artery (between L_1 and L_2). Each serves the kidney on its side.

Gonadal arteries (go-nă'dul). The paired gonadal arteries are called the **testicular arteries** in males and the **ovarian arteries** in females. The ovarian arteries extend into the pelvis to serve the ovaries and part of the uterine tubes. The much longer testicular arteries descend through the pelvis and inguinal canal to enter the scrotal sac, where they serve the testes.

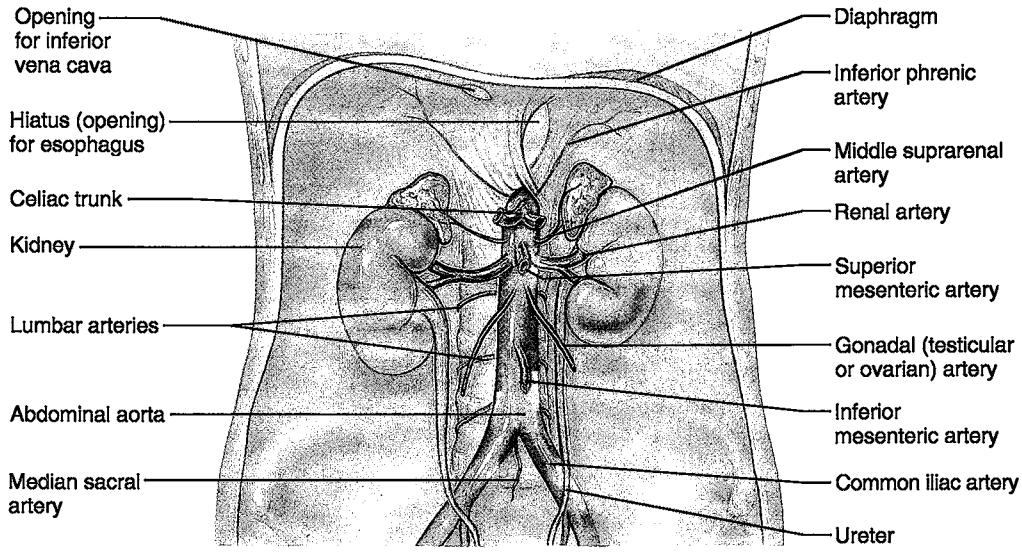
Inferior mesenteric artery. This final major branch of the abdominal aorta is unpaired and arises from the anterior aortic surface at the L_3 level. It serves the distal part of the large intestine—from the midpart of the transverse colon to the midrectum—via its **left colic, sigmoidal,** and **superior rectal branches** (Figure 19.23d). Looping anastomoses between the superior and inferior mesenteric arteries help ensure that blood will continue to reach the digestive viscera in cases of trauma to one of these abdominal arteries.

Lumbar arteries. Four pairs of lumbar arteries arise from the posterolateral surface of the aorta in the lumbar region. These segmental arteries supply the posterior abdominal wall.

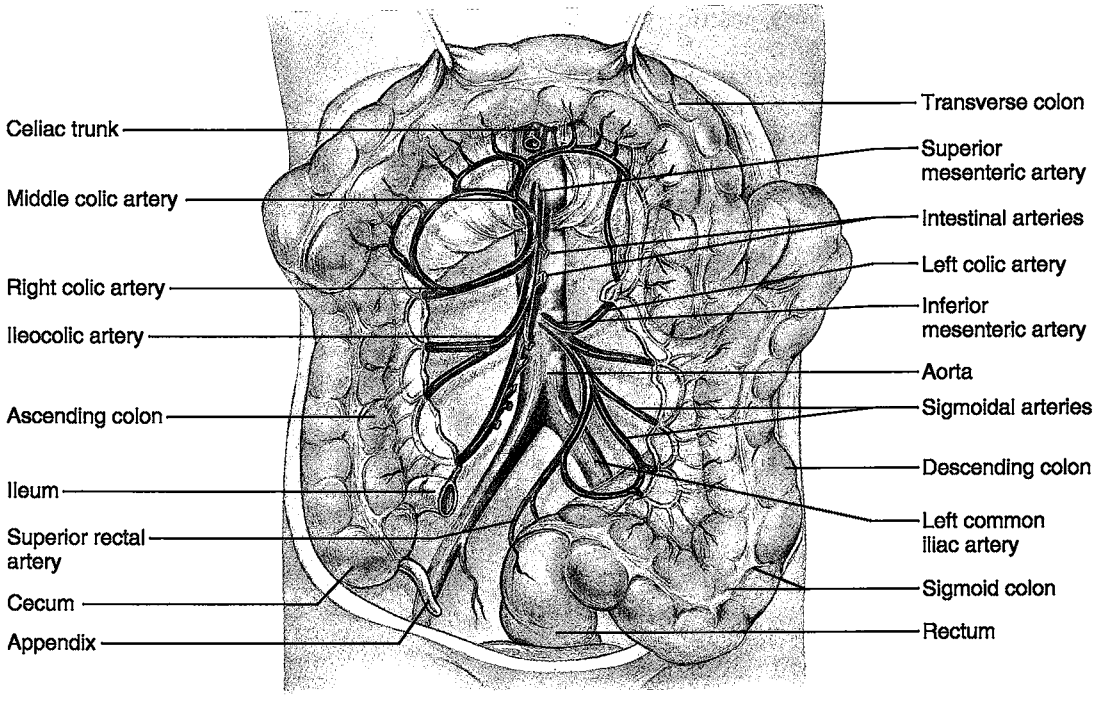
Median sacral artery. The unpaired median sacral artery issues from the posterior surface of the abdominal aorta at its terminus. This tiny artery supplies the sacrum and coccyx.

Common iliac arteries. At the L_4 level, the aorta splits into the right and left common iliac arteries, which supply blood to the lower abdominal wall, pelvic organs, and lower limbs (Figure 19.23c).

TABLE 19.7 *(continued)*



(c)



(d)

FIGURE 19.23 *(continued)* **Arteries of the abdomen. (c)** Major branches of the abdominal aorta. **(d)** Distribution of the superior and inferior mesenteric arteries. (The transverse colon has been reflected superiorly to provide a better view of these arteries.) (See *A Brief Atlas of the Human Body,* Figures 68 and 70.)

TABLE 19.8 **Arteries of the Pelvis and Lower Limbs**

At the level of the sacroiliac joints, the **common iliac arteries** divide into two major branches, the internal and external iliac arteries (Figure 19.24a). The internal iliacs distribute blood mainly to the pelvic region. The external iliacs serve the lower limbs; they also send some branches to the abdominal wall.

Description and Distribution

Internal iliac arteries. These paired arteries run into the pelvis and distribute blood to the pelvic walls and viscera (bladder, rectum, uterus, and vagina in the female and prostate gland and ductus deferens in the male). Additionally they serve the gluteal muscles via the **superior** and **inferior gluteal arteries,** adductor muscles of the medial thigh via the **obturator artery,** and external genitalia and perineum via the **internal pudendal artery** (not illustrated).

External iliac arteries. These arteries supply the lower limbs (Figure 19.24b). As they course through the pelvis, they give off branches to the anterior abdominal wall. After passing under the inguinal ligaments to enter the thigh, they become the femoral arteries.

Femoral arteries. As each of these arteries passes down the anteromedial thigh, it gives off several branches to the thigh muscles. The largest of the deep branches is the **deep artery of the thigh** (also called the **deep femoral artery**), which is the main supply to the thigh muscles (hamstrings, quadriceps, and adductors). Proximal branches of the deep femoral artery, the **lateral** and **medial circumflex femoral arteries,** encircle the neck of the femur. The medial circumflex artery supplies the head and neck of the femur. A long descending branch of the lateral circumflex artery supplies the vastus lateralis muscle. Near the knee the femoral artery passes posteriorly and through a gap in the adductor magnus muscle, the *adductor hiatus,* to enter the popliteal fossa, where its name changes to popliteal artery.

Popliteal artery. This posterior vessel contributes to an arterial anastomosis that supplies the knee region and then splits into the anterior and posterior tibial arteries of the leg.

Anterior tibial artery. The anterior tibial artery runs through the anterior compartment of the leg, supplying the extensor muscles along the way. At the ankle, it becomes the **dorsalis pedis artery,** which supplies the ankle and dorsum of the foot, and gives off a branch, the **arcuate artery,** which issues the **metatarsal arteries** to the metatarsus of the foot. The superficial dorsalis pedis ends by penetrating into the sole where it forms the medial part of the **plantar arch.** The dorsalis pedis artery provides a clinically important pulse point, the pedal pulse. If the pedal pulse is easily felt, it is fairly certain that the blood supply to the leg is good.

Posterior tibial artery. This large artery courses through the posteromedial part of the leg and supplies the flexor muscles. Proximally, it gives off a large branch, the **fibular (peroneal) artery,** which supplies the lateral

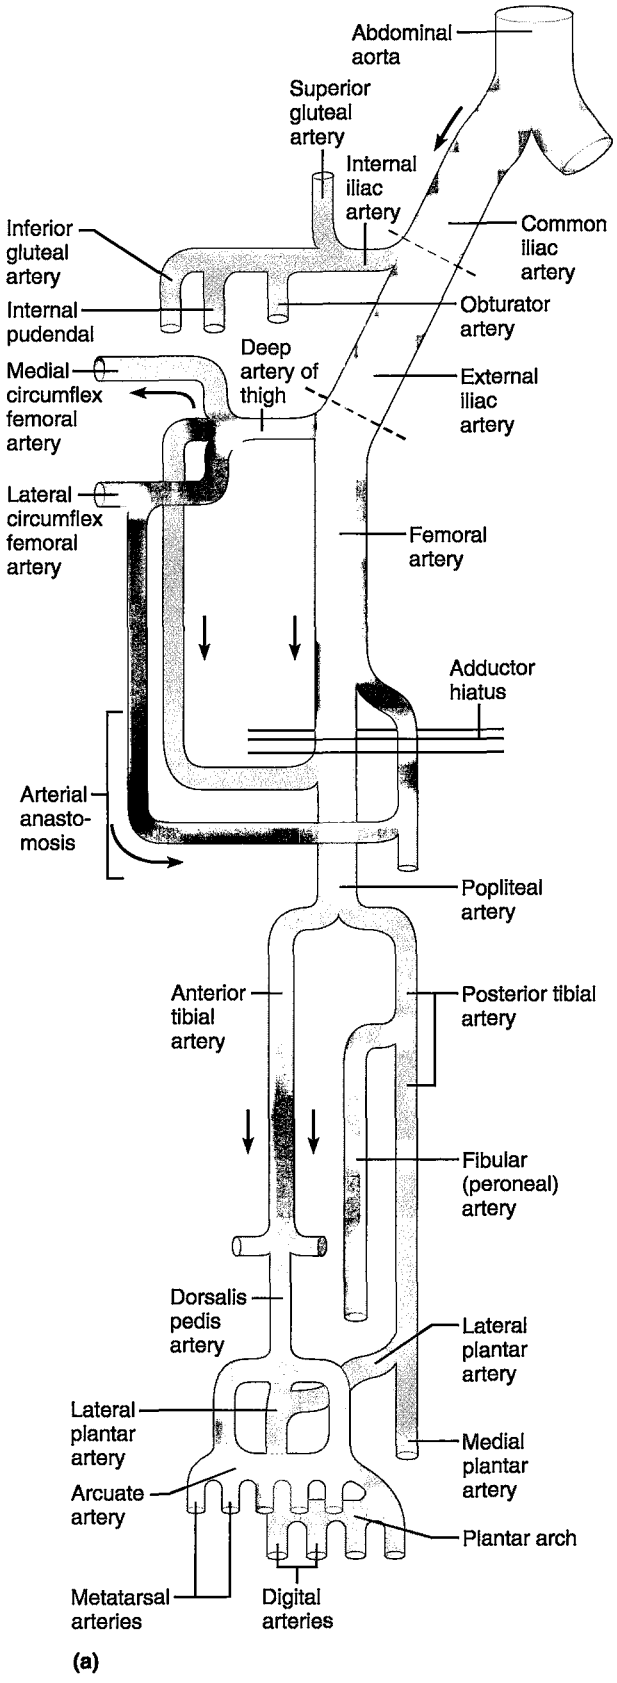


FIGURE 19.24 **Arteries of the right pelvis and lower limb. (a)** Schematic flowchart.

TABLE 19.8 *(continued)*

fibularis (peroneal) muscles of the leg. At the ankle, the posterior tibial artery divides into **lateral** and **medial plantar arteries** that serve the plantar surface of the foot. The lateral plantar artery forms the lateral end of the plantar arch. The **digital arteries** serving the toes arise from the plantar arch formed by the lateral plantar artery.

In our survey of the systemic veins, the major tributaries (branches) of the venae cavae are noted first in Figure 19.25, followed by a description in Tables 19.10 through 19.13 of the venous pattern of the various body regions. Because veins run toward the heart, the most distal veins are named first and those closest to the heart last. Because deep veins generally drain the same areas served by their companion arteries, they are not described in detail.

Description and Areas Drained

Superior vena cava. This great vein receives systemic blood draining from all areas superior to the diaphragm, except the heart wall. It is formed by the union of the **right** and **left brachiocephalic veins** and empties into the right atrium (Figure 19.25b). Notice that there are two brachiocephalic veins, but only one brachiocephalic artery (trunk). Each brachiocephalic vein is formed by the joining of the **internal jugular** and **subclavian veins** on its side. In most of the flowcharts that follow, only the vessels draining blood from the right side of the body are followed (except for the azygos circulation of the thorax).

Inferior vena cava. The widest blood vessel in the body, this vein returns blood to the heart from all body regions below the diaphragm. The abdominal aorta lies directly to its left. The distal end of the inferior vena cava is formed by the junction of the paired **common iliac veins** at L_5. From this point, it courses superiorly along the anterior aspect of the spine, receiving venous blood draining from the abdominal walls, gonads, and kidneys. Immediately above the diaphragm, the inferior vena cava ends as it enters the inferior aspect of the right atrium.

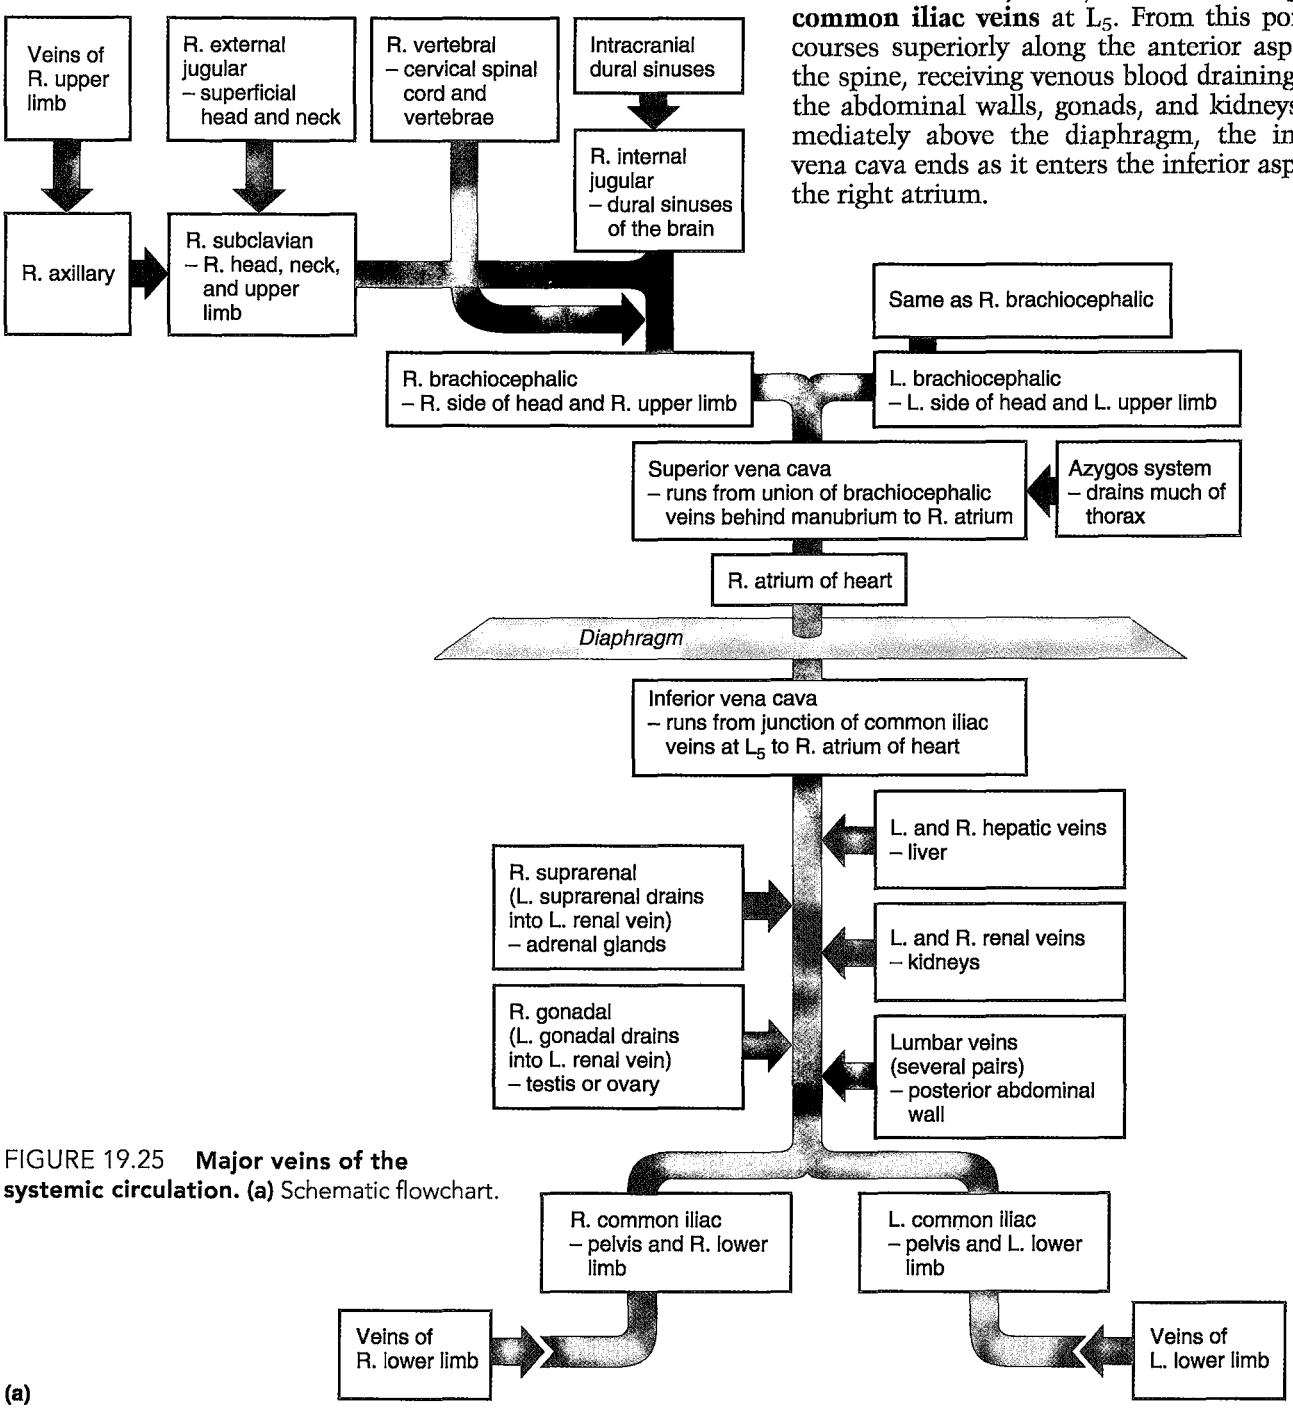

FIGURE 19.25 **Major veins of the systemic circulation. (a)** Schematic flowchart.

(a)

TABLE 19.9 *(continued)*

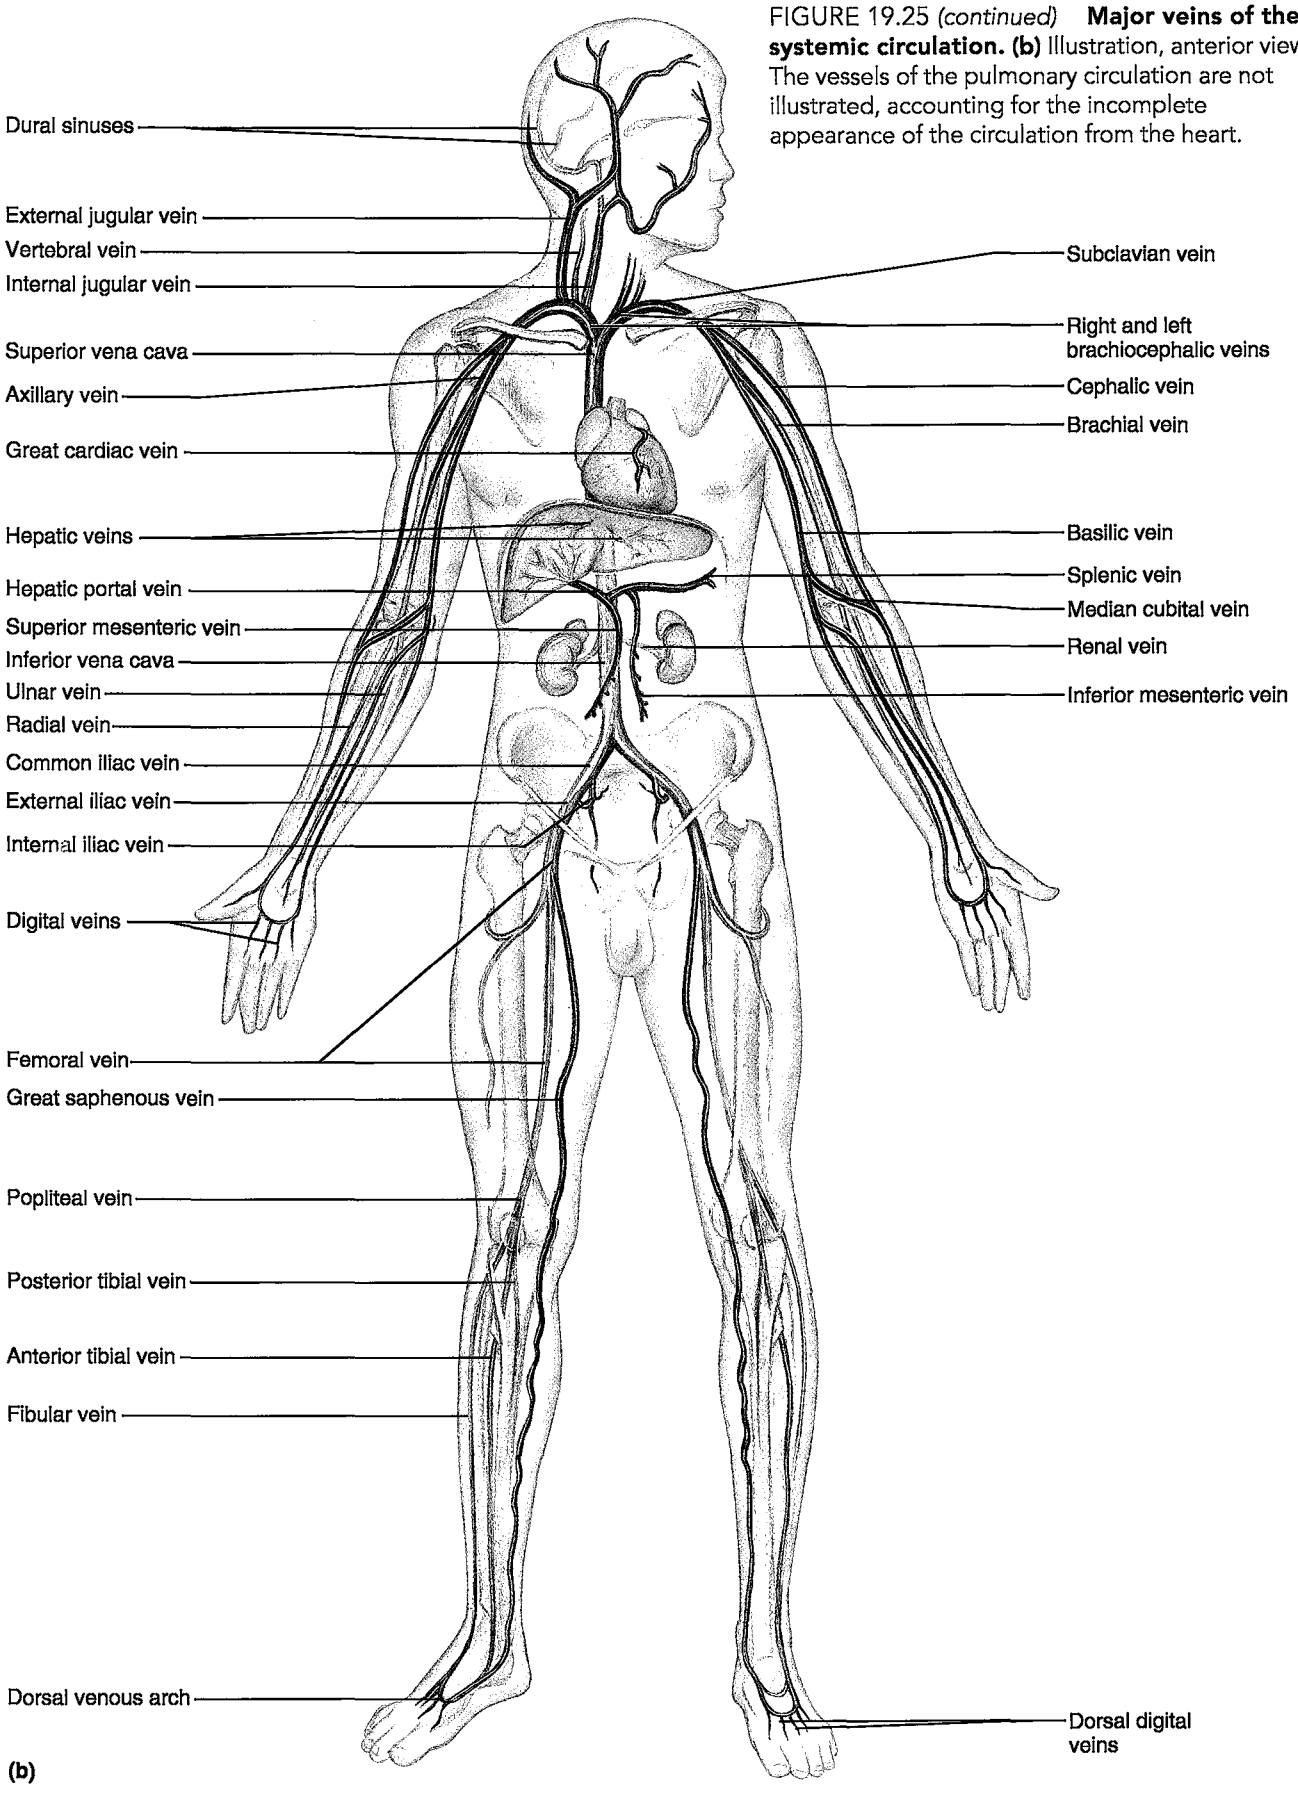

FIGURE 19.25 *(continued)* **Major veins of the systemic circulation. (b)** Illustration, anterior view. The vessels of the pulmonary circulation are not illustrated, accounting for the incomplete appearance of the circulation from the heart.

TABLE 19.10 Veins of the Head and Neck

Most blood draining from the head and neck is collected by three pairs of veins: the external jugular veins, which empty into the subclavians, the internal jugular veins, and the vertebral veins, which drain into the brachiocephalic vein (see Figure 19.26a). Although most extracranial veins have the same names as the extracranial arteries, their courses and interconnections differ substantially.

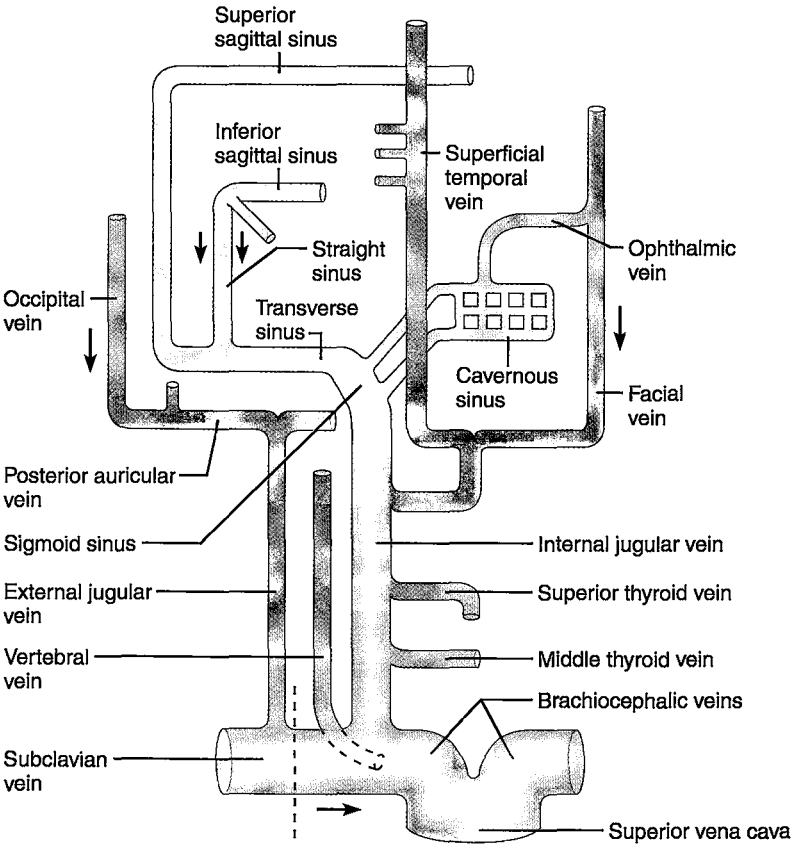
Most veins of the brain drain into the **dural sinuses,** an interconnected series of enlarged chambers located between the dura mater layers. The **superior** and **inferior sagittal sinuses** are in the falx cerebri, which dips down between the cerebral hemispheres. The inferior sagittal sinus drains into the **straight sinus** posteriorly (Figure 19.26a and c). The superior sagittal and straight sinuses then empty into the **transverse sinuses,** which run in shallow grooves on the internal surface of the occipital bone. These drain into the S-shaped **sigmoid sinuses,** which become the *internal jugular veins* as they leave the skull through the jugular foramen. The **cavernous sinuses,** which flank the sphenoid body, receive venous blood from the **ophthalmic veins** of the orbits and the facial veins, which drain the nose and upper lip area. The internal carotid artery and cranial nerves III, IV, VI, and part of V, all run *through* the cavernous sinus on their way to the orbit and face.

Description and Area Drained

External jugular veins. The right and left external jugular veins drain superficial scalp and face structures served by the external carotid arteries. However, their tributaries anastomose frequently, and some of the superficial drainage from these regions enters the internal jugular veins as well. As the external jugular veins descend through the lateral neck, they pass obliquely over the sternocleidomastoid muscles and then empty into the subclavian veins.

Vertebral veins. Unlike the vertebral arteries, the vertebral veins do not serve much of the brain. Instead they drain the cervical vertebrae, the spinal cord, and some small neck muscles. They run inferiorly through the transverse foramina of the cervical vertebrae and join the brachiocephalic veins at the root of the neck.

Internal jugular veins. The paired internal jugular veins, which receive the bulk of blood draining from the brain, are the largest of the paired veins draining the head and neck. They arise from the dural venous sinuses, exit the skull via the *jugular foramina,* and then descend through the neck alongside the internal carotid arteries. As they move inferiorly, they receive blood from some of the deep veins of the face and neck—branches of the **facial** and **superficial temporal veins** (Figure 19.26b). At the base of the neck, each internal jugular vein joins the subclavian vein on its own side to form a brachiocephalic vein. As already noted, the two brachiocephalic veins unite to form the superior vena cava.



(a)

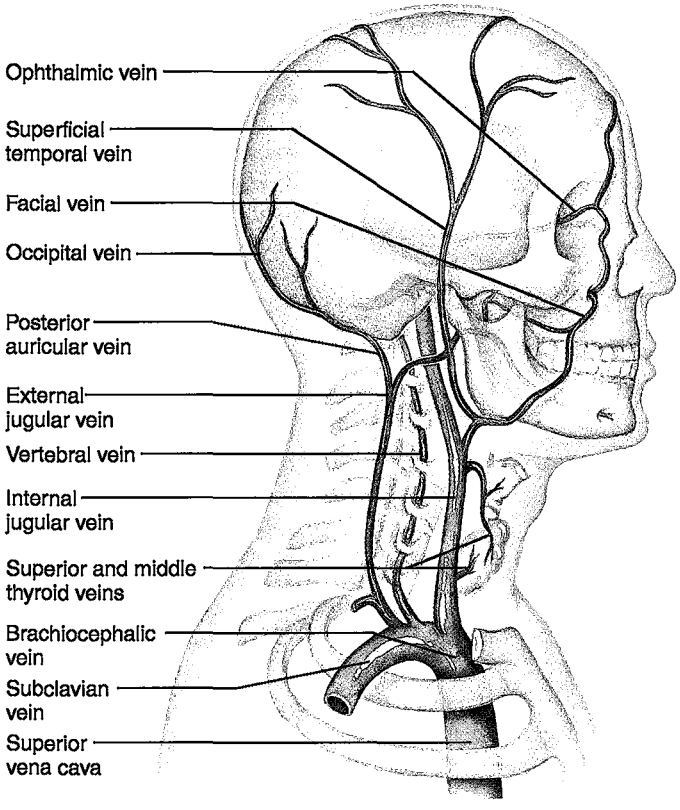
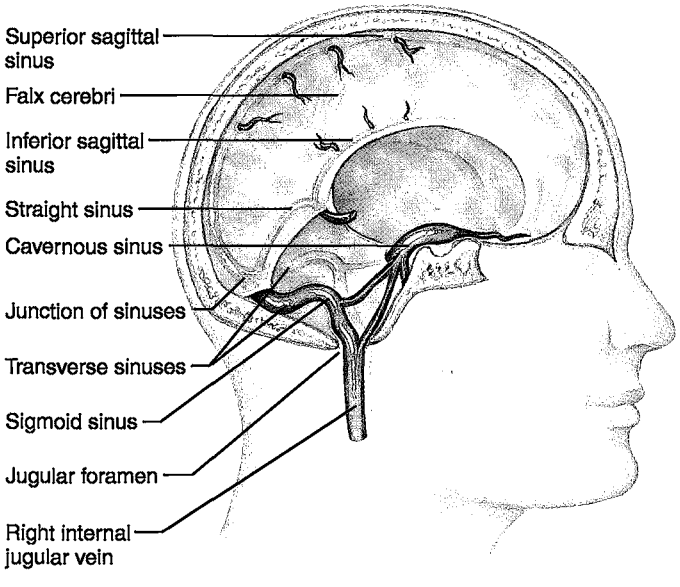
TABLE 19.10 *(continued)*



(b)

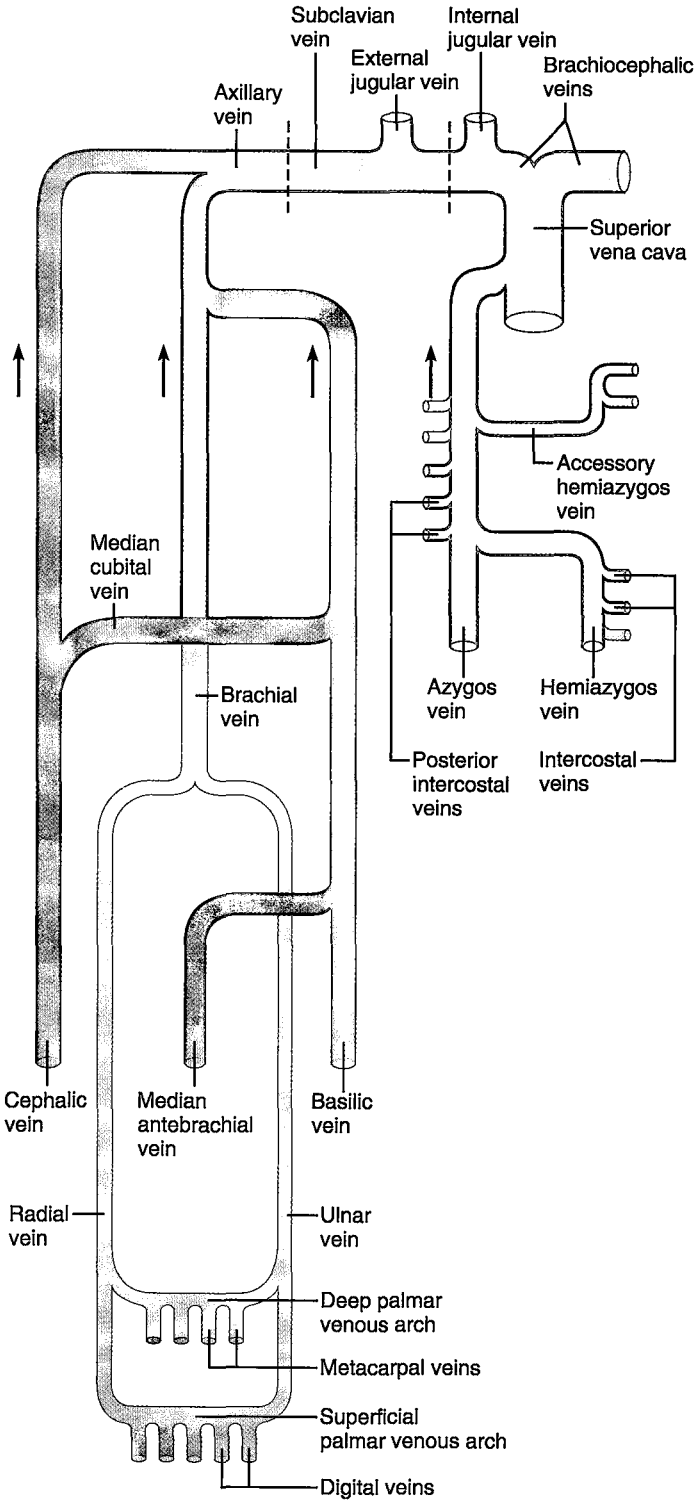


(c)

FIGURE 19.26 *(continued)* **Venous drainage of the head, neck, and brain.** **(b)** Veins of the head and neck, right superficial aspect. **(c)** Dural sinuses of the brain, right aspect.

TABLE 19.11 Veins of the Upper Limbs and Thorax

The deep veins of the upper limbs follow the paths of their companion arteries and have the same names (Figure 19.27a). However, except for the largest, most are paired veins that flank their artery. The superficial veins of the upper limbs are larger than the deep veins and are easily seen just beneath the skin. The median cubital vein, crossing the anterior aspect of the elbow, is commonly used to obtain blood samples or administer intravenous medications.



(a)

Blood draining from the mammary glands and the first two to three intercostal spaces enters the **brachiocephalic veins.** However, the vast majority of thoracic tissues and the thorax wall are drained by a complex network of veins called the **azygos system** (az′ĭ-gos). The branching nature of the azygos system provides a collateral circulation for draining the abdominal wall and other areas served by the inferior vena cava, and there are numerous anastomoses between the azygos system and the inferior vena cava.

Description and Areas Drained

Deep Veins of the Upper Limbs

The most distal deep veins of the upper limb are the radial and ulnar veins. The deep and superficial **palmar venous arches** of the hand empty into the **radial** and **ulnar veins** of the forearm, which then unite to form the **brachial vein** of the arm. As the brachial vein enters the axilla, it becomes the **axillary vein,** which becomes the **subclavian vein** at the level of the first rib.

Superficial Veins of the Upper Limbs

The superficial venous system begins with the **dorsal venous arch** (not illustrated), a plexus of superficial veins in the dorsum of the hand. In the distal forearm, this plexus drains into three major superficial veins—the cephalic and basilic veins and the median antebrachial vein of the forearm—which anastomose frequently as they course upward (see Figure 19.27b). The **cephalic vein** bends around the radius as it travels superiorly and then continues up the lateral superficial aspect of the arm to the shoulder, where it runs in the groove between the deltoid and pectoralis muscles to join the axillary vein. The **basilic vein** courses along the posteromedial aspect of the forearm, crosses the elbow, and then takes a deep course. In the axilla, it joins the brachial vein, forming the axillary vein. At the anterior aspect of the elbow, the **median cubital vein** connects the basilic and cephalic veins. The **median antebrachial vein** of the forearm lies between the radial and ulnar veins in the forearm and terminates (variably) at the elbow by entering either the basilic or the cephalic vein.

The Azygos System

The azygos system consists of the following vessels which flank the vertebral column laterally:

Azygos vein. Located against the right side of the vertebral column, the **azygos vein** (*azygos* = unpaired) originates in the abdomen, from the **right ascending lumbar vein** that drains most of the right abdominal cavity wall and from the **right posterior intercostal veins** (except the first) that drain the chest muscles. At the T_4 level, it arches over the great vessels that run to the right lung and empties into the superior vena cava.

TABLE 19.11 (continued)

Hemiazygos vein (hĕ'me-a-zi'gus; "half the azygos"). This vessel ascends on the left side of the vertebral column. Its origin, from the **left ascending lumbar vein** and the lower (9th–11th) **posterior intercostal veins,** mirrors that of the inferior portion of the azygos vein on the right. About midthorax, the hemiazygos vein passes in front of the vertebral column and joins the azygos vein.

Accessory hemiazygos vein. The accessory hemiazygos completes the venous drainage of the left (middle) thorax and can be thought of as a superior continuation of the hemiazygos vein. It receives blood from the 4th–8th posterior intercostal veins and then crosses to the right to empty into the azygos vein. Like the azygos, it receives venous blood from the lungs *(bronchial veins).*

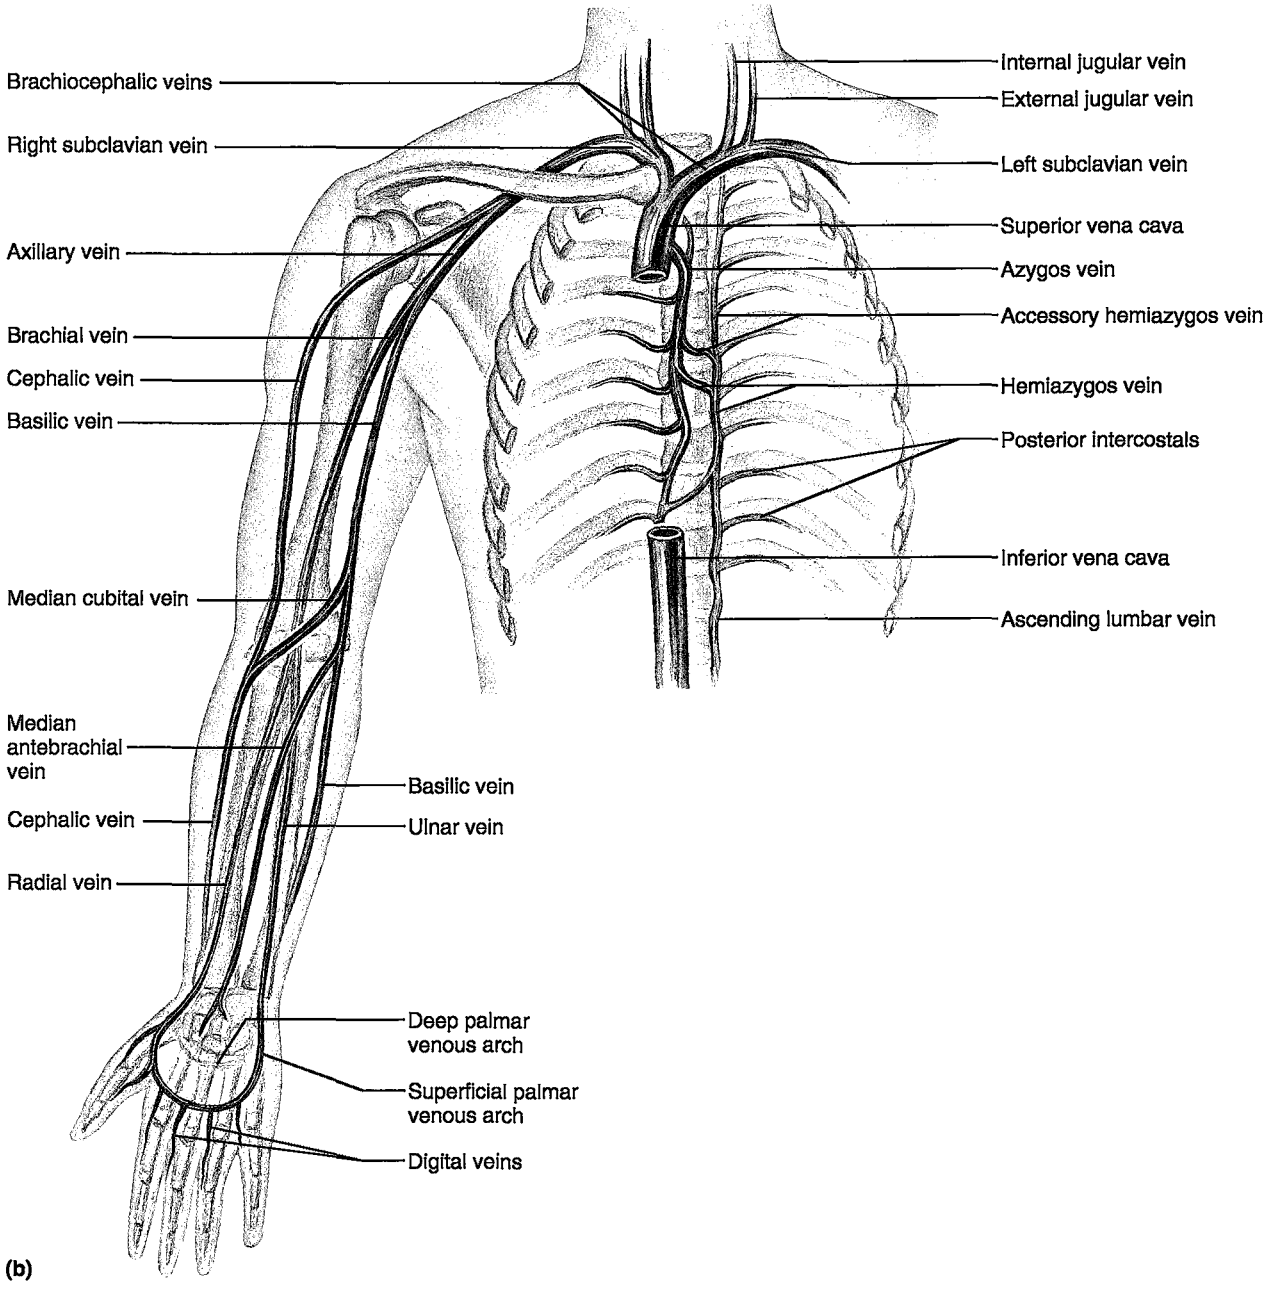


FIGURE 19.27 **Veins of the right upper limb and shoulder. (a)** Schematic flowchart. **(b)** Illustration. For clarity, the abundant branching and anastomoses of these vessels are not shown.

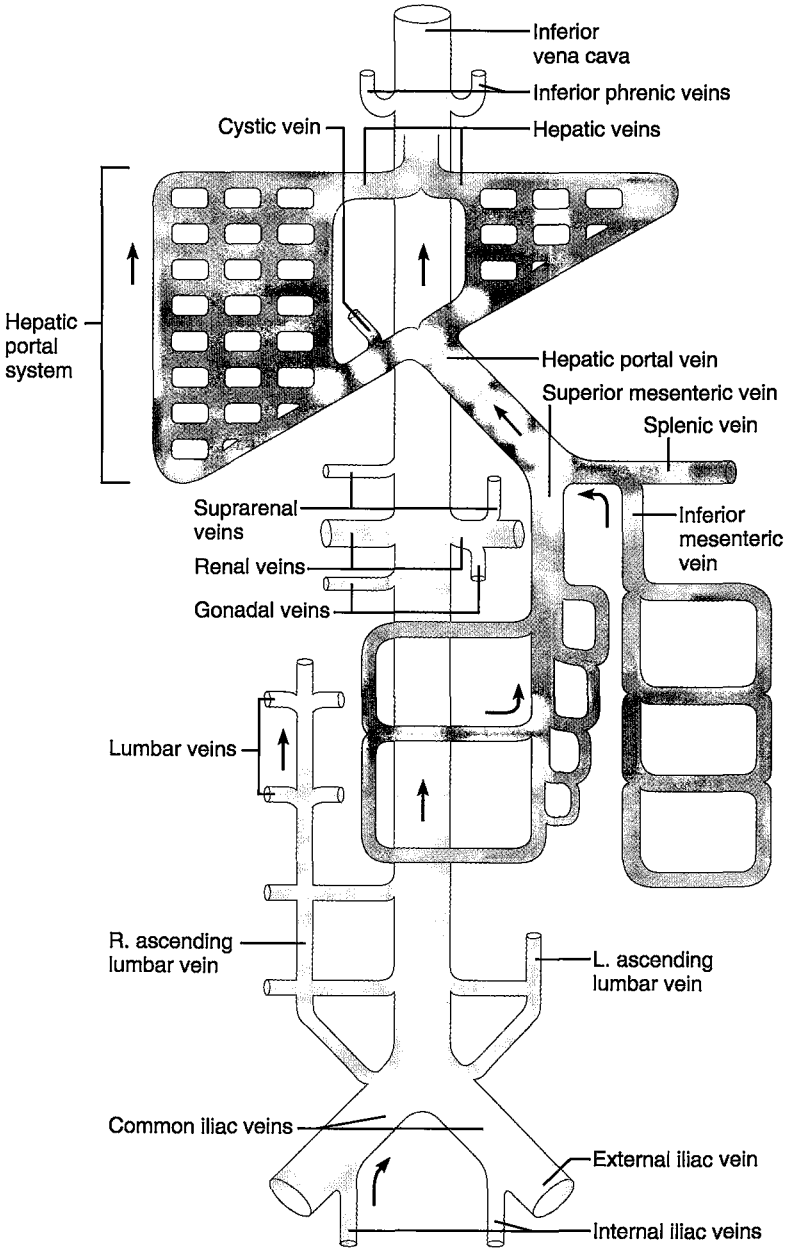
TABLE 19.12 Veins of the Abdomen

Blood draining from the abdominopelvic viscera and abdominal walls is returned to the heart by the **inferior vena cava** (Figure 19.28a). Most of its venous tributaries have names that correspond to the arteries serving the abdominal organs.

Veins draining the digestive viscera empty into a common vessel, the *hepatic portal vein*, which transports this venous blood into the liver before it is allowed to enter the major systemic circulation via the hepatic veins (Figure 19.28b). Such a venous system—veins to capillaries (or sinusoids) to veins—is called a *portal system* and always serves very specific regional tissue needs. The **hepatic portal system** carries nutrient-rich blood from the digestive organs to the liver. As the blood percolates slowly through the liver sinusoids, hepatocytes remove the nutrients they need for their various metabolic functions, and phagocytic cells lining the sinusoids rid the blood of bacteria and other foreign matter that has penetrated the digestive mucosa. The veins of the abdomen are listed in inferior to superior order.



(a)

Description and Areas Drained

Lumbar veins. Several pairs of lumbar veins drain the posterior abdominal wall. They empty both directly into the inferior vena cava and into the ascending lumbar veins of the azygos system of the thorax.

Gonadal (testicular or ovarian) veins. The right gonadal vein drains the ovary or testis on the right side of the body and empties into the inferior vena cava. The left member drains into the left renal vein superiorly.

Renal veins. The right and left renal veins drain the kidneys.

Suprarenal veins. The right suprarenal vein drains the adrenal gland on the right and empties into the inferior vena cava. The left suprarenal vein drains into the left renal vein.

Hepatic portal system. Like all portal systems, the hepatic portal system is a series of vessels in which two separate capillary beds lie between the arterial supply and the final venous drainage. In this case, the first capillary beds are in the stomach and intestines and drain into tributaries of the **hepatic portal vein,** which brings them to the second capillary bed in the liver. The short hepatic portal vein begins at the L_2 level. Numerous tributaries from the stomach and pancreas contribute to the hepatic portal system (Figure 19.28c), but the major vessels are as follows:

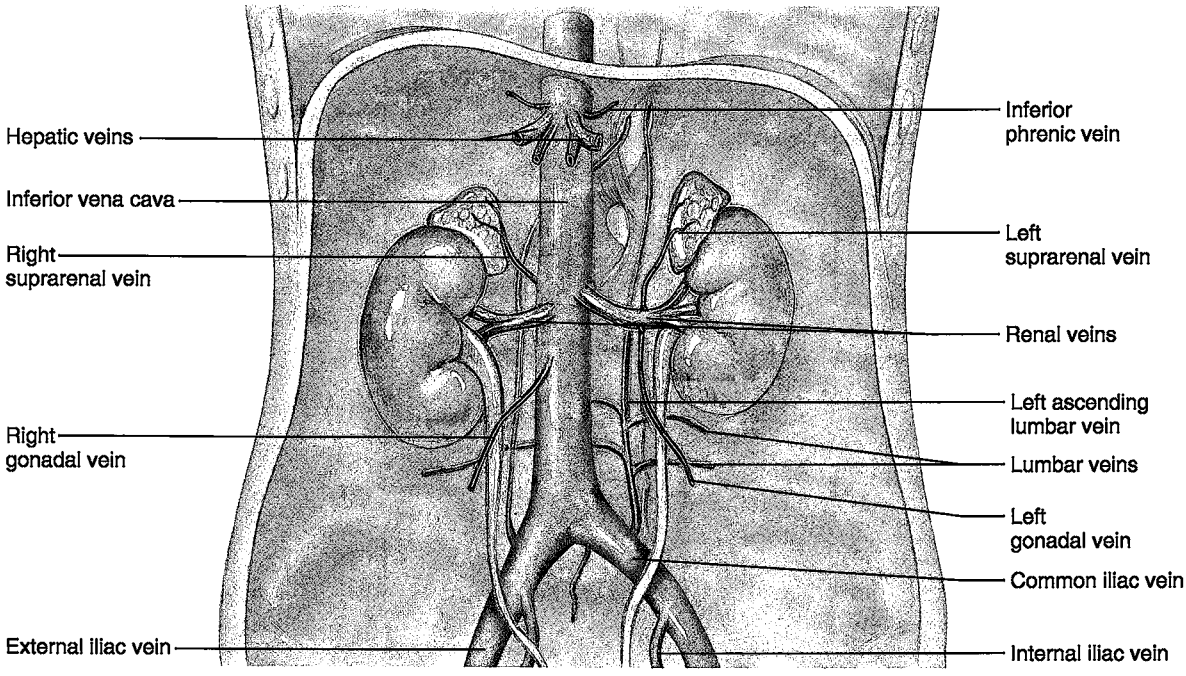
- **Superior mesenteric vein:** Drains the entire small intestine, part of the large intestine (ascending and transverse regions), and stomach.
- **Splenic vein:** Collects blood from the spleen, parts of the stomach and pancreas, and then joins the superior mesenteric vein to form the hepatic portal vein.
- **Inferior mesenteric vein:** Drains the distal portions of the large intestine and rectum and joins the splenic vein just before that vessel unites with the superior mesenteric vein to form the hepatic portal vein.

Hepatic veins. The right and left hepatic veins carry venous blood from the liver to the inferior vena cava.

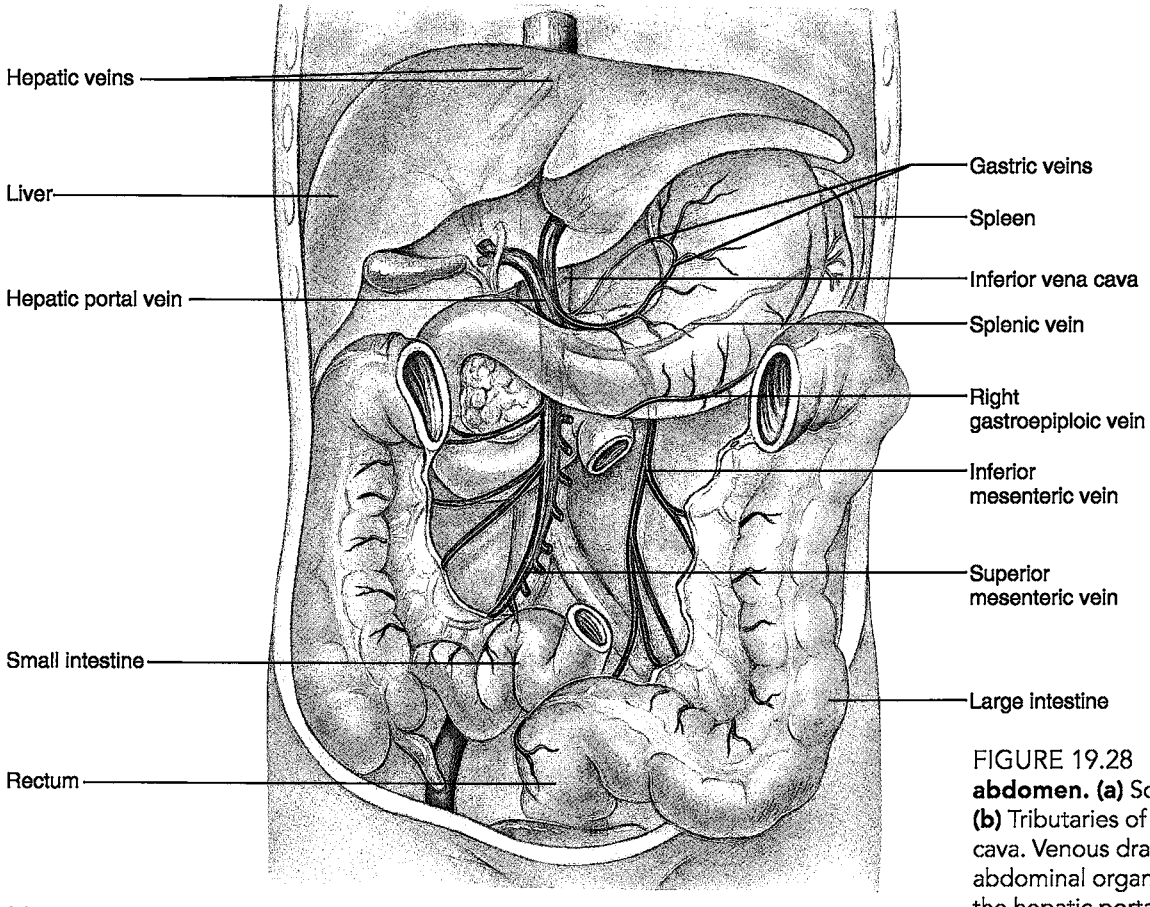
Cystic veins. The cystic veins drain the gallbladder and join the hepatic veins.

Inferior phrenic veins. The inferior phrenic veins drain the inferior surface of the diaphragm.

TABLE 19.12 (continued)



(b)



(c)

FIGURE 19.28 **Veins of the abdomen. (a)** Schematic flowchart. **(b)** Tributaries of the inferior vena cava. Venous drainage of abdominal organs not drained by the hepatic portal vein. **(c)** The hepatic portal circulation.

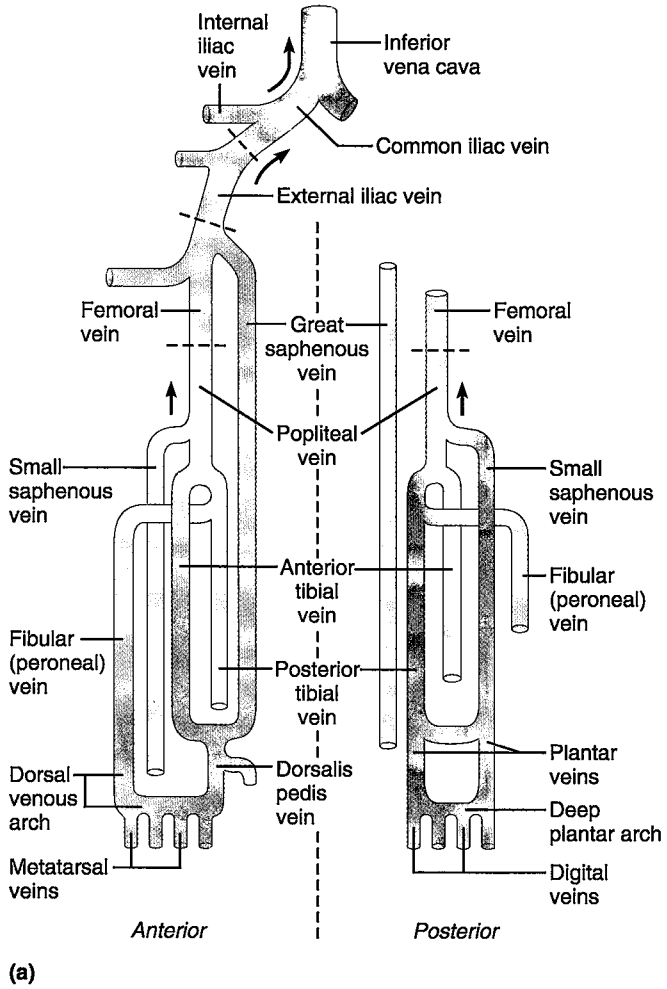
TABLE 19.13 Veins of the Pelvis and Lower Limbs

As in the upper limbs, most deep veins of the lower limbs have the same names as the arteries they accompany and many are double. The two superficial saphenous veins (great and small) are poorly supported by surrounding tissues, and are common sites of varicosities. The great saphenous (*saphenous* = obvious) vein is frequently excised and used as a coronary bypass vessel.

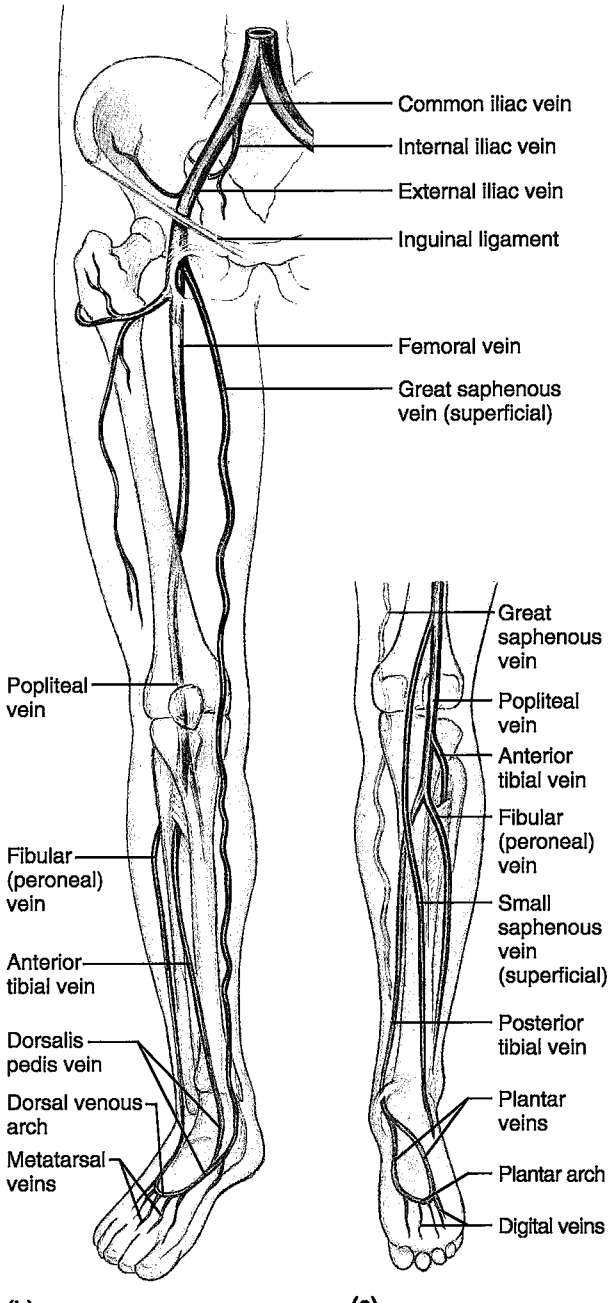
Description and Areas Drained

Deep veins. After being formed by the union of the **medial** and **lateral plantar veins,** the **posterior tibial vein** ascends deep in the calf muscle (Figure 19.29) and receives the **fibular (peroneal) vein.** The **anterior tibial vein,** which is the superior continuation of the **dorsalis pedis vein** of the foot, unites at the knee with the posterior tibial vein to form the **popliteal vein,** which crosses the back of the knee. As the popliteal vein emerges from the knee, it becomes the **femoral vein,** which drains the deep structures of the thigh. The femoral vein becomes the **external iliac vein** as it enters the pelvis. In the pelvis, the external iliac vein unites with the **internal iliac vein** to form the **common iliac vein.** The distribution of the internal iliac veins parallels that of the internal iliac arteries.

Superficial veins. The **great** and **small saphenous veins** (sah-fe'nus) issue from the **dorsal venous arch** of the foot (Figure 19.29b and c). These veins anastomose frequently with each other and with the deep veins along their course. The great saphenous vein is the longest vein in the body. It travels superiorly along the medial aspect of the leg to the thigh, where it empties into the femoral vein just distal to the inguinal ligament. The small saphenous vein runs along the lateral aspect of the foot and then through the deep fascia of the calf muscles, which it drains. At the knee, it empties into the popliteal vein.



(a)



(b) (c)

FIGURE 19.29 **Veins of the right lower limb.**
(a) Schematic flowchart of anterior and posterior vessels. **(b)** Anterior view of the lower limb. **(c)** Posterior view of the leg and foot.

Related Clinical Terms

Aneurysm (an'u-rizm; *aneurysm* = a widening) A balloon-like outpocketing of an artery wall that places the artery at risk for rupture; most often reflects gradual weakening of the artery by chronic hypertension or arteriosclerosis. The most common sites of aneurysm formation are the abdominal aorta and arteries feeding the brain and kidneys.

Angiogram (an'je-o-gram"; *angio* = a vessel; *gram* = writing) Diagnostic technique involving the infusion of a radiopaque substance into the circulation for X ray examination of specific blood vessels; the major technique for diagnosing coronary artery occlusion and risk of a heart attack.

Diuretic (*diure* = urinate) A chemical that promotes urine formation, thus reducing blood volume; diuretic drugs are frequently prescribed to manage hypertension.

Phlebitis (flĕ-bi'tis; *phleb* = vein; *itis* = inflammation) Inflammation of a vein accompanied by painful throbbing and redness of the skin over the inflamed vessel; most often caused by bacterial infection or local physical trauma.

Phlebotomy (flĕ-bot'o-me; *tomy* = cut) A venous incision made for the purpose of withdrawing blood or bloodletting.

Sclerotherapy Procedure used for removing varicose or spider veins; tiny needles are used to inject hardening agents into the abnormal vein; the vein scars, closes down, and is absorbed by the body.

Thrombophlebitis Condition of undesirable intravascular clotting initiated by a roughening of a venous lining; often follows severe episodes of phlebitis. An ever-present danger is that the clot may detach and form an embolus.

Chapter Summary

Media study tools that could provide you additional help in reviewing specific key topics of Chapter 19 are referenced below. IP = *InterActive Physiology*

PART 1: OVERVIEW OF BLOOD VESSEL STRUCTURE AND FUNCTION

1. Blood is transported throughout the body via a continuous system of blood vessels. Arteries transport blood away from the heart; veins carry blood back to the heart. Capillaries carry blood to tissue cells and are exchange sites.

Structure of Blood Vessel Walls (pp. 714–716)

1. All blood vessels except capillaries have three layers: tunica intima, tunica media, and tunica externa. Capillary walls are composed of the tunica intima only.

Arterial System (pp. 716–719)

1. Elastic (conducting) arteries are the large arteries close to the heart that expand during systole, acting as pressure reservoirs, and then recoil during diastole to keep blood moving. Muscular (distributing) arteries carry blood to specific organs; they are less stretchy and more active in vasoconstriction. Arterioles regulate blood flow into capillary beds.

2. Arteriosclerosis is a degenerative vascular disease that decreases the elasticity of arteries. Atherosclerosis is the formation of fatty subendothelial lesions.

Capillaries (pp. 720–722)

1. Capillaries are microscopic vessels with very thin walls. Most exhibit clefts, which aid in the exchange between the blood and interstitial fluid.

2. The most permeable capillaries are sinusoids (wide, tortuous channels). Fenestrated capillaries with pores are next most permeable. Least permeable are continuous capillaries, which lack pores.

3. Vascular shunts (metarteriole–thoroughfare channels) connect the terminal arteriole and venule at opposite ends of a capillary bed. Most true capillaries arise from and rejoin the shunt channels. The amount of blood flowing into the true capillaries is regulated by precapillary sphincters.

Venous System (pp. 722–723)

1. Veins have comparatively larger lumens than arteries, and a system of valves prevents backflow of blood.

2. Normally most veins are only partially filled; thus, they can serve as blood reservoirs.

Vascular Anastomoses (p. 723)

1. The joining together of arteries to provide alternate channels for blood to reach the same organ is called an anastomosis. Vascular anastomoses also form between veins and between arterioles and venules.

IP Cardiovascular System; Topic: Anatomy Review: Blood Vessel Structure and Function, pp. 1–28.

PART 2: PHYSIOLOGY OF CIRCULATION

Introduction to Blood Flow, Blood Pressure, and Resistance (pp. 723–724)

1. Blood flow is the amount of blood flowing through a vessel, an organ, or the entire circulation in a given period of time. Blood pressure is the force per unit area exerted on a vessel wall by the contained blood. Resistance is opposition to blood flow; blood viscosity and blood vessel length and diameter contribute to resistance.

2. Blood flow is directly proportional to blood pressure and inversely proportional to resistance.

IP Cardiovascular System; Topic: Factors that Affect Blood Pressure, pp. 1–15.

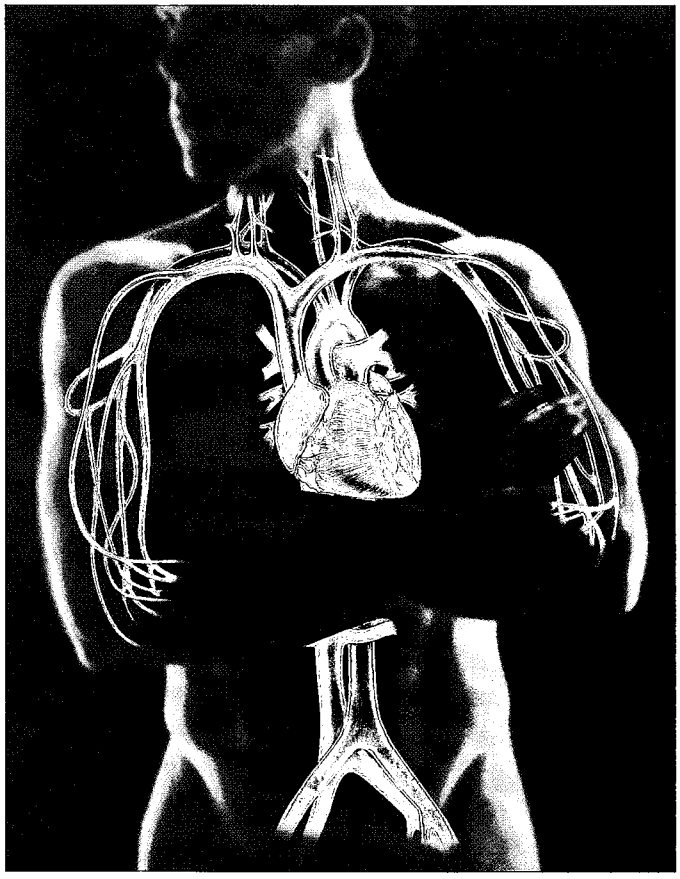
Systemic Blood Pressure (pp. 724–726)

1. Systemic blood pressure is highest in the aorta and lowest in the venae cavae. The steepest drop in BP occurs in the arterioles, where resistance is greatest.

2. Arterial BP depends on compliance of the elastic arteries and on how much blood is forced into them. Arterial blood pressure is pulsatile, and peaks during systole; this is measured as systolic pressure. During diastole, as blood is forced distally in the circulation by the rebound of elastic arteries, arterial BP drops to its lowest value, called the diastolic pressure.

MAKING CONNECTIONS

SYSTEM CONNECTIONS: Homeostatic Interrelationships Between the Cardiovascular System and Other Body Systems



Integumentary System

- The cardiovascular system delivers oxygen and nutrients; carries away wastes
- The skin vasculature is an important blood reservoir and provides a site for heat loss from the body

Skeletal System

- The cardiovascular system delivers oxygen and nutrients; carries away wastes
- Bones are the sites of hematopoiesis; protect cardiovascular organs by enclosure; and provide a calcium depot

Muscular System

- The cardiovascular system delivers oxygen and nutrients; carries away wastes
- The muscle "pump" aids venous return; aerobic exercise enhances cardiovascular efficiency and helps prevent atherosclerosis

Nervous System

- The cardiovascular system delivers oxygen and nutrients; carries away wastes
- The ANS regulates cardiac rate and force; sympathetic division maintains blood pressure and controls blood flow to skin for thermoregulation

Endocrine System

- The cardiovascular system delivers oxygen and nutrients; carries away wastes; blood serves as a transport vehicle for hormones
- Various hormones influence blood pressure (epinephrine, ANP, angiotensin II, thyroxine, ADH); estrogen maintains vascular health in women

Lymphatic System/Immunity

- The cardiovascular system delivers oxygen and nutrients to lymphatic organs, which house immune cells; provides transport medium for lymphocytes and antibodies; carries away wastes
- The lymphatic system picks up leaked fluid and plasma proteins and returns them to the cardiovascular system; its immune cells protect cardiovascular organs from specific pathogens

Respiratory System

- The cardiovascular system delivers oxygen and nutrients; carries away wastes
- The respiratory system carries out gas exchange: loads oxygen and unloads carbon dioxide from the blood; respiratory "pump" aids venous return

Digestive System

- The cardiovascular system delivers oxygen and nutrients; carries away wastes
- The digestive system provides nutrients to the blood including iron and B vitamins essential for RBC (and hemoglobin) formation

Urinary System

- The cardiovascular system delivers oxygen and nutrients; carries away wastes; blood pressure allows filtration in the kidneys
- The urinary system helps regulate blood volume and pressure by altering urine volume and releasing renin

Reproductive System

- The cardiovascular system delivers oxygen and nutrients; carries away wastes
- Estrogen maintains vascular and osseous health in women

CLOSER CONNECTIONS

THE CARDIOVASCULAR SYSTEM and Interrelationships with the Muscular, Nervous, and Urinary Systems

The cardiovascular system is the "king of systems." No body system can live without the blood that surges ceaselessly through cardiovascular channels. Likewise, it is nearly impossible to find a system that does not influence the cardiovascular system in some way. The respiratory and digestive systems enrich blood with oxygen and nutrients, respectively, and in turn take a share of the various riches the blood has to offer. By returning leaked plasma fluid to the vascular system, the lymphatic system helps to keep those vessels filled with blood so that circulation is possible. However, the three cardiovascular system partnerships that we will look at more closely here are those it has with the muscular, nervous, and urinary systems.

Muscular System

Talk about one hand washing the other—that's a pretty fair analogy for the interaction between the cardiovascular and muscular systems. Muscles cramp and become nonfunctional when deprived of an adequate supply of oxygen-rich blood, and their capillary supply expands (or atrophies) along with changes in muscle mass. The arterioles of skeletal muscle even have special beta-adrenergic receptors so that they can be dilated by circulating epinephrine when most other body arterioles are responding to vasoconstrictor "orders." When muscles are active and healthy, so too is the cardiovascular system. Without exercise, the heart weakens and loses mass; but when we exercise aerobically, the heart increases in size and strength. Heart rate goes down as stroke volume rises, and a lower HR means that the heart relaxes more and beats hundreds of thousands times less in a lifetime. Aerobic exercise also enhances HDL blood levels and reduces LDL levels—helping to clear fatty deposits from the vascular walls and deferring atherosclerosis, hypertension, and heart disease. Not a bad trade!

Nervous System

The brain must have absolutely continuous oxygen and glucose delivery; thus it should come as no surprise that the brain has the body's most precise autoregulatory circulation mechanism. Acting on acutely sensitive arterioles, this mechanism protects the brain. For this we can be profoundly thankful, for when neurons die, an important part of us dies as well. The cardiovascular system is just as dependent on the nervous system. Although an intrinsic pacemaker sets sinus rhythm, it does not even begin to adapt to stimuli that mobilize the cardiovascular system to peak efficiency in maintaining blood pressure during position changes and delivering blood faster during times of stress. This is the job of the autonomic nervous system, which initiates reflexes as necessary to increase or decrease cardiac output and peripheral resistance, and to redirect blood from one organ to others to serve specific needs and protect vital organs.

Urinary System

Like the lymphatic system, the urinary system (primarily the kidneys) helps maintain blood volume and circulatory dynamics, but in a much more complicated way. The kidneys use blood pressure (courtesy of the cardiovascular system) to form the filtrate which the kidney tubule cells then process. Essentially this processing involves reclaiming needed nutrients and water while allowing metabolic waste and excess ions (including H^+) to leave the body in urine. As a result, blood is continually refreshed and blood composition and volume are carefully regulated. So dedicated are the kidneys to preserving blood volume that urine output stops entirely when blood volume is severely depressed. On the other hand, the kidneys can increase systemic BP by releasing renin when the blood pressure becomes inadequate.

CLINICAL CONNECTIONS

Cardiovascular System

Case study: Mr. Hutchinson, another middle-aged victim of the collision on Route 91, has a tourniquet around his thigh when admitted in an unconscious state to Noble Hospital. The emergency technician who brings him in states that his right lower limb was pinned beneath the bus for at least 30 minutes. He is immediately scheduled for surgery. Admission notes include the following:

- Multiple contusions of lower limbs
- Compound fracture of the right tibia; bone ends covered with sterile gauze
- Right leg blanched and cold, no pulse
- Blood pressure 90/48; pulse 140/min and thready; patient diaphoretic (sweaty)

1. Relative to what you have learned about tissue requirements for oxygen, what is the condition of the tissues in the right lower limb?

2. Will the fracture be attended to, or will Mr. Hutchinson's other homeostatic needs take precedence? Explain your answer choice and predict his surgical treatment.

3. What do you conclude regarding Mr. Hutchinson's cardiovascular measurements (pulse and BP), and what measures do you expect will be taken to remedy the situation before commencing surgery?

(Answers in Appendix G)

3. Pulse pressure is systolic pressure minus diastolic pressure. The mean arterial pressure (MAP) = diastolic pressure plus one-third of pulse pressure and is the pressure that keeps blood moving throughout the cardiac cycle.

4. Low capillary pressure (35 to 15 mm Hg) protects the delicate capillaries from rupture while still allowing adequate exchange across the capillary walls.

5. Venous pressure is nonpulsatile and low (declining to zero) because of the cumulative effects of resistance. Venous valves, large lumens, functional adaptations (muscular and respiratory pumps), and sympathetic nervous system activity promote venous return.

Maintaining Blood Pressure (pp. 726–733)

1. Blood pressure varies directly with CO, peripheral resistance (*R*), and blood volume. Vessel diameter is the major factor determining resistance, and small changes in vessel (chiefly arteriolar) diameter significantly affect blood pressure.

IP Cardiovascular System; Topic: Measuring Blood Pressure, pp. 1–13.

2. BP is regulated by autonomic neural reflexes involving baroreceptors or chemoreceptors, the vasomotor center (a medullary center that regulates blood vessel diameter), and sympathetic vasomotor fibers, which act on vascular smooth muscle.

3. Activation of the receptors by falling BP (and to a lesser extent by a rise in blood CO_2, or falling blood pH or O_2 levels) stimulates the vasomotor center to increase vasoconstriction and the cardioacceleratory center to increase heart rate and contractility. Rising BP inhibits the vasomotor center (permitting vasodilation) and activates the cardioinhibitory center.

4. Higher brain centers (cerebrum and hypothalamus) may modify neural controls of BP via medullary centers.

5. Hormones that increase BP by promoting vasoconstriction include epinephrine and NE (these also increase heart rate and contractility), ADH, and angiotensin II (generated in response to renin release by kidney cells). Hormones that reduce BP by promoting vasodilation include atrial natriuretic peptide, which also causes a decline in blood volume.

6. The kidneys regulate blood pressure by regulating blood volume. Rising BP directly enhances filtrate formation and fluid losses in urine; falling BP causes the kidneys to retain more water, increasing blood volume.

7. Indirect renal regulation of blood volume involves the renin-angiotensin mechanism, a hormonal mechanism. When BP falls, the kidneys release renin, which triggers the formation of angiotensin II (a vasoconstrictor) and release of aldosterone, which causes salt and water retention.

IP Cardiovascular System; Topic: Blood Pressure Regulation, pp. 1–31.

8. Pulse and blood pressure measurements are used to assess cardiovascular efficiency.

9. The pulse is the alternating expansion and recoil of arterial walls with each heartbeat. Pulse points are also pressure points.

10. Blood pressure is routinely measured by the auscultatory method. Normal blood pressure in adults is 120/80 (systolic/diastolic). Hypotension is rarely a problem. Hypertension is the major cause of myocardial infarct, stroke, and renal disease.

IP Cardiovascular System; Topic: Measuring Blood Pressure, pp. 11, 12.

11. Hypotension, or low blood pressure (systolic pressure below 100 mm Hg), is a sign of health in the well conditioned. In other individuals it warns of poor nutrition, disease, or circulatory shock.

12. Chronic hypertension (high blood pressure) is persistent BP readings of 140/90 or higher. It indicates increased peripheral resistance, which strains the heart and promotes vascular complications of other organs, particularly the eyes and kidneys. Risk factors are high-fat, high-salt diet, obesity, diabetes mellitus, advanced age, smoking, stress, and being a member of the black race or a family with a history of hypertension.

IP Cardiovascular System; Topic: Measuring Blood Pressure, pp. 11, 12.

Blood Flow Through Body Tissues: Tissue Perfusion (pp. 733–742)

1. Blood flow is involved in delivering nutrients and wastes to and from cells, gas exchange, absorbing nutrients, and forming urine.

2. Blood flows fastest where the cross-sectional area of the vascular bed is least (aorta), and slowest where the total cross-sectional area is greatest (capillaries). The slow flow in capillaries allows time for nutrient-waste exchanges.

3. Autoregulation is the local adjustment of blood flow to individual organs based on their immediate requirements. It involves myogenic controls that maintain flow despite changes in blood pressure, and local chemical factors. Vasodilators include increased CO_2, H^+, and nitric oxide. Decreased O_2 and nutrient concentrations also cause vasodilation. Other factors, including endothelins, decrease blood flow.

IP Cardiovascular; Topic: Autoregulation and Capillary Dynamics, pp. 1–13.

4. In most instances, autoregulation is controlled by oxygen deficits and accumulation of local metabolites. However, autoregulation in the brain is controlled primarily by a drop in pH and by myogenic mechanisms; and vasodilation of pulmonary circuit vessels occurs in response to high levels of oxygen.

5. Nutrients, gases, and other solutes smaller than plasma proteins cross the capillary wall by diffusion. Water-soluble substances move through the clefts or fenestrations; fat-soluble substances pass through the lipid portion of the endothelial cell membrane; larger molecules are actively transported via pinocytotic vesicles or caveolae.

6. Bulk flow of fluids at capillary beds determines the distribution of fluids between the bloodstream and the interstitial space. It reflects the relative effect of outward (net hydrostatic pressure) forces minus the effect of inward (net osmotic pressure) forces. In general, fluid flows out of the capillary bed at the arterial end and reenters the capillary blood at the venule end.

IP Cardiovascular; Topic: Autoregulation and Capillary Dynamics, pp. 14–38.

7. The small net loss of fluid and protein into the interstitial space is collected by lymphatic vessels and returned to the cardiovascular system.

8. Circulatory shock occurs when blood perfusion of body tissues is inadequate. Most cases of shock reflect low blood volume (hypovolemic shock), abnormal vasodilation (vascular shock), or pump failure (cardiogenic shock).

PART 3: CIRCULATORY PATHWAYS: BLOOD VESSELS OF THE BODY

The Two Main Circulations of the Body (p. 742)

1. The pulmonary circulation transports O_2-poor, CO_2-laden blood to the lungs for oxygenation and carbon dioxide unloading. Blood returning to the right atrium of the heart is pumped by the right ventricle to the lungs via the pulmonary trunk. Blood issuing from the lungs is returned to the left atrium by the pulmonary veins. (See Table 19.3 and Figure 19.18.)

2. The systemic circulation transports oxygenated blood from the left ventricle to all body tissues via the aorta and its branches. Venous blood returning from the systemic circuit is delivered to the right atrium via the venae cavae.

Systemic Arteries and Veins: Differences in Pathways and Courses (p. 742)

3. All arteries are deep while veins are both deep and superficial. Superficial veins tend to have numerous interconnections. Dural sinuses and the hepatic portal circulation are unique venous drainage patterns.

Principal Vessels of the Systemic Circulation (pp. 742–743)

4. Tables 19.3 to 19.13 and Figures 19.19 to 19.29 illustrate and describe vessels of the systemic circulation.

Developmental Aspects of Blood Vessels (p. 743)

1. The fetal vasculature develops from embryonic blood islands and mesenchyme and is functioning in blood delivery by the fourth week.

2. Fetal circulation differs from circulation after birth. The pulmonary and hepatic shunts and special umbilical vessels are normally occluded shortly after birth.

3. Blood pressure is low in infants and rises to adult values. Age-related vascular problems include varicose veins, hypertension, and atherosclerosis. Hypertension is the most important cause of sudden cardiovascular death in middle-aged men. Atherosclerosis is the most important cause of cardiovascular disease in the aged.

Review Questions

Multiple Choice/Matching

(Some questions have more than one correct answer. Select the best answer or answers from the choices given.)

1. Which statement does not accurately describe veins? (a) They have less elastic tissue and smooth muscle than arteries, (b) they contain more fibrous tissue than arteries, (c) most veins in the extremities have valves, (d) they always carry deoxygenated blood.

2. Smooth muscle in the blood vessel wall (a) is found primarily in the tunica intima, (b) is mostly circularly arranged, (c) is most abundant in veins, (d) is usually innervated by the parasympathetic nervous system.

3. Peripheral resistance (a) is inversely proportional to the length of the vascular bed, (b) increases in anemia, (c) is decreased in obesity, (d) is inversely related to the diameter of the arterioles.

4. Which of the following can lead to decreased venous return of blood to the heart? (a) an increase in blood volume, (b) an increase in venous pressure, (c) damage to the venous valves, (d) increased muscular activity.

5. Arterial blood pressure increases in response to (a) increasing stroke volume, (b) increasing heart rate, (c) arteriosclerosis, (d) rising blood volume, (e) all of these.

6. Which of the following would *not* result in the dilation of the feeder arterioles and opening of the precapillary sphincters in systemic capillary beds? (a) a decrease in local tissue O_2 content, (b) an increase in local tissue CO_2, (c) a local increase in histamine, (d) a local increase in pH.

7. The structure of a capillary wall differs from that of a vein or an artery because (a) it has two tunics instead of three, (b) there is less smooth muscle, (c) it has a single tunic—only the tunica intima, (d) none of these.

8. The baroreceptors in the carotid sinus and aortic arch are sensitive to (a) a decrease in CO_2, (b) changes in arterial pressure, (c) a decrease in O_2, (d) all of these.

9. The myocardium receives its blood supply directly from (a) the aorta, (b) the coronary arteries, (c) the coronary sinus, (d) the pulmonary arteries.

10. Blood flow in the capillaries is steady despite the rhythmic pumping of the heart because of the (a) elasticity of the large arteries, (b) small diameter of capillaries, (c) thin walls of the veins, (d) venous valves.

11. Tracing the blood from the heart to the right hand, we find that blood leaves the heart and passes through the aorta, the right subclavian artery, the axillary and brachial arteries, and through either the radial or ulnar artery to arrive at the hand. Which artery is missing from this sequence? (a) coronary, (b) brachiocephalic, (c) cephalic, (d) right common carotid.

12. Which of the following do not drain directly into the inferior vena cava? (a) inferior phrenic veins, (b) hepatic veins, (c) inferior mesenteric vein, (d) renal veins.

13. In atherosclerosis, which layer of the vessel wall thickens most? (a) tunica media, (b) tunica intima, (c) tunica adventitia, (d) tunica externa.

14. Suppose that at a given point along a capillary, the following forces exist: capillary hydrostatic pressure (HP_c) = 30 mm Hg, interstitial fluid hydrostatic pressure (HP_{if}) = 0 mm Hg, capillary colloid osmotic pressure (OP_c) = 25 mm Hg and interstitial fluid colloid osmotic pressure (OP_{if}) = 2 mm Hg. The net filtration pressure at this point in the capillary is (a) 3 mm Hg, (b) −3 mm Hg, (c) −7 mm Hg, (d) 7 mm Hg.

15. Using the letters from column B, match the artery descriptions in column A. (Note that some require more than a single choice.)

Column A	Column B
____ (1) unpaired branch of abdominal aorta	(a) right common carotid
____ (2) second branch of aortic arch	(b) superior mesenteric
____ (3) branch of internal carotid	(c) left common carotid
____ (4) branch of external carotid	(d) external iliac
____ (5) origin of femoral arteries	(e) inferior mesenteric
	(f) superficial temporal
	(g) celiac trunk
	(h) facial
	(i) ophthalmic
	(j) internal iliac

Short Answer Essay Questions

16. How is the anatomy of capillaries and capillary beds well suited to their function?

17. Distinguish between elastic arteries, muscular arteries, and arterioles relative to location, histology, and functional adaptations.

18. Write an equation showing the relationship between peripheral resistance, blood flow, and blood pressure.

19. (a) Define blood pressure. Differentiate between systolic and diastolic blood pressure. (b) What is the normal blood pressure value for a young adult?

20. Describe the neural mechanisms responsible for controlling blood pressure.

21. Explain the reasons for the observed changes in blood flow velocity in the different regions of the circulation.

22. How does the control of blood flow to the skin for the purpose of regulating body temperature differ from the control of nutrient blood flow to skin cells?

23. Describe neural and chemical (both systemic and local) effects exerted on the blood vessels when one is fleeing from a mugger. (Be careful, this is more involved than it appears at first glance.)

24. How are nutrients, wastes, and respiratory gases transported to and from the blood and tissue spaces?

25. (a) What blood vessels contribute to the formation of the hepatic portal circulation? (b) What is the function of this circulation? (c) Why is a portal circulation a "strange" circulation?

26. Physiologists often consider capillaries and postcapillary venules together. (a) What functions do these vessels share? (b) Structurally, how do they differ?

Critical Thinking and Clinical Application Questions

1. Mrs. Johnson is brought to the emergency room after being involved in an auto accident. She is hemorrhaging and has a rapid, thready pulse, but her blood pressure is still within normal limits. Describe the compensatory mechanisms that are acting to maintain her blood pressure in the face of blood loss.

2. A 60-year-old man is unable to walk more than 100 yards without experiencing severe pain in his left leg; the pain is relieved by resting for 5–10 minutes. He is told that the arteries of his leg are becoming occluded with fatty material and is advised to have the sympathetic nerves serving that body region severed. Explain how such surgery might help to relieve this man's problem.

3. Your friend Joanie, who knows little about science, is reading a magazine article about a patient who had an "aneurysm at the base of his brain that suddenly grew much larger." The surgeons' first goal was to "keep it from rupturing," and the second goal was to "relieve the pressure on the brain stem and cranial nerves." The surgeons were able to "replace the aneurysm with a section of plastic tubing," so the patient recovered. Joanie asks you what all this means. Explain. (Hint: Check this chapter's Related Clinical Terms, p. 767.)

4. The Agawam High School band is playing some lively marches while the coaches are giving pep talks to their respective football squads. Although it is September, it is unseasonably hot (88°F/31°C) and the band uniforms are wool. Suddenly, Harry the tuba player becomes light-headed and faints. Explain his fainting in terms of vascular events.

5. When one is cold or the external temperature is low, most venous blood returning from the distal part of the arm travels in the deep veins where it picks up heat (countercurrent mechanism) from the nearby brachial artery en route. However, when one is hot, and especially during exercise, venous return from the distal arm travels in the superficial veins and those veins tend to bulge superficially in a person who is working out. Explain why venous return takes a different route in the second situation.

6. Edema (swelling due to an increase in interstitial fluid) is a common clinical problem. On one of your first days of an introductory clinical experience, you encounter four patients who all have severe edema for different reasons. Your challenge is to explain the cause of the edema. In each case, try to explain the edema in terms of either an increase or a decrease in one of the four pressures that causes bulk flow at capillaries (see Figure 19.16).
(1) First you encounter Mrs. Taylor in the medical ward awaiting a liver transplant. What is the connection between liver failure and her edema? (Hint: Think about the liver's role in producing plasma proteins.)
(2) Next you follow a resident to the obstetric ward, where Mrs. So is experiencing premature labor. Which of the pressures that drive bulk flow might be altered here? (Hint: What might the expanding uterus be pressing on?)
(3) Then you are called to emergency, where Mr. Herrera is in anaphylactic shock. In anaphylactic shock, the capillaries become leaky, allowing plasma proteins that are normally kept inside the blood vessels to escape into the interstitial fluid. Which of the pressures driving bulk flow is altered in this case and in what direction is the change?
(4) Finally, you go to the oncology ward where Mrs. O'Leary is recovering from surgery for advanced breast cancer that had infiltrated her right breast and axillary lymph nodes. All of her axillary lymph nodes were removed and unfortunately, this severed most of the lymphatic vessels draining her right arm. You notice that her right arm is quite edematous. Why? Mrs. O'Leary is given a compression sleeve to wear on this arm to help relieve the edema. Which of the pressures driving bulk flow at the capillaries will be altered by the compression sleeve?

CHAPTER

The Lymphatic System

1. List the functions of the lymphatic system.

Lymphatic Vessels (pp. 774–777)

2. Describe the structure and distribution of lymphatic vessels, and note their important functions.
3. Describe the source of lymph and mechanism(s) of lymph transport.

Lymphoid Cells and Tissues (p. 777)

4. Describe the basic structure and cellular population of lymphoid tissue. Differentiate between diffuse and follicular lymphoid tissues.

Lymph Nodes (pp. 778–779)

5. Describe the general location, histological structure, and functions of lymph nodes.

Other Lymphoid Organs (pp. 779–782)

6. Name and describe the other lymphoid organs of the body. Compare and contrast them with lymph nodes, structurally and functionally.

Developmental Aspects of the Lymphatic System (p. 783)

7. Outline lymphatic system development.

They can't all be superstars! When we mentally tick off the names of the body's organ systems, the lymphatic (lim-fat'ik) system is probably not the first to come to mind. Yet without this quietly working system, our cardiovascular system would stop working and our immune system would be hopelessly impaired. The **lymphatic system** actually consists of two semi-independent parts: (1) a meandering network of *lymphatic vessels* and (2) various *lymphoid tissues* and *organs* scattered throughout the body. The lymphatic vessels transport back to the blood any fluids that have escaped from the blood vascular system. The lymphoid organs house phagocytic cells and lymphocytes, which play essential roles in the body's defense mechanisms and its resistance to disease.

Lymphatic Vessels

As blood circulates through the body, nutrients, wastes, and gases are exchanged between the blood and the interstitial fluid. As explained in Chapter 19, the hydrostatic and colloid osmotic pressures operating at capillary beds force fluid out of the blood at the arterial ends of the beds ("upstream") and cause most of it to be reabsorbed at the venous ends ("downstream"). The fluid that remains behind in the tissue spaces, as much as 3 L daily, becomes part of the interstitial fluid. This leaked fluid, plus any plasma proteins that escape from the bloodstream, must be carried back to the blood to ensure that the cardiovascular system has sufficient blood volume to operate properly. This problem of circulatory dynamics is resolved by the **lymphatic vessels,** or **lymphatics,** an elaborate system of drainage vessels that collect the excess protein-containing interstitial fluid and return it to the bloodstream. Once interstitial fluid enters the lymphatics, it is called **lymph** (*lymph* = clear water).

Distribution and Structure of Lymphatic Vessels

The lymphatic vessels form a one-way system in which lymph flows only toward the heart. This transport system begins in microscopic blind-ended **lymphatic capillaries** (Figure 20.1a), which weave between the tissue cells and blood capillaries in the

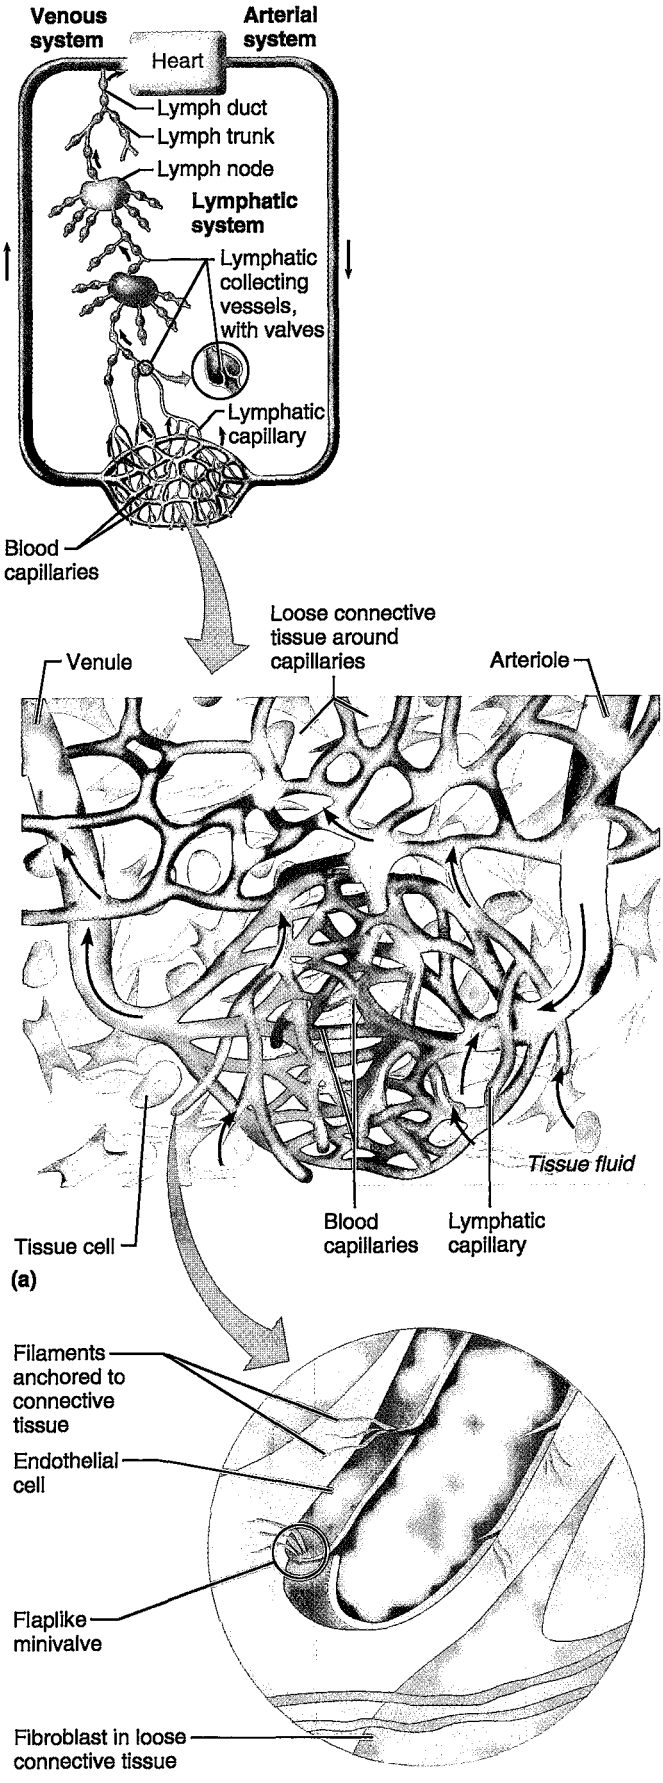

FIGURE 20.1 **Distribution and special structural features of lymphatic capillaries. (a)** Structural relationship between a capillary bed of the blood vascular system and lymphatic capillaries. Arrows indicate direction of fluid movement. **(b)** Lymphatic capillaries begin as blind-ended tubes. Adjacent endothelial cells in a lymphatic capillary overlap each other, forming flaplike minivalves.

loose connective tissues of the body. Lymphatic capillaries are widespread; however, they are absent from bones and teeth, bone marrow, and the entire central nervous system (where the excess tissue fluid drains into the cerebrospinal fluid).

Although similar to blood capillaries, lymphatic capillaries are so remarkably permeable that they were once thought to be open at one end like a straw. We now know that they owe their permeability to two unique structural modifications:

1. The endothelial cells forming the walls of lymphatic capillaries are not tightly joined; instead, the edges of adjacent cells overlap each other loosely, forming easily opened, flaplike *minivalves* (Figure 20.1b).
2. Collagen filaments anchor the endothelial cells to surrounding structures so that any increase in interstitial fluid volume opens the minivalves, rather than causing the lymphatic capillaries to collapse.

So, what we have is a system analogous to one-way swinging doors in the lymphatic capillary wall. When fluid pressure in the interstitial space is greater than the pressure in the lymphatic capillary, the minivalve flaps gape open, allowing fluid to enter the lymphatic capillary. However, when the pressure is greater *inside* the lymphatic capillary, the endothelial minivalve flaps are forced closed, preventing lymph from leaking back out as the pressure moves it along the vessel.

Proteins in the interstitial space are unable to enter blood capillaries, but they enter lymphatic capillaries easily. In addition, when tissues are inflamed, lymphatic capillaries develop openings that permit uptake of even larger particles such as cell debris, pathogens (disease-causing microorganisms such as bacteria and viruses), and cancer cells. The pathogenic agents and cancer cells can then use the lymphatics to travel throughout the body. This threat to the body is partly resolved by the fact that the lymph takes "detours" through the lymph nodes, where it is cleansed of debris and "examined" by cells of the immune system.

Highly specialized lymphatic capillaries called **lacteals** (lak'te-alz) are present in the fingerlike villi of the intestinal mucosa. The lymph draining from the digestive viscera is milky white (*lacte* = milk) rather than clear because the lacteals play a major role in absorbing digested fats from the intestine. This fatty lymph, called **chyle** ("juice"), is also delivered to the blood via the lymphatic stream.

From the lymphatic capillaries, lymph flows through successively larger and thicker-walled channels—first collecting vessels, then trunks, and finally the largest of all, the ducts (Figure 20.2). The **lymphatic collecting vessels** have the same three tunics as veins, but the collecting vessels are thinner-walled, have more internal valves, and anastomose more. In general, lymphatics in the skin travel along with superficial *veins*, while the deep lymphatic vessels of the trunk and digestive viscera travel with the deep *arteries*. The exact anatomical distribution of lymphatic vessels varies greatly between individuals, even more so than it does for veins.

The **lymphatic trunks** are formed by the union of the largest collecting vessels, and drain fairly large areas of the body. The major trunks, named mostly for the regions from which they collect lymph, are the paired **lumbar, bronchomediastinal, subclavian,** and **jugular trunks,** and the single **intestinal trunk** (Figure 20.2b).

Lymph is eventually delivered to one of two large *ducts* in the thoracic region. The **right lymphatic duct** drains lymph from the right upper arm and the right side of the head and thorax (Figure 20.2a). The much larger **thoracic duct** receives lymph from the rest of the body. It arises anterior to the first two lumbar vertebrae as an enlarged sac, the **cisterna chyli** (sis-ter'nah ki'li), that collects lymph from the two large lumbar trunks that drain the lower limbs and from the intestinal trunk that drains the digestive organs. As the thoracic duct runs superiorly, it receives lymphatic drainage from the left side of the thorax, left upper limb, and the head region. Each terminal duct empties its lymph into the venous circulation at the junction of the internal jugular vein and subclavian vein on its own side of the body (Figure 20.2b).

HOMEOSTATIC IMBALANCE

Like the larger blood vessels, the larger lymphatics receive their nutrient blood supply from a branching vasa vasorum. When lymphatic vessels are severely inflamed, the related vessels of the vasa vasorum become congested with blood. As a result, the pathway of the associated superficial lymphatics becomes visible through the skin as red lines that are tender to the touch. This unpleasant condition is called *lymphangitis* (lim"fan-ji'tis; *angi* = vessel). ●

Lymph Transport

The lymphatic system lacks an organ that acts as a pump. Under normal conditions, lymphatic vessels are low-pressure conduits, and the same mechanisms that promote venous return in blood vessels act here as well—the milking action of active skeletal muscles, pressure changes in the thorax during breathing, and valves to prevent backflow. Lymphatics are usually bundled together in connective tissue sheaths along with blood vessels, and pulsations of nearby arteries also promote lymph flow. In addition to these mechanisms, smooth muscle in the walls of

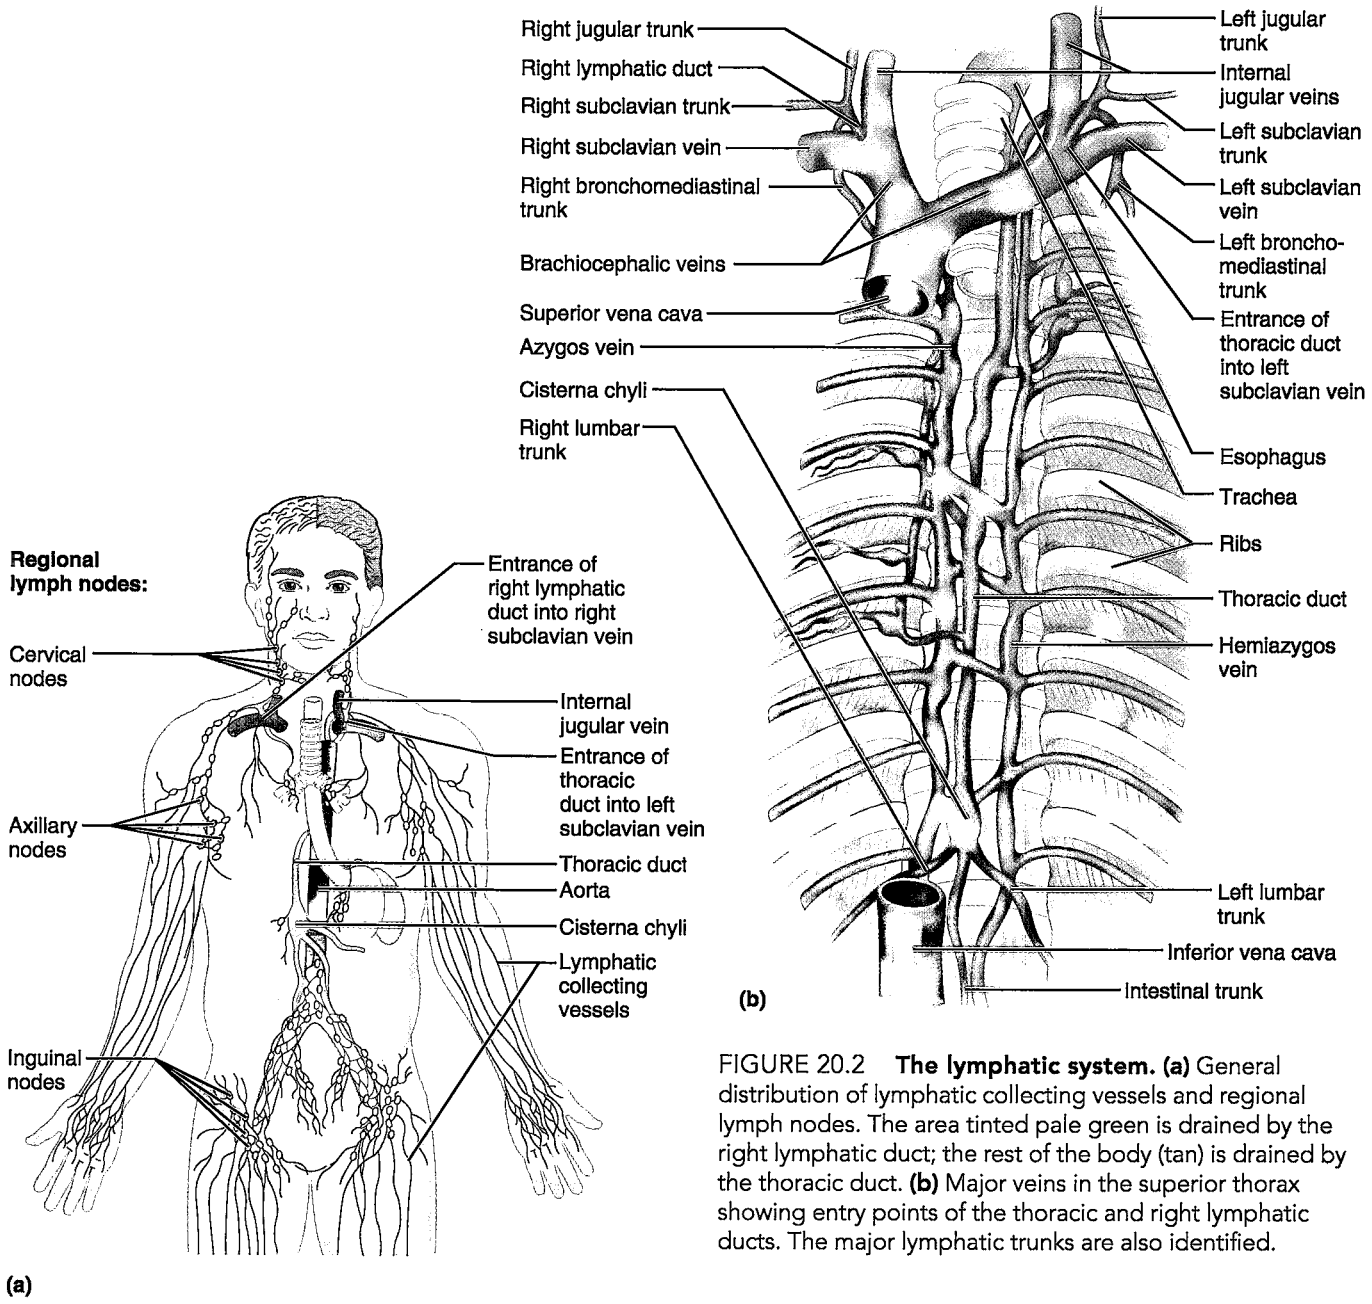

FIGURE 20.2 **The lymphatic system. (a)** General distribution of lymphatic collecting vessels and regional lymph nodes. The area tinted pale green is drained by the right lymphatic duct; the rest of the body (tan) is drained by the thoracic duct. **(b)** Major veins in the superior thorax showing entry points of the thoracic and right lymphatic ducts. The major lymphatic trunks are also identified.

the lymphatic trunks and thoracic duct contracts rhythmically, helping to pump the lymph along. Even so, lymph transport is sporadic and slow. About 3 L of lymph enters the bloodstream every 24 hours, a volume almost exactly equal to the amount of fluid lost to the tissue spaces from the bloodstream in the same time period. Movement of adjacent tissues is extremely important in propelling lymph through the lymphatics. When physical activity or passive movements increase, lymph flows much more rapidly (balancing the greater rate of fluid loss from the blood in such situations). Hence, it is a good idea to immobilize a badly infected body part to hinder flow of inflammatory material from that region.

HOMEOSTATIC IMBALANCE

Anything that prevents the normal return of lymph to the blood, such as blockage of the lymphatics by tumors or removal of lymphatics during cancer surgery, results in short-term but severe localized edema *(lymphedema)*. Usually, however, lymphatic drainage is eventually reestablished by regrowth from the vessels remaining in the area. ●

This completes the description of the lymphatic vessels. To summarize their functions, they (1) return excess tissue fluid to the bloodstream, (2) return leaked proteins to the blood, and (3) carry

absorbed fat from the intestine to the blood (through lacteals).

Lymphoid Cells and Tissues

In order to understand the basic aspects of the lymphatic system's role in the body, we investigate the components of lymphoid organs—lymphoid cells and lymphoid tissues—before considering the organs themselves.

Lymphoid Cells

Infectious microorganisms that manage to penetrate the body's epithelial barriers quickly proliferate in the underlying loose connective tissues. These invaders are fought off by the inflammatory response, by phagocytes (macrophages), and by lymphocytes.

Lymphocytes, the main warriors of the immune system, arise in red bone marrow (along with other formed elements). They then mature into one of the two main varieties of immunocompetent cells—**T cells (T lymphocytes)** or **B cells (B lymphocytes)**—that protect the body against antigens. (*Antigens* are anything the body perceives as foreign, such as bacteria and their toxins, viruses, mismatched RBCs, or cancer cells.) Activated T cells manage the immune response, and some of them directly attack and destroy infected cells. B cells protect the body by producing **plasma cells,** daughter cells that secrete antibodies into the blood (or other body fluids). Antibodies immobilize antigens until they can be destroyed by phagocytes or other means. The precise roles of the lymphocytes in immunity are explored in Chapter 21.

Lymphoid **macrophages** play a crucial role in body protection and in the immune response by phagocytizing foreign substances and by helping to activate T cells. So, too, do the spiny-looking **dendritic cells** that capture antigens and bring them back to the lymph nodes. Last but not least are the **reticular cells,** fibroblast-like cells that produce the reticular fiber **stroma** (stro'mah), which is the network that supports the other cell types in the lymphoid organs (Figure 20.3).

Lymphoid Tissue

Lymphoid (lymphatic) tissue is an important component of the immune system, mainly because it (1) houses and provides a proliferation site for lymphocytes and (2) furnishes an ideal surveillance vantage point for lymphocytes and macrophages. Lymphoid tissue, largely composed of a type of loose connective tissue called **reticular connective tissue,** dominates all the lymphoid organs except the thymus. Macrophages live on the fibers of the reticular network, and in the spaces of the network are huge

Q *How is reticular connective tissue classified?*

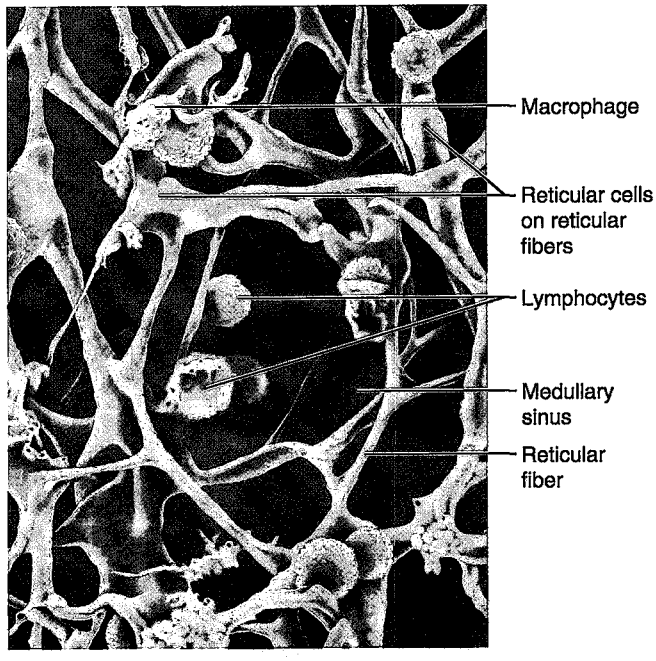

FIGURE 20.3 **Reticular tissue in a human lymph node.** Scanning electron micrograph (1100×).

numbers of lymphocytes that have squeezed through the walls of postcapillary venules coursing through this tissue. The lymphocytes reside temporarily in the lymphoid tissue (Figure 20.3), and then leave to patrol the body again. The cycling of lymphocytes between the circulatory vessels, lymphoid tissues, and loose connective tissues of the body ensures that lymphocytes reach infected or damaged sites quickly.

Lymphoid tissue comes in various "packages." **Diffuse lymphatic tissue,** consisting of a few scattered reticular tissue elements, is found in virtually every body organ, but larger collections appear in the lamina propria of mucous membranes and in lymphoid organs. **Lymphoid follicles (nodules)** represent another way lymphoid tissue is organized. Like diffuse lymphatic tissue, they lack a capsule, but follicles are solid, spherical bodies consisting of tightly packed reticular elements and cells. Follicles often have lighter-staining centers, called **germinal centers.** Follicular dendritic cells and B cells predominate in germinal centers, and these centers enlarge dramatically when the B cells are dividing rapidly and producing plasma cells. In many cases, the follicles are found forming part of larger lymphoid organs, such as lymph nodes. However, isolated aggregations of lymphoid follicles occur in the intestinal wall as Peyer's patches and in the appendix.

A Loose connective tissue proper.

Q *What is the benefit of having fewer efferent than afferent lymphatics in lymph nodes?*

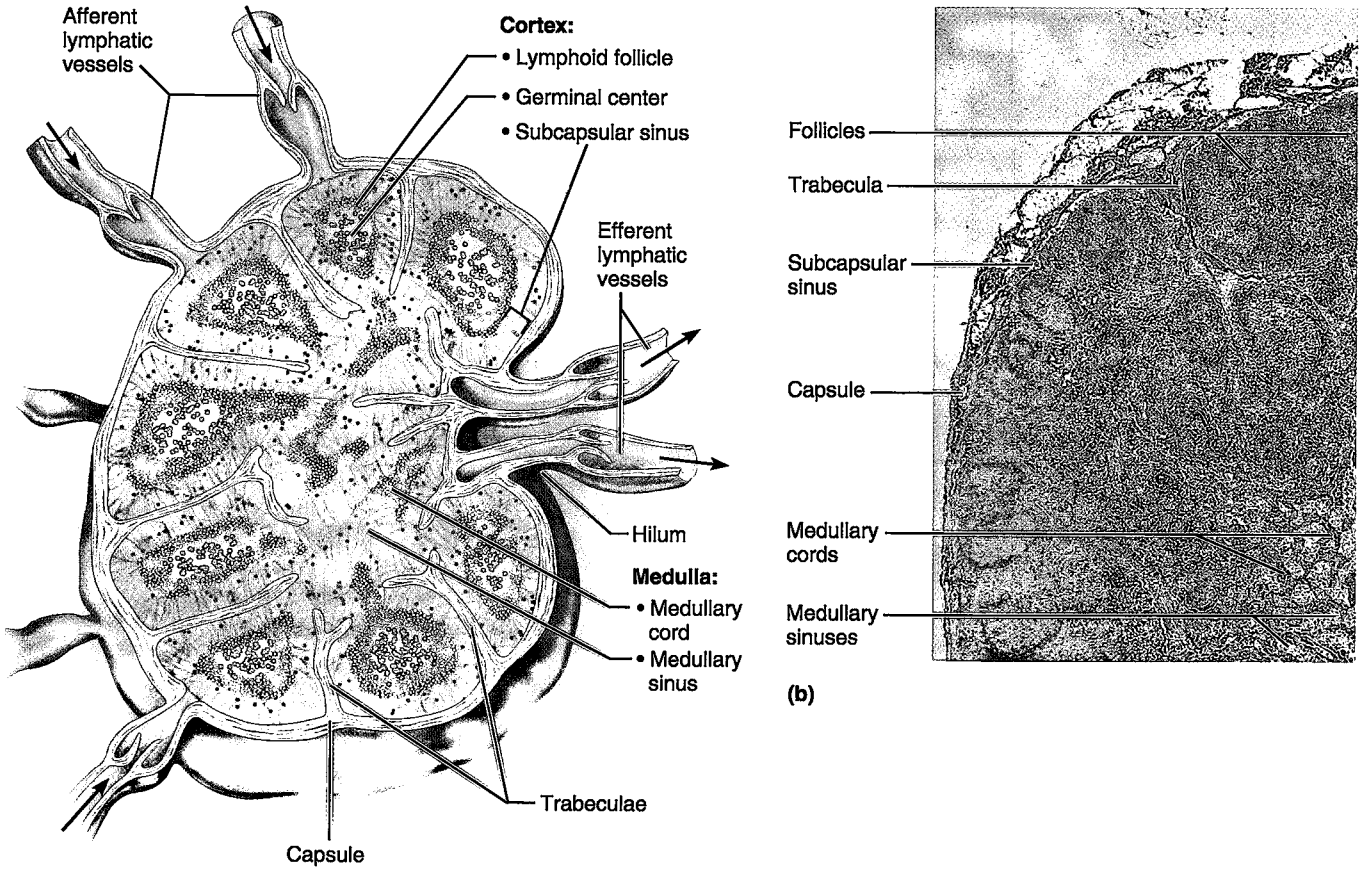

FIGURE 20.4 **Lymph node.** **(a)** Longitudinal view of the internal structure of a lymph node and associated lymphatics. Notice that several afferent lymphatics converge on its convex side, whereas fewer efferent lymphatics exit at its hilum. Arrows indicate the direction of lymph flow into and out of the node. **(b)** Photomicrograph of part of a lymph node (60×).

Lymph Nodes

The principal lymphoid organs in the body are the **lymph nodes,** which cluster along the lymphatic vessels of the body. As lymph is transported back to the bloodstream, it is filtered through the lymph nodes. There are hundreds of these small organs, but because they are usually embedded in connective tissue, they are not ordinarily seen. Large clusters of lymph nodes occur near the body surface in the inguinal, axillary, and cervical regions, places where the lymphatic collecting vessels converge to form trunks (see Figure 20.2a).

Lymph nodes have two basic functions, both concerned with body protection. (1) They act as lymph "filters." Macrophages in the nodes remove and destroy microorganisms and other debris that enter the lymph from the loose connective tissues, effectively preventing them from being delivered to the blood and spreading to other parts of the body. (2) They help activate the immune system. Lymphocytes, also strategically located in the lymph nodes, monitor the lymphatic stream for the presence of *antigens* and mount an attack against them. Let's look at how the structure of a lymph node supports these defensive functions.

A Having fewer efferents causes lymph to accumulate in lymph nodes, allowing more time for its cleansing.

Structure of a Lymph Node

Lymph nodes vary in shape and size, but most are bean shaped and less than 2.5 cm (1 inch) in length. Each node is surrounded by a dense fibrous **capsule** from which connective tissue strands called **trabeculae** extend inward to divide the node into a number of compartments (Figure 20.4). The node's internal framework or stroma of reticular fibers

physically supports the ever-changing population of lymphocytes.

A lymph node has two histologically distinct regions, the **cortex** and the **medulla.** The superficial part of the cortex contains densely packed follicles, many with germinal centers heavy with dividing B cells. Dendritic cells nearly encapsulate the follicles and abut the deeper part of the cortex, which primarily houses T cells in transit. The T cells circulate continuously between the blood, lymph nodes, and lymph, performing their surveillance role.

Medullary cords, which are thin inward extensions from the cortical lymphoid tissue, contain both types of lymphocytes plus plasma cells and they define the medulla. Throughout the node are **lymph sinuses,** large lymph capillaries spanned by criss-crossing reticular fibers. Numerous macrophages reside on these reticular fibers and phagocytize foreign matter in the lymph as it flows by in the sinuses. Additionally, some of the lymph-borne antigens in the percolating lymph leak into the surrounding lymphoid tissue, where they activate lymphocytes to mount an immune attack against them.

Circulation in the Lymph Nodes

Lymph enters the convex side of a lymph node through a number of **afferent lymphatic vessels.** It then moves through a large, baglike sinus, the **subcapsular sinus,** into a number of smaller sinuses that cut through the cortex and enter the medulla. The lymph meanders through these sinuses and finally exits the node at its **hilum** (hi'lum), the indented region on the concave side, via **efferent lymphatic vessels.** Because there are fewer efferent vessels draining the node than afferent vessels feeding it, the flow of lymph through the node stagnates somewhat, allowing time for the lymphocytes and macrophages to carry out their protective functions. Lymph passes through several nodes before it is completely cleansed.

HOMEOSTATIC IMBALANCE

Sometimes lymph nodes are overwhelmed by the agents they are trying to destroy. For example, when large numbers of bacteria are trapped in the nodes, the nodes become inflamed, swollen, and tender to the touch, a condition often referred to (erroneously) as swollen glands. Such infected lymph nodes are called *buboes* (bu'boz). (Buboes are the most obvious symptom of bubonic plague, the "Black Death" that killed much of Europe's population in the late Middle Ages.) Lymph nodes can also become secondary cancer sites, particularly in metastasizing cancers that enter lymphatic vessels and become trapped there. The fact that cancer-infiltrated lymph nodes are swollen but usually not painful helps distinguish cancerous lymph nodes from those infected by microorganisms. ●

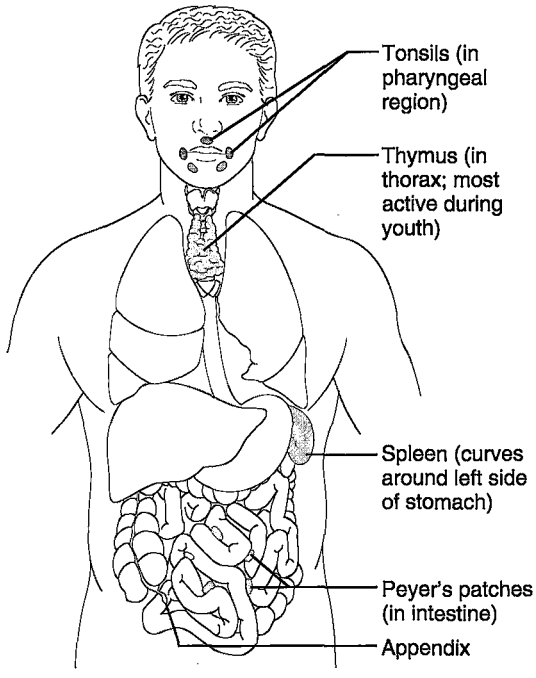

FIGURE 20.5 **Lymphoid organs.** Locations of the tonsils, spleen, thymus, Peyer's patches, and appendix.

Other Lymphoid Organs

Lymph nodes are just one example of the many types of **lymphoid organs** or aggregates of lymphatic tissue in the body. Others are the spleen, thymus, tonsils, and Peyer's patches of the intestine (Figure 20.5), as well as bits of lymphatic tissue scattered in the connective tissues. Except for the thymus, the common feature of all these organs is their tissue makeup: All are composed of *reticular connective tissue.* Although all lymphoid organs help protect the body, only the lymph nodes filter lymph. The other lymphoid organs and tissues typically have efferent lymphatics draining them, but lack afferent lymphatics.

Spleen

The soft, blood-rich **spleen** is about the size of a fist and is the largest lymphoid organ. Located in the left side of the abdominal cavity just beneath the diaphragm, it curls around the anterior aspect of the stomach (Figures 20.5 and 20.6). It is served by the large *splenic artery* and *vein,* which enter and exit the *hilum* on its slightly concave anterior surface.

The spleen provides a site for lymphocyte proliferation and immune surveillance and response. But perhaps even more important are its blood-cleansing

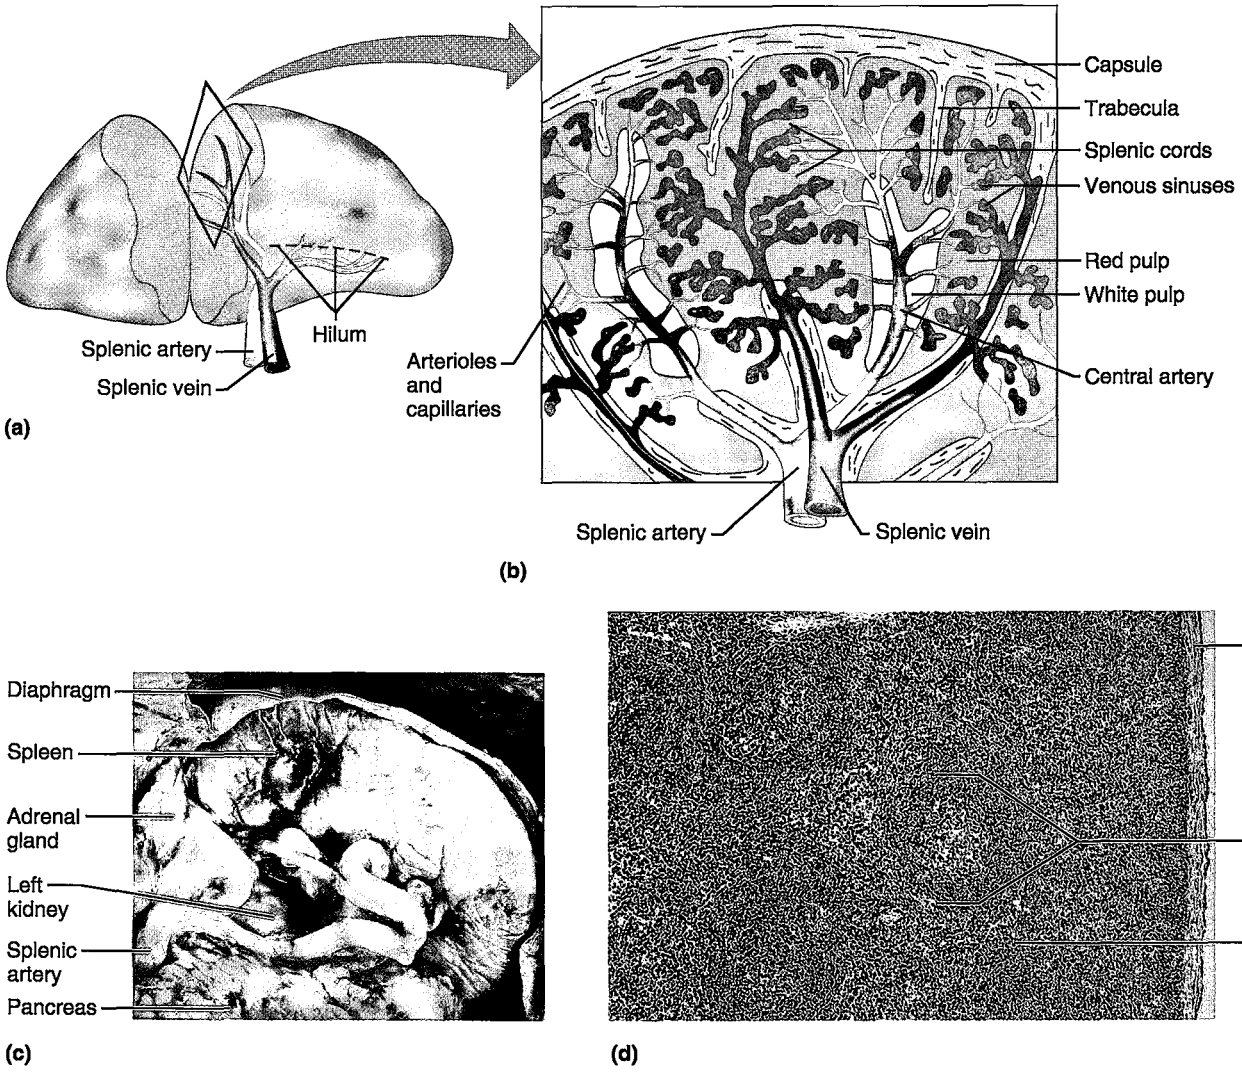

FIGURE 20.6 **The spleen. (a)** Gross structure. **(b)** Diagram of the histological structure. **(c)** Photograph of the spleen in its normal position in the abdominal cavity, anterior view. **(d)** Photomicrograph of spleen tissue showing white and red pulp regions (30×).

functions. Besides extracting aged and defective blood cells and platelets from the blood, its macrophages remove debris and foreign matter from blood flowing through its sinuses. The spleen also performs three additional, and related, functions.

1. It stores some of the breakdown products of red blood cells for later reuse (for example, it salvages iron for making hemoglobin) and releases others to the blood for processing by the liver.
2. It is a site of erythrocyte production in the fetus (a capability that normally ceases after birth).
3. It stores blood platelets.

Like lymph nodes, the spleen is surrounded by a fibrous capsule, has trabeculae that extend inward, and contains both lymphocytes and macrophages. Consistent with its blood-processing functions, it also contains huge numbers of erythrocytes. Areas composed mostly of lymphocytes suspended on reticular fibers are called **white pulp.** The white pulp clusters or forms "cuffs" around the *central arteries* (small branches of the splenic artery) in the organ and forms what appear to be islands in a sea of red pulp. **Red pulp** is essentially all remaining splenic tissue, that is, the venous sinuses (blood sinusoids) and the **splenic cords,** regions of reticular connective tissue exceptionally rich in macrophages. Red pulp is most concerned with disposing of worn-out red blood cells and bloodborne pathogens, whereas white pulp is involved with the immune functions of the spleen. The naming of the pulp regions reflects their appearance in fresh spleen tissue rather than their staining properties. Indeed, as can be seen in the photomicrograph in Figure 20.6d, the white pulp sometimes appears darker than the red pulp due to the darkly staining nuclei of the densely packed lymphocytes.

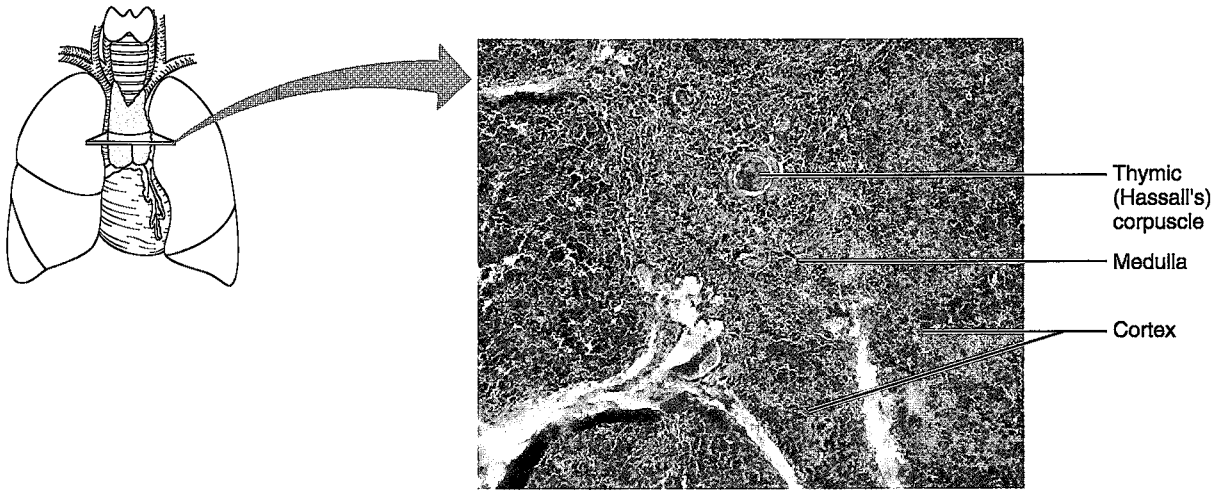

FIGURE 20.7 **The thymus.** The photomicrograph of a portion of the thymus shows part of a lobule with cortical and medullary regions (70×).

HOMEOSTATIC IMBALANCE

Because the spleen's capsule is relatively thin, a direct blow or severe infection may cause it to rupture, spilling blood into the peritoneal cavity. Once, removal of the ruptured spleen (a procedure called a *splenectomy*) was the standard treatment and thought necessary to prevent life-threatening hemorrhage and shock. During the past 20 years, surgeons have discovered that, if left alone, the spleen can often repair itself. At major trauma centers, the frequency of emergency splenectomies has decreased from 70% to 40%. If the spleen is removed, the liver and bone marrow take over most of its functions. In children younger than 12, the spleen will regenerate if a small part of it is left in the body. ●

Thymus

The bilobed **thymus** (thi'mus) has important functions primarily during the early years of life. It is found in the inferior neck and extends into the superior thorax, where it partially overlies the heart deep to the sternum (see Figures 20.5 and 20.7). By secreting the hormones thymopoietin and the thymosins, the thymus causes T lymphocytes to become immunocompetent; that is, it enables them to function against specific pathogens in the immune response. Prominent in newborns, the thymus continues to increase in size during the first year, when it is highly active. After puberty, it starts to atrophy gradually and by old age it has been replaced almost entirely by fibrous and fatty tissue and is difficult to distinguish from surrounding connective tissue.

To understand thymic histology, it helps to compare the thymus to a cauliflower head—the flowerets represent *thymic lobules*, each containing an outer cortex and an inner medulla (Figure 20.7). Most thymic cells are lymphocytes. In the cortical regions the rapidly dividing lymphocytes are densely packed, but a few macrophages are scattered among them. The lighter-staining medullary areas contain fewer lymphocytes plus some bizarre structures called **thymic (Hassall's) corpuscles.** Consisting of concentric whorls of keratinized epithelial cells, they are sites of T cell destruction. Because the thymus lacks B cells, it has no follicles.

The thymus differs from other lymphoid organs in two other important ways. First, it functions strictly in T lymphocyte maturation and thus is the only lymphoid organ that does not *directly* fight antigens. In fact, the so-called *blood-thymus barrier* keeps bloodborne antigens from leaking into the cortical regions to prevent premature activation of the immature lymphocytes. Second, the stroma of the thymus consists of epithelial cells rather than reticular fibers. These epithelial cells secrete the hormones that stimulate the lymphocytes to become immunocompetent.

Tonsils

The **tonsils** are the simplest lymphoid organs. They form a ring of lymphatic tissue around the entrance to the pharynx (throat), where they appear as swellings of the mucosa (Figures 20.5 and 22.3). The tonsils are named according to location. The paired **palatine tonsils** are located on either side at the posterior end of the oral cavity. These are the largest of the tonsils and the ones most often infected. A lumpy collection of lymphoid follicles at the base of the tongue is referred to collectively as the **lingual tonsil.** The **pharyngeal tonsil** (referred to as the *adenoids* if enlarged) is in the posterior wall of the

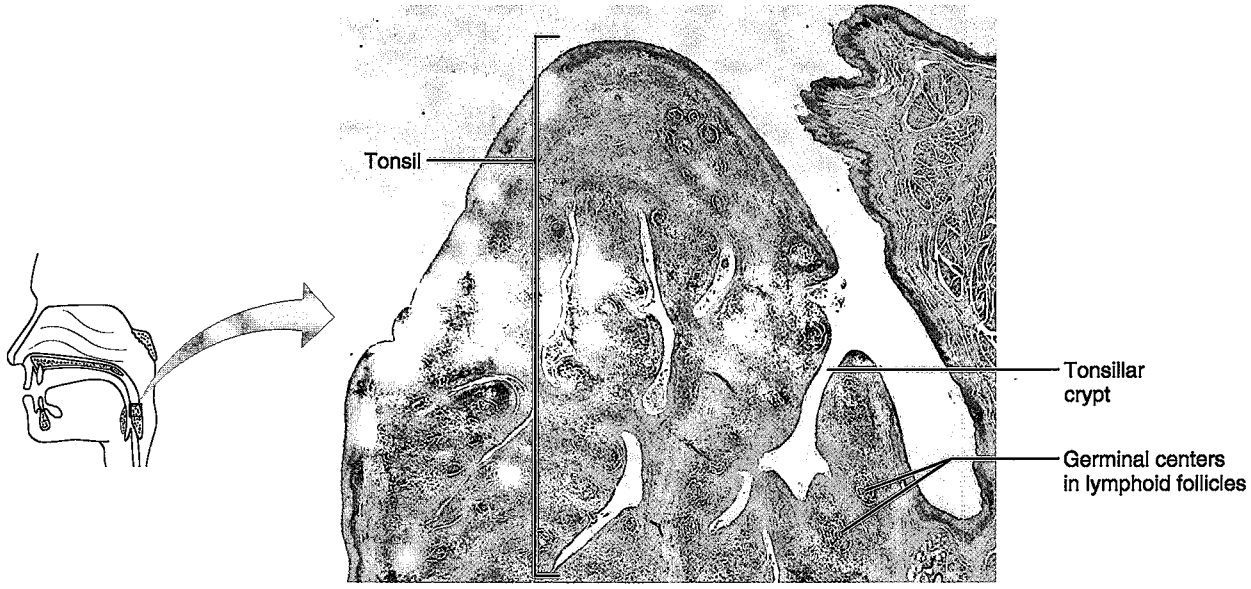

FIGURE 20.8 **Histology of the palatine tonsil.** The exterior surface of the tonsil is covered by squamous epithelium, which invaginates deeply to form tonsillar crypts (60×).

nasopharynx. The tiny **tubal tonsils** surround the openings of the auditory tubes into the pharynx. The tonsils gather and remove many of the pathogens entering the pharynx in food or in inhaled air.

The lymphoid tissue of the tonsils contains follicles with obvious germinal centers surrounded by diffusely scattered lymphocytes. The tonsils are not fully encapsulated, and the epithelium overlying them invaginates deep into their interior, forming blind-ended **tonsillar crypts** (Figure 20.8). The crypts trap bacteria and particulate matter, and the bacteria work their way through the mucosal epithelium into the lymphoid tissue, where most are destroyed. It seems a bit dangerous to "invite" infection this way, but this strategy produces a wide variety of immune cells that have a "memory" for the trapped pathogens. Thus, the body takes a calculated risk early on (during childhood) for the benefits of heightened immunity and better health later.

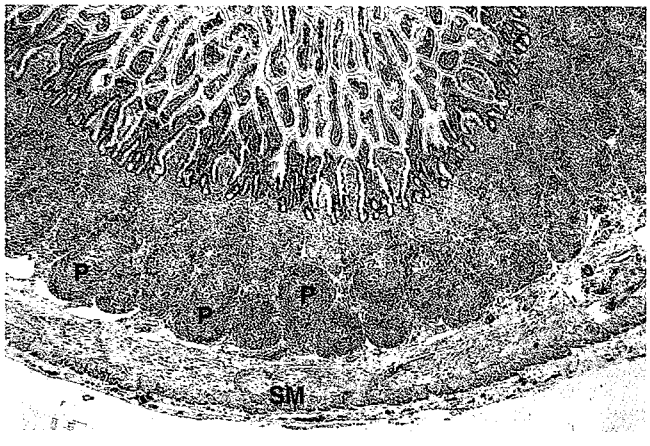

FIGURE 20.9 **Peyer's patches.** Histological structure of aggregated lymphoid follicles—Peyer's patches (P)—in the wall of the ileum of the small intestine (SM = submucosa) (20×).

Aggregates of Lymphoid Follicles

Peyer's patches (pi'erz) are large isolated clusters of lymphoid follicles, structurally similar to the tonsils, that are located in the wall of the distal portion of the small intestine (Figures 20.5 and 20.9). Lymphoid follicles are also heavily concentrated in the wall of the **appendix,** a tubular offshoot of the first part of the large intestine. Peyer's patches and the appendix are in an ideal position (1) to destroy bacteria (which are present in large numbers in the intestine), thereby preventing these pathogens from breaching the intestinal wall, and (2) to generate many "memory" lymphocytes for long-term immunity. Peyer's patches, the appendix, and the tonsils—all located in the digestive tract—and lymphoid follicles in the walls of the bronchi (organs of the respiratory tract) and in the mucosa of genitourinary organs, are part of the collection of small lymphoid tissues referred to as **mucosa-associated lymphatic tissue (MALT).** MALT protects passages that are open to the exterior from the never-ending onslaughts of foreign matter entering them.

Developmental Aspects of the Lymphatic System

By the fifth week of embryonic development, the beginnings of the lymphatic vessels and the main clusters of lymph nodes are apparent. These arise from the budding of **lymph sacs** from developing veins. The first of these, the *jugular lymph sacs*, arise at the junctions of the internal jugular and subclavian veins and form a branching system of lymphatic vessels throughout the thorax, upper extremities, and head. The two main connections of the jugular lymph sacs to the venous system are retained and become the right lymphatic duct and, on the left, the superior part of the thoracic duct. Caudally the elaborate system of abdominal lymphatics buds largely from the primitive inferior vena cava. The lymphatics of the pelvic region and lower extremities form from sacs on the iliac veins.

Except for the thymus, which is an endodermal derivative, the lymphoid organs develop from mesodermal mesenchymal cells that migrate to particular body sites and develop into reticular tissue. The thymus, the first lymphoid organ to appear, forms as an outgrowth of the lining of the primitive pharynx. It then detaches and migrates caudally to the thorax where it becomes infiltrated with immature lymphocytes derived from hematopoietic tissues elsewhere in the embryo's body. Except for the spleen and tonsils, the lymphoid organs are poorly developed before birth. Shortly after birth, they become heavily populated by lymphocytes, and their development parallels the maturation of the immune system. There is some evidence that the embryonic thymus produces hormones that control the development of the other lymphoid organs.

■ ■ ■

Although the functions of the lymphatic vessels and lymphoid organs overlap, each helps maintain body homeostasis in unique ways, as summarized in *Making Connections* (pp. 784–785). The lymphatic vessels help maintain blood volume. The macrophages of lymphoid organs remove and destroy foreign matter in lymph and blood. Additionally, lymphoid organs and tissues provide sites from which the immune system can be mobilized. In Chapter 21, we continue this story as we examine the inflammatory and immune responses that allow us to resist a constant barrage of pathogens.

Related Clinical Terms

Elephantiasis (el″lĕ-fan-ti′ah-sis) Typically a tropical disease in which the lymphatics (particularly those of the lower limbs and scrotum) become clogged with parasitic roundworms, an infectious condition called filariasis; swelling (due to edema) reaches enormous proportions.

Hodgkin's disease A malignancy of lymphoid tissue; symptoms include swollen, nonpainful lymph nodes, fatigue, and often intermittent fever and night sweats. Characterized by presence of giant Reed-Sternberg cells, which are malignantly transformed B cells. Infection with Epstein-Barr virus (see mononucleosis below) and genetic susceptibility appear to be predisposing factors. Treated with chemotherapy and radiation; high cure rate.

Lymphadenopathy (lim-fad″ĕ-nop′ah-the; *adeno* = a gland; *pathy* = disease) Any disease of the lymph nodes.

Lymphangiography (lim-fan″je-og′rah-fe) Diagnostic procedure in which the lymphatic vessels are injected with radiopaque dye and then visualized with X rays.

Lymphoma Any neoplasm (tumor) of the lymphoid tissue, whether benign or malignant.

Mononucleosis A viral disease common in adolescents and young adults; symptoms include fatigue, fever, sore throat, and swollen lymph nodes. Caused by the Epstein-Barr virus, which is transmitted in saliva ("kissing disease") and specifically attacks B lymphocytes. This attack leads to a massive activation of T lymphocytes, which in turn attack the virus-infected B cells. Large numbers of oversized T lymphocytes circulate in the bloodstream. (These lymphocytes were originally misidentified as monocytes: *mononucleosis* = a condition of monocytes.) Usually lasts four to six weeks.

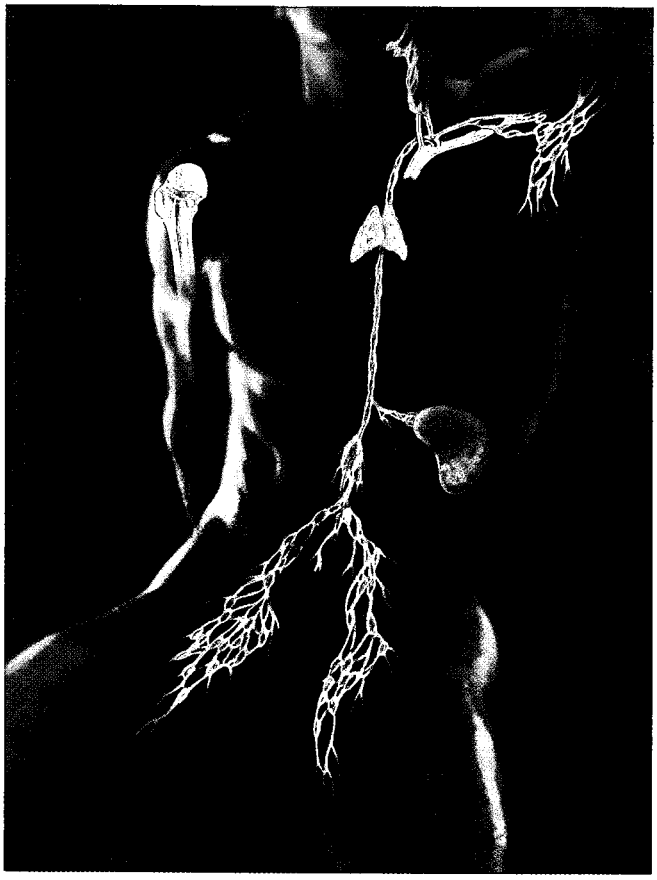
Non-Hodgkin's lymphoma Includes all cancers of lymphoid tissues except Hodgkin's disease. Involves uncontrolled multiplication and metastasis of undifferentiated lymphocytes, with swelling of the lymph nodes, spleen, and Peyer's patches; other organs may eventually become involved. The fifth most common cancer. A high-grade type, which primarily affects young people, grows quickly but is responsive to chemotherapy; up to a 75% remission rate. A low-grade type, which affects the elderly, is resistant to chemotherapy and so is often fatal.

Sentinel node The first node that receives lymph drainage from a body area suspected of being cancerous. When examined for presence of cancer cells, this node gives the best indication of whether metastasis through the lymph vessels has occurred.

Splenomegaly (sple″no-meg′ah-le; *mega* = big) Enlargement of the spleen due to accumulation of infectious microorganisms; typically caused by septicemia, mononucleosis, malaria, or leukemia.

Tonsillitis (ton″sĭ-li′tis; *itis* = inflammation) Inflammation of the tonsils, typically due to bacterial infection; they become red, swollen, and sore.

SYSTEM CONNECTIONS: Homeostatic Interrelationships Between the Lymphatic System/Immunity and Other Body Systems



Integumentary System

- Lymphatic vessels pick up leaked plasma fluid and proteins from the dermis; lymphocytes in lymph enhance the skin's protective role by defending against specific pathogens via the immune response
- The skin's keratinized epithelium provides a mechanical barrier to pathogens; epithelial dendritic cells and dermal macrophages act as antigen presenters in the immune response; acid pH of skin secretions inhibits growth of bacteria on the skin

Skeletal System

- Lymphatic vessels pick up leaked plasma fluid and proteins from the periostea; immune cells protect bones from pathogens
- The bones house hematopoietic tissue which produces the lymphocytes (and macrophages) that populate lymphoid organs and provide immunity

Muscular System

- Lymphatic vessels pick up leaked fluids and proteins; immune cells protect muscles from pathogens
- The skeletal muscle "pump" aids the flow of lymph; heat produced during muscle activity initiates fever-like effects

Nervous System

- Lymphatic vessels pick up leaked plasma fluid and proteins in PNS structures; immune cells protect PNS structures from specific pathogens
- The nervous system innervates larger lymphatics; opiate neuropeptides influence immune functions; the brain helps regulate immune response

Endocrine System

- Lymphatic vessels pick up leaked fluids and proteins; lymph distributes hormones; immune cells protect endocrine organs
- The thymus produces hormones that promote development of lymphatic organs and "program" T cells; stress hormones depress immune activity

Cardiovascular System

- Lymphatic vessels pick up leaked plasma and proteins; spleen removes and destroys aged RBCs and debris, and stores iron and platelets; immune cells protect cardiovascular organs from specific pathogens
- Blood is the source of lymph; lymphatics develop from veins; blood circulates immune elements

Respiratory System

- Lymphatic vessels pick up leaked fluids and proteins from respiratory organs; immune cells protect respiratory organs from specific pathogens; the tonsils and plasma cells in the respiratory mucosa (which secrete the antibody IgA) prevent pathogen invasion
- The lungs provide O_2 needed by lymphoid/immune cells and eliminate CO_2; the pharynx houses the tonsils; respiratory "pump" aids lymph flow

Digestive System

- Lymphatic vessels pick up leaked fluids and proteins from digestive organs; lymph transports some products of fat digestion to the blood; lymphoid follicles in the intestinal wall prevent invasion of pathogens
- The digestive system digests and absorbs nutrients needed by cells of lymphoid organs; gastric acidity inhibits pathogens' entry into blood

Urinary System

- Lymphatic vessels pick up leaked fluid and proteins from urinary organs; immune cells protect urinary organs from specific pathogens
- Urinary system eliminates wastes and maintains homeostatic water/acid-base/electrolyte balance of the blood for lymphoid/immune cell functioning; urine flushes some pathogens out of the urinary tract

Reproductive System

- Lymphatic vessels pick up leaked fluid and proteins; immune cells protect against pathogens
- Reproductive organs' hormones may influence immune functioning; acidity of vaginal secretions is bacteriostatic

THE LYMPHATIC SYSTEM: Immunity and Interrelationships with the Cardiovascular System

All living body cells are bathed by lymph. Nonetheless, the lymphatic system with its ghostly vessels and well-hidden (for the most part) organs and tissues is elusive and hard to pin down. Like a ground mole that tunnels throughout your yard, you know it's there, but you never see it as it quietly goes about its business. Since hormones made by endocrine organs are released into the extracellular space, and lymphatic vessels take up the fluid containing them, there is little question that lymph is an important medium for delivering hormones throughout the body. Lymph plays a similar delivery role as it delivers fats absorbed by the digestive organs.

Our immune system, charged with protecting the body from specific pathogens, is often considered a separate and independent functional system. However, it is impossible to divorce the immune system from the lymphatic system because lymphoid organs are the programming sites and seedbeds for the immune cells and provide crucial vantage points for monitoring blood and lymph for the presence of foreign substances. Less understood are the intimate interactions between the immune cells that populate the lymphoid tissues and the nervous and endocrine systems, but this interesting topic is deferred to Chapter 21 to give you the opportunity to consider the immune system in detail.

Although the lymphatic system serves the entire body, its chief "master" is the cardiovascular system. It is this relationship that we will explore further here.

Cardiovascular System

By now you are probably fairly comfortable with the fact that the lymphatic system picks up and returns leaked fluid and proteins to the blood vascular system. So, what's the big deal? We ingest water in virtually everything we eat and drink—lost water is replaceable in a few minutes, right? The answer, of course, is "true." But what would still be missing is the leaked proteins, and these plasma proteins (most made by the liver) take time and energy to make. Since plasma proteins play a *major* role in keeping fluid in blood vessels (or encouraging its return), without them our blood vessels would contain too little fluid to support blood circulation. And without blood circulation, the whole body would die for lack of oxygen and nutrients and drown in its own wastes. Lymphoid organs also help to maintain the health and purity of blood—lymph nodes filter microorganisms and other debris from lymph before it is allowed to reenter the blood, and the spleen performs the same cleansing service for blood. In addition, the spleen disposes of inefficient, deformed, or aged erythrocytes.

However, this relationship is not entirely one-way. Lymphatic vessels spring from veins of the cardiovascular system, and blood delivers oxygen and nutrients to all body organs, including lymphoid ones. Blood also provides a means for (1) rapid transport of lymphocytes (immune cells) that continuously patrol the body for foreign substances and (2) broad distribution of antibodies (made by B cells and plasma cells), which bind to foreign substances and immobilize them until they can be disposed of by phagocytosis or other means. Furthermore, the endothelial cells of capillaries express surface protein "signals" (integrins/adhesion molecules) that lymphocytes can recognize when the surrounding area is injured or infected. Hence, capillaries guide immune cells to the sites where their protective services are needed, and the extremely porous walls of the postcapillary venules allow them to slip through the vessel wall to get there.

Lymphatic System/Immunity

Case study: Back to following the progress of Mr. Hutchinson, we learn that the routine complete blood count (CBC) performed on admission revealed that his leukocyte count is dangerously low and follow-up lab tests show that his lymphocytes are deficient. One day postsurgery, he complains of pain in his right ring finger (that hand had a crush injury). When examined, it was noted that the affected finger and the dorsum of the right hand were edematous, and red streaks radiated superiorly on his right forearm. Higher than normal doses of antibiotics are prescribed, and a sling is applied to the affected arm. Nurses are instructed to apply gloves and gown when giving Mr. Hutchinson his care.

Relative to these observations:

1. What do the red streaks emanating from the bruised finger indicate? What would you conclude his problem was if there were no red streaks but the right arm was very edematous?
2. Why is it important that Mr. Hutchinson not move the affected arm excessively (i.e., why was the sling ordered)?
3. How might the low lymphocyte count, megadoses of antibiotics, and orders for additional clinical staff protection be related?
4. Do you predict that Mr. Hutchinson's recovery will be uneventful or problematic? Why?

(Answers in Appendix G)

Chapter Summary

1. Lymphatic vessels, lymph nodes, and other lymphoid organs and tissues make up the lymphatic system. This system returns fluids that have leaked from the blood vascular system back to the blood, protects the body by removing foreign material from the lymph stream, and provides a site for immune surveillance.

Lymphatic Vessels (pp. 774–777)

Distribution and Structure of Lymphatic Vessels (pp. 774–775)

1. Lymphatic vessels form a one-way network—lymphatic capillaries, collecting vessels, trunks, and ducts—in which fluid flows only toward the heart. The right lymphatic duct drains lymph from the right arm and right side of the upper body; the thoracic duct receives lymph from the rest of the body. These ducts empty into the blood vascular system at the junction of the internal jugular and subclavian veins in the neck.

Lymph Transport (pp. 775–777)

2. The flow of lymphatic fluid is slow; it is maintained by skeletal muscle contraction, pressure changes in the thorax, and contractions of the lymphatic vessels. Backflow is prevented by valves.

3. Lymphatic capillaries are exceptionally permeable, admitting proteins and particulate matter from the interstitial space.

4. Pathogens and cancer cells may spread through the body via the lymphatic stream.

Lymphoid Cells and Tissues (p. 777)

Lymphoid Cells (p. 777)

1. The cells in lymphoid tissues include lymphocytes (immunocompetent cells called T cells or B cells), plasma cells (antibody-producing offspring of B cells), macrophages and dendritic cells (phagocytes and cells that initiate an immune response), and reticular cells that form the lymphoid tissue stroma.

Lymphoid Tissue (p. 777)

2. Lymphoid tissue is reticular connective tissue. It houses macrophages and a continuously changing population of lymphocytes. It is an important element of the immune system.

3. Lymphoid tissue may be diffuse or packaged into dense follicles. Follicles often display germinal centers (areas where B cells are proliferating).

Lymph Nodes (pp. 778–779)

1. Lymph nodes, the principal lymphoid organs, are discrete encapsulated structures containing both diffusely arranged and dense reticular tissue. Clustered along lymphatic vessels, lymph nodes filter lymph and help activate the immune system.

Structure of a Lymph Node (pp. 778–779)

2. Each lymph node has a fibrous capsule, a cortex, and a medulla. The cortex contains mostly lymphocytes, which act in immune responses; the medulla contains macrophages, which engulf and destroy viruses, bacteria, and other foreign debris, as well as lymphocytes and plasma cells.

Circulation in the Lymph Nodes (p. 779)

3. Lymph enters the lymph nodes via afferent lymphatic vessels and exits via efferent vessels. There are fewer efferent vessels; therefore, lymph flow stagnates within the lymph node, allowing time for its cleansing.

Other Lymphoid Organs (pp. 779–782)

1. Unlike lymph nodes, the spleen, thymus, tonsils, and Peyer's patches do not filter lymph. However, most lymphoid organs contain both macrophages and lymphocytes.

Spleen (pp. 779–781)

2. The spleen provides a site for lymphocyte proliferation and immune function, and destroys aged or defective red blood cells and bloodborne pathogens. It also stores and releases the breakdown products of hemoglobin as necessary, stores platelets, and acts as a hematopoietic site in the fetus.

Thymus (p. 781)

3. The thymus is most functional during youth. Its hormones cause T lymphocytes to become immunocompetent.

Tonsils and Aggregates of Lymphoid Follicles (pp. 781–782)

4. Peyer's patches of the intestinal wall, lymphoid follicles of the appendix, tonsils of the pharynx and oral cavity, and follicles in the genitourinary and respiratory tract mucosae are known as MALT (mucosa-associated lymphatic tissue). They prevent pathogens in these passages from penetrating the mucous membrane lining.

Developmental Aspects of the Lymphatic System (p. 783)

1. Lymphatics develop as outpocketings of developing veins. The thymus develops from endoderm; the other lymphoid organs derive from mesenchymal cells of mesoderm.

2. The thymus, the first lymphoid organ to appear, plays a role in the development of other lymphoid organs.

3. Lymphoid organs are populated by lymphocytes, which arise from hematopoietic tissue.

Review Questions

Multiple Choice/Matching

(Some questions have more than one correct answer. Select the best answer or answers from the choices given.)

1. Lymphatic vessels (a) serve as sites for immune surveillance, (b) filter lymph, (c) transport leaked plasma proteins and fluids to the cardiovascular system, (d) are represented by vessels that resemble arteries, capillaries, and veins.

2. The saclike initial portion of the thoracic duct is the (a) lacteal, (b) right lymphatic duct, (c) cisterna chyli, (d) lymph sac.

3. Entry of lymph into the lymphatic capillaries is promoted by which of the following? (a) one-way minivalves formed by overlapping endothelial cells, (b) the respiratory pump, (c) the skeletal muscle pump, (d) greater fluid pressure in the interstitial space.

4. The structural framework of lymphoid organs is (a) areolar connective tissue, (b) hematopoietic tissue, (c) reticular tissue, (d) adipose tissue.

5. Lymph nodes are densely clustered in all of the following body areas *except* (a) the brain, (b) the axillae, (c) the groin, (d) the cervical region.

6. The germinal centers in lymph nodes are largely sites of (a) macrophages, (b) proliferating B lymphocytes, (c) T lymphocytes, (d) all of these.

7. The red pulp areas of the spleen are sites of (a) venous sinuses, macrophages, and red blood cells, (b) clustered lymphocytes, (c) connective tissue septa.

8. The lymphoid organ that functions primarily during youth and then begins to atrophy is the (a) spleen, (b) thymus, (c) palatine tonsils, (d) bone marrow.

9. Collections of lymphoid tissue (MALT) that guard mucosal surfaces include all of the following *except* (a) appendix follicles, (b) the tonsils, (c) Peyer's patches, (d) the thymus.

Short Answer Essay Questions

10. Compare and contrast blood, interstitial fluid, and lymph.

11. Compare the structure and functions of a lymph node to those of the spleen.

12. (a) What anatomical characteristic ensures that the flow of lymph through a lymph node is slow? (b) Why is this desirable?

13. Why doesn't the absence of lymphatic *arteries* represent a problem?

Critical Thinking and Clinical Application Questions

1. Mrs. Jackson, a 59-year-old woman, has undergone a left radical mastectomy (removal of the left breast and left axillary lymph nodes and vessels). Her left arm is severely swollen and painful, and she is unable to raise it to more than shoulder height. (a) Explain her signs and symptoms. (b) Can she expect to have relief from these symptoms in time? How so?

2. A friend tells you that she has tender, swollen "glands" along the left side of the front of her neck. You notice that she has a bandage on her left cheek that is not fully hiding a large infected cut there. Exactly what are her swollen "glands," and how did they become swollen?

3. Once almost a rite of childhood, tonsillectomy (surgical removal of the tonsils) is now rarely performed. Similarly, while ruptured spleens were once routinely removed, they are now conserved whenever possible. Why should these lymphoid organs be preserved when possible?

The Immune System: Innate and Adaptive Body Defenses

PART 1: INNATE DEFENSES

Surface Barriers: Skin and Mucosae (pp. 789–790)

1. Describe surface membrane barriers and their protective functions.

Internal Defenses: Cells and Chemicals (pp. 790–798)

2. Explain the importance of phagocytosis and natural killer cells in innate body defense.
3. Describe the inflammatory process. Identify several inflammatory chemicals and indicate their specific roles.
4. Name the body's antimicrobial substances and describe their function.
5. Explain how fever helps protect the body.

PART 2: ADAPTIVE DEFENSES

Antigens (pp. 799–800)

6. Define antigen and describe how antigens affect the immune system.
7. Define complete antigen, hapten, and antigenic determinant.
8. Follow antigen processing in the body.

Cells of the Adaptive Immune System: An Overview (pp. 800–803)

9. Compare and contrast the origin, maturation process, and general function of B and T lymphocytes.
10. Define immunocompetence and self-tolerance, and describe their development in B and T lymphocytes.
11. Name several antigen-presenting cells and describe their roles in adaptive defenses.

Humoral Immune Response (pp. 804–810)

12. Define humoral immunity.
13. Describe the process of clonal selection of a B cell.
14. Recount the roles of plasma cells and memory cells in humoral immunity.
15. Compare and contrast active and passive humoral immunity.
16. Describe the structure of an antibody monomer, and name the five classes of antibodies.
17. Explain the function(s) of antibodies and describe clinical uses of monoclonal antibodies.

Cell-Mediated Immune Response (pp. 810–820)

18. Define cell-mediated immunity and describe the process of activation and clonal selection of T cells.
19. Describe T cell functions in the body.
20. Indicate the tests ordered before an organ transplant is done, and methods used to prevent transplant rejection.

Homeostatic Imbalances of Immunity (pp. 820–825)

21. Give examples of immune deficiency diseases and of hypersensitivity states.
22. Cite factors involved in autoimmune disease.

Developmental Aspects of the Immune System (pp. 825–826)

23. Describe changes in immunity that occur with aging.
24. Briefly describe the role of the nervous system in regulating the immune response.

Every second of every day, an army of hostile bacteria, fungi, and viruses swarms on our skin and yet we stay amazingly healthy most of the time. The body seems to have evolved a single-minded approach to such foes—if you're not with us, you're against us! To implement that stance, it relies heavily on two intrinsic defense systems that act both independently and cooperatively to provide resistance to disease, or **immunity** (*immun* = free).

1. The **innate (nonspecific) defense system,** like a lowly foot soldier, is always prepared, responding within minutes to protect the body from all foreign substances. This system has two "barricades." The *first line of defense* is the external body membranes—intact skin and mucosae. The *second line of defense,* called into action whenever the first line has been penetrated, uses antimicrobial proteins, phagocytes, and other cells to inhibit the invaders' spread throughout the body. The hallmark of the second line of defense is inflammation.

2. The **adaptive** (or **specific**) **defense system*** is more like an elite fighting force equipped with high-tech weapons that attacks *particular* foreign substances and provides the body's *third line of defense.* This defensive response takes considerably more time to mount than the innate response. Although we consider them separately, the adaptive and innate systems always work hand in hand. An overview of these two systems is shown in Figure 21.1.

Although certain organs of the body (notably lymphoid organs) are intimately involved in the immune response, the **immune system** is a *functional system* rather than an organ system in an anatomical sense. Its "structures" are a diverse array of molecules plus trillions of immune cells (especially lymphocytes) that inhabit lymphoid tissues and circulate in body fluids.

When the immune system is operating effectively, it protects the body from most infectious microorganisms, cancer cells, and transplanted organs or grafts. It does this both directly, by cell attack, and indirectly, by releasing mobilizing chemicals and protective antibody molecules.

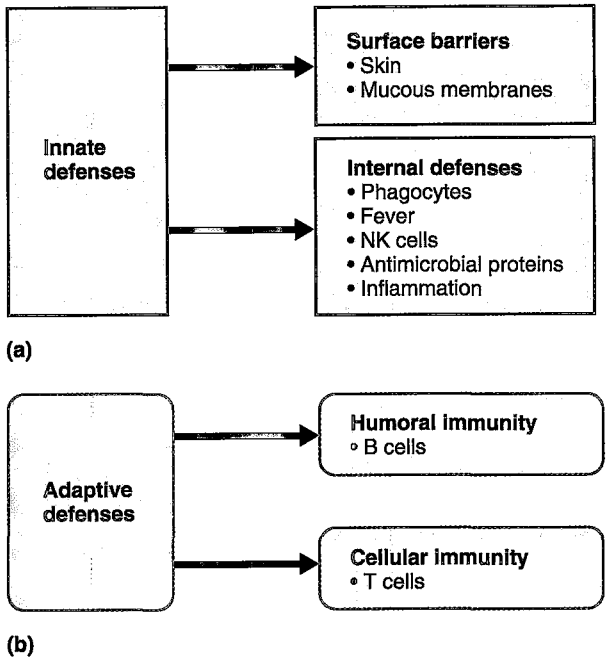

FIGURE 21.1 **Overview of innate and adaptive defenses.** Innate defenses include surface barriers and internal defenses. The distinct but overlapping areas of adaptive immunity are humoral (primarily involving B lymphocytes) and cellular (involving T lymphocytes). For simplicity, the many interactions between innate and adaptive defenses are not shown here. Portions of this diagram will reappear in subsequent figures to remind you of this overall scheme.

PART 1: INNATE DEFENSES

Because they are part and parcel of our anatomy, you could say we come fully equipped with innate or nonspecific defenses. The mechanical barriers that cover body surfaces and the cells and chemicals that act on the initial internal battlefronts are in place at birth, ready to ward off invading **pathogens** (harmful or disease-causing microorganisms) and infection. Many times, our innate defenses alone are able to destroy pathogens and ward off infection. In other cases, the adaptive immune system is called into action to reinforce and enhance the innate mechanisms. Either way, the innate defenses reduce the workload of the adaptive system by preventing the entry and spread of microorganisms in the body.

Surface Barriers: Skin and Mucosae

The body's first line of defense—the *skin* and the *mucous membranes,* along with the secretions these membranes produce—is highly effective. As long as the epidermis is unbroken, this heavily keratinized epithelial membrane presents a formidable physical barrier to most microorganisms that swarm on the skin. Keratin is also resistant to most weak acids and bases and to bacterial enzymes and toxins. Intact mucosae provide similar mechanical barriers within

*Sometimes the term *immune system* is equated with the adaptive defense system only. However, recent research has shown that (1) many defensive molecules are released and recognized by both the innate and adaptive arms; (2) the innate responses are not as nonspecific as once thought and may have specific pathways to target certain foreign substances; and (3) proteins released during innate responses alert cells of the adaptive system to the presence of specific foreign molecules in the body.

the body. Recall that mucous membranes line all body cavities that open to the exterior: the digestive, respiratory, urinary, and reproductive tracts. Besides serving as physical barriers, these epithelial membranes produce a variety of protective chemicals:

1. The acidity of skin secretions (pH 3 to 5) inhibits bacterial growth, and sebum contains chemicals that are toxic to bacteria. Vaginal secretions of adult females are also very acidic.
2. The stomach mucosa secretes a concentrated hydrochloric acid solution and protein-digesting enzymes. Both kill microorganisms.
3. Saliva, which cleanses the oral cavity and teeth, and lacrimal fluid of the eye contain **lysozyme,** an enzyme that destroys bacteria.
4. Sticky mucus traps many microorganisms that enter the digestive and respiratory passageways.

The respiratory tract mucosae also have structural modifications that counteract potential invaders. Tiny mucus-coated hairs inside the nose trap inhaled particles, and cilia on the mucosa of the upper respiratory tract sweep dust- and bacteria-laden mucus toward the mouth, preventing it from entering the lower respiratory passages, where the warm, moist environment provides an ideal site for bacterial growth.

Although the surface barriers are quite effective, they are breached occasionally by small nicks and cuts resulting, for example, from brushing your teeth or shaving. When this happens and microorganisms invade deeper tissues, the *internal* innate defenses come into play.

Internal Defenses: Cells and Chemicals

The body uses an enormous number of nonspecific cellular and chemical devices to protect itself, including phagocytes, natural killer cells, antimicrobial proteins, and fever. The inflammatory response enlists macrophages, mast cells, all types of white blood cells, and dozens of chemicals that kill pathogens and help repair tissue. All these protective ploys identify potentially harmful substances by recognizing surface carbohydrates unique to infectious organisms (bacteria, viruses, and fungi).

Phagocytes

Pathogens that get through the skin and mucosae into the underlying connective tissue are confronted by *phagocytes* (*phago* = eat). The chief phagocytes are **macrophages** ("big eaters"), which derive from white blood cells called **monocytes** that leave the bloodstream, enter the tissues, and develop into macrophages.

Free macrophages, like the alveolar macrophages of the lungs, wander throughout the tissue spaces in search of cellular debris or "foreign invaders." *Fixed macrophages* like *Kupffer cells* in the liver and microglia of the brain are permanent residents of particular organs. Whatever their mobility, all macrophages are similar structurally and functionally.

Neutrophils, the most abundant type of white blood cell, become phagocytic on encountering infectious material in the tissues. **Eosinophils,** another type of white blood cell, are only weakly phagocytic, but they are important in defending the body against parasitic worms. When they encounter such parasites, eosinophils position themselves against the worm and discharge the destructive contents of their large cytoplasmic granules all over their prey.

Mechanism of Phagocytosis

A phagocyte engulfs particulate matter much the way an amoeba ingests a food particle. Flowing cytoplasmic extensions bind to the particle and then pull it inside, enclosed within a membrane-lined vacuole. The **phagosome** thus formed is then fused with a *lysosome* to form a **phagolysosome** (steps ①–③ in Figure 21.2b).

Phagocytic attempts are not always successful. In order for a phagocyte to accomplish ingestion, **adherence** must occur. The phagocyte must first *adhere* or cling to the pathogen, a feat made possible by recognizing the pathogen's carbohydrate "signature." Recognition is particularly difficult with microorganisms such as pneumococcus, which have an external capsule made of complex sugars. These pathogens can sometimes elude capture because phagocytes cannot bind to their capsules. Adherence is both more probable and more efficient when complement proteins or antibodies coat foreign particles, a process called **opsonization** ("to make tasty"), because the coating provides "handles" to which phagocyte receptors can bind.

Sometimes the way neutrophils and macrophages kill ingested prey is more than simple digestion by lysosomal enzymes. For example, pathogens such as the tuberculosis bacillus and certain parasites are resistant to lysosomal enzymes and can even multiply within the phagolysosome. However, when the macrophage is stimulated by chemicals released by immune cells, additional enzymes are activated that produce the **respiratory burst,** an event that liberates a deluge of free radicals (including nitric oxide and superoxide), which have potent cell-killing ability. More widespread cell killing is caused by oxidizing chemicals (H_2O_2 and a substance identical to household bleach). In yet another mechanism of killing triggered by the respiratory burst, K^+ enters the phagolysosome, the pH rises, and the phagolysosome becomes hyperosmotic.

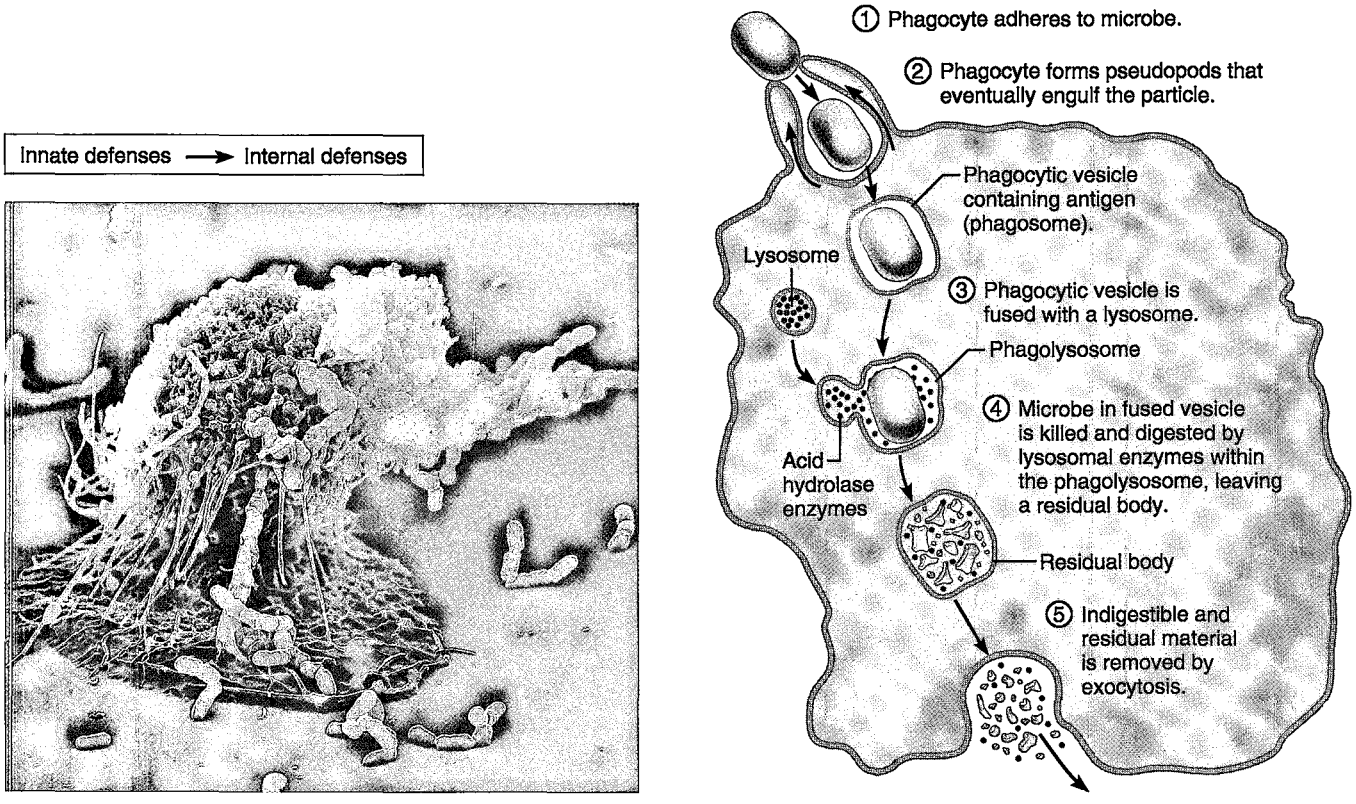

FIGURE 21.2 **Phagocytosis. (a)** In this scanning electron micrograph (2600×), a macrophage uses its long cytoplasmic extensions to pull sausage-shaped *E. coli* bacteria toward it. **(b)** Events of phagocytosis.

This activates protein-digesting enzymes that digest the invader. Neutrophils also produce antimicrobial chemicals, called *defensins* (see p. 833), that pierce the pathogen's membrane.

When phagocytes are unable to ingest their targets (because of size, for example), they can release their toxic chemicals into the extracellular fluid. Whether killing ingested or extracellular targets, neutrophils rapidly destroy themselves in the process, whereas macrophages are more robust and can go on to kill another day.

Natural Killer Cells

Natural killer (NK) cells, which "police" the body in blood and lymph, are a unique group of defensive cells that can lyse and kill cancer cells and virus-infected body cells before the adaptive immune system is activated. Sometimes called the "pit bulls" of the defense system, NK cells are part of a small group of *large granular lymphocytes*. Unlike lymphocytes of the adaptive immune system, which recognize and react only against *specific* virus-infected or tumor cells, NK cells are far less picky. They can eliminate a variety of infected or cancerous cells by detecting the lack of "self" cell surface receptors and by recognizing certain surface sugars on the target cell. The name "natural" killer cells reflects this nonspecificity of NK cells.

NK cells are not phagocytic. Their mode of killing, which involves direct contact and induces the target cell to undergo apoptosis (programmed cell death), uses the same killing mechanisms used by cytotoxic T cells (described fully on p. 815). NK cells also secrete potent chemicals that enhance the inflammatory response.

Inflammation: Tissue Response to Injury

The **inflammatory response** is triggered whenever body tissues are injured by physical trauma (a blow), intense heat, irritating chemicals, or infection by viruses, fungi, or bacteria. The inflammatory response has several beneficial effects:

1. Prevents the spread of damaging agents to nearby tissues
2. Disposes of cell debris and pathogens
3. Sets the stage for repair

Q *Why is it important that the capillaries become leaky during the inflammatory response?*

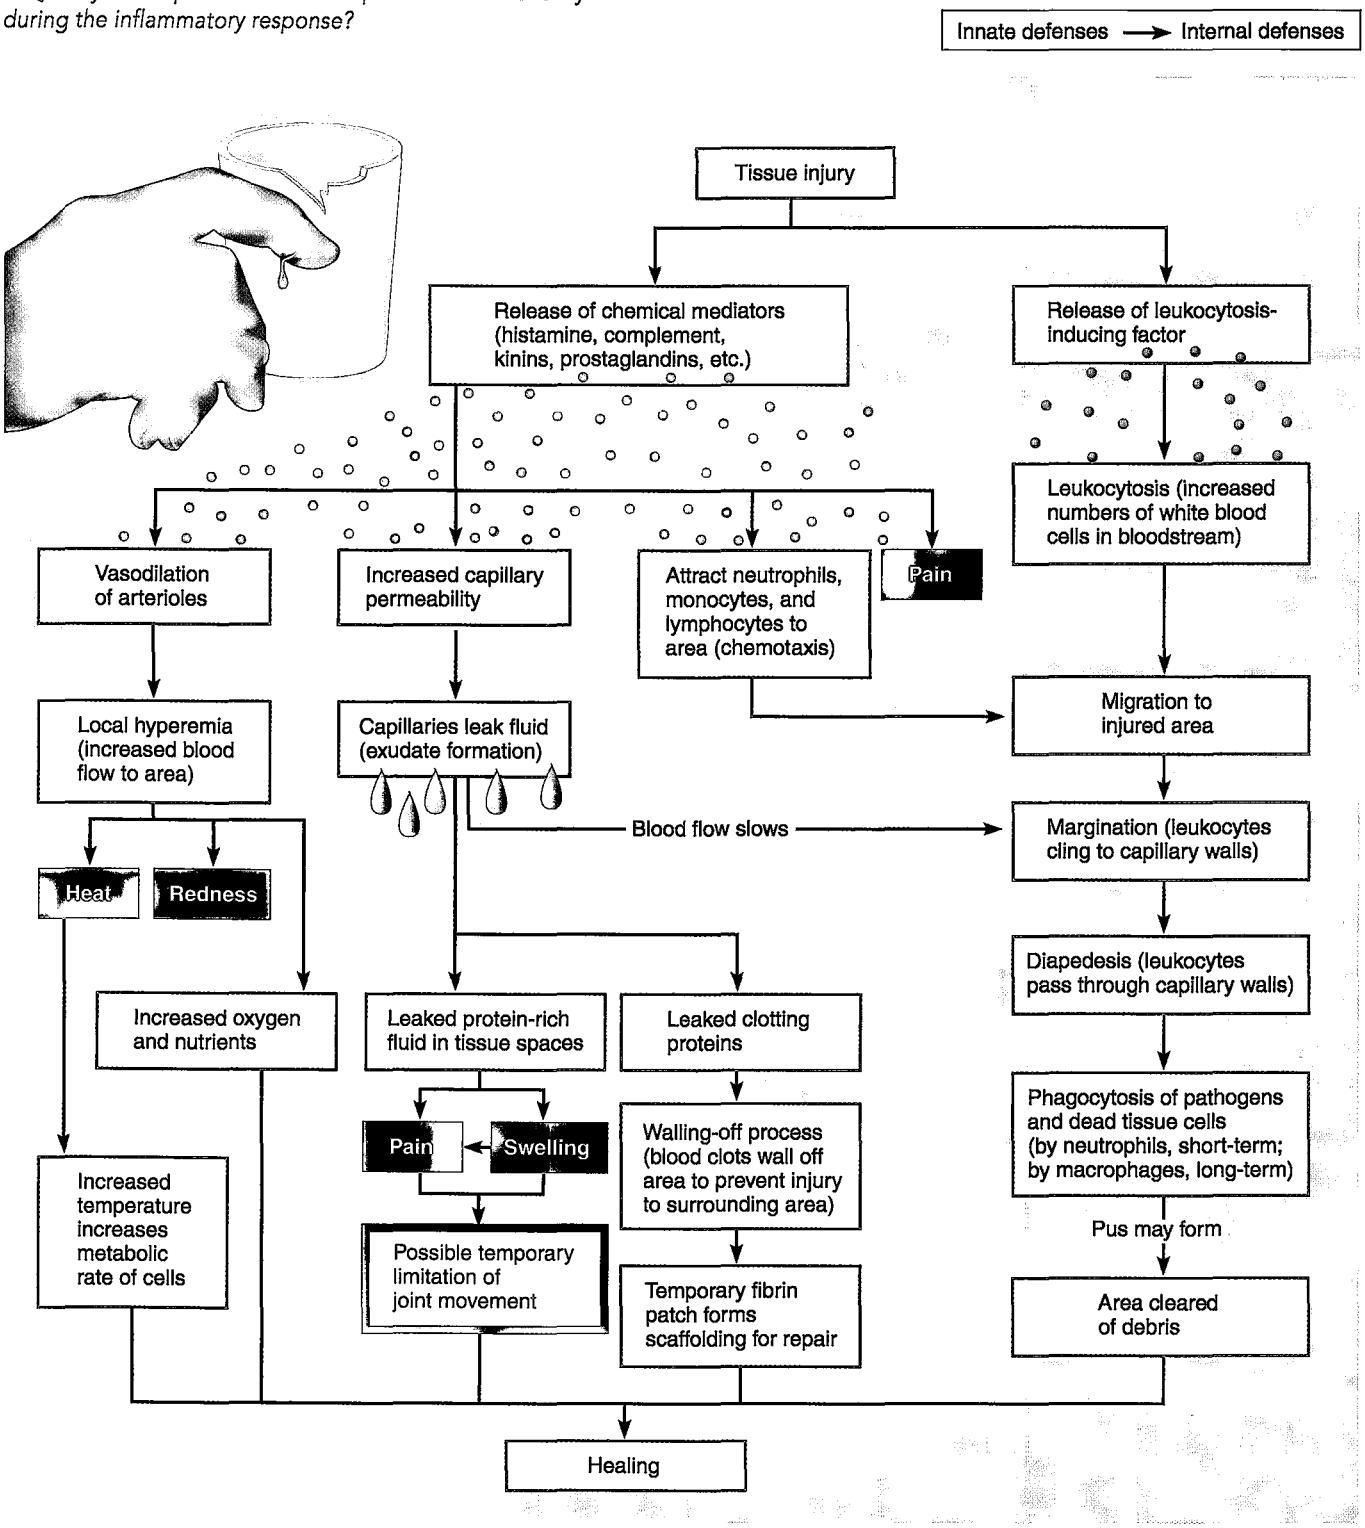

FIGURE 21.3 **Flowchart of events in inflammation.** The four cardinal signs of acute inflammation are shown in red boxes, as is limitation of joint movement, which in some cases constitutes a fifth cardinal sign (impairment of function).

21

This allows more filtrate containing blood-clotting proteins, antibodies, and complement to enter the inflamed area.

TABLE 21.1 Inflammatory Chemicals

CHEMICAL	SOURCE	PHYSIOLOGICAL EFFECTS
Histamine	Granules of basophils and mast cells; released in response to mechanical injury, presence of certain microorganisms, and chemicals released by neutrophils	Promotes vasodilation of local arterioles; increases permeability of local capillaries, promoting exudate formation
Kinins (bradykinin and others)	A plasma protein, kininogen, is cleaved by the enzyme kallikrein found in plasma, urine, saliva, and in lysosomes of neutrophils and other types of cells; cleavage releases active kinin peptides	Same as for histamine; also induce chemotaxis of leukocytes and prompt neutrophils to release lysosomal enzymes, thereby enhancing generation of more kinins; induce pain
Prostaglandins	Fatty acid molecules produced from arachidonic acid—found in all cell membranes; generated by enzymes of neutrophils, basophils, mast cells, and others	Sensitize blood vessels to effects of other inflammatory mediators; one of the intermediate steps of prostaglandin generation produces free radicals, which themselves can cause inflammation; induce pain
Platelet-derived growth factor (PDGF)	Secreted by platelets and endothelial cells	Stimulates fibroblast activity and repair of damaged tissues
Complement	See Table 21.2 (p. 796)	
Cytokines	See Table 21.4 (pp. 817–818)	

The four *cardinal signs* of short-term, or acute, inflammation are *redness, heat* (*inflam* = set on fire), *swelling,* and *pain* (Figure 21.3). If the inflamed area is a joint, joint movement may be hampered temporarily. This forces the injured part to rest, which aids healing. Some authorities consider *impairment of function* to be the fifth cardinal sign of acute inflammation.

Vasodilation and Increased Vascular Permeability

The inflammatory process begins with a chemical "alarm" as a flood of inflammatory chemicals are released into the extracellular fluid. Macrophages (and cells of certain boundary tissues such as epithelial cells lining the gastrointestinal and respiratory tracts) bear surface membrane receptors, called **Toll-like receptors (TLRs),** that play a central role in triggering immune responses. So far ten types of human TLRs have been identified, each recognizing a specific class of attacking microbe. For example, one type responds to a glycolipid in cell walls of the tuberculosis bacterium and another to a component of gram-negative bacteria such as *Salmonella*. Once activated, a TLR triggers the release of chemicals called *cytokines* that promote inflammation and attract WBCs to the scene. But macrophages are not the only sort of recognition "tool" in the innate system. **Mast cells,** a key component of the inflammatory response, release the potent inflammatory chemical **histamine** (his'tah-mēn). In addition, injured and stressed tissue cells, phagocytes, lymphocytes, basophils, and blood proteins are all sources of inflammatory mediators. These include not only histamine and cytokines, but **kinins** (ki'ninz), **prostaglandins** (pros"tah-glan'dinz), **leukotrienes,** and **complement.** Though some of these mediators have individual inflammatory roles as well (see Table 21.1), they all cause small blood vessels in the injured area to dilate. As more blood flows into the area, local **hyperemia** (congestion with blood) occurs, accounting for the *redness* and *heat* of an inflamed region.

The liberated chemicals also increase the permeability of local capillaries. Consequently, **exudate**—fluid containing clotting factors and antibodies—seeps from the blood into the tissue spaces. This exudate causes the local edema *(swelling)* that presses on adjacent nerve endings, contributing to a sensation of *pain.* Pain also results from the release of bacterial toxins, and the sensitizing effects of released prostaglandins and kinins. Aspirin and some other anti-inflammatory drugs produce their analgesic (pain-reducing) effects by inhibiting prostaglandin synthesis.

Although edema may seem detrimental, it isn't. The surge of protein-rich fluids into the tissue spaces helps to dilute harmful substances that may be present and delivers important proteins such as complement and clotting factors to the interstitial fluid (Figure 21.3). The clotting proteins form a gel-like fibrin mesh that forms a scaffold for permanent repair. This isolates the injured area and prevents the spread of bacteria and other harmful agents into surrounding tissues. Walling off the injured area is such an important defense mechanism that some bacteria (such as *Streptococcus*) have evolved enzymes that break down the clot,

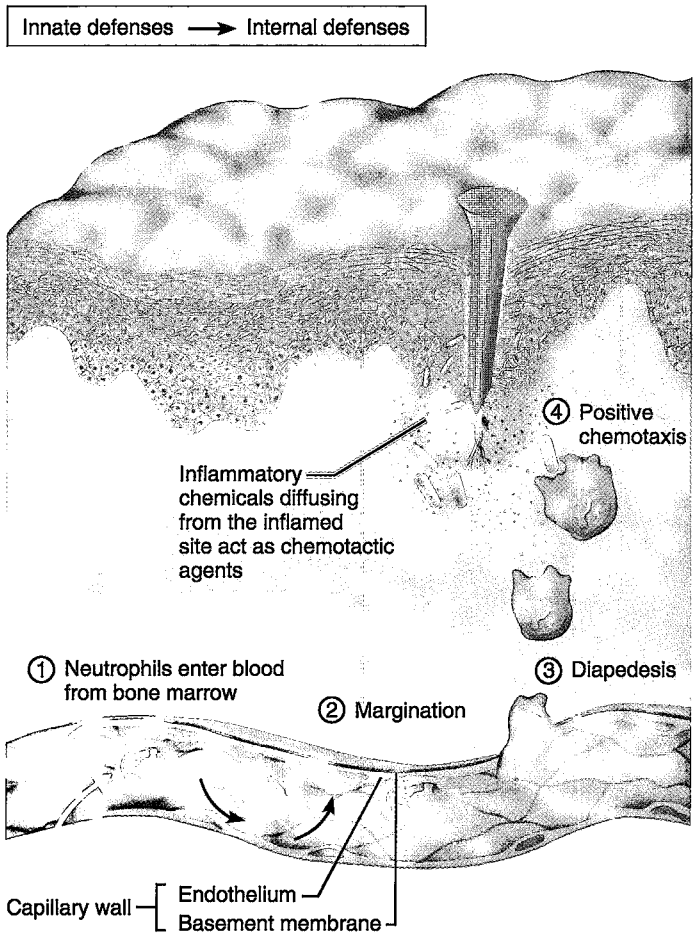

FIGURE 21.4 **Phagocyte mobilization.** When leukocytosis-inducing factors are released by injured cells at an inflamed site, ① neutrophils are released from the bone marrow to the blood. Because blood at the inflammatory site loses fluid, blood flow slows locally and the neutrophils roll along the vascular endothelium. ② Margination begins as neutrophil cell adhesion molecules (CAMs) cling to those of the capillary endothelial cells, and then ③ diapedesis occurs as the neutrophils squeeze through the capillary walls. ④ Positive chemotaxis is the continued migration toward the site where inflammatory chemicals are present. Once at the inflamed site, the neutrophils help rid the area of pathogens and cellular debris.

allowing the bacteria to spread rapidly into adjacent tissues.

At inflammatory sites where an epithelial barrier has been breached, additional chemicals enter the battle—β-defensins. These broad-spectrum antimicrobial chemicals are continuously present in epithelial mucosal cells in small amounts and help maintain the sterile environment of the body's internal passageways (urinary tract, respiratory bronchi, etc.). However, when the mucosal surface is abraded or penetrated and the underlying connective tissue becomes inflamed, β-defensin output increases dramatically, helping to control bacterial and fungal colonization in the exposed area.

Phagocyte Mobilization

Soon after inflammation begins, the damaged area is invaded by more phagocytes—neutrophils lead, followed by macrophages. If the inflammation was provoked by pathogens, a group of plasma proteins known as complement (discussed shortly) is activated and elements of adaptive immunity (lymphocytes and antibodies) also invade the injured site. The process by which phagocytes are mobilized to infiltrate the injured site is illustrated in Figure 21.4.

① **Leukocytosis.** Chemicals called **leukocytosis-inducing factors** released by injured cells promote rapid release of neutrophils from red bone marrow, and within a few hours the number of neutrophils in blood increases four- to fivefold. This increase in WBCs, called **leukocytosis,** is a characteristic of inflammation.

② **Margination.** Because of the tremendous outpouring of fluid from the blood into the injured area, blood flow in the region slows and the neutrophils begin to roll along the capillary endothelium as if "tasting" the local environment. In inflamed areas, the endothelial cells sprout cell adhesion molecules (CAMs) called *selectins.* These provide footholds (signal that "this is the place") for other CAMs (integrins) on the surfaces of the neutrophils to bind. When the complementary CAMs unite, the neutrophils cling to the inner walls of the capillaries and postcapillary venules. This phenomenon is known as **margination.**

③ **Diapedesis.** The continued chemical signaling prompts the neutrophils to squeeze through the capillary walls, a process called **diapedesis** or **emigration.**

④ **Chemotaxis.** Neutrophils usually migrate randomly, but inflammatory chemicals act as homing devices, or more precisely **chemotactic agents,** that attract the neutrophils and other white blood cells to the site of the injury. Within an hour after the inflammatory response has begun, neutrophils have collected at the site and are devouring any foreign material present.

As the counterattack continues, monocytes follow neutrophils into the injured area. Monocytes are fairly poor phagocytes, but within 12 hours of leaving the blood and entering the tissues, they swell and develop large numbers of lysosomes, becoming macrophages with insatiable appetites. These late-arriving macrophages replace the neutrophils on the battlefield. Macrophages are the central actors in the final disposal of cell debris as an acute inflammation subsides, and they predominate at sites of prolonged, or *chronic,* inflammation. The ultimate goal of an inflammatory response is to clear the injured area of pathogens, dead tissue cells, and any other debris so that tissue can be repaired. Once this is accomplished, healing usually occurs quickly.

HOMEOSTATIC IMBALANCE

In severely infected areas, the battle takes a considerable toll on both sides, and creamy, yellow **pus,** a mixture of dead or dying neutrophils, broken-down tissue cells, and living and dead pathogens, may accumulate in the wound. If the inflammatory mechanism fails to clear the area of debris, the sac of pus may be walled off by collagen fibers, forming an *abscess.* Surgical drainage of abscesses is often necessary before healing can occur.

Bacteria, such as tuberculosis bacilli, that are resistant to digestion by macrophages escape the effects of prescription antibiotics by remaining snugly enclosed within their macrophage hosts. In such cases, *infectious granulomas* form. These tumorlike growths contain a central region of infected macrophages surrounded by uninfected macrophages and an outer fibrous capsule. A person may harbor pathogens walled off in granulomas for years without displaying any symptoms. However, if the person's resistance to infection is ever compromised, the bacteria may be activated and break out, leading to clinical disease symptoms. ●

Antimicrobial Proteins

A variety of **antimicrobial proteins** enhance the innate defenses by attacking microorganisms directly or by hindering their ability to reproduce. The most important of these are interferons and complement proteins (Table 21.2).

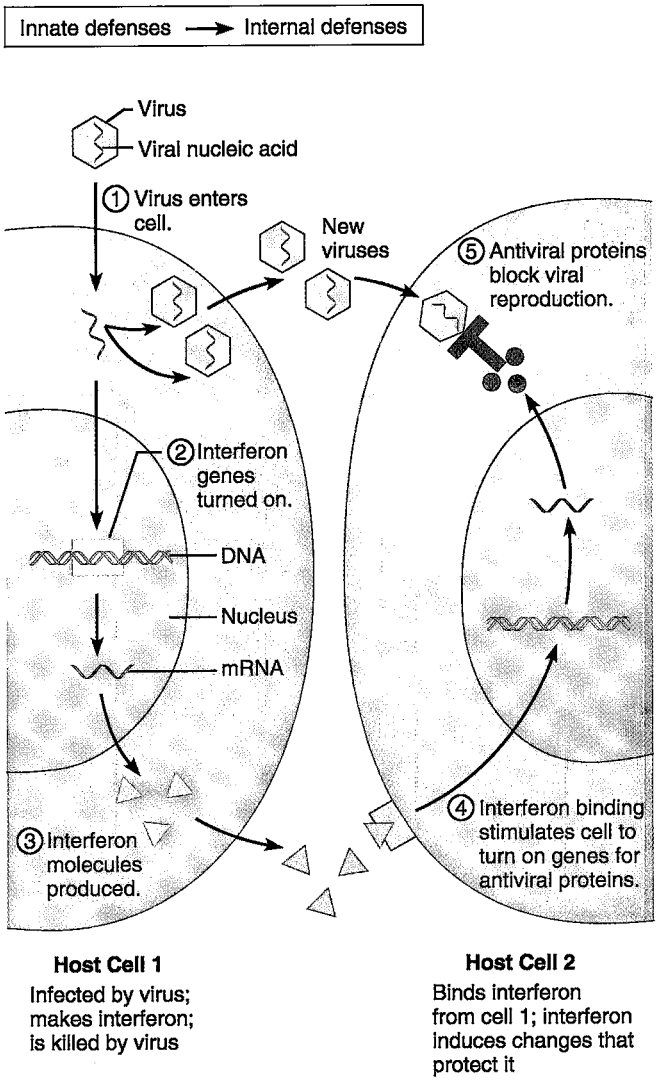

FIGURE 21.5 **The interferon mechanism against viruses.**

Interferons

Viruses—essentially nucleic acids surrounded by a protein coat—lack the cellular machinery to generate ATP or synthesize proteins. They do their "dirty work" or damage in the body by invading tissue cells and taking over the cellular metabolic machinery needed to reproduce themselves. Although the infected cells can do little to save themselves, some can secrete small proteins called **interferons (IFNs)** (in"ter-fēr'onz) to help protect cells that have not yet been infected. The IFNs diffuse to nearby cells, where they stimulate synthesis of proteins which then "interfere" with viral replication in the still-healthy cells by blocking protein synthesis and degrading viral RNA (Figure 21.5). Because IFN protection is not *virus specific,* IFNs produced against a particular virus protect against a variety of other viruses.

TABLE 21.2 Summary of Nonspecific Body Defenses

CATEGORY/ASSOCIATED ELEMENTS	PROTECTIVE MECHANISM
FIRST LINE OF DEFENSE: SURFACE MEMBRANE BARRIERS	
Intact skin epidermis	Forms mechanical barrier that prevents entry of pathogens and other harmful substances into body
▪ Acid mantle	Skin secretions (perspiration and sebum) make epidermal surface acidic, which inhibits bacterial growth; sebum also contains bactericidal chemicals
▪ Keratin	Provides resistance against acids, alkalis, and bacterial enzymes
Intact mucous membranes	Form mechanical barrier that prevents entry of pathogens
▪ Mucus	Traps microorganisms in respiratory and digestive tracts
▪ Nasal hairs	Filter and trap microorganisms in nasal passages
▪ Cilia	Propel debris-laden mucus away from lower respiratory passages
▪ Gastric juice	Contains concentrated hydrochloric acid and protein-digesting enzymes that destroy pathogens in stomach
▪ Acid mantle of vagina	Inhibits growth of most bacteria and fungi in female reproductive tract
▪ Lacrimal secretion (tears); saliva	Continuously lubricate and cleanse eyes (tears) and oral cavity (saliva); contain lysozyme, an enzyme that destroys microorganisms
▪ Urine	Normally acid pH inhibits bacterial growth; cleanses the lower urinary tract as it flushes from the body
SECOND LINE OF DEFENSE: INNATE, CELLULAR AND CHEMICAL DEFENSES	
Phagocytes	Engulf and destroy pathogens that breach surface membrane barriers; macrophages also contribute to immune response
Natural killer (NK) cells	Promote apoptosis (cell suicide) by direct cell attack against virus-infected or cancerous body cells; do not require specific antigen recognition; do not exhibit a memory response
Inflammatory response	Prevents spread of injurious agents to adjacent tissues, disposes of pathogens and dead tissue cells, and promotes tissue repair; chemical mediators released attract phagocytes (and immunocompetent cells) to the area
Antimicrobial proteins	
▪ Interferons (α, β, γ)	Proteins released by virus-infected cells and certain lymphocytes that protect uninfected tissue cells from viral takeover; mobilize immune system
▪ Complement	Lyses microorganisms, enhances phagocytosis by opsonization, and intensifies inflammatory and immune responses
Fever	Systemic response initiated by pyrogens; high body temperature inhibits microbial multiplication and enhances body repair processes

The IFNs are a family of related proteins produced by a variety of body cells, each having a slightly different physiological effect. Lymphocytes secrete gamma (γ), or immune, interferon, but most other leukocytes secrete alpha (α) interferon. Beta (β) interferon is secreted by fibroblasts. IFN-β and -α reduce inflammation. Besides their antiviral effects, interferons activate macrophages and mobilize NK cells. Because both macrophages and NK cells can act directly against malignant cells, the interferons play some anticancer role.

Genetically engineered IFNs have found a niche as antiviral agents. *IFN-α* is used to treat genital warts (caused by human papillomavirus) and is the first drug to have some success in combating hepatitis C (spread via blood and sexual intercourse), the most common and most dreaded form of hepatitis. *IFN-β* is used to treat patients with multiple sclerosis, a devastating demyelinating disease.

Complement

The term **complement system,** or simply **complement,** refers to a group of at least 20 plasma proteins that normally circulate in the blood in an inactive state. These proteins include C1 through C9, factors

Q *Which pathway can occur without the need for an adaptive immune response?*

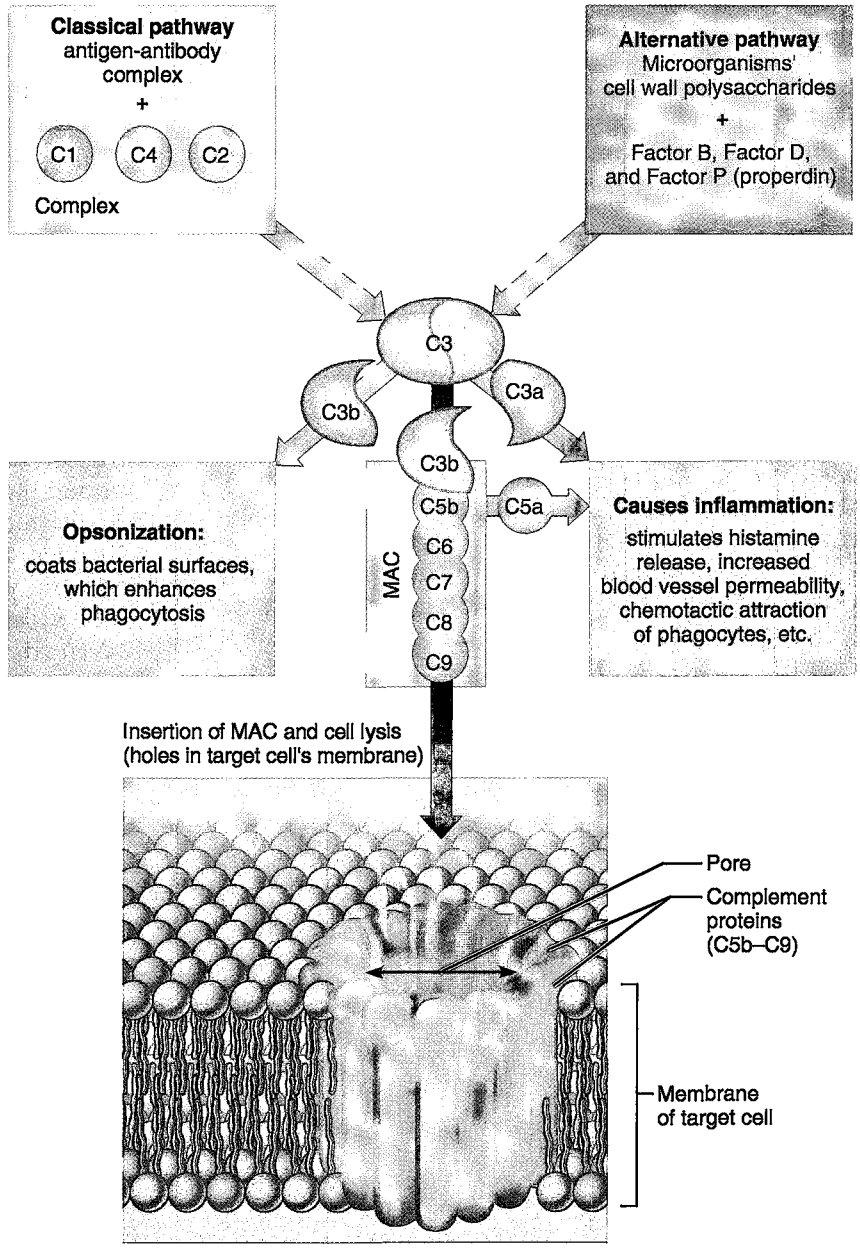

FIGURE 21.6 **Complement activation.** The classical pathway, mediated by 11 complement proteins designated C1–C9 (C1 incorporates three proteins), requires antigen-antibody interactions. The alternative pathway occurs when plasma proteins called factors B, D, and P interact with polysaccharides on the cell walls of certain bacteria and fungi. The two pathways converge to activate C3 (cleaving it into C3a and C3b), a step that initiates a common terminal sequence. Once bound to the target cell's surface, C3b initiates the remaining steps of complement activation. These steps result in the incorporation of MAC, the membrane attack complex (components C5b, and C6 to C9), into the target cell's membrane, creating a funnel-shaped pore that causes cell lysis. Bound C3b also enhances phagocytosis. Released C3a, C5a, and other products of complement activation promote the events of inflammation.

B, D, and P, plus several regulatory proteins. Complement provides a major mechanism for destroying foreign substances in the body. Its activation unleashes chemical mediators that amplify virtually all aspects of the inflammatory process. Another effect of complement activation is that certain bacteria and other cell types are killed by cell lysis. (Luckily our own cells are equipped with proteins that inactivate complement.) Although complement is a nonspecific defensive mechanism, it "complements" (enhances) the effectiveness of *both* innate and adaptive defenses.

Complement can be activated by the two pathways outlined in Figure 21.6. The **classical pathway** involves *antibodies*, water-soluble protein molecules that the adaptive immune system produces to fight off foreign invaders. The classical pathway depends on the binding of antibodies to the invading

A *The alternative pathway.*

organisms and the subsequent binding of C1 to the microorganism-antibody complexes, a step called *complement fixation* (described on pp. 809–810). The **alternative pathway** is triggered when factors B, D, and P interact with polysaccharide molecules present on the surface of certain microorganisms.

Like the blood clotting cascade, complement activation by either pathway involves a cascade in which proteins are activated in an orderly sequence—each step catalyzing the next. The two pathways converge on C3, cleaving it into C3a and C3b. This event initiates a common terminal pathway that causes cell lysis, promotes phagocytosis, and enhances inflammation.

The lytic events begin when C3b binds to the target cell's surface, triggering the insertion of a group of complement proteins called **MAC (membrane attack complex)** into the cell's membrane. MAC forms and stabilizes a hole in the membrane that ensures lysis of the target cell by inducing a massive influx of water.

The C3b molecules that coat the microorganism provide "handles" that receptors on macrophages and neutrophils can adhere to, allowing them to engulf the particle more rapidly. As noted earlier, this process is called *opsonization*. C3a and other cleavage products formed during complement fixation amplify the inflammatory response by stimulating mast cells and basophils to release histamine and by attracting neutrophils and other inflammatory cells to the area.

C-reactive protein (CRP), produced by the liver in response to inflammatory molecules, is used as a clinical marker to assess for the presence of an acute infection or an inflammatory condition and its response to treatment. Because it binds with a variety of physiological ligands, it has multiple roles in immunity. By binding to certain surface molecules of pathogens and exposed self-antigens of damaged body cells, it plays a surveillance role that results in their targeting for disposal by phagocytes and complement. CRP binding to C1 of the classical complement pathway activates complement and results in the deposit of C3 on the surface of bacteria (opsonization).

Fever

Inflammation is a localized response to infection, but sometimes the body's response to the invasion of microorganisms is more widespread. **Fever,** or abnormally high body temperature, is a systemic response to invading microorganisms. As described further in Chapter 24, body temperature is regulated by a cluster of neurons in the hypothalamus, commonly referred to as the body's thermostat. Normally set at approximately 37°C (98.6°F), the thermostat is reset upward in response to chemicals called **pyrogens** (*pyro* = fire), secreted by leukocytes and macrophages exposed to foreign substances in the body.

High fevers are dangerous because excess heat denatures enzymes. Mild or moderate fever, however, is an adaptive response that seems to benefit the body. In order to multiply, bacteria require large amounts of iron and zinc, but during a fever the liver and spleen sequester these nutrients, making them less available. Fever also increases the metabolic rate of tissue cells in general, speeding up repair processes.

PART 2: ADAPTIVE DEFENSES

Most of us would find it wonderfully convenient if we could walk into a single clothing store and buy a complete wardrobe—hat to shoes—that fit perfectly regardless of any special figure problems. We know that such a service would be next to impossible to find. And yet, we take for granted our **adaptive immune system,** the body's built-in *specific defensive system* that stalks and eliminates with nearly equal precision almost any type of pathogen that intrudes into the body.

When it operates effectively, the adaptive immune system protects us from a wide variety of infectious agents, as well as from abnormal body cells. When it fails, or is disabled, the result is such devastating diseases as cancer and AIDS. The activity of the adaptive immune system tremendously amplifies the inflammatory response and is responsible for most complement activation. At first glance, the adaptive system seems to have a major shortcoming. Unlike the innate system, which is always ready and able to react, the adaptive system must "meet" or be primed by an initial exposure to a specific foreign substance (antigen) before it can protect the body against that substance, and this priming takes precious time.

The basis of this specific immunity was revealed in the late 1800s, when researchers demonstrated that animals surviving a serious bacterial infection have in their blood protective factors (the proteins we now call *antibodies*) that defend against future attacks by the same pathogen. Furthermore, it was shown that if antibody-containing serum from the surviving animals was injected into animals that had *not* been exposed to the pathogen, those injected animals would also be protected. These landmark experiments were exciting because they revealed three important aspects of the adaptive immune response:

1. It is specific: It recognizes and is directed against *particular* pathogens or foreign substances that initiate the immune response.

2. It is systemic: Immunity is not restricted to the initial infection site.

3. It has "memory": After an initial exposure, it recognizes and mounts even stronger attacks on the previously encountered pathogens.

At first antibodies were thought to be the sole artillery of the adaptive immune system, but in the mid-1900s it was discovered that injection of antibody-containing serum did *not* always protect the recipient from diseases the serum donor had survived. In such cases, however, injection of the donor's lymphocytes *did* provide immunity. As the pieces fell into place, two separate but overlapping arms of adaptive immunity were recognized, each using a variety of attack mechanisms that vary with the intruder.

Humoral immunity (hu'mor-ul), also called **antibody-mediated immunity,** is provided by antibodies present in the body's "humors," or fluids (blood, lymph, etc.). Though they are produced by lymphocytes (or their offspring), antibodies circulate freely in the blood and lymph, where they bind primarily to bacteria, to bacterial toxins, and to free viruses, inactivating them temporarily and marking them for destruction by phagocytes or complement.

When lymphocytes themselves rather than antibodies defend the body, the immunity is called **cellular** or **cell-mediated immunity** because the protective factor is living cells. Cellular immunity also has cellular targets—virus-infected or parasite-infected tissue cells, cancer cells, and cells of foreign grafts. The lymphocytes act against such targets either *directly,* by killing the foreign cells, or *indirectly,* by releasing chemical mediators that enhance the inflammatory response or activate other lymphocytes or macrophages. Thus, as you can see, although both arms of the adaptive immune system respond to virtually the same foreign substances, they do it in very different ways.

Before describing the humoral and cell-mediated responses, we will consider the *antigens* that trigger the activity of the remarkable cells involved in these immune responses.

Antigens

Antigens (an'tĭ-jenz) are substances that can mobilize the immune system and provoke an immune response. As such, they are the ultimate targets of all immune responses. Most antigens are large, complex molecules (both natural and synthetic) that are not normally present in the body. Consequently, as far as our immune system is concerned, they are intruders, or **nonself.**

Complete Antigens and Haptens

Antigens can be *complete* or *incomplete.* **Complete antigens** have two important functional properties:

1. Immunogenicity, which is the ability to stimulate proliferation of specific lymphocytes and antibodies. (*Antigen* is a contraction of "*anti*body *gen*erating," which refers to this particular antigenic property.)

2. Reactivity, which is the ability to react with the activated lymphocytes and the antibodies released by immunogenic reactions.

An almost limitless variety of foreign molecules can act as complete antigens, including virtually all foreign proteins, many large polysaccharides, and some lipids and nucleic acids. Of these, proteins are the strongest antigens. Pollen grains and microorganisms—such as bacteria, fungi, and virus particles—are all immunogenic because their surfaces bear many different foreign macromolecules.

As a rule, small molecules—such as peptides, nucleotides, and many hormones—are not immunogenic. But, if they link up with the body's own proteins, the adaptive immune system may recognize the combination as foreign and mount an attack that is harmful rather than protective. (These reactions, called *hypersensitivities,* are described later in the chapter.) In such cases, the troublesome small molecule is called a **hapten** (hap'ten; *haptein* = grasp) or **incomplete antigen.** Unless attached to protein carriers, haptens have reactivity but not immunogenicity. Besides certain drugs (particularly penicillin), chemicals that act as haptens are found in poison ivy, animal dander, detergents, cosmetics, and a number of common household and industrial products.

Antigenic Determinants

The ability of a molecule to act as an antigen depends on both its size and its complexity. Only certain parts of an entire antigen, called **antigenic determinants,** are immunogenic. Free antibodies or lymphocyte receptors bind to these sites in much the same manner an enzyme binds to a substrate.

Most naturally occurring antigens have a variety of antigenic determinants (Figure 21.7) on their surfaces, some more potent than others in provoking an immune response. Because different antigenic determinants are "recognized" by different lymphocytes, a single antigen may mobilize several lymphocyte populations and may stimulate formation of many kinds of antibodies. Large proteins have hundreds of chemically different antigenic determinants, which accounts for their high immunogenicity and reactivity. However, large simple molecules such as plastics,

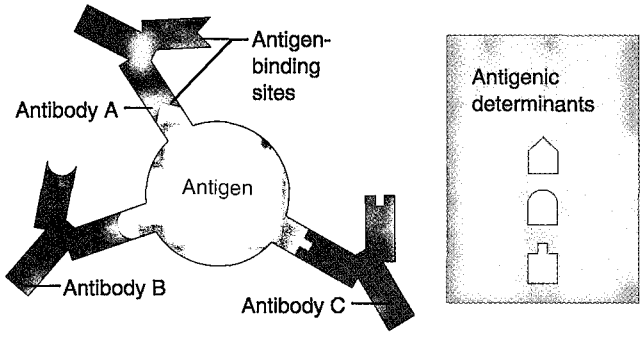

FIGURE 21.7 **Antigenic determinants.** Antibodies (and related receptors on lymphocytes) bind to antigenic determinants on the antigen surface. Most antigens have several different antigenic determinants, which means that different antibodies can bind to a given antigen. In this example, three types of antibodies react with different antigenic determinants on the same antigen molecule. (On a real antigen molecule, each antigenic determinant would be represented many times.)

which have many identical, regularly repeating units (and thus are not chemically complex), have little or no immunogenicity. Such substances are used to make artificial implants because the substances are not seen as foreign and rejected by the body.

Self-Antigens: MHC Proteins

The external surfaces of all our cells are dotted with a huge variety of protein molecules. Assuming our immune system has been properly "programmed," these **self-antigens** are not foreign or antigenic to us, but they are strongly antigenic to other individuals. (This is the basis of transfusion reactions and graft rejection.) Among the cell surface proteins that mark a cell as *self* is a group of glycoproteins called **MHC proteins,** coded for by genes of the **major histocompatibility complex (MHC).** Because millions of combinations of these genes are possible, it is unlikely that any two people except identical twins have the same MHC proteins.

There are two major groups of MHC proteins, distinguished by location. Class I MHC proteins are found on virtually *all* body cells, but class II MHC proteins are found *only on certain cells* that act in the immune response.

Each MHC molecule has a deep groove that typically displays a peptide. In healthy cells, peptides displayed by class I MHC come from the breakdown of cellular proteins during normal protein recycling and tend to be quite diverse. However, in infected cells, class I MHC also binds to fragments of foreign antigens that come from within the infected cell. Peptides displayed by class II MHC come from outside the cell. As described shortly, these displayed peptides play a crucial role in mobilizing the immune system.

Cells of the Adaptive Immune System: An Overview

The three crucial cell types of the adaptive immune system are two distinct populations of lymphocytes, and *antigen-presenting cells (APCs).* **B lymphocytes** or **B cells** oversee humoral immunity. **T lymphocytes** or **T cells** are non-antibody-producing lymphocytes that constitute the cell-mediated arm of adaptive immunity. Unlike the lymphocytes, APCs do not respond to specific antigens but instead play essential auxiliary roles.

Lymphocytes

Like all other blood cells, lymphocytes originate in red bone marrow from hematopoietic stem cells. During development, lymphocytes are "educated." The aim of this education is twofold: (1) Each lymphocyte must become able (competent) to recognize its one specific antigen by binding to it. This ability is called **immunocompetence.** (2) Each lymphocyte must be relatively unresponsive to self-antigens so that it does not attack the body's own cells. This is called **self-tolerance.**

B and T cells are educated in different parts of the body. T cells undergo this two- to three-day maturation process in the thymus under the direction of thymic hormones. B cells become immunocompetent and self-tolerant in the bone marrow. The lymphoid organs where the lymphocytes become immunocompetent (thymus and bone marrow) are called **primary lymphoid organs** (Figure 21.8). All other lymphoid organs are referred to as **secondary lymphoid organs.**

Development of Immunocompetence and Self-Tolerance

When B or T cells become immunocompetent, they display a unique type of receptor on their surface. These receptors (some 10^5 per cell) enable the lymphocyte to recognize and bind to a specific antigen. Once these receptors appear, the lymphocyte is committed to react to one distinct antigenic determinant, and one only, because *all* of its antigen receptors are the same. The receptors on B cells are in fact membrane-bound antibodies, while the receptors on T cells are not antibodies but are products of the same gene superfamily. These similar structures have similar functions, and both cell types are capable of responding to the same antigens.

For T cells, the education in the thymus ensures that they meet two essential criteria for life

Q *What is the advantage of having lymphocytes that are mobile rather than fixed in the lymphoid organs?*

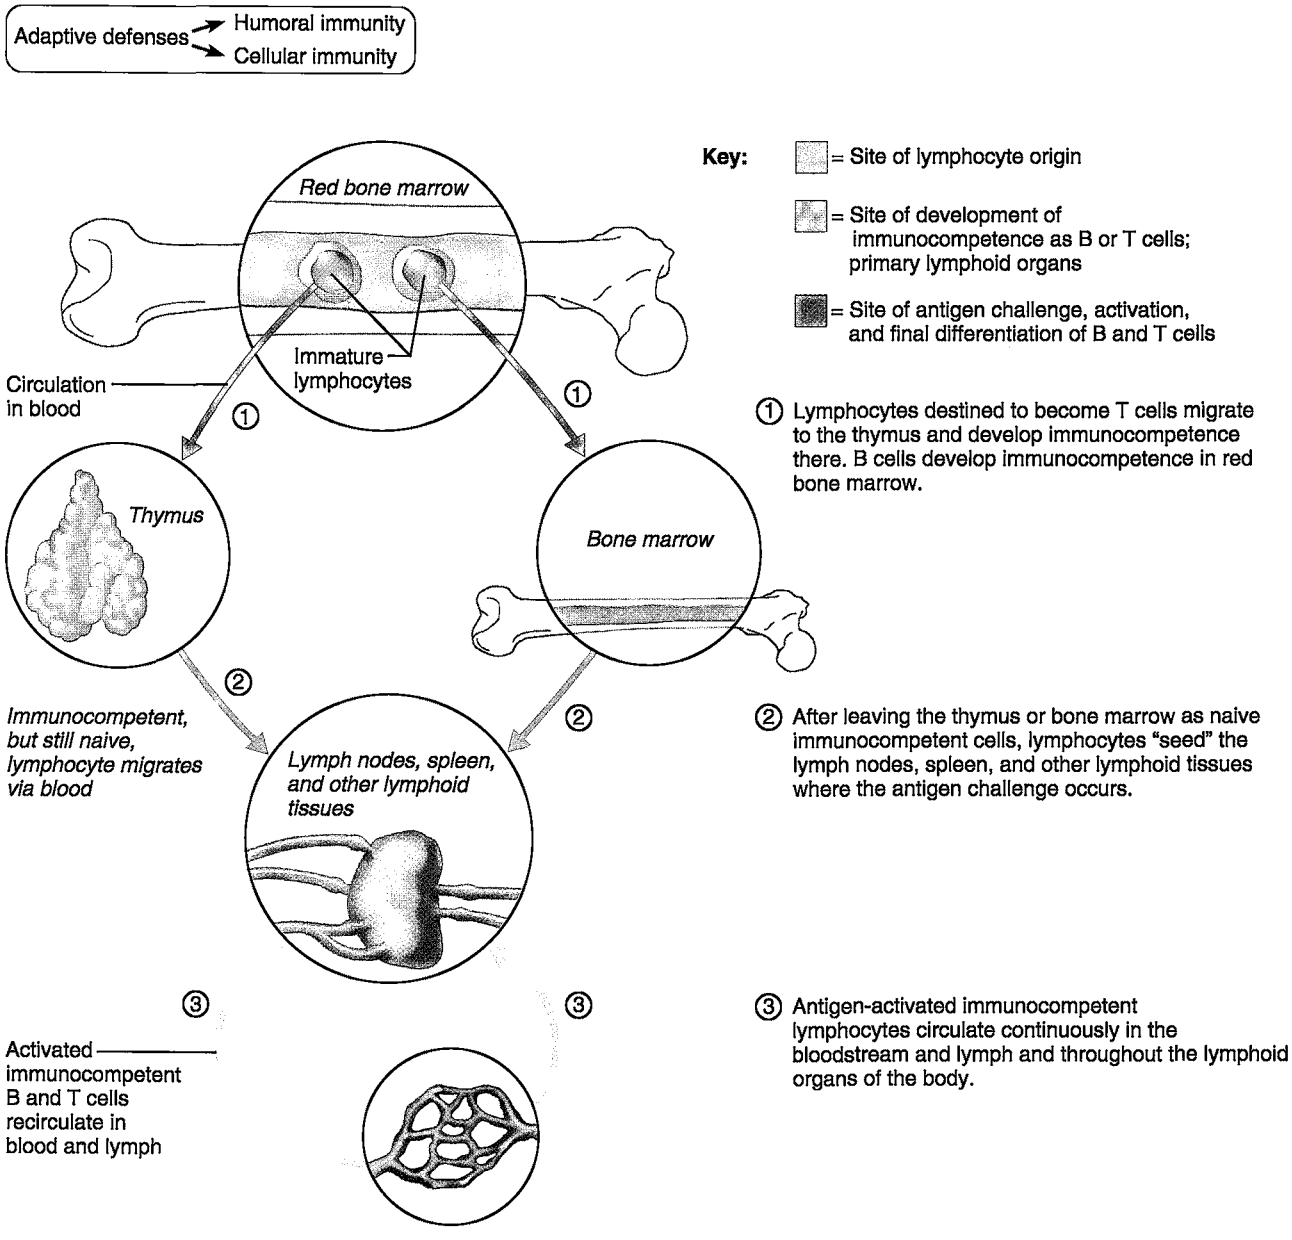

FIGURE 21.8 **Lymphocyte traffic.** Immature lymphocytes arise in red bone marrow. (Note that red marrow is not found in the medullary cavity of the diaphysis of long bones in adults.)

as a successful T cell. First, the T cell must be able to bind MHC molecules, since it is on these molecules that antigens are presented to the T cell for recognition. Second, the T cell must not react strongly to self-antigens that are normally found in the body. In order to ensure that all T cells meet these criteria, their education consists of positive and negative selection (Figure 21.9). **Positive selection,** which occurs in the thymic cortex, is essentially an **MHC restriction process.** It identifies T cells whose receptors are capable of recognizing self-MHC molecules, thus producing an army of self-MHC-restricted T cells. T cells that make it through positive selection are then tested to make

A *It allows them to come into contact with a broader spectrum of antigens and other body cells.*

Q *What cell types act as APCs?*

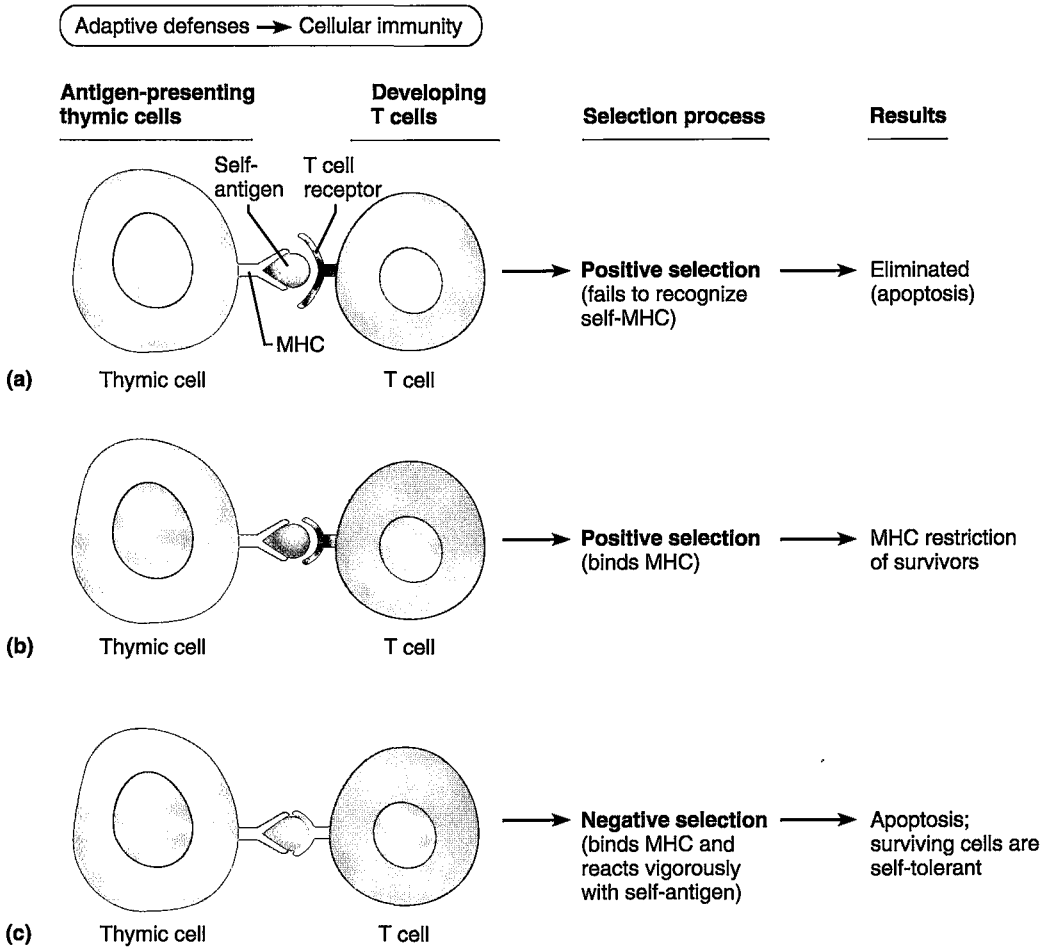

FIGURE 21.9 **T cell selection in the thymus. (a, b)** During positive selection, T cells must show the ability to recognize self-MHC in order to continue maturing. Those that survive the self-MHC test are later tested for reaction to self-antigen. **(c)** In negative selection, the trait of reacting strongly to self-antigens causes the T cell to be eliminated.

sure that they do not react vigorously to self-antigens bound to self-MHC. If they do, they are eliminated by apoptosis (programmed cell death). This is **negative selection,** and it occurs in the inner edge of the thymic cortex. Negative selection ensures immunologic self-tolerance, making sure that T cells don't attack the body's own cells, which would cause autoimmune disorders. This education of T cells is expensive indeed—only about 2% of T cells survive it and continue on to become successful immunocompetent, self-tolerant T cells.

Less is known about the factors that control B cell maturation in humans. In the bone marrow, self-reactive B cells are either eliminated by apoptosis *(clonal deletion),* or are given a chance to change their self-reactive antigen receptor by *receptor editing,* in which there is a secondary rearrangement of the antigen-binding part of the receptor. Nevertheless, some self-reacting B cells do leave the bone marrow. In the periphery, these self-reactive B cells are inactivated (a phenomenon called *anergy*).

Immunocompetent T and B cells that have not yet been exposed to antigen are called *naive*. Naive T cells and B cells are exported to the lymph nodes, spleen, and other secondary lymphoid organs, where the encounters with antigens occur (Figure 21.8). Then, when the lymphocytes bind with recognized antigens, the lymphocytes complete their differentiation into fully functional T cells and B cells.

A Dendritic cells, macrophages, and B cells, to name a few.

Generation of Antigen Receptor Diversity in Lymphocytes

We know that lymphocytes become immunocompetent *before* meeting the antigens they may later attack. Thus, *it is our genes, not antigens, that determine what specific foreign substances our immune system will be able to recognize and resist.* Another way of saying the same thing is that the immune cell receptors represent our genetically acquired knowledge of the microbes that are likely to be in our environment. An antigen simply determines which of the existing T or B cells will proliferate and mount the attack against it. Only some of the antigens our lymphocytes are programmed to resist will ever invade our bodies. Consequently, only some members of our army of immunocompetent cells are mobilized in our lifetime. The others are forever idle.

Our lymphocytes make over a billion different types of antigen receptors. Because these receptors, like all other proteins, are specified by genes, it would seem that an individual must have billions of genes. Not so; each body cell contains perhaps 25,000 genes that code for all the proteins the cell must make.

How can a limited number of genes generate a seemingly limitless number of different antigen receptors? Molecular genetic studies have shown that the genes that dictate the structure of each antigen receptor are not present as such in embryonic cells. Instead of a complete set of "antigen receptor genes," embryonic cells contain a few hundred genetic bits and pieces that can be thought of as a "Lego set" for antigen receptor genes. These gene segments are shuffled and combined in different ways (a process called **somatic recombination**) by each lymphocyte as it becomes immunocompetent. The information of the newly assembled genes is then expressed as the surface receptors of B and T cells and as the antibodies later released by the B cell's "offspring."

Antigen-Presenting Cells

The major role of **antigen-presenting cells (APCs)** in immunity is to engulf antigens and then present fragments of them, like signal flags, on their own surfaces where they can be recognized by T cells—that is, they *present antigens* to the cells that will deal with the antigens. The major types of cells acting as APCs are *dendritic cells* (present in connective tissues and in the epidermis, where they are also called *Langerhans' cells*), *macrophages*, and *B lymphocytes*.

Notice that all these cell types are in sites that make it easy to encounter and process antigens. Dendritic cells are at the body's frontiers, best situated to act as mobile sentinels. Macrophages are widely distributed throughout the lymphoid organs and connective tissues. When they present antigens, dendritic cells and macrophages activate T cells. Activated T cells, in turn, release chemicals that rev up the mobilization and maturation of dendritic cells and prod macrophages to become *activated macrophages*, true "killers" that are insatiable phagocytes and secrete bactericidal chemicals. As you will see, interactions between various lymphocytes, and between lymphocytes and APCs, underlie virtually all phases of the immune response.

Macrophages tend to remain fixed in the lymphoid organs, as if waiting for antigens to come to them. But lymphocytes, especially the T cells (which account for 65–85% of bloodborne lymphocytes), circulate continuously throughout the body. This circulation greatly increases a lymphocyte's chance of coming into contact with antigens located in different parts of the body, as well as with huge numbers of macrophages and other lymphocytes. Although lymphocyte recirculation appears to be random, the lymphocyte emigration to the tissues where their protective services are needed is highly specific, regulated by homing signals (CAMs) displayed on vascular endothelial cells.

Because lymphatic capillaries pick up proteins and pathogens from nearly all body tissues, immune cells in lymph nodes are in a strategic position to encounter a large variety of antigens. Lymphocytes and APCs in the tonsils act primarily against microorganisms that invade the oral and nasal cavities, whereas the spleen acts as a filter to trap bloodborne antigens.

In addition to T cell recirculation and passive delivery of antigens to lymphoid organs by lymphatics, a third delivery mechanism—migration of dendritic cells to secondary lymphoid organs—may be an even more important way of ensuring that the immune cells encounter invading antigens. With their long veil-like extensions, dendritic cells are very efficient antigen catchers, and once they have internalized antigens by phagocytosis, they enter nearby lymphatics to get to the lymphoid organ where they will present the antigens to T cells. Indeed, dendritic cells are the most effective antigen presenters known—it's their only job. Dendritic cells are a key link between innate and adaptive immunity, initiating adaptive immune responses particularly tailored to the type of pathogen that they have encountered.

In summary, the two-fisted adaptive immune system uses lymphocytes, APCs, and specific molecules to identify and destroy all substances—both living and nonliving—that are in the body but not recognized as self. The system's response to such threats depends on the ability of its cells (1) to recognize antigens in the body by binding to them and (2) to communicate with one another so that the whole system mounts a response specific to those antigens.

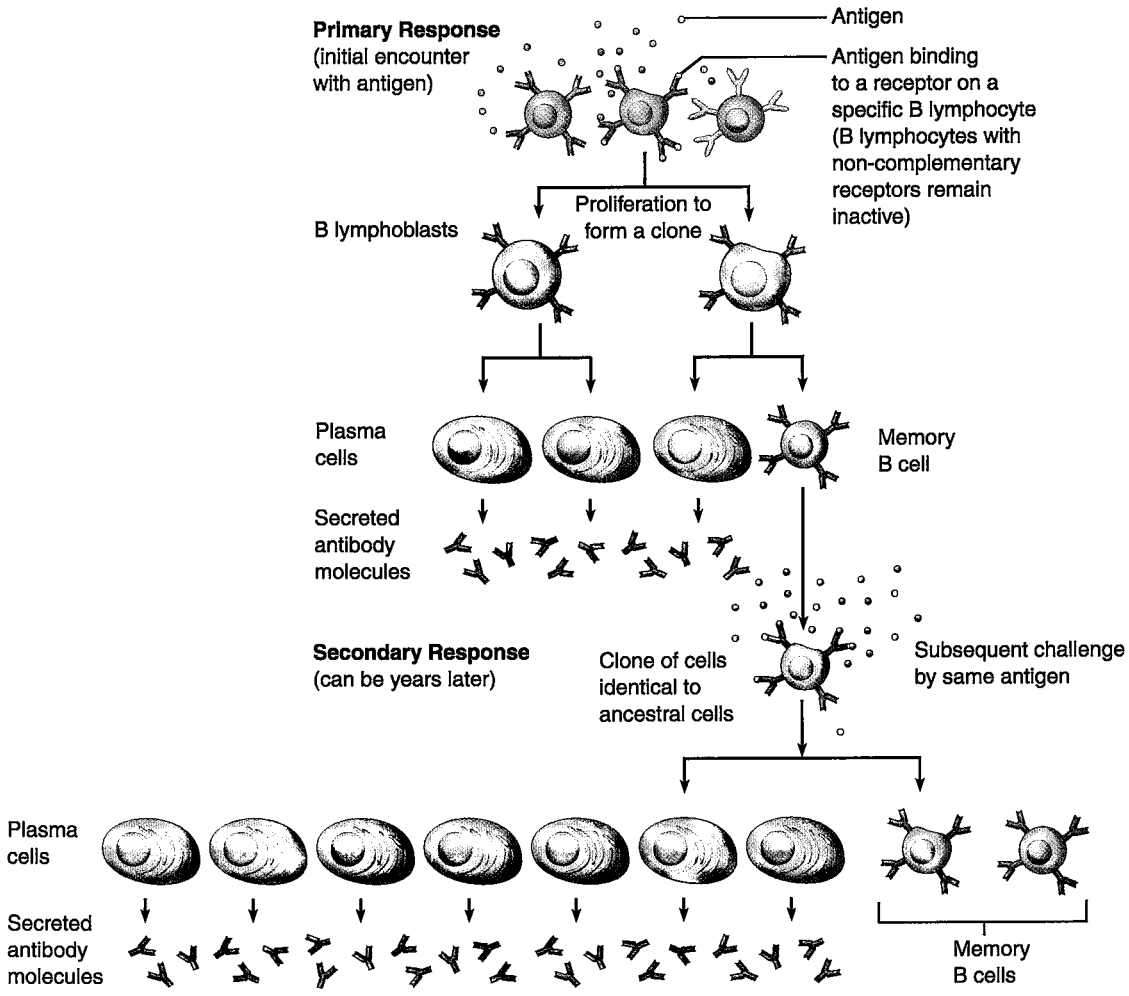

FIGURE 21.10 **Clonal selection of a B cell.** The initial meeting between a B cell and antigen stimulates the primary response in which the B cell proliferates rapidly, forming many identical B cells (a clone), most of which differentiate into antibody-producing plasma cells. (Though not indicated in the figure, the production of mature plasma cells takes about 5 days and 12 cell generations.) Cells that do not differentiate into plasma cells become memory cells primed to respond to subsequent exposures to the same antigen. Should such a meeting occur, the memory cells quickly produce more memory cells and larger numbers of effector plasma cells with the same antigen specificity. Responses generated by memory cells are called secondary responses.

Humoral Immune Response

The **antigen challenge,** the first encounter between an immunocompetent but naive lymphocyte and an invading antigen, usually takes place in the spleen or in a lymph node, but it may happen in any lymphoid tissue. If the lymphocyte is a B cell, the challenging antigen provokes the *humoral immune response,* in which antibodies are produced against the challenger.

Clonal Selection and Differentiation of B Cells

An immunocompetent but naive B lymphocyte is *activated* (stimulated to complete its differentiation) when antigens bind to its surface receptors and cross-link adjacent receptors together. Antigen binding is quickly followed by receptor-mediated endocytosis of the cross-linked antigen-receptor complexes. These events (plus some interactions with T cells described shortly) trigger **clonal selection** (klo'nul). That is, the events stimulate the B cell to grow and then multiply rapidly to form an army of cells all exactly like itself and bearing the same antigen-specific receptors (Figure 21.10). The resulting family of identical cells, all descended from the *same* ancestor cell, is called a **clone.** It is the antigen that does the selecting in clonal selection by "choosing" a lymphocyte with complementary receptors.

Most cells of the clone become **plasma cells,** the antibody-secreting effector cells of the humoral response. Although B cells secrete limited amounts of

antibodies, plasma cells develop the elaborate internal machinery (largely rough endoplasmic reticulum) needed to secrete antibodies at the unbelievable rate of about 2000 molecules per second. Each plasma cell functions at this breakneck pace for 4 to 5 days and then dies. The secreted antibodies, each with the same antigen-binding properties as the receptor molecules on the surface of the parent B cell, circulate in the blood or lymph, where they bind to free antigens and mark them for destruction by other innate or adaptive mechanisms. Clone cells that do not differentiate into plasma cells become long-lived **memory cells** that can mount an almost immediate humoral response if they encounter the same antigen again at some future time (see Figure 21.10).

Immunological Memory

The cellular proliferation and differentiation just described constitute the **primary immune response,** which occurs on first exposure to a particular antigen. The primary response typically has a lag period of 3 to 6 days after the antigen challenge. This lag period mirrors the time required for the few B cells specific for that antigen to proliferate and for their offspring to differentiate into plasma cells. After the mobilization period, plasma antibody levels rise, reach peak levels in about 10 days, and then decline (Figure 21.11).

If (and when) someone is reexposed to the same antigen, whether it's the second or the twenty-second time, a **secondary immune response** occurs. Secondary immune responses are faster, more prolonged, and more effective, because the immune system has already been primed to the antigen, and sensitized memory cells are already in place "on alert." These memory cells provide what is commonly called **immunological memory.**

Within hours after recognition of the "old enemy" antigen, a new army of plasma cells is being generated. Within 2 to 3 days the antibody titer (concentration) in the blood rises steeply to reach much higher levels than were achieved in the primary response. Secondary response antibodies not only bind with greater affinity (more tightly), but their blood levels remain high for weeks to months. (Hence, when the appropriate chemical signals are present, plasma cells can keep functioning for much longer than the 4 to 5 days seen in primary responses.) Memory cells persist for long periods in humans and many retain their capacity to produce powerful secondary humoral responses for life.

The same general phenomena occur in the cellular immune response: A primary response sets up a pool of activated lymphocytes (in this case, T cells) and generates memory cells that can then mount secondary responses.

Why is the secondary response so much faster than the primary response?

Adaptive defenses → Humoral immunity

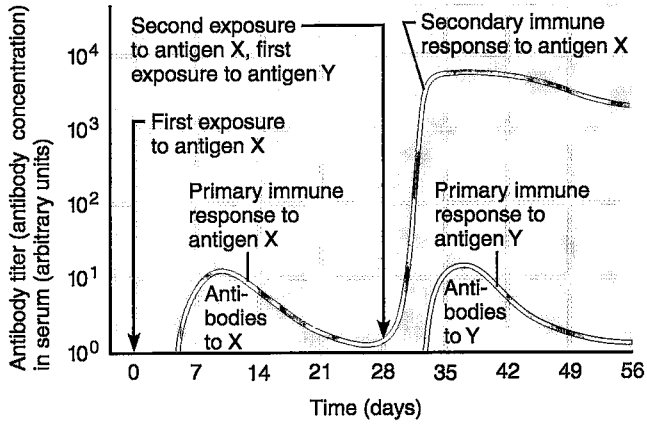

FIGURE 21.11 **Primary and secondary humoral responses.** The blue graph line shows a primary and a secondary response to antigen X. In the primary response, there is a 5-day time lag followed by a rapid rise and fairly rapid decline in the level of antibodies in the blood. A second exposure to antigen X on day 28 elicits a secondary response that has a very short lag time and is both more rapid and more intense. Additionally, antibody levels remain high for a much longer time. If a second antigen, antigen Y, were also encountered at day 28, the reaction to that antigen would be a primary response, not a secondary one, and its graph line (red) would show a pattern similar to that seen during the primary response to antigen X. (Time shown on the horizontal axis is given for example only. The time for response to different antigens varies greatly.)

Active and Passive Humoral Immunity

When your B cells encounter antigens and produce antibodies against them, you are exhibiting **active humoral immunity** (Figure 21.12). Active immunity is (1) *naturally acquired* when you get a bacterial or viral infection, during which time you may develop symptoms of the disease and suffer a little (or a lot), and (2) *artificially acquired* when you receive **vaccines.** Indeed, once it was realized that secondary responses are so much more vigorous than primaries, the race was on to develop vaccines to "prime" the immune response by providing a first meeting with the antigen.

Sensitization and "tooling up" have already occurred. Hence, all that is required is that the memory cells increase in number.

Q *Why is no immunological memory established in passive forms of immunity?*

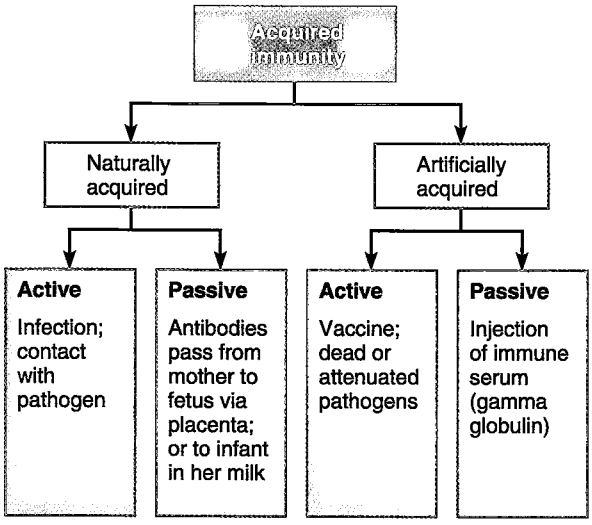

FIGURE 21.12 **Types of acquired immunity.** Immunological memory is established via active immunity, never via passive immunity.

Most vaccines contain dead or *attenuated* (living, but extremely weakened) pathogens, or their components. Vaccines provide two benefits:

1. They spare us most of the symptoms and discomfort of the disease that would otherwise occur during the primary response.
2. Their weakened antigens provide functional antigenic determinants that are both immunogenic and reactive.

Vaccine *booster shots,* which may intensify the immune response at later meetings with the same antigen, are also available.

Vaccines have wiped out smallpox and have substantially lessened the illness caused by such former childhood killers as whooping cough, polio, and measles. Although vaccines have dramatically reduced hepatitis B, tetanus, and pneumonia in adults, immunization of adults in the U.S. has a much lower priority than that of children and as a result more than 50,000 Americans die each year from vaccine-preventable infections (pneumonia, influenza, and hepatitis).

Conventional vaccines have shortcomings. Although it was originally believed that the immune response was about the same regardless of how an antigen got into the body (under its own power or via a vaccine), that has proved not to be the case. Apparently vaccines mainly target the type of helper T cell (more details shortly) that revs up B cell defenses and antibody formation (the T_H2 cell) as opposed to the type (T_H1) that generates strong cell-mediated responses. As a result, lots of antibodies are formed that provide immediate protection, but cellular immunological memory is only poorly established. (The immune system is deprived of the learning experience that comes with clearing an infection via a T_H1-mediated response.) In extremely rare cases, vaccines cause the very disease they are trying to prevent because the attenuated virus isn't weakened enough. In other cases, contaminating proteins (e.g., egg albumin) cause allergic responses to the vaccine. The new "naked DNA" antiviral vaccines, blasted into the skin with a gene gun, and *edible* vaccines taken orally appear to circumvent these problems.

Passive humoral immunity differs from active immunity, both in the antibody source and in the degree of protection it provides (see Figure 21.12). Instead of being made by your plasma cells, the antibodies are harvested from the serum of an immune human or animal donor. As a result, your B cells are *not* challenged by antigens, immunological memory does *not* occur, and the protection provided by the "borrowed" antibodies ends when they naturally degrade in the body.

Passive immunity is conferred *naturally* on a fetus or infant when the mother's antibodies cross the placenta or are ingested with the mother's milk. For several months after birth, the baby is protected from all the antigens to which the mother has been exposed. Passive immunity is *artificially* conferred via a serum such as *gamma globulin,* which is administered after exposure to hepatitis. Other immune sera are used to treat poisonous snake bites (antivenom), botulism, rabies, and tetanus (antitoxin) because these rapidly fatal diseases would kill a person before active immunity could be established. The donated antibodies provide immediate protection, but their effect is short-lived (two to three weeks).

Antibodies

Antibodies, also called **immunoglobulins (Igs)** (im"u-no-glob'u-linz), constitute the **gamma globulin** part of blood proteins. As mentioned earlier, antibodies are proteins secreted by activated B cells or plasma cells in response to an antigen, and they are capable of binding specifically with that antigen. They are formed in response to an incredible number of different antigens. Despite their variety, all antibodies can be grouped into one of five Ig classes, each slightly different in structure and function. Before seeing how these Ig classes differ from one another, let's take a look at how all antibodies are alike.

A Because sensitization does not occur and no memory cells are generated. The antibody protection provided by passive immunity is donated and temporary.

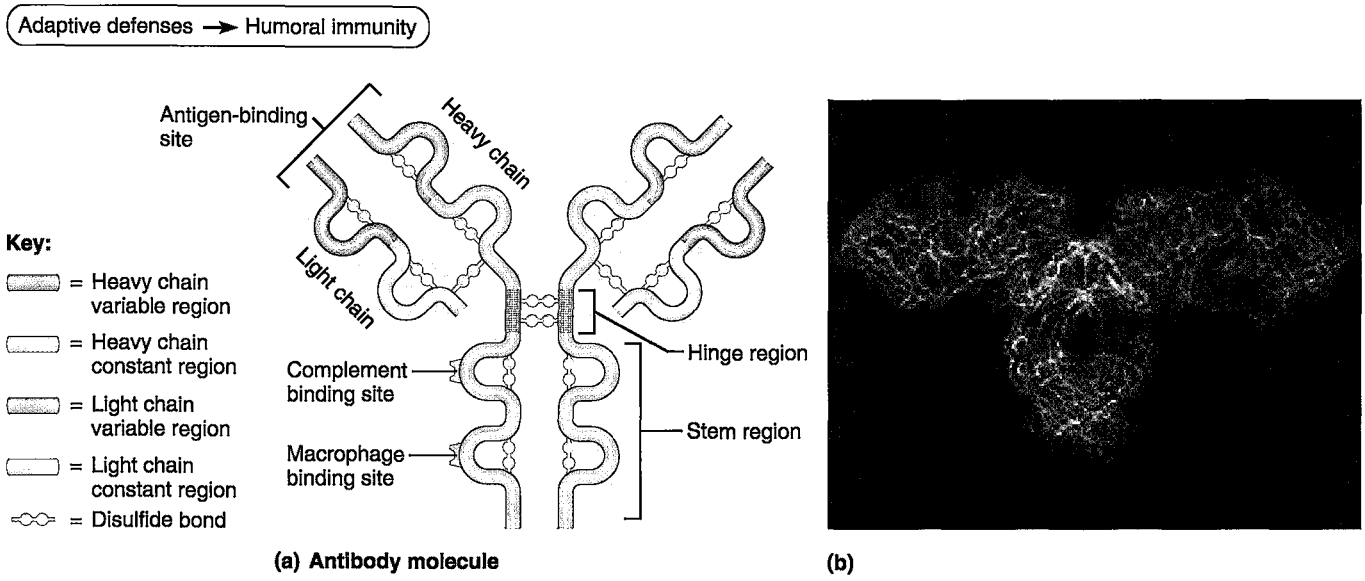

FIGURE 21.13 **Antibody structure.** **(a)** Basic antibody structure (based on IgG) consists of four polypeptide chains joined together by disulfide bonds (S—S). Two of the chains are short *light chains;* the other two are long *heavy chains.* Each chain has a V (variable) region (different in antibodies from different cells) and a C (constant) region (essentially identical in different antibodies of the same class). Because the variable regions are the antigen-binding sites, each antibody monomer has two antigen-binding sites. **(b)** Computer-generated image of antibody structure. The tiny dots show the surface of the molecule.

Basic Antibody Structure

Regardless of its class, each antibody has a basic structure consisting of four looping polypeptide chains linked together by disulfide (sulfur-to-sulfur) bonds (Figure 21.13). Two of these chains, the **heavy (H) chains,** are identical to each other and contain more than 400 amino acids each. The other two chains, the **light (L) chains,** are also identical to each other, but only about half as long as each H chain. The heavy chains have a flexible *hinge* region at their approximate "middles." The "loops" on each chain are created by disulfide bonds between amino acids that are in the same chain but about 60–70 amino acids apart; the bonds cause the intervening parts of the polypeptide chains to loop out. The four chains combined form a molecule, called an **antibody monomer** (mon'o-mer), with two identical halves, each consisting of a heavy and a light chain. The molecule as a whole is T or Y shaped.

Each chain forming an antibody has a **variable (V) region** at one end and a much larger **constant (C) region** at the other end. Antibodies responding to different antigens have very different V regions, but their C regions are the same (or nearly so) in all antibodies of a given class. The V regions of the heavy and light chains in each arm of the monomer combine to form an **antigen-binding site** shaped to "fit" a specific antigenic determinant. Hence, each antibody monomer has two such antigen-binding regions.

The C regions that form the *stem* of the antibody monomer determine the antibody class and serve common functions in all antibodies: These are the *effector regions* of the antibody that dictate (1) the cells and chemicals the antibody can bind to, and (2) how the antibody class functions in antigen elimination. For example, some antibodies can fix complement, some circulate in blood and others are found primarily in body secretions, some cross the placental barrier, and so on.

Antibody Classes

The five major immunoglobulin classes are designated IgM, IgA, IgD, IgG, and IgE, on the basis of the C regions in their heavy chains. (Remember the name MADGE to recall the five Ig types.) As illustrated in Table 21.3, IgD, IgG, and IgE have the same basic Y-shaped structure and thus are *monomers.* IgA occurs in both monomer and *dimer* (two linked monomers) forms. (Only the dimer is shown in the table.) Compared to the other antibodies, IgM is a huge antibody, a *pentamer* (*penta* = five) constructed from five linked monomers.

The antibodies of each class have different biological roles and locations in the body. IgM is the first antibody class *released* to the blood by plasma cells. IgG is the most abundant antibody in plasma and the only Ig class that crosses the placental barrier. Hence, the passive immunity that a mother transfers to her fetus is courtesy of her IgG antibodies.

TABLE 21.3 Immunoglobulin Classes

IgD (monomer)	IgD is virtually always attached to the external surface of a B cell, where it functions as the antigen receptor of the B cell; important in B cell activation.
 *IgM (pentamer)*	IgM exists in monomer and pentamer (five united monomers) forms. The monomer, which is attached to the B cell surface, serves as an antigen receptor. The pentamer (illustrated) circulates in blood plasma and is the first Ig class released by plasma cells during the primary response. (This fact is diagnostically useful because presence of IgM in plasma usually indicates current infection by the pathogen eliciting IgM's formation.) Because of its numerous antigen-binding sites, IgM is a potent agglutinating agent and readily fixes and activates complement.
IgG (monomer)	IgG is the most abundant and diverse antibody in plasma, accounting for 75–85% of circulating antibodies. It protects against bacteria, viruses, and toxins circulating in blood and lymph, readily fixes complement, and is the main antibody of both secondary and late primary responses. It crosses the placenta and confers passive immunity from the mother to the fetus.
 *IgA (dimer)*	IgA monomer exists in limited amounts in plasma. The dimer (illustrated), referred to as secretory IgA, is found in body secretions such as saliva, sweat, intestinal juice, and milk, and helps prevent attachment of pathogens to epithelial cell surfaces (including mucous membranes and the epidermis).
IgE (monomer)	IgE is slightly larger than the IgG antibody. It is secreted by plasma cells in skin, mucosae of the gastrointestinal and respiratory tracts, and tonsils. Its stem region becomes bound to mast cells and basophils, and when its receptor ends are triggered by an antigen, it causes the cells to release histamine and other chemicals that mediate inflammation and an allergic reaction. Typically only traces of IgE are found in plasma, but levels rise during severe allergic attacks or chronic parasitic infections of the gastrointestinal tract.

Only IgM and IgG can fix complement. The IgA dimer, also called **secretory IgA,** is found primarily in mucus and other secretions that bathe body surfaces. It plays a major role in preventing pathogens from gaining entry into the body. IgD is always bound to a B cell surface; hence it acts as a B cell receptor. IgE antibodies, found in minute quantities in blood, are the "troublemaker" antibodies involved in some allergies. These and other characteristics unique to each immunoglobulin class are summarized in Table 21.3.

Mechanisms of Antibody Diversity

Recall from p. 803 that the billions of different kinds of antibodies produced by plasma cells come about as the result of somatic recombination of a limited number of genes. The genes for the heavy and light chains occur on separate chromosomes, but for each chain, the sections of coding DNA (exons) are separated by chunks of noncoding DNA (introns); this structure is essential for somatic recombination. The L and H chains are manufactured separately and then joined to form the antibody monomer. The events forming the chains are similar, but the process for the heavy chains is more complex because of the larger variety of gene segments needed for the C regions of the H chains (remember, the C regions of heavy chains determine antibody class).

The random mixing of gene segments to make unique antibody genes specifying the H and L chains accounts for only part of the huge variability seen in antibodies. Certain areas of the V gene segments in activated B cells, the so-called *hypervariable regions,* are "hot spots" for somatic mutations that enormously increase antibody variation.

A single plasma cell can switch from making one kind of H chain to making another kind, thereby producing two or more different antibody classes having the same antigen specificity. For example, the first antibody released in the primary response is IgM; then the plasma cell begins to secrete IgG. During secondary responses, almost all of the Ig protein is IgG.

Antibody Targets and Functions

Though antibodies cannot themselves destroy antigens, they can inactivate them and tag them for destruction (Figure 21.14). The common event in all antibody-antigen interactions is formation of **antigen-antibody** (or **immune**) **complexes.** Defensive mechanisms used by antibodies include neutralization, agglutination, precipitation, and complement fixation, with the first two most important.

Neutralization, the simplest effector mechanism, occurs when antibodies block specific sites on viruses or bacterial exotoxins (toxic chemicals secreted by bacteria). As a result, the virus or exotoxin

Q *Both complement fixation and agglutination aid phagocytosis, but they do so in different ways. What is this difference?*

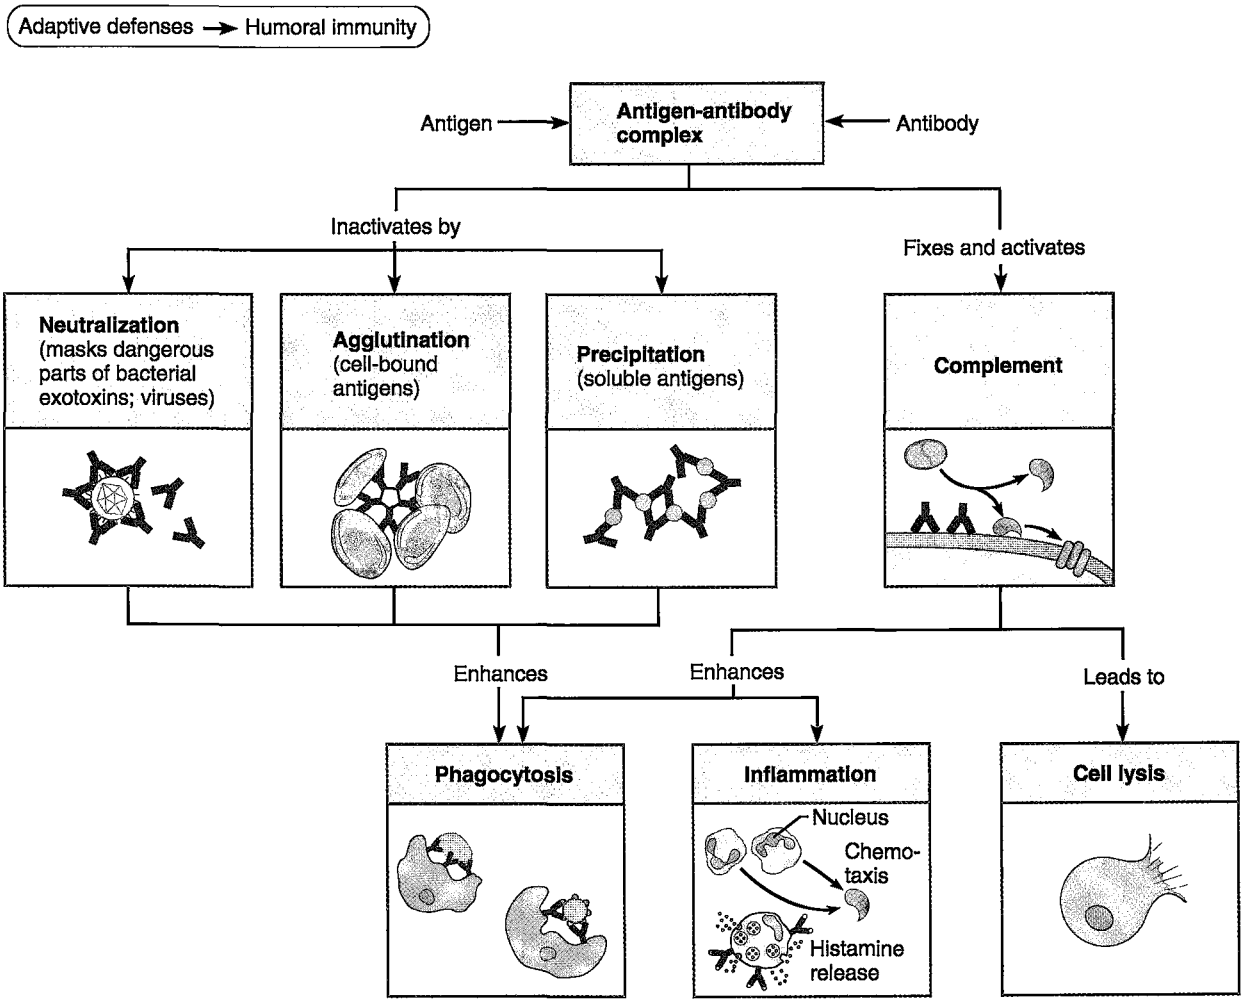

FIGURE 21.14 **Mechanisms of antibody action.** Antibodies act against free viruses, red blood cell antigens, bacterial toxins, intact bacteria, fungi, and parasitic worms.

loses its toxic effect because it cannot bind to receptors on tissue cells to cause injury. The antigen-antibody complexes are eventually destroyed by phagocytes.

Because antibodies have more than one antigen-binding site, they can bind to the same determinant on more than one antigen at a time; consequently, antigen-antibody complexes can be cross-linked into large lattices. When cell-bound antigens are cross-linked the process causes clumping, or **agglutination,** of the foreign cells. IgM, with ten antigen-binding sites (see Table 21.3), is an especially potent agglutinating agent. Recall from Chapter 17 that this type of reaction occurs when mismatched blood is transfused (the foreign red blood cells are clumped) and is the basis of tests used for blood typing.

In **precipitation,** soluble molecules (instead of cells) are cross-linked into large complexes that settle out of solution. Like agglutinated bacteria, precipitated antigen molecules are much more easily captured and engulfed by phagocytes than are freely moving antigens.

Complement fixation and activation is the chief antibody ammunition used against cellular antigens, such as bacteria or mismatched red blood cells. When antibodies bind to cells, the antibodies change shape to expose complement-binding sites

A *With complement fixation, C3b molecules coat the cellular antigen surface, providing rough spots to which phagocytes can bind. Agglutination forms large clumps of antigen which can't go anywhere, making the clumps fair game for the phagocytes.*

on their stem regions (see Figure 21.13a). This triggers complement fixation into the antigenic cell's surface, followed by cell lysis. Additionally, as described earlier, molecules released during complement activation tremendously amplify the inflammatory response and promote phagocytosis via opsonization. Hence, a positive feedback cycle that enlists more and more defensive elements is set into motion.

A quick and dirty way to remember how antibodies work is to remember they have a PLAN of action—**p**recipitation, **l**ysis (by complement), **a**gglutination, and **n**eutralization.

Monoclonal Antibodies

In addition to their role in providing passive immunity, commercially prepared antibodies are used in research, clinical testing, and treatment. **Monoclonal antibodies,** used for such purposes, are produced by descendants of a single cell, and are pure antibody preparations specific for a single antigenic determinant.

Monoclonal antibodies are made by fusing tumor cells and B lymphocytes. The resulting cell hybrids, called **hybridomas** (hi″brĭ-do′mahz), have desirable traits of both parent cells. Like tumor cells, hybridomas proliferate indefinitely in culture; like B cells, they produce a single type of antibody.

Monoclonal antibodies are used to diagnose pregnancy, certain sexually transmitted diseases, some types of cancer, hepatitis, and rabies. These monoclonal antibody tests are more specific, more sensitive, and faster than their conventional counterparts. Monoclonal antibodies are also being used to treat leukemia and lymphomas, cancers that are present in the circulation and thus easily accessible to injected antibodies. They also serve as "guided missiles" to deliver anticancer drugs only to cancerous tissue, and to treat certain autoimmune diseases (as discussed later).

Cell-Mediated Immune Response

Despite their immense versatility, antibodies provide only partial immunity. Their prey is the *obvious* pathogen. They are fairly useless against infectious microorganisms like viruses and the tuberculosis bacillus that quickly slip inside body cells to multiply there. In these cases, the cell-mediated arm of adaptive immunity comes into play.

The T cells that mediate cellular immunity are a diverse lot, much more complex than B cells in both classification and function. There are two major populations of effector T cells based on which of a pair of structurally related *cell differentiation glycoproteins*—CD4 or CD8—is displayed by a mature T cell (Figure 21.15). These glycoprotein surface receptors, which are distinct from the T cell antigen receptors, play a role in interactions between T cells and other cells or foreign antigens. **CD4 cells** are primarily **helper T cells (T_H),** whereas most **CD8 cells** are **cytotoxic T cells (T_C),** whose role is to destroy any cells in the body that harbor anything foreign. In addition to these two major groups of T cells, there are regulatory T cells (T_{Reg}), memory T cells, and some fairly rare subgroups. Details of T cells' roles are provided shortly.

Before going into the details of the cell-mediated immune response, we will recap and compare the relative importance of the humoral and cellular responses in adaptive immunity. Antibodies, produced by plasma cells, are in many ways the simplest ammunition of the immune response. They are specialized to latch onto intact bacteria and soluble foreign molecules *in extracellular environments*—that is, free in body secretions and tissue fluid and circulating in blood and lymph. Antibodies never invade solid tissues unless a lesion is present. At the most basic level, antibody production and pathogen multiplication are in a race against each other and the fate of antibody targets is a case of "the quick or the dead." Remember, however, that forming antibody-antigen complexes does *not* destroy the antigens; instead, it prepares them for destruction by innate defenses.

In contrast to B cells and antibodies, T cells cannot "see" either free antigens or antigens that are in their natural state. T cells can recognize and respond only to *processed* fragments of protein antigens displayed on body cell surfaces (APCs and others) and then only under specific circumstances. Consequently, T cells are best suited for cell-to-cell interactions, and most of their direct attacks on antigens (mediated by the cytotoxic T cells) target body cells infected by viruses or bacteria; abnormal or cancerous body cells; and cells of infused or transplanted foreign tissues.

Clonal Selection and Differentiation of T Cells

The stimulus for clonal selection and differentiation is the same in B cells and T cells—binding of antigen. However, the mechanism by which T cells recognize "their" antigen is very different than that seen in B cells and has some unique restrictions.

Antigen Recognition and MHC Restriction

Like B cells, immunocompetent T cells are activated when the variable regions of their surface receptors

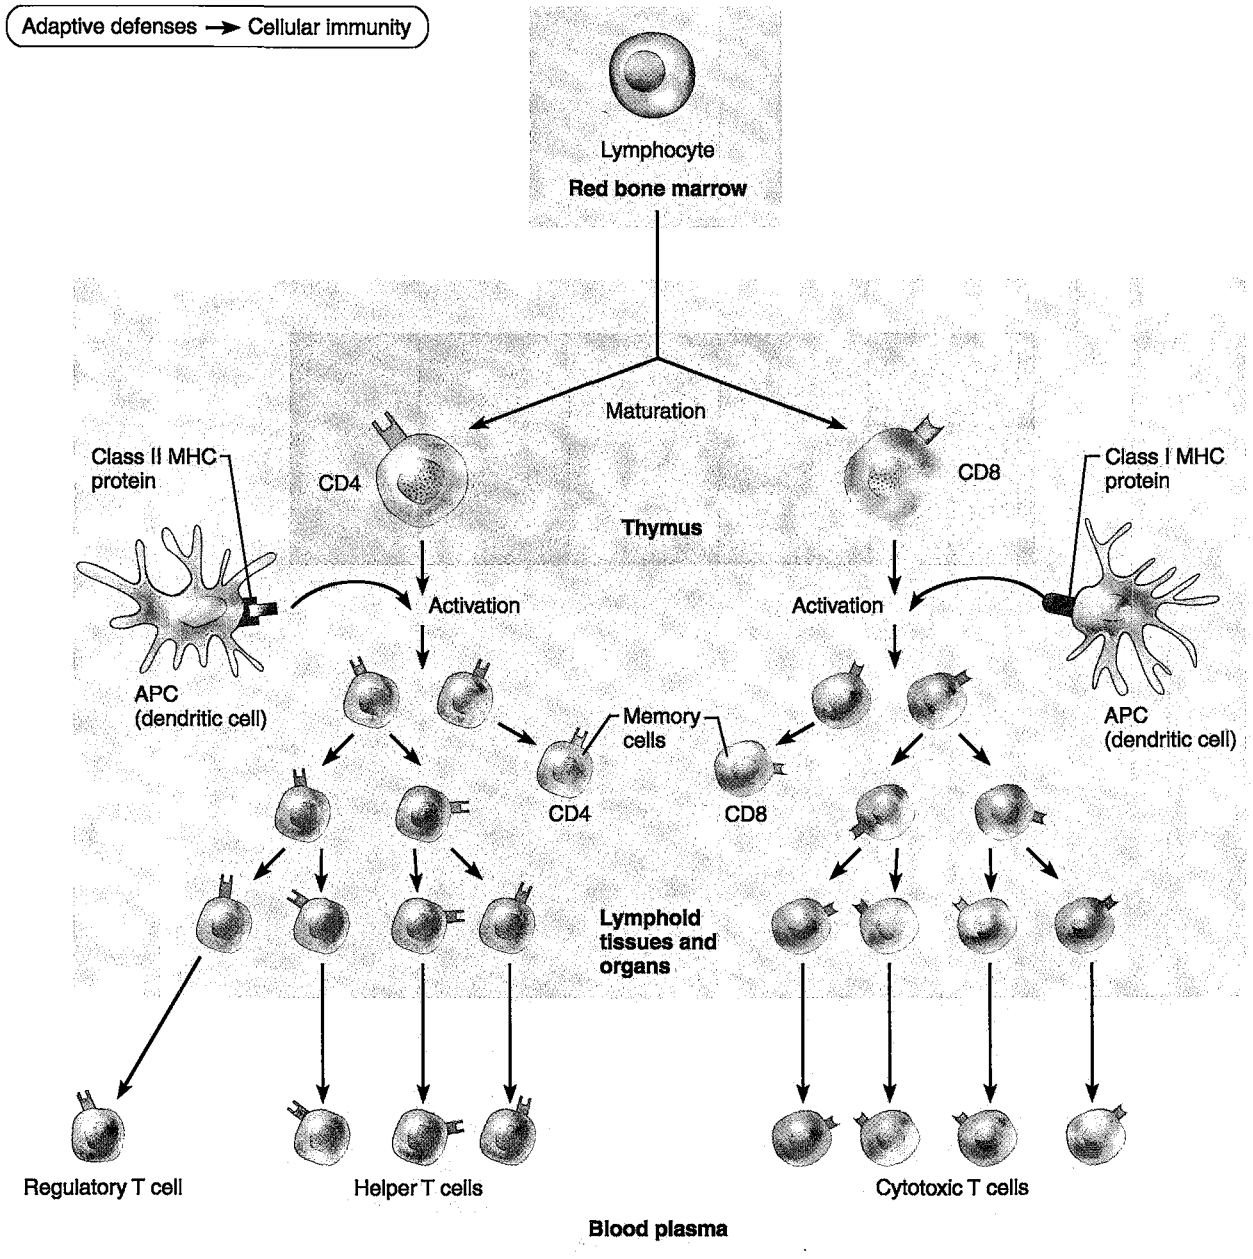

FIGURE 21.15 **Major types of T cells based on displayed cell differentiation glycoproteins (CD4, CD8).** (Regulatory T cells that do not express CD4 also exist but are not shown here.)

