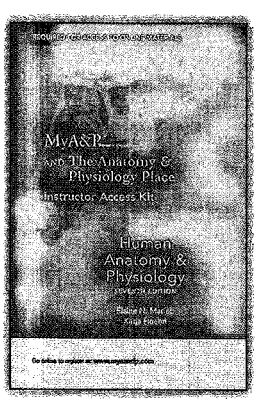
INFORMATION FOR INSTRUCTORS

HOW DO I KNOW WHICH OPTION IS BEST FOR MY COURSE?

MyA&P offers all of the rich content within the comprehensive online course management system CourseCompass, which is powered by Blackboard. The A&P Place offers the same content within a standard companion website format. Use the table below to determine which option has the most appropriate features for your course.

FEATURES	MyA&P powered by CourseCompass	The Anatomy & Physiology Place
Self-study quizzes, anatomy labeling exercises, a new histology tutorial, games and tutorials, case studies, a glossary, and flashcards.	●	●*
An E-book version of the text.	●	●
Access to *Get Ready for A&P*, *InterActive Physiology*™, PhysioEx™, and Anatomy 360°	●	●
A Gradebook that automatically scores and tracks online assessments.	●	●
An Assessment Manager that allows instructors to deploy exams from the textbook's computerized testbank and create their own exams for deployment.	●	
Communication Tools such as Discussion Board, Chat, and an Announcements page that can be modified by the instructor.	●	
Course Tools such as a Calendar, Address Book, and Digital Dropbox.	●	

* There is also an open-access version of the Anatomy and Physiology Place that offers this content in an open-access website and does not require a password.

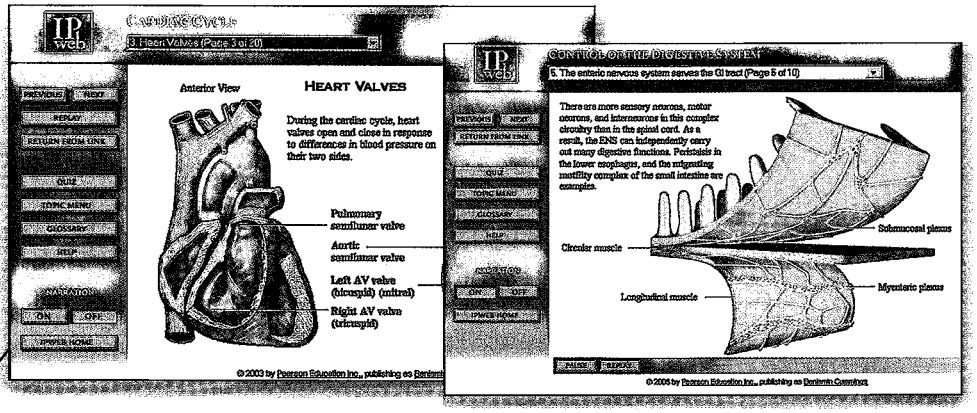


Get the Kit and Start Today!

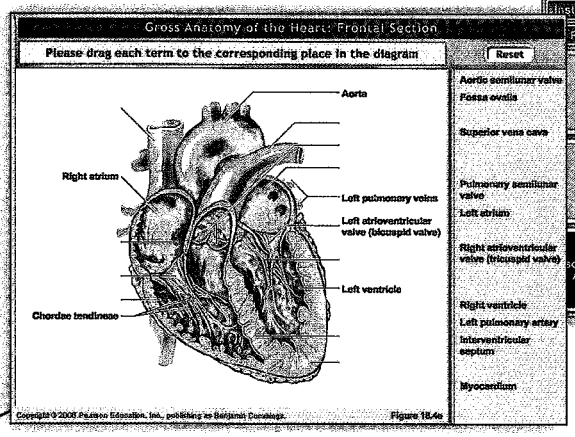
Locate the Instructor Access Kit that is packaged with your professional copy of this textbook. To access either MyA&P or the Anatomy & Physiology Place, you will need the access code in this kit. Simply follow the instructions in the booklet enclosed in the kit to get started with either site. Contact your Benjamin Cummings sales rep if you don't have a professional copy of the textbook or the accompanying Instructor Access Kit.

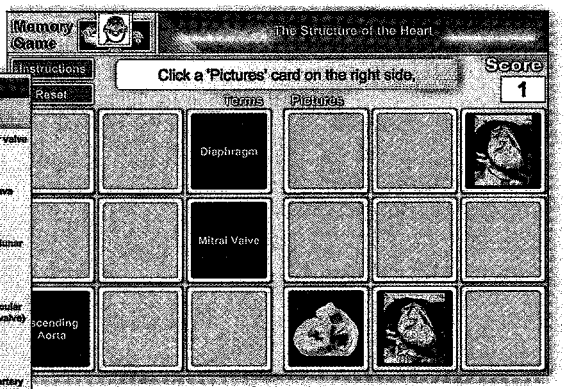
For access you will also need a valid email address and your school's zip code.

SAME SET OF POWERFUL TOOLS

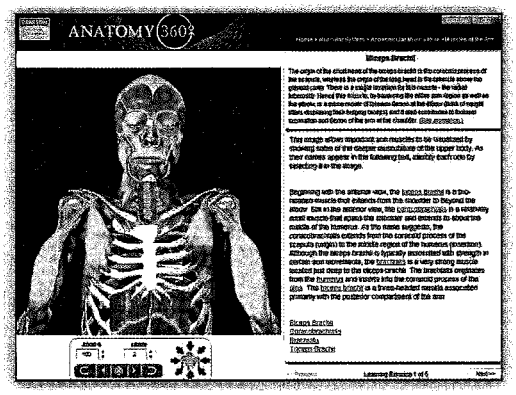


New! *InterActive Physiology*® 9-System Suite tutorial program
Helps students advance beyond memorization to a genuine understanding of complex physiological processes. Now includes the digestive system!

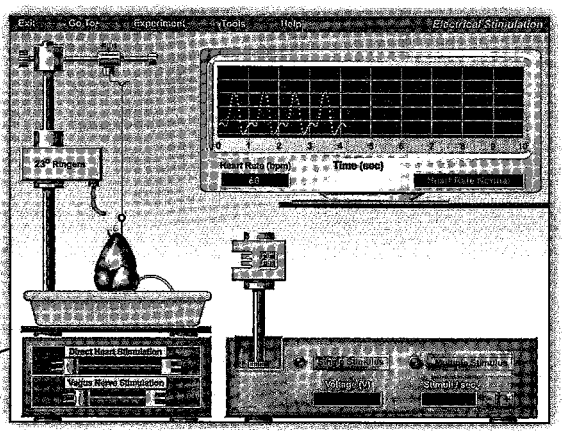




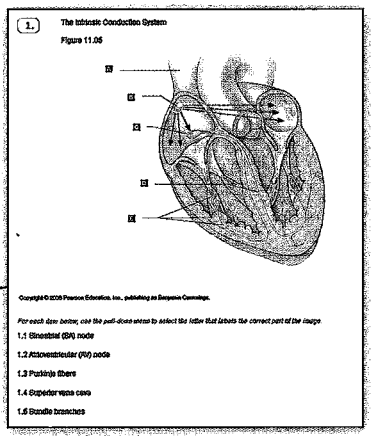
Learning Exercises
New games and activities encourage active learning and enforce key concepts.



Anatomy 360°
New Anatomy 360° program features accurate, high-quality, rotatable images, engaging learning exercises, and self-review questions.



PhysioEx™ 6.0 Laboratory Simulations
PhysioEx laboratory simulations supplement traditional wet labs safely and cost-effectively.

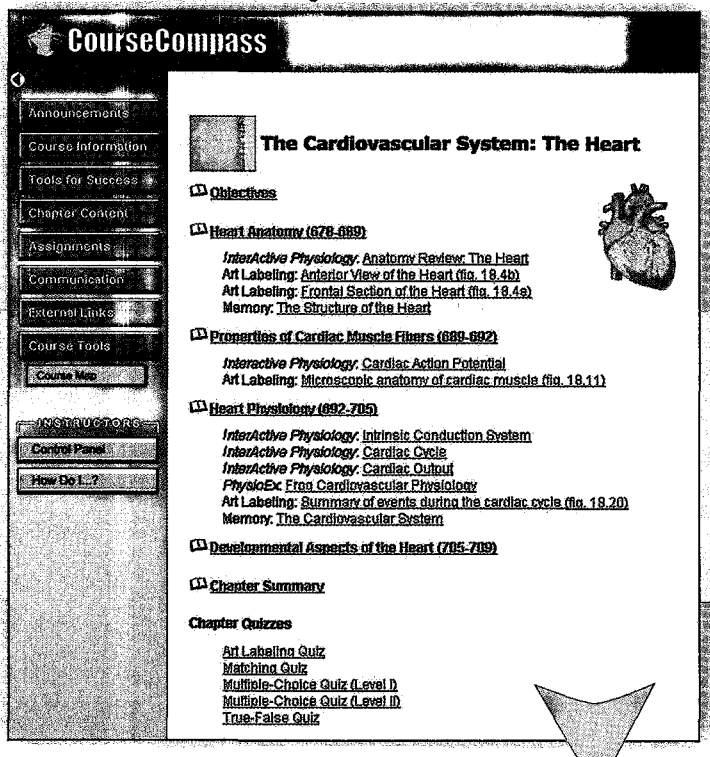


Self-Study Quizzes
Every chapter now has five self-study quizzes, including a new art labeling quiz and a more challenging multiple-choice quiz.

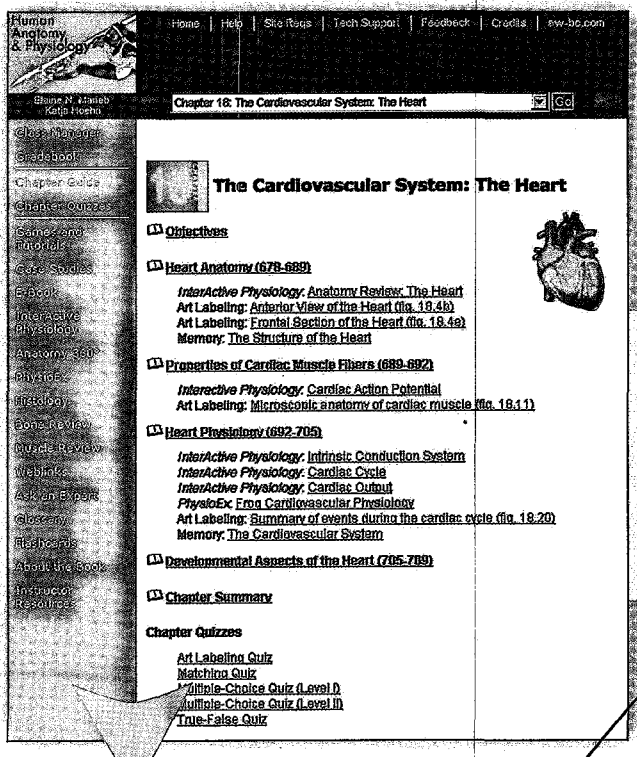
Live Tutor Center
Experienced instructors are available five days a week to provide tutoring services via internet whiteboard, email, telephone, and fax. *Included at no additional charge with a MyA&P course ID!*

TWO OPTIONS FOR CLASS MANAGEMENT

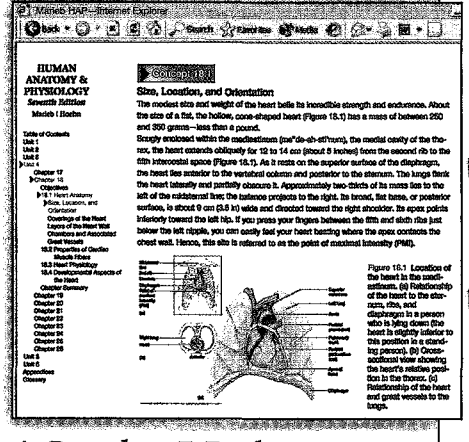
MyA&P



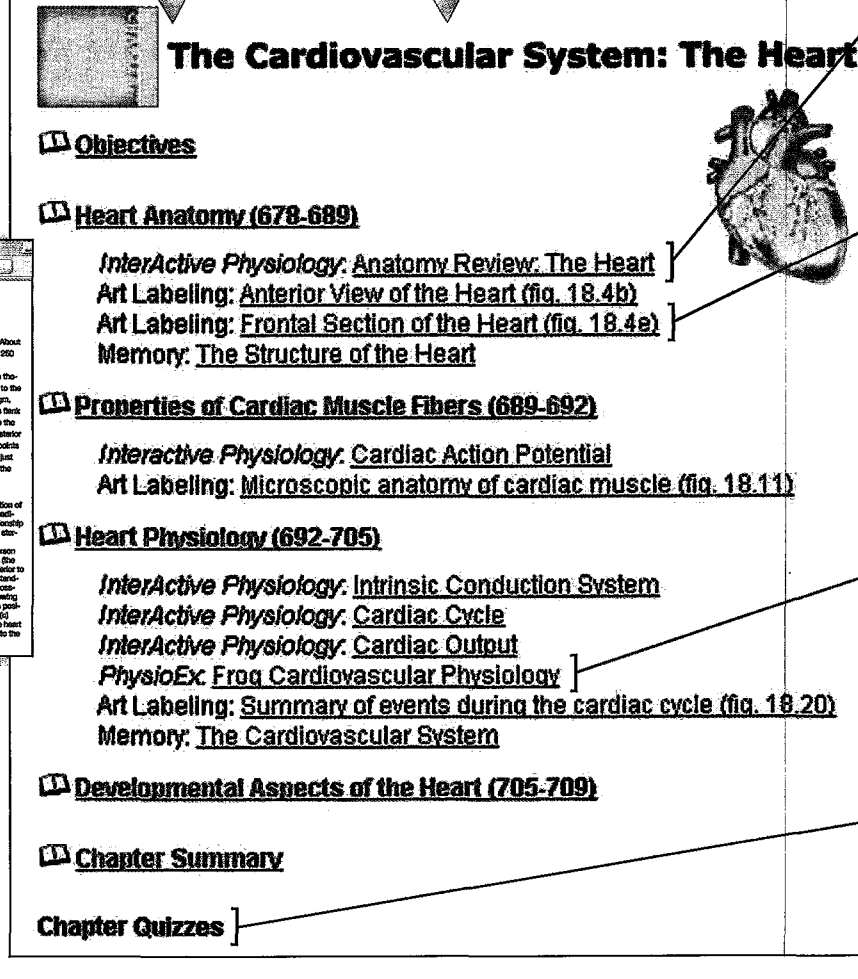
The Anatomy & Physiology Place

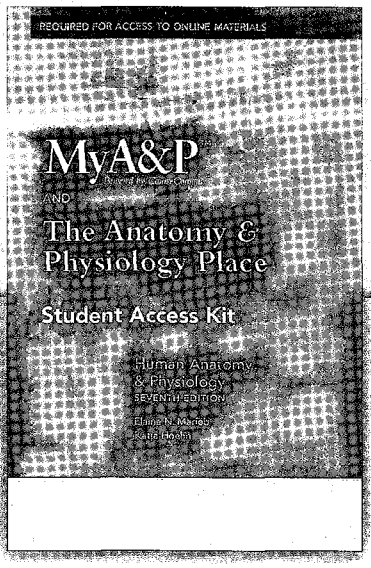


New! Easy to navigate
Chapter Guide pages organize all content with the chapter topics in *Human Anatomy & Physiology*, Seventh Edition



A Complete E-Book
The entire text is provided electronically and integrated with supporting media in the Chapter Guides.





Get the Kit and Raise Your Grades!

With your purchase of a new copy of Marieb's *Human Anatomy & Physiology*, Seventh Edition, you received a Student Access Kit for two great online resources. Ask your instructor which of the two online resources you should use.

With either site you can access all of the book's study tools and interactive media from one convenient location.

MyA&P™

powered by CourseCompass™

To activate your pre-paid subscription to the MyA&P course management system:

1. Ask your instructor for a CourseCompass Course ID. If you instructor does not provide you with a Course ID for MyA&P or a Class ID for the A&P Place, you can still use the A&P Place on your own. Please see the A&P Place instructions on the right.
2. Locate the Student Access Kit that came packaged with your textbook.
3. Go to www.MyAandP.com.
4. Select Register under "Student"
5. Click the appropriate book cover.
6. Click Register under "Yes–I have a Course ID"
7. Leave "No, I am a New User" selected.
8. Pull back the tab in the front cover of the Student Access Kit to reveal your access code.
9. Enter this code into the online form, lowercase or uppercase, without dashes.
10. Follow the on-screen registration instructions, referring to the booklet in your Student Access Kit as needed. *During registration, you will establish a personal login name and password to use for logging into the website. You will also be sent a registration confirmation email.*

Need a Kit?

If you did not purchase a new textbook or cannot locate the Student Access Kit and would like to access MyA&P, you may purchase access online with a major credit card at www.myaandp.com.

The Anatomy & Physiology Place

To activate your pre-paid subscription to the A&P Place course website:

1. Locate the Student Access Kit that came packaged with your textbook.
2. Go to www.anatomyandphysiology.com.
3. Click the appropriate book cover.
4. Click Register.
5. Leave "No, I am a New User" selected.
6. Pull back the tab in the front cover of the Student Access Kit to reveal your access code.
7. Enter this code into the online form, lowercase or uppercase, without dashes.
8. Follow the on-screen registration instructions, referring to the booklet in your Student Access Kit as needed. During registration, you will establish a personal login name and password to use for logging into the website. You will also be sent a registration confirmation email.
9. (Optional) Join a Class: Ask your instructor for an A&P Place Class ID. If your instructor provides a Class ID, log in to the A&P Place and click "Join a Class" and follow the onscreen instructions. If you instructor does not provide you with a Class ID, you can still use the A&P Place on your own.

Need a Kit?

If you did not purchase a new textbook or cannot locate the Student Access Kit and would like to access the A&P Place, you may purchase access online with a major credit card at www.anatomyandphysiology.com. First select your book cover, then click "Buy Now" on the login page.

hydr-, hydro- *water* dehydration, loss of body water
hyper- *excess* hypertension, excessive tension
hypno- *sleep* hypnosis, a sleeplike state
hypo- *below, deficient* hypodermic, beneath the skin; hypokalemia, deficiency of potassium
hyster-, hystero- *uterus or womb* hysterectomy, removal of the uterus; hysterodynia, pain in the womb
ile- *intestine* ileum, the last portion of the small intestine
im- *not* impermeable, not permitting passage, not permeable
inter- *between* intercellular, between the cells
intercal- *insert* intercalated discs, the end membranes between adjacent cardiac muscle cells
intra- *within, inside* intracellular, inside the cell
iso- *equal, same* isothermal, equal, or same, temperature
jugul- *throat* jugular veins, prominent vessels in the neck
juxta- *near, close to* juxtaglomerular apparatus, a cell cluster next to a glomerulus in the kidneys
karyo- *kernel, nucleus* karyotype, the assemblage of the nuclear chromosomes
kera- *horn* keratin, the water-repellent protein of the skin
kilo- *thousand* kilocalories, equal to 1000 calories
kin-, kines- *move* kinetic energy, the energy of motion
labi-, labri- *lip* labial frenulum, the membrane which joins the lip to the gum
lact- *milk* lactose, milk sugar
lacun- *space, cavity, lake* lacunae, the spaces occupied by cells of cartilage and bone tissue
lamell- *small plate* concentric lamellae, rings of bone matrix in compact bone
lamina *layer, sheet* basal lamina, part of the epithelial basement membrane
lat- *wide* latissimus dorsi, a broad muscle of the back
laten- *hidden* latent period of a muscle twitch
later- *side* lateral (directional term)
leuko- *white* leukocyte, white blood cell
leva- *raise, elevate* levator labii superioris, muscle that elevates upper lip
lingua- *tongue* lingual tonsil, adjacent to the tongue
lip-, lipo- *fat, lipid* lipophage, a cell that has taken up fat in its cytoplasm
lith- *stone* cholelithiasis, gallstones
luci- *clear* stratum lucidum, clear layer of the epidermis
lumen *light* lumen, center of a hollow structure
lut- *yellow* corpus luteum, a yellow, hormone-secreting structure in the ovary
lymph *water* lymphatic circulation, return of clear fluid to the bloodstream
macro- *large* macromolecule, large molecule
macula *spot* macula lutea, yellow spot on the retina
magn- *large* foramen magnum, largest opening of the skull
mal- *bad, abnormal* malfunction, abnormal functioning of an organ
mamm- *breast* mammary gland, breast
mast- *breast* mastectomy, removal of a mammary gland
mater *mother* dura mater, pia mater, membranes that envelop the brain
meat- *passage* external acoustic meatus, the ear canal
medi- *middle* medial (directional term)
medull- *marrow* medulla, the middle portion of the kidney, adrenal gland, and lymph node
mega- *large* megakaryocyte, large precursor cell of platelets
meio- *less* meiosis, nuclear division that halves the chromosome number
melan- *black* melanocytes, which secrete the black pigment melanin
men-, menstru- *month* menses, the cyclic menstrual flow
meningo- *membrane* meningitis, inflammation of the membranes of the brain
mer-, mero-, *a part* merocrine glands, the secretions of which do not include the cell
meso- *middle* mesoderm, middle germ layer
meta- *beyond, between, transition* metatarsus, the part of the foot between the tarsus and the phalanges
metro- *uterus* endometrium, the lining of the uterus
micro- *small* microscope, an instrument used to make small objects appear larger
mictur- *urinate* micturition, the act of voiding the bladder
mito- *thread, filament* mitochondria, small, filament-like structures located in cells
mnem- *memory* amnesia
mono- *single* monospasm, spasm of a single limb
morpho- *form* morphology, the study of form and structure or organisms
multi- *many* multinuclear, having several nuclei
mur- *wall* intramural ganglion, a nerve junction within an organ
muta- *change* mutation, change in the base sequence of DNA
myelo- *spinal cord, marrow* myeloblasts, cells of the bone marrow
myo- *muscle* myocardium, heart muscle
nano- *dwarf* nanometer, one-billionth of a meter
narco- *numbness* narcotic, a drug producing stupor or numbed sensations
natri- *sodium* atrial natriuretic peptide, a sodium-regulating hormone
necro- *death* necrosis, tissue death
neo- *new* neoplasm, an abnormal growth
nephro- *kidney* nephritis, inflammation of the kidney
neuro- *nerve* neurophysiology, the physiology of the nervous system
noci- *harmful* nociceptors, receptors for pain
nom- *name* innominate artery; innominate bone
noto- *back* notochord, the embryonic structure that precedes the vertebral column
nucle- *pit, kernel, little nut* nucleus
nutri- *feed, nourish* nutrition
ob- *before, against* obstruction, impeding or blocking up
oculo- *eye* monocular, pertaining to one eye
odonto- *teeth* orthodontist, one who specializes in proper positioning of the teeth in relation to each other
olfact- *smell* olfactory nerves
oligo- *few* oligodendrocytes, neuroglial cells with few branches
onco- *a mass* oncology, study of cancer
oo- *egg* oocyte, precursor of female gamete
ophthalmo- *eye* ophthalmology, the study of the eyes and related disease
orb- *circular* orbicularis oculi, muscle that encircles the eye
orchi- *testis* cryptorchidism, failure of the testes to descend into the scrotum
org- *living* organism
ortho- *straight, direct* orthopedic, correction of deformities of the musculoskeletal system
osm- *smell* anosmia, loss of sense of smell
osmo- *pushing* osmosis
osteo- *bone* osteodermia, bony formations in the skin
oto- *ear* otoscope, a device for examining the ear
ov-, ovi- *egg* ovum, oviduct
oxy- *oxygen* oxygenation, the saturation of a substance with oxygen
pan- *all, universal* panacea, a cure-all
papill- *nipple* dermal papillae, projections of the dermis into the epidermal area
para- *beside, near* paranuclear, beside the nucleus
pect-, pectus *breast* pectoralis major, a large chest muscle
pelv- *a basin* pelvic girdle, which cradles the pelvic organs
peni- *a tail* penis; penile urethra
penna- *feather* unipennate, bipennate muscles, whose fascicles have a feathered appearance
pent- *five* pentose, a 5-carbon sugar
pep-, peps-, pept- *digest* pepsin, a digestive enzyme of the stomach; peptic ulcer
per-, permea- *through* permeate; permeable
peri- *around* perianal, situated around the anus
phago- *eat* phagocyte, a cell that engulfs and digests particles or cells

caput- *head* decapitate, remove the head
carcin- *cancer* carcinogen, a cancer-causing agent
cardi-, cardio- *heart* cardiotoxic, harmful to the heart
carneo- *flesh* trabeculae carneae, ridges of muscle in the ventricles of the heart
carot- *(1) carrot, (2) stupor* (1) carotene, an orange pigment; (2) carotid arteries in the neck, blockage causes fainting
cata- *down* catabolism, chemical breakdown
caud- *tail* caudal (directional term)
cec- *blind* cecum of large intestine, a blind-ended pouch
cele- *abdominal* celiac artery, in the abdomen
cephal- *head* cephalometer, an instrument for measuring the head
cerebro- *brain, especially the cerebrum* cerebrospinal, pertaining to the brain and spinal cord
cervic-, cervix *neck* cervix of the uterus
chiasm- *crossing* optic chiasma, where optic nerves cross
chole- *bile* cholesterol; cholecystokinin, a bile-secreting hormone
chondr- *cartilage* chondrogenic, giving rise to cartilage
chrom- *colored* chromosome, so named because they stain darkly
cili- *small hair* ciliated epithelium
circum- *around* circumnuclear, surrounding the nucleus
clavic- *key* clavicle, a "skeleton key"
co-, con- *together* concentric, common center, together in the center
coccy- *cuckoo* coccyx, which is beak-shaped
cochlea *snail shell* the cochlea of the inner ear, which is coiled like a snail shell
coel- *hollow* coelom, the ventral body cavity
commis- *united* gray commissure of the spinal cord connects the two columns of gray matter
concha *shell* nasal conchae, coiled shelves of bone in the nasal cavity
contra- *against* contraceptive, agent preventing conception
corn-, cornu- *horn* stratum corneum, outer layer of the skin composed of (horny) cells
corona *crown* coronal suture of the skull
corp- *body* corpse, corpus luteum, hormone-secreting body in the ovary
cort- *bark* cortex, the outer layer of the brain, kidney, adrenal glands, and lymph nodes
cost- *rib* intercostal, between the ribs
crani- *skull* craniotomy, a skull operation
crypt- *hidden* cryptomenorrhea, a condition in which menstrual symptoms are experienced but no external loss of blood occurs
cusp- *pointed* bicuspid, tricuspid valves of the heart
cutic- *skin* cuticle of the nail
cyan- *blue* cyanosis, blue color of the skin due to lack of oxygen
cyst- *sac, bladder* cystitis, inflammation of the urinary bladder
cyt- *cell* cytology, the study of cells
de- *undoing, reversal, loss, removal* deactivation, becoming inactive
decid- *falling off* deciduous (milk) teeth
delta *triangular* deltoid muscle, roughly triangular in shape
den-, dent- *tooth* dentin of the tooth
dendr- *tree, branch* dendrites, telodendria, both branches of a neuron
derm- *skin* dermis, deep layer of the skin
desm- *bond* desmosome, which binds adjacent epithelial cells
di- *twice, double* dimorphism, having two forms
dia- *through, between* diaphragm, the wall through or between two areas
dialys- *separate, break apart* kidney dialysis, in which waste products are removed from the blood
diastol- *stand apart* cardiac diastole, between successive contractions of the heart
diure- *urinate* diuretic, a drug that increases urine output
dors- *the back* dorsal; dorsum; dorsiflexion
duc-, duct *lead, draw* ductus deferens which carries sperm from the epididymis into the urethra during ejaculation
dura *hard* dura mater, tough outer meninx
dys- *difficult, faulty, painful* dyspepsia, disturbed digestion
ec-, ex-, ecto- *out, outside, away from* excrete, to remove materials from the body
ectop- *displaced* ectopic pregnancy; ectopic focus for initiation of heart contraction
edem- *swelling* edema, accumulation of water in body tissues
ef- *away* efferent nerve fibers, which carry impulses away from the central nervous system
ejac- *to shoot forth* ejaculation of semen
embol- *wedge* embolus, an obstructive object traveling in the bloodstream
en-, em- *in, inside* encysted, enclosed in a cyst or capsule
enceph- *brain* encephalitis, inflammation of the brain
endo- *within, inner* endocytosis, taking particles into a cell
entero- *intestine* enterologist, one who specializes in the study of intestinal disorders
epi- *over, above* epidermis, outer layer of skin
erythr- *red* erythema, redness of the skin; erythrocyte, red blood cell
eso- *within* esophagus
eu- *well* euesthesia, a normal state of the senses
excret- *separate* excretory system
exo- *outside, outer layer* exophthalmos, an abnormal protrusion of the eye from the orbit
extra- *outside, beyond* extracellular, outside the body cells of an organism
extrins- *from the outside* extrinsic regulation of the heart
fasci-, fascia- *bundle, band* superficial and deep fascia
fenestr- *window* fenestrated capillaries
ferr- *iron* transferrin, ferritin, both iron-storage proteins
flagell- *whip* flagellum, the tail of a sperm cell
flat- *blow, blown* flatulence
folli- *bag, bellows* hair follicle
fontan- *fountain* fontanels of the fetal skull
foram- *opening* foramen magnum of the skull
foss- *ditch* fossa ovalis of the heart; mandibular fossa of the skull
gam-, gamet- *married, spouse* gametes, the sex cells
gangli- *swelling, or knot* dorsal root ganglia of the spinal nerves
gastr- *stomach* gastrin, a hormone that influences gastric acid secretion
gene *beginning, origin* genetics
germin- *grow* germinal epithelium of the gonads
gero-, geront- *old man* gerontology, the study of aging
gest- *carried* gestation, the period from conception to birth
glauc- *gray* glaucoma, which causes gradual blindness
glom- *ball* glomeruli, clusters of capillaries in the kidneys
glosso- *tongue* glossopathy, any disease of the tongue
gluco-, glyco- gluconeogenesis, the production of glucose from noncarbohydrate molecules
glute- *buttock* gluteus maximus, largest muscle of the buttock
gnost- *knowing* the gnostic sense, a sense of awareness of self
gompho- *nail* gomphosis, the term applied to the joint between tooth and jaw
gon-, gono- *seed, offspring* gonads, the sex organs
gust- *taste* gustatory sense, the sense of taste
hapt- *fasten, grasp* hapten, a partial antigen
hema-, hemato-, hemo- *blood* hematocyst, a cyst containing blood
hemi- *half* hemiglossal, pertaining to one-half of the tongue
hepat- *liver* hepatitis, inflammation of the liver
hetero- *different or other* heterosexuality, sexual desire for a person of the opposite sex
hiat- *gap* the hiatus of the diaphragm, the opening through which the esophagus passes
hippo- *horse* hippocampus of the brain, shaped like a seahorse
hirsut- *hairy* hirsutism, excessive body hair
hist- *tissue* histology, the study of tissues
holo- *whole* holocrine glands, whose secretions are whole cells
hom-, homo- *same* homeoplasia, formation of tissue similar to normal tissue; homocentric, having the same center
hormon- *to excite* hormones
humor- *a fluid* humoral immunity, which involves antibodies circulating in the blood
hyal- *clear* hyaline cartilage, which has no visible fibers

About the Authors

We dedicate this work to our students both present and past, who always inspire us to "push the envelope."

Elaine N. Marieb

For Elaine N. Marieb, taking the student's perspective into account has always been an integral part of her teaching style. Dr. Marieb began her teaching career at Springfield College, where she taught anatomy and physiology to physical education majors. She then joined the faculty of the Biological Science Division of Holyoke Community College in 1969 after receiving her Ph.D. in zoology from the University of Massachusetts at Amherst. While teaching at Holyoke Community College, where many of her students were pursuing nursing degrees, she developed a desire to better understand the relationship between the scientific study of the human body and the clinical aspects of the nursing practice. To that end, while continuing to teach full time, Dr. Marieb pursued her nursing education, which culminated in a Master of Science degree with a clinical specialization in gerontology from the University of Massachusetts. It is this experience, along with stories from the field—including those of former students now in health careers—that has informed the development of the unique perspective and accessibility for which her texts and laboratory manuals are known.

In her ongoing commitment to students and her realization of the challenges they face, Dr. Marieb has given generously to provide opportunities for students to further their education. She contributes to the New Directions, New Careers Program at Holyoke Community College by providing several full-tuition scholarships each year for women who are returning to college after a hiatus or attending college for the first time and would be unable to continue their studies without financial support. She funds the E. N. Marieb Science Research Awards at Mount Holyoke College, which promotes research by undergraduate science majors, and has underwritten renovation and updating of one of the biology labs in Clapp Laboratory at that college. Dr. Marieb is also a contributor to the University of Massachusetts at Amherst where she generously provided funding for reconstruction and instrumentation of a cutting-edge cytology research laboratory that bears her name.

In 1994, Dr. Marieb received the Benefactor Award from the National Council for Resource Development, American Association of Community Colleges, which recognizes her ongoing sponsorship of student scholarships, faculty teaching awards, and other academic contributions to Holyoke Community College. In May 2000, the science building at Holyoke Community College was named in her honor.

Dr. Marieb is an active member of the Human Anatomy and Physiology Society (HAPS) and the American Association for the Advancement of Science (AAAS). Additionally, while actively engaged as an author, Dr. Marieb serves as a consultant for the Benjamin Cummings/A.D.A.M.® *InterActive Physiology*® CD-ROM series. This text—*Human Anatomy & Physiology,* Seventh Edition—is the latest expression of her commitment to the needs of students in their pursuit of the study of A&P.

When not involved in academic pursuits, Dr. Marieb is a world traveler and has vowed to visit every country on this planet. Shorter term, she serves on the board of directors of the famed Marie Selby Botanical Gardens and on the scholarship committee of the Women's Resource Center of Sarasota County. She is an enthusiastic supporter of the local arts and enjoys a competitive match of doubles tennis.

Katja Hoehn

Dr. Katja Hoehn is an instructor in the Department of Chemical, Biological, and Environmental Sciences at Mount Royal College in Calgary, Canada. Dr. Hoehn received her M.D. (with Distinction) from the University of Saskatchewan, and her Ph.D. in Pharmacology from Dalhousie University. Dr. Hoehn has been a contributor to several books and has written numerous research papers in Neuroscience and Pharmacology. In 1991, the Dalhousie Medical Research Foundation presented her with the Max Forman (Jr.) Prize for excellence in medical research. During her Ph.D. and postdoctoral studies, Dr. Hoehn pursued her love of teaching by presenting guest lectures to first- and second-year medical students at Dalhousie University and at the University of Calgary.

During her 11 years at Mount Royal College, Dr. Hoehn has received numerous awards including a PanCanadian Educational Technology Faculty Award (1999), a Teaching Excellence Award from the Student's Association of Mount Royal College (2001), and the Mount Royal College Distinguished Faculty Teaching Award (2004). She is also actively involved in the Human Anatomy and Physiology Society (HAPS). When not teaching, Dr. Hoehn likes to spend time outdoors with her husband and two boys, compete in triathlons, and play Irish flute.

Preface to the Instructor

As educators, clinically trained individuals, and perennial students, we are continually challenged by the learning mind. What works best to get students over conceptual hurdles and to help them apply new information to the world they personally understand? Our clinical backgrounds have served our teaching and writing purposes well. Perhaps even more important, our clinical experience has allowed us to view our presentations through our students' eyes and from the vantage points of their career interests.

For this edition, as for those preceding it, feedback from both student and instructor reviews indicated areas of the text that needed to be revised for clarity, timeliness, and just plain reduction of verbal meatiness. Overall, feedback was positive, verifying that the approach of explaining fundamental principles and unifying themes first as a strong base for all that comes later is still viable. Furthermore, it is clear that backing up these explanations with comfortable analogies and familiar examples enhances the students' understanding of the workings of the human body.

Unifying Themes

Three integrating themes that organized, unified, and set the tone of the first edition of this text continue to be valid and are retained in this edition. These themes are:

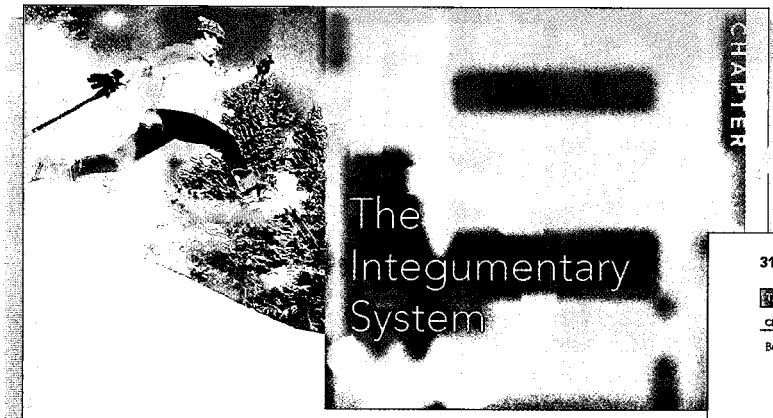
Interrelationships of body organ systems. The fact that nearly all regulatory mechanisms require interaction of several organ systems is continually emphasized. For example, Chapter 25, which deals with the structure and function of the urinary system, discusses the vital importance of the kidneys not only in maintaining adequate blood volume to ensure normal blood circulation, but also in continually adjusting the chemical composition of blood so that all body cells remain healthy. The unique *Making Connections* feature is the culmination of this approach and should help students think of the body as a dynamic community of interdependent parts rather than as a number of isolated structural units.

Homeostasis. The normal and most desirable condition of body functioning is homeostasis. Its loss or destruction always leads to some type of pathology—temporary or permanent. Pathological conditions are integrated with the text to clarify and illuminate normal functioning, not as an end in and of themselves. For example, Chapter 19, which deals with the structure and function of blood vessels, explains how the ability of healthy arteries to expand and recoil ensures continuous blood flow and proper circulation. The chapter goes on to discuss the effects on homeostasis when arteries lose their elasticity: high blood pressure and all of its attendant problems. These homeostatic imbalances are indicated visually by a purple symbol with a fulcrum.

Whenever students see the imbalance symbol in text, the concept of disease as a loss of homeostasis is reinforced.

Complementarity of structure and function. Students are encouraged to understand the structure of an organ, a tissue, or a cell as a prerequisite to comprehending its function. Concepts of physiology are explained and related to structural characteristics that promote or allow the various functions to occur. For example, the lungs can act as a gas exchange site because the walls of their air sacs present an incredibly thin barrier between blood and air.

HALLMARK FEATURES



A chapter outline with student objectives prefaces each chapter and guides students to concepts that are most important to know.

The Skin (pp. 152–158)

1. Name the tissue types composing the epidermis and dermis. List the major layers of each and describe the functions of each layer.
2. Describe the factors that normally contribute to skin color. Briefly describe how changes in skin color may be used as clinical signs of certain disease states.

Appendages of the Skin (pp. 158–163)

3. Compare the structure and locations of sweat and oil glands. Also compare the composition and functions of their secretions.
4. Compare and contrast eccrine and apocrine glands.
5. List the parts of a hair follicle and explain the function of each part. Also describe the functional relationship of arrector pili muscles to the hair follicle.
6. Name the regions of a hair and explain the basis of hair color. Describe the distribution, growth, replacement, and changing nature of hair during the life span.
7. Describe the structure of nails.

Functions of the Integumentary System (pp. 163–165)

8. Describe how the skin accomplishes at least five [illegible] functions.

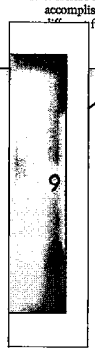
Homeostatic Imbalances of Skin (pp. 165–167, 170)

9. Summarize the characteristics of the three major types of skin cancers.
10. Explain why serious burns are life-threatening. Describe how to determine the extent of a burn and differentiate first-, second-, and third-degree burns.

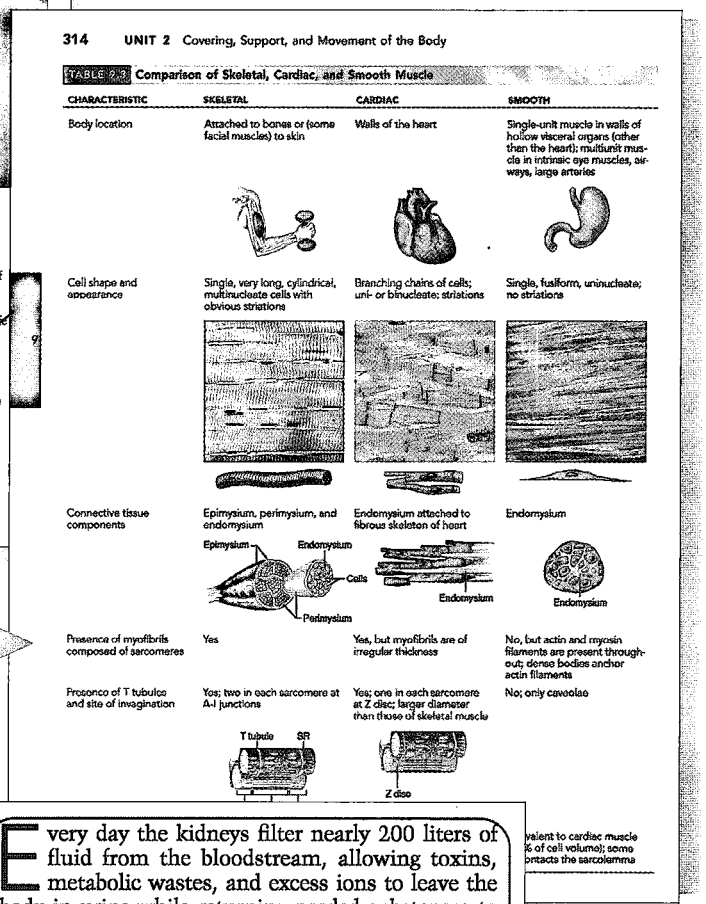
Developmental Aspects of the Integumentary System (pp. 170–171)

11. Describe and attempt to explain the causes of changes that occur in the skin from birth to old age.

Color-coded chapter and unit tabs help students find information quickly and easily.



Illustrated tables summarize complex information and serve as a "one-stop shopping" study tool.



Meaningful analogies and jargon-free explanations. Drawing on her own unique experience as an A&P professor and former nursing student, Marieb presents anatomy and physiology as a "story" that can be more easily understood and remembered.

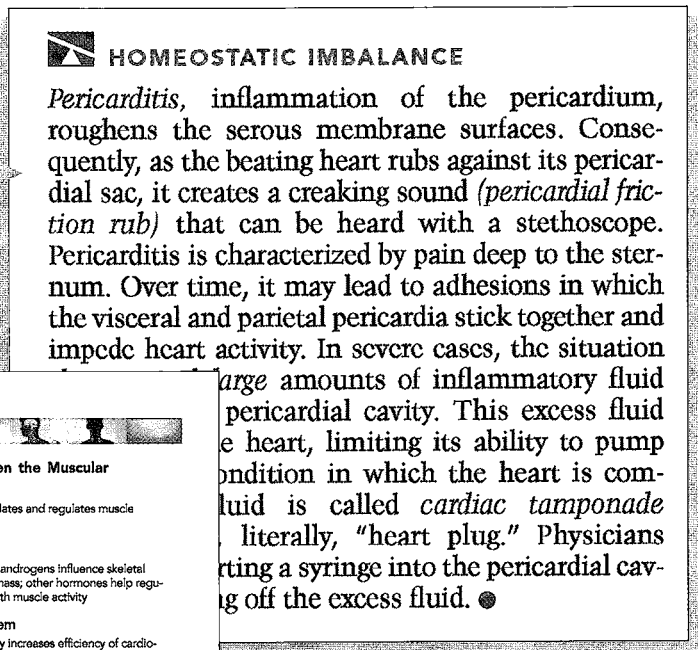
Every day the kidneys filter nearly 200 liters of fluid from the bloodstream, allowing toxins, metabolic wastes, and excess ions to leave the body in urine while returning needed substances to the blood. Much like a water purification plant that keeps a city's water drinkable and disposes of its wastes, the kidneys are usually unappreciated until they malfunction and body fluids become contaminated. Although the lungs and skin also participate in excretion, the kidneys are the major excretory organs.

As the kidneys perform these excretory functions, they also act as essential regulators of the volume and chemical makeup of the blood, maintaining the proper balance between water and salts and between acids and bases. Frankly, this would be tricky work for a chemical engineer, but the kidneys do it efficiently most of the time.

Other renal functions include

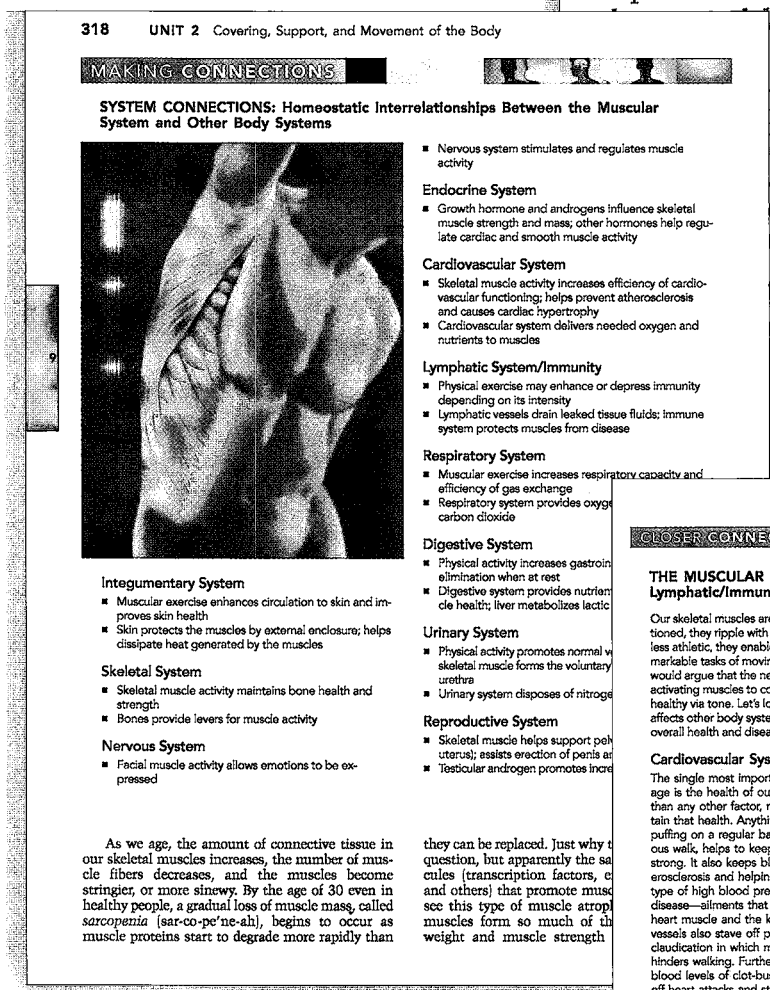
- Gluconeogenesis (see p. 966) during prolonged fasting.
- Producing the hormones renin and erythropoietin (see Chapter 16). *Renin* (re'nin; *ren* = kidney) acts as an enzyme to help regulate blood pressure and kidney function. *Erythropoietin* (ĕ-rith"ro-poi'ĕ-tin) stimulates red blood cell production.

Homeostasis icons alert the students to consequences of body systems not functioning optimally.



HOMEOSTATIC IMBALANCE

Pericarditis, inflammation of the pericardium, roughens the serous membrane surfaces. Consequently, as the beating heart rubs against its pericardial sac, it creates a creaking sound *(pericardial friction rub)* that can be heard with a stethoscope. Pericarditis is characterized by pain deep to the sternum. Over time, it may lead to adhesions in which the visceral and parietal pericardia stick together and impede heart activity. In severe cases, the situation ...*arge* amounts of inflammatory fluid ... pericardial cavity. This excess fluid ...e heart, limiting its ability to pump ...ndition in which the heart is com... ...luid is called *cardiac tamponade* ... literally, "heart plug." Physicians ...rting a syringe into the pericardial cav... ...g off the excess fluid.



318 UNIT 2 Covering, Support, and Movement of the Body

MAKING CONNECTIONS

SYSTEM CONNECTIONS: Homeostatic Interrelationships Between the Muscular System and Other Body Systems

Integumentary System
- Muscular exercise enhances circulation to skin and improves skin health
- Skin protects the muscles by external enclosure; helps dissipate heat generated by the muscles

Skeletal System
- Skeletal muscle activity maintains bone health and strength
- Bones provide levers for muscle activity

Nervous System
- Facial muscle activity allows emotions to be expressed
- Nervous system stimulates and regulates muscle activity

Endocrine System
- Growth hormone and androgens influence skeletal muscle strength and mass; other hormones help regulate cardiac and smooth muscle activity

Cardiovascular System
- Skeletal muscle activity increases efficiency of cardiovascular functioning; helps prevent atherosclerosis and causes cardiac hypertrophy
- Cardiovascular system delivers needed oxygen and nutrients to muscles

Lymphatic System/Immunity
- Physical exercise may enhance or depress immunity depending on its intensity
- Lymphatic vessels drain leaked tissue fluids; immune system protects muscles from disease

Respiratory System
- Muscular exercise increases respiratory capacity and efficiency of gas exchange
- Respiratory system provides oxyg... carbon dioxide

Digestive System
- Physical activity increases gastroin... elimination when at rest

Chapter 9 Muscles and Muscle Tissue 319

CLOSER CONNECTIONS

THE MUSCULAR SYSTEM and Interrelationships with the Cardiovascular, Endocrine, Lymphatic/Immunity, and Skeletal Systems

Our skeletal muscles are a marvel. In the well conditioned, they ripple with energy. In those of us who are less athletic, they enable us to perform the rather remarkable tasks of moving and getting around. No one would argue that the nervous system is indispensable for activating muscles to contract and for keeping them healthy via tone. Let's look at how skeletal muscle activity affects other body systems from the vantage point of overall health and disease prevention.

Cardiovascular System

The single most important barometer of how "well" we age is the health of our cardiovascular system. More than any other factor, regular exercise helps to maintain that health. Anything that gets you huffing and puffing on a regular basis, be it racquetball or a vigorous walk, helps to keep heart muscle healthy and strong. It also keeps blood vessels clear, delaying atherosclerosis and helping to prevent the most common type of high blood pressure and hypertensive heart disease—ailments that can lead to the deterioration of heart muscle and the kidneys. Uncluttered blood vessels also stave off painful or disabling intermittent claudication in which muscle pain due to ischemia hinders walking. Furthermore, regular exercise boosts blood levels of clot-busting enzymes, helping to ward off heart attacks and strokes, other scourges of old age.

Endocrine System

Muscle has a high rate of metabolism, and even at rest it uses much more energy than does fat. Consequently, exercise that builds moderate muscle mass helps to keep weight down and prevents obesity. Obesity is one of the risk factors for development of age-related diabetes mellitus—the metabolic disorder in which body cells are unresponsive to insulin (secreted by the pancreas) and, hence, unable to utilize glucose normally. Additionally, exercise helps to maintain normal cellular responses to insulin. On the other side of the coin, several hormones, including growth hormone, thyroid hormone, and sex hormones, are essential for normal development and maturation of the skeletal muscles.

Lymphatic System/Immunity

Physical exercise has a marked effect on immunity. Moderate or mild exercise causes a temporary rise in the number of phagocytes, T cells (a particular group of white blood cells), and antibodies, all of which populate lymphatic organs and mount the attack against infectious disease. By contrast, strenuous exercise depresses the immune system. The way in which exercise affects immunity—including these seemingly contradictory observations—is still a mystery, but the so-called stress hormones are definitely involved. Like major stressors such as surgery and serious burns, strenuous exercise increases blood levels of stress hormones such as epinephrine and glucocorticoids. These hormones depress the immune system during severe stress. This is thought to be a protective mechanism—a way of preventing large numbers of slightly damaged cells from being rejected.

Skeletal System

Last but not least, weight-bearing exercise of the skeletal muscles promotes skeletal strength and helps prevent osteoporosis. Since osteoporosis severely detracts from the quality of life by increasing risk of fractures, this is an extremely important interaction. But without their bony attachments, muscles would be ineffective in causing body movement.

CLINICAL CONNECTIONS

Muscular System

Case study: Let's continue our tale of Mrs. DeStephano's medical problems, this time looking at the notes made detailing observations of her skeletal musculature.
- Severe lacerations of the muscles of the right leg and knee
- Damage to the blood vessels serving the right leg and knee
- Transection of the sciatic nerve (the large nerve serving most of the lower limb), just above the right knee

Her physician orders daily passive range-of-motion (ROM) exercise and electrical stimulation for her right leg and a diet high in protein, carbohydrates, and vitamin C.

1. Describe the step-by-step process of wound healing that will occur in her fleshy (muscle) wounds, and note the consequences of the specific restorative process that occurs.
2. What complications in healing can be anticipated owing to vascular (blood vessel) damage in the right leg?
3. What complications in muscle structure and function result from transection of the sciatic nerve? Why are passive ROM and electrical stimulation of her right leg muscles ordered?
4. Explain the reasoning behind the dietary recommendations.

(Answers in Appendix G)

To help students understand the relationships between body systems, Marieb offers the focused, three-tiered presentation **Making Connections** at the end of each body system discussion:

- **Systems Connections** highlight the interrelationships between all of the body systems.
- **Closer Connections** focus in greater depth on selected systems interrelationships.
- **Clinical Connections** case studies encourage students to apply chapter concepts to a situation in a clinical setting.

Other hallmark features include:

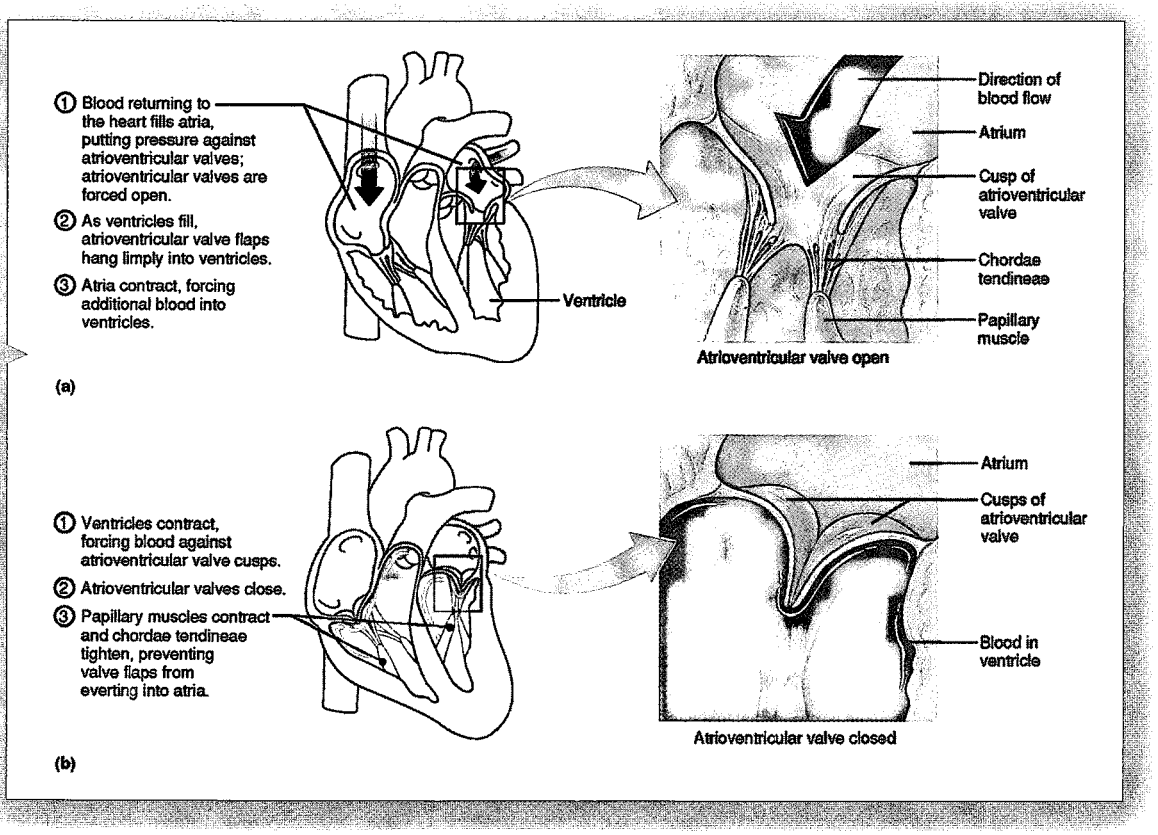
- **Key questions** accompany selected figures and prod the student to interpret the concepts or illustrated processes, or to make predictions about what's next. Answers can be found upside-down on the same page.
- **Closer Look** boxes on timely subjects such as medical technology, new discoveries in medical research, and important societal issues broaden the students' horizons.
- **Related Clinical Terms** help students prepare for the clinical world.
- **Comprehensive Chapter Summaries** with page references provide excellent study aids.
- **Review Questions** help students to evaluate their progress in the subject.

PEDAGOGICALLY DRIVEN ART

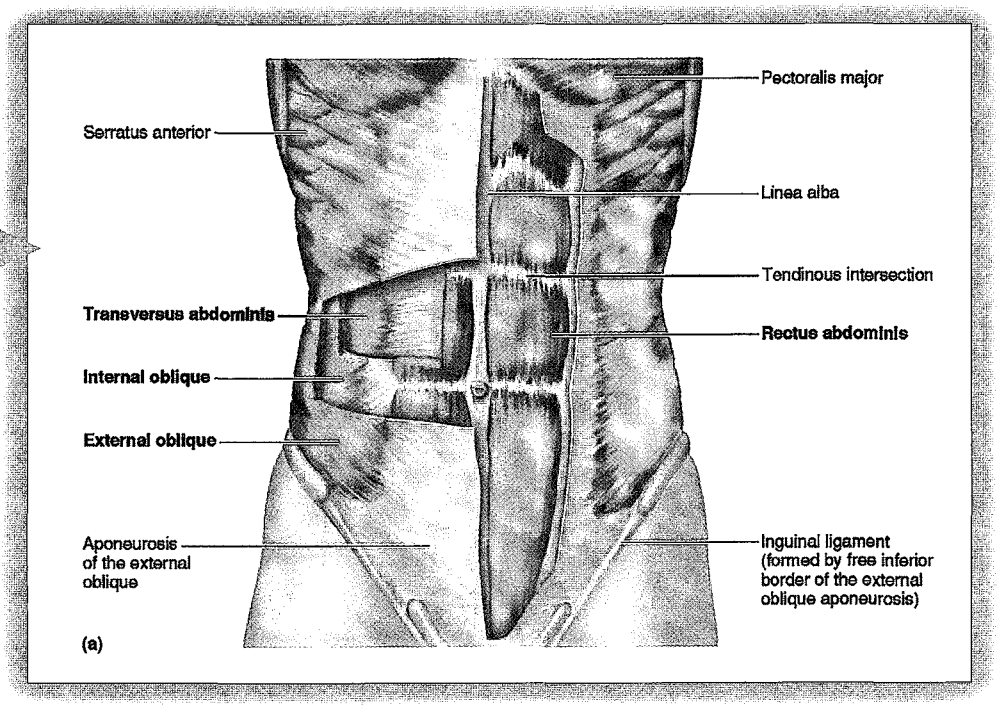
Art plays a critical role in helping students visualize anatomical and physiological concepts. In science texts, where page count is always an important consideration, the tendency is to try to make each piece of art "say" as much as it can. Realizing this, an important aspect of the art conception for this text has been restraint—limiting the information to one or at most two major concepts to be taught or clarified by each piece. This prevents the student from being overwhelmed and confused by concept overload.

Size is also a consideration when crystallizing pedagogically effective art. Art that is too small lacks significance, and students tend to skip over or neglect it. Hence, our art program provides the largest visuals deemed possible to depict and elucidate a given concept.

Process art breaks down complex processes into a series of clear, easy-to-follow steps.



Upgraded Muscle Gallery art presents a more realistic view of muscles.



NEW TO THE SEVENTH EDITION

Factual material updates. A major undertaking of this edition, as in earlier editions, was to update the factual material and topic boxes in all subject areas—a monumental task that demands painstaking selectivity. Certain areas are updated in every edition—immunity, cell signaling, and the offerings of genetic engineering—and this edition is no exception. However, other subjects of study are also attended to as appropriate for the changing literature. Specific examples from nervous system Chapters 11 and 12 illustrate this trend: Information on neurotransmitters has been updated, the brain's processing of language now has its own section, and the structure of voltage-gated ion channels in figures is now depicted more realistically according to recent Nobel Prize–winning research. Chapter 12 also features a new *Closer Look* box on "mad cow" disease and its human equivalent, Creutzfeldt-Jakob disease. Chapters 24 (Nutrition, Metabolism, and Body Temperature Regulation) and 29 (Heredity) also received some substantial attention. In Chapter 24, current diets are compared and assessed and the long-term role of leptin in feeding behavior and satiety is explored. Chapter 29 now has a new section, Beyond DNA: Regulation of Gene Expression that showcases new research findings on the importance of chromatin proteins and small RNAs in directing our genetic heritage.

Throughout the book, figures of G protein–mediated second-messenger systems have been updated and each step numbered in sequence, enhancing their accessibility to students. Although information changes even as a textbook goes to press, be assured that this intent and responsibility was carried out to the best of our ability.

Reorganization of specific chapters and topics. Chapter 15 (The Special Senses) has been reorganized. Vision, smell, and taste, having similar transduction mechanisms, are discussed in sequence, beginning with vision, which is the best understood. In response to reviewers' comments, the sequence of physiological events in skeletal muscle contractions has been reordered in Chapter 9.

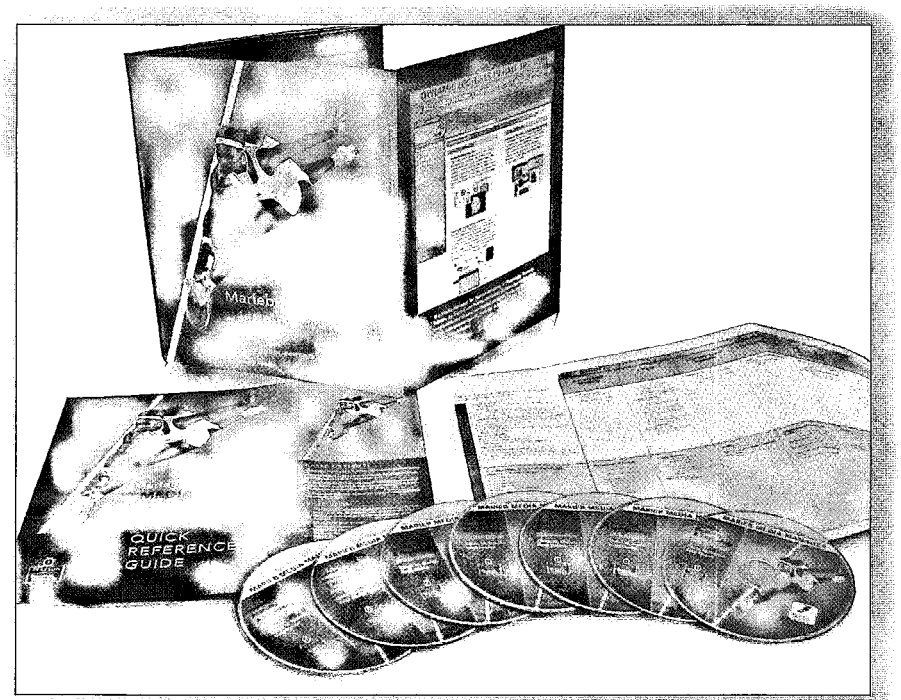
Revised art. Every piece of art in the book has been examined and the color palette has been revised to provide art that has richer, more organic color. Many pieces have been touched up to enhance their detail and many new views have been added. Many physiology figures have been rerendered to reflect recent research on functional processes. As before, the art has a consistent color protocol to encourage automatic learning. Every time you see an ATP starburst it is bright yellow; oxygen is red; cellular cytoplasm is routinely beige; and so on.

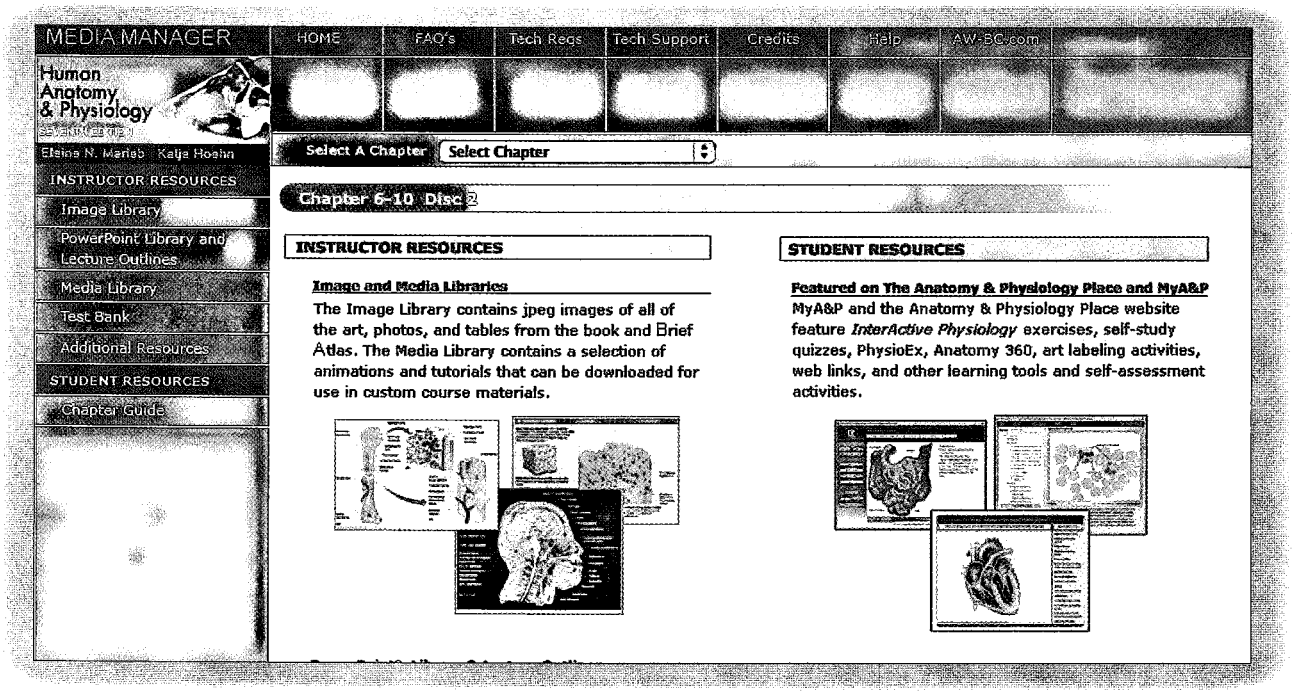
Photo usage. Additionally, there are many more photomicrographs and clinical photos in this edition, and many of those retained from earlier editions have been upsized. As pointed out by a conscientious reviewer, "If you can't see it clearly, then it's not worth having."

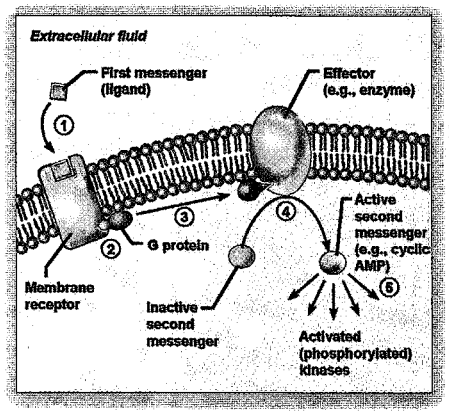
New! Marieb Media Manager (set of 7 CD-ROMs) (0-8053-7376-4)

This powerful new tool combines all instructor and student media into a seven-CD-ROM library with a fold-out Quick Reference Guide. The CDs contain:

- All of the images from the textbook and *A Brief Atlas of the Human Body,* Second Edition, in labeled, unlabeled, and leaders-only versions.
- PowerPoint resources including customizable Label Edit and Step Edit art, chapter Art Presentations, Active Lecture ("Clicker") Questions, Lecture Outlines with animations, and new *InterActive Physiology*® (IP) links that make it easy to use IP animations in any presentation.
- Microsoft Word versions of the Test Bank and Instructor's Guide.

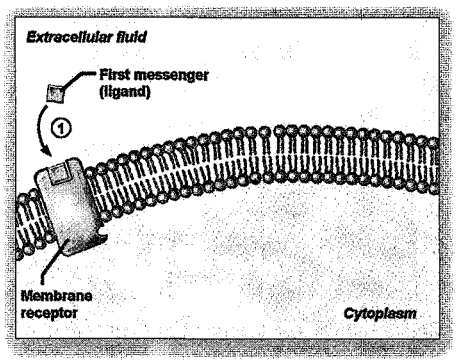




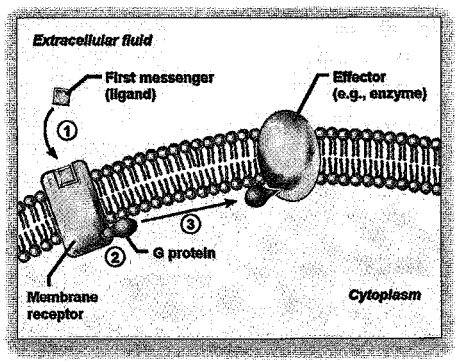


Slide 1

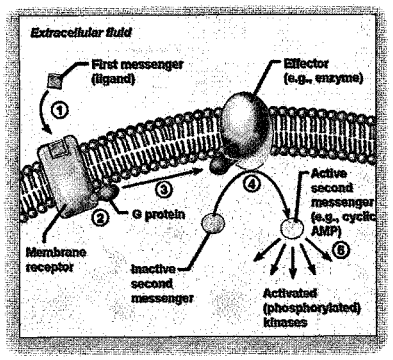
New! Step Edit art facilitates step-by-step presentation of complex topics. You can now customize each step by editing, removing, resizing, or highlighting the labels and leaders.



Slide 2

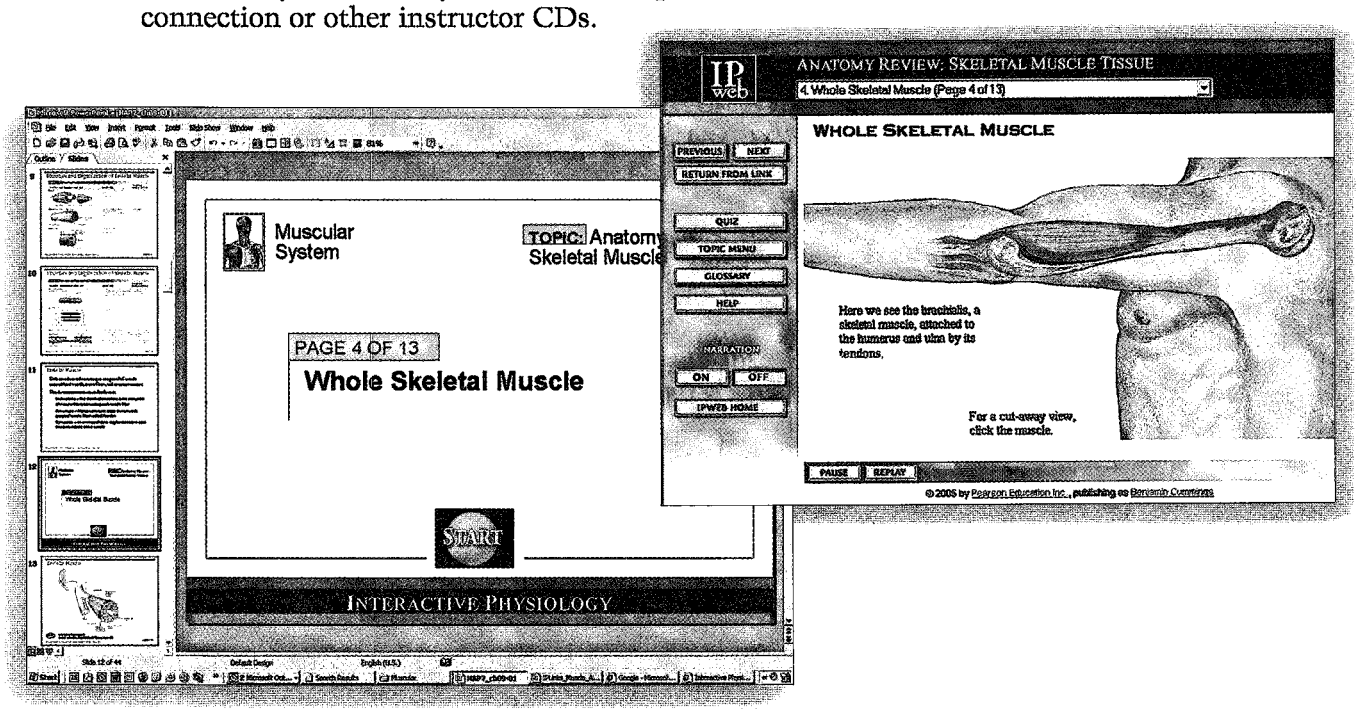


Slide 4



Slide 6

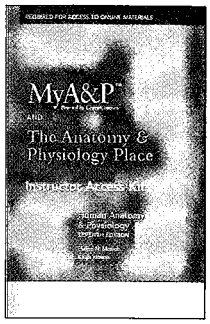
New! *InterActive Physiology*® (IP) Links make it easy to incorporate IP into any PowerPoint presentation. Following the built-in instructions, you can now link directly to IP from your PowerPoint presentation without the need for a web connection or other instructor CDs.



MyA&P™ Course Management System

(www.MyAandP.com)

Powered by CourseCompass, MyA&P™ now provides full integration of all media with powerful course management tools. Each chapter contains relevant tutorials and exercises from *InterActive Physiology®*, Anatomy 360°™, and PhysioEx™ as well as links to the complete E-book version of the text. Students can also access the online component of *Get Ready for A&P* (please see description under Supplements for the Student). In addition, MyA&P™ includes self-study quizzes, anatomy labeling exercises, a new histology tutorial, animations, games and tutorials, case studies, a glossary, and flashcards. An access kit is automatically packaged with each new copy of the text.



The Anatomy & Physiology Place Web Site

(www.anatomyandphysiology.com)

The A&P Place offers all the same premium content as MyA&P™ in a simplified course web site. Each chapter contains relevant tutorials and exercises from *InterActive Physiology®*, Anatomy 360°™, and PhysioEx™ as well as links to the complete E-book version of the text. Students can also access the online component of *Get Ready for A&P* (please see a description under Supplements for the Student). In addition, The A&P Place includes self-study quizzes, anatomy labeling exercises, a new histology tutorial, animations, games and tutorials, case studies, a glossary, and flashcards. Instructors can now track student progress with the new Gradebook feature. An access kit is automatically packaged with each new copy of the text.

WebCT and Blackboard Course Management Systems

These new WebCT and Blackboard cartridges no longer require student access codes, so getting students online is easier than ever. Both cartridges include all of the content found in The A&P Place (open-access version).

Instructor's Guide to Text and Media (0-8053-7379-9)

This fully revised Guide includes detailed objectives, lecture outlines, activities,online media resources, answers to End-of-Chapter Questions, and *InterActive Physiology®* Exercise Sheets and answer key. All the illustrations from the text are indexed as thumbnails in the Visual Resource Guide so instructors can easily locate and make the best use of the available media.

Printed Test Bank (0-8053-7378-0)

Computerized Test Bank (0-8053-7381-0)

With more than 3600 test questions, this Test Bank has been updated with new and revised questions that cover all major topics at a range of difficulty levels. All questions in the printed Test Bank are available in electronic format through both the Media Manager CD-ROM, as Word files, and the TestGen-EQ CD-ROM. Both electronic options are cross-platform and allow instructors to easily generate and customize tests.

Transparency Acetates (0-8053-7374-8)

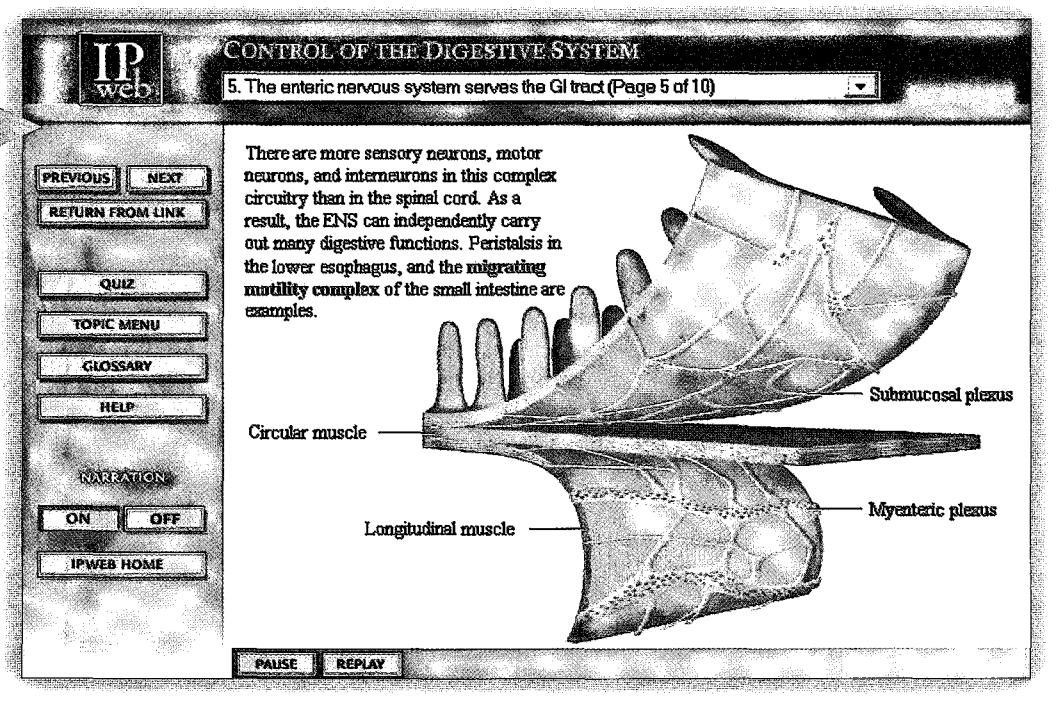
This package includes all illustrations, photos, and tables from the text—approximately 800 images—with labels that have been enlarged for easy viewing in the classroom or lecture hall.

Human Anatomy & Physiology Laboratory Manuals

Elaine N. Marieb's three widely used and acclaimed laboratory manuals complement this textbook and are designed to meet the varying needs of most laboratory courses: *Human Anatomy & Physiology Laboratory Manual: Cat Version,* Eighth Edition Update; *Main Version,* Seventh Edition Update; and *Pig Version,* Eighth Edition Update. Included with each laboratory manual is the PhysioEx™ 6.0 CD-ROM and a registration code for online access. PhysioEx™ 6.0 features 12 experiments and a redesigned Histology Tutorial.

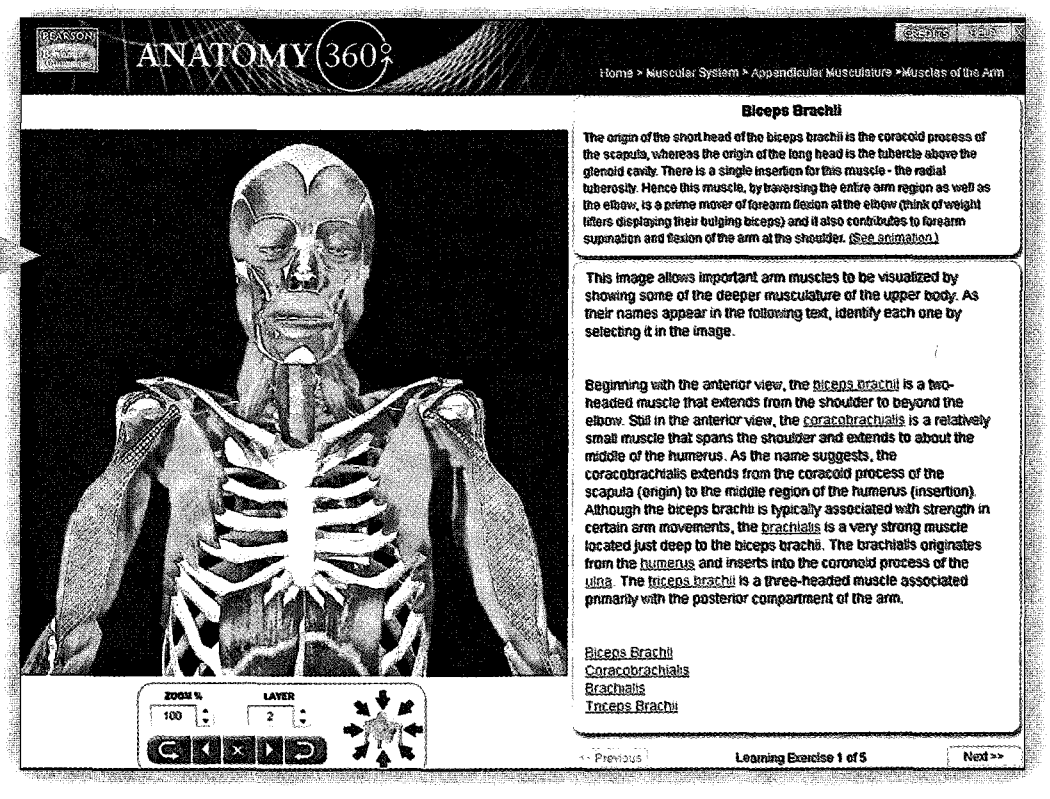
InterActive Physiology® 9-System Suite CD-ROM

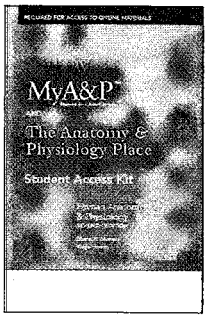
Featuring a long-awaited ninth module on the Digestive System, *InterActive Physiology®* uses tutorials, animations, and engaging quizzes to help students advance beyond simple memorization to a genuine understanding of the most difficult concepts in the A&P course. This award-winning tutorial series is conveniently referenced in the appropriate end-of-chapter summaries. It is packaged free with each new copy of the text.



New! Anatomy 360°™

This easy-to-follow anatomy tutorial program helps students learn hundreds of anatomy terms, locations, and concepts. Based on real data from the Visible Human Project, Anatomy 360°™ features accurate, high-quality, rotatable images, engaging interactive exercises, and self-review questions. Students can also email their results from a wide variety of learning exercises to their instructor. Anatomy 360°™ is available via MyA&P™ and The Anatomy and Physiology Place.





MyA&P™ and The Anatomy & Physiology Place Web Site

Please see Supplements for Instructors for a description.

New! Get Ready for A&P

(0-8053-8284-4)

This new workbook and online component was created to help students be better prepared for their A&P course. This hands-on workbook helps students get up to speed in their knowledge of basic study skills, math review, basic chemistry, cell biology, anatomical terminology, and the human body. Features include pre-tests, guided explanations followed by interactive quizzes and exercises, and end-of-chapter cumulative tests. The online component includes a gradeable diagnostic pre-test and post-test, self-study quizzes with feedback, animations and links, a glossary, and flashcards. It is available via MyA&P™ and The Anatomy & Physiology Place.

A Brief Atlas of the Human Body, Second Edition (0-8053-7373-X)

Revised for the seventh edition, this full-color atlas is bundled free with every new copy of the text, and includes 107 bone and 47 soft-tissue photographs with easy-to-read labels. This new edition of the atlas contains a brand-new, comprehensive histology photomicrograph section featuring over 50 slides of basic tissue and organ systems. Featuring photos taken by renowned biomedical photographer Ralph Hutchings, this high-quality photographic atlas makes an excellent resource for the classroom and laboratory, and is referenced in appropriate figure legends throughout the text.

The Anatomy & Physiology Place CD-ROM (0-8053-7383-7)

Contains all the resources found on The Anatomy & Physiology Place Web Site, and can be packaged with the text for no additional charge.

Study Guide (0-8053-7305-5)

Revised to accompany the Seventh Edition of *Human Anatomy & Physiology,* the study guide offers a wide variety of exercises that address different learning styles and call on students to develop their critical-thinking abilities. The three major sections, Building the Framework, Challenging Yourself, and Covering All Your Bases, help students build a base of knowledge using recall, reasoning, and imagination that can be applied to solving problems in both clinical and nonclinical situations.

The Tutor Center

Free tutoring is available to students with a valid MyA&P™ course ID number from their instructor. The Tutor Center is staffed with qualified A&P instructors who can tutor students on all the materials covered in the text. Tutoring content is restricted to the text material, and tutors will discuss only answers that are provided in the textbook. After an instructor authorizes student access to this service, students can contact the Tutor Center by phone, email, fax, or the Internet. The Tutor Center is open five days a week. For more information, visit www.aw-bc.com/tutorcenter.

Preface to the Student

This book is written for you. In a way, it is written by you (students) because it incorporates your suggestions, answers to questions most often asked, and explanations that have produced the greatest success in helping you learn about the human body. Human anatomy and physiology is more than just interesting—it is fascinating. To help get you involved in the study of this exciting subject, a number of special features are incorporated throughout the book.

The tone of this book is intentionally informal and unintimidating. There is absolutely no reason that you can't enjoy your learning task. This book is meant to be a guide to the understanding of your own body, not an encyclopedia of human anatomy and physiology. We have tried to be selective about the information included and have chosen facts that stress essential concepts. Physiological concepts are explained thoroughly; abundant analogies are used and examples are taken from familiar events whenever possible.

The illustrations and tables are designed with your learning needs in mind. The tables are summaries of important information in the text and should be valuable resources for reviewing for an exam. In all cases, the figures are referenced where their viewing would be most helpful in understanding the text. Those depicting physiological mechanisms often use the flowchart format so that you can see where you've been and where you're going. Additionally, many figures come equipped with questions that will help you to interpret the figures or to apply and integrate what you have learned. (Answers are provided at the bottom of the same page.) Special topic boxes, called *A Closer Look,* alert you to advances in medicine or present scientific information that can be applied to your daily life. The *Making Connections* feature includes three elements to support your studies: *System Connections* recaps the information that you should know when you complete each body system; *Closer Connections* broadens your horizon and enriches your understanding of the system being studied—you may or may not have covered all of its concepts; and *Clinical Connections* challenges you to apply your learning to clinical situations. Please use this feature; it will help you to learn this subject.

Each chapter begins with an outline of its major topics (and their page references), with specific learning objectives listed for each topic. Important terms within the chapter text are bold-faced (in dark type), and phonetic spellings are provided for terms that are likely to be unfamiliar to you. To use these phonetic aids, you will need to remember the following rules:

1. Syllables are separated by dashes.

2. Accent marks follow stressed syllables. Primary stress is shown by ' and secondary stress by ".

3. Unless otherwise noted, assume that vowels at the ends of syllables are long. Assume that all other vowels are short unless a bar, indicating a long vowel sound, appears above them.

For example, the phonetic spelling of "thrombophlebitis" is throm"bo-fleh-bi'tis. The fourth syllable (bi') receives the greatest stress, and the first syllable (throm") gets the secondary stress. The "o" in the second syllable and "i" in the fourth syllable are long. Further explanation of the pronunciation system can be found at the beginning of the Glossary.

Any exam causes anxiety. To help you prepare for an exam or comprehend the material you have just read, thorough summaries complete with page

references are found at the ends of the chapters, as are review questions that use a combination of testing techniques (multiple choice, matching, short answer essay, critical thinking, and clinical applications). Also remember that key figure questions are sprinkled throughout the chapter.

We hope that you enjoy *Human Anatomy & Physiology* and that this book makes learning about the body's structures and functions an exciting and rewarding process. Perhaps the best bit of advice we can give you is that memory depends on understanding. Thus, if you strive for understanding instead of rote memorization, your memory will not fail you often.

We would appreciate hearing from you about your experiences with this textbook or suggestions for improvements in future editions.

Acknowledgments

Writing or revising a textbook is a lesson in lonely perseverance. Hence we could hardly express our joy at coming to the end of this Seventh Edition update. This revision, a major one, has consumed most of our day and night hours for over a year. Text has been streamlined, rewritten for currency, or reorganized, and art has been reconceived once again. As usual, it's been difficult to keep up to date in the very broad field of anatomy and physiology, and then a wrenching ordeal to decide how much of it to use in the new edition. We want our students to be informed intellectually, but how rich a diet that requires is a persistent question.

But, enough complaints or we'll be forced to give equal time to all of those who toiled with us, and they are numerous. The sponsoring editor for this edition, Serina Beauparlant, has supported every aspect of this revision—from money to doughnuts (at meetings). Like Daryl Fox, publisher for this and the past three editions who has gone on to grander venues (sob), Serina is insightful and dedicated to producing the best educational product possible (both text and multimedia). New to the position of project editor for this text is Karoliina Tuovinen. Learning the intricacies of team coordination, wrestling with schedule deadlines, picking up manuscript loose ends, and trying to make a surly old author and an anxious new author work more quickly have made her life this past year a nightmare, we are sure. But she survived and has learned an incredible amount in the process. Claire Alexander, development manager, provided a steadying anchor for Karoliina when the going got rough. Once again, Lauren Harp, the executive marketing manager, has efficiently kept us abreast of the pulse of the marketplace—keeping in touch with professors and students and providing feedback on what they do or don't like about the text and media products. Stacey Weinberger's expertise as manufacturing buyer has served us well. A resounding dollop of gratitude also goes to those on the editorial team with whom we have had little or no personal contact but who have provided valuable services for the revision: Ryan Shaw, associate media editor, Jessica Brunner, assistant editor and Alex Streczyn, editorial assistant for the Seventh Edition supplements.

We also want to thank numerous expert reviewers who shared their knowledge with us as the manuscript was being updated: Bonnie Blazer-Yost, Indiana University—Purdue University at Indianapolis; Sunny K. Boyd, University of Notre Dame; Eldon Braun, University of Arizona; Norma J. Criley, Illinois Wesleyan University; Michael Ferrari, University of Missouri—Kansas City; Kathleen French, University of California—San Diego; Bruce Johnson, Cornell University; John J. Lepri, University of North Carolina—Greensboro; Teresa Marcus, Chattanooga State Technical Community College; Kerry McDonald, University of Missouri—Columbia; Anthony Paganini, Michigan State University; John Rash, Colorado State University; Lauri J. Sammartano, Roane State Community College; Brian Tsukimura, Cal State Fresno; Larry Weiskirch, Onondaga Community College; and Elizabeth Weiss, University of Texas—Austin. Their input resulted in the continued excellence and accuracy of this text's presentations.

We are also grateful for our reviewers and colleagues from the United States and abroad who, over the past three years, have made helpful suggestions and offered constructive criticism to improve this work regarding readability and level, areas particularly important to student success. A complete list of reviewers follows these acknowledgments.

Additionally, we want to acknowledge Katja's colleagues at Mount Royal College (Janice Meeking, Izak Paul, Michael Pollock, Nishan Sharma, and Trevor Day) for stimulating discussions of the text,

which they embraced as their own cause, providing feedback on changes and options.

Once again Wendy Earl Productions handled the production of this text. As always, Wendy Earl, the managing editor, selects highly qualified people to work with her. Michele Mangelli, production supervisor extraordinaire, guided us through the schedule with an expert hand. Her efficient management style and excellent problem-solving skills headed off many a storm, which the whole team appreciated. Laura Southworth, the art development editor, was charged with increasing the consistency of the art program to encourage automatic learning and helping to construct new pieces. All we had to say to Laura is "I don't like this piece of art; can't we do something to reconfigure it for more interest . . . more clarity . . . ?" Two days later there would be a mailer with a great new conceptualization of that figure. Laura is a dynamic, can-do woman! Recognition for a job well done is due Gillian Speeth, photo researcher, and David Novak, art coordinator. The talented artists at Imagineering generated the new art pieces conceived for this edition, and made any changes requested on existing art. It is their art that puts the zing in the book. The new modern text design is the handiwork of the talented Frances Baca, and the exciting cover image is a stunning photo of Serena Williams at the 2005 Australian Open. We feel that Serena's strength and power embody the spirit of our book. As always, a monumental thank-you goes to Anita Wagner, ultra-conscientious copyeditor. She edits with a light hand, all the while double-checking all statistics, drug names, and other technical data. We are also fortunate to have Martha Ghent returning as proofreader and Karen Hollister as indexer for this edition. As has been the practice with this text, Techbooks/GTS assembled the final pages with their customary expertise.

Once again, Harvey Howell, husband of Dr. Marieb for six years now, served as a sounding board for some of her ideas, manned the copy machine, and ran the manuscript to the UPS box daily with nary a complaint during the unbelievably busy days of the past year plus. Thanks also to Katja's husband, Dr. Lawrence W. Haynes, who as a fellow physiologist has provided invaluable assistance to her during the course of the revision. She also thanks her children, Eric and Stefan Haynes, who are an inspiration and a joy.

Well, our tenure on this edition is over, but there will be another edition three years hence. We would really appreciate hearing from you concerning your opinion—suggestions and constructive criticisms—of this text. It is this type of feedback that provides the basis of each revision, and underwrites its improvement.

CHAPTER

The Human Body: An Orientation

An Overview of Anatomy and Physiology (pp. 2–3)

1. Define anatomy and physiology and describe their subdivisions.
2. Explain the principle of complementarity.

Levels of Structural Organization (pp. 3–4, 6–7)

3. Name the different levels of structural organization that make up the human body, and explain their relationships.
4. List the 11 organ systems of the body, identify their components, and briefly explain the major function(s) of each system.

Maintaining Life (pp. 4–8)

5. List the functional characteristics necessary to maintain life in humans.
6. List the survival needs of the body.

Homeostasis (pp. 8–12)

7. Define homeostasis and explain its significance.
8. Describe how negative and positive feedback maintain body homeostasis.
9. Describe the relationship between homeostatic imbalance and disease.

The Language of Anatomy (pp. 12–19)

10. Describe the anatomical position.
11. Use correct anatomical terms to describe body directions, regions, and body planes or sections.
12. Locate and name the major body cavities and their subdivisions, and list the major organs contained within them.
13. Name the serous membranes and indicate their common function.
14. Name the nine regions or four quadrants of the abdominopelvic cavity and list the organs they contain.

As you make your way through this book, you will be learning about one of the most fascinating subjects possible—your own body. Such a study is not only highly personal, but timely as well. The current information blizzard brings news of some medical advance almost daily. If you are to appreciate emerging discoveries in genetic engineering, to understand new techniques for detecting and treating disease, and to make use of published facts on how to stay healthy, it is important to learn about the workings of your body. For those preparing for a career in the health sciences, the study of anatomy and physiology has added rewards because it provides the foundation needed to support your clinical experiences.

In this chapter we define and contrast anatomy and physiology and discuss how the human body is organized. Then we review needs and functional processes common to all living organisms. Three essential concepts—*the complementarity of structure and function, the hierarchy of structural organization,* and *homeostasis*—will unify and form the bedrock for your study of the human body. The final section of the chapter deals with the language of anatomy—terminology that anatomists use when they describe the body or its parts.

An Overview of Anatomy and Physiology

Two complementary branches of science—anatomy and physiology—provide the concepts that help us to understand the human body. **Anatomy** studies the *structure* of body parts and their relationships to one another. Anatomy has a certain appeal because it is concrete. Body structures can be seen, felt, and examined closely; it is not necessary to imagine what they look like. **Physiology** concerns the *function* of the body, in other words, how the body parts work and carry out their life-sustaining activities. When all is said and done, physiology is explainable only in terms of the underlying anatomy. To simplify the study of the body, most references to body structures and/or physiological values (body temperature, heart rate, and the like) assume that we are talking about a healthy young (22-year-old) male weighing about 155 lb (the *reference man*) or a healthy young female weighing about 125 lb (the *reference woman*).

Topics of Anatomy

Anatomy is a broad field with many subdivisions, each providing enough information to be a course in itself. **Gross,** or **macroscopic, anatomy** is the study of large body structures visible to the naked eye, such as the heart, lungs, and kidneys. Indeed, the term *anatomy* (derived from the Greek words meaning "to cut apart") relates most closely to gross anatomy because in such studies preserved animals or their organs are dissected (cut up) to be examined. Gross anatomy can be approached in different ways. In **regional anatomy,** all the structures (muscles, bones, blood vessels, nerves, etc.) in a particular region of the body, such as the abdomen or leg, are examined at the same time. In **systemic anatomy** (sis-tem'ik),* body structure is studied system by system. For example, when studying the cardiovascular system, you would examine the heart and the blood vessels of the entire body. Another subdivision of gross anatomy is **surface anatomy,** the study of internal structures as they relate to the overlying skin surface. You use surface anatomy when you identify the bulging muscles beneath a bodybuilder's skin, and clinicians use it to locate appropriate blood vessels in which to feel pulses and draw blood.

Microscopic anatomy deals with structures too small to be seen with the naked eye. For most such studies, exceedingly thin slices of body tissues are stained and mounted on slides to be examined under the microscope. Subdivisions of microscopic anatomy include **cytology** (si-tol'o-je), which considers the cells of the body, and **histology** (his-tol'o-je), the study of tissues.

Developmental anatomy traces structural changes that occur in the body throughout the life span. **Embryology** (em"bre-ol'o-je), a subdivision of developmental anatomy, concerns developmental changes that occur before birth.

Some highly specialized branches of anatomy are used primarily for medical diagnosis and scientific research. For example, *pathological anatomy* studies structural changes caused by disease. *Radiographic anatomy* studies internal structures as visualized by X-ray images or specialized scanning procedures. In *molecular biology,* the structure of biological molecules (chemical substances) is investigated. Molecular biology is actually a separate branch of biology, but it falls under the anatomy umbrella when we push anatomical studies to the subcellular level. As you can see, subjects of interest to anatomists range from easily seen structures down to the smallest molecule.

One essential tool for studying anatomy is a mastery of anatomical terminology. Others are observation, manipulation, and, in a living person, *palpation* (feeling organs with your hands) and *auscultation* (listening to organ sounds with a stethoscope). A simple example will illustrate how some of

*For the pronunciation guide rules, see the Preface to the Student.

these tools work together in an anatomical study. Let's assume that your topic is freely movable joints of the body. In the laboratory, you will be able to *observe* an animal joint, noting how its parts fit together. You can work the joint (*manipulate* it) to determine its range of motion. Using *anatomical terminology,* you can name its parts and describe how they are related so that other students (and your instructor) will have no trouble understanding you. The list of word roots (on the inside of the book cover) and the glossary will help you with this special vocabulary.

Although most of your observations will be made with the naked eye or with the help of a microscope, medical technology has developed a number of sophisticated tools that can peer into the body without disrupting it. These exciting medical imaging techniques are discussed in *A Closer Look* on pp. 20–21.

Topics of Physiology

Like anatomy, physiology has many subdivisions, most of which consider the operation of specific organ systems. For example, **renal physiology** concerns kidney function and urine production; **neurophysiology** explains the workings of the nervous system; and **cardiovascular physiology** examines the operation of the heart and blood vessels. While anatomy provides us with a static image of the body's architecture, physiology reveals the body's dynamic and animated nature.

Physiology often focuses on events at the cellular or molecular level. This is because the body's abilities depend on those of its individual cells, and cells' abilities ultimately depend on the chemical reactions that go on within them. Physiology also rests on principles of physics, which help to explain electrical currents, blood pressure, and the way muscles use bones to cause body movements, among other things. Basic chemical and physical principles are presented in Chapter 2 and throughout the book as needed to explain physiological topics.

Complementarity of Structure and Function

Although it is possible to study anatomy and physiology individually, they are really inseparable because function always reflects structure. That is, what a structure can do depends on its specific form. This is called the **principle of complementarity of structure and function.** For example, bones can support and protect body organs because they contain hard mineral deposits, and blood flows in one direction through the heart because the heart has valves that prevent backflow. Throughout this book, a description of a structure's anatomy is accompanied by an explanation of its function, and structural characteristics contributing to that function are emphasized.

Levels of Structural Organization

The human body has many levels of structural organization (Figure 1.1). The simplest level of the structural hierarchy is the **chemical level,** which we study in Chapter 2. At this level, *atoms,* tiny building blocks of matter, combine to form *molecules* such as water and proteins. Molecules, in turn, associate in specific ways to form *organelles,* basic components of the microscopic cells. *Cells* are the smallest units of living things. The **cellular level** is examined in Chapter 3. All cells have some common functions, but individual cells vary widely in size and shape, reflecting their unique functions in the body.

The simplest living creatures are composed of single cells, but in complex organisms such as human beings, the hierarchy continues on to the **tissue level.** *Tissues* are groups of similar cells that have a common function. The four basic tissue types in the human body are epithelium, muscle, connective tissue, and nervous tissue. Each tissue type has a characteristic role in the body, which we explore in Chapter 4. Briefly, epithelium covers the body surface and lines its cavities; muscle provides movement; connective tissue supports and protects body organs; and nervous tissue provides a means of rapid internal communication by transmitting electrical impulses.

An *organ* is a discrete structure composed of at least two tissue types (four is more common) that performs a specific function for the body. At the **organ level,** extremely complex functions become possible. Let's take the stomach for an example. Its lining is an epithelium that produces digestive juices; the bulk of its wall is muscle, which churns and mixes stomach contents (food); its connective tissue reinforces the soft muscular walls; and its nerve fibers increase digestive activity by stimulating the muscle to contract more vigorously and the glands to secrete more digestive juices. The liver, the brain, and a blood vessel are very different from the stomach, but they are organs as well. You can think of each organ of the body as a specialized functional center responsible for a necessary activity that no other organ can perform.

The next level of organization is the **organ system.** Organs that work together to accomplish a common purpose make up an *organ system.* For

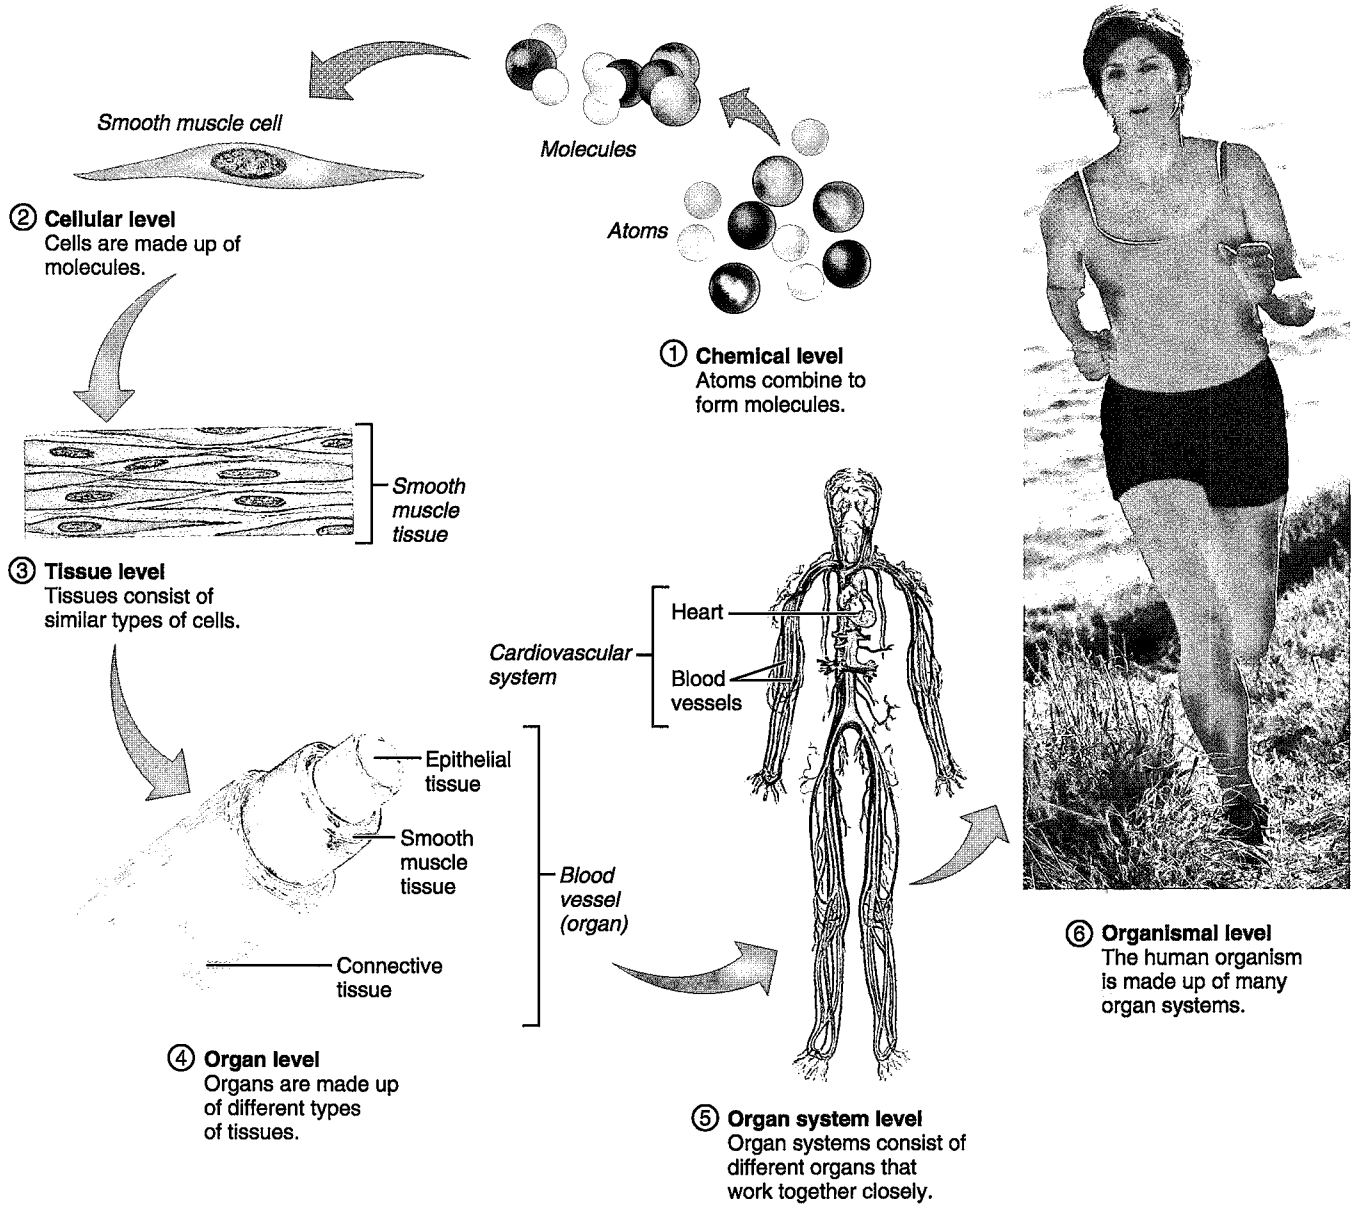

FIGURE 1.1 **Levels of structural organization.** Components of the cardiovascular system illustrate the levels of structural organization in a human being.

example, the heart and blood vessels of the cardiovascular system see to it that blood circulates continuously to carry oxygen and nutrients to all body cells. Besides the cardiovascular system, the other organ systems of the body are the integumentary, skeletal, muscular, nervous, endocrine, lymphatic, respiratory, digestive, urinary, and reproductive systems. Figure 1.3 on pp. 6 and 7 provides a brief overview of the 11 organ systems, which we study in more detail in Units 2–5.

The highest level of organization is the *organism,* the living human being. The **organismal level** represents the sum total of all structural levels working together to promote life.

Maintaining Life

Necessary Life Functions

Now that you know the structural levels composing the human body, the question that naturally follows is: What does this highly organized human body do? Like all complex animals, human beings maintain their boundaries, move, respond to environmental

changes, take in and digest nutrients, carry out metabolism, dispose of wastes, reproduce themselves, and grow. We will discuss each of these necessary life functions briefly here and in more detail in later chapters.

It cannot be emphasized too strongly that the multicellular state and parceling out of vital body functions to different organ systems result in interdependence of all body cells. Organ systems do not work in isolation; they work cooperatively to promote the well-being of the entire body. This theme is emphasized throughout the book, and some of the organ systems making major contributions to selected functional processes are identified in Figure 1.2. Also, as you read this section you will want to refer to the more detailed descriptions of the organ systems in Figure 1.3.

Maintaining Boundaries Every living organism must **maintain its boundaries** so that its internal environment (inside) remains distinct from the external environment surrounding it (outside). In single-celled organisms, the external boundary is a limiting membrane that encloses its contents and admits needed substances while restricting entry of potentially damaging or unnecessary substances. Similarly, all the cells of our body are surrounded by a selectively permeable membrane. Additionally, the body as a whole is enclosed and protected by the integumentary system, or skin, which protects our internal organs from drying out (a fatal change), bacteria, and the damaging effects of heat, sunlight, and an unbelievable number of chemicals in the external environment.

Movement **Movement** includes the activities promoted by the muscular system, such as propelling ourselves from one place to another by running or swimming, and manipulating the external environment with our nimble fingers. The skeletal system provides the bony framework that the muscles pull on as they work. Movement also occurs when substances such as blood, foodstuffs, and urine are propelled through internal organs of the cardiovascular, digestive, and urinary systems, respectively. On the cellular level, the muscle cell's ability to move by shortening is more precisely called **contractility.**

Responsiveness **Responsiveness,** or **irritability,** is the ability to sense changes (stimuli) in the environment and then respond to them. For example, if you cut your hand on broken glass, a withdrawal reflex occurs—you involuntarily pull your hand away from the painful stimulus (the broken glass). It is not necessary to think about it; it just happens! Likewise, when carbon dioxide in your blood rises to dangerously high levels, chemical sensors respond by sending messages to brain centers controlling respiration, and your breathing rate speeds up.

Because nerve cells are highly irritable and communicate rapidly with each other via electrical impulses, the nervous system is most involved with responsiveness. However, all body cells are irritable to some extent.

Digestion **Digestion** is the breaking down of ingested foodstuffs to simple molecules that can be absorbed into the blood. The nutrient-rich blood is

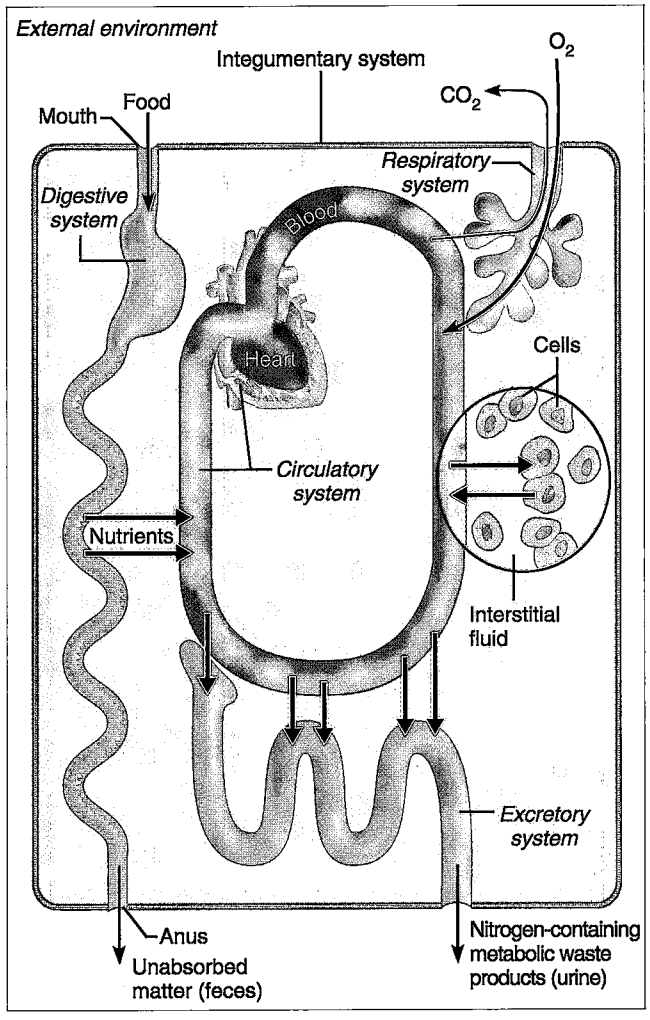

FIGURE 1.2 **Examples of interrelationships among body organ systems.** The integumentary system protects the body as a whole from the external environment. The digestive and respiratory systems, in contact with the external environment, take in nutrients and oxygen, respectively, which are then distributed by the blood to all body cells. Elimination of metabolic wastes is accomplished by the urinary and respiratory systems.

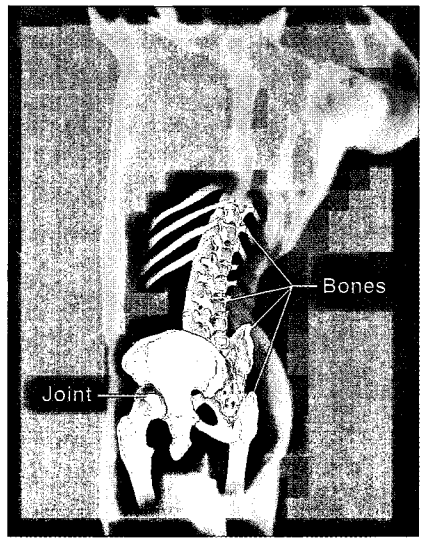
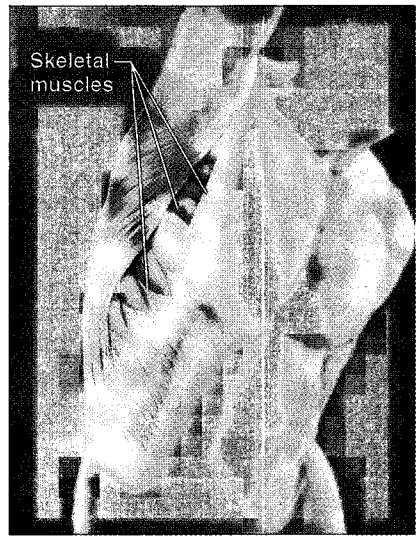
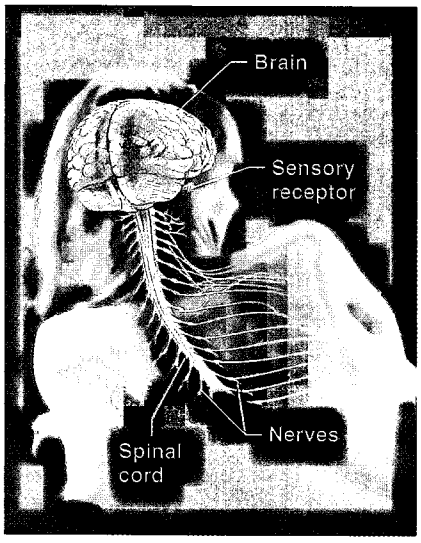
(a) Integumentary System
Forms the external body covering; protects deeper tissues from injury; synthesizes vitamin D; site of cutaneous (pain, pressure, etc.) receptors, and sweat and oil glands.



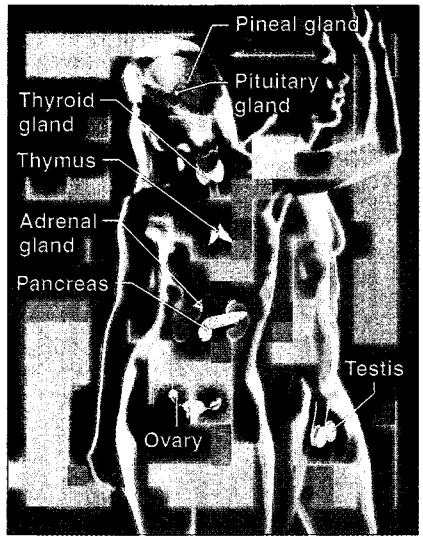
(b) Skeletal System
Protects and supports body organs; provides a framework the muscles use to cause movement; blood cells are formed within bones; stores minerals.



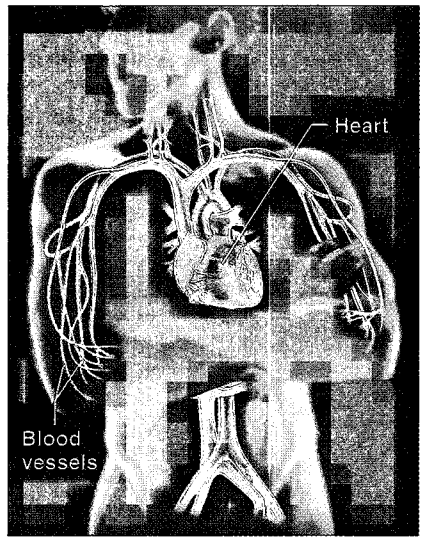
(c) Muscular System
Allows manipulation of the environment, locomotion, and facial expression; maintains posture; produces heat.



(d) Nervous System
Fast-acting control system of the body; responds to internal and external changes by activating appropriate muscles and glands.



(e) Endocrine System
Glands secrete hormones that regulate processes such as growth, reproduction, and nutrient use (metabolism) by body cells.

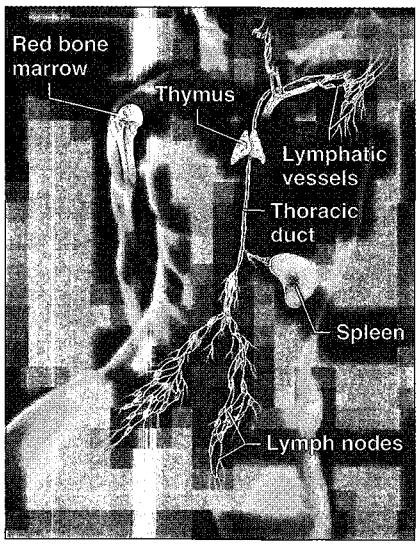


(f) Cardiovascular System
Blood vessels transport blood, which carries oxygen, carbon dioxide, nutrients, wastes, etc.; the heart pumps blood.

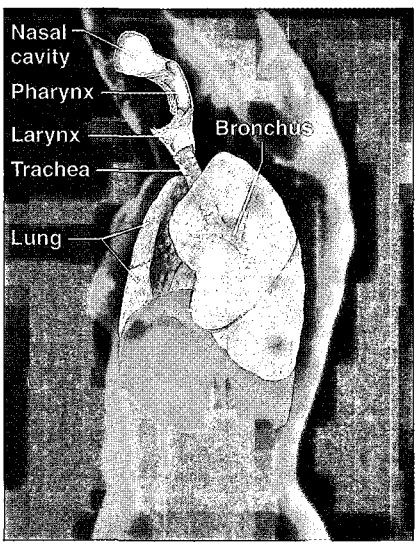
FIGURE 1.3 **Summary of the body's organ systems.** The structural components of each system are illustrated, and its major functions are listed below.

then distributed to all body cells by the cardiovascular system. In a simple, one-celled organism such as an amoeba, the cell itself is the "digestion factory," but in the multicellular human body, the digestive system performs this function for the entire body.

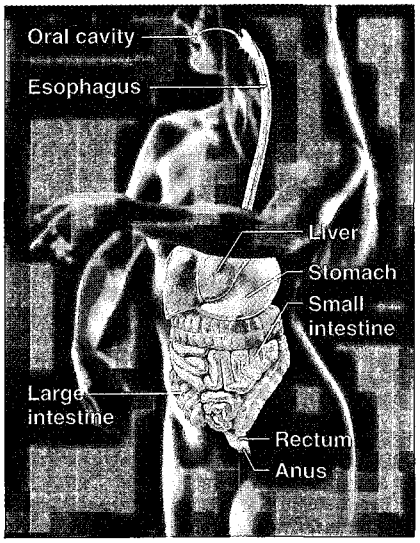
Metabolism **Metabolism** (mĕ-tab'o-lizm; "a state of change") is a broad term that includes all chemical reactions that occur within body cells. It includes breaking down substances into their simpler building blocks (more specifically called *catabolism*), synthesizing more complex cellular structures from



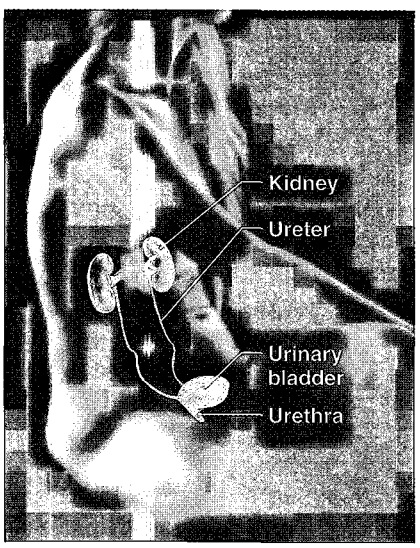
(g) Lymphatic System/Immunity
Picks up fluid leaked from blood vessels and returns it to blood; disposes of debris in the lymphatic stream; houses white blood cells (lymphocytes) involved in immunity. The immune response mounts the attack against foreign substances within the body.



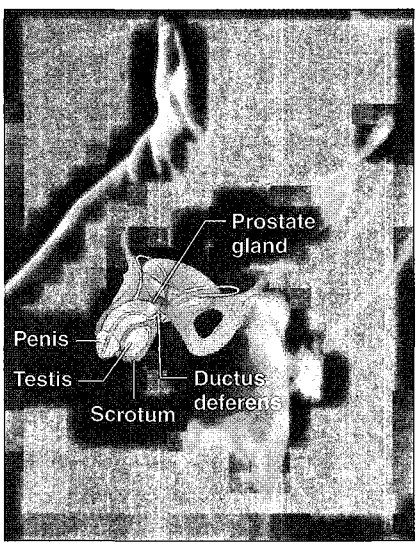
(h) Respiratory System
Keeps blood constantly supplied with oxygen and removes carbon dioxide; the gaseous exchanges occur through the walls of the air sacs of the lungs.

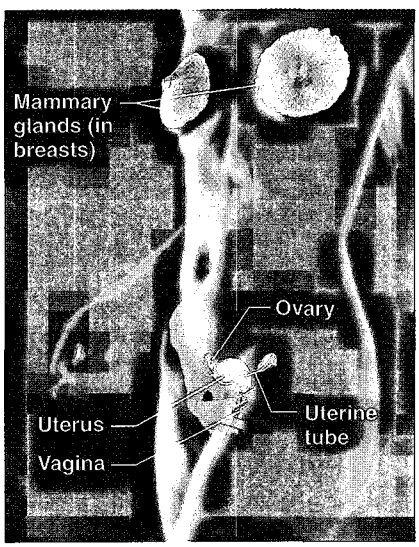


(i) Digestive System
Breaks down food into absorbable units that enter the blood for distribution to body cells; indigestible foodstuffs are eliminated as feces.



(j) Urinary System
Eliminates nitrogenous wastes from the body; regulates water, electrolyte and acid-base balance of the blood.





(k) Male Reproductive System **(l) Female Reproductive System**
Overall function is production of offspring. Testes produce sperm and male sex hormone; ducts and glands aid in delivery of sperm to the female reproductive tract. Ovaries produce eggs and female sex hormones; remaining structures serve as sites for fertilization and development of the fetus. Mammary glands of female breasts produce milk to nourish the newborn.

simpler substances *(anabolism)*, and using nutrients and oxygen to produce (via *cellular respiration*) ATP, the energy-rich molecules that power cellular activities. Metabolism depends on the digestive and respiratory systems to make nutrients and oxygen available to the blood and on the cardiovascular system to distribute these needed substances throughout the body. Metabolism is regulated largely by hormones secreted by endocrine system glands.

Excretion **Excretion** is the process of removing *excreta* (ek-skre'tah), or wastes, from the body. If the body is to operate as we expect it to, it must get rid of nonuseful substances produced during digestion and metabolism. Several organ systems participate in excretion. For example, the digestive system rids the body of indigestible food residues in feces, and the urinary system disposes of nitrogen-containing metabolic wastes, such as urea, in urine. Carbon dioxide, a by-product of cellular respiration, is carried in the blood to the lungs, where it leaves the body in exhaled air.

Reproduction **Reproduction** can occur at the cellular or organismal level. In cellular reproduction the original cell divides, producing two identical daughter cells that may then be used for body growth or repair. Reproduction of the human organism, or making a whole new person, is the major task of the reproductive system. When a sperm unites with an egg, a fertilized egg forms, which then develops into a baby within the mother's body. The reproductive system is directly responsible for producing offspring, but its function is exquisitely regulated by hormones of the endocrine system.

Because males produce sperm and females produce eggs (ova), there is a division of labor in the reproductive process, and the reproductive organs of males and females are different (see Figure 1.3). Additionally, the female's reproductive structures provide the site for fertilization of eggs by sperm, then protect and nurture the developing fetus until birth.

Growth **Growth** is an increase in size of a body part or the organism. It is usually accomplished by increasing the number of cells. However, individual cells also increase in size when not dividing. For true growth to occur, constructive activities must occur at a faster rate than destructive ones.

Survival Needs

The ultimate goal of all body systems is to maintain life. However, life is extraordinarily fragile and requires that several factors be present. These factors, which we will call *survival needs,* include nutrients (food), oxygen, water, and appropriate temperature and atmospheric pressure.

Nutrients, taken in via the diet, contain the chemical substances used for energy and cell building. Most plant-derived foods are rich in carbohydrates, vitamins, and minerals, whereas most animal foods are richer in proteins and fats. Carbohydrates are the major energy fuel for body cells. Proteins, and to a lesser extent fats, are essential for building cell structures. Fats also provide a reserve of energy-rich fuel. Selected minerals and vitamins are required for the chemical reactions that go on in cells and for oxygen transport in the blood. The mineral calcium helps to make bones hard and is required for blood clotting.

All the nutrients in the world are useless unless **oxygen** is also available. Because the chemical reactions that release energy from foods are *oxidative* reactions that require oxygen, human cells can survive for only a few minutes without oxygen. Approximately 20% of the air we breathe is oxygen. It is made available to the blood and body cells by the cooperative efforts of the respiratory and cardiovascular systems.

Water accounts for 60–80% of body weight and is the single most abundant chemical substance in the body. It provides the watery environment necessary for chemical reactions and the fluid base for body secretions and excretions. Water is obtained chiefly from ingested foods or liquids and is lost from the body by evaporation from the lungs and skin and in body excretions.

If chemical reactions are to continue at life-sustaining rates, **normal body temperature** must be maintained. As body temperature drops below 37°C (98.6°F), metabolic reactions become slower and slower, and finally stop. When body temperature is too high, chemical reactions occur at a frantic pace and body proteins lose their characteristic shape and stop functioning. At either extreme, death occurs. Most body heat is generated by the activity of the muscular system.

Atmospheric pressure is the force that air exerts on the surface of the body. Breathing and gas exchange in the lungs depend on *appropriate* atmospheric pressure. At high altitudes, where atmospheric pressure is lower and the air is thin, gas exchange may be inadequate to support cellular metabolism.

The mere presence of these survival factors is not sufficient to sustain life. They must be present in *appropriate* amounts; excesses and deficits may be equally harmful. For example, oxygen is essential, but excessive amounts are toxic to body cells. Similarly, the food we eat must be of high quality and in proper amounts; otherwise, nutritional disease, obesity, or starvation is likely. Also, while the needs listed above are the most crucial, they do not even begin to encompass all of the body's needs. For example, we can live without gravity if we must, but the quality of life suffers.

Homeostasis

When you think about the fact that your body contains trillions of cells in nearly constant activity, and that remarkably little usually goes wrong with

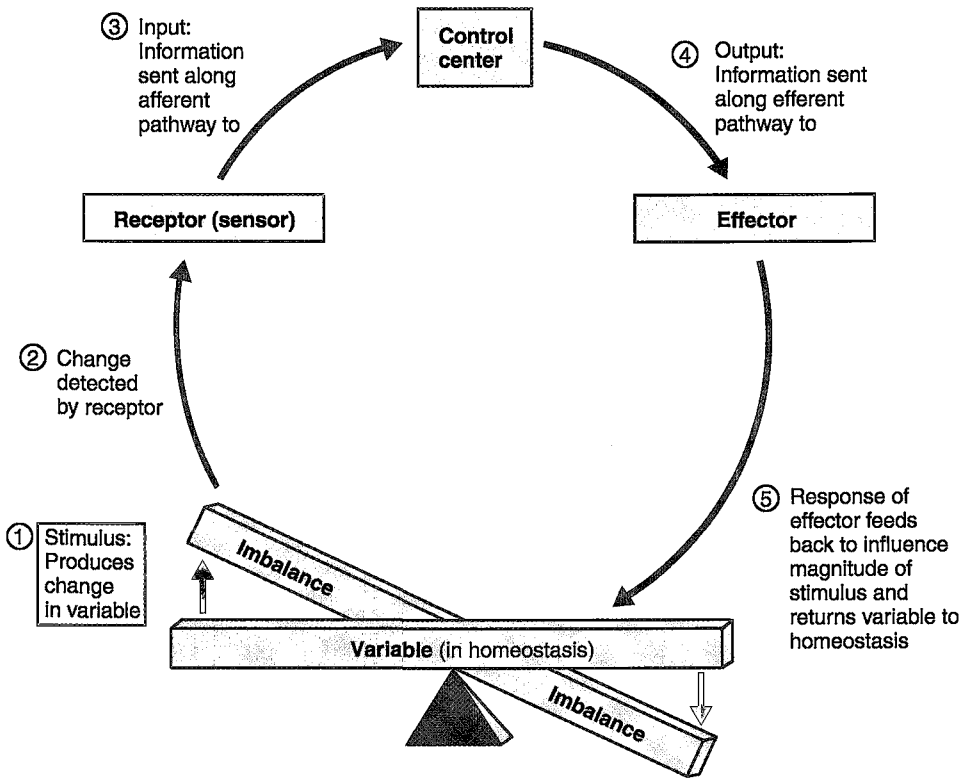


FIGURE 1.4 **The elements of a homeostatic control system.** Communication between the receptor, control center, and effector is essential for normal operation of the control system.

it, you begin to appreciate what a marvelous machine your body is. Walter Cannon, an American physiologist of the early twentieth century, spoke of the "wisdom of the body," and he coined the word **homeostasis** (ho"me-o-sta'sis) to describe its ability to maintain relatively stable internal conditions even though the outside world changes continuously. Although the literal translation of homeostasis is "unchanging," the term does not really mean a static, or unchanging, state. Rather, it indicates a *dynamic* state of equilibrium, or a balance, in which internal conditions vary, but always within relatively narrow limits. In general, the body is in homeostasis when its needs are adequately met and it is functioning smoothly.

Maintaining homeostasis is more complicated than it appears at first glance. Virtually every organ system plays a role in maintaining the constancy of the internal environment. Adequate blood levels of vital nutrients must be continuously present, and heart activity and blood pressure must be constantly monitored and adjusted so that the blood is propelled to all body tissues. Also, wastes must not be allowed to accumulate, and body temperature must be precisely controlled. A wide variety of chemical, thermal, and neural factors act and interact in complex ways—sometimes helping and sometimes hindering the body as it works to maintain its "steady rudder."

Homeostatic Control Mechanisms

Communication within the body is essential for homeostasis. Communication is accomplished chiefly by the nervous and endocrine systems, which use neural electrical impulses or bloodborne hormones, respectively, as information carriers. The details of how these two great regulating systems operate are covered in later chapters, but the basic characteristics of control systems that promote homeostasis are explained here.

Regardless of the factor or event being regulated—the **variable**—all homeostatic control mechanisms have at least three interdependent components (Figure 1.4). The first component, the **receptor,** is some type of sensor that monitors the environment and responds to changes, called *stimuli,* by sending information (input) to the second component, the *control center.* Input flows from the receptor to the control center along the so-called

afferent pathway. The **control center,** which determines the *set point* (the level or range at which a variable is to be maintained), analyzes the input it receives and then determines the appropriate response or course of action.

The third component, the **effector,** provides the means for the control center's response (output) to the stimulus. Information flows from the control center to the effector along the *efferent pathway.* The results of the response then *feed back* to influence the stimulus, either depressing it (negative feedback) so that the whole control mechanism is shut off or enhancing it (positive feedback) so that the reaction continues at an even faster rate. (To help you remember the difference between "afferent" and "efferent," you might note that information traveling along the afferent pathway approaches the control center and efferent information exits from the control center.)

Negative Feedback Mechanisms

Most homeostatic control mechanisms are **negative feedback mechanisms.** In these systems, the output shuts off the original stimulus or reduces its intensity. These mechanisms cause the variable to change in a direction *opposite* to that of the initial change, returning it to its "ideal" value; thus the name "negative" feedback mechanisms.

A good example of a nonbiological negative feedback system is a home heating system connected to a temperature-sensing thermostat (Figure 1.5). The thermostat houses both the receptor (thermometer) and the control center. If the thermostat is set at 20°C (68°F), the heating system (effector) is triggered ON when the house temperature drops below that setting. As the furnace produces heat and warms the air, the temperature rises, and when it reaches 20°C or slightly higher, the thermostat triggers the furnace OFF. This process results in a cycling of "furnace-ON" and "furnace-OFF" so that the temperature in the house stays very near the desired temperature of 20°C. Your body "thermostat," located in a part of your brain called the hypothalamus, operates in a similar fashion.

Regulation of body temperature is only one of the many ways the nervous system maintains the constancy of the internal environment. Another type of neural control mechanism is seen in the *withdrawal reflex* referred to earlier, in which the hand is jerked away from a painful stimulus such as broken glass. The endocrine system is equally important in maintaining homeostasis, however, and a good example of a hormonal negative feedback mechanism is the control of blood volume by antidiuretic hormone (ADH). As blood volume drops, the hypothalamus of the brain (the control center) is stimulated to release ADH to the blood. This in turn prompts the kidneys to reabsorb more water and return it to the bloodstream. The rising blood volume then ends the stimulus for ADH release.

The body's ability to regulate its internal environment is fundamental, and all negative feedback mechanisms have the same goal: preventing sudden severe changes within the body. Body temperature and blood volume are only two of the variables that need to be regulated. There are hundreds! Other negative feedback mechanisms regulate heart rate, blood pressure, the rate and depth of breathing, and blood levels of oxygen, carbon dioxide, and minerals. Now, let's take a look at the other type of feedback control mechanism—positive feedback.

Positive Feedback Mechanisms

In **positive feedback mechanisms,** the result or response enhances the original stimulus so that the activity (output) is accelerated. This feedback mechanism is "positive" because the change that occurs proceeds in the *same* direction as the initial disturbance, causing the variable to deviate further and further from its original value or range. In contrast to negative feedback controls, which maintain some physiological function or keep blood chemicals within narrow ranges, positive feedback mechanisms usually control infrequent events that do not require continuous adjustments. Typically, they set off a series of events that may be self-perpetuating and that, once initiated, have an amplifying or waterfall effect. Because of these characteristics, positive feedback mechanisms are often referred to as *cascades* (from the Italian word meaning "to fall"). Positive feedback mechanisms are likely to race out of control, and so they are rarely used to promote the moment-to-moment well-being of the body. However, two familiar examples of their use as homeostatic mechanisms are the enhancement of labor contractions during birth and blood clotting.

The positive feedback mechanism in which oxytocin, a hypothalamic hormone, intensifies labor contractions during the birth of a baby is described in Chapter 28 (see Figure 28.16). Oxytocin causes the contractions to become both more frequent and more powerful. The increased contractions cause more oxytocin to be released, which causes more contractions and so on until the baby is finally born, an event that ends the stimulus for oxytocin release and shuts off the positive feedback mechanism.

Blood clotting is a normal response to a break in the lining of a blood vessel and is an excellent

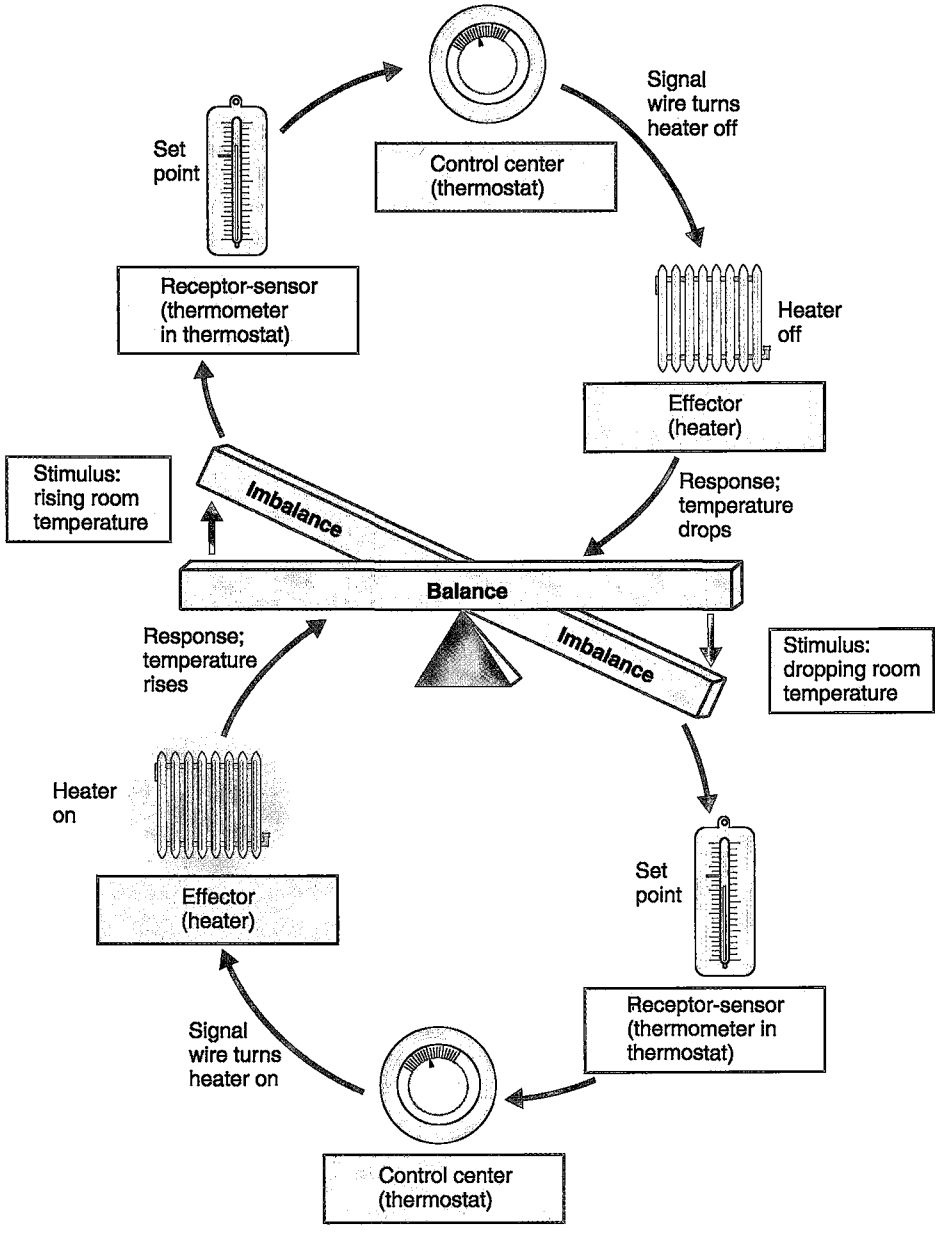

FIGURE 1.5 **Regulation of room temperature by a negative feedback mechanism.**

example of an important body function controlled by positive feedback. Basically, once vessel damage has occurred, blood elements called platelets immediately begin to cling to the injured site and release chemicals that attract more platelets. This rapidly growing pileup of platelets initiates the sequence of events that finally forms a clot (Figure 1.6).

Homeostatic Imbalance

Homeostasis is so important that most disease can be regarded as a result of its disturbance, a condition called **homeostatic imbalance.** As we age, our body's control systems become less efficient, and our internal environment becomes less and less stable. These events increase our risk for illness and produce the changes we associate with aging.

Another important source of homeostatic imbalance occurs when the usual negative feedback mechanisms are overwhelmed and destructive positive feedback mechanisms take over. Some instances of heart failure reflect this phenomenon.

Examples of homeostatic imbalance are provided throughout this book to enhance your understanding of normal physiological mechanisms. These homeostatic imbalance sections are preceded by the

Q *(1) Why is this control mechanism called a "positive feedback mechanism"? (2) What event ends the cascade or chain reaction seen in this positive feedback control mechanism?*

symbol to alert you to the fact that an abnormal condition is being described.

The Language of Anatomy

Although most of us are naturally curious about our bodies, our interest sometimes dwindles when we are confronted with the terminology used in the study of anatomy and physiology. Let's face it—you can't just pick up an anatomy and physiology book and read it as though it were a novel. Unfortunately, confusion is inevitable without such specialized terminology. For example, if you are looking at a ball, "above" always means the area over the top of the ball. Other directional terms can also be used consistently because the ball is a totally symmetrical object, a sphere. The human body, of course, has many bends and protrusions. Thus, the question becomes: above what? To prevent misunderstanding, anatomists use universally accepted terms to identify body structures precisely and with a minimum of words. This language of anatomy is presented and explained next.

Anatomical Position and Directional Terms

To describe body parts and position accurately, we need an initial reference point and must indicate direction. The anatomical reference point is a standard body position called the **anatomical position.** In the anatomical position, the body is erect with feet slightly apart. This position is easy to remember because it resembles "standing at attention," except that the palms face forward and the thumbs point away from the body. You can see the anatomical position in Table 1.1 (top) and Figure 1.7a. It is essential to understand the anatomical position because most of the directional terms used in this book refer to the body *as if it were in this position, regardless of its actual position.* Another point to remember is that the terms "right" and "left" refer to those sides of the person or the cadaver (deceased person) being viewed—not those of the observer.

Directional terms allow us to explain where one body structure is in relation to another. For example, we could describe the relationship between the ears and the nose informally by stating, "The ears are located on each side of the head to the right and left of the nose." Using anatomical terminology, this condenses to, "The ears are lateral to the nose." Clearly, using anatomical terms saves words and is less ambiguous. Commonly used orientation and directional terms are defined and illustrated in Table 1.1. Many of these terms are also used in everyday conversation, but keep in mind that their anatomical meanings are very precise.

Regional Terms

The two fundamental divisions of our body are its *axial* and *appendicular* (ap"en-dik'u-lar) parts. The **axial part,** which makes up the main *axis* of our body, includes the head, neck, and trunk. The **appendicular part** consists of the *appendages,* or *limbs,* which are attached to the body's axis.

A *(1) Because the response leads to an even greater response (i.e., platelets cling to damaged vessels and release chemicals that attract more platelets, which release more chemicals, etc.) rather than shutting off the stimulus, it involves positive feedback. (2) When the clot seals the break in the vessel, the cascade ends.*

TABLE 1.1 Orientation and Directional Terms

TERM	DEFINITION	EXAMPLE	
Superior (cranial)	Toward the head end or upper part of a structure or the body; above		The head is superior to the abdomen
Inferior (caudal)	Away from the head end or toward the lower part of a structure or the body; below		The navel is inferior to the chin
Ventral (anterior)*	Toward or at the front of the body; in front of		The breastbone is anterior to the spine
Dorsal (posterior)*	Toward or at the back of the body; behind		The heart is posterior to the breastbone
Medial	Toward or at the midline of the body; on the inner side of		The heart is medial to the arm
Lateral	Away from the midline of the body; on the outer side of		The arms are lateral to the chest
Intermediate	Between a more medial and a more lateral structure		The collarbone is intermediate between the breastbone and shoulder
Proximal	Closer to the origin of the body part or the point of attachment of a limb to the body trunk		The elbow is proximal to the wrist
Distal	Farther from the origin of a body part or the point of attachment of a limb to the body trunk		The knee is distal to the thigh
Superficial (external)	Toward or at the body surface		The skin is superficial to the skeletal muscles
Deep (internal)	Away from the body surface; more internal		The lungs are deep to the skin

*The terms *ventral* and *anterior* are synonymous in humans, but this is not the case in four-legged animals. Whereas *anterior* refers to the leading portion of the body (abdominal surface in humans, head in a cat), *ventral* specifically refers to the "belly" of a vertebrate animal and thus is the inferior surface of four-legged animals. Likewise, although the dorsal and posterior surfaces are the same in humans, the term *dorsal* specifically refers to an animal's back. Thus, the dorsal surface of four-legged animals is their superior surface.

Q *As you study this figure, determine precisely where you would be injured if you* ***(1)*** *pulled a muscle in your inguinal region,* ***(2)*** *cracked a bone in your olecranal region, and* ***(3)*** *received a cut on the fibular region.*

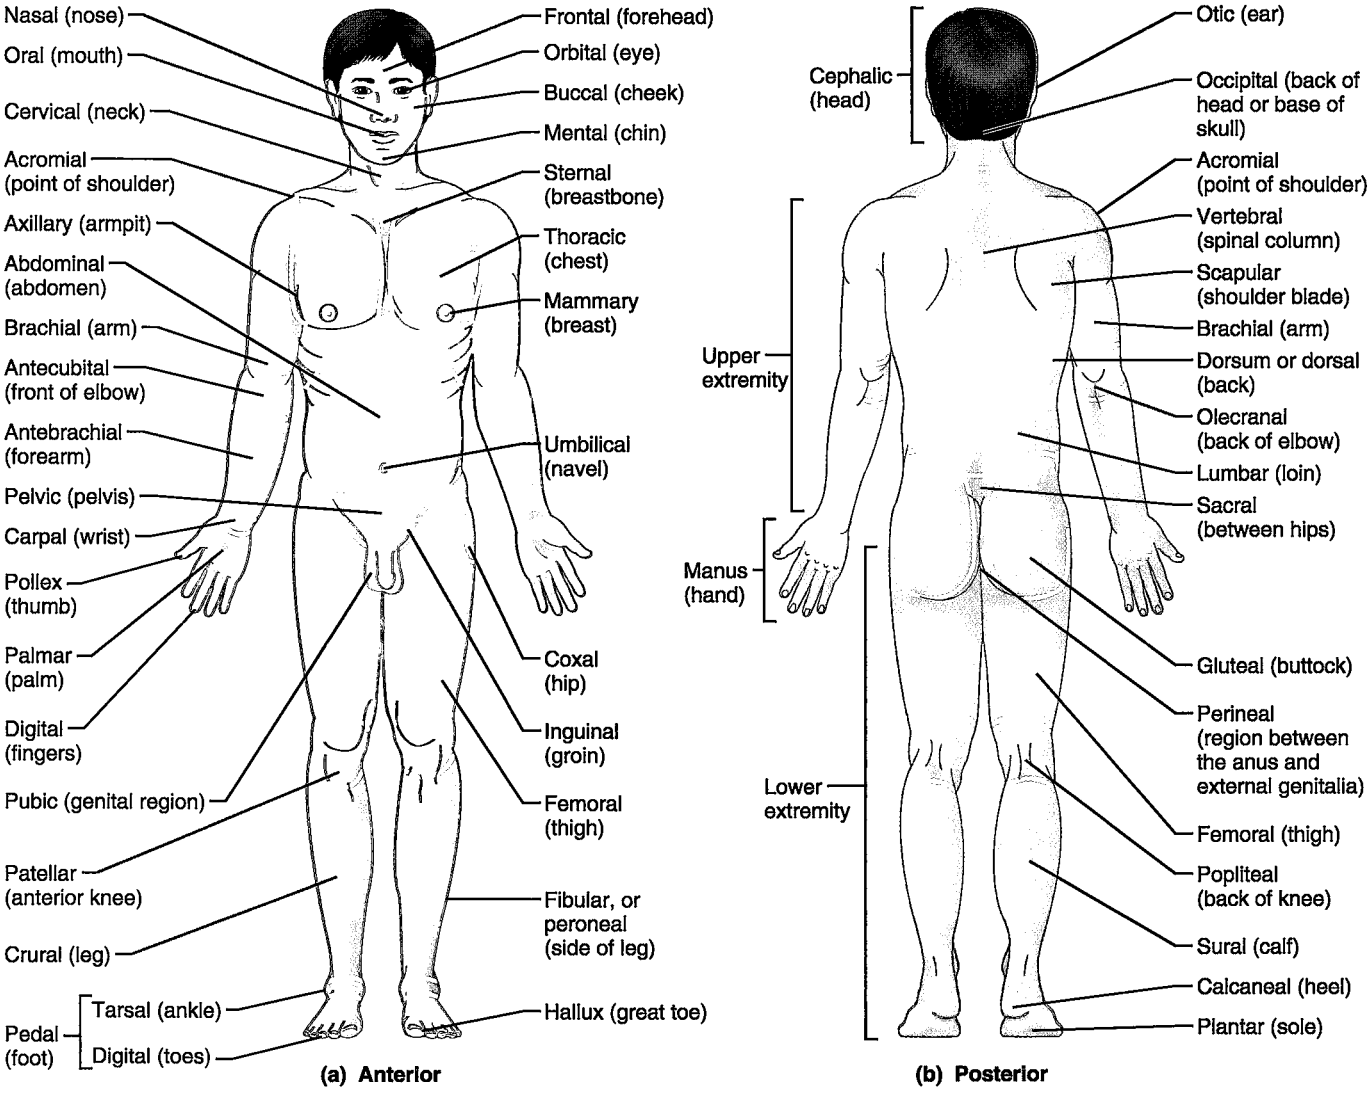

FIGURE 1.7 **Regional terms used to designate specific body areas. (a)** The anatomical position. **(b)** The heels are raised slightly to show the plantar surface of the foot, which is actually on the inferior surface of the body.

Regional terms used to designate specific areas within the major body divisions are indicated in Figure 1.7. The common term for each of these body regions is also provided (in parentheses).

A ***(1)*** *Your groin.* ***(2)*** *Posterior aspect of the elbow.* ***(3)*** *The side of your leg.*

Anatomical Variability

Although we use common directional and regional terms to refer to all human bodies, we know from observing the faces and body shapes of people around us that we humans differ in our external anatomy. The same kind of variability holds for our internal organs as well. In some bodies, for example, a nerve or blood vessel may be somewhat out of place, or a small muscle may be missing. Nonetheless, well over 90% of all structures present in any human body

match the textbook descriptions. Extreme anatomical variations are seldom seen because they are incompatible with life.

Body Planes and Sections

For anatomical studies, the body is often *sectioned* (cut) along a flat surface called a plane. The most frequently used body planes are sagittal, frontal, and transverse planes, which lie at right angles to one another (Figure 1.8). A section is named for the plane along which it is cut. Thus, a cut along a sagittal plane produces a sagittal section.

A **sagittal plane** (saj'ĭ-tal; "arrow") is a vertical plane that divides the body into right and left parts. A sagittal plane that lies exactly in the midline is the **median plane,** or **midsagittal plane** (Figure 1.8c). All other sagittal planes, offset from the midline, are **parasagittal planes** (*para* = near).

Frontal planes, like sagittal planes, lie vertically. Frontal planes, however, divide the body into anterior and posterior parts (Figure 1.8a). A frontal plane is also called a **coronal plane** (kŏ-ro'nal; "crown").

A **transverse,** or **horizontal, plane** runs horizontally from right to left, dividing the body into superior and inferior parts (Figure 1.8b). Of course, many different transverse planes exist, at every possible level from head to foot. A transverse section is also called a **cross section.** Cuts made diagonally between the horizontal and the vertical planes are called **oblique sections.** Such sections are often confusing and difficult to interpret and are seldom used.

The ability to interpret sections made through the body, especially transverse sections, is important in the clinical sciences. New medical imaging devices (pp. 20–21) produce sectional images rather than three-dimensional images. It can be difficult to decipher an object's overall shape from sectioned material. A cross section of a banana, for example, looks like a circle and gives no indication of the whole banana's crescent shape. Likewise, sectioning the body or an organ along different planes often results in very different views. For example, a transverse section of the body trunk at the level of the kidneys would show kidney structure in cross section very nicely; a frontal section of the body trunk would show a different view of kidney anatomy; and a midsagittal section would miss the kidneys completely. With practice, you will gradually learn to relate two-dimensional sections to three-dimensional shapes.

Body Cavities and Membranes

Anatomy and physiology textbooks typically describe two sets of internal body cavities called the dorsal and ventral body cavities. These cavities are closed to the outside and provide different degrees of protection to the organs contained within them. Because these two cavities differ in their mode of embryonic development, and their lining membranes, the dorsal body cavity is not recognized as such in many anatomical references. However, the idea of two sets of internal body cavities is a useful learning concept and is used here.

Dorsal Body Cavity

The **dorsal body cavity,** which protects the fragile nervous system organs (Figure 1.9), has two subdivisions. The **cranial cavity,** in the skull, encases the brain. The **vertebral,** or **spinal, cavity,** which runs within the bony vertebral column, encloses the delicate spinal cord. The spinal cord is essentially a continuation of the brain, and the cranial and spinal cavities are continuous with one another.

Ventral Body Cavity

The more anterior and larger of the closed body cavities is the **ventral body cavity** (see Figure 1.9). Like the dorsal cavity, it has two major subdivisions, the *thoracic cavity* and the *abdominopelvic cavity.* The ventral body cavity houses internal organs collectively called the **viscera** (vis'er-ah; *viscus* = an organ in a body cavity), or visceral organs.

The superior subdivision, the **thoracic cavity** (tho-ras'ik), is surrounded by the ribs and muscles of the chest. The thoracic cavity is further subdivided into lateral **pleural cavities** (ploo'ral), each enveloping a lung, and the medial **mediastinum** (me"de-ah-sti'num). The mediastinum contains the **pericardial cavity** (per"ĭ-kar'de-al), which encloses the heart, and it also surrounds the remaining thoracic organs (esophagus, trachea, and others).

The thoracic cavity is separated from the more inferior **abdominopelvic cavity** (ab-dom'ĭ-no-pel'vic) by the diaphragm, a dome-shaped muscle important in breathing. The abdominopelvic cavity, as its name suggests, has two parts. However, these regions are not physically separated by a muscular or membrane wall. Its superior portion, the **abdominal cavity,** contains the stomach, intestines, spleen, liver, and other organs. The inferior part, the **pelvic cavity,** lies in the bony pelvis and contains the bladder, some reproductive organs, and the rectum. The abdominal and pelvic cavities are not aligned with each other. Instead, the bowl-shaped pelvis tips away from the perpendicular.

HOMEOSTATIC IMBALANCE

When the body is subjected to physical trauma (as often happens in an automobile accident), the abdominopelvic organs are most vulnerable. This is because the walls of the abdominal cavity are formed only by trunk muscles and are not reinforced by bone. The pelvic organs receive a somewhat greater degree of protection from the bony pelvis. ●

Q *Which of these planes would separate the woman's arms?*

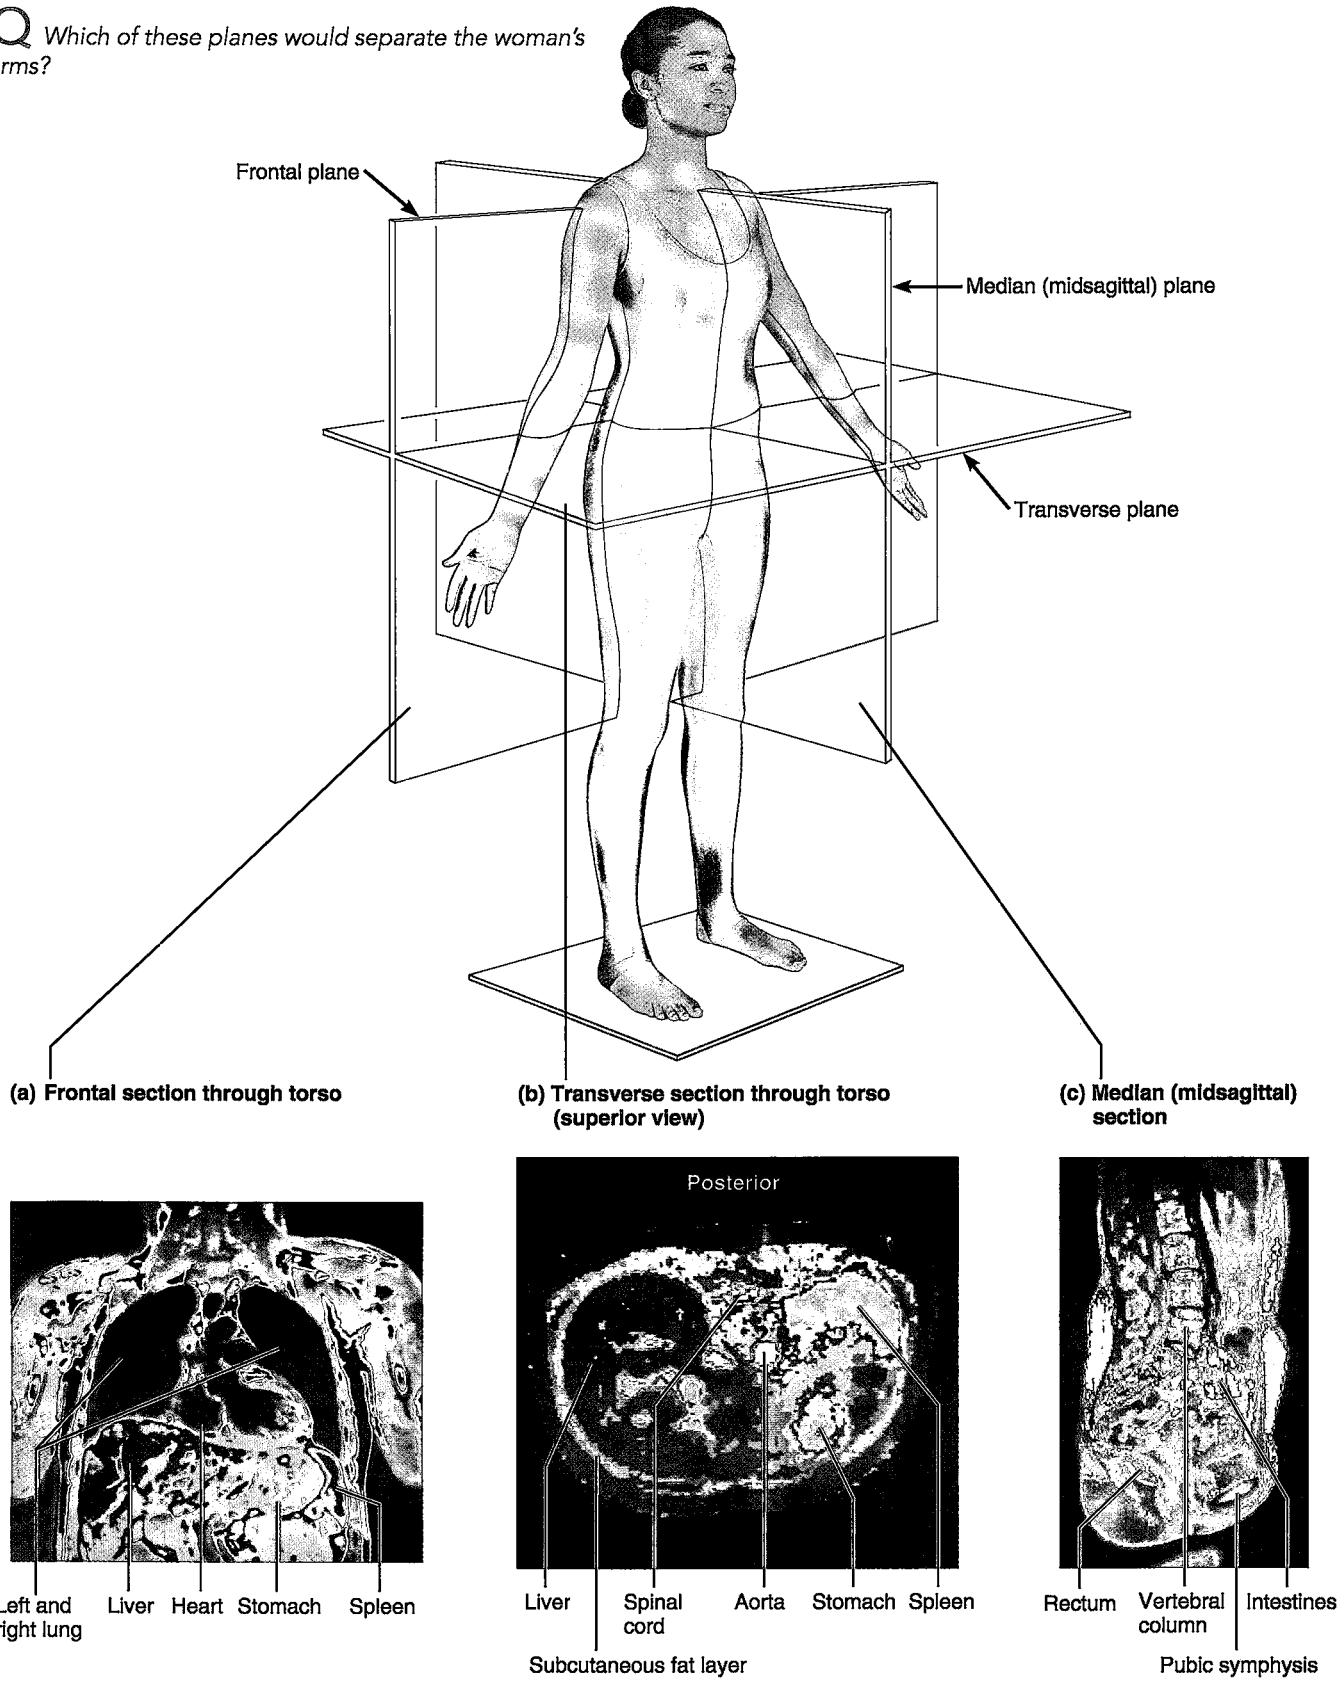

FIGURE 1.8 **Planes of the body—frontal, transverse, and median (midsagittal) with corresponding magnetic resonance imaging (MRI) scans.**

A Median or midsagittal.

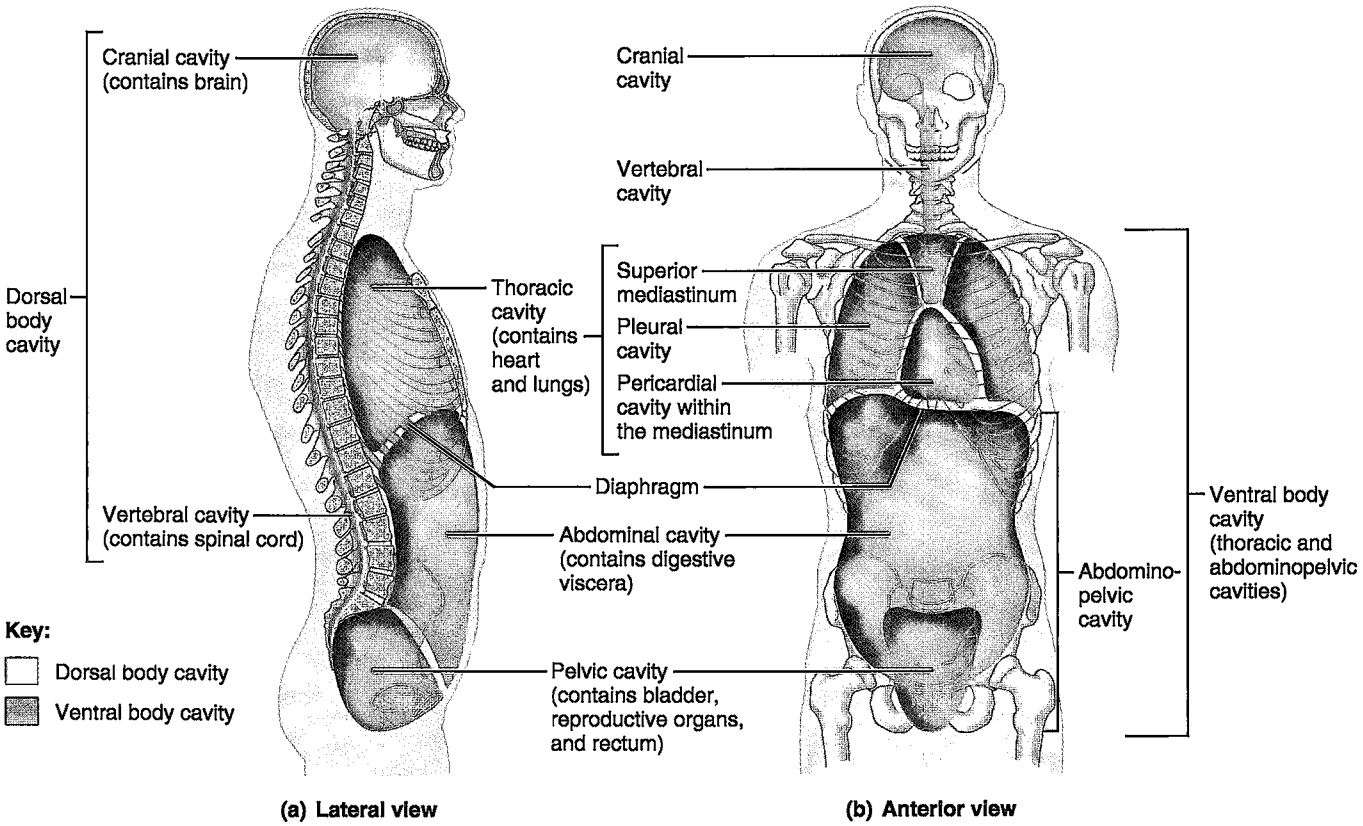

FIGURE 1.9 **Dorsal and ventral body cavities and their subdivisions.**

Membranes in the Ventral Body Cavity The walls of the ventral body cavity and the outer surfaces of the organs it contains are covered by a thin, double-layered membrane, the **serosa** (se-ro'sah), or **serous membrane.** The part of the membrane lining the cavity walls is called the **parietal serosa** (pah-ri'ĕ-tal; *parie* = wall). It folds in on itself to form the **visceral serosa,** covering the organs in the cavity.

You can visualize the relationship between the serosal layers by pushing your fist into a limp balloon (Figure 1.10a). The part of the balloon that clings to your fist can be compared to the visceral serosa clinging to the organ's external surface. The outer wall of the balloon then represents the parietal serosa that lines the walls of the cavity. (However, unlike the balloon, it is never exposed but is always fused to the cavity wall.) In the body, the serous membranes are separated not by air but by a thin layer of lubricating fluid, called **serous fluid,** which is secreted by both membranes. Although there is a potential space between the two membranes, the barely present, slit-like cavity is filled with serous fluid.

The slippery serous fluid allows the organs to slide without friction across the cavity walls and one another as they carry out their routine functions. This freedom of movement is especially important

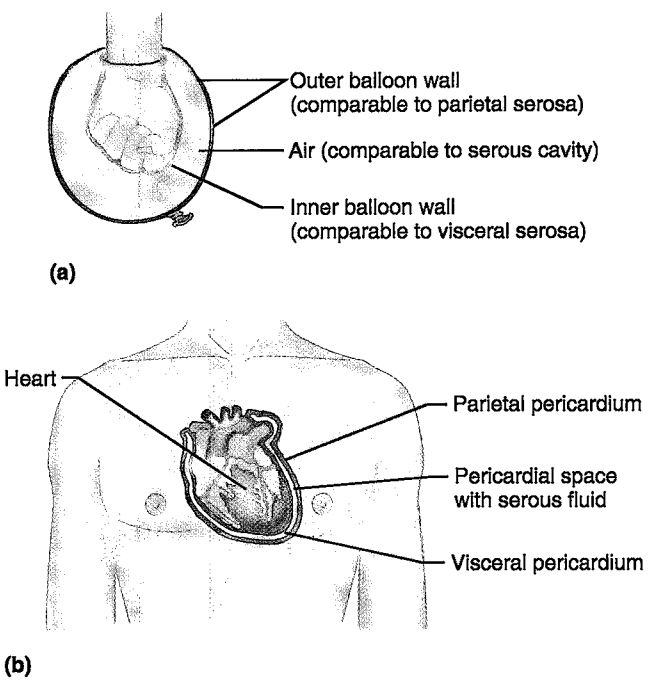

FIGURE 1.10 **Serous membrane relationships. (a)** A fist is thrust into a flaccid balloon to demonstrate the relationship between the parietal and visceral serous membrane layers. **(b)** The serosae associated with the heart. The parietal pericardium is the outer layer lining the pericardial cavity; the visceral pericardium clings to the external heart surface.

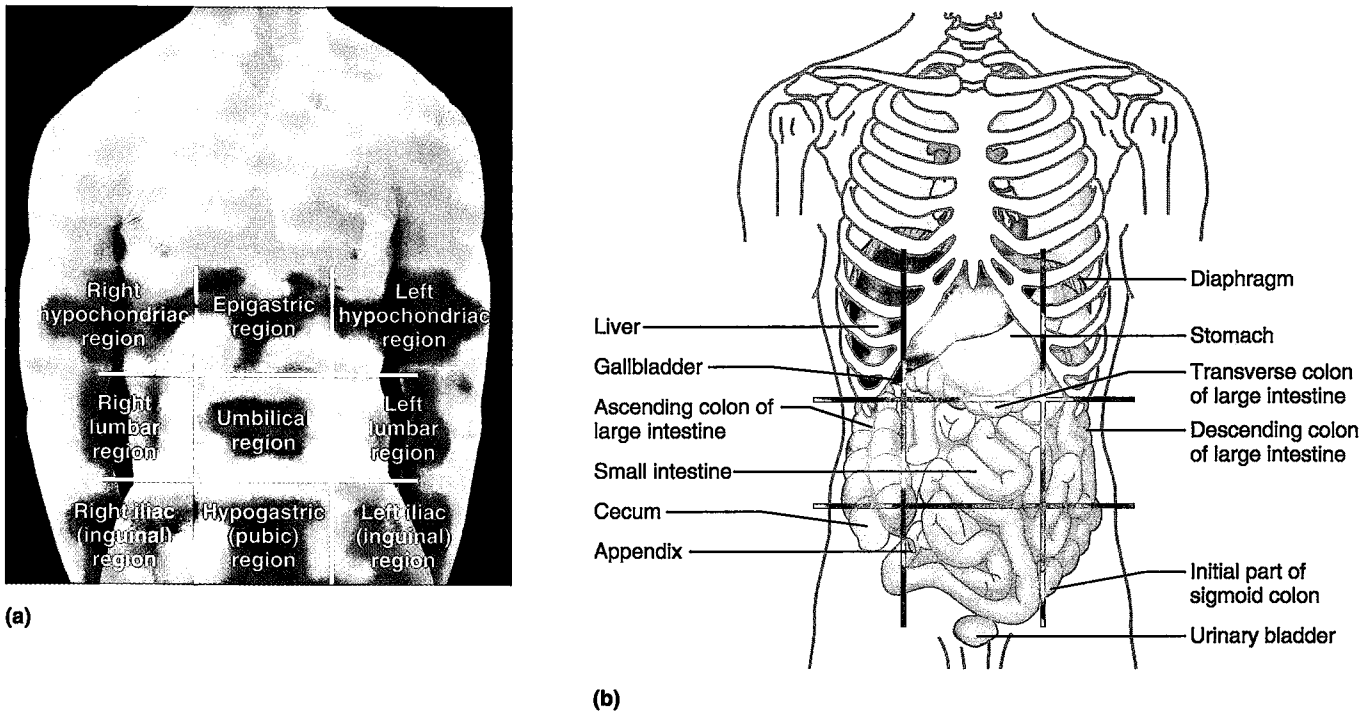

FIGURE 1.11 **The nine abdominopelvic regions. (a)** Division of the abdominopelvic cavity into nine regions delineated by four planes. The superior transverse plane is just inferior to the ribs; the inferior transverse plane is just superior to the hip bones; and the parasagittal planes lie just medial to the nipples. **(b)** Anterior view of the abdominopelvic cavity showing the superficial organs.

for mobile organs such as the pumping heart and the churning stomach.

The serous membranes are named for the specific cavity and organs with which they are associated. For example, as shown in Figure 1.10b, the *parietal pericardium* lines the pericardial cavity and reflects back as the *visceral pericardium*, which covers the heart. Likewise, the *parietal pleura* (ploo'rah) lines the walls of the thoracic cavity, and the *visceral pleura* covers the lungs. The *parietal peritoneum* (per"ĭ-to-ne'um) is associated with the walls of the abdominopelvic cavity, while the *visceral peritoneum* covers most of the organs within that cavity. (The pleural and peritoneal serosae are illustrated in Figure 4.12c on p. 142.)

HOMEOSTATIC IMBALANCE

When serous membranes are inflamed, their normally smooth surfaces become roughened. This leads to excruciating pain as the organs stick together and drag across one another, as anyone who has experienced *pleurisy* (inflammation of the pleurae) or *peritonitis* (inflammation of the peritonea) knows. ●

Abdominopelvic Regions and Quadrants

Because the abdominopelvic cavity is large and contains several organs, it helps to divide it into smaller areas for study. One division method, used primarily by anatomists, uses two transverse and two parasagittal planes. These planes, positioned like a tic-tac-toe grid on the abdomen, divide the cavity into nine regions (Figure 1.11):

- The **umbilical region** is the centermost region deep to and surrounding the umbilicus (navel).
- The **epigastric region** is located superior to the umbilical region (*epi* = upon, above; *gastri* = belly).
- The **hypogastric (pubic) region** is located inferior to the umbilical region (*hypo* = below).
- The **right** and **left iliac,** or **inguinal, regions** (ing'gwĭ-nal) are located lateral to the hypogastric region (*iliac* = superior part of the hip bone).
- The **right** and **left lumbar regions** lie lateral to the umbilical region (*lumbus* = loin).
- The **right** and **left hypochondriac regions** flank the epigastric region laterally (*chondro* = cartilage).

Medical personnel usually use a simpler scheme to localize the abdominopelvic cavity organs

(Figure 1.12). In this scheme, one transverse and one median sagittal plane pass through the umbilicus at right angles. The resulting quadrants are named according to their positions from the subject's point of view: the **right upper quadrant (RUQ), left upper quadrant (LUQ), right lower quadrant (RLQ),** and **left lower quadrant (LLQ).**

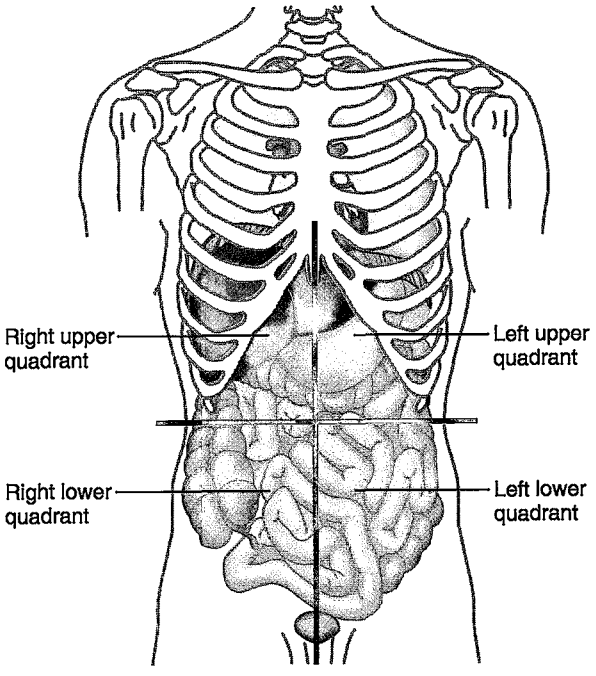

FIGURE 1.12 **The four abdominopelvic quadrants.** In this scheme, the abdominopelvic cavity is divided into four quadrants by two planes. The figure shows superficial organs within each quadrant.

Other Body Cavities

In addition to the large closed body cavities, there are several smaller body cavities (Figure 1.13). Most of these are in the head and most open to the body exterior:

1. Oral and digestive cavities. The oral cavity, commonly called the mouth, contains the teeth and tongue. This cavity is part of and continuous with the cavity of the digestive organs, which opens to the exterior at the anus.

2. Nasal cavity. Located within and posterior to the nose, the nasal cavity is part of the respiratory system passageways.

3. Orbital cavities. The orbital cavities (orbits) in the skull house the eyes and present them in an anterior position.

4. Middle ear cavities. The middle ear cavities carved into the skull lie just medial to the eardrums. These cavities contain tiny bones that transmit sound vibrations to the hearing receptors in the inner ears.

5. Synovial cavities (sĭ-no've-al). Synovial cavities are joint cavities. They are enclosed within fibrous capsules that surround freely movable joints of the body (such as the elbow and knee joints). Like the serous membranes, membranes lining synovial cavities secrete a lubricating fluid that reduces friction as the bones move across one another.

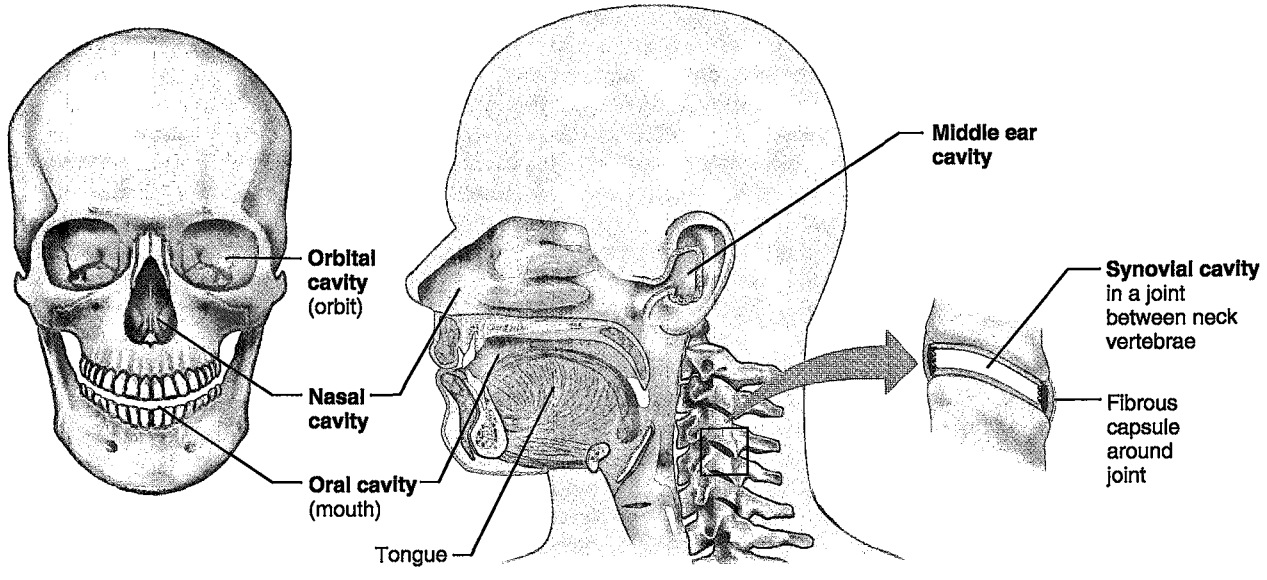

FIGURE 1.13 **Other body cavities.** The oral, nasal, orbital, and middle ear cavities are located in the head and open to the body exterior. Synovial cavities are found in the joints between many bones, such as the vertebrae of the spine.

A CLOSER LOOK

Medical Imaging: Illuminating the Body

Until 50 years ago, the magical but murky X ray was the only nonsurgical means to extract information from within a living body. Produced by directing *X rays,* electromagnetic waves of very short wavelength, at the body, an **X ray** or **radiograph** is essentially a shadowy negative of internal structures. Dense structures absorb the X rays most and so appear as light areas on the radiograph. Hollow air-containing organs and fat, which absorb the X rays less, show up as dark areas. What X rays do best is visualize hard, bony structures and locate abnormally dense structures (tumors, tuberculosis nodules) in the lungs.

The 1950s saw the advent of nuclear medicine, which uses radioisotopes to scan the body, and ultrasound techniques. The 1970s brought CT, PET, and MRI scans. These technologies not only reveal the structure of our "insides" but also wring out information about the private, and until then secret, workings of their molecules.

Computed tomography (CT, formerly called **computerized axial tomography, CAT)** utilizes a refined version of X-ray equipment. As the patient is slowly moved through the doughnut-shaped CT machine, its X-ray tube rotates around the body and sends beams from all directions to a specific level of the patient's body. Because at any moment its beam is confined to a "slice" of the body about as thick as a dime, CT ends the confusion resulting from overlapping structures seen in conventional X rays. The device's computer translates this information into a detailed, cross-sectional picture of each body region scanned. CT scans are at the forefront for evaluating most problems that affect the brain and abdomen [see photo (a)], and their clarity has all but eliminated exploratory surgery. Some found it troubling, when, in the early 2000s, CT-screening centers sprung up like weeds in many United States cities. The lure of these centers goes something like this: "You think you're healthy, right? So did Joe So-and-So until he died of a heart attack. Have a whole body scan to save yourself from life-threatening conditions." Most people that use CT-screening centers do so without medical consultation and then take the results to a doctor. Although such scans may save some lives, they also turn up anomalies that are not medically dangerous, resulting in unnecessary surgery and/or hospital stays at considerable expense. The assumption that there was a huge market of people willing to dip into their pockets has proven untrue and this "medical bubble" has rapidly deflated.

Xenon CT is a CT brain scan enhanced with xenon, a radioactive gas, to quickly trace blood flow. Inhaled xenon rapidly enters the bloodstream and distributes to different body tissues in proportion to their blood flow. Absence of xenon from part of the brain indicates that a stroke is occurring there, information that aids treatment.

Dynamic spatial reconstruction (DSR) uses ultrafast CT scanners to provide three-dimensional images of body organs from any angle, and scrutinize their movements and changes in their internal volumes at normal speed, in slow motion, and at a specific moment. DSR's greatest value has been to visualize the heart beating and blood flowing through blood vessels, allowing clinicians to evaluate heart defects, constricted or blocked blood vessels, and the status of coronary bypass grafts.

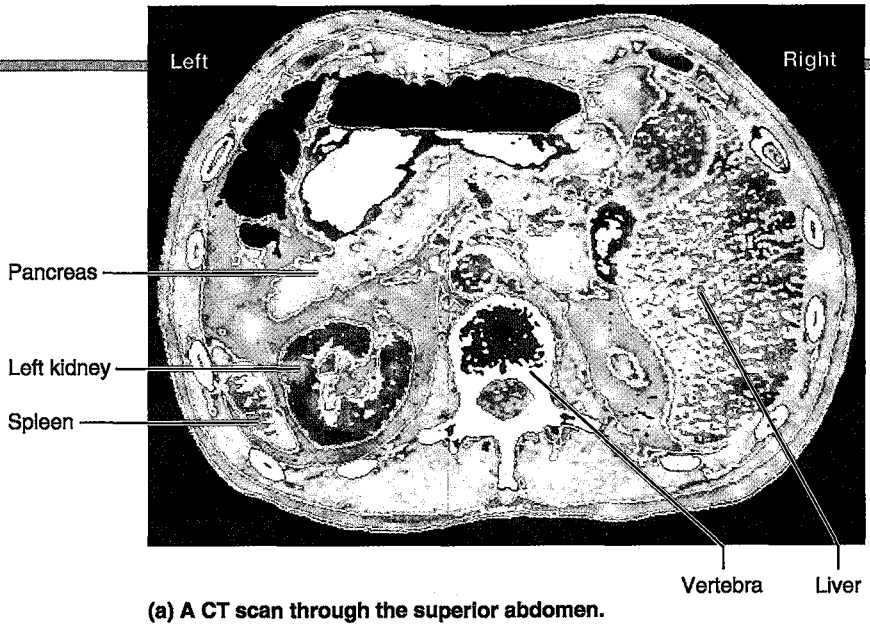
Another computer-assisted X-ray technique, **digital subtraction angiography (DSA)** (*angiography* = "vessel pictures"), provides an unobstructed view of small arteries. Conventional radiographs are taken before and after a contrast medium is injected into an artery. The computer subtracts the "before" image from the "after" image, eliminating all traces of body structures that obscure the vessel. DSA is often used to identify blockages in the arteries that supply the heart wall [photo (b)] and brain.

Just as the X ray spawned "big brothers," so too did nuclear medicine in the form of **positron emission tomography (PET).** PET excels in observing *metabolic processes.* The patient is given an injection of radioisotopes tagged to biological molecules (such as glucose) and is then positioned in the PET scanner. As the radioisotopes are absorbed by the most active brain cells, high-energy gamma rays are produced. The computer analyzes the gamma-ray emission and produces a live-action picture of the brain's biochemical activity in vivid colors. PET's greatest value has been its ability to provide insights into brain activity in people affected by mental illness, stroke, Alzheimer's disease, and epilepsy. One of its most exciting uses has been to determine which areas of the healthy brain are most active during certain tasks (e.g., speaking, listening to music, or figuring out a mathematical problem), providing direct evidence of the functions of specific brain regions.

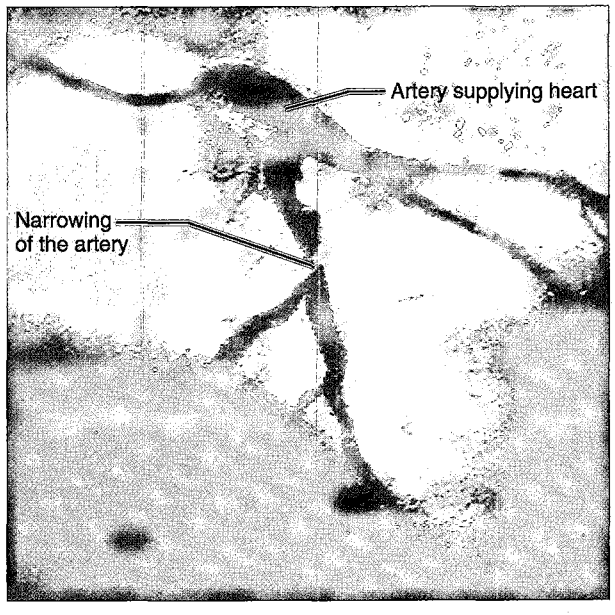
Sonography, or **ultrasound imaging,** has some distinct advantages over the approaches examined so far. The equipment is inexpensive and ultrasound used as its energy source seems to be safer than the ionizing forms of radiation used in nuclear medicine. The body is probed with pulses of sound waves that cause echoes when reflected and scattered by body tissues. A computer analyzes these echoes to construct somewhat blurry outlines of body organs. A single easy to use handheld device emits the sound and picks up the echoes, so sections can be scanned from many different body planes.

Because of its safety, ultrasound is the imaging technique of choice in obstetrics for determining fetal age and position and locating the placenta. However, sound waves have low penetrating power and rapidly dissipate in air, so sonography is of little value for looking at air-filled structures (the lungs) or those surrounded by bone (the brain and spinal cord).

Magnetic resonance imaging (MRI) produces high-contrast images of our soft tissues, an area in which X rays and CT scans are weak. As initially developed, MRI primarily maps the element hydrogen in the body, most of which is in water. The technique subjects the body to magnetic fields up to 60,000 times stronger than that of the earth to pry information from the body's molecules. The patient lies in a chamber within a huge magnet. Hydrogen molecules act like tiny magnets, spinning like tops in the magnetic field.



(a) A CT scan through the superior abdomen.



(b) A (DSA) image of the arteries that supply the heart.

Their energy is further enhanced by radio waves and when the radio waves are turned off, the energy released is translated into a visual image.

MRI distinguishes body tissues based on their water content, so it can differentiate between the fatty white matter and the more watery gray matter of the brain. Because dense structures do not show up at all in MRI, it peers easily into the skull and vertebral column, enabling the delicate nerve fibers of the spinal cord to be seen. MRI is also particularly good at detecting tumors and degenerative disease. Multiple sclerosis plaques do not show up well in CT scans, but are dazzlingly clear in MRI scans. MRI can also tune in on metabolic reactions, such as processes that generate energy-rich ATP molecules. Until recently, trying to diagnose asthma and other lung problems has been off limits to MRI scans because the lungs have a low water content. However, an alternate tack—filling the lungs with a gas that can be magnetized (hyperpolarized helium-3 or xenon-129)—has yielded spectacular pictures of the lungs in just the few seconds it takes the patient to inhale, hold the breath briefly, and then exhale—a distinct improvement over the hours required for conventional MRI. This technique has the additional advantage of using a magnetic field as little as one-tenth that of the conventional MRI.

Newer variations of MRI include **magnetic resonance spectroscopy (MRS),** which maps the distribution of elements other than hydrogen to reveal more about how disease changes body chemistry. Other advances in computer techniques display MRI scans in three dimensions to guide laser surgery. The **functional MRI** tracks blood flow into the brain in real time. Matching thoughts, deeds, and disease to brain activity has been the sole domain of PET. Because functional MRI does not require injections of tracers and can pinpoint much smaller brain areas than PET, it may provide a desirable alternative.

Despite its advantages, the powerful magnets of the clanging, claustrophobia-inducing MRI present some thorny problems. For example, they can "suck" metal objects, such as implanted pacemakers and loose tooth fillings, through the body. Moreover, although such strong magnetic fields are currently considered safe, there is no convincing evidence that they are risk free.

Although stunning, medical images other than straight X rays are abstractions assembled within the "mind" of a computer. They are artificially enhanced for sharpness and artificially colored to increase contrast (all their colors are "phony"). The images are several steps removed from direct observation.

As you can see, medical science offers remarkable diagnostic tools. Consider the M2A Swallowable Imaging Capsule, a tiny camera that is swallowed like a pill, then excreted normally 8–72 hours later. As the M2A travels through the digestive tract, it photographs the small intestine and beams the color images to a Walkman-sized receiver. A study found the device to be 60% effective at detecting intestinal problems, compared to a 35% success rate with other imaging techniques. At present the M2A can provide images only of the small intestine because the battery gives out before it enters the large intestine.

New imaging technologies also make long-distance surgery possible. Visual images of a diseased organ travel via fiber-optic cable to surgeons at another location (even a different country), who manipulate delicate robotic instruments to remove the organ. ■

Chapter Summary

An Overview of Anatomy and Physiology (pp. 2–3)

1. Anatomy is the study of body structures and their relationships. Physiology is the science of how body parts function.

Topics of Anatomy (pp. 2–3)

2. Major subdivisions of anatomy include gross anatomy, microscopic anatomy, and developmental anatomy.

Topics of Physiology (p. 3)

3. Typically, physiology concerns the functioning of specific organs or organ systems. Examples include cardiac physiology, renal physiology, and muscle physiology.

4. Physiology is explained by chemical and physical principles.

Complementarity of Structure and Function (p. 3)

5. Anatomy and physiology are inseparable: What a body can do depends on the unique architecture of its parts. This is called the complementarity of structure and function.

Levels of Structural Organization (pp. 3–4)

1. The levels of structural organization of the body, from simplest to most complex, are: chemical, cellular, tissue, organ, organ system, and organismal.

2. The 11 organ systems of the body are the integumentary, skeletal, muscular, nervous, endocrine, cardiovascular, lymphatic, respiratory, digestive, urinary, and reproductive systems. The immune system is a functional system closely associated with the lymphatic system. (For functions of these systems see pp. 6–7.)

Maintaining Life (pp. 4–8)

Necessary Life Functions (pp. 4–8)

1. All living organisms carry out certain vital functional activities necessary for life, including maintenance of boundaries, movement, responsiveness, digestion, metabolism, excretion, reproduction, and growth.

Survival Needs (p. 8)

2. Survival needs include nutrients, water, oxygen, and appropriate body temperature and atmospheric pressure.

Homeostasis (pp. 9–12)

1. Homeostasis is a dynamic equilibrium of the internal environment. All body systems contribute to homeostasis, but the nervous and endocrine systems are most important. Homeostasis is necessary for health.

Homeostatic Control Mechanisms (pp. 9–11)

2. Control systems of the body contain at least three elements: receptor(s), control center, and effector(s).

3. Negative feedback mechanisms reduce the original stimulus, and are essential for maintaining homeostasis. Body temperature, heart rate, breathing rate and depth, and blood levels of glucose and certain ions are regulated by negative feedback mechanisms.

4. Positive feedback mechanisms intensify the initial stimulus, leading to an enhancement of the response. They rarely contribute to homeostasis, but blood clotting and labor contractions are regulated by such mechanisms.

Homeostatic Imbalance (pp. 11–12)

5. With age, the efficiency of negative feedback mechanisms declines, and positive feedback mechanisms occur more frequently. These changes underlie certain disease conditions.

The Language of Anatomy (pp. 12–19)

Anatomical Position and Directional Terms (p. 12)

1. In the anatomical position, the body is erect, facing forward, feet together, arms at sides with palms forward.

2. Directional terms allow body parts to be located precisely. Terms used to describe body directions and orientation include: superior/inferior; anterior/posterior; ventral/dorsal; medial/lateral; intermediate; proximal/distal; and superficial/deep.

Regional Terms (pp. 12–14)

3. Regional terms are used to designate specific areas of the body (see Figure 1.7).

Anatomical Variability (pp. 14–15)

4. People vary internally as well as externally, although extreme variations are rare.

Body Planes and Sections (p. 15)

5. The body or its organs may be cut along planes, or imaginary lines, to produce different types of sections. Frequently used planes are sagittal, frontal, and transverse.

Body Cavities and Membranes (pp. 15, 17–19)

6. The body contains two major closed cavities. The dorsal cavity, subdivided into the cranial and spinal cavities, contains the brain and spinal cord. The ventral cavity is subdivided into the thoracic cavity, which houses the heart and lungs, and the abdominopelvic cavity, which contains the liver, digestive organs, and reproductive structures.

7. The walls of the ventral cavity and the surfaces of the organs it contains are covered with thin membranes, the parietal and visceral serosae, respectively. The serosae produce a thin fluid that decreases friction during organ functioning.

8. The abdominopelvic cavity may be divided by four planes into nine abdominal regions (epigastric, umbilical, hypogastric, right and left iliac, right and left lumbar, and right and left hypochondriac), or by two planes into four quadrants. (For boundaries and organs contained see Figures 1.11 and 1.12.)

9. There are several smaller body cavities. Most of these are in the head and open to the exterior.

Review Questions

Multiple Choice/Matching

(Some questions have more than one correct answer. Select the best answer or answers from the choices given.)

1. The correct sequence of levels forming the structural hierarchy is (a) organ, organ system, cellular, chemical, tissue, organismal; (b) chemical, cellular, tissue, organismal, organ, organ system; (c) chemical, cellular, tissue, organ, organ system, organismal; (d) organismal, organ system, organ, tissue, cellular, chemical.

2. The structural and functional unit of life is (a) a cell, (b) an organ, (c) the organism, (d) a molecule.

3. Which of the following is a *major* functional characteristic of all organisms? (a) movement, (b) growth, (c) metabolism, (d) responsiveness, (e) all of these.

4. Two of these organ systems bear the *major* responsibility for ensuring homeostasis of the internal environment. Which two? (a) nervous system, (b) digestive system, (c) cardiovascular system, (d) endocrine system, (e) reproductive system.

5. In (a)–(e), a directional term [e.g., distal in (a)] is followed by terms indicating different body structures or locations (e.g., the elbow/the wrist). In each case, choose the structure or organ that matches the given directional term.

(a) distal: the elbow/the wrist
(b) lateral: the hip bone/the umbilicus
(c) superior: the nose/the chin
(d) anterior: the toes/the heel
(e) superficial: the scalp/the skull

6. Assume that the body has been sectioned along three planes: (1) a median sagittal plane, (2) a frontal plane, and (3) a transverse plane made at the level of each of the organs listed below. Which organs would not be visible in all three cases? (a) urinary bladder, (b) brain, (c) lungs, (d) kidneys, (e) small intestine, (f) heart.

7. Relate each of the following conditions or statements to either the dorsal body cavity or the ventral body cavity.

(a) surrounded by the bony skull and the vertebral column
(b) includes the thoracic and abdominopelvic cavities
(c) contains the brain and spinal cord
(d) contains the heart, lungs, and digestive organs

8. Which of the following relationships is *incorrect*?

(a) visceral peritoneum/outer surface of small intestine
(b) parietal pericardium/outer surface of heart
(c) parietal pleura/wall of thoracic cavity

9. Which ventral cavity subdivision has no bony protection? (a) thoracic cavity, (b) abdominal cavity, (c) pelvic cavity.

10. Terms that apply to the backside of the body in the anatomical position include:

(a) ventral; anterior
(b) back; rear
(c) posterior; dorsal
(d) medial; lateral

Short Answer Essay Questions

11. According to the principle of complementarity, how does anatomy relate to physiology?

12. Construct a table that lists the 11 systems of the body, names two organs of each system (if appropriate), and describes the overall or major function of each system.

13. List and describe briefly five external factors that must be present or provided to sustain life.

14. Define homeostasis.

15. Compare and contrast the operation of negative and positive feedback mechanisms in maintaining homeostasis. Provide two examples of variables controlled by negative feedback mechanisms and one example of a process regulated by a positive feedback mechanism.

16. Describe and assume the anatomical position. Why is an understanding of this position important? What is the importance of directional terms?

17. Define plane and section.

18. Provide the anatomical term that correctly names each of the following body regions: (a) arm, (b) thigh, (c) chest, (d) fingers and toes, (e) anterior aspect of the knee.

19. Use as many directional terms as you can to describe the relationship between the elbow's olecranal region and your palm.

20. (a) Make a diagram showing the nine abdominopelvic regions, and name each region. Name two organs (or parts of organs) that could be located in each of the named regions. (b) Make a similar sketch illustrating how the abdominopelvic cavity may be divided into quadrants, and name each quadrant.

Critical Thinking and Clinical Application Questions

1. John has been suffering agonizing pain with each breath and has been informed by the physician that he has pleurisy. (a) Specifically, what membranes are involved in this condition? (b) What is their usual role in the body? (c) Explain why John's condition is so painful.

2. At the clinic, Harry was told that blood would be drawn from his antecubital region. What body part was Harry asked to hold out? Later, the nurse came in and gave Harry a shot of penicillin in the area just distal to his acromial region. Did Harry take off his shirt or drop his pants to receive the injection? Before Harry left, the nurse noticed that Harry had a nasty bruise on his gluteal region. What part of his body was black and blue?

3. A man is behaving abnormally, and his physician suspects that he has a brain tumor. Which of the following medical imaging devices would best localize the tumor in the man's brain (and why)? Conventional X ray, DSA, PET, sonography, MRI.

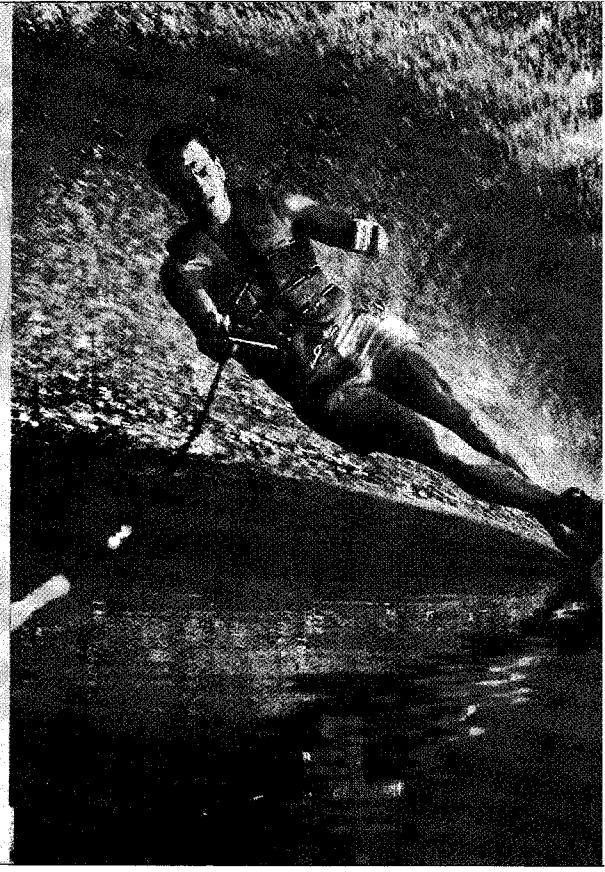
4. When we become dehydrated, we usually feel thirsty, which causes us to drink fluids. Decide whether the thirst sensation is part of a negative or positive feedback control system and defend your choice.

5. Mr. Harvey, a computer programmer, has been complaining of numbness and pain in his right hand. The nurse practitioner diagnosed his problem as carpal tunnel syndrome and prescribed use of a splint. Where will Mr. Harvey apply the splint?

LOOKING FOR MORE STUDY HELP?
A wide variety of quiz questions, tutorials, and learning exercises are available online at the Anatomy & Physiology Place (www.anatomyandphysiology.com) and, if your instructor has provided you with a MyA&P Course ID number, in MyA&P (www.myaandp.com).

CHAPTER

Chemistry Comes Alive



PART 1: BASIC CHEMISTRY

Definition of Concepts: Matter and Energy (pp. 25–26)

1. Differentiate between matter and energy and between potential energy and kinetic energy.
2. Describe the major energy forms.

Composition of Matter: Atoms and Elements (pp. 27–30)

3. Define chemical element and list the four elements that form the bulk of body matter.
4. Define atom. List the subatomic particles; describe their relative masses, charges, and positions in the atom.
5. Define atomic number, atomic mass, atomic weight, isotope, and radioisotope.

How Matter Is Combined: Molecules and Mixtures (pp. 30–31)

6. Distinguish between a compound and a mixture. Define molecule.
7. Compare solutions, colloids, and suspensions.

Chemical Bonds (pp. 31–36)

8. Explain the role of electrons in chemical bonding and in relation to the octet rule.
9. Differentiate among ionic, covalent, and hydrogen bonds.
10. Compare and contrast polar and nonpolar compounds.

Chemical Reactions (pp. 36–40)

11. Define the three major types of chemical reactions: synthesis, decomposition, and exchange. Comment on the nature of oxidation-reduction reactions and their importance.
12. Explain why chemical reactions in the body are often irreversible.
13. Describe factors that affect chemical reaction rates.

PART 2: BIOCHEMISTRY

Inorganic Compounds (pp. 40–43)

14. Explain the importance of water and salts to body homeostasis.
15. Define acid and base, and explain the concept of pH.

Organic Compounds (pp. 43–59)

16. Describe and compare the building blocks, general structures, and biological functions of carbohydrates, lipids, proteins, and nucleic acids.
17. Explain the role of dehydration synthesis and hydrolysis in the formation and breakdown of organic molecules.
18. Describe the four levels of protein structure.
19. Describe the general mechanism of enzyme activity.
20. Describe the function of molecular chaperones.
21. Compare and contrast DNA and RNA.
22. Explain the role of ATP in cell metabolism.

Why study chemistry in an anatomy and physiology course? The answer is simple. Your entire body is made up of chemicals, thousands of them, continuously interacting with one another at an incredible pace. Although it is possible to study anatomy without much reference to chemistry, chemical reactions underlie all physiological processes—movement, digestion, the pumping of your heart, and even your thoughts. This chapter presents the basic chemistry and biochemistry (the chemistry of living material) needed to understand body functions.

PART 1: BASIC CHEMISTRY

Definition of Concepts: Matter and Energy

Matter

Matter is the "stuff" of the universe. More precisely, **matter** is anything that occupies space and has mass. With some exceptions, it can be seen, smelled, and felt. For all practical purposes, we can consider mass to be the same as weight. However, this usage is not quite accurate. The *mass* of an object, which is equal to the actual amount of matter in the object, remains constant wherever the object is. In contrast, weight varies with gravity. So while your mass is the same at sea level and on a mountaintop, you weigh just slightly less on that mountaintop. The science of chemistry studies the nature of matter, especially how its building blocks are put together and interact.

States of Matter

Matter exists in *solid, liquid,* and *gaseous states.* Examples of each state are found in the human body. Solids, like bones and teeth, have a definite shape and volume. Liquids such as blood plasma have a definite volume, but they conform to the shape of their container. Gases have neither a definite shape nor a definite volume. The air we breathe is a gas.

Energy

Compared with matter, energy is less tangible. It has no mass, does not take up space, and can be measured only by its effects on matter. **Energy** is defined as the capacity to do work, or to put matter into motion. The greater the work done, the more energy is used doing it. A baseball player who has just hit the ball over the fence uses much more energy than a batter who just bunts the ball back to the pitcher.

Kinetic Versus Potential Energy

Energy exists in two forms, or work capacities, each transformable to the other. **Kinetic energy** (ki-net'ik) is energy in action. Kinetic energy is seen in the constant movement of the tiniest particles of matter (atoms) as well as in larger objects (a bouncing ball). It does work by moving objects, which in turn can do work by moving or pushing on other objects. For example, a push on a swinging door sets it into motion.

Potential energy is stored energy, that is, inactive energy that has the *potential,* or capability, to do work but is not presently doing so. The batteries in an unused toy have potential energy, as do your leg muscles when you sit still on the couch. When potential energy is released, it becomes kinetic energy and so is capable of doing work. For example, dammed water becomes a rushing torrent when the dam is opened, and that rushing torrent can move a turbine at a hydroelectric plant, or charge a battery.

Actually, energy is a topic of physics, but matter and energy are inseparable. Matter is the substance, and energy is the mover of the substance. All living things are composed of matter and they all require energy to grow and function. It is the release and use of energy by living systems that gives us the elusive quality called life. Thus, it is worth taking a brief detour to introduce the forms of energy used by the body as it does its work.

Forms of Energy

- **Chemical energy** is the form stored in the bonds of chemical substances. When chemical reactions occur that rearrange the atoms of the chemicals in a certain way, the potential energy is unleashed and becomes kinetic energy, or energy in action.

For example, some of the energy in the foods you eat is eventually converted into the kinetic energy of your moving arm. However, food fuels cannot be used to energize body activities directly. Instead, some of the food energy is captured temporarily in the bonds of a chemical called *adenosine triphosphate (ATP)* (ah-den'o-sēn tri"fos'fāt). Later, ATP's bonds are broken and the stored energy is released as needed to do cellular work. Chemical energy in the form of ATP is the most useful form of energy in living systems because it is used to run all functional processes.

- **Electrical energy** results from the movement of charged particles. In your home, electrical energy is found in the flow of electrons along the household wiring. In your body, electrical currents are generated when charged particles called *ions* move along or across cell membranes. The nervous system uses electrical currents, called *nerve impulses,* to transmit messages from one part of the body to another.

TABLE 2.1 Common Elements Composing the Human Body*

ELEMENT	ATOMIC SYMBOL	APPROX. % BODY MASS†	FUNCTIONS
MAJOR (96.1%)			
Oxygen	O	65.0	A major component of both organic (carbon-containing) and inorganic (non-carbon-containing) molecules; as a gas, it is needed for the production of cellular energy (ATP)
Carbon	C	18.5	A primary component of all organic molecules, which include carbohydrates, lipids (fats), proteins, and nucleic acids
Hydrogen	H	9.5	A component of all organic molecules; as an ion (proton), it influences the pH of body fluids
Nitrogen	N	3.2	A component of proteins and nucleic acids (genetic material)
LESSER (3.9%)			
Calcium	Ca	1.5	Found as a salt in bones and teeth; its ionic (Ca^{2+}) form is required for muscle contraction, conduction of nerve impulses, and blood clotting
Phosphorus	P	1.0	Part of calcium phosphate salts in bones and teeth; also present in nucleic acids; part of ATP
Potassium	K	0.4	Its ion (K^+) is the major positive ion (cation) in cells; necessary for conduction of nerve impulses and muscle contraction
Sulfur	S	0.3	Component of proteins, particularly muscle proteins
Sodium	Na	0.2	As an ion (Na^+), sodium is the major positive ion found in extracellular fluids (fluids outside of cells); important for water balance, conduction of nerve impulses, and muscle contraction
Chlorine	Cl	0.2	Ionic chlorine (Cl^-) is the most abundant negative ion (anion) in extracellular fluids
Magnesium	Mg	0.1	Present in bone; also an important cofactor in a number of metabolic reactions
Iodine	I	0.1	Needed to make functional thyroid hormones
Iron	Fe	0.1	Component of hemoglobin (which transports oxygen within red blood cells) and some enzymes
TRACE (LESS THAN 0.01%)			
Chromium (Cr); cobalt (Co); copper (Cu); fluorine (F); manganese (Mn); molybdenum (Mo); selenium (Se); silicon (Si); tin (Sn); vanadium (V); zinc (Zn)			
These elements are referred to as *trace elements* because they are required in very minute amounts; many are found as part of enzymes or are required for enzyme activation.			

*A listing of the elements by ascending order of atomic number appears in the periodic table, Appendix E.
†Percentage of "wet" body mass; includes water.

Electrical currents traveling across the heart stimulate it to contract (beat) and pump blood. (This is why a strong electrical shock, which interferes with such currents, can cause death.)

- **Mechanical energy** is energy *directly* involved in moving matter. When you ride a bicycle, your legs provide the mechanical energy that moves the pedals.
- **Radiant energy,** or **electromagnetic energy** (e-lek"tro-mag-net'ik), is energy that travels in waves. These waves, which vary in length, are collectively called the *electromagnetic spectrum* and include visible light, infrared waves, radio waves, ultraviolet waves, and X rays. Light energy, which stimulates the retinas of our eyes, is important in vision. Ultraviolet waves cause sunburn, but they also stimulate our body to make vitamin D.

Energy Form Conversions

With few exceptions, energy is easily converted from one form to another. For example, chemical energy

(gasoline) that powers the motor of a speedboat is converted into the mechanical energy of the whirling propeller that allows the boat to skim across the water. Energy conversions are quite inefficient; some of the initial energy supply is always "lost" to the environment as heat. (It is not really lost because energy cannot be created or destroyed, but that part given off as heat is at least partly *unusable.*) It is easy to demonstrate this principle. Electrical energy is converted into light energy in a lightbulb. But if you touch a lit bulb, you will soon discover that some of the electrical energy is producing heat instead. Likewise, all energy conversions that occur in the body liberate heat. This heat contributes to our relatively high body temperature, which has an important influence on body functioning. For example, when matter is heated, the kinetic energy of its particles increases and they begin to move more quickly. The higher the temperature, the faster the body's chemical reactions occur. We will learn more about this later.

Composition of Matter: Atoms and Elements

All matter is composed of **elements,** unique substances that cannot be broken down into simpler substances by ordinary chemical methods. Among the well-known elements are oxygen, carbon, gold, silver, copper, and iron. At present, 112 elements are known with certainty (and numbers 113, 114, 115, and 116 are alleged). Of these, 92 occur in nature. The rest are made artificially in particle accelerator devices. Four elements—carbon, oxygen, hydrogen, and nitrogen—make up about 96% of body weight; 20 others are present in the body, some in trace amounts. The elements contributing to body mass and their importance are given in Table 2.1. A kind of odd-shaped checkerboard called the **periodic table** provided in Appendix E provides a more complete listing of the known elements.

Each element is composed of more or less identical particles or building blocks, called **atoms.** The smallest atoms are less than 0.1 nanometer (nm) in diameter, and the largest are only about five times as large. [1 nm = 0.0000001 (or 10^{-7}) centimeter (cm), or 40 billionths of an inch!]

Every element's atoms differ from those of all other elements and give the element its unique physical and chemical properties. *Physical properties* are those we can detect with our senses (such as color and texture) or measure (such as boiling point and freezing point). *Chemical properties* pertain to the way atoms interact with other atoms (bonding behavior) and account for the facts that iron rusts, animals can digest their food, and so on.

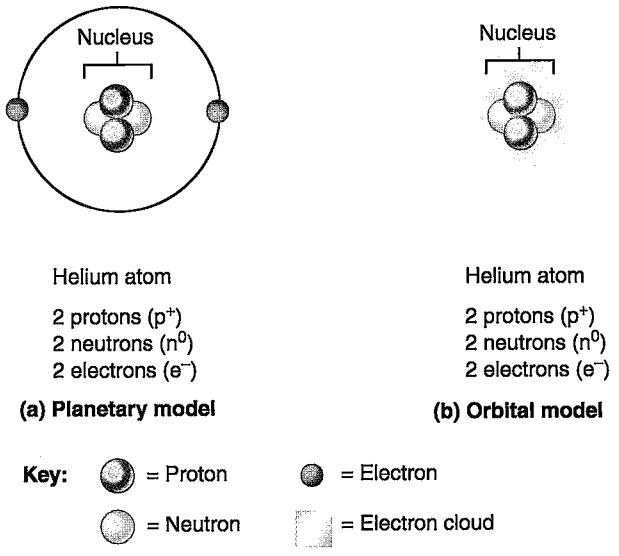


FIGURE 2.1 **The structure of an atom.** The dense central nucleus contains the protons and neutrons. **(a)** In the planetary model of atomic structure, the electrons move around the nucleus in fixed orbits. **(b)** In the orbital model, electrons are shown as a cloud of negative charge (electron cloud).

Each element is designated by a one- or two-letter chemical shorthand called an **atomic symbol,** usually the first letter(s) of the element's name. For example, C stands for carbon, O for oxygen, and Ca for calcium. In a few cases, the atomic symbol is taken from the Latin name for the element. For example, sodium is indicated by Na, from the Latin word *natrium.*

Atomic Structure

The word *atom* comes from the Greek word meaning "indivisible." However, we now know that atoms are clusters of even smaller particles called protons, neutrons, and electrons and that even those subatomic particles can be subdivided with high-technology tools. Even so, the old idea of atomic indivisibility is still helpful because an atom loses the unique properties of its element when it is split into its subatomic particles.

An atom's subatomic particles differ in mass, electrical charge, and position in the atom. An atom has a central **nucleus** containing protons and neutrons tightly bound together. The nucleus, in turn, is surrounded by orbiting electrons (Figure 2.1). **Protons** (p^+) bear a positive electrical charge, and **neutrons** (n^0) are neutral. Thus, the nucleus is positively charged overall. Protons and neutrons are heavy particles and have approximately the same

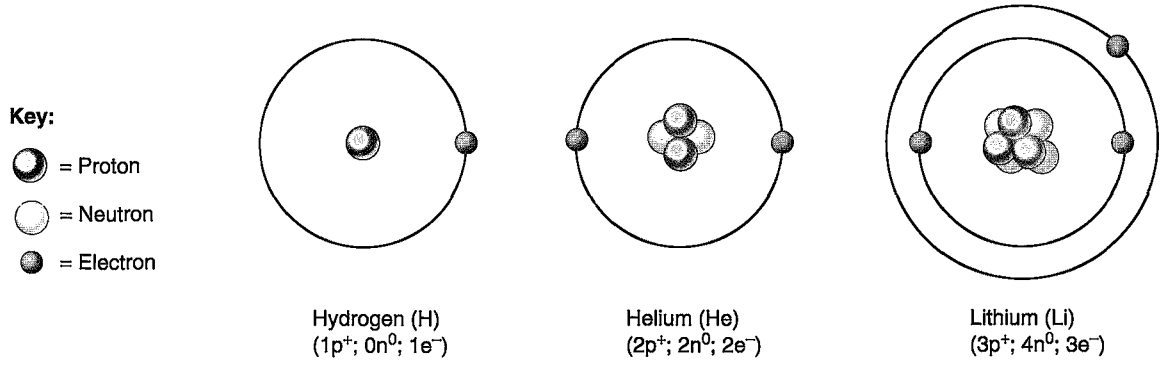

FIGURE 2.2 **Atomic structure of the three smallest atoms.**

mass, arbitrarily designated as 1 **atomic mass unit** (1 amu). Since all of the heavy subatomic particles are concentrated in the nucleus, the nucleus is fantastically dense and accounts for nearly the entire mass (99.9%) of the atom. The tiny **electrons** (e^-) bear a negative charge equal in strength to the positive charge of the proton. However, an electron has only about 1/2000 the mass of a proton, and the mass of an electron is usually designated as 0 amu.

All atoms are electrically neutral because the number of protons in an atom is precisely balanced by its number of electrons (the + and − charges will then cancel the effect of each other). Thus, hydrogen has one proton and one electron, and iron has 26 protons and 26 electrons. For any atom, the number of protons and electrons is always equal.

The **planetary model,** illustrated in Figure 2.1a, is a simplified (and now outdated) model of atomic structure. As you can see, it depicts electrons moving around the nucleus in fixed, generally circular orbits. But we can never determine the exact location of electrons at a particular time because they jump around following unknown trajectories. So, instead of speaking of specific orbits, chemists talk about **orbitals**—regions around the nucleus in which a given electron or electron pair is likely to be found most of the time. This more modern model of atomic structure, called the **orbital model,** is more useful for predicting the chemical behavior of atoms. As illustrated in Figure 2.1b, the orbital model depicts *probable* regions of greatest electron density by denser shading (this haze is called the *electron cloud*). However, because of the simplicity of the planetary model, most descriptions of atomic structure in this text will use that model.

Hydrogen, with just one proton and one electron, is the simplest atom. You can visualize the spatial relationships in the hydrogen atom by imagining it enlarged until its diameter equals the length of a football field. In that case, the nucleus could be represented by a lead ball the size of a gumdrop in the exact center of the sphere and its lone electron pictured as a fly buzzing about unpredictably within the sphere. Though not completely accurate, this mental picture should serve as a reminder that most of the volume of an atom is empty space, and nearly all of its mass is concentrated in the central nucleus.

Identifying Elements

All protons are alike, regardless of the atom considered. The same is true of all neutrons and all electrons. So what determines the unique properties of each element? The answer is that atoms of different elements are composed of *different numbers* of protons, neutrons, and electrons.

The simplest and smallest atom, hydrogen, has one proton, one electron, and no neutrons (Figure 2.2). Next in size is the helium atom, with two protons, two neutrons, and two orbiting electrons. Lithium follows with three protons, four neutrons, and three electrons. If we continued this step-by-step progression, we would get a graded series of atoms containing from 1 to 112 protons, an equal number of electrons, and a slightly larger number of neutrons at each step. However, all we really need to know to identify a particular element are its atomic number, mass number, and atomic weight. Taken together, these provide a fairly complete picture of each element.

Atomic Number

The **atomic number** of any atom is equal to the number of protons in its nucleus and is written as a subscript to the left of its atomic symbol. Hydrogen, with one proton, has an atomic number of 1 ($_1H$); helium, with two protons, has an atomic number of 2 ($_2He$); and so on. The number of protons is always equal to the number of electrons in an atom, so the atomic number *indirectly* tells us the number of electrons in the atom as well. As explained shortly,

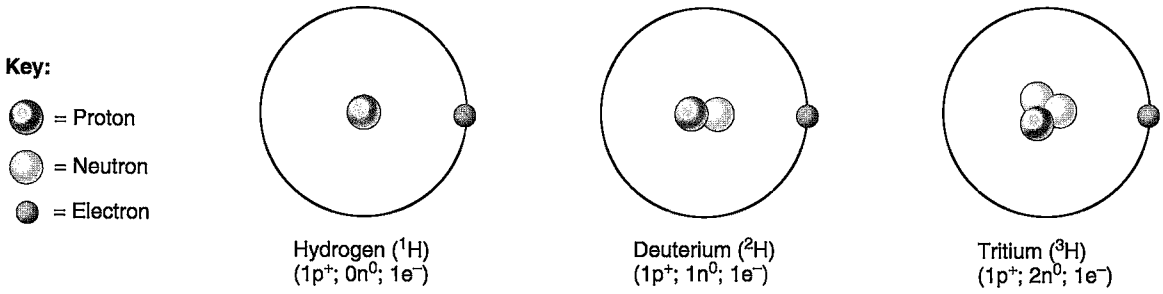

FIGURE 2.3 **Isotopes of hydrogen.**

this is important information indeed, because electrons determine the chemical behavior of atoms.

Mass Number and Isotopes

The **mass number** of an atom is the sum of the masses of its protons and neutrons. (The mass of the electrons is so small that it is ignored.) Recall that protons and neutrons have a mass of 1 amu. Hydrogen has only one proton in its nucleus, so its atomic and mass numbers are the same: 1. Helium, with two protons and two neutrons, has a mass number of 4. The mass number is usually indicated by a superscript to the left of the atomic symbol. Thus, helium is $^4_2$He. This simple notation allows us to deduce the total number and kinds of subatomic particles in any atom because it indicates the number of protons (the atomic number), the number of electrons (equal to the atomic number), and the number of neutrons (mass number minus atomic number).

From what we have said so far, it may appear as if each element has one, and only one, type of atom representing it. This is not the case. Nearly all known elements have two or more structural variations called **isotopes** (i'so-tōps), which have the same number of protons (and electrons), but differ in the number of neutrons they contain. Earlier, when we said that hydrogen has a mass number of 1, we were speaking of ^{1}H, its most abundant isotope. Some hydrogen atoms have a mass of 2 or 3 amu (atomic mass units), which means that they have one proton and, respectively, one or two neutrons (Figure 2.3). Carbon has several isotopic forms. The most abundant of these are ^{12}C, ^{13}C, and ^{14}C. Each of the carbon isotopes has six protons (otherwise it would not be carbon), but ^{12}C has six neutrons, ^{13}C has seven, and ^{14}C has eight. Isotopes are also written with the mass number following the symbol: C-14, for example.

Atomic Weight

It would seem that atomic weight should be the same as atomic mass, and this would be so if atomic weight referred to the weight of a single atom. However, **atomic weight** is an average of the relative weights (mass numbers) of *all* the isotopes of an element, taking into account their relative abundance in nature. As a rule, the atomic weight of an element is approximately equal to the mass number of its most abundant isotope. For example, the atomic weight of hydrogen is 1.008, which reveals that its lightest isotope (^{1}H) is present in much greater amounts in our world than its ^{2}H or ^{3}H forms.

Radioisotopes

The heavier isotopes of many elements are unstable, and their atoms decompose spontaneously into more stable forms. This process of atomic decay is called *radioactivity,* and isotopes that exhibit this behavior are called **radioisotopes** (ra"de-o-i'so-tōps). The disintegration of a radioactive nucleus may be compared to a tiny explosion. It occurs when subatomic *alpha* (α) *particles* (packets of 2p + 2n), *beta* (β) *particles* (electron-like negative particles), or *gamma* (γ) *rays* (electromagnetic energy) are ejected from the atomic nucleus. Why this happens is complex, and you only need to know that the dense nuclear particles are composed of even smaller particles called *quarks* that associate in one way to form protons and in another way to form neutrons. Apparently, the "glue" that holds these nuclear particles together is weaker in the heavier isotopes. When disintegration occurs, the element may transform to a different element.

Radioisotopes gradually lose their radioactive behavior. The time required for a radioisotope to lose one-half of its activity is called its *half-life.* The half-lives of radioisotopes vary dramatically from hours to thousands of years.

Because radioactivity can be detected with scanners, and radioactive isotopes share the same chemistry as their more stable isotopes, radioisotopes are valuable tools for biological research and medicine. Most radioisotopes used in the clinical setting are used for diagnosis, that is, to localize and illuminate

damaged or cancerous tissues. For example, iodine-131 is used to determine the size and activity of the thyroid gland and to detect thyroid cancer. The sophisticated PET scans described in *A Closer Look* in Chapter 1 use radioisotopes to probe the workings of molecules deep within our bodies. All types of radioactivity, regardless of the purpose for which they are used, damage living tissue.

Alpha emission has the lowest penetrating power and is least damaging to living tissue. Nonetheless, inhaled alpha particles from decaying radon are second only to smoking as a cause of lung cancer. (Radon results naturally from decay of uranium in the ground.) Gamma emission has the greatest penetrating power. Radium-226, cobalt-60, and certain other radioisotopes that decay by gamma emission are used to destroy localized cancers. Contrary to what some believe, ionizing radiation does not damage organic molecules directly. Instead, it knocks electrons out of other atoms and sends them flying, like bowling balls smashing through pins all along their path. It is the electron energy and the unstable molecules left behind that do the damage.

How Matter Is Combined: Molecules and Mixtures

Molecules and Compounds

Most atoms do not exist in the free state, but instead are chemically combined with other atoms. Such a combination of two or more atoms held together by chemical bonds is called a **molecule.**

If two or more atoms of the *same* element combine, the resulting substance is called a *molecule of that element.* When two hydrogen atoms bond, the product is a molecule of hydrogen gas and is written as H_2. Similarly, when two oxygen atoms combine, a molecule of oxygen gas (O_2) is formed. Sulfur atoms commonly combine to form sulfur molecules containing eight sulfur atoms (S_8).

When two or more *different* kinds of atoms bind, they form molecules of a **compound.** Two hydrogen atoms combine with one oxygen atom to form the compound water (H_2O), and four hydrogen atoms combine with one carbon atom to form the compound methane (CH_4). Notice again that molecules of methane and water are compounds, but molecules of hydrogen gas are not, because compounds always contain atoms of at least two different elements.

Compounds are chemically pure, and all of their molecules are identical. Thus, just as an atom is the smallest particle of an element that still exhibits the properties of the element, a molecule is the smallest particle of a compound that still displays the specific characteristics of the compound. This is an important concept because the properties of compounds are usually very different from those of the atoms they contain. Indeed, it is next to impossible to tell what atoms are in a compound without analyzing it chemically.

Mixtures

Mixtures are substances composed of two or more components *physically intermixed.* Although most matter in nature exists in the form of mixtures, there are only three basic types: *solutions, colloids,* and *suspensions.*

Solutions

Solutions are *homogeneous* mixtures of components that may be gases, liquids, or solids. Examples include the air we breathe (a mixture of gases) and seawater (a mixture of salts, which are solids, and water). The substance present in the greatest amount is called the **solvent** (or dissolving medium). Solvents are usually liquids. Substances present in smaller amounts are called **solutes.**

Water is the body's chief solvent. Most solutions in the body are *true solutions* containing gases, liquids, or solids dissolved in water. True solutions are usually transparent. Examples are saline solution [table salt (NaCl) and water] and a mixture of glucose and water. The solutes of true solutions are minute, usually in the form of individual atoms and molecules. Consequently, they are not visible to the naked eye, do not settle out, and do not scatter light. If a beam of light is passed through a true solution, you will not see the path of light.

Concentration of Solutions True solutions are described in terms of their *concentration,* which may be indicated in various ways. Solutions used in a college laboratory or a hospital are often described in terms of the **percent** (parts per 100 parts) of the solute in the total solution. This designation always refers to the solute percentage, and unless otherwise noted, water is assumed to be the solvent. Milligrams per deciliter (mg/dl) is another common concentration measurement. (A dl is 100 ml or 0.1 L.)

Still another way to express the concentration of a solution is in terms of its **molarity** (mo-lar'ĭ-te), or moles per liter, indicated by *M.* This method is more complicated but much more useful. To understand molarity, you must first understand what a mole is. A **mole** of any element or compound is equal to its atomic weight or **molecular weight** (sum of the atomic weights) weighed out in grams. This concept is easier than it seems, as illustrated by the following example.

Glucose is $C_6H_{12}O_6$, which indicates that it has 6 carbon atoms, 12 hydrogen atoms, and 6 oxygen atoms. To compute the molecular weight of glucose, you would look up the atomic weight of each of its atoms in the periodic table (see Appendix E) and compute its molecular weight as follows:

Atom	Number of Atoms		Atomic Weight		Total Atomic Weight
C	6	×	12.011	=	72.066
H	12	×	1.008	=	12.096
O	6	×	15.999	=	95.994
					180.156

Then, to make a *one-molar* solution of glucose, you would weigh out 180.156 grams (g), called a gram molecular weight, of glucose and add enough water to make 1 liter (L) of solution. Thus, a one-molar solution (abbreviated 1.0 *M*) of a chemical substance is one gram molecular weight of the substance (or one gram atomic weight in the case of elemental substances) in 1 L (1000 ml) of solution.

The beauty of using the mole as the basis of preparing solutions is its precision. One mole of any substance always contains exactly the same number of solute particles, that is, 6.02×10^{23}. This number is called **Avogadro's number** (av"o-gad'rōz). So whether you weigh out 1 mole of glucose (180 g) or 1 mole of water (18 g) or 1 mole of methane (16 g), in each case you will have 6.02×10^{23} molecules of that substance.* This allows almost mind-boggling precision to be achieved. Because solute concentrations in body fluids tend to be quite low, those values are usually reported in terms of millimoles (m*M*; 1/1000 mole).

Colloids

Colloids (kol'oidz), also called *emulsions*, are *heterogeneous* mixtures that often appear translucent or milky. Although the solute particles are larger than those in true solutions, they still do not settle out. However, they do scatter light, and so the path of a light beam shining through a colloidal mixture is visible.

Colloids have many unique properties, including the ability of some to undergo **sol-gel transformations,** that is, to change reversibly from a fluid (sol) state to a more solid (gel) state. Jell-O, or any gelatin product, is a familiar example of a nonliving colloid that changes from a sol to a gel when refrigerated (and that will liquefy again if placed in the sun). Cytosol, the semifluid material in living cells, is also a colloid, largely because of its dispersed proteins, and its sol-gel changes underlie many important cell activities, such as cell division.

Suspensions

Suspensions are *heterogeneous* mixtures with large, often visible solutes that tend to settle out. An example of a suspension is a mixture of sand and water. So is blood, in which the living blood cells are suspended in the fluid portion of blood (blood plasma). If left to stand, the suspended cells will settle out unless some means—mixing, shaking, or circulation in the body—is used to keep them in suspension.

As you can see, all three types of mixtures are found in both living and nonliving systems. In fact, living material is the most complex mixture of all, since it contains all three kinds of mixtures interacting with one another.

Distinguishing Mixtures from Compounds

Now we are ready to zero in on how to distinguish mixtures and compounds from one another. Mixtures differ from compounds in several important ways:

1. The chief difference between mixtures and compounds is that no chemical bonding occurs between the components of a mixture. The properties of atoms and molecules are not changed when they become part of a mixture. Remember they are only physically intermixed.

2. Depending on the mixture, its components can be separated by physical means—straining, filtering, evaporation, and so on. Compounds, by contrast, can be separated into their constituent atoms only by chemical means (breaking bonds).

3. Some mixtures are homogeneous, whereas others are heterogeneous. To say that a substance is *homogeneous* means that a sample taken from any part of the substance has exactly the same composition (in terms of the atoms or molecules it contains) as any other sample. A bar of 100% pure (elemental) iron is homogeneous, as are all compounds. *Heterogeneous* substances vary in their makeup from place to place. For example, iron ore is a heterogeneous mixture that contains iron and many other elements.

Chemical Bonds

As noted earlier, when atoms combine with other atoms, they are held together by **chemical bonds.** A chemical bond is not a physical structure like a pair

* The important exception to this rule concerns molecules that ionize and break up into charged particles (ions) in water, such as salts, acids, and bases (see p. 41). For example, simple table salt (sodium chloride) breaks up into two types of charged particles; therefore, in a 1.0-*M* solution of sodium chloride, there are actually *2 moles* of solute particles in solution.

of handcuffs linking two people together. Instead, it is an energy relationship between the electrons of the reacting atoms, and it is made or broken in less than a trillionth of a second.

The Role of Electrons in Chemical Bonding

Electrons forming the electron cloud around the nucleus of an atom occupy regions of space called **electron shells** that consecutively surround the atomic nucleus. The atoms known so far can have electrons in seven shells (numbered 1 to 7 from the nucleus outward), but the actual number of electron shells occupied in a given atom depends on the number of electrons that atom has. Each electron shell contains one or more orbitals.

It is important to understand that each electron shell represents a different **energy level,** because this prompts you to think of electrons as particles with a certain amount of potential energy. In general, the terms *electron shell* and *energy level* are used interchangeably.

The amount of potential energy an electron has depends on the energy level it occupies, because the attraction between the positively charged nucleus and negatively charged electrons is greatest closest to the nucleus and falls off with increasing distance. This statement explains why electrons farthest from the nucleus (1) have the greatest potential energy (it takes more energy to overcome the nuclear attraction and reach the more distant energy levels), and (2) are most likely to interact chemically with other atoms (they are the least tightly held by their own atomic nucleus and the most easily influenced by other atoms and molecules).

Each electron shell can hold a specific number of electrons. Shell 1, the shell immediately surrounding the nucleus, accommodates only 2 electrons. Shell 2 holds a maximum of 8; shell 3 has room for 18. Subsequent shells hold larger and larger numbers of electrons, and the shells tend to be filled with electrons consecutively. For example, shell 1 is completely filled before any electrons appear in shell 2.

When considering bonding behavior, the only electrons that are important are those in the atom's outermost energy level. Inner electrons usually do not take part in bonding because they are more tightly held by the atomic nucleus. When the outermost energy level of an atom is filled to capacity or contains eight electrons, the atom is stable. Such atoms are *chemically inert,* that is, unreactive. A group of elements called the *noble gases,* which include helium and neon, typify this condition (Figure 2.4a). On the other hand, atoms in which the outermost energy level contains fewer than eight electrons (Figure 2.4b) tend to gain, lose, or share electrons with other atoms to achieve stability.

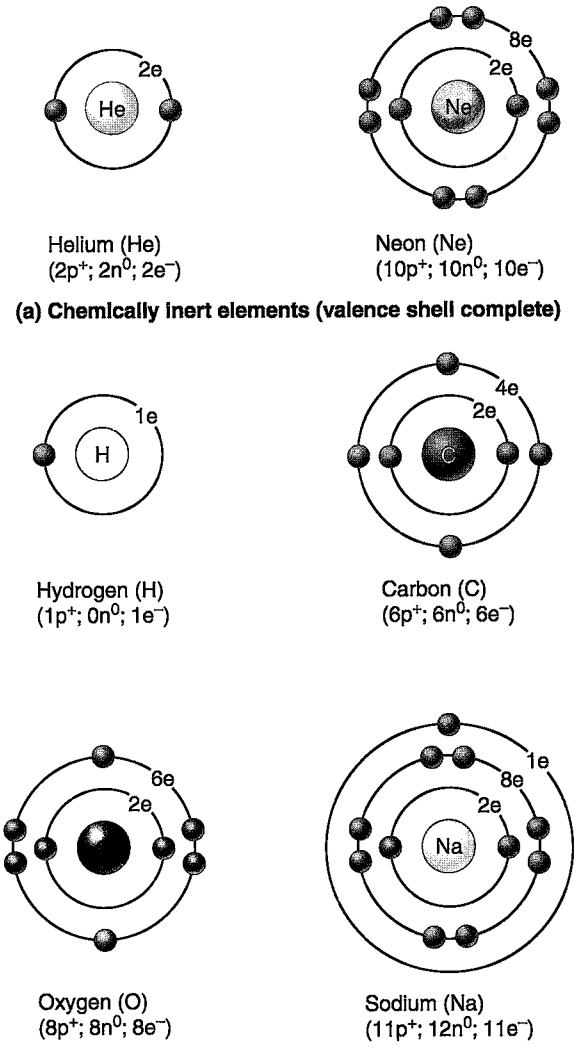

FIGURE 2.4 **Chemically inert and reactive elements.** **(a)** Helium and neon are chemically inert because in each case the outermost energy level (valence shell) is fully occupied by electrons. **(b)** Elements in which the valence shell is incomplete are chemically reactive. Such atoms tend to react with other atoms to gain, lose, or share electrons to fill their valence shells. (*Note:* For simplicity, each atomic nucleus is shown as a sphere with the atom's symbol; individual protons and neutrons are not shown.)

A possible point of confusion must be addressed here. In atoms that have more than 20 electrons, the energy levels beyond shell 2 can contain *more* than eight electrons. However, the number of electrons that can participate in bonding is still limited to a total of eight. The term **valence shell** (va'lens) is used specifically to indicate an atom's outermost energy level *or that portion of it* containing

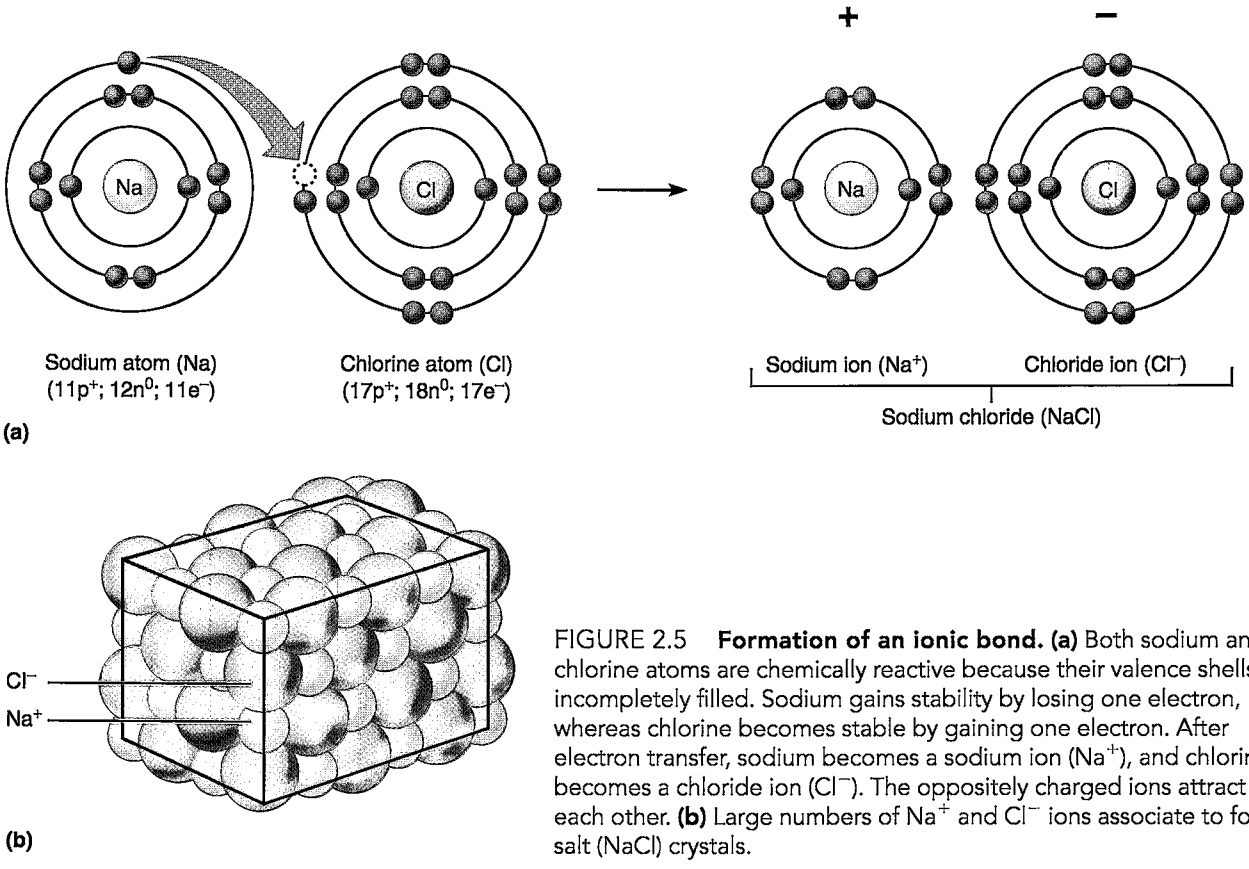

FIGURE 2.5 **Formation of an ionic bond. (a)** Both sodium and chlorine atoms are chemically reactive because their valence shells are incompletely filled. Sodium gains stability by losing one electron, whereas chlorine becomes stable by gaining one electron. After electron transfer, sodium becomes a sodium ion (Na^+), and chlorine becomes a chloride ion (Cl^-). The oppositely charged ions attract each other. **(b)** Large numbers of Na^+ and Cl^- ions associate to form salt (NaCl) crystals.

the electrons that are chemically reactive. Hence, the key to chemical reactivity is the **octet rule** (ok-tet'), or **rule of eights.** Except for shell 1, which is full when it has two electrons, atoms tend to interact in such a way that they have eight electrons in their valence shell.

Types of Chemical Bonds

Three major types of chemical bonds—*ionic, covalent,* and *hydrogen bonds*—result from attractive forces between atoms.

Ionic Bonds

Atoms are electrically neutral. However, electrons can be transferred from one atom to another, and when this happens, the precise balance of + and − charges is lost so that charged particles called **ions** are formed. An **ionic bond** (i-on'ik) is a chemical bond between atoms formed by the transfer of one or more electrons from one atom to the other. The atom that gains one or more electrons, the *electron acceptor,* acquires a net negative charge and is called an **anion** (an'i-on). The atom that loses electrons (the *electron donor*) acquires a net positive charge and is called a **cation** (kat'i-on). (It might help to think of the "t" in "cation" as a + sign.) Both anions and cations are formed whenever electron transfer between atoms occurs. Because opposite charges attract, these ions tend to stay close together, resulting in an ionic bond.

One example of ionic bonding is the formation of sodium chloride (NaCl), by interaction of sodium and chlorine atoms (Figure 2.5). Sodium, with an atomic number of 11, has only one valence shell electron, and it would be very difficult to attempt to fill this shell by adding seven more. However, if this single electron is lost, shell 2 with eight electrons becomes the valence shell (outermost energy level containing electrons) and is full. Thus, by losing the lone electron in its third energy level, sodium achieves stability and becomes a cation (Na^+). On the other hand, chlorine, atomic number 17, needs only one electron to fill its valence shell. By accepting an electron, chlorine becomes an anion and achieves stability. When these two atoms interact, this is exactly what happens. Sodium donates an electron to chlorine, and the ions created in this exchange attract each other, forming sodium chloride. Ionic bonds are commonly formed between atoms with one or two valence shell electrons (the metallic elements, such as sodium, calcium, and potassium) and atoms with seven valence shell electrons (such as chlorine, fluorine, and iodine).

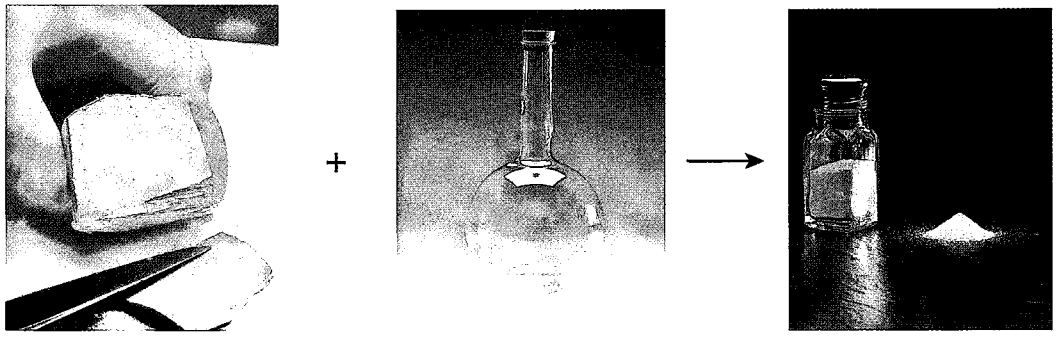

FIGURE 2.6 **Properties of a compound differ from those of its atoms.** In this example, the metal sodium combines with the poisonous gas chlorine to form the edible compound sodium chloride, or table salt.

Most ionic compounds fall in the chemical category called *salts*. In the dry state, salts such as sodium chloride do not exist as individual molecules. Instead, they form **crystals,** large arrays of cations and anions held together by ionic bonds (see Figure 2.5b).

Sodium chloride is an excellent example of the difference in properties between a compound and its constituent atoms (Figure 2.6). Sodium is a silvery white metal, and chlorine in its molecular state is a poisonous green gas used to make bleach. However, sodium chloride is a white crystalline solid that we sprinkle on our food.

Covalent Bonds

Electrons do not have to be completely transferred for atoms to achieve stability. Instead, they may be *shared* so that each atom is able to fill its outer electron shell at least part of the time. Electron sharing produces molecules in which the shared electrons occupy a single orbital common to both atoms and constitute **covalent bonds** (ko-va'lent).

Hydrogen with its single electron can fill its only shell (shell 1) by sharing a pair of electrons with another atom. When it shares with another hydrogen atom, a molecule of hydrogen gas is formed. The shared electron pair orbits around the molecule as a whole, satisfying the stability needs of each atom. Hydrogen can also share an electron pair with different kinds of atoms to form a compound (Figure 2.7a). Carbon has four electrons in its outermost shell, but needs eight to achieve stability, whereas hydrogen has one electron, but needs two. When a methane molecule (CH_4) is formed, carbon shares four pairs of electrons with four hydrogen atoms (one pair with each hydrogen). Again, the shared electrons orbit and "belong to" the whole molecule, ensuring the stability of each atom. When two atoms share one pair of electrons, a *single covalent bond* is formed (indicated by a single line connecting the atoms, such as H—H). In some cases, atoms share two or three electron pairs (Figure 2.7b and c), resulting in *double* or *triple covalent bonds* (indicated by double or triple connecting lines such as O=O or N≡N).

Polar and Nonpolar Molecules In the covalent bonds discussed thus far, the shared electrons are shared equally between the atoms of the molecule for the most part. The molecules formed are electrically balanced and are called **nonpolar molecules** (because they do not have separate + and − poles of charge). This is not always the case. When covalent bonds are formed, the resulting molecule always has a specific three-dimensional shape, with the bonds formed at definite angles. A molecule's shape helps determine what other molecules or atoms it can interact with; it may also result in unequal electron pair sharing and **polar molecules.** This is especially true in nonsymmetrical molecules that have atoms with different electron-attracting abilities. In general, *small* atoms with six or seven valence shell electrons, such as oxygen, nitrogen, and chlorine, are electron-hungry and attract electrons very strongly, a capability called **electronegativity.** Conversely, most atoms with only one or two valence shell electrons tend to be **electropositive;** that is, their electron-attracting ability is so low that they usually lose *their* valence shell electrons to other atoms. Potassium and sodium, each with one valence shell electron, are good examples of electropositive atoms.

Carbon dioxide and water illustrate how molecular shape and the relative electron-attracting abilities of atoms determine whether a covalently bonded molecule is nonpolar or polar. In carbon dioxide (CO_2), carbon shares four electron pairs with two oxygen atoms (two pairs are shared with each oxygen). Oxygen is very electronegative and so attracts the shared electrons much more strongly than does

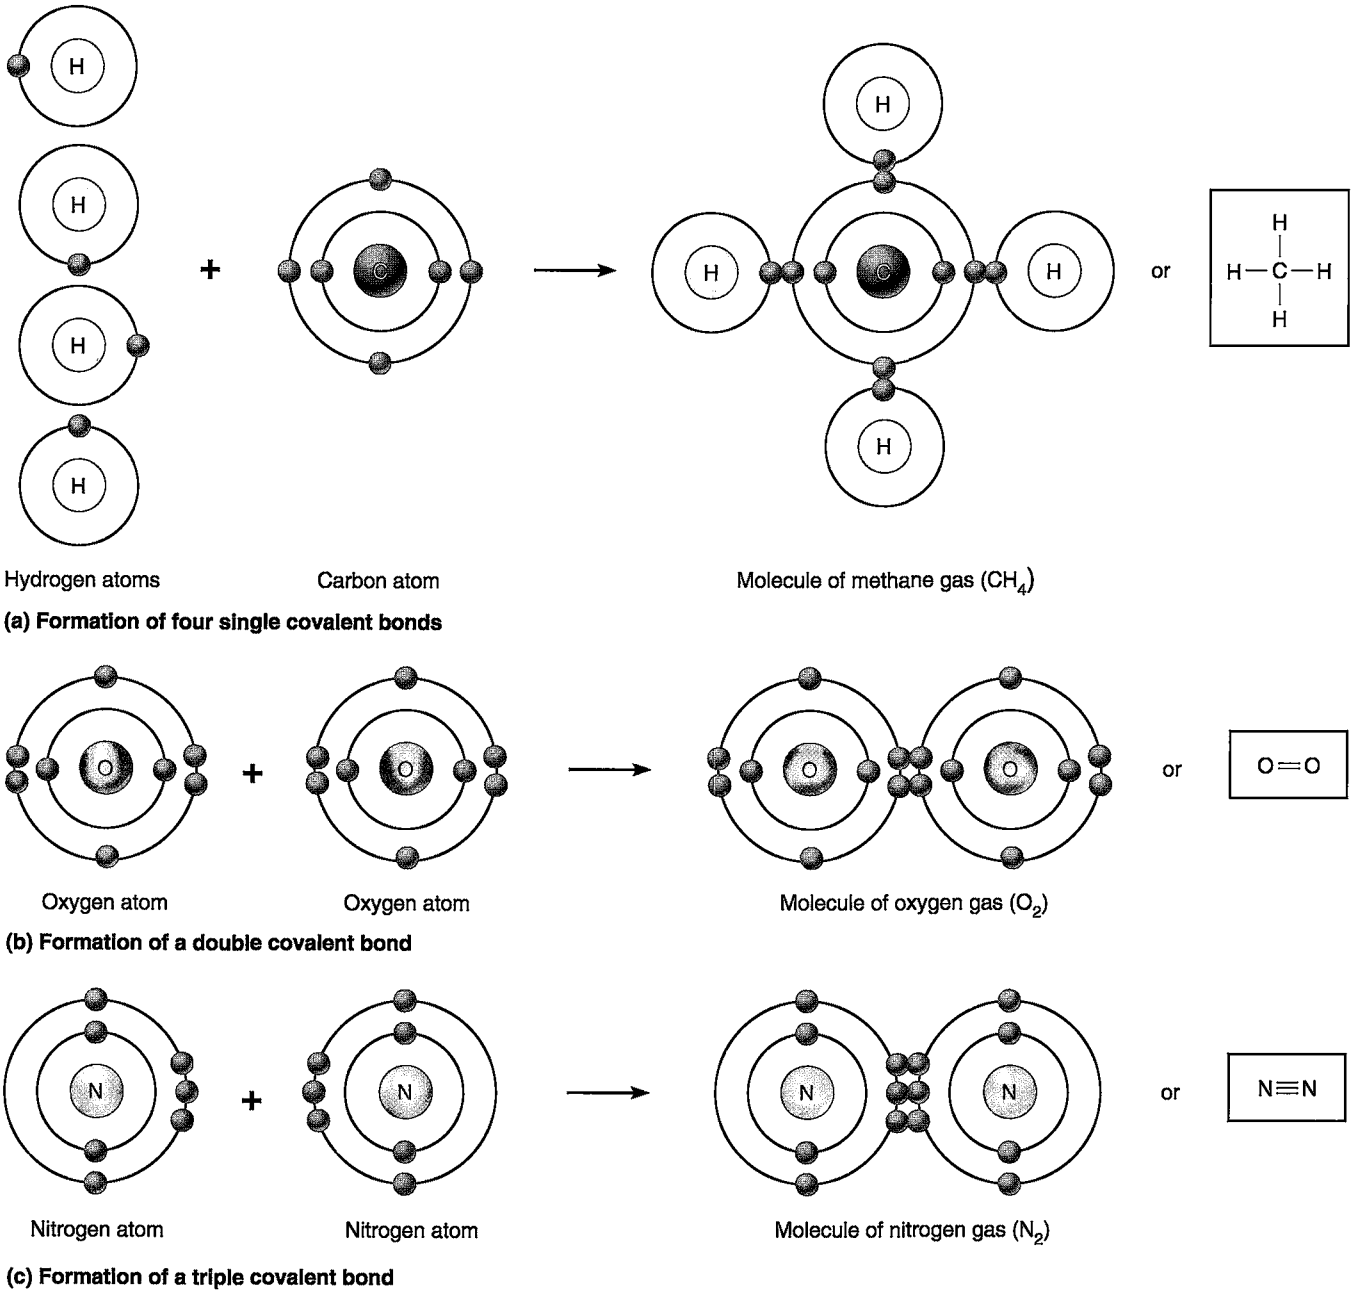

FIGURE 2.7 **Formation of covalent bonds.** Left, the electron-sharing patterns of interacting atoms; center, the resulting molecules; right, the structural formula shows each covalent bond as a single line between the atoms that share an electron pair.

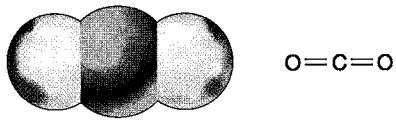
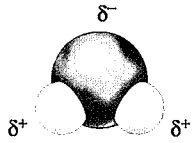
carbon. However, because the carbon dioxide molecule is linear and symmetrical (Figure 2.8a), the electron-pulling ability of one oxygen atom is offset by that of the other, like a standoff between equally strong teams in a game of tug-of-war. As a result, the shared electrons orbit the entire molecule and carbon dioxide is a nonpolar compound.

In contrast, a water molecule (H_2O) is V shaped (Figure 2.8b). The two hydrogen atoms are located at the same end of the molecule, and oxygen is at the opposite end. This arrangement allows oxygen to pull the shared electrons toward itself and away from the two hydrogen atoms. In this case, the electron pairs are *not* shared equally, but spend more time in the vicinity of oxygen. Because electrons are negatively charged, the oxygen end of the molecule is slightly more negative (the charge is indicated with a delta and minus as δ^-) and the hydrogen end slightly more positive (indicated by δ^+). Because water has two poles of charge, it is a *polar molecule,* or **dipole** (di'pōl). Polar molecules orient themselves toward other dipoles or toward charged particles (such as ions and some proteins), and they play essential roles in chemical reactions in body cells. The polarity



O=C=O

(a) Carbon dioxide (CO_2)



(b) Water (H_2O)

FIGURE 2.8 **Molecular models of carbon dioxide and water molecules.**

of water is particularly significant, as you will see later in this chapter.

Different molecules exhibit different degrees of polarity, and we can see a gradual change from ionic to nonpolar covalent bonding as summarized in Figure 2.9. Ionic bonds (complete electron transfer) and nonpolar covalent bonds (equal electron sharing) are the extremes of a continuum, with various degrees of unequal electron sharing in between.

Hydrogen Bonds

Unlike the stronger ionic and covalent bonds, hydrogen bonds are more like attractions than true bonds. Hydrogen bonds form when a hydrogen atom, already covalently linked to one electronegative atom (usually nitrogen or oxygen), is attracted by another electron-hungry atom, so that a "bridge" forms between them. Hydrogen bonding is common between dipoles such as water molecules, because the slightly negative oxygen atoms of one molecule attract the slightly positive hydrogen atoms of other molecules (Figure 2.10). The tendency of water molecules to cling together and form films, referred to as *surface tension*, helps explain why water beads up into spheres when it sits on a hard surface and why water striders can walk on a pond's surface.

Although hydrogen bonds are too weak to bind atoms together to form molecules, they are important as *intramolecular bonds*, which bind different parts of a single large molecule together into a specific three-dimensional shape. Some large biological molecules, such as proteins and DNA, have numerous hydrogen bonds that help maintain and stabilize their structures.

Chemical Reactions

As noted earlier, all particles of matter are in constant motion because of their kinetic energy. Movement of atoms or molecules in a solid is usually limited to vibration because the particles are united by fairly rigid bonds. But in liquids or gases, particles dart about randomly, sometimes colliding with one another and interacting to undergo chemical reactions. A **chemical reaction** occurs whenever chemical bonds are formed, rearranged, or broken.

Assume imaginary compound XY has a polar covalent bond. How does its charge distribution differ from that of XX molecules?

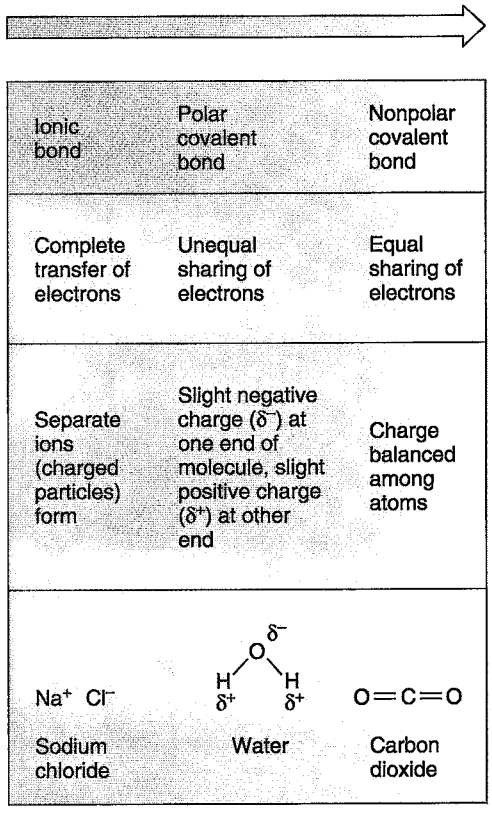


FIGURE 2.9 **Comparison of ionic, polar covalent, and nonpolar covalent bonds.** This display compares the status of electrons involved in bonding and the electrical charge distribution in the molecules formed.

Chemical Equations

Chemical reactions can be written in symbolic form as **chemical equations.** For example, joining two hydrogen atoms to form hydrogen gas is indicated as

$$\underset{\text{(reactants)}}{H + H} \rightarrow \underset{\text{(product)}}{H_2 \text{ (hydrogen gas)}}$$

Because X and Y are different atoms, one is bound to be more electronegative than the other. Consequently, there will be a separation of charge in XY, which is a dipole. In XX, the two atoms are the same and there will be equal e⁻ sharing; no dipole is formed.

FIGURE 2.10 **Hydrogen bonding between polar water molecules. (a)** The slightly positive ends (indicated by δ^+) of the water molecules become aligned with the slightly negative ends (indicated by δ^-) of other water molecules. **(b)** The high surface tension of water, a result of the combined strength of its hydrogen bonds, allows a water strider to walk on a pond without breaking its surface.

and combining four hydrogen atoms and one carbon atom to form methane is written

$$4H + C \rightarrow CH_4 \text{ (methane)}$$

Notice that a number written as a *subscript* indicates that the atoms are joined by chemical bonds. But a number written as a *prefix* denotes the number of *unjoined* atoms or molecules. Hence, CH_4 reveals that four hydrogen atoms are bonded together with carbon to form the methane molecule, but 4H signifies four unjoined hydrogen atoms.

A chemical equation is like a sentence describing what happens in a reaction. It contains the following information: the number and kinds of reacting substances, or **reactants;** the chemical composition of the **product(s);** and in balanced equations, the relative proportion of each reactant and product. In the examples used above, the reactants are atoms, as indicated by their atomic symbols (H, C). The product in each case is a molecule, as represented by its **molecular formula** (H_2, CH_4). The equation for the formation of methane may be read as *either* "four hydrogen atoms plus one carbon atom yield one molecule of methane" *or* "four moles of hydrogen atoms plus one mole of carbon yield one mole of methane." Using moles is more practical because it is impossible to measure out one atom or one molecule of anything!

Patterns of Chemical Reactions

Most chemical reactions exhibit one of three recognizable patterns: they are either *synthesis, decomposition,* or *exchange reactions.*

When atoms or molecules combine to form a larger, more complex molecule, the process is a **synthesis,** or **combination, reaction.** A synthesis reaction, which always involves bond formation, can be represented (using arbitrary letters) as

$$A + B \rightarrow AB$$

Synthesis reactions are the basis of constructive, or **anabolic,** activities in body cells, such as joining small molecules called amino acids into large protein molecules (Figure 2.11a). Synthesis reactions are conspicuous in rapidly growing tissues.

A **decomposition reaction** occurs when a molecule is broken down into smaller molecules or its constituent atoms:

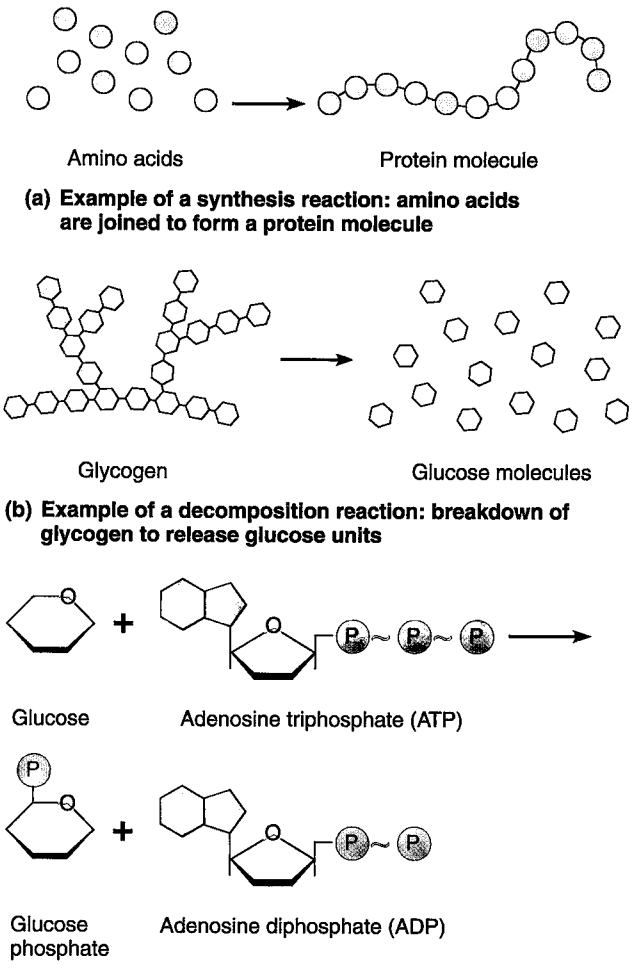
$$AB \rightarrow A + B$$

Essentially, decomposition reactions are reverse synthesis reactions; bonds are broken. Decomposition reactions underlie all degradative, or **catabolic,** processes that occur in body cells. For example, the bonds of glycogen molecules are broken to release simpler molecules of glucose sugar (Figure 2.11b).

Exchange, or **displacement, reactions** involve both synthesis and decomposition; bonds are both made and broken. In an exchange reaction, parts of the reactant molecules change partners, so to speak, producing different product molecules:

$$AB + C \rightarrow AC + B \quad \text{and} \quad AB + CD \rightarrow AD + CB$$

Q *Which of the reaction types depicted occurs when fats are digested in your small intestine?*



(a) Example of a synthesis reaction: amino acids are joined to form a protein molecule

(b) Example of a decomposition reaction: breakdown of glycogen to release glucose units

(c) Example of an exchange reaction: ATP transfers its terminal phosphate group to glucose to form glucose-phosphate

FIGURE 2.11 **Patterns of chemical reactions. (a)** In synthesis reactions, smaller particles are bonded together to form larger, more complex molecules. **(b)** Decomposition reactions involve bond breaking. **(c)** In exchange, or displacement, reactions, bonds are both made and broken.

An exchange reaction occurs when ATP reacts with glucose and transfers its end phosphate group (indicated by a circled P in Figure 2.11c) to glucose, forming glucose-phosphate. At the same time, the ATP becomes ADP. This important reaction occurs whenever glucose enters a body cell and it effectively traps the glucose fuel molecule inside the cell.

Another group of important chemical reactions in living systems is **oxidation-reduction reactions**—**redox reactions** for short. Oxidation-reduction reactions are decomposition reactions in that they are the basis of all reactions in which food fuels are catabolized for energy (that is, in which ATP is produced). They are also a special type of exchange reaction because electrons are exchanged between the reactants. The reactant losing the electrons is referred to as the *electron donor* and is said to be **oxidized;** the reactant taking up the transferred electrons is called the *electron acceptor* and is said to become **reduced.**

Redox reactions also occur when ionic compounds are formed. Recall that in the formation of NaCl (see Figure 2.5), sodium loses an electron to chlorine. Consequently, sodium is oxidized and becomes a sodium ion, and chlorine is reduced and becomes a chloride ion. However, not all oxidation-reduction reactions involve *complete transfer* of electrons—some simply change the pattern of electron sharing in covalent bonds. For example, a substance is oxidized both by losing hydrogen atoms and by combining with oxygen. The common factor in these events is that electrons that formerly "belonged" to the reactant molecule are lost, either entirely (as hydrogen is removed and takes its electron with it) or relatively (the shared electrons spend more time in the vicinity of the very electronegative oxygen atom).

To understand the importance of oxidation-reduction reactions in living systems, take a look at the overall equation for *cellular respiration,* which represents the major pathway by which glucose is broken down for energy in body cells:

$$\underset{\text{glucose}}{C_6H_{12}O_6} + \underset{\text{oxygen}}{6O_2} \rightarrow \underset{\text{carbon dioxide}}{6CO_2} + \underset{\text{water}}{6H_2O} + \underset{\text{cellular energy}}{ATP}$$

As you can see, it is an oxidation-reduction reaction. Glucose is oxidized to carbon dioxide as it loses hydrogen atoms, and oxygen is reduced to water as it accepts the hydrogen atoms. This reaction is described in detail in Chapter 24, along with other topics of cellular metabolism.

Energy Flow in Chemical Reactions

Because all chemical bonds represent stored chemical energy, all chemical reactions ultimately result in net absorption or release of energy. Reactions that release energy are called **exergonic reactions.** These reactions yield products with less energy than the initial reactants, along with energy that can be harvested for other uses. With a few exceptions, catabolic and oxidative reactions are exergonic.

In contrast, the products of energy-absorbing, or **endergonic,** reactions contain more potential energy

∀ Digestion of fats (triglycerides) to their fatty acid and glycerol building blocks is an example of (b) a decomposition reaction.

in their chemical bonds than did the reactants. Anabolic reactions are typically energy-absorbing endergonic reactions. Essentially this is a case of "one hand washing the other"—the energy released when fuel molecules are broken down (oxidized) is captured in ATP molecules and then used to synthesize the complex biological molecules the body needs to sustain life.

Reversibility of Chemical Reactions

All chemical reactions are theoretically reversible. If chemical bonds can be made, they can be broken, and vice versa. Reversibility is indicated by a double arrow. When the arrows differ in length, the longer arrow indicates the major direction in which the reaction proceeds:

$$A + B \rightleftharpoons AB$$

In this example, the forward reaction (reaction going to the right) predominates. Over time, the product (AB) accumulates and the reactants (A and B) decrease in amount.

When the arrows are of equal length, as in

$$A + B \rightleftharpoons AB$$

neither the forward reaction nor the reverse reaction is dominant; that is, for each molecule of product (AB) formed, one product molecule breaks down, releasing the reactants A and B. Such a chemical reaction is said to be in a state of **chemical equilibrium.** Once chemical equilibrium is reached, there is no further *net change* in the amounts of reactants and products unless more of either are added to the mix. Product molecules are still formed and broken down, but the situation established when equilibrium was reached (such as greater numbers of product molecules) remains unchanged. This is analogous to the admission scheme used by many large museums in which tickets are sold according to time of entry. If 300 tickets are issued for the 9 AM admission, 300 people will be admitted when the doors open. Thereafter, when 6 people leave, 6 are admitted, and when another 15 people leave, 15 more are allowed in. Although there is a continual turnover, the museum contains about 300 art lovers throughout the day.

Although all chemical reactions are reversible, many biological reactions show so little tendency to go in the reverse direction that they are irreversible for all practical purposes. Chemical reactions that release energy when going in one direction will not go in the opposite direction unless energy is put back into the system. For example, when our cells break down glucose via the reactions of cellular respiration to yield carbon dioxide and water, some of the energy released is trapped in the bonds of ATP. Because the cells need ATP's energy for various functions (and more glucose will be along with the next meal), this particular reaction is never reversed in our cells. Furthermore, if a product of a reaction is continuously removed from the reaction site, it is unavailable to take part in the reverse reaction. This situation occurs when the carbon dioxide that is released during glucose breakdown leaves the cell, enters the blood, and is eventually removed from the body by the lungs.

Factors Influencing the Rate of Chemical Reactions

For atoms and molecules to react chemically, they must *collide* with enough force to overcome the repulsion between their electrons. Interactions between valence shell electrons—the basis of bond making and breaking—cannot occur long distance. The force of collisions depends on how fast the particles are moving. Solid, forceful collisions between rapidly moving particles in which valence shells overlap are much more likely to cause reactions than are those in which the particles graze each other lightly.

Temperature Increasing the temperature of a substance increases the kinetic energy of its particles and the force of their collisions. Therefore, chemical reactions proceed quicker at higher temperatures.

Concentration Chemical reactions progress most rapidly when the reacting particles are present in high numbers, because the chance of successful collisions is greater. As the concentration of the reactants declines, chemical equilibrium eventually occurs unless additional reactants are added or products are removed from the reaction site.

Particle Size Smaller particles move faster than larger ones (at the same temperature) and tend to collide more frequently and more forcefully. Hence, the smaller the reacting particles, the faster a chemical reaction goes at a given temperature and concentration.

Catalysts Although many chemical reactions in nonliving systems can be speeded up simply by heating, drastic increases in body temperature are life threatening because important biological molecules are destroyed. Still, at normal body temperatures, most chemical reactions would proceed far too slowly to maintain life were it not for the presence of catalysts. **Catalysts** (kat'ah-lists) are substances that increase the rate of chemical reactions without themselves becoming chemically changed or part of the product. Biological catalysts are called

enzymes (en'zīmz). The mode of action of enzymes is described later in this chapter.

PART 2: BIOCHEMISTRY

Biochemistry is the study of the chemical composition and reactions of living matter. All chemicals in the body fall into one of two major classes: organic or inorganic compounds. **Organic compounds** contain carbon. All organic compounds are covalently bonded molecules, and many are large.

All other chemicals in the body are considered **inorganic compounds.** These include water, salts, and many acids and bases. Organic and inorganic compounds are equally essential for life. Trying to decide which is more valuable is like trying to decide whether the ignition system or the engine is more essential to run your car!

Inorganic Compounds

Water

Water is the most abundant and important inorganic compound in living material. It makes up 60–80% of the volume of most living cells. Among the properties that make water vital are its

1. High heat capacity. Water has a high heat capacity; that is, it absorbs and releases large amounts of heat before changing appreciably in temperature itself. This prevents sudden changes in temperature caused by external factors, such as sun or wind exposure, or by internal conditions that release heat rapidly, such as vigorous muscle activity. As part of blood, water redistributes heat among body tissues, ensuring temperature homeostasis.

2. High heat of vaporization. When water evaporates, or vaporizes, it changes from a liquid to a gas (water vapor). This transformation requires that large amounts of heat be absorbed to break the hydrogen bonds that hold water molecules together. This property is extremely beneficial when we sweat. As perspiration (mostly water) evaporates from our skin, large amounts of heat are removed from the body, providing an efficient cooling mechanism.

3. Polar solvent properties. Water is an unparalleled solvent; indeed, it is often called the **universal solvent.** Biochemistry is "wet chemistry." Biological molecules do not react chemically unless they are in solution, and virtually all chemical reactions occurring in the body depend on water's solvent properties.

Because of their polar nature, water molecules orient themselves with their slightly negative ends toward the positive ends of the solutes, and vice versa, first attracting them, then surrounding them. This property of water explains why ionic compounds and other small reactive molecules (such as acids and bases) *dissociate* in water, their ions separating from each other and becoming evenly scattered in the water, forming true solutions (Figure 2.12). Water also forms **hydration layers** (layers of water molecules) around large charged molecules such as proteins, shielding them from the effects of other charged substances in the vicinity and preventing them from settling out of solution. Such protein-water mixtures are *biological colloids.* Cerebrospinal fluid and blood are examples of colloids.

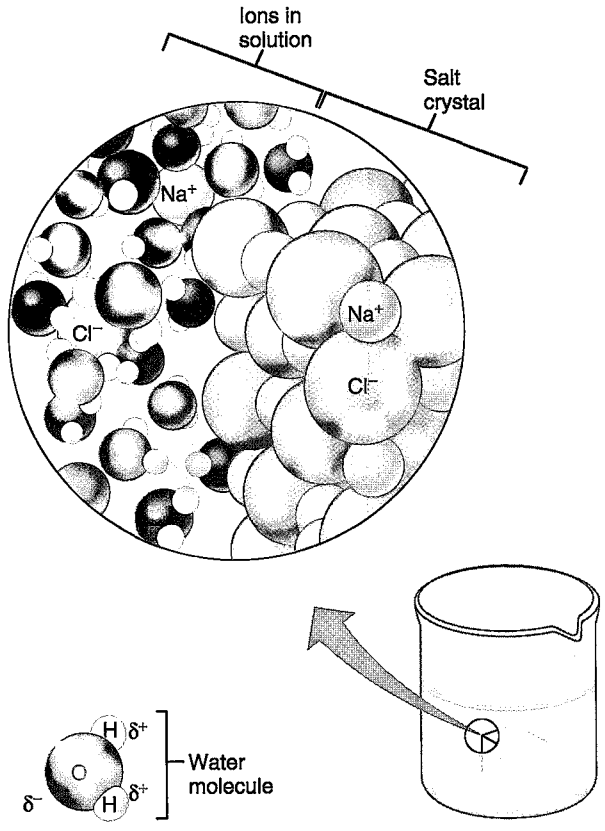


FIGURE 2.12 **Dissociation of a salt in water.** The slightly negative ends of the water molecules (δ^-) are attracted to Na^+, whereas the slightly positive ends of water molecules (δ^+) orient toward Cl^-, causing the ions to be pulled off the crystal lattice.

Water is the body's major transport medium because it is such an excellent solvent. Nutrients, respiratory gases, and metabolic wastes carried throughout the body are dissolved in blood plasma, and many metabolic wastes are excreted from the body in urine, another watery fluid. Specialized molecules that lubricate the body (e.g., mucus) also use water as their dissolving medium.

4. Reactivity. Water is an important *reactant* in many chemical reactions. For example, foods are

digested to their building blocks by adding a water molecule to each bond to be broken. Such decomposition reactions are more specifically called **hydrolysis reactions** (hi-drol'ĭ-sis; "water splitting"). Conversely, when large carbohydrate or protein molecules are synthesized from smaller molecules, a water molecule is removed for every bond formed, a reaction called **dehydration synthesis.**

5. Cushioning. By forming a resilient cushion around certain body organs, water helps protect them from physical trauma. The cerebrospinal fluid surrounding the brain exemplifies water's cushioning role.

Salts

A **salt** is an ionic compound containing cations other than H^+ and anions other than the hydroxyl ion (OH^-). As already noted, when salts are dissolved in water, they dissociate into their component ions (Figure 2.12). For example, sodium sulfate (Na_2SO_4) dissociates into two Na^+ ions and one SO_4^{2-} ion. This occurs easily because the ions are already formed. All that remains is for water to overcome the attraction between the oppositely charged ions. All ions are **electrolytes** (e-lek'tro-līts), substances that conduct an electrical current in solution. (Note that groups of atoms that bear an overall charge, such as sulfate, are called *polyatomic ions.*)

Salts commonly found in the body include NaCl, $CaCO_3$ (calcium carbonate), and KCl (potassium chloride). However, the most plentiful salts are the calcium phosphates that make bones and teeth hard. In their ionized form, salts play vital roles in body function. For instance, the electrolyte properties of sodium and potassium ions are essential for nerve impulse transmission and muscle contraction. Ionic iron forms part of the hemoglobin molecules that transport oxygen within red blood cells, and zinc and copper ions are important to the activity of some enzymes. Other important functions of the elements found in body salts are summarized in Table 2.1.

HOMEOSTATIC IMBALANCE

Maintaining proper ionic balance in our body fluids is one of the most crucial homeostatic roles of the kidneys. When this balance is severely disturbed, virtually nothing in the body works. All the physiological activities listed above and thousands of others are disrupted and grind to a stop.

Acids and Bases

Like salts, acids and bases are electrolytes; that is, they ionize and dissociate in water and can then conduct an electrical current.

Acids

Acids have a sour taste, can react with (dissolve) many metals, and "burn" a hole in your rug. But for our purposes the most useful definition of an acid is a substance that releases **hydrogen ions** (H^+) in detectable amounts. Because a hydrogen ion is just a hydrogen nucleus, or "naked" proton, acids are also defined as **proton donors.**

When acids dissolve in water, they release hydrogen ions (protons) and anions. It is the concentration of protons that determines the acidity of a solution. The anions have little or no effect on acidity. For example, hydrochloric acid (HCl), an acid produced by stomach cells that aids digestion, dissociates into a proton and a chloride ion:

$$\underset{}{HCl} \rightarrow \underset{\text{proton}}{H^+} + \underset{\text{anion}}{Cl^-}$$

Other acids found or produced in the body include acetic acid ($HC_2H_3O_2$, commonly abbreviated as HAc), which is the acidic portion of vinegar; and carbonic acid (H_2CO_3). The molecular formula for an acid is easy to recognize because the hydrogen is written first.

Bases

Bases have a bitter taste, feel slippery, and are **proton acceptors**—that is, they take up hydrogen ions (H^+) in detectable amounts. Common inorganic bases include the *hydroxides* (hi-drok'sīds), such as magnesium hydroxide (milk of magnesia) and sodium hydroxide (lye). Like acids, hydroxides dissociate when dissolved in water, but in this case **hydroxyl ions (OH^-)** (hi-drok'sil) and cations are liberated. For example, ionization of sodium hydroxide (NaOH) produces a hydroxyl ion and a sodium ion; the hydroxyl ion then binds to (accepts) a proton present in the solution. This produces water and simultaneously reduces the acidity (hydrogen ion concentration) of the solution:

$$\underset{}{NaOH} \rightarrow \underset{\text{cation}}{Na^+} + \underset{\text{hydroxyl ion}}{OH^-}$$

and then

$$\underset{}{OH^-} + H^+ \rightarrow \underset{\text{water}}{H_2O}$$

Bicarbonate ion (HCO_3^-), an important base in the body, is particularly abundant in blood. **Ammonia (NH_3),** a common waste product of protein breakdown in the body, is also a base. It has one pair of unshared electrons that strongly attracts

Q *Which ion is responsible for increasing acidity?*

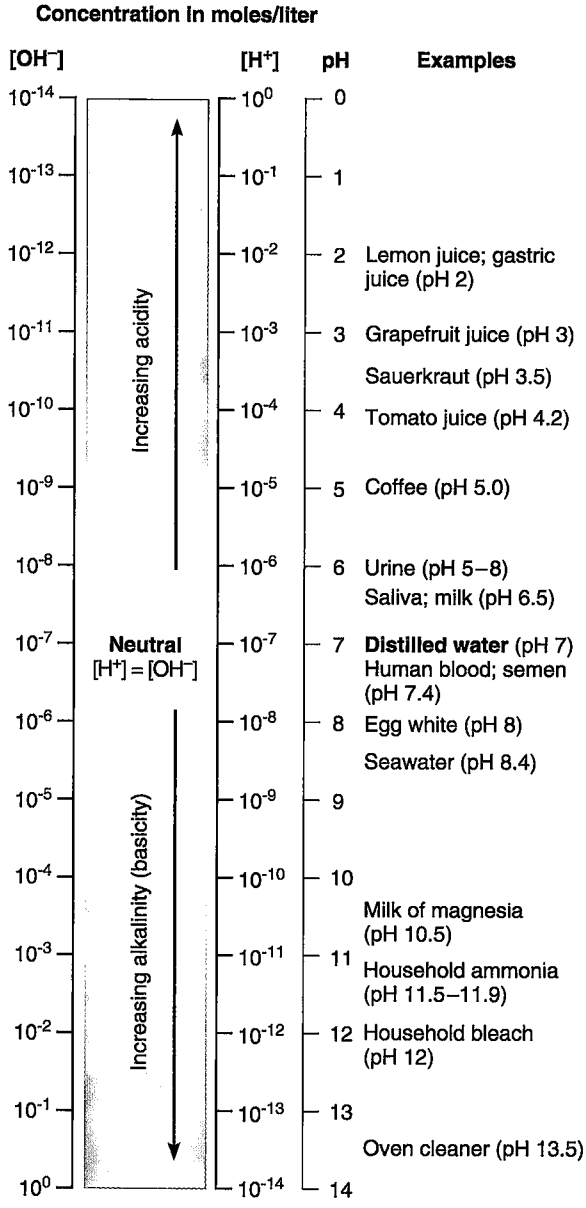

FIGURE 2.13 **The pH scale and pH values of representative substances.** The pH scale is based on the number of hydrogen ions in solution. The actual concentration of hydrogen ions, $[H^+]$, and hydroxyl ions, $[OH^-]$, in moles per liter are indicated for each pH value noted. At a pH of 7, the concentrations of hydrogen and hydroxyl ions are equal and the solution is neutral.

protons. By accepting a proton, ammonia becomes an ammonium ion:

$$NH_3 + H^+ \rightarrow \underset{\text{ammonium ion}}{NH_4^+}$$

A Hydrogen ion.

pH: Acid-Base Concentration

The more hydrogen ions in a solution, the more acidic the solution is. Conversely, the greater the concentration of hydroxyl ions (the lower the concentration of H^+), the more basic, or *alkaline* (al'kuh-līn), the solution becomes. The relative concentration of hydrogen ions in various body fluids is measured in concentration units called **pH units** (pe-āch').

The idea for a pH scale was devised by a Danish biochemist and part-time beer brewer named Sören Sörensen in 1909. He was searching for a convenient means of checking the acidity of his alcoholic product to prevent its spoilage by bacterial action. (Many bacteria are inhibited by acidic conditions.) The pH scale that resulted is based on the concentration of hydrogen ions in a solution, expressed in terms of moles per liter, or molarity. The pH scale runs from 0 to 14 and is logarithmic; that is, each successive change of one pH unit represents a tenfold change in hydrogen ion concentration (Figure 2.13). The pH of a solution is thus defined as the negative logarithm of the hydrogen ion concentration $[H^+]$ in moles per liter or $-\log[H^+]$. (Note that brackets [ ] indicate concentration of a substance.)

At a pH of 7 (at which $[H^+]$ is 10^{-7} M), the number of hydrogen ions exactly equals the number of hydroxyl ions (pH = pOH), and the solution is *neutral*—neither acidic nor basic. Absolutely pure (distilled) water has a pH of 7. Solutions with a pH below 7 are acidic; the hydrogen ions outnumber the hydroxyl ions. The lower the pH, the more acidic the solution. A solution with a pH of 6 has ten times as many hydrogen ions as a solution with a pH of 7.

Solutions with a pH higher than 7 are alkaline, and the relative concentration of hydrogen ions decreases by a factor of 10 with each higher pH unit. Thus, solutions with pH values of 8 and 12 have, respectively, 1/10 and 1/100,000 (1/10 × 1/10 × 1/10 × 1/10 × 1/10) as many hydrogen ions as a solution of pH 7. Notice that as the hydrogen ion concentration decreases, the hydroxyl ion concentration rises, and vice versa. The approximate pH of several body fluids and of a number of common substances also appears in Figure 2.13.

Neutralization

When acids and bases are mixed, they react with each other in displacement reactions to form water and a salt. For example, when hydrochloric acid and sodium hydroxide interact, sodium chloride (a salt) and water are formed.

$$\underset{\text{acid}}{HCl} + \underset{\text{base}}{NaOH} \rightarrow \underset{\text{salt}}{NaCl} + \underset{\text{water}}{H_2O}$$

This type of reaction is called a **neutralization reaction,** because the joining of H^+ and OH^- to form

water neutralizes the solution. Although the salt produced is written in molecular form (NaCl), remember that it actually exists as dissociated sodium and chloride ions when dissolved in water.

Buffers

Living cells are extraordinarily sensitive to even slight changes in the pH of the environment. In high concentrations, acids and bases are extremely damaging to living tissue. (Imagine what would happen to all those hydrogen bonds in biological molecules with large numbers of free H^+ running around.) Homeostasis of acid-base balance is carefully regulated by the kidneys and lungs and by chemical systems (proteins and other types of molecules) called **buffers.** Buffers resist abrupt and large swings in the pH of body fluids by releasing hydrogen ions (acting as acids) when the pH begins to rise and by binding hydrogen ions (acting as bases) when the pH drops. Because blood comes into close contact with nearly every body cell, regulation of its pH is particularly critical. Normally, blood pH varies within a very narrow range (7.35 to 7.45). If blood pH varies from these limits by more than a few tenths of a unit, it may be fatal.

To comprehend how chemical buffer systems operate, you must thoroughly understand strong and weak acids and bases. The first important concept is that the acidity of a solution reflects *only* the free hydrogen ions, not those still bound to anions. Consequently, acids that dissociate completely and irreversibly in water are called **strong acids,** because they can dramatically change the pH of a solution. Examples are hydrochloric acid and sulfuric acid. If we could count out 100 hydrochloric acid molecules and place them in 1 ml of water, we could expect to end up with 100 H^+, 100 Cl^-, and no undissociated hydrochloric acid molecules in that solution.

Acids that do not dissociate completely, like carbonic acid (H_2CO_3) and acetic acid (HAc), are **weak acids.** If we were to place 100 acetic acid molecules in 1 ml of water, the reaction would be something like this:

$$100\ HAc \rightarrow 90\ HAc + 10\ H^+ + 10\ Ac^-$$

Because undissociated acids do not affect pH, the acetic acid solution is much less acidic than the HCl solution. Weak acids dissociate in a predictable way, and molecules of the intact acid are in dynamic equilibrium with the dissociated ions. Consequently, the dissociation of acetic acid may also be written as

$$HAc \rightleftharpoons H^+ + Ac^-$$

This viewpoint allows us to see that if H^+ (released by a strong acid) is added to the acetic acid solution, the equilibrium will shift to the left and some H^+ and Ac^- will recombine to form HAc. On the other hand, if a strong base is added and the pH begins to rise, the equilibrium shifts to the right and more HAc molecules dissociate to release H^+. This characteristic of weak acids allows them to play important roles in the chemical buffer systems of the body.

The concept of strong and weak bases is more easily explained. Remember that bases are proton acceptors. Thus, **strong bases** are those, like hydroxides, that dissociate easily in water and quickly tie up H^+. On the other hand, sodium bicarbonate (commonly known as baking soda) ionizes incompletely and reversibly. Because it accepts relatively few protons, its released bicarbonate ion is considered a **weak base.**

Now let's examine how one buffer system helps to maintain pH homeostasis of the blood. Although there are other chemical blood buffers, the **carbonic acid–bicarbonate system** is a major one. Carbonic acid (H_2CO_3) dissociates reversibly releasing bicarbonate ions (HCO_3^-) and protons (H^+):

$$\underset{\substack{H^+ \text{ donor} \\ \text{(weak acid)}}}{H_2CO_3} \underset{\text{Response to drop in pH}}{\overset{\text{Response to rise in pH}}{\rightleftharpoons}} \underset{\substack{H^+ \text{ acceptor} \\ \text{(weak base)}}}{HCO_3^-} + \underset{\text{proton}}{H^+}$$

The chemical equilibrium between carbonic acid (a weak acid) and bicarbonate ion (a weak base) resists changes in blood pH by shifting to the right or left as H^+ ions are added to or removed from the blood. As blood pH rises (i.e., becomes more alkaline due to the addition of a strong base), the equilibrium shifts to the right, forcing more carbonic acid to dissociate. Similarly, as blood pH begins to drop (i.e., becomes more acidic due to the addition of a strong acid), the equilibrium shifts to the left as more bicarbonate ions begin to bind with protons. As you can see, strong bases are replaced by a weak base (bicarbonate ion) and protons released by strong acids are tied up in a weak one (carbonic acid). In either case, the blood pH changes much less than it would in the absence of the buffering system. Acid-base balance and buffers are discussed in more detail in Chapter 26.

Organic Compounds

Molecules unique to living systems—proteins, carbohydrates, lipids (fats), and nucleic acids—all contain carbon and hence are organic compounds. Although organic compounds are distinguished by the fact that they contain carbon and inorganic compounds are defined as compounds that lack carbon, there are a few irrational exceptions to this generalization that you should be aware of. Carbon dioxide, carbon monoxide, and carbides, for example, all

contain carbon but are considered inorganic compounds. For the most part, organic molecules are very large molecules and their interactions with other molecules typically involve only small, reactive parts of their structure called *functional groups* (acid groups, amines, and others). The most important functional groups involved in biochemical reactions are illustrated in Appendix B.

What makes carbon so special that "living" chemistry depends on its presence? To begin with, no other *small* atom is so precisely **electroneutral.** The consequence of its electroneutrality is that carbon never loses or gains electrons; it always shares them. Furthermore, with four valence shell electrons, carbon forms four covalent bonds with other elements, as well as with other carbon atoms. As a result, carbon is found in long, chainlike molecules (common in fats), ring structures (typical of carbohydrates and steroids), and many other structures that are uniquely suited for specific roles in the body.

Carbohydrates

Carbohydrates, a group of molecules that includes sugars and starches, represent 1–2% of cell mass. Carbohydrates contain carbon, hydrogen, and oxygen, and generally the hydrogen and oxygen atoms occur in the same 2:1 ratio as in water. This ratio is reflected in the word *carbohydrate* ("hydrated carbon").

A carbohydrate can be classified according to size and solubility as a monosaccharide ("one sugar"), disaccharide ("two sugars"), or polysaccharide ("many sugars"). Monosaccharides are the structural units, or building blocks, of the other carbohydrates. In general, the larger the carbohydrate molecule, the less soluble it is in water.