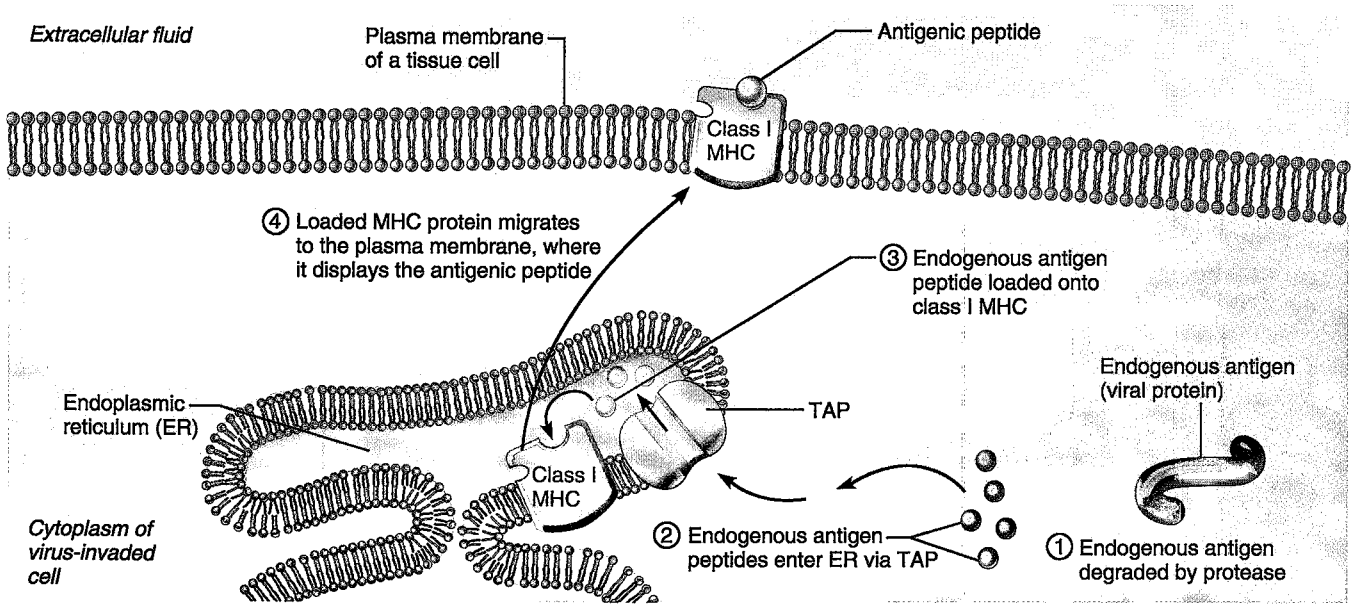
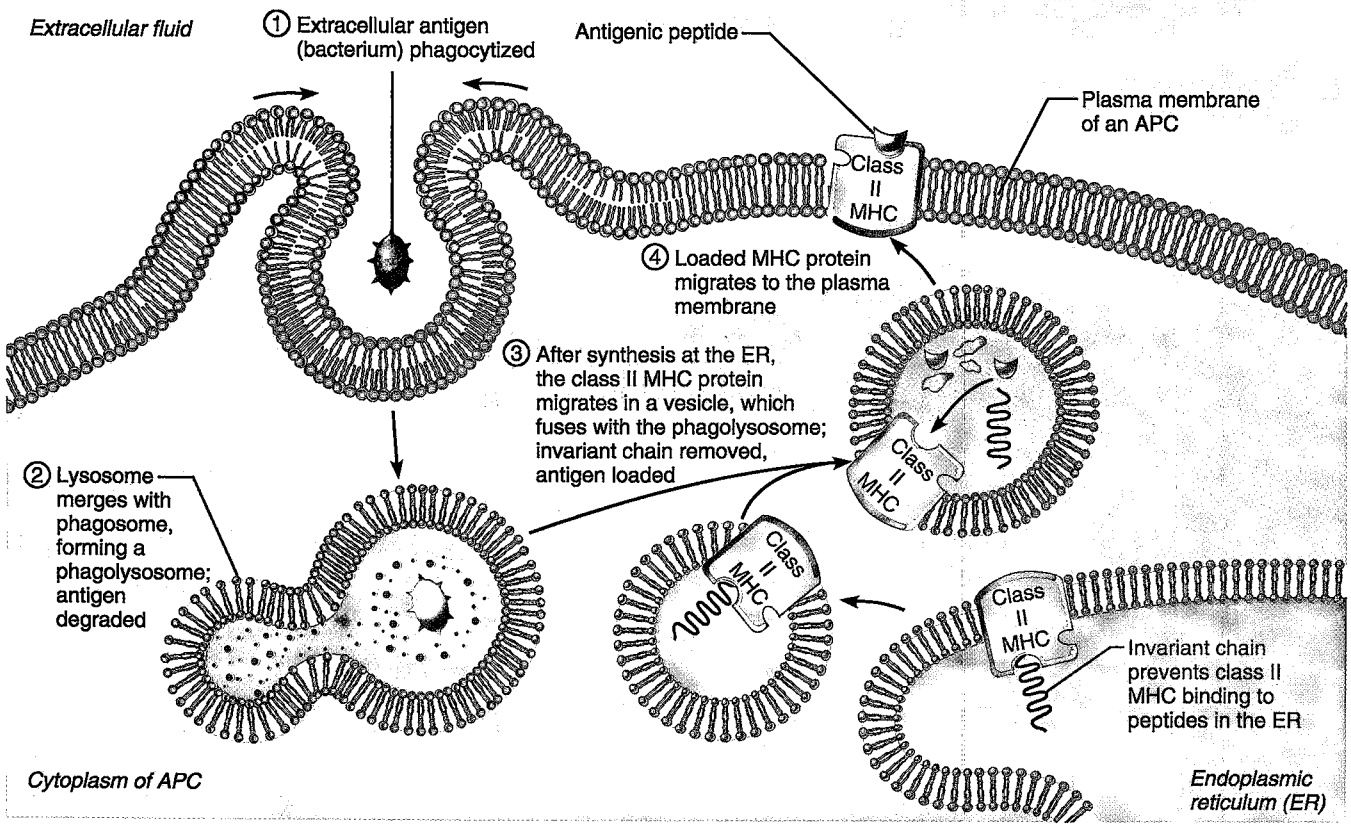
bind to a "recognized" antigen. However, T cells must accomplish *double recognition:* They must simultaneously recognize nonself (the antigen) and self (an MHC protein of a body cell).

Two types of MHC proteins are important to T cell activation. **Class I MHC proteins** are displayed by virtually all body cells except red blood cells and are recognized by cytotoxic (CD8) T cells. After being synthesized at the endoplasmic reticulum (Figure 21.16a), a class I MHC protein binds with a peptide 8 or 9 amino acids long ferried into the ER from the cytosol by transport proteins aptly called TAPs (transporter associated with antigen processing). The "loaded" class I MHC protein then migrates to the plasma membrane to display its attached protein fragment. This attached fragment is always part of some protein synthesized *in the cell*—either a bit of a cellular (self) protein or a peptide derived from an endogenous antigen that is broken down to peptides within a proteasome. **Endogenous antigens** are foreign proteins synthesized in a body cell. Two examples are the viral proteins produced by



(a)



(b)

FIGURE 21.16 **MHC proteins, and antigen processing and display. (a)** Class I MHC proteins pick up peptide fragments in the ER. These peptides may be derived from self-proteins or from foreign (viral or cancer) proteins made within the cell. The latter are called endogenous antigens. **(b)** Class II MHC proteins pick up peptide fragments from endocytosed vesicles where phagocytized foreign debris is degraded. Both MHC classes display the peptides at the cell surface.

virus-infected cells and alien (mutated) proteins made by a body cell that has become cancerous.

The role of class I MHC proteins in the immune response is crucially important—they provide the means for signaling to cytotoxic T cells that infectious microorganisms are hiding in body cells. Without such a mechanism, viruses and certain bacteria that thrive in cells could multiply unnoticed and unbothered. When class I MHC proteins are bound to fragments of our own (self) proteins, cytotoxic T cells passing by get the signal "Leave this cell alone, it's ours!" and ignore them. When class I MHC proteins are bound to antigenic peptides, they betray the invaders and "sound a molecular alarm" that signals invasion by (1) acting as antigen holders and (2) forming the self part of the self-nonself complexes that cytotoxic T cells must recognize in order to kill.

Unlike the widely distributed class I proteins, **class II MHC proteins** are typically found only on the surfaces of cells that present antigens to helper T cells: dendritic cells, macrophages, and B cells. Like their class I MHC counterparts, class II MHC proteins are synthesized at the ER and bind to peptide fragments (Figure 21.16b). However, the peptides they bind are longer (14–17 amino acids) and come from **exogenous antigens** (foreign antigens) that have been engulfed and broken down in the phagolysosome vesicle. While still in the ER, each class II MHC molecule binds a protein called an *invariant chain*, a coupling that prevents the MHC molecule from binding to a peptide while in the ER. The class II MHC protein then moves from the ER through the Golgi apparatus and into a phagolysosome. It is there that the invariant chain loosens its hold on the MHC molecule, allowing the "jaws" of MHC to close around a degraded protein fragment. Vesicles are then recycled to the cell surface, where the class II MHC proteins display their booty for recognition by (and possibly activation of) helper T cells.

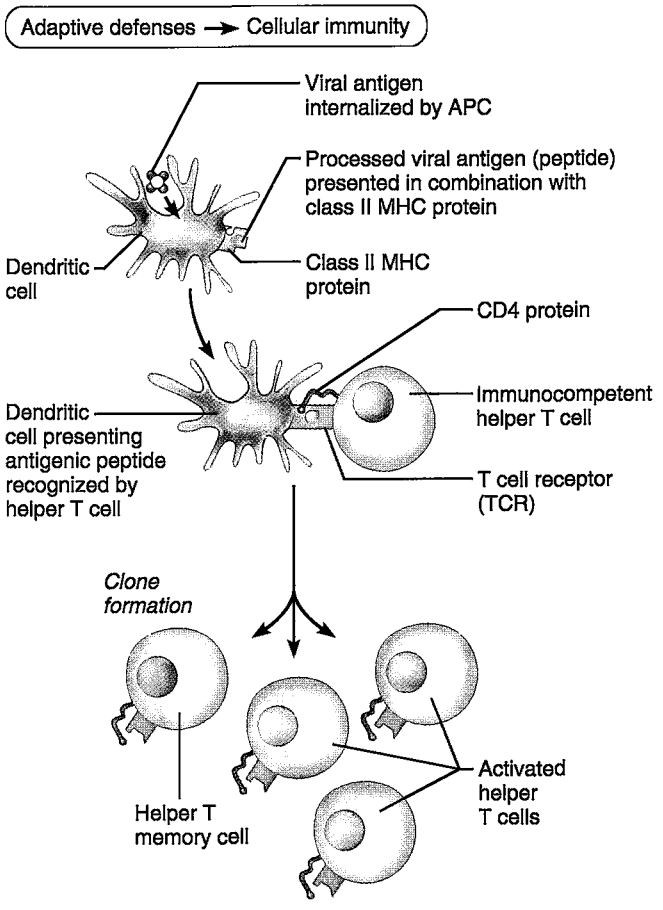


FIGURE 21.17 **Clonal selection of T_H and T_C cells involves simultaneous recognition of self and nonself.** Both T_H and T_C cells are stimulated to proliferate (clone) and complete their differentiation when they bind to parts of foreign antigens complexed to MHC proteins. Immunocompetent T_H cells are activated when they bind to exogenous antigens (nonself)—part of a free virus in this example—complexed to a class II MHC protein. Activation of T_C cells is similar, except that the processed antigen is complexed with a class I MHC protein and it often requires T_H cell help.

T Cell Activation

T cell activation is actually a two-step process involving antigen binding and co-stimulation. Both steps usually occur on the surface of the same antigen-presenting cell (APC). As described earlier, dendritic cells are the most potent APCs, displaying very small parts of antigens attached to their surface MHC proteins for recognition. In addition, dendritic cells actually migrate to the lymph nodes and other lymphoid tissues to present their antigens to T cells. As a result of this early alert, the body is spared a good deal of tissue damage that might otherwise occur.

Antigen Binding This first step mostly entails what has already been described: T cell antigen receptors (**TCRs**) bind to an antigen-MHC complex on the surface of an APC. Like B cell receptors, a TCR has variable and constant regions, but it consists of two rather than four polypeptide chains.

Helper and cytotoxic T cells have different requirements for the class of MHC protein that helps deliver the activation signal. This constraint, acquired during the education process in the thymus, is called *MHC restriction*. Helper T cells (CD4) can bind only to antigens linked to class II MHC proteins, which are typically displayed on APC surfaces (Figure 21.17). Cytotoxic T cells (CD8) are activated by antigen fragments complexed with class I MHC proteins, also found on the surface of APCs. Recall that in all other body cells, class I MHC proteins only display endogenous or self-antigens. Dendritic cells, however, have the special ability to take up

exogenous antigens (from, for example, dying virus-infected or tumor cells) and display them on class I MHCs in addition to class II MHCs.

The TCR that recognizes the nonself-self complex is linked to multiple intracellular signaling pathways. Besides the TCR, other T cell surface proteins are involved in this first step. For example, the CD4 and CD8 proteins used to identify the two major T cell groups (T_H and T_C) are adhesion molecules that help maintain the coupling during antigen recognition. Additionally, the CD4 and CD8 proteins are associated with kinase enzymes located inside the T cells that phosphorylate cell proteins, activating some and inactivating others when antigen binding occurs. Once antigen binding has occurred, the T cell is stimulated but is still "idling," like a car that has been started but not put into gear.

Co-stimulation The story isn't over yet because step 2 comes next. Before a T cell can proliferate and form a clone, it must recognize one or more **co-stimulatory signals.** This requires T cell binding to still other surface receptors on an APC. For example, dendritic cells and macrophages begin to sprout *B7 proteins* on their surfaces when the nonspecific defenses are being mobilized. B7 binding to the CD28 receptor on a T cell is a crucial co-stimulatory signal. After co-stimulation, cytokine chemicals such as interleukin 1 and 2 released by APCs or T cells themselves nudge the activated cells to proliferate and differentiate. As you might guess, there are several types of cytokines, each type promoting a different response in the activated T cells.

A T cell that binds to antigen without receiving the co-stimulatory signal becomes tolerant to that antigen and is unable to divide or to secrete cytokines. This state of unresponsiveness to antigen is called **anergy.** The two-signal sequence acts as a safeguard to prevent the immune system from destroying healthy cells. Without this safeguard, class I MHC proteins, which are found on all body cells and which display peptides from within the cell, could activate cytotoxic T cells, leading to widespread damage of healthy cells. The important thing to understand is that along with antigen binding, co-stimulation is crucial for T cell activation. To go back to our idling car analogy, the car will not go anywhere unless the car has both (1) been started and (2) put into gear.

Once activated, a T cell enlarges and proliferates to form a clone of cells that differentiate and perform functions according to their T cell class. This primary response peaks within a week of exposure to the triggering antigen. A period of apoptosis then occurs between days 7 and 30, during which time the activated T cells die off and effector activity wanes as the amount of antigen declines. This wholesale disposal of T cells has a critical protective role because activated T cells are potential hazards. They produce huge amounts of inflammatory cytokines, which contribute to infection-driven hyperplasia, and may promote malignancies in chronically inflamed tissue. Additionally, once they've done their job, the effector T cells are unnecessary and thus disposable. Thousands of clone members become memory T cells, persisting perhaps for life, and providing a reservoir of T cells that can later mediate secondary responses to the same antigen.

Cytokines

The chemical messengers involved in cellular immunity belong to a group of molecules called **cytokines,** a general term for mediators that influence cell development, differentiation, and responses in the immune system. Cytokines include interferons and interleukins. In Table 21.4 (pp. 817–818), you can see that there are a large variety of these molecules with myriad effects on target cells. They include hormone-like or paracrine-like glycoproteins released by a variety of cells. As mentioned previously, some cytokines act to promote T cell proliferation. For example, **interleukin 1 (IL-1),** released by macrophages, stimulates bound T cells to liberate **interleukin 2 (IL-2)** and to synthesize more IL-2 receptors. IL-2 is a key growth factor. Acting on the cells that release it, it sets up a positive feedback cycle that encourages activated T cells to divide even more rapidly. (Therapeutically IL-2 is used to treat melanoma and kidney cancers.)

Additionally, all activated T cells secrete one or more other cytokines that help amplify and regulate a variety of adaptive and innate immune responses. Some (such as tumor necrosis factor) are cell toxins; others (e.g., interferon) enhance the killing power of macrophages; and still others are inflammatory factors.

Specific T Cell Roles

Helper T Cells

Helper T cells play a central role in adaptive immunity (Figure 21.18). Once T_H cells have been primed by APC presentation of antigen, they activate macrophages, help activate B and T cells, and induce B and T cell proliferation. In fact, without the "director" T_H cells, there is *no* adaptive immune response. Their cytokines furnish the chemical help needed to recruit other immune cells to fight off intruders.

Helper T cells interact directly with B cells displaying antigen fragments bound to class II MHC receptors (Figure 21.18b), prodding the B cells into more rapid division and then, like the boss of an assembly line, signaling for antibody formation to

begin. Whenever a T_H cell binds to a B cell, the T cell releases interleukin 4 and other cytokines. Although B cells may be activated solely by binding to certain antigens called **T cell–independent antigens,** most antigens require T cell help to activate the B cells to which they bind. This more common variety of antigens is called **T cell–dependent antigens.** In general, T cell–independent antigen responses are weak and short-lived. B cell division continues as long as it is stimulated by the T_H cell. Thus, helper T cells help unleash the protective potential of B cells.

Cytokines released by T_H cells not only mobilize lymphocytes and macrophages but also attract other types of white blood cells into the area and tremendously amplify innate defenses. As the released chemicals summon more and more cells into the battle, the immune response gains momentum, and the antigens are overwhelmed by the sheer numbers of immune elements acting against them.

It is interesting, but not surprising, that different subsets of helper T cells exist. The subset that develops during T_H cell differentiation depends on the type of antigen and the site at which it is encountered as well as the cytokine exposure of the differentiating T_H cell. For example, IL-12 induces T_H1 differentiation, while IL-4 drives T_H2 differentiation. Generally speaking, the T_H1 cells stimulate inflammation, activate macrophages, and promote differentiation of cytotoxic T cells. That is, they mediate classical cell-mediated immunity. By contrast, T_H2 cells mainly promote the migration of eosinophils to the battlefield and activate immune responses that depend on B cells and antibody formation.

Cytotoxic T Cells

Cytotoxic T cells are the only T cells that can directly attack and kill other cells. Activated T_C cells roam the body, circulating in and out of the blood and lymph and through lymphoid organs in search of body cells displaying antigens to which the T_C cells have been sensitized. Their main targets are virus-infected cells, but they also attack tissue cells infected by certain intracellular bacteria or parasites, cancer cells, and foreign cells introduced into the body by blood transfusions or organ transplants. Because of their ability to kill target cells by causing their lysis, T_C cells are often called **cytolytic T cells.**

Before the onslaught can begin, the cytotoxic T cell must "dock" on the target cell by binding to a self-nonself complex. Remember, all body cells display class I MHC antigens, so all infected or abnormal body cells can be destroyed by these T cells. The attack on foreign human cells, such as those of a graft, is more difficult to explain because here *all* of the antigens are nonself. However, apparently the T_C cells sometimes "see" the foreign class I MHC antigens as a combination of self class I MHC protein bound to foreign antigen.

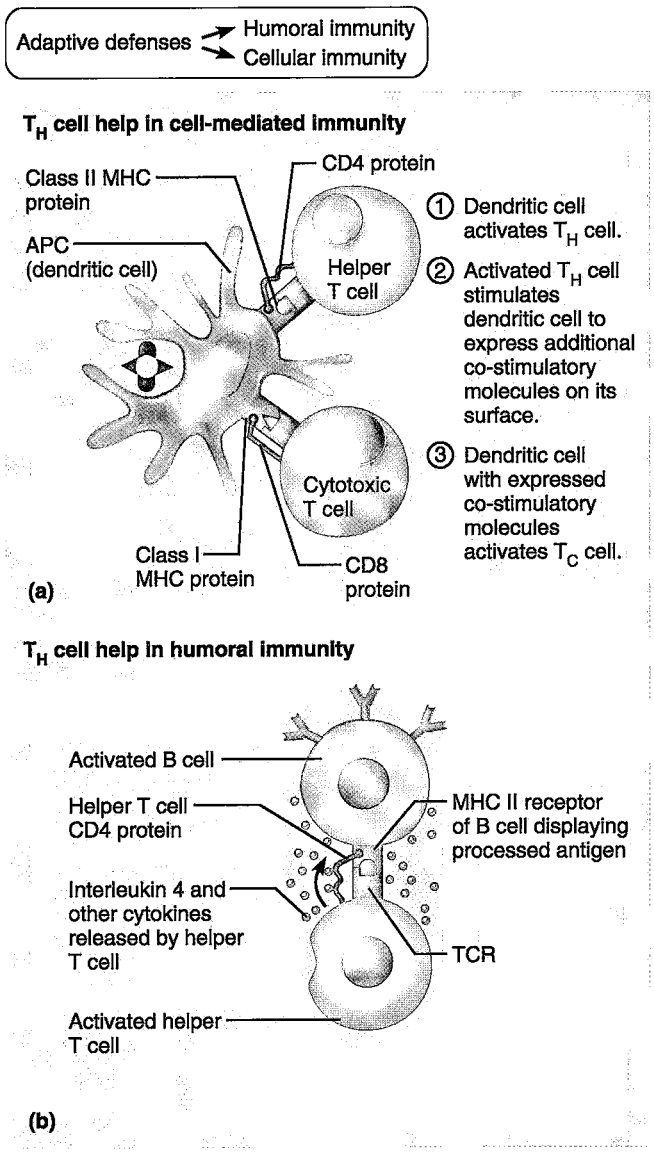

FIGURE 21.18 **The central role of T_H cells.** Helper T cells mobilize both arms (cellular and humoral) of the immune response. **(a)** Co-stimulatory molecules required for T_C cell activation are expressed by dendritic cells in response to T_H cell binding. (Some types of antigens induce these co-stimulatory molecules themselves, in which case T_H cell help may not be needed.) The activated T_C cell produces interleukin 2 (not shown), which acts on its own interleukin 2 receptors, causing the cell to proliferate and differentiate. **(b)** T_H and B cells usually must interact directly for full B cell activation. In such cases, T_H cells bind with the self-nonself complexes on activated B cell surfaces, and then release interleukins as co-stimulatory signals.

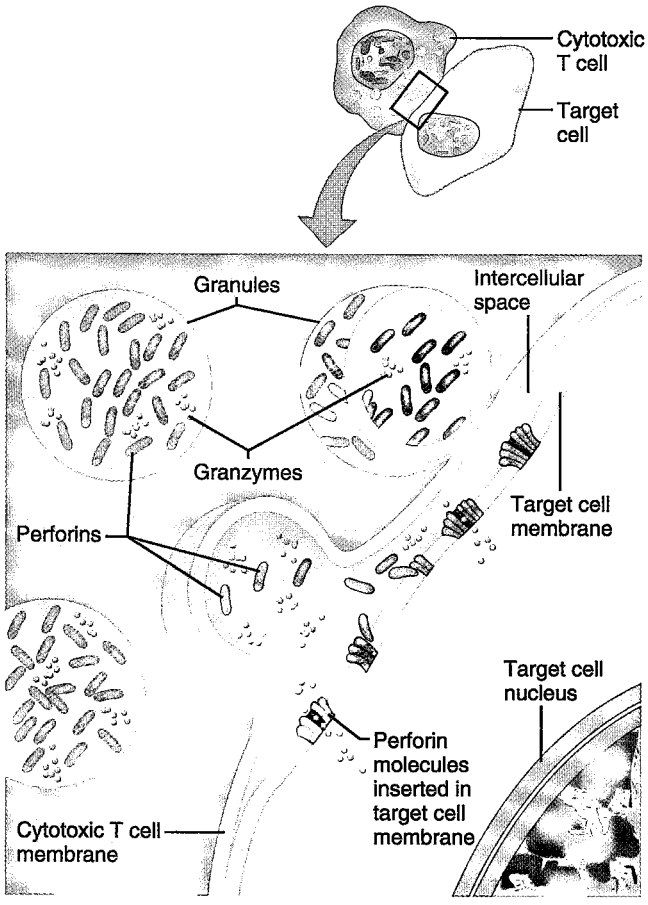
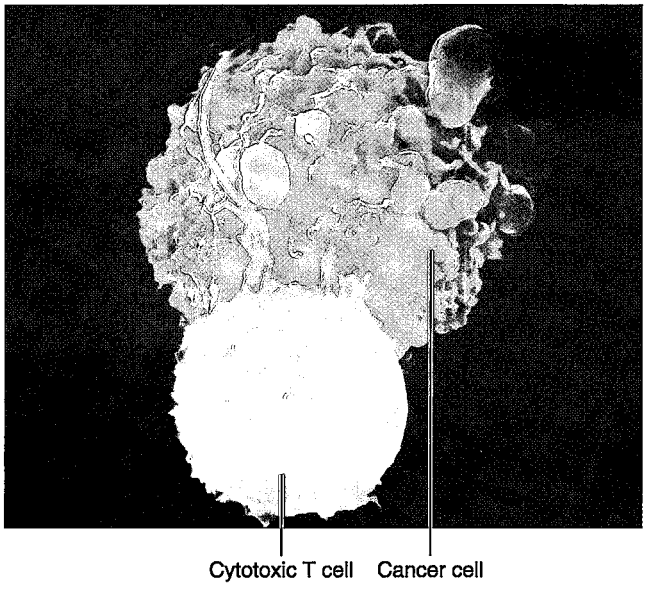
Once cytotoxic T cells recognize their targets, there are two major mechanisms by which they can deliver a **lethal hit.** One mechanism proceeds as follows:



(a)



(b)

FIGURE 21.19 **Cytotoxic T cells attack infected and cancerous cells. (a)** A proposed mechanism of target cell killing by T_C cells. The initial event is the tight binding of the cytotoxic cell to the target cell. During this binding period, granules in the T_C cell fuse with its plasma membrane and release perforin molecules which insert into the target cell membrane and later polymerize, forming cylindrical holes. The pores allow granzymes, also contained in the T_C granules, to enter the target cell. **(b)** Scanning electron micrograph of a T_C cell killing a cancer cell. (8300×).

1. The T_C cell binds tightly to the target cell and, during this period, the chemicals **perforin** and **granzymes** are released from the T cell's granules. The perforins insert into the plasma membrane of the target cell (Figure 21.19a).

2. In the presence of Ca^{2+}, the perforin molecules in the target cell membrane polymerize and create transmembrane pores very much like those produced by complement activation.

3. Granzymes enter the target cell via the pores. Once inside, these proteases degrade cellular contents, stimulating apoptosis.

4. The T_C cell then detaches and searches for another prey.

Another mechanism of killing by cytotoxic cells involves binding to a specific membrane receptor (a **Fas receptor**) on the target cell, an event that stimulates the target cell to undergo apoptosis. Cytokines released by T_C cells also contribute to T_C cells' killing ability. **Tumor necrosis factor beta (TFN-β)** and **gamma interferon** activate macrophages and indirectly enhance the killing process.

NK cells use the same key mechanisms for killing their target cells. NK cells, however, do not look for foreign antigen displayed on class I MHC proteins. Instead they search for other signs of abnormality, including the *lack* of class I MHC or the presence of antibody coating the target cell. Stressed cells also often express different surface markers (such as some belonging to a family called MIC), which can activate NK cells. Thus, NK cells stalk abnormal or foreign cells in the body that T_C cells can't "see." NK and T_C lymphocytes roam the body, adhering to and crawling over the surfaces of other cells, examining them for markers they might recognize, a process called **immune surveillance.** NK cells check to make sure each cell has "identity flags" (class I MHC proteins *inhibit* NK cell attack), whereas T_C cells check the "identity flags" to see if they look the way they are supposed to (foreign antigens *stimulate* T_C cell attack).

Other T Cells

In contrast to the role of T_H cells in activating adaptive immunity, related T cells called **regulatory T (T_{Reg}) cells** (formerly known as suppressor T cells)

TABLE 21.4 Cells and Molecules of the Adaptive Immune Response

ELEMENT	FUNCTION IN IMMUNE RESPONSE
CELLS	
B cell	Lymphocyte that matures in bone marrow. Induced to replicate by antigen binding, usually followed by helper T cell interactions in lymphoid tissues. Its progeny (clone members) form memory cells and plasma cells
Plasma cell	Antibody-producing "machine"; produces huge numbers of antibodies (immunoglobulins) with the same antigen specificity. Specialized B cell clone descendant
Helper T cell (T_H)	A CD4 T cell that is central to both humoral and cellular immunity. After binding with a specific antigen presented by an APC, it stimulates production of cytotoxic T cells and B cells to help fight invader, activates macrophages, and acts both directly and indirectly by releasing cytokines
Cytotoxic T cell (T_C)	A CD8 cell; also called a cytolytic (CTL) T cell. Activated by antigen presented by an antigen-presenting cell, often with helper T cell involvement. Its specialty is killing virus-invaded body cells and cancer cells; also involved in rejection of foreign tissue grafts
Regulatory T cell (T_{Reg})	Formerly called suppressor T cell; slows or stops activity of immune system. Thought to be important in controlling autoimmune diseases; likely several different populations exist
Memory cell	Descendant of activated B cell or any class of T cell; generated during initial immune response (primary response); may exist in body for years after, enabling it to respond quickly and efficiently to subsequent infections or meetings with same antigen
Antigen-presenting cell (APC)	Any of several cell types (dendritic cell, macrophage, B cell) that engulfs and digests antigens that it encounters, presenting parts of them on its plasma membrane (bound to an MHC protein) for recognition by T cells bearing receptors for same antigen. This function, antigen presentation, is essential for normal cell-mediated responses. Macrophages also release chemicals (cytokines) that activate T cells
MOLECULES	
Antibody (immunoglobulin)	Protein produced by B cell or by plasma cell. Antibodies produced by plasma cells are released into body fluids (blood, lymph, saliva, mucus, etc.), where they attach to antigens, causing complement fixation, neutralization, precipitation, or agglutination, which "mark" the antigens for destruction by complement or phagocytes
Perforin, granzymes	Released by T_C cells. Perforin creates large pores in the target cell's membrane, allowing entry of apoptosis-inducing granzymes
Complement	Group of bloodborne proteins activated after binding to antibody-covered antigens or certain molecules on the surface of microorganisms; enhances inflammatory response and causes lysis of some microorganisms
Antigen	Substance capable of provoking an immune response. Typically a large complex molecule (e.g., protein or modified protein) not normally present in the body

dampen the immune response either by direct contact or by releasing inhibitory cytokines such as IL-10 and TGF-β. T_{Reg} cells are important in preventing autoimmune reactions because they suppress self-reactive lymphocytes in the periphery. The function and development of these cells and their subpopulations is currently a hot research topic. For example, researchers hope to use T_{Reg} cells to induce tolerance to transplanted tissue.

Gamma delta T ($T_{\gamma\delta}$) cells represent about 5% of all T cells and are found mostly in the intestinal epithelium. These oddball T cells have a different type of T cell receptor (with γ and δ subunits rather than α and β subunits) and recognize markers expressed by stressed or damaged cells (such as the MIC family and phospholipids). This and their large granular appearance makes them more similar to NK cells than other T cell types.

■ ■ ■

In summary, each type of T cell has unique roles to play in the immune response, yet is heavily enmeshed in interactions with other immune cells and elements as summarized in Table 21.4 and in the overview of the entire primary response in Figure 21.20. The lesson to take away with you is that without helper T cells, *there is no adaptive immune response* because the helper cells direct or help complete the activation of *all* other immune cells. Their crucial role in immunity is painfully evident when they are destroyed, as in AIDS (see pp. 820–821).

TABLE 21.4 Cells and Molecules of the Adaptive Immune Response *(continued)*

ELEMENT	FUNCTION IN IMMUNE RESPONSE
CYTOKINES	
Interferons (IFNs)	
▪ Alpha (α) and beta (β)	Secreted by leukocytes, fibroblasts, and other cells; antiviral effects; activate macrophages and NK cells
▪ Gamma (γ)	Secreted by lymphocytes; activates macrophages; stimulates synthesis and expression of more class I and II MHC proteins; promotes differentiation of T_H cells into T_H1
Interleukins (ILs)	
▪ IL-1	Secreted by activated macrophages; promotes inflammation and T cell activation; causes fever (a pyrogen that resets the thermostat of the hypothalamus)
▪ IL-2	Secreted by T cells; stimulates proliferation of T cells; activates NK cells
▪ IL-3	Stimulates production of leukocytes and mast cells
▪ IL-4	Secreted by T_H cells; promotes differentiation to T_H2; promotes B cell activation; switches antibody production to IgE
▪ IL-5	Secreted by some T_H cells and mast cells; attracts and activates eosinophils; causes plasma cells to secrete IgA antibodies
▪ IL-6	Induces lymphocyte activation and increases antibody production; stimulates liver to secret C-reactive protein, which binds certain bacteria, resulting in complement activation and opsonization
▪ IL-7	Induces lymphocyte proliferation and maturation
▪ IL-8 (also called CXCL8)	Stimulates chemotaxis of neutrophils, basophils, and T cells; promotes angiogenesis
▪ IL-10	Inhibits macrophages and dendritic cells; turns down cellular and innate immune response
▪ IL-12	Secreted by dendritic cells and macrophages; stimulates T_C and NK cell activity; promotes T_H1 differentiation
▪ IL-13	Secreted by T_H cells; switches antibody production to IgE
Migration inhibitory factor (MIF)	Inhibits macrophage migration and keeps them in the area of antigen deposition; a generic term for a number of cytokines
Suppressor factors	A generic term for a number of cytokines that suppress the immune system, for example TGF-β and IL-10
Transforming growth factor beta (TGF-β)	A suppressor factor similar to IL-10
Tumor necrosis factors (TNFs)	Produced by lymphocytes and in large amounts by macrophages. Enhance nonspecific killing; slow tumor growth by selectively damaging tumor blood vessels; enhance granulocyte chemotaxis; help activate T cells, phagocytes, and eosinophils; promote cell death by apoptosis

21

Organ Transplants and Prevention of Rejection

Organ transplants, a viable treatment option for many patients with end-stage cardiac or renal disease, have been done with mixed success for over 30 years. Immune rejection presents a particular problem when the goal is to provide such patients with functional organs from a living or recently deceased donor.

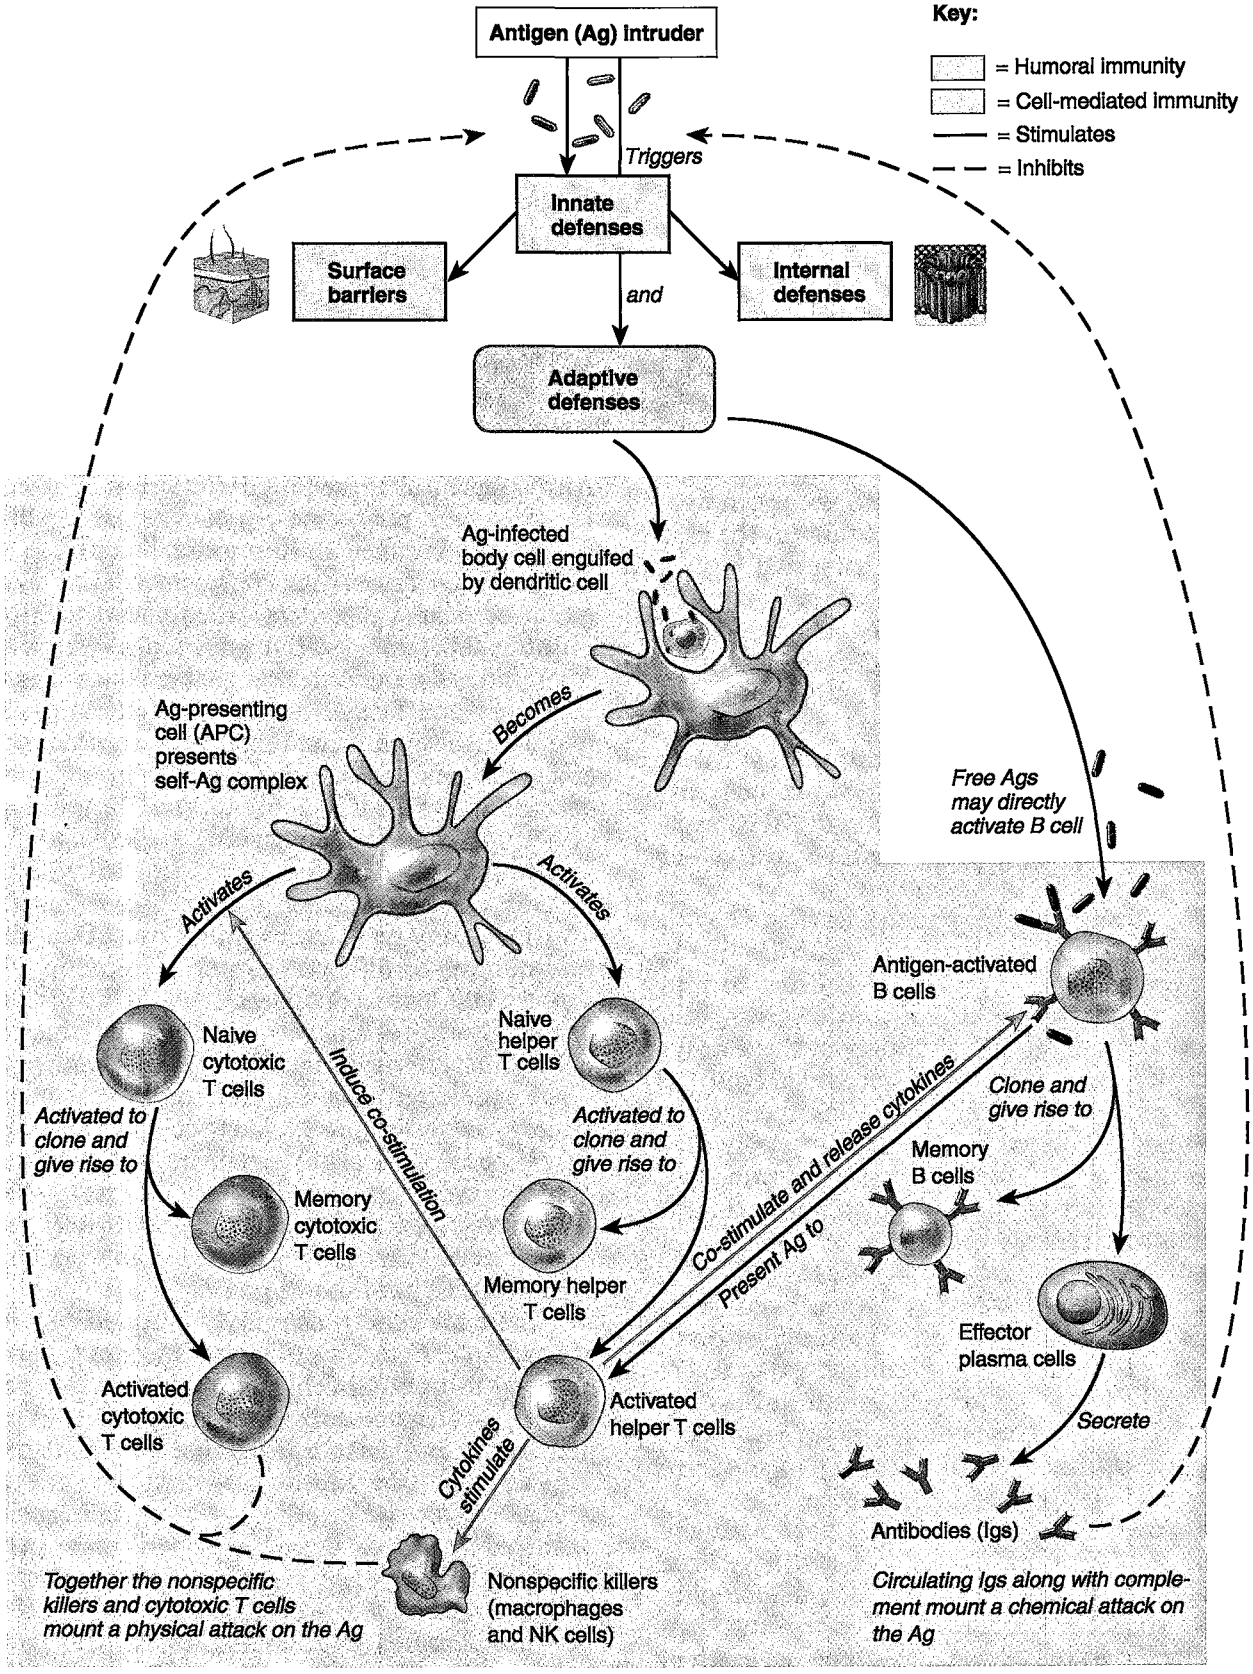
Essentially, there are four major varieties of grafts:

1. Autografts are tissue grafts transplanted from one body site to another in the *same person.*

2. Isografts are grafts donated to a patient by a *genetically identical individual,* the only example being identical twins.

FIGURE 21.20 **The primary immune response.** Activities of the humoral and cellular arms of adaptive immunity are indicated by different colored backgrounds. Co-stimulation usually requires direct cell-cell interactions; cytokines enhance these and many other events, only some of which are shown here. Although complement, NK cells, and phagocytes are innate defenses, they are enlisted in the fight by cytokines. (For simplicity, only B cell receptors are illustrated, and only a few of the myriad interactions between innate and adaptive immunity are shown.)

Q *What happens when antigens are bound in the absence of co-stimulators?*



A *A lymphocyte becomes unresponsive to that antigen, a state called anergy.*

3. **Allografts** are grafts transplanted from individuals that are *not genetically identical* but belong to the *same species.*

4. **Xenografts** are grafts taken *from another animal species,* such as transplanting a baboon heart into a human being.

Transplant success depends on the similarity of the tissues because T cells, NK cells, macrophages, and antibodies act vigorously to destroy any foreign tissue in the body. Autografts and isografts are the ideal donor tissues. Given an adequate blood supply and no infection, they are always successful because the MHC-encoded proteins are identical. Successful xenografts from genetically engineered animals are still just a promise on the horizon. Consequently, the problematic graft type, and also the type most frequently used, is the allograft, with the organ usually obtained from a living human donor (in the case of kidney, liver, bone marrow) or harvested from a human donor who has just died (heart or lung).

Before an allograft is attempted, the ABO and other blood group antigens of donor and recipient must be determined, because these antigens are also present on most body cells. Next, recipient and donor tissues are typed to determine their MHC antigen match. MHC variation among human tissues is tremendous, so matching for all MHC antigens is impossible. In general, however, the closer the match the less likely is rejection.

Following surgery the patient is treated with *immunosuppressive therapy* involving drugs of the following categories: (1) corticosteroid drugs to suppress inflammation; (2) antiproliferative drugs, and (3) immunosuppressant drugs. Many of these drugs kill rapidly dividing cells (such as activated lymphocytes), and all of them have severe side effects.

The major problem with immunosuppressive therapy is that the patient's suppressed immune system cannot protect the body against other foreign agents. As a result, overwhelming bacterial and viral infection remains the most frequent cause of death in transplant patients. The key to successful graft survival is to provide enough immunosuppression to prevent graft rejection but not enough to be toxic, and to use antibiotics to keep infection under control. Even with the best conditions, by ten years after receiving a transplant, roughly 50% of patients have rejected the donor organ.

In rare cases, transplant patients have naturally achieved a state of immune tolerance and have been able to "ditch the drugs." Finding a way to induce tolerance is the goal of the Immune Tolerance Network, a project launched by the National Institutes of Health in 1999. Currently their surgeons are temporarily suppressing the recipient's bone marrow and then dousing it with bone marrow from the same donors as the new organ in the hope that the transplanted marrow cells will establish themselves and create a **chimeric immune system** (**chimer** = monster) that treats the transplanted organ as self.

Homeostatic Imbalances of Immunity

Certain circumstances can cause the immune system to become depressed, to fail, or to act in a way that damages the body. Most such problems can be classified as immunodeficiencies, autoimmune diseases, or hypersensitivities.

Immunodeficiencies

Any congenital or acquired condition that causes immune cells, phagocytes, or complement to behave abnormally is called an **immunodeficiency.**

The most devastating *congenital conditions* are a group of related disorders called **severe combined immunodeficiency (SCID) syndromes,** which result from various genetic defects that produce a marked deficit of B and T cells. One SCID defect causes abnormalities in a subunit common to the receptors for several interleukins. Another results in a defective *adenosine deaminase (ADA)* enzyme. In the absence of normal ADA, metabolites that are lethal to T cells accumulate in the body. Children afflicted with SCID have little or no protection against disease-causing organisms of any type. Interventions must begin in the first months of life because minor infections easily shrugged off by most children cause SCID victims to become deathly ill and wasted. Untreated, this condition is fatal, but successful transplants of bone marrow tissue or cultured stem cells from umbilical cord blood improve survival rates. Lacking such a treatment, the only hope for survival has been living behind protective barriers that keep out all infectious agents. Recent genetic engineering techniques using viruses as vectors to transfer ADA minigenes to the victim's hematopoietic stem cells have shown promise.

There are various *acquired immunodeficiencies.* For example, *Hodgkin's disease,* cancer of the B cells, can lead to immunodeficiency by depressing lymph node cells. Immunosuppressive drugs used in transplantation and certain drugs used to treat cancer also suppress the immune system. But the most devastating of the acquired immunodeficiencies is **acquired immune deficiency syndrome (AIDS),** which cripples the immune system by interfering with the activity of helper T cells.

First identified in the United States in 1981 among homosexual men and intravenous drug users, AIDS is characterized by severe weight loss, night sweats, swollen lymph nodes, and increasingly frequent opportunistic infections, including a rare type of pneumonia called *pneumocystis pneumonia,* and the bizarre

malignancy *Kaposi's sarcoma*, a cancer of the blood vessels evidenced by purple skin lesions. Some AIDS victims develop severe dementia. The course of AIDS is often grim, finally ending in complete debilitation and death from cancer or overwhelming infection.

AIDS is caused by a virus transmitted in body secretions—especially blood, semen, and vaginal secretions. The virus commonly enters the body via blood transfusions or blood-contaminated needles and during sexual intercourse. It is also present in saliva and tears, and there are documented cases of transmission by oral sex. Early in the epidemic, hemophiliacs were also at particular risk because the blood factors they need were isolated from pooled blood donations. Although manufacturers began taking measures to kill the virus in 1984 and new genetically engineered factors became available, an estimated 60% of the hemophiliacs in the U.S. were already infected.

The virus, **HIV (human immunodeficiency virus)**, destroys T_H cells, thus depressing cell-mediated immunity. Although B cells and T_C cells initially mount a vigorous response to viral exposure, in time a profound deficit of antibodies develops and the cytotoxic T cell activity is impaired. The whole immune system is turned topsy-turvy. It is now clear that the virus multiplies steadily in the lymph nodes throughout most of the asymptomatic period, which averages ten years. Symptoms appear when the lymph nodes can no longer contain the virus and the immune system collapses. The virus also invades the brain (which accounts for the dementia of some AIDS patients). Most victims die within a few months to eight years.

The infectious specificity of HIV reflects the fact that CD4 proteins provide the avenue of attack. Researchers have identified an HIV coat glycoprotein complex (gp120/gp41) that fits into the CD4 receptor like a plug fits into a socket. However, HIV also needs a *second* receptor (e.g., CXCR4) on the target cell. Once all these proteins have connected, gp41 fuses the virus to the target cell. Once inside, HIV "sets up housekeeping," using the viral enzyme *reverse transcriptase* to produce DNA from the information encoded in its (viral) RNA. This DNA copy, now called a *provirus*, then inserts itself into the target cell's DNA and directs the cell to crank out new copies of viral RNA and proteins so that the virus can multiply and infect other cells. Although T_H cells are the main HIV targets, other body cells displaying CD4 proteins (macrophages, monocytes, and dendritic cells) are also at risk. The HIV reverse transcriptase enzyme is not very accurate and produces errors rather frequently, causing HIV's relatively high mutation rate and thus its changing resistance to drugs.

The years since 1981 have witnessed a global AIDS epidemic. By the end of 2003, 20 million people had died of AIDS since it was first identified, and about 40 million people were infected worldwide, almost 90% of them in the developing countries of Asia and sub-Saharan Africa. Half of the victims are women, a case distribution indicating that in the most heavily hit countries, most HIV transmission occurs via heterosexual contacts. The virus can also be transmitted from an infected mother to her fetus.

By 2004, the estimated number of Americans infected with HIV was fast approaching one million. Of these, a quarter didn't yet know that they were infected, either because anti-HIV antibodies were not yet detectable in the blood (this may take as long as six months after infection), or because (for one reason or another) they had not yet been tested. The "face of AIDS" is changing too. Though homosexual men still account for the bulk of cases transmitted by sexual contact, more and more heterosexuals are contracting this disease. Particularly disturbing is the number of diagnosed cases among teenagers and young adults, with AIDS now the fifth leading killer of all Americans ages 25 to 44.

No cure for AIDS has yet been found. Over 30 clinical trials of HIV vaccines are under way around the world. Disappointingly, the two largest trials testing the effectiveness of a vaccine targeting gp120 have failed to show any effect in blocking HIV infection, and it is unlikely that an approved vaccine will be available soon. Fortunately, a number of antiviral drugs are available, and these fall into three broad classes. *Reverse transcriptase inhibitors*, such as AZT and ddC, were early on the scene, followed by *protease inhibitors* (saquinavir, ritonavir, and others). These first two classes of drugs inhibit important viral enzymes after the virus has gained entry into the target cell. New to the scene are *fusion inhibitors* (such as enfuvirtide) that block gp41 and thereby prevent entry of the virus into the cell in the first place. Combination therapy using three drugs at once delivers a one-two punch to the virus; that is, it postpones drug resistance and causes the *viral load* (amount of HIV virus per milliliter of blood) to plummet while boosting the number of T_H cells. Sadly, even combination drug therapies fail as the virus becomes resistant. New hope comes from a class of drugs now being developed that blocks the viral enzyme integrase, responsible for integration of the HIV provirus into the target cell's DNA. However, drug research is slow and laborious and the clock is ticking.

Autoimmune Diseases

Occasionally the immune system loses its ability to distinguish friend (self) from foe (foreign antigens). When this happens, the artillery of the immune system, like friendly fire, turns against itself. The body produces antibodies *(autoantibodies)* and sensitized T_C cells that destroy its own tissues. This puzzling phenomenon is called **autoimmunity.** If a disease state results, it is referred to as **autoimmune disease.**

Some 5% of adults in North America—two-thirds of them women—are afflicted with autoimmune disease. Most common are

- *Multiple sclerosis,* which destroys the white matter of the brain and spinal cord (see p. 407)
- *Myasthenia gravis,* which impairs communication between nerves and skeletal muscles (see p. 289)
- *Graves' disease,* which prompts the thyroid gland to produce excessive amounts of thyroxine (see p. 624)
- *Type 1 (insulin-dependent) diabetes mellitus,* which destroys pancreatic beta cells, resulting in a deficit of insulin and inability to use carbohydrates (see p. 636)
- *Systemic lupus erythematosus (SLE),* a systemic disease that particularly affects the kidneys, heart, lungs, and skin (see Related Clinical Terms)
- *Glomerulonephritis,* a severe impairment of renal function
- *Rheumatoid arthritis,* which systematically destroys joints (see p. 274)

One line of therapy depresses certain aspects of the immune response. For example, antibodies against TNF-α have provided dramatic results in the treatment of rheumatoid arthritis. *Thalidomide,* used in the 1950s to alleviate morning sickness in pregnancy until it was found to cause tragic birth defects, has been given a second chance in treating autoimmune disease because it blocks TNF production. Another therapeutic approach uses antibodies against cell adhesion molecules on T lymphocytes, preventing them from exiting blood vessels into target areas. This approach shows promise in helping victims of a variety of autoimmune disorders, including multiple sclerosis.

How do autoimmune diseases arise? As you recall, lymphocytes undergo an extensive education in the bone marrow and thymus that weeds out self-reactive cells. This weeding is thorough, but not too thorough, since there are pathogens that look somewhat like self. Weakly self-reactive lymphocytes that can detect these kinds of pathogens are allowed into the periphery, where they may cause autoimmune disease if they become activated. Recall that activation of a T cell requires a co-stimulatory signal on an APC (see p. 814), and that these co-stimulatory signals are only present if the APC has received "danger" signals alerting it to the presence of damage or invaders. This is an important safety check that generally keeps both humoral and cellular immunity under control. In addition, regulatory T (T_{Reg}) cells also inhibit autoimmune reactions. Normally, these mechanisms are sufficient, but sometimes these self-reactive lymphocytes slip out of control. It appears that one of the following events may trigger this:

1. Foreign antigens resemble self-antigens. If the determinants on a self-antigen resemble those on a foreign antigen, antibodies made against the foreign antigen can cross-react with the self-antigen. For instance, antibodies produced during a streptococcal infection react with heart antigens, causing lasting damage to the heart muscle and valves, as well as to joints and kidneys. This age-old disease is called *rheumatic fever.*

2. New self-antigens appear. Self-proteins not previously exposed to the immune system may appear in the circulation. They may be generated by (1) gene mutations that cause new proteins to appear at the external cell surface, (2) changes in the structure of self-antigens by hapten attachment or as a result of infectious damage, or (3) release by trauma of novel self-antigens normally hidden behind barriers such as the blood-brain barrier. These newly generated proteins then become immune system targets.

Hypersensitivities

At first, the immune response was thought to be purely protective. However, it was not long before its dangerous potentials were discovered. **Hypersensitivities** result when the immune system causes tissue damage as it fights off a perceived threat (such as pollen or animal dander) that would otherwise be harmless to the body. People rarely die of hypersensitivities; they are just miserable with them.

The different types of hypersensitivity reactions are distinguished by (1) their time course, and (2) whether antibodies or T cells are involved. Hypersensitivities mediated by antibodies are the *immediate* and *subacute hypersensitivities.* T cells cause *delayed hypersensitivity.*

Immediate Hypersensitivities

The **immediate hypersensitivities,** also called **acute** or **type I hypersensitivities,** are simply what most of us would call **allergies** (*allo* = altered; *erg* = reaction). An **allergen** is an antigen that causes an allergic reaction. Allergic reactions begin within seconds after contact with the allergen and last about half an hour.

The initial meeting with an allergen produces no symptoms but it sensitizes the person. APCs digest the allergen and present its fragments to T_H cells as usual. In susceptible individuals, an abnormally large number of these T_H cells differentiate into IL-4-secreting T_H2 cells. IL-4 stimulates B cells to mature into IgE-secreting plasma cells, which spew out huge amounts of antibody specific for the allergen. When the IgE molecules attach to *mast cells* and *basophils,* sensitization is complete. An allergic reaction is triggered by later encounters with the same allergen, which promptly binds and cross-links the IgE antibodies on the surfaces of the mast cells and basophils. This event induces an enzymatic cascade that causes the mast cells and basophils to degranulate, releasing a flood of *histamine* and other

inflammatory chemicals that together induce the inflammatory response typical of allergy (Figure 21.21).

Allergic reactions may be local or systemic. Mast cells are abundant in connective tissues of the skin and beneath the mucosa of respiratory passages and the gastrointestinal tract, and these areas are common sites of local allergic reactions. Histamine causes blood vessels to become dilated and leaky, and is largely to blame for the best recognized symptoms of allergy: runny nose, itching reddened skin (hives), and watery eyes. When the allergen is inhaled, symptoms of *asthma* appear because smooth muscle in the walls of the bronchioles contracts, constricting those small passages and restricting air flow. When the allergen is ingested in food or via drugs, gastrointestinal discomfort (cramping, vomiting, or diarrhea) occurs. Over-the-counter antiallergy drugs contain antihistamines that counteract these effects.

The bodywide or systemic response known as **anaphylactic shock** is fairly rare. It typically occurs when the allergen directly enters the blood and circulates rapidly through the body, as might happen with certain bee stings or spider bites. It may also follow injection of a foreign substance (such as penicillin or other drugs which act as haptens). The mechanism of anaphylactic shock is essentially the same as that of local responses; but when mast cells and basophils are enlisted throughout the entire body, the outcome is life threatening. The bronchioles constrict (and the tongue may swell), making it difficult to breathe, and the sudden vasodilation and fluid loss from the bloodstream may cause circulatory collapse (hypotensive shock) and death within minutes. Epinephrine is the drug of choice to reverse these histamine-mediated effects.

Subacute Hypersensitivities

Like the immediate types, **subacute hypersensitivities** are caused by antibodies (IgG and IgM rather than IgE) and can be transferred via blood plasma or serum. However, their onset is slower (1–3 hours after antigen exposure) and the duration of the reaction is longer (10–15 hours).

Cytotoxic (type II) reactions occur when antibodies bind to antigens on specific body cells and subsequently stimulate phagocytosis and complement-mediated lysis of the cellular antigens. Type II hypersensitivity may occur after a patient has received a transfusion of mismatched blood and the foreign red blood cells are lysed by complement.

Immune-complex (type III) hypersensitivity results when antigens are widely distributed through the body or blood and the insoluble antigen-antibody complexes formed cannot be cleared from a particular area. (This may reflect a persistent infection or a situation in which huge amounts of antigen-antibody complexes are formed.) An intense inflammatory

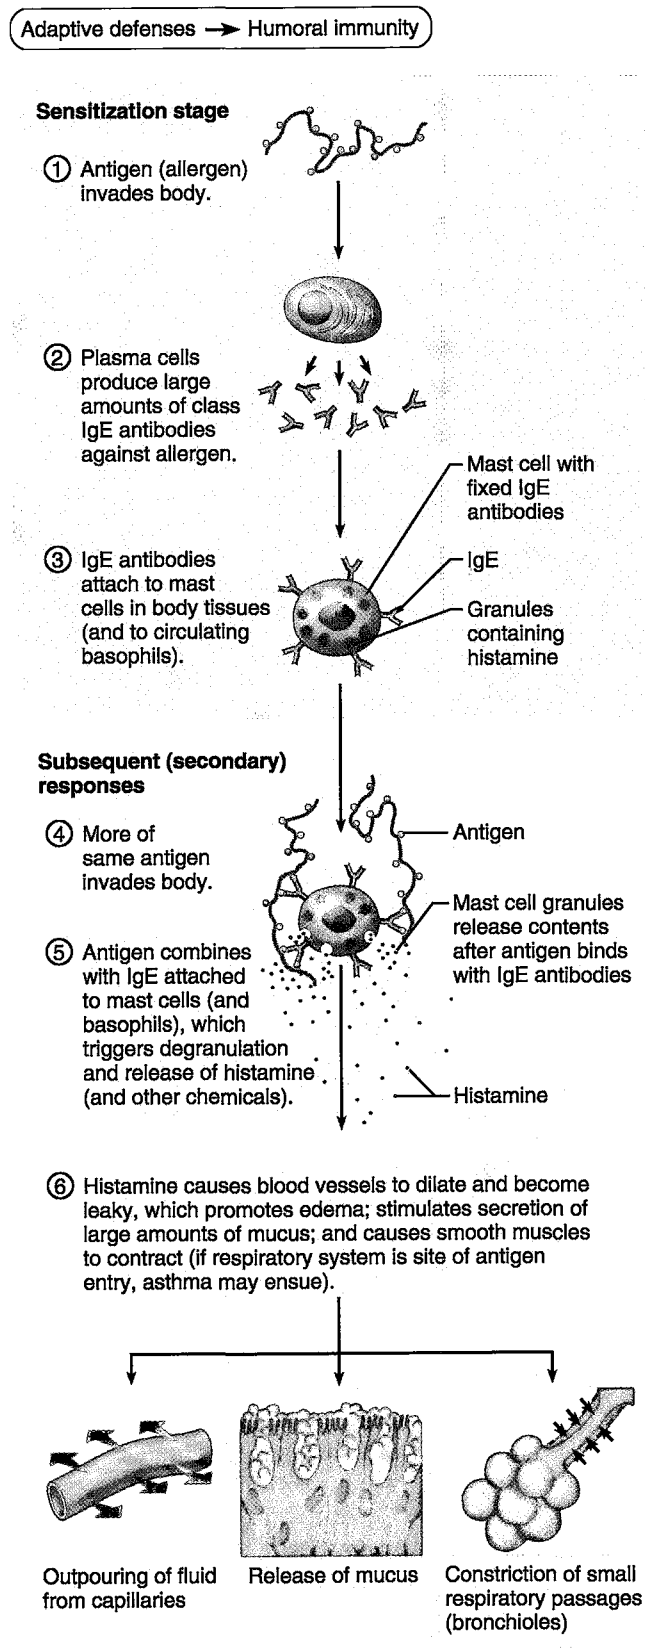


FIGURE 21.21 **Mechanism of an acute allergic (immediate hypersensitivity) response.**

A CLOSER LOOK

Too Clean for Our Own Good?

Ah, spring is here! You can tell by the sound of the wheezing and sneezing, not to mention the advertisements for hay fever medications. It seems that just about everyone is allergic to something. A century ago, this wasn't the case. Allergies were rare—a disease of rich city folk who had the best food, water, and medical care that money could buy. In cities of North America and Europe, allergies are now commonplace, and asthma is a serious problem for many children.

Asthma is a chronic inflammation of the small bronchioles of the lung. In allergic asthma, allergens trigger constriction of bronchiolar smooth muscle, making it difficult to breathe. This is uncomfortable, to say the least, and can be fatal. Eventually, this chronic inflammation leads to permanent damage. Over the past 20 years, the occurrence of asthma has increased by about 75% in the U.S. and Canada, yet asthma and allergy are still rare in developing countries and the former Communist bloc.

What is behind this? The cause can't be genetic because the increase in allergy and asthma has been much too rapid. Furthermore, children born in the U.S. to recent immigrants from developing countries have the same rates of allergy and asthma as do children whose parents have lived here for generations. Clearly, there is something about living in an industrialized society that increases the risk of allergy. The observation that the increase in allergy is correlated with the decrease in childhood diseases has led to the advent of the *hygiene hypothesis*. The twentieth century saw remarkable advances in public health, particularly in industrialized countries. Children no longer contract the serious diseases of the past: smallpox, polio, whooping cough, diphtheria, measles, cholera. Improvements in public sanitation and water supplies together with universal vaccination and the judicious use of antibiotics have kept us living longer, healthier lives and have drastically reduced infant mortality in the industrialized world. The cost? Allergy.

Allergy is caused by an overactive T_H2 response and a correspondingly underdeveloped T_H1 response. We all enter the world with stronger T_H2 than T_H1 responses. Cytokines secreted by the placenta seem to suppress T_H1 and T_C responses so that the fetus doesn't reject the mother (and vice versa). This is a good thing, naturally. During the first year of life, a strong T_H2 response also seems to reduce the destructive potential of novel viral infections, such as influenza. This is also a good thing because an overly aggressive T_H1 response could do irreparable damage to fragile, immature organs.

Back in the "good old days" when we lived in squalor, newborns fell prey to a wide variety of childhood diseases that would stimulate proliferation of T_H1 cells and shift the balance away from the T_H2 cells as the immune system matured. Those that survived the childhood diseases ended up with an immune system that had received a well-rounded education. Today, children are immunized against childhood infections and are often given antibiotics that wipe out beneficial symbiotic bacteria of the gut. Kept inside houses sterilized by antiseptic soaps, children don't play in (and eat) dirt as much as they used to. According to the hygiene hypothesis, the result is that children's immune systems aren't exposed to the large numbers of pathogens and toxins they once were and so retain a strong T_H2 response and a weak T_H1 response. As the T_H2 cells proliferate, they induce B cells to secrete excessive amounts of IgE, which in turn leads to histamine release from mast cells. Voilà! Allergy.

This simple story doesn't tell all, though. First, it isn't quite true that people in the third world don't get allergies—although they make plenty of IgE, they don't respond when exposed to allergens. It turns out that most people in developing countries are infected by parasites, particularly intestinal worms. When cured of their worm infections, they get allergies. Worms actively suppress the immune system,

reaction occurs, complete with complement-mediated cell lysis and cell killing by neutrophils that severely damages local tissues. One example of type III hypersensitivity is *farmer's lung* (induced by inhaling moldy hay). Additionally, many immune complex responses are involved in autoimmune disorders, such as glomerulonephritis, systemic lupus erythematosus, and rheumatoid arthritis.

Delayed Hypersensitivities

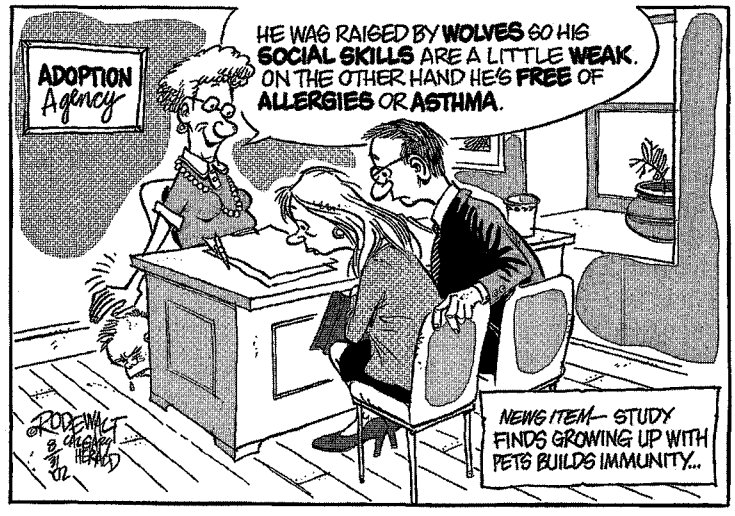
Delayed hypersensitivity (type IV) reactions are slower to appear (1–3 days) than antibody-mediated hypersensitivity reactions. The mechanism is basically that of a cell-mediated immune response, which depends on T_H1 and T_C cells. Inflammation and tissue damage comes about through the action of T_C cells and cytokine-activated macrophages. Delayed hypersensitivity to antigens can be passively transferred from one person to another by transfusions of whole blood containing the T cells that initiate the response. Cytokines released by activated T cells are the major mediators of these inflammatory responses; thus antihistamine drugs are not helpful. Corticosteroid drugs are used to provide relief.

The most familiar examples of delayed hypersensitivity reactions are those classified as **allergic contact dermatitis** which follow skin contact with poison ivy, some metals (nickel in jewelry), and certain cosmetic and deodorant chemicals. These agents act as haptens, and after diffusing through the skin and

causing the release of IL-10 and TGF-β. To prove the connection between worms and allergy suppression, Professor Koichiro Fujita at Tokyo Medical and Dental University has gone so far as to eat tapeworm eggs and is the proud host to three or four of these parasites (which can grow up to 10 m long). Fujita claims that his tapeworms have cleared up his hay fever and that he's even lost some weight.

A second problem with the hygiene hypothesis is that allergy isn't the only immune disorder on the rise. Autoimmune diseases in children and young adults, such as type 1 diabetes and multiple sclerosis, have also increased in industrial societies. These diseases are caused by activation of T_H1 cells, exactly the opposite of what the hygiene hypothesis predicts.

In science studies, these contradictions would usually be enough to doom a hypothesis. However, sometimes it is possible to look more deeply and arrive at a mechanism that can explain such seemingly contradictory observations. We know the immune system swings too far in one direction or the other, but what controls the swing? Special regulatory T (T_{Reg}) cells, capable of suppressing both T_H1 and T_H2 activity, develop in the gut and the respiratory tract upon exposure to antigens. Bacterial endotoxin and hepatitis A virus are two potent stimulators. Antigens in food and air are taken up by mucosal dendritic cells. These cells then make contact with precursor T_H cells in the presence of IL-10, causing the precursors to differentiate into T_{Reg} cells. As these T_{Reg} cells become established, the host becomes *tolerant* to the antigen, preventing allergy and autoimmune disorders. T_{Reg} development may also depend on the presence of the very bacteria depleted by antibiotics and excessive cleanliness. Thus, allergy and autoimmune disorders may be the result of faulty T_{Reg} cell development.



Perhaps, in our haste to rid ourselves of household dust, dirt, bacteria, and parasites, we have eliminated the signals our immune systems need to fully mature. Scientists are now seeking ways to imitate these lost signals. In one method, they inject patients with allergens linked to synthetic bacteria-like DNA (oligodeoxynucleotides). These activate the innate immune system's Toll-like receptors, setting off our alarm system to signal the presence of an invader. Innate immune system cells (APCs, NK cells, etc.), in turn, release a flood of cytokines that shift the immune system away from the allergy-producing T_H2 response and toward a more healthy T_H1 response.

Instead of relying on injections of synthetic "dirt," perhaps we need to rethink our obsession with cleanliness. Clearly, no one wants to return to the "good old days" of 25% infant mortality, but it may be that allowing babies to get a little dirtier early in life should be looked at as a golden opportunity to prevent allergy and asthma later on! ■

attaching to self-proteins, they are perceived as foreign by the immune system. The *Mantoux* and *tine tests*, two skin tests for tuberculosis, depend on delayed hypersensitivity reactions. When the tubercle antigens are introduced just under the skin, a small hard lesion forms that persists for days if the person has been sensitized to the antigen.

Delayed hypersensitivity reactions also involve a large number of protective reactions including (1) protection against viruses, bacteria, fungi, and protozoa; (2) resistance against cancer; and (3) rejection of foreign grafts or transplanted organs. They are particularly effective against **facultative intracellular pathogens (FIPs),** which include salmonella bacteria and some yeasts. FIPs are readily phagocytized by macrophages but are not killed and may multiply in a host unless the macrophages are activated to killer status by gamma interferon and certain other cytokines. Thus, the enhanced release of cytokines during delayed hypersensitivity reactions plays an important protective role.

Developmental Aspects of the Immune System

Stem cells of the immune system originate in the liver and spleen during weeks 1–9 of embryonic development. Later the bone marrow becomes the predominant source of stem cells, and it persists in this

role into adult life. In late fetal life and shortly after birth, the young lymphocytes develop self-tolerance and immunocompetence in their "programming organs" (thymus and bone marrow) and then populate the other lymphoid tissues. When challenged by an antigen, the naive T and B cells further differentiate into effector cells and memory cells.

The newborn's immune system depends primarily on antibodies, and hence on T_H2 lymphocytes. The T_H1 system is educated and gets stronger as a result of encounters with microbes—both harmful and harmless. If such "exercise" does *not* occur, immune balance is upset and the T_H2 system flourishes, causing the immune system to teeter toward allergies. Unhappily, our desire to keep our children squeaky clean with antibiotics that kill off both harmful and harmless bacteria may derail normal immune development (see *A Closer Look*).

The ability of the immune system to recognize foreign substances is controlled by genes. However, the nervous system also plays a role in the immune response, and studies of psychoneuroimmunology—a brain-twisting term coined to describe links between the brain and the immune system—have begun to reveal some answers. For example, the immune response is definitely impaired in individuals who are depressed or under severe stress, such as those mourning the death of a beloved family member or friend.

Our immune system normally serves us very well until late in life. Then its efficiency begins to wane, and its ability to fight infection declines. Old age is also accompanied by greater susceptibility to both immune deficiency and autoimmune diseases. The greater incidence of cancer in the elderly is assumed to be an example of the progressive failure of the immune system. Why the immune system begins to fail is not known, but we do know that the thymus begins to atrophy after puberty and the production of naive T and B cells declines with age, possibly because progenitor cells reach the limits of their ability to further divide.

■ ■ ■

The adaptive immune system provides remarkable defenses against disease. These amazingly diverse defenses are regulated by cellular interactions and a flood of chemicals. T cells and antibodies make perfect partners. Antibodies respond swiftly to toxins and molecules on the outer surfaces of foreign organisms, and T cells destroy foreign antigens hidden inside cells and our own cells that have become mutinous (cancer cells). The innate immune system exhibits a different arsenal for body defense, an arsenal that is simpler perhaps and more easily understood. However, these innate and adaptive defenses are tightly interlocked, each providing what the other cannot and amplifying each other's effects.

Related Clinical Terms

Congenital thymic aplasia An immune deficiency disease in which the thymus fails to develop. Affected individuals have no T cells, hence little or no immune protection; fetal thymic and bone marrow transplants have been helpful in some cases.

Eczema (ek'zĕ-mah) A type of immediate hypersensitivity response that results in "weeping" skin lesions and intense itching. Onset is in the first five years of life in 90% of cases. The allergen is uncertain, but familial predisposition is strong.

Hashimoto's thyroiditis An autoimmune disease in which the thyroid gland is attacked by both B and T lymphocytes. It is the most common cause of hypothyroidism, affecting mostly middle-aged and elderly women. Genetic factors associated with this autoimmune disease (certain MHC variants) make individuals susceptible to environmental triggers (possibly iodine, irradiation, or trauma).

Immunization The process of rendering a subject immune (by vaccination or injection of antiserum).

Immunology The study of immunity.

Immunopathology Disease of the immune system.

Septic shock (sepsis) A dangerous condition in which the inflammatory response goes out of control. Kills 175,000 people a year in the U.S. Results from especially severe bacterial infections or more ordinary infections that grow rapidly worse in patients with weakened defenses, such as the hospitalized elderly recovering from surgery. In an inflammatory response, neutrophils and other white blood cells leave the capillaries and enter the infected connective tissue, secreting cytokines that increase capillary permeability. Secretion of cytokines is normally moderate, but in sepsis, continued cytokine release makes capillaries so leaky that the bloodstream is depleted of fluid. Blood pressure falls and the body organs shut down, causing death in 50% of all cases. Sepsis has proven difficult to control and its incidence remains high.

Systemic lupus erythematosus (SLE) (er"ĭ-the'mah-to'sus) A systemic autoimmune disorder that occurs mainly in young females. Diagnosis is helped by finding antinuclear (anti-DNA) antibodies in the patient's serum. DNA–anti-DNA complexes (typical of type III hypersensitivity) localize in the kidneys (the capillary filters, or glomeruli), in blood vessels, in the brain, and in the synovial membranes of joints, resulting in glomerulonephritis, vascular problems, loss of memory and mental sharpness, and painful arthritis. Reddened skin lesions, particularly a "butterfly rash" (the sign of the wolf, or *lupus*) on the face, are common.

Chapter Summary

PART 1: INNATE DEFENSES

Surface Barriers: Skin and Mucosae (pp. 789–790)

1. Skin and mucous membranes constitute the first line of defense. Their role is to prevent pathogens from entering the body. Protective membranes line all body cavities and organs exposed to the exterior.

2. Surface membranes provide mechanical barriers to pathogens. Some have structural modifications and produce secretions that enhance their defensive effects: The skin's acidity, lysozyme, mucus, keratin, and ciliated cells are examples.

Internal Defenses: Cells and Chemicals (pp. 790–798)

1. The innate cellular and chemical defenses provide the body's second line of defense.

Phagocytes (pp. 790–791)

2. Phagocytes (macrophages, neutrophils, and the like) engulf and destroy pathogens that breach epithelial barriers. This process is facilitated when antibodies or complement to which the phagocyte's receptors can bind attach to the pathogen's surface. Cell killing is enhanced by the respiratory burst.

Natural Killer Cells (p. 791)

3. Natural killer cells are large granular lymphocytes that act nonspecifically to kill virus-infected and malignant cells.

Inflammation: Tissue Response to Injury (pp. 791–795)

4. The inflammatory response prevents the spread of harmful agents, disposes of pathogens and dead tissue cells, and promotes healing. Exudate is formed; protective leukocytes enter the area; the area is walled off by fibrin; and tissue repair occurs.

5. The cardinal signs of inflammation are swelling, redness, heat, and pain. These result from vasodilation and increased permeability of blood vessels induced by inflammatory chemicals. If the inflamed area is a joint, movement may be impaired.

Antimicrobial Proteins (pp. 795–798)

6. Interferons are a group of related proteins synthesized by virus-infected cells and certain immune cells that prevent viruses from multiplying in other body cells.

7. When complement (a group of plasma proteins) is fixed on a foreign cell's membrane, lysis of the target cell occurs. Complement also enhances phagocytosis and the inflammatory and adaptive immune responses.

8. C-reactive protein indicates the level of infection or inflammation in the body. It also activates complement, facilitates phagocytosis, and targets cells for disposal.

Fever (p. 798)

9. Fever enhances the body's fight against pathogens by increasing metabolism, which speeds up defensive actions and repair processes, and by prompting the liver and spleen to sequester iron and zinc needed for bacterial multiplication.

PART 2: ADAPTIVE DEFENSES

1. The adaptive immune system recognizes something as foreign and acts to immobilize, neutralize, or remove it. The adaptive immune response is antigen-specific, systemic, and has memory. It provides the body's third line of defense.

Antigens (pp. 799–800)

1. Antigens are substances capable of generating an immune response.

Complete Antigens and Haptens (p. 799)

2. Complete antigens have both immunogenicity and reactivity. Incomplete antigens or haptens must combine with a body protein before becoming immunogenic.

Antigenic Determinants (pp. 799–800)

3. Antigenic determinants are the portions of antigen molecules that are recognized as foreign. Most antigens have many such sites.

Self-Antigens: MHC Proteins (p. 800)

4. Major histocompatibility complex (MHC) proteins are membrane-bound glycoproteins that mark our cells as "self." Class I MHC proteins are found on all body cells (except RBCs); the class II variety is found on surfaces of cells that function in the adaptive immune response.

Cells of the Adaptive Immune System: An Overview (pp. 800–803)

Lymphocytes (p. 800–803)

1. Lymphocytes arise from the hemocytoblasts of the bone marrow and are educated to develop immunocompetence and self-tolerance. T cells are educated in the thymus and confer cell-mediated immunity. B cells are educated in the bone marrow and provide humoral immunity. Immunocompetence is signaled by the appearance of antigen-specific receptors on the surface of the lymphocyte. Immunocompetent lymphocytes seed the lymphoid organs, where the antigen challenge occurs, and circulate between the blood, lymph, and lymphoid organs.

2. In both B and T lymphocytes, antigen receptor diversity is generated by shuffling gene fragments.

Antigen-Presenting Cells (p. 803)

3. Antigen-presenting cells (APCs) include dendritic cells, macrophages, and B lymphocytes. They internalize antigens and present antigenic determinants on their surfaces for recognition by T cells.

Humoral Immune Response (pp. 804–810)

Clonal Selection and Differentiation of B Cells (pp. 804–805)

1. Clonal selection and differentiation of B cells occur when antigens bind to their receptors, causing them to proliferate. Most of the clone members become plasma cells, which secrete antibodies. This is the primary adaptive immune response.

Immunological Memory (p. 805)

2. Other clone members become memory B cells, capable of mounting a rapid attack against the same antigen in subsequent encounters (secondary immune responses). The memory cells provide humoral immunological memory.

Active and Passive Humoral Immunity (pp. 805–806)

3. Active humoral immunity is acquired during an infection or via vaccination and provides immunological memory. Passive immunity is conferred when a donor's antibodies are injected into the bloodstream, or when the mother's antibodies cross the placenta. Its protection is short-lived; immunological memory is not established.

Antibodies (pp. 806–810)

4. The antibody monomer consists of four polypeptide chains, two heavy and two light, connected by disulfide bonds. Each chain has both a constant and a variable region. Constant regions determine antibody function and class. Variable regions enable the antibody to recognize its appropriate antigen.

5. Five classes of antibodies exist: IgM, IgA, IgD, IgG, and IgE. They differ structurally and functionally.

6. Antibody functions include complement fixation and antigen neutralization, precipitation, and agglutination.

7. Monoclonal antibodies are pure preparations of a single antibody type useful in diagnostic tests and in treatment for some types of cancer. They are prepared by fusing B cells with tumor cells to produce hybridomas.

Cell-Mediated Immune Response (pp. 810–820)

Clonal Selection and Differentiation of T Cells (pp. 810–814)

1. Immunocompetent helper (T_H) and cytotoxic (T_C) T cells are activated by binding to an antigen-containing MHC protein displayed on the surface of an APC. A costimulatory signal is also essential. Clonal selection occurs and the clone members differentiate into the appropriate effector T cells that mount the primary immune response. Some clone members become memory T cells.

Specific T Cell Roles (pp. 814–818)

2. Helper T cells are required for full activation of most B and T cells, activate macrophages, and release essential cytokines. Cytotoxic T cells directly attack and kill infected cells and cancer cells. Regulatory (T_{Reg}) T cells help to maintain tolerance in the periphery. $T_{\gamma\delta}$ cells, found in the intestinal mucosae, recognize damaged cells and pathogens in a number of novel ways.

3. The immune response is enhanced by cytokines such as interleukin 1 released by macrophages, and interleukin 2, gamma interferon, and others released by activated T cells.

Organ Transplants and Prevention of Rejection (pp. 818–820)

4. Grafts or foreign organ transplants are rejected by cell-mediated responses unless the patient is immunosuppressed. Infections are major complications in such patients.

Homeostatic Imbalances of Immunity (pp. 820–825)

Immunodeficiencies (pp. 820–821)

1. Immunodeficiency diseases include severe combined immunodeficiency (SCID) syndromes and acquired immune deficiency syndrome (AIDS). Overwhelming infections are fatal because the immune system is unable to combat them.

Autoimmune Diseases (pp. 821–822)

2. Autoimmune disease occurs when the body regards its own tissues as foreign and mounts an immune attack against them. Examples include rheumatoid arthritis and multiple sclerosis.

Hypersensitivities (pp. 822–825)

3. Hypersensitivity is an abnormally intense reaction to an otherwise harmless antigen. Immediate hypersensitivities (allergies) are mounted by IgE antibodies. Subacute hypersensitivities, involving both antibodies and complement, include antibody-mediated cytotoxic and immune-complex hypersensitivities. Cell-mediated hypersensitivity is called delayed hypersensitivity.

Developmental Aspects of the Immune System (pp. 825–826)

1. Development of the immune response occurs around the time of birth. The ability of the immune system to recognize foreign substances is genetically determined.

2. The nervous system plays an important role in regulating immune responses, possibly through common mediators. Depression impairs immune function.

3. With aging, the immune system becomes less responsive. The elderly more often suffer from immune deficiency, autoimmune diseases, and cancer.

Review Questions

Multiple Choice/Matching

(Some questions have more than one correct answer. Select the best answer or answers from the choices given.)

1. All of the following are considered innate or nonspecific body defenses *except* (a) complement, (b) phagocytosis, (c) antibodies, (d) lysozyme, (e) inflammation.

2. The process by which neutrophils squeeze through capillary walls in response to inflammatory signals is called (a) diapedesis, (b) chemotaxis, (c) margination, (d) opsonization.

3. Antibodies released by plasma cells are involved in (a) humoral immunity, (b) immediate hypersensitivity reactions, (c) autoimmune disorders, (d) all of the above.

4. Which of the following antibodies can fix complement? (a) IgA, (b) IgD, (c) IgE, (d) IgG, (e) IgM.

5. Which antibody class is abundant in body secretions? (Use the choices from question 4.)

6. Small molecules that must combine with large proteins to become immunogenic are called (a) complete antigens, (b) kinins, (c) antigenic determinants, (d) haptens.

7. Lymphocytes that develop immunocompetence in the bone marrow are (a) T lymphocytes, (b) B lymphocytes, (c) NK cells, (d) B and T lymphocytes.

8. Cells that can directly attack target cells include all of the following *except* (a) macrophages, (b) cytotoxic T cells, (c) helper T cells, (d) natural killer cells.

9. Which of the following is involved in the activation of a B cell? (a) antigen, (b) helper T cell, (c) cytokine, (d) all of the above.

10. The cell type most often invaded by HIV is a(n) (a) eosinophil, (b) cytotoxic T cell, (c) natural killer cell, (d) helper T cell, (e) B cell.

11. Complement fixation promotes all of the following except (a) cell lysis, (b) inflammation, (c) opsonization, (d) interferon release, (e) chemotaxis of neutrophils and other cells.

12. Using the letters from column B, match the cell description in column A. (Note that all require more than a single choice.)

Column A	Column B
____ (1) phagocyte	(a) natural killer cells
____ (2) releases histamine	(b) neutrophil
____ (3) releases perforins	(c) dendritic cells
____ (4) lymphocyte	(d) mast cell
____ (5) can differentiate to form memory cells	(e) cytotoxic T cell
	(f) B cell
____ (6) antigen-presenting cell	(g) macrophage
	(h) helper T cell
	(i) basophil

Short Answer Essay Questions

13. Besides acting as mechanical barriers, the skin epidermis and mucosae of the body have other attributes that contribute to their protective roles. Cite the common body locations and the importance of mucus, lysozyme, keratin, acid pH, and cilia.

14. Explain why attempts at phagocytosis are not always successful; cite factors that increase the likelihood of success.

15. What is complement? How does it cause bacterial lysis? What are some of the other roles of complement?

16. Interferons are referred to as antiviral proteins. What stimulates their production, and how do they protect uninfected cells? What cells of the body secrete interferons?

17. Differentiate between humoral and cell-mediated adaptive immunity.

18. Although the adaptive immune system has two arms, it has been said, "no T cells, no immunity." Explain.

19. Define immunocompetence. What event (or observation) signals that a B or a T cell has developed immunocompetence?

20. Describe the process of activation of a helper T cell.

21. Differentiate between a primary and a secondary immune response. Which is more rapid and why?

22. Define antibody. Using an appropriately labeled diagram, describe the structure of an antibody monomer. Indicate and label variable and constant regions, heavy and light chains.

23. What is the role of the variable regions of an antibody? Of the constant regions?

24. Name the five antibody classes and describe where each is most likely to be found in the body.

25. How do antibodies help defend the body?

26. Do vaccines produce active or passive humoral immunity? Explain your answer. Why is passive immunity less satisfactory?

27. Describe the specific roles of helper, regulatory, and cytotoxic T cells in normal cell-mediated immunity.

28. Name several cytokines and describe their role in the immune response.

29. Define hypersensitivity. List three types of hypersensitivity reactions. For each, note whether antibodies or T cells are involved and provide two examples.

30. What events can result in autoimmune disease?

31. What accounts for the declining efficiency of the immune system with age?

Critical Thinking and Clinical Application Questions

1. Jenny, a 6-year-old child who has been raised in a germ-free environment from birth, is a victim of one of the most severe examples of an abnormal immune system. Jenny also suffers from cancer caused by the Epstein-Barr virus. Relative to this case: (a) What is the usual fate of children with Jenny's condition and similar circumstances if no treatment is attempted? (b) Why is Jenny's brother chosen as the bone marrow donor? (c) Why is her physician planning to use umbilical cord blood as a source of stem cells for a bone marrow transplant if transplant of her brother's marrow fails (what are the hoped-for results)? (d) Attempt to explain Jenny's cancer. (e) What similarities and dissimilarities exist between Jenny's illness and AIDS?

2. Some people with a deficit of IgA exhibit recurrent respiratory tract infections. Explain this observation.

3. Explain the underlying mechanisms responsible for the cardinal signs of acute inflammation: heat, pain, redness, swelling.

4. Costanza was picking grapes in her father's arbor when she felt a short prickling pain in her finger. She ran crying to her father, who removed an insect stinger and calmed her with a glass of lemonade. Twenty minutes later Costanza's finger was red, swollen, and throbbing where she had been stung. What type of immune response was she exhibiting? What treatment would relieve her discomfort?

5. Caroline, a pregnant 29-year-old, has been HIV-positive for at least 10 years, dating back to when she was homeless and injecting heroin on a regular basis. While she currently has no symptoms of AIDS, she is taking several medications and is worried about the possibility that her baby might be infected. How do you think the HIV virus might be transferred from a mother to her offspring? Which of Caroline's cells are infected by the virus and why is the viral attack on these cells so devastating? Why is Caroline taking medication even though she has no symptoms? What types of medications might she be taking and how do they affect the virus and its replication?

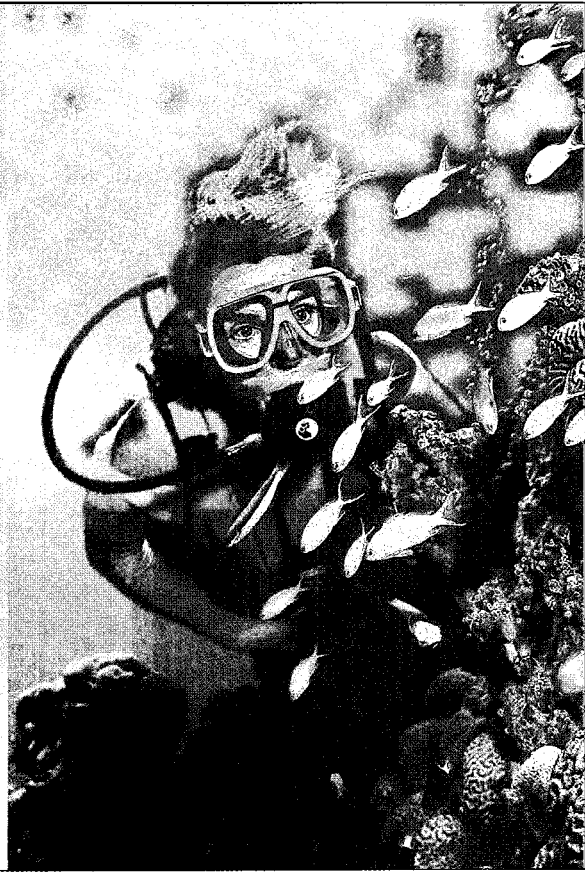
CHAPTER 22

The Respiratory System



Functional Anatomy of the Respiratory System (pp. 831–846)

1. Identify the organs forming the respiratory passageway(s) in descending order until the alveoli are reached. Distinguish between conducting and respiratory zone structures.
2. List and describe several protective mechanisms of the respiratory system.
3. Describe the makeup of the respiratory membrane, and relate structure to function.
4. Describe the gross structure of the lungs and pleurae.

Mechanics of Breathing (pp. 846–854)

5. Relate Boyle's law to events of inspiration and expiration.
6. Explain the relative roles of the respiratory muscles and lung elasticity in producing the volume changes that cause air to flow into and out of the lungs.
7. Explain the functional importance of the partial vacuum that exists in the intrapleural space.
8. List several physical factors that influence pulmonary ventilation.
9. Explain and compare the various lung volumes and capacities. Indicate types of information that can be gained from pulmonary function tests.
10. Define dead space.

Gas Exchanges Between the Blood, Lungs, and Tissues (pp. 854–858)

11. State Dalton's law of partial pressures and Henry's law.
12. Describe how atmospheric and alveolar air differ in composition, and explain these differences.
13. Relate Dalton's and Henry's laws to events of external and internal respiration.

Transport of Respiratory Gases by Blood (pp. 858–863)

14. Describe how oxygen is transported in the blood, and explain how oxygen loading and unloading is affected by temperature, pH, BPG, and P_{CO_2}.
15. Describe carbon dioxide transport in the blood.

Control of Respiration (pp. 863–869)

16. Describe the neural controls of respiration.
17. Compare and contrast the influences of lung reflexes, volition, emotions, arterial pH, and arterial partial pressures of oxygen and carbon dioxide on respiratory rate and depth.

Respiratory Adjustments (pp. 869–870)

18. Compare and contrast the hyperpnea of exercise with hyperventilation.
19. Describe the process and effects of acclimatization to high altitude.

Homeostatic Imbalances of the Respiratory System (pp. 870–873)

20. Compare the causes and consequences of chronic bronchitis, emphysema, asthma, tuberculosis, and lung cancer.

Developmental Aspects of the Respiratory System (pp. 873–875)

21. Trace the embryonic development of the respiratory system.
22. Describe normal changes that occur in the respiratory system from infancy to old age.

Far from self-sustaining, the body depends on the external environment, both as a source of substances the body needs to survive and as a catch basin for its wastes. The trillions of cells making up the body require a continuous supply of oxygen to carry out their vital functions. We cannot do without oxygen for even a little while, as we can without food or water. As cells use oxygen, they give off carbon dioxide, a waste product the body must get rid of. They also generate dangerous free radicals, the inescapable by-products of living in a world full of oxygen. But let's get to the topic of this chapter, the respiratory system.

The major function of the **respiratory system** is to supply the body with oxygen and dispose of carbon dioxide. To accomplish this function, at least four processes, collectively called **respiration,** must happen:

1. **Pulmonary ventilation:** movement of air into and out of the lungs so that the gases there are continuously changed and refreshed (commonly called breathing).
2. **External respiration:** movement of oxygen from the lungs to the blood and of carbon dioxide from the blood to the lungs.
3. **Transport of respiratory gases:** transport of oxygen from the lungs to the tissue cells of the body, and of carbon dioxide from the tissue cells to the lungs. This is accomplished by the cardiovascular system using blood as the transporting fluid.
4. **Internal respiration:** movement of oxygen from blood to the tissue cells and of carbon dioxide from tissue cells to blood.*

Only the first two processes are the special responsibility of the respiratory system, but it cannot accomplish its primary goal of obtaining oxygen and eliminating carbon dioxide unless the third and fourth processes also occur. Thus, the respiratory and circulatory systems are closely coupled, and if either system fails, the body's cells begin to die from oxygen starvation.

Because it moves air, the respiratory system is also involved with the sense of smell and with speech.

Functional Anatomy of the Respiratory System

The respiratory system includes the *nose* and *nasal cavity, pharynx, larynx, trachea, bronchi* and their smaller branches, and the *lungs,* which contain the terminal air sacs, or *alveoli* (Figure 22.1). Functionally, the system consists of two zones. The **respiratory zone,** the actual site of gas exchange, is composed of the respiratory bronchioles, alveolar ducts, and alveoli, all microscopic structures. The **conducting zone** includes all other respiratory passageways, which provide fairly rigid conduits for air to reach the gas exchange sites. The conducting zone organs also cleanse, humidify, and warm incoming air. Thus, air reaching the lungs has fewer irritants (dust, bacteria, etc.) than when it entered the system, and it is warm and damp, like the air of the tropics. The functions of the major organs of the respiratory system are summarized in Table 22.1 on p. 838.

In addition to these organs, some authorities also include the respiratory muscles (diaphragm, etc.) as part of this system. Although we will consider how these skeletal muscles bring about the volume changes that promote ventilation, we continue to classify them as part of the *muscular system.*

The Nose and Paranasal Sinuses

The nose is the only externally visible part of the respiratory system. Unlike the eyes and lips, facial features often referred to poetically, the nose is usually an irreverent target. We are urged to keep our nose to the grindstone and to keep it out of other people's business. However, considering its important functions, it deserves more esteem. The nose (1) provides an airway for respiration, (2) moistens and warms entering air, (3) filters and cleans inspired air, (4) serves as a resonating chamber for speech, and (5) houses the olfactory (smell) receptors.

The structures of the nose are divided into the *external nose* and the internal *nasal cavity* for ease of consideration. The surface features of the external nose (Figure 22.2a) include the *root* (area between the eyebrows), *bridge,* and *dorsum nasi* (anterior margin), the latter terminating in the *apex* (tip of the nose). Just inferior to the apex is a shallow vertical groove called the *philtrum* (fil'trum). The external openings of the nose, the *nostrils* or *nares* (na'rez), are bounded laterally by the flared *alae.* The skeletal framework of the external nose is fashioned by the nasal and frontal bones superiorly (forming the bridge and root, respectively), the maxillary bones laterally, and flexible plates of hyaline cartilage (the lateral, septal, and alar cartilages) inferiorly (Figure 22.2b). Noses vary a great deal in size and shape, largely because of differences in the nasal cartilages. The skin covering the nose's dorsal and lateral aspects is thin and contains many sebaceous glands.

The internal **nasal cavity** lies in and posterior to the external nose. During breathing, air enters the cavity by passing through the **nostrils,** or **nares**

*The actual use of oxygen and production of carbon dioxide by tissue cells, that is, *cellular respiration,* is the cornerstone of all energy-producing chemical reactions in the body. Cellular respiration, which occurs in all body cells, is discussed more appropriately in the metabolism section of Chapter 24.

Q *Which of the organs shown contains* both *conducting zone and respiratory zone structures?*

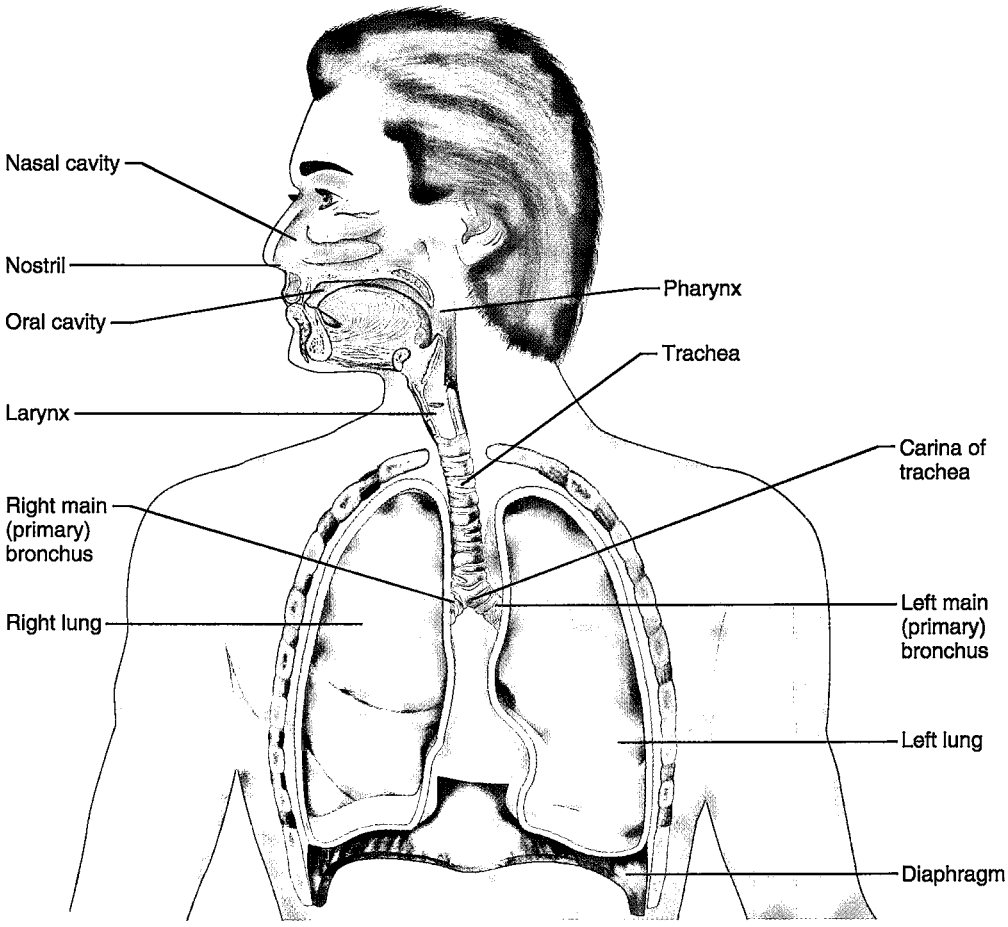


FIGURE 22.1 **The major respiratory organs in relation to surrounding structures.**

(Figure 22.2a and Figure 22.3b). The nasal cavity is divided by a midline **nasal septum,** formed anteriorly by the septal cartilage and posteriorly by the vomer bone and perpendicular plate of the ethmoid bone (see Figure 7.10b, p. 215). The nasal cavity is continuous posteriorly with the nasal portion of the pharynx through the **posterior nasal apertures,** also called the *choanae* (ko-a'ne; "funnels").

The roof of the nasal cavity is formed by the ethmoid and sphenoid bones of the skull. The floor is formed by the *palate,* which separates the nasal cavity from the oral cavity below. Anteriorly, where the palate is supported by the maxillary processes and palatine bones, it is called the **hard palate.** The unsupported posterior portion is the muscular **soft palate.**

The part of the nasal cavity just superior to the nostrils, called the **nasal vestibule,** is lined with skin containing sebaceous and sweat glands and numerous hair follicles. The hairs, or **vibrissae** (vi-bris'e; *vibro* = to quiver), filter coarse particles (dust, pollen) from inspired air. The rest of the nasal cavity is lined with two types of mucous membrane. The **olfactory mucosa,** lining the slitlike superior region of the nasal cavity, contains smell receptors. The balance of the nasal cavity mucosa, the **respiratory mucosa,** is a pseudostratified ciliated columnar epithelium, containing scattered *goblet cells,* that rests on a lamina propria richly supplied with *mucous* and *serous glands.* (Mucous cells secrete mucus, and serous cells secrete a watery fluid containing enzymes.) Each day, these glands secrete about a quart of mucus containing *lysozyme,* an antibacterial enzyme. The sticky mucus traps inspired dust, bacteria, and other debris, while lysozyme attacks and destroys bacteria chemically. The epithelial cells of the

(b)

FIGURE 22.2 **The external nose. (a)** Surface anatomy. **(b)** External skeletal framework.

respiratory mucosa also secrete *defensins*, natural antibiotics that help get rid of invading microbes. Additionally, the high water content of the mucus film acts to humidify the inhaled air.

The ciliated cells of the respiratory mucosa create a gentle current that moves the sheet of contaminated mucus posteriorly toward the throat, where it is swallowed and digested by stomach juices. We are usually unaware of this important action of our nasal cilia, but when exposed to cold air they become sluggish, allowing mucus to accumulate in the nasal cavity and then dribble out the nostrils. This along with the fact that water vapor in expired air tends to condense at lower temperatures helps explain why you might have a "runny" nose on a crisp, wintry day.

The nasal mucosa is richly supplied with sensory nerve endings, and contact with irritating particles (dust, pollen, and the like) triggers a sneeze reflex. The sneeze forces air outward in a violent burst—a somewhat crude way of expelling irritants from the nose.

Rich plexuses of capillaries and thin-walled veins underlie the nasal epithelium and warm incoming air as it flows across the mucosal surface. When the inspired air is cold, the vascular plexus becomes engorged with blood, thereby intensifying the air-heating process. Because of the abundance and superficial location of these blood vessels, nosebleeds are common and often profuse.

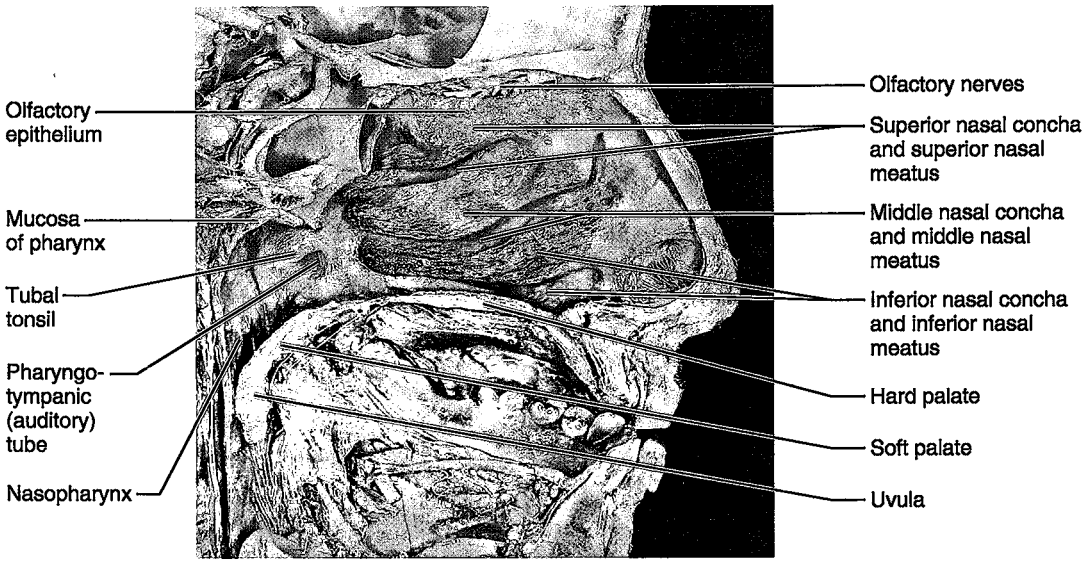
Protruding medially from each lateral wall of the nasal cavity are three scroll-like mucosa-covered projections, the *superior, middle,* and *inferior nasal conchae* (kong'ke) (Figure 22.3). The groove inferior to each concha is a *nasal meatus* (me-a'tus). The curved conchae greatly increase the mucosal surface area exposed to the air and enhance air turbulence in the cavity. The gases in inhaled air swirl through the twists and turns, but heavier, nongaseous particles tend to be deflected onto the mucus-coated surfaces, where they become trapped. As a result, few particles larger than 6 μm make it past the nasal cavity.

The conchae and nasal mucosa not only function during inhalation to filter, heat, and moisten the air, but also act during exhalation to reclaim this heat and moisture. That is, the inhaled air cools the conchae, then during exhalation these cooled conchae precipitate moisture and extract heat from the humid air flowing over them. This reclamation mechanism minimizes the amount of moisture and heat lost from the body through breathing, helping us to survive in dry and cold climates.

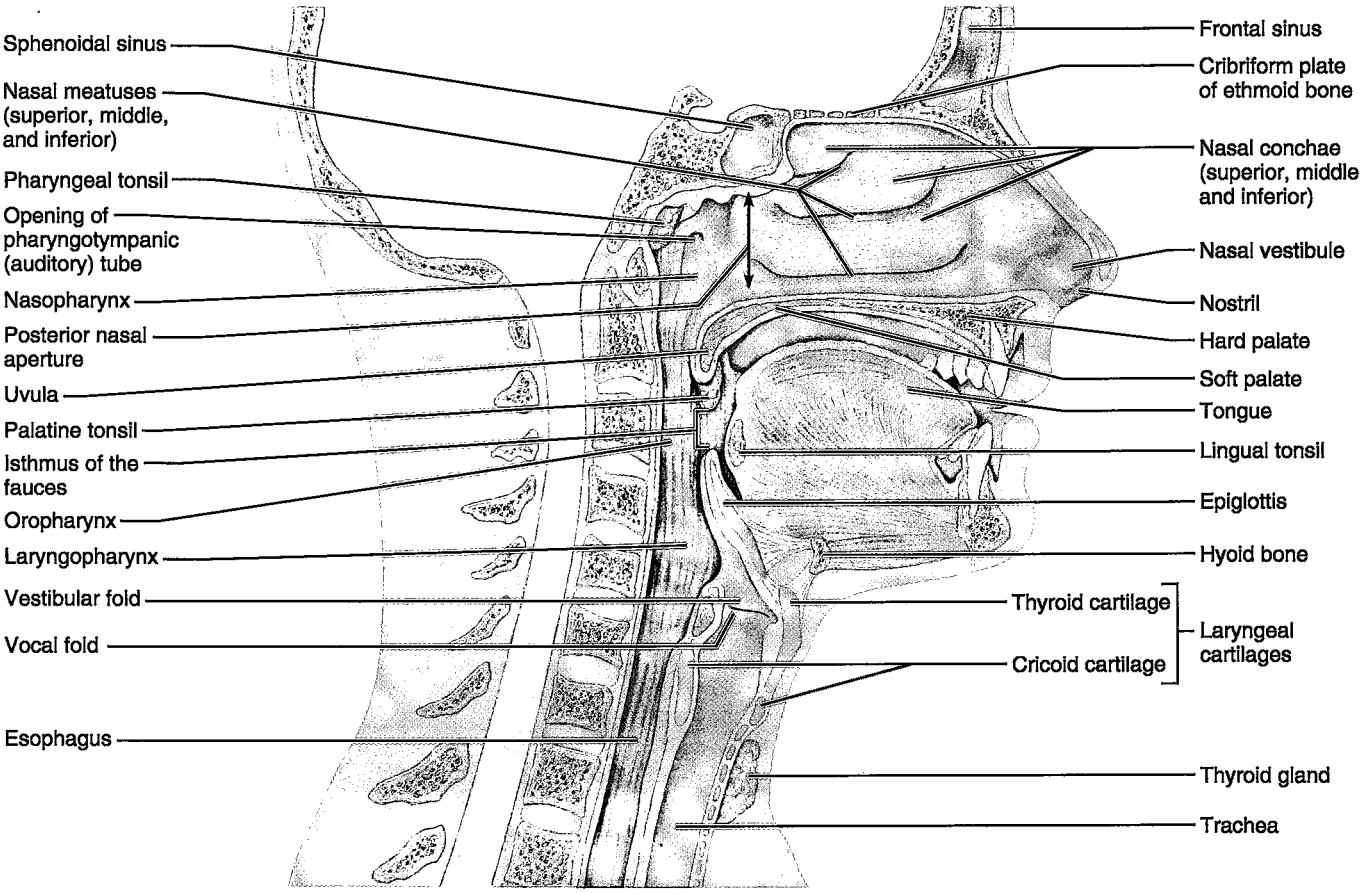
The nasal cavity is surrounded by a ring of **paranasal sinuses** (Figure 22.3b) located in the frontal, sphenoid, ethmoid, and maxillary bones (see also Figure 7.11, p. 218). The sinuses lighten the skull, and together with the nasal cavity they warm and moisten the air. The mucus they produce ultimately flows into the nasal cavity, and the suctioning effect created by nose blowing helps drain the sinuses.

HOMEOSTATIC IMBALANCE

Cold viruses, streptococcal bacteria, and various allergens can cause *rhinitis* (ri-ni'tis), inflammation of the nasal mucosa accompanied by excessive mucus production, nasal congestion, and postnasal drip. The nasal mucosa is continuous with that of the rest



(a)



(b)

FIGURE 22.3 **The upper respiratory tract.** Midsagittal section of the head and neck: **(a)** Photograph. (See *A Brief Atlas of the Human Body*, Figure 47.) **(b)** Illustration.

of the respiratory tract, explaining the typical nose to throat to chest progression of colds. Because the mucosa extends tentacle-like into the nasolacrimal (tear) ducts and paranasal sinuses, nasal cavity infections often spread to those regions, causing **sinusitis** (inflamed sinuses). When the passageways connecting the sinuses to the nasal cavity are blocked with mucus or infectious material, the air in the sinus cavities is absorbed. The result is a partial vacuum and a *sinus headache* localized over the inflamed areas.

The Pharynx

The funnel-shaped **pharynx** (far'ingks) connects the nasal cavity and mouth superiorly to the larynx and esophagus inferiorly. Commonly called the *throat*, the pharynx vaguely resembles a short length of garden hose as it extends for about 13 cm (5 inches) from the base of the skull to the level of the sixth cervical vertebra (Figure 22.1).

From superior to inferior, the pharynx is divided into three regions—the *nasopharynx*, *oropharynx*, and *laryngopharynx* (Figure 22.3b). The muscular pharynx wall is composed of skeletal muscle throughout its length (see Table 10.3, pp. 340–341), but the cellular composition of its mucosa varies from one pharyngeal region to another.

The Nasopharynx

The **nasopharynx** is posterior to the nasal cavity, inferior to the sphenoid bone, and superior to the level of the soft palate. Because it lies above the point where food enters the body, it serves *only* as an air passageway. During swallowing, the soft palate and its pendulous *uvula* (u'vu-lah; "little grape") move superiorly, an action that closes off the nasopharynx and prevents food from entering the nasal cavity. (When we giggle, this sealing action fails and fluids being swallowed can end up spraying out the nose.)

The nasopharynx is continuous with the nasal cavity through the posterior nasal apertures (see Figure 22.3b), and its pseudostratified ciliated epithelium takes over the job of propelling mucus where the nasal mucosa leaves off. High on its posterior wall is the **pharyngeal tonsil** (far-rin'je-al) (or *adenoids*), which traps and destroys pathogens entering the nasopharynx in air.

HOMEOSTATIC IMBALANCE

Infected and swollen adenoids block air passage in the nasopharynx, making it necessary to breathe through the mouth. As a result, the air is not properly moistened, warmed, or filtered before reaching the lungs. When the adenoids are chronically enlarged, both speech and sleep may be disturbed.

The *pharyngotympanic (auditory) tubes*, which drain the middle ear cavities and allow middle ear pressure to equalize with atmospheric pressure, open into the lateral walls of the nasopharynx (Figure 22.3a). A ridge of pharyngeal mucosa, referred to as a *tubal tonsil*, arches over each of these openings. Because of their strategic location, the tubal tonsils help protect the middle ear against infections likely to spread from the nasopharynx. The pharyngeal tonsil, superoposterior and medial to the tubal tonsils, also plays this protective role.

The Oropharynx

The **oropharynx** lies posterior to the oral cavity and is continuous with it through an archway called the **isthmus of the fauces** (faw'sēz; "throat") (see Figure 22.3b). Because the oropharynx extends inferiorly from the level of the soft palate to the epiglottis, both swallowed food and inhaled air pass through it.

As the nasopharynx blends into the oropharynx, the epithelium changes from pseudostratified columnar to a more protective stratified squamous epithelium. This structural adaptation accommodates the increased friction and greater chemical trauma accompanying food passage.

Two kinds of tonsils lie embedded in the oropharyngeal mucosa. The paired **palatine tonsils** lie in the lateral walls of the fauces. The **lingual tonsil** covers the base of the tongue.

The Laryngopharynx

Like the oropharynx above it, the **laryngopharynx** (lah-ring"go-far'ingks) serves as a passageway for food and air and is lined with a stratified squamous epithelium. It lies directly posterior to the upright epiglottis and extends to the larynx, where the respiratory and digestive pathways diverge. At that point the laryngopharynx is continuous with the esophagus posteriorly. The esophagus conducts food and fluids to the stomach; air enters the larynx anteriorly. During swallowing, food has the "right of way," and air passage temporarily stops.

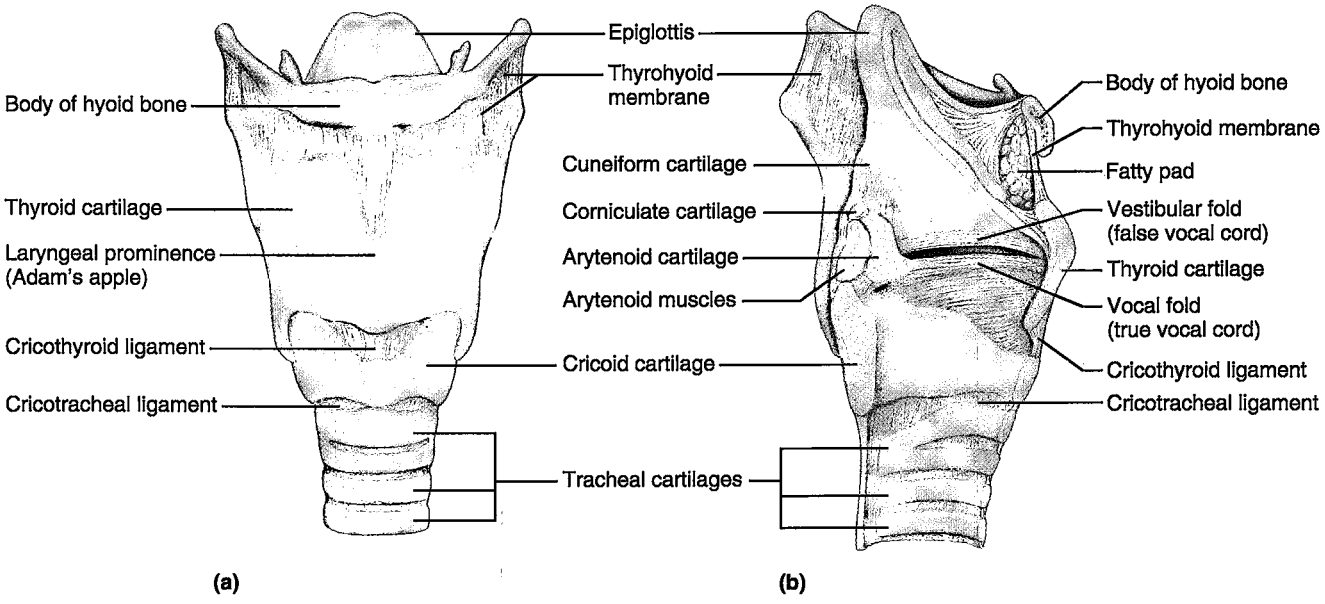
The Larynx

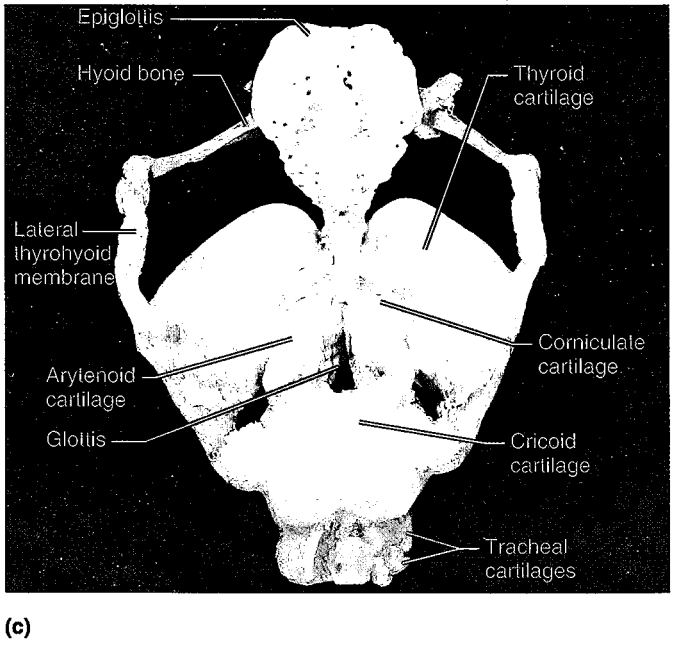
Basic Anatomy

The **larynx** (lar'ingks), or voice box, extends for about 5 cm (2 inches) from the level of the third to the sixth cervical vertebra. Superiorly it attaches to the hyoid bone and opens into the laryngopharynx. Inferiorly it is continuous with the trachea (Figure 22.3b).

The larynx has three functions. Its two main tasks are to provide a *patent* (open) airway and to act as a switching mechanism to route air and food into the proper channels. Because it houses the vocal cords, the third function of the larynx is voice production.

Q *Which structure seals the larynx when we swallow?*





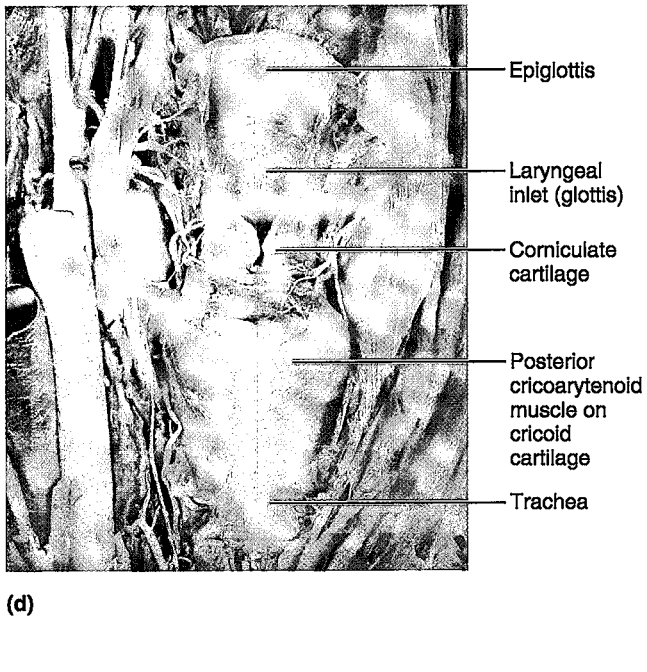


FIGURE 22.4 **The larynx. (a)** Anterior superficial view. **(b)** Sagittal view; anterior surface to the right. **(c)** Photograph of the cartilaginous framework of the larynx, posterior view. **(d)** Photograph of posterior aspect.

The framework of the larynx is an intricate arrangement of nine cartilages connected by membranes and ligaments (Figure 22.4). Except for the epiglottis, all laryngeal cartilages are hyaline cartilages. The large, shield-shaped **thyroid cartilage** is formed by the fusion of two cartilage plates. The midline **laryngeal prominence** (lah-rin'je-al), which marks the fusion point, is obvious externally as the *Adam's apple*. The thyroid cartilage is typically larger in males than in females because male sex hormones stimulate its growth during puberty. Inferior to the thyroid cartilage is the ring-shaped **cricoid cartilage** (kri'koid), perched atop and anchored to the trachea inferiorly.

A The epiglottis.

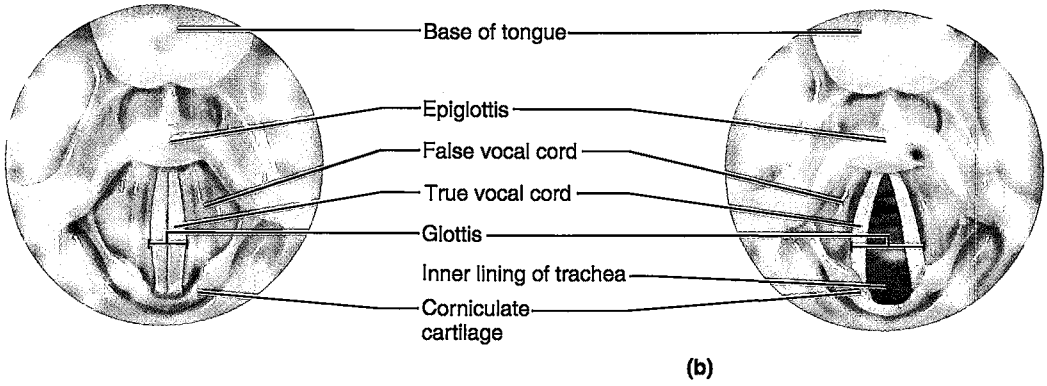

FIGURE 22.5 **Movements of the vocal cords.** Superior views of the larynx and vocal cords, mucous membranes in place. **(a)** Vocal cords in closed position. **(b)** Vocal cords in open position. (See *A Brief Atlas of the Human Body*, Figure 62.)

Three pairs of small cartilages, **arytenoid** (ar"ĭ-te'noid), **cuneiform** (ku-ne'ĭ-form), and **corniculate cartilages,** form part of the lateral and posterior walls of the larynx. The most important of these are the pyramid-shaped arytenoid cartilages, which anchor the vocal cords.

The ninth cartilage, the flexible, spoon-shaped **epiglottis** (ep"ĭ-glot'is; "above the glottis"), is composed of elastic cartilage and is almost entirely covered by a taste bud–containing mucosa. The epiglottis extends from the posterior aspect of the tongue to its anchoring point on the anterior rim of the thyroid cartilage (see Figure 22.4b and c). When only air is flowing into the larynx, the inlet to the larynx is open wide and the free edge of the epiglottis projects upward. During swallowing, the larynx is pulled superiorly and the epiglottis tips to cover the laryngeal inlet. Because this action keeps food out of the lower respiratory passages, the epiglottis has been called the guardian of the airways. Anything other than air entering the larynx initiates the cough reflex, which acts to expel the substance. Because this protective reflex does not work when we are unconscious, it is never a good idea to administer liquids when attempting to revive an unconscious person.

Lying under the laryngeal mucosa on each side are the **vocal ligaments,** which attach the arytenoid cartilages to the thyroid cartilage. These ligaments, composed largely of elastic fibers, form the core of mucosal folds called the **vocal folds,** or **true vocal cords,** which appear pearly white because they lack blood vessels (Figure 22.5). The vocal folds vibrate, producing sounds as air rushes up from the lungs. The vocal folds and the medial opening between them through which air passes are called the **glottis.** Superior to the vocal folds is a similar pair of mucosal folds called the **vestibular folds,** or **false vocal cords.** These play no part in sound production but help to close the glottis when we swallow.

The superior portion of the larynx, an area subject to food contact, is lined by stratified squamous epithelium. Below the vocal folds the epithelium is a pseudostratified ciliated columnar type that acts as a dust filter. The power stroke of its cilia is directed upward toward the pharynx so that mucus is continually moved *away* from the lungs. We help to move mucus up and out of the larynx when we "clear our throat."

Voice Production

Speech involves the intermittent release of expired air and the opening and closing of the glottis. The length of the true vocal cords and the size of the glottis change with the action of the intrinsic laryngeal muscles that clothe the cartilages. Most of these muscles move the arytenoid cartilages. As the length and tension of the cords change, the pitch of the sound varies. Generally, the tenser the cords, the faster they vibrate and the higher the pitch. The glottis is wide (Figure 22.5b) when we produce deep tones and narrows to a slit for high-pitched sounds. As a boy's larynx enlarges during puberty, his true vocal cords become longer and thicker. Because this causes them to vibrate more slowly, his voice becomes deeper. Until the young man learns to control his newly enlarged true vocal cords, his voice "cracks."

Loudness of the voice depends on the force with which the airstream rushes across the vocal cords. The greater the force, the stronger the vibration and the louder the sound. The vocal cords do not move at all when we whisper, but they vibrate vigorously when we yell. The power source for creating the airstream is the muscles of the chest, abdomen, and back.

The vocal folds actually produce buzzing sounds. The perceived quality of the voice depends on the coordinated activity of many structures above the glottis. For example, the entire length of the pharynx acts as a resonating chamber, to amplify and enhance

TABLE 22.1 Principal Organs of the Respiratory System

STRUCTURE	DESCRIPTION, GENERAL AND DISTINCTIVE FEATURES	FUNCTION
Nose	Jutting external portion supported by bone and cartilage; internal nasal cavity divided by midline nasal septum and lined with mucosa	Produces mucus; filters, warms, and moistens incoming air; resonance chamber for speech
	Roof of nasal cavity contains olfactory epithelium	Receptors for sense of smell
	Paranasal sinuses around nasal cavity	Same as for nasal cavity; also lighten skull
Pharynx	Passageway connecting nasal cavity to larynx and oral cavity to esophagus; three subdivisions: nasopharynx, oropharynx, and laryngopharynx	Passageway for air and food
	Houses tonsils (lymphoid tissue masses involved in protection against pathogens)	Facilitates exposure of immune system to inhaled antigens
Larynx	Connects pharynx to trachea; framework of cartilage and dense connective tissue; opening (glottis) can be closed by epiglottis or vocal folds	Air passageway; prevents food from entering lower respiratory tract
	Houses vocal folds (true vocal cords)	Voice production
Trachea	Flexible tube running from larynx and dividing inferiorly into two main bronchi; walls contain C-shaped cartilages that are incomplete posteriorly where connected by trachealis muscle	Air passageway; cleans, warms, and moistens incoming air
Bronchial tree	Consists of right and left main bronchi, which subdivide within the lungs to form lobar and segmental bronchi and bronchioles; bronchiolar walls contain complete layer of smooth muscle; constriction of this muscle impedes expiration	Air passageways connecting trachea with alveoli; cleans, warms, and moistens incoming air
Alveoli	Microscopic chambers at termini of bronchial tree; walls of simple squamous epithelium underlain by thin basement membrane; external surfaces intimately associated with pulmonary capillaries	Main sites of gas exchange
	Special alveolar cells produce surfactant	Reduces surface tension; helps prevent lung collapse
Lungs	Paired composite organs located within pleural cavities of thorax; composed primarily of alveoli and respiratory passageways; stroma is fibrous elastic connective tissue, allowing lungs to recoil passively during expiration	House respiratory passages smaller than the main bronchi
Pleurae	Serous membranes; parietal pleura lines thoracic cavity; visceral pleura covers external lung surfaces	Produce lubricating fluid and compartmentalize lungs

the sound quality. The oral, nasal, and sinus cavities also contribute to vocal resonance. In addition, good enunciation depends on the "shaping" of sound into recognizable consonants and vowels by muscles in the pharynx, tongue, soft palate, and lips.

HOMEOSTATIC IMBALANCE

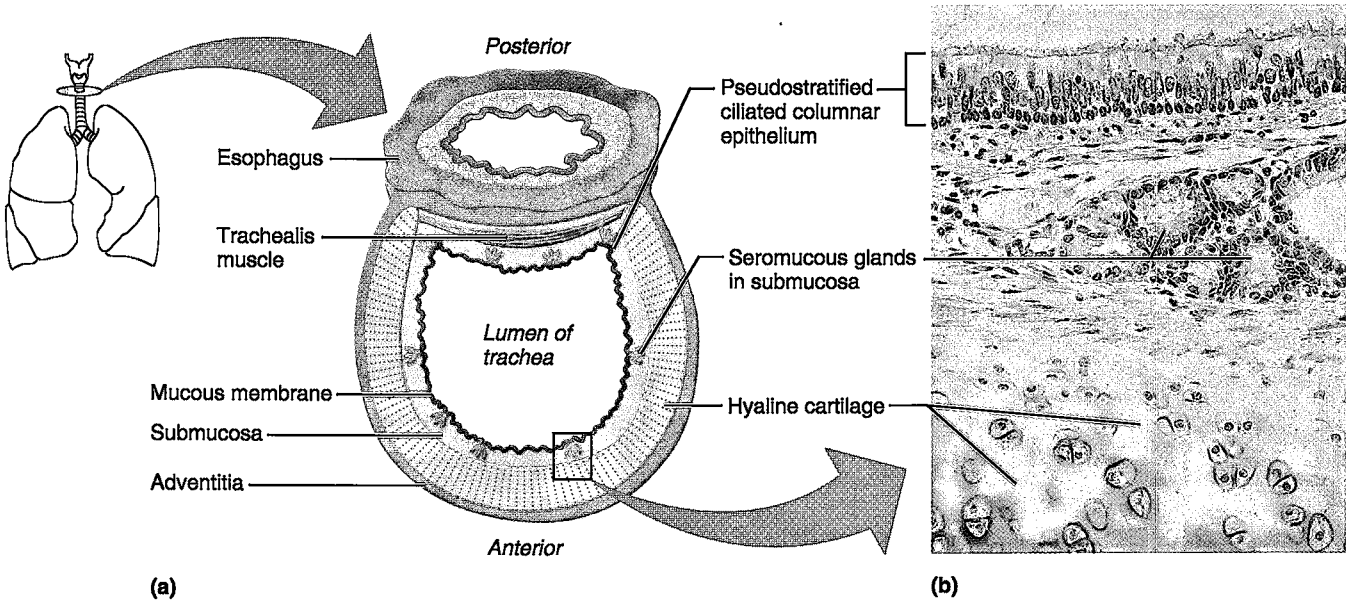
Inflammation of the vocal folds, or **laryngitis,** causes the vocal folds to swell, interfering with their vibration. This produces a change in the voice tone, hoarseness, or in severe cases inability to speak above a whisper. Laryngitis is also caused by overuse of the voice, very dry air, bacterial infections, tumors on the vocal folds, and inhalation of irritating chemicals. ●

Sphincter Functions of the Larynx

Under certain conditions, the vocal folds act as a sphincter that prevents air passage. During abdominal straining associated with defecation, the glottis closes to prevent exhalation and the abdominal muscles contract, causing the intra-abdominal pressure to rise. These events, collectively known as **Valsalva's maneuver,** help empty the rectum and can also splint (stabilize) the body trunk when one lifts a heavy load.

The Trachea

The **trachea** (tra'ke-ah), or *windpipe,* descends from the larynx through the neck and into the mediastinum. It ends by dividing into the two main



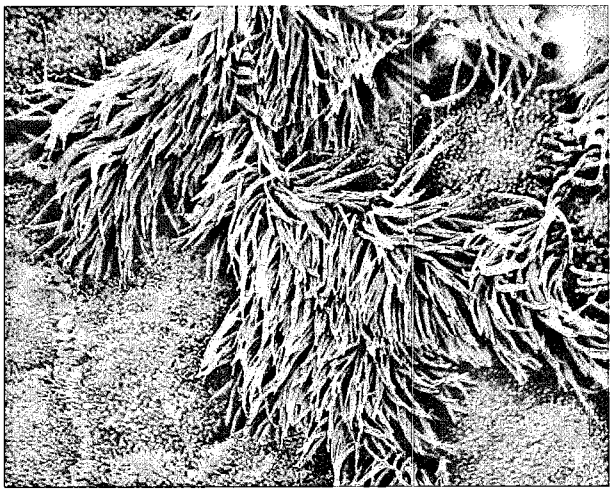


FIGURE 22.6 **Tissue composition of the tracheal wall.** **(a)** Cross-sectional view of the trachea, illustrating its relationship to the esophagus, the position of the supporting hyaline cartilage rings, and the trachealis muscle connecting the free ends of the cartilage rings. **(b)** Photomicrograph of a portion of the tracheal wall (cross-sectional view; 225×). **(c)** Scanning electron micrograph of cilia in the trachea (13,500×). The cilia appear as yellow, grasslike projections. Mucus-secreting goblet cells (orange) with short microvilli are interspersed between the ciliated cells. (See *A Brief Atlas of the Human Body*, Plate 40.)

bronchi at midthorax (see Figure 22.1). In humans, it is 10–12 cm (about 4 inches) long and 2 cm (3/4 inch) in diameter, and very flexible and mobile. Interestingly, early anatomists mistook the trachea for a rough-walled artery (*trachea* = rough).

The tracheal wall consists of several layers that are common to many tubular body organs—the *mucosa, submucosa,* and *adventitia* (Figure 22.6). The **mucosa** has the same goblet cell–containing pseudostratified epithelium that occurs throughout most of the respiratory tract. Its cilia continually propel debris-laden mucus toward the pharynx. This epithelium rests on a fairly thick lamina propria that has a rich supply of elastic fibers.

HOMEOSTATIC IMBALANCE

Smoking inhibits and ultimately destroys cilia, after which coughing is the only means of preventing mucus from accumulating in the lungs. For this reason, smokers with respiratory congestion should avoid medications that inhibit the cough reflex. ●

The **submucosa,** a connective tissue layer deep to the mucosa, contains seromucous glands that help produce the mucus "sheets" within the trachea. The outermost **adventitia** layer is a connective tissue layer reinforced internally by 16 to 20 C-shaped rings of hyaline cartilage (Figure 22.6). Because of its elastic elements, the trachea is flexible enough to stretch and move inferiorly during inspiration and recoil during expiration, but the cartilage rings prevent it from collapsing and keep the airway patent despite the pressure changes that occur during breathing. The open posterior parts of the cartilage rings, which abut the esophagus (see Figure 22.6a), are connected by smooth muscle fibers of the **trachealis muscle** and by soft connective tissue. Because this portion of the tracheal wall is not rigid, the esophagus can expand anteriorly as swallowed food passes through it. Contraction of the trachealis muscle decreases the trachea's diameter, causing expired air to rush upward from the lungs with greater force. This action helps to expel

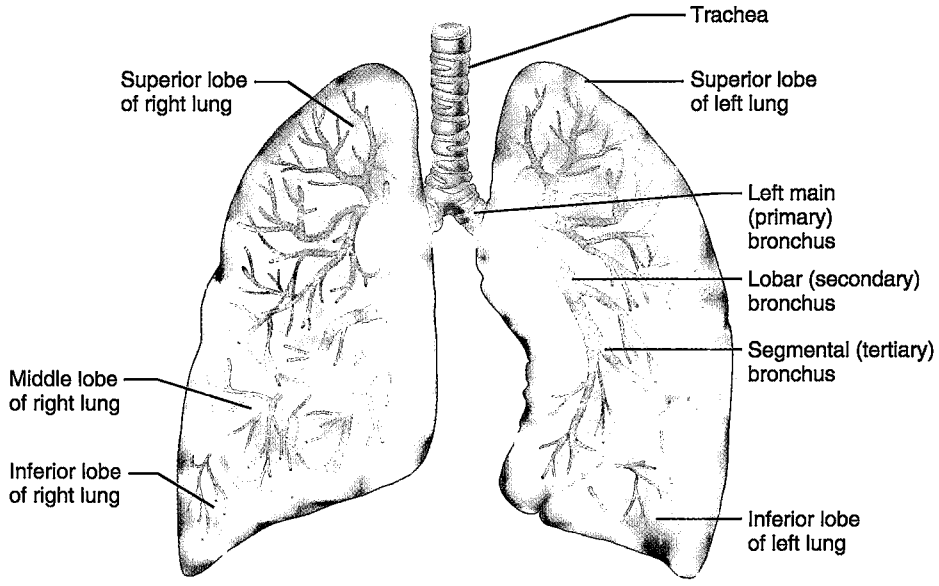

FIGURE 22.7 **Conducting zone passages.** The air pathway inferior to the larynx consists of the trachea and the main, lobar, and segmental bronchi, which branch into the smaller bronchi and bronchioles until the terminal bronchioles of the lungs are reached.

mucus from the trachea when we cough by accelerating the exhaled air to speeds of 100 mph! The last tracheal cartilage is expanded, and a spar of cartilage, called the **carina** (kar-ri'nah; "keel"), projects posteriorly from its inner face, marking the point where the trachea branches into the two *main bronchi.* The mucosa of the carina is highly sensitive and violent coughing is triggered when a foreign object makes contact with it.

HOMEOSTATIC IMBALANCE

Tracheal obstruction is life threatening. Many people have suffocated after choking on a piece of food that suddenly closed off their trachea. The **Heimlich maneuver,** a procedure in which air in the victim's lungs is used to "pop out," or expel, an obstructing piece of food, has saved many people from becoming victims of "café coronaries." The maneuver is simple to learn and easy to do. However, it is best learned by demonstration because cracked ribs are a distinct possibility when it is done incorrectly. ●

The Bronchi and Subdivisions: The Bronchial Tree

The bronchial tree (Figure 22.7) is the site where conducting zone structures give way to respiratory zone structures (Figure 22.8).

Conducting Zone Structures

The **right** and **left main (primary) bronchi** (brong'ki) are formed by the division of the trachea approximately at the level of T_7 in an erect (standing) person. Each bronchus runs obliquely in the mediastinum before plunging into the medial depression (hilum) of the lung on its own side (Figure 22.7). The right main bronchus is wider, shorter, and more vertical than the left and is the more common site for an inhaled foreign object to become lodged. By the time incoming air reaches the bronchi, it is warm, cleansed of most impurities, and saturated with water vapor.

Once inside the lungs, each main bronchus subdivides into **lobar (secondary) bronchi**—three on the right and two on the left—each supplying one lung lobe. The lobar bronchi branch into third-order **segmental (tertiary) bronchi,** which divide repeatedly into smaller and smaller bronchi (fourth-order, fifth-order, etc.). Overall, there are about 23 orders of branching air passageways in the lungs. Passages smaller than 1 mm in diameter are called **bronchioles** ("little bronchi"), and the tiniest of these, the **terminal bronchioles,** are less than 0.5 mm in diameter. Because of this branching pattern, the conducting network within the lungs is often called the **bronchial** or **respiratory tree.**

The tissue composition of the walls of the main bronchi mimics that of the trachea, but as the

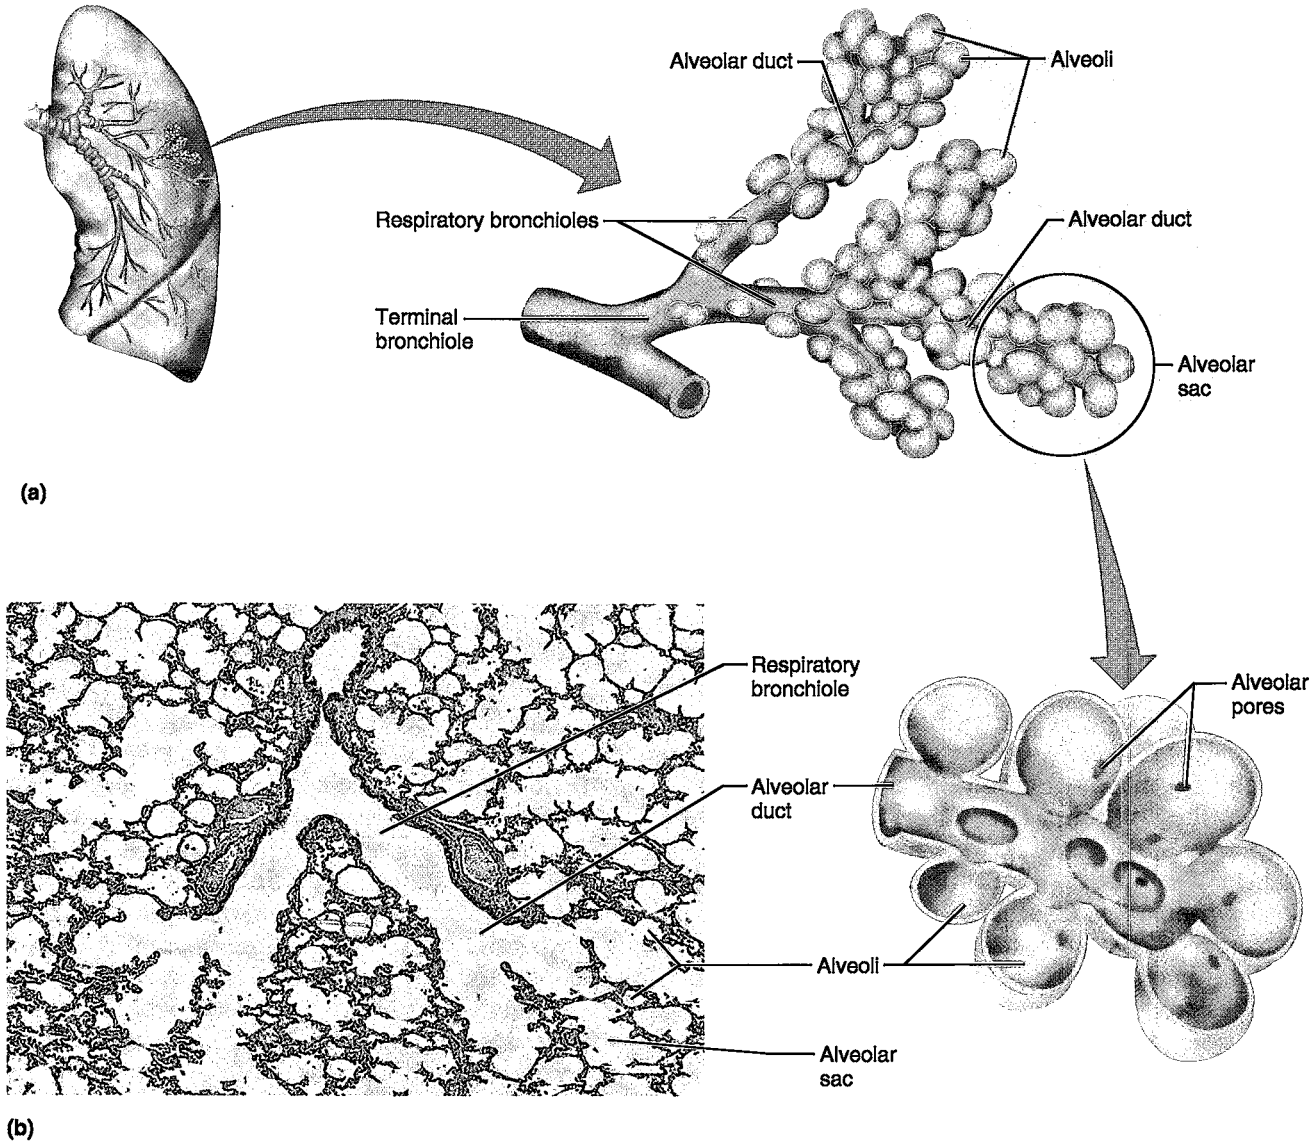

FIGURE 22.8 **Respiratory zone structures. (a)** Diagrammatic view of respiratory bronchioles, alveolar ducts, alveolar sacs, and alveoli. **(b)** Photomicrograph of a section of human lung, showing the respiratory structures that form the final divisions of the bronchial tree (40×). Notice the thinness of the alveolar walls. (See *A Brief Atlas of the Human Body,* Plate 41.)

conducting tubes become smaller, the following structural changes occur:

1. Support structures change. The cartilage rings are replaced by irregular *plates* of cartilage, and by the time the bronchioles are reached, supportive cartilage is no longer present in the tube walls. However, elastic fibers are found in the tube walls throughout the bronchial tree.

2. Epithelium type changes. The mucosal epithelium thins as it changes from pseudostratified columnar to columnar and then to cuboidal in the terminal bronchioles. Cilia are sparse, and mucus-producing cells are absent in the bronchioles. Thus, most airborne debris found at or below the level of the bronchioles is removed by macrophages in the alveoli.

3. Amount of smooth muscle increases. The relative amount of smooth muscle in the tube walls increases as the passageways become smaller. A complete layer of circular smooth muscle in the bronchioles and the lack of supporting cartilage (which would hinder constriction) allows the bronchioles to provide substantial resistance to air passage under certain conditions (described later).

Respiratory Zone Structures

Defined by the presence of thin-walled air sacs called **alveoli** (al-ve'o-li; *alveol* = small cavity), the

respiratory zone begins as the terminal bronchioles feed into **respiratory bronchioles** within the lung (Figure 22.8). Protruding from these smallest bronchioles are scattered alveoli. The respiratory bronchioles lead into winding **alveolar ducts,** whose walls consist of diffusely arranged rings of smooth muscle cells, connective tissue fibers, and outpocketing alveoli. The alveolar ducts lead into terminal clusters of alveoli called **alveolar sacs.** Many people mistakenly equate alveoli, the site of gas exchange, with alveolar sacs, but they are not the same thing. The alveolar sac is analogous to a bunch of grapes, and the alveoli are the individual grapes. The 300 million or so gas-filled alveoli in the lungs account for most of the lung volume and provide a tremendous surface area for gas exchange.

The Respiratory Membrane The walls of the alveoli are composed primarily of a single layer of squamous epithelial cells, called **type I cells,** surrounded by a flimsy basement membrane. The thinness of their walls is hard to imagine, but a sheet of tissue paper is much thicker. The external surfaces of the alveoli are densely covered with a "cobweb" of pulmonary capillaries (Figure 22.9). Together, the alveolar and capillary walls and their fused basement membranes form the **respiratory membrane,** a 0.5-μm-thick *air-blood barrier* that has gas on one side and blood flowing past on the other (Figure 22.9d). Gas exchanges occur readily by simple diffusion across the respiratory membrane—O_2 passes from the alveolus into the blood, and CO_2 leaves the blood to enter the gas-filled alveolus.

Scattered amid the type I squamous cells that form the major part of the alveolar walls are cuboidal **type II cells** (Figure 22.9c). The type II cells secrete a fluid containing surfactant that coats the gas-exposed alveolar surfaces. (Surfactant's role in reducing the surface tension of the alveolar fluid is described later in this chapter.)

The alveoli have three other significant features: (1) They are surrounded by fine elastic fibers of the same type that surround the entire bronchial tree. (2) Open **alveolar pores** connecting adjacent alveoli allow air pressure throughout the lung to be equalized and provide alternate air routes to any alveoli whose bronchi have collapsed due to disease. (3) Remarkably efficient **alveolar macrophages** crawl freely along the internal alveolar surfaces. Although huge numbers of infectious microorganisms are continuously carried into the alveoli, alveolar surfaces are usually sterile. Because the alveoli are "dead ends," aged and dead macrophages must be prevented from accumulating in them. Most macrophages simply get swept up by the ciliary current of superior regions and carried passively to the pharynx. In this manner, we clear and swallow over 2 million alveolar macrophages per hour!

The Lungs and Pleurae

Gross Anatomy of the Lungs

The paired **lungs** occupy all of the thoracic cavity except the mediastinum, which houses the heart, great blood vessels, bronchi, esophagus, and other organs (Figure 22.10). Each cone-shaped lung is suspended in its own pleural cavity and connected to the mediastinum by vascular and bronchial attachments, collectively called the lung **root.** The anterior, lateral, and posterior lung surfaces lie in close contact with the ribs and form the continuously curving **costal surface.** Just deep to the clavicle is the **apex,** the narrow superior tip of the lung. The concave, inferior surface that rests on the diaphragm is the **base.** On the mediastinal surface of each lung is an indentation, the **hilum,** through which pulmonary and systemic blood vessels enter and leave the lungs. Each main bronchus also plunges into the hilum on its own side and begins to branch almost immediately. All conducting and respiratory passageways distal to the main bronchi are found in the lungs.

Because the apex of the heart is slightly to the left of the median plane, the two lungs differ slightly in shape and size. The left lung is smaller than the right, and the **cardiac notch**—a concavity in its medial aspect—is molded to and accommodates the heart (see Figure 22.10a). The left lung is subdivided into superior and inferior **lobes** by the *oblique fissure,* whereas the right lung is partitioned into superior, middle, and inferior lobes by the *oblique* and *horizontal fissures.* Each lobe contains a number of pyramid-shaped **bronchopulmonary segments** separated from one another by connective tissue septa. Each segment is served by its own artery and vein and receives air from an individual segmental (tertiary) bronchus. Initially each lung contains ten bronchopulmonary segments arranged in similar (but not identical) patterns (Figure 22.11), but subsequent fusion of adjacent segmental arteries reduces the number in the left lung to eight or nine segments. The bronchopulmonary segments are clinically important because pulmonary disease is often confined to one or a few segments. Their connective tissue partitions allow diseased segments to be surgically removed without damaging neighboring healthy segments or impairing their blood supply.

The smallest subdivisions of the lung visible with the naked eye are the **lobules,** which appear at the lung surface as hexagons ranging from the size of a pencil eraser to the size of a penny (Figure 22.10b). Each lobule is served by a large bronchiole and its

branches. In most city dwellers and in smokers, the connective tissue that separates the individual lobules is blackened with carbon.

As mentioned earlier, the lungs consist largely of air spaces. The balance of lung tissue, or its **stroma** (literally "mattress" or "bed"), is mostly elastic connective tissue. As a result, the lungs are soft, spongy, elastic organs that together weigh just over 1 kg (2.2 lb). The elasticity of healthy lungs helps to reduce the work of breathing, as described shortly.

Blood Supply and Innervation of the Lungs

The lungs are perfused by two circulations, the pulmonary and the bronchial, which differ in size, origin, and function. Systemic venous blood that is to be oxygenated in the lungs is delivered by the **pulmonary arteries,** which lie anterior to the main bronchi (Figure 22.10c). In the lungs, the pulmonary arteries branch profusely along with the bronchi and finally feed into the **pulmonary capillary networks** surrounding the alveoli (see Figure 22.9a). Freshly oxygenated blood is conveyed from the respiratory zones of the lungs to the heart by the **pulmonary veins,** whose tributaries course back to the hilum both with the corresponding bronchi and in the connective tissue septa separating the bronchopulmonary segments.

The large-volume, low-pressure venous blood entering the lungs via the pulmonary arteries contrasts with the small-volume, high-pressure input via the bronchial arteries. The **bronchial arteries,** which provide systemic blood to lung tissue, arise from the aorta, enter the lungs at the hilum, and then run along the branching bronchi, supplying all lung tissues except the alveoli (these are supplied by the pulmonary circulation). Although some systemic venous blood is drained from the lungs by the tiny bronchial veins, there are multiple anastomoses between the two circulations, and most venous blood returns to the heart via the pulmonary veins.

Because *all* of the body's blood passes through the lungs about once each minute, the lung capillary endothelium is an ideal location for enzymes that act on materials in the blood. Examples include *angiotensin converting enzyme,* which activates an important blood pressure hormone, and enzymes that inactivate certain prostaglandins.

The lungs are innervated by parasympathetic and sympathetic motor fibers, and visceral sensory fibers. These nerve fibers enter each lung through the **pulmonary plexus** on the lung root and run along the bronchial tubes and blood vessels in the lungs. Parasympathetic fibers constrict the air tubes, whereas the sympathetic nervous system dilates them.

The Pleurae

The **pleurae** (ploo're; "sides") form a thin, double-layered serosa (see Figure 22.10). The layer called the **parietal pleura** covers the thoracic wall and superior face of the diaphragm. It continues around the

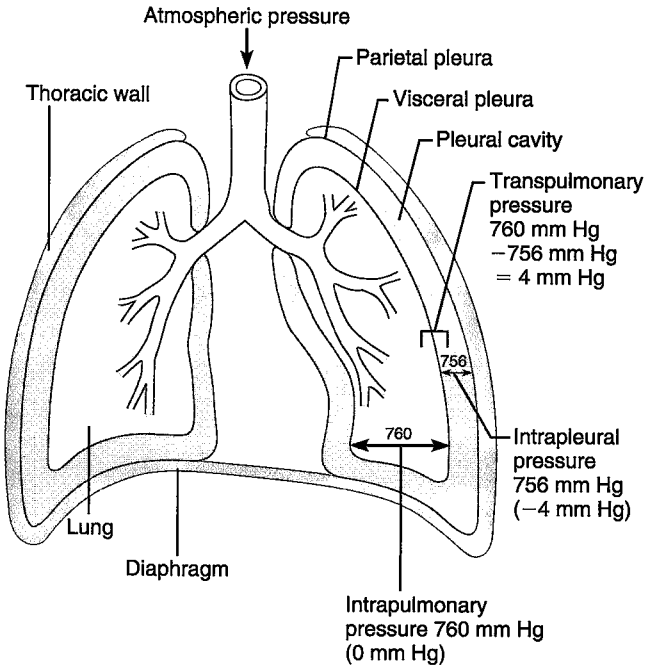

FIGURE 22.12 **Intrapulmonary and intrapleural pressure relationships.** Differences in pressure relative to atmospheric pressure (760 mm Hg) are given in parentheses. Values shown are at the end of a normal expiration. For illustration, the size of the pleural cavity has been greatly exaggerated.

heart and between the lungs, forming the lateral walls of the mediastinal enclosure and snugly enclosing the lung root. From here, the pleura extends as the layer called the **visceral pleura** to cover the external lung surface, dipping into and lining its fissures.

The pleurae produce **pleural fluid,** which fills the slitlike **pleural cavity** between them. This lubricating secretion allows the lungs to glide easily over the thorax wall during our breathing movements. Although the pleurae slide easily across each other, their separation is strongly resisted by the surface tension of the pleural fluid. Consequently, the lungs cling tightly to the thorax wall and are forced to expand and recoil passively as the volume of the thoracic cavity alternately increases and decreases during breathing.

The pleurae also help divide the thoracic cavity into three chambers—the central mediastinum and the two lateral pleural compartments, each containing a lung. This compartmentalization helps prevent one mobile organ (for example, the lung or heart) from interfering with another. It also limits the spread of local infections.

HOMEOSTATIC IMBALANCE

Pleurisy (ploo'rĭ-se), inflammation of the pleurae, often results from pneumonia. Inflamed pleurae become rough, resulting in friction and stabbing pain with each breath. As the disease progresses, the pleurae may produce an excessive amount of fluid. This increased fluid relieves the pain caused by pleural surfaces rubbing together, but may exert pressure on the lungs and hinder breathing movements.

Other fluids that may accumulate in the pleural cavity include blood (leakage from damaged blood vessels) and blood filtrate (the watery fluid that oozes from the lung capillaries when left-sided heart failure occurs). The general term for fluid accumulation in the pleural cavity is *pleural effusion.* ●

Mechanics of Breathing

Breathing, or **pulmonary ventilation,** consists of two phases: **inspiration,** the period when air flows into the lungs, and **expiration,** the period when gases exit the lungs.

Pressure Relationships in the Thoracic Cavity

Before we can begin to describe the breathing process, it is important to understand that *respiratory pressures are always described relative to* **atmospheric pressure (P_{atm}),** which is the pressure exerted by the air (gases) surrounding the body. At sea level, atmospheric pressure is 760 mm Hg (the pressure exerted by a column of mercury 760 mm high). This pressure can also be expressed in atmosphere units: atmospheric pressure = 760 mm Hg = 1 atm. A negative respiratory pressure in any respiratory area, such as −4 mm Hg, indicates that the pressure in that area is lower than atmospheric pressure by 4 mm Hg (760 − 4 = 756 mm Hg). A positive respiratory pressure is higher than atmospheric pressure and zero respiratory pressure is equal to atmospheric pressure. Now we are ready to examine the pressure relationships that normally exist in the thoracic cavity.

Intrapulmonary Pressure

The **intrapulmonary** (intra-alveolar) **pressure (P_{pul})** is the pressure in the alveoli. Intrapulmonary pressure rises and falls with the phases of breathing, but it *always* eventually equalizes with the atmospheric pressure (Figure 22.12).

Intrapleural Pressure

The pressure in the pleural cavity, the **intrapleural pressure (P_{ip}),** also fluctuates with breathing phases, but is always about 4 mm Hg less than P_{pul}. That is, P_{ip} is *always* negative relative to P_{pul}.

The question often asked is "How is this negative intrapleural pressure established?" or "What causes it?" Let's examine the forces that exist in the thorax to see if we can answer these questions. First of all, we know there are opposing forces. Two forces act to pull the lungs (visceral pleura) away from the thorax wall (parietal pleura) and cause lung collapse:

1. **The lungs' natural tendency to recoil.** Because of their elasticity, lungs always assume the smallest size possible.
2. **The surface tension of the alveolar fluid.** The surface tension of the alveolar fluid constantly acts to draw the alveoli to their smallest possible dimension.

However, these lung-collapsing forces are opposed by the natural elasticity of the chest wall, a force that tends to pull the thorax outward and to enlarge the lungs.

So which force wins? The answer is neither in a healthy person, because of the strong adhesive force between the parietal and visceral pleura. Pleural fluid secures the pleurae together in the same way a drop of water holds two glass slides together. The pleurae slide from side to side easily, but they remain closely apposed, and separating them requires extreme force. The net result of the dynamic interplay between these forces is a negative P_{ip}.

The amount of pleural fluid in the pleural cavity must remain minimal in order for the negative P_{ip} to be maintained. Active pumping of the pleural fluid out of the pleural cavity into the lymphatics occurs continuously. If it didn't, fluid would accumulate in the intrapleural space (remember, fluids move from high to low pressure), producing a positive pressure in the pleural cavity.

The importance of negative pressure in the intrapleural space and the tight coupling of the lungs to the thorax wall cannot be overemphasized. Any condition that equalizes P_{ip} with the intrapulmonary (or atmospheric) pressure causes *immediate lung collapse.* It is the **transpulmonary pressure**—the difference between the intrapulmonary and intrapleural pressures ($P_{pul} - P_{ip}$)—that keeps the air spaces of the lungs open or, phrased another way, keeps the lungs from collapsing. Moreover, it is the size of the transpulmonary pressure that determines the size of the lungs at any time—the greater the transpulmonary pressure, the larger the lungs.

HOMEOSTATIC IMBALANCE

Atelectasis (at"ĕ-lik'tah-sis), or lung collapse, occurs when a bronchiole becomes plugged (as may follow pneumonia). Its associated alveoli then absorb all of their air and collapse. Atelectasis can also occur when air enters the pleural cavity either through a chest wound, or due to rupture of the visceral pleura, which allows air to enter the pleural cavity from the respiratory tract. The presence of air in the intrapleural space is referred to as a **pneumothorax** (nu"mo-tho'raks; "air thorax"). The condition is reversed by closing the "hole" and drawing air out of the intrapleural space with chest tubes, which allows the lung to reinflate and resume its normal function. Note that because the lungs are in separate cavities, one lung can collapse without interfering with the function of the other. ●

Pulmonary Ventilation: Inspiration and Expiration

Pulmonary ventilation is a mechanical process that depends on volume changes in the thoracic cavity. A rule to keep in mind throughout the following discussion is that *volume changes* lead to *pressure changes,* and pressure changes lead to the *flow of gases* to equalize the pressure.

The relationship between the pressure and volume of a gas is given by **Boyle's law:** At constant temperature, the pressure of a gas varies inversely with its volume. That is,

$$P_1V_1 = P_2V_2$$

where P is the pressure of the gas, V is its volume, and subscripts 1 and 2 represent the initial and resulting conditions respectively.

Gases always *fill* their container. Therefore, in a large container, the molecules in a given amount of gas will be far apart and the pressure will be low. But if the volume of the container is reduced, the gas molecules will be forced closer together and the pressure will rise. A good example is an inflated automobile tire. The tire is hard and strong enough to bear the weight of the car because air is compressed to about one-third of its atmospheric volume in the tire, providing the high pressure. Now let us see how this relates to inspiration and expiration.

Inspiration

Visualize the thoracic cavity as a gas-filled box with a single entrance at the top, the tubelike trachea. The volume of this box is changeable and can be increased by enlarging all of its dimensions, thereby decreasing the gas pressure inside it. This drop in pressure causes air to rush into the box from the atmosphere, because gases always flow down their pressure gradients.

The same thing happens during normal quiet inspiration, when the **inspiratory muscles**—the diaphragm and external intercostal muscles—are activated. Here's how quiet inspiration works:

	Sequence of events	Changes in anterior-posterior and superior-inferior dimensions	Changes in lateral dimensions
Inspiration	① Inspiratory muscles contract (diaphragm descends; rib cage rises) ↓ ② Thoracic cavity volume increases ↓ ③ Lungs stretched; intrapulmonary volume increases ↓ ④ Intrapulmonary pressure drops (to −1 mm Hg) ↓ ⑤ Air (gases) flows into lungs down its pressure gradient until intrapulmonary pressure is 0 (equal to atmospheric pressure)		Expiration	① Inspiratory muscles relax (diaphragm rises; rib cage descends due to recoil of costal cartilages) ↓ ② Thoracic cavity volume decreases ↓ ③ Elastic lungs recoil passively; intrapulmonary volume decreases ↓ ④ Intrapulmonary pressure rises (to +1 mm Hg) ↓ ⑤ Air (gases) flows out of lungs down its pressure gradient until intrapulmonary pressure is 0		
FIGURE 22.13 **Changes in thoracic volume during inspiration (top) and expiration (bottom).** The sequence of events in the left column includes volume changes during inspiration and expiration. The lateral views in the middle column show changes in the superior-inferior dimension (as the diaphragm alternately contracts and relaxes) and in the anterior-posterior dimension (as the external intercostal muscles alternately contract and relax). The superior views of transverse thoracic sections in the right column show lateral dimension changes resulting from alternate contraction and relaxation of the external intercostal muscles.

1. Action of the diaphragm. When the dome-shaped diaphragm contracts, it moves inferiorly and flattens out (Figure 22.13, top). As a result, the superior-inferior dimension (height) of the thoracic cavity increases.

2. Action of the intercostal muscles. Contraction of the external intercostal muscles lifts the rib cage and pulls the sternum superiorly (Figure 22.13, top). Because the ribs curve downward as well as forward around the chest wall, the broadest lateral and anteroposterior dimensions of the rib cage are normally directed obliquely downward. But when the ribs are raised and drawn together, they swing outward,

expanding the diameter of the thorax both laterally and in the anteroposterior plane. This is much like the action that occurs when a curved bucket handle is raised.

Although these actions expand the thoracic dimensions by only a few millimeters along each plane, this is enough to increase thoracic volume by almost 500 ml—the usual volume of air that enters the lungs during a normal quiet inspiration. Of the two types of inspiratory muscles, the diaphragm is far more important in producing the volume changes that lead to normal quiet inspiration.

As the thoracic dimensions increase during inspiration, the lungs are stretched and the intrapulmonary volume increases. As a result, P_{pul} drops about 1 mm Hg relative to P_{atm}. Anytime the intrapulmonary pressure is less than the atmospheric pressure ($P_{pul} < P_{atm}$), air rushes into the lungs along the pressure gradient. Inspiration ends when $P_{pul} = P_{atm}$. During the same period, P_{ip} declines to about −6 mm Hg relative to P_{atm} (Figure 22.14).

During the *deep* or *forced inspirations* that occur during vigorous exercise and in some chronic obstructive pulmonary diseases, the thoracic volume is further increased by activity of accessory muscles. Several muscles, including the scalenes and sternocleidomastoid muscles of the neck and the pectoralis minor of the chest, raise the ribs even more than occurs during quiet inspiration. Additionally, the back extends as the thoracic curvature is straightened by the erector spinae muscles.

Expiration

Quiet expiration in healthy individuals is a passive process that depends more on lung elasticity than on muscle contraction. As the inspiratory muscles relax and resume their resting length, the rib cage descends and the lungs recoil. Thus, both the thoracic and intrapulmonary volumes decrease. This volume decrease compresses the alveoli, and P_{pul} rises to about 1 mm Hg above atmospheric pressure (see Figure 22.14). When $P_{pul} > P_{atm}$, the pressure gradient forces gases to flow out of the lungs.

Forced expiration is an active process produced by contraction of abdominal wall muscles, primarily the oblique and transversus muscles. These contractions (1) increase the intra-abdominal pressure, which forces the abdominal organs superiorly against the diaphragm, and (2) depress the rib cage. The internal intercostal muscles also help to depress the rib cage and decrease thoracic volume.

Control of accessory muscles of expiration is important when precise regulation of air flow from the lungs is desired. For instance, the ability of a trained vocalist to hold a musical note depends on the coordinated activity of several muscles normally used in forced expiration.

Q *As thoracic volume increases, what happens to the intrapulmonary pressure? To the intrapleural pressure?*

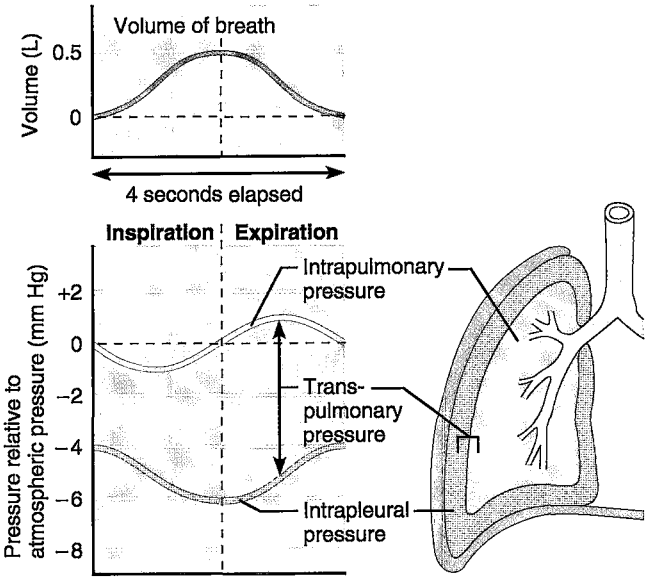

FIGURE 22.14 **Changes in intrapulmonary and intrapleural pressures during inspiration and expiration.** Notice that normal atmospheric pressure (760 mm Hg) is given a value of 0 on the scale.

Physical Factors Influencing Pulmonary Ventilation

As we have seen, the lungs are stretched during inspiration and recoil passively during expiration. The inspiratory muscles consume energy to enlarge the thorax. Energy is also used to overcome various factors that hinder air passage and pulmonary ventilation. These factors are examined next.

Airway Resistance

The major *nonelastic* source of resistance to gas flow is friction, or drag, encountered in the respiratory passageways. The relationship between gas flow (F), pressure (P), and resistance (R) is given by the following equation:

$$F = \frac{\Delta P}{R}$$

Notice that the factors determining gas flow in the respiratory passages and blood flow in the cardiovascular system are equivalent. The amount of gas flowing into and out of the alveoli is directly proportional to ΔP, the *difference* in pressure, or the pressure gradient,

A They both decrease.

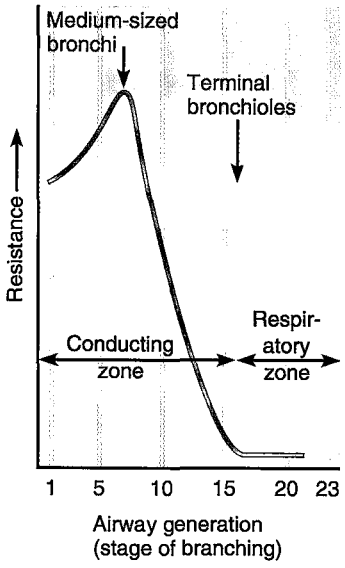

FIGURE 22.15 **Resistance in respiratory passageways.** Airway resistance peaks in the medium-sized bronchi and then declines sharply as the total cross-sectional area of the airway increases rapidly.

between the external atmosphere and the alveoli. Normally, very small differences in pressure produce large changes in the volume of gas flow. The average pressure gradient during normal quiet breathing is 2 mm Hg or less, and yet it is sufficient to move 500 ml of air in and out of the lungs with each breath.

But, as the equation also indicates, gas flow changes *inversely* with resistance. That is, gas flow decreases as resistance increases. As with the cardiovascular system, resistance in the respiratory tree is determined mostly by the diameters of the conducting tubes. However, as a rule, airway resistance is insignificant for two reasons:

1. Airway diameters in the first part of the conducting zone are huge, relative to the low viscosity of air.
2. As the airways get progressively smaller, there are progressively more branches. As a result, although individual bronchioles are tiny, there are an enormous number of them in parallel, so the total cross-sectional area is huge.

Hence, as shown in Figure 22.15, the greatest resistance to gas flow occurs in the medium-sized bronchi. At the terminal bronchioles, gas flow stops and diffusion takes over as the main force driving gas movement, so resistance is no longer an issue.

HOMEOSTATIC IMBALANCE

Smooth muscle of the bronchiolar walls is exquisitely sensitive to neural controls and certain chemicals. For example, inhaled irritants activate a reflex of the parasympathetic division of the nervous system that causes vigorous constriction of the bronchioles and dramatically reduces air passage. During an *acute asthma attack,* histamine and other inflammatory chemicals can cause such strong bronchoconstriction that pulmonary ventilation almost completely stops, regardless of the pressure gradient. Conversely, epinephrine released during sympathetic nervous system activation or administered as a drug dilates bronchioles and reduces airway resistance. Local accumulations of mucus, infectious material, or solid tumors in the passageways are important sources of airway resistance in those with respiratory disease.

Whenever airway resistance rises, breathing movements become more strenuous, but such compensation has its limits. When the bronchioles are severely constricted or obstructed, even the most magnificent respiratory efforts cannot restore ventilation to life-sustaining levels. ◉

Alveolar Surface Tension

At any gas-liquid boundary, the molecules of the liquid are more strongly attracted to each other than to the gas molecules. This unequal attraction produces a state of tension at the liquid surface, called **surface tension,** that (1) draws the liquid molecules closer together and reduces their contact with the dissimilar gas molecules, and (2) resists any force that tends to increase the surface area of the liquid.

Water is composed of highly polar molecules and has a very high surface tension. Because water is the major component of the liquid film that coats the alveolar walls, it is always acting to reduce the alveoli to their smallest possible size. If the film was pure water, the alveoli would collapse between breaths. But the alveolar film contains **surfactant** (ser-fak'tant), a detergent-like complex of lipids and proteins produced by the type II alveolar cells. Surfactant decreases the cohesiveness of water molecules, much the way a laundry detergent reduces the attraction of water for water, allowing water to interact with and pass through fabric. As a result, the surface tension of alveolar fluid is reduced, and less energy is needed to overcome those forces to expand the lungs and discourage alveolar collapse. Breaths that are deeper than normal stimulate type II cells to secrete more surfactant.

HOMEOSTATIC IMBALANCE

When too little surfactant is present, surface tension forces can collapse the alveoli. Once this happens, the alveoli must be completely reinflated during each inspiration, an effort that uses tremendous amounts of energy. This is the problem faced by newborns

with **infant respiratory distress syndrome (IRDS)**, a condition peculiar to premature babies. Since inadequate pulmonary surfactant is produced until the last two months of fetal development, babies born prematurely often are unable to keep their alveoli inflated between breaths. IRDS is treated with positive-pressure respirators that force air into the alveoli, keeping them open between breaths. Spraying natural or synthetic surfactant into the newborn's respiratory passageways also helps.

Many IRDS survivors suffer from *bronchopulmonary dysplasia*, a chronic lung disease, during childhood and beyond. This condition is believed to result from inflammatory injury to respiratory zone structures caused by use of the respirator on the newborn's delicate lungs. ●

Lung Compliance

Healthy lungs are unbelievably stretchy, and this distensibility is referred to as **lung compliance.** Specifically, lung compliance (C_L) is a measure of the change in lung volume (ΔV_L) that occurs with a given change in the transpulmonary pressure [$\Delta(P_{pul} - P_{ip})$]. This is stated as

$$C_L = \frac{\Delta V_L}{\Delta(P_{pul} - P_{ip})}$$

The more a lung expands for a given rise in transpulmonary pressure, the greater its compliance. Said another way, the higher the lung compliance, the easier it is to expand the lungs at any given transpulmonary pressure.

Lung compliance is determined largely by two factors: (1) distensibility of the lung tissue, and (2) alveolar surface tension. Because lung distensibility is generally high and alveolar surface tension is kept low by surfactant, the lungs of healthy people tend to have high compliance, which favors efficient ventilation.

Lung compliance is diminished by a decrease in the natural resilience of the lungs. Chronic inflammation, or infections such as tuberculosis, can cause nonelastic scar tissue to replace normal lung tissue *(fibrosis)*. Another factor that can decrease lung compliance is a decrease in production of surfactant. The lower the lung compliance, the more energy is needed just to breathe.

Since the lungs are contained within the thoracic cavity, we also need to consider the compliance (distensibility) of the thoracic wall. Factors that decrease the compliance of the thoracic wall hinder the expansion of the lungs. The total compliance of the respiratory system is comprised of lung compliance and thoracic wall compliance.

HOMEOSTATIC IMBALANCE

Deformities of the thorax, ossification of the costal cartilages (common during old age), and paralysis of the intercostal muscles all reduce total respiratory compliance by hindering thoracic expansion. ●

Respiratory Volumes and Pulmonary Function Tests

The amount of air flushed in and out of the lungs depends on the conditions of inspiration and expiration. Consequently, several respiratory volumes can be described. Specific combinations of these respiratory volumes, called *respiratory capacities*, are measured to gain information about a person's respiratory status.

Respiratory Volumes

The four **respiratory volumes** of interest are tidal, inspiratory reserve, expiratory reserve, and residual. The values recorded in Figure 22.16a (and used in the following text) represent normal values for a healthy 20-year-old male weighing about 70 kg (155 lb). Figure 22.16b provides average values for males and females.

During normal quiet breathing, about 500 ml of air moves into and then out of the lungs with each breath. This respiratory volume is the **tidal volume (TV).** The amount of air that can be inspired forcibly beyond the tidal volume (2100 to 3200 ml) is called the **inspiratory reserve volume (IRV).**

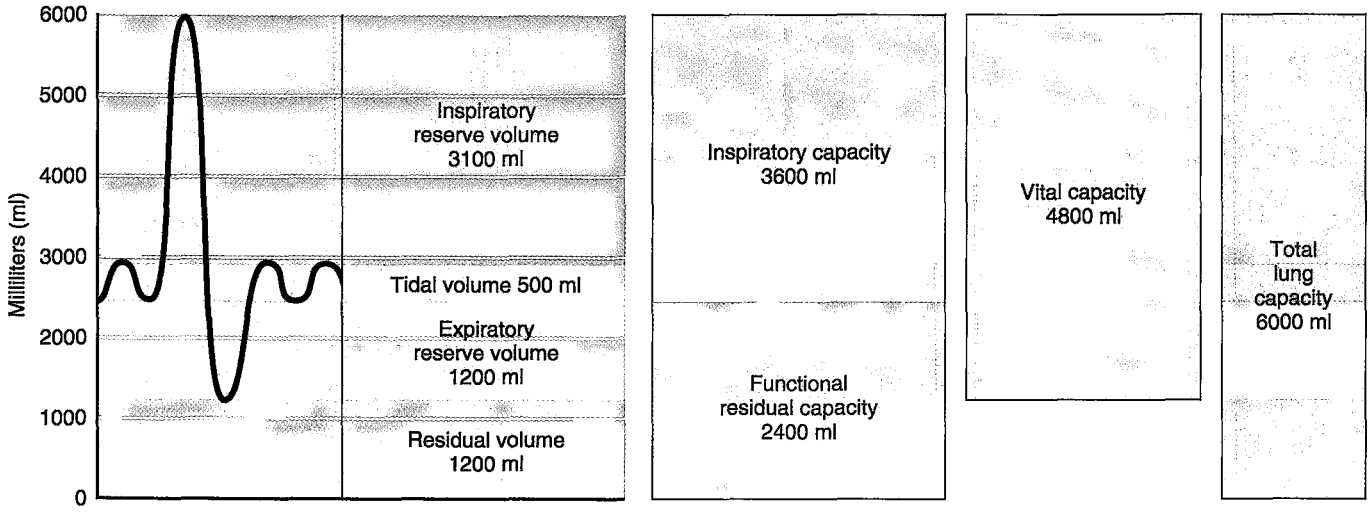
The **expiratory reserve volume (ERV)** is the amount of air—normally 1000 to 1200 ml—that can be evacuated from the lungs after a tidal expiration. Even after the most strenuous expiration, about 1200 ml of air remains in the lungs; this is the **residual volume (RV),** which helps to keep the alveoli patent (open) and to prevent lung collapse.

Respiratory Capacities

The **respiratory capacities** include inspiratory capacity, functional residual capacity, vital capacity, and total lung capacity (Figure 22.16). As noted, the respiratory capacities always consist of two or more lung volumes.

The **inspiratory capacity (IC)** is the total amount of air that can be inspired after a tidal expiration; thus, it is the sum of TV and IRV. The **functional residual capacity (FRC)** is the combined RV and ERV and represents the amount of air remaining in the lungs after a tidal expiration.

Vital capacity (VC) is the total amount of exchangeable air. It is the sum of TV, IRV, and ERV. In healthy young males, VC is approximately 4800 ml. The **total lung capacity (TLC)** is the sum of all lung volumes and is normally around 6000 ml. As



(a) Spirographic record for a male

	Measurement	Adult male average value	Adult female average value	Description
Respiratory volumes	Tidal volume (TV)	500 ml	500 ml	Amount of air inhaled or exhaled with each breath under resting conditions
	Inspiratory reserve volume (IRV)	3100 ml	1900 ml	Amount of air that can be forcefully inhaled after a normal tidal volume inhalation
	Expiratory reserve volume (ERV)	1200 ml	700 ml	Amount of air that can be forcefully exhaled after a normal tidal volume exhalation
	Residual volume (RV)	1200 ml	1100 ml	Amount of air remaining in the lungs after a forced exhalation
Respiratory capacities	Total lung capacity (TLC)	6000 ml	4200 ml	Maximum amount of air contained in lungs after a maximum inspiratory effort: TLC = TV + IRV + ERV + RV
	Vital capacity (VC)	4800 ml	3100 ml	Maximum amount of air that can be expired after a maximum inspiratory effort: VC = TV + IRV + ERV (should be 80% TLC)
	Inspiratory capacity (IC)	3600 ml	2400 ml	Maximum amount of air that can be inspired after a normal expiration: IC = TV + IRV
	Functional residual capacity (FRC)	2400 ml	1800 ml	Volume of air remaining in the lungs after a normal tidal volume expiration: FRC = ERV + RV

(b) Summary of respiratory volumes and capacities for males and females

FIGURE 22.16 **Respiratory volumes and capacities. (a)** Idealized spirographic record of respiratory volumes, in a healthy young 70-kg adult male. **(b)** Respiratory volumes and capacities for males and females.

indicated in Figure 22.16b, lung volumes and capacities (with the possible exception of TV) tend to be smaller in women than in men because of women's smaller size.

Dead Space

Some of the inspired air fills the conducting respiratory passageways and never contributes to gas exchange in the alveoli. The volume of these conducting zone conduits, which make up the **anatomical dead space,** typically amounts to about 150 ml. (The rule of thumb is that the anatomical dead space volume in a healthy young adult is equal to 1 ml per pound of ideal body weight.) This means that if TV is 500 ml, only 350 ml of it is involved in alveolar ventilation. The remaining 150 ml of the tidal breath is in the anatomical dead space.

If some alveoli cease to act in gas exchange (due to alveolar collapse or obstruction by mucus, for example), the **alveolar dead space** is added to the anatomical dead space, and the sum of the

TABLE 22.2 Effects of Breathing Rate and Depth on Alveolar Ventilation of Three Hypothetical Patients

BREATHING PATTERN OF HYPOTHETICAL PATIENT	DEAD SPACE VOLUME (*DSV*)	TIDAL VOLUME (*TV*)	RESPIRATORY RATE*	MINUTE VENTILATION (MVR)	ALVEOLAR VENTILATION (AVR)	% EFFECTIVE VENTILATION (AVR/MVR)
I—Normal rate and depth	150 ml	500 ml	20/min	10,000 ml/min	7000 ml/min	70%
II—Slow, deep breathing	150 ml	1000 ml	10/min	10,000 ml/min	8500 ml/min	85%
III—Rapid, shallow breathing	150 ml	250 ml	40/min	10,000 ml/min	4000 ml/min	40%

*Respiratory rate values are artificially adjusted to provide equivalent minute respiratory volumes as a baseline for comparison of alveolar ventilation.

nonuseful volumes is referred to as **total dead space.**

Pulmonary Function Tests

Because the various lung volumes and capacities are often abnormal in people with pulmonary disorders, they are routinely measured in such patients. The original clinical measuring device, a **spirometer** (spi-rom'ĕ-ter), was a simple instrument utilizing a hollow bell inverted over water. Now patients simply blow into a small electronic measuring device. Spirometry is most useful for evaluating losses in respiratory function and for following the course of certain respiratory diseases. Although it cannot provide a specific diagnosis, it can distinguish between *obstructive pulmonary disease* involving increased airway resistance (such as chronic bronchitis) and *restrictive disorders* involving a reduction in total lung capacity resulting from structural or functional changes in the lungs (due to diseases such as tuberculosis, or to fibrosis due to exposure to certain environmental agents such as asbestos). Increases in TLC, FRC, and RV may occur as a result of hyperinflation of the lungs in obstructive disease, whereas VC, TLC, FRC, and RV are reduced in restrictive diseases, which limit lung expansion.

More information can be obtained about a patient's ventilation status by assessing the rate at which gas moves into and out of the lungs. The **minute ventilation** is the total amount of gas that flows into or out of the respiratory tract in 1 minute. During normal quiet breathing, the minute ventilation in healthy people is about 6 L/min (500 ml per breath multiplied by 12 breaths per minute). During vigorous exercise, the minute ventilation may reach 200 L/min.

Two other useful tests are FVC and FEV. **FVC,** or **forced vital capacity,** measures the amount of gas expelled when a subject takes a deep breath and then forcefully exhales maximally and as rapidly as possible. **FEV,** or **forced expiratory volume,** determines the amount of air expelled during specific time intervals of the FVC test. For example, the volume exhaled during the first second is FEV_1. Those with healthy lungs can exhale about 80% of the FVC within 1 second. Those with obstructive pulmonary disease exhale considerably less than 80% of the FVC within 1 second, while those with restrictive disease can exhale 80% or more of FVC in 1 second even though their FVC is reduced.

Alveolar Ventilation

Minute ventilation values provide a rough yardstick for assessing respiratory efficiency, but the **alveolar ventilation rate (AVR)** is a better index of effective ventilation. The AVR takes into account the volume of air wasted in the dead space and measures the flow of fresh gases in and out of the alveoli during a particular time interval. AVR is computed with this equation:

$$\underset{\text{(ml/min)}}{\text{AVR}} = \underset{\text{(breaths/min)}}{\text{frequency}} \times \underset{\text{(ml/breath)}}{(\text{TV} - \text{dead space})}$$

In healthy people, AVR is usually about 12 breaths per minute times the difference of 500 − 150 ml per breath, or 4200 ml/min.

Because anatomical dead space is constant in a particular individual, increasing the volume of each inspiration (breathing depth) enhances AVR and gas exchange more than raising the respiratory rate. AVR drops dramatically during rapid shallow breathing because most of the inspired air never reaches the exchange sites. Furthermore, as tidal volume approaches the dead space value, effective ventilation approaches zero, regardless of how fast a person is breathing. The effects of breathing rate and breathing depth on alveolar ventilation are summarized for three hypothetical patients in Table 22.2.

TABLE 22.3 Nonrespiratory Air (Gas) Movements

MOVEMENT	MECHANISM AND RESULT
Cough	Taking a deep breath, closing glottis, and forcing air superiorly from lungs against glottis; glottis opens suddenly and a blast of air rushes upward; can dislodge foreign particles or mucus from lower respiratory tract and propel such substances superiorly
Sneeze	Similar to a cough, except that expelled air is directed through nasal cavities as well as through oral cavity; depressed uvula routes air upward through nasal cavities; sneezes clear upper respiratory passages
Crying	Inspiration followed by release of air in a number of short expirations; primarily an emotionally induced mechanism
Laughing	Essentially same as crying in terms of air movements produced; also an emotionally induced response
Hiccups	Sudden inspirations resulting from spasms of diaphragm; believed to be initiated by irritation of diaphragm or phrenic nerves, which serve diaphragm; sound occurs when inspired air hits vocal folds of closing glottis
Yawn	Very deep inspiration, taken with jaws wide open; not believed to be triggered by levels of oxygen or carbon dioxide in blood; ventilates all alveoli (not the case in normal quiet breathing)

Nonrespiratory Air Movements

Many processes other than breathing move air into or out of the lungs, and these processes may modify the normal respiratory rhythm. Most of these **nonrespiratory air movements** result from reflex activity, but some are produced voluntarily. The most common of these movements are described in Table 22.3.

Gas Exchanges Between the Blood, Lungs, and Tissues

As you've discovered, during *external respiration* oxygen enters and carbon dioxide leaves the blood in the lungs. At the body tissues, where the process is called *internal respiration*, the same gases move in opposite directions by the same mechanism (diffusion). To understand these processes, we must examine some of the physical properties of gases and consider the composition of alveolar gas.

Basic Properties of Gases

Two more gas laws provide most of the information we need—*Dalton's law of partial pressures* reveals how a gas behaves when it is part of a mixture of gases, and *Henry's law* will help us understand movement of gases into and out of solution.

Dalton's Law of Partial Pressures

Dalton's law of partial pressures states that the total pressure exerted by a mixture of gases is the sum of the pressures exerted independently by each gas in the mixture. Further, the pressure exerted by each gas—its **partial pressure**—is directly proportional to the percentage of that gas in the gas mixture.

As indicated in Table 22.4, nitrogen makes up about 79% of air, and the partial pressure of nitrogen (P_{N_2}) is 78.6% × 760 mm Hg, or 597 mm Hg. Oxygen gas, which accounts for nearly 21% of the atmosphere, has a partial pressure (P_{O_2}) of 159 mm Hg (20.9% × 760 mm Hg). Thus, nitrogen and oxygen together contribute about 99% of the total atmospheric pressure. Air also contains 0.04% carbon dioxide, up to 0.5% water vapor, and insignificant amounts of inert gases (such as argon and helium).

At high altitudes, where the atmosphere is less influenced by gravity, partial pressures decline in direct proportion to the decrease in atmospheric pressure. For example, at 10,000 feet above sea level where the atmospheric pressure is 523 mm Hg, P_{O_2} is 110 mm Hg. Moving in the opposite direction, atmospheric pressure increases by 1 atm (760 mm Hg) for each 33 feet of descent (in water) below sea level. Thus, at 99 feet below sea level, the total pressure exerted on the body is equivalent to 4 atm, or 3040 mm Hg, and the partial pressure exerted by each component gas is also quadrupled.

Henry's Law

According to **Henry's law,** when a mixture of gases is in contact with a liquid, each gas will dissolve in the liquid in proportion to its partial pressure. Thus the greater the concentration of a particular gas in the gas phase, the more and the faster that gas will go into solution in the liquid. At equilibrium, the gas partial pressures in the two phases are the same. If, however, the partial pressure of one of the gases later becomes greater in the liquid than in the adjacent gas phase, some of the dissolved gas molecules will reenter the gaseous phase. So the direction and amount of movement of each gas is determined by its partial pressure in the two phases. This flexible situation is exactly

TABLE 22.4 Comparison of Gas Partial Pressures and Approximate Percentages in the Atmosphere and in the Alveoli

	ATMOSPHERE (SEA LEVEL)		ALVEOLI	
GAS	APPROXIMATE PERCENTAGE	PARTIAL PRESSURE (mm Hg)	APPROXIMATE PERCENTAGE	PARTIAL PRESSURE (mm Hg)
N_2	78.6	597	74.9	569
O_2	20.9	159	13.7	104
CO_2	0.04	0.3	5.2	40
H_2O	0.46	3.7	6.2	47
	100.0%	760	100.0%	760

what occurs when gases are exchanged in the lungs and tissues.

How much of a gas will dissolve in a liquid at any given partial pressure also depends on the solubility of the gas in the liquid and on the temperature of the liquid. The gases in air have very different solubilities in water (and in plasma). Carbon dioxide is most soluble. Oxygen is only 1/20 as soluble as CO_2, and N_2 is only half as soluble as O_2. Thus, at a given partial pressure, much more CO_2 than O_2 dissolves in water, and practically no N_2 goes into solution. The effect of increasing the liquid's temperature is to decrease gas solubility. Think of club soda, which is produced by forcing CO_2 gas to dissolve in water under high pressure. If you take the cap off a refrigerated bottle of club soda and allow it to stand at room temperature, in just a few minutes you will have plain water—all the CO_2 gas will have escaped from solution.

Hyperbaric oxygen chambers provide clinical applications of Henry's law. These chambers contain O_2 gas at pressures higher than 1 atm and are used to force greater-than-normal amounts of O_2 into the blood of patients suffering from carbon monoxide poisoning or tissue damage following radiation therapy. Hyperbaric therapy is also used to treat individuals with gas gangrene, because the anaerobic bacteria causing this infection cannot live in the presence of high O_2 levels. Scuba diving provides another illustration of Henry's law (see *A Closer Look* on pp. 868–869).

HOMEOSTATIC IMBALANCE

Although breathing O_2 gas at 2 atm is not a problem for short periods, **oxygen toxicity** develops rapidly when P_{O_2} is greater than 2.5–3 atm. Excessively high O_2 concentrations generate huge amounts of harmful free radicals, resulting in profound CNS disturbances, coma, and death. ●

Composition of Alveolar Gas

As shown in Table 22.4, the gaseous makeup of the atmosphere is quite different from that in the alveoli. The atmosphere is almost entirely O_2 and N_2; the alveoli contain more CO_2 and water vapor and much less O_2. These differences reflect the effects of (1) gas exchanges occurring in the lungs (O_2 diffuses from the alveoli into the pulmonary blood and CO_2 diffuses in the opposite direction), (2) humidification of air by conducting passages, and (3) the mixing of alveolar gas that occurs with each breath. Because only 500 ml of air is inspired with each tidal inspiration, gas in the alveoli is actually a mixture of newly inspired gases and gases remaining in the respiratory passageways between breaths.

The alveolar partial pressures of O_2 and CO_2 are easily changed by increasing breathing depth and rate. A high AVR brings more O_2 into the alveoli, increasing alveolar P_{O_2}, and rapidly eliminates CO_2 from the lungs.

External Respiration: Pulmonary Gas Exchange

During external respiration, dark red blood flowing through the pulmonary circuit is transformed into the scarlet river that is returned to the heart for distribution by systemic arteries to all body tissues. Although this color change is due to O_2 uptake and binding to hemoglobin in red blood cells (RBCs), CO_2 exchange (unloading) is occurring equally fast.

The following three factors influence the movement of oxygen and carbon dioxide across the respiratory membrane:

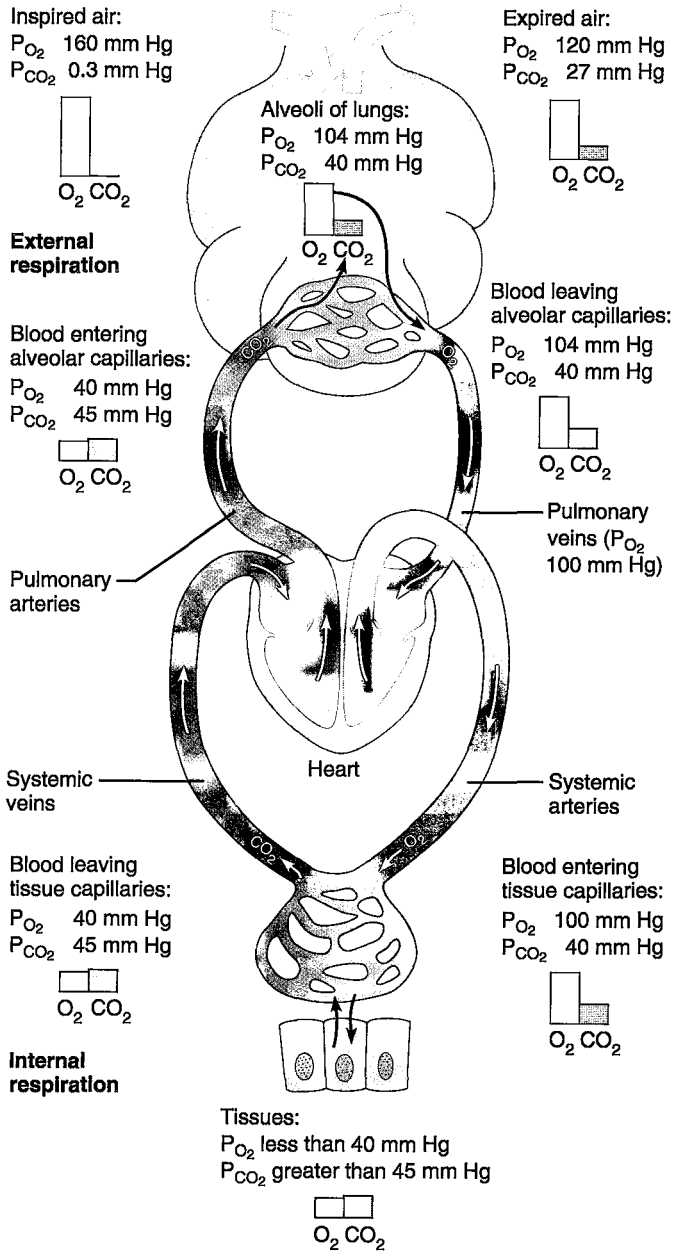


FIGURE 22.17 **Partial pressure gradients promoting gas movements in the body.** Top: Gradients promoting O_2 and CO_2 exchange across the respiratory membrane in the lungs. Bottom: Gradients promoting gas movements across systemic capillary membranes in body tissues. (Note that the composition of alveolar air and expired air are different because some dead space air mixes with the air being expired. The small decrease in P_{O_2} in pulmonary venous blood is due to partial dilution of pulmonary capillary blood with less oxygenated blood.)

1. Partial pressure gradients and gas solubilities
2. Matching of alveolar ventilation and pulmonary blood perfusion
3. Structural characteristics of the respiratory membrane

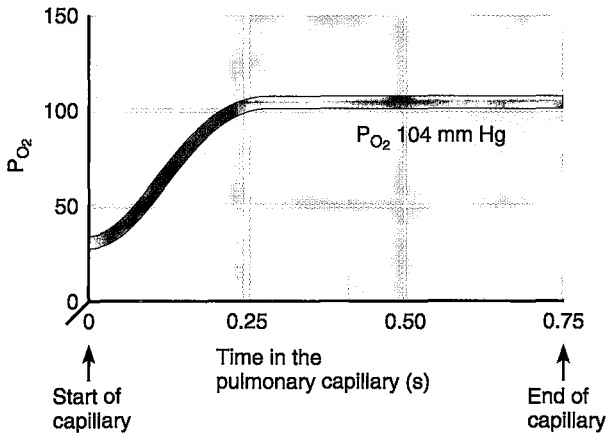

FIGURE 22.18 **Oxygenation of blood in the pulmonary capillaries at rest.** Note that the time from blood entering the pulmonary capillaries (indicated by 0) until the P_{O_2} is 104 mm Hg is approximately 0.25 second.

Partial Pressure Gradients and Gas Solubilities

Because the P_{O_2} of venous blood in the pulmonary arteries is only 40 mm Hg, as opposed to a P_{O_2} of approximately 104 mm Hg in the alveoli, a steep oxygen partial pressure gradient exists, and O_2 diffuses rapidly from the alveoli into the pulmonary capillary blood (Figure 22.17). Equilibrium—that is, a P_{O_2} of 104 mm Hg on both sides of the respiratory membrane—usually occurs in 0.25 second, which is about one-third the time a red blood cell is in a pulmonary capillary (Figure 22.18). The lesson here is that the blood can flow through the pulmonary capillaries three times as quickly and still be adequately oxygenated. Carbon dioxide moves in the opposite direction along a much gentler partial pressure gradient of about 5 mm Hg (45 mm Hg to 40 mm Hg) until equilibrium occurs at 40 mm Hg. Carbon dioxide is then expelled gradually from the alveoli during expiration. Even though the O_2 pressure gradient for oxygen diffusion is much steeper than the CO_2 gradient, equal amounts of these gases are exchanged because CO_2 is 20 times more soluble in plasma and alveolar fluid than O_2.

Ventilation-Perfusion Coupling

For gas exchange to be efficient, there must be a close match, or coupling, between *ventilation* (the amount of gas reaching the alveoli) and *perfusion* (the blood flow in pulmonary capillaries). As explained in Chapter 19 and illustrated in Figure 22.19, local autoregulatory mechanisms continuously respond to alveolar conditions.

Q *Suppose a patient is receiving oxygen by mask. What is the condition of the arterioles leading into O_2-enriched alveoli? What is the advantage of this response?*

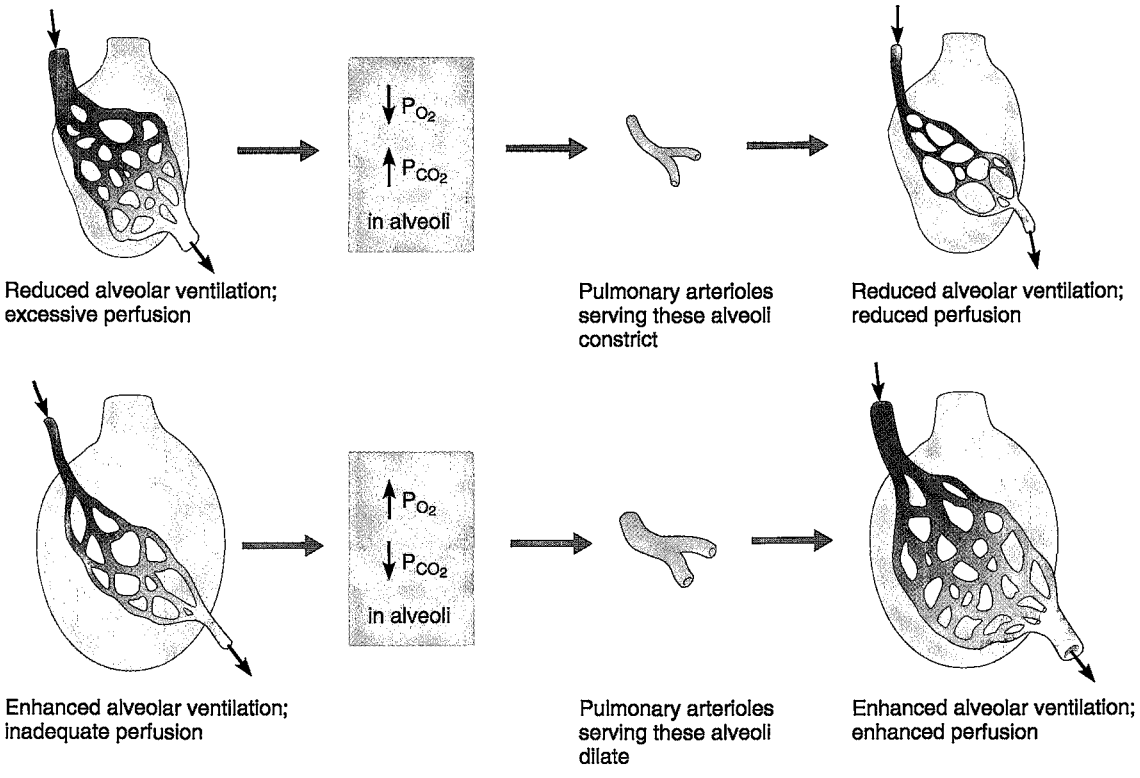

FIGURE 22.19 **Ventilation-perfusion coupling.** Autoregulatory events that result in local matching of blood flow (perfusion) through the pulmonary capillaries and conditions of alveolar ventilation.

In alveoli where ventilation is inadequate, P_{O_2} is low. As a result, the terminal arterioles constrict, and blood is redirected to respiratory areas where P_{O_2} is high and oxygen pickup may be more efficient. In alveoli where ventilation is maximal, pulmonary arterioles dilate, increasing blood flow into the associated pulmonary capillaries. Notice that the autoregulatory mechanism controlling pulmonary vascular muscle is the opposite of the mechanism controlling most arterioles in the systemic circulation.

While changes in alveolar P_{O_2} affect the diameter of pulmonary blood vessels (arterioles), changes in alveolar P_{CO_2} cause changes in the diameters of the *bronchioles*. Passageways servicing areas where alveolar CO_2 levels are high dilate, allowing CO_2 to be eliminated from the body more rapidly, while those serving areas where P_{CO_2} is low constrict.

As a result of modifications made by these two systems, alveolar ventilation and pulmonary perfusion are synchronized. Poor alveolar ventilation results in low oxygen and high carbon dioxide levels in the alveoli; consequently, the pulmonary arterioles constrict and the airways dilate, bringing air flow and blood flow into closer physiological match. High P_{O_2} and low P_{CO_2} in the alveoli cause respiratory passageways serving the alveoli to constrict, and promote flushing of blood into the pulmonary capillaries. Although these homeostatic mechanisms provide appropriate conditions for efficient gas exchange, they never completely balance ventilation and perfusion in every alveolus because (1) gravity causes regional variations in both blood and air flow in the lungs, and (2) the occasional alveolar duct plugged with mucus creates unventilated areas. These factors, together with the shunting

A *They would be dilated. This response allows matching of blood flow to availability of oxygen.*

of blood from bronchial veins, account for the slight drop in P_{O_2} from alveolar air (104 mm Hg) to pulmonary venous blood (100 mm Hg), as shown in Figure 22.17.

Thickness and Surface Area of the Respiratory Membrane

In healthy lungs, the respiratory membrane is only 0.5 to 1 μm thick, and gas exchange is usually very efficient.

HOMEOSTATIC IMBALANCE

If the lungs become waterlogged and edematous (as in pneumonia or left heart failure, see p. 705), the exchange membrane thickens dramatically. Under such conditions, even the total time (0.75 s) that red blood cells are in transit through the pulmonary capillaries may not be enough for adequate gas exchange, and body tissues begin to suffer from oxygen deprivation. ●

The greater the surface area of the respiratory membrane, the more gas can diffuse across it in a given time period. The alveolar surface area is enormous in healthy lungs. Spread flat, the total gas exchange surface of these tiny sacs in an adult male's lungs is about 90 m^2, approximately 40 times greater than the surface area of his skin!

HOMEOSTATIC IMBALANCE

In certain pulmonary diseases, the alveolar surface area actually functioning in gas exchange is drastically reduced. This occurs in emphysema, when the walls of adjacent alveoli break through and the alveolar chambers become larger. It also occurs when tumors, mucus, or inflammatory material blocks gas flow into the alveoli. ●

Internal Respiration: Capillary Gas Exchange in the Body Tissues

In internal respiration, the partial pressure and diffusion gradients are reversed from the situation described for external respiration and pulmonary gas exchange. However, the factors promoting gas exchanges between the systemic capillaries and the tissue cells are essentially identical to those acting in the lungs (Figure 22.17). Tissue cells continuously use O_2 for their metabolic activities and produce CO_2. Because P_{O_2} in the tissues is always lower than that in the systemic arterial blood (40 mm Hg versus 100 mm Hg), O_2 moves rapidly from the blood into the tissues until equilibrium is reached, and CO_2 moves quickly along its pressure gradient into the blood. As a result, venous blood draining the tissue capillary beds and returning to the heart has a P_{O_2} of 40 mm Hg and a P_{CO_2} of 45 mm Hg.

In summary, the gas exchanges that occur between the blood and the alveoli and between the blood and the tissue cells take place by simple diffusion driven by the partial pressure gradients of O_2 and CO_2 that exist on the opposite sides of the exchange membranes.

Transport of Respiratory Gases by Blood

Oxygen Transport

External and internal respiration have been considered consecutively to emphasize their similarities, but keep in mind that it is the blood that transports O_2 and CO_2 between these two exchange sites.

Molecular oxygen is carried in blood in two ways: bound to hemoglobin within red blood cells and dissolved in plasma (see Figure 22.22, p. 862). Oxygen is poorly soluble in water, so only about 1.5% of the oxygen transported is carried in the dissolved form. Indeed, if this were the *only* means of oxygen transport, a P_{O_2} of 3 atm or a cardiac output of 15 times normal would be required to provide the oxygen levels needed by body tissues! This problem, of course, has been solved by hemoglobin, and 98.5% of the oxygen ferried from the lungs to the tissues is carried in a loose chemical combination with hemoglobin.

Association of Oxygen and Hemoglobin

As described in Chapter 17, hemoglobin (Hb) is composed of four polypeptide chains, each bound to an iron-containing heme group (see Figure 17.4). Because the iron atoms bind oxygen, each hemoglobin molecule can combine with four molecules of O_2, and oxygen loading is rapid and reversible.

The hemoglobin-oxygen combination, called **oxyhemoglobin** (ok″sĭ-he″mo-glo′bin), is written **HbO_2.** Hemoglobin that has released oxygen is called **reduced hemoglobin,** or **deoxyhemoglobin,** and is written **HHb.** Loading and unloading of O_2 can be indicated by a single reversible equation:

$$HHb + O_2 \underset{\text{Tissuess}}{\overset{\text{Lungs}}{\rightleftharpoons}} HbO_2 + H^+$$

After the first O_2 molecule binds to iron, the Hb molecule changes shape. As a result, it more readily takes up two more O_2 molecules, and uptake of the fourth is even more facilitated. When all four heme

groups are bound to O_2, a hemoglobin molecule is said to be *fully saturated.* When one, two, or three oxygen molecules are bound, hemoglobin is *partially saturated.* By the same token, unloading of one oxygen molecule enhances the unloading of the next, and so on. Thus, the *affinity* (binding strength) of hemoglobin for oxygen changes with the extent of oxygen saturation, and both loading and unloading of oxygen are very efficient.

The rate at which Hb reversibly binds or releases O_2 is regulated by P_{O_2}, temperature, blood pH, P_{CO_2}, and blood concentration of an organic chemical called BPG. These factors interact to ensure adequate deliveries of O_2 to tissue cells.

Influence of P_{O_2} on Hemoglobin Saturation

Because the affinity of hemoglobin for O_2 changes with O_2 binding as just described, the relationship between the degree of hemoglobin saturation and the P_{O_2} of blood is not linear, as the **oxygen-hemoglobin dissociation curve** of Figure 22.20 shows. This S-shaped curve has a steep slope for P_{O_2} values between 10 and 50 mm Hg and then flattens out (plateaus) between 70 and 100 mm Hg.

Under normal resting conditions (P_{O_2} = 100 mm Hg), arterial blood hemoglobin is 98% saturated, and 100 ml of systemic arterial blood contains about 20 ml of O_2. This *oxygen content* of arterial blood is written as 20 vol % (volume percent). As arterial blood flows through the systemic capillaries, about 5 ml of O_2 per 100 ml of blood is released, yielding an Hb saturation of 75% (and an O_2 content of 15 vol %) in venous blood.

The nearly complete saturation of Hb in arterial blood explains why breathing deeply (which increases both the alveolar and arterial blood P_{O_2}) causes very little increase in the O_2 saturation of hemoglobin. Remember, P_{O_2} measurements indicate only the amount of O_2 dissolved in plasma, not the amount bound to hemoglobin. However, P_{O_2} values are a good index of lung function, and when arterial P_{O_2} is significantly less than alveolar P_{O_2}, some degree of respiratory impairment exists.

A hemoglobin saturation curve (Figure 22.20) reveals two other important facts. First, Hb is almost completely saturated at a P_{O_2} of 70 mm Hg, and further increases in P_{O_2} produce only small increases in O_2 binding. The adaptive value of this is that O_2 loading and delivery to the tissues can still be adequate when the P_{O_2} of inspired air is well below its usual levels, a situation common at higher altitudes and in those with cardiopulmonary disease. Moreover, because most O_2 *unloading* occurs on the steep portion of the curve, a small drop in P_{O_2} will cause a large increase in unloading. Normally, only 20–25% of bound oxygen is unloaded during one systemic circuit, and substantial amounts of O_2 are still available in venous blood (the *venous reserve*). Thus, if O_2 drops to very low levels in the tissues, as might occur during vigorous exercise, much more O_2 will dissociate from hemoglobin to be used by the tissue cells without any increase in respiratory rate or cardiac output.

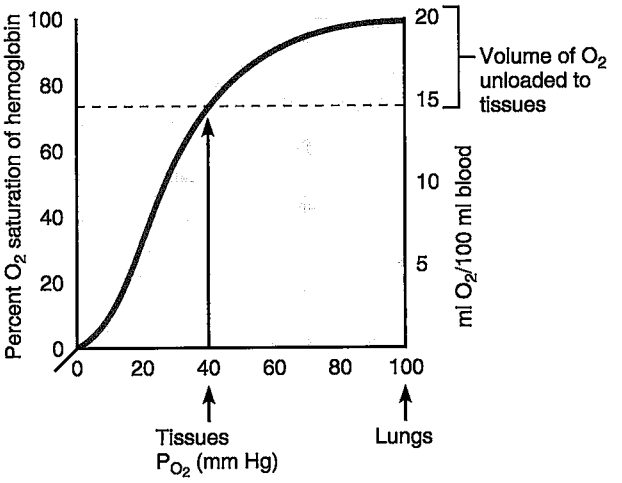

FIGURE 22.20 **Oxygen-hemoglobin dissociation curve.** Changes in Hb saturation and blood O_2 content as P_{O_2} changes. Notice that hemoglobin is almost completely saturated at a P_{O_2} of 70 mm Hg. Rapid loading and unloading of O_2 to and from hemoglobin occur at P_{O_2} values in the steep portion of the curve. In the systemic circuit, approximately 25% of Hb-bound O_2 is unloaded to the tissues (that is, approximately 5 ml of the 20 ml of O_2 per 100 ml of blood is released). Thus, hemoglobin of venous blood is still about 75% saturated with oxygen after one round through the body.

Influence of Other Factors on Hemoglobin Saturation

Temperature, blood pH, P_{CO_2}, and the amount of BPG in the blood all influence hemoglobin saturation at a given P_{O_2}. BPG (2,3-bisphosphoglycerate), which binds reversibly with hemoglobin, is produced by red blood cells (RBCs) as they break down glucose by the anaerobic process called glycolysis.

All of these factors influence Hb saturation by modifying hemoglobin's three-dimensional structure, and thereby its affinity for O_2. Generally speaking, an *increase* in temperature, P_{CO_2}, H^+ content of the blood (Figure 22.21), or BPG levels in blood decreases Hb's affinity for O_2 and causes the oxygen-hemoglobin dissociation curve to shift to the right. This enhances oxygen unloading from the blood. Conversely, a *decrease* in any of these factors increases hemoglobin's affinity for oxygen and shifts the dissociation curve to the left.

If you give a little thought to how these factors might be related, you'll realize that they all tend to

Q *Do increasing temperature and P_{CO_2} affect O_2 unloading in the same or opposite directions?*

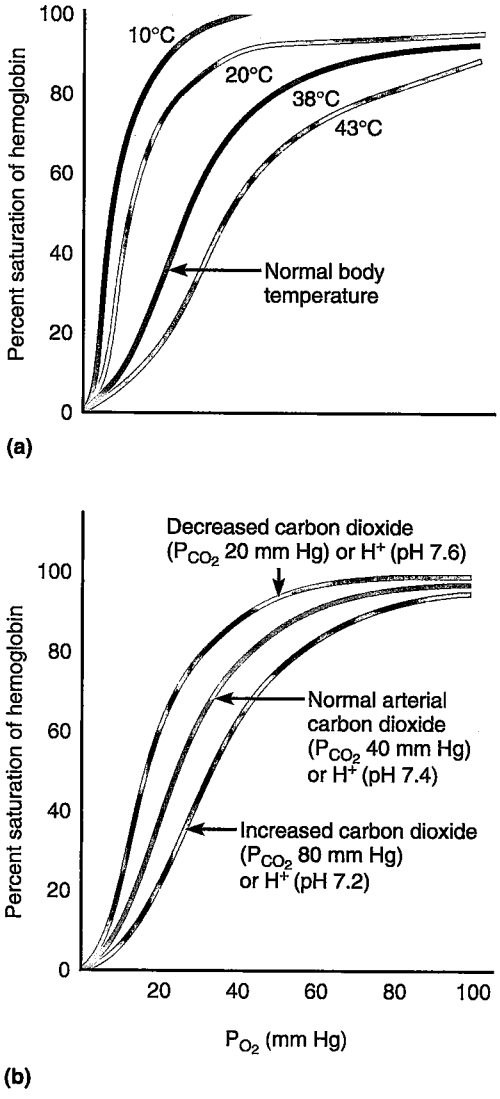

FIGURE 22.21 **Effect of temperature, P_{CO_2}, and blood pH on the oxygen-hemoglobin dissociation curve.** Oxygen unloading is accelerated at conditions of **(a)** increased temperature, **(b)** increased P_{CO_2}, and/or hydrogen ion concentration (decreased pH), causing the dissociation curve to shift to the right. This response is called the Bohr effect.

be at their highest levels in the systemic capillaries where oxygen unloading is the goal. As cells metabolize glucose and use O_2, they release CO_2, which increases the P_{CO_2} and H^+ levels in the capillary blood. Both declining blood pH (acidosis) and increasing P_{CO_2} weaken the Hb-O_2 bond, a phenomenon called the **Bohr effect.** As a result, oxygen unloading is enhanced where it is most needed. Additionally, heat is a by-product of metabolic activity, and active tissues are usually warmer than less active ones. A rise in temperature affects hemoglobin's affinity for O_2 both directly and indirectly (via its influence on RBC metabolism and BPG synthesis). Collectively, these factors see to it that Hb unloads much more O_2 in the vicinity of hard-working tissue cells.

The Hemoglobin–Nitric Oxide Partnership in Gas Exchange

Nitric oxide (NO), secreted by vascular endothelial cells, is a well-known vasodilator. Hemoglobin, on the other hand, has a formidable reputation as a NO scavenger—its iron-containing heme group destroys NO, which should result in vasoconstriction. Yet—and here's the paradox—local vessels dilate where gases are being unloaded and loaded. Some researchers believe that this is because hemoglobin transports NO (attached not to the heme, which would destroy it, but to the globin) along with O_2, and unloads both at the tissues. The vasodilation that would follow NO unloading could resolve the paradox. Other researchers believe that hemoglobin inside red blood cells is too far away from the endothelium to either scavenge or donate NO and that vasodilation is due only to NO release by local endothelial cells. The evidence either way is not yet conclusive.

HOMEOSTATIC IMBALANCE

Whatever the cause, inadequate oxygen delivery to body tissues is called **hypoxia** (hi-pok'se-ah). This condition is observed more easily in fair-skinned people because their skin and mucosae take on a bluish cast (become *cyanotic*) when Hb saturation falls below 75%. In dark-skinned individuals, this color change can be observed only in the mucosae and nail beds.

Classification of hypoxia based on cause is as follows:

1. **Anemic hypoxia** reflects poor O_2 delivery resulting from too few RBCs or from RBCs that contain abnormal or too little Hb.
2. **Ischemic (stagnant) hypoxia** results when blood circulation is impaired or blocked. Congestive heart failure may cause bodywide ischemic hypoxia, whereas emboli or thrombi block oxygen delivery only to tissues distal to the obstruction.

A The same direction.

3. Histotoxic hypoxia occurs when body cells are unable to use O_2 even though adequate amounts are delivered. This variety of hypoxia is the consequence of metabolic poisons, such as cyanide.

4. Hypoxemic hypoxia is indicated by reduced arterial P_{O_2}. Possible causes include disordered or abnormal ventilation-perfusion coupling, pulmonary diseases that impair ventilation, and breathing air containing scant amounts of O_2.

Carbon monoxide poisoning is a unique type of hypoxemic hypoxia, and a leading cause of death from fire. Carbon monoxide (CO) is an odorless, colorless gas that competes vigorously with O_2 for heme binding sites. Moreover, because Hb's affinity for CO is more than 200 times greater than its affinity for oxygen, CO is a highly successful competitor. Even at minuscule partial pressures, carbon monoxide can displace oxygen.

CO poisoning is particularly dangerous because it does not produce the characteristic signs of hypoxia—cyanosis and respiratory distress. Instead the victim is confused and has a throbbing headache. In rare cases, fair skin becomes cherry red (the color of the Hb-CO complex), which the eye of the beholder interprets as a healthy "blush." Those with CO poisoning are given hyperbaric therapy (if available) or 100% O_2 until the CO has been cleared from the body. ●

Carbon Dioxide Transport

Normally active body cells produce about 200 ml of CO_2 each minute—exactly the amount excreted by the lungs. Blood transports CO_2 from the tissue cells to the lungs in three forms (Figure 22.22):

1. Dissolved in plasma (7–10%). The smallest amount of CO_2 is transported simply dissolved in plasma.

2. Chemically bound to hemoglobin (just over 20%). In this form, CO_2 is carried in the RBCs as **carbaminohemoglobin** (kar-bam"ĭ-no-he"mo-glo'bin):

$$CO_2 + Hb \rightleftharpoons HbCO_2$$

carbaminohemoglobin

This reaction is rapid and does not require a catalyst. Because carbon dioxide binds directly to the amino acids of *globin* (and not to the heme), carbon dioxide transport in RBCs does not compete with the oxyhemoglobin transport mechanism.

CO_2 loading and unloading to and from Hb are directly influenced by the P_{CO_2} and the degree of Hb oxygenation. Carbon dioxide rapidly dissociates from hemoglobin in the lungs, where the P_{CO_2} of alveolar air is lower than that in blood. Carbon dioxide is loaded in the tissues, where the P_{CO_2} is higher than that in the blood. Deoxygenated hemoglobin combines more readily with carbon dioxide than does oxygenated hemoglobin (see the discussion of the Haldane effect on p. 863).

3. As bicarbonate ion in plasma (about 70%). Most carbon dioxide molecules entering the plasma quickly enter the RBCs, where most of the reactions that prepare carbon dioxide for transport as **bicarbonate ions (HCO_3^-)** in plasma occur. As illustrated in Figure 22.22a, when CO_2 diffuses into the RBCs, it combines with water, forming carbonic acid (H_2CO_3). H_2CO_3 is unstable and quickly dissociates into hydrogen ions and bicarbonate ions:

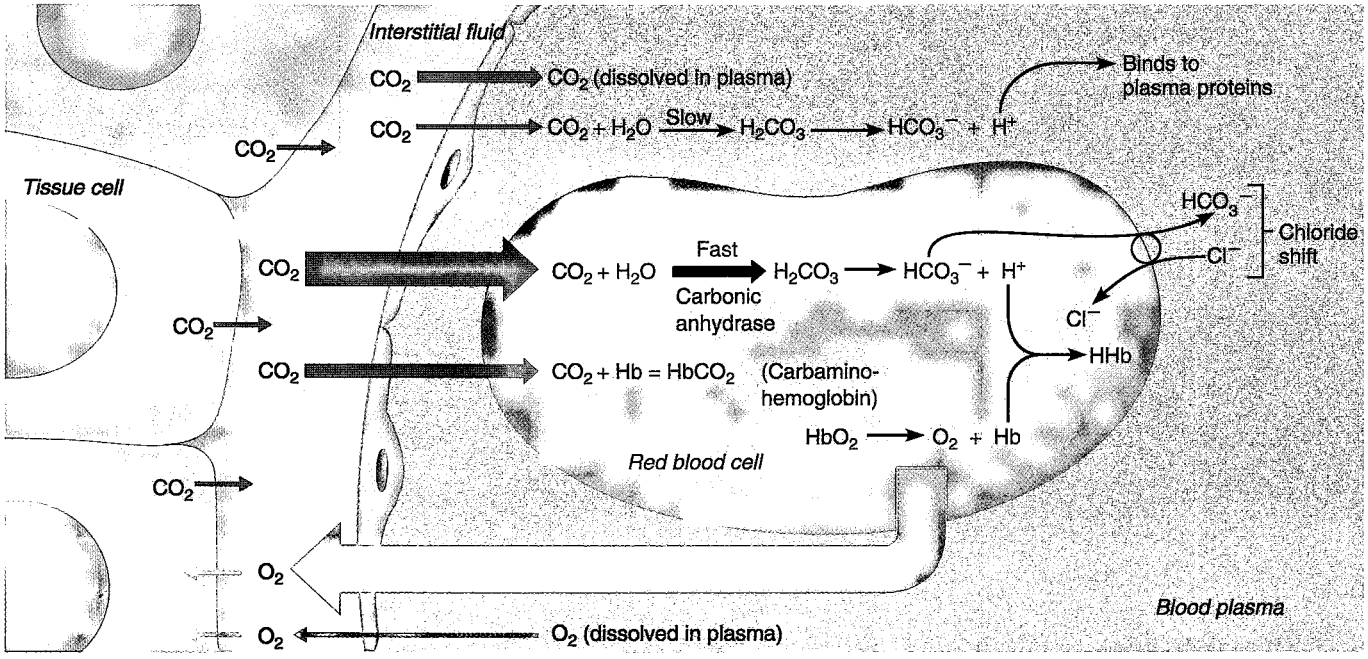
$$\underset{\text{carbon dioxide}}{CO_2} + \underset{\text{water}}{H_2O} \rightleftharpoons \underset{\text{carbonic acid}}{H_2CO_3} \rightleftharpoons \underset{\text{hydrogen ion}}{H^+} + \underset{\text{bicarbonate ion}}{HCO_3^-}$$

Although this reaction also occurs in plasma, it is thousands of times faster in RBCs because they (and not plasma) contain **carbonic anhydrase** (kar-bon'ik an-hi'drās), an enzyme that reversibly catalyzes the conversion of carbon dioxide and water to carbonic acid. Hydrogen ions released during the reaction (as well as CO_2 itself) bind to Hb, triggering the Bohr effect; thus, O_2 release is enhanced by CO_2 loading. Because of the buffering effect of Hb, the liberated H^+ causes little change in pH under resting conditions. Hence, blood becomes only slightly more acidic (the pH declines from 7.4 to 7.34) as it passes through the tissues.

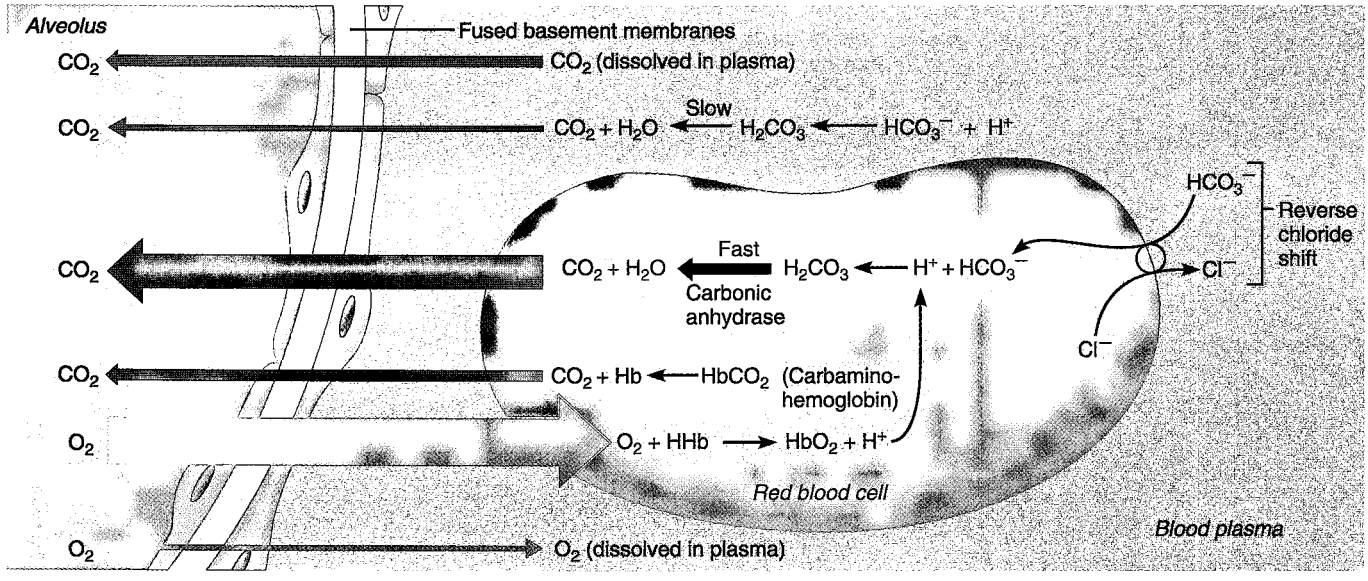
Once generated, HCO_3^- moves quickly from the RBCs into the plasma, where it is carried to the lungs. To counterbalance the rapid outrush of these anions from the RBCs, chloride ions (Cl^-) move from the plasma into the RBCs. This ion exchange process, called the **chloride shift,** occurs via facilitated diffusion through an RBC membrane protein.

In the lungs, the process is reversed (Figure 22.22b). As blood moves through the pulmonary capillaries, its P_{CO_2} declines from 45 mm Hg to 40 mm Hg. For this to occur, CO_2 must first be freed from its "bicarbonate housing." HCO_3^- reenters the RBCs (and Cl^- moves into the plasma) and binds with H^+ to form carbonic acid, which is then split by carbonic anhydrase to release CO_2 and water. This CO_2, along with that released from hemoglobin and from solution in plasma, then diffuses along its partial pressure gradient from the blood into the alveoli.

Q *Rapidly metabolizing tissues generate large amounts of CO_2 and H^+. How does this affect O_2 unloading?*



(a) Oxygen release and carbon dioxide pickup at the tissues



(b) Oxygen pickup and carbon dioxide release in the lungs

FIGURE 22.22 **Transport and exchange of CO_2 and O_2.** Gas exchanges occurring **(a)** at the tissues and **(b)** in the lungs. CO_2 is transported primarily as bicarbonate ion (HCO_3^-) in plasma (70%); smaller amounts are transported bound to hemoglobin (indicated as $HbCO_2$) in the red blood cells (22%) or in solution in plasma (7%). Nearly all O_2 transported in blood is bound to Hb as oxyhemoglobin (HbO_2) in RBCs. Very small amounts (about 1.5%) are carried dissolved in plasma. (Reduced hemoglobin is HHb.) Relative sizes of the transport arrows indicate the proportionate amounts of O_2 and CO_2 moved by each method.

A *Both CO_2 and H^+ increase O_2 unloading by binding to Hb. This is called the Bohr effect.*

The Haldane Effect

The amount of carbon dioxide transported in blood is markedly affected by the degree of oxygenation of the blood. The lower the P_{O_2} and the lower the extent of Hb saturation with oxygen, the more CO_2 that can be carried in the blood (Figure 22.23). This phenomenon, called the **Haldane effect,** reflects the greater ability of reduced hemoglobin to form carbaminohemoglobin and to buffer H^+ by combining with it. As CO_2 enters the systemic bloodstream, it causes more oxygen to dissociate from Hb (Bohr effect), which allows more CO_2 to combine with Hb and more HCO_3^- to be formed (Haldane effect).

In the pulmonary circulation (Figure 22.22b), the situation is reversed—uptake of O_2 facilitates release of CO_2. As Hb becomes saturated with O_2, the H^+ released combines with HCO_3^-, helping to unload CO_2 from the pulmonary blood. The Haldane effect encourages CO_2 exchange in both the tissues and lungs.

Influence of CO_2 on Blood pH

Typically, the H^+ released during carbonic acid dissociation is buffered by Hb or other proteins within the RBCs or in plasma. The HCO_3^- generated in the red blood cells diffuses into the plasma, where it acts as the *alkaline reserve* part of the blood's carbonic acid–bicarbonate buffer system. The **carbonic acid–bicarbonate buffer system** is very important in resisting shifts in blood pH (see the equation in point 3 on p. 861 concerning CO_2 transport). For example, if the hydrogen ion concentration in blood begins to rise, excess H^+ is removed by combining with HCO_3^- to form carbonic acid (a weak acid that dissociates very little at either physiological or acidic pH). If H^+ concentration drops below desirable levels in blood, carbonic acid dissociates, releasing hydrogen ions and lowering the pH again.

Changes in respiratory rate or depth can produce dramatic changes in blood pH by altering the amount of carbonic acid in the blood. Slow, shallow breathing allows CO_2 to accumulate in the blood. As a result, carbonic acid levels increase and blood pH drops. Conversely, rapid, deep breathing quickly flushes CO_2 out of the blood, reducing carbonic acid levels and increasing blood pH. Thus, respiratory ventilation can provide a fast-acting system to adjust blood pH (and P_{CO_2}) when it is disturbed by metabolic factors. Respiratory adjustments play a major role in the acid-base balance of the blood, as discussed in Chapter 26.

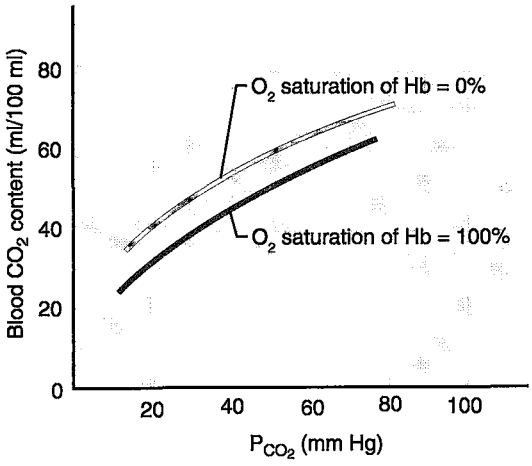


FIGURE 22.23 **The Haldane effect.** Equilibrium curves for blood CO_2 content relative to fully oxygenated hemoglobin (O_2 saturation of Hb = 100%) and deoxygenated Hb. The lower the degree of Hb saturation, the greater the amount of CO_2 that can be transported by the blood.

Control of Respiration

Neural Mechanisms and Generation of Breathing Rhythm

Although our tidelike breathing seems so beautifully simple, its control is fairly complex, involving neurons in the reticular formation of the medulla and pons. Because the medulla sets the respiratory rhythm, we will begin there.

Medullary Respiratory Centers

Clustered neurons in two areas of the medulla oblongata appear to be critically important in respiration. These are (1) the **dorsal respiratory group (DRG),** located dorsally near the root of cranial nerve IX, and (2) the **ventral respiratory group (VRG),** a network of neurons that extends in the ventral brain stem from the spinal cord to the pons-medulla junction. The VRG appears to be a rhythm-generating and integrative center. It contains groups of neurons that fire during inspiration and others that fire during expiration in a dance of mutual inhibition. When its inspiratory neurons fire, a burst of impulses travels along the **phrenic** and **intercostal nerves** to excite the diaphragm and external intercostal muscles, respectively (Figure 22.24). As a result, the thorax expands and air rushes into the lungs. When the VRG's expiratory neurons fire, the output stops, and expiration occurs passively as the inspiratory muscles relax and the lungs recoil. This cyclic on/off activity of the inspiratory and expiratory neurons repeats continuously and produces a respiratory rate of 12–15

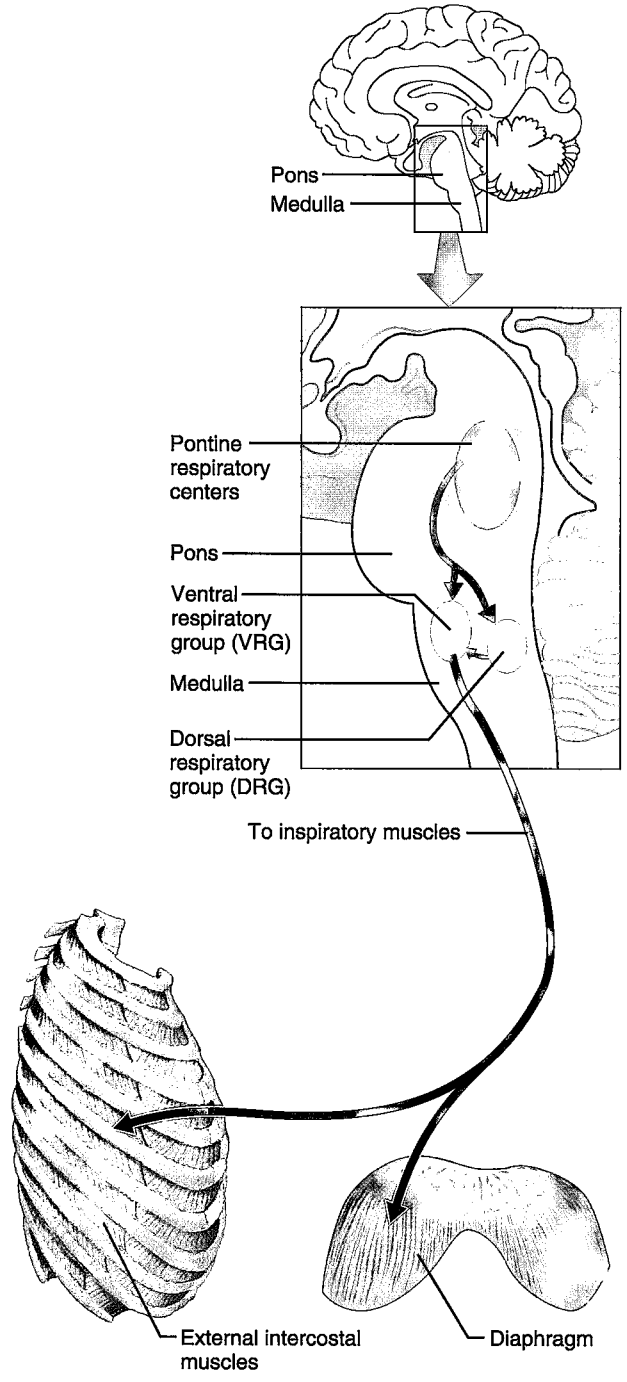

FIGURE 22.24 **Locations of respiratory centers and their postulated connections.** The ventral respiratory group (VRG) contains rhythm generators whose output drives respiration. During normal quiet breathing, a group of VRG inspiratory neurons fire, activating respiratory motor neurons that cause inspiratory muscles to contract. Passive expiration occurs when a group of expiratory neurons fire, inhibiting the VRG output and allowing the inspiratory muscles to relax. Neurons of the dorsal respiratory group (DRG) integrate peripheral sensory input and modify the rhythms generated by the VRG. The pontine respiratory centers interact with the medullary centers to smooth the breathing pattern. (The efferent pathway is incomplete. Medullary neurons communicate with lower motor neurons in the spinal cord. For simplicity, the lower motor neurons, which innervate the muscles of respiration, are not illustrated.)

breaths per minute, with inspiratory phases lasting about 2 seconds followed by expiratory phases lasting about 3 seconds. This normal respiratory rate and rhythm is referred to as **eupnea** (ūp-ne'ah; *eu* = good, *pne* = breath). During severe hypoxia, VRG networks generate gasping (perhaps in a last-ditch effort to restore O_2 to the brain). When a certain cluster of VRG neurons is completely suppressed, as by an overdose of morphine, or alcohol, respiration stops completely.

Until recently, it was thought that the DRG acts as an inspiratory center, performing many of the tasks now known to be performed by the VRG. We now know that in almost all mammals including humans, the DRG integrates input from peripheral stretch and chemoreceptors (described shortly) and communicates this information to the VRG. It may seem surprising, but many of the details of this system so essential to life are still being worked out.

Pontine Respiratory Centers

Although the VRG generates the basic respiratory rhythm, the pontine respiratory centers influence and modify the activity of medullary neurons. For example, pontine centers appear to smooth out the transitions from inspiration to expiration, and vice versa; and when lesions are made in its superior region, inspirations become very prolonged, a phenomenon called *apneustic breathing*.

The **pontine respiratory group** [formerly called the *pneumotaxic center* (noo"mo-tak'sik)] and other pontine centers transmit impulses to the VRG of the medulla (Figure 22.24). This modifies and fine-tunes the breathing rhythms generated by the VRG during certain activities such as vocalization, sleep, and exercise. As you would expect from these functions, the pontine respiratory centers, like the DRG, receive input from higher brain centers and from various sensory receptors in the periphery.

Genesis of the Respiratory Rhythm

Although there is little question that breathing is rhythmic, we still cannot fully explain the origin of its rhythm. One hypothesis is that there are *pacemaker neurons*, which have intrinsic (automatic) rhythmicity like the pacemaker cells found in the heart. Though pacemaker activity has been demonstrated in rostral VRG neurons in newborns,

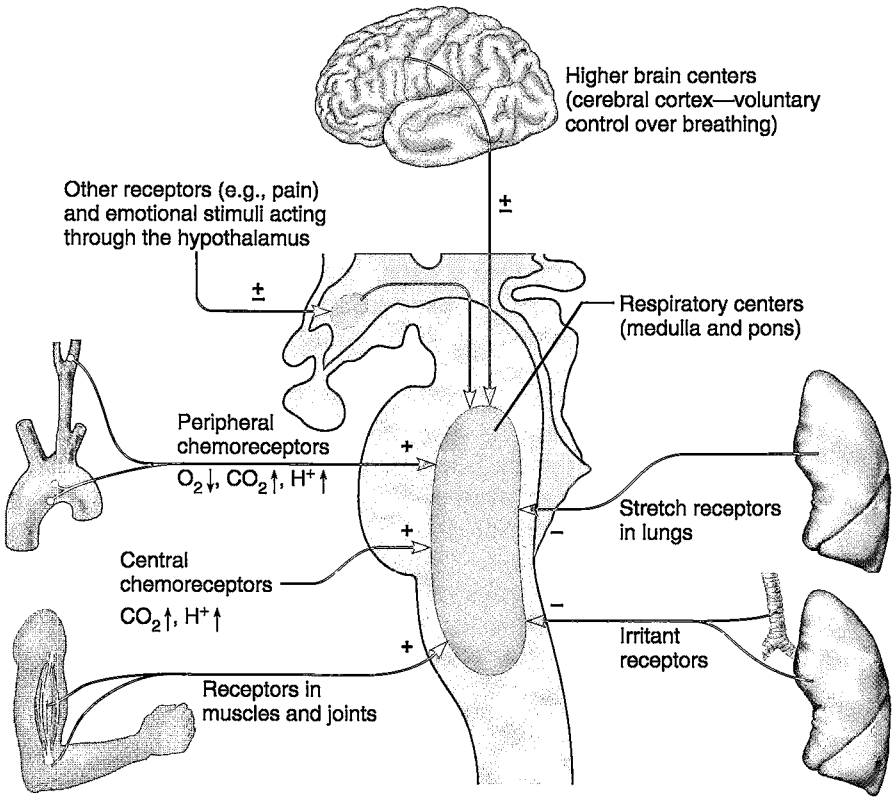

FIGURE 22.25 **Neural and chemical influences on brain stem respiratory centers.** Excitatory influences (+) increase the frequency of impulses sent to the muscles of respiration and recruit additional motor units, resulting in deeper, faster breathing. Inhibitory influences (−) have the reverse effect. In some cases, the impulses may be excitatory or inhibitory (±), depending on which receptors or brain regions are activated. The cerebral cortex also directly innervates respiratory muscle motor neurons.

no such activity has been found in adults. This leads us to the second (and most popular) hypothesis: Normal respiratory rhythm is a result of reciprocal inhibition of interconnected neuronal networks in the medulla. Rather than a single set of pacemaker neurons, there are two sets that inhibit each other and so cycle their activity to generate the rhythm.

Factors Influencing Breathing Rate and Depth

Inspiratory depth is determined by how actively the respiratory center stimulates the motor neurons serving the respiratory muscles. The greater the stimulation, the greater the number of motor units excited and the greater the force of respiratory muscle contractions. Respiratory rate is determined by how long the inspiratory center is active or how quickly it is switched off.

Depth and rate of breathing can be modified in response to changing body demands. The respiratory centers in the medulla and pons are sensitive to both excitatory and inhibitory stimuli. These stimuli are described next and summarized in Figure 22.25.

Chemical Factors

Among the factors that influence breathing rate and depth, the most important are changing levels of CO_2, O_2, and H^+ in arterial blood. Sensors responding to such chemical fluctuations, called **chemoreceptors,** are found in two major body locations. The **central chemoreceptors** are located bilaterally in the ventrolateral medulla. The **peripheral chemoreceptors** are found in the aortic arch and carotid arteries.

Influence of P_{CO_2} Of all the chemicals influencing respiration, CO_2 is the most potent and the most closely controlled. Normally, arterial P_{CO_2} is 40 mm Hg and is maintained within ±3 mm Hg of this level by an exquisitely sensitive homeostatic mechanism that is mediated mainly by the effect that rising CO_2 levels have on the central chemoreceptors of the brain stem (Figure 22.26). CO_2 diffuses easily from the blood into the cerebrospinal fluid, where it is hydrated and forms carbonic acid. As the acid dissociates, H^+ is liberated. This is the same reaction that occurs when CO_2 enters RBCs (see pp. 861–862). Unlike RBCs or plasma, however, cerebrospinal fluid contains virtually no proteins that can buffer the added H^+. Thus, as P_{CO_2} levels rise, a condition referred to as **hypercapnia** (hi"per-kap'ne-ah), the cerebrospinal fluid pH drops, exciting the central chemoreceptors, which make abundant synapses with the respiratory regulatory centers. As a result, the depth and rate of breathing are increased. This enhanced alveolar ventilation quickly flushes CO_2 out of the blood, increasing blood pH. An elevation of only 5 mm Hg in arterial P_{CO_2} results in a doubling of alveolar ventilation, even when arterial O_2 levels and pH are

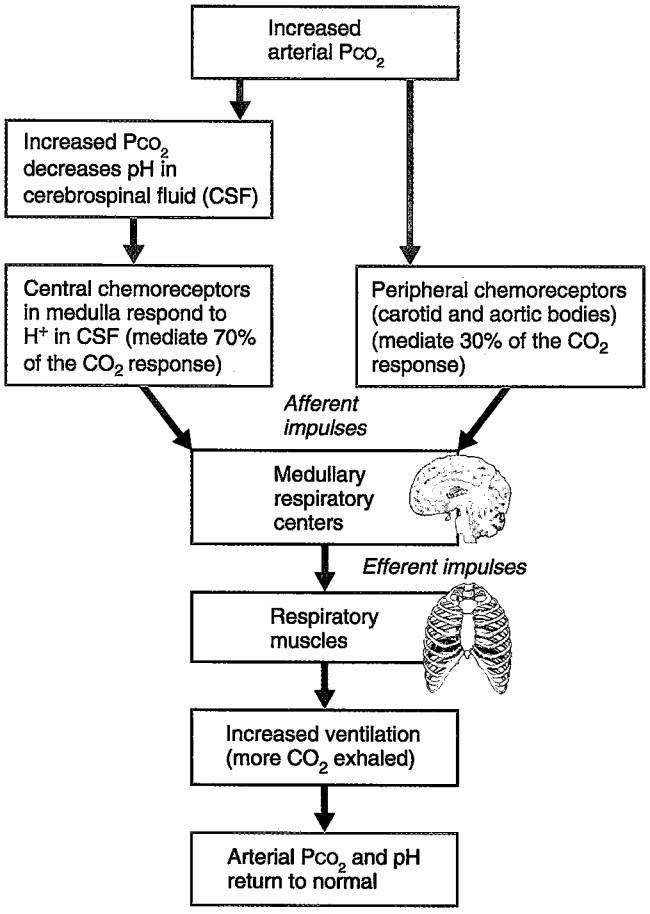

FIGURE 22.26 **Negative feedback mechanism by which changes in P_{CO_2} and blood pH regulate ventilation.**

unchanged. When P_{O_2} and pH are below normal, the response to elevated P_{CO_2} is even greater. Increased ventilation is normally self-limiting, ending when homeostatic blood P_{CO_2} levels are restored.

Notice that while rising CO_2 levels act as the initial stimulus, it is rising H^+ levels that prod the *central* chemoreceptors into activity. In the final analysis, control of breathing during rest is aimed primarily at *regulating the H^+ concentration in the brain.*

HOMEOSTATIC IMBALANCE

Hyperventilation is an increase in the rate and depth of breathing that exceeds the body's need to remove CO_2. A person experiencing an anxiety attack may hyperventilate involuntarily to the point where he or she becomes dizzy or faints. This happens because low CO_2 levels in the blood **(hypocapnia)** cause cerebral blood vessels to constrict, reducing brain perfusion and producing cerebral ischemia. Earlier symptoms of hyperventilation are tingling and involuntary muscle spasms (tetany) in the hands and face caused by blood Ca^{2+} levels falling as pH rises. Such attacks may be averted by breathing into a paper bag because then the air being inspired is expired air, rich in carbon dioxide, which causes carbon dioxide to be retained in the blood. ●

When P_{CO_2} is abnormally low, respiration is inhibited and becomes slow and shallow. In fact, periods of **apnea** (breathing cessation) may occur until arterial P_{CO_2} rises and again stimulates respiration.

Sometimes swimmers voluntarily hyperventilate so that they can hold their breath longer during swim meets. This is incredibly dangerous for the following reasons. Blood O_2 content rarely drops much below 60% of normal during regular breath-holding, because as P_{O_2} drops, P_{CO_2} rises enough to make breathing unavoidable. However, strenuous hyperventilation can lower P_{CO_2} so much that a lag period occurs before it rebounds enough to stimulate respiration again. This lag may allow oxygen levels to fall well below 50 mm Hg, causing the swimmer to black out (and perhaps drown) before he or she has the urge to breathe.

Influence of P_{O_2} Cells sensitive to arterial O_2 levels are found in the peripheral chemoreceptors, that is, in the **aortic bodies** of the aortic arch and in the **carotid bodies** at the bifurcation of the common carotid arteries (Figure 22.27). Those in the carotid bodies are the main oxygen sensors.

Under normal conditions, the effect of declining P_{O_2} on ventilation is slight and mostly limited to enhancing the sensitivity of peripheral receptors to increased P_{CO_2}. Arterial P_{O_2} must drop *substantially,* to at least 60 mm Hg, before O_2 levels become a major stimulus for increased ventilation. This is not as strange as it may appear. Remember, there is a huge reservoir of O_2 bound to Hb, and Hb remains almost entirely saturated unless or until the P_{O_2} of alveolar gas and arterial blood falls below 60 mm Hg. The central chemoreceptors then begin to suffer from O_2 starvation, and their activity is depressed. At the same time, the peripheral chemoreceptors become excited and stimulate the respiratory centers to increase ventilation, even if P_{CO_2} is normal. Thus, the peripheral chemoreceptor system can maintain ventilation when alveolar O_2 levels are low even though brain stem centers are depressed by hypoxia.

HOMEOSTATIC IMBALANCE

In people who retain CO_2 because of pulmonary disease (e.g., emphysema and chronic bronchitis), arterial P_{CO_2} is chronically elevated and, as a result, chemoreceptors adapt to this chemical stimulus. In such cases, a declining P_{O_2} acting on the oxygen-sensitive peripheral chemoreceptors provides the principal respiratory stimulus, the **hypoxic drive.** Thus, gas mixtures administered to such patients during respiratory distress are only slightly enriched with O_2 because inspiration of pure oxygen would slow their breathing, further elevating their P_{CO_2}. ●

Influence of Arterial pH Changes in arterial pH can modify respiratory rate and rhythm even when CO_2 and O_2 levels are normal. Because little H^+ diffuses from the blood into the cerebrospinal fluid, the direct effect of arterial H^+ concentration on central chemoreceptors is insignificant compared to the effect of H^+ generated by elevations in P_{CO_2}. The increased ventilation that occurs in response to falling arterial pH is mediated through the peripheral chemoreceptors.

Although changes in P_{CO_2} and H^+ concentration are interrelated, they are distinct stimuli. A drop in blood pH may reflect CO_2 retention, but it may also result from metabolic causes, such as accumulation of lactic acid during exercise or of fatty acid metabolites (ketone bodies) in patients with poorly controlled diabetes mellitus. Regardless of cause, as arterial pH declines, respiratory system controls attempt to compensate and raise the pH by eliminating CO_2 (and carbonic acid) from the blood; thus, respiratory rate and depth increase.

Summary of Interactions of P_{CO_2}, P_{O_2}, and Arterial pH Although every cell in the body must have O_2 to live, the body's need to rid itself of CO_2 is the most important stimulus for breathing in a healthy person. However, CO_2 does not act in isolation, and various chemical factors enforce or inhibit one another's effects. These interactions are summarized here:

1. Rising CO_2 levels are the most powerful respiratory stimulant. As CO_2 is hydrated in cerebrospinal fluid, liberated H^+ acts directly on the central chemoreceptors, causing a reflexive increase in breathing rate and depth. Low P_{CO_2} levels depress respiration.

2. Under normal conditions, blood P_{O_2} affects breathing only indirectly by influencing chemoreceptor sensitivity to changes in P_{CO_2}. Low P_{O_2} augments P_{CO_2} effects; high P_{O_2} levels diminish the effectiveness of CO_2 stimulation.

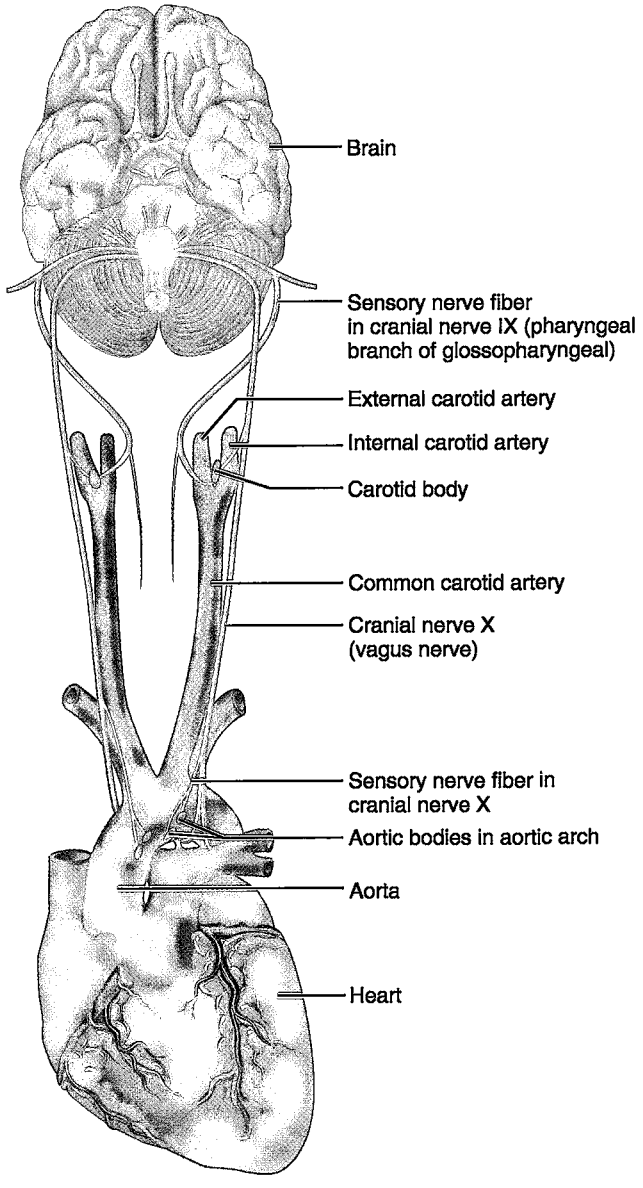

FIGURE 22.27 **Location of the peripheral chemoreceptors in the carotid and aortic bodies.** Also shown are the sensory pathways from these receptors through cranial nerves IX and X to the respiratory centers in the medulla.

3. When arterial P_{O_2} falls below 60 mm Hg, it becomes the major stimulus for respiration, and ventilation is increased via reflexes initiated by the peripheral chemoreceptors. This may increase O_2 loading into the blood, but it also causes hypocapnia (low P_{CO_2} blood levels) and an increase in blood pH, both of which inhibit respiration.

4. Changes in arterial pH resulting from CO_2 retention or metabolic factors act indirectly through the peripheral chemoreceptors to promote changes in ventilation, which in turn modify arterial P_{CO_2} and

A CLOSER LOOK

Dangerous Raptures of the Deep

Even the nonswimmers among us are beckoned by photos of scuba divers examining brightly colored coral and other ocean creatures as they glide effortlessly through sparkling blue water. "What a life," we think enviously. But hidden beneath that veneer of breathtaking beauty is life-threatening danger for the inexperienced, the careless, and the unlucky. In addition to the significant risk of drowning, scuba divers are exposed to the omnipresent danger of two other medical emergencies—air embolism and decompression sickness.

As divers descend to greater and greater depths underwater, the pressure on their bodies rises proportionately [1 atmosphere (760 mm Hg) of pressure for each 10 m (33 ft) of descent] because of the increasing weight of the water. **Scuba gear** (**s**elf-**c**ontained **u**nderwater **b**reathing **a**pparatus) has freed divers from air lines to the surface and heavy pressurized suits because it permits continual equalization of the air pressure (provided by the mixture of compressed air in the tank) with the water pressure; that is, air enters the lungs at a higher-than-normal pressure. Thus descent is not usually a problem, unless divers descend below 100 feet and remain there for an extended time.

Although nitrogen ordinarily has little effect on body functioning, hyperbaric conditions for an extended time force so much nitrogen into solution in the blood that it provokes a narcotic effect called *nitrogen narcosis.* Nitrogen is far more soluble in lipids than in water, so it tends to concentrate in lipid-rich tissues such as the central nervous system, bone marrow, and fat deposits. Divers become dizzy, giddy, and appear to be intoxicated, which is why this condition is sometimes called "rapture of the deep."

Assuming divers take care to avoid these narcotizing effects, and ascend to the surface gradually (see the graph), dissolved nitrogen gas can be driven out of the tissues and eliminated by the lungs without problems. But if the ascent is rapid, the P_{N_2} decreases abruptly and the poorly soluble nitrogen gas appears to "boil" from the tissues and out of solution in the body fluids. Gas bubbles in blood represent potentially lethal emboli, and those formed within joints, bones, and muscles can cause excruciating musculoskeletal pain, commonly called the "bends." Other signs of this *decompression sickness* are mood changes, seizures, nausea, numbness, "migrating" skin rashes, and a syndrome called *chokes.* Chokes, or cardiovascular bends, involves substernal pain, coughing, dyspnea, and, in severe cases, shock due to gas bubbles in the pulmonary capillaries. Although these signs usually appear within an hour of surfacing, they can be delayed as long as 36 hours. Even if divers experienced no apparent problems underwater, they could experience symptoms later. Decompression sickness can also strike at high altitudes, such as in unpressurized aircraft flying above 18,000 feet.

If divers ascend suddenly and without exhaling, the alveoli are likely to rupture. This situation usually occurs when they panic after aspirating seawater or encountering other

pH. Arterial pH does not influence the central chemoreceptors directly.

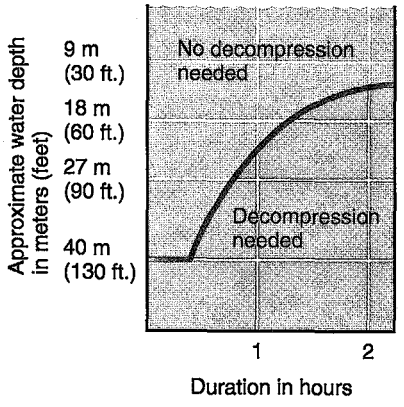
Influence of Higher Brain Centers

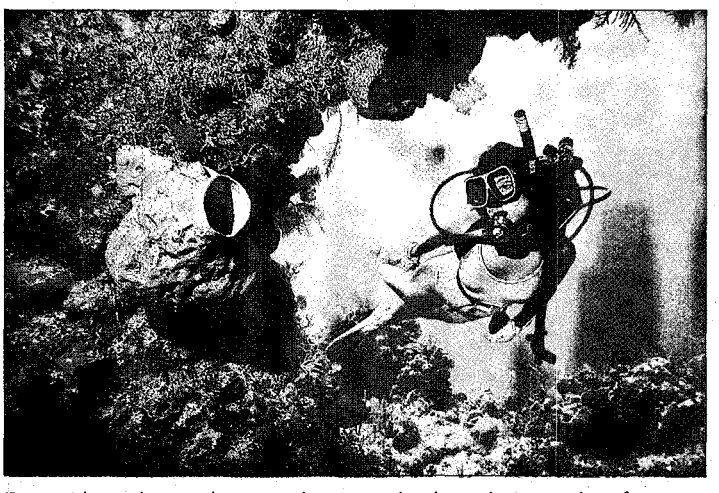
Hypothalamic Controls Acting through the hypothalamus and the rest of the limbic system, strong emotions and pain send signals to the respiratory centers, modifying respiratory rate and depth. For example, have you ever touched something cold and clammy and gasped? That response was mediated through the hypothalamus. So too is the breath holding that occurs when we are angry and the increased respiratory rate that occurs when we are excited. A rise in body temperature acts to increase the respiratory rate, while a drop in body temperature produces the opposite effect; and sudden chilling of the body (a dip in the north Atlantic Ocean in late October) can cause cessation of breathing (apnea)—or at the very least, gasping.

Cortical Controls Although breathing is normally regulated involuntarily by the brain stem respiratory centers, we can also exert conscious (volitional) control over the rate and depth of our breathing—choosing to hold our breath or to take an extra deep breath, for example. During voluntary control, the cerebral motor cortex sends signals to the motor neurons that stimulate the respiratory muscles, bypassing the medullary centers. Our ability to voluntarily hold our breath is limited, however, because the brain stem respiratory centers automatically reinitiate breathing when the blood concentration of CO_2 reaches critical levels. That explains why drowning victims typically have water in their lungs.

Pulmonary Irritant Reflexes

The lungs contain receptors that respond to an enormous variety of irritants. When activated, these receptors communicate with the respiratory





Even with modern scuba gear, divers need to know how to adjust from high underwater pressures to the lower pressures at the surface.

hazards, such as equipment failure, strong currents, or rough waters. Under such conditions, connections occur between the alveoli and the pulmonary bloodstream, and life-threatening gas emboli develop. Since divers typically ascend head-up, the emboli usually invade the cerebral circulation. Seizures, localized motor and sensory deficits, and unconsciousness are all possibilities. Indeed, many scuba-related drownings appear to follow loss of consciousness due to arterial gas embolism.

The usual and most effective treatment for decompression sickness is hyperbaric therapy: reinstituting compression and then redoing decompression . . . slowly. When a gas embolus is suspected, oxygen and antiseizure medications are given until hyperbaric therapy can begin.

People with high body fat content or recent limb injuries are more vulnerable to decompression sickness. Consuming alcohol or exercising strenuously before a dive also increase the risk. The best therapy is to avoid the need for treatment by making sure that divers know the potential risks and are well trained in using their equipment. Assuming that is done, the vacation should be GREAT! ■

centers via vagal nerve afferents. Accumulated mucus, inhaled debris such as dust, or noxious fumes stimulate receptors in the bronchioles that promote reflex constriction of those air passages. The same irritants stimulate a cough when present in the trachea or bronchi, and a sneeze when present in the nasal cavity.

The Inflation Reflex

The visceral pleurae and conducting passages in the lungs contain numerous stretch receptors that are vigorously stimulated when the lungs are inflated. These receptors signal the medullary respiratory centers via afferent fibers of the vagus nerves, sending inhibitory impulses that end inspiration and allow expiration to occur. As the lungs recoil, the stretch receptors become quiet, and inspiration is initiated once again. This reflex, called the **inflation reflex,** or **Hering-Breuer reflex** (her'ing broy'er), is thought to be more a protective response (to prevent excessive stretching of the lungs) than a normal regulatory mechanism.

Respiratory Adjustments

Adjustments During Exercise

Respiratory adjustments during exercise are geared both to intensity and duration of the exercise. Working muscles consume tremendous amounts of O_2 and produce large amounts of CO_2; thus, ventilation can increase 10- to 20-fold during vigorous exercise. This increase in ventilation in response to metabolic needs is called **hyperpnea** (hi"perp-ne'ah). It differs from hyperventilation in that the respiratory changes in hyperpnea do not lead to significant changes in blood O_2 and CO_2 levels. By contrast, hyperventilation is excessive ventilation, and is characterized by low P_{CO_2} and alkalosis.

Exercise-enhanced ventilation does *not* appear to be prompted by rising P_{CO_2} and declining P_{O_2} and pH in the blood for two reasons. First, ventilation increases abruptly as exercise begins, followed by a gradual increase, and then a steady state of ventilation. When exercise stops, there is an initial small

but abrupt decline in ventilation rate, followed by a gradual decrease to the pre-exercise value. Second, although venous levels change, arterial P_{CO_2} and P_{O_2} levels remain surprisingly constant during exercise. In fact, P_{CO_2} may decline to below normal and P_{O_2} may rise slightly because of the efficiency of the respiratory adjustments. Our present understanding of the mechanisms that produce these observations is sketchy, but the most accepted explanation is as follows.

The abrupt increase in ventilation that occurs as exercise begins reflects interaction of three neural factors:

1. Psychological stimuli (our conscious anticipation of exercise)
2. Simultaneous cortical motor activation of skeletal muscles and respiratory centers
3. Excitatory impulses reaching respiratory centers from proprioceptors in moving muscles, tendons, and joints

The subsequent gradual increase and then plateauing of respiration probably reflect the rate of CO_2 delivery to the lungs (the "CO_2 flow"). The small but abrupt decrease in ventilation that occurs as exercise ends reflects the shutting off of the three neural factors listed above. The subsequent gradual decline to baseline ventilation likely reflects a decline in the CO_2 flow that occurs as the oxygen debt is being repaid. The rise in lactic acid levels that contributes to O_2 debt is *not* a result of inadequate respiratory function, because alveolar ventilation and pulmonary perfusion are as well matched during exercise as during rest (hemoglobin remains fully saturated). Rather, it reflects cardiac output limitations or inability of the skeletal muscles to further increase their oxygen consumption. In light of this fact, the practice of inhaling pure O_2 by mask, used by some football players to replenish their "oxygen-starved" bodies as quickly as possible, is useless. The panting athlete *does* have an O_2 deficit, but inspiring extra oxygen will not help, because the shortage is in the muscles—not the lungs.

Adjustments at High Altitude

Most people live between sea level and an altitude of approximately 2400 m (8000 feet). In this range, differences in atmospheric pressure are not great enough to cause healthy people any problems when they spend brief periods in the higher-altitude areas. However, when you travel quickly from sea level to elevations above 8000 ft, where air density and P_{O_2} are lower, your body responds with symptoms of *acute mountain sickness (AMS)*—headaches, shortness of breath, nausea, and dizziness. AMS is common in travelers to ski resorts such as Vail, Colorado (8120 ft), and Brian Head, Utah (a heart-pounding 9600 ft). In severe cases of AMS, lethal pulmonary and cerebral edema may occur.

When you move on a *long-term* basis from sea level to the mountains, your body begins to make respiratory and hematopoietic adjustments via an adaptive response called **acclimatization.** As already explained, decreases in arterial P_{O_2} cause the peripheral chemoreceptors to become more responsive to increases in P_{CO_2}, and a substantial decline in P_{O_2} directly stimulates the peripheral chemoreceptors. As a result, ventilation increases as the brain attempts to restore gas exchange to previous levels. Within a few days, the minute respiratory volume stabilizes at a level 2–3 L/min higher than the sea level rate. Because increased ventilation also reduces arterial CO_2 levels, the P_{CO_2} of individuals living at high altitudes is typically below 40 mm Hg (its value at sea level).

Because less O_2 is available to be loaded, high-altitude conditions always result in lower-than-normal hemoglobin saturation levels. For example, at about 19,000 ft above sea level, O_2 saturation of arterial blood is only 67% (compared to nearly 98% at sea level). But Hb unloads only 20–25% of its oxygen at sea level, which means that even at the reduced saturations at high altitudes, the O_2 needs of the tissues are still met adequately under resting conditions. Additionally, at high altitudes hemoglobin's affinity for O_2 is reduced because of increases in BPG concentration, with the result that more O_2 is released to the tissues during each circulatory round.

Although the tissues in a person at high altitude receive adequate oxygen under normal conditions, problems arise when all-out efforts are demanded of the cardiovascular and respiratory systems (as discovered by athletes competing in the 1968 Summer Olympics on the high mesa of Mexico City, at 7370 ft). Unless one is fully acclimatized, such conditions almost guarantee that body tissues will become severely hypoxic.

When blood O_2 levels decline, the kidneys accelerate production of erythropoietin, which stimulates bone marrow production of RBCs (see Chapter 17). This phase of acclimatization, which occurs slowly, provides long-term compensation for living at high altitudes.

Homeostatic Imbalances of the Respiratory System

The respiratory system is particularly vulnerable to infectious diseases because it is wide open to airborne pathogens. Many of these inflammatory conditions, such as rhinitis and laryngitis, were considered earlier in the chapter. Here we turn our attention to the most disabling disorders: *chronic obstructive*

pulmonary disease (COPD), asthma, tuberculosis, and *lung cancer.* COPD and lung cancer are living proof of the devastating effects of cigarette smoking on the body. Long known to promote cardiovascular disease, cigarettes are perhaps even more effective at destroying the lungs.

Chronic Obstructive Pulmonary Disease

The **chronic obstructive pulmonary diseases (COPD),** exemplified best by chronic bronchitis and emphysema, are a major cause of death and disability in North America and are becoming increasingly prevalent. The key physiological feature of these diseases is an irreversible decrease in the ability to force air out of the lungs. These diseases also share other common features (Figure 22.28):

1. More than 80% of patients have a history of smoking.

2. Dyspnea (disp-ne'ah), difficult or labored breathing often referred to as "air hunger," occurs and gets progressively more severe.

3. Coughing and frequent pulmonary infections are common.

4. Most COPD victims develop respiratory failure manifested as **hypoventilation** (insufficient ventilation in relation to metabolic needs, causing CO_2 retention), respiratory acidosis, and hypoxemia.

Emphysema is distinguished by permanent enlargement of the alveoli, accompanied by destruction of the alveolar walls. Invariably the lungs lose their elasticity. This has three important consequences: (1) Accessory muscles must be enlisted to breathe, and victims are perpetually exhausted because breathing requires 15–20% of their total body energy supply (as opposed to 5% in healthy individuals). (2) For complex reasons, the bronchioles open during inspiration but collapse during expiration, trapping huge volumes of air in the alveoli. This hyperinflation leads to development of a permanently expanded "barrel chest" and flattens the diaphragm, thus reducing ventilation efficiency. (3) Damage to the pulmonary capillaries as the alveolar walls disintegrate increases resistance in the pulmonary circuit, forcing the right ventricle to overwork and consequently become enlarged. In addition to cigarette smoking, hereditary factors (e.g., alpha-1 antitrypsin deficiency) cause emphysema in some patients.

In **chronic bronchitis,** inhaled irritants lead to chronic excessive mucus production by the mucosa of the lower respiratory passageways and to inflammation and fibrosis of that mucosa. These responses obstruct the airways and severely impair lung ventilation and gas exchange. Pulmonary infections are

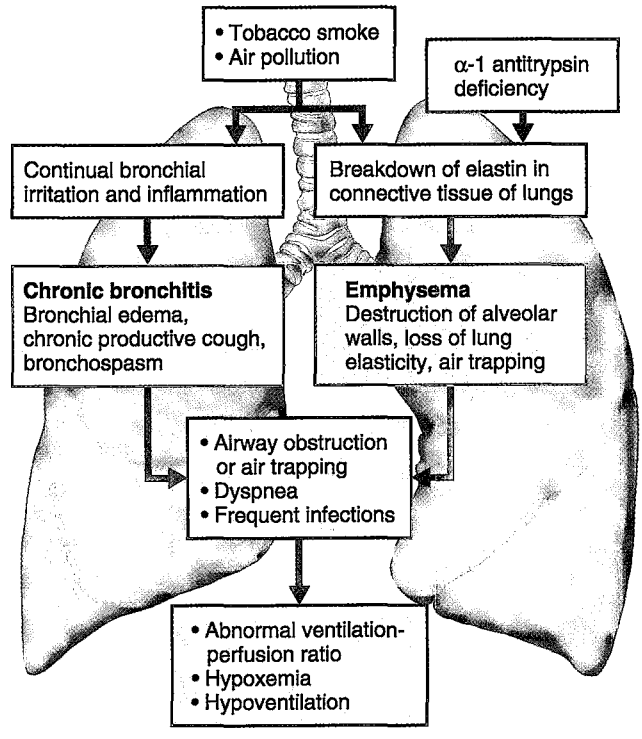


FIGURE 22.28 **The pathogenesis of COPD.**

frequent because bacteria thrive in the stagnant pools of mucus. However, the degree of dyspnea is usually moderate compared to that of emphysema sufferers. In addition to the major factor of cigarette smoking, environmental pollution may contribute to the development of chronic bronchitis.

In the clinical setting you might see two very different patterns that represent the extremes of patients with COPD. One pattern has traditionally been called the "pink puffer": these patients work so hard maintaining adequate ventilation that they lose weight, becoming thin but still having nearly normal blood gases. In contrast, "blue bloaters," commonly of stocky build, become sufficiently hypoxic that they are obviously cyanotic. The hypoxia causes constriction of pulmonary blood vessels, which leads to pulmonary hypertension and right-sided heart failure. Traditionally, "pink puffers" were associated with emphysema while "blue bloaters" were associated with chronic bronchitis. As usual, things are not that clear-cut. It turns out that patients with the same underlying disease can display either one of these two clinical patterns, and this may depend on a third factor—the strength of their innate respiratory drive. Most COPD patients fall in between these two clinical extremes.

COPD is routinely treated with bronchodilators and corticosteroids in aerosol form (inhalers). Severe dyspnea and hypoxia mandate oxygen use. Surgical treatment for COPD, called *lung volume*

reduction surgery, is still highly controversial. In this procedure, part of the grossly enlarged lungs is removed to give the remaining lung tissue room to expand. While this surgery does not prolong life, it can offer certain COPD patients increased exercise capability and a higher quality of life, although at a high cost.

Asthma

Asthma is characterized by episodes of coughing, dyspnea, wheezing, and chest tightness—alone or in combination. Most acute attacks are accompanied by a sense of panic. Although sometimes classed with COPD because it is an obstructive disorder, asthma is marked by acute exacerbations followed by symptom-free periods—that is, the obstruction is *reversible.*

The cause of asthma has been hard to pin down. Initially it was viewed as a consequence of bronchospasm triggered by various factors such as cold air, exercise, or allergens. However, when it was discovered that bronchoconstriction has relatively little effect on air flow through normal lungs, researchers probed more deeply and found that in asthma, active inflammation of the airways comes first. The airway inflammation is an immune response under the control of T_H2 cells, a subset of T lymphocytes that, by secreting certain interleukins, stimulate the production of IgE and recruit inflammatory cells (notably eosinophils) to the site. Once someone has allergic asthma, the inflammation persists even during symptom-free periods and makes the airways hypersensitive to almost any irritant. (It now appears the most common triggers are in the home—the allergens from dust mites, cockroaches, cats, dogs, and fungi.) Once the airway walls are thickened with inflammatory exudate, the effect of bronchospasm is vastly magnified and can dramatically reduce air flow.

About one in ten people in North America suffer from asthma—children more than adults. Over the past 20 years, the number of cases of asthma has risen dramatically, an increase which may now be plateauing. While asthma remains a major health problem, better treatment options have begun to reduce the number of deaths due to asthma. Instead of treating the symptoms of asthma with fast-acting bronchodilators, we now treat the underlying inflammation using inhaled corticosteroids. New approaches to limiting the airway inflammation include antileukotrienes and antibodies against the patient's own IgE class of antibodies.

Tuberculosis

Tuberculosis (TB), the infectious disease caused by the bacterium *Mycobacterium tuberculosis,* is spread by coughing and primarily enters the body in inhaled air. TB mostly affects the lungs but can spread through the lymphatics to affect other organs. One-third of the world's population is infected, but most people never develop active TB because a massive inflammatory and immune response usually contains the primary infection in fibrous, or calcified, nodules (tubercles) in the lungs. However, the bacteria survive in the nodules and when the person's immunity is low, they may break out and cause symptomatic TB, involving fever, night sweats, weight loss, a racking cough, and spitting up blood.

Until the 1930s, TB was responsible for one-third of all deaths among 20- to 45-year-old adults in the U.S. With the advent of antibiotics in the 1940s, this killer was put into retreat and its prevalence declined dramatically. During the mid-1980s, there was an alarming increase in TB due to TB-infected HIV patients. This has now been brought under control and TB rates in the U.S. are again decreasing. Of potential concern are deadly strains of drug-resistant (even multidrug-resistant) TB that develop when treatment is incomplete or inadequate. Such strains are found elsewhere in the world and are becoming more common in North America. Ideal breeding grounds for such strains are shelters for the homeless with their densely packed populations. The TB bacterium grows very slowly and drug therapy entails a 12-month course of antibiotics. The transient nature of shelter populations makes it difficult to track TB patients and ensure they take their medications for the full 12 months. The threat of TB epidemics is so real that health centers in some cities are detaining such patients in sanatoriums against their will for as long as it takes to complete a cure.

Lung Cancer

Lung cancer is the leading cause of cancer death for both men and women in North America, causing more deaths than breast, prostate, and colorectal cancer combined. This is tragic, because lung cancer is largely preventable—nearly 90% of lung cancers are the result of smoking. The cure rate for lung cancer is notoriously low, with most victims dying within one year of diagnosis. The overall five-year survival of those with lung cancer is about 17%. Because lung cancer is aggressive and metastasizes rapidly and widely, most cases are not diagnosed until they are well advanced.

Lung cancer appears to follow closely the oncogene-activating steps outlined in *A Closer Look* in Chapter 4. Ordinarily, nasal hairs, sticky mucus, and cilia do a fine job of protecting the lungs from chemical and biological irritants, but when one smokes, these devices are overwhelmed and eventually stop functioning. In particular, smoking paralyzes the cilia

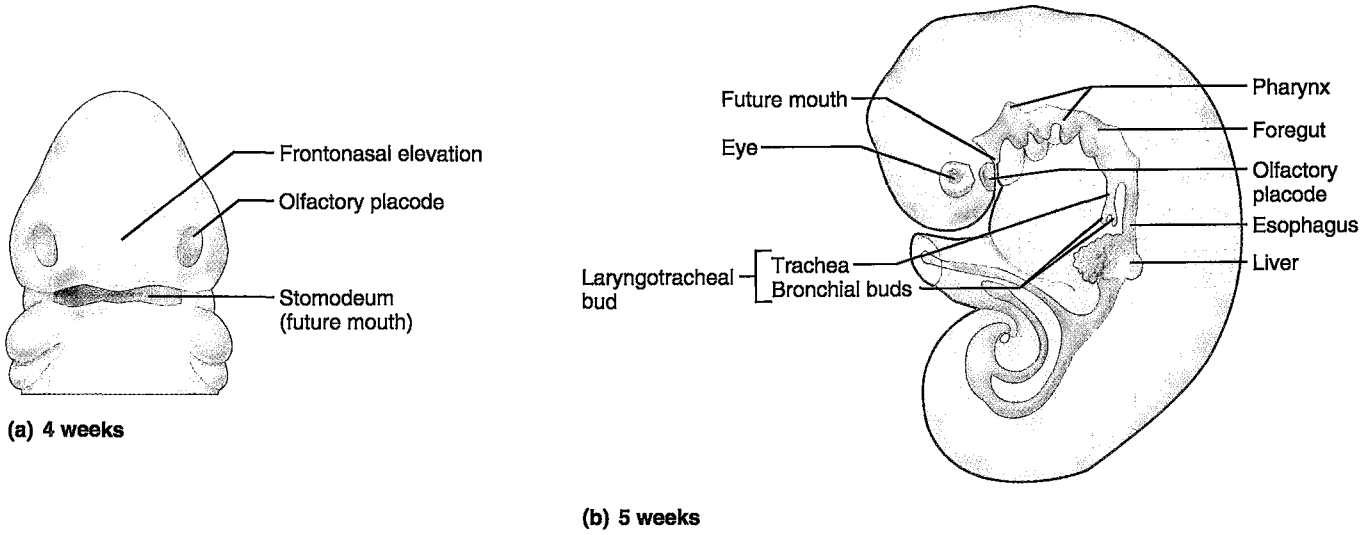

FIGURE 22.29 **Embryonic development of the respiratory system.** **(a)** Anterior superficial view of the embryo's head. **(b)** Left lateral view of the developing lower respiratory passageway mucosae.

that clear mucus from the airways, allowing irritants and pathogens to accumulate. The "cocktail" of free radicals and other carcinogens in tobacco smoke eventually translates into lung cancer.

The three most common types of lung cancer are (1) **squamous cell carcinoma** (25–30% of cases), which arises in the epithelium of the bronchi or their larger subdivisions and tends to form masses that may cavitate (hollow out) and bleed, (2) **adenocarcinoma** (about 40%), which originates in peripheral lung areas as solitary nodules that develop from bronchial glands and alveolar cells, and (3) **small cell carcinoma** (about 20%), which contains round lymphocyte-sized cells that originate in the main bronchi and grow aggressively in small grapelike clusters within the mediastinum. Subsequent metastasis from the mediastinum is especially rapid. Some small cell carcinomas cause problems beyond their effects on the lungs because they become ectopic sites of hormone production. For example, some secrete ACTH (leading to Cushing's syndrome) or ADH (which results in SIADH, see p. 619).