Monosaccharides

Monosaccharides (mon"o-sak'ah-rīdz), or *simple sugars,* are single-chain or single-ring structures containing from three to seven carbon atoms (Figure 2.14a). Usually the carbon, hydrogen, and oxygen atoms occur in the ratio 1:2:1, so a general formula for a monosaccharide is $(CH_2O)n$, where n is the number of carbons in the sugar. Glucose, for example, has six carbon atoms, and its molecular formula is $C_6H_{12}O_6$. Ribose, with five carbons, is $C_5H_{10}O_5$.

Monosaccharides are named generically according to the number of carbon atoms they contain. Most important in the body are the pentose (five-carbon) and hexose (six-carbon) sugars. For example, the pentose *deoxyribose* (de-ok"sī-ri'bōs) is part of DNA, and *glucose,* a hexose, is blood sugar. Two other hexoses, *galactose* and *fructose,* are **isomers** (i'so-mers) of glucose. That is, they have the same molecular formula ($C_6H_{12}O_6$), but their atoms are arranged differently, giving them different chemical properties.

Disaccharides

A **disaccharide** (di-sak'ah-rīd), or *double sugar,* is formed when two monosaccharides are joined by *dehydration synthesis* (Figure 2.14b). In this synthesis reaction, a water molecule is lost as the bond is made, as illustrated by the synthesis of sucrose (soo'krōs):

$$\underset{\text{glucose + fructose}}{2C_6H_{12}O_6} \rightarrow \underset{\text{sucrose}}{C_{12}H_{22}O_{11}} + \underset{\text{water}}{H_2O}$$

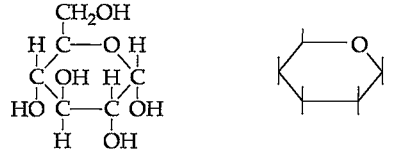
Notice that the molecular formula for sucrose contains two hydrogen atoms and one oxygen atom less than the total number of hydrogen and oxygen atoms in glucose and fructose, because a water molecule is released during bond formation.

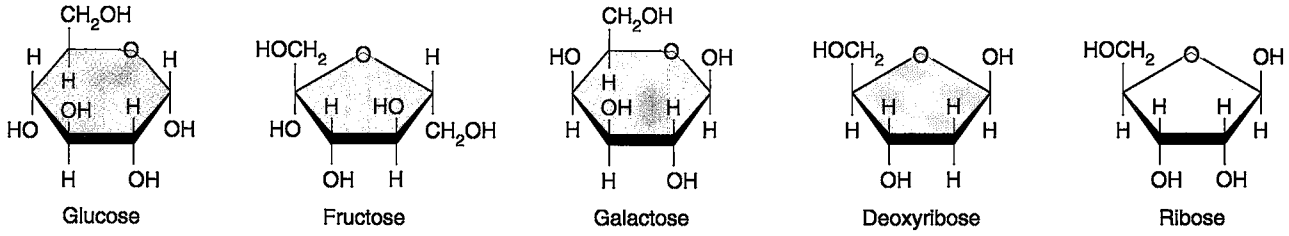
Important disaccharides in the diet are *sucrose* (glucose + fructose), which is cane or table sugar; *lactose* (glucose + galactose), found in milk; and *maltose* (glucose + glucose), also called malt sugar (see Figure 2.14b). Disaccharides are too large to pass through cell membranes, so they must be digested to their simple sugar units to be absorbed from the digestive tract into the blood. This decomposition process, called *hydrolysis,* is essentially the reverse of dehydration synthesis. A water molecule is added to each bond, breaking the bonds and releasing the simple sugar units.

Polysaccharides

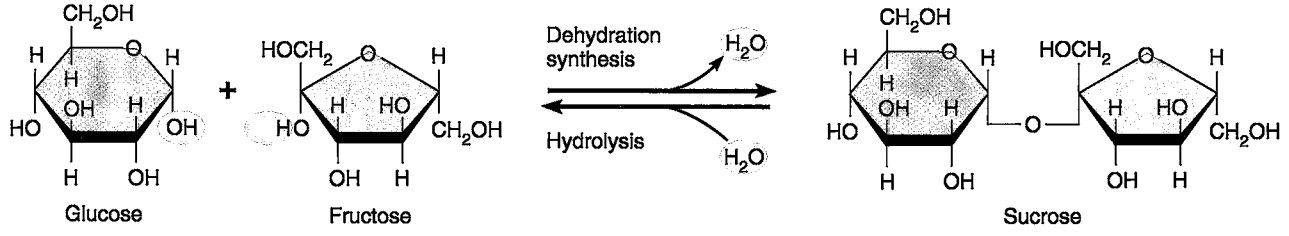
Polysaccharides (pol"e-sak'ah-rīdz) are long chains of simple sugars linked together by dehydration synthesis. Such chainlike molecules made of many similar units are called **polymers.** Because polysaccharides are large, fairly insoluble molecules, they are ideal storage products. Another consequence of their large size is that they lack the sweetness of the simple and double sugars. Only two polysaccharides are of major importance to the body: starch and glycogen. Both are polymers of glucose. Only their degree of branching differs.

*Notice that in Figure 2.14 the carbon (C) atoms present at the angles of the carbohydrate ring structures are not illustrated and in Figure 2.14c only the oxygen atoms are shown. For example, the illustrations below show the full structure of glucose on the left and the shorthand structure on the right. This type of shorthand is used for nearly all organic ringlike structures illustrated in this chapter.

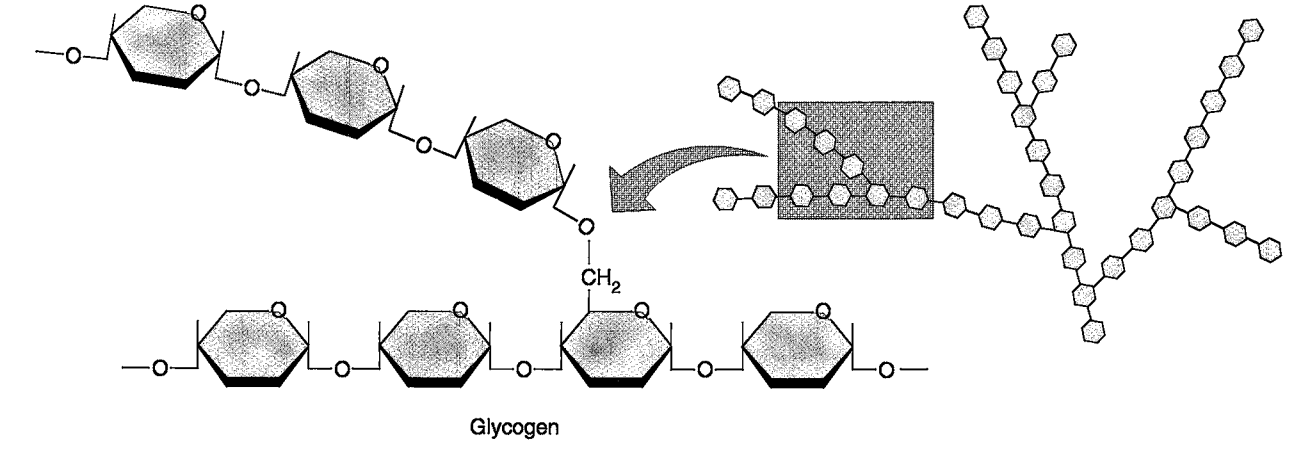




(a) Monosaccharides



(b) Disaccharides



(c) Portion of a polysaccharide molecule (glycogen)

FIGURE 2.14 **Carbohydrate molecules.*** **(a)** Monosaccharides important to the body. The hexose sugars glucose, fructose, and galactose are isomers: They have the same molecular formula ($C_6H_{12}O_6$), but the arrangement of their atoms differs, as shown here. Deoxyribose and ribose are pentose sugars. **(b)** Disaccharides are two monosaccharides linked together by dehydration synthesis. Formation of sucrose ($C_{12}H_{22}O_{11}$) from glucose and fructose molecules is illustrated. In the reverse reaction (hydrolysis), sucrose is broken down to glucose and fructose. Other important disaccharides are maltose and lactose (both $C_{12}H_{22}O_{11}$). **(c)** Simplified representation of part of a glycogen molecule, a polysaccharide formed from glucose units.

* See footnote on facing page concerning the complete structure of these sugars.

Starch is the storage carbohydrate formed by plants. The number of glucose units composing a starch molecule is high and variable. When we eat starchy foods such as grain products and potatoes, the starch must be digested for its glucose units to be absorbed. We are unable to digest *cellulose,* another polysaccharide found in all plant products. However, it is important in providing the *bulk* (one form of fiber) that helps move feces through the colon.

Glycogen (gli'ko-jen), the storage carbohydrate of animal tissues, is stored primarily in skeletal muscle and liver cells. Like starch, it is highly branched and is a very large molecule (see Figure 2.14c). When blood sugar levels drop sharply, liver cells break down glycogen and release its glucose units to the blood. Since there are many branch endings from which glucose can be released simultaneously, body cells have almost instant access to glucose fuel.

Carbohydrate Functions

The major function of carbohydrates in the body is to provide a ready, easily used source of cellular fuel. Most cells can use only a few simple sugars, and glucose is at the top of the "cellular menu." As described in our earlier discussion of oxidation-reduction reactions (p. 38), glucose is broken down and oxidized within cells. During these chemical reactions, electrons are transferred. This relocation of electrons releases the bond energy stored in glucose, and this energy is used to synthesize ATP. When ATP supplies are sufficient, dietary carbohydrates are converted to glycogen or fat and stored. Those of us who have gained weight from eating too many carbohydrate-rich snacks have personal experience with this conversion process!

Only small amounts of carbohydrates are used for structural purposes. For example, some sugars are found in our genes. Others are attached to the external surfaces of cells where they act as "road signs" to guide cellular interactions.

Lipids

Lipids are insoluble in water but dissolve readily in other lipids and in organic solvents such as alcohol and ether. Like carbohydrates, all lipids contain carbon, hydrogen, and oxygen, but the proportion of oxygen in lipids is much lower. In addition, phosphorus is found in some of the more complex lipids. Lipids include *triglycerides, phospholipids* (fos"fo-lip'idz), *steroids* (stĕ'roidz), and a number of other lipoid substances. Table 2.2 on page 48 gives the locations and functions of some lipids found in the body.

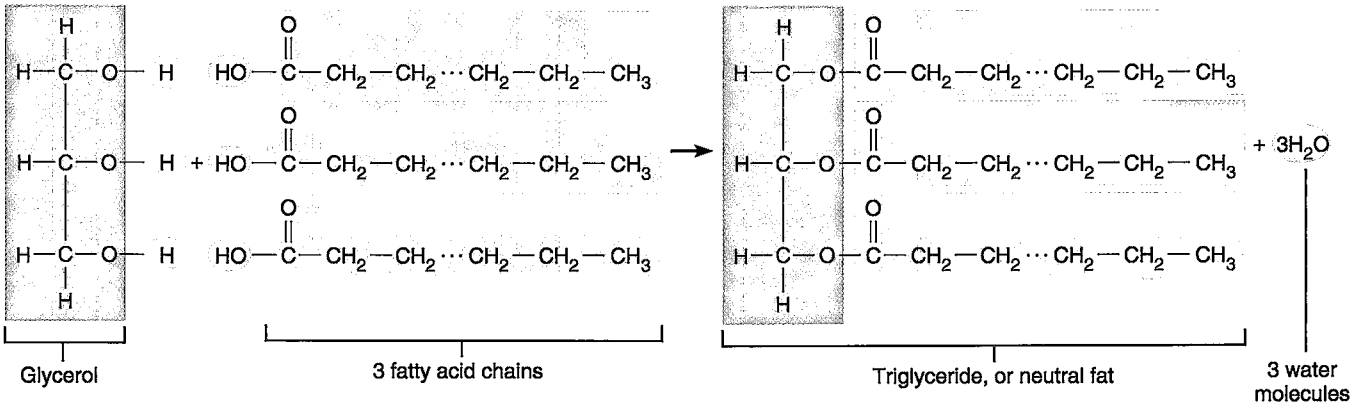
Triglycerides (Neutral Fats)

Triglycerides (tri-glis'er-īdz), also called **neutral fats,** are commonly known as *fats* when solid or *oils* when liquid. A triglyceride is composed of two types of building blocks, **fatty acids** and **glycerol** (glis'er-ol), in a 3:1 ratio of fatty acids to glycerol (Figure 2.15a). Fatty acids are linear chains of carbon and hydrogen atoms (hydrocarbon chains) with an organic acid group (—COOH) at one end. Glycerol is a modified simple sugar (a sugar alcohol). Fat synthesis involves attaching three fatty acid chains to a single glycerol molecule by dehydration synthesis; the result is an E-shaped molecule. The glycerol backbone is the same in all triglycerides, but the fatty acid chains vary, resulting in different kinds of fats and oils. These are large molecules, often consisting of hundreds of atoms, and ingested fats and oils must be broken down to their building blocks before they can be absorbed. Their hydrocarbon chains make the triglycerides nonpolar molecules. Because polar and nonpolar molecules do not interact, oil (or fats) and water do not mix. Consequently, triglycerides provide the body's most efficient and compact form of stored energy, and when they are oxidized, they yield large amounts of energy.

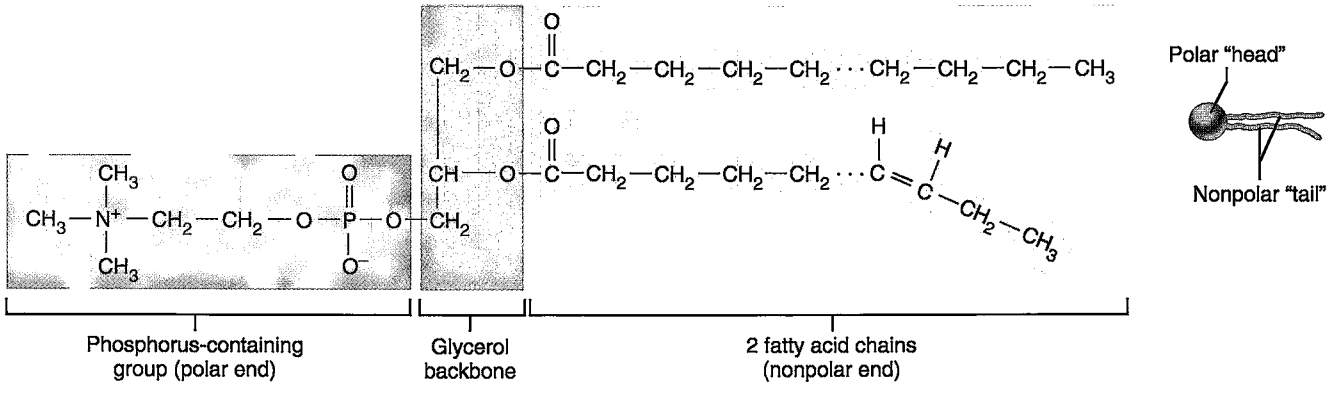
Deposits of triglycerides are found mainly beneath the skin, where they insulate the deeper body tissues from heat loss and protect them from mechanical trauma. Women are usually more successful English Channel swimmers than men. This is due partly to their thicker subcutaneous fatty layer, which helps insulate them from the bitterly cold water of the Channel.

The length of a triglyceride's fatty acid chains and their degree of saturation with H atoms determine how solid the molecule is at a given temperature. Fatty acid chains with only single covalent bonds between carbon atoms are referred to as **saturated.** Their fatty acid chains are straight and, at room temperature, the molecules of a saturated fat are packed closely together, forming a solid. Fatty acids that contain one or more double bonds between carbon atoms are said to be **unsaturated** (**monounsaturated** and **polyunsaturated,** respectively). The double bonds cause the fatty acid chains to kink so that they cannot be packed closely enough to solidify. Hence, triglycerides with short fatty acid chains or unsaturated fatty acids are oils (liquid at room temperature) and are typical of plant lipids. Examples include olive and peanut oils (rich in monounsaturated fats) and corn, soybean, and safflower oils, which contain a high percentage of polyunsaturated fatty acids. Longer fatty acid chains and more saturated fatty acids are common in animal fats such as butterfat and the fat of meats, which are solid at room temperature. Of the two types of fatty acids, the unsaturated variety, especially olive oil, is said to be more "heart healthy."

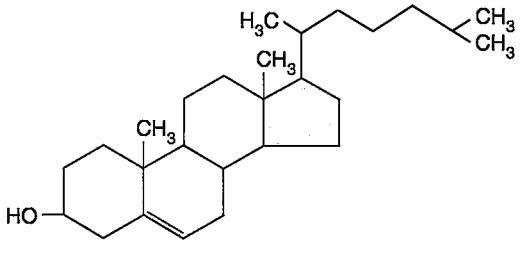
Trans fats, common in many margarines and baked products, are oils that have been solidified by



(a) Formation of a triglyceride



(b) Phospholipid molecule (phosphatidylcholine)



(c) Cholesterol

FIGURE 2.15 **Lipids. (a)** The triglycerides, or neutral fats, are synthesized by dehydration synthesis. **(b)** Structure of a typical phospholipid molecule. Two fatty acid chains and a phosphorus-containing group are attached to the glycerol backbone. In the commonly used schematic to the right, the polar end ("head") is depicted as a sphere, and the nonpolar end ("tail") is depicted as two wavy lines. **(c)** The generalized structure of cholesterol. Cholesterol is the basis for all steroids formed in the body.

addition of H atoms at sites of double carbon bonds. They have recently been branded as increasing the risk of heart disease even more than the solid animal fats. Conversely, the **omega-3 fatty acids,** found naturally in cold-water fish, appear to decrease the risk of heart disease and some inflammatory diseases.

Phospholipids

Phospholipids are modified triglycerides, that is, they are diglycerides with a phosphorus-containing group and two, rather than three, fatty acid chains (Figure 2.15b). The phosphorus-containing group gives phospholipids their distinctive chemical properties. Although the hydrocarbon portion (the "tail") of the molecule is nonpolar and interacts only with nonpolar molecules, the phosphorus-containing part (the "head") is polar and attracts other polar or charged particles, such as water or ions. Molecules that have both polar and nonpolar regions are *amphipathic* (am-fe-path'ik). As you will see in Chapter 3, cells use this unique characteristic of phospholipids in building their membranes. Some biologically important phospholipids and their functions are listed in Table 2.2.

Steroids

Structurally, steroids differ quite a bit from fats and oils. **Steroids** are basically flat molecules made of four interlocking hydrocarbon rings. Like triglycerides, steroids are fat soluble and contain little oxygen. The single most important molecule in our steroid chemistry is *cholesterol* (ko-les'ter-ol) (Figure 2.15c). We ingest cholesterol in animal products such as eggs, meat, and cheese, and our liver produces some.

TABLE 2.2 Representative Lipids Found in the Body

LIPID TYPE	LOCATION/FUNCTION
***Triglycerides* (Neutral Fats)**	In fat deposits (subcutaneous tissue and around organs); protect and insulate body organs; the major source of *stored* energy in the body
Phospholipids (phosphatidylcholine; cephalin; others)	Chief component of cell membranes; may participate in the transport of lipids in plasma; prevalent in nervous tissue
Steroids	
Cholesterol	The structural basis for manufacture of all body steroids
Bile salts	Breakdown products of cholesterol; released by the liver into the digestive tract, where they aid fat digestion and absorption
Vitamin D	A fat-soluble vitamin produced in the skin on exposure to UV radiation; necessary for normal bone growth and function
Sex hormones	Estrogen and progesterone (female hormones) and testosterone (a male hormone) are produced in the gonads and are necessary for normal reproductive function
Adrenocortical hormones	Cortisol, a glucocorticoid, is a metabolic hormone necessary for maintaining normal blood glucose levels; aldosterone helps to regulate salt and water balance of the body by targeting the kidneys
Other Lipoid Substances	
Fat-soluble vitamins:	
A	Found in orange-pigmented vegetables and fruits; converted in the retina to retinal, a part of the photoreceptor pigment involved in vision
E	Found in plant products such as wheat germ and green leafy vegetables; claims have been made (but not proved in humans) that it promotes wound healing, contributes to fertility; and may help to neutralize highly reactive particles called free radicals believed to be involved in triggering some types of cancer
K	Made available to humans largely by the action of intestinal bacteria; also prevalent in a wide variety of foods; necessary for proper clotting of blood
Eicosanoids (prostaglandins; leukotrienes; thromboxanes)	Group of molecules derived from fatty acids found in all cell membranes; the potent prostaglandins have diverse effects, including stimulation of uterine contractions, regulation of blood pressure, control of gastrointestinal tract motility, and secretory activity; both prostaglandins and leukotrienes are involved in inflammation; thromboxanes are powerful vasoconstrictors
Lipoproteins	Lipoid and protein-based substances that transport fatty acids and cholesterol in the bloodstream; major varieties are high-density lipoproteins (HDLs) and low-density lipoproteins (LDLs)

Cholesterol has earned bad press because of its role in arteriosclerosis, but it is essential for human life. Cholesterol is found in cell membranes and is the raw material of vitamin D, steroid hormones, and bile salts. Although steroid hormones are present in the body in only small quantities, they are vital to homeostasis. Without sex hormones, reproduction would be impossible, and a total lack of the corticosteroids produced by the adrenal glands is fatal.

Eicosanoids

The **eicosanoids** (i-ko'sah-noyds) are diverse lipids chiefly derived from a 20-carbon fatty acid (arachidonic acid) found in all cell membranes. Most important of these are the *prostaglandins* and their relatives, which play roles in various body processes (see Table 2.2) including blood clotting, inflammation, and labor contractions.

Proteins

The full set of proteins made by the body, called the *proteome,* and the way those proteins network in the body or change with disease, is a matter of intense biotech research.

Protein composes 10–30% of cell mass and is the basic structural material of the body. However, not all

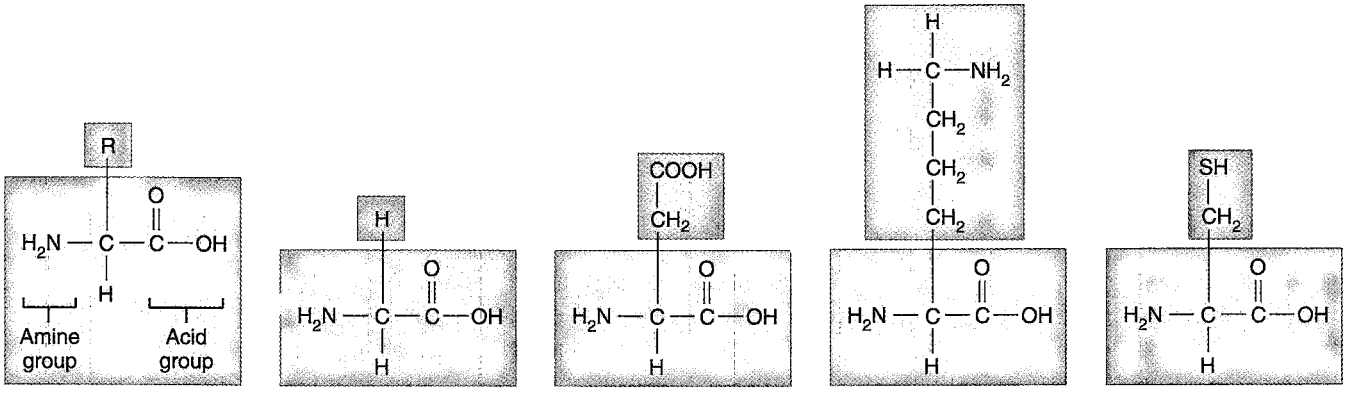


FIGURE 2.16 **Amino acid structures.** **(a)** Generalized structure of amino acids. All amino acids have both an amine ($—NH_2$) group and an acid (—COOH) group; they differ only in the atomic makeup of their R groups (green). **(b–e)** Specific structures of four amino acids. **(b)** The simplest (glycine) has an R group consisting of a single hydrogen atom. **(c)** An acid group in the R group, as in aspartic acid, makes the amino acid more acidic. **(d)** An amine group in the R group, as in lysine, makes the amino acid more basic. **(e)** The presence of a sulfhydryl (—SH) group in the R group of cysteine suggests that this amino acid is likely to participate in intramolecular bonding.

proteins are construction materials; many play vital roles in cell function. Proteins, which include enzymes (biological catalysts), hemoglobin of the blood, and contractile proteins of muscle, have the most varied functions of any molecules in the body. All proteins contain carbon, oxygen, hydrogen, and nitrogen, and many contain sulfur and phosphorus as well.

Amino Acids and Peptide Bonds

The building blocks of proteins are molecules called **amino acids,** of which there are 20 common types (see Appendix C). All amino acids have two important functional groups: a basic group called an *amine* (ah'mēn) *group* ($—NH_2$), and an organic *acid group* (—COOH). An amino acid may therefore act either as a base (proton acceptor) or an acid (proton donor). In fact, all amino acids are identical except for a single group of atoms called their *R group.* Differences in the R group make each amino acid chemically unique (Figure 2.16).

Proteins are long chains of amino acids joined together by dehydration synthesis, with the amine end of one amino acid linked to the acid end of the next. The resulting bond produces a characteristic arrangement of linked atoms called a **peptide bond** (Figure 2.17). Two united amino acids form a *dipeptide,* three a *tripeptide,* and ten or more a *polypeptide.* Although polypeptides containing more than 50 amino acids are called proteins, most proteins are **macromolecules,** large, complex molecules containing from 100 to over 10,000 amino acids.

Because each type of amino acid has distinct properties, the sequence in which they are bound together produces proteins that vary widely in both structure and function. We can think of the 20 amino acids as a 20-letter "alphabet" used in specific combinations to form "words" (proteins). Just as a change in one letter can produce a word with an entirely different meaning (flour → floor) or that is nonsensical (flour → fllur), changes in the kinds or positions of amino acids can yield proteins with different functions or proteins that are nonfunctional. Nevertheless, there are thousands of different proteins in the body, each with distinct functional properties, and all constructed from different combinations of the 20 common amino acids.

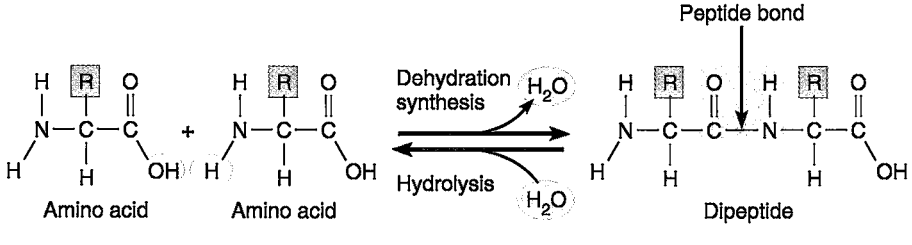

FIGURE 2.17 **Amino acids are linked together by dehydration synthesis.** The acid group of one amino acid is bonded to the amine group of the next, with loss of a water molecule. The bond formed is called a peptide bond. Peptide bonds are broken when water is added to the bond (i.e., during hydrolysis).

Structural Levels of Proteins

Proteins can be described in terms of four structural levels. The linear sequence of amino acids composing the polypeptide chain is called the *primary structure* of a protein. This structure, which resembles a strand of amino acid "beads," is the backbone of the protein molecule (Figure 2.18a).

Proteins do not normally exist as simple, linear chains of amino acids. Instead, they twist or bend upon themselves to form a more complex *secondary structure.* The most common type of secondary structure is the **alpha (α)-helix,** which resembles a Slinky toy or the coils of a telephone cord (Figure 2.18b). The α-helix, formed by coiling of the primary chain, is stabilized by hydrogen bonds formed between NH and CO groups in amino acids in the primary chain which are approximately four amino acids apart. Hydrogen bonds in α-helices always link different parts of the *same* chain together. In another type of secondary structure, the **beta (β)-pleated sheet,** the primary polypeptide chains do not coil, but are linked side by side by hydrogen bonds to form a pleated, ribbonlike structure (Figure 2.18c) that resembles an accordion. Notice that in this type of secondary structure, the hydrogen bonds may link together *different polypeptide chains* as well as *different parts* of the same chain that has folded back on itself. A single polypeptide chain may exhibit both types of secondary structure at various places along its length.

Many proteins have *tertiary structure* (ter'shea"re), the next higher level of complexity, which is superimposed on secondary structure. Tertiary structure is achieved when α-helical or β-pleated regions of the polypeptide chain fold upon one another to produce a compact ball-like, or globular, molecule. The tertiary structure (and underlying secondary structure) of a beta polypeptide chain of hemoglobin, the oxygen-binding protein found in red blood cells, is shown in Figure 2.18d. This unique structure is maintained by both covalent and hydrogen bonds between amino acids that are often far apart in the primary chain. When two or more polypeptide chains aggregate in a regular manner to form a complex protein, the protein has *quaternary structure* (kwah'ter-na"re). Hemoglobin (Figure 2.18e) exhibits this structural level.

Although a protein with tertiary or quaternary structure looks a bit like a clump of congealed pasta, the ultimate overall structure of any protein is very specific and is dictated by its primary structure. This reflects the fact that the types and relative positions of amino acids in the protein backbone determine where bonds can form to produce the complex coiled or folded structures that keep water-loving amino acids near the surface and water-fleeing amino acids buried in the protein's core. In addition, cells decorate many proteins by attaching sugars or fatty acids to them in ways that are difficult to imagine or predict.

Fibrous and Globular Proteins

The overall structure of a protein determines its biological function. In general, proteins are classified according to their overall appearance and shape as either fibrous or globular.

Fibrous proteins are extended and strandlike. Many exhibit only secondary structure, but some have quaternary structure as well. For example, *collagen* (kol'ah-jen) is a composite of the helical tropocollagen molecules packed together side by side to form a strong ropelike structure. Fibrous proteins are insoluble in water, and very stable—qualities ideal for providing mechanical support and tensile strength to the body's tissues. Besides collagen, which is the single most abundant protein in the body, the fibrous proteins include keratin, elastin, and certain contractile proteins of muscle (Table 2.3). Because fibrous proteins are the chief building materials of the body, they are also known as **structural proteins.**

Globular proteins are compact, spherical proteins that have at least tertiary structure; some also exhibit quaternary structure. The globular proteins are water soluble, chemically active molecules, and they play crucial roles in virtually all biological processes. Consequently, this group is also called **functional proteins.** Some (antibodies) help to provide immunity, others (protein-based hormones) regulate growth and development, and still others (enzymes) are catalysts that oversee just about every chemical reaction in the body. The roles of these and selected other proteins found in the body are summarized in Table 2.3.

Protein Denaturation

Fibrous proteins are stable, but globular proteins are quite the opposite. The activity of a protein depends on its specific three-dimensional structure, and intramolecular bonds, particularly hydrogen bonds, are important in maintaining that structure. However, hydrogen bonds are fragile and easily broken by many chemical and physical factors, such as excessive acidity or temperature. Although individual proteins vary in their sensitivity to environmental conditions, hydrogen bonds begin to break when the pH drops or the temperature rises above normal (physiological) levels, causing proteins to unfold and lose their specific three-dimensional shape. In this condition, a protein is said to be **denatured.** Fortunately, the disruption is reversible in most cases, and the "scrambled" protein regains its native structure

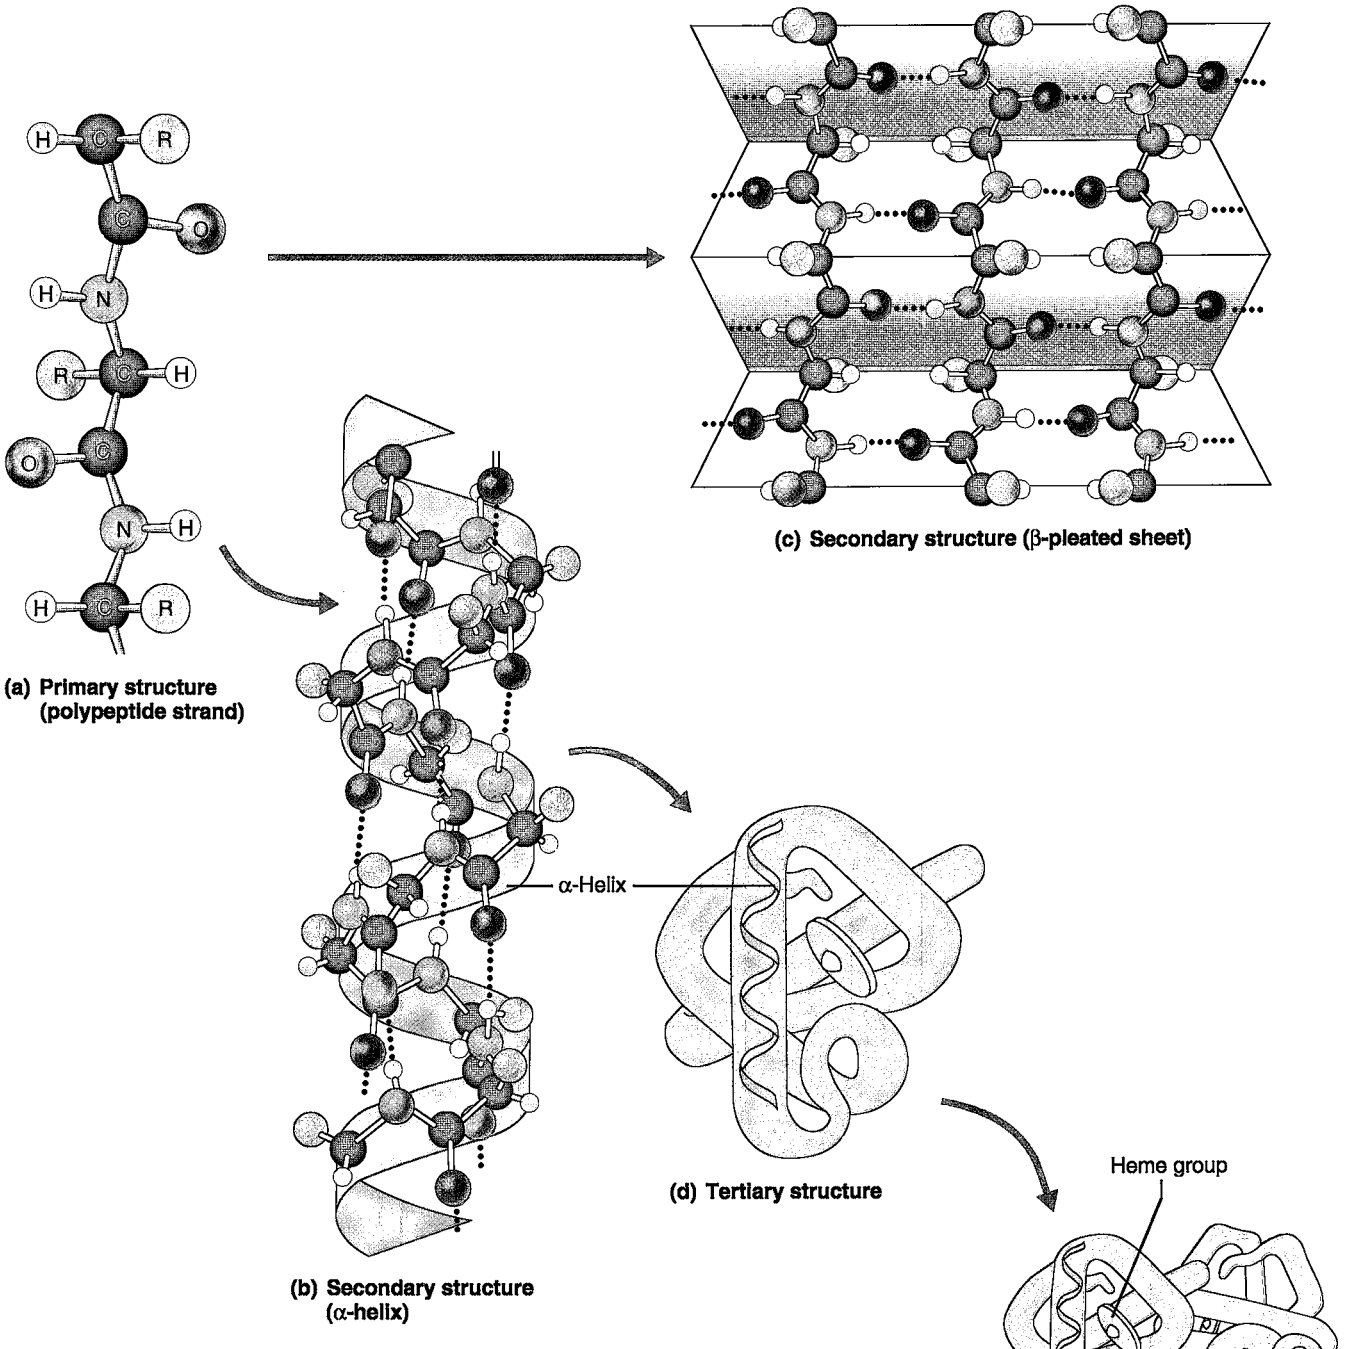

FIGURE 2.18 **Levels of protein structure. (a)** Primary structure. Amino acids are linked together to form a polypeptide strand. **(b)** Secondary structure—the α-helix. The primary chain is coiled upon itself to form a spiral structure that is maintained by hydrogen bonds (indicated by dotted lines). **(c)** Secondary structure—the β-pleated sheet. Two or more primary chains are linked side by side by hydrogen bonds to form an undulating ribbonlike structure. **(d)** Tertiary structure is superimposed on secondary structure (in this example on α-helical regions) to form a basically spherical molecule that is maintained by intramolecular bonds. The molecule shown is a beta chain, one of the four polypeptide chains of hemoglobin. **(e)** Quaternary structure of hemoglobin. Hemoglobin is formed from four polypeptide chains that are linked together in a specific manner.

TABLE 2.3 Representative Types of Proteins in the Body

CLASSIFICATION ACCORDING TO OVERALL STRUCTURE	GENERAL FUNCTION	EXAMPLES FROM THE BODY
Fibrous	Structural framework/ mechanical support	*Collagen,* found in all connective tissues, is the single most abundant protein in the body. It is responsible for the tensile strength of bones, tendons, and ligaments.
		Keratin is the structural protein of hair and nails and a waterproofing material of skin.
		Elastin is found, along with collagen, where durability and flexibility are needed, such as in the ligaments that bind bones together.
		Spectrin internally reinforces and stabilizes the surface membrane of some cells, particularly red blood cells. *Dystrophin* reinforces and stabilizes the surface membrane of muscle cells. *Titin* helps organize the intracellular structure of muscle cells and accounts for the elasticity of skeletal muscles.
	Movement	*Actin and myosin,* contractile proteins, are found in substantial amounts in muscle cells, where they cause muscle cell shortening (contraction); they also function in cell division in all cell types. Actin is important in intracellular transport, particularly in nerve cells.
Globular	Catalysis	Protein enzymes are essential to virtually every biochemical reaction in the body; they increase the rates of chemical reactions by at least a millionfold. Examples include salivary amylase (in saliva), which catalyzes the breakdown of starch, and oxidase enzymes, which act to oxidize food fuels.
	Transport	*Hemoglobin* transports oxygen in blood, and *lipoproteins* transport lipids and cholesterol. Other transport proteins in the blood carry iron, hormones, or other substances. Some globular proteins in plasma membranes are involved in membrane transport (as carriers or channels).
	Regulation of pH	Many plasma proteins, such as *albumin,* function reversibly as acids or bases, thus acting as buffers to prevent wide swings in blood pH.
	Regulation of metabolism	*Peptide* and *protein hormones* help to regulate metabolic activity, growth, and development. For example, *growth hormone* is an anabolic hormone necessary for optimal growth; *insulin* helps regulate blood sugar levels.
	Body defense	*Antibodies* (immunoglobulins) are specialized proteins released by immune cells that recognize and inactivate foreign substances (bacteria, toxins, some viruses). *Complement proteins,* which circulate in blood, enhance both immune and inflammatory responses.
		Molecular chaperones aid folding of new proteins in both healthy and damaged cells and transport of metal ions into and within the cell. They also promote breakdown of damaged proteins.

when desirable conditions are restored. However, if the temperature or pH change is so extreme that protein structure is damaged beyond repair, the protein is *irreversibly denatured.* The coagulation of egg white (primarily albumin protein) that occurs when you boil or fry an egg is an example of irreversible protein denaturation. There is no way to restore the white, rubbery protein to its original translucent form.

When globular proteins are denatured, they can no longer perform their physiological roles because their function depends on the presence of specific arrangements of atoms, called **active sites,** on their surfaces. The active sites are regions that fit and interact chemically with other molecules of complementary shape and charge. Because atoms contributing to an active site may actually be far apart in the primary chain, disruption of intramolecular bonds separates them and destroys the active site (Figure 2.19). Hemoglobin becomes totally unable to bind and transport oxygen when blood pH is too acidic, because the structure needed for its function has been destroyed.

Most body proteins are described in conjunction with the organ systems or functional processes to which they are closely related. However, two groups of proteins—*molecular chaperones* and *enzymes*—are intimately involved in the normal functioning of all cells, and so these incredibly complex molecules are considered here.

Molecular Chaperones

In addition to the ubiquitous enzymes, all cells contain a class of unrelated globular proteins called

Q *What event, which is possible in situation (a), can no longer occur in situation (b)?*

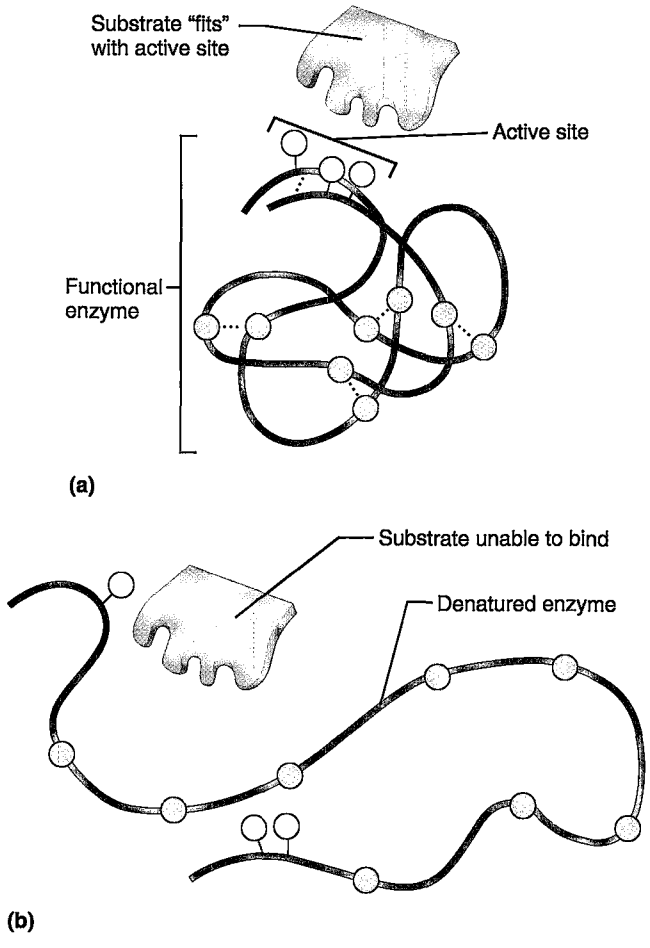

FIGURE 2.19 **Denaturation of a globular protein such as an enzyme. (a)** The molecule's globular structure is maintained by intramolecular bonds. Atoms composing the active site of the enzyme are shown as stalked particles. The substrate, or interacting molecule, has a corresponding binding site, and the two sites fit together precisely. **(b)** Breaking the intramolecular bonds that maintain the secondary and tertiary structure of the enzyme results in a linear molecule, with atoms of the former active site widely separated. Enzyme-substrate binding can no longer occur.

molecular chaperones, or **chaperonins,** which, among other things, help proteins to achieve their functional three-dimensional structure. Although its amino acid sequence determines the precise way a protein folds, the folding process also requires the help of molecular chaperones to ensure that the folding is quick and accurate. Apparently, molecular chaperones have numerous protein-related roles to play. For example, specific chaperonins

- Prevent accidental, premature, or incorrect folding of polypeptide chains or their association with other polypeptides
- Aid the desired folding and association process
- Help to translocate proteins and certain metal ions (copper, iron, zinc) across cell membranes
- Promote the breakdown of damaged or denatured proteins

The first such proteins discovered were called *heat shock proteins (hsp)* because they seemed to protect cells from the destructive effects of heat. It was later found that these proteins are produced in response to a variety of traumatizing stimuli—for example, in the oxygen-deprived cells of a heart attack patient—and the name *stress proteins* replaced hsp for that particular group of chaperonins. It is now clear that chaperonins are vitally important to cell function in all types of stressful circumstances.

Enzymes and Enzyme Activity

Characteristics of Enzymes **Enzymes** are globular proteins that act as biological catalysts. *Catalysts* are substances that regulate and accelerate the rate of biochemical reactions but are not used up or changed in those reactions. More specifically, enzymes can be thought of as chemical traffic cops that keep our metabolic pathways flowing. Enzymes cannot force chemical reactions to occur between molecules that would not otherwise react; they can only increase the speed of reaction. Without enzymes, biochemical reactions proceed so slowly that for practical purposes they do not occur at all.

Some enzymes are purely protein. In other cases, the functional enzyme consists of two parts, collectively called a **holoenzyme:** an **apoenzyme** (the protein portion) and a **cofactor.** Depending on the enzyme, the cofactor may be an ion of a metal element such as copper or iron, or an organic molecule needed to assist the reaction in some particular way. Most organic cofactors are derived from vitamins (especially the B complex vitamins); this type of cofactor is more precisely called a **coenzyme.**

Each enzyme is chemically specific. Some enzymes control only a single chemical reaction. Others exhibit a broader specificity in that they can bind with similar (but not identical) molecules and thus regulate a small group of related reactions. The presence of specific enzymes thus determines not only which reactions will be speeded up, but also which reactions will occur—no enzyme, no reaction. This also means that unwanted or unnecessary chemical reactions do not occur. Most enzymes are named for the type of reaction they catalyze. *Hydrolases*

A *The substrate can no longer bind to the enzyme's active site in (b) because the atoms composing the active site are no longer in their functional relationship to one another.*

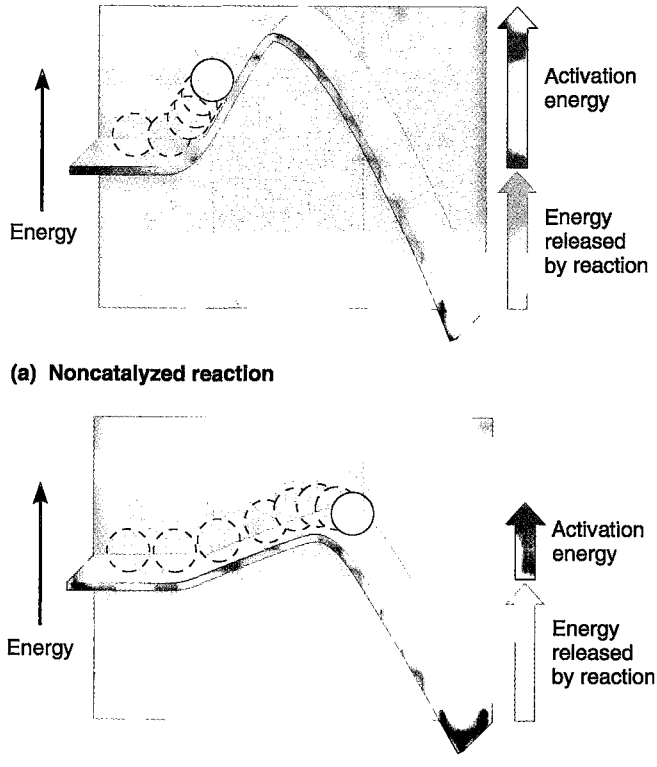

FIGURE 2.20 **Enzymes lower the energy barrier for a reaction. (a)** The reacting particles, indicated by the ball, must achieve a certain energy level before they can interact. The amount of energy that must be absorbed to reach that state is the activation energy. **(b)** The energy barrier and thus the activation energy is lower in the same reaction catalyzed by an enzyme.

(hi'druh-lās-es) add water during hydrolysis reactions; *oxidases* (ok'sĭ-dās-es) add oxygen; and so on. Most enzyme names can be recognized by the suffix *-ase.*

In many cases, enzymes are part of cellular membranes in a bucket-brigade type of arrangement; that is, the product of one enzyme-catalyzed reaction becomes the substrate of the abutting enzyme, and so on. Some enzymes are produced in an inactive form and must be activated in some way before they can function, often by a change in the pH of their surroundings. For example, digestive enzymes produced in the pancreas are activated in the small intestine, where they actually do their work. If they were produced in active form, the pancreas would digest itself. Sometimes, enzymes are inactivated immediately after they have performed their catalytic function. This is true of enzymes that promote blood clot formation when the wall of a blood vessel is damaged. Once clotting is triggered, those enzymes are inactivated. Otherwise, you would have blood vessels full of solid blood instead of one protective blood clot.

Mechanism of Enzyme Activity How do enzymes perform their catalytic role? Every chemical reaction requires that a certain amount of energy, called **activation energy,** be absorbed to prime the reaction. The activation energy is the amount of energy required to break the bonds of the reactants so that they can rearrange themselves and become the product. It is present when kinetic energy pushes the reactants to an energy level where their random collisions are forceful enough to ensure interaction. This is true regardless of whether the overall reaction is ultimately energy absorbing or energy releasing.

One obvious way to increase kinetic energy is to increase the temperature, but in living systems this would denature proteins. (This is why a high fever can be a serious event.) Enzymes allow reactions to occur at normal body temperature by decreasing the amount of activation energy required (Figure 2.20). Exactly how enzymes accomplish this remarkable feat is not fully understood. However, we know that, due to structural and electrostatic factors, they decrease the randomness of reactions by binding the reacting molecules temporarily to the enzyme surface and presenting them to each other in the proper position for chemical interaction to occur.

Three basic steps appear to be involved in the mechanism of enzyme action (Figure 2.21).

① The enzyme's active site must first bind with the substance(s) on which it acts. These substances are called the **substrates** of the enzyme. Substrate binding causes the active site to change shape so that the substrate and the active site fit together precisely. Although enzymes are specific for particular substrates, other (nonsubstrate) molecules may act as *enzyme inhibitors* if their structure is similar enough to occupy or block the enzyme's active site.

② The enzyme-substrate complex undergoes internal rearrangements that form the product.

③ The enzyme releases the product of the reaction. This step shows the catalytic role of an enzyme: If the enzyme became part of the product, it would be a reactant and not a catalyst.

Because the unaltered enzymes can act again and again, cells need only small amounts of each enzyme. Catalysis occurs with incredible speed; most enzymes can catalyze millions of reactions per minute.

Nucleic Acids (DNA and RNA)

The **nucleic acids** (nu-kle'ic), composed of carbon, oxygen, hydrogen, nitrogen, and phosphorus, are the largest molecules in the body. Their structural units, called **nucleotides,** are quite complex. Each nucleotide

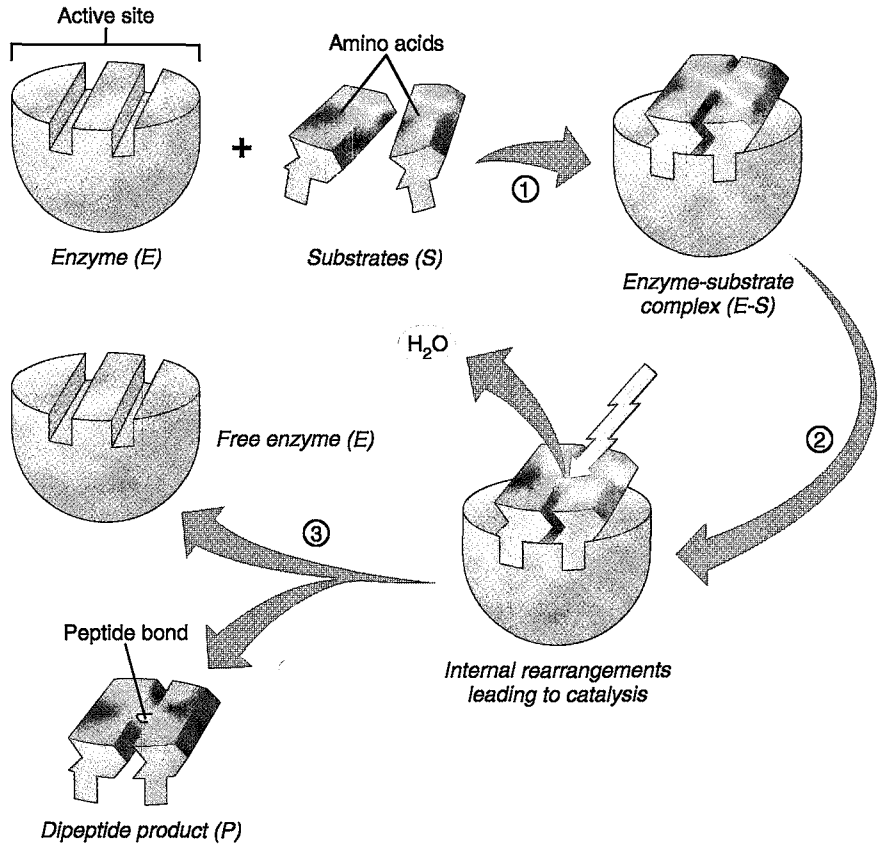

FIGURE 2.21 **Mechanism of enzyme action.** In this example, the enzyme catalyzes the formation of a dipeptide from specific amino acids. ① The enzyme-substrate complex (E-S) is formed. ② Internal rearrangements occur. In this case, energy is absorbed (indicated by the yellow arrow) as a water molecule is removed and a peptide bond is formed. ③ The enzyme releases the product (P) of the reaction, the dipeptide. The free enzyme has not changed in the course of the reaction and is now available to catalyze another such reaction.
Summary: E + S → E-S → P + E

consists of three components (Figure 2.22a): a nitrogen-containing base, a pentose sugar, and a phosphate group. Five major varieties of nitrogen-containing bases can contribute to nucleotide structure: **adenine,** abbreviated **A** (ad'ĕ-nēn); **guanine, G** (gwan'ēn); **cytosine, C** (si'to-sēn); **thymine, T** (thi'mēn); and **uracil, U** (u'rah-sil). Adenine and guanine are large, two-ring bases (called purines), whereas cytosine, thymine, and uracil are smaller, single-ring bases (called pyrimidines).

The stepwise synthesis of a nucleotide involves the attachment of a base to the pentose sugar to form first a *nucleoside,* named for the nitrogenous base it contains. The nucleotide is formed when a phosphate group is bonded to the sugar of the nucleoside.

The nucleic acids include two major classes of molecules, **deoxyribonucleic acid (DNA)** (de-ok"sĭ-ri"bo-nu-kle'ik) and **ribonucleic acid (RNA).** Although DNA and RNA are both composed of nucleotides, they differ in many respects. Typically, DNA is found in the nucleus (control center) of the cell, where it constitutes the *genetic material,* also called the *genes,* or more recently the *genome.* DNA has two fundamental roles: It replicates (reproduces) itself before a cell divides, ensuring that the genetic information in the descendant cells is identical, and it provides the basic instructions for building every protein in the body. By providing the information for protein synthesis, DNA determines what type of organism you will be—frog, human, oak tree—and directs your growth and development. Although we have said that enzymes govern all chemical reactions, remember that enzymes, too, are proteins formed at the direction of DNA. RNA is located chiefly outside the nucleus and can be considered a "molecular slave" of DNA. That is, RNA carries out the orders for protein synthesis issued by DNA. [Viruses in which RNA (rather than DNA) is the genetic material are an exception to this generalization.]

DNA is a long, double-stranded polymer—a double chain of nucleotides (Figure 2.22b and c). The bases in DNA are A, G, C, and T, and its pentose sugar is *deoxyribose* (as reflected in its name). Its two nucleotide chains are held together by hydrogen

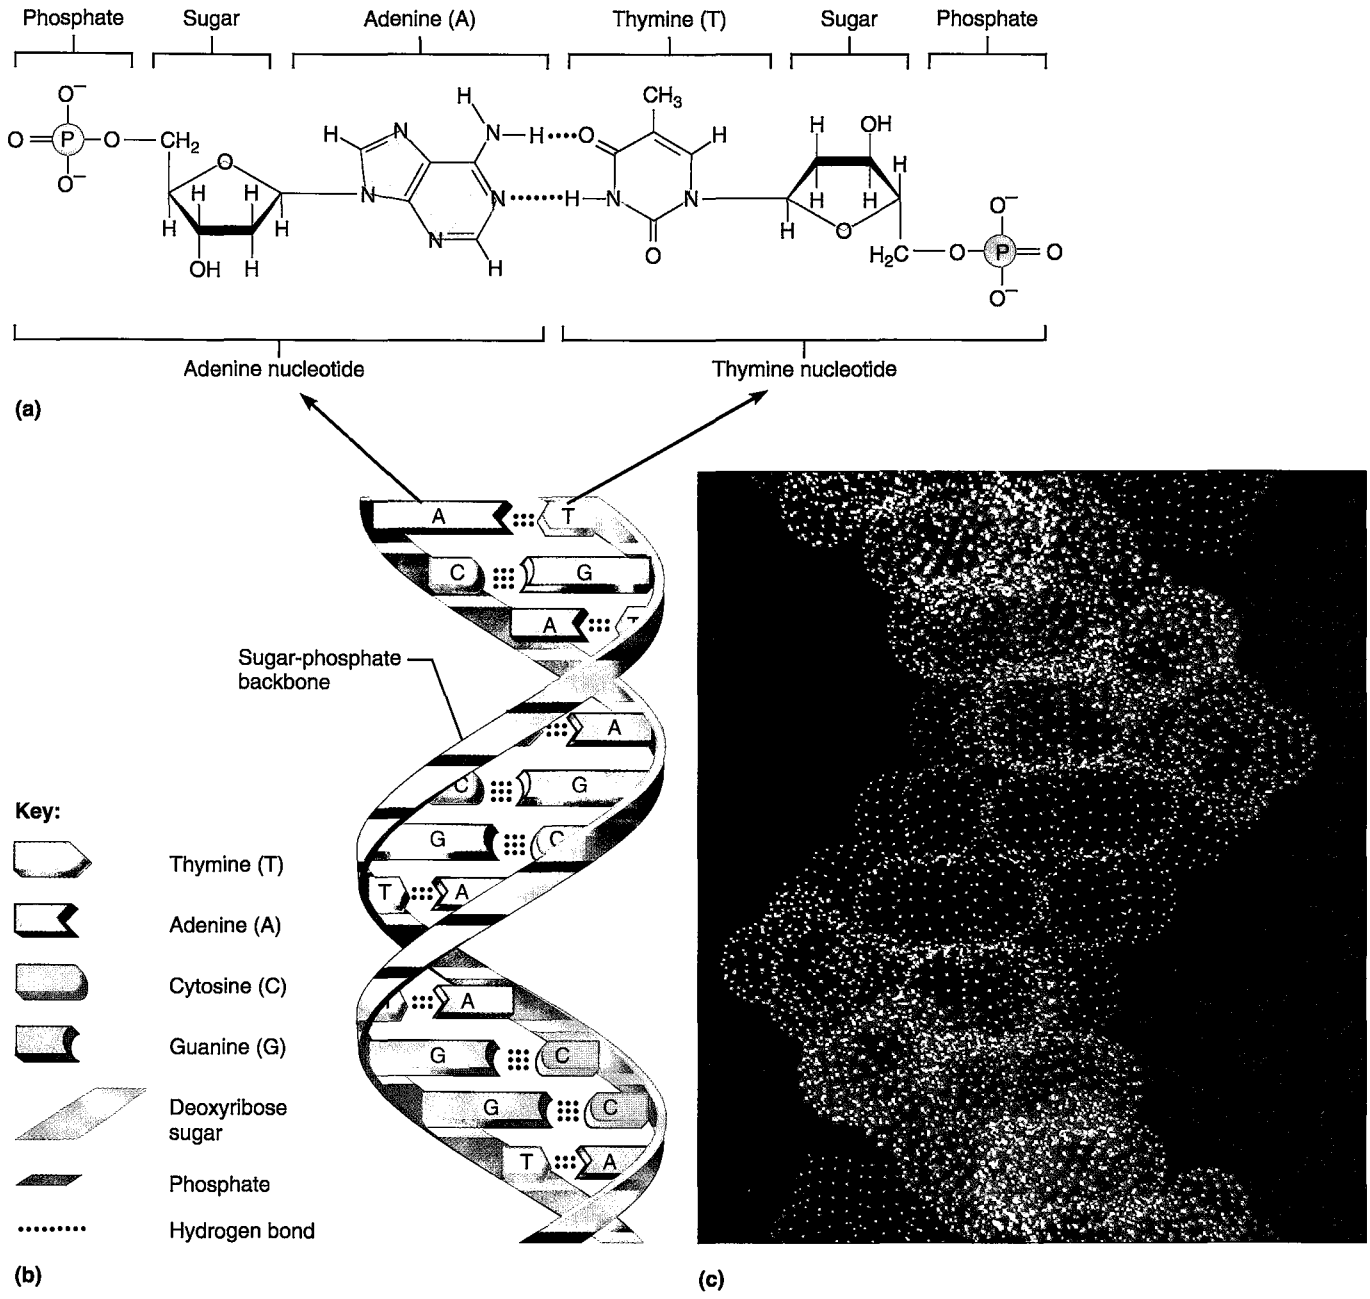

FIGURE 2.22 **Structure of DNA.** **(a)** The unit of DNA is the nucleotide, which is composed of a deoxyribose sugar molecule linked to a phosphate group, with a base attached to the sugar. Two nucleotides, linked by hydrogen bonds between their complementary bases, are illustrated. **(b)** DNA is a coiled double polymer of nucleotides (a double helix). The backbones of the ladderlike molecule are formed by alternating sugar and phosphate units. The rungs are formed by the binding together of complementary bases (A-T and G-C) by hydrogen bonds (shown by dotted lines). **(c)** Computer-generated image of a DNA molecule.

bonds between the bases, so that a ladderlike molecule is formed. Alternating sugar and phosphate molecules of each chain form the *backbones* or "uprights" of the "ladder," and the joined bases form the "rungs." The whole molecule is coiled into a spiral staircase–like structure called a **double helix.** Bonding of the bases is very specific: A always bonds to T, and G always bonds to C. A and T are therefore called **complementary bases,** as are C and G. Hence, ATGA on one nucleotide strand would necessarily be bonded to TACT (a complementary base sequence) on the other strand.

RNA molecules are single strands of nucleotides. RNA bases include A, G, C, and U (U replaces the T found in DNA), and its sugar is *ribose* instead of deoxyribose (Table 2.4). The three major

TABLE 2.4 Comparison of DNA and RNA

CHARACTERISTIC	DNA	RNA
Major cellular site	Nucleus	Cytoplasm (cell area outside the nucleus)
Major functions	Is the genetic material; directs protein synthesis; replicates itself before cell division	Carries out the genetic instructions for protein synthesis
Sugar	Deoxyribose	Ribose
Bases	Adenine, guanine, cytosine, thymine	Adenine, guanine, cytosine, uracil
Structure	Double strand coiled into a double helix	Single strand, straight or folded

varieties of RNA (messenger RNA, ribosomal RNA, and transfer RNA) are distinguished by their relative size and shape, and each has a specific role to play in carrying out DNA's instructions for protein synthesis. In addition to these three RNAs, there are small RNA molecules called *microRNAs (miRNAs)* that appear to control genetic expression by shutting down genes or altering their expression. We discuss DNA replication and the relative roles of DNA and RNA in protein synthesis in Chapter 3. DNA can also help solve forensic mysteries, as described in *A Closer Look* on pages 58 and 59.

Adenosine Triphosphate (ATP)

Although glucose is the most important cellular fuel, none of the chemical energy contained in its bonds is used directly to power cellular work. Instead, energy released during glucose catabolism is coupled to **adenosine triphosphate (ATP)** synthesis—that is, it is captured and stored as small packets of energy in the bonds of ATP. ATP, in turn, acts as a chemical "drive shaft" to provide a form of energy that is immediately usable by all body cells.

Structurally, ATP is an adenine-containing RNA nucleotide to which two additional phosphate groups have been added (Figure 2.23). Chemically, the triphosphate tail of ATP can be compared to a tightly coiled spring ready to uncoil with tremendous energy when the catch is released. Actually, ATP is a very unstable energy-storing molecule because its three negatively charged phosphate groups are closely packed and repel each other. When its terminal high-energy phosphate bonds are broken (hydrolyzed), the chemical "spring" relaxes and the molecule as a whole becomes more stable. Cells tap ATP's bond energy during coupled reactions by using enzymes to transfer the terminal phosphate groups from ATP to other compounds. The newly *phosphorylated* molecules are said to be "primed" and temporarily become more energetic and capable of performing some type of cellular work. In the process of doing their work, they lose the phosphate group. The amount of energy released and transferred during ATP hydrolysis corresponds closely to that needed to drive most biochemical reactions. As a result, cells are protected from excessive energy release that might be damaging, and energy squandering is kept to a minimum.

Cleaving the terminal phosphate bond of ATP yields a molecule with two phosphate groups—*adenosine diphosphate (ADP)*—and an inorganic

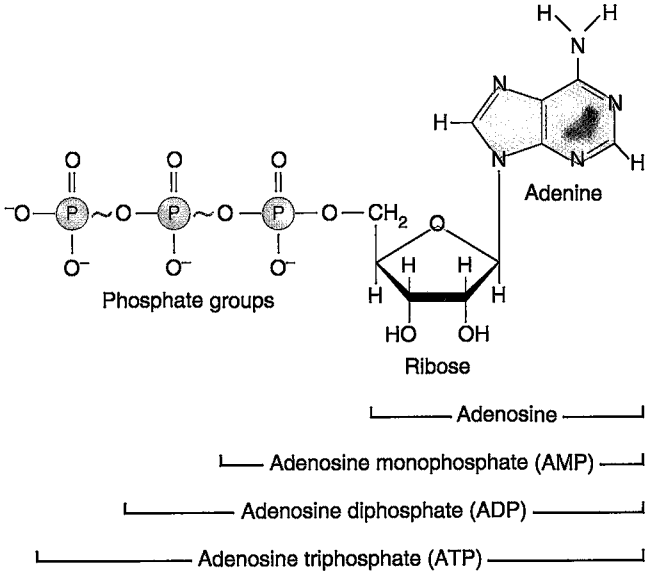

FIGURE 2.23 **Structure of ATP (adenosine triphosphate).** ATP is an adenine nucleotide to which two additional phosphate groups have been attached during breakdown of food fuels. (The phosphate bonds that can be hydrolyzed to liberate energy are indicated by the wavy red lines.) When the terminal phosphate group is cleaved off, energy is released to do useful work and ADP (adenosine diphosphate) is formed. When the terminal phosphate group is cleaved off ADP, a similar amount of energy is released and AMP (adenosine monophosphate) is formed.

A CLOSER LOOK

DNA Fingerprinting: Cracking Our Genetic "Barcode"

The terrorist attacks on New York City's World Trade Center left nearly 3000 people dead, their bodies buried in tons of rubble. As the weeks passed, it became clear that even if victims could be recovered from the wreckage, their bodies would probably be mangled, crushed, burned, or decomposed to a point where even family members would not recognize them.

In a situation like this, how can we identify individuals with any certainty? The New York Medical Examiner's Office turned to **DNA fingerprinting,** a technique for analyzing minuscule samples of DNA taken from semen, skin, blood, or other body tissues. DNA fingerprinting is based on the fact that no two members of a species, except for identical twins, possess identical sets of genetic material. In effect, DNA fingerprinting creates a unique genetic "barcode" that distinguishes each of us from all other humans. Let's see how it works.

Creating a DNA Profile

Recall that DNA contains four nucleotides—A, G, T, and C—that form complementary base pairs. In members of the same species, 99.9% of the DNA is identical. This means that only 0.1% of your DNA differs from that of other humans—but this is enough to make you genetically unique. In a DNA string 3 billion units long, that 0.1% translates into 3 million variations that differ slightly from everyone else's—even close relatives. Unless you are an identical sibling, your set of DNA is yours alone. DNA fingerprinting involves analyzing an individual's DNA, mapping its unique pattern, and comparing it to other DNA profiles to determine whether there's a match.

A standard technique for creating a DNA profile focuses on 13 specific sites on our chromosomes. At these sites, short segments of nuclear DNA are arranged in a repeating sequence. Individuals vary greatly in the number of repetitions, from 1 to 30 sets or more. While it is theoretically possible that unrelated people could have identical repeats at all 13 sites, the odds are less than one in 1 trillion.

Sometimes it can be difficult to obtain sufficient nuclear DNA for analysis. DNA samples recovered from crime scenes, for example, are often contaminated with dirt, fibers, and debris. Many body parts recovered from the World Trade Center are charred, ground into dust, or badly decomposed, limiting the amount of testable tissue. DNA retrieval can become a race against time as microbes, enzymes, insects, and environmental factors such as heat and humidity accelerate the decomposition process. However, mitochondria also contain DNA, some of which can survive in bones, teeth, and hair. Mitochondrial DNA too can be profiled to find a match, and sometimes it can be combined with a partial nuclear profile to give a positive identification.

DNA electrophoresis. *A scientist looking at DNA fragments in an electrophoresis gel. The fragments have been stained with ethidium bromide. This fluoresces under ultraviolet light and makes the positions of the fragments easier to see. A face visor has to be worn to protect the eyes against the UV light.*

Sorting and Identifying DNA

For DNA to be profiled, it must first be cut into manageable fragments by *restriction enzymes,* enzymes that "recognize" a specific base sequence and cleave the DNA at that location. This breaks down chromosomes into millions of different-sized pieces, which are then subjected to *gel electrophoresis* (see the photo), a technique that separates them by length. The DNA is placed on a gel and positioned in an electric field. The negatively charged DNA fragments are attracted to the positively charged electrode and migrate toward it. Because the smaller pieces move through the gel faster than their larger cousins, the fragments end up sorted by size.

To locate a specific repeating sequence, researchers make a DNA *probe* with a complementary sequence and tag it with a radioactive compound. The probe binds to the complementary site and when the product is exposed to X-ray film, the image shows dark bands where the probe bound to the DNA. A victim's DNA profile is then compared with known references to find one that matches. In the case of the World Trade Center attack, DNA references were obtained from victim's personal effects such as toothbrushes and combs, entered into a computer, and sorted to find a match.

DNA Fingerprinting and Forensics

DNA fingerprinting has become a vital tool in forensic medicine (the application of medical knowledge to questions of law). For example, DNA fingerprinting is used to identify "John and Jane Doe's" unknown human remains. The U.S. military takes blood and saliva samples from every recruit so that it can identify soldiers killed in the line of duty. DNA fingerprinting can also identify victims of mass disasters such as airplane crashes. The World Trade Center tragedy called for genetic analysis on an unprecedented scale—some 1 million DNA tests were necessary to identify all the missing. DNA fingerprinting can prove that a suspect was actually at the scene of a crime, and in the United States, some communities require criminal offenders to provide DNA samples, which are

classified and stored. DNA profiles can also establish innocence. At least ten people in the U.S. have been released from death row after genetic evidence exonerated them.

DNA profiles can also verify relationships in cases of disputed property, identify long-lost relatives, and establish paternity, even paternity cases that are centuries old. Historians have fiercely debated whether Thomas Jefferson, our third president, fathered any children by his slave Sally Hemings. Modern DNA researchers entered the fray by profiling Jefferson's Y chromosome. (Paternally related males have the same Y chromosome because it is passed directly from father to son.) The researchers couldn't test male descendants of Jefferson himself because none of his sons survived to adulthood, but they profiled descendants of several paternal relatives. A comparison of 19 genetic markers on the Jefferson Y chromosomes and those of Hemings's descendants found identical matches between the Jefferson line and Hemings's youngest son. Could it be chance? Not hardly! ■

phosphate group, indicated by P_i, accompanied by a transfer of energy:

$$ATP \xrightleftharpoons[H_2O]{H_2O} ADP + P_i + \text{energy}$$

As ATP is hydrolyzed to provide energy for cellular needs, ADP accumulates. Cleavage of the terminal phosphate bond of ADP liberates a similar amount of energy and produces adenosine monophosphate (AMP). ATP supplies are replenished as glucose and other fuel molecules are oxidized and their bond energy is released. The same amount of energy that is liberated when ATP's terminal phosphates are cleaved off must be captured and used to reverse the reaction to reattach phosphates and re-form the energy-transferring phosphate bonds. Without ATP, molecules cannot be made or degraded, cells cannot transport substances across their membrane boundaries, muscles cannot shorten to tug on other structures, and life processes cease (Figure 2.24).

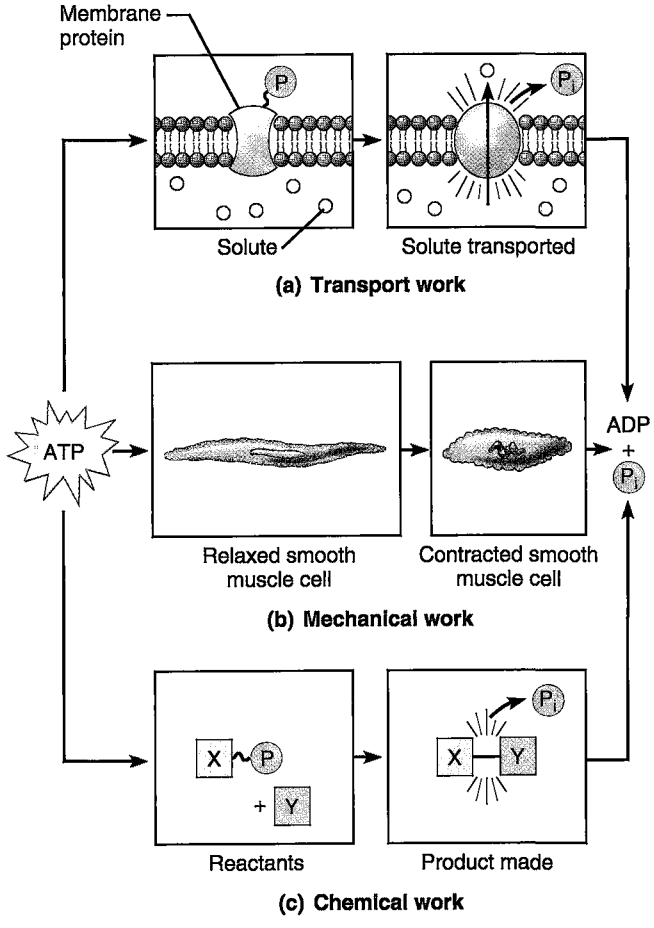

FIGURE 2.24 **Three examples of how ATP drives cellular work.** The high-energy bonds of ATP are like coiled springs that release energy for use by the cell when they are broken. **(a)** ATP drives the transport of certain solutes (amino acids, for example) across cell membranes. **(b)** ATP activates contractile proteins in muscle cells so that the cells can shorten and perform mechanical work. **(c)** ATP provides the energy to drive endergonic (energy-absorbing) chemical reactions.

Related Clinical Terms

Acidosis (as″ĭ-do′sis; *acid* = sour, sharp) A condition of acidity or low pH (below 7.35) of the blood; high hydrogen ion concentration.

Alkalosis (al″kah-lo′sis) A condition of basicity or high pH (above 7.45) of the blood; low hydrogen ion concentration.

Heavy metals Metals with toxic effects on the body, including arsenic, mercury, and lead. Iron, also included in this group, is toxic in high concentrations.

Ionizing radiation Radiation that causes atoms to ionize; for example, radioisotope emissions and X rays.

Ketosis (ke-to′sis) A form of acidosis resulting from excessive ketones (breakdown products of fats) in the blood; common during starvation and acute attacks of diabetes mellitus.

Radiation sickness Disease resulting from exposure of the body to radioactivity; digestive system organs are most affected.

Chapter Summary

Media study tools that could provide you additional help in reviewing specific key topics of Chapter 2 are referenced below.
IP = *InterActive Physiology*

PART 1: BASIC CHEMISTRY

Definition of Concepts: Matter and Energy (pp. 25–26)

Matter (p. 25)

1. Matter is anything that takes up space and has mass.

Energy (pp. 25–26)

2. Energy is the capacity to do work or put matter into motion.

3. Energy exists as potential energy (stored energy or energy of position) and kinetic energy (active or working energy).

4. Forms of energy involved in body functioning are chemical, electrical, radiant, and mechanical. Of these, chemical (bond) energy is most important.

5. Energy may be converted from one form to another, but some energy is always unusable (lost as heat) in such transformations.

Composition of Matter: Atoms and Elements (pp. 27–30)

1. Elements are unique substances that cannot be decomposed into simpler substances by ordinary chemical methods. Four elements (carbon, hydrogen, oxygen, and nitrogen) make up 96% of body weight.

Atomic Structure (pp. 27–28)

2. The building blocks of elements are atoms.

3. Atoms are composed of positively charged protons, negatively charged electrons, and uncharged neutrons. Protons and neutrons are located in the atomic nucleus, constituting essentially the atom's total mass; electrons are outside the nucleus in the electron shells. In any atom, the number of electrons equals the number of protons.

Identifying Elements (p. 28)

4. Atoms may be identified by their atomic number (p^+) and mass number ($p^+ + n^0$). The notation ${}^4_2He$ means that helium (He) has an atomic number of 2 and a mass number of 4.

5. Isotopes of an element differ in the number of neutrons they contain. The atomic weight of any element is approximately equal to the mass number of its most abundant isotope.

Radioisotopes (pp. 29–30)

6. Many heavy isotopes are unstable (radioactive). These so-called radioisotopes decompose to more stable forms by emitting alpha or beta particles or gamma rays. Radioisotopes are useful in medical diagnosis and treatment and in biochemical research.

How Matter Is Combined: Molecules and Mixtures (pp. 30–31)

Molecules and Compounds (p. 30)

1. A molecule is the smallest unit resulting from the chemical bonding of two or more atoms. If the atoms are different, they form a molecule of a compound.

Mixtures (pp. 30–31)

2. Mixtures are physical combinations of solutes in a solvent. Mixture components retain their individual properties.

3. The types of mixtures, in order of increasing solute size, are solutions, colloids, and suspensions.

4. Solution concentrations are typically designated in terms of percent or molarity.

Distinguishing Mixtures from Compounds (p. 31)

5. Compounds are homogeneous; their elements are chemically bonded. Mixtures may be homogeneous or heterogeneous; their components are physically combined and separable.

Chemical Bonds (pp. 31–36)

The Role of Electrons in Chemical Bonding (pp. 32–33)

1. Electrons of an atom occupy areas of space called electron shells or energy levels. Electrons in the shell farthest from the nucleus (valence shell) are most energetic.

2. Chemical bonds are energy relationships between valence shell electrons of the reacting atoms. Atoms with a full valence shell or eight valence shell electrons are chemically unreactive (inert); those with an incomplete valence shell interact with other atoms to achieve stability.

Types of Chemical Bonds (pp. 33–36)

3. Ionic bonds are formed when valence shell electrons are completely transferred from one atom to another.

4. Covalent bonds are formed when atoms share electron pairs. If the electron pairs are shared equally, the molecule is nonpolar; if they are shared unequally, it is polar (a dipole).

5. Hydrogen bonds are weak bonds formed between hydrogen and nitrogen or hydrogen and oxygen. They bind together different molecules (e.g., water molecules) or different parts of the same molecule (as in protein molecules).

Chemical Reactions (pp. 36–40)

Chemical Equations (pp. 36–37)

1. Chemical reactions involve the formation, breaking, or rearrangement of chemical bonds.

Patterns of Chemical Reactions (pp. 37–38)

2. Chemical reactions include synthesis, decomposition, and exchange reactions. Oxidation-reduction reactions may be considered a special type of exchange (or catabolic) reaction.

Energy Flow in Chemical Reactions (p. 38–39)

3. Bonds are energy relationships and there is a net loss or gain of energy in every chemical reaction.

4. In exergonic reactions, energy is liberated; in endergonic reactions, energy is absorbed.

Reversibility of Chemical Reactions (p. 39)

5. If reaction conditions remain unchanged, all chemical reactions eventually reach a state of chemical equilibrium in which the reaction proceeds in both directions at the same rate.

6. All chemical reactions are theoretically reversible, but many biological reactions go in only one direction because of energy requirements or the removal of reaction products.

Factors Influencing the Rate of Chemical Reactions (pp. 39–40)

7. Chemical reactions occur only when particles collide and valence shell electrons interact.

8. The smaller the reacting particles, the greater their kinetic energy and the faster the reaction rate. Higher temperature or reactant concentration, as well as the presence of catalysts, increases chemical reaction rates.

PART 2: BIOCHEMISTRY

Inorganic Compounds (pp. 40–43)

1. Most inorganic compounds do not contain carbon. Those found in the body include water, salts, and inorganic acids and bases.

Water (pp. 40–41)

2. Water is the single most abundant compound in the body. It absorbs and releases heat slowly, acts as a universal solvent, participates in chemical reactions, and cushions body organs.

Salts (p. 41)

3. Salts are ionic compounds that dissolve in water and act as electrolytes. Calcium and phosphorus salts contribute to the hardness of bones and teeth. Ions of salts are involved in many physiological processes.

Acids and Bases (pp. 41–43)

4. Acids are proton donors; in water, they ionize and dissociate, releasing hydrogen ions (which account for their properties) and anions.

[P] Fluid, Electrolyte and Acid/Base Balance; Topic: Acid Base Homeostasis, pp. 1–12, 16, 17.

5. Bases are proton acceptors. The most important inorganic bases are the hydroxides; bicarbonate ion and ammonia are important bases in the body.

6. pH is a measure of hydrogen ion concentration of a solution (in moles per liter). A pH of 7 is neutral; a higher pH is alkaline, and a lower pH is acidic. Normal blood pH is 7.35–7.45. Buffers help to prevent excessive changes in the pH of body fluids.

[P] Fluid, Electrolyte and Acid/Base Balance; Topic: Introduction to Body Fluids, pp. 1–8.

Organic Compounds (pp. 43–59)

1. Organic compounds contain carbon. Those found in the body include carbohydrates, lipids, proteins, and nucleic acids, all of which are synthesized by dehydration synthesis and digested by hydrolysis. All of these biological molecules contain C, H, and O. Proteins and nucleic acids also contain N.

Carbohydrates (pp. 44–46)

2. Carbohydrate building blocks are monosaccharides, the most important of which are hexoses (glucose, fructose, galactose) and pentoses (ribose, deoxyribose).

3. Disaccharides (sucrose, lactose, maltose) and polysaccharides (starch, glycogen) are composed of linked monosaccharide units.

4. Carbohydrates, particularly glucose, are the major energy fuel for forming ATP. Excess carbohydrates are stored as glycogen or converted to fat for storage.

Lipids (pp. 46–48)

5. Lipids dissolve in fats or organic solvents, but not in water.

6. Triglycerides are composed of fatty acid chains and glycerol. They are found chiefly in fatty tissue where they provide insulation and reserve body fuel. Unsaturated fatty acid chains produce oils; saturated fatty acids produce solid fats typical of animal fats.

7. Phospholipids are modified phosphorus-containing triglycerides that have polar and nonpolar portions. They are found in all plasma membranes.

8. The steroid cholesterol is found in cell membranes and is the basis of steroid hormones, bile salts, and vitamin D.

Proteins (pp. 48–54)

9. The unit of proteins is the amino acid; 20 common amino acids are found in the body.

10. Many amino acids joined by peptide bonds form a polypeptide. A protein (one or more polypeptides) is distinguished by the number and sequence of amino acids in its chain(s) and by the complexity of its three-dimensional structure.

11. Fibrous proteins, such as keratin and collagen, have secondary (α-helix or β-pleated sheet) and perhaps quaternary structure. Fibrous proteins are used as structural materials.

12. Globular proteins achieve tertiary or quaternary structure and are generally spherical, soluble molecules. Globular proteins (e.g., enzymes, some hormones, antibodies, hemoglobin) perform special functional roles for the cell (e.g., catalysis, molecule transport).

13. Proteins are denatured by extremes of temperature or pH. Denatured globular proteins are unable to perform their usual function.

14. Molecular chaperones assist in folding proteins into their functional 3-D shape. They are synthesized in greater amounts when cells are stressed by environmental factors and begin to accumulate denatured proteins.

15. Enzymes are biological catalysts; they increase the rate of chemical reactions by decreasing the amount of activation energy needed. They do this by combining with the reactants and holding them in the proper position to interact. Many enzymes require cofactors to function.

Nucleic Acids (DNA and RNA) (pp. 54–57)

16. Nucleic acids include deoxyribonucleic acid (DNA) and ribonucleic acid (RNA). The structural unit of nucleic acids is the nucleotide, which consists of a nitrogenous base (adenine, guanine, cytosine, thymine, or uracil), a sugar (ribose or deoxyribose), and a phosphate group.

17. DNA is a double-stranded helix: it contains deoxyribose and the bases A, G, C, and T. DNA specifies protein structure and replicates itself exactly before cell division.

18. RNA is single-stranded; it contains ribose and the bases A, G, C, and U. RNAs involved in carrying out DNA's instructions for protein synthesis include messenger, ribosomal, and transfer RNA.

Adenosine Triphosphate (ATP) (pp. 56–59)

19. ATP is the universal energy compound of body cells. Some of the energy liberated by the breakdown of glucose and other food fuels is captured in the bonds of ATP molecules and transferred via coupled reactions to energy-consuming reactions.

Review Questions

Multiple Choice/Matching

(Some questions have more than one correct answer. Select the best answer or answers from the choices given.)

1. Which of the following forms of energy are in use during vision? (a) chemical, (b) electrical, (c) mechanical, (d) radiant.

2. All of the following are examples of the four major elements contributing to body mass except (a) hydrogen, (b) carbon, (c) nitrogen, (d) sodium, (e) oxygen.

3. The mass number of an atom is (a) equal to the number of protons it contains, (b) the sum of its protons and neutrons, (c) the sum of all of its subatomic particles, (d) the average of the mass numbers of all of its isotopes.

4. A deficiency in this element can be expected to reduce the hemoglobin content of blood: (a) Fe, (b) I, (c) F, (d) Ca, (e) K.

5. Which set of terms best describes a proton? (a) negative charge, massless, in the orbital; (b) positive charge, 1 amu, in the nucleus; (c) uncharged, 1 amu, in the nucleus.

6. The subatomic particles responsible for the chemical behavior of atoms are (a) electrons, (b) ions, (c) neutrons, (d) protons.

7. In the body, carbohydrates are stored in the form of (a) glycogen, (b) starch, (c) cholesterol, (d) polypeptides.

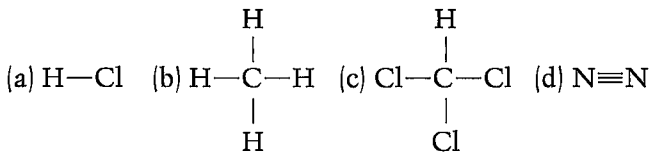
8. Which of the following does *not* describe a mixture? (a) properties of its components are retained, (b) chemical bonds are formed, (c) components can be separated physically, (d) includes both heterogeneous and homogeneous examples.

9. In a beaker of water, the water-water bonds can properly be called (a) ionic bonds, (b) polar covalent bonds, (c) nonpolar covalent bonds, (d) hydrogen bonds.

10. When a pair of electrons is shared between two atoms, the bond formed is called (a) a single covalent bond, (b) a double covalent bond, (c) a triple covalent bond, (d) an ionic bond.

11. Molecules formed when electrons are shared unequally are (a) salts, (b) polar molecules, (c) nonpolar molecules.

12. Which of the following covalently bonded molecules are polar?



13. Identify each reaction as (a) a synthesis reaction, (b) a decomposition reaction, or (c) an exchange reaction.

(1) $2Hg + O_2 \rightarrow 2HgO$

(2) $HCl + NaOH \rightarrow NaCl + H_2O$

14. Factors that accelerate the rate of chemical reactions include all but (a) the presence of catalysts, (b) increasing the temperature, (c) increasing the particle size, (d) increasing the concentration of the reactants.

15. Which of the following molecules is an inorganic molecule? (a) sucrose, (b) cholesterol, (c) collagen, (d) sodium chloride.

16. Water's importance to living systems reflects (a) its polarity and solvent properties, (b) its high heat capacity, (c) its high heat of vaporization, (d) its chemical reactivity, (e) all of these.

17. Acids (a) release hydroxyl ions when dissolved in water, (b) are proton acceptors, (c) cause the pH of a solution to rise, (d) release protons when dissolved in water.

18. A chemist, during the course of an analysis, runs across a chemical composed of carbon, hydrogen, and oxygen in the proportion 1:2:1 and having a six-sided molecular shape. It is probably (a) a pentose, (b) an amino acid, (c) a fatty acid, (d) a monosaccharide, (e) a nucleic acid.

19. A triglyceride consists of (a) glycerol plus up to three fatty acids, (b) a sugar-phosphate backbone to which two amino groups are attached, (c) two to several hexoses, (d) amino acids that have been thoroughly saturated with hydrogen.

20. A chemical has an amine group and an organic acid group. It does not, however, have any peptide bonds. It is (a) a monosaccharide, (b) an amino acid, (c) a protein, (d) a fat.

21. The lipid(s) used as the basis of vitamin D, sex hormones, and bile salts is/are (a) triglycerides, (b) cholesterol, (c) phospholipids, (d) prostaglandin.

22. Enzymes are organic catalysts that (a) alter the direction in which a chemical reaction proceeds, (b) determine the nature of the products of a reaction, (c) increase the speed of a chemical reaction, (d) are essential raw materials for a chemical reaction that are converted into some of its products.

Short Answer Essay Questions

23. Define or describe energy, and explain the relationship between potential and kinetic energy.

24. Some energy is lost in every energy conversion. Explain the meaning of this statement. (Direct your response to answering the question: Is it really lost? If not, what then?)

25. Provide the atomic symbol for each of the following elements: (a) calcium, (b) carbon, (c) hydrogen, (d) iron, (e) nitrogen, (f) oxygen, (g) potassium, (h) sodium.

26. Consider the following information about three atoms:

$^{12}_{6}C$ $^{13}_{6}C$ $^{14}_{6}C$

(a) How are they similar to one another? (b) How do they differ from one another? (c) What are the members of such a

group of atoms called? (d) Using the planetary model, draw the atomic configuration of $^{12}_{6}C$ showing the relative position and numbers of its subatomic particles.

27. How many moles of aspirin, $C_9H_8O_4$, are in a bottle containing 450 g by weight? (*Note:* The approximate atomic weights of its atoms are C = 12, H = 1, and O = 16.)

28. Given the following types of atoms, decide which type of bonding, ionic or covalent, is most likely to occur: (a) two oxygen atoms; (b) four hydrogen atoms and one carbon atom; (c) a potassium atom ($^{39}_{19}K$) and a fluorine atom ($^{19}_{9}F$).

29. What are hydrogen bonds and how are they important in the body?

30. The following equation, which represents the oxidative breakdown of glucose by body cells, is a reversible reaction.

Glucose + oxygen → carbon dioxide + water + ATP

(a) How can you indicate that the reaction is reversible? (b) How can you indicate that the reaction is in chemical equilibrium? (c) Define chemical equilibrium.

31. (a) Differentiate clearly between primary, secondary, and tertiary protein structure. (b) What level of structure do most fibrous proteins achieve? (c) How do globular proteins relate to the structural levels?

32. Dehydration and hydrolysis reactions are essentially opposite reactions. How are they related to the synthesis and degradation (breakdown) of biological molecules?

33. Describe the mechanism of enzyme activity. In your discussion, explain how enzymes decrease activation energy requirements.

34. Explain the importance of molecular chaperones.

35. Explain why, if you pour water into a glass very carefully, you can "stack" the water slightly above the rim of the glass.

36. Water is a precious natural resource in Florida and it is said that supplies are dwindling. Desalinizing (removing salt from) ocean water has been recommended as a solution to the problem. Why shouldn't we drink salt water?

Critical Thinking and Clinical Application Questions

1. As Ben jumped on his bike and headed for the freshwater lake, his mother called after him, "Don't swim if we have an electrical storm—it looks threatening." This was a valid request. Why?

2. Some antibiotics act by binding to certain essential enzymes in the target bacteria. (a) How might these antibiotics influence the chemical reactions controlled by the enzymes? (b) What is the anticipated effect on the bacteria? On the person taking the antibiotic prescription?

3. Mrs. Roberts, in a diabetic coma, has just been admitted to Noble Hospital. Her blood pH indicates that she is in severe acidosis, and measures are quickly instituted to bring her blood pH back within normal limits. (a) Define pH and note the normal pH of blood. (b) Why is severe acidosis problematic?

4. Jimmy, a 12-year-old boy, was awakened suddenly by a loud crash. As he sat up in bed, straining to listen, his fright was revealed by his rapid breathing (hyperventilation), a breathing pattern effective in ridding the blood of CO_2. At this point, was his blood pH rising or falling?

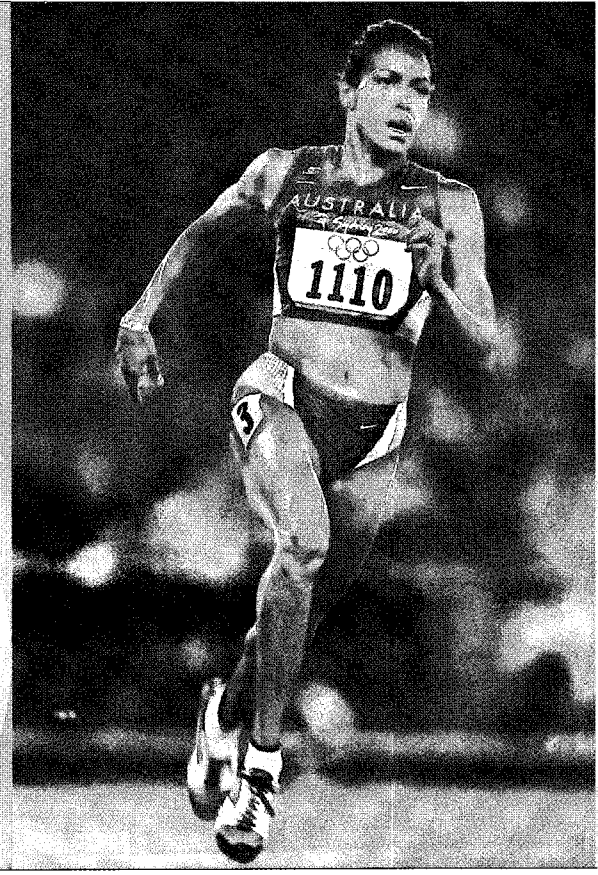
CHAPTER 3

Cells: The Living Units



Overview of the Cellular Basis of Life (pp. 65–66)

1. Define cell.
2. List the three major regions of a generalized cell and indicate the function of each.

The Plasma Membrane: Structure (pp. 66–70)

3. Describe the chemical composition of the plasma membrane and relate it to membrane functions.
4. Compare the structure and function of tight junctions, desmosomes, and gap junctions.

The Plasma Membrane: Functions (pp. 70–84)

5. Relate plasma membrane structure to active and passive transport mechanisms. Differentiate between these transport processes relative to energy source, substances transported, direction, and mechanism.
6. Define membrane potential and explain how the resting membrane potential is maintained.
7. Describe the role of the glycocalyx when cells interact with their environment.
8. List several roles of membrane receptors and that of voltage-sensitive membrane channel proteins.

The Cytoplasm (pp. 84–95)

9. Describe the composition of the cytosol; define inclusions and list several types.
10. Discuss the structure and function of mitochondria.
11. Discuss the structure and function of ribosomes, the endoplasmic reticulum, and the Golgi apparatus including functional interrelationships among these organelles.
12. Compare the functions of lysosomes and peroxisomes.
13. Name and describe the structure and function of cytoskeletal elements.
14. Describe the roles of centrioles in mitosis and in formation of cilia and flagella.

The Nucleus (pp. 95–97)

15. Outline the structure and function of the nuclear envelope, nucleolus, and chromatin.

Cell Growth and Reproduction (pp. 97–111)

16. List the phases of the cell life cycle and describe the key events of each phase.
17. Describe the process of DNA replication.
18. Define gene and genetic code and explain the function of genes.
19. Name the two phases of protein synthesis and describe the roles of DNA, mRNA, tRNA, and rRNA in each phase. Contrast triplets, codons, and anticodons.
20. Describe the importance of ubiquitin degradation of soluble proteins.

Extracellular Materials (p. 111)

21. Name and describe the composition of extracellular materials.

Developmental Aspects of Cells (pp. 111–112)

22. Discuss some theories of cell differentiation and aging.

Just as bricks and timbers are the structural units of a house, **cells** are the structural units of all living things, from one-celled "generalists" like amoebas to complex multicellular organisms such as humans, dogs, and trees. The human body has 50 to 100 trillion of these tiny building blocks.

This chapter focuses on structures and functions shared by all cells. Specialized cells and their unique functions are addressed in later chapters.

Overview of the Cellular Basis of Life

The English scientist Robert Hooke first observed plant cells with a crude microscope in the late 1600s. However, it was not until the 1830s that two German scientists, Matthias Schleiden and Theodor Schwann, were bold enough to insist that all living things are composed of cells. The German pathologist Rudolf Virchow extended this idea by contending that cells arise only from other cells. Virchow's proclamation was revolutionary because it openly challenged the widely accepted *theory of spontaneous generation,* which held that organisms arise spontaneously from garbage or other nonliving matter. Since the late 1800s, cell research has been exceptionally fruitful and provided us with four concepts collectively known as the **cell theory:**

1. A cell is the basic structural and functional unit of living organisms. So when you define cell properties you are in fact defining the properties of life.

2. The activity of an organism depends on both the individual and the collective activities of its cells.

3. According to the *principle of complementarity,* the biochemical activities of cells are dictated by the relative number of their specific subcellular structures.

4. Continuity of life has a cellular basis.

We will expand on all of these concepts as we progress. Let us begin with the idea that the cell is the smallest living unit. Whatever its form, however it behaves, the cell is the microscopic package that contains all the parts necessary to survive in an ever-changing world. It follows then that loss of cellular homeostasis underlies virtually every disease.

The trillions of cells in the human body include over 200 different cell types that vary greatly in shape, size, and function (Figure 3.1). The spherical fat cells, disc-shaped red blood cells, branching nerve cells, and cubelike cells of kidney tubules are just a few examples of the shapes cells take. Depending on type, cells also vary greatly in length—ranging from 2 micrometers (1/12,000 of an inch) in the smallest cells to over a meter in the nerve cells that cause you to wiggle your toes. A cell's shape reflects its function. For example, the flat, tilelike epithelial cells that line the inside of your cheek fit closely together, forming a living barrier that protects underlying tissues from bacterial invasion.

Regardless of type, all cells are composed chiefly of carbon, hydrogen, nitrogen, oxygen, and trace

amounts of several other elements. In addition, all cells have the same basic parts and some common functions. Thus, it is possible to speak of a **generalized,** or **composite, cell** (Figure 3.2). Human cells have three main parts: the plasma membrane, the cytoplasm, and the nucleus. The *plasma membrane,* a fragile barrier, is the outer boundary of the cell. Internal to this membrane is the *cytoplasm* (si'to-plazm), the intracellular fluid that is packed with organelles, small structures that perform specific cell functions. The *nucleus* (nu'kle-us) controls cellular activities and lies near the cell's center. These cell structures are summarized in Table 3.3 (pp. 94–95) and are described next.

The Plasma Membrane: Structure

The flexible **plasma membrane** defines the extent of a cell, thereby separating two of the body's major fluid compartments—the *intracellular* fluid within cells and the *extracellular* fluid outside cells. The term *cell membrane* is commonly used as a synonym for plasma membrane, but because nearly all cellular organelles are enclosed in a membrane, in this book we will always refer to the cell's surface or outer limiting membrane as the plasma membrane. The plasma membrane is much more than a passive envelope. As you will see, its unique structure allows it to play a dynamic role in many cellular activities.

Q *Some membrane proteins float freely in the lipid phase of the membrane. Others are secured in specific locations. According to this diagram, what would serve as the anchoring structures in the latter case?*

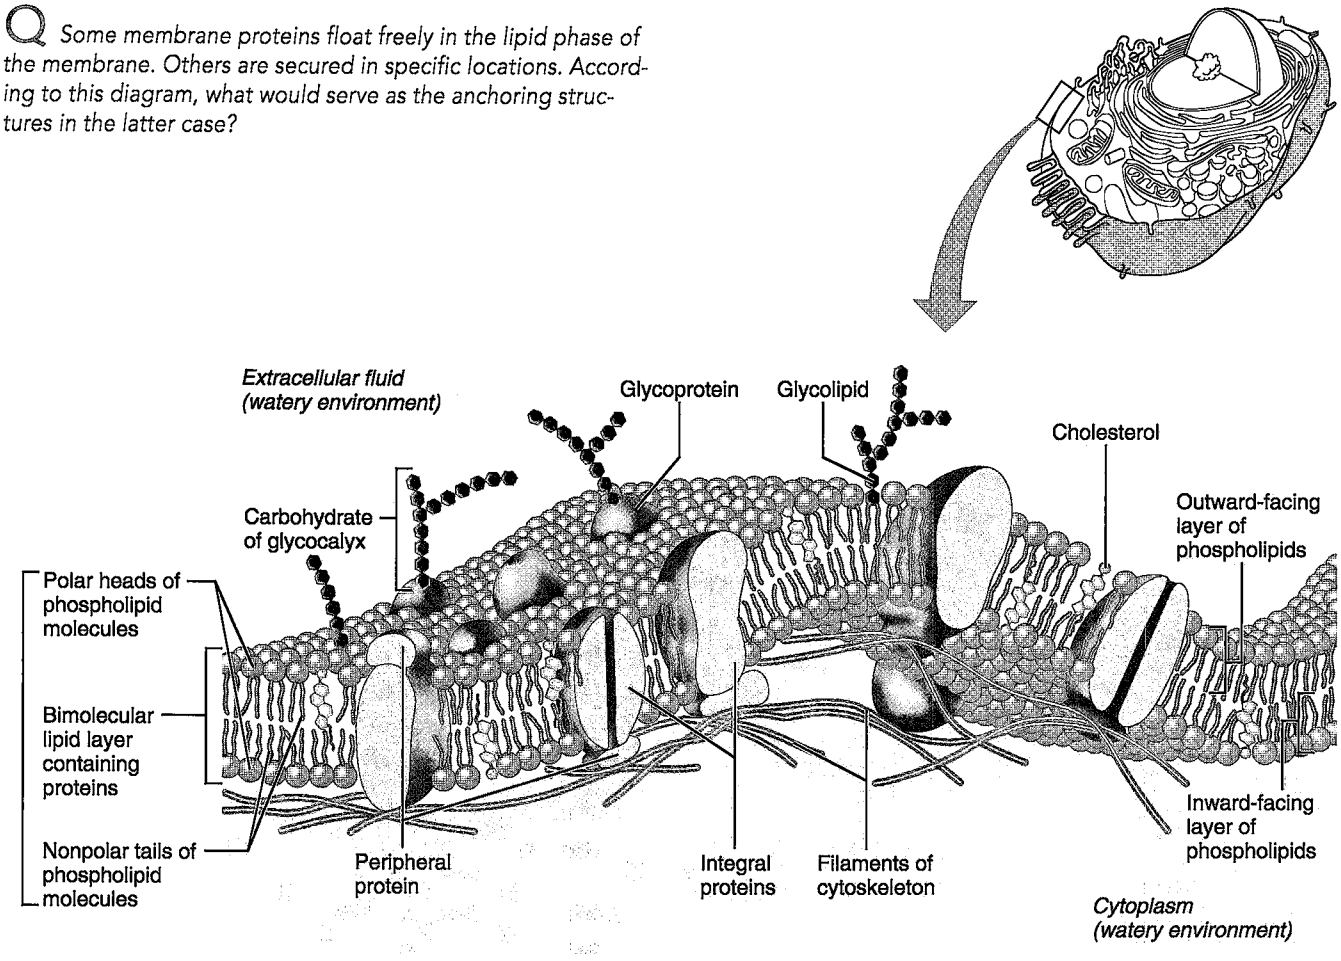

FIGURE 3.3 **Structure of the plasma membrane according to the fluid mosaic model.**

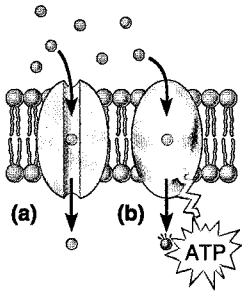
The Fluid Mosaic Model

The **fluid mosaic model** of membrane structure (Figure 3.3) depicts the plasma membrane as an exceedingly thin (7–10 nm) structure composed of a double layer, or bilayer, of lipid molecules with protein molecules dispersed in it. The proteins, many of which float in the fluid *lipid bilayer,* form a constantly changing mosaic pattern; hence the name of the model.

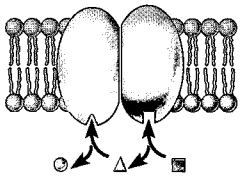
The lipid bilayer, which forms the basic "fabric" of the membrane, is constructed largely of *phospholipids,* with smaller amounts of *cholesterol* and *glycolipids.* Each lollipop-shaped phospholipid molecule has a polar "head" that is charged and is **hydrophilic** (*hydro* = water, *philic* = loving), and an uncharged, nonpolar "tail" that is made of two fatty acid chains and is **hydrophobic** (*phobia* = hating). The polar heads are attracted to water—the main constituent of both the intracellular and extracellular fluids—and so they lie on both the inner and outer surfaces of the membrane. The nonpolar tails, being hydrophobic, avoid water and line up in the center of the membrane. The result is that all biological membranes share a common sandwich-like structure: They are composed of two parallel sheets of phospholipid molecules lying tail to tail, with their polar heads exposed to water inside and outside the cell. This self-orienting property of phospholipids encourages biological membranes to self-assemble into closed, generally spherical, structures and to reseal themselves quickly when torn. It also enables scientists to suck out and replace a cell's nucleus in *cloning experiments,* a hot scientific area today.

The inward-facing and outward-facing surfaces of the plasma membrane differ in the kinds and amounts of lipids they contain. The majority of membrane phospholipids are unsaturated (like phosphatidylcholine), a condition which kinks their tails (increasing the space between them) and increases membrane fluidity. **Glycolipids** (gli"ko-lip'idz), phospholipids with attached sugar groups, are found only on the outer plasma membrane surface and account for about 5% of the total membrane lipid. Their sugar

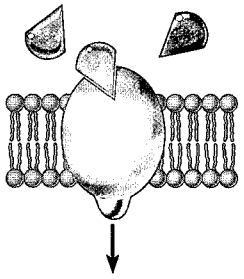
A Filaments of the cytoskeleton.



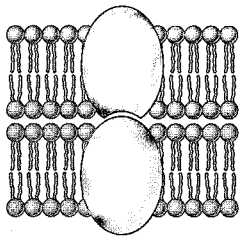
Transport
(a) A protein that spans the membrane may provide a hydrophilic channel across the membrane that is selective for a particular solute. **(b)** Some transport proteins hydrolyze ATP as an energy source to actively pump substances across the membrane.



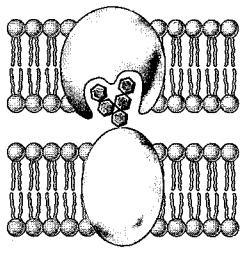
Enzymatic activity
A protein built into the membrane may be an enzyme with its active site exposed to substances in the adjacent solution. In some cases, several enzymes in a membrane act as a team that catalyzes sequential steps of a metabolic pathway as indicated (right to left) here.



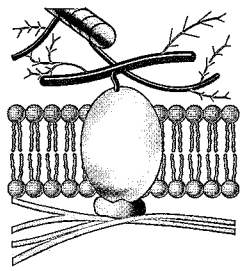
Receptors for signal transduction
A membrane protein exposed to the outside of the cell may have a binding site with a specific shape that fits the shape of a chemical messenger, such as a hormone. The external signal may cause a conformational change in the protein that initiates a chain of chemical reactions in the cell.



Intercellular joining
Membrane proteins of adjacent cells may be hooked together in various kinds of intercellular junctions. Some membrane proteins (CAMs) of this group provide temporary binding sites that guide cell migration and other cell-to-cell interactions.



Cell-cell recognition
Some glycoproteins (proteins bonded to short chains of sugars) serve as identification tags that are specifically recognized by other cells.



Attachment to the cytoskeleton and extracellular matrix (ECM)
Elements of the cytoskeleton (cell's internal supports) and the extracellular matrix (ECM) may be anchored to membrane proteins, which help maintain cell shape and fix the location of certain membrane proteins. Others play a role in cell movement or bind adjacent cells together.

groups, like the phosphate-containing groups of phospholipids, make that end of the glycolipid molecule polar, whereas the fatty acid tails are nonpolar. Some 20% of membrane lipid is cholesterol, which wedges its platelike hydrocarbon rings between the phospholipid tails, decreasing their orderliness and increasing the mobility of the phospholipids.

About 20% of the outer membrane surface contains **lipid rafts,** dynamic assemblies of saturated phospholipids (which pack together tightly) associated with unique lipids called sphingolipids and lots of cholesterol. These quiltlike patches are more stable and orderly and less fluid than the rest of the membrane, and can include or exclude specific proteins to various extents. Because of these qualities, lipid rafts are assumed to be concentrating platforms for molecules needed for cell signaling. (Cell signaling is discussed on pp. 83–84.)

There are two distinct populations of membrane proteins, integral and peripheral (see Figure 3.3). Proteins make up about half of the plasma membrane by mass and are responsible for most of the specialized membrane functions (Figure 3.4). **Integral proteins** are firmly inserted into the lipid bilayer. Some protrude from one membrane face only, but most are *transmembrane proteins* that span the entire width of the membrane and protrude on both sides. Whether transmembrane or not, all integral proteins have both hydrophobic and hydrophilic regions. This structural feature allows them to interact both with the nonpolar lipid tails buried in the membrane and with water inside and outside the cell. Transmembrane proteins are mainly involved in transport. Some cluster together to form *channels,* or pores, through which small, water-soluble molecules or ions can move, thus bypassing the lipid part of the membrane. Others act as *carriers* that bind to a substance and then move it through the membrane. Still others are receptors for hormones or other chemical messengers and relay messages to the cell interior (a process called *signal transduction*).

Peripheral proteins, in contrast, are not embedded in the lipid. Instead, they attach rather loosely to integral proteins or membrane lipids and are easily removed without disrupting the membrane. Peripheral proteins include a network of filaments that helps support the membrane from its cytoplasmic side. Some peripheral proteins are enzymes. Others are involved in mechanical functions, such as changing cell shape during cell division and muscle cell contraction, or linking cells together.

Many of the proteins that abut the extracellular space are glycoproteins that sport branching sugar

FIGURE 3.4 **Some functions of membrane proteins.** A single protein may perform some combination of these tasks.

groups. The term **glycocalyx** (gli"ko-kal'iks; "sugar covering") is used to describe the fuzzy, sticky carbohydrate-rich area at the cell surface. You can think of your cells as sugar-coated. The glycocalyx that clings to each cell's surface is enriched both by glycolipids and by glycoproteins secreted by the cell.

Because every cell type has a different pattern of sugars in its glycocalyx, the glycocalyx provides highly specific biological markers by which approaching cells recognize each other. For example, a sperm recognizes an ovum (egg cell) by the ovum's unique glycocalyx, and cells of the immune system identify a bacterium by binding to certain membrane glycoproteins in the bacterial glycocalyx.

HOMEOSTATIC IMBALANCE

Definite changes in the glycocalyx occur in a cell that is becoming cancerous. In fact, a cancer cell's glycocalyx may change almost continuously, allowing it to keep ahead of immune system recognition mechanisms and avoid destruction. (Cancer is discussed on pp. 146–147.) ●

The plasma membrane is a dynamic fluid structure that is in constant flux. Its consistency is like that of olive oil. The lipid molecules of the bilayer move freely from side to side, parallel to the membrane surface, but their polar-nonpolar interactions prevent them from flip-flopping or moving from one leaflet (half of the bilayer) to the other. Some of the proteins float freely. Others, particularly the peripheral proteins, are restricted in their movements because they are "tethered" to intracellular structures that make up the *cytoskeleton* (see Figure 3.4).

Specializations of the Plasma Membrane

Microvilli

Microvilli (mi"kro-vil'i; "little shaggy hairs") are minute, fingerlike extensions of the plasma membrane that project from a free, or exposed, cell surface (Figures 3.2 and 3.5). They increase the plasma membrane surface area tremendously and are most often found on the surface of absorptive cells such as intestinal and kidney tubule cells. Microvilli have a core of actin filaments. Actin is a contractile protein, but in microvilli it appears to function as a mechanical "stiffener."

Membrane Junctions

Although certain cell types—blood cells, sperm cells, and some phagocytic cells—are "footloose" in the body, many other types, particularly epithelial cells, are knit into tight communities. Typically, three factors act to bind cells together:

1. Glycoproteins in the glycocalyx act as an adhesive.
2. Wavy contours of the membranes of adjacent cells fit together in a tongue-and-groove fashion.
3. Special membrane junctions are formed (Figure 3.5). Because this last factor is the most important let us look more closely at the various types of junctions.

Tight Junctions In a **tight junction,** a series of integral protein molecules (including occludins and claudins) in the plasma membranes of adjacent cells fuse together, forming an *impermeable junction* that encircles the cell (Figure 3.5a). Tight junctions help prevent molecules from passing through the extracellular space between adjacent cells. For example, tight junctions between epithelial cells lining the digestive tract keep digestive enzymes and microorganisms in the intestine from seeping into the bloodstream. (Although called "impermeable" junctions, some tight junctions are somewhat leaky and may allow certain types of ions to pass.)

Desmosomes **Desmosomes** (des'mo-sōmz; "binding bodies") are *anchoring junctions*—mechanical couplings scattered like rivets along the sides of abutting cells that prevent their separation (Figure 3.5b). On the cytoplasmic face of each plasma membrane is a buttonlike thickening called a *plaque.* Adjacent cells are held together by thin linker protein filaments (cadherins) that extend from the plaques and interdigitate like the teeth of a zipper in the intercellular space. Thicker protein filaments (intermediate filaments, which form part of the cytoskeleton) extend from the cytoplasmic side of the plaque across the width of the cell to anchor to the plaque on the cell's opposite side. Thus, desmosomes not only bind neighboring cells together, they also contribute to a continuous internal network of strong "guy-wires." This arrangement distributes tension throughout a cellular sheet and reduces the chance of tearing when it is subjected to pulling forces. Desmosomes are abundant in tissues subjected to great mechanical stress, such as skin and heart muscle.

Gap Junctions A **gap junction,** or *nexus* (nek'sus; "bond"), is a communicating junction between adjacent cells. At gap junctions the adjacent plasma membranes are very close, and the cells are connected by hollow cylinders called *connexons* (kŏ-nek'sonz), composed of transmembrane proteins. The many different types of connexon proteins vary the selectivity of the gap junction channels. Ions, simple sugars, and other small molecules pass through these water-filled channels from one cell to the next (Figure 3.5c). Gap junctions are present in electrically excitable tissues, such as the heart and smooth muscle, where ion passage from cell to cell helps synchronize their electrical activity and contraction.

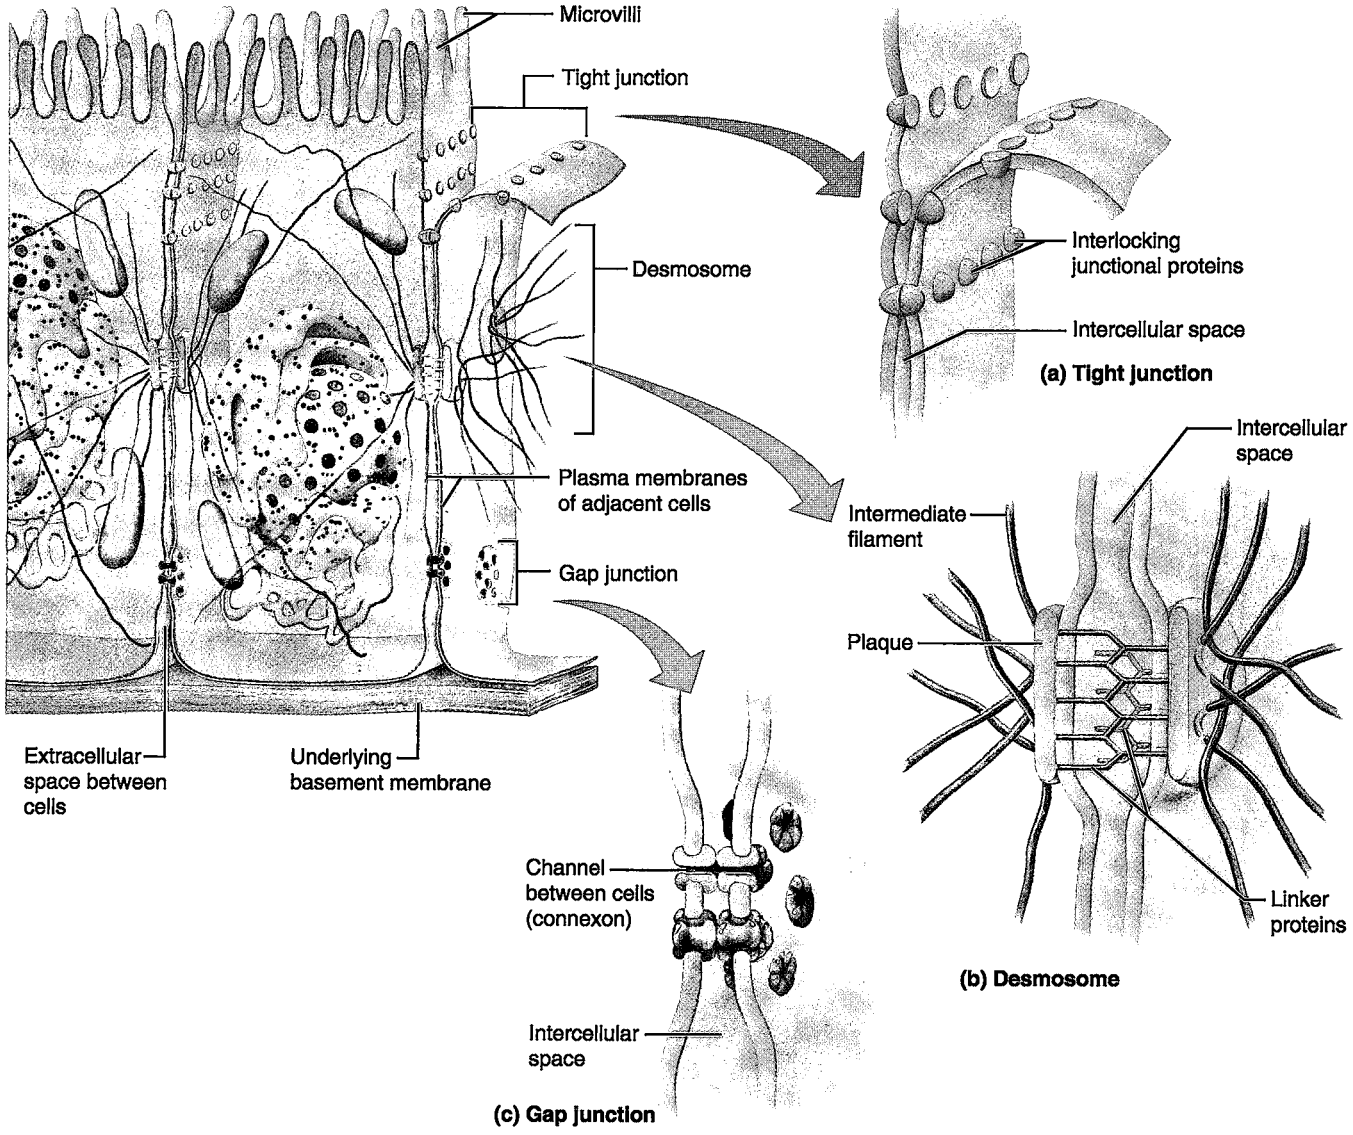


FIGURE 3.5 **Cell junctions.** An epithelial cell is shown joined to adjacent cells by three common types of cell junctions: **(a)** tight junctions, **(b)** desmosomes, and **(c)** gap junctions. (Note: Except for epithelia, it is unlikely that a single cell will have all three junction types.)

The Plasma Membrane: Functions

Membrane Transport

Our cells are bathed in an extracellular fluid called **interstitial fluid** (in"ter-stish'al) that is derived from the blood. Interstitial fluid is like a rich, nutritious "soup." It contains thousands of ingredients, including amino acids, sugars, fatty acids, vitamins, regulatory substances such as hormones and neurotransmitters, salts, and waste products. To remain healthy, each cell must extract from this mix the exact amounts of the substances it needs at specific times.

Although there is continuous traffic across the plasma membrane, it is a **selectively,** or **differentially, permeable** barrier, meaning that it allows some substances to pass while excluding others. Thus, it allows nutrients to enter the cell, but keeps many undesirable substances out. At the same time, it keeps valuable cell proteins and other substances in the cell, but allows wastes to exit.

Substances move through the plasma membrane in essentially two ways—passively or actively. In **passive processes,** substances cross the membrane without any energy input from the cell. In **active processes,** the cell provides the metabolic energy (ATP) needed to move substances across the membrane. The various transport processes that occur in

cells are summarized in Table 3.1 on p. 75 and Table 3.2 on p. 80. Let's examine each of these types of membrane transport.

HOMEOSTATIC IMBALANCE

Selective permeability is a characteristic of healthy, intact cells. When a cell (or its plasma membrane) is severely damaged, the membrane becomes permeable to virtually everything, and substances flow into and out of the cell freely. This phenomenon is evident when someone has been severely burned. Precious fluids, proteins, and ions "weep" from the dead and damaged cells. ●

Passive Processes

The two main types of passive transport in cells are *diffusion* (di-fu'zhun) and *filtration*. Diffusion is an important means of passive membrane transport for every cell of the body. By contrast, filtration generally occurs only across capillary walls.

Diffusion **Diffusion** is the tendency of molecules or ions to scatter evenly throughout the environment (Figure 3.6). Recall that all molecules possess kinetic energy and are in constant motion (see p. 25). As molecules move about randomly at high speeds, they collide and ricochet off one another, changing direction with each collision. The overall effect of this erratic movement is that molecules move away from areas where they are in higher concentration to areas where their concentration is lower, so we say that molecules diffuse *along*, or *down*, their **concentration gradient.** The greater the difference in concentration between the two areas, the faster the net diffusion of the particles.

Because the driving force for diffusion is the kinetic energy of the molecules themselves, the speed of diffusion is influenced by molecular *size* (the smaller, the faster) and by *temperature* (the warmer, the faster). In a closed container, diffusion eventually produces a uniform mixture of molecules. In other words, the system reaches equilibrium, with molecules moving equally in all directions (no *net* movement). Examples of diffusion are familiar to everyone. When you peel onions, you get teary-eyed because the cut onion releases volatile substances that diffuse through the air, dissolve in the fluid film covering your eyes, and form irritating sulfuric acid.

Because of its hydrophobic core, the plasma membrane is a physical barrier to free diffusion. However, a molecule *will* diffuse through the membrane if the molecule is (1) lipid soluble, (2) small enough to pass through membrane channels, or (3) assisted by a carrier molecule. The unassisted diffusion of lipid-soluble or very small particles is called **simple diffusion.** A special name, *osmosis*, is given

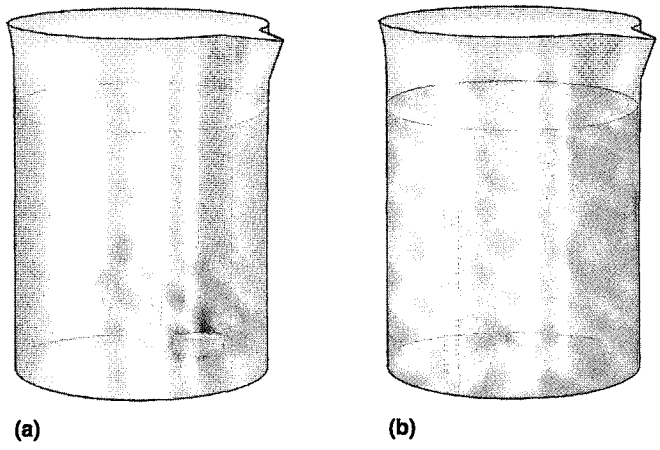

FIGURE 3.6 **Diffusion.** Molecules in solution move continuously and collide constantly with other molecules. As a result, molecules tend to move away from areas of their highest concentration and become evenly distributed. **(a)** Diagram of dye molecules diffusing from a dye pellet into the surrounding water. **(b)** Dye molecules from pellet have diffused evenly throughout the water.

to the unassisted diffusion of a solvent (usually water) through a membrane. Assisted diffusion is known as *facilitated diffusion*.

1. Simple diffusion. Nonpolar and lipid-soluble substances diffuse directly through the lipid bilayer (Figure 3.7a). Such substances include oxygen, carbon dioxide, and fat-soluble vitamins. Because oxygen concentration is always higher in the blood than in tissue cells, oxygen continuously diffuses from the blood into the cells, whereas carbon dioxide (in higher concentration within the cells) diffuses from tissue cells into the blood.

2. Facilitated diffusion. Certain molecules, notably glucose and other sugars, amino acids, and ions are transported passively even though they are unable to pass through the lipid bilayer. Instead they move through the membrane by a passive transport process called **facilitated diffusion** in which the transported substance either (1) binds to protein carriers in the membrane and is ferried across or (2) moves through water-filled protein channels.

▪ **Carriers.** A **carrier** is a transmembrane integral protein that shows specificity for molecules of a certain polar substance or class of substances that are too large to pass through membrane channels, such as sugars and amino acids. Although it was initially believed that the integral proteins that act as carriers either flip-flopped or physically crossed the membrane like ferryboats, the most popular model for this process indicates that changes in the shape of the carrier allow it to first envelop and then release the

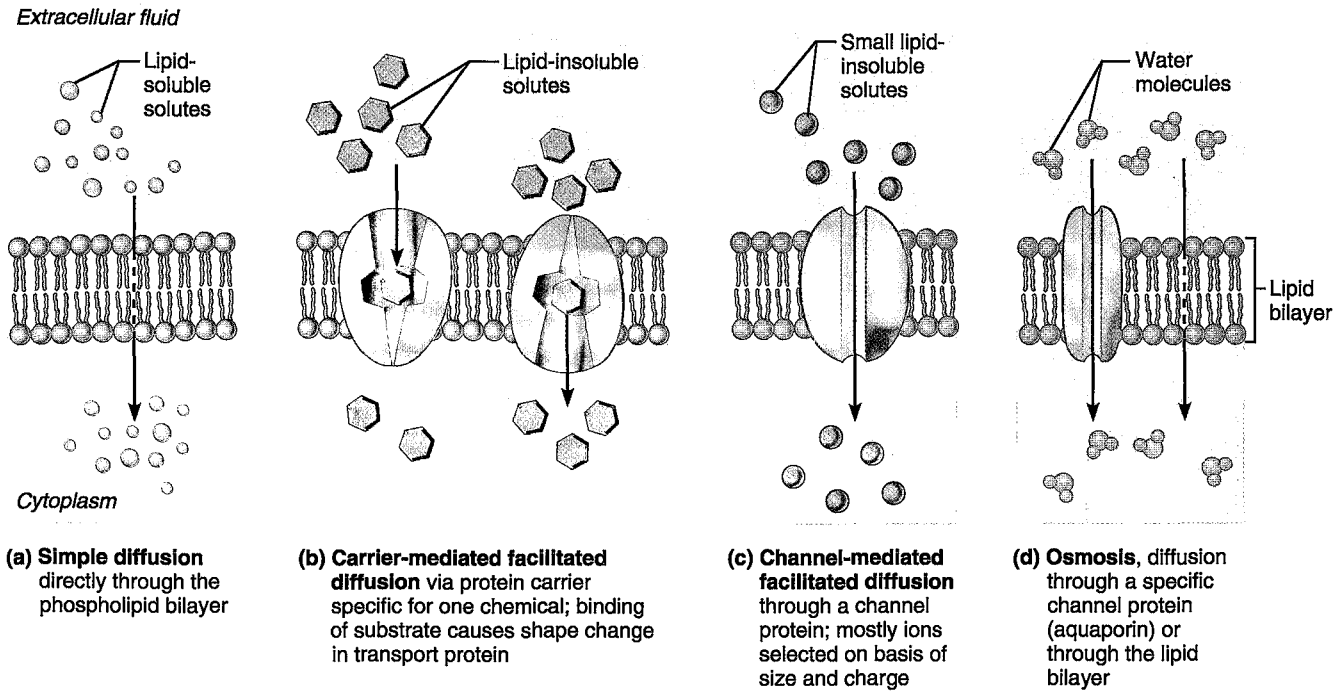

FIGURE 3.7 **Diffusion through the plasma membrane. (a)** In simple diffusion, fat-soluble molecules diffuse directly through the lipid bilayer of the plasma membrane, in which they can dissolve. **(b)** In facilitated diffusion using protein carriers, large, lipid-insoluble molecules (e.g., glucose) are moved across the membrane via a transport protein. **(c)** In facilitated diffusion via membrane channels, small polar or charged particles diffuse through membrane channels constructed by channel proteins. **(d)** In osmosis, water moves across the plasma membrane via specific channels (aquaporins) or diffuses directly through the lipid portion of the membrane.

transported substance, shielding it en route from the nonpolar regions of the membrane (Figure 3.7b). Essentially, the binding site is moved from one face of the membrane to the other by changes in the conformation of the carrier protein.

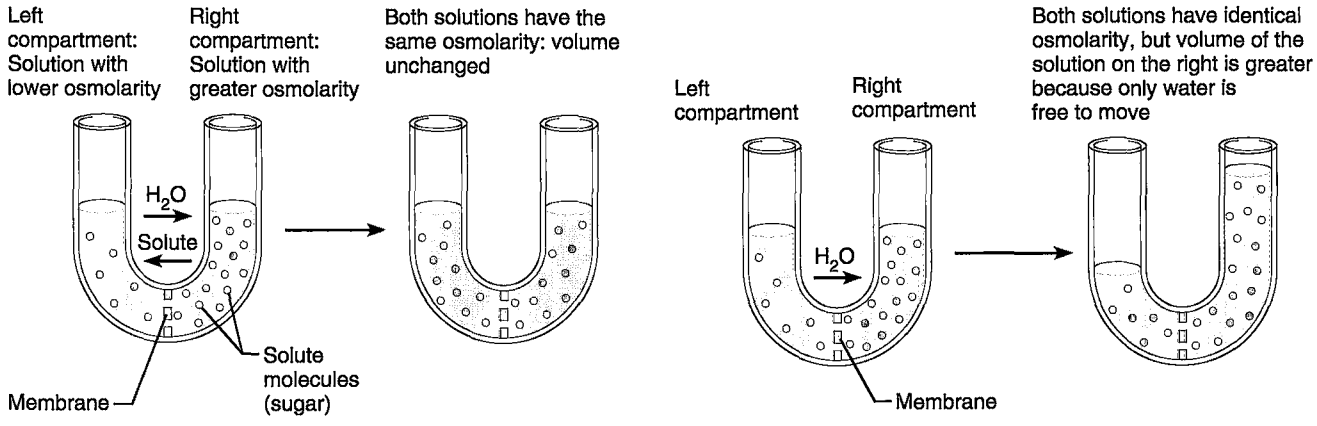
Just as in any simple diffusion process, a substance transported by carrier-mediated facilitated diffusion, like glucose, moves down its concentration gradient. Glucose is normally in higher concentrations in the blood than in the cells, where it is rapidly used for ATP synthesis. So, within the body glucose transport is *typically* unidirectional—into the cells. However, carrier-mediated transport is limited by the number of receptors present. For example, when all the glucose carriers are "engaged," they are said to be *saturated*, and glucose transport is occurring at its maximum rate.

▪ **Channels. Channels** are transmembrane proteins that serve to transport substances, usually ions or water, through aqueous channels from one side of the membrane to the other (Figure 3.7c and d). Binding or association sites exist within the channels, and the channels are selective due to pore size and the charges of the amino acids lining the channel. Some channels, the so-called leakage channels, are always open and simply allow ion or water fluxes according to concentration gradients. Others are gated and controlled (opened or closed) by various chemical or electrical signals.

Like carriers, many channels can be inhibited by certain molecules, show saturation, and tend to be specific. Substances moving through them also honor the concentration gradient (always moving down the gradient). When a substance crosses the membrane by simple diffusion, the rate of diffusion is not controllable because the lipid solubility of the membrane is not immediately changeable. By contrast, the rate of facilitated diffusion *is* controllable because the permeability of the membrane can be altered by regulating the activity or number of individual carriers or channels.

Oxygen, water, glucose, and various ions are vitally important to cellular homeostasis. Thus, their passive transport by diffusion (either simple or facilitated) represents a tremendous saving of cellular energy. Indeed, if these substances had to be transported actively, cell expenditures of ATP would increase exponentially!

3. Osmosis. The diffusion of a solvent, such as water, through a selectively permeable membrane is **osmosis** (oz-mo'sis; *osmos* = pushing). Even though water is highly polar, it passes via osmosis through the lipid bilayer (Figure 3.7d). This is surprising



(a) Membrane permeable to both solute molecules and water

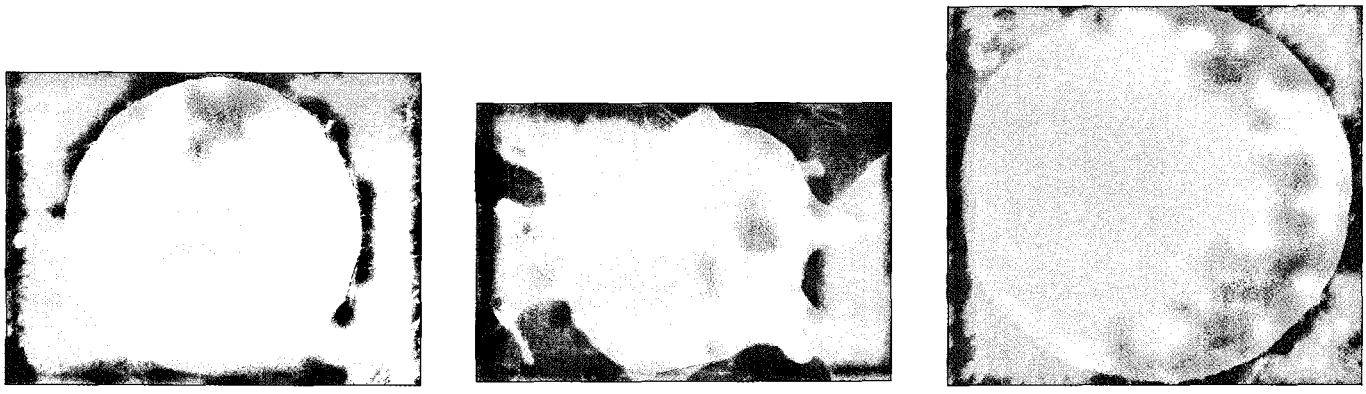
(b) Membrane impermeable to solute molecules, permeable to water

FIGURE 3.8 **Influence of membrane permeability on diffusion and osmosis. (a)** In this system, the membrane is permeable to both water and solute (sugar) molecules. Water moves from the solution with lower osmolarity (left compartment) to the solution with greater osmolarity (right compartment). The solute moves along its own concentration gradient in the opposite direction. When the system comes to equilibrium (right), the solutions have the same osmolarity and volume. **(b)** This system is identical to that in (a) except that the membrane is impermeable to the solute. Water moves by osmosis from the left to the right compartment, until its concentration and that of the solutions are identical. Because the solute is prevented from moving, the volume of the solution in the right compartment increases.

because you'd expect it to be repelled by the hydrophobic lipid tails. Although still hypothetical, one explanation is that random movements of the membrane lipids open small gaps between their wiggling tails, allowing water to slip and slide its way through the membrane by moving from gap to gap. Water also moves freely and reversibly through water-specific channels constructed by transmembrane proteins called **aquaporins (AQP).** Although aquaporins are believed to be present in all cell types, they are particularly abundant in red blood cells and in cells involved in water balance such as kidney tubule cells.

Osmosis occurs whenever the water concentration differs on the two sides of a membrane. If distilled water is present on both sides of a selectively permeable membrane, no *net* osmosis occurs, even though water molecules move in both directions through the membrane. If the solute concentration on the two sides of the membrane differs, water concentration differs as well (as solute concentration increases, water concentration decreases). The extent to which water's concentration is decreased by solutes depends on the *number,* not the *type,* of solute particles, because one molecule or one ion of solute (theoretically) displaces one water molecule. The total concentration of all solute particles in a solution is referred to as the solution's **osmolarity** (oz″mo-lar′ĭ-te). When equal volumes of aqueous solutions of different osmolarity are separated by a membrane that is *permeable to all molecules* in the system, net diffusion of both solute and water occurs, each moving down its own concentration gradient (Figure 3.8a). Eventually, equilibrium is reached when the water concentration on the left equals that on the right, and the solute concentration on both sides is the same. If we consider the same system, but make the membrane *impermeable to solute molecules,* we see quite a different result (Figure 3.8b). Water quickly diffuses from the left to the right compartment and continues to do so until its concentration is the same on the two sides of the membrane. Notice that in this case equilibrium results from the movement of water alone (the solutes are prevented from moving). Notice also that the movement of water leads to dramatic changes in the volumes of the two compartments.

The last example mimics osmosis across plasma membranes of living cells, with one major difference. In our examples, the volumes of the compartments are infinitely expandable and the effect of pressure exerted by the added weight of the higher fluid column is not considered. In living plant cells, which have rigid cell walls external to their plasma membranes, this is not the case. As water diffuses into the cell, the point is finally reached where the **hydrostatic pressure** (the back pressure exerted by water against the membrane) within the cell is equal to its **osmotic pressure**—the cell's tendency to resist further (net) water entry. As a rule, the higher the amount of nondiffusible (or nonpenetrating) solutes in a cell, the higher the osmotic pressure and the greater the hydrostatic pressure that must be developed to resist further net water entry.



(a) (b) (c)

FIGURE 3.9 **The effect of solutions of varying tonicities on living red blood cells. (a)** In isotonic solutions (same solute/water concentrations as inside cells), cells retain their normal size and shape. **(b)** In a hypertonic solution (containing more solutes than are present inside the cells), the cells lose water and shrink (crenate). **(c)** In a hypotonic solution (containing fewer solutes than are present inside the cell), the cells take in water by osmosis until they become bloated and burst (lyse).

However, such major changes in hydrostatic (and osmotic) pressures do not occur in living animal cells, which lack rigid cell walls. Osmotic imbalances cause animal cells to swell or shrink (due to net water gain or loss) until either the solute concentration is the same on both sides of the plasma membrane, or the membrane is stretched to its breaking point.

This leads us to the important concept of *tonicity* (to-nis'ĭ-te). As noted, many molecules, particularly intracellular proteins and selected ions, are prevented from diffusing through the plasma membrane. Consequently, any change in their concentration alters the water concentration on the two sides of the membrane and results in a net loss or gain of water by the cell.

The ability of a solution to change the shape or tone of cells by altering their internal water volume is called **tonicity** (*tono* = tension). Solutions with the same concentrations of nonpenetrating solutes as those found in cells (0.9% saline or 5% glucose) are **isotonic** ("the same tonicity"). Cells exposed to such solutions retain their normal shape, and exhibit no net loss or gain of water (Figure 3.9a). As you might expect, the body's extracellular fluids and most intravenous solutions (solutions infused into the body via a vein) are isotonic. Solutions with a higher concentration of nonpenetrating solutes than seen in the cell (for example, a strong saline solution) are **hypertonic.** Cells immersed in hypertonic solutions lose water and shrink, or *crenate* (kre'nāt) (Figure 3.9b). Solutions that are more dilute (contain a lower concentration of nonpenetrating solutes) than cells are called **hypotonic.** Cells placed in a hypotonic solution plump up rapidly as water rushes into them (Figure 3.9c). Distilled water represents the most extreme example of hypotonicity. Because it contains *no* solutes, water continues to enter cells until they finally burst or *lyse*.

Notice that osmolarity and tonicity are not the same thing. A solution's osmolarity is based solely on its total solute concentration; its tonicity is based on how the solution affects cell volume, which depends on (1) solute concentration and (2) solute permeability of the plasma membrane. Osmolarity is expressed as osmoles per liter (osmol/L) where 1 osmol is equal to 1 mole of nonionizing molecules.* A 0.3-osmol/L solution of NaCl is isotonic because sodium ions are usually prevented from diffusing through the plasma membrane. But if the cell is immersed in a 0.3-osmol/L solution of a penetrating solute, the solute will enter the cell and water will follow. The cell will swell and burst, just as if it had been placed in pure water.

Osmosis is extremely important in determining distribution of water in the various fluid-containing compartments of the body (in cells, in blood, and so on). In general, osmosis continues until osmotic and hydrostatic pressures acting at the membrane are equal. For example, water is forced out of capillary blood by the hydrostatic pressure of the blood against the capillary wall, but the presence in blood of solutes that are too large to cross the capillary membrane draws water back into the bloodstream. As a result, very little net loss of plasma fluid occurs.

Simple diffusion and osmosis occurring directly through the plasma membrane are not selective processes. In those processes, whether a molecule can

*Osmolarity (Osm) is determined by multiplying molarity (moles per liter, or *M*) by the number of particles resulting from ionization. For example, since NaCl ionizes to $Na^+ + Cl^-$, a 1-*M* solution of NaCl is a 2-Osm solution. For substances that do not ionize (e.g., glucose), molarity and osmolarity are the same.

TABLE 3.1 Passive Membrane Transport Processes

PROCESS	ENERGY SOURCE	DESCRIPTION	EXAMPLES
DIFFUSION			
Simple diffusion	Kinetic energy	Net movement of particles (ions, molecules, etc.) from an area of their higher concentration to an area of their lower concentration, that is, along their concentration gradient	Movement of fats, oxygen, carbon dioxide through the lipid portion of the membrane
Facilitated diffusion	Kinetic energy	Same as simple diffusion, but the diffusing substance is attached to a lipid-soluble membrane carrier protein or moves through a membrane channel	Movement of glucose and some ions into cells
Osmosis	Kinetic energy	Simple diffusion of water through a selectively permeable membrane	Movement of water into and out of cells directly through the lipid phase of the membrane or via membrane pores (aquaporins)
FILTRATION			
	Hydrostatic pressure	Movement of water and solutes through a semipermeable membrane (either through the plasma membrane or between cells) from a region of higher hydrostatic pressure to a region of lower hydrostatic pressure, that is, along a pressure gradient	Movement of water, nutrients, and gases through a capillary wall; formation of kidney filtrate

pass through the membrane depends chiefly on its size or its solubility in lipid, not on its unique structure. Facilitated diffusion, on the other hand, *is* often highly selective. The carrier for glucose, for example, combines specifically with glucose, in much the same way an enzyme binds to its specific substrate and ion channels allow only selected ions to pass.

HOMEOSTATIC IMBALANCE

Hypertonic solutions are sometimes infused intravenously into the bloodstream of edematous patients (those swollen because water is retained in their tissues) to draw excess water out of the extracellular space and move it into the bloodstream so that it can be eliminated by the kidneys. Hypotonic solutions may be used (with care) to rehydrate the tissues of extremely dehydrated patients. In less extreme cases of dehydration, drinking hypotonic fluids (colas, apple juice, and sports drinks) usually does the trick. ●

Filtration **Filtration** is the process that forces water and solutes through a membrane or capillary wall by *fluid,* or *hydrostatic,* pressure. Like diffusion, filtration is a passive transport process and involves a gradient. However, the gradient for filtration is a **pressure gradient** that pushes solute-containing fluid (filtrate) from a higher-pressure area to a lower-pressure area. As already mentioned, in the body hydrostatic pressure exerted by the blood forces fluid out of the capillaries, and this fluid contains solutes that are vital to the tissues. Filtration also provides the fluid ultimately excreted by the kidneys as urine. Filtration is not selective; only blood cells and protein molecules too large to pass through membrane pores or the paracellular path (between cells) are held back. Table 3.1 summarizes passive membrane transport processes.

Active Processes

Whenever a cell uses the bond energy of ATP to move solutes across the membrane, the process is referred to as *active.* Substances moved actively across the plasma membrane are usually unable to pass in the necessary direction by passive transport processes. The substance may be too large to pass through the channels, incapable of dissolving in the lipid bilayer, or unable to move down its concentration gradient. There are two major mechanisms of active membrane transport: active transport and vesicular transport.

Active Transport **Active transport,** like carrier-mediated facilitated diffusion, requires carrier proteins that combine *specifically* and *reversibly*

Q *(1) What happens when the pump protein is phosphorylated? (2) What happens when potassium binds to the pump protein?*

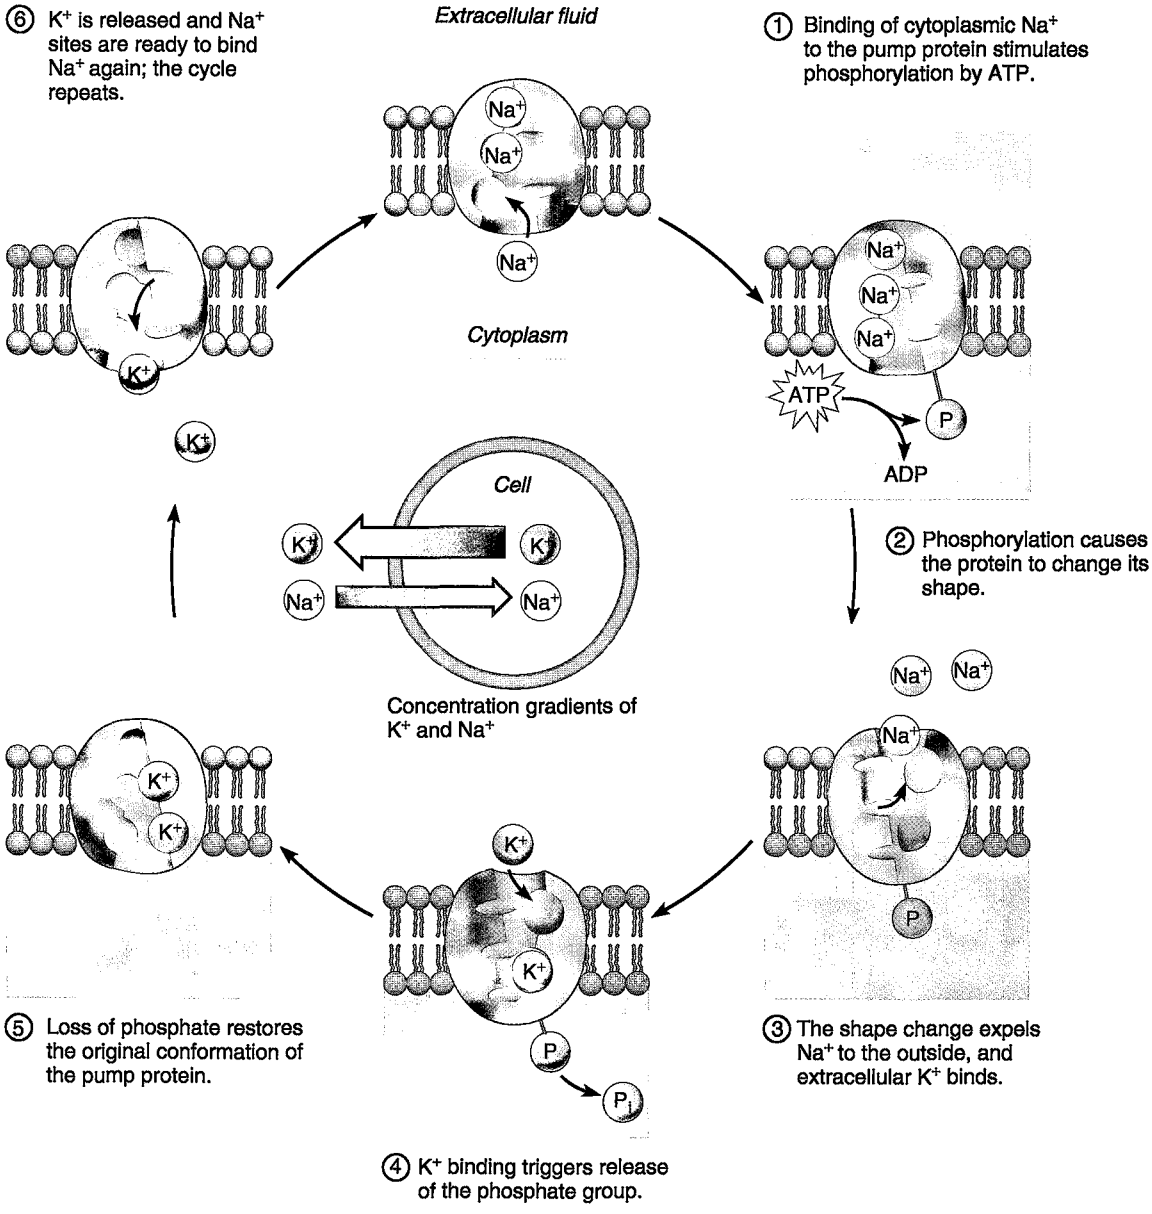


FIGURE 3.10 **Operation of the sodium-potassium pump, an antiport pump (Na^+-K^+ ATPase).** Hydrolysis of a molecule of ATP provides energy for an antiport "pump" protein to move three sodium ions out of the cell and two potassium ions into the cell. Both ions are moved against their concentration gradients, indicated in the center diagram by colored arrows moving through the membrane (yellow arrow = Na^+ gradient; green arrow = K^+ gradient).

A *(1) The protein changes shape, expelling sodium to the extracellular fluid and loading potassium ions. (2) The cleaved phosphate group is released.*

with the transported substances. However, facilitated diffusion always honors concentration gradients because its driving force is kinetic energy. In contrast, the active transporters or **solute pumps** move solutes, most importantly ions (such as Na^+, K^+, and Ca^{2+}), "uphill" *against* a concentration gradient. To do this work, cells must expend the energy of ATP.

Active transport processes are distinguished according to their source of energy. In *primary active transport,* the energy to do work comes directly from hydrolysis of ATP. In *secondary active transport,* transport is driven indirectly by energy stored in ionic gradients created by operation of primary active transport pumps. Secondary active transport systems are all *coupled systems;* that is, they move more than one substance at a time. If the two transported substances are moved in the same direction, the system is a **symport system** (*sym* = same). If the transported substances "wave to each other" as they cross the membrane in opposite directions, the system is an **antiport system** (*anti* = opposite, against). Let's examine these processes more carefully.

1. Primary active transport. In primary active transport, hydrolysis of ATP results in the phosphorylation of the transport protein, a step that causes the protein to change its conformation in such a manner that it "pumps" the bound solute across the membrane.

The most investigated example of a primary active transport system is the operation of the **sodium-potassium pump** (Figure 3.10), for which the carrier is an enzyme called **Na^+-K^+ ATPase.** The concentration of K^+ inside the cell is some 10 times higher than that outside, and the reverse is true of Na^+. These ionic concentration differences are essential for excitable cells like muscle and nerve cells to function normally and for all body cells to maintain their normal fluid volume. Because Na^+ and K^+ leak slowly but continuously through leakage channels in the plasma membrane along their concentration gradient (and cross more rapidly in stimulated muscle and nerve cells), the Na^+-K^+ pump operates more or less continuously as an antiporter to simultaneously drive Na^+ out of the cell against a steep concentration gradient and pump K^+ back in. Other examples of primary active transport include the calcium pumps that actively sequester ionic calcium from the intracellular fluid into specific organelles or eject it from the cell.

2. Secondary active transport. A single ATP-powered pump, such as the Na^+-K^+ pump, can indirectly drive the secondary active transport of several other solutes (Figure 3.11). By moving sodium across the plasma membrane against its concentration gradient, the pump stores energy (in the ion gradient). Then, just as water pumped uphill can do work as it flows back down (turn a turbine or water wheel), a substance pumped across a membrane can do work as it leaks back, propelled downhill along its concentration gradient. Thus, as sodium moves back into the cell with the help of a carrier protein (facilitated diffusion), other substances are "dragged along" or cotransported by a common carrier protein. For example, some sugars, amino acids, and many ions are cotransported in this way into cells lining the small intestine. Though the cotransported substances both move passively, Na^+ has to be pumped back out into the lumen (cavity) of the intestine to maintain its diffusion gradient. Ion gradients can also be used to drive antiport systems such as those that help to regulate intracellular pH by using the sodium gradient to expel hydrogen ions.

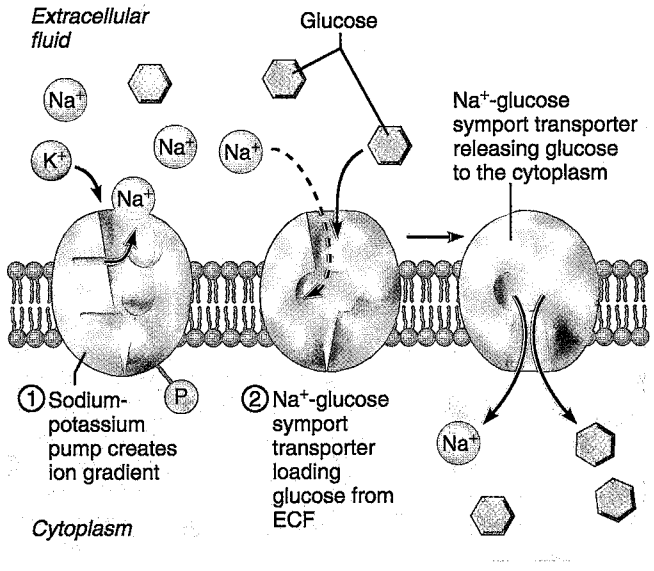

FIGURE 3.11 **Secondary active transport.** In this example, ① the ATP-driven Na^+-K^+ pump stores energy by creating a steep concentration gradient for Na^+ entry into the cell. ② As Na^+ diffuses back across the membrane through a membrane cotransporter protein, it drives glucose against its concentration gradient into the cell. (ECF = extracellular fluid)

Regardless of whether the energy is provided directly (primary active transport) or indirectly (secondary active transport), each membrane pump or cotransporter transports only specific substances. Hence, active transport systems provide a way for the cell to be very selective in cases where substances cannot pass by diffusion. (No pump—no transport.)

Vesicular Transport Large particles, macromolecules, and fluids are transported across plasma and intracellular membranes by **vesicular transport.** Vesicular transport is the mechanism used for **exocytosis** (ek"so-si-to'sis; "out of the cell"),

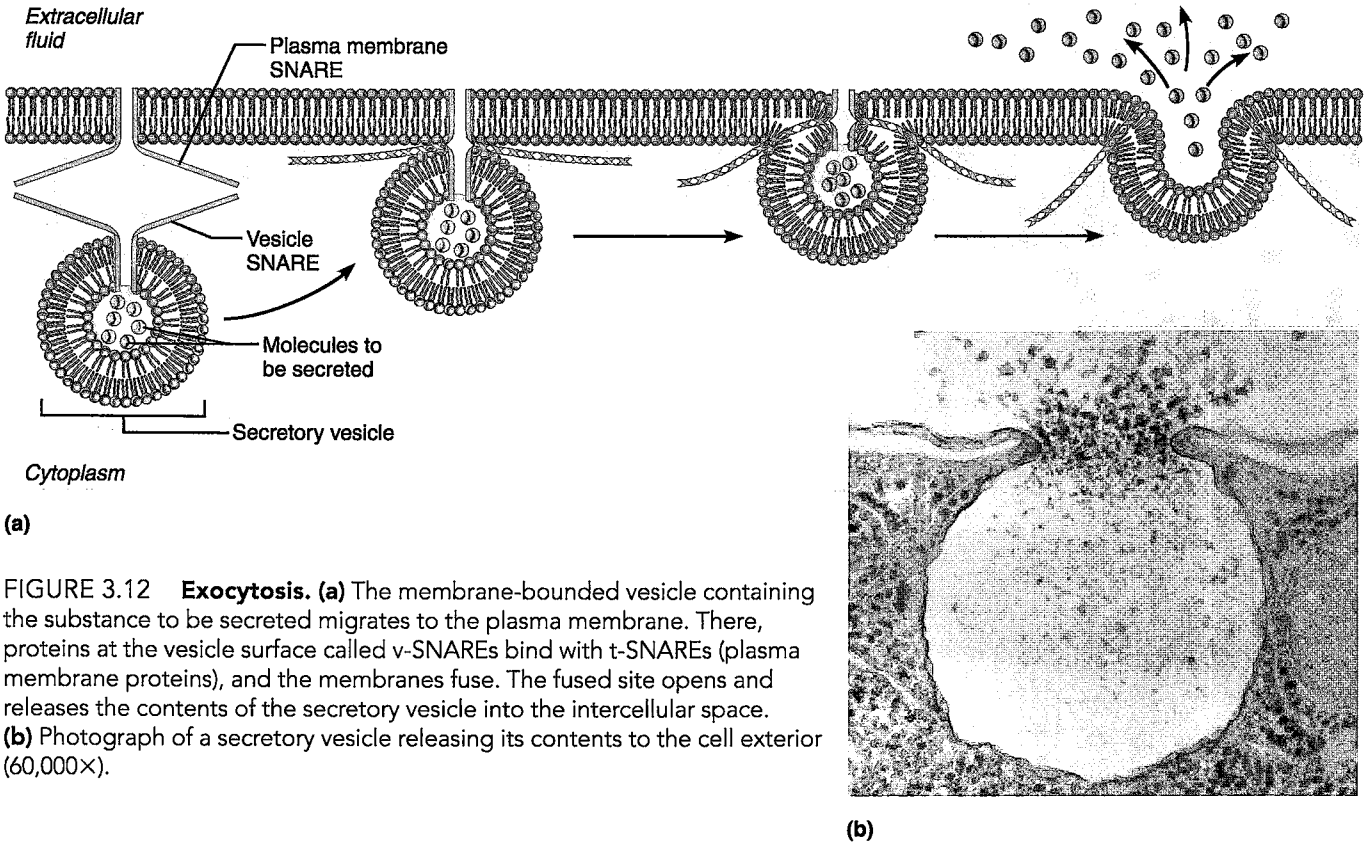

FIGURE 3.12 **Exocytosis. (a)** The membrane-bounded vesicle containing the substance to be secreted migrates to the plasma membrane. There, proteins at the vesicle surface called v-SNAREs bind with t-SNAREs (plasma membrane proteins), and the membranes fuse. The fused site opens and releases the contents of the secretory vesicle into the intercellular space. **(b)** Photograph of a secretory vesicle releasing its contents to the cell exterior (60,000×).

moving substances from the cell interior to the extracellular space; and **endocytosis** (en"do-si-to'sis; "within the cell"), moving substances across the plasma membrane into the cell from the extracellular environment.

Vesicular transport is also used for combination processes such as *transcytosis,* moving substances into, across, and then out of the cell; and *substance,* or *vesicular, trafficking,* moving substances from one area (or organelle) in the cell to another.

Like solute pumping, vesicular transport processes are energized by ATP (or in some cases *GTP*—guanosine triphosphate, another energy-rich compound).

1. Exocytosis. This mechanism, typically stimulated by a cell-surface signal such as binding of a hormone to a membrane receptor, accounts for hormone secretion, neurotransmitter release, mucus secretion, and in some cases, ejection of wastes. The substance to be removed from the cell is first enclosed in a membranous sac called a **vesicle.** In most cases, the vesicle migrates to the plasma membrane, fuses with it, and then ruptures, spilling the sac contents out of the cell (Figure 3.12). The mechanism involves a "docking" process in which transmembrane proteins on the vesicles, fancifully called v-SNAREs (*v* for vesicle), recognize certain plasma membrane proteins, called t-SNAREs (*t* for target), and bind with them. This causes the membranes to "corkscrew" together, rearranging the lipid monolayers without mixing them. As described shortly, membrane material added by exocytosis is removed by endocytosis—the reverse process.

In selected cases (particularly in cases of neurotransmitter secretion by some neurons of the brain), the membranes do not fuse. Instead, a fusion pore flickers open, part of the vesicle contents are released, and then the fusion pore closes. Called "kiss and run," this mechanism of exocytosis saves energy. Because the vesicles do not collapse into the plasma membrane, they can be reused.

2. Endocytosis, transcytosis, and vesicular trafficking. Virtually all the remaining forms of vesicular transport involve the use of an assortment of protein-coated vesicles of three types and, with some exceptions, all are mediated by membrane receptors. Let's look at the specialties of each type of coated vesicular transport.

▪ ***Clathrin-coated vesicles.*** Clathrin-coated vesicles provide the main route for endocytosis and transcytosis of bulk solids, most macromolecules, and fluids. These vesicles are also hijacked on occasion by pathogens seeking entry into a cell. Basically, the substance to be taken into the cell by endocytosis is progressively enclosed by an infolding portion of the plasma membrane called a *coated pit,* a term that

Q *Phagocytic cells gather in the air sacs of the lungs, especially in the lungs of smokers. What is the connection?*

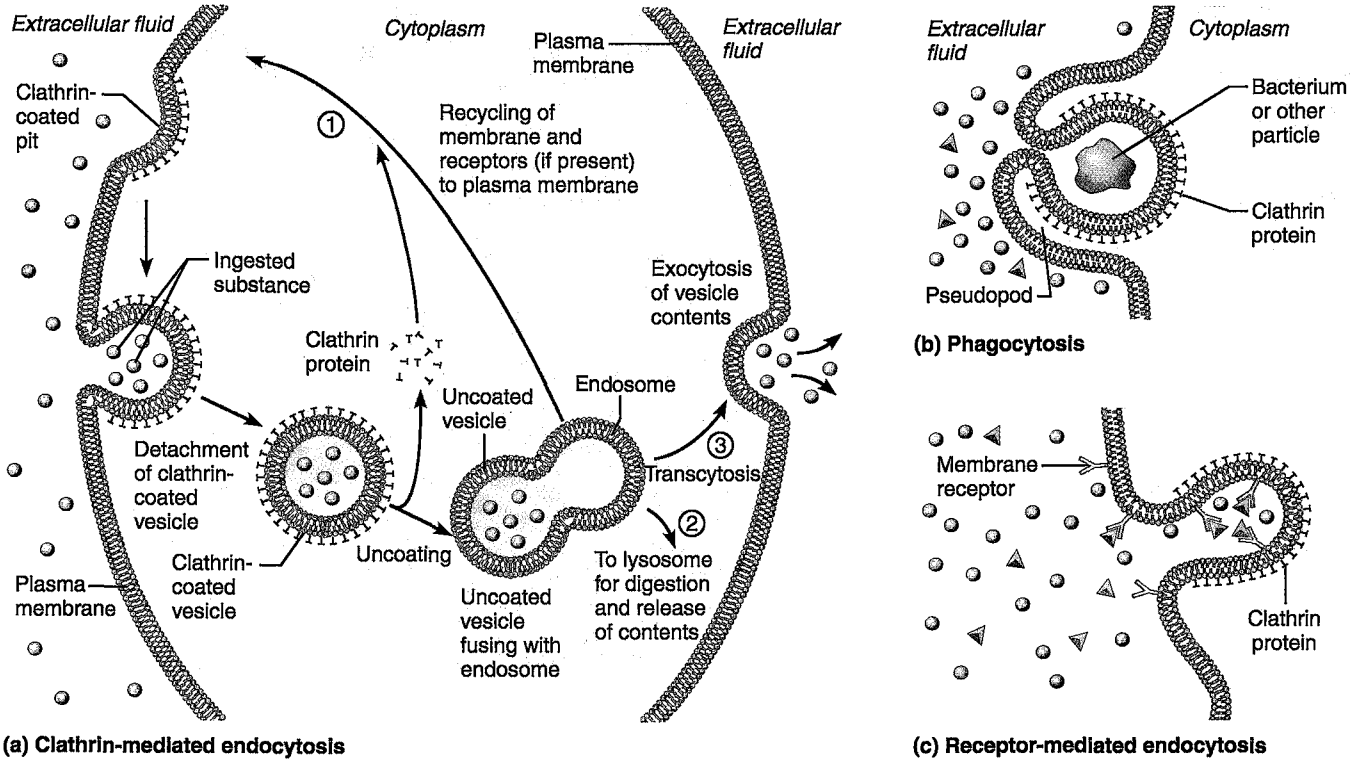

FIGURE 3.13 **Clathrin-mediated endocytosis. (a)** Events of clathrin-mediated endocytosis, including three possible fates for the vesicle and its contents. **(b)** Phagocytosis. **(c)** Receptor-mediated endocytosis.

refers to the bristlelike **clathrin** (kla'thrin; "lattice clad") protein coating on the cytoplasmic face of the vesicle (Figure 3.13a). The clathrin coat (clathrin and some accessory proteins) acts both in cargo selection and in deforming the membrane to produce the vesicle.

Once inside, the vesicle loses its fuzzy coat and then typically fuses with a processing and sorting vesicle called an *endosome*. As shown in Figure 3.13a, contents of the endosome may be ① recycled back to the plasma membrane (applies to many receptors and membrane components), ② combined with a *lysosome* (li'so-some), a specialized cell structure containing digestive enzymes, where the ingested substance is degraded or released (if iron or cholesterol), or ③ transported completely across the cell and released by exocytosis on the opposite side *(transcytosis)*. Transcytosis is common in the endothelial cells lining blood vessels because it provides a quick means to get substances from the blood to the interstitial fluid. Based on the nature and quantity of material taken up and the mechanism of uptake, three types of endocytosis that use clathrin-coated vesicles are recognized: phagocytosis, pinocytosis, and receptor-mediated endocytosis.

Phagocytosis (fag"o-si-to'sis; "cell eating") is the type of endocytosis in which some relatively large or solid material, such as a clump of bacteria or cell debris, is engulfed by the cell. When a particle binds to receptors on the cell's surface, cytoplasmic extensions called pseudopods (soo'do-pahdz; *pseudo* = false, *pod* = foot) form and flow around the particle and engulf it (Figure 3.13b). The endocytotic vesicle thus formed is called a **phagosome** (fag'o-sōm; "eaten body"). In most cases, the phagosome then fuses with a lysosome and its contents are digested.

In the human body only macrophages and certain white blood cells are "experts" at phagocytosis. They help police and protect the body by ingesting and disposing of bacteria, other foreign substances, and dead tissue cells. The disposal of dying cells is

A Lungs, open to the external environment, collect dust and other airborne debris. In the lungs of smokers, carbon particles are added to this debris.

TABLE 3.2 Active Membrane Transport Processes

PROCESS	ENERGY SOURCE	DESCRIPTION	EXAMPLES
ACTIVE TRANSPORT			
Primary active transport	ATP	Transport of substances against a concentration (or electrochemical) gradient; across the plasma membrane by a solute pump; directly uses energy of ATP hydrolysis	Ions (Na^+, K^+, H^+, Ca^{2+}, and others)
Secondary active transport	Ion concentration gradient maintained with ATP	Cotransport (coupled transport) of two solutes across the membrane; energy is supplied by the ion gradient created by a primary active solute pump (indirectly); symporters move the transported substances in the same direction; antiporters move transported substances in opposite directions across the membrane	Movement of polar or charged solutes, e.g., amino acids (into cell by symporters); Ca^{2+}, H^+ (out of cells via antiporters)
VESICULAR TRANSPORT			
Exocytosis	ATP	Secretion or ejection of substances from a cell; the substance is enclosed in a membranous vesicle, which fuses with the plasma membrane and ruptures, releasing the substance to the exterior	Secretion of neurotransmitters, hormones, mucus, etc.; ejection of cell wastes
Endocytosis	ATP		
▪ Via clathrin-coated vesicles			
Phagocytosis	ATP	"Cell eating": A large external particle (proteins, bacteria, dead cell debris) is surrounded by a "seizing foot" and becomes enclosed in a vesicle (phagosome)	In the human body, occurs primarily in protective phagocytes (some white blood cells and macrophages)
Pinocytosis (fluid-phase endocytosis)	ATP	Plasma membrane sinks beneath an external fluid droplet containing small solutes; membrane edges fuse, forming a fluid-filled vesicle; clathrin-coated vesicles formed	Occurs in most cells; important for taking in dissolved solutes by absorptive cells of the kidney and intestine
Receptor-mediated endocytosis	ATP	Selective endocytosis and transcytosis; external substance binds to membrane receptors, and clathrin-coated pits are formed	Means of intake of some hormones, cholesterol, iron, and most macromolecules
▪ Via caveolin-coated vesicles (caveolae)	ATP	Selective endocytosis (and transcytosis); external substance binds to membrane receptors (often associated with lipid rafts); caveolin-coated vesicles formed	Roles not fully known; proposed roles include cholesterol regulation and trafficking; platforms for signal transduction
Intracellular vesicular trafficking			
▪ Via coatomer-coated vesicles	ATP	Vesicles coated with coatomer proteins pinch off from organelles and travel to other organelles to deliver their cargo	Accounts for nearly all intracellular trafficking of molecules

crucial, because dead cell remnants trigger inflammation in the surrounding area or may stimulate an undesirable immune response. Most phagocytes move about by **amoeboid motion** (ah-me'boyd; "changing shape"); that is, the flowing of their cytoplasm into temporary pseudopods allows them to creep along.

In **pinocytosis** ("cell drinking"), also called **fluid-phase endocytosis,** a bit of infolding plasma membrane surrounds a very small volume of extracellular fluid containing dissolved molecules. This droplet enters the cell and fuses with an endosome. Unlike phagocytosis, pinocytosis is a routine activity of

most cells, affording them a nonselective way of sampling the extracellular fluid. It is particularly important in cells that absorb nutrients, such as cells that line the intestines.

As mentioned, bits of the plasma membrane are removed when the membranous sacs are internalized. However, these membranes are recycled back to the plasma membrane by exocytosis, so the surface area of the plasma membrane remains remarkably constant.

Receptor-mediated endocytosis is the main mechanism for the specific endocytosis and transcytosis of most macromolecules by body cells, and it is exquisitely selective (Figure 3.13c). The receptors for this process are plasma membrane proteins that bind only with certain substances. Both the receptors and attached molecules are internalized in a clathrin-coated pit and then dealt with in one of the ways discussed above. Substances taken up by receptor-mediated endocytosis include enzymes, insulin (and some other hormones), low-density lipoproteins (such as cholesterol attached to a transport protein), and iron. Unfortunately, flu viruses, diphtheria, and cholera toxins use this route to enter and attack our cells.

▪ ***Non-clathrin-coated vesicles.*** ***Caveolae*** (ka"ve-o'le; "little caves"), tubular or flask-shaped inpocketings of the plasma membrane seen in many cell types, also seem to be involved in a kind of receptor-mediated endocytosis. Like clathrin-coated pits, they capture specific molecules (folate, tetanus toxin) from the extracellular fluid in coated vesicles and participate in some forms of transcytosis. However, caveolae are smaller than clathrin-coated vesicles. Additionally, their coat is thinner and composed of a different protein called **caveolin** (Figure 3.14). Because of the close association of caveolae with lipid rafts that are platforms for signaling molecules such as G proteins, receptors for hormones (e.g., insulin), and enzymes involved in cell regulation, these vesicles may provide important sites for cell signaling and cross talk between the same or different signaling pathways. Their precise role in the cell is still being worked out.

Virtually all intracellular *vesicular trafficking,* in which vesicles pinch off from organelles and travel to other organelles to unload their contents [for example, proteins made at the endoplasmic reticulum are sent to the Golgi apparatus (see Figure 3.20, p. 88)], uses vesicles coated with **coatomer (COP1 and COP2) proteins.**

Table 3.2 summarizes active membrane transport processes.

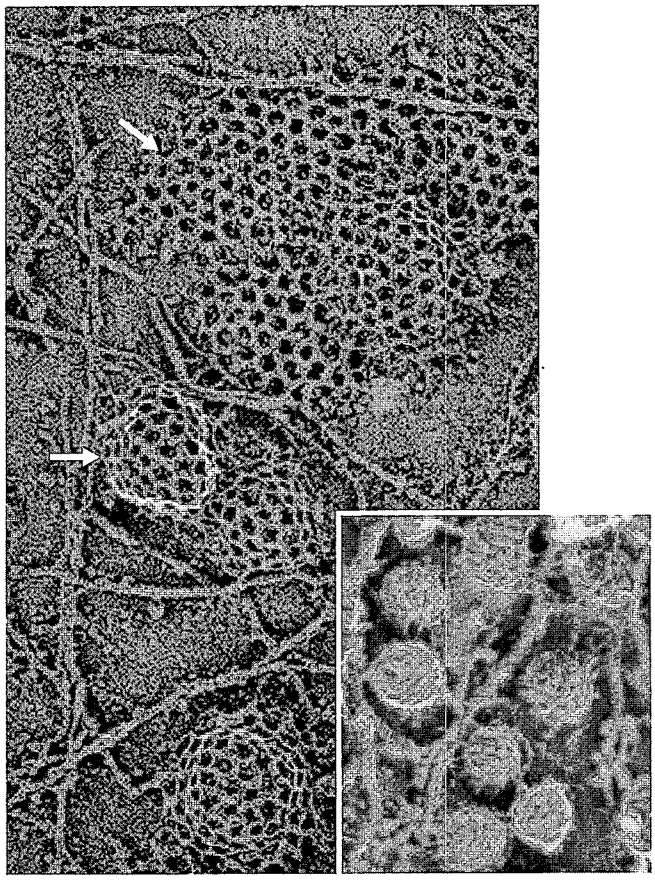

FIGURE 3.14 **Clathrin-coated versus caveolin-coated vesicles.** Structural differences between the two vesicle types are shown in electron micrographs of cells that have been sheared open by freeze-fracturing. The larger photo shows the inner surface of the plasma membrane, upon which many polygonal lattices are visible. Some lattices are relatively flat (these are the clathrin-coated pits pointed out by the yellow arrow); others curve around a vesicle (clathrin-coated vesicle indicated by the white arrow). The clathrin lattices are easily distinguished from the striped coats of caveolin protein that characterize caveolae (seen in the inset).

Generating and Maintaining a Resting Membrane Potential

As you're now aware, the selective permeability of the plasma membrane can lead to dramatic osmotic flows, but that is not its only consequence. An equally important result is the generation of a **membrane potential,** or voltage, across the membrane. A *voltage* is electrical potential energy resulting from the separation of oppositely charged particles. In cells, the oppositely charged particles are ions, and the barrier that keeps them apart is the plasma membrane.

In their resting state, all body cells exhibit a **resting membrane potential** that typically ranges from −50 to −100 millivolts (mV), depending on cell type. Hence, all cells are said to be **polarized.** The minus sign before the voltage indicates that the *inside* of the cell is negative compared to its outside. This voltage (or charge separation) exists only at the

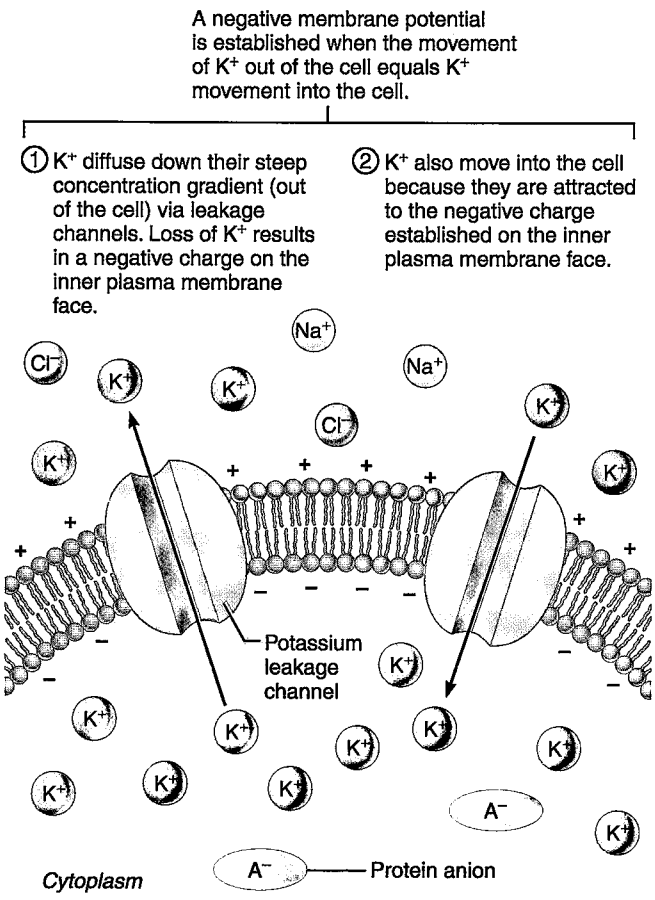

FIGURE 3.15 **The role of K^+ in generating the resting membrane potential.** The resting membrane potential is largely determined by K^+ because the membrane is much more permeable to K^+ than to Na^+ at rest. K^+ moves more easily across the membrane by diffusing through membrane leakage channels. The net effect of this K^+ movement is that the outside membrane face becomes more electrically positive (more positive ions build up) than the inside, which is relatively more negative. The active transport of sodium and potassium ions (in a ratio of 3:2) by the Na^+-K^+ pump maintains these conditions.

membrane. If we were to add up all the negative and positive charges in the cytoplasm, we would find that the cell interior is electrically neutral. Likewise, the positive and negative charges in the extracellular fluid balance each other exactly.

So how does the resting membrane potential come about, and how is it maintained? Although many kinds of ions are found both inside cells and in the extracellular fluid, the resting membrane potential is determined mainly by the concentration gradient of K^+, and by the differential permeability of the plasma membrane to K^+ and other ions. As mentioned, K^+ and protein anions predominate inside body cells and the extracellular fluid contains relatively more Na^+, which is largely balanced by Cl^-. The unstimulated plasma membrane is somewhat permeable to K^+ because of leakage channels, but impermeable to the protein anions. Potassium therefore diffuses out of the cell along its concentration gradient but the protein anions are unable to follow, so loss of positive charges makes the membrane interior more negative (Figure 3.15). As more and more K^+ leaves the cell, the negativity of the inner membrane face becomes great enough to attract K^+ back toward and even into the cell. At the point where potassium's concentration gradient is balanced by the membrane potential (−90 mV), one K^+ enters the cell as one leaves.

In many cells, sodium also contributes to the resting membrane potential. Sodium is strongly attracted to the cell interior by its concentration gradient, bringing the resting membrane potential to −70 mV. However, potassium still largely determines the resting membrane potential because the membrane is much more permeable to K^+ than to Na^+. In most cells, Cl^- does not contribute to the resting membrane potential because, even though the membrane is permeable to Cl^-, its entry is resisted by the negative charge of the interior. Although it is tempting to believe that massive flows of K^+ ions are needed to generate the resting potential, this is not the case. Surprisingly, the number of ions producing the membrane potential is so small that it does not change ion concentrations in any significant way.

In a cell at rest, very few ions cross its plasma membrane. However, Na^+ and K^+ are not at equilibrium and there is some net movement of K^+ out of the cell and of Na^+ into the cell because of its strong pull into the cell by both its concentration gradient and the interior negative charge. If only passive forces were at work, these ion concentrations would eventually become equal inside and outside the cell.

Instead, the cell exhibits a *steady state* in which diffusion causes ionic imbalances that polarize the membrane, and active transport processes *maintain* that membrane potential. The rate of active transport is equal to, and depends on, the rate of Na^+ diffusion into the cell. If more Na^+ enters, more is pumped out. (This is like being in a leaky boat. The more water that comes in, the faster you bail!) The Na^+-K^+ pump couples sodium and potassium transport and, on average, each "turn" of the pump ejects $3Na^+$ out of the cell and carries $2K^+$ back in (see Figure 3.10). Because the membrane is always 50 to 100 times more permeable to K^+, the ATP-dependent Na^+-K^+ pump maintains both the membrane potential and the osmotic balance. Indeed, were Na^+ not continuously removed from cells, in time so much would accumulate intracellularly that the osmotic gradient would draw water into the cells, causing them to burst.

Now that we've introduced the membrane potential, we can add a detail or two to our discussion of diffusion. Earlier we said that solutes diffuse down their concentration gradient. This is true for uncharged solutes, but only partially true for ions. The negatively and positively charged faces of the plasma membrane can help or hinder diffusion of ions driven by a concentration gradient. It is more correct to say that ions diffuse according to **electrochemical gradients,** thereby recognizing the effect of both electrical and concentration (chemical) forces. Consequently, although diffusion of K^+ across the plasma membrane is aided by the membrane's greater permeability to it and by the ion's concentration gradient, its diffusion is resisted somewhat by the positive charge on the cell exterior. In contrast, Na^+ is drawn into the cell by a steep electrochemical gradient; the limiting factor is the membrane's relative impermeability to it. As we will describe in detail in later chapters, "upsetting" the resting membrane potential by transient opening of Na^+ and K^+ channels in the plasma membrane is a normal means of activating neurons and muscle cells.

Cell-Environment Interactions

Cells are biological minifactories and, like other factories, they receive and send orders from and to the outside community. But *how* does a cell interact with its environment, and what activates it to carry out its homeostatic functions?

Although cells sometimes interact directly with other cells, this is not always the case. In many cases cells respond to extracellular chemicals, such as hormones and neurotransmitters distributed in body fluids. Cells also interact with molecules in the substratum that act as signposts to guide cell migration during development and repair.

Whether cells interact directly or indirectly, however, the glycocalyx is always involved. The best understood of the participating glycocalyx molecules fall into two large families—cell adhesion molecules and plasma membrane receptors (see Figure 3.4). Another group of membrane proteins, the voltage-sensitive channel proteins, are important in cells that respond to electrical signals.

Roles of Cell Adhesion Molecules

Thousands of **cell adhesion molecules (CAMs)** are found on almost every cell in the body. They play key roles in embryonic development and wound repair (situations where cell mobility is important) and in immunity. These sticky glycoproteins (*cadherins* and *integrins*) act as

1. The molecular "Velcro" that cells use to anchor themselves to molecules in the extracellular space and to each other (see desmosome discussion on p. 69)
2. The "arms" that migrating cells use to haul themselves past one another
3. SOS signals sticking out from the blood vessel lining that rally protective white blood cells to a nearby infected or injured area
4. Mechanical sensors that respond to local tension at the cell surface by stimulating synthesis or degradation of adhesive membrane junctions
5. Transmitters of intracellular signals that direct cell migration, proliferation, and specialization.

Roles of Membrane Receptors

A huge and diverse group of integral proteins and glycoproteins that serve as binding sites are collectively known as **membrane receptors.** Some function in contact signaling, and others in chemical signaling. Let's take a look.

Contact Signaling *Contact signaling,* the actual coming together and touching of cells, is the means by which cells recognize one another. It is particularly important for normal development and immunity. Some bacteria and other infectious agents use contact signaling to identify "preferred" target tissues or organs.

Chemical Signaling Most plasma membrane receptors are involved in *chemical signaling,* and this group will receive the bulk of our attention. Signaling chemicals that bind specifically to plasma membrane receptors are called **ligands.** Among these ligands are most *neurotransmitters* (nervous system signals), *hormones* (endocrine system signals), and *paracrines* (chemicals that act locally and are rapidly destroyed). Different cells respond in different ways to the same ligand. Acetylcholine, for instance, stimulates skeletal muscle cells to contract, but inhibits heart muscle. Thus, a target cell's response depends on the internal machinery that the receptor is linked to, not the specific ligand that binds to it.

Though cell responses to receptor binding vary widely, there is a fundamental similarity. When a ligand binds to a membrane receptor, the receptor's structure changes, and cell proteins are altered in some way; for example, muscle proteins change shape to generate force. Some of these membrane receptor proteins are *catalytic proteins* that function as enzymes. Others, such as the *chemically-gated channel-linked receptors* common in muscle and nerve cells, respond to ligands by transiently opening or closing ion gates or channels, which in turn changes the excitability of the cell. Still other receptors are coupled to enzymes or ion channels by a regulatory molecule called a G protein. Because nearly every cell in the body displays at least some of these receptors, we will spend a bit more time with them. The lipid rafts mentioned earlier group together many receptor-mediated elements, thus facilitating cell signaling.

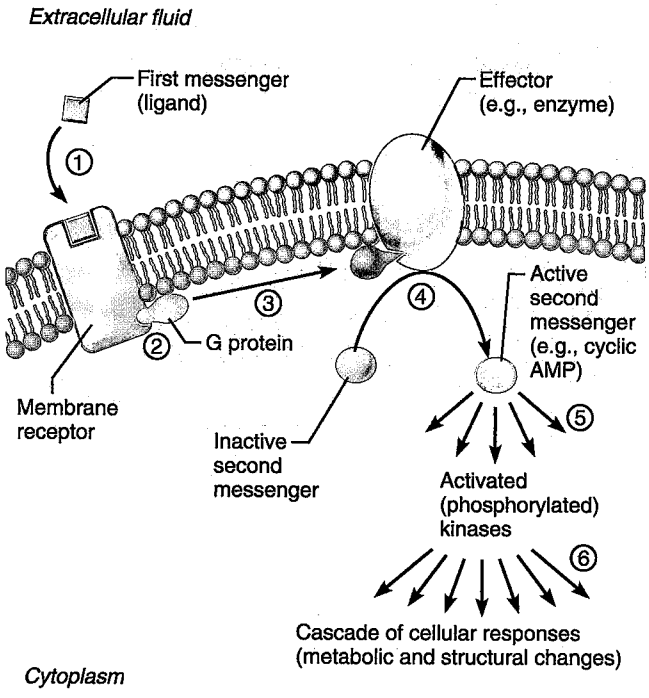

FIGURE 3.16 **Model of the operation of a G protein–linked receptor.** In this simplified diagram, ① an extracellular molecule (ligand) is a first messenger that binds to a specific receptor protein. ② The receptor activates a G protein that acts as a relay to ③ stimulate an effector protein. ④ The effector is an enzyme that produces a second messenger inside the cell. ⑤ The second messenger, cyclic AMP in this model, activates kinase enzymes. ⑥ The kinase enzymes can activate a whole series of enzymes that trigger the various responses of the cell.

G protein–linked receptors exert their effect indirectly through a **G protein,** which acts as a middleman or relay to activate (or inactivate) a membrane-bound enzyme or ion channel (Figure 3.16). As a result, one or more intracellular chemical signals, commonly called **second messengers,** are generated and connect plasma membrane events to the internal metabolic machinery of the cell. Two very important second messengers are **cyclic AMP** and ionic calcium, both of which typically activate protein kinase enzymes. By transferring phosphate groups from ATP to other proteins, the protein kinases can activate a whole series of enzymes that bring about the desired cellular activity. Because a single enzyme can catalyze hundreds of reactions, the amplification effect of such a chain of events is tremendous. These and other receptor systems are described in greater detail in Chapter 16.

One more signaling molecule must be mentioned, even though it doesn't fit any of the mechanisms described. *Nitric oxide (NO),* made of a single atom of nitrogen and one of oxygen, is one of nature's simplest molecules, an environmental pollutant, and the first gas known to act as a biological messenger. Because of its tiny size, it slips into and out of cells easily. Its unpaired electron makes it a highly reactive free radical that reacts with head-spinning speed with other key molecules to spur cells into a broad array of activities. You will be hearing more about NO later (in the neural, cardiovascular, and immune system chapters).

Role of Voltage-Sensitive Membrane Channel Proteins

Electrical Signaling In the process known as *electrical signaling,* certain plasma membrane proteins are channel proteins that respond to changes in membrane potential by opening or closing the channel. Such voltage-gated channels are common in excitable tissues like neural and muscle tissues, and are indispensable to their normal functioning.

The Cytoplasm

Cytoplasm ("cell-forming material") is the cellular material between the plasma membrane and the nucleus. It is the site where most cellular activities are accomplished. Although early microscopists thought that the cytoplasm was a structureless gel, the electron microscope has revealed that it consists of three major elements: the cytosol, organelles, and inclusions.

The **cytosol** (si'to-sol) is the viscous, semitransparent fluid in which the other cytoplasmic elements are suspended. It is a complex mixture with properties of both a colloid and a true solution. Dissolved in the cytosol, which is largely water, are proteins, salts, sugars, and a variety of other solutes.

The **cytoplasmic organelles** are the metabolic machinery of the cell. Each type of organelle is "engineered" to carry out a specific function for the cell—some synthesize proteins, others package those proteins, and so on.

Inclusions are chemical substances that may or may not be present, depending on cell type. Examples include stored nutrients, such as the glycogen granules abundant in liver and muscle cells; lipid droplets common in fat cells; pigment (melanin) granules seen in certain cells of skin and hair; water-containing vacuoles; and crystals of various types.

Cytoplasmic Organelles

The cytoplasmic organelles ("little organs") are specialized cellular compartments, each performing its own job to maintain the life of the cell. Some organelles, the *nonmembranous organelles,* lack membranes. Examples are the cytoskeleton,

centrioles, and ribosomes. However, most organelles are bounded by a membrane similar in composition to the plasma membrane (minus the glycocalyx), and this membrane enables such *membranous organelles* to maintain an internal environment different from that of the surrounding cytosol. This compartmentalization is crucial to cell functioning. Without it, thousands of enzymes would be randomly mixed and biochemical activity would be chaotic. The cell's membranous organelles include the mitochondria, peroxisomes, lysosomes, endoplasmic reticulum, and Golgi apparatus. Besides providing "splendid isolation," an organelle's membrane often unites it with the rest of an interactive intracellular system called the *endomembrane system* (see pp. 89–90). Now, let us consider what goes on in each of the workshops of our cellular factory.

Mitochondria

Mitochondria (mi"to-kon'dre-ah) are threadlike (*mitos* = thread) or sausage-shaped membranous organelles (Figure 3.17). In living cells they squirm, elongate, and change shape almost continuously. They are the power plants of a cell, providing most of its ATP supply. The density of mitochondria in a particular cell reflects that cell's energy requirements, and mitochondria are generally clustered where the action is. Busy cells like kidney and liver cells have hundreds of mitochondria, whereas relatively inactive cells (such as unchallenged lymphocytes) have just a few.

Mitochondria are enclosed by *two* membranes, each with the general structure of the plasma membrane. The outer membrane is smooth and featureless, but the inner membrane folds inward, forming shelflike **cristae** (krĭ'ste; "crests") that protrude into the *matrix*, the gel-like substance within the mitochondrion. Intermediate products of food fuels (glucose and others) are broken down to water and carbon dioxide by teams of enzymes, some dissolved in the mitochondrial matrix and others forming part of the crista membrane.

As the metabolites are broken down and oxidized, some of the energy released is captured and used to attach phosphate groups to ADP molecules to form ATP. This multistep mitochondrial process (described in Chapter 24) is generally referred to as *aerobic cellular respiration* (a-er-o'bik) because it requires oxygen.

Mitochondria are complex organelles: They contain their own DNA and RNA and are able to reproduce themselves. Mitochondrial genes (some 37 of them) direct the synthesis of some 5% of the proteins required for mitochondrial function, and the DNA of the cell's nucleus encodes the remaining proteins needed to carry out cellular respiration. When cellular requirements for ATP increase, the

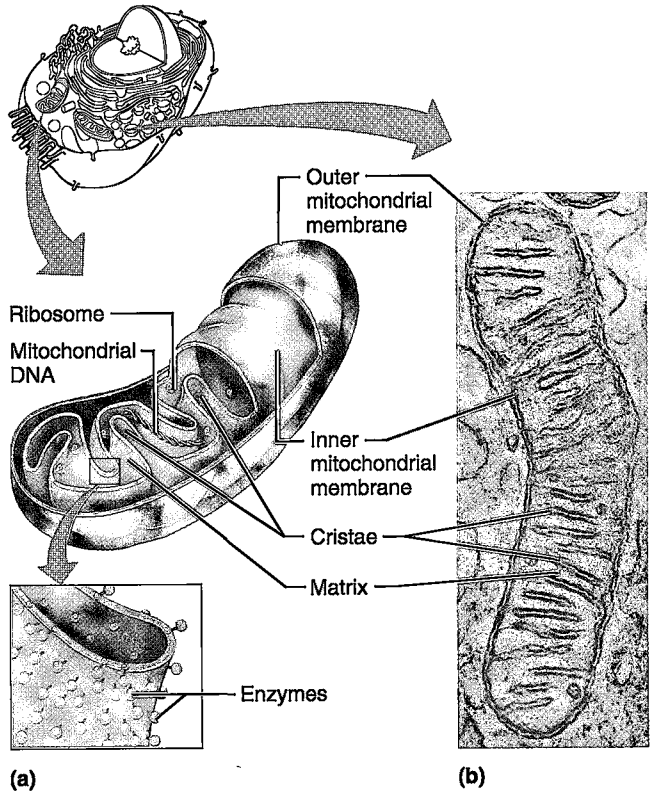

FIGURE 3.17 **Mitochondrion. (a)** Diagrammatic view of a longitudinally sectioned mitochondrion. **(b)** Electron micrograph of a mitochondrion (28,400×).

mitochondria synthesize more cristae or simply pinch in half (a process called *fission*) to increase their number, then grow to their former size.

Intriguingly, mitochondria are similar to a specific group of bacteria (the purple bacteria phylum), and mitochondrial DNA is similar to that found in bacterial cells. It is now widely believed that mitochondria arose from bacteria that invaded the ancient ancestors of plant and animal cells.

Ribosomes

Ribosomes (ri'bo-sōmz) are small, dark-staining granules composed of proteins and a variety of RNA called *ribosomal RNA*. Each ribosome has two globular subunits that fit together like the body and cap of an acorn (Figure 3.18c). Ribosomes are sites of protein synthesis, a function we discuss in detail later in this chapter.

Some ribosomes float freely in the cytoplasm; others are attached to membranes, forming a complex called the *rough endoplasmic reticulum*. These two ribosomal populations appear to divide the chore of protein synthesis. *Free ribosomes* make soluble proteins that function in the cytosol. *Membrane-bound ribosomes* synthesize proteins destined either for incorporation into cell membranes or for export

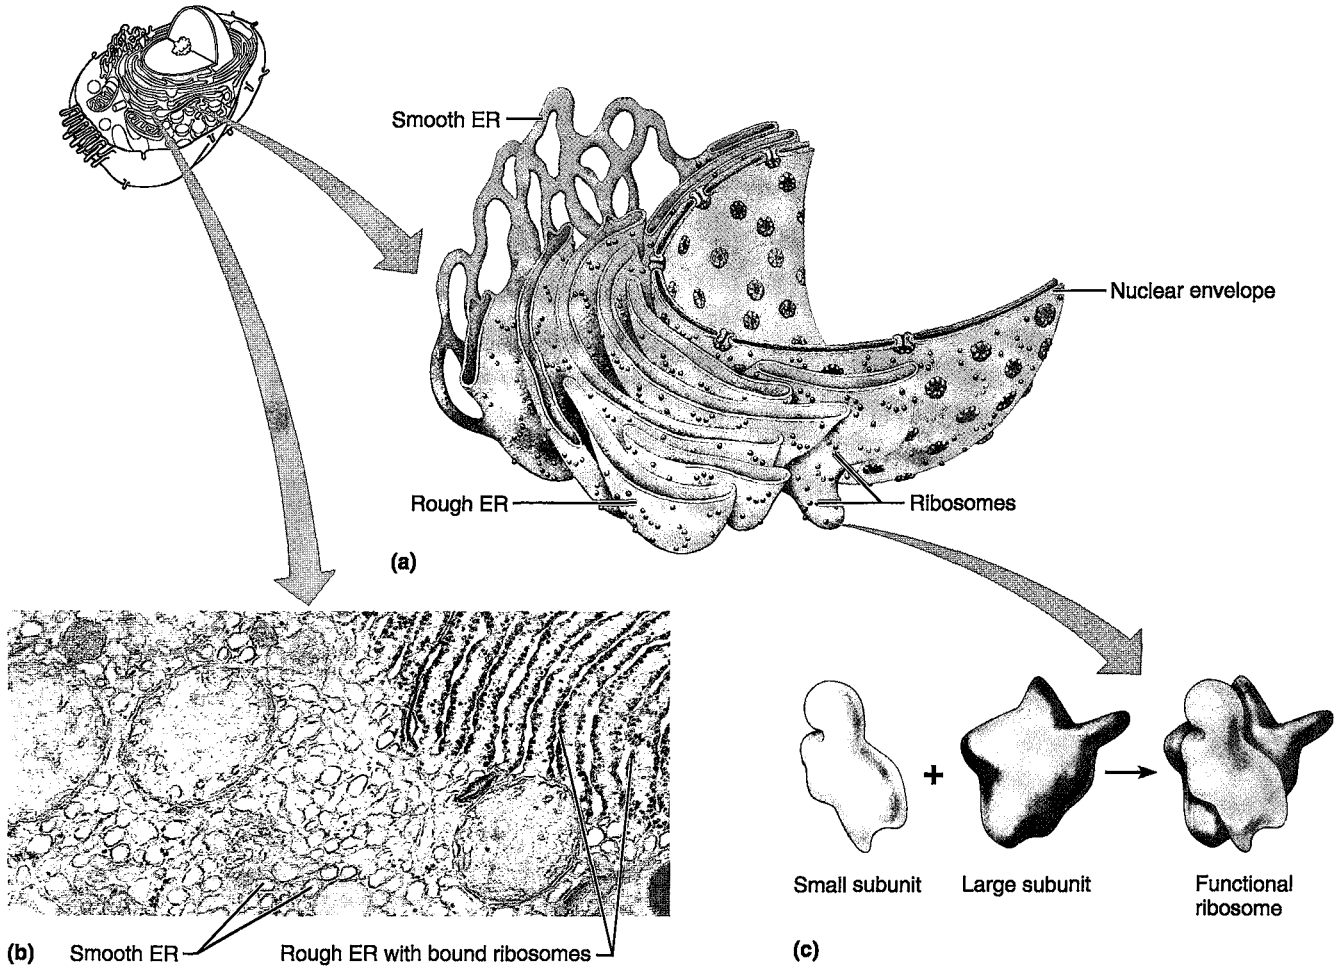

FIGURE 3.18 **The endoplasmic reticulum (ER) and ribosomes. (a)** Diagram of the rough ER and smooth ER in a cell. **(b)** Electron micrograph of smooth and rough endoplasmic reticulum (15,000×). **(c)** Diagram of a functional ribosome made from small and large subunits.

from the cell. Ribosomes can switch back and forth between these two functions, attaching to and detaching from the membranes of the endoplasmic reticulum, according to the type of protein they are making at a given time.

Endoplasmic Reticulum

The **endoplasmic reticulum (ER)** (en"do-plaz'mik re-tik'u-lum; "network within the cytoplasm") is an extensive system of interconnected tubes and parallel membranes enclosing fluid-filled cavities, or **cisternae** (sis-ter'ne), that coils and twists through the cytosol. The ER is continuous with the nuclear membrane and accounts for about half of the cell's membranes. There are two distinct varieties of ER: rough ER and smooth ER.

Rough Endoplasmic Reticulum The external surface of the **rough ER** is studded with ribosomes (Figure 3.18a). Proteins assembled on these ribosomes thread their way into the fluid-filled interior of the ER cisternae, where various fates await them (as described shortly). The rough ER has several functions. Its ribosomes manufacture all proteins secreted from cells. Thus, the rough ER is particularly abundant and well developed in most secretory cells, antibody-producing plasma cells, and liver cells, which produce most blood proteins. It is also the cell's "membrane factory" because integral proteins and phospholipids that form part of all cellular membranes are manufactured there. The enzymes needed to catalyze lipid synthesis have their active sites on the external (cytosolic) face of the ER membrane, where the needed substrates are readily available.

As mentioned, ribosomes attach to and detach from the rough ER. When a short "leader" peptide called a **signal sequence** is present in a protein being synthesized, the associated ribosome attaches to the membrane of the rough ER. This signal sequence, with its attached "cargo" of ribosome and messenger RNA (mRNA), is guided to the appropriate receptor sites on the ER membrane by a **signal-recognition particle (SRP),** which cycles between the ER and the cytosol. The subsequent events occurring at the ER are detailed in Figure 3.19.

Smooth Endoplasmic Reticulum The **smooth ER** (see Figures 3.2 and 3.18) is in communication with the rough ER and consists of tubules arranged in a looping network. Its enzymes (all integral proteins forming part of its membranes) play no role in protein synthesis. Instead, they catalyze reactions involved with the following processes:

1. Lipid metabolism, cholesterol synthesis, and synthesis of the lipid components of lipoproteins (in liver cells)
2. Synthesis of steroid-based hormones such as sex hormones (testosterone-synthesizing cells of the testes are full of smooth ER)
3. Absorption, synthesis, and transport of fats (in intestinal cells)
4. Detoxification of drugs, certain pesticides, and carcinogens (in liver and kidneys)
5. Breakdown of stored glycogen to form free glucose (in liver cells especially)

Additionally, skeletal and cardiac muscle cells have an elaborate smooth ER (called the sarcoplasmic reticulum) that plays an important role in calcium ion storage and release during muscle contraction. Except for the examples given above, most body cells contain little, if any, true smooth ER.

Golgi Apparatus

The **Golgi apparatus** (gol'je) consists of stacked and flattened membranous sacs, shaped like hollow dinner plates, associated with swarms of tiny membranous vesicles (Figure 3.20). The Golgi apparatus is the principal "traffic director" for cellular proteins. Its major function is to modify, concentrate, and package the proteins and lipids made at the rough ER. The transport vesicles that bud off from the rough ER move to and fuse with the membranes at its convex *cis face,* the "receiving" side of the Golgi apparatus. Inside the apparatus, the proteins are modified: Some sugar groups are trimmed while others are added, and in some cases, phosphate groups are added. The various proteins are "tagged" for delivery to a specific address, sorted, and packaged in at least three types of vesicles that bud from the concave *trans face* (the "shipping" side) of the Golgi stack.

Q *The transport vesicle shown has a coatamer protein coat. How does that differ from the protein coat of a vesicle taken in by receptor-mediated endocytosis?*

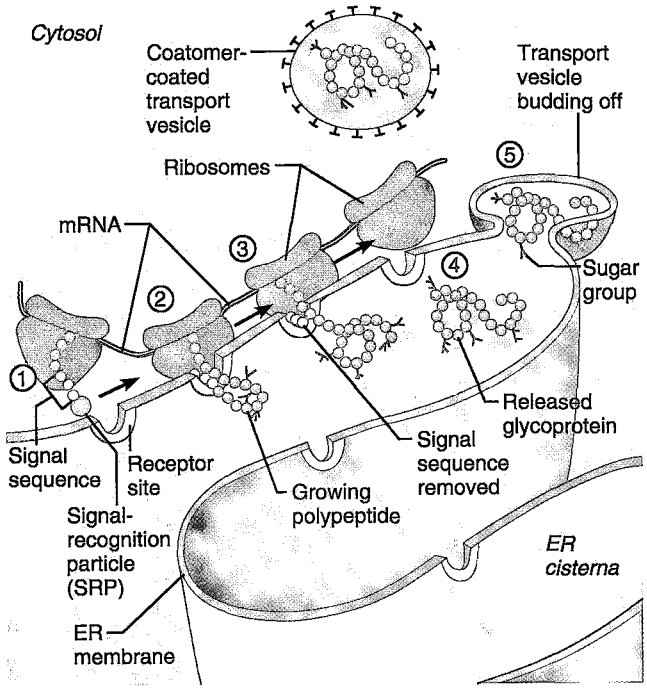

FIGURE 3.19 **The signal mechanism targets ribosomes to the ER for protein synthesis.** Steps in the signal mechanism of protein synthesis: ① Presence of a short signal sequence on a newly forming protein causes the signal-recognition particle (SRP) to direct the mRNA-ribosome complex to the rough ER. The SRP binds to the protein-translocation site (a receptor site that includes a pore and an enzyme to clip the signal sequence). ② Once attached to the ER receptor site, the SRP is released and the growing polypeptide snakes through the ER membrane into the cisterna. ③ The signal sequence initially remains attached to the receptor but is soon clipped off by an enzyme. As protein synthesis continues, sugar groups may be added to the protein. ④ In this example, the completed protein is released from the ribosome and folds into its 3-D conformation, a process aided by molecular chaperones (see p. 53). Transmembrane proteins are only partially translocated and remain embedded in the membrane. ⑤ The protein is enclosed within a coatomer-coated transport vesicle that pinches off the ER. The transport vesicles make their way to the Golgi apparatus, where further processing of the proteins occurs (see Figure 3.20).

Vesicles containing proteins destined for export pinch off from the trans face as **secretory vesicles,** or **granules,** which migrate to the plasma membrane and discharge their contents from the cell by exocytosis (pathway 1, Figure 3.21). Specialized secretory cells,

A *The protein coating on the endocytosed vesicle would be clathrin protein.*

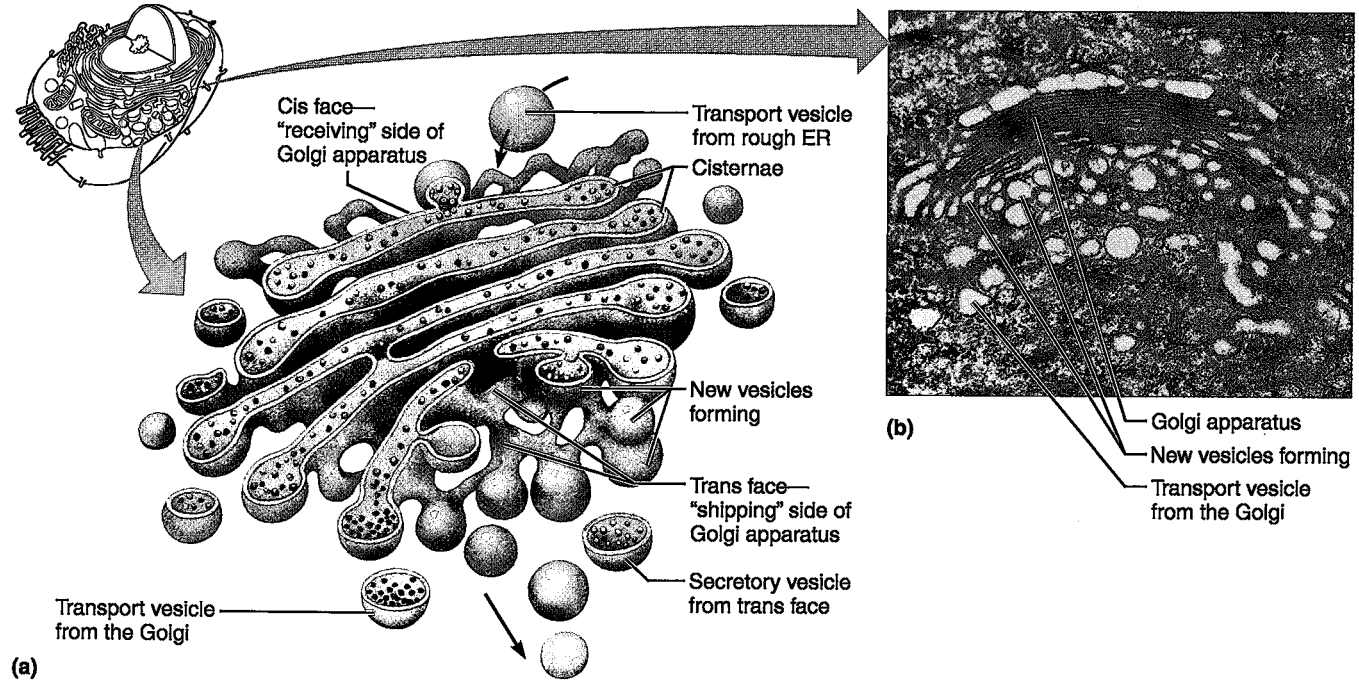

FIGURE 3.20 **Golgi apparatus.** (a) Diagrammatic view of the Golgi apparatus. (b) Electron micrograph of the Golgi apparatus (28,000×). Notice the vesicles in the process of pinching off from the membranous Golgi apparatus. (The various and abundant vesicles shown would have coatomer proteins on their external surfaces; these proteins have been omitted from the diagram for simplicity.)

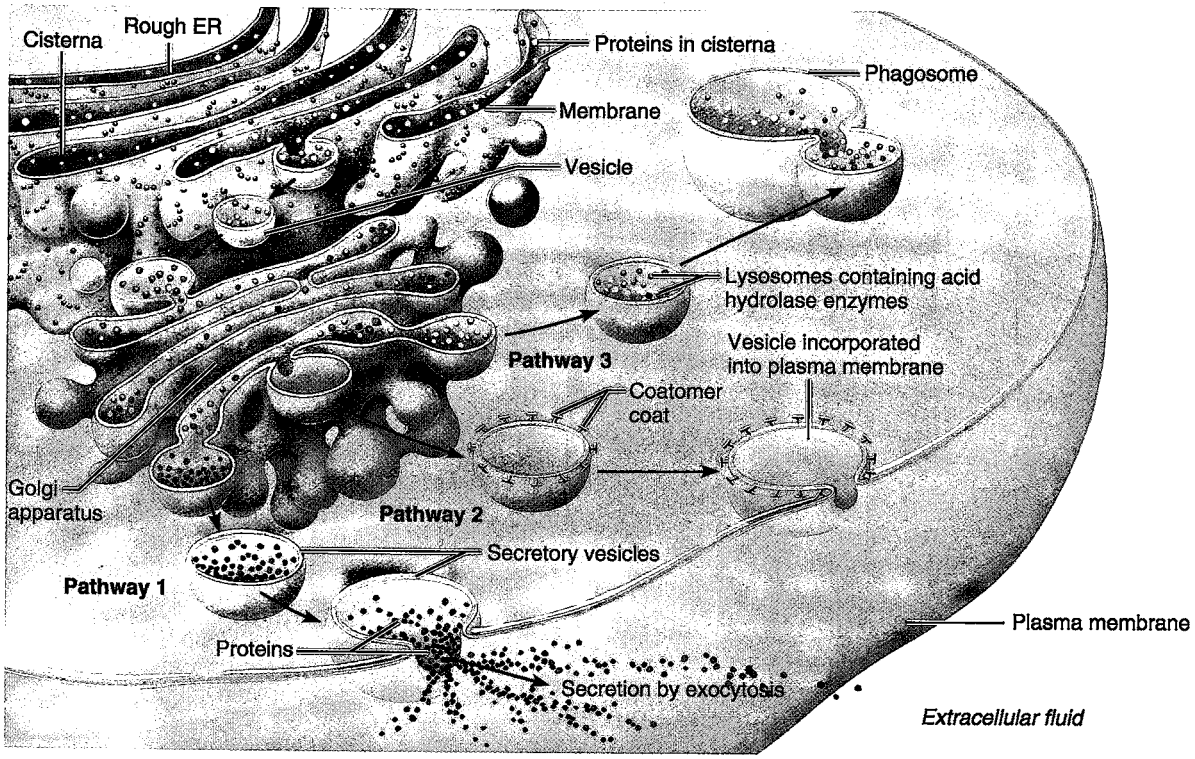

FIGURE 3.21 **The sequence of events from protein synthesis on the rough ER to the final distribution of those proteins.** Protein-containing vesicles pinch off the rough ER and migrate to fuse with the membranes of the Golgi apparatus. Within the Golgi compartments, the proteins are modified; they are then packaged within different Golgi vesicle types, depending on their ultimate destination (pathways 1–3 as shown).

such as the enzyme-producing cells of the pancreas, have a very prominent Golgi apparatus. Besides its packaging-for-release function, the Golgi apparatus pinches off vesicles containing lipids and transmembrane proteins destined for a "home" in the plasma membrane (pathway 2, Figure 3.21) or other membranous organelles. It also packages digestive enzymes into membranous lysosomes that remain in the cell (pathway 3 in Figure 3.21, and discussed next).

Lysosomes

Lysosomes ("disintegrator bodies") are spherical membranous organelles containing digestive enzymes (Figure 3.22). As you might guess, lysosomes are large and abundant in phagocytes, the cells that dispose of invading bacteria and cell debris. Lysosomal enzymes can digest almost all kinds of biological molecules. They work best in acidic conditions and thus are called *acid hydrolases* (hi"drah-la'siz). The lysosomal membrane is adapted to serve lysosomal functions in two important ways: (1) It contains H^+ (proton) "pumps," ATPases that gather hydrogen ions from the surrounding cytosol to maintain the organelle's acidic pH, and (2) it retains the dangerous acid hydrolases while permitting the final products of digestion to escape so that they can be used by the cell or excreted. Hence, lysosomes provide sites where digestion can proceed *safely* within a cell.

Lysosomes function as a cell's "demolition crew" by

- Digesting particles taken in by endocytosis, particularly ingested bacteria, viruses, and toxins
- Degrading worn-out or nonfunctional organelles
- Performing metabolic functions, such as glycogen breakdown and release
- Breaking down nonuseful tissues, such as the webs between the fingers and toes of a developing fetus and the uterine lining during menstruation
- Breaking down bone to release calcium ions into the blood

Some unique lysosomes called *secretory lysosomes* are found mainly in white blood cells, immune cells, and melanocytes (pigment-producing cells). They appear to have the ability to store and then secrete by exocytosis newly synthesized proteins in response to external stimuli.

The lysosomal membrane is ordinarily quite stable, but it becomes fragile when the cell is injured or deprived of oxygen and when excessive amounts of vitamin A are present. Lysosomal rupture results in self-digestion of the cell, a process called **autolysis** (aw"tol'ĭ-sis). Autolysis is the basis for desirable destruction of cells (see fourth bullet point above).

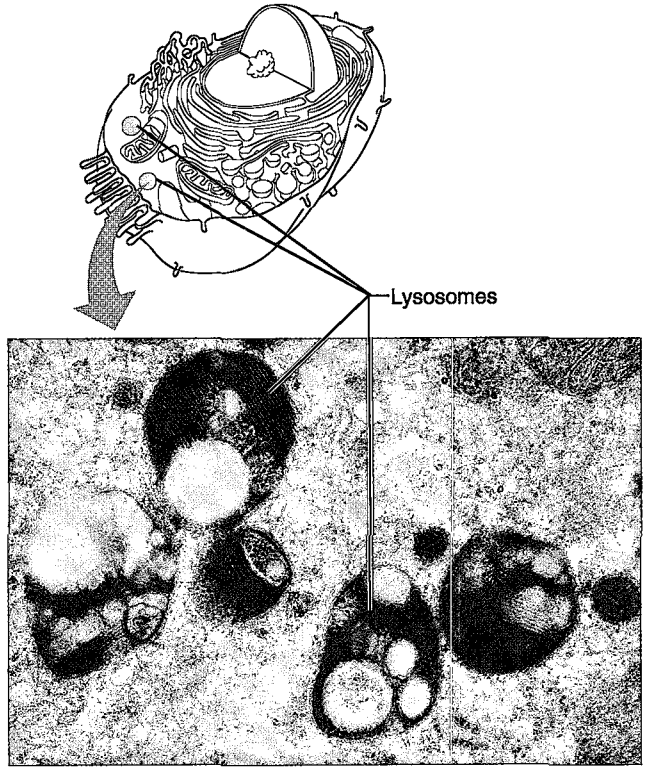

FIGURE 3.22 **Lysosomes.** Electron micrograph of a cell containing lysosomes (90,000×).

HOMEOSTATIC IMBALANCE

Glycogen and certain lipids in the brain are degraded by lysosomes at a relatively constant rate. In *Tay-Sachs disease,* an inherited condition seen mostly in Jews from Central Europe, the lysosomes lack an enzyme needed to break down a glycolipid abundant in nerve cell membranes. As a result, the nerve cell lysosomes swell with the undigested lipids, which interfere with nervous system functioning. Affected infants typically have doll-like features and pink translucent skin. At 3 to 6 months of age, the first signs of disease appear (listlessness, motor weakness). These progress to mental retardation, seizures, blindness, and ultimately death within 18 months. ●

Summary of Interactions in the Endomembrane System

The **endomembrane system** (Figure 3.23) is a system of organelles (most described above) that work together mainly (1) to produce, store, and export biological molecules, and (2) to degrade potentially harmful substances. It includes the ER, Golgi apparatus, secretory vesicles, and lysosomes, as well as the nuclear membrane—that is, all of the membranous organelles or elements that are either structurally continuous or arise via forming or fusing

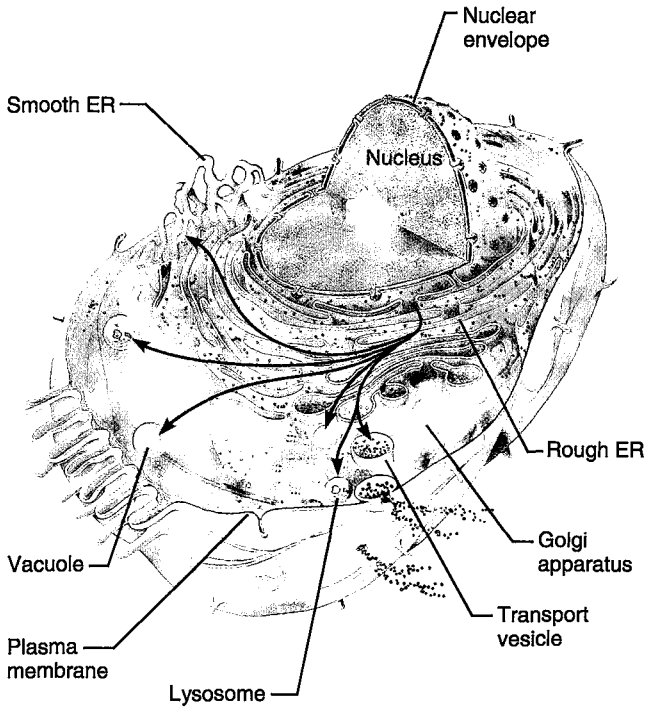

FIGURE 3.23 **The endomembrane system.**

transport vesicles. There are continuities between the nuclear envelope (itself an extension of the rough ER) and the rough and smooth ER. The plasma membrane, though not actually an *endo* membrane, is also functionally part of this system. Besides these direct structural relationships, a wide variety of indirect interactions (indicated by arrows in Figure 3.23) occur among the members of the system. Some of the vesicles "born" in the ER migrate to and fuse with the Golgi apparatus or the plasma membrane, and vesicles arising from the Golgi apparatus can become part of the plasma membrane, secretory vesicles, or lysosomes.

Peroxisomes

Peroxisomes (pĕ-roks'ĭ-sōmz; "peroxide bodies") are membranous sacs containing a variety of powerful enzymes, the most important of which are oxidases and catalases. Oxidases use molecular oxygen (O_2) to detoxify harmful substances, including alcohol and formaldehyde. However, their most important function is to neutralize dangerous **free radicals,** highly reactive chemicals with unpaired electrons that can scramble the structure of biological molecules. Oxidases convert free radicals to hydrogen peroxide, which is also reactive and dangerous but is quickly converted to water by catalase enzymes. Free radicals and hydrogen peroxide are normal by-products of cellular metabolism, but they have devastating effects on cells if allowed to accumulate. Peroxisomes are especially numerous in liver and kidney cells, which are very active in detoxification.

Although peroxisomes look like small lysosomes (see Figure 3.2), they are self-replicating organelles formed by a simple pinching in half of preexisting peroxisomes. Unlike lysosomes, they do not arise by budding from the Golgi apparatus.

Cytoskeleton

The **cytoskeleton,** literally, "cell skeleton," is an elaborate series of rods running through the cytosol. This network acts as a cell's "bones," "muscles," and "ligaments" by supporting cellular structures and providing the machinery to generate various cell movements. The three types of rods in the cytoskeleton are *microtubules, microfilaments,* and *intermediate filaments.* None of these is membrane covered.

Microtubules (mi"kro-tu'būlz), the elements with the largest diameter, are hollow tubes made of spherical protein subunits called *tubulins* (Figure 3.24c). Most microtubules radiate from a small region of cytoplasm near the nucleus called the *centrosome* or *cell center* (see Figure 3.26). These stiff but bendable microtubules determine the overall shape of the cell, as well as the distribution of cellular organelles. Mitochondria, lysosomes, and secretory granules attach to the microtubules like ornaments hanging from tree branches. These attached organelles are continually pulled along the microtubules and repositioned by tiny protein machines called **motor proteins** (*kinesins, dyneins,* and others) that act like train engines by inching along or moving "hand-over-hand" like an orangutan on the microtubular "railroad tracks" (see Figure 3.25a). Microtubules are remarkably dynamic organelles, constantly growing out from the centrosome, disassembling, and then reassembling.

Microfilaments (mi"kro-fil'ah-ments), the thinnest elements of the cytoskeleton, are strands of the protein *actin* ("ray"). Each cell has its own unique arrangement of microfilaments; thus no two cells are alike. However, nearly all cells have a fairly dense cross-linked network of microfilaments (Figure 3.24a) attached to the cytoplasmic side of their plasma membrane that strengthens the cell surface. Most microfilaments are involved in cell motility or changes in cell shape. You could say that cells move when they get their act(in) together. For example, actin microfilaments interact with another protein, **unconventional myosin** (mi'o-sin), to generate contractile forces in a cell (Figure 3.25b) and to form the cleavage furrow that pinches one cell into two during cell division.

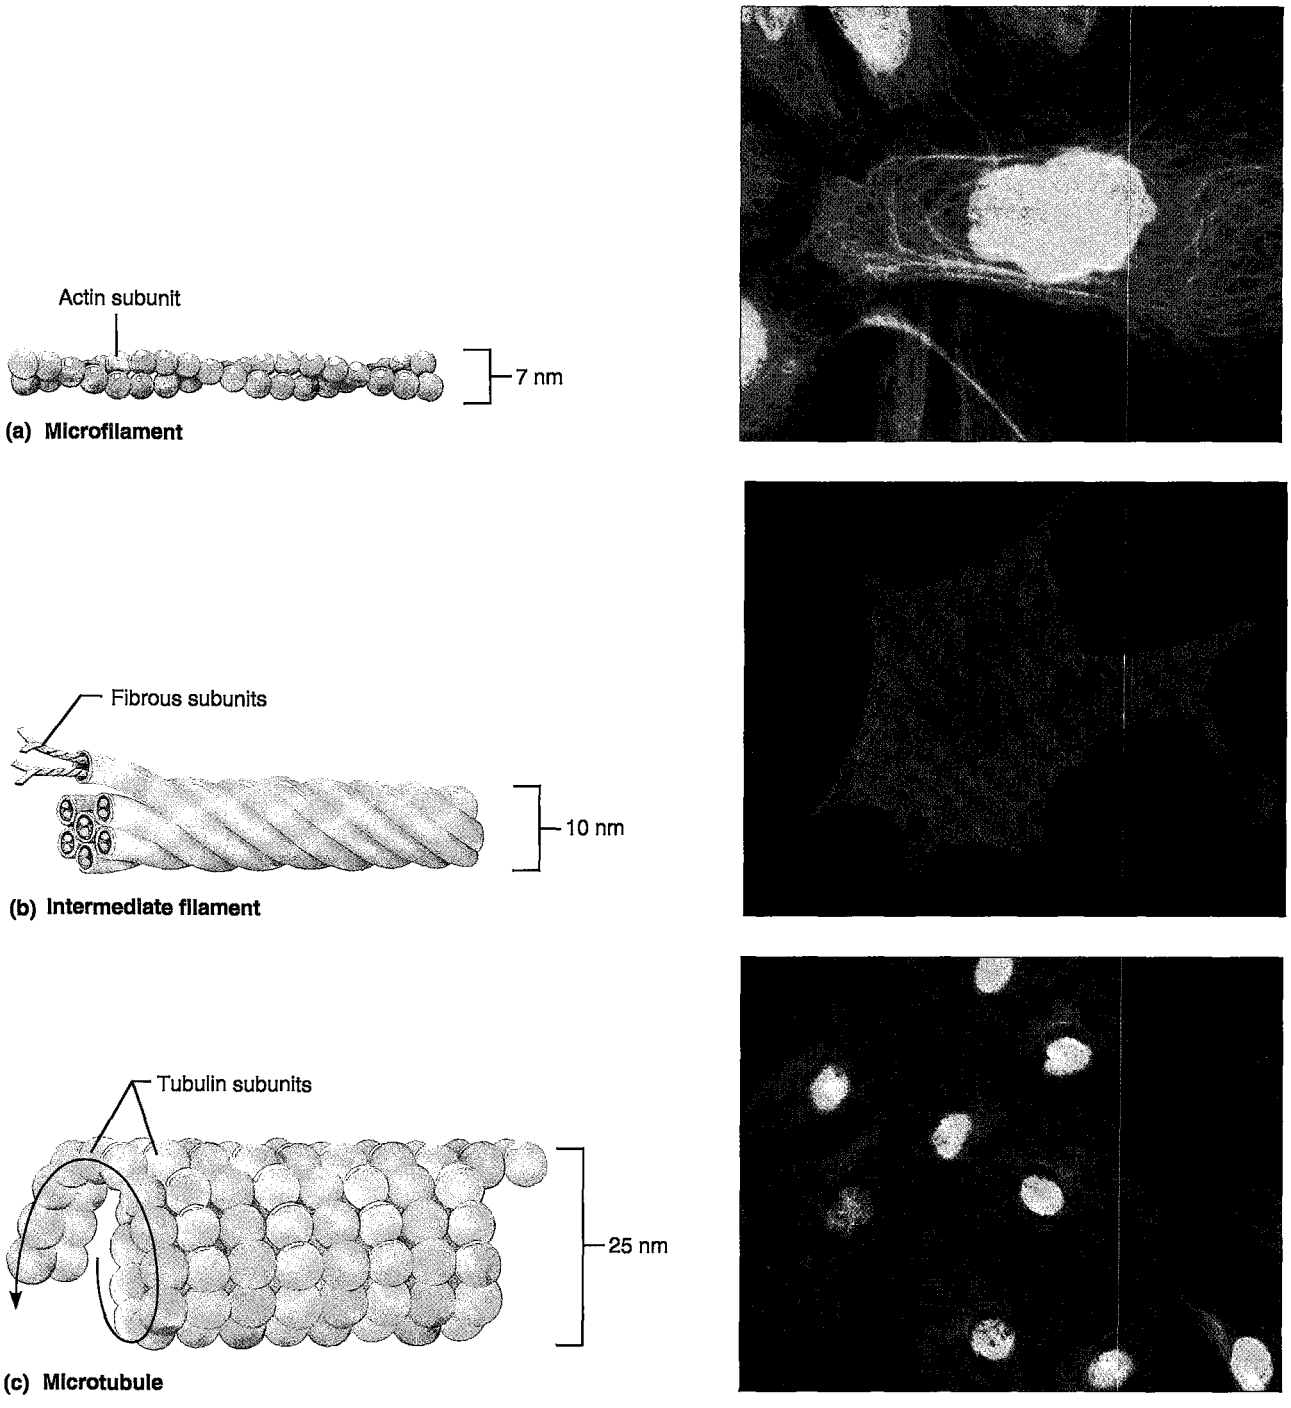

FIGURE 3.24 **Cytoskeleton.** Diagrammatic views (left) and photos (right) of the cytoskeletal elements. **(a)** Microfilaments show up as green strands. **(b)** Intermediate filaments form a red batlike network in this view. **(c)** Microtubules appear as green networks surrounding the cells' blue nuclei.

Microfilaments attached to CAMs (see Figure 3.4) are responsible for the crawling movements of amoeboid motion, and for the membrane changes that accompany endocytosis and exocytosis. Except in muscle cells, where they are highly developed, stable, and long-lived, actin filaments are constantly breaking down and re-forming from smaller subunits whenever and wherever their services are needed.

Intermediate filaments are tough, insoluble protein fibers that have a diameter between those of microfilaments and microtubules (Figure 3.24b). Constructed like woven ropes, intermediate filaments are the most stable and permanent of the

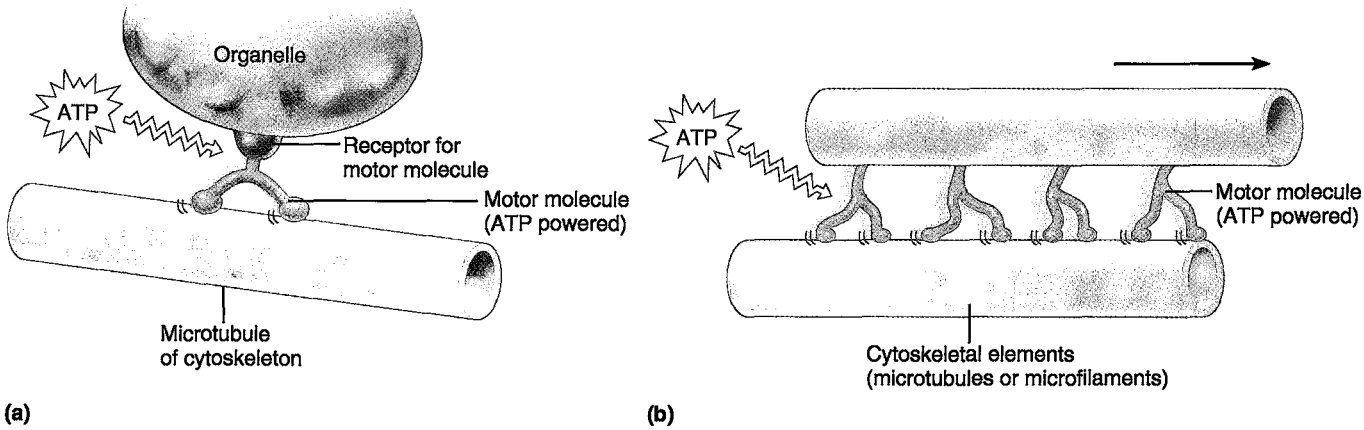

FIGURE 3.25 **Interaction of motor molecules (motor proteins) with cytoskeletal elements.** Microtubules and microfilaments function in motility by interacting with protein complexes called motor molecules. The various motor molecules, all powered by ATP, work by changing their shapes, moving back and forth something like microscopic legs. With each cycle of shape changes, the motor molecule releases at its free end and grips at a site farther along the microtubule or microfilament. **(a)** Motor molecules can attach to receptors on organelles, such as mitochondria or ribosomes, and "walk" the organelles along the microtubules of the cytoskeleton. **(b)** In some types of cell motility, motor molecules attached to one element of the cytoskeleton can cause it to slide over another element. For example, the sliding of one set of microfilaments past another underlies muscle contraction, and the sliding of neighboring microtubules moves cilia.

cytoskeletal elements and have high tensile strength. Unlike microtubules and microfilaments, intermediate filaments do not bind ATP or serve as "tracks" for molecular motors to transport intracellular substances. They attach to desmosomes, and their main job is to act as internal guy-wires to resist pulling forces exerted on the cell. Because the protein composition of intermediate filaments varies in different cell types, there are numerous names for these cytoskeletal elements—for example, they are called neurofilaments in nerve cells and keratin filaments in epithelial cells.

Centrosome and Centrioles

As mentioned, microtubules are anchored at one end in a region near the nucleus called the **centrosome.** The centrosome, which acts as a *microtubule organizing center,* has few distinguishing marks other than a granular-looking *matrix* that contains paired **centrioles,** small, barrel-shaped organelles oriented at right angles to each other (Figure 3.26). The centrosome matrix is best known for its generation of microtubules and its role of organizing the mitotic

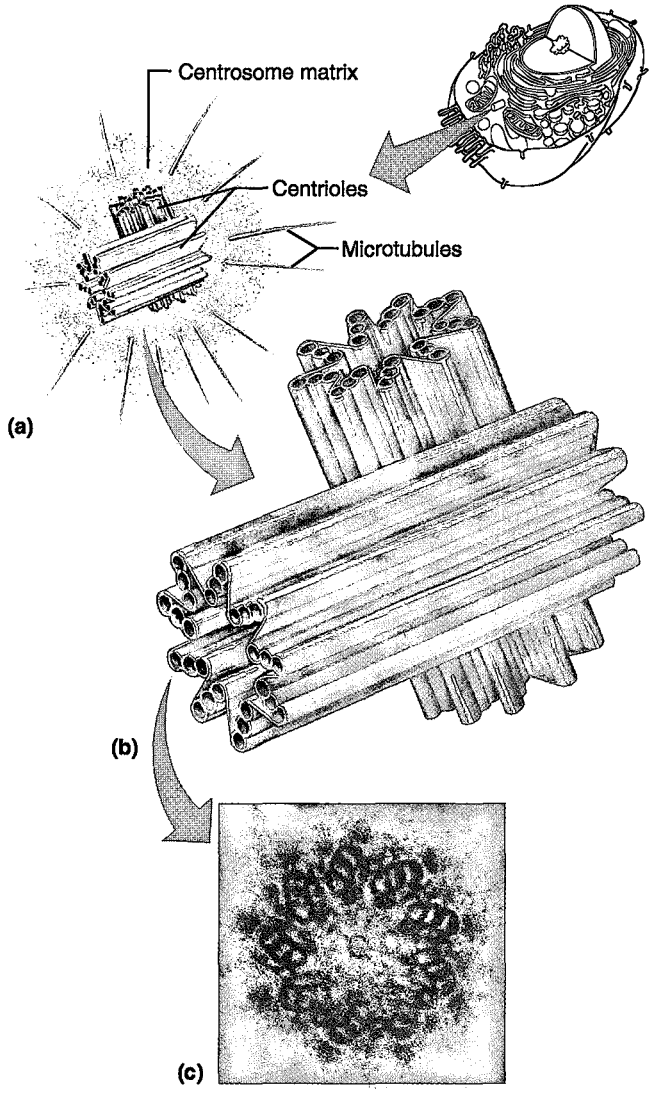

FIGURE 3.26 **Centrioles. (a, b)** Three-dimensional views of a centriole pair oriented at right angles, as they are usually seen in the cell. The centrioles are located in an inconspicuous region to one side of the nucleus called the centrosome, or cell center. **(c)** An electron micrograph showing a cross section of a centriole (180,000×). Notice that it is composed of nine microtubule triplets.

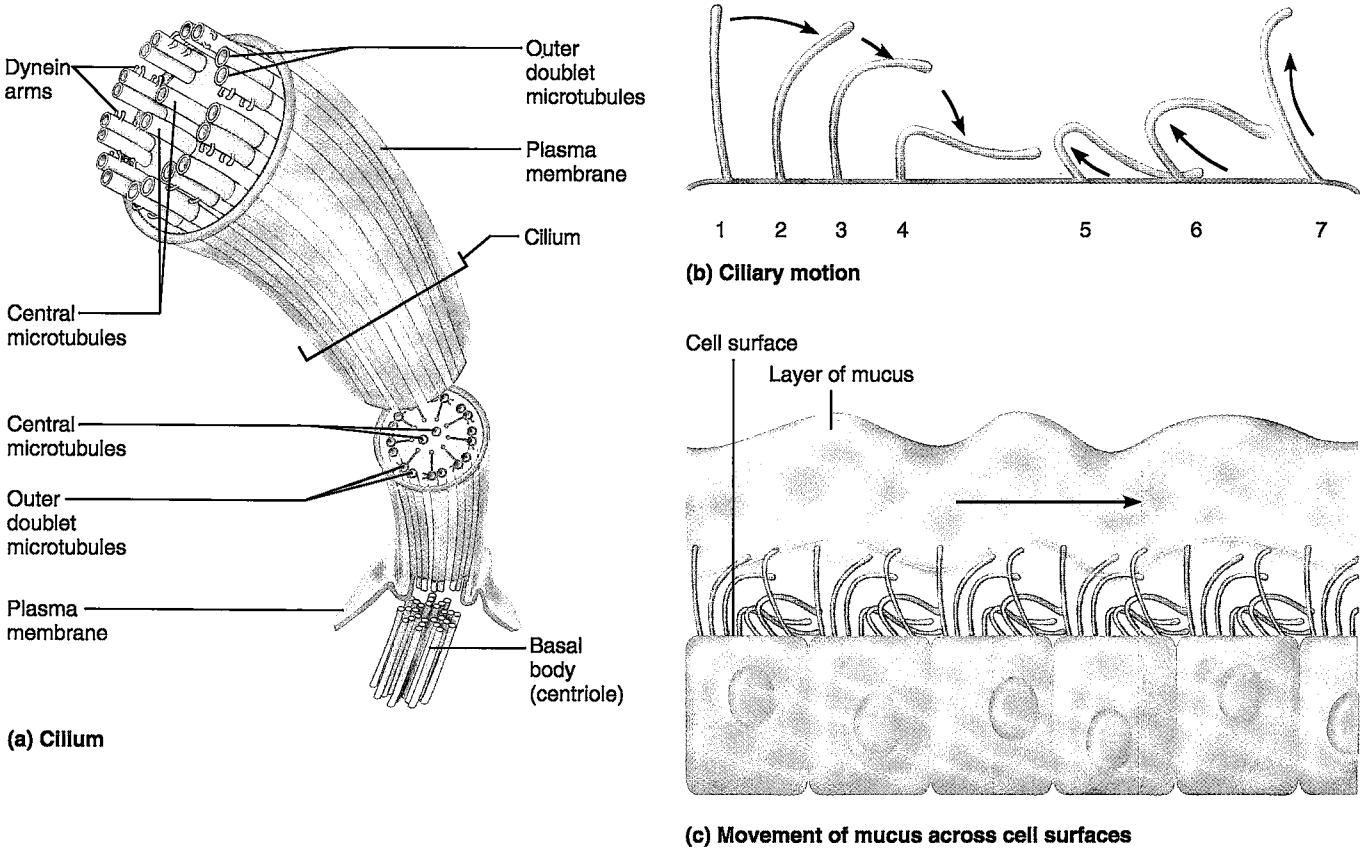

FIGURE 3.27 **Cilia structure and function.** **(a)** Three-dimensional diagram of a cross section through a cilium, showing its nine pairs of peripheral microtubules and one central microtubule pair. **(b)** Diagram of the phases of ciliary motion. 1–4 are part of the power (propulsive) stroke; 5–7 are phases of the recovery (nonpropulsive) stroke when the cilium is resuming its initial position. **(c)** A representation of the traveling wave created by the activity of many cilia acting together to propel mucus across the cell surfaces.

spindle (see Figure 3.32 on pp. 102–103) in cell division. Each centriole consists of a pinwheel array of nine *triplets* of microtubules, arranged to form a hollow tube. Centrioles also form the bases of cilia and flagella.

Cellular Extensions

Cilia and Flagella

Cilia (sil'e-ah; "eyelashes") are whiplike, motile cellular extensions (Figure 3.27) that occur, typically in large numbers, on the exposed surfaces of certain cells. Ciliary action moves substances in one direction across cell surfaces. For example, ciliated cells that line the respiratory tract propel mucus laden with dust particles and bacteria upward away from the lungs.

When a cell is about to form cilia, the centrioles multiply and line up beneath the plasma membrane at the free cell surface. Microtubules then begin to "sprout" from each centriole, forming the ciliary projections by exerting pressure on the plasma membrane. When the projections formed by centrioles are substantially longer, they are called **flagella** (flah-jel'ah). The single example of a flagellated cell in the human body is a sperm, which has one propulsive flagellum, commonly called a tail. Notice that cilia *propel other substances* across a cell's surface, whereas a flagellum *propels the cell itself.*

Centrioles forming the bases of cilia and flagella are commonly referred to as **basal bodies** (ba'sal) (Figure 3.27a) because they were thought to be different from the structures seen in the centrosome. We now know that centrioles and basal bodies are identical. However, the pattern of microtubules in the cilium or flagellum itself (nine *doublets*, or pairs, of microtubules encircling one central pair) differs slightly from that of a centriole (nine microtubule *triplets*).

Just how cilia activity is coordinated is not fully understood, but microtubules are definitely involved. Extending from the microtubule doublets are arms

TABLE 3.3 Parts of the Cell: Structure and Function

CELL PART	STRUCTURE	FUNCTIONS
PLASMA MEMBRANE (FIGURE 3.3)		
	Membrane made of a double layer of lipids (phospholipids, cholesterol, and so on) within which proteins are embedded; proteins may extend entirely through the lipid bilayer or protrude on only one face; externally facing proteins and some lipids have attached sugar groups	Serves as an external cell barrier; acts in transport of substances into or out of the cell; maintains a resting potential that is essential for functioning of excitable cells; externally facing proteins act as receptors (for hormones, neurotransmitters, and so on) and in cell-to-cell recognition
CYTOPLASM		
	Cellular region between the nuclear and plasma membranes; consists of fluid **cytosol,** containing dissolved solutes, **organelles** (the metabolic machinery of the cytoplasm), and **inclusions** (stored nutrients, secretory products, pigment granules)	
Cytoplasmic Organelles		
▪ Mitochondria (Figure 3.17)	Rodlike, double-membrane structures; inner membrane folded into projections called cristae	Site of ATP synthesis; powerhouse of the cell
▪ Ribosomes (Figures 3.18, 3.19)	Dense particles consisting of two subunits, each composed of ribosomal RNA and protein; free or attached to rough endoplasmic reticulum	The sites of protein synthesis
▪ Rough endoplasmic reticulum (Figures 3.18, 3.19)	Membrane system enclosing a cavity, the cisterna, and coiling through the cytoplasm; externally studded with ribosomes	Sugar groups are attached to proteins within the cisternae; proteins are bound in vesicles for transport to the Golgi apparatus and other sites; external face synthesizes phospholipids
▪ Smooth endoplasmic reticulum (Figure 3.18)	Membranous system of sacs and tubules; free of ribosomes	Site of lipid and steroid (cholesterol) synthesis, lipid metabolism, and drug detoxification
▪ Golgi apparatus (Figures 3.20, 3.21)	A stack of smooth membrane sacs and associated vesicles close to the nucleus	Packages, modifies, and segregates proteins for secretion from the cell, inclusion in lysosomes, and incorporation into the plasma membrane
▪ Lysosomes (Figure 3.22)	Membranous sacs containing acid hydrolases	Sites of intracellular digestion
▪ Peroxisomes (Figure 3.2)	Membranous sacs of oxidase enzymes	The enzymes detoxify a number of toxic substances; the most important enzyme, catalase, breaks down hydrogen peroxide
▪ Microtubules (Figures 3.24–3.27)	Cylindrical structures made of tubulin proteins	Support the cell and give it shape; involved in intracellular and cellular movements; form centrioles and cilia and flagella, if present
▪ Microfilaments (Figures 3.24, 3.25)	Fine filaments of the contractile protein actin	Involved in muscle contraction and other types of intracellular movement; help form the cell's cytoskeleton
▪ Intermediate filaments (Figure 3.24)	Protein fibers; composition varies	The stable cytoskeletal elements; resist mechanical forces acting on the cell
▪ Centrioles (Figure 3.26)	Paired cylindrical bodies, each composed of nine triplets of microtubules	Organize a microtubule network during mitosis to form the spindle and asters; form the bases of cilia and flagella
Inclusions	Varied; includes stored nutrients such as lipid droplets and glycogen granules, protein crystals, pigment granules	Storage for nutrients, wastes, and cell products

TABLE 3.3 *(continued)*

CELL PART	STRUCTURE	FUNCTIONS
CELLULAR EXTENSIONS		
▪ Cilia (Figure 3.27)	Short, cell surface projections; each cilium composed of nine pairs of microtubules surrounding a central pair	Move in unison, creating a unidirectional current that propels substances across cell surfaces
▪ Flagella	Like cilium, but longer; only example in humans is the sperm tail	Propels the cell
▪ Microvilli (Figure 3.2)	Tubular extensions of the plasma membrane; contain a bundle of actin filaments	Increase surface area for absorption
NUCLEUS (FIGURE 3.28)		
	Largest organelle; surrounded by the nuclear envelope; contains fluid nucleoplasm, nucleoli, and chromatin	Control center of the cell; responsible for transmitting genetic information and providing the instructions for protein synthesis
▪ Nuclear envelope (Figure 3.28)	Double-membrane structure; pierced by pores; outer membrane continuous with the endoplasmic reticulum	Separates the nucleoplasm from the cytoplasm and regulates passage of substances to and from the nucleus
▪ Nucleoli (Figure 3.28)	Dense spherical (non-membrane-bounded) bodies; composed of ribosomal RNA and proteins	Site of ribosome subunit manufacture
▪ Chromatin (Figures 3.28, 3.29)	Granular, threadlike material composed of DNA and histone proteins	DNA constitutes the genes

composed of the motor protein *dynein*. Cilia move when the dynein side arms grip adjacent doublets and start to crawl along their length, much like cats dig in their claws to climb a tree. The collective bending action of all the doublets causes the cilium to bend.

As a cilium moves, it alternates rhythmically between a propulsive *power stroke*, when it is nearly straight and moves in an arc, and a *recovery stroke*, when it bends and returns to its initial position (Figure 3.27b). With these two strokes, the cilium produces a pushing motion in a single direction that is repeated some 10 to 20 times per second. The activity of cilia in a particular region is coordinated so that the bending of one cilium is quickly followed by the bending of the next and then the next, creating a current at the cell surface that brings to mind the traveling waves that pass across a field of grass on a windy day (Figure 3.27c).

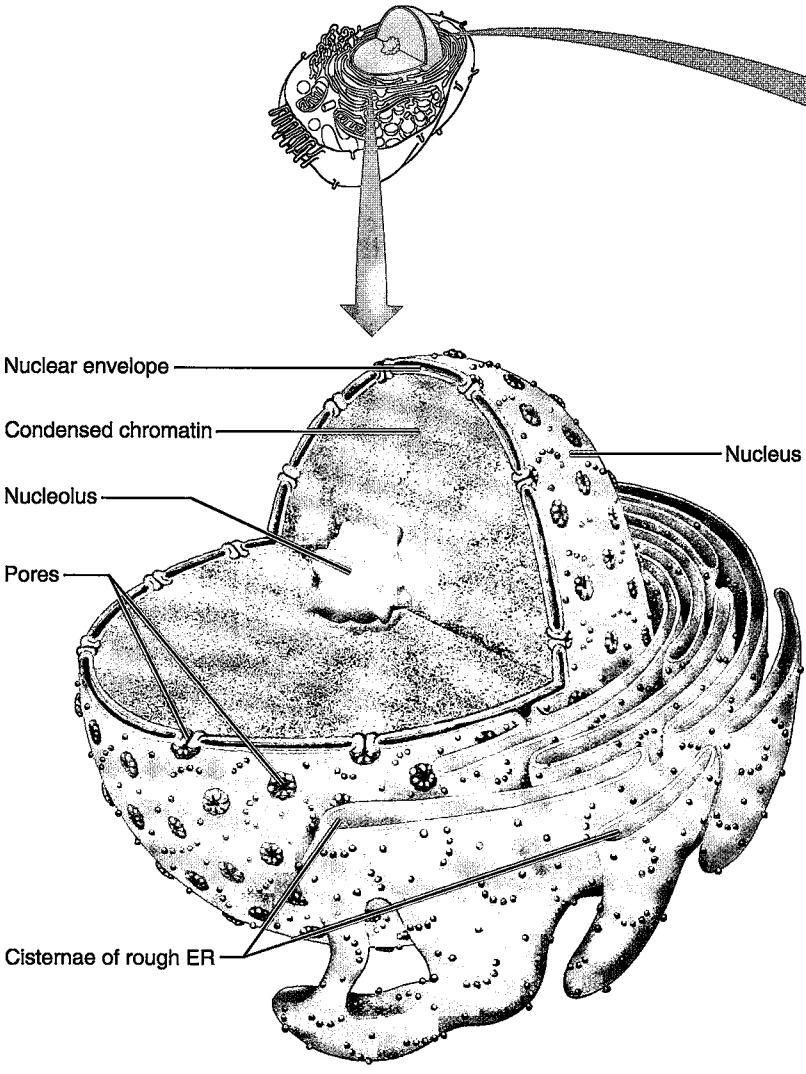
The Nucleus

Anything that works, works best when it is controlled. For cells, the control center is the gene-containing **nucleus** (*nucle* = pit, kernel). The nucleus can be compared to a computer, design department, construction boss, and board of directors—all rolled into one. As the genetic library, it contains the instructions needed to build nearly all the body's proteins. Additionally, it dictates the kinds and amounts of proteins to be synthesized at any one time in response to signals acting on the cell.

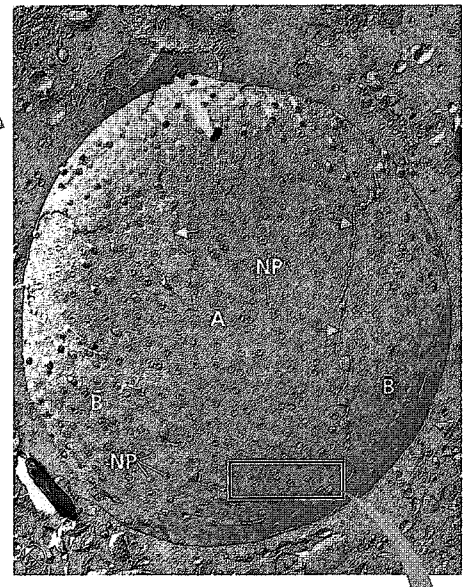
Most cells have only one nucleus, but some, including skeletal muscle cells, bone destruction cells, and some liver cells, are **multinucleate** (mul"tĭ-nu'kle-āt); that is, they have many nuclei. The presence of more than one nucleus usually signifies that a larger-than-usual cytoplasmic mass must be regulated. With one exception, all of our body cells are nucleated. The exception is mature red blood cells, whose nuclei are ejected before the cells enter the bloodstream. These **anucleate** (a-nu'kle-āt; *a* = without) cells cannot reproduce and therefore live in the bloodstream for only three to four months before they begin to deteriorate. Without a nucleus, a cell cannot produce mRNA to make proteins, and when its enzymes and cell structures start to break down (as all eventually do), they cannot be replaced.

The nucleus, averaging 5 μm in diameter, is larger than any of the cytoplasmic organelles. Although most often spherical or oval, its shape usually conforms to the shape of the cell. The nucleus has three recognizable regions or structures: the *nuclear envelope*

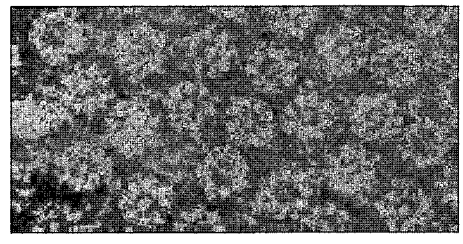
Q *Methylene blue binds to DNA. What nuclear structure would be stained by this dye?*



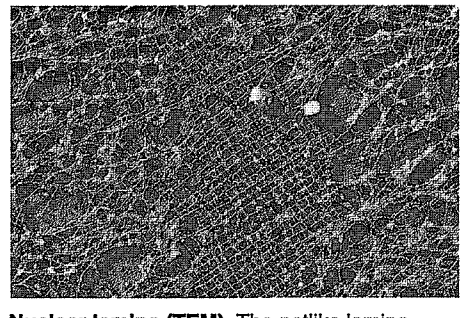
(a)



Surface of nuclear envelope. TEM prepared by freeze-fracture. A, inner membrane; B, outer membrane; NP, nuclear pore (pore complex); White arrows, fracture lines of outer membrane.



Pore complexes (TEM). Each pore is ringed by protein particles.



Nuclear lamina (TEM). The netlike lamina composed of intermediate filaments called lamins lines the inner surface of the nuclear envelope.

(b)

FIGURE 3.28 **The nucleus. (a)** Three-dimensional diagrammatic view of the nucleus, showing the continuity of its double membrane with the ER. **(b)** From top to bottom, freeze-fracture electron micrographs of the outer face of the nuclear envelope, the nuclear pore complexes, and the nuclear lamina on the inner face of the nuclear envelope.

A *The chromatin, which contains DNA complexed with histone proteins.*

(membrane), nucleoli, and *chromatin* (Figure 3.28). Besides these structures, there are several distinct compartments (a splicing factor compartment and others) rich in specific sets of proteins. These are not limited by membranes and are in a constant state of dynamic flux. Much remains to be learned about them.

The Nuclear Envelope

The nucleus is bounded by the **nuclear envelope,** a *double* membrane barrier separated by a fluid-filled space (similar to the mitochondrial membrane). The outer nuclear membrane is continuous with the rough ER of the cytoplasm and is studded with ribosomes on its external face. The inner nuclear membrane is lined by the *nuclear lamina,* a network of *lamins* (rod-shaped proteins of the intermediate filament class), that maintains the shape of the nucleus and acts as a scaffold to organize DNA in the nucleus.

At various points, the two layers of the nuclear envelope interconnect to form the edges of **nuclear pores.** An intricate complex of proteins, called a *pore complex,* lines each pore forming an aqueous transport channel and regulating the entry and exit of large particles into and out of the nucleus.

Like other cell membranes, the nuclear envelope is selectively permeable, but here passage of substances is much freer than elsewhere. Protein molecules imported from the cytoplasm and RNA molecules exported from the nucleus pass easily through the relatively large nuclear pore complexes, transported in an energy-dependent process by soluble transport proteins (importins and others).

The nuclear envelope encloses a jellylike fluid called *nucleoplasm* (nu'kle-o-plazm) in which other nuclear elements are suspended. Like the cytosol, the nucleoplasm contains dissolved salts, nutrients, and other essential solutes.

Nucleoli

Nucleoli (nu-kle'o-li; "little nuclei") are the dark-staining spherical bodies found within the nucleus. They are not membrane bounded. Typically, there are one or two nucleoli per nucleus, but there may be more. Because they are sites where ribosome subunits are assembled, nucleoli are usually large in growing cells that are making large amounts of tissue proteins. Nucleoli are associated with *nucleolar organizer regions,* which contain the DNA that issues genetic instructions for synthesizing ribosomal RNA (rRNA). As molecules of rRNA are synthesized, they are combined with proteins to form the two kinds of ribosomal subunits. (The proteins are manufactured on ribosomes in the cytoplasm and "imported" into the nucleus.) Most of these subunits leave the nucleus through the nuclear pores and enter the cytoplasm, where they join to form functional ribosomes.

Chromatin

Seen through a light microscope, **chromatin** (kro'mah-tin) appears as a fine, unevenly stained network, but special techniques reveal it as a system of bumpy threads weaving their way through the nucleoplasm (Figure 3.29a). Chromatin is composed of about 30% **DNA,** which is traditionally called our genetic material, about 60% globular **histone proteins** (his'tōn), and about 10% RNA chains, newly formed or forming. The fundamental units of chromatin, **nucleosomes** (nu'kle-o-sōmz; "nuclear bodies"), consist of flattened disc-shaped cores or clusters of eight histone proteins connected like beads on a string by a DNA molecule. The DNA winds (like a ribbon of Velcro) twice around each nucleosome and continues on to the next cluster via *linker DNA* segments (Figure 3.29a). In addition to providing a physical means for packing the very long DNA molecules in a compact, orderly way, the histones play an important role in gene regulation. In a nondividing cell, for example, the presence of methyl groups on histone proteins shuts down the nearby DNA, and attachment of a phosphate group to a particular histone protein may indicate that the cell is about to commit suicide. On the other hand, addition of acetyl groups to histone exposes different DNA segments, or genes, so that they can dictate the specifications for protein synthesis or for various small RNA species. Such active chromatin segments, referred to as *extended chromatin,* are not usually visible under the light microscope. The generally inactive *condensed chromatin* segments are darker staining and so are more easily detected. Understandably, the most active body cells have much larger amounts of extended chromatin.

When a cell is preparing to divide, the chromatin threads coil and condense enormously to form short, barlike bodies called **chromosomes** ("colored bodies") (Figure 3.29b). Chromosome compactness avoids entanglement and breakage of the delicate chromatin strands during the movements that occur during cell division. The functions of DNA and the events of cell division are described in the next section.

Cell Growth and Reproduction

The Cell Life Cycle

The **cell life cycle,** the series of changes a cell goes through from the time it is formed until it reproduces, encompasses two major periods: *interphase,*

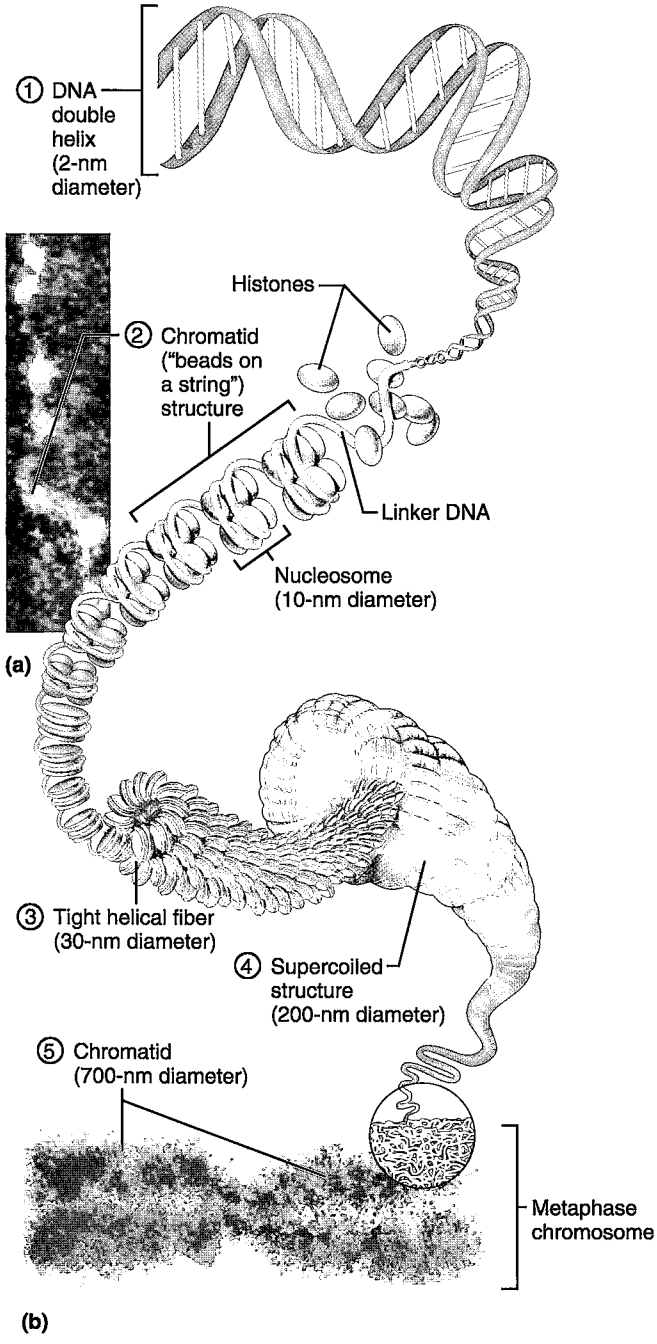


FIGURE 3.29 **Chromatin and chromosome structure.** **(a)** Electron micrograph of chromatin fibers (10,000×). **(b)** DNA packing in a chromosome. The levels of increasing structural complexity (coiling) from the DNA helix to the metaphase chromosome are indicated in numerical order. (Metaphase is a stage of nuclear division that occurs before the genetic material is distributed to the daughter cells.) Notice the structure of the nucleosomes, the fundamental units of chromatin that give it the "beads on a string" appearance. Each nucleosome is composed of a flattened disc-like core of eight histone proteins wrapped by two winds of the DNA helix.

in which the cell grows and carries on its usual activities, and *cell division,* or the *mitotic phase,* during which it divides into two cells (Figure 3.30).

Interphase

Interphase is the period from cell formation to cell division. Early cytologists, unaware of the constant molecular activity in cells and impressed by the obvious movements of cell division, called interphase the resting phase of the cell cycle. (The term *interphase* reflects this idea of a stage *between* cell divisions.) However, this image is grossly misleading because during interphase a cell is carrying out all its routine activities and is "resting" only from dividing. Perhaps a more accurate name for this phase would be *metabolic phase* or *growth phase.*

Subphases In addition to carrying on its life-sustaining reactions, an interphase cell prepares for the next cell division. Interphase is divided into G_1, S, and G_2 subphases (the Gs stand for gaps before and after the S phase; S is for synthetic). In all three subphases, the cell grows by producing proteins and organelles; however, chromatin is reproduced only during the S subphase. During **G_1 (gap 1),** the cell is metabolically active, synthesizing proteins rapidly and growing vigorously. This is the most variable phase in terms of length. In cells that divide rapidly, G_1 typically lasts several minutes to hours; in those that divide slowly, it may last for days or even years. Cells that permanently cease dividing are said to be in the **G_0 phase.** For most of G_1, virtually no activities directly related to cell division occur. However, as G_1 ends, the centrioles start to replicate in preparation for cell division.

During the **S phase,** DNA is replicated, ensuring that the two future cells being created will receive identical copies of the genetic material. New histones are made and assembled into chromatin. One thing is sure: Without a proper S phase, there can be no correct mitotic phase. (We will describe DNA replication next.)

The final phase of interphase, called G_2, is brief. Enzymes and other proteins needed for division are synthesized and moved to their proper sites. By the end of G_2, centriole replication (begun in G_1) is complete. The cell is now ready to divide. Throughout S and G_2, the cell continues to grow and carries on with business as usual.

DNA Replication Before a cell can divide, its DNA must be replicated exactly, so that identical copies of the cell's genes can be passed on to each of its offspring. Replication begins simultaneously on several chromatin threads and continues until all the DNA has been replicated.

This process, still being studied, appears to involve the following events:

1. The DNA helices begin unwinding from the nucleosomes.

2. A *helicase* enzyme untwists the double helix and gradually separates the DNA molecule into two complementary nucleotide chains, exposing the nitrogenous bases. The site of separation is called the *replication bubble;* the Y-shaped region at each end of the replication bubble is called the *replication fork.* Figure 3.31b shows a replication fork at one end of a replication bubble.

3. Each nucleotide strand then serves as a *template,* or set of instructions, for building a new complementary nucleotide strand from free DNA precursors dissolved in the nucleoplasm.

Recall from Chapter 2 that nucleotide base pairing is always complementary: *adenine (A)* bonds to *thymine (T),* and *guanine (G)* bonds to *cytosine (C).* Hence the order of the nucleotides on the template strand determines the order on the strand being built. For example, a TACTGC sequence on a template strand would bond to new nucleotides with the order ATGACG.

4. At sites where DNA synthesis is to occur, the needed "machinery" gradually accumulates until several different proteins (mostly enzymes) are present in a large complex called a **replisome.** The actual initiation of DNA synthesis requires formation of short (about ten bases long) **RNA primers** by primase enzymes which are part of the replisome (Figure 3.31a).

5. Once the primer is in place, **DNA polymerase III** comes into the picture. Continuing from the primer, it positions complementary nucleotides along the template strand and then covalently links them together. DNA polymerase works only in one direction. Consequently, one strand, the *leading strand,* is synthesized continuously (once primed by the RNA primer) following the movement of the replication fork. The other strand, called the *lagging strand,* is constructed in segments in the opposite direction and requires that a primer initiate replication of each segment. These primers are eventually erased and replaced with DNA nucleotides by DNA polymerases (Figure 3.31a).

6. The short segments of DNA are then spliced together by **DNA ligase.** The end result is that two DNA molecules are formed from the original DNA helix and are identical to it. Each new molecule consists of one old and one new nucleotide strand. This mechanism of DNA replication is referred to as **semiconservative replication** (Figure 3.31b). Replication also involves the generation of two new telomeres (*tel* = end; *mer* = piece), snugly fitting nucleoprotein caps that prevent degradation of the ends of the chromatin strands.

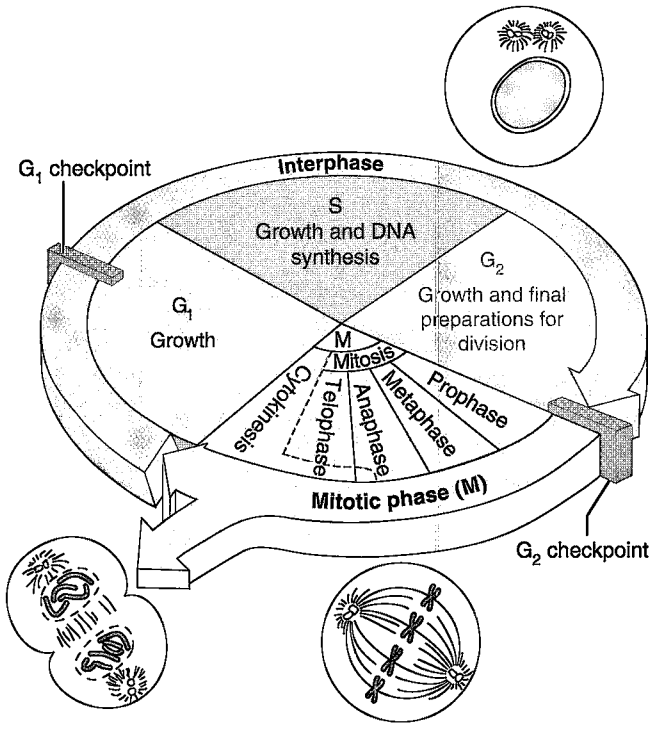

FIGURE 3.30 **The cell cycle.** During G_1, cells grow rapidly and carry out their routine functions. The S phase is the period of DNA synthesis. In G_2, materials needed for cell division are synthesized and growth continues. During the M phase (cell division), mitosis and cytokinesis occur, producing two daughter cells. Important checkpoints at which mitosis may be prevented from occurring are found throughout interphase; two are shown on the diagram.

7. As soon as replication ends, histones (synthesized in the cytoplasm and imported into the nucleus) associate with the DNA, completing the formation of two new chromatin strands. The chromatin strands, united by a buttonlike centromere (a stretch of repetitive DNA), condense to form **chromatids** (see Figure 3.29b). The chromatids remain attached, held together by the centromere and a protein complex called *cohesin,* until the cell enters the anaphase stage of mitotic cell division (see p. 103). They are then distributed to the daughter cells, as described next, ensuring that each cell has identical genetic information.

Cell Division

Cell division is essential for body growth and tissue repair. Cells that continually wear away, such as cells of the skin and intestinal lining, reproduce themselves almost continuously. Others, such as liver cells, divide more slowly (to maintain the particular size of the organ they compose) but retain the ability to reproduce quickly if the organ is damaged. Most

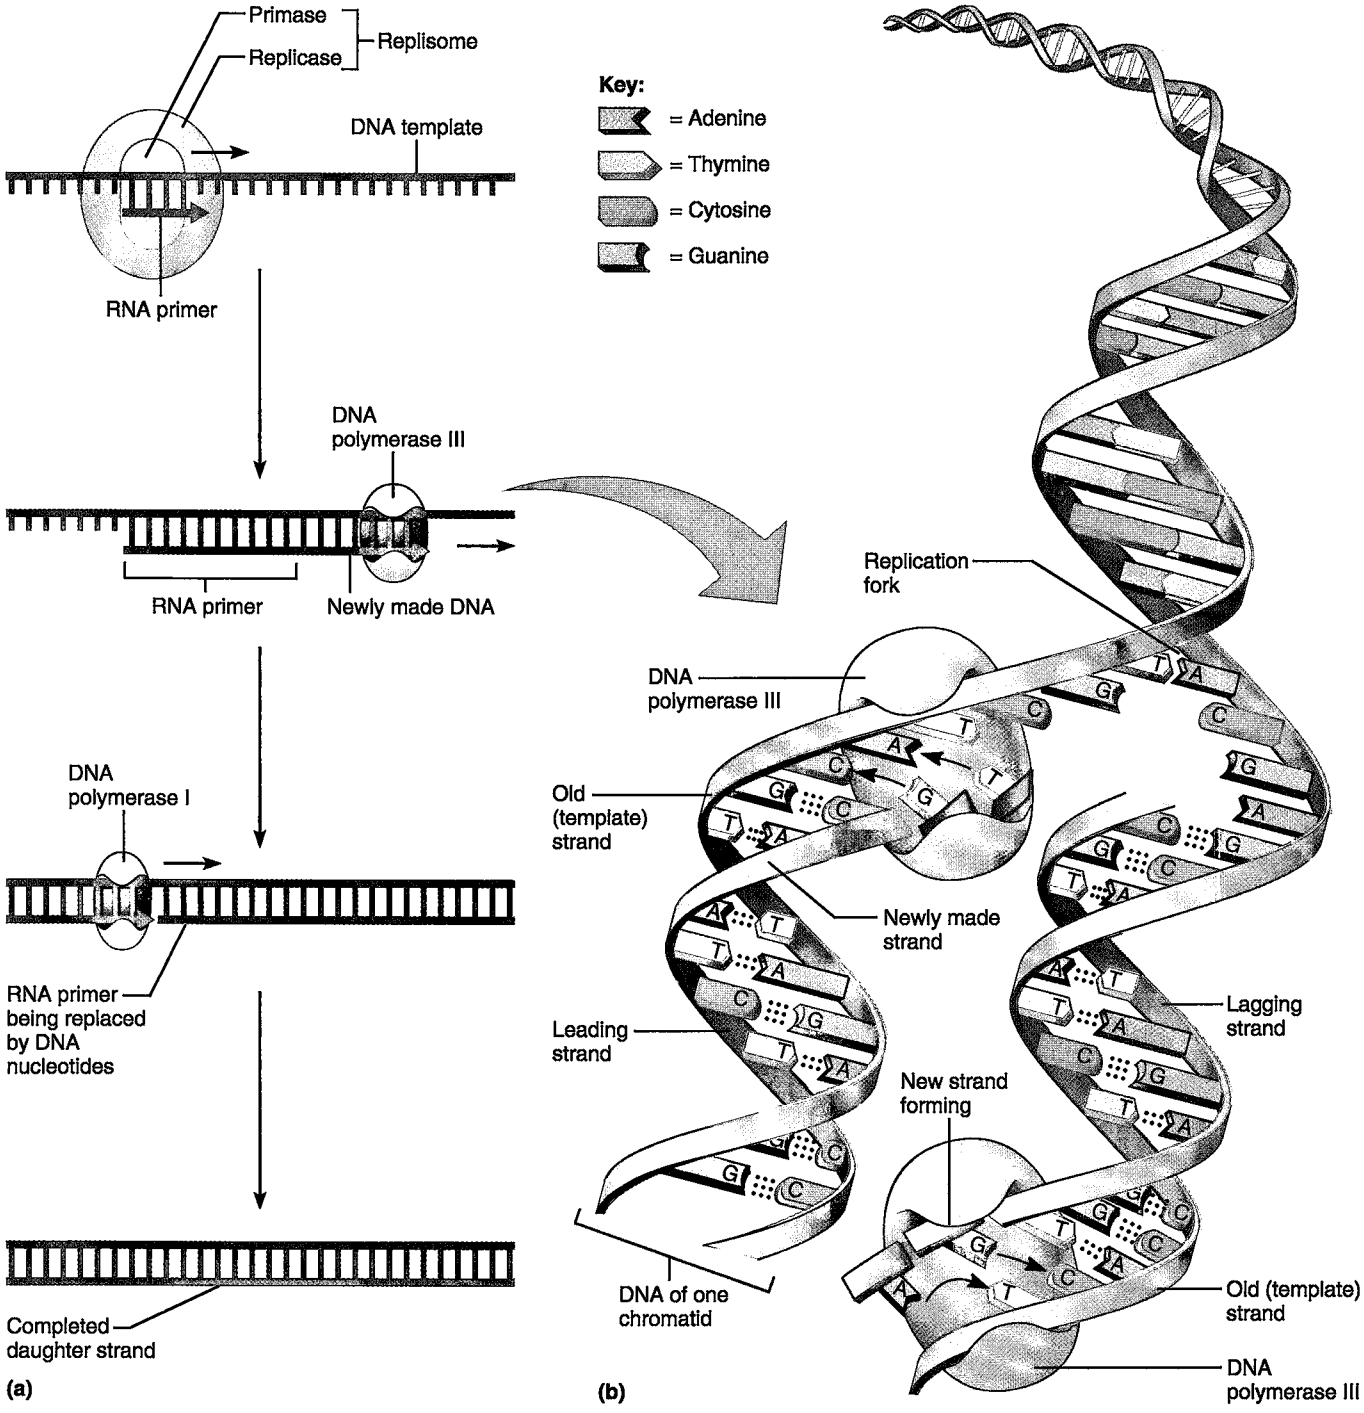

FIGURE 3.31 **Replication of DNA.** **(a)** Role of the RNA primer. The RNA primer initiates DNA synthesis. The primer is synthesized by primase, an RNA polymerase, that is part of a protein complex called a replisome and that uses a single strand of DNA as its template. When a short stretch of RNA is available, DNA polymerase III is able to initiate DNA synthesis. The primer is eventually removed by DNA polymerase I, which replaces the ribonucleotides with deoxyribonucleotides. **(b)** Sequential events of DNA synthesis. The DNA helix uncoils, and the hydrogen bonds between its base pairs are broken. Then each nucleotide strand of the DNA acts as a template for the construction of a complementary strand, as illustrated in the bottom portion of the diagram. DNA polymerases work in one direction only, so the two new strands (leading and lagging) are synthesized in opposite directions. For simplicity, the DNA ligase enzymes that join the DNA fragments on the lagging strand are not illustrated. Each DNA molecule formed consists of one old (template) strand and one newly assembled strand and constitutes a chromatid of a chromosome.

cells of nervous tissue, skeletal muscle, and heart muscle lose their ability to divide when they are fully mature, and repairs are made with scar tissue (a fibrous type of connective tissue).

Events of Cell Division In most body cells, cell division, which is called the **M (mitotic) phase** of the cell life cycle (see Figure 3.30), involves two distinct events: **mitosis** (mi-to'sis; *mit* = thread; *osis* = process), or division of the nucleus, and **cytokinesis** (si-to-kĭ-ne'sis; *kines* = movement), or division of the cytoplasm. A somewhat different process of nuclear division called *meiosis* (mi-o'sis) produces sex cells (ova and sperm) with only half the number of genes found in other body cells. The details of meiosis are discussed in Chapter 27. Here we concentrate on mitotic cell division.

Mitosis Mitosis is the series of events that parcel out the replicated DNA of the mother cell to two daughter cells (Figure 3.32). It is described in terms of four phases: **prophase, metaphase, anaphase,** and **telophase,** but it is actually a continuous process, with one phase merging smoothly into the next. Its duration varies according to cell type, but in human cells it typically lasts about an hour or less from start to finish.

Cytokinesis Cytokinesis, or the division of the cytoplasm, begins during late anaphase and is completed after mitosis ends. The plasma membrane over the center of the cell (the spindle equator) is drawn inward to form a **cleavage furrow** by the activity of a *contractile ring* made of actin filaments. The furrow deepens until the cytoplasmic mass is pinched into two parts, so that at the end of cytokinesis there are two daughter cells. Each is smaller and has less cytoplasm than the mother cell, but is *genetically* identical to it. The daughter cells then enter the interphase portion of the life cycle until it is their turn to divide.

Control of Cell Division The signals that prod cells to divide are poorly understood, but we know that the ratio of cell surface area to cell volume is important. The amount of nutrients a growing cell requires is directly related to its volume. Volume increases with the cube of cell radius, whereas surface area increases with the square of the radius. Thus, for example, a 64-fold (4^3) increase in cell volume is accompanied by only a 16-fold (4^2) increase in surface area. Consequently, the surface area of the plasma membrane becomes inadequate for nutrient and waste exchange when a cell reaches a certain critical size. Cell division solves this problem because the smaller daughter cells have a favorable surface-area-to-volume ratio. These surface-volume relationships help explain why most cells are microscopic in size.

Two other mechanisms that influence when cells divide are chemical signals (growth factors, hormones, and others) released by other cells and the availability of space. Normal cells stop proliferating when they begin touching, a phenomenon called *contact inhibition.* Cancer cells lack many of the normal controls and therefore divide wildly, which makes them dangerous to their host.

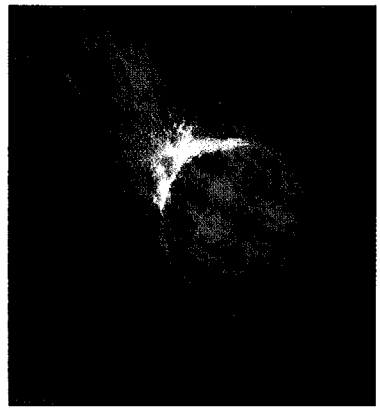
The cell life cycle is controlled by a system that has been compared to an automatic washer's timer control. Like that timer, the cell life cycle control system is driven by a built-in clock. However, just as the washer's cycle is subject to adjustments (by regulating the flow from the faucet, say, or by an internal water-level sensor), the cell cycle is regulated by both internal and external factors.

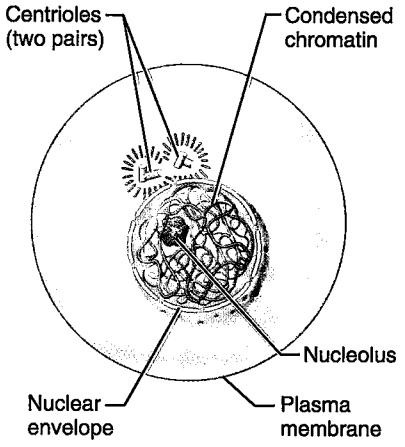
Although triggers for cell division are still being researched, we do know that throughout interphase a number of "switches" and checkpoints are involved. Thus far, two groups of proteins appear crucial to the ability of a cell to accomplish the S phase and enter mitosis—**cyclins** (regulatory proteins whose levels rise and fall during each life cycle) and **Cdks (cyclin-dependent kinases),** which are present in a constant concentration in the cell and are activated by binding to particular cyclins. In response to specific signals, a new batch of cyclins accumulates during each interphase. Subsequent joining of specific Cdk and cyclin proteins initiates enzymatic cascades that phosphorylate histones and other proteins needed for the various stages of cell division. At the end of mitosis, the cyclins are abruptly destroyed by proteasomes.

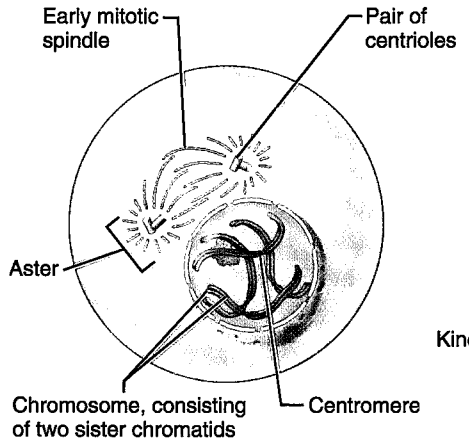
As mentioned, a number of crucial checkpoints occur throughout interphase. These built-in stop signals halt the cell cycle until overridden by internal or external go-ahead signals. In many cells, a G_1 checkpoint (see Figure 3.30), called the *restriction point,* seems to be most important. If the cell is diverted from dividing at this checkpoint, it enters the nondividing state (G_0). Another important checkpoint, and the first to be understood, occurs late in G_2, when a threshold amount of a protein complex called **MPF (M-phase promoting factor)** is required to give the okay signal to pass the G_2 checkpoint and enter the M phase. Later in M phase, MPF is inactivated.

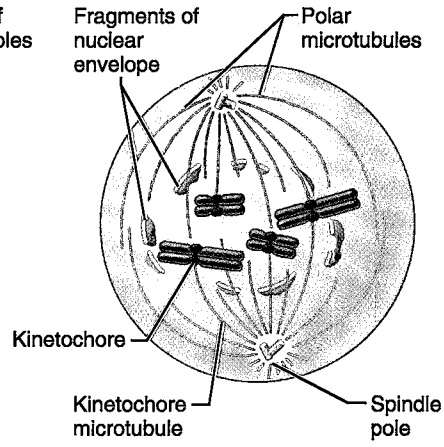
Protein Synthesis

In addition to directing its own replication, DNA serves as the master blueprint for protein synthesis. Although cells also make lipids and carbohydrates, DNA does not dictate their structure. Historically,









Interphase

Interphase is the period of a cell's life when it is carrying out its normal metabolic activities and growing. During interphase, the chromosomal material is seen in the form of extended and condensed chromatin, and the nuclear envelope and nucleolus are intact and visible. Microtubule arrays (asters) are seen extending from the centrosomes. During various periods of this phase, the centrioles begin replicating (G_1 through G_2), DNA is replicated (S), and the final preparations for mitosis are completed (G_2). The centriole pair finishes replicating into two pairs during G_2.

Early prophase

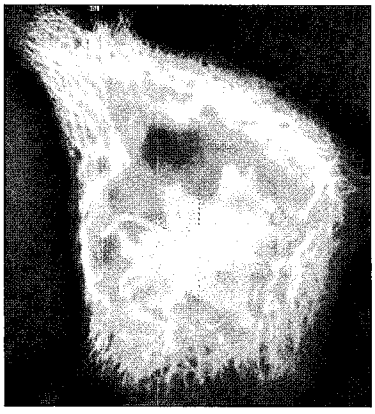
As mitosis begins, microtubule arrays called *asters* ("stars") are seen extending from the centrosome matrix around the centrioles. Early in *prophase,* the first and longest phase of mitosis, the chromatin threads coil and condense, forming barlike *chromosomes* that are visible with a light microscope. Since DNA replication has occurred during interphase, each chromosome is actually made up of two identical chromatin threads, now called *chromatids.* The chromatids of each chromosome are held together by a small, buttonlike body called a *centromere* and a protein complex called cohesin. (After the chromatids separate, each is considered a new chromosome.)

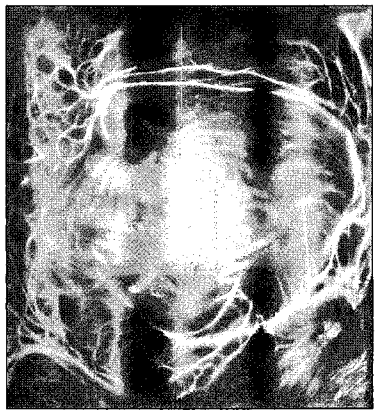
As the chromosomes appear, the nucleoli disappear, and the cytoskeletal microtubules disassemble. The centriole pairs separate from one another. The centrioles act as focal points for growth of a new assembly of microtubules called the **mitotic spindle.** As these microtubules lengthen, they push the centrioles farther and farther apart, propelling them toward opposite ends (poles) of the cell.

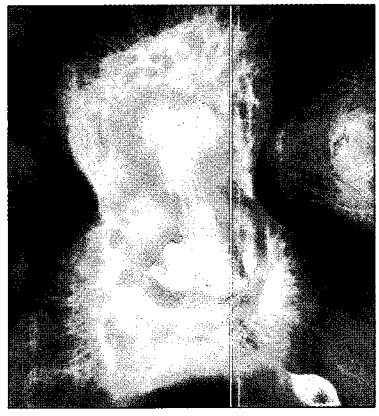
Late prophase

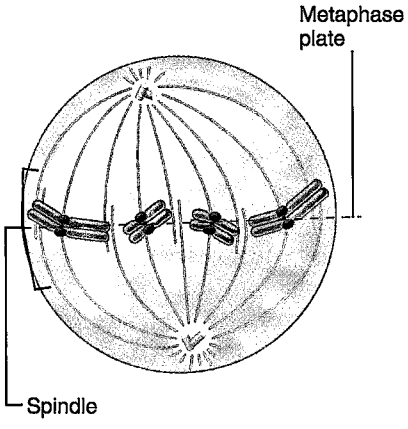
While the centrioles are still moving away from each other, the nuclear envelope fragments and is dispersed to the ER, allowing the spindle to occupy the center of the cell and to interact with the chromosomes. Meanwhile, some of the growing spindle microtubules attach to special protein-DNA complexes, called *kinetochores* (ki-ne´to-korz), at each chromosome's centromere. Such microtubules are called *kinetochore microtubules.* The remaining spindle microtubules, which do not attach to any chromosomes, are called *polar microtubules.* The tips of the polar microtubules are linked near the center; these push against each other, forcing the poles apart. Meanwhile, the kinetochore microtubules pull on each chromosome from both poles in a tug-of-war that ultimately draws the chromosomes to the middle of the cell.

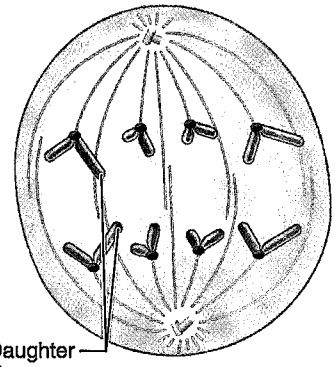
FIGURE 3.32 **The stages of mitosis.** The light micrographs show dividing lung cells from a newt. The chromosomes appear blue and the microtubules green. (The red fibers are intermediate filaments.) The schematic drawings show details not visible in the micrographs. For simplicity, only four chromosomes are drawn.

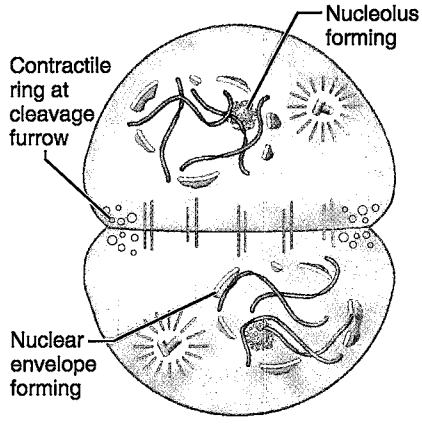












Metaphase

Metaphase is the second phase of mitosis. The chromosomes cluster at the middle of the cell, with their centromeres precisely aligned at the exact center, or *equator,* of the spindle. This arrangement of the chromosomes along a plane midway between the poles is called the *metaphase* plate.

An enzyme called *separase* cleaves cohesin, triggering separation of the chromatids at the metaphase-anaphase transition.

Anaphase

Anaphase, the third phase of mitosis, begins abruptly as the centromeres of the chromosomes split, and each chromatid now becomes a chromosome in its own right. The kinetochore fibers, moved along by motor proteins in the kinetochores, rapidly disassemble at their kinetochore ends by removing tubulin subunits, and gradually pull each chromosome toward the pole it faces. By contrast the polar microtubules slide past each other and lengthen (a process presumed to be driven by kinesin motor molecules), and push the two poles of the cell apart, causing the cell to elongate. Anaphase is easy to recognize because the moving chromosomes look V-shaped. The centromeres, which are attached to the kinetochore microtubules, lead the way, and the chromosomal "arms" dangle behind them. Anaphase is the shortest stage of mitosis; it typically lasts only a few minutes.

This process of moving and separating the chromosomes is helped by the fact that the chromosomes are short, compact bodies. Diffuse threads of extended chromatin would tangle, trail, and break, which would damage the genetic material and result in its imprecise "parceling out" to the daughter cells.

Telophase and cytokinesis

Telophase begins as soon as chromosomal movement stops. This final phase is like prophase in reverse. The identical sets of chromosomes at the opposite poles of the cell uncoil and resume their threadlike extended-chromatin form. A new nuclear envelope, derived from components of the original nuclear envelope stored temporarily in the rough ER, re-forms around each chromatin mass. Nucleoli reappear within the nuclei, and the spindle breaks down and disappears. Mitosis is now ended. The cell, for just a brief period, is binucleate (has two nuclei) and each new nucleus is identical to the original mother nucleus.

As a rule, as mitosis draws to a close, *cytokinesis* completes the division of the cell into two daughter cells. Cytokinesis occurs as a contractile ring of peripheral microfilaments forms at the *cleavage furrow* and squeezes the cells apart. Cytokinesis actually begins during late anaphase and continues through and beyond telophase.

DNA is said to specify *only* the structure of protein molecules, including the enzymes that catalyze the synthesis of all classes of biological molecules. Most of the metabolic machinery of the cell is concerned in some way with protein synthesis. This is not surprising, seeing as structural proteins constitute most of the dry cell material, and functional proteins direct almost all cellular activities. Essentially, cells are miniature protein factories that synthesize the huge variety of proteins that determine the chemical and physical nature of cells—and therefore of the whole body.