Complete removal of the diseased lung has the greatest potential for prolonging life and providing a cure. However, this choice is open to few lung cancer patients because the cancer has often metastasized before it is discovered. In most cases, radiation therapy and chemotherapy are the only options, but these have low success rates. Fortunately, there are several new therapies on the horizon. These include (1) antibodies that target specific growth factors or other molecules required by the tumor or that deliver toxic agents directly to the tumor, (2) cancer vaccines to stimulate the immune system to fight the tumor, and (3) various forms of gene therapy to replace the defective genes that make tumor cells divide continuously. As clinical trials progress, we will learn which of these approaches is most effective.

Developmental Aspects of the Respiratory System

Because embryos develop in a cephalocaudal (head-to-tail) direction, the upper respiratory structures appear first. By the fourth week of development, two thickened plates of ectoderm, the **olfactory placodes** (plak'ōds), are present on the anterior aspect of the head (Figure 22.29). These quickly invaginate to form **olfactory pits** that form the nasal cavities. The olfactory pits then extend posteriorly to connect with the developing pharynx, which forms at the same time from the endodermal germ layer.

The epithelium of the lower respiratory organs develops as an outpocketing of the foregut endoderm, which becomes the pharyngeal mucosa. This protrusion, called the **laryngotracheal bud,** is present by the fifth week of development. The proximal part of the bud forms the tracheal lining, and its distal end splits and forms the mucosae of the bronchi and all their subdivisions, including (eventually) the lung alveoli. Mesoderm covers these endoderm-derived linings and forms the walls of the respiratory passageways and the stroma of the lungs. By 28 weeks, the respiratory system has developed sufficiently to allow a baby born prematurely to breathe on its own. As noted earlier, infants born before this time tend to exhibit infant respiratory distress syndrome resulting from inadequate surfactant production.

During fetal life, the lungs are filled with fluid and all respiratory exchanges are made by the placenta. Vascular shunts cause circulating blood to largely bypass the lungs (see Chapter 28, p. 1131). At birth, the fluid-filled pathway empties, and the respiratory passageways fill with air. As the P_{CO_2} in the baby's blood rises, the respiratory centers are excited, causing the baby to take its first breath. The alveoli inflate and begin to function in gas exchange, but it is nearly two weeks before the lungs are fully inflated.

HOMEOSTATIC IMBALANCE

Important birth defects of the respiratory system include *cleft palate* (described in Chapter 7) and *cystic fibrosis*. **Cystic fibrosis (CF),** the most common lethal genetic disease in North America, strikes in one out of every 2400 births. CF causes secretion of abnormally viscous mucus that clogs the respiratory passages, providing a breeding ground for airborne bacteria that predisposes the child to respiratory infections. It appears that infection of CF victims' lungs with the bacterium *Pseudomonas aeruginosa* trips a genetic switch that causes the disabled cells to churn out oceans of abnormal mucin (the primary component of mucus). The bacteria then feed on the stagnant pools of mucus and keep sending signals to the cells to make more. Toxins released by the bacteria and the local inflammatory reaction set up by the immune response both damage the lungs. Unable to reach the bacteria embedded in the mucus, the immune cells begin to attack the lung tissue, turning the air sacs into bloated cysts. Repeated cycles of infection, chronic inflammation, and resulting tissue damage eventually result in such extensive damage that it can be treated only by a lung transplant. The disease also impairs food digestion by clogging ducts that deliver pancreatic enzymes and bile to the small intestine, and sweat glands of CF patients produce an extremely salty perspiration.

At the root of CF is a faulty gene that codes for the *CFTR* (cystic fibrosis transmembrane conductance regulator) *protein*. The normal CFTR protein works as a membrane channel to control Cl^- flow in and out of cells. In those with the mutated gene, CFTR lacks an essential amino acid and so it gets "stuck" in the endoplasmic reticulum, unable to reach the membrane and perform its normal role. Consequently, less Cl^- is secreted and less water follows, resulting in the thick mucus typical of CF.

Conventional therapy for CF has been mucus-dissolving drugs, "clapping" the chest to loosen the thick mucus, and antibiotics to prevent infection. The basic goal of CF research is to restore normal salt and water movements by (1) using disabled cold viruses to carry normal CFTR genes into respiratory tract mucosa cells, (2) prodding another channel protein to take over the duties of transporting Cl^-, and (3) developing techniques to free the CFTR protein from the ER. A drug derived from the curry spice turmeric appears to do just that, and is just beginning clinical trials. Suppressing the inflammatory response in the lungs is another goal. Among anti-inflammatory agents being tested is a fatty acid found in fish oils, docosahexanoic acid (DHA). Alone or in combination, these therapies provide new hope to patients with CF. ●

The respiratory rate is highest in newborn infants (40–80 respirations per minute). At five years of age it is around 25 per minute, and in adults it is between 12 and 18 per minute. In old age, the rate often increases again. At birth, only about one-sixth of the final number of alveoli are present. The lungs continue to mature and more alveoli are formed until young adulthood. However, if smoking begins in the early teens, the lungs never completely mature, and those additional alveoli are lost forever.

In infants, the ribs take a nearly horizontal course. Thus, infants rely almost entirely on descent of the diaphragm to increase thoracic volume for inspiration. By the second year, the ribs are positioned more obliquely, and the adult form of breathing is established.

HOMEOSTATIC IMBALANCE

Most respiratory system problems that occur are the result of external factors—for example, viral or bacterial infections or obstruction of the trachea by a piece of food. For many years, bacterial pneumonia was one of the worst killers in North America. Antibiotics have greatly decreased its lethality, but it is still a dangerous disease, particularly in the elderly. By far the most problematic diseases *at present* are those described earlier: COPD, asthma, lung cancer, and multidrug-resistant tuberculosis. ●

The maximum amount of oxygen we can use during aerobic metabolism, $\dot{V}_{O_{2max}}$, declines about 9% per decade in inactive people beginning in their mid-20s. In those that remain active, $\dot{V}_{O_{2max}}$ still declines but much less. As we age, the thoracic wall becomes more rigid and the lungs gradually lose their elasticity, resulting in a decreasing ability to ventilate the lungs. Vital capacity declines by about one-third by the age of 70. Blood O_2 levels decline slightly, and many old people tend to become hypoxic during sleep and exhibit *sleep apnea* (temporary cessation of breathing during sleep).

The number of glands in the nasal mucosa decreases as does blood flow to this mucosa. Thus, the

nose dries and produces a thick mucus that makes us want to clear our throat. Additionally, many of the respiratory system's protective mechanisms become less effective with age. Ciliary activity of the mucosa decreases, and the macrophages in the lungs become sluggish. The net result is that the elderly are more at risk for respiratory tract infections, particularly pneumonia and influenza.

■ ■ ■

Lungs, bronchial tree, heart, and connecting blood vessels—together, these organs fashion a remarkable system that ensures that blood is oxygenated and relieved of carbon dioxide and that all tissue cells have access to these services. Although the cooperation of the respiratory and cardiovascular systems is obvious, all organ systems of the body depend on the functioning of the respiratory system, as summarized in *Making Connections* on pp. 876–877.

Related Clinical Terms

Acute respiratory distress syndrome (ARDS) A dangerous lung condition that can develop after severe illness or injury to the body. Neutrophils leave the body's capillaries in large numbers and then secrete chemicals that increase capillary permeability. The capillary-rich lungs are heavily affected. As the lungs fill with the fluids of edema, the patient suffocates. Even with mechanical ventilation, ARDS is hard to control and often lethal.

Adenoidectomy (adenotonsillectomy) Surgical removal of an infected pharyngeal tonsil (adenoids).

Aspiration (as″pĭ-ra′shun) (1) The act of inhaling or drawing something into the lungs or respiratory passages. Pathological aspiration in which vomit or excessive mucus is drawn into the lungs may occur when a person is unconscious or anesthetized; turning the head to one side is preventive. (2) Withdrawal of fluid by suction (use of an aspirator); done during surgery to keep an area free of blood or other body fluids; mucus is aspirated from the trachea of tracheotomy patients.

Bronchoscopy (*scopy* = viewing) Use of a viewing tube inserted through the nose or mouth to examine the internal surface of the main bronchi in the lung. Forceps attached to the tip of the tube can remove trapped objects or take samples of mucus for examination.

Cheyne-Stokes breathing (chān′stōks) Abnormal breathing pattern sometimes seen just before death (the "death rattle") and in people with combined neurological and cardiac disorders. It consists of bursts of tidal volume breaths (increasing and then decreasing in depth) alternating with periods of apnea. Trauma and hypoxia of the brain stem centers, as well as P_{CO_2} imbalances between arterial blood and cerebrospinal fluid, may be causative factors.

Deviated septum Condition in which the nasal septum takes a more lateral course than usual and may obstruct breathing; often manifests in old age or from nose trauma.

Endotracheal tube A thin plastic tube threaded into the trachea through the nose or mouth; used to deliver oxygen to patients who are breathing inadequately, in a coma, or under anesthesia.

Epistaxis (ep″ĭ-stak′sis; *epistazo* = to bleed at the nose) Nosebleed; commonly follows trauma to the nose or excessive nose blowing. Most nasal bleeding is from the highly vascularized anterior septum and can be stopped by pinching the nostrils closed or packing them with cotton.

Nasal polyps Mushroomlike benign neoplasms of the nasal mucosa; sometimes caused by infections, but most often cause is unknown; may block airflow.

Orthopnea (or″thop-ne′ah; *ortho* = straight, upright) Inability to breathe in the horizontal (lying down) position.

Otorhinolaryngology (o″to-ri″no-lar″in-gol′o-je; *oto* = ear; *rhino* = nose) Branch of medicine that deals with diagnosis and treatment of diseases of the ears, nose, and throat.

Pneumonia Infectious inflammation of the lungs, in which fluid accumulates in the alveoli; the seventh most common cause of death in the United States. Most of the more than 50 different varieties of pneumonia are viral or bacterial.

Pulmonary embolism Obstruction of the pulmonary artery or one of its branches by an embolus (most often a blood clot that has been carried from the lower limbs and through the right side of the heart into the pulmonary circulation). Symptoms are chest pain, productive bloody cough, tachycardia, and rapid, shallow breathing. Can cause sudden death unless treated quickly; usual treatment is oxygen by mask, pain relievers, and anticoagulant drugs. For severe cases, clot busters (thrombolytic drugs) are also used.

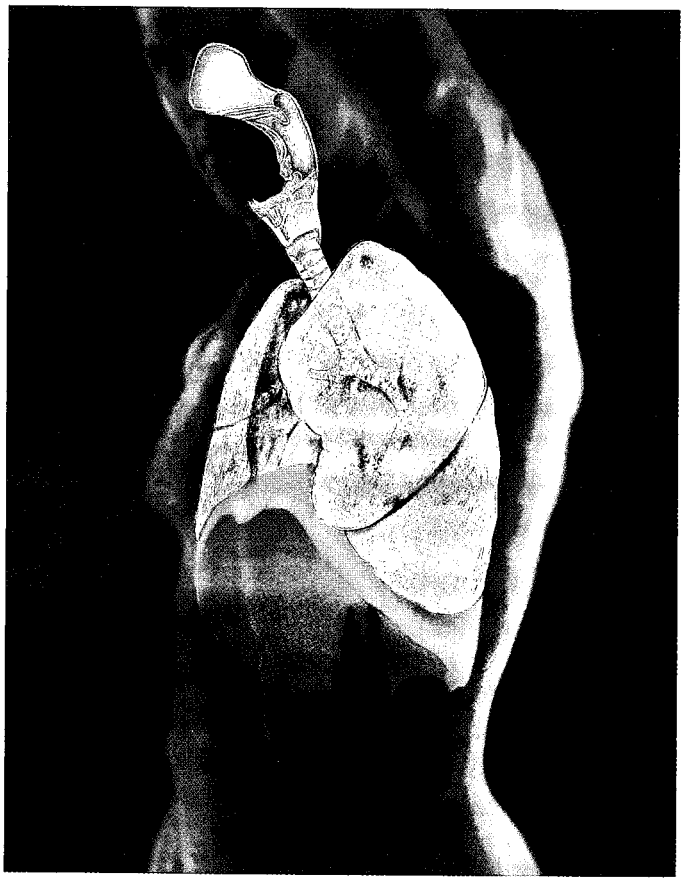
Stuttering A problem of voice production in which the first syllable of words is repeated in "machine-gun" fashion. Primarily a problem with neural control of the larynx and other voice-producing structures. Many stutterers become fluent when whispering or singing, both of which involve a change in the manner of vocalization.

Sudden infant death syndrome (SIDS) Unexpected death of an apparently healthy infant during sleep. Commonly called crib death, SIDS is one of the most frequent causes of death in infants under 1 year old. Believed to be a problem of immaturity of the respiratory control centers. Most cases occur in infants placed in a prone position (on their abdomen) to sleep—a position which may result in hypoxia and hypercapnia due to rebreathing exhaled (CO_2-rich) air. Since 1992, a campaign recommending placing infants on their back to sleep has led to a decline of 40% or more in the incidence of SIDS in the U.S.

Tracheotomy (tra″ke-ot′o-me) Surgical opening of the trachea; done to provide an alternate route for air to reach the lungs when more superior respiratory passageways are obstructed (as by food or a crushed larynx).

MAKING CONNECTIONS

SYSTEMS CONNECTIONS: Homeostatic Interrelationships Between the Respiratory System and Other Body Systems



Integumentary System

- Respiratory system provides oxygen; disposes of carbon dioxide
- Skin protects respiratory system organs by forming surface barriers

Skeletal System

- Respiratory system provides oxygen; disposes of carbon dioxide
- Bones protect lungs and bronchi by enclosure

Muscular System

- Respiratory system provides oxygen needed for muscle activity; disposes of carbon dioxide
- Activity of the diaphragm and intercostal muscles essential for producing volume changes that lead to pulmonary ventilation; regular exercise increases respiratory efficiency

Nervous System

- Respiratory system provides oxygen needed for normal neuronal activity; disposes of carbon dioxide
- Medullary and pons centers regulate respiratory rate and depth; stretch receptors in lungs and chemoreceptors provide feedback

Endocrine System

- Respiratory system provides oxygen; disposes of carbon dioxide; angiotensin converting enzyme in lungs converts antiotensin I to angiotensin II
- Epinephrine dilates the bronchioles; testosterone promotes laryngeal enlargement in pubertal males; glucocorticoids promote surfactant production

Cardiovascular System

- Respiratory system provides oxygen; disposes of carbon dioxide; carbon dioxide present in blood as HCO_3^- and H_2CO_3 contributes to blood buffering
- Blood is the transport medium for respiratory gases

Lymphatic System/Immunity

- Respiratory system provides oxygen; disposes of carbon dioxide; tonsils in pharynx house immune cells
- Lymphatic system helps to maintain blood volume required for respiratory gas transport; immune system protects respiratory organs from bacteria, bacterial toxins, viruses, protozoa, fungi, and cancer

Digestive System

- Respiratory system provides oxygen; disposes of carbon dioxide
- Digestive system provides nutrients needed by respiratory system organs

Urinary System

- Respiratory system provides oxygen; disposes of carbon dioxide to provide short-term pH homeostasis
- Kidneys dispose of metabolic wastes of respiratory system organs (other than carbon dioxide) and maintain long-term pH homeostasis

Reproductive System

- Respiratory system provides oxygen; disposes of carbon dioxide

CLOSER CONNECTIONS

THE RESPIRATORY SYSTEM and Interrelationships with the Cardiovascular, Lymphatic/Immune, and Muscular Systems

Every day we inhale and exhale nearly 10,000 L of air. This accomplishes two things—it supplies the body with the oxygen it needs to oxidize food and release energy, and it expels carbon dioxide, the major waste product of that process. As crucial as breathing is, most of us don't think very often about the importance of having fresh air on call. But the phenomenon of gasping for air is familiar to every athlete. Indeed, the respiratory rate of a competitive swimmer may jump to over 40 breaths/min and the amount of air inhaled per breath may soar from the usual 500 ml to as much as 6 to 7 L.

The respiratory system is beautifully engineered for its function. Its alveoli are flushed with new air more than 15,000 times each day and the alveolar walls are so indescribably thin that red blood cells moving single-file through the pulmonary capillaries can make the gaseous "swaps" with the air-filled alveoli within a fraction of a second. Although every cell in the body depends on this system for the oxygen it needs to live, the respiratory system interactions that we will consider here are those it has with the cardiovascular, lymphatic, and muscular systems.

Cardiovascular System

The interaction between the respiratory and cardiovascular systems is so intimate that these two systems are inseparable. Respiratory system organs, as important as they are, can make only the external gas exchanges, those that occur in the lungs. Although all body cells depend on the respiratory system to provide needed oxygen, they pick up that oxygen not from the lungs but from the blood. Thus, without blood to act as the intermediary and the heart and blood vessels to act as the hardware to pump the blood around the body, all the efforts of the respiratory system would be useless.

In turn, angiotensin converting enzyme on lung capillary endothelium plays an important role in blood pressure regulation.

Lymphatic System/Immunity

Of all body systems, only the respiratory system is completely exposed to the external environment (yes, the skin is exposed but its exposed parts are all dead). Because air contains a rich mix of potentially dangerous inhabitants (bacteria, viruses, fungi, asbestos fibers, etc.), the respiratory system is continuously at risk for infection or damage from external agents. Lymphoid outposts help protect the respiratory tract and enhance the defenses (cilia, mucus) that the respiratory system itself erects. Particularly well situated to apprehend intruders at the oral-nasal-pharynx junction are the palatine, pharyngeal, lingual, and tubal tonsils. Their macrophages engulf foreign antigens and they provide sites where lymphocytes are sensitized to mount immune responses.

Muscular System

Skeletal muscle cells, like other body cells, need oxygen to live. The notable part of this interaction is that most respiratory compensations that occur service increased muscular activity. (It is difficult to think of incidents where this is not the case—the exceptions concern disease conditions.) When we are at rest, the respiratory system operates at basal levels, but any time physical activity becomes more vigorous, the respiratory rhythm picks up the beat to match supply with need and to maintain the acid-base balance of the blood.

CLINICAL CONNECTIONS

Respiratory System

Case study: Barbara Joley was in the bus that was hit broadside. When she was freed from the wreckage, she was deeply cyanotic and her respiration had stopped. Her heart was still beating, but her pulse was fast and thready. The emergency medical technician reported that when Barbara was found, her head was cocked at a peculiar angle and it looked like she had a fracture at the level of the C_2 vertebra. The following questions refer to these observations.

1. How might the "peculiar" head position explain Barbara's cessation of breathing?
2. What procedures (do you think) should have been initiated immediately by the emergency personnel?
3. Why is Barbara cyanotic? Explain cyanosis.
4. Assuming that Barbara survives, how will her accident affect her lifestyle in the future?

Barbara survived transport to the hospital and notes recorded at admission included the following observations.

- Right thorax compressed; ribs 7 to 9 fractured
- Right lung atelectasis

Relative to these notes:

5. What is atelectasis and why is only the right lung affected?
6. How do the recorded injuries relate to the atelectasis?
7. What treatment will be done to reverse the atelectasis? What is the rationale for this treatment?

(Answers in Appendix G)

Chapter Summary

Media study tools that could provide you additional help in reviewing specific key topics of Chapter 22 are referenced below.
IP = *InterActive Physiology*

1. Respiration involves four processes: ventilation, external respiration, transport of respiratory gases in the blood, and internal respiration. Both the respiratory system and the cardiovascular system are involved in respiration.

Functional Anatomy of the Respiratory System (pp. 831–846)

2. Respiratory system organs are divided functionally into conducting zone structures (nose to bronchioles), which filter, warm, and moisten incoming air; and respiratory zone structures (respiratory bronchioles to alveoli), where gas exchanges occur.

The Nose and Paranasal Sinuses (pp. 831–835)

3. The nose provides an airway for respiration; warms, moistens, and cleanses incoming air; and houses the olfactory receptors.

4. The external nose is shaped by bone and cartilage plates. The nasal cavity, which opens to the exterior, is divided by the nasal septum. Paranasal sinuses and nasolacrimal ducts drain into the nasal cavities.

The Pharynx (p. 835)

5. The pharynx extends from the base of the skull to the level of C_6. The nasopharynx is an air conduit; the oropharynx and laryngopharynx are common passageways for food and air. Tonsils are found in the oropharynx and nasopharynx.

The Larynx (pp. 835–838)

6. The larynx, or voice box, contains the vocal folds (cords). It also provides a patent airway and serves as a switching mechanism to route food and air into the proper channels.

7. The epiglottis prevents food or liquids from entering the respiratory channels during swallowing.

The Trachea (pp. 838–840)

8. The trachea extends from the larynx to the main bronchi. The trachea is reinforced by C-shaped cartilage rings, which keep the trachea patent, and its mucosa is ciliated.

The Bronchi and Subdivisions: The Bronchial Tree (pp. 840–842)

9. The right and left main bronchi run into their respective lungs, within which they continue to subdivide into smaller and smaller passageways.

10. The terminal bronchioles lead into respiratory zone structures: respiratory bronchioles, alveolar ducts, alveolar sacs, and finally alveoli. Gas exchange occurs in the alveoli, across the respiratory membrane.

11. As the respiratory conduits become smaller, cartilage is reduced in amount and finally lost; the mucosa thins, and smooth muscle in the walls increases.

IP Respiratory System; Topic: Anatomy Review: Respiratory Structures, p. 6.

The Lungs and Pleurae (pp. 842–846)

12. The lungs, the paired organs of gas exchange, flank the mediastinum in the thoracic cavity. Each is suspended in its own pleural cavity via its root and has a base, an apex, and medial and costal surfaces. The right lung has three lobes; the left has two.

13. The lungs are primarily air passageways/chambers, supported by an elastic connective tissue stroma.

14. The pulmonary arteries carry blood returned from the systemic circulation to the lungs, where gas exchange occurs. The pulmonary veins return newly oxygenated (and most bronchial venous) blood back to the heart to be distributed throughout the body. The bronchial arteries provide the nutrient blood supply of the lungs.

15. The parietal pleura lines the thoracic wall and mediastinum; the visceral pleura covers external lung surfaces. Pleural fluid reduces friction during breathing movements.

IP Respiratory System; Topic: Anatomy Review: Respiratory Structures, pp. 1–5.

Mechanics of Breathing (pp. 846–854)

Pressure Relationships in the Thoracic Cavity (pp. 846–847)

1. Intrapulmonary pressure is the pressure within the alveoli. Intrapleural pressure is the pressure within the pleural cavity; it is always negative relative to intrapulmonary pressures.

IP Respiratory System; Topic: Pulmonary Ventilation, pp. 7–9.

Pulmonary Ventilation: Inspiration and Expiration (pp. 847–849)

2. Gases travel from an area of higher pressure to an area of lower pressure.

3. Inspiration occurs when the diaphragm and external intercostal muscles contract, increasing the dimensions (and volume) of the thorax. As the intrapulmonary pressure drops, air rushes into the lungs until the intrapulmonary and atmospheric pressures are equalized.

4. Expiration is largely passive, occurring as the inspiratory muscles relax and the lungs recoil. When intrapulmonary pressure exceeds atmospheric pressure, gases flow from the lungs.

IP Respiratory System; Topic: Pulmonary Ventilation, pp. 3–6, 11–13.

Physical Factors Influencing Pulmonary Ventilation (pp. 849–851)

5. Friction in the air passageways causes resistance, which decreases air passage and causes breathing movements to become more strenuous. The greatest resistance to air flow occurs in the midsize bronchi.

6. Surface tension of alveolar fluid acts to reduce alveolar size and collapse the alveoli. This tendency is resisted in part by surfactant.

7. Premature infants have problems keeping their lungs inflated owing to the lack of surfactant in their alveoli, resulting in infant respiratory distress syndrome (IRDS). Surfactant formation begins late in fetal development.

8. Total respiratory compliance depends on elasticity of lung tissue and flexibility of the bony thorax. When compliance is impaired, inspiration becomes more difficult.

IP Respiratory System; Topic: Pulmonary Ventilation, pp. 14–18.

Respiratory Volumes and Pulmonary Function Tests (pp. 851–853)

9. The four respiratory volumes are tidal, inspiratory reserve, expiratory reserve, and residual. The four respiratory

capacities are vital, functional residual, inspiratory, and total lung. Respiratory volumes and capacities may be measured by spirometry.

10. Anatomical dead space is the air-filled volume (about 150 ml) of the conducting passageways. If alveoli become nonfunctional in gas exchange, their volume is added to the anatomical dead space, and the sum is the total dead space.

11. Alveolar ventilation is the best index of ventilation efficiency because it accounts for anatomical dead space.

$$AVR = (TV - \text{dead space}) \times \text{respiratory rate}$$

12. The FVC and FEV tests, which determine the rate at which VC air can be expelled, are particularly valuable in distinguishing between obstructive and restrictive disease.

Nonrespiratory Air Movements (p. 854)

13. Nonrespiratory air movements are voluntary or reflex actions that clear the respiratory passageways or express emotions.

Gas Exchanges Between the Blood, Lungs, and Tissues (pp. 854–858)

Basic Properties of Gases (pp. 854–855)

1. Dalton's law states that each gas in a mixture of gases exerts pressure in proportion to its percentage in the total mixture.

2. Henry's law states that the amount of gas that will dissolve in a liquid is proportional to the partial pressure of the gas. Solubility of the gas in the liquid and the temperature are other important factors.

Respiratory System; Topic: Gas Exchange, pp. 1–6.

Composition of Alveolar Gas (p. 855)

3. Alveolar gas contains more carbon dioxide and water vapor and considerably less oxygen than atmospheric air.

External Respiration: Pulmonary Gas Exchange (pp. 855–858)

4. External respiration is the process of gas exchange that occurs in the lungs. Oxygen enters the pulmonary capillaries; carbon dioxide leaves the blood and enters the alveoli. Factors influencing this process include the partial pressure gradients, the thickness of the respiratory membrane, surface area available, and the matching of alveolar ventilation and pulmonary perfusion.

Internal Respiration: Capillary Gas Exchange in the Body Tissues (p. 858)

5. Internal respiration is the gas exchange that occurs between the systemic capillaries and the tissues. Carbon dioxide enters the blood, and oxygen leaves the blood and enters the tissues.

Respiratory System; Topic: Gas Exchange, pp. 6–11, 15–16.

Transport of Respiratory Gases by Blood (pp. 858–863)

Oxygen Transport (pp. 858–861)

1. Molecular oxygen is carried bound to hemoglobin in the blood cells. The amount of oxygen bound to hemoglobin depends on the P_{O_2} and P_{CO_2} of blood, blood pH, the presence of BPG, and temperature. A small amount of oxygen gas is transported dissolved in plasma.

2. Hypoxia occurs when inadequate amounts of oxygen are delivered to body tissues. When this occurs, the skin and mucosae may become cyanotic.

Carbon Dioxide Transport (pp. 861–863)

3. CO_2 is transported in the blood dissolved in plasma, chemically bound to hemoglobin, and (primarily) as bicarbonate ion in plasma. Loading and unloading of O_2 and CO_2 are mutually beneficial.

4. Accumulation of CO_2 leads to decreased pH; depletion of CO_2 from blood leads to increased blood pH.

Respiratory System; Topic: Gas Transport, pp. 1–15.

Control of Respiration (pp. 863–869)

Neural Mechanisms and Generation of Breathing Rhythm (pp. 863–865)

1. Medullary respiratory centers are the dorsal and ventral respiratory groups. The ventral respiratory group is likely responsible for the rhythmicity of breathing.

2. The pontine respiratory centers influence the activity of the medullary respiratory centers.

Factors Influencing Breathing Rate and Depth (pp. 865–869)

3. Important chemical factors modifying baseline respiratory rate and depth are arterial levels of CO_2, H^+, and O_2.

4. An increasing P_{CO_2} is the most powerful respiratory stimulant. It acts (via release of H^+ in the CSF) on the central chemoreceptors to cause a reflexive increase in the rate and depth of breathing. Hypocapnia depresses respiration and results in decreased ventilation and, possibly, apnea.

5. Arterial P_{O_2} levels below 60 mm Hg constitute the hypoxic drive.

6. Decreased pH and a decline in blood P_{O_2} act on peripheral chemoreceptors and enhance the response to CO_2.

7. Emotions, pain, body temperature changes, and other stressors can alter respiration by acting through hypothalamic centers. Respiration can also be controlled voluntarily for short periods.

8. Pulmonary irritant reflexes are initiated by dust, mucus, fumes, and pollutants.

9. The inflation (Hering-Breuer) reflex is a protective reflex initiated by extreme overinflation of the lungs; it acts to terminate inspiration.

Respiratory System; Topic: Control of Respiration, pp. 6–14.

Respiratory Adjustments (pp. 869–870)

Adjustments During Exercise (pp. 869–870)

1. As exercise begins, there is an abrupt increase in ventilation (hyperpnea) followed by a more gradual increase. When exercise stops, there is an abrupt decrease in ventilation followed by a gradual decline to baseline values.

2. P_{O_2}, P_{CO_2}, and blood pH remain quite constant during exercise and hence do not appear to account for changes in ventilation. Inputs from higher centers and proprioceptors may contribute.

Adjustments at High Altitude (p. 870)

3. At high altitudes, there is a decrease in arterial P_{O_2} and hemoglobin saturation levels because of the decrease in barometric pressure compared to sea level. Hyperventilation helps restore P_{O_2} to physiological levels.

4. Long-term acclimatization involves increased erythropoiesis.

Homeostatic Imbalances of the Respiratory System (pp. 870–873)

1. Two major respiratory disorders are COPD (emphysema and chronic bronchitis) and lung cancer; a significant cause is cigarette smoking. A third major disorder is asthma. Multidrug-resistant tuberculosis may become a major health problem.

Chronic Obstructive Pulmonary Disease (pp. 871–872)

2. COPD is characterized by an irreversible decrease in the ability to force air out of the lungs. Patients may become cyanotic as a result of chronic hypoxia.

3. Emphysema is characterized by permanent enlargement and destruction of alveoli. The lungs lose their elasticity, and expiration becomes an active process.

4. Chronic bronchitis is characterized by excessive mucus production in the lower respiratory passageways, which severely impairs ventilation and gas exchange.

Asthma (p. 872)

5. Asthma is a reversible obstructive condition caused by an immune response that causes its victims to wheeze and gasp for air as their inflamed respiratory passages constrict. It is marked by exacerbations and periods of relief from symptoms.

Tuberculosis (p. 872)

6. Tuberculosis (TB), an infectious disease caused by an airborne bacterium, mainly affects the lungs. Although most infected individuals remain asymptomatic by walling off the bacteria in tubercles, disease symptoms ensue when immunity is depressed. Some patients' failure to complete drug therapy have produced multidrug-resistant TB strains.

Lung Cancer (pp. 872–873)

7. Lung cancer, promoted by free radicals and other carcinogens, is extremely aggressive and metastasizes rapidly.

Developmental Aspects of the Respiratory System (pp. 873–875)

1. The superior respiratory system mucosa develops from the invagination of the ectodermal olfactory placodes; that of the inferior passageways develops from an outpocketing of the endodermal foregut lining. Mesoderm forms the walls of the respiratory conduits and the lung stroma.

2. Cystic fibrosis (CF), the most common fatal hereditary disease, results from an abnormal CFTR protein that fails to form a chloride channel. The result is thick mucus which clogs respiratory passages and invites infection.

3. With age, the thorax becomes more rigid, the lungs become less elastic, and vital capacity declines. In addition, sleep apnea becomes more common, and respiratory system protective mechanisms are less effective.

Review Questions

Multiple Choice/Matching

(Some questions have more than one correct answer. Select the best answer or answers from the choices given.)

1. Cutting the phrenic nerves will result in (a) air entering the pleural cavity, (b) paralysis of the diaphragm, (c) stimulation of the diaphragmatic reflex, (d) paralysis of the epiglottis.

2. Which of the following laryngeal cartilages is/are not paired? (a) epiglottis, (b) arytenoids, (c) cricoid, (d) cuneiform, (e) corniculate.

3. Under ordinary circumstances, the inflation reflex is initiated by (a) the inspiratory center, (b) the ventral respiratory group, (c) overinflation of the alveoli and bronchioles, (d) the pontine respiratory centers.

4. The detergent-like substance that keeps the alveoli from collapsing between breaths because it reduces the surface tension of the water film in the alveoli is called (a) lecithin, (b) bile, (c) surfactant, (d) reluctant.

5. Which of the following determines the *direction* of gas movement? (a) solubility in water, (b) partial pressure gradient, (c) temperature, (d) molecular weight and size of the gas molecule.

6. When the inspiratory muscles contract, (a) the size of the thoracic cavity is increased in diameter, (b) the size of the thoracic cavity is increased in length, (c) the volume of the thoracic cavity is decreased, (d) the size of the thoracic cavity is increased in both length and diameter.

7. The nutrient blood supply of the lungs is provided by (a) the pulmonary arteries, (b) the aorta, (c) the pulmonary veins, (d) the bronchial arteries.

8. Oxygen and carbon dioxide are exchanged in the lungs and through all cell membranes by (a) active transport, (b) diffusion, (c) filtration, (d) osmosis.

9. Which of the following would not normally be treated by 100% oxygen therapy? (Choose all that apply.) (a) anoxia, (b) carbon monoxide poisoning, (c) respiratory crisis in an emphysema patient, (d) eupnea.

10. Most oxygen carried in the blood is (a) in solution in the plasma, (b) combined with plasma proteins, (c) chemically combined with the heme in red blood cells, (d) in solution in the red blood cells.

11. Which of the following has the greatest stimulating effect on the respiratory center in the brain? (a) oxygen, (b) carbon dioxide, (c) calcium, (d) willpower.

12. In mouth-to-mouth artificial respiration, the rescuer blows air from his or her own respiratory system into that of the victim. Which of the following statements are correct?

(1) Expansion of the victim's lungs is brought about by blowing air in at higher than atmospheric pressure (positive-pressure breathing).
(2) During inflation of the lungs, the intrapleural pressure increases.
(3) This technique will not work if the victim has a hole in the chest wall, even if the lungs are intact.
(4) Expiration during this procedure depends on the elasticity of the alveolar and thoracic walls.

(a) all of these, (b) 1, 2, 4, (c) 1, 2, 3, (d) 1, 4.

13. A baby holding its breath will (a) have brain cells damaged because of low blood oxygen levels, (b) automatically start to breathe again when the carbon dioxide levels in the blood reach a high enough value, (c) suffer heart damage because of increased pressure in the carotid sinus and aortic arch areas, (d) be called a "blue baby."

14. Under ordinary circumstances, which of the following blood components is of no physiological significance? (a) bicarbonate ions, (b) carbaminohemoglobin, (c) nitrogen, (d) chloride.

15. Damage to which of the following would most likely result in cessation of breathing? (a) the pontine respiratory group, (b) the ventral respiratory group of the medulla, (c) the stretch receptors in the lungs, (d) the dorsal respiratory group of the medulla.

16. The bulk of carbon dioxide is carried (a) chemically combined with the amino acids of hemoglobin as carbaminohemoglobin in the red blood cells, (b) as the ion HCO_3^- in the plasma after first entering the red blood cell, (c) as carbonic acid in the plasma, (d) chemically combined with the heme portion of Hb.

Short Answer Essay Questions

17. Trace the route of air from the external nares to an alveolus. Name subdivisions of organs where applicable, and differentiate between conducting and respiratory zone structures.

18. (a) Why is it important that the trachea is reinforced with cartilage rings? (b) Of what advantage is it that the rings are incomplete posteriorly?

19. Briefly explain the anatomical "reason" why most men have deeper voices than boys or women.

20. The lungs are mostly passageways and elastic tissue. (a) What is the role of the elastic tissue? (b) Of the passageways?

21. Describe the functional relationships between volume changes and gas flow into and out of the lungs.

22. What is it about the structure of the respiratory membrane that makes the alveoli ideal sites for gas exchange?

23. Discuss how airway resistance, lung compliance, and alveolar surface tension influence pulmonary ventilation.

24. (a) Differentiate clearly between minute respiratory volume and alveolar ventilation rate. (b) Which provides a more accurate measure of ventilatory efficiency, and why?

25. State Dalton's law of partial pressures and Henry's law.

26. (a) Define hyperventilation. (b) If you hyperventilate, do you retain or expel more carbon dioxide? (c) What effect does hyperventilation have on blood pH?

27. Describe age-related changes in respiratory function.

Critical Thinking and Clinical Application Questions

1. Harry, the swimmer with the fastest time on the Springfield College swim team, routinely hyperventilates before a meet, as he says, "to sock some more oxygen into my lungs so I can swim longer without having to breathe." First of all, what basic fact about oxygen loading has Harry forgotten (a lapse leading to false thinking)? Second, how is Harry jeopardizing not only his time but his life?

2. A member of the "Blues" gang was rushed into an emergency room after receiving a knife wound in the left side of his thorax. The diagnosis was pneumothorax and a collapsed lung. Explain exactly (a) why the lung collapsed, and (b) why only one lung (not both) collapsed.

3. A surgeon removed three adjacent bronchopulmonary segments from the left lung of a patient with TB. Almost half of the lung was removed, yet there was no severe bleeding, and relatively few blood vessels had to be cauterized (closed off). Why was the surgery so easy to perform?

4. After a week of scuba diving in the Bahamas, Mary Ann boards an airplane. During her flight home, she develops aching joints, nausea, and dyspnea, which resolve upon landing. During the flight, the cabin pressure was equivalent to an altitude of 8000 feet. Explain her problems.

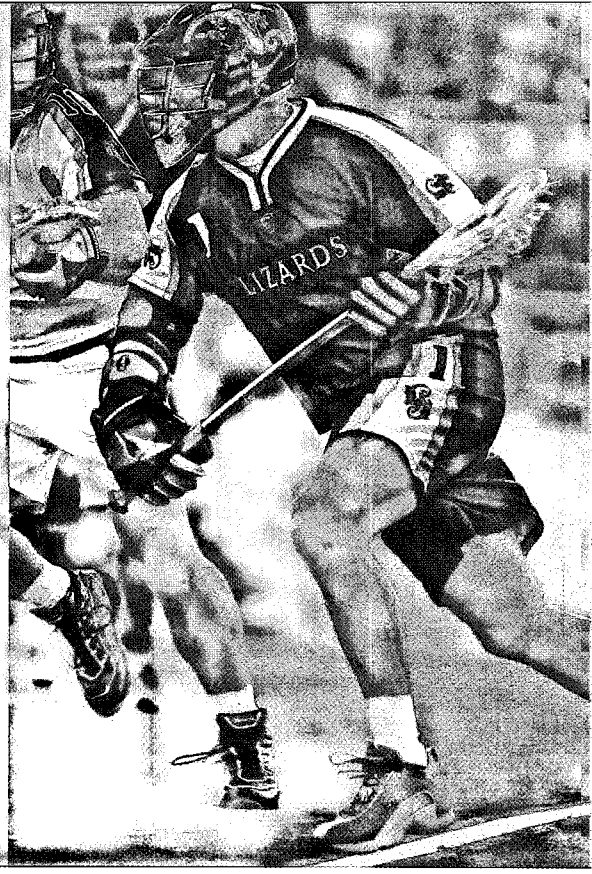
CHAPTER

The Digestive System



PART 1: OVERVIEW OF THE DIGESTIVE SYSTEM (pp. 883–889)

1. Describe the function of the digestive system, and differentiate between organs of the alimentary canal and accessory digestive organs.
2. List and define the major processes occurring during digestive system activity.
3. Describe the location and function of the peritoneum. Define retroperitoneal and name the retroperitoneal organs.
4. Describe the tissue composition and the general function of each of the four layers of the alimentary canal.

PART 2: FUNCTIONAL ANATOMY OF THE DIGESTIVE SYSTEM (pp. 889–927)

5. Describe the anatomy and basic function of each organ and accessory organ of the alimentary canal.
6. Explain the dental formula and differentiate clearly between deciduous and permanent teeth.
7. Describe the composition and functions of saliva, and explain how salivation is regulated.
8. Describe the mechanisms of chewing and swallowing.
9. Identify structural modifications of the wall of the stomach and small intestine that enhance the digestive process in these regions.
10. Describe the composition of gastric juice, name the cell types responsible for secreting its components, and indicate the importance of each component in stomach activity.
11. Explain regulation of gastric secretion and stomach motility.
12. Describe the function of intestinal hormones and paracrines.
13. State the roles of bile and of pancreatic juice in digestion.
14. Describe how entry of pancreatic juice and bile into the small intestine is regulated.
15. List the major functions of the large intestine, and describe the regulation of defecation.

PART 3: PHYSIOLOGY OF CHEMICAL DIGESTION AND ABSORPTION (pp. 927–933)

16. List the enzymes involved in chemical digestion; name the foodstuffs on which they act and the end products of protein, fat, carbohydrate, and nucleic acid digestion.
17. Describe the process of absorption of digested foodstuffs that occurs in the small intestine.

Developmental Aspects of the Digestive System (pp. 933, 936–937)

18. Describe embryonic development of the digestive system.
19. Describe abnormalities of the gastrointestinal tract at different stages of life.

Q *Which of the internal organs depicted here have been met while studying other organ systems?*

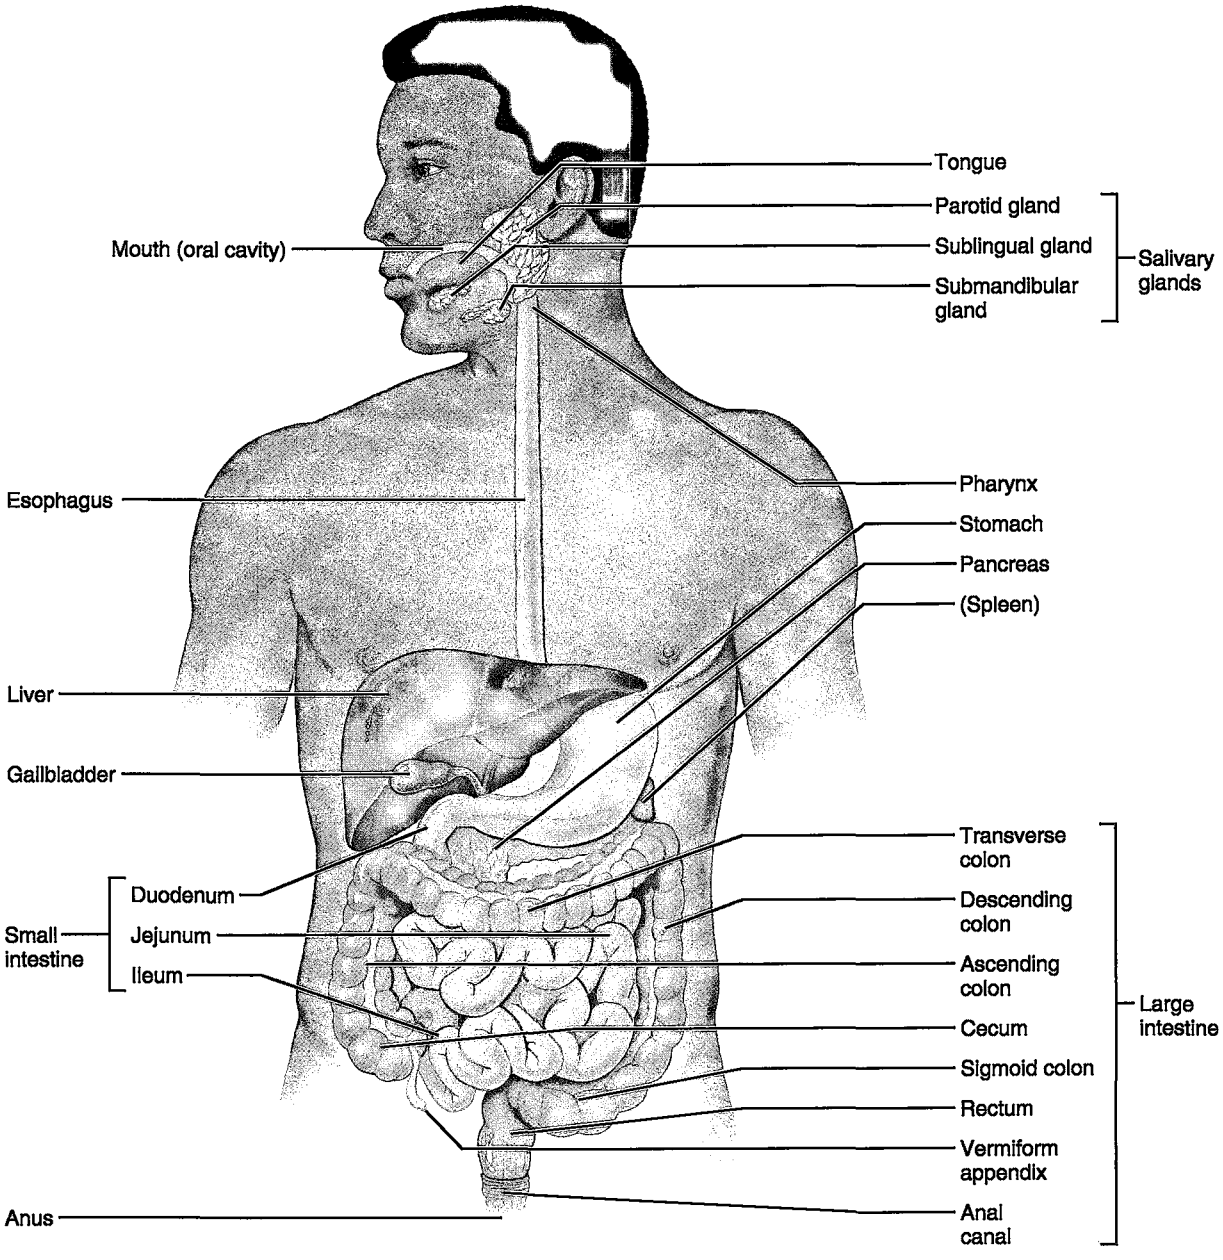


FIGURE 23.1 **Alimentary canal and related accessory digestive organs.**
(See *A Brief Atlas of the Human Body*, figure 64a.)

Children are fascinated by the workings of the digestive system. They relish crunching a potato chip, delight in making "mustaches" with milk, and giggle when their stomach "growls." As adults, we know that a healthy digestive system is essential to maintaining life, because it converts foods into the raw materials that build and fuel our body's cells. Specifically, the **digestive system** takes in food, breaks it down into nutrient molecules, absorbs these molecules into the bloodstream, and then rids the body of the indigestible remains.

PART 1: OVERVIEW OF THE DIGESTIVE SYSTEM

The organs of the digestive system (Figure 23.1) fall into two main groups: (1) those of the *alimentary canal*

A *The pancreas (part of the endocrine system), the spleen (part of the immune system and a "graveyard" for old RBCs), and the pharynx (part of the respiratory system).*

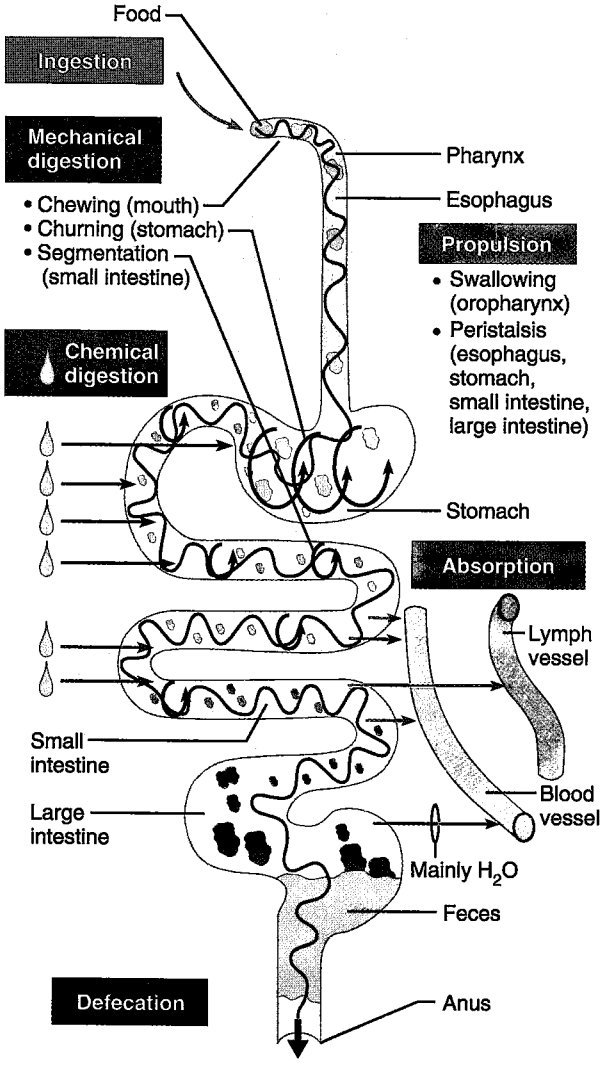

FIGURE 23.2 **Gastrointestinal tract activities.** Gastrointestinal tract activities include ingestion, mechanical digestion, chemical (enzymatic) digestion, propulsion, absorption, and defecation. Sites of chemical digestion are also sites that produce enzymes or that receive enzymes or other secretions made by accessory organs outside the alimentary canal. The mucosa of the GI tract secretes mucus, which protects and lubricates.

(al″ĭ-men′tar-e; *aliment* = nourish) and (2) *accessory digestive organs.*

The **alimentary canal,** also called the **gastrointestinal (GI) tract** or **gut,** is the continuous, muscular digestive tube that winds through the body. It **digests** food—breaks it down into smaller fragments (*digest* = dissolved)—and **absorbs** the digested fragments through its lining into the blood. The organs of the alimentary canal are the *mouth, pharynx, esophagus, stomach, small intestine,* and *large intestine.* The large intestine leads to the terminal opening, or *anus.* In a cadaver, the alimentary canal is approximately 9 m (about 30 ft) long, but in a living person, it is considerably shorter because of its muscle tone. Food material in this tube is technically outside the body because the canal is open to the external environment at both ends.

The **accessory digestive organs** are the *teeth, tongue, gallbladder,* and a number of large digestive glands—the *salivary glands, liver,* and *pancreas.* The teeth and tongue are in the mouth, or oral cavity, while the digestive glands and gallbladder lie outside the GI tract and connect to it by ducts. The accessory digestive glands produce a variety of secretions that contribute to the breakdown of foodstuffs.

Digestive Processes

The digestive tract can be viewed as a "disassembly line" in which food becomes less complex at each step of processing and its nutrients become available to the body. The processing of food by the digestive system involves six essential activities: ingestion, propulsion, mechanical digestion, chemical digestion, absorption, and defecation (Figure 23.2).

1. **Ingestion** is simply taking food into the digestive tract, usually via the mouth.

2. **Propulsion,** which moves food through the alimentary canal, includes *swallowing,* which is initiated voluntarily, and *peristalsis* (per″ĭ-stal′sis), an involuntary process. **Peristalsis** (*peri* = around; *stalsis* = constriction), the major means of propulsion, involves alternate waves of contraction and relaxation of muscles in the organ walls (Figure 23.3a). Its main effect is to squeeze food along the tract, but some mixing occurs as well. In fact, peristaltic waves are so powerful that, once swallowed, food and fluids will reach your stomach even if you stand on your head.

3. **Mechanical digestion** physically prepares food for chemical digestion by enzymes. Mechanical processes include chewing, mixing of food with saliva by the tongue, churning food in the stomach, and segmentation, or rhythmic local constrictions of the intestine (Figure 23.3b). **Segmentation** mixes food with digestive juices and increases the efficiency of absorption by repeatedly moving different parts of the food mass over the intestinal wall.

4. **Chemical digestion** is a series of catabolic steps in which complex food molecules are broken down to their chemical building blocks by enzymes secreted into the lumen of the alimentary canal. Chemical digestion of foodstuffs begins in the mouth and is essentially complete in the small intestine.

5. **Absorption** is the passage of digested end products (plus vitamins, minerals, and water) from the

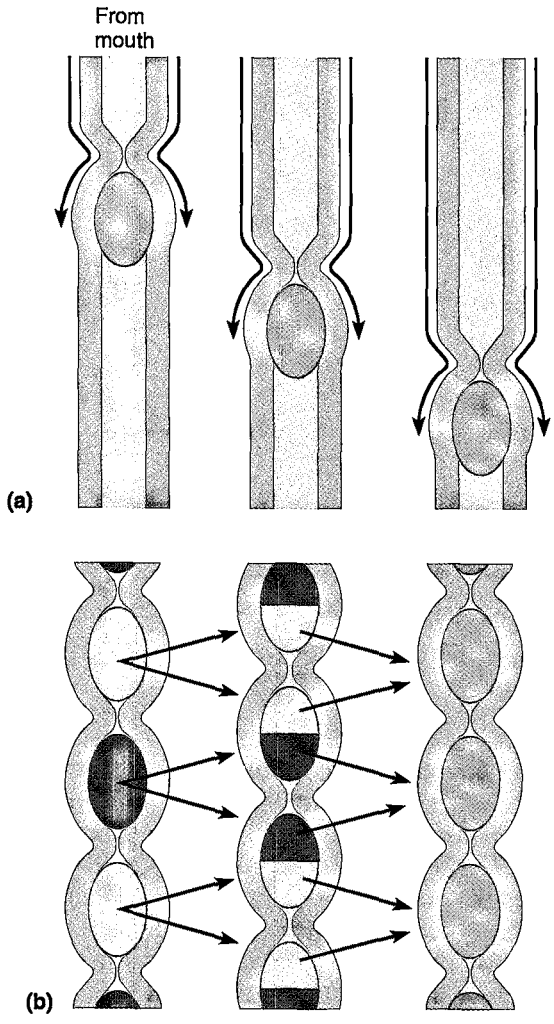

FIGURE 23.3 **Peristalsis and segmentation. (a)** In peristalsis, adjacent segments of the intestine (or other alimentary tract organs) alternately contract and relax, which moves food along the tract distally. **(b)** In segmentation, nonadjacent segments of the intestine alternately contract and relax, moving the food now forward and then backward. This results mainly in food mixing, but slow food propulsion also occurs.

lumen of the GI tract through the mucosal cells by active or passive transport into the blood or lymph. The small intestine is the major absorptive site.

6. Defecation eliminates indigestible substances from the body via the anus in the form of feces.

Some of these processes are the job of a single organ. For example, only the mouth ingests and only the large intestine defecates. But most digestive system activities require the cooperation of several organs and occur bit by bit as food moves along the tract. Later, we will consider which of these specific processes each GI tract organ performs and the neural or hormonal factors that regulate these processes.

Basic Functional Concepts

A theme stressed in this book is the body's efforts to maintain the constancy of its internal environment. Most organ systems respond to changes in that environment either by attempting to restore some plasma variable to its former levels or by changing their own function. The digestive system, however, creates an optimal environment for its functioning in the lumen (cavity) of the GI tract, an area that is actually *outside* the body, and essentially all digestive tract regulatory mechanisms act to control luminal conditions so that digestion and absorption can occur there as effectively as possible.

Two facts apply to these regulatory mechanisms:

1. Digestive activity is provoked by a range of mechanical and chemical stimuli. Sensors (mechanoreceptors and chemoreceptors) involved in controls of GI tract activity are located in the walls of the tract organs (Figure 23.4). These sensors respond to several stimuli; the most important are stretching of the organ by food in the lumen, osmolarity (solute concentration) and pH of the contents, and the presence of substrates and end products of digestion. When stimulated, these receptors initiate reflexes that (1) activate or inhibit glands that secrete digestive juices into the lumen or hormones into the blood or (2) mix lumen contents and move them along the tract by stimulating smooth muscle of the GI tract walls.

2. Controls of digestive activity are both extrinsic and intrinsic. Many of the controlling systems of the

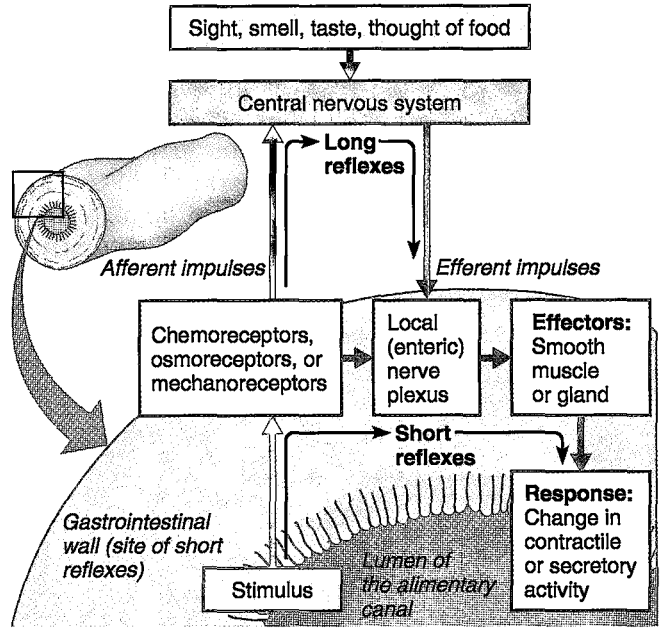

FIGURE 23.4 **Neural reflex pathways initiated by stimuli inside or outside the gastrointestinal tract.**

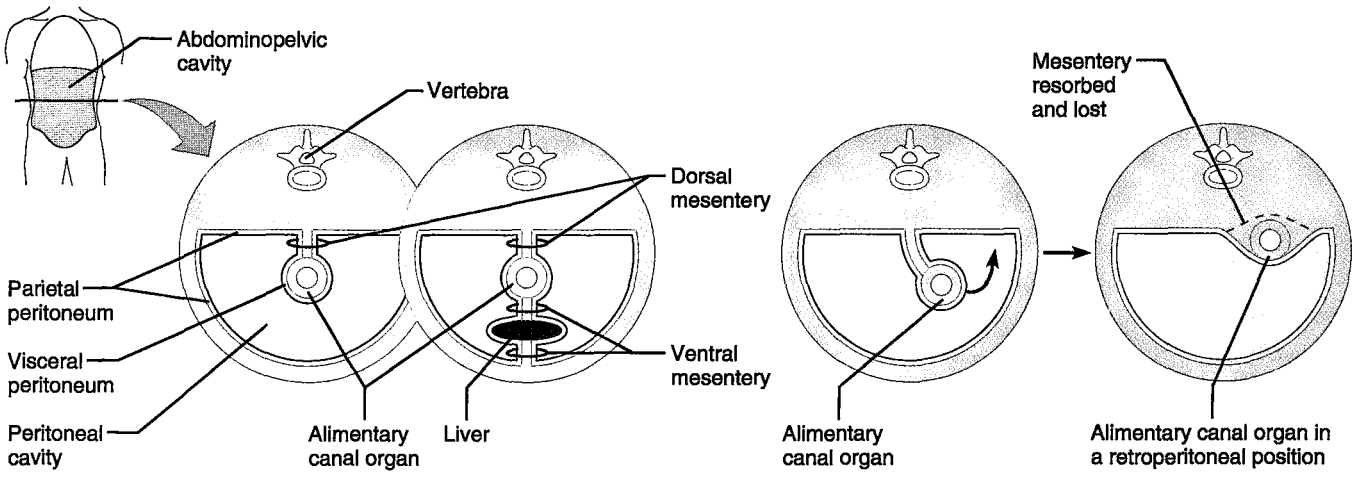

FIGURE 23.5 **The peritoneum and the peritoneal cavity. (a)** Simplified cross sections through the abdominal cavity showing the relative locations of the visceral and parietal peritoneums, and dorsal (left) and ventral (right) mesenteries. Note that the peritoneal cavity is much smaller than depicted here. **(b)** Some alimentary canal organs lose their mesentery during development and become retroperitoneal.

digestive tract are intrinsic—a product of "in-house" nerve plexuses or hormone-producing cells. The wall of the alimentary canal contains nerve plexuses which spread like chicken wire along the entire length of the GI tract and influence each other both in the same and in different digestive organs. As a result, two kinds of reflex activity occur, short and long. *Short reflexes* are mediated entirely by the local *(enteric)* plexuses (the so-called gut brain) in response to GI tract stimuli. *Long reflexes* are initiated by stimuli arising inside or outside the GI tract and involve CNS centers and extrinsic autonomic nerves (Figure 23.4). Generally speaking, nerve fibers that excite smooth muscle secrete acetylcholine or substance P, whereas those that inhibit smooth muscle release vasoactive intestinal peptide (VIP) or nitric oxide.

The stomach and small intestine also contain hormone-producing cells that, when appropriately stimulated, release their products to the interstitial fluid in the extracellular space. These hormones are distributed via blood and interstitial fluid to their target cells in the same or different digestive tract organs, which they prod to secrete or contract.

Digestive System Organs: Relationship and Structural Plan

Relationship of the Digestive Organs to the Peritoneum

Most digestive system organs reside in the abdominopelvic cavity. Recall from Chapter 1 that all ventral body cavities contain slippery *serous membranes.* The **peritoneum** of the abdominopelvic cavity is the most extensive of these membranes (Figure 23.5a). The **visceral peritoneum** covers the external surfaces of most digestive organs and is continuous with the **parietal peritoneum** that lines the body wall. Between the two peritoneums is the **peritoneal cavity,** a slitlike potential space containing fluid secreted by the serous membranes. The serous fluid lubricates the mobile digestive organs, allowing them to glide easily across one another and along the body wall as they carry out their digestive activities.

A **mesentery** (mes'en-ter"e) is a double layer of peritoneum—a sheet of two serous membranes fused back to back—that extends to the digestive organs from the body wall. Mesenteries provide routes for blood vessels, lymphatics, and nerves to reach the digestive viscera; hold organs in place; and store fat. In most places the mesentery is *dorsal* and attaches to the posterior abdominal wall, but there are *ventral* mesenteries as well (Figure 23.5a). Some of the mesenteries, or peritoneal folds, are given specific names (such as the *omenta*), as described later.

Not all alimentary canal organs are suspended by a mesentery. For example, some parts of the small intestine adhere to the dorsal abdominal wall (Figure 23.5b). In so doing, they lose their mesentery and come to lie posterior to the peritoneum. These organs, which include most of the pancreas and parts of the large intestine, are called **retroperitoneal organs** (*retro* = behind). By contrast, digestive organs (like the stomach) that keep their mesentery and remain in the peritoneal cavity are called **intraperitoneal** or **peritoneal organs.**

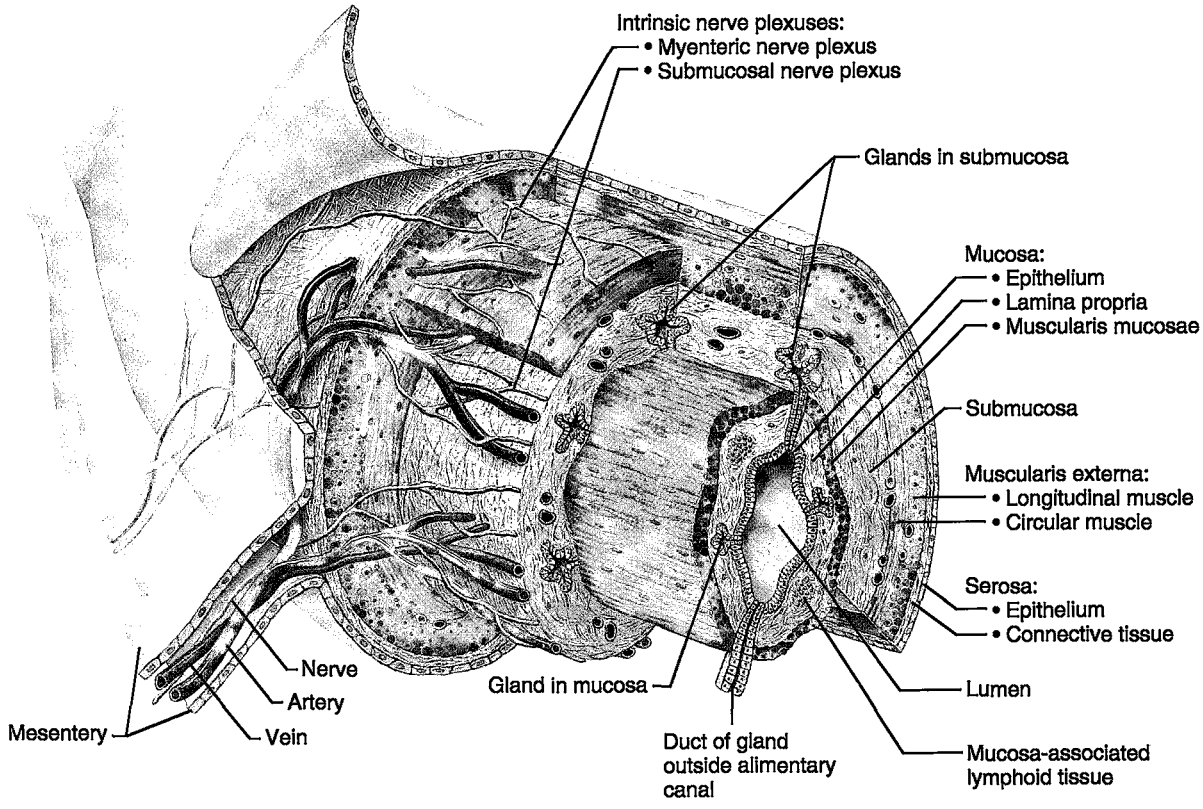

FIGURE 23.6 **Basic structure of the alimentary canal.** Its four basic layers are the mucosa, submucosa, muscularis externa, and serosa.

HOMEOSTATIC IMBALANCE

Peritonitis, or inflammation of the peritoneum, can arise from a piercing abdominal wound or from a perforating ulcer that leaks stomach juices into the peritoneal cavity, but most commonly it results from a burst appendix (that sprays bacteria-containing feces all over the peritoneum). In peritonitis, the peritoneal coverings tend to stick together around the infection site. This localizes the infection, providing time for macrophages to attack to prevent the inflammation from spreading. If peritonitis becomes widespread within the peritoneal cavity, it is dangerous and often lethal. Treatment includes removing as much infectious debris as possible from the peritoneal cavity and administering megadoses of antibiotics. ●

Blood Supply: The Splanchnic Circulation

The **splanchnic circulation** includes those arteries that branch off the abdominal aorta to serve the digestive organs and the *hepatic portal circulation.* The arterial supply—the hepatic, splenic, and left gastric branches of the celiac trunk that serve the spleen, liver, and stomach, and the mesenteric arteries (superior and inferior) that serve the small and large intestines (see pp. 908 and 922)—normally receives one-quarter of the cardiac output. This percentage (blood volume) increases after a meal has been eaten. The hepatic portal circulation (described on pp. 764–765) collects nutrient-rich venous blood draining from the digestive viscera and delivers it to the liver. The liver collects the absorbed nutrients for metabolic processing or for storage before releasing them back to the bloodstream for general cellular use.

Histology of the Alimentary Canal

Each digestive organ has only a share of the work of digestion. Consequently, it helps to consider structural characteristics that promote similar functions in all parts of the alimentary canal before we consider the functional anatomy of the digestive system.

From the esophagus to the anal canal, the walls of the alimentary canal have the same four basic layers, or *tunics* (Figure 23.6)—*mucosa, submucosa, muscularis externa,* and *serosa*—each containing a predominant tissue type that plays a specific role in food breakdown.

The Mucosa

The **mucosa,** or **mucous membrane**—the innermost layer—is a moist epithelial membrane that lines the alimentary canal lumen from mouth to anus. Its major functions are (1) *secretion* of mucus,

digestive enzymes, and hormones, (2) *absorption* of the end products of digestion into the blood, and (3) *protection* against infectious disease. The mucosa in a particular region of the GI tract may express one or all three of these capabilities.

More complex than most other mucosae in the body, the typical digestive mucosa consists of three sublayers: (1) a lining epithelium, (2) a lamina propria, and (3) a muscularis mucosae. Typically, the **epithelium** of the mucosa is a *simple columnar epithelium* rich in mucus-secreting *goblet cells.* The slippery mucus it produces protects certain digestive organs from being digested themselves by enzymes working within their cavities and eases food passage along the tract. In the stomach and small intestine, the mucosa also contains both enzyme-synthesizing and hormone-secreting cells. Thus, in such sites, the mucosa is a diffuse kind of endocrine organ as well as part of the digestive organ.

The **lamina propria** (*proprius* = one's own), which underlies the epithelium, is loose areolar connective tissue. Its capillaries nourish the epithelium and absorb digested nutrients. Its isolated lymphoid follicles, part of **MALT,** the mucosa-associated lymphatic tissue described on p. 782, help defend us against bacteria and other pathogens, which have rather free access to our digestive tract. Particularly large collections of lymphoid follicles occur within the pharynx (as the tonsils) and in the appendix.

External to the lamina propria is the **muscularis mucosae,** a scant layer of smooth muscle cells that produces local movements of the mucosa. For example, twitching of this muscle layer dislodges food particles that have adhered to the mucosa. In the small intestine, it throws the mucosa into a series of small folds that immensely increase its surface area.

The Submucosa

The **submucosa,** just external to the mucosa, is a moderately dense connective tissue containing blood and lymphatic vessels, lymphoid follicles, and nerve fibers. Its rich supply of elastic fibers enables the stomach to regain its normal shape after temporarily storing a large meal. Its extensive vascular network supplies surrounding tissues of the GI tract wall.

The Muscularis Externa

Just deep to the submucosa is the **muscularis externa,** also simply called the **muscularis.** This layer is responsible for segmentation and peristalsis. It typically has an inner *circular layer* and an outer *longitudinal layer* of smooth muscle cells (Figure 23.6). In several places along the tract, the circular layer thickens, forming *sphincters* that act as valves to prevent backflow and control food passage from one organ to the next.

The Serosa

The **serosa,** the protective outermost layer of the intraperitoneal organs, is the *visceral peritoneum.* It is formed of areolar connective tissue covered with *mesothelium,* a single layer of squamous epithelial cells.

In the esophagus, which is located in the thoracic instead of the abdominopelvic cavity, the serosa is replaced by an **adventitia** (ad"ven-tish'e-ah). The adventitia is ordinary fibrous connective tissue that binds the esophagus to surrounding structures. Retroperitoneal organs have *both* a serosa (on the side facing the peritoneal cavity) and an adventitia (on the side abutting the dorsal body wall).

Enteric Nervous System of the Alimentary Canal

The alimentary canal has its own in-house nerve supply, staffed by the so-called **enteric neurons** (*enter* = gut), which communicate widely with one another to regulate digestive system activity. These semiautonomous enteric neurons constitute the bulk of the two major *intrinsic nerve plexuses* (ganglia interconnected by unmyelinated fiber tracts) found in the walls of the alimentary canal: the submucosal and myenteric nerve plexuses (Figure 23.6).

The **submucosal nerve plexus** occupies the submucosa, includes sensory as well as motor neurons, and chiefly regulates the activity of glands and smooth muscle in the mucosa. The large **myenteric nerve plexus** (mi-en'ter-ik; "intestinal muscle") lies between the circular and longitudinal muscle layers of the muscularis externa. Enteric neurons of this plexus provide the major nerve supply to the GI tract wall and control GI tract motility. Control of the patterns of segmentation and peristalsis is largely automatic, involving local reflex arcs between enteric neurons in the same or different plexuses or (even) organs.

The enteric nervous system is also linked to the central nervous system by afferent visceral fibers and by sympathetic and parasympathetic branches (motor fibers) of the autonomic nervous system that enter the intestinal wall and synapse with neurons in the intrinsic plexuses. Thus, digestive activity is also subject to extrinsic controls exerted by autonomic fibers via long reflex arcs. Generally speaking, parasympathetic inputs enhance secretory activity and motility, whereas sympathetic impulses inhibit digestive activities. But the largely independent enteric ganglia are much more than just way stations

What is the protective value of having several sets of tonsils at the oral entry to the pharynx?

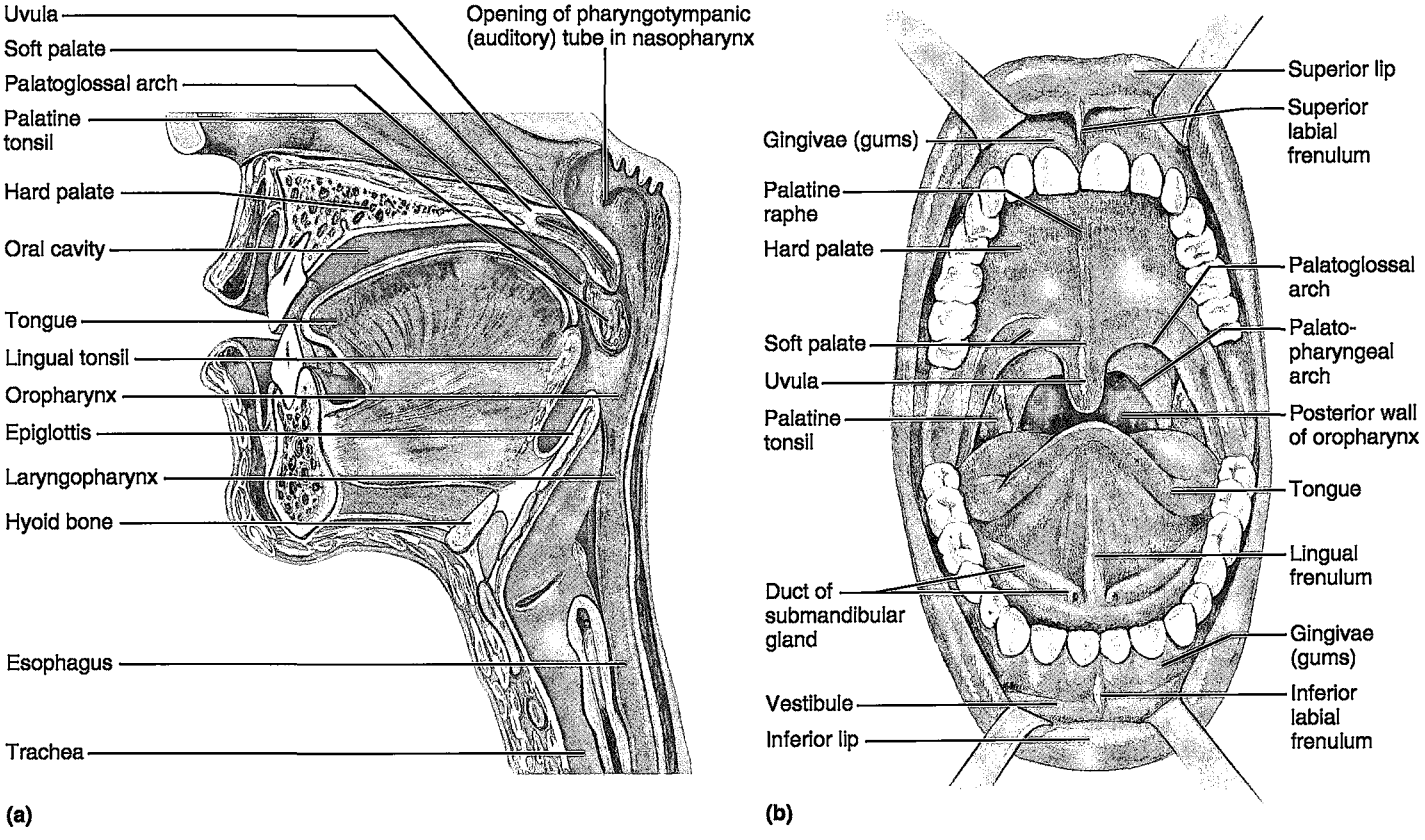

FIGURE 23.7 **Anatomy of the oral cavity (mouth). (a)** Sagittal section of the oral cavity and pharynx. **(b)** Anterior view.

for the autonomic nervous system as is the case in other organ systems. Indeed, the enteric nervous system contains over 100 million neurons, more than the entire spinal cord.

PART 2: FUNCTIONAL ANATOMY OF THE DIGESTIVE SYSTEM

Now that we have summarized some points that unify the digestive system organs, we are ready to consider the special structural and functional capabilities of each organ of this system. Most of the digestive organs are shown in their normal body positions in Figure 23.1, so you may find it helpful to refer back to that illustration from time to time as you read the following sections.

Tonsils contain immune cells (lymphocytes and macrophages) that can remove some foreign substances (bacteria and the like) and prevent them from reaching the stomach and intestines.

The Mouth, Pharynx, and Esophagus

The mouth is the only part of the alimentary canal involved in ingestion. However, most digestive functions associated with the mouth reflect the activity of the related accessory organs, such as the teeth, salivary glands, and tongue, because in the mouth food is chewed and mixed with saliva containing enzymes that begin the process of chemical digestion. The mouth also begins the propulsive process of swallowing, which carries food through the pharynx and esophagus to the stomach.

The Mouth and Associated Organs

The Mouth

The **mouth,** a mucosa-lined cavity, is also called the **oral cavity,** or **buccal cavity** (buk'al). Its boundaries are the lips anteriorly, cheeks laterally, palate superiorly, and tongue inferiorly (Figure 23.7). Its anterior opening is the **oral orifice.** Posteriorly, the oral cavity is continuous with the *oropharynx.* The walls of the mouth are

lined with stratified squamous epithelium which can withstand considerable friction. The epithelium on the gums, hard palate, and dorsum of the tongue is slightly keratinized for extra protection against abrasion during eating. Like all moist surface linings, the oral mucosa responds to injury by producing antimicrobial peptides called *defensins,* which helps to explain how the mouth, a site teeming with disease-causing microbes, remains so remarkably healthy.

The Lips and Cheeks The **lips (labia)** and the **cheeks** have a core of skeletal muscle covered externally by skin. The *orbicularis oris muscle* forms the fleshy lips; the cheeks are formed largely by the *buccinators.* The lips and cheeks help keep food between the teeth when we chew and play a small role in speech. The recess bounded externally by the lips and cheeks and internally by the gums and teeth is called the **vestibule** ("porch"). The area that lies within the teeth and gums is the **oral cavity proper.**

The lips are much larger than most people think; anatomically they extend from the inferior margin of the nose to the superior boundary of the chin. The reddened area where one applies lipstick or lands a kiss is called the **red margin.** This transitional zone, where keratinized skin meets the oral mucosa, is poorly keratinized and translucent, allowing the red color of blood in the underlying capillaries to show through. The lack of sweat or sebaceous glands in this region means it must be moistened with saliva periodically to prevent it from becoming dry and cracked (chapped lips). The **labial frenulum** (fren'u-lum) is a median fold that joins the internal aspect of each lip to the gum (Figure 23.7b).

The Palate The **palate,** forming the roof of the mouth, has two distinct parts: the hard palate anteriorly and the soft palate posteriorly (see Figure 23.7). The **hard palate** is underlain by the palatine bones and the palatine processes of the maxillae, and it forms a rigid surface against which the tongue forces food during chewing. The mucosa on either side of its *raphe* (ra'fe), a midline ridge, is slightly corrugated, which helps to create friction.

The **soft palate** is a mobile fold formed mostly of skeletal muscle. Projecting downward from its free edge is the fingerlike **uvula** (u'vu-lah). The soft palate rises reflexively to close off the nasopharynx when we swallow.

- To demonstrate this action, try to breathe and swallow at the same time.

Laterally, the soft palate is anchored to the tongue by the **palatoglossal arches** and to the wall of the oropharynx by the more posterior **palatopharyngeal arches.** These two paired folds form the boundaries of the **fauces** (faw'sēz; *fauc* = throat), the arched area of the oropharynx that contains the palatine tonsils.

The Tongue

The **tongue** occupies the floor of the mouth and fills most of the oral cavity when the mouth is closed (see Figure 23.7). The tongue is composed of interlacing bundles of skeletal muscle fibers, and during chewing, it grips the food and constantly repositions it between the teeth. The tongue also mixes food with saliva and forms it into a compact mass called a **bolus** (bo'lus; "a lump"), and then initiates swallowing by pushing the bolus posteriorly into the pharynx. The versatile tongue also helps us form consonants (k, d, t, and so on) when we speak.

The tongue has both intrinsic and extrinsic skeletal muscle fibers. The **intrinsic muscles** are confined in the tongue and are not attached to bone. Their muscle fibers, which run in several different planes, allow the tongue to change its shape (but not its position), becoming thicker, thinner, longer, or shorter as needed for speech and swallowing. The **extrinsic muscles** extend to the tongue from their points of origin on bones of the skull or the soft palate, as described in Chapter 10 (see Table 10.2 and Figure 10.7). The extrinsic muscles alter the tongue's position; they protrude it, retract it, and move it from side to side. The tongue has a median septum of connective tissue, and each half contains identical muscle groups. A fold of mucosa, called the **lingual frenulum,** secures the tongue to the floor of the mouth and limits posterior movements of the tongue.

HOMEOSTATIC IMBALANCE

Children born with an extremely short lingual frenulum are often referred to as "tongue-tied" because of speech distortions that result when tongue movement is restricted. This congenital condition, called *ankyloglossia* ("fused tongue"), is corrected surgically by snipping the frenulum. ●

The superior tongue surface bears papillae, peglike projections of the underlying mucosa (Figure 23.8). The conical **filiform papillae** give the tongue surface a roughness that aids in licking semisolid foods (such as ice cream) and provide friction for manipulating foods in the mouth. These papillae, the smallest and most numerous type, align in parallel rows on the tongue dorsum. They contain keratin, which stiffens them and gives the tongue its whitish appearance.

The mushroom-shaped **fungiform papillae** are scattered widely over the tongue surface. Each has a vascular core that gives it a reddish hue. Ten to twelve large **circumvallate,** or **vallate, papillae** are located in a V-shaped row at the back of the tongue. They resemble the fungiform papillae but have an additional surrounding furrow. Pleatlike **foliate papillae** are located on the lateral aspects of the

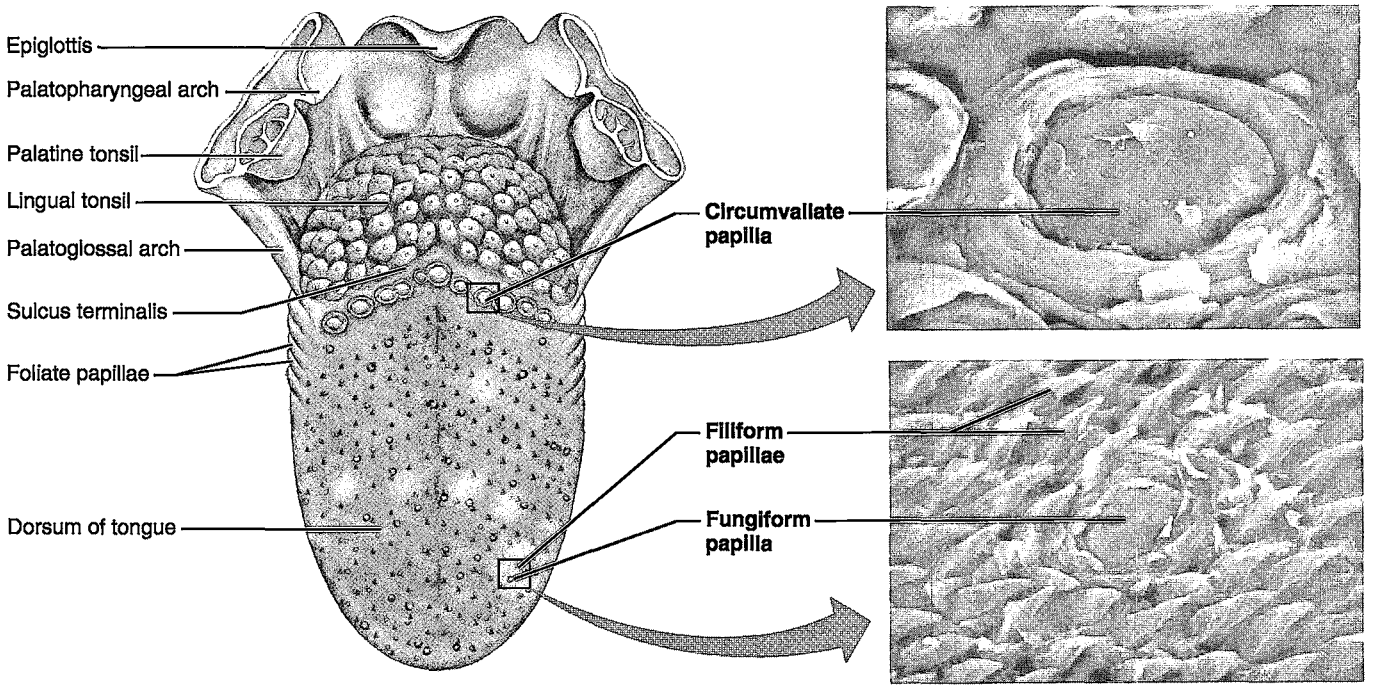

FIGURE 23.8 **Dorsal surface of the tongue.** Also shown are the tonsils, and the locations and detailed structures of the circumvallate, fungiform, filiform, and foliate papillae. (Top right, 300×; bottom right, 100×) (See *A Brief Atlas of the Human Body*, figure 62.)

posterior tongue. The fungiform, circumvallate, and foliate papillae house taste buds; however, those on the foliate papillae function in taste primarily in infancy and early childhood.

Immediately posterior to the circumvallate papillae is the **sulcus terminalis,** a groove that distinguishes the anterior two-thirds of the tongue that lies in the oral cavity from its posterior third residing in the oropharynx. The mucosa covering the root of the tongue lacks papillae, but it is still bumpy because of the nodular *lingual tonsil,* which lies just deep to its mucosa (see Figure 23.8).

The Salivary Glands

A number of glands associated with the oral cavity secrete **saliva.** Saliva (1) cleanses the mouth, (2) dissolves food chemicals so that they can be tasted, (3) moistens food and aids in compacting it into a bolus, and (4) contains enzymes that begin the chemical breakdown of starchy foods.

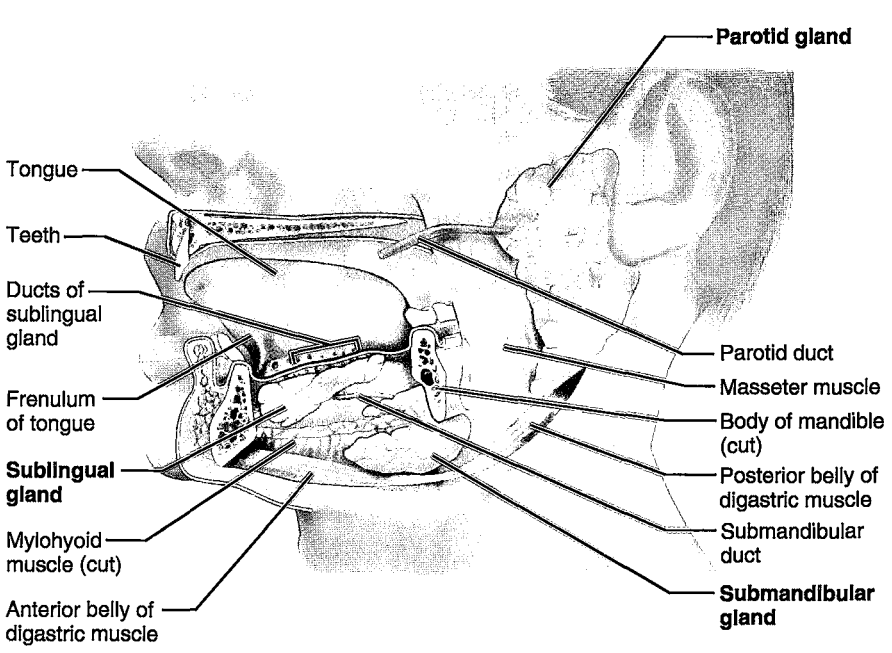
Most saliva is produced by **extrinsic salivary glands** that lie outside the oral cavity and empty their secretions into it. Their output is augmented slightly by small **intrinsic salivary glands,** also called **buccal glands,** scattered throughout the oral cavity mucosa.

The extrinsic salivary glands are paired compound tubuloalveolar glands that develop from the oral mucosa and remain connected to it by ducts (Figure 23.9). The large **parotid gland** (pah-rot'id; *par* = near, *otid* = the ear) lies anterior to the ear between the masseter muscle and the skin. The prominent parotid duct parallels the zygomatic arch, pierces the buccinator muscle, and opens into the vestibule next to the second upper molar. Branches of the facial nerve run through the parotid gland on their way to the muscles of facial expression. For this reason, surgery on this gland can result in facial paralysis.

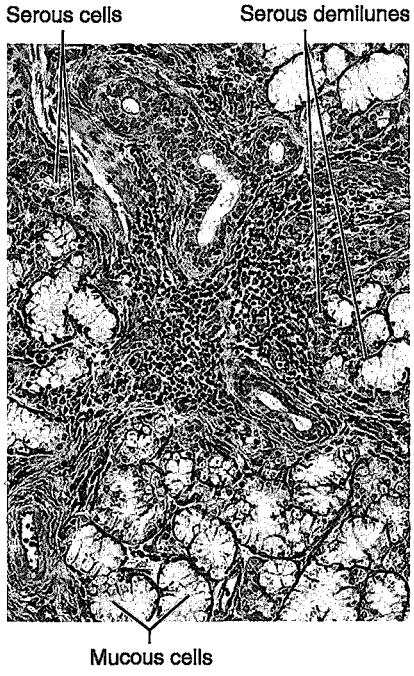
HOMEOSTATIC IMBALANCE

Mumps, a common children's disease, is an inflammation of the parotid glands caused by the mumps virus *(myxovirus),* which spreads from person to person in saliva. If you check the location of the parotid glands in Figure 23.9a, you can understand why people with mumps complain that it hurts to open their mouth or chew. Besides that discomfort, other signs and symptoms of mumps include moderate fever and pain when swallowing acid foods (sour pickles, grapefruit juice, etc.). Mumps viral infections in adult males carry a 25% risk that the testes may become infected as well, leading to sterility. ●

About the size of a walnut, the **submandibular gland** lies along the medial aspect of the mandibular body. Its duct runs beneath the mucosa of the oral cavity floor and opens at the base of the lingual



(a)



(b)

FIGURE 23.9 **The salivary glands. (a)** The parotid, submandibular, and sublingual salivary glands associated with the left aspect of the oral cavity. **(b)** Photomicrograph of the sublingual salivary gland (40×), which is a mixed salivary gland. Mucus-producing cells stain light blue and serous-secreting units stain purple. The serous cells sometimes form demilunes (caps) around the bases of the mucous cells.

frenulum (see Figure 23.7). The small **sublingual gland** lies anterior to the submandibular gland under the tongue and opens via 10–12 ducts into the floor of the mouth.

To a greater or lesser degree, the salivary glands are composed of two types of secretory cells: mucous and serous. **Serous cells** produce a watery secretion containing enzymes, ions, and a tiny bit of mucin, whereas the **mucous cells** produce **mucus,** a stringy, viscous solution. The parotid glands contain only serous cells. Submandibular and buccal glands have approximately equal numbers of serous and mucous cells. The sublingual glands contain mostly mucous cells.

Composition of Saliva Saliva is largely water—97 to 99.5%—and therefore is hypo-osmotic. Its osmolarity depends on the precise glands that are active and the nature of the stimulus for salivation. As a rule, saliva is slightly acidic (pH 6.75 to 7.00), but its pH may vary. Its solutes include electrolytes (Na^+, K^+, Cl^-, PO_4^-, and HCO_3^-); the digestive enzyme salivary amylase; the proteins mucin (mu'sin), lysozyme, and IgA; and metabolic wastes (urea and uric acid). In addition, secretions of the intrinsic salivary glands contain *lingual lipase*, a fat-digesting enzyme that is optimally active at an acid pH. When dissolved in water, the glycoprotein *mucin* forms thick mucus that lubricates the oral cavity and hydrates foodstuffs.

Protection against microorganisms is provided by (1) *IgA antibodies;* (2) *lysozyme,* a bacteriostatic enzyme that inhibits bacterial growth in the mouth and may help to prevent tooth decay; (3) a cyanide compound; and (4) *defensins* (see p. 657). Besides acting as a local antibiotic, defensins function as cytokines to call defensive cells (lymphocytes, neutrophils, etc.) into the mouth for battle. In addition to these four protectors, the friendly bacteria that live on the back of the tongue convert food-derived nitrates in saliva into nitrites which, in turn, are converted into *nitric oxide* in an acid environment. This transformation occurs around the gums, where acid-producing bacteria tend to cluster, and in the hydrochloric acid–rich secretions of the stomach. The highly toxic nitric oxide is believed to act as a bactericidal agent in these locations.

Control of Salivation The intrinsic salivary glands secrete saliva continuously in amounts just sufficient to keep the mouth moist. But when food enters the mouth, the extrinsic glands are activated and copious amounts of saliva pour out. The average output of saliva is 1000–1500 ml per day.

Salivation is controlled primarily by the parasympathetic division of the autonomic nervous system.

When we ingest food, chemoreceptors and mechanoreceptors in the mouth send signals to the **salivatory nuclei** in the brain stem (pons and medulla). As a result, parasympathetic nervous system activity increases and impulses sent via motor fibers in the *facial (VII)* and *glossopharyngeal (IX) nerves* trigger a dramatically increased output of watery (serous), enzyme-rich saliva. The chemoreceptors are activated most strongly by acidic substances such as vinegar and citrus juice. The mechanoreceptors are activated by virtually any mechanical stimulus in the mouth—even rubber bands.

Sometimes just the sight or smell of food is enough to get the juices flowing. The mere thought of hot fudge sauce on peppermint stick ice cream will make many a mouth water! Irritation of the lower regions of the GI tract by bacterial toxins, spicy foods, or hyperacidity—particularly when accompanied by a feeling of nausea—also increases salivation. This response may help wash away or neutralize the irritants.

In contrast to parasympathetic controls, the sympathetic division (specifically fibers in T_1–T_3) causes release of a thick, mucin-rich saliva. Extremely strong activation of the sympathetic division constricts blood vessels serving the salivary glands and almost completely inhibits saliva release, causing a dry mouth *(xerostomia)*. Dehydration also inhibits salivation because low blood volume results in reduced filtration pressure at capillary beds.

HOMEOSTATIC IMBALANCE

Any disease process that inhibits saliva secretion causes a marked increase in dental caries (cavities) and difficulty in talking, swallowing, and eating. Because decomposing food particles are allowed to accumulate and bacteria flourish, *halitosis* (hal″ĭ-to′sis; "bad breath") can result. The odor is caused mainly by the metabolic activity of anaerobic protein-digesting bacteria at the back of the tongue that yields hydrogen sulfide (rotten egg smell), methyl mercaptan (also in feces), cadaverine (associated with rotting corpses), and others. ●

The Teeth

The **teeth** lie in sockets (alveoli) in the gum-covered margins of the mandible and maxilla. The role of the teeth in food processing needs little introduction. We *masticate*, or chew, by opening and closing our jaws and moving them from side to side while continually using our tongue to move the food between our teeth. In the process, the teeth tear and grind the food, breaking it down into smaller fragments.

Dentition and the Dental Formula Ordinarily by age 21, two sets of teeth, the **primary** and **permanent dentitions,** have formed (Figure 23.10). The primary dentition consists of the **deciduous teeth** (de-sid′u-us; *decid* = falling off), also called **milk** or **baby teeth.** The first teeth to appear, at about age 6 months, are the lower central incisors. Additional pairs of teeth erupt at one- to two-month intervals until about 24 months, when all 20 milk teeth have emerged.

As the deep-lying **permanent teeth** enlarge and develop, the roots of the milk teeth are resorbed from below, causing them to loosen and fall out between the ages of 6 and 12 years. Generally, all the teeth of the permanent dentition but the third molars have erupted by the end of adolescence. The third molars, also called *wisdom teeth*, emerge between the ages of 17 and 25 years. There are usually 32 permanent teeth in a full set, but sometimes the wisdom teeth never erupt or are completely absent.

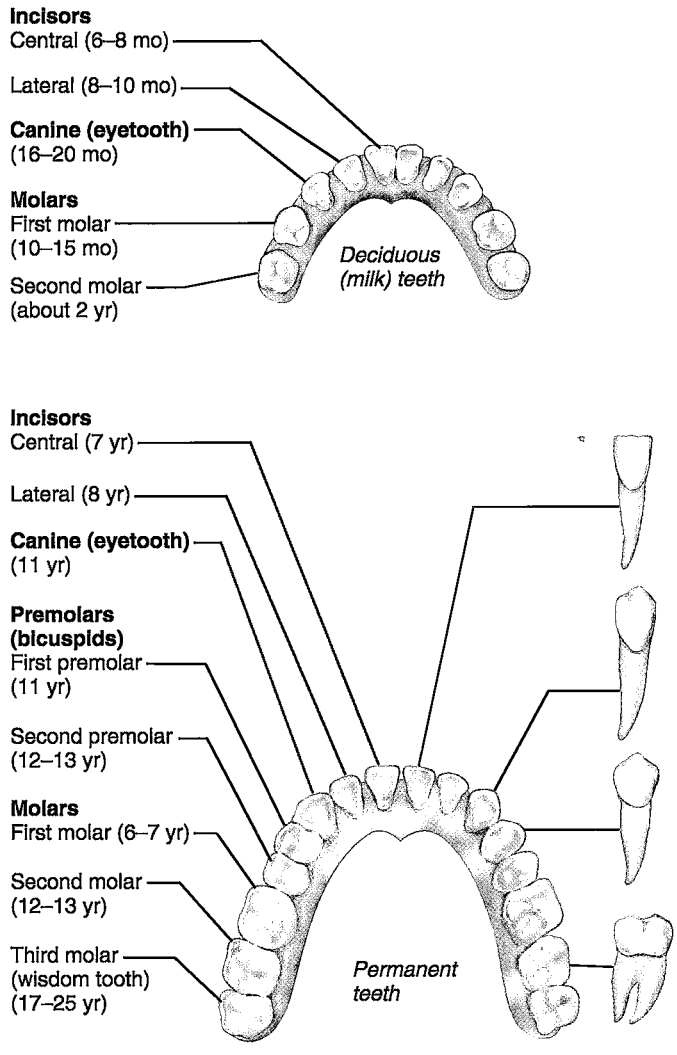


FIGURE 23.10 **Human deciduous and permanent teeth of the lower jaw.** Approximate age at which tooth erupts is shown in parentheses. The shapes of individual teeth are shown on the right.

Q *Which material forms the bulk of the tooth?*

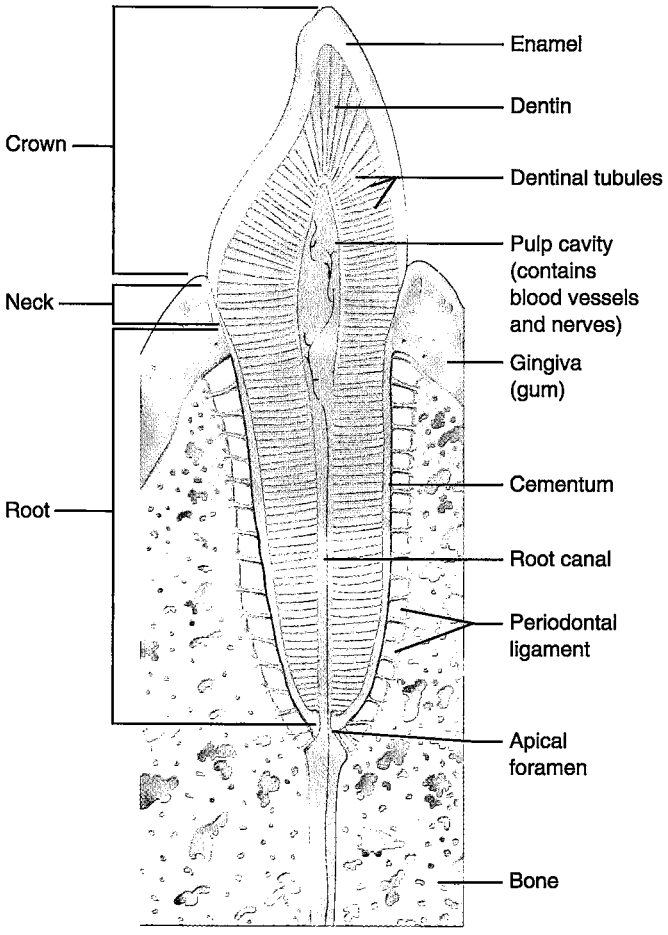

FIGURE 23.11 **Longitudinal section of a canine tooth within its bony alveolus.**

HOMEOSTATIC IMBALANCE

When a tooth remains embedded in the jawbone, it is said to be *impacted.* Impacted teeth can cause a good deal of pressure and pain and must be removed surgically. Wisdom teeth are most commonly impacted. ●

Teeth are classified according to their shape and function as incisors, canines, premolars, and molars (Figure 23.10). The chisel-shaped **incisors** are adapted for cutting or nipping off pieces of food. The conical or fanglike **canines** (cuspids or eyeteeth) tear and pierce. The **premolars** (bicuspids) and **molars** have broad crowns with rounded cusps (tips) and are best suited for grinding or crushing. The molars (literally, "millstones"), with four or five cusps, are the best grinders. During chewing, the upper and lower molars repeatedly lock together, an action that generates tremendous crushing forces.

The **dental formula** is a shorthand way of indicating the numbers and relative positions of the different types of teeth in the mouth. This formula is written as a ratio, uppers over lowers, for *one-half* of the mouth. Since the other side is a mirror image, the total dentition is obtained by multiplying the dental formula by 2. The primary dentition consists of two incisors (I), one canine (C), and two molars (M) on each side of each jaw, and its dental formula is written as

$$\frac{2\text{I, 1C, 2M (upper jaw)}}{2\text{I, 1C, 2M (lower jaw)}} \times 2 \text{ (20 teeth)}$$

Similarly, the permanent dentition [two incisors, one canine, two premolars (PM), and three molars] is

$$\frac{2\text{I, 1C, 2PM, 3M}}{2\text{I, 1C, 2PM, 3M}} \times 2 \text{ (32 teeth)}$$

Tooth Structure Each tooth has two major regions: the crown and the root (Figure 23.11). The enamel-covered **crown** is the exposed part of the tooth above the **gingiva** (jin'jĭ-vah), or **gum,** which surrounds the tooth like a tight collar. **Enamel,** an acellular, brittle material that directly bears the force of chewing, is the hardest substance in the body. It is heavily mineralized with calcium salts, and its densely packed hydroxyapatite (mineral) crystals are oriented in force-resisting columns perpendicular to the tooth's surface. The cells that produce enamel degenerate when the tooth erupts; consequently, any decayed or cracked areas of the enamel will not heal and must be artificially filled.

The portion of the tooth embedded in the jawbone is the **root.** Canine teeth, incisors, and premolars have one root, although the first upper premolars commonly have two. The first two upper molars have three roots, while the corresponding lower molars have two. The root pattern of the third molar varies, but a fused single root is most common.

The crown and root are connected by a constricted tooth region called the **neck.** The outer surface of the root is covered by **cementum,** a calcified connective tissue, which attaches the tooth to the thin **periodontal ligament** (per"e-o-don'tal; "around the tooth"). This ligament anchors the tooth in the bony alveolus of the jaw, forming a fibrous joint called a *gomphosis.* Where the gingiva borders on a tooth, it dips downward to form a shallow groove called the *gingival sulcus.* In youth, the gingiva

A Dentin

adheres tenaciously to the enamel covering the crown. But as the gums begin to recede with age, the gingiva adheres to the more sensitive cementum covering the superior region of the root. As a result, the teeth *appear* to get longer in old age—hence the expression "long in the tooth" sometimes applied to elderly people.

Dentin, a bonelike material, underlies the enamel cap and forms the bulk of a tooth. It surrounds a central **pulp cavity** containing a number of soft tissue structures (connective tissue, blood vessels, and nerve fibers) collectively called **pulp.** Pulp supplies nutrients to the tooth tissues and provides for tooth sensation. Where the pulp cavity extends into the root, it becomes the **root canal.** At the proximal end of each root canal is an **apical foramen** that allows blood vessels, nerves, and other structures to enter the pulp cavity. The teeth are served by the superior and inferior alveolar nerves, branches of the trigeminal nerve (see Table 13.2, p. 504), and by the superior and inferior alveolar arteries, branches of the maxillary artery (see Figure 19.21, p. 749).

Dentin contains unique radial striations called *dentinal tubules* (Figure 23.11). Each tubule contains an elongated process of an **odontoblast** (o-don'to-blast; "tooth former"), the cell type that secretes and maintains the dentin. The cell bodies of odontoblasts line the pulp cavity just deep to the dentin. Dentin is formed throughout adult life and gradually encroaches on the pulp cavity. New dentin can also be laid down fairly rapidly to compensate for tooth damage or decay. Although enamel, dentin, and cementum are all calcified and resemble bone, they differ from bone in that they are avascular. Enamel also differs from cementum and dentin because it lacks collagen as its main organic component.

HOMEOSTATIC IMBALANCE

Death of a tooth's nerve and consequent darkening of the tooth is commonly caused by a blow to the jaw. Local swelling pinches off the blood supply to the tooth and the nerve dies. Typically the pulp becomes infected by bacteria sometime later and must be removed by *root canal therapy.* After the cavity is sterilized and filled with an inert material, the tooth is capped. ●

Tooth and Gum Disease **Dental caries** (kār'ēz; "rottenness"), or **cavities,** result from gradual demineralization of enamel and underlying dentin by bacterial action. Decay begins when **dental plaque** (a film of sugar, bacteria, and other mouth debris) adheres to the teeth. Bacterial metabolism of the trapped sugars produces acids, which can dissolve the calcium salts of the teeth. Once the salts are leached out, the remaining organic matrix of the tooth is readily digested by protein-digesting enzymes released by the bacteria. Frequent brushing and flossing daily help prevent damage by removing forming plaque.

More serious than tooth decay is the effect of unremoved plaque on the gums. As dental plaque accumulates, it calcifies, forming **calculus** (kal'ku-lus; "stone") or tartar, which disrupts the seals between the gingivae and the teeth, deepening the sulcus and putting the gums at risk for infection by pathogenic anaerobic bacteria. In the early stages of such an infection, called *gingivitis* (jin"ji-vi'tis), the gums are red, sore, swollen, and may bleed. Gingivitis is reversible if the calculus is removed, but if it is neglected the bacteria eventually form pockets of infection which elicit the inflammatory response. Neutrophils and immune system cells (lymphocytes and macrophages) attack not only the intruders but also the body tissues, carving deep pockets around the teeth, destroying the periodontal ligament and activating osteoclasts which dissolve the bone away. This more serious condition, called **periodontal disease,** or **periodontitis,** affects up to 95% of all people over the age of 35 and accounts for 80–90% of tooth loss in adults.

Still, tooth loss is not inevitable. Even advanced periodontitis can be treated by scraping the teeth, cleaning the infected pockets, then cutting the gums to shrink the pockets, and following up with anti-inflammatory and antibiotic therapy. Together, these treatments alleviate the bacterial infestations and encourage reattachment of the surrounding tissues to the teeth and bone. Much less painful are (1) a new laser approach for destroying the diseased tissues and (2) a nonsurgical therapy now in clinical trials in which an antibiotic-impregnated film is temporarily glued to the exposed root surface. Clinical treatment is followed up by a home regimen of plaque removal by consistent frequent brushing and flossing and hydrogen peroxide rinses.

There may be more at risk than teeth in those with periodontal disease. Some contend that it increases the risk of heart disease and stroke in at least two ways: (1) the chronic inflammation promotes atherosclerotic plaque formation, and (2) bacteria entering the blood from infected gums stimulate clot formation that helps to clog coronary and cerebral arteries. Risk factors for periodontal disease include smoking, diabetes mellitus, and oral (tongue or lip) piercing.

The Pharynx

From the mouth, food passes posteriorly into the **oropharynx** and then the **laryngopharynx** (see Figure 23.7), both common passageways for food, fluids, and air. (The nasopharynx has no digestive role.)

Q *What is the* functional *significance of the epithelial change seen in part (b)?*

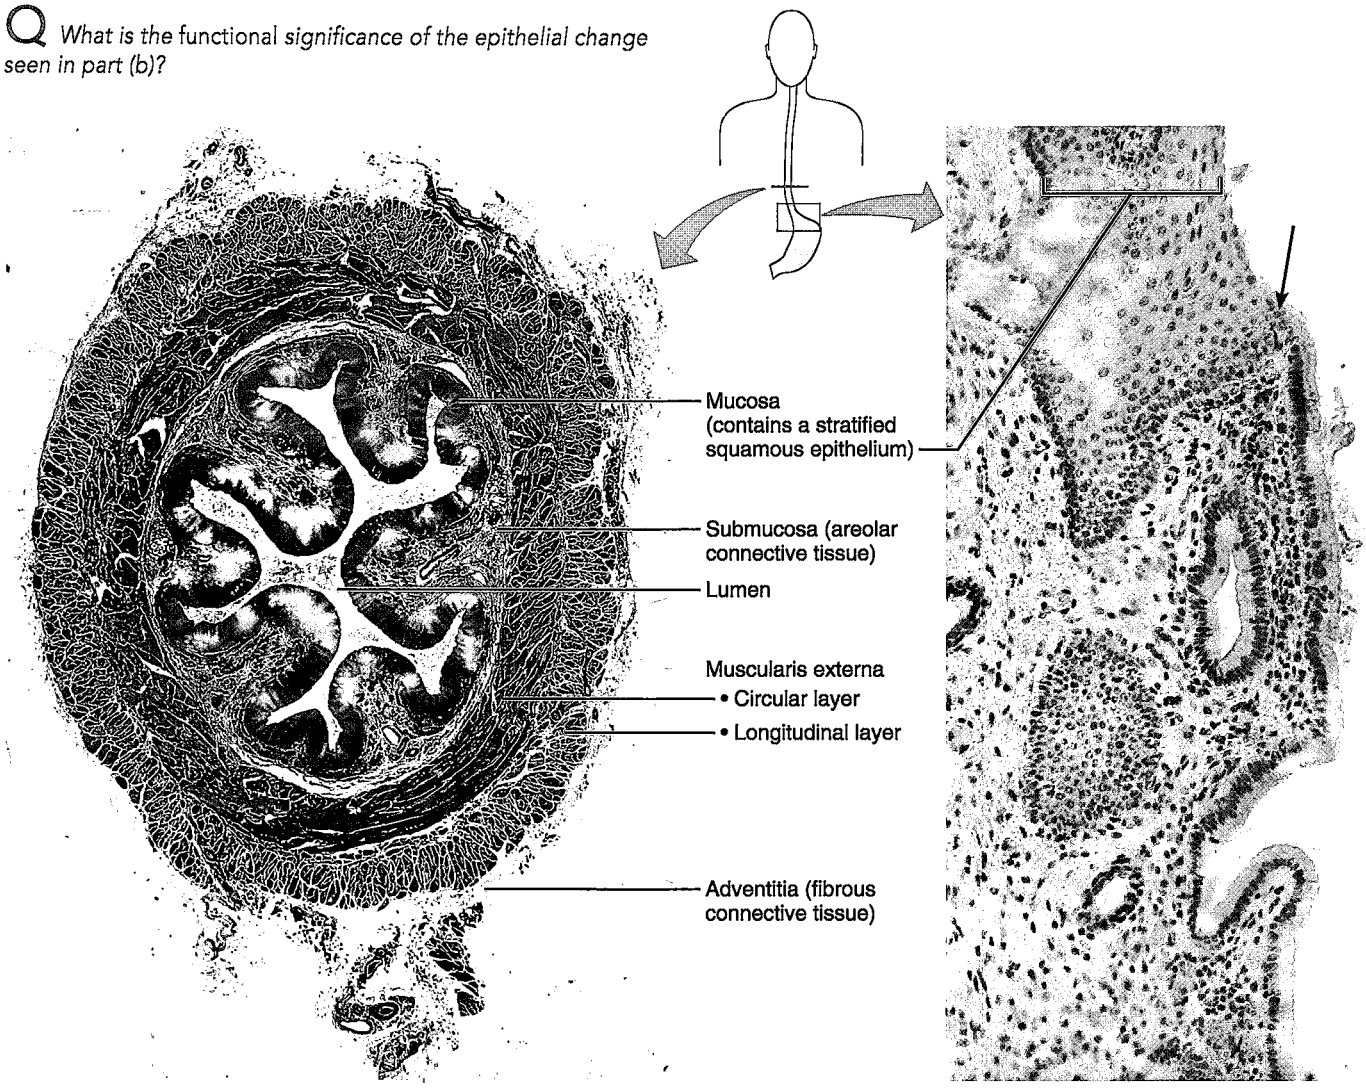

FIGURE 23.12 **Microscopic structure of the esophagus. (a)** Cross-sectional view of the esophagus showing its four tunics (5×). The section shown is taken from the region close to the stomach junction, so the muscularis is composed of smooth muscle. **(b)** Longitudinal section through the esophagus-stomach junction (80×). Arrow shows the point of abrupt transition from the stratified squamous epithelium of the esophagus (top) to the simple columnar epithelium of the stomach (bottom).

The histology of the pharyngeal wall resembles that of the oral cavity. The mucosa contains a friction-resistant stratified squamous epithelium well supplied with mucus-producing glands. The external muscle layer consists of two *skeletal muscle* layers. The cells of the inner layer run longitudinally. Those of the outer layer, the *pharyngeal constrictor muscles,* encircle the wall like three stacked fists (see Figure 10.8). Contractions of these muscles propel food into the esophagus below.

A The presence of the stratified squamous epithelium indicates the esophagus is mainly a chute and thus must accommodate high friction, whereas the stomach has a secretory simple columnar epithelium, reflecting its secretory role in chemical digestion.

The Esophagus

The **esophagus** (ĕ-sof'ah-gus; "carry food"), a muscular tube about 25 cm (10 inches) long, is collapsed when not involved in food propulsion (Figure 23.12). After food moves through the laryngopharynx, it is routed into the esophagus posteriorly as the epiglottis closes off the larynx to food entry.

As shown in Figure 23.1, the esophagus takes a fairly straight course through the mediastinum of the thorax and pierces the diaphragm at the

esophageal hiatus (hi-a'tus; "gap") to enter the abdomen. It joins the stomach at the **cardiac orifice.** The cardiac orifice is surrounded by the **gastroesophageal** or **cardiac sphincter** (gas"tro-ĕ sof"ah-je'al) (see Figure 23.13), which is a *physiological* sphincter. That is, it acts as a valve, but the only structural evidence of this sphincter is a slight thickening of the circular smooth muscle at that point. The muscular diaphragm, which surrounds this sphincter, helps keep it closed when food is not being swallowed.

HOMEOSTATIC IMBALANCE

Heartburn, the first symptom of *gastroesophageal reflux disease (GERD),* is the burning, radiating substernal pain that occurs when the acidic gastric juice regurgitates into the esophagus. Symptoms are so similar to those of a heart attack that many first-time sufferers of heartburn are rushed to the hospital emergency room. Heartburn is most likely to happen when one has eaten or drunk to excess, and in conditions that force abdominal contents superiorly, such as extreme obesity, pregnancy, and running, which causes stomach contents to splash upward with each step (runner's reflux). It is also common in those with a **hiatal hernia,** a structural abnormality (most often due to an abnormal relaxation or weakening of the gastroesophageal sphincter) in which the superior part of the stomach protrudes slightly above the diaphragm. Since the diaphragm no longer reinforces the sphincter, gastric juice may enter the esophagus, particularly when lying down. If the episodes are frequent and prolonged, *esophagitis* (inflammation of the esophagus) and *esophageal ulcers* may result. An even more threatening sequel is esophageal cancer. However, these consequences can usually be prevented or managed by avoiding late-night snacks and by using antacid preparations. ●

Unlike the mouth and pharynx, the esophagus wall has all four of the basic alimentary canal layers described earlier. Some features of interest:

1. The esophageal mucosa contains a nonkeratinized stratified squamous epithelium. At the esophagus-stomach junction, that abrasion-resistant epithelium changes abruptly to the simple columnar epithelium of the stomach, which is specialized for secretion (Figure 23.12b).

2. When the esophagus is empty, its mucosa and submucosa are thrown into longitudinal folds (Figure 23.12a). When food is in transit in the esophagus, these folds flatten out.

3. The submucosa contains mucus-secreting *esophageal glands.* As a bolus moves through the esophagus, it compresses these glands, causing them to secrete mucus that "greases" the esophageal walls and aids food passage.

4. The muscularis externa is skeletal muscle in its superior third, a mixture of skeletal and smooth muscle in its middle third, and entirely smooth muscle in its inferior third.

5. Instead of a serosa, the esophagus has a fibrous adventitia composed entirely of connective tissue, which blends with surrounding structures along its route.

Digestive Processes Occurring in the Mouth, Pharynx, and Esophagus

The mouth and its accessory digestive organs are involved in most digestive processes. The mouth (1) ingests, (2) begins mechanical digestion by chewing, and (3) initiates propulsion by swallowing. Salivary amylase, the main enzyme in saliva, starts the chemical breakdown of polysaccharides (starch and glycogen) into smaller fragments of linked glucose molecules. (If you chew a piece of bread for a few minutes, it will begin to taste sweet as sugars are released.) Lingual lipase, another enzyme in saliva, acts in the acidic environment of the stomach. Except for a few drugs that are absorbed through the oral mucosa (for example, nitroglycerine), essentially no absorption occurs in the mouth.

In contrast to the multifunctional mouth, the pharynx and esophagus merely serve as conduits to pass food from the mouth to the stomach. Their single digestive function is food propulsion, accomplished by the role they play in swallowing.

Since chemical digestion is covered in a special physiology section later in the chapter, only the mechanical processes of chewing and swallowing are discussed here.

Mastication (Chewing)

As food enters the mouth, its mechanical breakdown begins with **mastication,** or chewing. The cheeks and closed lips hold food between the teeth, the tongue mixes food with saliva to soften it, and the teeth cut and grind solid foods into smaller morsels. Mastication is partly voluntary and partly reflexive. We voluntarily put food into our mouths and contract the muscles that close our jaws. The pattern and rhythm of continued jaw movements are controlled mainly by stretch reflexes and in response to pressure inputs from receptors in the cheeks, gums, and tongue, but they can also be voluntary as desired.

Deglutition (Swallowing)

To send food on its way from the mouth, it is first compacted by the tongue into a bolus and then

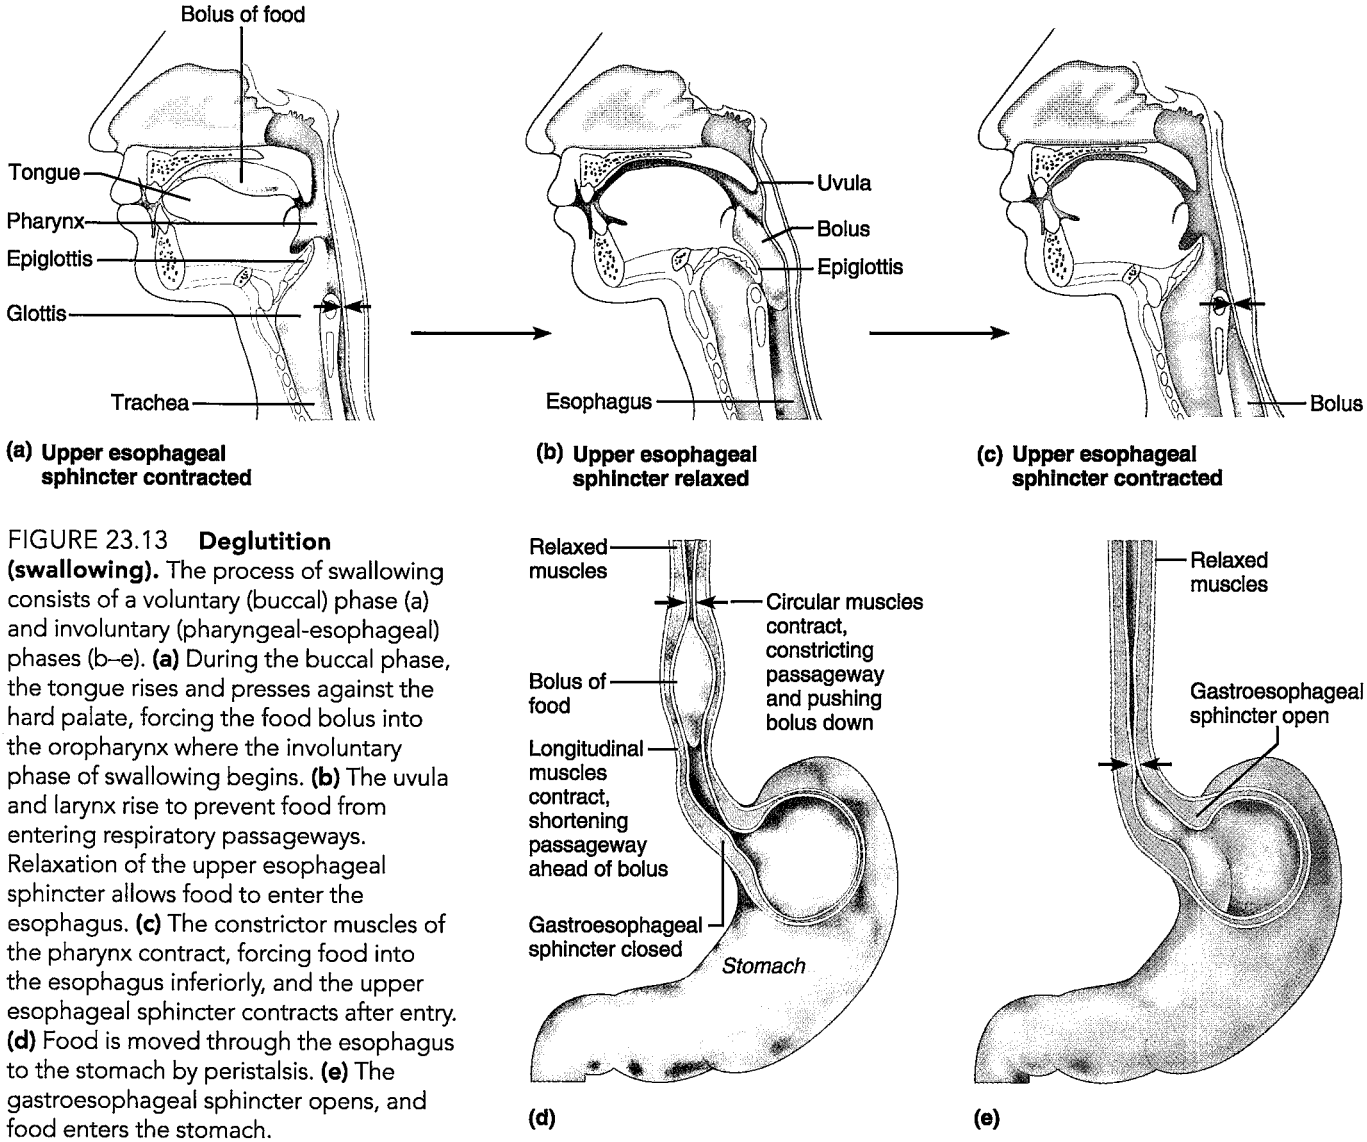

FIGURE 23.13 **Deglutition (swallowing).** The process of swallowing consists of a voluntary (buccal) phase (a) and involuntary (pharyngeal-esophageal) phases (b–e). **(a)** During the buccal phase, the tongue rises and presses against the hard palate, forcing the food bolus into the oropharynx where the involuntary phase of swallowing begins. **(b)** The uvula and larynx rise to prevent food from entering respiratory passageways. Relaxation of the upper esophageal sphincter allows food to enter the esophagus. **(c)** The constrictor muscles of the pharynx contract, forcing food into the esophagus inferiorly, and the upper esophageal sphincter contracts after entry. **(d)** Food is moved through the esophagus to the stomach by peristalsis. **(e)** The gastroesophageal sphincter opens, and food enters the stomach.

swallowed. **Deglutition** (deg"loo-tish'un), or swallowing, is a complicated process that involves coordinated activity of over 22 separate muscle groups. It has two major phases, the buccal and the pharyngeal-esophageal.

The **buccal phase** occurs in the mouth and is voluntary. In the buccal phase, we place the tip of the tongue against the hard palate, and then contract the tongue to force the bolus into the oropharynx (Figure 23.13a). As food enters the pharynx and stimulates tactile receptors there, it passes out of our control and into the realm of involuntary reflex activity.

Triggered by that "bit of saliva" or food reaching receptors in the posterior pharynx, the involuntary **pharyngeal-esophageal phase** of swallowing is controlled by the swallowing center located in the brain stem (medulla and lower pons). Motor impulses from that center are transmitted via various cranial nerves, most importantly the vagus nerves, to the muscles of the pharynx and esophagus. Once food enters the pharynx, respiration is momentarily inhibited and as illustrated in Figure 23.13b, all routes except the desired one—into the digestive tract—are blocked off:

- The tongue blocks off the mouth.
- The soft palate rises to close off the nasopharynx.
- The larynx rises so that the epiglottis covers its opening into the respiratory passageways, and the upper esophageal sphincter relaxes.

Food is moved along through the pharynx and into the esophagus by pressure gradients created by wavelike peristaltic contractions (Figure 23.13c–e). Solid foods pass from the oropharynx to the stomach in about 8 seconds; fluids, aided by gravity, pass in 1 to 2 seconds. Just before the peristaltic wave (and food) reaches the end of the esophagus, the gastroesophageal sphincter relaxes reflexively to allow food to enter the stomach. After food entry, that sphincter closes, preventing regurgitation.

Q *What structural modification of a tunic underlies the stomach's ability to mechanically digest food?*

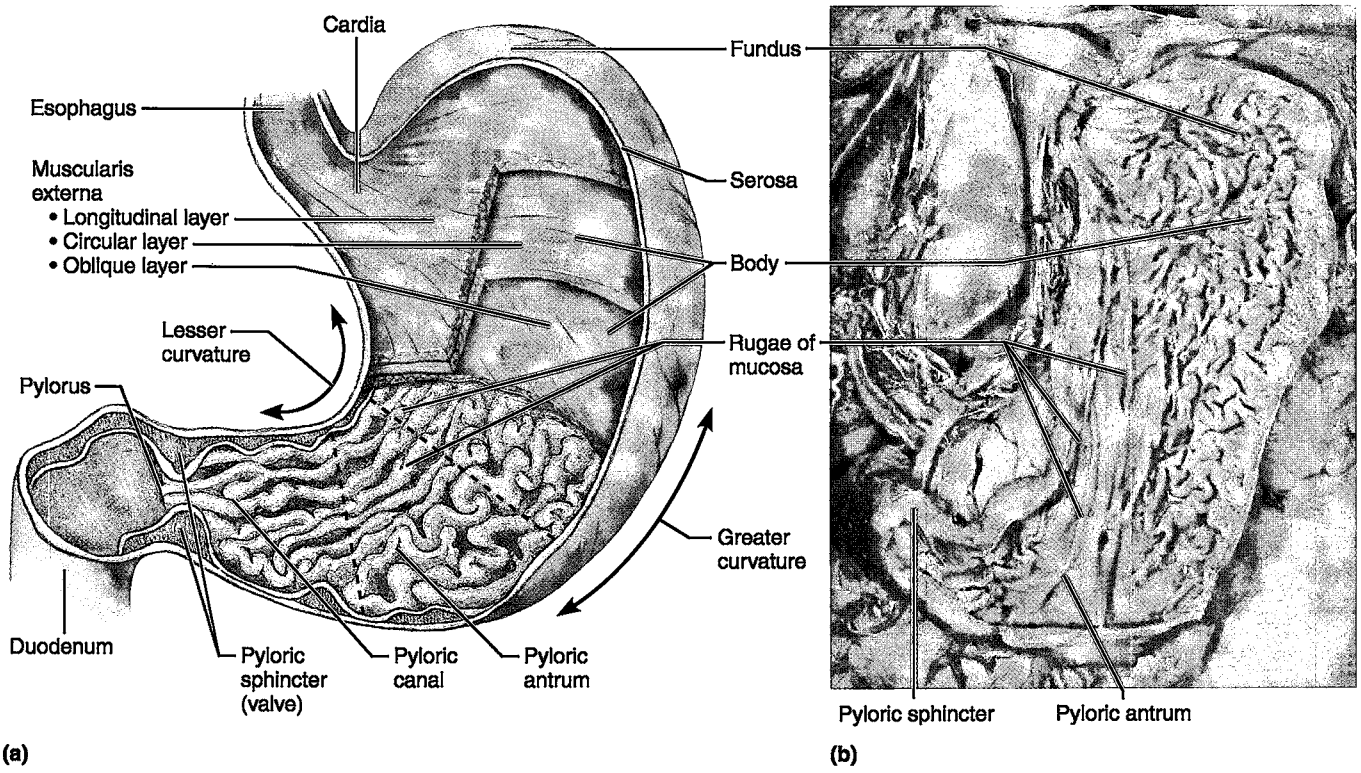

FIGURE 23.14 **Anatomy of the stomach. (a)** Gross internal anatomy (frontal section). **(b)** Photograph of internal aspect of stomach. (See *A Brief Atlas of the Human Body*, figure 69a.)

If we try to talk or inhale while swallowing, the various protective mechanisms may be short-circuited and food may enter the respiratory passageways instead. This event typically triggers the cough reflex in an attempt to expel the food.

The Stomach

Below the esophagus, the GI tract expands to form the **stomach** (see Figure 23.1), a temporary "storage tank" where chemical breakdown of proteins begins and food is converted to a creamy paste called **chyme** (kīm; "juice"). The stomach lies in the upper left quadrant of the peritoneal cavity, nearly hidden by the liver and diaphragm. Specifically, it lies in the left hypochondriac, epigastric, and umbilical regions of the abdomen. Though relatively fixed at both ends, the stomach is quite movable in between. It tends to lie high and run horizontally in short, stout people (a steer-horn stomach) and is often elongated vertically in tall, thin people (a J-shaped stomach).

A *The muscularis externa has a third layer of smooth muscle in which the fibers run obliquely, allowing the stomach to exhibit churning movements that physically break down the food.*

Gross Anatomy

The adult stomach varies from 15 to 25 cm (6 to 10 inches) long, but its diameter and volume depend on how much food it contains. An empty stomach has a volume of about 50 ml and a cross-sectional diameter only slightly larger than the large intestine, but when it is really distended it can hold about 4 L (1 gallon) of food and may extend nearly all the way to the pelvis! When empty, the stomach collapses inward, throwing its mucosa (and submucosa) into large, longitudinal folds called **rugae** (roo'ge; *ruga* = wrinkle, fold).

The major regions of the stomach are shown in Figure 23.14a. The small **cardiac region,** or **cardia** ("near the heart"), surrounds the cardiac orifice through which food enters the stomach from the esophagus. The **fundus** is its dome-shaped part, tucked beneath the diaphragm, that bulges superolaterally to the cardia. The **body,** the midportion of

the stomach, is continuous inferiorly with the funnel-shaped **pyloric region.** The wider and more superior part of the pyloric region, the **pyloric antrum** (*antrum* = cave) narrows to form the **pyloric canal,** which terminates at the **pylorus.** The pylorus is continuous with the duodenum (the first part of the small intestine) through the **pyloric sphincter,** which controls stomach emptying (*pylorus* = gatekeeper).

The convex lateral surface of the stomach is its **greater curvature,** and its concave medial surface is the **lesser curvature.** Extending from these curvatures are two mesenteries, called *omenta* (o-men'tah), that help tether the stomach to other digestive organs and the body wall (see Figure 23.30, p. 924). The **lesser omentum** runs from the liver to the lesser curvature of the stomach, where it becomes continuous with the visceral peritoneum covering the stomach. The **greater omentum** drapes inferiorly from the greater curvature of the stomach to cover the coils of the small intestine. It then runs dorsally and superiorly, wrapping the spleen and the transverse portion of the large intestine before blending with the *mesocolon,* a dorsal mesentery that secures the large intestine to the parietal peritoneum of the posterior abdominal wall. The greater omentum is riddled with fat deposits (*oment* = fatty skin) that give it the appearance of a lacy apron. It also contains large collections of lymph nodes. The immune cells and macrophages in these nodes "police" the peritoneal cavity and intraperitoneal organs.

The stomach is served by the autonomic nervous system. Sympathetic fibers from thoracic splanchnic nerves are relayed through the celiac plexus. Parasympathetic fibers are supplied by the vagus nerve. The arterial supply of the stomach is provided by branches (gastric and splenic) of the celiac trunk (see Figure 19.23). The corresponding veins are part of the hepatic portal system (see Figure 19.28c) and ultimately drain into the hepatic portal vein.

Microscopic Anatomy

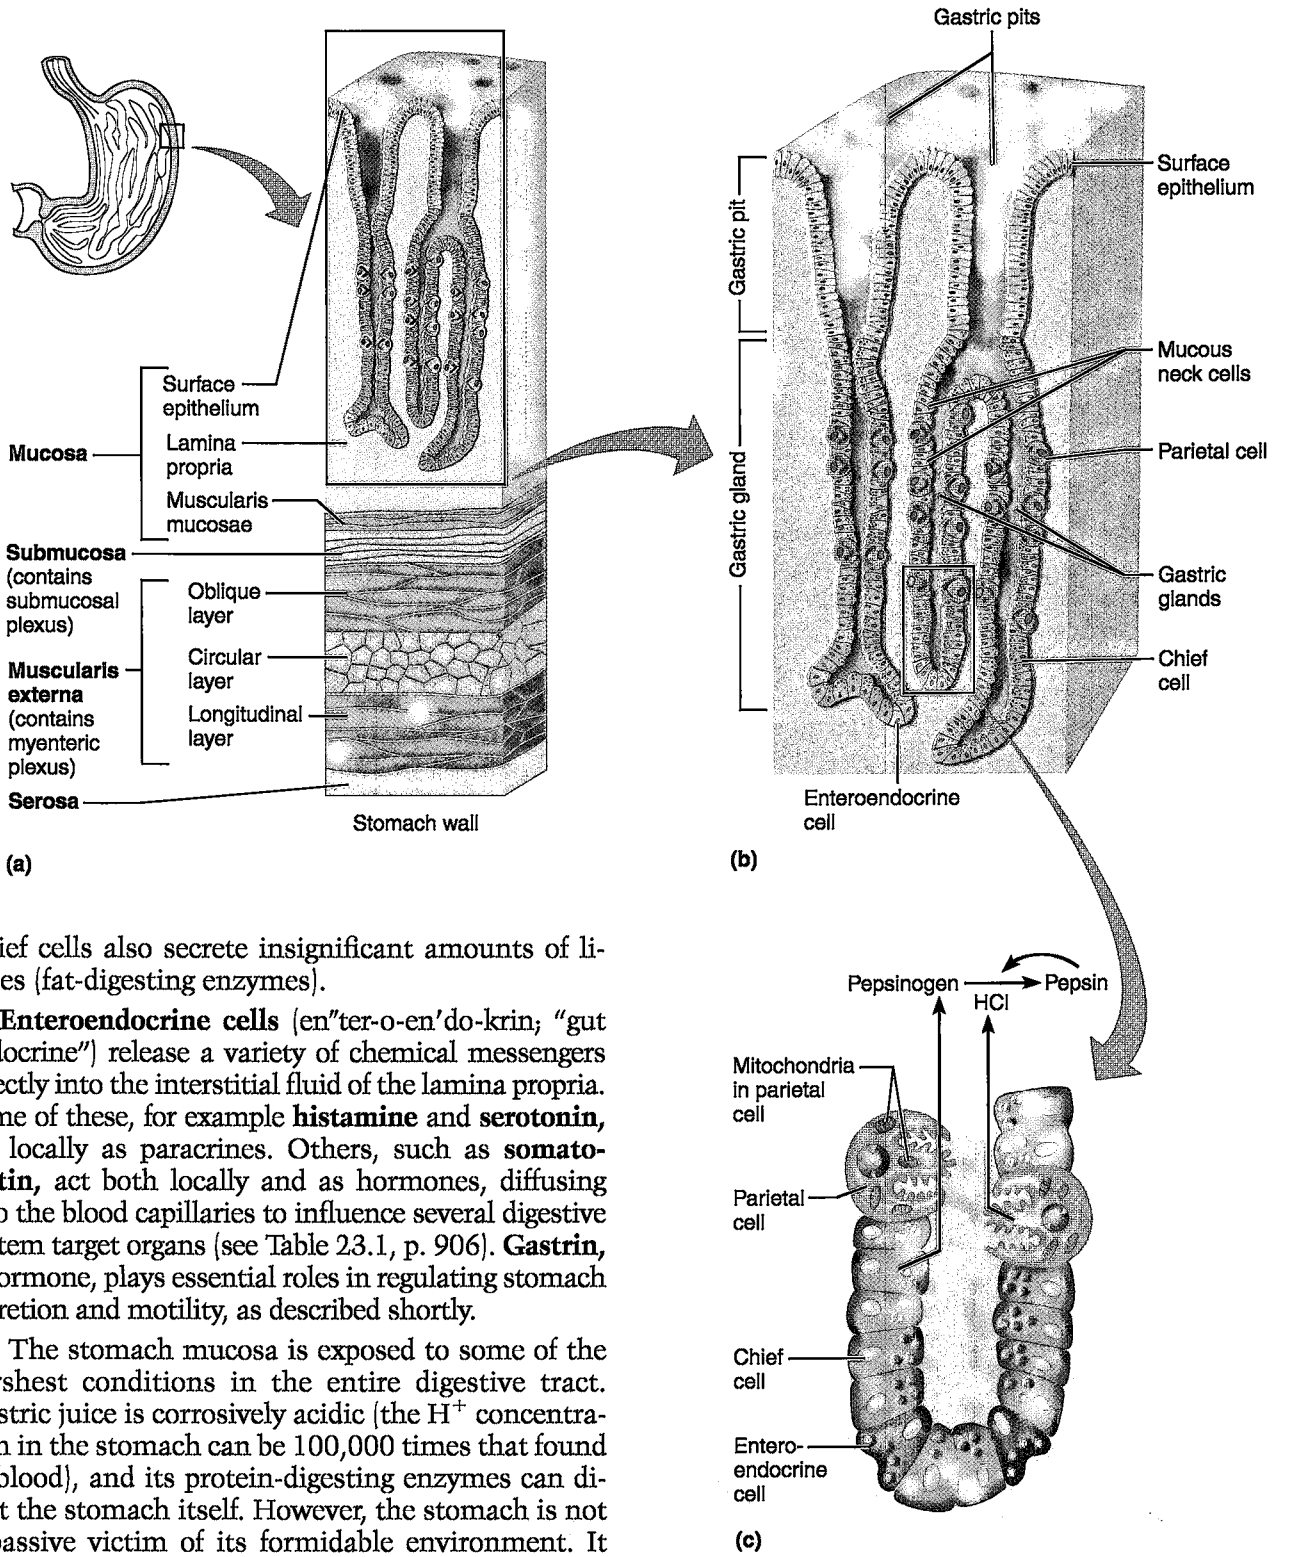
The stomach wall contains the four tunics typical of most of the alimentary canal, but its muscularis and mucosa are modified for the special roles of the stomach. Besides the usual circular and longitudinal layers of smooth muscle, the muscularis externa has an innermost smooth muscle layer that runs *obliquely* (Figure 23.14a and Figure 23.15). This arrangement allows the stomach not only to move food along the tract, but also to churn, mix, and pummel the food, physically breaking it down into smaller fragments.

The lining epithelium of the stomach mucosa is a simple columnar epithelium composed entirely of goblet cells, which produce a protective two-layer coat of alkaline mucus in which the surface layer consists of viscous mucus that traps a layer of bicarbonate-rich fluid beneath it. This otherwise smooth lining is dotted with millions of deep **gastric pits** (Figure 23.15), which lead into the **gastric glands** that produce the stomach secretion called **gastric juice.** The cells forming the walls of the gastric pits are primarily goblet cells, but those composing the gastric glands vary in different stomach regions. For example, the cells in the glands of the cardia and pylorus are primarily mucus secreting, whereas cells of the pyloric antrum produce mucus and several hormones including most of the stimulatory hormone called gastrin. Glands of the stomach fundus and body, where most chemical digestion occurs, are substantially larger and produce the majority of the stomach secretions. The glands in these regions contain a variety of secretory cells, including the four types described here:

1. Mucous neck cells, found in the upper, or "neck," regions of the glands, produce a thin, quite different type of mucus from that secreted by the goblet cells of the surface epithelium. It is not yet understood what special function this *acidic* mucus performs.

2. Parietal cells, found mainly in the middle region of the glands scattered among the chief cells (described next), simultaneously secrete *hydrochloric acid (HCl)* and *intrinsic factor.* Although the parietal cells appear spherical when viewed with a light microscope, they actually have three prongs that exhibit dense microvilli (they look like fuzzy pitchforks!). This structure provides a huge surface area for secreting H^+ and Cl^- into the stomach lumen. HCl makes the stomach contents extremely acidic (pH 1.5–3.5), a condition necessary for activation and optimal activity of pepsin. The acidity also helps in food digestion by denaturing proteins and breaking down cell walls of plant foods, and is harsh enough to kill many of the bacteria ingested with foods. Intrinsic factor is a glycoprotein required for vitamin B_{12} absorption in the small intestine.

3. Chief cells produce *pepsinogen* (pep-sin'o-jen), the inactive form of the protein-digesting enzyme **pepsin.** The chief cells occur mainly in the basal regions of the gastric glands. When chief cells are stimulated, the first pepsinogen molecules they release are activated by HCl encountered in the apical region of the gland (Figure 23.15c). But once pepsin is present, it also catalyzes the conversion of pepsinogen to pepsin. This positive feedback process is limited only by the amount of pepsinogen present. The activation process involves removal of a small peptide fragment from the pepsinogen molecule, causing it to change shape and expose its active site.



Chief cells also secrete insignificant amounts of lipases (fat-digesting enzymes).

4. Enteroendocrine cells (en"ter-o-en'do-krin; "gut endocrine") release a variety of chemical messengers directly into the interstitial fluid of the lamina propria. Some of these, for example **histamine** and **serotonin,** act locally as paracrines. Others, such as **somatostatin,** act both locally and as hormones, diffusing into the blood capillaries to influence several digestive system target organs (see Table 23.1, p. 906). **Gastrin,** a hormone, plays essential roles in regulating stomach secretion and motility, as described shortly.

The stomach mucosa is exposed to some of the harshest conditions in the entire digestive tract. Gastric juice is corrosively acidic (the H^+ concentration in the stomach can be 100,000 times that found in blood), and its protein-digesting enzymes can digest the stomach itself. However, the stomach is not a passive victim of its formidable environment. It mounts an aggressive counterattack to protect itself, producing what is called the **mucosal barrier.** Three factors create this barrier:

1. A thick coating of bicarbonate-rich mucus is built up on the stomach wall.
2. The epithelial cells of the mucosa are joined together by tight junctions that prevent gastric juice from leaking into the underlying tissue layers.

FIGURE 23.15 **Microscopic anatomy of the stomach.** **(a)** Layers of stomach wall (longitudinal section). **(b)** Enlarged view of gastric pits. **(c)** Locations of the HCl-producing parietal cells and the pepsin-secreting chief cells in the gastric pit. (See *A Brief Atlas of the Human Body,* Plate 44.)

3. Damaged epithelial mucosal cells are shed and quickly replaced by division of *undifferentiated stem cells* that reside where the gastric pits join the gastric glands. The stomach surface epithelium is completely renewed every three to six days. (However, glandular cells deep within the gastric glands have a much longer life span.)

HOMEOSTATIC IMBALANCE

Anything that breaches the gel-like mucosal barrier causes inflammation of the stomach wall, a condition called *gastritis*. Persistent damage to the underlying tissues can promote **gastric ulcers,** erosions of the stomach wall. The most distressing symptom of gastric ulcers is gnawing epigastric pain that seems to bore through to your back. The pain typically occurs 1–3 hours after eating and is often relieved by eating again. The danger posed by ulcers is perforation of the stomach wall followed by peritonitis and, perhaps, massive hemorrhage.

For years, the blame for causing ulcers was put on factors that favor high HCl production or low mucus secretion such as aspirin and nonsteroidal anti-inflammatory drugs (ibuprofen), smoking, spicy food, alcohol, coffee, and stress. Although acid conditions *are* necessary for ulcer formation, acidity in and of itself is not sufficient to cause ulcer formation. Most recurrent ulcers (90%) are the work of acid-resistant, corkscrew-shaped *Helicobacter pylori* bacteria, which burrow much like a drill bit through the mucus and destroy the protective mucosal layer, leaving denuded areas. These pathological effects occur in 10–20% of infected individuals. The antimicrobial activity of gastric mucin appears to play a major role in protecting the remaining 80–90% from *H. pylori*'s invasive attacks. The bacterial causal theory has been difficult to prove because the bacterium is also found in more than 50% of healthy people. Even more troubling are studies that link this bacterium to some stomach cancers.

These bacteria release several chemicals that help them do their "dirty work," including (1) some that curb HCl production and release ammonia (the ammonia then acts as a base to neutralize some of the stomach acid in their locale), (2) a *cytotoxin* that lesions the stomach epithelium, and (3) several proteins, some that cause the epithelial cells to detach from each other and others that act as chemotactic agents to attract macrophages and other defensive cells into the area, thus promoting a chronic inflammatory response.

The presence or absence of *H. pylori* is easily detected by a breath test. In ulcers colonized by it, the goal is to kill the embedded bacteria. A one- to two-week-long course of antibiotics (preferably two antibiotics with complementary effects, such as metronidazole and tetracycline) in combination with a bismuth-containing compound, promotes healing and prevents recurrence. (Bismuth is the active ingredient in Pepto-Bismol.) For active ulcers, a H_2-receptor blocker, which inhibits HCl secretion by blocking histamine's effects (see Figure 23.17), may also help. In noninfectious cases, H_2-receptor blocker drugs such as cimetidine (Tagamet) and ranitidine (Zantac) are the therapy of choice. ●

Digestive Processes Occurring in the Stomach

Except for ingestion and defecation, the stomach is involved in the whole "menu" of digestive activities. Besides serving as a holding area for ingested food, the stomach continues the demolition job begun in the oral cavity by further degrading food both physically and chemically. It then delivers chyme, the product of its activity, into the small intestine.

Protein digestion is initiated in the stomach and is the only significant type of enzymatic digestion that occurs there. Dietary proteins are denatured by HCl produced by stomach glands in preparation for enzymatic digestion. (The unfolded amino acid chain is more accessible to the enzymes.) The most important protein-digesting enzyme produced by the gastric mucosa is pepsin. In infants, however, the stomach glands also secrete **rennin,** an enzyme that acts on milk protein (casein), converting it to a curdy substance that looks like soured milk. Additionally, lingual lipase released by the intrinsic salivary glands may digest some triglycerides in the stomach. Two common lipid-soluble substances—alcohol and aspirin—pass easily through the stomach mucosa into the blood. Alcohol and aspirin may cause gastric bleeding, so these substances should be avoided by those with gastric ulcers.

Despite the obvious benefits of preparing food to enter the intestine, the only stomach function essential to life is secretion of intrinsic factor. **Intrinsic factor** is required for intestinal absorption of vitamin B_{12}, needed to produce mature erythrocytes; in its absence, *pernicious anemia* results. However, if vitamin B_{12} is administered by injection, individuals can survive with minimal digestive problems even after total gastrectomy (stomach removal). (The stomach's activities are summarized in Table 23.2, p. 920).

Since chemical digestion and absorption are described later, here we will focus on events that (1) control secretory activity of the gastric glands and (2) regulate stomach motility and emptying.

Regulation of Gastric Secretion

Gastric secretion is controlled by both neural and hormonal mechanisms. Under normal conditions

Q *Distension of the stomach and duodenal walls have differing effects on stomach secretory activity. What are these effects?*

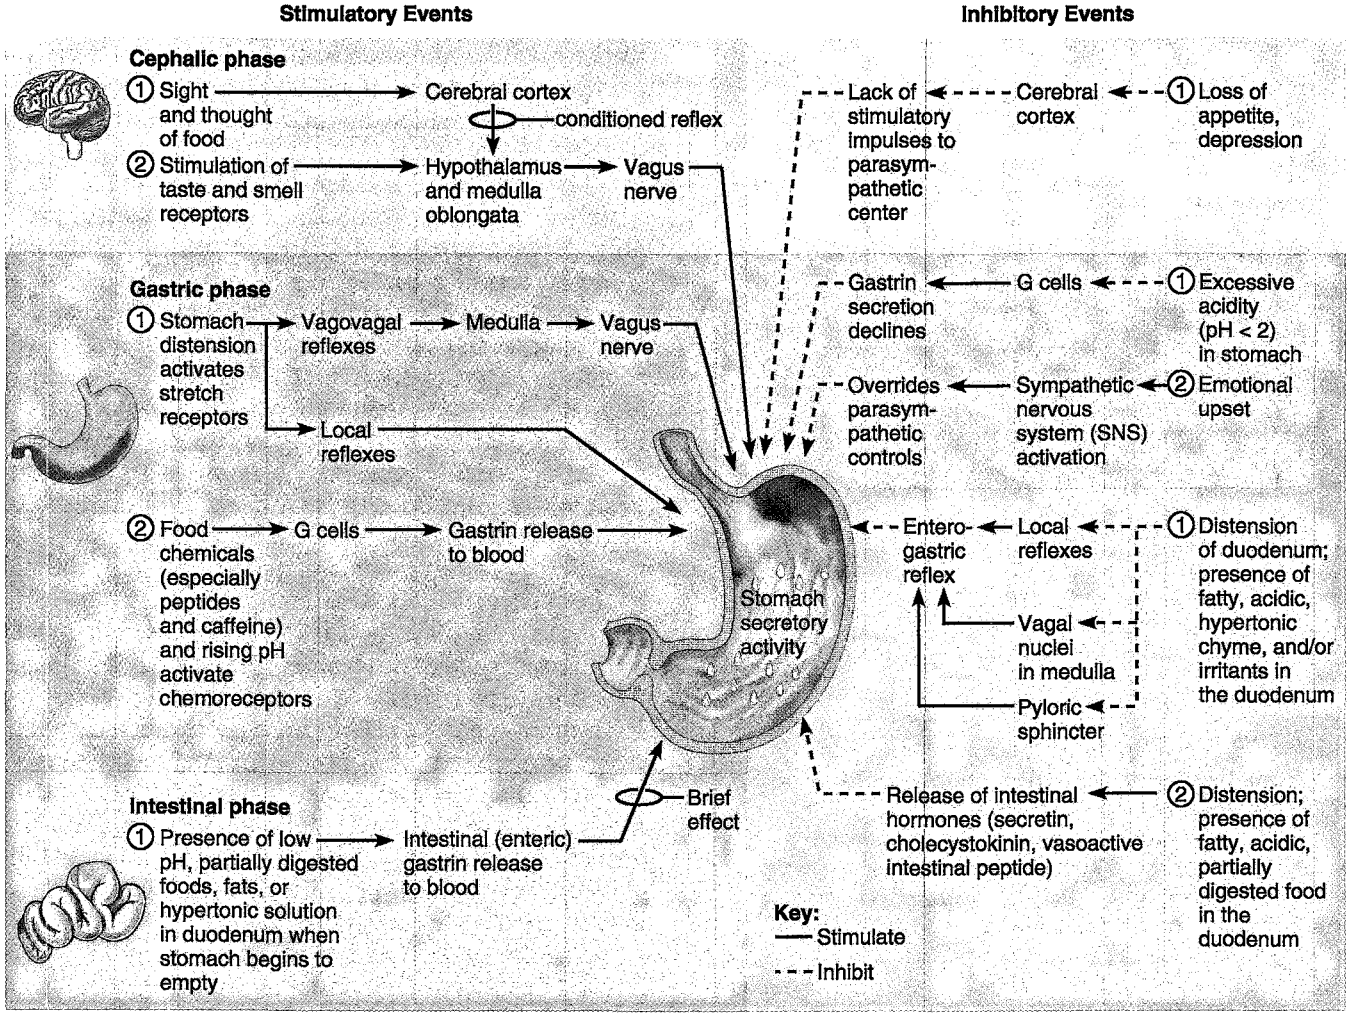


FIGURE 23.16 **Neural and hormonal mechanisms that regulate release of gastric juice.** Stimulatory factors are shown on the left; inhibitory factors are shown on the right.

the gastric mucosa pours out as much as 3 L of gastric juice—an acid brew so potent it can dissolve nails—every day. Nervous control is provided by long (vagus nerve–mediated) and short (local enteric) nerve reflexes. When the vagus nerves stimulate the stomach, secretory activity of virtually all of its glands increases. (By contrast, activation of sympathetic nerves depresses secretory activity.) Hormonal control of gastric secretion is largely the province of gastrin, which stimulates secretion of enzymes and HCl, and of hormones produced by the small intestine, which are mostly gastrin antagonists.

Stimuli acting at three distinct sites—the head, stomach, and small intestine—provoke or inhibit gastric secretory activity and, accordingly, the three phases of gastric secretion are called the *cephalic, gastric,* and *intestinal phases* (Figure 23.16). However, the effector site is the stomach in all cases and, once initiated, one or all three phases may be occurring at the same time.

Phase 1: Cephalic (Reflex) The **cephalic, or reflex, phase** of gastric secretion occurs *before* food enters the stomach. Only a few minutes long, this phase is triggered by the aroma, taste, sight, or

A *Distension of the stomach promotes increased secretory activity whereas stretching the wall of the duodenum causes hormones to be released that inhibit stomach secretory activity.*

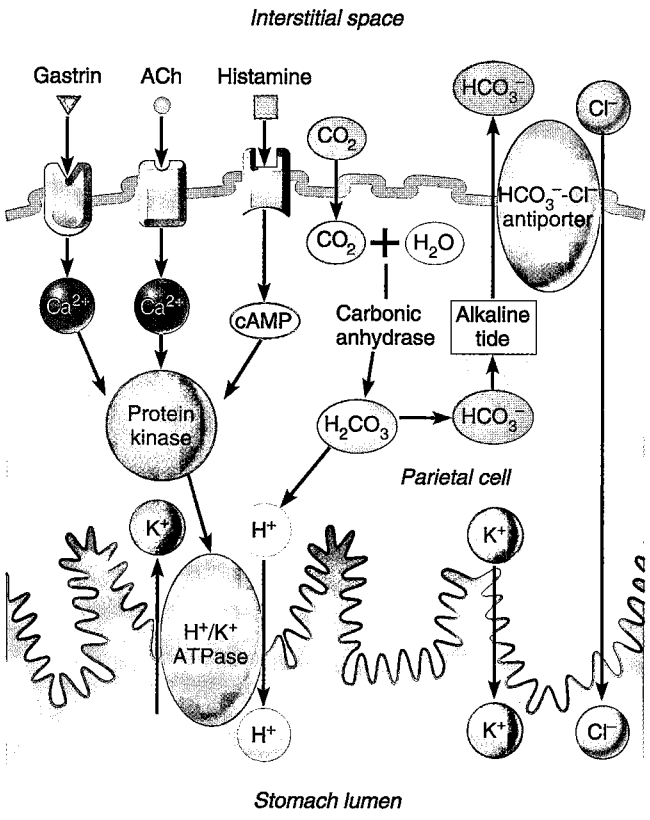

FIGURE 23.17 **Regulation and mechanism of HCl secretion.** Binding of histamine, gastrin, and acetylcholine (ACh) to parietal cell membrane receptors initiates intracellular events (mediated by second-messenger systems) that lead to HCl secretion into the stomach lumen. H^+ and HCO_3^- (bicarbonate ions) are generated from the dissociation of carbonic acid (H_2CO_3). As H^+-K^+ ATPase pumps H^+ into the lumen, K^+ enters the cell. Meanwhile, the HCO_3^--Cl^- antiporter transports HCO_3^- into the interstitial space in exchange for chloride ions (Cl^-). Cl^- and K^+ then diffuse into the lumen through membrane channels (membrane channels not depicted).

thought of food, and it gets the stomach ready for its upcoming digestive chore. Inputs from activated olfactory receptors and taste buds are relayed to the hypothalamus, which in turn stimulates the vagal nuclei of the medulla oblongata, causing motor impulses to be transmitted via the vagus nerves to parasympathetic enteric ganglia. Enteric ganglionic neurons in turn stimulate the stomach glands. The enhanced secretory activity that results when we see or think of food is a *conditioned reflex* and occurs only when we like or want the food. If we are depressed or have no appetite, this part of the cephalic reflex is suppressed.

Phase 2: Gastric Once food reaches the stomach, local neural and hormonal mechanisms initiate the **gastric phase.** This phase is three to four hours long and provides about two-thirds of the gastric juice released. The most important stimuli are distension, peptides, and low acidity. Stomach distension activates stretch receptors and initiates both local (myenteric) reflexes and the long vagovagal reflexes. In the latter type of reflex, impulses travel to the medulla and then back to the stomach via vagal fibers. Both types of reflexes lead to acetylcholine (ACh) release, which in turn stimulates the output of more gastric juice.

Though neural influences initiated by stomach distension are important, the hormone gastrin probably plays a greater role in stimulating stomach gland secretion during the gastric phase. Chemical stimuli provided by partially digested proteins, caffeine, and rising pH directly activate gastrin-secreting enteroendocrine cells called **G cells** in the stomach antrum. Although gastrin also stimulates the release of enzymes, its main target is the HCl-secreting parietal cells, which it prods to spew out even more HCl (Figure 23.17). Highly acidic (pH below 2) gastric contents *inhibit* gastrin secretion.

When protein foods are in the stomach, the pH of the gastric contents generally rises because proteins act as buffers to tie up H^+. The rise in pH stimulates gastrin and subsequently HCl release, which in turn provides the acidic conditions needed for protein digestion. The more protein in the meal, the greater the amount of gastrin and HCl released. As proteins are digested, the gastric contents gradually become more acidic, which again inhibits the gastrin-secreting cells. This negative feedback mechanism helps maintain optimal pH and working conditions for the gastric enzymes.

G cells are also activated by the neural reflexes already described. Emotional upsets, fear, anxiety, or anything that triggers the fight-or-flight response inhibits gastric secretion because (during such times) the sympathetic division overrides parasympathetic controls of digestion (Figure 23.16).

The control of the HCl-secreting parietal cells is multifaceted. HCl secretion is stimulated by three chemicals, all of which work through second-messenger systems (Figure 23.17): *ACh* released by parasympathetic nerve fibers and *gastrin* secreted by G cells bring about their effects by increasing intracellular Ca^{2+} levels. *Histamine,* released by the so-called *enterochromaffin-like* (ECL) cells in response to gastrin (and to a lesser extent by ACh) acts through cyclic AMP (cAMP). When only one of the three chemicals binds to the parietal cells, HCl secretion is scanty, but when all three bind, HCl pours forth as if shot out by a high-pressure hose. (As noted earlier, antihistamines, such as cimetidine, which bind to and block the H_2 receptors of parietal cells, are used to treat gastric ulcers due to hyperacidity.)

The process of HCl formation within the parietal cells is complicated. The consensus is that H^+ is actively pumped into the stomach lumen against a tremendous concentration gradient by H^+-K^+ ATPases as K^+ ions are moved into the cell from the interstitial fluid. Chloride ions (Cl^-) are also pumped into the lumen to maintain an electrical balance in the stomach. The Cl^- is obtained from blood plasma, while H^+ comes from the breakdown of carbonic acid (formed by the combination of carbon dioxide and water) within the parietal cell (Figure 23.17):

$$CO_2 + H_2O \rightarrow H_2CO_3 \rightarrow H^+ + HCO_3^-$$

As H^+ is pumped from the cell and HCO_3^- (bicarbonate ion) accumulates within the cell, HCO_3^- is ejected through the basal cell membrane into the capillary blood. As a result, blood draining from the stomach is more alkaline than the blood serving it. This phenomenon is called the **alkaline tide.** Notice that HCO_3^- and Cl^- are moved by a HCO_3^--Cl^- antiporter in the basolateral membrane, and this is the means of entry of the Cl^- that moves into the lumen as the chloride part of the HCl product. K^+ and Cl^- move into the lumen by diffusing through membrane channels.

Phase 3: Intestinal The **intestinal phase** of gastric secretion has two components—one excitatory and the other inhibitory (Figure 23.16). The *excitatory* aspect is set into motion as partially digested food fills the initial part (duodenum) of the small intestine. This stimulates intestinal mucosal cells to release a hormone that encourages the gastric glands to continue their secretory activity. The effects of this hormone mirror those of gastrin, so it has been named **intestinal (enteric) gastrin.** However, this stimulatory effect is brief because as the intestine distends with chyme containing large amounts of H^+, fats, partially digested proteins, and various irritating substances, the *inhibitory* component is triggered in the form of the **enterogastric reflex.**

The enterogastric reflex is actually a trio of reflexes that (1) inhibit the vagal nuclei in the medulla, (2) inhibit local reflexes, and (3) activate sympathetic fibers that cause the pyloric sphincter to tighten and prevent further food entry into the small intestine. As a result, gastric secretory activity declines. These "brakes" on gastric activity protect the small intestine from excessive acidity and match the small intestine's processing abilities to the amount of chyme entering it at a given time.

In addition, the factors just named trigger the release of several intestinal hormones, collectively called **enterogastrones,** which include **secretin** (se-kre'tin), **cholecystokinin (CCK)** (ko"le-sis"to-ki'nin), and **vasoactive intestinal peptide (VIP).** All of these hormones inhibit gastric secretion when the stomach is very active and also play other roles, which are summarized in Table 23.1.

Gastric Motility and Emptying

Stomach contractions not only cause its emptying but also compress, knead, twist, and continually mix the food with gastric juice to produce chyme. Because the mixing movements are accomplished by a unique type of peristalsis (for example, in the pylorus it is bidirectional rather than unidirectional), the processes of mechanical digestion and propulsion are inseparable in the stomach.

Response of the Stomach to Filling The stomach stretches to accommodate incoming food, but internal stomach pressure remains constant until about 1.5 L of food has been ingested. Thereafter, the pressure rises. The relatively unchanging pressure in a filling stomach is due to (1) the reflex-mediated receptive relaxation of the stomach muscle and (2) the plasticity of visceral smooth muscle.

Receptive relaxation of smooth muscle in the stomach fundus and body occurs both in anticipation of and in response to food movement through the esophagus and into the stomach. This process is coordinated by the swallowing center of the brain stem and mediated by the vagus nerves acting on serotonin and NO-releasing enteric neurons. **Plasticity** is the intrinsic ability of visceral smooth muscle to exhibit the stress-relaxation response, that is, to be stretched without greatly increasing its tension and contracting expulsively. As described in Chapter 9, this capability is very important in hollow organs, like the stomach, that must serve as temporary reservoirs.

Gastric Contractile Activity As in the esophagus, the stomach exhibits peristalsis. After a meal, peristalsis begins near the gastroesophageal sphincter, where it produces gentle rippling movements of the thin stomach wall. But as the contractions approach the pylorus, where the stomach musculature is thicker, they become much more powerful. Consequently, the contents of the fundus and body (food storage area) remain relatively undisturbed, while foodstuffs in and around the pyloric antrum receive a truly lively pummeling and mixing.

The pyloric region of the stomach, which holds about 30 ml of chyme, acts as a "dynamic filter" that allows only liquids and small particles to pass through the barely open pyloric valve during the digestive period. Normally, each peristaltic wave reaching the pyloric muscle "spits" or squirts 3 ml or less of chyme into the small intestine. Because the

TABLE 23.1 Hormones and Paracrines That Act in Digestion*

HORMONE	SITE OF PRODUCTION	STIMULUS FOR PRODUCTION	TARGET ORGAN	ACTIVITY
Gastrin	Stomach mucosa	Food (particularly partially digested proteins) in stomach (chemical stimulation); acetylcholine released by nerve fibers	Stomach	▪ Causes gastric glands to increase secretory activity; most pronounced effect is on HCl secretion ▪ Stimulates gastric emptying
			Small intestine	▪ Stimulates contraction of intestinal muscle
			Ileocecal valve	▪ Relaxes ileocecal valve
			Large intestine	▪ Stimulates mass movements
Serotonin	Stomach mucosa	Food in stomach	Stomach	▪ Causes contraction of stomach muscle
Histamine	Stomach mucosa	Food in stomach	Stomach	▪ Activates parietal cells to release HCl
Somatostatin	Stomach mucosa; duodenal mucosa	Food in stomach; stimulation by sympathetic nerve fibers	Stomach	▪ Inhibits gastric secretion of all products; inhibits gastric motility and emptying
			Pancreas	▪ Inhibits secretion
			Small intestine	▪ Inhibits GI blood flow; thus inhibits intestinal absorption
			Gallbladder	▪ Inhibits contraction and bile release
Intestinal gastrin	Duodenal mucosa	Acidic and partially digested foods in duodenum	Stomach	▪ Stimulates gastric glands and motility
Secretin	Duodenal mucosa	Acidic chyme (also partially digested proteins, fats, hypertonic or hypotonic fluids, or irritants in chyme)	Stomach	▪ Inhibits gastric gland secretion and gastric motility during gastric phase of secretion
			Pancreas	▪ Increases output of pancreatic juice rich in bicarbonate ions; potentiates CCK's action
			Liver	▪ Increases bile output
Cholecystokinin (CCK)	Duodenal mucosa	Fatty chyme, in particular, but also partially digested proteins	Liver/pancreas	▪ Potentiates secretin's actions on these organs
			Pancreas	▪ Increases output of enzyme-rich pancreatic juice
			Gallbladder	▪ Stimulates organ to contract and expel stored bile
			Hepatopancreatic sphincter (of Oddi)	▪ Relaxes sphincter to allow entry of bile and pancreatic juice into duodenum
Vasoactive intestinal peptide (VIP)	Duodenal mucosa	Chyme containing partially digested foods	Duodenum	▪ Stimulates buffer secretion; dilates intestinal capillaries
			Stomach	▪ Inhibits HCl production
			Small intestine	▪ Relaxes intestinal smooth muscle
Motilin	Duodenal mucosa	Fasting; periodic release every 1½–2 hours by neural stimuli	Proximal duodenum	▪ Stimulates migrating motility complex

*Except for somatostatin, all of these polypeptides also stimulate the growth (particularly of the mucosa) of the organs they affect.

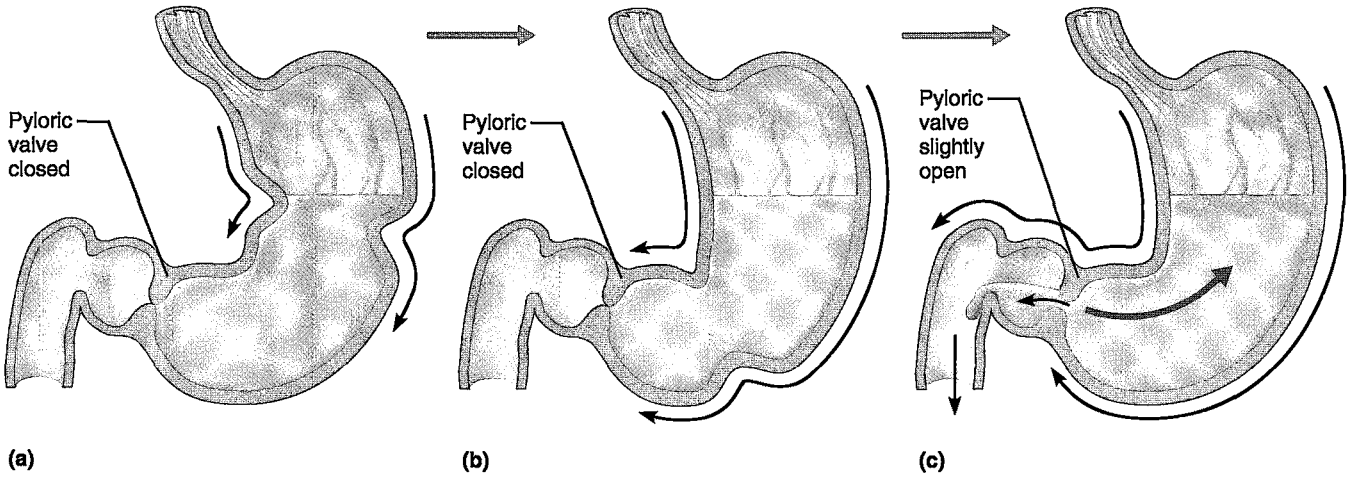

FIGURE 23.18 **Peristaltic waves in the stomach. (a)** Peristaltic waves move toward the pylorus. **(b)** The most vigorous peristalsis and mixing action occurs close to the pylorus. **(c)** The pyloric end of the stomach acts as a pump that delivers small amounts of chyme into the duodenum, simultaneously forcing most of its contained material backward into the stomach, where it undergoes further mixing.

contraction also *closes* the valve, which is normally partially relaxed, the rest (about 27 ml) is propelled backward into the stomach, where it is mixed further (Figure 23.18). This back-and-forth pumping action (retropulsion) effectively breaks up solids in the gastric contents.

Although the intensity of the stomach's peristaltic waves can be modified, their rate is constant—always around three per minute. This contractile rhythm is set by the spontaneous activity of *pacemaker cells* located in the longitudinal smooth muscle layer. The pacemaker cells, muscle-like noncontractile cells called *interstitial cells of Cajal* (ka-hal'), depolarize and repolarize spontaneously three times each minute, establishing the so-called *cyclic slow waves* of the stomach, or its **basic electrical rhythm (BER).** Since the pacemakers are electrically coupled to the rest of the smooth muscle sheet by gap junctions, their "beat" is transmitted efficiently and quickly to the entire muscularis. The pacemakers set the maximum rate of contraction, but they do not initiate the contractions or regulate their force. Instead, they generate subthreshold depolarization waves, which are then "ignited" (enhanced by further depolarization and brought to threshold) by neural and hormonal factors.

Factors that increase the strength of stomach contractions are the same factors that enhance gastric secretory activity. Distension of the stomach wall by food activates stretch receptors and gastrin-secreting cells, which both ultimately stimulate gastric smooth muscle and so increase gastric motility. Thus, the more food there is in the stomach, the more vigorous the stomach mixing and emptying movements will be—within certain limits—as described next.

Regulation of Gastric Emptying The stomach usually empties completely within four hours after a meal. However, the larger the meal (the greater the stomach distension) and the more liquid its contents, the faster the stomach empties. Fluids pass quickly through the stomach. Solids linger, remaining until they are well mixed with gastric juice and converted to the liquid state.

The rate of gastric emptying depends as much—and perhaps more—on the contents of the duodenum as on what is happening in the stomach. The stomach and duodenum act in tandem like a "coupled meter" that functions at less than full capacity. As chyme enters the duodenum, receptors in its wall respond to chemical signals and to stretch, initiating the enterogastric reflex and the hormonal (enterogastrone) mechanisms that inhibit acid and pepsin secretion as described earlier. These mechanisms inhibit gastric secretory activity and prevent further duodenal filling by reducing the force of pyloric contractions (Figure 23.19).

A carbohydrate-rich meal moves through the duodenum rapidly, but fats form an oily layer at the top of the chyme and are digested more slowly by enzymes acting in the intestine. Thus, when chyme entering the duodenum is fatty, food may remain in the stomach six hours or more.

HOMEOSTATIC IMBALANCE

Vomiting, or **emesis,** is an unpleasant experience that causes stomach emptying by a different route. Many factors signal the stomach to "launch lunch," but the most common are extreme stretching of the stomach or intestine or the presence of irritants such

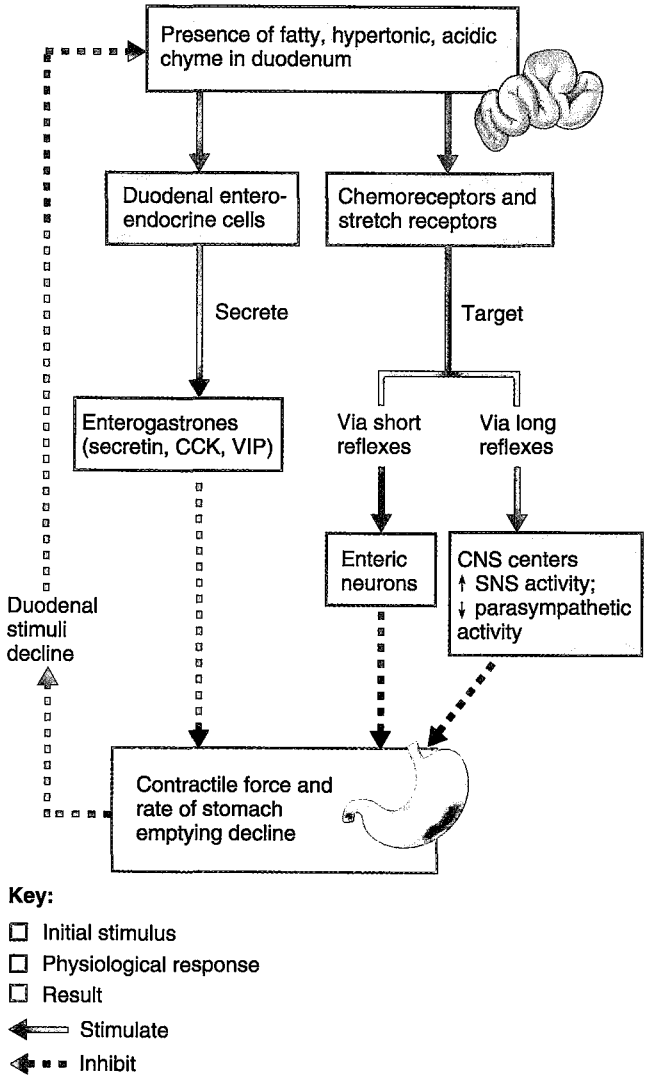

FIGURE 23.19 **Neural and hormonal factors inhibiting gastric emptying.** These controls ensure that the food will be well liquefied in the stomach and prevent the small intestine from being overwhelmed.

as bacterial toxins, excessive alcohol, spicy foods, and certain drugs in those organs. Both bloodborne molecules and sensory impulses streaming from the irritated sites to the **emetic center** (e-met'ik) of the medulla initiate a number of motor responses. The diaphragm and abdominal wall muscles contract, increasing intra-abdominal pressure, the cardiac sphincter relaxes, and the soft palate rises to close off the nasal passages. As a result, the stomach (and perhaps duodenal) contents are forced upward through the esophagus and pharynx and out the mouth. Before vomiting, an individual typically is pale, feels nauseated, and salivates. Excessive vomiting can cause dehydration and may lead to severe disturbances in the electrolyte and acid-base balance of the body. Since large amounts of HCl are lost in vomitus, the blood becomes alkaline as the stomach attempts to replace its lost acid. ◉

The Small Intestine and Associated Structures

In the small intestine, usable food is finally prepared for its journey into the cells of the body. However, this vital function cannot be accomplished without the aid of secretions from the liver (bile) and pancreas (digestive enzymes). Thus, these necessary accessory organs will also be considered in this section.

The Small Intestine

The **small intestine** is the body's major digestive organ. Within its twisted passageways, digestion is completed and virtually all absorption occurs.

Gross Anatomy

The small intestine is a convoluted tube extending from the pyloric sphincter in the epigastric region to the **ileocecal valve** (il"e-o-se'kal) in the right iliac region where it joins the large intestine (see Figure 23.1). It is the longest part of the alimentary tube, but is only about half the diameter of the large intestine, ranging from 2.5 to 4 cm (1–1.6 inches). Although it is 6–7 m long (approximately 20 ft, or as tall as a two-story building) in a cadaver, the small intestine is only about 2–4 m (7–13 ft) long during life because of muscle tone.

The small intestine has three subdivisions: the duodenum, which is mostly retroperitoneal, and the jejunum and ileum, both intraperitoneal organs. The relatively immovable **duodenum** (du"o-de'num; "twelve finger widths long"), which curves around the head of the pancreas (Figure 23.20), is about 25 cm (10 inches) long. Although it is the shortest intestinal subdivision, the duodenum has the most features of interest. The bile duct, delivering bile from the liver, and the main pancreatic duct, carrying pancreatic juice from the pancreas, unite in the wall of the duodenum in a bulblike point called the **hepatopancreatic ampulla** (hep"ah-to-pan"kre-at'ik am-pul'ah; *ampulla* = flask). The ampulla opens into the duodenum via the volcano-shaped **major duodenal papilla.** The entry of bile and pancreatic juice is controlled by a muscular valve called the **hepatopancreatic sphincter,** or **sphincter of Oddi.**

The **jejunum** (jĕ-joo'num; "empty"), about 2.5 m (8 ft) long, extends from the duodenum to the ileum. The **ileum** (il'e-um; "twisted"), approximately 3.6 m (12 ft) in length, joins the large intestine at the ileocecal valve. The jejunum and ileum hang in

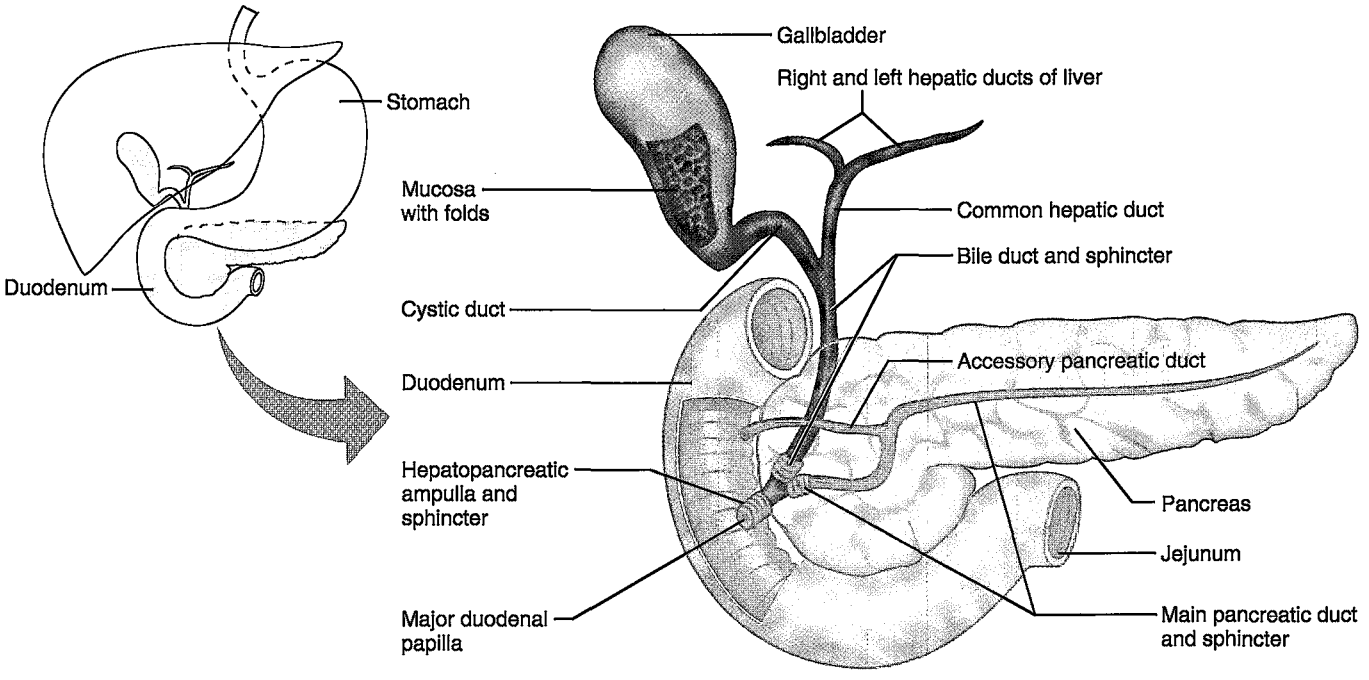

FIGURE 23.20 **The duodenum of the small intestine, and related organs.**
Emptying into the duodenum are ducts from the pancreas, gallbladder, and liver.

sausagelike coils in the central and lower part of the abdominal cavity, suspended from the posterior abdominal wall by the fan-shaped *mesentery* (see Figure 23.30). These more distal parts of the small intestine are encircled and framed by the large intestine.

Nerve fibers serving the small intestine include parasympathetics from the vagus and sympathetics from the thoracic splanchnic nerves, both relayed through the superior mesenteric (and celiac) plexus. The arterial supply is primarily from the superior mesenteric artery (pp. 754–755). The veins parallel the arteries and typically drain into the superior mesenteric vein. From there, the nutrient-rich venous blood from the small intestine drains into the hepatic portal vein, which carries it to the liver.

Microscopic Anatomy

Modifications for Absorption The small intestine is highly adapted for nutrient absorption. Its length alone provides a huge surface area, and its wall has three structural modifications—plicae circulares, villi, and microvilli—that amplify its absorptive surface enormously (by a factor of more than 600 times). One estimate is that the intestinal surface area is about equal to the floor space of an average two-story house! Most absorption occurs in the proximal part of the small intestine, so these specializations decrease in number toward its distal end.

The **circular folds,** or **plicae circulares** (pli'ke ser"ku-lar'ēs), are deep, permanent folds of the mucosa and submucosa (Figure 23.21a). Nearly 1 cm tall, these folds force chyme to spiral through the lumen, slowing its movement and allowing time for full nutrient absorption.

Villi (vil'i; "tufts of hair") are fingerlike projections of the mucosa, over 1 mm high, that give it a velvety texture, much like the soft nap of a towel (Figures 23.21b and Figure 23.22a). The epithelial cells of the villi are chiefly absorptive columnar cells. In the core of each villus is a dense capillary bed and a wide lymph capillary called a **lacteal** (lak'te-al). Digested foodstuffs are absorbed through the epithelial cells into both the capillary blood and the lacteal. The villi are large and leaflike in the duodenum (the intestinal site of most active absorption) and gradually narrow and shorten along the length of the small intestine. A "slip" of smooth muscle in the villus core allows it to alternately shorten and lengthen, pulsations that (1) increase the contact between the villus and the contents of the intestinal lumen, making absorption more efficient, and (2) "milk" lymph along through the lacteals.

Microvilli, tiny projections of the plasma membrane of the absorptive cells of the mucosa, give the mucosal surface a fuzzy appearance called the **brush**

Q *What is a lacteal and what is its function?*

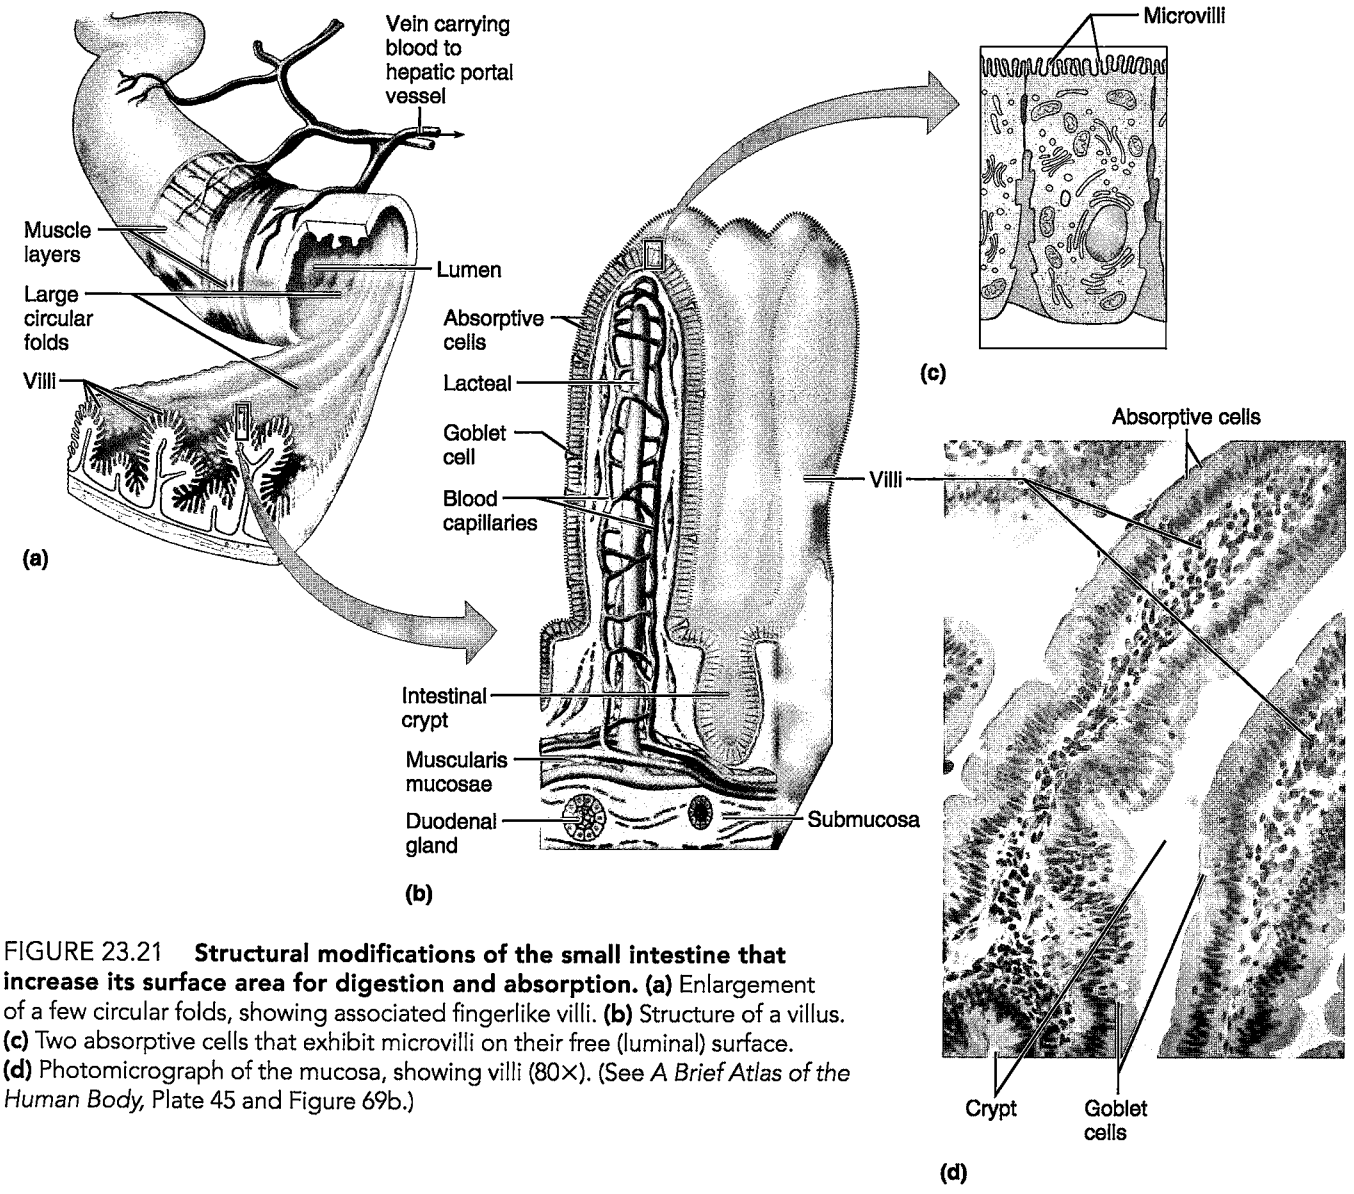

FIGURE 23.21 **Structural modifications of the small intestine that increase its surface area for digestion and absorption. (a)** Enlargement of a few circular folds, showing associated fingerlike villi. **(b)** Structure of a villus. **(c)** Two absorptive cells that exhibit microvilli on their free (luminal) surface. **(d)** Photomicrograph of the mucosa, showing villi (80×). border (Figures 23.21c and Figure 23.22b). The plasma membranes of the microvilli bear enzymes referred to as **brush border enzymes,** which complete the digestion of carbohydrates and proteins in the small intestine.

Histology of the Wall Externally the subdivisions of the small intestine appear to be nearly identical, but their internal and microscopic anatomies reveal some important differences. The four tunics typical of the GI tract are also seen here, but the mucosa and submucosa are modified to reflect the intestine's functions in the digestive pathway.

The epithelium of the mucosa is largely simple columnar *absorptive cells* bound by tight junctions and richly endowed with microvilli. It also has many mucus-secreting *goblet cells;* scattered *enteroendocrine cells* (the source of the enterogastrones—secretin and cholecystokinin to name two), and interspersed T cells called *intraepithelial lymphocytes (IELs),* which represent an important immunological compartment. Unlike other T cells, IELs do *not* need "priming." Upon encountering antigens, they immediately release cytokines that cause killing of infected target cells.

A lymphatic capillary that receives some of the fatty materials absorbed from the intestine.

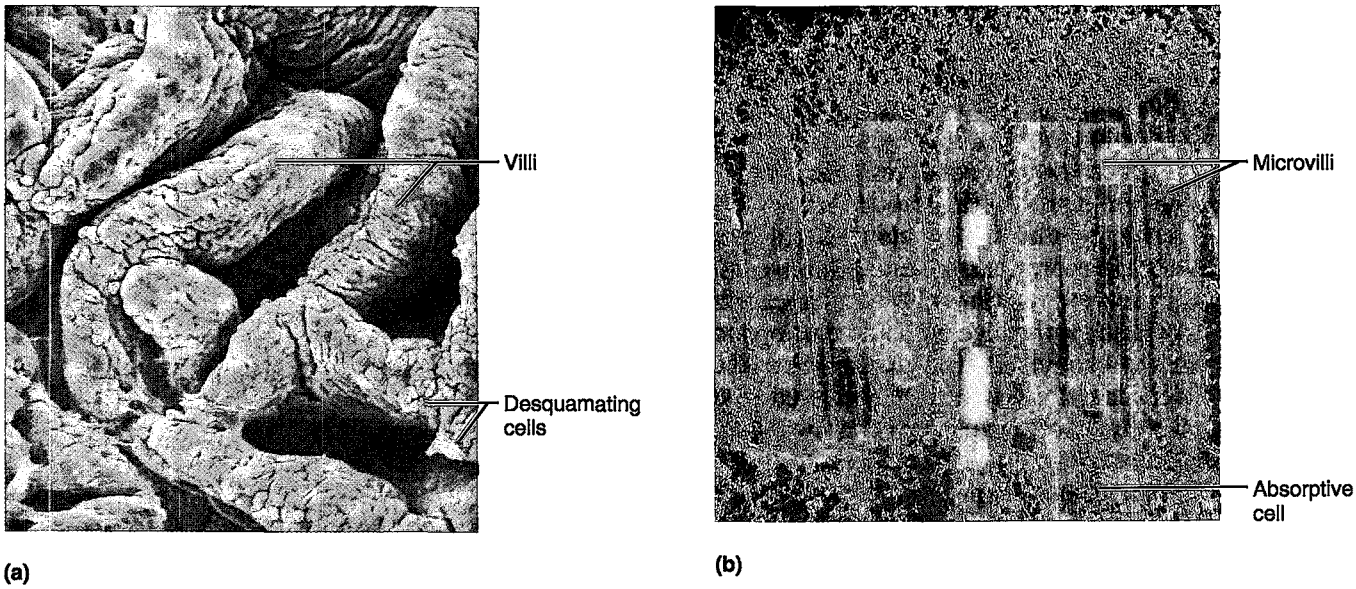

FIGURE 23.22 **Villi and microvilli of the small intestine.** False-color electron micrographs. **(a)** Villi (700×). Dead desquamating cells seen on the ridges of the villi are colored yellow and orange. **(b)** Microvilli (40,000×) of absorptive cells appear as red projections from the surface of the absorptive cell. Yellow granules are mucus granules.

Between the villi, the mucosa is studded with *pits* that lead into tubular intestinal glands called **intestinal crypts,** or **crypts of Lieberkühn** (le'berkun). The epithelial cells that line these crypts secrete *intestinal juice,* a watery mixture containing mucus that serves as a carrier fluid for absorbing nutrients from chyme. Deep in the crypts are specialized secretory cells called *Paneth cells,* which fortify the small intestine's defenses by releasing antimicrobial agents such as defensins and *lysozyme,* an antibacterial enzyme. The crypts decrease in number along the length of the small intestine, but the goblet cells become more abundant.

The various epithelial cells arise from rapidly dividing stem cells in the crypts. As the daughter cells gradually migrate up the villi, they differentiate, becoming specialized cell types. They are shed from the villus tips, renewing the villus epithelium every three to six days. The rapid replacement of intestinal (and gastric) epithelial cells has clinical as well as physiological significance. Treatments for cancer, such as radiation therapy and chemotherapy, preferentially target rapidly dividing cells. This kills cancer cells, but it also nearly obliterates the GI tract epithelium, causing nausea, vomiting, and diarrhea after each treatment.

The submucosa is typical areolar connective tissue, and it contains both individual and *aggregated lymphoid follicles,* the latter called **Peyer's patches** (pi'erz). Peyer's patches increase in abundance toward the end of the small intestine, reflecting the fact that this region of the small intestine contains huge numbers of bacteria that must be prevented from entering the bloodstream. Elaborate mucus-secreting **duodenal** *(Brunner's)* **glands** are found in the submucosa of the duodenum only. These glands (see Figure 23.21b) produce an alkaline (bicarbonate-rich) mucus that helps neutralize the acidic chyme moving in from the stomach. When this protective mucus barrier is inadequate, the intestinal wall erodes and *duodenal ulcers* result.

The muscularis is typical and bilayered. Except for the bulk of the duodenum, which is retroperitoneal and has an adventitia, the external intestinal surface is covered by visceral peritoneum (serosa).

Intestinal Juice: Composition and Control

The intestinal glands normally secrete 1 to 2 L of **intestinal juice** daily. The major stimulus for its production is distension or irritation of the intestinal mucosa by hypertonic or acidic chyme. Normally, intestinal juice is slightly alkaline (7.4–7.8), and isotonic with blood plasma. Intestinal juice is largely water but it also contains some mucus, which is secreted both by the duodenal glands and by goblet cells of the mucosa. Intestinal juice is enzyme-poor because intestinal enzymes are limited to the bound enzymes of the brush border.

The Liver and Gallbladder

The *liver* and *gallbladder* are accessory organs associated with the small intestine. The liver, one of the body's most important organs, has many metabolic and regulatory roles. However, its *digestive* function is to produce bile for export to the duodenum. Bile is a fat emulsifier; that is, it breaks up fats into tiny particles so that they are more accessible to digestive enzymes. We will describe bile and the emulsification process when we discuss the digestion and absorption of fats later in the chapter. Although the liver also processes nutrient-laden venous blood delivered to it directly from the digestive organs, this is a metabolic rather than a digestive role. (See Chapter 24.) The gallbladder is chiefly a storage organ for bile.

Gross Anatomy of the Liver

The ruddy, blood-rich **liver** is the largest gland in the body, weighing about 1.4 kg (3 lb) in the average adult. Shaped like a wedge, it occupies most of the right hypochondriac and epigastric regions, extending farther to the right of the body midline than to the left. Located under the diaphragm, the liver lies almost entirely within the rib cage, which provides some protection (see Figures 23.1 and 23.23c).

Typically, the liver is said to have four primary lobes. The largest of these, the *right lobe,* is visible on all liver surfaces and separated from the smaller *left lobe* by a deep fissure (Figure 23.23a). The posteriormost *caudate lobe* and the *quadrate lobe,* which lies inferior to the left lobe, are visible in an inferior view of the liver (Figure 23.23b). A mesentery, the **falciform ligament,** separates the right and left lobes anteriorly and suspends the liver from the diaphragm and anterior abdominal wall (see also Figure 23.30a and d, p. 924). Running along the inferior edge of the falciform ligament is the **round ligament,** or **ligamentum teres** (te'rēz; "round"), a fibrous remnant of the fetal umbilical vein. Except for the superiormost liver area (the *bare area*), which touches the diaphragm, the entire liver is enclosed by the visceral peritoneum. As mentioned earlier, a ventral mesentery, the lesser omentum (see Figure 23.30b), anchors the liver to the lesser curvature of the stomach. The **hepatic artery** and the **hepatic portal vein,** which enter the liver at the **porta hepatis** ("gateway to the liver"), and the common hepatic duct, which runs inferiorly from the liver, all travel through the lesser omentum to reach their destinations. The gallbladder rests in a recess on the inferior surface of the right liver lobe.

The traditional scheme of defining liver lobes (outlined above) has been criticized because it is based on superficial features of the liver. Some anatomists emphasize that the primary lobes of the liver should be defined as the territories served by the right and left hepatic ducts. These two territories are delineated by a plane drawn from the indentation (sulcus) of the inferior vena cava to the gallbladder recess (see Figure 23.23b). Those to the right of the plane are the *right lobe* and those to its left constitute the *left lobe.* According to this scheme, the small quadrate and caudate lobes are part of the left lobe.

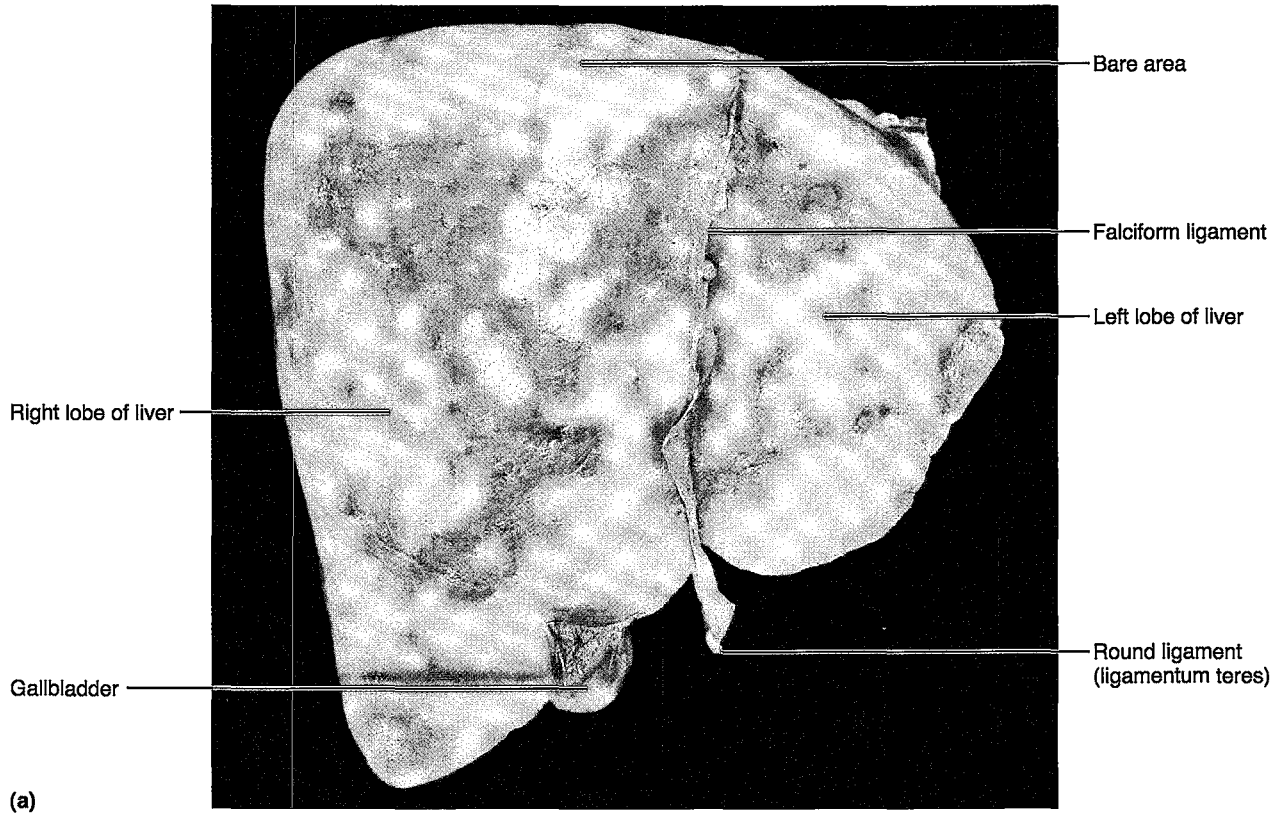
Bile leaves the liver through several bile ducts that ultimately fuse to form the large **common hepatic duct,** which travels downward toward the duodenum. Along its course, that duct fuses with the **cystic duct** draining the gallbladder to form the **bile duct** (Figure 23.20).

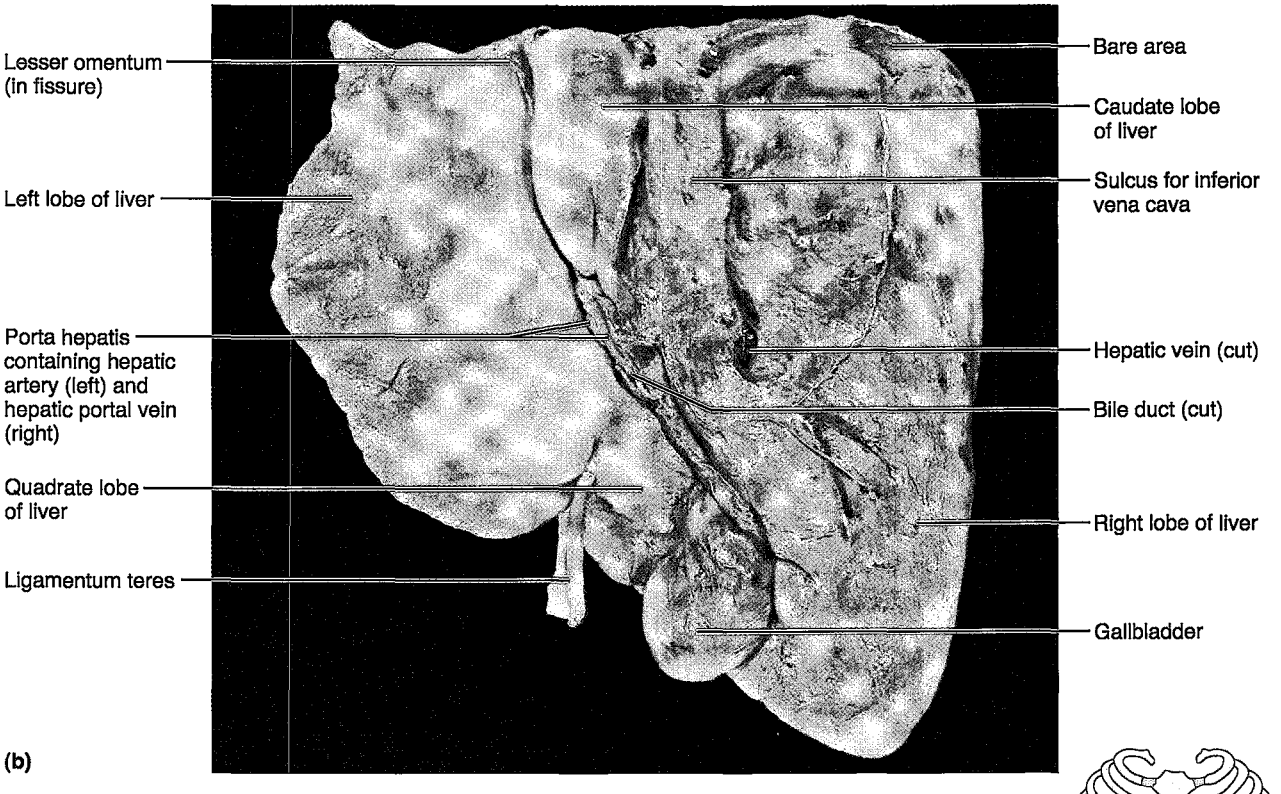
Microscopic Anatomy of the Liver

The liver is composed of sesame seed–sized structural and functional units called **liver lobules** (Figure 23.24). Each lobule is a roughly hexagonal (six-sided) structure consisting of plates of *liver cells,* or **hepatocytes** (hep'ah-to-sīts), organized like bricks in a garden wall. The hepatocyte plates radiate outward from a **central vein** running in the longitudinal axis of the lobule. To make a rough "model" of a liver lobule, open a thick paperback book until its two covers meet: The pages represent the plates of hepatocytes and the hollow cylinder formed by the rolled spine represents the central vein.

If you keep in mind that the liver's main function is to filter and process the nutrient-rich blood delivered to it, the description of its anatomy that follows will make a lot of sense. At each of the six corners of a lobule is a **portal triad** (*portal tract* region), so named because three basic structures are always present there: a branch of the *hepatic artery* (supplying oxygen-rich arterial blood to the liver), a branch of the *hepatic portal vein* (carrying venous blood laden with nutrients from the digestive viscera), and a *bile duct.* Between the hepatocyte plates are enlarged, leaky capillaries, the **liver sinusoids.** Blood from both the hepatic portal vein and the hepatic artery percolates from the triad regions through these sinusoids and empties into the central vein. From the central veins blood eventually enters the hepatic veins, which drain the liver, and empty into the inferior vena cava. Forming part of the sinusoid walls are star-shaped **hepatic macrophages,** also called **Kupffer cells** (koop'fer) (Figure 23.24d), which remove debris such as bacteria and worn-out blood cells from the blood as it flows past.

The versatile hepatocytes have large amounts of both rough and smooth ER, Golgi apparatuses, peroxisomes, and mitochondria. Thus equipped, the hepatocytes not only can produce bile but can also (1) process the bloodborne nutrients in various ways (e.g., they store glucose as glycogen and use amino





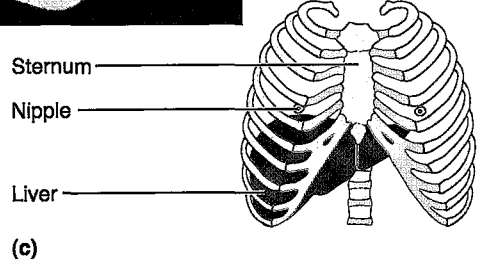


FIGURE 23.23 **Gross anatomy of the human liver. (a)** Anterior view of the liver. **(b)** Posteroinferior aspect (visceral surface) of the liver. The four liver lobes are separated by a group of fissures in this view. The porta hepatis is a deep fissure that contains the hepatic portal vein, hepatic artery, hepatic duct, and lymphatics. (Note: Another scheme classifies the caudate and quadrate lobes as part of the left liver lobe.) **(c)** Diagrammatic view of the liver's location in the body. (See *A Brief Atlas of the Human Body,* Figures 64 and 65.)

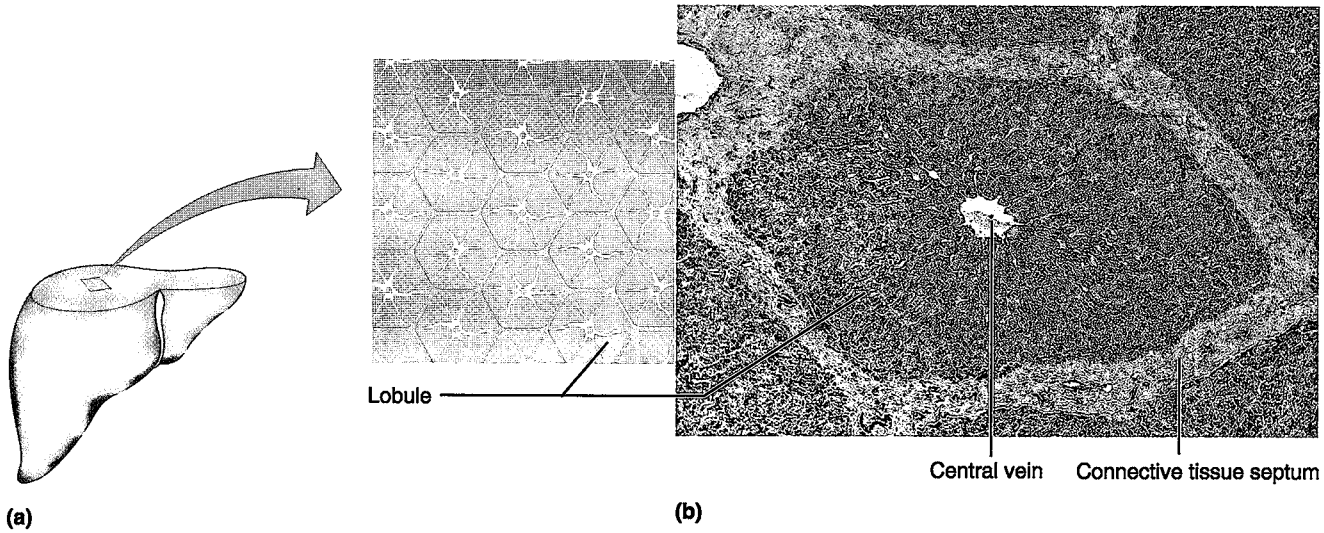

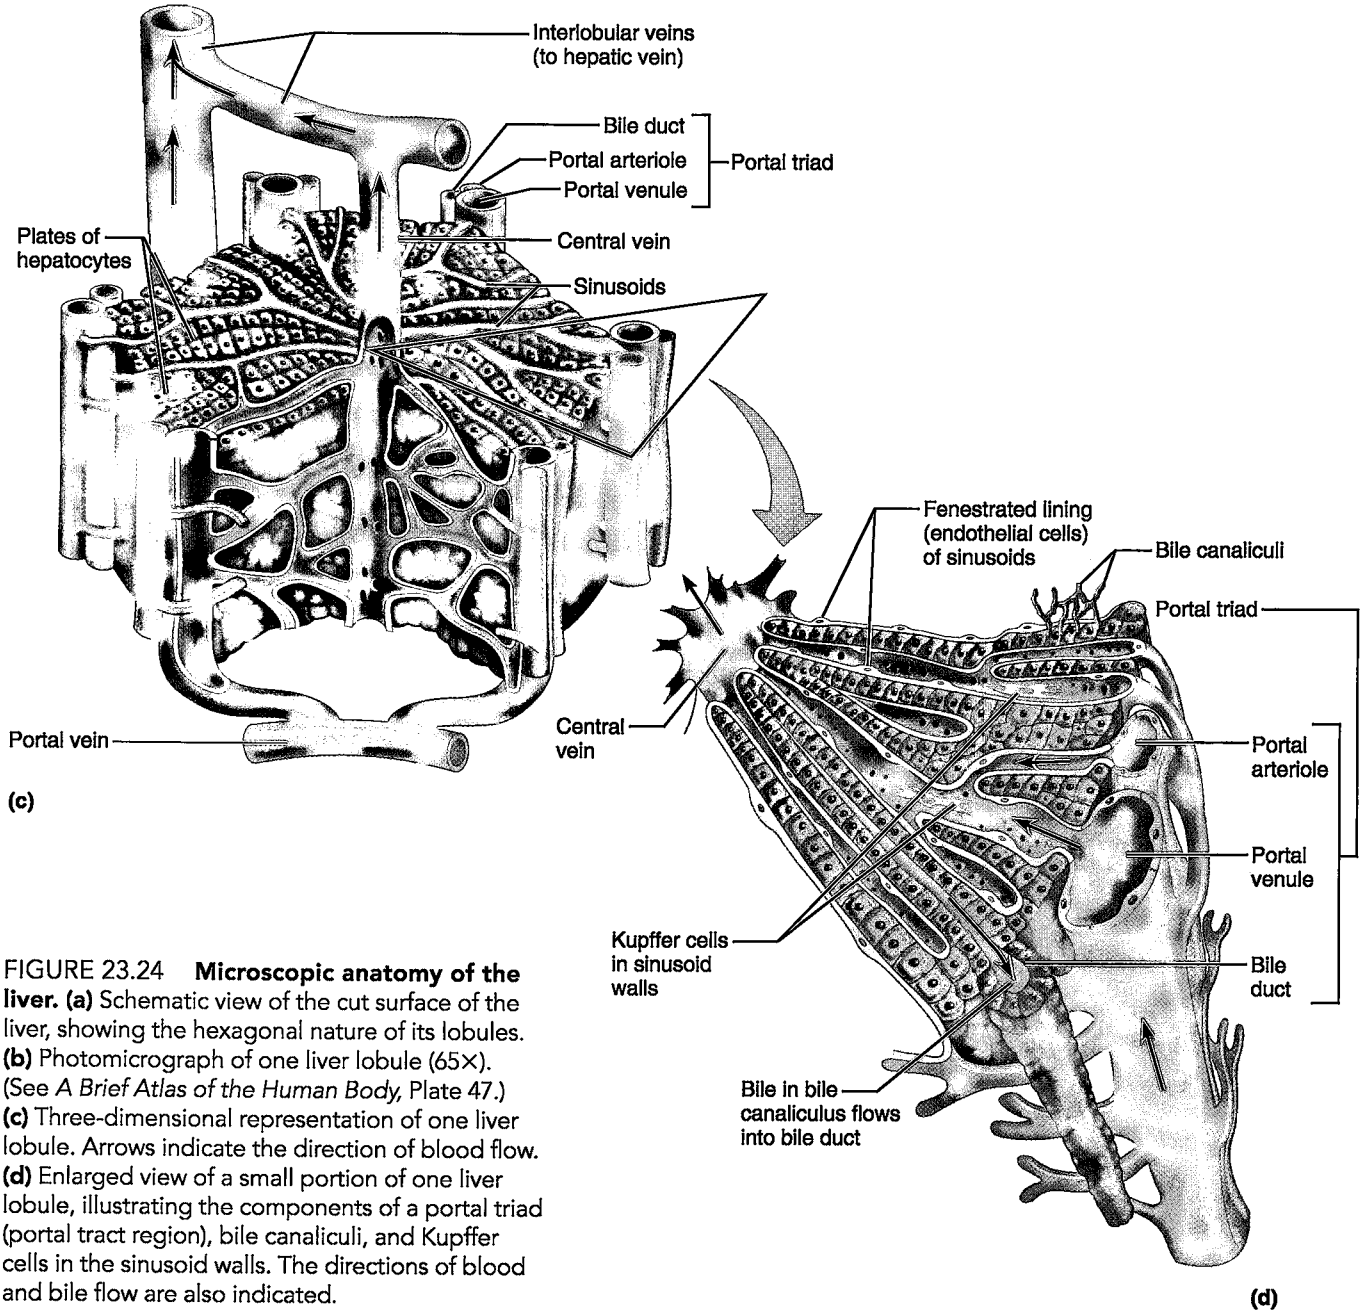

FIGURE 23.24 **Microscopic anatomy of the liver. (a)** Schematic view of the cut surface of the liver, showing the hexagonal nature of its lobules. **(b)** Photomicrograph of one liver lobule (65×). (See *A Brief Atlas of the Human Body,* Plate 47.) **(c)** Three-dimensional representation of one liver lobule. Arrows indicate the direction of blood flow. **(d)** Enlarged view of a small portion of one liver lobule, illustrating the components of a portal triad (portal tract region), bile canaliculi, and Kupffer cells in the sinusoid walls. The directions of blood and bile flow are also indicated.

acids to make plasma proteins); (2) store fat-soluble vitamins; and (3) play important roles in detoxification, such as ridding the blood of ammonia by converting it to urea (Chapter 24). Thanks to these various jobs, the processed blood leaving the liver contains fewer nutrients and waste materials than the blood that entered it. The intimate relationship between the hepatocytes and their blood supply has liver growth and repair consequences in addition to its role in providing the hepatocytes with blood for processing and nutrition. During liver injury, hepatocytes secrete *vascular endothelial growth factor (VEGF)* which binds to specific receptors on endothelial cells lining the sinusoids. The endothelial cells proliferate and release other growth factors, such as hepatocyte growth factor (HGF) and interleukin 6, which in turn prompt the hepatocytes to multiply and replace dead and dying liver tissue. The regenerative capacity of the liver is exceptional; it can regenerate to its former size even after surgical removal or loss of 70% of its normal mass.

Secreted bile flows through tiny canals, called **bile canaliculi** (kan"ah-lik'u-li; "little canals"), that run between adjacent hepatocytes toward the bile duct branches in the portal triads (see Figure 23.24d). Notice that blood and bile flow in opposite directions in the liver lobule. Bile entering the bile ducts eventually leaves the liver via the common hepatic duct to travel toward the duodenum.

HOMEOSTATIC IMBALANCE

Hepatitis (hep"ah-ti'tis), or inflammation of the liver, is most often due to viral infection. Thus far the catalogue of hepatitis-causing viruses numbers six—from the hepatitis A virus (HVA) to the hepatitis F virus (HVF). Of these, two (HVA and HVE) are transmitted enterically and the infections they cause tend to be self-limiting. Those transmitted via blood—most importantly HVB and HVC—are linked to chronic hepatitis and liver cirrhosis (see discussion below). HVD is a mutated virus that needs HVB to be infectious. Thus far, little is known about HVF. Nonviral causes of acute hepatitis include drug toxicity and wild mushroom poisoning.

In the United States, over 40% of hepatitis cases are due to HVB, which is transmitted via blood transfusions, contaminated needles, or sexual contact. A serious problem in its own right, hepatitis B carries with it a greater menace—an elevated risk of liver cancer. However, childhood immunization using vaccine produced in bacteria is sweeping the feet out from under HVB, and the incidence of acute hepatitis from this strain has fallen dramatically since its peak in 1985.

Hepatitis A, accounting for about 32% of cases, is a more benign form frequently observed in day-care centers. It is transmitted via sewage-contaminated food, raw shellfish, water, and by the feces-mouth route, which explains why it is important for restaurant employees to scrub their hands after using the washroom. Hepatitis E is transmitted in a similar way. It causes waterborne epidemics, largely in developing countries, and is a major cause of death in pregnant women. It is relatively insignificant in the United States.

Hepatitis C has emerged as the most important liver disease in the United States because it produces persistent or chronic liver infections (as opposed to acute infections). More than 4 milion Americans are infected and over 10,000 die annually due to sequels of HVC infection. However, the life-threatening C form of hepatitis is now being successfully treated by combination drug therapy entailing weekly injections of interferon (Pegasys, PEG-Intron) and ribavirin (Rebetol), an oral antiviral drug.

Cirrhosis (sĭr-ro'sis; "orange colored") is a progressive chronic inflammation of the liver that typically results from chronic alcoholism or severe chronic hepatitis. The alcohol-poisoned or damaged hepatocytes regenerate, but the liver's connective (scar) tissue regenerates faster. As a result, the liver becomes fatty and fibrous and its activity is depressed. As the scar tissue shrinks, it obstructs blood flow throughout the hepatic portal system, causing **portal hypertension.** Fortunately, some veins of the portal system anastomose with veins that drain into the venae cavae *(portal-caval anastomoses).* The main ones are (1) veins in the inferior esophagus, (2) hemorrhoidal veins in the anal canal, and (3) superficial veins around the umbilicus. However, these connecting veins are small and tend to burst when forced to carry large volumes of blood. Signs of their failure include vomiting blood, and a snakelike network of distended veins surrounding the navel. This network is called *caput medusae* (kap'ut mĕ-du'se; "medusa head") after a monster in Greek mythology whose hair was made of writhing snakes. Other complications due to portal hypertension include swollen veins in the esophagus (esophageal varices) and *ascites,* an accumulation of fluid in the peritoneal cavity.

Liver transplants are the only clinically proven effective treatment for patients with end-stage liver disease. The one- and five-year survival rate of such transplants is approximately 90% and 75% respectively. However, donor organs are very scarce and many patients die while waiting for a suitable organ.

Composition of Bile

Bile is a yellow-green, alkaline solution containing bile salts, bile pigments, cholesterol, triglycerides, phospholipids (lecithin and others), and a variety of electrolytes. Of these, *only* bile salts and phospholipids aid the digestive process.

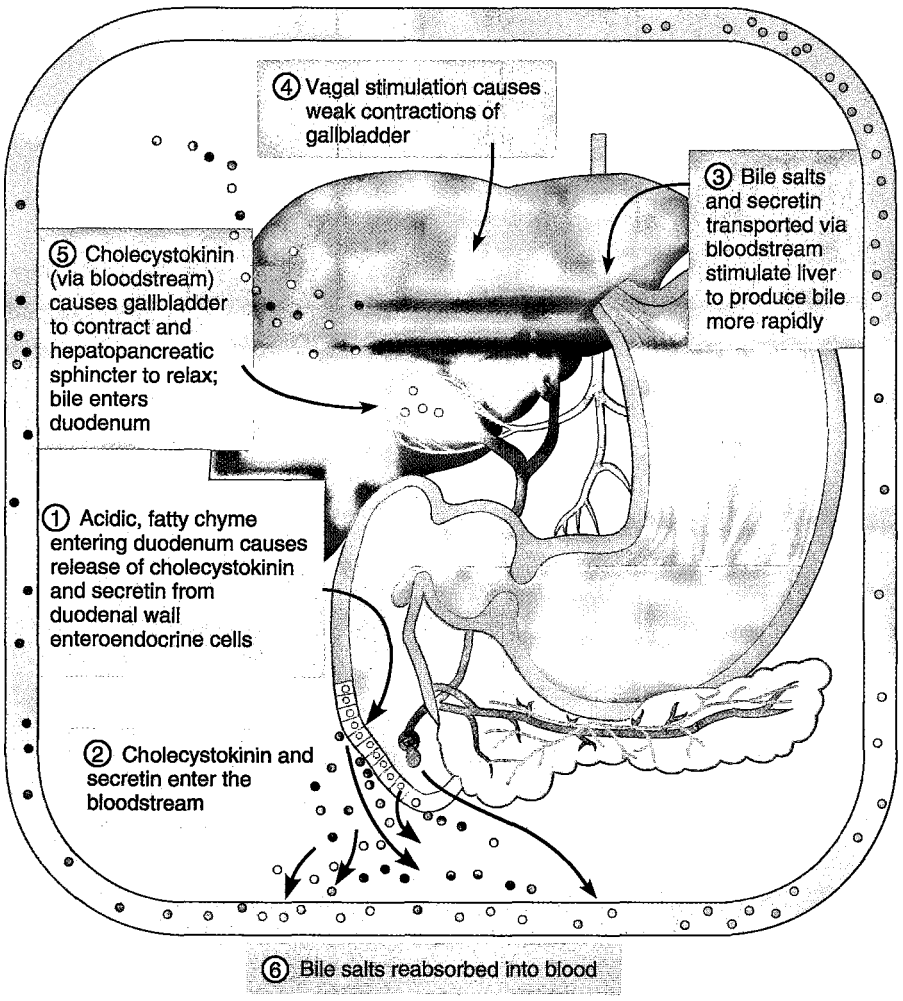

FIGURE 23.25 **Mechanisms promoting secretion of bile.** When digestion is not occurring, bile is stored and concentrated in the gallbladder. When acidic fatty chyme enters the small intestine, several mechanisms are initiated that accelerate the liver's output of bile and cause the gallbladder to contract and the hepatopancreatic sphincter to relax. This allows bile (and pancreatic juice) to enter the small intestine. The single most important stimulus of bile secretion is an increased level of bile salts in the enterohepatic circulation.

Bile salts, primarily cholic and chenodeoxycholic acids, are cholesterol derivatives. Their role is to *emulsify* fats—that is, to distribute them throughout the watery intestinal contents, just as a dish detergent breaks up a pool of fat drippings in a roasting pan. (Another example of emulsification is homogenization, which distributes cream throughout the watery phase of milk.) As a result, large fat globules entering the small intestine are physically separated into millions of small, more accessible fatty droplets that provide large surface areas for the fat-digesting enzymes to work on. Bile salts also facilitate fat and cholesterol absorption (discussed later) and help solubilize cholesterol, both that contained in bile and that entering the small intestine in food. Although many substances secreted in bile leave the body in feces, bile salts are not among them. Instead, bile salts are conserved by means of a recycling mechanism called the **enterohepatic circulation.** In this process, bile salts are (1) reabsorbed into the blood by the ileum, (2) returned to the liver via the hepatic portal blood, and then (3) resecreted in newly formed bile.

The chief bile pigment is **bilirubin** (bil″ĭ-roo′bin), a waste product of the heme of hemoglobin formed during the breakdown of worn-out erythrocytes (see Chapter 17). The globin and iron parts of hemoglobin are saved and recycled, but bilirubin is absorbed from the blood by the liver cells, excreted into bile, and metabolized in the small intestine by resident bacteria. One of its breakdown products, *stercobilin* (ster′ko-bi″lin), gives feces a brown color. In the absence of bile, feces are gray-white in color and have fatty streaks (because essentially no fats are digested or absorbed).

The liver produces 500 to 1000 ml of bile daily, and production is stepped up when the GI tract contains fatty chyme. Bile salts themselves are the major stimulus for enhanced bile secretion (Figure 23.25), and when the enterohepatic circulation is returning large amounts of bile salts to the liver, its output of bile rises dramatically. *Secretin,* released by intestinal cells exposed to fatty chyme, also stimulates liver cells to secrete bile.

The Gallbladder

The **gallbladder** is a thin-walled green muscular sac about 10 cm (4 inches) long. Roughly the size of a kiwi fruit, it snuggles in a shallow fossa on the

ventral surface of the liver (see Figures 23.1 and 23.23). Its rounded fundus protrudes from the inferior margin of the liver. The gallbladder stores bile that is not immediately needed for digestion and concentrates it by absorbing some of its water and ions. (In some cases, bile released from the gallbladder is ten times as concentrated as that entering it.) When empty, or when storing only small amounts of bile, its mucosa is thrown into honeycomb-like folds that, like the rugae of the stomach, allow the organ to expand as it fills. When its muscular wall contracts, bile is expelled into its duct, the *cystic duct,* and then flows into the bile duct. The gallbladder, like most of the liver, is covered by visceral peritoneum.

Regulation of Bile Release into the Small Intestine

When no digestion is occurring, the hepatopancreatic sphincter (guarding the entry of bile and pancreatic juice into the duodenum) is closed and the released bile backs up the cystic duct into the gallbladder, where it is stored until needed. Although the liver makes bile continuously, bile does not usually enter the small intestine until the gallbladder contracts. The major stimulus for gallbladder contraction is *cholecystokinin (CCK),* an intestinal hormone (Figure 23.25) released to the blood when acidic, fatty chyme enters the duodenum. Besides causing the gallbladder to contract, CCK (1) stimulates secretion of pancreatic juice, and (2) relaxes the hepatopancreatic sphincter so that bile and pancreatic juice can enter the duodenum. CCK and the other digestive hormones are summarized in Table 23.1. Parasympathetic impulses delivered by the vagus nerves are a minor stimulus for gallbladder contraction.

HOMEOSTATIC IMBALANCE

Bile is the major vehicle for cholesterol excretion from the body, and bile salts keep the cholesterol dissolved within bile. Too much cholesterol or too few bile salts leads to cholesterol crystallization, forming **gallstones,** or *biliary calculi* (bil'e-a"re kal'ku-li), which obstruct the flow of bile from the gallbladder. Then, when the gallbladder or its duct contracts, the sharp crystals cause agonizing pain that radiates to the right thoracic region. Treatments for gallstones include dissolving the crystals with drugs, pulverizing them with ultrasound vibrations (lithotripsy), vaporizing them with lasers, and the classical treatment, surgically removing the gallbladder. When the gallbladder is removed, the bile duct enlarges to assume the bile-storing role. Gallstones are easy to diagnose because they show up well with ultrasound imaging.

Bile duct blockage prevents both bile salts and bile pigments from entering the intestine. As a result, yellow bile pigments accumulate in blood and eventually are deposited in the skin, causing it to become yellow, or *jaundiced.* Jaundice caused by blocked ducts is called *obstructive jaundice,* but jaundice may also reflect liver disease (in which the liver is unable to carry out its normal metabolic duties). ●

The Pancreas

The **pancreas** (pan'kre-as; *pan* = all, *creas* = flesh, meat) is a soft, tadpole-shaped gland that extends across the abdomen from its *tail* (abutting the spleen) to its *head,* which is encircled by the C-shaped duodenum (see Figures 23.1 and 23.20). Most of the pancreas is retroperitoneal and lies deep to the greater curvature of the stomach.

An accessory digestive organ, the pancreas is important to the digestive process because it produces enzymes that break down all categories of foodstuffs, which the pancreas then delivers to the duodenum. This exocrine product, called **pancreatic juice,** drains from the pancreas via the centrally located **main pancreatic duct.** The pancreatic duct generally fuses with the bile duct just as it enters the duodenum (at the hepatopancreatic ampulla). A smaller *accessory pancreatic duct* empties directly into the duodenum just proximal to the main duct.

Within the pancreas are the **acini** (as'ĭ-ni; singular: acinus), clusters of secretory cells surrounding ducts (Figure 23.26). These cells are full of rough endoplasmic reticulum and exhibit deeply staining **zymogen granules** (zi'mo-jen; "fermenting") containing the digestive enzymes they manufacture.

Scattered amid the acini are the more lightly staining *pancreatic islets (islets of Langerhans).* These mini-endocrine glands release insulin and glucagon, hormones that play an important role in carbohydrate metabolism, as well as several other hormones (see Chapter 16).

Composition of Pancreatic Juice

Approximately 1200 to 1500 ml of clear pancreatic juice is produced daily. It consists mainly of water, and contains enzymes and electrolytes (primarily bicarbonate ions). The acinar cells produce the enzyme-rich component of pancreatic juice. The epithelial cells lining the smallest pancreatic ducts release the bicarbonate ions that make it alkaline (about pH 8). The high pH of pancreatic fluid helps neutralize acid chyme entering the duodenum and provides the optimal environment for activity of intestinal and pancreatic enzymes. Like pepsin of the stomach, pancreatic proteases (protein-digesting enzymes) are produced and released in inactive forms, which are activated in the duodenum, where they do their work. This prevents the pancreas from self-digestion. For example,

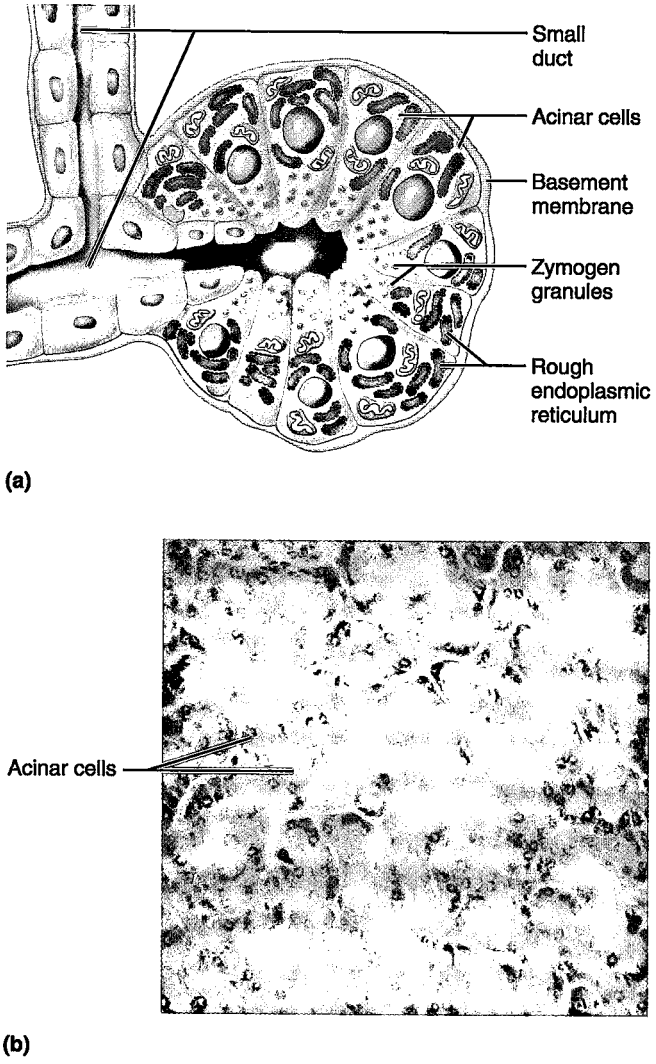

FIGURE 23.26 **Structure of the enzyme-producing tissue of the pancreas. (a)** One acinus (a secretory unit). The cell apices contain abundant zymogen (enzyme-containing) granules. **(b)** Photomicrograph of pancreatic acinar tissue (200×).

within the duodenum, *trypsinogen* is activated to **trypsin** by **enteropeptidase** (formerly called *enterokinase)*, an intestinal brush border protease. Trypsin, in turn, activates two other pancreatic proteases *(procarboxypeptidase* and *chymotrypsinogen)* to their active forms, **carboxypeptidase** (kar-bok"se-pep'tĭ-dās) and **chymotrypsin** (ky"mo-trip'sin), respectively (Figure 23.27). Other pancreatic enzymes—**amylase, lipases,** and **nucleases**—are secreted in active form, but require that ions or bile be present in the intestinal lumen for optimal activity.

Regulation of Pancreatic Secretion

Secretion of pancreatic juice is regulated both by hormones and by the parasympathetic nervous system (Figure 23.28). The more important hormonal

Q *What is the significance of the fact that pancreatic enzymes are activated in the small intestine?*

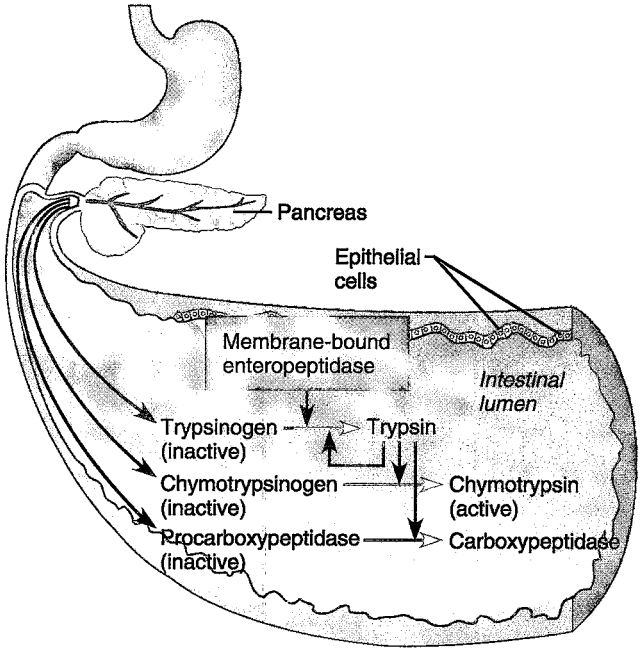

FIGURE 23.27 **Activation of pancreatic proteases in the small intestine.** Pancreatic proteases are secreted in an inactive form and are activated in the duodenum.

mechanism is exerted by two intestinal hormones. Both hormones act on the pancreas, but secretin released in response to the presence of HCl in the intestine mainly targets the duct cells, prompting their release of watery *bicarbonate-rich* pancreatic juice. CCK, released in response to the entry of proteins and fats, stimulates the acini to release *enzyme-rich* pancreatic juice, and potentiates the effect of secretin. Hence, substantially more bicarb-rich juice is secreted when both hormones are present. Vagal stimulation causes release of pancreatic juice primarily during the cephalic and gastric phases of gastric secretion.

Normally, the amount of HCl produced in the stomach is exactly balanced by the amount of bicarbonate (HCO_3^-) secreted by the pancreas, and as HCO_3^- is secreted into the pancreatic juice, H^+ enters the blood. Consequently, the pH of venous blood returning to the heart remains relatively unchanged because alkaline blood draining from the stomach is neutralized by the acidic blood draining the pancreas.

A *They are activated in the small intestine where they work and where the cells exposed to them are protected by mucus. No such protection exists in the pancreas.*

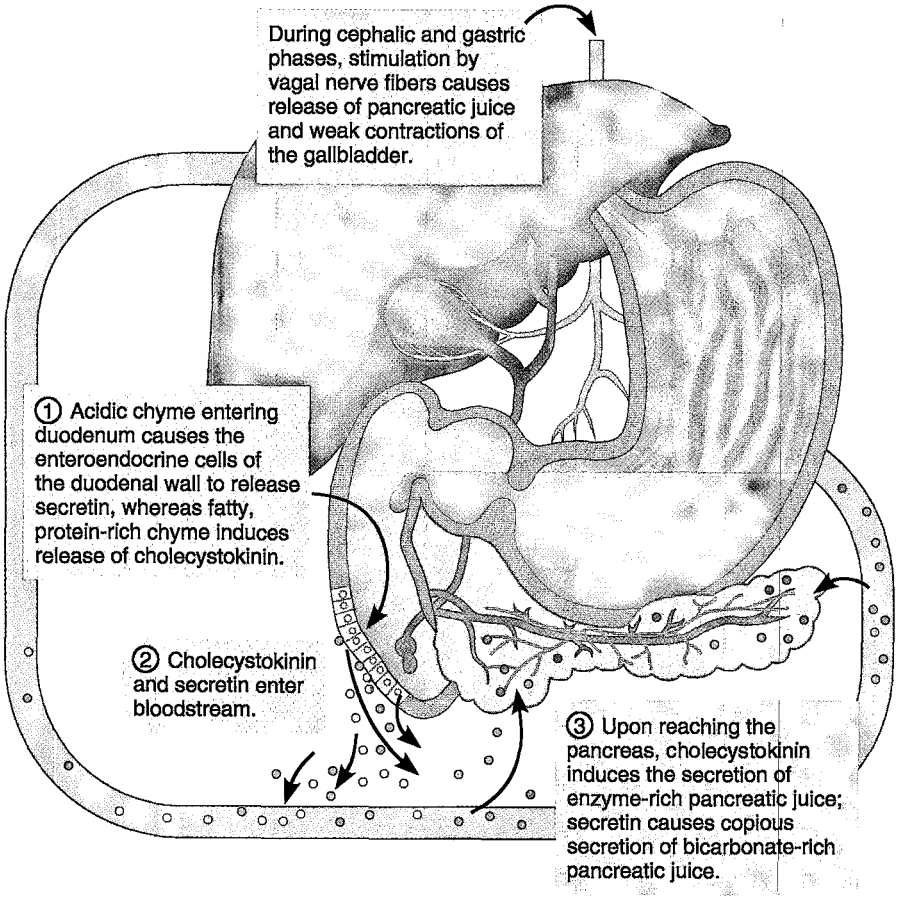

FIGURE 23.28 **Regulation of pancreatic juice secretion.** Hormonal controls, exerted by secretin and cholecystokinin (steps ①–③), are the main regulatory factors. Neural control is mediated by parasympathetic fibers of the vagus nerves.

Digestive Processes Occurring in the Small Intestine

Food reaching the small intestine is unrecognizable, but it is far from being digested chemically. Carbohydrates and proteins are partially degraded, but virtually no fat digestion has occurred to this point. The process of food digestion is accelerated during the chyme's tortuous journey of three to six hours through the small intestine, and it is here that absorption of most of the water and virtually all nutrients occurs. Like the stomach, the small intestine plays no part in ingestion or defecation.

Requirements for Optimal Intestinal Digestive Activity

Although a primary function of the small intestine is digestion, intestinal juice provides little of what is needed to perform this function. Most substances required for chemical digestion—bile, digestive enzymes (except for the brush border enzymes), and bicarbonate ions (to provide the proper pH for enzymatic catalysis)—are *imported* from the liver and pancreas. Hence, anything that impairs liver or pancreatic function or delivery of their juices to the small intestine severely hinders our ability to digest food and absorb nutrients. The other primary function of the small intestine—absorption—is efficiently accomplished by its absorptive cells with their rich crop of apical microvilli.

Optimal digestive activity in the small intestine also depends on a slow, measured delivery of chyme from the stomach. Why is this so? Entering chyme is usually hypertonic. Thus, if large amounts of chyme were rushed into the small intestine, the osmotic water loss from the blood into the intestinal lumen would result in dangerously low blood volume. Additionally, the low pH of entering chyme must be adjusted upward and the chyme must be well mixed with bile and pancreatic juice for digestion to continue. These modifications take time. Thus, food movement into the small intestine is carefully controlled by the pumping action of the stomach pylorus (see pp. 905 and 907) to prevent the duodenum from being overwhelmed. Since the actual chemistry of digestion and absorption is covered in detail later, next we will examine how the small intestine mixes and propels food along its length, and how its motility is regulated.

Motility of the Small Intestine

Intestinal smooth muscle mixes chyme thoroughly with bile and pancreatic and intestinal juices, and moves food residues through the ileocecal valve into

TABLE 23.2 Overview of the Functions of the Gastrointestinal Organs

ORGAN	MAJOR FUNCTIONS*	COMMENTS/ADDITIONAL FUNCTIONS
Mouth and associated accessory organs	■ Ingestion: food is voluntarily placed into oral cavity ■ Propulsion: voluntary (buccal) phase of deglutition (swallowing) initiated by tongue; propels food into pharynx ■ Mechanical digestion: mastication (chewing) by teeth and mixing movements by tongue ■ Chemical digestion: chemical breakdown of starch is begun by salivary amylase present in saliva produced by salivary glands	Mouth serves as a receptacle; most functions performed by associated accessory organs. Mucus present in saliva helps dissolve foods so they can be tasted and moistens food so that tongue can compact it into a bolus that can be swallowed. Oral cavity and teeth cleansed and lubricated by saliva
Pharynx and esophagus	■ Propulsion: peristaltic waves move food bolus to stomach, thus accomplishing involuntary (pharyngeal-esophageal) phase of deglutition	Primarily food chutes; mucus produced helps to lubricate food passageways
Stomach	■ Mechanical digestion and propulsion: peristaltic waves mix food with gastric juice and propel it into the duodenum ■ Chemical digestion: digestion of proteins begun by pepsin ■ Absorption: absorbs a few fat-soluble substances (aspirin, alcohol, some drugs)	Also serves as storage site for food until it can be moved into the duodenum. Hydrochloric acid produced is a bacteriostatic agent and activates protein-digesting enzymes. Mucus produced helps lubricate and protect stomach from self-digestion. Intrinsic factor produced is required for intestinal absorption of vitamin B_{12}
Small intestine and associated accessory organs (liver, gallbladder, pancreas)	■ Mechanical digestion and propulsion: segmentation by smooth muscle of the small intestine continually mixes contents with digestive juices and moves food along tract and through ileocecal valve at a slow rate, allowing sufficient time for digestion and absorption ■ Chemical digestion: digestive enzymes conveyed in from pancreas and brush border enzymes attached to villi membranes complete digestion of all classes of foods ■ Absorption: breakdown products of carbohydrate, protein, fat, and nucleic acid digestion, plus vitamins, electrolytes, and water, are absorbed by active and passive mechanisms	Small intestine is highly modified for digestion and absorption (circular folds, villi, and microvilli). Alkaline mucus produced by intestinal glands and bicarbonate-rich juice ducted in from pancreas help neutralize acidic chyme and provide proper environment for enzymatic activity. Bile produced by liver emulsifies fats and enhances (1) fat digestion and (2) absorption of fatty acids, monoglycerides, cholesterol, phospholipids, and fat-soluble vitamins. Gallbladder stores and concentrates bile; bile is released to small intestine in response to hormonal signals
Large intestine	■ Chemical digestion: some remaining food residues are digested by enteric bacteria (which also produce vitamin K and some B vitamins) ■ Absorption: absorbs most remaining water, electrolytes (largely NaCl), and vitamins produced by bacteria ■ Propulsion: propels feces toward rectum by peristalsis, haustral churning, and mass movements ■ Defecation: reflex triggered by rectal distension; eliminates feces from body	Temporarily stores and concentrates residues until defecation can occur. Copious mucus produced by goblet cells eases passage of feces through colon

*The colored boxes beside the functions correspond to the color coding of digestive functions (gastrointestinal tract activities) illustrated in Figure 23.2.

the large intestine. In contrast to the peristaltic waves of the stomach, *segmentation* is the most common motion of the small intestine.

If X-ray fluoroscopy is used to examine the small intestine after it is "loaded" with a meal, it looks like the intestinal contents are being massaged—that is, the chyme is simply moved backward and forward in the lumen a few centimeters at a time by alternating contraction and relaxation of rings of smooth muscle. These segmenting movements of the intestine (see Figure 23.3b), like the peristalsis of the stomach, are initiated by intrinsic pacemaker

TABLE 23.3 Control of Small Intestinal Motility

PHASE	STIMULUS	MECHANISM	EFFECT ON MOTILITY
Gastric 	↑ Gastric motility and emptying	Long neural reflexes (gastroileal reflex)	↑ Activity in ileum
		Gastrin	↑ Segmenting movements in ileum; relaxes ileocecal sphincter
Intestinal 	Distension of small intestine	Long and short neural reflexes	↑ Strength of segmentation
	Reduced intestinal volume; fasting	Long and short neural reflexes; initiated by ↑ blood levels of motilin	Initiates migrating motility complex (peristalsis); repeats until next meal

cells in the longitudinal smooth muscle layer. However, unlike the stomach pacemakers, which have only one rhythm, the pacemakers in the duodenum depolarize more frequently (12–14 contractions per minute) than those in the ileum (8 or 9 contractions per minute). As a result, segmentation moves intestinal contents slowly and steadily toward the ileocecal valve at a rate that allows ample time to complete digestion and absorption. The intensity of segmentation is altered by long and short reflexes (which parasympathetic activity enhances and sympathetic activity decreases) and hormones (Table 23.3). The more intense the contractions, the greater the mixing effect; however, the basic contractile rhythms of the various intestinal regions remain unchanged.

True peristalsis occurs late in the intestinal phase only after most nutrients have been absorbed. At this point, segmenting movements wane and the duodenal mucosa begins to release the hormone *motilin*. As motilin blood levels rise, peristaltic waves are initiated in the proximal duodenum and begin to sweep slowly along the intestine, moving 50–70 cm (about 2 ft) before dying out. Each successive wave is initiated a bit more distally, and this pattern of peristaltic activity is called the **migrating motility complex (MMC).** A complete "trip " from duodenum to ileum takes about two hours. The process then repeats itself, sweeping the last remnants of the meal plus bacteria, sloughed-off mucosal cells, and other debris into the large intestine. This "housekeeping" function is critical for preventing the overgrowth of bacteria that migrate from the large intestine into the small intestine. As food again enters the stomach with the next meal, peristalsis is replaced by segmentation.

The local enteric neurons of the GI tract wall coordinate these intestinal motility patterns. The physiological diversity of the enteric neurons allows a variety of effects to occur depending on which neurons are activated or inhibited. For example, a given ACh-releasing (cholinergic) sensory neuron in the small intestine, once activated, may simultaneously send messages to several different interneurons in the myenteric plexus that regulate peristalsis:

- Impulses sent proximally by cholinergic effector neurons cause contraction and shortening of the circular muscle layer.
- Impulses sent distally to certain interneurons cause shortening of the longitudinal muscle layer and distension of the intestine, in response to ACh-releasing effector neurons.

As a result, as the proximal area constricts and forces chyme along the tract, the lumen of the distal part of the intestine enlarges to receive it.

Most of the time, the ileocecal sphincter is constricted and closed. However, two mechanisms—one neural and the other hormonal—cause it to relax and allow food residues to enter the cecum when ileal motility increases. Enhanced activity of the stomach initiates the **gastroileal reflex** (gas"tro-il'e-ul), a long reflex that enhances the force of segmentation in the ileum. In addition, gastrin released by the stomach increases the motility of the ileum and relaxes the ileocecal sphincter. Once the chyme has passed through, it exerts backward pressure that closes the valve's flaps, preventing regurgitation into the ileum. This reflex ensures that the contents of the previous meal are swept completely out of the stomach and small intestine as the next meal is eaten.

HOMEOSTATIC IMBALANCE

Injury to the intestinal wall by severe stretching, some bacterial infections, or mechanical trauma may lead to a total cessation of small intestine motility, a phenomenon called intestino-intestinal reflex. ●

The Large Intestine

The **large intestine** (see Figure 23.1) frames the small intestine on three sides and extends from the ileocecal valve to the anus. Its diameter, at about 7 cm, is greater than that of the small intestine (hence, *large* intestine), but it is less than half as long (1.5 m versus 6 m). In terms of digestive system functioning, its major function is to absorb most of the remaining water from indigestible food residues (delivered to it in a fluid state), store the residues temporarily, and then eliminate them from the body as semisolid **feces** (fe'sēz).

Gross Anatomy

The large intestine exhibits three features not seen elsewhere—teniae coli, haustra, and epiploic appendages. Except for its terminal end, the longitudinal muscle layer of its muscularis is reduced to three bands of smooth muscle called **teniae coli** (ten'ne-e ko'li; "ribbons of the colon"). Their tone causes the wall of the large intestine to pucker into pocketlike sacs called **haustra** (haw'strah; "to draw up"). Another obvious feature of the large intestine is its **epiploic appendages** (ep"ĭ-plo'ik), small fat-filled pouches of visceral peritoneum that hang from its surface (Figure 23.29a). Their significance is not known.

Subdivisions

The large intestine has the following subdivisions: cecum, appendix, colon, rectum, and anal canal. The saclike **cecum** (se'kum; "blind pouch"), which lies below the ileocecal valve in the right iliac fossa, is the first part of the large intestine (Figure 23.29a). Attached to its posteromedial surface is the blind, wormlike **vermiform appendix.** The appendix contains masses of lymphoid tissue, and as part of MALT (see p. 782), it plays an important role in body immunity. However, it has an important structural shortcoming—its twisted structure provides an ideal location for enteric bacteria to accumulate and multiply.

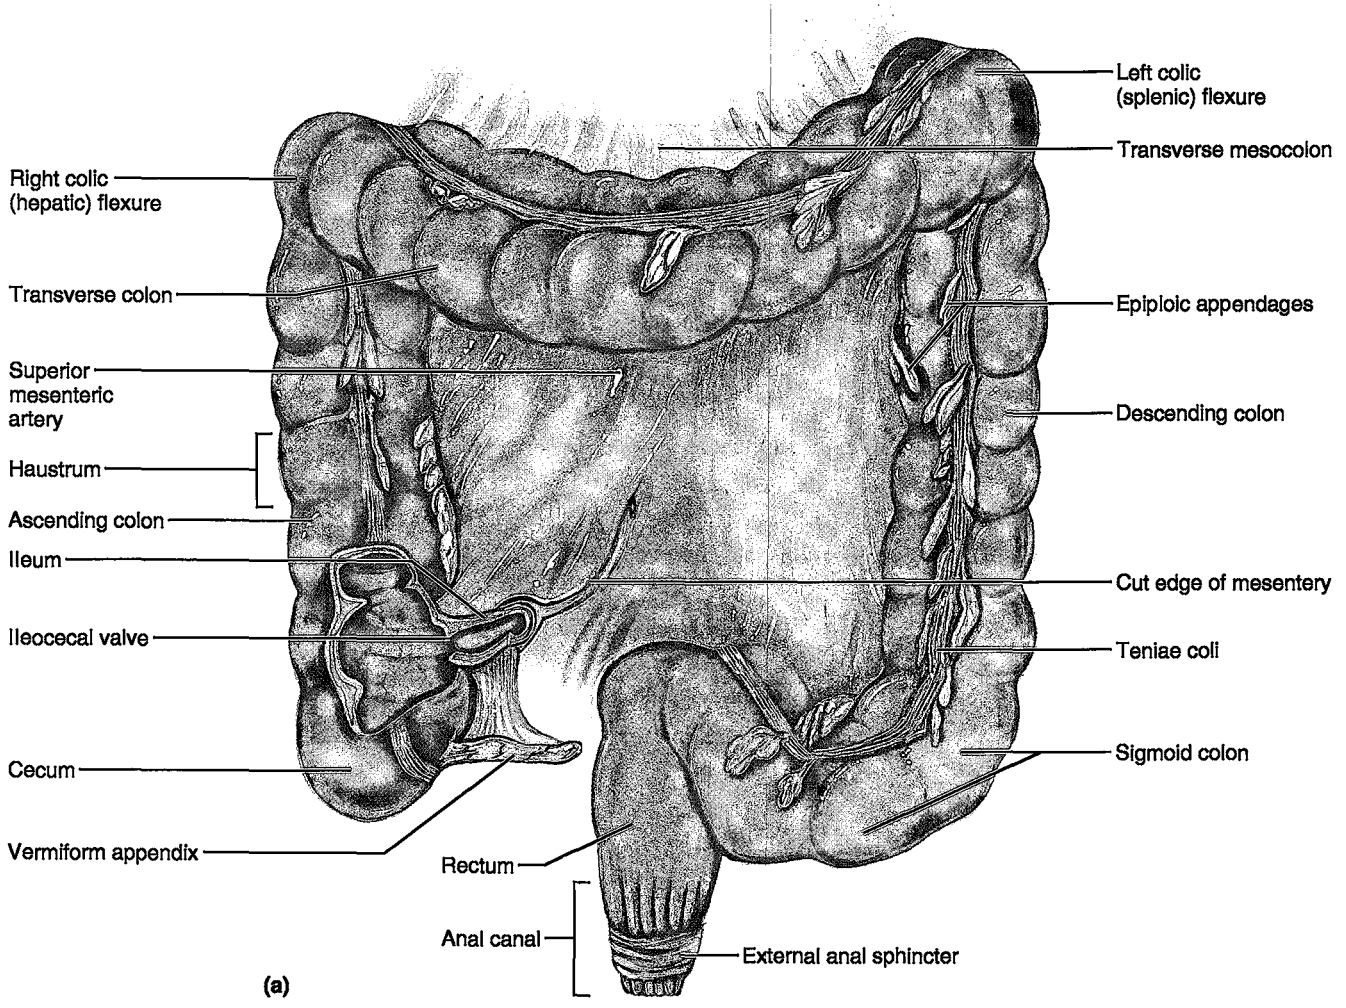
HOMEOSTATIC IMBALANCE

Acute inflammation of the appendix, or **appendicitis,** results from a blockage (often by feces) that traps infectious bacteria in its lumen. Unable to empty its contents, the appendix swells, squeezing off venous drainage, which may lead to ischemia and necrosis (death and decay) of the appendix. If the appendix ruptures, feces containing bacteria spray over the abdominal contents, causing *peritonitis.* Although the symptoms of appendicitis are variable, the first is usually pain in the umbilical region. Loss of appetite, nausea and vomiting, and relocalization of pain to the lower right abdominal quadrant follow. Immediate surgical removal of the appendix (appendectomy) is the accepted treatment for suspected appendicitis. Appendicitis is most common during adolescence, when the entrance to the appendix is at its widest. ●

The **colon** has several distinct regions. As the **ascending colon,** it travels up the right side of the abdominal cavity to the level of the right kidney. Here it makes a right-angle turn—the **right colic,** or **hepatic, flexure**—and travels across the abdominal cavity as the **transverse colon.** Directly anterior to the spleen, it bends acutely at the **left colic (splenic) flexure** and descends down the left side of the posterior abdominal wall as the **descending colon.** Inferiorly, it enters the pelvis, where it becomes the S-shaped **sigmoid colon.** Except for the transverse and sigmoid parts of the colon, which are intraperitoneal and anchored to the posterior abdominal wall by mesentery sheets called **mesocolons** (see Figure 23.30c and d), the colon is retroperitoneal.

In the pelvis, at the level of the third sacral vertebra, the sigmoid colon joins the **rectum,** which runs posteroinferiorly just in front of the sacrum. The position of the rectum allows a number of pelvic organs (e.g., the prostate gland of males) to be examined digitally (with a finger) through the anterior rectal wall. This is called a **rectal exam.** Despite its name (*rectum* = straight), the rectum has three lateral curves or bends, represented internally as three transverse folds called **rectal valves** (Figure 23.29b). These valves separate feces from flatus, that is, they stop feces from being passed along with gas.

The **anal canal,** the last segment of the large intestine, lies in the perineum, entirely external to the abdominopelvic cavity. About 3 cm long, it begins where the rectum penetrates the levator ani muscle of the pelvic floor and opens to the body exterior at the **anus.** The anal canal has two sphincters, an involuntary **internal anal sphincter** composed of smooth muscle (part of the muscularis), and a voluntary **external anal sphincter** composed of skeletal muscle. The sphincters, which act rather like purse



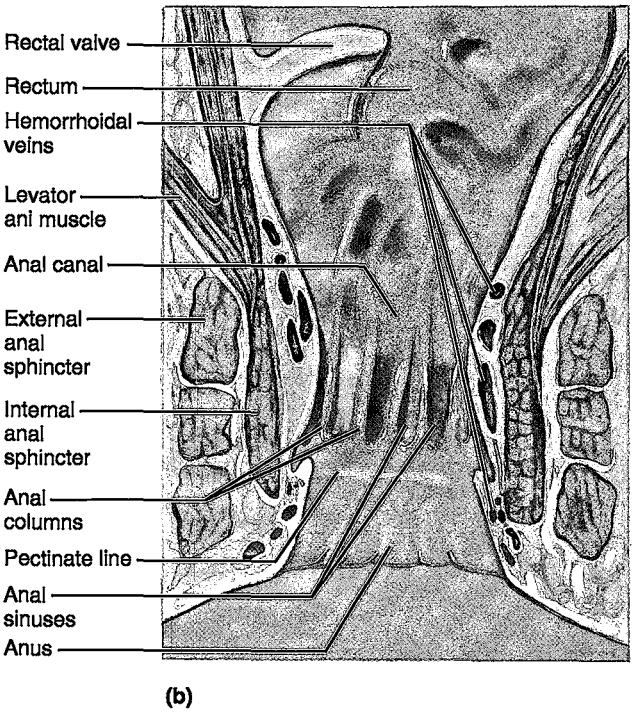


FIGURE 23.29 **Gross anatomy of the large intestine.** **(a)** Diagrammatic view. **(b)** Structure of the anal canal.

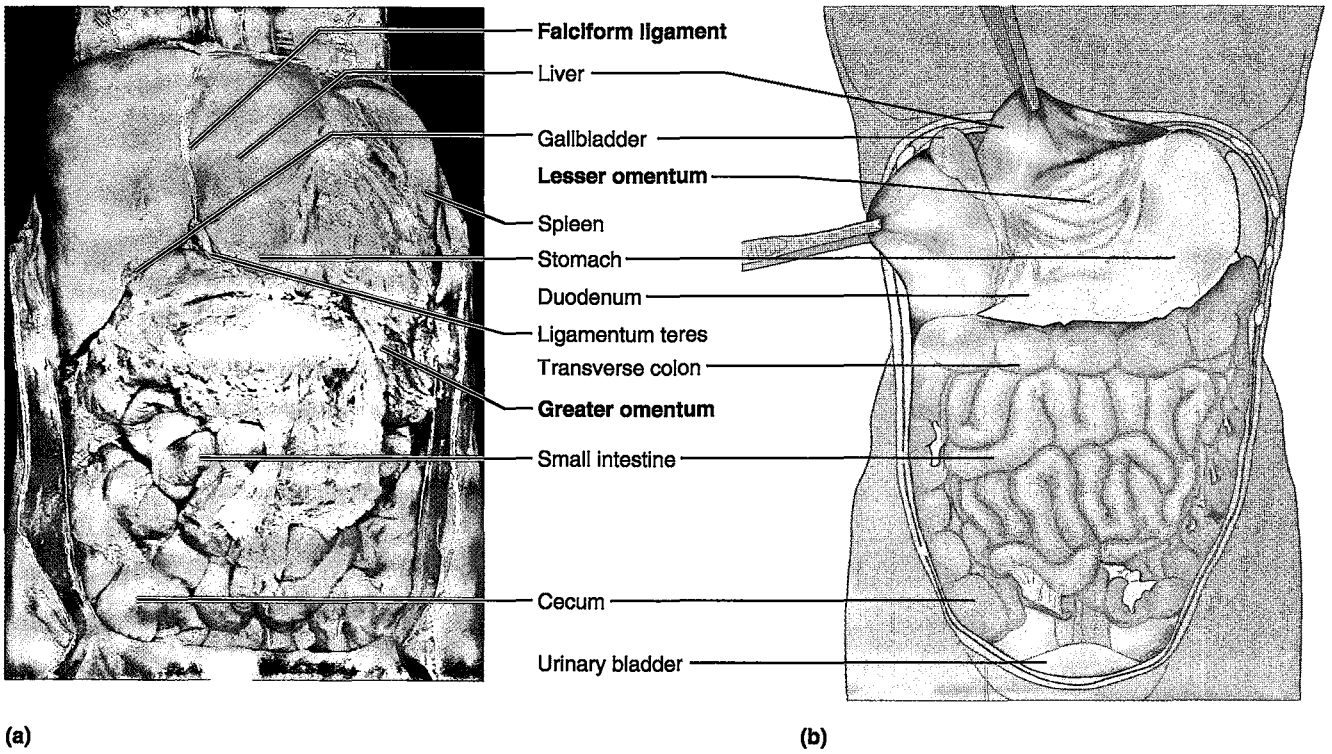
strings to open and close the anus, are ordinarily closed except during defecation.

Microscopic Anatomy

The wall of the large intestine (Figure 23.31) differs in several ways from that of the small intestine. The colon *mucosa* is simple columnar epithelium except in the anal canal. Because most food is absorbed before reaching the large intestine, there are no circular folds, no villi, and virtually no cells that secrete digestive enzymes. However, its mucosa is thicker, its abundant crypts are deeper, and there are tremendous numbers of goblet cells in the crypts (Figure 23.31). Mucus produced by goblet cells eases the passage of feces and protects the intestinal wall from irritating acids and gases released by resident bacteria in the colon.

The mucosa of the anal canal, a stratified squamous epithelium, merges with the true skin surrounding the anus and is quite different from that of the rest of the colon, reflecting the greater abrasion that this region receives. Superiorly, it hangs in long



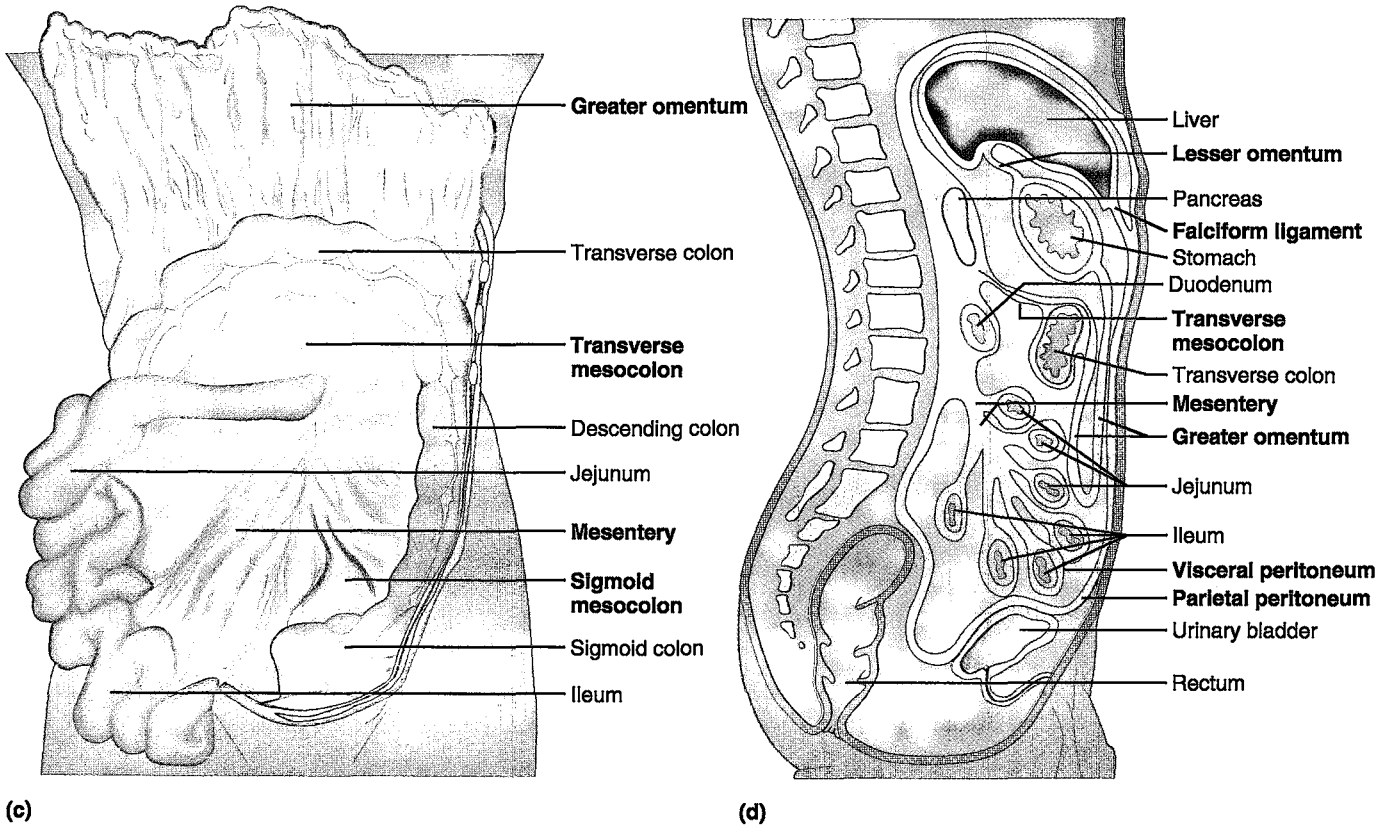


FIGURE 23.30 **Mesenteries of the abdominal digestive organs. (a)** The greater omentum, a dorsal mesentery, is shown in its normal position covering the abdominal viscera. **(b)** The lesser omentum, a ventral mesentery attaching the liver to the lesser curvature of the stomach (the liver and gallbladder have been reflected superiorly). **(c)** The greater omentum has been reflected superiorly to reveal the mesentery attachments of the small and large intestine. **(d)** Sagittal section of the abdominopelvic cavity of a male.

ridges or folds called **anal columns. Anal sinuses** (Figure 23.29b), recesses between the anal columns, exude mucus when compressed by feces, which aids in emptying the anal canal. The horizontal, tooth-shaped line that parallels the inferior margins of the anal sinuses is called the *pectinate line.* Superior to this line, the mucosa is innervated by visceral sensory fibers and is relatively insensitive to pain. The area inferior to the pectinate line is very sensitive to pain, a reflection of the somatic sensory fibers serving it. Two superficial venous plexuses are associated with the anal canal, one with the anal columns and the other with the anus itself. If these (hemorrhoidal) veins are inflamed, itchy varicosities called *hemorrhoids* result.

Teniae coli and haustra are absent in the rectum and anal canal. However, consistent with its need to generate strong contractions to perform its expulsive role in defecation, the rectum's muscularis muscle layers are complete and well developed.

Bacterial Flora

Although most bacteria entering the cecum from the small intestine are dead (having been killed by the action of lysozyme, defensins, HCl, and protein-digesting enzymes), some are still "alive and kicking." Together with bacteria that enter the GI tract via the anus, these constitute the **bacterial flora** of the large intestine, over 700 species of them. These bacteria colonize the colon, metabolize some host-derived proteins (mucin, heparin, and hyaluronic acid) and ferment some of the indigestible carbohydrates (cellulose, xylan, and others), releasing irritating acids and a mixture of gases (including dimethyl sulfide, H_2, N_2, CH_4, and CO_2). Some of these gases (such as dimethyl sulfide) are quite odorous. About 500 ml of gas (flatus) is produced each day, much more when certain carbohydrate-rich foods (such as beans) are eaten. The bacterial flora also synthesize B complex vitamins and most of the vitamin K the liver requires to synthesize some of the clotting proteins.

Although the huge population of bacteria would seem to be enough (feces) inhabitants, there are more—including viruses and protozoans. Of these, at least 20 are known pathogens.

Most enteric bacteria are commensals that coexist peacefully with their host as long as they remain in the gut lumen. An elegant system keeps the commensals from breaching the mucosal barrier. In response to specific bacterial components, the epithelial cells of the gut mucosa release chemicals that recruit immune cells, particularly dendritic cells, into the mucosa. The dendritic cells pry open tight junctions between the epithelial cells and send

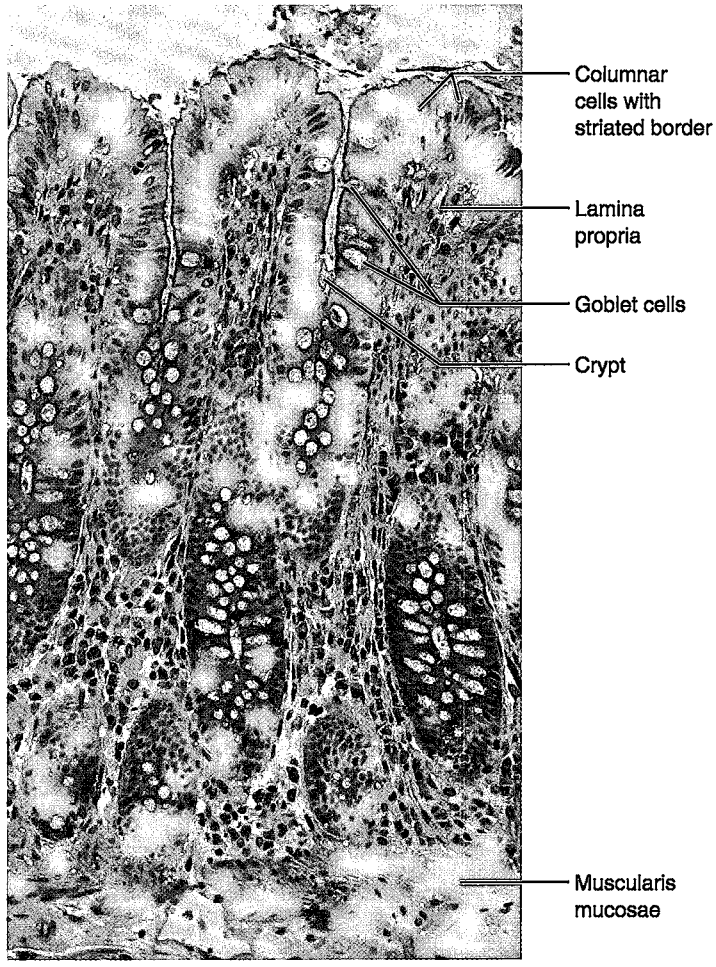

FIGURE 23.31 **The mucosa of the large intestine.** Light photomicrograph (500×).

extensions into the lumen to sample the microbial antigens. They then migrate to the nearby lymphoid follicles (MALT) within the gut mucosa where they present the antigens to T cells. As a result, an IgA antibody–mediated response restricted to the gut lumen is triggered that prevents the commensals from straying beyond the mucosa where they might elicit a much more widespread systemic response.

Digestive Processes Occurring in the Large Intestine

What is finally delivered to the large intestine contains few nutrients, but it still has 12 to 24 hours more to spend there. Except for a small amount of digestion of that residue by the enteric bacteria, no further food breakdown occurs in the large intestine.

Although the large intestine harvests vitamins made by the bacterial flora and reclaims most of the remaining water and some of the electrolytes

(particularly sodium and chloride), absorption is not the *major* function of this organ. As mentioned, the primary concerns of the large intestine are propulsive activities that force the fecal material toward the anus and then eliminate it from the body (defecation).

While the large intestine is important for our comfort, it is not essential for life. If the colon is removed, as may be necessitated by colon cancer, the terminal ileum is brought out to the abdominal wall in a procedure called an *ileostomy* (il"e-os'to-me), and food residues are eliminated from there into a sac attached to the abdominal wall. Another surgical technique, *ileoanal juncture,* links the ileum directly to the anal canal.

Motility of the Large Intestine

The large intestine musculature is inactive much of the time, but pressure in the ileum terminus opens the ileocecal sphincter and then closes it, preventing backward movement of the chyme. When presented with food residue the colon becomes motile, but its contractions are sluggish or short lived. The movements most seen in the colon are **haustral contractions,** slow segmenting movements lasting about one minute that occur every 30 minutes or so. These contractions, which occur mainly in the transverse and descending colon, reflect local controls of smooth muscle within the walls of the individual haustra. As a haustrum fills with food residue, the distension stimulates its muscle to contract, which propels the luminal contents into the next haustrum. These movements also mix the residue, which aids in water absorption.

Mass movements (mass peristalsis) are long, slow-moving, but powerful contractile waves that move over large areas of the colon three or four times daily and force the contents toward the rectum. Typically, they occur during or just after eating, which indicates that the presence of food in the stomach activates the gastroileal reflex in the small intestine and the propulsive **gastrocolic reflex** in the colon. Bulk, or fiber, in the diet increases the strength of colon contractions and softens the stool, allowing the colon to act like a well-oiled machine.

HOMEOSTATIC IMBALANCE

When the diet lacks bulk and the volume of residues in the colon is small, the colon narrows and its contractions become more powerful, increasing the pressure on its walls. This promotes formation of *diverticula* (di"ver-tik'u-lah), small herniations of the mucosa through the colon walls. This condition, called **diverticulosis,** most commonly occurs in the sigmoid colon, and affects over half of people over the age of 70. In about 20% of cases, diverticulosis progresses to **diverticulitis,** in which the diverticula become inflamed and may rupture, leaking feces into the peritoneal cavity, which can be life threatening.

Irritable bowel syndrome is a functional GI disorder not explained by anatomical or biochemical abnormalities. Affected individuals have recurring (or persistent) abdominal pain that is relieved by defecation, changes in the consistency (watery to stonelike) and frequency of their stools, and varying complaints of bloating, flatulence, nausea, and depression. Psychological and/or physiological stress are common precipitating factors, and stress management is an important aspect of treatment.

The semisolid product delivered to the rectum, called feces or the stool, contains undigested food residues, mucus, sloughed-off epithelial cells, millions of bacteria, and just enough water to allow its smooth passage. Of the 500 ml or so of food residue entering the cecum daily, approximately 150 ml becomes feces.

Defecation

The rectum is usually empty, but when feces are forced into it by mass movements, stretching of the rectal wall initiates the **defecation reflex** (Figure 23.32). This is a spinal cord–mediated parasympathetic reflex that causes the sigmoid colon and the rectum to contract, the internal anal sphincter to relax, and the external anal sphincter to contract (initially). As feces are forced into the anal canal, messages reach the brain allowing us to decide whether the external (voluntary) anal sphincter should be opened or remain constricted to stop feces passage temporarily. If defecation is delayed, the reflex contractions end within a few seconds, and the rectal walls relax. With the next mass movement, the defecation reflex is initiated again—and so on, until one chooses to defecate or the urge to defecate becomes unavoidable.

During defecation, the muscles of the rectum contract to expel the feces. We aid this process voluntarily by closing the glottis and contracting our diaphragm and abdominal wall muscles to increase the intra-abdominal pressure (a procedure called *Valsalva's maneuver*). We also contract the levator ani muscle (pp. 350–351), which lifts the anal canal superiorly. This lifting action leaves the feces below the anus—and outside the body. Involuntary or automatic defecation (incontinence of feces) occurs in infants because they have not yet gained control of their external anal sphincter. It also occurs in those with spinal cord transections.

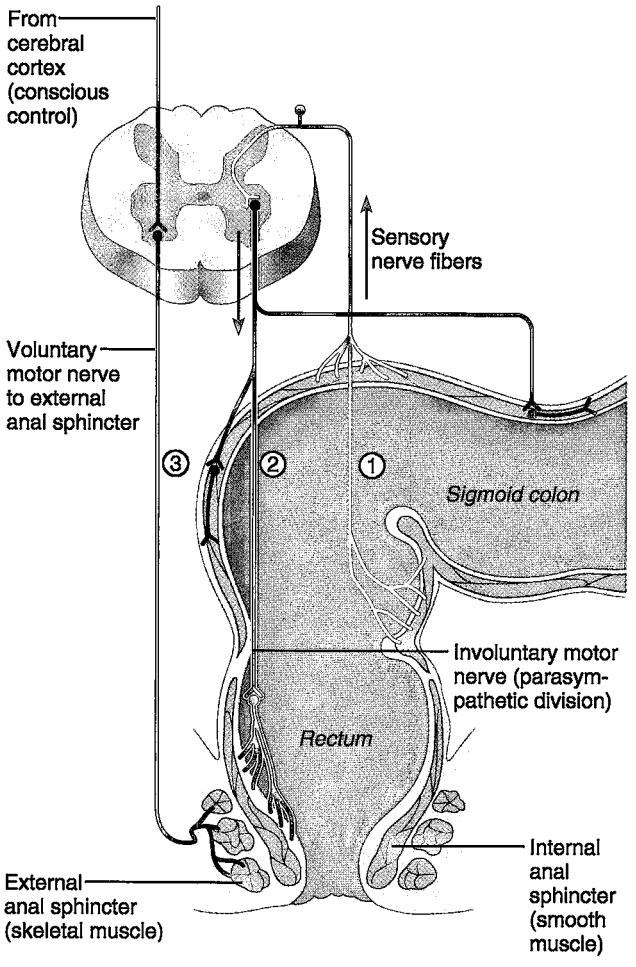

FIGURE 23.32 **Defecation reflex.** ① Distension, or stretch, of the rectal walls caused by movement of feces into the rectum triggers the depolarization of sensory (afferent) fibers, which synapse with spinal cord neurons. ② Parasympathetic motor (efferent) fibers, in turn, stimulate contraction of the rectal walls and relaxation of the internal anal sphincter. ③ If it is convenient to defecate, voluntary signals stimulate relaxation of the external anal sphincter. Defecation may be delayed temporarily by conscious (cortical) controls, which allow voluntary constriction of the external sphincter.