Proteins, you will recall from Chapter 2, are composed of polypeptide chains, which in turn are made up of amino acids. For purposes of this discussion, we can define a **gene** as a segment of a DNA molecule that carries instructions for creating one polypeptide chain (however, some genes specify the structure of certain varieties of RNA as their final product).

The four nucleotide bases (A, G, T, and C) are the "letters" of the genetic dictionary, and the information of DNA is found in the sequence of these bases. Each sequence of three bases, called a **triplet,** can be thought of as a "word" that specifies a particular amino acid. For example, the triplet AAA calls for the amino acid phenylalanine, and CCT calls for glycine. The sequence of triplets in each gene forms a "sentence" that tells exactly how a particular polypeptide is to be made; it specifies the number, kinds, and order of amino acids needed to build a particular polypetide. Variations in the arrangement of A, T, C, and G allow our cells to make all the different kinds of proteins needed. Even an unusually "small" gene has an estimated 210 base pairs in sequence. Because the ratio between DNA bases in the gene and amino acids in the polypeptide is 3:1, the polypeptide specified by such a gene would be expected to contain 70 amino acids. Additionally, most genes of higher organisms contain **exons,** amino acid–specifying informational sequences, separated by **introns,** which are noncoding, often repetitive, segments that range from 60 to 100,000 nucleotides. Once considered a type of "junk DNA," intron DNA is now believed to represent a genome scrapyard that provides a reservoir of ready-to-use DNA segments for genome evolution, as well as a rich source of a large variety of small RNA molecules.

The Role of RNA

By itself, DNA is like a strip of magnetic recording tape: The information it contains cannot be used without a decoding mechanism. Furthermore, most polypeptides are manufactured at ribosomes in the cytoplasm, but in interphase cells, DNA never leaves the nucleus. So, DNA requires not only a decoder, but a messenger as well. The decoding and messenger functions are carried out by RNA, the second type of nucleic acid.

As you learned in Chapter 2, RNA differs from DNA in being single stranded and in having the sugar ribose instead of deoxyribose and the base uracil (U) instead of thymine (T). Three forms of RNA typically act together to carry out DNA's instructions for polypeptide synthesis:

1. **Transfer RNA (tRNA),** small, roughly cloverleaf-shaped molecules
2. **Ribosomal RNA (rRNA),** part of the ribosomes
3. **Messenger RNA (mRNA),** relatively long nucleotide strands resembling "half-DNA" molecules, or one of the two strands of a DNA molecule coding for protein structure

All types of RNA are formed on the DNA in the nucleus in much the same way as DNA replicates itself: The DNA helix separates and one of its strands serves as a template for synthesizing a complementary RNA strand. Once formed, the RNA molecule is released from the DNA template and migrates into the cytoplasm. Its job done, the DNA simply recoils into its helical, inactive form. Approximately 2% of the nuclear DNA codes for the synthesis of short-lived mRNA, so named because it carries, from gene to ribosome, the "message" containing the instructions for building a polypeptide. DNA in the nucleolar organizer regions (mentioned previously) codes for the synthesis of rRNA, which is long-lived and stable, as is tRNA coded by other DNA sequences. Because rRNA and tRNA do not transport codes for synthesizing other molecules, they are the final products of the genes that code for them. Ribosomal RNA and tRNA act together to "translate" the message carried by mRNA.

The rules by which the base sequence of a gene is translated into an amino acid sequence are called the **genetic code.** Essentially, polypeptide synthesis involves two major steps: (1) *transcription,* in which DNA's information is encoded in mRNA, and (2) *translation,* in which the information carried by mRNA is decoded and used to assemble polypeptides. These steps are shown in simplified form in Figure 3.33 and described in more detail next.

Transcription

A transcriptionist converts a message from a recording or shorthand notes into a word-processed or electronic copy. In other words, the same information is transformed, or transferred, from one form or format to another. In cells, **transcription** involves the transfer of information from a DNA gene's base sequence to the complementary base sequence of an

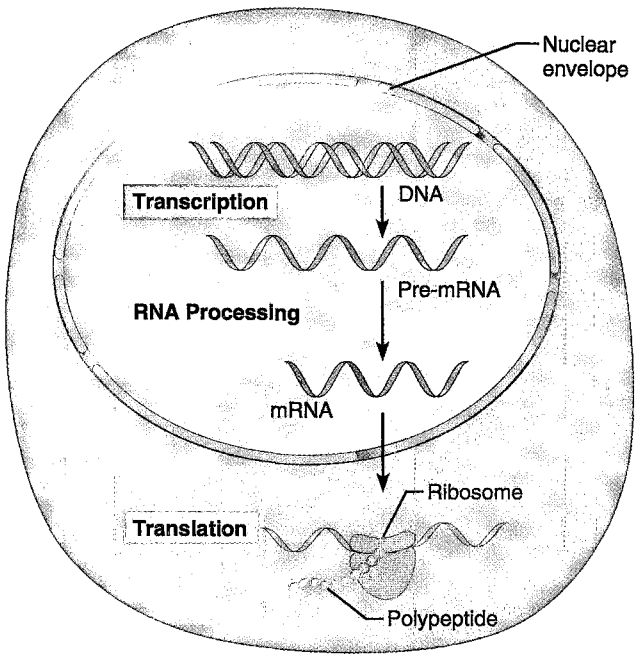


FIGURE 3.33 **Simplified scheme of information flow from the DNA gene to protein structure.** Information flows from DNA to mRNA during transcription. (The RNA is first synthesized as pre-mRNA, which is processed by enzymes before leaving the nucleus.) During translation, information flows from mRNA to synthesize a protein as amino acids are joined together in the designated order.

mRNA molecule. The form is different, but the same information is being conveyed. Once the mRNA molecule is made, it detaches and leaves the nucleus via a nuclear pore.

Let us follow the transcription process when a particular polypeptide is to be made.

Making the mRNA Complement Transcription cannot begin until a gene-activating chemical called a *transcription factor* stimulates loosening of the histones at the site-to-be of gene transcription and then binds to the promoter. The **promoter** is a special DNA sequence adjacent to the *start point* of the structural gene that specifies where mRNA synthesis starts and which DNA strand is going to serve as the *template strand* (Figure 3.34a). Once gene activation has occurred, transcription is ready to begin.

The transcription factor mediates the binding of **RNA polymerase,** the enzyme that oversees the synthesis of mRNA. Once bound, the polymerase unwinds 16 to 18 base pairs of the DNA helix at a time (Figure 3.34b). Then, using incoming ribonucleoside triphosphates as substrates, it aligns them with complementary DNA bases on the template strand and joins the RNA nucleotides together. For example, if a particular DNA triplet is AGC, the mRNA sequence synthesized at that site will be UCG. [The uncoiled DNA strand not used as a template is called the *coding strand* because the mRNA to be built will have the same (coded) sequence except for the use of U instead of T in mRNA.] As RNA polymerase elongates the mRNA strand one base at a time, it unwinds the DNA helix in front of it, and rewinds the helix behind it so that only a small region—the *DNA-RNA hybrid* (Figure 3.34b)—of the template DNA and mRNA is united at any one time. When the polymerase codes a special sequence called a *termination signal,* transcription ends and the newly formed messenger pulls off the DNA template.

For each triplet, or three-base sequence, on DNA, the corresponding three-base sequence on mRNA is called a **codon.** Since there are four kinds of RNA (or DNA) nucleotides, there are 4^3, or 64, possible codons. Three of these 64 codons are "stop signs" that call for termination of a polypeptide. All the rest code for amino acids. Because there are only about 20 amino acids, some are specified by more than one codon. This redundancy in the genetic code helps protect against problems due to transcription (and translation) errors. The genetic code and a complete codon list is found in Figure 3.35.

Editing of mRNA Although it would appear that translation can begin as soon as the mRNA is made, the process is a bit more complex. As mentioned before, mammalian DNA like ours has coding regions (exons) separated by non-protein-coding regions (introns). Because the DNA gene is transcribed sequentially, the mRNA initially made, called *pre-mRNA* or *primary transcript,* is littered with intron "junk" or "nonsense." Before the newly formed RNA can be used as a messenger, it must be edited or processed—that is, sections corresponding to introns must be removed. This job is done by *spliceosomes,* large RNA-protein complexes that snip out the introns and splice together the remaining exon-coded sections in the order in which they occurred in the DNA gene, producing the functional mRNA that directs translation at the ribosome.

Although many introns naturally degrade, some contain active segments (such as microRNAs) that can function to control, interfere with, or silence other genes. Additionally, before the edited mRNA can become involved in protein synthesis, a number of specific RNA-binding proteins, called *mRNA complex proteins,* must become associated with it. These mRNA complex proteins guide its export from the nucleus, determine its localization, translation, and stability, and check it for premature termination codons.

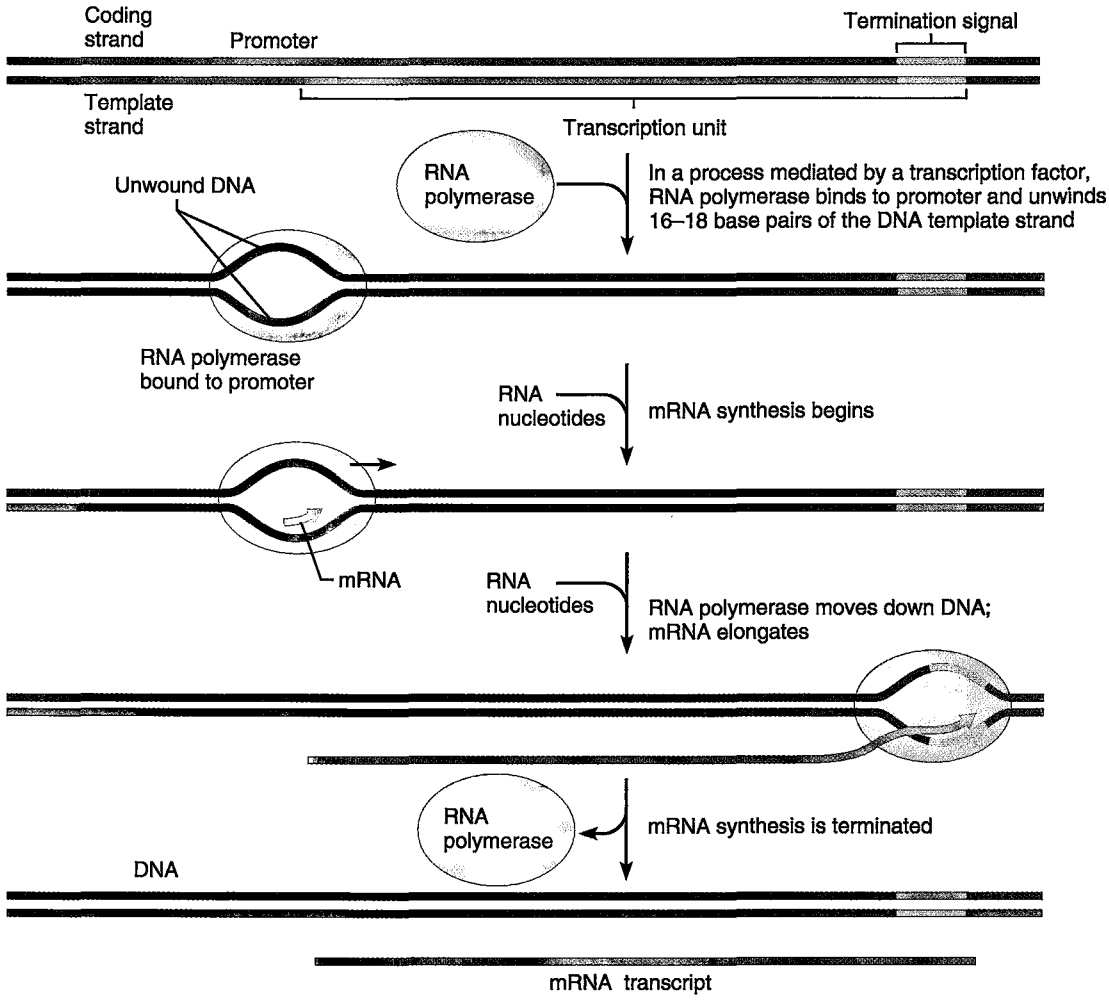

FIGURE 3.34 **An overview of transcription. (a)** Transcription of DNA occurs in these stages: binding of RNA polymerase to a DNA promoter; initiation of transcription on the template DNA strand; elongation of the mRNA chain; and termination of transcription accompanied by the release of RNA polymerase and the completed mRNA from the DNA template. **(b)** Elongation of mRNA. During mRNA elongation, RNA polymerase binds to about 30 base pairs of DNA. At any given moment, 16 to 18 base pairs of DNA are unwound, and the most recently synthesized mRNA is still hydrogen-bonded to the DNA, forming a short RNA-DNA hybrid. This hybrid is up to about 12 base pairs long.

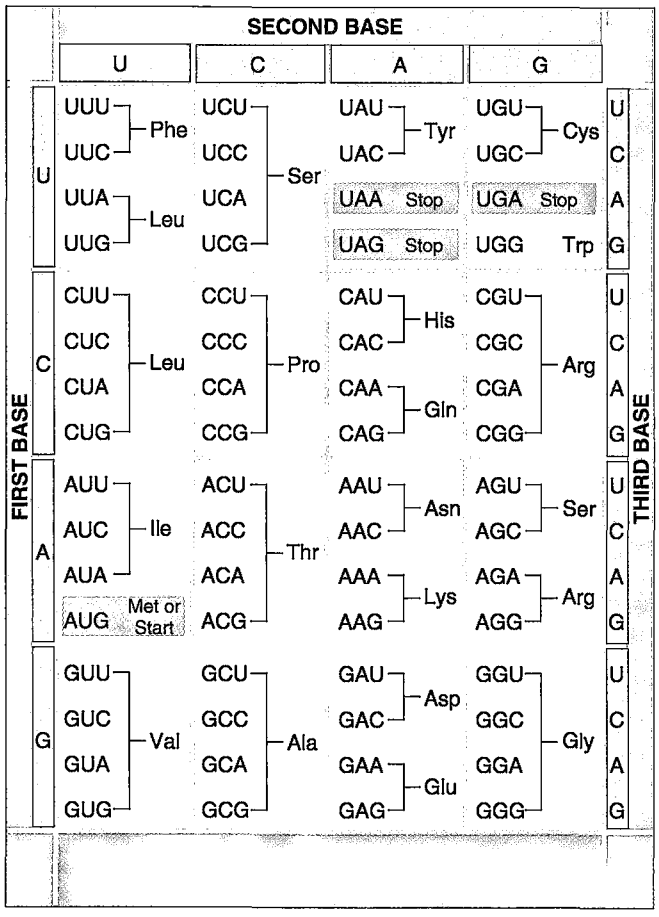

FIGURE 3.35 **The genetic code.** The three bases in an mRNA codon are designated as the first, second, and third, starting at the 5′ end. Each set of three specifies a particular amino acid, represented here by a three-letter abbreviation (see list below). The codon AUG (which specifies the amino acid methionine) is the usual start signal for protein synthesis. The word *stop* indicates the codons that serve as signals to terminate protein synthesis.

Abb.*	Amino acid	Abb.*	Amino acid
Ala	alanine	Leu	leucine
Arg	arginine	Lys	lysine
Asn	asparagine	Met	methionine
Asp	aspartic acid	Phe	phenylalanine
Cys	cysteine	Pro	proline
Glu	glutamic acid	Ser	serine
Gln	glutamine	Thr	threonine
Gly	glycine	Trp	tryptophan
His	histidine	Tyr	tyrosine
Ile	isoleucine	Val	valine

* Abbreviation for the amino acid

Translation

A translator takes a message in one language and restates it in another. In the **translation** step of protein synthesis, the language of nucleic acids (base sequence) is translated into the language of proteins (amino acid sequence). The process of translation occurs in the cytoplasm and involves the mRNAs, tRNAs, and rRNAs mentioned above (Figure 3.36).

When it reaches the cytoplasm, the mRNA molecule carrying instructions for a particular protein binds to a small ribosomal subunit by base pairing to rRNA. Then tRNA comes into the picture, its job being to *transfer* amino acids, dissolved in the cytosol, to the ribosome. There are approximately 45 different types of tRNA, each capable of binding with a specific amino acid. The attachment process is controlled by a synthetase enzyme and is activated by ATP. Once its amino acid is loaded, the tRNA migrates to the ribosome, where it maneuvers the amino acid into the proper position, as specified by the mRNA codons.

Shaped like a handheld drill, tRNA is well suited to its dual function. The amino acid is bound to one end of tRNA, at a region called the stem. At the other end, the head, is its **anticodon** (an″ti-ko′don), a three-base sequence complementary to the mRNA codon calling for the amino acid carried by that particular tRNA. Anticodons form hydrogen bonds with complementary codons, meaning that a tRNA is the link between the language of nucleic acids and the language of proteins. Thus, if the mRNA codon is UUU, which specifies phenylalanine, the tRNAs carrying phenylalanine will have the anticodon AAA, which can bind to the correct codons.

The ribosome is more than just a passive attachment site for mRNA and tRNA. Besides its binding site for mRNA, it has three binding sites for tRNA: an A (aminoacyl) site for incoming tRNA, a P (peptidyl) site for the tRNA holding the growing polypeptide chain, and an E (exit) site for outgoing tRNA. Like a vise, the ribosome holds the tRNA and mRNA close together to coordinate the coupling of codons and anticodons, and positions the next (incoming) amino acid for addition to the growing polypeptide chain.

Initiation of translation requires that a number of events occur. The newly formed mRNA attaches to the small ribosomal subunit by a *leader sequence* of bases that functions only to make this attachment. As a methionine-charged **initiator tRNA** also binds, a large ribosomal subunit attaches to the smaller one, forming a functional ribosome, with the mRNA positioned in the "groove" between the two ribosomal particles. The ribosome scans along the leader sequence until it reaches the "start" codon (AUG) which is recognized and bound by the anticodon (UAC) of the initiator tRNA. This initiation process requires the help of a number of initiation factors and is energized by GTP.

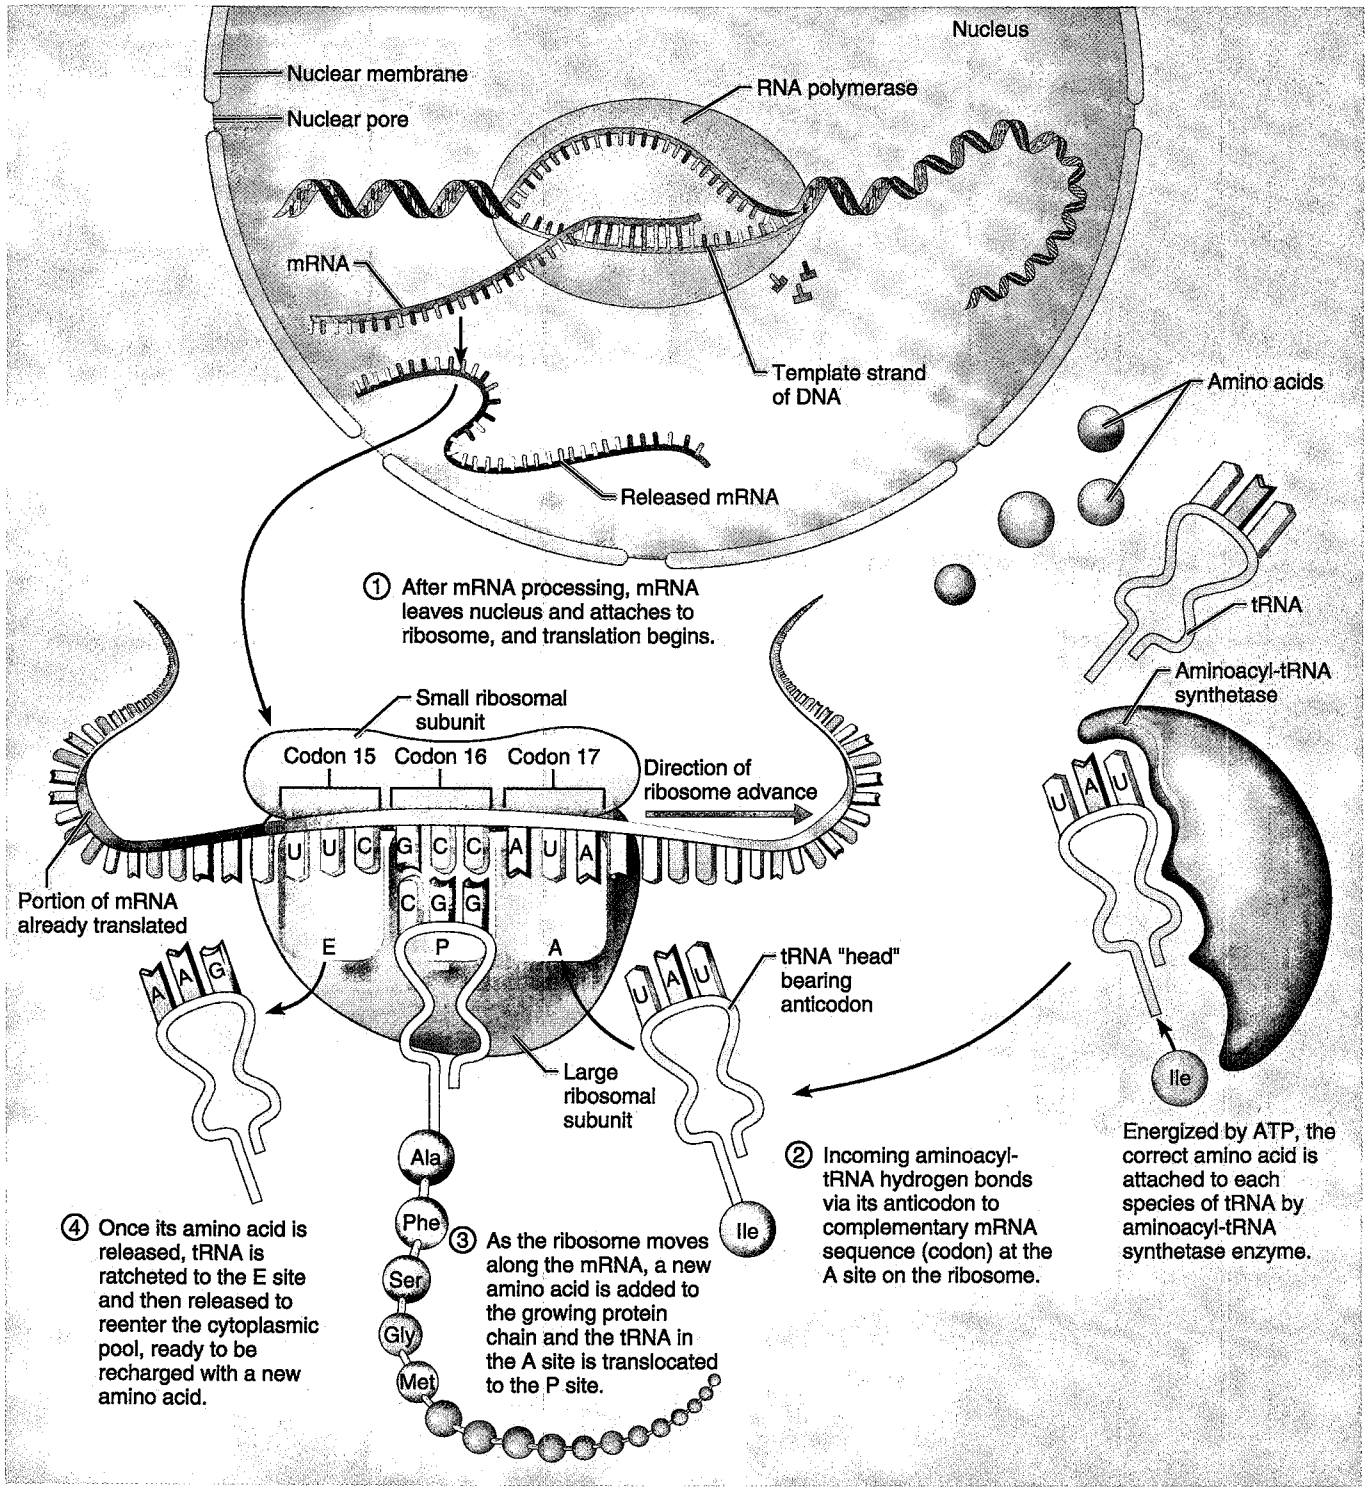

FIGURE 3.36 **Translation.** Once transcription of a DNA segment, or gene, has occurred in the nucleus and a complementary mRNA is formed, translation can begin. ① The messenger RNA attaches to a small ribosomal subunit in the cytoplasm. ② Transfer RNA transports its amino acid to the mRNA strand and recognizes the mRNA codon calling for its amino acid by base pairing to it (via its anticodon) at the A site. ③ The ribosome moves along the mRNA strand and each codon is read in sequence. As each successive amino acid is bound to the next by a peptide bond, its tRNA is translocated to the P site. ④ Once its amino acid is released, tRNA is ratcheted from the P site to the E site and then released. The polypeptide is released when the stop codon is read.

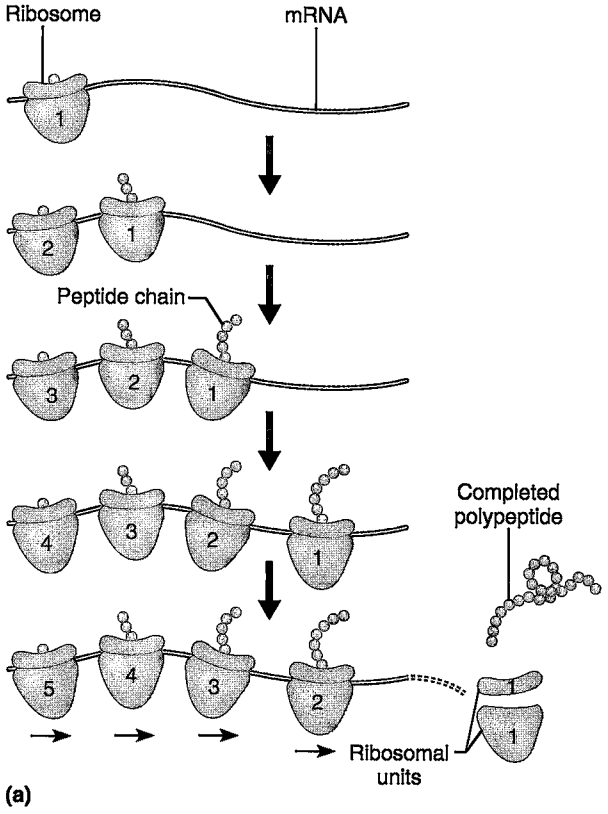

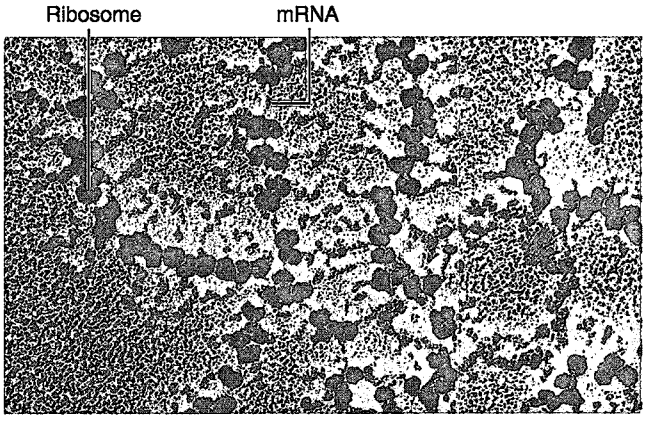

FIGURE 3.37 **Polyribosomes.** Each polyribosome consists of one strand of mRNA that is being read by several ribosomes simultaneously. **(a)** In this diagram, the mRNA is moving through the ribosome to the left and the "oldest" functional ribosome is farthest to the right. Polyribosome arrays allow a single strand of mRNA to produce hundreds of the same polypeptide molecules in a short time. **(b)** Micrograph (120,000×).

When the initiator tRNA binds to the mRNA, it occupies the P site on the ribosome and the A and E sites are vacant. Now the ribosome slides the mRNA strand along, bringing the next codon into position to be "read" by an aminoacyl-tRNA coming into the A site. It is at this point that the ribosome does a little "proofreading" to make sure of the codon-anticodon match. That accomplished, a catalytic component in the large ribosomal particle peptide-bonds the amino acid of the initiator tRNA to that of the tRNA at the A site. The ribosome then translocates the tRNA that is now carrying two amino acids to the P site, and ratchets the initiator tRNA to the E site, from which it moves away from the ribosome.

This kind of "musical chairs" situation continues: the peptidyl-tRNAs transferring their polypeptide cargo to the aminoacyl-tRNAs, and then the P-site-to-E-site, and A-site-to-P-site movements of the tRNAs (Figure 3.36). As mRNA is progressively read, its initial portion passes through the ribosome and may become attached successively to several other ribosomes, all reading the same message simultaneously and sequentially. Such a multiple ribosome-mRNA complex is called a *polyribosome* (Figure 3.37), and it provides an efficient system for producing many copies of the same protein. The mRNA strand continues to be read sequentially until its last codon, the *stop codon* (one of UGA, UAA, or UAG) enters the ribosomal groove. The stop codon is the "period" at the end of the mRNA sentence that tells the ribosome that translation of that mRNA is finished. The completed polypeptide chain is then released from the ribosome (Figure 3.37), and the ribosome separates into its two subunits.

The genetic information of a cell is translated into the production of proteins via a sequence of information transfer that is completely directed by complementary base pairing (Figure 3.38). Thus, the transfer of information goes from DNA base sequence (triplets) to the complementary base sequence of mRNA (codons) and then to the tRNA base sequence (anticodons), which replicates that of DNA except for the substitution of uracil (U) for thymine (T).

Other Roles of DNA

The story of DNA doesn't end with the production of proteins encoded by exons. Scientists are finding that other intron or "junk" DNA actually codes for a surprising variety of active RNA species, including:

- **Antisense RNAs,** made on the DNA strand complementary to the protein coding strand, can intercept and bind to the protein-coding mRNA strand and prevent it from being translated into protein.

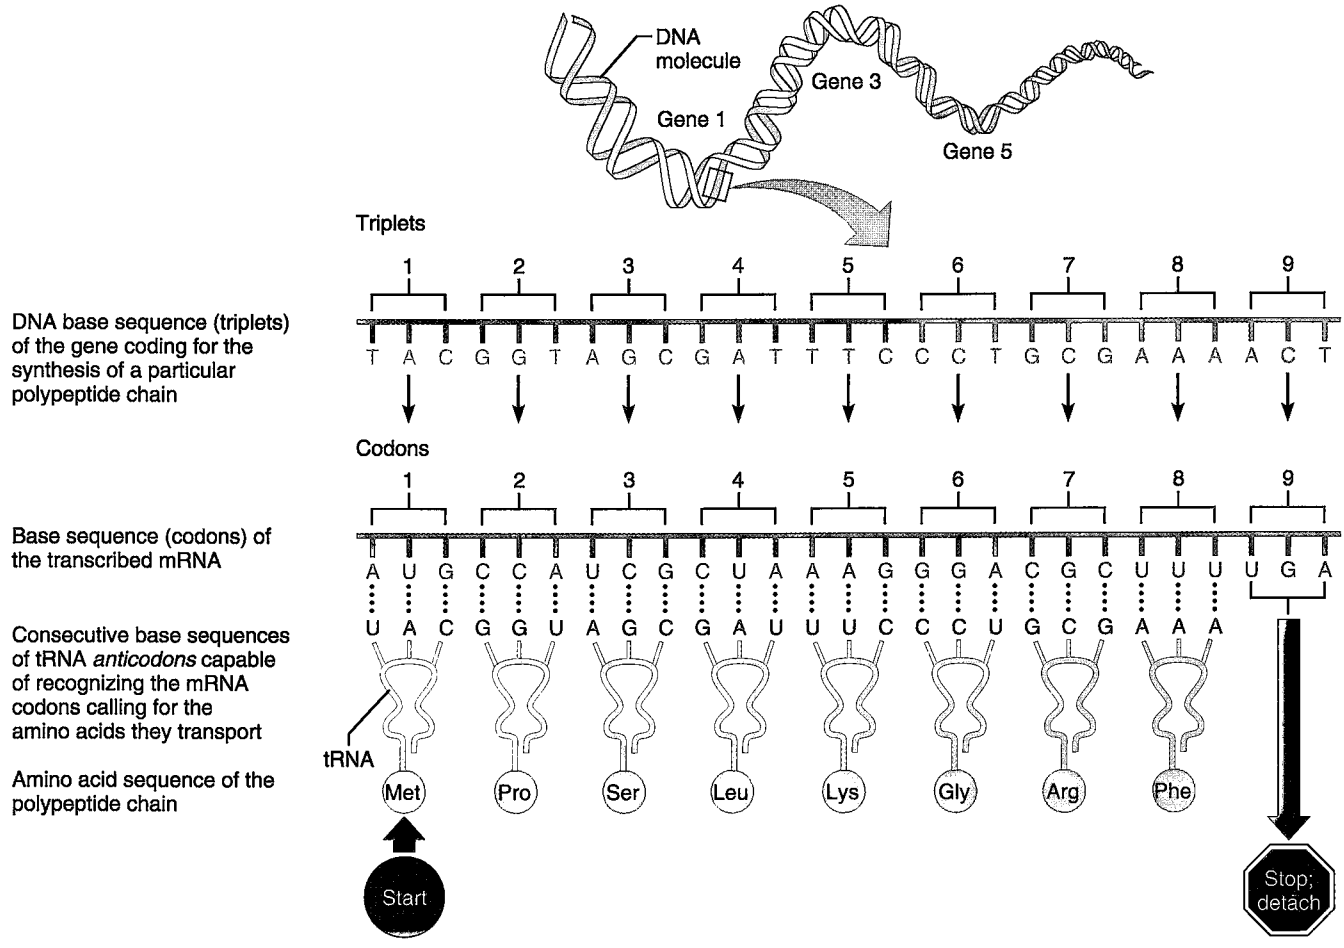

FIGURE 3.38 **Information transfer from DNA to RNA.** Information is transferred from the DNA of the gene to the complementary messenger RNA molecule, whose codons are then "read" by transfer RNA anticodons. Notice that the "reading" of the mRNA by tRNA anticodons reestablishes the base (triplet) sequence of the DNA genetic code (except that T is replaced by U).

- **MicroRNAs** are small RNAs that can use RNA interference machinery to interfere with and suppress mRNAs made by certain exons, thus effectively silencing them.
- **Riboswitches** are folded RNAs that code, like mRNA, for a particular protein. What sets them apart from other mRNAs is a region that acts as a switch to turn protein synthesis on or off in response to specific changes in the environment, such as temperature shifts or changes in the concentration of vitamins, amino acids, or other small molecules in the cell. When it senses these changes, the riboswitch changes shape, thereby stopping or starting production of the protein it specifies.

We still have much to learn about these versatile RNA species that arise from intron and "junk" DNA and appear to play a role in heredity. This topic is saved for Chapter 29.

Cytosolic Protein Degradation

To carry out their physiological roles, proteins must be in the right place at the right time and in the right amounts. Like everything else, proteins outlive their usefulness and are eventually degraded. Organelle proteins are digested by lysosomes, but lysosomal enzymes do not have access to misfolded, damaged, or unneeded soluble proteins in the cytosol that need to be disposed of. For example, these might include some proteins used only in cell division, or short-lived transcription factors. To prevent such proteins from accumulating while preventing wholesale destruction of virtually all soluble proteins by the cytosolic enzymes, doomed proteins are marked for attack (proteolysis) by attachment of proteins called *ubiquitins* (u-bĭ'kwĭ-tin) by ubiquitin ligases in an ATP-dependent reaction. The tagged proteins are hydrolyzed to small peptides by soluble enzymes or by

giant "waste disposal" complexes composed of protein-digesting enzymes called *proteasomes,* and the ubiquitin is recycled. (Structurally, proteasomes are remarkably similar to one variety of molecular chaperone and may in fact be members of that protein group.)

Extracellular Materials

Extracellular materials are any substances contributing to body mass that are found outside the cells. One class of extracellular materials is *body fluids,* mainly interstitial fluid, blood plasma, and cerebrospinal fluid. These fluids are important transport and dissolving media. *Cellular secretions,* also extracellular materials, include substances that aid in digestion (intestinal and gastric fluids) and some that act as lubricants (saliva, mucus, and serous fluids).

By far the most abundant extracellular material is the *extracellular matrix.* Most body cells are in contact with a jellylike substance composed of proteins and polysaccharides. These molecules are secreted by the cells and self-assemble into an organized mesh in the extracellular space, where they serve as a universal "cell glue" that helps to hold body cells together. The extracellular matrix is particularly abundant in connective tissues—so much so, in some cases, that it (rather than living cells) accounts for the bulk of that tissue type. Depending on the structure to be formed, the extracellular matrix in connective tissue ranges from soft to rock-hard.

Developmental Aspects of Cells

We all begin life as a single cell, the fertilized egg, from which arise all the cells of our body. Very early in development, cells begin to specialize; some become liver cells, some nerve cells, and so on. All our cells carry the same genes, so how can one cell be so different from another? This is a fascinating question. Apparently, cells in various regions of the embryo are exposed to different chemical signals that channel them into specific pathways of development. When the embryo consists of just a few cells (these are the embryonic *stem cells* you keep hearing about) the major signals may be nothing more than slight differences in oxygen and carbon dioxide concentrations between the more superficial and the deeper cells. But as development continues, cells release chemicals that influence development of neighboring cells by triggering processes that switch some genes "off." Some genes are active in all cells. For example, genes for protein and ATP synthesis are "on" in all cells, but genes for synthesizing the enzymes needed to produce thyroxine are "on" only in cells that are going to be part of the thyroid gland. Hence, the secret of cell specialization lies in the kinds of proteins made and reflects differential gene activation in different cell types.

Cell specialization leads to *structural* variation—different organelles come to predominate in different cells. For example, muscle cells make large amounts of actin and myosin, and their cytoplasm fills with microfilaments. Liver and phagocytic cells produce more lysosomes. The development of specific and distinctive features in cells is called **cell differentiation.**

During early development, cell death and destruction are normal events. Nature takes few chances. More cells than are needed are produced and excesses are eliminated later in a type of programmed cell death called **apoptosis** (ap"o-to'sis; "falling away"). This process of controlled cellular suicide eliminates cells that are stressed, unneeded, excessive, or aged. In response to damaged macromolecules within the cell or to some extracellular signal, a series of intracellular enzymes is activated. These enzymes, called *caspases,* destroy the cell's DNA, cytoskeleton, and so on, producing a quick, neat death. The apoptotic cell shrinks without leaking its contents into the surrounding tissue, detaches from other cells, and rounds up. Because the dying cell releases the chemical lysophosphatidylcholine, which attracts macrophages, and sprouts "eat me" signals, it is immediately phagocytized. Cancer cells do not undergo apoptosis, but oxygen-starved cells do so excessively (heart-muscle and brain cells during heart attacks and strokes, for example). Apoptosis is particularly common in the developing nervous system and is also responsible for "carving out" fingers and toes from their embryonic precursors.

Most organs are well formed and functional long before birth, but the body continues to grow and enlarge by forming new cells throughout childhood and adolescence. Once adult size has been reached, cell division is important mainly to replace short-lived cells and repair wounds.

During young adulthood, cell numbers remain fairly constant. However, local changes in the rate of cell division are common. For example, when one is anemic, bone marrow undergoes **hyperplasia** (hi"per-pla'ze-ah), or accelerated growth (*hyper* = over; *plas* = grow), so that red blood cells are produced at a faster rate. If the anemia is remedied, the excessive marrow activity ceases. **Atrophy** (at'ro-fe), a decrease in size of an organ or body tissue, can result from loss of normal stimulation. Muscles that lose their nerve supply atrophy and waste away, and lack of exercise leads to thinned, brittle bones.

Cell aging occurs and it accounts for most problems associated with old age. Cell aging is a complicated process with many causes. The *wear-and-tear theory* attributes aging to little chemical insults and formation of free radicals, both of which have cumulative effects. For example, environmental toxins such as pesticides, alcohol, and bacterial toxins may damage cell membranes, poison enzyme systems, or cause "mistakes" in DNA replication. Temporary lack of oxygen, which occurs increasingly with age as our blood vessels clog with fatty materials, leads to accelerated rates of cell death throughout the body. Most free radicals are produced in the mitochondria, because these organelles have the highest metabolic rate. This finding implies that diminished energy production by radical-damaged mitochondria, due perhaps to an increasing burden of mutations in mitochondrial DNA, weakens (and ages) cells. X rays and other types of radiation, and some chemicals, also generate huge numbers of free radicals, which can overwhelm the peroxisomal enzymes. Vitamins C and E act as antioxidants in the body and may help to prevent excessive free radical formation. With age, glucose (blood sugar) becomes party to cross-linking proteins together, a condition that severely disrupts protein function and accelerates the course of arteriosclerosis.

Another theory attributes cell aging to progressive disorders in the immune system. According to this theory, cell damage results from (1) autoimmune responses, which means the immune system turns against one's own tissues, and (2) a progressive weakening of the immune response, so that the body is less and less able to get rid of cell-damaging pathogens.

Perhaps the most widely accepted theory of cell aging is the *genetic theory,* which suggests that cessation of mitosis and cell aging are "programmed into our genes." One interesting notion here is that a *telomere clock* determines the number of times a cell can divide. **Telomeres** (*telo* = end; *mer* = piece) are strings of nucleotides that cap the end of chromosomes, protecting them from fraying or fusing with other chromosomes. In human telomeres, the base sequence TTAGGG is repeated a thousand times or more (like a DNA stutter). Though telomeres carry no genes, they appear to be vital for chromosomal survival, because each time DNA is replicated, 50 to 100 of the end nucleotides are lost and the telomeres get a bit shorter. When telomeres reach a certain minimum length, the stop-division signal is given. The idea that cell longevity depends on telomere integrity was supported by the discovery of *telomerase,* an enzyme that protects telomeres from degrading. Pegged as the "immortality enzyme," telomerase is found in germ line cells (cells that give rise to sperm and ova), but it is barely detectable or absent in other adult cell types.

■ ■ ■

We have described here the structure and function of the generalized cell. One of the wonders of the cell is the disparity between its minute size and its extraordinary activity, which reflects the amazing diversity of its organelles. The evidence for division of labor and functional specialization among organelles is inescapable. Only ribosomes synthesize proteins, while protein packaging is the bailiwick of the Golgi apparatus. Membranes compartmentalize most organelles, allowing them to work without hindering or being hindered by other cell activities, and the plasma membrane regulates molecular traffic across the cell's boundary. Now that you know what cells have in common, you are ready to explore how they differ in the various body tissues.

Related Clinical Terms

Anaplasia (an"ah-pla'ze-ah; *an* = without, not; *plas* = to grow) Abnormalities in cell structure; for example, cancer cells typically lose the appearance of the parent cells and come to resemble undifferentiated or embryonic cells.

Dysplasia (dis-pla'ze-ah; *dys* = abnormal) A change in cell size, shape, or arrangement due to chronic irritation or inflammation (infections, etc.).

Hypertrophy (hi-per'tro-fe) Growth of an organ or tissue due to an increase in the size of its cells. Hypertrophy is a normal response of skeletal muscle cells when they are challenged to lift excessive weight; differs from hyperplasia, which is an increase in size due to an increase in cell number.

Liposomes (lip'o-sōmz) Hollow microscopic sacs formed of phospholipids that can be filled with a variety of drugs. Serve as multipurpose vehicles for drugs, genetic material, and cosmetics.

Mutation A change in DNA base sequence leading to incorporation of incorrect amino acids in particular positions in the resulting protein; the affected protein may remain unimpaired or may function abnormally or not at all, leading to disease.

Necrosis (nĕ-kro'sis; *necros* = death; *osis* = process) Death of a cell or group of cells due to injury or disease. Acute injury causes the cells to swell and burst, and induces the inflammatory response. (This is *uncontrolled* cell death, in contrast to apoptosis described in the text.)

Chapter Summary

Media study tools that could provide you additional help in reviewing specific key topics of Chapter 3 are referenced below.
IP = *InterActive Physiology*

Overview of the Cellular Basis of Life (pp. 65–66)

1. All living organisms are composed of cells—the basic structural and functional units of life. Cells vary widely in both shape and size.

2. The principle of complementarity states that the biochemical activity of cells reflects the operation of organelles.

3. The generalized cell is a concept that typifies all cells. The generalized cell has three major regions—the nucleus, cytoplasm, and plasma membrane.

The Plasma Membrane: Structure (pp. 66–70)

1. The plasma membrane encloses cell contents, mediates exchanges with the extracellular environment, and plays a role in cellular communication.

The Fluid Mosaic Model (pp. 67–69)

2. The fluid mosaic model depicts the plasma membrane as a fluid bilayer of lipids (phospholipids, cholesterol, and glycolipids) within which proteins are inserted.

3. The lipids have both hydrophilic and hydrophobic regions that organize their aggregation and self-repair. The lipids form the structural part of the plasma membrane.

4. Most proteins are integral transmembrane proteins that extend entirely through the membrane. Some, appended to the integral proteins, are peripheral proteins.

5. Proteins are responsible for most specialized membrane functions: some are enzymes, some are receptors, and others mediate membrane transport functions. Externally facing glycoproteins contribute to the glycocalyx.

Specializations of the Plasma Membrane (p. 69)

6. Microvilli are extensions of the plasma membrane that increase its surface area for absorption.

7. Membrane junctions join cells together and may aid or inhibit movement of molecules between or past cells. Tight junctions are impermeable junctions; desmosomes mechanically couple cells into a functional community; gap junctions allow joined cells to communicate.

The Plasma Membrane: Functions (pp. 70–84)

Membrane Transport (pp. 70–81)

1. The plasma membrane acts as a selectively permeable barrier. Substances move across the plasma membrane by passive processes, which depend on the kinetic energy of molecules or on pressure gradients, and by active processes, which depend on the use of cellular energy (ATP).

2. Diffusion is the movement of molecules (driven by kinetic energy) down a concentration gradient. Fat-soluble solutes can diffuse directly through the membrane by dissolving in the lipid.

3. Facilitated diffusion is the passive movement of certain solutes across the membrane either by their binding with a membrane carrier protein or by their moving through a membrane channel. As with other diffusion processes, it is driven by kinetic energy, but the carriers and channels are selective.

4. Osmosis is the diffusion of a solvent, such as water, through a selectively permeable membrane. Water diffuses through membrane pores (aquaporins) or directly through the lipid portion of the membrane from a solution of lesser osmolarity to a solution of greater osmolarity.

5. The presence of solutes unable to permeate the plasma membrane leads to changes in cell tone that may cause the cell to swell or shrink. Net osmosis ceases when the solute concentration on both sides of the plasma membrane reaches equilibrium.

6. Solutions that cause a net loss of water from cells are hypertonic; those causing net water gain are hypotonic; those causing neither gain nor loss of water are isotonic.

7. Filtration occurs when a filtrate is forced across a membrane by hydrostatic pressure. It is nonselective and limited only by pore size. The pressure gradient is the driving force.

8. Active transport (solute pumping) depends on a carrier protein and ATP. Substances transported move against concentration or electrical gradients. In primary active transport, such as that provided by the Na^+-K^+ pump, ATP directly provides the energy. In secondary active transport, the energy of an ion gradient (produced by a primary active transport process) is used to transport a substance passively. Many active transport systems are coupled; cotransported substances move in either the same (symport) or opposite (antiport) directions across the membrane.

9. Vesicular transport also requires ATP. Exocytosis, which uses SNAREs to anchor the vesicles to the plasma membrane, ejects substances (hormones, wastes, secretions) from the cell. Endocytosis brings substances into the cell in protein-coated vesicles. If the substance is particulate, the process is called phagocytosis; if the substance is dissolved molecules, the process is pinocytosis. Receptor-mediated endocytosis is selective; engulfed particles attach to receptors on the membrane before endocytosis occurs.

10. Most endocytosis (and transcytosis) is mediated by clathrin-coated vesicles. Caveolin-coated vesicles engulf some substances but appear to be more important as sites that accumulate receptors involved in cell signaling. Coatomer-coated vesicles mediate substance (vesicular) trafficking within the cell.

Generating and Maintaining a Resting Membrane Potential (pp. 81–83)

11. All cells in the resting stage exhibit a voltage across their membrane, called the resting membrane potential. Because of the membrane potential, both concentration and electrical gradients determine the ease of an ion's diffusion.

12. The resting membrane potential is generated by concentration gradients of and differential permeability of the plasma membrane to ions, particularly potassium ions. Sodium is in high extracellular–low intracellular concentration, and the membrane is poorly permeable to it. Potassium is in high concentration in the cell and low concentration in the extracellular fluid. The membrane is more permeable to potassium than to sodium. Protein anions in the cell are too large to cross the membrane and Cl^-, the main anion in extracellular fluid, is repelled by the negative charge on the inner membrane face.

13. Essentially, a negative membrane potential is established when the movement of K^+ out of the cell equals K^+ movement into the cell. Na^+ movements across the membrane contribute minimally to establishing the membrane potential. The greater outward diffusion of potassium (than inward diffusion of sodium) leads to a charge separation at the membrane (inside negative). This charge separation is maintained by the operation of the sodium-potassium pump.

IP Nervous System I; Topics: Ion Channels, pp. 3, 8, 9; The Membrane Potential, pp. 1–17.

Cell-Environment Interactions (pp. 83–84)

14. Cells interact directly and indirectly with other cells. Indirect interactions involve extracellular chemicals carried in body fluids or forming part of the extracellular matrix.

15. Molecules of the glycocalyx are intimately involved in cell-environment interactions. Most are cell adhesion molecules or membrane receptors.

16. Activated membrane receptors act as catalysts, regulate channels, or, like G protein–linked receptors, act through second messengers such as cyclic AMP and Ca^{2+}. Ligand binding results in changes in protein structure or function within the targeted cell.

The Cytoplasm (pp. 84–95)

1. The cytoplasm, the cellular region between the nuclear and plasma membranes, consists of the cytosol (fluid cytoplasmic environment), inclusions (nonliving nutrient stores—lipid droplets, glycosomes—pigment granules, crystals, etc.), and cytoplasmic organelles.

Cytoplasmic Organelles (pp. 84–93)

2. The cytoplasm is the major functional area of the cell. These functions are mediated by cytoplasmic organelles.

3. Mitochondria, organelles limited by a double membrane, are sites of ATP formation. Their internal enzymes carry out the oxidative reactions of cellular respiration.

4. Ribosomes, composed of two subunits containing ribosomal RNA and proteins, are the sites of protein synthesis. They may be free or attached to membranes.

5. The rough endoplasmic reticulum is a ribosome-studded membrane system. Its cisternae act as sites for protein modification. Its external face acts in phospholipid synthesis. Vesicles pinched off from the ER transport the proteins to other cell sites.

6. The smooth endoplasmic reticulum synthesizes lipid and steroid molecules. It also acts in fat metabolism and in drug detoxification. In muscle cells, it is a calcium ion depot.

7. The Golgi apparatus is a membranous system close to the nucleus that packages protein secretions for export, packages enzymes into lysosomes for cellular use, and modifies proteins destined to become part of cellular membranes.

8. Lysosomes are membranous sacs of acid hydrolases packaged by the Golgi apparatus. Sites of intracellular digestion, they degrade worn-out organelles, and tissues that are no longer useful, and release ionic calcium from bone.

9. Peroxisomes are membranous sacs containing oxidase enzymes that protect the cell from the destructive effects of free radicals and other toxic substances by converting them first to hydrogen peroxide and then water.

10. The cytoskeleton includes microfilaments, intermediate filaments, and microtubules. Microfilaments, formed of contractile proteins, are important in cell motility or movement of cell parts. Microtubules organize the cytoskeleton and are important in intracellular transport. Motility functions involve motor proteins. Intermediate filaments help cells resist mechanical stress and connect other elements.

Cellular Extensions (pp. 93–95)

11. Centrioles form the mitotic spindle and are the basis of cilia and flagella.

The Nucleus (pp. 95–97)

1. The nucleus is the control center of the cell. Most cells have a single nucleus. Without a nucleus, a cell cannot divide or synthesize more proteins; thus, it is destined to die.

2. The nucleus is surrounded by the nuclear envelope, a double membrane penetrated by fairly large pores.

3. Nucleoli are nuclear sites of ribosome subunit synthesis.

4. Chromatin is a complex network of slender threads containing histone proteins and DNA. The chromatin units are called nucleosomes. When a cell begins to divide, the chromatin coils and condenses, forming chromosomes.

Cell Growth and Reproduction (pp. 97–111)

The Cell Life Cycle (pp. 97–101)

1. The cell life cycle is the series of changes that a cell goes through from the time it is formed until it divides.

2. Interphase is the nondividing phase of the cell life cycle. Interphase consists of G_1, S, and G_2 subphases. During G_1, the cell grows and centriole replication begins; during the S phase, DNA replicates; and during G_2, the final preparations for division are made. Many checkpoints occur during interphase at which the cell gets the go-ahead signal to go through mitosis or is prevented from continuing to mitosis.

3. DNA replication occurs before cell division; it ensures that all daughter cells have identical genes. The DNA helix uncoils, and each DNA nucleotide strand acts as a template for the formation of a complementary strand. Base pairing provides the guide for the proper positioning of nucleotides.

4. The products of the semiconservative replication of a DNA molecule are two DNA molecules identical to the parent molecule, each formed of one "old" and one "new" strand.

5. Cell division, essential for body growth and repair, occurs during the M phase. Cell division is stimulated by certain chemicals (including growth factors and some hormones) and increasing cell size. Lack of space and inhibitory chemicals deter cell division. Cell division is regulated by cyclin-Cdk complexes, of which one example is MPF. Cell division consists of two distinct phases: mitosis and cytokinesis.

6. Mitosis, consisting of prophase, metaphase, anaphase, and telophase, results in the parceling out of the replicated chromosomes to two daughter nuclei, each genetically identical to the mother nucleus. Cytokinesis, which begins late in mitosis, divides the cytoplasmic mass into two parts.

Protein Synthesis (pp. 101–109)

7. A gene is defined as a DNA segment that provides the instructions for the synthesis of one polypeptide chain. Since the major structural materials of the body are proteins, and all enzymes are proteins, this amply covers the synthesis of all biological molecules.

8. The base sequence of exon DNA provides the information for protein structure. Each three-base sequence (triplet) calls for a particular amino acid to be built into a polypeptide chain.

9. The RNA molecules acting in protein synthesis are synthesized on single strands of the DNA template. RNA nucleotides are joined following base-pairing rules.

10. Ribosomal RNA forms part of the protein synthesis sites; messenger RNA carries instructions for making a polypeptide chain from the DNA to the ribosomes;

transfer RNA ferries amino acids to the ribosomes and recognizes codons on the mRNA strand specifying its amino acid.

11. Protein synthesis involves (1) transcription, synthesis of a complementary mRNA, and (2) translation, "reading" of the mRNA by tRNA and peptide bonding of the amino acids into the polypeptide chain. Ribosomes coordinate translation.

Other Roles of DNA (pp. 109–110)

12. Intron and other junk DNA encodes many RNA species that may interfere with or promote the function of specific genes.

Cytosolic Protein Degradation (pp. 110–111)

13. Soluble proteins that are damaged or no longer needed are targeted for destruction by attachment of ubiquitin. Such proteins are degraded by cytosolic enzymes or proteasomes.

Extracellular Materials (p. 111)

1. Extracellular materials are substances found outside the cells. These include body fluids, cellular secretions, and extracellular matrix. Extracellular matrix is particularly abundant in connective tissues.

Developmental Aspects of Cells (pp. 111–112)

1. The first cell of an organism is the fertilized egg. Early in development, cell specialization begins and reflects differential gene activation.

2. Apoptosis is programmed cell death. Its function is to dispose of damaged or unnecessary cells.

3. During adulthood, cell numbers remain fairly constant; cell division occurs primarily to replace lost cells.

4. Cellular aging may reflect chemical insults, progressive disorders of immunity, or a genetically programmed decline in the rate of cell division with age.

Review Questions

Multiple Choice/Matching

(Some questions have more than one correct answer. Select the best answer or answers from the choices given.)

1. The smallest unit capable of life by itself is (a) the organ, (b) the organelle, (c) the tissue, (d) the cell, (e) the nucleus.

2. The major types of lipid found in the plasma membranes are (choose two) (a) cholesterol, (b) triglycerides, (c) phospholipids, (d) fat-soluble vitamins.

3. Membrane junctions that allow nutrients or ions to flow from cell to cell are (a) desmosomes, (b) gap junctions, (c) tight junctions, (d) all of these.

4. A person drinks a six-pack of beer and has to make several trips to the bathroom. This increase in urination reflects an increase in what process occurring in the kidneys? (a) diffusion, (b) osmosis, (c) solute pumping, (d) filtration.

5. The term used to describe the type of solution in which cells will lose water to their environment is (a) isotonic, (b) hypertonic, (c) hypotonic, (d) catatonic.

6. Osmosis always involves (a) a selectively permeable membrane, (b) a difference in solvent concentration, (c) diffusion, (d) active transport, (e) a, b, and c.

7. A physiologist observes that the concentration of sodium inside a cell is decidedly lower than that outside the cell. Yet sodium does diffuse easily across the plasma membrane of such cells when they are dead, but *not* when they are alive. Which of the following terms applies best to this cellular function that is lacking in dead cells? (a) osmosis, (b) diffusion, (c) active transport (solute pumping), (d) dialysis.

8. The solute-pumping type of active transport is accomplished by (a) exocytosis, (b) phagocytosis, (c) electrical forces in the cell membrane, (d) conformational-positional changes in carrier molecules in the plasma membrane.

9. The endocytotic process in which a sampling of particulate matter is engulfed and brought into the cell is called (a) phagocytosis, (b) fluid-phase endocytosis, (c) exocytosis.

10. The nuclear substance composed of histone proteins and DNA is (a) chromatin, (b) the nucleolus, (c) nuclear sap, or nucleoplasm, (d) nuclear pores.

11. The information sequence that determines the nature of a protein is the (a) nucleotide, (b) gene, (c) triplet, (d) codon.

12. Mutations may be caused by (a) X rays, (b) certain chemicals, (c) radiation from ionizing radioisotopes, (d) all of these.

13. The phase of mitosis during which centrioles reach the poles and chromosomes attach to the spindle is (a) anaphase, (b) metaphase, (c) prophase, (d) telophase.

14. Final preparations for cell division are made during the life cycle subphase called (a) G_1, (b) G_2, (c) M, (d) S.

15. The RNA synthesized on one of the DNA strands is (a) mRNA, (b) tRNA, (c) rRNA, (d) all of these.

16. The RNA species that carries the coded message, specifying the sequence of amino acids in the protein to be made, from the nucleus to the cytoplasm is (a) mRNA, (b) tRNA, (c) rRNA, (d) all of these.

17. If DNA has a sequence of AAA, then a segment of mRNA synthesized on it will have a sequence of (a) TTT, (b) UUU, (c) GGG, (d) CCC.

18. A nerve cell and a lymphocyte are presumed to differ in their (a) specialized structure, (b) suppressed genes and embryonic history, (c) genetic information, (d) a and b, (e) a and c.

19. A pancreas cell makes proteins (enzymes) which it releases to the small intestine. Which of the following best describes the path of these proteins from synthesis to exocytosis at the pancreatic cell's plasma membrane (PM)? (a) Golgi → rough ER → PM, (b) smooth ER → Golgi → lysosome → PM, (c) rough ER → Golgi → PM, (d) nucleus → Golgi → PM.

Short Answer Essay Questions

20. (a) Name the organelle that is the major site of ATP synthesis. (b) Name three organelles involved in protein synthesis or modification or both. (c) Name two organelles that contain enzymes, and describe their relative functions.

21. Explain why mitosis can be thought of as cellular immortality.

22. If a cell loses or ejects its nucleus, what is its fate and why?

23. The external faces of some of the proteins in the plasma membrane have carbohydrate groups attached to them. What role do such "sugar-coated" proteins play in the life of the cell?

24. Cells are living units. However, three classes of nonliving substances are found outside the cells. What are these classes, and what functional roles do they play?

25. Comment on the role of the sodium-potassium pump in maintaining a cell's resting membrane potential.

26. Differentiate clearly between primary and secondary active transport processes.

Critical Thinking and Clinical Application Questions

1. Explain why limp celery becomes crisp and the skin of your fingertips wrinkles when placed in tap water. (The principle is exactly the same.)

2. A "red-hot" bacterial infection of the intestinal tract irritates the intestinal cells and interferes with digestion. Such a condition is often accompanied by diarrhea, which causes loss of body water. On the basis of what you have learned about osmotic water flows, explain why diarrhea may occur.

3. Two examples of chemotherapeutic drugs (drugs used to treat cancer) and their cellular actions are listed below. Explain why each drug could be fatal to a cell.

- Vincristine: damages the mitotic spindle
- Adriamycin: binds to DNA and blocks mRNA synthesis

4. The normal function of one tumor-suppressor gene is to prevent cells with damaged chromosomes and DNA from "progressing from G_1 to S," whereas another tumor-suppressor gene prevents "passage from G_2 to M." When these tumor-suppressor genes fail to work, cancer can result. Explain what the phrases in quotations mean.

5. In their anatomy lab, many students are exposed to the chemical preservatives phenol, formaldehyde, and alcohol. Our cells break down these toxins very effectively. What cellular organelle is responsible for this?

6. Dynein is missing from the cilia and flagella of individuals with a specific inherited disorder. These individuals have severe respiratory problems and, if males, are sterile. What is the structural connection between these two symptoms?

7. Explain why alcoholics are likely to have much more smooth ER than teetotalers.

CHAPTER 4

Tissue: The Living Fabric

Preparing Human Tissue for Microscopy (p. 118)

1. List the steps involved in preparing animal tissue for microscopic viewing.

Epithelial Tissue (pp. 118–126)

2. List several structural and functional characteristics of epithelial tissue.
3. Name, classify, and describe the various types of epithelia; also indicate their chief function(s) and location(s).
4. Define gland. Differentiate between exocrine and endocrine glands and multicellular and unicellular glands.
5. Describe how multicellular exocrine glands are classified structurally and functionally.

Connective Tissue (pp. 126–139)

6. Indicate common characteristics of connective tissue, and list and describe its structural elements.
7. Describe the types of connective tissue found in the body, and indicate their characteristic functions.

Nervous Tissue (p. 139)

8. Indicate the general characteristics of nervous tissue.

Muscle Tissue (pp. 139–141)

9. Compare and contrast the structures and body locations of the three types of muscle tissue.

Covering and Lining Membranes (pp. 141–143)

10. Describe the structure and function of cutaneous, mucous, and serous membranes.

Tissue Repair (pp. 143–145)

11. Outline the process of tissue repair involved in normal healing of a superficial wound.

Developmental Aspects of Tissues (p. 145)

12. Indicate the embryonic origin of each tissue class.
13. Briefly describe tissue changes that occur with age.

Amoebas and other unicellular (one-cell) organisms are rugged individualists. Each cell alone obtains and digests its food, ejects its wastes, and carries out all the other activities necessary to keep itself alive and "buzzin' around on all cylinders." But in the multicellular human body, cells do not operate independently. Instead, they form tight cell communities that live and work together.

Individual body cells are specialized, with each type performing specific functions that help maintain homeostasis and benefit the body as a whole. Cell specialization is obvious: How muscle cells look and act differs greatly from skin cells, which in turn are easy to distinguish from brain cells. Cell specialization allows the body to function in sophisticated ways, but division of labor has certain hazards. When a particular group of cells is indispensable, its loss or injury can severely disable or even destroy the body.

Groups of cells that are similar in structure and perform a common or related function are called **tissues** (*tissu* = woven). Four primary tissue types interweave to form the "fabric" of the body. These basic tissues are epithelial (ep"i-the'le-ul), connective, muscle, and nervous tissue, and each has numerous subclasses or varieties. If we had to assign a single term to each primary tissue type that would best describe its general role, the terms would most likely be *covering* (epithelial), *support* (connective), *movement* (muscle), and *control* (nervous). However, these terms reveal only a fraction of the functions that each tissue performs.

As explained in Chapter 1, tissues are organized into organs such as the kidneys and the heart. Most organs contain all four tissue types, and their arrangement determines the organ's structure and capabilities. The study of tissues, or **histology,** complements the study of gross anatomy. Together they provide the structural basis for understanding organ physiology.

Preparing Human Tissue for Microscopy

Elaborate steps are taken to prepare human or animal tissue for microscopic viewing. The specimen must be **fixed** (preserved) and then cut into **sections** (slices) thin enough to transmit light or electrons. Finally the specimen must be stained to enhance contrast. The stains used in light microscopy are beautifully colored organic dyes, most of which were originally developed by clothing manufacturers in the mid-1800s. Many dyes consist of negatively or positively charged molecules (acidic and basic stains respectively) that bind within the tissue to macromolecules of the opposite charge. Because different parts of cells and tissues take up different dyes, the stains distinguish different anatomical structures.

For transmission electron microscopy, tissue sections are "stained" with heavy metal salts. These metals deflect electrons in the beam to different extents, providing contrast in the image. Electron-microscope images are in shades of gray because color is a property of light, not of electron waves, but the image may be artificially colored to enhance contrast. Another kind of electron microscopy, scanning electron microscopy (SEM), provides three-dimensional pictures of an unsectioned tissue surface. These striking images are scattered throughout this book.

Preserved tissue seen under the microscope has been exposed to many procedures that alter its original condition and introduce minor distortions called **artifacts.** Hence, keep in mind that most microscopic structures we view are not exactly like those in living tissue.

Epithelial Tissue

Epithelial tissue, or an **epithelium** (plural: epithelia), is a sheet of cells that covers a body surface or lines a body cavity (*epithe* = laid on, covering). It occurs in the body as (1) *covering and lining epithelium* and (2) *glandular epithelium.* Covering and lining epithelium forms the outer layer of the skin, dips into and lines the open cavities of the cardiovascular, digestive, and respiratory systems, and covers the walls and organs of the closed ventral body cavity. Glandular epithelium fashions the glands of the body.

Epithelia form boundaries between different environments. For example, the epidermis of the skin lies between the inside and the outside of the body, and epithelium lining the urinary bladder separates underlying cells of the bladder wall from urine. Furthermore, nearly all substances received or given off by the body must pass through an epithelium.

In its role as an interface tissue, epithelium accomplishes many functions, including (1) protection, (2) absorption, (3) filtration, (4) excretion, (5) secretion, and (6) sensory reception. Each of these functions is described in detail later, but to illustrate these functions briefly: The epithelium of the skin protects underlying tissues from mechanical and chemical injury and bacterial invasion and contains nerve endings that respond to various stimuli acting at the skin surface (pressure, heat, etc.). The epithelium lining the digestive tract is specialized to absorb substances; and that found in the kidneys performs nearly the whole functional "menu"—excretion, absorption, secretion, and filtration. Secretion is the specialty of glands.

Special Characteristics of Epithelium

Epithelial tissues have many characteristics that distinguish them from other tissue types.

1. Polarity. All epithelia have an **apical surface,** an upper free surface exposed to the body exterior or the cavity of an internal organ, and a lower attached **basal surface.** Hence, all epithelia exhibit *apical-basal polarity,* meaning that cell regions near the apical surface differ from those near the basal surface in both structure and function, a situation maintained, at least in part, by the highly ordered cytoskeleton of epithelial cells.

Although some apical surfaces are smooth and slick, most have **microvilli,** fingerlike extensions of the plasma membrane. Microvilli tremendously increase the exposed surface area, and in epithelia that absorb or secrete substances (those lining the intestine or kidney tubules, for instance), the microvilli are often so dense that the cell apices have a fuzzy appearance called a *brush border.* Some epithelia, such as that lining the trachea, have motile **cilia** that propel substances along their free surface.

Lying adjacent to the basal surface of an epithelium is a thin supporting sheet called the **basal lamina** (lam'ĭ-nah; "sheet"). This noncellular, adhesive sheet consists largely of glycoproteins secreted by the epithelial cells. The basal lamina acts as a selective filter that determines which molecules diffusing from the underlying connective tissue are allowed to enter the epithelium. The basal lamina also acts as a scaffolding along which epithelial cells can migrate to repair a wound.

2. Specialized contacts. Except for glandular epithelia (discussed on pp. 124–125), epithelial cells fit close together to form continuous sheets. Adjacent cells are bound together at many points by lateral contacts, including *tight junctions* and *desmosomes* (see Chapter 3). The tight junctions help keep proteins in the apical region of the plasma membrane from diffusing into the basal region, and thus help to maintain epithelial polarity.

3. Supported by connective tissue. All epithelial sheets rest upon and are supported by connective tissue. Just deep to the basal lamina is the **reticular lamina,** a layer of extracellular material containing a fine network of collagen protein fibers that "belongs to" the underlying connective tissue. Together the two laminae form the **basement membrane.** The basement membrane reinforces the epithelial sheet, helping it to resist stretching and tearing forces, and defines the epithelial boundary.

HOMEOSTATIC IMBALANCE

An important characteristic of cancerous epithelial cells is their failure to respect this boundary, which they penetrate to invade the tissues beneath.

4. Avascular but innervated. Although epithelium is *innervated* (supplied by nerve fibers), it is *avascular* (contains no blood vessels). Epithelial cells are nourished by substances diffusing from blood vessels in the underlying connective tissue.

5. Regeneration. Epithelium has a high regenerative capacity. Some epithelia are exposed to friction and their surface cells rub off. Others are damaged by hostile substances in the external environment (bacteria, acids, smoke). If and when their apical-basal polarity and lateral contacts are destroyed, epithelial cells begin to reproduce themselves rapidly. As long as epithelial cells receive adequate nutrition, they can replace lost cells by cell division.

Classification of Epithelia

Each epithelium is given two names. The first name indicates the number of cell layers present; the second describes the shape of its cells (Figure 4.1). Based on the number of cell layers, there are simple and stratified epithelia. **Simple epithelia** are composed of a single cell layer. They are typically found where absorption and filtration occur and a thin epithelial barrier is desirable. **Stratified epithelia,** consisting of two or more cell layers stacked one on top of the other, are common in high-abrasion areas where protection is important, such as the skin surface and the lining of the mouth.

In cross section, all epithelial cells have six (somewhat irregular) sides, and an apical surface view of an epithelial sheet looks like a honeycomb. This polyhedral shape allows the cells to be closely packed. However, epithelial cells vary in height, and on that basis, there are three common shapes of epithelial cells. **Squamous cells** (skwa'mus) are flattened and scalelike (*squam* = scale); **cuboidal cells** (ku-boi'dahl) are boxlike, approximately as tall as they are wide; and **columnar cells** (kŏ-lum'nar) are tall and column shaped. In each case, the shape of the nucleus conforms to that of the cell. The nucleus of a squamous cell is a flattened disc; that of a cuboidal cell is spherical; and a columnar cell nucleus is elongated from top to bottom and usually located close to the cell base. Keep nuclear shape in mind when you attempt to identify epithelial types.

Simple epithelia are easy to classify by cell shape because all cells in the layer usually have the same shape. In stratified epithelia, however, the cell shapes usually differ among the different cell layers. To avoid ambiguity, stratified epithelia are named according to the shape of the cells in the *apical* layer. This naming system will become clearer as we explore the specific epithelial types.

As you read about the epithelial classes, study Figure 4.2. Using the photomicrographs, try to pick out the individual cells within each epithelium. This

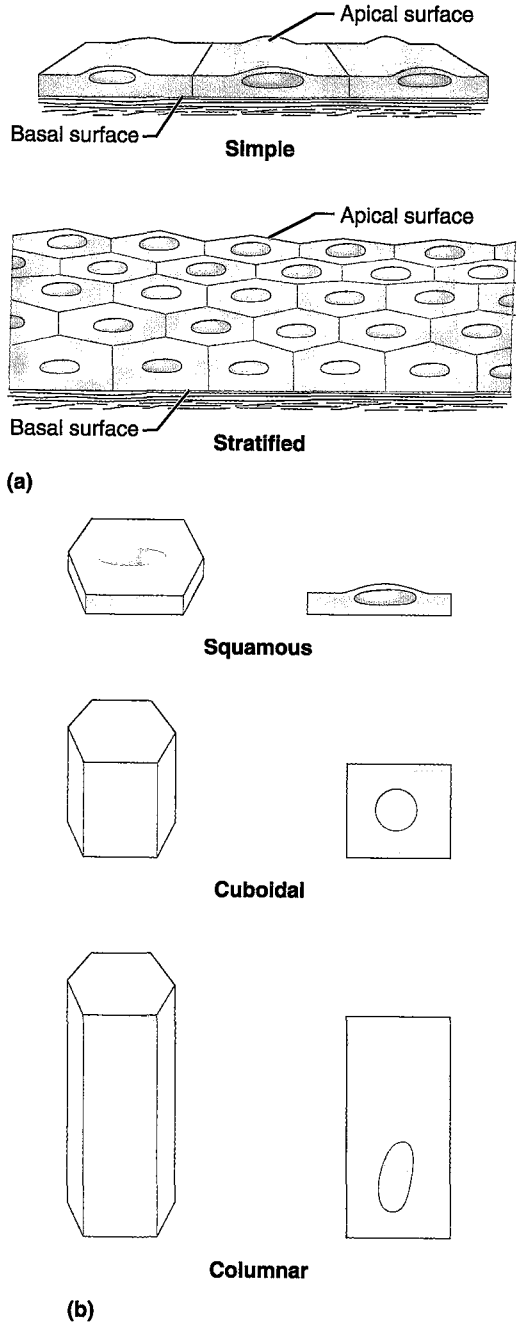

FIGURE 4.1 **Classification of epithelia. (a)** Classification on the basis of number of layers. **(b)** Classification on the basis of cell shape. For each category, a whole cell is shown on the left and a longitudinal section is shown on the right.

is not always easy, because the boundaries between epithelial cells often are indistinct. Furthermore, the nucleus of a particular cell may or may not be visible, depending on the precise plane of the cut made to prepare the tissue slides.

Simple Epithelia

The simple epithelia are most concerned with absorption, secretion, and filtration. Because they consist of a single cell layer and are usually very thin, protection is not one of their specialties.

Simple Squamous Epithelium The cells of a **simple squamous epithelium** are flattened laterally, and their cytoplasm is sparse (Figure 4.2a). In a surface view, the close-fitting cells resemble a tiled floor. When the cells are cut perpendicular to their free surface, they resemble fried eggs seen from the side, with their cytoplasm wisping out from the slightly bulging nucleus. Thin and often permeable, this epithelium is found where filtration or the exchange of substances by rapid diffusion is a priority. In the kidneys, simple squamous epithelium forms part of the filtration membrane; in the lungs, it forms the walls of the air sacs across which gas exchange occurs.

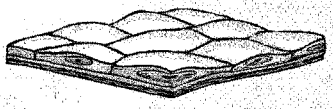
Two simple squamous epithelia in the body have special names that reflect their location. **Endothelium** (en"do-the'le-um; "inner covering") provides a slick, friction-reducing lining in lymphatic vessels and in all hollow organs of the cardiovascular system—blood vessels and the heart. Capillaries consist exclusively of endothelium, and its exceptional thinness encourages the efficient exchange of nutrients and wastes between the bloodstream and surrounding tissue cells. **Mesothelium** (mez"o-the'le-um; "middle covering") is the epithelium found in serous membranes lining the ventral body cavity and covering its organs.

Simple Cuboidal Epithelium **Simple cuboidal epithelium** consists of a single layer of cells as tall as they are wide (Figure 4.2b). The spherical nuclei stain darkly, causing the cell layer to look like a string of beads when viewed microscopically. Important functions of simple cuboidal epithelium are secretion and absorption. This epithelium forms the walls of the smallest ducts of glands and of many kidney tubules.

Simple Columnar Epithelium **Simple columnar epithelium** is seen as a single layer of tall, closely packed cells, aligned like soldiers in a row (Figure 4.2c). It lines the digestive tract from the stomach through the rectum. Columnar cells are mostly associated with absorption and secretion, and the digestive tract lining has two distinct modifications that make it ideal for that dual function: (1) dense microvilli on the apical surface of absorptive cells and (2) **goblet cells** that secrete a protective lubricating mucus. The goblet cells are named for their goblet-shaped "cups" of mucus that occupy most of the apical cell volume (see Figures 4.2d and 4.3). Some simple columnar epithelia display cilia on their free surfaces, which help to move substances or cells through an internal passageway.

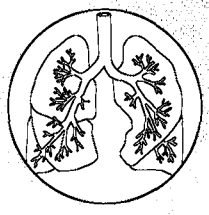
(a) Simple squamous epithelium

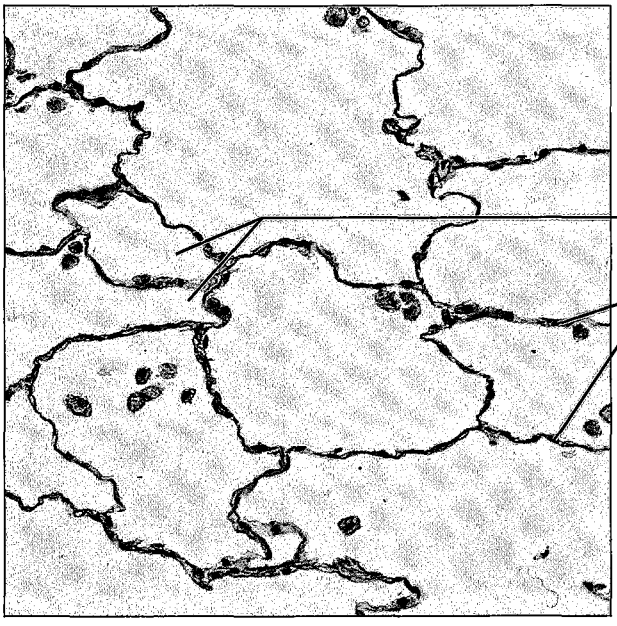
Description: Single layer of flattened cells with disc-shaped central nuclei and sparse cytoplasm; the simplest of the epithelia.



Function: Allows passage of materials by diffusion and filtration in sites where protection is not important; secretes lubricating substances in serosae.

Location: Kidney glomeruli; air sacs of lungs; lining of heart, blood vessels, and lymphatic vessels; lining of ventral body cavity (serosae).

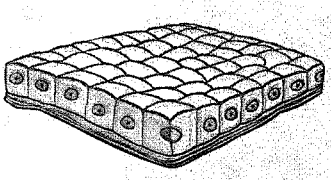




Photomicrograph: Simple squamous epithelium forming part of the alveolar (air sac) walls (400×).

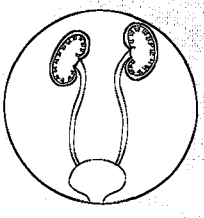
(b) Simple cuboidal epithelium

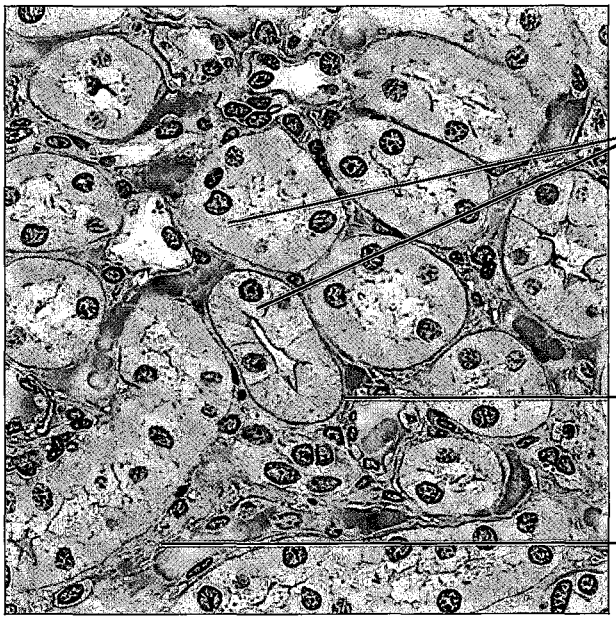
Description: Single layer of cubelike cells with large, spherical central nuclei.



Function: Secretion and absorption.

Location: Kidney tubules; ducts and secretory portions of small glands; ovary surface.



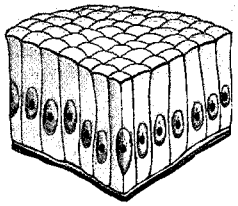


Photomicrograph: Simple cuboidal epithelium in kidney tubules (400×).

FIGURE 4.2 **Epithelial tissues. (a)** and **(b)** Simple epithelium.

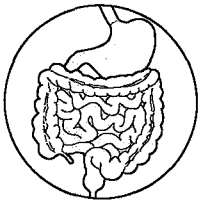
(c) Simple columnar epithelium

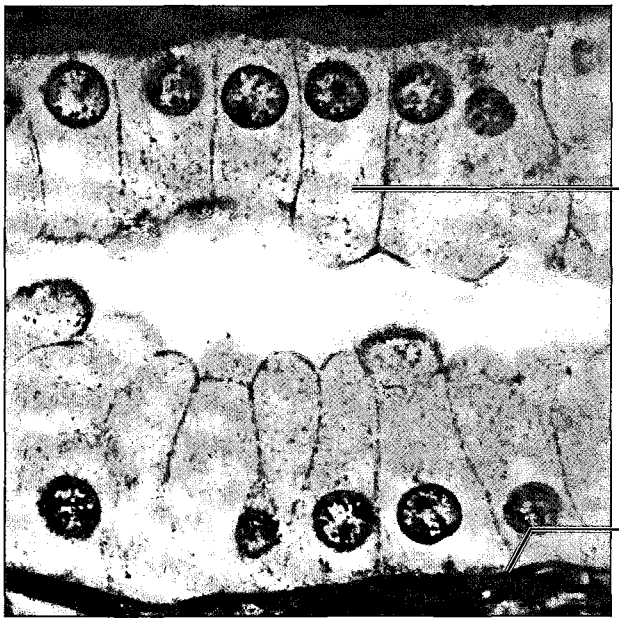
Description: Single layer of tall cells with *round* to *oval* nuclei; some cells bear cilia; layer may contain mucus-secreting unicellular glands (goblet cells).



Function: Absorption; secretion of mucus, enzymes, and other substances; ciliated type propels mucus (or reproductive cells) by ciliary action.

Location: Nonciliated type lines most of the digestive tract (stomach to anal canal), gallbladder, and excretory ducts of some glands; ciliated variety lines small bronchi, uterine tubes, and some regions of the uterus.

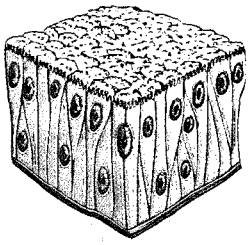




Photomicrograph: Simple columnar epithelium of the stomach mucosa (1300×).

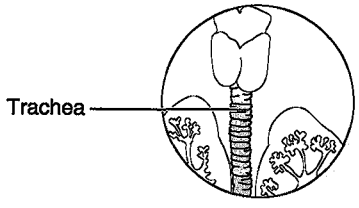
(d) Pseudostratified columnar epithelium

Description: Single layer of cells of differing heights, some not reaching the free surface; nuclei seen at different levels; may contain goblet cells and bear cilia.



Function: Secretion, particularly of mucus; propulsion of mucus by ciliary action.

Location: Nonciliated type in male's sperm-carrying ducts and ducts of large glands; ciliated variety lines the trachea, most of the upper respiratory tract.



Photomicrograph: Pseudostratified ciliated columnar epithelium lining the human trachea (400×).

FIGURE 4.2 **Epithelial tissues.** *(continued)* **(c)** and **(d)** Simple epithelium.

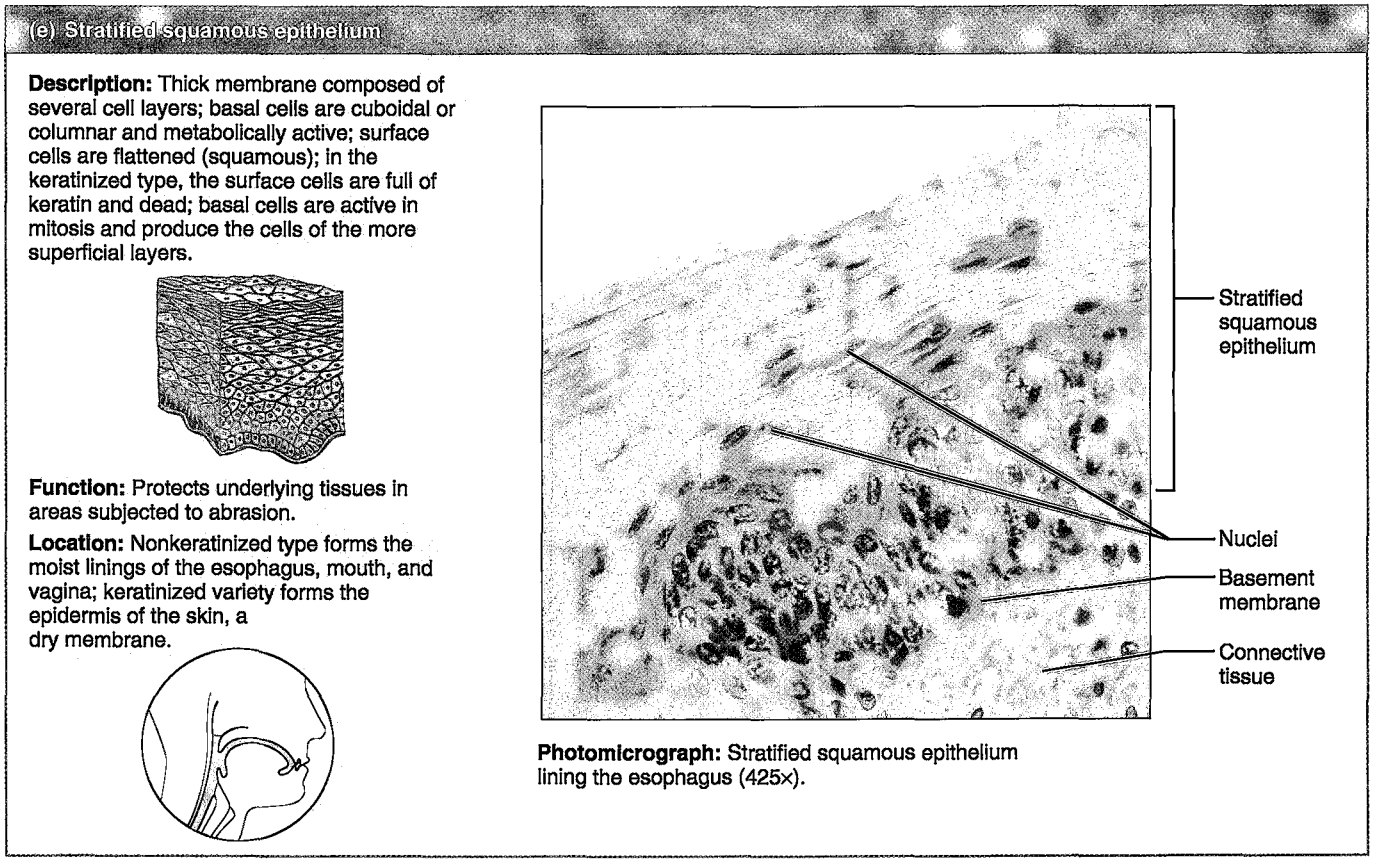


FIGURE 4.2 *(continued)* **(e)** Stratified epithelium.

Pseudostratified Columnar Epithelium The cells of **pseudostratified columnar epithelium** (soo"do-străʹtĭ-fīd) vary in height (Figure 4.2d). All of its cells rest on the basement membrane, but only the tallest reach the free surface of the epithelium. Because the cell nuclei lie at different levels above the basement membrane, the tissue gives the false (pseudo) impression that several cell layers are present; hence "pseudostratified." The short cells are relatively unspecialized and give rise to the taller cells. This epithelium, like the simple columnar variety, secretes or absorbs substances. A ciliated version containing goblet cells lines most of the respiratory tract. Here the motile cilia propel sheets of dust-trapping mucus superiorly away from the lungs.

Stratified Epithelia

Stratified epithelia contain two or more cell layers. They regenerate from below; that is, the basal cells divide and push apically to replace the older surface cells. Considerably more durable than the simple epithelia, the major (but not the only) role of stratified epithelia is protection.

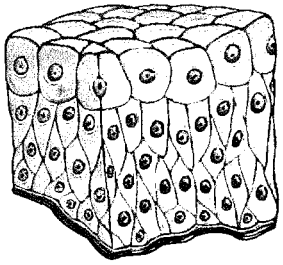
Stratified Squamous Epithelium **Stratified squamous epithelium** is the most widespread of the stratified epithelia (Figure 4.2e). Composed of several layers, it is thick and well suited for its protective role in the body. Its free surface cells are squamous; cells of the deeper layers are cuboidal or columnar. This epithelium is found in areas subjected to wear and tear, and its surface cells are constantly being rubbed away and replaced by division of its basal cells. Because epithelium depends on diffusion of nutrients from a deeper connective tissue layer, the epithelial cells farther from the basement membrane are less viable and those at the apical surface are often flattened and atrophied.

To avoid memorizing all its locations simply remember that this epithelium forms the external part of the skin and extends a short distance into every body opening that is directly continuous with the skin. The outer layer, or *epidermis*, of the skin is *keratinized* (ker'ah-tin"īzd), meaning its surface cells contain *keratin*, a tough protective protein. (The epidermis is discussed in Chapter 5.) The other stratified squamous epithelia of the body are *nonkeratinized*.

Stratified Cuboidal and Columnar Epithelia **Stratified cuboidal epithelium** is quite rare in the body, mostly found in the ducts of some of the larger glands (sweat glands, mammary glands). It typically has two layers of cuboidal cells.

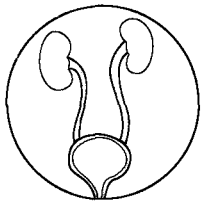
(f) Transitional epithelium

Description: Resembles both stratified squamous and stratified cuboidal; basal cells cuboidal or columnar; surface cells dome shaped or squamouslike, depending on degree of organ stretch.



Function: Stretches readily and permits distension of urinary organ by contained urine.

Location: Lines the ureters, bladder, and part of the urethra.



Photomicrograph: Transitional epithelium lining the bladder, relaxed state (500×); note the bulbous, or rounded, appearance of the cells at the surface; these cells flatten and become elongated when the bladder is filled with urine.

FIGURE 4.2 **Epithelial tissues.** *(continued)* **(f)** Stratified epithelium.

Stratified columnar epithelium also has a limited distribution in the body. Small amounts are found in the pharynx, the male urethra, and lining some glandular ducts. This epithelium also occurs at transition areas or junctions between two other types of epithelia. Only its apical layer of cells is columnar. Because of their relative scarcity in the body, these two stratified epithelia are not illustrated in Figure 4.2.

Transitional Epithelium **Transitional epithelium** forms the lining of hollow urinary organs, which stretch as they fill with urine (Figure 4.2f). Cells of its basal layer are cuboidal or columnar. The apical cells vary in appearance, depending on the degree of distension of the organ. When the organ is distended with urine, the transitional epithelium thins from about six cell layers to three, and its domelike apical cells flatten and become squamouslike. The ability of transitional cells to change their shape (undergo "transitions") allows a greater volume of urine to flow through a tubelike organ. In the bladder, it allows more urine to be stored.

Glandular Epithelia

A **gland** consists of one or more cells that make and secrete (export) a particular product. This product, called a **secretion,** is an aqueous (water-based) fluid that usually contains proteins, but there is variation—for example, some glands release a lipid- or steroid-rich secretion. Secretion is an active process; glandular cells obtain needed substances from the blood and transform them chemically into a product that is then discharged from the cell. Notice that the term *secretion* can refer to both the gland's *product* and the *process* of making and releasing that product.

Glands are classified as *endocrine* ("internally secreting") or *exocrine* ("externally secreting") depending on where they release their product, and as *unicellular* ("one-celled") or *multicellular* ("many-celled") based on the relative cell number making up the gland. Unicellular glands are scattered within epithelial sheets. By contrast, most multicellular epithelial glands form by invagination (inward growth) or evagination (outward growth) from an epithelial sheet and, at least initially, most have *ducts,* tubelike connections to the epithelial sheets.

Endocrine Glands

Because **endocrine glands** eventually lose their ducts, they are often called *ductless glands.* They produce **hormones,** regulatory chemicals that they secrete by exocytosis directly into the extracellular space. From there the hormones enter the blood or lymphatic fluid and travel to specific target organs. Each hormone

prompts its target organ(s) to respond in some characteristic way. For example, hormones produced by certain intestinal cells cause the pancreas to release enzymes that help digest food in the digestive tract.

Endocrine glands are structurally diverse, so one description does not fit all. Although most endocrine glands are compact multicellular organs, some individual hormone-producing cells are scattered in the digestive tract mucosa and in the brain, giving rise to their collective description as the *diffuse endocrine system.* Their secretions are also varied, ranging from modified amino acids to peptides, glycoproteins, and steroids. Since not all endocrine glands are epithelial derivatives, we defer consideration of their structure and function to Chapter 16.

Exocrine Glands

Exocrine glands are numerous, and many of their products are familiar. All exocrine glands secrete their products onto body surfaces (skin) or into body cavities—the unicellular glands directly (by exocytosis) and the multicellular glands via an epithelium-walled duct that transports the secretion to the epithelial surface. Exocrine glands are a diverse lot. They include mucous, sweat, oil, and salivary glands, the liver (which secretes bile), the pancreas (which synthesizes digestive enzymes), and many others.

Unicellular Exocrine Glands The only important example of a **unicellular** (or one-celled) **gland** is the *goblet cell.* True to its name, a goblet cell is shaped like a goblet (a drinking glass with a stem). Goblet cells are sprinkled in the epithelial linings of the intestinal and respiratory tracts amid columnar cells with other functions (see Figures 4.3 and 4.2d). In humans, all such glands produce **mucin** (mu'sin), a complex glycoprotein that dissolves in water when secreted. Once dissolved, mucin forms **mucus,** a slimy coating that both protects and lubricates surfaces.

Multicellular Exocrine Glands Compared to the unicellular glands, **multicellular exocrine glands** are structurally more complex. They have two basic parts: an epithelium-derived *duct* and a *secretory unit (acinus)* consisting of secretory cells. In all but the simplest glands, *supportive connective tissue* surrounds the secretory unit and supplies it with blood vessels and nerve fibers, and forms a *fibrous capsule* that extends into the gland proper and divides the gland into *lobes.*

- **Structural classification.** On the basis of their duct structures, multicellular exocrine glands are either simple or compound (Figure 4.4). **Simple glands** have an unbranched duct, whereas **compound glands** have a branched duct. The glands are further categorized by their secretory units as (1) **tubular** if the secretory cells form tubes; (2) **alveolar** (al-ve'o-lar) if the secretory cells form small, flasklike sacs (*alveolus* = "small hollow cavity"); and (3) **tubuloalveolar** if they have both types of secretory units. Note that the term **acinar** (as'ĭ-nar; "berrylike") is used interchangeably with alveolar.

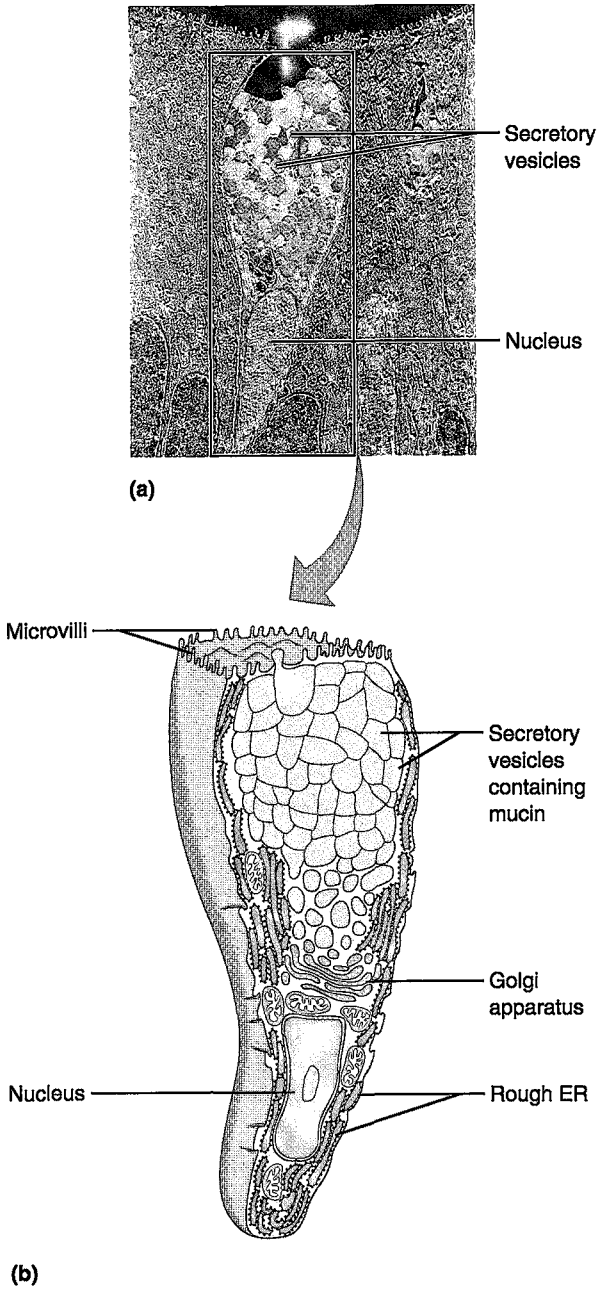


FIGURE 4.3 **Goblet cells (unicellular exocrine glands). (a)** Photomicrograph of a mucus-secreting goblet cell in the simple columnar epithelium lining the small intestine (approx. 2000×). **(b)** Diagram of a goblet cell. Notice the secretory vesicles and well-developed rough ER and Golgi apparatus.

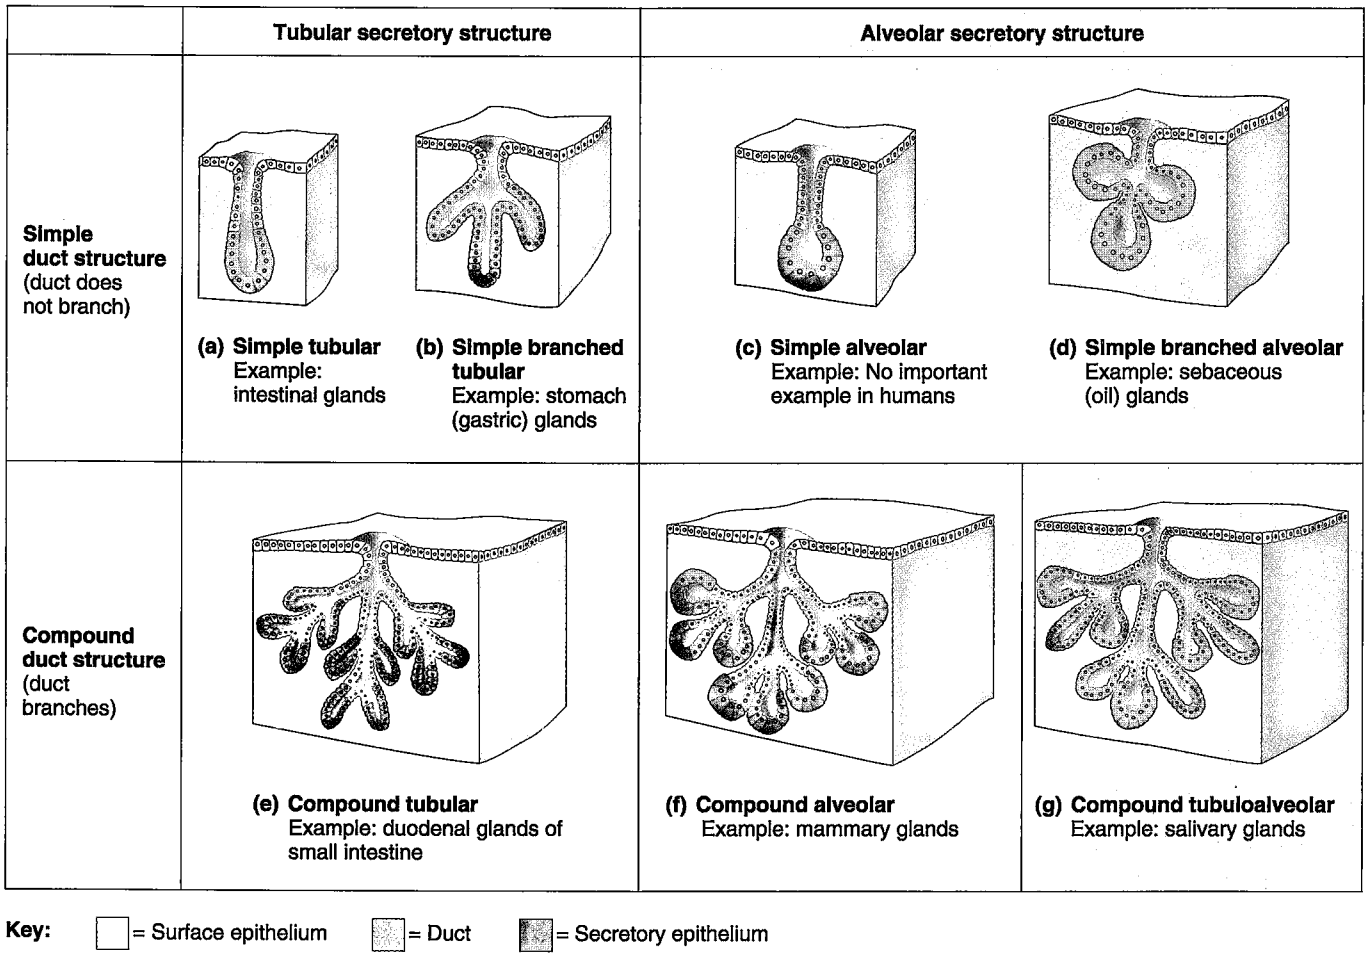

FIGURE 4.4 **Types of multicellular exocrine glands.** Multicellular glands are classified according to duct type (simple or compound) and the structure of their secretory units (tubular, alveolar, or tubuloalveolar).

▪ **Modes of secretion.** Multicellular exocrine glands secrete their products in different ways, so they can also be described functionally. Most are **merocrine glands** (mer'o-krin), which secrete their products by exocytosis as they are produced. The secretory cells are not altered in any way. The pancreas, most sweat glands, and salivary glands belong to this class (Figure 4.5a).

Secretory cells of **holocrine glands** (hol'o-krin) accumulate their products within them until they rupture. (They are replaced by the division of underlying cells.) Because holocrine gland secretions include the synthesized product plus dead cell fragments (*holos* = all), you could say that their cells "die for their cause." Sebaceous (oil) glands of the skin are the only true example of holocrine glands (Figure 4.5b).

Although *apocrine glands* (ap'o-krin) are definitely present in other animals, there is some controversy over whether humans have this third gland type. Like holocrine glands, apocrine glands accumulate their products, but in this case only just beneath the free surface. Eventually, the apex of the cell pinches off (*apo* = from, off), releasing the secretory granules and a small amount of cytoplasm. The cell repairs its damage and the process repeats again and again. The best possibility in humans is the release of lipid droplets by the mammary glands, but most histologists classify mammary glands as merocrine glands because this is the means by which milk proteins are secreted.

Connective Tissue

Connective tissue is found everywhere in the body. It is the most abundant and widely distributed of the primary tissues, but its amount in particular organs varies. For example, skin consists primarily of connective tissue, while the brain contains very little. There are four main classes of connective tissue and several subclasses. The main classes are (1) *connective tissue proper* (which includes fat and the fibrous

tissue of ligaments), (2) *cartilage,* (3) *bone tissue,* and (4) *blood.*

Connective tissue does much more than just *connect* body parts; it has many forms and functions. Its major functions include (1) *binding and support,* (2) *protection,* (3) *insulation,* and as blood, (4) *transportation* of substances within the body. For example, bone and cartilage support and protect body organs by providing the hard underpinnings of the skeleton; fat cushions insulate and protect body organs and provide reserve energy fuel.

Common Characteristics of Connective Tissue

Despite their many and diverse functions in the body, connective tissues have some common properties that set them apart from other primary tissues:

1. Common origin. All connective tissues arise from *mesenchyme* (an embryonic tissue) and hence have a common kinship (Figure 4.6).

2. Degrees of vascularity. Connective tissues run the entire gamut of vascularity. Cartilage is avascular; dense connective tissue is poorly vascularized; and the other types of connective tissue have a rich supply of blood vessels.

3. Extracellular matrix. Whereas all other primary tissues are composed mainly of cells, connective tissues are largely nonliving **extracellular matrix** (ma'triks; "womb"), which separates, often widely, the living cells of the tissue. Because of its matrix, connective tissue is able to bear weight, withstand great tension, and endure abuses, such as physical trauma and abrasion, that no other tissue would be able to tolerate.

Structural Elements of Connective Tissue

Connective tissues have three main elements: *ground substance, fibers,* and *cells.* Ground substance and fibers make up the extracellular matrix. (Note that some authors use the term *matrix* to indicate the ground substance only.)

The properties of the cells and the composition and arrangement of extracellular matrix elements vary tremendously. The result is an amazing diversity of connective tissues, each adapted to perform its specific function in the body. For example, the matrix can be delicate and fragile to form a soft "packing" around an organ, or it can form "ropes" (tendons and ligaments) of incredible strength. Nonetheless, connective tissues have a common structural plan, and we use *areolar connective tissue* (ah-re'o-lar) as our *prototype,* or model, for this group of tissues (see Figure 4.8). All other subclasses are simply variants of this common tissue type.

Which of the gland types illustrated would have the highest rate of cellular mitosis? Why?

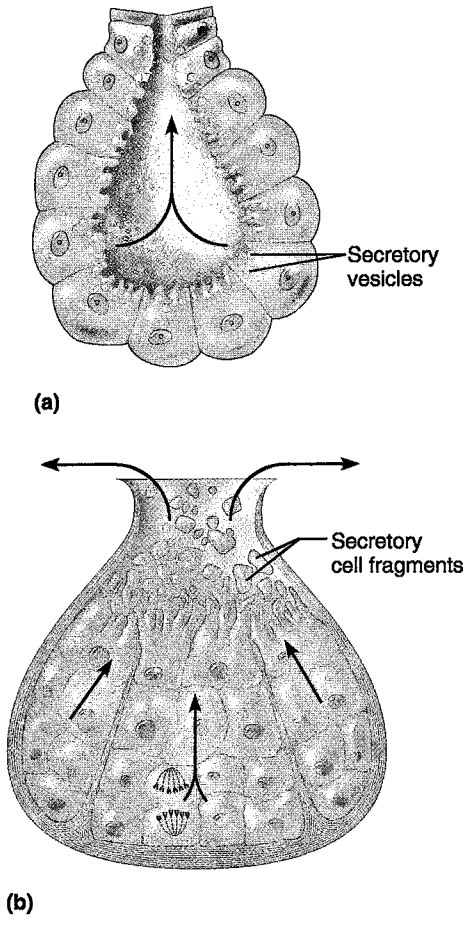

FIGURE 4.5 **Chief modes of secretion in human exocrine glands. (a)** Merocrine glands secrete their products by exocytosis. **(b)** In holocrine glands, the entire secretory cell ruptures, releasing secretions and dead cell fragments.

Ground Substance

Ground substance is the unstructured material that fills the space between the cells and contains the fibers. It is composed of *interstitial (tissue) fluid, cell adhesion proteins,* and *proteoglycans* (pro"te-o-gli'kanz). Cell adhesion proteins (*fibronectin, laminin,* and others) serve mainly as a connective tissue glue that allows connective tissue cells to attach themselves to matrix elements. The proteoglycans consist

∀ The holocrine gland, because cells that are fragmented and secreted have to be replaced.

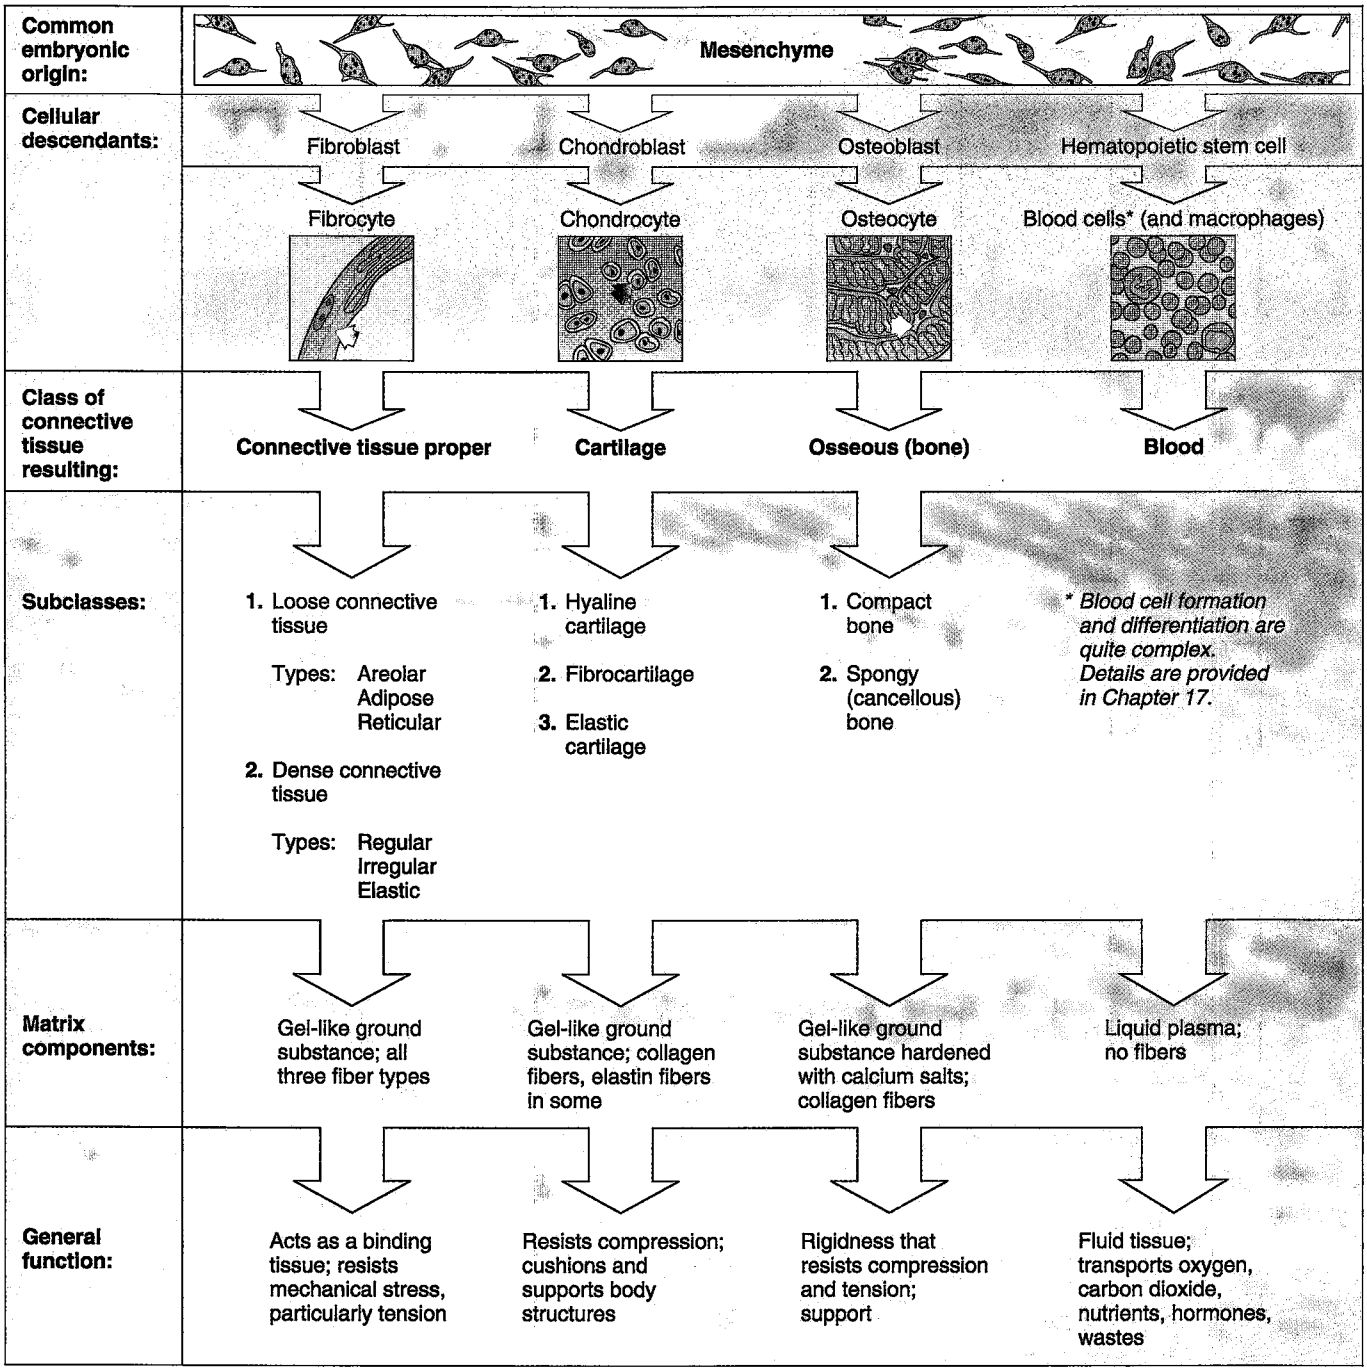

FIGURE 4.6 **Major classes of connective tissue.** All these classes arise from the same embryonic tissue type (mesenchyme).

of a protein core to which *glycosaminoglycans* (GAGs) (gli"kos-ah-me"no-gli'kanz) are attached. The strandlike GAGs are large, negatively charged polysaccharides that stick out from the core protein like the fibers of a bottle brush (Figure 4.7). Important examples of GAGs in connective tissues include *chondroitin* and *keratan sulfates* and *hyaluronic acid* (hi"ah-lu-ron'ik). The proteoglycans tend to form huge aggregates (often attached to a hyaluronic acid molecule). The GAGs intertwine and trap water, forming a substance that varies from a fluid to a viscous gel; in general, the higher the GAG content, the more viscous the ground substance.

The ground substance holds large amounts of fluid and functions as a molecular sieve, or medium, through which nutrients and other dissolved substances can diffuse between the blood capillaries and the cells. The fibers embedded in the ground substance make it less pliable and impede diffusion somewhat.

Fibers

The *fibers* of connective tissue provide support. Three types of fibers are found in connective tissue matrix: collagen, elastic, and reticular fibers. Of these, collagen fibers are by far the strongest and most abundant.

Collagen fibers are constructed primarily of the fibrous protein *collagen*. Collagen molecules are secreted into the extracellular space, where they assemble spontaneously into cross-linked fibrils, which in turn are bundled together into the thick collagen fibers seen with a microscope. Because of the cross-linking of their fibrils, collagen fibers are extremely tough and provide high tensile strength (that is, the ability to resist longitudinal stress) to the matrix. Indeed, stress tests show that collagen fibers are stronger than steel fibers of the same size! When fresh, they have a glistening white appearance; they are therefore also called *white fibers*.

Elastic fibers are long, thin fibers that form branching networks in the extracellular matrix. These fibers contain a rubberlike protein, *elastin*, that allows them to stretch and recoil like rubber bands. Connective tissue can stretch only so much before its thick, ropelike collagen fibers become taut. Then, when the tension lets up, elastic fibers snap the connective tissue back to its normal length and shape. Elastic fibers are found where greater elasticity is needed, for example, in the skin, lungs, and blood vessel walls. Because fresh elastic fibers appear yellow, they are sometimes called *yellow fibers*.

Reticular fibers are short, fine, collagenous fibers (with a slightly different chemistry and form) and are continuous with collagen fibers. They branch extensively, forming delicate networks (*reticul* = network) that surround small blood vessels and support the soft tissue of organs. They are particularly abundant where connective tissue abuts other tissue types, for example, in the basement membrane of epithelial tissues, and around capillaries, where they form fuzzy "nets" that allow more "give" than the larger collagen fibers.

Cells

Each major class of connective tissue has a fundamental cell type that exists in immature and mature forms (see Figure 4.6). The undifferentiated cells, indicated by the suffix *blast* (literally, "bud" or "sprout," but the suffix means "forming"), are actively mitotic cells that secrete the ground substance and the fibers characteristic of their particular matrix. The primary blast cell types by connective tissue class are (1) connective tissue proper: **fibroblast;** (2) cartilage: **chondroblast** (kon'dro-blast"); (3) bone: **osteoblast** (os'te-o-blast"); and (4) blood: **hematopoietic stem cell** (hem"ah-to-poy-et'ik). Although the hematopoietic stem cell is an undifferentiated blast cell that produces blood cells, it differs from the other blast cells in that it is not located in "its" tissue (blood) and does not make the fluid matrix (plasma) of that tissue.

Once they synthesize the matrix, the blast cells assume their less active, mature mode, indicated by the suffix *cyte* (see Figure 4.6). The mature cells

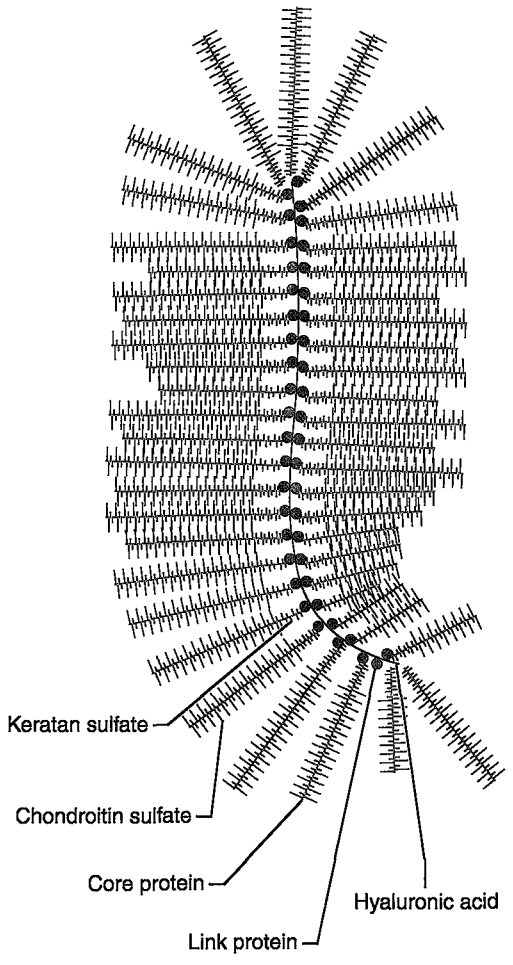

FIGURE 4.7 **Proteoglycan aggregate in cartilage.** A schematic drawing of the GAGs keratan sulfate and chondroitin sulfate linked to core protein molecules, forming proteoglycans, which in turn attach to a long hyaluronic acid molecule with the aid of a link protein to form the aggregate.

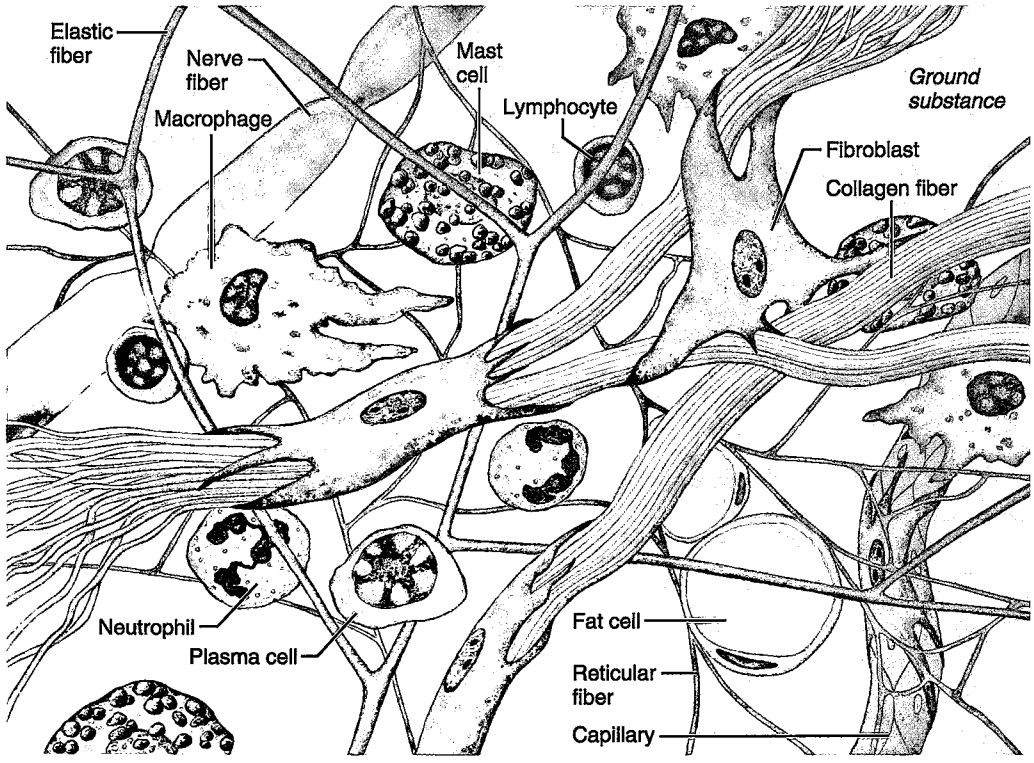

FIGURE 4.8 **Areolar connective tissue: A prototype (model) connective tissue.** This tissue underlies epithelia and surrounds capillaries. Note the various cell types and the three classes of fibers (collagen, reticular, elastic) embedded in the ground substance. (See Figure 4.9a for a less idealized version.)

maintain the health of the matrix. However, if the matrix is injured, they can easily revert to their more active state to repair and regenerate the matrix. (The blood-forming hematopoietic stem cell found in bone marrow is always actively mitotic.)

Additionally, connective tissue is home to an assortment of other cell types, such as nutrient-storing *fat cells* and mobile cells that migrate into the connective tissue matrix from the bloodstream. The latter include defensive **white blood cells** (neutrophils, eosinophils, lymphocytes) and other cell types concerned with tissue response to injury, such as *mast cells*, *macrophages* (mak'ro-fāj-es), and antibody-producing **plasma cells.** This wide variety of cells is particularly obvious in our prototype, areolar connective tissue (Figure 4.8).

All of these accessory cell types are described in later chapters, but mast cells and macrophages are so important to overall body defense that they deserve a brief mention here. The oval **mast cells** typically cluster along blood vessels. These cells act as sensitive sentinels to detect foreign substances (e.g., bacteria, fungi) and initiate local inflammatory responses against them. In the mast cell cytoplasm are conspicuous secretory granules (mast = "stuffed full of granules") containing several chemicals that mediate inflammation, especially in severe allergies. These include (1) *heparin* (hep'ah-rin), an anticoagulant chemical that prevents blood clotting when free in the bloodstream (but in human mast cells it appears to bind to and regulate the action of other mast cell chemicals); (2) *histamine* (his'tah-mēn), a substance that makes capillaries leaky; and (3) *proteases* (protein-degrading enzymes).

Macrophages (*macro* = large; *phago* = eat) are large, irregularly shaped cells that avidly phagocytize a broad variety of foreign materials, ranging from foreign molecules to entire bacteria to dust particles. These "big eaters" also dispose of dead tissue cells, and they are central actors in the immune system. In connective tissues, they may be attached to connective tissue fibers (fixed) or may migrate freely through the matrix.

Macrophages are peppered throughout loose connective tissue, bone marrow, and lymphatic tissue. Those in certain sites are given specific names; for example, those in the lungs are called dust cells. Some macrophages have selective appetites; for example, those of the spleen primarily dispose of aging red blood cells, but they will not turn down other "delicacies" that come their way.

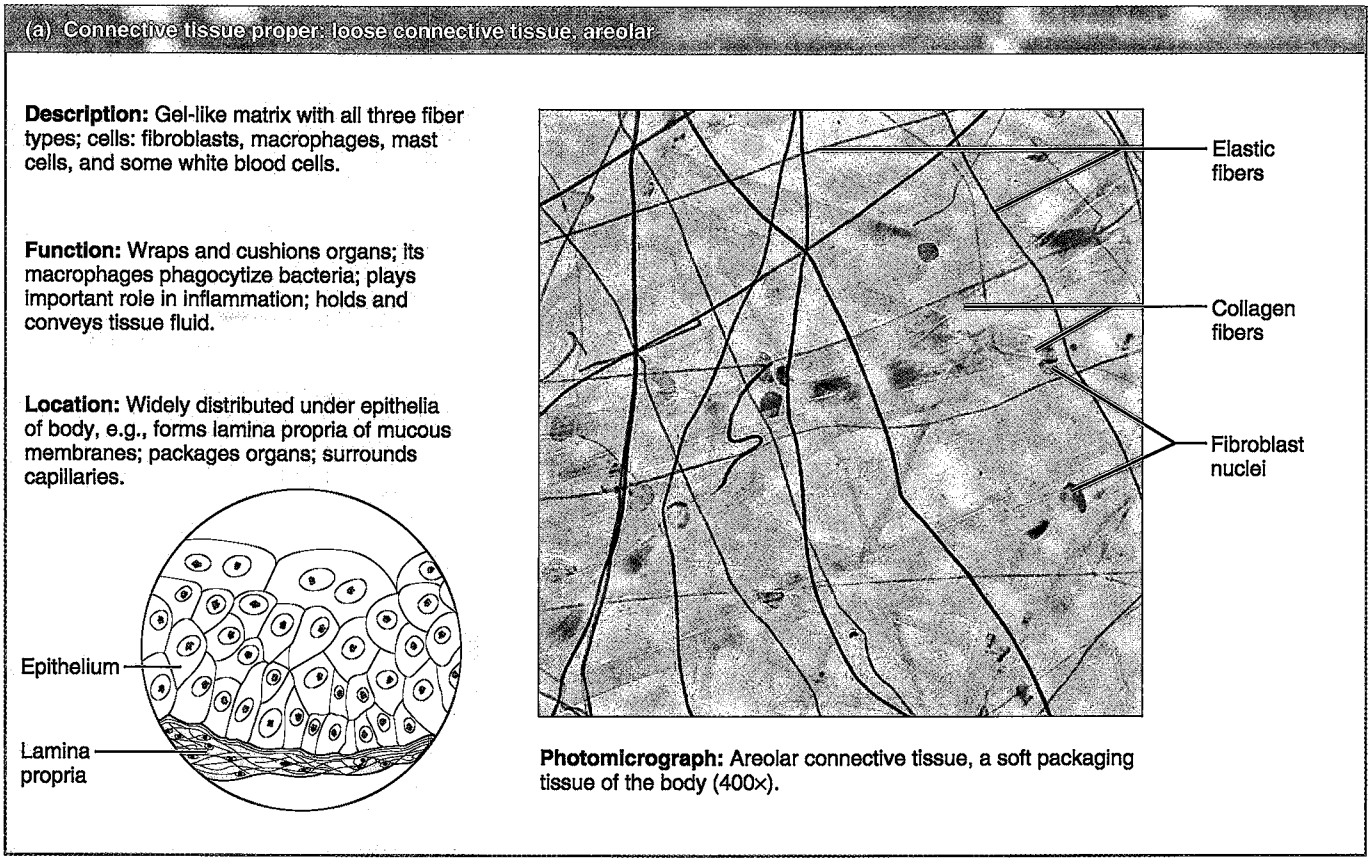

FIGURE 4.9 **Connective tissues. (a)** Connective tissue proper.

Types of Connective Tissue

As noted, all classes of connective tissue consist of living cells surrounded by a matrix. Their major differences reflect cell type, and fiber types and relative amounts, as summarized in Figure 4.6. The connective tissues described in this section are illustrated in Figure 4.9. Mature connective tissues arise from a common embryonic tissue, called **mesenchyme** (meh'zin-kīm), derived from embryonic mesoderm (see Figure 4.14, p. 145). Mesenchyme has a fluid ground substance containing fine sparse fibers and star-shaped *mesenchymal cells* (see the top bar of Figure 4.6). It arises during the early weeks of embryonic development and eventually differentiates (specializes) into all other connective tissue cells. However, some mesenchymal cells remain and provide a source of new cells in mature connective tissues.

Connective Tissue Proper

Connective tissue proper has two subclasses: the **loose connective tissues** (areolar, adipose, and reticular) and **dense connective tissues** (dense regular, dense irregular, and elastic). Except for bone, cartilage, and blood, all mature connective tissues belong to this class.

Areolar Connective Tissue The functions of **areolar connective tissue,** shared by some but not all connective tissues, include (1) supporting and binding other tissues (the job of the fibers); (2) holding body fluids (the ground substance's role); (3) defending against infection (via the activity of white blood cells and macrophages); and (4) storing nutrients as fat (in fat cells) (Figure 4.9a).

Fibroblasts, flat, branching cells that appear spindle shaped in profile, predominate, but numerous macrophages are also seen and present a formidable barrier to invading microorganisms. Fat cells appear singly or in clusters, and occasional mast cells are identified easily by the large, darkly stained cytoplasmic granules that often obscure their nuclei. Other cell types are scattered throughout.

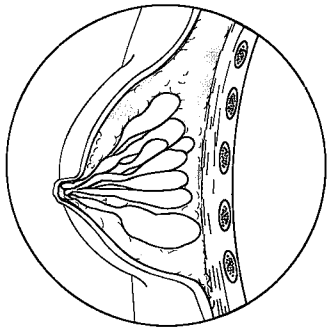
The most obvious structural feature of this tissue is the loose arrangement of its fibers; hence, its classification as a *loose* connective tissue is fitting. The rest of the matrix, occupied by ground substance, appears to be empty space when viewed through the microscope; in fact, the Latin term *areola* means "a small open space." Because of its loose nature, areolar connective tissue provides a reservoir of water and salts for surrounding body tissues, always holding approximately as much fluid as

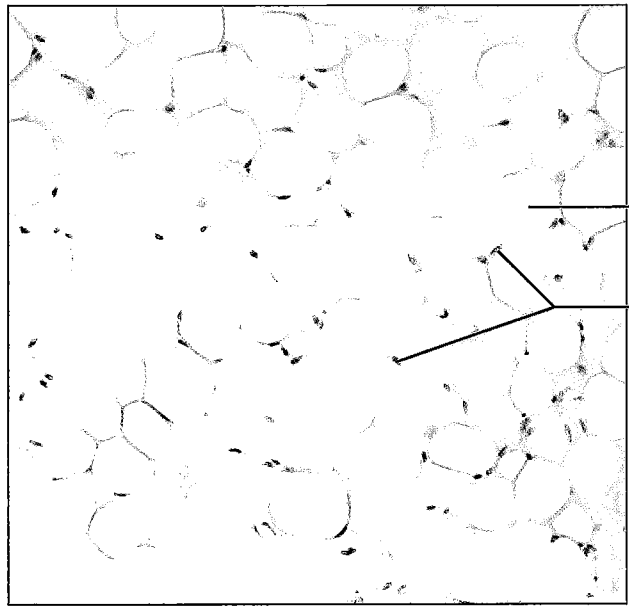
(b) Connective tissue proper: loose connective tissue, adipose

Description: Matrix as in areolar, but very sparse; closely packed adipocytes, or fat cells, have nucleus pushed to the side by large fat droplet.

Function: Provides reserve food fuel; insulates against heat loss; supports and protects organs.

Location: Under skin; around kidneys and eyeballs; within abdomen; in breasts.





Photomicrograph: Adipose tissue from the subcutaneous layer under the skin (450×).

FIGURE 4.9 **Connective tissues.** *(continued)* **(b)** Connective tissue proper.

there is in the entire bloodstream. Essentially all body cells obtain their nutrients from and release their wastes into this "tissue fluid." However, its high content of hyaluronic acid makes the ground substance quite viscous, like molasses, which may hinder the movement of cells through it. Some white blood cells, which protect the body from disease-causing microorganisms, secrete the enzyme hyaluronidase to liquefy the ground substance and ease their passage. (Unhappily, some potentially harmful bacteria have the same ability.) When a body region is inflamed, the areolar tissue in the area soaks up excess fluids like a sponge, and the affected area swells and becomes puffy, a condition called **edema** (ĕ-de′mah).

Areolar connective tissue is the most widely distributed connective tissue in the body and it serves as a kind of universal packing material between other tissues. It binds body parts together while allowing them to move freely over one another; wraps small blood vessels and nerves; surrounds glands; and forms the subcutaneous tissue, which cushions and attaches the skin to underlying structures. It is present in all mucous membranes as the *lamina propria.* (Mucous membranes line body cavities open to the exterior.)

Adipose (Fat) Tissue **Adipose tissue** (ad′ĭ-pōs) is similar to areolar tissue in structure and function but its nutrient-storing ability is much greater. Consequently, **adipocytes** (ad′ĭ-po-sītz), commonly called *adipose* or *fat cells,* predominate and account for 90% of this tissue's mass. The matrix is scanty and the cells are packed closely together, giving a chicken wire appearance to the tissue. A glistening oil droplet (almost pure triglyceride) occupies most of a fat cell's volume and displaces the nucleus to one side so that only a thin rim of surrounding cytoplasm is seen (Figure 4.9b). Mature adipocytes are among the largest cells in the body. As they take up or release fat, they become plumper or more wrinkled looking, respectively.

Adipose tissue is richly vascularized, indicating its high metabolic activity. Without the fat stores in our adipose tissue, we could not live for more than a few days without eating. Adipose tissue is certainly abundant: It constitutes 18% of an average person's body weight. Indeed, a chubby person's body can be 50% fat without being considered morbidly obese.

Adipose tissue may develop almost anywhere areolar tissue is plentiful, but it usually accumulates in subcutaneous tissue, where it also acts as a

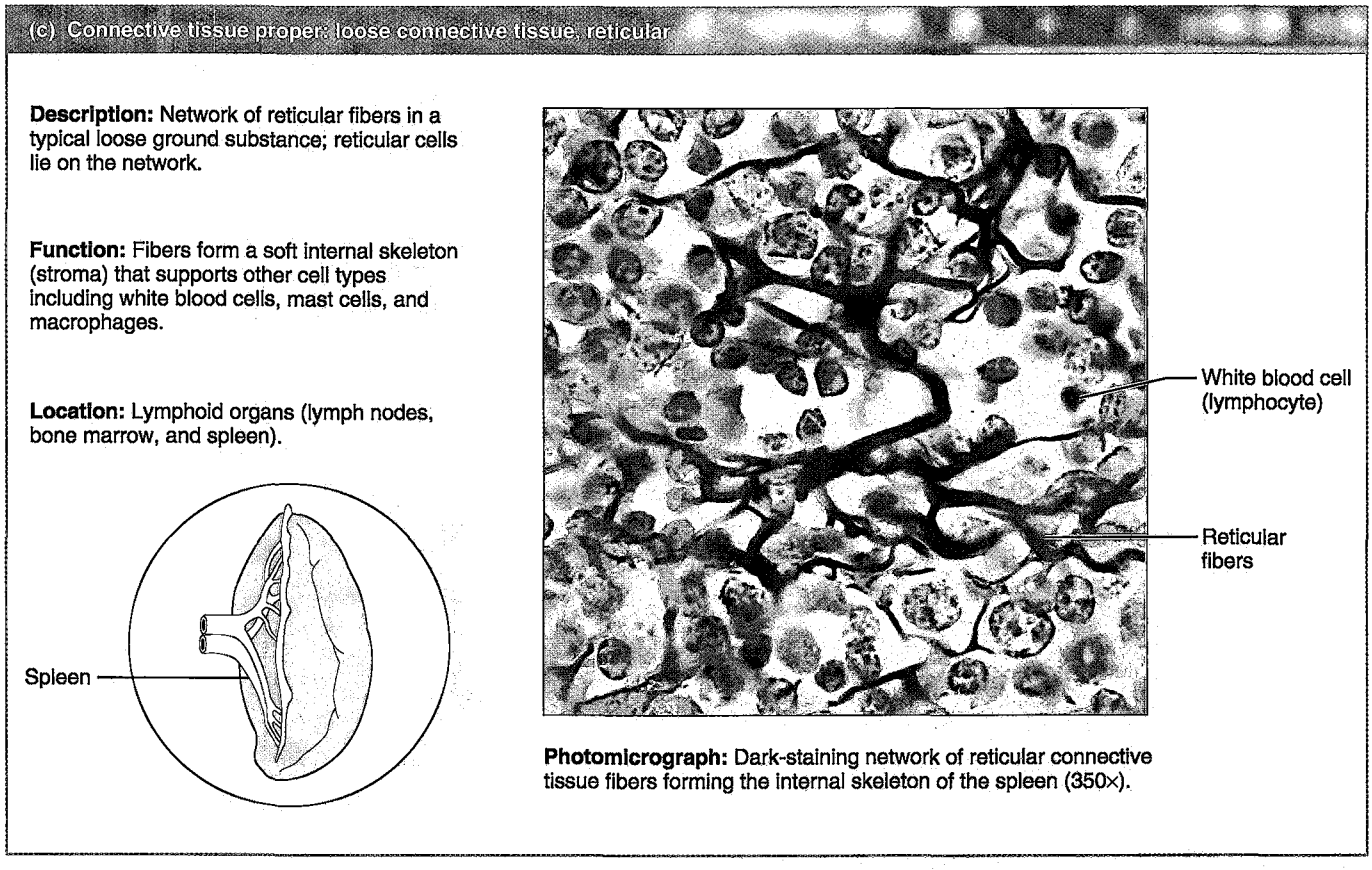


FIGURE 4.9 *(continued)* **(c)** Connective tissue proper.

shock absorber, as insulation, and as an energy storage site. Because fat is a poor conductor of heat, it helps prevent heat loss from the body. Other sites where fat accumulates include surrounding the kidneys, behind the eyeballs, and at genetically determined fat depots such as the abdomen and hips.

Whereas the abundant fat beneath the skin serves the general nutrient needs of the entire body, smaller depots of fat serve the local nutrient needs of highly active organs. Such depots occur around the hard-working heart and around lymph nodes (where cells of the immune system are furiously fighting infection), within some muscles, and as individual fat cells in the bone marrow, where new blood cells are produced at a rapid rate. Many of these local depots are highly enriched in special lipids.

The adipose tissue just described is sometimes called *white fat,* or *white adipose tissue,* to distinguish it from **brown fat,** or **brown adipose tissue.** Whereas white fat stores nutrients, brown fat adipose cells contain abundant mitochondria, which use the lipid fuels to heat the bloodstream to warm the body rather than to produce ATP molecules. The richly vascular brown fat occurs only in babies who (as yet) lack the ability to produce body heat by shivering. Most such deposits are located between the shoulder blades, on the anterolateral neck, and on the anterior abdominal wall.

Reticular Connective Tissue **Reticular connective tissue** resembles areolar connective tissue, but the only fibers in its matrix are reticular fibers, which form a delicate network along which fibroblasts called **reticular cells** lie scattered (Figure 4.9c). Although reticular *fibers* are widely distributed in the body, reticular *tissue* is limited to certain sites. It forms a labyrinth-like **stroma** (literally, "bed" or "mattress"), or internal framework, that can support many free blood cells (largely lymphocytes) in lymph nodes, the spleen, and bone marrow.

Dense Regular Connective Tissue **Dense regular connective tissue** (Figure 4.9d) is one variety of the dense connective tissues, all of which have fibers as their predominant element. For this reason, the dense connective tissues are often referred to as **fibrous connective tissues.**

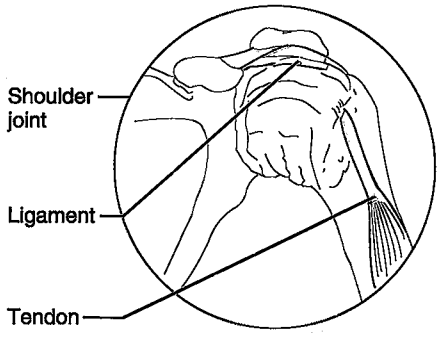
Dense regular connective tissue contains closely packed bundles of collagen fibers running in the same direction, parallel to the direction of pull.

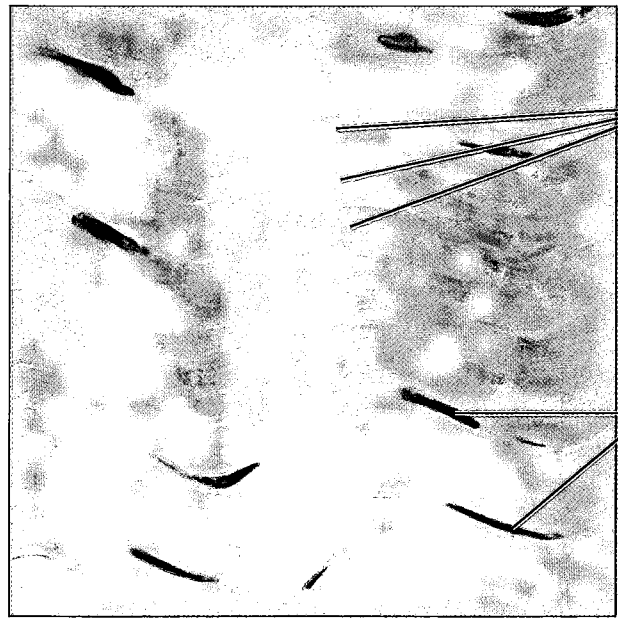
(d) Connective tissue proper: dense connective tissue, dense regular

Description: Primarily parallel collagen fibers; a few elastin fibers; major cell type is the fibroblast.

Function: Attaches muscles to bones or to muscles; attaches bones to bones; withstands great tensile stress when pulling force is applied in one direction.

Location: Tendons, most ligaments, aponeuroses.





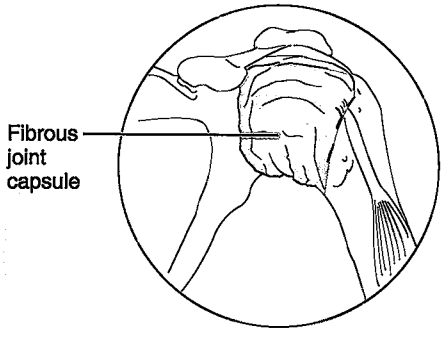
Photomicrograph: Dense regular connective tissue from a tendon (1000×).

(e) Connective tissue proper: dense connective tissue, dense irregular

Description: Primarily irregularly arranged collagen fibers; some elastic fibers; major cell type is the fibroblast.

Function: Able to withstand tension exerted in many directions; provides structural strength.

Location: Dermis of the skin; submucosa of digestive tract; fibrous capsules of organs and of joints.



Photomicrograph: Dense irregular connective tissue from the dermis of the skin (400×).

FIGURE 4.9 **Connective tissues.** *(continued)* **(d)** and **(e)** Connective tissue proper.

This results in white, flexible structures with great resistance to tension (pulling forces) where the tension is exerted in a single direction. Crowded between the collagen fibers are rows of fibroblasts that continuously manufacture the fibers and scant ground substance. As seen in Figure 4.9d, collagen fibers are slightly wavy. This allows the tissue to stretch a little, but once the fibers are straightened out by a pulling force, there is no further "give" to this tissue. Unlike our model (areolar) connective tissue, this tissue has few cells other than fibroblasts and it is poorly vascularized.

With its enormous tensile strength, dense regular connective tissue forms the *tendons,* which are cords that attach muscles to bones, and flat, sheetlike tendons called *aponeuroses* (ap"o-nu-ro'sēz) that attach muscles to other muscles or to bones. It also forms fascia (fash'e-ah; "a bond"), a fibrous membrane that wraps around muscles, groups of muscles, blood vessels, and nerves, binding those structures together like plastic sandwich wrap; and the ligaments that bind bones together at joints. Ligaments contain more elastic fibers than tendons and are slightly more stretchy. A few ligaments, such as the *ligamenta nuchae* and *flava* connecting adjacent vertebrae, are very elastic, so much so that the connective tissue in those structures is referred to as *elastic connective tissue.*

Dense Irregular Connective Tissue **Dense irregular connective tissue** has the same structural elements as the regular variety. However, the bundles of collagen fibers are much thicker and they are arranged irregularly; that is, they run in more than one plane (Figure 4.9e). This type of tissue forms sheets in body areas where tension is exerted from many different directions. It is found in the skin as the leathery *dermis,* and it forms fibrous joint capsules and the fibrous coverings that surround some organs (kidneys, bones, cartilages, muscles, and nerves).

Cartilage

Cartilage (kar'tĭ-lij), which stands up to both tension *and* compression, has qualities intermediate between dense connective tissue and bone. It is tough but flexible, providing a resilient rigidity to the structures it supports. Cartilage lacks nerve fibers and is avascular. It receives its nutrients by diffusion from blood vessels located in the connective tissue membrane (perichondrium) surrounding it. Its ground substance contains large amounts of the GAGs chrondroitin sulfate and hyaluronic acid, firmly bound collagen fibers (and in some cases elastic fibers), and is quite firm. Cartilage matrix also contains an exceptional amount of tissue fluid; in fact, cartilage is up to 80% water! The movement of tissue fluid in its matrix enables cartilage to rebound after being compressed and also helps to nourish the cartilage cells.

Chondroblasts, the predominant cell type in growing cartilage, produce new matrix until the skeleton stops growing at the end of adolescence. The firmness of the cartilage matrix prevents the cells from becoming widely separated, so **chondrocytes,** or mature cartilage cells, are typically found in small groups within cavities called *lacunae* (lah-ku'ne; "pits").

HOMEOSTATIC IMBALANCE

Because cartilage is avascular and aging cartilage cells lose their ability to divide, cartilages heal slowly when injured. This phenomenon is excruciatingly familiar to those who have experienced sports injuries. During later life, cartilages tend to calcify or even ossify (become bony). In such cases, the chondrocytes are poorly nourished and die.

There are three varieties of cartilage: *hyaline cartilage, elastic cartilage,* and *fibrocartilage,* each dominated by a particular fiber type.

Hyaline Cartilage **Hyaline cartilage** (hi'ah-līn), or *gristle,* is the most abundant cartilage type in the body. Although it contains large numbers of collagen fibers, they are not apparent and the matrix appears amorphous and glassy (*hyalin* = glass) blue-white when viewed by the unaided eye (Figure 4.9f). Chondrocytes account for only 1–10% of the cartilage volume.

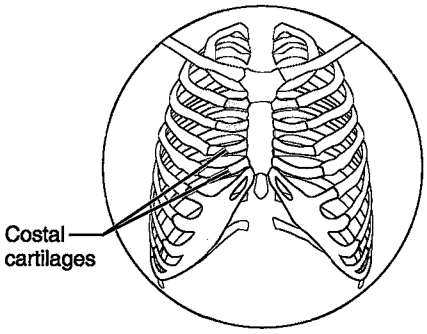
Hyaline cartilage provides firm support with some pliability. It covers the ends of long bones as *articular cartilage,* providing springy pads that absorb compression at joints. Hyaline cartilage also supports the tip of the nose, connects the ribs to the sternum, and supports most of the respiratory system passages. Most of the embryonic skeleton is formed of hyaline cartilage before bone is formed. Skeletal hyaline cartilage persists during childhood as the *epiphyseal plates* (e"pĭ-fis'e-ul), actively growing regions near the end of long bones that provide for continued growth in length.

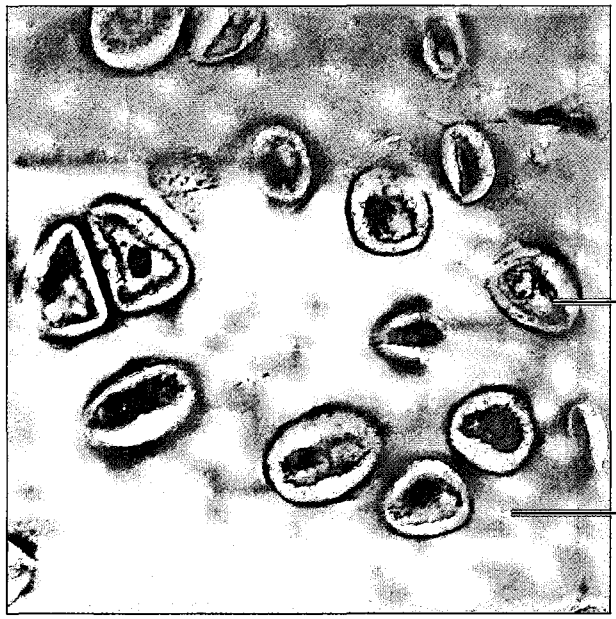
(f) Cartilage: hyaline

Description: Amorphous but firm matrix; collagen fibers form an imperceptible network; chondroblasts produce the matrix and when mature (chondrocytes) lie in lacunae.

Function: Supports and reinforces; has resilient cushioning properties; resists compressive stress.

Location: Forms most of the embryonic skeleton; covers the ends of long bones in joint cavities; forms costal cartilages of the ribs; cartilages of the nose, trachea, and larynx.





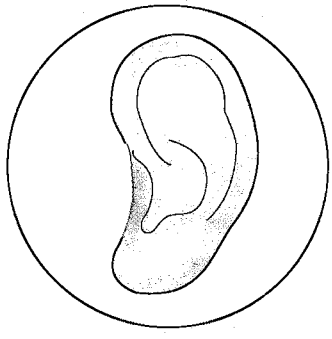
Photomicrograph: Hyaline cartilage from the trachea (300×).

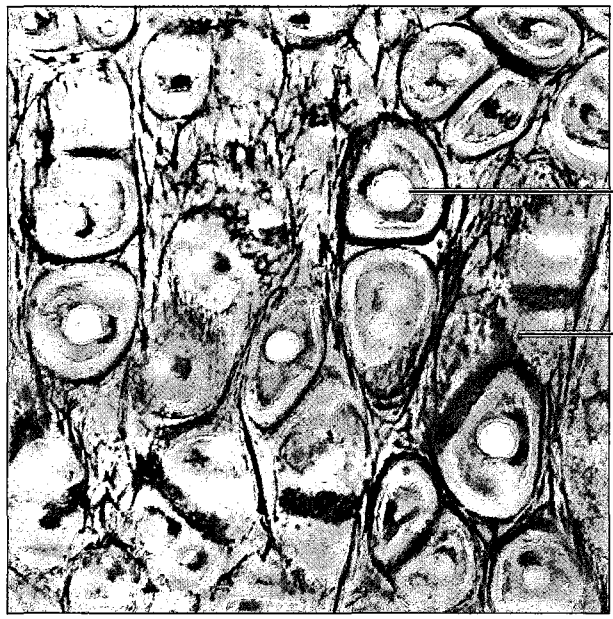
(g) Cartilage: elastic

Description: Similar to hyaline cartilage, but more elastic fibers in matrix.

Function: Maintains the shape of a structure while allowing great flexibility.

Location: Supports the external ear (pinna); epiglottis.





Photomicrograph: Elastic cartilage from the human ear pinna; forms the flexible skeleton of the ear (640×).

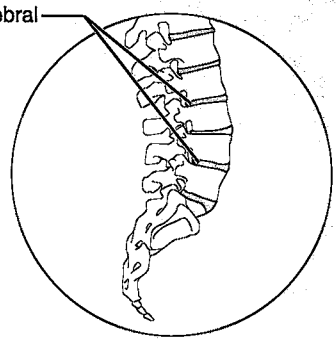
FIGURE 4.9 **Connective tissues.** *(continued)* **(f)** and **(g)** Cartilage.

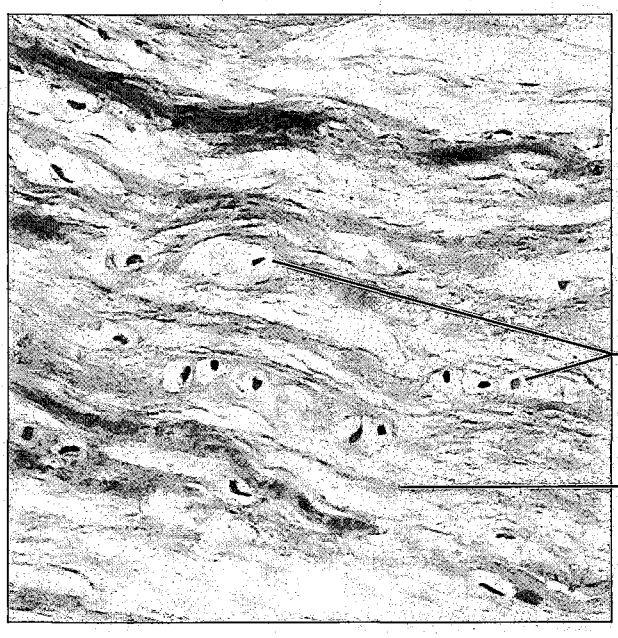
(h) Cartilage: fibrocartilage

Description: Matrix similar to but less firm than that in hyaline cartilage; thick collagen fibers predominate.

Function: Tensile strength with the ability to absorb compressive shock.

Location: Intervertebral discs; pubic symphysis; discs of knee joint.





Photomicrograph: Fibrocartilage of an intervertebral disc (200×). Special staining produced the blue color seen.

FIGURE 4.9 *(continued)* **(h)** Cartilage.

Elastic Cartilage Histologically, **elastic cartilage** (Figure 4.9g) is nearly identical to hyaline cartilage. However, there are many more elastin fibers in elastic cartilage. Found where strength and exceptional stretchability are needed, elastic cartilage forms the "skeletons" of the external ear and the epiglottis. (The epiglottis is the flap that covers the opening to the respiratory passageway when we swallow, preventing food or fluids from entering the lungs.)

Fibrocartilage **Fibrocartilage** is a perfect structural intermediate between hyaline cartilage and dense regular connective tissues. Its rows of chondrocytes (a cartilage feature) alternate with rows of thick collagen fibers (a feature of dense regular connective tissue) (Figure 4.9h). Because it is compressible and resists tension well, fibrocartilage is found where strong support and the ability to withstand heavy pressure are required. For example, the intervertebral discs (resilient cushions between the bony vertebrae) and the spongy cartilages of the knee (menisci) are fibrocartilage structures (see Figure 6.1, p. 177).

Bone (Osseous Tissue)

Because of its rocklike hardness, **bone,** or **osseous tissue** (os'e-us), has an exceptional ability to support and protect body structures. Bones of the skeleton also provide cavities for fat storage and synthesis of blood cells. Bone matrix is similar to that of cartilage but is harder and more rigid because, in addition to its more abundant collagen fibers, bone has an added matrix element—inorganic calcium salts (bone salts).

Osteoblasts produce the organic portion of the matrix; then bone salts are deposited on and between the fibers. Mature bone cells, or **osteocytes,** reside in the lacunae within the matrix they have made (Figure 4.9i). In cross section, bone tissue is seen as closely packed structural units called *osteons* formed of concentric rings of bony matrix (lamellae) surrounding central canals containing the blood vessels and nerves serving the bone. Unlike cartilage, the next firmest connective tissue, bone is well supplied by invading blood vessels.

Blood

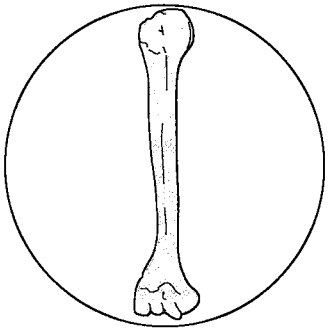
Blood, the fluid within blood vessels, is the most atypical connective tissue. It does *not* connect things or give mechanical support. It is classified as a connective tissue because it develops from mesenchyme and consists of blood *cells,* surrounded by a nonliving fluid matrix called *blood plasma* (Figure 4.9j).

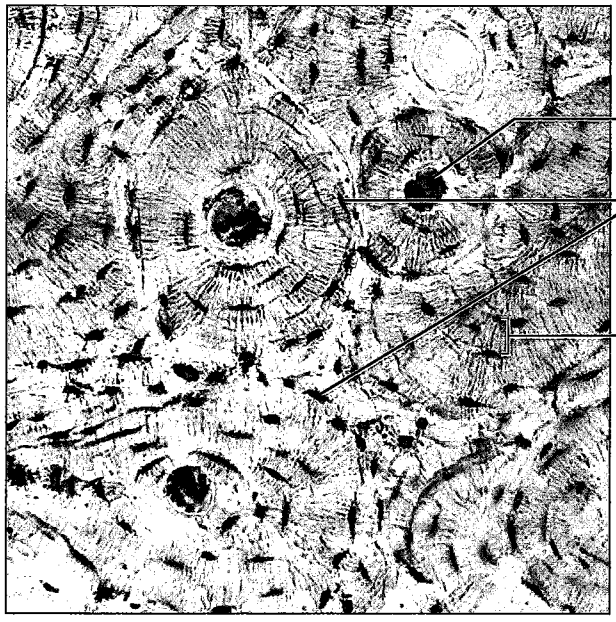
(i) Others: bone (osseous tissue)

Description: Hard, calcified matrix containing many collagen fibers; osteocytes lie in lacunae. Very well vascularized.

Function: Bone supports and protects (by enclosing); provides levers for the muscles to act on; stores calcium and other minerals and fat; marrow inside bones is the site for blood cell formation (hematopoiesis).

Location: Bones





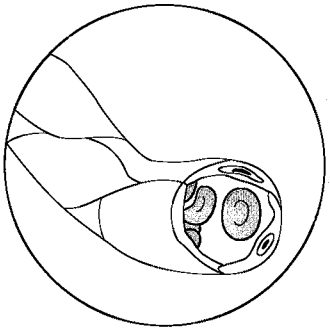
Photomicrograph: Cross-sectional view of bone (70×).

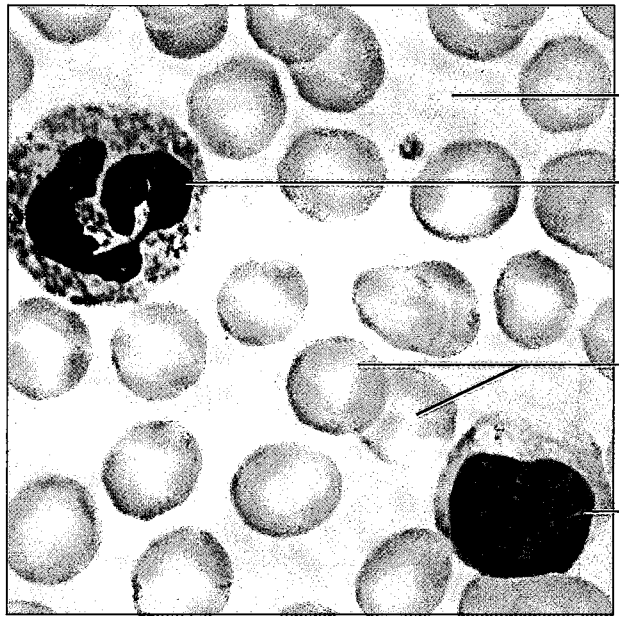
(j) Others: blood

Description: Red and white blood cells in a fluid matrix (plasma).

Function: Transport of respiratory gases, nutrients, wastes, and other substances.

Location: Contained within blood vessels.



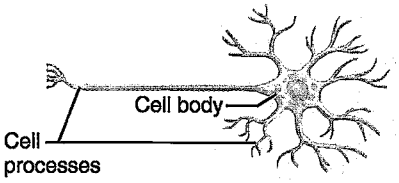


Photomicrograph: Smear of human blood (1500×); two white blood cells (neutrophil in upper left and lymphocyte in lower right) are seen surrounded by red blood cells.

FIGURE 4.9 **Connective tissues.** *(continued)* **(i)** Bone. **(j)** Blood.

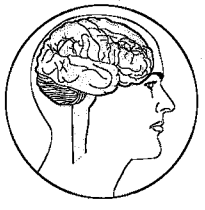
Nervous tissue

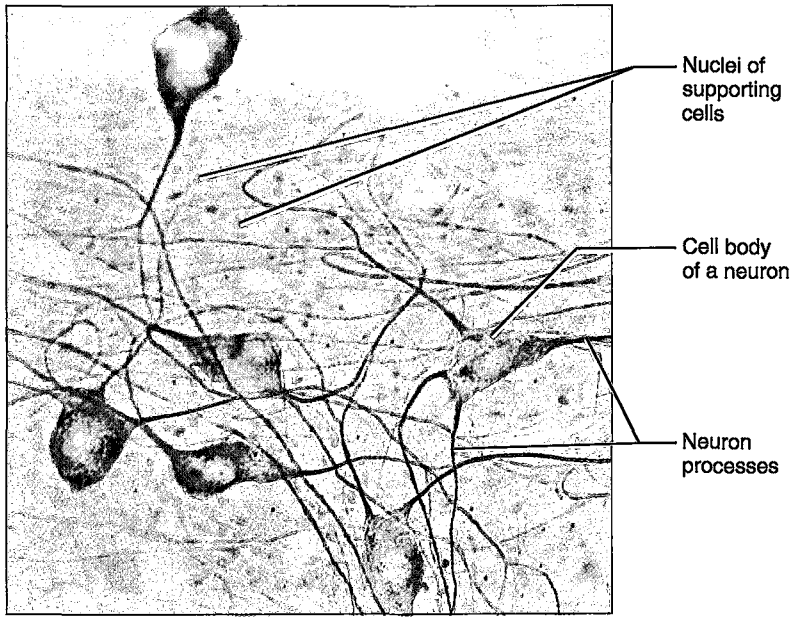
Description: Neurons are branching cells; cell processes that may be quite long extend from the nucleus-containing cell body; also contributing to nervous tissue are nonirritable supporting cells (not illustrated).



Function: Transmit electrical signals from sensory receptors and to effectors (muscles and glands) which control their activity.

Location: Brain, spinal cord, and nerves.





Photomicrograph: Neurons (100×)

FIGURE 4.10 **Nervous tissue.**

The vast majority of blood cells are red blood cells or erythrocytes, but scattered white blood cells (neutrophils, lymphocytes, monocytes, eosinophils, basophils) are also seen. The "fibers" of blood are soluble protein molecules that precipitate, forming large visible fiberlike structures during blood clotting. Blood functions as the transport vehicle for the cardiovascular system, carrying nutrients, wastes, respiratory gases, and many other substances throughout the body.

Nervous Tissue

Nervous tissue is the main component of the nervous system—the brain, spinal cord, and nerves—which regulates and controls body functions. It contains two major cell types. **Neurons** are highly specialized nerve cells that generate and conduct nerve impulses (Figure 4.10). Typically, they are branching cells with cytoplasmic extensions or processes. Their processes allow them to respond to stimuli (a role of *dendrites*) and to transmit electrical impulses over substantial distances within the body (the job of *axons*, which may be very long and myelinated, that is, covered with a fatty sheath that increases the speed of nerve transmission). The balance of nervous tissue consists of various types of supporting cells, nonconducting cells that support, insulate, and protect the delicate neurons. A more complete discussion of nervous tissue appears in Chapter 11.

Muscle Tissue

Muscle tissues are highly cellular, well-vascularized tissues that are responsible for most types of body movement. Muscle cells possess **myofilaments,** elaborate versions of the *actin* and *myosin* filaments that bring about movement or contraction in all cell types. There are three kinds of muscle tissue: skeletal, cardiac, and smooth.

Skeletal muscle tissue is packaged by connective tissue sheets into organs called *skeletal muscles* that are attached to the bones of the skeleton. These muscles form the flesh of the body, and as they contract, they pull on bones or skin, causing body movements. Skeletal muscle cells, also called **muscle fibers,** are long, cylindrical cells that contain many nuclei. Their obvious banded, or *striated,* appearance reflects the precise alignment of their myofilaments (Figure 4.11a).

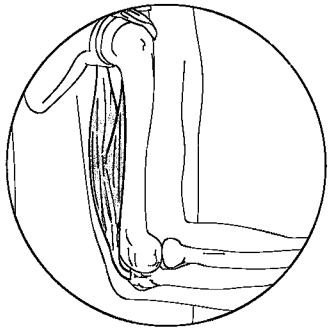
Cardiac muscle is found only in the wall of the heart. Its contractions help propel blood through the blood vessels to all parts of the body. Like skeletal muscle cells, cardiac muscle cells are striated.

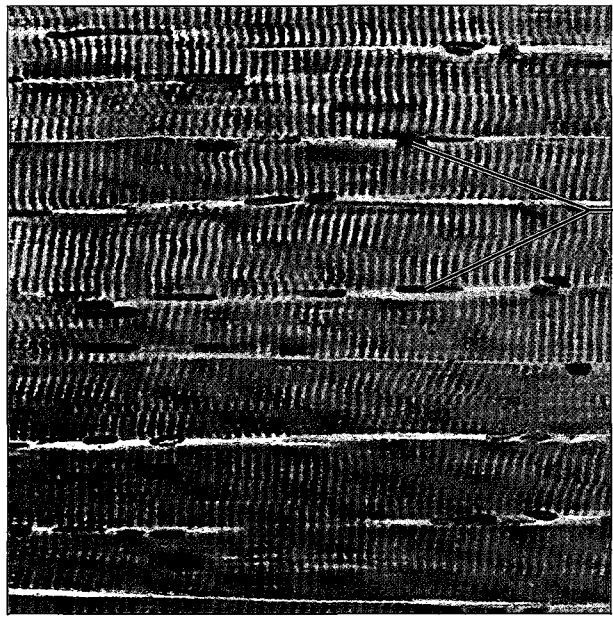
(a) Skeletal muscle

Description: Long, cylindrical, multinucleate cells; obvious striations.

Function: Voluntary movement; locomotion; manipulation of the environment; facial expression; voluntary control.

Location: In skeletal muscles attached to bones or occasionally to skin.





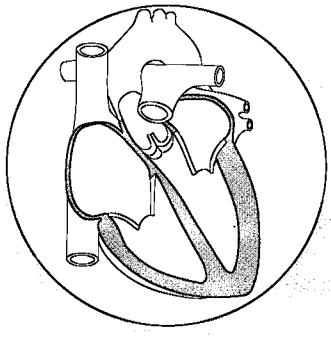
Photomicrograph: Skeletal muscle (approx. 300×). Notice the obvious banding pattern and the fact that these large cells are multinucleate.

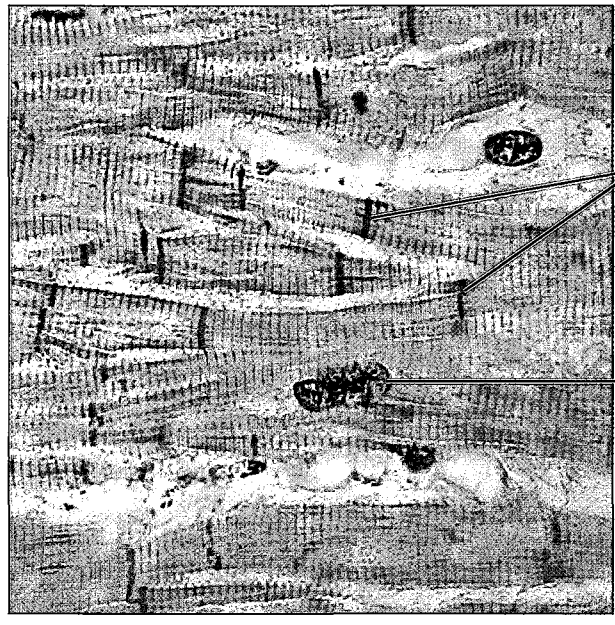
(b) Cardiac muscle

Description: Branching, striated, generally uninucleate cells that interdigitate at specialized junctions (intercalated discs).

Function: As it contracts, it propels blood into the circulation; involuntary control.

Location: The walls of the heart.





Photomicrograph: Cardiac muscle (800×); notice the striations, branching of cells, and the intercalated discs.

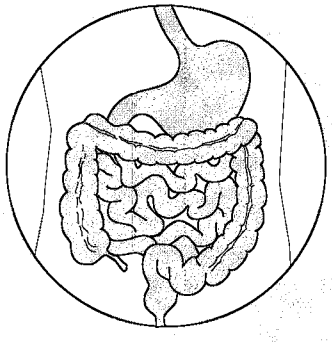
FIGURE 4.11 **Muscle tissues. (a)** Skeletal muscle tissue. **(b)** Cardiac muscle tissue.

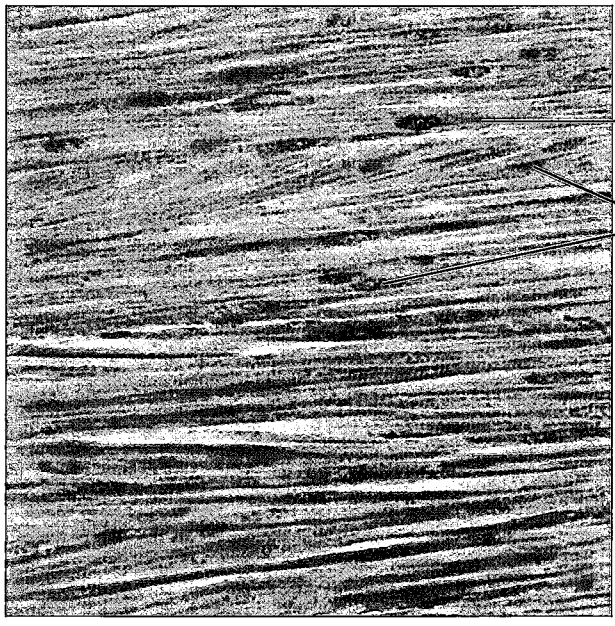
(c) Smooth muscle

Description: Spindle-shaped cells with central nuclei; no striations; cells arranged closely to form sheets.

Function: Propels substances or objects (foodstuffs, urine, a baby) along internal passageways; involuntary control.

Location: Mostly in the walls of hollow organs.





Photomicrograph: Sheet of smooth muscle (approx. 600×).

FIGURE 4.11 *(continued)* **(c)** Smooth muscle tissue.

However, they differ structurally in that cardiac cells (1) are uninucleate and (2) are branching cells that fit together tightly at unique junctions called **intercalated discs** (in-ter'kah-la"ted) (Figure 4.11b).

Smooth muscle is so named because its cells have no visible striations. Individual smooth muscle cells are spindle shaped and contain one centrally located nucleus (Figure 4.11c). Smooth muscle is found mainly in the walls of hollow organs other than the heart (digestive and urinary tract organs, uterus, and blood vessels). It acts to squeeze substances through these organs by alternately contracting and relaxing.

Because skeletal muscle contraction is under our conscious control, skeletal muscle is often called **voluntary muscle,** and the other two types are called **involuntary muscle.** Skeletal muscle and smooth muscle are described in detail in Chapter 9; cardiac muscle is discussed in Chapter 18.

Covering and Lining Membranes

Now that we have described all four primary tissues, we can consider the body's membranes that incorporate more than one type of tissue. The covering and lining membranes are of three types: *cutaneous, mucous,* or *serous.* Essentially they all are continuous multicellular sheets composed of at least two primary tissue types: an epithelium bound to an underlying layer of connective tissue proper. Hence, these membranes are simple organs. The *synovial membranes,* which line joint cavities and consist of connective tissue only, are described in Chapter 8.

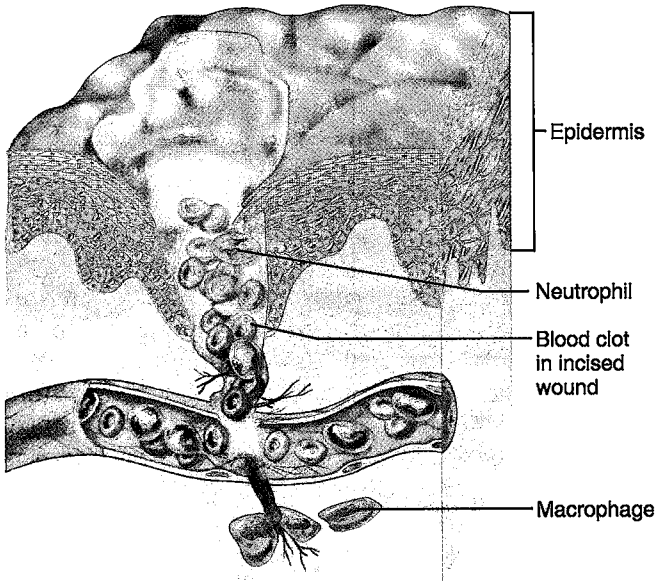
Cutaneous Membrane

The **cutaneous membrane** (ku-ta'ne-us; *cutis* = skin) is your skin (Figure 4.12a). It is an organ system consisting of a keratinized stratified squamous epithelium (epidermis) firmly attached to a thick layer of dense irregular connective tissue (dermis). Unlike other epithelial membranes, the cutaneous membrane is exposed to the air and is a dry membrane. Chapter 5 is devoted to this unique organ system.

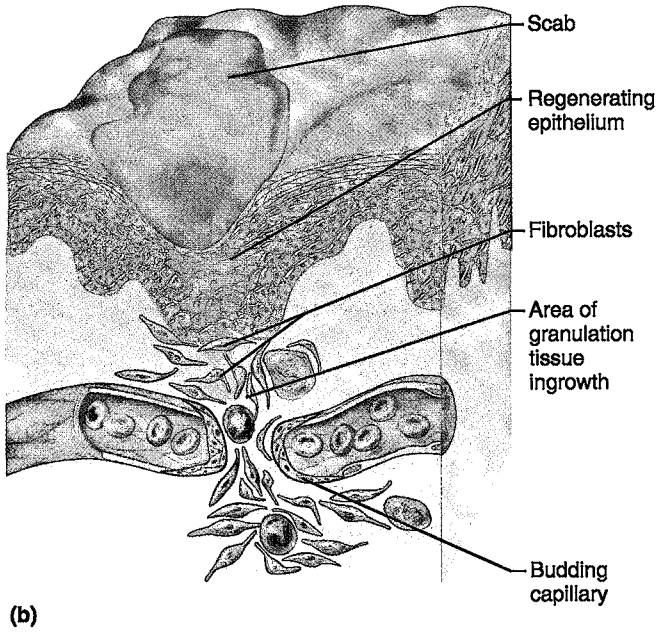
Mucous Membranes

Mucous membranes, or **mucosae** (mu-ko'se), line body cavities that open to the exterior, such as those of the hollow organs of the digestive, respiratory, and urogenital tracts (Figure 4.12b). In all cases, they are "wet," or moist, membranes bathed by secretions or, in the case of the urinary mucosa, urine. Notice that the term *mucosa* refers to the location of the membrane, *not* its cell composition, which varies.

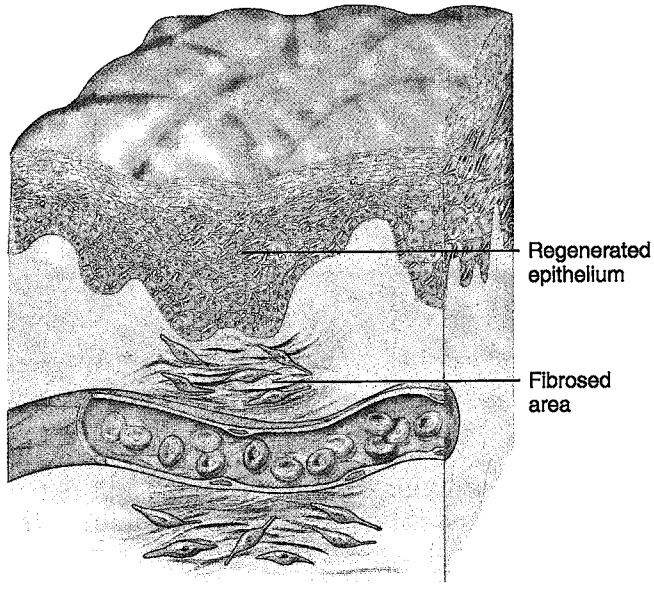
Q *(1) What is the makeup of granulation tissue formed at the injured site? (2) Where do the new capillaries that invade the injured area come from? (3) How would this pictorial series look different if repair by regeneration was not possible?*



(a)



(b)



(c)

FIGURE 4.13 **Tissue repair of a nonextensive skin wound: regeneration and fibrosis. (a)** Severed blood vessels bleed. Inflammatory chemicals are released, and local blood vessels dilate and become more permeable, allowing white blood cells, fluid, clotting proteins, and other plasma proteins to invade the injured site. Clotting proteins initiate clotting; surface dries and forms a scab. **(b)** Granulation tissue is formed. Capillaries invade the clot, restoring a vascular supply. Fibroblasts secrete soluble collagen, which constructs collagen fibers that bridge the gap. Macrophages phagocytize dead and dying cell debris. Surface epithelial cells proliferate and migrate over the granulation tissue. **(c)** Approximately one week later, the fibrosed area (scar) has contracted and regeneration of the epithelium is in progress.

and blood-forming tissue regenerate extremely well. Smooth muscle and dense regular connective tissue have a moderate capacity for regeneration, but skeletal muscle and cartilage have a weak regenerative capacity. Cardiac muscle and the nervous tissue in the brain and spinal cord have virtually no *functional* regenerative capacity, and they are routinely replaced by scar tissue. However, recent studies have shown that some unexpected (and highly selective) cellular division occurs in both these tissues after damage, and efforts are under way to coax them to regenerate better.

In nonregenerating tissues and in exceptionally severe wounds, fibrosis totally replaces the lost tissue. Over a period of months, the fibrous mass shrinks and becomes more and more compact. The resulting scar appears as a pale, often shiny area composed mostly of collagen fibers. Scar tissue is strong, but it lacks the flexibility and elasticity of most normal tissues. Also, it cannot perform the normal functions of the tissue it has replaced.

A *(1) Budding capillaries and loose connective tissue. (2) They bud from uninjured blood vessels in the area. (3) The epidermis would not be continuous. The tissue in the injured region would be totally replaced by scar tissue.*

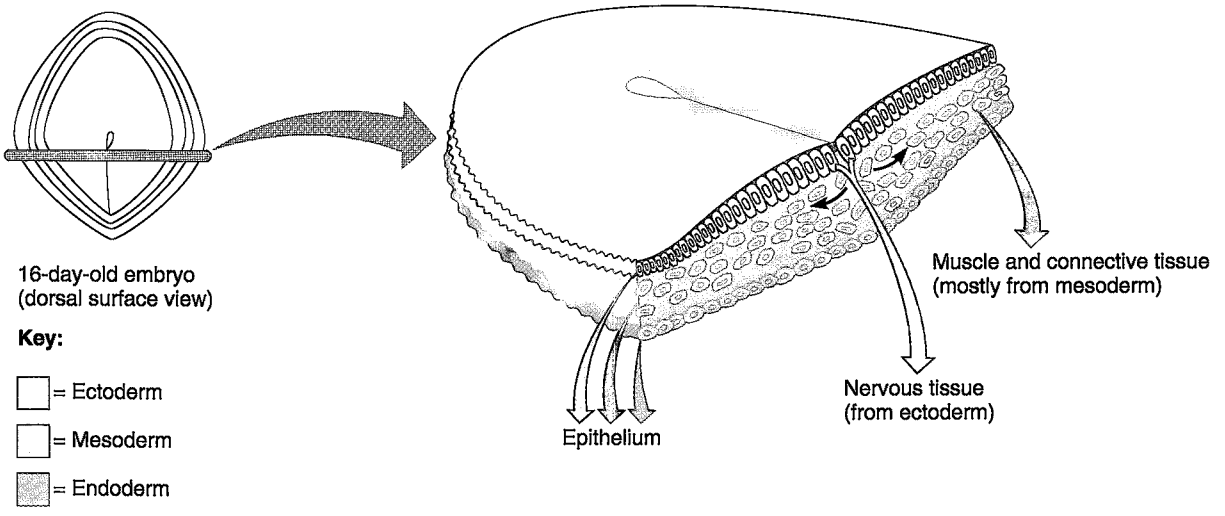


FIGURE 4.14 **Embryonic germ layers and the primary tissue types they produce.** The three embryonic layers collectively form the very early embryonic body.

HOMEOSTATIC IMBALANCE

Scar tissue that forms in the wall of the urinary bladder, heart, or other muscular organ may severely hamper the function of that organ. The normal shrinking of the scar reduces the internal volume of an organ and may hinder or even block movement of substances through a hollow organ. Scar tissue hampers muscle's ability to contract and may interfere with its normal excitation by the nervous system. In the heart, these problems may lead to progressive heart failure. In irritated visceral organs, particularly following abdominal surgery, *adhesions* may form as the newly forming scar tissue connects adjacent organs together. Such adhesions can prevent the normal shifting about (churning) of loops of the intestine, dangerously obstructing the flow of foodstuffs through it. Adhesions can also restrict heart movements and immobilize joints. ●

Developmental Aspects of Tissues

One of the first events of embryonic development is the formation of the three **primary germ layers,** which lie one atop the next like a three-layered cellular pancake. From superficial to deep, these layers are the **ectoderm, mesoderm** (mez'o-derm), and **endoderm.** As shown in Figure 4.14, these primary germ layers then specialize to form the four primary tissues from which all body organs are derived.

By the end of the second month of development, the primary tissues have appeared, and all major organs are in place. In general, tissue cells remain mitotic and produce the rapid growth that occurs before birth. The division of nerve cells, however, stops or nearly stops during the fetal period. After birth, the cells of most other tissues continue to divide until adult body size is achieved. Cellular division then slows greatly, although many tissues retain the ability to regenerate. In adults, only epithelia and blood-forming tissues are highly mitotic. Some tissues that regenerate through life, such as the glandular cells of the liver, do so through division of their mature (specialized) cells. Others, like the epidermis of the skin and cells lining the intestine, have abundant *stem cells,* relatively undifferentiated cells that divide as necessary to produce new cells.

Given good nutrition, good circulation, and relatively infrequent wounds and infections, our tissues normally function efficiently through youth and middle age. But with increasing age, epithelia thin and are more easily breached. Tissue repair is less efficient, and bone, muscle, and nervous tissues begin to atrophy. These events are due partly to decreased circulatory efficiency, which reduces delivery of nutrients to the tissues, but in some cases, diet is a contributing factor. As income declines or as chewing becomes more difficult, older people tend to eat soft foods, which may be low in protein and vitamins. As a result, tissue health suffers.

Another problem of aging tissues is the likelihood of DNA mutations in the most actively mitotic cells, which increases the risk of cancer (as indicated in the *Closer Look Box* on p. 146).

■ ■ ■

Cancer—The Intimate Enemy

The word *cancer* elicits dread in everyone. Why does cancer strike some and not others?

Although once perceived as disorganized cell growth, this disease is now known to be a logical, coordinated process in which a precise sequence of tiny alterations changes a normal cell into a killer. Let's take a closer look at what cancer really is.

When cells fail to honor normal controls of cell division and multiply excessively, an abnormal mass of proliferating cells called a *neoplasm* (ne'o-plazm, "new growth") results. Neoplasms are classified as **benign** ("kindly") or **malignant** ("bad"). A benign neoplasm is strictly a local affair. Its cells remain compacted, are often encapsulated, tend to grow slowly, and seldom kill their hosts if they are removed before they compress vital organs. In contrast, cancers are malignant neoplasms, nonencapsulated masses that grow relentlessly and may become killers. Their cells resemble immature cells, and they invade their surroundings rather than pushing them aside, as reflected in the name *cancer,* from the Latin word for "crab." Whereas normal cells become fatally "homesick" and die when they lose contact with the surrounding matrix, malignant cells tend to break away from the parent mass, the primary tumor, and travel via blood or lymph to other body organs, where they survive and form *secondary cancer masses.* This capability for traveling to other parts of the body, called **metastasis** (mĕ-tas'tah-sis), probably has a lot to do with cell surface glycoproteins the cancer cells bear. For example, a carbohydrate called sialyl Lewis X binds to adhesion molecules on epithelial cells and platelets. Metastasis and invasiveness distinguish cancer cells from the cells of benign neoplasms. Cancer cells consume an exceptional amount of the body's nutrients, leading to weight loss and tissue wasting that contribute to death.

Mechanisms of Carcinogenesis

Autopsies on individuals aged 50–70 who died of another cause have revealed that most of them (us) have microscopic (but dormant) in situ neoplasms. So what causes a normal cell to **transform** or change into a cancerous one? Some physical factors (radiation, mechanical trauma), certain viral infections, chronic inflammations, and many chemicals (tobacco tars, saccharine, some natural food chemicals) can act as **carcinogens** (cancer-causers). What these factors have in common: They all cause *mutations*—changes in DNA that alter the expression of certain genes. However, not all carcinogens do damage because most are eliminated by peroxisomal or lysosomal enzymes or by the immune system. Furthermore, one mutation usually isn't enough; it takes several genetic changes to transform a normal cell into a cancerous cell.

A clue to the role of genes in cancer was provided by the discovery of **oncogenes** (Greek *onco* = tumor), or cancer-causing genes, in rapidly spreading cancers. **Proto-oncogenes,** benign forms of oncogenes in normal cells, were discovered later. Proto-oncogenes code for proteins that are essential for cell division, growth, and cellular adhesion, among other things. Many have fragile sites that break when exposed to carcinogens, converting them to oncogenes. Failure to code for certain proteins may lead to loss of an enzyme that controls an important metabolic process. Oncogenes, now known to number over 100, may also "switch on" dormant genes that allow cells to become invasive and metastasize.

Oncogenes have been detected in only 15–20% of human cancers, so investigators were not too surprised by the discovery of **tumor suppressor genes,** or **antioncogenes,** which suppress cancer by inactivating carcinogens, aiding DNA repair, or enhancing the immune system's counterattack. In fact, over half of all cancers involve malfunction or loss of just two of the 15 identified tumor suppressor genes—*p53* and *p16.* This is not surprising when you learn that *p53* prompts most cells to make proteins that put the brakes on cell division in stressed cells by promoting apoptosis or cell cycle arrest. Hence, its impairment invites uncontrolled division and cancer. Furthermore, although each type of cancer is genetically distinct, human cancers appear to share a common master set of genes—an activated group of 67 genes—and almost all cancer cells have gained or lost entire chromosomes. Whatever genetic factors are at work, the "seeds" of cancer do appear to be in our own genes. Thus, cancer is an intimate enemy indeed.

The illustration depicts some of the mutations involved in colorectal cancer, one of the best-understood human cancers. As with most cancers, a metastasis develops gradually. One of the first signs is a polyp, a small benign growth consisting of apparently normal mucosa cells. As cell division continues, the growth enlarges, becoming an adenoma. As various tumor-suppressor genes are inactivated and the *K-ras* oncogene is mobilized, the mutations pile up and the adenoma becomes increasingly abnormal. The final consequence is colon carcinoma, a form of cancer that metastasizes quickly.

Cancer Prevalence

Almost half of all Americans develop cancer in their lifetime and a fifth of us will die of it. Cancer can arise from almost any cell type, but the most common cancers originate in the skin, lung, colon, breast, and prostate gland. Although stomach and colon cancer incidence is down, skin and lymphoid cancer rates are up.

Many cancers are preceded by observable lumps or other structural changes in tissue—for instance, *leukoplakia,* white patches in the mouth caused by the chronic irritation of ill-fitting dentures or heavy smoking. Although these lesions sometimes progress to cancer, in many cases they remain stable or even revert to normal if the environmental stimulus is removed.

Diagnosis and Staging

Screening procedures are vital for early detection. Examples include *mammography,* examining breasts or testicles for lumps, and checking fecal samples for blood. Unfortunately, most cancers are diagnosed only after symptoms

have already appeared. In this case the diagnostic method is usually a **biopsy:** removing a tissue sample surgically and examining it microscopically for malignant cells. Increasingly, diagnosis is made by chemical or genetic analysis of the sample. Typing cancer cells by what genes are switched on or off tells clinicians which drugs to use. For example, taxol, quite successful with breast and ovarian cancer, works only against tumors with a specific genetic makeup. Medical imaging techniques (MRI, CT) can detect large tumors.

Several techniques (physical and histological examinations, lab tests, and imaging techniques) are used to determine the extent of the disease (size of the neoplasm, degree of metastasis, etc.). Then, the cancer is assigned a **stage** from 1 to 4 according to the probability of cure (stage 1 has the best probability, stage 4 the worst).

Cancer Treatments

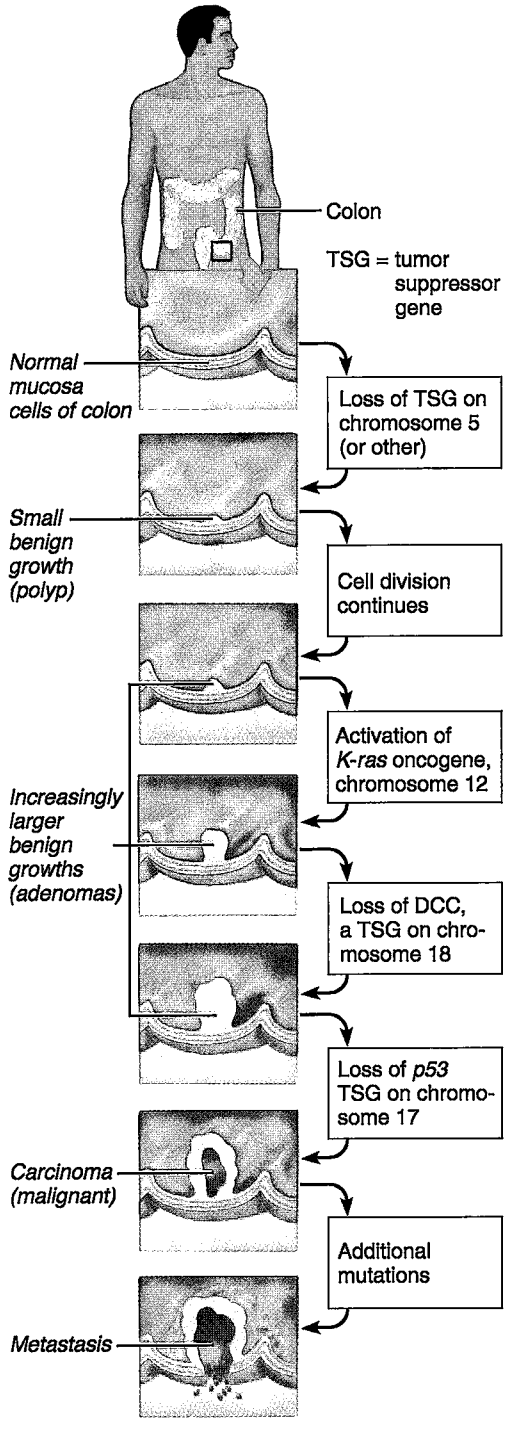
Most cancers are removed surgically if possible. To destroy metastasized cells, surgery is commonly followed by radiation therapy (X irradiation and/or treatment with radioisotopes) and chemotherapy (treatment with cytotoxic drugs). Chemotherapy is beset with the problem of resistance. Some cancer cells can eject the drugs in tiny bubbles or flattened vesicles dubbed exosomes, and these cells proliferate, forming new tumors that are invulnerable to chemotherapy. Furthermore, anticancer drugs have unpleasant side effects—nausea, vomiting, hair loss—because they kill all rapidly dividing cells, including normal tissues and cells. X rays also have side effects because, in passing through the body, they destroy healthy tissue in their path as well as cancer cells.

Promising New Therapies

Traditional cancer treatments—"cut, burn, and poison"—are widely recognized as crude and painful. Promising new therapies focus on

- Targeted drugs that interrupt the signaling pathways which fuel the cancer's growth. Examples include imatinib (Gleevec), which incapacitates a mutated enzyme that triggers uncontrolled division of cells in two rare blood and digestive system cancers, and trastuzumab (Herceptin), used to treat breast cancer patients. These drugs have been strikingly successful in providing a few extra weeks of life, before their protective effects wear off and the disease progresses again.
- Delivering drugs more precisely to the cancer while sparing normal tissue. One approach is to inject the patient with tiny drug-coated metal beads, which are guided to the tumor by a powerful magnet positioned over the body site. Or, a patient might take light-sensitive drugs that are drawn naturally into rapidly dividing cancer cells. Exposure to certain frequencies of laser light sets off a series of reactions that kill the malignant cells.
- Starving cancer cells by cutting off their blood supply. For instance, researchers are testing a drug, called the "icon molecule," that attacks endothelial cells lining the blood vessels in tumors. However, several clinical studies have found that hypoxic cancer cells sometimes go into a protective mode that produces angiogenic proteins to attract new blood vessels and prompts the cancer cells to become more aggressive.

Other experimental treatments seek to fix defective tumor-suppressor genes and oncogenes, destroy cancer cells with viruses, or signal cancer cells to commit suicide by apoptosis. One promising technique extracts and then infuses hand-picked immune cells (T cells) that have shown an enhanced ability to attack the cancer cells. Additionally, a cancer vaccine (TRICOM) still in clinical studies, contains genetically engineered viruses carrying genes for a cancer protein called carcinoembryonic antigen (CEA). When these proteins are delivered into the patient's body they stimulate an immune response which then orchestrates an attack on all CEA-bearing cancer cells.



Development of colon cancer.

At present, about half of all cancer cases are cured. Although average survival rates have not increased, the quality of life of cancer patients has improved in the last decade. We can offer better treatments for cancer-associated pain, and antinausea drugs and other helpful medicines can soothe the side effects of chemotherapy. ■

As we have seen, body cells combine to form four discrete tissue types: epithelial, connective, muscle, and nervous tissues. The cells making up each of these tissues share certain features but are by no means identical. They "belong" together because they have basic functional similarities. The connective tissues assume many guises, but perhaps the most versatile cells are those of epithelium: They protect our outer and inner surfaces, permit us to obtain oxygen, absorb vital nutrients into the blood, and allow our kidneys to excrete wastes. The important concept to carry away with you is that tissues, despite their unique abilities, cooperate to keep the body safe, healthy, and whole.

Related Clinical Terms

Adenoma (ad"ĕ-no'mah; *aden* = gland, *oma* = tumor) Any neoplasm of glandular epithelium, benign or malignant. The malignant type is more specifically called *adenocarcinoma.*

Autopsy (aw'top-se) Examination of the body, its organs, and its tissues after death to determine the actual cause of death; also called postmortem examination and necropsy.

Carcinoma (kar"sĭ-no'mah; *karkinos* = crab, cancer) Cancer arising in an epithelium; accounts for 90% of human cancers.

Healing by first intention The simplest type of healing; occurs when the edges of the wound are brought together by sutures, staples, or other means used to close surgical incisions. Only small amounts of granulation tissue need be formed.

Healing by second intention The wound edges remain separated, and the gap is bridged by relatively large amounts of granulation tissue; the manner in which unattended wounds heal. Healing is slower than in wounds in which the edges are brought together, and larger scars result.

Keloid (ke'loid) Abnormal proliferation of connective tissue during healing of skin wounds; results in large, unsightly mass of scar tissue at the skin surface.

Lesion (le'zhun; "wound") Any injury, wound, or infection that affects tissue over an area of a definite size (as opposed to being widely spread throughout the body).

Marfan's syndrome Genetic disease resulting in abnormalities of connective tissues due to a defect in fibrillin, a protein that is associated with elastin in elastic fibers. Clinical signs include loose-jointedness, long limbs and spiderlike fingers and toes, visual problems, and weakened blood vessels (especially the aorta) due to poor connective tissue reinforcement.

Pathology (pah-thol'o-je) Scientific study of changes in organs and tissues produced by disease.

Pus A collection of tissue fluid, bacteria, dead and dying tissue cells, white blood cells, and macrophages in an inflamed area.

Sarcoma (sar-ko'mah; *sarkos* = flesh; *oma* = tumor) Cancer arising in the mesenchyme-derived tissues, that is, in connective tissues and muscle.

Scurvy A nutritional deficiency caused by lack of adequate vitamin C needed to synthesize collagen; signs and symptoms include blood vessel disruption, delay in wound healing, weakness of scar tissue, and loosening of teeth.

VAC (vacuum-assisted closure) Innovative healing process for open-skin wounds and skin ulcers. Often induces healing when all other methods fail. Involves covering the wound with a special sponge, and then applying suction through the sponge. In response to the subsequent skin stretching, fibroblasts in the wound form more collagen tissue and new blood vessels proliferate, bringing more blood into the injured area, which also promotes healing.

Chapter Summary

Media study tools that could provide you additional help in reviewing specific key topics of Chapter 4 are referenced below. IP = *InterActive Physiology*

Tissues are collections of structurally similar cells with related functions. The four primary tissues are epithelial, connective, muscle, and nervous tissues.

Preparing Human Tissue for Microscopy (p. 118)

1. Preparation of tissues for microscopic examination involves the use of dyes to stain the tissue, and knives to cut thin sections of the tissue. Artifacts result from modifications introduced by the tissue preparation process.

Epithelial Tissue (pp. 118–126)

1. Epithelial tissue is the covering, lining, and glandular tissue of the body. Its functions include protection, absorption, excretion, filtration, secretion, and sensory reception.

Special Characteristics of Epithelium (pp. 118–119)

2. Epithelial tissues exhibit specialized contacts, polarity, avascularity, support from connective tissue, and high regenerative capacity.

Classification of Epithelia (pp. 119–124)

3. Epithelium is classified by arrangement as simple (one layer) or stratified (more than one) and by cell shape as squamous, cuboidal, or columnar. The terms denoting cell shape and arrangement are combined to describe the epithelium fully.

4. Simple squamous epithelium is a single layer of squamous cells. Highly adapted for filtration and exchange of substances, it forms walls of air sacs of the lungs and lines blood vessels. It contributes to serosae as mesothelium and lines all hollow circulatory system organs as endothelium.

5. Simple cuboidal epithelium, commonly active in secretion and absorption, is found in glands and in kidney tubules.

6. Simple columnar epithelium, specialized for secretion and absorption, consists of a single layer of tall columnar cells that exhibit microvilli and often goblet cells. It lines most of the digestive tract.

7. Pseudostratified columnar epithelium is a simple columnar epithelium that appears stratified. Its ciliated variety, rich in goblet cells, lines most of the upper respiratory passages.

8. Stratified squamous epithelium is multilayered; cells at the free edge are squamous. It is adapted to resist abrasion.

It lines the esophagus and vagina; its keratinized variety forms the skin epidermis.

9. Stratified cuboidal epithelia are rare in the body, and are found chiefly in ducts of large glands. Stratified columnar epithelium has a very limited distribution, found mainly in the male urethra and at transition areas between other epithelia types.

10. Transitional epithelium is a modified stratified squamous epithelium, adapted for responding to stretch. It lines hollow urinary system organs.

Glandular Epithelia (pp. 124–126)

11. A gland is one or more cells specialized to secrete a product.

12. On the basis of site of product release, glands are classified as exocrine or endocrine. Glands are classified structurally as multicellular or unicellular.

13. Unicellular glands, also called goblet cells, are mucus-secreting single-celled glands.

14. Multicellular exocrine glands are classified according to duct structure as simple or compound, and according to the structure of their secretory parts as tubular, alveolar, or tubuloalveolar.

15. Multicellular exocrine glands of humans are classified functionally as merocrine or holocrine.

Connective Tissue (pp. 126–139)

1. Connective tissue is the most abundant and widely distributed tissue of the body. Its functions include support, protection, binding, insulation, and transportation (blood).

Common Characteristics of Connective Tissue (p. 127)

2. Connective tissues originate from embryonic mesenchyme and exhibit matrix. Depending on type, a connective tissue may be well vascularized (most), poorly vascularized (dense connective tissue), or avascular (cartilage).

Structural Elements of Connective Tissue (pp. 127–130)

3. The structural elements of all connective tissues are extracellular matrix and cells.

4. Extracellular matrix consists of ground substance and fibers (collagen, elastic, and reticular). It may be fluid, gel-like, or firm.

5. Each connective tissue type has a primary cell type that can exist as a mitotic, matrix-secreting cell (blast) or as a mature cell (cyte) responsible for maintaining the matrix. The chief cell type of connective tissue proper is the fibroblast; that of cartilage is the chondroblast; that of bone is the osteoblast; and that of blood-forming tissue is the hematopoietic stem cell.

Types of Connective Tissue (pp. 131–139)

6. Embryonic connective tissue is called mesenchyme.

7. Connective tissue proper consists of loose and dense varieties. The loose connective tissues are
   - Areolar: semifluid ground substance; all three fiber types loosely interwoven; a variety of cells; forms the lamina propria and soft packing around body organs; the prototype.
   - Adipose: consists largely of adipocytes; scant matrix; insulates and protects body organs; provides reserve energy fuel. Brown fat, present only in infants, is more important for generating body heat.
   - Reticular: finely woven reticular fibers in soft ground substance; the stroma of lymphoid organs and bone marrow.

8. Dense connective tissue proper includes
   - Dense regular: dense parallel bundles of collagen fibers; few cells, little ground substance; high tensile strength; forms tendons, ligaments, aponeuroses; in cases where this tissue also contains numerous elastic fibers it is called elastic connective tissue.
   - Dense irregular: like regular variety, but fibers are arranged in different planes; resists tension exerted from many different directions; forms the dermis of the skin and organ capsules.

9. Cartilage exists as
   - Hyaline: firm ground substance containing collagen fibers; resists compression well; found in fetal skeleton, at articulating surfaces of bones, and trachea; most abundant type.
   - Elastic cartilage: elastic fibers predominate; provides flexible support of the external ear and epiglottis.
   - Fibrocartilage: coarse parallel collagen fibers; provides support with compressibility; forms intervertebral discs and knee cartilages.

10. Bone (osseous tissue) consists of a hard, collagen-containing matrix embedded with calcium salts; forms the bony skeleton.

11. Blood consists of blood cells in a fluid matrix (plasma).

Nervous Tissue (p. 139)

1. Nervous tissue forms organs of the nervous system. It is composed of neurons and supporting cells.

2. Neurons are branching cells that receive and transmit electrical impulses; they are involved in body regulation.

Nervous System I; Topic: Anatomy Review, pp. 1, 3.

Muscle Tissue (pp. 139–141)

1. Muscle tissue consists of elongated cells specialized to contract and cause movement.

2. Based on structure and function, the muscle tissues are
   - Skeletal muscle: attached to and moves the bony skeleton; cells are cylindrical and striated.
   - Cardiac muscle: forms the walls of the heart; pumps blood; cells are branched and striated.
   - Smooth muscle: in the walls of hollow organs; propels substances through the organs; cells are spindle shaped and lack striations.

Covering and Lining Membranes (pp. 141–143)

1. Membranes are simple organs, consisting of an epithelium bound to an underlying connective tissue layer. They include mucosae, serosae, and the cutaneous membrane.

Tissue Repair (pp. 143–145)

1. Inflammation is the body's response to injury. Tissue repair begins during the inflammatory process. It may lead to regeneration, fibrosis, or both.

2. Tissue repair begins with organization, during which the blood clot is replaced by granulation tissue. If the wound is small and the damaged tissue is actively mitotic, the tissue will regenerate and cover the fibrous tissue. When a wound is extensive or the damaged tissue amitotic, it is repaired only by fibrous connective (scar) tissue.

Developmental Aspects of Tissues (p. 145)

1. Epithelium arises from all three primary germ layers (ectoderm, mesoderm, endoderm); muscle and connective tissue from mesoderm; and nervous tissue from ectoderm.

2. The decrease in mass and viability seen in most tissues during old age often reflects circulatory deficits or poor nutrition.

Review Questions

Multiple Choice/Matching

(Some questions have more than one correct answer. Select the best answer or answers from the choices given.)

1. Use the key to classify each of the following described tissue types into one of the four major tissue categories.

Key: (a) connective tissue (c) muscle
(b) epithelium (d) nervous tissue

____ (1) Tissue type composed largely of nonliving extracellular matrix; important in protection and support
____ (2) The tissue immediately responsible for body movement
____ (3) The tissue that enables us to be aware of the external environment and to react to it
____ (4) The tissue that lines body cavities and covers surfaces

2. An epithelium that has several layers, with an apical layer of flattened cells, is called (choose all that apply): (a) ciliated, (b) columnar, (c) stratified, (d) simple, (e) squamous.

3. Match the epithelial types named in column B with the appropriate description(s) in column A.

Column A	Column B
____ (1) Lines most of the digestive tract	(a) pseudostratified ciliated columnar
____ (2) Lines the esophagus	(b) simple columnar
____ (3) Lines much of the respiratory tract	(c) simple cuboidal
____ (4) Forms the walls of the air sacs of the lungs	(d) simple squamous
____ (5) Found in urinary tract organs	(e) stratified columnar
____ (6) Endothelium and mesothelium	(f) stratified squamous
	(g) transitional

4. The gland type that secretes products such as milk, saliva, bile, or sweat through a duct is (a) an endocrine gland, (b) an exocrine gland.

5. The membrane which lines body cavities that open to the exterior is a(n) (a) endothelium, (b) cutaneous membrane, (c) mucous membrane, (d) serous membrane.

6. Scar tissue is a variety of (a) epithelium, (b) connective tissue, (c) muscle tissue, (d) nerve tissue, (e) all of these.

Short Answer Essay Questions

7. Define tissue.

8. Name four important functions of epithelial tissue and provide at least one example of a tissue that exemplifies each function.

9. Describe the criteria used to classify covering and lining epithelia.

10. Explain the functional classification of multicellular exocrine glands and supply an example for each class.

11. Name four important functions of connective tissue and provide examples from the body that illustrate each function.

12. Name the primary cell type in connective tissue proper; in cartilage; in bone.

13. Name the two major components of matrix and, if applicable, subclasses of each component.

14. Matrix is extracellular. How does the matrix get to its characteristic position?

15. Name the specific connective tissue type found in the following body locations: (a) forming the soft packing around organs, (b) supporting the ear pinna, (c) forming "stretchy" ligaments, (d) first connective tissue in the embryo, (e) forming the intervertebral discs, (f) covering the ends of bones at joint surfaces, (g) main component of subcutaneous tissue.

16. What is the function of macrophages?

17. Differentiate clearly between the roles of neurons and the supporting cells of nervous tissue.

18. Compare and contrast skeletal, cardiac, and smooth muscle tissue relative to structure, body location, and specific function.

19. Describe the process of tissue repair, making sure you indicate factors that influence this process.

20. Name the three embryonic germ layers, and indicate which primary tissue classes derive from each layer.

21. Cell division typically yields two daughter cells, each with one nucleus. How is the multinucleate condition of a skeletal muscle cell explained?

Critical Thinking and Clinical Application Questions

1. John has sustained a severe injury during football practice and is told that he has a torn knee cartilage. Can he expect a quick, uneventful recovery? Explain your response.

2. The epidermis (epithelium of the cutaneous membrane or skin) is a keratinized stratified squamous epithelium. Explain why that epithelium is much better suited for protecting the body's external surface than a mucosa consisting of a simple columnar epithelium would be.

3. Your friend is trying to convince you that if the ligaments binding the bones together at your freely movable joints (such as your knee, shoulder, and hip joints) contained more elastic fibers, you would be much more flexible. Although there is *some* truth to this statement, such a condition would present serious problems. Why?

4. In adults, over 90% of all cancers are either adenomas (adenocarcinomas) or carcinomas. (See Related Clinical Terms for this chapter.) In fact, cancers of the skin, lung, colon, breast, and prostate are all in these categories. Which one of the four basic tissue types gives rise to most cancers? Why do you think this is so?

5. Cindy, an overweight high school student, is overheard telling her friend that she's going to research how she can transform some of her white fat to brown fat. What is her rationale here (assuming it is possible)?

6. Mrs. Delancy went to the local meat market and bought a beef tenderloin (cut from the loin, the region along the steer's vertebral column) and some tripe (cow's stomach). What type of muscle was she preparing to eat in each case?

CHAPTER 5

The Integumentary System

The Skin (pp. 152–158)

1. Name the tissue types composing the epidermis and dermis. List the major layers of each and describe the functions of each layer.
2. Describe the factors that normally contribute to skin color. Briefly describe how changes in skin color may be used as clinical signs of certain disease states.

Appendages of the Skin (pp. 158–163)

3. Compare the structure and locations of sweat and oil glands. Also compare the composition and functions of their secretions.
4. Compare and contrast eccrine and apocrine glands.
5. List the parts of a hair follicle and explain the function of each part. Also describe the functional relationship of arrector pili muscles to the hair follicle.
6. Name the regions of a hair and explain the basis of hair color. Describe the distribution, growth, replacement, and changing nature of hair during the life span.
7. Describe the structure of nails.

Functions of the Integumentary System (pp. 163–165)

8. Describe how the skin accomplishes at least five different functions.

Homeostatic Imbalances of Skin (pp. 165–167, 170)

9. Summarize the characteristics of the three major types of skin cancers.
10. Explain why serious burns are life threatening. Describe how to determine the extent of a burn and differentiate first-, second-, and third-degree burns.

Developmental Aspects of the Integumentary System (pp. 170–171)

11. Describe and attempt to explain the causes of changes that occur in the skin from birth to old age.

Would you be enticed by an advertisement for a coat that is waterproof, stretchable, washable, and permanent-press, that automatically repairs small cuts, rips, and burns, and that is guaranteed to last a lifetime with reasonable care? Sounds too good to be true, but you already have such a coat—your skin. The skin and its derivatives (sweat and oil glands, hairs, and nails) make up a complex set of organs that serves several functions, mostly protective. Together, these organs form the **integumentary system** (in-teg″u-men′tar-e).

The Skin

The skin ordinarily receives little respect from its inhabitants, but architecturally it is a marvel. It covers the entire body, has a surface area of 1.2 to 2.2 square meters, weighs 4 to 5 kilograms (4–5 kg = 9–11 lb), and accounts for about 7% of total body weight in the average adult. Also called the integument, which simply means "covering," the skin's functions go well beyond serving as a large, opaque bag for the body contents. It is pliable yet tough, allowing it to take constant punishment from external agents. Without our skin, we would quickly fall prey to bacteria and perish from water and heat loss.

The skin, which varies in thickness from 1.5 to 4.0 millimeters (mm) or more in different parts of the body, is composed of two distinct regions, the *epidermis* (ep″ĭ-der′mis) and the *dermis* (Figure 5.1). The epidermis (*epi* = upon), composed of epithelial cells, is the outermost protective shield of the body. The underlying dermis, making up the bulk of the skin, is a tough, leathery layer composed of fibrous connective tissue. Only the dermis is vascularized. Nutrients reach the epidermis by diffusing through the tissue fluid from blood vessels in the dermis.

The subcutaneous tissue just deep to the skin is known as the **hypodermis** (Figure 5.1). Strictly speaking, the hypodermis is not really part of the skin, but it shares some of the skin's protective functions. The hypodermis, also called **superficial fascia** because it is superficial to the tough connective tissue wrapping (fascia) of the skeletal muscles, consists mostly of adipose tissue. Besides storing fat, the hypodermis anchors the skin to the underlying structures (mostly to muscles), but loosely enough that the skin can slide relatively freely over those structures. Sliding skin protects us by ensuring that many blows just glance off our bodies. Because of its fatty composition, the hypodermis also acts as a shock absorber and an insulator that prevents heat loss from the body. The hypodermis thickens markedly when one gains weight. In females, this "extra" subcutaneous fat accumulates first in the thighs and breasts, but in males it first collects in the anterior abdomen (as a "beer belly").

Epidermis

Structurally, the **epidermis** is a keratinized stratified squamous epithelium consisting of four distinct cell types and four or five distinct layers.

Cells of the Epidermis

The cells populating the epidermis include *keratinocytes, melanocytes, Merkel cells,* and *Langerhans' cells* (Figure 5.2). Most epidermal cells are keratinocytes, so we will consider them first. The chief role of **keratinocytes** (kĕ-rat′ĭ-no-sīts″; "keratin cells") is to produce **keratin,** the fibrous protein that helps give the epidermis its protective properties (Greek *kera* = horn). Tightly connected to one another by desmosomes, the keratinocytes arise in the deepest part of the epidermis from a layer of cells (stratum basale) that undergo almost continuous mitosis. As these cells are pushed upward by the production of new cells beneath them, they make the keratin that eventually dominates their cell contents. By the time the keratinocytes reach the free surface of the skin, they are dead, scalelike structures that are little more than keratin-filled plasma membranes. Millions of these dead cells rub off every day, giving us a totally new epidermis every 25 to 45 days. In body areas regularly subjected to friction, such as the hands and feet, both cell production and keratin formation are accelerated. Persistent friction (from a poorly fitting shoe, for example) causes a thickening of the epidermis called a *callus.*

Melanocytes (mel′ah-no-sīts), the spider-shaped epithelial cells that synthesize the pigment **melanin** (mel′ah-nin; *melan* = black), are found in the deepest layer of the epidermis (Figure 5.2). As melanin is made, it is accumulated in membrane-bound granules called *melanosomes* that are moved along actin filaments by motor proteins to the ends of the melanocyte's processes (the "spider arms") from where they are taken up by nearby keratinocytes. The melanin granules accumulate on the superficial, or "sunny," side of the keratinocyte nucleus, forming a pigment shield that protects the nucleus from the damaging effects of ultraviolet (UV) radiation in sunlight.

The star-shaped **Langerhans' cells** (lahng′er-hanz) arise from bone marrow and migrate to the epidermis. Also called **epidermal dendritic cells,** they are phagocytes that ingest foreign substances and help to activate our immune system, as described later in this chapter. Their slender processes extend among the surrounding keratinocytes, forming a more or less continuous network (Figure 5.2).

Occasional **Merkel cells** are present at the epidermal-dermal junction. Shaped like a spiky hemisphere (Figure 5.2), each Merkel cell is intimately

Q *What cell component of the hypodermis makes it a good shock absorber and insulator?*

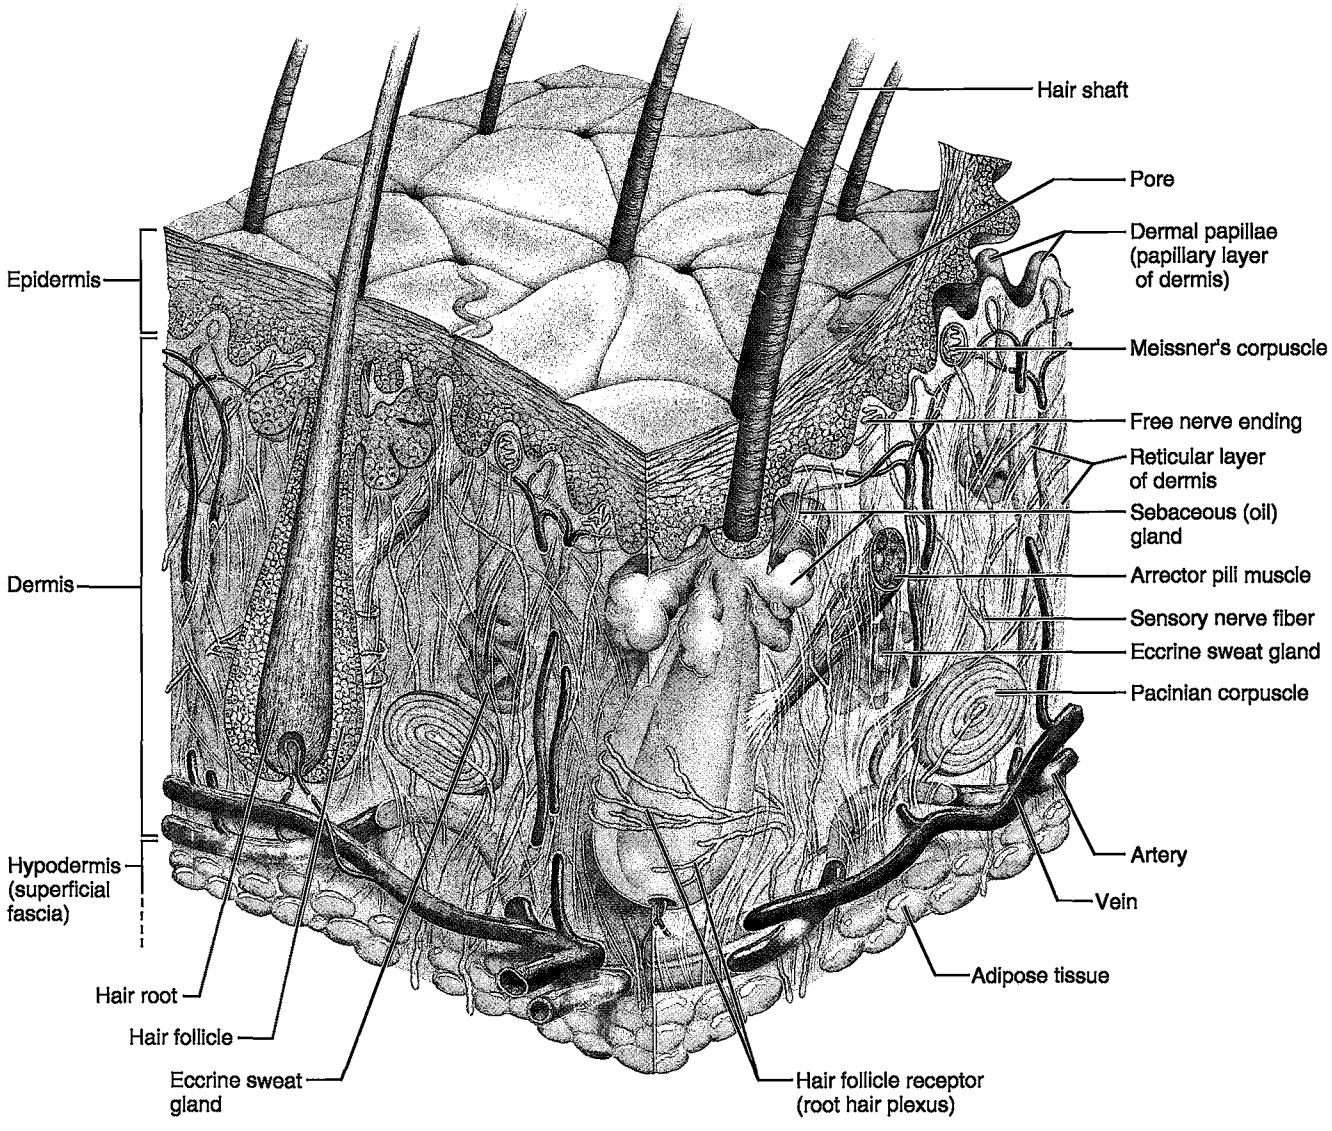

FIGURE 5.1 **Skin structure.** Three-dimensional view of the skin and underlying subcutaneous tissue. The epidermal and dermal layers have been pulled apart at the right corner to reveal the dermal papillae.

associated with a disclike sensory nerve ending. The combination, called a *Merkel disc,* functions as a sensory receptor for touch.

Layers of the Epidermis

Variation in epidermal thickness determines if skin is *thick* or *thin.* In **thick skin,** which covers the palms, fingertips, and soles of the feet, the epidermis consists of five layers, or *strata* (stra'tah; "bed sheets"). From deep to superficial, these layers are stratum basale, stratum spinosum, stratum granulosum, stratum lucidum, and stratum corneum. In thin skin, which covers the rest of the body, the stratum lucidum appears to be absent and the other strata are thinner (Figure 5.2).

Stratum Basale (Basal Layer) The **stratum basale** (stra'tum ba-să'le), the deepest epidermal layer, is attached to the underlying dermis along a wavy borderline that reminds one of corrugated cardboard. For the most part, it consists of a single row of cells—a continually renewing cell population—representing the youngest keratinocytes. The many mitotic nuclei

A Adipose cells.

Q *(1) Why are the desmosomes connecting the keratinocytes so important? (2) Given that epithelia are avascular, which epidermal layer would be expected to have the best-nourished cells?*

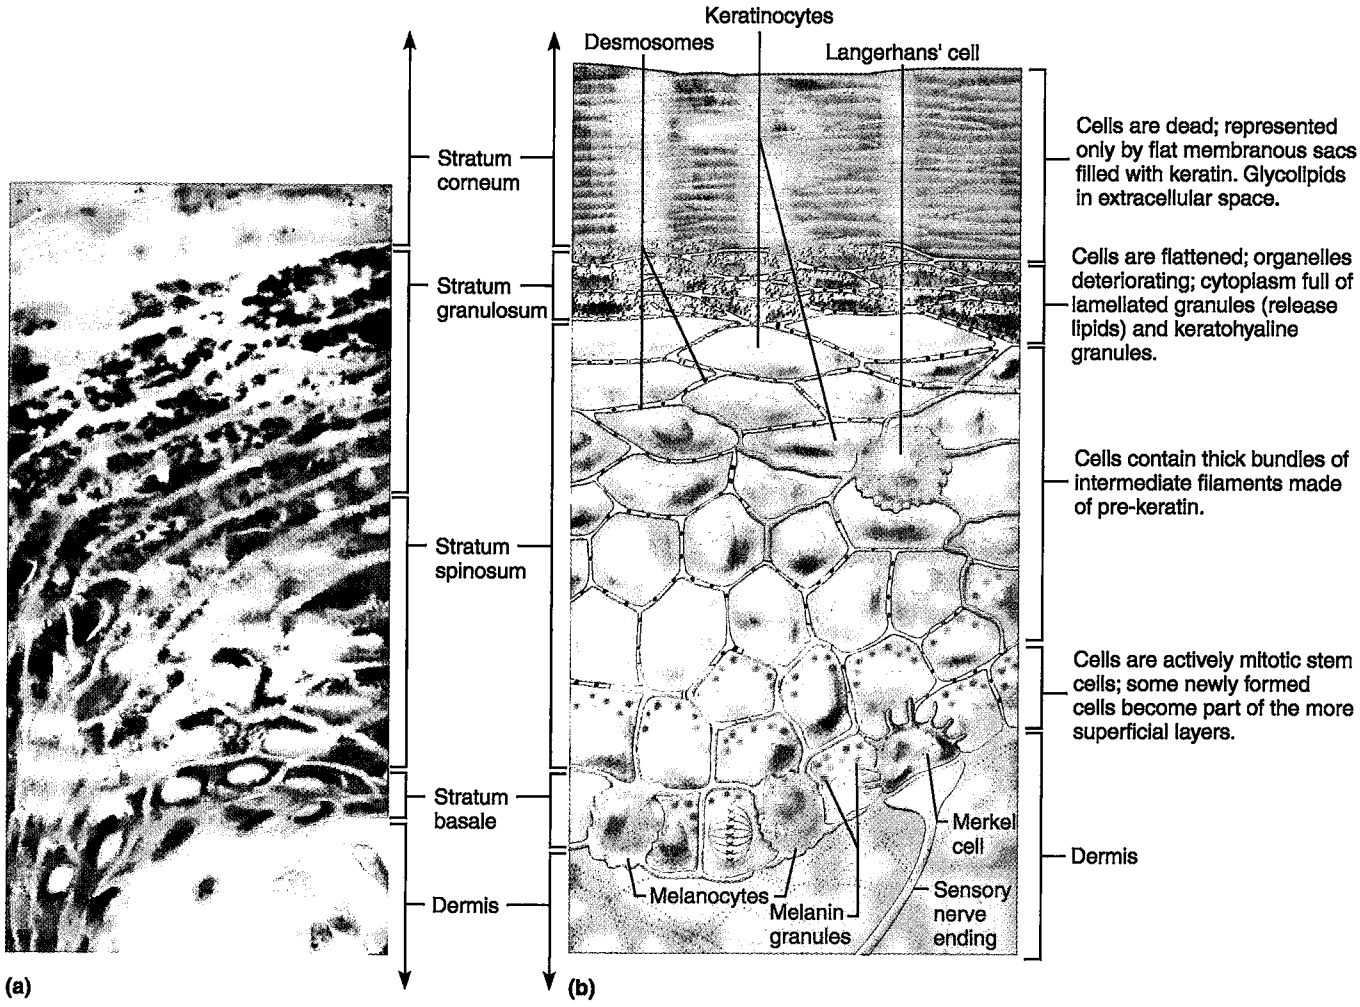

FIGURE 5.2 **The main structural features in skin epidermis. (a)** Photomicrograph of the four major epidermal layers. **(b)** Diagram showing the layers and relative distribution of the different cell types. The keratinocytes (tan) form the bulk of the epidermis. Less numerous are the melanocytes (gray), which produce the pigment melanin; Langerhans' cells (blue), which function as immune cells; and Merkel cells (purple). A sensory nerve ending (yellow), extending to the Merkel cell from the dermis (pink), is shown associated with the Merkel cell forming a Merkel disc (touch receptor). Notice that the keratinocytes, but not the other cell types, are joined by numerous desmosomes. The stratum lucidum, present in thick skin, is not illustrated here. Only a portion of the stratum corneum is illustrated in each case. (See *A Brief Atlas of the Human Body*, Plate 37.)

seen in this layer reflect the rapid division of these cells and account for its alternate name, **stratum germinativum** (jer'mĭ-nă"tiv-um; "germinating layer").

Some 10–25% of the cells in the stratum basale are melanocytes, and their branching processes extend among the surrounding cells, reaching well into the more superficial stratum spinosum layer. Occasional Merkel cells are also seen in this stratum.

Stratum Spinosum (Prickly Layer) The **stratum spinosum** (spi'no-sum; "prickly") is several cell layers thick. These cells contain a weblike system of intermediate filaments, mainly tension-resisting bundles of pre-keratin filaments, which span their cytosol to attach to desmosomes. The keratinocytes

(1) The desmosomes connecting the keratinocytes are important to maintain continuity of the epidermis which is subjected to frequent friction. (2) The stratum basale or basal layer of the epidermis.

in this layer appear irregular (spiny) in shape, causing them to be called *prickle cells*. The spines do not exist in the living cells; they are artifacts that arise during tissue preparation when these cells shrink but their numerous desmosomes hold tight. Scattered among the keratinocytes are melanin granules and Langerhans' cells, which are most abundant in this epidermal layer.

Stratum Granulosum (Granular Layer) The thin **stratum granulosum** (gran"u-lo'sum) consists of three to five cell layers in which keratinocyte appearance changes drastically. These cells flatten, their nuclei and organelles begin to disintegrate, and they accumulate two types of granules: The *keratohyaline granules* (ker"ah-to-hi'ah-lin) help to form keratin in the upper layers, as we will see. The *lamellated granules* (lam'ĭ-la-ted; "plated") contain a waterproofing glycolipid that is spewed into the extracellular space and is a major factor in slowing water loss across the epidermis. The plasma membranes of these cells thicken as cytosol proteins bind to the inner membrane face and lipids released by the lamellated granules coat their external surfaces. This makes them more resistant to destruction, so you might say that the keratinocytes are "toughening up" to make the outer strata the strongest skin region.

Like all epithelia, the epidermis relies on capillaries in the underlying connective tissue (the dermis in this case) for its nutrients. Above the stratum granulosum, the epidermal cells are too far from the dermal capillaries, so they die. This is a completely normal sequence of events.

Stratum Lucidum (Clear Layer) Through the light microscope, the **stratum lucidum** (loo'sid-um; "light") appears as a thin translucent band just above the stratum granulosum. It consists of a few rows of clear, flat, dead keratinocytes with indistinct boundaries. Here, or in the stratum corneum above, the gummy substance of the keratohyaline granules clings to the keratin filaments in the cells, causing them to aggregate in parallel arrays. As mentioned before, the stratum lucidum is visible only in thick skin.

Stratum Corneum (Horny Layer) The outermost **stratum corneum** (kor'ne-um) is a broad zone 20 to 30 cell layers thick that accounts for up to three-quarters of the epidermal thickness. Keratin and the thickened plasma membranes of cells in this stratum protect the skin against abrasion and penetration, and the glycolipid between its cells waterproofs this layer. Hence, the stratum corneum provides a durable "overcoat" for the body, protecting deeper cells from the hostile external environment (air) and from water loss, and rendering the body relatively insensitive to biological, chemical, and physical assaults. It is amazing that a layer of dead cells can still play so many roles.

The shingle-like cell remnants of the stratum corneum are referred to as *cornified,* or *horny, cells* (*cornu* = horn). They are familiar to everyone as the dandruff shed from the scalp and the flakes that slough off dry skin. [The average person sheds 18 kg (40 lb) of these skin flakes in a lifetime, providing a lot of fodder for the dust mites that inhabit our homes and bed linens.] The common saying "Beauty is only skin deep" is especially interesting in light of the fact that nearly everything we see when we look at someone is dead!

Dermis

The **dermis** (*derm* = skin), the second major skin region, is strong, flexible connective tissue. Its cells are typical of those found in any connective tissue proper: fibroblasts, macrophages, and occasional mast cells and white blood cells, and its semifluid matrix is heavily embedded with fibers. The dermis binds the entire body together like a body stocking. It is your "hide" and corresponds exactly to animal hides used to make leather products.

The dermis is richly supplied with nerve fibers, blood vessels, and lymphatic vessels. The major portions of hair follicles, as well as oil and sweat glands, are derived from epidermal tissue but reside in the dermis.

The dermis has two layers: the papillary and reticular. The thin superficial **papillary layer** (pap'il-er-e) is areolar connective tissue in which the collagen and elastin fibers form a loosely woven mat that is heavily invested with blood vessels. Its superior surface is thrown into peglike projections called **dermal papillae** (pah-pil'e; *papill* = nipple) that indent the overlying epidermis (see Figure 5.1). Many dermal papillae contain capillary loops (of the *subpapillary plexus*); others house free nerve endings (pain receptors) and touch receptors called *Meissner's corpuscles* (mīs'nerz kor'pus-lz). On the palms of the hands and soles of the feet, these papillae lie atop larger mounds called *dermal ridges,* which in turn cause the overlying epidermis to form *epidermal ridges* that increase friction and enhance the gripping ability of the fingers and feet. Epidermal ridge patterns are genetically determined and unique to each of us. Because sweat pores open along their crests, our fingertips leave identifying films of sweat called *fingerprints* on almost anything they touch.

The deeper **reticular layer,** accounting for about 80% of the thickness of the dermis, is dense irregular connective tissue. The network of blood vessels that nourishes this layer, the *cutaneous plexus*, lies between this layer and the hypodermis. Its extracellular

A CLOSER LOOK

Wrinkle Wrinkle Go Away—Or I'll Shoot You (with Botox)

When it comes to staving off wrinkles, it helps to have good genes, to not smoke, to use a good sunscreen, and to think pleasant thoughts. Good genes speak for themselves—it's partly the luck of the draw whether you look your age or not. Smoking ages the skin by increasing production of an enzyme referred to as MMP, which destroys collagen. Collagen supports the skin and provides it with resilience and elasticity. So with less of it, wrinkles appear. UV radiation damage to the skin from too much unprotected exposure to the sun is covered on p. 157. Treatment with an Alexandrite laser, more commonly used to lighten skin pigmentation, heats up the dermis, which causes collagens to reorganize, thus reducing wrinkling to some extent. For those wrinkled by years of smoking and sun damage, a surgical face-lift that removes the excess and sagging skin followed by laser resurfacing or microdermabrasion to lift out the remaining small wrinkles seems to be the only way the wrinkles can be banished.

However, for those who sport frown lines, furrowed brows, or crow's feet due not to skin damage but to frequent and repetitive facial expressions, cosmetic injections of Botox may be the answer to regaining younger-looking skin. Botulinum toxin type A, more familiarly called Botox Cosmetic, is a toxin produced by the bacterium *Clostridium botulinum*, which causes botulism, a dreaded form of food poisoning. Used in a medical setting in injectable doses (considerably less than the amount that would induce botulism), the purified toxin helps regulate acetylcholine (ACh) release by nerve cells. (ACh plays a key role in relaying messages from nerves to muscles.) By selectively inhibiting the underlying muscles' ability to contract, existing lines or furrows are smoothed out and nearly invisible in a week.

Woman receiving Botox injection.

Botox was first approved in 1989 to treat two eye muscle disorders—blepharospasm (uncontrollable blinking) and strabismus (misaligned eyes). In 2000, Botox was approved to treat muscle dystonia, painful neuromuscular disorders leading to sustained and disabling muscle spasms that cause abnormal body twisting or postures. The discovery that Botox could be used cosmetically was serendipitous—physicians using the toxin to counter abnormal eye contractions noticed that the vertical frown lines between the eyes (which make people look tired, angry, or displeased) had softened.

The recent rise in popularity of Botox "shots" has led to changes in the way it is marketed. Some physicians buy the toxin in bulk and arrange "Botox parties" or "Botox happy hours," get-togethers for 10 to 15 people which make the treatment both more relaxed and more affordable. One by one, as their names are called, each "guest" slips away for about 15 minutes to a private examining room to be injected with Botox Cosmetic. Anesthesia is rarely needed, but sedatives and numbing agents are usually available. The U.S. Food and Drug Administration is concerned that gathering as many patients as possible may trivialize a medical treatment and has the potential for being abused as unqualified people begin to dispense the toxin in salons, gyms, and other retail establishments.

Although there is no chance of contracting botulism from the injections, the process has some risks. If too much toxin is injected or injected into the wrong area, a person can end up with droopy eyelid muscles for weeks, or temporary muscle weakness. The effects of Botox Cosmetic last only three to six months; still, battling the signs of age in a noninvasive way is appealing to many. Also, the fact that there is little or no recovery time allows one to be treated during a lunch hour. The attraction of Botox to physicians is both professional (a new tool to fight wrinkles) and monetary (truly dedicated patients are back for injections every three to six months). Vanity pays! ■

matrix contains thick bundles of interlacing collagen fibers that run in various planes; however, most run parallel to the skin surface. Separations, or less dense regions, between these bundles form *cleavage,* or *tension, lines,* in the skin. These externally invisible lines tend to run longitudinally in the skin of the head and limbs and in circular patterns around the neck and trunk. Cleavage lines are important to both surgeons and their patients. When an incision is made *parallel* to these lines, the skin gapes less and heals more readily than when the incision is made *across* cleavage lines.

The collagen fibers of the dermis give skin strength and resiliency that prevent most jabs and scrapes from penetrating the dermis. In addition, collagen binds water, helping to keep skin hydrated. Elastin fibers provide the stretch-recoil properties of skin.

In addition to the epidermal ridges and cleavage lines, a third type of skin marking, *flexure lines,* reflects dermal modifications. Flexure lines are dermal

folds that occur at or near joints, where the dermis is tightly secured to deeper structures (notice the deep creases on your palms). Since the skin cannot slide easily to accommodate joint movement in such regions, the dermis folds and deep skin creases form. Flexure lines are also visible on the wrists, fingers, soles, and toes.

HOMEOSTATIC IMBALANCE

Extreme stretching of the skin, such as occurs during pregnancy, can tear the dermis. Dermal tearing is indicated by silvery white scars called *striae* (stri'e; "streaks"), commonly called "stretch marks." Short-term but acute trauma (as from a burn or wielding a hoe) can cause a *blister*, the separation of the epidermal and dermal layers by a fluid-filled pocket.

Skin Color

Three pigments contribute to skin color: melanin, carotene, and hemoglobin. Of these, only melanin is made in the skin. **Melanin,** a polymer made of tyrosine amino acids, ranges in color from yellow to reddish-brown to black. Its synthesis depends on an enzyme in melanocytes called tyrosinase (ti-ro'sĭ-nās) and, as noted earlier, it passes from melanocytes to the basal keratinocytes.

Human skin comes in different colors. However, distribution of those colors is not random—populations of darker-skinned people tend to be found nearer the equator (where greater protection from the sun is needed), whereas those with the lightest skin are found closer to the poles. Since all humans have the same relative number of melanocytes, individual and racial differences in skin coloring reflect the relative kind and amount of melanin made and retained. Melanocytes of black- and brown-skinned people produce many more and darker melanosomes than those of fair-skinned individuals, and their keratinocytes retain it longer. *Freckles* and *pigmented moles* are local accumulations of melanin.

Melanocytes are stimulated to greater activity when we expose our skin to sunlight. Prolonged sun exposure causes a substantial melanin buildup, which helps protect the DNA of viable skin cells from UV radiation by absorbing the light and dissipating the energy as heat. Indeed, the initial signal for speeding up melanin synthesis seems to be a faster rate of repair of photodamaged DNA. In all but the darkest people, this response causes visible darkening of the skin (a tan).

HOMEOSTATIC IMBALANCE

Despite melanin's protective effects, excessive sun exposure eventually damages the skin. It causes clumping of elastin fibers, which results in leathery skin; temporarily depresses the immune system; and can alter the DNA of skin cells and in this way lead to skin cancer. The fact that dark-skinned people get skin cancer less often than fair-skinned people and get it in areas with less pigment—the soles of the feet and nail beds—attests to melanin's effectiveness as a natural sunscreen.

Ultraviolet radiation has other consequences as well. It destroys the body's folate stores necessary for DNA synthesis, which can have serious consequences, particularly in pregnant women because the deficit may impair the development of the embryo's nervous system. Many chemicals induce photosensitivity; that is, they heighten the skin's sensitivity to UV radiation, setting sun worshippers up for an unsightly skin rash. Such substances include some antibiotic and antihistamine drugs, and many chemicals in perfumes and detergents. Small, itchy, blisterlike lesions erupt all over the body; then the peeling begins, in sheets!

Carotene (kar'o-tēn) is a yellow to orange pigment found in certain plant products such as carrots. It tends to accumulate in the stratum corneum and in fatty tissue of the hypodermis. Its color is most obvious in the palms and soles, where the stratum corneum is thickest (for example the skin of the heels), and most intense when large amounts of carotene-rich foods are eaten. However, the yellowish tinge of the skin of some Asian peoples is due to variations in melanin, as well as to carotene.

The pinkish hue of fair skin reflects the crimson color of oxygenated **hemoglobin** (he'mo-glo"bin) in the red blood cells circulating through the dermal capillaries. Because Caucasian skin contains only small amounts of melanin, the epidermis is nearly transparent and allows hemoglobin's color to show through.

HOMEOSTATIC IMBALANCE

When hemoglobin is poorly oxygenated, both the blood and the skin of Caucasians appear blue, a condition called *cyanosis* (si"ah-no'sis; *cyan* = dark blue). Skin often becomes cyanotic during heart failure and severe respiratory disorders. In dark-skinned individuals, the skin does not appear cyanotic because of the masking effects of melanin, but cyanosis is apparent in their mucous membranes and nail beds (the same sites where the red cast of normally oxygenated blood is visible).

Many alterations in skin color signal certain disease states, and in many people emotional states:

- *Redness*, or *erythema* (er"ĭ-the'mah): Reddened skin may indicate embarrassment (blushing), fever, hypertension, inflammation, or allergy.

- *Pallor,* or *blanching:* During fear, anger, and certain other types of emotional stress, some people become pale. Pale skin may also signify anemia or low blood pressure.
- *Jaundice* (jawn'dis), or *yellow cast:* An abnormal yellow skin tone usually signifies a liver disorder, in which yellow bile pigments accumulate in the blood and are deposited in body tissues. [Normally, the liver cells secrete the bile pigments (bilirubin) as a component of bile.]
- *Bronzing:* A bronze, almost metallic appearance of the skin is a sign of Addison's disease, hypofunction of the adrenal cortex.
- *Black-and-blue marks,* or *bruises:* Black-and-blue marks reveal where blood escaped from the circulation and clotted beneath the skin. Such clotted blood masses are called *hematomas* (he"mah-to'mah; "blood swelling").

5

Appendages of the Skin

Along with the skin itself, the integumentary system includes several derivatives of the epidermis. These **skin appendages** include the nails, sweat glands, sebaceous (oil) glands, and hair follicles and hair. Each of these plays a unique role in maintaining body homeostasis. A key step in beginning to form any of the skin's appendages is formation of an epithelial bud. This is stimulated by a reduced production of cell adhesion factor (cadherin). Once the cell-to-cell attractions are broken, the cells can move about and rearrange themselves, allowing an epithelial bud to form.

Sweat (Sudoriferous) Glands

Sweat glands, also called **sudoriferous glands** (su"dorif'er-us; *sudor* = sweat), are distributed over the entire skin surface except the nipples and parts of the external genitalia. Their number is staggering—up to 3 million of them per person. There are two types of sweat glands: eccrine and apocrine.

Eccrine sweat glands (ek'rin; "secreting"), also called **merocrine sweat glands,** are far more numerous and are particularly abundant on the palms, soles of the feet, and forehead. Each is a simple, coiled, tubular gland. The secretory part lies coiled in the dermis; the duct extends to open in a funnel-shaped *pore* (*por* = channel) at the skin surface (see Figure 5.3b). (These sweat pores are different from the so-called pores of one's complexion, which are actually the external outlets of hair follicles.)

Eccrine gland secretion, commonly called sweat, is a hypotonic filtrate of the blood that passes through the secretory cells of the sweat glands and is released by exocytosis. It is 99% water, with some salts (mostly sodium chloride), vitamin C, antibodies, a microbe-killing peptide dubbed *dermicidin,* and traces of metabolic wastes (urea, uric acid, and ammonia). The exact composition depends on heredity and diet. Small amounts of ingested drugs may also be excreted by this route. Normally, sweat is acidic with a pH between 4 and 6.

Sweating is regulated by the sympathetic division of the autonomic nervous system, over which we have little control. Its major role is to prevent overheating of the body. Heat-induced sweating begins on the forehead and then spreads inferiorly over the remainder of the body. Emotionally induced sweating—the so-called "cold sweat" brought on by fright, embarrassment, or nervousness—begins on the palms, soles, and axillae (armpits) and then spreads to other body areas.

Apocrine sweat glands* (ap'o-krin), approximately 2000 of them, are largely confined to the axillary and anogenital areas. They are larger than eccrine glands, and their ducts empty into hair follicles. Apocrine secretion contains the same basic components as true sweat, plus fatty substances and proteins. Consequently, it is quite viscous and sometimes has a milky or yellowish color. The secretion is odorless, but when its organic molecules are decomposed by bacteria on the skin, it takes on a musky and generally unpleasant odor, the basis of body odor.

Apocrine glands begin functioning at puberty under the influence of androgens and have little role to play in thermoregulation. Their precise function is not yet known, but they are activated by sympathetic nerve fibers during pain and stress. Because their activity is increased by sexual foreplay, and they enlarge and recede with the phases of a woman's menstrual cycle, they may be the human equivalent of the sexual scent glands of other animals.

Ceruminous glands (sĕ-roo'mĭ-nus; *cera* = wax) are modified apocrine glands found in the lining of the external ear canal. They secrete a sticky, bitter substance called *cerumen,* or earwax, that is thought to deter insects and block entry of foreign material.

Mammary glands, another variety of specialized sweat glands, secrete milk. Although they are properly part of the integumentary system, we consider the mammary glands in Chapter 27, along with female reproductive organs.

---

* The term *apocrine sweat glands* is a misnomer. These glands were originally thought to release their product by the apocrine mode (in which the apical surface pinches off) and were named accordingly. Subsequent studies proved them to be merocrine glands, which release their product by exocytosis like the eccrine sweat glands.

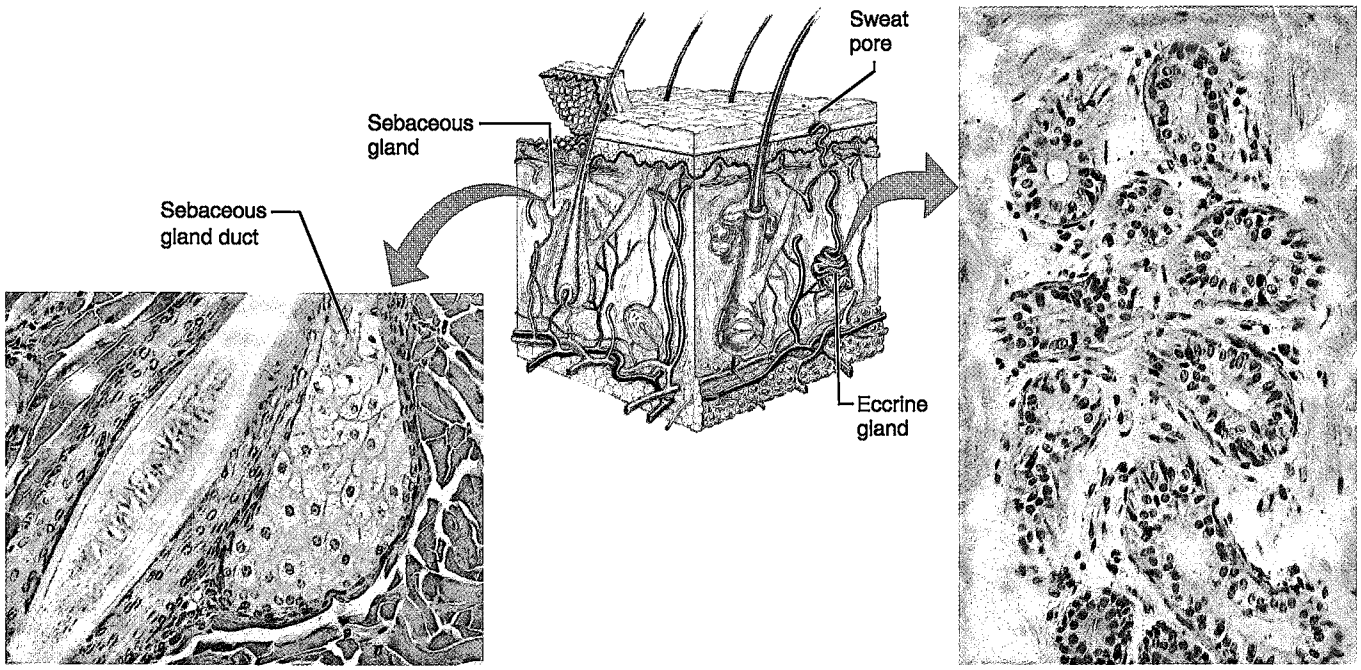

FIGURE 5.3 **Cutaneous glands.** **(a)** Photomicrograph of a sebaceous gland (160×). **(b)** Photomicrograph of eccrine sweat glands (250×).

Sebaceous (Oil) Glands

The **sebaceous glands** (se-ba'shus; "greasy"), or **oil glands** (see Figure 5.3a), are simple branched alveolar glands that are found all over the body except on the palms and soles. They are small on the body trunk and limbs, but quite large on the face, neck, and upper chest. These glands secrete an oily secretion called **sebum** (se'bum). The central cells of the alveoli accumulate oily lipids until they become so engorged that they burst, so functionally these glands are *holocrine glands* (see p. 126). The accumulated lipids and cell fragments constitute sebum. Sebum is secreted into a hair follicle, or occasionally to a pore on the skin surface. Sebum softens and lubricates the hair and skin, prevents hair from becoming brittle, and slows water loss from the skin when the external humidity is low. Perhaps even more important is its *bactericidal* (bacterium-killing) action.

The secretion of sebum is stimulated by hormones, especially androgens. These glands are relatively inactive during childhood but are activated in both sexes during puberty, when androgen production begins to rise.

HOMEOSTATIC IMBALANCE

If a sebaceous gland duct is blocked by accumulated sebum, a *whitehead* appears on the skin surface. If the material oxidizes and dries, it darkens to form a *blackhead*. *Acne* is an active inflammation of the sebaceous glands accompanied by "pimples" (pustules or cysts) on the skin. It is usually caused by bacterial infection, particularly by staphylococcus, and can be mild or extremely severe, leading to permanent scarring. Seborrhea (seb"o-re'ah; "fast-flowing sebum"), known as "cradle cap" in infants, is caused by overactive sebaceous glands. It begins on the scalp as pink, raised lesions that gradually become yellow to brown and begin to slough off oily scales. ●

Hairs and Hair Follicles

Hair is an important part of our body image—consider, for example, the spiky hair style of punk rockers and the flowing, glossy manes of some high-fashion models. Millions of hairs are distributed over our entire skin surface except our palms, soles, lips, nipples, and parts of the external genitalia (the head of the penis, for instance). Although hair helps to keep other mammals warm, our sparse body hair is far less luxuriant and useful. Its main function in humans is to sense insects on the skin before they bite or sting us. Hair on the scalp guards the head against physical trauma, heat loss, and sunlight. Eyelashes shield the eyes, and nose hairs filter large particles like lint and insects from the air we inhale.

Structure of a Hair

Hairs, or **pili** (pi'li), are flexible strands produced by hair follicles and consist largely of dead, keratinized

FIGURE 5.4 **Hair shaft emerging from a follicle at the epidermal surface.** Notice how the scalelike cells of the cuticle overlap one another (scanning electron micrograph, 1300×).

cells. The *hard keratin* that dominates hairs and nails has two advantages over the *soft keratin* found in typical epidermal cells: (1) It is tougher and more durable, and (2) its individual cells do not flake off.

The chief regions of a hair are the *shaft*, which projects from the skin (Figure 5.4), and the *root*, the part embedded in the skin (Figure 5.5). If the shaft is flat and ribbonlike in cross section, the hair is kinky; if it is oval, the hair is silky and wavy; if it is perfectly round, the hair is straight and tends to be coarse.

A hair has three concentric layers of keratinized cells (Figure 5.5a and b). Its central core, the *medulla* (mĕ-dul'ah; "middle"), consists of large cells and air spaces. The medulla is absent in fine hairs. The *cortex*, a bulky layer surrounding the medulla, consists of several layers of flattened cells. The outermost **cuticle** is formed from a single layer of cells that overlap one another from below like shingles on a roof (Figure 5.4). This arrangement helps to keep neighboring hairs apart so that the hair does not mat. (Hair conditioners smooth out the rough surface of the cuticle and make our hair look shiny.) The most heavily keratinized part of the hair, the cuticle provides strength and helps keep the inner layers tightly compacted. Because it is subjected to the most abrasion, the cuticle tends to wear away at the tip of the hair shaft, allowing the keratin fibrils in the cortex and medulla to frizz out, creating "split ends."

Hair pigment is made by melanocytes at the base of the hair follicle and transferred to the cortical cells. Various proportions of melanins of different colors (yellow, rust, brown, and black) combine to produce hair color from blond to pitch black. Additionally, red hair is colored by the iron-containing pigment called *trichosiderin*. Gray or white hair results from decreased melanin production (mediated by delayed-action genes) and from the replacement of melanin by air bubbles in the hair shaft.

Structure of a Hair Follicle

Hair follicles (*folli* = bag) fold down from the epidermal surface into the dermis. In the scalp, they may even extend into the hypodermis. The deep end of the follicle, located about 4 mm (1/6 in.) below the skin surface, is expanded, forming a **hair bulb** (Figure 5.5c and d). A knot of sensory nerve endings called a **hair follicle receptor,** or **root hair plexus,** wraps around each hair bulb (see Figure 5.1), and bending the hair stimulates these endings. Consequently, our hairs act as sensitive touch receptors.

▪ Feel the tickle as you run your hand over the hairs on your forearm.

A *hair papilla*, a nipplelike bit of dermal tissue, protrudes into the hair bulb. This papilla contains a knot of capillaries that supplies nutrients to the growing hair and signals it to grow. Except for its specific location, this papilla is similar to the dermal papillae underlying other epidermal regions.

The wall of a hair follicle is composed of an outer **connective tissue root sheath,** derived from the dermis; a thickened basement membrane called the *glassy membrane*; and an inner **epithelial root sheath,** derived mainly from an invagination of the epidermis (Figure 5.5c and d). The epithelial root sheath, which has external and internal parts, thins as it approaches the hair bulb, so that only a single layer of epithelial cells covers the papilla. However, the cells that compose the **hair matrix,** or actively dividing area of the hair bulb that produces the hair, originate in a region called the *hair bulge* located a fraction of a millimeter above the hair bulb. When chemical signals diffusing from the papilla reach the hair bulge, some of its cells migrate toward the papilla, where they divide to produce the hair cells. As new hair cells are produced

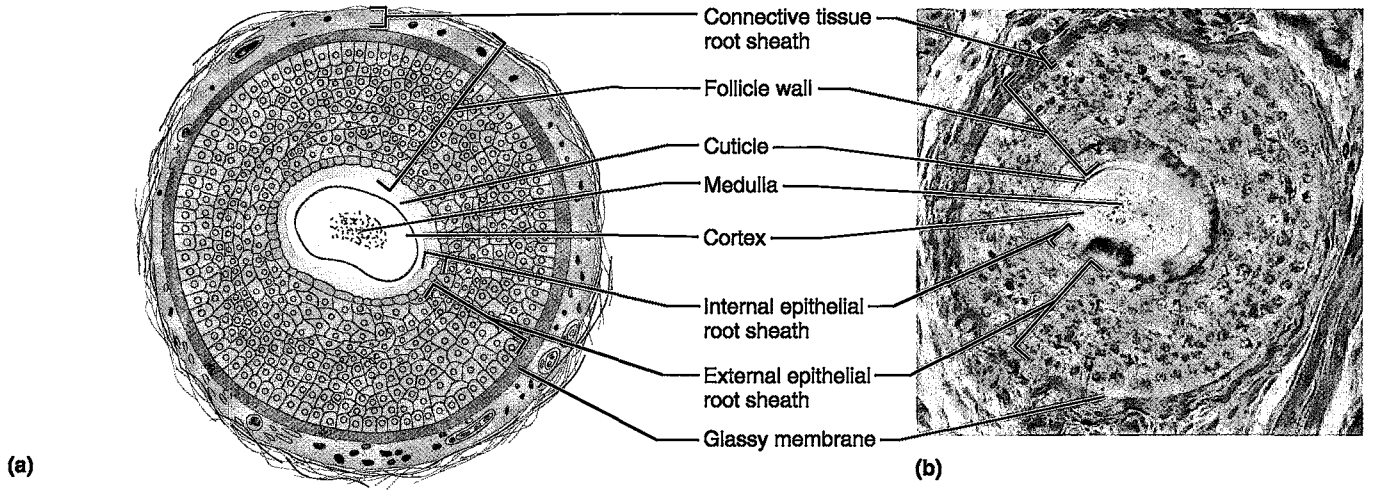

FIGURE 5.5 **Structure of a hair and hair follicle.** **(a)** Cross section of a hair within its follicle, diagrammatic view. **(b)** Photomicrograph of a cross section of a hair and hair follicle (250×). **(c)** Diagram of a longitudinal view of the expanded hair bulb of the follicle, which encloses the matrix, the actively dividing epithelial cells that produce the hair. **(d)** Photomicrograph of a longitudinal view of the hair bulb in the follicle (160×).

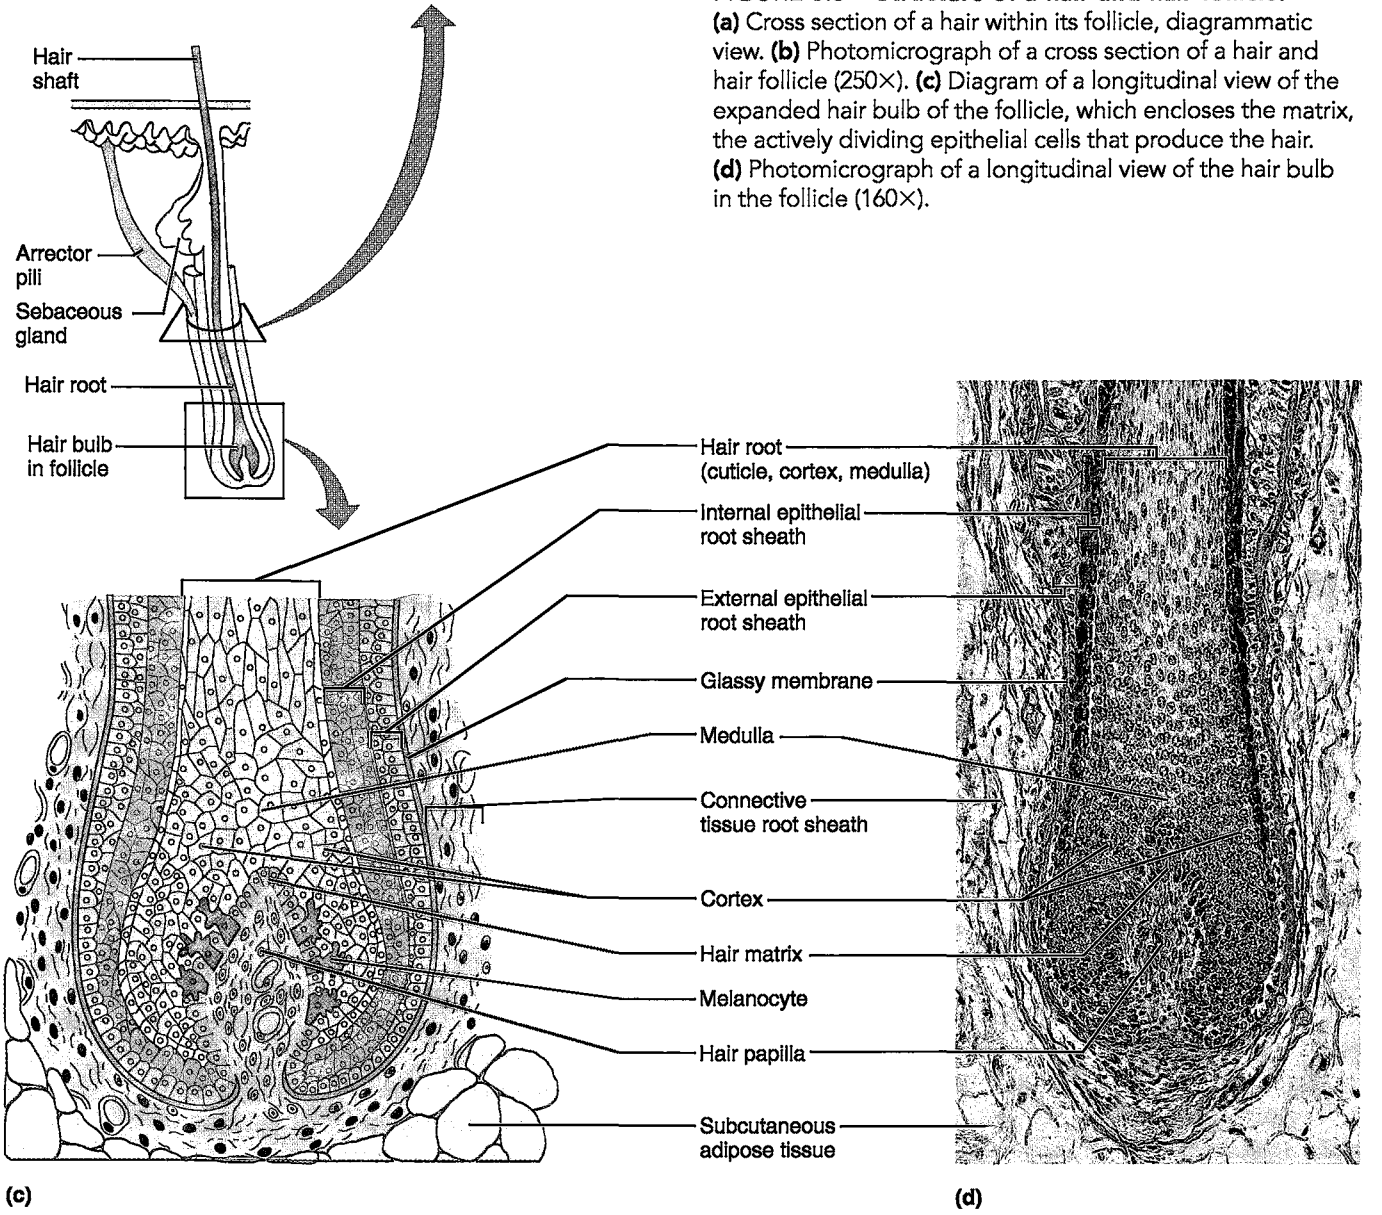

by the matrix, the older part of the hair is pushed upward, and its fused cells become increasingly keratinized and die.

Associated with each hair follicle is a bundle of smooth muscle cells called an **arrector pili** (ah-rek'tor pi'li; "raiser of hair") muscle. As you can see in Figure 5.1, most hair follicles approach the skin surface at a slight angle. The arrector pili muscles are attached in such a way that their contraction pulls the hair follicle into an upright position and dimples the skin surface to produce goose bumps in response to cold external temperatures or fear. This "hair-raising" response is not very useful to humans, with our short sparse hairs, but it is an important heat retention and protection mechanism in other animals. Furry animals can stay warmer by trapping a layer of insulating air in their fur; and a scared animal with its hair on end looks larger and more formidable to its enemy.

Types and Growth of Hair

Hairs come in various sizes and shapes, but as a rule, they can be classified as vellus or terminal. The body hair of children and adult females is of the pale, fine **vellus hair** (vel'us; *vell* = wool, fleece) variety. The coarser, longer hair of the eyebrows and scalp is **terminal hair;** terminal hair may also be darker. At puberty, terminal hairs appear in the axillary and pubic regions of both sexes and on the face and chest (and typically the arms and legs) of males. These terminal hairs grow in response to the stimulating effects of male sex hormones called *androgens* (of which *testosterone* is the most important), and when male hormones are present in large amounts, terminal hair growth is luxuriant.

Hair growth and density are influenced by many factors, but most importantly by nutrition and hormones. Poor nutrition means poor hair growth, whereas conditions that increase local dermal blood flow (such as chronic physical irritation or inflammation) may enhance local hair growth. Many old-time bricklayers who carried their hod on one shoulder all the time developed one hairy shoulder. Undesirable hair growth (such as on a woman's upper lip) may be arrested by *electrolysis* or laser treatments, which use electricity or light energy, respectively, to destroy the hair roots.

HOMEOSTATIC IMBALANCE

In women, small amounts of androgens are normally produced by both the ovaries and the adrenal glands. Excessive hairiness, or *hirsutism* (her'sootizm; *hirsut* = hairy), as well as other signs of masculinization, may result from an adrenal gland or ovarian tumor that secretes abnormally large amounts of androgens. Since few women want a beard or hairy chest, such tumors are surgically removed as soon as possible.

The rate of hair growth varies from one body region to another and with sex and age, but it averages 2.5 mm per week. Each follicle goes through *growth cycles.* In each cycle, an active growth phase, ranging from weeks to years, is followed by a regressive phase, when the hair matrix cells die and the follicle base and hair bulb shrivel somewhat. The follicle then enters a resting phase for one to three months. After the resting phase, the matrix proliferates again and forms a new hair to replace the old one that has fallen out or will be pushed out by the new hair.

The life span of hairs varies and appears to be under the control of a slew of proteins. The follicles of the scalp remain active for six to ten years before becoming inactive for a few months. Because only a small percentage of the hair follicles are shed at any one time, we lose an average of 90 scalp hairs daily. The follicles of the eyebrow hairs remain active for only three to four months, which explains why your eyebrows are never as long as the hairs on your head.

Hair Thinning and Baldness

A follicle has only a limited number of cycles in it. Given ideal conditions, hair grows fastest from the teen years to the 40s; then its growth slows. The fact that hairs are not replaced as fast as they are shed leads to hair thinning and some degree of baldness, or **alopecia** (al"o-pe'she-ah), in both sexes. Much less dramatic in women, the process usually begins at the anterior hairline and progresses posteriorly. Coarse terminal hairs are replaced by vellus hairs, and the hair becomes increasingly wispy.

True, or *frank, baldness* is a different story entirely. The most common type, **male pattern baldness,** is a genetically determined, sex-influenced condition. It is thought to be caused by a delayed-action gene that "switches on" in adulthood and changes the response of the hair follicles to DHT (dihydrotestosterone), a metabolite of testosterone. As a result, the follicular growth cycles become so short that many hairs never even emerge from their follicles before shedding, and those that do are fine vellus hairs that look like peach fuzz in the "bald" area. Until recently, the only cure for male pattern baldness was drugs that inhibit testosterone production, but they also cause loss of sex drive—a trade-off few men would choose. Quite by accident, it was discovered that minoxidil, a drug used to reduce high blood pressure, has an interesting side effect in some bald men; it stimulates hair regrowth. Although its results are variable, minoxidil is available over the counter in dropper bottles or spray form for application to the scalp. Finasteride, according to some the

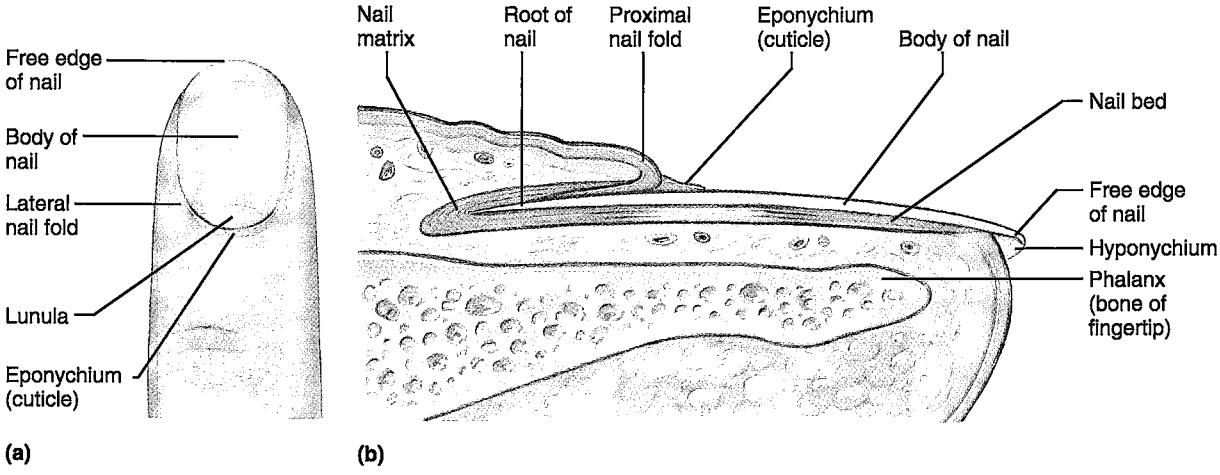

FIGURE 5.6 **Structure of a nail.** **(a)** Surface view of the distal part of a finger. **(b)** Sagittal section of the fingertip. The nail matrix that forms the nail lies beneath the lunula.

most promising cure ever developed for male pattern baldness, hit pharmacy shelves in early 1998 and has had moderate success. Available only by prescription in once-a-day pill form, it must be taken for the rest of one's life. Once the patient stops taking it, all of the new growth falls out, and so does what remains of the "old" hair.

HOMEOSTATIC IMBALANCE

Hair thinning can be induced by a number of factors that upset the normal balance between hair loss and replacement. Outstanding examples are acutely high fever, surgery, severe emotional trauma, and certain drugs (excessive vitamin A, some antidepressants and blood thinners, anabolic steroids, and most chemotherapy drugs). Protein-deficient diets and lactation lead to hair thinning because new hair growth stops when protein needed for keratin synthesis is not available or is being used for milk production. In all of these cases, hair regrows if the cause of thinning is removed or corrected. In the rare condition called *alopecia areata* the follicles are attacked by the immune system and the hair falls out in patches. But again, the follicles survive. However, hair loss due to severe burns, excessive radiation, or other factors that eliminate the follicles is permanent. ●

Nails

A **nail** is a scalelike modification of the epidermis that forms a clear protective covering on the dorsal surface of the distal part of a finger or toe (Figure 5.6). Nails, which correspond to the hooves or claws of other animals, are particularly useful as "tools" to help pick up small objects and to scratch an itch. As noted, in contrast to *soft keratin* of the epidermis, nails contain *hard keratin*. Each nail has a *free edge*, a *body* (visible attached portion), and a proximal *root* (embedded in the skin). The deeper layers of the epidermis extend beneath the nail as the *nail bed;* the nail itself corresponds to the superficial keratinized layers. The thickened proximal portion of the nail bed, called the **nail matrix,** is responsible for nail growth. As the nail cells produced by the matrix become heavily keratinized, the nail body slides distally over the nail bed.

Nails normally appear pink because of the rich bed of capillaries in the underlying dermis. However, the region that lies over the thick nail matrix appears as a white crescent called the *lunula* (lu'nu-lah; "little moon"). The proximal and lateral borders of the nail are overlapped by skin folds, called **nail folds.** The proximal nail fold projects onto the nail body as the **cuticle** or **eponychium** (ep"o-nik'e-um; "on the nail"). The region beneath the free edge of the nail where dirt and debris tend to accumulate is the **hyponychium** ("below nail"), informally called the quick.

Functions of the Integumentary System

The skin and its derivatives perform a variety of functions that affect body metabolism and prevent external factors from upsetting body homeostasis. Given its superficial location it is our most vulnerable organ system, exposed to bacteria, abrasion, temperature extremes, and harmful chemicals.

Protection

The skin constitutes at least three types of barriers: chemical, physical, and biological.

Chemical Barriers

The chemical barriers include skin secretions and melanin. Although the skin's surface teems with bacteria, the low pH of skin secretions, or the so-called **acid mantle,** retards their multiplication. In addition, many bacteria are killed outright by bactericidal substances in sebum. Skin cells also secrete a natural antibiotic called *human defensin* that literally punches holes in bacteria, making them look like sieves. Wounded skin releases large quantities of protective peptides called *cathelicidins* that are particularly effective in preventing infection by group A streptococcus bacteria. As discussed earlier, melanin provides a chemical pigment shield to prevent UV damage to the viable skin cells.

Physical/Mechanical Barriers

Physical, or mechanical, barriers are provided by the continuity of skin and the hardness of its keratinized cells. As a physical barrier, the skin is a remarkable compromise. A thicker epidermis would be more impenetrable, but we would pay the price in loss of suppleness and agility. Epidermal continuity works hand in hand with the acid mantle to ward off bacterial invasion. The waterproofing glycolipids of the epidermis block the diffusion of water and water-soluble substances between cells, preventing both their loss from and entry into the body through the skin. Substances that *do* penetrate the skin in limited amounts include (1) *lipid-soluble substances,* such as oxygen, carbon dioxide, fat-soluble vitamins (A, D, E, and K), and steroids; (2) *oleoresins* (o"le-o-rez'inz) of certain plants, such as poison ivy and poison oak; (3) *organic solvents,* such as acetone, dry-cleaning fluid, and paint thinner, which dissolve the cell lipids; (4) *salts of heavy metals,* such as lead and mercury; and (5) drug agents called *penetration enhancers* that help ferry other drugs into the body.

HOMEOSTATIC IMBALANCE

Organic solvents and heavy metals are devastating to the body and can be lethal. Passage of organic solvents through the skin into the blood can cause the kidneys to shut down and can also cause brain damage. Absorption of lead results in anemia and neurological defects. These substances should never be handled with bare hands. ●

Biological Barriers

Biological barriers include the Langerhans' (dendritic) cells of the epidermis, macrophages in the dermis, and DNA itself. Langerhans' cells are active elements of the immune system. For the immune response to be activated, the foreign substances, or *antigens,* must be presented to specialized white blood cells called lymphocytes. In the epidermis, it is the Langerhans' cells that play this role. Dermal macrophages constitute a second line of defense to dispose of viruses and bacteria that have managed to penetrate the epidermis. They, too, act as antigen "presenters." Although melanin provides a fairly good chemical sunscreen, DNA itself is a remarkably effective biologically based sunscreen. Electrons in DNA molecules absorb UV radiation and transfer it to the atomic nuclei, which heat up and vibrate vigorously. However, since the heat dissipates to surrounding water molecules instantaneously, the DNA converts potentially destructive radiation into harmless heat.

Body Temperature Regulation

The body works best when its temperature remains within homeostatic limits. Like car engines, we need to get rid of the heat generated by our internal reactions. As long as the external temperature is lower than body temperature, the skin surface loses heat to the air and to cooler objects in its environment, just as a car radiator loses heat to the air and other nearby engine parts.

Under normal resting conditions, and as long as the environmental temperature is below 31–32°C (88–90°F), sweat glands continuously secrete unnoticeable amounts of sweat [about 500 ml (0.5 L) of sweat per day]. When body temperature rises, dermal blood vessels dilate and the sweat glands are stimulated into vigorous secretory activity. Sweat becomes noticeable and can account for the loss of up to 12 L of body water in one day. Evaporation of sweat from the skin surface dissipates body heat and efficiently cools the body, thus preventing overheating.

When the external environment is cold, dermal blood vessels constrict. This causes the warm blood to bypass the skin temporarily and allows skin temperature to drop to that of the external environment. Once this has happened, passive heat loss from the body is slowed, thus conserving body heat. Body temperature regulation is discussed in greater detail in Chapter 24.

Cutaneous Sensation

The skin is richly supplied with **cutaneous sensory receptors,** which are actually part of the nervous system. The cutaneous receptors are classified as *exteroceptors* (ek"ster-o-sep'torz) because they respond to stimuli arising outside the body. For example, Meissner's corpuscles (in the dermal papillae) and Merkel discs allow us to become aware of a caress or the feel of our clothing against our skin, whereas Pacinian corpuscles (in the deeper dermis or hypodermis) alert us to bumps or contacts involving

deep pressure. Hair follicle receptors report on wind blowing through our hair and a playful tug on a pigtail. Painful stimuli (irritating chemicals, extreme heat or cold, and others) are sensed by free nerve endings that meander throughout the skin. Detailed discussion of these cutaneous receptors is deferred to Chapter 13, but those mentioned above are illustrated in Figure 5.1. One, a Merkel disc, is also shown in Figure 5.2b.

Metabolic Functions

When sunlight bombards the skin, modified cholesterol molecules circulating through dermal blood vessels are converted to a vitamin D precursor, and transported via the blood to other body areas to play various roles in calcium metabolism. For example, calcium cannot be absorbed from the digestive tract without vitamin D.

Besides synthesizing the vitamin D precursor, the epidermis has a host of other metabolic functions. It makes chemical conversions that supplement those of the liver—for example, keratinocyte enzymes can (1) "disarm" many cancer-causing chemicals that penetrate the epidermis; (2) convert some harmless chemicals into carcinogens; and (3) activate some steroid hormones; for instance, they can transform cortisone applied to irritated skin into hydrocortisone, a potent anti-inflammatory drug. Skin cells also make several biologically important proteins, including collagenase, an enzyme that aids the natural turnover of collagen (and deters wrinkles).

Blood Reservoir

The dermal vascular supply is extensive and can hold large volumes of blood (about 5% of the body's entire blood volume). When other body organs, such as vigorously working muscles, need a greater blood supply, the nervous system constricts the dermal blood vessels. This shunts more blood into the general circulation, making it available to the muscles and other body organs.

Excretion

Limited amounts of nitrogen-containing wastes (ammonia, urea, and uric acid) are eliminated from the body in sweat, although most such wastes are excreted in urine. Profuse sweating is an important avenue for water and salt (sodium chloride) loss.

Homeostatic Imbalances of Skin

When skin rebels, it is quite a visible revolution. Loss of homeostasis in body cells and organs reveals itself on the skin, sometimes in startling ways. The skin can develop more than 1000 different conditions and ailments. The most common skin disorders are bacterial, viral, or yeast infections. A number of these are summarized in Related Clinical Terms on p. 171. Less common, but far more damaging to body well-being, are skin cancer and burns, considered next.

Skin Cancer

One in five Americans develop skin cancer at some point. Most tumors that arise in the skin are benign and do not spread (metastasize) to other body areas. (A wart, a neoplasm caused by a virus, is one example.) However, some skin tumors are malignant, or cancerous, and invade other body areas. A crucial risk factor for skin cancer is overexposure to the UV radiation in sunlight, which damages DNA bases. Adjacent pyrimidine bases often respond by fusing, forming lesions called *dimers*. UV radiation also appears to disable a tumor suppressor gene [*p53* or the patched (*ptc*) gene]. In limited numbers of cases, however, frequent irritation of the skin by infections, chemicals, or physical trauma seems to be a predisposing factor.

Interestingly, sunburned skin accelerates its production of Fas, a protein that causes genetically damaged skin cells to commit suicide, thus reducing the risk of mutations that will cause sun-linked skin cancer. It is the death of these gene-damaged cells that causes the skin to peel after a sunburn. Good news for sun worshippers is the newly developed skin lotions that can fix damaged DNA before the involved cells can develop into cancer cells. These lotions contain tiny oily vesicles (liposomes) filled with enzymes that initiate repair of the DNA mutations most commonly caused by sunlight. The liposomes penetrate the epidermis and enter the keratinocytes, ultimately making their way into the nuclei to bind to specific sites where two DNA bases have fused. There, by selective cutting of the DNA strands, they begin a DNA repair process that is completed by cellular enzymes.

Basal Cell Carcinoma

Basal cell carcinoma (kar"sĭ-no'mah) is the least malignant and most common skin cancer; over 30% of all white people get it in their lifetime. Stratum basale cells proliferate, invading the dermis and hypodermis. The cancer lesions occur most often on sun-exposed areas of the face and appear as shiny, dome-shaped nodules that later develop a central ulcer with a pearly, beaded edge (Figure 5.7a). Basal cell carcinoma is relatively slow-growing, and metastasis seldom occurs before it is noticed. Full cure by surgical excision is the rule in 99% of cases.

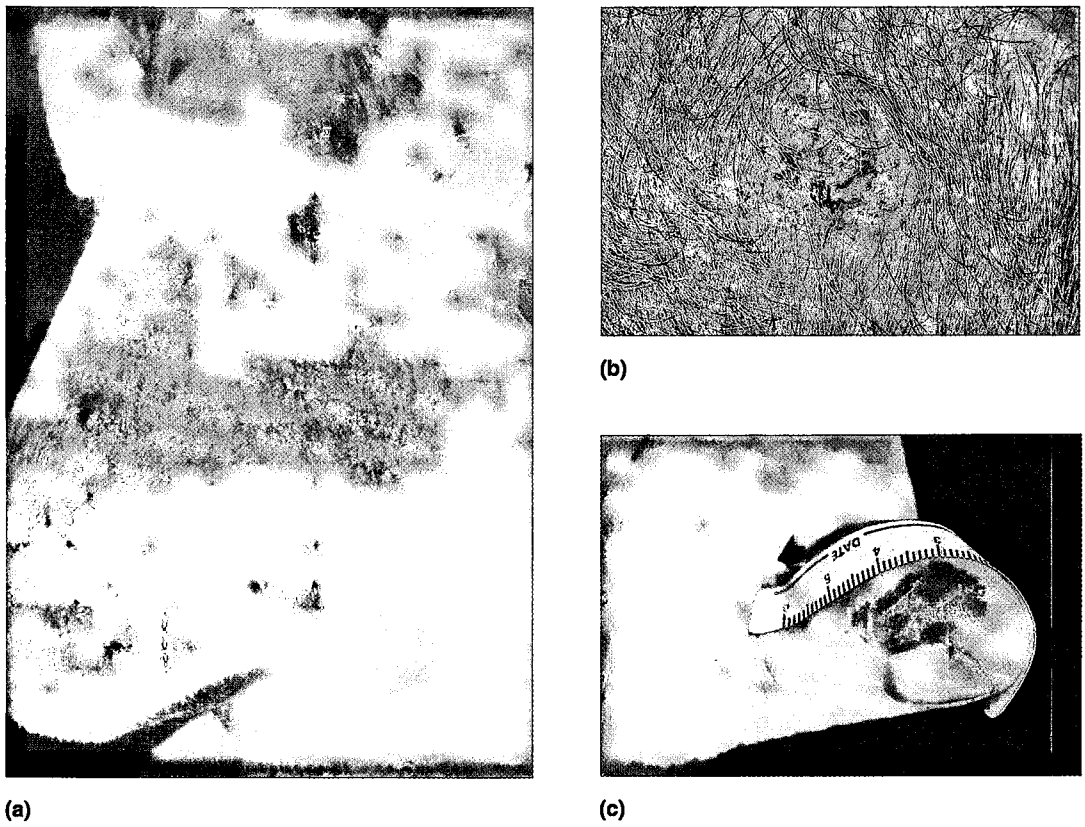

FIGURE 5.7 **Photographs of skin cancers. (a)** Basal cell carcinoma. **(b)** Squamous cell carcinoma. **(c)** Melanoma.

Squamous Cell Carcinoma

Squamous cell carcinoma arises from the keratinocytes of the stratum spinosum. The lesion appears as a scaly reddened papule (small, rounded elevation) that arises most often on the head (scalp, ears, and lower lip), and hands (Figure 5.7b). It tends to grow rapidly and metastasize if not removed. If it is caught early and removed surgically or by radiation therapy, chance of complete cure is good.

Melanoma

Melanoma (mel"ah-no'mah), cancer of melanocytes, is the most dangerous skin cancer because it is highly metastatic and resistant to chemotherapy. It accounts for only about 5% of skin cancers, but its incidence is increasing rapidly (by 3–8% per year in the United States). Melanoma can begin wherever there is pigment. Most such cancers appear spontaneously; about one-third develop from preexisting moles. It usually appears as a spreading brown to black patch (Figure 5.7c) that metastasizes rapidly to surrounding lymph and blood vessels. The key to surviving melanoma is early detection. The chance of survival is poor if the lesion is over 4 mm thick. The usual therapy for melanoma is wide surgical excision accompanied by immunotherapy (immunizing the body against its cancer cells).

The American Cancer Society suggests that sun worshippers regularly examine their skin for new moles or pigmented spots and apply the **ABCD rule** for recognizing melanoma. **A. Asymmetry:** The two sides of the pigmented spot or mole do not match. **B. Border irregularity:** The borders of the lesion exhibit indentations. **C. Color:** The pigmented spot contains several colors (blacks, browns, tans, and sometimes blues and reds). **D. Diameter:** The spot is larger than 6 mm in diameter (the size of a pencil eraser). Some experts have found that adding an **E,** for elevation above the skin surface, improves diagnosis, so they use the ABCD(E) rule.

Burns

Burns are a devastating threat to the body primarily because of their effects on the skin. A **burn** is tissue damage inflicted by intense heat, electricity, radiation, or certain chemicals, all of which denature cell proteins and cause cell death in the affected areas.

The immediate threat to life resulting from severe burns is a catastrophic loss of body fluids containing proteins and electrolytes, resulting in dehydration

Although the anterior head and face represent a very small proportion of the body surface, burns to this region are often much more serious than burns to the trunk. Why?

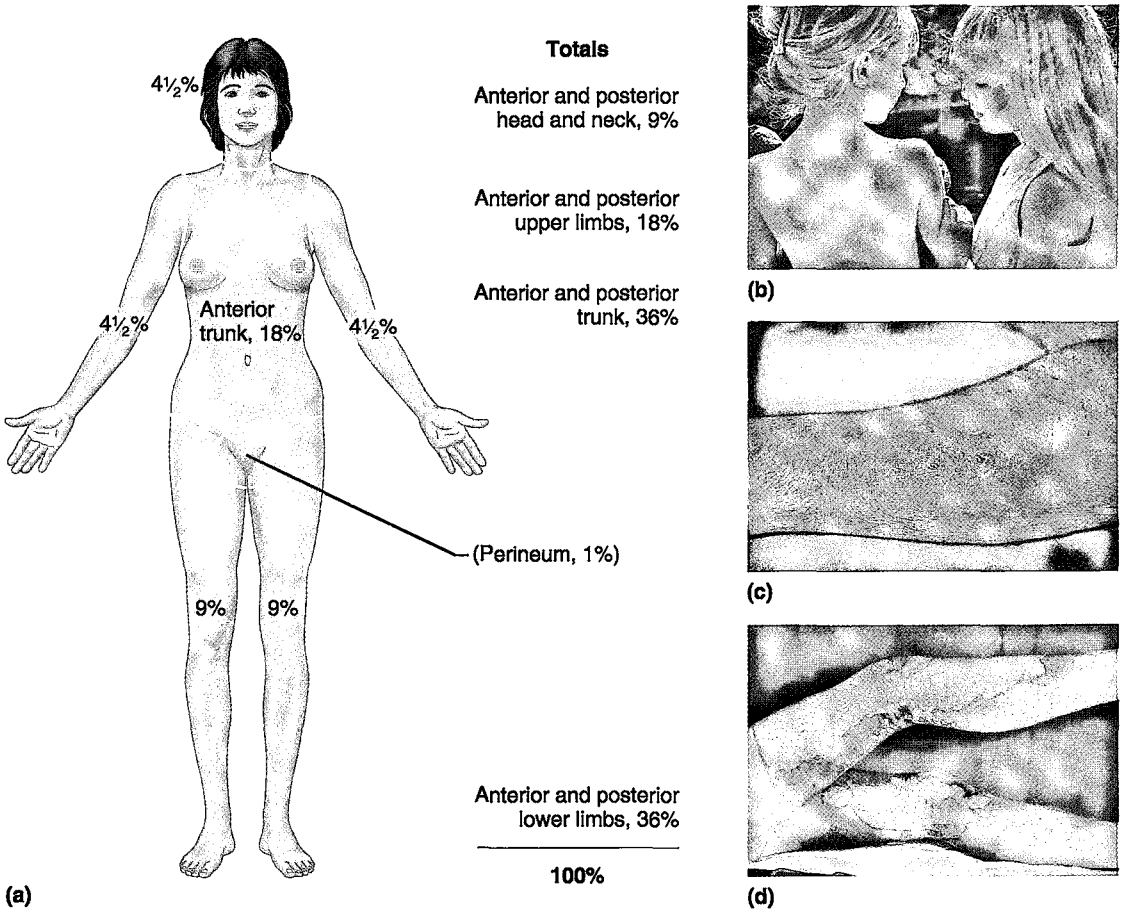

FIGURE 5.8 **Estimating the extent and severity of burns. (a)** The extent of burns is estimated by using the rule of nines. Surface area values for the anterior body surface are indicated on the human figure. Total surface area (anterior and posterior body surfaces) for each body region is indicated to the right of the figure. Severity of burns depends on the depth of tissue damage. **(b)** In first-degree burns only the epidermis is destroyed. **(c)** In second-degree burns, the epidermis and part of the dermis are involved and blistering occurs. **(d)** In third-degree burns the epidermis and dermis (and often part of the hypodermis) are destroyed.

and electrolyte imbalance. These, in turn, lead to renal shutdown and circulatory shock (inadequate blood circulation due to reduced blood volume). To save the patient, the lost fluids must be replaced immediately via the intravenous (IV) route. In adults, the volume of fluid lost can be estimated by computing the percentage of body surface burned (extent of the burns) using the **rule of nines.** This method divides the body into 11 areas, each accounting for 9% of total body area, plus an additional area surrounding the genitals accounting for 1% of body surface area (Figure 5.8). This method is only approximate, so special tables are used when greater accuracy is desired.

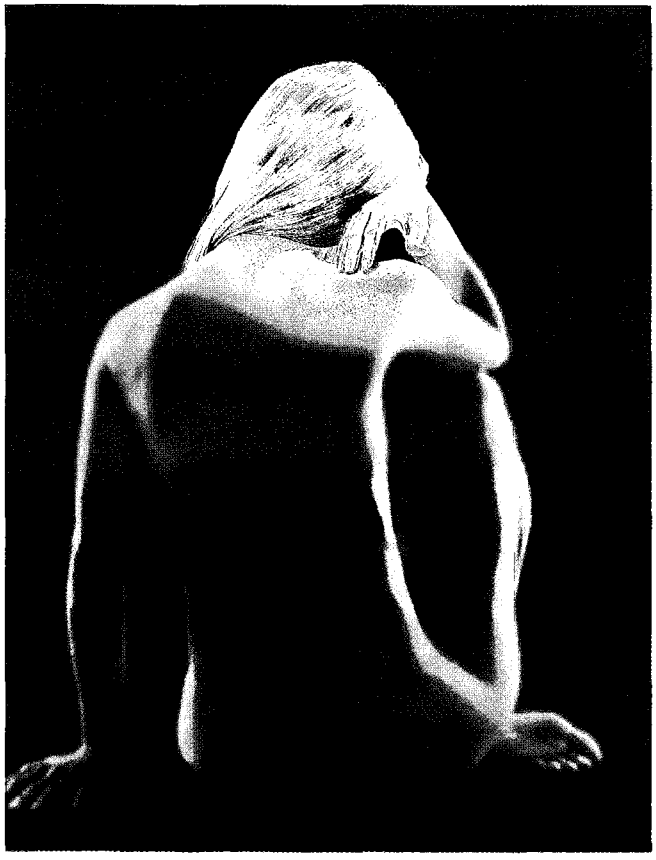
Burn patients also need thousands of extra food calories daily to replace lost proteins and allow tissue repair. No one can eat enough food to provide these calories, so burn patients are given supplementary nutrients through gastric tubes and IV lines. After the initial crisis has passed, infection becomes the main threat and is the leading cause of death in burn victims. Burned skin is sterile for about 24 hours. Thereafter, bacteria, fungi, and other pathogens easily invade areas where the skin barrier is destroyed, and they multiply rapidly in the nutrient-rich environment of dead tissues. Adding to this problem is the fact that the immune system becomes deficient within one to two days after severe burn injury.