HOMEOSTATIC IMBALANCE

Watery stools, or **diarrhea,** result from any condition that rushes food residue through the large intestine before that organ has had sufficient time to absorb the remaining water. Causes include irritation of the colon by bacteria or, less commonly, prolonged physical jostling of the digestive viscera (occurs in marathon runners). Prolonged diarrhea may result in dehydration and electrolyte imbalance (acidosis and loss of potassium). Conversely, when food remains in the colon for extended periods, too much water is absorbed and the stool becomes hard and difficult to pass. This condition, called **constipation,** may result from lack of fiber in the diet, improper bowel habits (failing to heed the "call"), lack of exercise, emotional upset, or laxative abuse. ●

PART 3: PHYSIOLOGY OF CHEMICAL DIGESTION AND ABSORPTION

So far in this chapter, we have examined the structure and overall function of the organs that make up the digestive system. Now we will investigate the entire chemical processing (enzymatic breakdown and absorption) of each class of foodstuffs as it moves through the GI tract. These matters are summarized in Figure 23.33.

Chemical Digestion

After foodstuffs have spent even a short time in the stomach, they are unrecognizable. Nonetheless, they are still mostly the starchy, carbohydrate-rich foods, meat proteins, butter and other fats, and so on that we ingested. Only their appearance has been changed by mechanical digestive activities. By contrast, the products of chemical digestion are the chemical building blocks of the ingested foods and are very different molecules chemically. Let us look more closely at the process of chemical digestion.

Mechanism of Chemical Digestion: Enzymatic Hydrolysis

Chemical digestion is a catabolic process in which large food molecules are broken down to *monomers* (chemical building blocks), which are small enough to be absorbed by the GI tract lining. Chemical digestion is accomplished by enzymes secreted by both intrinsic and accessory glands into the lumen of the alimentary canal. The enzymatic breakdown of any type of food molecule is **hydrolysis** (hi-drol'ĭ-sis) because it involves addition of a water molecule to each molecular bond to be broken (lysed).

Chemical Digestion of Specific Food Groups

Carbohydrates

Most of us ingest between 200 and 600 grams of carbohydrate foods each day. **Monosaccharides** (simple sugars), the monomers of carbohydrates, are absorbed immediately without further ado. Only three of these are common in our diet: *glucose, fructose,* and *galactose.* The more complex carbohydrates

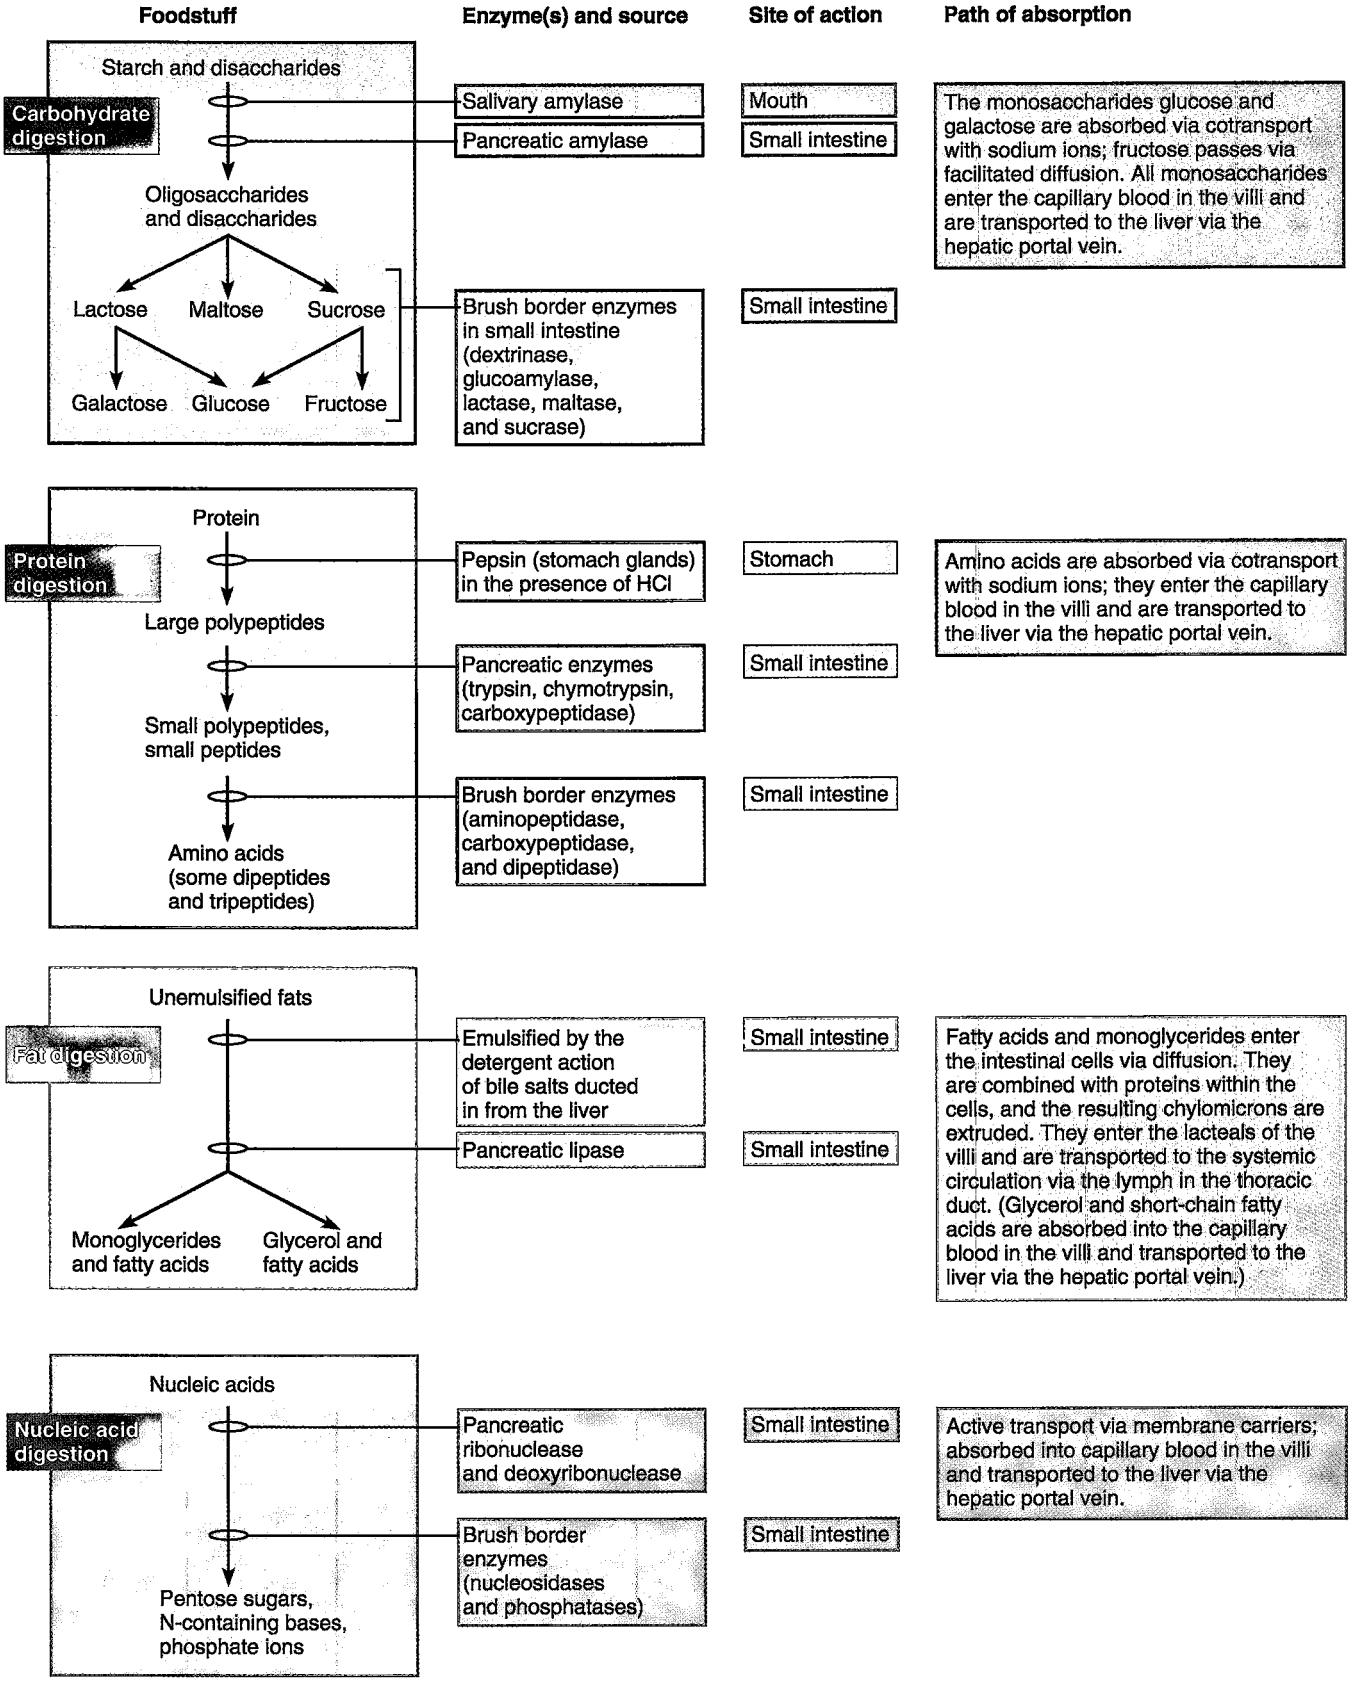

FIGURE 23.33 **Flowchart of chemical digestion and absorption of foodstuffs.**

that our digestive system is able to break down to monosaccharides are the disaccharides *sucrose* (table sugar), *lactose* (milk sugar), and *maltose* (grain sugar) and the polysaccharides *glycogen* and *starch*. In the average diet, most digestible carbohydrates are in the form of starch, with smaller amounts of disaccharides and monosaccharides. Humans lack enzymes capable of breaking down most other polysaccharides, such as cellulose. Thus, indigestible polysaccharides do not nourish us but they do help move the food along the GI tract by providing bulk, or fiber.

Chemical digestion of starch (and perhaps glycogen) begins in the mouth. **Salivary amylase,** present in saliva, splits starch into *oligosaccharides*, smaller fragments of two to eight linked glucose molecules. Salivary amylase works best in the slightly acid to neutral environment (pH of 6.75–7.00) maintained in the mouth by the buffering effects of bicarbonate and phosphate ions in saliva. Starch digestion continues until amylase is inactivated by stomach acid and broken apart by the stomach's protein-digesting enzymes. Generally speaking, the larger the meal, the longer amylase continues to work in the stomach because foodstuffs in its relatively immobile fundus are poorly mixed with gastric juices.

Starchy foods and other digestible carbohydrates that escape being broken down by salivary amylase are acted on by **pancreatic amylase** in the small intestine (see Figure 23.33). Within about ten minutes of entering the small intestine, starch is entirely converted to various oligosaccharides, mostly maltose. Intestinal brush border enzymes further digest these products to monosaccharides. The most important of the brush border enzymes are **dextrinase** and **glucoamylase,** which act on oligosaccharides composed of more than three simple sugars, and **maltase, sucrase,** and **lactase,** which hydrolyze maltose, sucrose, and lactose respectively into their constituent monosaccharides. Because the colon does not secrete digestive enzymes, chemical digestion *officially ends* in the small intestine. As noted earlier, however, resident colon bacteria do break down and metabolize the residual complex carbohydrates further, adding much to their own nutrition but essentially nothing to ours.

HOMEOSTATIC IMBALANCE

In some people, intestinal lactase is present at birth but then becomes deficient due to genetic factors. In such cases, the person becomes intolerant of milk products (the source of lactose), and undigested lactose creates osmotic gradients that not only prevent water from being absorbed in the small and large intestines but also pull water from the interstitial space into the intestines. The result is diarrhea. Bacterial metabolism of the undigested solutes produces large amounts of gas that result in bouts of bloating, flatulence, and cramping pain. The solution to this problem is simple—add lactase enzyme "drops" to your milk or take a lactase tablet before meals containing milk products. ●

Proteins

Proteins digested in the GI tract include not only dietary proteins (typically about 125 g per day), but also 15–25 g of enzyme proteins secreted into the GI tract lumen by its various glands and (probably) an equal amount of protein derived from sloughed and disintegrating mucosal cells. In healthy individuals, much of this protein is digested all the way to its **amino acid** monomers.

Protein digestion begins in the stomach when pepsinogen secreted by the chief cells is activated to **pepsin** (actually a group of protein-digesting enzymes). Pepsin functions optimally in the acidic pH range found in the stomach: 1.5–2.5. It preferentially cleaves bonds involving the amino acids tyrosine and phenylalanine so that proteins are broken into polypeptides and small numbers of free amino acids (see Figure 23.33). Pepsin, which hydrolyzes 10–15% of ingested protein, is inactivated by the high pH in the duodenum, so its proteolytic activity is restricted to the stomach. **Rennin** (the enzyme that coagulates milk protein) is not produced in adults.

Protein fragments entering the small intestine from the stomach are greeted by a host of proteolytic enzymes (Figure 23.33). **Trypsin** and **chymotrypsin** secreted by the pancreas cleave the proteins into smaller peptides, which in turn become the grist for other enzymes. The pancreatic and brush border enzyme **carboxypeptidase** splits off one amino acid at a time from the end of the polypeptide chain that bears the carboxyl group. Other brush border enzymes such as **aminopeptidase** and **dipeptidase** liberate the final amino acid products (Figure 23.34). Aminopeptidase digests a protein, one amino acid at a time, by working from the amine end. Both carboxypeptidase and aminopeptidase can independently dismantle a protein, but the teamwork between these enzymes and between trypsin and chymotrypsin, which attack the more internal parts of the protein, speeds up the process tremendously.

Lipids

Although the American Heart Association recommends a low-fat diet, the amount of lipids (fats) ingested daily varies tremendously among American adults, ranging from 30 g to 150 g or more. The small intestine is essentially the sole site of lipid digestion because the pancreas is the only significant source of fat-digesting enzymes, or **lipases** (Figure 23.33).

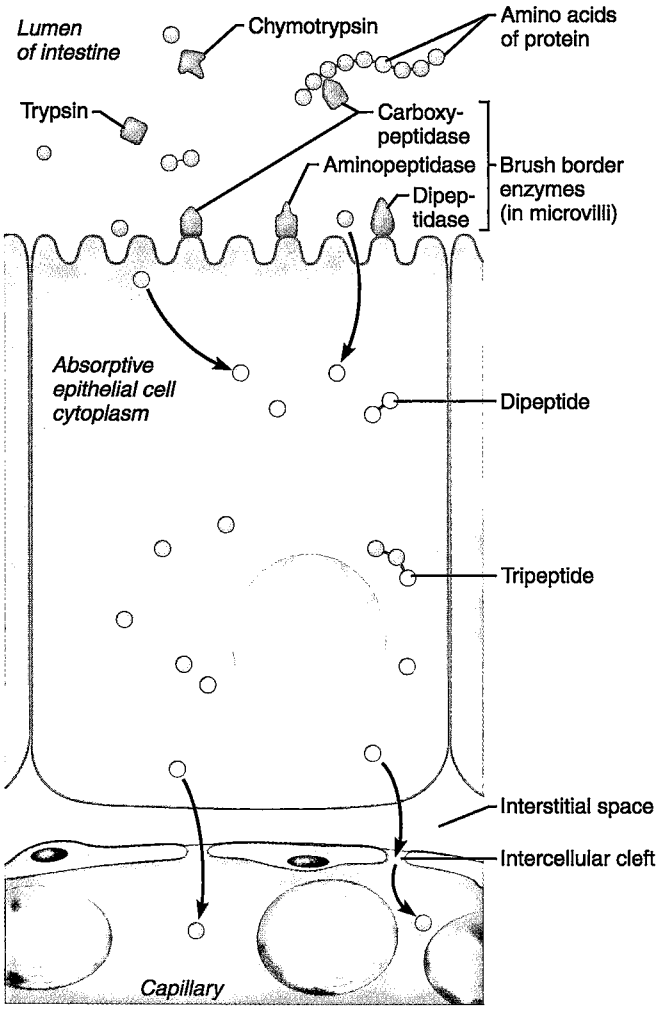

FIGURE 23.34 **Protein digestion and absorption in the small intestine.** Proteins and protein fragments are digested to amino acids by the action of pancreatic proteases (trypsin, chymotrypsin, and carboxypeptidase), and by brush border enzymes of the intestinal mucosal cells. The amino acids are then absorbed by active transport into the absorptive cells, move to their opposite side (transcytosis), and then enter the capillary via intercellular clefts.

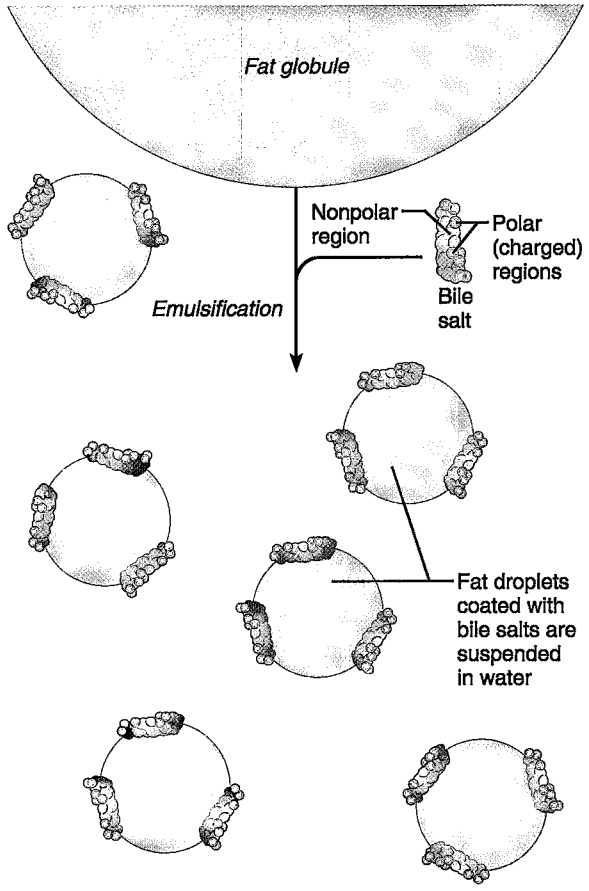

FIGURE 23.35 **Role of bile salts in fat emulsification.** As large aggregates of fats enter the small intestine, bile salts cling via their nonpolar parts to the fat molecules (triglycerides). Their polar parts, facing the aqueous phase, interact with water and repel each other, causing the fatty globule to be physically broken up into smaller fat droplets.

Triglycerides (neutral fats or triacylglycerols) are the most abundant fats in the diet.

Because triglycerides and their breakdown products are insoluble in water, fats need special "pretreatment" with bile salts to be digested and absorbed in the watery environment of the small intestine. In aqueous solutions, triglycerides aggregate to form large fat globules, and only the triglyceride molecules at the surfaces of such fatty masses are accessible to the water-soluble lipase enzymes. However, this problem is quickly resolved because as the fat globules enter the duodenum, they are coated with detergent-like bile salts (Figure 23.35). Bile salts have both nonpolar and polar regions. Their nonpolar (hydrophobic) parts cling to the fat molecules, and their polar (ionized hydrophilic) parts allow them to repel each other and to interact with water. As a result, fatty droplets are pulled off the large fat globules, and a stable *emulsion*—an aqueous suspension of fatty droplets, each about 1 mm in diameter—is formed. Emulsification does *not* break chemical bonds. It just reduces the attraction between fat molecules so that they can be more widely dispersed. This process vastly increases the number of triglyceride molecules exposed to the pancreatic lipases. Without bile, lipids would be incompletely digested in the time food is in the small intestine.

The pancreatic lipases catalyze the breakdown of fats by cleaving off two of the fatty acid chains, thus yielding free **fatty acids** and **monoglycerides** (glycerol with one fatty acid chain attached). Fat-soluble vitamins that ride with fats require no digestion.

Nucleic Acids

Both DNA and RNA, present in the nuclei of cells forming the ingested foods, are hydrolyzed to their

nucleotide monomers by **pancreatic nucleases** present in pancreatic juice. The nucleotides are then broken apart by intestinal brush border enzymes (**nucleosidases** and **phosphatases**), which release their free bases, pentose sugars, and phosphate ions (see Figure 23.33).

Absorption

Up to 10 L of food, drink, and GI secretions enter the alimentary canal daily, but only 1 L or less reaches the large intestine. Virtually all of the foodstuffs, 80% of the electrolytes, and most of the water (remember water follows salt) are absorbed in the small intestine. Although absorption occurs all along the length of the small intestine, most of it is completed by the time chyme reaches the ileum. Hence, the major absorptive role of the ileum is to reclaim bile salts to be recycled back to the liver for resecretion. It is virtually impossible to exceed the absorptive capacity of the human gut, and at the end of the ileum, all that remains is some water, indigestible food materials (largely plant fibers such as cellulose), and millions of bacteria. This debris is passed on to the large intestine.

To understand absorption, you need to remember that the fluid mosaic structure of the plasma membrane dictates that nonpolar substances, which can dissolve in the lipid core of the membrane, can be absorbed passively, and that polar substances must be absorbed by carrier mechanisms. Most nutrients are absorbed through the mucosa of the intestinal villi by *active transport* processes driven directly or indirectly (secondarily) by metabolic energy (ATP). They then enter the capillary blood in the villus to be transported in the hepatic portal vein to the liver. The exception is some lipid digestion products, which are absorbed passively by diffusion and then enter the lacteal in the villus to be carried to the blood via lymphatic fluid. Because the epithelial cells of the intestinal mucosa are joined at their luminal surfaces by tight junctions, substances cannot move *between* the cells. Consequently, materials must pass *through* the epithelial cells and into the interstitial fluid abutting their basolateral membranes (via transcytosis) if they are to enter the blood capillaries. Absorption of each nutrient class is described next and summarized on the right-hand side of Figure 23.33.

Absorption of Specific Nutrients

Carbohydrates

The monosaccharides glucose and galactose, liberated by the breakdown of starch and disaccharides, are shuttled by secondary active transport (cotransport with Na^+) into the epithelial cells by common protein carriers. They then move out of these cells by facilitated diffusion and pass into the capillaries via intercellular clefts. By contrast, fructose moves entirely by facilitated diffusion. The transport proteins, which are located very close to the disaccharidase enzymes on the microvilli, combine with the monosaccharides as soon as the disaccharides are broken down.

Proteins

Several types of carriers transport the different amino acids resulting from protein digestion. Most of these carriers, like those for glucose and galactose, are coupled to the active transport of sodium. Short chains of two or three amino acids (dipeptides and tripeptides, respectively) are also actively absorbed, but are digested to their amino acids within the epithelial cells before entering the capillary blood by diffusion (see Figure 23.34).

HOMEOSTATIC IMBALANCE

Whole proteins are not usually absorbed, but in rare cases intact proteins are taken up by endocytosis and released on the opposite side of the epithelial cell by exocytosis. This process, most common in newborn infants, reflects the immaturity of their intestinal mucosa and accounts for many early food allergies. The immune system "sees" the intact proteins as antigenic and mounts an attack. These food allergies usually disappear as the mucosa matures. This mechanism may also provide a route for IgA antibodies present in breast milk to reach an infant's bloodstream. These antibodies confer some passive immunity on the infant (temporary protection against antigens to which the mother has been sensitized). ●

Lipids

Just as bile salts accelerate lipid digestion, they are also essential for the absorption of its end products. As the water-insoluble products of fat digestion—the monoglycerides and free fatty acids—are liberated by lipase activity, they quickly become associated with bile salts and *lecithin* (a phospholipid found in bile) to form micelles. **Micelles** (mi-selz') are collections of fatty elements clustered together with bile salts in such a way that the polar (hydrophilic) ends of the molecules face the water and the nonpolar portions form the core. Also nestled in the hydrophobic core are cholesterol molecules and fat-soluble vitamins. Although micelles are similar to emulsion droplets, they are much smaller "vehicles" and easily diffuse between microvilli to come into close contact with the luminal cell surface (Figure 23.36). The various lipid substances then leave the micelles and move

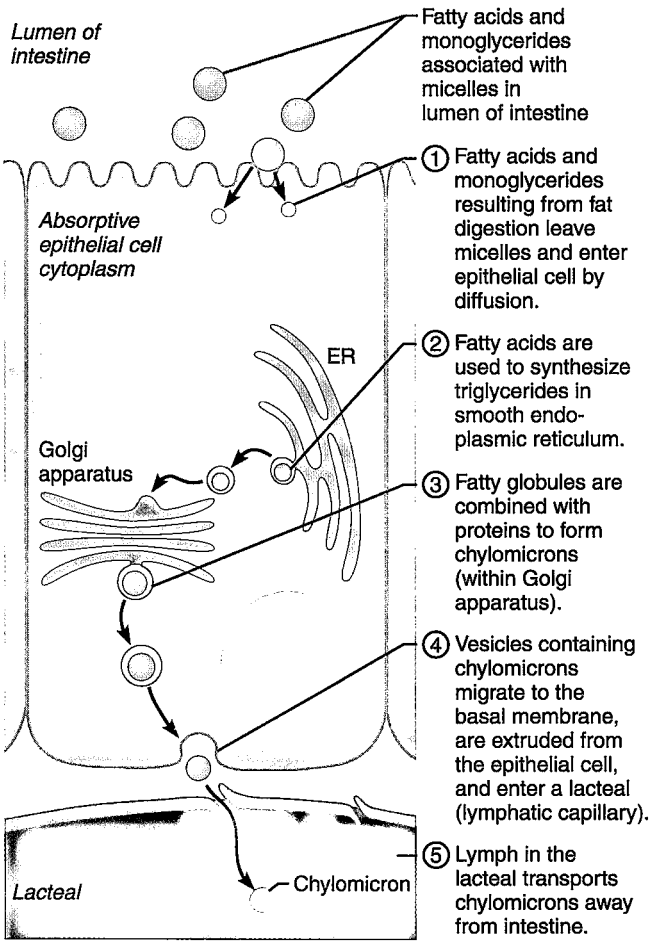

FIGURE 23.36 **Fatty acid absorption.** Digestion products of fat breakdown, lecithin, and cholesterol associate with bile salts to form micelles, which serve to "ferry" them to the intestinal mucosa. They then dissociate and enter the mucosal cells by diffusion. In the mucosal epithelial cells, they are recombined to lipids and packaged with other lipoid substances and protein to form chylomicrons. The chylomicrons are extruded from the epithelial cells by exocytosis and enter the lacteal for distribution in the lymph. Free fatty acids and monoglycerides enter the capillary bed.

through the lipid phase of the plasma membrane by simple diffusion. Without the micelles, the lipids simply float on the surface of the chyme (like oil on water), inaccessible to the absorptive surfaces of the epithelial cells. Generally, fat absorption is completed in the ileum, but in the absence of bile (as might occur when a gallstone blocks the cystic duct) it happens so slowly that most of the fat passes into the large intestine and is lost in feces.

Once inside the epithelial cells, the free fatty acids and monoglycerides are resynthesized into triglycerides. The triglycerides are then combined with phospholipids and cholesterol, and coated with a "skin" of proteins to form water-soluble lipoprotein droplets called **chylomicrons** (ki"lo-mi'kronz). These are processed by the Golgi apparatus for extrusion from the cell. This series of events is quite different from the absorption of amino acids and simple sugars, which pass through the epithelial cells unchanged.

Although a few free fatty acids enter the capillary blood, the milky-white chylomicrons are too large to pass through the basement membranes of the blood capillaries and instead enter the more permeable lacteals. Thus, most fat enters the lymphatic stream and is eventually emptied into the venous blood in the neck region via the thoracic duct, which drains the digestive viscera. While in the bloodstream, the triglycerides of the chylomicrons are hydrolyzed to free fatty acids and glycerol by **lipoprotein lipase,** an enzyme associated with the capillary endothelium. The fatty acids and glycerol can then pass through the capillary walls to be used by tissue cells for energy or stored as fats in adipose tissue. The residual chylomicron material is combined with proteins by the liver cells, and these "new" lipoproteins are used to transport cholesterol in the blood.

Nucleic Acids

The pentose sugars, nitrogenous bases, and phosphate ions resulting from nucleic acid digestion are transported actively across the epithelium by special carriers in the villus epithelium. They then enter the blood.

Vitamins

The small intestine absorbs dietary vitamins, and the large intestine absorbs some of the K and B vitamins made by its enteric bacterial "guests." As already noted, fat-soluble vitamins (A, D, E, and K) dissolve in dietary fats, become incorporated into the micelles, and move across the villus epithelium by passive diffusion. It follows that gulping pills containing fat-soluble vitamins without simultaneously eating some fat-containing food results in little or no absorption of these vitamins.

Most water-soluble vitamins (B vitamins and vitamin C) are absorbed easily by diffusion or via specific active or passive transporters. The exception is vitamin B_{12}, which is a very large, charged molecule. *Intrinsic factor,* produced by the stomach, binds to vitamin B_{12}. The vitamin B_{12}–intrinsic factor complex then binds to specific mucosal receptor sites in the terminal ileum, which trigger its active uptake by endocytosis.

Electrolytes

Absorbed electrolytes come from both ingested foods and gastrointestinal secretions. Most ions are actively absorbed along the entire length of the small intestine. However, iron and calcium absorption is largely limited to the duodenum.

As noted, absorption of sodium ions in the small intestine is coupled to active absorption of glucose and amino acids. For the most part, anions passively follow the electrical potential established by sodium transport. That is, Na^+ is actively pumped out of the epithelial cells by a Na^+-K^+ pump after entering those cells. Chloride ions are also transported actively, and in the terminus of the small intestine $HCO3^-$ is actively secreted into the lumen in exchange for Cl^-.

Potassium ions move across the intestinal mucosa passively by facilitated diffusion (or via leaky tight functions) in response to changing osmotic gradients. As water is absorbed from the lumen, the resulting rise in potassium levels in chyme creates a concentration gradient for its absorption. Thus, anything that interferes with water absorption (resulting in diarrhea) not only reduces potassium absorption but also "pulls" K^+ from the interstitial space into the intestinal lumen.

For most nutrients, the amount *reaching* the intestine is the amount absorbed, regardless of the nutritional state of the body. In contrast, absorption of iron and calcium is intimately related to the body's need for them at the time.

Ionic iron, essential for hemoglobin production, is actively transported into the mucosal cells, where it binds to the protein **ferritin** (fer'ĭ-tin). This phenomenon is called the *mucosal iron barrier.* The intracellular iron-ferritin complexes then serve as local storehouses for iron. When body reserves of iron are adequate, little is allowed to pass into the portal blood, and most of the stored iron is lost as the epithelial cells later slough off. However, when iron reserves are depleted (as during acute or chronic hemorrhage), iron uptake from the intestine and its release to the blood are accelerated. Menstrual bleeding is a major route of iron loss in females, and the intestinal epithelial cells of women have about four times as many iron transport proteins as do those of men. In the blood, iron binds to **transferrin,** a plasma protein that transports it in the circulation.

Calcium absorption is closely related to blood levels of ionic calcium. It is locally regulated by the active form of **vitamin D,** which acts as a cofactor to facilitate active calcium absorption. Decreased blood levels of ionic calcium prompt *parathyroid hormone (PTH)* release from the parathyroid glands. Besides facilitating the release of calcium ions from bone matrix and enhancing the reabsorption of calcium by the kidneys, PTH stimulates activation of vitamin D by the kidneys, which in turn accelerates calcium ion absorption in the small intestine.

Water

Approximately 9 L of water, mostly derived from GI tract secretions, enter the small intestine daily. Water is the most abundant substance in chyme, and 95% of it is absorbed in the small intestine by osmosis. The normal rate of water absorption is 300 to 400 ml per hour. Water moves freely in both directions across the intestinal mucosa, but *net osmosis* occurs whenever a concentration gradient is established by the active transport of solutes (particularly Na^+) into the mucosal cells. Thus, water uptake is effectively coupled to solute uptake and, in turn, affects the rate of absorption of substances that normally pass by diffusion. As water moves into the mucosal cells, these substances follow along their concentration gradients.

Malabsorption of Nutrients

Malabsorption, or impaired nutrient absorption, has many and varied causes. It can result from anything that interferes with the delivery of bile or pancreatic juice to the small intestine, as well as factors that damage the intestinal mucosa (severe bacterial infections and antibiotic therapy with neomycin) or reduce its absorptive surface area. A common (one in 100 people) malabsorption syndrome is *gluten-sensitive enteropathy* or *celiac disease.* This chronic genetic condition is caused by an immune reaction to gluten, a protein plentiful in some grains (wheat, rye, barley). Breakdown products of gluten interact with molecules of the immune system in the GI tract, forming complexes that activate T cells, which then mount an attack on the intestinal lining. As a result, the intestinal villi are damaged and the length of the microvilli of the brush border is reduced. The resulting bloating, diarrhea, pain, and malnutrition are usually controlled by eliminating gluten-containing grains (all grains but rice and corn) from the diet. Not many children can conceive of a world without cookies or pizza, but these are just two of the foods celiac disease victims must avoid.

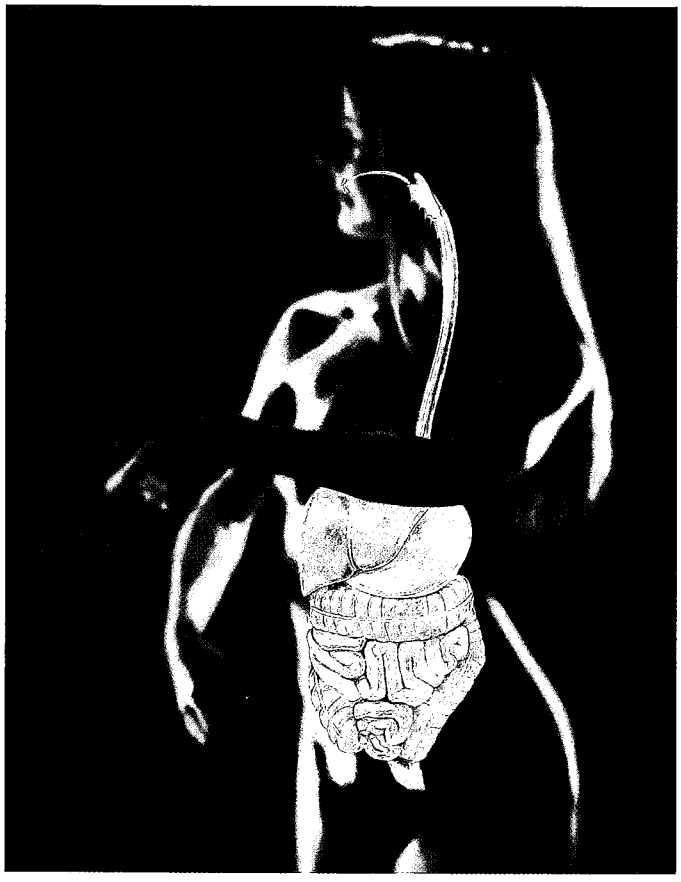
Developmental Aspects of the Digestive System

As described many times before, the very young embryo is flat and consists of three germ layers, which, from top to bottom, are ectoderm, mesoderm, and endoderm. However, this flattened cell mass soon folds to form a cylindrical body, and its internal cavity becomes the cavity of the alimentary tube, which is initially closed at both ends. The epithelial lining of the developing alimentary tube, or **primitive gut,** forms from endoderm (Figure 23.37a). The rest of the wall arises from mesoderm. The anteriormost endoderm (that of the foregut) touches a depressed area of the surface ectoderm called the **stomodeum** (sto"mo-de'um; "on the way to becoming the mouth"). The two membranes fuse, forming the **oral**

(Text continues on p. 936)

MAKING CONNECTIONS

SYSTEM CONNECTIONS: Homeostatic Interrelationships Between the Digestive System and Other Body Systems



Integumentary System

- Digestive system provides nutrients needed for energy, growth, and repair; supplies fats that provide insulation in the dermis and subcutaneous tissue
- The skin synthesizes vitamin D needed for calcium absorption from the intestine; protects by enclosure

Skeletal System

- Digestive system provides nutrients needed for energy, growth, and repair; absorbs calcium needed for bone salts
- Skeletal system protects some digestive organs by bone; cavities store some nutrients (e.g., calcium, fats)

Muscular System

- Digestive system provides nutrients needed for energy, growth, and repair; liver removes lactic acid, resulting from muscle activity, from the blood
- Skeletal muscle activity increases motility of GI tract

Nervous System

- Digestive system provides nutrients needed for normal neural functioning; nutrient signals influence neural regulation of satiety
- Neural controls of digestive function; in general, parasympathetic fibers accelerate and sympathetic fibers inhibit digestive activity; reflex and voluntary controls of defecation

Endocrine System

- Liver removes hormones from blood, ending their activity; digestive system provides nutrients needed for energy, growth, and repair; pancreas, stomach, and small intestine have hormone-producing cells
- Hormones and paracrines help regulate digestive function

Cardiovascular System

- Digestive system provides nutrients to heart and blood vessels; absorbs iron needed for hemoglobin synthesis; absorbs water necessary for normal plasma volume; liver secretes bilirubin resulting from hemoglobin breakdown in bile and stores iron for reuse
- Cardiovascular system transports nutrients absorbed by alimentary canal to all tissues of body; distributes hormones of the digestive tract

Lymphatic System/Immunity

- Digestive system provides nutrients for normal functioning; lysozyme of saliva and HCl of stomach provide nonspecific protection against bacteria
- Lacteals drain fatty lymph from digestive tract organs and convey it to blood; Peyer's patches and lymphoid tissue in mesentery house macrophages and immune cells that protect digestive tract organs against infection; plasma cells provide IgA in digestive tract secretions

Respiratory System

- Digestive system provides nutrients needed for energy metabolism, growth, and repair
- Respiratory system provides oxygen to and carries away carbon dioxide produced by digestive system organs

Urinary System

- Digestive system provides nutrients for energy fuel, growth, and repair; excretes some bilirubin produced by the liver
- Kidneys transform vitamin D to its active form, which is needed for calcium absorption

Reproductive System

- Digestive system provides nutrients for energy, growth, and repair and extra nutrition needed to support fetal growth

CLOSER CONNECTIONS

THE DIGESTIVE SYSTEM and Interrelationships with the Cardiovascular, Lymphatic, and Endocrine Systems

As body systems go, the digestive system is very independent. Although the central nervous system can and does influence its activity, that is not a requirement. Indeed, most digestive system activities can be regulated entirely by local controls. Consider, for example, the following: (1) stomach and intestinal muscle is self-pacing, (2) the enteric neurons of the GI tract's intrinsic nerve plexuses carry out reflex activity that can regulate not only the organ they reside in but also adjacent and more distant GI tract organs, and (3) its enteroendocrine cells are probably even more important than neural influences in controlling digestive activity. Also unique is the fact that the digestive system operates in and regulates an environment that is actually outside the body. This is a difficult chore indeed—consider how quickly that environment can be changed by incoming foods (pizza and beer) or intestinal outflow (diarrhea).

Every cell in the body needs nutrients to stay healthy and grow, so the importance of the digestive system to virtually all body systems is clear-cut. But what systems are essential to the digestive system? If we ignore universal services, like gas exchange and renal regulation of body fluids, then the most crucial interactions are those with the cardiovascular, lymphatic, and endocrine systems. Let's take a look.

Cardiovascular and Lymphatic Systems

The important elements in this interaction are the pickup vessels. Indeed, all digestive activity would be for naught if the digested end products were not absorbed into the blood capillaries and lacteals, where they are accessible to all body cells. Besides its transport function, the lymphatic system also offers protective services via its tonsils, Peyer's patches, and individual lymphoid follicles dispersed all along the length of the alimentary tube. Again, the fact that the alimentary canal is open at both ends makes it easy prey for both pathogenic and opportunistic bacteria and fungi.

Endocrine System

The digestive tract not only has major interactions with the endocrine system, it is itself the largest and most complex endocrine organ in the body. It makes hormones that regulate GI tract motility and secretory activity of the stomach, small intestine, liver, and pancreas (e.g., secretin, CCK), as well as cause local blood vessels to dilate to receive the digested food products being absorbed (VIP). Furthermore, some digestive organ hormones (CCK and glucagon, for example) help mediate hunger or satiety, and pancreatic hormones (insulin and glucagon) are involved in bodywide regulation of carbohydrate, fat, and amino acid metabolism.

CLINICAL CONNECTIONS

Digestive System

Case study: Remember Mr. Gutteman, the gentleman who was dehydrating? It seems that his tremendous output of urine was only one of his current problems. Today, he complains of a headache, gnawing epigastric pain, and has "the runs" (diarrhea). To pinpoint the problem, he is asked the following questions.

- Have you had these symptoms previously? (Re935 sponse: "Yes, but never this bad.")
- Are you allergic to any foods? (Response: "Shellfish doesn't like me and milk gives me the runs.")

As a result of his responses, a lactose-free diet is ordered for Mr. Gutteman instead of the regular diet originally prescribed.

1. Why is the new diet prescribed? (What is believed to be his problem?)

Mr. Gutteman's problem continues despite the diet change. In fact, the frequency of diarrhea increases and by the end of the next day, he is complaining of severe abdominal pain. Again, he is asked some questions to probe his condition. One is whether he has traveled outside the country recently. He has not, reducing the possibility of infection with *Shigella* bacteria, which is associated with poor sanitation. Other questions:

- Do you drink alcohol and how much? (Response: "Little or none.")
- Have you recently eaten raw eggs or a salad containing mayonnaise at a gathering? (Response: "No.")
- Are there certain foods that seem to precipitate these attacks? (Response: "Yes, when I have coffee and a sandwich.")

2. On the basis of these responses, what do you think Mr. Gutteman's diarrhea stems from? How will it be diagnosed and treated?

(Answers in Appendix G)

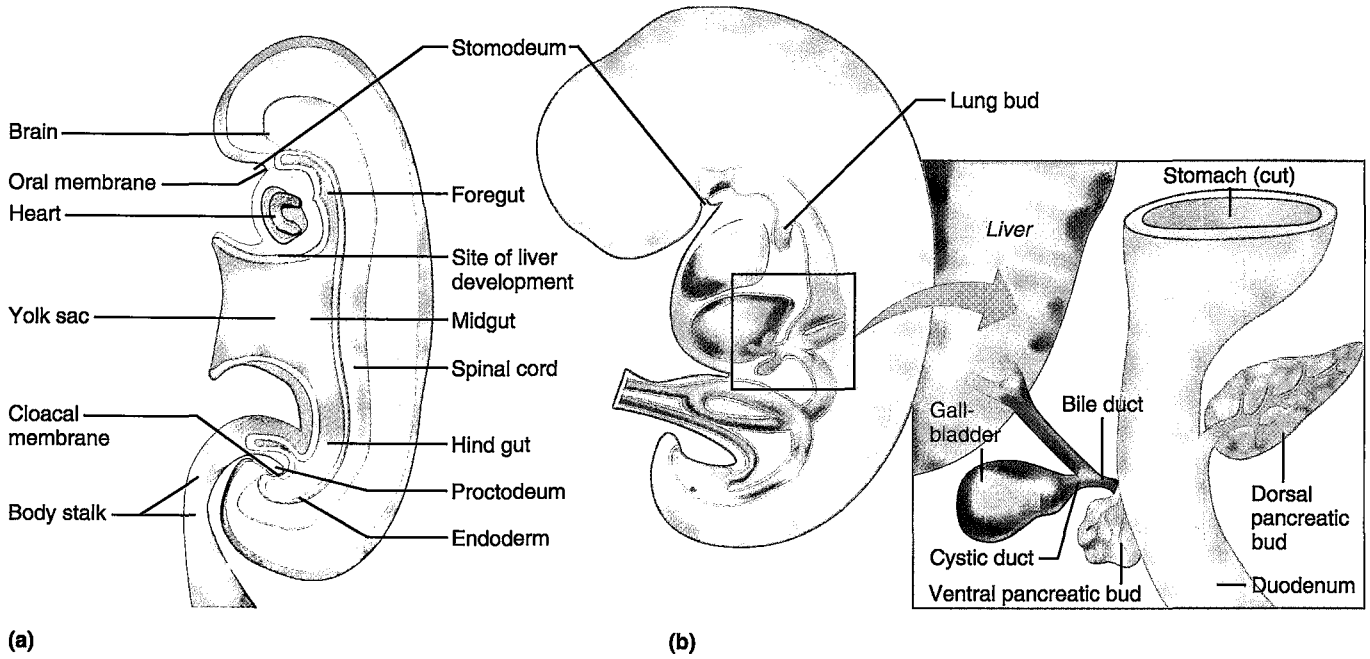


FIGURE 23.37 **Embryonic development of the digestive system. (a)** Three-week-old embryo. The endoderm has folded, and the foregut and hindgut have formed. (The midgut is still open and continuous with the yolk sac.) **(b)** By eight weeks of development, the accessory organs are budding out from the endodermal layer, as shown in the enlargement.

membrane, which shortly breaks through to form the opening of the mouth. Similarly, the end of the hindgut fuses with an ectodermal depression, called the **proctodeum** (*procto* = anus), to form the **cloacal membrane** (*cloaca* = sewer), which then breaks through to form the anus. By week 8, the alimentary canal is a continuous "tube" extending from the mouth to the anus and is open to the external environment at each end. Shortly after, the glandular organs (salivary glands, liver with gallbladder, and pancreas) bud out from the mucosa at various points along its length (Figure 23.37b). These glands retain their connections, which become ducts leading into the digestive tract.

HOMEOSTATIC IMBALANCE

The digestive system is susceptible to many congenital defects that interfere with feeding. The most common are *cleft palate,* in which the palatine bones or palatine processes of the maxillae (or both) fail to fuse, and *cleft lip,* which often occur together. Of the two, cleft palate is far more serious because the child is unable to suck properly. Another common defect is *tracheoesophageal fistula,* in which there is an opening between the esophagus and the trachea, and the esophagus often lacks a connection to the stomach. The baby chokes and becomes cyanotic during feedings because food enters the respiratory passageways. These defects are usually corrected surgically.

Cystic fibrosis (described in more detail in Chapter 22, p. 874) primarily affects the lungs, but it also impairs the activity of the pancreas. In this genetic disease, the mucous glands produce abnormally thick mucus, which blocks the ducts or passageways of involved organs. Blockage of the pancreatic duct prevents pancreatic juice from reaching the small intestine. As a result, digestion of chyme is less than optimal and most fats and fat-soluble vitamins are not digested or absorbed. Consequently the stools are bulky and fat laden. The pancreatic problems can be handled by administering pancreatic enzymes with meals.

During fetal life, the developing infant receives all of its nutrients through the placenta. Nonetheless, the fetal GI tract is "trained" in utero for future food digestion as the fetus naturally swallows some of the surrounding amniotic fluid. This fluid contains several chemicals that stimulate GI maturation, including gastrin and epidermal growth factor. By contrast, feeding is a newborn baby's most important activity, and several reflexes enhance the infant's ability to obtain food: The *rooting reflex* helps the infant find the nipple, and the *sucking reflex* helps the baby hold onto the nipple and swallow.

Newborn babies tend to double their birth weight within six months, and their caloric intake and food processing ability are extraordinary. For example, a 6-week-old infant weighing about 4 kg (less

than 9 lb) drinks about 600 ml of milk daily. A 65-kg adult (143 lb) would have to drink 10 L of milk to ingest a corresponding volume of fluid! However, the stomach of a newborn infant is very small, so feeding must be frequent (every 3–4 hours). Peristalsis is inefficient, and vomiting of the feeding is not unusual. As the teeth break through the gums, the infant progresses to solid foods and is usually eating an adult diet by the age of 2 years.

As a rule, the digestive system operates throughout childhood and adulthood with relatively few problems. However, contaminated food or extremely spicy or irritating foods sometimes cause an inflammation of the GI tract, called **gastroenteritis** (gas"tro-en"tĕ-ri'tis). Ulcers and gallbladder problems—inflammation or **cholecystitis** (ko"le-sis-ti'tis), and gallstones—are problems of middle age.

During old age, GI tract activity declines. Fewer digestive juices are produced, absorption is less efficient, and peristalsis slows. The result is less frequent bowel movements and, often, constipation. Taste and smell are less acute, and periodontal disease often develops. Many elderly people live alone or on a reduced income. These factors, along with increasing physical disability, tend to make eating less appealing, and many of our elderly citizens are inadequately nourished.

Diverticulosis, fecal incontinence, and cancer of the GI tract are fairly common problems of the aged. Stomach and colon cancers rarely have early signs, and have often metastasized (making it inoperable) before a person seeks medical attention. Should metastasis occur, secondary cancer of the liver is almost guaranteed because of the "detour" the splanchnic venous blood takes through the liver via the hepatic portal circulation. However, when detected early, these cancers are treatable. Perhaps the best advice is to have regular dental and medical checkups. Most oral cancers are detected during routine dental examinations, 50% of all rectal cancers can be felt digitally, and nearly 80% of colon cancers can be seen and removed during a colonoscopy.

Presently, colon cancer is the second largest cause of cancer deaths (behind lung cancer) in males in the United States. Since most colorectal cancers derive from initially benign mucosal tumors called polyps, and the incidence of polyp formation increases with age, an occult blood examination once a year should be a health priority in everyone over the age of 50, and colonoscopies should be conducted at 3- to 10-year intervals depending on prior findings. As described in *A Closer Look* in Chapter 4, development of colon cancer is a gradual process that involves mutations in several regulatory genes. Recent studies have identified the mutant gene responsible for nearly 50% of all colon cancers. Dubbed *p53*, the gene normally acts as a watchdog to make sure that errors in DNA are not passed on before being corrected. When *p53* is damaged or inhibited, its tumor suppressor effect is lost and damaged DNA accumulates, resulting in carcinogenesis.

■ ■ ■

As summarized in *Making Connections*, the digestive system keeps the blood well supplied with the nutrients needed by all body tissues to fuel their energy needs and to synthesize new proteins for growth and maintenance of health. Now we are ready to examine how these nutrients are used by body cells, the topic of Chapter 24.

Related Clinical Terms

Ascites (ah-si'tēz; *asci* = bag, bladder) Abnormal accumulation of fluid within the peritoneal cavity; if excessive, causes visible bloating of the abdomen. May result from portal hypertension caused by liver cirrhosis or by heart or kidney disease.

Barrett's esophagus A pathological change in the epithelium of the lower esophagus from stratified squamous to a metaplastic columnar epithelium. A possible sequel to untreated chronic gastroesophageal reflux due to hiatal hernia, it predisposes the individual to aggressive esophageal cancer (adenocarcinoma).

Bruxism (bruck'sizm) Grinding or clenching of teeth, usually at night during sleep in response to stress. Can wear down and crack the teeth.

Bulimia (bu-lim'e-ah; *bous* = ox; *limos* = hunger) Binge-purge behavior—episodes of massive overeating are followed by some method of purging (self-induced vomiting, taking laxatives or diuretics, or excessive exercise). Most common in high school or college age women and in high school males in certain athletic activities (wrestling). Rooted in a pathological fear of being fat, and a need for control; provides a means of handling stress and depression. Consequences include erosion of tooth enamel and stomach trauma or rupture (from vomiting) and severe electrolyte disturbances which impair heart activity. Therapy includes hospitalization to control behavior, and nutritional counseling.

Dysphagia (dis-fa'je-ah; *dys* = difficult, abnormal; *phag* = eat) Difficulty swallowing; usually due to obstruction or physical trauma to the esophagus.

Endoscopy (en-dos'ko-pe; *endo* = within, inside; *scopy* = viewing) Visual examination of a ventral body cavity or the interior of a visceral organ with a flexible tubelike device called an endoscope, which contains a light source and a lens. A general term for a colonoscopy (viewing the colon), sigmoidoscopy (viewing the sigmoid colon), etc.

Enteritis (*enteron* = intestine) Inflammation of the intestine, especially the small intestine.

Hemochromatosis (he"mo-kro"mah-to'sis; *hemo* = blood; *chroma* = color; *osis* = condition of) A disorder in iron metabolism due to excessive/prolonged iron intake or a breakdown of the mucosal iron barrier; excess iron is deposited in the tissues, causing increased skin pigmentation and increased incidence of hepatic cancer and liver cirrhosis; also called *bronze diabetes* and *iron storage disease.*

Ileus (il'e-us) A condition in which all GI tract movement stops and the gut appears to be paralyzed. Can result from electrolyte imbalances and blockade of parasympathetic impulses by drugs (such as those commonly used during abdominal surgery); usually reversed when these interferences end. Restoration of motility is indicated by the reappearance of bowel (intestinal) sounds (gurgling, etc.).

Inflammatory bowel disease A noncontagious, periodic inflammation of the intestinal wall now understood to be an abnormal immune and inflammatory response to bacterial antigens that normally occur in the intestine. Affects up to two of every 1000 people. Symptoms include cramping, diarrhea, weight loss, and intestinal bleeding. Two subtypes occur: Crohn's disease, a syndrome characterized by relapsing and remitting periods, is more serious, with deep ulcers and fissures developing along the whole intestine, but mostly in the terminal ileum. Ulcerative colitis, by contrast, is characterized by a shallow inflammation of the large-intestinal mucosa, mainly in the rectum. They are treated with a special diet, reducing stress, antibiotics, and anti-inflammatory and immunosuppressant drugs.

Laparoscopy (lap"ah-ros'ko-pe; *lapar* = the flank; *scopy* = observation) Examination of the peritoneal cavity and its organs with an endoscope inserted through the anterior abdominal wall. Often used to assess the condition of the digestive organs and the pelvic reproductive organs of females.

Orthodontics (or"tho-don'tiks; *ortho* = straight) Branch of dentistry that prevents and corrects misaligned teeth.

Pancreatitis (pan"kre-ah-ti'tis) A rare but extremely serious inflammation of the pancreas. May result from excessively high levels of fat in the blood, but most often results from activation of pancreatic enzymes in the pancreatic duct, causing the pancreatic tissue and duct to be digested. This painful condition can lead to nutritional deficiencies because pancreatic enzymes are essential to food digestion in the small intestine.

Peptic ulcers Term referring to gastric and duodenal ulcers.

Proctology (prok-tol'o-je; *procto* = rectum, anus; *logy* = study of) Branch of medicine dealing with treatment of diseases of the colon, rectum, and anus.

Pyloric stenosis (pi-lor'ik stĕ-no'sis; *stenosis* = narrowing, constriction) Congenital abnormality in which the pyloric sphincter is abnormally constricted. There is usually no problem until the baby begins to take solid food, and then projectile vomiting begins. Corrected surgically.

Vagotomy (va-got'o-me) Cutting or severing of the vagus nerve to decrease secretion of gastric juice in those with peptic ulcers that do not respond to medication.

Xerostomia (ze"ro-sto'me-ah; *zer* = dry, *stom* = mouth) Extreme dryness of the mouth; can be caused by blockage of salivary glands by cysts or autoimmune invasion of the salivary glands or ducts (Sjögren's syndrome).

Chapter Summary

Media study tools that could provide you additional help in reviewing specific key topics of Chapter 24 are referenced below.
IP = *InterActive Physiology*

PART 1: OVERVIEW OF THE DIGESTIVE SYSTEM

1. The digestive system includes organs of the alimentary canal (mouth, pharynx, esophagus, stomach, small and large intestines) and accessory digestive system organs (teeth, tongue, salivary glands, liver, gallbladder, and pancreas).

Digestive Processes (pp. 884–885)

1. Digestive system activities include six processes: ingestion, or food intake; propulsion, or movement of food through the tract; mechanical digestion, or processes that physically mix or break foods down into smaller fragments; chemical digestion, or food breakdown by enzymatic action; absorption, or transport of products of digestion through the intestinal mucosa into the blood; and defecation, or elimination of the undigested residues (feces) from the body.

Basic Functional Concepts (pp. 885–886)

1. The digestive system controls the environment within its lumen to ensure optimal conditions for digestion and absorption of foodstuffs.

2. Receptors and hormone-secreting cells in the alimentary canal wall respond to stretch and chemical signals that result in stimulation or inhibition of GI secretory activity or motility. The alimentary canal has an intrinsic nerve supply.

IP Digestive System; Topic: Control of the Digestive System, pp. 1, 3, 4–5, 8.

Digestive System Organs: Relationship and Structural Plan (pp. 886–889)

1. The parietal and visceral layers of the peritoneum are continuous with one another via several extensions (mesenteries, falciform ligament, lesser and greater omenta), and are separated by a potential space containing serous fluid, which decreases friction during organ activity.

2. The digestive viscera is served by the splanchnic circulation, consisting of arterial branches of the celiac trunk and aorta and the hepatic portal circulation.

3. All organs of the GI tract have the same basic pattern of tissue layers in their walls; all have a mucosa, a submucosa, a muscularis, and a serosa (or adventitia). Intrinsic nerve plexuses (enteric nervous system) are found within the wall.

PART 2: FUNCTIONAL ANATOMY OF THE DIGESTIVE SYSTEM

The Mouth, Pharynx, and Esophagus (pp. 889–899)

1. Food enters the GI tract via the mouth, which is continuous with the oropharynx posteriorly. The boundaries of the mouth are the lips and cheeks, palate, and tongue.

2. The oral mucosa is stratified squamous epithelium, an adaptation seen where abrasion occurs.

3. The tongue is mucosa-covered skeletal muscle. Its intrinsic muscles allow it to change shape; its extrinsic muscles allow it to change position.

4. Saliva is produced by many small buccal glands and three pairs of major salivary glands—parotid, submandibular, and sublingual—that secrete their product into the mouth via ducts. Largely water, saliva also contains ions, proteins, metabolic wastes, lysozyme, defensins, IgA, salivary amylase, a cyanide compound, and mucin.

5. Saliva moistens and cleanses the mouth; moistens foods, aiding their compaction; dissolves food chemicals to allow for taste; and begins chemical digestion of starch (salivary amylase). Saliva output is increased by parasympathetic reflexes initiated by activation of chemical and pressure receptors in the mouth and by conditioned reflexes. The sympathetic nervous system depresses salivation.

6. The 20 deciduous teeth begin to be shed at the age of 6 and are gradually replaced during childhood and adolescence by the 32 permanent teeth.

7. Teeth are classed as incisors, canines, premolars, and molars. Each tooth has an enamel-covered crown and a cementum-covered root. The bulk of the tooth is dentin, which surrounds the central pulp cavity. A periodontal ligament secures the tooth to the bony alveolus.

8. Food propelled from the mouth passes through the oropharynx and laryngopharynx. The mucosa of the pharynx is stratified squamous epithelium; skeletal muscles in its wall (constrictor muscles) move food toward the esophagus.

9. The esophagus extends from the laryngopharynx and joins the stomach at the cardiac orifice, which is surrounded by the gastroesophageal sphincter.

10. The esophageal mucosa is stratified squamous epithelium. Its muscularis is skeletal muscle superiorly and changes to smooth muscle inferiorly. It has an adventitia rather than a serosa.

11. The mouth and associated accessory organs accomplish food ingestion and mechanical digestion (chewing and mixing), initiate the chemical digestion of starch (salivary amylase), and propel food into the pharynx (buccal phase of swallowing).

12. Teeth function to masticate food. Chewing is initiated voluntarily and is then controlled reflexively.

13. The tongue mixes food with saliva, compacts it into a bolus, and initiates swallowing (the voluntary phase). The pharynx and esophagus are primarily food conduits that conduct food to the stomach by peristalsis. The swallowing center in the medulla and pons controls this phase reflexively. When the peristaltic wave approaches the gastroesophageal sphincter, the sphincter relaxes to allow food entry to the stomach.

Digestive System; Topic: Motility, pp. 3–5.

The Stomach (pp. 899–908)

1. The C-shaped stomach lies in the upper left quadrant of the abdomen. Its major regions are the cardia, fundus, body, and pyloric region. When empty, its internal surface exhibits rugae.

2. The stomach muscularis contains a third (oblique) layer of smooth muscle that allows it to churn and mix food.

3. The stomach mucosa is simple columnar epithelium dotted with gastric pits that lead into gastric glands. Secretory cells in the gastric glands include pepsinogen-producing chief cells; parietal cells, which secrete hydrochloric acid and intrinsic factor; mucous neck cells, which produce mucus; and enteroendocrine cells, which secrete hormones.

4. The mucosal barrier, which protects the stomach from self-digestion and HCl, reflects the fact that the mucosal cells are connected by tight junctions, secrete a thick mucus, and are quickly replaced when damaged.

5. Protein digestion is initiated in the stomach by activated pepsin and requires acidic conditions (provided by HCl). Few substances are absorbed.

6. Gastric secretory activity is controlled by both nervous and hormonal factors. The three phases of gastric secretion are the cephalic, gastric, and intestinal. Most stimuli acting on the head and stomach (cephalic and gastric respectively) stimulate gastric secretion. Most stimuli acting on the small intestine trigger the enterogastric reflex and release of secretin and CCK, all of which inhibit gastric secretory activity. Sympathetic activity also inhibits gastric secretion.

7. Mechanical digestion in the stomach is triggered by stomach distension and coupled to food propulsion and stomach emptying. Food movement into the duodenum is controlled by the pylorus and feedback signals from the small intestine. Pacemaker cells in the smooth muscle sheet set the maximal rate of peristalsis.

Digestive System; Topic: Control of the Digestive System, pp. 3, 5–6, 8.

The Small Intestine and Associated Structures (pp. 908–922)

1. The small intestine is the major digestive and absorptive organ. It extends from the pyloric sphincter to the ileocecal valve. Its three subdivisions are the duodenum, jeju-num, and ileum. The bile duct and pancreatic duct join to form the hepatopancreatic ampulla and empty their secretions into the duodenum through the hepatopancreatic sphincter (of Oddi).

2. Circular folds, villi, and microvilli increase the intestinal surface area for digestion and absorption.

3. The duodenal submucosa contains elaborate mucus-secreting duodenal glands (Brunner's glands); that of the ileum contains Peyer's patches (lymphoid follicles). The duodenum is covered not with a serosa but an adventitia.

4. Intestinal juice is largely water and is relatively enzyme-poor. The major stimuli for its release are stretch and chemicals.

5. The liver is a lobed organ overlying the stomach. Its digestive role is to produce bile, which it secretes into the common hepatic duct.

6. The structural and functional units of the liver are the liver lobules. Blood flowing to the liver via the hepatic artery and hepatic portal vein flows into its sinusoids, from which Kupffer cells remove debris and hepatocytes remove nutrients. Hepatocytes store glucose as glycogen, use amino acids to make plasma proteins, and detoxify metabolic wastes and drugs.

7. Bile is made continuously by the hepatocytes. Bile salts, secretin, and vagal stimulation stimulate bile production.

8. The gallbladder, a muscular sac that lies beneath the right liver lobe, stores and concentrates bile.

9. Bile contains electrolytes, a variety of fatty substances, bile salts, and bile pigments in an aqueous medium. Bile salts are emulsifying agents; they disperse fats and form water-soluble micelles, which solubilize the products of fat digestion.

10. Cholecystokinin released by the small intestine stimulates the gallbladder to contract and the hepatopancreatic sphincter to relax, allowing bile (and pancreatic juice) to enter the duodenum.

11. The pancreas is retroperitoneal between the spleen and small intestine. Its exocrine product, pancreatic juice, is carried to the duodenum via the pancreatic duct.

12. Pancreatic juice is an HCO_3^--rich fluid containing enzymes that digest all categories of foods. Its secretion of pancreatic juice is controlled by intestinal hormones and the vagus nerves.

IP Digestive System; Topic: Secretion, pp. 11–14.

13. Mechanical digestion and propulsion in the small intestine mix chyme with digestive juices and bile and force the residues, largely by segmentation, through the ileocecal valve. Pacemaker cells set the rate of segmentation. Ileocecal valve opening is controlled by the gastroileal reflex and gastrin.

The Large Intestine (pp. 922–927)

1. The subdivisions of the large intestine are the cecum (and appendix), colon (ascending, transverse, descending, and sigmoid portions), rectum, and anal canal. It opens to the body exterior at the anus.

2. The mucosa of most of the large intestine is simple columnar epithelium containing abundant goblet cells. The longitudinal muscle in the muscularis is reduced to three bands (teniae coli), which pucker its wall, producing haustra.

3. The major functions of the large intestine are absorption of water, some electrolytes, and vitamins made by enteric bacteria, and defecation (evacuation of food residues from the body).

4. The defecation reflex is triggered when feces enter the rectum. It involves parasympathetic reflexes leading to the contraction of the rectal walls and is aided by Valsalva's maneuver.

IP Digestive System; Topic: Anatomy Review, pp. 3–5.

PART 3: PHYSIOLOGY OF CHEMICAL DIGESTION AND ABSORPTION

Chemical Digestion (pp. 927–931)

1. Chemical digestion is accomplished by hydrolysis, catalyzed by enzymes.

2. Most chemical digestion is done in the small intestine by intestinal (brush border) enzymes and, more importantly, by pancreatic enzymes. Alkaline pancreatic juice neutralizes the acidic chyme and provides the proper environment for operation of the enzymes. Both pancreatic juice (the main source of lipases) and bile are necessary for fat breakdown.

Absorption (pp. 931–933)

1. Virtually all of the foodstuffs and most of the water and electrolytes are absorbed in the small intestine. Except for fat digestion products, fat-soluble vitamins, and most water-soluble vitamins (which are absorbed by diffusion), most nutrients are absorbed by active transport processes.

2. Fat breakdown products are solubilized by bile salts (in micelles), resynthesized to triglycerides in the intestinal mucosal cells, and combined with other lipids and protein as chylomicrons that enter the lacteals. Other absorbed substances enter the villus blood capillaries and are transported to the liver via the hepatic portal vein.

Developmental Aspects of the Digestive System (pp. 933, 936–937)

1. The glandular accessory organs (salivary glands, liver, pancreas, and gallbladder) form from outpocketings of the foregut endoderm. The mucosa of the alimentary canal develops from the endoderm, which folds to form a tube. The remaining three tunics of the alimentary canal wall are formed by mesoderm.

2. Important congenital abnormalities of the digestive tract include cleft palate/lip, tracheoesophageal fistula, and cystic fibrosis. All interfere with normal nutrition.

3. Various inflammations plague the digestive system throughout life. Appendicitis is common in adolescents, gastroenteritis and food poisoning can occur at any time (given the proper irritating factors), ulcers and gallbladder problems increase in middle age.

4. The efficiency of all digestive system processes declines in the elderly, and periodontal disease is common. Diverticulosis, fecal incontinence, and GI tract cancers such as stomach and colon cancer appear with increasing frequency in an aging population.

Review Questions

Multiple Choice/Matching

(Some questions have more than one correct answer. Select the best answer or answers from the choices given.)

1. The peritoneal cavity (a) is the same thing as the abdominopelvic cavity, (b) is filled with air, (c) like the pleural and pericardial cavities is a potential space containing serous fluid, (d) contains the pancreas and all of the duodenum.

2. Obstruction of the hepatopancreatic sphincter impairs digestion by reducing the availability of (a) bile and HCl, (b) HCl and intestinal juice, (c) pancreatic juice and intestinal juice, (d) pancreatic juice and bile.

3. The action of an enzyme is influenced by (a) its chemical surroundings, (b) its specific substrate, (c) the presence of needed cofactors or coenzymes, (d) all of these.

4. Carbohydrates are acted on by (a) peptidases, trypsin, and chymotrypsin, (b) amylase, maltase, and sucrase, (c) lipases, (d) peptidases, lipases, and galactase.

5. The parasympathetic nervous system influences digestion by (a) relaxing smooth muscle, (b) stimulating peristalsis and secretory activity, (c) constricting sphincters, (d) none of these.

6. The digestive juice product containing enzymes capable of digesting all four major foodstuff categories is (a) pancreatic, (b) gastric, (c) salivary, (d) biliary.

7. The vitamin associated with calcium absorption is (a) A, (b) K, (c) C, (d) D.

8. Someone has eaten a meal of buttered toast, cream, and eggs. Which of the following would you expect to happen? (a) Compared to the period shortly after the meal, gastric motility and secretion of HCl decrease when the food reaches the duodenum; (b) gastric motility increases even as the person is chewing the food (before swallowing); (c) fat will be emulsified in the duodenum by the action of bile; (d) all of these.

9. The site of production of VIP and cholecystokinin is (a) the stomach, (b) the small intestine, (c) the pancreas, (d) the large intestine.

10. Which of the following is not characteristic of the large intestine? (a) It is divided into ascending, transverse, and descending portions; (b) it contains abundant bacteria, some of which synthesize certain vitamins; (c) it is the main absorptive site; (d) it absorbs much of the water and salts remaining in the wastes.

11. The gallbladder (a) produces bile, (b) is attached to the pancreas, (c) stores and concentrates bile, (d) produces secretin.

12. The sphincter between the stomach and duodenum is (a) the pyloric sphincter, (b) the cardiac sphincter, (c) the hepatopancreatic sphincter, (d) the ileocecal sphincter.

In items 13–17, trace the path of a single protein molecule that has been ingested.

13. The protein molecule will be digested by enzymes secreted by (a) the mouth, stomach, and colon, (b) the stomach, liver, and small intestine, (c) the small intestine, mouth, and liver, (d) the pancreas and stomach.

14. The protein molecule must be digested before it can be transported to and utilized by the cells because (a) protein is only useful directly, (b) protein has a low pH, (c) proteins in the circulating blood produce an adverse osmotic pressure, (d) the protein is too large to be readily absorbed.

15. The products of protein digestion enter the bloodstream largely through cells lining (a) the stomach, (b) the small intestine, (c) the large instestine, (d) the bile duct.

16. Before the blood carrying the products of protein digestion reaches the heart, it first passes through capillary networks in (a) the spleen, (b) the lungs, (c) the liver, (d) the brain.

17. Having passed through the regulatory organ selected above, the products of protein digestion are circulated throughout the body. They will enter individual body cells as a result of (a) active transport, (b) diffusion, (c) osmosis, (d) phagocytosis.

Short Answer Essay Questions

18. Make a simple line drawing of the organs of the alimentary tube and label each organ. Then add three labels to your drawing—salivary glands, liver, and pancreas—and use arrows to show where each of these organs empties its secretion into the alimentary tube.

19. Sara was on a diet but she could not eat less and kept claiming her stomach had a mind of its own. She was joking, but indeed, there is a "gut brain" called the enteric nervous system. Is it part of the parasympathetic and sympathetic nervous system? Explain.

20. Name the layers of the alimentary tube wall. Note the tissue composition and major function of each layer.

21. What is a mesentery? Mesocolon? Greater omentum?

22. Name the six functional activities of the digestive system.

23. (a) Describe the boundaries of the oral cavity. (b) Why do you suppose its mucosa is stratified squamous epithelium rather than the more typical simple columnar epithelium?

24. (a) What is the normal number of permanent teeth? Of deciduous teeth? (b) What substance covers the tooth crown? Its root? (c) What substance makes up the bulk of a tooth? (d) What and where is pulp?

25. Describe the two phases of swallowing, noting the organs involved and the activities that occur.

26. Describe the role of these cells found in gastric glands: parietal, chief, mucous neck, and enteroendocrine.

27. Describe the regulation of the cephalic, gastric, and intestinal phases of gastric secretion.

28. (a) What is the relationship between the cystic, common hepatic, bile, and pancreatic ducts? (b) What is the point of fusion of the bile and pancreatic ducts called?

29. Explain why fatty stools result from the absence of bile or pancreatic juice.

30. Indicate the function of the Kupffer cells and the hepatocytes of the liver.

31. What are (a) brush border enzymes? (b) chylomicrons?

32. Name one inflammatory condition particularly common to adolescents, two common in middle age, and one common in old age.

33. What are the effects of aging on digestive system activity?

Critical Thinking and Clinical Application Questions

1. You are a research assistant at a pharmaceutical company. Your group has been asked to develop an effective laxative that (1) provides bulk and (2) is nonirritating to the intestinal mucosa. Explain why these requests are important by describing what would happen if the opposite conditions were present.

2. After a heavy meal rich with fried foods, Debby Collins, an overweight 45-year-old woman, was rushed to the emergency room with severe spasmodic pains in her epigastric region that radiated to the right side of her rib cage. She indicated that the attack came on suddenly, and her abdomen was found to be tender to the touch and somewhat rigid. What do you think is this patient's problem and why is her pain discontinuous (colicky)? What are the treatment options and what might happen if the problem is not resolved?

3. A baby is admitted to the hospital with a history of diarrhea and watery feces occurring over the last three days. The baby has sunken fontanels, indicating extreme dehydration. Tests indicate that the baby has a bacterium-induced colitis, and antibiotics are prescribed. Because of the baby's loss of intestinal juices, do you think that his blood pH would indicate acidosis or alkalosis? Explain your reasoning.

4. Gary Francis, a middle-aged salesman, complains of a burning pain in the "pit of his stomach," usually beginning about two hours after eating and abating after drinking a glass of milk. When asked to indicate the site, he points to his epigastric region. The GI tract is examined by X-ray fluoroscopy. A gastric ulcer is visualized, and drug therapy using an antibiotic-bismuth approach is recommended. (a) Why is this treatment suggested? (b) What are the possible consequences of nontreatment?

5. Dr. Dolan used an endoscope to view Mr. Habib's colon. He noted the presence of several polyps and removed them during the same procedure. What is an endoscope? Why did Dr. Dolan opt to remove the polyps immediately?

6. Mr. Holden has had severe diarrhea all day and is severely weakened. Explain why his nurse is concerned about his present condition.

CHAPTER

Nutrition, Metabolism, and Body Temperature Regulation

Nutrition (pp. 943–956)

1. Define nutrient, essential nutrient, and calorie.
2. List the six major nutrient categories. Note important sources and main cellular uses.
3. Distinguish between simple and complex carbohydrate sources.
4. Distinguish between saturated, unsaturated, and trans fatty acid sources.
5. Distinguish between nutritionally complete and incomplete proteins.
6. Define nitrogen balance and indicate possible causes of positive and negative nitrogen balance.
7. Distinguish between fat- and water-soluble vitamins, and list the vitamins in each group.
8. For each vitamin, list important sources, body functions, and consequences of its deficit or excess.
9. List minerals essential for health; note important dietary sources and describe how each is used.

Metabolism (pp. 956–981)

10. Define metabolism. Explain how catabolism and anabolism differ.
11. Define oxidation and reduction and indicate the importance of these reactions in metabolism. Indicate the role of coenzymes used in cellular oxidation reactions.
12. Explain the difference between substrate-level phosphorylation and oxidative phosphorylation.
13. Follow the oxidation of glucose in body cells. Summarize important events and products of glycolysis, the Krebs cycle, and electron transport.
14. Define glycogenesis, glycogenolysis, and gluconeogenesis.
15. Describe the process by which fatty acids are oxidized for energy.
16. Define ketone bodies, and indicate the stimulus for their formation.
17. Describe how amino acids are metabolized for energy.
18. Describe the need for protein synthesis in body cells.
19. Explain the concept of amino acid or carbohydrate-fat pools and describe pathways by which substances in these pools can be interconverted.
20. List important events of absorptive and postabsorptive states, and explain how these events are regulated.
21. Describe several metabolic functions of the liver.
22. Differentiate between LDLs and HDLs relative to their structures and major roles in the body.

Energy Balance (pp. 981–989)

23. Explain what is meant by body energy balance.
24. Describe some current theories of food intake regulation.
25. Define basal metabolic rate and total metabolic rate. Name factors that influence each.
26. Describe how body temperature is regulated, and indicate the common mechanisms regulating heat production/retention and heat loss from the body.

Developmental Aspects of Nutrition and Metabolism (pp. 989, 992)

27. Describe the effects of inadequate protein intake on the fetal nervous system.
28. Describe the cause and consequences of the low metabolic rate typical of the elderly.
29. List ways that medications commonly used by aged people may influence their nutrition and health.

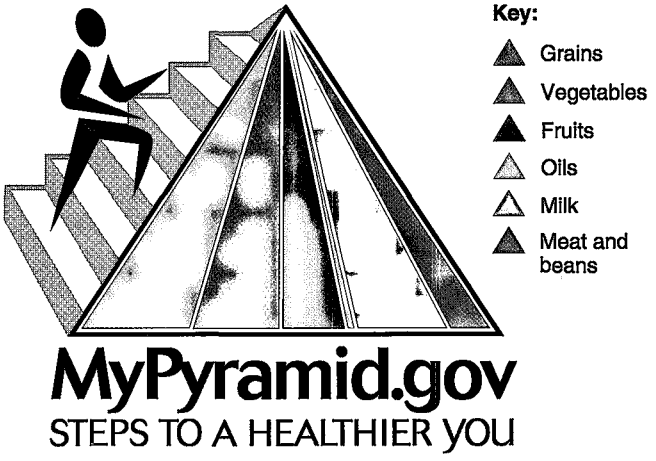
Are you a food lover? Most of us can be divided into two camps according to our reactions to food—those who live to eat and those who eat to live. The saying "you are what you eat" is true in that part of the food we eat is converted to our living flesh. In other words, some nutrients are used to build cell structures, replace worn-out parts, and synthesize functional molecules. However, most nutrients we ingest are used as metabolic fuel. That is, they are oxidized and transformed to **ATP**, the chemical energy form used by cells. The energy value of foods is measured in **kilocalories (kcal)** or "large calories (C)." One kilocalorie is the amount of heat energy needed to raise the temperature of 1 kilogram of water 1°C (1.8°F) and is the unit conscientiously counted by dieters.

In Chapter 23, we considered how foods are digested and absorbed, but what happens to these foods once they enter the blood? Why do we need bread, meat, and fresh vegetables? Why does everything we eat seem to turn to fat? This chapter will try to answer these questions as it explains both the nature of nutrients and their metabolic roles.

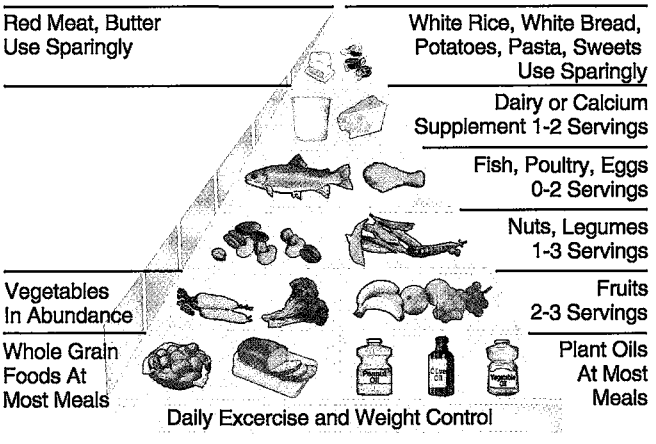
Nutrition

A nutrient is a substance in food used by the body to promote normal growth, maintenance, and repair. The nutrients needed for health divide neatly into six categories. Three of these—carbohydrates, lipids, and proteins—are collectively called the **major nutrients** and make up the bulk of what we eat. The fourth and fifth categories, vitamins and minerals, though equally crucial for health, are required in minute amounts. In a strict sense, water, which accounts for about 60% by volume of the food we eat, is also a major nutrient. However, because its importance in the body is described in Chapter 2, only the five nutrient categories listed above will be considered in detail here.

Most foods offer a combination of nutrients. For example, cream of mushroom soup contains all the major nutrients plus some vitamins and minerals. A diet consisting of foods from each of the five food groups—grains, fruits, vegetables, meats and fish, and milk products—normally guarantees adequate amounts of all the needed nutrients. There are several examples of food guide pyramids around; two are provided in Figure 24.1. Fresh out of the oven on April 19, 2005, the USDA's new version of the food guide pyramid—MyPyramid—is a significant departure from traditional food pyramids. MyPyramid separates the food categories vertically (rather than horizontally). Narrowing of each food group from bottom to top of the pyramid suggests moderation in selecting foods from each food group (more "picks"



(a) USDA food guide pyramid



(b) Healthy eating pyramid

FIGURE 24.1 **Food guide pyramids. (a)** The USDA food guide pyramid MyPyramid, issued by the U.S. Department of Agriculture in the spring of 2005. **(b)** The Healthy Eating Pyramid, presented by Walter Willett of Harvard.

from food choices at the bottom of the food band which contain less added sugar and solid fats). Also new to this food pyramid version is the emphasis on at least 30 minutes daily of physical activity as represented by the stick person climbing the steps. Considered very important is the fact that one's diet can be personalized by age, sex, and activity level by logging on to the Internet (www.mypyramid.gov) where information is available to help consumers make healthy choices and determine the size and number of servings recommended daily.

The Healthy Eating Pyramid was presented by Walter Willett of Harvard as a healthier alternative to the previous (1992) USDA food guide pyramid. It uses the traditional orientation of food groups, and emphasizes eating whole grain foods and abundant (nonstarchy) fruits and vegetables. It also recommends substituting plant oils and nuts for animal fats, and restricting red meat, sweets, and starchy foods.

The ability of cells, especially those of the liver, to convert one type of molecule to another is truly remarkable. These interconversions allow the body to use the wide range of chemicals found in foods and to adjust to varying food intakes. But there are limits to this ability to conjure up new molecules from old. At least 45 and possibly 50 molecules, called **essential nutrients,** cannot be made fast enough to meet the body's needs and so must be provided by the diet. As long as all the essential nutrients are ingested, the body can synthesize the hundreds of additional molecules required for life and good health. The use of the word "essential" to describe the chemicals that must be obtained from outside sources is unfortunate and misleading, because both essential and nonessential nutrients are equally vital for normal functioning.

Carbohydrates

Dietary Sources

Except for milk sugar (lactose) and negligible amounts of glycogen in meats, all the carbohydrates we ingest are derived from plants. Sugars (monosaccharides and disaccharides) come from fruits, sugar cane, sugar beets, honey, and milk. The polysaccharide starch is found in grains and vegetables. There are two varieties of polysaccharides that provide fiber. Cellulose, a polysaccharide plentiful in most vegetables, is not digested by humans but provides roughage, or *insoluble fiber,* which increases the bulk of the stool and facilitates defecation. *Soluble fiber,* or pectin, found in apples and citrus fruits, reduces blood cholesterol levels, a desirable goal in those with cardiac disease.

Uses in the Body

The monosaccharide **glucose** is the carbohydrate molecule ultimately used as fuel by body cells to produce ATP. Carbohydrate digestion also yields fructose and galactose, but these monosaccharides are converted to glucose by the liver before they enter the general circulation. Although many body cells use fats as energy sources, neurons and red blood cells rely almost entirely on glucose for their energy needs. Because even a temporary shortage of blood glucose can severely depress brain function and lead to neuron death, the body carefully monitors and regulates blood glucose levels. Any glucose in excess of what is needed for ATP synthesis is converted to glycogen or fat and stored for later use.

Other uses of monosaccharides are meager. Small amounts of pentose sugars are used to synthesize nucleic acids, and a variety of sugars are attached to externally facing plasma membrane proteins and lipids.

Dietary Requirements

The low-carbohydrate diet of the Inuit (Eskimos) and the high-carbohydrate diet of peoples in the Far East indicate that humans can be healthy even with wide variations in carbohydrate intake. The minimum requirement for carbohydrates is not known, but 100 grams per day is presumed to be the smallest amount needed to maintain adequate blood glucose levels. The recommended dietary allowance (130 g/d) is based on the amount needed to fuel the brain, not the total amount need to supply all daily activities. Recommended carbohydrate intake to maintain health is 45–65% of one's total calorie intake, with the emphasis on *complex* carbohydrates (whole grains and vegetables). When less than 50 grams per day is consumed, tissue proteins and fats are used for energy fuel.

American adults typically consume about 46% of dietary food energy in the form of carbohydrates. Because starchy foods (rice, pasta, breads) are less expensive than meat and other high-protein foods, carbohydrates make up an even greater percentage of the diet in low-income groups. Vegetables, fruits, whole grains, and milk have many valuable nutrients, such as vitamins and minerals. By contrast, highly refined carbohydrate foods such as candy and soft drinks provide concentrated energy sources only—the term "empty calories" is commonly used to describe such foods. Eating refined, sugary foods instead of more complex carbohydrates may cause nutritional deficiencies as well as obesity. Other possible consequences of excessive intake of simple carbohydrates are listed in Table 24.1.

Lipids

Dietary Sources

The most abundant dietary lipids are triglycerides, also called neutral fats or triacylglycerols (Chapter 2). We eat saturated fats in animal products such as meat and dairy foods, in a few tropical plant products such as coconut, and in hydrogenated oils (trans fats) such as margarine and solid shortenings used in baking. Unsaturated fats are present in seeds, nuts, olive oil, and most vegetable oils. Fats are digested to monoglycerides or all the way to fatty acids and glycerol, and then reconverted to triglycerides for transport in the lymph. Major sources of cholesterol are egg yolk, meats and organ meats, shellfish, and milk products. However, it is estimated that the liver produces about 85% of blood cholesterol.

Although the liver is adept at converting one fatty acid to another, it cannot synthesize *linoleic acid* (lin"o-le'ik), a fatty acid component of *lecithin* (les'ĭ-thin). Thus, linoleic acid, an omega-6 fatty acid, is an *essential fatty acid* that must be ingested.

TABLE 24.1 Summary of Carbohydrate, Lipid, and Protein Nutrients

FOOD SOURCES	RECOMMENDED DIETARY ALLOWANCE (RDA) FOR ADULTS	PROBLEMS	
		EXCESSES	DEFICITS
CARBOHYDRATES			
Total Digestible ▪ *Complex carbohydrates (starches):* bread, cereal, crackers, flour, pasta, nuts, rice, potatoes ▪ *Simple carbohydrates (sugars):* carbonated drinks, candy, fruit, ice cream, pudding, young (immature) vegetables	130 g 45–65% of total caloric intake	Obesity; nutritional deficits; dental caries; gastrointestinal irritation; elevated triglycerides in plasma	Tissue wasting (in extreme deprivation); metabolic acidosis resulting from accelerated fat use for energy
Total Fiber	25–30 g		
LIPIDS			
▪ *Animal sources:* lard, meat, poultry, eggs, milk, milk products ▪ *Plant sources:* chocolate; corn, soy, cottonseed, olive oils; coconut; corn; peanuts	80–100 g 20–35% of total caloric intake	Obesity and increased risk of cardiovascular disease (particularly if excesses of saturated and trans fat)	Weight loss; fat stores and tissue proteins catabolized to provide metabolic energy; problems controlling heat loss (due to depletion of subcutaneous fat)
▪ *Essential fatty acids:* fish oil, corn, cottonseed, soy oils; wheat germ; vegetable shortenings	10–17 g	Excess dietary intake of omega-3 fatty acid, may increase risk of stroke	Poor growth; skin lesions (eczema-like); depression
▪ *Cholesterol:* organ meats (liver, kidneys, brains), egg yolks, fish roe; smaller concentrations in milk products and meat	250 mg or less	Increased levels of plasma cholesterol and LDL lipoproteins; correlated with increased risk of cardiovascular disease	Increased risk of stroke (CVA) in susceptible individuals
PROTEINS			
▪ *Complete proteins:* eggs, milk, milk products, meat (fish, poultry, pork, beef, lamb) ▪ *Incomplete proteins:* legumes (soybeans, lima beans, kidney beans, lentils); nuts and seeds; grains and cereals; vegetables	0.8 g/kg body weight 12–20% of total caloric intake	Obesity; enhanced calcium excretion and bone loss; high cholesterol levels in blood; kidney stones	Profound weight loss and tissue wasting; growth retardation in children; anemia; edema (due to deficits of plasma proteins) During pregnancy: miscarriage or premature birth

Linolenic acid, an omega-3 fatty acid, may also be essential. Fortunately, these two fatty acids are found in most vegetable oils.

Uses in the Body

Fats have fallen into disfavor, particularly among those for whom the "battle of the bulge" is constant. But fats make foods tender, flaky, or creamy, and make us feel full and satisfied. Furthermore, dietary fats *are* essential for several reasons. They help the body absorb fat-soluble vitamins; triglycerides are the major energy fuel of hepatocytes and skeletal muscle; and phospholipids are an integral component of myelin sheaths and cellular membranes. Fatty deposits in adipose tissue provide (1) a protective cushion around body organs, (2) an insulating layer beneath the skin, and (3) an easy-to-store concentrated source of energy fuel. Regulatory molecules called *prostaglandins* (pros"tah-glan'dinz), formed from linoleic acid via arachidonic acid (ah"rah-kĭ-don'ik),

play a role in smooth muscle contraction, control of blood pressure, and inflammation.

Unlike triglycerides, cholesterol is not used for energy. It is important as a stabilizing component of plasma membranes and is the precursor from which bile salts, steroid hormones, and other essential molecules are formed.

Dietary Requirements

Fats represent over 40% of the calories in the typical American diet. There are no precise recommendations on amount or type of dietary fats, but the American Heart Association suggests that (1) fats should represent 30% or less of total caloric intake, (2) saturated fats should be limited to 10% or less of total fat intake, and (3) daily cholesterol intake should be no more than 300 mg (the amount in one egg yolk). The goal of these recommendations is to keep total blood cholesterol and triglycerides to less than 200 mg/dl. Because a diet high in saturated fats and cholesterol may contribute to cardiovascular disease, these are wise guidelines. Sources of the various lipid classes and consequences of their deficient or excessive intake are summarized in Table 24.1.

Fat Substitutes

In an attempt to reduce fat intake without losing fat's appetizing aspects, many people have turned to fat substitutes or foods prepared with them. Perhaps the oldest fat substitute is air (beaten into a product to make it fluffy). Other fat substitutes are modified starches and gums, and more recently milk whey protein (Simplesse). Except for those based on dietary fibers (gums), such products are metabolized and provide calories. One of the newest substitutes, Olestra, a fat-based product made from cottonseeds, is not metabolized because it is not digested or absorbed.

Most fat substitutes have two drawbacks: (1) They don't stand up to the intense heat needed to fry foods, and (2) although manufacturers claim otherwise, they don't taste nearly as good as the "real thing." The ones that are not absorbed tend to cause flatus (gas) or diarrhea, and may interfere with absorption of fat-soluble drugs, vitamins, and phytochemicals such as beta-carotene, a precursor of vitamin A.

Proteins

Dietary Sources

Animal products contain the highest-quality proteins, that is, those with the greatest amount and best ratios of essential amino acids (Figure 24.2). Proteins in eggs, milk, fish, and most meats (Table 24.1) are **complete proteins** that meet all the body's amino acid requirements for tissue maintenance and growth. Legumes (beans and peas), nuts, and cereals are protein-rich, but their proteins are nutritionally incomplete because they are low in one or more of the essential amino acids. Leafy green vegetables are well balanced in all essential amino acids except methionine, but contain only small amounts of protein. Strict vegetarians must carefully plan their diets to obtain all the essential amino acids and prevent protein malnutrition. When ingested together, cereal grains and legumes provide all the essential amino acids (Figure 24.2b), and some combination of these foods is found in the diets of all cultures (most obviously in the rice and beans seen on nearly every plate in a Mexican restaurant). For nonvegetarians, grains and legumes are useful as partial substitutes for more expensive animal proteins.

Uses in the Body

Proteins are important structural materials of the body, including, for example, keratin in skin, collagen and elastin in connective tissues, and muscle proteins. In addition, functional proteins such as enzymes and some hormones regulate an incredible variety of body functions. Whether amino acids are used to synthesize new proteins or are burned for energy depends on a number of factors:

1. The all-or-none rule. All amino acids needed to make a particular protein must be present in a cell at the same time and in sufficient amounts. If one is missing, the protein cannot be made. Because essential amino acids cannot be stored, those not used immediately to build proteins are oxidized for energy or converted to carbohydrates or fats.

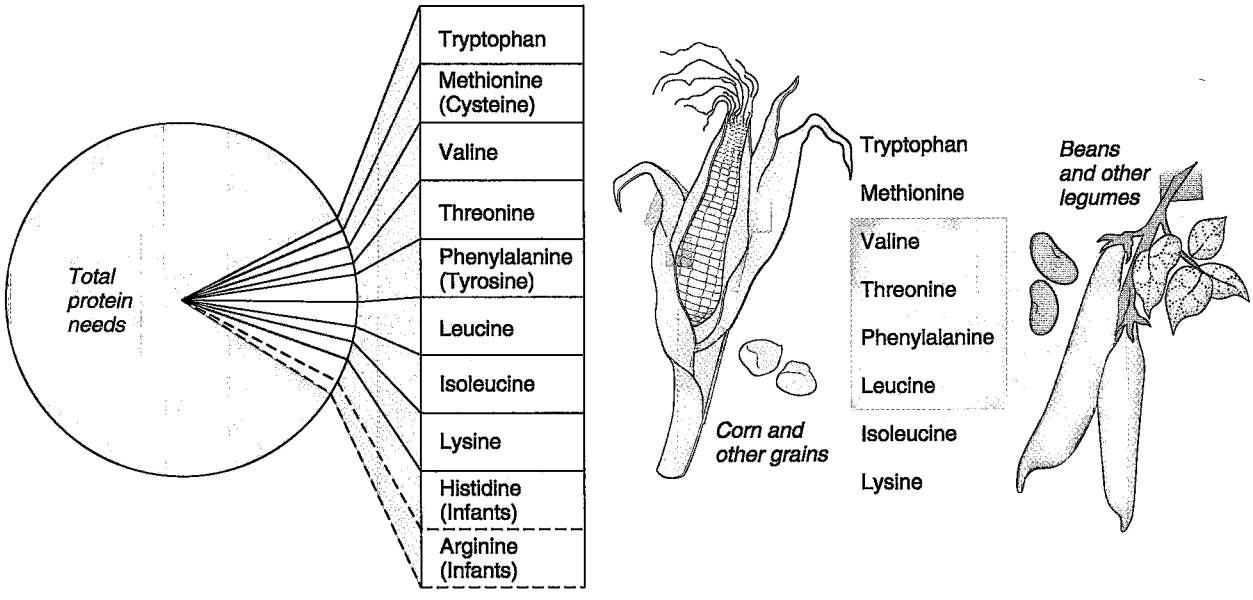
2. Adequacy of caloric intake. For optimal protein synthesis, the diet must supply sufficient carbohydrate or fat calories for ATP production. When it doesn't, dietary and tissue proteins are used for energy.

3. Nitrogen balance. In healthy adults the rate of protein synthesis equals the rate of protein breakdown and loss. This homeostatic state is reflected in the body's **nitrogen balance.** The body is in nitrogen balance when the amount of nitrogen ingested in proteins equals the amount excreted in urine and feces.

The body is in *positive nitrogen balance* when the amount of protein being incorporated into tissue is greater than the amount being broken down and used for energy—the normal situation in growing children and pregnant women. A positive balance also occurs when tissues are being repaired following illness or injury.

In *negative nitrogen balance,* protein breakdown for energy exceeds the amount of protein being

Q *John eats nothing but baked bean sandwiches. Is he getting all the essential amino acids in this rather restricted diet?*



(a) Essential amino acids

(b) Vegetarian diets providing the eight essential amino acids for humans

FIGURE 24.2 **Essential amino acids.** In order for protein synthesis to occur, ten amino acids must be available simultaneously and in the correct relative amounts. **(a)** Relative amounts of the essential amino acids and total proteins needed by adults. Notice that the essential amino acids represent only a small percentage of the total recommended protein intake. Histidine and arginine are graphed with dashed lines because they are made in inadequate amounts in infants, and thus are essential in infants but not in adults. The amino acids shown in parentheses are *not* essential but can substitute in part for methionine and phenylalanine. **(b)** Vegetarian diets must be carefully constructed to provide all essential amino acids. As shown, corn has little isoleucine and lysine. Beans have ample isoleucine and lysine but little tryptophan and methionine. All essential amino acids can be obtained by consuming a meal of corn and beans.

incorporated into tissues. This occurs during physical and emotional stress (for example, infection, injury, or burns), or when the quality or quantity of dietary protein is poor, or during starvation.

4. Hormonal controls. Certain hormones, called *anabolic hormones*, accelerate protein synthesis and growth. The effects of these hormones vary continually throughout life. For example, pituitary *growth hormone* stimulates tissue growth during childhood and conserves protein in adults, and the *sex hormones* trigger the growth spurt of adolescence. Other hormones, such as the adrenal *glucocorticoids* released during stress, enhance protein breakdown and conversion of amino acids to glucose.

A Yes. He has both grain and beans, which together contain all the essential amino acids.

Dietary Requirements

Besides supplying essential amino acids, dietary proteins furnish the raw materials for making nonessential amino acids and various nonprotein nitrogen-containing substances. The amount of protein a person needs reflects his or her age, size, metabolic rate, and current state of nitrogen balance. As a rule of thumb, nutritionists recommend a daily intake of 0.8 g per kilogram of body weight. About 30 g of protein is supplied by a small serving of fish and a glass of milk. Most Americans eat far more protein than they need. Prolonged high protein consumption may lead to bone loss. This may occur because metabolizing sulfur-containing amino acids makes the blood more acidic and calcium is pulled from the bones to buffer these acids.

Vitamins

Vitamins (*vita* = life) are potent organic compounds needed in minute amounts for growth and good

health. Unlike other organic nutrients, vitamins are not used for energy and do not serve as building blocks, but they are crucial in helping the body use those nutrients that do. Without vitamins, all the carbohydrates, proteins, and fats we eat would be useless.

Most vitamins function as **coenzymes** (or parts of coenzymes), which act with an enzyme to accomplish a particular chemical task. For example, the B vitamins riboflavin and niacin act as coenzymes in the oxidation of glucose for energy. We will describe the roles of some vitamins in the metabolism discussion.

Because most vitamins are not made in the body, they must be taken in via foods or vitamin supplements. The exceptions are vitamin D made in the skin, and small amounts of B vitamins and vitamin K synthesized by intestinal bacteria. In addition, the body can convert *beta-carotene* (kar'o-tēn), the orange pigment in carrots and other foods, to vitamin A. (Thus, beta-carotene and substances like it are called *provitamins.*) Vitamins are found in all major food groups, but no one food contains all the required vitamins. Thus, a balanced diet is the best way to ensure a full vitamin complement.

Initially vitamins were given a convenient letter designation that indicated the order of their discovery. Although more chemically descriptive names have been assigned to the vitamins, this earlier terminology is still commonly used.

Vitamins are either **fat soluble** or **water soluble.** The water-soluble vitamins, which include B-complex vitamins and vitamin C, are absorbed along with water from the gastrointestinal tract. (The exception is vitamin B_{12}, which must bind to gastric intrinsic factor to be absorbed.) Because only insignificant amounts of water-soluble vitamins are stored in lean tissue of the body, any ingested amounts not used within an hour or so are excreted in urine. Consequently, few conditions resulting from excessive levels of these vitamins *(hypervitaminoses)* are known.

TABLE 24.2 Vitamins

VITAMIN	DESCRIPTION, COMMENTS	SOURCES AND RECOMMENDED DAILY AMOUNTS (RDA) FOR ADULTS	IMPORTANCE IN BODY	PROBLEMS	
				EXCESSES	DEFICITS
FAT-SOLUBLE VITAMINS					
A (retinol)	Group of compounds including retinol and retinal; 90% is stored in liver, which can supply body needs for a year; stable to heat, acids, alkalis; easily oxidized; rapidly destroyed by exposure to light	Formed from provitamin beta-carotene in intestine, liver, kidneys; carotene found in deep-yellow and deep-green leafy vegetables; vitamin A found in fish liver oils, egg yolk, liver, fortified foods (milk, margarine) RDA: males 900 µg, females 700 µg	Required for synthesis of photoreceptor pigments, integrity of skin and mucosae, normal tooth and bone development, normal reproductive capabilities; important antioxidant (hence, anticancer and antiatherosclerosis effects)	Toxic when ingested in excess of 10 mg daily for months; symptoms: nausea, vomiting, anorexia, headache, hair loss, bone and joint pain, bone fragility, enlargement of liver and spleen; may increase smokers' risk of lung cancer	Night blindness; epithelial changes; dry skin and hair, skin sores; increased respiratory, digestive, urogenital infections; drying of conjunctiva; clouding of cornea; in pregnant women, developmental defects of the embryo
D (antirachitic factor)	Group of chemically distinct sterols; concentrated in liver and to lesser extent in skin, kidneys, spleen, other tissues; stable to heat, light, acids, alkalis, oxidation	Vitamin D_3 is chief form in body cells; produced in skin by irradiation of 7-dehydrocholesterol by UV light; active form (1,25-dihydroxyvitamin D_3) produced by chemical modification of vitamin D_3 in liver, then kidneys; major food sources: fish liver oils, egg yolk, fortified milk RDA: 5 µg	Functionally a hormone; increases calcium blood levels by enhancing absorption of calcium; with PTH mobilizes calcium from bones; both mechanisms serve calcium homeostasis of blood (essential for normal neuromuscular function, blood clotting, bone and tooth formation)	22–25 µg/day may be toxic to children, massive doses induce toxicity in adults; symptoms: vomiting, diarrhea, fatigue, weight loss, hypercalcemia and calcification of soft tissues, irreversible cardiac and renal damage	Faulty mineralization of bones and teeth; rickets in children, osteomalacia in adults; poor muscle tone and leg weakness; restlessness, irritability

TABLE 24.2 *(continued)*

VITAMIN	DESCRIPTION, COMMENTS	SOURCES AND RECOMMENDED DAILY AMOUNTS (RDA) FOR ADULTS	IMPORTANCE IN BODY	*PROBLEMS* EXCESSES	*PROBLEMS* DEFICITS
E (antisterility factor)	Group of related compounds called tocopherols, chemically related to sex hormones; stored primarily in muscle and adipose tissues; resistant to heat, light, acids; unstable in presence of oxygen	Wheat germ and vegetable oils, nuts, whole grains, dark-green leafy vegetables RDA: 15 mg (actual RDA depends on diet; high-fat diet requires a higher RDA)	An antioxidant that disarms free radicals; helps prevent oxidation of unsaturated fatty acids and cholesterol, thus helps prevent oxidative damage to cell membranes and atherosclerosis	Few side effects even at massive doses; slow wound healing; decreased platelet adhesion and increased clotting time	Extremely rare, precise effects uncertain: possible decreased life span and hemolysis of RBCs, fragile capillaries; spinocerebellar degeneration
K (coagulation vitamin)	Number of related compounds known as quinones; small amounts stored in liver; heat resistant; destroyed by acids, alkalis, light, oxidizing agents; antagonized by certain anticoagulants and antibiotics that interfere with synthetic activity of enteric bacteria	Most synthesized by bacteria in large intestine; food sources: leafy green vegetables, broccoli, cabbage, cauliflower, pork, liver RDA: males 120 µg, females 90 µg; obtaining adequate amount is not a problem	Essential for formation of clotting proteins and some other proteins made by liver; as intermediate in electron transport chain, participates in oxidative phosphorylation in all body cells	None known, not stored in appreciable amounts	Easy bruising and bleeding (prolonged clotting time)
WATER-SOLUBLE VITAMINS					
C (ascorbic acid)	Simple 6-carbon crystalline compound derived from glucose; rapidly destroyed by heat, light, alkalis; about 1500 mg is stored in body, particularly in adrenal gland, retina, intestine, pituitary; when tissues are saturated, excess excreted by kidneys	Fruits and vegetables, particularly citrus, cantaloupe, strawberries, tomatoes, fresh potatoes, leafy green vegetables RDA: 75 mg for females, 90 mg for males, and an extra 35 mg for those who smoke	Antioxidant; acts in hydroxylation reactions in connective tissue formation, in conversion of tryptophan to serotonin and of cholesterol to bile salts; enhances iron absorption and use; required for activation of folacin (a B vitamin)	Result of megadoses (10 or more times RDA); diarrhea; enhanced mobilization of bone minerals and blood coagulation; high uric acid levels and exacerbation of gout, kidney stone formation	Defective formation of intercellular cement; joint pains, poor tooth and bone growth; poor wound healing, increased susceptibility to infection; extreme deficit causes scurvy (bleeding gums, anemia, degeneration of muscle and cartilage, weight loss)
B_1 (thiamin)	Rapidly destroyed by heat; very limited amount stored in body; excess eliminated in urine	Lean meats, liver, fish, eggs, whole grains, leafy green vegetables, legumes RDA: 1.2 mg	Part of coenzyme cocarboxylase, which acts in carbohydrate metabolism; required for transformation of pyruvic acid to acetyl CoA, for synthesis of pentose sugars and acetylcholine; for oxidation of alcohol	None known	Beriberi; decreased appetite, vision disturbances; unsteadiness when standing or walking, confusion, loss of memory; profound fatigue; heart enlargement, tachycardia

TABLE 24.2 **Vitamins** *(continued)*

VITAMIN	DESCRIPTION, COMMENTS	SOURCES AND RECOMMENDED DAILY AMOUNTS (RDA) FOR ADULTS	IMPORTANCE IN BODY	PROBLEMS: EXCESSES	PROBLEMS: DEFICITS
WATER-SOLUBLE VITAMINS *(continued)*					
B_2 (riboflavin)	Named for its similarity to ribose sugar: has green-yellow fluorescence; quickly decomposed by UV, visible light, alkalis; body stores are carefully guarded; excess eliminated in urine	Widely varying sources such as liver, yeast, egg white, whole grains, meat, poultry, fish, legumes; major source is milk RDA: 1.1–1.3 mg	Present in body as coenzymes FAD and FMN (flavin mononucleotide), which act as hydrogen acceptors in body; also is component of amino acid oxidases	None known	Dermatitis; cracking of lips at corners (cheilosis); lips and tongue become purple-red and shiny; ocular problems: light sensitivity, blurred vision; one of the most common vitamin deficiencies
B_3 (niacin, nicotinamide)	Simple organic compounds stable to acids, alkalis, heat, light, oxidation (even boiling does not decrease potency); very limited amount stored in body, day-to-day supply is desirable; excess secreted in urine	Diets with adequate protein usually provide adequate niacin because amino acid tryptophan is easily converted to niacin; preformed niacin provided by poultry, meat, fish; less important sources: liver, yeast, peanuts, potatoes, leafy green vegetables RDA: 16 mg males; 14 mg females	Constituent of NAD^+ (nicotinamide adenine dinucleotide) coenzyme involved in glycolysis, oxidative phosphorylation, fat breakdown, DNA repair, transcriptional regulation; inhibits cholesterol synthesis; peripheral vascular dilator	Result of megadoses; hyperglycemia; vasodilation leading to flushing of skin, tingling sensations; possible liver damage; gout	Pellagra after months of deprivation (rare in U.S.); early signs—listlessness, headache, loss of appetite—progress to sore tongue and lips, nausea, vomiting, diarrhea, skin rough and ulcerated, neurological symptoms; characterized by the 4 Ds: dermatitis, diarrhea, dementia, and death (in final stage)
B_6 (pyridoxine)	Group of three pyridines occurring in both free and phosphorylated forms in body; stable to heat, acids; destroyed by alkalis, light; body stores very limited	Meat, poultry, fish, whole grains, bananas; less important sources: potatoes, sweet potatoes, tomatoes, spinach RDA: 1.3 mg	Active form is coenzyme pyridoxal phosphate, which functions with several enzymes involved in amino acid metabolism; required for conversion of tryptophan to niacin, for glycogenolysis, for formation of antibodies and hemoglobin, and for breakdown of homocysteine	Depressed deep tendon reflexes, numbness and loss of sensation in extremities; difficulty walking; nerve damage	Infants: nervous irritability, convulsions, anemia, vomiting, weakness, abdominal pain; adults: seborrhea lesions around eyes and mouth; increased risk of heart disease
B_5 (pantothenic acid)	Quite stable, little loss of activity with cooking except in acidic or alkaline solutions; liver, kidneys, brain, adrenal, heart tissues contain large amounts	Name derived from Greek *panthos* meaning "everywhere"; widely distributed in animal foods, whole grains, legumes; liver, yeast, egg yolk, meat especially good sources; some produced by enteric bacteria RDA: 5 mg	Functions in form of coenzyme A in reactions that remove or transfer acetyl group, e.g., formation of acetyl CoA from pyruvic acid, oxidation and synthesis of fatty acids; also involved in synthesis of steroids and heme of hemoglobin	None known	Symptoms vague: loss of appetite, abdominal pain, mental depression, pains in arms and legs, muscle spasms, neuromuscular degeneration (neuropathy of alcoholics is thought to be related to deficits)

TABLE 24.2 *(continued)*

VITAMIN	DESCRIPTION, COMMENTS	SOURCES AND RECOMMENDED DAILY AMOUNTS (RDA) FOR ADULTS	IMPORTANCE IN BODY	PROBLEMS	
				EXCESSES	DEFICITS
Biotin	Urea derivative containing sulfur; crystalline in its free form; stable to heat, light, acids; in tissues, is usually combined with protein; stored in minute amounts, particularly in liver, kidneys, brain, adrenal glands	Liver, egg yolk, legumes, nuts; some synthesized by bacteria in gastrointestinal tract RDA: not established, probably about 0.3 mg (assumed that formation of the vitamin by enteric bacteria provides far more than is needed)	Functions as coenzyme for a number of enzymes that catalyze carboxylation, decarboxylation, deamination reactions; essential for reactions of Krebs cycle, for formation of purines and nonessential amino acids, for use of amino acids for energy	None known	Scaly skin, muscle pains, pallor, anorexia, nausea, fatigue; elevated blood cholesterol levels
B_{12} (cyanocobalamin)	Most complex vitamin; contains cobalt; stable to heat; inactivated by light and strongly acidic or basic solutions; intrinsic factor required for transport across intestinal membrane; stored principally in liver; liver stores of 2000–3000 µg sufficient to provide body needs for 3–5 years	Liver, meat, poultry, fish, dairy foods except butter, eggs; not found in plant foods RDA: 2.4 µg	Functions as coenzyme in all cells, particularly in gastrointestinal tract, nervous system, and bone marrow; in bone marrow, acts in synthesis of DNA; when absent, erythrocytes do not divide but continue to enlarge; essential for synthesis of methionine and choline	None known	Pernicious anemia, signified by pallor, anorexia, dyspnea, weight loss, neurological disturbances; most cases reflect impaired absorption rather than actual deficit
Folic acid (folacin)	Pure vitamin is bright-yellow crystalline compound; stable to heat; easily oxidized in acidic solutions and light; stored mainly in liver	Liver, orange juice, deep-green vegetables, yeast, lean beef, eggs, veal, whole grains; synthesized by enteric bacteria RDA: 400 µg	Basis of coenzymes that act in synthesis of methionine and certain other amino acids, choline, DNA; essential for formation of red blood cells and for normal neural tube development in the embryo; helps breakdown of homocysteine	None known	Macrocytic or megaloblastic anemia; gastrointestinal disturbances; diarrhea; spina bifida risk in newborn; low birth weight and neurological deficits; increased risk of heart attack and stroke

Notes

1. Because vitamin D is present in natural foods in only very small amounts, infants, pregnant and lactating women, and people who have little exposure to sunlight should use vitamin D supplements (or supplemented foods, e.g., fortified milk).

2. Vitamins A and D are toxic in excessive amounts and should be used in supplementary form only when prescribed by a physician. Because most water-soluble vitamins are excreted in urine when ingested in excess, the effectiveness of taking supplements is questionable.

3. Many vitamin deficiencies are secondary to disease (including anorexia, vomiting, diarrhea, or malabsorption diseases) or reflect increased metabolic requirements due to fever or stress factors. Specific vitamin deficiencies require therapy with the vitamins that are lacking.

Fat-soluble vitamins (A, D, E, and K) bind to ingested lipids and are absorbed along with their digestion products. Anything that interferes with fat absorption also interferes with the uptake of fat-soluble vitamins. Except for vitamin K, fat-soluble vitamins are stored in the body, and pathologies due to fat-soluble vitamin toxicity, particularly vitamin A hypervitaminosis, are well documented clinically. Vitamin K is filtered out by the kidneys in modest amounts.

As described in the next section, metabolism uses oxygen, and during these reactions some potentially harmful free radicals are generated. Vitamins C, E, and A (in the form of its dimer beta-carotene) and the mineral selenium are *antioxidants* that neutralize tissue-damaging free radicals. The whole story of how antioxidants interact in the body is still murky, but chemists propose that they act much like a bucket brigade to pass the dangerous free electron from one molecule to the next, until it is finally absorbed by a chemical such as glutathione and flushed from the body in urine. Broccoli, cabbage, cauliflower, and brussels sprouts are all good sources of vitamins A and C and other chemicals that, collectively, appear to have anticancer effects.

Controversy abounds concerning the ability of vitamins to work wonders, such as the idea that huge doses of vitamin C will prevent colds. The notion that megadoses of vitamin supplements are the road to eternal youth and glowing health is useless at best and, at worst, may cause serious health problems, particularly in the case of fat-soluble vitamins. Table 24.2 contains an overview of the roles of vitamins in the body.

Minerals

The body requires moderate amounts of seven **minerals** (calcium, phosphorus, potassium, sulfur, sodium, chlorine, magnesium) and trace amounts of about a dozen others (Table 24.3). Minerals make up about 4% of the body by weight, with calcium and phosphorus (as bone salts) accounting for about three-quarters of this amount.

Minerals, like vitamins, are not used for fuel but work with other nutrients to ensure a smoothly

TABLE 24.3 Minerals

MINERAL	DISTRIBUTION IN BODY, COMMENTS	SOURCES AND RECOMMENDED DAILY AMOUNTS (RDA) FOR ADULTS	IMPORTANCE IN BODY	PROBLEMS	
				EXCESSES	DEFICITS
Calcium (Ca)	Most stored in salt form in bones; the most abundant cation in body; absorbed from intestine in presence of vitamin D; excess excreted in feces; blood levels regulated by PTH and calcitonin (during youth)	Milk, milk products, leafy green vegetables, egg yolk, shellfish RDA: 1300 mg, dropping to 1000 mg after age 25	In salt form, required for hardness of bones, teeth; ionic calcium in blood and cells essential for normal membrane permeability, transmission of nerve impulses, muscle contraction, normal heart rhythm, blood clotting; activates certain enzymes; helps prevent hypertension	Depressed neural function; lethargy and confusion; muscle pain and weakness; calcium salt deposit in soft tissues; kidney stones	Muscle tetany; osteomalacia, osteoporosis; retarded growth and rickets in children
Chlorine (Cl)	Exists in body almost entirely as chloride ion; principal anion of extracellular fluid; highest concentrations in cerebrospinal fluid and gastric juice; excreted in urine	Table salts (as for sodium); usually ingested in excess RDA: not established; normal diet contains 3–9 g	With sodium, helps maintain osmotic pressure and pH of extracellular fluid; required for HCl formation by stomach glands; activates salivary amylase; aids in transport of CO_2 by blood (chloride shift)	Vomiting	Severe vomiting or diarrhea leads to Cl loss and alkalosis; muscle cramps; apathy

TABLE 24.3 *(continued)*

MINERAL	DISTRIBUTION IN BODY, COMMENTS	SOURCES AND RECOMMENDED DAILY AMOUNTS (RDA) FOR ADULTS	IMPORTANCE IN BODY	PROBLEMS	
				EXCESSES	DEFICITS
Sulfur (S)	Widely distributed: particularly abundant in hair, skin, nails; excreted in urine	Meat, milk, eggs, legumes (all rich in sulfur-containing amino acids) RDA: not established; diet adequate in proteins meets body's needs	Essential constituent of many proteins (insulin), some vitamins (thiamin and biotin); found in mucopolysaccharides present in cartilage, tendons, bone	Not known	Not known
Potassium (K)	Principal intracellular cation, 97% within cells; fixed proportion of K is bound to proteins, and measurements of body K are used to determine lean body mass; K^+ leaves cells during protein catabolism, dehydration, glycogenolysis; most excreted in urine	Widely distributed in foods; normal diet provides 2–6 g/day; avocados, dried apricots, meat, fish, fowl, cereals RDA: not established; diet adequate in calories provides ample amount, i.e., 2500 mg	Helps maintain intracellular osmotic pressure; needed for normal nerve impulse conduction, muscle contraction, glycogenesis, protein synthesis	Usually a complication of renal failure or severe dehydration, but may result from severe alcoholism; paresthesias, muscular weakness, cardiac abnormalities	Rare but may result from diuretic therapy, severe diarrhea, or vomiting; muscular weakness, paralysis, nausea, vomiting, tachycardia, heart failure
Sodium (Na)	Widely distributed: 50% found in extracellular fluid, 40% in bone salts, 10% within cells; absorption is rapid and almost complete; excretion, chiefly in urine, controlled by aldosterone	Table salt (1 tsp = 2000 mg); cured meats (ham, etc.), sauerkraut, cheese; diet supplies substantial excess RDA: not established; probably about 2500 mg	Most abundant cation in extracellular fluid: principal electrolyte maintaining osmotic pressure of extracellular fluids and water balance; as part of bicarbonate buffer system, aids in acid-base balance of blood; needed for normal neuromuscular function; part of pump for transport of glucose and other nutrients	Hypertension; edema	Rare but can occur with excessive vomiting, diarrhea, sweating, or poor dietary intake; nausea, abdominal and muscle cramping, convulsions
Magnesium (Mg)	In all cells, particularly abundant in bones; absorption parallels that of calcium; excreted chiefly in urine	Milk, dairy products, whole-grain cereals, nuts, legumes, leafy green vegetables RDA: 400 mg for males; 320 mg for females	Constituent of many coenzymes that play a role in conversion of ATP to ADP; required for normal muscle and nerve irritability	Diarrhea	Neuromuscular problems, tremors, muscle weakness, irregular heartbeat; vasospasm and hypertension; sudden cardiac death; seen in alcoholism, severe renal disease, prolonged diarrhea, and with diuretic drugs

TABLE 24.3 **Minerals** *(continued)*

MINERAL	DISTRIBUTION IN BODY, COMMENTS	SOURCES AND RECOMMENDED DAILY AMOUNTS (RDA) FOR ADULTS	IMPORTANCE IN BODY	PROBLEMS	
				EXCESSES	DEFICITS
Phosphorus (P)	About 80% found in inorganic salts of bones, teeth; remainder in muscle, nervous tissue, blood; absorption aided by vitamin D; about 1/3 dietary intake excreted in feces; metabolic byproducts excreted in urine	Diets rich in proteins are usually rich in phosphorus; plentiful in milk, eggs, meat, fish, poultry, legumes, nuts, whole grains RDA: 700 mg	Component of bones and teeth, nucleic acids, proteins, phospholipids, ATP, phosphates (buffers) of body fluids; thus, important for energy storage and transfer, muscle and nerve activity, cell permeability	Not known, but excess in diet may depress absorption of iron and manganese	Rickets, poor growth
TRACE MINERALS*					
Fluorine (F)	Component of bones, teeth, other body tissues; excreted in urine	Fluoridated water RDA: 3–4 mg	Important for tooth structure; may help prevent dental caries (particularly in children) and osteoporosis in adults	Mottling of teeth	Not known
Cobalt (Co)	Found in all cells; larger amounts in bone marrow	Liver, lean meat, poultry, fish, milk RDA: not established	A constituent of vitamin B_{12}, which is needed for normal maturation of red blood cells	Goiter, polycythemia, heart disease	See deficit of vitamin B_{12} (Table 24.2)
Chromium (Cr)	Widely distributed	Liver, meat, cheese, whole grains, brewer's yeast, wine RDA: 35 µg for males; 25 µg for females	Required for synthesis of glucose tolerance factor (GTF) needed for proper glucose metabolism; enhances effectiveness of insulin on carbohydrate metabolism; may increase blood levels of HDLs while decreasing levels of LDLs	Not known	Impairs ability of insulin to work, hence increases insulin secretion and risk of adult-onset diabetes mellitus
Copper (Cu)	Concentrated in liver, heart, brain, spleen; excreted in feces	Liver, shellfish, whole grains, legumes, meat; typical diet provides 2–5 mg daily RDA: 900 µg	Required for synthesis of hemoglobin; essential for manufacture of melanin, myelin, some intermediates of electron transport chain	Rare; abnormal storage in Wilson's disease	Rare

*Trace minerals together account for less than 0.005% of body weight.

TABLE 24.3 *(continued)*

MINERAL	DISTRIBUTION IN BODY, COMMENTS	SOURCES AND RECOMMENDED DAILY AMOUNTS (RDA) FOR ADULTS	IMPORTANCE IN BODY	PROBLEMS	
				EXCESSES	DEFICITS
Iodine (I)	Found in all tissues, but in high concentrations only in thyroid gland; absorption controlled by blood levels of protein-bound iodine; excreted in urine	Cod liver oil, iodized salt, shellfish, vegetables grown in iodine-rich soil RDA: 150 µg	Required to form thyroid hormones (T_3 and T_4), which are important in regulating cellular metabolic rate	Depressed synthesis of thyroid hormones	Hypothyroidism: cretinism in infants, myxedema in adults (if less severe, simple goiter); impaired learning and motivation in children
Iron (Fe)	60–70% in hemoglobin; remainder in skeletal muscle, liver, spleen, bone marrow bound to ferritin; only 2–10% of dietary iron is absorbed because of mucosal barrier; lost from body in urine, perspiration, menstrual flow, shed hair, sloughed skin and mucosal cells	Best sources: meat, liver, also in shellfish, egg yolk, dried fruit, nuts, legumes, molasses RDA: males 8 mg, females 15–18 mg	Part of heme of hemoglobin, which binds bulk of oxygen transported in blood; component of cytochromes, which function in oxidative phosphorylation	Hemochromatosis (inherited condition of iron excess); damage to liver (cirrhosis and liver cancer), heart, pancreas (causing diabetes)	Iron-deficiency anemia; pallor, lethargy, flatulence, anorexia, paresthesias, impaired cognitive performance in children; inability to maintain body temperature; depressed killing by phagocytes (due to inability to produce the respiratory burst)
Manganese (Mn)	Most concentrated in liver, kidneys, spleen; excreted largely in feces	Nuts, legumes, whole grains, leafy green vegetables, fruit RDA: 1.8–2.3 mg	Acts with enzymes catalyzing synthesis of fatty acids, cholesterol, urea, hemoglobin; needed for normal neural function, lactation, oxidation of carbohydrates, protein hydrolysis	Appears to contribute to obsessive behavior, hallucinations, and violent behavior	Not known
Selenium (Se)	Stored in liver, kidneys	Meat, seafood, cereals RDA: 55 µg	Antioxidant; constituent of certain enzymes; spares vitamin E	Nausea, vomiting, irritability, fatigue, weight loss, loss of hair	Oxidative damage
Zinc (Zn)	Concentrated in liver, kidneys, brain; excreted in feces	Seafood, meat, cereals, legumes, nuts, wheat germ, yeast RDA: 11 mg for males; 8 mg for females	Constituent of several enzymes (e.g., carbonic anhydrase); plays a structural role in a variety of proteins (e.g., transcription factors and tumor suppressor protein p53); required for normal growth, wound healing, taste, smell, sperm production	Difficulty in walking; slurred speech; tremors; interferes with body's ability to absorb copper, which can lead to weakened immunity	Loss of taste and smell; growth retardation; learning impairment; depressed immunity

functioning body. Incorporation of minerals into structures gives added strength. For example, calcium, phosphorus, and magnesium salts harden the teeth and strengthen the skeleton. Most minerals are ionized in body fluids or bound to organic compounds to form phospholipids, hormones, enzymes, and other functional proteins. For example, iron is essential to the oxygen-binding heme of hemoglobin, and sodium and chloride ions are the major electrolytes in blood. The amount of a particular mineral in the body gives very few clues to its importance in body function—just a few milligrams of iodine (required for thyroid hormone synthesis) can make a critical difference to health.

A fine balance between uptake and excretion is crucial for retaining needed amounts of minerals while preventing toxic overload. The sodium present in virtually all natural and minimally processed foods poses little or no health risk. However, the large amounts added to processed foods and that sprinkled on prior to eating may contribute to fluid retention and high blood pressure. This is particularly true in American blacks, whose kidneys have a greater tendency to retain salt than do those of American whites.

Fats and sugars are practically devoid of minerals, and highly refined cereals and grains are poor sources. The most mineral-rich foods are vegetables, legumes, milk, and some meats.

Metabolism

Overview

Once inside body cells, nutrients become involved in an incredible variety of biochemical reactions known collectively as **metabolism** (*metabol* = change). During metabolism, substances are constantly being built up and torn down. Cells use energy to extract more energy from foods, and then use some of this extracted energy to drive their activities. Even at rest, the body uses energy on a grand scale.

Anabolism and Catabolism

Metabolic processes are either *anabolic* (synthetic, building up) or *catabolic* (degradative, tearing down). **Anabolism** (ah-nab'o-lizm) is the general term for all reactions in which larger molecules or structures are built from smaller ones; for example, the bonding together of amino acids to make proteins. **Catabolism** (kah-tab'o-lizm) refers to all processes that break down complex structures to simpler ones, one example being hydrolysis of foods in the digestive tract. In the group of catabolic reactions collectively called **cellular respiration,** food fuels, particularly glucose, are broken down in cells and some of the energy released is captured to form ATP, the cells' energy currency. ATP then serves as the "chemical drive shaft" that links energy-releasing catabolic reactions to cellular work.

Recall from Chapter 2 that reactions driven by ATP are coupled. ATP is never hydrolyzed directly. Instead enzymes shift its high-energy phosphate groups to other molecules, which are then said to be **phosphorylated** (fos"for-ĭ-la'ted). Phosphorylation primes the molecule to change in a way that increases its activity, produces motion, or does work. For example, many regulatory enzymes that catalyze key steps in metabolic pathways are activated by phosphorylation.

Three major stages are involved in the processing of energy-containing nutrients in the body (Figure 24.3):

- Stage 1 is digestion in the gastrointestinal tract, described in Chapter 23. The absorbed nutrients are then transported in blood to the tissue cells.
- In stage 2, which occurs in the cell cytoplasm, newly delivered nutrients are either built into lipids, proteins, and glycogen by anabolic pathways or broken down by catabolic pathways to *pyruvic acid* (pi-roo'vik) and *acetyl CoA* (as'ĕ-til ko-a').
- Stage 3, which is almost entirely catabolic, occurs in the mitochondria, requires oxygen, and completes the breakdown of foods, producing carbon dioxide and water and harvesting large amounts of ATP.

The primary function of *cellular respiration,* which consists of glycolysis of stage 2 and all events of stage 3, is to generate ATP, which traps some of the chemical energy of the original food molecules in its own high-energy bonds. Thus, food fuels, such as glycogen and fats, *store* energy in the body, and these stores are later *mobilized to produce ATP for cellular use.*

You do not need to memorize Figure 24.3, but as you will soon see, it provides a cohesive summary of nutrient processing and metabolism in the body.

Oxidation-Reduction Reactions and the Role of Coenzymes

Many of the reactions that take place within cells are **oxidation reactions.** *Oxidation* was originally defined as the combination of oxygen with other elements. Examples are the rusting of iron (the slow formation of iron oxide) and the burning of wood and other fuels. In burning, oxygen combines rapidly with carbon, producing carbon dioxide, water, and an enormous amount of energy, which is liberated as heat and light. Later it was discovered that oxidation *also* occurs when hydrogen atoms are *removed* from compounds and so the definition was expanded to its current form: *Oxidation is the gain of oxygen or the loss of hydrogen.* As explained in Chapter 2, whichever way oxidation occurs, the oxidized substance always *loses* (or nearly loses) electrons as they move to (or toward) a substance that more strongly attracts them.

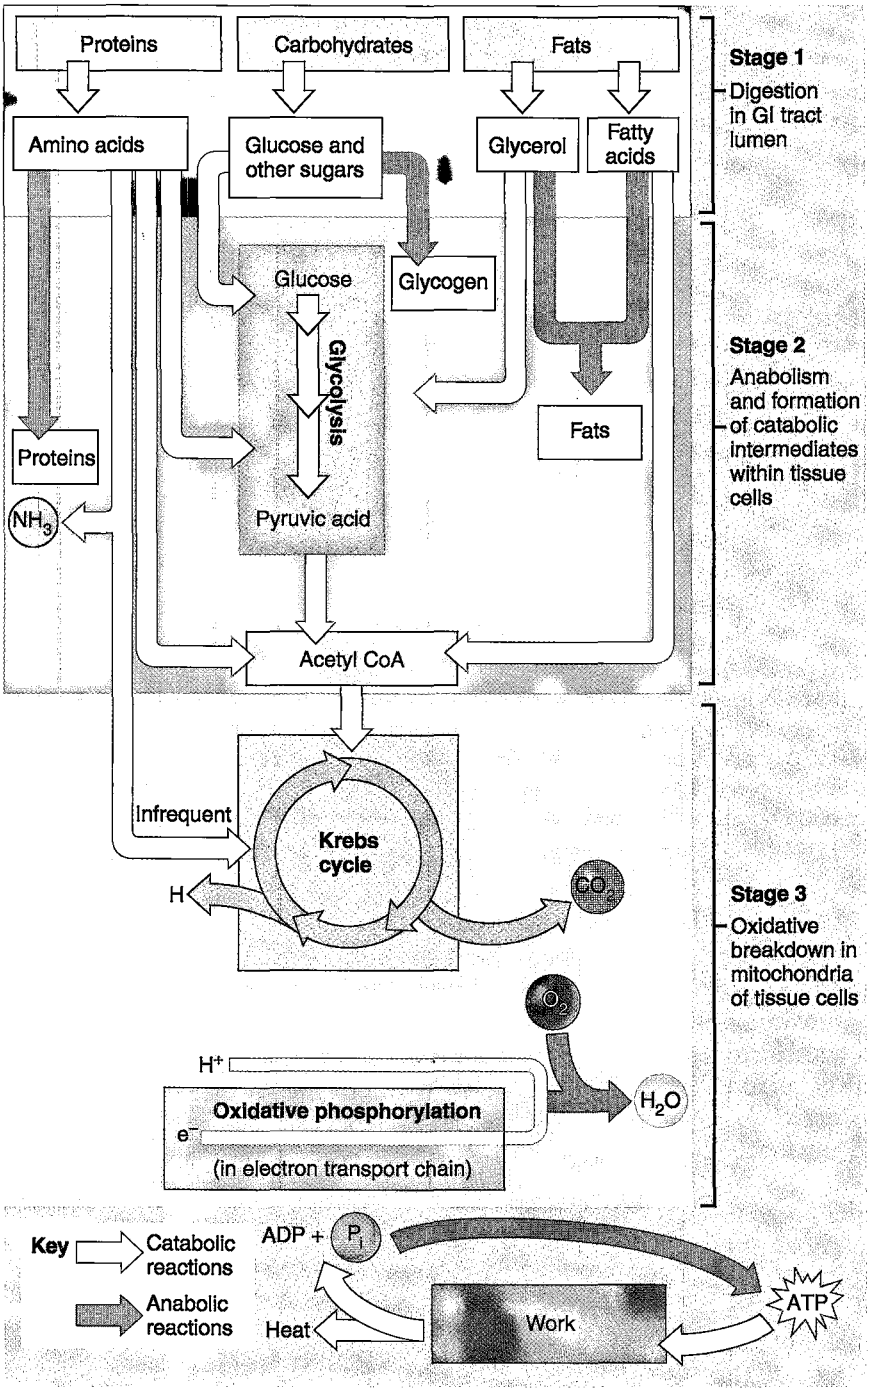


FIGURE 24.3 **Three stages of metabolism of energy-containing nutrients.** In stage 1, foods are degraded to absorbable forms by digestive enzymes in the GI tract.

In stage 2, the absorbed nutrients are transported in blood to the body cells, where they may be incorporated into molecules (anabolism) or broken down via glycolysis and other reactions to pyruvic acid and/or acetyl CoA, and then funneled into the pathways of stage 3.

Stage 3 consists of the catabolic pathways of the Krebs cycle and oxidative phosphorylation, both of which take place in the mitochondria. During the Krebs cycle, acetyl CoA is broken apart: Its carbon atoms are liberated as carbon dioxide (CO_2), and the hydrogen atoms removed are delivered to a chain of receptors (the electron transport chain), which ultimately delivers them (as protons and free electrons) to molecular oxygen so that water is formed. Some of the energy released during the electron transport chain reactions is used to form ATP. Stages 2 and 3 collectively constitute cellular respiration.

This loss of electrons can be explained by reviewing the consequences of different electron-attracting abilities of atoms (see p. 33). Consider a molecule made up of a hydrogen atom plus some other kinds of atoms. Because hydrogen is very electropositive, its lone electron usually spends more time orbiting the other atoms of the molecule. But when a hydrogen *atom* is removed, its electron goes with it, and the molecule as a whole loses that electron. Conversely, oxygen is very electron-hungry (electronegative), and so when oxygen binds with other atoms the shared electrons spend more time in oxygen's vicinity. Again, the molecule as a whole loses electrons. As you will soon see, essentially all oxidation of food fuels involves the step-by-step removal of pairs of hydrogen atoms (and thus pairs of electrons) from the substrate molecules, eventually leaving only carbon dioxide (CO_2). Molecular oxygen (O_2) is the *final* electron acceptor. It combines with the removed hydrogen atoms at the very end of the process, to form water (H_2O).

Whenever one substance loses electrons (is oxidized), another substance gains them (is reduced). Thus, oxidation and reduction are coupled reactions and we speak of **oxidation-reduction reactions,** or

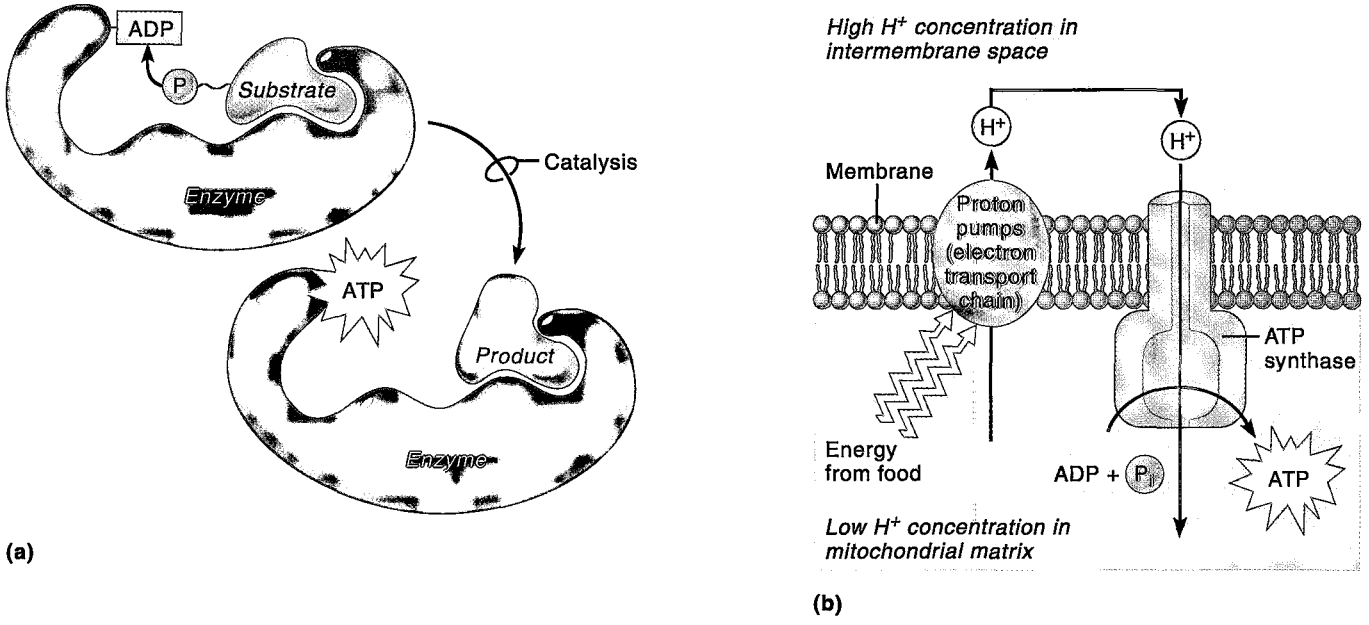

FIGURE 24.4 **Mechanisms of phosphorylation. (a)** Substrate-level phosphorylation occurs when a high-energy phosphate group is transferred directly from a substrate to ADP to form ATP. This reaction occurs both in the cytoplasm and in the mitochondrial matrix. **(b)** Oxidative phosphorylation, which occurs in mitochondria, reflects the activity of electron transport proteins that act as proton "pumps" to create a proton gradient across the cristae membranes. The source of energy for this pumping is energy released during oxidation of food molecules. As the protons flow passively back into the mitochondrial fluid matrix, the energy of the electrochemical gradient is used to bind phosphate groups to ADP.

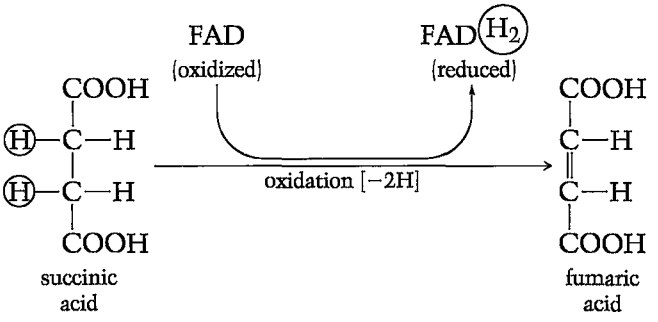
more commonly, **redox reactions.** The key understanding about redox reactions is that "oxidized" substances *lose* energy and "reduced" substances *gain* energy as energy-rich electrons are transferred from the former to the latter. Consequently, as food fuels are oxidized, their energy is transferred to a "bucket brigade" of other molecules and ultimately to ADP to form energy-rich ATP.

Like all other chemical reactions in the body, redox reactions are catalyzed by enzymes. Those that catalyze redox reactions in which hydrogen atoms are removed are called **dehydrogenases** (de-hi'dro-jen-ās"ez), while those catalyzing the transfer of oxygen are **oxidases.** Most of these enzymes require the help of a specific coenzyme, typically derived from one of the B vitamins. Although the enzymes catalyze the removal of hydrogen atoms to oxidize a substance, they cannot *accept* the hydrogen (hold on or bond to it). Their *coenzymes,* however, act as hydrogen (or electron) acceptors, becoming reduced each time a substrate is oxidized. Two very important coenzymes of the oxidative pathways are **nicotinamide adenine dinucleotide (NAD$^+$)** (nik"o-tin'ah-mīd), based on *niacin,* and **flavin adenine dinucleotide (FAD),** derived from *riboflavin.* The oxidation of succinic acid to fumaric acid and the simultaneous reduction of FAD to $FADH_2$, an example of a coupled redox reaction, is



Mechanisms of ATP Synthesis

How do our cells capture some of the energy liberated during cellular respiration to make ATP molecules? There appear to be two mechanisms—substrate-level phosphorylation and oxidative phosphorylation.

Substrate-level phosphorylation occurs when high-energy phosphate groups are transferred directly from phosphorylated substrates (metabolic intermediates such as glyceraldehyde phosphate) to ADP (Figure 24.4a). Essentially, this process occurs because the high-energy bonds attaching the phosphate groups to the substrates are even more unstable than those in ATP. ATP is synthesized by this route during one of the steps in glycolysis, and once during

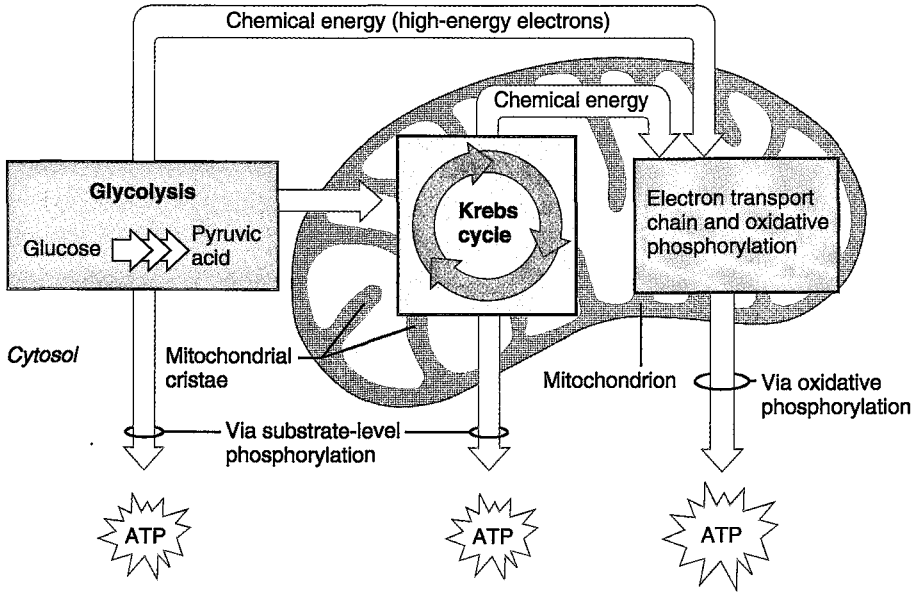


FIGURE 24.5 **Sites of ATP formation during cellular respiration.** Glycolysis occurs in the cytosol. The Krebs cycle and the electron transport chain reactions occur in the mitochondria. During glycolysis, each glucose molecule is broken down to two molecules of pyruvic acid. The pyruvic acid enters the mitochondrial matrix, where the Krebs cycle decomposes it to CO_2. During glycolysis and the Krebs cycle, small amounts of ATP are formed by substrate-level phosphorylation. Chemical energy from glycolysis and the Krebs cycle, in the form of energy-rich electrons picked up by coenzymes, is then transferred to the electron transport chain, which is built into the membrane of the cristae. The electron transport chain carries out oxidative phosphorylation, which accounts for most of the ATP generated by cellular respiration.

each turn of the Krebs cycle (Figure 24.5). The enzymes catalyzing substrate-level phosphorylations are located in both the cytoplasm and in the watery matrix inside the mitochondria.

Oxidative phosphorylation is much more complicated, but it also releases most of the energy that is eventually captured in ATP bonds during cellular respiration. This process, which is carried out by electron transport proteins forming part of the mitochondria cristae, is an example of a chemiosmotic process. **Chemiosmotic processes** couple the movement of substances across membranes to chemical reactions. In this case, some of the energy released during the oxidation of food fuels (the "chemi" part of the term) is used to pump (*osmo* = push) protons (H^+) across the cristae membrane into the intermembrane space (Figure 24.4b). This creates a steep concentration gradient for protons across the membrane. Then, when H^+ does flow back across the membrane (through a membrane channel protein called *ATP synthase*), some of this gradient energy is captured and used to attach phosphate groups to ADP.

Carbohydrate Metabolism

Because all food carbohydrates are eventually transformed to glucose, the story of carbohydrate metabolism is really a tale of glucose metabolism. Glucose enters the tissue cells by facilitated diffusion, a process that is greatly enhanced by insulin. Immediately upon entry into the cell, glucose is phosphorylated to *glucose-6-phosphate* by transfer of a phosphate group to its sixth carbon during a coupled reaction with ATP:

$$\text{Glucose} + \text{ATP} \rightarrow \text{glucose-6-PO}_4 + \text{ADP}$$

Most body cells lack the enzymes needed to reverse this reaction, so it effectively traps glucose inside the cells. Because glucose-6-phosphate is a *different* molecule from simple glucose, the reaction also keeps intracellular glucose levels low, maintaining a concentration gradient for glucose entry. Only intestinal mucosa cells, kidney tubule cells, and liver cells have the enzymes needed to reverse this phosphorylation reaction, which reflects their central roles in glucose uptake *and* release. The catabolic and anabolic pathways for carbohydrates all begin with glucose-6-phosphate.

Oxidation of Glucose

Glucose is the pivotal fuel molecule in the oxidative (ATP-producing) pathways. Glucose is catabolized via the reaction

$$\underset{\text{glucose}}{C_6H_{12}O_6} + \underset{\text{oxygen}}{6O_2} \rightarrow \underset{\text{water}}{6H_2O} + \underset{\text{carbon dioxide}}{6CO_2} + 38\ \text{ATP} + \text{heat}$$

This equation gives few hints that glucose breakdown is complex and involves three of the pathways included in Figures 24.3 and 24.5:

Q *What would happen in this pathway if O_2 were absent and NADH + H^+ could not transfer its "picked-up" hydrogens to pyruvic acid?*

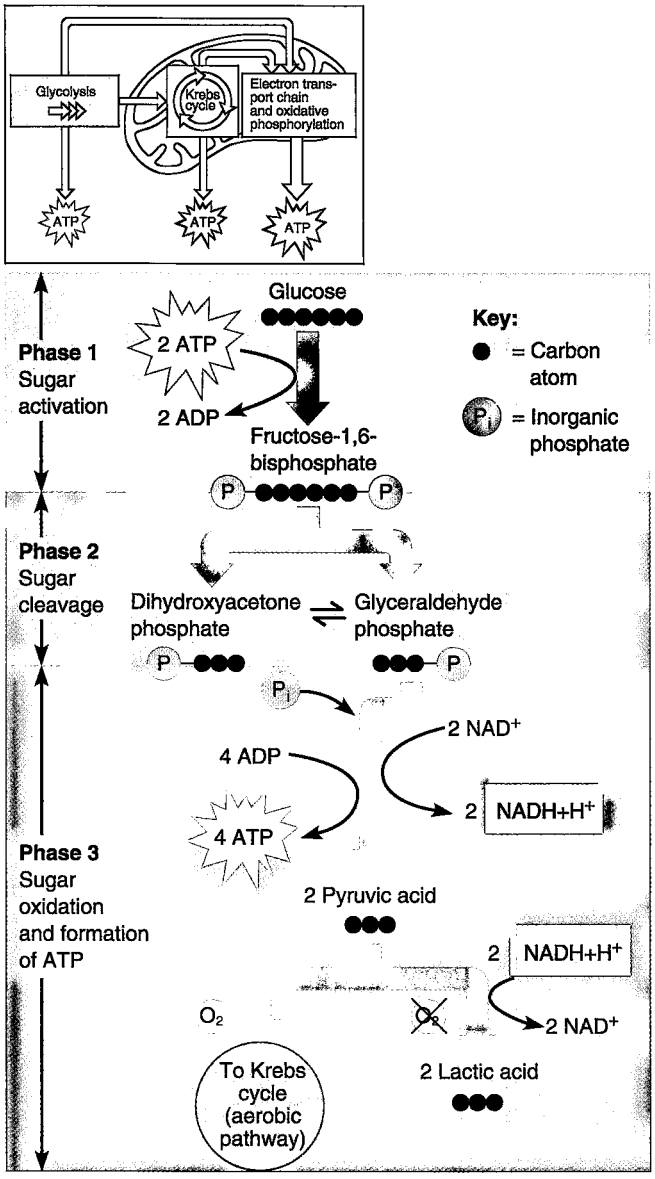

FIGURE 24.6 **The three major phases of glycolysis.** During phase 1, glucose is activated by phosphorylation and converted to fructose-1,6-bisphosphate. In phase 2, fructose-1,6-bisphosphate is cleaved into two 3-carbon fragments (reversible isomers). In phase 3, the 3-carbon fragments are oxidized (by removal of hydrogen) and 4 ATP molecules are formed. The fate of pyruvic acid depends on whether or not molecular O_2 is available.

A *Glycolysis would come to a halt because the oxidase enzyme cannot hold onto the H^+ removed during substrate oxidation. If all the coenzymes are already reduced and can't release hydrogen, the oxidase enzyme can't continue to function.*

1. Glycolysis (color-coded light orange throughout the chapter)
2. The Krebs cycle (color-coded pale-green)
3. The electron transport chain and oxidative phosphorylation (color-coded violet)

These metabolic pathways occur in a definite order, and we will consider them sequentially.

Glycolysis A series of ten chemical steps by which glucose is converted to two *pyruvic acid* molecules, **glycolysis** (gli-kol'ĭ-sis; "sugar splitting") occurs in the cytosol of cells. All steps except the first, during which glucose entering the cell is phosphorylated to glucose-6-phosphate, are fully *reversible.*

Glycolysis is an *anaerobic process* (an-a'er-ōb-ik; *an* = without, *aero* = air). Although this term is sometimes mistakenly interpreted to mean the pathway occurs only in the absence of oxygen, the correct interpretation is that glycolysis *does not use oxygen and occurs whether or not oxygen is present.* Figure 24.6 shows the three major phases of the glycolytic pathway. The complete glycolytic pathway appears in Appendix D.

1. Sugar activation. In phase 1, glucose is phosphorylated and converted to fructose-6-phosphate, which is then phosphorylated again. These three steps yield fructose-1,6-bisphosphate and use two ATP molecules. The two separate reactions of the sugar with ATP provide the *activation energy* needed to prime the later stages of the pathway—hence phase 1 is sometimes called the *energy investment phase.* (The importance of activation energy is described in Chapter 2.)

2. Sugar cleavage. During phase 2, fructose-1, 6-bisphosphate is split into two 3-carbon fragments that exist (reversibly) as one of two isomers: glyceraldehyde (glis"er-al'dĕ-hīd) 3-phosphate or dihydroxyacetone (dī"hi-drok"se-as'ĕ-tōn) phosphate.

3. Oxidation and ATP formation. In phase 3, consisting of six steps, two major events happen. First, the two 3-carbon fragments are oxidized by the removal of hydrogen, which is picked up by NAD^+. Hence, some of glucose's energy is transferred to NAD^+. Second, inorganic phosphate groups (P_i) are attached to each oxidized fragment by high-energy bonds. Later, as these terminal phosphates are cleaved off, enough energy is captured to form four ATP molecules. As noted earlier, formation of ATP this way is called *substrate-level phosphorylation.*

The final products of glycolysis are two molecules of **pyruvic acid** and two molecules of reduced NAD^+ (NADH + H^+),* with a net gain of two ATP molecules per glucose molecule. Four ATPs are produced,

*NAD carries a positive charge (NAD^+); thus, when it accepts the hydrogen pair, NADH + H^+ is the resulting reduced product.

but remember that two are consumed in phase 1 to "prime the pump." Each pyruvic acid molecule has the formula $C_3H_4O_3$, and glucose is $C_6H_{12}O_6$. Thus, between them the two pyruvic acid molecules have lost four hydrogen atoms, which are now bound to two molecules of NAD^+. Although a small amount of ATP has been harvested, the other two products of glucose oxidation (H_2O and CO_2) have yet to appear.

The fate of pyruvic acid, which still contains most of glucose's chemical energy, depends on the availability of oxygen at the time the pyruvic acid is produced. Because the supply of NAD^+ is limited, glycolysis can continue only if the reduced coenzymes (NADH + H^+) formed during glycolysis are relieved of their extra hydrogen. Only then can they continue to act as hydrogen acceptors. When oxygen is readily available, this is no problem. NADH + H^+ delivers its burden of hydrogen atoms to the enzymes of the electron transport chain in the mitochondria, which deliver them to O_2, forming water. However, when oxygen is not present in sufficient amounts, as might occur during strenuous exercise, NADH + H^+ unloads its hydrogen atoms *back onto pyruvic acid,* thus reducing it. This addition of two hydrogen atoms to pyruvic acid yields **lactic acid** (see bottom right of Figure 24.6), some of which diffuses out of the cells and is transported to the liver. When oxygen is again available, lactic acid is oxidized back to pyruvic acid and enters the **aerobic pathways** (the oxygen-requiring Krebs cycle and electron transport chain within the mitochondria), and is completely oxidized to water and carbon dioxide. The liver may also convert lactic acid all the way back to glucose-6-phosphate (reverse glycolysis) and then store it as glycogen or free it of its phosphate and release it to the blood if blood sugar levels are low.

Although glycolysis generates ATP rapidly, only 2 ATP molecules are produced per glucose molecule, as compared to the 38 ATP per glucose harvested when glucose is completely oxidized. Except for red blood cells (which typically carry out *only* glycolysis), prolonged anaerobic metabolism ultimately results in acid-base problems. Consequently, *totally* anaerobic conditions resulting in lactic acid formation provide only a temporary route for rapid ATP production. It can go on without tissue damage for the longest periods in skeletal muscle, for much shorter periods in cardiac muscle, and almost not at all in the brain.

Krebs Cycle Named after its discoverer Hans Krebs, the **Krebs cycle** is the next stage of glucose oxidation. The Krebs cycle occurs in the fluid mitochondrial matrix and is fueled largely by pyruvic acid produced during glycolysis and by fatty acids resulting from fat breakdown.

After pyruvic acid enters the mitochondria, the first order of business is a transitional phase that converts it to *acetyl CoA* via a three-step process (Figure 24.7):

1. **Decarboxylation,** in which one of pyruvic acid's carbons is removed and released as carbon dioxide gas. CO_2 diffuses out of the cells into the blood to be expelled by the lungs.
2. **Oxidation** by the removal of hydrogen atoms, which are picked up by NAD^+.
3. Combination of the resulting acetic acid with *coenzyme A* to produce the final product, **acetyl coenzyme A (acetyl CoA).** Coenzyme A (CoA-SH) is a sulfur-containing coenzyme derived from pantothenic acid, a B vitamin.

Acetyl CoA is now ready to enter the Krebs cycle and be broken down completely by mitochondrial enzymes. Coenzyme A shuttles the 2-carbon acetic acid to an enzyme that condenses it with a 4-carbon acid called **oxaloacetic acid** (ok"sah-lo"ah-sēt'ik) to produce the 6-carbon **citric acid.** Because citric acid is the first substrate of the cycle, biochemists prefer to call the Krebs cycle the **citric acid cycle.**

As the cycle moves through its eight successive steps, the atoms of citric acid are rearranged to produce different intermediate molecules, most called **keto acids.** The acetic acid that enters the cycle is broken apart carbon by carbon (decarboxylated) and oxidized, simultaneously generating NADH + H^+ and $FADH_2$. At the end of the cycle, acetic acid has been totally disposed of and oxaloacetic acid, the *pickup molecule,* is regenerated. Because two *decarboxylations* and four *oxidations* occur, the products of the Krebs cycle are two CO_2 molecules and four molecules of reduced coenzymes (3 NADH + H^+ and 1 $FADH_2$). The addition of water at certain steps accounts for some of the released hydrogen. One molecule of ATP is formed (via substrate-level phosphorylation) during each turn of the cycle. The detailed events of each of the eight steps of the Krebs cycle are described in Appendix D.

Now let's account for the pyruvic acid molecules entering the mitochondria. Each pyruvic acid yields three CO_2 molecules and five molecules of reduced coenzymes—1 $FADH_2$ and 4 NADH + H^+ (equal to the removal of 10 hydrogen atoms). The products of glucose oxidation in the Krebs cycle are twice that (remember 1 glucose = 2 pyruvic acids): six CO_2, ten molecules of reduced coenzymes, and two ATP molecules. Notice that it is these Krebs cycle reactions that produce the CO_2 evolved during glucose oxidation. The reduced coenzymes, which carry their extra electrons in high-energy linkages, must now be oxidized if the Krebs cycle and glycolysis are to continue.

Although the glycolytic pathway is exclusive to carbohydrate oxidation, breakdown products of carbohydrates, fats, and proteins can feed into the Krebs cycle to be oxidized for energy. On the other hand, some Krebs cycle intermediates can be siphoned off

Q *What two major kinds of chemical reactions occur in this cycle, and how are these reactions indicated symbolically?*

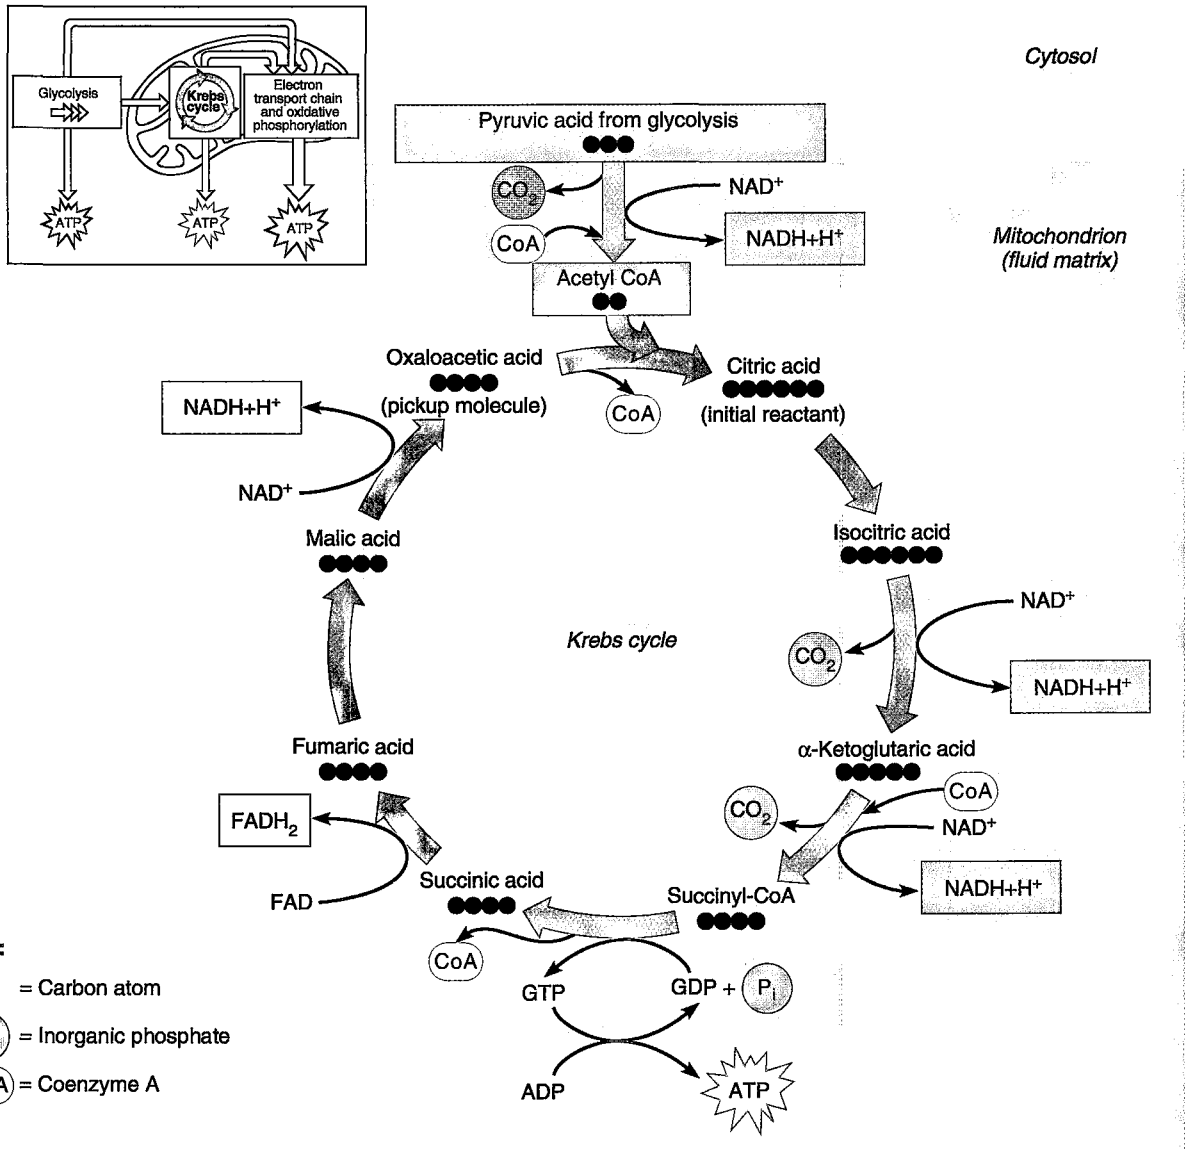

FIGURE 24.7 **Simplified version of the Krebs (citric acid) cycle.** During each turn of the cycle, two carbon atoms are removed from the substrates as CO_2 (decarboxylation reactions); four oxidations by removal of hydrogen atoms occur, producing four molecules of reduced coenzymes (3 NADH + H^+ and 1 $FADH_2$); and one ATP is synthesized by substrate-level phosphorylation. An additional decarboxylation and an oxidation reaction occur to convert pyruvic acid, the product of glycolysis, to acetyl CoA, the molecule that enters the Krebs cycle pathway.

▲ *Decarboxylation, shown as removal of CO_2, and oxidation, shown as reduction of coenzymes, e.g., $NAD^+ \rightarrow NADH + H^+$.*

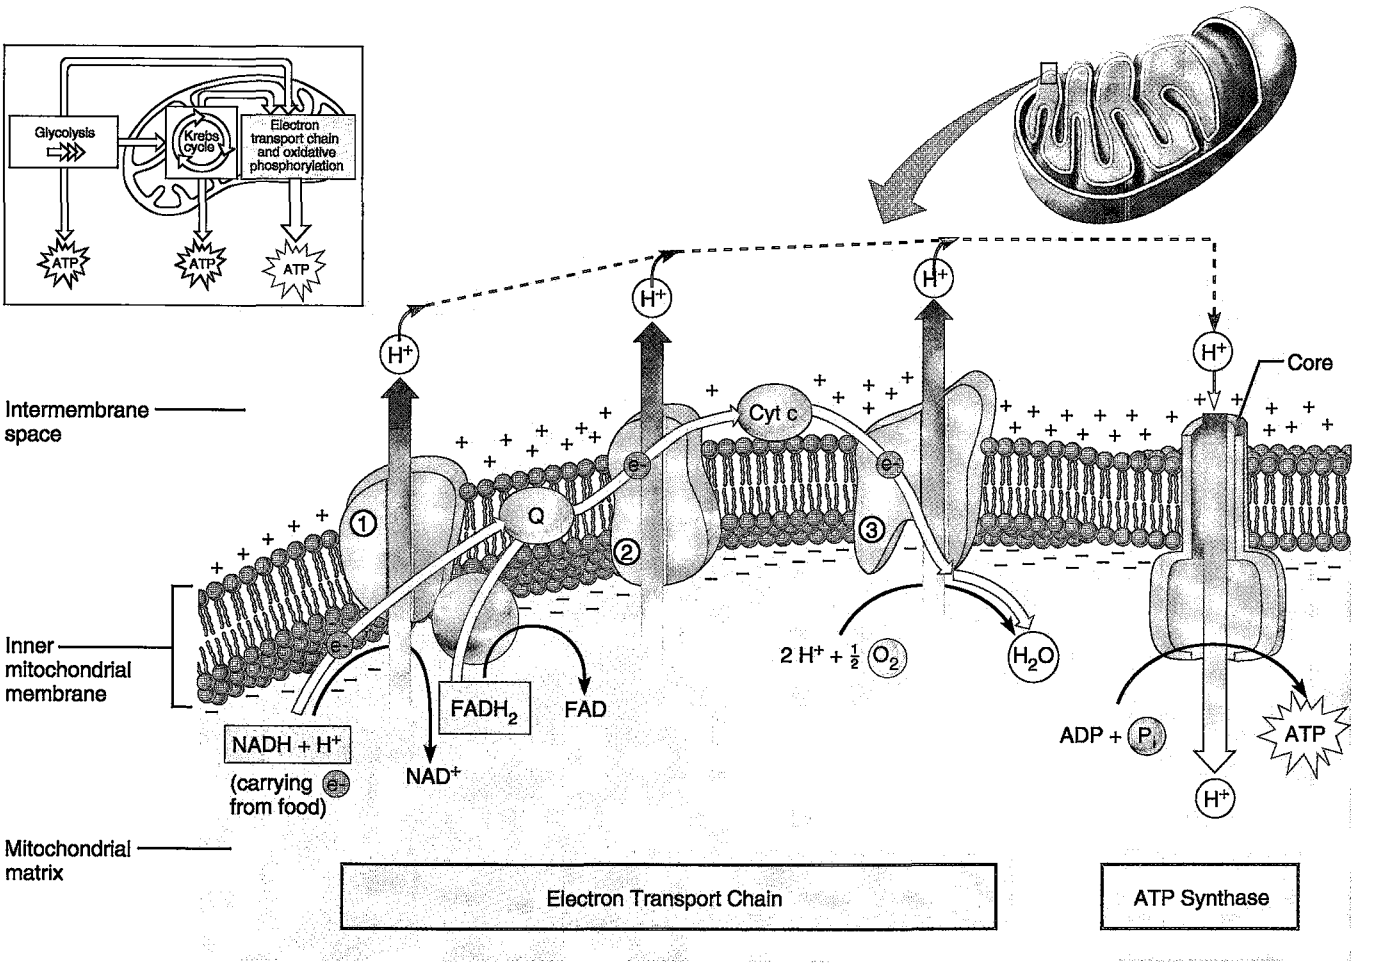

FIGURE 24.8 **Mechanism of oxidative phosphorylation.** Schematic diagram showing the flow of electrons through the three major respiratory enzyme complexes—① NADH dehydrogenase (FMN, Fe-S), ② cytochrome b-c_1, and ③ cytochrome oxidase (a-a_3)—of the electron transport chain during the transfer of two electrons from reduced NAD^+ to oxygen. Coenzyme Q (ubiquinone) and cytochrome c are mobile and act as carriers between the complexes.

The electron transport chain is an energy converter, transforming chemical energy to the energy of a H^+ gradient. As electrons flow along their energy gradient, some of the energy is used by each complex to pump H^+ from the mitochondrial matrix into the intermembrane space. These H^+ ions create an electrochemical proton gradient that drives them back across the inner membrane through the ATP synthase complex. ATP synthase uses the energy of H^+ flow (electrical energy) to synthesize ATP from ADP and P_i. Oxidation of each NADH + H^+ to NAD^+ yields 3 ATP. Because $FADH_2$ unloads its H atoms to coenzyme Q beyond the first respiratory complex, less energy (2 ATP) is captured as a result of its oxidation.

to make fatty acids and nonessential amino acids. Thus the Krebs cycle, besides serving as the final common pathway for the oxidation of food fuels, is a source of building materials for anabolic reactions.

Electron Transport Chain and Oxidative Phosphorylation Like glycolysis, none of the reactions of the Krebs cycle use oxygen directly. This is the exclusive function of the **electron transport chain,** which oversees the final catabolic reactions that occur on the mitochondrial cristae. However, because the reduced coenzymes produced in the Krebs cycle are the substrates for the electron transport chain, these pathways are coupled, and both phases are considered to be oxygen requiring (aerobic).

In the electron transport chain, the hydrogens removed during the oxidation of food fuels are combined with O_2, and the energy released during those reactions is harnessed to attach P_i groups to ADP. As noted earlier, this type of phosphorylation process is called *oxidative phosphorylation.* Let us peek under the hood of a cell's power plant and look more closely at this rather complicated process.

Most components of the electron transport chain are proteins that are bound to metal atoms *(cofactors).* These proteins, which form multiprotein complexes that are firmly embedded in the mitochondrial cristae membranes, vary in composition (Figure 24.8). For example, some of the proteins, the

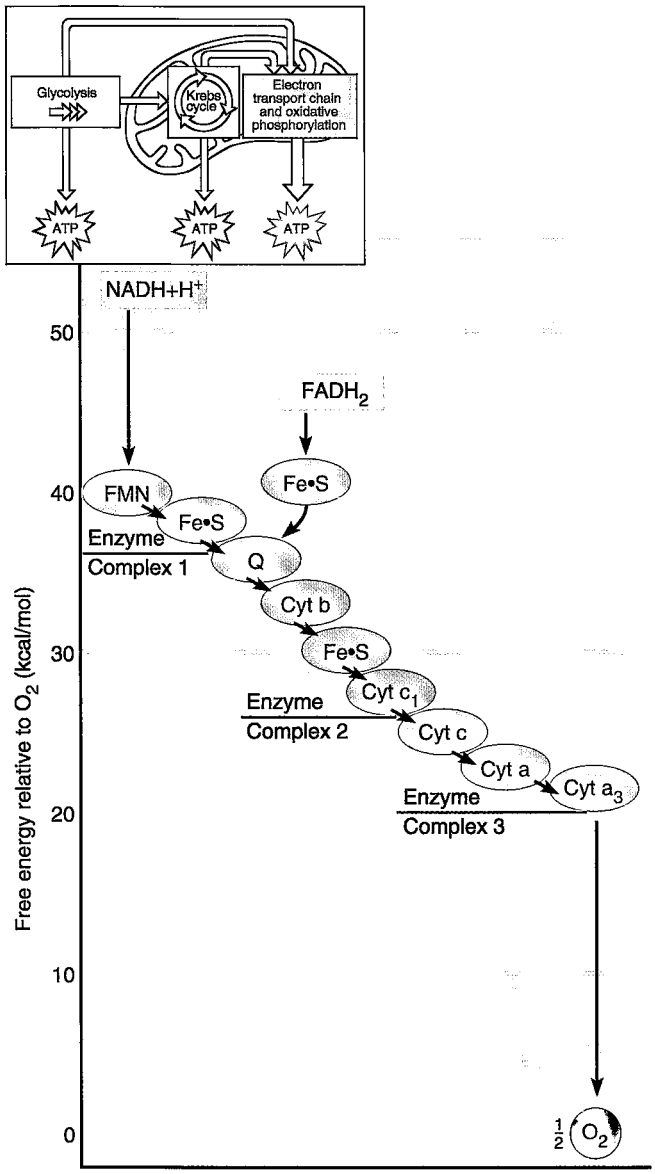

FIGURE 24.9 **Electronic energy gradient in the electron transport chain.** Each member of the chain (respiratory enzyme complex) oscillates between a reduced state and an oxidized state. A member becomes reduced by accepting electrons from its "uphill" neighbor and then reverts to its oxidized form as it passes electrons to its "downhill" neighbor (which has a greater affinity for the electrons). Oxygen, at the "bottom" of the chain, is *very* electronegative. The overall energy drop for electrons traveling from NADH to oxygen is 53 kcal/mol, but this fall is broken up into smaller steps by the electron transport chain.

flavins, contain flavin mononucleotide (FMN) derived from the vitamin riboflavin, and others contain both sulfur (S) and iron (Fe). Most, however, are brightly colored iron-containing pigments called **cytochromes** (si'to-krōmz; *cyto* = cell, *chrom* = color). Neighboring carriers are clustered together to form three major **respiratory enzyme complexes** that are alternately reduced and oxidized by picking up electrons and passing them on to the next complex in the sequence. The first such complex accepts hydrogen atoms from NADH + H^+, oxidizing it to NAD^+. $FADH_2$ transfers its hydrogen atoms slightly farther along the chain to coenzyme Q (also called ubiquinone). The hydrogen atoms delivered to the electron transport chain by the reduced coenzymes are quickly split into protons (H^+) plus electrons. The electrons are shuttled along the crista membrane from one acceptor to the next, losing energy with each transfer. The protons escape into the watery matrix only to be picked up and deposited ("pumped") across the crista membrane into the intermembrane space by one of the three major respiratory enzyme complexes. Ultimately the electron pairs are delivered to half a molecule of O_2 (in other words, to an oxygen atom), creating oxygen ions (O^-) that strongly attract H^+ and form water as indicated by the reaction

$$2H^+ + 2e^- + \tfrac{1}{2}O_2 \rightarrow H_2O$$

Virtually all the water resulting from glucose oxidation is formed during oxidative phosphorylation. Because NADH + H^+ and $FADH_2$ are oxidized as they release their burden of picked-up hydrogen atoms, the net reaction for the electron transport chain is

$$\underset{\text{reduced coenzyme}}{\text{Coenzyme-2H}} + \tfrac{1}{2}O_2 \rightarrow \underset{\text{oxidized coenzyme}}{\text{coenzyme}} + H_2O$$

The transfer of electrons from NADH + H^+ to oxygen releases large amounts of energy. If hydrogen combined directly with molecular oxygen, the energy would be released in one big burst and most of it would be lost to the environment as heat. Instead energy is released in many small steps as the electrons stream from one electron acceptor to the next. Each successive carrier has a greater affinity for electrons than those preceding it. Therefore, the electrons cascade "downhill" from NADH + H^+ to progressively lower energy levels until they are finally delivered to oxygen, which has the greatest affinity of all for electrons (Figure 24.9). You could say that oxygen "pulls" the electrons down the chain.

By using the stepwise release of electronic energy to pump protons from the matrix into the intermembrane space, the electron transport chain functions as an energy converter. Because the crista membrane is nearly impermeable to H^+, this chemiosmotic process creates an **electrochemical proton (H^+) gradient** across that membrane that has potential energy. This energy source is referred to as *proton motive force* to emphasize the capacity of the gradient to do work.

The proton gradient (1) creates a pH gradient, with the H^+ concentration in the matrix much lower than that in the intermembrane space; and (2) generates a voltage across the membrane that is negative on the matrix side and positive between the mitochondrial membranes. Both conditions strongly attract H^+ back into the matrix. However, the only areas of the membrane freely permeable to H^+ are at large enzyme-protein complexes called **ATP synthases,** which lay claim to being nature's smallest rotary motors. As the protons take this "route" they create an electrical current, and ATP synthase harnesses this electrical energy to catalyze attachment of a phosphate group to ADP to form ATP (Figure 24.8). The enzyme's subunits appear to work together like gears. As the ATP synthase core rotates, ADP and inorganic phosphate are pulled in and ATP is churned out, thus completing the process of oxidative phosphorylation.

Studies of the molecular structure of ATP synthase are providing an understanding of how it works (Figure 24.10). The enzyme complex consists of two major linked parts, each with several protein subunits: (1) F_0, a *rotor* embedded in the crista membrane, and (2) F_1, a *knob* extending into the mitochondrial matrix, with a *rod* connecting the two. The current created by the downhill flow of H^+ causes the rotor and rod to rotate, just as flowing water turns a water wheel. This rotation activates catalytic sites in the knob where ADP and P_i are combined to make ATP.

Notice something here. The ATP synthase works like an ion pump running in reverse. Recall from Chapter 3 that ion pumps use ATP as their energy source to transport ions against an electrochemical gradient. Here we have ATP synthases using the energy of a proton gradient to power ATP synthesis. The proton gradient also supplies energy to pump needed metabolites (ADP, pyruvic acid, inorganic phosphate) and calcium ions across the relatively impermeable crista membrane. The outer membrane is quite freely permeable to these substances, so no "help" is needed there. However, the supply of energy from oxidation is not limitless; so when more of the proton motive force or gradient energy is used to drive these transport processes, less is available to make ATP.

HOMEOSTATIC IMBALANCE

Studies of metabolic poisons support the chemiosmotic model of oxidative phosphorylation. For example, cyanide (the gas used in gas chambers) disrupts the process by binding to cytochrome oxidase and blocking electron flow from cytochrome a_3 to oxygen. Poisons commonly called "uncouplers" abolish the proton gradient by making the crista membrane permeable to H^+. Consequently, although the electron transport chain continues to deliver electrons to oxygen at a furious pace, and oxygen consumption rises, no ATP is made. ●

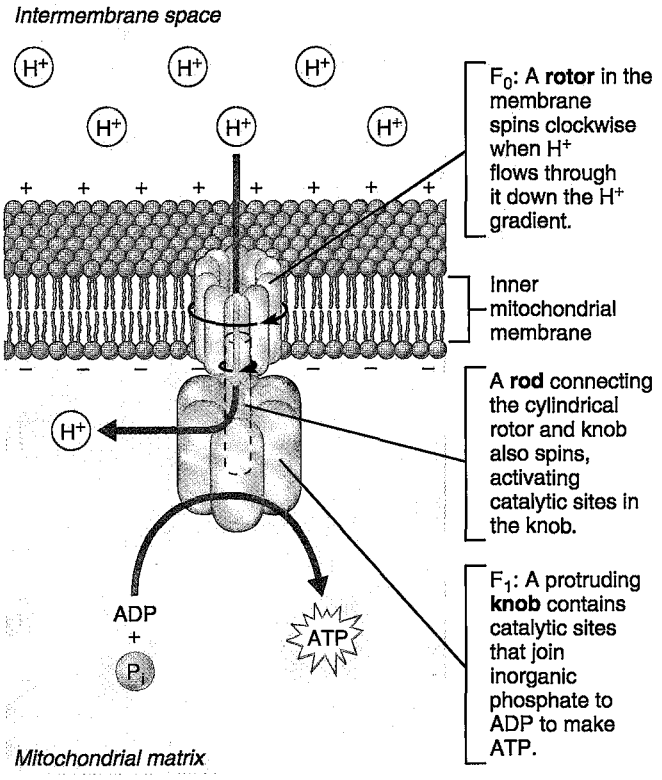

FIGURE 24.10 **Structure of ATP synthase.**

The stimulus for ATP production is entry of *ADP* into the mitochondrial fluid matrix. As ADP is transported in, ATP is moved out in a coupled transport process.

Summary of ATP Production The average person at rest uses energy at the rate of roughly 100 kcal/hour, which is equal to 116 watts or slightly more than that of a standard lightbulb. This seems to be a minuscule amount, but from a biochemical standpoint it places a staggering power demand on our mitochondria. Luckily, they are up to the task. When O_2 is present, cellular respiration is remarkably efficient. Of the 686 kcal of energy present in 1 mole of glucose, as much as 262 kcal can be captured in ATP bonds. (The rest is liberated as heat.) This corresponds to an energy capture of about 38%, making cells far more efficient than any human-made machines, which use only 10–30% of the energy available to them.

During cellular respiration, most energy flows in this sequence: Glucose → NADH + H^+ → electron transport chain → proton motive force → ATP. Let's do a little bookkeeping to summarize the net energy

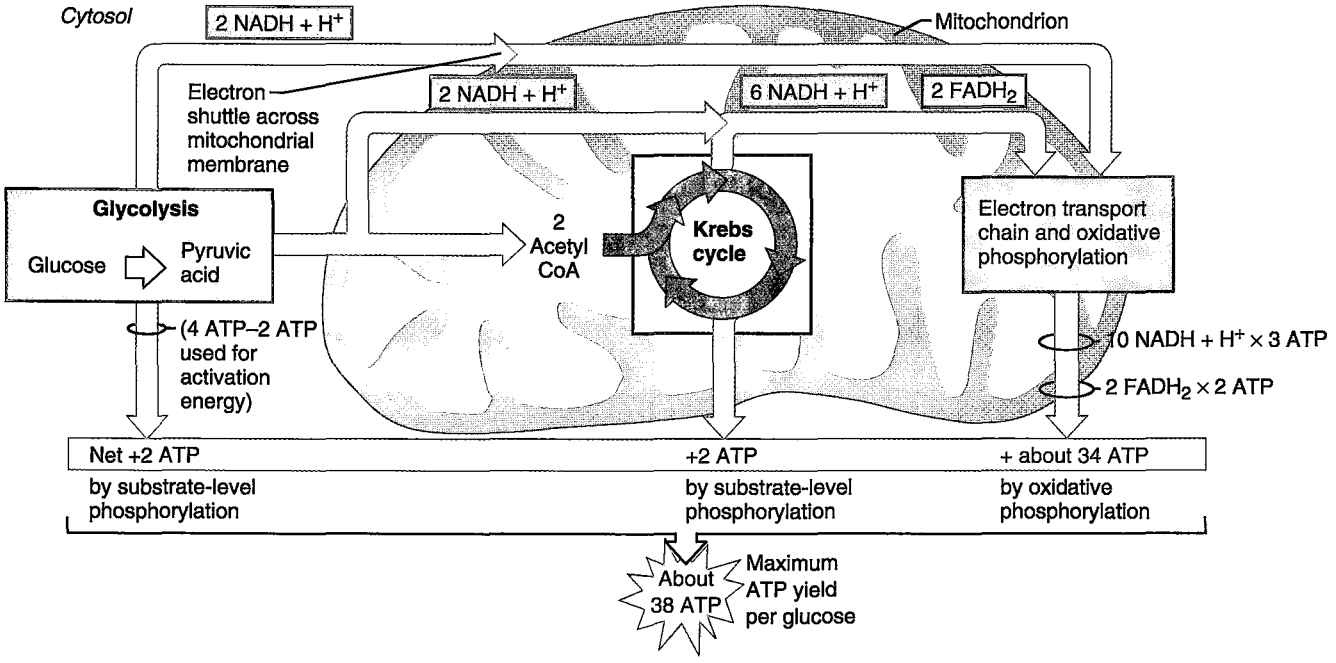

FIGURE 24.11 **Energy yield during cellular respiration.**

gain from one glucose molecule. Once we have tallied the net gain of 4 ATP produced directly by substrate-level phosphorylations (2 during glycolysis and 2 during the Krebs cycle), all that remains to be calculated is the number of ATP molecules produced by oxidative phosphorylation (Figure 24.11).

Each NADH + H^+ that transfers a pair of high-energy electrons to the electron transport chain contributes enough energy to the proton gradient to generate between 2 and 3 ATP molecules. (We will round this yield off to 3 to simplify our calculations.)

The oxidation of $FADH_2$ is less efficient because it doesn't donate electrons to the "top" of the electron transport chain as does NADH + H^+, but to a lower energy level (at coenzyme Q). So, for each 2 H delivered by $FADH_2$, just about 2 ATPs are produced (instead of 2+ or 3). Thus, the 8 NADH + H^+ and the 2 $FADH_2$ produced during the Krebs cycle are "worth" 24 and 4 ATPs respectively. The 2 NADH + H^+ generated during glycolysis yields 6 ATP molecules. Overall, complete oxidation of 1 glucose molecule to CO_2 and H_2O yields a maximum of 38 molecules of ATP (Figure 24.11).

However, there is an uncertainty about the energy yield of reduced NAD^+ generated *outside* the mitochondria by glycolysis. The crista membrane is *not* permeable to reduced NAD^+ generated in the cytosol, so NADH + H^+ formed during glycolysis uses a *shuttle molecule* to deliver its extra electron pair to the electron transport chain. It appears that cells using the malate/aspartate shuttle harvest the whole 3 ATP from oxidation of reduced NAD^+, but in cells using a different shuttle (the glycerol phosphate shuttle for example) the shuttle has an energy cost. At present, the consensus is that the net energy yield for reoxidation of reduced NAD^+ in this case is probably the same as for $FADH_2$, that is, 2 ATP per electron pair. Thus, if we deduct 2 ATP to cover the "fare" for the shuttle, our bookkeeping comes up with a grand total of 36 ATP per glucose as the maximum possible energy yield. (Actually our figures are probably still too high because, as mentioned earlier, the proton motive force is also used to do other work and the electron transport chain may not work at maximum capacity all of the time.)

Glycogenesis and Glycogenolysis

Although most glucose is used to generate ATP molecules, unlimited amounts of glucose do *not* result in unlimited ATP synthesis, because cells cannot store large amounts of ATP. When more glucose is available than can be immediately oxidized, rising intracellular ATP concentrations eventually inhibit glucose catabolism and initiate processes that store glucose as either glycogen or fat. Because the body can store much more fat than glycogen, fats account for 80–85% of stored energy.

When glycolysis is "turned off" by high ATP levels, glucose molecules are combined in long chains to form glycogen, the animal carbohydrate storage product. This process, called **glycogenesis** (*glyco* = sugar; *genesis* = origin), begins when glucose entering cells is phosphorylated to glucose-6-phosphate and then converted to its isomer, *glucose-1-phosphate*. The terminal phosphate group is cleaved off as the enzyme *glycogen synthase* catalyzes the

attachment of glucose to the growing glycogen chain (Figure 24.12). Liver and skeletal muscle cells are most active in glycogen synthesis and storage.

When blood glucose levels drop, glycogen lysis (splitting) occurs. This process is known as **glycogenolysis** (gli"ko-jĕ-nol'ĭ-sis). The enzyme *glycogen phosphorylase* oversees phosphorylation and cleavage of glycogen to release glucose-1-phosphate, which is then converted to glucose-6-phosphate, a form that can enter the glycolytic pathway to be oxidized for energy.

In muscle cells and most other cells, the glucose-6-phosphate resulting from glycogenolysis is trapped because it cannot cross the cell membrane. However, hepatocytes (and some kidney and intestinal cells) contain *glucose-6-phosphatase,* an enzyme that removes the terminal phosphate, producing free glucose. Because glucose readily diffuses from the cell into the blood, the liver can use its glycogen stores to provide blood sugar for the benefit of other organs when blood glucose levels drop. Liver glycogen is also an important energy source for skeletal muscles that have depleted their own glycogen reserves.

A common misconception is that athletes need to eat large amounts of protein to improve their performance and maintain their muscle mass. Actually, a diet rich in complex carbohydrates, which stores more muscle glycogen, is much more effective in sustaining intense muscle activity than are high-protein meals. Notice that the emphasis is on *complex* carbohydrates. Eating a candy bar before an athletic event to provide "quick" energy does more harm than good because it stimulates insulin secretion, which favors glucose use and retards fat use at a time when fat use should be maximal. Building muscle protein or avoiding its loss requires not only extra protein, but also extra (protein-sparing) complex carbohydrate calories to meet the greater energy needs of the increasingly massive muscles.

Endurance athletes, long-distance runners in particular, are well aware of the practice of glycogen loading, popularly called "carbo loading," for endurance events. Glycogen loading "tricks" the muscles into storing more glycogen than they normally would. Carbo loading generally involves eating a carbohydrate-rich diet (75% of energy intake) for three to four days before an endurance event while decreasing activity. This has been shown to increase muscle glycogen stores to as much as twice the normal amount. Carbo loading is now standard practice among marathon runners and distance cyclists, because studies have shown that it improves performance and endurance. While the initial studies were of male athletes, more recent studies of females have shown less dramatic effects.

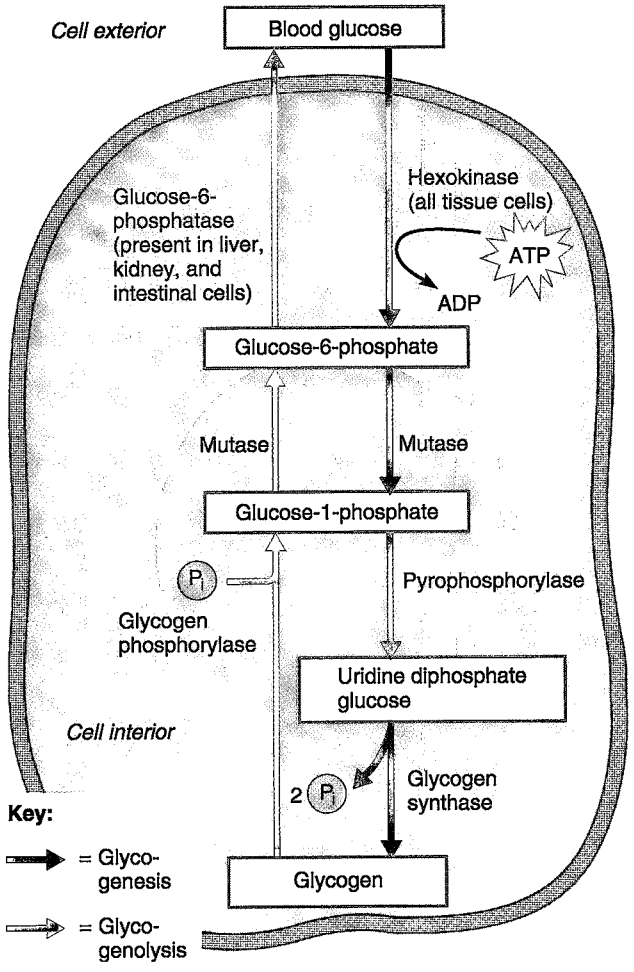

FIGURE 24.12 **Glycogenesis and glycogenolysis.** When glucose supplies exceed demands, glycogenesis, the conversion of glucose to glycogen for storage, occurs. Glycogenolysis, the breakdown of glycogen to release glucose, is stimulated by falling blood glucose levels. Notice that glycogen is synthesized and degraded by different enzymatic pathways.

Gluconeogenesis

When too little glucose is available to stoke the "metabolic furnace," glycerol and amino acids are converted to glucose. **Gluconeogenesis,** the process of forming new *(neo)* glucose from *noncarbohydrate* molecules, occurs in the liver. It takes place when dietary sources and glucose reserves have been depleted and blood glucose levels are beginning to drop. Gluconeogenesis protects the body, the nervous system in particular, from the damaging effects of low blood sugar *(hypoglycemia)* by ensuring that ATP synthesis can continue.

Lipid Metabolism

Fats are the body's most concentrated source of energy. They contain very little water, and the energy yield from fat catabolism is approximately twice that

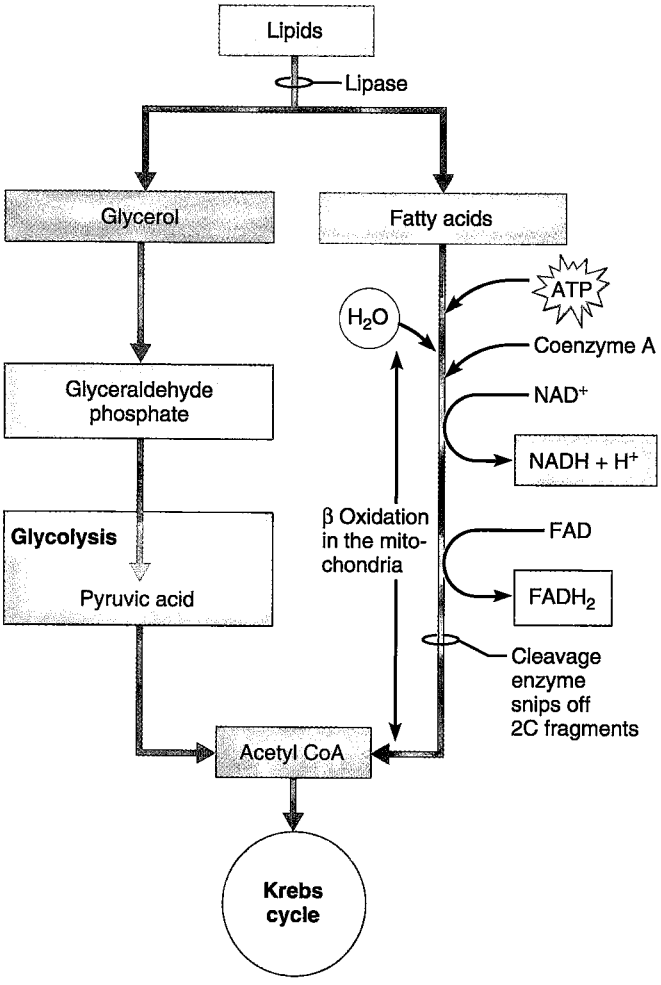

FIGURE 24.13 **Initial phase of lipid oxidation.** The glycerol portion is converted to glyceraldehyde phosphate, a glycolysis intermediate, and completes the glycolytic pathway through pyruvic acid to acetyl CoA. The fatty acids undergo beta oxidation. In this process the fatty acids are first activated by a coupled reaction with ATP and combined with coenzyme A. After being oxidized twice (reducing NAD^+ and FAD), the acetyl CoA created in β oxidation is cleaved off and the process begins again.

from either glucose or protein catabolism—9 kcal per gram of fat versus 4 kcal per gram of carbohydrate or protein. Most products of fat digestion are transported in lymph in the form of fatty-protein droplets called *chylomicrons* (see Chapter 23). Eventually, the lipids in the chylomicrons are hydrolyzed by plasma enzymes, and the resulting fatty acids and glycerol are taken up by body cells and processed in various ways.

Oxidation of Glycerol and Fatty Acids

Of the various lipids, only triglycerides are routinely oxidized for energy. Their catabolism involves the separate oxidation of their two different building blocks: glycerol and fatty acid chains (Figure 24.13).

Most body cells easily convert glycerol to glyceraldehyde phosphate, a glycolysis intermediate that enters the Krebs cycle. Glyceraldehyde is equal to half a glucose molecule, and ATP energy harvest from its complete oxidation is approximately half that of glucose (18 ATP/glycerol).

Beta oxidation, the initial phase of fatty acid oxidation, occurs in the mitochondria. Although oxidation, dehydration, and other reactions are involved, the net result is that the fatty acid chains are broken apart into two-carbon *acetic acid* fragments, and coenzymes are reduced (Figure 24.13). Each acetic acid molecule is fused to coenzyme A, forming acetyl CoA. The term "beta oxidation" reflects the fact that the carbon in the beta (third) position is oxidized during the process and cleavage of the fatty acid in each case occurs between the alpha and beta carbons. Acetyl CoA is then picked up by oxaloacetic acid and enters the aerobic pathways to be oxidized to CO_2 and H_2O.

Notice that unlike glycerol, which enters the glycolytic pathway, acetyl CoA resulting from fatty acid breakdown *cannot* be used for gluconeogenesis because the metabolic pathway is irreversible past pyruvic acid.

Lipogenesis and Lipolysis

There is a continuous turnover of triglycerides in adipose tissue. New fats are "put in the larder" for later use, while stored fats are broken down and released to the blood. That bulge of fatty tissue you see today does *not* contain the same fat molecules it did a month ago.

Glycerol and fatty acids from dietary fats not immediately needed for energy are recombined into triglycerides and stored. About 50% ends up in subcutaneous tissue; the balance is stockpiled in other fat depots of the body. Triglyceride synthesis, or **lipogenesis** (Figure 24.14), occurs when cellular ATP and glucose levels are high. Excess ATP also leads to an accumulation of acetyl CoA and glyceraldehyde-PO_4, two intermediates of glucose metabolism that would otherwise feed into the Krebs cycle. But when these two metabolites are present in excess, they are channeled into triglyceride synthesis pathways. Acetyl CoA molecules are condensed together, forming fatty acid chains that grow two carbons at a time. (This accounts for the fact that almost all fatty acids in the body contain an even number of carbon atoms.) Because acetyl CoA, an intermediate in glucose catabolism, is also the *starting point* for fatty acid synthesis, glucose is easily converted to fat. Glyceraldehyde-PO_4 is converted to glycerol, which is condensed with fatty acids to form triglycerides. Thus, even if the diet is fat-poor, carbohydrate intake can provide *all the raw materials* needed to form neutral fats. When blood sugar is high, lipogenesis is

What is the central molecule in lipid metabolism?

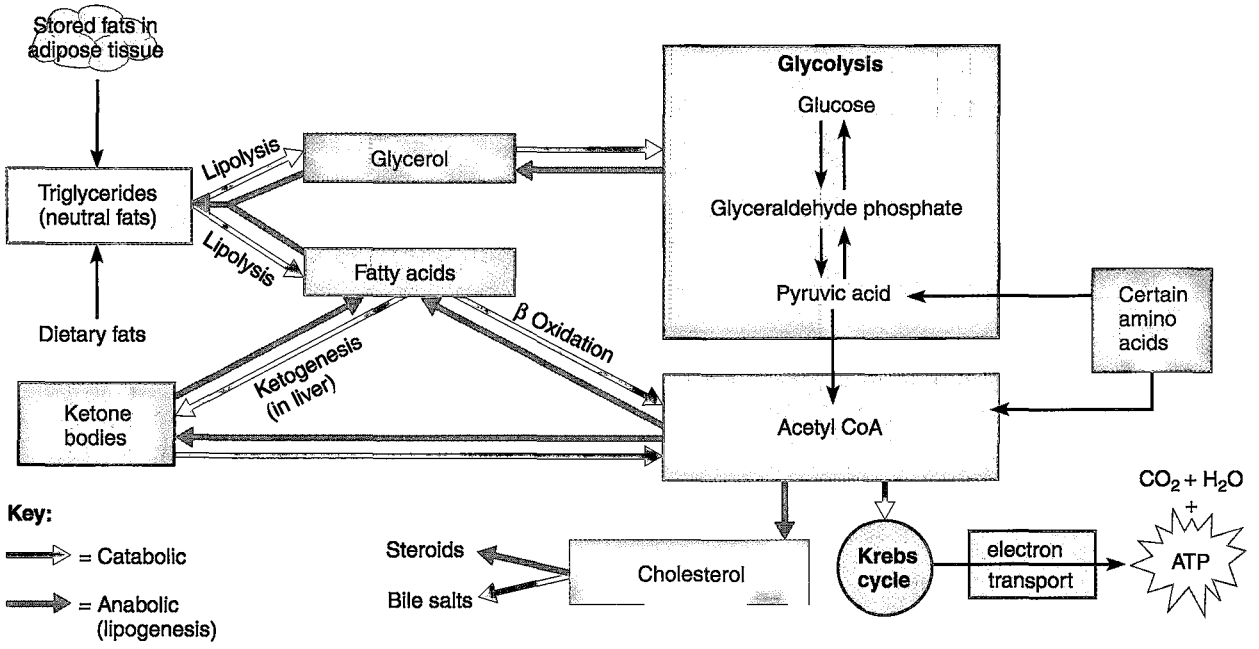

FIGURE 24.14 **Metabolism of triglycerides.** When needed for energy, dietary or stored fats enter the catabolic pathways. Glycerol enters the glycolytic pathway (as glyceraldehyde phosphate) and the fatty acids are broken down by beta oxidation to acetyl CoA, which enters the Krebs cycle. When fats are to be synthesized (lipogenesis) and stored in fat depots, the intermediates are drawn from glycolysis and the Krebs cycle in a reversal of the processes noted above. Likewise, excess dietary fats are stored in adipose tissues. When triglycerides are in excess or are the primary energy source, the liver releases their breakdown products (fatty acids → acetyl CoA) in the form of ketone bodies. Excessive amounts of carbohydrates and amino acids are also converted to triglycerides (lipogenesis).

the major activity in adipose tissues and is also an important liver function.

Lipolysis (lī-pol'ĭ-sis; "fat splitting"), the breakdown of stored fats into glycerol and fatty acids, is essentially lipogenesis in reverse. The fatty acids and glycerol are released to the blood, helping to ensure that body organs have continuous access to fat fuels for aerobic respiration. (The liver, cardiac muscle, and resting skeletal muscles actually prefer fatty acids as an energy fuel.) The meaning of the adage "fats burn in the flame of carbohydrates" becomes clear when carbohydrate intake is inadequate. Under such conditions, lipolysis is accelerated as the body attempts to fill the fuel gap with fats. However, the ability of acetyl CoA to enter the Krebs cycle depends on the availability of oxaloacetic acid to act as the pickup molecule. When carbohydrates are deficient, oxaloacetic acid is converted to glucose (to fuel the brain). Without oxaloacetic acid, fat oxidation is incomplete, acetyl CoA accumulates, and via a process called **ketogenesis,** the liver converts acetyl CoA molecules to **ketone bodies,** or **ketones,** which are released into the blood. Ketone bodies include acetoacetic acid, β-hydroxybutyric acid, and acetone, all formed from acetic acid. (The *keto acids* cycling through the Krebs cycle and the *ketone bodies* resulting from fat metabolism are quite different and should not be confused.)

HOMEOSTATIC IMBALANCE

When ketone bodies accumulate in the blood, *ketosis* results and large amounts of ketone bodies are excreted in the urine. Ketosis is a common consequence of starvation, unwise dieting (in which inadequate amounts of carbohydrates are eaten), and diabetes mellitus. Because most ketone bodies are organic acids, the outcome of ketosis is *metabolic acidosis.* The body's buffer systems cannot tie up the acids (ketones) fast enough, and blood pH drops to dangerously low levels. The person's breath smells fruity as acetone vaporizes from the lungs, and breathing becomes more rapid as the respiratory system tries to reduce blood carbonic acid by blowing off CO_2 to force the blood pH up. In severe untreated cases, the person may become comatose or even die as the acid pH depresses the nervous system. ●

Acetyl CoA

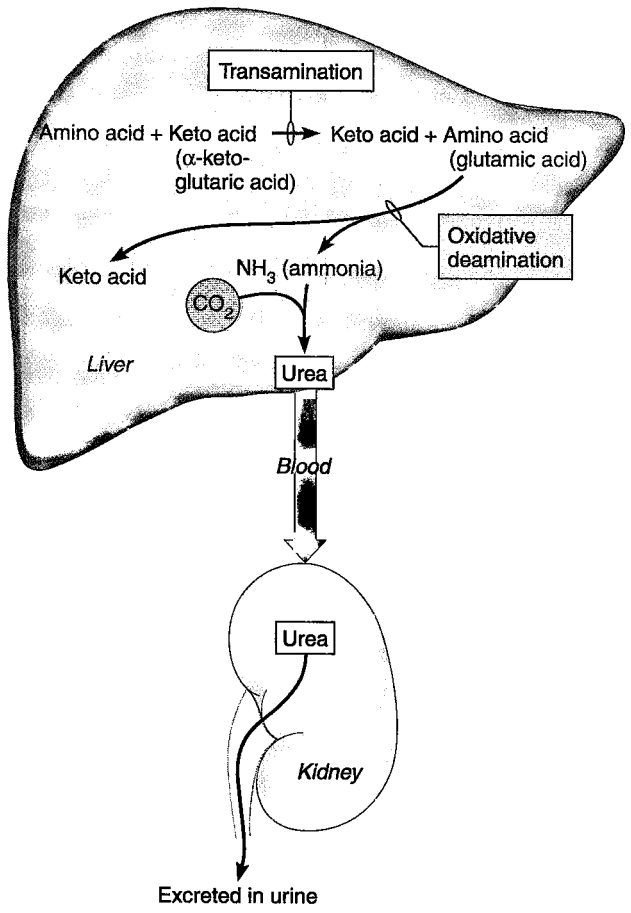

FIGURE 24.15 **Transamination and oxidative processes that occur when amino acids are oxidized for energy.** Transamination involves the switching of an amine group from an amino acid to a keto acid, usually α-ketoglutaric acid. As a result the original amino acid becomes a keto acid, and the keto acid becomes an amino acid, typically glutamic acid. In oxidative deamination the amine group of glutamic acid is released as ammonia and then combined with CO_2 by the liver cells to form urea.

Synthesis of Structural Materials

All body cells use phospholipids and cholesterol to build their membranes. Phospholipids are also important components of myelin sheaths of neurons. In addition, the liver (1) synthesizes lipoproteins for transport of cholesterol, fats, and other substances in the blood; (2) synthesizes cholesterol from acetyl CoA; and (3) uses cholesterol to form bile salts. The ovaries, testes, and adrenal cortex use cholesterol to synthesize their steroid hormones.

Protein Metabolism

Like all other biological molecules, proteins have a limited life span and must be broken down and replaced before they begin to deteriorate. As proteins are broken down, their amino acids are recycled and used in building new proteins or modified to form a different N-containing compound. Newly ingested amino acids transported in the blood are taken up by cells by active transport processes and used to *replace* tissue proteins at the rate of about 100 grams each day. Although popular opinion has it that excess protein can be stored by the body, nothing is farther from the truth. When more protein is available than is needed for these anabolic purposes, amino acids are oxidized for energy or converted to fat for future energy needs.

Oxidation of Amino Acids

Before amino acids can be oxidized for energy, they must be *deaminated,* that is, their amine group (NH_2) must be removed. (In sulfur-containing amino acids, such as methionine and cysteine, sulfur is released prior to deamination.) The resulting molecule is then converted to pyruvic acid or to one of the keto acid intermediates in the Krebs cycle [acetyl CoA, alpha (α) ketoglutaric acid, succinyl CoA, fumaric acid, or oxaloacetic acid]. The key molecule in these conversions is the nonessential amino acid *glutamic acid* (gloo-tam'ik). The events that occur (Figure 24.15) are:

1. Transamination (trans"am-ĭ-na'shun). A number of amino acids can transfer their amine group to α-ketoglutaric acid (a Krebs cycle keto acid), thereby transforming α-ketoglutaric acid to glutamic acid. In the process, the original amino acid becomes a keto acid (that is, it has an oxygen atom where the amine group formerly was). This reaction is fully reversible.

2. Oxidative deamination. In the liver, the amine group of glutamic acid is removed as **ammonia (NH_3),** and α-ketoglutaric acid is regenerated. The liberated NH_3 molecules are combined with CO_2, yielding **urea** and water. The urea is released to the blood and removed from the body in urine. Because ammonia is toxic to body cells, the ease with which glutamic acid funnels amine groups into the **urea cycle** is extremely important. This mechanism rids the body not only of NH_3 produced during oxidative deamination, but also of bloodborne NH_3 produced by intestinal bacteria.

3. Keto acid modification. The goal of amino acid degradation is to produce molecules that can be either oxidized in the Krebs cycle or converted to glucose. Hence, keto acids resulting from transamination are altered as necessary to produce metabolites that can enter the Krebs cycle. The most important of these metabolites are pyruvic acid, acetyl CoA, α-ketoglutaric acid, and oxaloacetic acid (Figure 24.7). Because the reactions of glycolysis are reversible, deaminated amino acids that are converted to pyruvic acid can be reconverted to glucose and contribute to gluconeogenesis.

TABLE 24.4 Thumbnail Summary of Metabolic Reactions

CARBOHYDRATES	
Cellular respiration	Reactions that together complete the oxidation of glucose, yielding CO_2, H_2O, and ATP
Glycolysis	Conversion of glucose to pyruvic acid
Glycogenesis	Polymerization of glucose to form glycogen
Glycogenolysis	Hydrolysis of glycogen to glucose monomers
Gluconeogenesis	Formation of glucose from noncarbohydrate precursors
Krebs cycle	Complete breakdown of pyruvic acid to CO_2, yielding small amounts of ATP and reduced coenzymes
Electron transport chain	Energy-yielding reactions that split H removed during oxidations to H^+ and e^- and create a proton gradient used to bond ADP to P_i (forming ATP)
LIPIDS	
Beta oxidation	Conversion of fatty acids to acetyl CoA
Lipolysis	Breakdown of lipids to fatty acids and glycerol
Lipogenesis	Formation of lipids from acetyl CoA and glyceraldehyde phosphate
PROTEINS	
Transamination	Transfer of an amine group from an amino acid to α-ketoglutaric acid, thereby transforming α-ketoglutaric acid to glutamic acid
Oxidative deamination	Removal of an amine group from glutamic acid as ammonia and regenerating α-ketoglutaric acid (NH_3 is converted to urea by the liver)

Protein Synthesis

Amino acids are the most important anabolic nutrients. Not only do they form all protein structures, but they form the bulk of the body's functional molecules as well. As described in Chapter 3, protein synthesis occurs on ribosomes, where ribosomal enzymes oversee the formation of peptide bonds linking the amino acids together into protein polymers. The amount and type of protein synthesized are precisely controlled by hormones (growth hormone, thyroxine, sex hormones, insulin-like growth factors, and others), and so protein anabolism reflects the hormonal balance at each stage of life.

During your lifetime, your cells will have synthesized 225–450 kg (about 500–1000 lb) of proteins, depending on your size. However, you do not need to consume anywhere near that amount of protein because nonessential amino acids are easily formed by siphoning keto acids from the Krebs cycle and transferring amine groups to them. Most of these transformations occur in the liver, which provides nearly all the nonessential amino acids needed to produce the relatively small amount of protein that the body synthesizes each day. However, a complete set of amino acids must be present for protein synthesis to take place, so all essential amino acids must be provided by the diet. If some are not, the rest are oxidized for energy even though they may be needed for anabolism. In such cases, negative nitrogen balance results because body protein is broken down to supply the essential amino acids needed.

The various metabolic reactions described thus far are summarized briefly in Table 24.4.

Catabolic-Anabolic Steady State of the Body

The body exists in a *dynamic catabolic-anabolic state* as organic molecules are continuously broken down and rebuilt—frequently at a head-spinning rate.

The blood is the transport pool for all body cells, and it contains many kinds of energy sources—glucose, ketone bodies, fatty acids, glycerol, and lactic acid. Some organs routinely use blood energy sources other than glucose, thus saving glucose for tissues with stricter glucose requirements (see Table 24.5 on p. 977).

The body **nutrient pools**—amino acid, carbohydrate, and fat stores—can be drawn on to meet its varying needs (Figure 24.16). These pools are interconvertible because their pathways are linked by key

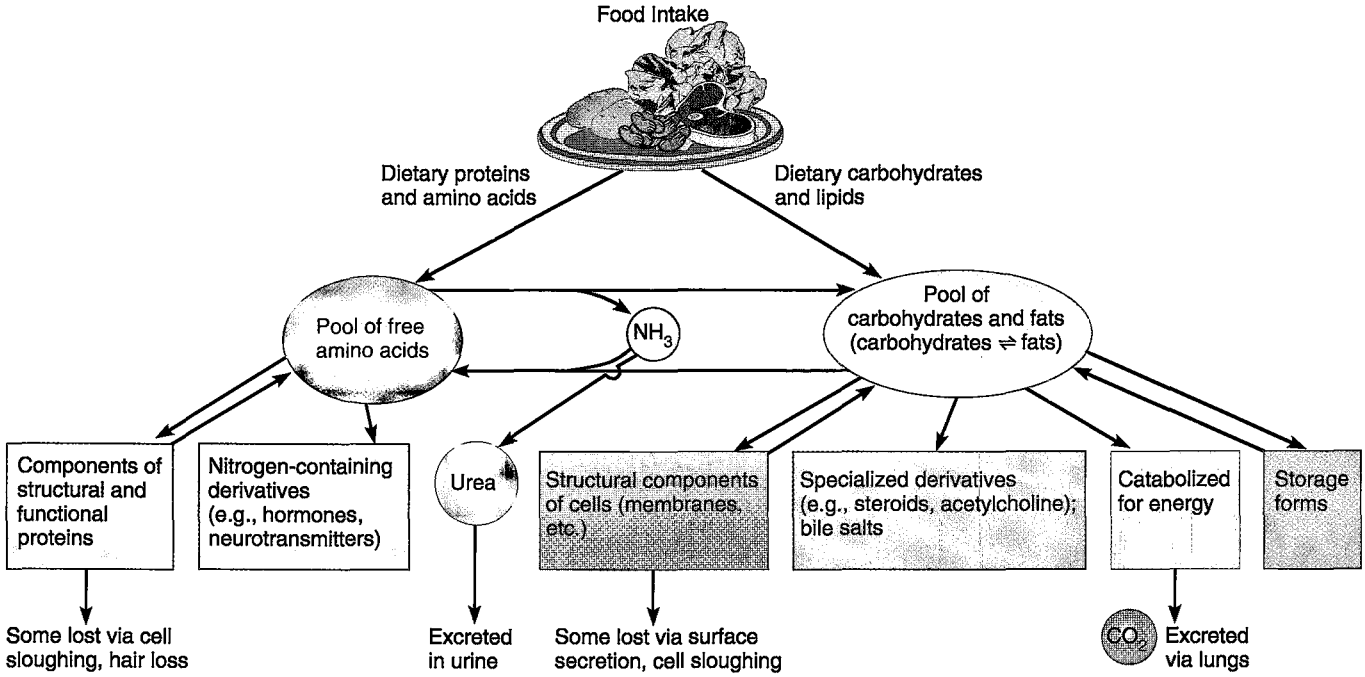

FIGURE 24.16 **Carbohydrate/fat and amino acid pools.**

intermediates (see Figure 24.17). The liver, adipose tissue, and skeletal muscles are the primary effector organs determining the amounts and direction of the conversions shown in the figure.

The **amino acid pool** is the body's total supply of free amino acids. Small amounts of animo acids and proteins are lost daily in urine and in sloughed hairs and skin cells. Typically, these lost molecules are replaced via the diet; otherwise, amino acids arising from tissue breakdown return to the pool. This pool is the source of amino acids used for protein synthesis and in the formation of amino acid derivatives. In addition, as described above, deaminated amino acids can participate in gluconeogenesis. Not all events of amino acid metabolism occur in all cells. For example, *only* the liver forms urea.

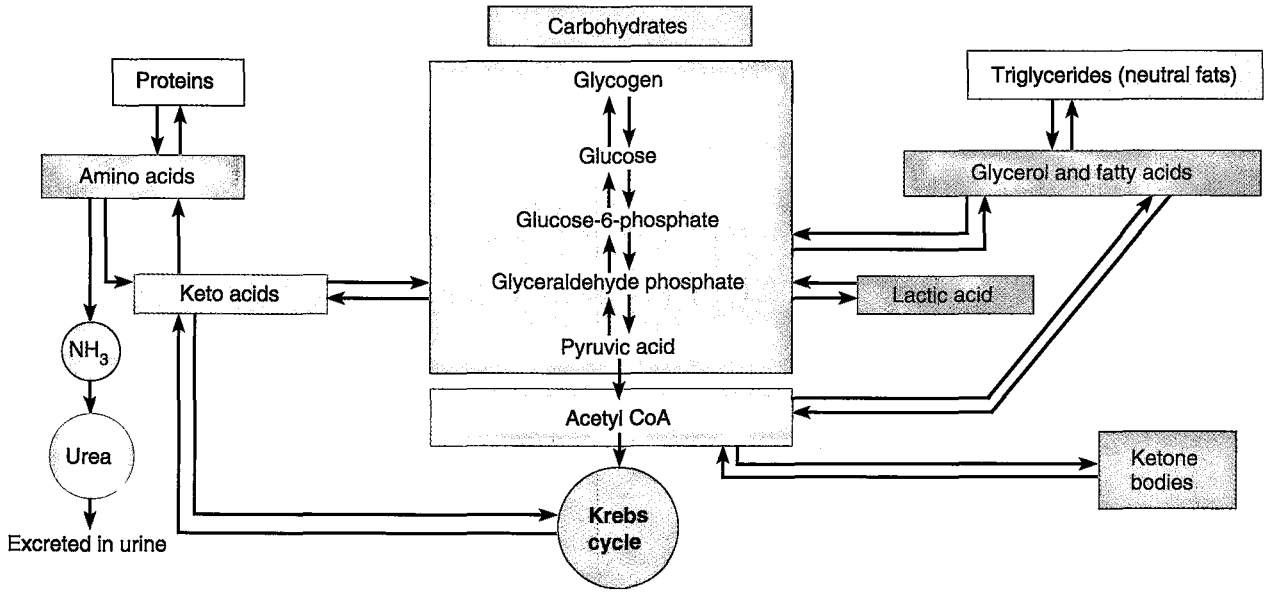

FIGURE 24.17 **Interconversion of carbohydrates, fats, and proteins.** The liver, adipose tissue, and skeletal muscles are the primary effector organs determining the amounts and direction of the conversions shown.

Nonetheless, the concept of a common amino acid pool is valid because all cells are connected by the blood.

Because carbohydrates are easily and frequently converted to fats, the **carbohydrate** and **fat pools** are usually considered together (Figures 24.16 and 24.17). There are two major differences between this pool and the amino acid pool: (1) Fats and carbohydrates are oxidized directly to produce cellular energy, whereas amino acids can be used to supply energy *only after being converted to a carbohydrate intermediate* (a keto acid). (2) Excess carbohydrate and fat can be stored as such, whereas excess amino acids are *not* stored as protein. Instead, they are oxidized for energy or converted to fat or glycogen for storage.

Absorptive and Postabsorptive States

Metabolic controls act to equalize blood concentrations of energy sources between two nutritional states. Sometimes referred to as the *fed state,* the **absorptive state** is the time during and shortly after eating, when nutrients are flushing into the blood from the gastrointestinal tract. The **postabsorptive** *(fasting)* **state** is the period when the GI tract is empty and energy sources are supplied by the breakdown of body reserves. Those who eat "three squares" a day are in the absorptive state for the four hours during and after each meal and in the postabsorptive state in the late morning, late afternoon, and all night. However, postabsorptive mechanisms can sustain the body for much longer intervals if necessary—even to accommodate weeks of fasting—as long as water is taken in.

Absorptive State

During the absorptive state (Figure 24.18) anabolism exceeds catabolism. Glucose is the major energy fuel. Dietary amino acids and fats are used to remake degraded body protein or fat, and small amounts are oxidized to provide ATP. Excess metabolites, regardless of source, are transformed to fat if not used for anabolism. We will consider the fate and hormonal control of each nutrient group during this phase.

Carbohydrates Absorbed monosaccharides are delivered directly to the liver, where fructose and galactose are converted to glucose. Glucose, in turn, is released to the blood or converted to glycogen and fat. Glycogen formed in the liver is stored there, but most fat synthesized there is packaged with proteins as *very low density lipoproteins (VLDLs)* and released to the blood to be picked up for storage by adipose tissues. Bloodborne glucose not sequestered by the liver enters body cells to be metabolized for energy; any excess is stored in skeletal muscle cells as glycogen or in adipose cells as fat.

Triglycerides Nearly all products of fat digestion enter the lymph in the form of chylomicrons, which are hydrolyzed to fatty acids and glycerol before they can pass through the capillary walls. *Lipoprotein lipase,* the enzyme that catalyzes fat hydrolysis, is particularly active in the capillaries of muscle and fat tissues. Adipose cells, skeletal muscle cells, and liver cells use triglycerides as their primary energy source, and when dietary carbohydrates are limited, other cells begin to oxidize more fat for energy. Although some fatty acids and glycerol are used for anabolic purposes by tissue cells, most enter adipose tissue to be reconverted to triglycerides and stored.

Amino Acids Absorbed amino acids are delivered to the liver, which deaminates some of them to keto acids. The keto acids may flow into the Krebs cycle to be used for ATP synthesis, or they may be converted to liver fat stores. The liver also uses some of the amino acids to synthesize plasma proteins, including albumin, clotting proteins, and transport proteins. However, most amino acids flushing through the liver sinusoids remain in the blood for uptake by other body cells, where they are used for protein synthesis. Figure 24.18 has been simplified to show nonliver amino acid uptake only by muscle.

Hormonal Control **Insulin** directs essentially all events of the absorptive state (Figure 24.19). Rising blood glucose levels after a carbohydrate-containing meal act as a humoral stimulus that prods the beta cells of the pancreatic islets to secrete more insulin. [This glucose-induced stimulation of insulin release is enhanced by the GI tract hormone glucose-dependent insulinotropic peptide (GIP) and parasympathetic stimulation.] A second important stimulus for insulin release is elevated amino acid levels in the blood. As insulin binds to membrane receptors of its target cells, it stimulates the translocation of the glucose transporter (GLUT-4 in muscle and adipose tissue) to the plasma membrane, thus enhancing the carrier-mediated facilitated diffusion of glucose into the cells. Within minutes, the rate of glucose entry into tissue cells (particularly muscle, adipose, and liver cells) increases about 20-fold. (The exception is brain cells, which take up glucose whether or not insulin is present.) Once glucose enters tissue cells, insulin enhances glucose oxidation for energy and stimulates its conversion to glycogen and, in adipose tissue, to triglycerides. Insulin also "revs up" the active transport of amino acids into cells, promotes protein synthesis, and inhibits liver export of glucose and virtually all liver enzymes that promote gluconeogenesis.

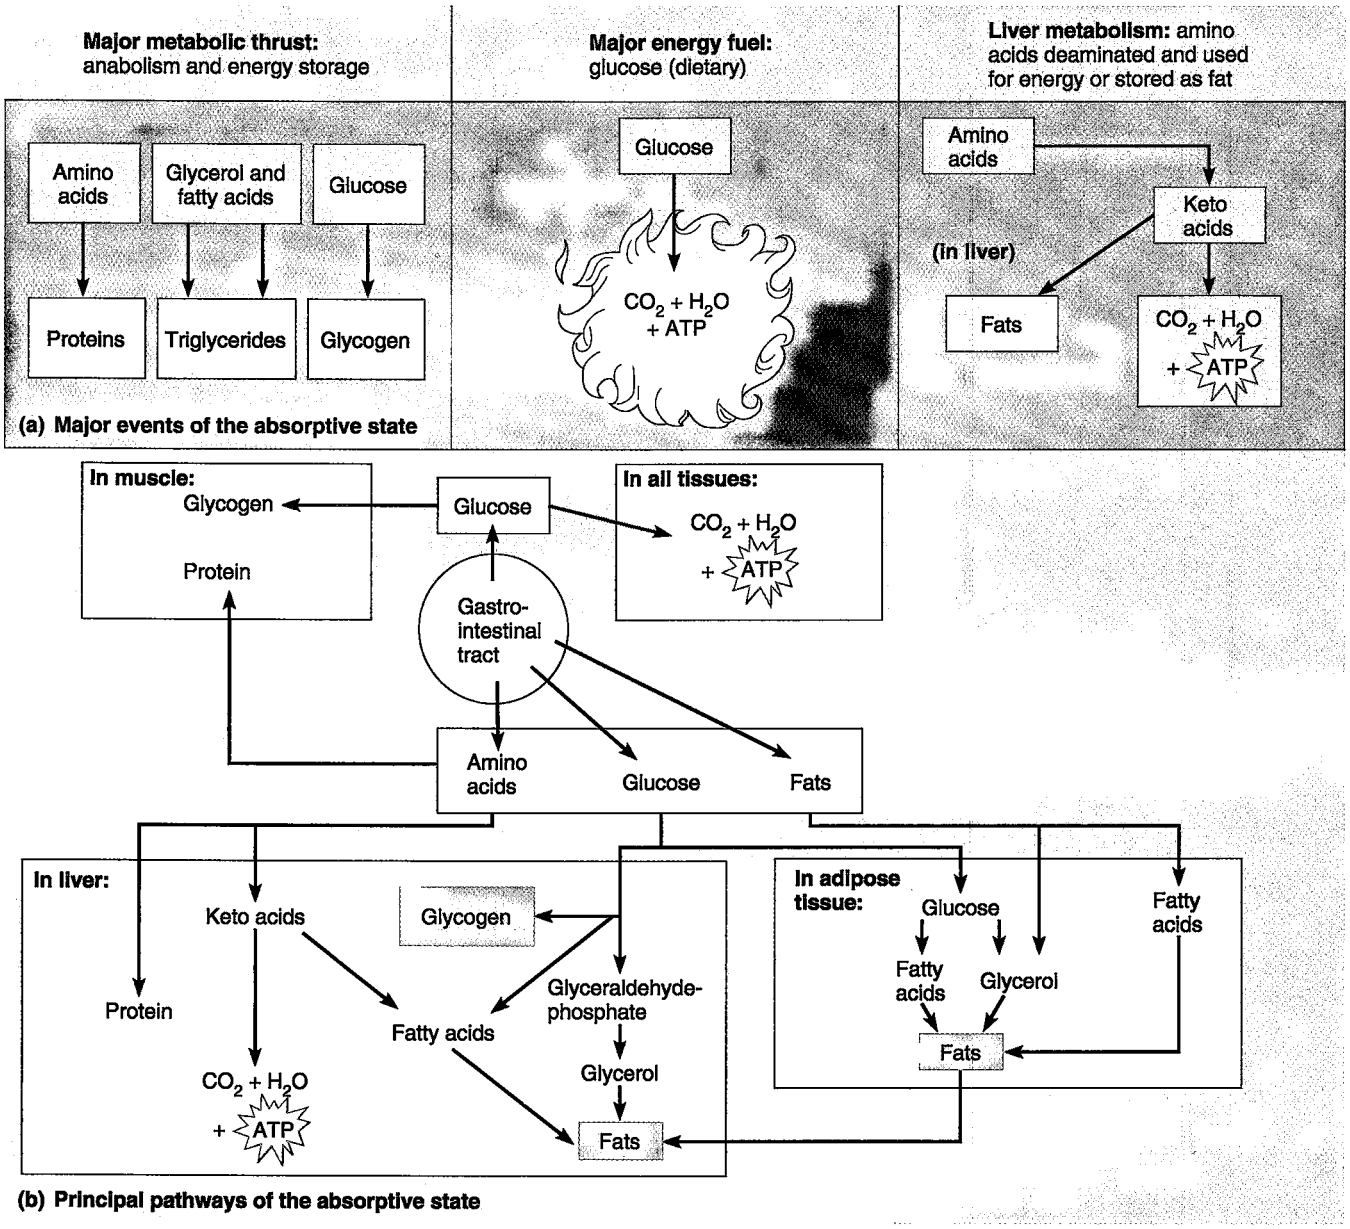

FIGURE 24.18 **Major events and principal metabolic pathways of the absorptive state.** Although not indicated in (b), amino acids are also taken up by tissue cells and used for protein synthesis, and fats (triglycerides) are the primary energy fuel of muscle, liver cells, and adipose tissue.

As you can see, insulin is a **hypoglycemic hormone** (hi"po-gli-se'mik). It sweeps glucose out of the blood into the tissue cells, thereby lowering blood glucose levels. Additionally, it enhances glucose oxidation or storage while simultaneously inhibiting any process that might increase blood glucose levels.

HOMEOSTATIC IMBALANCE

Diabetes mellitus is a consequence of inadequate insulin production or abnormal insulin receptors. Without insulin or receptors that "recognize" it, glucose becomes unavailable to most body cells. Thus, blood glucose levels remain high, and large amounts of glucose are excreted in urine. Metabolic acidosis, protein wasting, and weight loss occur as large amounts of fats and tissue proteins are used for energy. (Diabetes mellitus is described in more detail in Chapter 16.) ●

Postabsorptive State

In the postabsorptive state, net synthesis of fat, glycogen, and proteins ceases, and catabolism of these substances begins to occur. The primary goal

TABLE 24.5 Profiles of the Major Body Organs in Fuel Metabolism

TISSUE	FUEL STORES	PREFERRED FUEL	FUEL SOURCES EXPORTED
Brain	None	Glucose (ketone bodies during starvation)	None
Skeletal muscle (resting)	Glycogen	Fatty acids	None
Skeletal muscle (during exertion)	None	Glucose	Lactate
Heart muscle	None	Fatty acids	None
Adipose tissue	Triglycerides	Fatty acids	Fatty acids, glycerol
Liver	Glycogen, triglycerides	Amino acids, glucose, fatty acids	Fatty acids, glucose, ketone bodies

Adapted from Mathews, van Holde, and Ahern, 2000, *Biochemistry* 3/e, San Francisco: Addison Wesley Longman, p. 832.

during this state, that is, between meals when blood glucose levels are dropping, is to maintain blood glucose levels within the homeostatic range (70–110 mg of glucose per 100 ml). The importance of constant blood glucose has already been explained, chiefly that the brain almost always uses glucose as its energy source. Most events of the postabsorptive state either make glucose available to the blood or save glucose for the organs that need it most by using fats for energy (Figure 24.20).

Sources of Blood Glucose Glucose can be obtained from stored glycogen, from tissue proteins, and in limited amounts from fats (Table 24.5).

1. Glycogenolysis in the liver. The liver's glycogen stores (about 100 g) are the first line of glucose reserves. They are mobilized quickly and efficiently and can maintain blood sugar levels for about four hours during the postabsorptive state.

2. Glycogenolysis in skeletal muscle. Glycogen stores in skeletal muscle are approximately equal to those of the liver. Before liver glycogen is exhausted, glycogenolysis begins in skeletal muscle (and to a lesser extent in other tissues). However, the glucose produced is not released to the blood because, unlike the liver, skeletal muscle does not have the enzymes needed to dephosphorylate glucose. Instead, glucose is partly oxidized to pyruvic acid (or, during anaerobic conditions, lactic acid), which enters the blood, is reconverted to glucose by the liver, and is released to the blood again. Thus, skeletal muscle contributes to blood glucose homeostasis indirectly, via liver mechanisms.

3. Lipolysis in adipose tissues and the liver. Adipose and liver cells produce glycerol by lipolysis, and the liver converts the glycerol to glucose (gluconeogenesis), which is released to the blood. Because acetyl CoA, a product of the beta oxidation of fatty

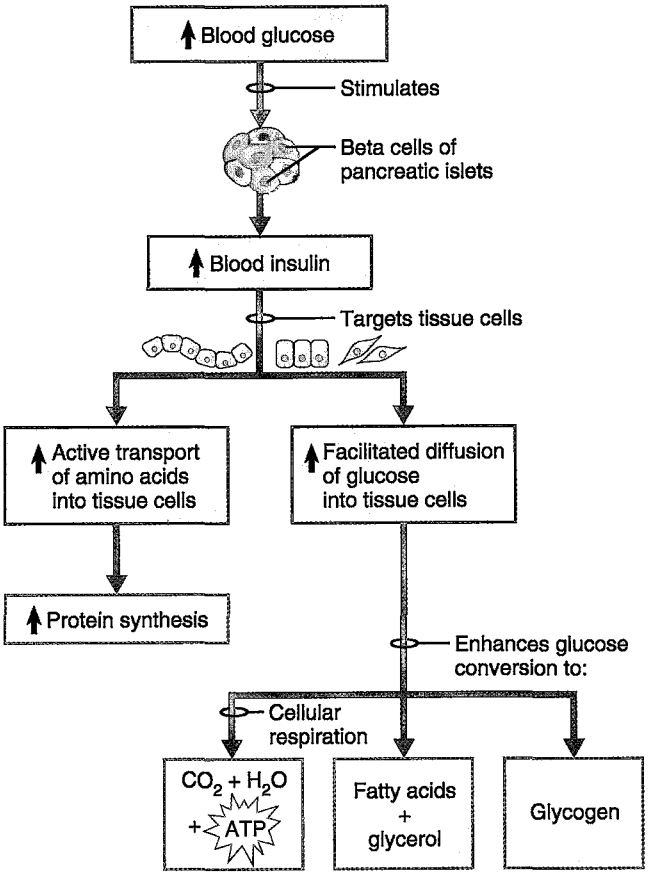

FIGURE 24.19 **Effects of insulin on metabolism.** When insulin concentrations are low (during the postabsorptive period), these normal effects of insulin are inhibited and glycogenolysis and gluconeogenesis occur, that is, the insulin-mediated intracellular reactions are reversed. (Note: Not all effects shown occur in all cells.)

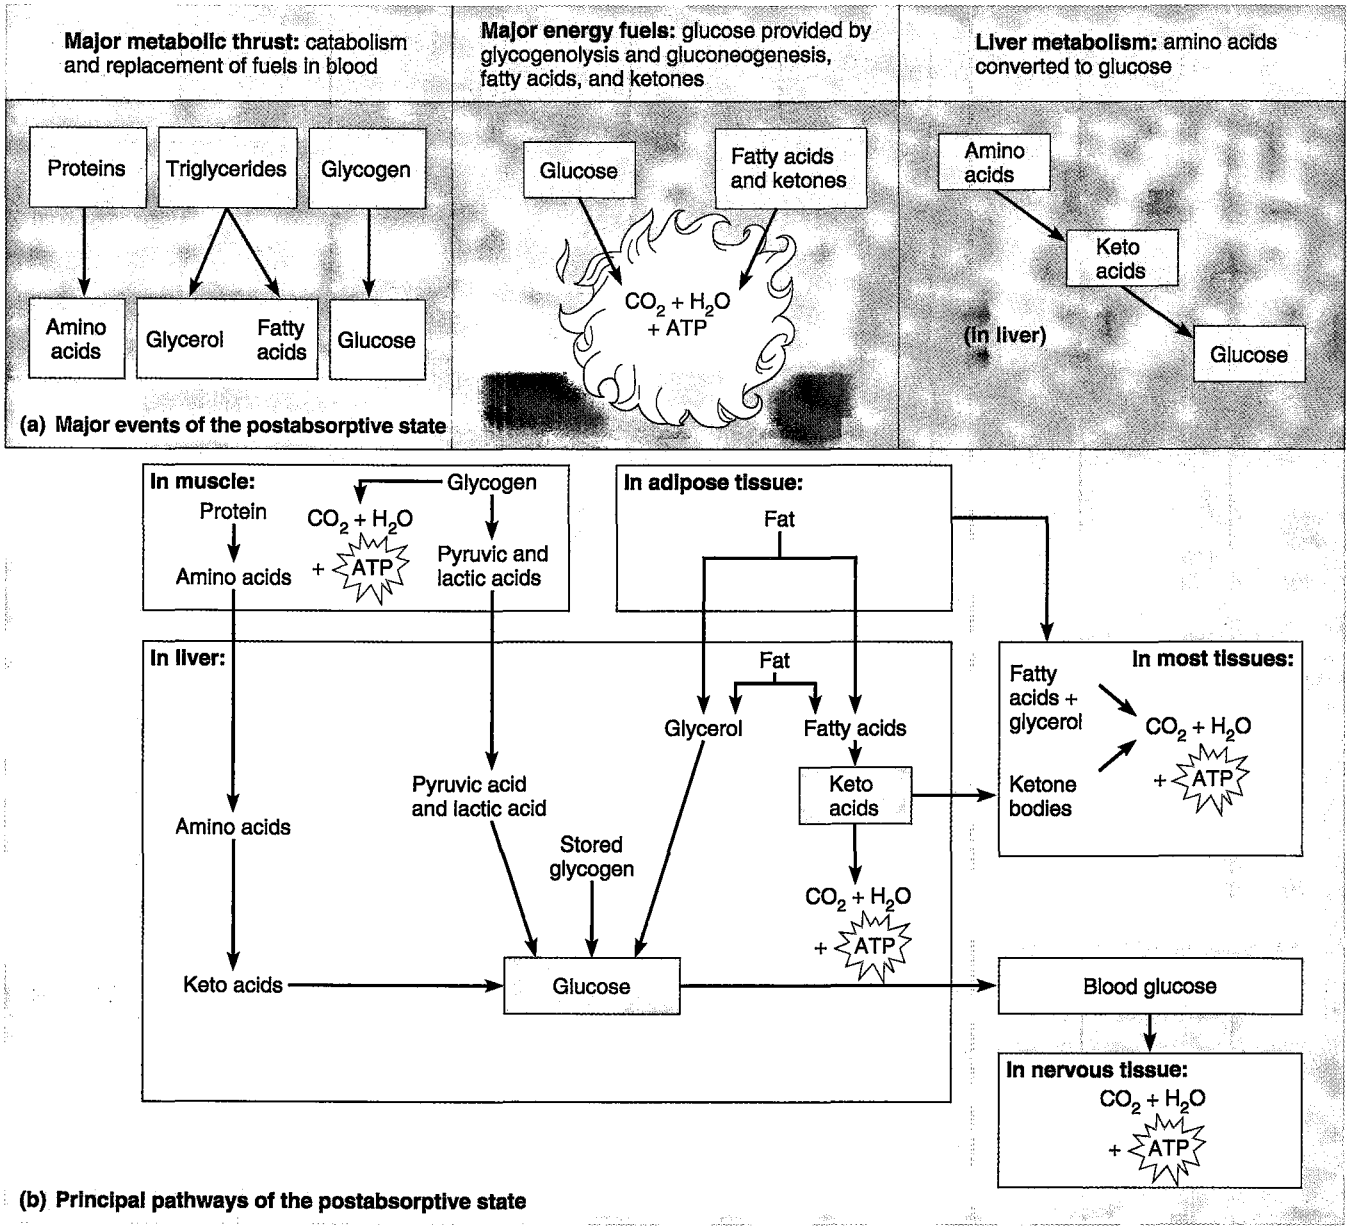

FIGURE 24.20 **Major events and principal metabolic pathways of the postabsorptive state.**

acids, is produced beyond the *reversible* steps of glycolysis, fatty acids *cannot* be used to bolster blood glucose levels.

4. Catabolism of cellular protein. Tissue proteins become the major source of blood glucose when fasting is prolonged and glycogen and fat stores are nearly exhausted. Cellular amino acids (mostly from muscle) are deaminated and converted to glucose in the liver. During fasts lasting several weeks, the kidneys also carry out gluconeogenesis and contribute fully as much glucose to the blood as does the liver.

Even during prolonged fasting or starvation, the body sets priorities. Muscle proteins are the first to go (to be catabolized). Movement is not nearly as important as maintaining wound healing and the immune response. But as long as life continues, so does the body's ability to produce the ATP needed to drive life processes. Obviously, there are limits to the amount of tissue protein that can be catabolized before the body stops functioning. The heart is almost entirely muscle protein, and when it is severely catabolized, the result is death. In general, the amount of fat the body contains determines the time one can survive without food.

Glucose Sparing Even collectively, all of the manipulations aimed at increasing blood glucose are not enough to provide energy supplies for prolonged

fasting. Luckily, the body can adapt to burn more fats and proteins, which enter the Krebs cycle along with glucose breakdown products. The increased use of noncarbohydrate fuel molecules (especially triglycerides) to conserve glucose is called **glucose sparing.**

As the body progresses from absorptive to postabsorptive state, the brain continues to take its share of blood glucose; but virtually every other organ switches to fatty acids as its major energy source, thus sparing glucose for the brain. During this transition phase, lipolysis begins in adipose tissues and released fatty acids are picked up by tissue cells and oxidized for energy. In addition, the liver oxidizes fats to ketone bodies and releases them to the blood for use by tissue cells. If fasting continues for longer than four or five days, the brain too begins to use large quantities of ketone bodies as well as glucose as its energy fuel (Table 24.5). The survival value of the brain's ability to use an alternative fuel source is obvious—much less tissue protein has to be ravaged to form glucose.

Hormonal and Neural Controls The sympathetic nervous system and several hormones interact to control events of the postabsorptive state. Consequently, regulation of this state is much more complex than that of the absorptive state when a single hormone, insulin, holds sway.

An important trigger for initiating postabsorptive events is damping of insulin release, which occurs as blood glucose levels drop. As insulin levels decline, all insulin-induced cellular responses are inhibited as well.

Declining glucose levels also stimulate the alpha cells of the pancreatic islets to release the insulin antagonist **glucagon.** Like other hormones acting during the postabsorptive state, glucagon is a *hyperglycemic hormone,* that is, it promotes a rise in blood glucose levels. Glucagon targets the liver and adipose tissue (Figure 24.21). The hepatocytes respond by accelerating glycogenolysis and gluconeogenesis. Adipose cells mobilize their fatty stores (lipolysis) and release fatty acids and glycerol to the blood. Thus, glucagon "refurbishes" blood energy sources by enhancing both glucose and fatty acid levels. Under certain hormonal conditions and persistent low glucose levels or prolonged fasting, most of the fat mobilized is converted to ketone bodies. Glucagon release is inhibited after the next meal or whenever blood glucose levels rise and insulin secretion begins again.

Thus far, the picture is pretty straightforward. Increasing blood glucose levels trigger insulin release, which "pushes" glucose out of the blood and into the cells. This drop in blood glucose stimulates secretion of glucagon, which "pulls" glucose from

Q *What hormone is glucagon's main antagonist?*

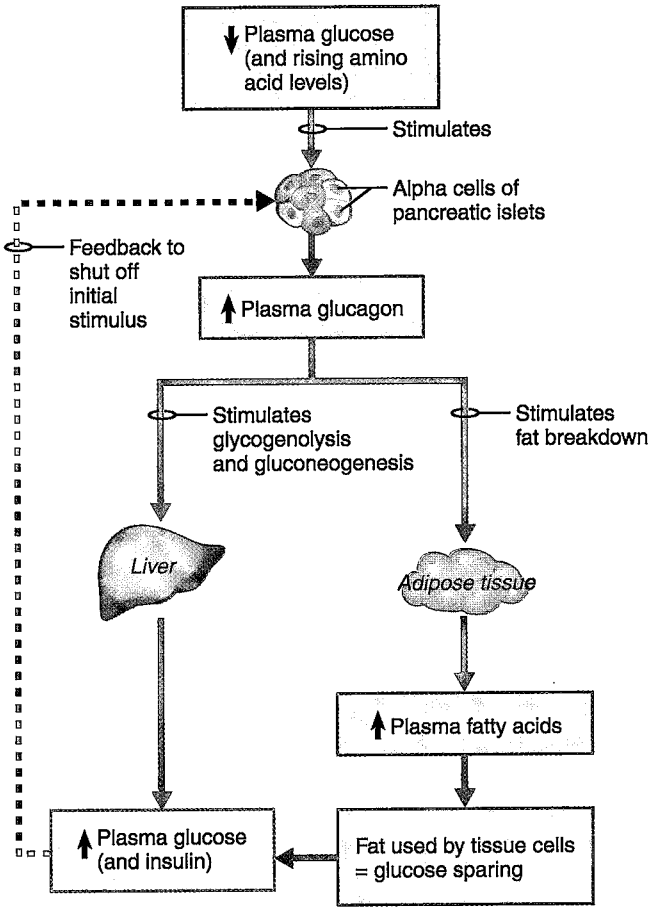

FIGURE 24.21 **Influence of glucagon on blood glucose levels.** Negative feedback control exerted by rising plasma glucose levels on glucagon secretion is indicated by the dashed arrow.

the cells into the blood. However, there is more than a push-pull mechanism here because *both* insulin and glucagon release are strongly stimulated by rising amino acid levels in the blood. This effect is insignificant when we eat a balanced meal, but it has an important adaptive role when we eat a high-protein, low-carbohydrate meal. In this instance, the stimulus for insulin release is strong, and if it were not counterbalanced, the brain might be damaged by the abrupt onset of hypoglycemia as glucose is

Insulin

TABLE 24.6 Summary of Normal Hormonal Influences on Metabolism

HORMONE'S EFFECTS	INSULIN	GLUCAGON	EPINEPHRINE	GROWTH HORMONE	THYROXINE	CORTISOL	TESTOSTERONE

rushed out of the blood. Simultaneous release of glucagon modulates the effects of insulin and helps stabilize blood glucose levels.

The sympathetic nervous system also plays a crucial role in supplying fuel quickly when blood glucose levels drop suddenly. Adipose tissue is well supplied with sympathetic fibers, and epinephrine released by the adrenal medulla in response to sympathetic activation acts on the liver, skeletal muscle, and adipose tissues. Together, these stimuli mobilize fat and promote glycogenolysis—essentially the same effects prompted by glucagon. Injury, anxiety, or any other stressor that mobilizes the fight-or-flight response will trigger this control pathway, as does exercise. During exercise, large amounts of fuels must be made available for muscle use, and the metabolic profile is essentially the same as that of a fasting person when glucagon and the sympathetic nervous system are in control except that the facilitated diffusion of glucose into muscle is enhanced. (The mechanism of this enhancement is not yet understood.)

In addition to glucagon and epinephrine, a number of other hormones—including growth hormone, thyroxine, sex hormones, and corticosteroids—influence metabolism and nutrient flow. Growth hormone secretion is enhanced by prolonged fasting or rapid declines in blood glucose levels, and GH exerts important anti-insulin effects; for example, it reduces the ability of insulin to promote glucose uptake in fat and muscle. However, the release and activity of most of these hormones are not specifically related to absorptive or postabsorptive metabolic events. Typical metabolic effects of various hormones are described in Table 24.6.

The Metabolic Role of the Liver

The liver is one of the most biochemically complex organs in the body. It processes nearly every class of nutrients and plays a major role in regulating plasma cholesterol levels. While mechanical contraptions can, in a pinch, stand in for a failed heart, lungs, or kidney, the only thing that can do the versatile liver's work is a hepatocyte.

General Metabolic Functions

The hepatocytes carry out some 500 or more intricate metabolic functions. A description of all of these functions is well beyond the scope of this text, but a brief summary is provided in Table 24.7.

Cholesterol Metabolism and Regulation of Blood Cholesterol Levels

Cholesterol, though an important dietary lipid, has received little attention in this discussion so far, primarily because it is not used as an energy source. It serves instead as the structural basis of bile salts, steroid hormones, and vitamin D and as a major component of plasma membranes. Additionally, cholesterol is part of a key signaling molecule (the *hedgehog protein*) that helps direct embryonic development. About 15% of blood cholesterol comes from the diet. The other 85% is made from acetyl CoA by

TABLE 24.7 Summary of Metabolic Functions of the Liver

METABOLIC PROCESSES TARGETED	FUNCTIONS
CARBOHYDRATE METABOLISM	
Particularly important in maintaining blood glucose homeostasis	▪ Converts galactose and fructose to glucose ▪ Glucose buffer function: stores glucose as glycogen when blood glucose levels are high; in response to hormonal controls, performs glycogenolysis and releases glucose to blood ▪ Gluconeogenesis; converts amino acids and glycerol to glucose when glycogen stores are exhausted and blood glucose levels are falling ▪ Converts glucose to fats for storage
FAT METABOLISM	
Although most cells are capable of some fat metabolism, liver bears the major responsibility	▪ Primary body site of beta oxidation (breakdown of fatty acids to acetyl CoA) ▪ Converts excess acetyl CoA to ketone bodies for release to tissue cells ▪ Stores fats ▪ Forms lipoproteins for transport of fatty acids, fats, and cholesterol to and from tissues ▪ Synthesizes cholesterol from acetyl CoA; catabolizes cholesterol to bile salts, which are secreted in bile
PROTEIN METABOLISM	
Other metabolic functions of the liver could be dispensed with and body could still survive; however, without liver metabolism of proteins, severe survival problems ensue: many essential clotting proteins would not be made, and ammonia would not be disposed of, for example	▪ Deaminates amino acids (required for their conversion to glucose or use for ATP synthesis); amount of deamination that occurs outside the liver is unimportant ▪ Forms urea for removal of ammonia from body; inability to perform this function (e.g., in cirrhosis or hepatitis) results in accumulation of ammonia in blood ▪ Forms most plasma proteins (exceptions are gamma globulins and some hormones and enzymes); plasma protein depletion causes rapid mitosis of the hepatocytes and actual growth of liver, which is coupled with increase in synthesis of plasma proteins until blood values are again normal ▪ Transamination: intraconversion of nonessential amino acids; amount that occurs outside liver is inconsequential
VITAMIN/MINERAL STORAGE	
	▪ Stores vitamin A (1–2 years' supply) ▪ Stores sizable amounts of vitamins D and B_{12} (1–4 months' supply) ▪ Stores iron; other than iron bound to hemoglobin, most of body's supply is stored in liver as ferritin until needed; releases iron to blood as blood levels drop
BIOTRANSFORMATION FUNCTIONS	
	▪ Relative to alcohol and drug metabolism, performs synthetic reactions which yield inactive products that can be secreted by the kidneys and nonsynthetic reactions which may result in products that are more active, changed in activity, or less active ▪ Processes bilirubin resulting from RBC breakdown and excretes bile pigments in bile ▪ Metabolizes bloodborne hormones to forms that can be excreted in urine

the liver, and to a lesser extent other body cells, particularly intestinal cells. Cholesterol is lost from the body when it is catabolized and secreted in bile salts, which are eventually excreted in feces.

Cholesterol Transport Because triglycerides and cholesterol are insoluble in water, they do not circulate free in the blood. Instead, they are transported to and from tissue cells bound to small lipid-protein complexes called **lipoproteins.** These complexes solubilize the hydrophobic lipids, and the protein part of the complexes contains signals that regulate lipid entry and exit at specific target cells.

Lipoproteins vary considerably in their relative fat-protein composition, but they all contain triglycerides, phospholipids, and cholesterol in addition to protein (Figure 24.22). In general, the higher the percentage of lipid in the lipoprotein, the lower its density; and the greater the proportion of protein, the higher its density. On this basis, there are **high-density lipoproteins (HDLs), low-density lipoproteins (LDLs),** and **very low density lipoproteins (VLDLs).** *Chylomicrons,* which transport absorbed lipids from the GI tract, are a separate class and have the lowest density of all.

The liver is the primary source of VLDLs, which transport triglycerides from the liver to the peripheral tissues, but mostly to *adipose tissues.* Once the triglycerides are unloaded, the VLDL residues are converted to LDLs, which are cholesterol-rich. The role of the LDLs is to transport cholesterol to *peripheral tissues,* making it available to the tissue cells for membrane or hormone synthesis and for storage for later use. The LDLs also regulate cholesterol synthesis in the tissue cells. Docking of LDL to the LDL receptor triggers receptor-mediated endocytosis of the entire particle.

The major function of HDLs, which are particularly rich in phospholipids and cholesterol, is to scoop up and transport excess cholesterol *from peripheral tissues to the liver,* where it is broken down and becomes part of bile. The liver makes the protein envelopes of the HDL particles and then ejects them into the bloodstream in collapsed form, rather like deflated beach balls. Once in the blood, these still-incomplete HDL particles fill with cholesterol picked up from the tissue cells and "pulled" from the artery walls. HDL also services the needs of steroid-producing organs, like the ovaries and adrenal glands, for their raw material (cholesterol). These organs have the ability to selectively remove cholesterol from the HDL particles without engulfing them.

Recommended Total Cholesterol, HDL, and LDL Levels For adults, a total cholesterol level of 200 mg/100 ml of blood (or lower) is recommended. Blood cholesterol levels above 200 mg/100 ml have been linked to risk of atherosclerosis, which clogs the arteries and causes strokes and heart attacks. However, it is not enough to simply measure total cholesterol. The form in which cholesterol is transported in the blood is more important clinically.

As a rule, high levels of HDLs are considered *good* because the transported cholesterol is destined for degradation. In the United States, the average HDL level in males is 40–50 and in women is 50–60. Levels below 40 are considered undesirable. HDL levels above 60 are thought to protect against heart disease.

High LDL levels (130 or above) are considered *bad* because when LDLs are excessive, potentially lethal cholesterol deposits are laid down in the artery walls. The goal for LDL levels is 100 or less, but new guidelines for those at risk for cardiac disease recommend 70 mg/100 ml or less. A good rule of thumb is that HDL levels can't be too high and LDL levels can't be too low.

If LDLs are "bad" cholesterol, then one variety of LDL—lipoprotein (a)—is "really nasty." This lipid appears to promote plaque formation that thickens and stiffens the blood vessel walls. High levels of lipoprotein (a) in the blood can double a man's risk of a heart attack before the age of 55. It is estimated that one in five males has elevated levels of this lipoprotein in the blood. (See *A Closer Look* in Chapter 19 for more information.)

Factors Regulating Plasma Cholesterol Levels A negative feedback loop partially adjusts the amount of cholesterol produced by the liver according to the amount of cholesterol in the diet. A high cholesterol intake inhibits its synthesis by the liver, but it is not a one-to-one relationship because the liver produces a certain basal amount of cholesterol (about 85%) even when dietary intake is excessive. For this reason, severe restriction of dietary cholesterol, although helpful, does not lead to a steep reduction in plasma cholesterol levels. Additionally, severe restriction of dietary cholesterol may remove important nutrients found in meats, shellfish, and dairy products from a person's diet.

The relative amounts of saturated and unsaturated fatty acids in the diet have an important effect on blood cholesterol levels. Saturated fatty acids *stimulate liver synthesis* of cholesterol and *inhibit its excretion* from the body. In contrast, unsaturated (mono- and polyunsaturated) fatty acids (found in olive oil and in most vegetable oils respectively) *enhance excretion* of cholesterol and its catabolism to bile salts, thereby reducing total cholesterol levels. The unhappy exception to this good news about unsaturated fats concerns "healthy" oils that have been

Q *Are the lipoprotein particles with the most healthy effects those with high protein and low cholesterol or those with high cholesterol and low protein?*

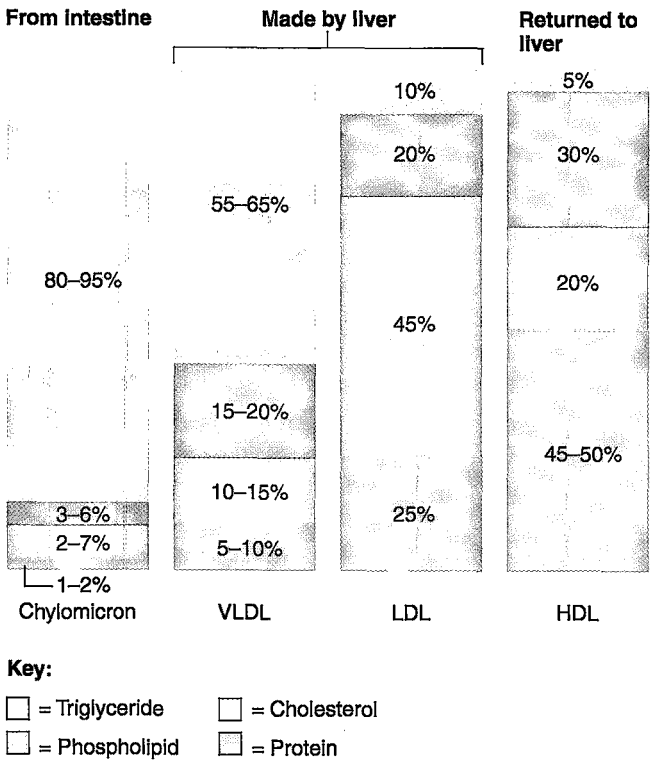

FIGURE 24.22 **Approximate composition of lipoproteins that transport lipids in body fluids.** VLDL = very low density lipoprotein; LDL = low-density lipoprotein; HDL = high-density lipoprotein.

hardened by hydrogenation to make them more solid. Hydrogenation changes the fatty acids in the oils to *trans fatty acids*, which cause serum changes worse than those caused by saturated fats—they spark a greater increase in LDLs and a greater reduction in HDLs, thus producing the unhealthiest ratio of total cholesterol to HDL.

The unsaturated omega-3 fatty acids found in especially large amounts in some cold-water fish lower the proportions of both saturated fats and cholesterol. The omega-3 fatty acids have a powerful antiarrhythmic effect on the heart and also make blood platelets less sticky, thus helping prevent spontaneous clotting that can block blood vessels. They also appear to lower blood pressure (even in nonhypertensive people). In those with moderate to high cholesterol levels, replacing half of the lipid- and cholesterol-rich animal proteins in the diet with soy protein lowers cholesterol significantly.

A *Those with high protein and low cholesterol.*

Factors other than diet also influence blood cholesterol levels. For example, cigarette smoking, coffee drinking, and stress appear to lower HDL levels, whereas regular aerobic exercise and estrogen lower LDL levels and increase HDL levels. Interestingly, body shape, that is, the distribution of body fat, provides clues to risky blood levels of cholesterol and fats. "Apples" (people with upper body and abdominal fat distribution, seen more often in men) tend to have higher levels of cholesterol in general and higher LDLs in particular than "pears" where fat is localized in the hips and thighs, a pattern more common in women.

Most cells other than liver and intestinal cells obtain the bulk of the cholesterol they need for membrane synthesis from the blood. When a cell needs cholesterol, it makes receptor proteins for LDL and inserts them in its plasma membrane. LDL binds to the receptors and is engulfed in coated pits by endocytosis. Within 15 minutes the endocytotic vesicles fuse with lysosomes, where the cholesterol is freed for use. When excessive cholesterol accumulates in a cell, it inhibits both the cell's own cholesterol synthesis and its synthesis of LDL receptors.

HOMEOSTATIC IMBALANCE

Previously, high cholesterol and LDL:HDL ratios were considered the most valid predictors of risk for atherosclerosis, cardiovascular disease, and heart attack. However, almost half of those who get heart disease have normal cholesterol levels, while others with poor lipid profiles remain free of heart disease. Presently, LDL levels and assessments of risk factors are believed to be more accurate indicators of whether treatment is needed or not, and many physicians recommend dietary changes regardless of total cholesterol or HDL levels. Cholesterol-lowering drugs such as the *statins* (e.g., lovastatin and pravastatin) are routinely prescribed for cardiac patients with LDL levels over 130. It is estimated that more than 10 million Americans are now taking statins, and tests of a vaccine that lowers LDL while raising HDL are under way. ●

Energy Balance

When any fuel is burned, it consumes oxygen and liberates heat. The "burning" of food fuels by our cells is no exception. As described in Chapter 2, energy can be neither created nor destroyed—only converted from one form to another. If we apply this principle (actually the *first law of thermodynamics*) to cell metabolism, it means that bond energy released as foods are catabolized must be precisely balanced by the total energy output of the body.

Thus, a dynamic balance exists between the body's energy intake and its energy output:

Energy intake = energy output
(heat + work + energy storage)

Energy intake is the energy liberated during food oxidation. (Undigested foods are not part of the equation because they contribute no energy.) **Energy output** includes energy (1) immediately lost as heat (about 60% of the total), (2) used to do work (driven by ATP), and (3) stored as fat or glycogen. (Because losses of organic molecules in urine, feces, and perspiration are very small in healthy people, they are usually ignored in calculating energy output.) A close look at this situation reveals that *nearly all the energy derived from foodstuffs is eventually converted to heat.* Heat is lost during every cellular activity—when ATP bonds are formed and when they are cleaved to do work, as muscles contract, and through friction as blood flows through blood vessels. Though cells cannot use this energy to do work, the heat warms the tissues and blood and helps maintain the homeostatic body temperature that allows metabolic reactions to occur efficiently. Energy storage is an important part of the equation only during periods of growth and net fat deposit.

Regulation of Food Intake

When energy intake and energy output are balanced, body weight remains stable. When they are not, weight is either gained or lost. Body weight in most people is surprisingly stable. This fact indicates the existence of physiological mechanisms that control food intake (and hence, the amount of food oxidized) or heat production or both. Unhappily for many people, the body's weight-controlling systems appear to be designed more to protect against weight loss than weight gain. Some methods used by the obese to lose or control their weight are discussed in *A Closer Look* on pp. 990–991.

Control of food intake poses difficult questions to researchers. For example, what type of receptor could sense the body's total calorie content and alert one to start eating or to put down that fork? Despite heroic research efforts, no such single receptor type has been found.

It has been known for some time that the hypothalamus, particularly its *arcuate nucleus (ARC),* releases several peptides that influence feeding behavior. Most importantly, this reflects the activity of two distinct sets of neurons. The NPY/AgRP group release neuropeptide Y (NPY) and agouti-related peptide (AgRP), which collectively enhance appetite while reducing metabolism. The other neuron group consists of the POMC/CART neurons which release pro-opiomelanocortin (POMC) and cocaine- and amphetamine-regulated transcript (CART), appetite-suppressing peptides.

Current theories of how feeding behavior and hunger are regulated focus on one or more of five factors: neural signals from the digestive tract, blood-borne signals related to body energy stores, hormones, body temperature, and psychological factors. All these factors appear to operate through feedback signals to the feeding centers of the brain. Brain receptors include thermoreceptors, chemoreceptors (for glucose, insulin, and others), and receptors that respond to a number of peptides (leptin, neuropeptide Y, and others). Although the hypothalamic nuclei play an essential role in regulating hunger and satiety, brain stem areas are also involved. Sensors in peripheral locations have also been suggested, with the liver and gut itself (alimentary canal) the prime candidates.

Neural Signals from the Digestive Tract

One way the brain evaluates the contents of the gut depends on vagal nerve fibers that carry on a two-way conversation between gut and brain. For example, clinical tests show that 2 kcal worth of protein produces a 30–40% larger and longer response in vagal afferents than does 2 kcal worth of glucose, and activation of stretch receptors ultimately inhibits appetite. Using these signals, together with others it receives, the brain can decode what is eaten and how much.

Nutrient Signals Related to Energy Stores

At any time, blood levels of glucose, amino acids, and fatty acids provide information to the brain that may help adjust energy intake to energy output. For example, nutrient signals that indicate fullness or satiety include

1. Rising blood glucose levels. When we eat, blood glucose levels rise and subsequent activation of glucose receptors in the brain ultimately depresses eating. During fasting, this signal is absent, resulting in hunger and a "turning on" of food-seeking behavior.
2. Elevated blood levels of amino acids depress eating, but the precise mechanism mediating this effect is unknown.
3. Blood concentrations of fatty acids provide a mechanism for controlling hunger. According to this theory, the greater the fat reserves, the larger the baseline amount of fatty acids released to the blood and the more eating behavior is inhibited.

Hormones

Insulin, released during food absorption, depresses hunger and is presumed to be an important satiety signal, as are cholecystokinin and PYY, gut hormones secreted during food digestion, and *leptin*

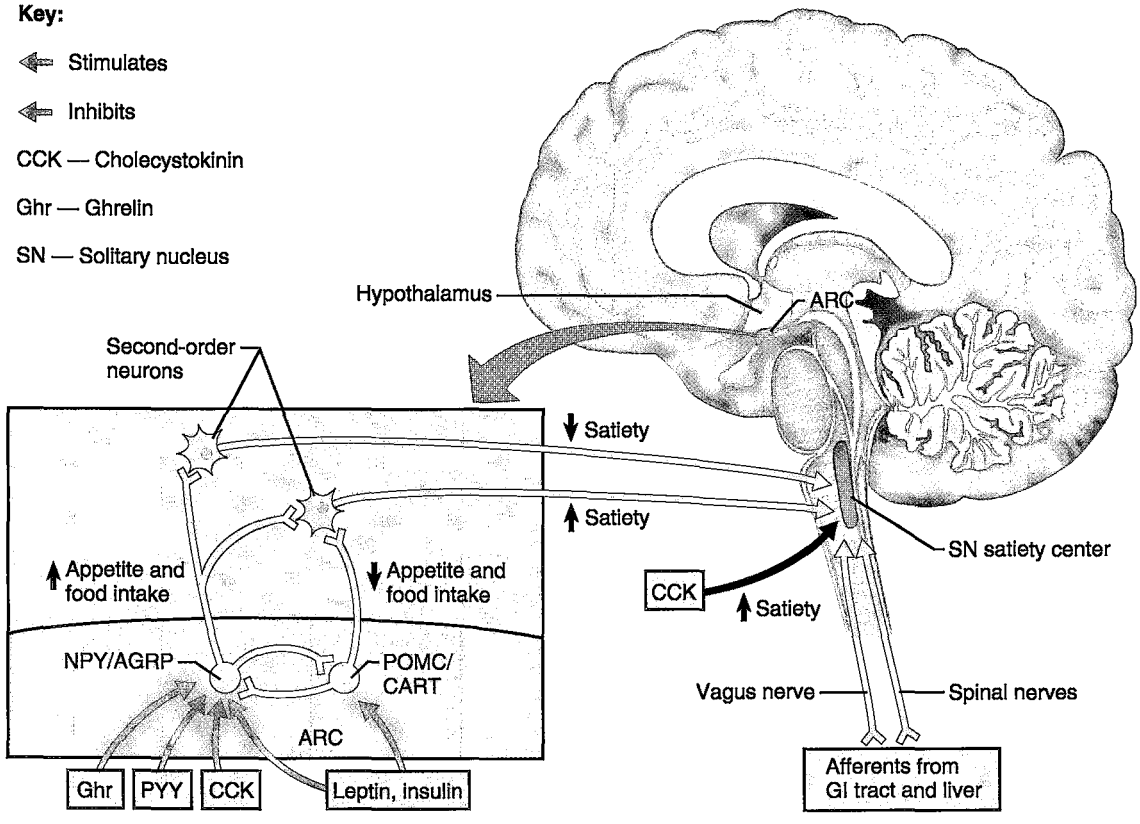

FIGURE 24.23 **Model for hypothalamic command of appetite and food intake.** The arcuate nucleus (ARC) of the brain contains two sets of neurons with opposing effects. Activation of NPY/AGRP neurons enhances appetite whereas activation of POMC/CART neurons has the opposite effect. These centers connect with interneurons in other brain centers, and signals are transmitted through the brain stem to the body. Many appetite-regulating hormones act through the ARC, though they may also exert direct effects on other brain centers as is shown for cholecystokinin (CCK) acting directly on the solitary nucleus (SN) satiety center.

("thin"), a hormone released by fat cells which serves as an indicator of the body's total energy stores in adipose tissue. In contrast, glucagon and epinephrine levels rise during fasting and stimulate hunger. Ghrelin (Ghr), produced by the stomach, is a powerful appetite stimulant.

Body Temperature

Increased body temperature may inhibit eating. Such a thermal signal would help explain why people in cold climates normally eat more than those in warm climates.

Psychological Factors

Although the mechanisms described thus far are reflexive, their final outcome may be enhanced or inhibited by psychological factors that have little to do with caloric balance. Appetite and food intake is definitely influenced by the appearance, smell, and taste of food—what disgusts the senses will not be ingested. Stress may increase or decrease appetite.

Psychological factors are thought to be very important in obese people. However, even when psychological factors are the underlying cause of obesity, individuals do *not* continue to gain weight endlessly. Their feeding controls still operate, but they have a higher "set point," which maintains total energy content at higher-than-normal levels.

A Hypothetical Model: Interrelationship of Factors in Control of Food Intake

Whew! How does all this information fit together? So far we only have bits and pieces of the story, but the best current hypothesis based on animal studies is shown in Figure 24.23.

A key component of the long-term controls of feeding behavior and satiety appears to be **leptin.** Over a period of hours, leptin is secreted exclusively by fat tissue in response to an increase in body fat mass. Leptin binds to receptors in the choroid plexuses of the ventricles, where it gains entry to the brain. There, it acts on the hypothalamus to regulate the amount of body fat via controls of appetite and energy output by suppressing the activity of NPY/AgRP neurons and stimulating POMC neurons. Neuropeptide Y (NPY) is the most potent appetite stimulant known; hence, by blocking its action leptin decreases appetite and (subsequently) food intake while simultaneously cranking up metabolic activity and heat production, eventually promoting weight loss. When fat stores shrink, leptin blood levels drop, which directly activates the NPY/AgRP neurons and blocks the activity of the POMC/CART center. Consequently, appetite and food intake increase, metabolic rate drops, and weight gain occurs.

It initially seemed that leptin was the magic bullet that obesity researchers were looking for, but their hopes were soon dashed because while rising leptin levels promote weight loss, they do so only to a certain point, beyond which that capability ends. Furthermore, obese individuals have higher-than-normal leptin blood levels, but for some unknown reason, they are resistant to its action. Thus, now the consensus is that leptin's main role is to protect against weight loss in times of nutritional deprivation.

An important outcome of the leptin studies was elucidation of the role of the arcuate nucleus in long- and short-term weight control. Although leptin has received the most attention as a long-term appetite and metabolism regulator, there are several other players. Insulin, which acts on receptors throughout the brain, also acts on ARC receptors. Like leptin it inhibits NPY release in non-insulin-resistant individuals, but its effect is less potent.

Three peptides appear to target and control short-term food intake and satiety. Ghrelin (Ghr), a hormone that stimulates growth hormone production by the anterior pituitary, also acts on ARC neurons to stimulate appetite. In fact, it appears to be the "dinner bell" or trigger for meal initiation. Its levels peak just before mealtime, letting the brain know that it's time to eat, and then trough out after the meal. In contrast, cholecystokinin and PYY, two other peptides formed in the digestive tract, act to thwart the appetite-inducing effect of NPY.

Metabolic Rate and Heat Production

The body's rate of energy output is called the **metabolic rate.** It is the total heat produced by all the chemical reactions and mechanical work of the body. It can be measured directly or indirectly. In the *direct method,* a person enters a chamber called a **calorimeter** and heat liberated by the body is absorbed by water circulating around the chamber. The rise in water temperature is directly related to the heat produced by the person's body. The *indirect method* uses a **respirometer** to measure oxygen consumption, which is directly proportional to heat production. For each liter of oxygen used, the body produces about 4.8 kcal of heat.

Because many factors influence metabolic rate, it is usually measured under standardized conditions. The person is in a postabsorptive state (has not eaten for at least 12 hours), is reclining, and is mentally and physically relaxed. The temperature of the room is a comfortable 20–25°C. The measurement obtained under these circumstances is called the **basal metabolic rate (BMR)** and reflects the energy the body needs to perform only its most essential activities, such as breathing and maintaining resting levels of organ function. Although named the *basal* metabolic rate, this measurement is *not* the lowest metabolic state of the body. That situation occurs during sleep, when the skeletal muscles are completely relaxed. The BMR, often referred to as the "energy cost of living," is reported in kilocalories per square meter of body surface per hour (kcal/m^2/h).

A 70-kg adult has a BMR of approximately 66 kcal/h. You can approximate your BMR by multiplying weight in kilograms (2.2 lb = 1 kg) by 1 if you are male and by 0.9 if you are female.

Factors influencing BMR include body surface area, age, gender, stress, and hormones. Although BMR is related to overall weight and size, the critical factor is body surface area. This reflects the fact that as the ratio of body surface area to body volume increases, heat loss to the environment increases and the metabolic rate must be higher to replace the lost heat. Hence, if two people weigh the same, the taller or thinner person will have the higher BMR.

In general, the younger a person, the higher the BMR. Children and adolescents require large amounts of energy for growth. In old age, BMR declines dramatically as skeletal muscles begin to atrophy. (This helps explain why those elderly who fail to reduce their caloric intake gain weight.) Gender also plays a role. Metabolic rate is disproportionately higher in males than in females, because males typically have more muscle, which is very active metabolically even during rest. Fatty tissue, present in greater relative amounts in females, is metabolically more sluggish than muscle. Surprisingly, physical training has little effect on BMR. Although it would appear that athletes, especially those with greatly enhanced muscle mass, should have much higher BMRs than nonathletes, there is little difference between those of the same sex and surface area.

Body temperature and BMR tend to rise and fall together. Thus, fever (hyperthermia) results in a marked increase in metabolic rate. Stress, whether physical or emotional, increases BMR by mobilizing the sympathetic nervous system. Bloodborne norepinephrine and epinephrine (released by adrenal medullary cells) provoke a rise in BMR primarily by stimulating fat catabolism.

The amount of **thyroxine** produced by the thyroid gland is probably the most important hormonal factor in determining BMR; hence, thyroxine has been dubbed the "metabolic hormone." Its direct effect on most body cells (except brain cells) is to increase O_2 consumption and heat production, presumably by accelerating the use of ATP to operate the sodium-potassium pump. As ATP reserves decline, cellular respiration accelerates. Thus, the more thyroxine produced, the higher the BMR.

HOMEOSTATIC IMBALANCE

Hyperthyroidism causes a host of problems resulting from the excessive BMR it produces. The body catabolizes stored fats and tissue proteins, and, despite increased hunger and food intake, the person often loses weight. Bones weaken and muscles, including the heart, begin to atrophy. In contrast, *hypothyroidism* results in slowed metabolism, obesity, and diminished thought processes.

The **total metabolic rate (TMR)** is the rate of kilocalorie consumption needed to fuel *all* ongoing activities—involuntary and voluntary. BMR accounts for a surprisingly large part of TMR. For example, a woman whose total energy needs per day are about 2000 kcal may spend 1400 kcal or so supporting vital body activities. Skeletal muscle activity causes the most dramatic short-term changes in TMR, reflecting the fact that skeletal muscles make up nearly half of body mass. Even slight increases in muscular work can cause remarkable leaps in TMR and heat production. When a well-trained athlete exercises vigorously for several minutes, TMR may increase 20-fold, and it remains elevated for several hours after exercise stops. Food ingestion also induces a rapid increase in TMR. This effect, called **food-induced thermogenesis,** is greatest when proteins are eaten. The heightened metabolic activity of the liver during such periods probably accounts for the bulk of additional energy use. In contrast, fasting or very low caloric intake depresses TMR and results in a slower breakdown of body reserves.

Regulation of Body Temperature

As shown in Figure 24.24, body temperature represents the balance between heat production and heat loss. Although all body tissues produce heat, those most active metabolically produce the greatest amounts. When the body is at rest, most heat is generated by the liver, heart, brain, and endocrine organs, with the inactive skeletal muscles accounting for only 20–30%. This situation changes dramatically with even slight alterations in muscle tone, however; and during vigorous exercise, heat production by the skeletal muscles can be 30 to 40 times that of the rest of the body. Clearly, a change in muscle activity is one of the most important means of modifying body temperature.

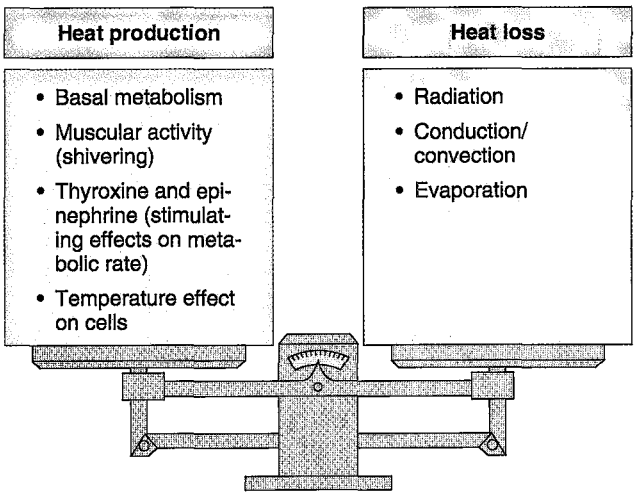

FIGURE 24.24 **Body temperature remains constant as long as heat production and heat loss are balanced.**

Body temperature averages 37°C ± 0.5°C (98.6°F) and is usually maintained within the range 35.8–38.2°C (96–101°F), despite considerable change in external (air) temperature. A healthy individual's body temperature fluctuates approximately 1°C (1.8°F) in 24 hours, with the low occurring in early morning and the high in late afternoon or early evening.

The adaptive value of this precise temperature homeostasis becomes obvious when we consider the effect of temperature on the rate of enzymatic activity. At normal body temperature, conditions are optimal for enzymatic activity. As body temperature rises, enzymatic catalysis is accelerated: With each rise of 1°C, the rate of chemical reactions increases about 10%. As the temperature spikes above the homeostatic range, neurons are depressed and proteins begin to denature. Children below the age of 5 go into convulsions when body temperature reaches 41°C (106°F), and 43°C (about 109°F) appears to be the absolute limit for life. In contrast, most body tissues can withstand marked reductions in temperature if other conditions are carefully controlled. This fact underlies the use of body cooling during open heart surgery when the heart must be stopped. Low body temperature reduces metabolic rate (and consequently nutrient requirements of body tissues and

FIGURE 24.25 **Mechanisms of heat exchange.** Passengers enjoying a hot tub on a cruise to Alaska illustrate several mechanisms of heat exchange between the body and its environment. **(1)** Conduction: Heat transfers from the hot water to the skin. **(2)** Radiation: Heat transfers from the exposed part of the body to the cooler air. **(3)** Convection: Warmed air moves away from the body via breezes. There may also be **(4)** evaporation of perspiration: Excess body heat is carried away.

the heart), allowing more time for surgery without incurring tissue damage.

Core and Shell Temperatures

Different body regions have different resting temperatures. The body's **core** (organs within the skull and the thoracic and abdominal cavities) has the highest temperature and its **shell** (essentially the skin) has the lowest temperature in most circumstances. Of the two body sites used routinely to obtain body temperature clinically, the rectum typically has a temperature about 0.4°C (0.7°F) higher than the mouth and is a better indicator of core temperature.

It is core temperature that is precisely regulated. Blood serves as the major *agent of heat exchange* between the core and shell. Whenever the shell is warmer than the external environment, heat is lost from the body as warm blood is allowed to flush into the skin capillaries. On the other hand, when heat must be conserved, blood largely bypasses the skin. This reduces heat loss and allows the shell temperature to fall toward that of the environment. Thus, while the core temperature stays relatively constant, the temperature of the shell may fluctuate substantially [between 20°C (68°F) and 40°C (104°F) for instance] as its "thickness" is adapted to changes in body activity and external temperature. (You really *can* have cold hands and a warm heart.)