(Text continues on p. 170.)

Burn injury to the facial area may burn the respiratory passages, putting the patient at risk for suffocation as the burned tissues swell.

MAKING CONNECTIONS

SYSTEM CONNECTIONS: Homeostatic Interrelationships Between the Integumentary System and Other Body Systems



Skeletal System

- Skin protects bones; skin synthesizes vitamin D that bones need for normal calcium absorption and deposit of bone (calcium) salts, which make bones hard
- Skeletal system provides support for skin

Muscular System

- Skin protects muscles
- Active muscles generate large amounts of heat, which increases blood flow to the skin and may promote activation of sweat glands of skin

Nervous System

- Skin protects nervous system organs; cutaneous sensory receptors located in skin (see Figure 5.1)
- Nervous system regulates diameter of blood vessels in skin; activates sweat glands, contributing to thermoregulation; interprets cutaneous sensation; activates arrector pili muscles

Endocrine System

- Skin protects endocrine organs; converts some hormones to their active forms
- Androgens produced by the endocrine system activate sebaceous glands and are involved in regulation of hair growth

Cardiovascular System

- Skin protects cardiovascular organs; prevents fluid loss from body; serves as blood reservoir
- Cardiovascular system transports oxygen and nutrients to skin and removes wastes from skin; provides substances needed by skin glands to make their secretions

Lymphatic System/Immunity

- Skin protects lymphatic organs; prevents pathogen invasion; Langerhans' cells and macrophages help activate the immune system
- Lymphatic system prevents edema by picking up excessive leaked fluid; immune system protects skin cells

Respiratory System

- Skin protects respiratory organs
- Respiratory system furnishes oxygen to skin cells and removes carbon dioxide via gas exchange with blood

Digestive System

- Skin protects digestive organs; provides vitamin D needed for calcium absorption; performs some of the same chemical conversions as liver cells
- Digestive system provides needed nutrients to the skin

Urinary System

- Skin protects urinary organs; excretes salts and some nitrogenous wastes in sweat
- Urinary system activates vitamin D precursor made by keratinocytes; disposes of nitrogenous wastes of skin metabolism

Reproductive System

- Skin protects reproductive organs; cutaneous receptors respond to erotic stimuli; highly modified sweat glands (mammary glands) produce milk. During pregnancy, skin stretches to accommodate growing fetus; changes in skin pigmentation may occur

CLOSER CONNECTIONS

THE INTEGUMENTARY SYSTEM and Interrelationships with the Nervous, Cardiovascular, and Lymphatic/Immune Systems

First and foremost, our skin is a barrier. Like the skin of a grape, it keeps its contents juicy and whole. The skin, however, is a master at self (wound) repair, and interacts intimately with other body systems by making vitamin D (necessary for hard bones) and other potent molecules, all the while protecting deeper tissues from damaging external agents. Perhaps the most crucial roles of the skin in terms of overall body homeostasis are those it plays with the nervous, cardiovascular, and lymphatic systems. These interactions are detailed next.

Nervous System

The skin houses the tiny sensory receptors that provide a great deal of information about our external environment—its temperature, the pressure exerted by objects, and the presence of dangerous substances. What if we stepped on broken glass or hot pavement but did not have neural monitors in our skin? If we did not actually see, hear, taste, or smell such a damaging event, no reports would be sent to the nervous system. Consequently, the nervous system would be left "in the dark," unable to evaluate the need for a response and to order the steps needed to protect us from further damage or to get first aid. Thus, the whole body benefits from the skin's interaction with the nervous system.

Nervous and Cardiovascular System

Skin provides the site both for sensing external temperature and for responding to temperature changes. Dermal blood vessels (cardiovascular system organs) and sweat glands (controlled by the nervous system) play crucial roles in thermoregulation. So too do blood and the hot and cold receptors in the skin. When we are chilled, our blood loses heat to internal organs and cools. This alerts the nervous system to retain heat by constricting blood vessels. When body and blood temperature rises, dermal vessels dilate and sweating begins.

Thermoregulation is vital: When the body overheats, life-threatening changes occur. Chemical reactions speed up, and if excessive, they destroy vital proteins and cells die. Cold has the opposite effect; cellular activity slows and ultimately stops.

Lymphatic System/Immunity

The role of the skin in immunity is complex. Keratinocytes in the skin manufacture interferons (proteins that block viral infection) and other proteins important to the immune response. Langerhans' cells in the skin interact with antigens (foreign substances) that have penetrated the stratum corneum. The Langerhans' cells then migrate to lymphatic organs, where they present bits of the antigens to cells that will mount the immune response against them. This "messenger" function alerts the immune system early on to the presence of pathogens in the body.

Even a mild sunburn disrupts the normal immune response because UV radiation disables the skin's presenter cells. This may explain why many people infected by the cold sore virus tend to have a cold sore eruption after sun exposure.

CLINICAL CONNECTIONS

Integumentary System

A terrible collision between a trailer truck and a bus has occurred on Route 91. Several of the passengers are rushed to area hospitals for treatment. We will follow a few of these people in clinical case studies that will continue through the book from one organ system to the next.

Case Study: Examination of Mrs. DeStephano, a 45-year-old woman, reveals several impairments of homeostasis. Relative to her integumentary system, the following comments are noted on her chart:

- Epidermal abrasions of the right arm and shoulder
- Severe lacerations of the right cheek and temple
- Cyanosis apparent

The lacerated areas are cleaned, sutured, and bandaged by the emergency room (ER) personnel, and Mrs. DeStephano is admitted for further tests.

Relative to her signs:

1. What protective mechanisms are impaired or deficient in the abraded areas?
2. Assuming that bacteria are penetrating the dermis in these areas, what remaining skin defense mechanisms might act to prevent further bacterial invasion?
3. What benefit is conferred by suturing the lacerations? (Hint: see Chapter 4, p. 148.)
4. Mrs. DeStephano's cyanotic skin may hint at what additional problem (and impairment of what body systems or functions)?

(Answers in Appendix G)

Burns are classified according to their severity (depth) as first-, second-, or third-degree burns (Figure 5.8b–d). In **first-degree burns,** only the epidermis is damaged. Symptoms include localized redness, swelling, and pain. First-degree burns tend to heal in two to three days without special attention. Sunburn is usually a first-degree burn. **Second-degree burns** injure the epidermis and the upper region of the dermis. Symptoms mimic those of first-degree burns, but blisters also appear. Skin regeneration occurs with little or no scarring within three to four weeks if care is taken to prevent infection. First- and second-degree burns are referred to as *partial-thickness* burns.

Third-degree burns are *full-thickness* burns, involving the entire thickness of the skin. The burned area appears gray-white, cherry red, or blackened, and initially there is little or no edema. Since the nerve endings in the area have been destroyed, the burned area is not painful. Although skin regeneration might eventually occur by proliferation of epithelial cells at the edges of the burn or from stem cells in hair follicles, it is usually impossible to wait that long because of fluid loss and infection. Thus, skin grafting is usually necessary.

To prepare the burned area for grafting, the *eschar* (es'kar), or burned skin, must first be debrided (removed). To prevent infection and fluid loss, the area is then flooded with antibiotics and covered temporarily with a synthetic membrane, animal (pig) skin, cadaver skin, or "living bandage" made from the thin amniotic sac membrane that surrounds a fetus. Then healthy skin is transplanted to the burned site. Unless the graft is taken from the patient (an autograft), however, there is a good chance that it will be rejected by the patient's immune system (see p. 815 in Chapter 21). Even if the graft "takes," extensive scar tissue often forms in the burned areas.

An exciting technique is eliminating many of the traditional problems of skin grafting and rejection. Synthetic skin made of a silicone "epidermis" bound to a spongy "dermal" layer composed of collagen and ground cartilage is applied to the debrided area. In time, the patient's own dermal tissue replaces and absorbs the artificial one. Then the silicone sheet is peeled off and replaced with a network of epidermal cells cultured from the patient's own skin. The artificial skin is not rejected by the body, saves lives, and results in minimal scarring. However, it is more likely to become infected than is an autograft.

In general, burns are considered critical if any of the following conditions exists: (1) over 25% of the body has second-degree burns, (2) over 10% of the body has third-degree burns, or (3) there are third-degree burns of the face, hands, or feet. Facial burns introduce the possibility of burned respiratory passageways, which can swell and cause suffocation. Burns at joints are also troublesome because scar tissue formation can severely limit joint mobility.

Developmental Aspects of the Integumentary System

The epidermis develops from the embryonic ectoderm, and the dermis and hypodermis develop from mesoderm. By the end of the fourth month of development, the skin is fairly well formed: The epidermis has all its strata, dermal papillae are obvious, and rudimentary epidermal derivatives are present. During the fifth and sixth months, the fetus is covered with a downy coat of delicate hairs called the *lanugo coat* (lah-nu'go; "wool"). This hairy cloak is shed by the seventh month, and vellus hairs make their appearance.

When a baby is born, its skin is covered with *vernix caseosa* (ver'niks kă-se-o'sah; "varnish of cheese"), a white, cheesy-looking substance produced by the sebaceous glands that protects the fetus's skin within the water-filled amnion. The newborn's skin is very thin and often has accumulations in the sebaceous glands on the forehead and nose that appear as small white spots called *milia* (mil'e-ah). These normally disappear by the third week after birth. During infancy and childhood, the skin thickens, and more subcutaneous fat is deposited. Although we all have approximately the same number of sweat glands, the number that begin to function increases in the first two years after birth and is determined by climate. Hence, people who grow up in hot climates have more active sweat glands than those raised in cooler areas of the world.

During adolescence, the skin and hair become oilier as sebaceous glands are activated, and acne may appear. Acne generally subsides in early adulthood, and skin reaches its optimal appearance when we reach our 20s and 30s. Thereafter, the skin starts to show the effects of cumulative environmental assaults (abrasion, wind, sun, chemicals). Scaling and various kinds of skin inflammation, or **dermatitis** (der"mah-ti'tis), become more common.

As old age approaches, the rate of epidermal cell replacement slows, the skin thins, and its susceptibility to bruises and other types of injury increases. All of the lubricating substances produced by the skin glands that make young skin so soft start to become deficient. As a result, the skin becomes dry and itchy. However, those with naturally oily skin seem to postpone this dryness until later in life. Elastic fibers clump, and collagen fibers become fewer and stiffer. The subcutaneous fat layer diminishes, leading to the intolerance to cold so common in elderly people. The decreasing elasticity of the skin, along with the loss of subcutaneous tissue, inevitably leads to wrinkling. (See the *Closer Look* box on p. 156.) Decreasing numbers of melanocytes and Langerhans' cells enhance the risk and incidence of skin cancer in this age group. As a rule, redheads and fair-skinned individuals, who have less melanin to begin

with, show age-related changes more rapidly than do those with darker skin and hair.

By the age of 50 years, the number of active hair follicles has declined by two-thirds and continues to fall, resulting in hair thinning. Hair loses its luster in old age, and the delayed-action genes responsible for graying and male pattern baldness become active.

Although there is no known way to avoid the aging of the skin, one of the best ways to slow the process is to shield your skin from the sun with sunscreens and protective clothing. Remember, the same sunlight that produces that fashionable tan also causes the sagging, blotchy, wrinkled skin of old age complete with pigmented "liver spots." (It is instructive to note that aged skin that has been protected from the sun has lost some elasticity and is thinned as noted, but it remains unwrinkled and unmarked.) Much of this havoc is due to UV activation of enzymes called matrix metalloproteinases, which degrade collagen and other dermal components. A drug called tretinoin, related to vitamin A, inhibits these enzymes and is now being used in some skin creams to slow photo-aging. Good nutrition, plenty of fluids, and cleanliness may also delay the process.

■ ■ ■

The skin is only about as thick as a paper towel—not too impressive as organ systems go. Yet, when it is severely damaged, nearly every body system reacts. Metabolism accelerates or may be impaired, immune system changes occur, bones may soften, the cardiovascular system may fail—the list goes on and on. On the other hand, when the skin is intact and performing its functions, the body as a whole benefits. Homeostatic interrelationships between the integumentary system and other organ systems are summarized in *Making Connections* on pp. 168–169.

Related Clinical Terms

Albinism (al'bĭ-nizm; *alb* = white) Inherited condition in which melanocytes do not synthesize melanin owing to a lack of tyrosinase. An albino's skin is pink, the hair pale or white, and the irises of the eyes unpigmented or poorly so.

Boils and carbuncles (kar'bung-klz; "little glowing embers") Inflammation of hair follicles and sebaceous glands in which an infection has spread to the underlying hypodermis; common on the dorsal neck. Carbuncles are composite boils. A common cause is bacterial infection.

Cold sores (fever blisters) Small fluid-filled blisters that itch and smart; usually occur around the lips and in the mucosa of the mouth; caused by a herpes simplex infection. The virus localizes in a cutaneous nerve, where it remains dormant until activated by emotional upset, fever, or UV radiation.

Contact dermatitis Itching, redness, and swelling, progressing to blister formation; caused by exposure of the skin to chemicals (e.g., poison ivy oleoresin) that provoke an allergic response in sensitive individuals.

Decubitus ulcer (de-ku'bĭ-tus) Localized breakdown and ulceration of skin due to interference with its blood supply. Usually occurs over a bony prominence, such as the hip or heel, that is subjected to continuous pressure; also called a bedsore.

Dermatology The branch of medicine that studies and treats disorders of the skin.

Epidermolysis bullosa (EB) A group of hereditary disorders characterized by inadequate or faulty synthesis of keratin, collagen, and/or basement membrane "cement" that results in lack of cohesion between layers of the skin and mucosa; a simple touch causes layers to separate and blister. For this reason, EB victims are called "touch-me-nots." In severe cases fatal blistering occurs in major vital organs. Because the blisters rupture easily, victims suffer frequent infections; treatments are aimed at relieving the symptoms and preventing infection.

Impetigo (im"pĕ-ti'go; *impet* = an attack) Pink, fluid-filled, raised lesions (common around the mouth and nose) that develop a yellow crust and eventually rupture. Caused by staphylococcus infection, contagious, and common in school-age children.

Mongolian spot Blue-black spot appearing in the skin of the sacral region, which results from the unusual presence of a cluster of melanocytes in the dermis; the light-scattering effect of the epidermis causes these dermal melanin-containing regions to appear blue. Disappears by age 3 or 4.

Porphyria (por-fer'e-ah; "purple")An inherited condition in which certain enzymes essential to form the heme of hemoglobin of blood are lacking. Without these enzymes, metabolic intermediates of the heme pathway called porphyrins build up, spill into the circulation, and eventually cause lesions throughout the body, especially when exposed to sunlight. The skin becomes lesioned and scarred; fingers, toes, and nose are disfigured; gums degenerate and teeth become prominent; thus it's believed to be the basis of folklore about vampires.

Psoriasis (so-ri'ah-sis) A chronic condition characterized by raised, reddened epidermal lesions covered with dry silvery scales that itch, burn, crack, and sometimes bleed or become infected. When severe, it may be disfiguring and debilitating. Autoimmune attack in affected regions is suspect; attacks are often triggered by trauma, infection, hormonal changes, and stress. Phototherapy with UV light in conjunction with chemotherapeutic drugs provides some relief.

Vitiligo (vit"ĭ-li'go; *viti* = a vine, winding) The most prevalent skin pigmentation disorder, characterized by a loss of melanocytes and uneven dispersal of melanin, i.e., unpigmented skin regions (light spots) surrounded by normally pigmented areas. Probably an autoimmune disorder.

Chapter Summary

The Skin (pp. 152–158)

1. The skin, or integument, is composed of two discrete tissue layers, an outer epidermis and a deeper dermis, resting on subcutaneous tissue, the hypodermis.

Epidermis (pp. 152–155)

2. The epidermis is an avascular, keratinized sheet of stratified squamous epithelium. Most epidermal cells are keratinocytes. Scattered among the keratinocytes in the deepest epidermal layers are melanocytes, Merkel cells, and Langerhans' cells.

3. From deep to superficial, the strata, or layers of the epidermis, are the basale, spinosum, granulosum, lucidum, and corneum. The stratum lucidum is absent in thin skin. The actively mitotic stratum basale is the source of new cells for epidermal growth. The most superficial layers are increasingly keratinized and less viable.

Dermis (pp. 155–157)

4. The dermis, composed mainly of dense, irregular connective tissue, is well supplied with blood vessels, lymphatic vessels, and nerves. Cutaneous receptors, glands, and hair follicles reside within the dermis.

5. The more superficial papillary layer exhibits dermal papillae that protrude into the epidermis above, as well as dermal ridges, and the epidermal ridges that produce fingerprints.

6. In the deeper, thicker reticular layer, the connective tissue fibers are much more densely interwoven. Less dense regions between the collagen bundles produce cleavage, or tension, lines in the skin. Points of tight dermal attachment to the hypodermis produce dermal folds, or flexure lines.

Skin Color (pp. 157–158)

7. Skin color reflects the amount of pigments (melanin and carotene) in the skin and the oxygenation level of hemoglobin in blood.

8. Melanin production is stimulated by exposure to ultraviolet radiation in sunlight. Melanin, produced by melanocytes and transferred to keratinocytes, protects the keratinocyte nuclei from the damaging effects of UV radiation.

9. Skin color is affected by emotional state. Alterations in normal skin color (jaundice, bronzing, erythema, and others) may indicate certain disease states.

Appendages of the Skin (pp. 158–163)

1. Skin appendages, which derive from the epidermis, include hairs and hair follicles, nails, and glands (sweat and sebaceous).

Sweat (Sudoriferous) Glands (pp. 158–159)

2. Eccrine (merocrine) sweat glands, with a few exceptions, are distributed over the entire body surface. Their primary function is thermoregulation. They are simple coiled tubular glands that secrete a salt solution containing small amounts of other solutes. Their ducts usually empty to the skin surface via pores.

3. Apocrine sweat glands, which may function as scent glands, are found primarily in the axillary and anogenital areas. Their secretion is similar to eccrine secretion, but it also contains proteins and fatty substances on which bacteria thrive.

Sebaceous (Oil) Glands (p. 159)

4. Sebaceous glands occur all over the body surface except for the palms and soles. They are simple alveolar glands; their oily holocrine secretion is called sebum. Sebaceous gland ducts usually empty into hair follicles.

5. Sebum lubricates the skin and hair, prevents water loss from the skin, and acts as a bactericidal agent. Sebaceous glands are activated (at puberty) and controlled by androgens.

Hairs and Hair Follicles (pp. 159–163)

6. A hair, produced by a hair follicle, consists of heavily keratinized cells. A typical hair has a central medulla, a cortex, and an outer cuticle and root and shaft portions. Hair color reflects the amount and kind of melanin present.

7. A hair follicle consists of an inner epithelial root sheath, enclosing the matrix (region of the hair bulb that produces the hair), and an outer connective tissue root sheath derived from the dermis. A hair follicle is richly vascularized and well supplied with nerve fibers. Arrector pili muscles pull the follicles into an upright position and produce goose bumps.

8. Except for hairs of the scalp and around the eyes, hairs formed initially are fine vellus hairs; at puberty, under the influence of androgens, coarser, darker terminal hairs appear in the axillae and genital region.

9. The rate of hair growth varies in different body regions and with sex and age. Differences in life span of hairs account for differences in length on different body regions. Hair thinning reflects factors that lengthen follicular resting periods, age-related atrophy of hair follicles, and a delayed-action gene.

Nails (p. 163)

10. A nail is a scalelike modification of the epidermis that covers the dorsum of a finger (or toe) tip. The actively growing region is the nail matrix.

Functions of the Integumentary System (pp. 163–165)

1. Protection. The skin protects by chemical barriers (the antibacterial nature of sebum, human defensin, cathelicidins, the acid mantle, and the UV shield of melanin), physical barriers (the hardened keratinized and lipid-rich surface), and biological barriers (Langerhans' cells, macrophages, and DNA).

2. Body temperature regulation. The skin vasculature and sweat glands, regulated by the nervous system, play an important role in maintaining body temperature homeostasis.

3. Cutaneous sensation. Cutaneous sensory receptors respond to temperature, touch, pressure, and pain stimuli.

4. Metabolic functions. Vitamin D is synthesized from cholesterol by epidermal cells. Skin cells also play a role in some chemical conversions.

5. Blood reservoir. The extensive vascular supply of the dermis allows the skin to act as a blood reservoir.

6. Excretion. Sweat contains small amounts of nitrogenous wastes and plays a minor role in excretion.

Homeostatic Imbalances of Skin (pp. 165–167, 170)

1. The most common skin disorders result from infections.

Skin Cancer (pp. 165–166)

2. The most common cause of skin cancer is exposure to ultraviolet radiation.

3. Basal cell carcinoma and squamous cell carcinoma are cured if they are removed before metastasis. Melanoma, a cancer of melanocytes, is less common but dangerous.

Burns (pp. 166–167, 170)

4. In severe burns, the initial threat is loss of protein- and electrolyte-rich body fluids, which may lead to circulatory collapse. The second threat is overwhelming bacterial infection.

5. The extent of a burn may be evaluated by using the rule of nines. The severity of burns is indicated by the terms first degree, second degree, and third degree. Third-degree burns require grafting for successful recovery.

Developmental Aspects of the Integumentary System (pp. 170–171)

1. The epidermis develops from embryonic ectoderm; the dermis (and hypodermis) develop from mesoderm.

2. The fetus exhibits a downy lanugo coat. Fetal sebaceous glands produce vernix caseosa, which helps protect the fetus's skin from its watery environment.

3. A newborn's skin is thin. During childhood the skin thickens and more subcutaneous fat is deposited. At puberty, sebaceous glands are activated and terminal hairs appear in greater numbers.

4. In old age, the rate of epidermal cell replacement declines and the skin and hair thin. Skin glands become less active. Loss of collagen and elastin fibers and subcutaneous fat leads to wrinkling; delayed-action genes cause graying and balding. Photodamage is a major cause of skin aging.

Review Questions

Multiple Choice/Matching

(Some questions have more than one correct answer. Select the best answer or answers from the choices given.)

1. Which epidermal cell type is most numerous? (a) keratinocyte, (b) melanocyte, (c) Langerhans' cell, (d) Merkel cell.

2. Which cell functions as part of the immune system? (a) a keratinocyte, (b) a melanocyte, (c) a Langerhans' cell, (d) a Merkel cell.

3. The epidermis provides a physical barrier due largely to the presence of (a) melanin, (b) carotene, (c) collagen, (d) keratin.

4. Skin color is determined by (a) the amount of blood, (b) pigments, (c) oxygenation level of the blood, (d) all of these.

5. The sensations of touch and pressure are picked up by receptors located in (a) the stratum germinativum, (b) the dermis, (c) the hypodermis, (d) the stratum corneum.

6. Which is not a true statement about the papillary layer of the dermis? (a) It produces the pattern for fingerprints, (b) it is most responsible for the toughness of the skin, (c) it contains nerve endings that respond to stimuli, (d) it is highly vascular.

7. Skin surface markings that reflect points of tight dermal attachment to underlying tissues are called (a) tension lines, (b) papillary ridges, (c) flexure lines, (d) epidermal papillae.

8. Which of the following is not an epidermal derivative? (a) hair, (b) sweat gland, (c) sensory receptor, (d) sebaceous gland.

9. You can cut hair without feeling pain because (a) there are no nerves associated with hair, (b) the shaft of the hair consists of dead cells, (c) hair follicles develop from epidermal cells and the epidermis lacks a nerve supply, (d) hair follicles have no source of nourishment and therefore cannot respond.

10. An arrector pili muscle (a) is associated with each sweat gland, (b) can cause a hair to stand up straight, (c) enables each hair to be stretched when wet, (d) provides new cells for continued growth of its associated hair.

11. The product of this type of sweat gland includes protein and lipid substances that become odoriferous as a result of bacterial action: (a) apocrine gland, (b) eccrine gland, (c) sebaceous gland, (d) pancreatic gland.

12. Sebum (a) lubricates the surface of the skin and hair, (b) consists of dead cells and fatty substances, (c) in excess may cause seborrhea, (d) all of these.

13. The rule of nines is helpful clinically in (a) diagnosing skin cancer, (b) estimating the extent of a burn, (c) estimating how serious a cancer is, (d) preventing acne.

Short Answer Essay Questions

14. Which epidermal cells are also called prickle cells? Which contain keratohyaline and lamellated granules?

15. Is a bald man really hairless? Explain.

16. Both newborn infants and aged individuals have very little subcutaneous tissue. How does this affect their sensitivity to cold environmental temperature?

17. You go to the beach to swim on an extremely hot, sunny summer afternoon. Describe two ways in which your integumentary system acts to preserve homeostasis during your outing.

18. Distinguish clearly between first-, second-, and third-degree burns.

19. Describe the process of hair formation, and list several factors that may influence (a) growth cycles and (b) hair texture.

20. What is cyanosis and what does it reflect?

21. Why does skin wrinkle and what factors accelerate the wrinkling process?

22. Explain each of these familiar phenomena in terms of what you learned in this chapter: (a) pimples, (b) dandruff, (c) greasy hair and "shiny nose," (d) stretch marks from gaining weight, (e) freckles, (f) leaving fingerprints.

23. Count Dracula, the most famous vampire, rumored to have killed at least 200,000 people, was based on a real person who lived in eastern Europe about 600 years ago. He was indeed a "monster," although he was not a real vampire. The historical Count Dracula may have suffered from which of the following? (a) porphyria, (b) EB, (c) halitosis, (d) vitiligo. Explain your answer.

24. Why are there no skin cancers that originate from stratum corneum cells?

25. A man got his finger caught in a machine at the factory. The damage was less serious than expected, but the entire nail was torn off his right index finger. The parts lost were the body, root, bed, matrix, and eponychium of the nail. First, define each of these parts. Then, tell if this nail is likely to grow back.

26. On a diagram of the human body, mark off various regions according to the rule of nines. What percentage of the total body surface is affected if the skin over the following

body parts is burned? (a) the entire posterior trunk and buttocks, (b) an entire lower limb, (c) the entire front of the left upper limb.

Critical Thinking and Clinical Application Questions

1. Dean, a 40-year-old aging beach boy, is complaining to you that although his suntan made him popular when he was young, now his face is all wrinkled, and he has several darkly pigmented moles that are growing rapidly and are as big as large coins. He shows you the moles, and immediately you think "ABCD." What does that mean and why should he be concerned?

2. Victims of third-degree burns demonstrate the loss of vital functions performed by the skin. What are the two most important problems encountered clinically with such patients? Explain each in terms of the absence of skin.

3. Thelma, 30-year-old resident of a mental hospital, has an abnormal growth of hair on the dorsum of her right index finger. The orderly comments that she gnaws on that finger continuously. What do you think is the relationship between Thelma's gnawing activity and her hairy finger?

4. A model is concerned about a new scar on her abdomen. She tells her surgeon that there is practically no scar from the appendix operation done when she was 16, but this new gallbladder scar is "gross." Her appendectomy scar is small and obliquely located on the inferior abdominal surface—it is very indistinct. By contrast, the gallbladder scar is large and lumpy and runs at right angles to the central axis of the body trunk. Can you explain why the scars are so different?

5. Mrs. Gaucher received second-degree burns on her abdomen when she dropped a kettle of boiling water. She asked her doctor (worriedly) if she would need to have a skin graft. What do you think he told her?

CHAPTER

Bones and Skeletal Tissues

Skeletal Cartilages (p. 176)

1. Describe the functional properties of the three types of cartilage tissue.
2. Locate the major cartilages of the adult skeleton.
3. Explain how cartilage grows.

Classification of Bones (pp. 176–178)

4. Name the major regions of the skeleton and describe their relative functions.
5. Compare and contrast the structure of the four bone classes and provide examples of each class.

Functions of Bones (pp. 178–179)

6. List and describe five important functions of bones.

Bone Structure (pp. 179–184)

7. Describe the gross anatomy of a typical long bone and a flat bone. Indicate the locations and functions of red and yellow marrow, articular cartilage, periosteum, and endosteum.
8. Indicate the functional importance of bone markings.
9. Describe the histology of compact and spongy bone.
10. Discuss the chemical composition of bone and the relative advantages conferred by the organic and inorganic components.

Bone Development (pp. 184–187)

11. Compare and contrast intramembranous ossification and endochondral ossification.
12. Describe the process of long bone growth that occurs at the epiphyseal plates.

Bone Homeostasis: Remodeling and Repair (pp. 187–193)

13. Compare the locations and remodeling functions of the osteoblasts, osteocytes, and osteoclasts.
14. Explain how hormones and physical stress regulate bone remodeling.
15. Describe the steps of fracture repair.

Homeostatic Imbalances of Bone (pp. 193–195, 198)

16. Contrast the disorders of bone remodeling seen in osteoporosis, osteomalacia, and Paget's disease.

Developmental Aspects of Bones: Timing of Events (p. 198)

17. Describe the timing and cause of changes in bone architecture and bone mass throughout life.

All of us have heard the expressions "bone tired" and "bag of bones"—rather unflattering and inaccurate images of one of our most phenomenal tissues and our main skeletal elements. Our brains, not our bones, convey feelings of fatigue. As for "bag of bones," they are indeed more prominent in some of us, but without bones to form our internal skeleton we would all creep along the ground like slugs, lacking any definite shape or form. Along with its bones, the skeleton contains resilient cartilages, which we briefly discuss in this chapter. However, our major focus is the structure and function of bone tissue and the dynamics of its formation and remodeling throughout life.

Skeletal Cartilages

Although the human skeleton is initially made up of cartilages and fibrous membranes, most of these early supports are soon replaced by bone. The few cartilages that remain in adults are found mainly in regions where flexible skeletal tissue is needed.

Basic Structure, Types, and Locations

A **skeletal cartilage** is made of some variety of *cartilage tissue,* which consists primarily of water. The high water content of cartilage accounts for its resilience, that is, its ability to spring back to its original shape after being compressed. The cartilage, which contains no nerves or blood vessels, is surrounded by a layer of dense irregular connective tissue, the *perichondrium* (per"ĭ-kon'dre-um; "around the cartilage"). The perichondrium acts like a girdle to resist outward expansion when the cartilage is compressed. Additionally, the perichondrium contains the blood vessels from which nutrients diffuse through the matrix to reach the cartilage cells. This mode of nutrient delivery limits cartilage thickness.

As described in Chapter 4, there are three types of cartilage tissue in the body: hyaline, elastic, and fibrocartilage. All three types have the same basic components—cells called *chondrocytes,* encased in small cavities (lacunae) within an *extracellular matrix* containing a jellylike ground substance and fibers. The skeletal cartilages contain representatives from all three types (Figure 6.1).

Hyaline cartilages, which look like frosted glass when freshly exposed, provide support with flexibility and resilience. They are the most abundant skeletal cartilages. When viewed under the microscope, their chondrocytes appear spherical (see Figure 4.9f). The only fiber type in their matrix is fine collagen fibers (which, however, are not detectable microscopically). Skeletal hyaline cartilages include (1) *articular cartilages,* which cover the ends of most bones at movable joints; (2) *costal cartilages,* which connect the ribs to the sternum (breastbone); (3) *respiratory cartilages,* which form the skeleton of the *larynx (voicebox),* and reinforce other respiratory passageways; and (4) *nasal cartilages,* which support the external nose.

Elastic cartilages look very much like hyaline cartilages (see Figure 4.9g), but they contain more stretchy elastic fibers and so are better able to stand up to repeated bending. They are found in only two skeletal locations (Figure 6.1)—the external ear and the epiglottis (the flap that bends to cover the opening of the larynx each time we swallow).

Fibrocartilages are highly compressible and have great tensile strength. The perfect intermediate between hyaline and elastic cartilages, fibrocartilages consist of roughly parallel rows of chondrocytes alternating with thick collagen fibers (see Figure 4.9h). Fibrocartilages occur in sites that are subjected to both heavy pressure and stretch, such as the padlike cartilages (menisci) of the knee and the discs between vertebrae (Figure 6.1).

Growth of Cartilage

Unlike bone, which has a hard matrix, cartilage has a flexible matrix which can accommodate mitosis. Hence, it is the ideal tissue to use to lay down the embryonic skeleton and to provide for new skeletal growth. Cartilage grows in two ways. In **appositional growth** (ap"o-zish'un-al; "growth from outside"), cartilage-forming cells in the surrounding perichondrium secrete new matrix against the external face of the existing cartilage tissue. In **interstitial growth** (in"ter-stish'al; "growth from inside"), the lacunae-bound chondrocytes divide and secrete new matrix, expanding the cartilage from within. Typically, cartilage growth ends during adolescence when the skeleton stops growing.

Under certain conditions—during normal bone growth in youth and during old age—calcium salts may be deposited in the matrix and cause it to harden, a process called calcification. Note, however, that calcified cartilage is *not* bone; cartilage and bone are always distinct tissues.

Classification of Bones

The 206 named bones of the human skeleton are divided into two groups: axial and appendicular. The **axial skeleton** forms the long axis of the body and includes the bones of the skull, vertebral column, and rib cage. Generally speaking these bones are most involved in protecting, supporting, or carrying other body parts. The **appendicular skeleton** (ap"en-dik'ular) consists of the bones of the upper and lower limbs

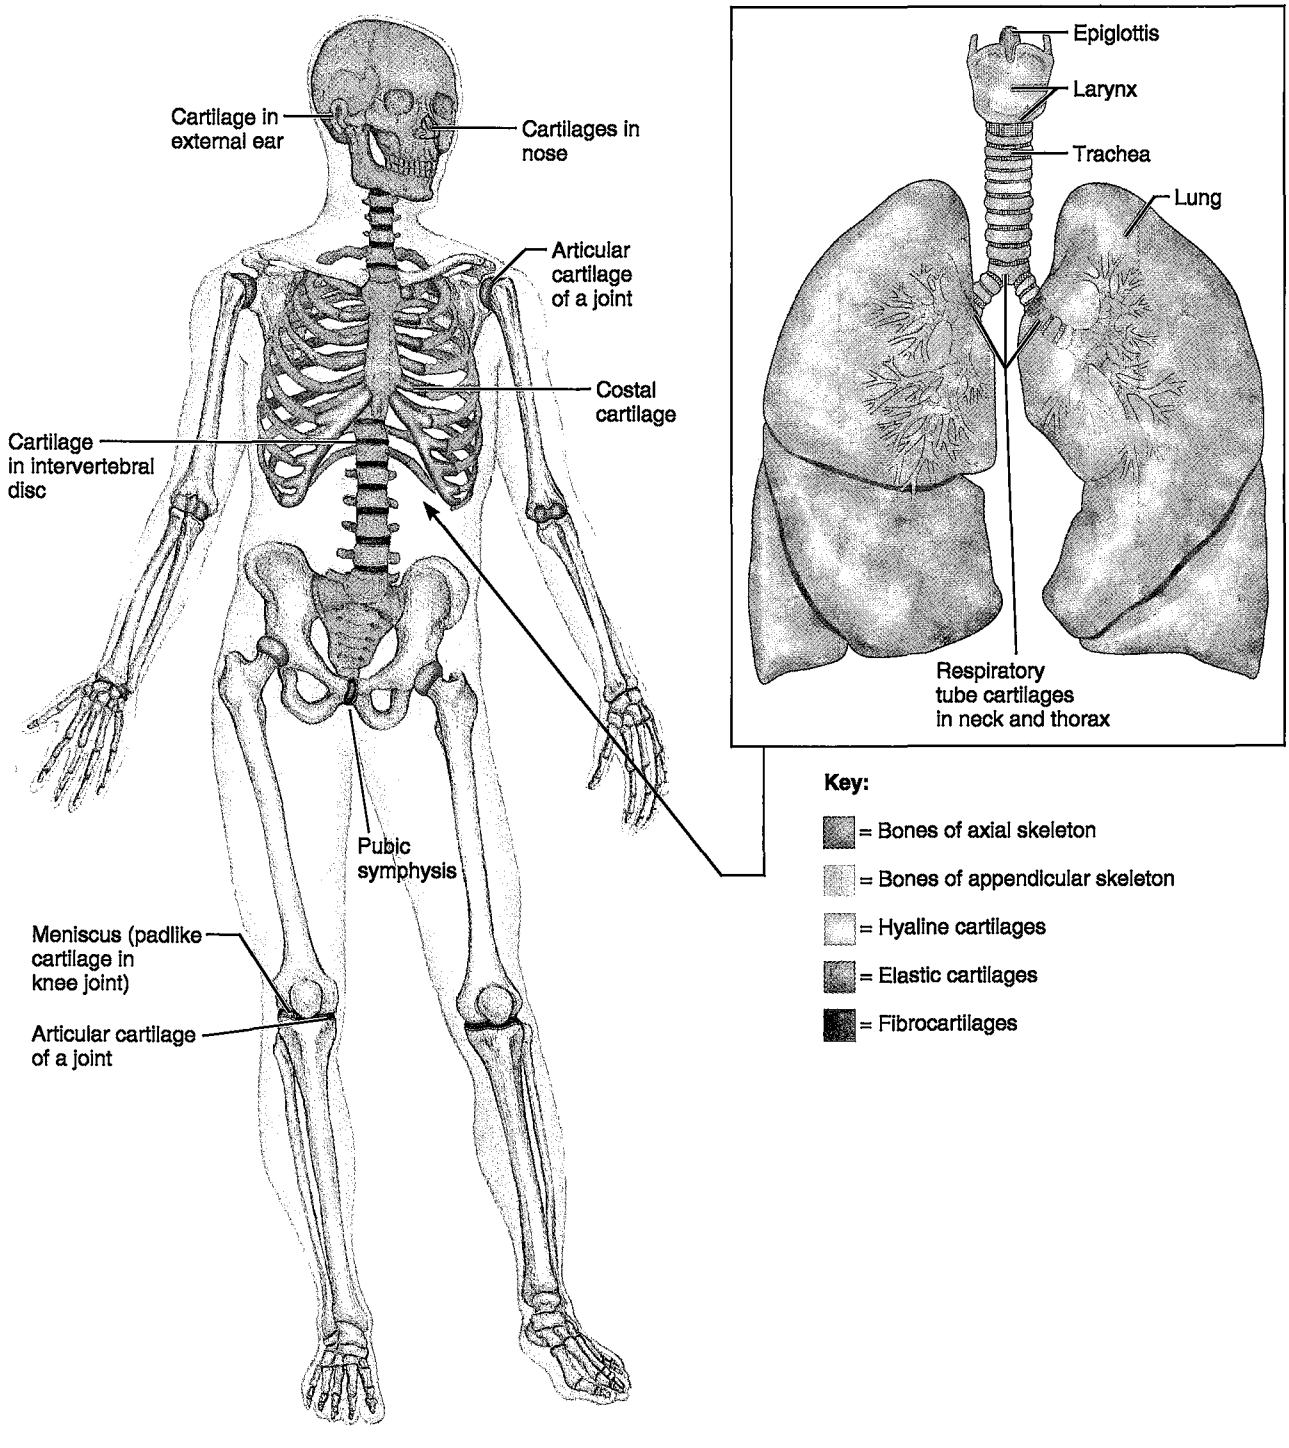

FIGURE 6.1 **The bones and cartilages of the human skeleton.**

and the girdles (shoulder bones and hip bones) that attach the limbs to the axial skeleton. Bones of the limbs help to get us from place to place (locomotion) and to manipulate our environment. An overview of the human skeleton appears in Figure 6.1.

Bones come in many sizes and shapes. For example, the pisiform bone of the wrist is the size and shape of a pea, whereas the femur (thigh bone) is nearly 2 feet long in some people and has a large ball-shaped head. The unique shape of each bone fulfills a particular need. The femur, for example, withstands great weight and pressure, and its hollow-cylinder design provides maximum strength with minimum weight.

For the most part, bones are classified by their shape as long, short, flat, and irregular (Figure 6.2).

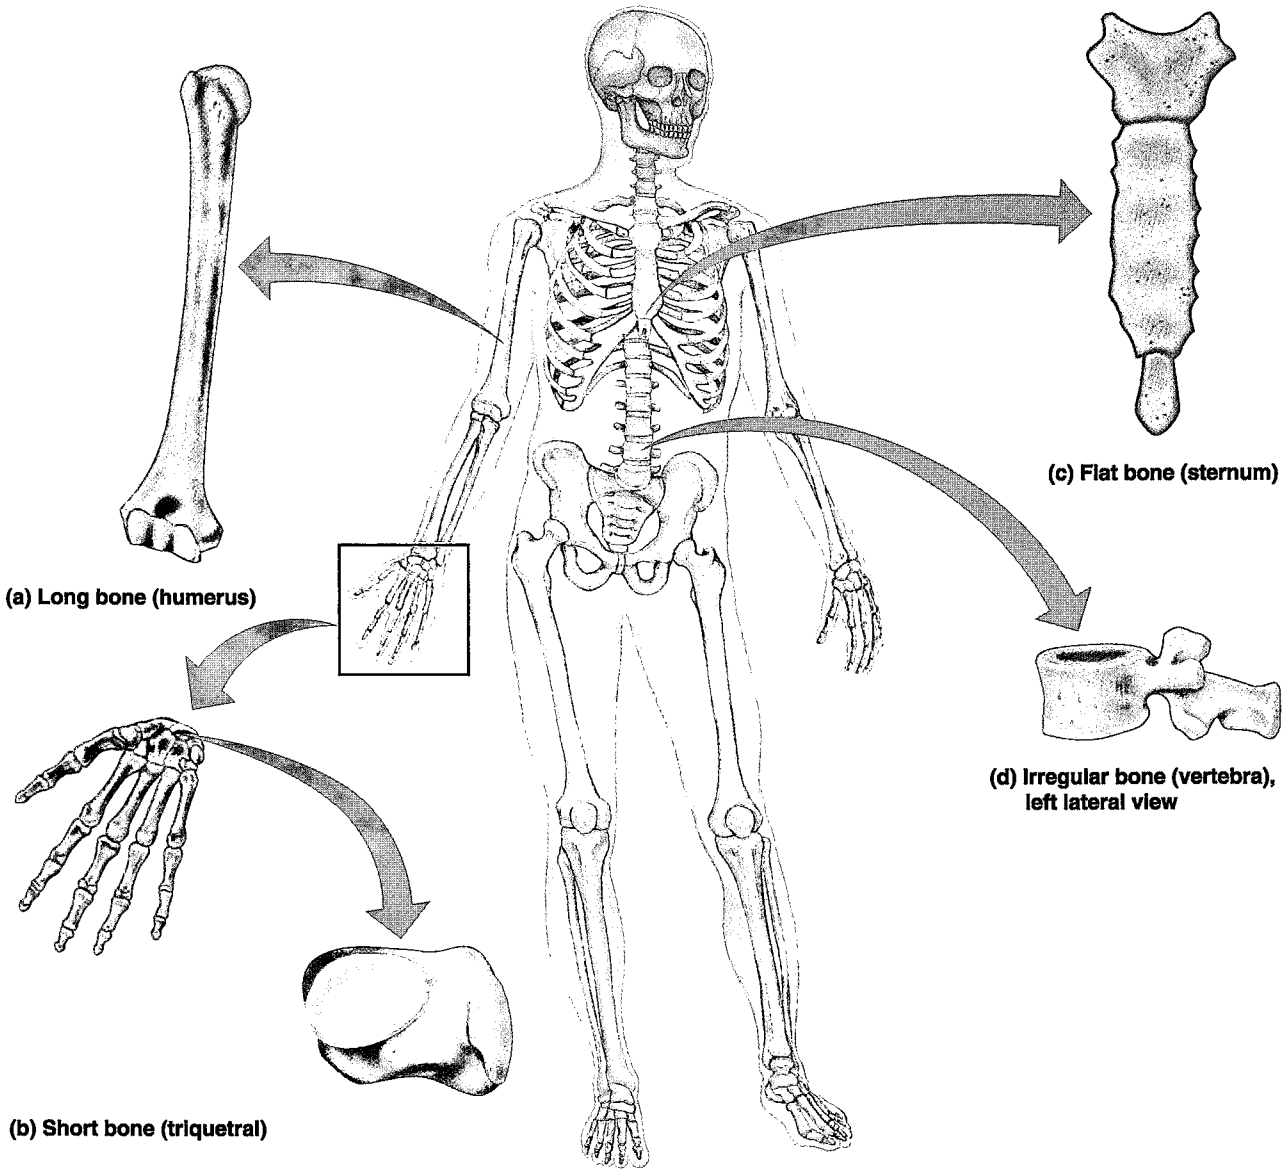

FIGURE 6.2 **Classification of bones on the basis of shape.**

1. Long bones, as their name suggests, are considerably longer than they are wide. A long bone has a shaft plus two ends. All limb bones except the patella (kneecap) and the wrist and ankle bones are long bones. Notice that these bones are named for their elongated shape, *not* their overall size. The three bones in each of your fingers are long bones, even though they are very small.

2. Short bones are roughly cube shaped. The bones of the wrist and ankle are examples.

Sesamoid bones (ses'ah-moid; "shaped like a sesame seed") are a special type of short bone that form in a tendon (for example, the patella). They vary in size and number in different individuals. Some sesamoid bones clearly act to alter the direction of pull of a tendon; the function of others is not known.

3. Flat bones are thin, flattened, and usually a bit curved. The sternum (breastbone), scapulae (shoulder blades), ribs, and most skull bones are flat bones.

4. Irregular bones have complicated shapes that fit none of the preceding classes. Examples include the vertebrae and the hip bones.

Functions of Bones

Besides contributing to body shape and form, our bones perform several important functions:

1. Support. Bones provide a framework that supports the body and cradles its soft organs. For example, bones of lower limbs act as pillars to support the body trunk when we stand, and the rib cage supports the thoracic wall.

2. Protection. The fused bones of the skull protect the brain. The vertebrae surround the spinal cord, and the rib cage helps protect the vital organs of the thorax.

3. Movement. Skeletal muscles, which attach to bones by tendons, use bones as levers to move the body and its parts. As a result, we can walk, grasp objects, and breathe. The design of joints determine the types of movement possible.

4. Mineral and growth factor storage. Bone is a reservoir for minerals, most importantly calcium and phosphate. The stored minerals are released into the bloodstream as needed for distribution to all parts of the body. Indeed, "deposits" and "withdrawals" of minerals to and from the bones go on almost continuously. Additionally, mineralized bone matrix stores important growth factors such as insulin-like growth factors, transforming growth factor, bone morphogenic proteins, and others.

5. Blood cell formation. Most blood cell formation, or *hematopoiesis* (hem"ah-to-poi-e'sis), occurs in the marrow cavities of certain bones.

Bone Structure

Because they contain various types of tissue, bones are *organs*. (Recall that an organ contains several different tissues.) Although bone (osseous) tissue dominates bones, they also contain nervous tissue in their nerves, cartilage in their articular cartilages, fibrous connective tissue lining their cavities, and muscle and epithelial tissues in their blood vessels. We will consider bone structure at three levels: gross, microscopic, and chemical.

Gross Anatomy

Bone Markings

The external surfaces of bones are rarely smooth and featureless. Instead, they display projections, depressions, and openings that serve as sites of muscle, ligament, and tendon attachment, as joint surfaces, or as conduits for blood vessels and nerves. These **bone markings** are named in different ways. Projections (bulges) that grow outward from the bone surface include heads, trochanters, spines, and others, each having distinguishing features and functions. In most cases, bone projections are indications of the stresses created by muscles attached to and pulling on them or are modified surfaces where bones meet and form joints. Depressions and openings include fossae, sinuses, foramina, and grooves; these usually serve to allow passage of nerves and blood vessels. The most important types of bone markings are described in Table 6.1. You should familiarize yourself with these terms because you will meet them again as identifying marks of the individual bones studied in the lab.

TABLE 6.1 Bone Markings

NAME OF BONE MARKING	DESCRIPTION
PROJECTIONS THAT ARE SITES OF MUSCLE AND LIGAMENT ATTACHMENT	
Tuberosity (too"bĕ-ros'ĭ-te)	Large rounded projection; may be roughened
Crest	Narrow ridge of bone; usually prominent
Trochanter (tro-kan'ter)	Very large, blunt, irregularly shaped process (the only examples are on the femur)
Line	Narrow ridge of bone; less prominent than a crest
Tubercle (too'ber-kl)	Small rounded projection or process
Epicondyle (ep"ĭ-kon'dĭl)	Raised area on or above a condyle
Spine	Sharp, slender, often pointed projection
Process	Any bony prominence
PROJECTIONS THAT HELP TO FORM JOINTS	
Head	Bony expansion carried on a narrow neck
Facet	Smooth, nearly flat articular surface
Condyle (kon'dĭl)	Rounded articular projection
Ramus (ra'mus)	Armlike bar of bone
DEPRESSIONS AND OPENINGS ALLOWING BLOOD VESSELS AND NERVES TO PASS	
Meatus (me-a'tus)	Canal-like passageway
Sinus	Cavity within a bone, filled with air and lined with mucous membrane
Fossa (fos'ah)	Shallow, basinlike depression in a bone, often serving as an articular surface
Groove	Furrow
Fissure	Narrow, slitlike opening
Foramen (fo-ra'men)	Round or oval opening through a bone

Bone Textures: Compact and Spongy Bone

Every bone has a dense outer layer that looks smooth and solid to the naked eye. This external layer is **compact bone** (Figures 6.3 and 6.4). Internal to this is **spongy bone** (also called *cancellous bone*), a honeycomb of small needle-like or flat pieces called

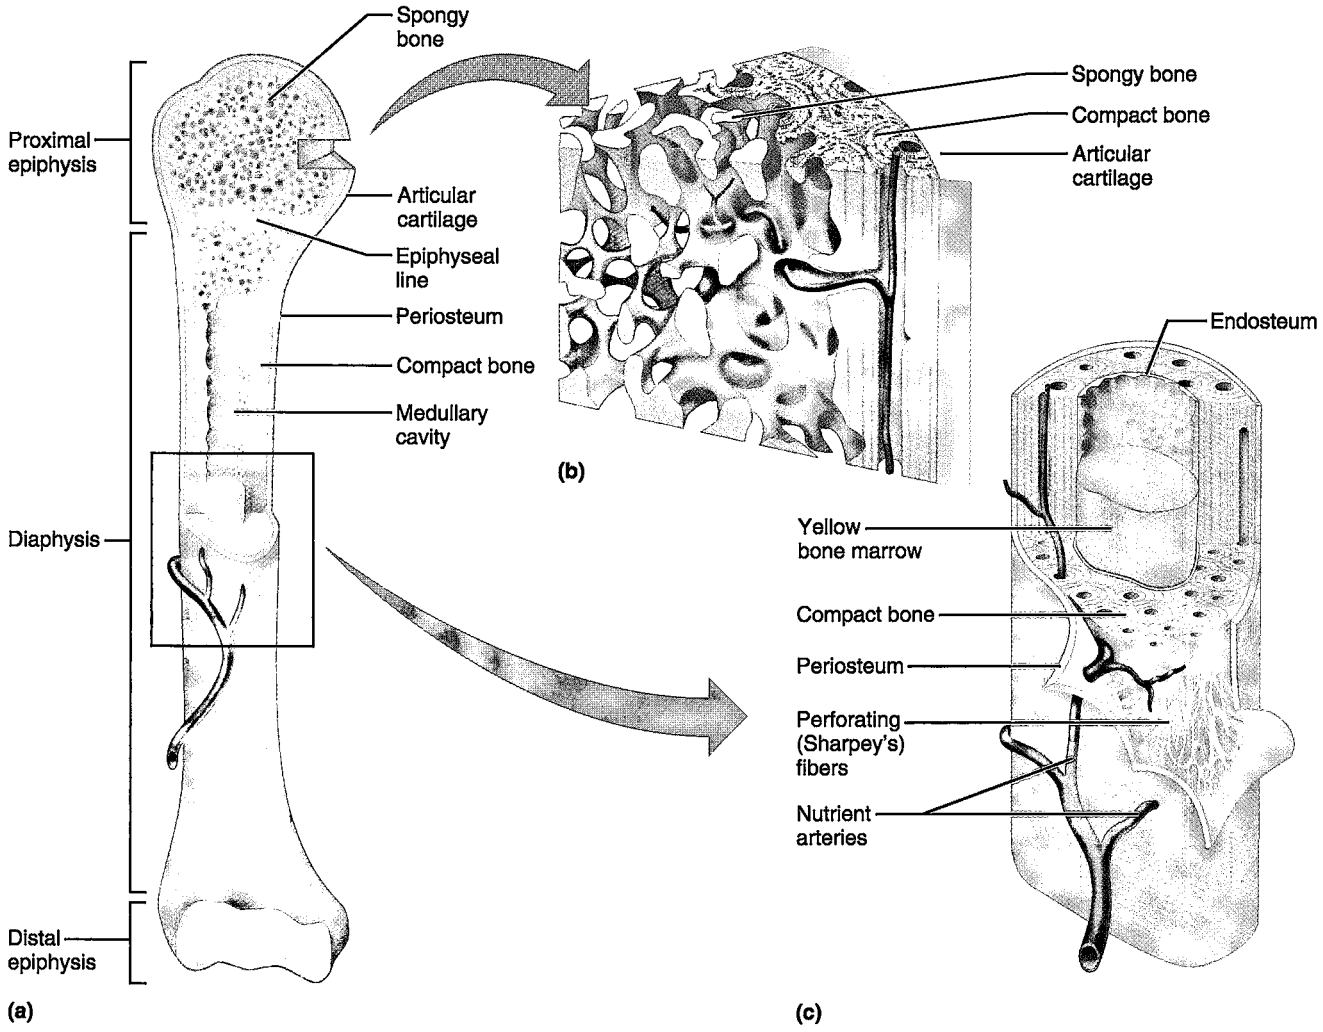

FIGURE 6.3 **The structure of a long bone (humerus of arm). (a)** Anterior view with bone sectioned frontally to show the interior at the proximal end. **(b)** Enlarged view of spongy bone and compact bone of the epiphysis of (a). **(c)** Enlarged cross-sectional view of the shaft (diaphysis) of (a). Note that the external surface of the diaphysis is covered by periosteum, but the articular surface of the epiphysis is covered with hyaline cartilage.

trabeculae (trah-bek'u-le; "little beams"). In living bones the open spaces between trabeculae are filled with red or yellow bone marrow.

Structure of a Typical Long Bone

With few exceptions, all long bones have the same general structure (Figure 6.3).

Diaphysis A tubular **diaphysis** (di-af'ĭ-sis; *dia* = through, *physis* = growth), or shaft, forms the long axis of the bone. It is constructed of a relatively thick *collar* of compact bone that surrounds a central **medullary cavity** (med'u-lar-e; "middle") or *marrow cavity*. In adults, the medullary cavity contains fat (yellow marrow) and is called the **yellow bone marrow cavity.**

Epiphyses The **epiphyses** (e-pif'ĭ-sēz; singular: epiphysis) are the bone ends (*epi* = upon). In many cases, they are more expanded than the diaphysis. Compact bone forms the exterior of epiphyses; their interior contains spongy bone. The joint surface of each epiphysis is covered with a thin layer of articular (hyaline) cartilage, which cushions the opposing bone ends during joint movement and absorbs stress. Between the diaphysis and each epiphysis of an adult long bone is an **epiphyseal line,** a remnant of the **epiphyseal plate,** a disc of hyaline cartilage that grows during childhood to lengthen the bone. The region where the diaphysis and epiphysis meet, whether it is the epiphyseal plate or line, is sometimes called the *metaphysis*.

Membranes A third structural feature of long bones is membranes. The external surface of the entire bone except the joint surfaces is covered by a glistening white, double-layered membrane called the **periosteum** (per"e-os'te-um; *peri* = around,

osteo = bone). The outer *fibrous layer* is dense irregular connective tissue. The inner *osteogenic layer,* abutting the bone surface, consists primarily of bone-forming cells, **osteoblasts** (os'te-o-blasts; "bone germinators"), and bone-destroying cells, **osteoclasts** ("bone breakers").

The periosteum is richly supplied with nerve fibers, lymphatic vessels, and blood vessels, which enter the diaphysis via a **nutrient foramen** (fo-ra'min; "opening").

The periosteum is secured to the underlying bone by *perforating (Sharpey's) fibers* (Figure 6.3), tufts of collagen fibers that extend from its fibrous layer into the bone matrix. The periosteum also provides anchoring points for tendons and ligaments. At these points the perforating fibers are exceptionally dense.

Internal bone surfaces are covered with a delicate connective tissue membrane called the **endosteum** (en-dos'te-um; "within the bone"). The endosteum (Figure 6.3) covers the trabeculae of spongy bone and lines the canals that pass through the compact bone. Like the periosteum, the endosteum contains both osteoblasts and osteoclasts.

Structure of Short, Irregular, and Flat Bones

Short, irregular, and flat bones share a simple design: They all consist of thin plates of periosteum-covered compact bone on the outside and endosteum-covered spongy bone within. However, these bones are not cylindrical and so they have no shaft or epiphyses. They contain bone marrow (between their trabeculae), but no significant marrow cavity is present.

Figure 6.4 shows a typical flat bone of the skull. In flat bones, the spongy bone is called the **diploë** (dip'lo-e; "folded") and the whole arrangement resembles a stiffened sandwich.

Location of Hematopoietic Tissue in Bones

Hematopoietic tissue, **red marrow,** is typically found within the trabecular cavities of spongy bone of long bones and in the diploë of flat bones. For this reason, both these cavities are often referred to as **red marrow cavities.** In newborn infants, the medullary cavity of the diaphysis and all areas of spongy bone contain red bone marrow. In most adult long bones, the fat-containing medullary cavity extends well into the epiphysis, and little red marrow is present in the spongy bone cavities. Hence, blood cell production in adult long bones routinely occurs only in the heads of the femur and humerus (the long bone of the arm). The red marrow found in the diploë of flat bones (such as the sternum) and in some irregular bones (such as the hip bone) is much more active in hematopoiesis, and these are the sites routinely used for obtaining red marrow samples when problems with the blood-forming tissue are suspected. However,

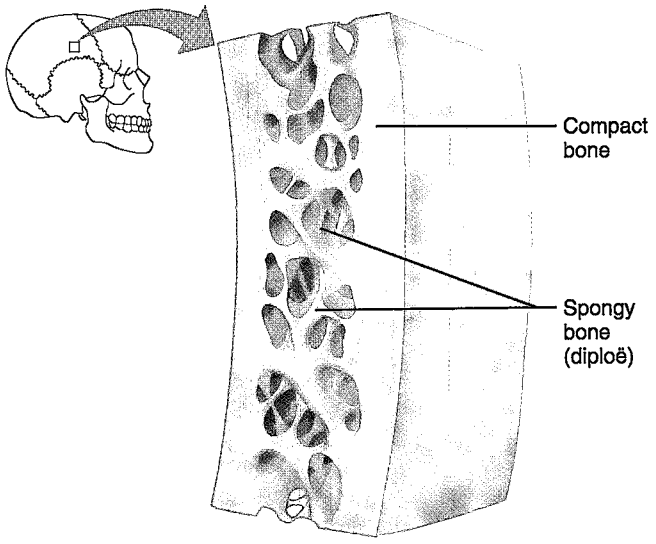

FIGURE 6.4 **Structure of a flat bone.** Flat bones consist of a layer of spongy bone (the diploë) sandwiched between two thin layers of compact bone.

yellow marrow in the medullary cavity can revert to red marrow if a person becomes very anemic and needs enhanced red blood cell production.

Microscopic Anatomy of Bone

Essentially, four major cell types populate bone tissue: osteogenic cells, osteoblasts, osteocytes, and osteoclasts. These, like other connective tissue cells, are surrounded by an extracellular matrix of their making. The **osteogenic cells**, also called **osteoprogenitor cells,** are actively mitotic stem cells found in the membranous periosteum and endosteum. Some of their progeny differentiate into osteoblasts (bone-forming cells) while others persist as bone stem cells to provide osteoblasts in the future. The structure and function of the remaining three types of bone cells are described below.

Compact Bone

Although compact bone looks dense and solid, a microscope reveals that it is riddled with passageways that serve as conduits for nerves, blood vessels, and lymphatic vessels (see Figure 6.6). The structural unit of compact bone is called either the **osteon** (os'te-on) or the **Haversian system** (ha-ver'zhen). Each osteon is an elongated cylinder oriented parallel to the long axis of the bone. Functionally, osteons are tiny weight-bearing pillars. As shown in the "exploded" view in Figure 6.5, an osteon is a group of hollow tubes of bone matrix, one placed outside the next like the growth rings of a tree trunk. Each matrix tube is a **lamella** (lah-mel'ah; "little plate"), and for this reason compact bone is often called **lamellar**

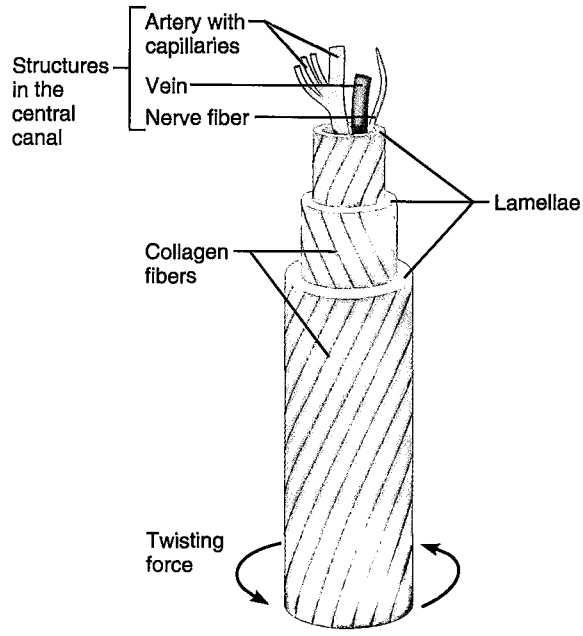

FIGURE 6.5 **A single osteon.** The osteon is drawn as if pulled out like a telescope to illustrate the individual lamellae. The slanted lines in each lamella indicate the direction of its collagen fibers.

bone. Although all of the collagen fibers in a particular lamella run in a single direction, the collagen fibers in adjacent lamellae always run in opposite directions. This alternating pattern is beautifully designed to withstand torsion stresses—the adjacent lamellae reinforce one another to resist twisting. You can think of the osteon's design as a "twister resister." Collagen fibers are not the only part of bone lamellae that are beautifully ordered. The tiny crystals of bone salts align with the collagen fibers and thus also alternate their direction in adjacent lamellae.

Running through the core of each osteon is the **central,** or **Haversian, canal** containing small blood vessels and nerve fibers that serve the needs of the osteon's cells. Canals of a second type called **perforating canals,** or **Volkmann's canals** (folk'mahnz), lie at right angles to the long axis of the bone and connect the blood and nerve supply of the periosteum to those in the central canals and the medullary cavity (Figure 6.6a). Like all other internal bone cavities, these canals are lined with endosteum.

Spider-shaped **osteocytes** (mature bone cells) occupy **lacunae** (*lac* = hollow; *una* = little) at the junctions of the lamellae. Hairlike canals called **canaliculi** (kan"ah-lik'u-li) connect the lacunae to each other and to the central canal. The manner in which canaliculi are formed is interesting. When bone is being formed, the osteoblasts secreting bone matrix surround blood vessels and maintain contact with one another by tentacle-like projections containing gap junctions. Then, as the newly secreted matrix hardens and the maturing cells become trapped within it, a system of tiny canals—the canaliculi, filled with tissue fluid and containing the osteocyte extensions—is formed. The canaliculi tie all the osteocytes in an osteon together, permitting nutrients and wastes to be relayed from one osteocyte to the next throughout the osteon. Although bone matrix is hard and impermeable to nutrients, its canaliculi and cell-to-cell relays (via gap junctions) allow bone cells to be well nourished. One function of osteocytes is to maintain the bone matrix. If they die, the surrounding matrix is resorbed. The osteocytes also act as stress or strain "sensors" in cases of bone deformation or other damaging stimuli. They communicate this information to the cells responsible for bone remodeling (osteoblasts and osteoclasts) so that countermeasures can be taken or repairs made. The bone-destroying osteoclast is discussed on p. 188 in conjunction with the topic of bone remodeling.

Not all the lamellae in compact bone are part of osteons. Lying between intact osteons are incomplete lamellae called **interstitial lamellae** (in"ter-stish'al) (Figure 6.6c). These either fill the gaps between forming osteons or are remnants of osteons that have been cut through by bone remodeling (discussed later). **Circumferential lamellae,** located just deep to the periosteum and just superficial to the endosteum, extend around the entire circumference of the diaphysis (Figure 6.6a) and effectively resist twisting of the long bone.

Spongy Bone

In contrast to compact bone, spongy bone looks like a poorly organized, even haphazard, tissue (Figure 6.4 and Figure 6.3b). However, the trabeculae in spongy bone align precisely along lines of stress and help the bone resist stress as much as possible. Thus, these tiny bone struts are as carefully positioned as the flying buttresses of a Gothic cathedral.

Only a few cells thick, trabeculae contain irregularly arranged lamellae and osteocytes interconnected by canaliculi. No osteons are present. Nutrients reach the osteocytes of spongy bone by diffusing through the canaliculi from capillaries in the endosteum surrounding the trabeculae.

Chemical Composition of Bone

Bone has both organic and inorganic components. Its *organic components* include the cells (osteogenic cells, osteoblasts, osteocytes, and osteoclasts) and **osteoid** (os'te-oid), the organic part of the matrix. Osteoid, which makes up approximately one-third of the matrix, includes ground substance (composed of proteoglycans and glycoproteins) and collagen fibers,

Q *What membrane lines the internal canals and covers the trabeculae of spongy bone?*

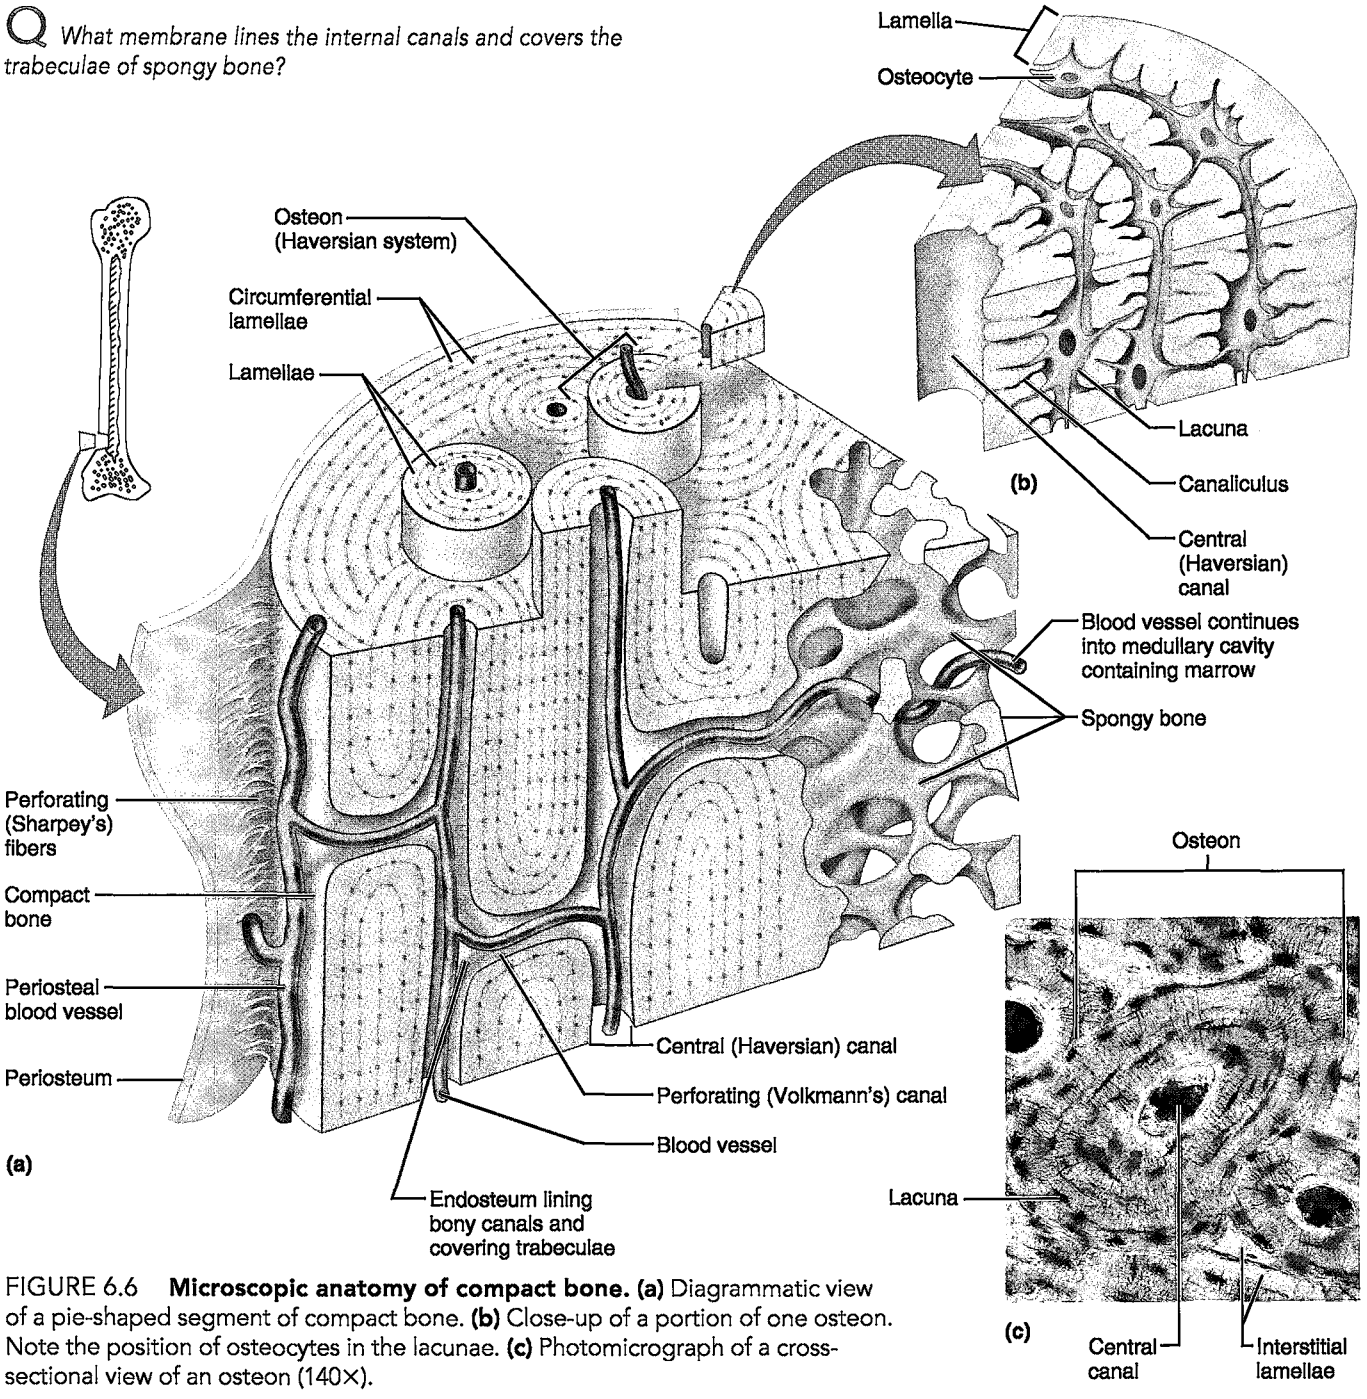

FIGURE 6.6 **Microscopic anatomy of compact bone. (a)** Diagrammatic view of a pie-shaped segment of compact bone. **(b)** Close-up of a portion of one osteon. Note the position of osteocytes in the lacunae. **(c)** Photomicrograph of a cross-sectional view of an osteon (140×).

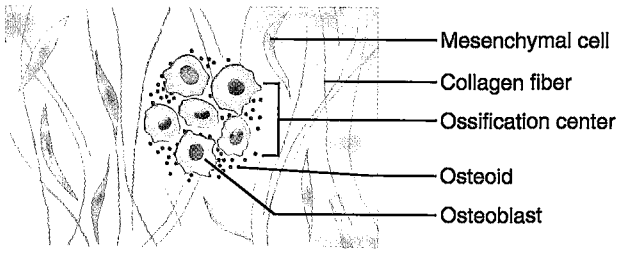
A *Endosteum.*

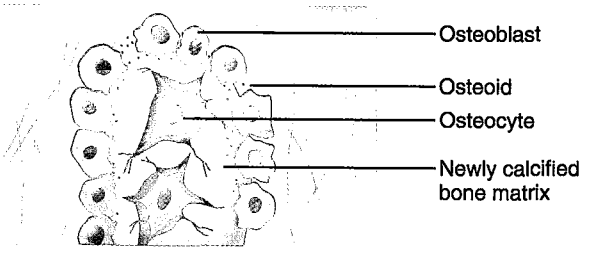
both of which are made and secreted by osteoblasts. These organic substances, particularly collagen, contribute not only to a bone's structure but also to the flexibility and great tensile strength that allow the bone to resist stretch and twisting. Bone's exceptional toughness and tensile strength has been the subject of intense research. It now appears that this resilience comes from the presence of *sacrificial bonds* in or between collagen molecules that break easily on impact, dissipating energy to prevent the force from rising to a fracture value. In the absence of continued or additional trauma, most of the sacrificial bonds re-form.

The balance of bone tissue (65% by mass) consists of inorganic *hydroxyapatites* (hi-drok"se-ap'ah-tīz), or *mineral salts,* largely calcium phosphates present in the form of tiny, tightly packed crystals in and around the collagen fibers in the extracellular matrix. The crystals account for the most notable characteristic of bone—its exceptional hardness, which allows it to resist compression.



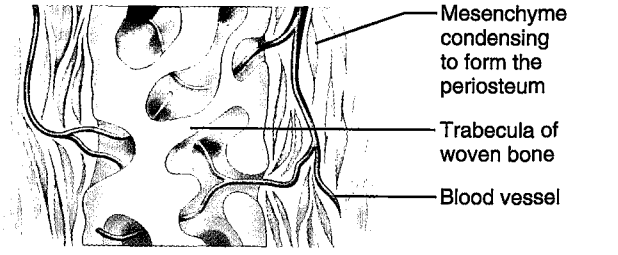
① **An ossification center appears in the fibrous connective tissue membrane.**

- Selected centrally located mesenchymal cells cluster and differentiate into osteoblasts, forming an ossification center.



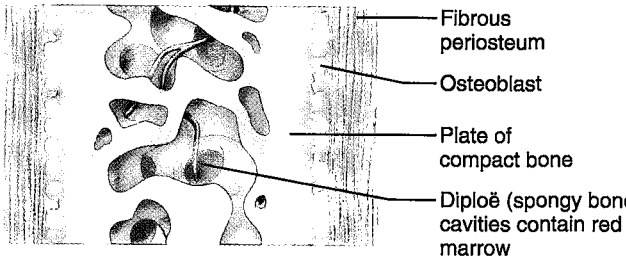
② **Bone matrix (osteoid) is secreted within the fibrous membrane.**

- Osteoblasts begin to secrete osteoid, which is mineralized within a few days.
- Trapped osteoblasts become osteocytes.



③ **Woven bone and periosteum form.**

- Accumulating osteoid is laid down between embryonic blood vessels, which form a random network. The result is a network (instead of lamellae) of trabeculae.
- Vascularized mesenchyme condenses on the external face of the woven bone and becomes the periosteum.



④ **Bone collar of compact bone forms and red marrow appears.**

- Trabeculae just deep to the periosteum thicken, forming a woven bone collar that is later replaced with mature lamellar bone.
- Spongy bone (diploë), consisting of distinct trabeculae, persists internally and its vascular tissue becomes red marrow.

The proper combination of organic and inorganic matrix elements allows bones to be exceedingly durable and strong without being brittle. Healthy bone is half as strong as steel in resisting compression and fully as strong as steel in resisting tension.

Because of the salts they contain, bones last long after death and provide an enduring "monument." In fact, skeletal remains many centuries old have revealed the shapes and sizes of ancient peoples, the kinds of work they did, and many of the ailments they suffered from (arthritis, for example).

Bone Development

Ossification and **osteogenesis** (os"te-o-jen'ĕ-sis) are synonyms meaning the process of bone formation (*os* = bone, *genesis* = beginning). In embryos this process leads to the *formation of the bony skeleton.* Later another form of ossification known as *bone growth* goes on until early adulthood as the body continues to increase in size. Bones are capable of growing in thickness throughout life. However, ossification in adults serves mainly for bone *remodeling* and repair.

Formation of the Bony Skeleton

Before week 8, the skeleton of a human embryo is constructed entirely from fibrous membranes and hyaline cartilage. Bone tissue begins to develop at about this time and eventually replaces most of the existing fibrous or cartilage structures. When a bone develops from a fibrous membrane, the process is *intramembranous ossification,* and the bone is called a **membrane bone.** Bone development by replacing hyaline cartilage is called *endochondral ossification* (*endo* = within, *chondro* = cartilage), and the resulting bone is called a **cartilage,** or **endochondral, bone.** The beauty of using structures (membranes and cartilages) that are flexible and resilient to fashion the embryonic skeleton is that they can accommodate mitosis. Were the early skeleton composed of bone tissue from the onset, growth would be much more difficult.

Intramembranous Ossification

Intramembranous ossification (Figure 6.7) results in the formation of cranial bones of the skull (frontal, parietal, occipital, and temporal bones) and the clavicles. All bones formed by this process are flat bones. Fibrous connective tissue membranes

FIGURE 6.7 **Intramembranous ossification.** Diagrams ③ and ④ represent much lower magnification than diagrams ① and ②.

Q *What is the composition of the periosteal bud?*

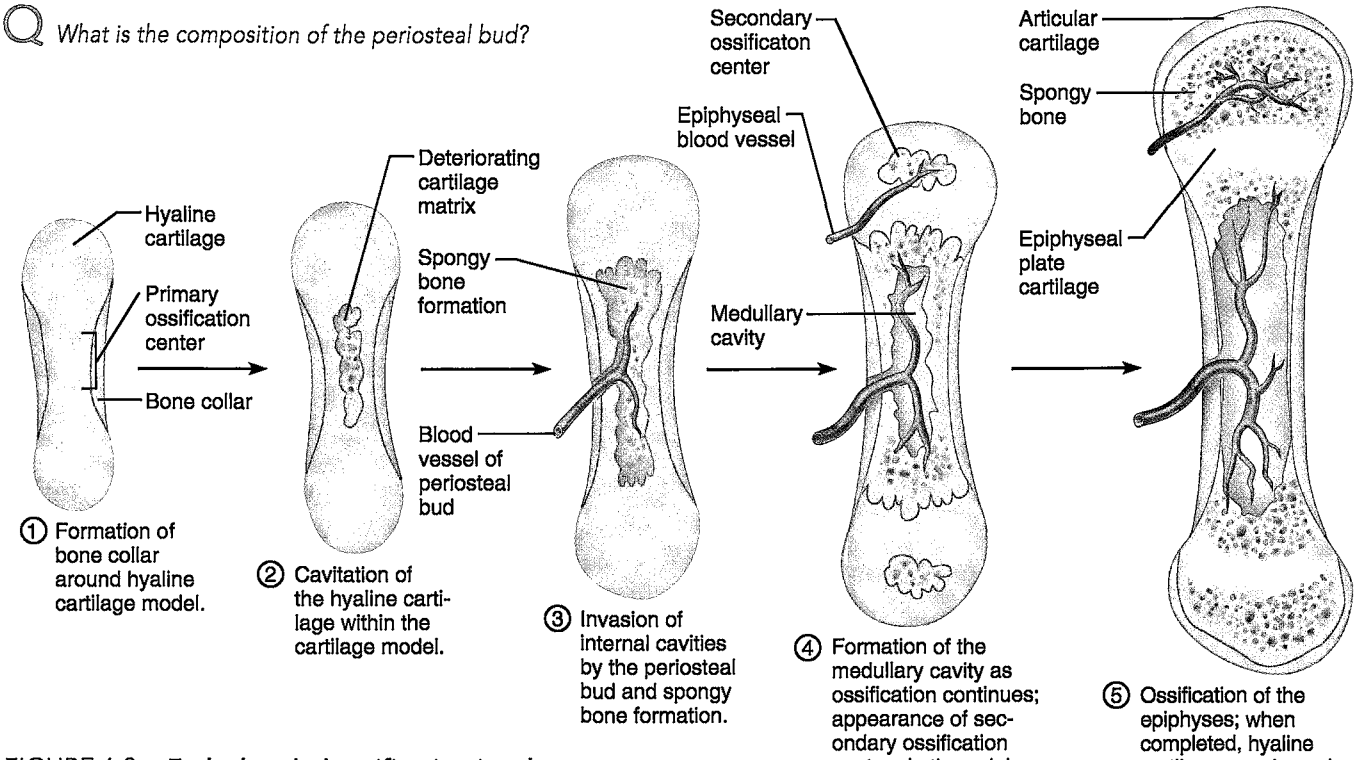


FIGURE 6.8 **Endochondral ossification in a long bone.** Stages ①–③ occur during the fetal period (week 9 to month 9 of development). Stage ④ represents the situation shortly before or just after birth. Stage ⑤ is the process of long bone growth during childhood and adolescence.

formed by *mesenchymal cells* are the supporting structures on which ossification begins at about week 8 of development. Essentially, the process involves the four major steps depicted in Figure 6.7.

Endochondral Ossification

Except for the clavicles, essentially all bones of the skeleton below the base of the skull form by **endochondral ossification** (en″do-kon′dral). This process, which begins in the second month of development, uses hyaline cartilage "bones" formed earlier as models, or patterns, for bone construction. It is more complex than intramembranous ossification because the hyaline cartilage must be broken down as ossification proceeds. We will use a forming long bone as our example.

The formation of a long bone typically begins in the center of the hyaline cartilage shaft at a region called the **primary ossification center.** First, the perichondrium covering the hyaline cartilage "bone" is infiltrated with blood vessels, converting it to a vascularized periosteum. As a result of this change in nutrition, the underlying mesenchymal cells specialize into osteoblasts. The stage is now set for ossification to begin, as illustrated in Figure 6.8.

① A bone collar forms around the diaphysis of the hyaline cartilage model. Osteoblasts of the newly converted periosteum secrete osteoid against the hyaline cartilage diaphysis, encasing it in a bone collar.

② Cartilage in the center of the diaphysis calcifies and then cavitates. As the bone collar forms, chondrocytes within the shaft hypertrophy (enlarge) and signal the surrounding cartilage matrix to calcify. Because calcified cartilage matrix is impermeable to diffusing nutrients, the chondrocytes die and the matrix begins to deteriorate. Although this deterioration opens up cavities, the hyaline cartilage model is stabilized by the bone collar. Elsewhere, the cartilage remains healthy and continues to grow briskly, causing the cartilage model to elongate.

③ The periosteal bud invades the internal cavities and spongy bone forms. In month 3, the forming cavities are invaded by a collection of elements called the **periosteal bud,** which contains a nutrient artery and vein, lymphatics, nerve fibers, red marrow elements, osteoblasts, and osteoclasts. The entering osteoclasts partially erode the calcified cartilage matrix, and the osteoblasts secrete osteoid

A *Blood vessels, nerve fibers, lymph vessels, osteoblasts, osteoclasts, and red marrow elements.*

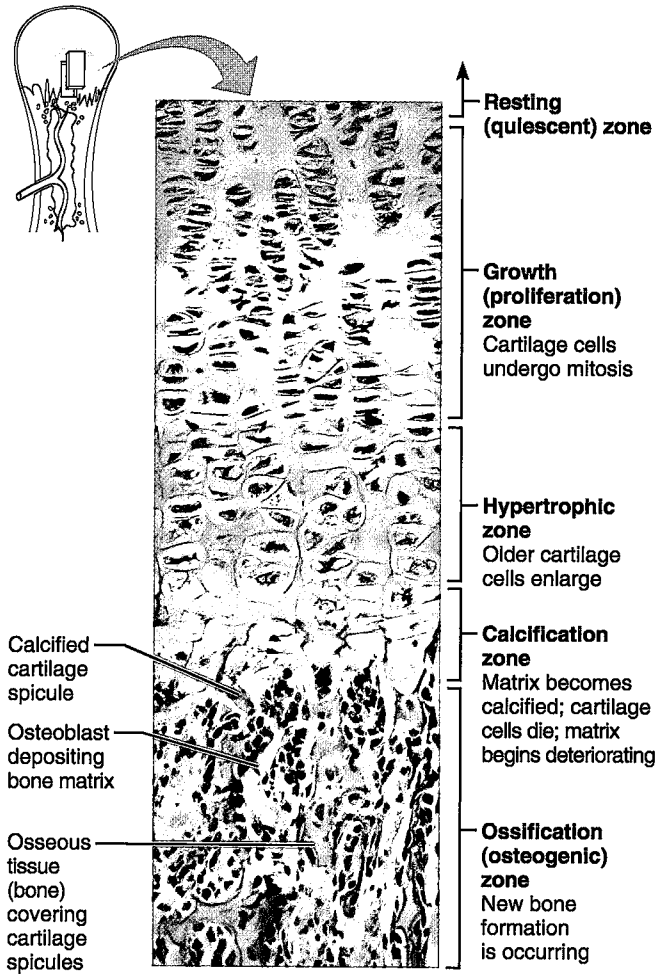

FIGURE 6.9 **Growth in length of a long bone.** The side of the epiphyseal plate facing the epiphysis (distal face) contains resting cartilage cells. The cells of the epiphyseal plate proximal to the resting cartilage area are arranged in four zones—growth, hypertrophic, calcification, and ossification (80×).

around the remaining fragments of hyaline cartilage, forming bone-covered cartilage trabeculae. In this way, the earliest version of spongy bone in a developing long bone forms.

④ **The diaphysis elongates and a medullary cavity forms.** As the primary ossification center enlarges, osteoclasts break down the newly formed spongy bone and open up a medullary cavity in the center of the diaphysis. Throughout the fetal period, the rapidly growing epiphyses consist only of cartilage, and the hyaline cartilage models continue to elongate by division of viable cartilage cells at the epiphyses. Because cartilage is calcifying, being eroded, and then being replaced by bony spicules on the epiphyseal surfaces facing the medullary cavity, ossification "chases" cartilage formation along the length of the shaft.

⑤ **The epiphyses ossify.** When we are born, most of our long bones have a bony diaphysis surrounding remnants of spongy bone, a widening medullary cavity, and two cartilaginous epiphyses. Shortly before or after birth, **secondary ossification centers** appear in one or both epiphyses, and the epiphyses gain bony tissue. (Typically, the large long bones form secondary centers in both epiphyses, whereas the small long bones form only one secondary ossification center.) The cartilage in the center of the epiphysis calcifies and deteriorates, opening up cavities that allow a periosteal bud to enter. Then bone trabeculae appear, just as they did earlier in the primary ossification center. (In short bones, only the primary ossification center is formed. Most irregular bones develop from several distinct ossification centers.)

Secondary ossification reproduces almost exactly the events of primary ossification, except that the spongy bone in the interior is retained and no medullary cavity forms in the epiphyses. When secondary ossification is complete, hyaline cartilage remains only at two places: (1) on the epiphyseal surfaces, as the *articular cartilages*, and (2) at the junction of the diaphysis and epiphysis, where it forms the *epiphyseal plates*.

Postnatal Bone Growth

During infancy and youth, long bones lengthen entirely by interstitial growth of the epiphyseal plates, and all bones grow in thickness by appositional growth. Most bones stop growing during adolescence; however, some facial bones, such as those of the nose and lower jaw, continue to grow almost imperceptibly throughout life.

Growth in Length of Long Bones

Longitudinal bone growth mimics many of the events of endochondral ossification. On the side of the epiphyseal plate facing the epiphysis, a region called the *resting* or *quiescent zone*, the cartilage is relatively inactive. But the epiphyseal plate cartilage abutting the diaphysis organizes into a pattern that allows fast, efficient growth. The cartilage cells here form tall columns, like coins in a stack. The cells at the "top" (epiphysis-facing side) of the stack abutting the resting zone comprise the *growth zone* (Figure 6.9). These cells divide quickly, pushing the epiphysis away from the diaphysis, causing the entire long bone to lengthen.

Meanwhile, the older chondrocytes in the stack, which are closer to the diaphysis (*hypertrophic zone* in Figure 6.9), hypertrophy, and their lacunae erode and enlarge. Subsequently, the surrounding cartilage matrix calcifies and these chondrocytes die and deteriorate, producing the *calcification zone*. This leaves long spicules of calcified cartilage at the epiphysis-diaphysis junction, which look like stalactites hanging

from the roof of a cave. These calcified spicules ultimately become part of the *ossification* or *osteogenic zone*, and are invaded by marrow elements from the medullary cavity. The cartilage spicules are partly eroded by osteoclasts and then quickly covered with bone matrix by osteoblasts, forming spongy bone. The spicule tips are eventually digested by osteoclasts; thus, the medullary cavity also grows longer as the long bone lengthens. During growth, the epiphyseal plate maintains a constant thickness because the rate of cartilage growth on its epiphysis-facing side is balanced by its replacement with bony tissue on its diaphysis-facing side.

Longitudinal growth is accompanied by almost continuous remodeling of the epiphyseal ends to maintain the proper proportions between the diaphysis and epiphyses (Figure 6.10). Bone remodeling, involving both new bone formation and bone resorption (destruction), is described in more detail below in conjunction with the changes that occur in adult bones.

As adolescence draws to an end, the chondroblasts of the epiphyseal plates divide less often and the plates become thinner and thinner until they are entirely replaced by bone tissue. Longitudinal bone growth ends when the bone of the epiphysis and diaphysis fuses. This process, called *epiphyseal plate closure*, happens at about 18 years of age in females and 21 years of age in males. However, as noted earlier, an adult bone can still increase in diameter or thickness by appositional growth if stressed by excessive muscle activity or body weight.

Growth in Width (Thickness)

Growing bones widen as they lengthen. As with cartilages, bones increase in thickness or, in the case of long bones, diameter, by appositional growth. Osteoblasts beneath the periosteum secrete bone matrix on the external bone surface as osteoclasts on the endosteal surface of the diaphysis remove bone (see Figure 6.10). However, there is normally slightly less breaking down than building up. This unequal process produces a thicker, stronger bone but prevents it from becoming too heavy.

Hormonal Regulation of Bone Growth

The growth of bones that occurs until young adulthood is exquisitely controlled by a symphony of hormones. During infancy and childhood, the single most important stimulus of epiphyseal plate activity is *growth hormone* released by the anterior pituitary gland. Thyroid hormones modulate the activity of growth hormone, ensuring that the skeleton has proper proportions as it grows. At puberty, male and female sex hormones (testosterone and estrogens, respectively) are released in increasing amounts.

What would a long bone look like at the end of adolescence if remodeling did not occur?

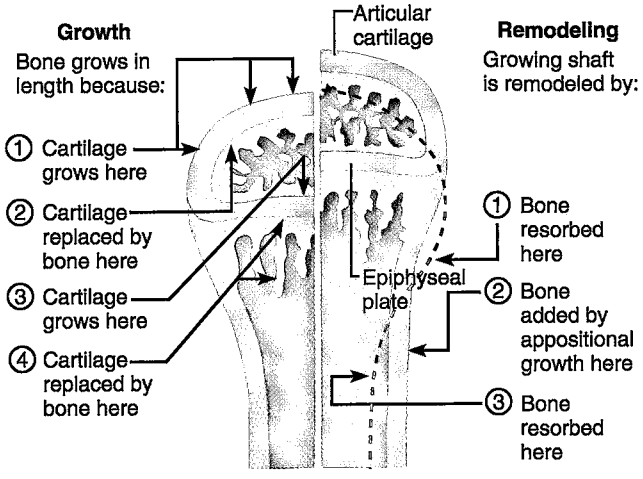

FIGURE 6.10 **Long bone growth and remodeling during youth.** The events at the left depict endochondral ossification that occurs at the articular cartilages and epiphyseal plates as the bone grows in length. Events at the right show bone remodeling during long bone growth to maintain proper bone proportions.

Initially these sex hormones promote the growth spurt typical of adolescence, as well as the masculinization or feminization of specific parts of the skeleton. Later the hormones induce epiphyseal plate closure, ending longitudinal bone growth.

Excesses or deficits of any of these hormones can result in obviously abnormal skeletal growth. For example, hypersecretion of growth hormone in children results in excessive height (gigantism), and deficits of growth hormone or thyroid hormone produce characteristic types of dwarfism.

Bone Homeostasis: Remodeling and Repair

Bones appear to be the most lifeless of body organs, and may even summon images of a graveyard. But as you have just learned, appearances can be deceiving. Bone is a dynamic and active tissue, and small-scale changes in bone architecture occur continually. Every week we recycle 5–7% of our bone mass, and as much as half a gram of calcium may enter or leave the adult skeleton each day! Spongy bone is replaced every three to four years; compact bone, every ten years or so. This is fortunate because when bone

A shaft would still be its original length, and it would have two very elongated and expanded ends (epiphyses).

remains in place for long periods the calcium crystallizes and becomes more brittle—ripe conditions for fracture. And when we break bones—the most common disorder of bone homeostasis—they undergo a remarkable process of self-repair.

Bone Remodeling

In the adult skeleton, bone deposit and bone resorption (removal) occur both at the surface of the periosteum and the surface of the endosteum. Together, the two processes constitute **bone remodeling,** and they are coupled and coordinated by "packets" of adjacent osteoblasts and osteoclasts called *remodeling units* (with help from the stress-sensing osteocytes). In healthy young adults, total bone mass remains constant, an indication that the rates of bone deposit and resorption are essentially equal. Remodeling does not occur uniformly, however. For example, the distal part of the femur, or thigh bone, is fully replaced every five to six months, whereas its shaft is altered much more slowly.

Bone deposit occurs wherever bone is injured or added bone strength is required. For optimal bone deposit, a healthy diet rich in proteins, vitamin C, vitamin D, vitamin A, and several minerals (calcium, phosphorus, magnesium, and manganese, to name a few) is essential.

New matrix deposits by osteocytes are marked by the presence of an *osteoid seam,* an unmineralized band of gauzy-looking bone matrix 10–12 μm wide. Between the osteoid seam and the older mineralized bone, there is an abrupt transition called the *calcification front.* Because the osteoid seam is always of constant width and the change from unmineralized to mineralized matrix is sudden, it seems that the osteoid must mature for about a week before it can calcify. The precise trigger for calcification is still controversial. However, one critical factor is the product of the local concentrations of calcium and phosphate (P_i) ions (the $Ca^{2+} \cdot P_i$ product). When this product reaches a certain level, tiny crystals of hydroxyapatite form spontaneously and then catalyze further crystallization of calcium salts in the area. Other factors involved are matrix proteins that bind and concentrate calcium, and the enzyme *alkaline phosphatase* (shed by the osteoblasts), which is essential for mineralization. Once proper conditions are present, calcium salts are deposited all at once and with great precision throughout the "matured" matrix.

Bone resorption is accomplished by osteoclasts, giant multinucleate cells that arise from the same hematopoietic stem cells that differentiate into macrophages. Osteoclasts move along a bone surface, digging grooves as they break down the bone matrix. The part of the osteoclast that touches the bone is highly folded to form a ruffled membrane that clings tightly to the bone, sealing off the area of bone destruction. The ruffled border secretes (1) *lysosomal enzymes* that digest the organic matrix and (2) *hydrochloric acid* that converts the calcium salts into soluble forms that pass easily into solution. Osteoclasts may also phagocytize the demineralized matrix and dead osteocytes. The digested matrix end products, growth factors, and dissolved minerals are then endocytosed, transported across the osteoclast (by transcytosis), and released at the opposite side where they enter first the interstitial fluid and then the blood. Although there is much to learn about osteoclast activation, proteins secreted by T cells of the immune system appear to be important.

Control of Remodeling

The remodeling that goes on continuously in the skeleton is regulated by two control loops that serve different "masters." One is a negative feedback hormonal mechanism that maintains Ca^{2+} homeostasis in the blood. The other involves responses to mechanical and gravitational forces acting on the skeleton.

The hormonal mechanism becomes much more meaningful when you understand calcium's importance in the body. Ionic calcium is necessary for an amazing number of physiological processes, including transmission of nerve impulses, muscle contraction, blood coagulation, secretion by glands and nerve cells, and cell division. The human body contains 1200–1400 g of calcium, more than 99% present as bone minerals. Most of the remainder is in body cells. Less than 1.5 g is present in blood, and the hormonal control loop normally maintains blood Ca^{2+} within the very narrow range of 9–11 mg per dl (100 ml) of blood. Calcium is absorbed from the intestine under the control of vitamin D metabolites. The daily calcium requirement is 400–800 mg from birth until the age of 10, and 1200–1500 mg from ages 11 to 24.

Hormonal Mechanism The hormonal mechanism primarily involves **parathyroid hormone (PTH),** produced by the parathyroid glands. To a much lesser extent it involves **calcitonin** (kal"sĭ-to'nin), produced by parafollicular cells (C cells) of the thyroid gland (Figure 6.11). PTH is released when blood levels of ionic calcium decline. The increased PTH level stimulates osteoclasts to resorb bone, releasing calcium to the blood. Osteoclasts are no respecters of matrix age. When activated, they break down both old and new matrix. Only osteoid, which lacks calcium salts, escapes digestion. As blood concentrations of calcium rise, the stimulus for PTH release ends. The decline of PTH reverses its effects and causes blood Ca^{2+} levels to fall.

What is the result of the negative feedback of calcitonin (particularly in children)?

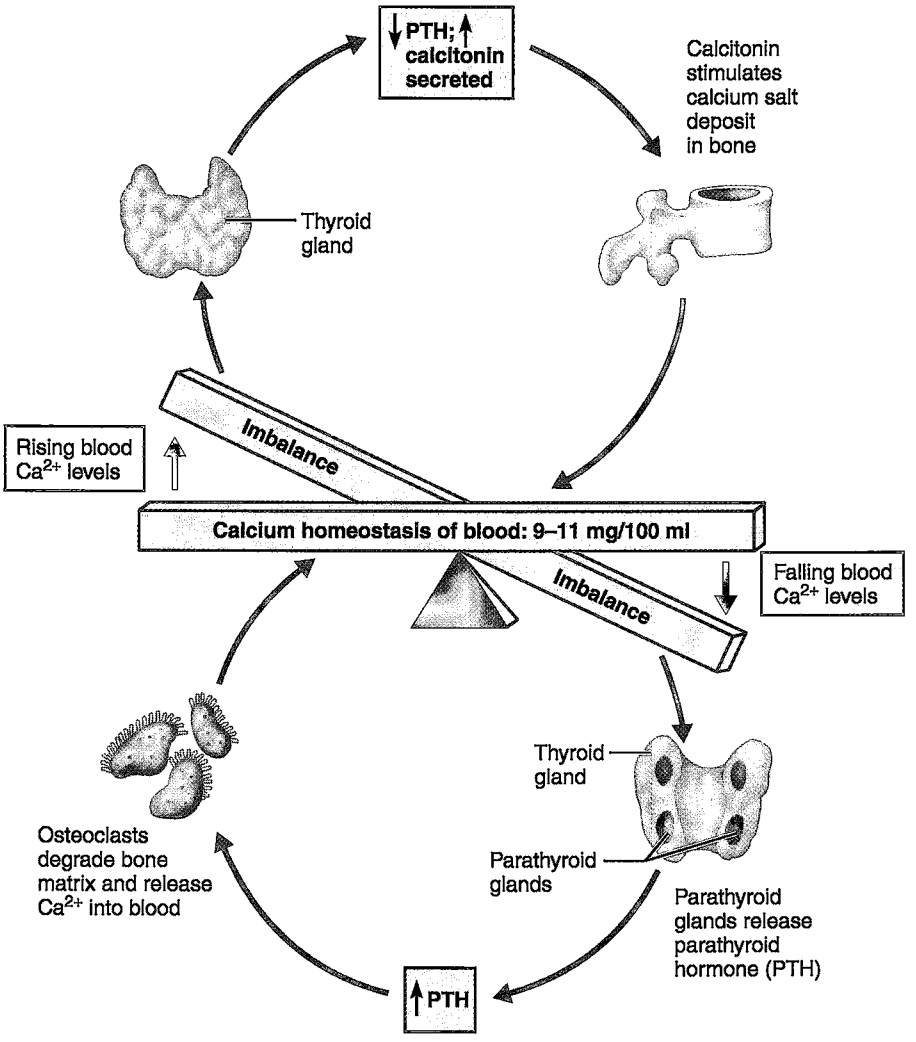

FIGURE 6.11 **Hormonal control of blood calcium levels.** PTH and to a lesser extent calcitonin operate in negative feedback fashion to control blood calcium levels.

Calcitonin, secreted when blood calcium levels rise, inhibits bone resorption and encourages calcium salt deposit in bone matrix, effectively reducing blood calcium levels. As blood calcium levels fall, calcitonin release wanes. Calcitonin is most effective in reducing blood Ca^{2+} levels in children. In adults, its effects appear to be negligible.

These hormonal controls act not to preserve the skeleton's strength or well-being but rather to maintain blood calcium homeostasis. In fact, if blood calcium levels are low for an extended time, the bones become so demineralized that they develop large, punched-out-looking holes. Thus, the bones serve as a storehouse from which ionic calcium is drawn as needed.

Calcium salts are deposited in bone, and blood Ca^{2+} levels fall.

HOMEOSTATIC IMBALANCE

Minute changes from the homeostatic range for blood calcium can lead to severe neuromuscular problems ranging from hyperexcitability (when blood Ca^{2+} levels are too low) to nonresponsiveness and inability to function (with high blood Ca^{2+} levels). In addition, sustained high blood levels of Ca^{2+}, a condition known as *hypercalcemia* (hi"per-kal-se'me-ah), can lead to undesirable deposits of calcium salts in the blood vessels, kidneys, and other soft organs, which may hamper the functioning of these organs. ●

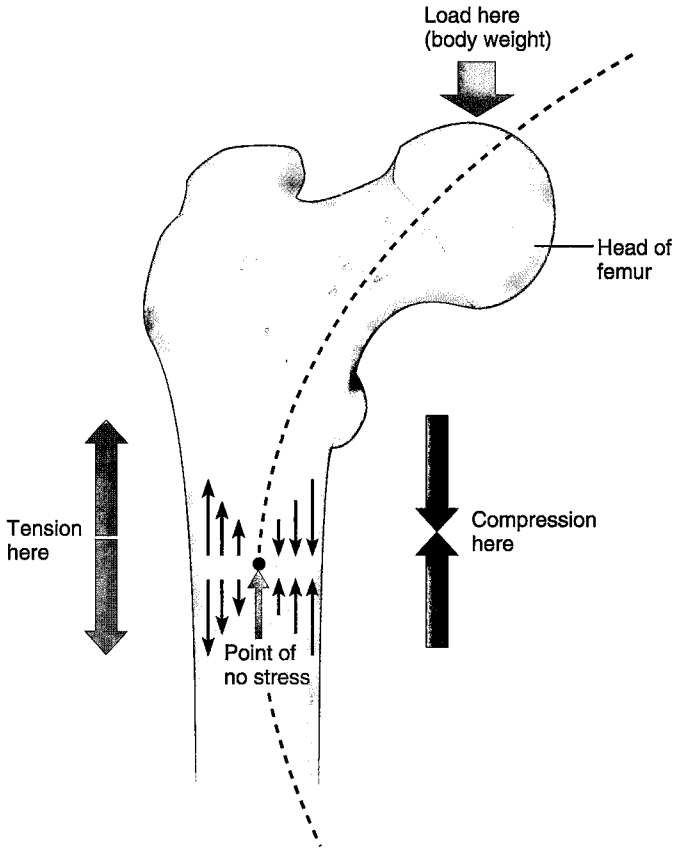

FIGURE 6.12 **Bone anatomy and stress.** When loaded, bones are subjected to bending stress. In this example using the femur of the thigh, body weight transmitted to the head of the femur threatens to bend the bone along the indicated arc. This bending compresses the bone on one side (converging arrows), and stretches it on the other side (diverging arrows). Because these two forces cancel each other internally, much less bone material is needed internally than superficially.

In addition to the hormones that regulate bone remodeling in response to blood calcium levels, it is now established that *leptin*, a fat-derived hormone, plays a role in regulating bone density. Best known for its effects on weight and energy balance (see pp. 982–983), in animal studies leptin appears to inhibit osteoblasts through an additional pathway mediated by the hypothalamus which activates sympathetic nerves serving bones. However, the full scope of leptin's bone-modifying activity in humans is still being worked out.

Response to Mechanical Stress The second set of controls regulating bone remodeling, bone's response to mechanical stress (muscle pull) and gravity, serves the needs of the skeleton by keeping the bones strong where stressors are acting. *Wolff's law* holds that a bone grows or remodels in response to the demands placed on it. The first thing to understand is that a bone's anatomy reflects the common stresses it encounters. For example, a bone is loaded (stressed) whenever weight bears down on it or muscles pull on it. This loading is usually off center, however, and tends to *bend* the bone. Bending compresses the bone on one side and subjects it to tension (stretching) on the other (Figure 6.12). But both forces are minimal toward the center of the bone (they cancel each other out), so a bone can "hollow out" for lightness (using spongy bone instead of compact bone) without jeopardy.

Other observations explained by Wolff's law include these: (1) Long bones are thickest midway along the diaphysis, exactly where bending stresses are greatest (bend a stick and it will split near the middle); (2) curved bones are thickest where they are most likely to buckle; (3) the trabeculae of spongy bone form trusses, or struts, along lines of compression; and (4) large, bony projections occur where heavy, active muscles attach. (The bones of weight lifters have enormous thickenings at the attachment sites of the most used muscles.) Wolff's law also explains the featureless bones of the fetus and the atrophied bones of bedridden people—situations in which bones are not stressed.

How do mechanical forces communicate with the cells responsible for remodeling? Although the mechanisms by which bone responds to mechanical stimuli are still uncertain, we do know that deforming a bone produces an electrical current. Because compressed and stretched regions are oppositely charged, it has been suggested that electrical signals direct remodeling. This principle and some of the devices currently used to speed bone repair and the healing of fractures are discussed in *A Closer Look* (pp. 194–195).

The skeleton is continuously subjected to both hormonal influences and mechanical forces. At the risk of constructing too large a building on too small a foundation, we can speculate that the hormonal loop determines *whether* and *when* remodeling occurs in response to changing blood calcium levels, and mechanical stress determines *where* it occurs. For example, when bone must be broken down to increase blood calcium levels, PTH is released and targets the osteoclasts. However, mechanical forces determine *which* osteoclasts are most sensitive to PTH stimulation, so that bone in the *least* stressed areas (which is temporarily dispensable) is broken down.

Bone Repair

Despite their remarkable strength, bones are susceptible to **fractures,** or breaks. During youth, most fractures result from exceptional trauma that twists or smashes the bones (sports injuries, automobile

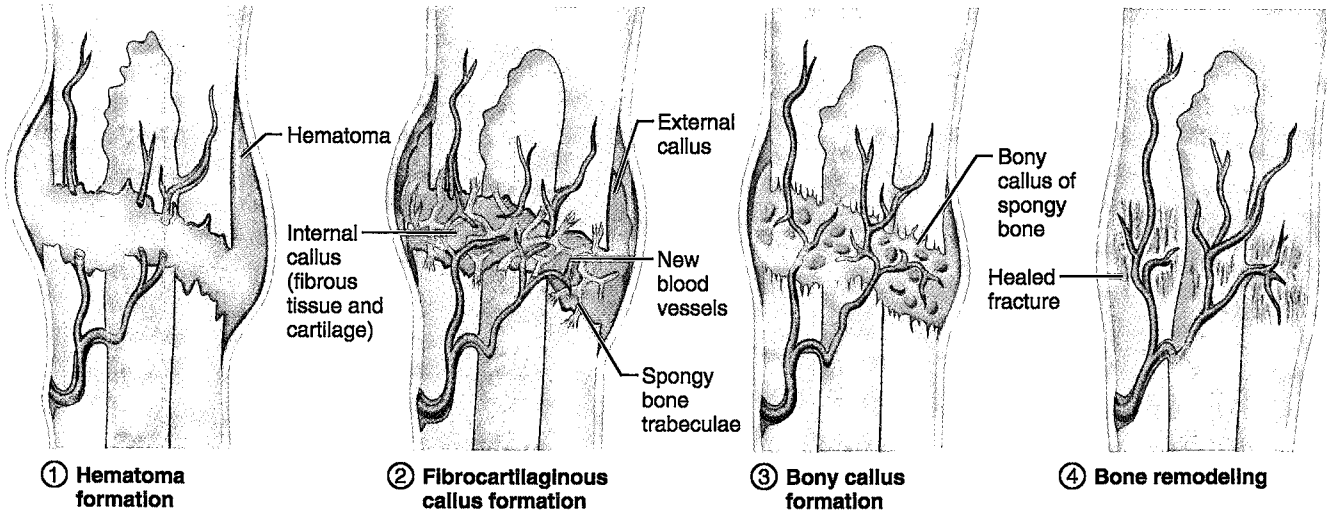

FIGURE 6.13 **Stages in the healing of a bone fracture.**

accidents, and falls, for example). Excessive intake of vitamin A and elevated blood levels of the protein homocysteine (a known risk factor for atherosclerosis) appear to increase fracture risk in some people. In old age, most fractures occur as bones thin and weaken.

Fractures may be classified by

1. Position of the bone ends after fracture. In *nondisplaced fractures* the bone ends retain their normal position; in *displaced fractures* the bone ends are out of normal alignment.

2. Completeness of the break. If the bone is broken through, the fracture is a *complete fracture;* if not, it is an *incomplete fracture.*

3. Orientation of the break relative to the long axis of the bone. If the break parallels the long axis, the fracture is *linear;* if the break is perpendicular to the bone's long axis, it is *transverse.*

4. Whether the bone ends penetrate the skin. If so, the fracture is an *open (compound) fracture;* if not it is a *closed (simple) fracture.*

In addition to these four either-or classifications, all fractures can be described in terms of the location of the fracture, the external appearance of the fracture, and/or the nature of the break. Table 6.2 summarizes the various descriptions.

A fracture is treated by *reduction,* the realignment of the broken bone ends. In *closed* or *external reduction,* the bone ends are coaxed into position by the physician's hands. In *open (internal) reduction,* the bone ends are secured together surgically with pins or wires. After the broken bone is reduced, it is immobilized either by a cast or traction to allow the healing process to begin. For a simple fracture the healing time is six to eight weeks for small or medium-sized bones in young adults, but it is much longer for large, weight-bearing bones and for bones of elderly people (because of their poorer circulation).

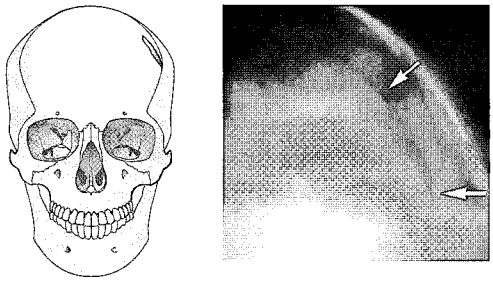
Repair in a simple fracture involves four major stages (Figure 6.13).

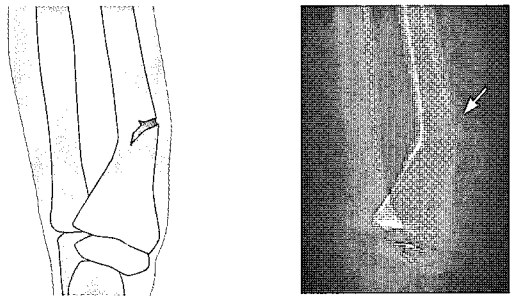
① **Hematoma formation.** When a bone breaks, blood vessels in the bone and periosteum, and perhaps in surrounding tissues, are torn and hemorrhage. As a result, a **hematoma** (he"mah-to'mah), a mass of clotted blood, forms at the fracture site. Soon, bone cells deprived of nutrition die, and the tissue at the site becomes swollen, painful, and inflamed.

② **Fibrocartilaginous callus formation.** Within a few days, several events lead to the formation of soft *granulation tissue,* also called the *soft callus* (kal'us; "hard skin"). Capillaries grow into the hematoma and phagocytic cells invade the area and begin cleaning up the debris. Meanwhile, fibroblasts and osteoblasts invade the fracture site from the nearby periosteum and endosteum and begin reconstructing the bone. The fibroblasts produce collagen fibers that span the break and connect the broken bone ends, and some differentiate into chondroblasts that secrete cartilage matrix. Within this mass of repair tissue, osteoblasts begin forming spongy bone, but those farthest from the capillary supply secrete an externally bulging cartilaginous matrix that later calcifies. This entire mass of repair tissue, now called the **fibrocartilaginous callus,** splints the broken bone.

③ **Bony callus formation.** Within a week, new bone trabeculae begin to appear in the fibrocartilaginous callus and gradually convert it to a **bony (hard) callus** of spongy bone. Bony callus formation continues until a firm union is formed about two months later.

TABLE 6.2 Common Types of Fractures

FRACTURE TYPE	DESCRIPTION AND COMMENTS	FRACTURE TYPE	DESCRIPTION AND COMMENTS
Comminuted	Bone fragments into three or more pieces Particularly common in the aged, whose bones are more brittle	***Compression***	Bone is crushed Common in porous bones (i.e., osteoporotic bones) subjected to extreme trauma, as in a fall
			Spiral	Ragged break occurs when excessive twisting forces are applied to a bone Common sports fracture	***Epiphyseal***	Epiphysis separates from the diaphysis along the epiphyseal plate Tends to occur where cartilage cells are dying and calcification of the matrix is occurring
			Depressed	Broken bone portion is pressed inward Typical of skull fracture	***Greenstick***	Bone breaks incompletely, much in the way a green twig breaks. Only one side of the shaft breaks; the other side bends Common in children, whose bones have relatively more organic matrix and are more flexible than those of adults
			




④ **Bone remodeling.** Beginning during bony callus formation and continuing for several months after, the bony callus is remodeled. The excess material on the diaphysis exterior and within the medullary cavity is removed, and compact bone is laid down to reconstruct the shaft walls. The final structure of the remodeled area resembles that of the original unbroken bony region because it responds to the same set of mechanical stressors.

Homeostatic Imbalances of Bone

Imbalances between bone deposit and bone resorption underlie nearly every disease that affects the adult skeleton.

Osteomalacia and Rickets

Osteomalacia (os"te-o-mah-la'she-ah; "soft bones") includes a number of disorders in which the bones are inadequately mineralized. Osteoid is produced, but calcium salts are not deposited, so bones soften and weaken. The main symptom is pain when weight is put on the affected bones.

Rickets is the analogous disease in children. Because young bones are still growing rapidly, rickets is much more severe than adult osteomalacia. Bowed legs and deformities of the pelvis, skull, and rib cage are common. Because the epiphyseal plates cannot be calcified, they continue to widen, and the ends of long bones become visibly enlarged and abnormally long.

Osteomalacia and rickets are caused by insufficient calcium in the diet or by a vitamin D deficiency. Hence, drinking vitamin D–fortified milk and exposing the skin to sunlight (which spurs the body to form vitamin D) usually cure these disorders. Although the seeming elimination of rickets in the United States has been heralded as a public health success, rickets still rears its head in isolated situations. For example, if a mother who breastfeeds her infant becomes vitamin D deficient because of dreary winter weather, the infant too will be vitamin D deficient and will develop rickets.

Osteoporosis

For most of us, the phrase "bone problems of the elderly" brings to mind the stereotype of a victim of osteoporosis—a hunched-over old woman shuffling behind her walker. **Osteoporosis** (os"te-o-po-ro'sis) refers to a group of diseases in which bone resorption outpaces bone deposit. The bones become so fragile that something as simple as a hearty sneeze or stepping off a curb can cause them to break. The composition of the matrix remains normal but bone mass is reduced, and the bones become porous and light (Figure 6.14). Even though osteoporosis affects the entire skeleton, the spongy bone of the spine is most vulnerable, and compression fractures of the vertebrae are common. The femur, particularly its neck, is also very susceptible to fracture (called a *broken hip*) in people with osteoporosis.

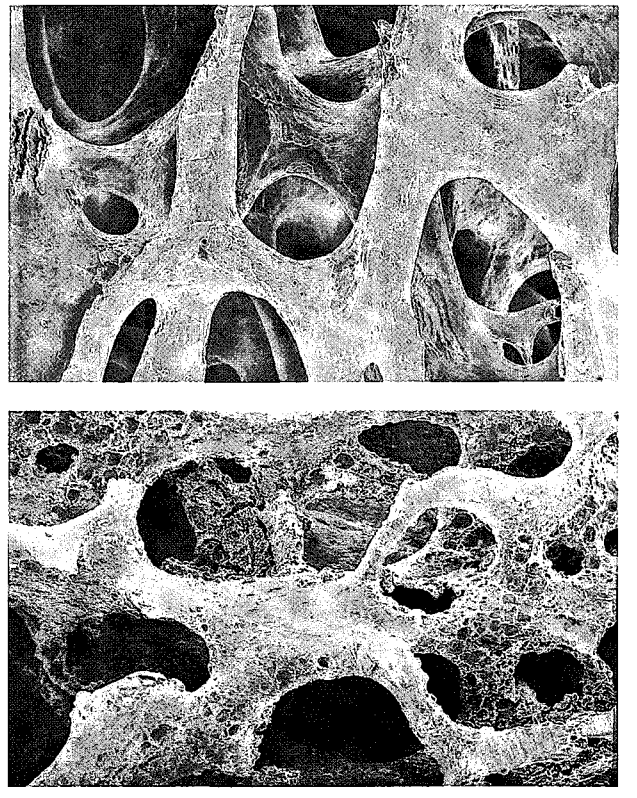


FIGURE 6.14 **Normal versus osteoporotic bone.** The contrasting architecture of **(a)** normal bone and **(b)** osteoporotic bone as shown in scanning electron micrographs (both 300×).

Osteoporosis occurs most often in the aged, particularly in postmenopausal women. Although men develop it to a lesser degree, 30% of American women have osteoporosis between the ages of 60 and 70; 70% have it by age 80. Moreover, 30% of all Caucasian women (the most susceptible group) will experience a bone fracture due to osteoporosis. Sex hormones, particularly estrogen help to maintain the health and normal density of the skeleton by restraining osteoclast activity and by promoting deposit of new bone. After menopause, however, estrogen secretion wanes and estrogen deficiency is strongly implicated in osteoporosis in older women. Other factors that contribute to osteoporosis include a petite body form, insufficient exercise to stress the bones, a diet poor in calcium and protein, abnormal vitamin D receptors, smoking (which reduces estrogen levels), and hormone-related conditions (such as

A CLOSER LOOK

Them Bones, Them Bones Goin' to Walk Around—Clinical Advances in Bone Repair

Although bones have remarkable self-regenerative powers, some conditions frustrate even their most heroic efforts. Outstanding examples include massive shattering (as in automobile accidents), poor circulation in old bones, and certain birth defects. However, recent medical advances address healing problems that bones cannot handle themselves. Let's take a look.

- **Electrical stimulation.** In large or slowly healing fractures, electrical stimulation of the fracture site dramatically increases the speed of healing. A lesson from geology notes that minute electrical currents are produced when minerals are stressed, a phenomenon called the *piezo-electric effect.* Bone tissue is deposited in regions of negative electrical charge (stressed areas) and absorbed in areas of positive charge, but the process by which applied electricity promotes healing is poorly understood. One theory is that the electrical fields prevent PTH from stimulating the bone-absorbing osteoclasts at the fracture site, thus allowing increased accumulation of bony tissue. Another theory holds that the electrical fields induce production of growth factors that stimulate the osteoblasts.
- **Ultrasound treatments.** Daily exposure to pulsed low-intensity ultrasound waves reduces the healing time of broken arms and shinbones by 35–45%. This treatment seems to stimulate cartilage cells to make callus.
- **Free vascular fibular graft.** This technique uses pieces of the fibula (the sticklike bone of the leg) to replace missing or severely damaged bone. In the past, extensive bone grafts (typically using pieces of bone from the hip) usually failed because blood could not reach their interior, necessitating eventual amputation. This new technique grafts normal blood vessels along with the bone section. Subsequent remodeling leads to a good replica of the bone normally present.

Although bone implants have proved effective in adults, they have been less desirable for children with growing bones because of the limb-length discrepancy that results. This problem has been partially resolved, at least for knee replacement candidates, with *self-extending endoprostheses.* The telescopic sleeve of these devices (see the figure) undergoes continual automatic limb elongation enforced by knee bending. Overlengthening of the prosthesis is prevented by tension in the surrounding soft tissue, which increases after each elongation and then gradually decreases as the soft tissue grows.

- **Vascular endothelial growth factor (VEGF).** VEGF is a protein that stimulates the growth of blood vessels. Researchers have been exploring its potential to create new arteries in people with heart disease, and more recently they began studying VEGF as a way to build new bone tissue. Experiments on mice with bone fractures show that VEGF stimulates the formation of osteoblasts and proteins associated with bone growth.
- **Nanobiotechnology.** Researchers are experimenting with *nanostructures* (Greek *nanos* = dwarf) that mimic the structure of bone at a microscopic level. Scientists at Northwestern University assembled molecules of synthetic materials into a network of tiny fibers—each 10,000 times narrower than a human hair—similar to the collagen framework of bone tissue. When exposed to calcium and phosphate ions, the fibers developed crystalline deposits similar to those that form bone. Although still in the experimental stage, these fibers could someday be incorporated into a gel and packed into fracture sites to speed healing.
- **Bone substitutes.** Desperate for bone fillers, surgeons have traditionally resorted to using crushed bone from cadavers or synthetic materials. Crushed bone induces the body to

hyperthyroidism, low blood levels of thyroid stimulating hormone (better known for its role in stimulating the secretion of thyroid hormones), and diabetes mellitus). In addition, osteoporosis can occur at any age as a result of immobility.

Osteoporosis has traditionally been treated with calcium and vitamin D supplements, weight-bearing exercise, and *hormone (estrogen) replacement therapy (HRT).* Frustratingly, HRT only slows the loss of bone; it does not reverse it. Additionally, because of the increased risk of heart attack, stroke, and breast cancer associated with estrogen replacement therapy, it is a controversial treatment these days. Newer drugs are available. These include alendronate, a drug that suppresses osteoclast activity and shows promise in reversing osteoporosis in the spine; and selective estrogen receptor modulators (SERMs), such as raloxifene, dubbed "estrogen light" because it mimics estrogen's beneficial bone-sparing properties without targeting the uterus or breast. Additionally, *statins,* drugs used by tens of thousands of people to lower cholesterol levels, have been shown to have an unexpected side effect of increasing bone mineral density up to 8% over four years. Although not a substitute for HRT, estrogenic compounds in soy protein (principally the isoflavones daidzein and genistein) offer a good addition or adjunct for some patients.

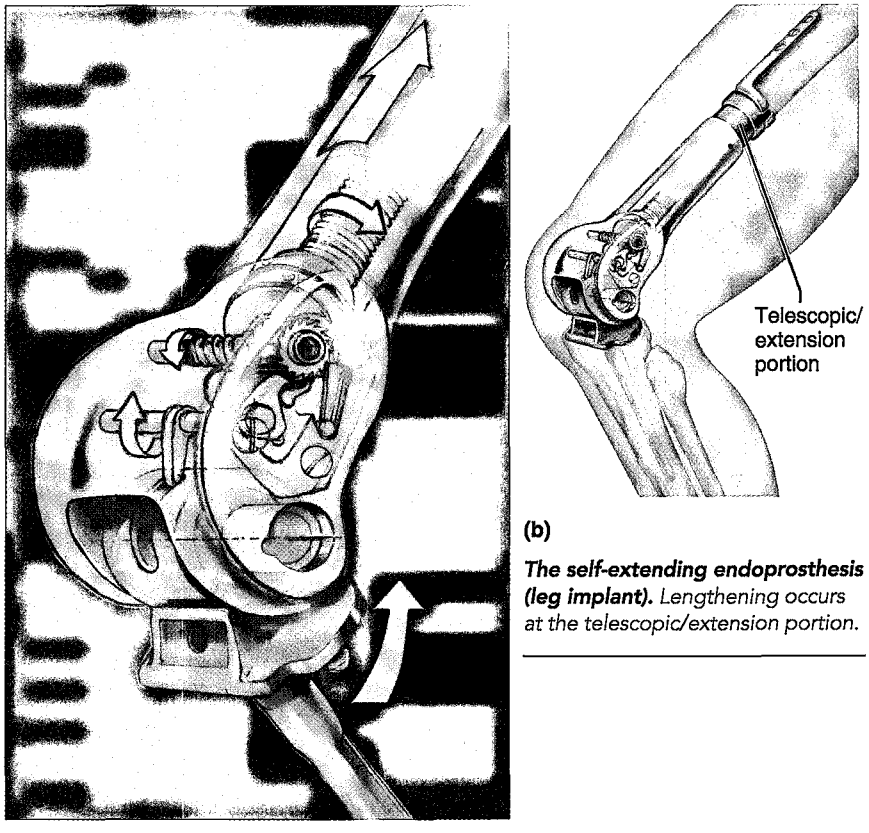
Osteoporosis can be prevented (or at least delayed). The first requirement is to get enough calcium while your bones are still increasing in density (bones

form new bone of its own. When mixed with water, it can be molded to the shape of the desired bone or packed into small, difficult-to-reach spaces. Thus, it avoids the often painful and time-consuming procedure of bone grafting. The same can be said for most synthetic bone substitutes, but both approaches have shortcomings. Cadaveric bone carries a small (but real) risk of hepatitis or HIV infection. Additionally, as foreign tissue, it may be rejected by the immune system. Synthetics tend to cause inflammation which hinders healing and promotes infection.

Pro Osteon (made from coral) avoids both problems. The coral is heat-treated to kill the living coral cells and convert its mineral structure to hydroxyapatite, the salt in bone. The brittle coral graft is then carved to the desired shape, sterilized by irradiation with gamma rays, and coated with *bone morphogenic protein (BMP)*, a natural substance that enhances bone growth. Osteoblasts and blood vessels migrate from the adjacent natural bone into the coral implant, gradually replacing it with living bone.

Research has also produced several types of artificial bone. One is TCP, a biodegradable ceramic substance soft enough to be shaped, but not very strong. TCP's biggest application has been to replace parts of non-weight-bearing bones, such as skull bones.

Norian SRS, a bone cement made of calcium phosphate, provides immediate structural support to fractured or osteoporotic sites. Mixed at the time of surgery, Norian SRS starts out as a paste that can be injected into damaged areas to create an "internal cast." The paste hardens in minutes and cures into a substance with greater compressive strength than spongy bone. Because its crystalline structure and chemistry are the same as that of natural bone, it is gradually remodeled and replaced by host bone cells. A limitation is that Norian SRS can be used only on the ends of long bones, because it cannot resist the twisting and flexing experienced by the central shaft. ■



(a) (b)

The self-extending endoprosthesis (leg implant). *Lengthening occurs at the telescopic/extension portion.*

reach their peak density during early adulthood). Second, drinking fluoridated water hardens bones (as well as teeth); conversely, excessive intake of carbonated beverages leaches minerals from bone and decreases bone density. Finally, getting plenty of weight-bearing exercise (walking, jogging, tennis, etc.) throughout life will increase bone mass above normal values and provide a greater buffer against age-related bone loss.

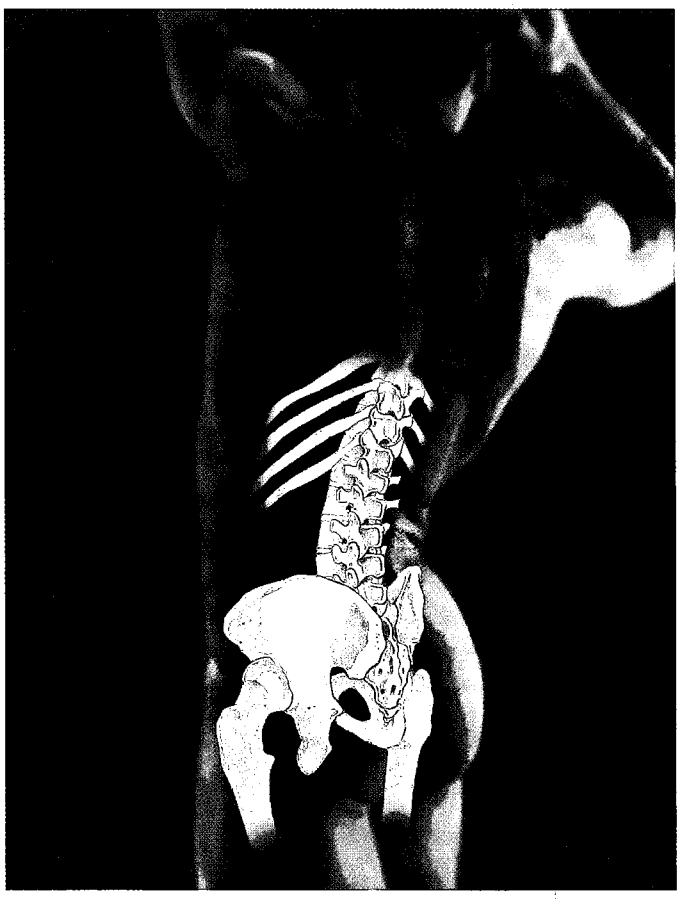
Paget's Disease

Often discovered by accident when X rays are taken for some other reason, **Paget's disease** (paj'ets) is characterized by excessive and haphazard bone deposit and resorption. The newly formed bone, called *Pagetic bone*, is hastily made and has an abnormally high ratio of spongy bone to compact bone. This, along with reduced mineralization, causes a spotty weakening of the bones. Late in the disease, osteoclast activity wanes, but osteoblasts continue to work, often forming irregular bone thickenings or filling the marrow cavity with Pagetic bone.

Paget's disease may affect any part of the skeleton, but it is usually a localized condition. The spine, pelvis, femur, and skull are most often involved and become increasingly deformed and painful. It rarely occurs before the age of 40, and it affects about 3% of North American elderly people.

MAKING CONNECTIONS

SYSTEM CONNECTIONS: Homeostatic Interrelationships Between the Skeletal System and Other Body Systems



Integumentary System

- Skeletal system provides support for body organs including the skin
- Skin provides vitamin D needed for proper calcium absorption and use

Muscular System

- Skeletal system provides levers plus ionic calcium for muscle activity
- Muscle pull on bones increases bone strength and viability; helps determine bone shape

Nervous System

- Skeletal system protects brain and spinal cord; provides depot for calcium ions needed for neural function
- Nerves innervate bone and joint capsules, providing for pain and joint sense

Endocrine System

- Skeletal system provides some bony protection; stores calcium needed for second-messenger signaling mechanisms
- Hormones regulate uptake and release of calcium from bone; promote long bone growth and maturation

Cardiovascular System

- Bone marrow cavities provide site for blood cell formation; matrix stores calcium needed for cardiac muscle activity
- Cardiovascular system delivers nutrients and oxygen to bones; carries away wastes

Lymphatic System/Immunity

- Skeletal system provides some protection to lymphatic organs; bone marrow is site of origin for lymphocytes involved in immune response
- Lymphatic system drains leaked tissue fluids; immune cells protect against pathogens

Respiratory System

- Skeletal system protects lungs by enclosure (rib cage)
- Respiratory system provides oxygen; disposes of carbon dioxide

Digestive System

- Skeletal system provides some bony protection to intestines, pelvic organs, and liver
- Digestive system provides nutrients needed for bone health and growth

Urinary System

- Skeletal system protects pelvic organs (bladder, etc.)
- Urinary system activates vitamin D; disposes of nitrogenous wastes

Reproductive System

- Skeletal system protects some reproductive organs by enclosure
- Gonads produce hormones that influence form of skeleton and epiphyseal closure

CLOSER CONNECTIONS

THE SKELETAL SYSTEM and Interrelationships with the Muscular, Endocrine, and Integumentary Systems

Our skeleton supports us, protects our "innards" (the protection our brain gets from the skull is indispensable), gives us stature (for some reason, tall people get more respect), contributes to our shape (women *are* shaped differently than men), and allows us to move. Obviously, the skeletal system has important interactions with many other body systems, not the least of which are the endocrine and integumentary systems. However, its most intimate and mutually beneficial relationship is with the muscular system, so we will consider that first.

Muscular System

The codependence of the skeletal and muscular systems is striking—as one system goes, so goes the other. If we participate in weight-bearing exercise (run, play tennis, do aerobics) regularly, our muscles become more efficient and exert more force on our bones. As a result, our bones stay healthy and strong and increase their mass to assume the added stress.

Since both spongy and compact bone reach peak density during midlife, weight-bearing exercise during youth is important, especially in females who have less bone mass than males and lose it faster.

Regular exercise also stretches the connective tissues binding bones to muscles and to other bones, and reinforcing joints. Since this increases overall flexibility, we have fewer injuries, allowing us to stay active well into old age. (Pain makes couch potatoes.)

Endocrine System

Although mechanical factors are undeniably important in shaping the skeleton and helping to keep it strong, hormones acting individually and in concert direct skeletal growth during youth, and enhance (or impair) skeletal strength in adults. Growth hormone is essential for normal skeletal growth and maintenance throughout life, whereas thyroid and sex hormones ensure that normal skeletal proportions are established during childhood and adolescence. Conversely, PTH and calcitonin serve not the skeleton but a different master—homeostasis of blood calcium levels. Any interference with normal hormonal functioning is soon apparent as a skeletal abnormality or malproportion.

Integumentary System

The skeletal system is absolutely dependent on the integumentary system (the skin) for the calcium that keeps the bones hard and strong. The relationship is indirect to be sure: In the presence of sunlight, a vitamin D precursor is produced in the dermal capillary blood. It is activated elsewhere, and (among its other roles) it regulates the carrier system that absorbs calcium from ingested foods into the blood. Because calcium is required for so many body functions, and bones provide the "calcium bank," the bones become increasingly soft and weak in the absence of vitamin D because no daily rations of calcium are allowed to enter the blood from the digestive tract.

CLINICAL CONNECTIONS

Skeletal System

Case study: Remember Mrs. DeStephano? When we last heard about her she was being admitted for further studies. Relative to her skeletal system, the following notes have been added to her chart.

- Fracture of superior right tibia (shinbone of leg); skin lacerated; area cleaned and protruding bone fragments subjected to internal (open) reduction and casted
- Nutrient artery of tibia damaged
- Medial meniscus (hyaline cartilage disc) of right knee joint crushed; knee joint inflamed and painful

Relative to these notes:

1. What type of fracture does Mrs. DeStephano have?
2. What problems can be predicted with such fractures and how are they treated?
3. What is internal reduction? Why was a cast applied?
4. Given an uncomplicated recovery, approximately how long should it take before Mrs. DeStephano has a good solid bony callus?
5. What complications might be predicted by the fact that the nutrient artery is damaged?
6. What new techniques might be used to enhance fracture repair if healing is delayed or impaired?
7. How likely is it that Mrs. DeStephano's knee cartilage will regenerate? Why?

(Answers in Appendix G)

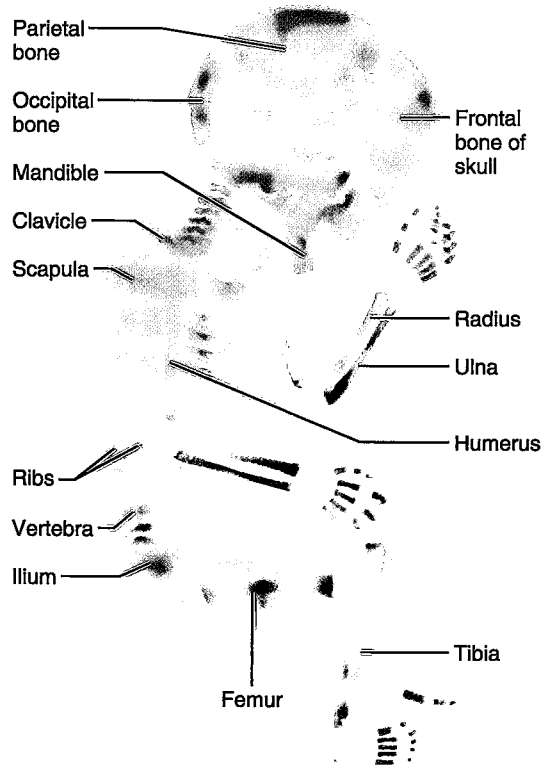


FIGURE 6.15 **Fetal primary ossification centers at 12 weeks.** The darker areas indicate primary ossification centers in the skeleton of a 12-week-old fetus.

Its cause is unknown, but it may be initiated by a virus. Drug therapies include calcitonin (now administered by a nasal inhaler), and the newer bisphosphonates (etidronate, alendronate, and others) which have shown success in preventing bone breakdown.

Developmental Aspects of Bones: Timing of Events

Bones are on a precise schedule from the time they form until death. The mesoderm germ layer gives rise to embryonic mesenchymal cells, which in turn produce the membranes and cartilages that form the embryonic skeleton. These structures then ossify according to an amazingly predictable timetable that allows fetal age to be determined easily from either X rays or sonograms. Although each bone has its own developmental schedule, most long bones begin ossifying by 8 weeks after conception and have obvious primary ossification centers by 12 weeks (Figure 6.15).

At birth, most long bones of the skeleton are well ossified except for their epiphyses. After birth, secondary ossification centers develop in a predictable sequence. The epiphyseal plates persist and provide for long bone growth during childhood and the sex hormone–mediated growth spurt at adolescence. By the age of 25 years, nearly all bones are completely ossified and skeletal growth ceases.

In children and adolescents, bone formation exceeds bone resorption; in young adults, these processes are in balance; in old age, resorption predominates. Despite the environmental factors (listed above) that influence bone density, genetics still plays the major role in determining how much one's bone density will change over a lifetime. A single gene that codes for vitamin D's cellular docking site helps determine both the tendency to accumulate bone mass during early life and one's risk of osteoporosis later in life. Beginning in the fourth decade of life, bone mass decreases with age; the only exception appears to be in bones of the skull. Among young adults, skeletal mass is generally greater in males than in females, and greater in blacks than in whites. Age-related bone loss is faster in whites than in blacks (who have greater bone density to begin with) and faster in females than in males. Qualitative changes also occur: More osteons remain incompletely formed, mineralization is less complete, and the amount of nonviable bone increases, reflecting a diminished blood supply to the bones in old age.

■ ■ ■

Skeletal cartilages and bones—their architecture, composition, and dynamic nature—have been examined in this chapter. We have also discussed the role of bones in maintaining overall body homeostasis, as summarized in *Making Connections*. Now we are ready to look at the individual bones of the skeleton and how they contribute to its functions, both collectively and individually.

Related Clinical Terms

Achondroplasia (a-kon″dro-pla′ze-ah; *a* = without; *chondro* = cartilage; *plasi* = mold, shape) A congenital condition involving defective cartilage and endochondral bone growth so that the limbs are too short but the membrane bones are of normal size; a type of dwarfism.

Bony spur Abnormal projection from a bone due to bony overgrowth; common in aging bones.

Ostealgia (os″te-al′je-ah; *algia* = pain) Pain in a bone.

Osteitis (os″te-i′tis; *itis* = inflammation) Inflammation of bony tissue.

Osteogenesis imperfecta Also called brittle bone disease, a disorder in which the bone matrix contains inadequate amounts of collagen, putting it at risk for shattering.

Osteomyelitis (os″te-o-mi″ĕ-l-li′tis) Inflammation of bone and bone marrow caused by pus-forming bacteria that enter the body via a wound (e.g., compound bone fracture), or spread from an infection near the bone. Commonly affects the long bones, causing acute pain and fever. May result in joint stiffness, bone destruction, and shortening of a limb. Treatment involves antibiotic therapy, draining of any abscesses (local collections of pus) formed, and removal of dead bone fragments (which prevent healing).

Osteosarcoma (os″te-o-sar-ko′mah) A form of bone cancer typically arising in a long bone of a limb and most often in those 10–25 years of age. Grows aggressively, painfully eroding the bone; tends to metastasize to the lungs and cause secondary lung tumors. Usual treatment is amputation of the affected bone or limb, followed by chemotherapy and surgical removal of any metastases. Survival rate is about 50% if detected early.

Pathologic fracture Fracture in a diseased bone involving slight (coughing or a quick turn) or no physical trauma. For example, a hip bone weakened by osteoporosis may break and cause the person to fall, rather than breaking because of the fall.

Traction ("pulling") Placing sustained tension on a body region to keep the parts of a fractured bone in proper alignment; also prevents spasms of skeletal muscles, which would separate the fractured bone ends or crush the spinal cord in the case of vertebral column fractures.

Chapter Summary

Skeletal Cartilages (p. 176)

Basic Structure, Types, and Locations (p. 176)

1. A skeletal cartilage exhibits chondrocytes housed in lacunae (cavities) within the extracellular matrix (ground substance and fibers). It contains large amounts of water (which accounts for its resilience), lacks nerve fibers, is avascular, and is surrounded by a fibrous perichondrium that resists expansion.

2. Hyaline cartilages appear glassy; the fibers are collagenic. They provide support with flexibility and resilience and are the most abundant skeletal cartilages, accounting for the articular, costal, respiratory, and nasal cartilages.

3. Elastic cartilages contain abundant elastic fibers, in addition to collagen fibers, and are more flexible than hyaline cartilages. They support the outer ear and epiglottis.

4. Fibrocartilages, which contain thick collagen fibers, are the most compressible cartilages and are resistant to stretch. They form vertebral discs and knee joint cartilages.

Growth of Cartilage (p. 176)

5. Cartilages grow from within (interstitial growth) and by addition of new cartilage tissue at the periphery (appositional growth).

Classification of Bones (pp. 176–178)

1. Bones are classified as long, short, flat, or irregular on the basis of their shape and their proportion of compact or spongy bone.

Functions of Bones (pp. 178–179)

1. Bones give the body shape; protect and support body organs; provide levers for muscles to pull on; store calcium and other minerals; and are the site of blood cell production.

Bone Structure (pp. 179–184)

Gross Anatomy (pp. 179–181)

1. Bone markings are important anatomical landmarks that reveal sites of muscle attachment, points of articulation, and sites of blood vessels and nerve passage.

2. A long bone is composed of a diaphysis (shaft) and epiphyses (ends). The medullary cavity of the diaphysis contains yellow marrow; the epiphyses contain spongy bone. The epiphyseal line is the remnant of the epiphyseal plate. Periosteum covers the diaphysis; endosteum lines inner bone cavities. Hyaline cartilage covers joint surfaces.

3. Flat bones consist of two thin plates of compact bone enclosing a diploë (spongy bone layer). Short and irregular bones resemble flat bones structurally.

4. In adults, hematopoietic tissue is found within the diploë of flat bones and occasionally within the epiphyses of long bones. In infants red marrow is also found in the medullary cavity.

Microscopic Anatomy of Bone (pp. 181–182)

5. The structural unit of compact bone, the osteon, consists of a central canal surrounded by concentric lamellae of bone matrix. Osteocytes, embedded in lacunae, are connected to each other and the central canal by canaliculi.

6. Spongy bone has slender trabeculae containing irregular lamellae, which enclose red marrow–filled cavities.

Chemical Composition of Bone (pp. 182–184)

7. Bone is composed of living cells (osteogenic cells, osteoblasts, osteocytes, and osteoclasts) and matrix. The matrix includes osteoid, organic substances that are secreted by osteoblasts and give the bone tensile strength. Its inorganic components, the hydroxyapatites (calcium salts), make bone hard.

Bone Development (pp. 184–187)

Formation of the Bony Skeleton (pp. 184–186)

1. Intramembranous ossification forms the clavicles and most skull bones. The ground substance of the bone matrix is deposited between collagen fibers within the fibrous membrane to form spongy bone. Eventually, compact bone plates enclose the diploë.

2. Most bones are formed by endochondral ossification of a hyaline cartilage model. Osteoblasts beneath the periosteum secrete bone matrix on the cartilage model, forming the bone collar. Deterioration of the cartilage model internally opens up cavities, allowing periosteal bud entry. Bone matrix is deposited around the cartilage remnants but is later broken down.