Mechanisms of Heat Exchange

The mechanisms that govern heat exchange between our skin and the external environment (Figure 24.25) are the same as those governing heat exchange between inanimate objects. It helps to think of an object's temperature—whether that object is the skin or a radiator—as a guide to its heat content (*think* "heat concentration"). Then just remember that heat always flows down its concentration gradient from a warmer region to a cooler region. The body uses four mechanisms of heat transfer—radiation, conduction, convection, and evaporation.

Radiation is the loss of heat in the form of infrared waves (thermal energy). Any object that is warmer than objects in its environment—for example, a radiator and (usually) the body—will transfer heat to those objects. Under normal conditions, close to half of body heat loss occurs by radiation.

Because the direction of radiant energy flow is always from warmer to cooler, radiation explains why an initially cold room warms up shortly after it is filled with people (the "body heat furnace," so to speak). The body also gains heat by radiation, as demonstrated by the warming of the skin during sunbathing.

Conduction is the transfer of heat from a warmer object to a cooler one when the two are in direct contact with each other. For example, when we step into a hot tub, some of the heat of the water is transferred to our skin, and warm buttocks transfer heat to the seat of a chair by conduction.

The process called **convection** occurs because warm air expands and rises and cool air (being denser) falls. Thus, the warmed air enveloping the body is continually being replaced by cooler air molecules. Convection substantially enhances heat transfer from the body surface to the air because the cooler air absorbs heat by conduction more rapidly than the already-warmed air. Together, conduction and convection account for 15–20% of heat loss to the environment. These processes are enhanced by anything that moves air more rapidly across the body surface such as wind or a fan, that is, by *forced convection*.

The fourth mechanism by which the body loses heat is **evaporation.** Water evaporates because its molecules absorb heat from the environment and become energetic enough (that is, vibrate fast enough) to escape as gas (water vapor). The heat absorbed by

water during evaporation is called **heat of vaporization.** Because water absorbs a great deal of heat before vaporizing, its evaporation from body surfaces removes large amounts of body heat. For every gram of water evaporated, about 0.58 kcal of heat is removed from the body.

There is a basal level of body heat loss due to the continuous evaporation of water from the lungs, from the oral mucosa, and through the skin. The unnoticeable water loss occurring via these routes is called **insensible water loss,** and the heat loss that accompanies it is called **insensible heat loss.** Insensible heat loss dissipates about 10% of the basal heat production of the body and is a constant not subject to body temperature controls. When necessary, however, the control mechanisms do initiate heat-promoting activities to counterbalance this insensible heat loss.

Evaporative heat loss becomes an active *(sensible)* process when body temperature rises and sweating produces increased amounts of water for vaporization. Extreme emotional states activate the sympathetic nervous system, causing body temperature to rise one degree or so, and vigorous exercise can thrust body temperature upward as much as 2–3°C (3.6–5.4°F). During vigorous muscular activity, 1–2 L/h of perspiration can be produced and evaporated, removing 600–1200 kcal of heat from the body each hour. This is more than 30 times the amount of heat lost via insensible heat loss!

HOMEOSTATIC IMBALANCE

When sweating is heavy and prolonged, especially in untrained individuals, losses of water and NaCl may cause painful muscle spasms called *heat cramps.* This situation is easily rectified by ingesting fluids.

Role of the Hypothalamus

Although other brain regions contribute, the hypothalamus, particularly its *preoptic* region, is the main integrating center for thermoregulation. Together the **heat-loss center** (located more anteriorly) and the **heat-promoting center** make up the brain's **thermoregulatory centers.**

The hypothalamus receives afferent input from (1) **peripheral thermoreceptors** located in the shell (the skin), and (2) **central thermoreceptors** sensitive to blood temperature and located in the body core including the anterior portion of the hypothalamus. Much like a thermostat, the hypothalamus responds to this input by reflexively initiating appropriate heat-promoting or heat-loss activities via autonomic effector pathways. Although the central thermoreceptors are more critically located than the peripheral ones, varying inputs from the shell probably alert the hypothalamus of the need to act to prevent temperature changes in the core; that is, they allow the hypothalamus to anticipate possible changes to be made.

Heat-Promoting Mechanisms

When the external temperature is low or blood temperature falls for any reason, the heat-promoting center is activated and triggers one or more of the following mechanisms to maintain or increase core body temperature (Figure 24.26).

1. Constriction of cutaneous blood vessels. Activation of the sympathetic vasoconstrictor fibers serving the blood vessels of the skin causes strong vasoconstriction. As a result, blood is restricted to deep body areas and largely bypasses the skin. Because the skin is separated from deeper organs by a layer of insulating subcutaneous (fatty) tissue, heat loss from the shell is dramatically reduced and shell temperature drops toward that of the external environment.

HOMEOSTATIC IMBALANCE

Restricting blood flow to the skin is not a problem for a brief period, but if it is extended (as during prolonged exposure to very cold weather), skin cells deprived of oxygen and nutrients begin to die. This extremely serious condition is called *frostbite.*

2. Shivering. Shivering, involuntary shuddering contractions, is triggered when brain centers controlling muscle tone are activated and muscle tone reaches sufficient levels to alternately stimulate stretch receptors in antagonistic muscles. Shivering is very effective in increasing body temperature because muscle activity produces large amounts of heat.

3. Increase in metabolic rate. Cold stimulates the release of epinephrine and norepinephrine by the adrenal medulla in reponse to sympathetic nerve stimuli, which elevates the metabolic rate and enhances heat production. This mechanism, called **chemical,** or **nonshivering, thermogenesis,** is known to occur in infants but still controversial in adults.

4. Enhanced thyroxine release. When environmental temperature decreases gradually, as in the transition from summer to winter, the hypothalamus of infants releases *thyrotropin-releasing hormone.* This activates the anterior pituitary to release *thyroid-stimulating hormone,* which induces the thyroid to liberate larger amounts of thyroid hormone to the blood. Because thyroid hormone increases metabolic rate, body heat production increases. A similar TSH response to cold exposure does not appear to occur in adults.

Beside these involuntary adjustments, we humans make a number of *behavioral modifications* to prevent overcooling of our body core:

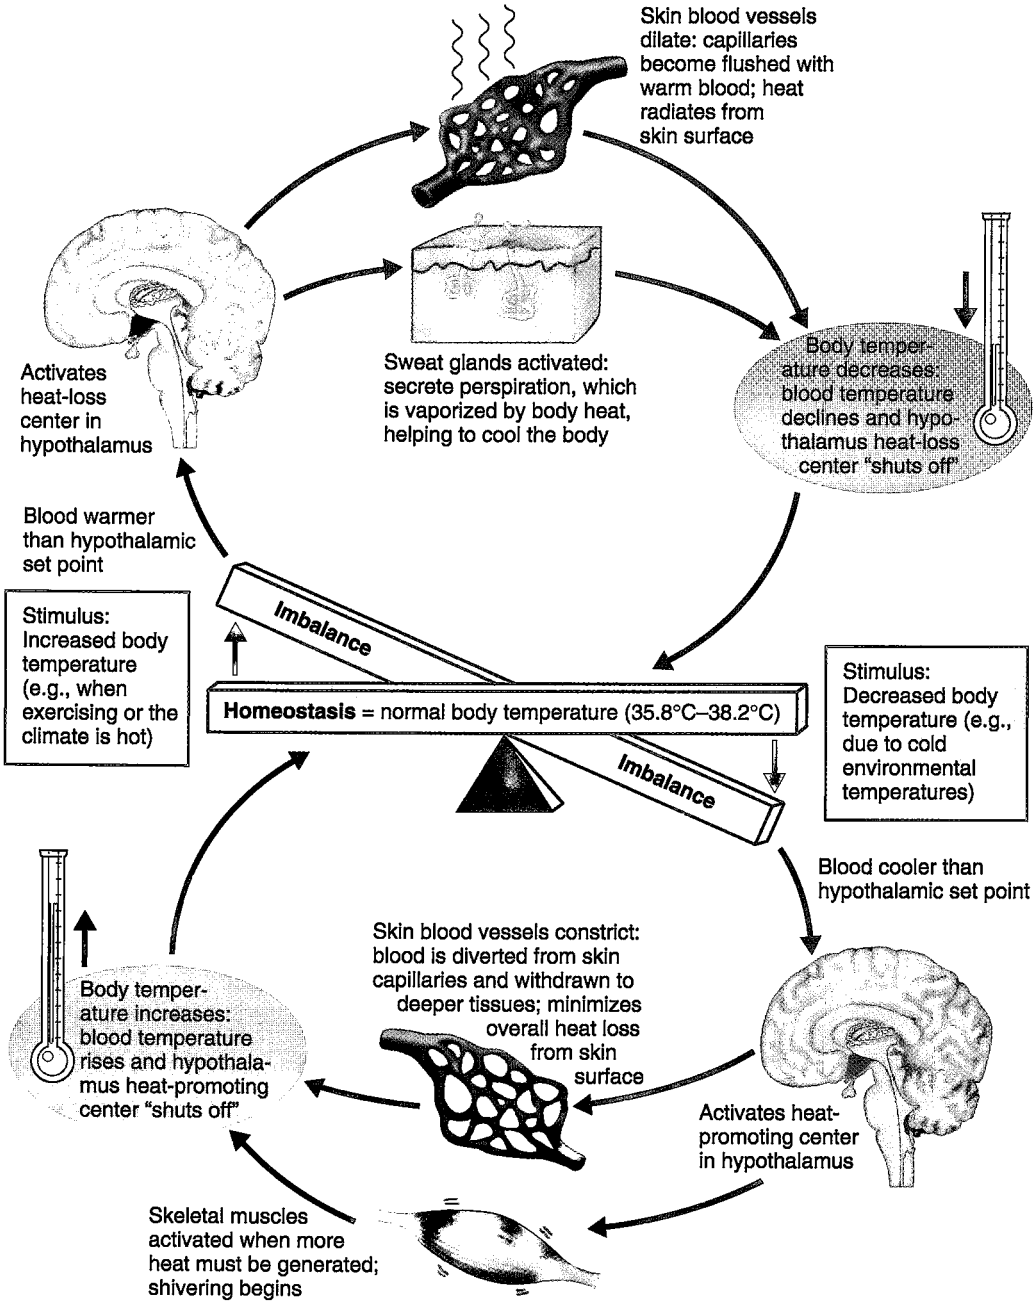

FIGURE 24.26 **Mechanisms of body temperature regulation.**

- Putting on more or warmer clothing to restrict heat loss (a hat, gloves, and "insulated" outer garments)
- Drinking hot fluids
- Changing posture to reduce exposed body surface area (hunching over or clasping the arms across the chest)
- Increasing physical activity to generate more heat (jumping up and down, clapping the hands)

Heat-Loss Mechanisms

Heat-loss mechanisms protect the body from excessively high temperatures. Most heat loss occurs through the skin via radiation, conduction, convection, and evaporation. How do the heat-exchange mechanisms fit into the heat-loss temperature regulation scheme? The answer is quite simple. Whenever core body temperature rises above normal, the hypothalamic heat-promoting center is inhibited. At the same time, the heat-loss center is activated and so triggers one or both of the following (Figure 24.26):

1. Dilation of cutaneous blood vessels. Inhibiting the vasomotor fibers serving blood vessels of the skin allows the vessels to dilate. As the blood vessels swell with warm blood, heat is lost from the shell by radiation, conduction, and convection.

2. Enhanced sweating. If the body is extremely overheated or if the environment is so hot [over 33°C (about 92°F)] that heat cannot be lost by other means, evaporation becomes necessary. The sweat glands are strongly activated by sympathetic fibers and spew out large amounts of perspiration. Evaporation of perspiration is an efficient means of ridding the body of surplus heat as long as the air is dry. However, when the relative humidity is high, evaporation occurs much more slowly. In such cases, the heat-liberating mechanisms cannot work well, and we feel miserable and irritable.

Behavioral or voluntary measures commonly taken to reduce body heat include

- Reducing activity ("laying low")
- Seeking a cooler environment (a shady spot) or using a device to increase convection (a fan) or cooling (an air conditioner)
- Wearing light-colored, loose clothing that reflects radiant energy. (This is actually cooler than being nude because bare skin absorbs most of the radiant energy striking it.)

HOMEOSTATIC IMBALANCE

Under conditions of overexposure to a hot and humid environment, normal heat-loss processes become ineffective. The **hyperthermia** (elevated body temperature) that ensues depresses the hypothalamus. At a core temperature of around 105°F, heat-control mechanisms are suspended, creating a vicious *positive feedback cycle*. Increasing temperatures increase the metabolic rate, which increases heat production. The skin becomes hot and dry and, as the temperature continues to spiral upward, multiple organ damage becomes a distinct possibility, including brain damage. This condition, called **heat stroke,** can be fatal unless corrective measures are initiated immediately (immersing the body in cool water and administering fluids).

The terms *heat exhaustion* and *exertion-induced heat exhaustion* are often used to describe the heat-associated collapse of an individual during or following vigorous physical activity accompanied by extreme sweating. This condition, evidenced by elevated body temperature and mental confusion and/or fainting, is due to dehydration and consequent low blood pressure. In contrast to heat stroke, heat-loss mechanisms are still functional in heat exhaustion; indeed, the symptoms are a direct consequence of those mechanisms. However, heat exhaustion can rapidly progress to heat stroke if the body is not cooled and rehydrated promptly.

Hypothermia (hi"po-ther'me-ah) is low body temperature resulting from prolonged uncontrolled exposure to cold. Vital signs (respiratory rate, blood pressure, and heart rate) decrease as cellular enzymes become sluggish. Drowsiness sets in and, oddly, the person becomes comfortable even though previously he or she felt extremely cold. Shivering stops at a core temperature of 30–32°C (87–90°F) when the body has exhausted its heat-generating capabilities. Uncorrected, the situation progresses to coma and finally death (by cardiac arrest), when body temperatures approach 21°C (70°F). ●

Fever

Fever is *controlled hyperthermia.* Most often, it results from infection somewhere in the body, but it may be caused by cancer, allergic reactions, or CNS injuries. Whatever the cause, macrophages and other cells release cytokines, originally called *pyrogens* (literally, "fire starters"), at least two of which are now known to be interleukins. These chemicals act on the hypothalamus, causing release of prostaglandins which reset the hypothalamic thermostat to a higher-than-normal temperature, so that heat-promoting mechanisms kick in. As a result of vasoconstriction, heat loss from the body surface declines, the skin cools, and shivering begins to generate heat. These "chills" are a sure sign body temperature is rising. The temperature rises until it reaches the new setting, and then is maintained at that setting until natural body defenses or antibiotics reverse the disease process, and chemical messengers called *cryogens* (vasopressin and others) act to prevent fever from becoming excessive and reset the thermostat to a lower (or normal) level. Then, heat-loss mechanisms swing into action; sweating begins and the skin becomes flushed and warm. Physicians have long recognized these signs as signals that body temperature is falling (aah, she has passed the crisis).

As explained in Chapter 21, fever, by increasing the metabolic rate, helps speed healing, and it also appears to inhibit bacterial growth. The danger of fever is that if the body thermostat is set too high, proteins may be denatured and permanent brain damage may occur.

Developmental Aspects of Nutrition and Metabolism

Good nutrition is essential in utero, as well as throughout life. If the mother is ill nourished, the development of her infant is affected. Most serious is the lack of adequate calories, proteins, and vitamins needed for fetal tissue growth, especially brain growth. Additionally, because brain growth continues for the first three years after birth, inadequate nutrients during this time will lead to mental deficits or learning disorders. Proteins are needed for

(Text continues on p. 992.)

A CLOSER LOOK

Obesity: Magical Solution Wanted

How fat is too fat? What distinguishes an obese person from one who is merely overweight? The bathroom scale is an inaccurate guide because body weight tells little of body composition. Dense bones and well-developed muscles can make a person technically overweight. Arnold Schwarzenegger, for example, has tipped the scales at a hefty 257 lb.

The official medical measure of obesity and body fatness is the *body mass index (BMI)*, an index of a person's weight relative to height. To estimate BMI, multiply weight in pounds by 705 and then divide by your height in inches squared:

$$BMI = wt(lb) \times 705/ht(inches)^2$$

Overweight is defined by a BMI between 25 and 30 and having some health risk; obesity is a BMI greater than 30 with markedly increased health risk. The most common view of obesity is that it is a condition of excessive triglyceride storage. We bewail our inability to rid ourselves of fat, but the real problem is that we keep refilling the storehoses by consuming too many calories. A body fat content of 18–20% of body weight (males and females respectively) is deemed normal for adults.

However it's defined, obesity is perplexing and poorly understood, and the economic toll of obesity-related disease is staggering. Despite its adverse health effects (the obese have a higher incidence of atherosclerosis, diabetes mellitus, hypertension, heart disease, and osteoarthritis), the U.S. is big and getting bigger, at least around its middle. Two out of three adults are overweight; of that, one out of three is obese and one in twelve has diabetes, a common sequel of weight problems. U.S. kids are getting fatter too: 20 years ago, 5% were overweight; today 15% are and more are headed that way. Furthermore, because they are opting for video games and nachos instead of tag or touch football and an apple, their general cardiovascular fitness is declining as well and health risks associated with excess weight start frighteningly early. For example, obesity-related heart problems, such as an enlarged heart—a risk factor for heart attack and CHF—may start developing in the early teens or even younger.

Besides the physical toll, the social stigma and economic disadvantages of obesity are legendary. A fat person pays higher insurance premiums, is discriminated against in the job market, has fewer clothing choices, and endures frequent humiliation throughout life. It's a fair bet that few people choose to become obese. So what causes it?

Theories of Obesity Causes

1. Overeating during childhood promotes adult obesity. Some believe that the "clean your plate" order sets the stage for adult obesity by increasing the number of adipose cells formed during childhood. The more adipose cells there are, the more fat can be stored.

2. Obese people are more fuel efficient and more effective "fat storers." Although it is often assumed that the obese eat more, this is not necessarily true—many actually eat less than people of normal weight. When yo-yo dieters lose weight, their metabolic rate falls sharply. But, when they subsequently gain weight, their metabolic rate increases like a furnace being stoked. Each successive weight loss occurs more slowly, but regaining weight occurs three times as fast. Furthermore, fats pack more wallop per calorie (are more fattening) than are proteins or carbohydrates because of the way the body processes them. If 100 excess carbohydrate calories are ingested, 23 are used in metabolic processing and 77 are stored. However, if the 100 excess calories come from fat, only 3 calories are "burned" and the rest (97) are stored. These facts apply to everyone, but when you are obese the picture is even bleaker. Adipose cells of overweight people sprout more alpha receptors, which favor fat accumulation, and enteroendocrine cells of the stomach secrete much larger amounts of ghrelin (which ratchets up the appetite just before eating) in those that have recently lost weight. Furthermore, the enzyme lipoprotein lipase, which unloads fat from the blood (usually to fat cells) is exceptionally efficient in the obese. Although it would appear that the so-called satiety chemicals (hormones and others) should prevent massive fat deposit, this seems not to be the case in the obese. It may be that excess weight promotes not only insulin resistance (the enlarged adipose cells spew out tumor necrosis factor alpha, which can act as a trigger) but leptin resistance as well.

3. Genetic predisposition. Morbid obesity is the destiny of those inheriting two obesity genes. These people, given extra calories, will always lay them down as fat, as opposed to those that lay down more muscle with some of the excess. However, a true genetic predisposition for "fatness" appears to account for only about 5% of the American obese.

Treatments—The Bad and the Good

Some so-called treatments for obesity are almost more dangerous than the disease itself. Unfortunate strategies include

1. "Water pills." Diuretics prompt the kidneys to excrete more water and may cause a few pounds of weight loss for a few hours. They can also cause serious dehydration and electrolyte imbalance.

2. Diets. Diet products and books sell well, but do any of the currently popular diets work and are they safe? At the present time there is a duel between those promoting low-carbohydrate (high-protein and -fat) diets such as the Atkins and South Beach diets, and

those espousing the traditional low-fat (high–complex carbohydrates) diet. Clinical studies show that those on the low-carbohydrate diets lose weight more quickly at first, but tend to plateau at 6 months. They seem to preferentially lose fat from the body trunk, a weight distribution pattern (the "apple") associated with heart disease and diabetes mellitus. (This propensity to these diseases, called "metabolic syndrome," appears to be due to the large amounts of inflammatory cytokines released by visceral fat cells.) When dieting was continued for a year, those on the low-fat diets lost just as much weight as did those on the low-carbohydrate diets and they experienced fewer episodes of diarrhea, constipation, headache, and muscle cramps. Although there was concern that the low-carbohydrate diets would promote undesirable plasma cholesterol and lipid values, for the most part this has not been the case.

Diets that have users counting the glycemic indexes of the food they eat, such as the New Glucose Revolution diet, distinguish between good carbs (whole grains, nonstarchy vegetables and fruits) and bad carbs (starches, sugary foods, refined grains) and have the approval of many physicians. The oldie-but-goodie Weight Watcher's diet, which has dieters counting points, still works and allows virtually any food choice as long as the allowed point count isn't exceeded.

Some over-the-counter liquid high-protein diets contain such poor-quality (incomplete) protein that they are actually dangerous. The worst are those that contain collagen protein instead of milk or soybean sources.

3. Surgery. Sometimes sheer desperation prompts surgical solutions: wiring the jaws shut; reducing stomach volume by banding; gastric bypass surgery, which may involve stomach stapling and intestinal bypass surgery, or the more radical biliopancreatic diversion (BPD); and liposuction (removal of fat by suctioning).

BPD rearranges the digestive tract. Up to two-thirds of the stomach is removed and the small intestine is cut

in half and one portion is sutured to the stomach opening. Pancreatic juice and bile are diverted away from the "new intestine" so far fewer nutrients and no fats are absorbed. Many of these procedures have been remarkably effective at promoting weight loss and restoring health. (Blood pressure returns to normal in many that were originally hypertensive, and sleep apnea is reduced.) Patients can eat anything they want without gaining weight, but exceeding the stomach capacity leads to the dumping syndrome, in which nausea and vomiting occur.

Liposuction reshapes the body by suctioning off fat deposits, but it is not a good choice for losing weight. Like BPD, it carries all the risks of surgery, and unless eating habits change, fat depots elsewhere in the body overfill.

4. Diet drugs and weight-loss supplements. Currently popular weight-loss drugs include phentermine, sibutramine, and orlistat. Phentermine is one-half of the former fen-phen (Redux) combination that caused heart problems, deaths, and litigation for its producer in the 1990s. It acts via increased sympathetic nervous system activity, which increases blood pressure and heart rate. Sibutramine (Meridia) inhibits reclamation of the neurotransmitters norepinephrine and serotonin and has amphetamine-like effects. It has recently come under fire because of suspected cardiovascular side effects. Orlistat (Xenical) interferes with pancreatic lipase so that part of the fat eaten is not digested or absorbed, which also interferes with the absorption of fat-soluble vitamins. Although it is effective as a weight-loss agent, its side effects, which include diarrhea and anal leakage, are unpleasant to say the least. Currently a number of drugs are being developed that act at several different CNS sites, including neuropeptide Y inhibitors.

Some over-the-counter weight-loss supplements that are claimed to increase metabolism and burn calories at an accelerated rate have proved to be very dangerous. For example:

- Capsules containing usnic acid, a chemical found in some lichens, damages hepatocytes and has led to liver failure in a few cases.
- Ephedra-containing supplements are notorious—over 100 deaths and 16,000 cases of problems including strokes, seizures, and headaches have been reported.

When it comes to such supplements, the burden of proof is on the FDA to show that the product is unsafe. Hence, the true extent of ills caused by weight-loss supplements is not known—while the worst cases attract attention, less serious ones go unreported or undiagnosed.

So are there any good treatments for obesity? The best way to lose weight—indeed the only realistic way—is to take in fewer calories and increase physical activity. Fidgeting helps and so does resistance exercise, which increases muscle mass. Furthermore, low activity levels actually stimulate eating, while physical exercise depresses appetite and increases metabolic rate not only during activity but also for some time after. The only way to keep the weight off is to make dietary and exercise changes lifelong habits. ■

muscle and bone growth, and calcium is required for strong bones. Although anabolic processes are less critical after growth is completed, sufficient nutrients are still essential to maintain normal tissue replacement and metabolism.

HOMEOSTATIC IMBALANCE

There are many inborn errors of metabolism (or genetic disorders), but perhaps the two most common are *cystic fibrosis* and *phenylketonuria (PKU)* (fen"il-ke"to-nu're-ah). Cystic fibrosis is described in Chapter 22. In PKU, the tissue cells are unable to use the amino acid phenylalanine (fen"il-al'ah-nīn), which is present in all protein foods. The defect involves a deficiency of the enzyme that converts phenylalanine to tyrosine. Phenylalanine cannot be metabolized, so it and its deaminated products accumulate in the blood and act as neurotoxins that cause brain damage and retardation within a few months. These consequences are uncommon today because most states require a urine or blood test to identify affected newborns, and these children are put on a low-phenylalanine diet. When this special diet should be terminated is controversial. Some believe it should be continued through adolescence; others order it discontinued when the child is 6 years old. Expectant women are sometimes encouraged to return to the controlled phenylalanine diet during their pregnancy.

There are a number of other enzyme defects, classified according to the impaired process as carbohydrate, lipid, or mineral metabolic disorders. The carbohydrate deficit *galactosemia* results from an abnormality in or lack of the liver enzymes needed to transform galactose to glucose. Galactose accumulates in the blood and leads to mental deficits. In the carbohydrate disorder *glycogen storage disease,* glycogen synthesis is normal, but one of the enzymes needed to convert it back to glucose is missing. As excessive amounts of glycogen are stored, its storage organs (liver and skeletal muscles) become glutted with glycogen and enlarge tremendously. ●

With the exception of *insulin-dependent diabetes mellitus,* children free of genetic disorders rarely exhibit metabolic problems. However, by middle age and particularly old age, *non-insulin-dependent diabetes mellitus* becomes a major problem, particularly in the obese.

Metabolic rate declines throughout the life span. In old age, muscle and bone wasting and declining efficiency of the endocrine system take their toll. Because many elderly are also less active, the metabolic rate is sometimes so low that it becomes nearly impossible to obtain adequate nutrition without gaining weight. The elderly also use more medications than any other group, at a time of life when the liver has become less efficient in its detoxifying duties. Consequently, many of the agents prescribed for age-related medical problems influence nutrition. For example:

- Some diuretics prescribed for congestive heart failure or hypertension (to flush fluids out of the body) can cause severe hypokalemia by promoting excessive loss of potassium.
- Some antibiotics, for example, sulfa drugs, tetracycline, and penicillin, interfere with food digestion and absorption. They may also cause diarrhea, thereby decreasing nutrient absorption further.
- Although its use is discouraged by physicians because it interferes with absorption of fat-soluble vitamins, mineral oil is still a popular laxative with the elderly.
- Alcohol is used by about half the elderly population in the U.S. When it is substituted for food, nutrient stores can be depleted. Excessive alcohol intake leads to absorption problems, certain vitamin and mineral deficiencies, deranged metabolism, and damage to the liver and pancreas.

In short, the elderly are at risk not only from the declining efficiency of their metabolic processes, but also from a huge variety of lifestyle and medication factors that affect their nutrition.

Although malnutrition and a waning metabolic rate present problems to some elderly, certain nutrients—notably glucose—appear to contribute to the aging process in people of all ages. Nonenzymatic reactions (the so-called *browning reactions*) between glucose and proteins, long known to discolor and toughen foods, may have the same effects on body proteins. When enzymes attach sugars to proteins, they do so at specific sites and the glycoproteins produced play well-defined roles in the body. By contrast, nonenzymatic binding of glucose to proteins (a process that increases with age) is haphazard and eventually causes cross-links between proteins. The increase in this type of binding probably contributes to lens clouding, atherosclerotic plaque formation, and the general tissue stiffening and loss of elasticity so common in the aged.

■ ■ ■

Nutrition is one of the most overlooked areas in clinical medicine. Yet, what we eat and drink influences nearly every phase of metabolism and plays a major role in our overall health. Now that we have examined the fates of nutrients in body cells, we are ready to study the urinary system, the organ system that works tirelessly to rid the body of nitrogen wastes resulting from metabolism and to maintain the purity of our internal fluids.

Related Clinical Terms

Appetite A desire for food. A psychological phenomenon dependent on memory and associations, as opposed to hunger, which is a physiological need to eat.

Familial hypercholesterolemia (hi"per-ko-les"ter-ol-e'me-ah). An inherited condition in which the LDL receptors are absent or abnormal, the uptake of cholesterol by tissue cells is blocked, and the total concentration of cholesterol (and LDLs) in the blood is enormously elevated (e.g., 680 mg of cholesterol per 100 ml of blood). Affected individuals develop atherosclerosis at an early age, heart attacks begin in the third or fourth decade, and most die by age 60 from coronary artery disease. Treatment entails dietary modifications, exercise, and various cholesterol-reducing drugs.

Kwashiorkor (kwash"e-or'kor) Severe protein and calorie deficiency which is particularly devastating in children, resulting in mental retardation and failure to grow. A consequence of malnutrition or starvation, it is characterized by a bloated abdomen because the level of plasma proteins is inadequate to keep fluid in the bloodstream. Skin lesions and infections likely.

Marasmus (mah-raz'mus) Protein-calorie malnutrition, accompanied by progressive wasting. Often due to ingestion of food of very poor quality. Growth for age is severely stunted.

Pica (pi'kah) Craving and eating substances not normally considered nutrients, such as clay, cornstarch, or dirt.

Skin-fold test Clinical test of body fatness. A skin fold in the back of the arm or below the scapula is measured with a caliper. A fold over 1 inch in thickness indicates excess fat. Also called the fat-fold test.

Chapter Summary

Media study tools that could provide you additional help in reviewing specific key topics of Chapter 24 are referenced below. IP = *InterActive Physiology*

Nutrition (pp. 943–956)

1. Nutrients include water, carbohydrates, lipids, proteins, vitamins, and minerals. The bulk of the organic nutrients is used as fuel to produce cellular energy (ATP). The energy value of foods is measured in kilocalories (kcal).

2. Essential nutrients are those that are inadequately synthesized by body cells and must be ingested in the diet.

Carbohydrates (pp. 944–945)

3. Carbohydrates are obtained primarily from plant products. Absorbed monosaccharides other than glucose are converted to glucose by the liver.

4. Monosaccharides are used primarily for cellular fuel. Small amounts are used for nucleic acid synthesis and to glycosylate plasma membranes.

5. Recommended carbohydrate intake for adults is 45–65% of daily caloric intake.

Lipids (pp. 944–946)

6. Most dietary lipids are triglycerides. The primary sources of saturated fats are animal products, tropical oils, and hydrogenated oils; unsaturated fats are present in plant products, nuts, and cold-water fish. The major sources of cholesterol are egg yolk, meats, and milk products.

7. Linoleic and linolenic acids are essential fatty acids.

8. Triglycerides provide reserve energy, cushion body organs, and insulate the body. Phospholipids are used to synthesize plasma membranes and myelin. Cholesterol is used in plasma membranes and is the structural basis of vitamin D, steroid hormones, and bile salts.

9. Fat intake should represent 35% or less of caloric intake, and saturated and trans fats should be replaced by mono- and polyunsaturated fats if possible. The liver makes a basal amount of cholesterol (85%) even when dietary cholesterol intake is excessive.

Proteins (pp. 945, 946–947)

10. Animal products provide high-quality complete protein containing all (10) essential amino acids. Most plant products lack one or more of the essential amino acids.

11. Amino acids are the structural building blocks of the body and of important regulatory molecules.

12. Protein synthesis can and will occur if all essential amino acids are present and sufficient carbohydrate (or fat) calories are available to produce ATP. Otherwise, amino acids will be burned for energy.

13. Nitrogen balance occurs when protein synthesis equals protein loss.

14. A dietary intake of 0.8 g of protein per kg of body weight is recommended for most healthy adults.

Vitamins (pp. 947–952)

15. Vitamins are organic compounds needed in minute amounts. Most act as coenzymes. The richest sources are whole grains, vegetables, legumes, and fruit.

16. Except for vitamin D and the K and B vitamins made by enteric bacteria, vitamins are not made in the body.

17. Water-soluble vitamins (B and C) are not stored to excess in the body. Fat-soluble vitamins include vitamins A, D, E, and K; all but vitamin K are stored and can accumulate to toxic amounts.

Minerals (pp. 952–956)

18. Besides calcium, phosphorus, potassium, sulfur, sodium, chloride, and magnesium, the body requires trace amounts of at least a dozen other minerals.

19. Minerals are not used for energy. Some are used to mineralize bone; others are bound to organic compounds or exist as ions in body fluids, where they play various roles in cell processes and metabolism.

20. Mineral uptake and excretion are carefully regulated to prevent mineral toxicity. The richest sources of minerals are animal products, vegetables, seeds, and legumes.

Metabolism (pp. 956–981)

Overview (pp. 956–959)

1. Metabolism encompasses all chemical reactions necessary to maintain life. Metabolic processes are either anabolic or catabolic.

2. Cellular respiration refers to catabolic processes during which energy is released and some is captured in ATP bonds.

3. Energy is released when organic compounds are oxidized. Cellular oxidation is accomplished primarily by the

removal of hydrogen (electrons). When molecules are oxidized, others are simultaneously reduced by accepting hydrogen (or electrons).

4. Most enzymes catalyzing oxidation-reduction reactions require coenzymes as hydrogen acceptors. Two important coenzymes in these reactions are NAD^+ and FAD.

5. In animal cells, the two mechanisms of ATP synthesis are substrate-level phosphorylation and oxidative phosphorylation.

IP Muscular System; Topic: Muscle Metabolism, pp. 3–8.

Carbohydrate Metabolism (pp. 959–967)

6. Carbohydrate metabolism is essentially glucose metabolism.

7. Phosphorylation of glucose on entry into cells effectively traps it in most tissue cells.

8. Glucose is oxidized to carbon dioxide and water via three successive pathways: glycolysis, Krebs cycle, and electron transport chain. Some ATP is harvested in each pathway, but the bulk is captured in the electron transport chain.

9. Glycolysis is a reversible pathway in which glucose is converted to two pyruvic acid molecules; two molecules of reduced NAD^+ are formed, and there is a net gain of 2 ATP. Under aerobic conditions, pyruvic acid enters the Krebs cycle; under anaerobic conditions, it is reduced to lactic acid.

10. The Krebs cycle is fueled by pyruvic acid (and fatty acids). To enter the cycle, pyruvic acid is converted to acetyl CoA. The acetyl CoA is then oxidized and decarboxylated. Complete oxidation of two pyruvic acid molecules yields 6 CO_2, 8 NADH + H^+, 2 $FADH_2$, and a net gain of 2 ATP. Much of the energy originally present in the bonds of pyruvic acid is now present in the reduced coenzymes.

11. In the electron transport chain, (a) reduced coenzymes are oxidized by delivering hydrogen to a series of oxidation-reduction acceptors; (b) hydrogen is split into hydrogen ions and electrons (as electrons run downhill from acceptor to acceptor, the energy released is used to pump H^+ into the mitochondrial intermembrane space, which creates an electrochemical proton gradient); (c) the energy stored in the electrochemical proton gradient drives H^+ back through ATP synthase, which uses the energy to form ATP; (d) H^+ and electrons are combined with oxygen to form water.

12. For each glucose molecule oxidized to carbon dioxide and water, there is a net gain of 38 ATP: 4 ATP from substrate-level phosphorylation and 34 ATP from oxidative phosphorylation. The shuttle for reduced NAD^+ produced in the cytosol may use 2 ATP of that amount.

13. When cellular ATP reserves are high, glucose catabolism is inhibited and glucose is converted to glycogen (glycogenesis) or to fat (lipogenesis). Much more fat than glycogen is stored.

14. Gluconeogenesis is the formation of glucose from noncarbohydrate (fat or protein) molecules. It occurs in the liver when blood glucose levels begin to fall.

IP Muscular System; Topic: Muscle Metabolism, pp. 10–22.

Lipid Metabolism (pp. 967–970)

15. End products of lipid digestion (and cholesterol) are transported in blood in the form of chylomicrons.

16. Glycerol is converted to glyceraldehyde-PO_4 and enters the Krebs cycle or is converted to glucose.

17. Fatty acids are oxidized by beta oxidation into acetic acid fragments. These are bound to coenzyme A and enter the Krebs cycle as acetyl CoA. Dietary fats not needed for energy or structural materials are stored in adipose tissue.

18. There is a continual turnover of fats in fatty depots. Breakdown of fats to fatty acids and glycerol is called lipolysis.

19. When excessive amounts of fats are used, the liver converts acetyl CoA to ketone bodies and releases them to the blood. Excessive levels of ketone bodies (ketosis) lead to metabolic acidosis.

20. All cells use phospholipids and cholesterol to build their plasma membranes. The liver forms many functional molecules (lipoproteins, bile salts, etc.) from lipids.

Protein Metabolism (pp. 970–971)

21. To be oxidized for energy, amino acids are converted to keto acids that can enter the Krebs cycle. This involves transamination, oxidative deamination, and keto acid modification.

22. Amine groups removed during deamination (as ammonia) are combined with carbon dioxide by the liver to form urea. Urea is excreted in urine.

23. Deaminated amino acids may also be converted to fatty acids and glucose.

24. Amino acids are the body's most important building blocks. Nonessential amino acids are made in the liver by transamination.

25. In adults, most protein synthesis serves to replace tissue proteins and to maintain nitrogen balance.

26. Protein synthesis requires the presence of all ten essential amino acids. If any are lacking, amino acids are used as energy fuels.

Catabolic-Anabolic Steady State of the Body (pp. 971–973)

27. The amino acid pool provides amino acids for synthesis of proteins and amino acid derivatives, ATP synthesis, and energy storage. To be stored, amino acids are first deaminated and then converted to fats or glycogen.

28. The carbohydrate-fat pool primarily provides fuels for ATP synthesis and other molecules that can be stored as energy reserves.

29. The nutrient pools are connected by the bloodstream; fats, carbohydrates, and proteins may be interconverted via common intermediates.

Absorptive and Postabsorptive States (pp. 973–978)

30. During the absorptive state (during and shortly after a meal), glucose is the major energy source; needed structural and functional molecules are made; excesses of carbohydrates, fats, and amino acids are stored as glycogen and fat.

31. Events of the absorptive state are controlled by insulin, which enhances the entry of glucose (and amino acids) into cells and accelerates its use for ATP synthesis or storage as glycogen or fat.

32. The postabsorptive state is the period when bloodborne fuels are provided by breakdown of energy reserves. Glucose is made available to the blood by glycogenolysis, lipolysis, and gluconeogenesis. Glucose sparing begins and, if fasting is prolonged (4–5 days), the brain also begins to metabolize ketone bodies.

33. Events of the postabsorptive state are controlled largely by glucagon and the sympathetic nervous system, which mobilize glycogen and fat reserves and trigger gluconeogenesis.

The Metabolic Role of the Liver (pp. 978–981)

34. The liver is the body's main metabolic organ and it plays a crucial role in processing (or storing) virtually every nutrient group. It helps maintain blood energy sources, metabolizes hormones, and detoxifies drugs and other substances.

35. The liver synthesizes cholesterol, catabolizes cholesterol and secretes it in the form of bile salts, and makes lipoproteins.

36. LDLs transport triglycerides and cholesterol from the liver to the tissues, whereas HDLs transport cholesterol from the tissues to the liver (for catabolism and elimination).

37. Excessively high LDL levels are implicated in atherosclerosis, cardiovascular disease, and strokes.

Energy Balance (pp. 981–991)

1. Body energy intake (derived from food oxidation) is precisely balanced by energy output (heat, work, and energy storage). Eventually, all of the energy intake is converted to heat.

2. When energy balance is maintained, weight remains stable. When excess amounts of energy are stored, obesity results (condition of excessive fat storage, 20% or more above the norm).

Regulation of Food Intake (pp. 982–984)

3. The hypothalamus (particularly its arcuate nucleus) and other brain centers are involved in the regulation of eating behavior.

4. Factors thought to be involved in regulating food intake include (a) neural signals from the gut to the brain, (b) nutrient signals related to total energy storage (e.g., large fatty reserves and increased plasma levels of glucose and amino acids depress hunger and eating); (c) plasma concentrations of hormones that control events of the absorptive and postabsorptive states, and hormones that provide feedback signals to brain feeding centers (leptin appears to exert the main long-term controls of appetite and energy metabolism); (d) body temperature; and (e) psychological factors.

Metabolic Rate and Heat Production (pp. 984–985)

5. Energy used by the body per hour is the metabolic rate.

6. Basal metabolic rate (BMR), reported in kcal/m^2/h, is the measurement obtained under basal conditions: the person is at comfortable room temperature, supine, relaxed, and in the postabsorptive state. BMR indicates energy needed to drive only the resting body processes.

7. Factors influencing metabolic rate include age, sex, size, body surface area, thyroxine levels, specific dynamic action of foods, and muscular activity.

Regulation of Body Temperature (pp. 985–989)

8. Body temperature reflects the balance between heat production and heat loss and is normally 37°C (± 0.5°C), which is optimal for physiological activities.

9. At rest, most body heat is produced by the liver, heart, brain, kidneys, and endocrine organs. Activation of skeletal muscles causes dramatic increases in body heat production.

10. The body core (organs within the skull and the ventral body cavity) generally has the highest temperature. The shell (the skin) is the heat-exchange surface, and is usually coolest.

11. Blood serves as the major heat-exchange agent between the core and the shell. When skin capillaries are flushed with blood and the skin is warmer than the environment, heat is lost from the body. When blood is withdrawn to deep organs, heat loss from the shell is inhibited.

12. Heat-exchange mechanisms include radiation, conduction, convection, and evaporation. Evaporation, the conversion of water to water vapor, requires the absorption of heat. For each gram of water vaporized, about 0.6 kcal of heat is absorbed.

13. The hypothalamus acts as the body's thermostat. Its heat-promotion and heat-loss centers receive inputs from peripheral and central thermoreceptors, integrate these inputs, and initiate responses leading to heat loss or heat promotion.

14. Heat-promoting mechanisms include constriction of skin vasculature, increase in metabolic rate in infants (via release of norepinephrine), and shivering. If environmental cold is prolonged, the thyroid gland may be stimulated to release more thyroxine.

15. When heat must be removed from the body, dermal blood vessels are dilated, allowing heat loss through radiation, conduction, and convection. When greater heat loss is mandated (or the environmental temperature is so high that radiation and conduction are ineffective), sweating is initiated. Evaporation of perspiration is an efficient means of heat loss as long as the humidity is low.

16. Profuse sweating can lead to heat exhaustion, indicated by a rise in temperature, a drop in blood pressure, and collapse. When the body cannot rid itself of surplus heat, body temperature rises to the point where all thermoregulatory mechanisms become ineffective—a potentially lethal condition called heat stroke.

17. Fever is controlled hyperthermia, which follows thermostat resetting to higher levels by prostaglandins and initiation of heat-promotion mechanisms, evidenced by the chills. When the disease process is reversed, heat-loss mechanisms are initiated.

Developmental Aspects of Nutrition and Metabolism (pp. 989, 992)

1. Good nutrition is essential for normal fetal development and normal growth during childhood.

2. Inborn errors of metabolism include cystic fibrosis, PKU, glycogen storage disease, galactosemia, and many others. Hormonal disorders, such as lack of insulin or thyroid hormone, may also lead to metabolic abnormalities. Diabetes mellitus is the most significant metabolic disorder in middle-aged and older adults.

3. In old age, metabolic rate declines as enzyme and endocrine systems become less efficient and skeletal muscles atrophy. Reduced caloric needs make it difficult to obtain adequate nutrition without becoming overweight.

4. Elderly individuals ingest more medications than any other age group, and many of these drugs negatively affect their nutrition.

Review Questions

Multiple Choice/Matching

(Some questions have more than one correct answer. Select the best answer or answers from the choices given.)

1. Which of the following reactions would liberate the most energy? (a) complete oxidation of a molecule of sucrose to CO_2 and water, (b) conversion of a molecule of ADP to ATP, (c) respiration of a molecule of glucose to lactic acid, (d) conversion of a molecule of glucose to carbon dioxide and water.

2. The formation of glucose from glycogen is (a) gluconeogenesis, (b) glycogenesis, (c) glycogenolysis, (d) glycolysis.

3. The net gain of ATP from the complete metabolism (aerobic) of glucose is closest to (a) 2, (b) 30, (c) 38, (d) 4.

4. Which of the following *best* defines cellular respiration? (a) intake of carbon dioxide and output of oxygen by cells, (b) excretion of waste products, (c) inhalation of oxygen and

exhalation of carbon dioxide, (d) oxidation of substances by which energy is released in usable form to the cells.

5. During aerobic respiration, electrons are passed down the electron transport chain and _____ is formed. (a) oxygen, (b) water, (c) glucose, (d) $NADH + H^+$.

6. Metabolic rate is relatively low in (a) youth, (b) physical exercise, (c) old age, (d) fever.

7. In a temperate climate under ordinary conditions, the greatest loss of body heat occurs through (a) radiation, (b) conduction, (c) evaporation, (d) none of the above.

8. Which of the following is *not* a function of the liver? (a) glycogenolysis and gluconeogenesis, (b) synthesis of cholesterol, (c) detoxification of alcohol and drugs, (d) synthesis of glucagon, (e) deamination of amino acids.

9. Amino acids are essential (and important) to the body for all the following *except* (a) production of some hormones, (b) production of antibodies, (c) formation of most structural materials, (d) as a source of quick energy.

10. A person has been on a hunger strike for seven days. Compared to normal, he has (a) increased release of fatty acids from adipose tissue, ketosis, and ketonuria, (b) elevated glucose concentration in the blood, (c) increased plasma insulin concentration, (d) increased glycogen synthetase (enzyme) activity in the liver.

11. Transamination is a chemical process by which (a) protein is synthesized, (b) an amine group is transferred from an amino acid to a keto acid, (c) an amine group is cleaved from the amino acid, (d) amino acids are broken down for energy.

12. Three days after removal of the pancreas from an animal, the researcher finds a persistent increase in (a) acetoacetic acid concentration in the blood, (b) urine volume, (c) blood glucose, (d) all of the above.

13. Hunger, appetite, obesity, and physical activity are interrelated. Thus, (a) hunger sensations arise *primarily* from the stimulation of receptors in the stomach and intestinal tract in response to the absence of food in these organs; (b) obesity, in most cases, is a result of the abnormally high enzymatic activity of the fat-synthesizing enzymes in adipose tissue; (c) in all cases of obesity, the energy content of the ingested food has exceeded the energy expenditure of the body; (d) in a normal individual, increasing blood glucose concentration increases hunger sensations.

14. Body temperature regulation is (a) influenced by temperature receptors in the skin, (b) influenced by the temperature of the blood perfusing the heat regulation centers of the brain, (c) subject to both neural and hormonal control, (d) all of the above.

15. Which of the following yields the greatest caloric value per gram? (a) fats, (b) proteins, (c) carbohydrates, (d) all are equal in caloric value.

Short Answer Essay Questions

16. What is cellular respiration? What is the common role of FAD and NAD^+ in cellular respiration?

17. Describe the site, major events, and outcomes of glycolysis.

18. Pyruvic acid is a product of glycolysis, but it is not the substance that enters the Krebs cycle. What is that substance, and what must occur if pyruvic acid is to be transformed into this molecule?

19. Define glycogenesis, glycogenolysis, gluconeogenesis, and lipogenesis. Which is (are) likely to be occurring (a) shortly after a carbohydrate-rich meal, (b) just before waking up in the morning?

20. What is the harmful result when excessive amounts of fats are burned for energy? Name two conditions that might lead to this result.

21. Make a flowchart that indicates the pivotal intermediates through which glucose can be converted to fat.

22. Distinguish between the role of HDLs and that of LDLs.

23. List some factors that influence plasma cholesterol levels. Also list the sources and fates of cholesterol in the body.

24. What is meant by "body energy balance," and what happens if the balance is not precise?

25. Explain the effect of the following on metabolic rate: thyroxine levels, eating, body surface area, muscular exercise, emotional stress, starvation.

26. Explain the terms "core" and "shell" relative to body temperature balance. What serves as the heat-transfer agent from one to the other?

27. Compare and contrast mechanisms of heat loss with mechanisms of heat promotion, and explain how these mechanisms determine body temperature.

Critical Thinking and Clinical Application Questions

1. Calculate the number of ATP molecules that can be harvested during the complete oxidation of an 18-carbon fatty acid. (Take a deep breath and think about it—you *can* do it.)

2. Every year dozens of elderly people are found dead in their unheated apartments and listed as victims of hypothermia. What is hypothermia, and how does it kill? Why are the elderly more susceptible to hypothermia than the young?

3. Frank Moro has been diagnosed as having severe atherosclerosis and high blood cholesterol levels. He is told that he is at risk for a stroke or a heart attack. First, what foods would you suggest that he avoid like the plague? What foods would you suggest he add or substitute? What activities would you recommend?

4. In the 1940s, some physicians prescribed low doses of a chemical called dinitrophenol (DNP) to help patients lose weight. This drug therapy was abandoned after a few patients died. DNP uncouples the chemiosmotic machinery. Explain how this causes weight loss.

5. While attempting to sail solo from Los Angeles to Tahiti, Simon encountered a storm that marooned him on an uninhabited island. He was able, using his ingenuity and a pocket knife, to obtain plenty of fish to eat, and roots were plentiful. However, the island was barren of fruits and soon his gums began to bleed and he started to develop several infections. Analyze his problem. (The tables might help.)

6. Gregor, a large beefy man, came home from the doctor's office and complained to his wife that his blood tests "were bad." He told her that the doctor said he would have to give up some of his steaks and butter. He went on to mourn the fact that he would have to start eating more cottage cheese and olive oil instead. What kind of problem was revealed by his "bad" blood tests? How should his wife respond to his choice of food substitutes and why? What foods should she suggest?

A wide variety of quiz questions, tutorials, and learning exercises are available online at the Anatomy & Physiology Place (www.anatomyandphysiology.com) and, if your instructor has provided you with a MyA&P Course ID number, in MyA&P (www.myaandp.com).

CHAPTER 25

The Urinary System

Kidney Anatomy (pp. 998–1006)

1. Describe the gross anatomy of the kidney and its coverings.
2. Trace the blood supply through the kidney.
3. Describe the anatomy of a nephron.

Kidney Physiology: Mechanisms of Urine Formation (pp. 1007–1021)

4. List several kidney functions that help maintain body homeostasis.
5. Identify the nephron parts responsible for filtration, reabsorption, and secretion, and describe mechanisms underlying each of these functional processes.
6. Explain the role of aldosterone and of atrial natriuretic peptide in sodium and water balance.
7. Describe the mechanisms responsible for the medullary osmotic gradient.
8. Explain formation of dilute versus concentrated urine.

Urine (pp. 1021–1023)

9. Describe the normal physical and chemical properties of urine.
10. List several abnormal urine components, and name the condition characterized by the presence of detectable amounts of each.

Ureters (pp. 1023–1024)

11. Describe the general location, structure, and function of the ureters.

Urinary Bladder (pp. 1024–1026)

12. Describe the general location, structure, and function of the urinary bladder.

Urethra (p. 1026)

13. Describe the general location, structure, and function of the urethra.
14. Compare the course, length, and functions of the male urethra with those of the female.

Micturition (p. 1027)

15. Define micturition and describe its neural control.

Developmental Aspects of the Urinary System (pp. 1027–1030)

16. Trace the embryonic development of the urinary organs.
17. List several changes in urinary system anatomy and physiology that occur with age.

Every day the kidneys filter nearly 200 liters of fluid from the bloodstream, allowing toxins, metabolic wastes, and excess ions to leave the body in urine while returning needed substances to the blood. Much like a water purification plant that keeps a city's water drinkable and disposes of its wastes, the kidneys are usually unappreciated until they malfunction and body fluids become contaminated. Although the lungs and skin also participate in excretion, the kidneys are the major excretory organs.

As the kidneys perform these excretory functions, they also act as essential regulators of the volume and chemical makeup of the blood, maintaining the proper balance between water and salts and between acids and bases. Frankly, this would be tricky work for a chemical engineer, but the kidneys do it efficiently most of the time.

Other renal functions include

- Gluconeogenesis (see p. 967) during prolonged fasting.
- Producing the hormones renin and erythropoietin (see Chapter 16). *Renin* (re'nin; *ren* = kidney) acts as an enzyme to help regulate blood pressure and kidney function. *Erythropoietin* (ĕ-rith"ro-poi'ĕ-tin) stimulates red blood cell production.
- Metabolizing vitamin D to its active form (see Chapter 16).

Besides the urine-forming kidneys, the **urinary system** includes the *urinary bladder,* a temporary storage reservoir for urine, plus three tubelike organs—the paired *ureters* (u-re'terz) and the *urethra* (u-re'thrah), all three of which furnish transportation channels for urine (Figure 25.1).

Kidney Anatomy

Location and External Anatomy

The bean-shaped kidneys lie in a retroperitoneal position (between the dorsal body wall and the parietal peritoneum) in the *superior* lumbar region (Figure 25.2). Extending approximately from T_{12} to L_3, the kidneys receive some protection from the lower part of the rib cage (Figure 25.2b). The right kidney is crowded by the liver and lies slightly lower than the left. An adult's kidney has a mass of about 150 g (5 ounces) and its average dimensions are 12 cm long, 6 cm wide, and 3 cm thick—about the size of a large bar of soap. The lateral surface is convex. The medial surface is concave and has a vertical cleft called the **renal hilum** that leads into an internal space within the kidney called the *renal sinus.* The ureter, renal blood vessels, lymphatics, and nerves all join each kidney at the hilum and occupy the sinus. Atop each kidney is an *adrenal* (or *suprarenal*) *gland,* an endocrine gland that is functionally unrelated to the kidney.

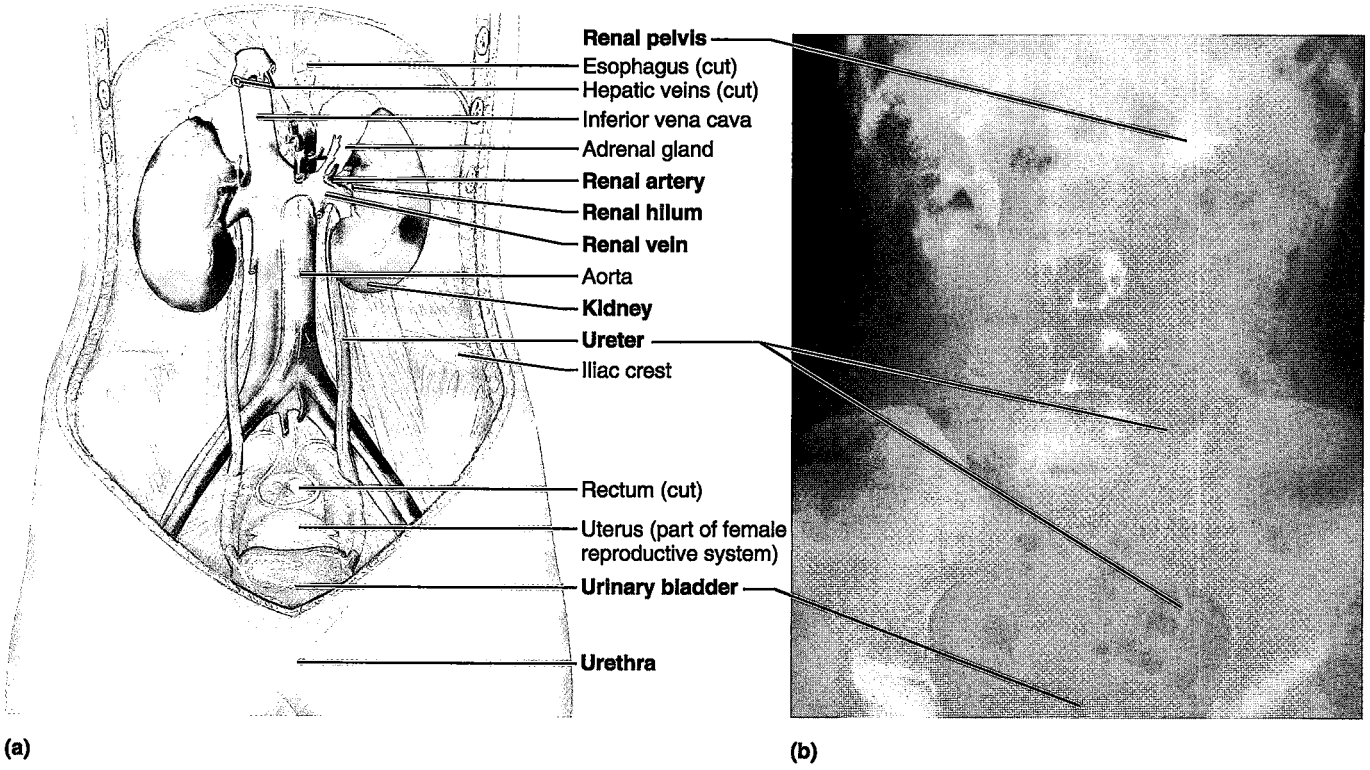

FIGURE 25.1 **The urinary system.** Anterior view of the female urinary organs. (Most unrelated abdominal organs have been omitted.) **(a)** Diagrammatic view. **(b)** X ray of urinary organs after injection of contrast medium. (See *A Brief Atlas of the Human Body,* Figure 70.)

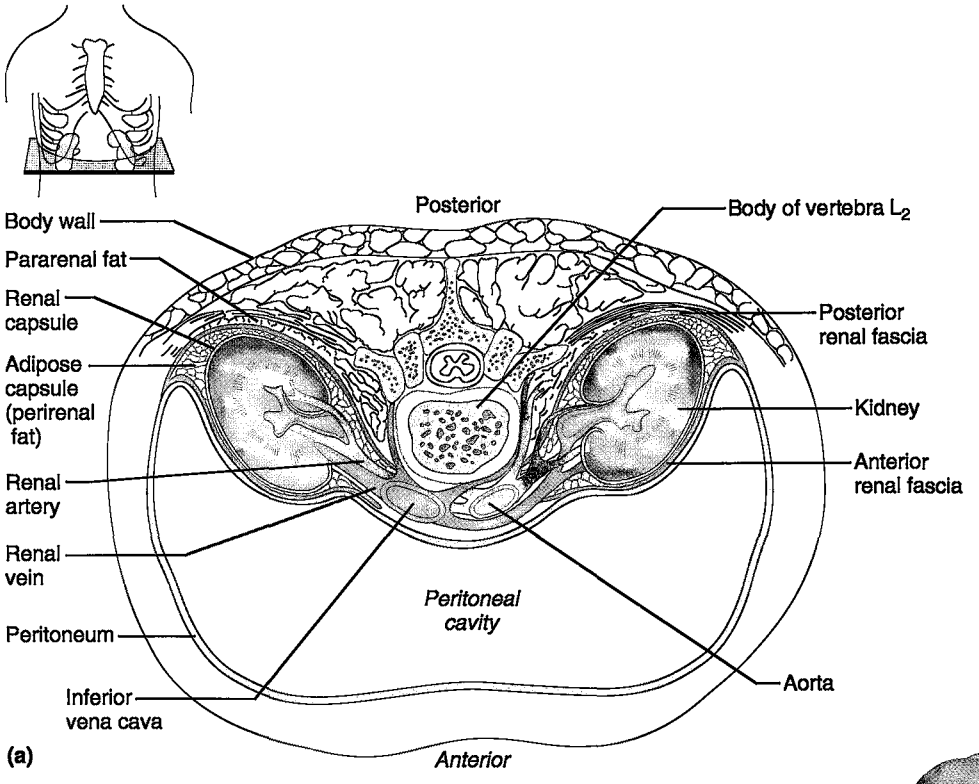

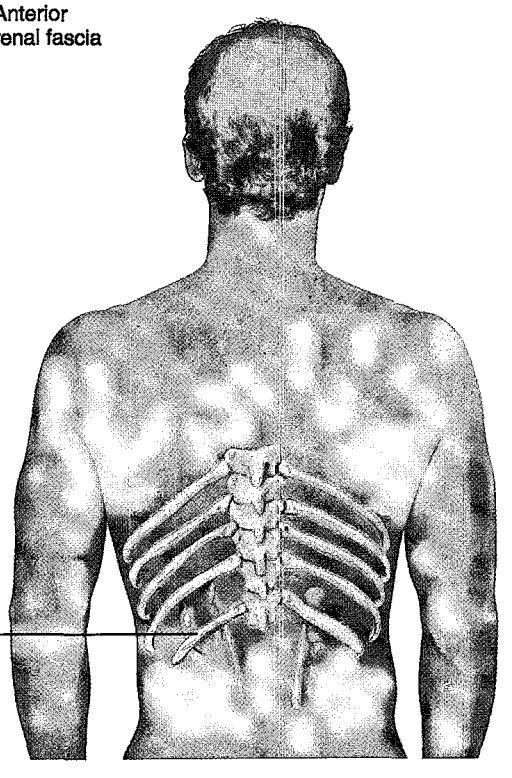

FIGURE 25.2 **Position of the kidneys against the posterior body wall. (a)** Cross-sectional view showing that the kidneys are retroperitoneal and surrounded by three layers of supportive tissue: the fibrous capsule, the perirenal fat capsule, and the renal fascia. **(b)** Posterior in situ view showing relationship of the kidneys to the 12th rib pair.

Three layers of supportive tissue surround each kidney:

1. The **fibrous capsule,** a transparent capsule that prevents infections in surrounding regions from spreading to the kidneys
2. The **perirenal fat capsule,** a fatty mass that attaches the kidney to the posterior body wall and cushions it against blows
3. The **renal fascia,** an outer layer of dense fibrous connective tissue that anchors the kidney and the adrenal gland to surrounding structures

HOMEOSTATIC IMBALANCE

The fatty encasement of the kidneys is important in holding the kidneys in their normal body position. If the amount of fatty tissue dwindles (as with extreme emaciation or rapid weight loss), one or both kidneys may drop to a lower position, an event called *renal ptosis* (to'sis; "a fall"). Renal ptosis may cause a ureter to become kinked, which creates problems because the urine, unable to drain, backs up into the kidney and exerts pressure on its tissue. Backup of urine from ureteral obstruction or other causes is called *hydronephrosis* (hi"dro-nĕ-fro'sis; "water in the kidney"). Hydronephrosis can severely damage the kidney, leading to necrosis (tissue death) and renal failure. ●

Internal Anatomy

A frontal section through a kidney reveals three distinct regions: *cortex, medulla,* and *pelvis* (Figures 25.3 and 25.4a). The most superficial region, the **renal cortex,** is light in color and has a granular appearance. Deep to the cortex is the darker, reddish-brown **renal medulla,** which exhibits cone-shaped tissue

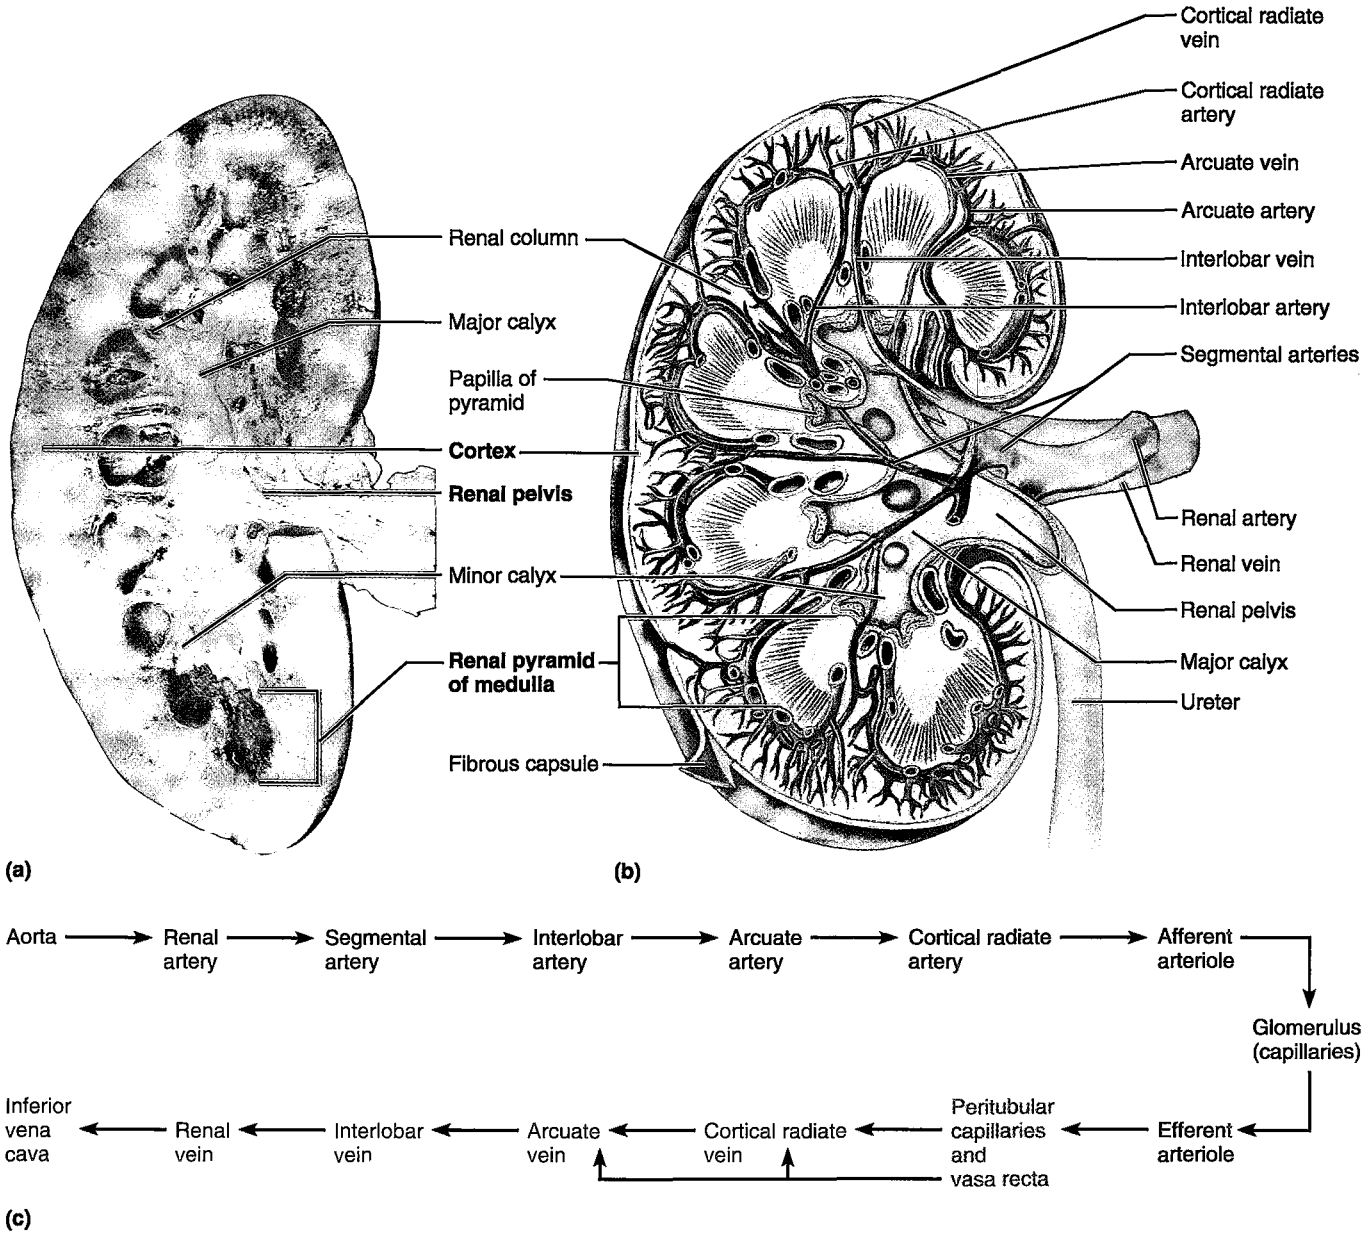

FIGURE 25.3 **Internal anatomy of the kidney. (a)** Photograph of a frontal section of a triple-injected kidney. (Arteries and veins are injected with red and blue latex respectively; pelvis and ureter are injected with yellow latex.) **(b)** Diagrammatic view of a frontally sectioned kidney, illustrating major blood vessels. **(c)** Summary of renal vasculature pathway.

masses called **medullary** or **renal pyramids.** The broad *base* of each pyramid faces toward the cortex, and its apex, or *papilla* ("nipple"), points internally. The pyramids appear striped because they are formed almost entirely of parallel bundles of microscopic urine-collecting tubules and capillaries. The **renal columns,** inward extensions of cortical tissue, separate the pyramids. Each pyramid and its surrounding cortical tissue constitutes one of approximately eight **lobes** of a kidney.

The **renal pelvis,** a funnel-shaped tube, is continuous with the ureter leaving the hilum. Branching extensions of the pelvis form two or three **major calyces** (ka'lih-sēz; singular: calyx), each of which subdivides to form several **minor calyces,** cup-shaped areas that enclose the papillae. The calyces collect urine, which drains continuously from the papillae, and empty it into the renal pelvis. The urine then flows through the renal pelvis and into the ureter, which moves it to the bladder to be stored. The walls of the calyces, pelvis, and ureter contain smooth muscle that contracts rhythmically to propel urine along its course by peristalsis.

HOMEOSTATIC IMBALANCE

Infection of the renal pelvis and calyces produces the condition called *pyelitis* (pi″ĕ-li′tis). Infections or inflammations that affect the entire kidney are *pyelonephritis* (pi″ĕ-lo-nĕ-fri′tis). Kidney infections in females are usually caused by fecal bacteria that spread from the anal region to the urinary tract. Less often they result from bloodborne bacteria (traveling from other infected sites) that lodge and multiply in the kidneys. In severe cases of pyelonephritis, the kidney swells, abscesses form, and the pelvis fills with pus. Untreated, the kidneys may be severely damaged, but antibiotic therapy can usually treat the infection successfully. ●

Blood and Nerve Supply

The kidneys continuously cleanse the blood and adjust its composition, and so it is not surprising that they have a rich blood supply. Under normal resting conditions, the large **renal arteries** deliver one-fourth of the total cardiac output (about 1200 ml) to the kidneys each minute. The renal arteries issue at right angles from the abdominal aorta; because the aorta lies to the left of the midline, the right renal artery is longer than the left. As it approaches a kidney, each renal artery divides into five **segmental arteries.** Within the renal sinus, each segmental artery branches further to form several **interlobar arteries.**

At the medulla-cortex junction, the interlobar arteries branch into the **arcuate arteries** (ar′ku-āt) that arch over the bases of the medullary pyramids. Small **cortical radiate arteries** radiate outward from the arcuate arteries to supply the cortical tissue (see Figure 25.3a). More than 90% of the blood entering the kidney perfuses the renal cortex.

Veins pretty much trace the pathway of the arterial supply in reverse. Blood leaving the renal cortex drains sequentially into the **cortical radiate, arcuate, interlobar,** and finally **renal veins.** (There are no segmental veins.) The renal veins issue from the kidneys and empty into the inferior vena cava. Because the inferior vena cava lies to the right of the vertebral column, the left renal vein is about twice as long as the right.

The **renal plexus,** a variable network of autonomic nerve fibers and ganglia, provides the nerve supply of the kidney and its ureter. An offshoot of the celiac plexus, the renal plexus is largely supplied by sympathetic fibers from the least thoracic and first lumbar splanchnic nerves, which course along with the renal artery to reach the kidney. These sympathetic vasomotor fibers regulate renal blood flow by adjusting the diameter of renal arterioles and also influence the urine-forming role of the nephrons.

Nephrons

Nephrons (nef′ronz) are the structural and functional units of the kidneys. Each kidney contains over 1 million of these tiny blood-processing units, which carry out the processes that form urine (Figure 25.4b). In addition, there are thousands of *collecting ducts,* each of which collects fluid from several nephrons and conveys it to the renal pelvis.

Each **nephron** consists of a **glomerulus** (glo-mer′u-lus; *glom* = ball of yarn), which is a tuft of capillaries, and a **renal tubule.** The cup-shaped end of the renal tubule, the **glomerular capsule** (or **Bowman's capsule**) is blind and completely surrounds the glomerulus (much as a well-worn baseball glove encloses a ball). Collectively, the glomerular capsule and the enclosed glomerulus are called the **renal corpuscle.** The endothelium of the glomerular capillaries is *fenestrated* (penetrated by many pores), which makes them exceptionally porous. This allows large amounts of solute-rich, virtually protein-free fluid to pass from the blood into the glomerular capsule. This plasma-derived fluid or **filtrate** is the raw material that the renal tubules process to form urine.

The external *parietal layer* of the glomerular capsule (Figures 25.4b, 25.6, and 25.7) is simple squamous epithelium. This layer simply contributes to the capsule structure and plays no part in forming filtrate. The *visceral layer,* which clings to the glomerular capillaries, consists of highly modified, branching epithelial cells called **podocytes** (pod′o-sīts; "foot cells"). The octopus-like podocytes terminate in **foot processes,** which intertwine as they cling to the basement membrane of the glomerulus. The clefts or openings between the foot processes are called **filtration slits.** Through these slits, filtrate enters the **capsular space** inside the glomerular capsule.

The remainder of the renal tubule is about 3 cm (1.2 inches) long and has three major parts. It leaves the glomerular capsule as the elaborately coiled **proximal convoluted tubule (PCT),** makes a hairpin loop called the **loop of Henle** (also called **Henle's loop**), and then winds and twists again as the **distal convoluted tubule (DCT)** before emptying into a collecting duct. The terms *proximal* and *distal* indicate relationship of the convoluted tubules to the renal corpuscle—filtrate from the renal corpuscle passes through the PCT first and then the DCT, which is thus "further away" from the renal corpuscle. The meandering nature of the renal tubule increases its length and enhances its filtrate processing capabilities.

The **collecting ducts,** each of which receives filtrate from many nephrons, run through the medullary pyramids and give them their striped appearance. As the collecting ducts approach the renal pelvis, they fuse together and deliver urine into the minor calyces via papillae of the pyramids.

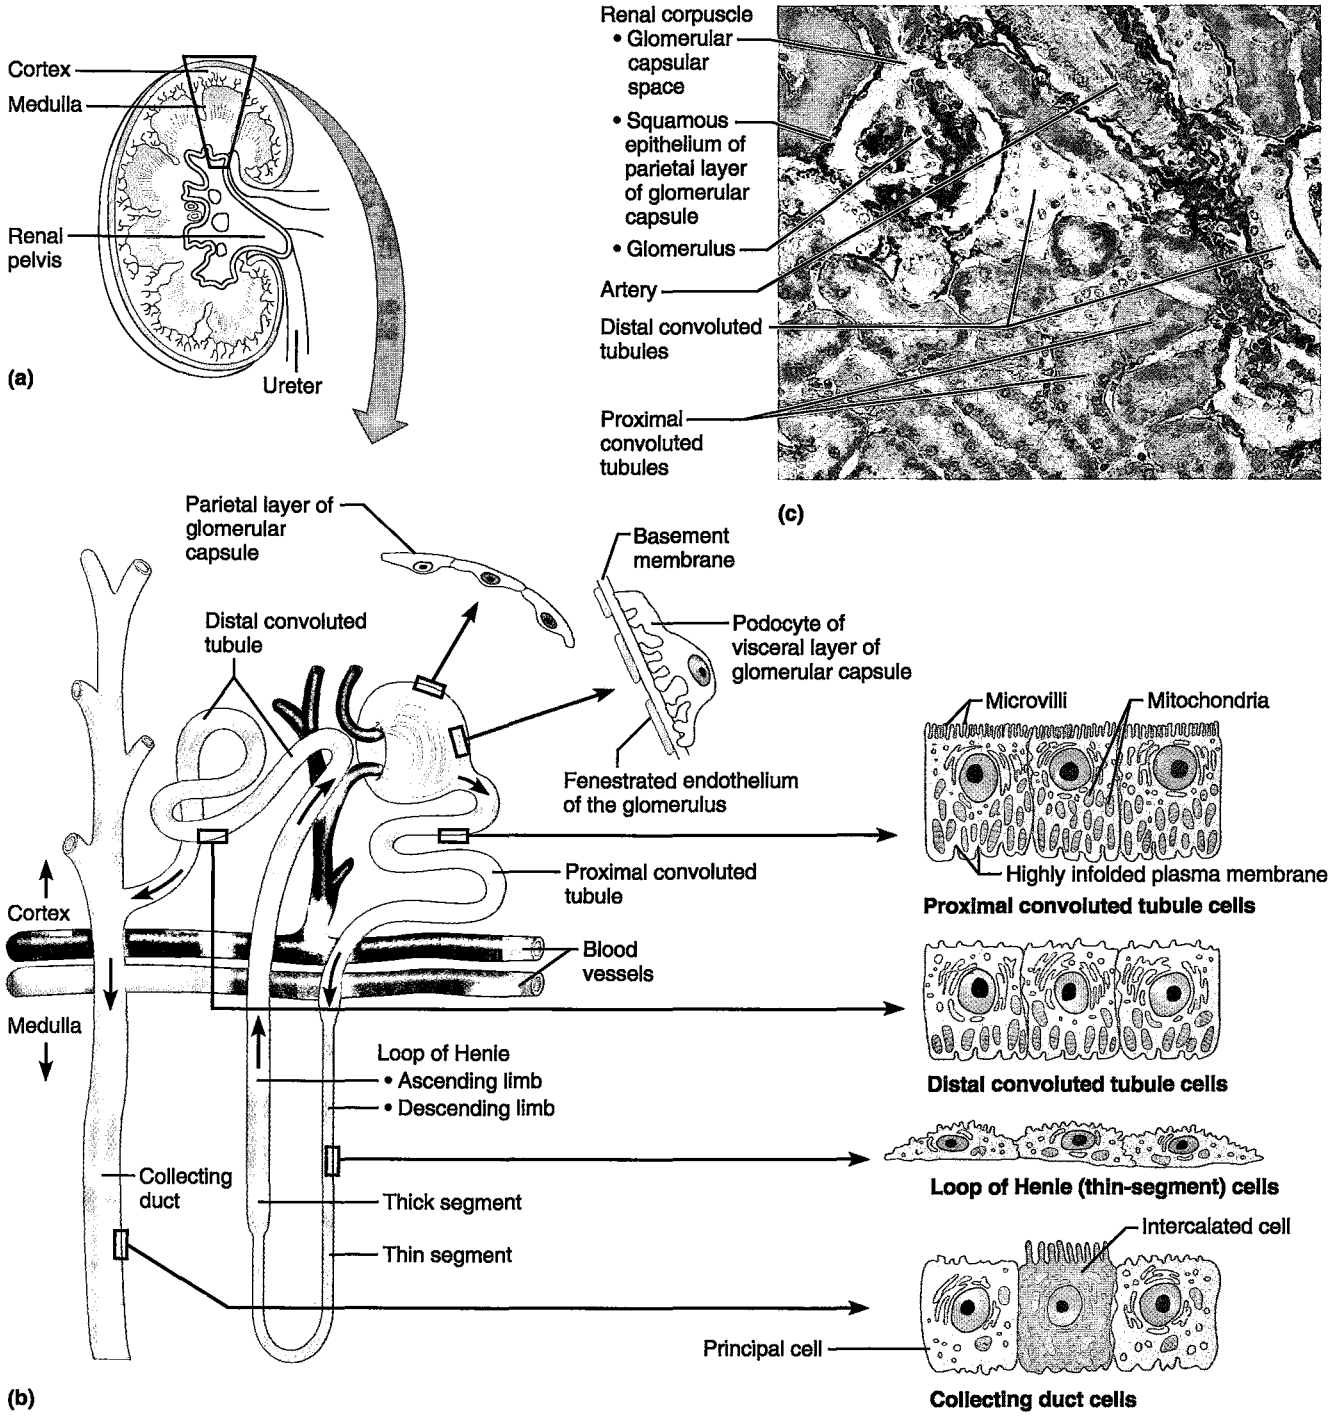

FIGURE 25.4 **Location and structure of nephrons. (a)** Diagram showing the orientation of nephrons; such a segment contains more than 100,000 nephrons. **(b)** Schematic view of a nephron depicting the structural characteristics of epithelial cells forming its various regions. **(c)** Photomicrograph of renal cortical tissue. Notice the renal corpuscles and the sections through the various tubules. In the proximal convoluted tubules, the lumens appear "fuzzy" because they are filled with the long microvilli of the epithelial cells that form the tubule walls. In the distal tubules, by contrast, the lumens are clear (300×). (See *A Brief Atlas of the Human Body*, Plates 48 and 49.)

Throughout its length, the renal tubule consists of a single layer of polar epithelial cells on a basement membrane, but each of its regions has a unique cellular anatomy that reflects its role in processing filtrate. The walls of the PCT are formed by cuboidal epithelial cells with large mitochondria; their luminal (exposed) surfaces bear dense microvilli (Figure 25.4b and c). Just as in the intestine, this *brush border* dramatically increases the surface area and capacity for reabsorbing water and solutes from the filtrate and secreting substances into it.

The U-shaped *loop of Henle* has *descending* and *ascending limbs*. The proximal part of the descending limb is continuous with the proximal tubule and its cells are similar. The rest of the descending limb, called the **thin segment,** is a simple squamous epithelium freely permeable to water. The epithelium becomes cuboidal or even low columnar in the ascending part of the loop of Henle, which therefore becomes the **thick segment.** In some nephrons, the thin segment is found only in the descending limb. In others, it extends into the ascending limb as well.

The epithelial cells of the DCT, like those of the PCT, are cuboidal and confined to the cortex, but they are thinner and almost entirely lack microvilli. The transition between the DCT and the collecting duct is marked by the appearance of a heterogeneous collection of cells. The two cell types seen in the collecting ducts are *intercalated cells,* cuboidal cells with abundant microvilli, and the more numerous *principal cells,* which have sparse, short microvilli. The two varieties (type A and B) of intercalated cells play a major role in maintaining the acid-base balance of the blood. The principal cells help maintain the body's water and Na^+ balance.

Cortical nephrons represent 85% of the nephrons in the kidneys. Except for small parts of their loops of Henle that dip into the outer medulla, they are located entirely in the cortex. The remaining **juxtamedullary nephrons** (juks"tah-mĕ'dul-ah-re) originate close to (*juxta* = near to) the cortex-medulla junction, and they play an important role in the kidneys' ability to produce concentrated urine. Their loops of Henle deeply invade the medulla, and their thin segments are much more extensive than those of cortical nephrons (Figure 25.5).

Nephron Capillary Beds

Every nephron is closely associated with two capillary beds: the *glomerulus* and the *peritubular capillaries* (Figure 25.5). The glomerulus, in which the capillaries run in parallel, is specialized for filtration. It differs from all other capillary beds in the body in that it is both fed and drained by arterioles—the **afferent arteriole** and the **efferent arteriole,** respectively. The afferent arterioles arise from the *cortical radiate arteries* that run through the renal cortex. Because (1) arterioles are high-resistance vessels and (2) the afferent arteriole has a larger diameter than the efferent, the blood pressure in the glomerulus is extraordinarily high for a capillary bed and easily forces fluid and solutes out of the blood into the glomerular capsule. Most of this filtrate (99%) is reabsorbed by the renal tubule cells and returned to the blood in the peritubular capillary beds.

The **peritubular capillaries** arise from the efferent arterioles draining the glomeruli. These capillaries cling closely to adjacent renal tubules and empty into nearby venules. They are low-pressure, porous capillaries that readily absorb solutes and water from the tubule cells as these substances are reclaimed from the filtrate.

Notice that the efferent arterioles serving the juxtamedullary nephrons tend *not* to break up into peritubular capillaries. Instead they form bundles of long straight vessels called **vasa recta** (va'sah rek'tah; "straight vessels") that extend deep into the medulla paralleling the longest loops of Henle (Figure 25.5a). The thin-walled vasa recta play an important role in forming concentrated urine, as described shortly.

In summary, the microvasculature of the nephrons consists of two capillary beds separated by intervening efferent arterioles. The first capillary bed (glomerulus) produces the filtrate. The second (peritubular capillaries) reclaims most of that filtrate.

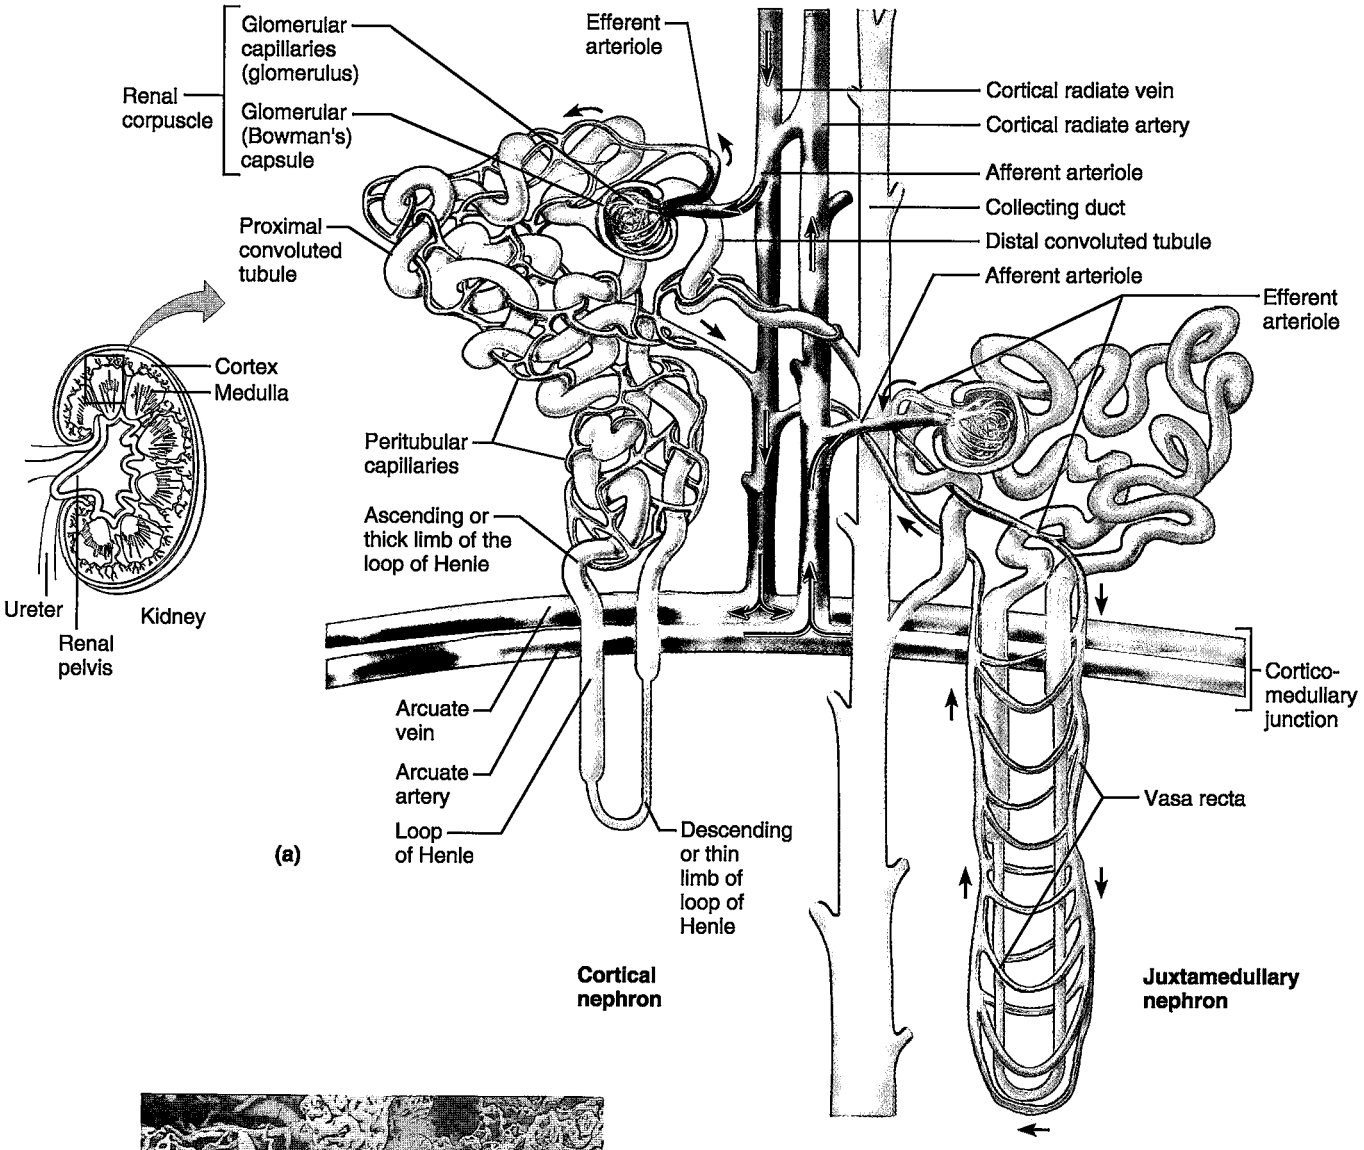
Vascular Resistance in the Microcirculation

Blood flowing through the renal circulation encounters high resistance, first in the afferent and then in the efferent arterioles. As a result, renal blood pressure declines from approximately 95 mm Hg in the renal arteries to 8 mm Hg or less in the renal veins. The resistance of the afferent arterioles protects the glomeruli from large fluctuations in systemic blood pressure. Resistance in the efferent arterioles reinforces the high glomerular pressure and reduces the hydrostatic pressure in the peritubular capillaries.

Juxtaglomerular Apparatus

Each nephron has a region called a **juxtaglomerular apparatus (JGA)** (juks"tah-glo-mer'u-lar), where the most distal portion of the ascending limb of the loop of Henle lies against the afferent arteriole feeding the glomerulus (and sometimes the efferent arteriole) (Figure 25.6). Both the ascending limb and the afferent arteriole are modified at the point of contact.

In the arteriole walls are the **granular cells** [also called **juxtaglomerular (JG) cells**]—enlarged, smooth muscle cells with prominent secretory granules containing renin. Granular cells act as mechanoreceptors that sense the blood pressure in the afferent



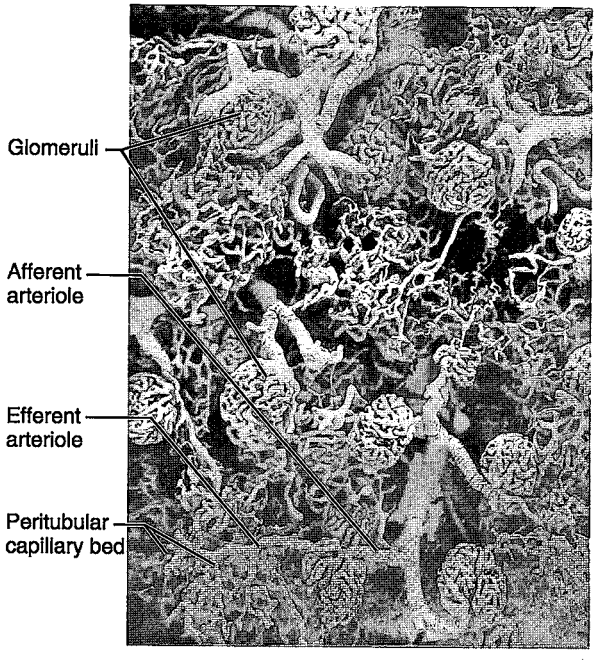


FIGURE 25.5 **Comparison of cortical and juxtamedullary nephron anatomy. (a)** Peritubular capillaries arise from efferent arterioles draining cortical nephrons (as shown on the left). The vasa recta dipping deep into the medulla to surround the long loops of Henle of the juxtamedullary nephrons arise from efferent arterioles of the juxtamedullary nephrons (as shown on the right). Arrows indicate direction of blood flow. **(b)** Scanning electron micrograph of a cast of blood vessels associated with nephrons (90×). *Photo: R.G. Kessel and R.H. Kardon/Visuals Unlimited*

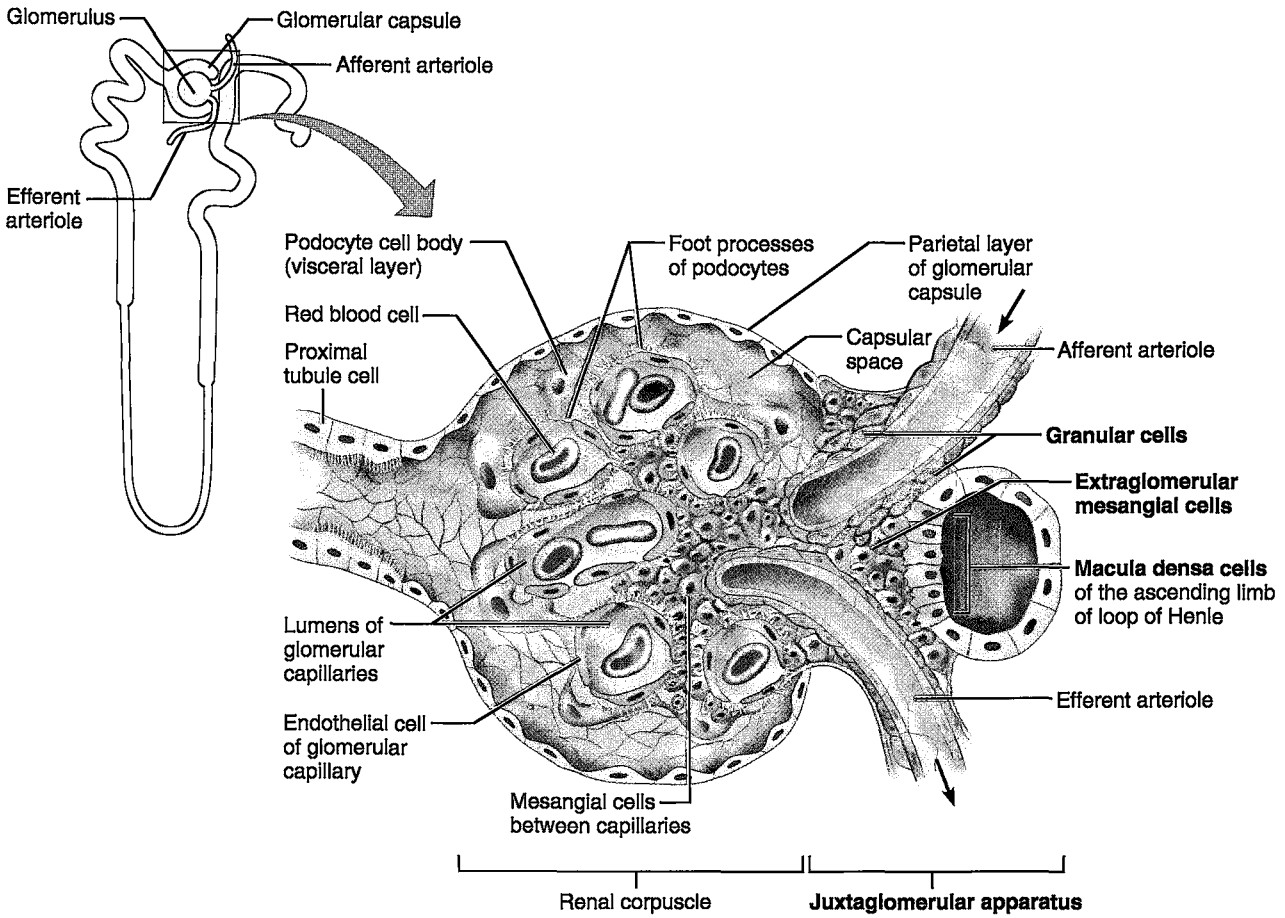

FIGURE 25.6 **Juxtaglomerular apparatus (JGA) of a nephron.** The JGA is made up of the granular cells of the arterioles, the macula densa cells of the thick ascending limb of the loop of Henle, and the extraglomerular mesangial cells. Other (glomerular) mesangial cells surround the glomerular capillaries.

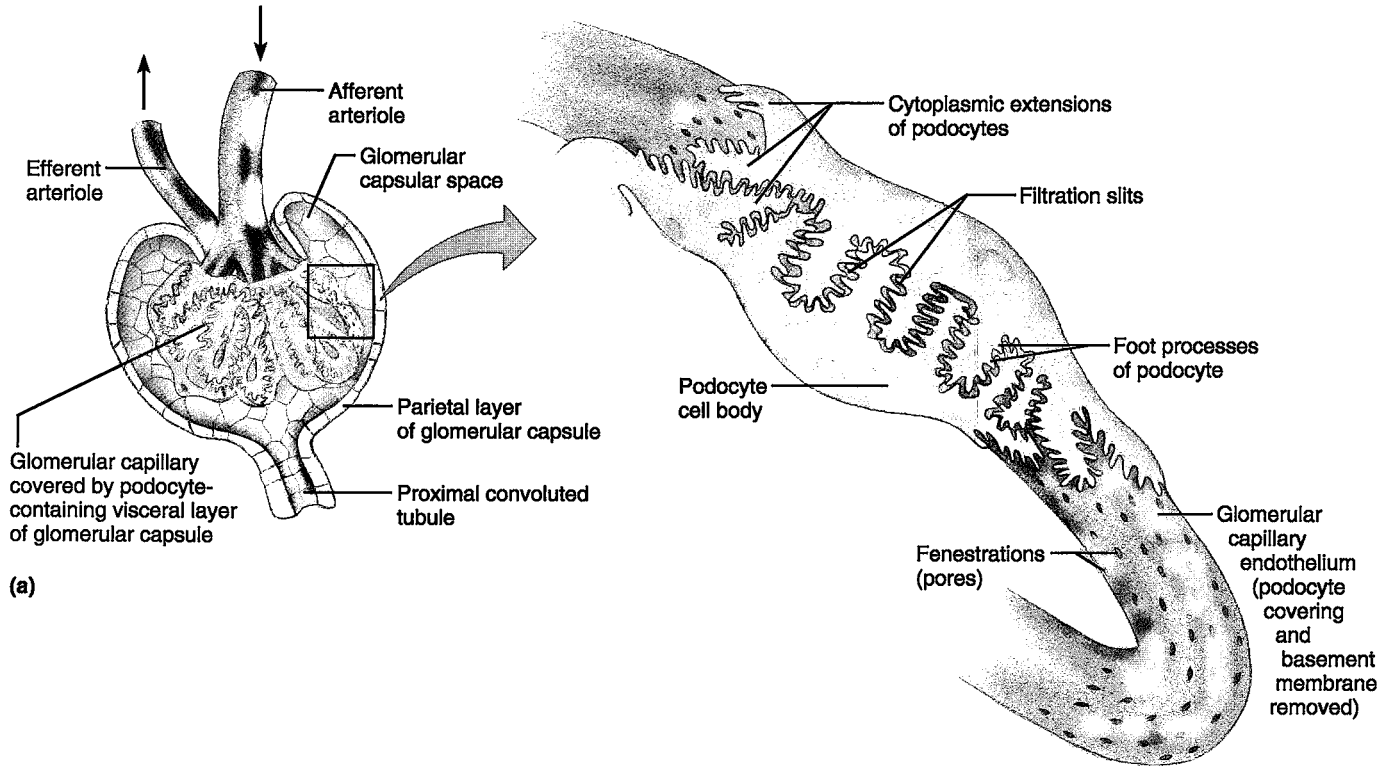
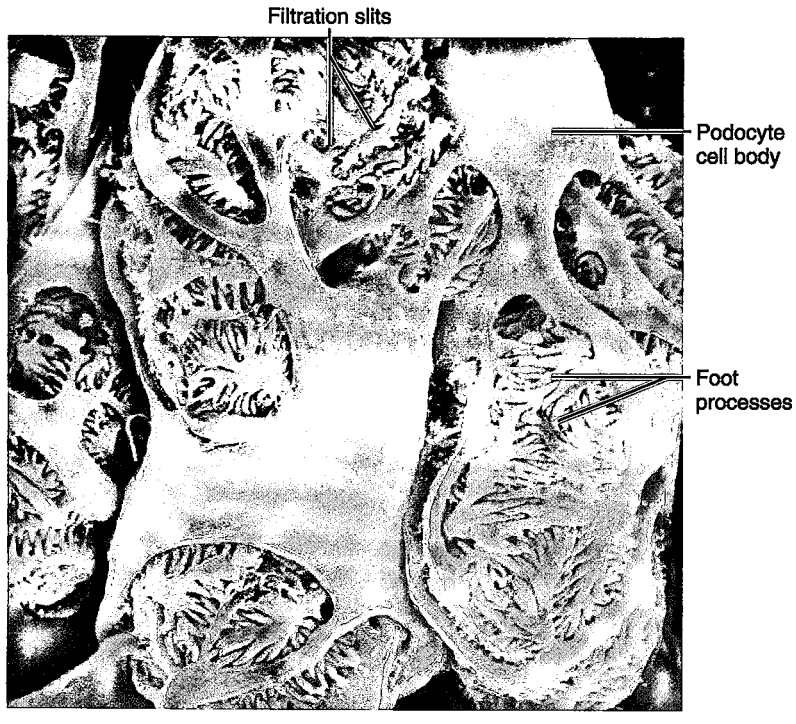
arteriole. The **macula densa** (mak'u-lah den'sah; "dense spot") is a group of tall, closely packed cells of the ascending limb of the loop of Henle that lies adjacent to the granular cells (Figure 25.6). The macula densa cells are chemoreceptors that respond to changes in the NaCl content of the filtrate. These two cell populations play important roles in regulating the rate of filtrate formation and systemic blood pressure, as described shortly. *Extraglomerular mesangial cells* are also part of the JGA, but their function remains unclear.

The Filtration Membrane

The **filtration membrane** lies between the blood and the interior of the glomerular capsule (Figure 25.7). It is a porous membrane that allows free passage of water and solutes smaller than plasma proteins. Its three layers are (1) the fenestrated endothelium of the glomerular capillaries, (2) the visceral membrane of the glomerular capsule, made of podocytes, and (3) the intervening basement membrane composed of the fused basal laminae of the other layers.

The fenestrations (capillary pores) allow passage of all plasma components but not blood cells. The basement membrane restricts all but the smallest proteins while permitting most other solutes to pass. The structural makeup of the gel-like basement membrane also confers electrical selectivity on the filtration process. Most of the proteins in the membrane are negatively charged glycoproteins that repel other macromolecular anions and hinder their passage into the tubule. Because most plasma proteins also bear a net negative charge, this electrical repulsion reinforces the plasma protein blockage imposed by molecular size. Macromolecules that do manage to make it through the basement membrane may still be blocked by thin membranes *(slit diaphragms)* that extend across the filtration slits. Macromolecules that get "hung up" in the filtration membrane are engulfed and degraded by mesangial cells within the glomerulus. These *glomerular mesangial cells* can also contract, changing the total surface area of the capillaries available for filtration.





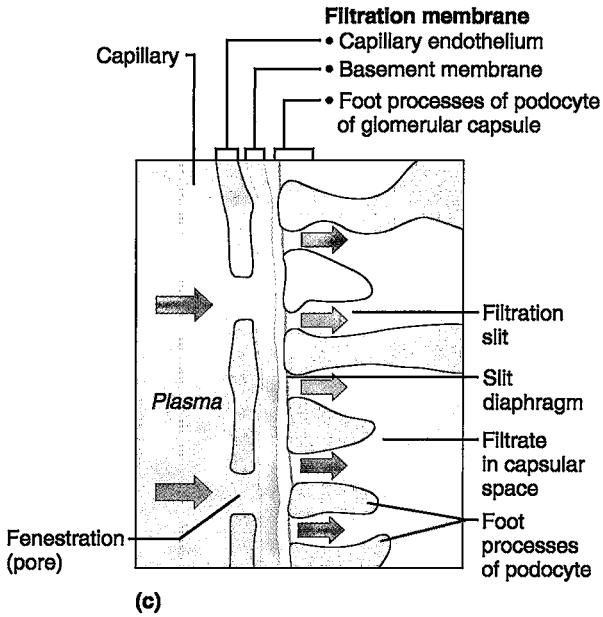


FIGURE 25.7 **The filtration membrane.** The filtration membrane is composed of three layers: the fenestrated endothelium of the glomerular capillaries, the podocyte-containing visceral layer of the glomerular capsule, and the intervening basement membrane. **(a)** Diagrammatic view of the relationship of the visceral layer of the glomerular capsule to the glomerular capillaries. The visceral epithelium is drawn incompletely to show the fenestrations in the underlying capillary wall. **(b)** Scanning electron micrograph of the visceral layer. Filtration slits between the podocyte foot processes are evident (3000×). **(c)** Diagrammatic view of a section through the filtration membrane showing all three structural elements.

Kidney Physiology: Mechanisms of Urine Formation

Of the approximately 1200 ml of blood that passes through the glomeruli each minute, some 650 ml is plasma, and about one-fifth of this (120–125 ml) is forced into the renal tubules. This is equivalent to filtering out your entire plasma volume more than 60 times each day! Considering the magnitude of their task, it is not surprising that the kidneys (which account for only 1% of body weight) consume 20–25% of all oxygen used by the body at rest.

Filtrate and urine are quite different. Filtrate contains everything found in blood plasma except proteins, but by the time filtrate flows into the collecting ducts, it has lost most of its water, nutrients, and ions. What remains, now called **urine,** contains mostly metabolic wastes and unneeded substances. The kidneys process about 180 L (47 gallons!) of blood-derived fluid daily. Of this amount, less than 1% (1.5 L) typically leaves the body as urine; the rest returns to the circulation.

Urine formation and the adjustment of blood composition involve three major processes: *glomerular filtration* by the glomeruli, and *tubular reabsorption* and *tubular secretion* in the renal tubules (Figure 25.8). In addition, the collecting ducts work in concert with the nephrons to concentrate or dilute the urine.

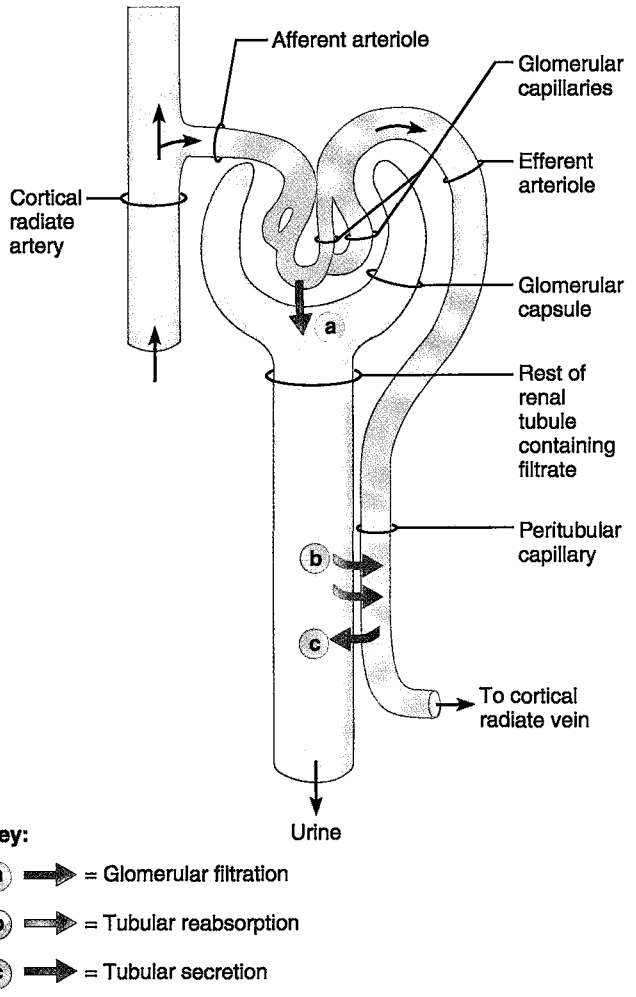

FIGURE 25.8 **The kidney depicted schematically as a single, uncoiled nephron.** A kidney actually has millions of nephrons acting in parallel. The three major mechanisms by which the kidneys adjust plasma composition are **(a)** glomerular filtration, **(b)** tubular reabsorption, and **(c)** tubular secretion.

Step 1: Glomerular Filtration

Glomerular filtration is a passive process in which hydrostatic pressure forces fluids and solutes through a membrane (see Chapters 3 and 19). Because filtrate formation does not consume metabolic energy, the glomeruli can be viewed as simple mechanical filters. The glomerulus is a much more efficient filter than are other capillary beds because (1) its *filtration membrane* (Figure 25.7) has a large surface area and is thousands of times more permeable to water and solutes, and (2) glomerular blood pressure is much higher than that in other capillary beds (approximately 55 mm Hg as opposed to 18 mm Hg or less), resulting in a much higher *net filtration pressure.* As a result of these differences, the kidneys produce about 180 L of filtrate daily, in contrast to the 3 to 4 L formed daily by all other capillary beds of the body combined.

Molecules smaller than 3 nm in diameter—such as water, glucose, amino acids, and nitrogenous wastes—pass freely from the blood into the glomerular capsule. Hence, these substances usually show similar concentrations in the blood and the glomerular filtrate. Larger molecules pass with greater difficulty, and those larger than 5 nm are generally barred from entering the tubule. Keeping the plasma proteins *in* the capillaries maintains the colloid osmotic (oncotic) pressure of the glomerular blood, preventing the loss of all its water to the renal tubules. The presence of proteins or blood cells in the urine usually indicates a problem with the filtration membrane.

Net Filtration Pressure

The **net filtration pressure (NFP),** responsible for filtrate formation, involves forces acting at the glomerular bed (Figure 25.9). **Glomerular hydrostatic pressure (HP_g)** (essentially glomerular blood pressure) is the chief force pushing water and solutes out of the blood and across the filtration membrane. Although theoretically the colloid osmotic pressure in the intracapsular space of the glomerular capsule "pulls" the filtrate into the tubule, this pressure is essentially zero because virtually no proteins enter

Q *How would liver disease affect the process shown here?*

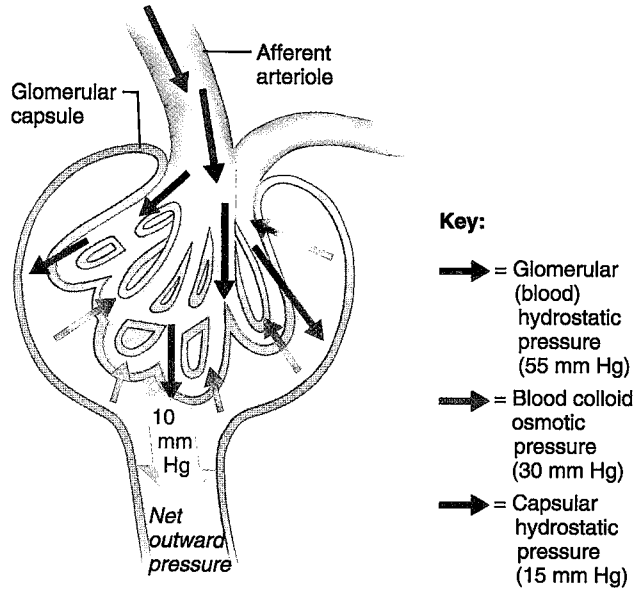

FIGURE 25.9 **Forces determining glomerular filtration and filtration pressure.** The glomerular hydrostatic (blood) pressure is the major factor forcing fluids and solutes out of the blood. This pressure is opposed by the colloid osmotic pressure of the blood and the hydrostatic pressure in the glomerular capsule. The pressure values cited in the diagram are approximate.

the capsule. The HP_g is opposed by two forces that inhibit fluid loss from glomerular capillaries. These filtration-opposing forces are (1) **colloid osmotic (oncotic) pressure of glomerular blood (OP_g)** and (2) **capsular hydrostatic pressure (HP_c)** exerted by fluids in the glomerular capsule. Thus, using the values shown in Figure 25.9, the NFP responsible for forming renal filtrate from plasma is 10 mm Hg:

$$\begin{aligned} NFP &= HP_g - (OP_g + HP_c) \\ &= 55 \text{ mm Hg} - (30 \text{ mm Hg} + 15 \text{ mm Hg}) \\ &= 10 \text{ mm Hg} \end{aligned}$$

Glomerular Filtration Rate

The **glomerular filtration rate** or **GFR** is the volume of filtrate formed each minute by the combined activity of all 2 million glomeruli of the kidneys. Factors governing filtration rate at the capillary beds are (1) total surface area available for filtration, (2) filtration membrane permeability, and (3) NFP. In adults the normal GFR in both kidneys is 120–125 ml/min.

Because glomerular capillaries are exceptionally permeable and have a huge surface area (collectively equal to the surface area of the skin), huge amounts of filtrate can be produced even with the usual modest NFP of 10 mm Hg. The opposite side of this "coin" is that a drop in glomerular pressure of only 18% stops filtration altogether.

Because the GFR is *directly proportional* to the NFP, any change in any of the pressures acting at the filtration membrane (Figure 25.9) changes both the NFP and the GFR. In the absence of regulation, an increase in arterial (and glomerular) blood pressure in the kidneys increases the GFR. As we shall see in the next section however, GFR is tightly regulated.

Regulation of Glomerular Filtration

GFR is regulated by both intrinsic and extrinsic controls. These two types of controls serve two different (and sometimes opposing) needs. The kidneys need a relatively constant GFR in order to do their job and maintain extracellular homeostasis. On the other hand, the body as a whole needs a constant blood pressure, and therefore a constant blood volume. Intrinsic controls *(renal autoregulation)* act locally within the kidney to maintain GFR, while extrinsic controls by the nervous and endocrine systems maintain blood pressure. In extreme changes of blood pressure (mean arterial pressure less than 80 or greater than 180 mm Hg), extrinsic controls take precedence over intrinsic controls. Both types of control are examined next.

Intrinsic Controls: Renal Autoregulation By adjusting its own resistance to blood flow, a process called **renal autoregulation,** the kidney can maintain a nearly constant GFR despite fluctuations in systemic arterial blood pressure. Renal autoregulation entails two types of controls: (1) a *myogenic mechanism* and (2) a *tubuloglomerular feedback mechanism* (Figure 25.10).

1. Myogenic mechanism. The **myogenic mechanism** (mi"o-jen'ik) reflects the tendency of vascular smooth muscle to contract when stretched. Increasing systemic blood pressure causes the afferent arterioles to constrict, which restricts blood flow into the glomerulus and prevents glomerular blood pressure from rising to damaging levels. Declining systemic blood pressure causes dilation of afferent arterioles and raises glomerular hydrostatic pressure. Both responses help maintain a normal GFR.

2. Tubuloglomerular feedback mechanism. Autoregulation by the flow-dependent **tubuloglomerular feedback mechanism** is "directed" by the *macula densa cells* of the *juxtaglomerular apparatus* (see Figure 25.6). These cells, located in the walls of the ascending limb of Henle's loop, respond to filtrate

A *With liver disease you probably wouldn't have a normal supply of plasma proteins. Hence, more filtrate would be formed due to lower osmotic pressure in the blood.*

Q *Why are the myogenic and tubuloglomerular mechanisms called autoregulatory mechanisms?*

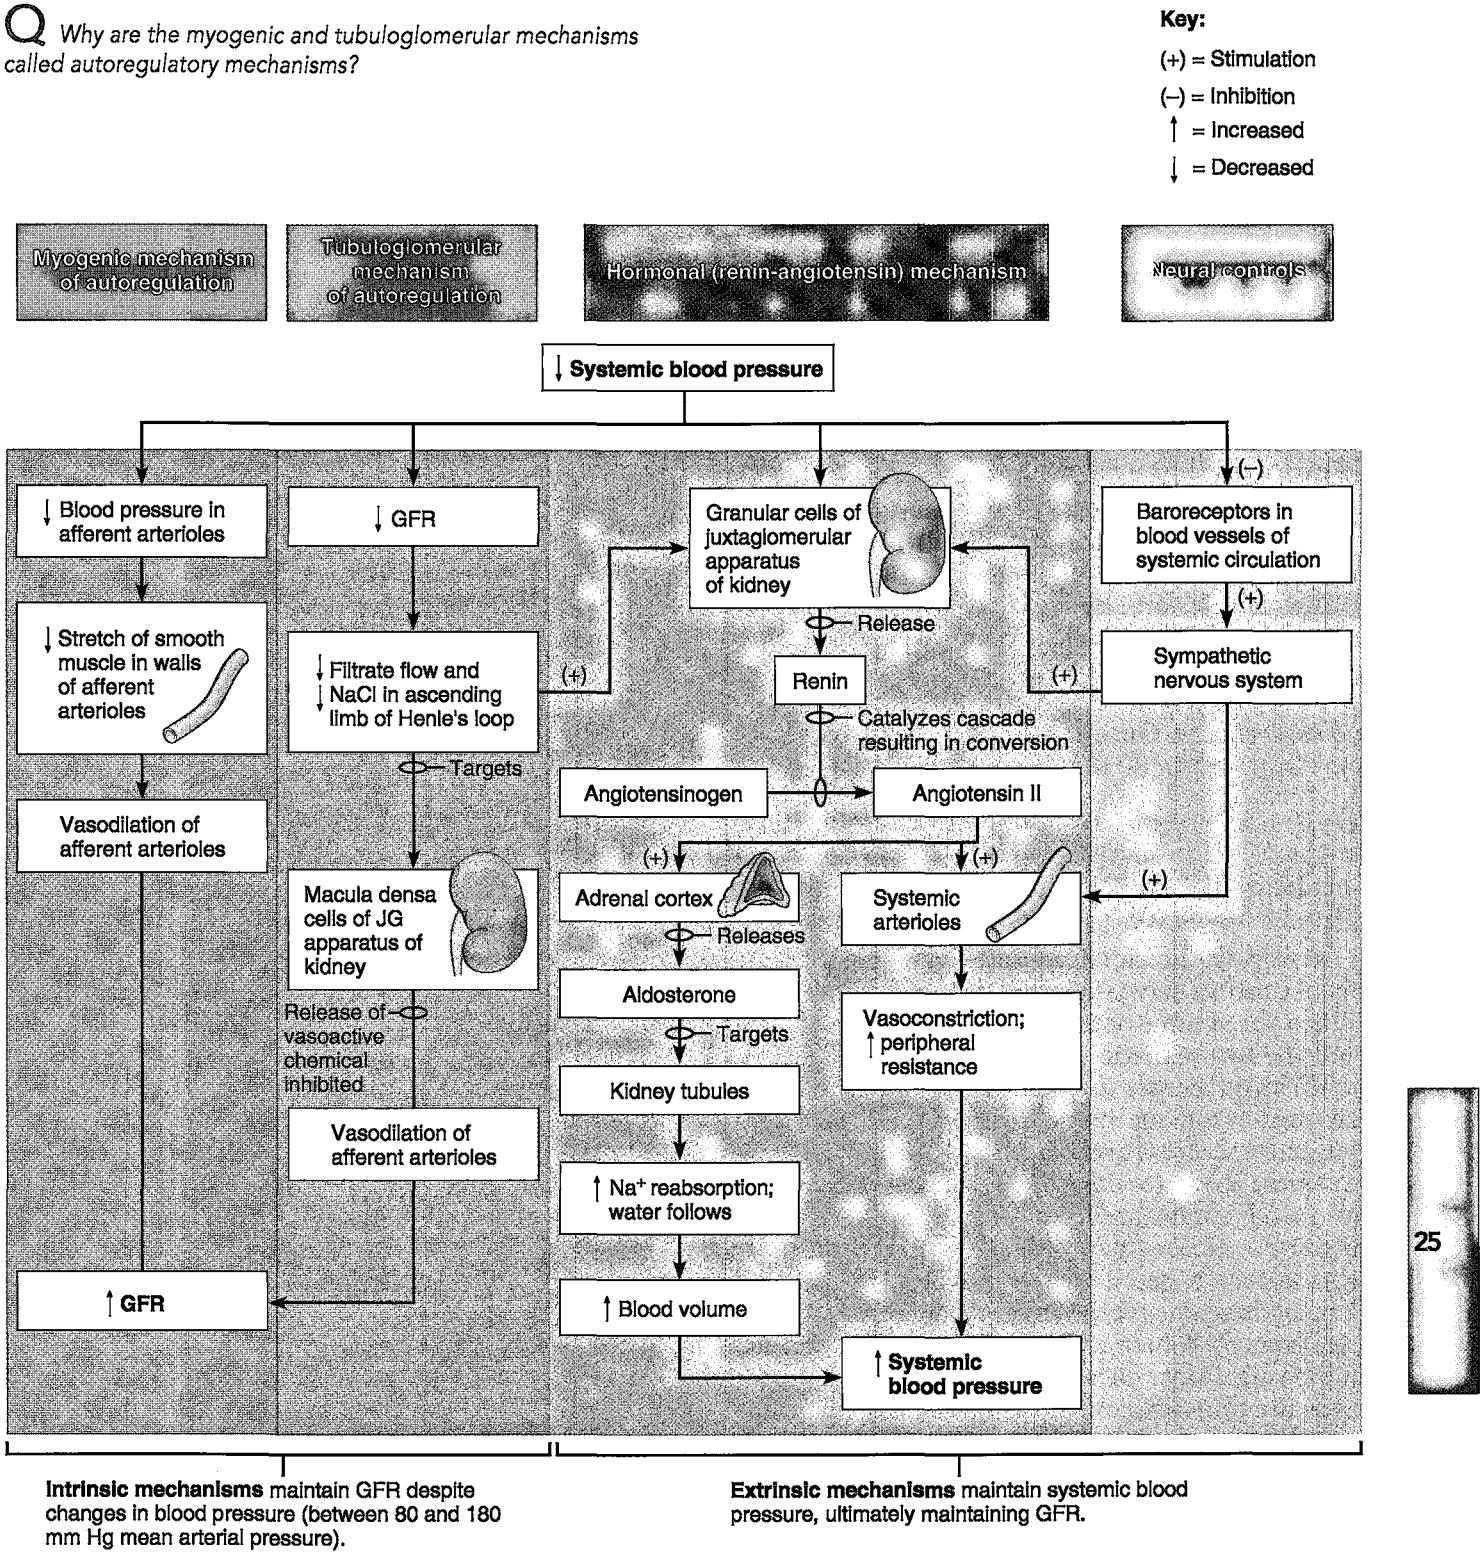

FIGURE 25.10 **Physiological mechanisms regulating glomerular filtration rate (GFR) in the kidneys.** (Note that while the extrinsic controls are aimed at maintaining blood pressure, they also maintain GFR since blood pressure drives filtration in the kidneys.)

A Because they are initiated by and within the kidney and allow the kidney to control its own (auto) rate of blood flow and GFR.

NaCl concentration (which varies directly with filtrate flow rate). When GFR increases, there is insufficient time for reabsorption and the concentration of NaCl in the filtrate remains high. This causes the macula densa cells to release a vasoconstrictor chemical (probably ATP) that causes intense constriction of the afferent arteriole. This hinders blood flow into the glomerulus, which decreases the NFP and GFR, allowing more time for filtrate processing (NaCl absorption). On the other hand, when the macula densa cells are exposed to slowly flowing filtrate with its low NaCl concentration (Figure 25.10), ATP release is inhibited, causing vasodilation of the afferent arterioles. This allows more blood to flow into the glomerulus, thus increasing the NFP and GFR.

Autoregulatory mechanisms maintain a relatively constant blood flow through the kidneys over an arterial pressure range from about 80 to 180 mm Hg. Consequently, large changes in water and solute excretion are prevented. However, the intrinsic controls cannot handle extremely low systemic blood pressure, such as might result from serious hemorrhage *(hypovolemic shock)*. Once the mean systemic blood pressure drops below 80 mm Hg, autoregulation ceases.

Extrinsic Controls: Neural and Hormonal Mechanisms The purpose of the extrinsic controls regulating the GFR is to maintain systemic blood pressure—sometimes to the detriment of the kidneys.

1. Sympathetic nervous system controls. Neural renal controls serve the needs of the body as a whole. When the volume of the extracellular fluid is normal and the sympathetic nervous system is at rest, the renal blood vessels are maximally dilated and renal autoregulation mechanisms prevail. However, during extreme stress or emergency when it is necessary to shunt blood to vital organs, neural controls may overcome renal autoregulatory mechanisms. Norepinephrine released by sympathetic nerve fibers (and epinephrine released by the adrenal medulla) acts on alpha-adrenergic receptors on vascular smooth muscle, strongly constricting afferent arterioles, thereby inhibiting filtrate formation. This, in turn, indirectly trips the renin-angiotensin mechanism by stimulating the macula densa cells. The sympathetic nervous system also directly stimulates the granular cells to release renin, as discussed next.

2. Renin-angiotensin mechanism. The **renin-angiotensin mechanism** is triggered when various stimuli cause the granular cells to release the hormone **renin.** Renin acts enzymatically on **angiotensinogen,** a plasma globulin made by the liver, converting it to **angiotensin I.** This, in turn, is converted to **angiotensin II** by **angiotensin converting enzyme (ACE)** associated with the capillary endothelium in various body tissues, particularly the lungs.

Angiotensin II acts in five ways to stabilize systemic blood pressure and extracellular fluid volume. (1) As a potent vasoconstrictor, it activates smooth muscle of arterioles throughout the body, raising mean arterial blood pressure. (2) Angiotensin II stimulates reabsorption of sodium, both directly by acting on renal tubules and indirectly by triggering the release of aldosterone from the adrenal cortex. Because water follows sodium osmotically, blood volume and blood pressure rise (Figure 25.10). (3) Angiotensin II stimulates the hypothalamus to release antidiuretic hormone and activates the hypothalamic thirst center, both of which increase blood volume (see Chapter 26). (4) Angiotensin II also increases fluid reabsorption by decreasing peritubular capillary hydrostatic pressure. This pressure drop occurs because the efferent arterioles constrict, and the downstream drop in hydrostatic pressure allows more fluid to move back into the peritubular capillary bed. (5) Finally, angiotensin II targets the glomerular mesangial cells, causing them to contract and reduce the GFR by decreasing the total surface area of glomerular capillaries available for filtration. While this seems like a daunting list at first, it will help if you remember that all of the effects of angiotensin II are aimed at restoring blood volume and blood pressure. Of angiotensin II's many effects, the first two are the most important.

Several factors acting independently or collectively can trigger renin release.

- Reduced stretch of the granular cells. A drop in mean systemic blood pressure below 80 mm Hg (as might be due to hemorrhage, dehydration, etc.) reduces the stretch of the granular cells and stimulates them to release more renin.
- Stimulation of the granular cells by input from activated macula densa cells. When macula densa cells sense low NaCl concentration (slowly moving filtrate), they signal the granular cells to release renin. This signal may be *decreased* release of ATP (also thought to be the tubuloglomerular feedback messenger), *increased* release of the prostaglandin PGE_2, or both.
- Direct stimulation of granular cells via β_1-adrenergic receptors by renal sympathetic nerves.

Other Factors Affecting GFR Renal cells produce a battery of chemicals, many of which act as paracrines (local signaling molecules).

1. Prostaglandin E_2 (PGE_2): The vasodilatory paracrine PGE_2, in addition to its role discussed above, counteracts vasoconstriction by norepinephrine and angiotensin II within the kidney. The adaptive value of these opposing actions is to prevent renal damage while responding to body demands to increase peripheral resistance.

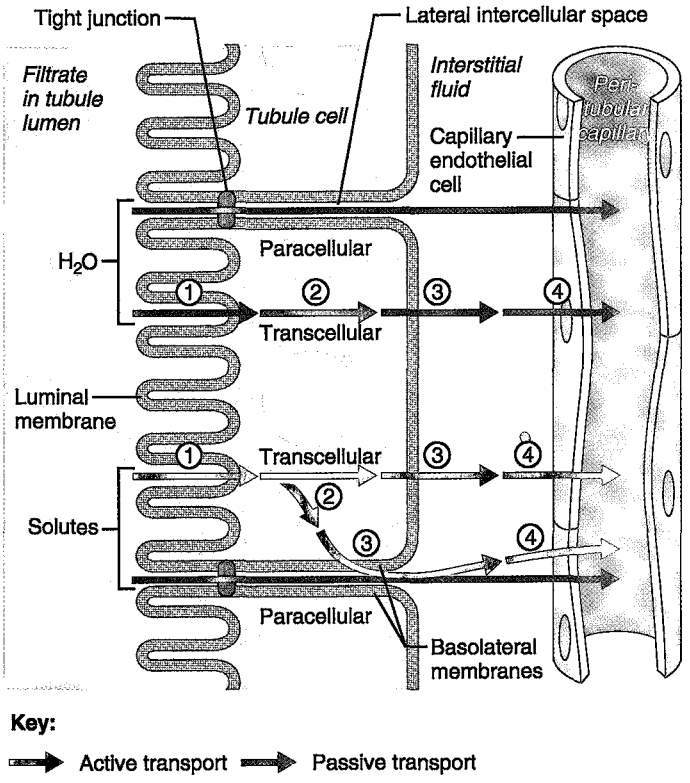

FIGURE 25.11 **Transcellular and paracellular routes of tubular reabsorption.** Water and solutes move from inside the tubular lumen into the peritubular capillaries via either transcellular or paracellular routes. The transcellular route consists of four steps: ① transport across the luminal membrane, ② diffusion through the cytosol, ③ transport across the basolateral membrane, and ④ movement through the interstitial fluid and into the capillary. Transcellular transport often involves the lateral intercellular spaces because ATP-dependent pumps located on the basolateral membrane pump ions into these spaces. Water and solutes following the paracellular route move through leaky tight junctions, particularly in the PCT. (Transporters, ion channels, and aquaporins are not depicted.)

2. Intrarenal angiotensin II: Although we usually think of angiotensin II as a hormone, the kidney has recently been shown to make its own, locally acting, angiotensin II that reinforces the effects of hormonal angiotensin II. It also dampens the resulting renal vasoconstriction by causing PGE_2 release.

3. Adenosine: Adenosine can be released as such or produced extracellularly from ATP released by macula densa cells. Although it functions as a vasodilator systemically, adenosine constricts the renal vasculature.

HOMEOSTATIC IMBALANCE

Abnormally low urinary output (less than 50 ml/day), called *anuria* (ah-nu're-ah), may indicate that glomerular blood pressure is too low to cause filtration. However, renal failure and anuria can result from situations in which the nephrons cease to function for a variety of other reasons, including acute nephritis, transfusion reactions, and crush injuries. ●

Step 2: Tubular Reabsorption

Our total plasma volume filters into the renal tubules about every 22 minutes, so all our plasma would be drained away as urine in less than 30 minutes were it not for the fact that most of the tubule contents are quickly reclaimed and returned to the blood. This reclamation process, called **tubular reabsorption**, is a selective *transepithelial process* that begins as soon as the filtrate enters the proximal tubules. To reach the blood, transported substances move through *three* barriers—the *luminal* and *basolateral membranes* of the tubule cells and the *endothelium* of the peritubular capillaries. Because the tubule cells are connected by tight junctions, movement of substances between the cells is limited, although some important ions (Ca^{2+}, Mg^{2+}, K^+, and some Na^+) may use the *paracellular pathway* (Figure 25.11).

Given healthy kidneys, virtually all organic nutrients such as glucose and amino acids are completely reabsorbed to maintain or restore normal plasma concentrations. On the other hand, the reabsorption of water and many ions is continuously regulated and adjusted in response to hormonal signals. Depending on the substances transported, the reabsorption process may be *passive* (no ATP required) or *active* (at least one of its steps is driven by ATP directly or indirectly).

Sodium Reabsorption

Sodium ions are the single most abundant cation in the filtrate, and about 80% of the energy used for active transport is devoted to their reabsorption. Sodium reabsorption is almost always active and via the transcellular (transepithelial) route. In general, two basic processes that promote active Na^+ reabsorption occur in each tubule segment: Na^+ (1) enters the tubule cells from the filtrate at the luminal membrane and then (2) is actively transported out of the tubule cell by a Na^+-K^+ ATPase pump present in the basolateral membrane (Figure 25.12). From there, Na^+ is swept along by the bulk flow of water into adjacent peritubular capillaries. This bulk flow of water and solutes into the peritubular capillaries is rapid because of that blood's low hydrostatic pressure and high osmotic pressure (remember, most proteins are not filtered out of the blood into the tubule).

Q *How are primary and secondary active transport processes (both shown here) different?*

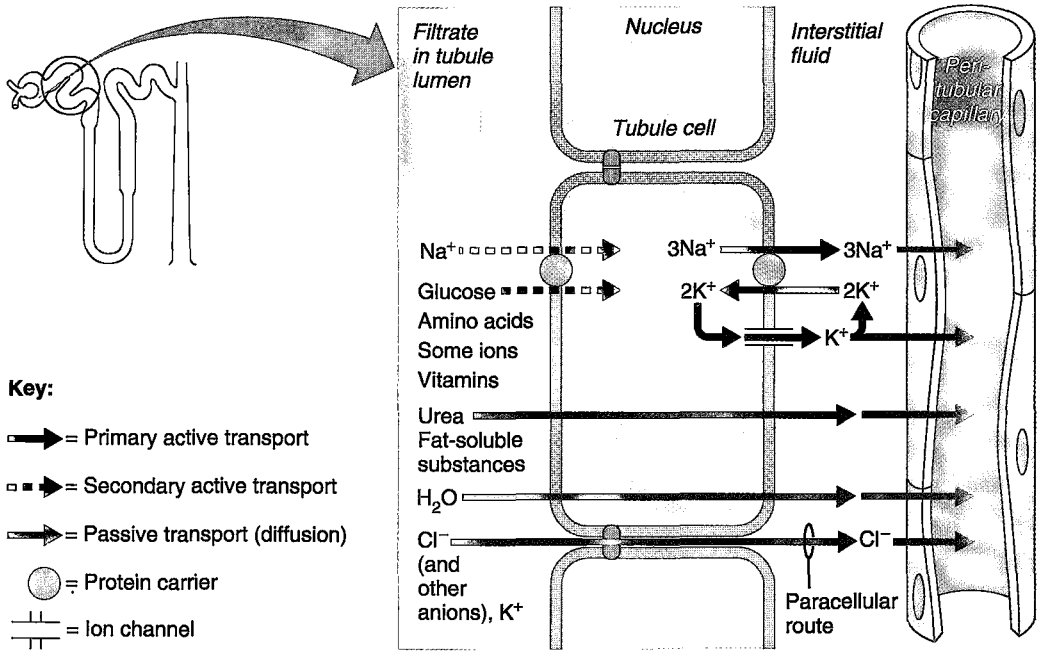

FIGURE 25.12 **Reabsorption by PCT cells.** "Downhill" Na^+ entry at the luminal surface is usually coupled to the transport of another solute (a cotransport process referred to as secondary active transport). After Na^+ enters, it diffuses to the basolateral membrane, where it is pumped into the interstitial space by a sodium pump (Na^+-K^+ ATPase). From there it diffuses into the peritubular capillary. Active pumping of Na^+ at the basolateral membrane creates concentration and osmotic gradients that drive reabsorption of water by osmosis, of anions and fat-soluble substances by diffusion, and of organic nutrients and selected cations by secondary active transport (symport with Na^+ at the luminal membrane). Though not illustrated here, most organic nutrients reabsorbed in the PCT move through the basolateral membrane by facilitated diffusion. (Luminal microvilli not illustrated.)

Active pumping of Na^+ from the tubule cells results in a strong electrochemical gradient that favors its passive entry at the luminal face via cotransport (symport or antiport) carriers or via facilitated diffusion through channels. This occurs because (1) the pump maintains the intracellular Na^+ concentration at low levels, and (2) the K^+ pumped into the tubule cells almost immediately diffuses out into the interstitial fluid via leakage channels, leaving the interior of the tubule cell with a net negative charge.

Because each tubule segment plays a slightly different role in reabsorption, the precise mechanism by which Na^+ is reabsorbed at the luminal membrane varies. However, the net effect is that Na^+ reabsorption by primary active transport provides the energy and the means for reabsorbing most other solutes.

Reabsorption of Water, Ions, and Nutrients

In **passive tubular reabsorption,** which encompasses diffusion, facilitated diffusion, and osmosis, substances move along their electrochemical gradient without the use of ATP. As they move through the tubule cells into the peritubular capillary blood, Na^+ ions establish an electrical gradient that favors passive reabsorption of anions (Cl^- and HCO_3^- for example) to restore electrical neutrality in the filtrate and plasma.

As we have seen, Na^+ movement also establishes a strong osmotic gradient, and water moves by osmosis into the peritubular capillaries, a process aided by water-filled channels called *aquaporins.* In continuously water-permeable regions of the renal

∀ *In primary active transport, the energy for the process is provided directly by the cleavage of ATP. In secondary active transport, the energy for the process is provided by the Na^+ concentration gradient. As Na^+ moves down its own concentration gradient established by the active pumping of Na^+ occurring elsewhere in the cell, it drives the movement of another substance (e.g., glucose) against its concentration gradient.*

tubules, such as the PCT, aquaporins are constant components of the tubule cell membranes. Because these channels are always present, the body is "obliged" to absorb water in the proximal nephron regardless of its state of over- or underhydration. This water flow is referred to as **obligatory water reabsorption.** Aquaporins are virtually absent in the luminal membranes of the collecting duct unless antidiuretic hormone (ADH) is present.

As water leaves the tubules, the concentration of solutes in the filtrate increases and, if able, they too begin to follow their concentration gradients into the peritubular capillaries (Figure 25.12). This phenomenon of solutes following solvent explains the passive reabsorption of a number of solutes present in the filtrate, such as cations, fatty acids, and some urea. It also explains in part why lipid-soluble drugs and environmental toxins are difficult to excrete: Since lipid-soluble compounds can generally pass through membranes, they will follow their concentration gradients and be reabsorbed, even if this is "not desirable."

Substances reabsorbed by **secondary active transport** (the "push" comes from the gradient created by Na^+-K^+ pumping at the basolateral membrane) include glucose, amino acids, lactate, vitamins, and most cations. In nearly all these cases, a luminal carrier moves Na^+ down its concentration gradient as it cotransports (symports) another solute (Figure 25.12). Cotransported solutes diffuse (via different transport proteins) across the basolateral membrane before moving into the peritubular capillaries. Although there is some overlap of carriers, the transport systems for the various solutes are quite specific *and limited.*

Excluding Na^+, there is a **transport maximum (T_m)** for nearly every substance that is actively reabsorbed. The T_m (reported in mg/min) reflects the number of carriers in the renal tubules available to ferry each particular substance. In general, there are plenty of carriers and therefore high T_m values for substances such as glucose that need to be retained, and few or no carriers for substances of no use to the body. When the carriers are saturated—that is, all bound to the substance they transport—the excess is excreted in urine. This is what happens in individuals who become hyperglycemic because of uncontrolled diabetes mellitus. As levels of glucose approach and exceed 180 mg/100 ml of plasma, the glucose T_m is exceeded and large amounts of glucose are lost in the urine even though the renal tubules are still functioning normally.

Any plasma proteins that squeeze through the filtration membrane are removed from the filtrate in the proximal tubule by endocytosis, digested to their amino acids, and moved into the peritubular blood.

Nonreabsorbed Substances

Some substances are either not reabsorbed or are reabsorbed incompletely because they (1) lack carriers or channels, (2) are not lipid soluble, or (3) are too large to pass through tight junctions between the tubular cells. The most important of these are the nitrogenous end products of protein and nucleic acid metabolism: **urea, creatinine,** and **uric acid.** Urea handling in the nephron is complicated and will be discussed on p. 1018, but the net effect is that 50–60% of the urea present in filtrate is reclaimed. Creatinine, a large, lipid-insoluble molecule, is not reabsorbed at all. Its plasma concentration remains stable as long as muscle mass is stable, which makes it useful for measuring the GFR and glomerular function.

Absorptive Capabilities of the Renal Tubules and Collecting Ducts

Proximal Convoluted Tubule Table 25.1 compares the reabsorptive abilities of various regions of the renal tubules and collecting ducts. Although the entire renal tubule is involved in reabsorption to some degree, the PCT cells are by far the most active "reabsorbers" and the events just described occur mainly in this tubular segment. Normally, the PCT reabsorbs all of the glucose, lactate, and amino acids in the filtrate and 65% of the Na^+ and water. Additionally, 90% of the filtered bicarbonate (HCO_3^-), 60% of the Cl^-, and about 55% of the K^+ are reclaimed in the PCT. The bulk of the reabsorption of electrolytes is accomplished by the time the filtrate reaches the loop of Henle. Nearly all of the uric acid is reabsorbed in the proximal tubule, but it is later secreted back into the filtrate.

Loop of Henle Beyond the PCT, the permeability of the tubule epithelium changes dramatically. Here, for the first time, water reabsorption is not coupled to solute reabsorption. Water can leave the descending limb of the loop of Henle but *not* the ascending limb, where aquaporins are scarce or absent in the tubule membrane. For reasons that will be explained shortly, these permeability differences play a vital role in the kidneys' ability to form dilute and concentrated urine.

The rule for water is that it leaves the descending (but not the ascending) limb of Henle's loop; the opposite is true for solutes. Virtually no solute reabsorption occurs in the descending limb, but both active and passive reabsorption of solute occurs in the ascending limb. In the thin portion of the ascending limb, Na^+ moves passively down the concentration gradient created by water reabsorption. A Na^+-K^+-$2Cl^-$ symporter is the main means of Na^+ entry at the luminal surface in the thick portion of the ascending limb. However, this segment also has

TABLE 25.1 Reabsorption Capabilities of Different Segments of the Renal Tubules and Collecting Ducts

TUBULE SEGMENT	SUBSTANCE REABSORBED	MECHANISM
PROXIMAL CONVOLUTED TUBULE		
	Sodium ions (Na^+)	Primary active transport via basolateral Na^+-K^+ pump; sets up electrochemical gradient for passive solute diffusion, osmosis, and secondary active transport (cotransport) with Na^+
	Virtually all nutrients (glucose, amino acids, vitamins)	Secondary active transport with Na^+
	Cations (K^+, Mg^{2+}, Ca^{2+}, and others)	Passive transport driven by electrochemical gradient for most; the paracellular route is important
	Anions (Cl^-, HCO_3^-)	Passive transport; paracellular diffusion driven by electrochemical gradient for Cl^-; secondary active transport (with Na^+) for HCO_3^-
	Water	Osmosis; driven by solute reabsorption (obligatory)
	Urea and lipid-soluble solutes	Passive diffusion driven by the concentration gradient created by reabsorption of water
	Small proteins	Endocytosed by tubule cells and digested to amino acids within tubule cells
LOOP OF HENLE		
Descending limb	Water	Osmosis
Ascending limb	Na^+, Cl^-, K^+	Secondary active transport of Cl^-, Na^+, and K^+ via Na^+-K^+-$2Cl^-$ cotransporter in thick portion; paracellular diffusion; Na^+-H^+ antiport
	Ca^{2+}, Mg^{2+}	Passive paracellular diffusion driven by electrochemical gradient
DISTAL CONVOLUTED TUBULE		
	Na^+, Cl^-	Primary active Na^+ transport at basolateral membrane; secondary active transport at luminal membrane via Na^+-Cl^- symporter and channels; aldosterone-regulated at distal portion
	Ca^{2+}	Passive uptake via PTH-modulated channels in luminal membrane; primary and secondary active transport (antiport with Na^+) in basolateral membrane
COLLECTING DUCT		
	Na^+, H^+, K^+, HCO_3^-, Cl^-	Primary active transport of Na^+ (requires aldosterone) and the medullary gradient create the conditions for passive transport of some HCO_3^- and Cl^- and cotransport of H^+, Cl^-, and HCO_3^-; K^+ is both reabsorbed and secreted (aldosterone dependent), usually resulting in net K^+ secretion
	Water	Osmosis; controlled (facultative) water reabsorption; ADH required to insert aquaporins
	Urea	Facilitated diffusion in response to concentration gradient in the deep medulla region; recycles and contributes to medullary osmotic gradient

Na^+-H^+ antiporters, and some 50% of Na^+ passes via the paracellular route in this region. A Na^+-K^+ ATPase operates at the basolateral membrane to create the ionic gradient that drives the symporter.

Distal Convoluted Tubule and Collecting Duct

By the time the DCT is reached, only about 10% of the originally filtered NaCl and 25% of the water remain in the tubule. Some unregulated NaCl reabsorption occurs in the DCT via Na^+-Cl^- symporters. However, most reabsorption from this point on depends on the body's needs at the time and is regulated by hormones (mainly aldosterone for Na^+, ADH for water, and PTH for Ca^{2+} as described in Chapter 26). If necessary, nearly all of the water and Na^+ reaching these regions can be reclaimed. In the absence of regulatory hormones, the DCT and collecting duct are relatively impermeable to water. Reabsorption of more water depends on the presence of antidiuretic hormone (ADH), which makes the collecting ducts more permeable to water by inserting aquaporins into the collecting duct luminal membranes.

Aldosterone "fine-tunes" reabsorption of the remaining Na^+. Decreased blood volume or blood pressure, low extracellular Na^+ concentration (hyponatremia), or high extracellular K^+ concentration (hyperkalemia) can cause the adrenal cortex to release aldosterone to the blood. Except for hyperkalemia (which *directly* stimulates the adrenal cortex to secrete aldosterone), these conditions promote the renin-angiotensin mechanism, which in turn prompts the release of aldosterone (see Figure 25.10). Aldosterone targets the principal cells of the collecting ducts and cells of the distal portion of the DCT (prodding them to open or synthesize more luminal Na^+ and K^+ channels, and more basolateral Na^+-K^+ ATPases). As a result, little or no Na^+ leaves the body in urine. In the absence of aldosterone, much less Na^+ is reabsorbed by these segments, resulting in Na^+ losses of about 2% of Na^+ filtered daily, an amount incompatible with life.

A second effect of aldosterone is to facilitate water reabsorption: As Na^+ is reabsorbed, water follows it back into the blood (if it can). Aldosterone also reduces blood K^+ concentrations because aldosterone-induced reabsorption of Na^+ is coupled to K^+ secretion in the principal cells, that is, as Na^+ enters, K^+ moves into the lumen.

In contrast to aldosterone, which acts to conserve Na^+, atrial natriuretic peptide (ANP) reduces blood Na^+, thereby decreasing blood volume and blood pressure. Released by cardiac atrial cells when blood volume or blood pressure is elevated, ANP exerts several effects that lower blood Na^+ levels. For example, it (1) acts directly on medullary collecting ducts to inhibit Na^+ reabsorption, (2) indirectly inhibits Na^+ reabsorption by counteracting the stimulatory effect of angiotensin II on aldosterone secretion by the adrenal cortex, and (3) indirectly stimulates an increased GFR by targeting the renal arterioles, thereby reducing water reabsorption and blood volume.

Step 3: Tubular Secretion

The failure of tubule cells to reabsorb some solutes is an important means of clearing plasma of unwanted substances. A second such mechanism is **tubular secretion**—essentially, reabsorption in reverse. Substances such as H^+, K^+, NH_4^+, creatinine, and certain organic acids either move into the filtrate from the peritubular capillaries through the tubule cells or are synthesized in the tubule cells and secreted. Thus, the urine eventually excreted contains *both filtered and secreted substances.* With one major exception (K^+), the PCT is the main site of secretion, but the cortical parts of the collecting ducts and the late regions of the distal tubules are also active (see Figure 25.16, p. 1020).

Tubular secretion is important for

1. Disposing of substances, such as certain drugs and metabolites, which are tightly bound to plasma proteins. Such substances are not readily filtered and so must be secreted.
2. Eliminating undesirable substances or end products that have been reabsorbed by passive processes (urea and uric acid).
3. Ridding the body of excess K^+. Because virtually all K^+ present in the filtrate is reabsorbed in the PCT and ascending loop of Henle, nearly all K^+ in urine is from aldosterone-driven active tubular secretion into the late DCT and collecting ducts.
4. Controlling blood pH. When blood pH drops toward the acidic end of its homeostatic range, the renal tubule cells actively secrete more H^+ into the filtrate and retain more HCO_3^- (a base). As a result, the blood pH rises and the urine drains off the excess H^+. Conversely, when blood pH approaches the alkaline end of its range, Cl^- is reabsorbed instead of HCO_3^-, which is allowed to leave the body in urine. The kidneys' role in pH homeostasis is discussed in more detail in Chapter 26.

Regulation of Urine Concentration and Volume

A solution's **osmolality** (oz"mo-lal'ĭ-te) is the number of solute particles dissolved in 1 kg of water and reflects the solution's ability to cause osmosis. For any solution interfacing with a semipermeable membrane, this ability, called *osmotic activity,* is

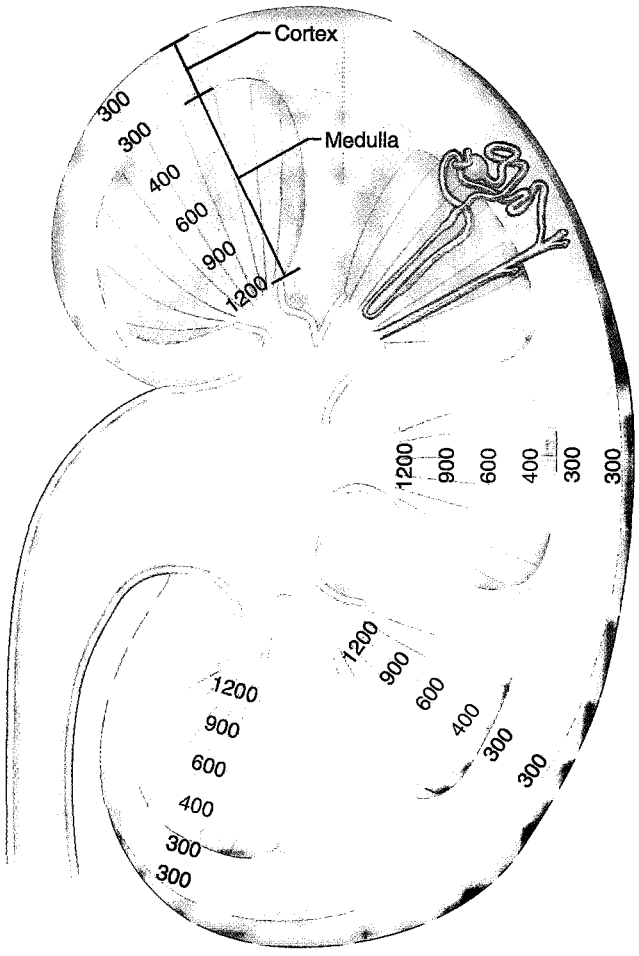

FIGURE 25.13 **Osmotic gradient in the renal medulla and its relationship to the loops of Henle and collecting ducts.** The osmolality of the interstitial fluid in the renal cortex is isotonic at 300 mOsm, but the osmolality of the interstitial fluid in the renal medulla increases progressively from 300 mOsm at the corticomedullary junction to 1200 mOsm at the medullary-pelvis junction. One greatly enlarged nephron and its collecting duct are depicted to show their positions relative to the medullary gradient.

25

determined only by the number of nonpenetrating solute particles (solute particles unable to pass through the membrane) and is independent of their type. Ten sodium ions have the same osmotic activity as ten glucose molecules or ten amino acids in the same volume of water. Because one *osmol* (equivalent to 1 mole of particles) is a fairly large unit, the **milliosmol (mOsm)** (mil″e-oz′mōl), equal to 0.001 osmol, is generally used. In the discussion that follows, we use mOsm to mean mOsm/kg.

One crucial renal function is to keep the solute load of body fluids constant at about 300 mOsm, the osmotic concentration of blood plasma, by regulating urine concentration and volume. The kidneys accomplish this feat using **countercurrent mechanisms.** In the kidneys, the term *countercurrent* means that fluid flows through adjacent tubes in opposite directions. These countercurrent mechanisms are (1) the interaction between the flow of filtrate through the ascending and descending limbs of the long loops of Henle of juxtamedullary nephrons (the *countercurrent multiplier*), and (2) the flow of blood through the ascending and descending portions of the vasa recta blood vessels (the *countercurrent exchanger*).* The countercurrent mechanisms establish and maintain an osmotic gradient extending from the cortex through the depths of the medulla that allows the kidneys to vary urine concentration dramatically.

The osmolality of the filtrate entering the PCT is identical to that of plasma, about 300 mOsm. As described earlier, because of PCT reabsorption of water *and* solutes, the filtrate is still isosmotic with plasma by the time the descending limb of the loop of Henle is reached. However, its osmolality increases from 300 to about 1200 mOsm in the deepest part of the medulla (Figure 25.13). How does this increase in concentration occur? The answer lies in the unique workings of the long loops of Henle of the juxtamedullary nephrons, and the vasa recta. Notice in Figure 25.14 that in each case the fluids involved—filtrate in the loops of Henle and blood in the vasa recta—first descend and then ascend through parallel limbs.

The Countercurrent Multiplier

First, we will follow filtrate processing through the loop of Henle, as portrayed in Figure 25.14a, to see how the loop functions as a **countercurrent multiplier** to establish the osmotic gradient. The countercurrent multiplier functions because of three factors:

1. The descending limb of the loop of Henle is relatively impermeable to solutes and freely permeable to water. Because the osmolality of the medullary interstitial fluid increases all along the descending limb (the mechanism of this increase is explained shortly), water passes osmotically out of the filtrate all along this course. Thus, the filtrate osmolality reaches its highest point (1200 mOsm) at the bend of the loop.

2. The ascending limb is permeable to solutes, but not to water. As the filtrate rounds the bend into the ascending limb, the tubule permeability changes, becoming impermeable to water and selectively permeable to salt. The Na^+ and Cl^- concentration in the filtrate entering the ascending limb is very high (and

* The term "countercurrent" is commonly misunderstood to mean that the direction of fluid flow in the loops of Henle is opposite that of the blood in the vasa recta. In fact, there is no one-to-one relationship between individual loops of Henle and capillaries of the vasa recta as might be suggested by two-dimensional diagrams such as Figures 25.5 and 25.14. Instead, there are many tubules and capillaries packed together. Each tubule is surrounded by many blood vessels, whose flow is not necessarily counter to flow in that tubule.

Q *What portion of the nephron acts as the countercurrent multiplier? As the countercurrent exchanger?*

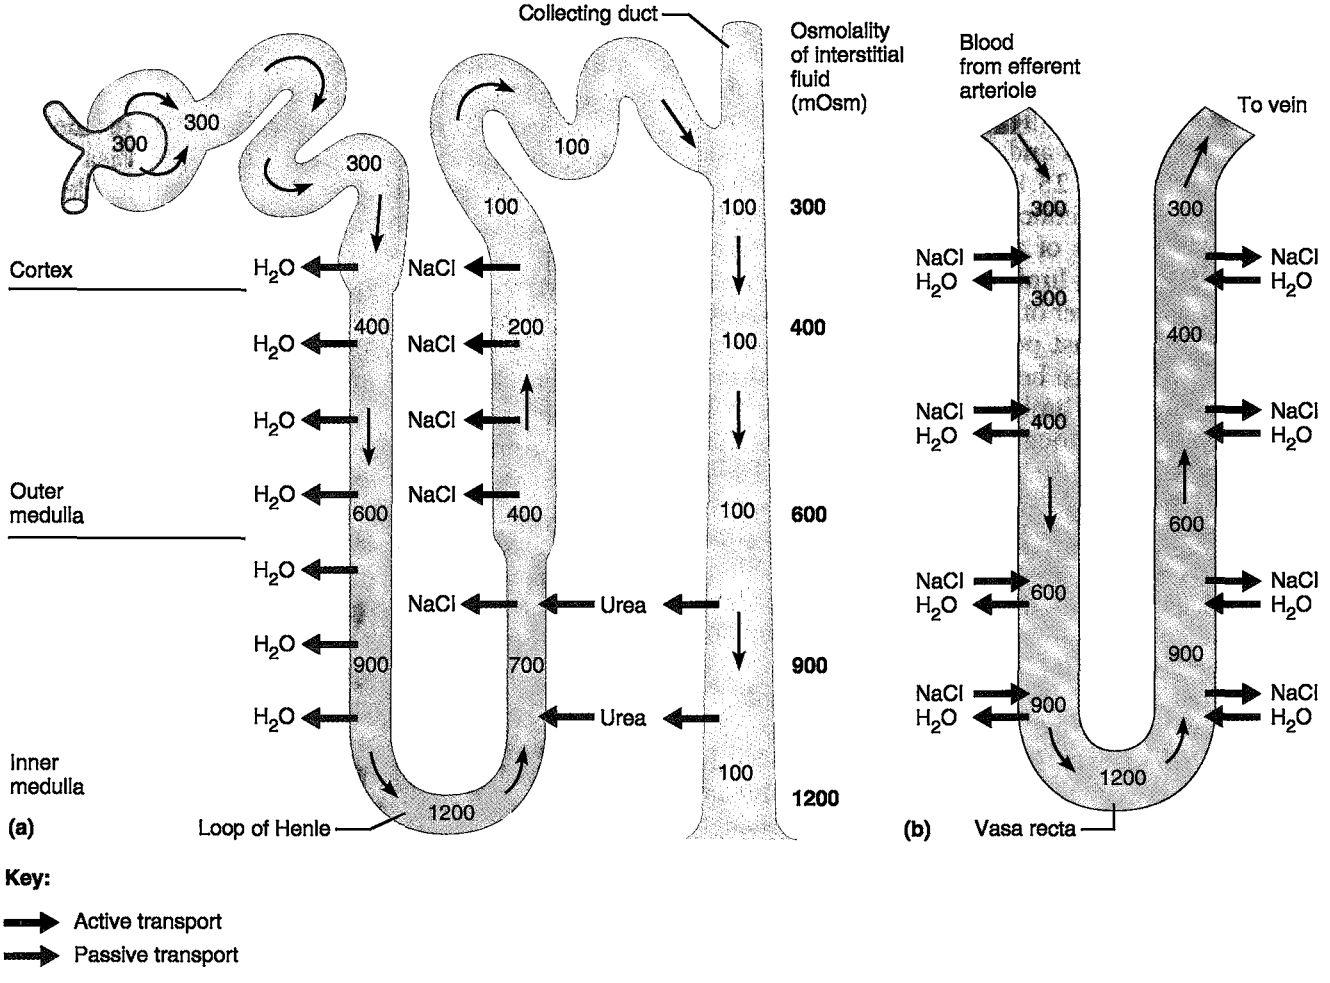

FIGURE 25.14 **Countercurrent mechanism for establishing and maintaining the medullary osmotic gradient. (a)** Filtrate entering the descending limb of the loop of Henle is isosmotic to both blood plasma and cortical interstitial fluid. As the filtrate flows from the cortex to the medulla in the descending limb, water leaves the tubule by osmosis and the filtrate osmolality increases from 300 to 1200 mOsm. As the filtrate flows into the ascending limb, the permeability of the tubule epithelium changes from being permeable to water and impermeable to salt to the opposite condition: water impermeable, salt permeable. Consequently, NaCl leaves the ascending limb, diluting the filtrate as it approaches the cortex. Thus the descending limb produces increasingly salty filtrate, while the ascending limb uses this high salt concentration to establish the high osmolality of the interstitial fluid in the medulla and the medullary osmotic gradient. Diffusion of urea from the lower portion of the collecting duct also contributes to the high osmolality in the medulla. **(b)** Dissipation of the medullary osmotic gradient is prevented because the blood in the vasa recta continuously becomes isosmotic to the interstitial fluid—becoming more concentrated as it descends deeper into the medulla and less concentrated as it approaches the cortical region. This occurs because of the high porosity and sluggish blood flow in the vasa recta.

25

A *The countercurrent multiplier is the loop of Henle of juxtamedullary nephrons. The countercurrent exchanger is the vasa recta.*

interstitial fluid concentrations of these two ions are lower). Na^+ and Cl^- reabsorption in the ascending limb is both passive (mostly in the thin segment) and active (via the Na^+-K^+-$2Cl^-$ cotransporter in the thick segment). As Na^+ and Cl^- are extruded from the filtrate into the medullary interstitial fluid, they contribute to the high osmolality there. Because it loses salt but not water, the filtrate in the ascending limb becomes increasingly dilute until, at 100 mOsm at the DCT, it is hypo-osmotic, or hypotonic, to blood plasma and cortical interstitial fluids.

Notice in Figure 25.14 that there is a constant difference in filtrate concentration (200 mOsm) between the two limbs of the loop of Henle, and between the ascending limb and the interstitial fluid. This reflects the power of the ascending limb's NaCl pumps, which are just powerful enough to create a 200 mOsm difference between the inside and outside of the ascending limb. A 200-mOsm gradient by itself would not be enough to allow excretion of very concentrated urine. The beauty of this system lies in the fact that, because of countercurrent flow, the loop of Henle is able to "multiply" these small changes in solute concentration into a gradient change along the vertical length of the loop (both inside and outside) that is closer to 900 mOsm (1200 mOsm − 300 mOsm).

Although the two limbs of the loop of Henle are not in direct contact with each other, they are close enough to influence each other's exchanges with the interstitial fluid they share. Hence, water diffusing out of the descending limb produces the increasingly "salty" filtrate that the ascending limb uses to raise the osmolality of the medullary interstitial fluid. Furthermore, the more NaCl the ascending limb extrudes, the more water diffuses out of the descending limb and the saltier the filtrate in the descending limb becomes. This establishes a positive feedback mechanism that produces the high osmolality of the fluids in the descending limb and the interstitial fluid.

3. Urea recycling contributes to the medullary osmotic gradient. In the thin limbs of the loop of Henle, urea enters the filtrate by facilitated diffusion. As the filtrate moves on, water is reabsorbed but urea is left behind because the tubule between Henle's thin limb and the collecting duct is not permeable to urea. When filtrate reaches the collecting duct in the deep medullary region, urea, now highly concentrated, is transported by facilitated diffusion out of the tubule into the interstitial fluid of the medulla, forming a pool of urea that recycles back into the thin limb of the loop of Henle. This pool of urea contributes substantially to the high osmolality in the medulla. Antidiuretic hormone (ADH), which stimulates excretion of highly concentrated urine (as we will see shortly), enhances urea transport in the medullary collecting duct. When ADH is present, urea recycling is enhanced, the medullary osmotic gradient is enhanced, and more concentrated urine can be formed.

The Countercurrent Exchanger

As shown in Figure 25.14b, the vasa recta function as **countercurrent exchangers,** maintaining the osmotic gradient established by the cycling of salt while delivering blood to cells in the area. Because these vessels receive only about 10% of the renal blood supply, blood flow through the vasa recta is sluggish. Moreover, they are freely permeable to water and NaCl, allowing blood to make passive exchanges with the surrounding interstitial fluid and achieve equilibrium. Consequently, as the blood flows into the medullary depths, it loses water and gains salt (becomes hypertonic). Then, as it emerges from the medulla into the cortex, the process is reversed: It picks up water and loses salt. Because blood leaving and reentering the cortex via the vasa recta has the same solute concentration, the vessels of the vasa recta act as countercurrent exchangers. This system does not create the medullary gradient, but it protects it by preventing rapid removal of salt from the medullary interstitial space, and by removing reabsorbed water.

Formation of Dilute Urine

Because tubular filtrate is diluted as it travels through the ascending limb of the loop of Henle, all the kidney needs to do to secrete dilute (hypo-osmotic) urine is allow the filtrate to continue on its way into the renal pelvis (Figure 25.15a). When ADH is not being released by the posterior pituitary, that is exactly what happens. The collecting ducts remain essentially impermeable to water due to the absence of aquaporins in their luminal cell membranes, and no further water reabsorption occurs. Moreover, as noted, Na^+ and selected other ions can be removed from the filtrate by DCT and collecting duct cells so that urine becomes even more dilute before entering the renal pelvis. The osmolality of urine can plunge as low as 70 mOsm, about one-fourth the concentration of glomerular filtrate or blood plasma.

Formation of Concentrated Urine

As its name reveals, **antidiuretic hormone (ADH)** inhibits *diuresis* (di"u-re'sis), or urine output. It accomplishes this via a second-messenger system using cyclic AMP that causes insertion of aquaporins into the luminal membrane of the principal cells of the collecting ducts. Consequently water passes easily into and through the cells into the interstitial space, and the osmolality of the filtrate becomes equal to that of the interstitial fluid.

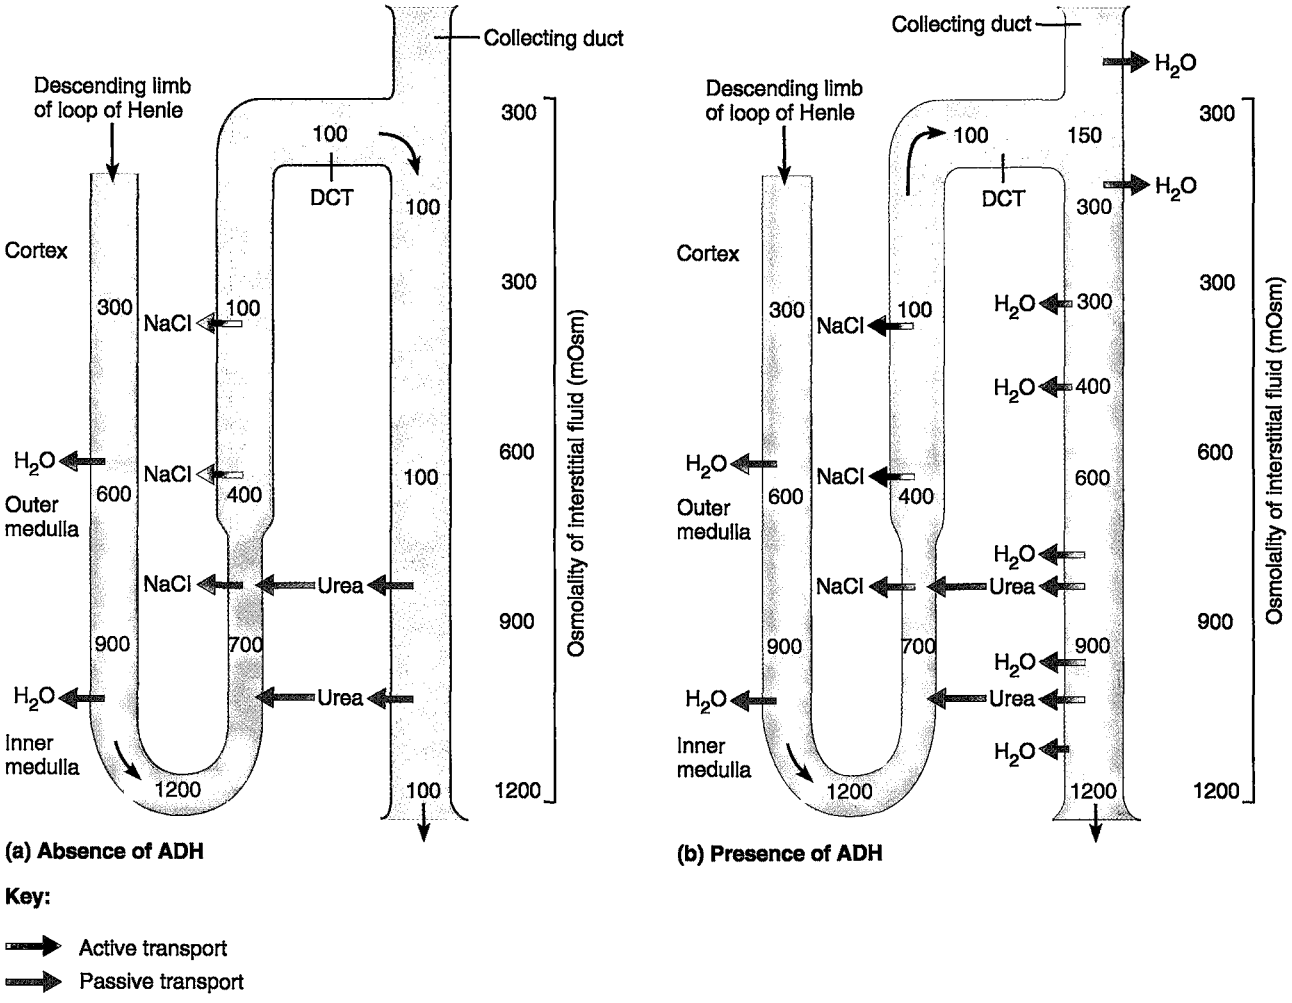

FIGURE 25.15 **Mechanisms for forming dilute and concentrated urine.** **(a)** In the absence of ADH, dilute filtrate produced by the countercurrent mechanism remains dilute as it passes through the collecting duct. **(b)** In the presence of ADH, concentrated urine is excreted. ADH causes insertion of aquaporins in luminal membranes of principal cells of the collecting duct. Consequently water rapidly leaves the filtrate in the collecting duct.

In the distal tubules, the filtrate osmolality is approximately 100 mOsm, but as the filtrate flows through the collecting ducts and is subjected to the hyperosmolar conditions in the medulla, water, followed by urea, rapidly leaves the filtrate (Figures 25.15b and 25.16e). Depending on the amount of ADH released (which is keyed to the level of body hydration), urine concentration may rise as high as 1200 mOsm, the concentration of interstitial fluid in the deepest part of the medulla. With maximal ADH secretion, up to 99% of the water in the filtrate is reabsorbed and returned to the blood, and half a liter per day of highly concentrated urine is excreted. The ability of our kidneys to produce such concentrated urine is critically tied to our ability to survive without water. Water reabsorption that depends on the presence of ADH is called **facultative water reabsorption.**

ADH is released more or less continuously unless the blood solute concentration drops too low. Release of ADH is enhanced by any event that raises plasma osmolality above 300 mOsm such as sweating or diarrhea, or greatly reduced blood volume or blood pressure (see Chapter 26). Although release of ADH is the "signal" to produce concentrated urine that opens the door for water reabsorption (through aquaporins), the kidneys' ability to respond to this signal depends on the high medullary osmotic gradient.

Diuretics

There are several types of **diuretics,** chemicals that enhance urinary output. An *osmotic diuretic* is a substance that is not reabsorbed and that carries water out with it (for example, the high blood glucose levels of a diabetes mellitus patient). Alcohol,

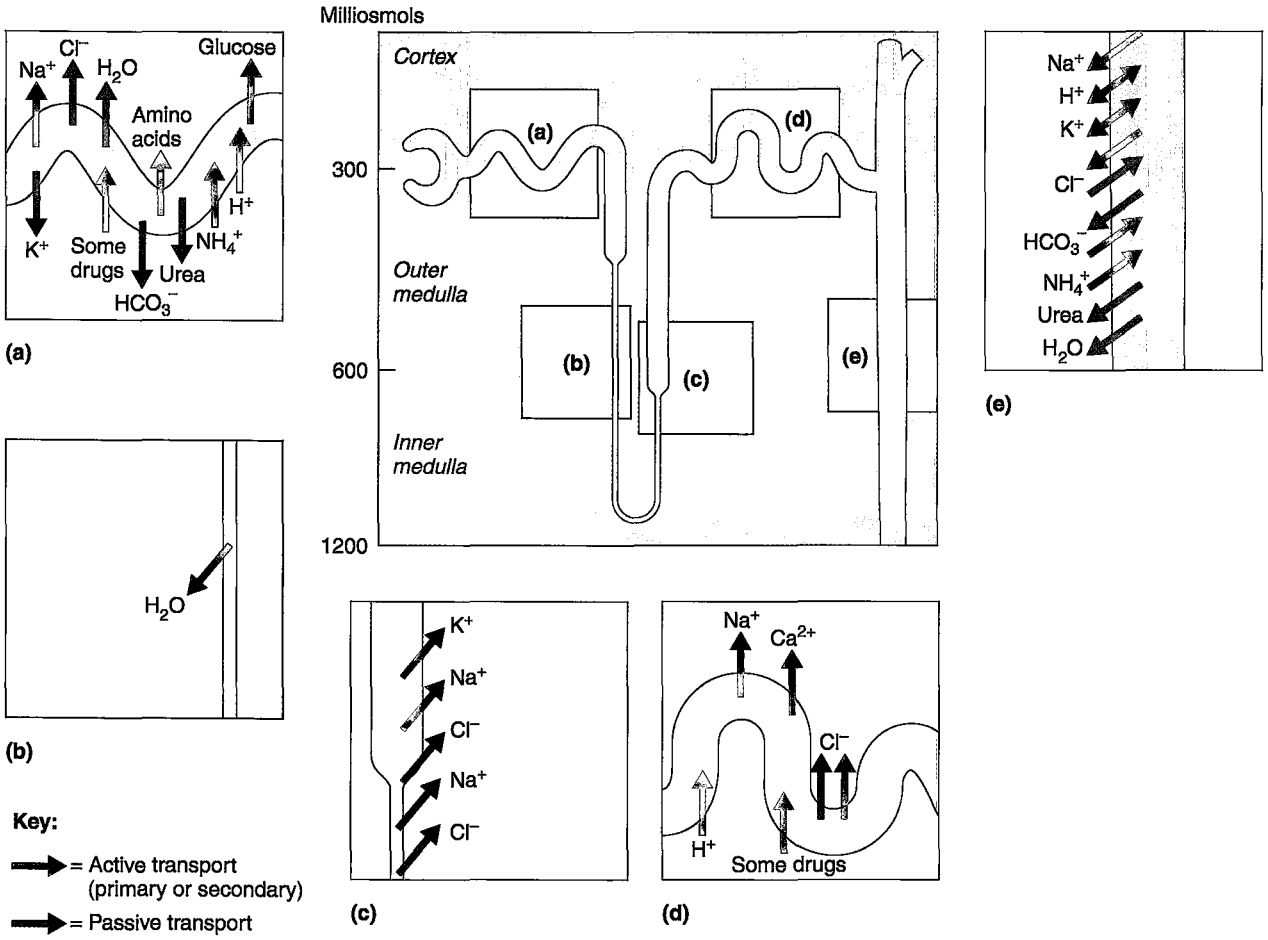

FIGURE 25.16 **Summary of nephron functions.** The glomerulus provides the filtrate processed by the renal tubule. The various regions of the renal tubule carry out reabsorption and secretion and maintain a gradient of osmolality within the medullary interstitial fluid. Varying osmolality at different points in the interstitial fluid is symbolized in the central figure by gradients of color. The inserts that accompany the central figure describe the main transport functions of the four regions of the nephron tubule and of the collecting duct. **(a) Proximal tubule.** Filtrate that enters the PCT from the glomerular capsule has about the same osmolality as blood plasma. The main activity of the PCT transport epithelium is reabsorption of certain solutes from the filtrate back into the blood. Nearly all nutrients and about 65% of Na^+ are actively transported out of the PCT and enter the peritubular capillaries; Cl^- and water follow passively. PCT cells also secrete ammonium and other nitrogenous wastes into the filtrate and help maintain a constant pH in blood and interstitial fluid by the secretion of H^+ and reabsorption of HCO_3^-. By the end of the proximal tubule, the filtrate volume has been reduced by 65%. **(b) Descending limb.** The descending limb of the loop of Henle is freely permeable to water but not to NaCl. As filtrate in this limb descends into the medulla, the filtrate loses water by osmosis to the interstitial fluid, which is increasingly hypertonic in that direction. Consequently, salt and other solutes become more concentrated in the filtrate. **(c) Ascending limb.** The ascending limb of the loop of Henle is impermeable to water but permeable to Na^+ and Cl^-. These ions, which became concentrated in the descending limb, move passively out of the thin portion of the ascending limb, are actively pumped out of the thick portion of the ascending limb, and contribute to the high osmolality of interstitial fluid in the inner medulla. K^+ is cotransported with Na^+ and Cl^-. The tubule epithelium here is not permeable to water, so the filtrate becomes more and more dilute as the exodus of salt from the filtrate continues. **(d) Distal tubule.** The DCT, like the PCT, is specialized for selective secretion and reabsorption. Na^+ and Cl^- are cotransported, H^+ may be secreted, and in the presence of aldosterone, more Na^+ is reabsorbed. The water permeability of the DCT is extremely low and almost no further H_2O absorption occurs there. **(e) Collecting duct.** The urine, normally quite dilute at this point, begins its journey via the collecting duct back into the medulla, with its increasing osmolality gradient. In the cortical collecting duct, K^+, H^+, and/or HCO_3^- ions may be reabsorbed or secreted depending on what is required to maintain homeostasis. The wall of the medullary region of the collecting duct is permeable to urea and is made more so by the presence of ADH. Some urea diffuses out of the collecting duct and contributes to the high osmolality of the inner medulla. In the absence of ADH, the collecting duct is nearly impermeable to water, and dilute urine is excreted. In the presence of ADH, more aquaporins are inserted into the collecting duct, and the filtrate loses water by osmosis as it passes through medullary regions of increasing osmolality. Consequently, water is conserved, and concentrated urine is excreted.

25

essentially a sedative, encourages diuresis by inhibiting release of ADH. Other diuretics increase urine flow by inhibiting Na^+ reabsorption and the obligatory water reabsorption that normally follows. Examples include caffeine (found in coffee, tea, and colas) and many drugs prescribed for hypertension or the edema of congestive heart failure. Common diuretics inhibit Na^+-associated symporters. "Loop diuretics" [like furosemide (Lasix)] are powerful because they inhibit formation of the medullary gradient by acting at the ascending limb of Henle's loop. Thiazides are less potent and act at the DCT.

Renal Clearance

Renal clearance refers to the volume of plasma that is cleared of a particular substance in a given time, usually 1 minute. Renal clearance tests are done to determine the GFR, which allows us to detect glomerular damage and follow the progress of renal disease (discussed in A Closer Look, p. 1022).

The renal clearance rate (RC) of any substance, in ml/min, is calculated from the equation

$$RC = UV/P$$

where

U = concentration of the substance in urine (mg/ml)

V = flow rate of urine formation (ml/min)

P = concentration of the substance in plasma (mg/ml)

Because it is freely filtered and neither reabsorbed nor secreted by the kidneys, *inulin* (in'u-lin) is the standard used to determine the GFR. A polysaccharide with a molecular weight of approximately 5000, inulin's renal clearance value is equal to the GFR. When inulin is infused such that its plasma concentration is 1 mg/ml (P = 1 mg/ml), then generally U = 125 mg/ml, and V = 1 ml/min. Therefore, its renal clearance is RC = (125 × 1)/1 = 125 ml/min, meaning that in 1 minute the kidneys have removed (cleared) all the inulin present in 125 ml of plasma.

A clearance value less than that of inulin means that a substance is partially reabsorbed. An example is urea with an RC of 70 ml/min, meaning that of the 125 ml of glomerular filtrate formed each minute, approximately 70 ml is completely cleared of urea, while the urea in the remaining 55 ml is recovered and returned to the plasma. If the RC is zero (such as for glucose in healthy individuals), reabsorption is complete or the substance is not filtered. If the RC is greater than that of inulin, the tubule cells are secreting the substance into the filtrate. This is the case with most drug metabolites. Knowing a drug's renal clearance value is essential because if it is high, the drug dosage must also be high and administered frequently to maintain a therapeutic level. Creatinine, which has an RC of 140 ml/min, is freely filtered but also secreted in small amounts. It is often used nevertheless to give a "quick and dirty" estimate of GFR.

Urine

Physical Characteristics

Color and Transparency

Freshly voided urine is clear and pale to deep yellow. Its yellow color is due to **urochrome** (u'ro-krōm), a pigment that results from the body's destruction of hemoglobin (via bilirubin or bile pigments). The more concentrated the urine, the deeper the yellow color. An abnormal color such as pink or brown, or a smoky tinge, may result from eating certain foods (beets, rhubarb) or may be due to the presence in the urine of bile pigments or blood. Additionally, some commonly prescribed drugs and vitamin supplements alter the color of urine. Cloudy urine may indicate a urinary tract infection.

Odor

Fresh urine is slightly aromatic, but if allowed to stand, it develops an ammonia odor as bacteria metabolize its urea solutes. Some drugs and vegetables alter the usual odor of urine, as do some diseases. For example, in uncontrolled diabetes mellitus the urine smells fruity because of its acetone content.

pH

Urine is usually slightly acidic (around pH 6), but changes in body metabolism or diet may cause the pH to vary from about 4.5 to 8.0. A predominantly *acidic* diet that contains large amounts of protein and whole wheat products produces acidic urine. A vegetarian *(alkaline)* diet, prolonged vomiting, and bacterial infection of the urinary tract all cause the urine to become alkaline.

Specific Gravity

Because urine is water plus solutes, a given volume has a greater mass than the same volume of distilled water. The ratio of the mass of a substance to the mass of an equal volume of distilled water is its **specific gravity.** The specific gravity of distilled water is 1.0 and that of urine ranges from 1.001 to 1.035, depending on its solute concentration.

A CLOSER LOOK

Chronic Renal Disease: A National Health Crisis in the Making

How long has it been since you had a urinalysis? If you're like most of us, the answer is: too long. This simple, inexpensive, painless test can detect renal disease years before any symptoms appear, buying time for early treatment and preventing life-threatening complications.

Unfortunately, urinalysis is often omitted from routine medical check-ups. Unfortunate, because chronic renal disease is a major burden to the U.S. health care system. Some 10–20 million Americans—one out of every 15—have some degree of kidney dysfunction. More than 2.6 million Americans suffer major impairment, and nearly 350,000 require dialysis or a kidney transplant just to stay alive.

In addition to its physical toll on individuals, chronic renal disease creates a huge financial burden for the nation. The U.S. spends $22.8 billion annually to treat these patients, a figure that is projected to increase to $38.35 billion by 2010. Medicare spending for renal failure rises by 5–10% every year. People with chronic kidney disease make up only 0.6% of the Medicare population, but consume 6% of its budget.

Stages of Renal Disease

Renal failure can strike as an acute crisis, perhaps due to trauma, infections, or poisoning by heavy metals or organic solvents. More often, though, it develops silently and insidiously over many years. Filtrate formation decreases gradually, nitrogenous wastes accumulate in the blood, and blood pH drifts toward the acidic range.

Chronic renal disease refers to this gradual loss of kidney function, defined as either kidney damage or a GFR of less than 60 ml/min for at least three months. Kidney damage is defined as the presence of structural or functional abnormalities, or of damage markers such as abnormal components in blood and urine.

Clinicians classify chronic renal disease into five stages according to the level of kidney function:

- Stage 1: Signs of kidney damage with GFR≥90
- Stage 2: Signs of kidney damage with GFR of 60–89
- Stage 3: GFR 30–59
- Stage 4: GFR 15–29
- Stage 5: GFR <15

Patients in stage 5 are considered to be in renal failure (also called end-stage renal disease). At this point they have only 10–15% of kidney function left, and most require dialysis or a transplant to survive.

Symptoms and Risk Factors

Warning signs of kidney trouble may include high blood pressure, frequent urination, difficult or painful urination, puffy eyes, or swollen hands or feet. But all too often, there are few noticeable symptoms until advanced stages, when a significant percentage of kidney function has already been lost. Urinalysis is valuable because it can detect proteinuria, a sensitive early marker of kidney damage.

The most abundant protein found in urine is albumin. Normally urinary albumin averages less than 100 mg/day (as measured over a 24-hour period); excretion of more than 300 mg/day signals clinical proteinuria.

Other tests that can evaluate kidney function include

- Creatinine clearance, which measures filtering efficiency by comparing the creatinine level in the blood to that in the urine.
- Serum creatinine, which detects levels of creatinine in the blood.
- Blood urea nitrogen (BUN), which measures the amount of urea in the blood. Generally, if creatinine is abnormal, BUN will be too.

Where did this kidney crisis come from? In adults, chronic renal disease often develops in conjunction with other chronic health conditions. As the U.S. population ages and gains weight (see *A Closer Look* in Chapter 24), risk factors for renal problems multiply.

The leading cause is diabetes mellitus, which accounts for approximately 44% of new cases each year. Hypertension is a close second, accounting for about 28% of cases. Note that hypertension is both a cause and a symptom: High blood pressure impairs kidney function by damaging renal blood vessels and reducing circulation to the organs, even as hypertension-battered kidneys push blood pressure upward. Atherosclerosis compounds the problem by further impairing circulation.

Race and ethnicity may play a role; African Americans are nearly four times more likely to develop renal failure than Caucasian Americans. Hispanics

25

Chemical Composition

Water accounts for about 95% of urine volume; the remaining 5% consists of solutes. The largest component of urine by weight, apart from water, is *urea*, which is derived from the normal breakdown of amino acids. Other **nitrogenous wastes** in urine include *uric acid* (an end product of nucleic acid metabolism) and *creatinine* (a metabolite of creatine phosphate, which stores energy for the regeneration of ATP and is found in large amounts in skeletal muscle tissue). Normal solute constituents of urine, in order of decreasing concentration, are urea, Na^+, K^+, PO_4^{3-}, SO_4^{2-}, creatinine, and uric acid. Much smaller but highly variable amounts of Ca^{2+}, Mg^{2+}, and HCO_3^- are also present in urine. Unusually high concentrations of any solute, or the presence of abnormal substances such as blood proteins, WBCs

and Native Americans are two times more likely, and Asians have 1.3 times the risk. Researchers ascribe this in part to the prevalence of type 2 diabetes in these populations.

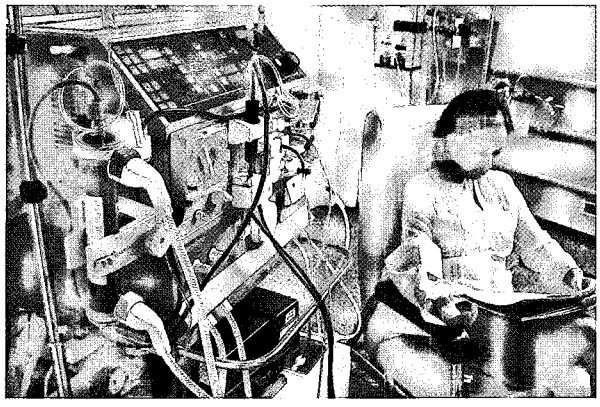
Genetic factors, as yet poorly understood, may also be involved, since a family history of chronic kidney disease, diabetes, or hypertension seems to increase the risk. Studies are under way to identify genes that influence susceptibility to renal disease.

Treatments and New Research

Tight control of blood glucose and blood pressure can slow the progression of kidney disease and possibly forestall renal failure. Diabetics who maintain glucose levels within the normal range can prevent many renal complications. The National Heart, Lung and Blood Institute recommends that people in early stages of chronic renal disease keep their blood pressure below 130/80 mm Hg. Angiotensin converting enzyme (ACE) inhibitor drugs seem to be especially effective for lowering blood pressure while protecting the kidneys.

Even in early stages, a special diet can do much to relieve the kidneys' workload and control the accumulation of waste products. In particular, renal dietitians advise patients to limit their intake of protein, phosphorus, and sodium. Too much protein causes urea to build up; too much phosphorus leaches calcium from the skeleton and weakens bones; high sodium intake tends to raise blood pressure.

If renal disease progresses, hemodialysis may become necessary. In *hemodialysis,* which uses an "artificial kidney" apparatus, the patient's blood is passed through a membrane tubing that is permeable only to selected substances, and the tubing is immersed in a bathing solution that differs slightly from normal cleansed plasma (see illustration). As blood circulates through the tubing, substances such as nitrogenous wastes and K^+ present in the blood (but not in the bath) diffuse out of the blood into the surrounding solution, and substances to be added to the blood, mainly buffers for H^+ (and glucose for malnourished patients), move from the bathing solution into the blood. In this way, needed substances are retained in the blood or added to it, while wastes and ion excesses are removed.



Hemodialysis.

Transplant surgery is the treatment of last resort, but unless the new kidney comes from an identical twin, recipients must take immunosuppressive drugs for the rest of their lives to prevent rejection. Kidney transplants in the U.S. during 2001 numbered 15,311, almost 5000 of them from living donors. But this leaves 57,000 Americans still waiting for a kidney, more than for any other organ.

If this sounds bleak, consider that 40 years ago, people who reached end-stage renal failure survived for only a few days. Today, they can live for years or even decades, and researchers are laboring to improve both life span and quality of life. Infection is a constant hazard in hemodialysis, since back filtration can accidentally return bacteria-contaminated solution into the patient. Researchers are developing a dialysis membrane of bioengineered cells capable of removing toxic solutes.

Stem cell research may provide the ultimate answer. Recently, scientists cloned kidney cells from adult cow skin cell nuclei, grew them on three-dimensional molds, and placed the molds in incubators, where the cells attached and formed tissue. When transplanted back into the cows that donated the original nuclei, the cell-mold structures excreted a urinelike fluid containing metabolic waste products, and they did not trigger an immune response. In short, they behaved tantalizingly like miniature kidneys. ■

(pus), or bile pigments, may indicate pathology (Table 25.2). (Normal urine values are listed in Appendix F.)

Ureters

The **ureters** are slender tubes that convey urine from the kidneys to the bladder (see Figure 25.1). Each ureter begins at the level of L_2 as a continuation of the renal pelvis. From there, it descends behind the peritoneum and runs obliquely through the posterior bladder wall. This arrangement prevents backflow of urine during bladder filling because any increase in bladder pressure compresses and closes the distal ends of the ureters.

Histologically, the ureter wall is trilayered. The transitional epithelium of its lining *mucosa* is continuous with that of the kidney pelvis superiorly and the bladder medially. Its middle *muscularis* is

TABLE 25.2 **Abnormal Urinary Constituents**

SUBSTANCE	NAME OF CONDITION	POSSIBLE CAUSES
Glucose	Glycosuria	Nonpathological; excessive intake of sugary foods Pathological: diabetes mellitus
Proteins	Proteinuria, or albuminuria	Nonpathological; excessive physical exertion; pregnancy; high-protein diet Pathological (over 250 mg/day): heart failure, severe hypertension; glomerulonephritis; often initial sign of asymptomatic renal disease
Ketone bodies	Ketonuria	Excessive formation and accumulation of ketone bodies, as in starvation and untreated diabetes mellitus
Hemoglobin	Hemoglobinuria	Various: transfusion reaction, hemolytic anemia, severe burns, etc.
Bile pigments	Bilirubinuria	Liver disease (hepatitis, cirrhosis) or obstruction of bile ducts from liver or galbladder
Erythrocytes	Hematuria	Bleeding urinary tract (due to trauma, kidney stones, infection, or neoplasm)
Leukocytes (pus)	Pyuria	Urinary tract infection

composed chiefly of two smooth muscle sheets: the internal longitudinal layer and the external circular layer. An additional smooth muscle layer, the external longitudinal layer, appears in the lower third of the ureter. The *adventitia* covering the ureter's external surface is typical fibrous connective tissue (Figure 25.17).

The ureter plays an active role in transporting urine. Incoming urine distends the ureter and stimulates its muscularis to contract, propelling urine into the bladder. (Urine does *not* reach the bladder through gravity alone.) The strength and frequency of the peristaltic waves are adjusted to the rate of urine formation. Although each ureter is innervated by both sympathetic and parasympathetic fibers, neural control of peristalsis appears to be insignificant compared to the way ureteral smooth muscle responds to stretch.

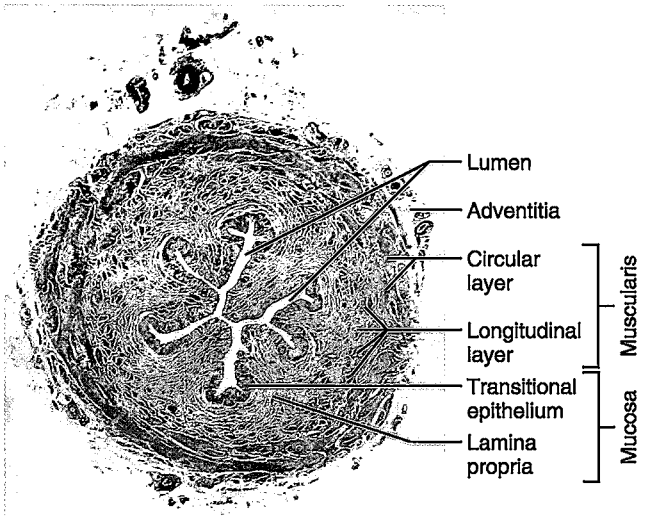


FIGURE 25.17 **Cross-sectional view of the ureter wall (15×).**

HOMEOSTATIC IMBALANCE

On occasion, calcium, magnesium, or uric acid salts in urine may crystallize and precipitate in the renal pelvis, forming **renal calculi** (kal'ku-li; *calculus* = little stone), or kidney stones. Most calculi are under 5 mm in diameter and pass through the urinary tract without causing problems. However, larger calculi can obstruct a ureter and block urine drainage. Increasing pressure in the kidney causes excruciating pain, which radiates from the flank to the anterior abdominal wall on the same side. Pain also occurs when the contracting ureter wall closes in on the sharp calculi as they are being eased through a ureter by peristalsis.

Predisposing conditions are frequent bacterial infections of the urinary tract, urine retention, high blood levels of calcium, and alkaline urine. Surgical removal of calculi has been almost entirely replaced by *shock wave lithotripsy*, a noninvasive procedure that uses ultrasonic shock waves to shatter the calculi. The pulverized, sandlike remnants of the calculi are then painlessly eliminated in the urine. People with a history of kidney stones are encouraged to acidify their urine by drinking cranberry juice and to ingest enough water to keep the urine dilute. ●

Urinary Bladder

The **urinary bladder** is a smooth, collapsible, muscular sac that stores urine temporarily. It is located retroperitoneally on the pelvic floor just posterior to

Q *How do the internal and external urethral sphincters differ structurally and functionally?*

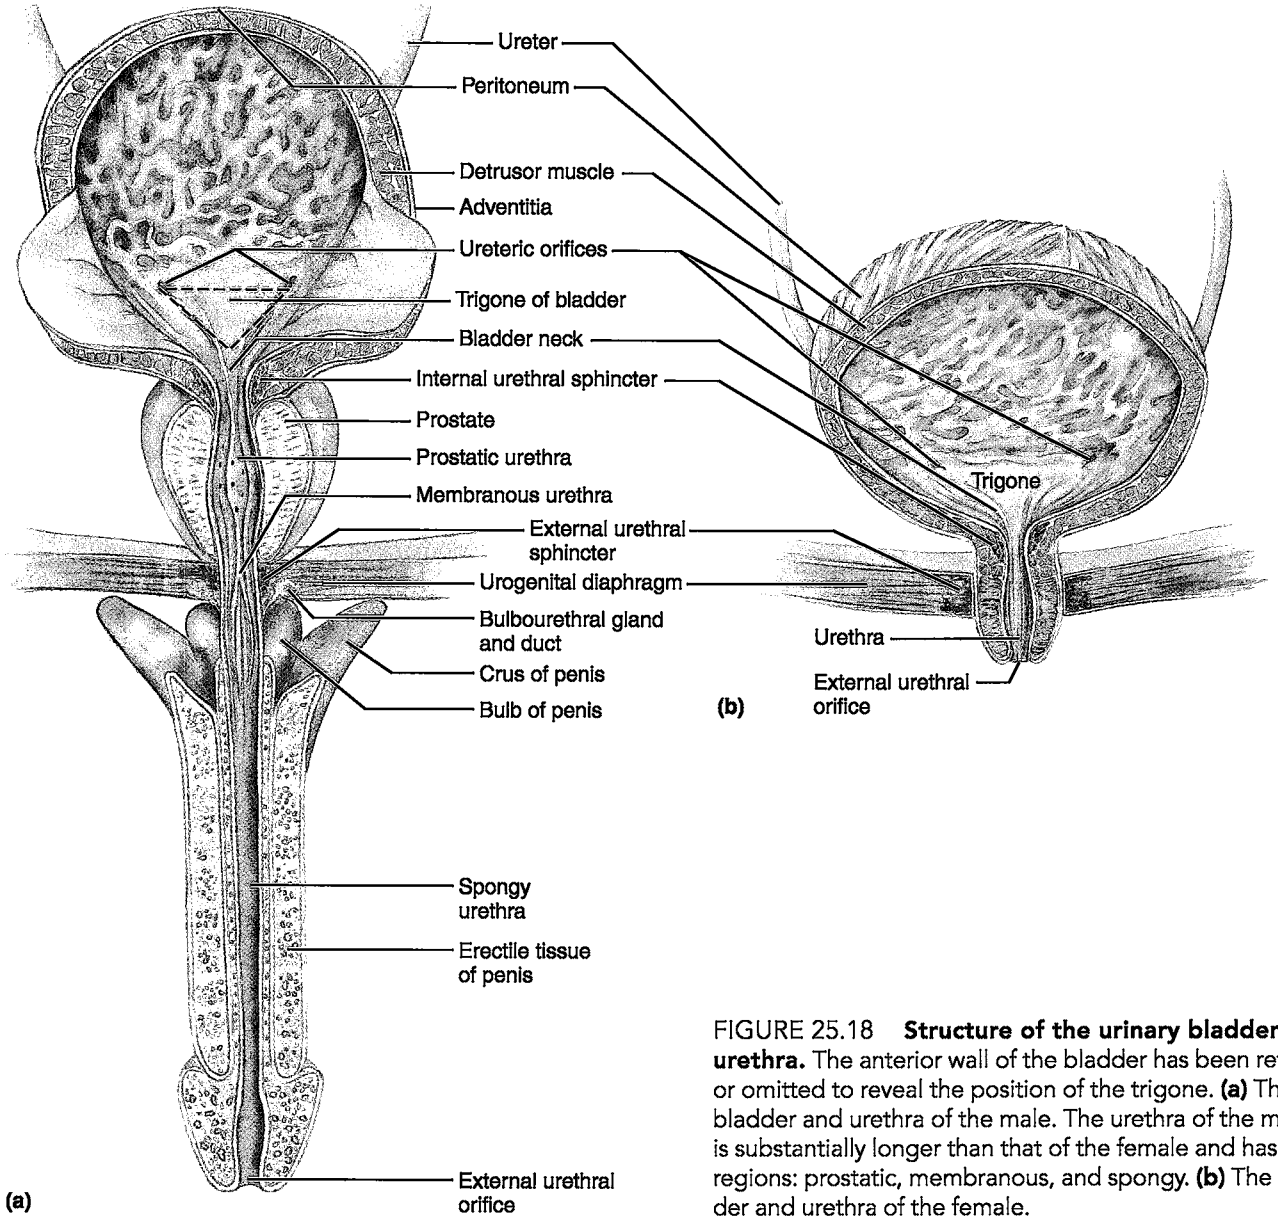

FIGURE 25.18 **Structure of the urinary bladder and urethra.** The anterior wall of the bladder has been reflected or omitted to reveal the position of the trigone. **(a)** The bladder and urethra of the male. The urethra of the male is substantially longer than that of the female and has three regions: prostatic, membranous, and spongy. **(b)** The bladder and urethra of the female.

25

the pubic symphysis. The prostate (part of the male reproductive system) surrounds the bladder neck inferiorly where it empties into the urethra. In females, the bladder is anterior to the vagina and uterus.

The interior of the bladder has openings for both ureters and the urethra (Figure 25.18). The smooth, triangular region of the bladder base outlined by these three openings is the **trigone** (tri'gōn; *trigon* = triangle), important clinically because infections tend to persist in this region.

The bladder wall has three layers: a mucosa containing transitional epithelium, a thick muscular layer, and a fibrous adventitia (except on its superior surface, where it is covered by the peritoneum). The muscular layer, called the **detrusor muscle** (de-tru'sor;

A *The internal sphincter, composed of smooth muscle, is controlled involuntarily; the external sphincter, of skeletal muscle, is controlled voluntarily.*

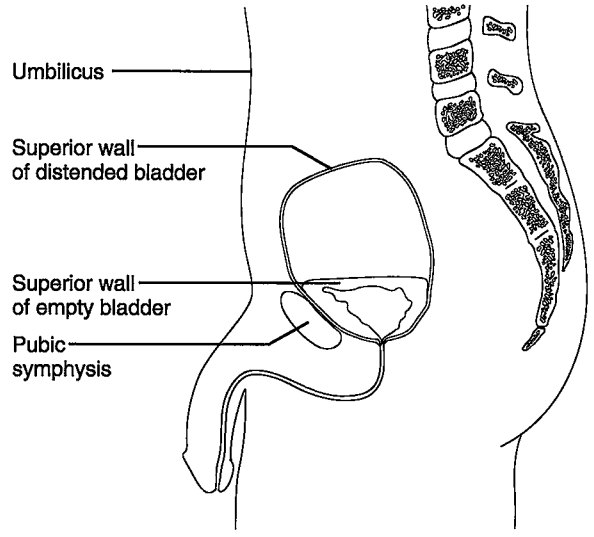

FIGURE 25.19 **Position and shape of a distended and an empty urinary bladder in an adult male.**

"to thrust out"), consists of intermingled smooth muscle fibers arranged in inner and outer longitudinal layers and a middle circular layer.

The bladder is very distensible and uniquely suited for its function of urine storage. When empty, the bladder collapses into its basic pyramidal shape and its walls are thick and thrown into folds *(rugae)*. As urine accumulates, the bladder expands, becomes pear shaped, and rises superiorly in the abdominal cavity (Figure 25.19). The muscular wall stretches and thins, and rugae disappear. These changes allow the bladder to store more urine without a significant rise in internal pressure. A moderately full bladder is about 12 cm (5 inches) long and holds approximately 500 ml (1 pint) of urine, but it can hold nearly double that if necessary. When tense with urine, it can be palpated well above the pubic symphysis. The maximum capacity of the bladder is 800–1000 ml and when it is overdistended, it may burst. Although urine is formed continuously by the kidneys, it is usually stored in the bladder until its release is convenient.

Urethra

The **urethra** is a thin-walled muscular tube that drains urine from the bladder and conveys it out of the body. The epithelium of its mucosal lining is mostly pseudostratified columnar epithelium. However, near the bladder it becomes transitional epithelium, and near the external opening it changes to a protective stratified squamous epithelium.

At the bladder-urethra junction a thickening of the detrusor smooth muscle forms the **internal urethral sphincter** (Figure 25.18). This involuntary sphincter keeps the urethra closed when urine is not being passed and prevents leaking between voiding. This sphincter is unusual in that contraction opens it and relaxation closes it. The **external urethral sphincter** surrounds the urethra as it passes through the *urogenital diaphragm*. This sphincter is formed of skeletal muscle and is voluntarily controlled. The *levator ani* muscle of the pelvic floor also serves as a voluntary constrictor of the urethra (see Table 10.7, p. 350).

The length and functions of the urethra differ in the two sexes. In females the urethra is only 3–4 cm (1.5 inches) long and tightly bound to the anterior vaginal wall by fibrous connective tissue. Its external opening, the **external urethral orifice,** lies anterior to the vaginal opening and posterior to the clitoris.

In males the urethra is approximately 20 cm (8 inches) long and has three regions. The **prostatic urethra,** about 2.5 cm (1 inch) long, runs within the prostate. The **membranous urethra,** which runs through the urogenital diaphragm, extends about 2 cm from the prostate to the beginning of the penis. The **spongy urethra,** about 15 cm long, passes through the penis and opens at its tip via the **external urethral orifice.** The male urethra has a double function: It carries semen as well as urine out of the body. The reproductive function of the male urethra is discussed in Chapter 27.

HOMEOSTATIC IMBALANCE

Because the female's urethra is very short and its external orifice is close to the anal opening, improper toilet habits (wiping back to front after defecation) can easily carry fecal bacteria into the urethra. Actually, most urinary tract infections occur in sexually active women, because intercourse drives bacteria from the vagina and external genital region toward the bladder. The use of spermicides magnifies this problem, because the spermicide kills helpful bacteria, allowing infectious fecal bacteria to colonize the vagina. Overall, 40% of all women get urinary tract infections.

The urethral mucosa is continuous with that of the rest of the urinary tract, and an inflammation of the urethra *(urethritis)* can ascend the tract to cause bladder inflammation *(cystitis)* or even renal inflammations *(pyelitis* or *pyelonephritis)*. Symptoms of urinary tract infection include *dysuria* (painful urination), urinary *urgency* and *frequency,* fever, and sometimes cloudy or blood-tinged urine. When the kidneys are involved, back pain and a severe headache often occur. Most urinary tract infections are easily cured by antibiotics. ●

Micturition

Micturition (mik"tu-rish'un; *mictur* = urinate), also called urination or **voiding,** is the act of emptying the bladder. However, most of the time we are not micturating, but storing urine with the help of our storage reflexes. As urine accumulates, distension of the bladder walls activates stretch receptors there. Impulses from the activated receptors travel via visceral afferent fibers to the sacral region of the spinal cord, setting up spinal reflexes that (1) increase sympathetic inhibition of the bladder detrusor muscle, which keeps the internal sphincter closed (temporarily), and (2) stimulate contraction of the external urethral sphincter by activating pudendal motor fibers (Figure 25.20a).

When about 200 ml of urine has accumulated, afferent impulses are transmitted to the brain, creating the urge to void. Contractions of the bladder become more frequent and more urgent and if it is convenient to empty the bladder (a decision made by the cerebral cortex), voiding reflexes are initiated. Visceral afferent impulses activate the *micturition center* of the dorsolateral pons. Acting as an on/off switch for micturition, this center signals the parasympathetic neurons that stimulate contraction of the detrusor muscle, opening the internal sphincter. It also inhibits somatic efferents, relaxing the external sphincter, and allowing urine to flow (Figure 25.20b).

When one chooses not to void, reflex bladder contractions subside within a minute or so and urine continues to accumulate. Because the external sphincter is voluntarily controlled, we can choose to keep it closed and postpone bladder emptying temporarily. After another 200–300 ml or so has collected, the micturition reflex occurs again and, if urination is delayed again, is damped once more. The urge to void eventually becomes irresistible and micturition occurs when urine volume exceeds 500–600 ml, whether one wills it or not. After normal micturition, only about 10 ml of urine remains in the bladder.

HOMEOSTATIC IMBALANCE

After the toddler years, **incontinence** is usually a result of emotional problems, physical pressure during pregnancy, or nervous system problems. In *stress incontinence,* a sudden increase in intra-abdominal pressure (during laughing and coughing) forces urine through the external sphincter. This condition is common during pregnancy when the heavy uterus stretches the muscles of the pelvic floor and the urogenital diaphragm that support the external sphincter. In *overflow incontinence,* urine dribbles from the urethra whenever the bladder overfills.

In **urinary retention,** the bladder is unable to expel its contained urine. Urinary retention is normal after general anesthesia (it seems that it takes a little time for the detrusor muscle to regain its activity). Urinary retention in men often reflects hypertrophy of the prostate, which narrows the urethra, making it difficult to void. When urinary retention is prolonged, a slender rubber drainage tube called a **catheter** (kath'ĕ-ter) must be inserted through the urethra to drain the urine and prevent bladder trauma from excessive stretching.

Developmental Aspects of the Urinary System

As the kidneys develop in a young embryo, it almost seems as if they are unable to "make up their mind" how to go about it. As illustrated in Figure 25.21, three different sets of kidneys develop from the *urogenital ridges,* paired elevations of the intermediate mesoderm that give rise to both the urinary organs and the reproductive organs. Only the last set persists to become adult kidneys.

During the fourth week of development, the first tubule system, the **pronephros** (pro-nef'ros; "prekidney"), forms and then quickly degenerates as a second, lower set appears. Although the pronephros never functions and is gone by the sixth week, the **pronephric duct** that connects it to the cloaca persists and is used by the later-developing kidneys. (The cloaca is the terminal part of the gut that opens to the body exterior.) As the second renal system, the **mesonephros** (mez"o-nef'ros; "middle kidney"), claims the pronephric duct, it comes to be called the **mesonephric duct.** The mesonephric kidneys degenerate (with remnants incorporated into the male reproductive system) once the third set, the **metanephros** (met"ah-nef'ros; "after kidney"), makes its appearance.

The metanephros starts to develop at about five weeks as hollow **ureteric buds** that push superiorly from the mesonephric duct into the urogenital ridge, inducing the mesoderm there to form nephrons. The distal ends of the ureteric buds form the renal pelves, calyces, and collecting ducts; their unexpanded proximal parts, now called the **ureteric ducts,** become the ureters.

Because the kidneys develop in the pelvis and then ascend to their final position, they receive their blood supply from successively higher sources. Although the lower blood vessels usually degenerate, they sometimes persist so that multiple renal arteries are common. The metanephric kidneys are excreting urine by the third month of fetal life, and most of the amniotic fluid that surrounds a developing fetus is fetal urine. Nonetheless,

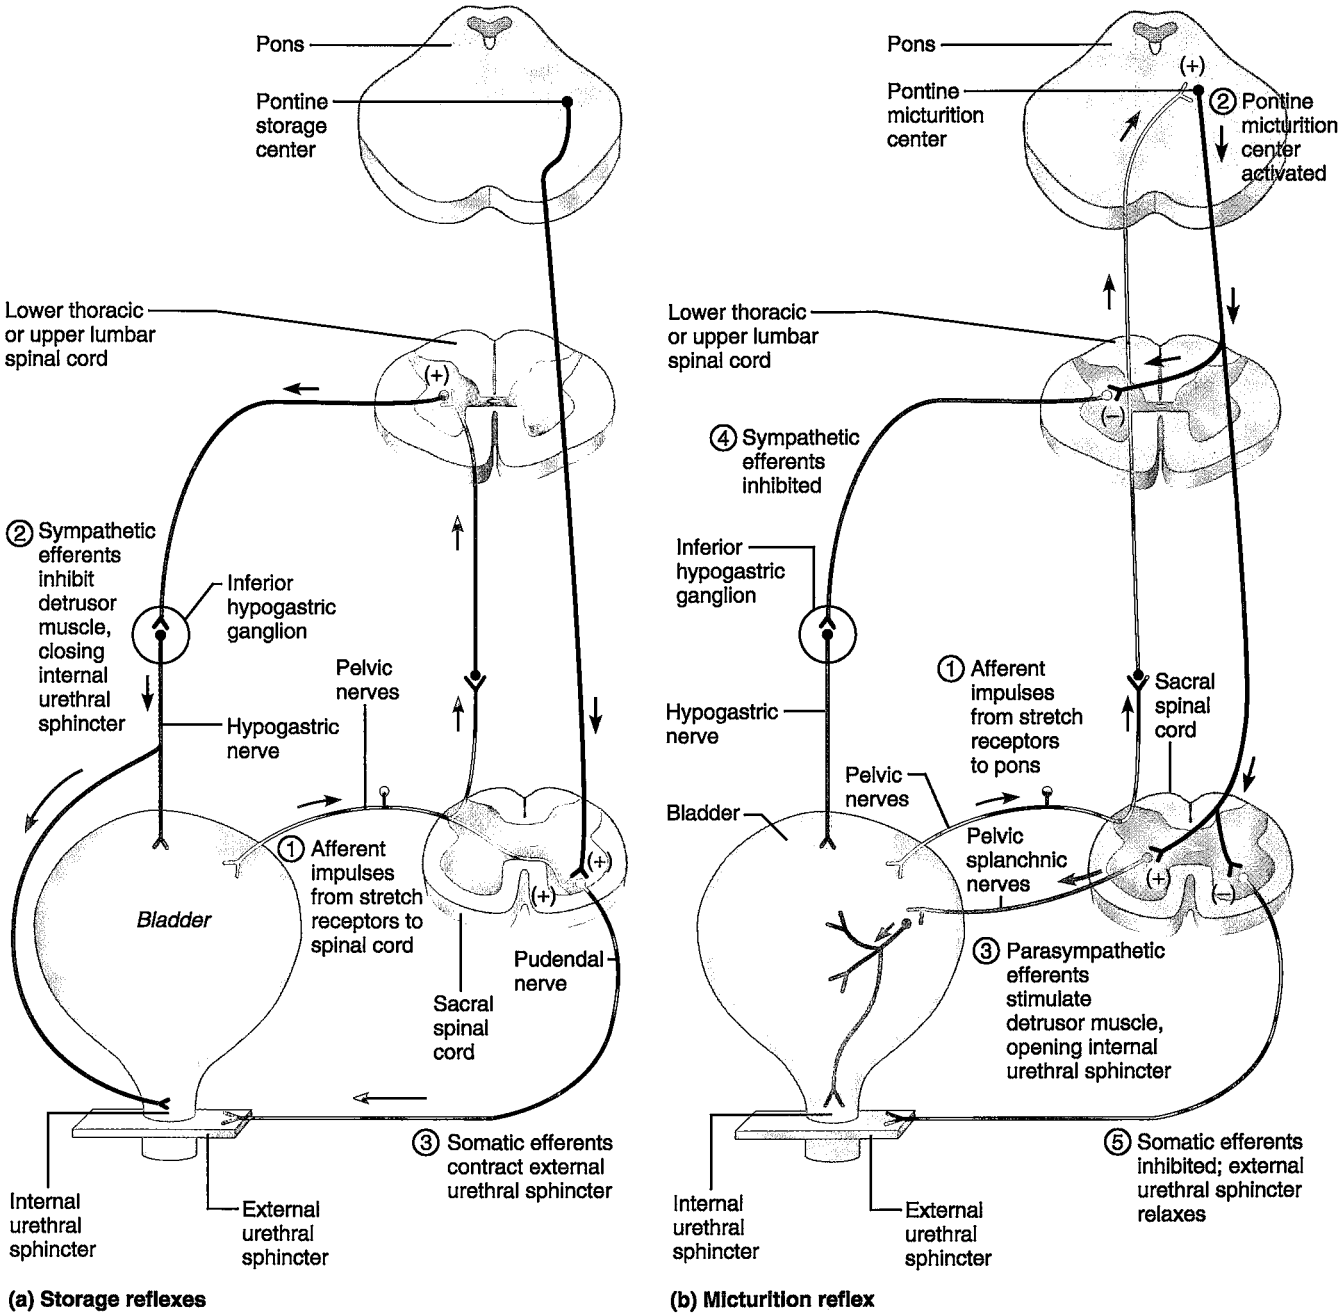

FIGURE 25.20 **Neural circuits controlling continence and micturition. (a)** As the bladder fills with urine, distension of the bladder wall initiates storage reflexes. **(b)** The micturition reflex is initiated either by further bladder distension, which increases afferent impulses to the pontine micturition center, or by input from higher brain centers (not shown) initiating voluntary micturition.

the fetal kidneys do not work nearly as hard as they will after birth because exchange through the placenta allows the mother's urinary system to clear most of the undesirable substances from the fetal blood.

As the metanephros is developing, the cloaca subdivides to form the future rectum and anal canal and the **urogenital sinus,** into which the urinary and genital ducts empty. The urinary bladder and the urethra then develop from the urogenital sinus.

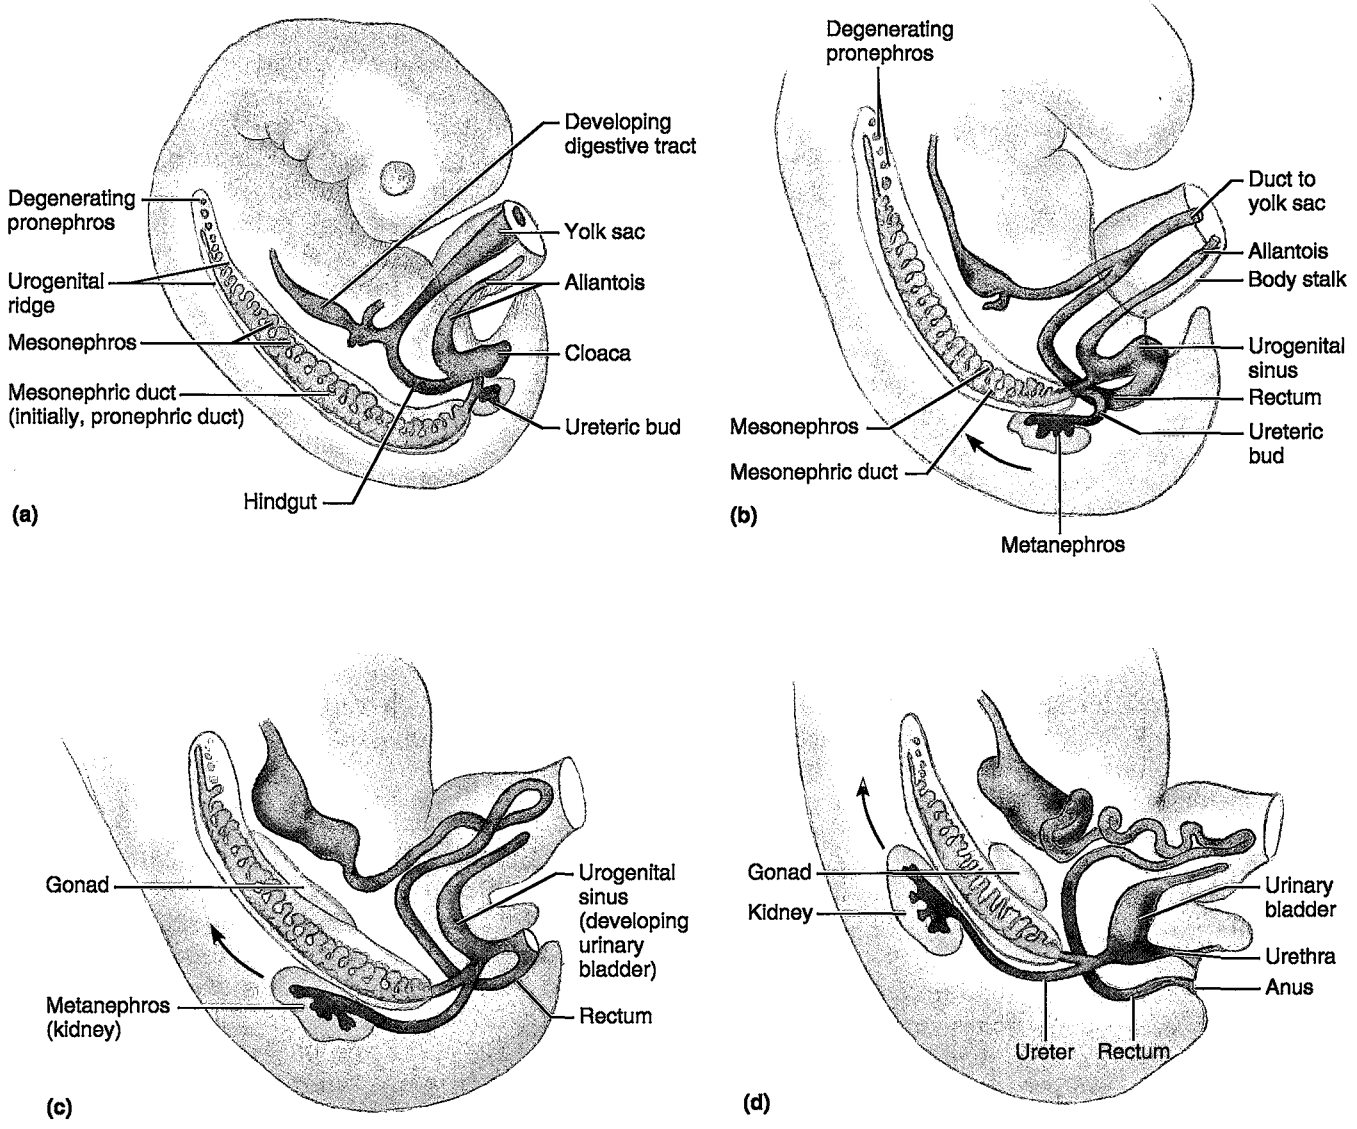

FIGURE 25.21 **Development of the urinary system of the embryo. (a)** Fifth week. **(b)** Sixth week. **(c)** Seventh week. **(d)** Eighth week. (Direction of metanephros migration as it develops is indicated by red arrows.)

25

HOMEOSTATIC IMBALANCE

Three of the most common congenital abnormalities of the urinary system are horseshoe kidney, hypospadias, and polycystic kidney.

When ascending from the pelvis the kidneys are very close together, and in 1 out of 600 people they fuse across the midline, forming a single, U-shaped *horseshoe kidney*. This condition is usually asymptomatic, but it may be associated with other kidney abnormalities, such as obstructed drainage, that place a person at risk for frequent kidney infections.

Hypospadias (hi"po-spa'de-as), found in male infants only, is the most common congenital abnormality of the urethra. It occurs when the urethral orifice is located on the ventral surface of the penis. This problem is corrected surgically when the child is around 12 months old.

Polycystic kidney disease (PKD) is a group of disorders characterized by the presence of many fluid-filled cysts in the kidneys, which interfere with renal function, ultimately leading to renal failure. These disorders can be grouped into two general forms. The less severe form is inherited in an autosomal dominant manner and is much more common, affecting 1 in 500 people. The cysts develop so gradually that they produce no symptoms until about 40 years of age. Then both kidneys begin to enlarge as blisterlike cysts containing fluid accumulate. The damage caused by these cysts progresses slowly, and many victims live without problems until their 60s. Ultimately, however, the kidneys become "knobby"

and grossly enlarged, reaching a mass of up to 14 kg (30 lb) each.

The much less common and more severe form follows an autosomal recessive pattern of inheritance. Almost half of newborns with recessive PKD die just after birth, and survivors generally develop renal failure in early childhood. Recessive PKD results from a mutation in a single huge gene, but the dominant form of PKD (described above) is usually caused by a mutation in one of two different genes, which code for proteins involved in cell signaling. It is not yet clear how defects in these proteins lead to cyst formation. As yet, the only treatments are the usual treatments for kidney failure—renal dialysis or a kidney transplant. ●

Because its bladder is very small and its kidneys are less able to concentrate urine for the first two months, a newborn baby voids 5 to 40 times daily, depending on fluid intake. By 2 months of age, the infant is voiding approximately 400 ml/day, and the amount steadily increases until adolescence, when adult urine output (about 1500 ml/day) is achieved.

Incontinence, the inability to control micturition, is normal in infants because they have not yet learned to control the external urethral sphincter. Reflex voiding occurs each time a baby's bladder fills enough to activate the stretch receptors. Control of the voluntary urethral sphincter goes hand in hand with nervous system development. By 15 months, most toddlers know when they have voided. By 18 months, they can usually hold urine for about two hours. This is the first sign that toilet training can begin. Daytime control usually is achieved first; it is unrealistic to expect complete nighttime control before age 4.

From childhood through late middle age, most urinary system problems are infectious conditions. *Escherichia coli* (esh"ĕ-rik'e-ah ko'li) bacteria are normal residents of the digestive tract and generally cause no problems there, but these bacteria account for 80% of all urinary tract infections. *Sexually transmitted diseases* can also inflame the urinary tract and clog some of its ducts. Childhood streptococcal infections such as strep throat and scarlet fever, if not treated promptly, may cause long-term inflammatory renal damage.

Only about 3% of elderly people have histologically normal kidneys, and kidney function declines with advancing age. The kidneys shrink as the nephrons decrease in size and number, and the tubule cells become less efficient. By age 80, the GFR is only half that of middle-aged adults, possibly due to atherosclerotic narrowing of the renal arteries. Diabetics are particularly at risk for renal disease, and nearly 50% of those who have had diabetes mellitus for 20 years are in renal failure.

The bladder of an aged person is shrunken, with less than half the capacity of a young adult (250 ml versus 600 ml). Loss of bladder tone causes an annoying increase in frequency of micturition. *Nocturia* (nok-tu're-ah), the need to get up during the night to urinate, plagues almost two-thirds of this population. Many people eventually experience incontinence, which can usually be treated with exercise, medications, or surgery.

■ ■ ■

The ureters, urinary bladder, and urethra play important roles in transporting, storing, and eliminating urine from the body, but when the term "urinary system" is used, it is the kidneys that capture center stage. As summarized in *Making Connections* in Chapter 26, other organ systems of the body contribute to the well-being of the urinary system in many ways. In turn, without continuous kidney function, the electrolyte and fluid balance of the blood is dangerously disturbed, and internal body fluids quickly become contaminated with nitrogenous wastes. No body cell can escape the harmful effects of such imbalances.

Now that renal mechanisms have been described, we are ready to integrate kidney function into the larger topic of fluid and electrolyte balance in the body—the focus of Chapter 26.

25

Related Clinical Terms

Acute glomerulonephritis (GN) (glo-mer"u-lo-nef-ri'tis) Inflammation of the glomeruli, leading to increased permeability of the filtration membrane. In some cases, circulating immune complexes (antibodies bound to foreign substances, such as streptococcal bacteria) become trapped in the glomerular basement membranes. In other cases, immune responses are mounted against one's own kidney tissues, leading to glomerular damage. In either case, the inflammatory response that follows damages the filtration membrane, allowing blood proteins and even blood cells to pass into the renal tubules and into the urine. As the osmotic pressure of blood drops, fluid seeps from the bloodstream into the tissue spaces, causing bodywide edema. Renal shutdown requiring dialysis may occur temporarily, but normal renal function usually returns within a few months. If permanent glomerular damage occurs, chronic GN and ultimately renal failure result.

Bladder cancer Bladder cancer, three times more common in men than in women, accounts for about 2% of all cancer deaths. It usually involves neoplasms of the bladder's lining epithelium and may be induced by carcinogens from the

environment or the workplace that end up in urine. Smoking, exposure to industrial chemicals, and arsenic in drinking water also have been linked to bladder cancer. Blood in the urine is a common warning sign.

Cystocele (sis'to-sēl; *cyst* = a sac, the bladder; *cele* = hernia, rupture) Herniation of the urinary bladder into the vagina; a common result of tearing of the pelvic floor muscles during childbirth.

Cystoscopy (sis-tos'ko-pe; *cyst* = bladder; *scopy* = observation) Procedure in which a thin viewing tube is threaded into the bladder through the urethra to examine the bladder's mucosal surface.

Diabetes insipidus (in-sī'pĭ-dus; *insipid* = tasteless, bland) Condition in which large amounts (up to 40 L/day) of dilute urine flush from the body; results from malfunction or deficiency of aquaporins or ADH receptors in the collecting duct (nephrogenic diabetes insipidus), or little or no ADH release due to injury to, or a tumor in, the hypothalamus or posterior pituitary. Can lead to severe dehydration and electrolyte imbalances unless the individual drinks large volumes of liquids. See Chapter 16, p. 617.

Intravenous pyelogram (IVP) (pi'ĕ-lo-gram; *pyelo* = kidney pelvis; *gram* = written) An X ray of the kidney and ureter obtained after intravenous injection of a contrast medium (as in Figure 25.1b). Allows assessment for obstructions, viewing of renal anatomy (pelvis and calyces), and determination of rate of excretion of the contrast medium.

Nephrotoxin A substance (heavy metal, organic solvent, or bacterial toxin) that is toxic to the kidney.

Nocturnal enuresis (NE) (en"u-re'sis) An inability to control urination at night during sleep; bed-wetting. In children over 6, called primary NE if control has never been achieved and secondary NE if control was achieved and then lost. Secondary NE often has psychological causes. Primary NE is more common and results from a combination of inadequate nocturnal ADH production, unusually sound sleep, or a small bladder capacity. Synthetic ADH (as tablet or nasal spray) often corrects the problem.

Renal infarct Area of dead, or necrotic, renal tissue due to blockage of the vascular supply to the kidney or hemorrhage. A common cause of localized renal infarct is obstruction of an interlobar artery. Because interlobar arteries are end arteries (do not anastomose), their obstruction leads to ischemic necrosis of the portions of the kidney they supply.

Urinalysis Analysis of urine as an aid to diagnosing health or disease. The most significant indicators of disease in urine are proteins, glucose, acetone, blood, and pus.

Urologist (u-rol'o-jist) Physician who specializes in diseases of urinary structures in both sexes and in diseases of the reproductive tract of males.

Chapter Summary

Media study tools that could provide you additional help in reviewing specific key topics of Chapter 25 are referenced below. IP = *InterActive Physiology*

Kidney Anatomy (pp. 998–1006)

Location and External Anatomy (pp. 998–999)

1. The paired kidneys are retroperitoneal in the superior lumbar region.

2. A fibrous capsule, a perirenal fat capsule, and renal fascia surround each kidney. The perirenal fat capsule helps hold the kidneys in position.

Internal Anatomy (pp. 999–1001)

3. A kidney has a superficial cortex, a deeper medulla consisting mainly of medullary pyramids, and a medial pelvis. Extensions of the pelvis (calyces) surround and collect urine draining from the apices of the medullary pyramids.

Blood and Nerve Supply (p. 1001)

4. The kidneys receive 25% of the total cardiac output per minute.

5. The vascular pathway through a kidney is as follows: renal artery → segmental arteries → interlobar arteries → arcuate arteries → cortical radiate arteries → afferent arterioles → glomeruli → efferent arterioles → peritubular capillary beds → cortical radiate veins → arcuate veins → interlobar veins → renal vein.

6. The nerve supply of the kidneys is derived from the renal plexus.

Nephrons (pp. 1001–1006)

7. Nephrons are the structural and functional units of the kidneys.

8. Each nephron consists of a glomerulus (a high-pressure capillary bed) and a renal tubule. Subdivisions of the renal tubule (from the glomerulus) are the glomerular capsule, proximal convoluted tubule, loop of Henle, and distal convoluted tubule. A second capillary bed, the low-pressure peritubular capillary bed, is closely associated with the renal tubule of each nephron.

9. The more numerous cortical nephrons are located almost entirely in the cortex; only a small part of their loop of Henle penetrates into the medulla. Glomeruli of juxtamedullary nephrons are located at the cortex-medulla junction, and their loop of Henle dips deeply into the medulla. Instead of directly forming peritubular capillaries, the efferent arterioles of many of the juxtamedullary nephrons form unique bundles of straight vessels, called vasa recta, that serve tubule segments in the medulla. Juxtamedullary nephrons and the vasa recta play an important role in establishing the medullary osmotic gradient.

10. Collecting ducts receive urine from many nephrons and help concentrate urine. They form the medullary pyramids.

11. The juxtaglomerular apparatus is at the point of contact between the afferent arteriole and the most distal part of the ascending limb of the loop of Henle. It consists of the granular cells and the macula densa.

IP Urinary System; Topic: Anatomy Review, pp. 1–20.

12. The filtration membrane consists of the fenestrated glomerular endothelium, the intervening basement membrane, and the podocyte-containing visceral layer of the glomerular capsule. It permits free passage of substances smaller than (most) plasma proteins.

Kidney Physiology: Mechanisms of Urine Formation (pp. 1007–1021)

1. Functions of the nephrons include filtration, tubular reabsorption, and tubular secretion. Via these functional

processes, the kidneys regulate the volume, composition, and pH of the blood, and eliminate nitrogenous metabolic wastes.

Step 1: Glomerular Filtration (pp. 1007–1011)

2. The glomeruli function as filters. High glomerular blood pressure (55 mm Hg) occurs because the glomeruli are fed and drained by arterioles, and the afferent arterioles are larger in diameter than the efferent arterioles.

3. About one-fifth of the plasma flowing through the kidneys is filtered from the glomeruli into the renal tubules.

4. Usually about 10 mm Hg, the net filtration pressure (NFP) is determined by the relationship between forces favoring filtration (glomerular hydrostatic pressure) and forces that oppose it (capsular hydrostatic pressure and blood colloid osmotic pressure).

5. The glomerular filtration rate (GFR) is directly proportional to the net filtration pressure and is about 125 ml/min (180 L/day).

6. Renal autoregulation, which enables the kidneys to maintain a relatively constant renal blood flow and glomerular filtration rate, involves a myogenic mechanism and a tubuloglomerular feedback mechanism mediated by the macula densa.

7. Extrinsic control of GFR, via nerves and hormones, maintains blood pressure. Strong sympathetic nervous system activation causes constriction of the afferent arterioles, which decreases filtrate formation and stimulates renin release by the granular cells.

IP Urinary System; Topic: Glomerular Filtration, pp. 1–15.

8. The renin-angiotensin mechanism mediated by the granular cells raises systemic blood pressure via generation of angiotensin II, which promotes aldosterone secretion.

Step 2: Tubular Reabsorption (pp. 1011–1015)

9. During tubular reabsorption, needed substances are removed from the filtrate by the tubule cells and returned to the peritubular capillary blood. The primary active transport of Na^+ by a Na^+-K^+ ATPase pump at the basolateral membrane accounts for Na^+ reabsorption and establishes the electrochemical gradient that drives the reabsorption of most other solutes and H_2O. Na^+ enters at the luminal surface of the tubule cell via facilitated diffusion through channels or as part of a cotransport mechanism.

10. Passive tubular reabsorption is driven by electrochemical gradients established by active reabsorption of sodium ions. Water, many anions, and various other substances (for example, urea) are reabsorbed passively by diffusion via transcellular or paracellular pathways.

11. Secondary active tubular reabsorption occurs by cotransport with Na^+ via protein carriers. Transport of such substances is limited by the number of carriers available. Actively reabsorbed substances include glucose, amino acids, and some ions.

12. Certain substances (creatinine, drug metabolites, etc.) are not reabsorbed or are reabsorbed incompletely because of the lack of carriers, their size, or non–lipid solubility.

13. The proximal tubule cells are most active in reabsorption. Most of the nutrients, 65% of the water and sodium ions, and the bulk of actively transported ions are reabsorbed in the proximal convoluted tubules.

14. Reabsorption of additional sodium ions and water occurs in the distal tubules and collecting ducts and is hormonally controlled. Aldosterone increases the reabsorption of sodium (and water that follows it); antidiuretic hormone enhances water reabsorption by the collecting ducts.

Step 3: Tubular Secretion (p. 1015)

15. Tubular secretion is a means of adding substances to the filtrate (from the blood or tubule cells). It is an active process that is important in eliminating drugs, certain wastes, and excess ions and in maintaining the acid-base balance of the blood.

Regulation of Urine Concentration and Volume (pp. 1015–1021)

16. The graduated hyperosmolality of the medullary fluids (largely due to the cycling of NaCl and urea) ensures that the filtrate reaching the distal convoluted tubule is dilute (hypo-osmolar). This allows urine with osmolalities ranging from 70 to 1200 mOsm to be formed.

- The descending limb of the loop of Henle is permeable to water, which leaves the filtrate and enters the medullary interstitium. The filtrate and medullary fluid at the bend of the loop of Henle are hyperosmolar.
- The ascending limb is impermeable to water. Na^+ and Cl^- move out of the filtrate into the interstitial space, passively in the thin limb and actively in the thick limb. The filtrate becomes more dilute.
- As filtrate flows through the collecting ducts in the inner medulla, urea diffuses into the interstitial space. From here, urea reenters the thin limb and is recycled.
- The blood flow in the vasa recta is sluggish, and the contained blood equilibrates with the medullary interstitial fluid. Hence, blood entering and exiting the medulla in the vasa recta is isotonic to blood plasma and the high solute concentration of the medulla is maintained.

17. In the absence of antidiuretic hormone, dilute urine is formed because the dilute filtrate reaching the collecting duct is simply allowed to pass from the kidneys.

18. As blood levels of antidiuretic hormone rise, the collecting ducts become more permeable to water, and water moves out of the filtrate as it flows through the hyperosmotic medullary areas. Consequently, more concentrated urine is produced, and in smaller amounts.

IP Urinary System; Topics: Early Filtrate Processing, pp. 1–22; Late Filtrate Processing, pp. 1–13.

Renal Clearance (p. 1021)

19. Renal clearance is the volume of plasma that is completely cleared of a particular substance per minute. Studies of renal clearance provide information about renal function or the course of renal disease.

Urine (pp. 1021–1023)

1. Urine is typically clear, yellow, aromatic, and slightly acidic. Its specific gravity ranges from 1.001 to 1.035.

2. Urine is 95% water; solutes include nitrogenous wastes (urea, uric acid, and creatinine) and various ions (always sodium, potassium, sulfate, and phosphate).

3. Substances not normally found in urine include glucose, proteins, erythrocytes, leukocytes, hemoglobin, and bile pigments.

4. Daily urinary volume is typically 1.5–1.8 L, but this depends on the state of hydration of the body.

Ureters (pp. 1023–1024)

1. The ureters are slender tubes running retroperitoneally from each kidney to the bladder. They conduct urine by peristalsis from the renal pelvis to the urinary bladder.

Urinary Bladder (pp. 1024–1026)

1. The urinary bladder, which functions to store urine, is a distensible muscular sac that lies posterior to the pubic symphysis. It has two inlets (ureters) and one outlet (urethra) that outline the trigone. In males, the prostate surrounds its outlet.

2. The bladder wall consists of a transitional epithelium-containing mucosa, a three-layered detrusor muscle, and an adventitia.

Urethra (p. 1026)

1. The urethra is a muscular tube that conveys urine from the bladder to the body exterior.

2. Where the urethra leaves the bladder, it is surrounded by an internal urethral sphincter, an involuntary smooth muscle sphincter. Where it passes through the urogenital diaphragm, the voluntary external urethral sphincter is formed by skeletal muscle.

3. In females the urethra is 3–4 cm long and conducts only urine. In males it is 20 cm long and conducts both urine and semen.

Micturition (p. 1027)

1. Micturition is emptying of the bladder.

2. Stretching of the bladder wall by accumulating urine initiates the micturition reflex, in which parasympathetic fibers, in response to signals from the micturition center of the pons, cause the detrusor muscle to contract and the internal urethral sphincter to open.

3. Because the external sphincter is voluntarily controlled, micturition can usually be delayed temporarily.

Developmental Aspects of the Urinary System (pp. 1027–1030)

1. Three sets of kidneys (pronephric, mesonephric, and metanephric) develop from the intermediate mesoderm. The metanephros is excreting urine by the third month of development.

2. Common congenital abnormalities are horseshoe kidney, polycystic kidney, and hypospadias.

3. The kidneys of newborns are less able to concentrate urine; their bladder is small and voiding is frequent. Neuromuscular maturation generally allows toilet training for micturition to begin by 18 months of age.

4. The most common urinary system problems in children and young to middle-aged adults are bacterial infections.

5. Renal failure has serious consequences: the kidneys are unable to concentrate urine, nitrogenous wastes accumulate in the blood, and acid-base and electrolyte imbalances occur.

6. With age, nephrons are lost, the filtration rate decreases, and tubule cells become less efficient at concentrating urine.

7. Bladder capacity and tone decrease with age, leading to frequent micturition and (often) incontinence. Urinary retention is a common problem of elderly men.

Review Questions

Multiple Choice/Matching

(Some questions have more than one correct answer. Select the best answer or answers from the choices given.)

1. The lowest blood concentration of nitrogenous waste occurs in the (a) hepatic vein, (b) inferior vena cava, (c) renal artery, (d) renal vein.

2. The glomerular capillaries differ from other capillary networks in the body because they (a) have a larger area of anastomosis, (b) are derived from and drain into arterioles, (c) are not made of endothelium, (d) are sites of filtrate formation.

3. Damage to the renal medulla would interfere *first* with the functioning of the (a) glomerular capsules, (b) distal convoluted tubules, (c) collecting ducts, (d) proximal convoluted tubules.

4. Which is reabsorbed by the proximal convoluted tubule cells? (a) Na^+, (b) K^+, (c) amino acids, (d) all of the above.

5. Glucose is not normally found in the urine because it (a) does not pass through the walls of the glomerulus, (b) is kept in the blood by colloid osmotic pressure, (c) is reabsorbed by the tubule cells, (d) is removed by the body cells before the blood reaches the kidney.

6. Filtration at the glomerulus is inversely related to (a) water reabsorption, (b) capsular hydrostatic pressure, (c) arterial blood pressure, (d) acidity of the urine.

7. Tubular reabsorption (a) of glucose and many other substances is a T_m-limited active transport process, (b) of chloride is always linked to the passive transport of Na^+, (c) is the movement of substances from the blood into the nephron, (d) of sodium occurs only in the proximal tubule.

8. If a freshly voided urine sample contains excessive amounts of urochrome, it has (a) an ammonia-like odor, (b) a pH below normal, (c) a dark yellow color, (d) a pH above normal.

9. Conditions such as diabetes mellitus, starvation, and low-carbohydrate diets are closely linked to (a) ketonuria, (b) pyuria, (c) albuminuria, (d) hematuria.

10. Which of the following is/are true about ADH? (a) It promotes obligatory water reabsorption, (b) it is secreted in response to an increase in extracellular fluid osmolality, (c) it causes insertion of aquaporins in the PCT, (d) it promotes Na^+ reabsorption.

Short Answer Essay Questions

11. What is the importance of the perirenal fat capsule that surrounds the kidney?

12. Trace the pathway a creatinine molecule takes from a glomerulus to the urethra. Name every microscopic or gross structure it passes through on its journey.

13. Explain the important differences between blood plasma and renal filtrate, and relate the differences to the structure of the filtration membrane.

14. Describe the mechanisms that contribute to renal autoregulation.

15. Describe the physiological role and mechanisms of extrinsic regulation of GFR.

16. Describe what is involved in active and passive tubular reabsorption.

17. Explain how the peritubular capillaries are adapted for receiving reabsorbed substances.

18. Explain the process and purpose of tubular secretion.

19. How does aldosterone modify the chemical composition of urine?

20. Explain why the filtrate becomes hypotonic as it flows through the ascending limb of the loop of Henle. Also explain why the filtrate at the bend of the loop of Henle (and the interstitial fluid of the deep portions of the medulla) is hypertonic.

21. How does urinary bladder anatomy support its storage function?

22. Define micturition and describe the storage and micturition reflexes.

23. Describe the changes that occur in kidney and bladder anatomy and physiology in old age.

Critical Thinking and Clinical Application Questions

1. Mrs. Bigda, a 60-year-old woman, was brought to the hospital by the police after falling to the pavement. She is found to have alcoholic hepatitis. She is put on a salt- and protein-restricted diet and diuretics are prescribed to manage her ascites (accumulated fluid in the peritoneal cavity). How will diuretics reduce this excess fluid? Name and describe the mechanisms of action of three types of diuretics. Why is her diet salt-restricted?

2. While repairing a frayed utility wire, Herbert, an experienced lineman, slips and falls to the ground. Medical examination reveals a fracture of his lower spine and transection of the lumbar region of the spinal cord. How will Herbert's micturition be controlled from this point on? Will he ever again feel the need to void? Will there be dribbling of urine between voidings? Explain the reasoning behind all your responses.

3. What is cystitis? Why are women more frequent cystitis sufferers than men?

4. Hattie, aged 55, is awakened by excruciating pain that radiates from her right abdomen to the loin and groin regions on the same side. The pain is not continuous but recurs at intervals of 3 to 4 minutes. Diagnose her problem, and cite factors that might favor its occurrence. Also, explain why Hattie's pain comes in "waves."

5. Why does use of a spermicide increase a woman's risk for urinary tract infection?

6. Why are renal failure patients undergoing dialysis at risk for anemia and osteoporosis? What medications or supplements could you give them to prevent these problems?

CHAPTER 24

Fluid, Electrolyte, and Acid-Base Balance

Body Fluids (pp. 1036–1038)

1. List the factors that determine body water content and describe the effect of each factor.
2. Indicate the relative fluid volume and solute composition of the fluid compartments of the body.
3. Contrast the overall osmotic effects of electrolytes and nonelectrolytes.
4. Describe factors that determine fluid shifts in the body.

Water Balance and ECF Osmolality (pp. 1039–1043)

5. List the routes by which water enters and leaves the body.
6. Describe feedback mechanisms that regulate water intake and hormonal controls of water output in urine.
7. Explain the importance of obligatory water losses.
8. Describe possible causes and consequences of dehydration, hypotonic hydration, and edema.

Electrolyte Balance (pp. 1043–1049)

9. Indicate the routes of electrolyte entry and loss from the body.
10. Describe the importance of ionic sodium in fluid and electrolyte balance of the body, and indicate its relationship to normal cardiovascular system functioning.
11. Describe mechanisms involved in regulating sodium balance, blood volume, and blood pressure.
12. Explain how potassium, calcium, and anion balance of plasma is regulated.

Acid-Base Balance (pp. 1049–1057, 1060)

13. List important sources of acids in the body.
14. List the three major chemical buffer systems of the body and describe how they resist pH changes.
15. Describe the influence of the respiratory system on acid-base balance.
16. Describe how the kidneys regulate hydrogen and bicarbonate ion concentrations in the blood.
17. Distinguish between acidosis and alkalosis resulting from respiratory and metabolic factors. Describe the importance of respiratory and renal compensations to acid-base balance.

Developmental Aspects of Fluid, Electrolyte, and Acid-Base Balance (p. 1060)

18. Explain why infants and the aged are at greater risk for fluid and electrolyte imbalances than are young adults.

Have you ever wondered why on certain days you don't urinate for hours at a time, while on others you void every few minutes? Or why on occasion you cannot seem to quench your thirst? These situations and many others reflect one of the body's most important functions: maintaining fluid, electrolyte, and acid-base balance.

Cell function depends not only on a continuous supply of nutrients and removal of metabolic wastes, but also on the physical and chemical homeostasis of the surrounding fluids. This was recognized with style in 1857 by the French physiologist Claude Bernard, who said, "It is the fixity of the internal environment which is the condition of free and independent life." In this chapter, we first examine the composition and distribution of fluids in the internal environment and then consider the roles of various body organs and functions in establishing, regulating, and altering this balance.

Body Fluids

Body Water Content

If you are a healthy young adult, water probably accounts for about half your body mass. However, not all bodies contain the same amount of water. Total body water is a function not only of age and body mass, but also of sex and the relative amount of body fat. Because of their low body fat and low bone mass, infants are 73% or more water (this high level of hydration accounts for their "dewy" skin, like that of a freshly picked peach). After infancy total body water declines throughout life, accounting for only about 45% of body mass in old age. A healthy young man is about 60% water; a healthy young woman about 50%. This difference between the sexes reflects the fact that females have relatively more body fat and relatively less skeletal muscle than males. Of all body tissues, adipose tissue is *least* hydrated (containing up to 20% water); even bone contains more water than does fat. By contrast, skeletal muscle is about 75% water. Thus, people with greater muscle mass have proportionately more body water.

Fluid Compartments

Water occupies two main **fluid compartments** within the body (Figure 26.1). A little less than two-thirds by volume is in the **intracellular fluid (ICF) compartment,** which actually consists of trillions of tiny individual "compartments": the cells. In an adult male of average size (70 kg, or 154 lb), ICF accounts for about 25 L of the 40 L of body water. The remaining one-third or so of body water is outside

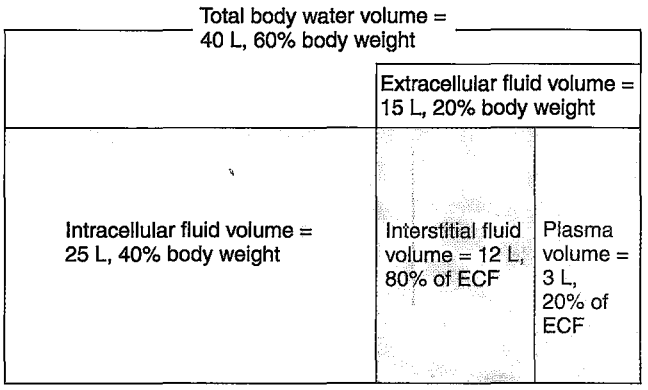

FIGURE 26.1 **The major fluid compartments of the body.** [Values are for a 70-kg (154-lb) male.]

cells, in the **extracellular fluid (ECF) compartment.** The ECF constitutes the body's "internal environment" referred to by Claude Bernard and is the external environment of each cell. The ECF compartment is divisible into two *subcompartments:* (1) **plasma,** the fluid portion of blood, and (2) **interstitial fluid (IF),** the fluid in the microscopic spaces between tissue cells. There are numerous other examples of ECF that are distinct from both plasma and interstitial fluid—lymph, cerebrospinal fluid, humors of the eye, synovial fluid, serous fluid, secretions of the gastrointestinal tract—but most of these are similar to IF and are usually considered part of it.

Composition of Body Fluids

Electrolytes and Nonelectrolytes

Water serves as the *universal solvent* in which a variety of solutes are dissolved. Solutes may be classified broadly as *electrolytes* and *nonelectrolytes.* **Nonelectrolytes** have bonds (usually covalent bonds) that prevent them from dissociating in solution; therefore, no electrically charged species are created when nonelectrolytes dissolve in water. Most nonelectrolytes are organic molecules—glucose, lipids, creatinine, and urea, for example. In contrast, **electrolytes** are chemical compounds that *do* dissociate into ions in water. (See Chapter 2 if necessary to review these concepts of chemistry.) Because ions are charged particles, they can conduct an electrical current—hence the name *electrolyte.* Typically, electrolytes include inorganic salts, both inorganic and organic acids and bases, and some proteins.

Although all dissolved solutes contribute to the osmotic activity of a fluid, electrolytes have much greater osmotic power than nonelectrolytes because each electrolyte molecule dissociates into at least

two ions. For example, a molecule of sodium chloride (NaCl) contributes twice as many solute particles as glucose (which remains undissociated), and a molecule of magnesium chloride ($MgCl_2$) contributes three times as many:

$NaCl \rightarrow Na^+ + Cl^-$ (electrolyte; two particles)

$MgCl_2 \rightarrow Mg^{2+} + 2Cl^-$ (electrolyte; three particles)

glucose → glucose (nonelectrolyte; one particle)

Regardless of the type of solute particle, water moves according to osmotic gradients—from an area of lesser osmolality to an area of greater osmolality. Thus, electrolytes have the greatest ability to cause fluid shifts.

Electrolyte concentrations of body fluids are usually expressed in **milliequivalents per liter (mEq/L)**, a measure of the number of electrical charges in 1 liter of solution. The concentration of any ion in solution can be computed using the equation

$$\text{mEq/L} = \frac{\text{ion concentration (mg/L)}}{\text{atomic weight of ion (mg/mmol)}} \times \begin{matrix}\text{no. of}\\ \text{electrical}\\ \text{charges on}\\ \text{one ion}\end{matrix}$$

Thus, to compute the mEq/L of sodium or calcium ions in solution in plasma, we would determine the normal concentration of these ions in plasma, look up their atomic weights in the periodic table (see Appendix E), and plug these values into the equation:

$$Na^+: \frac{3300 \text{ mg/L}}{23 \text{ mg/mmol}} \times 1 = 143 \text{ mEq/L}$$

$$Ca^{2+}: \frac{100 \text{ mg/L}}{40 \text{ mg/mmol}} \times 2 = 5 \text{ mEq/L}$$

Notice that for ions with a single charge, 1 mEq is equal to 1 mOsm, whereas 1 mEq of bivalent ions (those with a double charge like calcium) is equal to 1/2 mOsm. In either case, 1 mEq provides the same amount of charge.

Comparison of Extracellular and Intracellular Fluids

A quick glance at the bar graphs in Figure 26.2 reveals that each fluid compartment has a distinctive pattern of electrolytes. Except for the relatively high protein content in plasma, however, the extracellular fluids are very similar. Their chief cation is sodium, and their major anion is chloride. However, plasma contains somewhat fewer chloride ions than interstitial fluid, because the nonpenetrating plasma proteins are normally anions and plasma is electrically neutral.

In contrast to extracellular fluids, the ICF contains only small amounts of Na^+ and Cl^-. Its most abundant cation is potassium, and its major anion is HPO_4^{2-}. Cells also contain substantial quantities of soluble proteins (about three times the amount found in plasma).

Notice that sodium and potassium ion concentrations in ECF and ICF are nearly opposite (Figure 26.2). The characteristic distribution of these ions on the two sides of cellular membranes reflects the activity of cellular ATP-dependent sodium-potassium pumps, which keep intracellular Na^+ concentrations low and K^+ concentrations high. Renal mechanisms can reinforce these ion distributions by secreting K^+ into the filtrate as Na^+ is reabsorbed from the filtrate.

Electrolytes are the most abundant solutes in body fluids and determine most of their chemical and physical reactions, but they do not constitute the *bulk* of dissolved solutes in these fluids. Proteins and some of the nonelectrolytes (phospholipids, cholesterol, and triglycerides) found in the ECF are large molecules. They account for about 90% of the mass of dissolved solutes in plasma, 60% in the IF, and 97% in the ICF.

Fluid Movement Among Compartments

The continuous exchange and mixing of body fluids are regulated by osmotic and hydrostatic pressures. Although water moves freely between the compartments along osmotic gradients, solutes are unequally distributed because of their size, electrical charge, or dependence on transport proteins. Anything that changes the solute concentration in any compartment leads to net water flows.

Exchanges between plasma and IF occur across capillary membranes. The pressures driving these fluid movements are described in detail in Chapter 19 on pp. 739–740. Here we will simply review the outcome of these mechanisms. Nearly protein-free plasma is forced out of the blood into the interstitial space by the hydrostatic pressure of blood. This filtered fluid is then almost completely reabsorbed into the bloodstream in response to the colloid osmotic (oncotic) pressure of plasma proteins. Under normal circumstances, the small net leakage that remains behind in the interstitial space is picked up by lymphatic vessels and returned to the blood.

Exchanges between the IF and ICF occur across plasma membranes and depend on the membranes' complex permeability properties. As a general rule,

Q *What is the major cation in ECF? In ICF? What are the intracellular anion counterparts of ECF's chloride ions?*

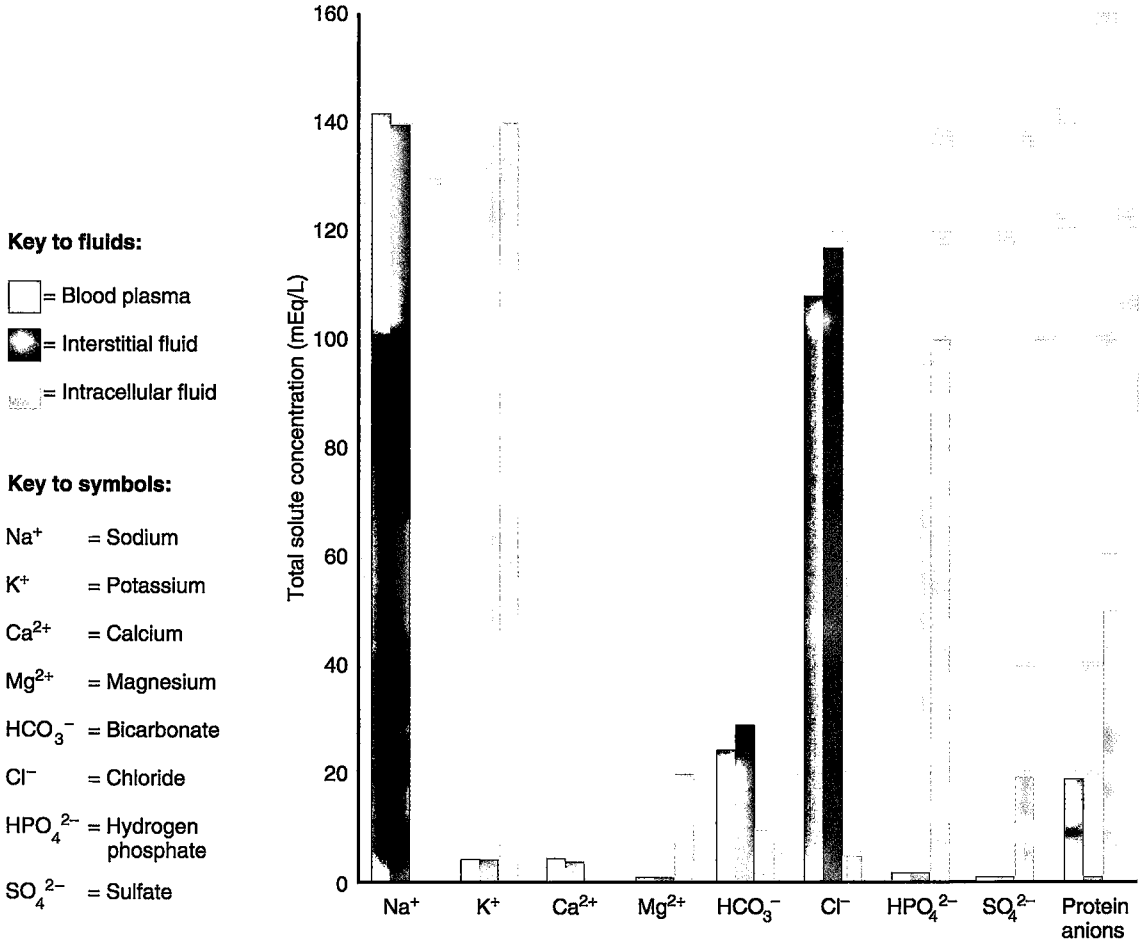

FIGURE 26.2 **Electrolyte composition of blood plasma, interstitial fluid, and intracellular fluid.** The very low intracellular Ca^{2+} concentration (10^{-7} *M*) does not include Ca^{2+} stores sequestered inside organelles. The high concentration of intracellular HPO_4^{2-} includes large amounts bound to intermediate metabolites, proteins, and lipids.

two-way osmotic flow of water is substantial. But ion fluxes are restricted and, in most cases, ions move selectively by active transport or through channels. Movements of nutrients, respiratory gases, and wastes are typically unidirectional. For example, glucose and oxygen move into the cells and metabolic wastes move out.

Plasma circulates throughout the body and links the external and internal environments (Figure 26.3). Exchanges occur almost continuously in the lungs, gastrointestinal tract, and kidneys. Although these exchanges alter plasma composition and volume, compensating adjustments in the other two fluid compartments follow quickly so that balance is restored.

Many factors can change ECF and ICF volumes. Because water moves freely between compartments, however, the osmolalities of all body fluids are equal (except during the first few minutes after a change in one of the fluids occurs). Increasing the ECF solute content (mainly the NaCl concentration) can be expected to cause osmotic and volume changes in the ICF—namely, a shift of water out of the cells. Conversely, decreasing ECF osmolality causes water to move into the cells. Thus, the ICF volume is determined by the ECF solute concentration. These concepts underlie all events that control fluid balance in the body and should be understood thoroughly.

▲ Na^+, K^+, HPO_4^{2-}, protein anions.

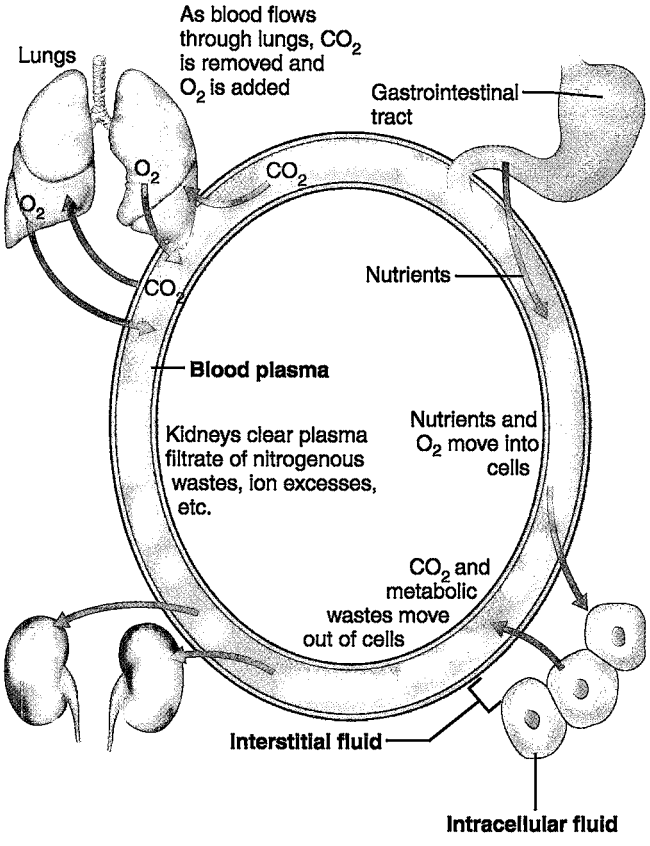

FIGURE 26.3 **The continuous mixing of body fluids.** Exchanges of nutrients and wastes between the intracellular fluid and the plasma occur through the interstitial fluid. Blood plasma transports nutrients and wastes between the cells and the external environment of the body.

Water Balance and ECF Osmolality

For the body to remain properly hydrated, water intake must equal water output. *Water intake* varies widely from person to person and is strongly influenced by habit, but it is typically about 2500 ml a day in adults (Figure 26.4). Most water enters the body through ingested liquids and solid foods. Body water produced by cellular metabolism is called **metabolic water** or **water of oxidation.**

Water output occurs by several routes. Water that vaporizes out of the lungs in expired air or diffuses directly through the skin is called **insensible water loss.** Some is lost in obvious perspiration and in feces. The balance (about 60%) is excreted by the kidneys in urine.

Healthy people have a remarkable ability to maintain the tonicity of their body fluids within very narrow limits (280–300 mOsm/kg). A rise in plasma osmolality triggers (1) thirst, which prompts us to drink water, and (2) release of antidiuretic hormone (ADH), which causes the kidneys to conserve water

Q *How would the values shown here be affected by* ***(1)*** *drinking a six-pack of beer?* ***(2)*** *a fast in which only water is ingested?*

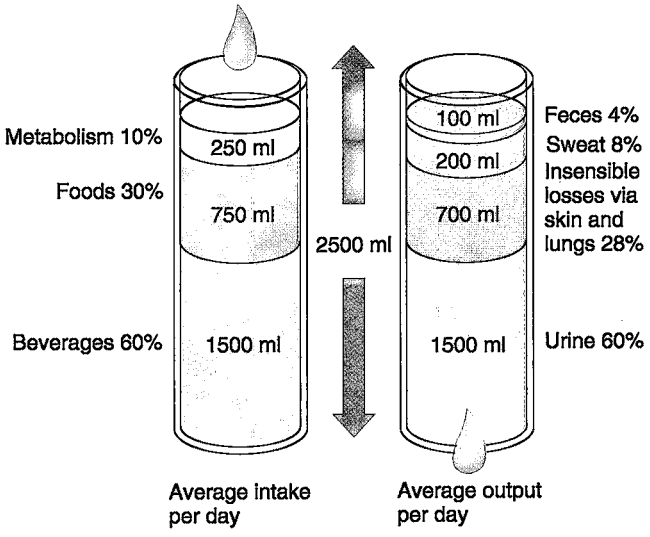

FIGURE 26.4 **Major sources of water intake and output.** When intake and output are in balance, the body is adequately hydrated.

and excrete concentrated urine. On the other hand, a decline in osmolality inhibits both thirst and ADH release, the latter followed by output of large volumes of dilute urine.

Regulation of Water Intake

The **thirst mechanism** is the driving force for water intake. An increase in plasma osmolality of only 2–3% excites the hypothalamic *thirst center.* A dry mouth also occurs because the rise in plasma oncotic pressure causes less fluid to leave the bloodstream. Because the salivary glands obtain the water they require from the blood, less saliva is produced, reinforcing the drive to drink. The same response is produced by a decline in blood volume (or pressure). However, because a substantial decrease (10–15%) is required, this is the less potent stimulus.

The hypothalamic thirst center neurons are stimulated when their *osmoreceptors* lose water by osmosis to the hypertonic ECF, or are activated by angiotensin II, by baroreceptor inputs, or other stimuli. Collectively, these events cause a subjective

A ***(1)*** *Much more water intake from beverages; much greater water output in urine (and perhaps in vomit, if too much alcohol was imbibed, an output route not illustrated).* ***(2)*** *Beverage intake would represent a higher percentage of water intake; water intake from foods and metabolism would drop drastically. Less urine would be made and excreted by the kidneys.*

Q *What effect would eating pretzels have on this mechanism?*

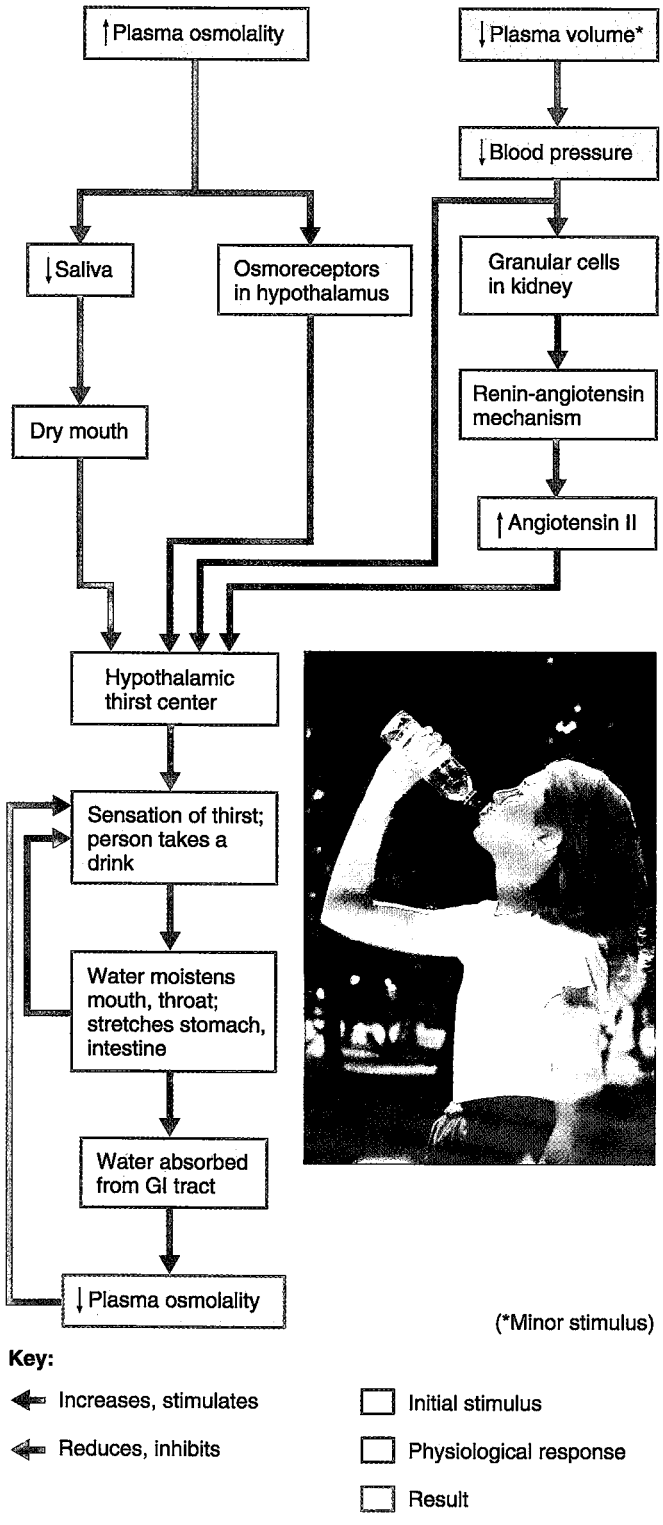

FIGURE 26.5 **The thirst mechanism for regulating water intake.** The major stimulus is increased osmolality of blood plasma. (Not all effects of angiotensin II are depicted.)

A *Because pretzels are salty, blood osmolality would increase, activating osmoreceptors in the hypothalamus, thus increasing thirst.*

sensation of thirst, which motivates us to get a drink (Figure 26.5). This mechanism helps explain why it is that some cocktail lounges and bars provide free *salty* snacks to their patrons.

Curiously, thirst is quenched almost as soon as we begin drinking water, even though the water has yet to be absorbed into the blood. The damping of thirst begins as the mucosa of the mouth and throat is moistened and continues as stretch receptors in the stomach and intestine are activated, providing feedback signals that inhibit the thirst center. This premature quenching of thirst prevents us from drinking more than we need and overdiluting our body fluids, and allows time for the osmotic changes to come into play as regulatory factors.

As effective as thirst is, it is not always a reliable indicator of need. This is particularly true during athletic events, when thirst can be satisfied long before sufficient liquids have been drunk to maintain the body in top form. Additionally, elderly or confused people may not recognize or heed thirst signals, and fluid-overloaded renal or cardiac patients may feel thirsty despite their condition.

Regulation of Water Output

Output of certain amounts of water is unavoidable. Such **obligatory water losses** help to explain why we cannot survive for long without drinking. Even the most heroic conservation efforts by the kidneys cannot compensate for zero water intake. Obligatory water loss includes the *insensible water losses* described above, water that accompanies undigested food residues in feces, and a minimum daily **sensible water loss** of 500 ml in urine. Obligatory water loss in urine reflects the facts that (1) when we eat an adequate diet, our kidneys must excrete 900–1200 mOsm of solutes to maintain blood homeostasis, and (2) human kidneys must flush urine solutes (end products of metabolism and so forth) out of the body in water.

Beyond obligatory water loss, the solute concentration and volume of urine excreted depend on fluid intake, diet, and water loss via other avenues. For example, if you perspire profusely on a hot day, much less urine than usual has to be excreted to maintain water balance. Normally, the kidneys begin to eliminate excess water about 30 minutes after it is ingested. This delay reflects the time required to inhibit ADH release. Diuresis reaches a peak in 1 hour after drinking and then declines to its lowest level after 3 hours.

The body's water volume is closely tied to a powerful water "magnet," ionic sodium. Moreover, our ability to maintain water balance through urinary output is really a problem of sodium *and* water balance because the two are always regulated in tandem

by mechanisms that serve cardiovascular function and blood pressure. However, before dealing with Na^+ issues, we will recap ADH's effect on water output.

Influence of ADH

The amount of water reabsorbed in the renal collecting ducts is proportional to ADH release. When ADH levels are low, most of the water reaching the collecting ducts is not reabsorbed but simply allowed to pass through because the lack of aquaporins in the luminal membranes of the principal cells prevents the movement of water. The result is dilute urine and a reduced volume of body fluids. When ADH levels are high, aquaporins are inserted in the principal cell luminal membranes and nearly all of the filtered water is reabsorbed; a small volume of concentrated urine is excreted.

Osmoreceptors of the hypothalamus sense the ECF solute concentration and trigger or inhibit ADH release from the posterior pituitary accordingly (Figure 26.6). A decrease in ECF osmolality inhibits ADH release and allows more water to be excreted in urine, restoring normal blood osmolality. In contrast, an increase in ECF osmolality stimulates ADH release by stimulating the hypothalamic osmoreceptors.

ADH secretion is also influenced by *large* changes in blood volume or blood pressure. A decrease in BP triggers an increase in ADH secretion from the posterior pituitary either directly via baroreceptors in the atria and various blood vessels or indirectly via the renin-angiotensin mechanism. The key word here is "large" because changes in ECF osmolality are much more important as stimulatory or inhibitory factors. Factors that trigger ADH release by reducing blood volume include prolonged fever; excessive sweating, vomiting, or diarrhea; severe blood loss; and traumatic burns. Under these conditions, ADH also acts to constrict arterioles, directly increasing blood pressure—hence its other name: *vasopressin*. Figure 26.9 (p. 1046) summarizes how renal mechanisms involving aldosterone, angiotensin II, and ADH tie into overall controls of blood volume and blood pressure.

Disorders of Water Balance

Few people really appreciate the importance of water in keeping the body's "machinery" working at peak efficiency. The principal abnormalities of water balance are dehydration, hypotonic hydration, and edema, and each of these conditions presents a special set of problems for its victims.

Dehydration

When water output exceeds intake over a period of time and the body is in negative fluid balance, the

Q *ADH, by itself, cannot reduce an increase in osmolality. Why not? What other mechanism is required?*

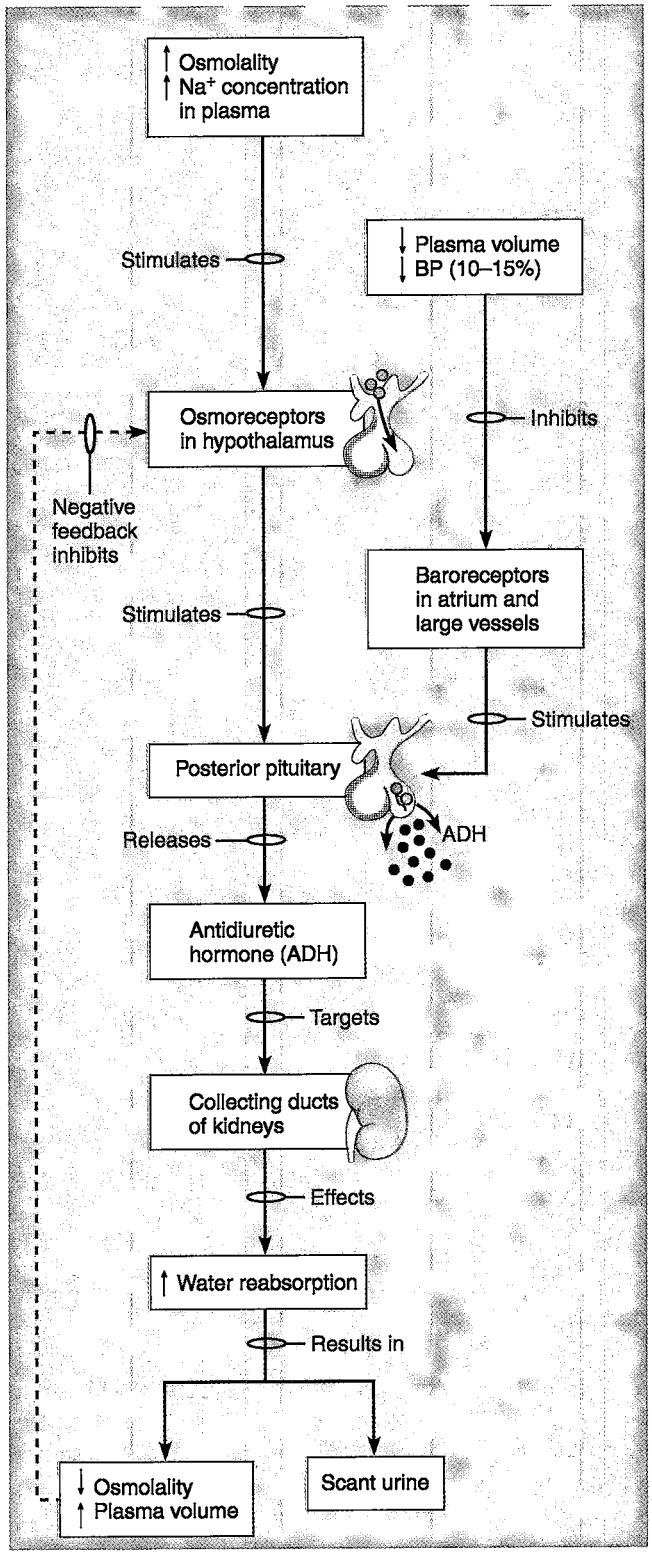

FIGURE 26.6 **Mechanisms and consequences of ADH release.** (Vasoconstrictor effects of ADH are not shown.)

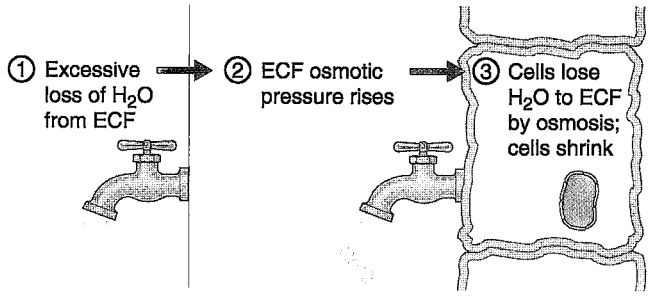
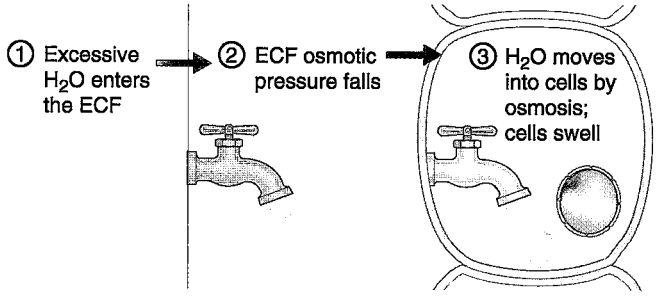
A *ADH cannot add H_2O. It can only conserve what is already there. The thirst mechanism is required.*



(a) Mechanism of dehydration



(b) Mechanism of hypotonic hydration

FIGURE 26.7 **Disturbances in water balance.**

result is **dehydration**. Dehydration is a common sequel to hemorrhage, severe burns, prolonged vomiting or diarrhea, profuse sweating, water deprivation, and diuretic abuse. Dehydration may also be caused by endocrine disturbances, such as diabetes mellitus or diabetes insipidus (see Chapter 16). Early signs and symptoms of dehydration include a "cottony" or sticky oral mucosa, thirst, dry flushed skin, and decreased urine output *(oliguria)*. If prolonged, dehydration may lead to weight loss, fever, and mental confusion. Another serious consequence of water loss from plasma is inadequate blood volume to maintain normal circulation and ensuing *hypovolemic shock*.

In all these situations, water is lost from the ECF (Figure 26.7a). This is followed by the osmotic movement of water from the cells into the ECF, which equalizes the osmolality of the extracellular and intracellular fluids even though the total fluid volume has been reduced. Though the overall effect is called dehydration, it rarely involves only a water deficit, because most often electrolytes are lost as well.

Hypotonic Hydration

When the ECF osmolality starts to drop (usually this reflects a deficit of Na^+), several compensatory mechanisms are set into motion. ADH release is inhibited, and as a result, less water is reabsorbed and excess water is quickly flushed from the body in urine. But, when there is renal insufficiency or when an extraordinary amount of water is drunk very quickly, a type of cellular *overhydration* called **hypotonic hydration** may occur. In either case, the ECF is diluted—its sodium content is normal, but excess water is present. Thus, the hallmark of this condition is **hyponatremia** (low ECF Na^+), which promotes net osmosis into the tissue cells, causing them to swell as they become abnormally hydrated (Figure 26.7b). This leads to severe metabolic disturbances evidenced by nausea, vomiting, muscular cramping, and cerebral edema. Hypotonic hydration is particularly damaging to neurons. Uncorrected cerebral edema quickly leads to disorientation, convulsions, coma, and death. Sudden and severe hyponatremia (as in overhydrated athletes) is treated by intravenous administration of hypertonic saline to reverse the osmotic gradient and "pull" water out of the cells.

Edema

Edema (ĕ-de'mah; "a swelling") is an atypical accumulation of fluid in the interstitial space, leading to tissue swelling. Edema may be caused by any event that steps up the flow of fluid out of the blood or hinders its return.

Factors that accelerate fluid loss from the blood include increases in capillary hydrostatic pressure and permeability. Increased capillary hydrostatic pressure can result from incompetent venous valves, localized blood vessel blockage, congestive heart failure, or high blood volume. Whatever the cause, the abnormally high capillary hydrostatic pressure intensifies filtration at the capillary beds.

Increased capillary permeability is usually due to an ongoing inflammatory response. Recall from p. 791 that inflammatory chemicals cause local capillaries to become very porous, allowing large amounts of exudate (containing not only clotting proteins but also other plasma proteins, nutrients, and immune elements) to form.

Edema caused by hindered fluid return to the blood usually reflects an imbalance in the colloid osmotic pressures on the two sides of the capillary membranes. For example, **hypoproteinemia** (hi"po-pro"te-ĭ-ne'me-ah), a condition of unusually low levels of plasma proteins, results in tissue edema because protein-deficient plasma has an abnormally low colloid osmotic pressure. Fluids are forced out of the capillary beds at the arterial ends by blood pressure as usual, but fail to return to the blood at the venous ends. Thus, the interstitial spaces become congested with fluid. Hypoproteinemia may result from protein malnutrition, liver disease, or *glomerulonephritis* (in which plasma proteins pass through "leaky" renal filtration membranes and are lost in urine).

Although the cause differs, the result is the same when lymphatic vessels are blocked or have been surgically removed. The small amounts of plasma proteins that seep out of the bloodstream are not returned to the blood as usual. As the leaked proteins accumulate in the IF, they exert an ever-increasing colloid osmotic pressure, which draws fluid from the blood and holds it in the interstitial space. Because excess fluid in the interstitial space increases the distance nutrients and oxygen must diffuse between the blood and the cells, edema can impair tissue function. However, the most serious problems resulting from edema affect the cardiovascular system. When fluid leaves the bloodstream and accumulates in the interstitial space, both blood volume and blood pressure decline and the efficiency of the circulation can be severely impaired.

Electrolyte Balance

Electrolytes include salts, acids, and bases, but the term **electrolyte balance** usually refers to the salt balance in the body. Salts are important in controlling fluid movements and provide minerals essential for excitability, secretory activity, and membrane permeability. Although many electrolytes are crucial for cellular activity, here we will specifically examine the regulation of sodium, potassium, and calcium. Acids and bases, which are more intimately involved in determining the pH of body fluids, are considered in the next section.

Salts enter the body in foods and fluids, and small amounts are generated during metabolic activity. For example, phosphates are liberated during catabolism of nucleic acids and bone matrix. Obtaining enough electrolytes is usually not a problem. Indeed, most of us have a far greater taste than need for salt. We shake table salt (NaCl) on our food even though natural foods contain ample amounts and processed foods contain exorbitant quantities. The taste for very salty foods is learned, but some liking for salt may be innate to ensure adequate intake of these two vital ions.

Salts are lost from the body in perspiration, feces, and urine. Even though sweat is normally hypotonic, large amounts of salt can be lost on a hot day simply because more sweat is produced. Gastrointestinal disorders can also lead to large salt losses in feces or vomitus. Thus, the flexibility of renal mechanisms that regulate the electrolyte balance of the blood is a critical asset. Some causes and consequences of electrolyte imbalances are summarized in Table 26.1.

HOMEOSTATIC IMBALANCE

Severe electrolyte deficiencies may prompt a craving for salty or sour foods, such as smoked meats or pickled eggs. This is common in those with *Addison's disease*, a disorder entailing deficient mineralocorticoid hormone production by the adrenal cortex. When minerals such as iron are deficient, a person may even eat substances not usually considered foods, like chalk, clay, starch, and burnt match tips. This appetite for abnormal substances is called *pica*.

The Central Role of Sodium in Fluid and Electrolyte Balance

Sodium holds a central position in fluid and electrolyte balance and overall body homeostasis. Indeed, regulating the balance between sodium input and output is one of the most important renal functions. The salts $NaHCO_3$ and NaCl account for 90–95% of all solutes in the ECF, and they contribute about 280 mOsm of the total ECF solute concentration (300 mOsm). At its normal plasma concentration of about 142 mEq/L, Na^+ is the single most abundant cation in the ECF and the only one exerting *significant* osmotic pressure. Additionally, cellular plasma membranes are relatively impermeable to Na^+, but some does manage to diffuse in and must be pumped out against its electrochemical gradient. These two qualities give sodium the primary role in controlling ECF volume and water distribution in the body.

It is important to understand that while the sodium content of the body may change, *its ECF concentration normally remains stable* because of immediate adjustments in water volume. Remember, *water follows salt.* Furthermore, because all body fluids are in osmotic equilibrium, a change in plasma Na^+ levels affects not only plasma volume and blood pressure, but also the ICF and IF volumes. In addition, sodium ions continuously move back and forth between the ECF and body secretions. For example, about 8 L of Na^+-containing secretions (gastric, intestinal, and pancreatic juice, saliva, bile) are spewed into the digestive tract daily, only to be almost completely reabsorbed. Finally, renal acid-base control mechanisms (discussed shortly) are coupled to Na^+ transport.

Regulation of Sodium Balance

Despite the crucial importance of sodium, receptors that specifically monitor Na^+ levels in body fluids have yet to be found. Regulation of the Na^+-water balance is inseparably linked to blood pressure and volume, and involves a variety of neural and hormonal controls. Reabsorption of Na^+ does *not* exhibit a transport maximum, and in healthy individuals nearly all Na^+ in the urinary filtrate can be reabsorbed. We will begin our coverage of sodium balance by reviewing the

TABLE 26.1 Causes and Consequences of Electrolyte Imbalances

ION	ABNORMALITY (SERUM VALUE)	POSSIBLE CAUSES	CONSEQUENCES
Sodium	Hypernatremia (Na^+ excess: >145 mEq/L)	Dehydration; uncommon in healthy individuals; may occur in infants or the confused aged (individuals unable to indicate thirst) or may be a result of excessive intravenous NaCl administration	Thirst: CNS dehydration leads to confusion and lethargy progressing to coma; increased neuromuscular irritability evidenced by twitching and convulsions
	Hyponatremia (Na^+ deficit: <135 mEq/L)	Solute loss, water retention, or both (e.g., excessive Na^+ loss through vomiting, diarrhea, burned skin, tubal drainage of stomach, and as a result of excessive use of diuretics); deficiency of aldosterone (Addison's disease); renal disease; excess ADH release; excess H_2O ingestion	Most common signs are those of neurologic dysfunction due to brain swelling. If sodium amounts are actually normal but water is excessive, the symptoms are the same as those of water excess: mental confusion; giddiness; coma if development occurs slowly; muscular twitching, irritability, and convulsions if the condition develops rapidly. In hyponatremia accompanied by water loss, the main signs are decreased blood volume and blood pressure (circulatory shock)
Potassium	Hyperkalemia (K^+ excess: >5.5 mEq/L)	Renal failure; deficit of aldosterone; rapid intravenous infusion of KCl; burns or severe tissue injuries which cause K^+ to leave cells	Nausea, vomiting, diarrhea; bradycardia; cardiac arrhythmias, depression, and arrest; skeletal muscle weakness; flaccid paralysis
	Hypokalemia (K^+ deficit: <3.5 mEq/L)	Gastrointestinal tract disturbances (vomiting, diarrhea), gastrointestinal suction; Cushing's disease; inadequate dietary intake (starvation); hyperaldosteronism; diuretic therapy	Cardiac arrhythmias, flattened T wave; muscular weakness; metabolic alkalosis; mental confusion; nausea; vomiting
Phosphate	Hyperphosphatemia (HPO_4^{2-} excess: >2.9 mEq/L)	Decreased urinary loss due to renal failure; hypoparathyroidism; major tissue trauma; increased intestinal absorption	Clinical symptoms arise because of reciprocal changes in Ca^{2+} levels rather than directly from changes in plasma phosphate concentrations
	Hypophosphatemia (HPO_4^{2-} deficit: <1.6 mEq/L)	Decreased intestinal absorption; increased urinary output; hyperparathyroidism	
Chloride	Hyperchloremia (Cl^- excess: >105 mEq/L)	Dehydration; increased retention or intake; metabolic acidosis; hyperparathyroidism	No direct clinical symptoms; symptoms generally associated with the underlying cause, which is often related to pH abnormalities
	Hypochloremia (Cl^- deficit: <95 mEq/L)	Metabolic alkalosis (e.g., due to vomiting or excessive ingestion of alkaline substances); aldosterone deficiency	
Calcium	Hypercalcemia (Ca^{2+} excess: >5.2 mEq/L or 10.5 mg%)*	Hyperparathyroidism; excessive vitamin D; prolonged immobilization; renal disease (decreased excretion); malignancy	Decreased neuromuscular excitability leading to cardiac arrhythmias and arrest, skeletal muscle weakness, confusion, stupor, and coma; kidney stones; nausea and vomiting
	Hypocalcemia (Ca^{2+} deficit: <4.5 mEq/L or 9 mg%)*	Burns (calcium trapped in damaged tissues); hypoparathyroidism; vitamin D deficiency; renal tubular disease; renal failure; hyperphosphatemia; diarrhea; alkalosis	Increased neuromuscular excitability leading to tingling of fingers, tremors, skeletal muscle cramps, tetany, convulsions; depressed excitability of the heart; osteomalacia; fractures
Magnesium	Hypermagnesemia (Mg^{2+} excess: >2.2 mEq/L)	Rare; occurs in renal failure when Mg is not excreted normally; excessive ingestion of Mg^{2+}-containing antacids	Lethargy; impaired CNS functioning, coma, respiratory depression; cardiac arrest
	Hypomagnesemia (Mg^{2+} deficit: <1.4 mEq/L)	Alcoholism; loss of intestinal contents, severe malnutrition; diuretic therapy	Tremors, increased neuromuscular excitability, tetany, convulsions

*1 mg% = 1 mg/100 ml

regulatory effect of aldosterone. Then we will examine various feedback loops that interact to regulate sodium and water balance and blood pressure.

Influence of Aldosterone

The hormone **aldosterone** "has the most to say" about renal regulation of sodium ion concentrations in the ECF. But whether aldosterone is present or not, some 65% of the Na^+ in the renal filtrate is reabsorbed in the proximal tubules of the kidneys and another 25% is reclaimed in the loops of Henle (see Chapter 25).

When aldosterone concentrations are high, essentially all the remaining filtered Na^+ is actively reabsorbed in the distal convoluted tubules and collecting ducts. Water follows if it can, that is, if the collecting duct permeability has been increased by ADH. Thus, aldosterone usually promotes both sodium and water retention. When aldosterone release is inhibited, virtually no Na^+ reabsorption occurs beyond the distal tubule. So, although urinary excretion of large amounts of Na^+ *always* results in the excretion of large amounts of water as well, the reverse is *not* true. Substantial amounts of nearly sodium-free urine can be eliminated as needed to achieve water balance.

The most important trigger for aldosterone release from the adrenal cortex is the renin-angiotensin mechanism mediated by the juxtaglomerular apparatus of the renal tubules (see Figures 26.8 and 26.9). When the juxtaglomerular (JG) apparatus responds to (1) sympathetic stimulation, (2) decreased filtrate NaCl concentration, or (3) decreased stretch (due to decreased blood pressure), the granular cells release renin. Renin catalyzes the series of reactions that produce angiotensin II, which prompts aldosterone release. Conversely, high renal blood pressure and high filtrate NaCl concentrations depress release of renin, angiotensin II, and aldosterone. The adrenal cortical cells are also directly stimulated to release aldosterone by elevated K^+ levels in the ECF (Figure 26.8).

Aldosterone brings about its effects slowly, over a period of hours to days. The principal effects of aldosterone are to diminish urinary output and increase blood volume. However, before these factors can change by more than a few percent, feedback mechanisms for blood volume control come into play. In addition to releasing aldosterone, angiotensin II also has a number of other actions, all aimed at raising blood volume and blood pressure. These were described in Chapter 25 (p. 1010).

HOMEOSTATIC IMBALANCE

People with Addison's disease (hypoaldosteronism) lose tremendous amounts of NaCl and water to urine. They are perpetually teetering on the brink of hypovolemia, but as long as they ingest adequate amounts of salt and fluids, people with this condition can avoid problems with Na^+ balance. ●

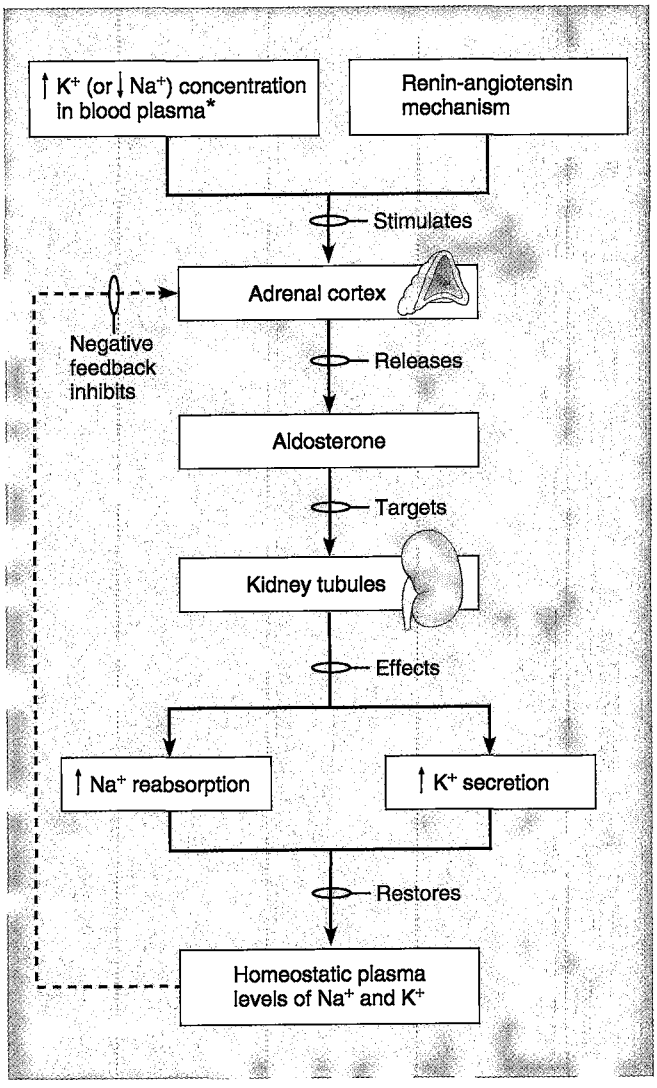


FIGURE 26.8 **Mechanisms and consequences of aldosterone release.**

*The adrenal cortex is much less sensitive to decreased plasma Na^+ than to increased plasma K^+.

Cardiovascular Baroreceptors

Blood volume is carefully monitored and regulated to maintain blood pressure and cardiovascular function. As blood volume (hence pressure) rises, baroreceptors in the heart and in the large vessels of the neck and thorax (carotid arteries and aorta) alert the cardiovascular centers in the brain stem. Shortly after, sympathetic nervous system impulses to the kidneys decline, allowing the afferent arterioles to dilate. As the glomerular filtration rate rises, Na^+ output and water output increase. This phenomenon,

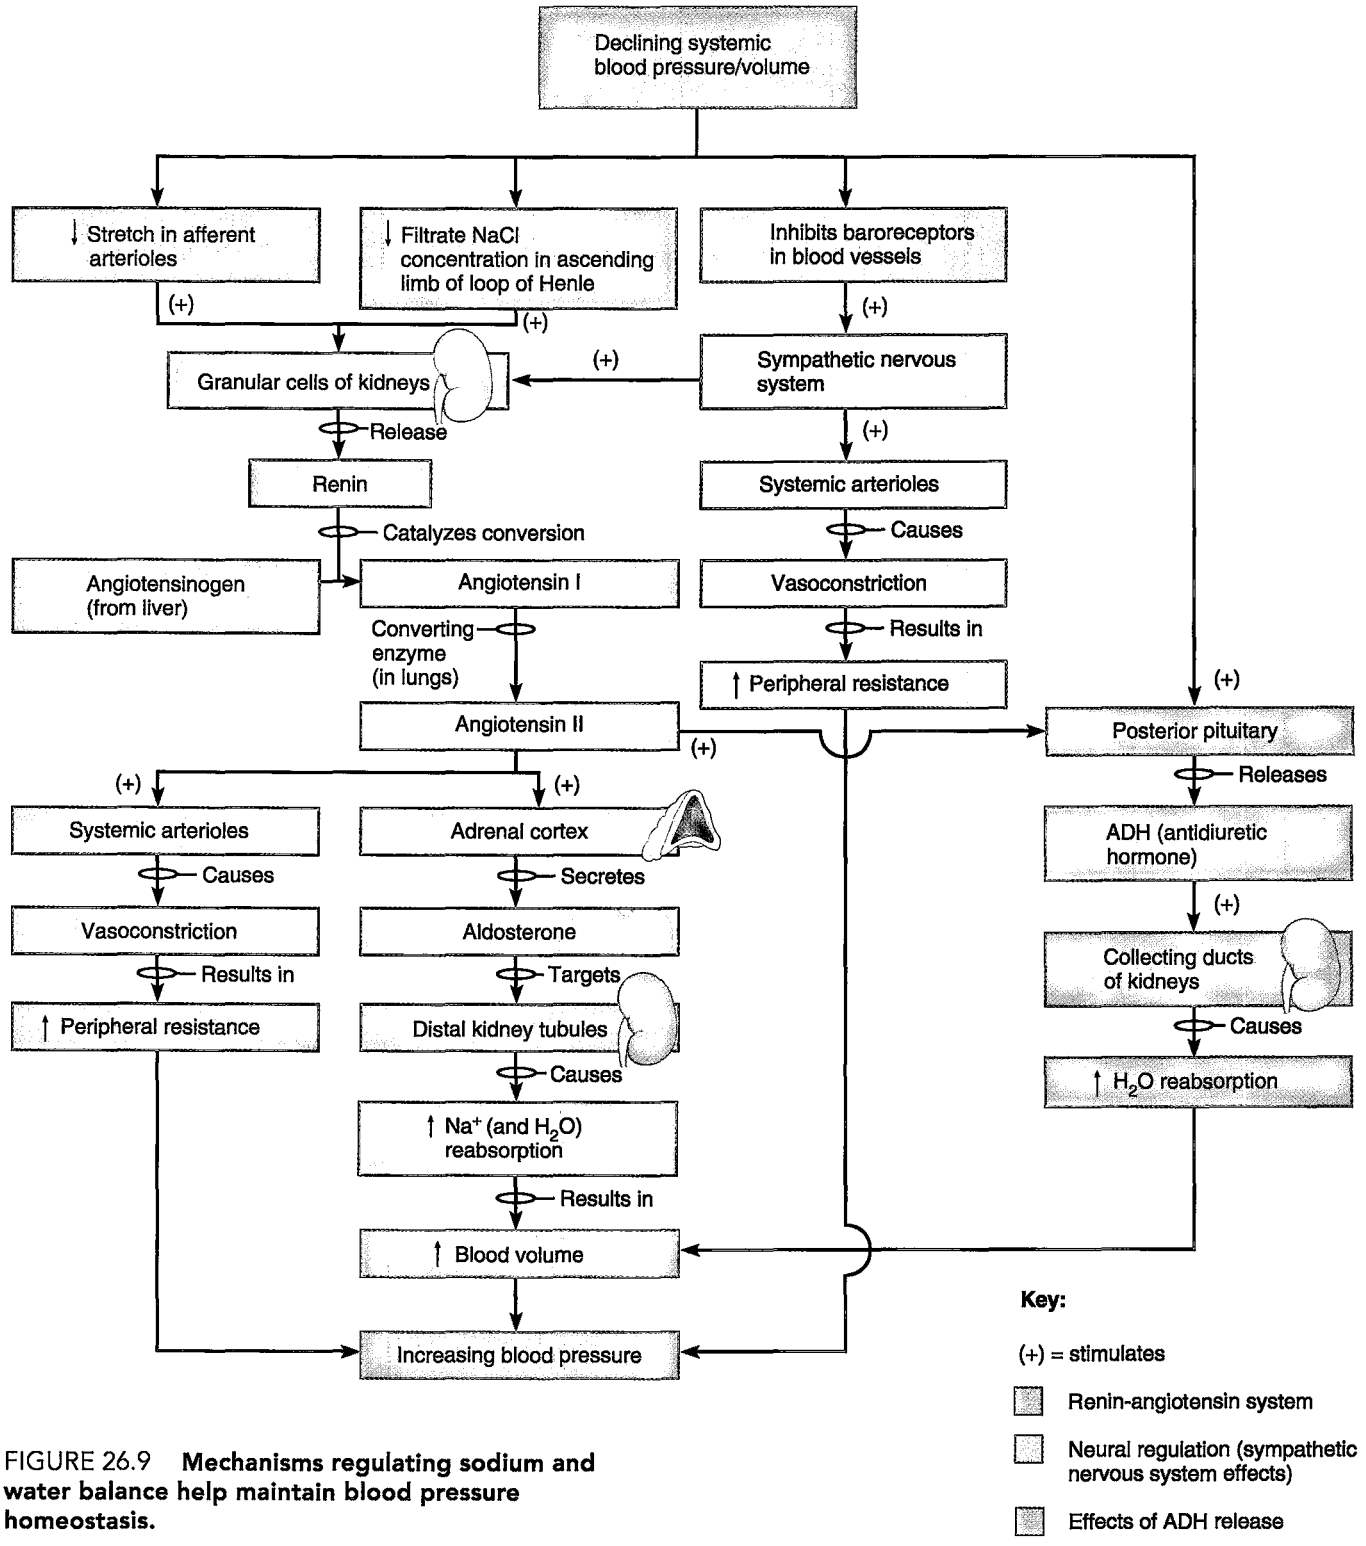

FIGURE 26.9 **Mechanisms regulating sodium and water balance help maintain blood pressure homeostasis.**

part of the baroreceptor reflex described in Chapter 19 (p. 727), reduces blood volume and blood pressure.

Drops in systemic blood pressure lead to reflex constriction of systemic arterioles including the afferent arterioles, which reduces filtrate formation and urinary output and increases systemic blood pressure (see Figure 26.9). Thus, the baroreceptors provide information on the "fullness" or volume of the circulation that is critical for maintaining cardiovascular homeostasis. Because Na^+ concentration determines fluid volume, the baroreceptors might be regarded as "sodium receptors."

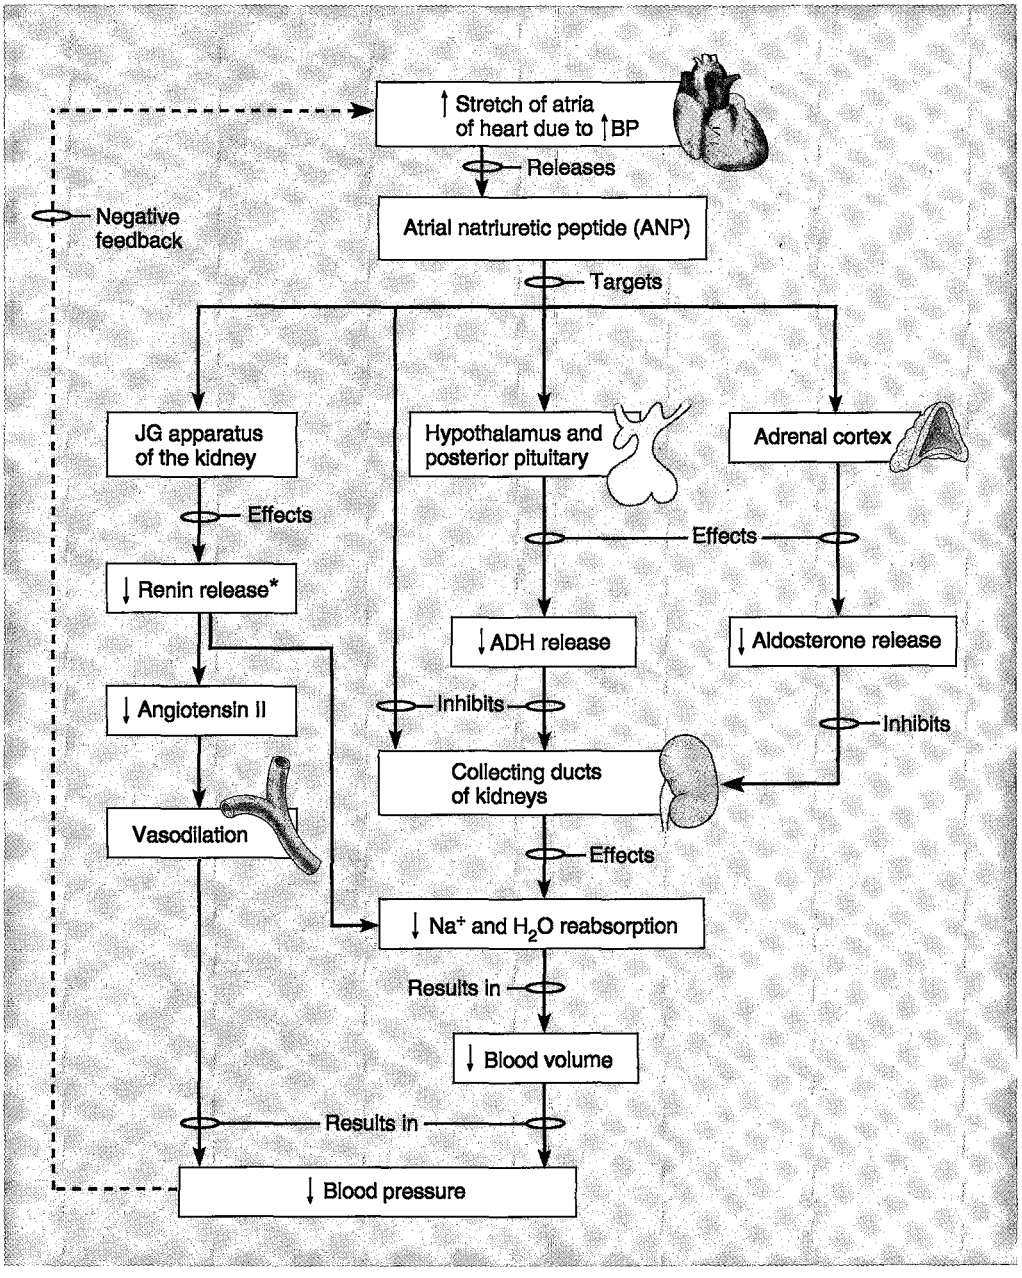

FIGURE 26.10 **Mechanisms and consequences of ANP release.**

*↓ Renin release also inhibits ADH and aldosterone release and hence the effects of those hormones.

Influence of Atrial Natriuretic Peptide

The influence of **atrial natriuretic peptide (ANP)** can be summarized in one sentence: It reduces blood pressure and blood volume by inhibiting nearly all events that promote vasoconstriction and Na^+ and water retention (Figure 26.10). A hormone that is released by certain cells of the heart atria when they are stretched by the effects of elevated blood pressure, ANP has potent diuretic and natriuretic (salt-excreting) effects. It promotes excretion of Na^+ and water by the kidneys by inhibiting the ability of the collecting duct to reabsorb Na^+ and by suppressing the release of ADH, renin, and aldosterone. Additionally, ANP acts both directly and indirectly (by inhibiting renin-induced generation of angiotensin II) to relax vascular smooth muscle; thus it causes vasodilation. Collectively, these effects reduce blood pressure.

Influence of Other Hormones

Female Sex Hormones The **estrogens** are chemically similar to aldosterone and, like aldosterone, enhance NaCl reabsorption by the renal tubules. Because water follows, many women retain

fluid as their estrogen levels rise during the menstrual cycle. The edema experienced by many pregnant women is also largely due to the effect of estrogens. **Progesterone** appears to decrease Na^+ reabsorption by blocking the effect aldosterone has on the renal tubules. Thus, progesterone has a diuretic-like effect and promotes Na^+ and water loss.

Glucocorticoids The usual effect of **glucocorticoids**, such as cortisol and hydrocortisol, is to enhance tubular reabsorption of Na^+, but they also promote an increased glomerular filtration rate that may mask their effects on the tubules. However, when their plasma levels are high, the glucocorticoids exhibit potent aldosterone-like effects and promote edema.

Regulation of Potassium Balance

Potassium, the chief intracellular cation, is required for normal neuromuscular functioning as well as for several essential metabolic activities. Because the relative ICF-ECF potassium concentration directly affects a cell's resting membrane potential, even slight changes in K^+ concentration in the ECF have profound effects on neurons and muscle fibers that can be extremely dangerous. K^+ excess in the ECF decreases their membrane potential, causing depolarization, often followed by reduced excitability. Too little K^+ in the ECF causes hyperpolarization and nonresponsiveness. The heart is particularly sensitive to K^+ levels. Both too much and too little K^+ (hyperkalemia and hypokalemia respectively) can disrupt electrical conduction in the heart, leading to sudden death (Table 26.1).

Potassium is also part of the body's buffer system, which resists changes in the pH of body fluids. Shifts of hydrogen ions (H^+) into and out of cells induce corresponding shifts of K^+ in the opposite direction to maintain cation balance. Thus, ECF potassium levels rise with acidosis, as K^+ leaves and H^+ enters the cells, and fall with alkalosis, as K^+ moves into the cells and H^+ leaves them to enter the ECF. Although these pH-driven shifts do not change the total amount of K^+ in the body, they can seriously interfere with the activity of excitable cells.

Regulatory Site: The Cortical Collecting Duct

Like Na^+ balance, K^+ balance is maintained chiefly by renal mechanisms. However, there are important differences in the way this balance is achieved. The amount of Na^+ reabsorbed in the tubules is precisely tailored to need, and Na^+ is *never* secreted into the filtrate.

In contrast, the proximal tubules predictably reabsorb about 60–80% of the filtered K^+, and the thick ascending limb of Henle's loop absorbs another 10–20% or so, leaving about 10% to be lost in urine regardless of need. The responsibility for K^+ balance falls chiefly on the cortical collecting ducts, and is accomplished mainly by changing the amount of K^+ *secreted* into the filtrate.

As a rule, K^+ levels in the ECF are sufficiently high that K^+ needs to be excreted, and the rate at which the principal cells of the cortical collecting ducts secrete K^+ into the filtrate is accelerated over basal levels. (At times, the amount of K^+ excreted may actually exceed the amount filtered.) When ECF potassium concentrations are abnormally low, K^+ moves from the tissue cells into the ECF and the renal principal cells conserve K^+ by reducing its secretion and excretion to a minimum. Note that these principal cells are the same cells that mediate aldosterone-induced reabsorption of Na^+ and the ADH-stimulated reabsorption of water. Additionally, *type A intercalated cells*, a unique population of collecting duct cells, can reabsorb some of the K^+ left in the filtrate (in conjunction with active secretion of H^+), thus helping to reestablish K^+ (and pH) balance. However, keep in mind that the main thrust of renal regulation of K^+ is to *excrete* it. Because the kidneys have a limited ability to retain K^+, it may be lost in urine even in the face of a deficiency. Consequently, failure to ingest potassium-rich substances eventually results in a severe deficiency.

Influence of Plasma Potassium Concentration

The single most important factor influencing K^+ secretion is the K^+ concentration in blood plasma. A high-potassium diet increases the K^+ content of the ECF. This favors entry of K^+ into the principal cells of the cortical collecting duct and prompts them to secrete K^+ into the filtrate so that more of it is excreted. Conversely, a low-potassium diet or accelerated K^+ loss depresses its secretion (and promotes its limited reabsorption) by the collecting ducts.

Influence of Aldosterone

The second factor influencing K^+ secretion into the filtrate is aldosterone. As it stimulates the principal cells to reabsorb Na^+, aldosterone simultaneously enhances K^+ secretion (see Figure 26.8). Thus, as plasma Na^+ levels rise, K^+ levels fall proportionately.

Adrenal cortical cells are *directly* sensitive to the K^+ content of the ECF bathing them. When it increases even slightly, the adrenal cortex is strongly stimulated to release aldosterone, which increases K^+ secretion by the exchange process just described. Thus, K^+ controls its own concentrations in the ECF via feedback regulation of aldosterone release.

Aldosterone is also secreted in response to the renin-angiotensin mechanism previously described.

HOMEOSTATIC IMBALANCE

In an attempt to reduce NaCl intake, many people have turned to salt substitutes, which are high in potassium. However, heavy consumption of these substitutes is safe only when aldosterone release in the body is normal. In the absence of aldosterone, hyperkalemia is swift and lethal regardless of K^+ intake (Table 26.1). Conversely, when a person has an adrenocortical tumor that pumps out tremendous amounts of aldosterone, ECF potassium levels fall so low that neurons all over the body hyperpolarize and paralysis occurs. ●

Regulation of Calcium and Phosphate Balance

About 99% of the body's calcium is found in bones in the form of calcium phosphate salts, which provide strength and rigidity to the skeleton. The bony skeleton provides a dynamic reservoir from which calcium and phosphate can be withdrawn or deposited to maintain the balance of these electrolytes in the ECF. Ionic calcium in the ECF is important for normal blood clotting, cell membrane permeability, and secretory behavior, but its most important effect by far is on neuromuscular excitability. Hypocalcemia increases excitability and causes muscle tetany. Hypercalcemia is equally dangerous because it inhibits neurons and muscle cells and may cause life-threatening cardiac arrhythmias (Table 26.1).

ECF calcium ion levels are closely regulated, rarely deviating from normal limits. Under normal circumstances about 98% of the filtered Ca^{2+} is reabsorbed owing to the action of **parathyroid hormone (PTH).*** This hormone is released by the tiny parathyroid glands located on the posterior aspect of the thyroid gland in the pharynx. Declining plasma levels of Ca^{2+} directly stimulate the parathyroid glands to release PTH, which promotes an increase in calcium levels by targeting the following organs (see also Figure 16.12 on p. 625):

1. Bones. PTH activates osteoclasts (bone-digesting cells), which break down the bone matrix, resulting in the release of Ca^{2+} and HPO_4^{2-} to the blood.

2. Small intestine. PTH enhances intestinal absorption of Ca^{2+} indirectly by stimulating the kidneys to transform vitamin D to its active form, which is necessary for Ca^{2+} absorption by the small intestine.

3. Kidneys. PTH increases Ca^{2+} reabsorption by the renal tubules while decreasing phosphate ion reabsorption. Thus, calcium conservation and phosphate excretion go hand in hand. Hence, the *product* of Ca^{2+} and HPO_4^{2-} concentrations in the ECF remains constant, preventing calcium-salt deposits in bones or soft body tissues.

Most Ca^{2+} is reabsorbed passively in the PCT via diffusion through the paracellular route (a process driven by the electrochemical gradient). However, as with other ions, "fine-tuning" of Ca^{2+} reabsorption occurs in the distal nephron. PTH-regulated Ca^{2+} channels control Ca^{2+} entry into DCT cells at the luminal membrane, while Ca^{2+} pumps and antiporters export it at the basolateral membrane.

As a rule, 75% of the filtered phosphate ions (including $H_2PO_4^-$, HPO_4^{2-}, and PO_4^{3-}) are reabsorbed in the PCT by active transport. Phosphate reabsorption is set by its transport maximum. Amounts present in excess of that maximum simply flow out in urine. PTH inhibits active transport of phosphate by decreasing its T_m.

When ECF calcium levels are within normal limits (9–11 mg/100 ml of blood) or higher, PTH secretion is inhibited. Consequently, release of Ca^{2+} from bone is inhibited, larger amounts of Ca^{2+} are lost in feces and urine, and more phosphate is retained. Hormones other than PTH alter phosphate reabsorption. For example, insulin increases it while glucagon decreases it.

Regulation of Anions

Chloride is the major anion accompanying Na^+ in the ECF and, like sodium, Cl^- helps maintain the osmotic pressure of the blood. When blood pH is within normal limits or slightly alkaline, about 99% of filtered Cl^- is reabsorbed. In the PCT, it moves passively and simply follows sodium ions out of the filtrate and into the peritubular capillary blood. In most other tubule segments, Na^+ and Cl^- transport are coupled.

When acidosis occurs, less Cl^- accompanies Na^+ because HCO_3^- reabsorption is stepped up to restore blood pH to its normal range. Thus, the choice between Cl^- and HCO_3^- serves acid-base regulation. Most other anions, such as sulfates and nitrates, have transport maximums, and when their concentrations in the filtrate exceed the amount that can be reabsorbed, excesses spill into urine.

Acid-Base Balance

Because of their abundant hydrogen bonds, all functional proteins (enzymes, hemoglobin, cytochromes, and others) are influenced by H^+ concentration. It

* Although calcitonin is often thought of as a calcium-lowering hormone (as discussed in Chapter 16, p. 624), its effects on blood calcium levels in adults are negligible.

Q *To minimize the pH shift that occurs in situation (a), would it be better to add a strong base or a weak base? Why?*

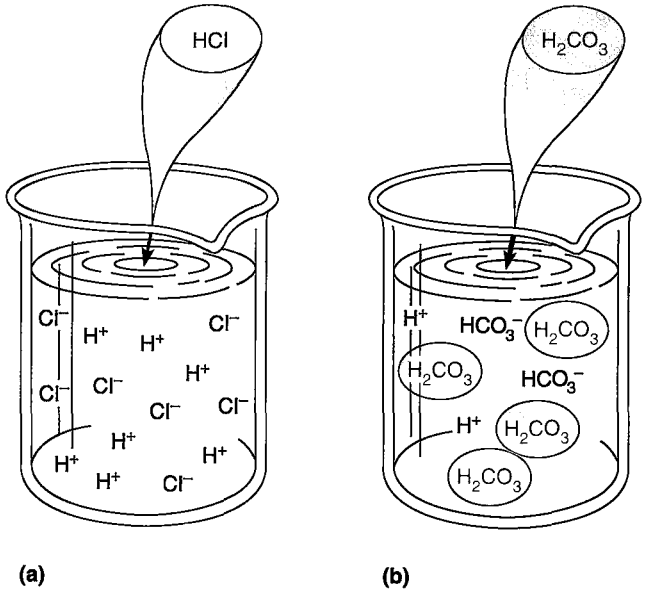

FIGURE 26.11 **Dissociation of strong and weak acids.** **(a)** When added to water, the strong acid HCl dissociates completely into its ions (H^+ and Cl^-). **(b)** By contrast, dissociation of H_2CO_3, a weak acid, is incomplete, and some molecules of H_2CO_3 remain undissociated (symbols shown in green ovals) in solution.

follows then that nearly all biochemical reactions are influenced by the pH of their fluid environment, and the acid-base balance of body fluids is closely regulated. (For a review of the basic principles of acid-base reactions and pH, see Chapter 2.)

Optimal pH varies from one body fluid to another, but not by much. The normal pH of arterial blood is 7.4, that of venous blood and IF is 7.35, and that of ICF averages 7.0. The lower pH in cells and venous blood reflects their greater amounts of acidic metabolites and carbon dioxide, which combines with water to form carbonic acid, H_2CO_3.

Whenever the pH of arterial blood rises above 7.45, a person is said to have **alkalosis** (al″kah-lo′sis) or **alkalemia.** A drop in arterial pH to below 7.35 results in **acidosis** (as″ĭ-do′sis) or **acidemia.** Because pH 7.0 is neutral, chemically speaking 7.35 is not acidic. However, it is a higher-than-optimal H^+ concentration for most cells, so any arterial pH between 7.35 and 7.0 is called *physiological acidosis.*

Although small amounts of acidic substances enter the body via ingested foods, most hydrogen ions originate as metabolic by-products or end products. For example, (1) breakdown of phosphorus-containing proteins releases *phosphoric acid* into the ECF, (2) anaerobic respiration of glucose produces *lactic acid,* (3) fat metabolism yields other organic acids, such as fatty acids and *ketone bodies,* and (4) the loading and transport of carbon dioxide in the blood as HCO_3^- liberates hydrogen ions. Finally, although hydrochloric acid produced by the stomach is not really *in* the body, it is a source of H^+ that must be buffered if digestion is to occur normally in the small intestine.

The H^+ concentration in blood is regulated sequentially by (1) chemical buffers, (2) the brain stem respiratory centers, and (3) renal mechanisms. Chemical buffers act within a fraction of a second to resist pH changes and are the first line of defense. Within 1–3 minutes, changes in respiratory rate and depth are occurring to compensate for acidosis or alkalosis. The kidneys, the body's most potent acid-base regulatory system, ordinarily require hours to a day or more to effect changes in blood pH.

Chemical Buffer Systems

Recall that acids are *proton donors,* and that the acidity of a solution reflects only the *free* hydrogen ions, not those bound to anions. *Strong acids,* which dissociate completely and liberate all their H^+ in water (Figure 26.11a), can dramatically change a solution's pH. By contrast, *weak acids* dissociate only partially (Figure 26.11b), and so have a much slighter effect on pH. However, weak acids are efficient at preventing pH changes, and this feature allows them to play important roles in chemical buffer systems.

Bases are *proton acceptors.* Strong bases are those that dissociate easily in water and quickly tie up H^+. Conversely, weak bases are slower to accept protons.

A **chemical buffer** is a system of one or more compounds that acts to resist changes in pH when a strong acid or base is added. They do this by binding to H^+ whenever the pH drops and releasing them when pH rises. The three major chemical buffer systems in the body are the *bicarbonate, phosphate,* and *protein buffer systems.* Anything that causes a shift in H^+ concentration in one fluid compartment simultaneously causes a change in the others. Thus, the buffer systems actually buffer one another, so that any drifts in pH are resisted by the *entire* buffer system.

Bicarbonate Buffer System

The **bicarbonate buffer system** is a mixture of carbonic acid (H_2CO_3) and its salt, sodium bicarbonate ($NaHCO_3$), in the same solution. Although it also buffers the ICF, it is the *only* important *ECF* buffer.

Carbonic acid, a weak acid, does not dissociate to any great extent in neutral or acidic solutions.

A weak base, because its ability to loosely tie up H^+ allows it to act as a buffer.

Thus, when a strong acid such as HCl is added to this buffer system, most of the existing carbonic acid remains intact. However, the bicarbonate ions of the salt act as weak bases to tie up the H^+ released by the stronger acid (HCl), forming *more* carbonic acid:

$$\underset{\text{strong acid}}{HCl} + \underset{\text{weak base}}{NaHCO_3} \rightarrow \underset{\text{weak acid}}{H_2CO_3} + \underset{\text{salt}}{NaCl}$$

Because it is converted to the weak acid H_2CO_3, HCl lowers the pH of the solution only slightly.

When a strong base such as sodium hydroxide (NaOH) is added to the same buffer solution, a weak base such as sodium bicarbonate ($NaHCO_3$) does not dissociate under the alkaline conditions and so does not contribute to the rise in pH. However, the added base forces the carbonic acid to dissociate further, donating more H^+ to tie up the OH^- released by the strong base:

$$\underset{\text{strong base}}{NaOH} + \underset{\text{weak acid}}{H_2CO_3} \rightarrow \underset{\text{weak base}}{NaHCO_3} + \underset{\text{water}}{H_2O}$$

The net result is replacement of a strong base (NaOH) by a weak one ($NaHCO_3$), so that the pH of the solution rises very little.

Although the bicarbonate salt in the example is sodium bicarbonate, other bicarbonate salts function in the same way because the HCO_3^- is the important ion, not the cation it is paired with. In cells, where little Na^+ is present, potassium and magnesium bicarbonates are part of the bicarbonate buffer system.

The buffering power of this type of system is directly related to the concentrations of the buffering substances. Thus, if acids enter the blood at such a rate that all the available HCO_3^- ions, often referred to as the **alkaline reserve,** are tied up, the buffer system becomes ineffective and blood pH changes. The bicarbonate ion concentration in the ECF is normally around 25 mEq/L and is closely regulated by the kidneys. The concentration of H_2CO_3 is just over 1 mEq/L but the supply of carbonic acid (which comes from the CO_2 released during cellular respiration) is almost limitless, so obtaining that member of the buffer pair is usually not a problem. The carbonic acid content of the blood is subject to respiratory controls.

Phosphate Buffer System

The operation of the **phosphate buffer system** is nearly identical to that of the bicarbonate buffer. The components of the phosphate system are the sodium salts of dihydrogen phosphate ($H_2PO_4^-$) and monohydrogen phosphate (HPO_4^{2-}). NaH_2PO_4 acts as a weak acid. Na_2HPO_4, with one less hydrogen atom, acts as a weak base.

Again, H^+ released by strong acids is tied up in weak acids:

$$\underset{\text{strong acid}}{HCl} + \underset{\text{weak base}}{Na_2HPO_4} \rightarrow \underset{\text{weak acid}}{NaH_2PO_4} + \underset{\text{salt}}{NaCl}$$

and strong bases are converted to weak bases:

$$\underset{\text{strong base}}{NaOH} + \underset{\text{weak acid}}{NaH_2PO_4} \rightarrow \underset{\text{weak base}}{Na_2HPO_4} + \underset{\text{water}}{H_2O}$$

Because the phosphate buffer system is present in low concentrations in the ECF (approximately one-sixth that of the bicarbonate buffer system), it is relatively unimportant for buffering blood plasma. However, it is a very effective buffer in urine and in ICF, where phosphate concentrations are usually higher.

Protein Buffer System

Proteins in plasma and in cells are the body's most plentiful and powerful source of buffers, and constitute the **protein buffer system.** In fact, at least three-quarters of all the buffering power of body fluids resides in cells, and most of this reflects the buffering activity of intracellular proteins.

As described in Chapter 2, proteins are polymers of amino acids. Some of the linked amino acids have exposed groups of atoms called *organic acid (carboxyl) groups (—COOH),* which dissociate to release H^+ when the pH begins to rise:

$$R^*\text{–}COOH \rightarrow R\text{–}COO^- + H^+$$

Other amino acids have exposed groups that can act as bases and accept H^+. For example, an exposed $—NH_2$ group can bind with hydrogen ions, becoming $—NH_3^+$:

$$R\text{–}NH_2 + H^+ \rightarrow R\text{–}NH_3^+$$

Because this removes free hydrogen ions from the solution, it prevents the solution from becoming too acidic. Consequently, a single protein molecule can function reversibly as either an acid or a base depending on the pH of its environment. Molecules with this ability are called **amphoteric molecules** (am"fo-ter'ik).

Hemoglobin of red blood cells is an excellent example of a protein that functions as an intracellular buffer. As explained earlier, CO_2 released from the tissues forms H_2CO_3, which dissociates to liberate H^+ and HCO_3^- in the blood. Meanwhile, hemoglobin is unloading oxygen, becoming reduced hemoglobin, which carries a negative charge. Because H^+

* Note that R indicates the rest of the organic molecule, which contains many atoms.

rapidly binds to the hemoglobin anions, pH changes are minimized. In this case, carbonic acid, a weak acid, is buffered by an even weaker acid, hemoglobin.

Respiratory Regulation of H^+

Respiratory system regulation of acid-base balance provides a *physiological buffering system.* Although such a buffer system acts more slowly than a chemical buffer system, it has one to two times the buffering power of all the body's chemical buffers combined. As described in Chapter 22, the respiratory system eliminates CO_2 from the blood while replenishing its supply of O_2. Carbon dioxide generated by cellular respiration enters erythrocytes in the circulation and is converted to bicarbonate ions for transport in the plasma:

$$CO_2 + H_2O \underset{\text{carbonic anhydrase}}{\rightleftharpoons} \underset{\text{carbonic acid}}{H_2CO_3} \rightleftharpoons \underset{\text{bicarbonate ion}}{H^+ + HCO_3^-}$$

The first set of double arrows indicates a reversible equilibrium between dissolved carbon dioxide and water on the left and carbonic acid on the right. The second set indicates a reversible equilibrium between carbonic acid on the left and hydrogen and bicarbonate ions on the right. Because of these equilibria, an increase in any of these chemical species pushes the reaction in the opposite direction. Notice also that the right side of the equation is equivalent to the bicarbonate buffer system.

In healthy individuals, CO_2 is expelled from the lungs at the same rate it is formed in the tissues. During carbon dioxide unloading, the reaction shifts to the left, and H^+ generated from carbonic acid is reincorporated into water. Because of the protein buffer system, H^+ produced by CO_2 transport is not allowed to accumulate and has little or no effect on blood pH. However, when hypercapnia occurs, it activates medullary chemoreceptors (via cerebrospinal fluid acidosis promoted by excessive accumulation of CO_2) that respond by increasing respiratory rate and depth. Additionally, a rising plasma H^+ concentration resulting from any metabolic process excites the respiratory center indirectly (via peripheral chemoreceptors) to stimulate deeper, more rapid respiration. As ventilation increases, more CO_2 is removed from the blood, pushing the reaction to the left and reducing the H^+ concentration.

When blood pH rises, the respiratory center is depressed. As respiratory rate drops and respiration becomes shallower, CO_2 accumulates; the equilibrium is pushed to the right, causing the H^+ concentration to increase. Again blood pH is restored to the normal range. These respiratory system–mediated corrections of blood pH are accomplished within a minute or so.

Changes in alveolar ventilation can produce dramatic changes in blood pH—far more than is needed. For example, a doubling or halving of alveolar ventilation can raise or lower blood pH by about 0.2 pH unit. Because normal arterial pH is 7.4, a change of 0.2 pH unit yields a blood pH of 7.6 or 7.2—both well beyond the normal limits of blood pH. Actually, alveolar ventilation can be increased about 15-fold or reduced to zero. Thus, respiratory controls of blood pH have a tremendous reserve capacity.

Anything that impairs respiratory system functioning causes acid-base imbalances. For example, net carbon dioxide retention (hypoventilation) leads to acidosis; hyperventilation, which causes net elimination of CO_2, causes alkalosis. When the cause of the pH imbalance is respiratory system problems, the resulting condition is either *respiratory acidosis* or *respiratory alkalosis* (see Table 26.2 on p. 1056).

Renal Mechanisms of Acid-Base Balance

Chemical buffers can tie up excess acids or bases temporarily, but they cannot eliminate them from the body. And while the lungs can dispose of the **volatile acid** carbonic acid by eliminating CO_2, only the kidneys can rid the body of other acids generated by cellular metabolism: phosphoric, uric, and lactic acids, and ketone bodies. These acids are sometimes referred to as **metabolic (fixed) acids,** but this terminology is both unfortunate and incorrect because CO_2 and hence carbonic acid are also products of metabolism. Additionally, only the kidneys can regulate blood levels of alkaline substances and renew chemical buffers that are used up in regulating H^+ levels in the ECF. (HCO_3^-, which helps regulate H^+ levels, is lost from the body when CO_2 flushes from the lungs.) Thus, the ultimate acid-base regulatory organs are the kidneys, which act slowly but surely to compensate for acid-base imbalances resulting from variations in diet or metabolism or from disease.

The most important renal mechanisms for regulating acid-base balance of the blood involve (1) conserving (reabsorbing) or generating new HCO_3^-, and (2) excreting HCO_3^-. If we look back at the equation for the operation of the carbonic acid–bicarbonate buffer system of the blood, it is obvious that losing a HCO_3^- from the body produces the same net effect as gaining a H^+, because it pushes the equation to the right, increasing the H^+ level. By the same token, generating or reabsorbing HCO_3^- is the same as losing H^+ because it pushes the equation to the left, decreasing the H^+ level. Therefore, to reabsorb

bicarbonate, H^+ has to be secreted, and when we excrete excess HCO_3^-, H^+ is retained (not secreted).

Because the mechanisms for regulating acid-base balance depend on H^+ being secreted into the filtrate, we consider that process first. Secretion of H^+ occurs mainly in the PCT and in type A intercalated cells of the collecting duct. The H^+ secreted is obtained from the dissociation of carbonic acid, created from the combination of CO_2 and water within the tubule cells (Figure 26.12), a reaction catalyzed by *carbonic anhydrase*. For each H^+ secreted into the tubule lumen, one Na^+ is reabsorbed from the filtrate, maintaining the electrical balance.

The rate of H^+ secretion rises and falls with CO_2 levels in the ECF. The more CO_2 in the peritubular capillary blood, the faster the rate of H^+ secretion. Because blood CO_2 levels directly relate to blood pH, this system can respond to both rising and falling H^+ concentrations. Notice that secreted H^+ can combine with HCO_3^- in the filtrate, generating CO_2 and water. In this case, H^+ is bound in water. The rising concentration of CO_2 in the filtrate creates a steep diffusion gradient for its entry into the tubule cell, where it promotes still more H^+ secretion.

Conserving Filtered Bicarbonate Ions: Bicarbonate Reabsorption

Bicarbonate ions (HCO_3^-) are an important part of the bicarbonate buffer system, the most important inorganic blood buffer. If this reservoir of base, or *alkaline reserve*, is to be maintained, the kidneys must do more than just eliminate enough hydrogen ions to counter rising blood H^+ levels. Depleted stores of HCO_3^- have to be replenished. This is more complex than it seems because the tubule cells are almost completely impermeable to the HCO_3^- in the filtrate—they cannot reabsorb them. However, the kidneys can conserve filtered HCO_3^- in a rather roundabout way, also illustrated in Figure 26.12. As you can see, dissociation of carbonic acid liberates HCO_3^- as well as H^+. Although the tubule cells cannot reclaim HCO_3^- directly from the filtrate, they can and do shunt HCO_3^- generated within them (as a result of splitting H_2CO_3) into the peritubular capillary blood. HCO_3^- leaves the tubule cell either accompanied by Na^+ or in exchange for Cl^-. Thus, reabsorption of HCO_3^- depends on the active secretion of H^+, mostly by a Na^+-H^+ antiporter, but also by an H^+ ATPase. In the filtrate H^+ combines with filtered HCO_3^-. For each filtered HCO_3^- that "disappears," a HCO_3^- generated within the tubule cells enters the blood—a one-for-one exchange. When large amounts of H^+ are secreted, correspondingly large amounts of HCO_3^- enter the peritubular blood, and the net effect is that HCO_3^- is almost completely removed from the filtrate.

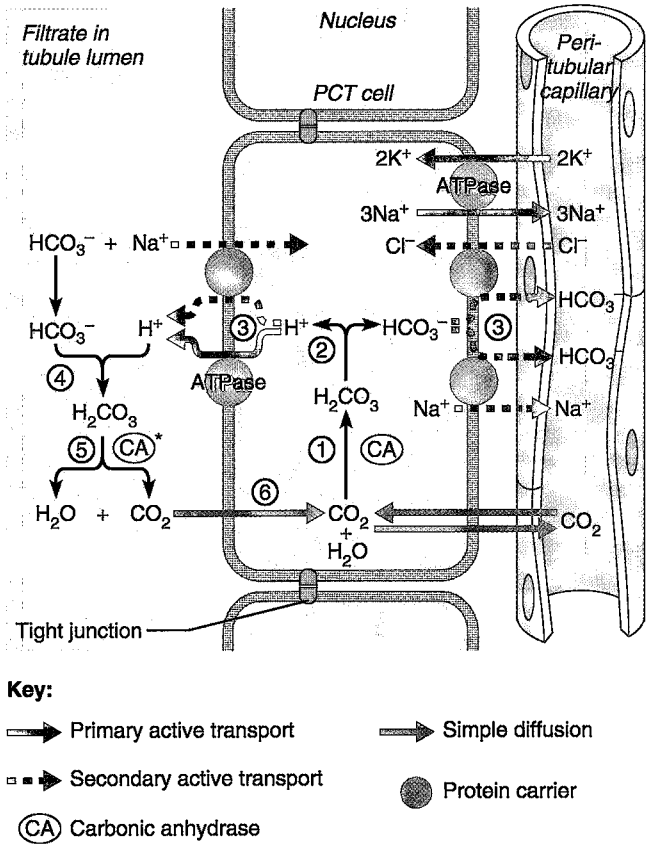

FIGURE 26.12 **Reabsorption of filtered HCO_3^- is coupled to H^+ secretion.** (Numbers by reaction lines indicate the sequence of events.)
① CO_2 combines with water within the tubule cell, forming H_2CO_3.
② H_2CO_3 is quickly split, forming H^+ and HCO_3^-.
③ For each H^+ secreted into the filtrate, a bicarbonate ion (HCO_3^-) enters the peritubular capillary blood by cotransport (either via symport with Na^+ or via antiport with Cl^-).
④ Secreted H^+ combines with HCO_3^- present in the tubular filtrate, forming carbonic acid (H_2CO_3). Thus, HCO_3^- disappears from the filtrate at the same rate that HCO_3^- (formed within the tubule cell) enters the peritubular capillary blood.
⑤ The H_2CO_3 formed in the filtrate dissociates to release carbon dioxide and water.
⑥ Carbon dioxide then diffuses into the tubule cell, where it acts to trigger further H^+ secretion.

*The breakdown of H_2CO_3 to CO_2 and H_2O in the tubule *lumen* is catalyzed by carbonic anhydrase *only* in the PCT.

Generating New Bicarbonate Ions

Two renal mechanisms commonly carried out by the type A intercalated cells of the collecting ducts generate *new* HCO_3^- that can be added to plasma. Both mechanisms involve renal excretion of acid, *via secretion and excretion* of either H^+ or ammonium ions in urine. Let's examine how these mechanisms differ.

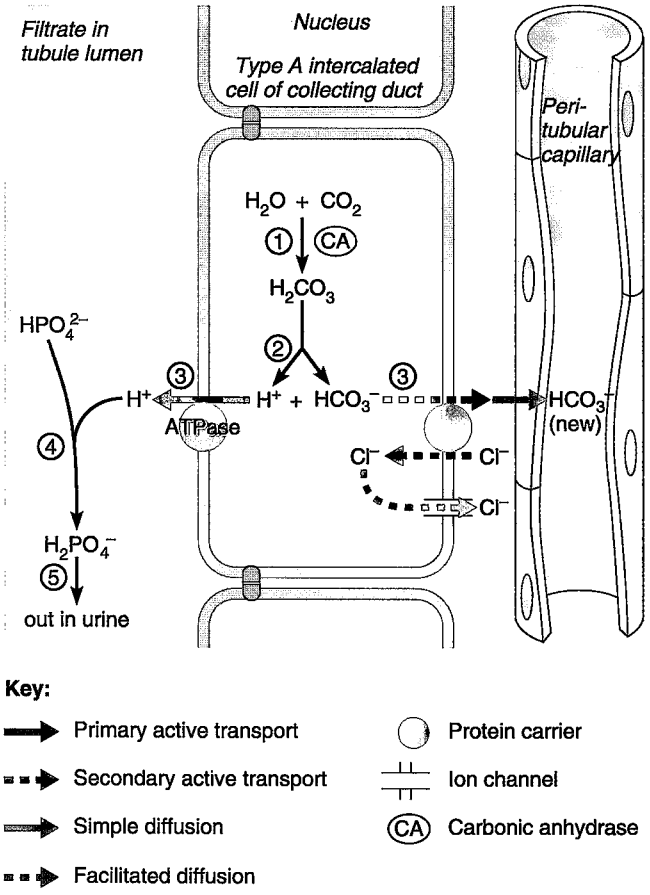

FIGURE 26.13 **Generation of new HCO_3^- via buffering of excreted H^+ by monohydrogen phosphate (HPO_4^{2-}).** H^+ from the dissociation of H_2CO_3 is actively secreted by a H^+ ATPase pump and combines with HPO_4^{2-} in the lumen. HCO_3^- generated at the same time leaves the basolateral membrane via an antiport carrier in a HCO_3^--Cl^- exchange process.

Via Excretion of Buffered H^+ As long as *filtered bicarbonate* is reclaimed (Figure 26.12), the secreted H^+ is *not excreted or lost* from the body in urine. Instead, the H^+ is buffered by HCO_3^- in the filtrate and ultimately becomes part of water molecules (most of which are reabsorbed).

However, once the filtered HCO_3^- is "used up" (this has usually been accomplished by the time the collecting ducts are reached), any additional H^+ secreted is excreted in urine. More often than not, this is the case.

Reclaiming filtered HCO_3^- simply restores the bicarbonate concentration of plasma that exists at the time. However, a normal diet introduces new H^+ into the body, and this additional H^+ must be balanced by the generation of new HCO_3^- (as opposed to filtered HCO_3^-) which moves into the blood to counteract acidosis. This process of alkalinizing the blood is the way the kidneys compensate for acidosis. The excreted H^+ also must bind with buffers in the filtrate. Otherwise, a urine pH incompatible with life would result. (H^+ secretion ceases when urine pH falls to 4.5.) The most important urine buffer is the *phosphate buffer system*, specifically its weak base *monohydrogen phosphate* (HPO_4^{2-}).

The components of the phosphate buffer system filter freely into the tubules, and about 75% of the filtered phosphate is reabsorbed. However, their absorption is inhibited during acidosis; therefore, the buffer pair becomes more and more concentrated as the filtrate moves through the renal tubules. As shown in Figure 26.13, the type A intercalated cells secrete H^+ actively via a H^+-ATPase pump and via a K^+-H^+ antiporter (not illustrated). The secreted H^+ combines with HPO_4^{2-}, forming $H_2PO_4^-$ which then flows out in urine. Bicarbonate ions generated in the cells during the same reaction move into the interstitial space via a HCO_3^--Cl^- antiport process and then move passively into the peritubular capillary blood. Notice again that when H^+ is being excreted, "brand new" bicarbonate ions are added to the blood—over and above those reclaimed from the filtrate. Thus, in response to acidosis, the kidneys generate new HCO_3^- and add it to the blood (alkalinizing the blood) while adding an equal amount of H^+ to the filtrate (acidifying the urine).

Via NH_4^+ Excretion The second and more important mechanism for excreting acid uses the ammonium ion (NH_4^+) produced by glutamine metabolism in the PCT cells (Figure 26.14). Ammonium ions are weak acids that donate few H^+ at physiological pH. For each glutamine metabolized (deaminated, oxidized, and acidified by combination with H^+), two NH_4^+ and two HCO_3^- result. The HCO_3^- moves through the basolateral membrane into the blood. The NH_4^+, in turn, is excreted and lost in urine. As with the phosphate buffer system, this buffering mechanism replenishes the alkaline reserve of the blood, because as NH_4^+ is secreted the newly made HCO_3^- enters the blood.

Bicarbonate Ion Secretion

When the body is in alkalosis, another population of intercalated cells (type B) in the collecting ducts exhibit net HCO_3^- secretion (rather than net HCO_3^- reabsorption) while reclaiming H^+ to acidify the blood. Overall the type B cells can be thought of as "flipped" type A cells and the HCO_3^- secretion process can be visualized as the exact opposite of the HCO_3^- reabsorption process illustrated in Figure 26.12. However, the predominant process in the nephrons and collecting ducts is HCO_3^- reabsorption, and even during alkalosis, the amount of HCO_3^- excreted is much less than the amount conserved.

Abnormalities of Acid-Base Balance

All cases of acidosis and alkalosis can be classed according to cause as *respiratory* or *metabolic* (Table 26.2). The methods for determining the cause of an acid-base disturbance and whether it is being compensated (whether the lungs or kidneys are taking steps to correct the imbalance) are described in *A Closer Look* on p. 1057.

Respiratory Acidosis and Alkalosis

Respiratory pH imbalances result from some failure of the respiratory system to perform its normal pH-balancing role. The partial pressure of carbon dioxide (P_{CO_2}) is the single most important indicator of the adequacy of respiratory function. When respiratory function is normal, the P_{CO_2} fluctuates between 35 and 45 mm Hg. Generally speaking, higher values indicate respiratory acidosis, and lower values indicate respiratory alkalosis.

Respiratory acidosis is the most common cause of acid-base imbalance. It most often occurs when a person breathes shallowly or when gas exchange is hampered by diseases such as pneumonia, cystic fibrosis, or emphysema. Under such conditions, CO_2 accumulates in the blood. Thus, respiratory acidosis is characterized by falling blood pH and rising P_{CO_2}.

Respiratory alkalosis results when carbon dioxide is eliminated from the body faster than it is produced, causing the blood to become more alkaline. This is called *hyperventilation* (see p. 866). While respiratory acidosis is frequently associated with respiratory system pathology, respiratory alkalosis is often due to stress or pain.

Metabolic Acidosis and Alkalosis

Metabolic pH imbalances include all abnormalities of acid-base imbalance *except* those caused by too much or too little carbon dioxide in the blood. Bicarbonate ion levels below or above the normal range of 22–26 mEq/L indicate a metabolic acid-base imbalance.

The second most common cause of acid-base imbalance, **metabolic acidosis,** is recognized by low blood pH and HCO_3^- levels. Typical causes of metabolic acidosis are ingestion of too much alcohol (which is metabolized to acetic acid) and excessive loss of HCO_3^-, as might result from persistent diarrhea. Other causes are accumulation of lactic acid during exercise or shock, the ketosis that occurs in diabetic crisis or starvation, and, infrequently, kidney failure.

Metabolic alkalosis, indicated by rising blood pH and HCO_3^- levels, is much less common than metabolic acidosis. Typical causes are vomiting of the acidic contents of the stomach (or loss of those secretions through gastrointestinal suctioning) and intake of excess base (antacids, for example).

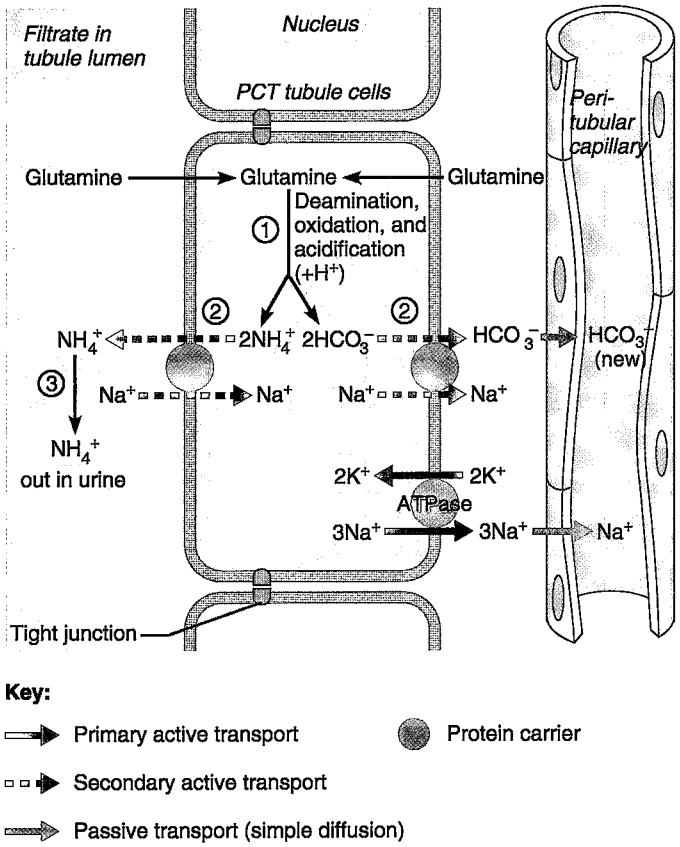

FIGURE 26.14 **Generation of new HCO_3^- via glutamine metabolism and NH_4^+ secretion.** PCT cells metabolize glutamine to NH_4^+ and HCO_3^-. NH_4^+ (a weak acid) is then actively secreted by occupying the H^+ site on the H^+-Na^+ antiporter. The new HCO_3^- generated moves into the peritubular capillary blood.

Effects of Acidosis and Alkalosis

The absolute blood pH limits for life are a low of 7.0 and a high of 7.8. When blood pH falls below 7.0, the central nervous system is so depressed that the person goes into coma and death soon follows. When blood pH rises above 7.8, the nervous system is overexcited, leading to such characteristic signs as muscle tetany, extreme nervousness, and convulsions. Death often results from respiratory arrest.

Respiratory and Renal Compensations

When an acid-base imbalance is due to inadequate functioning of one of the physiological buffer systems (the lungs or kidneys), the other system tries to compensate. The respiratory system attempts to compensate for metabolic acid-base imbalances, and the kidneys (although much slower) work to correct imbalances caused by respiratory disease. These **respiratory** and **renal compensations** can be recognized by changes in plasma P_{CO_2} and bicarbonate ion

TABLE 26.2 Causes and Consequences of Acid-Base Imbalances

CONDITION AND HALLMARK	POSSIBLE CAUSES; COMMENTS
METABOLIC ACIDOSIS	
uncompensated (uncorrected) (HCO_3^- <22 mEq/L; pH <7.35)	**Severe diarrhea:** bicarbonate-rich intestinal (and pancreatic) secretions rushed through digestive tract before their solutes can be reabsorbed; bicarbonate ions are replaced by renal mechanisms that generate new bicarbonate ions **Renal disease:** failure of kidneys to rid body of acids formed by normal metabolic processes **Untreated diabetes mellitus:** lack of insulin or inability of tissue cells to respond to insulin, resulting in inability to use glucose; fats are used as primary energy fuel, and ketoacidosis occurs **Starvation:** lack of dietary nutrients for cellular fuels; body proteins and fat reserves are used for energy—both yield acidic metabolites as they are broken down for energy **Excess alcohol ingestion:** results in excess acids in blood **High ECF potassium concentrations:** potassium ions compete with H^+ for secretion in renal tubules; when ECF levels of K^+ are high, H^+ secretion is inhibited
METABOLIC ALKALOSIS	
uncompensated (HCO_3^- >26 mEq/L; pH >7.45)	**Vomiting or gastric suctioning:** loss of stomach HCl requires that H^+ be withdrawn from blood to replace stomach acid; thus H^+ decreases and HCO_3^- increases proportionately **Selected diuretics:** cause K^+ depletion and H_2O loss. Low K^+ directly stimulates the tubule cells to secrete H^+. Reduced blood volume elicits the renin-angiotensin mechanism, which stimulates Na^+ reabsorption and H^+ secretion. **Ingestion of excessive sodium bicarbonate (antacid):** bicarbonate moves easily into ECF, where it enhances natural alkaline reserve **Excess aldosterone** (e.g., adrenal tumors): promotes excessive reabsorption of Na^+, which pulls increased amount of H^+ into urine. Hypovolemia promotes the same relative effect because aldosterone secretion is increased to enhance Na^+ (and H_2O) reabsorption.
RESPIRATORY ACIDOSIS (HYPOVENTILATION)	
uncompensated (>45 mm Hg; pH <7.35)	**Impaired lung function** (e.g., in chronic bronchitis, cystic fibrosis, emphysema): impaired gas exchange or alveolar PCO_2 ventilation **Impaired ventilatory movement:** paralysis of respiratory muscles, chest injury, extreme obesity **Narcotic or barbiturate overdose or injury to brain stem:** depression of respiratory centers, resulting in hypoventilation and respiratory arrest
RESPIRATORY ALKALOSIS (HYPERVENTILATION)	
uncompensated (P_{CO_2} <35 mm Hg; pH >7.45)	**Strong emotions**: pain, anxiety, fear, panic attack **Hypoxia:** asthma, pneumonia, high altitude; represents effort to raise P_{O_2} at the expense of excessive CO_2 excretion **Brain tumor or injury**: abnormality of respiratory controls

concentrations (see *A Closer Look*). Because the compensations act to restore normal blood pH, the pH may actually be in the normal range when the patient has a significant medical problem.

Respiratory Compensations As a rule, changes in respiratory rate and depth are evident when the respiratory system is attempting to compensate for metabolic acid-base imbalances. In metabolic acidosis, the respiratory rate and depth are usually elevated—an indication that the respiratory centers are stimulated by the high H^+ levels. The blood pH is low (below 7.35) and the HCO_3^- level is below 22 mEq/L. As the respiratory system "blows off" CO_2 to rid the blood of excess acid, the P_{CO_2} falls below 35 mm Hg. By contrast,

A CLOSER LOOK

Sleuthing: Using Blood Values to Determine the Cause of Acidosis or Alkalosis

Students, particularly nursing students, are often given blood values and asked to determine (1) whether the patient is in acidosis or alkalosis, (2) the cause of the condition (respiratory or metabolic), and (3) whether the condition is being compensated. If they are approached systematically, such determinations are not nearly as difficult as they may appear. To analyze a person's acid-base balance, scrutinize the blood values in the following order:

1. Note the pH. This tells you whether the person is in acidosis (pH below 7.35) or alkalosis (pH above 7.45), but it does *not* tell you the cause.

2. Next, check the P_{CO_2} to see if this is the cause of the acid-base imbalance. Because the respiratory system is a fast-acting system, an excessively high or low P_{CO_2} may indicate either that the condition is respiratory system–caused or that the respiratory system is compensating. For example, if the pH indicates acidosis and

a. The P_{CO_2} is over 45 mm Hg, the respiratory system is the *cause* of the problem and the condition is a respiratory acidosis

b. The P_{CO_2} is below normal limits (below 35 mm Hg), the respiratory system is *not the cause but is compensating*

c. The P_{CO_2} is within normal limits, the condition is *neither caused nor compensated* by the respiratory system

3. Check the bicarbonate level. If step 2 proves that the respiratory system is not responsible for the imbalance, then the condition is metabolic and should be reflected in increased or decreased bicarbonate levels. Metabolic acidosis is indicated by HCO_3^- values below 22 mEq/L, and metabolic alkalosis by values over 26 mEq/L. Notice that whereas P_{CO_2} levels vary inversely with blood pH (P_{CO_2} rises as blood pH falls), HCO_3^- levels vary directly with blood pH (increased HCO_3^- results in increased pH).

Beyond this bare-bones approach there is something else to consider when you are assessing acid-base problems. If an imbalance is *fully* compensated, the pH may be normal even while the patient is in trouble. Hence, when the pH is normal, carefully scrutinize the P_{CO_2} or HCO_3^- values for clues to what imbalance may be occurring.

Consider the following two examples of the three-step approach.

Problem 1

Blood values: pH 7.5; P_{CO_2} 24 mm Hg; HCO_3^- 23 mEq/L

Analysis:

1. The pH is elevated: alkalosis.

2. The P_{CO_2} is very low: the cause of the alkalosis.

3. The HCO_3^- value is within normal limits.

Conclusion: This is a respiratory alkalosis not compensated by renal mechanisms, as might occur during short-term hyperventilation.

Problem 2

Blood values: pH 7.48; P_{CO_2} 46 mm Hg; HCO_3^- 33 mEq/L

Analysis:

1. The pH is elevated: alkalosis.

2. The P_{CO_2} is elevated: the cause of *acidosis,* not alkalosis; thus, the respiratory system is compensating and is not the cause.

3. The HCO_3^- is elevated: the cause of the alkalosis.

Conclusion: This is a metabolic alkalosis being compensated by respiratory acidosis (retention of CO_2 to restore blood pH to the normal range).

See the accompanying simple chart to help you in your future determinations.

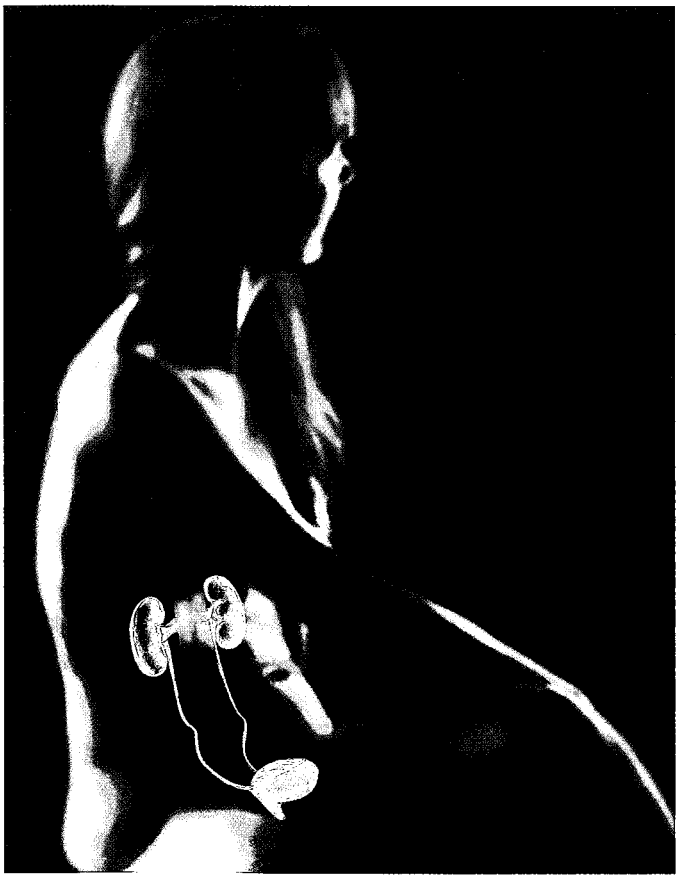
	Normal Range in Plasma		
Acid-base Disturbance	**pH 7.35–7.45**	**P_{CO_2} 35–45 mm HG**	**HCO_3^- 22–26 mEq/L**
Respiratory acidosis	↓	↑	↑ if compensating
Respiratory alkalosis	↑	↓	↓ if compensating
Metabolic acidosis	↓	↓ if compensating	↓
Metabolic alkalosis	↑	↑ if compensating	↑

in respiratory acidosis, the respiratory rate is often depressed and *is the immediate cause of the acidosis* (with some exceptions such as pneumonia or emphysema where gas exchange is impaired).

Respiratory compensation for metabolic alkalosis involves slow, shallow breathing, which allows CO_2 to accumulate in the blood. A metabolic alkalosis being compensated by respiratory mechanisms is revealed by a pH over 7.45 at least initially, elevated bicarbonate levels (over 26 mEq/L), and a P_{CO_2} above 45 mm Hg.

Renal Compensations When an acid-base imbalance is of respiratory origin, renal mechanisms are stepped up to correct the imbalance. For example,

SYSTEM CONNECTIONS: Homeostatic Interrelationships Between the Urinary System and Other Body Systems



Integumentary System

- Kidneys dispose of nitrogenous wastes; maintain fluid, electrolyte, and acid-base balance of blood
- Skin provides external protective barrier; site of water loss (via perspiration); vitamin D synthesis site

Skeletal System

- Kidneys dispose of nitrogenous wastes; maintain fluid, electrolyte, and acid-base balance of blood
- Bones of rib cage provide some protection to kidneys; form major store of calcium and phosphate ions

Muscular System

- Kidneys dispose of nitrogenous wastes; maintain fluid, electrolyte, and acid-base balance of blood; renal regulation of Na^+, K^+, and Ca^{2+} content in ECF crucial for muscle excitability and contractility
- Muscles of pelvic diaphragm and external urethral sphincter function in voluntary control of micturition; creatinine is a nitrogenous waste product of muscle metabolism that must be excreted by the kidneys

Nervous System

- Kidneys dispose of nitrogenous wastes; maintain fluid, electrolyte, and acid-base balance of blood; renal control of Na^+, K^+, and Ca^{2+} in ECF essential for normal neural function
- Neural controls involved in micturition; sympathetic nervous system activity triggers the renin-angiotensin mechanism

Endocrine System

- Kidneys dispose of nitrogenous wastes; maintain fluid, electrolyte, and acid-base balance of blood; produce erythropoietin; renal regulation of Na^+ and water balance essential for blood pressure homeostasis and hormone transport in blood
- ADH, aldosterone, ANP, and other hormones help regulate renal reabsorption of water and electrolytes

Cardiovascular System

- Kidneys dispose of nitrogenous wastes; maintain fluid, electrolyte, and acid-base balance of blood; renal regulation of Na^+/water balance essential for blood pressure homeostasis. Na^+, K^+, and Ca^{2+} regulation maintains cardiac irritability
- Systemic arterial blood pressure is the driving force for glomerular filtration; heart secretes atrial natriuretic peptide; blood transports nutrients, oxygen, etc. to urinary organs

Lymphatic System/Immunity

- Kidneys dispose of nitrogenous wastes; maintain fluid, electrolyte, and acid-base balance of blood
- By returning leaked plasma fluid to cardiovascular system, lymphatic vessels help ensure normal systemic arterial pressure required for kidney function; immune cells protect urinary organs from infection and cancer

Respiratory System

- Kidneys dispose of nitrogenous wastes; maintain fluid, electrolyte, and long-term acid-base balance of blood
- Respiratory system provides oxygen required by kidney cells for their high metabolic activity; disposes of carbon dioxide; rapid acid-base balance of blood; lung capillary endothelial cells convert angiotensin I to angiotensin II

Digestive System

- Kidneys dispose of nitrogenous wastes; maintain fluid, electrolyte, and acid-base balance of blood; also, metabolize vitamin D to the active form needed for calcium absorption
- Digestive organs provide nutrients needed for kidney cell health; liver synthesizes urea and glutamine to transport waste nitrogen to the kidneys for excretion

Reproductive System

- Kidneys dispose of nitrogenous wastes; maintain fluid, electrolyte, and acid-base balance of blood

THE URINARY SYSTEM and Interrelationships with the Cardiovascular, Endocrine, and Nervous Systems

A drink of water—such a simple thing. It quenches a powerful thirst, but that's not all. Inadequate hydration can cause poor functioning, both mental and physical, and fatigue, illness, and even death. The body also needs water to regulate its temperature via perspiration, to wash wastes and toxins out of the body in urine, to maintain proper blood volume and pressure, and to keep the skeletal muscles well hydrated (otherwise they feel weak and tire quickly, and even stop working altogether). A drink provides that needed water, but it takes the kidneys to keep it pure so that all of these vital activities can continue to occur. Seemingly wise, the exceedingly tiny nephrons "know" which blood solutes are valuable and which disposable, and that alcohol and caffeine are diuretics and as such drain water from the body. Make no mistake about it, the kidneys are crucially important to the body—all systems, all cells. The body systems that most influence the kidneys' ability to do their life-sustaining work are the cardiovascular, endocrine, and nervous systems.

Cardiovascular System

As important as they are, and as intricate as their functioning is, the kidneys cannot work without blood to process and blood pressure to drive filtrate through the glomerular filters. When we hemorrhage severely, the GFR drops and the kidneys stop functioning altogether. When blood pressure is normal, it provides the driving force that allows the nephrons to perform their job. On the other hand, by excreting or retaining water, the kidneys maintain the blood volume that furnishes that filtration pressure.

Endocrine System and Nervous System

The kidneys have a whole "toolbox" of ways to ensure that their own blood pressure is normal. However, autoregulation can be overridden by hormonal mechanisms (the renin-angiotensin mechanism which calls aldosterone and ADH into service, and release of ANP by the heart) in order to maintain systemic blood pressure. Sympathetic activity also ensures that bodywide blood pressure is maintained within homeostatic limits so as to maintain adequate GFR. Alternatively, the kidneys' needs are overcome as necessary by the same sympathetic fibers to make sure that the heart and brain receive adequate blood perfusion in periods of dramatically falling blood pressure. Now that's flexibility!

CLINICAL CONNECTIONS

Urinary System

Case study: Mr. Heyden, a somewhat stocky 72-year-old man, is brought in to the emergency room (ER). The paramedics report that his left arm and the left side of his body trunk were pinned beneath some wreckage, and that when he was freed, his left hypogastric and lumbar areas appeared to be compressed and his left arm was blanched and without sensation. On admission, Mr. Heyden is alert, slightly cyanotic, and complaining of pain in his left side; he loses consciousness shortly thereafter. His vital signs are taken, blood is drawn for laboratory tests, and Mr. Heyden is catheterized and immediately scheduled for a CT scan of his left abdominal region.

Analyze the information that was subsequently recorded on Mr. Heyden's chart:

- Re vital signs: Temperature 102°F; BP 90/50 mm Hg and falling; heart rate 116 beats/min and thready; 30 respirations/min

1. Given the values above and his attendant cyanosis, what would you guess is Mr. Heyden's immediate problem? Explain your reasoning.

- Re CT scan: CT scan reveals a ruptured spleen and a large hematoma in the upper left abdominal quadrant. Splenic repair surgery is scheduled but unsuccessful; the spleen is removed.

2. Rupture of the spleen results in massive hemorrhage. Explain this observation. What organs (if any) will compensate for the removal of Mr. Heyden's spleen?

- Re hematology data: Most blood tests yield normal results. However, renin, aldosterone, and ADH levels are elevated.

3. Explain the cause and consequence of each of the hematology findings.

- Re urinalysis: Some granular casts (particulate cell debris) are noted, and the urine is brownish-red in color; other values are normal, but urine output is very low. An order is given to force fluids.

4. What might account for (1) the low volume of urine output? (Name at least two possibilities.) (2) the casts and abnormal color of his urine? Can you see any possible relationship between his crush injury and these findings?

The next day, Mr. Heyden is awake and alert. He says that he now has feeling in his arm, but he is still complaining of pain. However, the pain site appears to have moved from the left upper quadrant to his lumbar region. His urine output is still low. He is scheduled once again for a CT scan, this time of his lumbar region. The order to force fluids is renewed and some additional and more specific blood tests are ordered. We will visit Mr. Heyden again shortly, but in the meantime think about what these new findings may indicate.

(Answers in Appendix G)

a hypoventilating individual will exhibit acidosis. When renal compensation is occurring, both the P_{CO_2} and the HCO_3^- levels are high. The high P_{CO_2} is the cause of the acidosis, and the rising HCO_3^- level indicates that the kidneys are retaining bicarbonate to offset the acidosis. Conversely, a person with renal-compensated respiratory alkalosis will have a high blood pH and a low P_{CO_2}. Bicarbonate ion levels begin to fall as the kidneys eliminate more HCO_3^- from the body by failing to reclaim it or by actively secreting it. Note that the kidneys cannot compensate for alkalosis or acidosis if that condition reflects a *renal* problem.

Developmental Aspects of Fluid, Electrolyte, and Acid-Base Balance

An embryo and a very young fetus are more than 90% water, but solids accumulate as fetal development continues, and at birth an infant is "only" 70–80% water. (The average value for adults is 58%.) Infants have proportionately more ECF than adults and, consequently, a much higher NaCl content in relation to K^+, Mg^{2+}, and PO_4^{3-} salts. Distribution of body water begins to change about two months after birth and achieves the adult pattern by the time the child is 2 years old. Although plasma electrolyte concentrations are similar in infants and adults, K^+ and Ca^{2+} values are higher and Mg^{2+}, HCO_3^-, and total protein levels are lower in the first few days of life than at any other time. At puberty, sex differences in body water content become obvious as males develop relatively greater amounts of skeletal muscle.

Problems with fluid, electrolyte, and particularly acid-base balance are most common in infancy, reflecting the following conditions:

1. The very low residual volume of infant lungs (approximately half that of adults relative to body weight). When respiration is altered, rapid and dramatic changes in P_{CO_2} can result.

2. The high rate of fluid intake and output in infants (about seven times higher than in adults). Infants may exchange fully half their ECF daily. Though infants have proportionately much more body water than adults, this does not protect them from excessive fluid shifts. Even slight alterations in fluid balance can cause serious problems. Further, although adults can live without water for about ten days, infants can survive for only three to four days.

3. The relatively high infant metabolic rate (about twice that of adults). The higher metabolic rate yields much larger amounts of metabolic wastes and acids that need to be excreted by the kidneys. This, along with buffer systems that are not yet fully effective, results in a tendency toward acidosis.

4. The high rate of insensible water loss in infants because of their larger surface area relative to body volume (about three times that of adults). Infants lose substantial amounts of water through their skin.

5. The inefficiency of infant kidneys. At birth, the kidneys are immature, only about half as proficient as adult kidneys at concentrating urine, and notably inefficient at ridding the body of acids.

All these factors put newborns at risk for dehydration and acidosis, at least until the end of the first month when the kidneys achieve reasonable efficiency. Bouts of vomiting or diarrhea greatly amplify the risk.

In old age, total body water often decreases (the loss is largely from the intracellular compartment) because muscle mass progressively declines and body fat rises. Although few changes occur in the solute concentrations of body fluids, the speed with which homeostasis is restored after being disrupted declines with age. Elders may be unresponsive to thirst cues and thus are at risk for dehydration. Additionally, they are the most frequent prey of diseases that lead to severe fluid, electrolyte, or acid-base problems, such as congestive heart failure (and its attendant edema) and diabetes mellitus. Because most fluid, electrolyte, and acid-base imbalances occur when body water content is highest or lowest, the very young and the very old are the most frequent victims.

■ ■ ■

This chapter has examined the chemical and physiological mechanisms that provide the optimal internal environment for survival. Although the kidneys are the "Rolex" among homeostatic organs in regulating water, electrolyte, and acid-base balance, they do not and cannot act alone. Rather, their activity is made possible by a host of hormones and enhanced both by bloodborne buffers, which give the kidneys time to react, and by the respiratory system, which shoulders a substantial responsibility for acid-base balance of the blood. Now that we have discussed the topics relevant to renal functioning, and once you read in *Making Connections* how the urinary system interacts with other body systems, the topics in Chapters 25 and 26 should draw together in an understandable way.

Related Clinical Terms

Antacid An agent that counteracts acidity, such as sodium bicarbonate, aluminum hydroxide gel, and magnesium trisilicate. Commonly used in the management of heartburn.

Hyperaldosteronism (Conn's disease) A condition of hypersecretion of aldosterone by adrenal cortical cells accompanied by excessive loss of potassium and generalized muscular weakness, hypernatremia, and hypertension. Usual cause is adrenal tumor; usual treatment is adrenal-suppressing drugs prior to tumor removal.

Renal tubular acidosis A metabolic acidosis resulting from impaired renal reabsorption of bicarbonate; the urine is alkaline.

Syndrome of inappropriate ADH secretion (SIADH) A group of disorders associated with excessive ADH secretion in the absence of appropriate (osmotic or nonosmotic) stimuli. Characterized by hyponatremia, concentrated urine, fluid retention, and weight gain. Usual causes are ectopic secretion of ADH by cancer cells (e.g., bronchogenic cancer cells) and brain disorders or trauma affecting the ADH-secreting hypothalamic neurons. Temporary management involves water restriction.

Chapter Summary

Media study tools that could provide you additional help in reviewing specific key topics of Chapter 26 are referenced below.
IP = *InterActive Physiology*

Body Fluids (pp. 1036–1038)

Body Water Content (p. 1036)

1. Water accounts for 45–75% of body weight, depending on age, sex, and amount of body fat.

Fluid Compartments (p. 1036)

2. About two-thirds (25 L) of body water is found within cells in the intracellular fluid (ICF) compartment; the balance (15 L) is in the extracellular fluid (ECF) compartment. The ECF includes plasma and interstitial fluid.

Composition of Body Fluids (pp. 1036–1037)

3. Solutes dissolved in body fluids include electrolytes and nonelectrolytes. Electrolyte concentration is expressed in mEq/L.

4. Plasma contains more proteins than does interstitial fluid; otherwise, extracellular fluids are similar. The most abundant ECF electrolytes are sodium, chloride, and bicarbonate ions.

5. Intracellular fluids contain large amounts of protein anions and potassium, phosphate, and magnesium ions.

IP Fluid, Electrolyte, and Acid/Base Balance; Topic: Introduction to Body Fluids, pp. 1–8.

Fluid Movement Among Compartments (pp. 1037–1039)

6. Fluid exchanges between compartments are regulated by osmotic and hydrostatic pressures: (a) Filtrate is forced out of the capillaries by hydrostatic pressure and pulled back in by colloid osmotic pressure. (b) Water moves freely between the ECF and the ICF by osmosis, but solute movements are restricted by size, charge, and dependence on transport proteins. (c) Water flows always follow changes in ECF osmolality.

7. Plasma links the internal and external environments.

IP Fluid, Electrolyte, and Acid/Base Balance; Topic: Introduction to Body Fluids, pp. 19–23.

Water Balance and ECF Osmolality (pp. 1039–1043)

1. Sources of body water are ingested foods and fluids and metabolic water.

2. Water leaves the body via the lungs, skin, gastrointestinal tract, and kidneys.

Regulation of Water Intake (pp. 1039–1040)

3. Increased plasma osmolality triggers the thirst mechanism, mediated by hypothalamic osmoreceptors. Thirst, inhibited by distension of the gastrointestinal tract by ingested water and then by osmotic signals, may be damped before body needs for water are met.

Regulation of Water Output (pp. 1040–1041)

4. Obligatory water loss is unavoidable and includes insensible water losses from the lungs, the skin, in feces, and about 500 ml of urine output daily.

5. Beyond obligatory water loss, the volume of urinary output depends on water intake and loss via other routes and reflects the influence of antidiuretic hormone and aldosterone on the renal tubules.

Influence of ADH (p. 1041)

6. Antidiuretic hormone causes aquaporins (water channels) to be inserted in the cell membranes of the collecting ducts, so that most filtered water is reabsorbed. ADH release is triggered if ECF osmolality is high, or if a large drop in blood volume or pressure occurs.

Disorders of Water Balance (pp. 1041–1043)

7. Dehydration occurs when water loss exceeds water intake over time. It is evidenced by thirst, dry skin, and decreased urine output. A serious consequence is hypovolemic shock.

8. Hypotonic hydration occurs when body fluids are excessively diluted and cells become swollen by water entry. The most serious consequence is cerebral edema.

9. Edema is an abnormal accumulation of fluid in the interstitial space, which may impair blood circulation.

IP Fluid, Electrolyte, and Acid/Base Balance; Topic: Water Homeostasis, pp. 1–27.

Electrolyte Balance (pp. 1043–1049)

1. Most electrolytes (salts) are obtained from ingested foods and fluids. Salts, particularly NaCl, are often ingested in excess of need.

2. Electrolytes are lost in perspiration, feces, and urine. The kidneys are most important in regulating electrolyte balance.

The Central Role of Sodium in Fluid and Electrolyte Balance (p. 1043)

3. Sodium salts are the most abundant solutes in ECF. They exert the bulk of ECF osmotic pressure and control water volume and distribution in the body.

4. Na^+ transport by the renal tubule cells is coupled to and helps regulate K^+, Cl^-, HCO_3^-, and H^+ concentrations in the ECF.

Regulation of Sodium Balance (pp. 1043–1048)

5. Sodium ion balance is linked to ECF volume and blood pressure regulation and involves both neural and hormonal controls.

6. Aldosterone promotes Na^+ reabsorption and H_2O conservation, unless other mechanisms favor water excretion.

7. Declining blood pressure and falling filtrate osmolality stimulate the granular cells to release renin. Renin, via angiotensin II, enhances systemic blood pressure and aldosterone release.

8. Cardiovascular system baroreceptors sense changing arterial blood pressure, prompting changes in sympathetic vasomotor activity. Rising arterial pressure leads to vasodilation and enhanced Na^+ and water loss in urine. Falling arterial pressure promotes vasoconstriction and conserves Na^+ and water.

9. Atrial natriuretic peptide, released by certain atrial cells in response to rising blood pressure (or blood volume), causes systemic vasodilation and inhibits renin, aldosterone, and ADH release. Hence, it enhances Na^+ and water excretion, reducing blood volume and blood pressure.

10. Estrogens and glucocorticoids increase renal retention of sodium. Progesterone promotes enhanced sodium and water excretion in urine.

Regulation of Potassium Balance (pp. 1048–1049)

11. About 90% of filtered potassium is reabsorbed by the more proximal regions of the nephrons.

12. The main thrust of renal regulation of K^+ is to excrete it. Potassium ion secretion by the principal cells of the cortical collecting ducts is enhanced by increased plasma K^+ content and aldosterone. Type A cells of the collecting duct reabsorb small amounts of K^+ during K^+ deficit.

Regulation of Calcium and Phosphate Balance (p. 1049)

13. Calcium balance is regulated primarily by parathyroid hormone (PTH), which enhances blood Ca^{2+} levels by targeting the bones, intestine, and kidneys. PTH-regulated reabsorption occurs primarily in the DCT.

14. PTH decreases renal reabsorption of phosphate ions.

Regulation of Anions (p. 1049)

15. When blood pH is normal or slightly high, chloride is the major anion accompanying sodium reabsorption. In acidosis, chloride is replaced by bicarbonate.

16. Reabsorption of most other anions is regulated by their transport maximums (T_m).

IP Fluid, Electrolyte, and Acid/Base Balance; Topic: Electrolyte Homeostasis, pp. 1–38.

Acid-Base Balance (pp. 1049–1057, 1060)

1. Acids are proton (H^+) donors; bases are proton acceptors. Acids that dissociate completely in solution are strong acids; those that dissociate incompletely are weak acids. Strong bases are more effective proton acceptors than are weak bases.

2. The homeostatic pH range of arterial blood is 7.35 to 7.45. A higher pH represents alkalosis; a lower pH reflects acidosis.

3. Some acids enter the body in foods, but most are generated by breakdown of phosphorus-containing proteins, incomplete oxidation of fats or glucose, and the loading and transport of carbon dioxide in the blood.

4. Acid-base balance is achieved by chemical buffers, respiratory regulation, and in the long term by renal regulation of bicarbonate ion (hence, hydrogen ion) concentration of body fluids.

IP Fluid, Electrolyte, and Acid/Base Balance; Topic: Acid/Base Homeostasis, pp. 1–15.

Chemical Buffer Systems (pp. 1050–1052)

5. Chemical buffers are single or paired sets (a weak acid and its salt) of molecules that act rapidly to resist excessive shifts in pH by releasing or binding H^+.

6. Chemical buffers of the body include the bicarbonate, phosphate, and protein buffer systems.

IP Fluid, Electrolyte, and Acid/Base Balance; Topic: Acid/Base Homeostasis, pp. 16–26.

Respiratory Regulation of H^+ (p. 1052)

7. Respiratory regulation of acid-base balance of the blood utilizes the bicarbonate buffer system and the fact that CO_2 and H_2O are in reversible equilibrium with H_2CO_3.

8. Acidosis activates the respiratory center to increase respiratory rate and depth, which eliminates more CO_2 and causes blood pH to rise. Alkalosis depresses the respiratory center, resulting in CO_2 retention and a fall in blood pH.

IP Fluid, Electrolyte, and Acid/Base Balance; Topic: Acid/Base Homeostasis, pp. 27–28.

Renal Mechanisms of Acid-Base Balance (pp. 1052–1054)

9. The kidneys provide the major long-term mechanism for controlling acid-base balance by maintaining stable HCO_3^- levels in the ECF. Metabolic acids (organic acids other than carbonic acid) can be eliminated from the body only by the kidneys.

10. Secreted hydrogen ions come from the dissociation of carbonic acid generated within the tubule cells.

11. Tubule cells are impermeable to bicarbonate in the filtrate, but they can conserve filtered bicarbonate ions indirectly by absorbing HCO_3^- generated within them (by dissociation of carbonic acid to HCO_3^- and H^+). For each HCO_3^- (and Na^+) reabsorbed, one H^+ is secreted into the filtrate, where it combines with HCO_3^-.

12. To generate and add new HCO_3^- to plasma to counteract acidosis, either of two mechanisms may be used:
- Secreted H^+, buffered by bases other than HCO_3^-, is excreted from the body in urine (the major urine buffer is the phosphate buffer system).
- NH_4^+ (derived from glutamine catabolism) is excreted in urine.

13. To counteract alkalosis, bicarbonate ion is secreted into the filtrate and H^+ is reabsorbed.

IP Fluid, Electrolyte, and Acid/Base Balance; Topic: Acid/Base Homeostasis, pp. 29–37.

Abnormalities of Acid-Base Balance (pp. 1055–1057, 1060)

14. Classification of acid-base imbalances as metabolic or respiratory indicates the cause of the acidosis or alkalosis.

15. Respiratory acidosis results from carbon dioxide retention; respiratory alkalosis occurs when carbon dioxide is eliminated faster than it is produced.

16. Metabolic acidosis occurs when fixed acids (lactic acid, ketone bodies, and others) accumulate in the blood or when bicarbonate is lost from the body; metabolic alkalosis occurs when bicarbonate levels are excessive.

17. Extremes of pH for life are 7.0 and 7.8.

18. Compensations occur when the respiratory system or kidneys act to reverse acid-base imbalances resulting from abnormal or inadequate functioning of the alternate system. Respiratory compensations involve changes in respiratory rate and depth. Renal compensations modify blood levels of HCO_3^-.

Fluid, Electrolyte, and Acid/Base Balance; Topic: Acid/Base Homeostasis, pp. 38–59.

Developmental Aspects of Fluid, Electrolyte, and Acid-Base Balance (p. 1060)

1. Infants have a higher risk of dehydration and acidosis because of their low lung residual volume, high rate of fluid intake and output, high metabolic rate, relatively large body surface area, and functionally immature kidneys at birth.

2. The elderly are at risk for dehydration because of their low percentage of body water and insensitivity to thirst cues. Diseases that promote fluid and acid-base imbalances (cardiovascular disease, diabetes mellitus, and others) are most common in the aged.

Review Questions

Multiple Choice/Matching

(Some questions have more than one correct answer. Select the best answer or answers from the choices given.)

1. Body water content is greatest in (a) infants, (b) young adults, (c) elderly adults.

2. Potassium, magnesium, and phosphate ions are the predominant electrolytes in (a) plasma, (b) interstitial fluid, (c) intracellular fluid.

3. Sodium balance is regulated primarily by control of amount(s) (a) ingested, (b) excreted in urine, (c) lost in perspiration, (d) lost in feces.

4. Water balance is regulated primarily by control of amount(s) (use choices in question 3).

5–10. Answer questions 5 through 10 by choosing responses from the following:

(a) ammonium ions	**(f)** magnesium
(b) bicarbonate	**(g)** phosphate
(c) calcium	**(h)** potassium
(d) chloride	**(i)** sodium
(e) hydrogen ions	**(j)** water

5. Three substances regulated (at least in part) by the influence of aldosterone on the kidney tubules.

6. Two substances regulated by parathyroid hormone.

7. Two substances secreted into the proximal convoluted tubules in exchange for sodium ions.

8. Part of an important chemical buffer system in plasma.

9. Two ions produced during catabolism of glutamine.

10. Substance regulated by ADH's effects on the renal tubules.

11. Which of the following factors will enhance ADH release? (a) increase in ECF volume, (b) decrease in ECF volume, (c) decrease in ECF osmolality, (d) increase in ECF osmolality.

12. The pH of blood varies *directly* with (a) HCO_3^-, (b) P_{CO_2}, (c) H^+, (d) none of the above.

13. In an individual with metabolic acidosis, a clue that the respiratory system is compensating is provided by (a) high blood bicarbonate levels, (b) low blood bicarbonate levels, (c) rapid, deep breathing, (d) slow, shallow breathing.

Short Answer Essay Questions

14. Name the body fluid compartments, noting their locations and the approximate fluid volume in each.

15. Describe the thirst mechanism, indicating how it is triggered and terminated.

16. Explain why and how ECF osmolality is maintained.

17. Explain why and how sodium balance, ECF volume, and blood pressure are jointly regulated.

18. Describe the role of the respiratory system in controlling acid-base balance.

19. Explain how the chemical buffer systems resist changes in pH.

20. Explain the relationship of the following to renal secretion and excretion of hydrogen ions: (a) plasma carbon dioxide levels, (b) phosphate, and (c) sodium bicarbonate reabsorption.

21. List several factors that place newborn babies at risk for acid-base imbalances.

Critical Thinking and Clinical Application Questions

1. Mr. Jessup, a 55-year-old man, is operated on for a cerebral tumor. About a month later, he appears at his physician's office complaining of excessive thirst. He claims to have been drinking about 20 liters of water daily for the past week and says he has been voiding nearly continuously. A urine sample is collected and its specific gravity is reported as 1.001. What is your diagnosis of Mr. Jessup's problem? What connection might exist between his previous surgery and his present problem?

2. For each of the following sets of blood values, name the acid-base imbalance (acidosis or alkalosis), determine its cause (metabolic or respiratory), decide whether the condition is being compensated, and cite at least one possible cause of the imbalance.

Problem 1: pH 7.63; P_{CO_2} 19 mm Hg; HCO_3^- 19.5 mEq/L

Problem 2: pH 7.22; P_{CO_2} 30 mm Hg; HCO_3^- 12.0 mEq/L

3. Explain how emphysema and congestive heart failure can lead to acid-base imbalance.

4. Mrs. Bush, a 70-year-old woman, is admitted to the hospital. Her history states that she has been suffering from diarrhea for three weeks. On admission, she complains of severe fatigue and muscle weakness. A blood chemistry study yields the following information: Na^+ 142 mEq/L; K^+ 1.5 mEq/L; Cl^- 92 mEq/L; P_{CO_2} 32 mm Hg. Which electrolytes are within normal limits? Which are so abnormal that the patient has a medical emergency? Which of the following represents the greatest danger to Mrs. Bush? (a) a fall due to her muscular weakness, (b) edema, (c) cardiac arrhythmia and cardiac arrest.

5. During a routine medical checkup, Candace, a 26-year-old physiotherapy student, is surprised to hear that her blood pressure is 180/110. She also has a rumbling systolic and diastolic abdominal bruit (murmur) that is loudest at the mid-epigastric area. Her physician suspects renal artery stenosis (narrowing). She orders an abdominal ultrasound and renal artery arteriography, which confirms that Candace has a small right kidney, and that the distal part of her right renal artery is narrowed by more than 70%. Her physician prescribes diuretics and calcium channel blockers as temporary measures, and refers Candace to a cardiovascular surgeon. Explain the connection between Candace's renal artery stenosis and her hypertension. Why is her right kidney smaller than her left? What would you expect Candace's blood levels of K^+, Na^+, aldosterone, angiotensin II, and renin to be?

CHAPTER

The Reproductive System

1. Describe the common function of the male and female reproductive systems.

Anatomy of the Male Reproductive System (pp. 1066–1072)

2. Describe the structure and function of the testes, and explain the importance of their location in the scrotum.
3. Describe the structure of the penis, and indicate its role in the reproductive process.
4. Describe the location, structure, and function of the accessory reproductive organs of the male.
5. Discuss the sources and functions of semen.

Physiology of the Male Reproductive System (pp. 1072–1082)

6. Describe the phases of the male sexual response.
7. Define meiosis. Compare and contrast it to mitosis.
8. Outline events of spermatogenesis.
9. Discuss hormonal regulation of testicular function and the physiological effects of testosterone on male reproductive anatomy.

Anatomy of the Female Reproductive System (pp. 1082–1091)

10. Describe the location, structure, and function of the ovaries.
11. Describe the location, structure, and function of each of the organs of the female reproductive duct system.
12. Describe the anatomy of the female external genitalia.
13. Discuss the structure and function of the mammary glands.

Physiology of the Female Reproductive System (pp. 1091–1100)

14. Describe the process of oogenesis and compare it to spermatogenesis.
15. Describe ovarian cycle phases, and relate them to events of oogenesis.
16. Describe the regulation of the ovarian and uterine cycles.
17. Discuss the physiological effects of estrogens and progesterone.
18. Describe the phases of the female sexual response.

Sexually Transmitted Diseases (pp. 1100–1101)

19. Indicate the infectious agents and modes of transmission of gonorrhea, syphilis, chlamydia, trichomoniasis, genital warts, and genital herpes.

Developmental Aspects of the Reproductive System: Chronology of Sexual Development (pp. 1101–1105, 1108)

20. Discuss the determination of genetic sex and prenatal development of male and female structures.
21. Describe the significant events of puberty and menopause.

Most organ systems of the body function almost continuously to maintain the well-being of the individual. The **reproductive system,** however, appears to "slumber" until puberty. The **primary sex organs,** or **gonads** (go'nadz; "seeds"), are the *testes* in males and the *ovaries* in females. The gonads produce sex cells, or **gametes** (gam'ēts; "spouses"), and secrete a variety of steroid hormones commonly called **sex hormones.** The remaining reproductive structures—ducts, glands, and external genitalia (jen-ĭ-ta'le-ah)—are referred to as **accessory reproductive organs.** Although male and female reproductive organs are quite different, their common purpose is to produce offspring.

The male's reproductive role is to manufacture male gametes called *sperm* and deliver them to the female reproductive tract, where fertilization can occur. The complementary role of the female is to produce female gametes, called *ova* or *eggs.* As a result of appropriately timed intercourse, a sperm and egg may fuse to form a fertilized egg, the first cell of the new individual, from which all body cells will arise. The male and female reproductive systems are equal partners in events leading up to fertilization, but once fertilization has occurred, the female partner's uterus provides the protective environment in which the embryo develops until birth. Sex hormones—androgens in males and estrogens and progesterone in females—play vital roles both in the development and function of the reproductive organs and in sexual behavior and drives. These hormones also influence the growth and development of many other organs and tissues of the body.

Anatomy of the Male Reproductive System

The sperm-producing **testes** (tes'tez; "witnesses"), or **male gonads,** lie within the *scrotum.* From the testes, the sperm are delivered to the body exterior through a system of ducts including (in order) the *epididymis,* the *ductus deferens,* the *ejaculatory duct,* and finally the *urethra,* which opens to the outside at the tip of the *penis.* The accessory sex glands, which empty their secretions into the ducts during ejaculation, are the *seminal vesicles, prostate,* and *bulbourethral glands.* Take a moment to trace the duct system in Figure 27.1, and identify the testis and accessory glands before continuing.

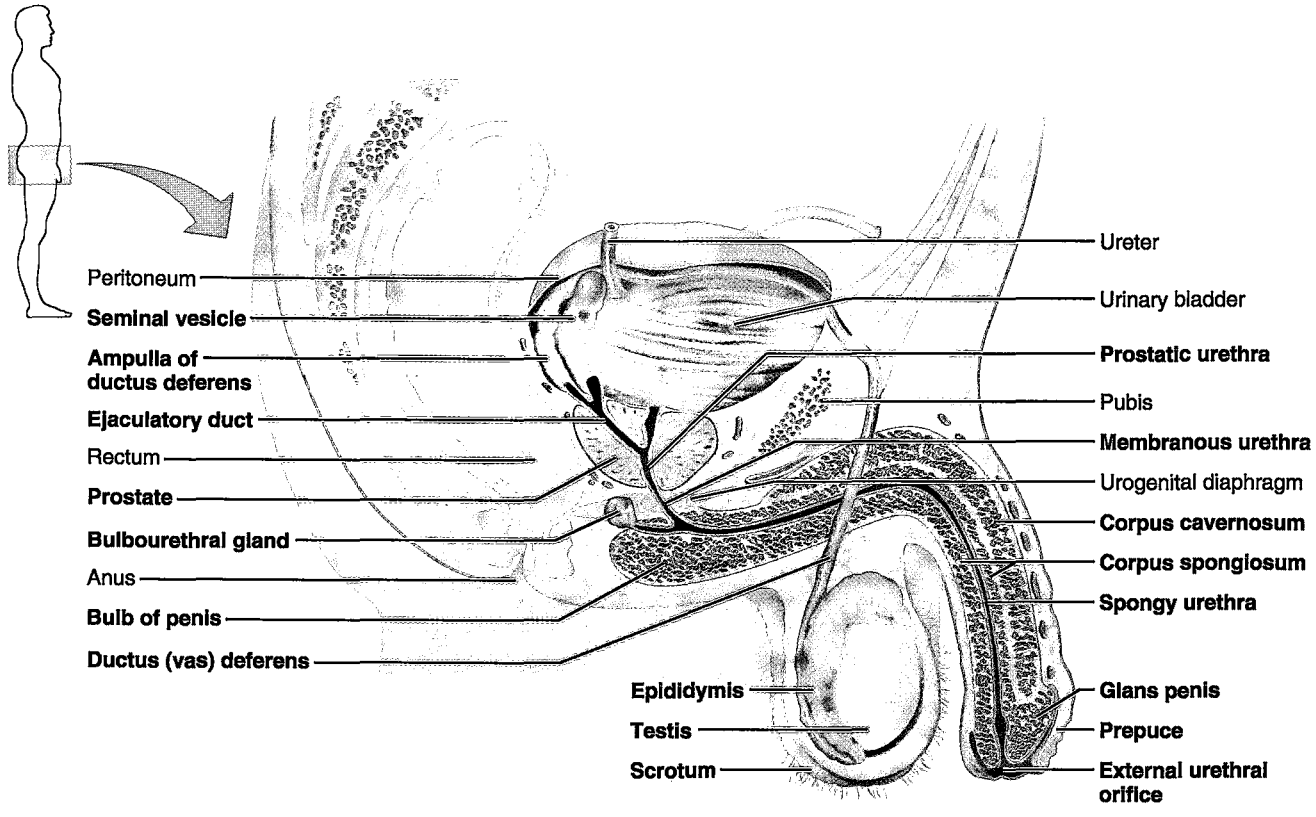

FIGURE 27.1 **Reproductive organs of the male, sagittal view.** A portion of the pubis of the coxal bone has been left to show the relationship of the ductus deferens to the bony pelvis. (See *A Brief Atlas of the Human Body,* Figures 72 and 73.)

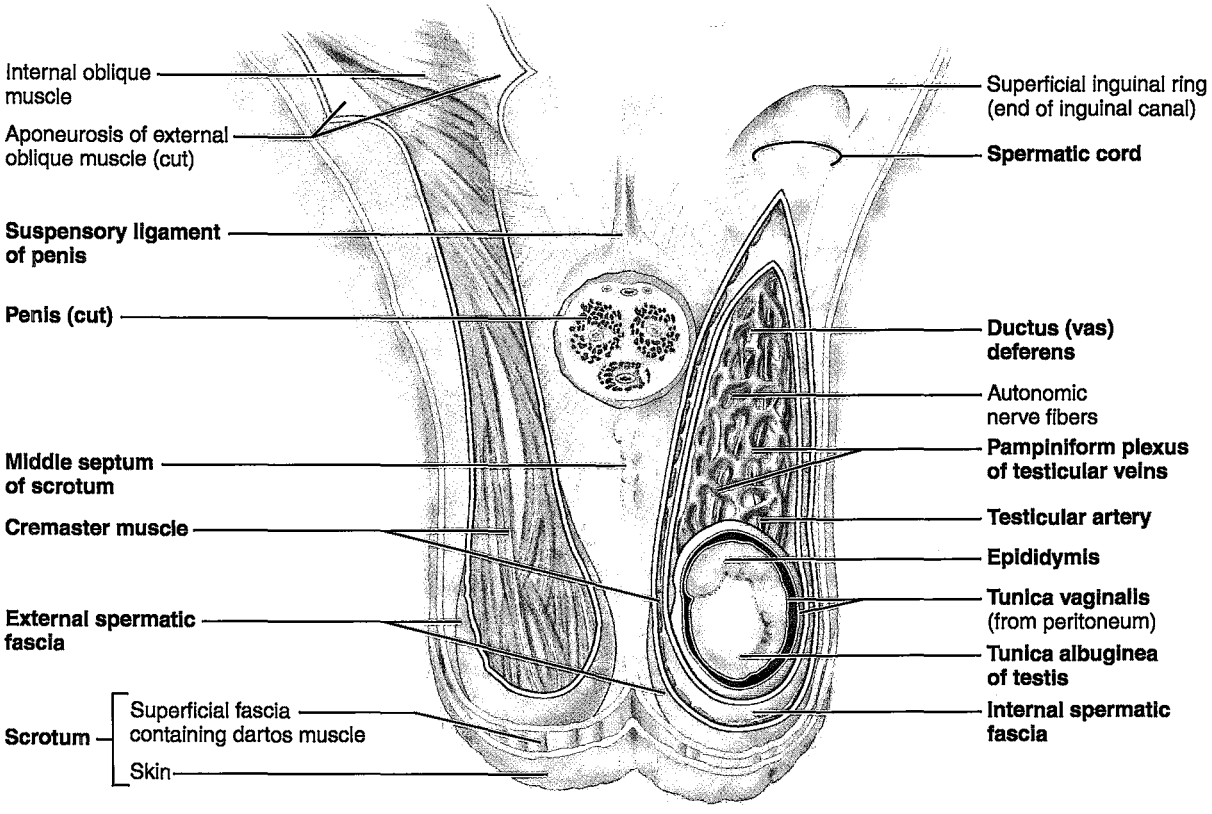

FIGURE 27.2 **Relationships of the testis to the scrotum and spermatic cord.** The scrotum has been opened and its anterior portion removed.

The Scrotum

The **scrotum** (skro'tum; "pouch") is a sac of skin and superficial fascia that hangs outside the abdominopelvic cavity at the root of the penis (Figure 27.2). It is covered with sparse hairs, and contains paired oval testes. A midline septum divides the scrotum, providing a compartment for each testis. This seems a rather vulnerable location for a man's testes, which contain his entire genetic heritage. However, because viable sperm cannot be produced in abundance at core body temperature (37°C), the superficial location of the scrotum, which provides a temperature about 3°C lower, is an essential adaptation. Furthermore, the scrotum responds to temperature changes. When it is cold, the testes are pulled closer to the warmth of the body wall, and the scrotum becomes shorter and heavily wrinkled, increasing its thickness to reduce heat loss. When it is warm, the scrotal skin is flaccid and loose to increase the surface area for cooling (sweating) and the testes hang lower, away from the body trunk. These changes in scrotal surface area help maintain a fairly constant intrascrotal temperature and reflect the activity of two sets of muscles. The **dartos muscle** (dar'tos; "skinned"), a layer of smooth muscle in the superficial fascia, wrinkles the scrotal skin. The **cremaster muscles** (kre-mas'ter; "a suspender"), bands of skeletal muscle that arise from the internal oblique muscles of the trunk, elevate the testes.

The Testes

Each plum-sized testis is approximately 4 cm (1.5 inches) long and 2.5 cm (1 inch) in width and is surrounded by two tunics. The outer tunic is the two-layered **tunica vaginalis** (vaj"ĭ-nal'is), derived from an outpocketing of the peritoneum (see Figures 27.2 and 27.3). Deep to this serous layer is the **tunica albuginea** (al"bu-jin'e-ah; "white coat"), the fibrous capsule of the testis. Septa extending from the tunica albuginea divide the testis into 250 to 300 wedge-shaped *lobules* (Figure 27.3), each containing one to four tightly coiled **seminiferous tubules** (sem"ĭ-nif'er-us; "sperm-carrying"), the actual "sperm factories." Surrounding each seminiferous tubule are smooth muscle–like **myoid cells** (see Figure 27.3b). By contracting rhythmically, these cells may help to squeeze sperm and testicular fluids through the tubules and out of the testes.

The seminiferous tubules of each lobule converge to form a **tubulus rectus,** a straight tubule that conveys sperm into the **rete testis** (re'te), a tubular network on the posterior side of the testis. From the

Q *Which of the tubular structures shown here are the "sperm factories"?*

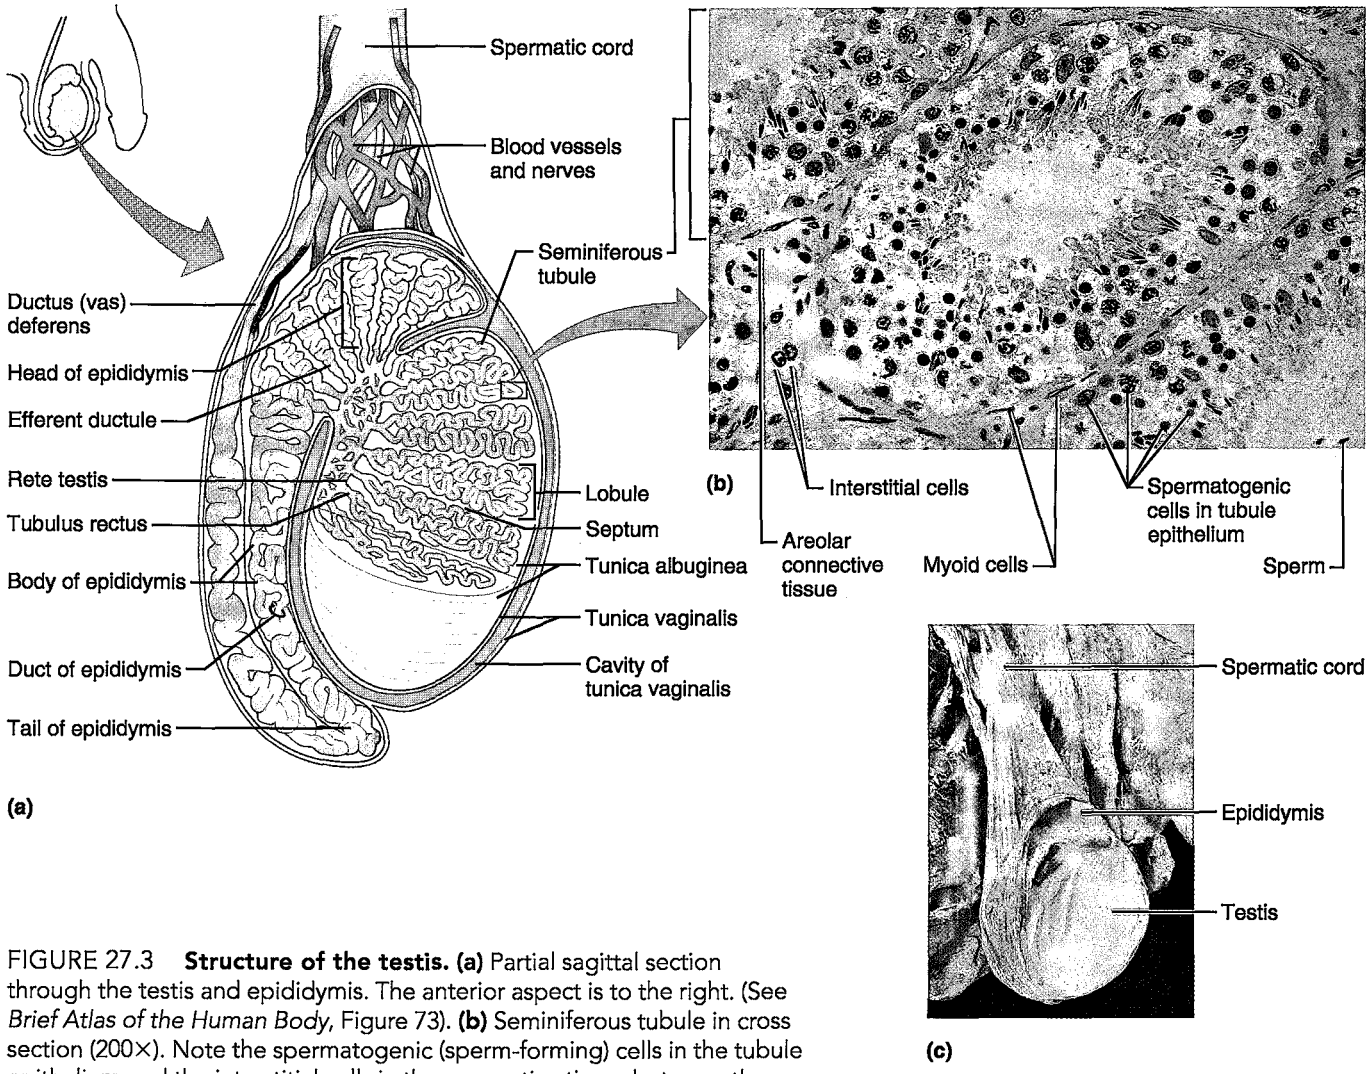

FIGURE 27.3 **Structure of the testis. (a)** Partial sagittal section through the testis and epididymis. The anterior aspect is to the right. (See *Brief Atlas of the Human Body*, Figure 73). **(b)** Seminiferous tubule in cross section (200×). Note the spermatogenic (sperm-forming) cells in the tubule epithelium and the interstitial cells in the connective tissue between the tubules. (See *A Brief Atlas of the Human Body*, Plate 51.) **(c)** External view of a testis from a cadaver; same orientation as in (a).

rete testis, sperm leave the testis through the *efferent ductules* and enter the *epididymis* (ep″ĭ-did′ĭ-mis), which hugs the external testis surface.

Lying in the soft connective tissue surrounding the seminiferous tubules are the **interstitial cells,** also called *Leydig cells* (Figure 27.3). These cells produce androgens (most importantly *testosterone*), which they secrete into the surrounding interstitial fluid. Thus, the sperm-producing and hormone-producing functions of the testis are carried out by completely different cell populations.

The long **testicular arteries,** which branch from the abdominal aorta superior to the pelvis (see *gonadal arteries* in Figure 19.23c, p. 755), supply the testes. The **testicular veins** draining the testes arise from a network called the **pampiniform plexus** (pam-pin′ĭ-form; "tendril-shaped") that surrounds the portion of the testicular artery within the scrotum like a climbing vine (see Figure 27.2). The pampiniform plexus absorbs heat from the arterial blood, cooling it before it enters the testes. Thus, this plexus provides an additional way to keep the testes at their cool homeostatic temperature.

A Seminiferous tubules.

The testes are served by both divisions of the autonomic nervous system. Associated sensory nerves transmit impulses that result in agonizing pain and nausea when the testes are hit forcefully. The nerve fibers are enclosed, along with the blood vessels and lymphatics, in a connective tissue sheath called the **spermatic cord** which passes through the inguinal canal (see Figure 27.2).

HOMEOSTATIC IMBALANCE

Although *testicular cancer* is relatively rare (affecting one of every 50,000 males), it is the most common cancer in young men (ages 15 to 35). A history of mumps or orchitis (inflammation of the testis) and substantial maternal exposure to environmental toxins before birth increases the risk, but the most important risk factor for this cancer is *cryptorchidism* (nondescent of the testes, see p. 1104). Because the most common sign of testicular cancer is a painless solid mass in the testis, self-examination of the testes should be practiced by every male. If detected early, it has an impressive cure rate. Over 90% of testicular cancers are cured by surgical removal of the cancerous testis *(orchiectomy)* either alone or in combination with radiation therapy or chemotherapy. ●

The Penis

The **penis** ("tail") is a copulatory organ, designed to deliver sperm into the female reproductive tract (Figures 27.1 and 27.4). The penis and scrotum, which hang suspended from the perineum, make up the external reproductive structures, or **external genitalia,** of the male. The male **perineum** (per"ĭ-ne'um; "around the anus") is the diamond-shaped region located between the pubic symphysis anteriorly, the coccyx posteriorly, and the ischial tuberosities laterally. The floor of the perineum is formed by muscles described in Chapter 10 (pp. 350–351).

The penis consists of an attached *root* and a free *shaft* or *body* that ends in an enlarged tip, the **glans penis.** The skin covering the penis is loose, and it slides distally to form a cuff called the **prepuce** (pre'pūs), or **foreskin,** around the glans. Frequently, the foreskin is surgically removed shortly after birth, a procedure called *circumcision* ("cutting around").

To understand penile anatomy, it is important to know that its dorsal and ventral surfaces are named in reference to the erect penis. Internally, the penis contains the spongy urethra and three long cylindrical bodies *(corpora)* of erectile tissue, each covered by a sheath of dense fibrous connective tissue. This *erectile tissue* is a spongy network of connective tissue and smooth muscle riddled with vascular spaces. During sexual excitement, the vascular spaces fill with blood, causing the penis to enlarge and become rigid. This event, called *erection,* enables the penis to serve as a penetrating organ. The midventral erectile body, the **corpus spongiosum** (spon"je-o'sum; "spongy body") surrounds the urethra. It expands distally to form the glans and proximally to form the part of the root called the **bulb of the penis.** The bulb is covered externally by the sheetlike bulbospongiosus muscle and is secured to the urogenital diaphragm. The paired dorsal erectile bodies, called the **corpora cavernosa** (kor'por-ah kă-verno'sah; "cavernous bodies"), make up most of the penis and are bound by fibrous tunica albuginea. Their proximal ends form the **crura of the penis** (kroo'rah; "legs"; singular: crus). Each crus is surrounded by an ischiocavernosus muscle and anchors to the pubic arch of the bony pelvis.

The Male Duct System

As mentioned earlier, sperm travel from the testes to the body exterior through a system of ducts. In order (proximal to distal), the **accessory ducts** are the epididymis, the ductus deferens, the ejaculatory duct, and the urethra.

The Epididymis

The cup-shaped **epididymis** (*epi* = beside; *didym* = the testes) is about 3.8 cm (1.5 inches) long (see Figures 27.1 and 27.3a, c). Its *head,* which contains the efferent ductules, caps the superior aspect of the testis. Its *body* and *tail* are on the posterolateral area of the testis. Most of the epididymis consists of the highly coiled *duct of the epididymis* with an uncoiled length of about 6 m (20 feet). Some pseudostratified epithelium cells of the duct mucosa exhibit long, nonmotile microvilli *(stereocilia).* The huge surface area of these stereocilia allows them to absorb excess testicular fluid and to pass nutrients to the many sperm stored temporarily in the lumen.

The immature, nearly nonmotile sperm that leave the testis are moved slowly along the duct of the epididymis through fluid that contains a number of antimicrobial proteins, including several β-defensins. As they move along its tortuous course (a trip that takes about 20 days), the sperm gain the ability to swim. Sperm are ejaculated from the epididymis, not the testes as many believe, and when a male is sexually stimulated and ejaculates, the smooth muscle in the epididymis walls contracts, expelling sperm into the next segment of the duct system, the *ductus deferens.* Sperm can be stored in the epididymis for several months, but if held longer, they are eventually phagocytized by epithelial cells of the epididymis.

The Ductus Deferens and Ejaculatory Duct

The **ductus deferens** (duk'tus def'er-ens; "carrying away"), or *vas deferens,* is about 45 cm (18 inches) long. It runs upward as part of the spermatic cord

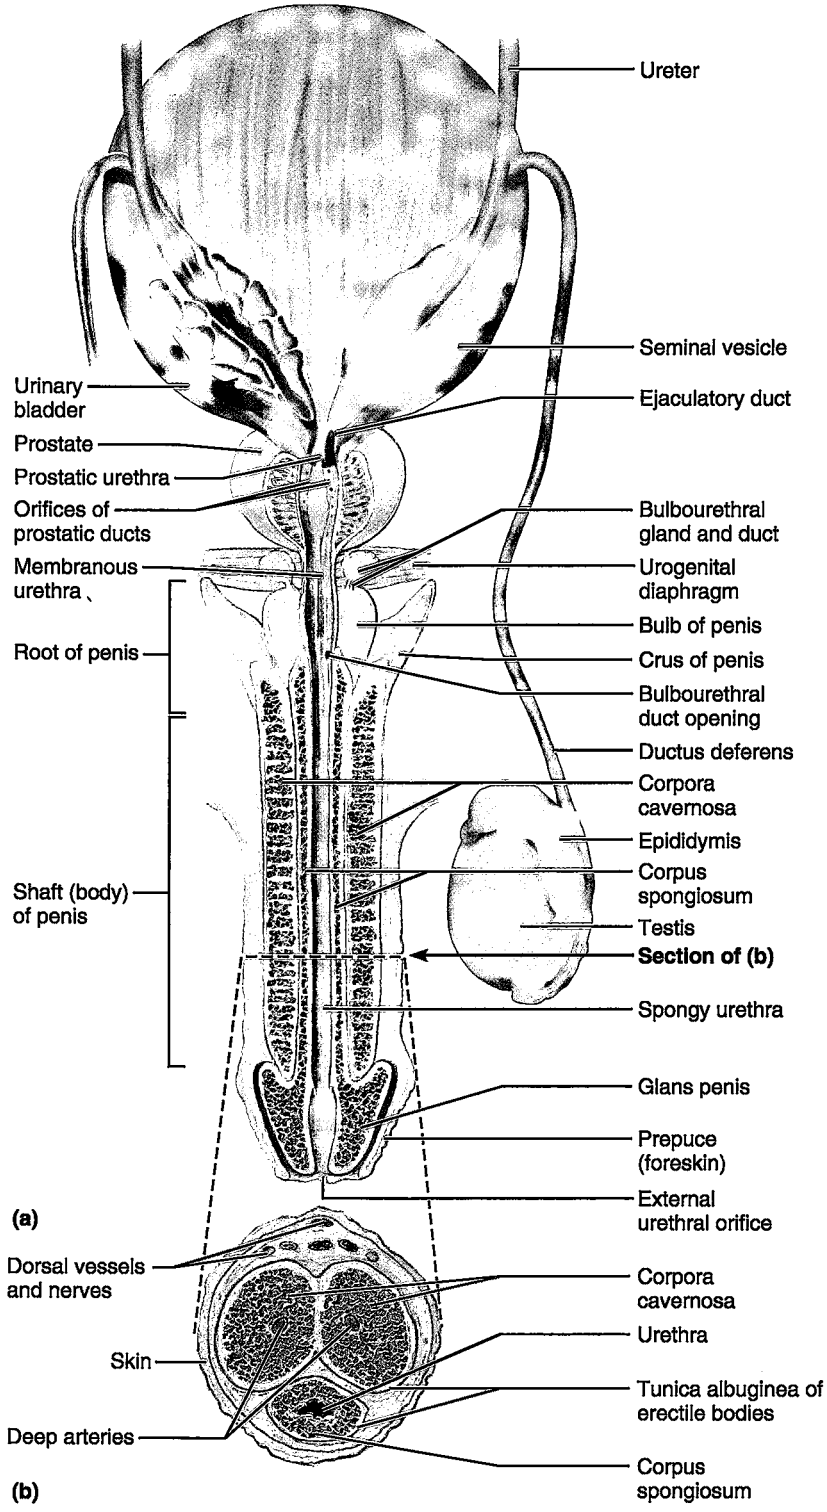

FIGURE 27.4 **Male reproductive structures. (a)** Posterior view showing longitudinal (coronal) section of the penis. **(b)** Transverse section of the penis.

from the epididymis through the inguinal canal into the pelvic cavity (see Figure 27.1). Easily palpated as it passes anterior to the pubic bone, it then loops medially over the ureter and descends along the posterior bladder wall. Its terminus expands to form the **ampulla** of the ductus deferens and then joins with the duct of the seminal vesicle (a gland) to form the short **ejaculatory duct.** Each ejaculatory duct enters the prostate; there it empties into the urethra.

Like that of the epididymis, the mucosa of the ductus deferens is pseudostratified epithelium. However, its muscular layer is extremely thick and

the duct feels like a hard wire when squeezed between the fingertips. At the moment of ejaculation, the thick layers of smooth muscle in its walls create strong peristaltic waves that rapidly squeeze the sperm forward along the tract and into the urethra.

As Figure 27.3 illustrates, part of the ductus deferens lies in the scrotal sac. Some men opt to take full responsibility for birth control by having a **vasectomy** (vah-sek'to-me; "cutting the vas"). In this relatively minor operation, the physician makes a small incision into the scrotum and then cuts through and ligates (ties off) the ductus deferens. Sperm are still produced, but they can no longer reach the body exterior. Eventually, they deteriorate and are phagocytized. Vasectomy is simple and provides highly effective birth control (close to 100%). For those wishing to reverse that procedure, the success rate is about 50%.

The Urethra

The **urethra** is the terminal portion of the male duct system (see Figures 27.1 and 27.4). It conveys both urine and semen (at different times), so it serves both the urinary and reproductive systems. Its three regions are (1) the *prostatic urethra,* the portion surrounded by the prostate; (2) the *membranous* (or *intermediate part of the*) *urethra* in the urogenital diaphragm; and (3) the *spongy (penile) urethra,* which runs through the penis and opens to the outside at the *external urethral orifice.* The spongy urethra is about 15 cm (6 inches) long and accounts for 75% of urethral length. Its mucosa contains scattered *urethral glands* that secrete mucus into the lumen just before ejaculation.

Accessory Glands

The **accessory glands** include the paired seminal vesicles and bulbourethral glands and the single prostate (Figures 27.1 and 27.4). Together these glands produce the bulk of *semen* (sperm plus accessory gland secretions).

The Seminal Vesicles

The **seminal vesicles** (sem'ĭ-nul) or **seminal glands,** lie on the posterior bladder surface. Each of these fairly large, hollow glands is about the shape and length (5–7 cm) of a little finger. However, because a seminal vesicle is pouched, coiled, and folded back on itself, its uncoiled length is actually about 15 cm. Its fibrous capsule encloses a thick layer of smooth muscle which contracts during ejaculation to empty the gland. Stored within the mucosa's honeycomb of crypts and blind alleys is a yellowish viscous alkaline fluid containing fructose sugar, ascorbic acid, a coagulating enzyme *(vesiculase),* and prostaglandins, as well as other substances that enhance sperm motility or fertilizing power. As noted, the duct of each seminal vesicle joins that of the ductus deferens on the same side to form the ejaculatory duct. Sperm and seminal fluid mix in the ejaculatory duct and enter the prostatic urethra together during ejaculation. Seminal gland secretion accounts for some 60% of the volume of semen.

The Prostate

The **prostate** (pros'tāt) is a single doughnut-shaped gland about the size of a peach pit (see Figures 27.1 and 27.4). It encircles the urethra just inferior to the bladder. Enclosed by a thick connective tissue capsule, it is made up of 20 to 30 compound tubuloalveolar glands embedded in a mass (stroma) of smooth muscle and dense connective tissue. The prostatic gland secretion enters the prostatic urethra via several ducts when prostatic smooth muscle contracts during ejaculation. It plays a role in activating sperm and accounts for up to one-third of the semen volume. It is a milky, slightly acid fluid that contains citrate (a nutrient source), several enzymes (fibrinolysin, hyaluronidase, acid phosphatase), and prostate-specific antigen (PSA).

HOMEOSTATIC IMBALANCE

The prostate has a reputation as a health destroyer (perhaps reflected in the common mispronunciation "prostrate"). Hypertrophy of the prostate gland, called *benign prostatic hyperplasia (BPH),* which affects nearly every elderly male, distorts the urethra. Although its precise cause is unknown, it may be associated with changes in hormone levels as a result of aging. The more the man strains to urinate, the more the valvelike prostatic mass blocks the opening, enhancing the risk of bladder infections (cystitis) and kidney damage. Traditional treatment has been surgical, but some newer options are gaining popularity, such as using microwaves or drugs to shrink the prostate; and inserting and inflating a small balloon to compress the prostate tissue away from the prostatic urethra. Another option is a procedure in which a catheter containing a tiny needle is inserted and burstlike releases of radio-frequency radiation are used to incinerate excess prostate tissue. Finasteride, which ratchets down production of dihydrotestosterone, the hormone linked to male pattern balding and prostate enlargement, is helpful in some cases. Additionally, several new drugs (such as doxazosin) are available that relax the smooth muscles at the bladder outlet, facilitating bladder emptying and providing relief.

Prostatitis (pros"tah-ti'tis), inflammation of the prostate, is the most common reason for a man to consult a urologist, and prostate cancer is the second

most common cause of cancer death in men (after lung cancer). Risk factors include fatty diet and genetic predisposition, and this cancer is twice as common in blacks as in whites, and half as common in Asians. Screening for prostate cancer typically involves digital examination of the prostate through the anterior rectal wall and assay of PSA levels in the blood. PSA, although a normal component of blood at levels below 0.4 ng/ml, is a tumor marker and its rising serum level follows BPH as well as the clinical disease course of prostate cancer. These screening procedures are followed by biopsies of suspicious prostate areas, if deemed necessary, and metastases (most commonly to the pelvic lymph nodes and the skeleton) are detected by bone or MRI scans. When possible, prostate cancer is treated surgically, alone or in conjunction with radiotherapy. Alternative therapies for metastasized cancers involve castration or therapy with drugs (flutamide) that block androgen receptors, or LHRH* analogues (such as leuprolide), which inhibit gonadotropin release. Deprived of the stimulatory effects of androgens, the prostatic tissue regresses and urinary symptoms typically decline. However, many prostate cancers are very slow growing and may never represent a threat to the patient. In such cases, frequent tests to monitor the tumor may be all that is necessary. ●

The Bulbourethral Glands

The **bulbourethral glands** (bul"bo-u-re'thral) are pea-sized glands inferior to the prostate gland (Figures 27.1 and 27.4). They produce a thick, clear mucus, some of which drains into the spongy urethra when a man becomes sexually excited and neutralizes traces of acidic urine in the urethra.

Semen

Semen (se'men) is a milky white, somewhat sticky mixture of sperm and accessory gland secretions. The liquid provides a transport medium and nutrients and contains chemicals that protect and activate the sperm and facilitate their movement. Mature sperm cells are streamlined cellular "missiles" containing little cytoplasm or stored nutrients. Catabolism of the fructose in seminal vesicle secretion provides nearly all the fuel needed for sperm ATP synthesis. Prostaglandins in semen decrease the viscosity of mucus guarding the entry (cervix) of the uterus and stimulate reverse peristalsis in the uterus, facilitating sperm movement through the female reproductive tract. The presence of the hormone *relaxin* and certain enzymes in semen enhance sperm motility. The relative alkalinity of semen as a whole (pH 7.2–7.6) helps neutralize the acid environment of the male's urethra and the female's vagina, thereby protecting the delicate sperm and enhancing their motility. Sperm are very sluggish under acidic conditions (below pH 6). Semen also contains substances that suppress the immune response in the female's reproductive tract and an antibiotic chemical called **seminalplasmin,** which destroys certain bacteria. Clotting factors found in semen coagulate it just after it is ejaculated. Soon, its contained fibrinolysin liquefies the sticky mass, enabling the sperm to swim out and begin their journey through the female duct system.

The amount of semen propelled out of the male duct system during ejaculation is relatively small, only 2–5 ml, but there are between 20 and 150 million sperm per milliliter.

Physiology of the Male Reproductive System

Male Sexual Response

Although there is more to it, the chief phases of the male sexual response are (1) *erection* of the penis, which allows it to penetrate the female vagina, and (2) *ejaculation,* which expels semen into the vagina.

Erection

Erection, enlargement and stiffening of the penis, results from engorgement of the erectile bodies with blood. When a man is not sexually aroused, arterioles supplying the erectile tissue are constricted and the penis is flaccid. However, during sexual excitement a parasympathetic reflex is triggered that promotes release of nitric oxide locally. NO relaxes vascular smooth muscle, causing these arterioles to dilate, which allows the erectile bodies to fill with blood. Expansion of the corpora cavernosa of the penis compresses their drainage veins, retarding blood outflow and maintaining engorgement. The corpus spongiosum expands but not nearly as much as the cavernosa; its main job is to keep the urethra open during ejaculation. It is important that the erect penis not kink or buckle during intercourse. This is prevented by the longitudinal and circular arrangement of collagen fibers surrounding the penis. Erection of the penis is one of the rare examples of parasympathetic control of arterioles. Another parasympathetic effect is stimulation of the bulbourethral glands, the secretion of which lubricates the glans penis.

Erection is initiated by a variety of sexual stimuli, such as touching the genital skin, mechanical stimulation of the pressure receptors in the penis,

* LHRH (luteinizing hormone–releasing hormone) is analogous to GnRH (gonadotropin-releasing hormone). See discussion of GnRH's effects on p. 616.

and erotic sights, sounds, and smells. The CNS responds to such stimuli by activating parasympathetic neurons that innervate the internal pudendal arteries serving the penis. Sometimes erection is induced solely by emotional or higher mental activity (the thought of a sexual encounter). Emotions and thoughts can also inhibit erection, causing vasoconstriction and resumption of the flaccid penile state. Impotence, the inability to attain erection, is considered in *A Closer Look* on p. 1074.

Ejaculation

Ejaculation (*ejac* = to shoot forth) is the propulsion of semen from the male duct system. Although erection is under parasympathetic control, *ejaculation* is under sympathetic control. When impulses provoking erection reach a certain critical level, a spinal reflex is initiated, and a massive discharge of nerve impulses occurs over the sympathetic nerves serving the genital organs (largely at the level of L_1 and L_2). As a result,

1. The reproductive ducts and accessory glands contract, emptying their contents into the urethra.
2. The bladder sphincter muscle constricts, preventing expulsion of urine or reflux of semen into the bladder.
3. The bulbospongiosus muscles of the penis undergo a rapid series of contractions, propelling semen at a speed of up to 500 cm/s (200 inches/s) from the urethra. These rhythmic contractions are accompanied by intense pleasure and many systemic changes, such as generalized muscle contraction, rapid heartbeat, and elevated blood pressure.

The entire ejaculatory event is referred to as **climax** or **orgasm.** Orgasm is quickly followed by muscular and psychological relaxation and vasoconstriction of the penile arterioles, which allows the penis to become flaccid once again. After ejaculation, there is a latent period, ranging in time from minutes to hours, during which a man is unable to achieve another orgasm. The latent period lengthens with age.

Spermatogenesis

Spermatogenesis (sper"mah-to-jen'ĕ-sis; "sperm formation") is the sequence of events in the seminiferous tubules of the testes that produces male gametes—*sperm* or *spermatozoa.* The process begins around the age of 14 years in males, and continues throughout life. Every day, a healthy adult male makes about 400 million sperm. It seems that nature has made sure that the human species will not be endangered for lack of sperm.

Before we describe the process of spermatogenesis, let's define some terms. First, having two sets of chromosomes, one from each parent, is a key factor

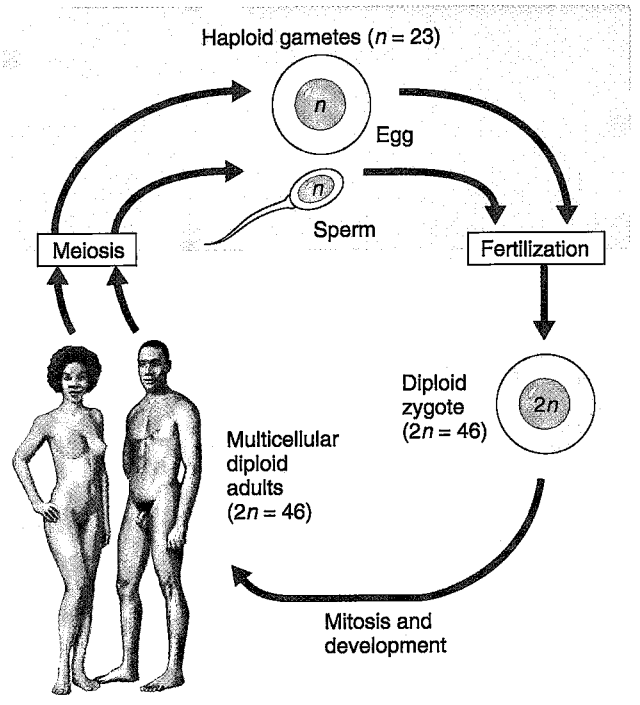

FIGURE 27.5 **The human life cycle.**

in the human life cycle (Figure 27.5). The normal chromosome number in most body cells is referred to as the **diploid chromosomal number** (dip'loid) of the organism, symbolized as ***2n.*** In humans, this number is 46, and such diploid cells contain 23 pairs of similar chromosomes called **homologous chromosomes** (ho-mol'ŏ-gus) or **homologues.** One member of each pair is from the male parent (the *paternal chromosome*); the other is from the female parent (the *maternal chromosome*). Generally speaking, the two homologues of each chromosome pair look alike and carry genes that code for the same traits, though not necessarily for identical expression of those traits. (Consider, for example, the homologous genes controlling the expression of freckles; the paternal gene might code for an ample sprinkling of freckles and the maternal gene for no freckles.) In Chapter 29, we will consider how mom's and dad's genes interact to produce our visible traits.

The number of chromosomes present in human gametes is 23, referred to as the **haploid chromosomal number** (hap'loid), or ***n;*** gametes contain only one member of each homologous pair. When sperm and egg fuse, they form a fertilized egg that reestablishes the typical diploid chromosomal number of human cells.

Gamete formation in both sexes involves **meiosis** (mi-o'sis; "a lessening"), a unique kind of nuclear division that, for the most part, occurs only in the gonads. Recall that *mitosis* (the process by which most body cells divide) distributes replicated chromosomes

A CLOSER LOOK

Erectile Dysfunction and Passion Pills

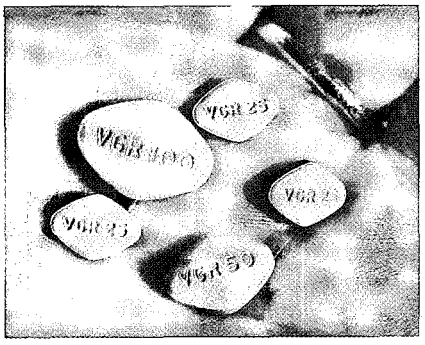
Erectile dysfunction (ED), a form of **impotence,** is the inability to attain an erection when desired. What is missing? In two words, nitric oxide. When males become aroused, parasympathetic nerves in the penis release nitric oxide, which activates cyclic GMP, an enzyme that causes smooth muscle in the penile blood vessel walls to relax. As it does so, blood rushes into the spongy cavernous tissue, stiffening the penis. And what blocks nitric oxide release or its effects? Psychological factors, alcohol, or certain drugs can cause temporary impotence even in healthy males. When chronic, the condition is largely the result of hormonal, vascular, or nervous system problems. The problem is not limited to older men; approximately 50% of American males over age 40 (some 32 million men) have some degree of erectile dysfunction.

For a long time, impotence was dismissed as "being in your head," but it now appears that psychological or emotional causes account for less than 20% of cases. Numerous drugs can produce impotence, including antihypertensives, antihistamines, antidepressants, the antiulcer drug cimetidine (Tagamet), and some appetite suppressants and cold remedies. Vascular problems that are common causes include arteriosclerosis, injury to penile blood vessels, or varicose veins in the penis, which create venous leaks that allow blood to leave the penis prematurely. Neural causes typically result from stroke, multiple sclerosis, tumors, physical trauma, or damage to penile nerves during surgery or radiation therapy. The single most important hormonal factor is diabetes mellitus, which leads to arterial blockages that reduce blood flow into the penis and nerve damage that makes erection difficult or impossible. Cushing's disease, hypothyroidism, and elevated levels of prolactin are other possible hormone-based causes.

Let's assume the cause is determined, but the problem still exists. What's a man to do? Until recently, most remedies were unpleasant and invasive. Using a vacuum pump to suck blood into the penis and thus pump up a flaccid penis often embarrasses its user and can take the romance out of the moment. Drugs such as papaverine and alprostadil (PGE_1) dilate the penile blood vessels but require painful injections into the penis, and alprostadil gel (Muse), a soft pellet that is inserted into the urethra, is said by users to hurt more than the injections. In cases of nonresponsive vascular disease or damage to penile nerves, the usual approaches are reconstructive surgery to repair damaged arteries or a venous leak, or implanting a device in the penis that will make it erect. However, surgery is expensive and has its shortcomings even in the most capable hands, and the implantable prostheses sometimes break down, requiring still more surgery.

As you might expect then, a little blue diamond-shaped pill called Viagra (sildenafil) was greeted with great enthusiasm by men who have an erectile dysfunction that allows them some erectile ability but not enough to permit penetration. To say that Viagra has been a big hit is a vast understatement. The FDA approved the drug in March 1998; by that September, 4 million prescriptions had been filled. In late 2003, two similar drugs—tadalis (Cialis), which claims its effects last for up to 36 hours, and vardenafil (Levitra), which works faster (in 30 minutes versus one hour for Viagra)—hit the marketplace.

Viagra works, but not for everyone; its success rate is 70%. Among Viagra's advantages are that it (1) works within the hour to produce a sustained erection by increasing the concentration of nitric oxide and blood flow in the penis, (2) is taken orally, and (3) has essentially no significant side effects in healthy males (i.e., those who do not have severe vascular problems or long-standing pyschogenic impotence). Some men experience transient blue-green vision, stuffy nose, headache, temporary facial flushing, or mild stomach upset—all trade-offs that many say they are ready to put up with in exchange for erections. The major problems with Viagra and similar drugs involve men with preexisting serious health problems (heart disease or diabetes mellitus) who ignore the drug's (or their physician's) warnings that Viagra also reduces systemic blood pressure as it works its "miracle." Consequently, some fatalities have occurred, most involving men taking nitrate drugs to dilate the coronary circulation. Nonetheless, Viagra is seen as a wonder drug.



Viagra pills.

Will it work equally well for women with problems with sexual arousal? The clitoris is physiologically similar to the penis and researchers have detected nitric oxide activity in the vagina and clitoris. Clinical trials are rolling, not only on Viagra and similar feminine-oriented oral products, but on creams and hormone sprays that are applied to the skin and a sexual arousal patch. More later. ■

equally between the two daughter cells. Consequently, each daughter cell receives a set of chromosomes identical to that of the mother cell. Meiosis, on the other hand, consists of two consecutive nuclear divisions, and its product is four daughter cells instead of two, each with *half* as many chromosomes as typical body cells. Thus, meiosis reduces the chromosomal number by half (from $2n$ to n) in gametes. Mitosis and meiosis are compared in Figure 27.6.

	Mitosis	Meiosis
Number of divisions	One, consisting of prophase, metaphase, anaphase, and telophase	Two, each consisting of prophase, metaphase, anaphase, and telophase. DNA replication does not occur between the two nuclear divisions. An event unique to meiosis is that during meiosis I, the homologous chromosomes synapse (join along their length), forming tetrads (groups of four chromatids)
Daughter cell number and genetic composition	Two, each diploid (*2n*) and identical to the mother cell	Four, each containing half as many chromosomes as the mother cell (hence haploid or *n*) and nonidentical to mother cell
Roles in the body	For development of multicellular adult from zygote; to produce cells for growth and tissue repair; to ensure constancy of genetic makeup of all body cells	To produce cells for reproduction (gametes); to introduce genetic variability in the gametes and reduce chromosomal number by half so that when fertilization occurs, the normal diploid chromosomal number is restored (in humans, $2n = 46$)

FIGURE 27.6 **Comparison of mitosis and meiosis in a mother cell with a diploid number (*2n*) of 4.** Mitosis is shown on the left, meiosis on the right. (Not all the phases of mitosis and meiosis are shown.)

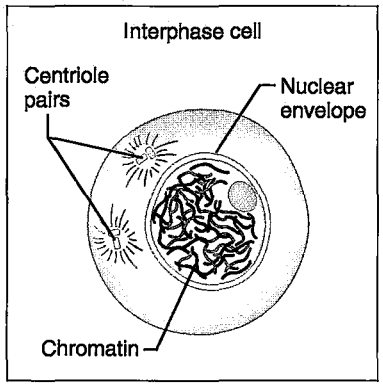
Meiosis

The two nuclear divisions of meiosis, called *meiosis I* and *meiosis II*, are divided into phases for convenience. Although these phases are given the same names as those of mitosis (prophase, metaphase, anaphase, and telophase), some events of meiosis I are quite different from those of mitosis, as detailed next.

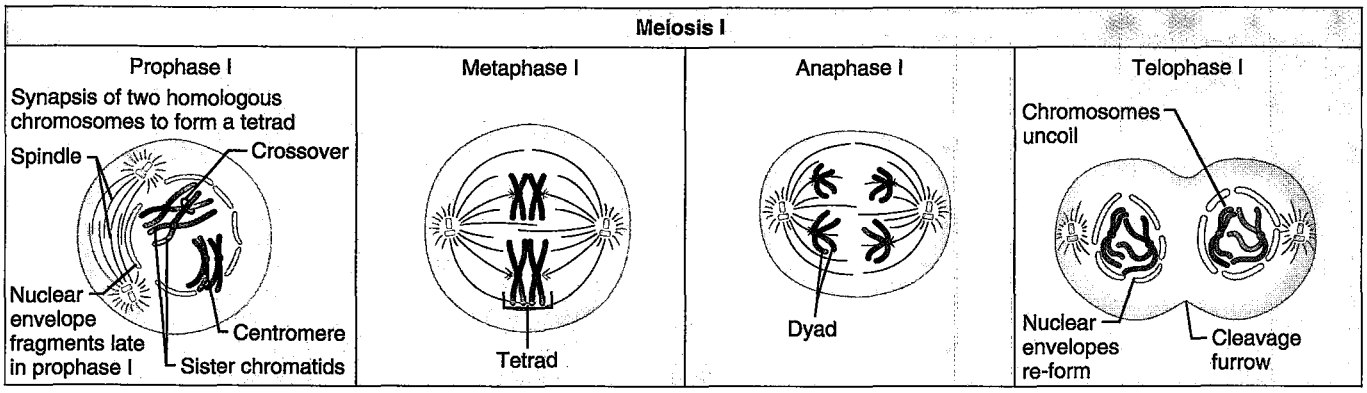
Recall that prior to mitosis all the chromosomes are replicated. Then the identical copies remain together as *sister chromatids* connected by a centromere throughout prophase and during metaphase. At anaphase, the centromeres split and the sister chromatids separate from each other so that each daughter cell inherits a copy of *every* chromosome possessed by the mother cell (see Figure 27.6). Let's look at how meiosis differs.

Meiosis I As in mitosis, chromosomes replicate before meiosis begins. But in prophase of meiosis I,

FIGURE 27.7 **Meiosis.** The series of events in meiotic cell division for an animal cell with a diploid number ($2n$) of 4. The behavior of the chromosomes is emphasized.



Interphase events
As in mitosis, meiosis is preceded by events occurring during interphase that lead to DNA replication and other preparations needed for the cell division process. Just before meiosis begins, the replicated chromatids, held together by centromeres, are ready and waiting.

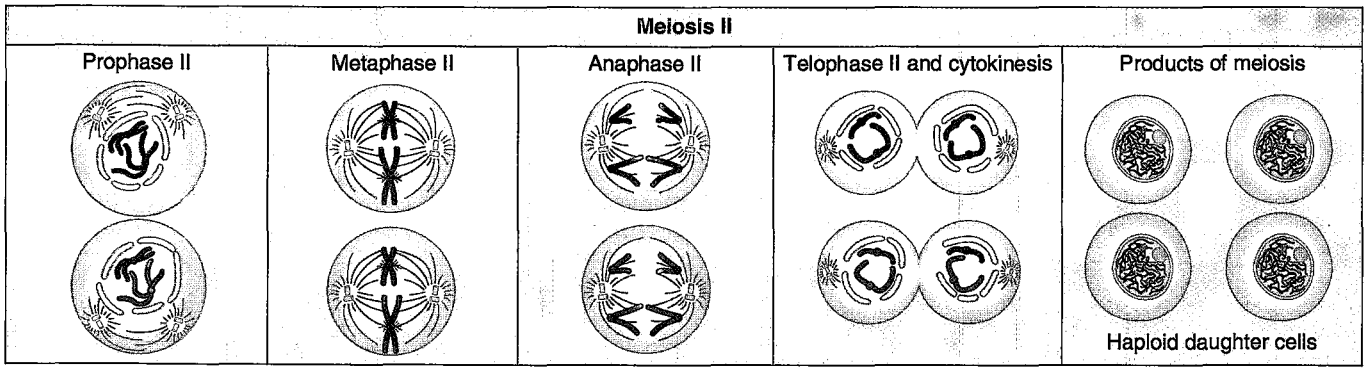


Prophase I
As in prophase of mitosis, the chromosomes coil and condense, the nuclear membrane and nucleolus break down and disappear, and the spindle is formed. However, a unique event not seen in mitosis, called synapsis, occurs in prophase I of meiosis. Synapsis involves the coming together of homologous chromosomes all along their length to form tetrads, little packets of four chromatids. While in synapsis, the "arms" of homologous chromatids become wrapped around each other, forming several points of crossover or chiasmata. (This process of crossover is shown between two of the four chromatids in one tetrad of the prophase I view, and the result of that one event of crossing over is followed through meiosis II.) Prophase I is the longest period of meiosis, accounting for about 90% of the total period. By its end, the tetrads have attached to the spindle and are moving toward the spindle equator, and the nonsister chromatids have traded segments at points of crossover.

Metaphase I
During metaphase I, the tetrads align on the spindle equator in preparation for anaphase.

Anaphase I
Unlike the anaphase events of mitosis, the centromeres do not break during anaphase I of meiosis, and so the sister chromatids (dyads) remain firmly attached. However, the homologous chromosomes do separate from each other and the dyads are moved toward opposite poles of the cell, guided by the spindle apparatus.

Telophase I
The nuclear membranes re-form around the chromosomal masses, the spindle breaks down, and the chromatin reappears as telophase and cytokinesis are completed, forming two daughter cells. The daughter cells (now haploid) enter a second interphase-like period, called interkinesis, before meiosis II occurs. There is no second replication of DNA before meiosis II.



Meiosis II begins with the products of meiosis I (two haploid daughter cells) and undergoes a mitosis-like nuclear division process referred to as the equational division of meiosis. After progressing through prophase, metaphase, anaphase, and telophase, followed by cytokinesis, the product is four haploid daughter cells each genetically different from the original mother cell. During human spermatogenesis the daughter cells remain interconnected by cytoplasmic extensions.

an event never seen in mitosis (nor in meiosis II for that matter) occurs. The replicated chromosomes seek out their homologous partners and pair up with them along their entire length (Figure 27.7). This alignment takes place at discrete spots along the length of the homologues—more like buttoning together than zipping. As a result of this process, called **synapsis,** little groups of four chromatids called **tetrads** are formed. During synapsis, a second unique event called crossover occurs. **Crossovers,** also called **chiasmata** (singular: chiasma), are formed within each tetrad as the free ends of one maternal and one paternal chromatid wrap around each other at one or more points. Crossover allows an exchange of genetic material between the paired maternal and paternal chromosomes.

During metaphase I, the tetrads line up randomly at the spindle equator; that is, either the paternal or maternal chromosome can be on a given side of the equator. During anaphase I, the sister chromatids representing each homologue behave as a unit—almost as if replication had not occurred—and the *homologous chromosomes* (each still composed of two joined sister chromatids) are distributed to opposite ends of the cell.

Thus, when meiosis I is completed, the following conditions exist: Each daughter cell has (1) *two* copies of one member of each homologous pair (either the paternal or maternal) and none of the other, and (2) a *haploid* chromosomal number (because the still-united sister chromatids are considered to be a single chromosome) but twice the amount of DNA. Because meiosis I reduces the chromosome number from $2n$ to n, it is sometimes called the **reduction division of meiosis.**

Meiosis II The second meiotic division, meiosis II, mirrors mitosis in every way, except that the chromosomes are *not* replicated before it begins. Instead, the sister chromatids in the two daughter cells of meiosis I are simply parceled out among four cells. Because the chromatids are distributed equally to the daughter cells (as in mitosis), meiosis II is sometimes referred to as the **equational division of meiosis** (Figure 27.7).

Meiosis accomplishes two important tasks: (1) It reduces the chromosomal number by half and (2) it introduces genetic variability. The random alignment of the homologous pairs during meiosis I provides tremendous variability in the resulting gametes by scrambling genetic characteristics of the two parents in different combinations. Variability is increased further by crossover—during late prophase I, the homologues break at crossover points and exchange chromosomal segments (see Figure 27.7). (This process is described in Chapter 29.) As a result, it is likely that no two gametes are exactly alike, and all are different from the original mother cells.

Spermatogenesis: Summary of Events in the Seminiferous Tubules

A histological section of an adult testis shows that most cells making up the epithelial walls of the seminiferous tubules are in various stages of cell division (Figure 27.8). These cells, collectively called **spermatogenic cells** (*spermatogenic* = sperm forming), give rise to sperm in the following series of cellular divisions and transformations.

Mitosis of Spermatogonia: Forming Spermatocytes The outermost tubule cells, which are in direct contact with the epithelial basal lamina, are stem cells called **spermatogonia** (sper"mah-to-go'ne-ah; "sperm seed"). The spermatogonia divide more or less continuously by *mitosis* and, until puberty, all their daughter cells become spermatogonia.

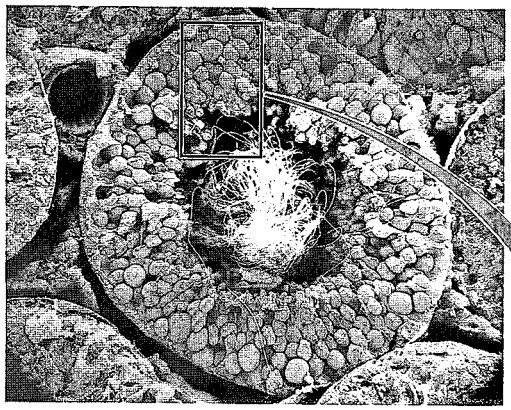
Spermatogenesis begins during puberty, and from then on, each mitotic division of a spermatogonium results in two distinctive daughter cells—*types A* and *B*. The **type A daughter cell** remains at the basement membrane to maintain the germ cell line. The **type B cell** gets pushed toward the lumen, where it becomes a **primary spermatocyte** destined to produce four sperm. (To keep these cell types straight, remember that just as the letter A is always at the beginning of our alphabet, a type A cell is always at the tubule basement membrane ready to begin a new generation of gametes.)

Meiosis: Spermatocytes to Spermatids Each primary spermatocyte generated during the first phase undergoes meiosis I, forming two smaller haploid cells called **secondary spermatocytes.** The secondary spermatocytes continue on rapidly into meiosis II, and their daughter cells, called **spermatids** (sper'mah-tidz), are small round cells with large spherical nuclei seen closer to the lumen of the tubule. Midway through spermatogenesis, the developing sperm "turn off" nearly all their genes and compact their DNA into dense pellets.

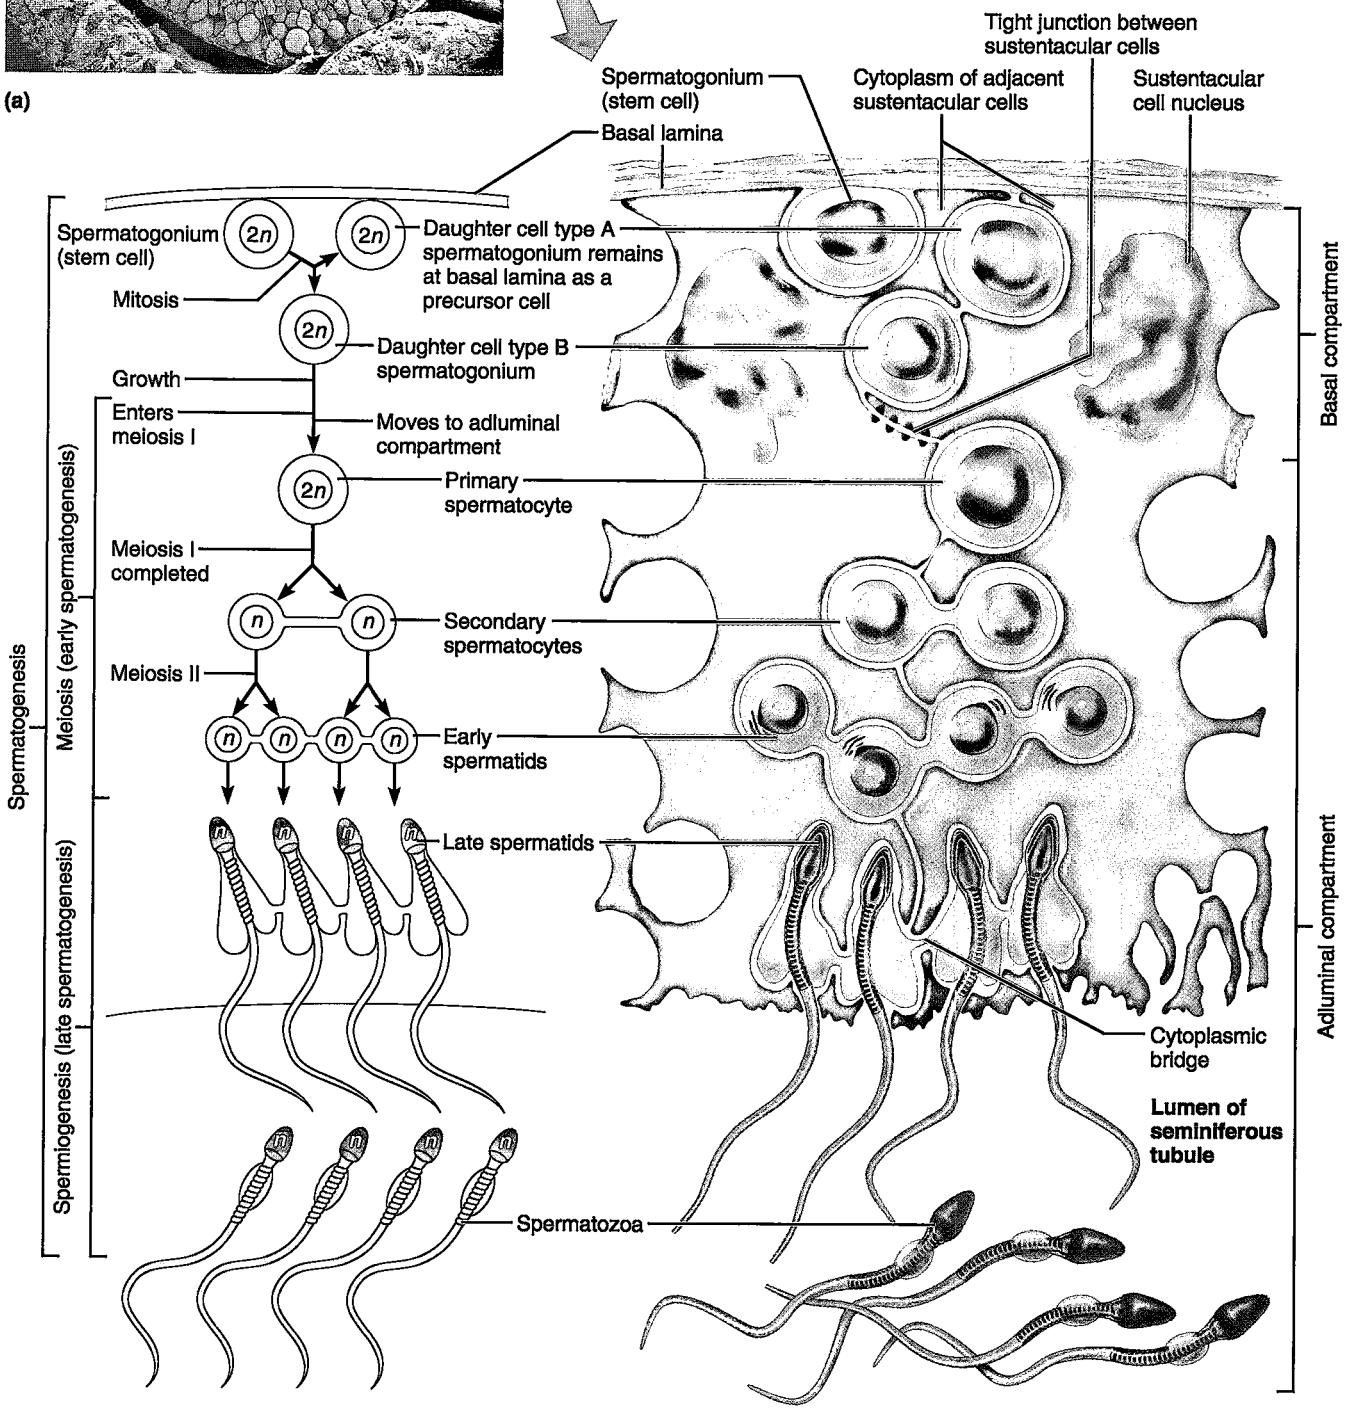
Spermiogenesis: Spermatids to Sperm Each spermatid has the correct chromosomal number for fertilization (n), but is nonmotile. It still must undergo a streamlining process called **spermiogenesis,** during which it elongates, sheds its excess cytoplasmic baggage, and forms a tail. Details of this process appear in Figure 27.9a. The resulting **sperm,** or **spermatozoon** (sper"mah-to-zo'on; "animal seed"), has a head, a midpiece, and a tail, which correspond roughly to *genetic, metabolic,* and *locomotor regions,* respectively. Sperm "pack" lightly. The **head** of a sperm consists almost entirely of its flattened nucleus, which contains the compacted DNA. Adhering to the top of the nucleus is a helmetlike **acrosome** (ak'ro-sōm; "tip piece"). The lysosome-like acrosome is produced by the Golgi apparatus

Q *What cell type results from meiosis?*

(*Note:* The process of spermatogenesis encompasses the phases through the production of sperm. Conversion of the haploid spermatids to sperm cells is specifically called spermiogenesis.)



(a)



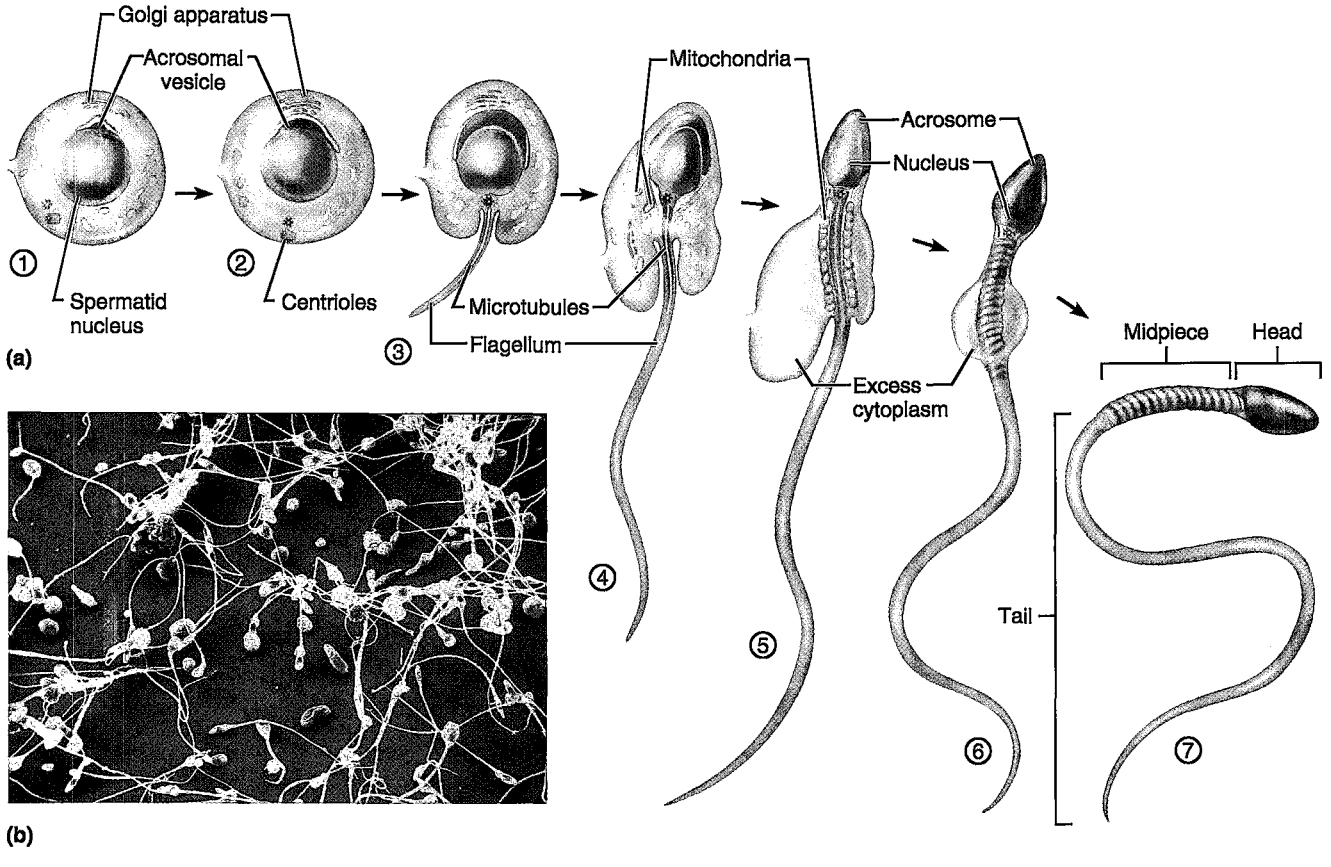


FIGURE 27.9 **Spermiogenesis: transformation of a spermatid into a functional sperm. (a)** The stepwise process of spermiogenesis consists of ① packaging of the acrosomal enzymes by the Golgi apparatus, ② forming the acrosome at the anterior end of the nucleus and positioning the centrioles at the opposite end of the nucleus, ③ elaboration of microtubules to form the flagellum, ④ mitochondrial multiplication and their positioning around the proximal portion of the flagellum, and ⑤ sloughing off excess cytoplasm. ⑥ Structure of an immature sperm that has just been released from a sustentacular cell. ⑦ Structure of a fully mature sperm. **(b)** Scanning electron micrograph of mature sperm (600×).

and contains hydrolytic enzymes that enable the sperm to penetrate and enter an egg. The sperm **midpiece** contains mitochondria spiraled tightly around the contractile filaments of the tail. The long **tail** is a typical flagellum produced by the centriole near the nucleus. The mitochondria provide the metabolic energy (ATP) needed for the whiplike movements of the tail that will propel the sperm along its way in the female reproductive tract.

Role of the Sustentacular Cells Throughout spermatogenesis, descendants of the same spermatogonium remain closely attached to one another by cytoplasmic bridges (see Figure 27.8). They are also surrounded by and connected to supporting cells of a special type, called **sustentacular cells** or **Sertoli cells,** which extend from the basal lamina to the lumen of the tubule. The sustentacular cells, bound to each other laterally by tight junctions, divide the seminiferous tubule into two compartments. The **basal compartment** extends from the basal lamina to their tight junctions and contains spermatogonia and the earliest primary spermatocytes. The **adluminal compartment** lies internal to the tight junctions and includes the meiotically active cells and the tubule lumen.

The tight junctions between the sustentacular cells form the **blood-testis barrier.** This barrier prevents the membrane antigens of differentiating sperm from escaping through the basal lamina into the bloodstream where they would activate the immune system. Because sperm are not formed until puberty, they are absent when the immune system is being programmed to recognize one's own tissues early in life. The spermatogonia, which are recognized as "self," are outside the barrier and thus can be influenced by bloodborne chemical messengers that prompt spermatogenesis. Following mitosis of the spermatogonia, the tight junctions of the sustentacular cells open to allow primary spermatocytes to pass into the adluminal compartment—much as locks in a canal open to allow a boat to pass.

In the adluminal compartment, spermatocytes and spermatids are nearly enclosed in recesses in the sustentacular cells (see Figure 27.8), anchored there by a particular glycoprotein on the spermatogenic cell's surface. The sustentacular cells provide essential signals and nutrients to the dividing cells, move them along to the lumen, secrete **testicular fluid** (rich in androgens and metabolic acids) that provides the transport medium for sperm in the lumen, and phagocytize the excess cytoplasm sloughed off the spermatids as they transform into sperm. The sustentacular cells also produce chemical mediators (inhibin and androgen-binding protein) that help regulate spermatogenesis as described below.

Spermatogenesis—from formation of a primary spermatocyte to release of immature sperm into the lumen—takes 64 to 72 days. Sperm in the lumen are unable to "swim" and are incapable of fertilizing an egg. They are pushed by the pressure of the testicular fluid through the tubular system of the testes into the epididymis, where they gain increased motility and fertilizing power.

HOMEOSTATIC IMBALANCE

Roughly one in seven American couples seek treatment for infertility, mostly because of problems with sperm quality or quantity. According to some studies, a gradual decline in male fertility has been occurring in the past 50 years. Some believe the main cause is *xenobiotics,* alien molecules that have invaded our lives in a variety of forms including environmental toxins, PVCs, phthalates (oily solvents that make plastics flexible), certain components in pesticides and herbicides, and especially compounds with estrogenic effects. These estrogen-like compounds, which block the action of male sex hormones as they program sexual development, are now found in our meat supply as well as in the air. Common antibiotics such as tetracycline may suppress sperm formation; and radiation, lead, marijuana, lack of selenium, and excessive alcohol can cause abnormal (two-headed, multiple-tailed, etc.) sperm to be produced. Male infertility may also be caused by the lack of a specific type of Ca^{2+} channel (Ca^{2+} is needed for normal sperm motility), anatomical obstructions, hormonal imbalances, and oxidative stress (which contributes to DNA fragmentation in sperm). A low sperm count accompanied by a high percentage of immature sperm may hint that a man has a *varicocele* (var'ĭ-ko-sēl"), a condition that hinders drainage of the testicular vein, resulting in an elevated temperature in the scrotum that interferes with normal sperm development. ●

Hormonal Regulation of Male Reproductive Function

The Brain-Testicular Axis

Hormonal regulation of spermatogenesis and testicular androgen production involves interactions between the hypothalamus, anterior pituitary gland, and testes, a relationship sometimes called the **brain-testicular axis.** The sequence of regulatory events, shown schematically in Figure 27.10, is as follows:

① The hypothalamus releases **gonadotropin-releasing hormone (GnRH),** which controls the release of the two anterior pituitary gonadotropins: **follicle-stimulating hormone (FSH)** and **luteinizing hormone (LH).** (Both FSH and LH were named for their effects on the female gonad.) GnRH reaches the anterior pituitary cells via the blood of the hypophyseal portal system.

② Binding of GnRH to pituitary cells (gonadotrophs) prompts them to secrete FSH and LH into the blood.

③ FSH stimulates spermatogenesis indirectly by stimulating the sustentacular cells to release **androgen-binding protein (ABP).** ABP prompts the spermatogenic cells to bind and concentrate **testosterone,** which in turn stimulates spermatogenesis. Thus, FSH makes the cells receptive to testosterone's stimulatory effects.

④ LH binds to the interstitial cells, prodding them to secrete testosterone (and a small amount of estrogen). Locally, testosterone serves as the final trigger for spermatogenesis. Testosterone entering the bloodstream exerts a number of effects at other body sites.

⑤ Testosterone inhibits hypothalamic release of GnRH and acts directly on the anterior pituitary to inhibit gonadotropin release. **Inhibin** (in-hib'in), a protein hormone produced by the sustentacular cells, serves as a "barometer" of the normalcy of spermatogenesis. When the sperm count is high, inhibin release increases and it inhibits anterior pituitary release of FSH and hypothalamic release of GnRH. When sperm count falls below 20 million/ml, inhibin secretion declines steeply.

As you can see, the amount of testosterone and sperm produced by the testes reflects a balance among three sets of hormones: (1) GnRH, which indirectly stimulates the testes via its effect on FSH and LH release; (2) gonadotropins, which directly stimulate the testes; and (3) testicular hormones (testosterone and inhibin), which exert negative feedback controls on the hypothalamus and anterior pituitary. Because the hypothalamus is also influenced by input from other brain areas, the whole axis is under CNS control. In the absence of GnRH

and gonadotropins, the testes atrophy, and sperm and testosterone production ceases.

Development of male reproductive structures (discussed later in the chapter) depends on prenatal secretion of male hormones, and for a few months after birth, a male infant has plasma gonadotropin and testosterone levels nearly equal to those of a midpubertal boy. Soon thereafter, blood levels of these hormones recede and they remain low throughout childhood. As puberty nears, much higher levels of testosterone are required to suppress hypothalamic release of GnRH. So as more GnRH is released, more testosterone is secreted by the testes, but the threshold for hypothalamic inhibition keeps rising until the adult pattern of hormone interaction is achieved, evidenced by the presence of mature sperm in the semen. Maturation of the brain-testicular axis takes about three years, and once established, the balance between the interacting hormones remains relatively constant. Consequently, an adult male's sperm and testosterone production also remains fairly stable.

Mechanism and Effects of Testosterone Activity

Testosterone, like all steroid hormones, is synthesized from cholesterol and exerts its effects by activating specific genes, which results in enhanced synthesis of certain proteins in the target cells. (See Chapter 16 for mechanisms of steroid hormone action.) In some target cells, testosterone must be transformed into another steroid to exert its effects. In the prostate, testosterone is converted to *dihydrotestosterone (DHT)* before it can bind in the nucleus, and in certain neurons of the brain, testosterone is converted to *estradiol* (es'trah-di-ol) to bring about its stimulatory effects.

As puberty ensues, testosterone not only prompts spermatogenesis but has multiple anabolic effects throughout the body (see Table 27.1, p. 1099). It targets accessory reproductive organs—ducts, glands, and the penis—causing them to grow and assume adult size and function. In adult males, normal plasma levels of testosterone maintain these organs: When the hormone is deficient or absent, all accessory organs atrophy, semen volume declines markedly, and erection and ejaculation are impaired. Thus, a man becomes both sterile and impotent. This situation is easily remedied by testosterone replacement therapy.

Male secondary sex characteristics—that is, features induced in the *nonreproductive* organs by the male sex hormones (mainly testosterone)—make their appearance at puberty. These include the appearance of pubic, axillary, and facial hair, enhanced hair growth on the chest or other body areas in some men, and a deepening of the voice as the larynx enlarges. The skin thickens and becomes oilier

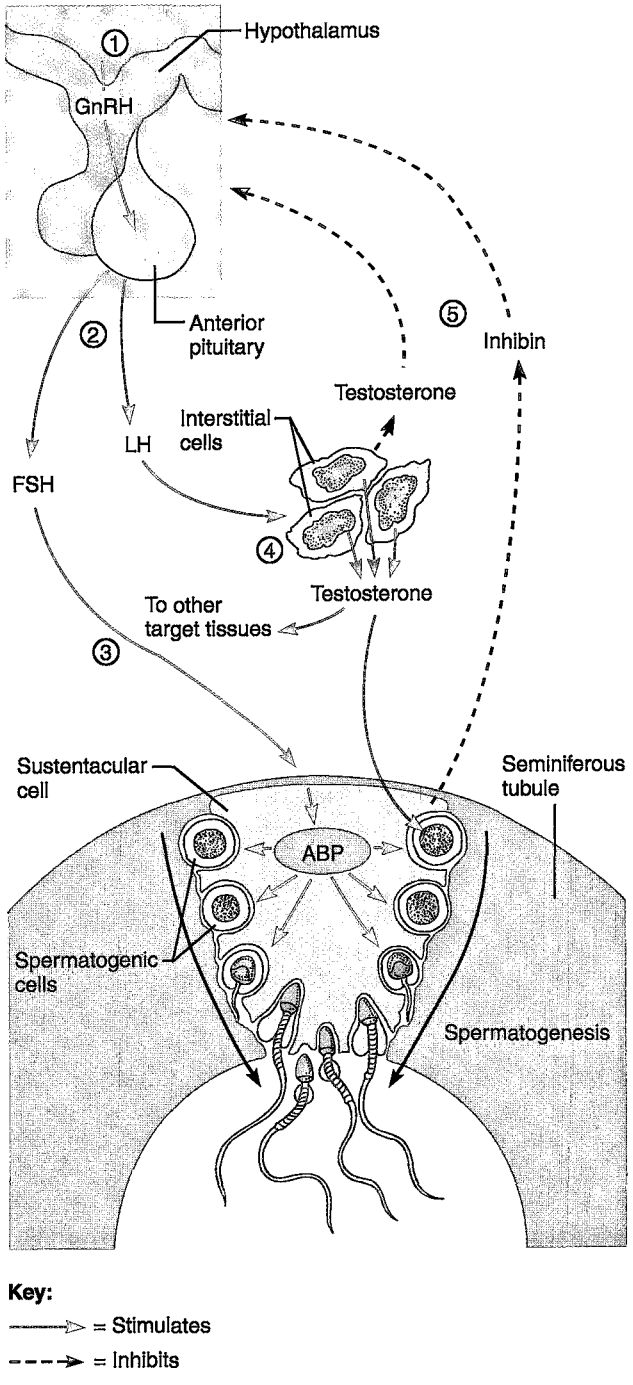

FIGURE 27.10 **Hormonal regulation of testicular function, the brain-testicular axis.** The hypothalamus releases gonadotropin-releasing hormone (GnRH). GnRH stimulates the anterior pituitary to release gonadotropins—follicle-stimulating hormone (FSH) and luteinizing hormone (LH). FSH causes the sustentacular cells to release androgen-binding protein (ABP). LH acts on the interstitial cells, stimulating their release of testosterone. ABP binding of testosterone then enhances spermatogenesis. Rising levels of testosterone and inhibin (released by the sustentacular cells) exert feedback inhibition on the hypothalamus and pituitary. (Only one sustentacular cell is depicted so that its structural relationship to the spermatogenic cells it encloses is clearly seen. However, it would be flanked by sustentacular cells on each side.)

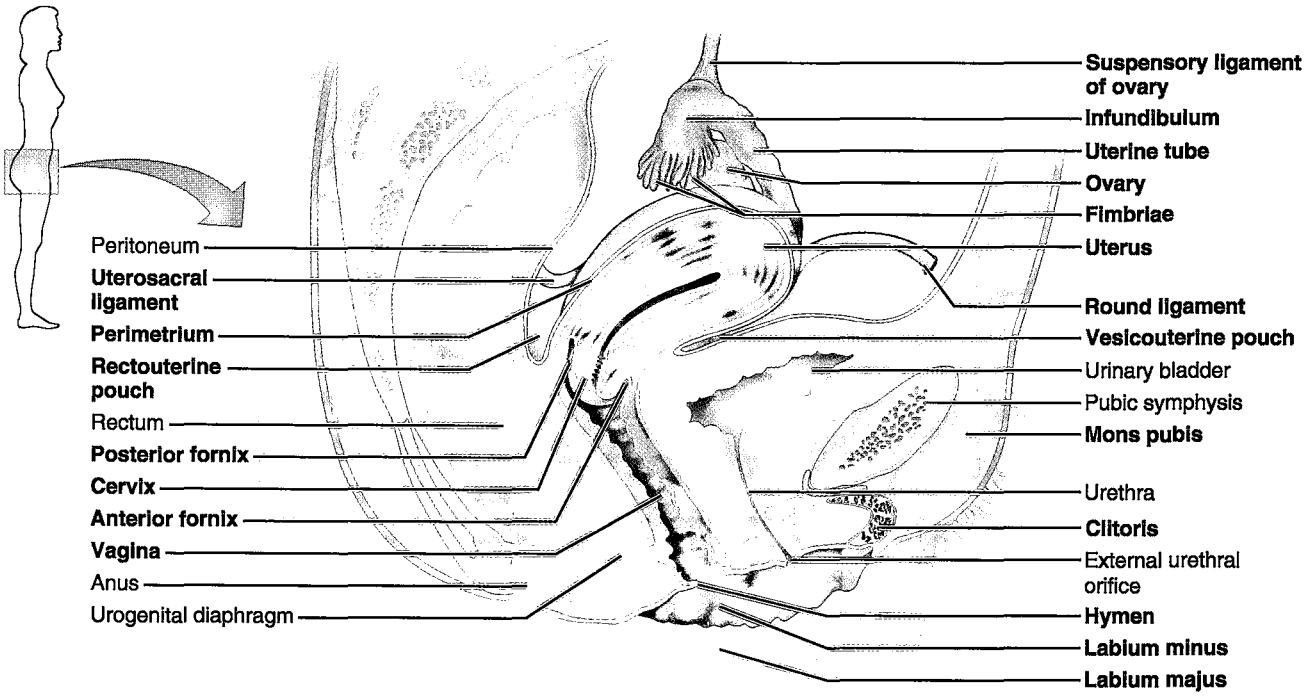

FIGURE 27.11 **Internal organs of the female reproductive system, midsagittal section.** (See *A Brief Atlas of the Human Body*, Figure 74.)

(which predisposes young men to acne), bones grow and increase in density, and skeletal muscles increase in size and mass. The last two effects are often referred to as the *somatic effects* of testosterone (*soma* = body). Epiphyseal plate closure occurs in response to rising estrogen levels late in puberty.

Testosterone also boosts basal metabolic rate and influences behavior. It is the basis of the sex drive (libido) in males and to some extent in females, be they heterosexual or homosexual. Thus, although testosterone is called a "male" sex hormone, it should not be specifically tagged as a promoter of male sexual activity. In embryos, the presence of testosterone masculinizes the brain. Testosterone also appears to continue to shape certain regions of the male brain well into adult life, as indicated by the differences in males' and females' brain areas involved in sexual arousal (for example, the amygdala).

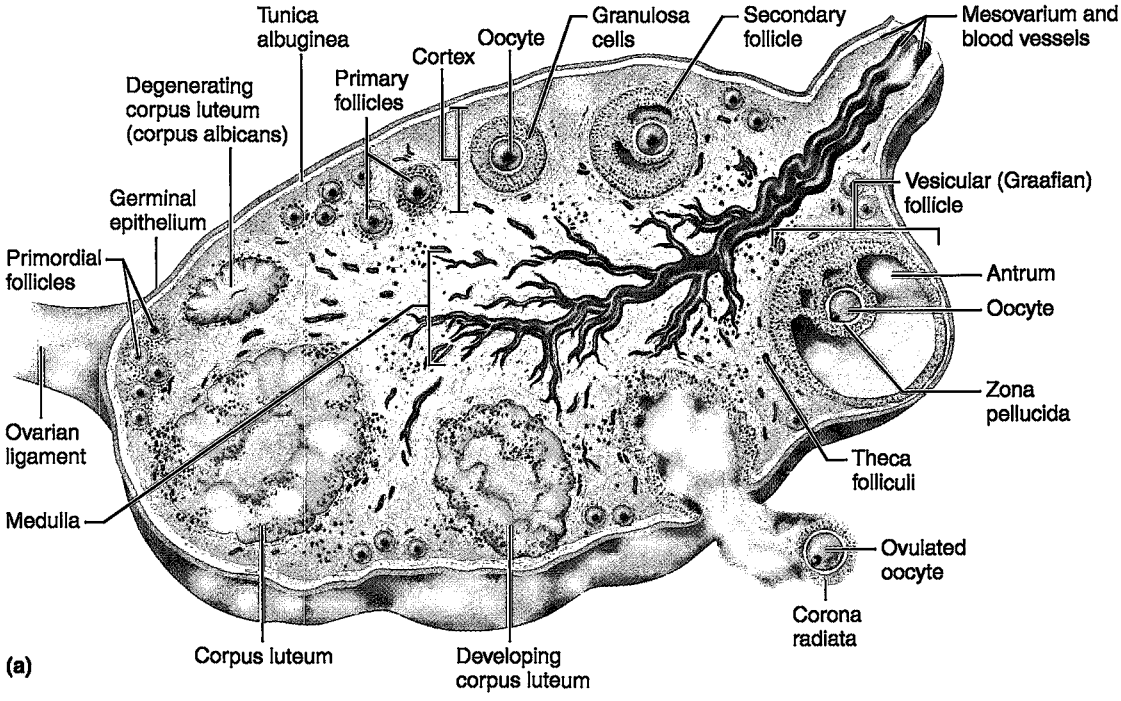
The testes are not the only source of androgens; the adrenal glands of both sexes also release androgens. However, the relatively small amounts of adrenal androgens are unable to support normal testosterone-mediated functions when the testes fail to produce androgens, so we can assume that it is the testosterone production by the testes that supports male reproductive function. However, as noted later (p. 1100), the adrenal androgen DHEA appears to be more important than testosterone in helping to determine the *female* libido.

Anatomy of the Female Reproductive System

The reproductive role of the female is far more complex than that of a male. Not only must she produce gametes, but her body must prepare to nurture a developing embryo for a period of approximately nine months. **Ovaries,** the **female gonads,** are the primary reproductive organs of a female, and like the male testes, ovaries serve a dual purpose: They produce the female gametes (ova) and sex hormones, the **estrogens*** and **progesterone** (pro-ges'tĕ-rōn). The accessory ducts (uterine tubes, uterus, and vagina) transport or otherwise serve the needs of the reproductive cells and a developing fetus.

As illustrated in Figure 27.11, the ovaries and duct system, collectively known as the **internal genitalia,** are mostly located in the pelvic cavity. The female's accessory ducts, from the vicinity of the ovary to the body exterior, are the *uterine tubes,* the *uterus,* and the *vagina.* The external sex organs of females are referred to as the **external genitalia.**

*The ovaries produce several different estrogens *(estradiol, estrone,* and *estriol).* Estradiol is the most abundant and is most responsible for estrogenic effects.



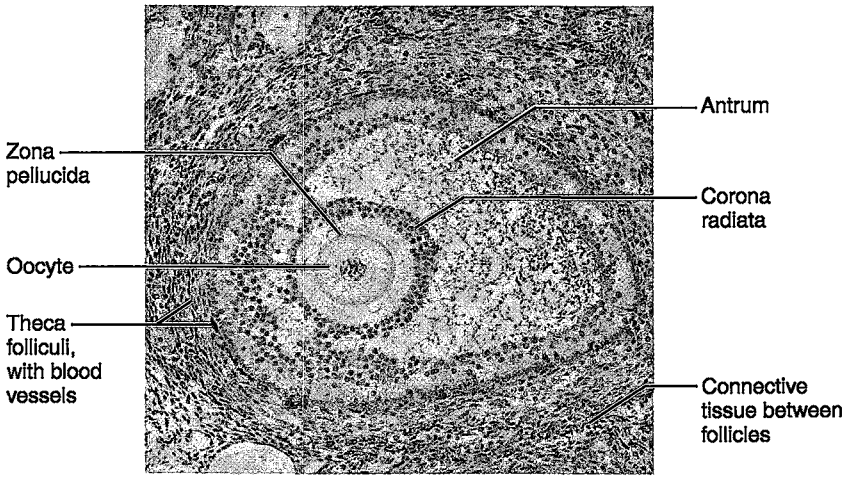


FIGURE 27.12 **Structure of an ovary. (a)** The ovary has been sectioned to reveal the follicles in its interior. Note that not all of these structures would appear in the ovary at the same time. **(b)** Photomicrograph of a mature vesicular (Graafian) follicle (108×). (See *A Brief Atlas of the Human Body*, Plate 52.)

The Ovaries

The paired ovaries flank the uterus on each side (see Figure 27.11). Shaped like an almond and about twice as large, each ovary is held in place in the fork of the iliac blood vessels within the peritoneal cavity by several ligaments. The **ovarian ligament** anchors the ovary medially to the uterus; the **suspensory ligament** anchors it laterally to the pelvic wall; and the **mesovarium** (mez"o-va're-um) suspends it in between (see Figures 27.11 and 27.14a). The suspensory ligament and the mesovarium are part of the **broad ligament,** a peritoneal fold that "tents" over the uterus and supports the uterine tubes, uterus, and vagina. The ovarian ligaments are enclosed by the broad ligament.

The ovaries are served by the **ovarian arteries,** branches of the abdominal aorta (see Figure 19.23c), and by the *ovarian branch of the uterine arteries.* The ovarian blood vessels reach the ovaries by traveling through the suspensory ligaments and mesovaria.

Like each testis, each ovary is surrounded externally by a fibrous **tunica albuginea** (Figure 27.12), which is in turn covered externally by a layer of cuboidal epithelial cells called the *germinal epithelium,* actually a continuation of the peritoneum. The ovary has an outer cortex, which houses the

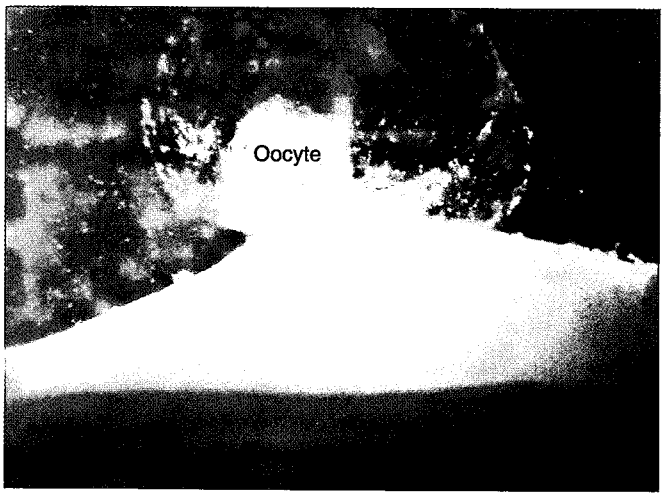

FIGURE 27.13 **Ovulation.** A secondary oocyte is released from a follicle at the surface of the ovary (30×). The orange mass below the ejected oocyte is part of the ovary. (Primary and secondary oocytes are explained in Figure 27.19 on p. 1091.)

forming gametes, and an inner medullary region, containing the largest blood vessels and nerves, but the relative extent of each region is poorly defined.

Embedded in the highly vascular connective tissue of the ovary cortex are many tiny saclike structures called **ovarian follicles.** Each follicle consists of an immature egg, called an **oocyte** (o'o-sīt; *oo* = egg), encased by one or more layers of very different cells. The surrounding cells are called **follicle cells** if a single layer is present, and **granulosa cells** when more than one layer is present. Follicles at different stages of maturation are distinguished by their structure. In a **primordial follicle,** one layer of squamouslike follicle cells surrounds the oocyte. A **primary follicle** has two or more layers of cuboidal or columnar-type granulosa cells enclosing the oocyte; it becomes a **secondary follicle** when fluid-filled spaces appear between the granulosa cells and then coalesce to form a central fluid-filled cavity called an *antrum.* At the mature **vesicular follicle,** or **Graafian follicle** (graf'e-an), stage, the follicle bulges from the surface of the ovary. The oocyte of the vesicular follicle "sits" on a stalk of granulosa cells at one side of the antrum. Each month in adult women, one of the ripening follicles ejects its oocyte from the ovary, an event called **ovulation** (Figure 27.13). After ovulation, the ruptured follicle is transformed into a very different looking glandular structure called the **corpus luteum** (lu'te-um; plural: corpora lutea), which eventually degenerates. As a rule, most of these structures can be seen within the same ovary. In older women, the surfaces of the ovaries are scarred and pitted, revealing that many oocytes have been released.

The Female Duct System

The Uterine Tubes

The **uterine tubes** (u'ter-in), also called **fallopian tubes** or **oviducts,** form the initial part of the female duct system (Figures 27.11 and 27.14a). They receive the ovulated oocyte and are the site where fertilization generally occurs. Each uterine tube is about 10 cm (4 inches) long and extends medially from the region of an ovary to empty into the superolateral region of the uterus via a constricted region called the **isthmus** (is'mus). The distal end of each uterine tube expands as it curves around the ovary, forming the **ampulla;** fertilization usually occurs in this region. The ampulla ends in the **infundibulum** (in"fun-dib'u-lum), an open, funnel-shaped structure bearing ciliated, fingerlike projections called **fimbriae** (fim'bre-e; "fringe") that drape over the ovary. Unlike the male duct system, which is continuous with the tubules of the testes, the uterine tubes have little or no actual contact with the ovaries. An ovulated oocyte is cast into the peritoneal cavity, and many oocytes are lost there. However, the uterine tube performs complex movements to capture oocytes—it bends to drape over the ovary while the fimbriae stiffen and sweep the ovarian surface. The beating cilia on the fimbriae then create currents in the peritoneal fluid that tend to carry an oocyte into the uterine tube, where it begins its journey toward the uterus.

The uterine tube contains sheets of smooth muscle, and its thick, highly folded mucosa contains both ciliated and nonciliated cells. The oocyte is carried toward the uterus by a combination of muscular peristalsis and the beating of the cilia. Nonciliated cells of the mucosa have dense microvilli and produce a secretion that keeps the oocyte (and sperm, if present) moist and nourished.

Externally, the uterine tubes are covered by visceral peritoneum and supported along their length by a short mesentery (part of the broad ligament) called the **mesosalpinx** (mez"o-sal'pinks; "mesentery of the trumpet"; *salpin* = trumpet), a reference to the trumpet-shaped uterine tube it supports (see Figure 27.14a).

HOMEOSTATIC IMBALANCE

The fact that the uterine tubes are not continuous with the ovaries places women at risk for *ectopic pregnancy* in which a zygote, fertilized in the peritoneal cavity or distal portion of the uterine tube, begins developing there. Because the tube lacks adequate mass and vascularization to support the full term of pregnancy, such pregnancies naturally abort, often with substantial bleeding. Another potential problem is infection spreading into the peritoneal

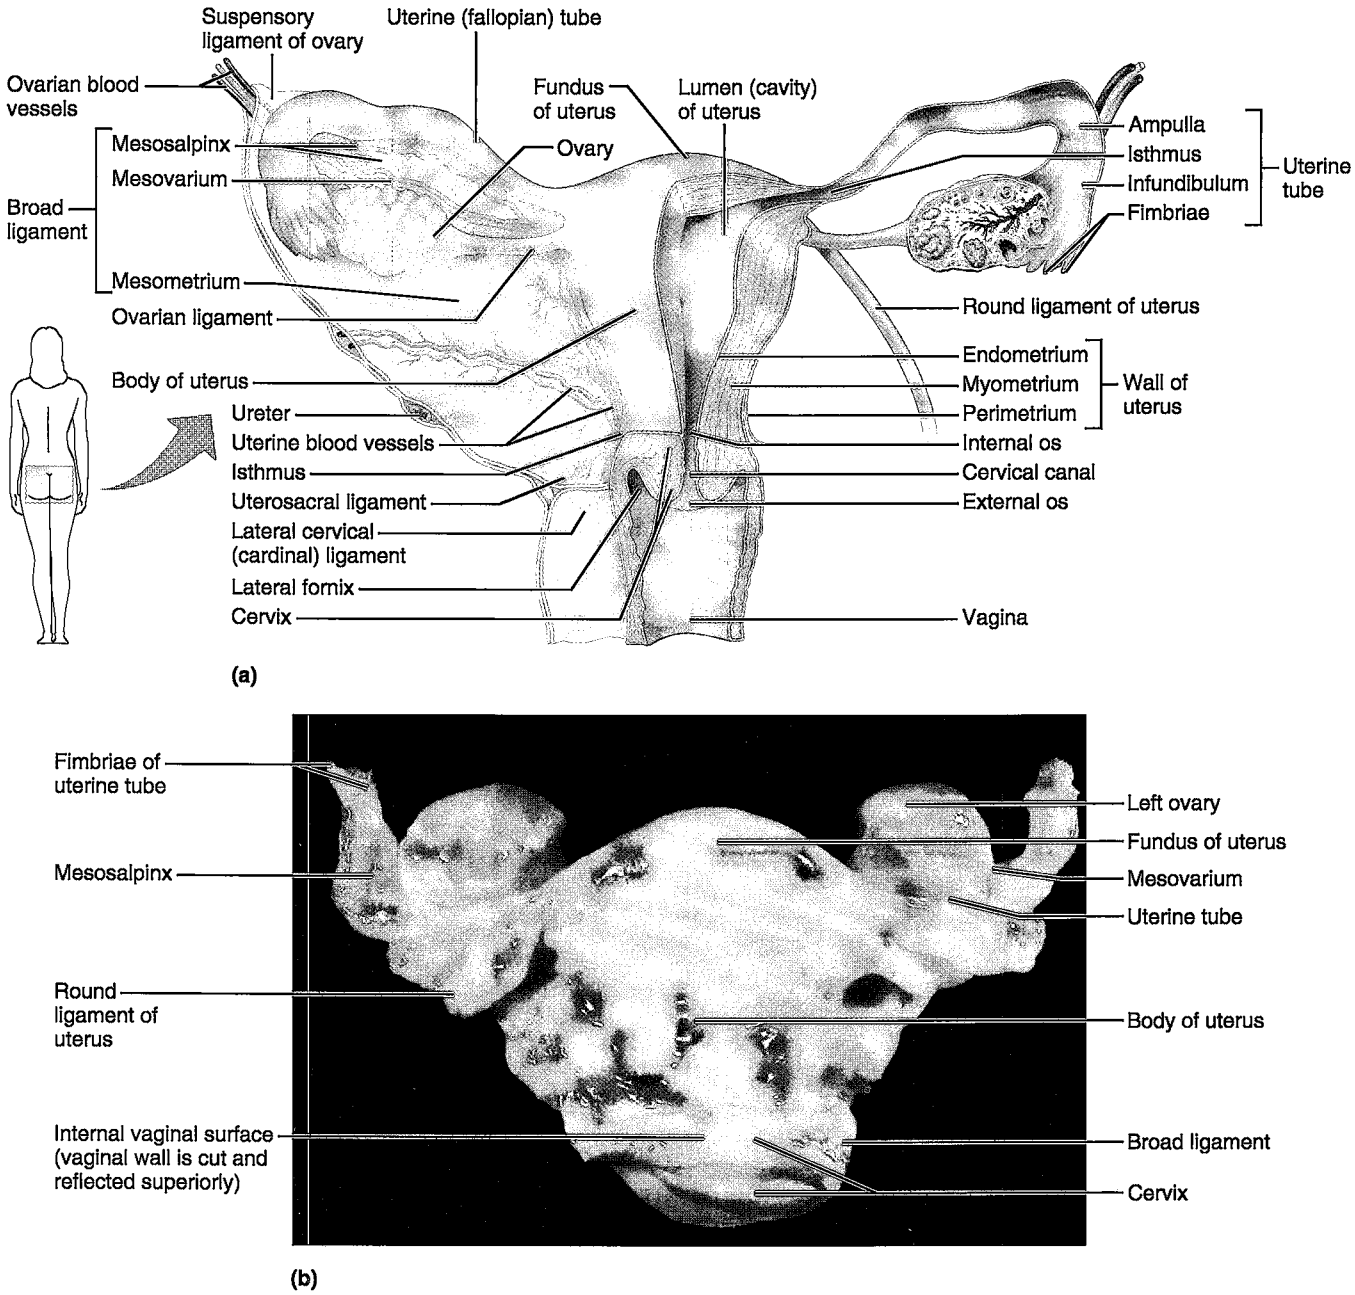

FIGURE 27.14 **Internal reproductive organs of a female. (a)** Posterior view of the female reproductive organs. The posterior walls of the vagina, uterus, and uterine tubes and the broad ligament (a peritoneal fold) have been removed on the right side to reveal the shape of the lumen of these organs. **(b)** Anterior view of the reproductive organs of a female cadaver. (See *A Brief Atlas of the Human Body,* Figure 75.)

cavity from other parts of the reproductive tract. Gonorrhea bacteria and other sexually transmitted microorganisms sometimes infect the peritoneal cavity in this way, causing an extremely severe inflammation called **pelvic inflammatory disease (PID).** Unless treated promptly with broad-spectrum antibiotics, PID can cause scarring of the narrow uterine tubes and of the ovaries, causing sterility. Indeed, scarring and closure of the uterine tubes, which have an internal diameter as small as the width of a human hair in some regions, is one of the major causes of female infertility. ●

The Uterus

The **uterus** (Latin for "womb") is located in the pelvis, anterior to the rectum and posterosuperior to the bladder (see Figures 27.11 and 27.14). It is a hollow, thick-walled, muscular organ that functions to

receive, retain, and nourish a fertilized ovum. In a premenopausal woman who has never been pregnant, the uterus is about the size and shape of an inverted pear, but it is usually somewhat larger in women who have borne children. Normally, the uterus flexes anteriorly where it joins the vagina, causing the uterus as a whole to be inclined forward, or *anteverted.* However, the organ is frequently turned backward, or *retroverted,* in older women.

The major portion of the uterus is referred to as the **body** (see Figures 27.11 and 27.14). The rounded region superior to the entrance of the uterine tubes is the **fundus,** and the slightly narrowed region between the body and the cervix is the *isthmus*. The **cervix** of the uterus is its narrow neck, or outlet, which projects into the vagina inferiorly. The cavity of the cervix, called the **cervical canal,** communicates with the vagina via the *external os* (*os* = mouth) and with the cavity of the uterine body via the *internal os.* The mucosa of the cervical canal contains *cervical glands* that secrete a mucus that fills the cervical canal and covers the external os, presumably to block the spread of bacteria from the vagina into the uterus. Cervical mucus also blocks the entry of sperm, except at midcycle, when it becomes less viscous and allows sperm to pass through.

HOMEOSTATIC IMBALANCE

Cancer of the cervix strikes about 450,000 women worldwide each year, killing about half. It is most common among women between the ages of 30 and 50. Risk factors include frequent cervical inflammations, sexually transmitted diseases including genital warts, and multiple pregnancies. The cancer cells arise from the epithelium covering the cervical tip. In a *Papanicolaou (Pap) smear,* or cervical smear test, some of these cells are scraped away and then examined for abnormalities. A Pap smear is the most effective way to detect this slow-growing cancer, and American Cancer Society guidelines advise women to have one yearly until the age of 70, when this monitoring can be stopped if there have been no abnormal results in the past 10 years. When results are inconclusive, a test for the sexually transmitted human papillomavirus (the cause of virtually all cervical cancer) can be done from the same Pap sample. New on the treatment horizon is a vaccine against that virus which appears to be 100% effective in clinical tests.

Supports of the Uterus The uterus is supported laterally by the **mesometrium** ("mesentery of the uterus") portion of the broad ligament (Figure 27.14a). More inferiorly, the **lateral cervical (cardinal) ligaments** extend from the cervix and superior vagina to the lateral walls of the pelvis, and the paired **uterosacral ligaments** secure the uterus to the sacrum posteriorly. The uterus is bound to the anterior body wall by the fibrous **round ligaments,** which run through the inguinal canals to anchor in the subcutaneous tissue of the labia majora. These ligaments allow the uterus a good deal of mobility, and its position changes as the rectum and bladder fill and empty.

HOMEOSTATIC IMBALANCE

Despite the many anchoring ligaments, the principal support of the uterus is provided by the muscles of the pelvic floor, namely the muscles of the urogenital and pelvic diaphragms (Table 10.7). These muscles are sometimes torn during childbirth. Subsequently, the unsupported uterus may sink inferiorly, until the tip of the cervix protrudes through the external vaginal opening. This condition is called **prolapse of the uterus.**

The undulating course of the peritoneum produces several cul-de-sacs, or blind-ended peritoneal pouches. The most important of these are the *vesicouterine pouch* (ves"i-ko-u'ter-in) between the bladder and uterus, and the *rectouterine pouch* between the rectum and uterus (see Figure 27.11).

The Uterine Wall The wall of the uterus is composed of three layers (Figure 27.14a). The **perimetrium,** the incomplete outermost serous layer, is the peritoneum. The **myometrium** (mi"o-me'tre-um; "muscle of the uterus") is the bulky middle layer, composed of interlacing bundles of smooth muscle, that contracts rhythmically during childbirth to expel the baby from the mother's body. The **endometrium** is the mucosal lining of the uterine cavity (Figure 27.15); it is a simple columnar epithelium underlain by a thick lamina propria. If fertilization occurs, the young embryo burrows into the endometrium (implants) and resides there for the rest of its development.

The endometrium has two chief *strata* (layers). The **stratum functionalis** (fungk-shun-a'lis), or **functional layer,** undergoes cyclic changes in response to blood levels of ovarian hormones and is shed during menstruation (approximately every 28 days). The thinner, deeper **stratum basalis** (ba-sā'lis), or **basal layer,** forms a new functionalis after menstruation ends. It is unresponsive to ovarian hormones. The endometrium has numerous *uterine glands* that change in length as endometrial thickness changes.

To understand the cyclic changes of the uterine endometrium (discussed later in the chapter), it is essential to understand the vascular supply of the uterus. The **uterine arteries** arise from the *internal iliacs* in the pelvis, ascend along the sides of the uterus, and send branches into the uterine wall (Figure 27.14a). These branches break up into several

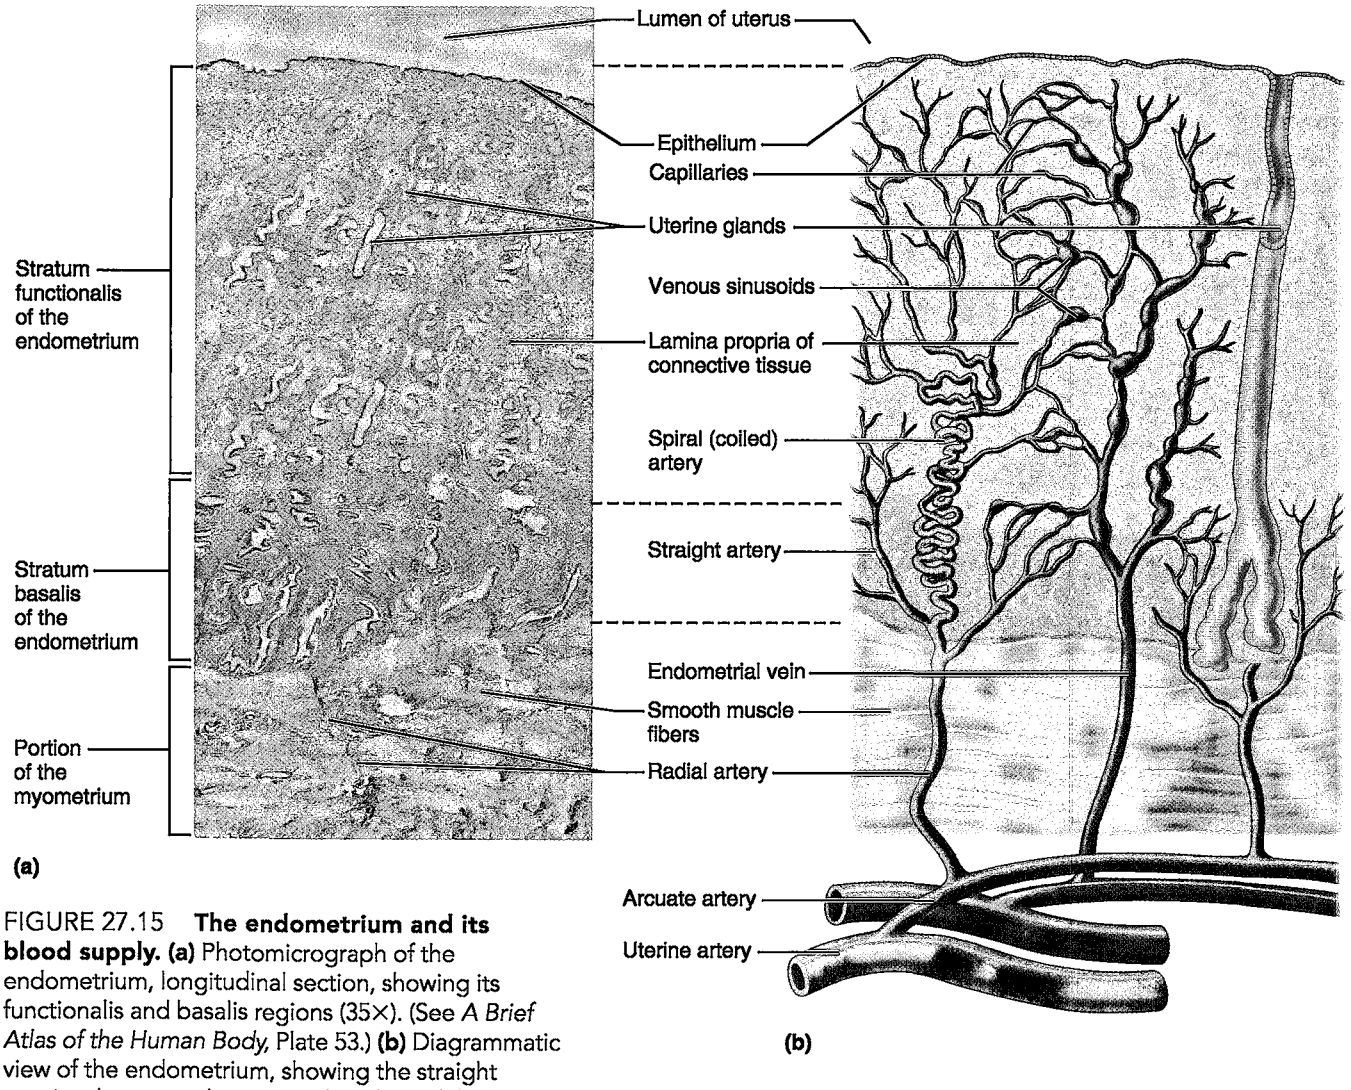

FIGURE 27.15 **The endometrium and its blood supply. (a)** Photomicrograph of the endometrium, longitudinal section, showing its functionalis and basalis regions (35×). (See *A Brief Atlas of the Human Body,* Plate 53.) **(b)** Diagrammatic view of the endometrium, showing the straight arteries that serve the stratum basalis and the spiral arteries that serve the stratum functionalis. The thin-walled veins and venous sinusoids are also illustrated.

arcuate arteries (ar'ku-āt) within the myometrium. The arcuate arteries send **radial branches** into the endometrium, where they in turn give off **straight arteries** to the stratum basalis and **spiral (coiled) arteries** to the stratum functionalis. The spiral arteries repeatedly degenerate and regenerate, and it is their spasms that actually cause the functionalis layer to be shed during menstruation. Veins in the endometrium are thin-walled and form an extensive network with occasional sinusoidal enlargements.

The Vagina

The **vagina** ("sheath") is a thin-walled tube, 8–10 cm (3–4 inches) long. It lies between the bladder and the rectum and extends from the cervix to the body exterior (see Figure 27.11). The urethra is embedded in its anterior wall. Often called the *birth canal,* the vagina provides a passageway for delivery of an infant and for menstrual flow. Since it receives the penis (and semen) during sexual intercourse, it is the *female organ of copulation.*

The distensible wall of the vagina consists of three coats: an outer fibroelastic *adventitia,* a smooth muscle *muscularis,* and a *mucosa* marked by transverse ridges or *rugae,* which stimulate the penis during intercourse. The mucosa is a stratified squamous epithelium adapted to stand up to friction. Certain mucosal cells *(dendritic cells)* act as antigen-presenting cells and are thought to provide the route of HIV transmission from an infected male to the female during sexual intercourse. (AIDS, the immune deficiency disease caused by HIV, is described in Chapter 21.) The vaginal mucosa has no glands; it is lubricated by the cervical mucous

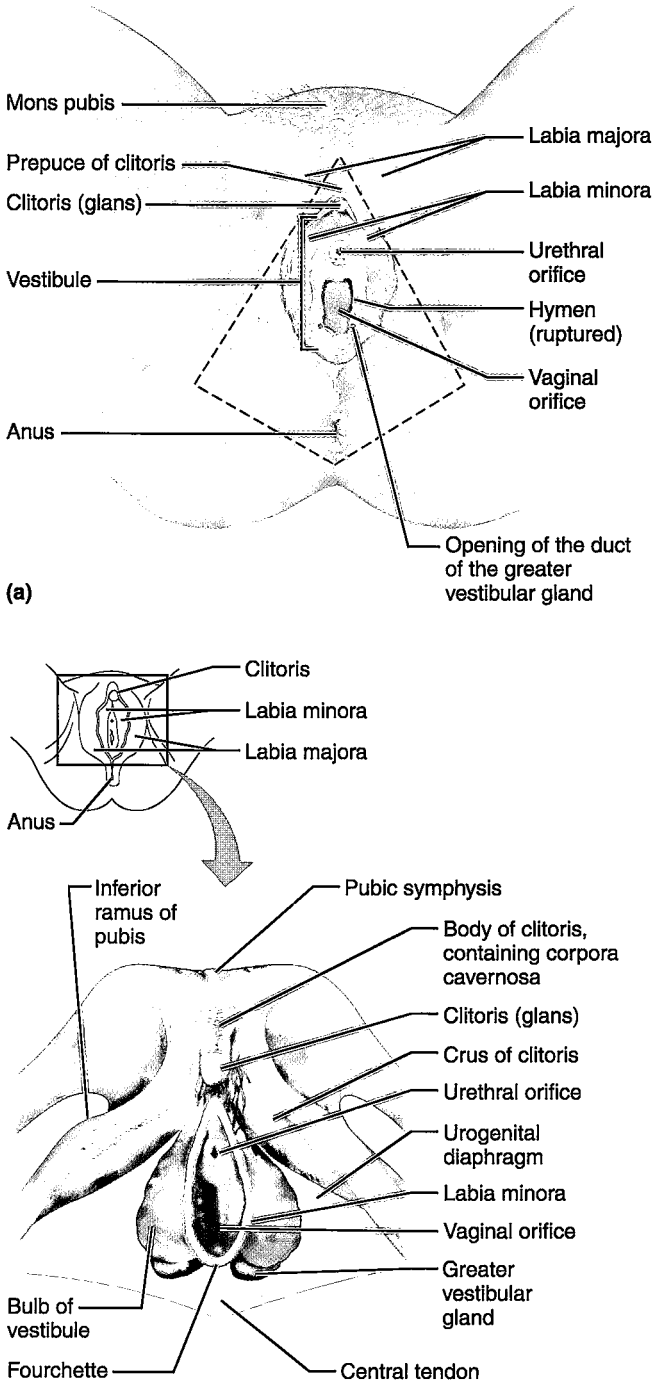

FIGURE 27.16 **The external genitalia (vulva) of the female. (a)** Superficial structures. The region enclosed by the dashed lines is the perineum. **(b)** Deep structures. The labia majora and associated skin have been removed to show the underlying erectile bodies. For the associated superficial muscles, see Figure 10.12 on p. 351.

glands. Its epithelial cells release large amounts of glycogen, which is anaerobically metabolized to lactic acid by resident bacteria. Consequently, the pH of a woman's vagina is normally quite acidic. This acidity helps keep the vagina healthy and free of infection, but it is also hostile to sperm. Although vaginal fluid of *adult* females is acidic, it tends to be alkaline in adolescents, predisposing sexually active teenagers to sexually transmitted diseases.

In virgins (those who have never participated in sexual intercourse), the mucosa near the distal **vaginal orifice** forms an incomplete partition called the **hymen** (hi'men) (Figure 27.16). The hymen is very vascular and tends to bleed when it is ruptured during the first coitus (sexual intercourse). However, its durability varies. In some females, it is ruptured during a sports activity, tampon insertion, or pelvic examination. Occasionally, it is so tough that it must be breached surgically if intercourse is to occur.

The upper end of the vaginal canal loosely surrounds the cervix of the uterus, producing a vaginal recess called the **vaginal fornix.** The posterior part of this recess, the *posterior fornix,* is much deeper than the *lateral* and *anterior fornices* (see Figures 27.11 and 27.14a). Generally, the lumen of the vagina is quite small and, except where it is held open by the cervix, its posterior and anterior walls are in contact with one another. The vagina stretches considerably during copulation and childbirth, but its lateral distension is limited by the ischial spines and the sacrospinous ligaments.

HOMEOSTATIC IMBALANCE

The uterus tilts away from the vagina. Hence, attempts by untrained persons to induce an abortion by entering the uterus with a surgical instrument may result in puncturing of the posterior wall of the vagina, followed by hemorrhage and—if the instrument is unsterile—peritonitis. ●

The External Genitalia

As mentioned earlier, the female reproductive structures that lie external to the vagina are called the *external genitalia* (see Figure 27.16). The external genitalia, also called the **vulva** (vul'vah; "covering") or **pudendum** ("shameful"), include the mons pubis, labia, clitoris, and structures associated with the vestibule.

The **mons pubis** (mons pu'bis; "mountain on the pubis") is a fatty, rounded area overlying the pubic symphysis. After puberty, this area is covered with pubic hair. Running posteriorly from the mons pubis are two elongated, hair-covered fatty skin folds, the **labia majora** (la'be-ah mah-jor'ah; "larger lips"). These are the female counterpart, or *homologue,* of the male scrotum (that is, they derive from the same embryonic tissue). The labia majora enclose the **labia minora** (mi-nor'ah; "smaller"), two thin, hair-free skin folds, homologous to the ventral penis. The

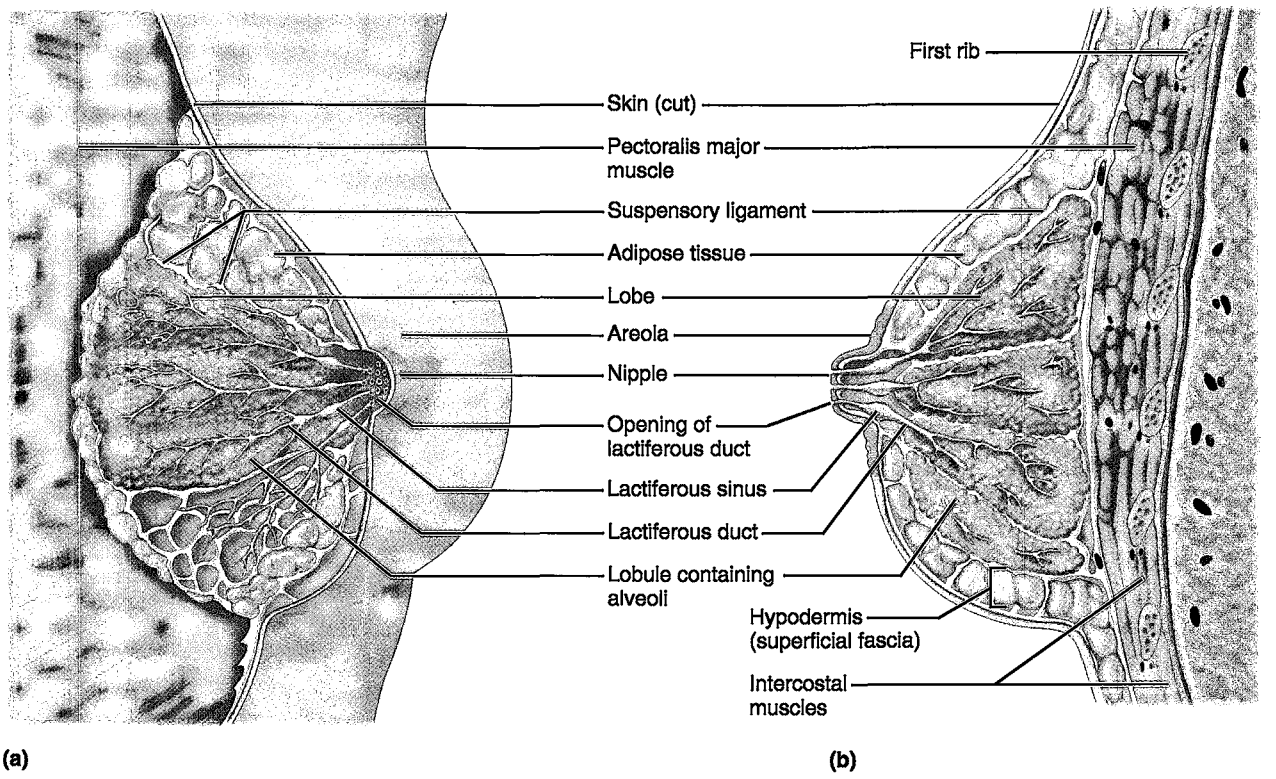

FIGURE 27.17 **Structure of lactating mammary glands. (a)** Anterior view of a partially dissected breast. **(b)** Sagittal section of a breast.

labia minora enclose a recess called the **vestibule** ("entrance hall"), which contains the external openings of the urethra and the vagina. Flanking the vaginal opening are the pea-size **greater vestibular glands,** homologous to the bulbourethral glands of males. These glands release mucus into the vestibule and help to keep it moist and lubricated, facilitating intercourse. At the extreme posterior end of the vestibule the labia minora come together to form a ridge called the **fourchette.**

Just anterior to the vestibule is the **clitoris** (klit' o-ris; "hill"), a small, protruding structure composed largely of erectile tissue, which is homologous to the penis of the male. Its exposed portion is called the **glans of the clitoris.** It is hooded by a skin fold called the **prepuce of the clitoris,** formed by the junction of the labia minora folds. The clitoris is richly innervated with sensory nerve endings sensitive to touch, and it becomes swollen with blood and erect during tactile stimulation, contributing to a female's sexual arousal. Like the penis, the body of the clitoris has dorsal erectile columns (corpora cavernosa) attached proximally by crura, but it lacks a corpus spongiosum that conveys a urethra. In males the urethra carries both urine and semen and runs through the penis, but the female urinary and reproductive tracts are completely separate. Instead, the **bulbs of the vestibule,** which lie along each side of the vaginal orifice and deep to the bulbospongiosus muscle, are the homologues of the single penile bulb and corpus spongiosum of the male, and during sexual stimulation the bulbs of the vestibule engorge with blood. This may help grip the penis within the vagina and also squeezes the urethral orifice shut, which prevents semen (and bacteria) from traveling superiorly into the bladder during intercourse.

The female **perineum** is a diamond-shaped region located between the pubic arch anteriorly, the coccyx posteriorly, and the ischial tuberosities laterally. The soft tissues of the perineum overlie the muscles of the pelvic outlet, and the posterior ends of the labia majora overlie the *central tendon,* into which most muscles supporting the pelvic floor insert (see Table 10.7).

The Mammary Glands

The **mammary glands** are present in both sexes, but they normally function only in females (Figure 27.17). The biological role of the mammary glands is to produce milk to nourish a newborn baby, so they are important only when reproduction has already been accomplished.

Developmentally, mammary glands are modified sweat glands that are really part of the *skin,* or

integumentary system. Each mammary gland is contained within a rounded skin-covered breast within the hypodermis (superficial fascia), anterior to the pectoral muscles of the thorax. Slightly below the center of each breast is a ring of pigmented skin, the **areola** (ah-re'o-lah), which surrounds a central protruding **nipple.** Large sebaceous glands in the areola make it slightly bumpy and produce sebum that reduces chapping and cracking of the skin of the nipple. Autonomic nervous system controls of smooth muscle fibers in the areola and nipple cause the nipple to become erect when stimulated by tactile or sexual stimuli and when exposed to cold.

Internally, each mammary gland consists of 15 to 25 **lobes** that radiate around and open at the nipple. The lobes are padded and separated from each other by fibrous connective tissue and fat. The interlobar connective tissue forms **suspensory ligaments** that attach the breast to the underlying muscle fascia and to the overlying dermis. As suggested by their name, the suspensory ligaments provide natural support for the breasts, like a built-in brassiere. Within the lobes are smaller units called **lobules,** which contain glandular **alveoli** that produce milk when a woman is lactating. These compound alveolar glands pass the milk into the **lactiferous ducts** (lak-tif'er-us), which open to the outside at the nipple. Just deep to the areola, each duct has a dilated region called a **lactiferous sinus** where milk accumulates during nursing. The process and regulation of lactation are described in Chapter 28.

The description of mammary glands given here applies only to nursing women or women in the last trimester of pregnancy. In nonpregnant women, the glandular structure of the breast is largely undeveloped and the duct system is rudimentary; hence breast size is largely due to the amount of fat deposits.

Breast Cancer

Invasive breast cancer is the most common malignancy and the second most common cause of cancer death of U.S. women. Thirteen percent of women in the general population (132 out of 1000 individuals) will develop this condition. Breast cancer usually arises from the epithelial cells of the smallest ducts, not from the alveoli. A small cluster of cancer cells grows into a lump in the breast from which cells eventually metastasize.

Known risk factors for developing breast cancer include (1) early onset menses and late menopause; (2) no pregnancies or first pregnancy later in life and no or short periods of breast feeding; (3) family history of breast cancer (especially in a sister or mother), and (4) postmenopausal estrogen-progesterone replacement. Some 10% of breast cancers stem from hereditary defects and half of these can be traced to dangerous mutations in a pair of genes, dubbed *BRCA1* (breast cancer 1) and *BRCA2,* which cause 80% of those who carry the altered gene to develop breast cancer. Notice that, with the possible exception of family history, these factors reflect increased lifelong exposure to estrogen. However, more than 70% of women who develop breast cancer have no known risk factors for the disease.

Breast cancer is often signaled by a change in skin texture, puckering, or leakage from the nipple. Since most breast lumps are discovered by women themselves in routine monthly breast exams, this simple examination should be a health maintenance priority in every woman's life. The American Cancer Society had recommended scheduling **mammography**—X-ray examination that detects breast cancers too small to feel (less than 1 cm)—every two years for women between 40 and 49 years old and yearly thereafter (Figure 27.18); however, some authorities suggest that yearly is too frequent. A new study suggests that at-risk women who carry a BRCA gene should preferably have diagnostic MRI scans.

Once diagnosed, breast cancer is treated in various ways depending on specific characteristics of the lesion. Current therapies include (1) radiation therapy, (2) chemotherapy, and (3) surgery, often followed by irradiation or chemotherapy to destroy stray cancer cells. Drug therapies include trastuzumab (Herceptin), a drug containing bioengineered antibodies that jam estrogen receptors that control aggressive growth in breast cancer cells; tamoxifen, an antiestrogen compound that blocks estrogen's effects and significantly improves the outcome for those (premenopausal women) with early- or late-stage breast cancer; and letrozole (Femara), which disables the enzyme needed to make estrogen and reduces breast cancer recurrences in women (particularly postmenopausal women) who have exhausted the usefulness of tamoxifen.

Until the 1970s, the standard treatment was **radical mastectomy** (mas-tek'to-me; "breast cutting"), removal of the entire affected breast, plus all underlying muscles, fascia, and associated lymph nodes. Most physicians now recommend **lumpectomy,** less extensive surgery in which only the cancerous part (lump) is excised, or **simple mastectomy,** removal of the breast tissue only (and perhaps some of the axillary lymph nodes). Many mastectomy patients opt for breast reconstruction to replace the excised tissue. Currently tissue "flaps," containing muscle, fat, and skin taken from the patient's abdomen or back, are providing acceptable alternatives for "sculpting" a natural-looking breast.

Physiology of the Female Reproductive System

Oogenesis

Gamete production in males begins at puberty and continues throughout life, but the situation is quite different in females. It has been assumed that a female's total supply of eggs is already determined by the time she is born, and the time span during which she releases them extends only from puberty to menopause (about the age of 50). However, a recent study in adult mice has indicated that germ stem cells are alive and generating little "egglets" throughout life and there are hints that egg stem cells also exist in adult women. Although these findings seem to overturn the assumption that the number of oocytes (thus, potential eggs) is limited—an idea that has been part of the bedrock of biology—it is still too early to retire the "no new eggs" doctrine.

Meiosis, the specialized nuclear division that occurs in the testes to produce sperm, also occurs in the ovaries. In this case, female sex cells are produced, and the process is called **oogenesis** (o"o-gen'e-sis; "the beginning of an egg"). The process of oogenesis (Figure 27.19) takes years to complete. First, in the fetal period the **oogonia,** the diploid stem cells of the ovaries, multiply rapidly by mitosis and then enter a growth phase and lay in nutrient reserves. Gradually, *primordial follicles* begin to appear as the oogonia are transformed into **primary oocytes** and become surrounded by a single layer of flattened follicle cells. The primary oocytes begin the first meiotic division, but become "stalled" late in prophase I and do not complete it. By birth, a female has been presumed to have her lifetime supply of primary oocytes; of the original 7 million oocytes approximately 2 million of them escape programmed death and are already in place in the cortical region of the immature ovary. Since they remain in their state of suspended animation all through childhood, the wait is a long one—10 to 14 years at the very least!

At puberty, perhaps 250,000 oocytes remain and beginning at this time a small number of primary oocytes are recruited (activated) each month in response to the LH surge midcycle (see Figure 27.22). However, only one is "selected" each time to continue meiosis I, ultimately producing two haploid cells (each with 23 replicated chromosomes) that are quite dissimilar in size. The smaller cell is called the **first polar body.** The larger cell, which contains nearly all the cytoplasm of the primary oocyte, is the **secondary oocyte.** The events of this first maturation division are interesting. A spindle forms at the very edge of the oocyte (see Figure 27.19, left), and a little "nipple," into which the polar body chromosomes will be cast, appears at that edge. This ensures that the polar body receives almost no cytoplasm or organelles.

The first polar body may continue its development and undergo meiosis II, producing two even smaller polar bodies. However, in humans, the secondary oocyte arrests in metaphase II and it is this cell (not a functional ovum) that is ovulated. If an ovulated secondary oocyte is not penetrated by a sperm, it simply deteriorates. But, if sperm penetration *does* occur, it quickly completes meiosis II, yielding one large **ovum** and a tiny **second polar**

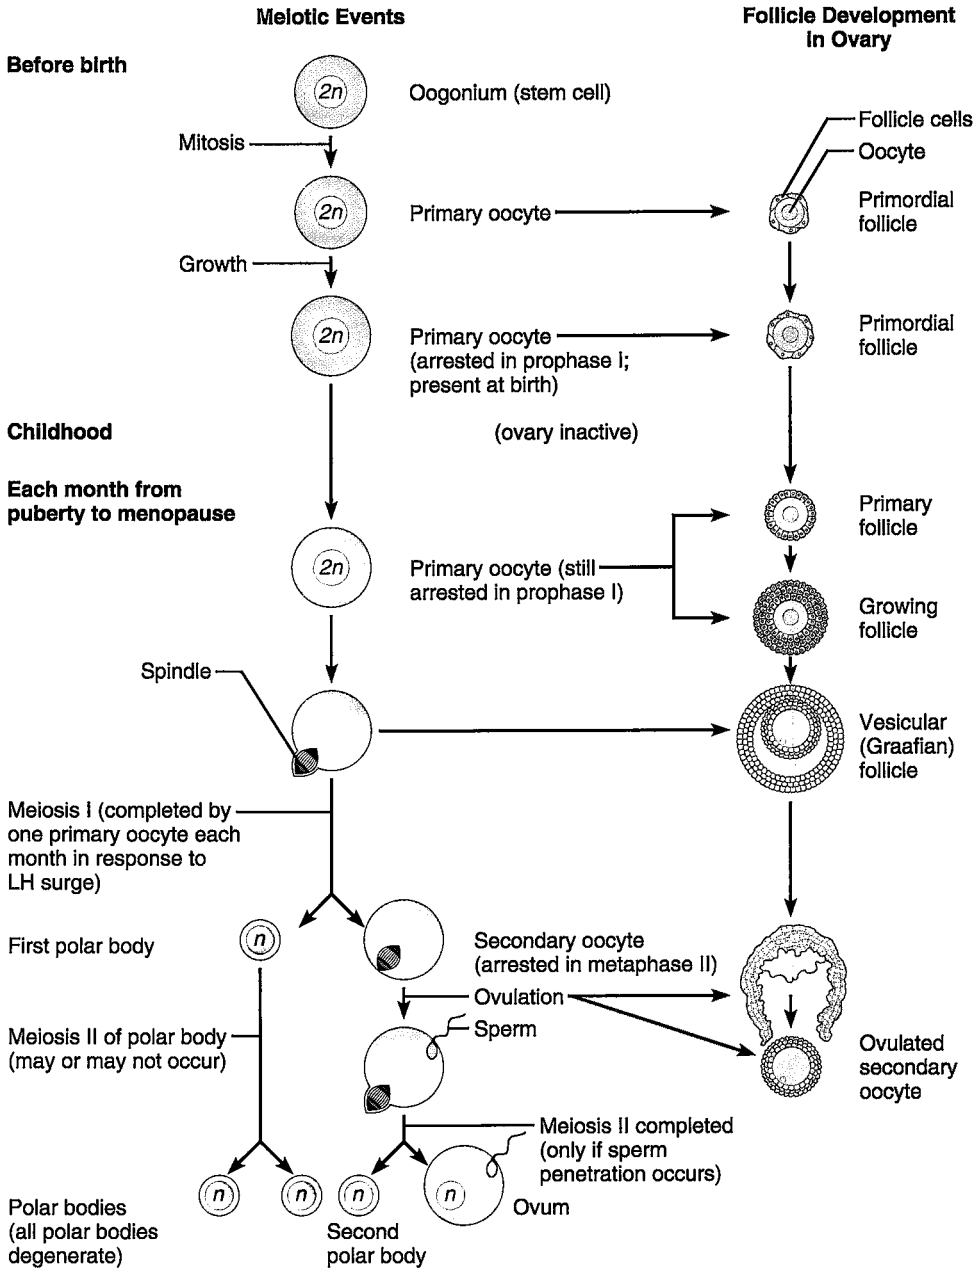

FIGURE 27.19 **Events of oogenesis.** Left, flowchart of meiotic events. Right, correlation with follicle development and ovulation in the ovary.

body (see Figure 27.19). The union of the egg and sperm nuclei, described in Chapter 28, constitutes fertilization. What you should realize now is that the potential end products of oogenesis are three tiny polar bodies, nearly devoid of cytoplasm, and one large ovum. All of these cells are haploid, but only the ovum is a *functional gamete.* This is quite different from spermatogenesis, where the product is four viable gametes—spermatozoa.

The unequal cytoplasmic divisions that occur during oogenesis ensure that a fertilized egg has ample nutrients for its six- to seven-day journey to the uterus. Without nutrient-containing cytoplasm the polar bodies degenerate and die. Since the reproductive life of a female is at most about 40 years (from the age of 11 to approximately 51) and typically only one ovulation occurs each month, fewer than 500 oocytes out of her estimated pubertal potential of 250,000 are released during a woman's lifetime. Again, nature has provided us with a generous oversupply of sex cells.

Perhaps the most striking difference between male and female meiosis is the error rate. As many as 20% of oocytes but only 3–4% of sperm have the wrong number of chromosomes, a situation that often results from failure of the homologues to separate during meiosis I. Thus, it appears that faced with meiotic disruption, meiosis in males grinds to a halt but in females it marches on.

Q *Which of the follicles shown contain a primary oocyte? Which contain a secondary oocyte?*

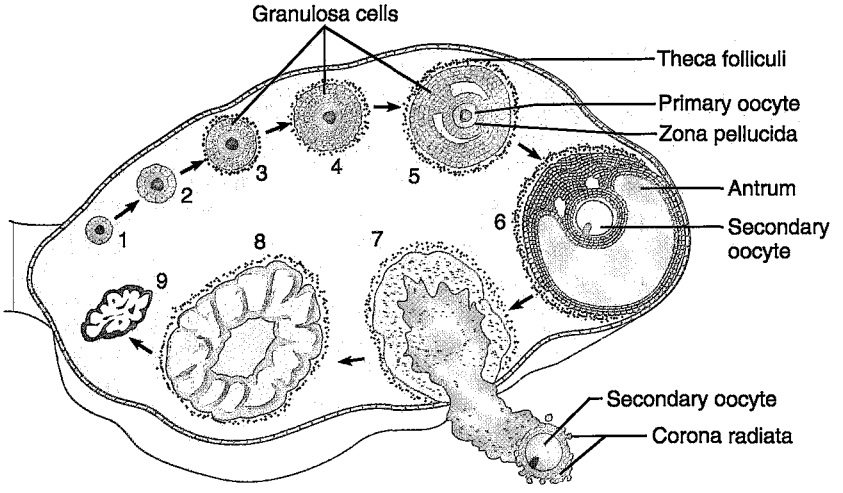

FIGURE 27.20 **Schematic view of the ovarian cycle: development and fate of ovarian follicles.** The numbers on the diagram indicate the sequence of events in follicle development, *not* the movement of a developing follicle within the ovary. ① Primordial follicle containing a primary oocyte surrounded by flattened cells. ② A primary follicle containing a primary oocyte surrounded by cuboidal follicle cells. ③ and ④ The growing primary follicle, which is secreting estrogen as it continues to mature. ⑤ The secondary follicle with its forming antrum. ⑥ The mature vesicular follicle, ready to be ovulated. Meiosis I, producing the secondary oocyte and first polar body, occurs in the mature follicle. ⑦ The ruptured follicle and ovulated secondary oocyte surrounded by its corona radiata of granulosa cells. ⑧ The corpus luteum, formed from the ruptured follicle under the influence of LH, produces progesterone (and estrogens). ⑨ The scarlike corpus albicans.

The Ovarian Cycle

The monthly series of events associated with the maturation of an egg is called the **ovarian cycle.** The ovarian cycle is best described in terms of two consecutive phases. The **follicular phase** is the period of follicle growth, typically indicated as lasting from the first to the fourteenth day of the cycle. The **luteal phase** is the period of corpus luteum activity, days 14–28. The so-called typical ovarian cycle repeats at intervals of 28 days, with *ovulation* occurring midcycle. However, only 10–15% of women naturally have 28-day cycles; cycles as long as 40 days or as short as 21 days are fairly common. In such cases, the length of the follicular phase and timing of ovulation vary, but the luteal phase remains constant: It is 14 days between the time of ovulation and the end of the cycle.

The Follicular Phase

Maturation of a primordial follicle to the mature state occupies the first half of the cycle and involves several events as shown in Figure 27.20, steps 1–6.

A Primordial Follicle Becomes a Primary Follicle
When a primordial follicle ① is activated (a process directed by the oocyte), the squamouslike cells surrounding the primary oocyte grow, becoming cuboidal cells, and the oocyte enlarges. The follicle is now called a primary follicle ②.

A Primary Follicle Becomes a Secondary Follicle
Next, follicular cells proliferate, forming a stratified epithelium around the oocyte ③. As soon as more than one cell layer is present, the follicle cells take on the name *granulosa cells.* The granulosa cells are connected to the developing oocyte by gap junctions, through which ions, metabolites, and signaling molecules can pass, and from this point on, bidirectional "conversations" occur between the oocyte and granulosa cells, so they guide one another's development. One of the signals passing from the granulosa cells to the oocyte "tells" the oocyte to grow. Others dictate asymmetry (polarity) in the future egg.

In the next stage ④, a layer of connective tissue condenses around the follicle, forming the **theca folliculi** (the'kah fah-lik'u-li; "box around the follicle"). As the follicle grows, the thecal and granulosa cells cooperate to produce estrogens (the inner thecal cells produce androgens, which the granulosa cells convert to estrogens). At the same time, the oocyte secretes a glycoprotein-rich substance that forms a thick transparent membrane, called the **zona pellucida** (pĕ-lu'sid-ah), that encapsulates it (see Figure 27.12). In phase ⑤, clear liquid accumulates between the granulosa cells and eventually coalesces to

A *1–5 contain a primary oocyte; 6 contains a secondary oocyte.*

form a fluid-filled cavity called the **antrum** ("cave"). The presence of an antrum distinguishes the new secondary follicle from the primary follicle.

A Secondary Follicle Becomes a Vesicular Follicle

The antrum continues to expand with fluid until it isolates the oocyte, along with its surrounding capsule of granulosa cells called a **corona radiata** ("radiating crown"), on a stalk on one side of the follicle. When a follicle is full size (about 2.5 cm, or 1 inch, in diameter), it becomes a vesicular follicle and bulges from the external ovarian surface like an "angry boil." This usually occurs by day 14.

As one of the final events of follicle maturation, the primary oocyte completes meiosis I to form the secondary oocyte and first polar body (see Figure 27.19). Once this has occurred (⑥ in Figure 27.20), the stage is set for ovulation. At this point, the granulosa cells send another important signal to the oocyte that says, in effect, "Wait, do not complete meiosis yet!"

Ovulation

Ovulation occurs when the ballooning ovary wall ruptures and expels the secondary oocyte (still surrounded by its *corona radiata*) into the peritoneal cavity ⑦. Some women experience a twinge of pain in the lower abdomen when ovulation occurs. This episode, called *mittelschmerz* (mit'el-shmārts; German for "middle pain"), is caused by the intense stretching of the ovarian wall during ovulation.

In the ovaries of adult females, there are always several follicles at different stages of maturation. As a rule, one follicle outstrips the others to become the *dominant follicle* and is at the peak stage of maturation when the hormonal (LH) stimulus is given for ovulation. How this follicle is selected, or selects itself, is still uncertain, but it is probably the one that attains the greatest FSH sensitivity the quickest. The others degenerate (undergo programmed cell death, or apoptosis) and are reabsorbed.

In 1–2% of all ovulations, more than one oocyte is ovulated. This phenomenon, which increases with age, can result in multiple births. Since, in such cases, different oocytes are fertilized by different sperm, the siblings are *fraternal*, or nonidentical, twins. *Identical twins* result from the fertilization of a single oocyte by a single sperm, followed by separation of the fertilized egg's daughter cells in early development. Additionally, it now appears that in some women, oocytes may be released at times unrelated to the woman's hormone levels, which may help to explain why a rhythm method of contraception sometimes fails and why some fraternal twins have different conception dates.

The Luteal Phase

After ovulation, the ruptured follicle collapses, and the antrum fills with clotted blood. This *corpus hemorrhagicum* is eventually absorbed. The remaining granulosa cells increase in size and along with the internal thecal cells they form a new, quite different endocrine gland, the *corpus luteum* ("yellow body") (see Figure 27.20, step ⑧), that begins to secrete progesterone and some estrogen. If pregnancy does not occur, the corpus luteum starts degenerating in about ten days and its hormonal output ends. In this case, all that ultimately remains is a scar ⑨ called the *corpus albicans* (al'bĭ-kans; "white body"). On the other hand, if the oocyte is fertilized and pregnancy ensues, the corpus luteum persists until the placenta is ready to take over its hormone-producing duties in about three months. The last two or three days of the luteal phase, when the endometrium is just beginning to erode, is sometimes called the *luteolytic* or *ischemic phase.*

Hormonal Regulation of the Ovarian Cycle

Ovarian events are much more complicated than those occurring in the testes, but the hormonal controls set into motion at puberty are similar in the two sexes. Gonadotropin-releasing hormone (GnRH), the pituitary gonadotropins, and, in this case, ovarian estrogen and progesterone interact to produce the cyclic events occurring in the ovaries. However, in females another hormone plays an important role in stimulating the hypothalamus to release GnRH. The onset of puberty in females is linked to adiposity, and the messenger from fatty tissue to the hypothalamus is *leptin*. If blood levels of lipids and leptin (better known for its role in energy production and appetite) are low, puberty is delayed.

Establishing the Ovarian Cycle

During childhood, the ovaries grow and continuously secrete small amounts of estrogens, which inhibit hypothalamic release of GnRH. As puberty nears, the hypothalamus becomes less sensitive to estrogen and begins to release GnRH in a rhythmic pulselike manner. GnRH, in turn, stimulates the anterior pituitary to release FSH and LH, which prompt the ovaries to secrete hormones (primarily estrogens).

Gonadotropin levels continue to increase for about four years and, during this time, pubertal girls are still not ovulating and thus are incapable of getting pregnant. Eventually, the adult cyclic pattern is achieved, and hormonal interactions stabilize. These events are heralded by the young woman's first menstrual period, referred to as **menarche** (mĕ-nar'ke; *men* = month, *arche* = first). Usually, it is

Q *Which of the events illustrated here is an example of positive feedback?*

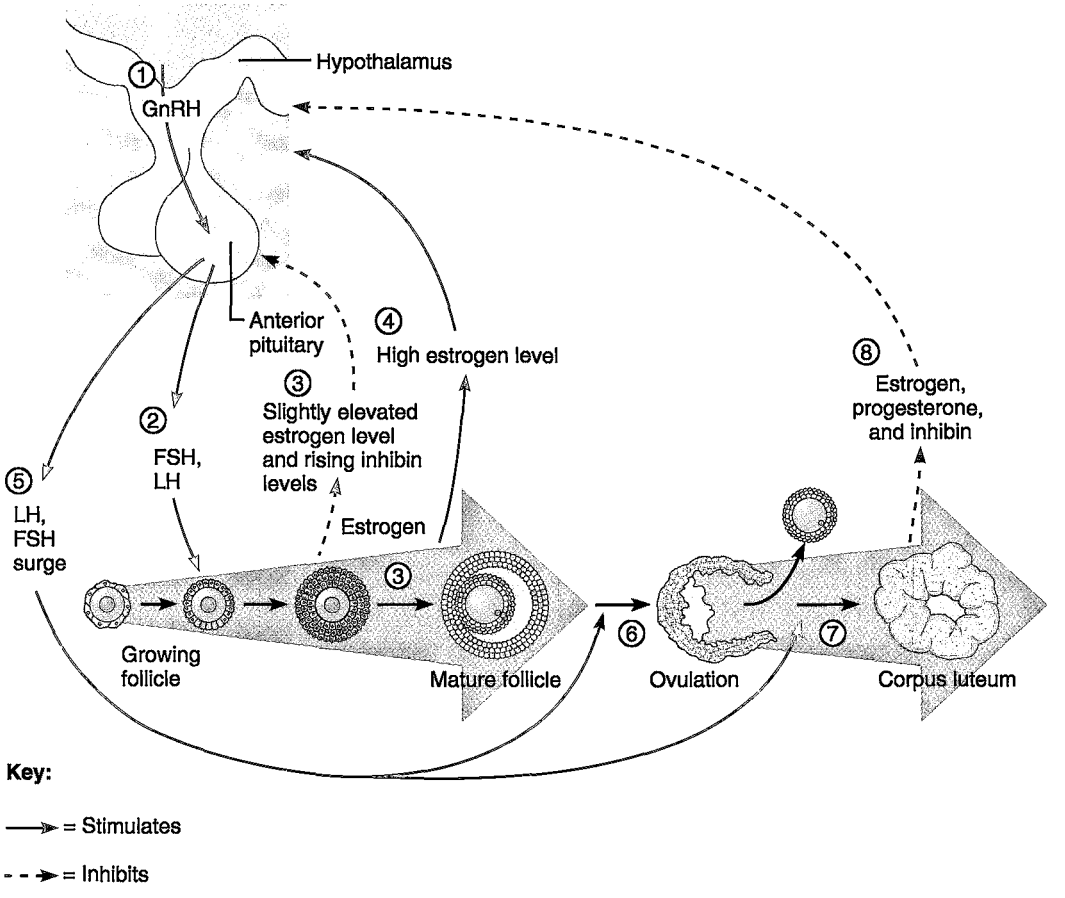

FIGURE 27.21 **Feedback interactions in the regulation of ovarian function.** Numbers refer to events listed in the text. Events that follow step 8 (negative feedback inhibition of the hypothalamus and anterior pituitary by progesterone and estrogens) are not depicted, but involve a gradual deterioration of the corpus luteum and, therefore, a decline in ovarian hormone production. Ovarian hormones reach their lowest blood levels around day 28.

not until the third year postmenarche that the cycles become regular and all are ovulatory.

Hormonal Interactions During the Ovarian Cycle

The waxing and waning of anterior pituitary gonadotropins (FSH and LH) and ovarian hormones and the positive and negative feedback interactions that regulate ovarian function are as described next. Notice that events 1–8 in the following discussion directly correspond to the same-numbered steps in Figure 27.21. A 28-day cycle is assumed.

A *Stimulation of LH (and FSH) surges by rising estrogen levels, steps 4 and 5.*

① On day 1 of the cycle, rising levels of GnRH from the hypothalamus stimulate increased production and release of follicle-stimulating hormone (FSH) and luteinizing hormone (LH) by the anterior pituitary.

② FSH and LH stimulate follicle growth and maturation and estrogen secretion. FSH exerts its main effects on the follicle cells, whereas LH (at least initially) targets the thecal cells. (Why only *some* follicles respond to these hormonal stimuli is still a mystery. However, there is little doubt that enhanced responsiveness is due to formation of more gonadotropin receptors.) As the follicles enlarge, LH prods the thecal cells to produce androgens. These diffuse through the basement membrane, where they are converted to estrogens by the granulosa cells. Only tiny amounts of ovarian androgens enter

the blood, because they are almost completely converted to estrogens within the ovaries.

③ The rising estrogen levels in the plasma exert *negative feedback* on the anterior pituitary, inhibiting its release of FSH and LH, while simultaneously prodding it to synthesize and accumulate these gonadotropins. Within the ovary, estrogen increases estrogen output by intensifying the effect of FSH on follicle maturation. *Inhibin,* released by the granulosa cells, also exerts negative feedback controls on FSH release during this period.

④ Although the initial small rise in estrogen blood levels inhibits the hypothalamic-pituitary axis, high estrogen levels have the opposite effect. Once estrogen reaches a critical blood concentration, it exerts *positive feedback* on the brain and anterior pituitary.

⑤ High estrogen levels set a cascade of events into motion. There is a sudden burstlike release of accumulated LH (and, to a lesser extent, FSH) by the anterior pituitary about midcycle (also see Figure 27.22a).

⑥ The LH surge stimulates the primary oocyte of the dominant follicle to complete the first meiotic division, forming a secondary oocyte that continues on to metaphase II. LH also triggers ovulation at or around day 14. Whatever the mechanism, blood stops flowing through the protruding part of the follicle wall and within 5 minutes, that region of the follicle wall bulges out, thins, and then ruptures. The role (if any) of FSH in this process is unknown. Shortly after ovulation, estrogen levels decline. This probably reflects the damage to the dominant estrogen-secreting follicle during ovulation.

⑦ The LH surge also transforms the ruptured follicle into a corpus luteum (hence the name "luteinizing" hormone), and stimulates the newly formed endocrine gland to produce progesterone and estrogen almost immediately after it is formed.

⑧ Rising progesterone and estrogen blood levels exert a powerful negative feedback effect on anterior pituitary release of LH and FSH. Corpus luteum release of inhibin enhances this inhibitory effect. Declining gonadotropin levels inhibit the development of new follicles and prevent additional LH surges that might cause additional oocytes to be ovulated.

As LH blood levels fall, the stimulus for luteal activity ends, and the corpus luteum degenerates. As goes the corpus luteum, so go the levels of ovarian hormones, and blood estrogen and progesterone levels drop sharply. The marked decline in ovarian hormones at the end of the cycle (days 26–28) ends their blockade of FSH and LH secretion, and the cycle starts anew.

Although the ovarian events are described as if we are following one follicle through the 28-day cycle, this is not really the case. What is happening is that the increase of FSH at the beginning of each cycle activates several follicles to mature. Then, with the midcycle LH surge, one (or more) Graafian follicles undergo ovulation. However, the ovulated oocyte would actually have been activated about 110 days (some three months) before, not 14 days before.

The Uterine (Menstrual) Cycle

Although the uterus is where the young embryo implants and develops, it is receptive to implantation for only a short period each month. Not surprisingly, this brief interval is exactly the time when a developing embryo would normally begin implanting, six to seven days after ovulation. The **uterine,** or **menstrual** (men'stroo-al), **cycle** is a series of cyclic changes that the uterine endometrium goes through each month as it responds to the waxing and waning of ovarian hormones in the blood. These endometrial changes are coordinated with the phases of the ovarian cycle, which are dictated by gonadotropins released by the anterior pituitary.

The events of the uterine cycle, depicted in Figure 27.22d, are as follows:

1. Days 1–5: Menstrual phase. In this phase, **menstruation** (men"stroo-a'shun), the uterus sheds all but the deepest part of its endometrium. (At the beginning of this stage, ovarian hormones are at their lowest normal levels and gonadotropins are beginning to rise. Then FSH levels begin to rise.) The thick, hormone-dependent functional layer of the endometrium detaches from the uterine wall, a process that is accompanied by bleeding for 3–5 days. The detached tissue and blood pass out through the vagina as the menstrual flow. By day 5, the growing ovarian follicles are starting to produce more estrogen (see Figure 27.22b).

2. Days 6–14: Proliferative (preovulatory) phase. In this phase, the endometrium rebuilds itself: Under the influence of rising blood levels of estrogens, the basal layer of the endometrium generates a new functional layer. As this new layer thickens, its glands enlarge and its spiral arteries increase in number (also see Figure 27.15). Consequently, the endometrium once again becomes velvety, thick, and well vascularized. During this phase, estrogens also induce synthesis of progesterone receptors in the endometrial cells, readying them for interaction with progesterone.

Normally, cervical mucus is thick and sticky, but rising estrogen levels cause it to thin and become crystalline, forming channels that facilitate the passage of sperm into the uterus. *Ovulation,* which takes less than five minutes, occurs in the ovary at the end of the proliferative stage (day 14) in response to the sudden release of LH from the anterior pituitary. LH also converts the ruptured follicle to a corpus luteum.

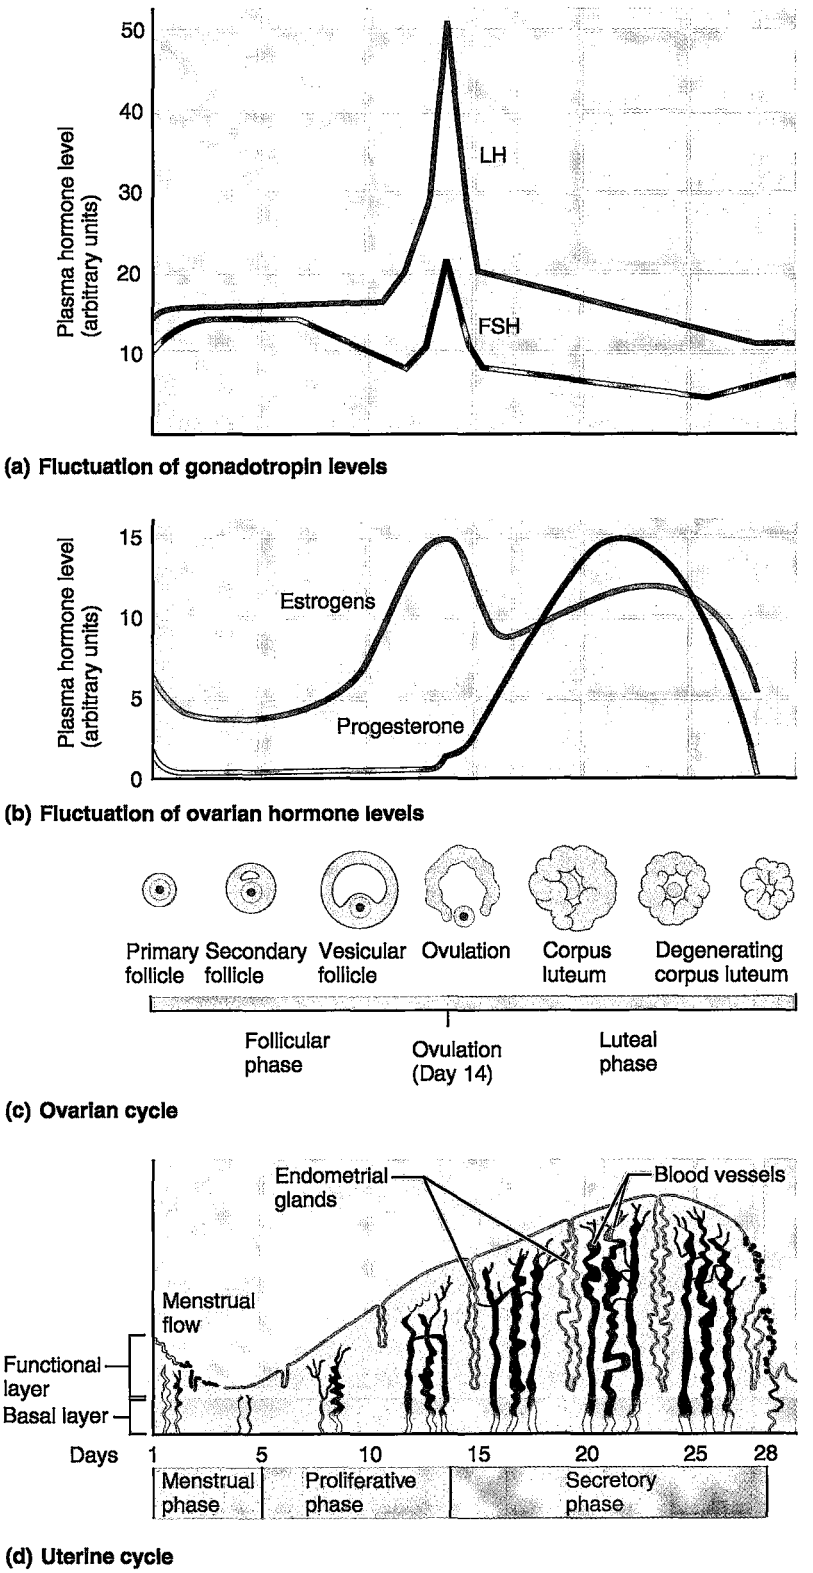

FIGURE 27.22 **Correlation of anterior pituitary and ovarian hormones with structural changes of the ovary and uterus.** The time bar at the bottom of the figure, reading Days 1 to 28, applies to all four parts of this figure. **(a)** The fluctuating levels of pituitary gonadotropins in the blood (FSH = follicle-stimulating hormone; LH = luteinizing hormone). These hormones regulate the events of the ovarian cycle. **(b)** The fluctuating levels of ovarian hormones (estrogens and progesterone) that cause the endometrial changes of the uterine cycle. The high estrogen levels are also responsible for the LH/FSH surge in (a). **(c)** Structural changes in the ovarian follicles during the 28-day ovarian cycle are correlated with (d) changes in the endometrium of the uterus during the uterine cycle. **(d)** The three phases of the uterine cycle: menstrual, proliferative, and secretory. Basically, the first phase is a shedding and the second is a rebuilding of the functional zone of the endometrium. Both of these events occur before ovulation and together they correspond to the follicular phase of the ovarian cycle. The third phase, the secretory phase which begins immediately after ovulation, enriches the blood supply and provides the nutrients that prepare the endometrium to receive an embryo. It corresponds in time to the luteal phase of the ovarian cycle. (See *A Brief Atlas of the Human Body*, Plate 53.)

3. Days 15–28: Secretory (postovulatory) phase. This 14-day phase is the most constant timewise. During the secretory phase the endometrium prepares for implantation of an embryo. Rising levels of progesterone from the corpus luteum act on the estrogen-primed endometrium, causing the spiral arteries to elaborate and converting the functional layer to a secretory mucosa. The uterine glands enlarge, coil, and begin secreting nutritious glycogen into the uterine cavity. These nutrients sustain the embryo until it has implanted in the blood-rich endometrial lining. Increasing progesterone levels also

cause the cervical mucus to become viscous again, forming the *cervical plug*, which blocks sperm entry and plays an important role in keeping the uterus "private" in the event an embryo has begun to implant. Rising progesterone (and estrogen) levels inhibit LH release by the anterior pituitary.

If fertilization has not occurred, the corpus luteum begins to degenerate toward the end of the secretory phase as LH blood levels decline. Progesterone levels fall, depriving the endometrium of hormonal support, and the spiral arteries kink and go into spasms. Denied oxygen and nutrients, the ischemic endometrial cells die, setting the stage for menstruation to begin on day 28. The spiral arteries constrict one final time and then suddenly relax and open wide. As blood gushes into the weakened capillary beds, they fragment, causing the functional layer to slough off. The menstrual cycle starts over again on this first day of menstrual flow.

Figure 27.22 also illustrates how the ovarian and uterine cycles fit together. Notice that the menstrual and proliferative phases overlap the follicular stage and ovulation in the ovarian cycle, and that the uterine secretory phase corresponds to the ovarian luteal phase.

Extremely strenuous activity can delay menarche in girls and can disrupt the normal menstrual cycle in adult women, even causing *amenorrhea* (a-men"o-re'ah), cessation of menses. Female athletes have little body fat, and fat deposits help convert adrenal androgens to estrogens and are the source of leptin which, as noted above, plays a critical permissive role in the onset of puberty in females. In mature females, leptin keeps the hypothalamus informed about whether energy stores are sufficient to support the high energy demands of reproduction. If not, the reproductive cycles are shut down. These effects are usually totally reversible when the athletic training is discontinued, but a worrisome consequence of amenorrhea in young, healthy adult women is that they suffer dramatic losses in bone mass normally seen only in old age. Once estrogen levels drop and the menstrual cycle stops (regardless of cause), bone loss begins.

Although menses has traditionally been viewed as a somewhat messy way of discarding a uterine lining "fattened" in anticipation of a baby that was never conceived, its adaptive value and expense to the female body in terms of tissue, blood, and nutrient (particularly iron) loss have been questioned. Why not just keep the prepared endometrium for the next cycle? A controversial view of menses is that the uterus is a hospitable receptacle for bacteria and viruses delivered via the male penis and piggy-backing in semen. This being so, menses is an aggressive way of cleaning house. Bleeding rids the body of the uterine lining where pathogens are likely to linger, and menstrual blood is loaded with macrophages which provide active protection.

Extrauterine Effects of Estrogens and Progesterone

With a name meaning "generators of sexual activity," estrogens are analogous to testosterone, the male steroid. As estrogen levels rise during puberty, they (1) promote oogenesis and follicle growth in the ovary and (2) exert anabolic effects on the female reproductive tract (see Table 27.1). Consequently, the uterine tubes, uterus, and vagina grow larger and become functional—ready to support a pregnancy. The uterine tubes and uterus exhibit enhanced motility; the vaginal mucosa thickens; and the external genitalia mature.

Estrogens also support the growth spurt at puberty that makes girls grow much more quickly than boys during the ages of 12 and 13. But this growth is short lived because rising estrogen levels also cause the epiphyses of long bones to close sooner, and females reach their full height between the ages of 15 and 17 years. In contrast, the aggressive growth of males continues until the age of 19 to 21 years, at which point rising estrogen levels cause epiphyseal closure.

The estrogen-induced secondary sex characteristics of females include (1) growth of the breasts; (2) increased deposit of subcutaneous fat, especially in the hips and breasts; and (3) widening and lightening of the pelvis (adaptations for childbirth). Estrogens have several metabolic effects, including maintaining low total blood cholesterol levels (and high HDL levels) and facilitating calcium uptake, which helps sustain the density of the skeleton. (These metabolic effects, though initiated under estrogen's influence during puberty, are not true secondary sex characteristics.)

Progesterone works with estrogen to establish and then help regulate the uterine cycle and promotes changes in cervical mucus (see Table 27.1). Its other effects are exhibited largely during pregnancy, when it inhibits uterine motility and takes up where estrogen leaves off in preparing the breasts for lactation. Indeed, progesterone is named for these important roles (*pro* = for; *gestation* = pregnancy). However, the source of progesterone and estrogen during most of pregnancy is the placenta, not the ovaries.

Female Sexual Response

The **female sexual response** is similar to that of males in most respects. During sexual excitement, the clitoris, vaginal mucosa, and breasts engorge with blood; the nipples erect; and increased activity of the vestibular glands lubricates the vestibule and facilitates entry of the penis. These events, though more widespread, are analogous to the *erection* phase in men. Sexual excitement is promoted by touch and psychological stimuli and is mediated along the same autonomic nerve pathways as in males.

TABLE 27.1 Summary of Hormonal Effects of Gonadal Estrogens, Progesterone, and Testosterone

SOURCE, STIMULUS, EFFECTS	ESTROGENS	PROGESTERONE	TESTOSTERONE
Major source	Ovary: developing follicles and corpus luteum	Ovary: mainly the corpus luteum	Testes: interstitial cells
Stimulus for release	FSH (and LH)	LH	LH and declining levels of inhibin produced by the sustentacular cells
Feedback effects exerted	Both negative and positive feedback exerted on anterior pituitary release of gonadotropins	Negative feedback exerted on anterior pituitary release of gonadotropins	Negative feedback suppresses release of LH by the anterior pituitary (and perhaps release of GnRH by the hypothalamus)
Effects on reproductive organs	Stimulate growth and maturation of reproductive organs and breasts at puberty and maintain their adult size and function. Promote the proliferative phase of the uterine cycle; stimulate production of watery (crystalline) cervical mucus and activity of fimbriae and uterine tube cilia	Cooperates with estrogen in stimulating growth of breasts and in regulating the uterine cycle (promotes the secretory phase of the uterine cycle); stimulates production of viscous cervical mucus	Stimulates formation of male reproductive ducts, glands, and external genitalia. Promotes descent of the testes. Stimulates growth and maturation of the internal and external genitalia at puberty; maintains their adult size and function
	Promote oogenesis and ovulation by stimulating formation of FSH and LH receptors on follicle cells. Stimulate capacitation of sperm in the female reproductive tract by affecting vaginal and uterine secretions	During pregnancy, quiets the myometrium and acts with estrogen to cause mammary glands to achieve their mature milk-producing state	Required for normal spermatogenesis via effects promoted by its binding to ABP on spermatogenic cells; suppresses mammary gland development
	During pregnancy stimulate growth of the uterus and enlargement of the external genitalia and mammary glands		
Promotion of secondary sex characteristics and somatic effects	Promote lengthening of long bones and feminization of the skeleton (particularly the pelvis); inhibit bone reabsorption and then stimulate epiphyseal closure; promote hydration of the skin and stimulate female pattern of fat deposit		Stimulates the growth spurt at puberty; promotes increased skeletal mass during adolescence; promotes growth of the larynx and vocal cords and deepening of the voice; enhances sebum secretion and hair growth, especially on the face, axillae, genital region, and chest
	During pregnancy act with relaxin (placental hormone) to induce softening and relaxation of the pelvic ligaments and pubic symphysis		
Metabolic effects	Generally anabolic; stimulate Na^+ reabsorption by the renal tubules, hence inhibit diuresis; enhance HDL (and reduce LDL) blood levels (cardiovascular sparing effect)	Promotes diuresis (antiestrogenic effect); increases body temperature	Generally anabolic; stimulates hematopoiesis; enhances the basal metabolic rate
Neural effects	Feminize the brain; along with DHEA (an androgen produced by the adrenal cortex) are partially responsible for sex drive (libido) in females		Responsible for libido in males; masculinizes the brain; promotes aggressiveness

The final phase of the female sexual response, *orgasm,* is not accompanied by ejaculation, but muscle tension increases throughout the body, pulse rate and blood pressure rise, and the uterus begins to contract rhythmically. As in males, orgasm is accompanied by a sensation of intense pleasure and followed by relaxation. Orgasm in females is not followed by a refractory period, so females may experience multiple orgasms during a single sexual experience. A man must achieve orgasm and ejaculate if

fertilization is to occur, but female orgasm is not required for conception. Indeed, some women never experience orgasm, yet are perfectly able to conceive.

Although the female libido was formerly believed to be prompted by testosterone, new studies indicate that dehydroepiandrosterone (DHEA), an androgen produced by the adrenal cortex, is in fact the male sex hormone associated with desire or lack of it in females.

Sexually Transmitted Diseases

Sexually transmitted diseases (STDs), also called *venereal diseases (VDs),* are infectious diseases spread through sexual contact. The United States has the highest rates of infection among developed countries. Over 12 million people in the United States, a quarter of them adolescents, get STDs each year.

As a group, STDs are the single most important cause of reproductive disorders. Until recently, the bacterial infections gonorrhea and syphilis were the most common STDs, but now viral diseases have taken center stage. AIDS, the most notorious STD, is caused by HIV, the virus that cripples the immune system. AIDS is described in Chapter 21; the other important bacterial and viral STDs are described here. Condoms are effective in helping to prevent the spread of STDs, and their use is strongly urged, particularly since the advent of AIDS.

Gonorrhea

The causative agent of **gonorrhea** (gon"o-re'ah) is *Neisseria gonorrhoeae,* which invades the mucosae of the reproductive and urinary tracts. These bacteria are spread by contact with genital, anal, and pharyngeal mucosal surfaces. Commonly called "the clap," gonorrhea occurs most frequently in adolescents and young adults.

The most common symptom of gonorrhea in males is *urethritis,* accompanied by painful urination and discharge of pus from the penis (penile "drip"). Symptoms vary in women, ranging from none (about 20% of cases) to abdominal discomfort, vaginal discharge, abnormal uterine bleeding, and occasionally, urethral symptoms similar to those seen in males.

Untreated gonorrhea can cause urethral constriction and inflammation of the entire male duct system. In women, it causes pelvic inflammatory disease and sterility. These consequences declined with the advent in the 1950s of penicillin, tetracycline, and certain other antibiotics. However, strains resistant to those antibiotics are becoming increasingly prevalent. Currently, ceftriaxone is the antibiotic used most often to treat gonorrhea.

Syphilis

Syphilis (sif'ĭ-lis), caused by *Treponema pallidum,* a corkscrew-shaped bacterium, is usually transmitted sexually, but it can be contracted congenitally from an infected mother. Indeed, an increasing number of women trading sex for "crack" (a cocaine derivative) are passing syphilis on to their fetuses. Fetuses infected with syphilis are usually stillborn or die shortly after birth. The bacterium easily penetrates intact mucosae and abraded skin. Within a few hours of exposure, an asymptomatic bodywide infection is in progress. After an incubation period of two to three weeks, a red, painless primary lesion called a *chancre* (shang'ker) appears at the site of bacterial invasion. In males, this is typically the penis, but in females the lesion often goes undetected within the vagina or on the cervix. The chancre ulcerates and becomes crusty; then it heals spontaneously and disappears within a few weeks.

If syphilis is untreated, its secondary signs appear several weeks later. A pink skin rash all over the body is one of the first symptoms. Fever and joint pain are common. These signs and symptoms disappear spontaneously in three to twelve weeks. Then the disease enters the *latent period* and is detectable only by a blood test. The latent stage may last a person's lifetime (or the bacteria may be killed by the immune system), or it may be followed by the signs of *tertiary syphilis.* Tertiary syphilis is characterized by *gummas* (gum'ahs), destructive lesions of the CNS, blood vessels, bones, and skin. Penicillin is still the treatment of choice for all stages of syphilis.

Chlamydia

Chlamydia (klah-mid'e-ah; *chlamys* = cloak) is a largely undiagnosed, silent epidemic that infects perhaps 4–5 million people yearly, making it the most common bacterial sexually transmitted disease in the United States. Chlamydia is responsible for 25–50% of all diagnosed cases of pelvic inflammatory disease (and, consequently, at least a 1 in 4 chance of ectopic pregnancy), and each year more than 150,000 infants are born to infected mothers. About 20% of men and 30% of women infected with gonorrhea are also infected by *Chlamydia trachomatis,* the causative agent of chlamydia.

Chlamydia is a bacterium with a viruslike dependence on host cells. Its incubation period within the body cells is about one week. Symptoms include urethritis (involving painful, frequent urination and a thick penile discharge); vaginal discharge; abdominal, rectal, or testicular pain; painful intercourse; and irregular menses. In men, it can cause arthritis as well as widespread urogenital tract infection. In women, 80% of whom suffer *no* symptoms from the

infection, it is a major cause of sterility. Newborns infected in the birth canal tend to develop conjunctivitis (or *trachoma*, a painful eye infection that leads to corneal scarring if untreated, often the case in third world countries) and respiratory tract inflammations including pneumonia. The disease can be diagnosed by cell culture techniques and is easily treated with tetracycline.

Trichomoniasis

Trichomoniasis is the most common *curable* STD in sexually active young women in the U.S. Accounting for about 7.4 million new cases of STD infections per year, this parasitic infection is easily and inexpensively treated once diagnosed. Trichomoniasis is indicated by a yellow-green vaginal discharge with a strong odor, however, many of its victims exhibit no symptoms.

Genital Warts

Genital warts due to the *human papillomavirus (HPV)*—actually a group of about 60 viruses—is the second most common STD in the United States. About 6.2 million new cases of genital warts develop in Americans each year, and it appears that HPV infection increases the risk for cancers in infected regions. Indeed, the virus is linked to 80% of all cases of invasive cervical cancer.

Treatment is difficult and controversial, and the warts tend to disappear. Some clinicians prefer to leave the warts untreated unless they become widespread, whereas others recommend their removal by cryosurgery, or laser therapy, and/or treatment with alpha interferon.

Genital Herpes

The common cause of **genital herpes** is the *human herpes virus type 2*, and these viruses are among the most difficult human pathogens to control. They remain silent for weeks or years and then suddenly flare up, causing a burst of blisterlike lesions. Direct transmission of the virus is via infectious secretions. The painful lesions that appear on the reproductive organs of infected adults are usually more of a nuisance than a threat. However, congenital herpes infections can cause severe malformations of a fetus. Most people who have genital herpes do not know it, and it has been estimated that one-quarter to one-half of all adult Americans harbor the type 2 herpes simplex virus. Only about 15% of that population displays signs of infection. The antiviral *acyclovir*, which speeds healing of the lesions and reduces the frequency of flare-ups, is the drug of choice for treatment. Once contracted, genital herpes never leaves; it just goes into periodic remissions.

Developmental Aspects of the Reproductive System: Chronology of Sexual Development

Thus far, we have described the reproductive organs as they exist and operate in adults. Now we are ready to look at events that cause us to become reproductive individuals. These events begin long before birth and end, at least in women, in late middle age.

Embryological and Fetal Events

Determination of Genetic Sex

Aristotle believed that the "heat" of lovemaking determined maleness. Not so! Genetic sex is determined at the instant the genes of a sperm combine with those of an ovum, and the determining factor is the **sex chromosomes** each gamete contains. Of the 46 chromosomes in the fertilized egg, two (one pair) are sex chromosomes. The other 44 are called **autosomes.** Two types of sex chromosomes, quite different in size, exist in humans: the large **X chromosome** and the much smaller **Y chromosome.** The body cells of females have two X chromosomes and are designated XX; the ovum resulting from normal meiosis in a female always contains an X chromosome. Males have one X chromosome and one Y in each body cell (XY). Approximately half of the sperm produced by normal meiosis in males contain an X and the other half a Y. If the fertilizing sperm delivers an X chromosome, the fertilized egg and its daughter cells will contain the female (XX) composition, and the embryo will develop ovaries. If the sperm bears the Y, the offspring will be male (XY) and will develop testes. A single gene on the Y chromosome— the *SRY* gene—is the master switch that initiates testes development and hence maleness. Thus, the father determines the genetic sex of the offspring, and all subsequent events of sexual differentiation depend on which gonads are formed during embryonic life. Mutation of the *SRY* gene can result in XY females with the male chromosome but female sex characteristics.

HOMEOSTATIC IMBALANCE

When meiosis distributes the sex chromosomes to the gametes improperly, an event called **nondisjunction,** abnormal combinations of sex chromosomes occur in the zygote and cause striking abnormalities in sexual and reproductive system development. For example, females with a single X chromosome (XO), a condition called *Turner's syndrome*, never develop ovaries. Males with no X chromosome (YO) die during embryonic development. Although most XXX

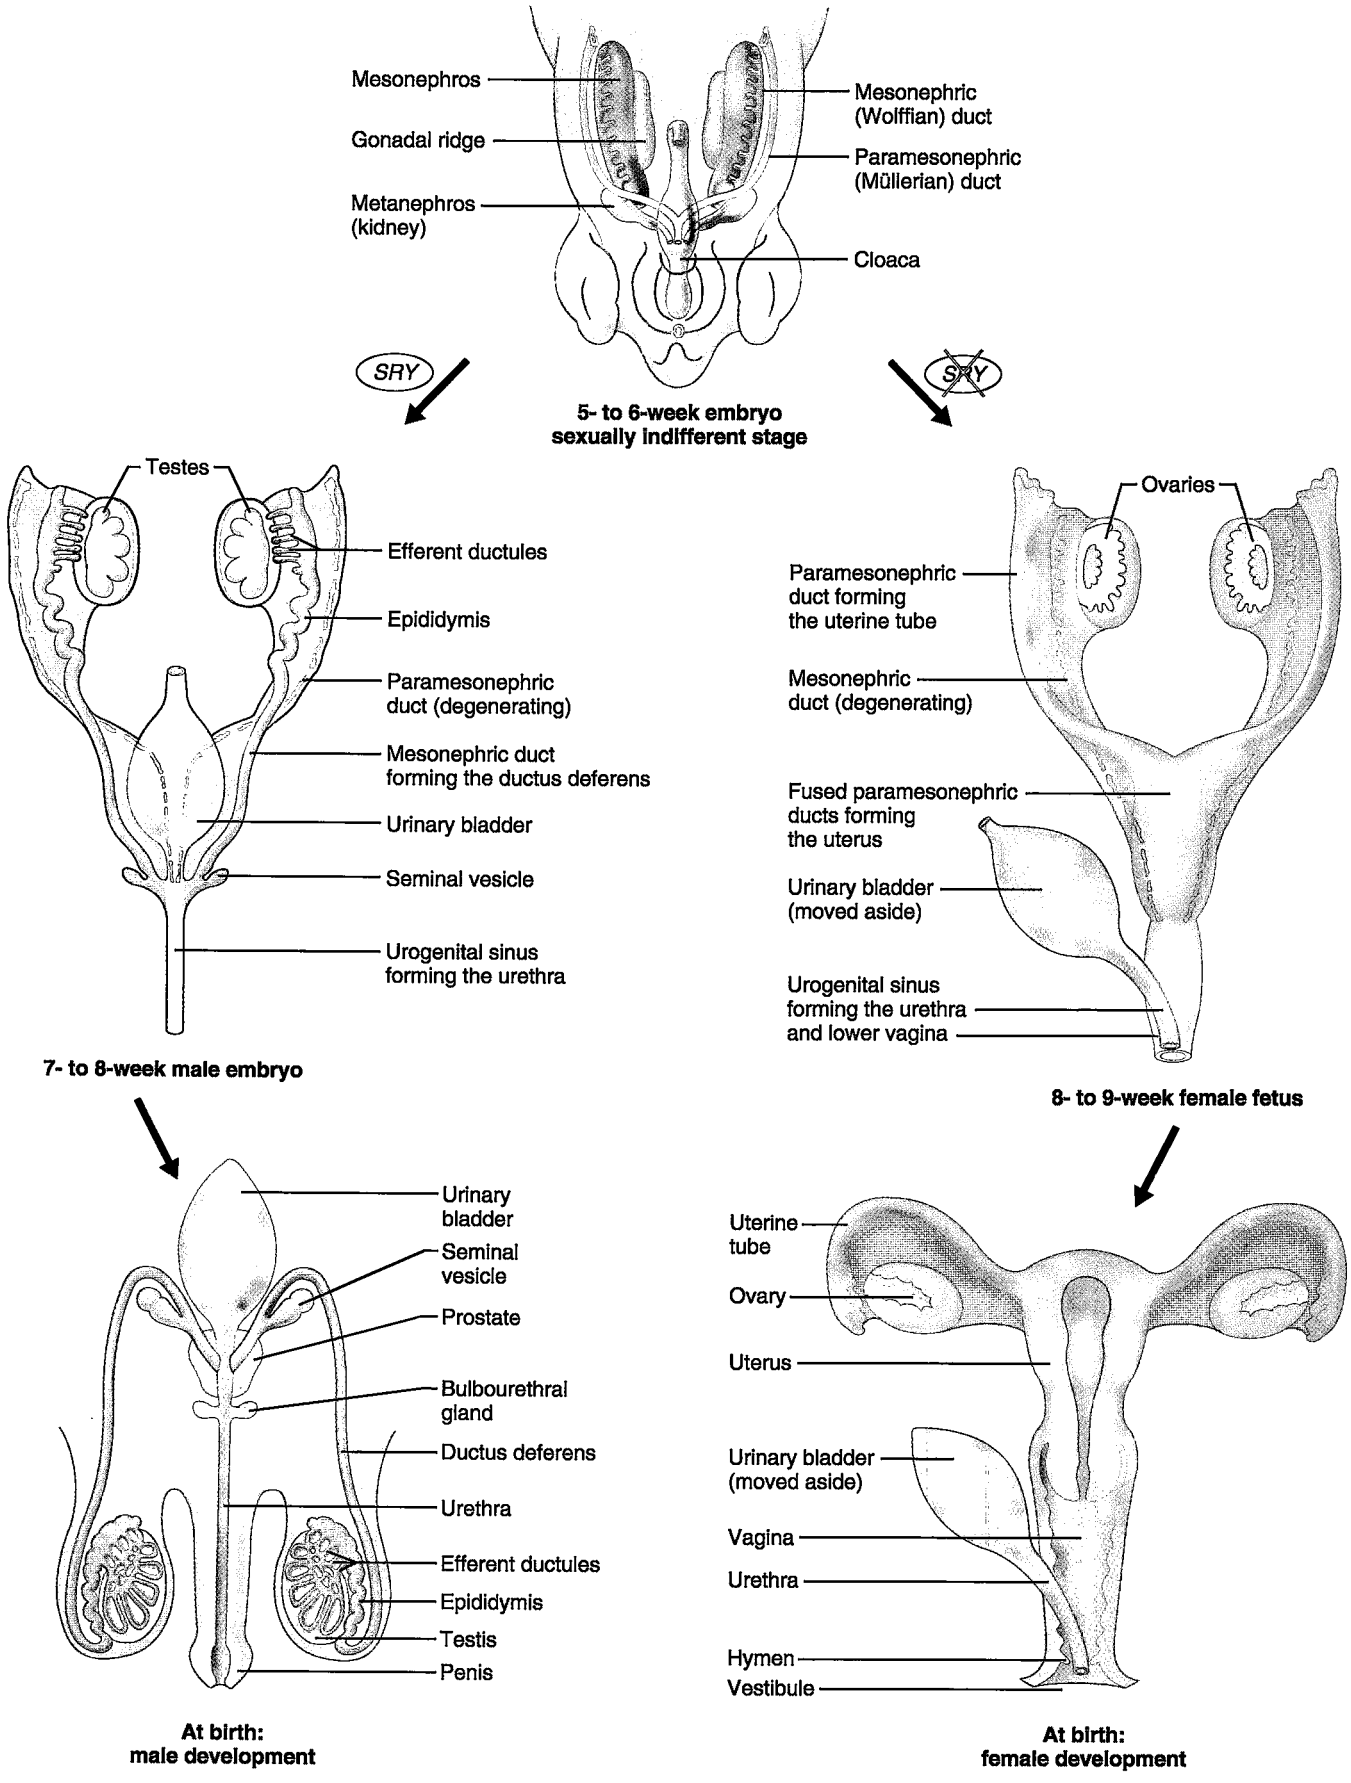

FIGURE 27.23 **Development of the internal reproductive organs.**

females have normal intelligence, females carrying four or more X chromosomes as a rule are mentally retarded and have underdeveloped ovaries and limited fertility. *Klinefelter's syndrome,* which affects one out of 500 live male births, is the most common sex chromosome abnormality. Affected individuals usually have a single Y chromosome, two or more X chromosomes, and are sterile males. Although XXY males are normal (or only slightly below normal) intellectually, the incidence of mental retardation increases as the number of X chromosomes rises.

Sexual Differentiation of the Reproductive System

The gonads of both males and females begin their development during week 5 of gestation as masses of mesoderm called the **gonadal ridges** (Figure 27.23). The gonadal ridges form bulges on the dorsal abdominal wall just medial to the mesonephros (a transient kidney system, see p. 1027). The **paramesonephric,** or **Müllerian, ducts** (future female ducts) develop lateral to the **mesonephric (Wolffian) ducts** (future male ducts), and both sets of ducts empty into a common chamber called the *cloaca.* At this stage of development, the embryo is said to be in the **sexually indifferent stage,** because the gonadal ridge tissue can develop into either male or female gonads and both duct systems are present.

Shortly after the gonadal ridges appear, **primordial germ cells** migrate to them from a different region of the embryo [presumably guided by a gradient of chemical signals (chemokines)], and seed the developing gonads with stem cells destined to become spermatogonia or oogonia. Once these cells are in residence, the gonadal ridges form testes or ovaries, depending on the genetic makeup of the embryo. The process begins in week 7 in male embryos. Seminiferous tubules form in the internal part of the gonadal ridges and join the mesonephric duct via the efferent ductules. Further development of the mesonephric duct produces the duct system of the male. The paramesonephric ducts play no part in male development and degenerate unless the tiny testes fail to secrete a hormone called *anti-Müllerian hormone (AMH).* [AMH causes the breakdown of the paramesonephric (Müllerian) ducts, which give rise to the female duct system (oviducts and uterus).]

In female embryos the process begins about a week later. The outer, or cortical, part of the immature ovaries forms follicles, and the paramesonephric ducts differentiate into the structures of the female duct system. The mesonephric ducts degenerate.

Like the gonads, the external genitalia arise from the same structures in both sexes (Figure 27.24). During the indifferent stage, all embryos exhibit a small projection called the **genital tubercle** on their external body surface. The urogenital sinus, which develops from subdivision of the cloaca (future urethra and bladder), lies deep to the tubercle. The **urethral groove,** the external opening of the urogenital sinus, is on the tubercle's inferior surface. The urethral groove is flanked laterally by the **urethral folds** and then the **labioscrotal swellings.**

During week 8, the external genitalia begin to develop rapidly. In males, the genital tubercle enlarges, forming the penis. The urethral folds fuse in the midline, forming the spongy urethra in the penis. Only the tips of the folds remain unfused to form the *urethral orifice* at the tip of the penis. The labioscrotal swellings also fuse in the body midline to form the scrotum. In females, the genital tubercle gives rise to the clitoris and the urethral groove persists as the vestibule. The unfused urethral folds become the labia minora, and the unfused labioscrotal folds become the labia majora.

Differentiation of accessory structures and the external genitalia as male or female structures depends on the presence or absence of testosterone. When testes are formed, they quickly begin to release testosterone, which continues until four to five days after birth and which causes the development of male accessory ducts and external genitalia. In the absence of testosterone, the female ducts and external genitalia develop.

HOMEOSTATIC IMBALANCE

Any interference with the normal pattern of sex hormone production in the embryo results in bizarre abnormalities. For example, if the embryonic testes do not produce testosterone, a genetic male develops the female accessory structures and external genitalia. If the testes fail to produce AMH, both the female and male duct systems form, but the external genitalia are those of the male. On the other hand, if a genetic female is exposed to testosterone (as might happen if the mother has an androgen-producing tumor of her adrenal gland), the embryo has ovaries but develops the male ducts and glands, as well as a penis and an empty scrotum. It appears that the female pattern of reproductive structures has an intrinsic ability to develop (is the default condition), and in the absence of testosterone it proceeds to do so, regardless of the embryo's genetic makeup.

Individuals with accessory reproductive structures that do not "match" their gonads are called *pseudohermaphrodites* (soo-do-her-maf'ro-dīts). (True *hermaphrodites* are rare and possess both ovarian and testicular tissue.) Many pseudohermaphrodites have sought sex-change operations to match their outer selves (external genitalia) with their inner selves (gonads).

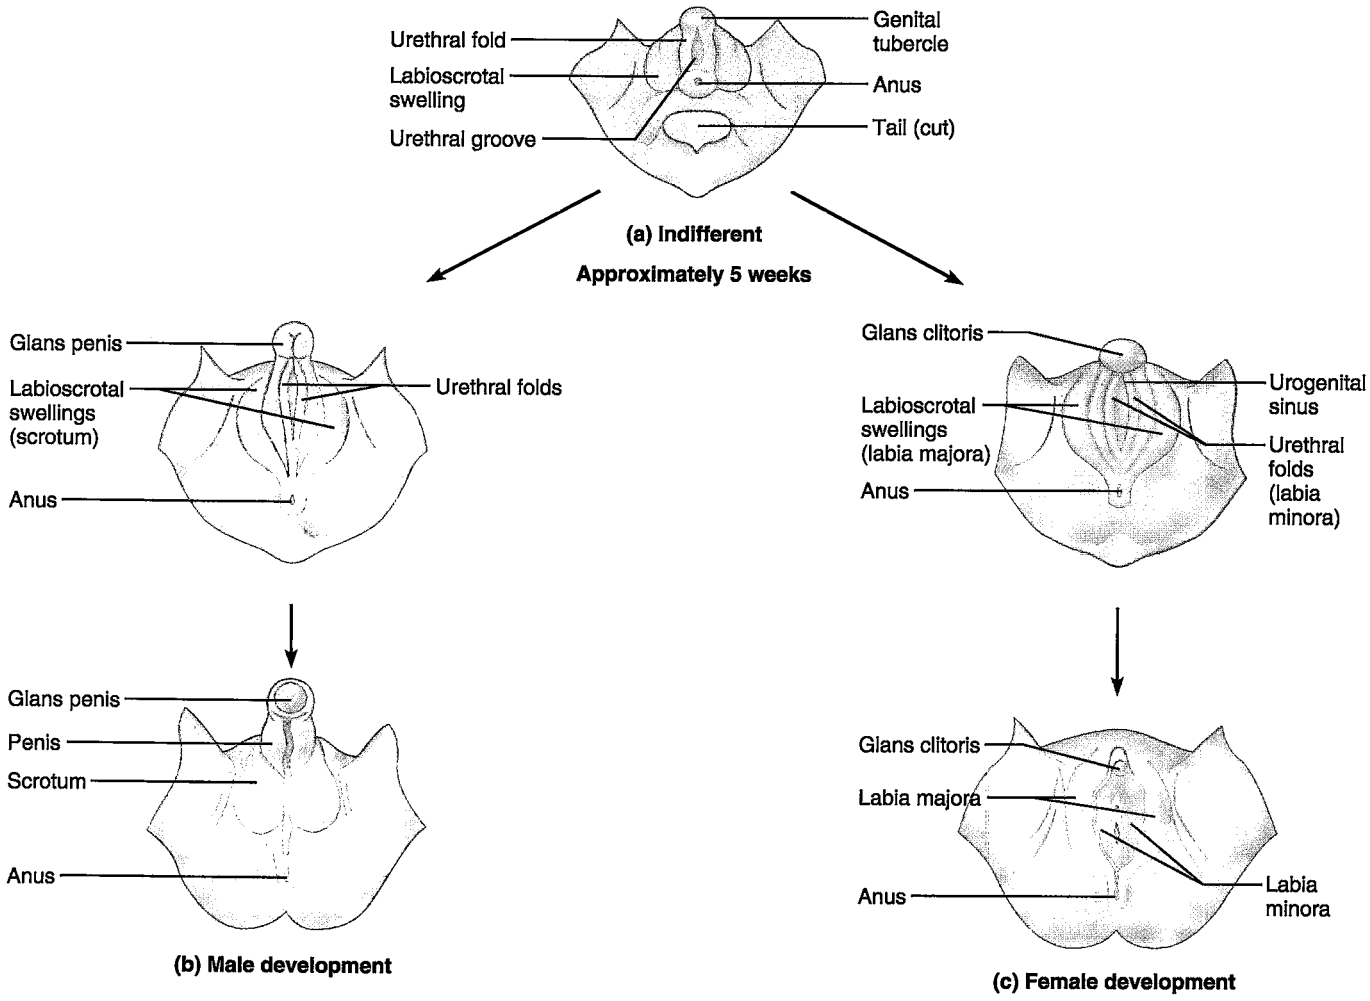

FIGURE 27.24 **Development of homologous structures of the external genitalia in both sexes.** The two pictures at the bottom of the figure show the fully developed perineal region.

Descent of the Gonads

About two months before birth, the testes begin their descent toward the scrotum, dragging their supplying blood vessels and nerves along behind them (Figure 27.25). They finally exit from the pelvic cavity via the inguinal canals and enter the scrotum. This migration is stimulated by testosterone made by the male fetus's testes, and is guided mechanically by a strong fibrous cord called the **gubernaculum** ("governor"), which extends from the testis to the floor of the scrotal sac. The *tunica vaginalis* covering of the testis that is pulled into the scrotum with the testis is derived from a fingerlike outpocketing of the parietal peritoneum, the *vaginal process*. The accompanying blood vessels, nerves, and fascial layers form part of the *spermatic cord*, which helps suspend the testis within the scrotum.

Like the testes, the ovaries descend during fetal development, but in this case only to the pelvic brim, where their progress is stopped by the tentlike broad ligament. Each ovary is guided in its descent by a gubernaculum (anchored in the labium majus) that later divides, becoming the ovarian and round ligaments that help support the internal genitalia in the pelvis.

HOMEOSTATIC IMBALANCE

Failure of the testes to make their normal descent leads to *cryptorchidism* (*crypt* = hidden, concealed; *orchi* = testicle). Because this condition causes sterility and increases the risk of testicular cancer, surgery is usually performed during early childhood to rectify this problem. ●

Puberty

FSH and LH levels, elevated at birth, fall to low levels within a few months and remain low throughout the prepubertal years. Between the ages of 10 and 15 years, a host of interacting hormones bring on the changes of puberty. **Puberty** is the period of life when

the reproductive organs grow to adult size and become functional. These changes occur in response to rising levels of gonadal hormones (testosterone in males and estrogen in females). The secondary sex characteristics and regulatory events of puberty were described earlier. But it is important to remember that puberty represents the earliest time that reproduction is possible.

The events of puberty occur in the same sequence in all individuals, but the age at which they occur varies widely. In males, secretion of adrenal androgens [particularly dehydroepiandrosterone (DHEA)] begins to rise several years before the testosterone surge of puberty and initiates facial, pubic, and axillary hair growth and other pubertal events. The major event that signals puberty's onset in males is enlargement of the testes and scrotum between the ages of 8 and 14. Growth of the penis goes on over the next two years, and sexual maturation is evidenced by the presence of mature sperm in the semen. In the meantime, the young man has unexpected, and often embarrassing, erections and frequent nocturnal emissions ("wet dreams") as his hormones surge and the hormonal control axis struggles to achieve a normal balance.

The first sign of puberty in females is budding breasts, apparent between the ages of 8 and 13 years, followed by the appearance of axillary and pubic hair. Menarche usually occurs about two years later. Dependable ovulation and fertility await the maturation of the hormonal controls, which takes nearly two more years.

Menopause

Most women reach the peak of their reproductive abilities in their late 20s. After that, ovarian function declines gradually, presumably because the ovaries become less and less responsive to gonadotropin signals. At the age of 30, there are still some 100,000 oocytes in the ovaries but the quality (hence fertility) has begun to decline; by the age of 50, there are probably 3 eggs left (the pantry is nearly bare). As estrogen production declines, many ovarian cycles become anovulatory, while in others 2 to 4 oocytes per month are ovulated, a sign of declining control. These increasingly frequent multiple ovulations explain why twins and triplets are more common in women who have deferred childbearing until their 30s. Menstrual periods become erratic and increasingly shorter. Eventually, ovulation and menses cease entirely. This normally occurs between the ages of 46 and 54 years, an event called menopause. **Menopause** is considered to have occurred when a whole year has passed without menstruation. As mentioned earlier, recent findings indicate that adult women generate new germ line stem cells throughout their reproductive life. If so, the question to be answered next is why these stem cells stop replenishing the oocyte supply as menopause nears. Is it simply declining levels of estrogen? Learning the answer to this question may allow menopause to be delayed if the stem cells can be stimulated to remain actively dividing in some way.

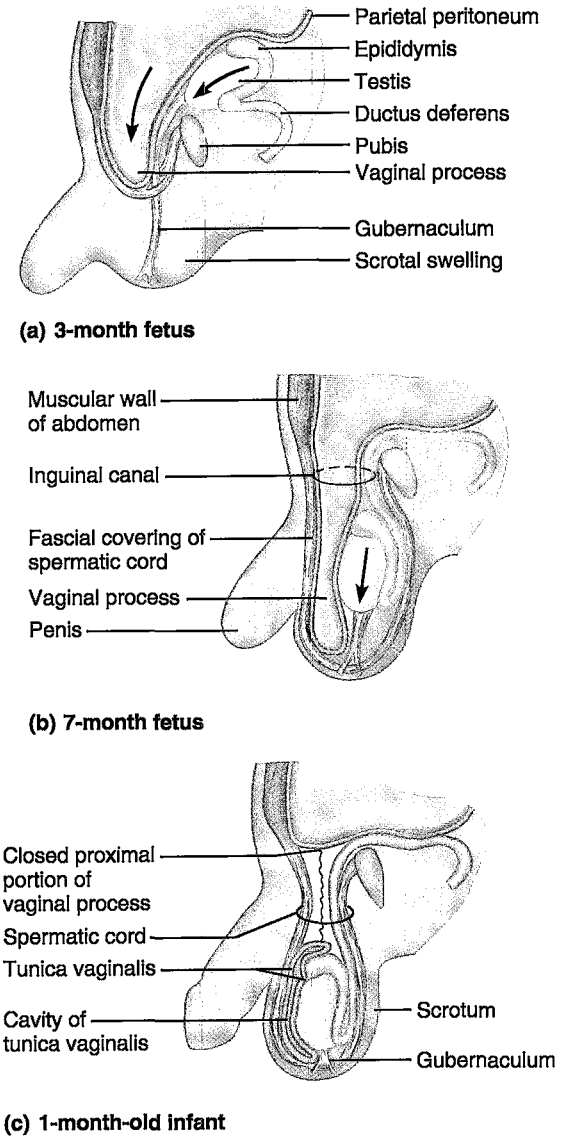

FIGURE 27.25 **Descent of the testes.** Sagittal sections through the pelvis of a male fetus and infant. **(a)** At 3 months, a testis begins to descend behind the peritoneum toward the inguinal region, and the vaginal process (a peritoneal extension) pushes caudally into the future scrotum (scrotal swellings). **(b)** By 7 months, the testis, accompanied by the vaginal process, descends rapidly into the scrotum via the inguinal canal. **(c)** In the one-month-old infant, descent is complete. The caudal part of the vaginal process has become the tunica vaginalis covering of the testis. The proximal portion of the vaginal process is obliterated.

MAKING CONNECTIONS

SYSTEM CONNECTION: Homeostatic Interrelationships Between the Reproductive System and Other Body Systems

Integumentary System

- Androgens activate oil glands that lubricate skin and hair; gonadal hormones stimulate characteristic fat distribution and appearance of pubic and axillary hair; estrogen increases skin hydration, and during pregnancy it enhances facial skin pigmentation
- Skin protects all body organs by external enclosure; mammary gland secretions (milk) nourish the infant

Skeletal System

- Androgens masculinize the skeleton and increase bone density; estrogen feminizes the skeleton and maintains bone mass in females
- The bony pelvis encloses some reproductive organs; if narrow, the bony pelvis may hinder vaginal delivery of an infant

Muscular System

- Androgens promote increase in muscle mass
- Abdominal muscles active during childbirth; muscles of the pelvic floor support reproductive organs and aid erection of penis/clitoris

Nervous System

- Sex hormones masculinize or feminize the brain and influence sex drive
- Hypothalamus regulates timing of puberty; neural reflexes regulate events of sexual response

Endocrine System

- Gonadal hormones exert feedback effects on hypothalamic-pituitary axis; placental hormones promote maternal hypermetabolism
- Gonadotropins (and GnRH) help regulate function of gonads; leptin signals the hypothalamus about the body's state of energy availability (in fat stores)

Cardiovascular System

- Estrogens lower blood cholesterol levels and promote cardiovascular health in premenopausal women; pregnancy increases workload of the cardiovascular system
- Cardiovascular system transports needed substances to organs of reproductive system; local vasodilation involved in erection; blood transports sex hormones

Lymphatic System/Immunity

- Developing embryo/fetus escapes immune surveillance (not rejected)
- Lymphatic vessels drain leaked tissue fluids; transport sex hormones; immune cells protect reproductive organs from disease; IgA is present in breast milk

Respiratory System

- Pregnancy impairs descent of the diaphragm, promotes dyspnea
- Respiratory system provides oxygen; disposes of carbon dioxide; vital capacity and respiratory rate increase during pregnancy

Digestive System

- Digestive organs crowded by developing fetus; heartburn, constipation common during pregnancy
- Digestive system provides nutrients needed for health

Urinary System

- Hypertrophy of the prostate inhibits urination; compression of bladder during pregnancy leads to urinary frequency and urgency
- Kidneys dispose of nitrogenous wastes and maintain acid-base balance of blood of mother and fetus; semen discharged through the urethra of the male

CLOSER CONNECTIONS

THE REPRODUCTIVE SYSTEM and Interrelationships with the Endocrine, Skeletal, and Muscular Systems

The reproductive system seems to be a particularly "selfish" system—interested only in its own well-being. But when we reflect on the importance of reproduction and continuity in the scheme of things, that selfishness is a benefit, not a drawback. Indeed, the reproductive system ensures (or tries to) that a person's gene pool passes on and, rather than directing its main energy to other body systems, it builds a whole new organism. Quite an incredible feat, don't you think?

Though reproductive system interactions with other body systems are relatively meager, one—that with the endocrine system—stands out and will receive the bulk of our attention. Indeed, these two systems are difficult to divorce from one another, particularly since the gonads themselves function as endocrine organs. Most other reproductive system interactions, such as those with the nervous and cardiovascular systems, are mediated through its hormones. For example, testosterone and estrogen imprint the brain as male or female, respectively, and estrogens help stave off atherosclerosis and help keep a woman's cardiovascular system (particularly her blood vessels) youthful. The gonadal hormones also play major roles in somatic development, particularly at puberty, and these are explored below.

Endocrine System

First of all, specific endocrine organs of the body—the hypothalamus via its gonadotropin-releasing hormones and the anterior pituitary gland via FSH and LH—help orchestrate virtually all reproductive functions. Without them, the gonads would never mature to adult functional status during adolescence, gametes would not be produced, and subsequent effects mediated by gonadal hormones would fail to occur. We would forever remain sexually infantile with a childlike reproductive system. On the other hand, if testosterone were not secreted by the tiny male fetal testes, the male reproductive tract would not be formed to begin with. Furthermore, gonadal hormones produced in response to gonadotropins also help to regulate gonadotropin release (via negative and positive feedback mechanisms), as well as that of GnRH. So what we have here is an interlocking cycle in which one part cannot function without the other. On the other hand, leptin should not be forgotten because that hormonal messenger from adipose tissue alerts the hypothalamus when the young woman's body is ready for reproduction.

Skeletal and Muscular Systems

Once the reproductive system gonads are "up and running," they in turn start producing hormones that not only cause maturation of their own system's accessory organs and help maintain gametogenesis, but also are crucial for the incredible growth spurt that occurs during puberty and converts the child's body to an adult's. The most important effects are the anabolic effects exerted on bone and skeletal muscle. The skeleton becomes taller, heavier, and denser, and in females its pelvis is shaped to accommodate birth. All through a woman's reproductive years, estrogen helps maintain a healthy bone mass. (Its lack is quickly obvious after menopause.) The skeletal muscles, too, increase in size and mass, and become capable of great strength. Testosterone in particular is the muscle builder. Although the gonadal hormones do not act alone, and their effects are superimposed on those of growth hormone and thyroid hormone, they certainly promote adult stature and are responsible for the musculoskeletal changes that distinguish the sexes anatomically.

CLINICAL CONNECTIONS

Reproductive System

Case study: We are back to look in on Mr. Heyden today. Since we last saw him (Chapter 26), he has had an X ray to try to determine the cause of his back pain, and his blood test results have come in. According to the note recorded from radiology:

- X irradiation of skeleton displays numerous carcinomatous metastases in his skull and lumbar vertebrae.

The hematology note of interest here reads:

- Serum acid phosphatase levels abnormally high.

1. What is carcinoma? What do you suppose is the primary source of the secondary carcinoma lesions in his skull and spine?
2. On what basis did you come to this conclusion?
3. What other tests might be of some diagnostic help here?
4. What type of therapy do you predict Mr. Heyden will be given to treat his carcinoma? Why?

(Answers in Appendix G)

Although ovarian estrogen production continues for a while after menopause, the ovaries finally stop functioning as endocrine organs. Without sufficient estrogen the reproductive organs and breasts begin to atrophy, the vagina becomes dry, and vaginal infections become increasingly common. Other sequels due to lack of estrogen include irritability and depression (in some); intense vasodilation of the skin's blood vessels, which causes uncomfortable, sweat-drenching "hot flashes"; gradual thinning of the skin, and loss of bone mass. Slowly rising total blood cholesterol levels and falling HDL levels place postmenopausal women at risk for cardiovascular disorders. At one time physicians prescribed low-dose estrogen-progesterone preparations to help women through this often difficult period and to prevent the skeletal and cardiovascular complications. These seemed like great bonuses and until July 2002, some 14 million American women were taking some form of estrogen-containing hormone replacement therapy (HRT). Then, on July 9, the Women's Health Initiative (WHI) abruptly ended a clinical trial of 16,000 postmenopausal women, reporting that in those taking a popular progesterone-estrogen hormone combination there was an increase of 51% in heart disease, 24% in invasive breast cancer, 31% in stroke, and a doubling of the risk of dementia compared to those taking placebos. The backlash of this finding is still spreading through physicians' offices and research labs and is restricting funding and the ability to find new volunteers for future studies. Why the effects seen in humans failed to match the lab animal studies remains to be determined, but in the meantime it has dampened enthusiasm for HRT in both the medical community and postmenopausal women.

There is no equivalent of menopause in males. While aging men do exhibit a steady decline in testosterone secretion and a longer latent period after orgasm, a male's reproductive capability seems unending. Healthy men are able to father offspring well into their eighth decade of life thanks to their small but enduring population of germ line stem cells (spermatogonia). However, there is a noticeable difference in sperm motility with aging. Sperm of a young man can make it up the uterine tubes in 20–50 minutes, whereas those of a 75-year-old take 2½ days for the same trip.

■ ■ ■

The reproductive system is unique among organ systems in at least two ways: (1) It is nonfunctional during the first 10–15 years of life, and (2) it is capable of interacting with the complementary system of another person—indeed, it *must* do so to carry out its biological function—pregnancy and birth. To be sure, having a baby is not always what the interacting partners have in mind, and we humans have devised a variety of techniques for preventing this outcome (see *A Closer Look* on p. 1128).

The major goal of the reproductive system is ensuring the healthy function of its own organs so that conditions are optimal for producing offspring. However, as illustrated in *Making Connections*, gonadal hormones do influence other body organs, and the reproductive system depends on other body systems for oxygen and nutrients and to carry away and dispose of its wastes.

Now that we know how the reproductive system functions to prepare itself for childbearing, we are ready to consider the events of pregnancy and prenatal development of a new living being, the topics of Chapter 28.

Related Clinical Terms

Dysmenorrhea (dis"men-ŏ-re'ah; *dys* = bad; *meno* = menses, a month) Painful menstruation; may reflect abnormally high prostaglandin activity during menses.

Endometrial cancer (en"do-me'tre-al; *endo* = within; *metrio* = the uterus, womb) Cancer which arises from the uterine endometrium (usually from uterine glands); the fourth most common cancer of women. Most important sign is vaginal bleeding, which allows early detection. Risk factors include obesity and HRT.

Endometriosis (en"do-me"tre-o'sis) An inflammatory condition in which endometrial tissue occurs and grows atypically in the pelvic cavity. Characterized by abnormal uterine or rectal bleeding, dysmenorrhea, and pelvic pain. May cause sterility.

Gynecology (gi"nĕ-kol'o-je; *gyneco* = woman; *ology* = study of) Specialized branch of medicine that deals with the diagnosis and treatment of female reproductive system disorders.

Gynecomastia (gi"nĕ-ko-mas'te-ah) Development of breast tissue in the male; a consequence of adrenal cortex hypersecretion of estrogens, certain drugs (cimetidine, spironolactone, and some chemotherapeutic agents), and marijuana use.

Hysterectomy (his"tĕ-rek'to-me; *hyster* = uterus; *ectomy* = cut out) Surgical removal of the uterus.

Inguinal hernia Protrusion of part of the intestine into the scrotum or through a separation in the abdominal muscles in the groin region. Since the inguinal canals represent weak points in the abdominal wall, inguinal hernia may be caused by heavy lifting or other activities that increase intra-abdominal pressure.

Laparoscopy (lap"ah-ros'ko-pe; *lapar* = the flank, *scopy* = observation) Examination of the abdominopelvic cavity with a laparoscope, a viewing device at the end of a thin tube inserted through the anterior abdominal wall. Laparoscopy is often used to assess the condition of the pelvic reproductive organs of females.

Oophorectomy (o"of-o-rek'to-me; *oophor* = ovary) Surgical removal of the ovary.

Orchitis (or-ki'tis; *orcho* = testis) Inflammation of the testes, sometimes caused by the mumps virus.

Ovarian cancer Malignancy that typically arises from the cells in the germinal epithelial covering of the ovary. The fifth most common reproductive system cancer, its incidence increases with age. Called the "disease that whispers" because early symptoms are nondescript and easily mistaken for other disorders (back pain, abdominal discomfort, nausea, bloating, and flatulence). Diagnosis may involve palpating a mass during a physical exam, visualizing it with an ultrasound probe, or conducting blood tests for a protein marker for ovarian cancer (CA-125). However, medical assessment is often delayed until after metastasis has occurred; five-year survival rate is 90% if the condition is diagnosed before metastasis.

Ovarian cysts The most common disorders of the ovary; some are tumors. Types include (1) *simple follicle retention cysts* in which single or clustered follicles become enlarged with a clear fluid; (2) *dermoid cysts,* which are filled with a thick yellow fluid and contain partially developed tissues of hair, teeth, bone, etc.; and (3) *chocolate cysts* filled with dark gelatinous material, which are the result of endometriosis of the ovary. None of these is malignant, but the latter two may become so.

Polycystic ovary syndrome (PCOS) The most common endocrinopathy in women and the most common cause of anovulatory infertility. Affects 5–10% of women; characterized by signs of androgen excess, increased cardiovascular risk (evidenced by high blood pressure, decreased HDL cholesterol levels, and high triglycerides); and linked to extreme obesity and some degree of insulin resistance. Treatment with insulin-sensitizing drugs results in a decrease in signs and symptoms of PCOS.

Salpingitis (sal"pin-ji'tis; *salpingo* = uterine tube) Inflammation of the uterine tubes.

Chapter Summary

1. The function of the reproductive system is to produce offspring. The gonads produce gametes (sperm or ova) and sex hormones. All other reproductive organs are accessory organs.

Anatomy of the Male Reproductive System (pp. 1066–1072)

The Scrotum (p. 1067)

1. The scrotum contains the testes. It provides a temperature slightly lower than that of the body, as required for viable sperm production.

The Testes (pp. 1067–1069)

2. Each testis is covered externally by a tunica albuginea that extends internally to divide the testis into many lobules. Each lobule contains sperm-producing seminiferous tubules and interstitial cells that produce androgens.

The Penis (p. 1069)

3. The penis, the male copulatory organ, is largely erectile tissue (corpus spongiosum and corpora cavernosa). Engorgement of the erectile tissue with blood causes the penis to become rigid, an event called erection.

4. The male perineum is the region encompassed by the pubic symphysis, ischial tuberosities, and coccyx.

The Male Duct System (pp. 1069–1071)

5. The epididymis hugs the external surface of the testis and serves as a site for sperm maturation and storage.

6. The ductus (vas) deferens, extending from the epididymis to the ejaculatory duct, propels sperm into the urethra by peristalsis during ejaculation. Its terminus fuses with the duct of the seminal vesicle, forming the ejaculatory duct, which empties into the urethra within the prostate.

7. The urethra extends from the urinary bladder to the tip of the penis. It conducts semen and urine to the body exterior.

Accessory Glands (pp. 1071–1072)

8. The accessory glands produce the bulk of the semen, which contains fructose from the seminal vesicles, activating fluid from the prostate, and mucus from the bulbourethral glands.

Semen (p. 1072)

9. Semen is an alkaline fluid that dilutes and transports sperm. Important chemicals in semen are nutrients, prostaglandins, and seminalplasmin. An ejaculation contains 2–5 ml of semen, with 20–150 million sperm/ml in normal adult males.

Physiology of the Male Reproductive System (pp. 1072–1082)

Male Sexual Response (pp. 1072–1073)

1. Erection is controlled by parasympathetic reflexes.

2. Ejaculation is expulsion of semen from the male duct system, promoted by the sympathetic nervous system. Ejaculation is part of male orgasm, which also includes pleasurable sensations and increased pulse and blood pressure.

Spermatogenesis (pp. 1073–1080)

3. Spermatogenesis, the production of male gametes in the seminiferous tubules, begins at puberty.

4. Meiosis, the basis of gamete production, consists of two consecutive nuclear divisions without DNA replication in between. Meiosis reduces the chromosomal number by half and introduces genetic variability. Events unique to meiosis include synapsis and crossover of homologous chromosomes.

5. Spermatogonia divide by mitosis to maintain the germ cell line. Some of their progeny become primary spermatocytes, which undergo meiosis I to produce secondary spermatocytes. Secondary spermatocytes undergo meiosis II, each producing a total of four haploid *(n)* spermatids.

6. Spermatids are converted to functional sperm by spermiogenesis, during which superfluous cytoplasm is stripped away and an acrosome and a flagellum (tail) are produced.

7. Sustentacular cells form the blood-testis barrier, nourish spermatogenic cells, move them toward the lumen of the tubules, and secrete fluid for sperm transport.

Hormonal Regulation of Male Reproductive Function (pp. 1080–1082)

8. GnRH, produced by the hypothalamus, stimulates the anterior pituitary gland to release FSH and LH. FSH causes sustentacular cells to produce androgen-binding protein (ABP). LH stimulates interstitial cells to release testosterone, which binds to ABP, stimulating spermatogenesis. Testosterone and inhibin (produced by sustentacular cells) feed back to inhibit the hypothalamus and anterior pituitary.

9. Maturation of hormonal controls occurs during puberty and takes about three years.

10. Testosterone stimulates maturation of the male reproductive organs and triggers the development of the secondary sex characteristics of the male. It exerts anabolic effects on the skeleton and skeletal muscles, stimulates spermatogenesis, and is responsible for sex drive.

Anatomy of the Female Reproductive System (pp. 1082–1091)

1. The female reproductive system produces gametes and sex hormones and houses a developing infant until birth.

The Ovaries (pp. 1083–1084)

2. The ovaries flank the uterus laterally and are held in position by the ovarian and suspensory ligaments and mesovaria.

3. Within each ovary are oocyte-containing follicles at different stages of development and corpora lutea.

The Female Duct System (pp. 1084–1088)

4. The uterine tube, supported by the mesosalpinx, extends from near the ovary to the uterus. Its fimbriated and ciliated distal end creates currents that help move an ovulated oocyte into the uterine tube. Cilia of the uterine tube mucosa help propel the oocyte toward the uterus.

5. The uterus has fundus, body, and cervical regions. It is supported by the broad, lateral cervical, uterosacral, and round ligaments.

6. The uterine wall is composed of the outer perimetrium, the myometrium, and the inner endometrium. The endometrium consists of a functional layer (stratum functionalis), which sloughs off periodically unless an embryo has implanted, and an underlying basal layer (stratum basalis), which rebuilds the functional layer.

7. The vagina extends from the uterus to the exterior. It is the copulatory organ and allows passage of the menstrual flow and a baby.

The External Genitalia (pp. 1088–1089)

8. The female external genitalia (vulva) include the mons pubis, labia majora and minora, clitoris, and the urethral and vaginal orifices. The labia majora house the mucus-secreting greater vestibular glands.

The Mammary Glands (pp. 1089–1091)

9. The mammary glands lie over the pectoral muscles of the chest and are surrounded by adipose and fibrous connective tissue. Each mammary gland consists of many lobules, which contain milk-producing alveoli.

Physiology of the Female Reproductive System (pp. 1091–1100)

Oogenesis (pp. 1091–1092)

1. Oogenesis, the production of eggs, begins in the fetus. Oogonia, the diploid stem cells of female gametes, are converted to primary oocytes before birth. The infant female's ovaries contain about 2 million primary oocytes arrested in prophase of meiosis I. This view of limited oocyte potential is now being questioned.

2. At puberty, meiosis resumes. Each month, one primary oocyte completes meiosis I, producing a large secondary oocyte and a tiny first polar body. Meiosis II of the secondary oocyte produces a functional ovum and a second polar body, but does not occur unless the secondary oocyte is penetrated by a sperm.

3. The ovum contains most of the primary oocyte's cytoplasm. The polar bodies are nonfunctional and degenerate.

The Ovarian Cycle (pp. 1093–1094)

4. During the follicular phase (days 1–14), several primary follicles begin to mature. The follicle cells proliferate and produce estrogens, and a connective tissue capsule (theca) is formed around the maturing follicle. Generally, only one follicle per month completes the maturation process and protrudes from the ovarian surface. Late in this phase, the oocyte in the dominant follicle completes meiosis I. Ovulation occurs, usually on day 14, releasing the secondary oocyte into the peritoneal cavity. Other developing follicles deteriorate.

5. In the luteal phase (days 15–28), the ruptured follicle is converted to a corpus luteum, which produces progesterone and estrogen for the remainder of the cycle. If fertilization does not occur, the corpus luteum degenerates after about ten days.

Hormonal Regulation of the Ovarian Cycle (pp. 1094–1096)

6. Beginning at puberty, the hormones of the hypothalamus, anterior pituitary, and ovaries interact to establish and regulate the ovarian cycle. Establishment of the mature cyclic pattern, indicated by menarche, takes about four years.

7. The hormonal events of each ovarian cycle are as follows: (1) GnRH stimulates the anterior pituitary to release FSH and LH, which stimulate follicle maturation and estrogen production. (2) When blood estrogen reaches a certain level, positive feedback exerted on the hypothalamic-pituitary axis causes a sudden release of LH that stimulates the primary oocyte to continue meiosis and triggers ovulation. LH then causes conversion of the ruptured follicle to a corpus luteum and stimulates its secretory activity. (3) Rising levels of progesterone and estrogen inhibit the hypothalamic-pituitary axis, the corpus luteum deteriorates, ovarian hormones drop to their lowest levels, and the cycle begins anew.

The Uterine (Menstrual) Cycle (pp. 1096–1098)

8. Varying levels of ovarian hormones in the blood trigger events of the uterine cycle.

9. During the menstrual phase of the uterine cycle (days 1–5), the functional layer sloughs off in menses. During the proliferative phase (days 6–14), rising estrogen levels stimulate its regeneration, making the uterus receptive to implantation about one week after ovulation. During the secretory phase (days 15–28), the uterine glands secrete glycogen, and endometrial vascularity increases further.

10. Falling levels of ovarian hormones during the last few days of the ovarian cycle cause the spiral arteries to become spastic and cut off the blood supply of the functional layer, and the uterine cycle begins again with menstruation.

Extrauterine Effects of Estrogens and Progesterone (p. 1098)

11. Estrogen promotes oogenesis. At puberty, it stimulates the growth of the reproductive organs and the growth spurt and promotes the appearance of the secondary sex characteristics.

12. Progesterone cooperates with estrogen in breast maturation and regulation of the uterine cycle.

Female Sexual Response (pp. 1098–1100)

13. The female sexual response is similar to that of males. Orgasm in females is not accompanied by ejaculation and is not necessary for conception.

Sexually Transmitted Diseases (pp. 1100–1101)

1. Sexually transmitted diseases (STDs) are infectious diseases spread via sexual contact. Gonorrhea, syphilis, chlamydia, and some forms of vaginitis are bacterial diseases; if untreated, they can cause sterility. Syphilis has broader consequences than most other sexually transmitted bacterial diseases since it can infect organs throughout the body. Trichomoniasis is a parasitic infection. Genital herpes and genital warts are viral infections implicated in cervical cancer. AIDS, a condition of immune suppression, can also be transmitted sexually.

Developmental Aspects of the Reproductive System: Chronology of Sexual Development (pp. 1101–1105, 1108)

Embryological and Fetal Events (pp. 1101–1104)

1. Genetic sex is determined by the sex chromosomes: an X from the mother, an X or a Y from the father. If the fertilized egg contains XX, it is a female and develops ovaries; if it contains XY, it is a male and develops testes.

2. Gonads of both sexes arise from the mesodermal gonadal ridges. The mesonephric ducts produce the male accessory ducts and glands. The paramesonephric ducts produce the female duct system.

3. The external genitalia arise from the genital tubercle and associated structures. The development of male accessory structures and external genitalia depends on the presence of testosterone produced by the embryonic testes. In its absence, female structures develop.

4. The testes form in the abdominal cavity and descend into the scrotum.

Puberty (pp. 1104–1105)

5. Puberty is the interval when reproductive organs mature and become functional. It begins in males with penile and scrotal growth and in females with breast development. Leptin serves a permissive role in puberty's onset, stimulating the hypothalamus when adipose tissue is sufficient for the energy requirements of reproduction.

Menopause (pp. 1105, 1108)

6. During menopause, ovarian function declines, and ovulation and menstruation cease. Hot flashes and mood changes may occur. Postmenopausal events include atrophy of the reproductive organs, bone mass loss, and increasing risk for cardiovascular disease.

Review Questions

Multiple Choice/Matching

(Some questions have more than one correct answer. Select the best answer or answers from the choices given.)

1. The structures that draw an ovulated oocyte into the female duct system are (a) cilia, (b) fimbriae, (c) microvilli, (d) stereocilia.

2. The usual site of embryo implantation is (a) the uterine tube, (b) the peritoneal cavity, (c) the vagina, (d) the uterus.

3. The male homologue of the female clitoris is (a) the penis, (b) the scrotum, (c) the penile urethra, (d) the testis.

4. Which of the following is correct relative to female anatomy? (a) The vaginal orifice is the most dorsal of the three openings in the perineum, (b) the urethra is between the vaginal orifice and the anus, (c) the anus is between the vaginal orifice and the urethra, (d) the urethra is the more ventral of the two orifices in the vulva.

5. Secondary sex characteristics are (a) present in the embryo, (b) a result of male or female sex hormones increasing in amount at puberty, (c) the testis in the male and the ovary in the female, (d) not subject to withdrawal once established.

6. Which of the following produces the male sex hormones? (a) seminal vesicles, (b) corpus luteum, (c) developing follicles of the testes, (d) interstitial cells.

7. Which will occur as a result of nondescent of the testes? (a) Male sex hormones will not be circulated in the body, (b) sperm will have no means of exit from the body, (c) inadequate blood supply will retard the development of the testes, (d) viable sperm will not be produced.

8. The normal diploid number of human chromosomes is (a) 48, (b) 47, (c) 46, (d) 23, (e) 24.

9. Relative to differences between mitosis and meiosis, choose the statements that apply *only* to events of meiosis. (a) tetrads present, (b) produces two daughter cells, (c) produces four daughter cells, (d) occurs throughout life, (e) reduces the chromosomal number by half, (f) synapsis and crossover of homologues occur.

10. Match the key choices with the descriptive phrases below.

Key: **(a)** androgen-binding protein; **(b)** estrogens; **(c)** FSH; **(d)** GnRh; **(e)** inhibin; **(f)** LH; **(g)** progesterone; **(h)** testosterone

____ **(1)** Hormones that directly regulate the ovarian cycle
____ **(2)** Chemicals in males that inhibit the pituitary-testicular axis
____ **(3)** Hormone that makes the cervical mucus viscous
____ **(4)** Potentiates the activity of testosterone on spermatogenic cells
____ **(5)** In females, exerts feedback inhibition on the hypothalamus and anterior pituitary
____ **(6)** Stimulates the secretion of testosterone

11. The menstrual cycle can be divided into three continuous phases. Starting from the first day of the cycle, their consecutive order is (a) menstrual, proliferative, secretory, (b) menstrual, secretory, proliferative, (c) secretory, menstrual, proliferative, (d) proliferative, menstrual, secretory, (e) secretory, proliferative, menstrual.

12. Spermatozoa are to seminiferous tubules as oocytes are to (a) fimbriae, (b) corpus albicans, (c) ovarian follicles, (d) corpora lutea.

13. Which of the following does not add a secretion that makes a major contribution to semen? (a) prostate, (b) bulbourethral glands, (c) testes, (d) vas deferens.

14. The corpus luteum is formed at the site of (a) fertilization, (b) ovulation, (c) menstruation, (d) implantation.

15. The sex of a child is determined by (a) the sex chromosome contained in the sperm, (b) the sex chromosome contained in the oocyte, (c) the number of sperm fertilizing the oocyte, (d) the position of the fetus in the uterus.

16. FSH is to estrogen as estrogen is to (a) progesterone, (b) LH, (c) FSH, (d) testosterone.

17. A drug that "reminds the pituitary" to produce gonadotropins might be useful as (a) a contraceptive, (b) a diuretic, (c) a fertility drug, (d) an abortion stimulant.

Short Answer Essay Questions

18. Why is the term *urogenital system* more applicable to males than to females?

19. The spermatid is haploid, but it is not a functional gamete. Name and describe the process during which a spermatid is converted to a motile sperm, and describe the major structural (and functional) regions of a sperm.

20. Oogenesis in the female results in one functional gamete—the egg, or ovum. What other cells are produced? What is the significance of this rather wasteful type of gamete production—that is, production of a single functional gamete instead of four, as seen in males?

21. List three secondary sex characteristics of females.

22. Describe the events and possible consequences of menopause.

23. Define menarche. What does it indicate?

24. Trace the pathway of a sperm from the male testes to the uterine tube of a female.

25. In menstruation, the stratum functionalis is shed from the endometrium. Explain the hormonal and physical factors responsible for this shedding. (Hint: See Figure 27.22.)

26. Both the epithelium of the vagina and the cervical glands of the uterus help prevent the invasion and spread of vaginal pathogens. Explain how each of these mechanisms works.

27. Some anatomy students were saying that the bulbourethral glands of males act like city workers who come around and clear parked cars from the street before a parade. What did they mean by this analogy?

28. A man swam in a cold lake for an hour and then noticed that his scrotum was shrunken and wrinkled. His first thought was that he had lost his testicles. What had really happened?

Critical Thinking and Clinical Application Questions

1. Gina Marciano, a 44-year-old mother of eight children, visited her physician complaining of a "bearing down" sensation in her pelvis, low backache, and urinary incontinence. A vaginal examination showed that the external os of her cervix was just inside the vaginal orifice and her perineum exhibited large keloids. Her history revealed that she was a member of a commune located in the nearby mountains that shunned hospital births (if at all possible). What do you think Gina's problem is and what caused it? (Be anatomically specific.)

2. Harry, a sexually active adolescent, appeared in the emergency room complaining of a penile "drip" and pain in urination. An account of his recent sexual behavior was requested and recorded. (a) What do you think Harry's problem is? (b) What is the causative agent of this disorder? (c) How is the condition treated, and what may happen if it isn't treated?

3. A 36-year-old mother of four is considering tubal ligation as a means of ensuring that her family gets no larger. She asks the physician if she will become "menopausal" after the surgery. (a) How would you answer her question and explain away her concerns? (b) Explain what a tubal ligation is.

4. Mr. Scanlon, a 76-year-old gentleman, is interested in a much younger woman. Concerned because of his age, he asks his urologist if he will be able to father a child. What questions would a physician ask of this man, and what diagnostic tests would be ordered?

5. Lucy had both her left ovary and her right uterine tube removed surgically at age 17 because of a cyst and a tumor in these organs. Now, at age 32, she remains healthy and is expecting her second child. How could Lucy conceive a child with just one ovary and one uterine tube, widely separated on opposite sides of the pelvis like this?

CHAPTER

Pregnancy and Human Development

From Egg to Zygote (pp. 1114–1117)

1. Describe the importance of sperm capacitation.
2. Explain the mechanism of the slow block to polyspermy.
3. Define fertilization.

Events of Embryonic Development: Zygote to Blastocyst Implantation (pp. 1117–1122)

4. Explain the process and product of cleavage.
5. Describe implantation and placenta formation, and list placental functions.

Events of Embryonic Development: Gastrula to Fetus (pp. 1122–1132)

6. Describe gastrulation and its consequence.
7. Name and describe the formation, location, and function of the extraembryonic membranes.
8. Define organogenesis and indicate the important roles of the three primary germ layers in this process.
9. Describe unique features of the fetal circulation.

Events of Fetal Development (p. 1133)

10. Indicate the duration of the fetal period, and note the major events of fetal development.

Effects of Pregnancy on the Mother (pp. 1133–1135)

11. Describe functional changes in maternal reproductive organs and in the cardiovascular, respiratory, and urinary systems during pregnancy.
12. Indicate the effects of pregnancy on maternal metabolism and posture.

Parturition (Birth) (pp. 1135–1137)

13. Explain how labor is initiated, and describe the three stages of labor.

Adjustments of the Infant to Extrauterine Life (pp. 1137–1138)

14. Outline the events leading to the first breath of a newborn.
15. Describe changes that occur in the fetal circulation after birth.

Lactation (pp. 1138–1139)

16. Explain how the breasts are prepared for lactation.

Assisted Reproductive Technology and Reproductive Cloning (pp. 1139–1140)

17. Describe some techniques of ART including IVF, ZIFT, and GIFT.

Because the birth of a baby is such a familiar event, we tend to lose sight of the wonder of this accomplishment: How does a single cell, the fertilized egg, grow to become a complex human being consisting of trillions of cells? The details of this process can fill a good-sized book. Our intention here is simply to outline the important events of gestation and to consider briefly the events occurring immediately after birth.

To get started, we need to define some terms. The term **pregnancy** refers to events that occur from the time of fertilization (conception) until the infant is born. The pregnant woman's developing offspring is called the **conceptus** (kon-sep'tus; "that which is conceived"). The time during which development occurs is referred to as the **gestation period** (*gestare* = to carry) and extends by convention from the last menstrual period (a date the woman is likely to remember) until birth, approximately 280 days. Thus, at the moment of fertilization, the mother is officially (but illogically) two weeks pregnant! From fertilization through week 8, the *embryonic period,* the conceptus is called an **embryo,** and from week 9 through birth, the *fetal period,* the conceptus is called a **fetus** ("the young in the womb"). At birth, it is an infant. Figure 28.1 shows the changing size and shape of the conceptus as it progresses from fertilization to the early fetal stage.

From Egg to Zygote

Accomplishing Fertilization

Before fertilization can occur, sperm must reach the ovulated secondary oocyte. The oocyte is viable for 12 to 24 hours after it is cast out of the ovary; the chance of pregnancy drops to almost zero the next day. Most sperm retain their fertilizing power for 24 to 48 hours after ejaculation. Consequently, for successful fertilization to occur, coitus must occur no more than two days before ovulation and no later than 24 hours after, at which point the oocyte is approximately one-third of the way down the length of the uterine tube. **Fertilization** occurs when a sperm fuses with an egg (actually a secondary oocyte) to form a fertilized egg, or **zygote** (zi'gōt; "yoked together"), the first cell of the new individual. Let's look at the events leading to fertilization.

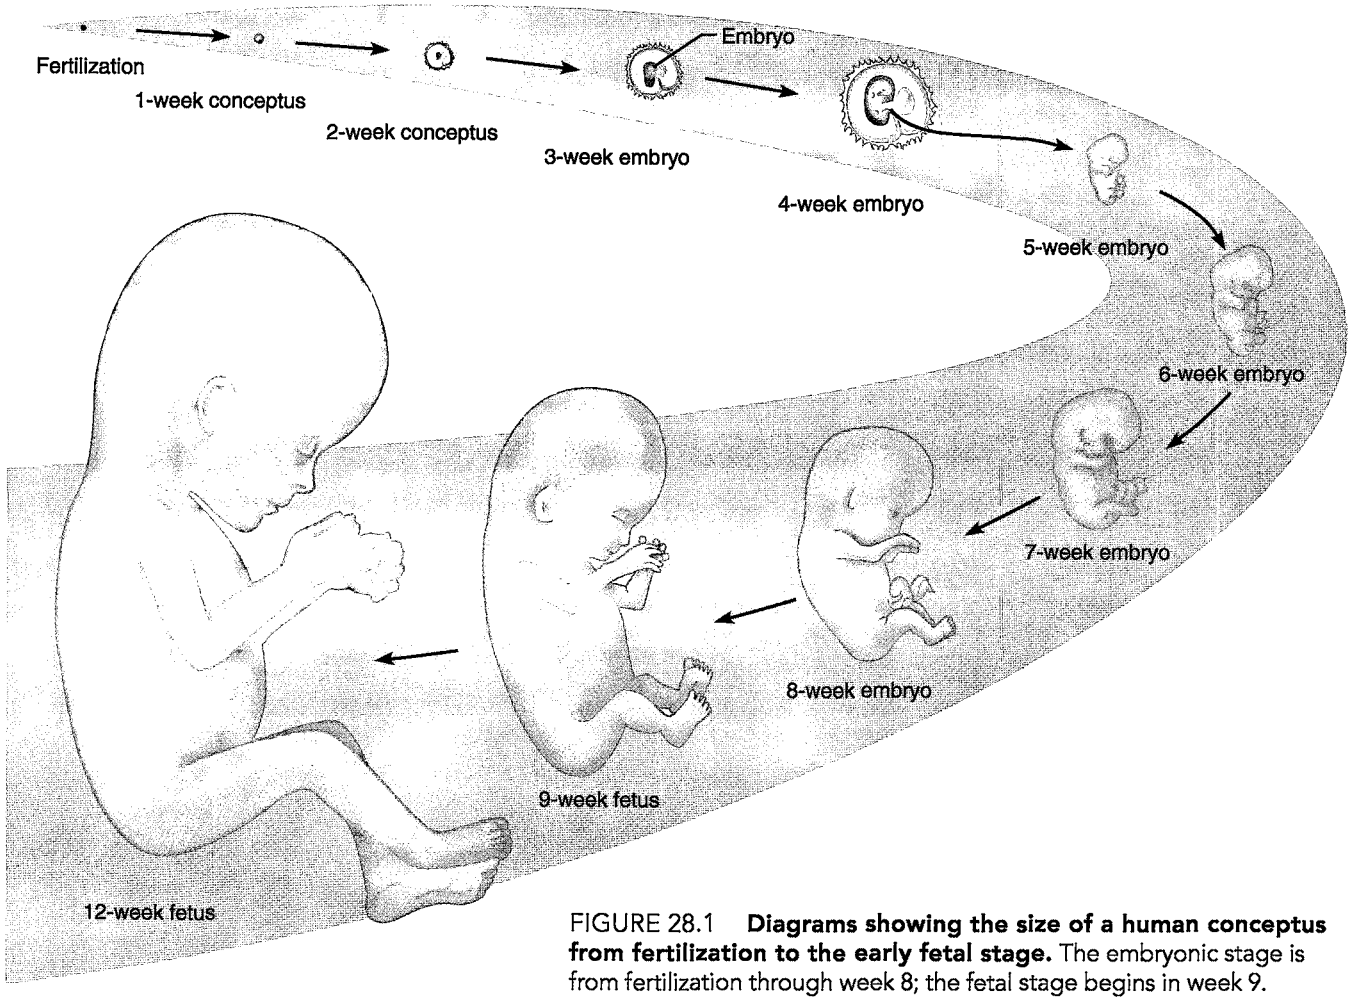

FIGURE 28.1 **Diagrams showing the size of a human conceptus from fertilization to the early fetal stage.** The embryonic stage is from fertilization through week 8; the fetal stage begins in week 9.

Sperm Transport and Capacitation

During copulation, a man expels millions of sperm with considerable force into his partner's vaginal canal. Despite this "head start," most sperm don't reach the oocyte, even though it is only about 5 inches away. Millions of sperm leak from the vagina almost immediately after being deposited there. Of those remaining, millions more are destroyed by the vagina's acidic environment and, unless the thick "curtain" of cervical mucus has been made fluid by estrogens, millions more fail to make it through the cervix. Those that do reach the uterus by their whip-like tail movements are then subjected to forceful uterine contractions that act in a washing machine–like manner to disperse them throughout the uterine cavity, where thousands more are destroyed by resident phagocytes. Only a few thousand (and sometimes fewer than 200) sperm, out of the millions in the male ejaculate, are conducted by reverse peristalsis into and up the uterine tubes, where the oocyte may be moving leisurely toward the uterus.

These difficulties aside, there is still another hurdle to overcome. Sperm freshly deposited in the vagina are incapable of penetrating an oocyte. They must first be **capacitated** over the next 6 to 8 hours; that is, their mobility is enhanced and their membranes must become fragile so that the hydrolytic enzymes in their acrosomes can be released. As sperm swim through the cervical mucus, uterus, and uterine tubes, secretions of the female tract cause some of their membrane proteins to be removed, and the cholesterol that keeps their acrosomal membranes "tough" and stable is depleted. Thus, even though the sperm may reach the oocyte within a few minutes, they must "wait around" (so to speak) for capacitation to occur. This is an elaborate mechanism for preventing the spilling of acrosomal enzymes. But consider the alternative—fragile acrosomal membranes in the male reproductive tract could rupture prematurely, causing some degree of autolysis (self-digestion) of the male reproductive system.

How sperm navigate to find a released oocyte in the uterine tube is an area of active research. It now appears that they "sniff" their way to the oocyte. Sperm are known to bear proteins called *olfactory receptors* that respond to chemical stimuli and it is presumed that the oocyte or its surrounding cells release signaling molecules that direct the sperm.

Acrosomal Reaction and Sperm Penetration

The ovulated oocyte is encapsulated by the corona radiata and the deeper zona pellucida, a transparent layer of glycoprotein-rich extracellular matrix secreted by the oocyte, and both must be breached before the oocyte can be penetrated. Once a sperm gets to the immediate vicinity of the oocyte, it penetrates the corona radiata, assisted by a cell-surface hyaluronidase that digests the intercellular cement between the granulosa cells in the immediate area, causing them to fall away from the oocyte. After breaching the corona, the sperm head binds to the ZP3 glycoprotein of the zona pellucida, which functions as a sperm receptor and helps trigger the acrosomal (ak'ro-som-al) reaction. The **acrosomal reaction** involves the breakdown of the plasma membrane and the acrosomal membrane, and release of acrosomal enzymes (acrosin, proteases, and others) which digest holes through the zona pellucida (Figure 28.2). Hundreds of acrosomes must undergo exocytosis to digest holes in the zona pellucida. This is one case that does not bear out the adage, "The early bird catches the worm." A sperm that comes along later, after hundreds of sperm have undergone acrosomal reactions to expose the oocyte membrane, is in the best position to be *the* fertilizing sperm.

Once a path has been cleared and a single sperm fuses with the oocyte's membrane receptors, its nucleus is pulled into the oocyte cytoplasm (Figure 28.2a). Each sperm carries a special two-part binding apparatus on its surface. The *beta protein* part acts first as it binds to a receptor on the oocyte membrane. This event engages the *alpha protein* part, causing it to insert into the membrane. This somehow causes the egg and sperm membranes to open and fuse together with such perfect contact that the contents of both cells are combined within a single membrane—all without spilling a drop. Interestingly, the region of the oocyte where the sperm enters determines the future right and left axes of the embryo's body.

Blocks to Polyspermy

Polyspermy (entry of several sperm into an egg) occurs in some animals, but in humans only one sperm is allowed to penetrate the oocyte, ensuring **monospermy,** the one-sperm-per-oocyte condition. Once the sperm has entered the oocyte, waves of Ca^{2+} are released by the oocyte's endoplasmic reticulum into its cytoplasm, which activates the oocyte to prepare for cell division. These calcium surges also cause the **cortical reaction** (see Figure 28.2a), in which granules located just inside the plasma membrane spill their enzymes into the extracellular space beneath the zona pellucida. These enzymes, called *zonal inhibiting proteins (ZIPs),* destroy the sperm receptors, preventing further sperm entry. Additionally, the spilled material binds water, and as it swells it detaches all sperm still bound to receptors on the oocyte membrane, accomplishing the so-called *slow block to polyspermy.* In rare cases of polyspermy that do occur, the embryos contain too much genetic material and are nonviable (die).

Completion of Meiosis II and Fertilization

After a sperm enters the oocyte it loses its tail and midpiece, and the centrosome in its midpiece elaborates microtubules which the sperm uses to find the oocyte nucleus. The sperm then locomotes its

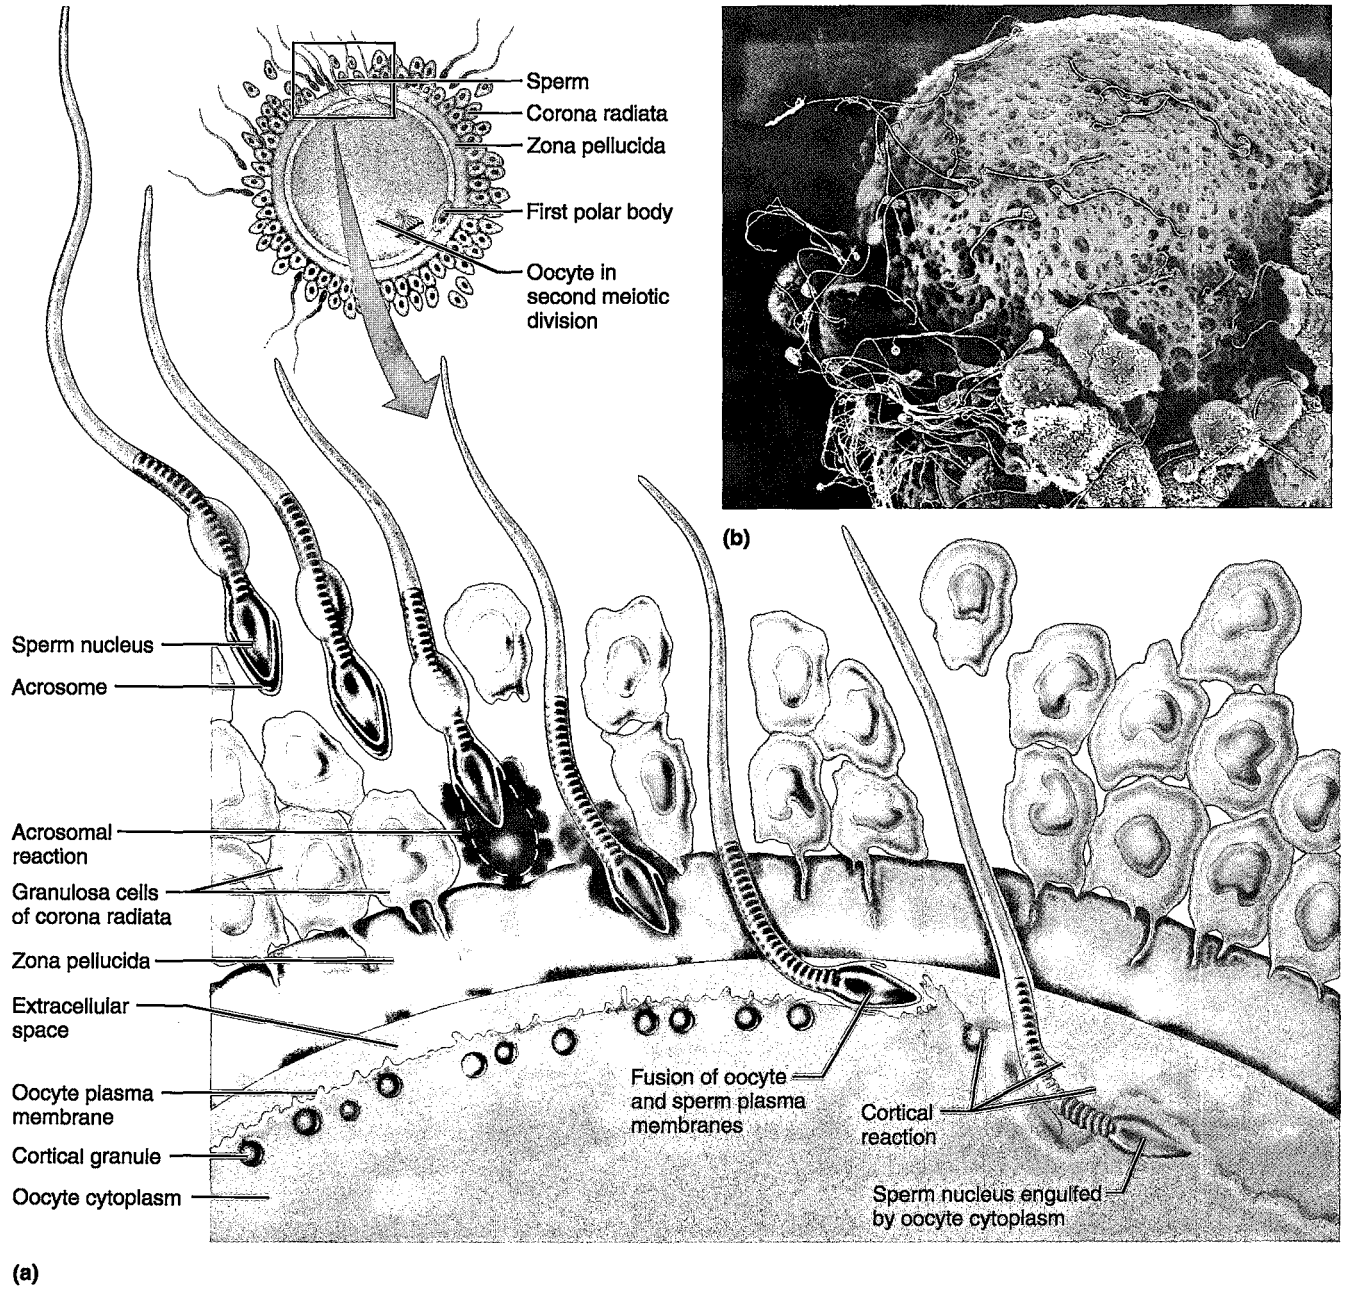

FIGURE 28.2 **Sperm penetration and the cortical reaction (slow block to polyspermy). (a)** The sequential steps of oocyte penetration by a sperm are depicted from left to right. Sperm penetration through the corona radiata and zona pellucida is accomplished by a surface-bound hyaluronidase, and by release of acrosomal enzymes by many sperm. Fusion of the plasma membrane of a single sperm with the oocyte membrane is followed by engulfment of the sperm by the oocyte cytoplasm and the cortical reaction (release of cortical granules' contents into the extracellular space) preventing the entry of more than one sperm. **(b)** Scanning electron micrograph of human sperm surrounding a human oocyte (650×). The smaller spherical cells are granulosa cells of the corona radiata.

DNA-rich nucleus toward the oocyte, its nucleus swelling to about five times its normal size to form the **male pronucleus** (pro-nu'kle-us; *pro* = before) on the way. Meanwhile the secondary oocyte, stimulated into activity by the calcium surges, completes meiosis II, forming the ovum nucleus and the second polar body (Figure 28.3a and b). This accomplished, the ovum nucleus swells, becoming the **female pronucleus,** and the two pronuclei approach each other. A mitotic spindle develops between them (Figure 28.3c), and the pronuclei membranes rupture, releasing their chromosomes into the immediate vicinity of the newly formed spindle. The true moment of fertilization occurs as the maternal and paternal chromosomes combine and produce the diploid *zygote,* or fertilized egg (Figure 28.3d).* Almost as soon as the male and female pronuclei

* Some sources define the term *fertilization* simply as the act of oocyte penetration by the sperm. However, unless the chromosomes in the male and female pronuclei are actually joined, the zygote is never formed in humans.

come together, their chromosomes replicate. Then, the first mitotic division of the conceptus begins (Figure 28.3d–f).

Events of Embryonic Development: Zygote to Blastocyst Implantation

Embryonic development begins with fertilization and continues as the embryo travels through the uterine tube, floats free in the cavity of the uterus, and finally implants in the uterine wall. Significant events of this early embryonic period are *cleavage*, which produces a structure called a blastocyst, and *implantation* of the blastocyst.

Cleavage and Blastocyst Formation

Cleavage is a period of fairly rapid mitotic divisions of the zygote following fertilization (Figure 28.4). Cleavage produces small cells with a high surface-to-volume ratio, which enhances their uptake of nutrients and oxygen and the disposal of wastes. It also provides a large number of cells to serve as building blocks for constructing the embryo. Consider, for a moment, the difficulty of trying to construct a building from one huge block of granite. If you now consider how much easier it would be if instead you could use hundreds of bricks, you will quickly grasp the importance of cleavage.

Some 36 hours after fertilization, the first cleavage division has produced two identical cells called *blastomeres*. These divide to produce four cells, then eight, and so on. By 72 hours after fertilization, a loose collection of cells that form a berry-shaped cluster of 16 or more cells called the **morula** (mor'u-lah; "little mulberry") has been formed. All the while, transport of the embryo toward the uterus continues. By day 3 or 4 after fertilization, the embryo consists

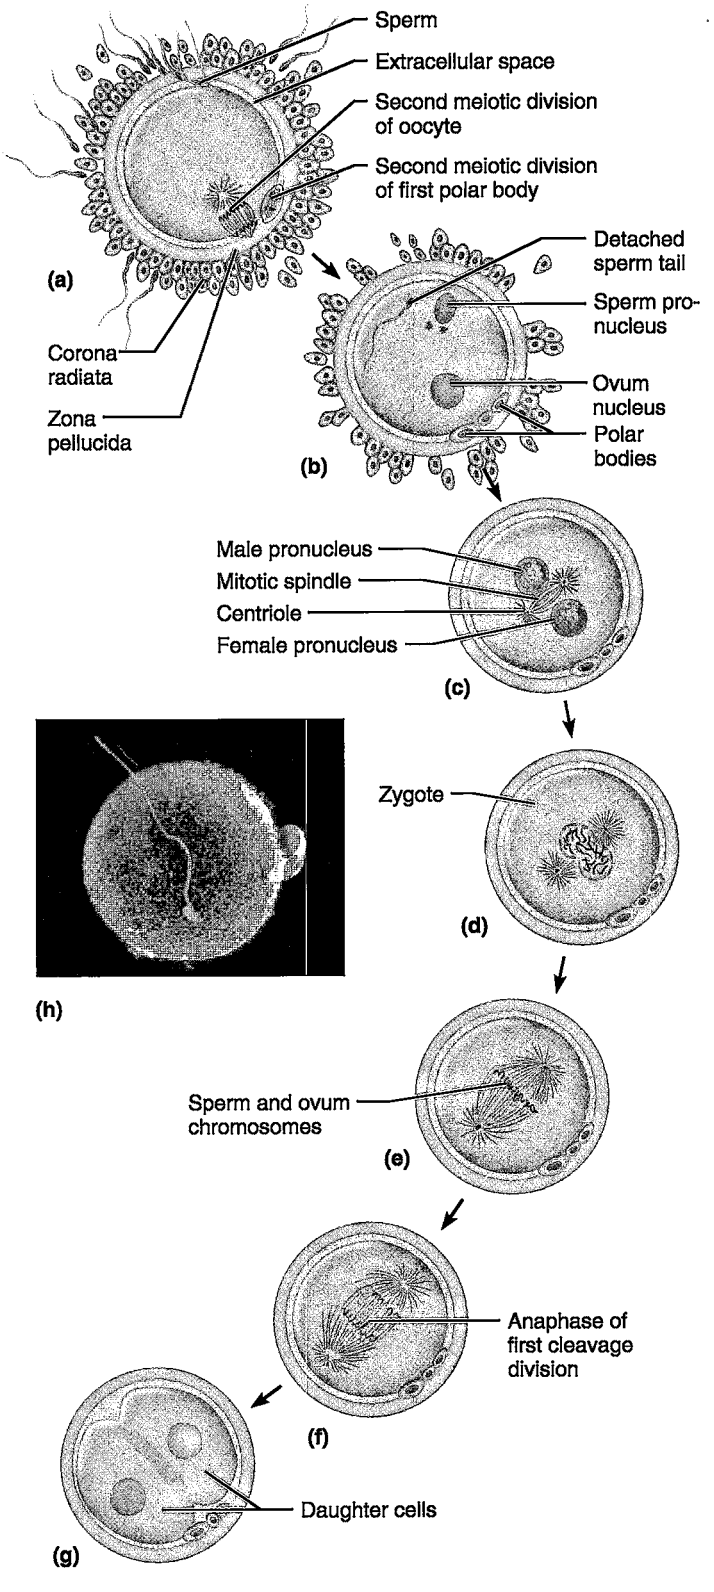

FIGURE 28.3 **Events immediately following sperm penetration. (a)** Once a sperm has entered the secondary oocyte, the oocyte completes meiosis II, forming the ovum nucleus and casting out the second polar body. The first polar body formed in the first meiotic division may also undergo division, producing two more polar bodies. **(b, c)** The ovum nucleus formed during meiosis II swells, and the sperm and egg nuclei (pronuclei) approach each other. **(d–g)** As the male and female pronuclei come together (fertilization), their DNA replicates. Chromosomes then form, attach to the mitotic spindle, and undergo a mitotic division. This division is the first cleavage division and results in two daughter cells. **(h)** Scanning electron micrograph of a fertilized egg (zygote). Notice the second polar body protruding at the right. A single sperm is seen against the zygote's surface (500×).

Q *Why is the multicellular blastocyst only slightly larger than the single-celled zygote?*

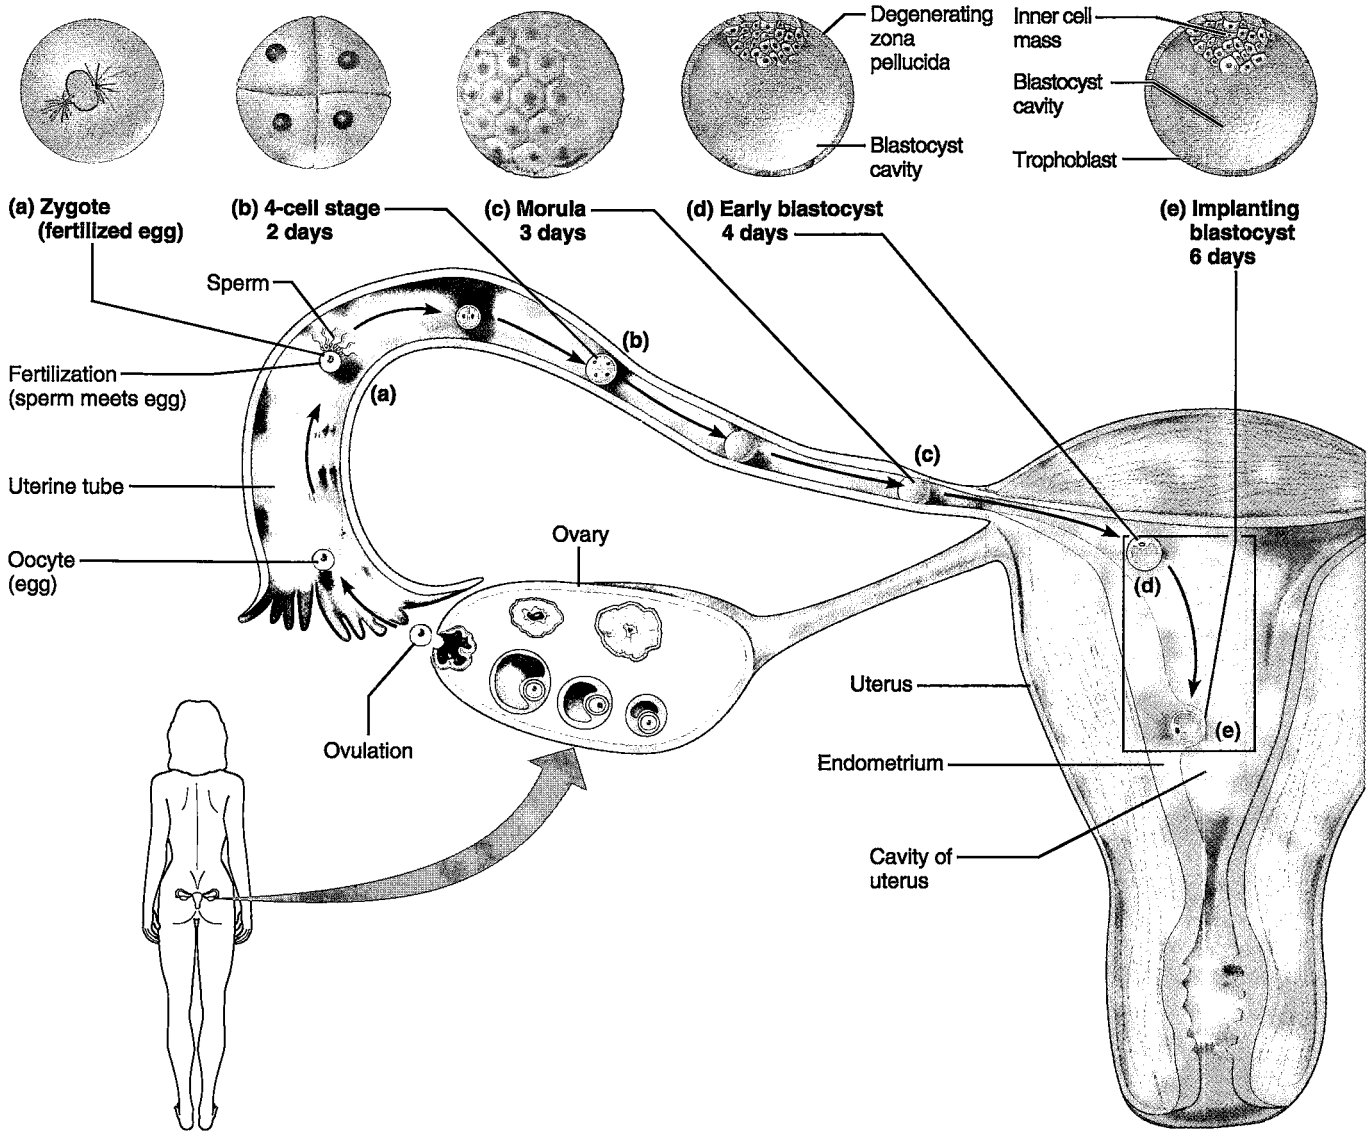

FIGURE 28.4 **Cleavage from zygote to blastocyst.** The zygote begins to divide about 24 hours after fertilization, and continues the rapid mitotic divisions of cleavage as it travels down the uterine tube. Three to four days after ovulation, the embryo reaches the uterus and floats freely for two to three days, nourished by secretions of the endometrial glands. At the late blastocyst stage, the embryo is implanting into the endometrium; this begins at about day 7 after ovulation. **(a)** Zygote. **(b)** Four-cell stage. **(c)** Morula, a solid ball of blastomeres. **(d)** Early blastocyst; the morula hollows out, fills with fluid, and "hatches" from the zona pellucida. **(e)** Late blastocyst, composed of an outer sphere of trophoblast cells and an eccentric cell cluster called the inner cell mass.

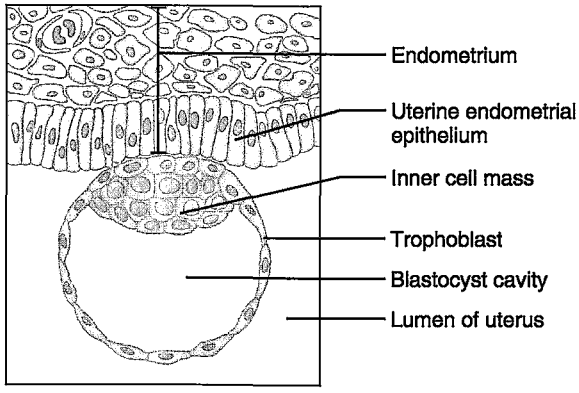
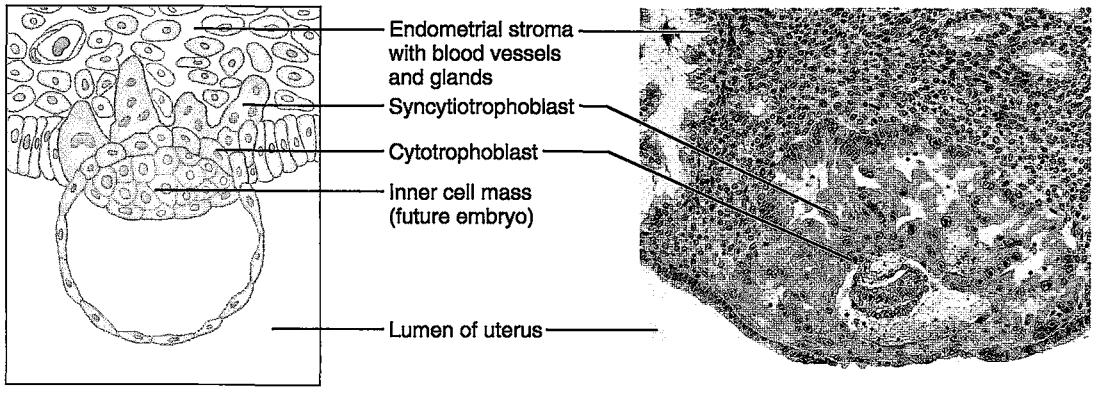
of about 100 cells and floats free in the uterus. By this time, it has tightened its connections between neighboring cells (a process called *compaction*) and begins accumulating fluid within an internal cavity. The zona pellucida now starts to break down and the inner structure, now called a blastocyst, "hatches" from it. The **blastocyst** (blas'to-sist) is a fluid-filled hollow sphere composed of a single layer of large, flattened cells called **trophoblast cells** (trof'o-blast) and a small cluster of 20 to 30 rounded cells, called the **inner cell mass,** located at one side (Figure 28.4e). Trophoblast cells begin to display L-selectin (adhesion) molecules on their surface soon after the blastocyst hatching. They also take part in placenta formation, a fact hinted at by the literal translation of "trophoblast" (nourishment generator), and secrete and display several factors with immunosuppressive effects that protect the trophoblast (hence the developing embryo)

A *Because virtually no growth occurs between the successive divisions of cleavage.*



(a)



(b) (c)

FIGURE 28.5 **Implantation of the blastocyst. (a)** View of a blastocyst that has just adhered to the uterine endometrium. **(b)** Slightly later stage of an implanting embryo (approximately seven days after ovulation), depicting the cytotrophoblast and syncytiotrophoblast of the eroding trophoblast. **(c)** Light micrograph of an implanted blastocyst (approximately 12 days after ovulation) (60×).

from attack by the mother's cells. The inner cell mass becomes the **embryonic disc,** which forms the embryo proper (and the extraembryonic membranes except the chorion, a trophoblast derivative).

Implantation

While the blastocyst floats in the uterine cavity for two to three days, it receives nourishment from glycogen-rich uterine secretions. Then, some six to seven days after ovulation, given a properly prepared endometrium, **implantation** begins. The receptivity of the endometrium to implantation—the so-called *window of implantation*—is opened by the surging levels of ovarian hormones (estrogens and progesterone) in the blood. If the mucosa is properly prepared, integrin and selectin proteins on the trophoblast cells bind respectively to the extracellular matrix components (collagen, fibronectin, laminin, and others) of the endometrial cells and to selectin-binding carbohydrates on the inner uterine wall, and the blastocyst implants high in the uterus. If the endometrium is not yet optimally mature, the blastocyst detaches and floats to a lower level, implanting when it finds a site with the proper receptors and chemical signals. The trophoblast cells overlying the inner cell mass adhere to the endometrium (Figure 28.5a) and secrete digestive enzymes and growth factors against the endometrial surface. The endometrium quickly thickens at the point of contact and takes on characteristics of an acute inflammatory response—the uterine blood vessels become more permeable and leaky, and inflammatory cells including lymphocytes, natural killer cells, and macrophages invade the area. The trophoblast then proliferates and forms two distinct layers (Figure 28.5b). The cells in the inner layer, collectively called the **cytotrophoblast** (si"to-trof'o-blast) or **cellular trophoblast,** retain their cell boundaries. The cells in the outer layer lose their plasma membranes and form a multinuclear cytoplasmic mass called the **syncytiotrophoblast** (sin-sit"e-o-trof'o-blast; *syn* = together, *cyt* = cell) or **syncytial trophoblast,** which invades the endometrium and rapidly digests the uterine cells it contacts. As the endometrium is eroded, the blastocyst burrows into this thick, velvety lining and is surrounded by a pool of blood leaked from degraded endometrial blood vessels. Shortly, the implanted blastocyst is covered over and sealed off from the uterine cavity by proliferation of the endometrial cells (Figure 28.5c).

In cases where implantation fails to occur, a receptive uterus becomes nonreceptive once again. It is estimated that a minimum of two-thirds of all zygotes formed fail to implant by the end of the first week or spontaneously abort. Moreover, an estimated 30% of implanted embryos later miscarry.

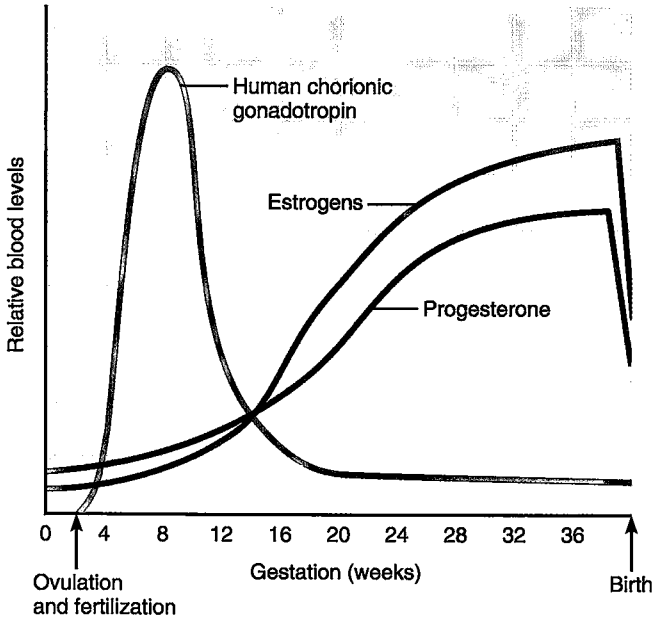


FIGURE 28.6 **Hormonal changes during pregnancy.** The relative changes in maternal blood levels of three hormones that maintain pregnancy are depicted, rather than actual blood concentrations.

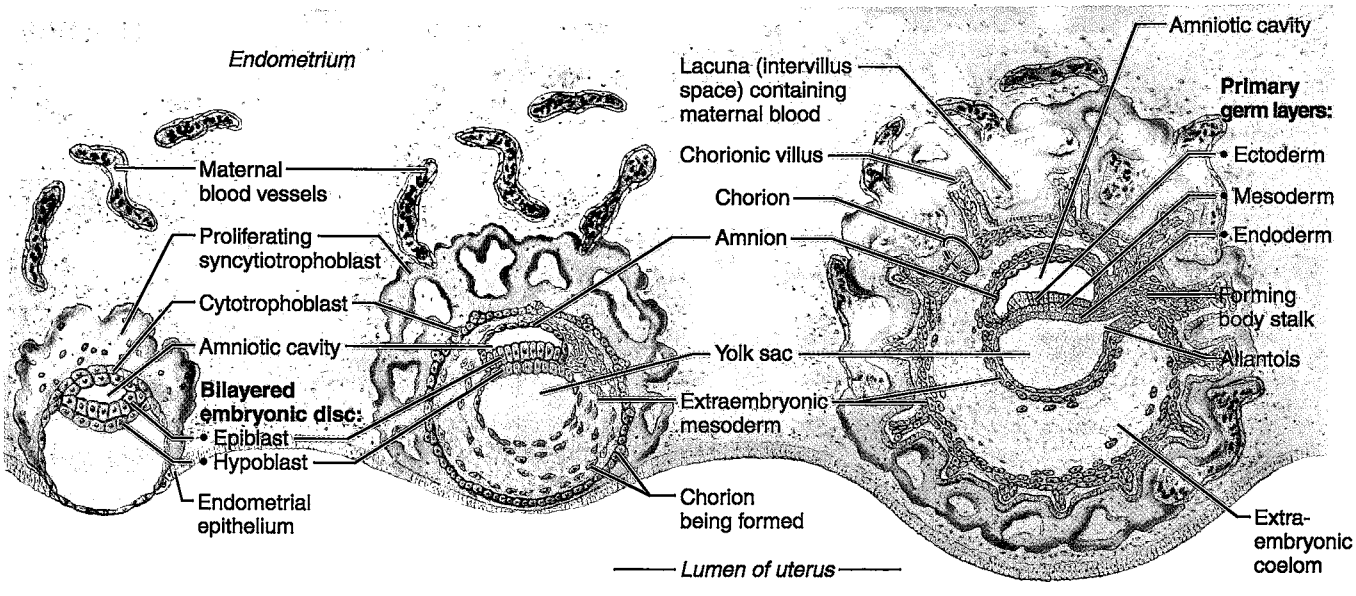
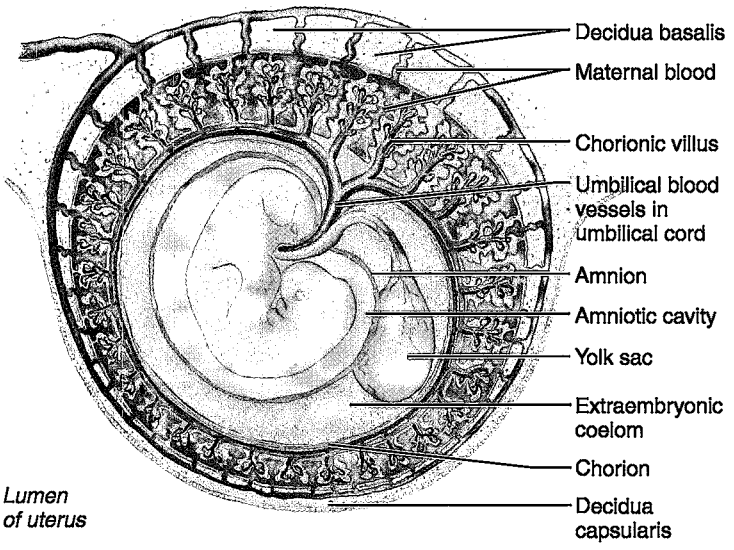
When successful, implantation takes about five days and is usually completed by the 12th day after ovulation—just before the endometrium normally begins to slough off in menses. Obviously, menses would flush away the embryo as well and must be prevented if the pregnancy is to continue. Viability of the corpus luteum is maintained by an LH-like hormone called **human chorionic gonadotropin (hCG)** (ko"re-on'ik go-nad"o-trōp'in) secreted by the trophoblast cells. hCG bypasses pituitary-ovarian controls at this critical time and prompts the corpus luteum to continue secreting progesterone and estrogen. The *chorion,* which develops from the trophoblast after implantation, continues this hormonal stimulus; thus, the developing conceptus takes over the hormonal control of the uterus during this early phase of development. Usually detectable in the mother's blood one week after fertilization, blood levels of hCG rise until the end of the second month and then decline sharply by four months to reach a low value, which persists for the remainder of gestation (Figure 28.6). Between the second and third month, the placenta (described next) assumes the role of progesterone and estrogen production for the remainder of the pregnancy. The corpus luteum then degenerates and the ovaries remain inactive until after birth. All pregnancy tests used today are antibody tests that detect hCG in a woman's blood or urine.

Initially, the implanted embryo obtains its nutrition by digesting the endometrial cells, but by the second month, the placenta is providing nutrients and oxygen to the embryo and carrying away embryonic metabolic wastes. Since placenta formation is a continuation of the events of implantation, we will consider it next, although we will be getting ahead of ourselves a little as far as embryonic development is concerned.

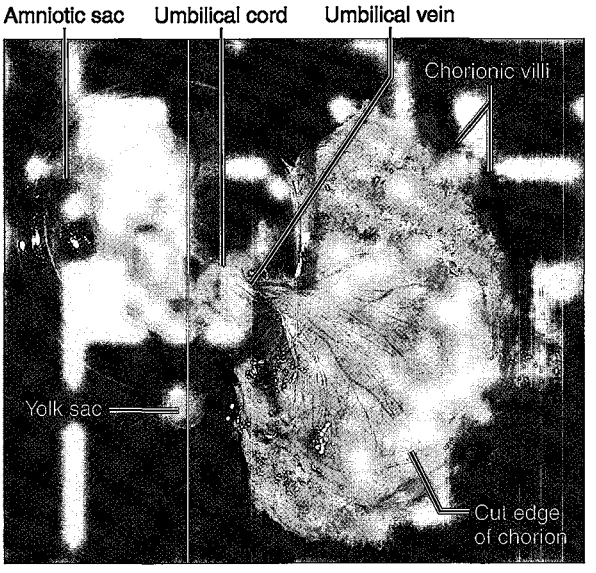
Placentation

Placentation (plas"en-ta'shun) refers to the formation of a **placenta** ("flat cake"), a temporary organ that originates from both embryonic and maternal (endometrial) tissues. Cells from the original inner cell mass give rise to a layer of extraembryonic mesoderm that lines the inner surface of the trophoblast (Figure 28.7b); together these become the **chorion.** The chorion develops fingerlike **chorionic villi**

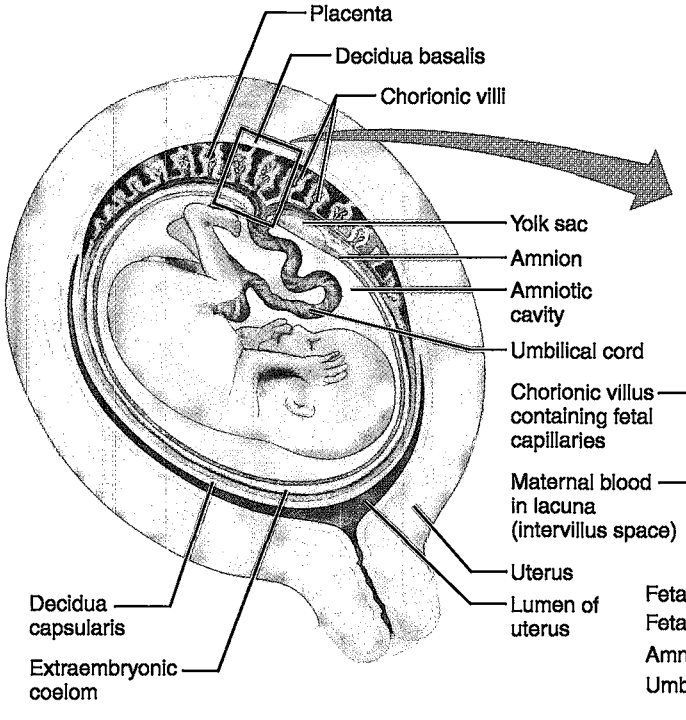




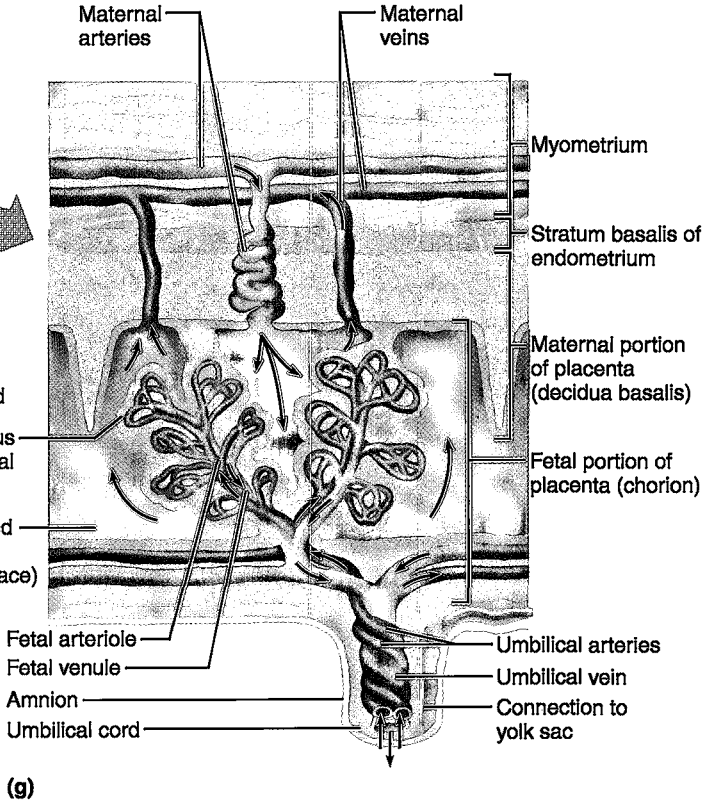
(d) 4½-week embryo



(e) 7-week embryo



(f) 13-week fetus



(g)

FIGURE 28.7 **Events of placentation, early embryonic development, and extraembryonic membrane formation.** Times given refer to the age of the conceptus, which is typically 2 weeks "younger" than the gestation age. **(a)** Implanting blastocyst. Endometrial erosion by the syncytiotrophoblast is ongoing, and cells of the embryonic disc are now separated by a fluid-filled space from the amnion. **(b)** Implantation is completed by day 12 and extraembryonic mesoderm is forming a discrete layer beneath the cytotrophoblast. **(c)** By day 16, the cytotrophoblast and associated mesoderm have become the chorion, and chorionic villi are elaborating. The embryo exhibits all three germ layers, a yolk sac (formed by endodermal cells), and an allantois, an outpocketing abutting the yolk sac that forms the structural basis of the body stalk, or umbilical cord. **(d)** At 4½ weeks, the decidua capsularis and decidua basalis are well formed. The chorionic villi lie in blood-filled intervillus spaces within the endometrium. Organogenesis is occurring in the embryo, which is now receiving its nutrition via the umbilical vessels that connect it (via the body stalk) to the placenta. The amnion and yolk sac are well developed. **(e)** A 7-week embryo and the extraembryonic membranes that will contribute to the placenta (at right). **(f)** 13-week fetus. **(g)** Detailed anatomy of the vascular relationships in the mature decidua basalis. This state of development has been accomplished by the end of the third month of development.

(Figure 28.7c), which are especially elaborate where they are in contact with maternal blood. Soon the mesodermal cores of the chorionic villi become richly vascularized by newly forming blood vessels, which extend to the embryo via the allantois as the umbilical arteries and vein. The continuing erosion produces large, blood-filled **lacunae,** or **intervillus spaces,** in the stratum functionalis of the endometrium (see Figure 27.15, p. 1087), and the villi come to lie in these spaces totally immersed in maternal blood (Figure 28.7d). The part of the endometrium that lies between the chorionic villi and the stratum basalis becomes the **decidua basalis** (de-sid'u-ah), whereas that surrounding the uterine cavity face of the implanted embryo forms the **decidua capsularis** (Figure 28.7d and f). Together, the chorionic villi and the decidua basalis form the disc-shaped placenta.

The fetal side of the placenta is easily recognized because it is slick and smooth, and the umbilical cord projects from its surface. In contrast, the maternal side is "bumpy," revealing the shape of the chorionic villus masses.

The placenta detaches and sloughs off after the infant is born, so the name of the maternal portion—*decidua* ("that which falls off")—is appropriate. The decidua capsularis expands to accommodate the fetus, which eventually fills and stretches the uterine cavity. As the developing fetus grows, the villi in the decidua capsularis are compressed and degenerate, and the villi in the decidua basalis increase in number and branch even more profusely.

The placenta is usually fully functional as a nutritive, respiratory, excretory, and endocrine organ by the end of the third month of pregnancy. However, well before this time, oxygen and nutrients are diffusing from maternal to embryonic blood, and embryonic metabolic wastes are passing in the opposite direction. The barriers to free passage of substances between the two blood supplies are embryonic barriers—the membranes of the chorionic villi and the endothelium of embryonic capillaries. Although the maternal and embryonic blood supplies are very close, they normally do not intermix.

While the placenta secretes hCG from the beginning, the ability of its syncytiotrophoblast cells (the "hormone manufacturers") to produce the estrogens and progesterone of pregnancy matures much more slowly. If, for some reason, placental hormones are inadequate when hCG levels wane, the endometrium degenerates and the pregnancy is aborted. Throughout pregnancy, blood levels of estrogens and progesterone continue to increase (see Figure 28.6), encouraging growth and further differentiation of the mammary glands and readying them for lactation. The placenta also produces other hormones, such as *human placental lactogen, human chorionic thyrotropin,* and *relaxin.* The effects of these hormones on the mother are described shortly.

Events of Embryonic Development: Gastrula to Fetus

Having followed placental development into the fetal stage, we will now backtrack and consider development of the embryo during and after implantation. Even while implantation is occurring, the blastocyst is being converted to a **gastrula** (gas'troo-lah), in which the three primary germ layers form, and the extraembryonic membranes develop. Before becoming three-layered, the inner cell mass first subdivides into two layers—the upper *epiblast* and the lower *hypoblast.*

Formation and Roles of the Extraembryonic Membranes

The **extraembryonic membranes** that form during the first two to three weeks of development include the amnion, yolk sac, allantois, and chorion (see Figure 28.7c). The **amnion** (am'ne-on) develops when cells of the epiblast fashion themselves into a transparent membranous sac. This sac, the amnion, becomes filled with **amniotic fluid.** Later, as the embryonic disc curves to form the tubular body, the amnion curves with it. Eventually, the sac extends all the way around the embryo, broken only by the umbilical cord (see Figure 28.7d).

Sometimes called the "bag of waters," the amnion provides a buoyant environment that protects the developing embryo against physical trauma, and helps maintain a constant homeostatic temperature. The fluid also prevents the rapidly growing embryonic parts from adhering and fusing together and allows the embryo considerable freedom of movement. Initially, the fluid is derived from the maternal blood, but as the fetal kidneys become functional later in development, fetal urine contributes to amniotic fluid volume.

The **yolk sac** forms from cells of the primitive gut (see below), which arrange themselves into a sac that hangs from the ventral surface of the embryo (see Figure 28.7b). Thus, the amnion and yolk sac resemble two balloons touching one another with the embryonic disc at the point of contact. In many species, the yolk sac is the main source of nutrition for the embryo, but human eggs contain very little yolk and nutritive functions have been taken over by the placenta. Nevertheless, the yolk sac is important in humans because it (1) forms part of the *gut* (digestive tube), and (2) produces the earliest blood cells and blood vessels.

The **allantois** (ah-lan'to-is) forms as a small outpocketing of embryonic tissue at the caudal end of the yolk sac (see Figure 28.7c). In animals that develop in shelled eggs, the allantois is a disposal site for solid metabolic wastes (excreta). In humans, the allantois is the structural base for the **umbilical cord** that links the embryo to the placenta, and becomes part of the urinary bladder. The fully formed umbilical cord contains a core of embryonic connective tissue (Wharton's jelly), the umbilical arteries and vein, and is covered externally by amniotic membrane.

The *chorion*, which helps to form the placenta, has already been described (see Figure 28.7c). As the outermost membrane, the chorion encloses the embryonic body and all other membranes.

Gastrulation: Germ Layer Formation

During week 3, the two-layered embryonic disc transforms into a three-layered *embryo* in which the **primary germ layers**—*ectoderm*, *mesoderm*, and *endoderm*—are present. This process, called **gastrulation** (gas"troo-la'shun), involves cellular rearrangements and migrations.

Gastrulation begins when a groove with raised edges called the **primitive streak** appears on the dorsal surface of the embryonic disc and establishes the longitudinal axis of the embryo (Figure 28.8e and f). Surface (epiblast) cells of the embryonic disc then migrate medially across other cells and enter the primitive streak. The first cells to enter the groove displace the hypoblast cells of the yolk sac and form the most inferior germ layer, the **endoderm.** Those that follow push laterally between the cells at the upper and lower surfaces, forming the **mesoderm** (see Figure 28.8g and h). The cells that remain on the embryo's dorsal surface are the **ectoderm.** The mesodermal cells immediately beneath the early primitive streak aggregate, forming a rod of mesodermal cells called the **notochord** (no'to-kord), the first axial support of the embryo (see Figure 28.9a). At this point, the embryo is about 2 mm long.

The three primary germ layers serve as the *primitive tissues* from which all body organs will derive. Ectoderm ("outer skin") fashions structures of the nervous system and the skin epidermis. Endoderm ("inner skin") forms the epithelial linings of the digestive, respiratory, and urogenital systems, and associated glands. Mesoderm ("middle skin") forms virtually everything else. Both ectoderm and endoderm consist mostly of cells that are securely joined to each other and are *epithelia*. Mesoderm, by contrast, is a *mesenchyme* [literally, "poured into the middle (of the embryo)"]. Notice, however, that the term **mesenchyme** indicates *any* embryonic tissue with star-shaped cells that are free to migrate widely within the embryo. Table 28.1 (p. 1130) lists the germ layer derivatives; some of the details of the differentiation processes are described next.

Organogenesis: Differentiation of the Germ Layers

Gastrulation lays down the basic structural framework of the embryo and sets the stage for the rearrangements of **organogenesis** (or"gah-no-jen'ĕ-sis), formation of body organs and organ systems. By the end of the embryonic period, when the embryo is about 22 mm (slightly less than 1 inch) long from head to buttocks (referred to as the *crown-rump measurement*), all the adult organ systems are recognizable. It is truly amazing how much organogenesis occurs in such a short time in such a small amount of living matter.

Specialization of the Ectoderm

The first major event in organogenesis is **neurulation,** the differentiation of ectoderm that produces the brain and spinal cord (Figure 28.9). This process is *induced* (stimulated to happen) by chemical signals from the *notochord*, the rod of mesoderm that defines the body axis, mentioned earlier. The ectoderm overlying the notochord thickens, forming the **neural plate** (Figure 28.9a), and then starts to fold inward as a **neural groove,** which forms prominent **neural folds** as it deepens (Figure 28.9b, c). By day 22, the superior margins of the neural folds fuse, forming a **neural tube,** which soon pinches off and becomes covered by surface ectoderm (Figure 28.9d). As described in Chapter 12, the anterior end of the neural tube becomes the brain and the rest becomes the spinal cord. The associated **neural crest cells** migrate widely and give rise to the cranial, spinal, and sympathetic ganglia (and associated nerves), to the medulla of the adrenal gland, and to pigment cells, and contribute to some connective tissues.

By the end of the first month of development, the three primary brain vesicles (fore-, mid-, and hindbrain) are obvious. By the end of the second month, all brain flexures are evident, the cerebral hemispheres cover the top of the brain stem (see Figure 12.3), and brain waves can be recorded. Most of the remaining ectoderm forming the surface layer of the embryonic body differentiates into the epidermis of the skin. Other ectodermal derivatives are indicated in Table 28.1.

Specialization of the Endoderm

As noted, the embryo starts off as a flat plate, but as it grows, it folds to achieve a cylindrical body shape which lifts off the yolk sac and protrudes into the

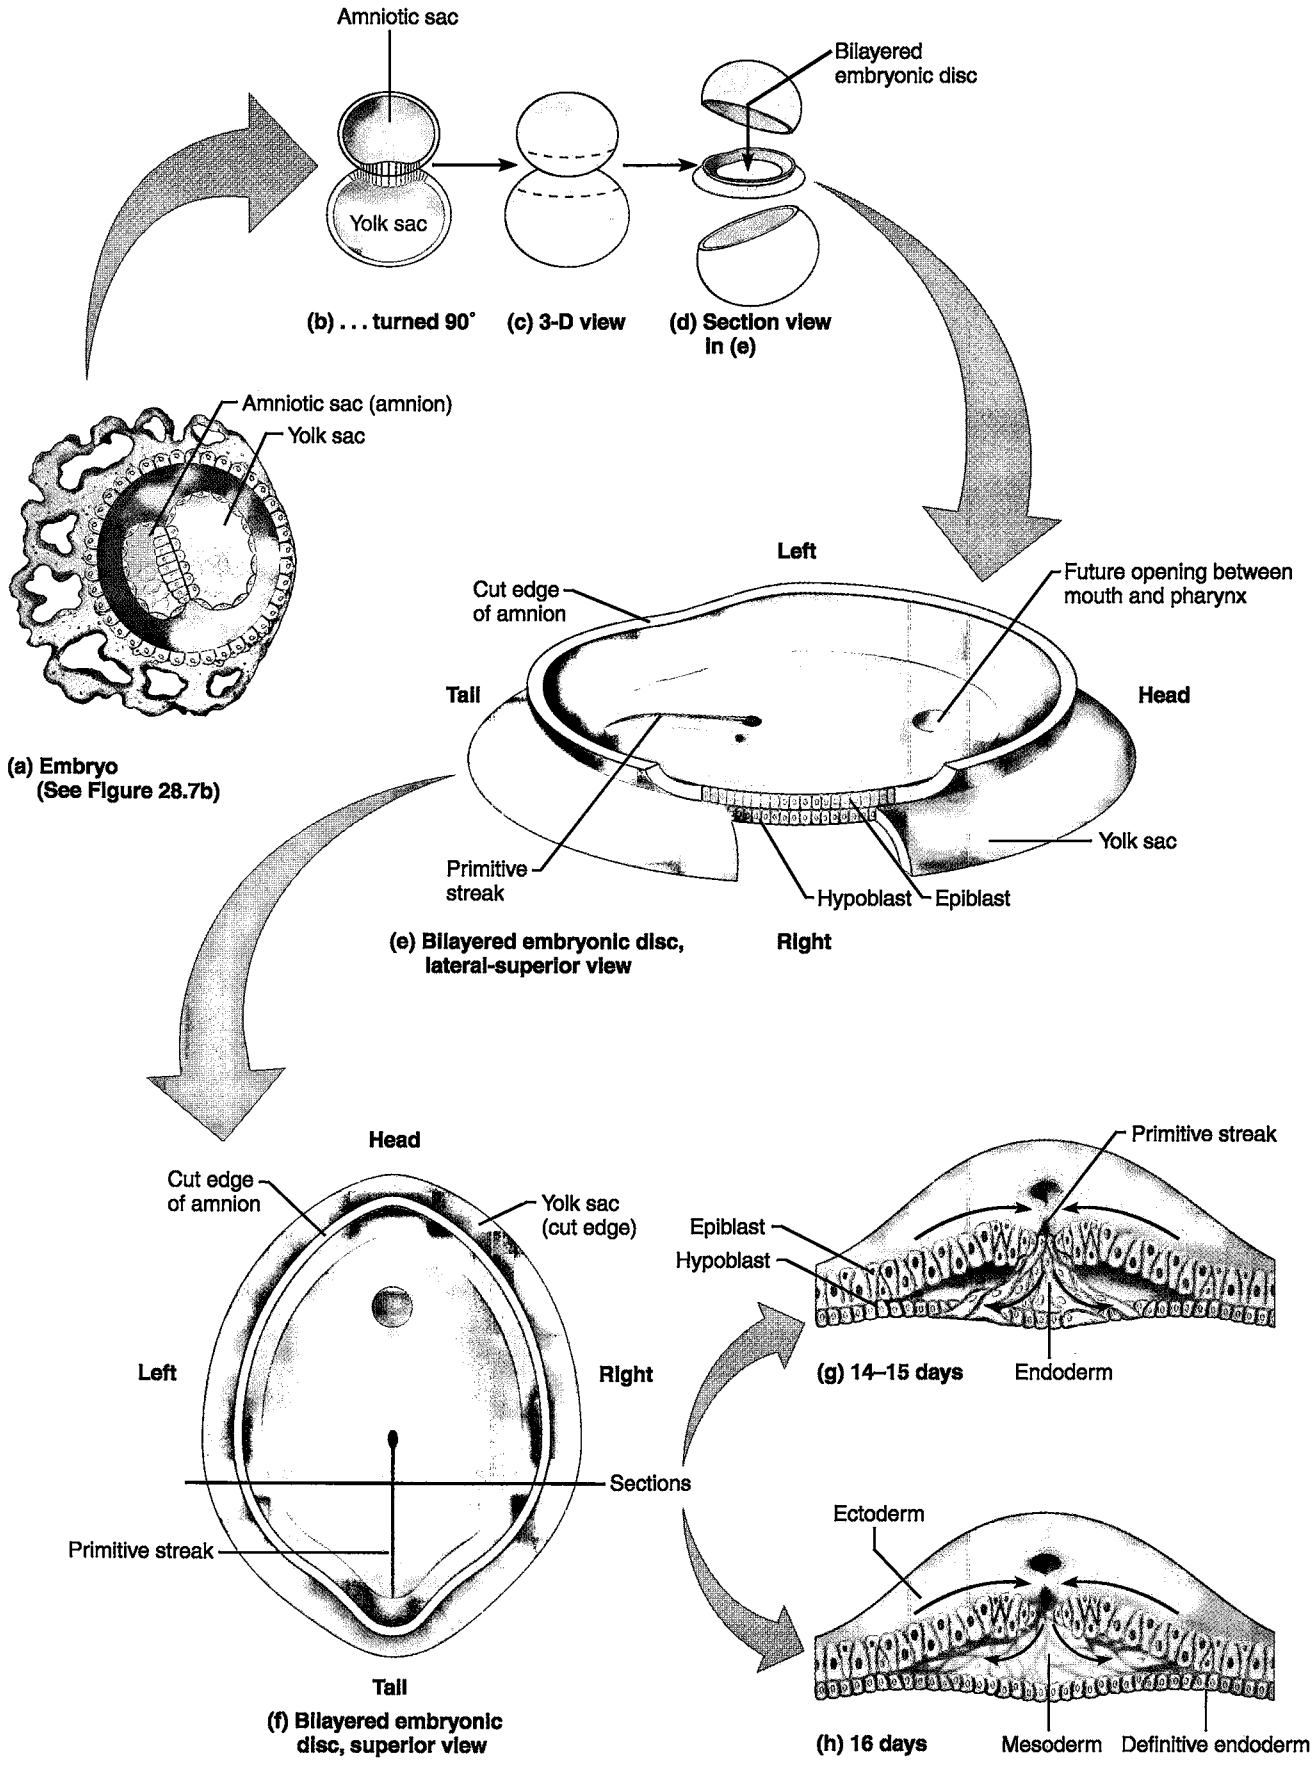


FIGURE 28.8 **Formation of the three primary germ layers. (a–d)** Orienting diagrams. **(e, f)** Surface views of an embryonic disc, amnion and yolk sac removed. **(g, h)** Cross sections of the embryonic disc, showing the germ layers resulting from cell migration. The first epiblast cells that migrate medially into the primitive streak (g) become endoderm. Those that follow (h) become mesoderm. The epiblast surface is now called ectoderm.

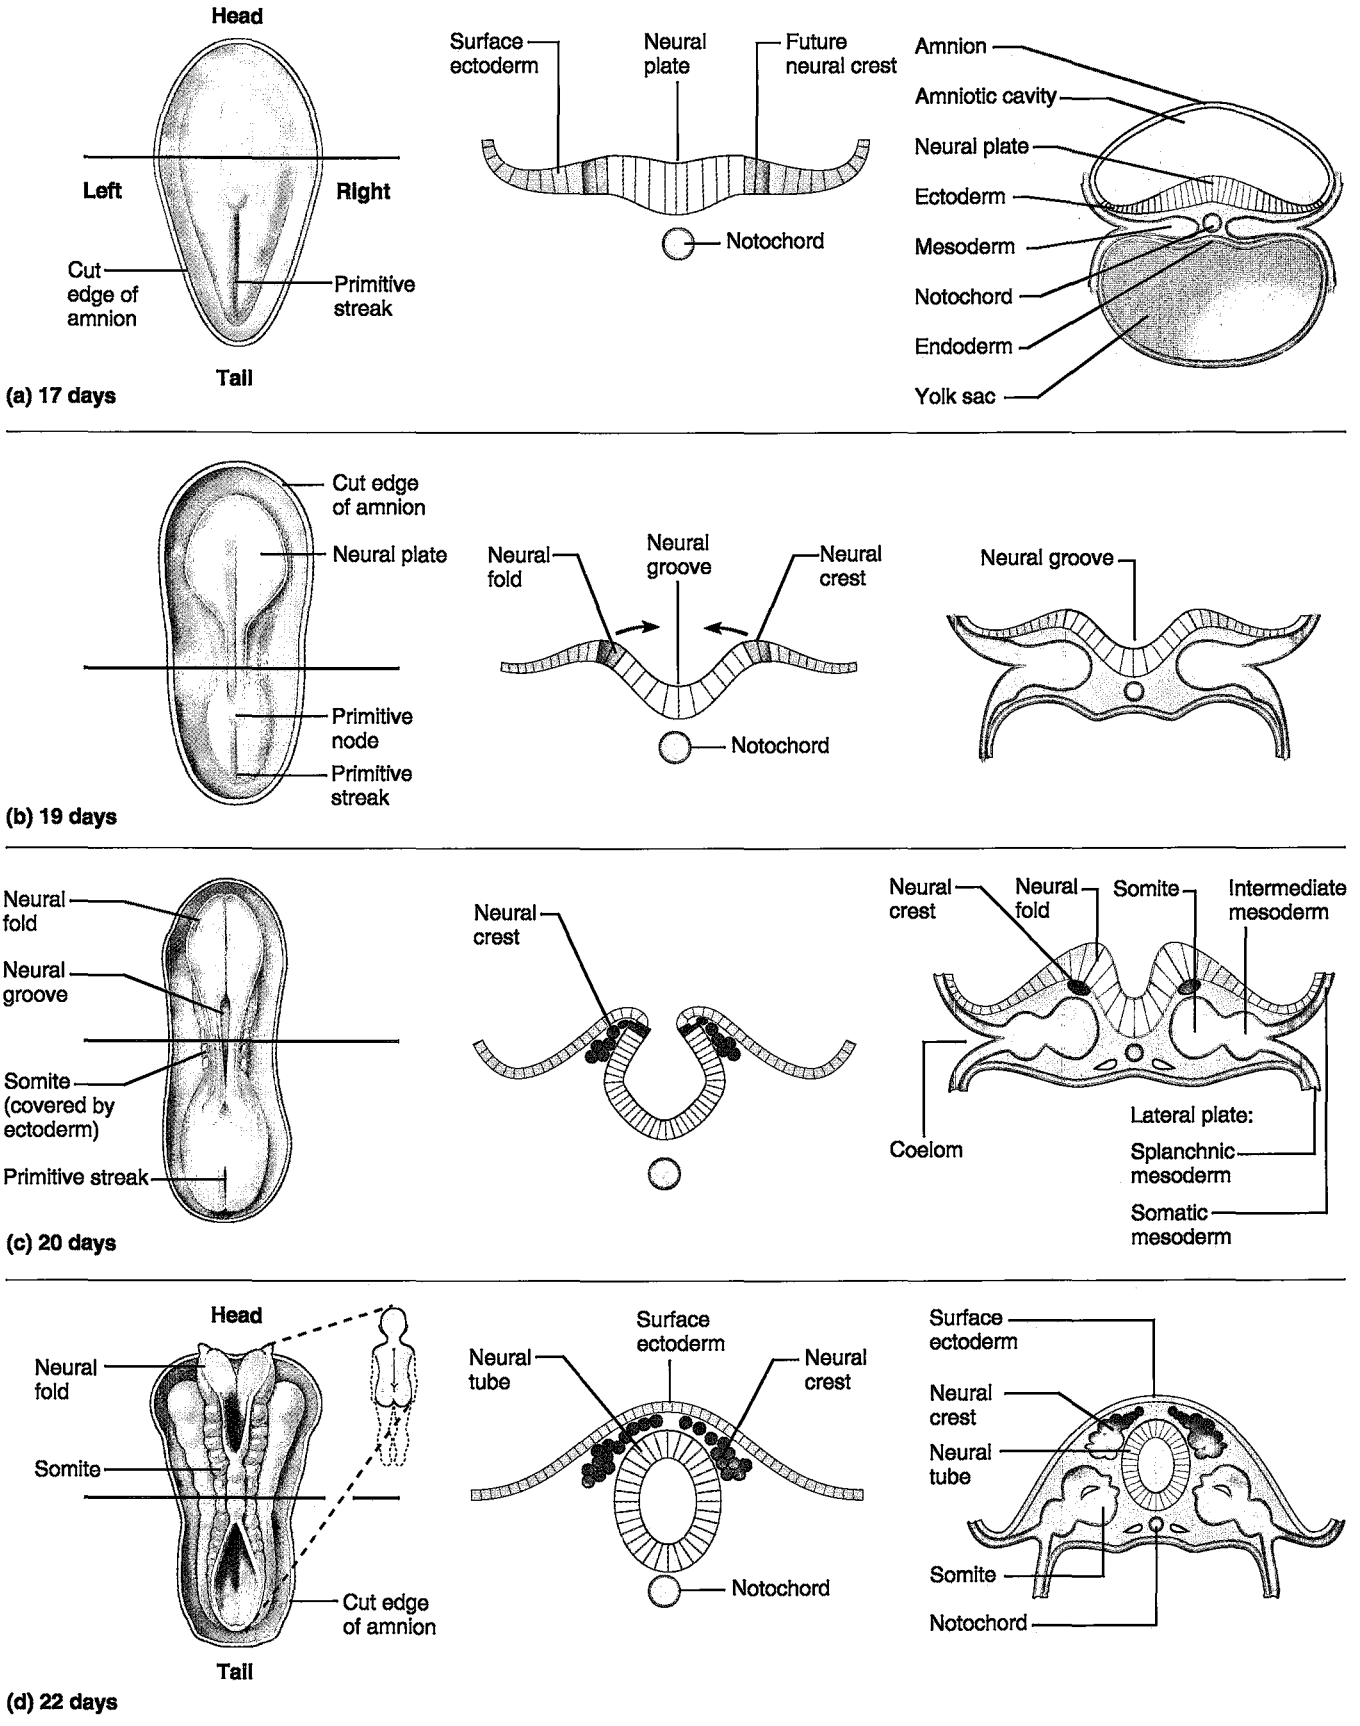

FIGURE 28.9 **Neurulation.** Dorsal surface views on the left; frontal sections on the right. **(a)** The flat three-layered embryo, which has accomplished gastrulation. The notochord and neural plate have formed. **(b)** The neural folds form by folding of the neural plate. **(c)** The neural folds begin to close. **(d)** The newly formed neural tube has detached from the surface ectoderm and lies between the surface ectoderm and the notochord; the neural crest is evident and the embryonic body is beginning to fold.

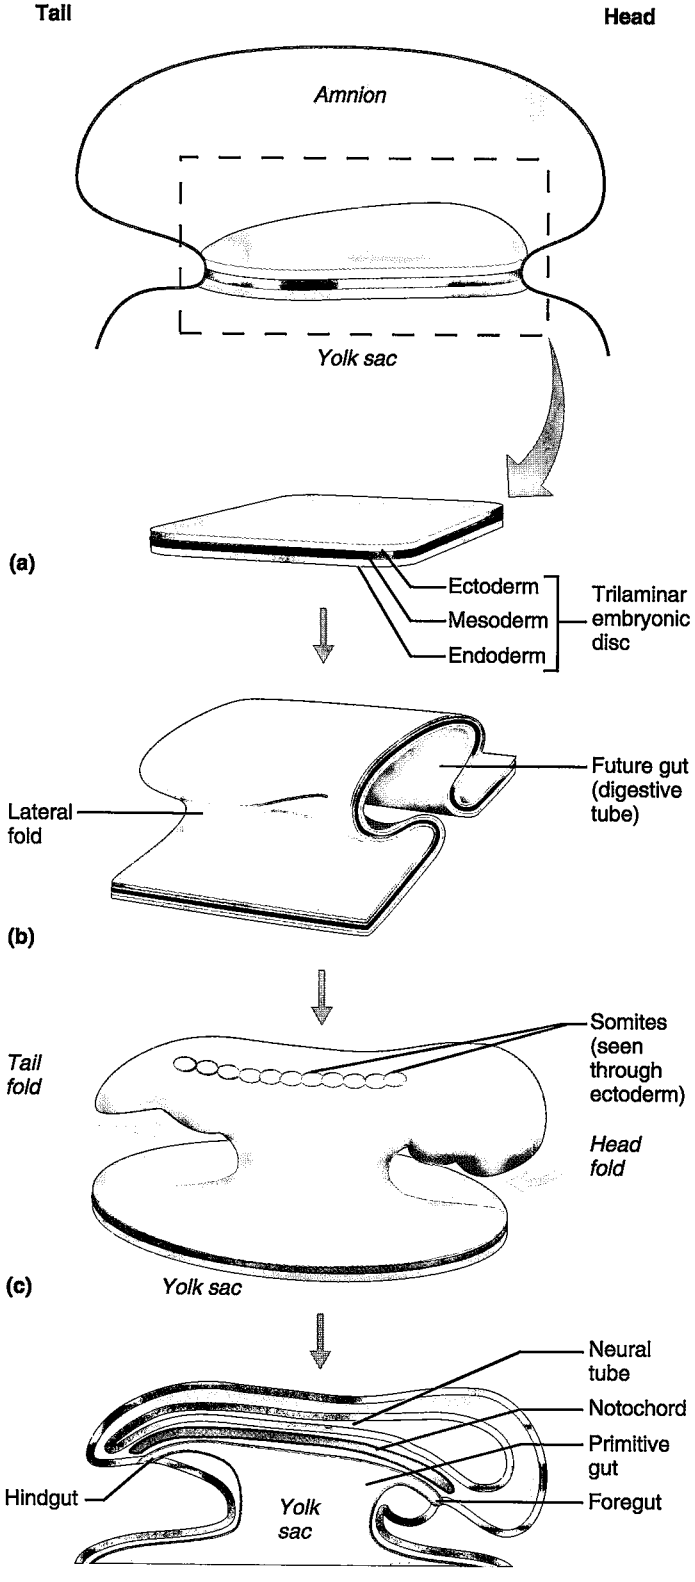

FIGURE 28.10 **Folding of the embryonic body.** Views are lateral, with the head on the right. **(a)** Model of the flat three-layered embryo as three sheets of paper. **(b, c)** Folding begins with lateral folds, then head and tail folds appear. **(d)** A 24-day embryo in sagittal section. Notice the primitive gut, which derives from the yolk sac, and the notochord and neural tube dorsally.

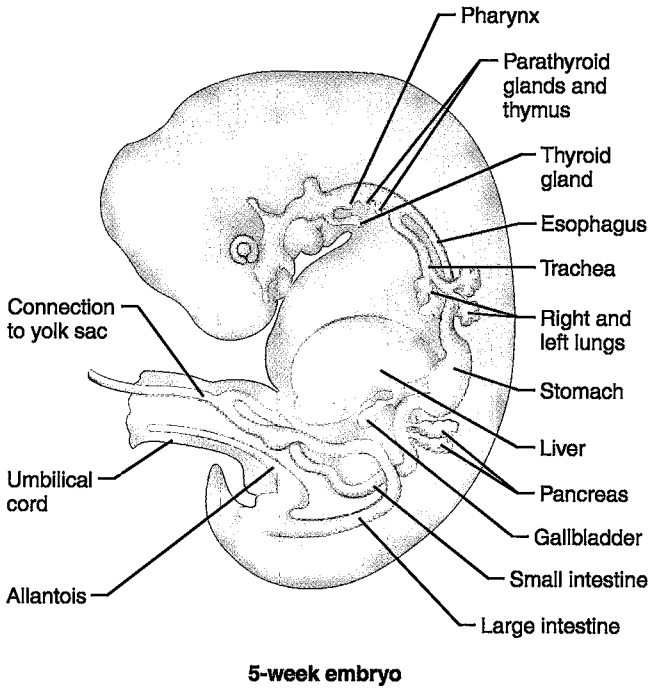

FIGURE 28.11 **Endodermal differentiation to form the epithelial linings of the digestive and respiratory tracts and associated glands.**

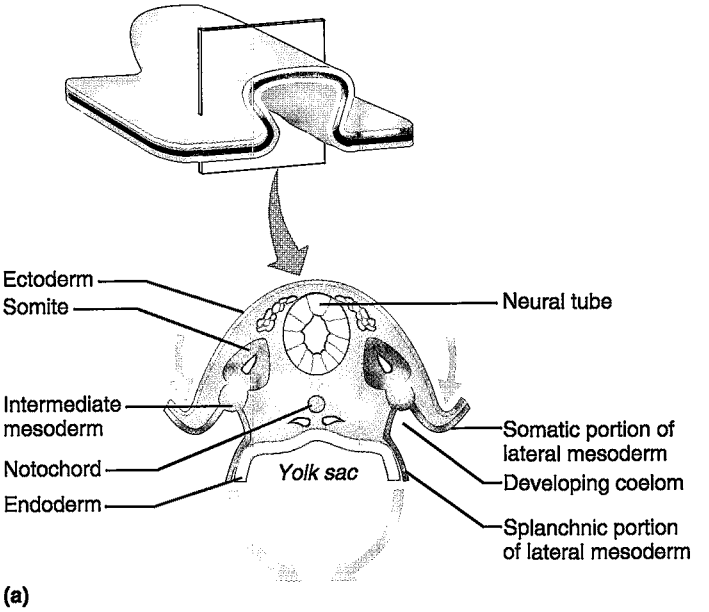
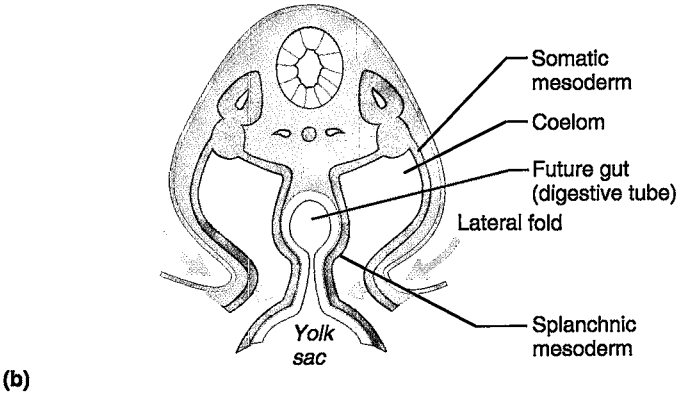
amniotic cavity (Figure 28.10). In the simplest sense, this process resembles three stacked sheets of paper folding laterally into a tube. At the same time, the head and tail regions fold under as shown in Figure 28.10c. The folding occurs from both ends, and progresses toward the central part of the embryonic body, where the yolk sac and umbilical vessels protrude. As the endoderm undercuts and its edges come together and fuse, it encloses part of the yolk sac. The tube of endoderm formed, called the **primitive gut,** forms the epithelial lining (mucosa) of the gastrointestinal tract (Figure 28.11). The organs of the GI tract (pharynx, esophagus, etc.) quickly become apparent, and then the oral and anal openings perforate. The mucosal lining of the respiratory tract forms as an outpocketing from the *foregut* (pharyngeal endoderm), and glands arise as endodermal outpocketings at various points further along the tract. For example, the epithelium of the thyroid, parathyroids, and thymus forms from the pharyngeal endoderm, and that of the liver and pancreas arises from the intestinal mucosa *(midgut)* more inferiorly.

Specialization of the Mesoderm

The first evidence of mesodermal differentiation is the appearance of the notochord in the embryonic disc (see Figure 28.9a). Although the notochord is eventually replaced by the vertebral column, its remnants persist in the springy *nucleus pulposus* of the intervertebral discs. Shortly thereafter, three mesodermal





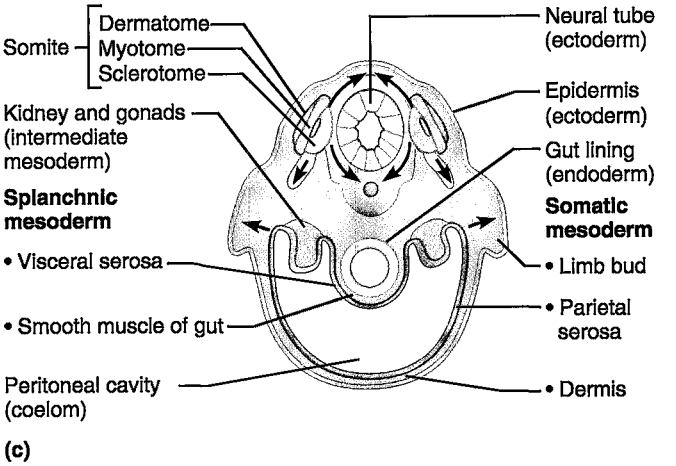


FIGURE 28.12 **Early mesodermal differentiation.** **(a)** Segregation of the mesoderm (with the exception of notochord formation, which occurs earlier) takes place as neurulation is occurring. The notochord becomes flanked bilaterally by a somite, intermediate mesoderm, and lateral mesoderm successively. **(b)** Schematic view of the undercutting of the lateral folds showing how the lateral mesodermal plates move ventrally, forming the coelom. **(c)** Mesodermal divisions and relationships in an undercut (folded) embryo. The sclerotome, dermatome, and myotome of each somite contribute to the formation of the vertebrae, skin dermis, and skeletal muscles, respectively. The intermediate mesoderm forms the kidneys, gonads, and associated structures. The somatic mesoderm portion of the lateral mesoderm forms the limb buds, parietal serosa, and contributes to the dermis. The splanchnic mesoderm forms the muscle, connective tissues, and serosae of the walls of the visceral organs, and the heart and blood vessels.

aggregates appear on either side of the notochord (Figures 28.9 b–d and 28.12a). The largest of these, the *somites* (so'mīts), are paired mesodermal blocks that hug the notochord on either side. All 40 pairs of somites are present by the end of week 4. Flanking the somites laterally are small clusters of segmented mesoderm called *intermediate mesoderm* and then double sheets of *lateral mesoderm.*

Each **somite** has three functional parts—*sclerotome, dermatome,* and *myotome.* Cells of the **sclerotome** (skle'ro-tōm; "hard piece") migrate medially, gather around the notochord and neural tube, and produce the vertebra and rib at the associated level. The **dermatome** ("skin piece") cells, which form the outer wall of each somite, help form the dermis of the skin in the dorsal part of the body. The **myotome** (mi'o-tōm; "muscle piece") consists of somite cells that remain behind and develop in conjunction with the vertebrae. They form the skeletal muscles of the neck, body trunk, and, via their **limb buds,** the muscles of the limbs.

Cells of the **intermediate mesoderm** form the gonads and kidneys. The **lateral mesoderm** consists of paired mesodermal plates: the *somatic mesoderm* and the *splanchnic mesoderm.* Cells of the **somatic mesoderm** (1) help to form the dermis of the skin in the ventral body region; (2) form the parietal serosa that lines the ventral body cavity; and (3) migrate into the forming limbs and produce the bones, ligaments, and dermis of the limbs (see Figure 28.12c). **Splanchnic mesoderm** provides the mesenchymal cells that form the heart and blood vessels and most connective tissues of the body. Splanchnic mesodermal cells also collect around the endodermal mucosal linings, where they form the smooth muscle, connective tissues, and serosal coverings (in other words, nearly the entire wall) of the digestive and respiratory organs. Thus the lateral mesodermal layers cooperate to form the serosae of the **coelom** (se'lom) or ventral body cavity.

By the end of the embryonic period, the bones have begun to ossify and the skeletal muscles are well formed and contracting spontaneously. Metanephric kidneys are developing, gonads are formed, and the lungs and digestive organs are attaining their final shape and body position. Blood delivery to and from

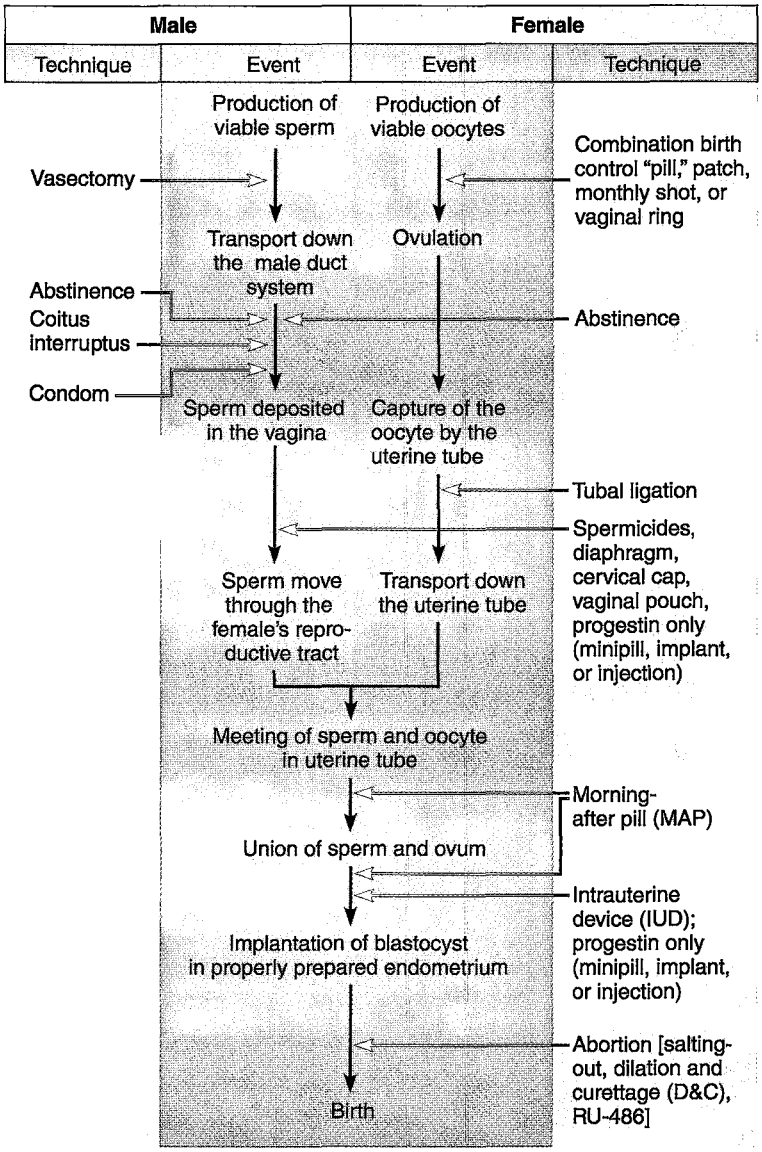
A CLOSER LOOK

Contraception: To Be or Not To Be

In a society such as ours, where many women opt for professional careers or work for economic reasons, **contraception** (*contra* = against; *cept* = taking), or birth control, is often seen as a necessity. Scientists are making headway in the search for a male contraceptive. Clinical tests of monthly injections of androgens and androgen-containing transdermal patches and implants, which suppress testicular testosterone production and subsequently spermatogenesis, are ongoing, and an effective antisperm vaccine exists. However, none of these male contraceptive methods have yet been approved for widespread use. Consequently, thus far the burden for birth control has fallen on women's shoulders, and most birth control products are female directed.

The key to birth control is dependability. As the red arrows in the accompanying flowchart show, the birth control techniques currently available have many sites of action for blocking reproduction. Let's examine a few of them more closely.

Coitus interruptus, or withdrawal of the penis just before ejaculation, is simply against nature, and control of ejaculation is never assured. *Rhythm* or *temporary abstinence methods* involve avoiding intercourse during periods of ovulation or fertility. This may be accomplished by (1) recording daily basal body temperatures (body temperature drops slightly immediately prior to ovulation and then rises slightly after ovulation) or (2) more simply by buying the over-the-counter *Ovulite Microscope*, which is the size of a lipstick. On awakening, a drop of saliva is placed on the microscope slide and examined for a particular pattern of crystals that indicate the optimal days for fertilization. These techniques require accurate record keeping for several cycles before they can be used with confidence, but have a high success rate for those willing to take the time necessary. With a failure rate of



Flowchart of the events that must occur to produce a baby. *Techniques or products that interfere with the process are indicated by colored arrows at the site of interference and act to prevent the next step from occurring.*

28

the placenta via the umbilical vessels is constant and efficient. The heart and the liver are competing for space and form a conspicuous bulge on the ventral surface of the embryo's body. All this by the end of eight weeks in an embryo about 1 inch long from crown to rump!

Development of the Fetal Circulation

Embryonic development of the cardiovascular system lays the groundwork for the fetal circulatory pattern, which is converted to the adult pattern at birth. The first blood cells arise in the yolk sac. Before week 3 of development, tiny spaces appear in

10–20%, it is obvious that some people are willing and some are not.

Barrier methods, such as diaphragms, cervical caps, male and female condoms, spermicidal foams, gels, and sponges, are quite effective, especially when used in combination—for example, condoms and spermicides. But many avoid them because they can reduce the spontaneity of sexual encounters, and sperm may be present in male secretions that precede ejaculation.

For several years, the second most used contraceptive method was the *intrauterine device (IUD),* and it is still one of the most commonly used methods in the world, largely because of its economy. Developed in 1909, this plastic or metal device is inserted into the uterus and prevents the fertilized egg from implanting in the endometrial lining. Although IUDs' failure rate was nearly as low as that of the pill, they were taken off the U.S. market because of occasional contraceptive failure, uterine perforation, or pelvic inflammatory disease. New IUD products that provide sustained local delivery of synthetic progesterone to the endometrium are particularly recommended for women who have given birth and are in monogamous relationships (i.e., who have a lower risk of developing PID).

The most-used contraceptive product in the United States is the *birth control pill,* or simply "the pill," first marketed in 1960. Supplied in 28-tablet packets, the first 20 or 21 tablets contain minute amounts of estrogens and progestins (progesterone-like hormones) taken daily; the last seven tablets are hormone free. The pill tricks the hypothalamic-pituitary axis and "lulls it to sleep," because the relatively constant blood levels of ovarian hormones make it appear that the woman is pregnant (both estrogen and progesterone are produced throughout pregnancy). Ovarian follicles do not develop, ovulation ceases, and menstrual flow is much reduced. However, since hormonal balance is one of the most precisely controlled body functions, some women cannot tolerate these changes—they become nauseated and/or hypertensive. The pill has adverse cardiovascular effects in a small number of users and there is still debate about whether it increases the risk of uterine, ovarian, or (particularly) breast cancer. Presently, well over 50 million women use the pill, and its failure rate is less than 1%.

Other delivery methods using the combination hormone approach include two slow-release products approved in 2001, a vaginal ring and a transdermal patch. *NuvaRing,* a flexible polymer ring that is inserted into the vagina, is left in place for three consecutive weeks, and then removed for one week to allow menstruation. *Ortho Evra,* a transdermal patch, delivers continuous levels of estrogen and progestin into the bloodstream. It is replaced each week for three consecutive weeks, followed by one week with no patch. Failure rates and side effects of NuvaRing and Ortho Evra are comparable to those of the pill, although in clinical trials the patch was less effective in women weighing more than 198 pounds.

Combination birth control pills with substantially higher hormone concentrations (marketed under various names including Ovral, Tetragynon, and Triphasil) are being used for *postcoital contraception.* Taken within three days of unprotected intercourse, these *morning-after pills (MAPs)* "mess up" normal hormonal signals enough to prevent a fertilized egg from implanting or prevent fertilization altogether.

Other hormonal approaches to contraception use progestin-only products which act by causing the cervical mucus to become thick, thus blocking sperm entry into the uterus, and make the endometrium inhospitable to implantion. These include the *minipill,* a tablet form; *Norplant,* which consists of two (originally six) tiny silicone rods implanted just under the skin that release progestin over a five-year period; and *Depo-Provera,* an injectible form that lasts for three months. The failure rates of Norplant and Depo-Provera are even less than that of the "pill."

Abortion is the termination of a pregnancy that is in progress. Spontaneous abortion, also called miscarriage, is common and frequently occurs before a woman is aware that she has conceived. Additionally, over a million American women choose to undergo abortions performed by physicians. *Mifepristone (RU-486),* the so-called abortion pill developed in France, enables a woman to end a pregnancy during the first 7 weeks and has a 96–98% success rate with few side effects. RU-486 is an antihormone that, when taken along with a tiny amount of prostaglandin to stimulate uterine contractions, induces miscarriage by blocking progesterone's quieting effect on the uterus.

Sterilization techniques, such as *tubal ligation* or *vasectomy* (cutting or cauterizing the uterine tubes or vas deferens, respectively,) are nearly foolproof and are the choice of approximately 33% of couples of childbearing age in the United States. Both procedures can be done in the physician's office. However, these techniques are usually permanent, making them unpopular with individuals who still plan to have children but want to select the time.

This summary doesn't even begin to touch on the experimental birth control drugs now awaiting clinical trials, and other methods are sure to be developed in the near future. In the final analysis, however, the only 100% effective means of birth control is the age-old one—*total abstinence.* ■

the splanchnic mesoderm. These are quickly lined by endothelial cells, covered with mesenchyme, and linked together into rapidly spreading vascular networks, destined to form the heart, blood vessels, and lymphatics. By the end of week 3, the embryo has a system of paired blood vessels, and the two vessels forming the heart have fused and bent into an S shape (see Figure 18.24). By 3½ weeks, the miniature heart is pumping blood for an embryo less than a quarter inch long.

Unique cardiovascular modifications seen only during prenatal development include the **umbilical**

TABLE 28.1 Derivatives of the Primary Germ Layers

ECTODERM	MESODERM	ENDODERM
All nervous tissue	Skeletal, smooth, and cardiac muscle	Epithelium of digestive tract (except that of oral and anal cavities)
Epidermis of skin and epidermal derivatives (hairs, hair follicles, sebaceous and sweat glands, nails)	Cartilage, bone, and other connective tissues	Glandular derivatives of digestive tract (liver, pancreas)
Cornea and lens of eye	Blood, bone marrow, and lymphoid tissues	Epithelium of respiratory tract, auditory tube, and tonsils
Epithelium of oral and nasal cavities, of paranasal sinuses, and of anal canal	Endothelium of blood vessels and lymphatics	Thyroid, parathyroid, and thymus glands
Tooth enamel	Serosae of ventral body cavity	Epithelium of reproductive ducts and glands
Epithelium of pineal and pituitary glands and adrenal medulla	Fibrous and vascular tunics of eyes	Epithelium of urethra and bladder
Melanocytes	Synovial membranes of joint cavities	
Some cranial bones and branchial cartilages (derived from neural crest)	Organs of urogenital system (ureters, kidneys, gonads, and reproductive ducts)	

arteries and **vein** and three *vascular shunts* (Figure 28.13). All of these structures are occluded at birth. As you read about these vessels, keep in mind that the heart the blood is flowing from and to is the fetal heart. The large umbilical vein carries freshly oxygenated blood returning from the placenta into the embryonic body, where it is conveyed to the liver. There, some of the returning blood percolates through the liver sinusoids and out the hepatic veins. Most of the blood coursing through the umbilical vein, however, enters the **ductus venosus** (duk'tus ve-no'sus), a venous shunt that bypasses the liver sinusoids. Both the hepatic veins and the ductus venosus empty into the inferior vena cava where the placental blood mixes with deoxygenated blood returning from the lower parts of the fetus's body. The vena cava in turn conveys this "mixed load" of blood directly to the right atrium of the heart. After birth, the liver plays an important role in nutrient processing, but during embryonic life these functions are performed by the mother's liver. Consequently, blood flow through the liver during development is important only to ensure viability of the liver cells.

Blood entering and leaving the heart encounters two more shunt systems, each serving to bypass the nonfunctional lungs. Some of the blood entering the right atrium flows directly into the left atrium via the **foramen ovale** ("oval hole"), an opening in the interatrial septum loosely closed by a flap of tissue. Blood that enters the right ventricle is pumped out into the pulmonary trunk. However, the second shunt, the **ductus arteriosus,** transfers most of that blood directly into the aorta, again bypassing the pulmonary circuit. (The lungs *do* receive adequate blood to maintain their growth.) Blood enters the two pulmonary bypass shunts because the heart chamber or vessel on the other side of each shunt is a lower-pressure area, owing to the low volume of venous return from the lungs. Blood flowing distally through the aorta eventually reaches the umbilical arteries, which are branches of the internal iliac arteries serving the pelvis. From here the largely deoxygenated blood, laden with metabolic wastes, is delivered back to the capillaries in the chorionic villi of the placenta. The changes in the circulatory plan that occur at birth are illustrated in Figure 28.13b.

HOMEOSTATIC IMBALANCE

Because many potentially harmful substances can cross placental barriers and enter the fetal blood, a pregnant woman should be aware of what she is taking into her body, particularly during the embryonic period when the body's foundations are laid down. **Teratogens** (ter'ah-to-jenz; *terato* = monster), factors that may cause severe congenital abnormalities or even fetal death, include alcohol, nicotine, many drugs (anticoagulants, sedatives, antihypertensives, and some antibiotics), and maternal infections, particularly German measles. For example, when a woman drinks alcohol, her fetus becomes inebriated as well. However, the fetal consequences may be much more lasting and result in the *fetal alcohol syndrome (FAS)* typified by microcephaly (small head), mental retardation, and abnormal growth. Nicotine hinders oxygen delivery to the fetus, impairing normal growth and development. The sedative **thalidomide** (thah-lid'o-mīd) was used by thousands of pregnant women in the 1960s to alleviate morning sickness. When taken during the period of limb bud differentiation (days 26–56), it sometimes resulted in tragically deformed infants with short flipperlike legs and arms.

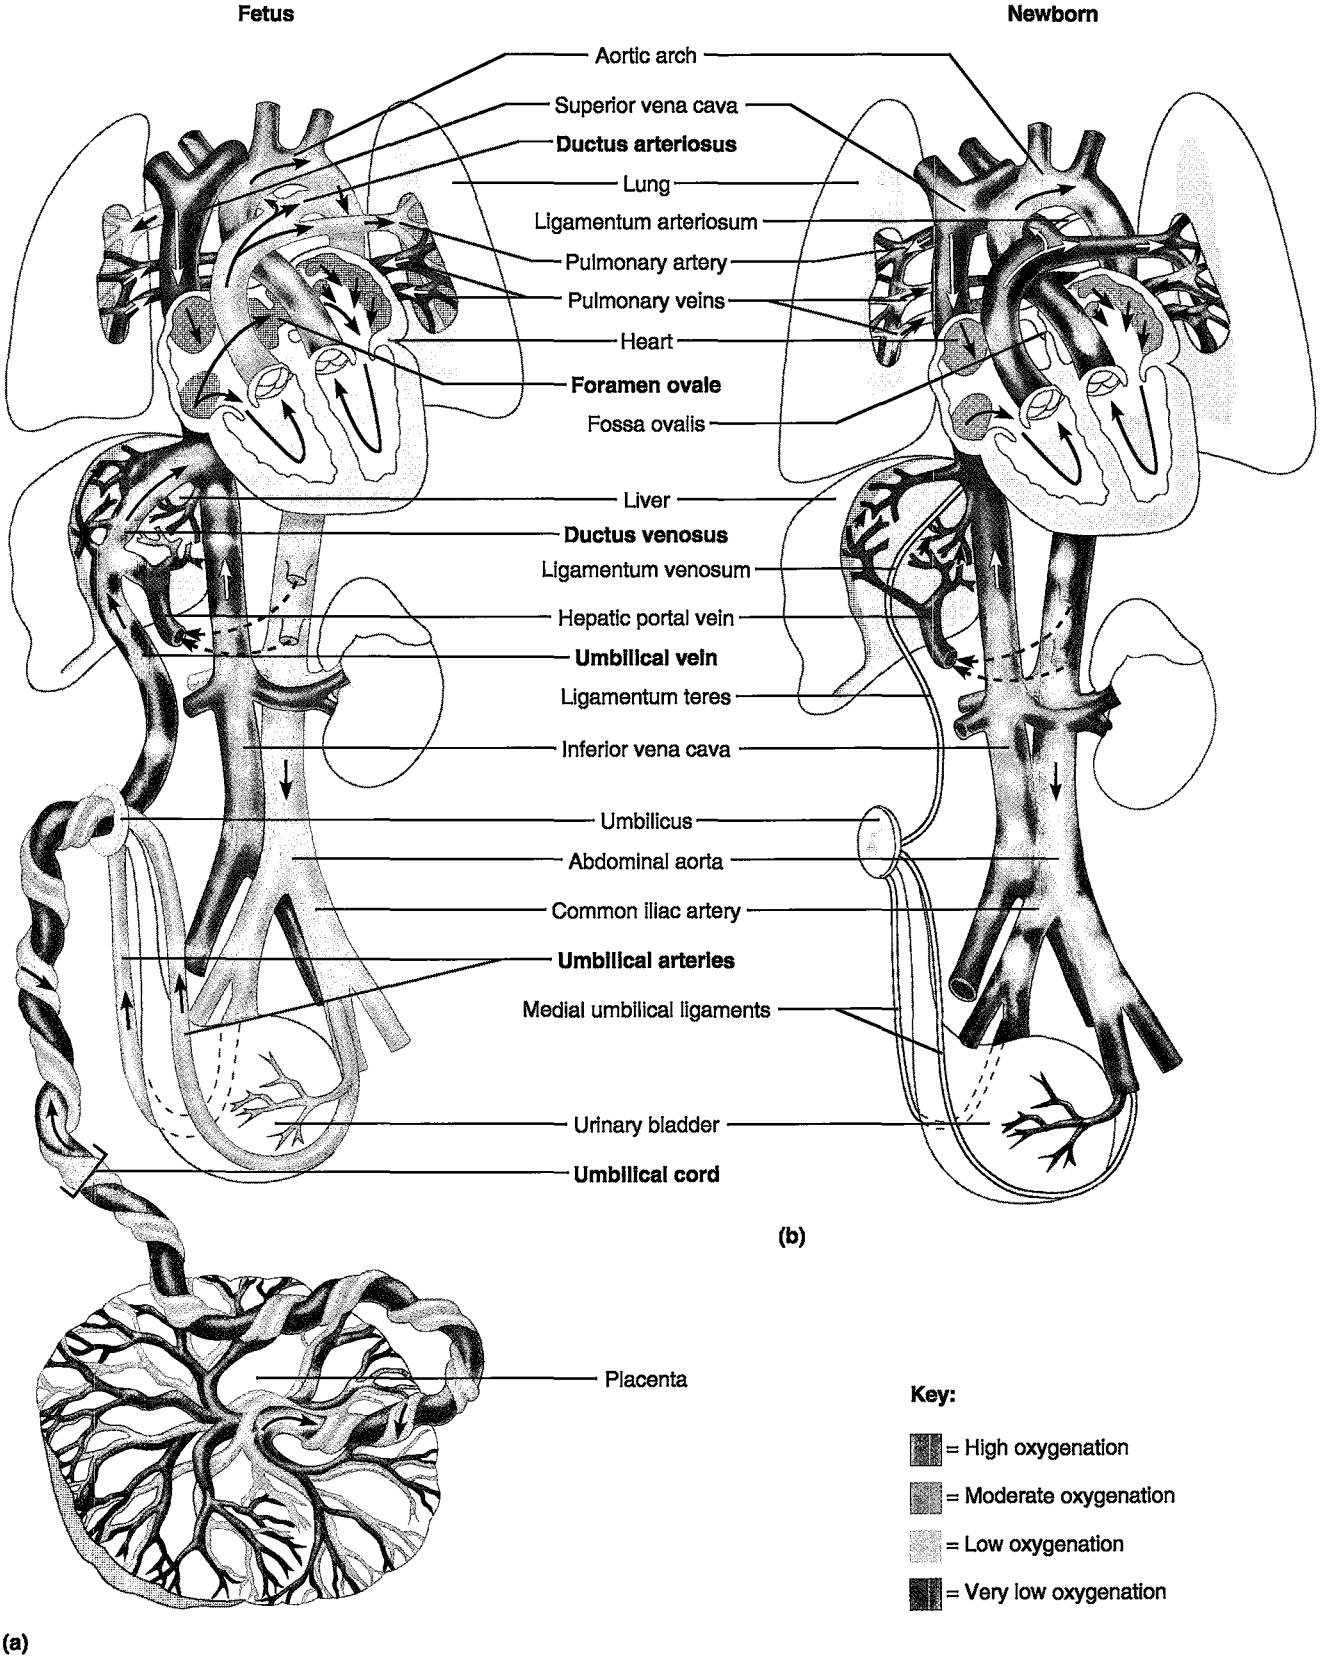


FIGURE 28.13 **Circulation in fetus and newborn.** Arrows indicate direction of blood flow. **(a)** Special adaptations for embryonic and fetal life. The umbilical vein carries oxygen- and nutrient-rich blood from the placenta to the fetus; the umbilical arteries carry waste-laden blood from the fetus to the placenta; the ductus arteriosus and foramen ovale bypass the nonfunctional lungs; and the ductus venosus allows blood to partially bypass the liver. **(b)** Changes in the cardiovascular system at birth. The umbilical vessels are occluded, as are the liver and lung bypasses (ductus venosus and arteriosus, and the foramen ovale).

TABLE 28.2 Developmental Events of the Fetal Period

TIME		CHANGES AND ACCOMPLISHMENTS
8 weeks (end of embryonic period)	8 weeks	Head nearly as large as body; all major brain regions present; first brain waves in brain stem Liver disproportionately large and begins to form blood cells Limbs present; digits are initially webbed, but fingers and toes are free by the end of this interval Ossification just begun; weak, spontaneous muscle contractions occur Cardiovascular system fully functional (heart has been pumping blood since the fourth week) All body systems present in at least rudimentary form Approximate crown-to-rump length: 22 mm (0.9 inches); weight: 2 grams (0.06 ounce)
9–12 weeks (month 3)	 12 weeks	Head still dominant, but body elongating; brain continues to enlarge, shows its general structural features; cervical and lumbar enlargements apparent in spinal cord; retina of eye is present Skin epidermis and dermis obvious; facial features present in crude form Liver prominent and bile being secreted; palate is fusing; most glands of endodermal origin are developed; walls of hollow visceral organs gaining smooth muscle Blood cell formation begins in bone marrow Notochord degenerating and ossification accelerating; limbs well molded Sex readily detected from the genitals Approximate crown-to-rump length at end of interval: 90 mm
13–16 weeks (month 4)	 16 weeks	Cerebellum becoming prominent; general sensory organs differentiated; eyes and ears assume characteristic position and shape; blinking of eyes and sucking motions of lips occur Face looks human and growth of the body beginning to outpace that of the head Glands developed in GI tract; meconium is collecting Kidneys attain typical structure Most bones are now distinct and joint cavities are apparent Approximate crown-to-rump length at end of interval: 140 mm
17–20 weeks (month 5)		Vernix caseosa (fatty secretions of sebaceous glands) covers body; lanugo (silklike hair) covers skin Fetal position (body flexed anteriorly) assumed because of space restrictions Limbs reach near-final proportions Quickening occurs (mother feels spontaneous muscular activity of fetus) Approximate crown-to-rump length at end of interval: 190 mm
21–30 weeks (months 6 and 7)		Period of substantial increase in weight (may survive if born prematurely at 27–28 weeks, but hypothalamic temperature regulation and lung production of surfactant are still inadequate) Myelination of cord begins; eyes are open Distal limb bones are beginning to ossify Skin is wrinkled and red; fingernails and toenails are present; tooth enamel is forming on deciduous teeth Body is lean and well proportioned Bone marrow becomes sole site of blood cell formation Testes reach scrotum in seventh month (in males) Approximate crown-to-rump length at end of interval: 280 mm
30–40 weeks (term) (months 8 and 9)	 At birth	Skin whitish pink; fat laid down in subcutaneous tissue (hypodermis) Approximate crown-to-rump length at end of interval: 360 mm (14 inches); weight: 3.2 kg (7 lb)

(a) (b)

FIGURE 28.14 **Photographs of a developing fetus. (a)** Fetus in month 3, about 6 cm long. **(b)** Fetus late in month 5, about 19 cm long. By birth, the fetus is typically 36 cm long from crown to rump.

Events of Fetal Development

The main events of the fetal period—weeks 9 through 38—are listed chronologically in Table 28.2. The fetal period is a time of rapid growth of the body structures that were established in the embryo. During the first half of this period, cells are still differentiating into specific cell types to form the body's distinctive tissues and are completing the fine details of body structure. During the fetal period, the developing fetus grows from a crown-to-rump length of about 22 mm (slightly less than 1 inch) and a weight of approximately 2 g (0.06 ounce) to about 360 mm (14 inches) and 3.2 kg (7 lb) or more. (Total body length at birth is about 550 mm, or 22 inches.) As you might expect with such tremendous growth, the changes in fetal appearance are quite dramatic (Figure 28.14). Nevertheless, the greatest amount of growth occurs in the first 8 weeks of life, when the embryo grows from one cell to a fetus of 1 inch.

Effects of Pregnancy on the Mother

Pregnancy can be a difficult time for the mother. Not only are there anatomical changes, but striking changes in her metabolism and physiology occur as well.

Anatomical Changes

As pregnancy progresses, the female reproductive organs become increasingly vascular and engorged with blood, and the vagina develops a purplish hue *(Chadwick's sign)*. The enhanced vascularity increases vaginal sensitivity and sexual intensity, and some women achieve orgasm for the first time when they are pregnant. The breasts, too, engorge with blood and, prodded by rising levels of estrogen and progesterone, they enlarge and their areolae darken. Some women develop increased pigmentation of facial skin of the nose and cheeks, a condition called *chloasma* (klo-az'mah; "to be green") or the "mask of pregnancy."

The degree of uterine enlargement during pregnancy is remarkable. Starting as a fist-sized organ, the uterus fills most of the pelvic cavity by 16 weeks (Figure 28.15b). Though the fetus is only about 140 mm long (crown-to-rump) at this time, the placenta is fully formed, uterine muscle is hypertrophied, and amniotic fluid volume is increasing. As pregnancy continues, the uterus pushes higher into the abdominal cavity, exerting pressure on both abdominal and pelvic organs (Figure 28.15c). As birth nears, the uterus reaches the level of the xiphoid process and occupies most of the abdominal cavity (Figure 28.15d). The crowded abdominal organs press superiorly against the diaphragm, which intrudes on the

Q *Using this figure as a reference, explain why many pregnant women complain of being "short-winded."*

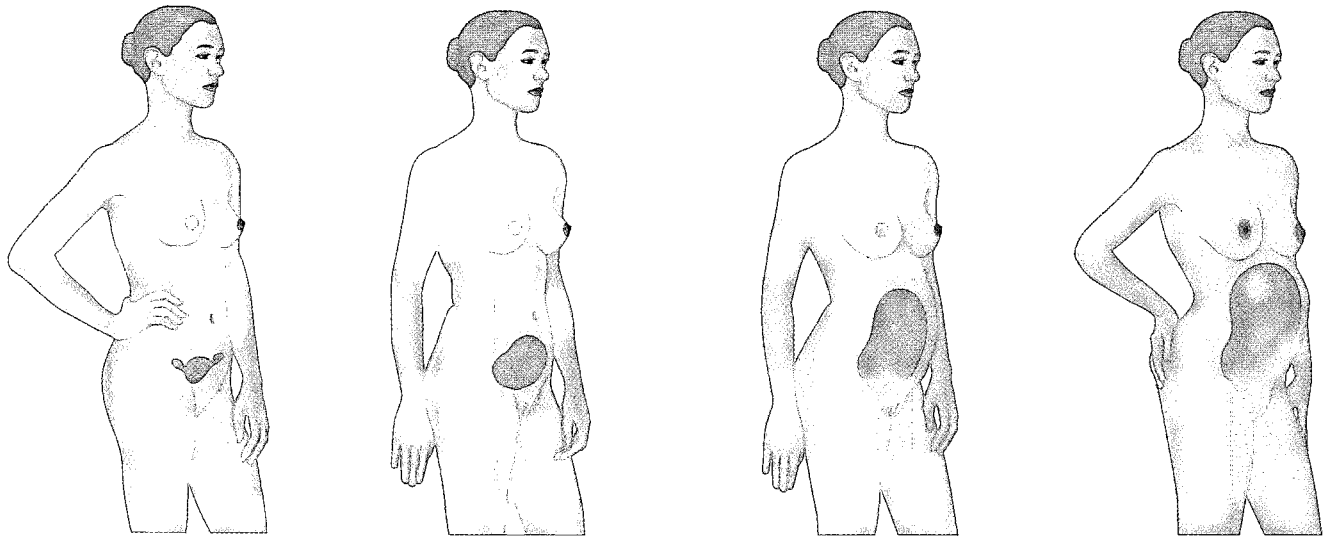

FIGURE 28.15 **Relative size of the uterus before conception and during pregnancy. (a)** Before conception, the uterus is the size of a fist and resides within the pelvis. **(b)** At 4 months, the fundus of the uterus is halfway between the pubic symphysis and the umbilicus. **(c)** At 7 months, the fundus is well above the umbilicus. **(d)** At 9 months, the fundus reaches the xiphoid process.

thoracic cavity. As a result, the ribs flare, causing the thorax to widen.

The increasing bulkiness of the anterior abdomen changes the woman's center of gravity, and many women develop lordosis (accentuated lumbar curvature) and backaches during the last few months of pregnancy. Placental production of the hormone **relaxin** causes pelvic ligaments and the pubic symphysis to relax, widen, and become more flexible. This increased motility eases birth passage, but it may result in a waddling gait in the meantime. Additionally, relaxin relaxes the springy ligaments supporting the bones of the foot and many women need to buy larger shoes during pregnancy.

Considerable weight gain occurs during a normal pregnancy. Because some women are over- or underweight before pregnancy begins, it is almost impossible to state the ideal or desirable weight gain. However, summing up the weight increases resulting from fetal and placental growth, growth of the maternal reproductive organs and breasts, and increased blood volume during pregnancy, a weight gain of approximately 13 kg (about 28 lb) usually occurs.

A *As the pregnancy advances, the uterus pushes higher in the abdomen, eventually pressing on the diaphragm and inhibiting its downward movement.*

Obviously, good nutrition is necessary all through pregnancy if the developing fetus is to have all the building materials (especially proteins, calcium, and iron) needed to form its tissues. Additionally, multivitamins containing folic acid reduce the risk of having a baby with neurological problems, including such birth defects as spina bifida and anencephaly. However, a pregnant woman needs only 300 additional calories daily to sustain proper fetal growth. The emphasis should be on eating high-quality food, not just more food. Not surprisingly, effects of the fetal environment may not show up until decades later. Below-normal birth weight, for instance, places females at risk for gestational diabetes and increases the general risk of cardiovascular disease later in life.

Metabolic Changes

As the placenta enlarges, it secretes increasing amounts of **human placental lactogen (hPL),** also called **human chorionic somatomammotropin (hCS),** which works cooperatively with estrogens and progesterone to stimulate maturation of the breasts for lactation. hPL also promotes growth of the fetus and exerts a glucose-sparing effect in the mother. Consequently, maternal cells metabolize more fatty acids and less glucose than usual, sparing glucose for use by the fetus. Gestational diabetes mellitus occurs in

about 10% of pregnancies, but over half of those women go on to develop type II diabetes later in life. The placenta also releases **human chorionic thyrotropin (hCT)**, a glycoprotein hormone similar to thyroid-stimulating hormone of the anterior pituitary. hCT activity increases the rate of maternal metabolism throughout the pregnancy, causing hypermetabolism. Because plasma levels of parathyroid hormone and activated vitamin D rise, pregnant women tend to be in positive calcium balance throughout pregnancy. This ensures that the developing fetus will have adequate calcium to mineralize its bones.

Physiological Changes

Gastrointestinal System

Many women suffer nausea, commonly called *morning sickness*, during the first few months of pregnancy, until their system adjusts to the elevated levels of progesterone and estrogens. (Nausea is also a side effect of many birth control pills.) *Heartburn*, due to reflux of stomach acid into the esophagus, is common because the esophagus is displaced and the stomach is crowded by the growing uterus. *Constipation* occurs because motility of the digestive tract declines during pregnancy.

Urinary System

The kidneys produce more urine during pregnancy because they have the additional burden of disposing of fetal metabolic wastes. As the growing uterus compresses the bladder, urination becomes more frequent, more urgent, and sometimes uncontrollable *(stress incontinence)*.

Respiratory System

The nasal mucosa responds to estrogens by becoming edematous and congested. Thus, nasal stuffiness and occasional nosebleeds may occur. Tidal volume and respiratory rate increase during pregnancy. But residual volume declines, and many women exhibit *dyspnea* (disp-ne'ah), or difficult breathing, during the later stages of pregnancy.

Cardiovascular System

The most dramatic physiological changes occur in the cardiovascular system. Total body water rises; blood volume increases 25–40% by the 32nd week to accommodate the additional needs of the fetus. The rise in blood volume also safeguards against blood loss during birth. Blood pressure and pulse typically rise and increase cardiac output by 20–40% at various stages of pregnancy. This helps propel the greater circulatory volume around the body. Because the uterus presses on the pelvic blood vessels, venous return from the lower limbs may be impaired, resulting in *varicose veins*.

HOMEOSTATIC IMBALANCE

A dangerous complication of pregnancy called *preeclampsia* results in an insufficient placental blood supply, which can starve a fetus of oxygen. The pregnant woman becomes edematous and hypertensive and proteinuria occurs. This condition, which affects one in ten pregnancies, is believed to be due to immunological abnormalities in some cases, because its occurrence seems to be positively correlated with the number of fetal cells that enter the maternal circulation.

Parturition (Birth)

Parturition (par"tu-rish'un; "bringing forth young") is the culmination of pregnancy—giving birth to the baby. It usually occurs within 15 days of the calculated due date (280 days from the last menstrual period). The series of events that expel the infant from the uterus are collectively called **labor.**

Initiation of Labor

Several events and hormones interlock to trigger labor. During the last few weeks of pregnancy, estrogens reach their highest levels in the mother's blood.* This has two important consequences: It stimulates the myometrial cells of the uterus to form abundant oxytocin receptors (Figure 28.16) and it

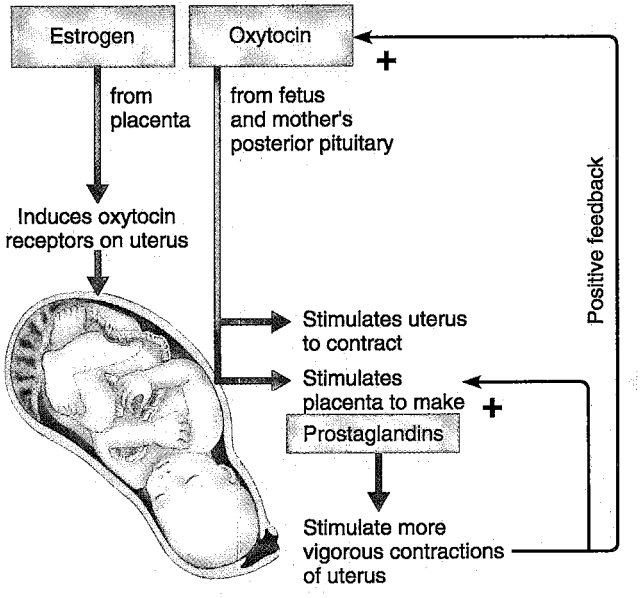

FIGURE 28.16 **Hormonal induction of labor.**

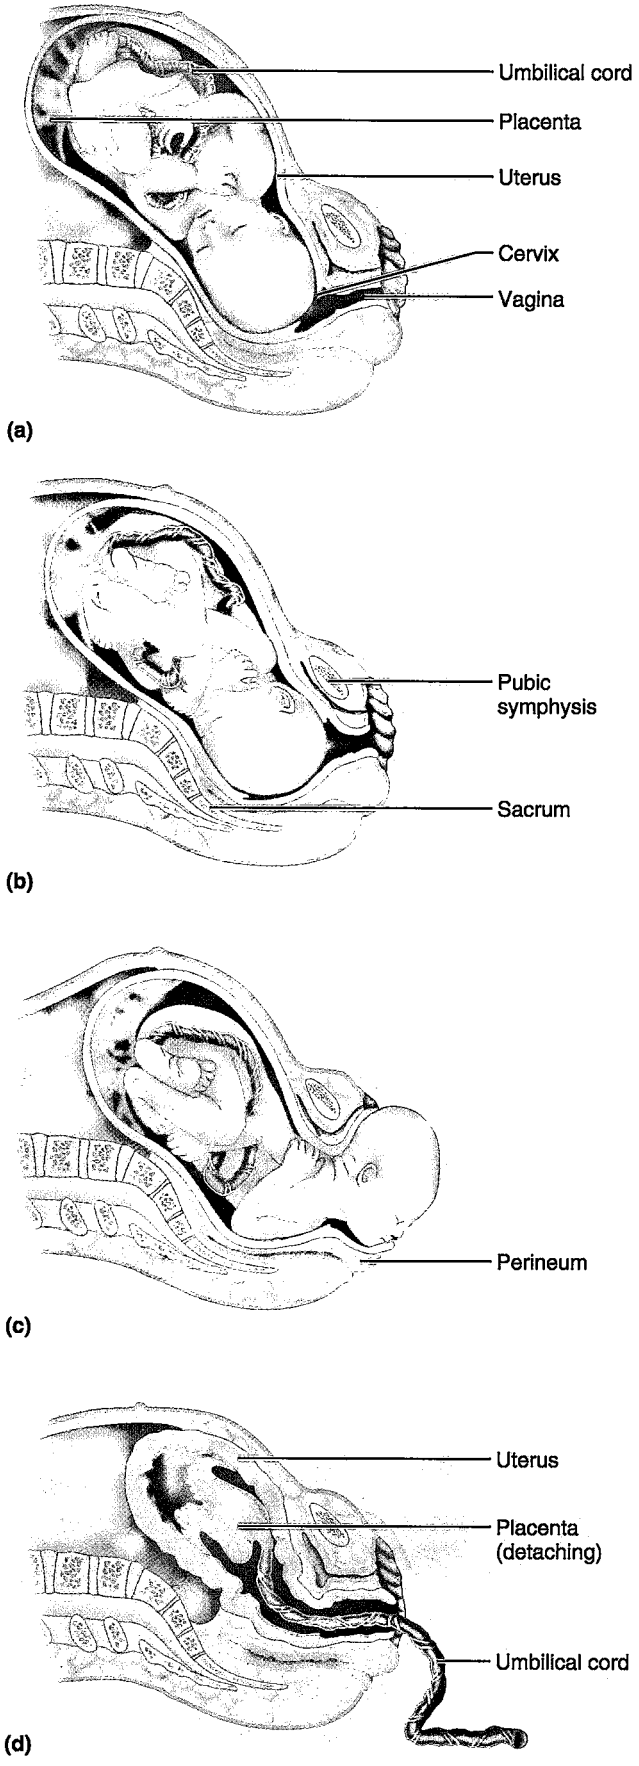
* Studies indicate that the fetus determines its own birth date. Rising levels of fetal adrenocortical hormones (especially cortisol) late in pregnancy are a major stimulus for the placenta to release such large amounts of estrogens.



antagonizes progesterone's quieting influence on uterine muscle. As a result, the myometrium becomes increasingly irritable, and weak, irregular uterine contractions begin to occur. These contractions, called *Braxton Hicks contractions,* have caused many women to go to the hospital, only to be told that they were in **false labor** and sent home.

As birth nears, two more chemical signals cooperate to convert these false labor pains into the real thing. Certain fetal cells begin to produce **oxytocin** (ok"sĭ-to'sin), which causes the placenta (Figure 28.16) to release **prostaglandins** (pros"tah-glan'dinz). Both hormones are powerful uterine muscle stimulants, and since the myometrium is now highly sensitive to oxytocin, contractions become more frequent and more vigorous. At this point, the increasing emotional and physical stresses activate the mother's hypothalamus, which signals for oxytocin release by the posterior pituitary. Together the elevated levels of oxytocin and prostaglandins trigger the rhythmic expulsive contractions of true labor. Once the hypothalamus is involved, a *positive feedback mechanism* is propelled into action—greater contractile force causes the release of more oxytocin, which causes greater contractile force, and so on (Figure 28.16). These expulsive contractions are aided by the fact that *fetal fibronectin,* a natural "stickum" (adhesive protein) that binds the fetal and maternal tissues of the placenta together throughout pregnancy, changes to a lubricant just before true labor begins. Increased production of *surfactant protein A (SF-A)* by the fetal lungs in the weeks before delivery appears to trigger an inflammatory response in the cervix that triggers its softening in preparation for labor.

Both oxytocin and prostaglandins are essential for initiating labor in humans. Untimely spurts of oxytocin may provoke some instances of premature birth, and interfering with production of either of these hormones will hinder onset of labor. For example, antiprostaglandin drugs such as ibuprofen can inhibit the early stages of labor and such drugs are used occasionally to prevent preterm births.

FIGURE 28.17 **Parturition. (a)** Dilation stage (early). The baby's head is engaged in the true pelvis. The widest head dimension is along the left-right axis. **(b)** Late dilation. The baby's head rotates so that its greatest dimension is in the anteroposterior axis as it moves through the pelvic outlet. Dilation of the cervix is nearly complete. **(c)** Expulsion stage. The baby's head extends as it reaches the perineum and is delivered. **(d)** Placental stage. After the baby is delivered, the placenta is detached by the continuing uterine contractions and removed.

Stages of Labor

Stage 1: Dilation Stage

The **dilation stage** (Figure 28.17a) is the time from labor's onset until the cervix is fully dilated by the baby's head (about 10 cm in diameter). As labor starts, weak but regular contractions begin in the upper part of the uterus and move toward the vagina. At first, only the superior uterine muscle is active, the contractions are 15–30 minutes apart, and they last for 10–30 seconds. As labor progresses, the contractions become more vigorous and rapid, and the lower uterine segment gets involved. As the infant's head is forced against the cervix with each contraction, the cervix softens and thins *(effaces)*, and dilates. Eventually the amnion ruptures, releasing the amniotic fluid, an event commonly called "breaking the water." The dilation stage is the longest part of labor, lasting 6–12 hours or more. Several events happen during this phase. *Engagement* occurs when the infant's head enters the true pelvis. As descent continues through the birth canal, the baby's head rotates so that its greatest dimension is in the anteroposterior line (Figure 28.17b), which allows it to navigate the narrow dimensions of the pelvic outlet.

Stage 2: Expulsion Stage

The **expulsion stage** (Figure 28.17c) lasts from full dilation to delivery of the infant, or actual childbirth. By the time the cervix is fully dilated, strong contractions are occurring every 2–3 minutes and lasting about 1 minute; a mother undergoing labor without local anesthesia has an increasing urge to push or bear down with the abdominal muscles. Although this phase may last 2 hours, it is typically 50 minutes in a first birth and around 20 minutes in subsequent births.

Crowning occurs when the largest dimension of the baby's head distends the vulva. At this point, an *episiotomy* (e-piz"e-ot'o-me) may be done to reduce tissue tearing. An episiotomy is an incision made to widen the vaginal orifice. The baby's neck extends as the head exits from the perineum, and once the head has been delivered, the rest of the baby's body is delivered much more easily. After birth, the umbilical cord is clamped and cut.

When the infant is in the usual *vertex,* or head-first, *presentation,* the skull (its largest diameter) acts as a wedge to dilate the cervix. The head-first presentation also allows the baby to be suctioned free of mucus and to breathe even before it has completely exited from the birth canal (Figure 28.17c). In *breech* (buttock-first) and other nonvertex presentations, these advantages are lost and delivery is much more difficult, often requiring the use of forceps.

HOMEOSTATIC IMBALANCE

If a woman has a deformed or malelike pelvis, labor may be prolonged and difficult. This condition is called *dystocia* (dis-to'se-ah; *dys* = difficult; *toc* = birth). Besides extreme maternal fatigue, another possible consequence of dystocia is fetal brain damage, resulting in cerebral palsy or epilepsy. To prevent these outcomes, a *cesarean (C-) section* (se-sa're-an) is performed in many such cases. A C-section is delivery of the infant through an incision made through the abdominal and uterine walls. ●

Stage 3: Placental Stage

The **placental stage** (Figure 28.17d), or the delivery of the placenta, is usually accomplished within 30 minutes after birth of the infant. The strong uterine contractions that continue after birth compress uterine blood vessels, limit bleeding, and shear the placenta off the uterine wall (cause placental detachment). The placenta and its attached fetal membranes, collectively called the **afterbirth,** are then easily removed by a gentle tug on the umbilical cord. It is very important that all placental fragments be removed to prevent continued uterine bleeding after birth *(postpartum bleeding)*.

Adjustments of the Infant to Extrauterine Life

The **neonatal period** is the four-week period immediately after birth. Here we will be concerned with the events of just the first few hours after birth in a normal infant. As you might suspect, birth represents quite a shock to the infant. Exposed to physical trauma during the birth process, it is suddenly cast out of its watery, warm environment and its placental life supports are severed. Now it must do for itself all that the mother had been doing for it—respire, obtain nutrients, excrete, and maintain its body temperature.

At 1 and 5 minutes after birth, the infant's physical status is assessed based on five signs: heart rate, respiration, color, muscle tone, and reflexes (tested by response to catheter in nostril). Each observation is given a score of 0 to 2, and the total is called the **Apgar score.** An Apgar score of 8 to 10 indicates a healthy baby. Lower scores reveal problems in one or more of the physiological functions assessed.

Taking the First Breath and Transition

The crucial first requirement is to breathe. Once carbon dioxide is no longer removed by the placenta, it accumulates in the baby's blood, causing central

acidosis. This excites respiratory control centers in the baby's brain and triggers the first inspiration. The first breath requires a tremendous effort—the airways are tiny, and the lungs are collapsed. However, once the lungs have been inflated in full-term babies, surfactant in alveolar fluid reduces surface tension in the alveoli, and breathing is easier. The rate of respiration is rapid (about 45 respirations/min) during the first two weeks and then gradually declines to normal levels.

Keeping the lungs inflated is much more difficult for premature infants (those weighing less than 2500 g, or about 5.5 lb, at birth) because surfactant production occurs during the last months of prenatal life. Consequently, preemies are usually put on respiratory assistance (a ventilator) until their lungs are mature enough to function on their own.

For 6–8 hours after birth, infants pass through an unstable **transitional period** marked by alternating periods of increased activity and sleep, and during which they adjust to extrauterine life. During the activity periods vital signs are irregular and the baby gags frequently as it regurgitates mucus and debris. After this, the infant stabilizes, with waking periods (dictated by hunger) occurring every 3–4 hours.

Occlusion of Special Fetal Blood Vessels and Vascular Shunts

After birth the special umbilical blood vessels and fetal shunts are no longer necessary (see Figure 28.13b). The umbilical arteries and vein constrict and become fibrosed. The proximal parts of the umbilical arteries persist as the *superior vesical arteries* that supply the urinary bladder; their distal parts become the **medial umbilical ligaments.** The remnant of the umbilical vein becomes the **round ligament of the liver,** or **ligamentum teres,** that attaches the umbilicus to the liver. The ductus venosus collapses as blood stops flowing through the umbilical vein and is eventually converted to the **ligamentum venosum** on the liver's undersurface.

As the pulmonary circulation becomes functional, left heart pressure increases and right heart pressure decreases, causing the pulmonary shunts to close. The flap of the foramen ovale is pushed to the shut position, and its edges fuse to the septal wall. Ultimately, only a slight depression, the **fossa ovalis,** marks its position. The ductus arteriosus constricts and is converted to the cordlike **ligamentum arteriosum,** connecting the aorta and pulmonary trunk.

Except for the foramen ovale, all of the special circulatory adaptations of the fetus are functionally occluded within 30 minutes after birth. Closure of the foramen ovale is usually complete within the year. As described in Chapter 18, failure of the ductus arteriosus or foramen ovale to close leads to congenital heart defects.

Lactation

Lactation is production of milk by the hormone-prepared mammary glands. Rising levels of (placental) estrogens, progesterone, and lactogen toward the end of pregnancy stimulate the hypothalamus to release prolactin-releasing hormone (PRH). The anterior pituitary gland responds by secreting **prolactin.** (This mechanism is described below.) After a delay of two to three days, true milk production begins. Serotonin, a well-known neurotransmitter, is synthesized by the mammary glands. Its role there appears to be to send feedback signals to the hypothalamus that slow down prolactin release (and milk production) once the mammary glands are full of milk.

During the initial delay (and during late gestation), a yellowish fluid called **colostrum** (ko-los'trum) is secreted. Colostrum has less lactose than milk and almost no fat, but it contains more protein, vitamin A, and minerals than true milk. Like milk, colostrum is rich in IgA antibodies. Since these antibodies are resistant to digestion in the stomach, they may help to protect the infant's digestive tract against bacterial infection. Additionally, these IgA antibodies are absorbed by endocytosis and subsequently enter the bloodstream to provide even broader immunity.

After birth, prolactin release gradually wanes, and continual milk production depends on mechanical stimulation of the nipples, normally provided by the sucking infant. Mechanoreceptors in the nipple send afferent nerve impulses to the hypothalamus, stimulating secretion of PRH. This results in a burstlike release of prolactin, which stimulates milk production for the next feeding. The same afferent impulses also prompt hypothalamic release of oxytocin from the posterior pituitary via a *positive feedback mechanism*. Oxytocin causes the **let-down reflex,** the actual ejection of milk from the alveoli of the mammary glands (Figure 28.18). Let-down occurs when oxytocin binds to myoepithelial cells surrounding the glands, after which milk is ejected from *both* breasts, not just the suckled one. During nursing oxytocin also stimulates the recently emptied uterus to contract, helping it to return to (nearly) its prepregnant size.

Breast milk has advantages for the infant: (1) Its fats and iron are better absorbed and its amino acids are metabolized more efficiently than those of cow's milk. (2) Besides IgA, it has a host of other beneficial chemicals, including complement, lysozyme,

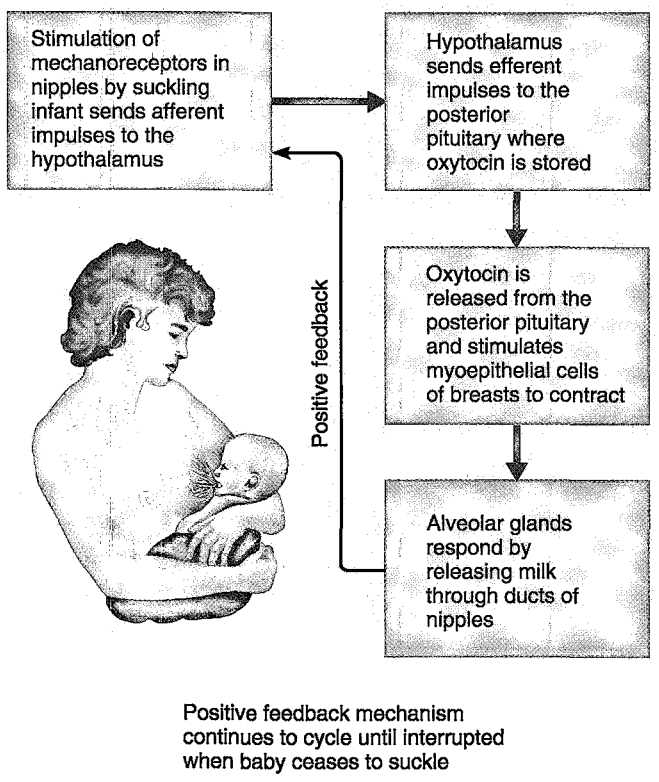


FIGURE 28.18 **Positive feedback mechanism of the milk let-down reflex.**

interferon, and lactoperoxidase, that protect infants from life-threatening infections. Mother's milk also contains interleukins and prostaglandins that prevent overzealous inflammatory responses, and a glycoprotein that deters the ulcer-causing bacterium *(H. pylori)* from attaching to the stomach mucosa. (3) Its natural laxative effect helps to cleanse the bowels of **meconium** (mĕ-ko'ne-um), a tarry green-black paste containing sloughed-off epithelial cells, bile, and other substances. Since meconium, and later feces, provides the route for eliminating bilirubin from the body, clearing meconium as quickly as possible helps to prevent *physiological jaundice* (see the Related Clinical Terms section). It also encourages bacteria (the source of vitamin K and some B vitamins) to colonize the large intestine.

When nursing is discontinued, the stimulus for prolactin release and milk production ends, and the mammary glands stop producing milk. Women who nurse their infants for six months or more lose a significant amount of calcium from their bones, but those on sound diets usually replace lost bone calcium after weaning the infant. While prolactin levels are high, the normal hypothalamic-pituitary controls of the ovarian cycle are damped, probably because stimulation of the hypothalamus by sucking causes it to release beta endorphin, a peptide hormone that inhibits hypothalamic release of GnRH and hence the release of gonadotropins by the pituitary. Because of this prolactin-induced inhibition of ovarian function, nursing has been called natural birth control. Nonetheless, there is a good deal of "slippage" in these controls, and most women begin to ovulate even while continuing to nurse their infants.

Assisted Reproductive Technology and Reproductive Cloning

So far we have been describing how babies are made. But if a couple lacks that capability for some reason, what recourse do they have? Hormone therapy may increase sperm or egg production in cases where that is the problem, and surgery can open blocked uterine tubes. Beyond that is *assisted reproductive technology (ART)*, procedures that entail surgical removal of oocytes from a woman's ovaries following hormone stimulation, fertilizing the oocytes, and then returning them to the woman's body. Unused oocytes, sperm, and embryos can be frozen for later attempts at accomplishing pregnancy.

In the most common ART process, *in vitro fertilization (IVF)*, harvested oocytes are incubated with sperm in culture dishes for several days to allow fertilization to occur. In cases where the quality or number of sperm is low, the oocytes are injected with sperm (Figure 28.19). Embryos reaching the two-cell or blastocyst stage are then carefully transferred into the woman's uterus in the hope that implantation will occur. In *zygote intrafallopian transfer (ZIFT)*, oocytes fertilized in vitro are immediately transferred to the woman's uterine (fallopian) tubes with the goal of development to the blastocyst stage there and normal implantation in the uterus. In *gamete intrafallopian transfer (GIFT)*, no in vitro procedures are used; instead sperm and harvested oocytes are transferred together into the woman's uterine tubes in the hope that fertilization will occur there. These procedures, now performed worldwide in major medical centers, have produced thousands of infants, but they are expensive, emotionally draining, and painful for the oocyte donor.

Although there is a great deal of hubbub in the scientific community about using cloning as another possible avenue to produce offspring, human beings have proved notoriously difficult to create and sustain past very early (blastocyst) development. Cloning entails insertion of a somatic cell nucleus into an oocyte and then an incubation period to dedifferentiate the

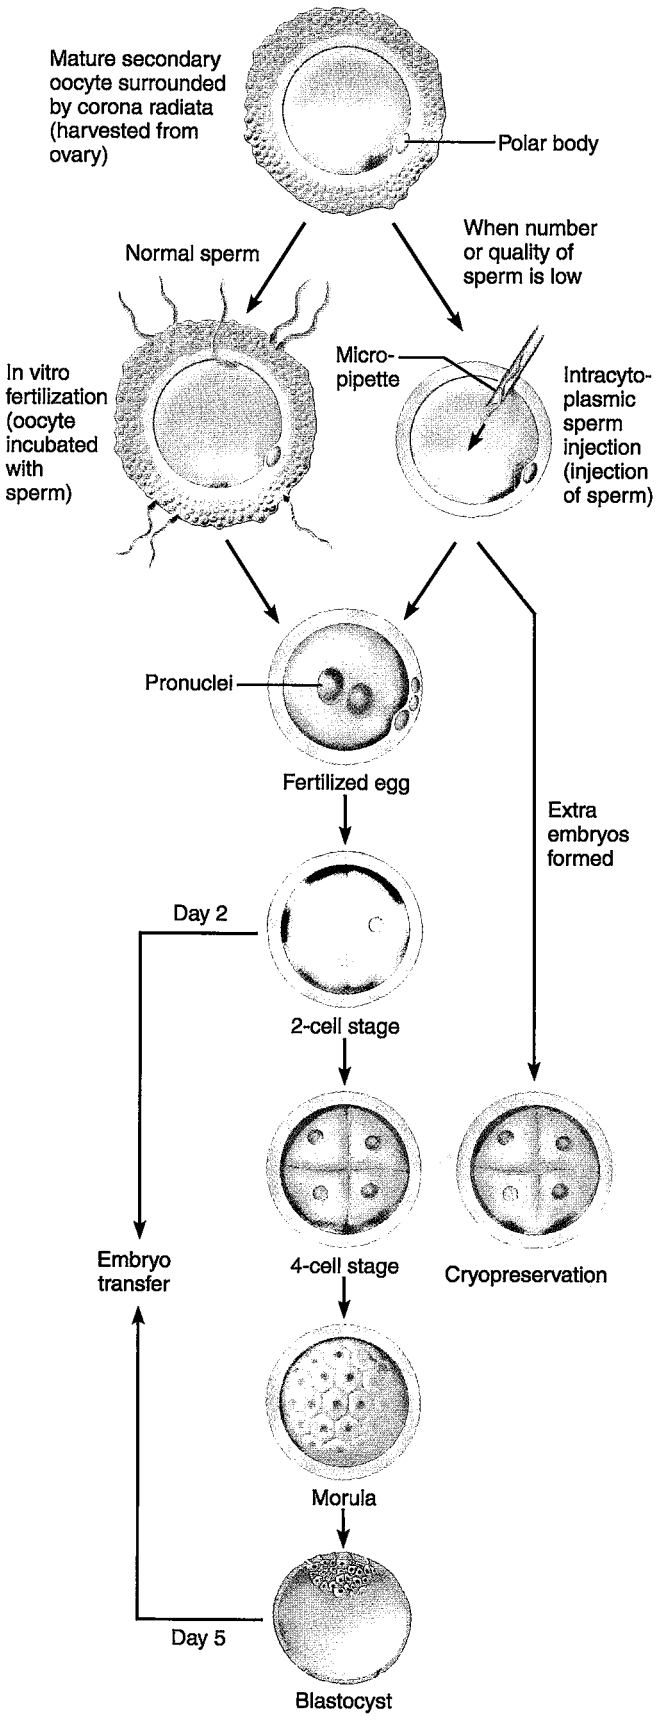

FIGURE 28.19 **Brief summary of selected techniques of assisted reproductive technology (ART).** Mature oocytes harvested from the ovary are incubated with sperm to allow natural fertilization to occur or are injected with sperm. The fertilized eggs are cultured in vitro to achieve the two-cell or blastocyst stage, at which time the embryo(s) is transferred to the receptive uterus. Extra embryos are frozen for future attempts.

inserted nucleus. This technique has proved more successful in creating stem cells for therapeutic use in treating selected diseases than for reproductive cloning to produce whole and healthy human offspring. Furthermore, human reproductive cloning is currently fraught with legal, moral, ethical, and political roadblocks.

■ ■ ■

In this chapter, we have focused on changes that occur during human development in utero. But having a baby is not always what the interacting partners have in mind, and we humans have devised a variety of techniques for preventing this outcome (see *A Closer Look* on p. 1128).

Getting back to human embryonic development, we must admit that the description here has fallen short because the phenomenon of differentiation has barely been touched upon. How does an unspecialized cell that can become *anything* in the body develop into a specific *something* (a heart cell, for example)? And what paces the developmental sequence, so that if a particular process fails to occur at a precise time, it never occurs at all? Scientists are beginning to believe that there are master switches in the genes. Chapter 29, the final chapter of this book, describes a small part of the "how" as it examines the interaction of genes that determine who we finally become.

Related Clinical Terms

Abortion (*abort* = born prematurely) Premature removal of the embryo or fetus from the uterus; may be spontaneous or induced.

Ectopic pregnancy (ek-top'ik; *ecto* = outside) A pregnancy in which the embryo implants in any site other than the uterus; most often the site is a uterine tube (tubal pregnancy). Since the uterine tube (as well as most other ectopic sites) is unable to establish a placenta or accommodate growth, the uterine tube ruptures unless the condition is diagnosed early, or the pregnancy spontaneously aborts.

Hydatid (hydatidiform) mole (hi'dah-tid; *hydat* = watery) Developmental abnormality of the placenta; the conceptus degenerates and the chorionic villi convert into a mass of vesicles that resemble tapioca. Signs include vaginal bleeding, which contains some of the grapelike vesicles.

Physiological jaundice (jawn'dis) Jaundice sometimes occurring in normal newborns within three to four days after birth. Fetal erythrocytes are short-lived, and they break down rapidly after birth; the infant's liver may be unable to process the bilirubin (breakdown product of hemoglobin pigment) fast enough to prevent its accumulation in blood and subsequent deposit in body tissues.

Placenta abruptio (ah-brup'she-o; *abrupt* = broken away from) Premature separation of the placenta from the uterine wall; if this occurs before labor, it can result in fetal death due to anoxia.

Placenta previa (pre've-ah) Placental formation adjacent to or across the internal os of the uterus. Represents a problem because as the uterus and cervix stretch, tearing of the placenta may occur. Additionally, the placenta precedes the infant during labor.

Ultrasonography (ul"trah-son-og'rah-fe) Noninvasive technique that uses sound waves to visualize the position and size of the fetus and placenta (see *A Closer Look*, Chapter 1).

Chapter Summary

1. The gestation period of approximately 280 days extends from the woman's last menstrual period to birth. The conceptus undergoes embryonic development for 8 weeks after fertilization, and fetal development from week 9 to birth.

From Egg to Zygote (pp. 1114–1117)

Accomplishing Fertilization (pp. 1114–1117)

1. An oocyte is fertilizable for up to 24 hours; most sperm are viable within the female reproductive tract for one to two days.

2. Sperm must survive the hostile environment of the vagina and become capacitated (capable of reaching and fertilizing the oocyte).

3. Hundreds of sperm must release their acrosomal enzymes to break down the egg's corona radiata and zona pellucida.

4. When one sperm binds to receptors on the egg, it triggers the slow block to polyspermy (release of cortical granules).

5. Following sperm penetration, the secondary oocyte completes meiosis II. Then the ovum and sperm pronuclei fuse (fertilization), forming a zygote.

Events of Embryonic Development: Zygote to Blastocyst Implantation (pp. 1117–1122)

Cleavage and Blastocyst Formation (pp. 1117–1119)

1. Cleavage, a rapid series of mitotic divisions without intervening growth, begins with the zygote and ends with a blastocyst. The blastocyst consists of the trophoblast and an inner cell mass. Cleavage produces a large number of cells with a favorable surface-to-volume ratio.

Implantation (pp. 1119–1120)

2. The trophoblast adheres to, digests, and implants in the endometrium. Implantation is completed when the blastocyst is entirely surrounded by endometrial tissue, about 12 days after ovulation.

3. hCG released by the blastocyst maintains hormone production by the corpus luteum, preventing menses. hCG levels decline after four months.

Placentation (pp. 1120–1122)

4. The placenta acts as the respiratory, nutritive, and excretory organ of the fetus and produces the hormones of pregnancy. It is formed from embryonic (chorionic villi) and maternal (endometrial decidua) tissues. The chorion develops when the trophoblast becomes associated with extraembryonic mesoderm. Typically, the placenta is functional as an endocrine organ by the third month.

Events of Embryonic Development: Gastrula to Fetus (pp. 1122–1132)

Formation and Roles of the Extraembryonic Membranes (pp. 1122–1123)

1. The fluid-filled amnion forms from cells of the superior surface (epiblast) of the embryonic disc. It protects the embryo from physical trauma and adhesion formation, provides a constant temperature, and allows fetal movements.

2. The yolk sac forms from the hypoblast of the embryonic disc; it is the source of early blood cells.

3. The allantois, a caudal outpocketing adjacent to the yolk sac, forms the structural basis of the umbilical cord.

4. The chorion is the outermost membrane and takes part in placentation.

Gastrulation: Germ Layer Formation (p. 1123)

5. Gastrulation involves cellular migrations that ultimately transform the inner cell mass into a three-layered embryo (gastrula) containing ectoderm, mesoderm, and endoderm. Cells that move through the midline primitive streak become endoderm if they form the most inferior layer of the embryonic disc and mesoderm if they ultimately occupy the middle layer. Cells remaining on the superior surface become ectoderm.

Organogenesis: Differentiation of the Germ Layers (pp. 1123–1132)

6. Ectoderm forms the nervous system and the epidermis of the skin and its derivatives. The first event of organogenesis is neurulation, which produces the brain and spinal cord. By the eighth week, all major brain regions are formed.

7. Endoderm forms the mucosa of the digestive and respiratory systems, and the epithelial cells of all associated glands (thyroid, parathyroids, thymus, liver, pancreas). It becomes a continuous tube when the embryonic body undercuts and fuses ventrally.

8. Mesoderm forms all other organ systems and tissues. It segregates early into (1) a dorsal superior notochord, (2) paired somites that form the vertebrae, skeletal trunk muscles, and part of the dermis, and (3) paired masses of intermediate and lateral mesoderm. The intermediate mesoderm forms the kidneys and gonads. The somatic layer of the lateral mesoderm forms the dermis of skin, parietal serosa, and bones and muscles of the limbs; the splanchnic layer forms the cardiovascular system and the visceral serosae.

9. The fetal cardiovascular system is formed in the embryonic period. The umbilical vein delivers nutrient- and oxygen-rich blood to the embryo; the paired umbilical arteries return oxygen-poor, waste-laden blood to the placenta. The ductus venosus allows most of the blood to bypass the liver; the foramen ovale and ductus arteriosus are pulmonary shunts.

Events of Fetal Development (p. 1133)

1. All organ systems are laid down during the embryonic period; growth and tissue/organ specialization are the major events of the fetal period.

2. During the fetal period, fetal length increases from about 22 mm to 360 mm, and weight increases from less than an ounce to 7 pounds or more.

Effects of Pregnancy on the Mother (pp. 1133–1135)

Anatomical Changes (pp. 1133–1134)

1. Maternal reproductive organs and breasts become increasingly vascularized during pregnancy, and the breasts enlarge.

2. The uterus eventually occupies nearly the entire abdominopelvic cavity. Abdominal organs are pushed superiorly and encroach on the thoracic cavity, causing the ribs to flare.

3. The increased abdominal mass changes the woman's center of gravity; lordosis and backache are common. A waddling gait occurs as pelvic ligaments and joints are loosened by placental relaxin.

4. A typical weight gain during pregnancy in a woman of normal weight is 28 pounds.

Metabolic Changes (pp. 1134–1135)

5. Human placental lactogen has anabolic effects and promotes glucose sparing in the mother. Human chorionic thyrotropin results in maternal hypermetabolism.

Physiological Changes (p. 1135)

6. Many women suffer morning sickness, heartburn, and constipation during pregnancy.

7. The kidneys produce more urine, and pressure on the bladder may cause frequency, urgency, and stress incontinence.

8. Tidal volume and respiratory rate increase, but residual volume decreases. Dyspnea is common.

9. Total body water and blood volume increase dramatically. Heart rate and blood pressure rise, resulting in enhancement of cardiac output in the mother.

Parturition (Birth) (pp. 1135–1137)

1. Parturition encompasses a series of events called labor.

Initiation of Labor (pp. 1135–1136)

2. When estrogen levels are sufficiently high, they induce oxytocin receptors on the myometrial cells and inhibit progesterone's quieting effect on uterine muscle. Weak, irregular contractions begin.

3. Fetal cells produce oxytocin, which stimulates prostaglandin production by the placenta. Both hormones stimulate contraction of uterine muscle. Increasing stress activates the hypothalamus, causing oxytocin release from the posterior pituitary; this sets up a positive feedback loop resulting in true labor.

Stages of Labor (p. 1137)

4. The dilation stage is from the onset of rhythmic, strong contractions until the cervix is fully dilated. The head of the fetus rotates as it descends through the pelvic outlet.

5. The expulsion stage extends from full cervical dilation until birth of the infant.

6. The placental stage is the delivery of the afterbirth (the placenta and attached fetal membranes).

Adjustments of the Infant to Extrauterine Life (pp. 1137–1138)

1. The infant's Apgar score is recorded immediately after birth.

Taking the First Breath and Transition (pp. 1137–1138)

2. After the umbilical cord is clamped, carbon dioxide accumulates in the infant's blood, causing respiratory centers in the brain to trigger the first inspiration.

3. Once the lungs are inflated, breathing is eased by the presence of surfactant, which decreases the surface tension of the alveolar fluid.

4. During transition, the first 8 hours after birth, the infant is physiologically unstable and adjusting. After stabilizing, the infant wakes approximately every 3–4 hours in response to hunger.

Occlusion of Special Fetal Blood Vessels and Vascular Shunts (p. 1138)

5. Inflation of the lungs causes pressure changes in the circulation; as a result, the umbilical arteries and vein, ductus venosus, and ductus arteriosus collapse, and the foramen ovale closes. The occluded blood vessels are converted to fibrous cords; the site of the foramen ovale becomes the fossa ovalis.

Lactation (pp. 1138–1139)

1. The breasts are prepared for lactation during pregnancy by high blood levels of estrogen, progesterone, and placental lactogen.

2. Colostrum, a premilk fluid, is a fat-poor fluid that contains more protein, vitamin A, and minerals than true milk. It is produced toward the end of pregnancy and for the first two to three days after birth.

3. True milk is produced around day 3 in response to suckling, which stimulates the hypothalamus to prompt anterior pituitary release of prolactin and posterior pituitary release of oxytocin. Prolactin stimulates milk production. Serotonin inhibits prolactin release when the mammary glands are full of milk, and oxytocin triggers milk let-down. Continued breast-feeding is required for continued milk production.

4. At first, ovulation and menses are absent or irregular during nursing, but in most women the ovarian cycle is eventually reestablished while still nursing.

Assisted Reproductive Technology and Reproductive Cloning (pp. 1139–1140)

1. Assisted reproductive technology (ART) procedures assist infertile couples to bear children. Among the most used techniques are IVF, ZIFT, and GIFT. IVF and ZIFT attempt to fertilize harvested oocytes in vitro and then return the embryo or zygote to the woman's body. GIFT utilizes in vivo methods—sperm and oocytes are transferred together to the woman's uterine tubes.

2. Reproductive cloning in humans has proved difficult to achieve and the practice has met several roadblocks.

Review Questions

Multiple Choice/Matching

(Some questions have more than one correct answer. Select the best answer or answers from the choices given.)

1. Indicate whether each of the following statements is describing (a) cleavage or (b) gastrulation.

____ (1) period during which a morula forms
____ (2) period when vast amounts of cell migration occur
____ (3) period when the three embryonic germ layers appear
____ (4) period during which the blastocyst is formed

2. Most systems are operational in the fetus by four to six months. Which system is the exception to this generalization, affecting premature infants? (a) the circulatory system, (b) the respiratory system, (c) the urinary system, (d) the digestive system.

3. The zygote contains chromosomes from (a) the mother only, (b) the father only, (c) both the mother and father, but half from each, (d) each parent and synthesizes others.

4. The outer layer of the blastocyst, which later attaches to the uterus, is the (a) decidua, (b) trophoblast, (c) amnion, (d) inner cell mass.

5. The fetal membrane that forms the basis of the umbilical cord is the (a) allantois, (b) amnion, (c) chorion, (d) yolk sac.

6. In the fetus, the ductus arteriosus carries blood from (a) the pulmonary artery to the pulmonary vein, (b) the liver to the inferior vena cava, (c) the right ventricle to the left ventricle, (d) the pulmonary trunk to the aorta.

7. Which of the following changes occur in the baby's cardiovascular system after birth? (a) Blood clots in the umbilical vein, (b) the pulmonary vessels dilate as the lungs expand, (c) the ductus venosus becomes obliterated, as does the ductus arteriosus, (d) all of these.

8. Following delivery of the infant, the delivery of the afterbirth includes the (a) placenta only, (b) placenta and decidua, (c) placenta and attached (torn) fetal membranes, (d) chorionic villi.

9. Identical twins result from the fertilization of (a) one ovum by one sperm, (b) one ovum by two sperm, (c) two ova by two sperm, (d) two ova by one sperm.

10. The umbilical vein carries (a) waste products to the placenta, (b) oxygen and food to the fetus, (c) oxygen and food to the placenta, (d) oxygen and waste products to the fetus.

11. The germ layer from which the skeletal muscles, heart, and skeleton are derived is the (a) ectoderm, (b) endoderm, (c) mesoderm.

12. Which of the following cannot pass through placental barriers? (a) blood cells, (b) glucose, (c) amino acids, (d) gases, (e) antibodies.

13. The most important hormone in initiating and maintaining lactation after birth is (a) estrogen, (b) FSH, (c) prolactin, (d) oxytocin.

14. The initial stage of labor, during which the neck of the uterus is stretched, is the (a) dilation stage, (b) expulsion stage, (c) placental stage.

15. Match each embryonic structure in Column A with its adult derivative in Column B.

Column A	Column B
____ (1) notochord	(a) kidney
____ (2) ectoderm (not neural tube)	(b) peritoneal cavity
____ (3) intermediate mesoderm	(c) pancreas, liver
____ (4) splanchnic mesoderm	(d) parietal serosa, dermis
____ (5) sclerotome	(e) nucleus pulposus
____ (6) coelom	(f) visceral serosa
____ (7) neural tube	(g) hair and epidermis
____ (8) somatic mesoderm	(h) brain
____ (9) endoderm	(i) ribs

Short Answer Essay Questions

16. Fertilization involves much more than a mere restoration of the diploid chromosome number. (a) What does the process of fertilization entail on the part of both the egg and sperm? (b) What are the effects of fertilization?

17. Cleavage is an embryonic event that mainly involves mitotic divisions. How does cleavage differ from mitosis occurring during life after birth, and what are its important functions?

18. The life span of the ovarian corpus luteum is extended for nearly three months after implantation, but otherwise it deteriorates. (a) Explain why this is so. (b) Explain why it is important that the corpus luteum remain functional following implantation.

19. The placenta is a marvelous, but temporary, organ. Starting with a description of its formation, show how it is an intimate part of both fetal and maternal anatomy and physiology during the gestation period.

20. Why is it that only one sperm out of the hundreds (or thousands) available enters the oocyte?

21. What is the function of gastrulation?

22. (a) What is a breech presentation? (b) Cite two problems with this type of presentation.

23. What factors are believed to bring about uterine contractions at the termination of pregnancy?

24. Explain how the flat embryonic disc takes on the cylindrical shape of a tadpole.

Critical Thinking and Clinical Application Questions

1. Jennie, a freshman in your dormitory, tells you she just discovered that she is three months pregnant. She recently bragged that since she came to college she has been drinking alcohol heavily and experimenting with every kind of recreational drug she could find. From the following, select the advice you would give her, and explain why it is the best choice. (a) She must stop taking drugs, but they could not have affected her fetus during these first few months of her pregnancy. (b) Harmful substances usually cannot pass from mother to embryo, so she can keep using drugs. (c) There could be defects in the fetus, so she should stop using drugs and visit a doctor as soon as possible. (d) If she has not taken any drugs in the last week, she is okay.

2. During Mrs. Jones's labor, the obstetrician decided that it was necessary to perform an episiotomy. What is an episiotomy, and why is it done?

3. A woman in substantial pain called her doctor and explained (between sobs) that she was about to have her baby "right here." The doctor calmed her and asked how she had come to that conclusion. She said that her water had broken and that her husband could see the baby's head. (a) Was she right? If so, what stage of labor was she in? (b) Do you think that she had time to make it to the hospital 60 miles away? Why or why not?

4. Mary is a heavy smoker and has ignored a friend's advice to stop smoking during her pregnancy. On the basis of what you know about the effect of smoking on physiology, describe how Mary's smoking might affect her fetus.

5. While Mortimer was cramming for his anatomy test, he read that some parts of the mesoderm become segmented. He suddenly realized that he could not remember what segmentation is. Define segmentation, and give two examples of segmented structures in the embryo.

6. Assume a sperm has penetrated a polar body and their nuclei fuse. Why would it be unlikely for the resulting cell to develop into a healthy embryo?

20 Heredity

The Vocabulary of Genetics (pp. 1146–1147)

1. Define allele.
2. Differentiate between genotype and phenotype.

Sexual Sources of Genetic Variation (pp. 1147–1149)

3. Describe events that lead to genetic variability of gametes.

Types of Inheritance (pp. 1149–1153)

4. Compare and contrast dominant-recessive inheritance with incomplete dominance and codominance.
5. Describe the mechanism of sex-linked inheritance.
6. Explain how polygene inheritance differs from that resulting from the action of a single pair of alleles.

Environmental Factors in Gene Expression (p. 1153)

7. Provide examples illustrating how gene expression may be modified by environmental factors.

Nontraditional Inheritance (pp. 1153–1154)

8. Describe how RNA-only genes and epigenetic marks affect gene expression.
9. Describe the basis of extranuclear (mitochondria-based) genetic disorders.

Genetic Screening, Counseling, and Therapy (pp. 1154–1157)

10. List and explain several techniques used to determine or predict genetic diseases.
11. Describe briefly some approaches of gene therapy.

The wondrous growth and development of a new individual is guided by the gene-bearing chromosomes it receives from its parents in egg and sperm. As described in Chapter 3, individual *genes,* or DNA segments, contain the "recipes" or genetic blueprints for proteins, many of which are enzymes that dictate the synthesis of virtually all the body's molecules. Consequently, genes are ultimately expressed in your hair color, sex, blood type, and so on. However, genes do not act as free agents. As you will see, a gene's ability to prompt the development of a specific trait is enhanced or inhibited by interactions with other genes, as well as by environmental factors.

Although the science of **genetics,** which studies the mechanism of heredity (*genes* = give birth to), is relatively young, our understanding of how human genes act and interact has advanced considerably since the basic principles of heredity were first proposed by Gregor Mendel in the mid-1800s. Part of the problem in unraveling the story of human genetics is that, unlike the pea plants Mendel studied, humans have long life spans, produce relatively few offspring, and cannot be mated experimentally just to examine the nature of their offspring. Furthermore, Mendel studied characteristics that vary in an either-or fashion rather than those that vary in a more-or-less fashion the way many human traits do. The urge to understand human inheritance is a powerful one, however, and recent advances provided by the *Human Genome Project,* which scanned and determined the human DNA sequence, are enabling geneticists to manipulate and engineer human genes to examine their expression. This research has tremendous promise for more sophisticated genetic screening, and for drug development to treat or cure disease. For example, by using viruses to introduce bioengineered genes into human cells, specific disease-causing genes can be silenced. Although we touch upon some of these newer topics, we will concentrate on the principles of heredity discovered by Mendel more than a century ago.

The Vocabulary of Genetics

The nuclei of all human cells except gametes contain the diploid number of chromosomes (46), consisting of 23 pairs of homologous chromosomes.* Two of the 46 are **sex chromosomes** (X and Y), which determine genetic sex (male = XY; female = XX). The other 44 are the 22 pairs of **autosomes** that guide the expression of most other traits. The complete human **karyotype** (kar'e-o-tīp), or diploid chromosomal complement displayed in homologous pairs, is illustrated in Figure 29.1. The diploid **genome** (je'nōm), or genetic (DNA) makeup, represents two sets of genetic instructions—one from the egg and the other from the sperm.

Gene Pairs (Alleles)

Because chromosomes are paired, it follows that the genes in them are paired as well. Consequently, each of us receives two genes, one from each parent (for the most part), that interact to dictate a particular trait. Any two matched genes, which are at the same *locus* (location) on homologous chromosomes, are called **alleles** (ah-lēlz') of each other. Alleles may code for the same or for alternative forms of a given trait. For example, of the alleles that dictate whether or not you have loose thumb ligaments, one variant might code for tight ligaments and the other for loose ligaments (the double-jointed thumb condition). When the two alleles controlling a trait are the same, a person is said to be **homozygous** (ho-mo-zi'gus) for that trait. When the two alleles are different, the individual is **heterozygous** (het"er-o-zi'gus) for the trait.

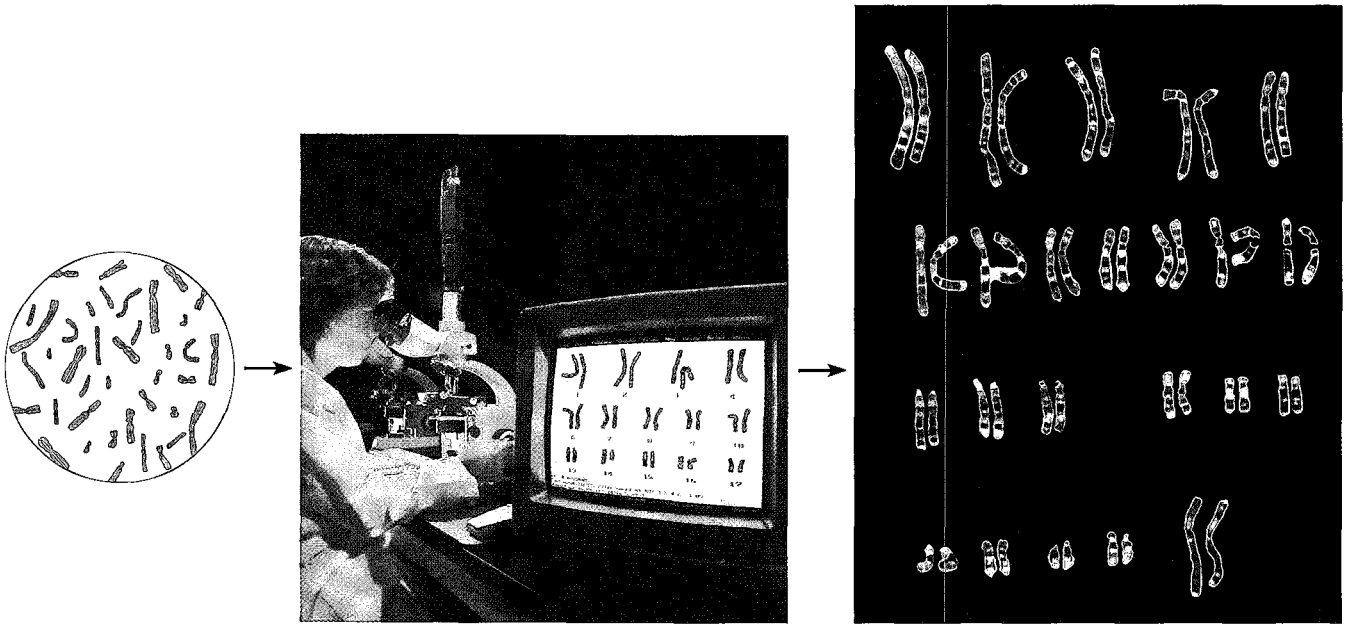
Sometimes, one allele masks or suppresses the expression of its partner. Such an allele is said to be **dominant,** whereas the allele that is masked is said to be **recessive.** By convention, a dominant allele is represented by a capital letter (for example, *J*), and a recessive allele by the lowercase form of the same letter *(j)*. Dominant alleles are expressed, or make themselves "known," when they are present in either single or double dose. For recessive alleles to be expressed, they must be present in double dose, that is, the homozygous condition. Returning to our thumb example, a person whose genetic makeup includes either the gene pair *JJ* (the homozygous dominant condition) or the gene pair *Jj* (the heterozygous condition) will have double-jointed thumbs. The combination *jj* (the homozygous recessive condition) is needed to produce tight thumb ligaments.

A common misconception is that dominant traits will be seen more often because they are expressed whether the allele is present in single or double dose. However, dominance and recessiveness alone do not determine the frequency of a trait in a population; this also depends on the relative abundance of the respective dominant or recessive alleles in that population. For example, five fingers per hand is recessive to six fingers per hand, yet we certainly see a lot more people with five fingers on each hand.

29

* Recall that homologous chromosomes are chromosome pairs—one from the father (sperm) and one from the mother (egg)—that look similar and carry genes for the same traits, but do not necessarily convey the same expressions of those traits.

Q *When a geneticist orders a karyotype, why are cells in metaphase studied instead of those in interphase?*



(a) The slide is viewed with a microscope, and the chromosomes are photographed.

(b) The photograph is entered into a computer, and the chromosomes are electronically rearranged into pairs according to size and structure.

(c) The resulting display is the karyotype.

FIGURE 29.1 **Preparing a karyotype.** After lymphocytes are stimulated to divide and grow in culture for several days, they are treated with a drug that arrests mitosis in metaphase, a stage when the chromosomes are easily identified. The cells are harvested, treated with a solution that makes their chromosomes spread out, and **(a)** transferred to a microscope for photography. **(b)** The photograph is entered into a computer for analysis and arrangement of the chromosomes into homologous pairs. **(c)** The karyotype is displayed for examination of chromosomal structure and number. The patterns of stained bands help to identify specific chromosomes and parts of chromosomes.

Genotype and Phenotype

A person's genetic makeup is referred to as his or her **genotype** (jen'o-tīp). The way that genotype is expressed in the body is called one's **phenotype** (fe'no-tīp). Thus, the double-jointed condition is the phenotype produced by a genotype of *JJ* or *Jj*.

Sexual Sources of Genetic Variation

Before we examine how genes interact, let us consider why (with the possible exception of identical siblings) each of us is one of a kind, with a unique genotype and phenotype. This variability reflects three events that occur before we are even a twinkle in our parents' eyes: independent assortment of chromosomes, crossover of homologues, and random fertilization of eggs by sperm.

Chromosome Segregation and Independent Assortment

As described in Chapter 27, each pair of homologous chromosomes synapses during meiosis I, forming a tetrad. This happens during both spermatogenesis and oogenesis. Because chance determines how the tetrads align on the meiosis I metaphase spindle, maternal and paternal chromosomes are randomly distributed to daughter nuclei. As illustrated in Figure 29.2, this simple event leads to an amazing amount of variation in gametes. The cell in our example has a diploid number of 6, and so three tetrads form. As you can see, the possible combinations of

A *The genetic material is more dispersed as chromatin during interphase, so no individual chromosomes are visible (or identifiable).*

Q *What event leads to the variability seen here?*

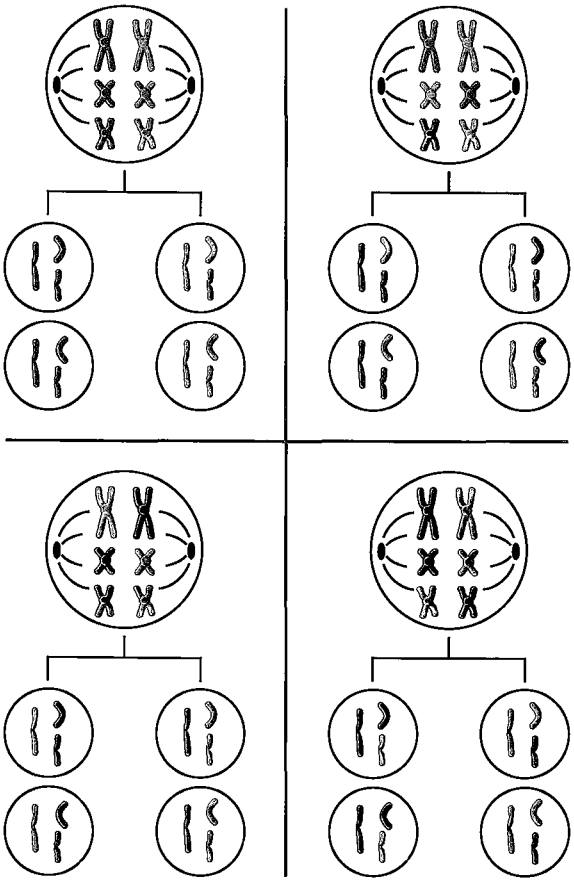


FIGURE 29.2 **Gamete variability resulting from independent assortment.** During metaphase of meiosis I, the tetrads of homologous chromosomes (two originals each with its replica) align independently of other tetrads. The large circles depict the possible alignments in a mother cell having a diploid number of 6 (paternal homologues purple; maternal, green). The small circles show the gametes arising from each alignment. Some gametes contain all maternal or all paternal chromosomes; others have maternal and paternal chromosomes in various combinations.

alignments of the three tetrads result in eight gamete possibilities. Because the way each tetrad aligns is random, and because many mother cells are undergoing meiosis simultaneously, each alignment and each type of gamete occurs with the same frequency as all others.

Two important points about meiosis I metaphase: (1) The two alleles determining each trait are **segregated,** which means that they are distributed to different gametes. (2) Alleles on different pairs of homologous chromosomes are distributed independently of each other. The net result is that each gamete has a single allele for each trait, and that allele represents only one of the four possible parental alleles.

The number of different gamete types resulting from **independent assortment** of homologues during meiosis I can be calculated for any genome from the formula 2^n, where n is the number of homologous pairs. In our example, $2^n = 2^3$ $(2 \times 2 \times 2)$, for a total of eight different gamete types. The number of gamete types increases dramatically as chromosome number increases. A cell with six pairs of homologues would produce 2^6, or 64, kinds of gametes. In a man's testes, the number of gamete types that can be produced on the basis of independent assortment alone is 2^{23}, or about 8.5 million—an incredible variety. Because a human female's ovaries complete at most 500 reduction divisions in her lifetime, the number of different gamete types produced simultaneously is significantly less. Still, each ovulated oocyte will most likely be novel genetically because of independent assortment.

Crossover of Homologues and Gene Recombination

Additional gamete variation results from the crossing over and exchange of chromosomal parts during meiosis I. Genes are arranged linearly along a chromosome's length, and genes on the same chromosome are said to be **linked** because they are physically connected and transmitted as a unit to daughter cells during mitosis. However, during meiosis, chromosomes can break and precisely exchange gene segments with their homologous counterparts, giving rise to **recombinant chromosomes** that have mixed contributions from each parent.

In the hypothetical example shown in Figure 29.3, the genes for hair and eye color are linked. The paternal chromosome contains alleles coding for blond hair and blue eyes, and the maternal alleles code for brown hair and brown eyes. In the **crossover,** or **chiasma,** shown, the break occurs between these linked genes, resulting in some gametes with alleles for blond hair and brown eyes and others with alleles for brown hair and blue eyes. As a result of the crossover, two of the four chromatids present in the tetrad end up with a mixed set of alleles—some maternal and some paternal. This means that when the chromatids segregate, each gamete will receive a unique combination of parental genes.

All four chromatids in a tetrad may take part in crossing over and recombination, and these may make many crossovers while synapsed. Furthermore, each crossover causes many genes to recombine, not just two as shown in our example. In general, crossovers occur at random points, and tend to occur nearer the medial regions of the chromatid arms.

A *Random alignment of the tetrads on the metaphase spindle.*

Because humans have 23 tetrads, with crossovers going on in most of them during meiosis I, the variability resulting from this factor alone is tremendous.

Random Fertilization

At any point in time, gametogenesis is turning out gametes with all variations possible from independent assortment and random crossovers. Compounding this variety is the fact that a single human egg will be fertilized by a single sperm on a totally haphazard or random basis. If we consider variation resulting only from independent assortment and random fertilization, any offspring represents one out of the close to 72 trillion (8.5 million × 8.5 million) zygotes possible. The additional variation introduced by crossovers increases this number exponentially. Perhaps now you can understand why brothers and sisters are so different, and marvel at how they can also be so alike in many ways.

Once these sources of variability are understood, it is easy to see that the concept most people have of inheritance is inaccurate. We often hear something like "I'm one-half German, one-quarter Scottish, and one-quarter Italian," which reveals a belief that genes from both sides of the family are parceled out in mathematically precise combinations. While it is true that we receive half of our genes from each parent, these genes do not contain one-quarter from each grandparent, one-eighth from each great grandparent, and so on. Additionally, there are no such things as German, Scottish, or Italian genes.

Types of Inheritance

Although a few human phenotypes can be traced to a single gene pair (as described shortly), most such traits are very limited in nature, or reflect variation in a single enzyme. Most human traits are determined by multiple alleles or by the interaction of several gene pairs.

Dominant-Recessive Inheritance

Dominant-recessive inheritance reflects the interaction of dominant and recessive alleles. A simple diagram, called the **Punnett square,** is used to figure

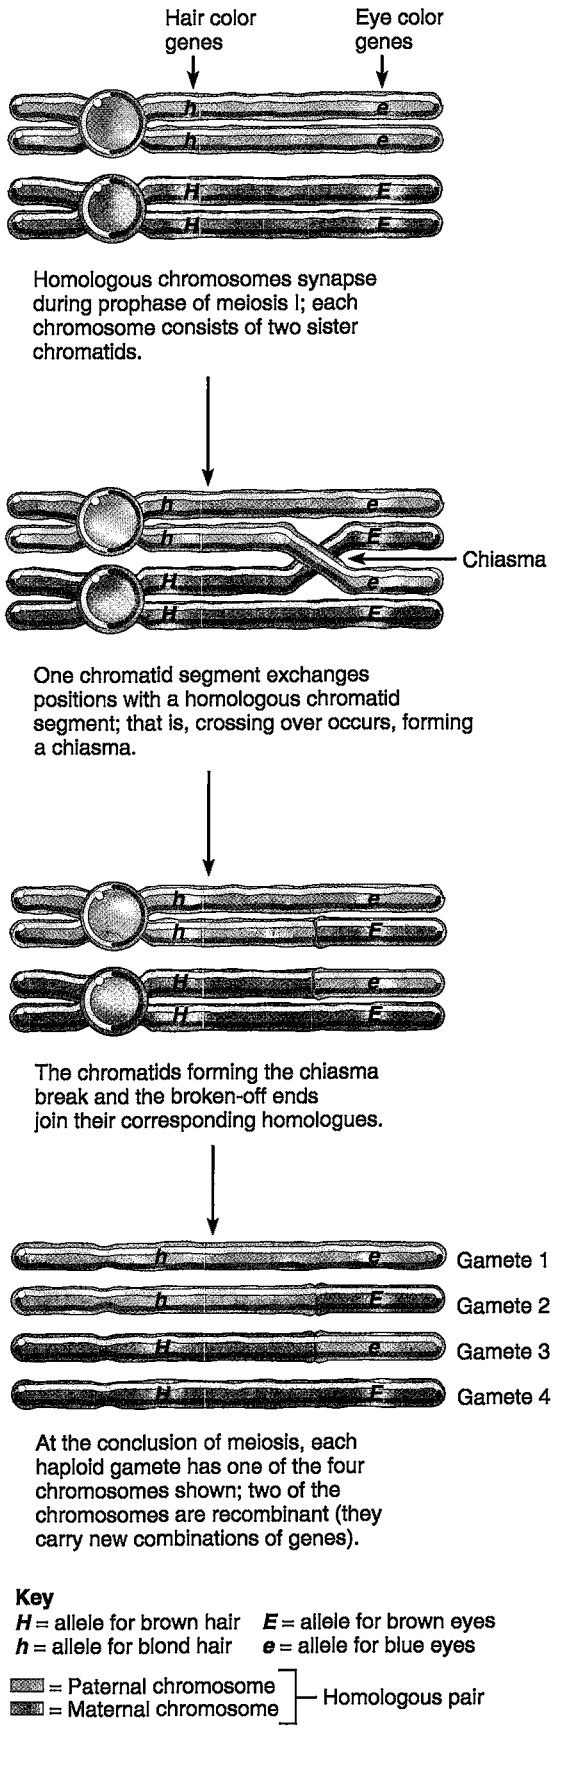

FIGURE 29.3 **Crossover and genetic recombination.** These meiosis I events increase genetic variability in the gametes formed. For simplicity, only two chromatids are shown taking part in crossover. Multiple crossovers result in more complex patterns.

A There would be a different selection of linked genes in the resulting gametes.

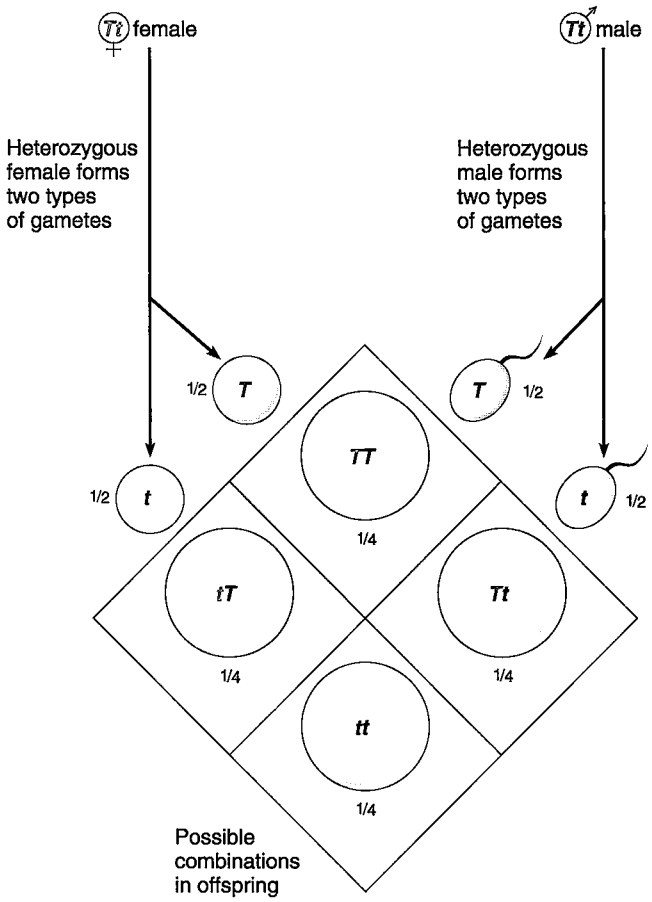

FIGURE 29.4 **Genotype and phenotype probabilities resulting from a mating of two heterozygous parents.** The Punnett square shows all possible combinations of a set of alleles in the zygote. In this example, the *T* allele is dominant and determines tongue-rolling ability; the *t* allele is recessive.

out, for a single trait, the possible gene combinations that would result from the mating of parents of known genotypes (Figure 29.4). In the example shown, both parents can roll their tongue into a U because both are heterozygous for the dominant allele *(T)* that confers this ability. In other words, each parent has the genotype *Tt*. The alleles of one parent are written along one side of the Punnett square, and the alleles for the other parent are shown along an adjacent side. The alleles are then combined down and across to determine the possible gene combinations (genotypes) and their expected frequency in the offspring of these two parents. As the completed Punnett square shows, the probability of these parents producing a homozygous dominant child *(TT)* is 25% (1 out of 4); of producing a heterozygous child *(Tt)*, 50% (2 out of 4); and of producing a homozygous recessive child, 25% (1 out of 4). The *TT* and *Tt* offspring will be tongue rollers; only the *tt* offspring will not be able to roll their tongues.

The Punnett square predicts only the *probability* of having a certain percentage of offspring with a particular genotype (and phenotype). The larger the number of offspring, the greater the likelihood that the ratios will conform to the predicted values—just as the chances of getting heads half the time and tails half the time increase with the number of tosses of a coin. If we toss only twice, we may well get heads both times. Likewise, if the couple in our example had only two children, it would not be surprising if both children had the genotype *Tt*.

What are the chances of having two children of the same genotype? To determine the probability of two events happening in succession, we must multiply the probabilities of the separate events happening. The probability of getting heads in one coin toss is ½, so the probability of getting two heads in a row is ½ × ½ = ¼. Now consider the chances of our couple's having two children who are both non–tongue rollers *(tt)*. The probability that one child will be *tt* is ¼, so the probability that both children will be *tt* is ¼ × ¼ = 1/16, only slightly better than 6%. Remember though that the production of each child, like each coin toss in a series, is an *independent event* that does not influence the production of any other child by the same couple. If you get heads on the first toss, the chance of getting heads the second time is still ½. Likewise, if our couple's first child is a *tt*, they still have a ¼ chance of getting a *tt* the next time.

Dominant Traits

Human traits dictated by dominant alleles include widow's peaks, dimples, and freckles.

Genetic disorders caused by dominant genes are uncommon because *lethal dominant genes* are almost always expressed and result in the death of the embryo, fetus, or child. Thus, the deadly genes are not usually passed along to successive generations. However, in some dominant disorders the person is less impaired or at least survives long enough to reproduce. One example is *achondroplasia* (a-kon"dropla'ze-ah), a rare type of dwarfism resulting from a fetus's inability to form cartilage (endochondral) bone. Another is *Huntington's disease*, a fatal nervous system disease involving degeneration of the basal nuclei. The latter involves a *delayed-action gene* that is expressed when the affected individual is about 40. Offspring of a parent with Huntington's disease have a 50% chance of inheriting the lethal gene. (The parent is heterozygous, because the dominant homozygous condition is lethal to the fetus.) Many informed offspring of such parents are opting not to become parents themselves. These and other dominant gene–determined traits are listed in Table 29.1.

TABLE 29.1 Traits Determined by Simple Dominant-Recessive Inheritance

PHENOTYPE DUE TO EXPRESSION OF:	
DOMINANT GENES (ZZ OR Zz)	**RECESSIVE GENES (zz)**
Tongue roller	Inability to roll tongue into a U shape
Astigmatism	Normal vision
Freckles	Absence of freckles
Dimples in cheeks	Absence of dimples
Feet with normal arches	Flat feet
PTC* taster	PTC nontaster
Widow's peak	Straight hairline
Double-jointed thumb	Tight thumb ligaments
Broad lips	Thin lips
Polydactyly (extra fingers and toes)	Normal number of fingers and toes
Syndactyly (webbed digits)	Normal digits
Achondroplasia (heterozygous: dwarfism; homozygous: lethal)	Normal cartilage bone formation
Huntington's disease	Absence of Huntington's disease
Normal skin pigmentation	Albinism
Absence of Tay-Sachs disease	Tay-Sachs disease
Absence of cystic fibrosis	Cystic fibrosis

*PTC is phenylthiocarbamide, a harmless bitter chemical.

Recessive Traits

Some examples of recessive inheritance are the more desirable genetic condition. For example, normal vision is dictated by recessive alleles, whereas astigmatism is prescribed by dominant alleles. However, many if not most genetic disorders are inherited as simple recessive traits. These include conditions as different as *albinism* (lack of skin pigmentation); *cystic fibrosis,* a condition of excessive mucus production that impairs lung and pancreatic functioning; and *Tay-Sachs disease,* a disorder of brain lipid metabolism, caused by an enzyme deficit that shows itself a few months after birth.

Recessive genetic disorders are more frequent than those caused by dominant alleles because those who carry a *single* recessive allele for a recessive genetic disorder do not themselves express the disease. However, they can pass the gene on to offspring and so are called *carriers* of the disorder. Conversely, as explained above, few individuals with dominant genetic disorders get a chance to pass on the detrimental gene.

Incomplete Dominance

In dominant-recessive inheritance, one allele variant completely masks the other. Some traits, however, exhibit **incomplete dominance.** In such instances, the heterozygote has a phenotype intermediate between those of homozygous dominant and homozygous recessive individuals. Incomplete dominance is uncommon in humans.

Perhaps the best human example is inheritance of the *sickling gene (s),* which causes a substitution of one amino acid in the beta chain of hemoglobin. Hemoglobin molecules containing the abnormal polypeptide chains crystallize when blood oxygen tension is low, causing the erythrocytes to assume a sickle shape (see Figure 17.8b, p. 656). Individuals with a double dose of the sickling allele *(ss)* have **sickle-cell anemia,** and any condition that lowers their blood oxygen level, such as respiratory difficulty or excessive exercise, can precipitate a *sickle-cell crisis.* The deformed erythrocytes jam up and fragment in small capillaries, causing intense pain.

Individuals heterozygous for the sickling gene *(Ss)* have **sickle-cell trait.** They make both normal and sickling hemoglobin. As a rule, these individuals are healthy, and do not display the signs and symptoms. However, they can suffer a crisis if there is prolonged reduction in blood oxygen levels, as might happen when traveling in high-altitude areas, and they can transmit the sickling gene to their offspring.

Multiple-Allele Inheritance

Although we inherit only two alleles for each gene, some genes exhibit more than two allele forms, leading to a phenomenon called **multiple-allele inheritance.** For example, three alleles determine the ABO blood types in humans: I^A, I^B, and i. Each of us receives two of these. The I^A and I^B alleles are *codominant,* and both are expressed when present. The i allele is recessive to the other two. Genotypes determining the four possible ABO blood groups are shown in Table 29.2 below.

TABLE 29.2 ABO Blood Groups

		FREQUENCY (% OF U.S. POPULATION)		
BLOOD GROUP (PHENOTYPE)	**GENOTYPE**	**WHITE**	**BLACK**	**ASIAN**
O	ii	45	49	40
A	I^AI^A or I^Ai	40	27	28
B	I^BI^B or I^Bi	11	20	27
AB	I^AI^B	4	4	5

Sex-Linked Inheritance

Inherited traits determined by genes on the sex chromosomes are said to be **sex-linked.** The X and Y sex chromosomes are not homologous in the true sense. The Y, which contains the gene (or genes) that determines maleness, is only about one-third as large as the X. The X bears over 2500 genes, and a disproportionately large number of them code for proteins important to brain function. The Y carries only 78 genes as of the last count. Hence the Y chromosome lacks many of the genes present on the X. For example, genes coding for certain clotting factors, cone pigments, and even testosterone receptors are present on X but not on Y. A gene found only on the X chromosome is said to be **X-linked.** Only relatively short regions at either end of the Y chromosome (corresponding to about 5% of the Y's DNA) code for nonsexual characteristics corresponding to those on the X, and those regions are the only areas that can participate in crossovers with the X. The balance of the Y chromosome contains eight stretches of DNA with sequences that are essentially mirror images of each other, creating what are called *genetic palindromes*—the equivalents of the sentence "MADAM I'M ADAM." The benefit of such a condition seems to be that if one of these sections bends in the middle, it can donate a gene to fix a defective copy in its neighboring area.

When a male inherits an X-linked recessive allele—for example, for hemophilia or for red-green color blindness—its expression is never masked or damped, because there is no corresponding allele on his Y chromosome. Consequently, the recessive gene is always expressed, even when present only in single dose. In contrast, females must have two X-linked recessive alleles to express such a disorder; as a result, very few females exhibit any X-linked conditions.

X-linked traits are typically passed from mother to son, never from father to son, because males receive no X chromosome from their father. Of course, the mother can also pass the recessive allele to her daughter, but unless the daughter receives another such allele from her father, she will not express the trait.

It should also be noted that some segments of the Y chromosome have no counterpart on the X chromosome. Traits coded for by genes in these segments (including the *SRY* gene necessary for proper male development and the gene for hairy ear pinnae) appear only in males and are passed from fathers to sons. This type of sex-linked gene transmission is referred to as **Y-linked inheritance.**

Polygene Inheritance

So far, we have considered only traits inherited by mechanisms of classical Mendelian genetics, which are fairly easily understood. Such traits typically have two, or perhaps three, alternate forms. However, many phenotypes depend on several gene pairs at different locations acting in tandem. Such **polygene inheritance** results in *continuous,* or *quantitative,* phenotypic variation between two extremes and explains many human characteristics. Examples of polygene traits in humans include skin color, height, and intelligence.

Skin color, for instance, is controlled by three separately inherited genes, each existing in two allelic forms: *A, a; B, b; C, c.* The *A, B,* and *C* alleles confer dark skin pigment, and their effects are additive. The *a, b,* and *c* alleles confer pale skin tone. Hence, an individual with an *AABBCC* genotype would be about as dark-skinned as a human can get, while an *aabbcc* person would be very fair. However, when individuals heterozygous for at least one of these gene pairs mate, a broad range of pigmentation is possible in their offspring. Such polygene inheritance results in a distribution of genotypes and phenotypes that, when plotted, yields a bell-shaped curve (Figure 29.5).

Height is controlled by four gene pairs, and different combinations of the tallness or shortness alleles are reflected in differences in stature in much the same way as described for inheritance of skin tone. The phenomenon of polygene inheritance helps explain why parents of average height can produce very tall or very short offspring.

Environmental Factors in Gene Expression

In many situations environmental factors override or at least influence gene expression. Although our genotype (discounting mutations) is as unchanging as the Rock of Gibraltar, our phenotype is more like clay. If this were not the case, we would never get a tan, women bodybuilders would never develop bulging muscles, and there would be no hope for treating genetic disorders.

Sometimes, such maternal factors as drugs or pathogens alter normal gene expression during embryonic development. Take, for example, the case of the "thalidomide babies" (discussed on p. 1130). As a result of their mothers taking that sedative, the embryos developed phenotypes (flipperlike appendages) not directed by their genes. Such environmentally produced phenotypes that mimic conditions that may be caused by genetic mutations (permanent transmissible changes in the DNA) are called **phenocopies.**

Equally significant are environmental factors that may influence genetic expression after birth, such as the effect of poor infant nutrition on brain growth, general body development, and height. In this way, a person with "tall genes" can be stunted by insufficient nutrition. Furthermore, hormonal deficits during childhood can lead to abnormal skeletal growth and proportions as exemplified by cretinism, a type of dwarfism resulting from hypothyroidism. This is an example of genes (or genetic abnormalities) other than those dictating height having an influence on the height phenotype. Hence, part of a gene's environment consists of the influence of other genes.

Nontraditional Inheritance

Mendel's writings underlie mainstream thinking about heredity, but some genetic outcomes fail to fit his rules. Among these nontraditional types of inheritance are influences due to RNA-only genes, to chemical groups attached to DNA or histone proteins, and to *extranuclear inheritance* conferred by mitochondrial DNA.

Beyond DNA: Regulation of Gene Expression

Our genome is a biochemical system of awesome complexity, with three basic levels of controls. The protein-coding genes that we have been describing to this point only make up the first level and account for less than 2% of the DNA of a human cell. This is the part of the genome traditionally considered to be a "blueprint" for protein structure.

Since the 1960s, scientists have been locating information important in directing development elsewhere—in the noncoding DNA and even totally outside the DNA sequences. They found, in many cases, that these second and third layers of information can account for certain cancers in cells that don't harbor mutations and for illnesses that run in families but pop up unpredictably, even differing in identical twins. For example, when one identical twin develops type 1 diabetes or schizophrenia, the other twin usually does not. So what are these other regulatory systems?

Small RNAs

The second layer appears to be the double-stranded RNA (dsRNA) product of the abundant "RNA-only genes" (see p. 109), formerly believed to be "junk," that are sequestered in the non-protein-coding DNA. They form a parallel regulatory or signaling system that consists of microRNAs (miRNAs) and short interfering RNAs (siRNAs), which can tame or inactivate aggressive (jumping) genes, called *transposons*, that tend to replicate themselves and then insert the copies into distant DNA sites, disabling or hyperactivating those genes. Small RNAs control timing of programmed cell death during development and can also prevent translation of another gene—for example, when invading viruses try to commandeer a cell's protein-making machinery to make viral proteins. Mutations in these RNA-only areas have already been linked to several conditions including prostate and lung cancers and schizophrenia. These small RNA molecules can act directly on DNA, other RNAs, or proteins and so they have an edge over proteins for transmitting information and regulating activity within the genome itself. As a result of

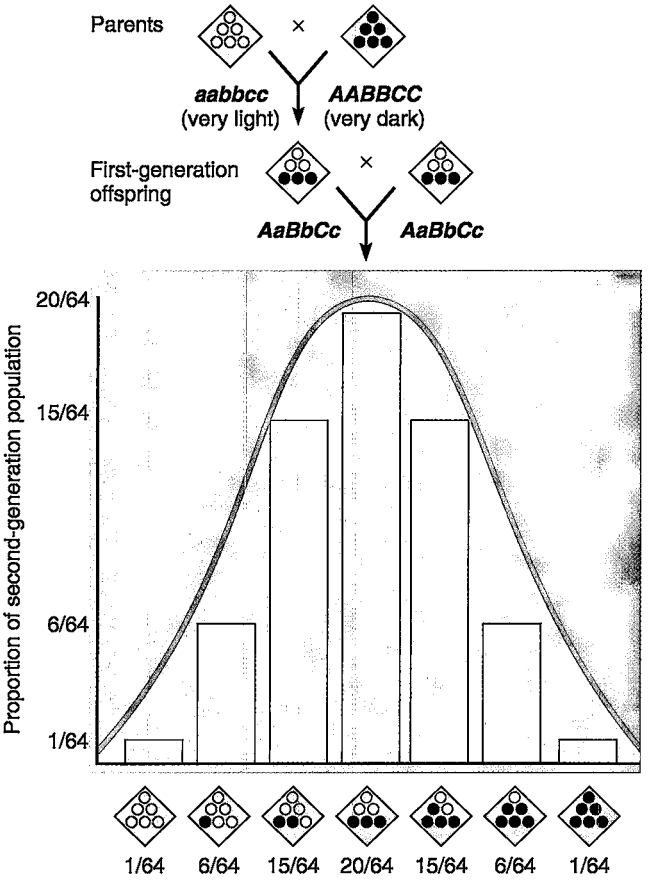

FIGURE 29.5 **Simplified model for polygenic inheritance of skin color based on three gene pairs.** Alleles for dark skin are incompletely dominant over those for light skin. Each dominant gene (*A, B, C*) contributes one "unit" of darkness (indicated by a dark dot) to the phenotypes. Here the parents are homozygotes at opposite ends of the phenotype range. Each child inherits 3 "units" of darkness (is a heterozygote) and has intermediate pigmentation. When they grow up and mate with those with a different gene pool, their offspring (second generation) may have a wide variation in pigmentation, as shown by the plotted distribution of skin colors.

the genome project, nucleotide sequences of these RNA-specifying DNA areas are now worked out and biochemical companies are investing heavily in gene therapy research. They are especially hot on synthesizing RNA-interfering drugs to silence or shut down particular genes to treat age-related macular degeneration, Parkinson's disease, cancer, hepatitis C, and a host of other disorders.

Epigenetic Marks

Epigenetic marks form the third layer of gene controls. This continually changing information is stored in the proteins and chemical groups that bind to and surround the DNA and in the manner in which chromatin is packaged in the cell. Epigenetic marks may even be passed from parent to child, yet they do not alter the associated DNA. Within cells, chemical tags such as methyl and acetyl groups bound to DNA segments and to histones determine whether the DNA is available for transcription (acetylation) or silenced (methylation), and recent evidence indicates that it is the small RNA molecules (see above) that direct the placement of chromatin tags. Epigenetic marks also account for the inactivation (by methylation) of one of the female's X chromosomes in the early embryo. Because tumor cell chromatin tends to be methyl-deficient, there is some consensus that epigenetic marks or lack of them may predispose for cell transformation from normal to cancerous. Beyond this, we now know that even slight deviations in the epigenetic marks on specific chromosomes can result in devastating human illness.

Epigenetic marks also underlie the phenomenon called genomic imprinting. For most genes, the maternal and paternal genes turn on or off at the same time. This balance is upset during gametogenesis when certain genes in both sperm and eggs are modified by the addition of methyl ($—CH_3$) groups. This process, called **genomic imprinting,** somehow tags the genes as paternal or maternal and confers important functional differences in the resulting embryo; this is essential for normal development. The developing embryo "reads" these tags, and then either expresses the mother's gene while the father's version remains idle or vice versa. The methylation process is reversible. In each generation, the old imprints are "erased" when new gametes are produced and all the chromosomes are newly imprinted according to the sex of the parents. Mutations of imprinted genes may lead to pathology. For example, victims of Prader-Willi syndrome are mildly to moderately retarded, short, and grossly obese. Children with Angelman syndrome are severely retarded, unable to speak coherently, laugh uncontrollably, and exhibit jerky, lurching movements as if tied to a puppeteer's strings (the French name for this condition is *marionette joyeuse*). The symptoms of these two disorders are very different, but the genetic cause is the same—deletion of a particular region of chromosome 15. If the defective chromosome comes from the father, the result is Prader-Willi syndrome; the mother's defective chromosome confers Angelman syndrome. Thus, it seems that the same allele can have different effects depending on which parent it comes from. Losing imprints in certain DNA segments may explain differences in the expression of schizophrenia and other inherited diseases seen in identical twins.

The power of these three levels of genetic expression and regulation is seen in a research study on a particular trait in sheep. The recipe for the trait and pedigree was seen to involve a standard protein-specifying gene, one or more RNA-only genes, and two epigenetic effects. It is now clear that protein-coding genes are not the only instructions to which cells refer. RNA matters, and so do the tiny chemical tags that attach to the chromatin.

Extranuclear (Mitochondrial) Inheritance

Although we have focused on the chromosomal basis of inheritance, remember that not all genes are in the cell's nucleus. Some 37 genes (referred to as mtDNA) are in mitochondria. Because the ovum donates essentially all the cytoplasm in the fertilized egg, mitochondrial genes are transmitted to the offspring almost exclusively by the mother. A growing list of disorders, all rare, is now being linked to errors (mutations) in mitochondrial genes. Most involve problems with oxidative phosphorylation within the mitochondria, or more rarely unusual degenerative muscle disorders or neurological problems. Some researchers suggest that Alzheimer's and Parkinson's disease may be among them.

Genetic Screening, Counseling, and Therapy

Genetic screening and *genetic counseling* provide information and options for prospective parents not even dreamed of 100 years ago. Newborn infants are routinely screened for a number of anatomical disorders (congenital hip dysplasia, imperforate anus, and others), and testing for phenylketonuria (PKU) and other metabolic diseases is mandated by law in many states. These tests are performed much too late to allow parental choice concerning whether or not to have the child, but they do alert the new parents that treatment is necessary to ensure the

well-being of their infant. Anatomical defects are usually treated surgically, and PKU is managed by strict dietary measures that exclude most phenylalanine-containing foods.

Adult children of parents with Huntington's disease are obvious candidates for these services, but many other genetic conditions also place babies at risk. For example, a woman pregnant at age 35 may wish to know if her baby has trisomy-21 or Down syndrome (see Related Clinical Terms, p. 1157), a chromosome abnormality with a high incidence in children of older mothers.

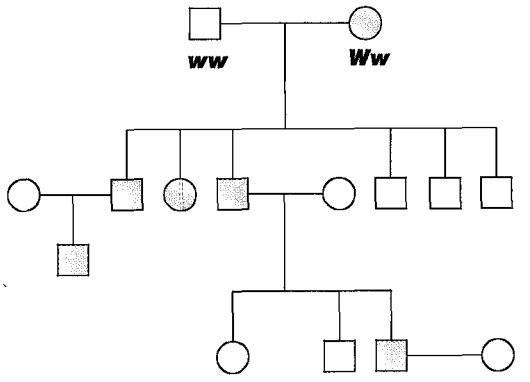
Depending on the condition being investigated, screening can occur before conception, by carrier recognition, or during fetal testing.

Carrier Recognition

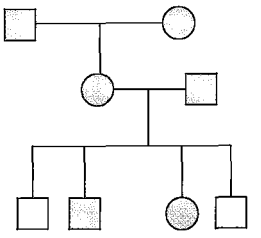
When a prospective parent displays a recessive genetic disorder but his or her partner does not, it is important to find out if the partner is heterozygous for the same recessive gene. If not, the offspring will receive only one such gene and will not express the trait. If the partner *is* a carrier, the child's chance of having two harmful genes is 50%.

There are two major avenues for identifying carriers: pedigrees and blood tests. A **pedigree** traces a genetic trait through several generations and helps predict the future. For prospective parents, a genetic counselor collects phenotype information on as many family members as possible and uses it to construct the pedigree. Figure 29.6a uses the rare woolly hair trait of northern Europeans to illustrate how a pedigree is constructed and read. Woolly hair, resulting from the presence of a dominant allele *(W)*, is fuzzy-textured and breaks easily. Individuals with the woolly hair phenotype (purple symbols) have at least one dominant gene *(WW* or *Ww)*, while those with normal hair must be homozygous recessive *(ww)*. By working backward from the bottom row and applying the rules of dominant-recessive inheritance, the counselor can deduce the genotypes of the parents (middle row). That three of their six offspring have normal hair *(ww)* tells the counselor that each parent must have at least one recessive gene. The mother has woolly hair, determined by the *W* gene, and so her genotype must be *Ww*. The father with normal hair must be homozygous recessive. You should be able to take it from here and figure out the genotypes of the offspring. (Try it!)

Figure 29.6b illustrates a pedigree analysis for albinism, a recessive trait. See what you can deduce from it. These pedigrees represent two of the simplest cases. Many human traits are controlled by multiple alleles or polygenes and are much more difficult to work out.



(a) Pedigree of a dominant trait



(b) Pedigree of a recessive trait

FIGURE 29.6 **Pedigree analysis to detect carriers of particular genes.** Circles represent females; squares represent males. Horizontal lines indicate a mating of connected individuals; vertical lines show offspring of a mating. **(a)** Pedigree tracing the dominant woolly hair gene in three generations of a family. Purple symbols represent individuals expressing the dominant woolly hair trait. White symbols represent those not expressing the trait; these individuals are homozygous recessive *(ww)*. **(b)** Pedigree tracing the recessive trait albinism (lack of skin pigmentation) through three generations (*P* = pigmented skin, dominant; *p* = albinism, recessive). Both parents in the second generation have pigmented skin (purple symbols), and yet two of their four children have the albino trait (white symbols). We can deduce that both these parents are heterozygous and have pigmented skin because the allele for that trait is dominant.

Simple blood tests are used to screen for the sickling gene in heterozygotes, and sophisticated *blood chemistry tests* and *DNA probes* can detect the presence of other unexpressed recessive genes. At present, carriers of the Tay-Sachs and cystic fibrosis genes can be identified with such tests.

Fetal Testing

Fetal testing is used when there is a known risk of a genetic disorder. The most common type of fetal testing is **amniocentesis** (am"ne-o-sen-te'sis). In this fairly simple procedure, a wide-bore needle is inserted into the amniotic sac through the mother's

Q *What noninvasive imaging technique is used to determine some aspects of fetal development? (You might want to check* A Closer Look *in Chapter 1 for this.)*

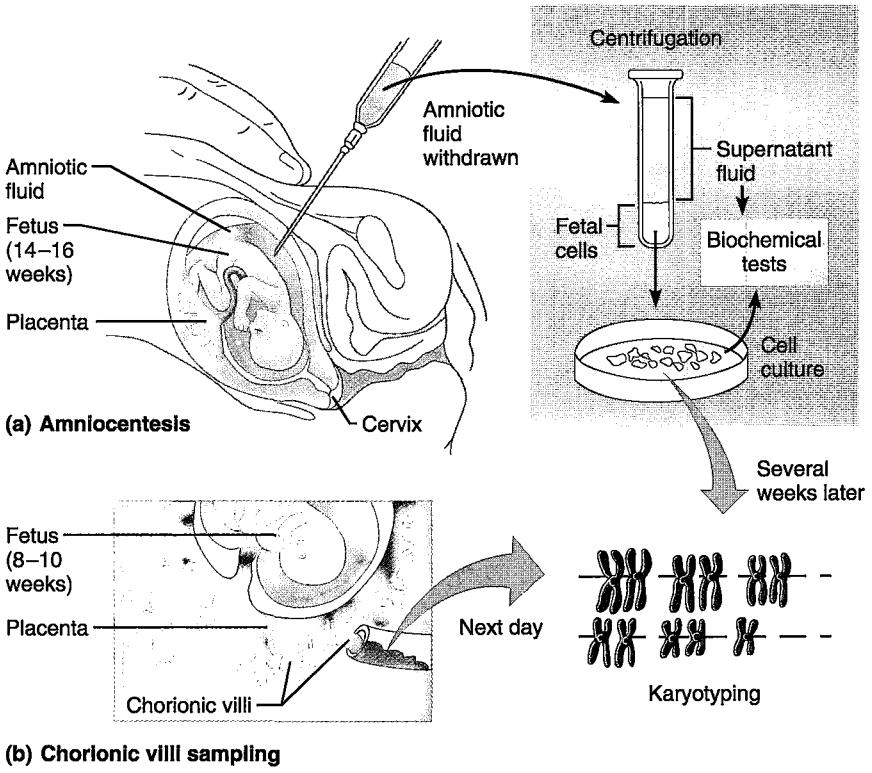


FIGURE 29.7 **Fetal testing. (a)** In amniocentesis, ultrasound is used to locate the fetus, and a small amount of amniotic fluid is extracted. Physicians can diagnose some disorders from chemicals in the fluid, and other disorders may show up in tests performed on cells cultured from fetal cells present in the fluid. These tests include biochemical tests to detect the presence of certain enzymes, and karyotyping, to determine whether fetal chromosomes are normal in number and appearance. **(b)** In chorionic villi sampling, a physician inserts a narrow tube through the cervix and suctions out a tiny sample of fetal tissue (chorionic villi) from the placenta. The fetal tissue sample is used immediately for karyotyping.

abdominal wall (Figure 29.7a), and about 10 ml of fluid is withdrawn. Because there is a chance of injuring the fetus before ample amniotic fluid is present, this procedure is not normally done before the 14th week of pregnancy. Using ultrasound to visualize the position of the fetus and the amniotic sac has dramatically reduced the risk of this procedure. Although the fluid is checked for enzymes and other chemicals that serve as markers for specific diseases, most tests are done on the sloughed-off fetal cells in the fluid. These cells are isolated and cultured in laboratory dishes over a period of several weeks. Then the cells are examined for DNA markers of genetic disease and karyotyped (see Figure 29.1) to check for chromosomal abnormalities.

Chorionic villi sampling (CVS) suctions off bits of the chorionic villi from the placenta for examination (Figure 29.7b). A small tube is inserted through the vagina and cervical canal and guided by ultrasound to an area where a piece of placental tissue can be removed. CVS allows testing at eight weeks (but waiting until after the tenth week is usually recommended) and is much faster than amniocentesis. Karyotyping can be done almost immediately on the rapidly dividing chorionic cells.

Because both of these procedures are invasive, they carry with them an inherent risk to both fetus and mother. (For example, increased fetal risk of finger and toe defects is linked to CVS.) Although these tests are routinely ordered for pregnant women over 35 (because of the enhanced risk of Down syndrome), they are performed on younger women only when the probability of finding a severe fetal disorder is greater than the probability of doing

A Ultrasound scanning.

harm during the procedure. If a serious genetic or congenital defect is detected in the developing fetus, the parents must decide whether or not to continue the pregnancy.

Human Gene Therapy

As indicated earlier, the genome project has opened an exciting world to scientists investigating gene expression. As advances have been made in diagnosing human genetic diseases, new applications of "gene therapy" to alleviate or even cure the disorders have been quick to follow, particularly in cases traced to a single defective gene or protein. Indeed, genetic engineering has the potential to replace a defective gene with a normal version. One approach (used successfully in treatment of SCID) is to "infect" the defective cells with a virus into which a functional gene has been inserted; another is to inject the "corrected" DNA directly into the patient's cells. Such therapies have had mixed results in treating cystic fibrosis and muscular dystrophy. However, genetic engineering processes are prohibitively expensive and raise some thorny ethical, religious, and societal questions: Who will pay? Who determines who will be treated with the new therapies? Are we playing God?

▪ ▪ ▪

In this chapter, we have explored some of the basic principles of genetics, the manner in which genes are expressed, and the means by which gene expression can be modified. Considering the precision required to make perfect copies of genes and chromosomes, and considering the incredible mechanical events of meiotic division, it is amazing that genetic defects are as rare as they are. Perhaps, after reading this chapter, you have a greater sense of wonder that you turned out as well as you did.

Related Clinical Terms

Deletion Chromosomal aberration in which part of a chromosome is lost.

Down syndrome Formerly called mongolism, this condition usually reflects the presence of an extra autosome (trisomy of chromosome 21); the child has slightly slanted eyes, flattened facial features, a large tongue, and a tendency toward short stature and stubby fingers. Some, but not all, affected people are mentally retarded. Down syndrome individuals have mitochondrial defects, which have been associated with neurodegeneration in other disorders. A distinctive feature of Down syndrome is early onset of Alzheimer's disease. The most important risk factor appears to be advanced maternal (or paternal) age.

Mutation (*mutare* = change) A permanent structural change in a gene; the mutation may or may not affect function, depending on the precise site and nature of the alteration.

Nondisjunction Abnormal segregation of chromosomes during meiosis, resulting in gametes receiving two or no copies of a particular parental chromosome; more common in female meiosis than in male meiosis. If the abnormal gamete participates in fertilization, the resulting zygote will have an abnormal chromosomal complement (monosomy or trisomy) for that particular chromosome (as in Down syndrome).

Chapter Summary

1. Genetics is the study of heredity and mechanisms of gene transmission.

The Vocabulary of Genetics (pp. 1146–1147)

1. A complete diploid set of chromosomes is called the karyotype of an organism; the complete genetic complement is the genome. A person's genome consists of two sets of instructions, one from each parent.

Gene Pairs (Alleles) (p. 1146)

2. Genes coding for the same trait and found at the same locus on homologous chromosomes are called alleles.

3. Alleles may be the same or different in expression. When the allele pair is identical, the person is homozygous for that trait; when the alleles differ, the person is heterozygous.

Genotype and Phenotype (p. 1147)

4. The actual genetic makeup of cells is the genotype; phenotype is the manner in which those genes are expressed.

Sexual Sources of Genetic Variation (pp. 1147–1149)

Chromosome Segregation and Independent Assortment (pp. 1147–1148)

1. During meiosis I of gametogenesis, tetrads align randomly on the metaphase plate, and chromatids are randomly distributed to the daughter cells. This is called independent assortment of the homologues. Each gamete receives only one allele of each gene pair.

2. Each different metaphase I alignment produces a different assortment of parental chromosomes in the gametes, and all combinations of maternal and paternal chromosomes are equally possible.

Crossover of Homologues and Gene Recombination (pp. 1148–1149)

3. During meiosis I, two to four of the four chromatids of each tetrad may cross over at one or more points and exchange corresponding gene segments. The recombinant

chromosomes contain new gene combinations, adding to the variability arising from independent assortment.

Random Fertilization (p. 1149)

4. The third source of genetic variation is random fertilization of eggs by sperm.

Types of Inheritance (pp. 1149–1153)

Dominant-Recessive Inheritance (pp. 1149–1151)

1. Dominant genes are expressed when present in single or double dose; recessive genes must be present in double dose to be expressed.

2. For traits following the dominant-recessive pattern, the laws of probability predict the outcome of a large number of matings.

3. Genetic disorders more often reflect the homozygous recessive condition than the homozygous dominant or heterozygous condition because dominant genes are expressed and, if they are lethal genes, the pregnancy usually results in miscarriage. Genetic disorders caused by dominant alleles include achondroplasia and Huntington's disease; recessive disorders include cystic fibrosis and Tay-Sachs disease.

4. Carriers are heterozygotes who carry a deleterious recessive gene (but do not express the trait) and have the potential of passing it on to offspring.

Incomplete Dominance (p. 1151)

5. In incomplete dominance, the heterozygote exhibits a phenotype intermediate between those of the homozygous dominant and recessive individuals. Inheritance of sickle-cell trait is an example of incomplete dominance.

Multiple-Allele Inheritance (p. 1151)

6. Multiple-allele inheritance involves genes that exist in more than two allelic forms in a population. Only two of the alleles are inherited, but on a random basis. Inheritance of ABO blood types is an example of multiple-allele inheritance in which the I^A and I^B alleles are codominant.

Sex-Linked Inheritance (p. 1152)

7. Traits determined by genes on the X and Y chromosomes are said to be sex-linked. The small Y chromosome lacks most genes present on the X chromosome. Recessive genes located only on the X chromosome are expressed in single dose in males. Examples of such X-linked conditions, passed from mother to son, include hemophilia and red-green color blindness. There are a few Y-linked genes, passed from father to son only.

Polygene Inheritance (pp. 1152–1153)

8. Polygene inheritance occurs when several gene pairs interact to produce phenotypes that vary quantitatively over a broad range. Height, intelligence, and skin pigmentation are examples.

Environmental Factors in Gene Expression (p. 1153)

1. Environmental factors may influence the expression of genotype.

2. Maternal factors that cross the placenta may alter expression of fetal genes. Environmentally provoked phenotypes that mimic genetically determined ones are called phenocopies. Nutritional deficits or hormonal imbalances may alter anticipated growth and development during childhood.

Nontraditional Inheritance (pp. 1153–1154)

Beyond DNA: Regulation of Gene Expression (pp. 1153–1154)

1. Three levels encompass the genome: protein-coding genes, RNA-only genes, and epigenetic marks. The latter two account for many cases of inherited disease that fail to follow traditional genetics.

2. The product of the RNA-only genes (siRNA and miRNA) may silence genes or prevent their expression and appear to play a role in directing apoptosis during development.

3. Epigenetic marks encompass the attachment of small chemical groups (methyl or acetyl) to DNA or histone proteins. In general, methylation prevents access to the DNA whereas acetylation provides access to the DNA. Genomic imprinting, which involves methylation of certain genes during gametogenesis, confers different effects and phenotypes on maternal and paternal genes. It is reversible, and occurs anew each generation.

Extranuclear (Mitochondrial) Inheritance (p. 1154)

4. Cytoplasmic (mitochondrial) genes pass to offspring via the ovum and help to determine certain characteristics. Deletions or mutations in mitochondrial genes are responsible for some problems with oxidative phosphorylation and some rare genetic diseases.

Genetic Screening, Counseling, and Therapy (pp. 1154–1157)

Carrier Recognition (p. 1155)

1. The likelihood of an individual carrying a deleterious recessive gene may be assessed by constructing a pedigree. Some of these genes can be deduced by various blood tests and DNA probes.

Fetal Testing (pp. 1155–1157)

2. Amniocentesis is fetal testing based on aspirated samples of amniotic fluid. Fetal cells in the fluid are cultured for several weeks, then examined for chromosomal defects (karyotyped) or for DNA markers of genetic disease. Amniocentesis cannot be performed until the 14th week of pregnancy.

3. Chorionic villi sampling is fetal testing based on a sample of the chorion. This tissue is rapidly mitotic, so karyotyping can be done almost immediately. Samples may be obtained by the eighth week.

Human Gene Therapy (p. 1157)

4. The Human Genome Project has allowed research on diagnosis of genetic disease and on its treatment to surge forward. Thus far, gene therapy has been particularly useful for correcting single-gene disorders. The most common approach involves transferring a corrected gene via a virus (or some other vector) to the affected cells to restore normal function.

Review Questions

Multiple Choice/Matching

(Some questions have more than one correct answer. Select the best answer or answers from the choices given.)

1. Match one of the following terms (a–i) with each of the appropriate descriptions below:

Key: (a) alleles (b) autosomes (c) dominant allele (d) genotype (e) heterozygote (f) homozygote (g) phenotype (h) recessive allele (i) sex chromosomes

____ (1) genetic makeup
____ (2) how genetic makeup is expressed
____ (3) chromosomes that dictate most body characteristics
____ (4) alternate forms of the same gene
____ (5) an individual bearing two alleles that are the same for a particular trait
____ (6) an allele that is expressed whether in single or double dose
____ (7) an individual bearing two alleles that differ for a particular trait
____ (8) an allele that must be present in double dose to be expressed

2. Match the following types of inheritance (a–e) with the descriptions below:

Key: (a) dominant-recessive (b) incomplete dominance (c) multiple-allele (d) polygene (e) sex-linked (f) extranuclear

____ (1) only sons show the trait
____ (2) homozygotes and heterozygotes have the same phenotype
____ (3) heterozygotes exhibit a phenotype intermediate between those of the homozygotes
____ (4) phenotypes of offspring may be more varied than those of the parents
____ (5) inheritance of ABO blood types
____ (6) inheritance of stature
____ (7) reflects activity of mitochondrial DNA

Short Answer Essay Questions

3. Describe the important mechanisms that lead to genetic variations in gametes.

4. The ability to taste PTC (phenylthiocarbamide) depends on the presence of a dominant gene *T*; nontasters are homozygous for the recessive gene *t*. This is a situation of classical dominant-recessive inheritance. (a) Consider a mating between heterozygous parents producing three offspring. What proportion of the offspring will be tasters? What is the chance that all three offspring will be tasters? Nontasters? What is the chance that two will be tasters and one will be a nontaster? (b) Consider a mating between *Tt* and *tt* parents. What is the anticipated percentage of tasters? Nontasters? What proportion can be expected to be homozygous recessive? Heterozygous? Homozygous dominant?

5. Most albino children are born to normally pigmented parents. Albinos are homozygous for the recessive gene *(aa)*. What can you conclude about the genotypes of the nonalbino parents?

6. A woman with blood type A has two children. One has type O blood and the other has type B blood. What is the genotype of the mother? What are the genotype and phenotype of the father? What is the genotype of each child?

7. In skin color inheritance, what will be the relative range of pigmentation in offspring arising from the following parental matches? (a) *AABBCC* × *aabbcc*, (b) *AABBCC* × *AaBbCc*, (c) *Aabbcc* × *aabbcc*.

8. Compare and contrast amniocentesis and chorionic villi sampling as to the time at which they can be performed and the techniques used to obtain information on the fetus's genetic status.

Critical Thinking and Clinical Application Questions

1. A color-blind man marries a woman with normal vision. The woman's father was also color-blind. (a) What is the chance that their first child will be a color-blind son? A color-blind daughter? (b) If they have four children, what is the chance that two will be color-blind sons? (Be careful on this one.)

2. Brian is a college student. His genetics assignment is to do a family pedigree for dimples in the cheeks. Absence of dimples is recessive; presence of dimples reflects a dominant allele. Brian has dimples, as do his three brothers. His mother and maternal grandmother are dimple free, but his father and all other grandparents have dimples. Construct a pedigree spanning three generations for Brian's family. Show the phenotype and genotype for each person.

3. Mr. and Mrs. Lehman have sought genetic counseling. Mrs. Lehman is concerned because she is unexpectedly pregnant and her husband's brother died of Tay-Sachs disease. She can recall no incidence of Tay-Sachs disease in her own family. Do you think biochemical testing should be recommended to detect the deleterious gene in Mrs. Lehman? Explain your answer.

4. The Browns are both carriers of the recessive allele that causes the metabolic disorder called phenylketonuria. What is the probability of each of the following occurring? (a) All three children will have the disorder. (b) None of their three children will have the disorder. (c) One or more of their children will have the disorder. (d) At least one of their children will be phenotypically normal.

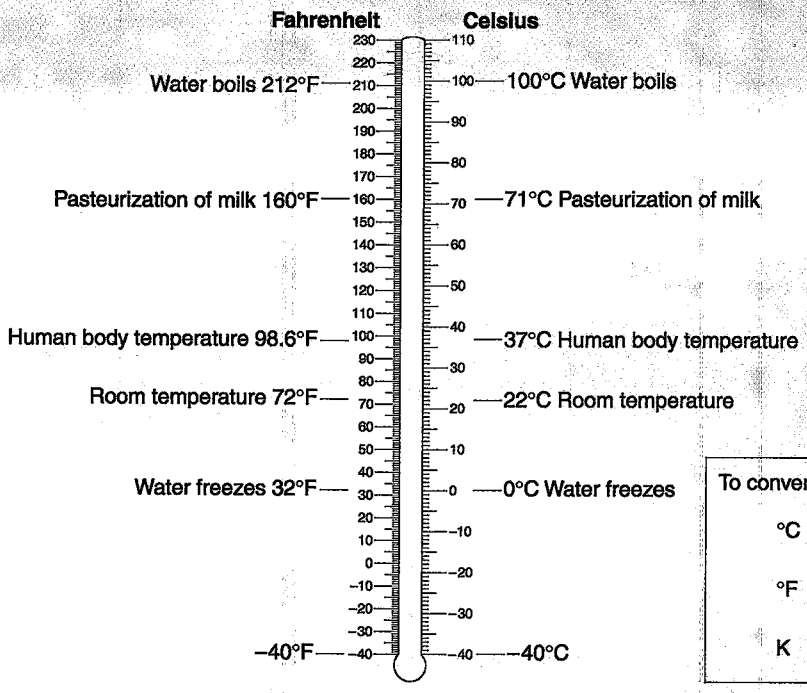
	1 milligram (mg)	= 0.001 gram	1 mg = approx. 0.015 grain	
	1 microgram (μg)	= 0.000001 gram		
Volume (solids)	1 cubic meter (m^3)	= 1,000,000 cubic centimeters	1 m^3 = 1.3080 cubic yards 1 m^3 = 35.315 cubic feet	1 cubic yard = 0.7646 m^3 1 cubic foot = 0.0283 m^3
	1 cubic centimeter (cm^3 or cc)	= 0.000001 cubic meter = 1 milliliter	1 cm^3 = 0.0610 cubic inch	1 cubic inch = 16.387 cm^3
	1 cubic millimeter (mm^3)	= 0.000000001 cubic meter		
Volume (liquids and gases)	1 kiloliter (kl or kL)	= 1000 liters	1 kL = 264.17 gallons	1 gallon = 3.785 L
	1 liter (l or L)	= 1000 milliliters	1 L = 0.264 gallon 1 L = 1.057 quarts	1 quart = 0.946 L
	1 milliliter (ml or mL)	= 0.001 liter = 1 cubic centimeter	1 ml = 0.034 fluid ounce 1 ml = approx. $\frac{1}{5}$ teaspoon 1 ml = approx. 15–16 drops (gtt)	1 quart = 946 ml 1 pint = 473 ml 1 fluid ounce = 29.57 ml 1 teaspoon = approx. 5 ml
	1 microliter (μl or μL)	= 0.000001 liter		
Time	1 second (s)	= $\frac{1}{60}$ minute		
	1 millisecond (ms)	= 0.001 second		
Temperature	Degrees Celsius (°C)		°F = $\frac{9}{5}$(°C) + 32	°C = $\frac{5}{9}$(°F − 32)



Fahrenheit and Celsius scales compared

To convert temperature scales:

$$°C = \frac{5(°F - 32)}{9}$$

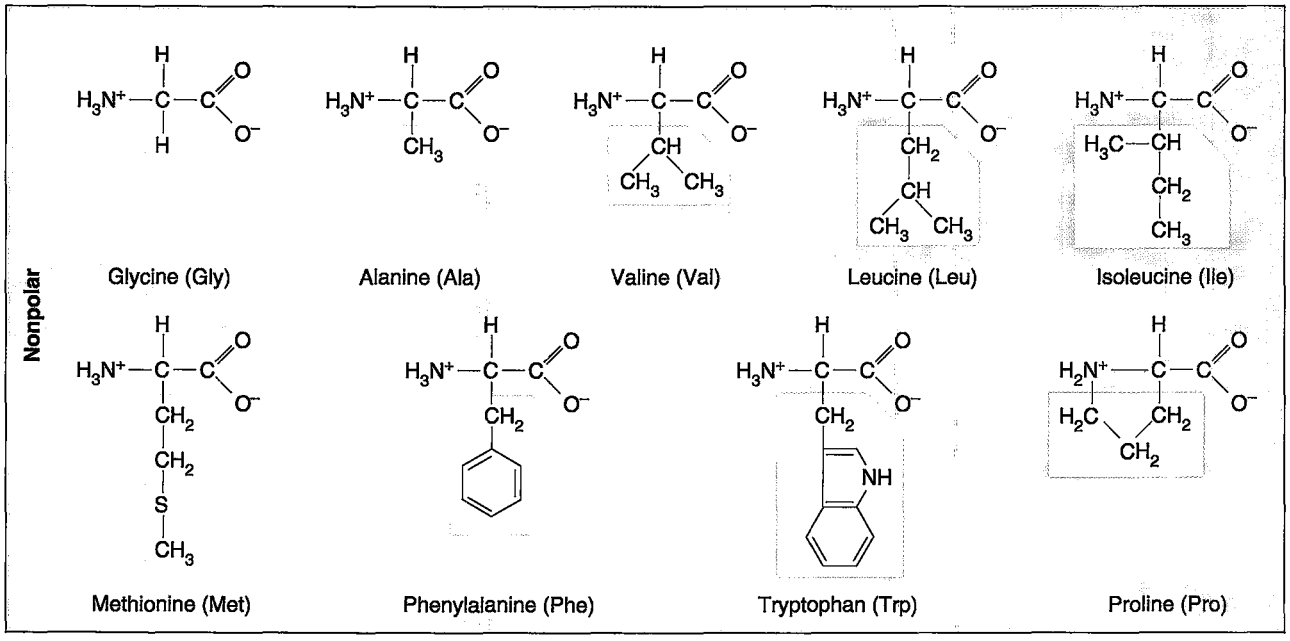
$$°F = \frac{9°(C)}{5} + 32$$

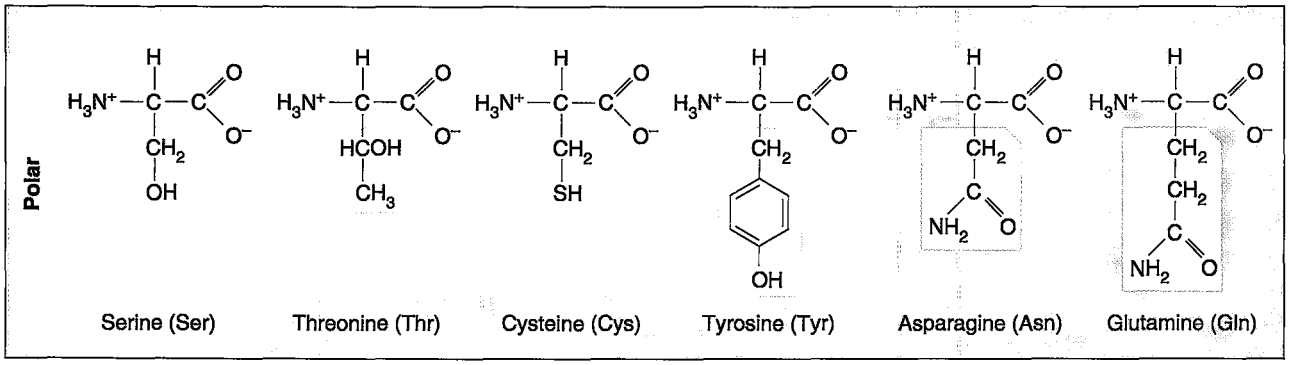
$$K = °C + 273$$

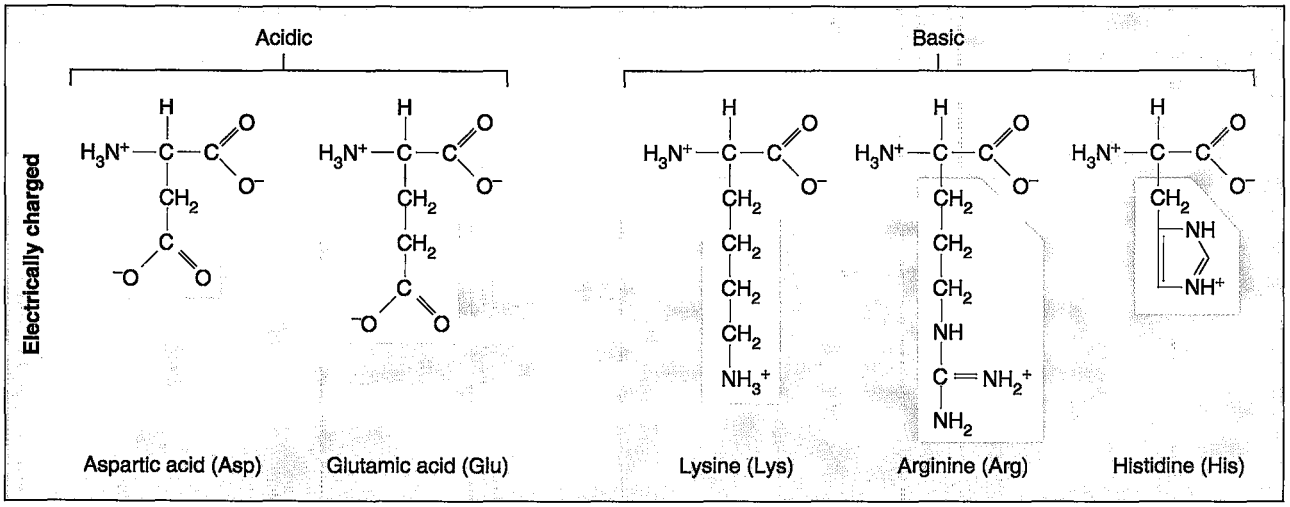
Appendix B
Functional Groups in Organic Molecules

Functional group	General formula	Name of compounds	Example	Where else found
Hydroxyl —OH (or HO—)	—O—H	Alcohols	 Ethanol	Sugars; water-soluble vitamins
Carbonyl 		Aldehydes	 Propanal	Some sugars; formaldehyde (a preservative)
		Ketones	 Acetone	Some sugars; "ketone bodies" in urine (from fat breakdown)
Carboxyl —COOH		Carboxylic acids	 Acetic acid	Amino acids; proteins; some vitamins; fatty acids
Amino —NH_2 (or H_2N—)		Amines	 Methylamine	Amino acids; proteins; urea in urine (from protein breakdown)

Appendix C
The Amino Acids







Appendix D
Two Important Metabolic Pathways

Step 1 Glucose enters the cell and is phosphorylated by the enzyme hexokinase, which catalyzes the transfer of a phosphate group, indicated as P_i, from ATP to the number six carbon of the sugar, producing glucose-6-phosphate. The electrical charge of the phosphate group traps the sugar in the cell because of the impermeability of the plasma membrane to ions. Phosphorylation of glucose also makes the molecule more chemically reactive. Although glycolysis is supposed to *produce* ATP, in step 1 ATP is actually consumed—an energy investment that will be repaid with dividends later in glycolysis.

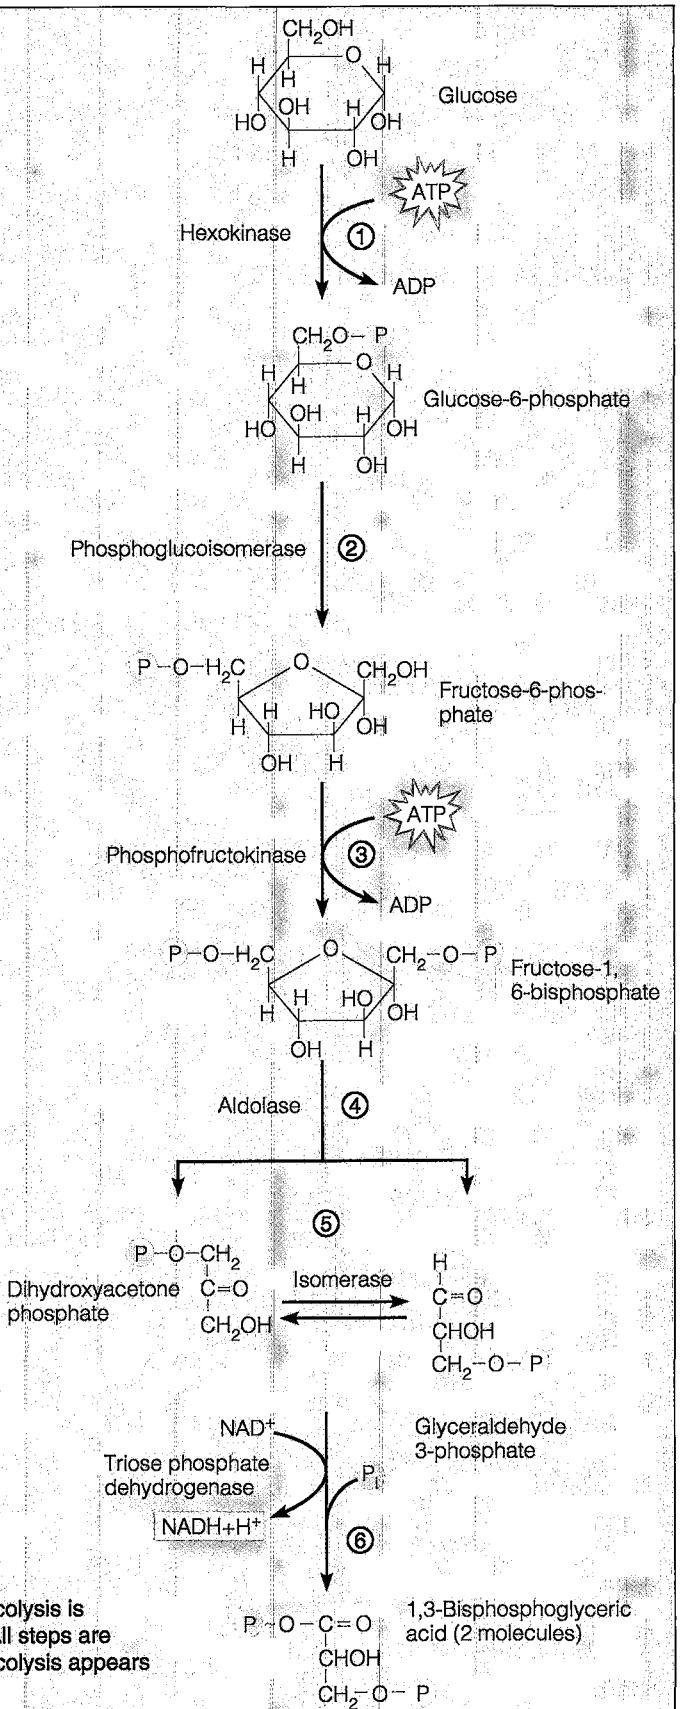
Step 2 Glucose-6-phosphate is rearranged and converted to its isomer, fructose-6-phosphate. Isomers, remember, have the same number and types of atoms but in different structural arrangements.

Step 3 In this step, still another molecule of ATP is used to add a second phosphate group to the sugar, producing fructose-1,6-bisphosphate. So far, the ATP ledger shows a debit of –2. With phosphate groups on its opposite ends, the sugar is now ready to be split in half.

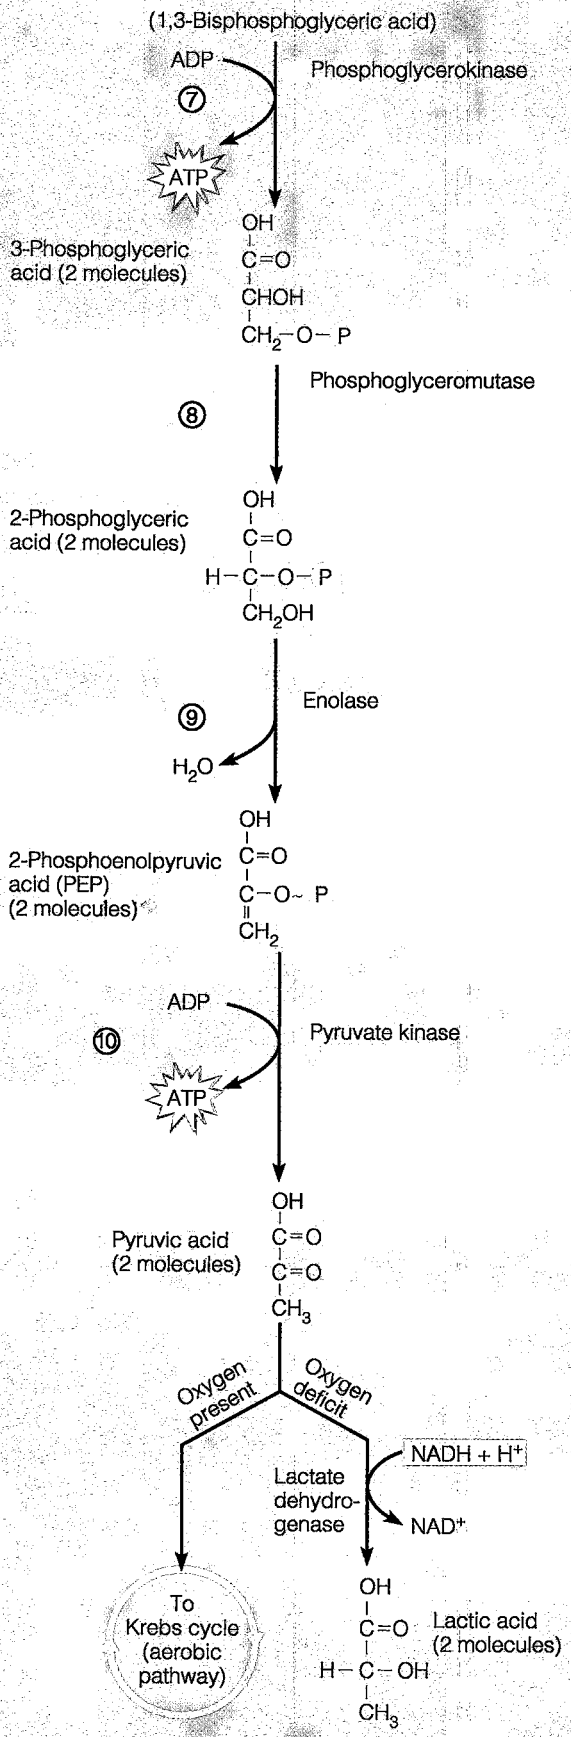
Step 4 This is the reaction from which glycolysis gets its name. An enzyme cleaves the sugar molecule into two different 3-carbon sugars: glyceraldehyde 3-phosphate and dihydroxyacetone phosphate. These two sugars are isomers of one another.

Step 5 The isomerase enzyme interconverts the 3-carbon sugars, and if left alone in a test tube, the reaction reaches equilibrium. This does not happen in the cell, however, because the next enzyme in glycolysis uses only glyceraldehyde phosphate as its substrate and is unreceptive to dihydroxyacetone phosphate. This pulls the equilibrium between the two 3-carbon sugars in the direction of glyceraldehyde phosphate, which is removed as fast as it forms. Thus, the net result of steps 4 and 5 is cleavage of a 6-carbon sugar into two molecules of glyceraldehyde phosphate; each will progress through the remaining steps of glycolysis.

Step 6 An enzyme now catalyzes two sequential reactions while it holds glyceraldehyde phosphate in its active site. First, the sugar is oxidized by the transfer of H from the number one carbon of the sugar to NAD, forming $NADH + H^+$. Here we see in metabolic context the oxidation-reduction reaction described in Chapter 24. This reaction releases substantial amounts of energy, and the enzyme capitalizes on this by coupling the reaction to the creation of a high-energy phosphate bond at the number one carbon of the oxidized substrate. The source of the phosphate is inorganic phosphate (P_i) always present in the cytosol. The enzyme releases $NADH + H^+$ and 1,3-bisphosphoglyceric acid as products. Notice in the figure that the new phosphate bond is symbolized with a squiggle (~), which indicates that the bond is at least as energetic as the high-energy phosphate bonds of ATP.



THE TEN STEPS OF GLYCOLYSIS Each of the ten steps of glycolysis is catalyzed by a specific enzyme found dissolved in the cytoplasm. All steps are reversible. An abbreviated version of the three major phases of glycolysis appears in the lower right-hand corner of the second page.

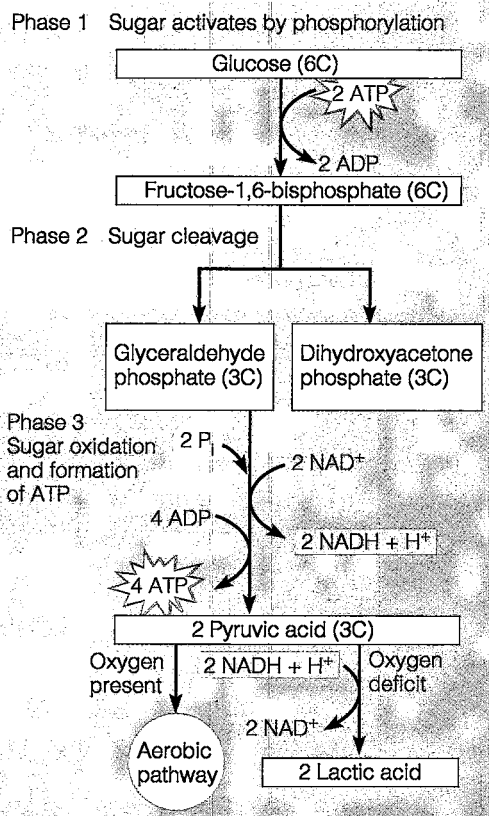


Step 7 Finally, glycolysis produces ATP. The phosphate group, with its high-energy bond, is transferred from 1,3-bisphosphoglyceric acid to ADP. For each glucose molecule that began glycolysis, step 7 produces two molecules of ATP, because every product after the sugar-splitting step (step 4) is doubled. Of course, two ATPs were invested to get sugar ready for splitting. The ATP ledger now stands at zero. By the end of step 7, glucose has been converted to two molecules of 3-phosphoglyceric acid. This compound is not a sugar. The sugar was oxidized to an organic acid back in step 6, and now the energy made available by that oxidation has been used to make ATP.

Step 8 Next, an enzyme relocates the remaining phosphate group of 3-phosphoglyceric acid to form 2-phosphoglyceric acid. This prepares the substrate for the next reaction.

Step 9 An enzyme forms a double bond in the substrate by removing a water molecule from 2-phosphoglyceric acid to form phosphoenolpyruvic acid, or PEP. This results in the electrons of the substrate being rearranged in such a way that the remaining phosphate bond becomes very unstable; it has been upgraded to high-energy status.

Step 10 The last reaction of glycolysis produces another molecule of ATP by transferring the phosphate group from PEP to ADP. Because this step occurs twice for each glucose molecule, the ATP ledger now shows a net gain of two ATPs. Steps 7 and 10 each produce two ATPs for a total credit of four, but a debt of two ATPs was incurred from steps 1 and 3. Glycolysis has repaid the ATP investment with 100% interest. In the meantime, glucose has been broken down and oxidized to two molecules of pyruvic acid, the compound produced from PEP in step 10.



Step 1 Two-carbon acetyl CoA is combined with oxaloacetic acid, a 4-carbon compound. The unstable bond between the acetyl group and CoA is broken as oxaloacetic acid binds and CoA is freed to prime another 2-carbon fragment derived from pyruvic acid. The product is the 6-carbon citric acid, for which the cycle is named.

Step 2 A molecule of water is removed, and another is added back. The net result is the conversion of citric acid to its isomer, isocitric acid.

Step 3 The substrate loses a CO_2 molecule, and the remaining 5-carbon compound is oxidized, forming an α-ketoglutaric acid and reducing NAD^+.

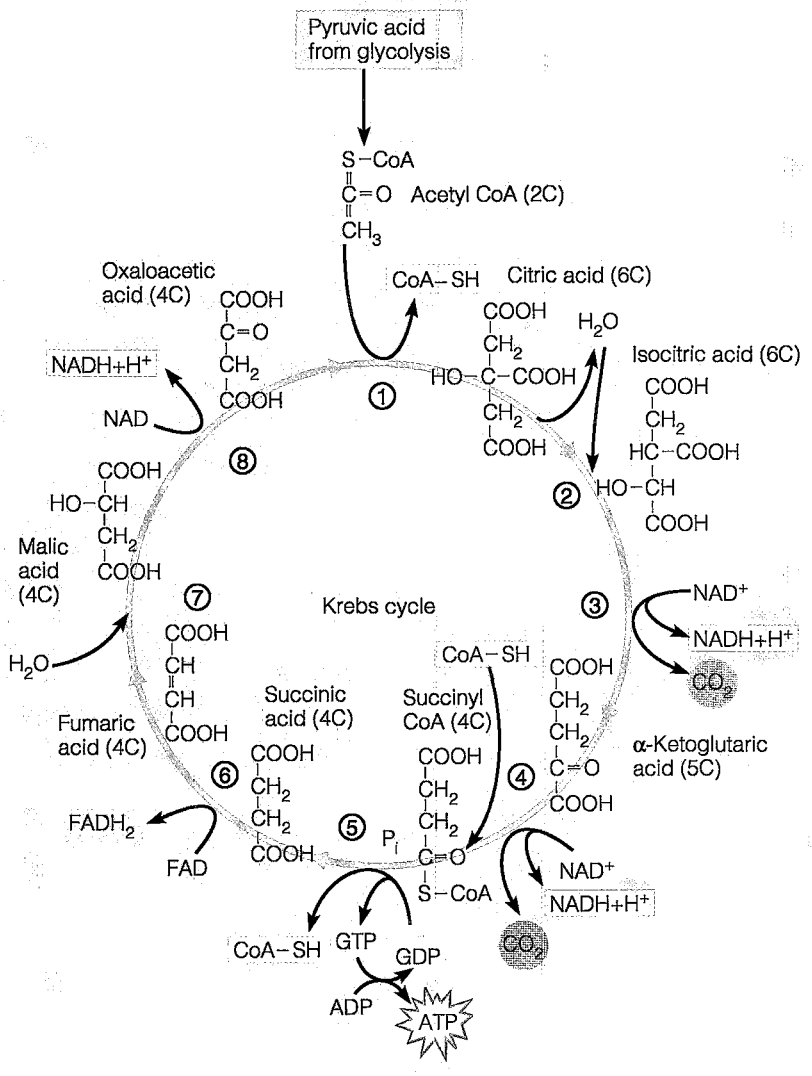
Step 4 This step is catalyzed by a multienzyme complex very similar to the one that converts pyruvic acid to acetyl CoA. CO_2 is lost; the remaining 4-carbon compound is oxidized by the transfer of electrons to NAD^+ to form $NADH+H^+$ and is then attached to CoA by an unstable bond. The product is succinyl CoA.

Step 5 Substrate-level phosphorylation occurs in this step. CoA is displaced by a phosphate group, which is then transferred to GDP to form guanosinetriphosphate (GTP). GTP is similar to ATP, which is formed when GTP donates a phosphate group to ADP. The products of this step are succinic acid and ATP.

Step 6 In another oxidative step, two hydrogens are removed from succinic acid, forming fumaric acid, and transferred to FAD to form $FADH_2$. The function of this coenzyme is similar to that of $NADH+H^+$, but $FADH_2$ stores less energy. The enzyme that catalyzes this oxidation-reduction reaction is the only enzyme of the cycle that is embedded in the mitochondrial membrane. All other enzymes of the citric acid cycle are dissolved in the mitochondrial matrix.

Step 7 Bonds in the substrate are rearranged in this step by the addition of a water molecule. The product is malic acid.

Step 8 The last oxidative step reduces another NAD^+ and regenerates oxaloacetic acid, which accepts a 2-carbon fragment from acetyl CoA for another turn of the cycle.



Krebs Cycle (Citric Acid Cycle) All but one of the steps (step 6) occur in the mitochondrial matrix. The preparation of pyruvic acid (by oxidation, decarboxylation, and reaction with coenzyme A) to enter the cycle as acetyl CoA is shown above the cycle. Acetyl CoA is picked up by oxaloacetic acid to form citric acid; and as it passes through the cycle, it is oxidized four more times [forming three molecules of reduced NAD ($NADH + H^+$) and one of reduced FAD ($FADH_2$)] and decarboxylated twice (releasing 2 CO_2). Energy is captured in the bonds of GTP, which then acts in a coupled reaction with ADP to generate one molecule of ATP by substrate-level phosphorylation.

Appendix E
Periodic Table of the Elements

Periodic Table of the Elements

The periodic table arranges elements according to atomic number and atomic weight into horizontal rows called periods and 18 vertical columns called groups or families. The elements in the groups are classified as being in either A or B classes.

Elements of each group of the A series have similar chemical and physical properties. This reflects the fact that members of a particular group have the same number of valence shell electrons, which is indicated by the number of the group. For example, group IA elements have one valence shell electron, group IIA elements have two, and group VA elements have five. In contrast, as you progress across a period from left to right, the properties of the elements change in discrete steps, varying gradually from the very metallic properties of groups IA and IIA elements to the nonmetallic properties seen in group VIIA (chlorine and others), and finally to the inert elements (noble gases) in group VIIIA. This change reflects the continual increase in the number of valence shell electrons seen in elements (from left to right) within a period.

Class B elements are referred to as transition elements. All transition elements are metals, and in most cases they have one or two valence shell electrons. (In these elements, some electrons occupy more distant electron shells before the deeper shells are filled.)

In this periodic table, the colors are used to convey information about the phase (solid, liquid, or gas) in which a pure element exists under standard conditions (25 degrees centigrade and 1 atmosphere of pressure). If the element's symbol is solid black, then the element exists as a solid. If its symbol is red, then it exists as a gas. If its symbol is dark blue, then it is a liquid. If the element's symbol is green, the element does not exist in nature and must be created by some type of nuclear reaction.

Appendix F
Reference Values for Selected Blood and Urine Studies

The reference values listed for the selected blood and urine studies are common ranges for adults, but specific "normals" are established by the laboratory performing the analysis. The values may be affected by a wide range of circumstances, including testing methods and equipment used, client age, body mass, sex, diet, activity level, medications, and extent of disease processes.

Reference values are identified in both standard or conventional units and in the system of international (SI) units. SI units (given in parentheses) are measurements of amount per volume and are used in most countries and scientific journals. SI units are often given as moles or millimoles per liter. Most clinical laboratories and textbooks in the United States use conventional or standard units, which measure mass per volume. These values are given as grams, milligrams, or milliequivalents per deciliter or liter. It is anticipated that the United States will eventually use SI units exclusively.

For enzymes, 1 international unit (IU) represents an arbitrary but defined amount of activity, whereas 1 katal (kat) is the amount of enzyme required to consume 1 mol of substrate per second.

Sample types in column 1 are serum (S), plasma (P), arterial whole blood (A), and whole blood (WB).

TEST (SAMPLE)	REFERENCE VALUES: CONVENTIONAL (SI)	PHYSIOLOGICAL INDICATION AND CLINICAL IMPLICATIONS
Blood Chemistry Studies		
Ammonia (P)	15–120 μg/dl (9–70 μmol/L)	Liver and renal function. Increased values in liver disease, renal failure, newborn hemolytic disease, heart failure, cor pulmonale. Decreased values in hypertension.
Amylase (S)	56–190 IU/L (0.4–2.1 μkat/L)	Pancreatic function. Increased values in pancreatitis, mumps, obstruction of pancreatic duct, ketoacidosis. Decreased values in kidney disease, pancreatic damage or cancer, toxemia of pregnancy.
Aspartate aminotransferase (AST, or SGOT) (S)	≤40 U/ml (≤0.7 μkat/L)	Cellular damage. Increased after myocardial infarction, acute liver disease, drug toxicity, muscle trauma. Decreased in pyridoxine (vitamin B_6) deficiency.
Bilirubin (S)	Total: 0.1–1.0 mg/dl (1.7–17.1 μmol/L) Direct: <0.4 mg/dl (<6.8 μmol/L) Indirect: 0.1–1.0 mg/dl (1.7–17.1 μmol/L) Newborn: <13.0 mg/dl (<222 μmol/L)	Liver function and red cell breakdown. Increased levels of direct in liver disease and biliary obstruction. Increased levels of indirect in hemolysis of red blood cells.
Blood urea nitrogen (S)	7–26 mg/dl (2.5–9.3 mmol/L)	Kidney function. Increased values in renal disease, dehydration, urinary obstruction, congestive heart failure, myocardial infarction, burns. Decreased values in liver failure, overhydration, impaired protein absorption, pregnancy.
Cholesterol	<200 mg/dl (<5.2 mmol/L)	Metabolism—fat utilization. Increased values in diabetes mellitus, pregnancy, use of oral contraceptives or anabolic steroids.
High-density lipoprotein (HDL) cholesterol (S)	20–30% of total >40 mg/dl (>1.0 mmol/L)	Increased levels in liver disease, aerobic exercise. Decreased levels in atherosclerotic heart disease, malnutrition.
Low-density lipoprotein (LDL) cholesterol (S)	60–70% of total <130 mg/dl (<3.4 mmol/L)	Increased values in hyperlipidemia, atherosclerotic heart disease. Decreased values in fat malabsorption and malnutrition.
Very low density lipoprotein cholesterol (VLDL) (S)	10–15% of total	Same as LDL.

TEST (SAMPLE)	REFERENCE VALUES: CONVENTIONAL (SI)	PHYSIOLOGICAL INDICATION AND CLINICAL IMPLICATIONS
Creatine kinase (CK) (S)	Female: ≤190 U/L (≤3.2 μkat/L) Male: ≤235 U/L (≤3.9 μkat/L)	Cellular damage. Increased values in myocardial infarction, muscular dystrophy, hypothyroidism, pulmonary infarction, cerebrovascular accident (CVA), shock, tissue damage, and trauma.
Creatinine (S)	0.5–1.2 mg/dl (44–106 μmol/L)	Renal function. Increased values in renal disease and acromegaly. Decreased in muscular dystrophy.
Gases (A)		Acid-base balance.
Bicarbonate	22–26 mEq/L (22–26 mmol/L)	Increased values in metabolic alkalosis and respiratory acidosis. Decreased values in metabolic acidosis and respiratory alkalosis.
Carbon dioxide content	Arterial: 19–24 mEq/L (19–24 mmol/L) Venous: 22–30 mEq/L (22–30 mmol/L)	
Carbon dioxide partial pressure (P_{CO2})	Arterial: 35–45 mm Hg Venous: 45 mm Hg	
Oxygen (O_2) saturation	95–98% (same)	Values increased slightly in hyperventilation. Decreased values (hypoxia) in pulmonary disease, hypoventilation, high altitude.
Oxygen partial pressure (P_{O2})	80–105 mm Hg	
pH	7.35–7.45 (same)	Increased values in metabolic and respiratory alkalosis. Decreased values in metabolic and respiratory acidosis.
Glucose (S)	70–120 mg/dl (3.9–6.7 mmol/L)	Metabolic function. Increased values in diabetes mellitus, Cushing's syndrome, liver disease, acute stress, and acromegaly. Decreased levels in Addison's disease, insulinomas.
Immunoglobulins (S)		
IgG	560–1800 mg/dl (5.6–18 g/L)	Immune response. Increased levels in chronic infections, rheumatic fever, liver disease, rheumatoid arthritis. Decreased levels in amyloidosis, leukemia, and preeclampsia.
IgE	<43.2 μg/dl (<432 μg/L)	Allergic responses. Increased values in allergic responses. Decreased values in agammaglobulinemia.
IgA	85–563 mg/dl (0.85–5.6 g/L)	Immune integrity. Increased values in liver disease, rheumatic fever, chronic infection, inflammatory bowel disease. Decreased values in immunodeficiency disorders and immunosuppression.
IgM	55–375 mg/dl (0.5–3.8 g/L)	Immune integrity. Increased in autoimmune disease (e.g., rheumatoid arthritis), acute infections. Decreased in amyloidosis and leukemia.
IgD	0.5–14 mg/dl (5–140 mg/L)	Immune integrity. Increased values in myelomas.
Ketone bodies (S or P)	Negative Toxic level >20 mg/dl (0.2 g/L)	Fatty acid catabolism. Increased values (ketosis, ketoacidosis) in starvation, low-carbohydrate diet, uncontrolled diabetes mellitus, aspirin overdose.
Lactate dehydrogenase (LDH) (S)	105–333 U/L (1.7–5.6 μkat/L)	Tissue damage of organs or striated muscle. Increased in myocardial infarction, pulmonary infarction, liver disease, cerebrovascular accident, infectious mononucleosis, muscular dystrophy, fractures.
Lactic acid (lactate) (P)	9–16 mg/dl (1.0–1.8 mmol/L)	Anaerobic tissue metabolism. Increased values in congestive heart failure, shock, hemorrhage, strenuous exercise.
Osmolality (S)	280–300 mOsm/kg H_2O (280–300 mmol/kg H_2O)	Fluid and electrolyte balance. Increased levels in hypernatremia, dehydration, kidney disease, alcohol ingestion. Decreased levels in hyponatremia, overhydration, and syndrome of inappropriate ADH secretion (SIADH).

TEST (SAMPLE)	REFERENCE VALUES: CONVENTIONAL (SI)	PHYSIOLOGICAL INDICATION AND CLINICAL IMPLICATIONS
Phosphate (S) (phosphorus)	2.5–4.5 mg/dl (0.8–1.5 mmol/L)	Parathyroid function; bone disease. Increased levels in hypoparathyroidism, renal failure, bone metastasis, hypocalcemia. Decreased values in hyperparathyroidism, hypercalcemia, alcoholism, vitamin D deficiency, ketoacidosis, osteomalacia.
Potassium (S)	3.5–5.5 mEq/L (3.5–5.5 mmol/L)	Fluid and electrolyte balance. Increased levels in renal disease, Addison's disease, ketoacidosis, burns, and crush injuries. Decreased levels in vomiting, diarrhea, Cushing's syndrome, alkalosis, diuretics.
Protein (S)		
Total	6.0–8.5 g/dl (60–85 g/L)	Osmotic pressure; immune system integrity. Increased values in multiple myeloma, dehydration, myxedema. Decreased values in protein malnutrition, burns, diarrhea, renal failure, liver failure.
Albumin	3.2–5.0 g/dl (32–50 g/L)	Osmotic pressure. Increased levels in dehydration. Decreased levels in liver disease, malnutrition, Crohn's disease, nephrotic syndrome, systemic lupus erythematosus.
Sodium (S)	135–145 mEq/L (135–145 mmol/L)	Fluid and electrolyte balance. Increased values in dehydration, diabetes insipidus, Cushing's syndrome. Decreased values in vomiting, diarrhea, burns, Addison's disease, myxedema, congestive heart failure, overhydration, syndrome of inappropriate ADH secretion (SIADH).
Triglycerides	10–150 mg/dl (0.1–1.5 g/L)	Increased values in diabetes mellitus, liver disease, nephrotic syndrome, pregnancy.
Uric acid (S)	Female: 2.0–7.3 mg/dl (119–434 μmol/L) Male: 2.1–8.5 mg/dl (125–506 μmol/L)	Renal function. Increased in lead poisoning, impaired renal function, gout, alcoholism, hematologic cancers. Decreased in Wilson's disease.
Hematology Studies		
Hemoglobin (S)	Female: 12–16 g/dl (120–160 g/L) Male: 13–18 g/dl (130–180 g/L)	Oxygenation status. Increased values in dehydration, polycythemia, congestive heart failure, chronic obstructive pulmonary disease, high altitudes. Decreased levels in anemia, hemorrhage, bone marrow cancer, renal disease, systemic lupus erythematosus, nutritional deficiency.
Hematocrit (WB)	Female: 37–47% (same) Male: 42–52% (same)	Oxygenation status. Increased levels in polycythemia, dehydration, congestive heart failure, shock, surgery. Decreased levels in anemia, hemorrhage, bone marrow disease, malnutrition, cirrhosis, rheumatoid arthritis.
Partial thromboplastin time (activated) (PTT or aPTT)	20–36 s (same)	Clotting mechanisms. Increased values in clotting factor deficiencies, cirrhosis, vitamin K deficiency, disseminated intravascular coagulation (DIC). Decreased values in early DIC, extensive cancer.
Platelet count (WB)	150,000–400,000/μl ($150–400 \times 10^9$/L)	Clotting mechanisms. Increased values in polycythemia, cancers, rheumatoid arthritis, trauma. Decreased values in liver disease, hemolytic uremic syndrome, disseminated intravascular coagulation (DIC), idiopathic thrombocytopenic purpura (ITP), systemic lupus erythematosus (SLE).
Prothrombin time (PT) (WB)	11–12.5 s (same) 1.5–2 × control (evaluating anticoagulant treatment)	Clotting mechanisms. Increased values in liver disease, vitamin K deficiency, salicylate intoxication. Decreased values in disseminated intravascular coagulation (DIC).

TEST (SAMPLE)	REFERENCE VALUES: CONVENTIONAL (SI)	PHYSIOLOGICAL INDICATION AND CLINICAL IMPLICATIONS
Hematology Studies (continued)		
Red blood cell count (RBC) (WB)	Female: 4.2–5.4 million/μl ($4.2–5.4 \times 10^{12}$/L) Male: 4.7–6.1 million/μl ($4.7–6.1 \times 10^{12}$/L)	Oxygenation status. Increased values in high altitudes, polycythemia, hemoconcentration, cor pulmonale. Decreased values in hemorrhage, hemolysis, anemias, chronic illness, nutritional deficiencies, leukemia, overhydration.
Reticulocyte count (WB)	0.5–2.0% (same)	Bone marrow function. Increased values in hemolytic anemia, sickle-cell anemia, leukemia, pregnancy. Decreased values in pernicious anemia, folic acid deficiency, cirrhosis, chronic infection, bone marrow depression or failure.
White blood cell count (WBC) (WB)		
Total (males)	4800–10,800 μl ($4.8–10.8 \times 10^{9}$/L)	Immune system integrity. Increased values in infection, trauma, stress, tissue necrosis, inflammation. Decreased values in bone marrow depression or failure, drug toxicity, overwhelming infection, malnutrition.
White blood cell count, differential (WB)		
Neutrophils	50–70% (same)	Immune system integrity. Increased values in acute bacterial infections, stress, Cushing's syndrome, inflammatory disorders, ketoacidosis, gout. Decreased levels in aplastic anemia, bone marrow suppression, and overwhelming bacterial infections.
Lymphocytes	25–40% (same)	Immune system integrity. Increased values in viral infections (e.g.), mumps, rubella, infectious mononucleosis, hepatitis), lymphocytic leukemia, certain bacterial infections. Decreased levels in leukemia, immunodeficiency, lupus erythematosus, bone marrow depressive drugs.
Eosinophils	1–4% (same)	Immune system integrity. Increased levels in allergic reactions, parasitic infections, leukemia. Decreased levels in excess adrenosteroid production.
Monocytes	3–8% (same)	Immune system integrity. Increased levels in certain infections (e.g., tuberculosis, malaria), inflammatory disorders.
Basophils	0.5–1.0% (same)	Immune system integrity. Increased levels in myeloproliferative disorders, leukemia. Decreased levels in allergic reactions, hyperthyroidism, stress.
Urine Tests		
Amylase (24 h)	<6000 Somogyi units/24 h 0–500 U/24 h (0–8.3 μkat/24h)	Pancreatic function. Increased values in pancreatic disease or obstruction, inflammation of the parotid or salivary glands, and cholecystitis.
Bilirubin (random)	Negative (same)	Liver function. Increased values in liver disease, extrahepatic obstruction (gallstones, tumor, inflammation).
Blood (hemoglobin) (random)	Negative (same)	Urinary system function. Increased values in cystitis, renal disease, hemolytic anemia, transfusion reaction, prostatitis, burns.
Osmolality (random or fasting)	Random: 50–1200 mOsm/kg H_2O (50–1200 mmol/kg H_2O) Fluid restriction: ≥850 mOsm/kg H_2O (≥850 mmol/kg H_2O)	Fluid and electrolyte balance, renal function, and endocrine function. Increased levels in hypernatremia, syndrome of inappropriate ADH secretion (SIADH), congestive heart failure, metabolic acidosis. Decreased levels in diabetes insipidus, water intoxication, pyelonephritis, renal tubular necrosis, aldosteronism.
Phosphate (24 h)	0.9–1.3g/24 hr (same)	Parathyroid function. Increased levels in hyperparathyroidism, osteomalacia, certain renal diseases, vitamin D deficiency. Decreased levels in hypoparathyroidism.

TEST (SAMPLE)	REFERENCE VALUES: CONVENTIONAL (SI)	PHYSIOLOGICAL INDICATION AND CLINICAL IMPLICATIONS
Urine Tests (continued)		
Potassium (24 h)	25–120 mEq/24 h (25–120 mmol/24 h)	Fluid and electrolyte balance. Increased values in renal tubular necrosis, metabolic acidosis, dehydration, aldosteronism, Cushing's syndrome. Decreased values in Addison's disease, malabsorption, acute renal failure.
Protein (random)	<8 mg/dl (<80 mg/L)	Renal function. Increased levels in nephrotic syndrome, renal trauma, hyperthyroidism, diabetic nephropathy, lupus erythematosus.
Sodium (24 h)	40–220 mEq/24 h (40–220 mmol/24 h)	Fluid and electrolyte balance. Increased values in dehydration, ketoacidosis, syndrome of inappropriate ADH secretion (SIADH), adrenocortical insufficiency. Decreased levels in congestive heart failure, renal failure, diarrhea, aldosteronism.
Uric acid (24 h)	250–750 mg/24 h (1.5–4.5 mmol/24 h)	Renal function and metabolism. Increased in gout, leukemia, liver disease, ulcerative colitis. Decreased in renal disease, alcoholism, lead toxicity, folic acid deficiency.
Urinalysis (random)		
Color	Straw, yellow, amber	Fluid balance and renal function. Darker in dehydration. Lighter in overhydration, diabetes insipidus. Color varies with disease states, diet, and medications.
Odor	Aromatic	Metabolic function, infection. Abnormal odors in infection, ketonuria, rectal fistula, hepatic failure, phenylketonuria.
Specific gravity	1.005–1.035	An indirect measurement of urine concentration (osmolality). Same physiological indications and clinical implications as osmolality.
Urobilinogen (24 h)	0.2–1.0 mg/dl (2–10 mg/L)	Liver function. Increased in hemolytic anemias, hepatitis, cirrhosis, biliary disease. Decreased in common bile duct obstruction.
Volume (24 h)	800–2000 ml/24 h (0.8–2.0 L/24 h)	Fluid and electrolyte balance, renal function. Increased values in diabetes insipidus, diabetes mellitus, renal disease. Decreased values in dehydration, syndrome of inappropriate ADH secretion (SIADH), renal disease.

Chapter 5
Clinical Connections **1.** The skin separates and protects the internal environment of the body from potentially dangerous elements in the external environment. Mrs. DeStephano's chart indicates epidermal abrasions, which represent the loss of this barrier. Epidermal loss will also cost Mrs. DeStephano the acid mantle of her skin, protection against UV radiation, and Langerhans' cells, which protect against invasion by microorganisms. **2.** Macrophages found in the dermis can act as a backup system against bacterial and viral invasion when the epidermis is damaged. **3.** Suturing brings the edges of wounds close together and promotes faster healing because smaller amounts of granulation tissue need to be formed. This is termed *healing by first intention.* **4.** Cyanosis signals a decrease in the amount of oxygen carried by hemoglobin in the blood. Respiratory system and/or cardiovascular system impairments can lead to cyanosis.
Review Questions **1.** a; **2.** c; **3.** d; **4.** d; **5.** b; **6.** b; **7.** c; **8.** c; **9.** b; **10.** b; **11.** a; **12.** d; **13.** b

Chapter 6
Clinical Connections **1.** Mrs. DeStephano's broken leg has a transverse fracture of the open variety because the broken ends of the bone are protruding through the skin. **2.** The laceration of the skin caused by the broken end of the bone creates a breach in the protective barrier created by the skin, providing an entry point for bacteria and other microorganisms. In addition, the protruding ends of the bone have now been exposed to the nonsterile external environment. This could result in the development of osteomyelitis, a bacterial infection, which can be treated with antibiotics. **3.** Reduction of a fracture is the clinical term for "setting the bone." Mrs. DeStephano's physician chose internal reduction, in which surgery is performed and the broken ends of the bone are secured together by pins or wires. A cast was applied to keep the aligned ends of the bone immobile until healing of the fracture has occurred. **4.** Healing of Mrs. DeStephano's fracture will begin as bony callus formation fills the break in the bone with bony tissue. This process begins 3–4 weeks after the break occurs and is completed within 2–3 months. **5.** Nutrient arteries supply blood to the bone tissue. In order for Mrs. DeStephano's break to heal normally, the bony tissue must be supplied with oxygen (to generate ATP for energy) and nutrients in order to rebuild the bone. Damage to a nutrient artery will decrease the delivery of these building materials and could slow the process of healing. **6.** For a fracture that is slow to heal, new techniques that promote healing include electrical stimulation, which promotes the deposition of new bone tissue; ultrasound treatments, known to speed healing; and possibly the addition of bone substitutes to the fractured area. **7.** At age 45, Mrs. DeStephano will most likely not regenerate her knee cartilage. (Cartilage growth typically ends during adolescence.) Cartilage damage that occurs during adulthood is slow to heal, due to the avascular nature of cartilage, and is usually irreparable. Surgical removal of torn cartilage to allow improved movement of the joint is the usual treatment for this type of damage.

Chapter 9
Clinical Connections **1.** The first reaction to tissue injury is the initiation of the inflammatory response. The inflammatory chemicals increase the permeability of the capillaries in the injured area, allowing white blood cells, fluid, and other substances to reach the injured area. The next step in healing involves the formation of granulation tissue, in which the vascular supply for the injured area is regenerated and collagen fibers to knit the torn edges of the tissue together are formed. Skeletal muscle does not regenerate well, so the damaged areas of Mrs. DeStephano's muscle tissue will probably be repaired primarily by the formation of fibrous tissue, creating scar tissue. **2.** Healing is aided by good circulation of blood within the injured area. Vascular damage compromises healing because the supply of oxygen and nutrients to the tissue is reduced. **3.** Under normal circumstances, skeletal muscles receive electrical signals from the nervous system continuously. These signals help to maintain muscle tone and readiness. Severing of the sciatic nerve removes this continuous nervous input to the muscles and will lead to muscle atrophy. Immobility of muscles will lead to a replacement of contractile muscle tissue with noncontractile fibrous connective tissue. Distal to the point of transection, the muscle will begin to decrease in size within 3–7 days of becoming immobile. This process can be delayed by electrically stimulating the tissues. Passive range-of-motion exercises also help prevent loss of muscle tone and joint range, and improve circulation in the injured areas. **4.** Mrs. DeStephano's physician wants to supply her damaged tissues with the necessary building materials to encourage healing. A high-protein diet will provide plenty of amino acids to rebuild or replace damaged proteins, carbohydrates will provide the fuel molecules needed to generate the required ATP, and vitamin C is important for the regeneration of connective tissue.

Chapter 14

Clinical Connections **1.** The location of Jimmy's lacerations and bruises and his inability to rise led the paramedics to suspect a head, neck, or back injury. They immobilized his head and torso to prevent any further damage to the brain and spinal cord. **2.** The worsening neurological signs indicate a probable intracranial hemorrhage. The blood escaping from the ruptured blood vessel(s) will begin to compress Jimmy's brain and increase his intracranial pressure. Jimmy's surgery will involve repair of the damaged vessel(s) and removal of the mass of clotted blood pressing on his brain. **3.** The blow to Jimmy's head caused his brain and spinal cord to swell (cerebral and spinal edema) as part of the inflammatory response to tissue injury. Dexamethasone is an anti-inflammatory drug that will decrease swelling and relieve intracranial pressure. **4.** Loss of motor and sensory function below the level of the nipples indicates a lesion at T_4. See Figure 13.12. **5.** Jimmy is suffering from spinal shock, which occurs as a result of injury to the spinal cord. Spinal shock is a temporary condition in which all reflex and motor activities caudal to the level of spinal cord injury are lost, so Jimmy's muscles are paralyzed, his blood pressure is low due to the loss of sympathetic tone in his vasculature. **6.** Jimmy's exaggerated reflexes are caused by damaged upper motor neuron axons in the spinal cord. These upper motor neurons normally inhibit spinal reflexes. He is incontinent because there are no longer pathways to support voluntary control of bowel and bladder emptying. **7.** This condition is called *autonomic dysreflexia* (or *autonomic hyperreflexia*). This is a condition in which a normal stimulus triggers a massive activation of autonomic neurons. **8.** Extremely high arterial blood pressure can cause a rupture of the cerebral blood vessels (as well as other blood vessels in the body) and put Jimmy's life at risk.

Chapter 16

Clinical Connections **1.** Rationale for orders: As Mr. Gutteman is unconscious, the level of damage to his brain is unclear. Monitoring his responses and vital signs every hour will provide information for his care providers about the extent of his injuries. Turning him every 4 hours and providing careful skin care will prevent decubitus ulcers (bedsores) as well as stimulating his proprioceptive pathways. **2.** Mr. Gutteman's condition is termed *diabetes insipidus*, a condition in which insufficient quantities of antidiuretic hormone (ADH) are produced or released. Diabetes insipidus patients excrete large volumes of urine but do not have glucose or ketones present in the urine. The head trauma could have damaged Mr. Gutteman's hypothalamus, which produces the hormone, or injured his posterior pituitary gland, which releases ADH into the bloodstream. **3.** Diabetes insipidus is not life threatening for most individuals with normal thirst mechanisms, as they will be thirsty and drink to replenish the lost fluid. However, Mr. Gutteman is comatose, so his fluid output must be monitored closely so that the volume lost can be replaced by IV line. His subsequent recovery may be complicated if he has suffered damage to his hypothalamus, which houses the thirst center neurons.

Review Questions **1.** b; **2.** a; **3.** c; **4.** d; **5.** (1)c, (2)a and b, (3)f, (4)d, (5)e, (6)g, (7)a, (8)h, (9)b and e, (10)a; **6.** d; **7.** c; **8.** b; **9.** d; **10.** b; **11.** d; **12.** b; **13.** c; **14.** d

Chapter 19

Clinical Connections **1.** The tissues in Mr. Hutchinson's right leg were deprived of oxygen and nutrients for at least one-half hour. When tissues are deprived of oxygen, tissue metabolism decreases and eventually ceases, so these tissues may have died due to anoxia. **2.** Mr. Hutchinson's vital signs (low BP, rapid, thready pulse) indicate that he is facing a life-threatening problem that must be stabilized before other, less vital problems can be addressed. As for surgery, he may be scheduled for open reduction of his crushed bone, depending upon the condition of the tissues in his crushed right leg. If tissue death has occurred in his leg, he may undergo amputation of that limb. **3.** Mr. Hutchinson's rapid, thready pulse and falling blood pressure are indications of hypovolemic shock, a type of shock resulting from decreased blood volume. Because his blood volume is low, his heart rate is elevated to increase cardiac output in an effort to maintain the blood supply to his vital organs. Mr. Hutchinson's blood volume must be increased as quickly as possible with blood transfusions or intravenous saline. This will stabilize his condition and allow his physicians to continue with his surgery.

Review Questions **1.** d; **2.** b; **3.** d; **4.** c; **5.** e; **6.** d; **7.** c; **8.** b; **9.** b; **10.** a; **11.** b; **12.** c; **13.** b; **14.** d; **15.** (1)b, e, g; (2)c; (3)i; (4) f, h; (5) d

Chapter 20

Clinical Connections **1.** The red streaks radiating from Mr. Hutchinson's finger indicate that his lymphatic vessels are inflamed. This inflammation may be caused by a bacterial infection. If Mr. Hutchinson's arm had exhibited edema without any accompanying red streaks, the problem would likely have been impaired lymph transport from his arm back to his trunk, due to injury or blockage of his lymphatic vessels. **2.** Mr. Hutchinson's arm was placed in a sling to immobilize it, slowing the drainage of lymph from the infected area in an attempt to limit the spread of the inflammation. **3.** Mr. Hutchinson's low lymphocyte count indicates that his body's ability to fight infection by bacteria or viruses is impaired. The antibiotics and additional staff protection will protect Mr. Hutchinson until his lymphocyte count increases again. Gloving and gowning also protect the staff caring for Mr. Hutchinson from any body infection he might have. **4.** Mr. Hutchinson's recovery may be problematic, as he probably already has an ongoing bacterial infection and his ability to raise a defense to this infection is impaired.

Review Questions **1.** c; **2.** c; **3.** a, d; **4.** c; **5.** a; **6.** b; **7.** a; **8.** b; **9.** d

Chapter 21

1. c; **2.** a; **3.** d; **4.** d, e; **5.** a; **6.** d; **7.** b; **8.** c; **9.** d; **10.** d; **11.** d; **12.** (1)b, g; (2)d, i; (3)a, e; (4)a, e, f, h; (5)e, f, h; (6)c, f, g

Chapter 22

Clinical Connections **1.** Spinal cord injury from a fracture at the level of the C_2 vertebra would interrupt the normal transmission of signals from the brain stem down the phrenic nerve to the diaphragm, and Barbara would be unable to breathe due to paralysis of the diaphragm. **2.** Barbara's head, neck, and torso should have been immobilized to prevent further damage to the spinal cord. In addition, she required assistance to breathe, so her airway was probably intubated to permit ventilation of her lungs. **3.** Cyanosis is a decrease in the degree of oxygen saturation of hemoglobin. As Barbara's respiratory efforts cease, her alveolar P_{O_2} will fall, so there is less diffusion of oxygen between the lungs and the bloodstream. In addition, her arterial P_{CO_2} will increase. Both of these conditions will promote the unloading of oxygen from hemoglobin. **4.** Injury to the spinal cord at the level of the C_2 vertebra will cause quadriplegia (paralysis of all four limbs). **5.** Atelectasis is the collapse of a lung. Because it is the right thorax that is compressed, only her right lung is affected. Because the lungs are in separate pleural cavities, only the right lung collapsed. **6.** Barbara's fractured ribs probably punctured her lung tissue and allowed air within the lung to enter the pleural cavity. **7.** The atelectasis will be reversed by closing the tear in her lung

tissue, then removing the air from the pleural cavity using chest tubes. This will allow her lung to re-inflate.

Review Questions **1.** b; **2.** a and c; **3.** c; **4.** c; **5.** b; **6.** d; **7.** d; **8.** b; **9.** c, d; **10.** c; **11.** b; **12.** b; **13.** b; **14.** c; **15.** b; **16.** b

Chapter 23

Clinical Connections **1.** Mr. Gutteman's statement about the effects of milk on his digestive tract suggests that he may be deficient in lactase, a brush border enzyme that breaks down lactose (milk sugar). **2.** His responses to the questions reduced the possibility that he has gastric ulcers. Mr. Gutteman's diarrhea may be due to gluten enteropathy. To verify this diagnosis, Mr. Gutteman's diet should be restricted by eliminating all grains but rice and corn and he should have a follow-up examination to see if his condition has improved.

Chapter 26

Clinical Connections **1.** Mr. Heyden's vital signs suggest that he is in hypovolemic shock, which is probably due to an internal hemorrhage. **2.** The spleen is a highly vascular organ due to its role as a blood filtering organ. The macrophages in Mr. Heyden's liver and bone marrow will help compensate for the loss of his spleen. **3.** Elevation of renin, aldosterone, and antidiuretic hormone indicate that Mr. Heyden's body is trying to compensate for his falling blood pressure and blood loss. *Renin:* released when renal blood flow is diminished and blood pressure falls. The angiotensin-aldosterone response is initiated by renin. The formation of angiotensin II leads to vasoconstriction, which will increase blood pressure, and to the release of aldosterone. *Aldosterone:* increases Na^+ reabsorption by the kidney. The movement of this reabsorbed Na^+ into the bloodstream will promote the movement of water from the interstitial fluid, resulting in an increase in blood volume. *Antidiuretic hormone (ADH):* released when the hypothalamic osmoreceptors sense an increase in osmolality. ADH has two consequences: it is a potent vasoconstrictor and will increase blood pressure, and it promotes water retention by the kidney, increasing blood volume. **4.** Mr. Heyden's urine production may be decreased for several reasons. The severe drop in his blood pressure would reduce renal blood flow, thus reducing glomerular blood pressure and decreasing his glomerular filtration rate. The elevation in his ADH levels can reduce urine output due to increased water reabsorption by the kidney. He may also have damage to the kidney due to his crush injury in the left lumbar region. The presence of casts and a brownish-red color in his urine are probably damaged cells and blood. If he has suffered kidney damage due to being crushed, he may have nephron damage that would include disruption of the filtration membrane, allowing red blood cells to pass into the filtrate and therefore the urine. He may also have damaged renal tubules and peritubular capillaries, allowing entry of blood and damaged renal tubule epithelial cells into the filtrate.

Review Questions **1.** a; **2.** c; **3.** b; **4.** b; **5.** h, i, j; **6.** c, g; **7.** a, e; **8.** b; **9.** a, b; **10.** j; **11.** b, d; **12.** a; **13.** c

Chapter 27

Clinical Connections **1.** *Carcinoma* is the term for cancer originating from epithelial tissue. The primary source of Mr. Heyden's cancer is likely to be the prostate. **2.** Elevation of serum acid phosphatase levels is diagnostic for carcinoma of the prostate. (In addition, Mr. Heyden's age places him in a group that is at relatively higher risk for this type of cancer.) **3.** Digital examination of Mr. Heyden's prostate should detect the presence of carcinoma in this tissue. In addition, serum levels of prostate-specific antigen (PSA) should be checked, as an increase in this antigen is specific for prostate cancer. **4.** Mr. Heyden's carcinoma has advanced to the point of metastasis. He will probably undergo a treatment that reduces the levels of androgens in his body, as androgens promote growth of the prostate-derived tissue. These treatments could include castration or administration of drugs that block the production and/or effects of androgens.

ĕ, hĕ, en		hen	oy		boy
er		her	sh		she
ew		new	u, mu, ūt		mute
g		go	ŭ, sŭ, un		sun
i, bi, īt		bite	z		zebra
ĭ, hĭ, im		him	zh		measure
ng		ring			

Abdomen (ab'do-men) Portion of the body between the diaphragm and the pelvis.

Abduct (ab-dukt') To move away from the midline of the body.

Absolute refractory period Period following stimulation during which no additional action potential can be evoked.

Absorption Process by which the products of digestion pass through the alimentary tube mucosa into the blood or lymph.

Accessory digestive organs Organs that contribute to the digestive process but are not part of the alimentary canal; include the tongue, teeth, salivary glands, pancreas, liver.

Accommodation The process of increasing the refractive power of the lens of the eye; focusing.

Acetabulum (as"ĕ-tab'u-lum) Cuplike cavity on lateral surface of the hip bone that receives the femur.

Acetylcholine (ACh) (as"ĕ-til-ko'lēn) Chemical transmitter substance released by some nerve endings.

Acetylcholinesterase (AChE) (as"ĕ-til-ko"lin-es'ter-ās) Enzyme present at the neuromuscular junction and synapses that degrades acetylcholine and terminates its action.

Achilles tendon. *See* Calcaneal tendon.

Acid A substance that releases hydrogen ions when in solution (compare with Base); a proton donor.

Acid-base balance Situation in which the pH of the blood is maintained between 7.35 and 7.45.

Acidosis (as"ĭ-do'sis) State of abnormally high hydrogen ion concentration in the extracellular fluid.

Actin (ak'tin) A contractile protein of muscle.

Action potential A large transient depolarization event, including polarity reversal, that is conducted along the membrane of a muscle cell or a nerve fiber.

Activation energy The amount of energy required to push a reactant to the level necessary for action.

Active immunity Immunity produced by an encounter with an antigen; provides immunological memory.

Active site Region on the surface of a functional (globular) protein where it binds and interacts chemically with other molecules of complementary shape and charge.

Active transport Membrane transport processes for which ATP is provided, e.g., solute pumping and endocytosis.

Adaptation (1) Any change in structure or response to suit a new environment; (2) decline in the transmission of a sensory nerve when a receptor is stimulated continuously and without change in stimulus strength.

Adduct (a-dukt') To move toward the midline of the body.

Adenine (A) (ad'ĕ-nēn) One of the two major purines found in both RNA and DNA; also found in various free nucleotides of importance to the body, such as ATP.

Adenohypophysis (ad"ĕ-no-hi-pof'ĭ-sis) Anterior pituitary; the glandular part of the pituitary gland.

Adenoids (ad'en-noids) Pharyngeal tonsil.

Adenosine triphosphate (ATP) (ah-den'o-sēn tri"fos'fāt) Organic molecule that stores and releases chemical energy for use in body cells.

Adipocyte (ad'ĭ-po-sīt) An adipose, or fat cell.

Adipose tissue (ad'ĭ-pōs) Areolar connective tissue modified to store nutrients; a connective tissue consisting chiefly of fat cells.

Adrenal glands (uh-drē'nul) Hormone-producing glands located superior to the kidneys; each consists of medulla and cortex areas.

Adrenergic fibers (ad"ren-er'jik) Nerve fibers that release norepinephrine.

Adrenocorticotropic hormone (ACTH) (ah-dre'no-kor"tĭ-ko-trō'pik) Anterior pituitary hormone that influences the activity of the adrenal cortex.

Adventitia (ad"ven-tish'e-ah) Outermost layer or covering of some organs.

Aerobic (a'er-ōb"ik) Oxygen-requiring.

Aerobic endurance The length of time a muscle can continue to contract using aerobic pathways.

Aerobic respiration Respiration in which oxygen is consumed and glucose is broken down entirely; water, carbon dioxide, and large amounts of ATP are the final products.

Afferent (af'er-ent) Carrying to or toward a center.

Afferent (sensory) nerve Nerve that contains processes of sensory neurons and carries nerve impulses to the central nervous system.

Afferent (sensory) neuron Nerve cell that carries impulses toward the central nervous system; initiates nerve impulses following receptor stimulation.

Agglutination (ah-gloo"tĭ-na'shun) Clumping of (foreign) cells; induced by cross-linking of antigen-antibody complexes.

Agonist (ag'o-nist) Muscle that bears the major responsibility for effecting a particular movement; a prime mover.

AIDS Acquired immune deficiency syndrome; caused by human immunodeficiency virus (HIV); symptoms include severe weight loss, night sweats, swollen lymph nodes, opportunistic infections.

Albumin (al-bu'min) The most abundant plasma protein.

Aldosterone (al-dos'ter-ōn) Hormone produced by the adrenal cortex that regulates Na^+ reabsorption and K^+secretion by the kidneys.

Alimentary canal (al"ĭ-men'tar-e) The continuous hollow tube extending from the mouth to the anus; its walls are constructed by the oral cavity, pharynx, esophagus, stomach, and small and large intestines.

Alkalosis (al"kah-lo'sis) State of abnormally low hydrogen ion concentration in the extracellular fluid.

Allantois (ah"lan'to-is) Embryonic membrane; its blood vessels develop into blood vessels of the umbilical cord.

Alleles Genes coding for the same trait and found at the same locus on homologous chromosomes.

Allergy A type of hypersensitivity (overzealous immune response to an otherwise harmless antigen) that involves IgE antibodies and histamine release.

Alopecia (al″o-pe′she-ah) Baldness.

Alpha (α)-helix The most common type of secondary structure of the amino acid chain in proteins; resembles the coils of a telephone cord.

Alveolar (acinar) gland (al-ve′o-lar) A gland whose secretory cells form small, flasklike sacs.

Alveolar ventilation rate (AVR) An index of respiratory efficiency; measures volume of fresh air that flows in and out of alveoli.

Alveolus (al-ve′o-lus) (1) One of the microscopic air sacs of the lungs; (2) tiny milk-producing glandular sac in the breast; (3) tooth socket.

Alzheimer's disease (altz′hi-merz) Degenerative brain disease resulting in progressive loss of memory and motor control, and increasing dementia.

Amino acid (ah-me′no) Organic compound containing nitrogen, carbon, hydrogen, and oxygen; building block of protein.

Ammonia (NH_3) Common waste product of protein breakdown in the body; a colorless volatile gas, very soluble in water and capable of forming a weak base; a proton acceptor.

Amniocentesis A common form of fetal testing in which a small sample of fluid is removed from the amniotic cavity.

Amnion (am′ne-on) Fetal membrane that forms a fluid-filled sac around the embryo.

Amoeboid motion (ah-me′boyd) The flowing movement of the cytoplasm of a phagocyte.

Amphiarthrosis (am″fe-ar-thro′sis) A slightly movable joint.

Ampulla (am-pul′lah) A localized dilation of a canal or duct.

Amylase Digestive system enzyme that breaks down starchy foods.

Anabolism (ah-nab′o-lizm) Energy-requiring building phase of metabolism in which simpler substances are combined to form more complex substances.

Anaerobic (an-a′er-ō̆b-ik) Not requiring oxygen.

Anaerobic glycolysis (gli-kol′ĭ-sis) Energy-yielding conversion of glucose to lactic acid in various tissues, notably muscle, when sufficient oxygen is not available.

Anaerobic threshold The point at which muscle metabolism converts to anaerobic glycolysis.

Anaphase Third stage of mitosis in which a full set of daughter chromosomes move toward each pole of a cell.

Anastomosis (ah-nas″to-mo′sis) A union or joining of nerves, blood vessels, or lymphatics.

Anatomy Study of the structure of living organisms.

Androgen (an′dro-jen) A hormone such as testosterone that controls male secondary sex characteristics.

Anemia (ah-ne′me-ah) Reduced oxygen-carrying ability of blood resulting from too few erythrocytes or abnormal hemoglobin.

Aneurysm (an′u-rizm) Blood-filled sac in an artery wall caused by dilation or weakening of the wall.

Angina pectoris (an′jĭ-nah pek′tor-is) Severe suffocating chest pain caused by brief lack of oxygen supply to heart muscle.

Angiotensin II (an″je-o-ten′sin) A potent vasoconstrictor activated by renin; also triggers release of aldosterone.

Anion (an′i-on) An ion carrying one or more negative charges and therefore attracted to a positive pole.

Anoxia (ah-nŏk′se-ah) Deficiency of oxygen.

Antagonist (an-tag′o-nist) (1) Muscle that reverses, or opposes, the action of another muscle. (2) Hormone that opposes the action of another hormone.

Anterior pituitary. *See* Adenohypophysis.

Antibody A protein molecule that is released by a plasma cell (a daughter cell of an activated B lymphocyte) and that binds specifically to an antigen; an immunoglobulin.

Anticodon (an″ti-ko′don) The three-base sequence complementary to the messenger RNA (mRNA) codon.

Antidiuretic hormone (ADH, also called **vasopressin)** (an″tī-dī″yer-eh′tik) Hormone produced by the hypothalamus and released by the posterior pituitary; stimulates the kidneys to reabsorb more water, reducing urine volume.

Antigen (Ag) (an′tĭ-jen) A substance or part of a substance (living or nonliving) that is recognized as foreign by the immune system, activates the immune system, and reacts with immune cells or their products.

Anucleate cell (a-nu′kle-āt) A cell without a nucleus.

Anus (a′nus) Distal end of digestive tract; outlet of rectum.

Aorta (a-or′tah) Major systemic artery; arises from the left ventricle of the heart.

Aortic body Receptor in the aortic arch sensitive to changing oxygen, carbon dioxide, and pH levels of the blood.

Apgar score Evaluation of an infant's physical status at 1 and 5 minutes after birth by assessing five criteria: heart rate, respiration, color, muscle tone, and reflexes.

Apnea Breathing cessation.

Apocrine sweat gland (ap′o-krin) The less numerous type of sweat gland; produces a secretion containing water, salts, proteins, and fatty acids.

Apoenzyme (ap′ō-en-zīm) The protein portion of an enzyme.

Aponeurosis (ap″o-nu-ro′sis) Fibrous or membranous sheet connecting a muscle and the part it moves.

Apoptosis A process of controlled cellular suicide; eliminates cells that are unneeded, stressed, or aged.

Appendicitis (ă-pen′dĭ-si′tis) Inflammation of the appendix (wormlike sac attached to the cecum of the large intestine).

Appendicular Relating to the limbs; one of the two major divisions of the body.

Appositional growth Growth accomplished by the addition of new layers onto those previously formed.

Aqueous humor (a′kwe-us) Watery fluid in the anterior segment of the eye.

Arachnoid (ah-rak-noid) Weblike; specifically, the weblike arachnoid mater, the middle layer of the three meninges.

Areola (ah-re′o-lah) Circular, pigmented area surrounding the nipple; any small space in a tissue.

Areolar connective tissue A type of loose connective tissue.

Arrector pili (ah-rek′tor pi′li) Tiny, smooth muscles attached to hair follicles; contraction causes the hair to stand upright.

Arrhythmia (a-rith′me-ah) Irregular heart rhythm, often caused by defects in the intrinsic conduction system.

Arteries Blood vessels that conduct blood away from the heart and into the circulation.

Arteriole (ar-tēr′e-ōl) A minute artery.

Arteriosclerosis (ar-tēr′e-o-skler-o′sis) Any of a number of proliferative and degenerative changes in the arteries leading to their decreased elasticity.

Arthritis Inflammation of the joints.

Arthroscopic surgery (ar-thro-skop′ik) Procedure enabling a surgeon to repair the interior of a joint through a small incision.

Articular capsule Double-layered capsule composed of an outer fibrous capsule lined by synovial membrane; encloses the joint cavity of a synovial joint.

Articular cartilage Hyaline cartilage covering bone ends at movable joints.

Articulation (joint) The junction of two or more bones.

Association areas Functional areas of the cerebral cortex that act mainly to integrate diverse information for purposeful action.

Astigmatism (ah-stig′mah-tizm) A condition in which unequal curvatures in different parts of the cornea or lens of the eye lead to blurred vision.

Astrocyte (as′tro-sīte) A type of CNS supporting cell; assists in exchanges between blood capillaries and neurons.

Ataxia (ah-tak′se-ah) Disruption of muscle coordination resulting in inaccurate movements.

Atelectasis (at″ĕ-lik′tah-sis) Lung collapse.

Atherosclerosis (a″ther-o″skler-o′sis) Changes in the walls of large arteries consisting of lipid deposits on the artery walls; the early stage of arteriosclerosis.

Atmospheric pressure Force that air exerts on the surface of the body (760 mm Hg at sea level).

Atom Smallest particle of an elemental substance that exhibits the properties of that element; composed of protons, neutrons, and electrons.

Atomic mass number Sum of the number of protons and neutrons in the nucleus of an atom.

Atomic number The number of protons in an atom.

Atomic symbol The one- or two-letter symbol used to indicate an element; usually the first letter(s) of the element's name.

Atomic weight The average of the mass numbers of all the isotopes of an element.

ATP (adenosine triphosphate) (ah-den′o-sēn tri″fos′fāt) Organic molecule that stores and releases chemical energy for use in body cells.

Atria (a′tre-ah) The two superior receiving chambers of the heart.

Atrial natriuretic peptide (ANP) (a′tre-al na″tre-u-ret′ik) A hormone released by certain cells of the heart atria that reduces blood pressure and blood volume by inhibiting nearly all events that promote vasoconstriction and Na^+ and water retention.

Atrioventricular (AV) bundle (a″tre-o-ven-trĭ′kyoo-ler) Bundle of specialized fibers that conduct impulses from the AV node to the right and left ventricles; also called bundle of His.

Atrioventricular (AV) node Specialized mass of conducting cells located at the atrioventricular junction in the heart.

Atrioventricular (AV) valve Valve that prevents backflow into the atrium when the connected ventricle is contracting.

Atrophy (at′ro-fe) Reduction in size or wasting away of an organ or cell resulting from disease or lack of use.

Auditory ossicles (ah′sih-kulz) The three tiny bones serving as transmitters of vibrations and located within the middle ear: the malleus, incus, and stapes.

Auditory tube *See* Pharyngotympanic tube.

Autoimmunity Production of antibodies or effector T cells that attack a person's own tissue.

Autolysis (aw″tol′ĭ-sis) Process of autodigestion (self-digestion) of cells, especially dead or degenerate cells.

Autonomic ganglion Collection of sympathetic or parasympathetic ganglionic neuronal cell bodies.

Autonomic nervous system (ANS) Efferent division of the peripheral nervous system that innervates cardiac and smooth muscles and glands; also called the involuntary or visceral motor system.

Autonomic (visceral) reflexes Reflexes that activate smooth or cardiac muscle and/or glands.

Autoregulation The automatic local adjustment of blood flow to a particular body area in response to its current requirements.

Autosomes Chromosomes number 1 to 22; do not include the sex chromosomes.

Avogadro's number (av″o-gad′rōz) The number of molecules in one mole of any substance, 6.02×10^{23}.

Axial Relating to the head, neck, and trunk; one of the two major divisions of the body.

Axolemma (ak″so-lem′ah) The plasma membrane of an axon.

Axon Neuron process that carries impulses away from the nerve cell body; efferent process; the conducting portion of a nerve cell.

Axon terminals (synaptic knobs, boutons) The bulbous distal endings of the terminal branches of an axon.

B cells Also called B lymphocytes; oversee humoral immunity; their descendants differentiate into antibody-producing plasma cells.

Baroreceptor (bayr″o-re-sep′tor) A sensory nerve ending in the wall of the carotid sinus or aortic arch sensitive to vessel stretching.

Basal body (ba′sal) An organelle structurally identical to a centriole and forming the base of a cilium or flagellum.

Basal ganglia *See* Basal nuclei.

Basal lamina (lam′ĭ-nah) Noncellular, adhesive supporting sheet consisting largely of glycoproteins secreted by epithelial cells.

Basal metabolic rate (BMR) Rate at which energy is expended (heat produced) by the body per unit time under controlled (basal) conditions: 12 hours after a meal, at rest.

Basal nuclei (basal ganglia) Specific gray matter areas located deep within the white matter of the cerebral hemispheres.

Basal surface The surface near the base or interior of a structure; nearest the lower side or bottom of a structure.

Base A substance capable of binding with hydrogen ions; a proton acceptor.

Basement membrane Extracellular material consisting of a basal lamina secreted by epithelial cells and a reticular lamina secreted by underlying connective tissue cells.

Basophil (ba′zo-fil) White blood cell whose granules stain purplish-black and nucleus purple with basic dye.

Benign (be-nīn′) Not malignant.

Biceps (bi′seps) Two-headed, especially applied to certain muscles.

Bile Greenish-yellow or brownish fluid produced in and secreted by the liver, stored in the gallbladder, and released into the small intestine.

Bilirubin (bil″i-roo′bin) Yellow pigment of bile.

Bipolar neuron Neuron with axon and dendrite that extend from opposite sides of the cell body.

Blastocyst (blas′to-sist) Stage of early embryonic development; the product of cleavage.

Blood pressure (BP) Force exerted by blood against a unit area of the blood vessel walls; differences in blood pressure between different areas of the circulation provide the driving force for blood circulation.

Blood-brain barrier Mechanism that inhibits passage of materials from the blood into brain tissues; reflects relative impermeability of brain capillaries.

Bolus (bo′lus) A rounded mass of food prepared by the mouth for swallowing; any soft round mass.

Bone marrow Fat- or blood-forming tissue found within bone cavities; called yellow and red bone marrow, respectively.

Bone (osseous tissue) (os′e-us) A connective tissue that forms the bony skeleton.

Bone remodeling Process involving bone formation and destruction in response to hormonal and mechanical factors.

Bone resorption The removal of osseous tissue; part of the continuous bone remodeling process.

Bowman's capsule (bo-manz) *See* Glomerular capsule.

Boyle's law States that when the temperature is constant, the pressure of a gas varies inversely with its volume.

Bradycardia (brad″e-kar′deah) A heart rate below 60 beats per minute.

Brain death State of irreversible coma, even though life-support measures may have restored other body organs.

Brain stem Collectively the midbrain, pons, and medulla of the brain.

Brain ventricle Fluid-filled cavity of the brain.

Branchial groove (brang′ke-al) An indentation of the surface ectoderm in the embryo; the external acoustic meatus develops from these.

Bronchioles Smaller (<1 mm in diameter) branching air passageways inside the lungs.

Bronchus (brong′kus) One of the two large branches of the trachea that leads to the lungs.

Buffer Chemical substance or system that minimizes changes in pH by releasing or binding hydrogen ions.

Burn Tissue damage inflicted by intense heat, electricity, radiation, or certain chemicals, all of which denature cell proteins and cause cell death in the affected areas.

Bursa (ber′sa) A fibrous sac lined with synovial membrane and containing synovial fluid; occurs between bones and muscle tendons (or other structures), where it acts to decrease friction during movement.

Bursitis Inflammation of a bursa.
Calcaneal tendon (kal-ka'ne-al) Tendon that attaches the calf muscles to the heelbone (calcaneus); also called the Achilles tendon.
Calcitonin (kal"sih-to'nin) Hormone released by the thyroid that promotes a decrease in calcium levels in the blood.
Calculus (kal'ku-lus) A stone formed within various body parts.
Callus (kal'lus) (1) Localized thickening of skin epidermis resulting from physical trauma; (2) repair tissue (fibrous or bony) formed at a fracture site.
Calorie (cal) Amount of energy needed to raise the temperature of 1 gram of water 1° Celsius. Energy exchanges associated with biochemical reactions are usually reported in kilocalories (1 kcal = 1000 cal), also called large calories (Cal).
Calyx (ka'liks) A cuplike extension of the pelvis of the kidney.
Canaliculus (kan"ah-lik'u-lus) Extremely small tubular passage or channel.
Cancer A malignant, invasive cellular neoplasm that has the capability of spreading throughout the body or body parts.
Capillaries (kap'il-layr"ēs) The smallest of the blood vessels and the sites of exchange between the blood and tissue cells.
Carbohydrate (kar"bo-hi'drāt) Organic compound composed of carbon, hydrogen, and oxygen; includes starches, sugars, cellulose.
Carbonic acid–bicarbonate buffer system Chemical system that helps maintain pH homeostasis of the blood.
Carbonic anhydrase (kar-bon'ik an-hi'dras) Enzyme that facilitates the combination of carbon dioxide with water to form carbonic acid.
Carcinogen (kar"sĭ'no-jin) Cancer-causing agent.
Cardiac cycle Sequence of events encompassing one complete contraction and relaxation of the atria and ventricles of the heart.
Cardiac muscle Specialized muscle of the heart.
Cardiac output (CO) Amount of blood pumped out of a ventricle in one minute.
Cardiac reserve The difference between resting and maximal cardiac output.
Cardiogenic shock Pump failure; the heart is so inefficient that it cannot sustain adequate circulation.
Cardiovascular system Organ system that distributes the blood to deliver nutrients and remove wastes.
Carotene (kar'o-tēn) Yellow to orange pigment that accumulates in the stratum corneum epidermal layer and in fatty tissue of the hypodermis.
Carotid body (kar-rot'id) A receptor in the common carotid artery sensitive to changing oxygen, carbon dioxide, and pH levels of the blood.
Carotid sinus (si-nus) A dilation of a common carotid artery; involved in regulation of systemic blood pressure.
Carrier A transmembrane protein that changes shape to envelop and transport a polar substance across the cell membrane.
Cartilage (kar'tĭ-lij) White, semiopaque connective tissue.
Cartilage bone (endochondral bone) Bone formed by using hyaline cartilage structures as models for ossification.
Cartilaginous joints (kar"ti-laj'ĭ-nus) Bones united by cartilage; no joint cavity is present.
Catabolism (kat-tab'o-lizm) Process in which living cells break down substances into simpler substances.
Catalyst (kat'ah-list) Substance that increases the rate of a chemical reaction without itself becoming chemically changed or part of the product.
Cataract Clouding of the eye's lens; often congenital or age-related.
Catecholamines (kat"ĕ-kol'ah-menz) Epinephrine, norepinephrine, and dopamine; a class of amines that act as chemical transmitters.
Cation (kat'i-on) An ion with a positive charge.
Caudal (kaw'dul) Literally, toward the tail; in humans, the inferior portion of the anatomy.
Cecum (se'kum) The blind-end pouch at the beginning of the large intestine.
Cell Structural unit of all living things.
Cell differentiation The development of specific and distinctive features in cells, from a single cell (the fertilized egg) to all the specialized cells of adulthood.
Cell division period One of two major periods in the cell life cycle; involves the division of the nucleus (mitosis) and the division of the cytoplasm (cytokinesis).
Cell life cycle Series of changes a cell goes through from the time it is formed until it reproduces itself.
Cell-mediated immunity Immunity conferred by activated T cells, which directly lyse infected or cancerous body cells or cells of foreign grafts and release chemicals that regulate the immune response.
Cell membrane. *See* Plasma membrane.
Cellular respiration Metabolic processes in which ATP is produced.
Cellulose (sel'u-lōs) A fibrous carbohydrate that is the main structural component of plant tissues.
Central (Haversian) canal (hah-ver'zhan) The canal in the center of each osteon that contains minute blood vessels and nerve fibers that serve the needs of the osteocytes.
Central nervous system (CNS) Brain and spinal cord.
Centriole (sen'tre-ol) Minute body found near the nucleus of the cell; active in cell division.
Centrosome (cell center) A region near the nucleus which contains paired organelles called centrioles.
Cerebellum (ser"ĕ-bel'um) Brain region most involved in producing smooth, coordinated skeletal muscle activity.
Cerebral aqueduct (ser'ĕ-bral, sĕ-re'bral) The slender cavity of the midbrain that connects the third and fourth ventricles.
Cerebral arterial circle (circle of Willis) An arterial anastomosis at the base of the brain.
Cerebral cortex The outer gray matter region of the cerebral hemispheres.
Cerebral dominance Designates the hemisphere that is dominant for language.
Cerebral palsy Neuromuscular disability in which voluntary muscles are poorly controlled or paralyzed as a result of brain damage.
Cerebral white matter Consists largely of myelinated fibers bundled into large tracts; provides for communication between cerebral areas and lower CNS centers.
Cerebrospinal fluid (CSF) (ser"ĕ-bro-spi'nal) Plasmalike fluid that fills the cavities of the CNS and surrounds the CNS externally; protects the brain and spinal cord.
Cerebrovascular accident (CVA) (ser"ĕ-bro-vas'ku-lar) Condition in which brain tissue is deprived of a blood supply, as in blockage of a cerebral blood vessel; a stroke.
Cerebrum (ser'ĕ-brum) The cerebral hemispheres and the structures of the diencephalon.
Cervical vertebrae The seven vertebrae of the vertebral column located in the neck.
Cervix Lower outlet of the uterus extending into the vagina.
Channel A transmembrane protein that helps form aqueous channels that transport substances from one side of the membrane to the other.
Chemical bond An energy relationship holding atoms together; involves the interaction of electrons.
Chemical digestion A series of catabolic steps in which complex food molecules are broken down to their building blocks by enzymes.
Chemical energy Energy stored in the bonds of chemical substances.
Chemical equilibrium A state of apparent repose created by two reactions proceeding in opposite directions at equal speed.
Chemical reaction Process in which molecules are formed, changed, or broken down.
Chemoreceptor (ke"mo-re-sep'ter) Receptor sensitive to various chemicals in solution.
Chemotaxis (ke"mo-tak'sis) Movement of a cell, organism, or part of an organism toward or away from a chemical substance.
Cholecystokinin (CCK) (ko"le-sis"to-ki'nin) An intestinal hormone that stimulates gallbladder contraction and pancreatic juice release.

Cholesterol (ko-les'ter-ol") Steroid found in animal fats as well as in most body tissues; made by the liver.
Cholinergic fibers (ko"lin-er'jik) Nerve endings that, upon stimulation, release acetylcholine.
Chondroblast (kon'dro-blast) Actively mitotic cell of cartilage.
Chondrocyte (kon'dro-sīt) Mature cell of cartilage.
Chorion (kor'e-on) Outermost fetal membrane; helps form the placenta.
Chorionic villi sampling (ko"re-on'ik vil'i) Fetal testing procedure in which bits of the chorionic villi from the placenta are snipped off and the cells karyotyped. This procedure can be done as early as 8 weeks into the pregnancy.
Choroid (ko'roid) The vascular middle layer of the eye.
Choroid plexus (ko'roid plex'sus) A capillary knot that protrudes into a brain ventricle; involved in forming cerebrospinal fluid.
Chromatin (kro'mah-tin) Structures in the nucleus that carry the hereditary factors (genes).
Chromosomes (kro'mo-somz) Barlike bodies of tightly coiled chromatin; visible during cell division.
Chronic obstructive pulmonary disease (COPD) Collective term for progressive, obstructive respiratory disorders; includes emphysema, chronic bronchitis.
Chyme (kīm) Semifluid, creamy mass consisting of partially digested food and gastric juice.
Cilia (sil'e-ah) Tiny, hairlike projections on cell surfaces that move in a wavelike manner.
Circumduction (ser"kum-duk'shun) Movement of a body part so that it outlines a cone in space.
Cirrhosis (sĭ-ro'sis) Chronic disease of the liver, characterized by an overgrowth of connective tissue or fibrosis.
Cisterna chyli (sis-ter'nah ki'li) An enlarged sac at the base of the thoracic duct; the origin of the thoracic duct.
Cisternae (sis-ter'ne) Any cavity or enclosed space serving as a reservoir.
Cleavage An early embryonic phase consisting of rapid mitotic cell divisions without intervening growth periods; product is a blastocyst.
Clonal selection (klo'nul) Process during which a B cell or T cell becomes sensitized through binding contact with an antigen.
Clone Descendants of a single cell.
Coagulation Process in which blood is transformed from a liquid to a gel; blood clotting.
Cochlea (kok'le-ah) Snail-shaped chamber of the bony labyrinth that houses the receptor for hearing [the spiral organ (of Corti)].
Codon (ko'don) The three-base sequence on a messenger RNA molecule that provides the genetic information used in protein synthesis.
Coenzyme (ko-en'zīm) Nonprotein substance associated with and activating an enzyme, typically a vitamin.
Cofactor Metal ion or organic molecule that is required for enzyme activity.
Collagen fiber The most abundant of the three fibers found in the matrix of connective tissue.
Colloid (kol'oid) A mixture in which the solute particles (usually proteins) do not settle out readily. Colloid in the thyroid gland contains thyroglobulin protein.
Colloid osmotic pressure (kol'oid ahz-mah'tik) Pressure created in a fluid by large nondiffusible molecules, such as plasma proteins that are prevented from moving through a (capillary) membrane. Such substances tend to draw water to them.
Colon Regions of the large intestine; includes ascending, transverse, descending, and sigmoid portions.
Combination (synthesis) reaction Chemical reaction in which larger, more complex atoms or molecules are formed from simpler ones.
Complement A group of bloodborne proteins, which, when activated, enhance the inflammatory and immune responses and may lead to cell lysis.
Complementarity of structure and function The relationship between a structure and its function; i.e., structure determines function.
Complementary base Refers to the ability of a nitrogenous base of DNA or RNA to bond to another nitrogenous base. For example, adenine (A) is the complementary base of thymine (T). The result is base pairing.
Complete blood count (CBC) Clinical test that includes counts of all formed elements, a hematocrit, and measurements of erythrocyte size and hemoglobin content.
Compound Substance composed of two or more different elements, the atoms of which are chemically united.
Concentration gradient The difference in the concentration of a particular substance between two different areas.
Conducting zone Includes all respiratory passageways that provide conduits for air to reach the sites of gas exchange (the respiratory zone).
Conductivity Ability to transmit an electrical impulse.
Cones One of the two types of photoreceptor cells in the retina of the eye; provide for color vision.
Congenital (kun-jeh'nih-tul) Existing at birth.
Congestive heart failure (CHF) Condition in which the pumping efficiency of the heart is depressed so that circulation is inadequate to meet tissue needs.
Conjunctiva (kon"junk-ti'vah) Thin, protective mucous membrane lining the eyelids and covering the anterior surface of the eye itself.
Connective tissue A primary tissue; form and function vary extensively. Functions include support, storage, and protection.
Connexons (kŏ-nek'sonz) Hollow cylinders made of transmembrane proteins that connect adjacent cells at gap junctions, allowing chemical substances to pass through.
Consciousness The ability to perceive, communicate, remember, understand, appreciate, and initiate voluntary movements.
Contraception The prevention of conception; birth control.
Contractility Muscle cell's ability to move by shortening.
Contraction To shorten or develop tension, an ability highly developed in muscle cells.
Contralateral Relating to the opposite side.
Control center One of three interdependent components of homeostatic control mechanisms; determines the set point.
Cornea (kor'ne-ah) Transparent anterior portion of the eyeball; part of the fibrous layer.
Corona radiata (kor-o'nah ra-de-ah'tah) (1) Arrangement of elongated follicle cells around a mature ovum; (2) crownlike arrangement of nerve fibers radiating from the internal capsule of the brain to every part of the cerebral cortex.
Coronary circulation The functional blood supply of the heart; shortest circulation in the body.
Cortex (kor'teks) Outer surface layer of an organ.
Corticosteroids (kor"tĭ-ko-stĕ'roidz) Steroid hormones released by the adrenal cortex.
Cortisol (hydrocortisone) (kor'tih-sol) Glucocorticoid produced by the adrenal cortex.
Covalent bond (ko-va'lent) Chemical bond created by electron sharing between atoms.
Cranial nerves The 12 nerve pairs that arise from the brain.
Craniosacral division Another name for the parasympathetic division of the autonomic nervous system.
Cranium (cranial bones) (kra'ne-um) Bony protective encasement of the brain and organs of hearing and equilibrium; also called the skull.
Creatine kinase (kre'ah-tin) Enzyme that catalyzes the transfer of phosphate from creatine phosphate to ADP, forming creatine and ATP; important in muscle contraction.
Creatine phosphate (CP) (fos-fāt) Compound that serves as an alternative energy source for muscle tissue.
Creatinine (kre-at'ĭ-nin) A nitrogenous waste molecule which is not reabsorbed by the kidney; this characteristic makes it useful for measurement of the GFR and glomerular function.

Crista ampullaris Sensory receptor organ within the ampulla of each semicircular canal of the inner ear; dynamic equilibrium receptor.

Cross section A cut running horizontally from right to left, dividing the body into superior and inferior parts.

Crystals A highly ordered 3-D lattice; formed when an element or compound solidifies or is in a dry state.

Cutaneous (ku-ta'ne-us) Pertaining to the skin.

Cutaneous sensory receptors Receptors located throughout the skin that respond to stimuli arising outside the body; part of the nervous system.

Cyclic AMP Intracellular second messenger that mediates the effects of the first (extracellular) messenger (hormone or neurotransmitter); formed from ATP by a plasma membrane enzyme (adenylate cyclase).

Cystic fibrosis (CF) Genetic disorder in which secretion of overly viscous mucus clogs the respiratory passages, predisposes to fatal respiratory infections.

Cytochromes (si'to-krōmz) Brightly colored iron-containing proteins that form part of the inner mitochondrial membrane and function as electron carriers in oxidative phosphorylation.

Cytokines Chemical mediators involved in cellular immunity.

Cytokinesis (si"to-ki-ne'sis) The division of cytoplasm that occurs after the cell nucleus has divided.

Cytoplasm (si'to-plazm) The cellular material surrounding the nucleus and enclosed by the plasma membrane.

Cytosine (C) (si'to-sēn) Nitrogen-containing base that is part of a nucleotide structure.

Cytoskeleton Literally, cell skeleton. An elaborate series of rods running through the cystol, supporting cellular structures and providing the machinery to generate various cell movements.

Cytosol Viscous, semitransparent fluid substance of cytoplasm in which other elements are suspended.

Cytotoxic T cell (T_C cell) Effector T cell that directly kills (lyses) foreign cells, cancer cells, or virus-infected body cells. Also called a cytolytic T cell.

Deamination (de'am"ih-na'shun) Removal of an amine group from an organic compound.

Decomposition reaction Chemical reaction in which a molecule is broken down into smaller molecules or its constituent atoms.

Defecation (def"ih-ka'shun) Elimination of the contents of the bowels (feces).

Deglutition (deg"loo-tish'un) Swallowing.

Dehydration (de"hi-dra'shun) Condition of excessive water loss.

Dehydration synthesis Process by which a large molecule is synthesized by removing water and covalently bonding smaller molecules together.

Dendrite (den'drīt) Branching neuron process that serves as a receptive, or input, region; transmits an electrical signal toward the cell body.

Dendritic cells Protective cells that phagocytize antigens, migrate to lymph nodes, and present the antigen to T cells, causing them to activate and mount an immune response; called Langerhans' cells in the skin.

Depolarization (de-po"ler-ah-za'shun) Loss of a state of polarity; loss or reduction of negative membrane potential.

Dermatome (der'mah-tōm) Portion of somite mesoderm that forms the dermis of the skin; also the area of skin innervated by the cutaneous branches of a single spinal nerve.

Dermis Layer of skin deep to the epidermis; composed of dense irregular tissue.

Desmosome (dez'muh-sōm) Cell junction composed of thickened plasma membranes joined by filaments.

Diabetes insipidus (di"ah-be'tez in-sih'pih-dus) Disease characterized by passage of a large quantity of dilute urine plus intense thirst and dehydration caused by inadequate release of antidiuretic hormone (ADH).

Diabetes mellitus (DM) (meh-li'tus) Disease caused by deficient insulin release or by insulin resistance, leading to inability of the body cells to use carbohydrates.

Dialysis (di-al'ah-sis) Diffusion of solute(s) through a semipermeable membrane.

Diapedesis (di"ah-pĕ-de'sis) Passage of white blood cells through intact vessel walls into tissue.

Diaphragm (di'ah-fram) (1) Any partition or wall separating one area from another; (2) a muscle that separates the thoracic cavity from the lower abdominopelvic cavity.

Diaphysis (di-af'ĭ-sis) Elongated shaft of a long bone.

Diarthrosis (di"ar-thro'sis) Freely movable joint.

Diastole (di-as'to-le) Period of the cardiac cycle when either the ventricles or the atria are relaxing.

Diastolic pressure (di-as-tah'lik) Arterial blood pressure reached during or as a result of diastole; lowest level of any given cardiac cycle.

Diencephalon (interbrain) (di"en-seh'fuh-lon) That part of the forebrain between the cerebral hemispheres and the midbrain including the thalamus, the third ventricle, and the hypothalamus.

Differential white blood cell count Diagnostic test to determine relative proportion of individual leukocyte types.

Diffusion (dĭ-fu'zhun) The spreading of particles in a gas or solution with a movement toward uniform distribution of particles.

Digestion Chemical or mechanical process of breaking down foodstuffs to substances that can be absorbed.

Digestive system System that processes food into absorbable units and eliminates indigestible wastes.

Dipeptide A combination of two amino acids united by means of a peptide bond.

Diploë (dip'lo-e) The internal layer of spongy bone in flat bones.

Diploid chromosomal number The chromosomal number characteristic of an organism, symbolized as $2n$; twice the chromosomal number (n) of the gamete; in humans, $2n = 46$.

Diplopia (dĭ-plo'pe-ah) Double vision.

Dipole (polar molecule) Nonsymmetrical molecules that contain electrically unbalanced atoms.

Disaccharide (di-sak'ah-rīd", di-sak'ah-rid) Literally, double sugar; e.g., sucrose, lactose.

Dislocation (luxation) Occurs when bones are forced out of their normal alignment at a joint.

Displacement (exchange) reaction Chemical reaction in which bonds are both made and broken; atoms become combined with different atoms.

Distal (dis'tul) Away from the attached end of a limb or the origin of a structure.

Diuretics (di"u-ret'iks) Chemicals that enhance urinary output.

Diverticulum (di"ver-tik'u-lum) A pouch or sac in the walls of a hollow organ or structure.

DNA (deoxyribonucleic acid) (de-ok"sĭ-ri"bo-nu-kla'ik) A nucleic acid found in all living cells; it carries the organism's hereditary information.

DNA replication Process that occurs before cell division; ensures that all daughter cells have identical genes.

Dominant traits Occurs when one allele masks or suppresses the expression of its partner.

Dominant-recessive inheritance Reflects the interaction of dominant and recessive alleles.

Dorsal (dor'sul) Pertaining to the back; posterior.

Dorsal root ganglion Peripheral collection of cell bodies of first-order afferent neurons whose central axons enter the spinal cord.

Double helix The secondary structure assumed by two strands of DNA, held together throughout their length by hydrogen bonds between bases on opposite strands.

Duct (dukt) A canal or passageway; a tubular structure that provides an exit for the secretions of a gland, or for conducting any fluid.

Ductus (vas) deferens Extends from the epididymis to the urethra; propels sperm into the urethra by peristalsis during ejaculation.

Duodenum (du"o-de'num) First part of the small intestine.

Dura mater (du'rah ma'ter) Outermost and toughest of the three membranes (meninges) covering the brain and spinal cord.

Dynamic equilibrium Sense that reports on angular (rotatory) acceleration or deceleration of the head in space.
Dyskinesia (dis-kĭ-ne'ze-ah) Disorders of muscle tone, posture, or involuntary movements.
Dyspnea (disp-ne'ah) Difficult or labored breathing; air hunger.
Eccrine glands (ek'rin) Sweat glands abundant on the palms, soles of feet, and the forehead.
Ectoderm (ek'to-derm) Embryonic germ layer; forms the epidermis of the skin and its derivatives, and nervous tissues.
Edema (ĕ-de'mah) Abnormal increase in the amount of interstitial fluid; causes swelling.
Effector (ef-ek'ter) Organ, gland, or muscle capable of being activated by nerve endings.
Efferent (ef'er-ent) Carrying away or away from, especially a nerve fiber that carries impulses away from the central nervous system.
Elastic cartilage Cartilage with abundant elastic fibers; more flexible than hyaline cartilage.
Elastic fiber Fiber formed from the protein elastin, which gives a rubbery and resilient quality to the matrix of connective tissue.
Electrical energy Energy formed by the movement of charged particles across cell membranes.
Electrocardiogram (ECG or EKG) (e-lek"tro-car'de-o-gram") Graphic record of the electrical activity of the heart.
Electrochemical gradient The combined difference in concentration and charge; influences the distribution and direction of diffusion of ions.
Electroencephalogram (EEG) (e-lek"tro-en-sef'ah-lo-gram") Graphic record of the electrical activity of nerve cells in the brain.
Electrolyte (e-lek'tro-līt) Chemical substances, such as salts, acids, and bases, that ionize and dissociate in water and are capable of conducting an electrical current.
Electrolyte balance Refers to the balance between input and output of salts (sodium, potassium, calcium, magnesium) in the body.
Electromagnetic radiation Emitted photons (wave packets) of energy, e.g., light, X ray, infrared.
Electron Negatively charged subatomic particle; orbits the atom's nucleus.
Electron shells (energy levels) Regions of space that consecutively surround the nucleus of an atom.
Element One of a limited number of unique varieties of matter that composes substances of all kinds; e.g., carbon, hydrogen, oxygen.
Embolism (em'bo-lizm) Obstruction of a blood vessel by an embolus (blood clot, fatty mass, bubble of air, or other debris) floating in the blood.
Embryo (em'bre-o) Developmental stage extending from fertilization to the end of the eighth week.
Emesis Reflexive emptying of the stomach through the esophagus and pharynx; also known as vomiting.
Encephalitis (en"seh-fuh-lī'tis) Inflammation of the brain.
Endergonic reaction Chemical reaction that absorbs energy, e.g., an anabolic reaction.
Endocardium (en"do-kar'de-um) Endothelial membrane that lines the interior of the heart.
Endochondral ossification (en"do-kon'dral) Embryonic formation of bone by the replacement of calcified cartilage; most skeletal bones are formed by this process.
Endocrine glands (en'do-krin) Ductless glands that empty their hormonal products directly into the blood.
Endocrine system Body system that includes internal organs that secrete hormones.
Endocytosis (en"do-si-to'sis) Means by which fairly large extracellular molecules or particles enter cells, e.g., phagocytosis, pinocytosis, receptor-mediated endocytosis.
Endoderm (en'do-derm) Embryonic germ layer; forms the lining of the digestive tube and its associated structures.
Endogenous (en-doj'ĕ-nŭs) Originating or produced within the organism or one of its parts.
Endometrium (en"do-me'tre-um) Mucous membrane lining of the uterus.
Endomysium (en"do-mis'e-um) Thin connective tissue surrounding each muscle cell.
Endoplasmic reticulum (ER) (en"do-plaz'mik rĕ-tik'u-lum) Membranous network of tubular or saclike channels in the cytoplasm of a cell.
Endosteum (en-dos'te-um) Connective tissue membrane covering internal bone surfaces.
Endothelium (en"do-the'le-um) Single layer of simple squamous cells that line the walls of the heart, blood vessels, and lymphatic vessels.
Energy The capacity to do work; may be stored (potential energy) or in action (kinetic energy).
Energy intake Energy liberated during food oxidation.
Energy output Sum of energy lost as heat, as work, and as fat or glycogen storage.
Enzyme (en'zīm) A protein that acts as a biological catalyst to speed up a chemical reaction.
Eosinophil (e"o-sin'o-fil) Granular white blood cell whose granules readily take up an acid stain called eosin.
Ependymal cell (ĕ-pen'dĭ-mul) A type of CNS supporting cell; lines the central cavities of the brain and spinal cord.
Epidermis (ep"ĭ-der'mis) Superficial layer of the skin; composed of keratinized stratified squamous epithelium.
Epididymis (ep"ĭ-dĭ'dĭ-mis) That portion of the male duct system in which sperm mature. Empties into the ductus (or vas) deferens.
Epidural space Area between the bony vertebrae and the dura mater of the spinal cord.
Epiglottis (eh"puh-glah'tis) Elastic cartilage at the back of the throat; covers the opening of the larynx during swallowing.
Epileptic seizures Abnormal electrical discharges of groups of brain neurons, during which no other messages can get through.
Epimysium (ep"ĭ-mis'e-um) Sheath of fibrous connective tissue surrounding a muscle.
Epinephrine (ep"ĭ-nef'rin) Chief hormone produced by the adrenal medulla. Also called adrenaline.
Epiphyseal plate (e"pĭ-fis'e-ul) Plate of hyaline cartilage at the junction of the diaphysis and epiphysis that provides for growth in length of a long bone.
Epiphysis (e-pif'ĭ-sis) The end of a long bone, attached to the shaft.
Epithalamus Most dorsal portion of the diencephalon; forms the roof of the third ventricle with the pineal gland extending from its posterior border.
Epithelium (epithelial tissue) (ep"ĭ-the'le-ul) Pertaining to a primary tissue that covers the body surface, lines its internal cavities, and forms glands.
Erythrocytes (e-rith'ro-sīts) Red blood cells.
Erythropoiesis (ĕ-rith"ro-poi-e'sis) Process of erythrocyte formation.
Erythropoietin (EPO) (ĕ-rith"ro-poi'ĕ-tin) Hormone that stimulates production of red blood cells.
Esophagus (ĕ-sof'ah-gus) Muscular tube extending from the laryngopharynx through the diaphragm to join the stomach; collapses when not involved in food propulsion.
Estrogens (es'tro-jenz) Hormones that stimulate female secondary sex characteristics; female sex hormones.
Eupnea (ūp-ne'ah) Normal respiratory rate and rhythm.
Exchange (displacement) reaction Chemical reaction in which bonds are both made and broken; atoms become combined with different atoms.
Excitation-contraction (E-C) coupling Sequence of events by which transmission of an action potential along the sarcolemma leads to the sliding of myofilaments.
Excitatory postsynaptic potential (EPSP) Depolarizing graded potential in a postsynaptic neuron.
Excretion (ek-skre'shun) Elimination of waste products from the body.
Exergonic reaction Chemical reaction that releases energy, e.g., a catabolic or oxidative reaction.

Exocrine glands (ek'so-krin) Glands that have ducts through which their secretions are carried to a particular site.
Exocytosis (ek"so-si-to'sis) Mechanism by which substances are moved from the cell interior to the extracellular space as a secretory vesicle fuses with the plasma membrane.
Exogenous (ek-sah'jeh-nus) Developing or originating outside an organ or part.
Exons Amino acid–specifying informational sequences (separated by introns) in the genes of higher organisms.
Extension Movement that increases the angle of a joint, e.g., straightening a flexed knee.
Exteroceptor (ek"ster-o-sep'tor) Sensory end organ that responds to stimuli from the external world.
Extracellular fluid (ECF) Internal fluid located outside cells; includes plasma and interstitial fluid.
Extracellular materials Substances found outside the cell; include interstitial fluid, blood plasma, and cerebrospinal fluid.
Extracellular matrix Nonliving material in connective tissue consisting of ground substance and fibers that separates the living cells.
Extrasystole (ek"strah-sis'to-le) Premature heart contraction.
Extrinsic (ek-strin'sik) Of external origin.
Extrinsic eye muscles The six skeletal muscles which attach to and move each eye.
Facilitated diffusion Passive transport process used by certain molecules, e.g., glucose and other simple sugars too large to pass through plasma membrane pores. Involves movement through channels or movement facilitated by a membrane carrier.
Fallopian tube (fah-lō'pē-un). *See* Uterine tube.
Fascia (fash'e-ah) Layers of fibrous tissue covering and separating muscle.
Fascicle (fas'ĭ-kl) Bundle of nerve or muscle fibers bound together by connective tissues.
Fatty acids Linear chains of carbon and hydrogen atoms (hydrocarbon chains) with an organic acid group at one end. A constituent of fat.
Feces (fe'sēz) Material discharged from the bowel; composed of food residue, secretions, bacteria.
Fenestrated (fen'es-tra-tid) Pierced with one or more small openings.
Fertilization Fusion of the sperm and egg nuclei.
Fetus Developmental stage extending from the ninth week of development to birth.
Fiber A slender threadlike structure or filament. *See also* Nerve fiber, Muscle fiber.
Fibrillation Condition of rapid and irregular or out-of-phase heart contractions.
Fibrin (fi'brin) Fibrous insoluble protein formed during blood clotting.
Fibrinogen (fi-brin'o-jin) A soluble blood protein that is converted to insoluble fibrin during blood clotting.
Fibrinolysis Process that removes unneeded blood clots when healing has occurred.
Fibroblast (fi'bro-blast) Young, actively mitotic cell that forms the fibers of connective tissue.
Fibrocartilage The most compressible type of cartilage; resistant to stretch. Forms vertebral discs and knee joint cartilages.
Fibrocyte (fi'bro-sīt) Mature fibroblast; maintains the matrix of fibrous types of connective tissue.
Fibrosis Proliferation of fibrous connective tissue called scar tissue.
Fibrous joints Bones joined by fibrous tissue; no joint cavity is present.
Filtrate A plasma-derived fluid that is processed by the renal tubules to form urine.
Filtration Passage of a solvent and dissolved substances through a membrane or filter.
First-degree burn A burn in which only the epidermis is damaged.
Fissure (fih'zher) (1) A groove or cleft; (2) the deepest depressions or inward folds on the brain.
Fixator (fix'a-ter) Muscle that immobilizes one or more bones, allowing other muscles to act from a stable base.
Flagellum (flah-jel'lum) Long, whiplike extension of the plasma membrane of some bacteria and of sperm; propels the cell.
Flexion (flek'shun) Movement that decreases the angle of the joint, e.g., bending the knee from a straight to an angled position.
Flexor (withdrawal) reflex Reflex initiated by a painful stimulus (actual or perceived); causes automatic withdrawal of the threatened body part from the stimulus.
Fluid mosaic model A depiction of the structure of the membranes of a cell as phospholipid bilayers in which proteins are dispersed.
Follicle (fah'lih-kul) (1) Ovarian structure consisting of a developing egg surrounded by one or more layers of follicle cells; (2) colloid-containing structure of the thyroid gland.
Follicle-stimulating hormone (FSH) Hormone produced by the anterior pituitary that stimulates ovarian follicle production in females and sperm production in males.
Fontanels (fon"tah-nelz') Fibrous membranes at the angles of cranial bones that accommodate brain growth in the fetus and infant.
Foramen (fo-ra'men) Hole or opening in a bone or between body cavities.
Forebrain (prosencephalon) Anterior portion of the brain consisting of the telencephalon and the diencephalon.
Formed elements Cellular portion of blood.
Fossa (fos'ah) A depression, often an articular surface.
Fovea (fo've-ah) A pit.
Fracture A break in a bone.
Free radicals Highly reactive chemicals with unpaired electrons that can scramble the structure of proteins, lipids, and nucleic acids.
Frontal (coronal) plane Longitudinal (vertical) plane that divides the body into anterior and posterior parts.
Fulcrum The fixed point on which a lever moves when a force is applied.
Fundus (fun'dus) Base of an organ; part farthest from the opening of the organ.
G protein Protein that relays signals between extracellular first messengers (hormones or neurotransmitters) and intracellular second messengers (such as cyclic AMP) via an effector enzyme.
Gallbladder Sac beneath the right lobe of the liver used for bile storage.
Gallstones (biliary calculi) Crystallized cholesterol that obstructs the flow of bile from the gallbladder.
Gamete (gam'ēt) Sex or germ cell.
Gametogenesis (gam"eh-to-jen'eh-sis) Formation of gametes.
Ganglion (gang'gle-on) Collection of nerve cell bodies outside the CNS.
Ganglionic neuron (gan"gle-ah'nik) Autonomic motor neuron that has its cell body in a peripheral ganglion and projects its (postganglionic) axon to an effector.
Gap junction A passageway between two adjacent cells; formed by transmembrane proteins called connexons.
Gastrin Hormone secreted in the stomach; regulates gastric juice secretion by stimulating HCl production.
Gastroenteritis Inflammation of the gastrointestinal tract.
Gastrulation (gas"troo-la'shun) Developmental process that produces the three primary germ layers (ectoderm, mesoderm, and endoderm).
Gene One of the biological units of heredity located in chromatin; transmits hereditary information.
Genetic code Refers to the rules by which the base sequence of a DNA gene is translated into protein structures (amino acid sequences).
Genitalia (jen"i-ta'le-ă) The internal and external reproductive organs.
Genome The complete set of chromosomes derived from one parent (the haploid genome); or the two sets of chromosomes, i.e., one set from the egg, the other from the sperm (the diploid genome).
Genotype (jen'o-tīp) One's genetic makeup or genes.
Germ layers Three cellular layers (ectoderm, mesoderm, and endoderm) that represent the initial specialization of cells in the embryonic body and from which all body tissues arise.

Gestation period (jes-ta'shun) The period of pregnancy; about 280 days for humans.
Gland Organ specialized to secrete or excrete substances for further use in the body or for elimination.
Glaucoma (glaw-ko'mah) Condition in which intraocular pressure increases to levels that cause compression of the retina and optic nerve; results in blindness unless detected early.
Glial cells (gle'al) *See* Neuroglia.
Glomerular capsule (glō-mer'yoo-ler) Double-walled cup at end of a renal tubule; encloses a glomerulus. Also called Bowman's capsule.
Glomerular filtration rate (GFR) Rate of filtrate formation by the kidneys.
Glomerulus (glo-mer'u-lus) (1) Cluster of capillaries forming part of the nephron; forms filtrate; (2) odor-specific processing unit in olfactory bulb.
Glottis (glah'tis) Opening between the vocal cords in the larynx.
Glucagon (gloo'kah-gon) Hormone formed by alpha cells of pancreatic islets; raises the glucose level of blood.
Glucocorticoids (gloo"ko-kor'tĭ-koidz) Adrenal cortex hormones that increase blood glucose levels and aid the body in resisting long-term stressors.
Gluconeogenesis (gloo"ko-ne"o-jen'ĕ-sis) Formation of glucose from noncarbohydrate molecules.
Glucose (gloo'kōs) Principal blood sugar; a hexose.
Glycerol (glis'er-ol) A modified simple sugar (a sugar alcohol); a building block of fats.
Glycocalyx (cell coat) (gli"ko-kal'iks) A layer of externally facing glycoproteins on a cell's plasma membrane that determines blood type; involved in the cellular interactions of fertilization, embryonic development, and immunity, and acts as an adhesive between cells.
Glycogen (gli'ko-jin) Main carbohydrate stored in animal cells; a polysaccharide.
Glycogenesis (gli"ko-jen'ĕ-sis) Formation of glycogen from glucose.
Glycogenolysis (gli"ko-jĕ-nol'ĭ-sis) Breakdown of glycogen to glucose.
Glycolipid (gli"ko-lip'id) A lipid with one or more covalently attached sugars.
Glycolysis (gli-kol'ĭ-sis) Breakdown of glucose to pyruvic acid—an anaerobic process.
Goblet cells Individual cells (unicellular glands) that produce mucus.
Golgi apparatus (gol'je) Membranous system close to the cell nucleus that packages protein secretions for export, packages enzymes into lysosomes for cellular use, and modifies proteins destined to become part of cellular membranes.
Golgi tendon organs Proprioceptors located in tendons; monitor muscle tension to prevent tearing and help smooth onset and termination of muscle contraction.
Gonad (go'nad) Primary reproductive organ; i.e., the testis of the male or the ovary of the female.
Gonadocorticoids (gon"ah-do-kor'tĭ-koidz) Sex hormones, primarily androgens, secreted by the adrenal cortex.
Gonadotropins (gon"ah-do-trōp'inz) Gonad-stimulating hormones produced by the anterior pituitary.
Graafian follicle (graf'e-an). *See* Vesicular follicle.
Graded muscle responses Variations in the degree of muscle contraction by changing either the frequency or strength of the stimulus.
Graded potential A local change in membrane potential that varies directly with the strength of the stimulus, declines with distance.
Graves' disease Disorder resulting from hyperactive thyroid gland.
Gray matter Gray area of the central nervous system; contains neuronal cell bodies and their dendrites.
Growth hormone (GH) Hormone that stimulates growth in general; produced in the anterior pituitary; also called somatotropin (STH).
Guanine (G) (gwan'ēn) One of two major purines occurring in all nucleic acids.
Gustation (gus-ta'shun) Taste.
Gyrus (ji'rus) An outward fold of the surface of the cerebral cortex.
Hair follicle Structure with outer and inner root sheaths extending from the epidermal surface into the dermis and from which new hair develops.
Hapten (hap'ten) An incomplete antigen; has reactivity but not immunogenicity.
Haversian system (hah-ver'zhen). *See* Osteon.
Heart attack (coronary). *See* Myocardial infarction.
Heart block Impaired transmission of impulses from atrium to ventricle resulting in abnormally slow heart rhythms.
Heart murmur Abnormal heart sound (usually resulting from valve problems).
Heimlich maneuver Procedure in which the air in a person's own lungs is used to expel an obstructing piece of food.
Helper T cell Type of T lymphocyte that orchestrates cellular immunity by direct contact with other immune cells and by releasing chemicals called cytokines; also helps to mediate the humoral response by interacting with B cells.
Hematocrit (he-mat'o-krit) The percentage of total blood volume occupied by erythrocytes.
Hematoma (he"mah-to'mah) Mass of clotted blood that forms at an injured site.
Hematopoiesis (hem"ah-to-poi-e'sis) Blood cell formation; hemopoiesis.
Heme (hēm) Iron-containing pigment that is essential to oxygen transport by hemoglobin.
Hemocytoblast (he"mo-si'to-blast) Bone marrow cell that gives rise to all the formed elements of blood; hematopoietic stem cell.
Hemoglobin (he'muh-glo-bin) Oxygen-transporting protein of erythrocytes.
Hemolysis (he-mah'lĕ-sis) Rupture of erythrocytes.
Hemophilia (he"mo-fil'e-ah) A term loosely applied to several different hereditary bleeding disorders that exhibit similar signs and symptoms.
Hemopoiesis (he"mo-poi-e'sis) *See* Hematopoiesis.
Hemorrhage (hem'or-ij) Loss of blood from the vessels by flow through ruptured walls; bleeding.
Hemostasis (he"mo-sta'sis) Stoppage of bleeding.
Heparin Natural anticoagulant secreted into blood plasma.
Hepatic portal system (hĕ-pat'ik) Circulation in which the hepatic portal vein carries dissolved nutrients to the liver tissues for processing.
Hepatitis (hep"ah-ti'tis) Inflammation of the liver.
Hernia (her'ne-ah) Abnormal protrusion of an organ or a body part through the containing wall of its cavity.
Heterozygous (het"er-o-zi'gus) Having different allelic genes at a given locus or (by extension) many loci.
Hilton's law Any nerve serving a muscle that produces movement at a joint also innervates the joint and the skin over the joint.
Hilum (hi'lum) The indented region of an organ from which blood and/or lymph vessels and nerves enter and exit.
Hippocampus Limbic system structure that plays a role in converting new information into long-term memories.
Histamine (his'tuh-mēn) A chemical messenger (neurotransmitter or paracrine); causes vasodilation and increased capillary permeability; in stomach causes acid secretion.
Histology (his-tol'o-je) Branch of anatomy dealing with the microscopic structure of tissues.
HIV (human immunodeficiency virus) Virus that destroys helper T cells, thus depressing adaptive immunity; symptomatic AIDS gradually appears when lymph nodes can no longer contain the virus.
Holocrine glands (hol'o-krin) Glands that accumulate their secretions within their cells; secretions are discharged only upon rupture and death of the cell.
Homeostasis (ho"me-o-sta'sis) A state of body equilibrium or stable internal environment of the body.

Homologous (ho-mol'ŏ-gus) Parts or organs corresponding in structure but not necessarily in function.

Homozygous (ho-mo-zi'gus) Having identical genes at one or more loci.

Hormones Steroidal or amino acid–based molecules released to the blood that act as chemical messengers to regulate specific body functions.

Humoral immunity (hu'mer-ul) Immunity conferred by antibodies present in blood plasma and other body fluids.

Huntington's disease Hereditary disorder leading to degeneration of the basal nuclei and the cerebral cortex.

Hyaline cartilage (hi'ah-līn) The most abundant cartilage type in the body; provides firm support with some pliability.

Hydrochloric acid (HCl) (hi"dro-klor'ik) Acid that aids protein digestion in the stomach; produced by parietal cells.

Hydrogen bond Weak bond in which a hydrogen atom forms a bridge between two electron-hungry atoms. An important intramolecular bond.

Hydrogen ion (H^+) A hydrogen atom minus its electron and therefore carrying a positive charge (i.e., a proton).

Hydrolysis (hi"drah'lă-sis) Process in which water is used to split a substance into smaller particles.

Hydrophilic (hi"dro-fil'ik) Refers to molecules, or portions of molecules, that interact with water and charged particles.

Hydrophobic (hi"dro-fo'bik) Refers to molecules, or portions of molecules, that interact only with nonpolar molecules.

Hydrostatic pressure (hi"dro-stă'tic) Pressure of fluid in a system.

Hydroxyl ion (OH^-) (hi-drok'sil) An ion liberated when a hydroxide (a common inorganic base) is dissolved in water.

Hyperalgesia Pain amplification.

Hypercapnia (hi"per-kap'ne-ah) High carbon dioxide levels in the blood.

Hyperemia An increase in blood flow into a tissue or organ; congested with blood.

Hyperglycemic (hi"per-gli-se'mik) Term used to describe hormones such as glucagon that elevate blood glucose level.

Hyperopia (hi"per-o'pe-ah) A condition in which visual images are routinely focused behind rather than on the retina; commonly known as farsightedness.

Hyperplasia (hi"per-pla'ze-ah) Accelerated growth, e.g., in anemia, the bone marrow produces red blood cells at a faster rate.

Hyperpnea (hi"perp-ne'ah) An increase in ventilation in response to metabolic need (e.g., during exercise).

Hyperpolarization An increase in membrane potential in which the membrane becomes more negative than resting membrane potential.

Hypersensitivity Overzealous immune response to an otherwise harmless antigen.

Hypertension (hi"per-ten'shun) High blood pressure.

Hypertonic (hi"per-ton'ik) Excessive, above normal, tone or tension.

Hypertonic solution A solution that has a higher concentration of nonpenetrating solutes than the reference cell; having greater osmotic pressure than the reference solution (blood plasma or interstitial fluid).

Hypertrophy (hi-per'trah-fe) Increase in size of a tissue or organ independent of the body's general growth.

Hyperventilation An increase in the depth and rate of breathing that is in excess of the body's need for removal of carbon dioxide.

Hypocapnia Low carbon dioxide levels in the blood.

Hypodermis (superficial fascia) Subcutaneous tissue just deep to the skin; consists of adipose plus some areolar connective tissue.

Hypoglycemic (hi"po-gli-se'mik) Term used to describe hormones such as insulin that decrease blood glucose level.

Hyponatremia Abnormally low concentrations of sodium ions in extracellular fluid.

Hypoproteinemia (hi"po-pro"te-ĭ-ne'me-ah) A condition of unusually low levels of plasma proteins causing a reduction in colloid osmotic pressure; results in tissue edema.

Hypotension Low blood pressure.

Hypothalamic-hypophyseal tract (hi"po-thah-lam'ik–hi"po-fiz'e-al) Nerve bundles that run through the infundibulum and connect the neurohypophysis and the hypothalamus.

Hypothalamus (hi"po-thal'ah-mus) Region of the diencephalon forming the floor of the third ventricle of the brain.

Hypotonic (hi"po-ton'ik) Below normal tone or tension.

Hypotonic solution A solution that is more dilute (containing fewer nonpenetrating solutes) than the reference cell. Cells placed in hypotonic solutions plump up rapidly as water rushes into them.

Hypoventilation A decrease in the depth and rate of breathing; characterized by an increase in blood carbon dioxide.

Hypovolemic shock (hi"po-vo-le'mik) Most common form of shock; results from extreme blood loss.

Hypoxia (hi-pok'se-ah) Condition in which inadequate oxygen is available to tissues.

Ileocecal valve (il"e-o-se'kal) Site where the small intestine joins the large intestine.

Ileum (il'e-um) Terminal part of the small intestine; between the jejunum and the cecum of the large intestine.

Immune system A functional system whose components attack foreign substances or prevent their entry into the body.

Immunity (im"ūn'ĭ-te) Ability of the body to resist many agents (both living and nonliving) that can cause disease; resistance to disease.

Immunocompetence Ability of the body's immune cells to recognize (by binding) specific antigens; reflects the presence of plasma membrane-bound receptors.

Immunodeficiency Any congenital or acquired condition causing a deficiency in the production or function of immune cells or certain molecules (complement, antibodies, etc.) required for normal immunity.

In vitro (in ve'tro) In a test tube, glass, or artificial environment.

In vivo (in ve'vo) In the living body.

Incompetent valve Valve which does not close properly.

Incontinence Inability to control micturition voluntarily.

Infarct (in'farkt) Region of dead, deteriorating tissue resulting from a lack of blood supply.

Infectious mononucleosis Highly contagious viral disease; marked by excessive agranulocytes.

Inferior (caudal) Pertaining to a position near the tail end of the long axis of the body.

Inferior vena cava Vein that returns blood from body areas below the diaphragm.

Inflammation (in"flah-ma'shun) An innate (nonspecific) defensive response of the body to tissue injury; includes dilation of blood vessels and an increase in vessel permeability; indicated by redness, heat, swelling, and pain.

Infundibulum (in"fun-dib'u-lum) (1) A stalk of tissue that connects the pituitary gland to the hypothalamus; (2) the distal end of the uterine (fallopian) tube.

Inguinal (ing'wĭ-nal) Pertaining to the groin region.

Inhibitory postsynaptic potential (IPSP) A graded potential in a postsynaptic neuron that inhibits action potential generation; usually hyperpolarizing.

Inner cell mass Accumulation of cells in the blastocyst from which the embryo develops.

Innervation (in"er-va'shun) Supply of nerves to a body part.

Inorganic compound Chemical substances that do not contain carbon, including water, salts, and many acids and bases.

Insertion Movable attachment of a muscle.

Insula Lobe of the cerebral cortex that is buried in the lateral sulcus beneath portions of the parietal, frontal, and temporal lobes.

Insulin A hormone that enhances the carrier-mediated diffusion of glucose into tissue cells, thus lowering blood glucose levels.

Insulin resistance State in which a greater than normal amount of insulin is required to maintain normal glucose blood levels.

Integration The process by which the nervous system processes and interprets sensory input and makes decisions about what should be done at each moment.

Integumentary system (in-teg″u-men′tar-e) Skin and its derivatives; provides the external protective covering of the body.
Intercalated discs (in-ter′kah-la″ted) Specialized connections between myocardial cells containing gap junctions and desmosomes.
Interferons (IFNs) (in-ter-fēr′ons) Proteins released from virus-infected (and other) cells that protect uninfected cells from viral takeover. Also inhibit some cancers.
Internal capsule Band of projection fibers that runs between the basal nuclei and the thalamus.
Internal respiration Exchange of gases between blood and tissue fluid and between tissue fluid and cells.
Interneuron (association neuron) Nerve cell located between motor and sensory neurons that shuttles signals through CNS pathways where integration occurs.
Interoceptor (in″ter-o-sep′tor) Sensory receptor nerve ending in the viscera, which is sensitive to changes and stimuli within the body's internal environment; also called visceroceptor.
Interphase One of two major periods in the cell life cycle; includes the period from cell formation to cell division.
Interstitial cells Cells located in the loose connective tissue surrounding the seminiferous tubules; they produce androgens (most importantly testosterone), which are secreted into the surrounding interstitial fluid.
Interstitial fluid (IF) (in″ter-stish′al) Fluid between the cells.
Interstitial lamellae Incomplete lamellae that lie between intact osteons, filling the gaps between forming osteons, or representing the remnants of an osteon that has been cut through by bone remodeling.
Intervertebral discs (in″ter-ver′teh-brul) Discs of fibrocartilage between vertebrae.
Intracapsular ligament Ligament located within and separate from the articular capsule of a synovial joint.
Intracellular fluid (ICF) (in″trah-sel′u-ler) Fluid within a cell.
Intrinsic factor Substance produced by the stomach that is required for vitamin B_{12} absorption.
Intron Noncoding segment or portion of DNA that ranges from 60 to 100,000 nucleotides long.
Involuntary muscle Muscle that cannot ordinarily be controlled voluntarily.
Involuntary nervous system The autonomic nervous system.
Ion (ī′on) Atom with a positive or negative electric charge.
Ionic bond (ī-ah′nik) Chemical bond formed by electron transfer between atoms.
Ipsilateral (ip″sih-la′ter-ul) Situated on the same side.
Irritability Ability to respond to stimuli.
Ischemia (is-ke′me-ah) Local decrease in blood supply.
Isograft Tissue graft donated by an identical twin.
Isomer (i′so-mer) One of two or more substances that has the same molecular formula but with its atoms arranged differently.
Isometric contraction (i″so-mĕ′trik) Contraction in which the muscle does not shorten (the load is too heavy) but its internal tension increases.
Isotonic contraction (i″so-tah′nik) Contraction in which muscle tension remains constant at a given joint angle and load, and the muscle shortens.
Isotonic solution A solution with a concentration of nonpenetrating solutes equal to that found in the reference cell.
Isotopes (i′so-tōps) Different atomic forms of the same element, vary only in the number of neutrons they contain; the heavier species tend to be radioactive.
Jejunum (jĕ-joo′num) The part of the small intestine between the duodenum and the ileum.
Joint (articulation) The junction of two or more bones.
Joint kinesthetic receptor (kin″es-thet′ik) Receptor that provides information on joint position and motion.
Juxtaglomerular apparatus (JGA) (juks″tah-glo-mer′ular) Cells of the distal part of the ascending limb of the loop of Henle and afferent arteriole located close to the glomerulus; involved in blood pressure regulation (via release of the hormone renin) and autoregulation of GFR.
Karyotype (kar′e-o-tīp) The diploid chromosomal complement, typically shown as homologous chromosome pairs arranged from longest to shortest (X and Y are arranged by size rather than paired).
Keratin (ker′ah-tin) Fibrous protein found in the epidermis, hair, and nails that makes those structures hard and water-repellent; precursor is keratohyaline.
Ketones (ketone bodies) (ke′tōnz) Fatty acid metabolites; strong organic acids.
Ketosis (kē-tō′sis) Excess levels of ketone bodies in blood. Called ketoacidosis if blood pH is low.
Killer T cell *See* Cytotoxic T cell.
Kilocalories (kcal) *See* Calorie.
Kinetic energy (ki-net′ik) The energy of motion or movement, e.g., the constant movement of atoms, or the push given to a swinging door that sets it into motion.
Krebs cycle Aerobic metabolic pathway occurring within mitochondria, in which food metabolites are oxidized and CO_2 is liberated, and coenzymes are reduced. Also called the citric acid cycle.
Labia (la′be-ah) Lips; singular: labium.
Labor Collective term for the series of events that expel the infant from the uterus.
Labyrinth (lab′ĭ-rinth″) Bony cavities and membranes of the inner ear.
Lacrimal (lak′ri-mal) Pertaining to tears.
Lactation (lak-ta′shun) Production and secretion of milk.
Lacteal (lak′te-al) Special lymphatic capillaries of the small intestine that take up lipids.
Lactic acid (lak′tik) Product of anaerobic metabolism, especially in muscle.
Lacunae (lah-ku′ne) A small space, cavity, or depression; lacunae in bone or cartilage are occupied by cells.
Lamella (lah-mel′ah) A layer, such as of bone matrix in an osteon of compact bone.
Lamina (lam′ĭ-nah) (1) A thin layer or flat plate; (2) the portion of a vertebra between the transverse process and the spinous process.
Large intestine Portion of the digestive tract extending from the ileocecal valve to the anus; includes the cecum, appendix, colon, rectum, and anal canal.
Larynx (lar′ingks) Cartilaginous organ located between the trachea and the pharynx; voice box.
Latent period Period of time between stimulation and the onset of muscle contraction.
Lateral Away from the midline of the body.
Leptin Hormone released by fat cells that signals satiety.
Leukemia Refers to a group of cancerous conditions of white blood cells.
Leukocytes (loo′ko-sīts) White blood cells; formed elements involved in body protection that take part in inflammatory and immune responses.
Leukocytosis An increase in the number of leukocytes (white blood cells); usually the result of a microbiological attack on the body.
Leukopenia (loo″ko-pe′ne-ah) Abnormally low white blood cell count.
Leukopoiesis The production of white blood cells.
Lever system Consists of a lever (bone), effort (muscle action), resistance (weight of object to be moved), and fulcrum (joint).
Ligament (lig′ah-ment) Band of regular fibrous tissue that connects bones.
Ligands Signaling chemicals that bind specifically to membrane receptors.
Limbic system (lim′bik) Functional brain system involved in emotional response and memory formation.
Lipid (lih′pid) Organic compound formed of carbon, hydrogen, and oxygen; examples are fats and cholesterol.
Lipolysis (lĭ-pol′ĭ-sis) The breakdown of stored fats into glycerol and fatty acids.
Liver Lobed accessory organ that overlies the stomach; produces bile to help digest fat, and serves other metabolic and regulatory functions.

Lumbar (lum'bar) Portion of the back between the thorax and the pelvis.
Lumbar vertebrae The five vertebrae of the lumbar region of the vertebral column, commonly called the small of the back.
Lumen (loo'min) Cavity inside a tube, blood vessel, or hollow organ.
Luteinizing hormone (LH) (lu'te-in-īz"ing) Anterior pituitary hormone that aids maturation of cells in the ovary and triggers ovulation in females. In males, causes the interstitial cells of the testis to produce testosterone.
Lymph (limf) Protein-containing fluid transported by lymphatic vessels.
Lymph node Small lymphoid organ that filters lymph; contains macrophages and lymphocytes.
Lymphatic system (lim-fat'ik) System consisting of lymphatic vessels, lymph nodes, and other lymphoid organs and tissues; drains excess tissue fluid from the extracellular space and provides a site for immune surveillance.
Lymphatics General term used to designate the lymphatic vessels that collect and transport lymph.
Lymphocyte Agranular white blood cell that arises from bone marrow and becomes functionally mature in the lymphoid organs of the body.
Lymphokines (lim'fo-kīnz) Proteins involved in cell-mediated immune responses that enhance immune and inflammatory responses.
Lysosomes (lī'so-sōmz) Organelles that originate from the Golgi apparatus and contain strong digestive enzymes.
Lysozyme (lī'so-zīm) Enzyme in sweat, saliva, and tears that is capable of destroying certain kinds of bacteria.
Macromolecules Large, complex molecules containing from 100 to over 10,000 amino acids.
Macrophage (mak'ro-fāj") Protective cell type common in connective tissue, lymphoid tissue, and many body organs; phagocytizes tissue cells, bacteria, and other foreign debris; important as an antigen presenter to T cells in the immune response.
Macula (mak'u-lah) (1) Static equilibrium receptor within the vestibule of the inner ear; (2) a colored area or spot.
Malignant (muh-lig'nent) Life threatening; pertains to neoplasms that spread and lead to death, such as cancer.
Malignant melanoma (mel"ah-no'mah) Cancer of the melanocytes; can begin wherever there is pigment.
Mammary glands (mam'mer-e) Milk-producing glands of the breast.
Mandible (man'dĭ-bl) Lower jawbone; U-shaped, largest bone of the face.
Mast cells Immune cells that function to detect foreign substances in the tissue spaces and initiate local inflammatory responses against them; typically found clustered deep to an epithelium or along blood vessels.
Mastication (mas"tĭ-ka'shun) Chewing.
Meatus (me-a'tus) External opening of a canal.
Mechanical advantage (power lever) Condition that occurs when the load is close to the fulcrum and the effort is applied far from the fulcrum; allows a small effort exerted over a relatively large distance to move a large load over a small distance.
Mechanical disadvantage (speed lever) Condition that occurs when the load is far from the fulcrum and the effort is applied near the fulcrum; the effort applied must be greater than the load to be moved.
Mechanical energy The energy directly involved in moving matter; e.g., in bicycle riding, the legs provide the mechanical energy that moves the pedals.
Mechanoreceptor (meh"kĕ-no-rē-sep'ter) Receptor sensitive to mechanical pressure such as touch, sound, or exerted by muscle contraction.
Medial (me'de-ahl) Toward the midline of the body.
Median (midsagittal) plane Specific sagittal plane that lies exactly in the midline.
Mediastinum (me"de-ah-sti'num) A subdivision of the thoracic cavity containing the pericardial cavity.
Medulla (mĕ-dul'ah) Central portion of certain organs.
Medulla oblongata (mĕ-dul'ah ob"long-gah'tah) Inferiormost part of the brain stem.
Medullary cavity Central cavity of a long bone. Contains yellow or red (bone) marrow.
Meiosis (mi-o'sis) Nuclear division process that reduces the chromosomal number by half and results in the formation of four haploid (*n*) cells; occurs only in certain reproductive organs.
Melanin (mel'ah-nin) Dark pigment formed by cells called melanocytes; imparts color to skin and hair.
Melatonin (mel"ah-to'nin) A hormone secreted by the pineal gland; secretion peaks at night and helps set sleep-wake cycles; also a powerful antioxidant.
Membrane potential Voltage across the plasma membrane.
Membrane receptors A large, diverse group of integral proteins and glycoproteins that serve as binding sites.
Memory cells Members of T cell and B cell clones that provide for immunological memory.
Menarche (mĕ-nar'ke) Establishment of menstrual function; the first menstrual period.
Meninges (mĕ-nin'jēz) Protective coverings of the central nervous system; from the most external to the most internal, the dura mater, arachnoid, and pia mater.
Meningitis (mĕ-nin-ji'tis) Inflammation of the meninges.
Menopause Period of life when, prompted by hormonal changes, ovulation and menstruation cease.
Menstruation (men"stroo-a'shun) The periodic, cyclic discharge of blood, secretions, tissue, and mucus from the mature female uterus in the absence of pregnancy.
Merocrine glands (mer'o-krin) Glands that produce secretions intermittently; secretions do not accumulate in the gland.
Mesencephalon (mes"en-sef'ah-lon) One of the three primary vesicles of the developing brain; becomes the midbrain.
Mesenchyme (meh'zin-kīm) Common embryonic tissue from which all connective tissues arise.
Mesenteries (mes"en-ter'ēz) Double-layered extensions of the peritoneum that support most organs in the abdominal cavity.
Mesoderm (mez'o-derm) Primary germ layer that forms the skeleton and muscles of the body.
Mesothelium (mez"o-the'le-um) The epithelium found in serous membranes lining the ventral body cavity and covering its organs.
Messenger RNA (mRNA) Long nucleotide strands that reflect the exact nucleotide sequences of the genetically active DNA and carry the message of the latter.
Metabolic (fixed) acid Acid generated by cellular metabolism that must be eliminated by the kidneys.
Metabolic rate (mĕt"ah-bol'ik) Energy expended by the body per unit time.
Metabolic water (water of oxidation) Water produced from cellular metabolism (about 10% of our body's water).
Metabolism (mĕ-tab'o-lizm) Sum total of the chemical reactions occurring in the body cells.
Metaphase Second stage of mitosis.
Metastasis (mĕ-tas'tah-sis) The spread of cancer from one body part or organ into another not directly connected to it.
Metencephalon (afterbrain) A secondary brain vesicle; anterior portion of the rhombencephalon of the developing brain; becomes the pons and the cerebellum.
MHC (major histocompatibility complex) proteins Molecules on the outer plasma membrane of all cells; help the immune system distinguish self from nonself. T cells recognize antigens only when combined with these proteins.
Microfilaments (mi"kro-fil'ah-ments) Thin strands of the contractile protein actin.
Microglia (mi-kro'gle-ah) A type of CNS supporting cell; can transform into phagocytes in areas of neural damage or inflammation.

Microtubules (mi"kro-tu'būlz) One of three types of rods in the cytoskeleton of a cell; hollow tubes made of spherical protein that determine the cell shape as well as the distribution of cellular organelles.

Microvilli (mi"kro-vil'i) Tiny projections on the free surfaces of some epithelial cells; increase surface area for absorption.

Micturition (mik"tu-rish'un) Urination, or voiding; emptying the bladder.

Midbrain (mesencephalon) Region of the brain stem between the diencephalon and the pons.

Midsagittal (median) plane Specific sagittal plane that lies exactly in the midline.

Milliequivalents per liter (mEq/L) The units used to measure electrolyte concentrations of body fluids; a measure of the number of electrical charges in 1 liter of solution.

Mineralocorticoid (min"er-al"ō-kor'tih-koyd) Steroid hormone of the adrenal cortex that regulates Na^+ and K^+ metabolism and fluid balance.

Minerals Inorganic chemical compounds found in nature; salts.

Mitochondria (mi"to-kon'dre-ah) Cytoplasmic organelles responsible for ATP generation for cellular activities.

Mitosis Process during which the chromosomes are redistributed to two daughter nuclei; nuclear division. Consists of prophase, metaphase, anaphase, and telophase.

Mitral (bicuspid) valve (mi'tral) The left atrioventricular valve.

Mixed nerves Nerves containing the processes of motor and sensory neurons; their impulses travel to and from the central nervous system.

Molar (mo'lar) A solution concentration determined by mass of solute—1 liter of solution contains an amount of solute equal to its molecular weight in grams.

Molarity (mo-lar'ĭ-te) A way to express the concentration of a solution; moles per liter of solution.

Mole (mōl) A mole of any element or compound is equal to its atomic weight or its molecular weight (sum of atomic weights) measured in grams.

Molecule Particle consisting of two or more atoms joined together by chemical bonds.

Monoclonal antibodies (mon"o-klo'nal) Pure preparations of identical antibodies that exhibit specificity for a single antigen.

Monocyte (mon'o-sīt) Large single-nucleus white blood cell; agranular leukocyte.

Monokines Chemical mediators that enhance the immune response; secreted by macrophages.

Monosaccharide (mon"o-sak'ah-rīd) Literally, one sugar; building block of carbohydrates; e.g., glucose.

Morula (mor'u-lah) The mulberry-like solid mass of blastomeres resulting from cleavage in the early conceptus.

Motor areas Functional areas in the cerebral cortex that control voluntary motor functions.

Motor end plate Troughlike part of a muscle fiber's sarcolemma that helps form the neuromuscular junction.

Motor (efferent) nerves Nerves that carry impulses leaving the brain and spinal cord, and destined for effectors.

Motor unit A motor neuron and all the muscle cells it stimulates.

Mucous membranes (mucosae) Membranes that form the linings of body cavities open to the exterior (digestive, respiratory, urinary, and reproductive tracts).

Mucus (myoo'kus) A sticky, thick fluid secreted by mucous glands and mucous membranes; keeps the free surface of membranes moist.

Multinucleate cell (mul"tĭ-nu'kle-āt) Cell with more than one nucleus, e.g., skeletal muscle cells, liver cells.

Multiple sclerosis (MS) Demyelinating disorder of the CNS; causes hardened patches (sclerosis) in the brain and spinal cord.

Multipolar neurons Neurons with three or more processes; most common neuron type in the CNS.

Muscarinic receptors (mus"kah-rin'ik) Acetylcholine-binding receptors of the autonomic nervous system's target organs; named for activation by the mushroom poison muscarine.

Muscle fiber A muscle cell.

Muscle spindle (neuromuscular spindle) Encapsulated receptor found in skeletal muscle that is sensitive to stretch.

Muscle tension The force exerted by a contracting muscle on some object.

Muscle tone Low levels of contractile activity in relaxed muscle; keeps the muscle healthy and ready to act.

Muscle twitch The response of a muscle to a single brief threshold stimulus.

Muscular dystrophy A group of inherited muscle-destroying diseases.

Muscular system The organ system consisting of the skeletal muscles of the body and their connective tissue attachments.

Myelencephalon (spinal brain) A secondary brain vesicle; lower part of the developing hindbrain, especially the medulla oblongata.

Myelin sheath (mi'ĕ-lin) Fatty insulating sheath that surrounds all but the smallest nerve fibers.

Myoblasts Embryonic mesoderm cells from which all muscle fibers develop.

Myocardial infarction (MI) (mi"o-kar'de-al in-fark'shun) Condition characterized by dead tissue areas in the myocardium; caused by interruption of blood supply to the area. Commonly called heart attack.

Myocardium (mi"o-kar'de-um) Layer of the heart wall composed of cardiac muscle.

Myofibril (mi"o-fi'bril) Rodlike bundle of contractile filaments (myofilaments) found in muscle fibers (cells).

Myofilament (mi"o-fil'ah-ment) Filament that constitutes myofibrils. Of two types: actin and myosin.

Myoglobin (mi"o-glo'bin) Oxygen-binding pigment in muscle.

Myogram A graphic recording of mechanical contractile activity produced by an apparatus that measures muscle contraction.

Myometrium (mi"o-me'tre-um) Thick uterine musculature.

Myopia (mi-o'pe-ah) A condition in which visual images are focused in front of rather than on the retina; nearsightedness.

Myosin (mi'o-sin) One of the principal contractile proteins found in muscle.

Myxedema (mik"sĕ-de'mah) Condition resulting from underactive thyroid gland.

Nares (na'rez) Nostrils.

Natural killer (NK) cell Defensive cell (a type of lymphocyte) that can lyse and kill cancer cells and virus-infected body cells before the adaptive immune system is activated.

Necrosis (nĕ-kro'sis) Death or disintegration of a cell or tissues caused by disease or injury.

Negative feedback mechanisms The most common homeostatic control mechanism. The net effect is that the output of the system shuts off the original stimulus or reduces its intensity.

Neonatal period The four-week period immediately after birth.

Neoplasm (ne'o-plazm) An abnormal mass of proliferating cells. Benign neoplasms remain localized; malignant neoplasms are cancers, which can spread to other organs.

Nephron (nef'ron) Structural and functional unit of the kidney; consists of the glomerulus and renal tubule.

Nerve A bundle of axons in the peripheral nervous system.

Nerve fiber Axon of a neuron.

Nerve growth factor (NGF) Protein that promotes survival and development of sympathetic and sensory neurons; secreted by the target cells of postganglionic axons.

Nerve impulse A self-propagating wave of depolarization; also called an action potential.

Nerve plexuses Interlacing nerve networks that occur in the cervical, brachial, lumbar, and sacral regions and primarily serve the limbs.

Nervous system Fast-acting control system that triggers muscle contraction or gland secretion.

Neural tube Fetal tissue which gives rise to the brain, spinal cord, and associated neural structures; formed from ectoderm by day 23 of embryonic development.

Neuroglia (nu-rog'le-ah) Nonexcitable cells of neural tissue that support, protect, and insulate the neurons; glial cells.

Neurohypophysis (nu"ro-hi-pof'ĭ-sis) Posterior pituitary plus infundibulum; portion of the pituitary gland derived from the brain.

Neuromuscular junction Region where a motor neuron comes into close contact with a skeletal muscle cell.

Neuron (nerve cell) (nu'ron) Cell of the nervous system specialized to generate and transmit electrical signals (action potentials and graded potentials).

Neuron cell body The biosynthetic center of a neuron; also called the perikaryon, or soma.

Neuronal pools Functional groups of neurons that process and integrate information.

Neuropeptides (nu"ro-pep'tīds) A class of neurotransmitters including beta endorphins and enkephalins (which act as euphorics and reduce perception of pain) and gut-brain peptides.

Neurotransmitter Chemical messenger released by neurons that may, upon binding to receptors of neurons or effector cells, stimulate or inhibit those neurons or effector cells.

Neutral fats Consist of fatty acid chains and glycerol; also called triglycerides or triacylglycerols. Commonly known as oils when liquid.

Neutralization reaction Displacement reaction in which mixing an acid and a base forms water and a salt.

Neutron (nu'tron) Uncharged subatomic particle; found in the atomic nucleus.

Neutrophil (nu'tro-fil) Most abundant type of white blood cell.

Nicotinic receptors (nik"o-tin'ik) Acetylcholine-binding receptors of all autonomic ganglionic neurons and skeletal muscle neuromuscular junctions; named for activation by nicotine.

Nitric oxide (NO) A gaseous chemical messenger; diverse functions include participation in memory formation in the brain, and causing vasodilation throughout the body.

Nociceptor (no"se-sep'tor) Receptor sensitive to potentially damaging stimuli that result in pain.

Nondisjunction Failure of sister chromatids to separate during mitosis or failure of homologous pairs to separate during meiosis; results in abnormal numbers of chromosomes in the resulting daughter cells.

Nonpolar molecules Electrically balanced molecules.

Norepinephrine (NE) (nor"ep-ĭ-nef'rin) A catecholamine neurotransmitter and adrenal medullary hormone, associated with sympathetic nervous system activation.

Nuclear envelope The double membrane barrier of a cell nucleus.

Nucleic acid (nu-kle'ik) Class of organic molecules that includes DNA and RNA.

Nucleoli (nu-kle'o-li) Dense spherical bodies in the cell nucleus involved with ribosomal subunit synthesis and storage.

Nucleosome (nu'kle-o-sōm) Fundamental unit of chromatin; consists of a strand of DNA wound around a cluster of eight histone proteins.

Nucleotide (nu'kle-o-tīd) Building block of nucleic acids; consists of a sugar, a nitrogen-containing base, and a phosphate group.

Nucleus (nu'kle-is) (1) Control center of a cell; contains genetic material; (2) clusters of nerve cell bodies in the CNS.

Nutrients Chemical substances taken in via the diet that are used for energy and cell building.

Oblique section A cut made diagonally between the horizontal and vertical plane of the body or an organ.

Occlusion (ah-kloo'zhun) Closure or obstruction.

Octet rule (rule of eights) (ok-tet') The tendency of atoms to interact in such a way that they have eight electrons in their valence shell.

Olfaction (ol-fak'shun) Smell.

Oligodendrocyte (ol'ĭ-go-den'dro-sīt) A type of CNS supporting cell that composes myelin sheaths.

Oocyte (o'o-sīt) Immature female gamete.

Oogenesis (o"o-jen'ĕ-sis) Process of ovum (female gamete) formation.

Ophthalmic (op-thal'mik) Pertaining to the eye.

Optic (op'tik) Pertaining to the eye or vision.

Optic chiasma (op'tik ki-az'muh) The partial crossover of fibers of the optic nerves.

Organ A part of the body formed of two or more tissues and adapted to carry out a specific function; e.g., the stomach.

Organ system A group of organs that work together to perform a vital body function; e.g., the nervous system.

Organelles (or"gah-nelz') Small cellular structures (ribosomes, mitochondria, and others) that perform specific metabolic functions for the cell as a whole.

Organic compound Any compound composed of atoms (some of which are carbon) held together by covalent (shared electron) bonds.

Organic Pertaining to carbon-containing molecules, such as proteins, fats, and carbohydrates.

Organism The living animal (or plant), which represents the sum total of all its organ systems working together to maintain life.

Origin Attachment of a muscle that remains relatively fixed during muscular contraction.

Osmolality The number of solute particles dissolved in 1 kilogram (1000 g) of water; reflects the solution's ability to cause osmosis.

Osmolarity (oz"mo-lar'ĭ-te) The number of solute particles present in 1 liter of a solution.

Osmoreceptor (oz"mo-re-sep'tor) Structure sensitive to osmotic pressure or concentration of a solution.

Osmosis (oz-mo'sis) Diffusion of a solvent through a membrane from a dilute solution into a more concentrated one.

Osmotic pressure A measure of the tendency of water to move into a more concentrated solution.

Ossicles (os'sik-kilz). *See* Auditory ossicles.

Ossification (os"ĭ-fi-ka'shun). *See* Osteogenesis.

Osteoblasts (os-'te-o-blasts) Bone-forming cells.

Osteoclasts (os'te-o-klasts) Large cells that resorb or break down bone matrix.

Osteocyte (os'te-o-sīt) Mature bone cell.

Osteogenesis (os"te-o-jen'e-sis) The process of bone formation; also called ossification.

Osteoid (os'te-oid) Unmineralized bone matrix.

Osteomalacia (os"te-o-mah-la'she-ah) Disorder in which bones are inadequately mineralized; soft bones.

Osteon (os'te-on) System of interconnecting canals in the microscopic structure of adult compact bone; unit of bone; also called Haversian system.

Osteoporosis (os"te-o-po-ro'sis) Decreased density and strength of bone resulting from a gradual decrease in rate of bone formation.

Ovarian cycle (o-vayr'e-an) Monthly cycle of follicle development, ovulation, and corpus luteum formation in an ovary.

Ovary (o'var-e) Female reproductive organ in which ova (eggs) are produced; female gonad.

Ovulation (ov"u-la'shun) Ejection of an immature egg (oocyte) from the ovary.

Ovum (o'vum) Female gamete; egg.

Oxidases Enzymes that catalyze the transfer of oxygen in oxidation-reduction reactions.

Oxidation (oks'ĭ-da"shun) Process of substances combining with oxygen or the removal of hydrogen.

Oxidation-reduction (redox) reaction A reaction that couples the oxidation (loss of electrons) of one substance with the reduction (gain of electrons) of another substance.

Oxidative phosphorylation (ok'sĭ-da"tiv fos"for-ĭ-la'shun) Process of ATP synthesis during which an inorganic phosphate group is attached to ADP; occurs via the electron transport chain within the mitochondria.

Oxygen debt The volume of oxygen required after exercise to replenish stores of O_2, ATP, creatine phosphate, and glycogen and oxidize the lactic acid formed during exercise.

Oxyhemoglobin (ok"sĭ-he"mo-glo'bin) Oxygen-bound form of hemoglobin.
Oxytocin (ok"sĭ-to'sin) Hormone synthesized in the hypothalamus and secreted by the posterior pituitary; stimulates contraction of the uterus during childbirth and the ejection of milk during nursing.
Paget's disease (paj'ets) Disorder characterized by excessive bone breakdown and abnormal bone formation.
Palate (pal'at) Roof of the mouth.
Pancreas (pan'kre-us) Gland located behind the stomach, between the spleen and the duodenum; produces both endocrine and exocrine secretions.
Pancreatic juice (pan"kre-at'ik) Bicarbonate-rich secretion of the pancreas containing enzymes for digestion of all food categories.
Papilla (pah-pil'ah) Small, nipplelike projection; e.g., dermal papillae are projections of dermal tissue into the epidermis.
Paracrine (par"ah-krin') A chemical messenger that acts locally within the same tissue and is rapidly destroyed. Examples are prostaglandins and nitric oxide.
Parasagittal planes All sagittal planes offset from the midline.
Parasympathetic division The division of the autonomic nervous system that oversees digestion, elimination, and glandular function; the resting and digesting subdivision.
Parasympathetic tone Normal (background) level of parasympathetic output; sustains normal gastrointestinal and urinary tract activity, lowers heart rate.
Parathyroid glands (par"ah-thi'roid) Small endocrine glands located on the posterior aspect of the thyroid gland.
Parathyroid hormone (PTH) Hormone released by the parathyroid glands that regulates blood calcium level.
Parietal (pah-ri'ĕ-tal) Pertaining to the walls of a cavity.
Parietal serosa The part of the double-layered membrane that lines the walls of the ventral body cavity.
Parkinson's disease Neurodegenerative disorder of the basal nuclei due to insufficient secretion of the neurotransmitter dopamine; symptoms include tremor and rigid movement.
Partial pressure The pressure exerted by a single component of a mixture of gases.
Parturition (par"tu-rish'un) Culmination of pregnancy; giving birth.
Passive immunity Short-lived immunity resulting from the introduction of "borrowed antibodies" obtained from an immune animal or human donor; immunological memory is not established.
Passive (transport) processes Membrane transport processes that do not require cellular energy (ATP), e.g., diffusion, which is driven by kinetic energy.
Pathogen (path'o-jen) Disease-causing microorganism.
Pectoral (pek'tor-al) Pertaining to the chest.
Pectoral (shoulder) girdle Bones that attach the upper limbs to the axial skeleton; includes the clavicle and scapula.
Pedigree Traces a particular genetic trait through several generations and helps predict the genotype of future offspring.
Pelvic girdle (hip girdle) Consists of the paired coxal bones that attach the lower limbs to the axial skeleton.
Pelvis (pel'vis) (1) Basin-shaped bony structure composed of the pelvic girdle, sacrum, and coccyx; (2) funnel-shaped tube within the kidney continuous with the ureter.
Penis (pe'nis) Male organ of copulation and urination.
Pepsin Enzyme capable of digesting proteins in an acid pH.
Peptide bond (pep'tid) Bond joining the amine group of one amino acid to the acid carboxyl group of a second amino acid with the loss of a water molecule.
Perforating canals Canals that run at right angles to the long axis of the bone, connecting the vascular and nerve supplies of the periosteum to those of the central canals and medullary cavity; also called Volkmann's canals.
Pericardium (per"ĭ-kar'de-um) Double-layered sac enclosing the heart and forming its superficial layer; has fibrous and serous layers.
Perichondrium (per"ĭ-kon'dre-um) Fibrous, connective-tissue membrane covering the external surface of cartilaginous structures.
Perimysium (per"ĭ-mis'e-um) Connective tissue enveloping bundles of muscle fibers.
Perineum (per"ĭ-ne'um) That region of the body spanning the region between the ischial tuberosities and extending from the pubic arch to the coccyx.
Periosteum (per"e-os'te-um) Double-layered connective tissue that covers and nourishes the bone.
Peripheral congestion Condition caused by failure of the right side of the heart; results in edema in the extremities.
Peripheral nervous system (PNS) Portion of the nervous system consisting of nerves and ganglia that lie outside of the brain and spinal cord.
Peripheral resistance A measure of the amount of friction encountered by blood as it flows through the blood vessels.
Peristalsis (per"i-stal'sis) Progressive, wavelike contractions that move foodstuffs through the alimentary tube organs (or that move other substances through other hollow body organs).
Peritoneum (per"ĭ-to-ne'um) Serous membrane lining the interior of the abdominal cavity and covering the surfaces of abdominal organs.
Peritonitis (per"ĭ-to-ni'tis) Inflammation of the peritoneum.
Permeability That property of membranes that permits passage of molecules and ions.
Peroxisomes (pĕ-roks'ĭ-sōmz) Membranous sacs in cytoplasm containing powerful oxidase enzymes that use molecular oxygen to detoxify harmful or toxic substances, such as free radicals.
Petechiae (pe-te'ke-ah) Small, purplish skin blotches caused by widespread hemorrhage due to thrombocytopenia.
Peyer's patches (pi'erz) Lymphoid organs located in the small intestine.
pH unit (pe-āch) The measure of the relative acidity or alkalinity of a solution.
Phagocytosis (fag"o-si-to'sis) Engulfing of foreign solids by (phagocytic) cells.
Phagosome (fag'o-sōm) Vesicle formed as a result of phagocytosis.
Pharmacological dose A drug dose that is dramatically higher than normal levels of that substance (e.g., hormone) in the body.
Pharyngotympanic tube Tube that connects the middle ear and the pharynx. Also called auditory tube, eustachian tube.
Pharynx (fayr'inks) Muscular tube extending from the region posterior to the nasal cavities to the esophagus.
Phenotype (fe'no-tīp) Observable expression of the genotype.
Phospholipid (fos"fo-lip'id) Modified lipid, contains phosphorus.
Phosphorylation A chemical reaction in which a phosphate molecule is added to a molecule; for example, phosphorylation of ADP yields ATP.
Photoreceptor (fo"to-re-sep'tor) Specialized receptor cells that respond to light energy; rods and cones.
Physiological acidosis (as"ĭ-do'sis) Arterial pH lower than 7.35 resulting from any cause.
Physiological dose A drug dose that replicates normal levels of that substance (e.g., hormone) in the body.
Physiology (fiz"e-ol'o-je) Study of the function of living organisms.
Pineal gland (body) (pin'e-al) A hormone-secreting part of the diencephalon of the brain thought to be involved in setting the biological clock and influencing reproductive function.
Pinocytosis (pe"no-si-to'sis) Engulfing of extracellular fluid by cells.
Pituitary gland (pĭ-tu'ih-tayr"e) Neuroendocrine gland located beneath the brain that serves a variety of functions including regulation of gonads, thyroid, adrenal cortex, lactation, and water balance.
Placenta (plah-sen'tah) Temporary organ formed from both fetal and maternal tissues that provides nutrients and oxygen to the developing fetus, carries away fetal metabolic wastes, and produces the hormones of pregnancy.
Plasma (plaz'mah) The nonliving fluid component of blood within which formed elements and various solutes are suspended and circulated.

Plasma cells Members of a B cell clone; specialized to produce and release antibodies.

Plasma membrane Membrane, composed of phospholipids, cholesterol, and proteins, that encloses cell contents; outer limiting cell membrane.

Platelet (plāt'let) Cell fragment found in blood; involved in clotting.

Pleura (ploo'rah) Two-layered serous membrane that lines the thoracic cavity and covers the external surface of the lung.

Pleural cavity (ploo'ral) A potential space between the two layers of pleura; contains a thin film of serous fluid.

Plexus (plek'sus) A network of converging and diverging nerve fibers, blood vessels, or lymphatics.

Polar molecules Nonsymmetrical molecules that contain electrically unbalanced atoms.

Polarized State of a plasma membrane of an unstimulated neuron or muscle cell in which the inside of the cell is relatively negative in comparison to the outside; the resting state.

Polycythemia (pol"e-si-the'me-ah) An abnormally high number of erythrocytes.

Polymer A substance of high molecular weight with long, chainlike molecules consisting of many similar (repeated) units.

Polypeptide (pol"e-pep'tīd) A chain of amino acids.

Polyps Benign mucosal tumors.

Polysaccharide (pol"e-sak'ah-rīd) Literally, many sugars, a polymer of linked monosaccharides; e.g., starch, glycogen.

Pons (1) Any bridgelike structure or part; (2) the part of the brain stem connecting the medulla with the midbrain, providing linkage between upper and lower levels of the central nervous system.

Pore The surface opening of the duct of a sweat gland.

Positive feedback mechanisms Feedback that tends to cause the level of a variable to change in the same direction as an initial change.

Posterior pituitary. *See* Neurohypophysis.

Postganglionic axon (fiber) (post"gang-gle-ah'nik) Axon of a ganglionic neuron, an autonomic motor neuron that has its cell body in a peripheral ganglion; the axon projects to an effector.

Potential energy Stored or inactive energy.

Preganglionic neuron Autonomic motor neuron that has its cell body in the central nervous system and projects its axon to a peripheral ganglion.

Presbyopia (pres"be-o'pe-ah) A condition that results in the loss of near focusing ability; typical onset is around age 40.

Pressure gradient Difference in hydrostatic pressure that drives filtration.

Primary active transport A type of active transport in which the energy needed to drive the transport process is provided directly by hydrolysis of ATP.

Prime mover Muscle that bears the major responsibility for effecting a particular movement; an agonist.

Process (1) Prominence or projection; (2) series of actions for a specific purpose.

Progesterone (pro-jes'ter-ōn) Hormone partly responsible for preparing the uterus for the fertilized ovum.

Prolactin (PRL) (pro-lak'tin) Adenohypophyseal hormone that stimulates the breasts to produce milk.

Pronation (pro-na'shun) Inward rotation of the forearm causing the radius to cross diagonally over the ulna—palms face posteriorly.

Prophase The first stage of mitosis, consisting of coiling of the chromosomes accompanied by migration of the two daughter centrioles toward the poles of the cell, and nuclear membrane breakdown.

Proprioceptor (pro"pre-o-sep'tor) Receptor located in a joint, muscle, or tendon; concerned with locomotion, posture, and muscle tone.

Prostaglandin (PG) (pros"tah-glan'din) A lipid-based chemical messenger synthesized by most tissue cells that acts locally as a paracrine.

Prostate Accessory reproductive gland; produces one-third of semen volume, including fluids that activate sperm.

Protein (pro'tēn) Complex substance containing carbon, oxygen, hydrogen, and nitrogen; composes 10–30% of cell mass.

Prothrombin time Diagnostic test to determine status of hemostasis system.

Proton (pro'ton) Subatomic particle that bears a positive charge; located in the atomic nucleus.

Proton acceptor A substance that takes up hydrogen ions in detectable amounts. Commonly referred to as a base.

Proton donor A substance that releases hydrogen ions in detectable amounts; an acid.

Proximal (prok'si-mul) Toward the attached end of a limb or the origin of a structure.

Pseudounipolar neuron (soo"do-u"nĭ-po'lar) Another term for unipolar neuron.

Puberty Period of life when reproductive maturity is achieved.

Pulmonary (pul'muh-nayr-e) Pertaining to the lungs.

Pulmonary arteries Vessels that deliver blood to the lungs to be oxygenated.

Pulmonary circuit System of blood vessels that serves gas exchange in the lungs; i.e., pulmonary arteries, capillaries, and veins.

Pulmonary edema (ĕ-de'muh) Leakage of fluid into the air sacs and tissue of the lungs.

Pulmonary veins Vessels that deliver freshly oxygenated blood from the respiratory zones of the lungs to the heart.

Pulmonary ventilation Breathing; consists of inspiration and expiration.

Pulse Rhythmic expansion and recoil of arteries resulting from heart contraction; can be felt from outside the body.

Pupil Opening in the center of the iris through which light enters the eye.

Purkinje fibers (pur-kin'je) Modified ventricular muscle fibers of the conduction system of the heart.

Pus Fluid product of inflammation composed of white blood cells, the debris of dead cells, and a thin fluid.

Pyloric sphincter (pi-lor'ik sfink'ter) Valve of the distal end of the stomach that controls food entry into the duodenum.

Pyramidal (corticospinal) tracts Major motor pathways concerned with voluntary movement; descend from pyramidal cells in the frontal lobes of each cerebral hemisphere.

Pyruvic acid An intermediate compound in the metabolism of carbohydrates.

Radioactivity The process of spontaneous decay seen in some of the heavier isotopes, during which particles or energy is emitted from the atomic nucleus; results in the atom becoming more stable.

Radioisotope (ra"de-o-i'so-tōp) Isotope that exhibits radioactive behavior.

Ramus (ra'mus) Branch of a nerve, artery, vein, or bone.

Rapid eye movement (REM) sleep Stage of sleep in which rapid eye movements, an alert EEG pattern, and dreaming occur.

Reactant A substance taking part in a chemical reaction.

Receptor (re-sep'tor) (1) A cell or nerve ending of a sensory neuron specialized to respond to particular types of stimuli; (2) protein that binds specifically with other molecules, e.g., neurotransmitters, hormones, paracrines, antigens.

Receptor-mediated endocytosis One of three types of endocytosis in which engulfed particles attach to receptors before endocytosis occurs.

Receptor potential A graded potential that occurs at a sensory receptor membrane.

Recessive traits A trait due to a particular allele that does not manifest itself in the presence of other alleles that generate traits dominant to it; must be present in double dose to be expressed.

Reduction Chemical reaction in which electrons and energy are gained by a molecule (often accompanied by gain of hydrogen ions) or oxygen is lost.

Referred pain Pain felt at a site other than the area of origin.

Reflex Automatic reaction to stimuli.

Refraction The bending of a light ray when it meets a different surface at an oblique rather than right angle.

Regeneration Replacement of destroyed tissue with the same kind of tissue.

Regulatory T cells (T_{Reg} cells) Population of T cells (usually expressing CD4) that suppress the immune response.

Relative refractory period Follows the absolute refractory period; interval when a threshold for action potential stimulation is markedly elevated.

Renal (re'nal) Pertaining to the kidney.

Renal autoregulation Process the kidney uses to maintain a nearly constant glomerular filtration rate despite fluctuations in systemic blood pressure.

Renal clearance The volume of plasma from which a particular substance is completely removed in a given time, usually 1 minute; provides information about renal function.

Renin (re'nin) Hormone released by the kidneys that is involved with raising blood pressure.

Rennin Stomach-secreted enzyme that acts on milk protein; not produced in adults.

Repolarization Movement of the membrane potential to the initial resting (polarized) state.

Reproductive system Organ system that functions to produce offspring.

Resistance exercise High-intensity exercise in which the muscles are pitted against high resistance or immovable forces and, as a result, muscle cells increase in size.

Respiration The processes involved in supplying the body with oxygen and disposing of carbon dioxide.

Respiratory system Organ system that carries out gas exchange; includes the nose, pharynx, larynx, trachea, bronchi, lungs.

Resting membrane potential The voltage that exists across the plasma membrane during the resting state of an excitable cell; ranges from −90 to −20 millivolts depending on cell type.

Reticular activating system (RAS) Diffuse brain stem neural network that receives a wide variety of sensory input and maintains wakefulness of the cerebral cortex.

Reticular fibers (ret-tik'u-lar) Fine network of connective tissue fibers that form the internal supporting framework of lymphoid organs.

Reticular formation Functional system that spans the brain stem; involved in regulating sensory input to the cerebral cortex, cortical arousal, and control of motor behavior.

Reticular lamina A layer of extracellular material containing a fine network of collagen protein fibers; together with the basal lamina it is a major component of the basement membrane.

Reticulocyte (rĕ-tik'u-lo-sīt) Immature erythrocyte.

Retina (ret'ĭ-nah) Neural layer of the eyeball; contains photoreceptors (rods, cones).

Rhombencephalon (hindbrain) (romb"en-sef'ah-lon) Caudal portion of the developing brain; constricts to form the metencephalon and myelencephalon; includes the pons, cerebellum, and medulla oblongata.

Ribosomal RNA (rRNA) A constituent of ribosome; exists within the ribosomes of cytoplasm and assists in protein synthesis.

Ribosomes (ri'bo-sōmz) Cytoplasmic organelles at which proteins are synthesized.

RNA (ribonucleic acid) (ri'bo-nu-kle'ik) Nucleic acid that contains ribose and the bases A, G, C, and U. Carries out DNA's instructions for protein synthesis.

Rods One of the two types of photosensitive cells in the retina.

Rotation The turning of a bone around its own long axis.

Rugae (ru'ge) Elevations or ridges, as in stomach mucosa.

Rule of nines Method of computing the extent of burns by dividing the body into a number of areas, each accounting for 9% (or a multiple thereof) of the total body area.

S (synthetic) phase The part of the interphase period of the cell life cycle in which DNA replicates itself, ensuring that the two future cells will receive identical copies of genetic material.

Sagittal plane (sa'jih-tul) A longitudinal (vertical) plane that divides the body or any of its parts into right and left portions.

Saliva Secretion of the salivary glands; cleanses and moistens the mouth and begins chemical digestion of starchy foods.

Saltatory conduction Transmission of an action potential along a myelinated fiber in which the nerve impulse appears to leap from node to node.

Sarcolemma The plasma membrane surface of a muscle fiber.

Sarcomere (sar'ko-mēr) The smallest contractile unit of muscle; extends from one Z disc to the next.

Sarcoplasm The nonfibrillar cytoplasm of a muscle fiber.

Sarcoplasmic reticulum (SR) (sar"ko-plaz'mik rĕ-tik'u-lum) Specialized endoplasmic reticulum of muscle cells.

Schwann cell A type of supporting cell in the PNS; forms myelin sheaths and is vital to peripheral nerve fiber regeneration.

Sclera (skle'rah) White opaque portion of the fibrous layer of the eyeball.

Scrotum (skro'tum) External sac enclosing the testes.

Sebaceous glands (oil glands) (se-ba'shus) Epidermal glands that produce an oily secretion called sebum.

Sebum (se'bum) Oily secretion of sebaceous glands.

Second-degree burn A burn in which the epidermis and the upper region of the dermis are damaged.

Second messenger Intracellular molecule generated by the binding of a chemical (hormone or neurotransmitter) to a plasma membrane receptor; mediates intracellular responses to the chemical messenger.

Secondary sex characteristics Anatomic features, not directly involved in the reproductive process, that develop under the influence of sex hormones, e.g., male or female pattern of muscle development, bone growth, body hair distribution, etc.

Secretion (se-kre'shun) (1) The passage of material formed by a cell to its exterior; (2) cell product that is transported to the exterior of a cell.

Secretory vesicles (granules) Vesicles containing proteins that migrate to the plasma membrane of a cell and discharge their contents from the cell by exocytosis.

Section A cut through the body (or an organ) that is made along a particular plane; a thin slice of tissue prepared for microscopic study.

Segregation During meiosis, the distribution of the members of the allele pair to different gametes.

Selectively permeable membrane A membrane that allows certain substances to pass while restricting the movement of others; also called differentially permeable membrane.

Semen (se'men) Fluid mixture containing sperm and secretions of the male accessory reproductive glands.

Semilunar valves (sĕ"me-loo'ner) Valves that prevent blood return to the ventricles after contraction; aortic and pulmonary valves.

Seminiferous tubules (sem"ĭ-nif'er-us) Highly convoluted tubes within the testes; form sperm.

Sense organs Localized collections of many types of cells working together to accomplish a specific receptive process.

Sensory (afferent) nerves Nerves that contain processes of sensory neurons and carry impulses to the central nervous system.

Sensory areas Functional areas of the cerebral cortex that provide for conscious awareness of sensation.

Sensory receptor Dendritic end organs, or parts of other cell types, specialized to respond to a stimulus.

Serosa (serous membrane) (se-ro'sah) The moist membrane found in closed ventral body cavities.

Serous fluid (sēr'us) Clear, watery fluid secreted by cells of a serous membrane.

Serum (sēr'um) Amber-colored fluid that exudes from clotted blood as the clot shrinks; plasma without clotting factors.

Sesamoid bones (ses'ah-moid) Short bones embedded in tendons, variable in size and number, many of which influence the action of muscles; largest is the patella (kneecap).

Severe combined immunodeficiency syndromes (SCIDs) Congenital conditions resulting in little or no protection against disease-causing organisms of any type.

Sex chromosomes The chromosomes, X and Y, that determine genetic sex (XX = female; XY = male); the 23rd pair of chromosomes.

Sex-linked inheritance Inherited traits determined by genes on the sex chromosomes, e.g., X-linked genes are passed from mother to son, Y-linked genes are passed from father to son.

Sexually transmitted disease (STD) Infectious disease spread through sexual contact.

Signal sequence A short peptide segment present in a protein being synthesized that causes the associated ribosome to attach to the membrane of rough ER.

Simple diffusion The unassisted transport across a plasma membrane of a lipid-soluble or very small particle.

Sinoatrial (SA) node (si″no-a′tre-al) Specialized myocardial cells in the wall of the right atrium; pacemaker of the heart.

Sinus (si′nus) (1) Mucous-membrane-lined, air-filled cavity in certain cranial bones; (2) dilated channel for the passage of blood or lymph.

Skeletal cartilage Composes most of the skeleton in early fetal life; articular cartilage, nasal cartilage in the adult skeleton.

Skeletal muscle Muscle composed of cylindrical multinucleate cells with obvious striations; the muscle(s) attached to the body's skeleton; voluntary muscle.

Skeletal system System of protection and support composed primarily of bone and cartilage.

Skull Bony protective encasement of the brain and the organs of hearing and equilibrium; includes the facial bones. Also called the cranium.

Small intestine Convoluted tube extending from the pyloric sphincter to the ileocecal valve where it joins the large intestine; the site where digestion is completed and virtually all absorption occurs.

Smooth muscle Spindle-shaped cells with one centrally located nucleus and no externally visible striations (bands). Found mainly in the walls of hollow organs.

Sodium-potassium (Na^+-K^+) pump A primary active transport system that simultaneously drives Na^+ out of the cell against a steep gradient and pumps K^+ back in.

Sol-gel transformation Reversible change of a colloid from a fluid (sol) to a more solid (gel) state.

Solute (sol′yoot) The substance that is dissolved in a solution.

Solute pump Enzyme-like protein carrier that mediates active transport of solutes such as amino acids and ions uphill against their concentration gradients.

Somatic nervous system (so-ma′tik) Division of the peripheral nervous system that provides the motor innervation of skeletal muscles; also called the voluntary nervous system.

Somatic reflexes Reflexes that activate skeletal muscle.

Somatosensory system That part of the sensory system dealing with reception in the body wall and limbs; receives inputs from exteroceptors, proprioceptors, and interoceptors.

Somite (so′mīt) A mesodermal segment of the body of an embryo that contributes to the formation of skeletal muscles, vertebrae, and dermis of skin.

Spatial discrimination The ability of neurons to identify the site or pattern of stimulation.

Special senses The senses of taste, smell, vision, hearing, and equilibrium.

Specific gravity Term used to compare the weight of a substance to the weight of an equal volume of distilled water.

Sperm (spermatozoon) Male gamete.

Spermatogenesis (sper″mah-to-jen′ĕ-sis) The process of sperm (male gamete) formation; involves meiosis.

Sphincter (sfink′ter) A circular muscle surrounding an opening; acts as a valve.

Spinal cord The bundle of nervous tissue that runs from the brain to the first to third lumbar vertebrae and provides a conduction pathway to and from the brain.

Spinal nerves The 31 nerve pairs that arise from the spinal cord.

Splanchnic circulation (splangk′nik) The blood vessels serving the digestive system.

Spleen Largest lymphoid organ; provides for lymphocyte proliferation, immune surveillance and response, and blood-cleansing functions.

Spongy bone Internal layer of skeletal bone. Also called cancellous bone.

Sprain Ligaments reinforcing a joint are stretched or torn.

Static equilibrium Sense of head position in space with respect to gravity.

Stenosis (stĕ-no′sis) Abnormal constriction or narrowing.

Steroids (stē′roidz) Group of chemical substances including certain hormones and cholesterol; they are fat soluble and contain little oxygen.

Stimulus (stim′u-lus) An excitant or irritant; a change in the environment that evokes a response.

Stomach Temporary reservoir in the gastrointestinal tract where chemical breakdown of proteins begins and food is converted into chyme.

Stressor Any stimulus that directly or indirectly causes the hypothalamus to initiate stress-reducing responses, such as the fight-or-flight response.

Stroke. *See* Cerebrovascular accident.

Stroke volume (SV) Amount of blood pumped out of a ventricle during one contraction.

Stroma (stro′mah) The basic internal structural framework of an organ.

Structural (fibrous) proteins Consist of extended, strandlike polypeptide chains forming a strong, ropelike structure that is linear, insoluble in water, and very stable; e.g., collagen.

Subcutaneous (sub″kyu-ta′ne-us) Beneath the skin.

Substrate A reactant on which an enzyme acts to cause a chemical action to proceed.

Sudoriferous gland (su″do-rif′er-us) Epidermal gland that produces sweat.

Sulcus (sul′kus) A furrow on the brain, less deep than a fissure.

Summation Accumulation of effects, especially those of muscular, sensory, or mental stimuli.

Superficial Located close to or on the body surface.

Superior Refers to the head or upper body regions.

Superior vena cava Vein that returns blood from body regions superior to the diaphragm.

Supination (soo″pĭ-na′shun) The outward rotation of the forearm causing palms to face anteriorly.

Surfactant (ser-fak′tant) Secretion produced by certain cells of the alveoli that reduces the surface tension of water molecules, thus preventing the collapse of the alveoli after each expiration.

Suspension Heterogeneous mixtures with large, often visible solutes that tend to settle out.

Suture (soo′cher) An immovable fibrous joint; with one exception, all bones of the skull are united by sutures.

Sweat gland. *See* Sudoriferous gland.

Sympathetic division The division of the autonomic nervous system that prepares the body for activity or to cope with some stressor (danger, excitement, etc.); the fight, fright, and flight subdivision.

Sympathetic (vasomotor) tone State of partial vasoconstriction of the blood vessels maintained by sympathetic fibers.

Symphysis (sim′fih-sis) A joint in which the bones are connected by fibrocartilage.

Synapse (sin′aps) Functional junction or point of close contact between two neurons or between a neuron and an effector cell.

Synapsis (sĭ-nap′sis) Pairing of homologous chromosomes during the first meiotic division.

Synaptic cleft (si-nap′tik) Fluid-filled space at a synapse.

Synaptic delay Time required for an impulse to cross a synapse between two neurons.

Synaptic vesicles Small membranous sacs containing neurotransmitter.

Synarthrosis (sin″ar-thro′sis) Immovable joint.
Synchondrosis (sin″kon-dro′sis) A joint in which the bones are united by hyaline cartilage.
Syndesmosis (sin″des-mo′sis) A joint in which the bones are united by a ligament or a sheet of fibrous tissue.
Synergist (sin′er-jist) (1) Muscle that aids the action of a prime mover by effecting the same movement or by stabilizing joints across which the prime mover acts to prevent undesirable movements. (2) Hormone that amplifies the effect of another hormone at a target cell.
Synostosis (sin″os-to′sis) A completely ossified joint; a fused joint.
Synovial fluid Fluid secreted by the synovial membrane; lubricates joint surfaces and nourishes articular cartilages.
Synovial joint Freely movable joint exhibiting a joint cavity; also called a diarthrosis.
Synthesis (combination) reaction A chemical reaction in which larger, more complex atoms or molecules are formed from simpler ones.
Systemic (sis-tem′ik) Pertaining to the whole body.
Systemic circuit System of blood vessels that serves gas exchange in the body tissues.
Systole (sis′to-le) Period when either the ventricles or the atria are contracting.
Systolic pressure (sis-tah′lik) Pressure exerted by blood on the blood vessel walls during ventricular contractions.
T cells Lymphocytes that mediate cellular immunity; include helper, cytotoxic, regulatory, and memory cells. Also called T lymphocytes.
T tubule (transverse tubule) Extension of the muscle cell plasma membrane (sarcolemma) that protrudes deeply into the muscle cell.
Tachycardia (tak″e-kar′de-ah) A heart rate over 100 beats per minute.
Taste buds Sensory receptor organs that house gustatory cells, which respond to dissolved food chemicals.
Telencephalon (endbrain) (tel″en-seh′fuh-lon) Anterior subdivision of the primary forebrain that develops into olfactory lobes, cerebral cortex, and basal nuclei.
Telophase The final phase of mitosis; begins when migration of chromosomes to the poles of the cell has been completed and ends with the formation of two daughter nuclei.
Tendon (ten′dun) Cord of dense fibrous tissue attaching muscle to bone.
Tendonitis Inflammation of tendon sheaths, typically caused by overuse.
Terminal branches Branching ends of an axon that allow it to form many axon terminals; telodendria.
Testis (tes′tis) Male primary reproductive organ that produces sperm; male gonad.
Testosterone (tes-tos′tĕ-rōn) Male sex hormone produced by the testes; during puberty promotes virilization, and is necessary for normal sperm production.
Tetanus (tet′ah-nus) (1) A smooth, sustained muscle contraction resulting from high-frequency stimulation; (2) an infectious disease caused by an anaerobic bacterium.
Thalamus (tha′luh-mis) A mass of gray matter in the diencephalon of the brain.
Thermogenesis (ther″mo-jen′ĕ-sis) Heat production.
Thermoreceptor (ther″mo-re-sep′ter) Receptor sensitive to temperature changes.
Third-degree burn A burn that involves the entire thickness of the skin; also called a full-thickness burn. Usually requires skin grafting.
Thoracic cage (bony thorax) Bones that form the framework of the thorax; includes sternum, ribs, and thoracic vertebrae.
Thoracic duct Large duct that receives lymph drained from the entire lower body, the left upper extremity, and the left side of the head and thorax.
Thorax (tho′raks) That portion of the body trunk above the diaphragm and below the neck.
Threshold stimulus Weakest stimulus capable of producing a response in an irritable tissue.
Thrombin (throm′bin) Enzyme that induces clotting by converting fibrinogen to fibrin.
Thrombocyte (throm′bo-sīt) Platelet; cell fragment that participates in blood coagulation.
Thrombocytopenia (throm″bo-si″to-pe′ne-ah) A reduction in the number of platelets circulating in the blood.
Thrombus (throm′bus) A clot that develops and persists in an unbroken blood vessel.
Thymine (T) (thi′mēn) Single-ring base (a pyrimidine) in DNA.
Thymus (thi′mus) Lymphoid organ and endocrine gland active in immune response; site of maturation of T lymphocytes.
Thyroid gland (thi′roid) One of the largest of the body's endocrine glands; straddles the anterior trachea.
Thyroid hormone (TH) The major hormone secreted by thyroid follicles; stimulates enzymes concerned with glucose oxidation.
Thyroid-stimulating hormone (TSH) Adenohypophyseal hormone that regulates secretion of thyroid hormones.
Thyroxine (T_4) (thi-rok′sin) Iodine-containing hormone secreted by the thyroid gland; accelerates cellular metabolic rate in most body tissues.
Tight junction Area where plasma membranes of adjacent cells are fused.
Tissue A group of similar cells and their intercellular substance specialized to perform a specific function; primary tissue types of the body are epithelial, connective, muscle, and nervous tissue.
Tissue perfusion Blood flow through body tissues or organs.
Tonicity (to-nis′ĭ-te) A measure of the ability of a solution to cause a change in cell shape or tone by promoting osmotic flows of water.
Tonsils A ring of lymphoid tissue around the entrance to the pharynx. *See also* adenoids.
Trabecula (trah-bek′u-lah) (1) Any of the fibrous bands extending from the capsule into the interior of an organ; (2) strut or thin plate of bone in spongy bone.
Trachea (tra′ke-ah) Windpipe; cartilage-reinforced tube extending from larynx to bronchi.
Tract A collection of axons in the central nervous system having the same origin, termination, and function.
Transcription One of the two major steps in the transfer of genetic code information involving the transfer of information from a DNA gene's base sequence to the complementary base sequence of an mRNA molecule.
Transduction (trans-duk′shun) The conversion of the energy of a stimulus into an electrical event.
Transepithelial transport (trans-ep″ĭ-the′le-al) Movement of substances through, rather than between, adjacent epithelial cells connected by tight junctions, such as absorption of nutrients in the small intestine.
Transfer RNA (tRNA) Short-chain RNA molecules that transfer amino acids to the ribosome.
Transfusion reaction Agglutination and destruction of red blood cells following transfusion of incompatible blood.
Translation One of the two major steps in the transfer of genetic code information, in which the information carried by mRNA is decoded and used to assemble polypeptides.
Transverse (horizontal) plane A plane running from right to left, dividing the body into superior and inferior parts.
Tricuspid valve (tri-kus′pid) The right atrioventricular valve.
Triglycerides (tri-glis′er-īdz) Fats and oils composed of fatty acids and glycerol; are the body's most concentrated source of energy fuel; also known as neutral fats.
Triiodothyronine (T_3) (tri″i-o″do-thi′ro-nēn) Thyroid hormone; secretion and function similar to those of thyroxine (T_4).
Tripeptide A combination of three amino acids united by means of peptide bonds.
Trophoblast (tro′fo-blast) Outer sphere of cells of the blastocyst.

Tropic hormone (trōp'ik) A hormone that regulates the secretory action of another endocrine organ.
Trypsin Proteolytic enzyme secreted by the pancreas.
Tubular reabsorption The movement of filtrate components from the renal tubules into the blood.
Tubular secretion The movement of substances (such as drugs, urea, excess ions) from blood into filtrate.
Tumor An abnormal growth of cells; a swelling; may be cancerous.
Tunica (too'nĭ-kah) A covering or tissue coat; membrane layer.
Tympanic membrane (tim-pan'ik) Eardrum.
Ulcer (ul'ser) Lesion or erosion of the mucous membrane, such as gastric ulcer of stomach.
Umbilical cord (um-bĭ'lĭ-kul) Structure bearing arteries and veins connecting the placenta and the fetus.
Umbilicus (um-bĭ'lĭ-kus) Navel; marks site where umbilical cord was attached in fetal stage.
Unipolar neuron Neuron in which embryological fusion of the two processes leaves only one process extending from the cell body.
Unmyelinated fibers (un-mi'ĕ-lĭ-nāt"ed) Axons lacking a myelin sheath and therefore conducting impulses quite slowly.
Uracil (U) (u'rah-sil) A smaller, single-ring base (a pyrimidine) found in RNA.
Urea (u-re'ah) Main nitrogen-containing waste excreted in urine.
Ureter (u-re'ter) Tube that carries urine from kidney to bladder.
Urethra (u-re'thrah) Canal through which urine passes from the bladder to outside the body.
Uric acid The nitrogenous waste product of nucleic acid metabolism; component of urine.
Urinary bladder A smooth, collapsible, muscular sac that stores urine temporarily.
Urinary system System primarily responsible for water, electrolyte, and acid-base balance and removal of nitrogenous wastes.
Uterine tube (u'ter-in) Tube through which the ovum is transported to the uterus. Also called fallopian tube.
Uterus (u'ter-us) Hollow, thick-walled organ that receives, retains, and nourishes fertilized egg; site where embryo/fetus develops.
Uvula (u'vu-lah) Tissue tag hanging from soft palate.
Vaccine Preparation that provides artificially acquired active immunity.
Vagina Thin-walled tube extending from the cervix to the body exterior; often called the birth canal.
Valence shell (va'lens) Outermost electron shell (energy level) of an atom that contains electrons.
Varicosities Knoblike swellings of certain autonomic axons containing mitochondria and synaptic vesicles.
Vas (vaz') A duct; vessel.
Vasa recta (va'sah rek'tah) Capillary branches that supply loops of Henle in the medulla region of the kidney.
Vascular Pertaining to blood vessels or richly supplied with blood vessels.
Vascular spasm Immediate response to blood vessel injury; results in constriction.
Vasoconstriction (vas"o-kon-strik'shun) Narrowing of blood vessels.
Vasodilation (vas"o-di-la'shun) Relaxation of the smooth muscles of the blood vessels, producing dilation.
Vasomotion (vas"o-mo'shun) Intermittent contraction or relaxation of the precapillary sphincters, resulting in a staggered blood flow when tissue needs are not extreme.
Vasomotor center (vas"o-mo'ter) Brain area concerned with regulation of blood vessel resistance.
Vasomotor fibers Sympathetic nerve fibers that cause the contraction of smooth muscle in the walls of blood vessels, thereby regulating blood vessel diameter.
Veins (vānz") Blood vessels that return blood toward the heart from the circulation.
Ventral Pertaining to the front; anterior.
Ventricle (1) Paired, inferiorly located heart chambers that function as the major blood pumps; (2) cavities in the brain.
Venule (ven'ūl) A small vein.
Vertebral column (spine) (ver'ti-brul) Formed of a number of individual bones called vertebrae and two composite bones (sacrum and coccyx).
Vesicle (vĕ'sĭ-kul) A small liquid-filled sac or bladder.
Vesicular (bulk) transport The movement of large particles and macromolecules across a plasma membrane.
Vesicular follicle Mature ovarian follicle.
Vestibule An enlarged area at the beginning of a canal, i.e., inner ear, nose, larynx.
Villus (vil'us) Fingerlike projections of the small intestinal mucosa that tremendously increase its surface area for absorption.
Visceral (vis'er-al) Pertaining to an internal organ of the body or the inner part of a structure.
Visceral muscle Type of smooth muscle; its cells contract as a unit and rhythmically, are electrically coupled by gap junctions, and often exhibit spontaneous action potentials.
Visceral organs (viscera) A group of internal organs housed in the ventral body cavity.
Visceral serosa (se-ro'sah) The part of the double-layered membrane that lines the outer surfaces of organs within the ventral body cavity.
Viscosity (vis'kos'ĭ-te) State of being sticky or thick.
Visual field The field of view seen when the head is still.
Vital capacity (VC) The volume of air that can be expelled from the lungs by forcible expiration after the deepest inspiration; total exchangeable air.
Vital signs Includes pulse, blood pressure, respiratory rate, and body temperature measurements.
Vitamins Organic compounds required by the body in minute amounts.
Vocal folds Mucosal folds that function in voice production (speech); also called the true vocal cords.
Volatile acid An acid that can be eliminated by the lungs; carbonic acid is converted to CO_2, which diffuses into the alveoli.
Volkmann's canals *See* Perforating canals.
Voluntary muscle Muscle under strict nervous control; skeletal muscle.
Voluntary nervous system The somatic nervous system.
Vulva (vul'vuh) Female external genitalia.
Wallerian degeneration (wal-er'ē-an) A process of disintegration of an axon that occurs when it is crushed or severed and cannot receive nutrients from the cell body.
White matter White substance of the central nervous system; myelinated nerve fibers.
Xenograft Tissue graft taken from another animal species.
Yolk sac (yōk) One of the extraembryonic membranes; involved in early blood cell formation.
Zygote (zi'gōt) Fertilized egg.

Index

Note: Page numbers in **boldface** indicate a definition. A *t* following a page number indicates tabular material, an *f* indicates an illustration, and a *b* indicates boxed material.

A (adenine), **55**–57, 56*f*, 57*t*
A bands (dark bands), **284**, 285*f*, 689, 690*f*
ABCD rule, **166**
Abdomen
  arteries, 752–755*t*
  blood flow at rest/during exercise, 734, 734*f*
  innervation, 514, 541
    aortic plexus, 539*f*, **541**
    wall, 509*f*, 510*f*, 515*f*, 515*t*
  muscles, 331*f*, 348*t*, 349*f*
    wall, 348–349*t*, 349*f*
  reflexes, **527**
  veins, 758*t*, **764**–765*t*
Abdominal cavity, **15**, 17*f*
Abdominopelvic cavity, **15**, 17*f*
  peritoneum of, 886, 886*f*
  quadrants, **19**, 19*f*
  regions, 18, 18*f*
  serosae of, 142*f*, 143
Abdominopelvic organs
  muscles that compress, 348*t*, 349*f*
  muscles that support, **350***t*, 351*f*
Abducens nerve (VI), 448*f*, 451, **500**, 501*f*
  muscles served by, 558, 559*f*
  origin/course/function, 505*f*, **505***t*
Abduction (movement), **261**, 262*f*
  of lower limbs, 379–380*t*, 380*f*
  of upper limbs, 362–363*t*, 363*f*
Abductor digiti minimi muscles
  of foot, **381***t*, 382*f*
  of hand, **364***t*, 365*f*
Abductor hallucis muscle, **381***t*, 382*f*
Abductor pollicis brevis muscle, **364***t*, 365*f*
Abductor pollicis longus muscle, **360***t*, 361*f*
  actions of (summary), 362*t*, 363*f*
ABO blood groups, **669**, 669*t*
  genotypes determining, 1151, 1151*t*
Abortion, 1129*b*, **1141**
ABP (androgen-binding protein), **1080**, 1081*f*
Absence seizures, 457
Absolute refractory periods, 406–407, 406*f*
  in cardiac muscle, 691, 691*f*
Absorption, **884**–885, 884*f*, 920*t*, **931**–933
  active transport mechanisms, 931
  of carbohydrates, 928*f*, 931
  flowchart, 928*f*
  of lipids, 928*f*, 931–932, 932*f*
  malabsorption of nutrients and, 933
  of proteins, 928*f*, 930*f*, 931
Absorptive cells, of small intestine, 910, 910*f*
Absorptive (fed) state, **973**–974
  major events/metabolic pathways, 974*f*
Accessory nerve (XI), 448*f*, 449*f*, **500**, 501*f*
  cervical plexus in relation to, 511*f*
  muscles served by, 342*t*, 352*t*
  origin/course/function, 508*f*, **508***t*
Acclimatization, **870**
Accommodation, 567*f*, **568**
Accommodation pupillary reflex, **568**
ACE (angiotensin converting enzyme), 845, 1009*f*, **1010**
Acetabular labrum, **270**, 270*f*
Acetabulum, **237**, 238*f*, 243*f*
  in females vs. males, 240*f*, 240*t*
Acetic acid, 41
  in muscle contraction, 289, 290*f*
Acetone breath, 635*f*
Acetylcholine (ACh), **289**, 290*f*, **417**–418
  as ANS neurotransmitter, 543, 544*t*
  Botox injections and, 156*b*
  excitatory effect of, 534
  receptors, **289**, 290, 290*f*, 312, 415*t*
  secretion sites/effects, 415*t*
  smooth muscle contraction and, 312
Acetylcholinesterase (AChE), **289**, 290*f*, **417**, 519
  inhibitors, 545*t*
Acetyl coenzyme A (acetyl CoA)
  in glycolysis, 956, 957*f*
  in Krebs cycle, 961, 962*f*, 963
  in lipolysis, 969, 969*f*
AChE. *See* Acetylcholinesterase
Achilles tendon. *See* Calcaneal (Achilles) tendon
Achondroplasia, **199**, 1150
ACh. *See* Acetylcholine
Acid-base balance, 1049–1057, 1060
  abnormalities, 1055–1060
    blood values to assess, 1057*b*
    causes/consequences, 1056*t*
    compensations, 1055–1057, 1060
    metabolic, 1055, 1056*t*
    respiratory, 1055, 1056*t*
  aging and, 1060
  buffer systems, 43, 52*t*
    chemical, 863, 1050–1052
    physiological, 1052
    renal, 1052–1054
    respiratory, 1052
  compensations
    renal, 1057, 1060
    respiratory, 1056–1057
  developmental aspects, 1060
  in diabetes mellitus, 635*f*
Acidemia, **1050**
Acid group of amino acids, 49, 49*f*
Acid hydrolases, 88*f*, 89
Acidic solutions, 42
Acid mantle
  of skin, **164**, 796*t*
  of vagina, 796*t*
Acidosis, **60**, **1050**
  metabolic, 1055, 1056*t*
  physiological, 1050
  respiratory, **1055**, 1056*t*
  using blood values to assess, 1057*b*
Acids, **41**–43, 42*f*, 52*t*
  in buffer systems, 1050–1052
  metabolic (fixed), **1052**
  pH scale, 42, 42*f*
  strong/weak, **43**
    dissociation of, 1050, 1050*f*
  volatile, 1052
Acinar cells/acini, **125**, 632, **917**, 918*f*
ACL (anterior cruciate ligament) injuries, 267, 267*f*, 268
Acne, 159, 170
Acoustic meatus
  external, 206*f*, **207**, 208*f*, 209*f*, **216***t*, 584*f*, **585**
    in relation to temporomandibular joint, 271*f*
  internal, 206*f*, 208*f*, **209**, **216***t*
Acquired immune deficiency syndrome (AIDS), **820**–821
Acquired immunity, 805–806, 806*f*
Acromegaly, **615**, 618*t*
Acromial end (clavicle), **229**, 230*f*, 234*f*, 236*t*
Acromioclavicular joint, 230*f*, **231**, 258*t*
Acromion, 230*f*, **231**, 234*f*, 236*t*, 257*f*, 269*f*
  joint of, 258*t*
Acrosomal reaction, **1115**, 1116*f*
Acrosome, **1077**, 1079, 1079*f*, 1116*f*
ACTH. *See* Adrenocorticotropic hormone
Actin, 52*t*, 90, 139, 282*t*, 285*f*, **286**–287, 286*f*
  in muscle contraction, 293–294, 293*f*–295*f*
Action potentials (APs), **288**, **402**
  as all-or-none event, 406
  in autorhythmic cells, 692–694, 694*f*
  in cardiac muscle, 689–692, 691*f*
  conduction distance in, 414*t*
  conduction velocity of, 407–408, 407*f*
  end plate potential and, 290
  function, 414*t*
  generation of, 290–291, 291*f*, 401*f*, 402–404
  neuromuscular junction and, 289–290, 290*f*
  peak membrane potential and, 414*t*
  as positive feedback mechanism, 404, 414*t*
  postsynaptic potentials vs., 414*t*
  propagation of, 290–291, 291*f*, 404–405, 405*f*
    impairment, 408
  refractory periods in, 406–407, 406*f*, 414*t*
  repolarization in, 414*t*
  sarcolemma permeability and, 291, 291*f*
  sliding of myofilaments and, 291–293, 292*f*
  stimulus intensity and, 406, 406*f*
Activation energy in chemical reactions, **54**, 54*f*
Active humoral immunity, **805**–806, 806*f*
Active membrane transport, **70**
  active transport, 75–77
    in absorption of nutrients, 931
    primary, 76*f*, 77
    secondary, 77, 77*f*
    in tubular reabsorption, 1012*f*, **1013**
  energy source/description/examples, 80*t*
  vesicular transport, 77–81
    endocytosis, 78–81
    exocytosis, 77–78
Active sites, **52**, 53*f*, 54, 55*f*
Acute respiratory distress syndrome (ARDS), **875**
AD (Alzheimer's disease), 462, **469**
Adaptation, **495**
  to light/dark, **574**–575
  olfactory, 580

Aminoacyl-tRNA synthetase, 108*f*
Aminopeptidase, 928*f*, **929**
Amitotic cells, 391
Ammonia, **41**–42, **970**, 970*f*
Ammonium ions, 42, 1054, 1055*f*
Ammonium salts, in blood plasma, 649*t*
Amniocentesis, **1155**–1156, 1156*f*
Amnion, 1120*f*, 1121*f*, **1122**, 1124*f*, 1125*f*, 1126*f*
Amniotic cavity, 1120*f*, 1121*f*, 1125*f*
Amniotic fluid, **1122**
Amniotic sac, 1121*f*, 1124*f*
Amoeboid motion, **80**, 91, **657**
AMP (adenosine monophosphate), 57*f*, 59, 59*f*
Amphetamines, 424–425*b*
Amphiarthroses, **253**, 258*t*, 259*f*
Amphipathic molecules, 47
Amphoteric molecules, **1051**
Amplitude (sound), **589**, 589*f*, 590*f*
Ampulla
semicircular canal, 586*f*, **587**
uterine tube, **1084**, 1085*f*
vas deferens, 1066*f*, **1070**
Amygdala, **454**, 455*f*
memory and, 455
pleasure centers and, 424*b*
Amylase, **918**
Amyotrophic lateral sclerosis (ALS), 481
Anabolic hormones, 52*t*, 947
Anabolic processes, **37**, **956**, 957*f*
Anabolic steroids, misuse/abuse of, **308***b*
Anabolism, 7, **956**

Anaerobic (cellular) respiration, 302, 303*f*, 315*t*
Anaerobic glycolysis, **302**, 303, 303*f*, 306, 306*f*
Anaerobic pathways
  of glycolysis, 960–961, 960*f*
  of muscle metabolism, **302**, 303*f*
Anaerobic threshold, **303**
Anal canal, **922**, 923*f*
Anal columns, 923*f*, **925**
Analgesia, **527**
Anal sinuses, 923*f*, **925**
Anal sphincters, **922**, 923*f*, 924
Anaphase, **101**, 103*f*, 1075*f*, 1076*f*
Anaphylactic shock, 742, **823**
Anaplasia, **112**
Anastomoses, 685*f*, 686, **723**, 750*f*, 756*f*, 915
Anatomical dead space, **852**–853
Anatomical neck of humerus, 231*f*, **232**, 234*f*
Anatomical position, **12**, 13*t*, 14*f*
Anatomical terminology, 12–19
  body cavities/membranes, 15, 17–19, 17*f*–19*f*
  body planes/sections, 15, 16*f*
  direction/orientation, 12, 13*t*
  regional, 12, 14, 14*f*
Anatomy, **2**–3
Anconeus muscle, 356*f*, **357**, **357***t*, 361*f*
  actions (summary), 362*t*
Androgen-binding protein (ABP), **1080**, 1081*f*
Androgens, **630**
  adrenal, 1082
  brain-testicular axis and, 1080–1081, 1081*f*
  hyper-/hyposecretion, 627*t*, 630–631
  sebum secretion and, 158, 159
  terminal hair response to, 162
Androstenedione, 308*b*, 630
Anemias, **655**, 902
  sickle-cell, **655**–656, 656*f*, **1151**
Anemic hypoxia, **860**
Anencephaly, **483**
Anergy, 802, **814**
Anesthetics
  blood-brain barrier and, 467
  propagation of nerve impulses and, 408
Aneurysm, **767**
Angina pectoris, **686**
Angiogenesis, 736
Angiogram, **767**
Angiotensin converting enzyme (ACE), 845, 1009*f*, **1010**
Angiotensin I, **1010**
Angiotensin II, **628**, 628*f*, **1010**
  blood pressure and, 729*t*, 730
Angiotensinogen, **628**, 628*f*, **1010**
Angle, sternal, 226*f*, **227**
Angular movements, 259, **260**–261, 260–262*f*
Anions, **33**
  acids and, 41
  in blood plasma/IF/ICF, 1038*f*
  reabsorption of, 1014*t*
  regulation of, 1049
Ankle (talus bone), **244**, 245*f*, 246*f*, 246*t*
  joint, 259*t*
  muscles, 373–378*t*, 379–380*t*, 380*f*
Ankyloglossia, 890
Ankylosing spondylitis, **276**
Ankylosis, 274
Annular ligament, **268**, 268*f*
Annular ring, **558**, 559*f*
Anopsias, 502*t*
Anosmias, 502*t*, 583
ANP. *See* Atrial natriuretic peptide
Ansa cervicalis, 340*t*, 511*f*, 511*t*
ANS. *See* Autonomic nervous system
Antacid, **1061**
Antagonist hormones, **611**
Antagonist muscles, **325**
Antebrachial veins, 762*f*, **762***t*, 763*f*
Antebrachium. *See* Forearm
Anterior association area. *See* Prefrontal cortex
Anterior orientation/direction, 13*t*
Anterior segment (cavity) of eye, 559, 560*f*, 564*f*
  chambers of, **564**, 564*f*
Anterograde amnesia, 463
Anterograde movement, 393
Anterolateral pathways, **475**–477, 476*f*, 477*t*
Antibodies (immunoglobulins), **659**, **806**–810
  active immunity and, 805–806, 806*f*
  antigen-binding sites and, 807, 807*f*
  as blood proteins, 52*t*, 806
  classes of, 807–808
    characteristics unique to, 808*t*
  complement activation and, 797–798, 797*f*
  diversity mechanisms, 808
  functions (summary), 817*t*
  mechanisms of action, 808–810, 809*f*
  monoclonal, 810
  as monomer molecules, 807, 807*f*
  passive immunity and, 806, 806*f*
  plasma cells as source of, 777, 806
  structure, 807, 807*f*
  targets, 808–810, 809*f*
Antibody-mediated immunity. *See* Humoral immunity
Anticoagulants, **665**
Anticodons, **107**, 108*f*, 109, 110*f*
Antidiuretic hormone (ADH), 10, 613, 613*f*, **617**–620
  blood pressure and, 729*t*, 730
  concentrated urine and, 1018–1019, 1019*f*
  hypersecretion, 619–620, 619*t*
  hyposecretion, 617–619, 619*t*
  summary of regulation/effects, 619*t*
  water balance and, 1041, 1041*f*
Antigen-antibody complex, 797*f*, **808**–809, 809*f*
Antigen-presenting cells (APCs), 164, 800, **803**, 813, 813*f*
  functions (summary), 817*t*
Antigens, **799**
  antigenic determinants, 799–800, 800*f*
  binding sites and, **807**, 807*f*
  complete, **799**
  endogenous, **811**, 812*f*, 813
  exogenous, **813**, 813*f*
  first encounters (antigen challenge), **804**
  functions (summary), 817*t*
  humoral immune response to, 804–810
  immunological memory and, 805
  incomplete, **799**
  mechanisms of action against, 797*f*, **808**–809, 809*f*
  self-antigens, 800
  T cell-independent/dependent, **815**
Antihemophilic factor (AHF), 663*t*, **668**
Antimicrobial proteins, **795**–798, 796*t*
  complement, 796–798
  interferons, 795–796
Antioncogenes, **146***b*
Antioxidants, 952
Antiport system, 76*f*, **77**
Antirachitic factor. *See* Vitamin D
Antisense RNAs/agents, **109**, 719*b*
Antisterility factor (vitamin E), 48*t*, 667, **949***t*
Antithrombin III, **667**
Antivenom serum, 806

  energy yield during, 965, 965*f*
  oxidation-reduction reactions of, 38–39
  primary function of, 956
  site of, 85, 959*f*
  summary, 971*t*
Cellulose, 46
  indigestibility of, 929
Cementum, **894**, 894*f*
Central artery of retina, 560*f*, 562*f*, **563**
Central canal (of spinal cord)
  brain ventricles and, 433, 434*f*
  CSF in relation to, 466*f*
  embryonic origins, 432*f*, 433
  gray commissure enclosure of, 472, 473*f*
Central (Haversian) canal, 137, 138*f*, **182**, 182*f*, 183*f*
Central nervous system (CNS), **388**, 389*f*, 430–489, **431**
  aging and, 484
  brain, 388, 389*f*, 431–456
    protection of, 463–470
  developmental aspects, 481–484
    embryonic, 1123–1128, 1130*t*
    fetal, 1132*t*, 1133
    neurulation and, 1123, 1125*f*
  diagnostic procedures, 481
  disorders, 447, 460, 463, 467–470, 480–481
  enteric nervous system and, 888–889
  mental functions, 456–463
  regenerative capacity, 500
  role in ANS control hierarchy, 547, 547*f*, 550
  role within nervous system, 388, 389*f*
  spinal cord, 388, 389*f*, 470–481
Central pattern generators (CPGs), **519**, 520*f*
Central sulcus, **434**, 435*f*, 436, 437*f*
Central tendon of diaphragm, 347*f*
Central tendon of perineum, **350**, 351*f*, 1089
Central vein of liver, **912**, 914*f*
Central vein of retina, 560*f*, 562*f*, **653**
Centrioles (basal bodies), 66*f*, 85, **92**–93, 92*f*, **93**
  in mitosis, 92–93, 102*f*
  structure/functions (summary), 94*t*
Centromeres, 102*f*, 103*f*
Centrosome (cell center), 90, **92**
  matrix, 66*f*, 92–93, 92*f*
Centrum, vertebral, 220*f*, **221**, 221*f*, 224*f*, 224*t*
Cephalic reflex phase, **903**–904, 903*f*
Cephalic vein, 759*f*, 762*f*, **762***t*, 763*f*
Cephalin, 48*t*
Cephalization, **431**
Cerebellar hemispheres, **452**, 452*f*
Cerebellar peduncles, 448, 448*f*, 449*f*, 450*f*, 451, **454**
Cerebellum, 445*f*, **451**–454, 452*f*
  cognitive functions of, 454
  embryonic origins, 432*f*, 433
  functions (summary), 453*t*
  gray/white matter arrangement in, 433, 433*f*
  hemispheres, **452**–454, 452*f*
  injury to, 454
  motor activity processing of, 454
  muscle contractions and, 451
  neural integration and, 495*f*
  peduncles, 448, 448*f*–450*f*, 451, **454**
  sensorimotor integration/control and, 520–521, 520*f*
  spinal cord tracts and, 476*f*
  vestibular nuclei in, 597, 597*f*
Cerebral angiography, 481
Cerebral aqueduct, **434**, 434*f*, 445*f*, 448, 450*f*
  CSF in relation to, 466*f*
  embryonic origins, 432*f*, 433
Cerebral arterial circle (circle of Willis), 749*f*, **749***t*
Cerebral arteries, 748*f*, **748***t*, 749*f*, **749***t*
Cerebral cortex, **436**–441, 437*f*
  embryonic origins, 432*f*, 433
  functional areas, 437*f*
    association, 440–441
    motor, 436–439
    sensory, 439–440
  functions (summary), 453*t*
  position in ANS control hierarchy, 547, 547*f*, 550

voluntary control of visceral activities and, 550
Cerebral dominance, **441**
Cerebral edema, **468**
Cerebral fissures, **434**, 435*f*
Cerebral hemispheres, **434**–443
basal nuclei, **443**, 444*f*
convolutions of, 433
cortex, **436**–441
embryonic origins, 432*f*, 433
fissures of, 435*f*, 436
functions (summary), 453*t*
lobes of, 435*f*, 436
white matter, **441**–443
Cerebral palsy, **482**–483
Cerebral peduncles, **448**, 450*f*, 480*f*
crus cerebri of, 448*f*
Cerebral vein, 466*f*
Cerebrospinal fluid (CSF), **465**–467, 466*f*
as biological colloid, 40
cushioning role of water in, 41
formation/location/circulation, 465, 466*f*
Cerebrovascular accidents (CVAs), **468**
cerebral angiography to diagnose, 481
nitric oxide and, 419
Cerebrum, **433**. *See also* Cerebral hemispheres
Cerumen, **585**
Ceruminous glands, **158**, **585**
Cervical canal, 1085*f*, **1086**
Cervical (cardinal) ligaments of uterus, 1085*f*, **1086**
Cervical curvatures, **219**, 219*f*, 247
Cervical enlargement, 471*f*, **472**, 509*f*
Cervical ganglia, 539*f*, **541**
Cervical glands, 1086
Cervical nerves, 471*f*, 509*f*
muscles served by, 340*t*, 342*t*, 343*t*, 353*t*
Cervical plexus, 509*f*, **511**–512, 511*f*
branches/nerves/structures served, 511*t*
muscles served by, 340*t*
Cervical plug, 1098
Cervical vertebrae, **219**, 219*f*
articulated, 223*f*
curvatures, **219**, 219*f*
features, 221–222, 222*f*
summary, 224*f*, 224*t*
movements allowed, 224*t*
transverse foramen, 221, 222*f*
Cervix, 1082*f*, 1085*f*, **1086**
Cesarean (C-) section, 1137
CF (cystic fibrosis), **874**
Chadwick's sign, 1133
Chalazion, 556
Chambers of eye, **564**, 564*f*
Chancre, 1100

  erythrocyte as example of, 650
Complementary bases, **56**, 56*f*
Complement (complement system), 52*t*, **796**–798
  activation pathways
    alternative, 797*f*, **798**
    classical, **797**–798, 797*f*
  fixation, 798, 809–810, 809*f*
  functions (summary), 817*t*
  as inflammatory chemicals, **793**, 793*t*
  MAC proteins and, 798
  protective mechanism (summary), 796*t*
Complete blood count (CBC), **671**–672
Compounds, **30**
  vs. mixtures, 31
Compression fractures, **192***t*
Computed tomography (CT), **20***b*
  to assess CNS dysfunction, 481
Computerized axial tomography (CAT). *See* Computed tomography
Concentration gradients, **71**, 72, 73, 73*f*
  electrochemical gradient and, 83, 393, 398, **399**
  nerve impulses and, 398–400, 399*f*
Concentration of solutions, 30–31
  in chemical reactions, 39
Concentric muscle contraction, **300**, 301*f*
Conceptus, **1114**
Conchae, nasal. *See* Nasal conchae
Concussion, **468**
Condoms, STDs and, 1100
Conducting (elastic) arteries, **716**, 716*f*, 717*f*
Conducting regions of neurons, compared, 396*t*
Conducting zone (respiratory system), **831**
  structures, **840**–841, 840*f*
Conduction
  continuous, **407**
  heat, **986**
  saltatory, **407**, 407*f*
Conduction deafness, **593**
Conductors (electrical), 398
Condyle (bone marking), 179*t*
Condyloid (ellipsoidal) joint, 259*t*, 264*f*, **265**
Cones, 562*f*, **563**, 570*f*
  excitation of, **572**
  visual pigments and, 569–571
Congenital disorders
  heart defects, **707**–708, 708*f*
  hip dysplasia, 247–248
  immunodeficiency disorders, **820**
  spina bifida, **248**
  thymic aplasia, **826**
Congestive heart failure (CHF), **704**
Conjunctiva, **557**, 557*f*, 559*f*
Conjunctival sac, **557**, 557*f*
Conjunctivitis, 557
Connective tissue, **126**–139
  characteristics, 127
  classes/subclasses, 126–127, 128*f*, 131–139
  embryonic origins, 127, 128*f*, 145, 145*f*
  functions, 127, 148
  regenerative capacity of, 144
  structural elements, 127–129
  vascularity of, 127
Connective tissue proper, 126, **131**–135
Connective tissue root sheath, **160**, 161*f*
Connexons, 69, 70*f*
Conn's disease, **1061**
Conscious mind, 436. *See also* Cerebral cortex
Consciousness, **457**–458
  epileptic seizures and, 457
  loss of, 458
Conscious proprioception, 475
Consensual light reflex, 575
Constant (C) regions of antibodies, **807**, 807*f*
Constipation, **927**
  in pregnancy, 1135
Contact dermatitis, **171**
  allergic, **824**–825
Contact inhibition, as property of normal cells, 101
Contact signaling of cells, 83
Continuous capillaries, **720**
Contraception, **1128**–1129*b*
  lactation and, 1139
Contractile myofilaments, 282*f*, 282*t*
Contractile proteins, 282*f*, 282*t*
  ATP as energy source, 59, 59*f*
Contractile ring, 101, 103*f*
Contractile unit, of skeletal muscle, 282*f*, 282*t*
Contractility, **5**, **280**
  of cardiac muscle, **701**–702, 701*f*
Contraction, of muscles. *See* Muscle contraction
Contractions (labor)

  classification
    by function, 253, 256*t*
    by structure, 253, 256*t*
  developmental aspects, 276
  dislocation (luxation), **273**
  exercise and, 276
  fibrous, **253**–254, 253*f*
    summary, 256*t*
  homeostatic imbalances, 272–274, 276
  inflammatory/degenerative conditions, 273–274, 276
  injuries common to, 272–273, 273*f*
  innervation of, 516, 518
  intervertebral, 254*f*, 255
  replacement, 275*b*
  replacement therapy, 275*b*
  sternocostal, 254*f*, 255
  synovial, **255**. *See also* Synovial joints
Joint stretch receptors (proprioceptors), pathways to, 476*f*
Jugular foramen, 208*f*, **209**, **216***t*, 760, 761*f*
Jugular lymphatic trunks, **775**, 776*f*
Jugular lymph sacs, 783
Jugular (suprasternal) notch, 226*f*, **227**
Jugular veins, 758*f*, **758***t*, 759*f*, 760*f*, **760***t*, 761*f*, 762*f*, 763*f*
Junctional folds, of sarcolemma, 289, 290*f*
Junctional rhythm, **694**–695, 697*f*
Junctions, cell
  anchoring, 69, 70*f*
  desmosomes, **69**, 70*f*
  gap, **69**, 70*f*
  impermeable, 69, 70*f*
  tight, **69**, 70*f*
  types of, 69, 70*f*
Juxtaglomerular apparatus (JGA), **1003**, 1005, 1005*f*
  tubuloglomerular feedback in, 1008, 1009*f*, 1010
Juxtaglomerular (granular) cells, **1003**, 1005, 1005*f*
Juxtamedullary nephrons, **1003**
  cortical nephrons vs., 1003, 1004*f*

Kaposi's sarcoma, 821
Karyotype, **1146**, 1147*f*
Kcal (kilocalories), **943**
Keloid, **148**
Keratan sulfate, 128, 129*f*
Keratin, **152**
  epidermal, 123
  functions/examples from body, 52*t*
  in hair, 163
  hard vs. soft, 160, 163
  in nails, 163
  protective mechanism, 796*t*
Keratinized cells, 123
Keratinocytes, **152**, 154*f*, 165
Keratohyaline granules, 155
Ketoacidosis, **634**, 635*f*, 636*b*, 637*b*
Keto acids, **961**, 962*f*, 970
Ketogenesis, 635*f*, **969**, 969*f*
Ketones (ketone bodies), **634**, **969**, 1024*t*, 1050
Ketonuria, 634, 635*f*, 1024*t*
Ketosis, **60**, 969
Kidneys, **998**
  in acid-base balance, 1052–1054
    compensations, 1057, 1060
  aging and, 1030
  anatomy, 998–1006
  blood pressure regulation by, 730–731
  blood supply, 1000*f*, 1001
    in nephrons, 1003, 1004*f*
  chronic renal disease, 1022–1023*b*
  diagnostic tests, 1022*b*
  hemodialysis, 1023*b*
  hormones produced by, 638, 638*t*
  innervation, 1001
    ANS effects, 539*f*, 541*t*, 546*t*, 547
  lobes, **1000**, 1000*f*
  renal calculi, 1024
  transplant surgery, 1023*b*
Kilocalories (kcal), **943**
Kinase enzymes, 312, 313*f*
Kinesins, 90, 103*f*
Kinetic energy, **25**
  in passive membrane transport processes, 75*t*
Kinetochores, 102*f*, 103*f*
Kinins, **793**
  source/effects, 793*t*
Kinocilium, 594*f*, 595, 595*f*
Klinefelter's syndrome, 1103
Knee
  bones, 239, 241, 241*f*
  injuries, 267, 267*f*
  ligaments, 265, 266*f*, 267
Kneecap (patella), 228*f*, 239, 241, 241*f*, **242**, 246*f*, 246*t*
Knee-jerk (patellar) reflex, 265, **523**–524, 523*f*
Knee joint, **265**–268, 266*f*
  articulating bones/movements allowed, 259*t*
  femoropatellar, **265**, 266*f*
  inflammatory conditions, 273
  innervation of, 515*f*, 515*t*, 516, 517*f*, 617*t*
  muscles acting on (summary), 379–380*t*, 380*f*
  muscles crossing, 367–372*t*
  replacement/prosthetic, 275*b*
  tibiofemoral, **265**, 266*f*
Knee replacements, 275*b*
Knuckle joints, 258*t*
Knuckles, 235, 235*f*
K-ras oncogene, 146*b*
Krebs cycle, 957*f*, 959*f*, **961**–963, 962*f*
  summary, 971*t*
Kupffer cells, **721**, 790, **912**, 914*f*
Kuru disease, 482–483*b*
Kwashiorkor, **993**
Kyphosis, 219, 248

Labia, mouth, 889*f*, **890**
Labial frenulum, 889*f*, **890**
Labia majora, **1088**, 1088*f*
Labia minora, **1088**–1089, 1088*f*
Labile factor, nature/origin/function/pathway, 663*t*
Labioscrotal swellings, 1102*f*, **1103**
Labor, **1135**
  false, **1136**
  hormonal induction, 1135–1136, 1135*f*
  oxytocin and, 10, 1135–**1136**, 1135*f*
  as positive feedback mechanism, 10, 1135*f*, 1136
  stages, 1136*f*, 1137
Labyrinth (inner ear), 584*f*, **586**–587, 586*f*
  bony (osseous), **586**–587, 586*f*
  disorders, 594
  membranous, **586**, 586*f*
Labyrinthitis, **599**
Lacrimal apparatus, **557**–558, 558*f*
Lacrimal bones, 205*f*, 206*f*, **213**
  orbits and, 213, 214*f*
  summary/important markings, **217***t*
Lacrimal canaliculi, **557**, 558*f*
Lacrimal caruncle, **556**, 557*f*
Lacrimal fossa, 206*f*, **213**, **217***t*
Lacrimal glands, **557**, 558*f*
  ANS effects, 546*t*
  orbits and, 213
  parasympathetic fibers, 537*f*
  sympathetic fibers, 539*f*
Lacrimal nuclei, 537
Lacrimal puncta, **557**, 558*f*
Lacrimal sac, 213, **557**, 558*f*
Lacrimal secretions (tears), **557**
  lysozyme and, 558, 790
  as protective mechanism, 796*t*
Lactase, 928*f*, **929**
Lactation, **1138**–1139, 1139*f*
Lacteals, **775**, **909**, 910*f*, 932, 932*f*
Lactic acid, **302**, 303*f*, 960*f*, **961**, 1050
  formation, 302, 303*f*
Lactiferous ducts, 1089*f*, **1090**
Lactiferous sinus, 1089*f*, **1090**
Lactose
  as a disaccharide, 44, 45*f*
  chemical digestion of, 928*f*, 929
Lactotrophs, **616**
Lacunae, 135, 136*f*, 138*f*, **182**, 183*f*
Lacunae (intervillus spaces), 1121*f*, **1122**
Lagging strand, in DNA replication, 99, 100*f*
Lambdoid suture, 203, 205*f*, 206*f*, **207**
Lamellae, 137, 138*f*, **179**, 183*f*
Lamellar bone, **181**–182
Lamellated granules, 155
Lamellated (Pacinian) corpuscles, 493*t*
Laminae, vertebral, **221**, 221*f*, 222*f*, 223*f*
Lamina propria, 131*f*, 132, **142**
  of large intestine mucosa, 925*f*
  stomach, 901*f*
Laminar flow (streamlining), 724
Laminectomy, **248**
Lamins, 96*f*, 97
Langerhans' cell (dendritic cell), **152**, 154*f*
  as antigen-presenting cell, 803
  as biological barrier, 164
  as lymphoid cell, **777**
Language, 436, 460
  cerebral dominance and, 441
Lanugo coat, 170
Laparoscopy, **938**, **1109**
Large intestine, 883*f*, **922**–927
  abdominal veins in relation to, 765*f*
  anatomy, gross, 922–923, 923*f*
  bacterial flora, **925**
  blood supply, 754*t*, 764*t*, 923*f*
  digestive processes, 925–927
  disorders, 922, 926, 927
  functions, 920*t*, 922
  mucosa, 925, 925*f*
  parasympathetic fibers, 536*f*, 537*f*
  sympathetic fibers, 539*f*
  sympathetic innervation, 541*t*
Laryngeal cartilages, 341*f*, 834*f*, 836–837, 836*f*
Laryngeal prominence, **836**, 836*f*
Laryngitis, **838**
Laryngopharynx, 834*f*, **835**, 889*f*, **895**–896
Laryngotracheal bud, **873**
Larynx, 832*f*, **835**–838
  cartilage skeleton of, 176, 177*f*
  features/functions, 838*t*
  hyoid bone and, 218
  sphincter functions, 838
  swallowing and, 340
Latent period of muscle twitch, **297**, 297*f*
Lateral excursion, of mandible, 271*f*, 272
Lateral horns, **472**, 473*f*, **538**, 540*f*
Lateralization, **441**
Lateral ligament, of temporomandibular joint, 271*f*, **272**
Lateral masses
  of atlas (C1), 221, 222*f*
  of ethmoid bone, **211**, 211*f*
Lateral orientation/direction, 13*t*
Lateral (small cell) nuclear group, 450*f*, **455**
Lateral thalamic nuclei, 445*f*, 446
Lateral ventricles (brain), **434**, 434*f*
  white matter fiber tracts and, 442*f*
Latissimus dorsi muscle, **354**, **354***t*, 356*f*
  actions of (summary), 362*t*
  arm movements and, 354, 354*t*
  as posterior thorax muscles, **352**, 353*f*
  superficial, 332*f*, 333*f*
Laughing, mechanism/result, 854*t*
LDLs (low-density lipoproteins), 48*t*, **980**, 981*f*

L-Dopa, 469
  pathway for synthesis of, 418*f*
Lead, 164
Leading strand, in DNA replication, 99, 100*f*
Leakage (nongated) ion channels, 72, **398**
Learning, hyperalgia and, 497*b*
Lecithin, 931, 944
Left lower quadrant (LLQ), **19**, 19*f*
Left upper quadrant (LUQ), **19**, 19*f*
Left ventricular assist devices (LVADs), 707*b*
Leg
  bones, 242–244, 242*f*, 243*f*, 246*f*, 246*t*
  innervation of, 515*f*, 515*t*
  muscles, 373–378*t*
    acting on, 367–372*t*
    actions of (summary), 379*t*, 380*f*
    superficial, 331*f*, 333*f*
Lemniscal system/tract, 476*f*, 477*t*, **478**, 592*f*, **593**
Lens, 560*f*, 564*f*, **565**
  refraction and, 565–566, 567*f*
Lens epithelium, 564*f*, **565**
Lens fibers, **565**
Lens vesicle, **598**
Lentiform nucleus, **443**, 444*f*
Leptin, 190, **638**, 982–983, 983*f*, **984**
  female puberty onset and, 1094, 1098
  source/trigger/effects, 638*t*
Lesion, **148**
Lesser curvature (stomach), 899*f*, **900**
Lesser omentum, **900**, 913*f*, 924*f*
Lesser sciatic notch, of ischium, **237**, 238*f*, 243*f*
Lesser trochanter, of femur, **241**, 241*f*, 243*f*
Lesser tubercle, of humerus, 231*f*, **232**, 234*f*, 236*t*
Let-down reflex, 617, **1138**, 1139*f*
  as positive-feedback mechanism, 1138
Lethal dominant genes, 1150
Lethal hit mechanisms, by cytotoxic T cells, **815**–816, 816*f*
Lethargy, 458
Leucine, 947*f*
Leukemias, 660
Leukocytes, **130**, 138*f*, 647, 647*f*, **656**–662
  disorders, 660, 662
  production of, 660, 661*f*
  structure, 656–657
  types of/percentages, 657, 657*f*, 659*f*
    agranulocytes, **659**–660
    granulocytes, **657**–659
    summary, 658*t*
  in urine, 1024*t*
Leukocytosis, **657**, **794**, 794*f*
Leukopenia, **660**
Leukoplakia, 146*b*
Leukopoiesis, **660**, 661*f*
Leukotrienes, 606, **793**, 793*t*
  location/function in body, 48*t*
Levator ani muscle, **350**, **350***t*, 351*f*, 923*f*, 1026
Levator labii superioris muscle, **336***t*, 337*f*
Levator palpebrae superioris muscle, 503*t*, **556**, 557*f*
Levator scapulae muscle, **352**, 353*f*, **353***t*
Levator veli palatini, 340, 341*f*
Levers, **326**
Lever systems (bone-muscle), **326**–330
  effort, muscle contraction as, 327, 328*f*
  fulcrum, joints as, 327, 328*f*
  lever
    bone as, 326–327
    first/second/third class, **328**, 329*f*
    power, 327–328, 328*f*
    speed, 327–328, 328*f*
  load, bone (plus weight) as, **326**–327, 328*f*
  mechanical advantage/disadvantage and, **327**–330, 328*f*
Leydig (interstitial) cells, **1068**, 1068*f*
LH. *See* Luteinizing hormone
Libido
  DHEA and, 630, 1082, 1100
  estrogens and, 1099*t*
  testosterone and, 1082, 1099*t*, 1100
Life cycle
  cell, 97–101
  functions essential to, 4–8
  survival needs for, 8
Ligamenta flava, 135
Ligament of head of femur, 239, 270*f*, **271**
Ligaments, **256**
  artificial, 272
  capsular, **256**, 268
  as connective tissue proper, 126
  elastic connective tissue of, 135

Longissimus muscles, 344*t*, 345*f*
Longitudinal arches, of foot, **244**, 245*f*
Longitudinal fissure (cerebral hemisphere), **434**, 435*f*
  white matter fiber tracts and, 442*f*
Longitudinal ligaments, **220**, 220*f*
Long reflexes of GI tract, 886, 908*f*, 921, 921*t*
Long-term memory (LTM), **461**, 461*f*
Long-term potentiation (LTP), 413
  memory formation and, 463
Loop of Henle, **1001**, 1002*f*, 1003, 1004*f*
  functions (summary), 1020*f*
  reabsorptive abilities, 1013, 1014*t*, 1015
Loose bodies, 272
Loose connective tissues, **131**
  areolar/adipose/reticular, 131–133, 131*f*–133*f*
Lordosis, 219, 247
Loudness of sound, **589**, 590*f*
  detection of, 593

Low-density lipoproteins (LDLs), **980**, 981*f*
  function in body, 48*t*
Lower limbs
  arteries, **746***t*, 756–757*t*
  bones, 239–246
    summary, 246*f*, 246*t*
  innervation, sympathetic, 541*t*
  innervation of, 514–517
    distribution of major peripheral nerves in, 515*f*
    skin, 516, 518*f*
  veins, 758*f*, 758*t*, 766*f*, **766***t*
LTP (long-term potentiation), 413
  in excitotoxicity, 468
  memory formation and, 463
Lubrication, weeping, 256
Lumbar arteries, 746*f*, 752*f*, **754***t*, 755*f*
Lumbar curvatures, **219**, 219*f*, 247
Lumbar enlargement, 471*f*, **472**, 509*f*
Lumbar lymphatic trunks, **775**, 776*f*
Lumbar nerves, 471*f*, 509*f*
  muscles served by, 344*t*
Lumbar plexus, 509*f*, **514**–516, 515*f*
  nerves/spinal roots/structures served, 515*t*
Lumbar puncture (tap), **470**, 472*f*
Lumbar veins, 758*f*, 762*f*, **762***t*, 763*f*, **763***t*, 764*f*, **764***t*, 765*f*
Lumbar vertebrae, 204*f*, **219**, 219*f*
  curvatures, **219**, 219*f*
  features, 223, 223*f*
    summary, 224*f*, 224*t*
  movements allowed, 224*t*
Lumbosacral plexus, **514**. *See also* Lumbar plexus; Sacral plexus
Lumbosacral trunk, **514**, 515*f*, 516
Lumbrical muscles
  of foot, **381***t*, 382*f*
  of hand, 359*f*, **364**, 365*f*, **366***t*
Lumen
  of blood vessels, **714**, 715*f*
  of esophagus, 896*f*
  of small intestine, 910*f*
  of uterus, 1085*f*, 1087*f*
Lumpectomy, **1090**
Lunate bone, **235**, 235*f*, 236*f*, 236*t*
Lungs, 832*f*, **842**, 845*f*
  ANS effects, 546*t*
  blood flow to and from, 738
  blood supply of, 845
  cancer of, 872–873
  features/functions, 838*t*
  fibrosis, 851
  heart in relation to, 679*f*
  innervation of, 845
  lung compliance, **851**
  in neonatal period, 1137–1138
  nonrespiratory air (gas) movements, **854**, 854*t*
  parasympathetic fibers, 536*f*, 537*f*
  sympathetic fibers, 536*f*, 539*f*
Lung volume reduction surgery, 871–872
Lunula, of nail matrix, 163
LUQ. *See* Left upper quadrant
Luteal phase, ovarian cycle, **1093**, 1093*f*, 1094
Luteinizing hormone (LH), **616**
  in ovarian cycle, 1094–1096, 1095*f*
  in spermatogenesis regulation, **1080**–1081, 1081*f*
  summary of regulation/effects, 619*t*
  in uterine cycle, 1096–1098, 1097*f*
Luxation (dislocation), **273**
LVADs (left ventricular assist devices), 707*b*
Lyme disease, **276**
Lymph, **774**

  connective tissues arising from, 127, 128*f*, **131**
  in intramembranous ossification, 184*f*
Mesenteric arteries, 746*f*, 747*f*, 752*f*, 753*f*, **754***t*, 755*f*, 923*f*
Mesenteric ganglia, 539*f*, **541**
Mesenteric veins, 759*f*, 764*f*, **764***t*, 765*f*
Mesenteries, **886**, 886*f*, 923*f*, 924*f*
Mesocolons, 900, **922**, 923*f*, 924*f*
Mesoderm, **145**, 145*f*, 1120*f*, **1123**, 1124*f*, 1125*f*, 1126*f*
  derivatives, 1126–1130
  intermediate, **1127**, 1127*f*
Mesometrium, 1085*f*, **1086**
Mesonephric duct, **1027**, 1029*f*
Mesonephric (Wolffian) ducts, 1102*f*, **1103**
Mesonephros, **1027**, 1029*f*
Mesosalpinx, **1084**, 1085*f*
Mesothelium, **120**
Mesovarium, **1083**, 1083*f*, 1085*f*
Messenger RNA (mRNA), 57, **104**–105, 105*f*, 107, 109
  signal sequence and, 87, 87*f*
Metabolic acidosis, 969, **1055**, 1056*t*
Metabolic alkalosis, **1055**, 1056*t*
Metabolic (fixed) acids, **1052**
Metabolic pathways, used to regenerate ATP, 301–303, 303*f*
Metabolic rate, **984**–985
  aging and, 992
  ANS effects, 546*t*
  basal, **984**–985
  thyroid hormone and, 621, 621*t*, 985
  total, **985**
Metabolic water, **1039**
Metabolism, **6**–7, **956**–981
  absorptive state, **973**–974, 974*f*
  aging and, 992
  anabolic, **956**, 957*f*
  carbohydrate, 959–967
  catabolic, **956**, 957*f*
  catabolic-anabolic steady state, 971–973
  cellular, 90, 649, 1039
  developmental aspects, 989, 992
  disorders, 992
  effects of insulin on, 973–974, 975*f*
  energy balance
    body temperature, 985–989
    food intake regulation, 982–984

continues

Metabolism (*cont.*)
heat production, 984–985
metabolic rate, 984–985
free radicals as byproduct of, 90
globular proteins in regulation of, 52*t*
gluconeogenesis, 967
heat as by-product of, 649
hormonal influences on, 978*t*
hydrogen peroxide as by-product of, 90
inborn errors, 992
lipids, 967–970, 969*f*
metabolic rate, **984**
nutrient pools and, **971**–973, 971*f*
overview, 956–959
postabsorptive state, **973**–978
protein, 970–971
reactions in (summary), 971*t*
water as by-product of, 1039
Metabotropic receptors, 421
Metacarpal arteries, 750*f*, **750***t*
Metacarpal bones, 228*f*, **235**, 235*f*, 236*f*, 236*t*
joints of, 258*t*
Metacarpal veins, 762*f*
Metacarpophalangeal (knuckle) joints, 258*t*
Metacarpus (palm), 233, **235**, 235*f*, 236*f*, 236*t*, 237
Metanephros, **1027**, 1029*f*
Metaphase, 98*f*, **101**, 103*f*, 1075*f*, 1076*f*
Metaphysis, 180
Metarteriole, 717*f*, **721**, 721*f*
Metarteriole-thoroughfare channel (vascular shunt), 721, 721*f*
Metastasis of malignant neoplasms, **146**
Metastatic calcification, 625
Metatarsal arteries, 756*f*, **756***t*, 757*f*
Metatarsal bones, 228*f*, **244**, 245*f*, 246*f*, 246*t*
joints, 259*t*
Metatarsal veins, 766*f*
Metatarsophalangeal joint, articulating bones/movements allowed, 259*t*
Metatarsus, **244**
Metencephalon, 432*f*, **433**
Methamphetamine ("speed"), 424*b*
Methane gas, 35*f*
Methane gas molecule, 35*f*
Methionine, 947*t*
MHC (major histocompatibility complex), **800**
restriction process, **801**–802, 802*f*
MHC proteins, **800**, **811**–813, 812*f*
Micelles, **931**, 932*f*
Microcephaly, **485**
Microcirculation, **721**
Microcytes, **655**
Microfilaments, 66*f*, **90**–91, 91*f*
interaction of motor proteins with, 92, 92*f*
structure/functions (summary), 94*t*
Microglia, 390*f*, **391**
MicroRNAs (miRNAs), 57, **110**
Microscopic anatomy, **2**
preparing tissue for, 118
Microtubules, 66*f*, **90**, 91*f*
centrosome matrix and, 90, 92
doublets, 93, 93*f*
interaction of motor proteins with, 92, 92*f*
kinetochore, 102*f*
polar, 102*f*
structure/functions (summary), 94*t*
triplets, 93
Microvilli, 66*f*, **69**, 70, **119**
of small intestine, **909**–910, 910*f*, 911*f*
structure/functions (summary), 95*t*
Micturition, **1027**
Micturition reflex, 1027, 1028*f*
Midbrain, 445*f*, 447*f*, **448**
diencephalon in relation to, 448–449*f*
embryonic origins, 431, 432*f*, 433
mesencephalon, **431**
functions (summary), 453*t*
nuclei of importance, 449, 450*f*
oculomotor nerve originating in, 503*f*, 503*t*
spinal cord tracts and, 476*f*
Middle ear, auditory ossicles of, **217***t*
Middle ear cavities, **19**, 19*f*
Midpalmar muscles, **366***t*
Midpiece, sperm, **1079**, 1079*f*
Midsagittal (median) plane, **15**, 16*f*
MIF (migration inhibitory factor), 818*t*
Migrating motility complex (MMC), **921**, 921*t*
Migration inhibitory factor (MIF), 818*t*
Milia, 170
Milk (deciduous) teeth, 893, 893*f*
Milliosmol (mOsm), **1016**
MI (myocardial infarction), **686**
Mind, 456
Mineralocorticoids, **627**–629
structure/regulation/effects, 627*t*
Minerals, **952**, 956
bone as storage reservoir for, 179
roles of in body (overview), 952–955*t*
Mineral salts (hydroxyapatites), 183
Minute ventilation, **853**
miRNAs (microRNAs), 57, **110**
MIT (monoiodotyrosine), 622, 622*f*
Mitochondria, 66*f*, **85**, 85*f*
in cardiac muscle cells, 689, 690*f*
fission process and, 85
as site of cellular respiration, 85, 956, 957*f*
skeletal muscle fiber, 288*f*, 290*f*
structure/functions (summary), 94*t*
Mitosis, 99, 99*f*, **101**, 102–103*f*, 1073–1074
centriole's role in, 92–93, 102*f*
meiosis vs., 101, 1074, 1075*f*
Mitotic spindle, **102***f*
centrioles and, 93
Mitral (bicuspid) valve, 683*f*, **686**, 687*f*
prolapse, **709**
Mitral cells, 579*f*, **580**
Mittelschmerz, 1094
Mixed nerves, **499**
cranial nerves and, 500–501
Mixtures, **30**–31
vs. compounds, 31
M line, **284**, 285*f*, 288*f*
MMC (migrating motility complex), **921**, 921*t*
Modiolus, **587**, 588*f*
Molarity, **30**–31
Molar teeth, 893*f*, **894**
Mole, **30**–31
Molecular biology, 2
Molecular chaperones, 52–**53**, 52*t*
Molecular formula, **37**
Molecular mimicry, 636*b*
Molecular "Velcro," 83
Molecular weight, **30**–31
Molecules, 3, **30**–31
amphipathic, 47
amphoteric, **1051**
nonpolar vs. polar, **34**–36, 35*f*, 36*f*
Moles
changes in, 166
pigmented, 157
Molybdenum, 26*t*
Mongolian spot, **171**
Monoclonal antibodies, **810**
Monocytes, 649*f*, 657*f*, **659**–660, 659*f*, **790**
summary, 658*t*
Monoglycerides, digestion and, 928*f*, 930
Monohydrogen phosphate, 1054, 1054*f*
Monoiodotyrosine (MIT or T1), 622, 622*f*
Monomers, 807, 927
Mononucleosis, **783**
Monosaccharides, **927**
Monosaccharides (simple sugars), **44**, 45*f*
Monospermy, **1115**
Monosynaptic reflexes, **521**, **524**
Monounsaturated fats, **46**
Mons pubis, 1082*f*, **1088**, 1088*f*
Morning sickness, 1135
Morula, **1117**, 1118*f*
Motilin
production site/stimuli/target/actions, 906*t*
in small intestine motility, 921, 921*t*
Motility
gastric, **905**–907, 907*f*
large intestine, 926
small intestine, 919–922
stomach, 905, 907
Motion sickness, **598**
Motor areas of cerebral cortex, **436**, 437*f*
Broca's, 437*f*, 439
cerebellar processing and, 454
frontal eye field, 437*f*, 439
premotor, 437*f*, 439
primary motor, 437*f*, 438–439, 438*f*
Motor cortex (primary), 437*f*, **438**–439, 438*f*
damage to, 439
major descending pathways, 479*t*, 480*f*
neural integration and, 495*f*
Motor (efferent) division of PNS, **388**, 389*f*
ANS division, **388**, 389*f*
somatic nervous system division, **388**, 389*f*
Motor (efferent) nerves, **499**
of ventral roots, **509**, 510*f*
Motor (efferent) neurons, **395**, 396–397*t*
Motor endings
autonomic, 519
peripheral, **289**, 290*f*, 491, **519**
Motor homunculi
cerebellar, 452*f*, 453
cortical, **438**–439, 438*f*
Motor integration, hierarchy, 519–520, 520*f*
Motor neurons
in motor unit, 296–297, 296*f*
muscle contraction and, 288–289, 296–297, 296*f*
myelinated axons and, 290*f*
in reflex arcs, **521**, 521*f*
Motor output, **388**, 388*f*
Motor proteins, **90**, 92*f*
Motor speech area of cerebral cortex, 439
Motor unit, **296**–297, 296*f*
force of muscle contraction and, 304
Mountain sickness, 870
Mouth (oral cavity), **19**, 19*f*, 832*f*, 883*f*, **889**–895, 889*f*
digestive processes occurring in, 897–899, 898*f*
major functions (overview), 920*t*
muscles forming floor of, 340*t*, 341*f*
Movement
anterograde, 393
retrograde, 393
Movements, body, **5**, **259**–263
agonist muscles and, 325, 326
allowed by synovial joints
angular, 260–261, 260–262*f*
rotation, 261–262, 262*f*
special movements, 262–263, 263*f*
allowed by vertebrae, 221, 224*t*
antagonist muscles and, 325, 326
biaxial, 259
contraction of muscles and, 281
fixator muscles and, 325, 326
multiaxial, 259
muscle's origin/insertion and, 259, 325
nonaxial, 259
prime mover muscles for specific kinds of, 325
role of bones in, 179
synergist muscles and, 325, 326
types of, 259–263, 260–263*f*
uniaxial, 259
MPF (M-phase promoting factor), **101**
M phase of cell life cycle, 90, 103*f*
M-phase promoting factor (MPF), **101**
MRI. *See* Magnetic resonance imaging
mRNA (messenger RNA), 57, **104**–105
polyribosomes and, 109, 109*f*
signal sequence and, 87, 87*f*
synthesis of, 105, 106*f*
in translation, 107, 108*f*, 109
MRS (magnetic resonance spectroscopy), **21***b*
MSH (melanocyte-stimulating hormone), 614

MS (multiple sclerosis), **407**–408, 822
Mucin, **125**, 125*f*, 874, 892
Mucosa-associated lymphatic tissue (MALT), **782**, 887*f*, **888**, 922
Mucosal barrier of stomach, **901**–902
Mucosal iron barrier, 933
Mucous cells, of salivary glands, **892**
Mucous membranes (mucosae), **141**, 142*f*
  of GI tract, **887**–888, 887*f*
    esophageal, 896*f*, 897

Telophase, **101**, 103*f*, 1076*f*
Temperature, chemical reactions and, 39
Temperature receptors, spinal cord pathways for, 476*f*, 477
Temperature stimuli, nerve endings responding to, 492
Template, DNA, 99, 100*f*, 105, 106*f*, 108*f*
Temporal arteries, 748*f*, **748***t*, 749*f*
Temporal bone, meninges in relation to, 464*f*
Temporal bones, 205*f*, 206*f*, **207**, 208*f*, 209*f*
summary/important markings, 216*t*
temporomandibular joint, 258*t*, **271**–272, 271*f*
Temporalis muscle, 337*f*, **338**, 339*f*
description/action/nerve supply, **338***t*
origin/insertion, 338*t*
superficial, 331*f*
Temporal lobe, role in memory consolidation/access, 462, 463
Temporal lobe of cerebral hemisphere, 434, 435*f*, **436**, 437*f*, 445*f*
cranial nerves in relation to, 501*f*
Temporal summation, **412**, 413*f*
Temporal veins, 760*f*, **760***t*, 761*f*
Temporomandibular joint (TMJ), 207, 211, 212*f*, **271**–272, 271*f*
dislocation, 272
movements allowed by, 258*t*, 271*f*, 272
Tendon, **284**
central, of diaphragm, 347*f*
as in indirect muscle attachment, 284
in relation to connective tissue sheath, 282*f*, 283, 283*f*
Tendonitis, **273**
Tendon of adductor magnus, 266*f*
Tendon of biceps muscle, 268, 268*f*, 359*f*
Tendon of long head of biceps brachii muscle, 257*f*, 269, 269*f*
Tendon of quadriceps femoris muscle, knee joint and, 266*f*
Tendon of quadriceps muscle, 265, 266*f*
Tendon of semimembranosus muscle, 266*f*
Tendon of subscapularis muscle, 269*f*
Tendon of triceps muscle, 268, 268*f*
Tendons
dense regular connective tissue of, 135
of knee, 266*f*, 267
of rotator cuff, 269
synovial joint stability and, 257, 257*f*, 259
Tendon sheath, **257**, 257*f*, 269*f*
inflammation, 273
Teniae coli, **922**, 923*f*
Tennis elbow, **384**
Tension (cleavage) lines, 156
Tensor fasciae latae muscle, 331*f*, **367**, 368*f*
actions of (summary), 379–380*t*, 380*f*
description/action/nerve supply, **370***t*
origin/insertion, **370***t*
Tensor muscle, 340
Tensor tympani muscle, 585*f*, **586**
Tensor veli palatini, 341*f*
TENS (transcutaneous electrical nerve stimulation), 497*b*

Tentorium cerebelli, **464**, 464*f*, 465*f*
CSF in relation to, 466*f*
Teratogens, **1130**
Teres major muscle, 353*f*, **354**, 356*f*
actions of (summary), 362*t*
description/action/nerve supply, **355***t*
origin/insertion, **355***t*
superficial, 333*f*
Teres minor muscle, 353*f*, **354**, 356*f*
actions of (summary), 362*t*
description/action/nerve supply, **355***t*
origin/insertion, **355***t*
Terminal arterioles, 717*f*, **721**, 721*f*
Terminal branches (telodendria) of axon, 392*f*, **393**
Terminal bronchioles, 841*f*, 842
Terminal cisternae, **287**, 288*f*
Terminal ganglia, **536**
Terminal hair, **162**
Termination signal, 105, 106*f*
Testes, **1066**, 1066*f*, 1067*f*
in brain-testicular axis, 1080–1081, 1081*f*
as endocrine system organ, 605*f*, 635
as primary sex organ, 1066
structure, 1067–1069, 1068*f*
Testicular cancer, 1069
Testicular fluid, **1080**
Testicular (gonadal) arteries, 746*f*, 747*f*, 752*f*, **754***t*, 1067*f*, **1068**
Testicular (gonadal) veins, 758*f*, 764*f*, **764***t*, 765*f*, **1068**
Testosterone, **635**, 1068, **1080**
in brain-testicular axis, 1080–1081, 1081*f*
CNS gender-specific development and, 481
EPO production and, 653
in "juice" (anabolic steroids), **308***b*
location/functions, 48*t*
mechanisms/effects, 1081–1082
source/stimulus/effects (summary), 1099*t*
structure/regulation/effects, 627*t*
terminal hair response to, 162
Tetanus (disease), 298, **320**
immunity and, 806
Tetanus/tetanic muscle contractions, **298**, 298*f*
frequency of stimulation and, 305
fused/complete, **298**, 298*f*
unfused/incomplete, **298**, 298*f*
Tetany, 625
Tetrads, 1076*f*, **1077**
Tetrahydrogestrinone (THG), 308*b*
Tetralogy of Fallot, 708, 708*f*
TF (tissue factor), 663*t*, 664*f*, **665**
Thalamic nuclei, 443, **445***f*, 446, 583*f*
anterior, as limbic structure, 454, 455*f*
functions (summary), 453*t*
Thalamic nucleus, 445*f*, 446
Thalamus, **443**, 445*f*, 446, 448*f*, 449*f*
basal nuclei in relation to, 444*f*
embryonic origins, 432*f*, 433
internal capsule and, 442*f*, 443, 446
memory and, 462*f*
as memory circuit, 462*f*
neural integration and, 495*f*
nuclei of, 443, 445*f*, 446
in pain pathway, 496*b*
spinal cord tracts and, 476*f*
Thalassemias, **655**
Thalidomide, **1130**
Theca folliculi, **1093**, 1093*f*
Thenar eminence, 364
Thenar muscles, 359*f*, **364***t*, 365*f*
Theory of spontaneous generation, 65
Thermogenesis
chemical (nonshivering), **987**
food-induced, **985**
Thermoreceptors, **491**, 493*t*
central, **987**
peripheral, **987**
Thermoregulation
brain centers for, **987**
heat-loss mechanisms, 988–989, 988*f*
heat-promoting mechanisms, 987–988, 988*f*
sympathetic ANS responses, 547
Theta brain waves, **456**, 457*f*, 459, 459*f*
THG (tetrahydrogestrinone), 308*b*
Thiamin (vitamin B1), **949***t*
Thick (myosin) filaments, 282*f*, 282*t*, **284**–286, 285*f*, 286*f*
in muscle contraction, 293–294, 295*f*
Thick segment, loop of Henle, 1002*f*, **1003**, 1004*f*
Thick skin, **153**
Thigh
bone, 239, 241, 241*f*, 246*f*, 246*t*
innervation of, 515*f*, 515*t*
muscles, 367–372*t*
actions of (summary), 379–380*t*
superficial, 331*f*, 333*f*
Thin (actin) filaments, 282*f*, 282*t*, **284**, 285*f*, 286–287, 286*f*
globular, 286
in muscle contraction, 293–294, 295*f*
Thinking
Alzheimer's disease and, 469
memory processing circuits, 462*f*
Thin segment, loop of Henle, 1002*f*, **1003**, 1004*f*
Third-class levers, **328**, 329*f*
Third-degree burns, 167*f*, **170**
Third-order neurons, **475**, 476*f*, 495
Third ventricle (brain), **434**, 434*f*, 449*f*
CSF in relation to, 466*f*
white matter fiber tracts and, 442*f*
Thirst center, hypothalamic, 446, 1039
Thirst mechanism, **1039**–1040, 1040*f*
aging and, 1060
Thoracic arteries, 750*f*, **750***t*, 751*f*, **751***t*
Thoracic cage (bony thorax), 203, 204*f*, **226**
in relation to spine, 226, 226*f*
ribs, 226*f*, 227–228, 227*f*
sternum, **226**–227, 226*f*
Thoracic cavity, **15**, 17*f*
anatomical relationships of organs in, 844*f*
Thoracic curvatures, **219**, 219*f*, 247
Thoracic lymphatic duct, **775**
Thoracic nerves, 471*f*, 509, 509*f*, 513*f*
muscles served by, 352*t*
rami communicantes and, 509, 510*f*
Thoracic splanchnic nerves, 540*f*
Thoracic vertebrae, **219**, 219*f*
articulated, 223*f*
curvatures, **219**, 219*f*, 247
features, 222, 223*f*
summary, 224*f*, 224*t*
movements allowed, 224*t*
in relation to ribs, 227*f*
Thoracic viscera arteries, **751***t*
Thoracoacromial arteries, 750*f*, **750***t*, 751*f*
Thoracodorsal nerve, muscles served by, 354*t*
Thoracolumbar division of ANS, **538**. *See also* Sympathetic division
Thorax

Zymogen granules, **917**, 918*f*

pheno- *show, appear* phenotype, the physical appearance of an individual
phleb- *vein* phlebitis, inflammation of the veins
pia *tender* pia mater, delicate inner membrane around the brain and spinal cord
pili *hair* arrector pili muscles of the skin, which make the hairs stand erect
pin-, pino- *drink* pinocytosis, the engulfing of small particles by a cell
platy- *flat, broad* platysma, broad, flat muscle of the neck
pleur- *side, rib* pleural serosa, the membrane that lines the thoracic cavity and covers the lungs
plex-, plexus *net, network* brachial plexus, the network of nerves that supplies the arm
pneumo- *air, wind* pneumothorax, air in the thoracic cavity
pod- *foot* podiatry, the treatment of foot disorders
poly- *multiple* polymorphism, multiple forms
post- *after, behind* posterior, places behind (a specific) part
pre-, pro- *before, ahead of* prenatal, before birth
procto- *rectum, anus* proctoscope, an instrument for examining the rectum
pron- *bent forward* prone; pronate
propri- *one's own* proprioception, awareness of body parts and movement
pseudo- *false* pseudotumor, a false tumor
psycho- *mind, psyche* psychogram, a chart of personality traits
ptos- *fall* renal ptosis, a condition in which the kidneys drift below their normal position
pub- *of the pubis* puberty
pulmo- *lung* pulmonary artery, which brings blood to the lungs
pyo- *pus* pyocyst, a cyst that contains pus
pyro- *fire* pyrogen, a substance that induces fever
quad-, quadr- *four-sided* quadratus lumborum, a muscle with a square shape
re- *back, again* reinfect
rect- *straight* rectus abdominis, rectum
ren- *kidney* renal, renin, an enzyme secreted by the kidney
retin, retic- *net, network* endoplasmic reticulum, a network of membranous sacs within a cell
retro- *backward, behind* retrogression, to move backward in development
rheum- *watery flow, change, or flux* rheumatoid arthritis, rheumatic fever
rhin-, rhino- *nose* rhinitis, inflammation of the nose
ruga- *fold, wrinkle* rugae, the folds of the stomach, gallbladder, and urinary bladder
sagitt- *arrow* sagittal (directional term)
salta- *leap* saltatory conduction, the rapid conduction of impulses along myelinated neurons
sanguin- *blood* consanguineous, indicative of a genetic relationship between individuals
sarco- *flesh* sarcomere, unit of contraction in skeletal muscle
saphen- *visible, clear* great saphenous vein, superficial vein of the thigh and leg
sclero- *hard* scleroderma titis, inflammatory thickening and hardening of the skin
seb- *grease* sebum, the oil of the skin
semen *seed, sperm* semen, the discharge of the male reproductive system
semi- *half* semicircular, having the form of half a circle
sens- *feeling* sensation; sensory
septi- *rotten* sepsis, infection; antiseptic
septum *fence* nasal septum
sero- *serum* serological tests, which assess blood conditions
serrat- *saw* serratus anterior, a muscle of the chest wall that has a jagged edge
sin-, sino- *a hollow* sinuses of the skull
soma- *body* somatic nervous system
somn- *sleep* insomnia, inability to sleep
sphin- *squeeze* sphincter
splanchn- *organ* splanchnic nerve, autonomic supply to abdominal viscera
spondyl- *vertebra* ankylosing spondylitis, rheumatoid arthritis affecting the spine
squam- *scale, flat* squamous epithelium, squamous suture of the skull
steno- *narrow* stenocoriasis, narrowing of the pupil
strat- *layer* strata of the epidermis, stratified epithelium
stria- *furrow, streak* striations of skeletal and cardiac muscle tissue
stroma *spread out* stroma, the connective tissue framework of some organs
sub- *beneath, under* sublingual, beneath the tongue
sucr- *sweet* sucrose, table sugar
sudor- *sweat* sudoriferous glands, the sweat glands
super- *above, upon* superior, quality or state of being above others or a part
supra- *above, upon* supracondylar, above a condyle
sym-, syn- *together, with* synapse, the region of communication between two neurons
synerg- *work together* synergism
systol- *contraction* systole, contraction of the heart
tachy- *rapid* tachycardia, abnormally rapid heartbeat
tact- *touch* tactile sense
telo- *the end* telophase, the end of mitosis
templ-, tempo- *time* temporal summation of nerve impulses
tens- *stretched* muscle tension
terti- *third* fibularis tertius, one of three fibularis muscles
tetan- *rigid, tense* tetanus of muscles
therm- *heat* thermometer, an instrument used to measure heat
thromb- *clot* thrombocyte; thrombus
thyro- *a shield* thyroid gland
tissu- *woven* tissue
tono- *tension* tonicity; hypertonic
tox- *poison* toxicology, study of poisons
trab- *beam, timber* trabeculae, spicules of bone in spongy bone tissue
trans- *across, through* transpleural, through the pleura
trapez- *table* trapezius, the four-sided muscle of the upper back
tri- *three* trifurcation, division into three branches
trop- *turn, change* tropic hormones, whose targets are endocrine glands
troph- *nourish* trophoblast, from which develops the fetal portion of the placenta
tuber- *swelling* tuberosity, a bump on a bone
tunic- *covering* tunica albuginea, the covering of the testis
tympan- *drum* tympanic membrane, the eardrum
ultra- *beyond* ultraviolet radiation, beyond the band of visible light
vacc- *cow* vaccine
vagin- *a sheath* vagina
vagus *wanderer* the vagus nerve, which starts at the brain and travels into the abdominopelvic cavity
valen- *strength* valence shells of atoms
venter, ventr- *abdomen, belly* ventral (directional term); ventricle
vent- *the wind* pulmonary ventilation
vert- *turn* vertebral column
vestibul- *a porch* vestibule, the anterior entryway to the mouth and nose
vibr- *shake, quiver* vibrissae, hairs of the nasal vestibule
villus *shaggy hair* microvilli, which have the appearance of hair in light microscopy
viscero- *organ, viscera* visceroinhibitory, inhibiting the movements of the viscera
viscos- *sticky* viscosity, resistance to flow
vita- *life* vitamin
vitre- *glass* vitreous humor, the clear jelly of the eye
viv- *live* in vivo