Postnatal Bone Growth (pp. 186–187)

3. Long bones increase in length by interstitial growth of the epiphyseal plate cartilage and its replacement by bone.

4. Appositional growth increases bone diameter/thickness.

Bone Homeostasis: Remodeling and Repair (pp. 187–193)

Bone Remodeling (pp. 188–190)

1. New bone is continually deposited and resorbed in response to hormonal and mechanical stimuli. Together these processes constitute bone remodeling.

2. An osteoid seam appears at areas of new bone deposit; calcium salts are deposited a few days later.

3. Osteoclasts release lysosomal enzymes and acids on bone surfaces to be resorbed. The dissolved products are transcytosed to the opposite face of the osteoclast for release to the extracellular fluid.

4. The hormonal mechanism of bone remodeling serves blood calcium homeostasis. When blood calcium levels decline, PTH is released and stimulates osteoclasts to digest bone matrix, releasing ionic calcium. When blood calcium levels rise, calcitonin is released, stimulating removal of calcium from the blood. Mechanical stress and gravity acting on the skeleton help maintain skeletal strength. Bones thicken, develop heavier prominences, or rearrange their trabeculae in sites where stressed.

Bone Repair (pp. 190–193)

5. Fractures are treated by open or closed reduction. The healing process involves formation of a hematoma, a fibrocartilaginous callus, a bony callus, and bone remodeling, in succession.

Homeostatic Imbalances of Bone (pp. 193–195, 198)

1. Imbalances between bone formation and resorption underlie all skeletal disorders.

2. Osteomalacia and rickets occur when bones are inadequately mineralized. The bones become soft and deformed. The most frequent cause is inadequate vitamin D.

3. Osteoporosis is any condition in which bone breakdown outpaces bone formation, causing bones to become weak and porous. Postmenopausal women are particularly susceptible.

4. Paget's disease is characterized by excessive and abnormal bone remodeling.

Developmental Aspects of Bones: Timing of Events (p. 198)

1. Osteogenesis is predictable and precisely timed.

2. Longitudinal long bone growth continues until the end of adolescence. Skeletal mass increases dramatically during puberty and adolescence, when formation exceeds resorption.

3. Bone mass is fairly constant in young adulthood, but beginning in the 40s, bone resorption exceeds formation.

Review Questions

Multiple Choice/Matching

(Some questions have more than one correct answer. Select the best answer or answers from the choices given.)

1. Which is a function of the skeletal system? (a) support, (b) hematopoietic site, (c) storage, (d) providing levers for muscle activity, (e) all of these.

2. A bone with approximately the same width, length, and height is most likely (a) a long bone, (b) a short bone, (c) a flat bone, (d) an irregular bone.

3. The shaft of a long bone is properly called the (a) epiphysis, (b) periosteum, (c) diaphysis, (d) compact bone.

4. Sites of hematopoiesis include all but (a) red marrow cavities of spongy bone, (b) the diploë of flat bones, (c) medullary cavities in bones of infants, (d) medullary cavities in bones of a healthy adult.

5. An osteon has (a) a central canal carrying blood vessels, (b) concentric lamellae, (c) osteocytes in lacunae, (d) canaliculi that connect lacunae to the central canal, (e) all of these.

6. The organic portion of matrix is important in providing *all but* (a) tensile strength, (b) hardness, (c) ability to resist stretch, (d) flexibility.

7. The flat bones of the skull develop from (a) areolar tissue, (b) hyaline cartilage, (c) fibrous connective tissue, (d) compact bone.

8. The remodeling of bone is a function of which cells? (a) chondrocytes and osteocytes, (b) osteoblasts and osteoclasts, (c) chondroblasts and osteoclasts, (d) osteoblasts and osteocytes.

9. Bone growth during childhood and in adults is regulated and directed by (a) growth hormone, (b) thyroid hormones, (c) sex hormones, (d) mechanical stress, (e) all of these.

10. Where within the epiphyseal plate are the *dividing* cartilage cells located? (a) nearest the shaft, (b) in the marrow cavity, (c) farthest from the shaft, (d) in the primary ossification center.

11. Wolff's law is concerned with (a) calcium homeostasis of the blood, (b) the thickness and shape of a bone being determined by mechanical and gravitational stresses placed on it, (c) the electrical charge on bone surfaces.

12. Formation of the bony callus in fracture repair is followed by (a) hematoma formation, (b) fibrocartilaginous callus formation, (c) bone remodeling to convert woven bone to compact bone, (d) formation of granulation tissue.

13. The fracture type in which the bone ends are incompletely separated is (a) greenstick, (b) compound, (c) simple, (d) comminuted, (e) compression.

14. The disorder in which bones are porous and thin but bone composition is normal is (a) osteomalacia, (b) osteoporosis, (c) Paget's disease.

Short Answer Essay Questions

15. Compare bone to cartilage tissue relative to its resilience, speed of regeneration, and access to nutrients.

16. Describe in proper order the events of endochondral ossification.

17. Compare compact and spongy bone in macroscopic appearance, microscopic structure, and relative location.

18. As we grow, our long bones increase in diameter, but the thickness of the bony collar of the shaft remains relatively constant. Explain this phenomenon.

19. Describe the process of new bone formation in an adult bone. Use the terms *osteoid seam* and *calcification front* in your discussion.

20. Compare and contrast controls of bone remodeling exerted by hormones and by mechanical and gravitational forces relative to the actual purpose of each control system and changes in bone architecture that might occur.

21. (a) During what period of life does skeletal mass increase dramatically? Begin to decline? (b) Why are fractures most common in elderly individuals? (c) Why are greenstick fractures most common in children?

22. Yolanda is asked to review a bone slide that her professor has set up under the microscope. She sees concentric layers surrounding a central cavity. Is this bone section taken from the diaphysis or the epiphyseal plate of the specimen?

Critical Thinking and Clinical Application Questions

1. Following a motorcycle accident, a 22-year-old man was rushed to the emergency room. X rays revealed a spiral fracture of his right tibia (main bone of the leg). Two months later, X rays revealed good bony callus formation. What is bony callus?

2. Mrs. Abbruzzo brought her 4-year-old daughter to the doctor, complaining that she didn't "look right." The child's forehead was enlarged, her rib cage was knobby, and her lower limbs were bent and deformed. X rays revealed very thick epiphyseal plates. Mrs. Abbruzzo was advised to increase dietary amounts of vitamin D and milk and to "shoo" the girl outside to play in the sun. Considering the child's signs and symptoms, what disease do you think she has? Explain the doctor's instructions.

3. You overhear some anatomy students imagining out loud what their bones would look like if they had compact bone on the inside and spongy bone on the outside, instead of the other way around. You tell them that such imaginary bones would be poorly designed mechanically and would break easily. Explain your reason for saying this.

4. Why do you think wheelchair-bound people with paralyzed lower limbs have thin, weak leg and thigh bones?

5. Jay Beckenstein went to weight-lifting camp in the summer between seventh and eighth grade. He noticed that the camp trainer put tremendous pressure on him and his friends to improve their strength. After an especially vigorous workout, Jay's arm felt extremely sore and weak around the elbow. He went to the camp doctor, who took X rays and then told him that the injury was serious, for the "end of his upper arm bone was starting to twist off." What had happened? Could the same thing happen to Jay's 23-year-old sister, Trixie, who was also starting a program of weight lifting? Why or why not?

6. After splashdown in the Atlantic Ocean, the American astronaut team was brought to the Naval Hospital for checkups. X rays revealed decreased bone mass in all of them. Isn't this surprising in view of the fact that they exercised regularly in the space capsule? Explain.

7. Old Norse stories tell of a famous Viking named Egil, who lived around 900 AD. His skull was greatly enlarged and misshapen, and the cranial bones were thickened (6 cm, more than 2 inches, thick). After he died, his skull was dug up and it withstood the blow of an ax without damage. In life, he had headaches from the pressure exerted by enlarged vertebrae on his spinal cord. So much blood was diverted to his bones to support their extensive remodeling that his fingers and toes always felt cold and his heart was damaged through overexertion. What bone disorder did Egil probably have?

8. The serving arm of many tennis players is often significantly larger (thicker) than the other arm. Explain this phenomenon.

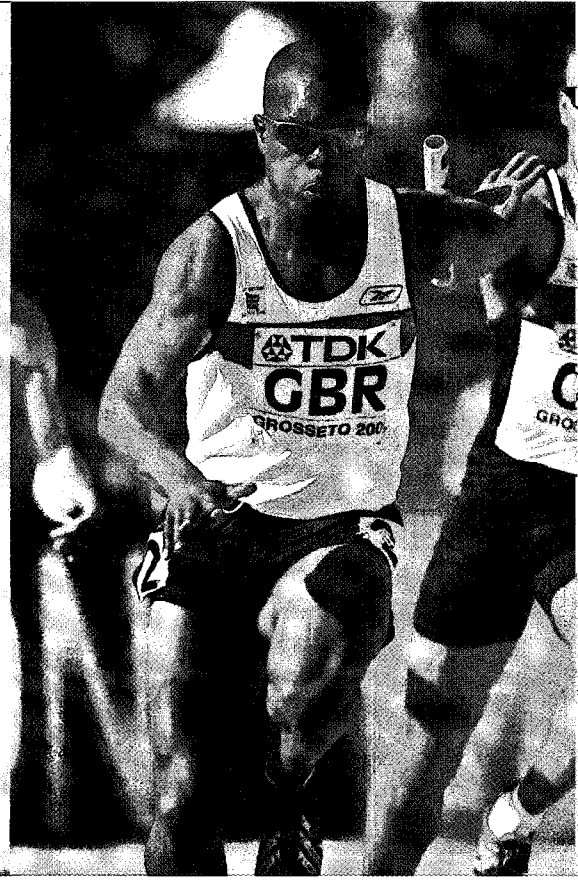
CHAPTER

The Skeleton



1. Name the major parts of the axial and appendicular skeletons and describe their relative functions.

PART 1: THE AXIAL SKELETON

The Skull (pp. 203–218)

2. Name, describe, and identify the skull bones. Identify their important markings.
3. Compare and contrast the major functions of the cranium and the facial skeleton.
4. Define the bony boundaries of the orbits, nasal cavity, and paranasal sinuses.

The Vertebral Column (pp. 218–225)

5. Describe the structure of the vertebral column, list its components, and describe its curvatures.
6. Indicate a common function of the spinal curvatures and the intervertebral discs.
7. Discuss the structure of a typical vertebra and describe regional features of cervical, thoracic, and lumbar vertebrae.

The Thoracic Cage (pp. 226–228)

8. Name and describe the bones of the thoracic cage (bony thorax).
9. Differentiate true from false ribs.

PART 2: THE APPENDICULAR SKELETON

The Pectoral (Shoulder) Girdle (pp. 229–231)

10. Identify bones forming the pectoral girdle and relate their structure and arrangement to the function of this girdle.
11. Identify important bone markings on the pectoral girdle.

The Upper Limb (pp. 231–237)

12. Identify or name the bones of the upper limb and their important markings.

The Pelvic (Hip) Girdle (pp. 237–239)

13. Name the bones contributing to the os coxa and relate the pelvic girdle's strength to its function.
14. Describe differences in the male and female pelves and relate these to functional differences.

The Lower Limb (pp. 239–246)

15. Identify the lower limb bones and their important markings.
16. Name the arches of the foot and explain their importance.

Developmental Aspects of the Skeleton (pp. 246–248)

17. Define fontanels and indicate their significance.
18. Describe how skeletal proportions change through life.
19. Discuss how age-related skeletal changes may affect health.

The word *skeleton* comes from the Greek word meaning "dried-up body" or "mummy," a rather unflattering description. Nonetheless, the human skeleton is a triumph of design and engineering that puts most skyscrapers to shame. It is strong, yet light, and almost perfectly adapted for the protective, locomotor, and manipulative functions it performs.

The **skeleton,** or **skeletal system,** composed of bones, cartilages, joints, and ligaments, accounts for about 20% of body mass (about 30 pounds in a 160-pound person). Bones make up most of the skeleton. Cartilages occur only in isolated areas, such as the nose, parts of the ribs, and the joints. Ligaments connect bones and reinforce joints, allowing required movements while restricting motions in other directions. Joints, the junctions between bones, provide for the remarkable mobility of the skeleton. Joints and ligaments are discussed separately in Chapter 8.

PART 1: THE AXIAL SKELETON

As described in Chapter 6, the skeleton is divided into *axial* and *appendicular* portions (see Figure 6.1) for descriptive purposes. The **axial skeleton** is structured from 80 bones segregated into three major regions: the *skull, vertebral column,* and *thoracic cage* (Figure 7.1). This part of the skeleton supports the head, neck, and trunk, and it protects the brain, spinal cord, and the organs in the thorax.

The Skull

The **skull** is the body's most complex bony structure. It is formed by *cranial* and *facial bones,* 22 in all. The cranial bones, or **cranium** (kra'ne-um), enclose and protect the fragile brain and furnish attachment sites for head and neck muscles. The facial bones (1) form the framework of the face, (2) contain cavities for the special sense organs of sight, taste, and smell, (3) provide openings for air and food passage, (4) secure the teeth, and (5) anchor the facial muscles of expression, which we use to show our feelings. As you will see, the individual skull bones are well suited to their assignments.

Most skull bones are flat bones. Except for the mandible, which is connected to the rest of the skull by a freely movable joint, all bones of the adult skull are firmly united by interlocking joints called **sutures** (soo'cherz). The suture lines have a saw-toothed or serrated appearance. The major skull sutures, the *coronal, sagittal, squamous,* and *lambdoid sutures,* connect cranial bones (Figures 7.2b and 7.3a). Most other skull sutures connect facial bones and are named according to the specific bones they connect.

Overview of Skull Geography

It is worth surveying basic skull "geography" before describing the individual bones. With the lower jaw removed, the skull resembles a lopsided, hollow, bony sphere. The facial bones form its anterior aspect, and the cranium forms the rest of the skull (see Figure 7.3a). The cranium can be divided into a vault and a base. The *cranial vault,* also called the *calvaria* (kal-va're-ah; "bald part of skull"), forms the superior, lateral, and posterior aspects of the skull, as well as the forehead. The *cranial base,* or *floor,* forms the skull's inferior aspect. Internally, prominent bony ridges divide the base into three distinct "steps" or fossae—the *anterior, middle,* and *posterior cranial fossae* (see Figure 7.4c on p. 208). The brain sits snugly in these cranial fossae, completely enclosed by the cranial vault. Overall, the brain is said to occupy the *cranial cavity.*

In addition to the large cranial cavity, the skull has many smaller cavities. These include the middle and internal ear cavities (carved into the lateral side of its base) and, anteriorly, the nasal cavity and the orbits (see Figure 1.13, p. 19). The *orbits* house the eyeballs. Several bones of the skull contain air-filled sinuses, which lighten the skull.

The skull also has about 85 named openings (foramina, canals, fissures, etc.). The most important of these provide passageways for the spinal cord, the major blood vessels serving the brain, and the 12 pairs of cranial nerves (numbered I through XII), which transmit impulses to and from the brain.

As you read about the bones of the skull, locate each bone on the different skull views in Figures 7.2, 7.3, and 7.4. The skull bones and their important markings are also summarized in Table 7.1 (pp. 216–217). The color-coded boxes before a bone's name in the text and in Table 7.1 correspond to the color of that bone in the figures.

Cranium

The eight cranial bones are the paired parietal and temporal bones and the unpaired frontal, occipital, sphenoid, and ethmoid bones. Together, these construct the brain's protective bony "helmet." Because its superior aspect is curved, the cranium is self-bracing. This allows the bones to be thin, and, like an eggshell, the cranium is remarkably strong for its weight.

Frontal Bone

The shell-shaped **frontal bone** (Figures 7.2a, 7.3, and 7.4b) forms the anterior cranium. It articulates posteriorly with the paired parietal bones via the prominent *coronal suture.*

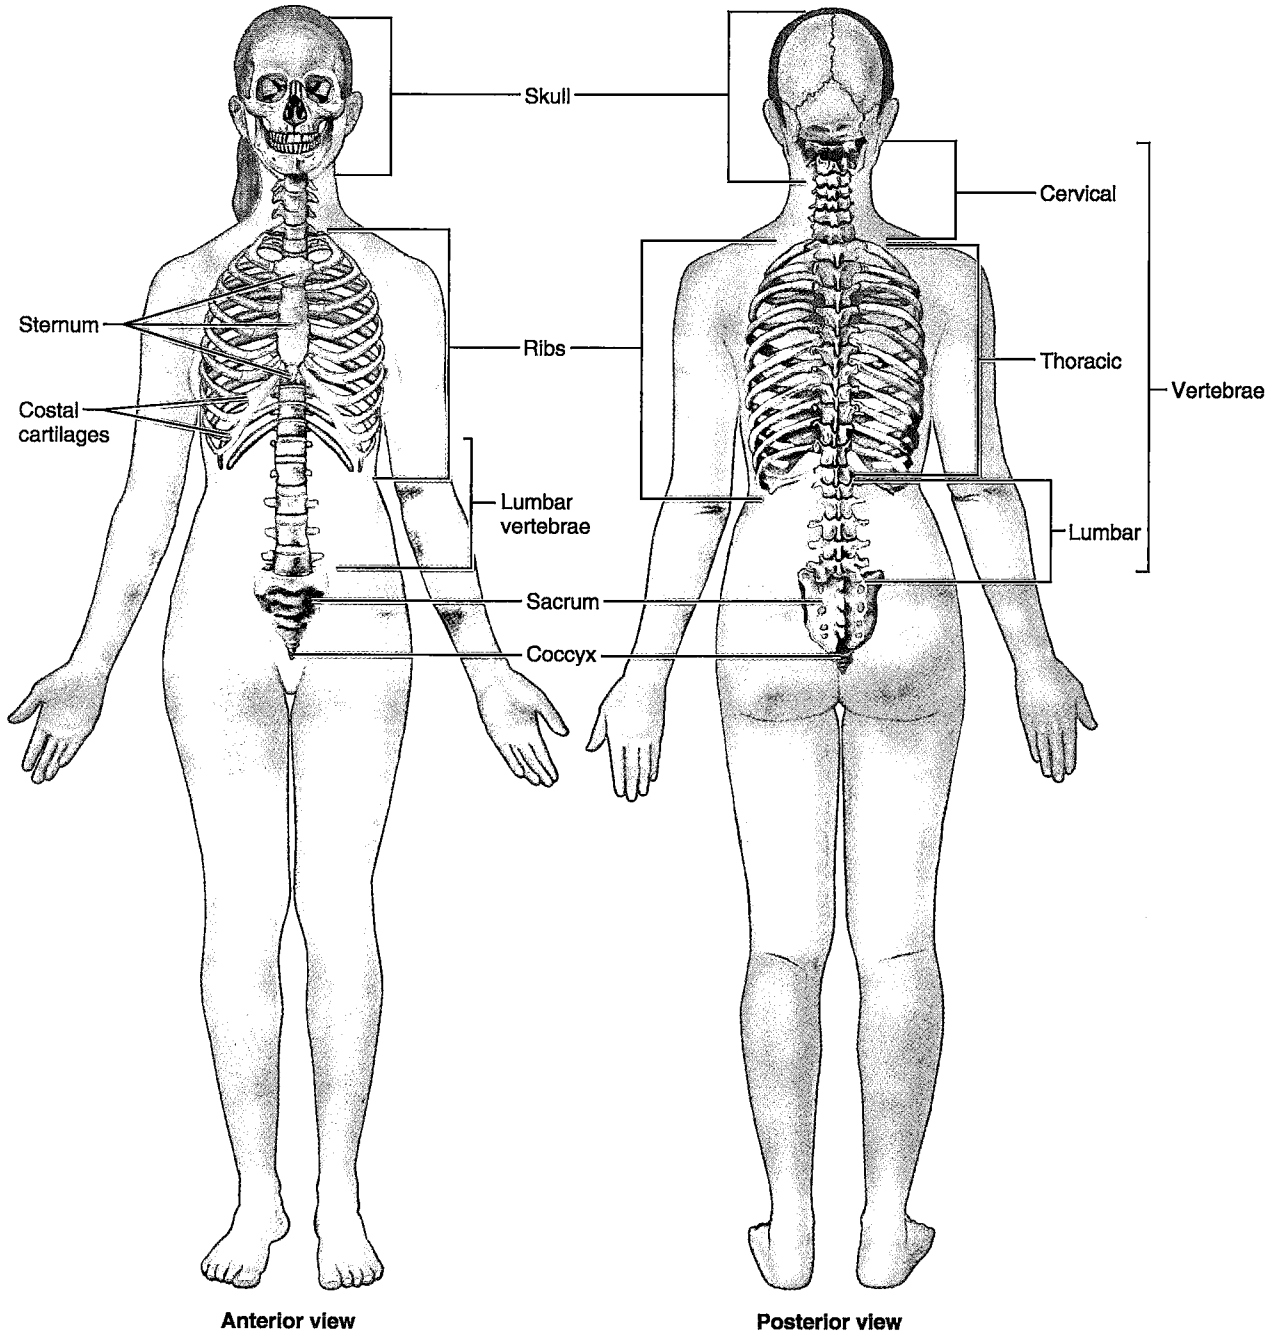


FIGURE 7.1 **Bones of the axial skeleton.** The three major subdivisions are the skull, thoracic cage (sternum and ribs), and vertebral column (vertebrae, sacrum, and coccyx).

The most anterior part of the frontal bone is the vertical *frontal squama,* commonly called the *forehead.* The frontal squama ends inferiorly at the **supraorbital margins,** the thickened superior margins of the orbits that lie under the eyebrows. From here, the frontal bone extends posteriorly, forming the superior wall of the *orbits* and most of the **anterior cranial fossa** (Figure 7.4b and c). This fossa supports the frontal lobes of the brain. Each supraorbital margin is pierced by a **supraorbital foramen (notch),** which allows the supraorbital artery and nerve to pass to the forehead.

The smooth portion of the frontal bone between the orbits is the **glabella** (glah-bel'ah). Just inferior to this the frontal bone meets the nasal bones at the *frontonasal suture* (Figure 7.2a). The areas lateral to the glabella are riddled internally with sinuses, called the **frontal sinuses** (Figures 7.3b and 7.11).

Q *(1) Which of the bones illustrated in view (a) are cranial bones? (2) Which two terms are used interchangeably to indicate the entire group of cranial bones?*

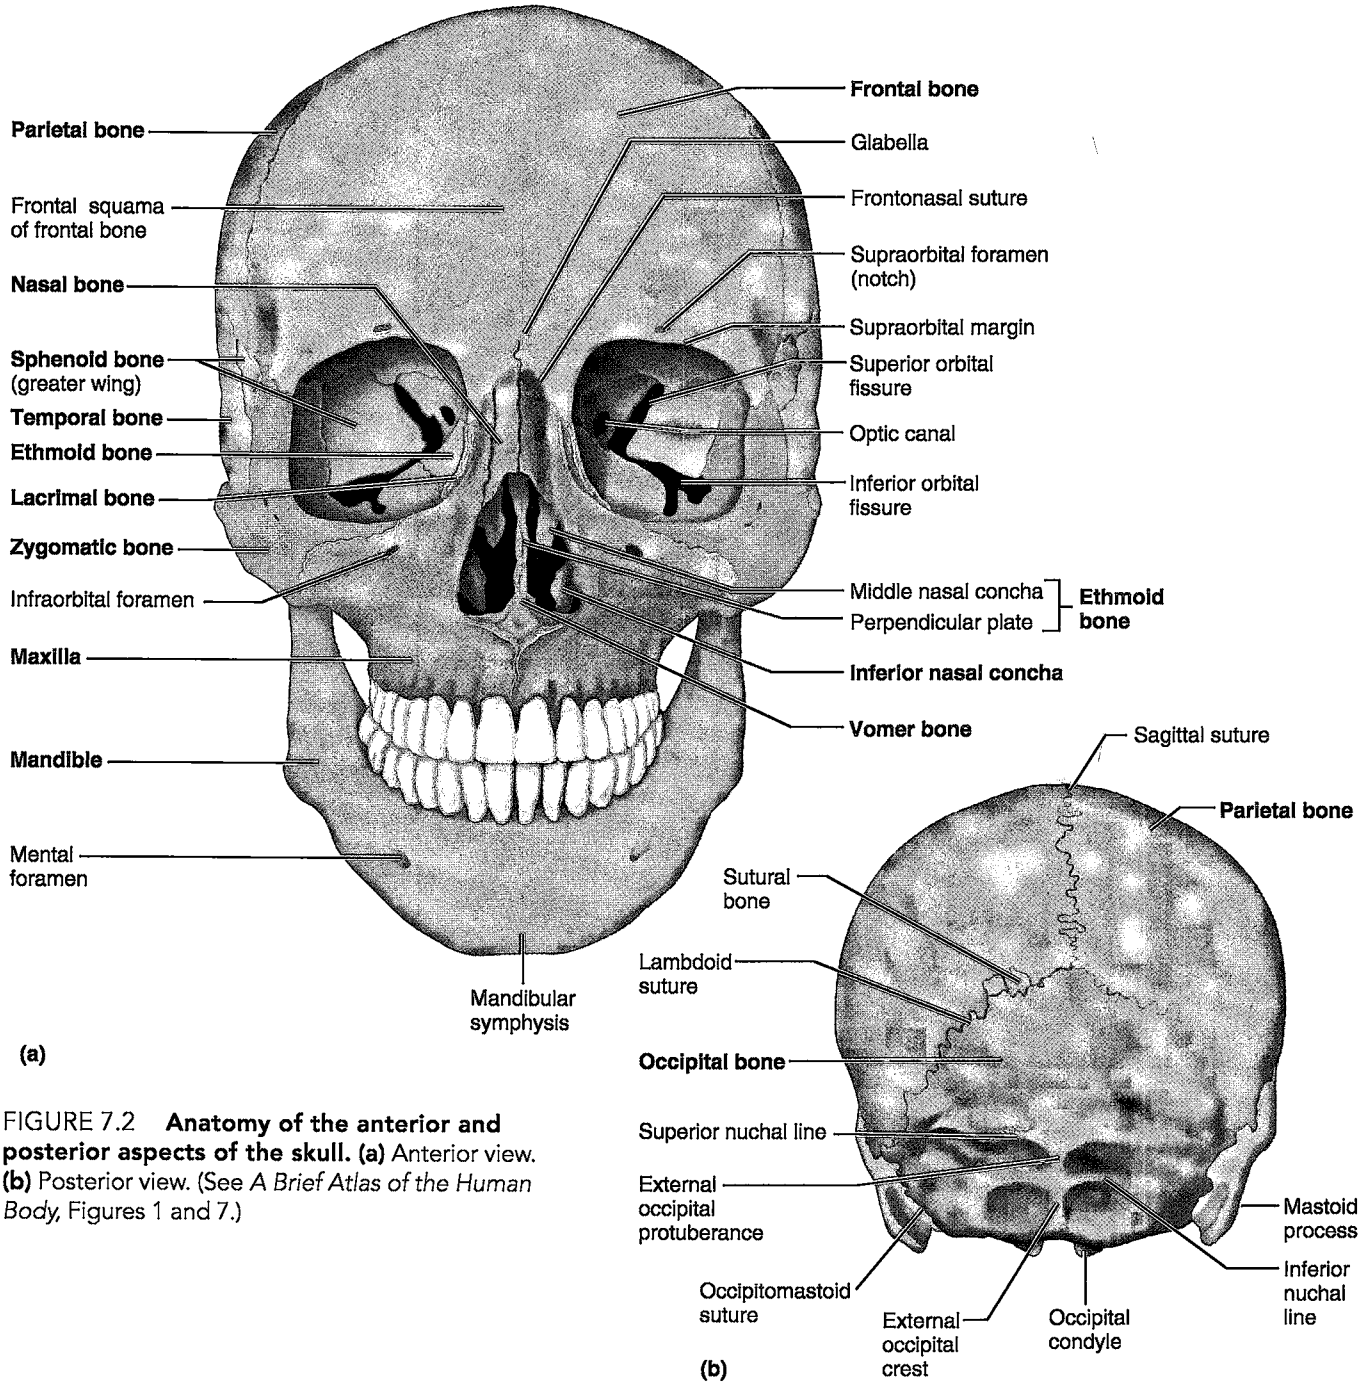

FIGURE 7.2 **Anatomy of the anterior and posterior aspects of the skull. (a)** Anterior view. **(b)** Posterior view. (See *A Brief Atlas of the Human Body*, Figures 1 and 7.)

A *(1) The temporals, parietals, frontal, ethmoid, and sphenoid are all cranial bones. (2) The cranial vault or calvaria.*

Parietal Bones and the Major Sutures

The two large **parietal bones** are curved, rectangular bones that form most of the superior and lateral aspects of the skull; hence they form the bulk of the

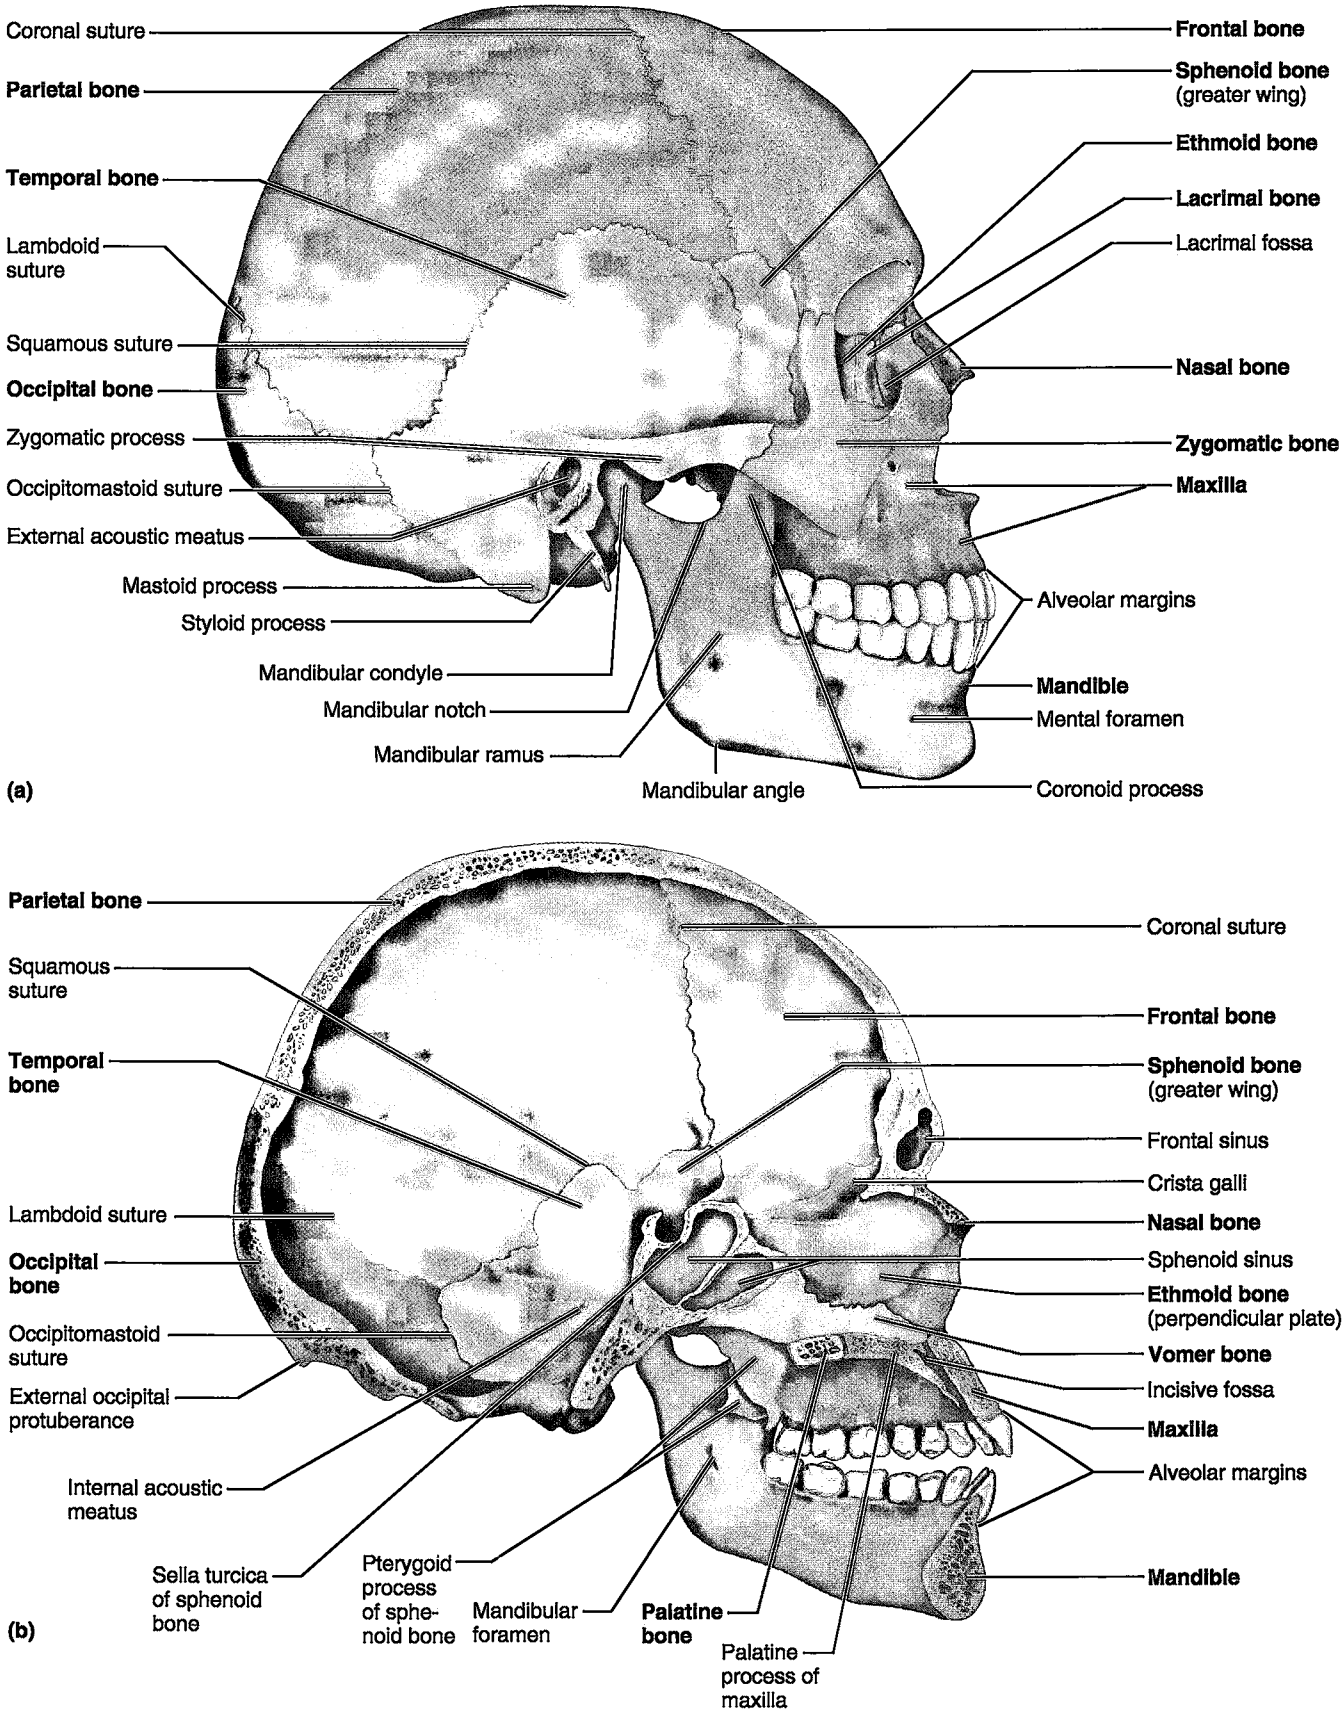

FIGURE 7.3 **Anatomy of the lateral aspects of the skull. (a)** External anatomy of the right lateral aspect of the skull. **(b)** Midsagittal view of the skull showing the internal anatomy of the left side of the skull. (See *A Brief Atlas of the Human Body,* Figures 2 and 3.)

cranial vault. The four largest sutures occur where the parietal bones articulate (form a joint) with other cranial bones:

1. The **coronal suture** (kŏ-ro'nul), where the parietal bones meet the frontal bone anteriorly (Figure 7.3)
2. The **sagittal suture,** where the parietal bones meet superiorly at the cranial midline (Figure 7.2b)
3. The **lambdoid suture** (lam'doid), where the parietal bones meet the occipital bone posteriorly (see Figures 7.2b and 7.3)
4. The **squamous** (or **squamosal**) **suture** (one on each side), where a parietal and temporal bone meet on the lateral aspect of the skull (see Figure 7.3)

Occipital Bone

The **occipital bone** (ok-sip'ĭ-tal) forms most of the skull's posterior wall and base. It articulates anteriorly with the paired parietal and temporal bones via the *lambdoid* and *occipitomastoid sutures,* respectively (Figure 7.3). It also joins with the sphenoid bone in the cranial floor via a plate called the *basiocciptal,* which bears a midline projection called the *pharyngeal tubercle* (fah-rin'je-ul) (Figure 7.4a).

Internally, the occipital bone forms the walls of the **posterior cranial fossa** (Figure 7.4b and c), which supports the cerebellum of the brain. In the base of the occipital bone is the **foramen magnum** ("large hole") through which the inferior part of the brain connects with the spinal cord. The foramen magnum is flanked laterally by two occipital condyles (Figure 7.4a). The rockerlike **occipital condyles** articulate with the first vertebra of the spinal column in a way that permits a nodding movement of the head. Hidden medially and superiorly to each occipital condyle is a **hypoglossal canal** (Figure 7.4b), through which a nerve of the same name passes.

Just superior to the foramen magnum is a median protrusion called the **external occipital protuberance** (see Figures 7.2b, 7.3b, and 7.4a). You can feel this knoblike projection just below the most bulging part of your posterior skull. A number of inconspicuous ridges, the *external occipital crest* and the *superior* and *inferior nuchal lines* (nu'kal), mark the occipital bone near the foramen magnum. The external occipital crest secures the *ligamentum nuchae* (lig"ah-men'tum noo'ke; *nucha* = back of the neck), an elastic ligament that connects the vertebrae of the neck to the skull. The nuchal lines, and the bony regions between them, anchor many neck and back muscles. The superior nuchal line marks the upper limit of the neck.

Temporal Bones

The two **temporal bones** are best viewed on the lateral skull surface (see Figure 7.3). They lie inferior to the parietal bones and meet them at the squamous sutures. The temporal bones form the inferolateral aspects of the skull and parts of the cranial floor. The use of the terms *temple* and *temporal,* from the Latin word *temporum,* meaning "time," came about because gray hairs, a sign of time's passing, usually appear first in the temple areas.

Each temporal bone has a complicated shape and is described in terms of its four major areas, the *squamous, tympanic, mastoid,* and *petrous regions.* The flaring **squamous region** abuts the squamous suture. It has a barlike **zygomatic process** that meets the zygomatic bone of the face anteriorly. Together, these two bony structures form the **zygomatic arch,** which you can feel as the projection of your cheek (*zygoma* = cheekbone). The small, oval **mandibular fossa** (man-dib'u-lar) on the inferior surface of the zygomatic process receives the condyle of the mandible (lower jawbone), forming the freely movable *temporomandibular joint.*

The **tympanic region** (tim-pan'ik; "eardrum") (Figure 7.5) of the temporal bone surrounds the **external acoustic meatus,** or external ear canal, through which sound enters the ear. The external acoustic meatus and the eardrum at its deep end are part of the *external ear.* In a dried skull, the eardrum has been removed; thus, part of the middle ear cavity deep to the external meatus can also be seen. Below the external acoustic meatus is the needle-like **styloid process** (sti'loid; "stakelike"), an attachment point for several tongue and neck muscles and for a ligament that secures the hyoid bone of the neck to the skull (see Figure 7.12).

The **mastoid region** (mas'toid; "breast") of the temporal bone exhibits the conspicuous **mastoid process,** an anchoring site for some neck muscles (see Figures 7.3a, 7.4a, and 7.5). The mastoid process can be felt as a lump just posterior to the ear. The **stylomastoid foramen,** between the styloid and mastoid processes, allows cranial nerve VII (the facial nerve) to leave the skull (Figure 7.4a).

HOMEOSTATIC IMBALANCE

The mastoid process is full of air cavities, the **mastoid sinuses,** or **air cells.** Its position adjacent to the middle ear cavity (a high-risk area for infections spreading from the throat) puts it at risk for infection itself. A mastoid sinus infection, or *mastoiditis,* is notoriously difficult to treat. Since the mastoid air cells are separated from the brain by only a very thin bony plate, mastoid infections may spread to the brain as well. Surgical removal of the mastoid process was once the best way to prevent life-threatening brain inflammations in people susceptible to repeated bouts of mastoiditis. Today, antibiotic therapy is the treatment of choice. ●

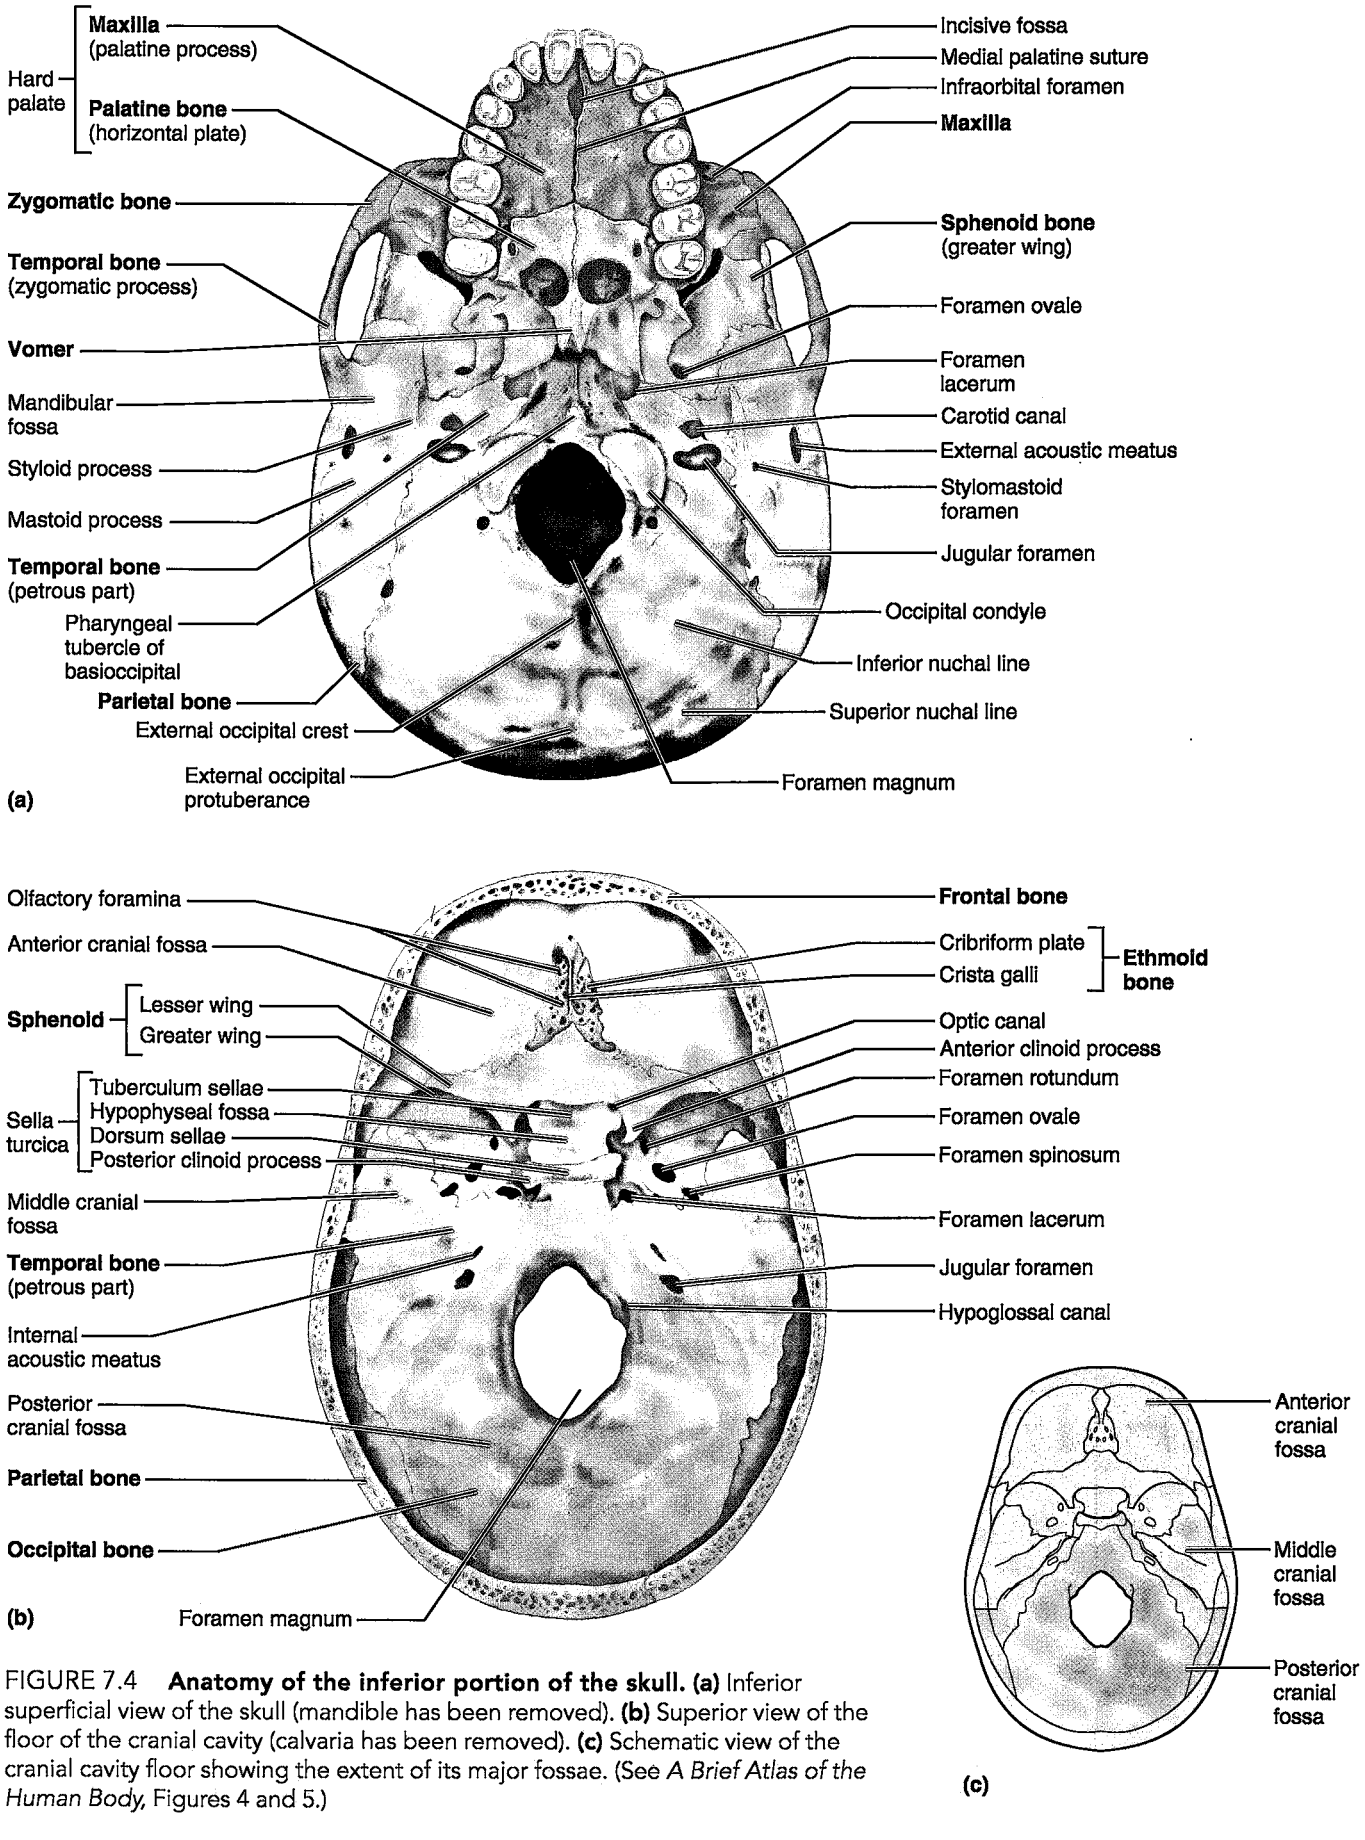

FIGURE 7.4 **Anatomy of the inferior portion of the skull. (a)** Inferior superficial view of the skull (mandible has been removed). **(b)** Superior view of the floor of the cranial cavity (calvaria has been removed). **(c)** Schematic view of the cranial cavity floor showing the extent of its major fossae. (See *A Brief Atlas of the Human Body*, Figures 4 and 5.)

The deep **petrous** (pet'rus) part of the temporal bone contributes to the cranial base (Figure 7.4). It looks like a miniature mountain ridge (*petrous* = rocky) between the occipital bone posteriorly and the sphenoid bone anteriorly. The posterior slope of this ridge lies in the posterior cranial fossa; the anterior slope is in the middle cranial fossa. Together, the sphenoid bone and the petrous portions of the temporal bones construct the **middle cranial fossa** (see Figure 7.4b and c), which supports the temporal lobes of the brain. Housed in the petrous are the *middle* and *internal ear cavities*, which contain sensory receptors for hearing and balance.

Several foramina penetrate the bone of the petrous region (Figure 7.4a). The large **jugular foramen** at the junction of the occipital and petrous temporal bones allows passage of the internal jugular vein and three cranial nerves. The **carotid canal** (kar-rot'id), just anterior to the jugular foramen, transmits the internal carotid artery into the cranial cavity. The two internal carotid arteries supply blood to over 80% of the cerebral hemispheres of the brain; their closeness to the internal ear cavities explains why, during excitement or exertion, we sometimes hear our rapid pulse as a thundering sound in the head. The **foramen lacerum** (la'ser-um) is a jagged opening (*lacerum* = torn or lacerated) between the petrous temporal bone and the sphenoid bone. It is almost completely closed by cartilage in a living person, but it is conspicuous in a dried skull, and students usually ask its name. The **internal acoustic meatus,** positioned superolateral to the jugular foramen (Figures 7.3b and 7.4b), transmits cranial nerves VII and VIII.

Sphenoid Bone

The butterfly-shaped **sphenoid bone** (sfe'noid; *sphen* = wedge) spans the width of the middle cranial fossa (Figure 7.4b). The sphenoid is considered the keystone of the cranium because it forms a central wedge that articulates with all other cranial bones. It is a challenging bone to study because of its complex shape. As shown in Figure 7.6, it consists of a central body and three pairs of processes: the greater wings, lesser wings, and pterygoid processes (ter'ĭ-goid). Within the **body** of the sphenoid are the paired **sphenoid sinuses** (see Figures 7.3b and 7.11).

The superior surface of the body bears a saddle-shaped prominence, the **sella turcica** (sel'ah ter'sĭ-kah), meaning "Turk's saddle." The seat of this saddle, called the **hypophyseal fossa,** forms a snug enclosure for the pituitary gland (hypophysis). This fossa is abutted anteriorly and posteriorly by the **tuberculum sellae** and the **dorsum sellae,** respectively. The dorsum sellae terminates laterally in the **posterior clinoid processes.**

The **greater wings** project laterally from the body, forming parts of (1) the middle cranial fossa

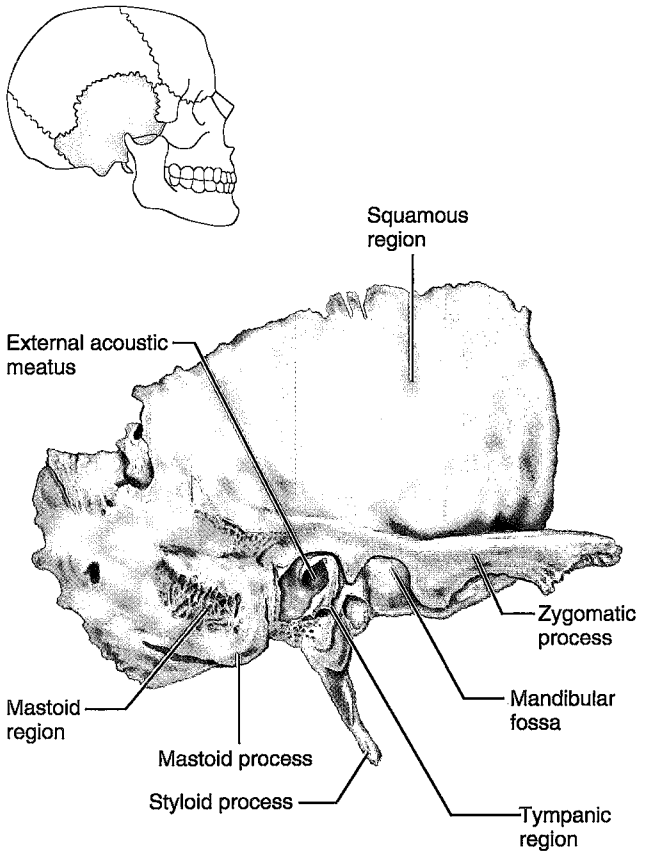

FIGURE 7.5 **The temporal bone.** Right lateral view. (See *A Brief Atlas of the Human Body,* Figures 2 and 8.)

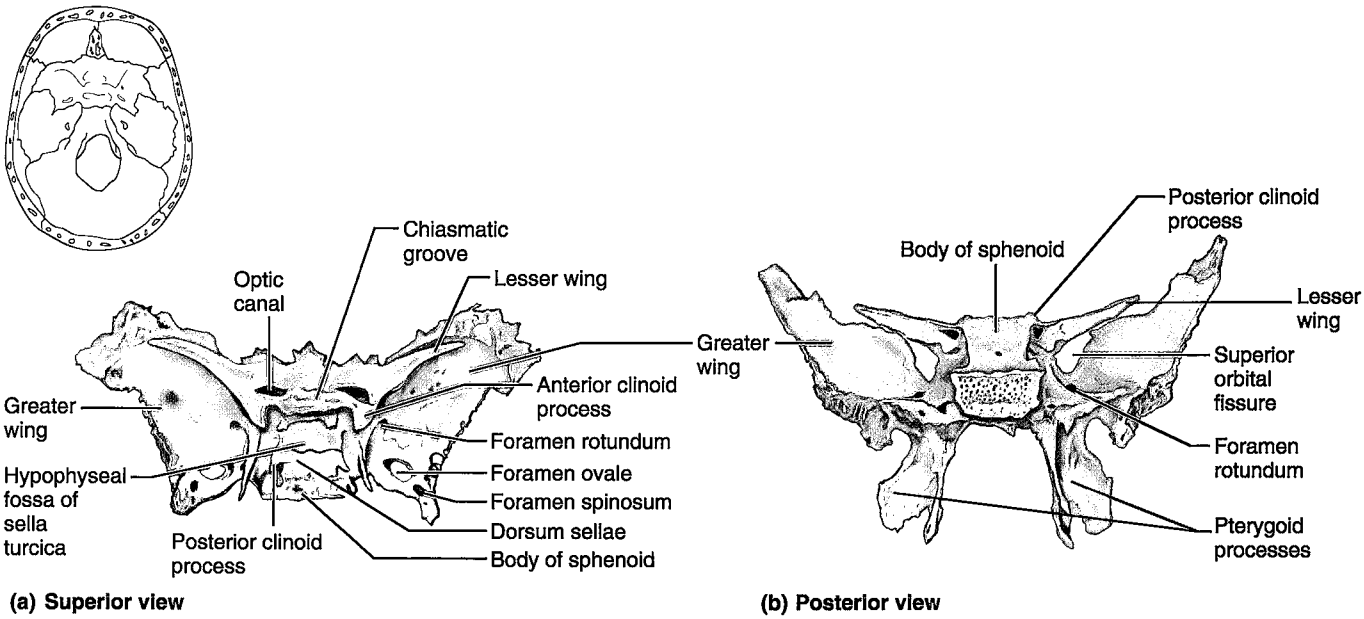
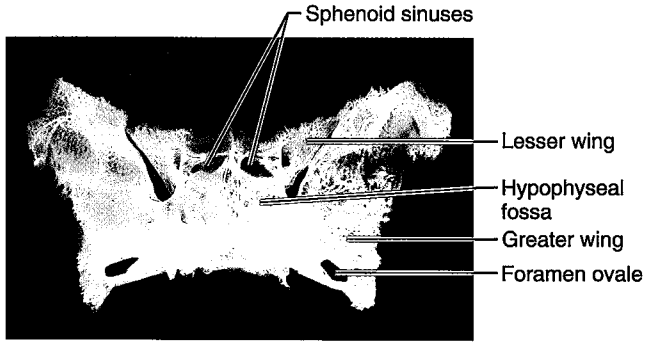
(see Figure 7.4b and c), (2) the dorsal walls of the orbits (see Figure 7.2a), and (3) the external wall of the skull, where they are seen as flag-shaped, bony areas medial to the zygomatic arch (see Figure 7.3). The hornlike **lesser wings** form part of the floor of the anterior cranial fossa (Figure 7.4b and c) and part of the medial walls of the orbits. These terminate medially in the **anterior clinoid processes,** which provide an anchoring site for securing the brain within the skull.





(c)

FIGURE 7.6 **The sphenoid bone. (a)** Superior view. **(b)** Posterior view. **(c)** High-resolution microradiograph of the sphenoid bone, superior view. Note in particular its body, contained sinuses, the greater and lesser wings, and the pterygoid processes. (See *A Brief Atlas of the Human Body,* Figures 5 and 9.)

The trough-shaped **pterygoid processes** project inferiorly from the junction of the body and greater wings (see Figure 7.6b). They anchor the pterygoid muscles, which are important in chewing.

A number of openings in the sphenoid bone are visible in Figures 7.4b and 7.6. The **optic canals,** connected by the *chiasmatic groove,* lie anterior to the sella turcica; they allow the optic nerves to pass to the eyes. On each side of the sphenoid body is a crescent-shaped row of four openings. The anteriormost of these, the **superior orbital fissure,** is a long slit between the greater and lesser wings. It allows cranial nerves that control eye movements (III, IV, VI) to enter the orbit. This fissure is most obvious in an anterior view of the skull (see Figure 7.2). The **foramen rotundum** and **foramen ovale** (o-vă'le) provide passageways for branches of cranial nerve V (the maxillary and mandibular nerves, respectively) to reach the face. The foramen rotundum is in the medial part of the greater wing and is usually oval, despite its name meaning "round opening." The foramen ovale, a large, oval foramen posterior to the foramen rotundum, is visible in an inferior view of the skull (see Figure 7.4a). Posterolateral to the foramen ovale is the small **foramen spinosum** (Figure 7.4b); it transmits the *middle meningeal artery,* which serves the internal faces of some of the cranial bones.

Ethmoid Bone

Like the temporal and sphenoid bones, the delicate **ethmoid bone** has a complex shape (Figure 7.7). Lying between the sphenoid and the nasal bones of the face, it is the most deeply situated bone of the skull. It forms most of the bony area between the nasal cavity and the orbits.

The superior surface of the ethmoid is formed by the paired horizontal **cribriform plates** (krib'rĭ-form) (see also Figure 7.4b), which help form the roof of the nasal cavities and the floor of the anterior cranial fossa. The cribriform plates are punctured by tiny holes (*cribr* = sieve) called *olfactory foramina* that allow the olfactory nerves to pass from the smell receptors in the nasal cavities to the brain. Projecting superiorly between the cribriform plates is

Q *Of what importance is the crista galli?*

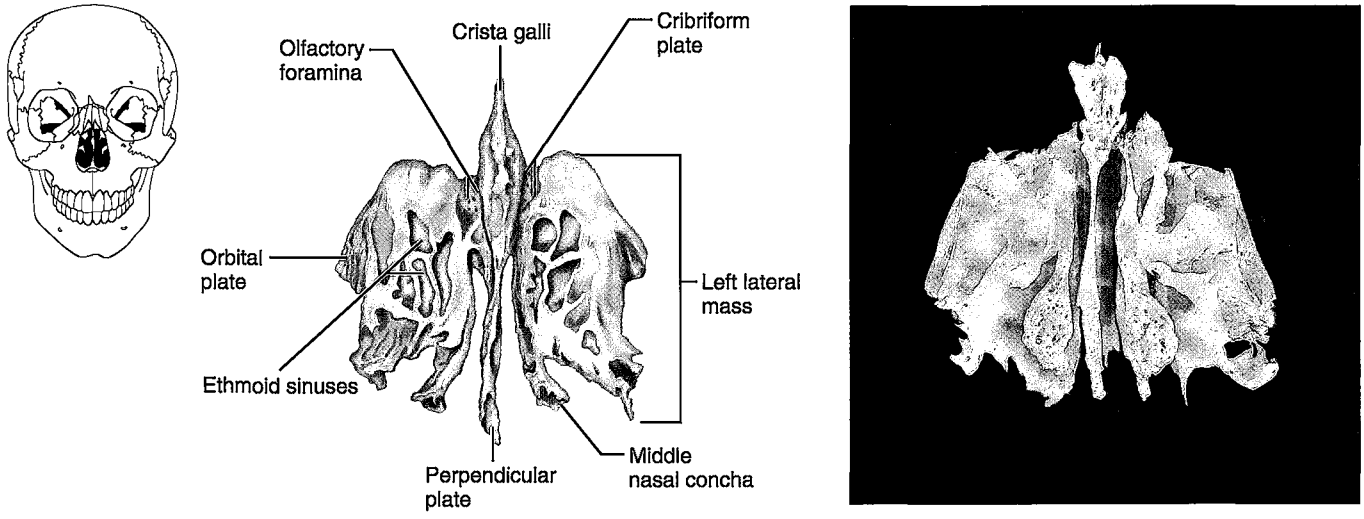


FIGURE 7.7 **The ethmoid bone.** Anterior view. (See *A Brief Atlas of the Human Body,* Figures 3 and 10.)

a triangular process called the **crista galli** (kris'tah gah'le; "rooster's comb"). The outermost covering of the brain (the dura mater) attaches to the crista galli and helps secure the brain in the cranial cavity.

The **perpendicular plate** of the ethmoid bone projects inferiorly in the median plane and forms the superior part of the nasal septum, which divides the nasal cavity into right and left halves (see Figure 7.3b). Flanking the perpendicular plate on each side is a **lateral mass** riddled with the **ethmoid sinuses** (Figures 7.7 and 7.11) for which the bone itself is named (*ethmos* = sieve). Extending medially from the lateral masses are the delicately coiled **superior** and **middle nasal conchae** (kong'ke; *concha* = shell), or **turbinates,** which protrude into the nasal cavity (Figures 7.7 and 7.10a). The lateral surfaces of the ethmoid's lateral masses are called **orbital plates** because they contribute to the medial walls of the orbits.

Sutural Bones

Sutural bones are tiny irregularly shaped bones or bone clusters that appear within sutures, most often in the lambdoid suture (see Figure 7.2b). Structurally unimportant, their number varies, and not all skulls exhibit them. Sutural bones represent additional ossification centers that appeared when the skull was expanding rapidly during fetal development.

A *It is the site to which the membranes surrounding the brain attach to secure the brain in the cranial cavity.*

Facial Bones

The facial skeleton is made up of 14 bones (see Figures 7.2a and 7.3a), of which only the mandible and the vomer are unpaired. The maxillae, zygomatics, nasals, lacrimals, palatines, and inferior conchae are paired bones. As a rule, the facial skeleton of men is more elongated than that of women; therefore, women's faces tend to be rounder and less angular.

Mandible

The U-shaped **mandible** (man'dĭ-bl), or lower jawbone (Figures 7.2, 7.3, and 7.8a), is the largest, strongest bone of the face. It has a *body,* which forms the chin, and two upright *rami* (*rami* = branches). Each ramus meets the body posteriorly at a **mandibular angle.** At the superior margin of each ramus are two processes separated by the **mandibular notch.** The anterior **coronoid process** (kor'o-noid; "crown-shaped") is an insertion point for the large temporalis muscle that elevates the lower jaw during chewing. The posterior **mandibular condyle** articulates with the mandibular fossa of the temporal bone, forming the *temporomandibular joint* on the same side.

The mandibular **body** anchors the lower teeth. Its superior border, called the **alveolar margin** (al-ve'o-lar), contains the sockets (*alveoli*) in which the teeth are embedded. In the midline of the mandibular body is a slight depression, the **mandibular symphysis** (sim'fih-sis), indicating where the two mandibular bones fused during infancy (see Figure 7.2a).

Large **mandibular foramina,** one on the medial surface of each ramus, permit the nerves

Q *Which of the bones illustrated is the keystone of the facial skeleton?*

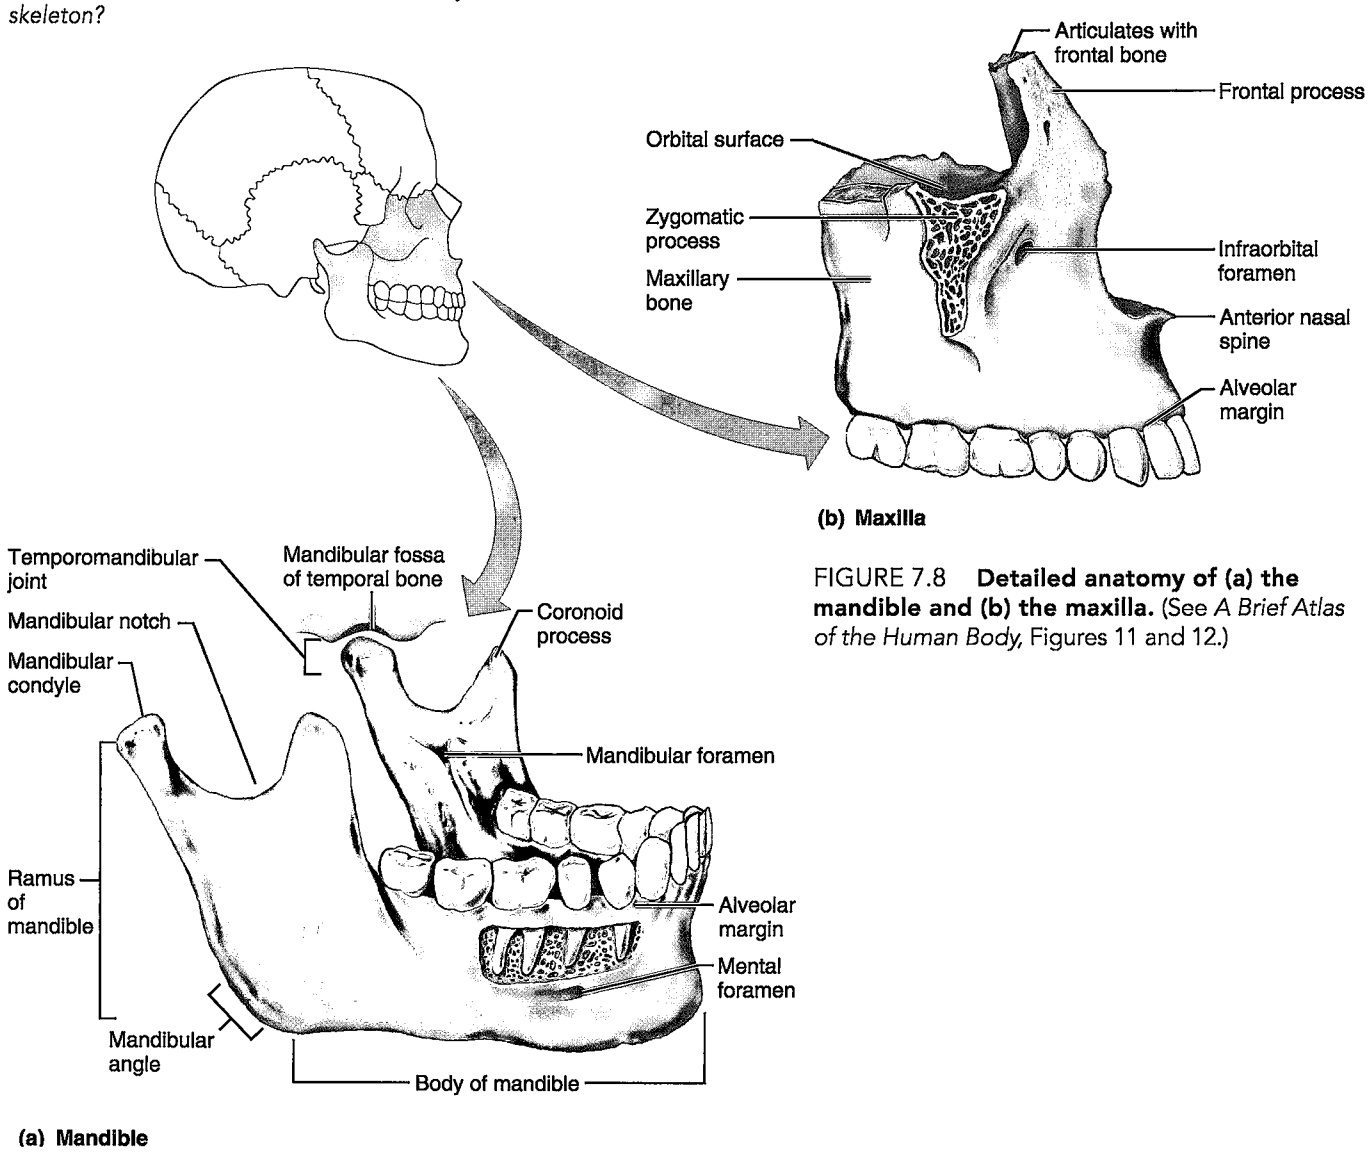

FIGURE 7.8 **Detailed anatomy of (a) the mandible and (b) the maxilla.** (See *A Brief Atlas of the Human Body*, Figures 11 and 12.)

responsible for tooth sensation to pass to the teeth in the lower jaw. Dentists inject lidocaine into these foramina to prevent pain while working on the lower teeth. The **mental foramina,** openings on the lateral aspects of the mandibular body, allow blood vessels and nerves to pass to the skin of the chin (*ment* = chin) and lower lip.

Maxillary Bones

The **maxillary bones,** or **maxillae** (mak-sil'le; "jaws") (see Figures 7.2 to 7.4 and 7.8b), are fused medially. They form the upper jaw and the central portion of the facial skeleton. All facial bones except the mandible articulate with the maxillae. Hence, the maxillae are considered the keystone bones of the facial skeleton.

The maxillae carry the upper teeth in their **alveolar margins.** Just inferior to the nose the maxillae meet medially, forming the pointed **anterior nasal spine** at their junction. The **palatine processes** (pă'lah-tīn) of the maxillae project posteriorly from the alveolar margins and fuse medially, forming the anterior two-thirds of the hard palate, or bony roof of the mouth (see Figures 7.3b and 7.4a). Just posterior to the teeth is a midline foramen, called the **incisive fossa,** which serves as a passageway for blood vessels and nerves.

A The maxilla is the keystone of the facial skeleton and forms the anterior portion of the hard palate.

The **frontal processes** extend superiorly to the frontal bone, forming part of the lateral aspects of the bridge of the nose (see Figures 7.2a and 7.8b). The regions that flank the nasal cavity laterally contain the **maxillary sinuses** (Figure 7.11), the largest of the paranasal sinuses. They extend from the orbits to the roots of the upper teeth. Laterally, the maxillae articulate with the zygomatic bones via their **zygomatic processes.**

The **inferior orbital fissure** is located deep within the orbit (see Figure 7.2a) at the junction of the maxilla with the greater wing of the sphenoid. It permits the zygomatic nerve, the maxillary nerve (a branch of cranial nerve V), and blood vessels to pass to the face. Just below the eye socket on each side is an **infraorbital foramen** that allows the infraorbital nerve (a continuation of the maxillary nerve) and artery to reach the face.

Zygomatic Bones

The irregularly shaped **zygomatic bones** (see Figures 7.2a, 7.3a, and 7.4a) are commonly called the cheekbones (*zygoma* = cheekbone). They articulate with the zygomatic processes of the temporal bones posteriorly, the zygomatic process of the frontal bone superiorly, and with the zygomatic processes of the maxillae anteriorly. The zygomatic bones form the prominences of the cheeks and part of the inferolateral margins of the orbits.

Nasal Bones

The thin, basically rectangular **nasal bones** (na'zal) are fused medially, forming the bridge of the nose (see Figures 7.2a and 7.3a). They articulate with the frontal bone superiorly, the maxillary bones laterally, and the perpendicular plate of the ethmoid bone posteriorly. Inferiorly they attach to the cartilages that form most of the skeleton of the external nose.

Lacrimal Bones

The delicate fingernail-shaped **lacrimal bones** (lak'rĭmal) contribute to the medial walls of each orbit (see Figures 7.2a and 7.3a). They articulate with the frontal bone superiorly, the ethmoid bone posteriorly, and the maxillae anteriorly. Each lacrimal bone contains a deep groove that helps form a **lacrimal fossa.** The lacrimal fossa houses the *lacrimal sac,* part of the passageway that allows tears to drain from the eye surface into the nasal cavity (*lacrima* = tears).

Palatine Bones

Each L-shaped **palatine bone** is fashioned from two bony plates, the *horizontal* and *perpendicular* (Figures 7.10a and 7.4a), and has three important articular processes, the *pyramidal, sphenoidal,* and *orbital.* The **horizontal plates** complete the posterior portion of the hard palate. The superiorly projecting **perpendicular (vertical) plates** form part of the posterolateral walls of the nasal cavity and a small part of the orbits.

Vomer

The slender, plow-shaped **vomer** (vo'mer; "plow") lies in the nasal cavity, where it forms part of the nasal septum (see Figures 7.2a and 7.10b). It is discussed below in connection with the nasal cavity.

Inferior Nasal Conchae

The paired **inferior nasal conchae** are thin, curved bones in the nasal cavity. They project medially from the lateral walls of the nasal cavity, just inferior to the middle nasal conchae of the ethmoid bone (see Figures 7.2a and 7.10a). They are the largest of the three pairs of conchae and, like the others, they form part of the lateral walls of the nasal cavity.

Special Characteristics of the Orbits and Nasal Cavity

Two restricted skull regions, the orbits and the nasal cavity, are formed from an amazing number of bones. Thus, even though the individual bones forming these structures have been described, a brief summary is provided here to pull the parts together.

The Orbits

The **orbits** are bony cavities in which the eyes are firmly encased and cushioned by fatty tissue. The muscles that move the eyes and the tear-producing lacrimal glands are also housed in the orbits. The walls of each orbit are formed by parts of seven bones—the frontal, sphenoid, zygomatic, maxilla, palatine, lacrimal, and ethmoid bones. Their relationships are shown in Figure 7.9. Also seen in the orbits are the superior and inferior orbital fissures and the optic canals, described earlier.

The Nasal Cavity

The **nasal cavity** is constructed of bone and hyaline cartilage (Figure 7.10a). The *roof* of the nasal cavity is formed by the cribriform plate of the ethmoid. The *lateral walls* are largely shaped by the superior and middle conchae of the ethmoid bone, the perpendicular plates of the palatine bones, and the inferior nasal conchae. The depressions under cover of the conchae on the lateral walls are called *meatuses* (*meatus* = passage), so there are superior, middle, and inferior meatuses. The *floor* of the nasal cavity is formed by the palatine processes of the maxillae and the palatine bones. The nasal cavity is divided into right and left parts by the *nasal septum.* The bony

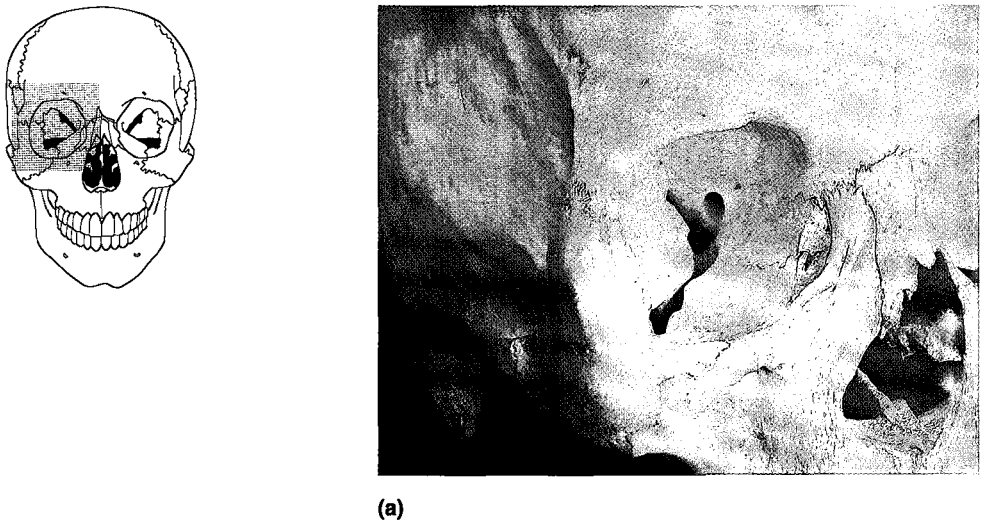

FIGURE 7.9 **Special anatomical characteristics of the orbits.** The contribution of each of the seven bones forming the right orbit is illustrated. **(a)** Photograph. **(b)** Diagrammatic view. (See *A Brief Atlas of the Human Body*, Figure 14.)

portion of the septum is formed by the vomer inferiorly and the perpendicular plate of the ethmoid bone superiorly (Figure 7.10b). A sheet of cartilage called the *septal cartilage* completes the septum anteriorly.

The nasal septum and conchae are covered with a mucus-secreting mucosa that moistens and warms the entering air and helps cleanse it of debris. The scroll-shaped conchae increase the turbulence of air flowing through the nasal cavity. This swirling forces more of the inhaled air into contact with the warm, damp mucosa and encourages trapping of airborne particles (dust, pollen, bacteria) in the sticky mucus.

Paranasal Sinuses

Five skull bones—the frontal, sphenoid, ethmoid, and paired maxillary bones—contain mucosa-lined, air-filled sinuses that give them a rather moth-eaten appearance in an X-ray image. These particular

TABLE 7.1 Bones of the Skull

BONE*	COMMENTS	IMPORTANT MARKINGS†
CRANIAL BONES		
Frontal (1) (Figures 7.2a, 7.3, and 7.4b)	Forms forehead; superior part of orbits and anterior cranial fossa; contains sinuses	**Supraorbital foramen (notch) (2):** allows the supraorbital arteries and nerves to pass
Parietal (2) (Figures 7.2 and 7.3)	Forms most of the superior and lateral aspects of the skull	
Occipital (1) (Figures 7.2b, 7.3, and 7.4)	Forms posterior aspect and most of the base of the skull	**Foramen magnum:** allows the spinal cord to issue from the brain stem to enter the vertebral canal **Hypoglossal canal (2):** allows passage of the hypoglossal nerve (cranial nerve XII) **Occipital condyle (2):** articulates with the atlas (first vertebra) **External occipital protuberance** and **nuchal lines:** sites of muscle attachment **External occipital crest:** attachment site of ligamentum nuchae
Temporal (2) (Figures 7.3, 7.4, and 7.5)	Forms inferolateral aspects of the skull and contributes to the middle cranial fossa; has squamous, mastoid, tympanic, and petrous regions	**Zygomatic process:** helps to form the zygomatic arch, which forms the prominence of the cheek **Mandibular fossa:** articular point of the mandibular condyle **External acoustic meatus:** canal leading from the external ear to the eardrum **Styloid process:** attachment site for hyoid bone and several neck muscles **Mastoid process:** attachment site for several neck and tongue muscles **Stylomastoid foramen:** allows cranial nerve VII (facial nerve) to pass **Jugular foramen:** allows passage of the internal jugular vein and cranial nerves IX, X, and XI **Internal acoustic meatus:** allows passage of cranial nerves VII and VIII **Carotid canal:** allows passage of the internal carotid artery
Sphenoid (1) (Figures 7.2a, 7.3, 7.4, and 7.6)	Keystone of the cranium; contributes to the middle cranial fossa and orbits; main parts are the body, greater wings, lesser wings, and pterygoid processes	**Sella turcica:** hypophyseal fossa portion is the seat of the pituitary gland **Optic canal (2):** allows passage of cranial nerve II and the ophthalmic arteries **Superior orbital fissure (2):** allows passage of cranial nerves III, IV, VI, part of V (ophthalmic division), and ophthalmic vein **Foramen rotundum (2):** allows passage of the maxillary division of cranial nerve V **Foramen ovale (2):** allows passage of the mandibular division of cranial nerve V **Foramen spinosum (2):** allows passage of the middle meningeal artery

*The color code beside each bone name corresponds to the bone's color in Figures 7.2 to 7.10. The number in parentheses ( ) following the bone name denotes the total number of such bones in the body.
†A (2) following the name of a marking indicates a pair of markings in an unpaired bone.

TABLE 7.1 *(continued)*

BONE*	COMMENTS	IMPORTANT MARKINGS†
CRANIAL BONES		
Ethmoid (1) (Figures 7.2a, 7.3, 7.4b, 7.7, and 7.10)	Helps to form the anterior cranial fossa; forms part of the nasal septum and the lateral walls and roof of the nasal cavity; contributes to the medial wall of the orbit	**Crista galli:** attachment point for the falx cerebri, a dural membrane **Cribriform plate (2):** allows passage of nerve filaments of the olfactory nerves (cranial nerve I) **Superior** and **middle nasal conchae (2):** forms part of lateral walls of nasal cavity; increase turbulence of air flow
Auditory ossicles (malleus, incus, and stapes) (2 each)	Found in middle ear cavity; involved in sound transmission; see Chapter 15	
FACIAL BONES		
Mandible (1) (Figures 7.2a, 7.3, and 7.8a)	The lower jaw	**Coronoid process (2):** insertion point for the temporalis muscle **Mandibular condyle (2):** articulates with the temporal bones in freely movable joints (temporomandibular joints) of the jaw **Mandibular symphysis:** medial fusion point of the mandibular bones **Alveoli:** sockets for the teeth **Mandibular foramen (2):** permits the inferior alveolar nerves to pass **Mental foramen (2):** allows blood vessels and nerves to pass to the chin and lower lip
Maxilla (2) (Figures 7.2a, 7.3, 7.4a, and 7.8b)	Keystone bones of the face; form the upper jaw and parts of the hard palate, orbits, and nasal cavity walls	**Alveoli:** sockets for the teeth **Zygomatic process:** helps form the zygomatic arch **Palatine process:** forms the anterior hard palate; processes meet in medial palatine suture **Frontal process:** forms part of lateral aspect of bridge of nose **Incisive fossa:** permits blood vessels and nerves to pass through hard palate (fused palatine processes) **Inferior orbital fissure:** permits maxillary branch of cranial nerve V, the zygomatic nerve, and blood vessels to pass **Infraorbital foramen:** allows passage of infraorbital nerve to skin of face
Zygomatic (2) (Figures 7.2a, 7.3a, and 7.4a)	Forms the cheek and part of the orbit	
Nasal (2) (Figures 7.2a and 7.3)	Constructs the bridge of the nose	
Lacrimal (2) (Figures 7.2a and 7.3a)	Forms part of the medial orbit wall	**Lacrimal fossa:** houses the lacrimal sac, which helps to drain tears into the nasal cavity
Palatine (2) (Figures 7.3b, 7.4a, and 7.10)	Forms posterior part of the hard palate and a small part of nasal cavity and orbit wall	
Vomer (1) (Figures 7.2a, 7.3b, and 7.10)	Part of the nasal septum	
Inferior nasal concha (2) (Figures 7.2a and 7.10a)	Forms part of the lateral wall of the nasal cavity	

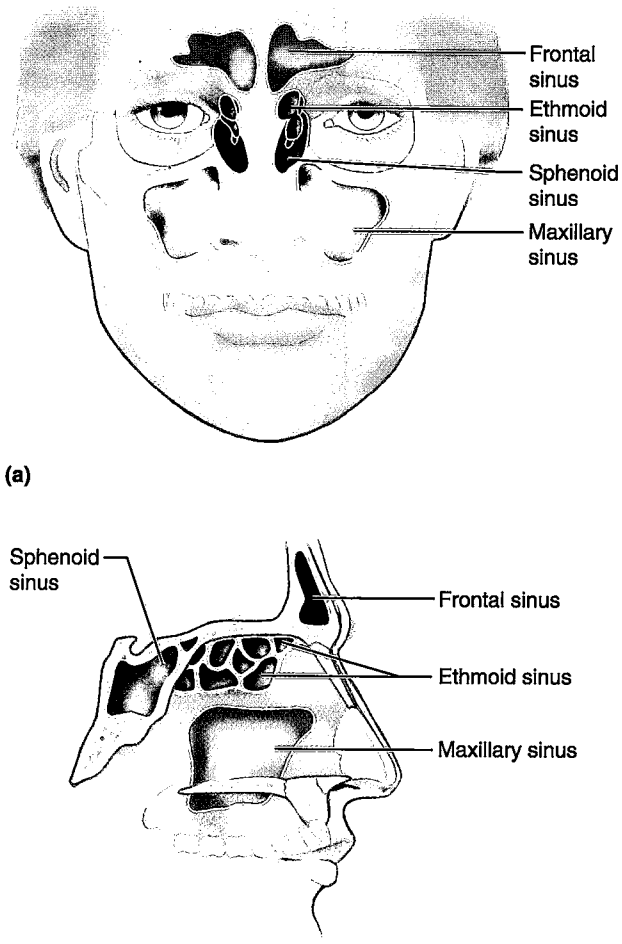

FIGURE 7.11 **Paranasal sinuses. (a)** Anterior aspect. **(b)** Medial aspect. (See *A Brief Atlas of the Human Body*, Figure 47.)

sinuses are called **paranasal sinuses** because they cluster around the nasal cavity (Figure 7.11). Small openings connect the sinuses to the nasal cavity and act as "two-way streets"; air enters the sinuses from the nasal cavity, and mucus formed by the sinus mucosae drains into the nasal cavity. The mucosae of the sinuses also help to warm and humidify inspired air. The paranasal sinuses lighten the skull and enhance the resonance of the voice.

The Hyoid Bone

Though not really part of the skull, the **hyoid bone** (hi'oid; "U-shaped") lies just inferior to the mandible in the anterior neck, and looks like a miniature version of it (Figure 7.12). The hyoid bone is unique in that it is the only bone of the body that does not articulate directly with any other bone. Instead, it is anchored by the narrow *stylohyoid ligaments* to the styloid processes of the temporal bones. Horseshoe-shaped, with a *body* and two pairs of *horns*, or *cornua*, the hyoid bone acts as a movable base for the tongue. Its body and greater horns are attachment points for neck muscles that raise and lower the larynx during swallowing and speech.

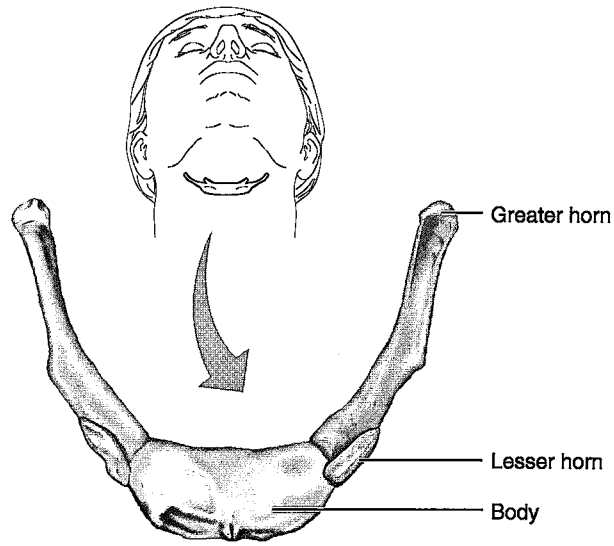

FIGURE 7.12 **The hyoid bone.** The hyoid bone is suspended in the mid-anterior neck by ligaments attached to the lesser horns (cornua) and the styloid processes of the temporal bones.

The Vertebral Column

General Characteristics

Some people think of the **vertebral column** as a rigid supporting rod, but this is inaccurate. Also called the **spine,** the vertebral column is formed from 26 irregular bones connected in such a way that a flexible, curved structure results (Figure 7.13). Serving as the axial support of the trunk, the spine extends from the skull to the pelvis, where it transmits the weight of the trunk to the lower limbs. It also surrounds and protects the delicate spinal cord and provides attachment points for the ribs and for the muscles of the back and neck. In the fetus and infant, the vertebral column consists of 33 separate bones, or **vertebrae** (ver'tĕ-bre). Inferiorly, nine of these eventually fuse to form two composite bones, the sacrum and the tiny coccyx. The remaining 24 bones persist as individual vertebrae separated by intervertebral discs.

Divisions and Curvatures

The vertebral column is about 70 cm (28 inches) long in an average adult and has five major divisions (Figure 7.13). The seven vertebrae of the neck are

the **cervical vertebrae** (ser'vi-kal), the next 12 are the **thoracic vertebrae** (tho-ras'ik), and the five supporting the lower back are the **lumbar vertebrae** (lum'bar). Remembering common meal times—7 AM, 12 noon, and 5 PM—will help you recall the number of bones in these three regions of the spine. The vertebrae become progressively larger from the cervical to the lumbar region, as they must support greater and greater weight.

Inferior to the lumbar vertebrae is the **sacrum** (sa'krum), which articulates with the hip bones of the pelvis. The terminus of the vertebral column is the tiny **coccyx** (kok'siks). All of us have the same number of cervical vertebrae. Variations in numbers of vertebrae in other regions occur in about 5% of people.

When you view the vertebral column from the side, you can see the four curvatures that give it its S, or sinusoid, shape. The **cervical** and **lumbar curvatures** are concave posteriorly; the **thoracic** and **sacral curvatures** are convex posteriorly. These curvatures increase the resilience and flexibility of the spine, allowing it to function like a spring rather than a rigid rod.

HOMEOSTATIC IMBALANCE

There are several types of abnormal spinal curvatures. Some are congenital (present at birth); others result from disease, poor posture, or unequal muscle pull on the spine. *Scoliosis* (sko"le-o'sis), literally, "twisted disease," is an abnormal *lateral* curvature that occurs most often in the thoracic region. It is quite common during late childhood, particularly in girls, for some unknown reason. Other, more severe cases result from abnormal vertebral structure, lower limbs of unequal length, or muscle paralysis. If muscles on one side of the body are nonfunctional, those of the opposite side exert an unopposed pull on the spine and force it out of alignment. Scoliosis is treated (with body braces or surgically) before growth ends to prevent permanent deformity and breathing difficulties due to a compressed lung.

Kyphosis (ki-fo'sis), or hunchback, is a *dorsally* exaggerated *thoracic* curvature. It is particularly common in elderly people because of osteoporosis, but may also reflect tuberculosis of the spine, rickets, or osteomalacia. *Lordosis*, or swayback, is an accentuated *lumbar* curvature. It, too, can result from spinal tuberculosis or osteomalacia. Temporary lordosis is common in those carrying a large load up front, such as men with "potbellies" and pregnant women. In an attempt to preserve their center of gravity, these individuals automatically throw back their shoulders, accentuating their lumbar curvature. ◉

Q *Why would it be anatomically "stupid" to have the sturdiest vertebrae in the cervical instead of the lumbar region of the spine?*

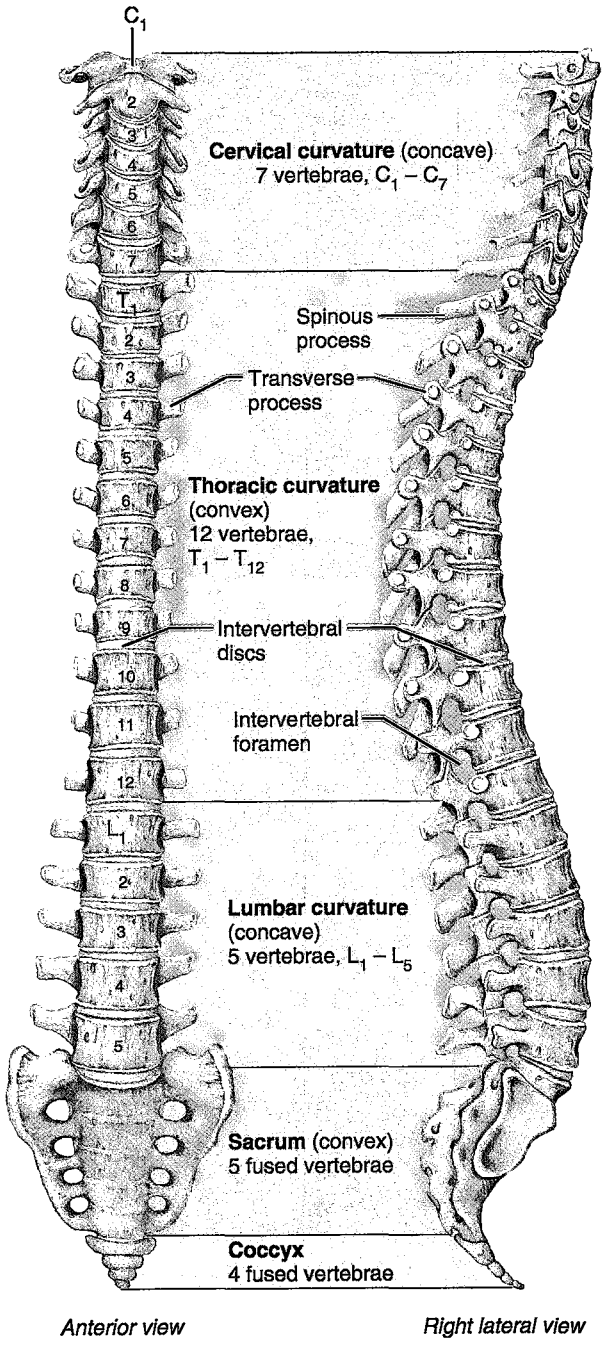

FIGURE 7.13 **The vertebral column.** Notice the curvatures in the lateral view. (The terms *convex* and *concave* refer to the curvature of the posterior aspect of the vertebral column.) (See *A Brief Atlas of the Human Body*, Figure 17.)

A *Because the lumbar region bears the greatest weight, its vertebrae are the sturdiest.*

7

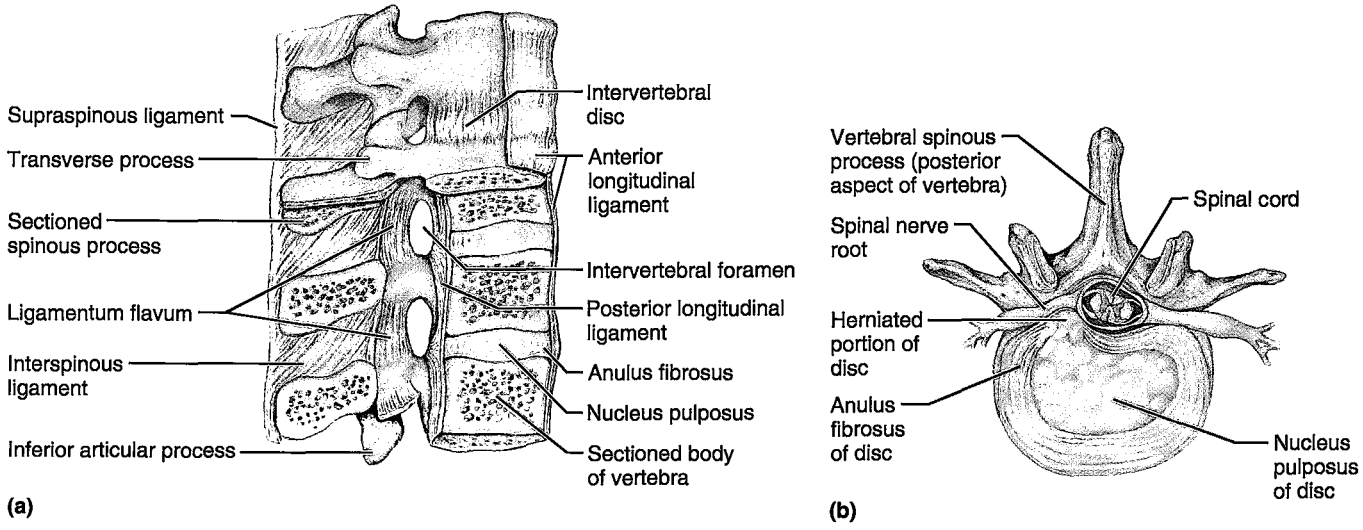

FIGURE 7.14 **Ligaments and fibrocartilage discs uniting the vertebrae.** **(a)** Median section of three vertebrae, illustrating the composition of the discs and the ligaments. **(b)** Superior view of a sectioned herniated disc (slipped disc).

Ligaments

Like a tall, tremulous TV transmitting tower, the vertebral column cannot possibly stand upright by itself. It must be held in place by an elaborate system of cablelike supports. In the case of the vertebral column, straplike ligaments and the trunk muscles assume this role. The major supporting ligaments are the **anterior** and **posterior longitudinal ligaments** (Figure 7.14). These run as continuous bands down the front and back surfaces of the spine from the neck to the sacrum. The broad anterior ligament is strongly attached to both the bony vertebrae and the discs. Along with its supporting role, it prevents hyperextension of the spine (bending too far backward). The posterior ligament, which resists hyperflexion of the spine (bending too sharply forward), is narrow and relatively weak. It attaches only to the discs. However, the *ligamentum flavum*, which contains elastic connective tissue, is especially strong. It stretches as we bend forward and then recoils when we resume an erect posture. Short ligaments connect each vertebra to those immediately above and below.

Intervertebral Discs

Each **intervertebral disc** is a cushionlike pad composed of two parts. The inner gelatinous **nucleus pulposus** (pul-po'sus; "pulp") acts like a rubber ball, giving the disc its elasticity and compressibility. Surrounding the nucleus pulposus is a strong collar composed of collagen fibers superficially and fibrocartilage internally, the **anulus fibrosus** (an'u-lus fibro'sus; "ring of fibers") (see Figure 7.14a). The anulus fibrosus limits the expansion of the nucleus pulposus when the spine is compressed. It also acts like a woven strap to bind successive vertebrae together, withstands twisting forces, and resists tension in the spine.

The intervertebral discs act as shock absorbers during walking, jumping, and running, and they allow the spine to flex and extend, and to a lesser extent to bend laterally. At points of compression, the discs flatten and bulge out a bit between the vertebrae. The discs are thickest in the lumbar and cervical regions, which enhances the flexibility of these regions. Collectively the discs account for about 25% of the height of the vertebral column. They flatten somewhat during the course of the day, so we are always a few centimeters shorter at night than when we awake in the morning.

HOMEOSTATIC IMBALANCE

Severe or sudden physical trauma to the spine—for example, from bending forward while lifting a heavy object—may result in herniation of one or more discs. A **herniated (prolapsed) disc** (commonly called a *slipped disc*) usually involves rupture of the anulus fibrosus followed by protrusion of the spongy nucleus pulposus through the anulus (see Figure 7.14b). If the protrusion presses on the spinal cord or on spinal nerves exiting from the cord, numbness or excruciating pain may result. Herniated discs are generally treated with moderate exercise, massage, heat therapy, and painkillers. If this fails, the protruding disc may have to be removed surgically and a bone graft done to fuse the adjoining vertebrae. For those preferring to avoid general anesthesia, the disc can be partially vaporized with a laser in an outpatient procedure called percutaneous laser disc

decompression that takes only 30 to 40 minutes. The patient leaves with only an adhesive bandage to mark the spot. ●

General Structure of Vertebrae

All vertebrae have a common structural pattern (Figure 7.15). Each vertebra consists of a **body,** or **centrum,** anteriorly and a **vertebral arch** posteriorly. The disc-shaped body is the weight-bearing region. Together, the body and vertebral arch enclose an opening called the **vertebral foramen.** Successive vertebral foramina of the articulated vertebrae form the long **vertebral canal,** through which the spinal cord passes.

The vertebral arch is a composite structure formed by two pedicles and two laminae. The **pedicles** (ped'ĭ-kelz; "little feet"), short bony pillars projecting posteriorly from the vertebral body, form the sides of the arch. The **laminae** (lam'ĭ-ne), flattened plates that fuse in the median plane, complete the arch posteriorly. Seven processes project from the vertebral arch. The **spinous process** is a median posterior projection arising at the junction of the two laminae. A **transverse process** extends laterally from each side of the vertebral arch. The spinous and transverse processes are attachment sites for muscles that move the vertebral column and for ligaments that stabilize it. The paired **superior** and **inferior articular processes** protrude superiorly and inferiorly, respectively, from the pedicle-lamina junctions. The smooth joint surfaces of the articular processes, called *facets* ("little faces"), are covered with hyaline cartilage. The inferior articular processes of each vertebra form movable joints with the superior articular processes of the vertebra immediately below. Thus, successive vertebrae join both at their bodies and at their articular processes.

The pedicles have notches on their superior and inferior borders, providing lateral openings between adjacent vertebrae called **intervertebral foramina** (see Figure 7.13). The spinal nerves issuing from the spinal cord pass through these foramina.

Regional Vertebral Characteristics

Beyond their common structural features, vertebrae exhibit variations that allow different regions of the spine to perform slightly different functions and movements. In general, movements that can occur between vertebrae are (1) flexion and extension (anterior bending and posterior straightening of the spine), (2) lateral flexion (bending the *upper body* to the right or left), and (3) rotation (in which vertebrae rotate on one another in the longitudinal axis of the spine). The regional vertebral characteristics described in this section are illustrated and summarized in Table 7.2 on p. 224.

Q *What structural parts of the vertebra are sites of muscle attachment?*

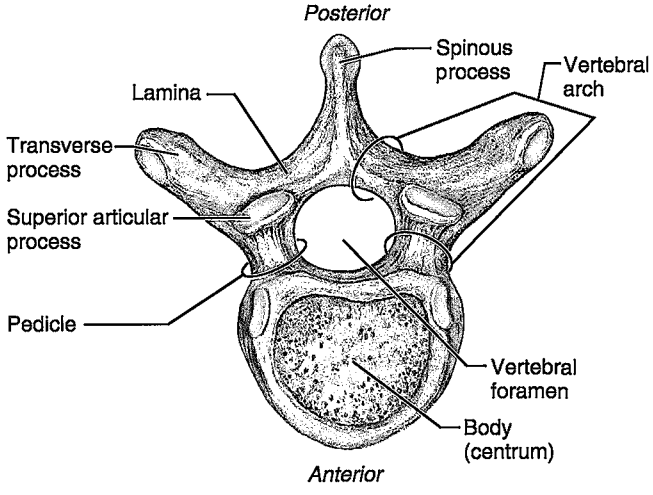

FIGURE 7.15 **Structure of a typical vertebra.** Superior view (inferior articulating surfaces not shown).

Cervical Vertebrae

The seven cervical vertebrae, identified as C_1–C_7, are the smallest, lightest vertebrae. The first two (C_1 and C_2) are unusual and we will skip them for the moment. The "typical" cervical vertebrae (C_3–C_7) have the following distinguishing features:

1. The body is oval—wider from side to side than in the anteroposterior dimension.
2. Except in C_7, the spinous process is short, projects directly back, and is *bifid* (bi'fid), or split at its tip.
3. The vertebral foramen is large and generally triangular.
4. Each transverse process contains a **transverse foramen** through which the vertebral arteries pass to service the brain.

The spinous process of C_7 is not bifid and is much larger than those of the other cervical vertebrae (see Figure 7.17a). Because its spinous process is visible through the skin, C_7 can be used as a landmark for counting the vertebrae and is called the **vertebra prominens** ("prominent vertebra").

The first two cervical vertebrae, the atlas and the axis, have no intervertebral disc between them, and they are highly modified, reflecting their special functions. The **atlas** (C_1) has no body and no spinous process (Figure 7.16a and b). Essentially, it is a ring of bone consisting of *anterior* and *posterior arches* and a *lateral mass* on each side. Each lateral

A *The spinous and transverse processes are sites of muscle attachment.*

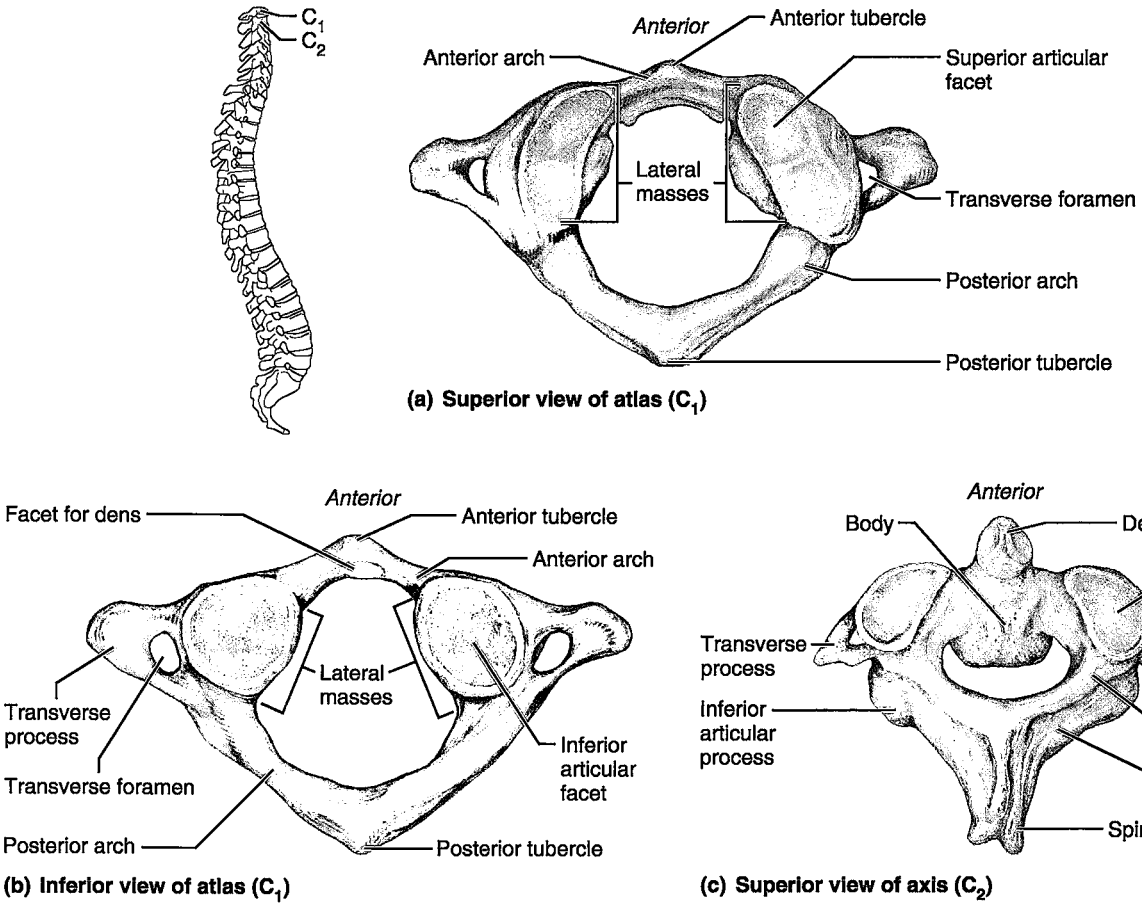

FIGURE 7.16 **The first and second cervical vertebrae.** (See *A Brief Atlas of the Human Body*, Figure 18.)

mass has articular facets on both its superior and inferior surfaces. The superior articular facets receive the occipital condyles of the skull; thus, they "carry" the skull, just as Atlas supported the heavens in Greek mythology. These joints allow you to nod "yes." The inferior articular facets form joints with the axis (C_2) below.

The **axis,** which has a body, spine, and the other typical vertebral processes, is not as specialized as the atlas. In fact, its only unusual feature is the knoblike **dens** (denz; "tooth"), or **odontoid process** (o-don'toid), projecting superiorly from its body. The dens is actually the "missing" body of the atlas, which fuses with the axis during embryonic development. Cradled in the anterior arch of the atlas by the transverse ligaments (Figure 7.17a), the dens acts as a pivot for the rotation of the atlas. Hence, this joint allows you to rotate your head from side to side to indicate "no."

Thoracic Vertebrae

The 12 thoracic vertebrae (T_1–T_{12}) all articulate with the ribs (see Table 7.2 and Figure 7.17b). The first looks much like C_7, and the last four show a progression toward lumbar vertebral structure. The thoracic vertebrae increase in size from the first to the last. Unique characteristics of these vertebrae include the following:

1. The body is roughly heart shaped. It typically bears two small *facets,* commonly called *demifacets* (half-facets), on each side, one at the superior edge (the *superior costal facet*) and the other at the inferior edge (the *inferior costal facet*). The demifacets receive the heads of the ribs. (The bodies of T_{10}–T_{12} vary from this pattern by having only a single facet to receive their respective ribs.)
2. The vertebral foramen is circular.
3. The spinous process is long and points sharply downward.
4. With the exception of T_{11} and T_{12}, the transverse processes have facets, the *transverse costal facets,* that articulate with the *tubercles* of the ribs.
5. The superior and inferior articular facets lie mainly in the frontal plane, a situation that prevents flexion and extension, but which allows rotation of this region of the spine.

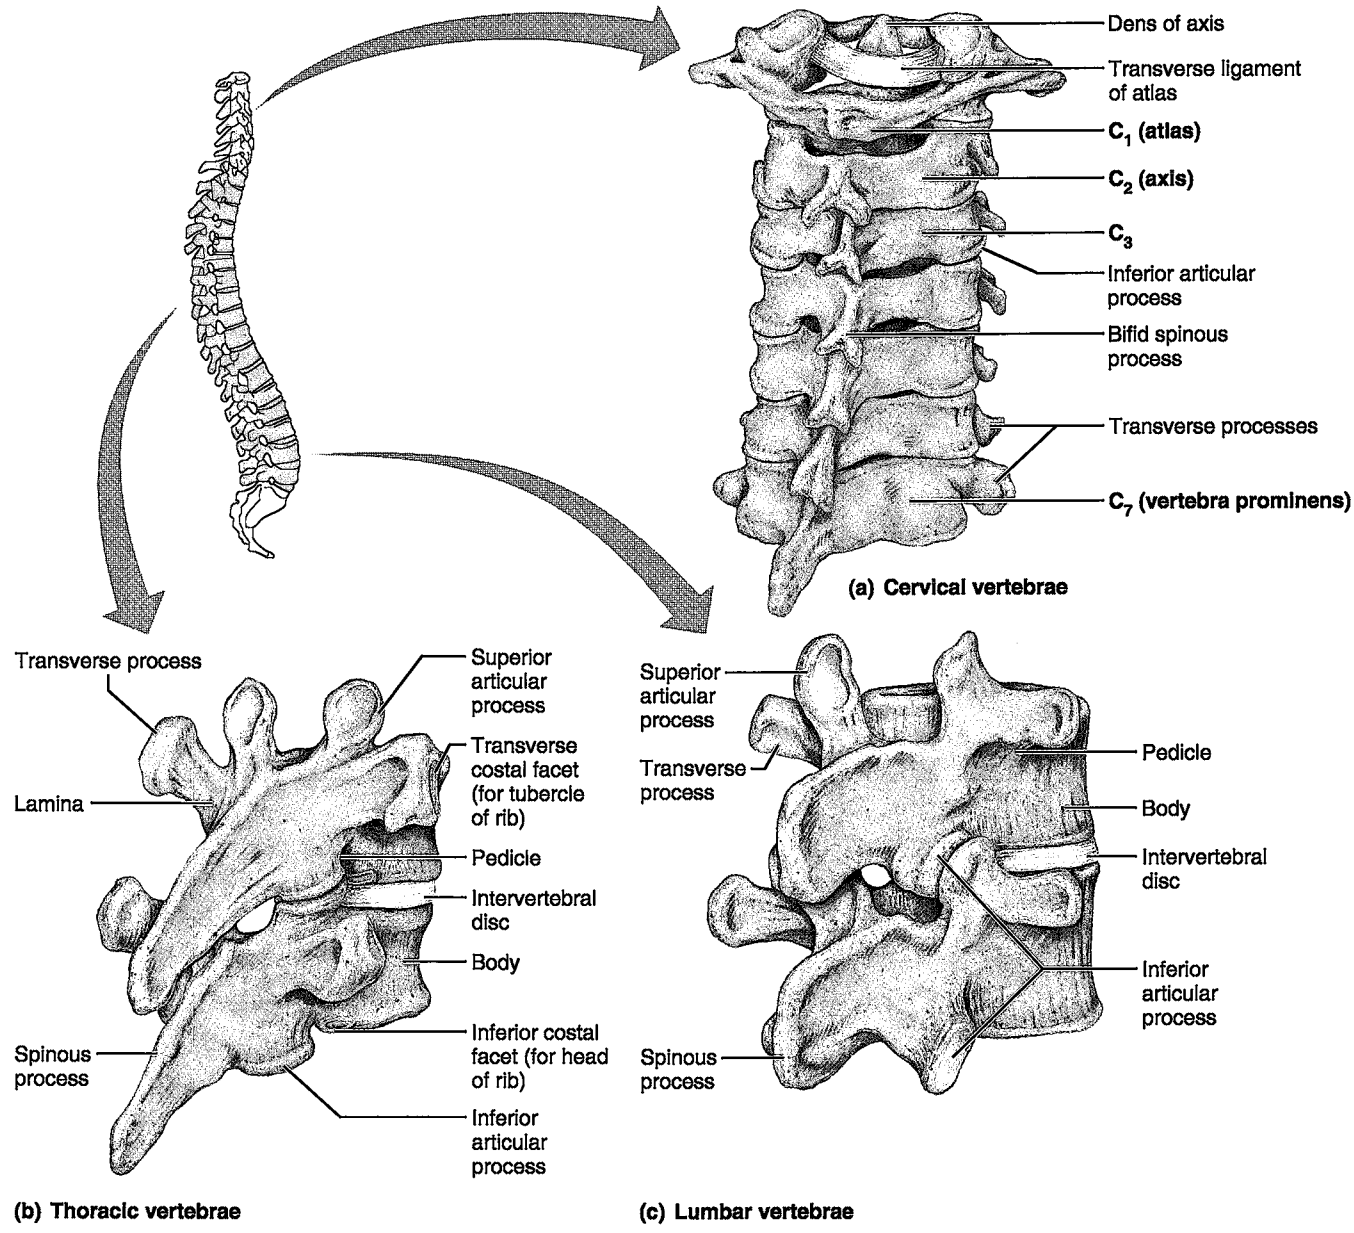

FIGURE 7.17 **Posterolateral views of articulated vertebrae.** Notice the bulbous tip on the spinous process of C_7, the vertebra prominens. (See *A Brief Atlas of the Human Body*, Figures 19, 20, and 21.)

Lumbar Vertebrae

The lumbar region of the vertebral column, commonly referred to as the small of the back, receives the most stress. The enhanced weight-bearing function of the five lumbar vertebrae (L_1–L_5) is reflected in their sturdier structure. Their bodies are massive and kidney shaped in a superior view (see Table 7.2 and Figure 7.17c). Other characteristics typical of these vertebrae:

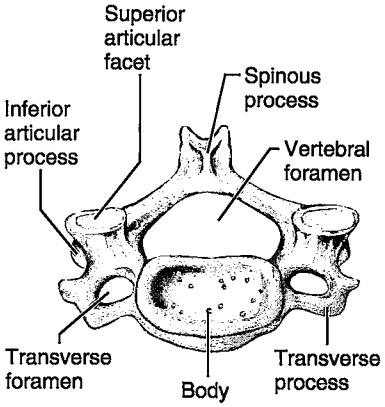
1. The pedicles and laminae are shorter and thicker than those of other vertebrae.
2. The spinous processes are short, flat, and hatchet shaped and are easily seen when a person bends forward. These processes are robust and project directly backward, adaptations for the attachment of the large back muscles.
3. The vertebral foramen is triangular.
4. The orientation of the facets of the articular processes of the lumbar vertebrae differs substantially from that of the other vertebra types (see Table 7.2). These modifications lock the lumbar vertebrae together and provide stability by preventing rotation of the lumbar spine.

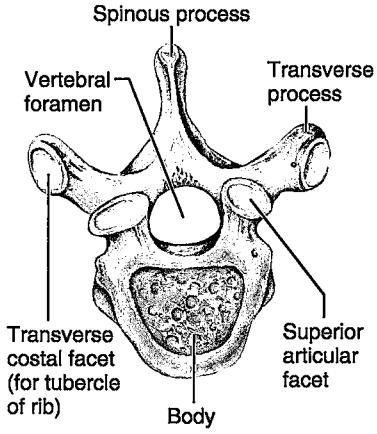
TABLE 7.2 Regional Characteristics of Cervical, Thoracic, and Lumbar Vertebrae

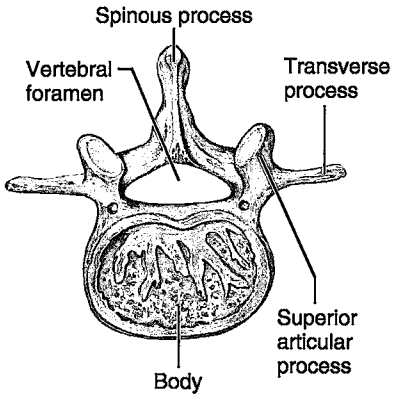
CHARACTERISTIC	CERVICAL (3–7)	THORACIC	LUMBAR
Body	Small, wide side to side	Larger than cervical; heart shaped; bears two costal facets	Massive; kidney shaped
Spinous process	Short; bifid; projects directly posteriorly	Long; sharp; projects inferiorly	Short; blunt; projects directly posteriorly
Vertebral foramen	Triangular	Circular	Triangular
Transverse processes	Contain foramina	Bear facets for ribs (except T_{11} and T_{12})	Thin and tapered
Superior and inferior articulating processes	Superior facets directed superoposteriorly	Superior facets directed posteriorly	Superior facets directed posteromedially (or medially)
	Inferior facets directed inferoanteriorly	Inferior facets directed anteriorly	Inferior facets directed anterolaterally (or laterally)
Movements allowed	Flexion and extension; lateral flexion; rotation; the spine region with the greatest range of movement	Rotation; lateral flexion possible but limited by ribs; flexion and extension prevented	Flexion and extension; some lateral flexion; rotation prevented

CERVICAL (3–7)	THORACIC	LUMBAR

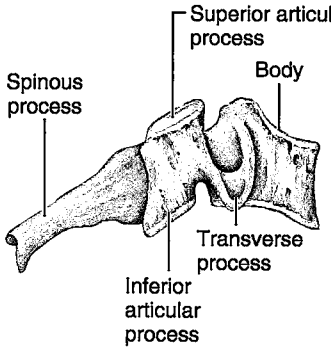
SUPERIOR VIEW

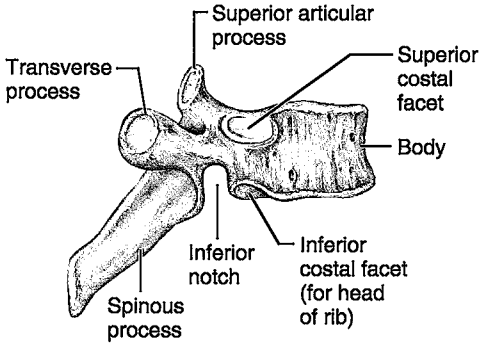


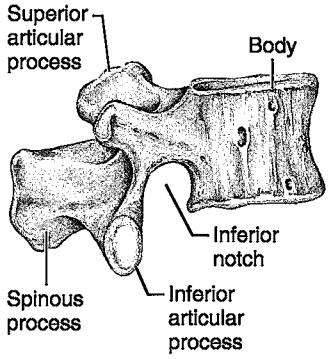




RIGHT LATERAL VIEW







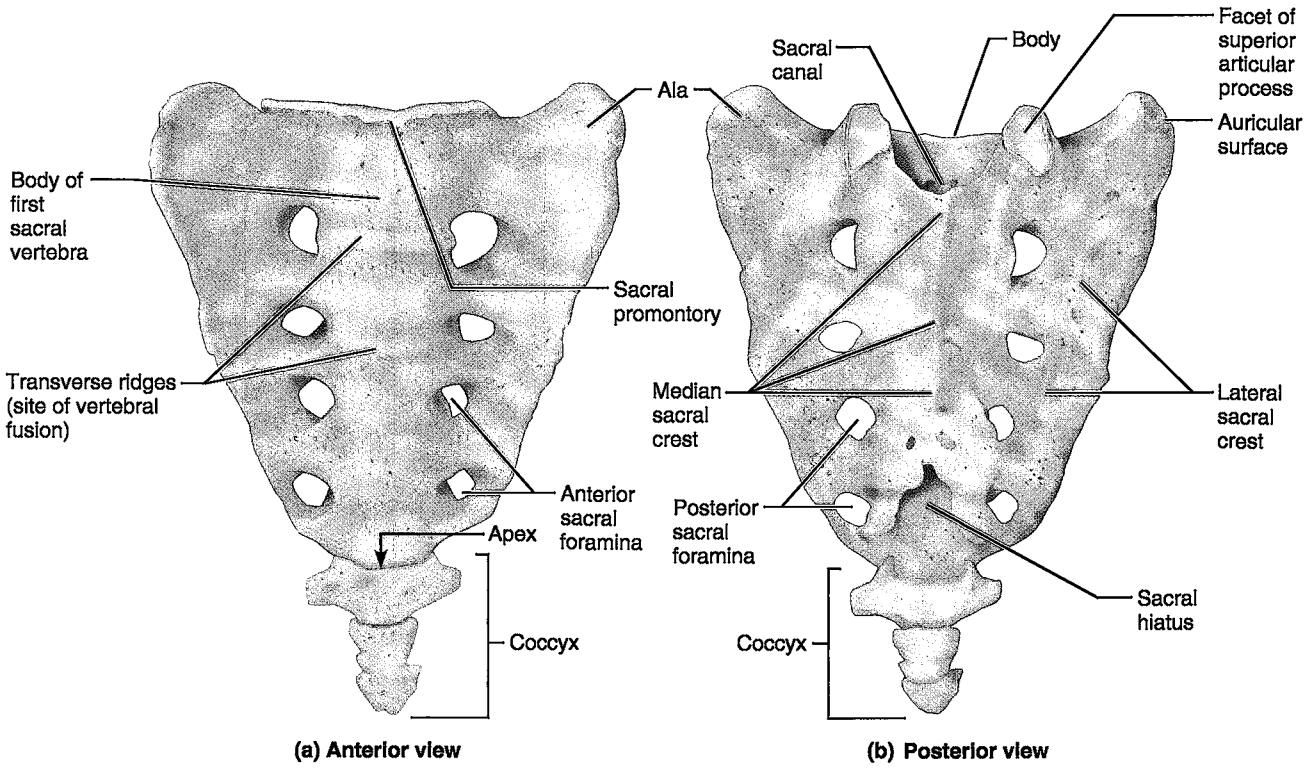


FIGURE 7.18 **The sacrum and coccyx.** (See *A Brief Atlas of the Human Body*, Figure 22.)

Sacrum

The triangular sacrum (Figure 7.18), which shapes the posterior wall of the pelvis, is formed by five fused vertebrae (S_1–S_5) in adults. It articulates superiorly (via its **superior articular processes**) with L_5 and inferiorly with the coccyx. Laterally, the sacrum articulates, via its **auricular surfaces,** with the two hip bones to form the **sacroiliac joints** (sa"kro-il'e-ak) of the pelvis.

The **sacral promontory** (prom'on-tor"e; "high point of land projecting into the sea"), the anterosuperior margin of the first sacral vertebra, bulges anteriorly into the pelvic cavity. The body's center of gravity lies about 1 cm posterior to this landmark. Four ridges, the **transverse ridges,** cross its concave anterior aspect, marking the lines of fusion of the sacral vertebrae. The **anterior sacral foramina** penetrate the sacrum at the lateral ends of these ridges and transmit blood vessels and anterior rami of the sacral spinal nerves. The regions lateral to these foramina expand superiorly as the winglike **alae.**

In its posterior midline the sacral surface is roughened by the **median sacral crest** (the fused spinous processes of the sacral vertebrae). This is flanked laterally by the **posterior sacral foramina,** which transmit the posterior rami of the sacral spinal nerves, and then the **lateral sacral crests** (remnants of the transverse processes of S_1–S_5).

The vertebral canal continues inside the sacrum as the **sacral canal.** Since the laminae of the fifth (and sometimes the fourth) sacral vertebrae fail to fuse medially, an enlarged external opening called the **sacral hiatus** (hi-a'tus; "gap") is obvious at the inferior end of the sacral canal.

Coccyx

The coccyx, our tailbone, is a small triangular bone (Figure 7.18). It consists of four (or in some cases three or five) vertebrae fused together. The coccyx articulates superiorly with the sacrum. (The name *coccyx* is from the Greek word meaning "cuckoo" and was so named because of its fancied resemblance to a bird's beak.) Except for the slight support the coccyx affords the pelvic organs, it is a nearly useless bone. Occasionally, a baby is born with an unusually long coccyx. In most such cases, this bony "tail" is discreetly snipped off by the physician.

■ ■ ■

The characteristics of the regional vertebrae are summarized in Table 7.2.

Q *Which ribs are also known as vertebrosternal ribs?*

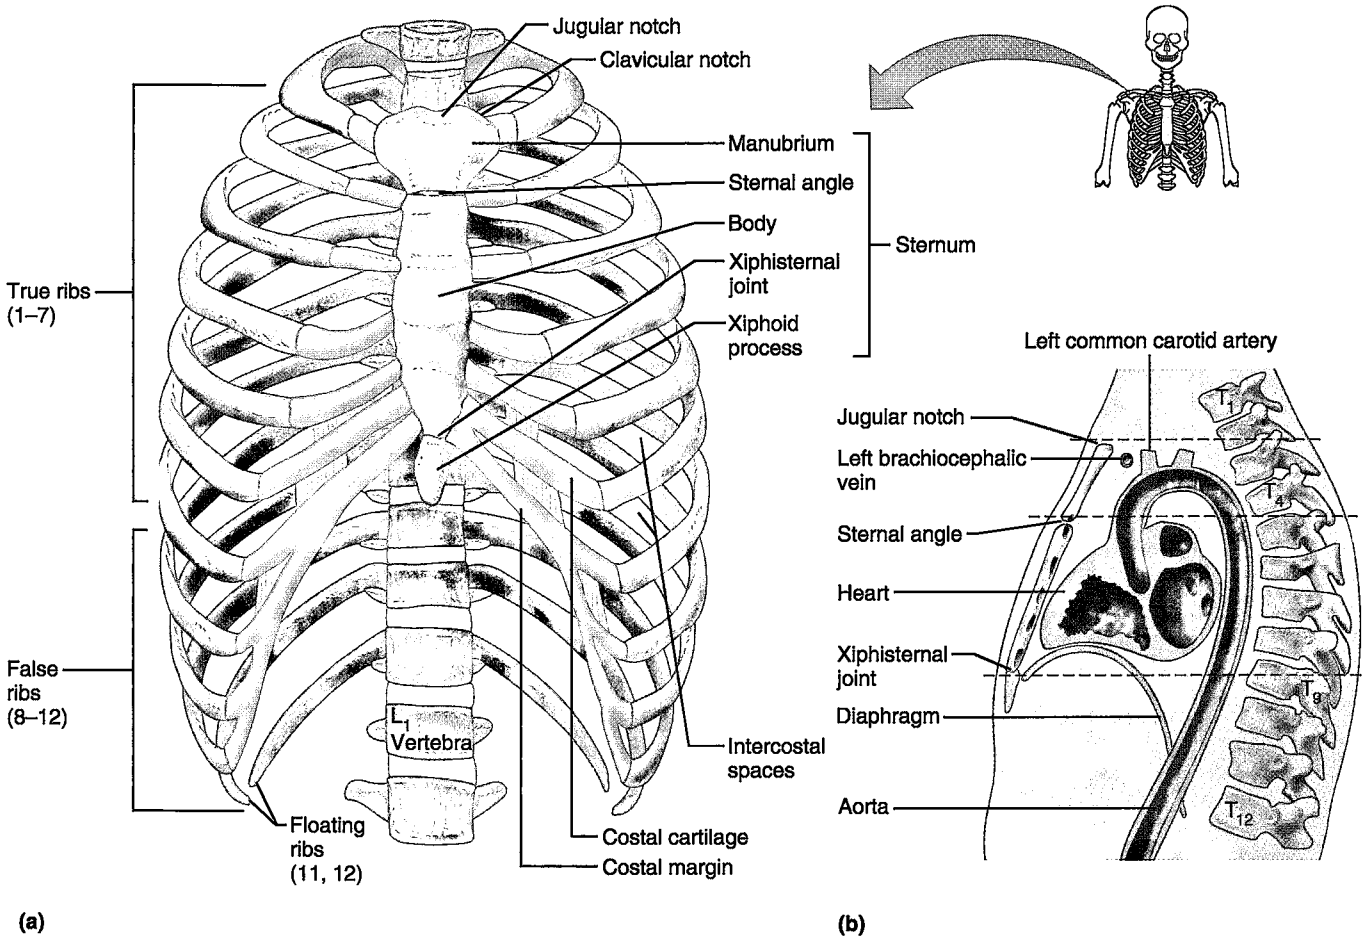

FIGURE 7.19 **The thoracic cage. (a)** Skeleton of the thoracic cage, anterior view (costal cartilages are shown in blue). **(b)** Left lateral view of the thorax, illustrating the relationship of the surface anatomical landmarks of the thorax to the vertebral column (thoracic portion). (See *A Brief Atlas of the Human Body,* Figure 23.)

The Thoracic Cage

Anatomically, the thorax is the chest, and its bony underpinnings are called the **thoracic cage** or **bony thorax.** Elements of the thoracic cage include the thoracic vertebrae dorsally, the ribs laterally, and the sternum and costal cartilages anteriorly. The costal cartilages secure the ribs to the sternum (Figure 7.19a). Roughly cone shaped with its broad dimension positioned inferiorly, the bony thorax forms a protective cage around the vital organs of the thoracic cavity (heart, lungs, and great blood vessels), supports the shoulder girdles and upper limbs, and provides attachment points for many muscles of the neck, back, chest, and shoulders. The *intercostal spaces* between the ribs are occupied by the intercostal muscles, which lift and depress the thorax during breathing.

A Rib pairs 1–7, the true ribs.

Sternum

The **sternum** (breastbone) lies in the anterior midline of the thorax. Vaguely resembling a dagger, it is a flat bone approximately 15 cm (6 inches) long, resulting from the fusion of three bones: the manubrium, the body, and the xiphoid process. The **manubrium** (mah-nu'bre-um), the superior portion shaped like the knot in a necktie, articulates via its **clavicular notches** (klah-vik'u-lar) with the clavicles (collarbones) laterally. It also articulates with the first two pairs of ribs. The **body,** or midportion, forms the bulk of the sternum. The sides of the body are notched where it articulates with the cartilages of the second to seventh ribs. The **xiphoid process**

(zif'oid; "swordlike") forms the inferior end of the sternum. This small, variably shaped process is a plate of hyaline cartilage in youth, but it is usually ossified in adults. The xiphoid process articulates only with the sternal body and serves as an attachment point for some abdominal muscles.

The sternum has three important anatomical landmarks: the jugular notch, the sternal angle, and the xiphisternal joint (see Figure 7.19). The easily palpated **jugular** (*suprasternal*) **notch** is the central indentation in the superior border of the manubrium. It is generally in line with the disc between the second and third thoracic vertebrae and the point where the left common carotid artery issues from the aorta (see Figure 7.19b). The **sternal angle** is felt as a horizontal ridge across the front of the sternum, where the manubrium joins the sternal body. This cartilaginous joint acts like a hinge, allowing the sternal body to swing forward when we inhale. The sternal angle is in line with the disc between the fourth and fifth thoracic vertebrae and at the level of the second pair of ribs. It is a handy reference point for finding the second rib and thus for counting the ribs during a physical examination and for listening to sounds made by specific heart valves. The **xiphisternal joint** (zif"ĭ-ster'nul) is the point where the sternal body and xiphoid process fuse. It lies opposite the ninth thoracic vertebra.

Ribs

Twelve pairs of **ribs** form the flaring sides of the thoracic cage (Figure 7.19a). All ribs attach posteriorly to the thoracic vertebrae (bodies and transverse processes) and curve inferiorly toward the anterior body surface. The superior seven rib pairs attach directly to the sternum by individual costal cartilages (bars of hyaline cartilage). These are **true** or **vertebrosternal ribs** (ver"tĕ-bro-ster'nal). (Notice that the anatomical name indicates the two attachment points of a rib—the posterior attachment given first.)

The remaining five pairs of ribs are called **false ribs;** they either attach indirectly to the sternum or entirely lack a sternal attachment. Rib pairs 8–10 attach to the sternum indirectly; each joins the costal cartilage immediately above it. These ribs are also called **vertebrochondral ribs** (ver"tĕ-bro-kon'dral). The inferior margin of the rib cage, or **costal margin,** is formed by the costal cartilages of ribs 7–10. Rib pairs 11 and 12 are called **vertebral ribs** or **floating ribs** because they have no anterior attachments. Instead, their costal cartilages lie embedded in the muscles of the lateral body wall. The ribs increase in length from pair 1 to pair 7, then decrease in length from pair 8 to pair 12. Except for the first rib, which lies deep to the clavicle, the ribs are easily felt in people of normal weight.

A typical rib is a bowed flat bone (Figure 7.20). The bulk of a rib is simply called the *shaft.* Its superior border is smooth, but its inferior border is sharp and thin and has a *costal groove* on its inner face that lodges the intercostal nerves and blood vessels. In addition to the shaft, each rib has a head, neck, and tubercle. The wedge-shaped *head,* the posteriormost end, articulates with the vertebral bodies by two facets: One joins the body of the same-numbered thoracic vertebra, the other articulates with the body of the vertebra immediately superior. The *neck* is the constricted portion of the rib just beyond the head. Lateral to this, the knoblike *tubercle* articulates with the costal facet of the transverse process of the same-numbered thoracic vertebra. Beyond the tubercle, the shaft angles sharply forward (at the angle of the rib) and then extends to attach to its costal cartilage anteriorly. The costal cartilages provide secure but flexible rib attachments to the sternum.

The first pair of ribs is quite atypical. They are flattened superiorly to inferiorly and are quite broad, forming a horizontal table that supports the subclavian blood vessels that serve the upper limbs. There are also other exceptions to the typical rib pattern. Rib 1 and ribs 10–12 articulate with only one vertebral body, and ribs 11 and 12 do not articulate with a vertebral transverse process.

PART 2: THE APPENDICULAR SKELETON

Bones of the limbs and their girdles are collectively called the **appendicular skeleton** because they are *appended to* the axial skeleton that forms the longitudinal axis of the body (see Figure 7.21). The yoke-like *pectoral girdles* (pek'tor-al; "chest") attach the upper limbs to the body trunk. The more sturdy *pelvic girdle* secures the lower limbs. Although the bones of the upper and lower limbs differ in their functions and mobility, they have the same fundamental plan: Each limb is composed of three major segments connected by movable joints.

The appendicular skeleton enables us to carry out the movements typical of our freewheeling and manipulative lifestyle. Each time we take a step, throw a ball, or pop a caramel into our mouth, we are making good use of our appendicular skeleton.

The Pectoral (Shoulder) Girdle

The **pectoral,** or **shoulder, girdle** consists of the *clavicle* (klav'ĭ-kl) anteriorly and the *scapula* (skap'u-lah) posteriorly (Figure 7.22 and Table 7.3 on p. 236).

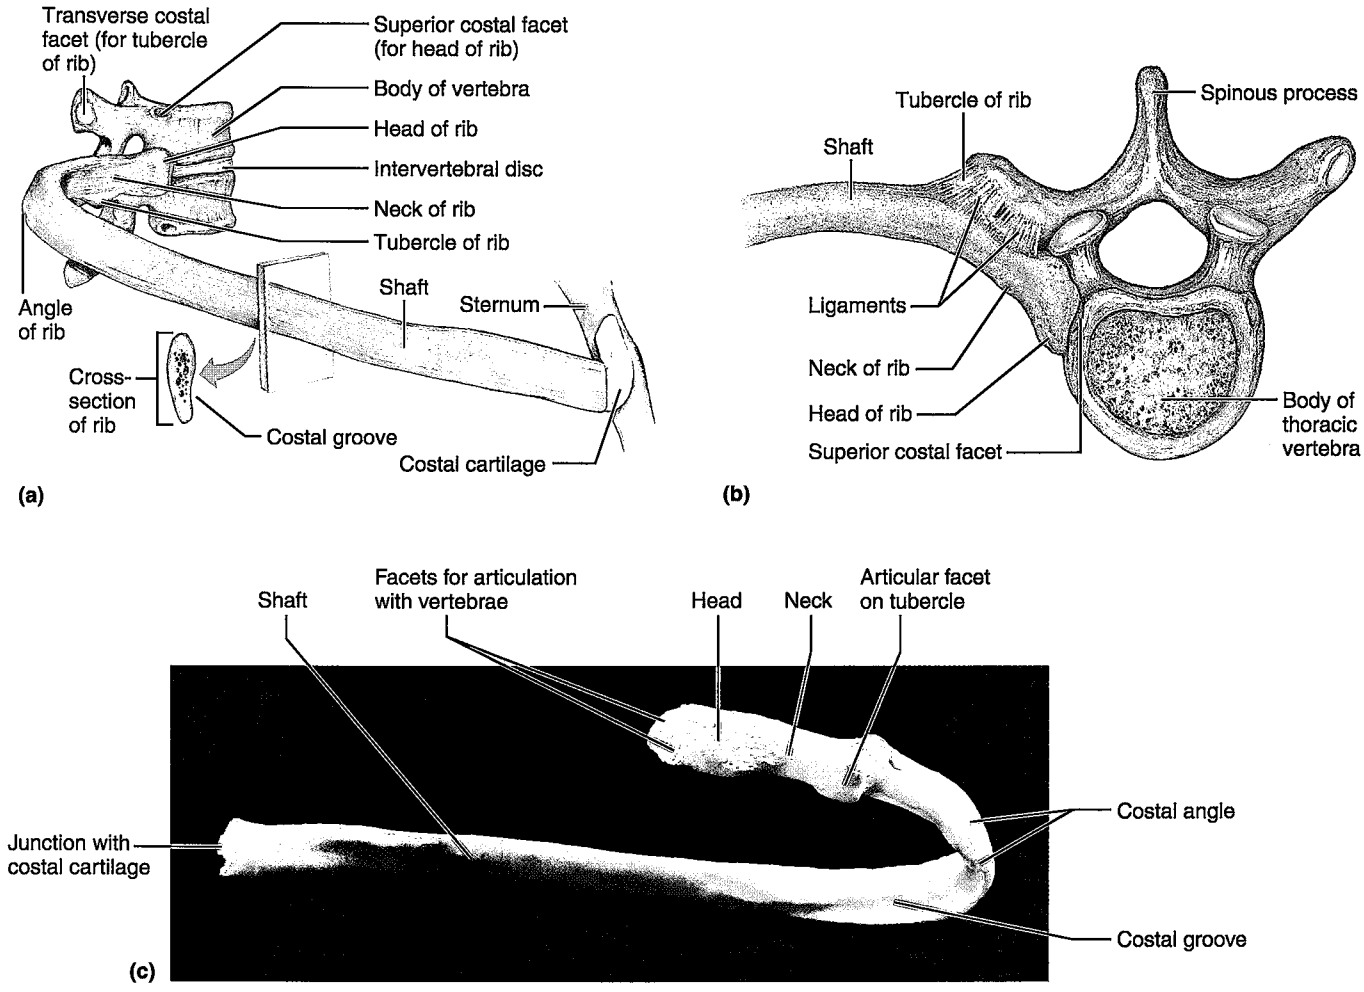

FIGURE 7.20 **Ribs. (a)** Vertebral and sternal articulations of a typical true rib. **(b)** Superior view of the articulation between a rib and a thoracic vertebra. **(c)** A typical rib (rib 6, right), posterior view. All ribs illustrated in this figure are right ribs. (See *A Brief Atlas of the Human Body*, Figure 23e and f.)

The paired pectoral girdles and their associated muscles form your shoulders. Although the term *girdle* usually signifies a beltlike structure encircling the body, a single pectoral girdle, or even the pair, does not quite satisfy this description. Anteriorly, the medial end of each clavicle joins the sternum; the distal ends of the clavicles meet the scapulae laterally. However, the scapulae fail to complete the ring posteriorly, because their medial borders do not join each other or the axial skeleton. Instead, the scapulae are attached to the thorax and vertebral column only by the muscles that clothe their surfaces.

The pectoral girdles attach the upper limbs to the axial skeleton and provide attachment points for many of the muscles that move the upper limbs. These girdles are very light and allow the upper limbs a degree of mobility not seen anywhere else in the body. This mobility is due to the following factors:

1. Because only the clavicle attaches to the axial skeleton, the scapula can move quite freely across the thorax, allowing the arm to move with it.
2. The socket of the shoulder joint (the scapula's glenoid cavity) is shallow and poorly reinforced, so it does not restrict the movement of the humerus (arm bone). Although this arrangement is good for flexibility, it is bad for stability: Shoulder dislocations are fairly common.

Clavicles

The **clavicles** ("little keys"), or collarbones, are slender, doubly curved long bones that can be felt along their entire course as they extend horizontally across the

superior thorax (Figures 7.22a–c and 7.25). Each clavicle is cone shaped at its medial **sternal end,** which attaches to the sternal manubrium, and flattened at its lateral **acromial end** (ah-kro'me-al), which articulates with the scapula. The medial two-thirds of the clavicle is convex anteriorly; its lateral third is concave anteriorly. Its superior surface is smooth, but the inferior surface is ridged and grooved by ligaments and by the action of the muscles that attach to it. The *conoid tubercle,* for example, is an anchoring point for a ligament which runs to attach to the first rib.

Besides anchoring many muscles, the clavicles act as braces: They hold the scapulae and arms out laterally, away from the narrower superior part of the thorax. This bracing function becomes obvious when a clavicle is fractured: The entire shoulder region collapses medially. The clavicles also transmit compression forces from the upper limbs to the axial skeleton, as when someone pushes a car to a gas station.

The clavicles are not very strong and are likely to fracture, for example, when a person uses outstretched arms to break a fall. The curves in the clavicle ensure that it usually fractures anteriorly (outward). If it were to collapse posteriorly (inward), bone splinters would damage the subclavian artery, which passes just deep to the clavicle to serve the upper limb. The clavicles are exceptionally sensitive to muscle pull and become noticeably larger and stronger in those who perform manual labor or athletics involving the shoulder and arm muscles.

Scapulae

The **scapulae,** or *shoulder blades,* are thin, triangular flat bones (Figures 7.22d–f and 7.25). Interestingly, their name derives from a word meaning "spade" or "shovel," for ancient cultures made spades from the shoulder blades of animals. The scapulae lie on the dorsal surface of the rib cage, between ribs 2 and 7. Each scapula has three borders. The *superior border* is the shortest, sharpest border. The *medial,* or *vertebral, border* parallels the vertebral column. The thick *lateral,* or *axillary, border* abuts the armpit and ends superiorly in a small, shallow fossa, the **glenoid cavity** (gle'noid). This cavity articulates with the humerus of the arm, forming the shoulder joint.

Like all triangles, the scapula has three corners or *angles.* The superior scapular border meets the medial border at the *superior angle* and the lateral border at the *lateral angle.* The medial and lateral borders join at the *inferior angle.* The inferior angle moves extensively as the arm is raised and lowered, and is an important landmark for studying scapular movements.

The anterior, or costal, surface of the scapula is concave and relatively featureless. Its posterior surface bears a prominent **spine** that is easily felt through the skin. The spine ends laterally in an

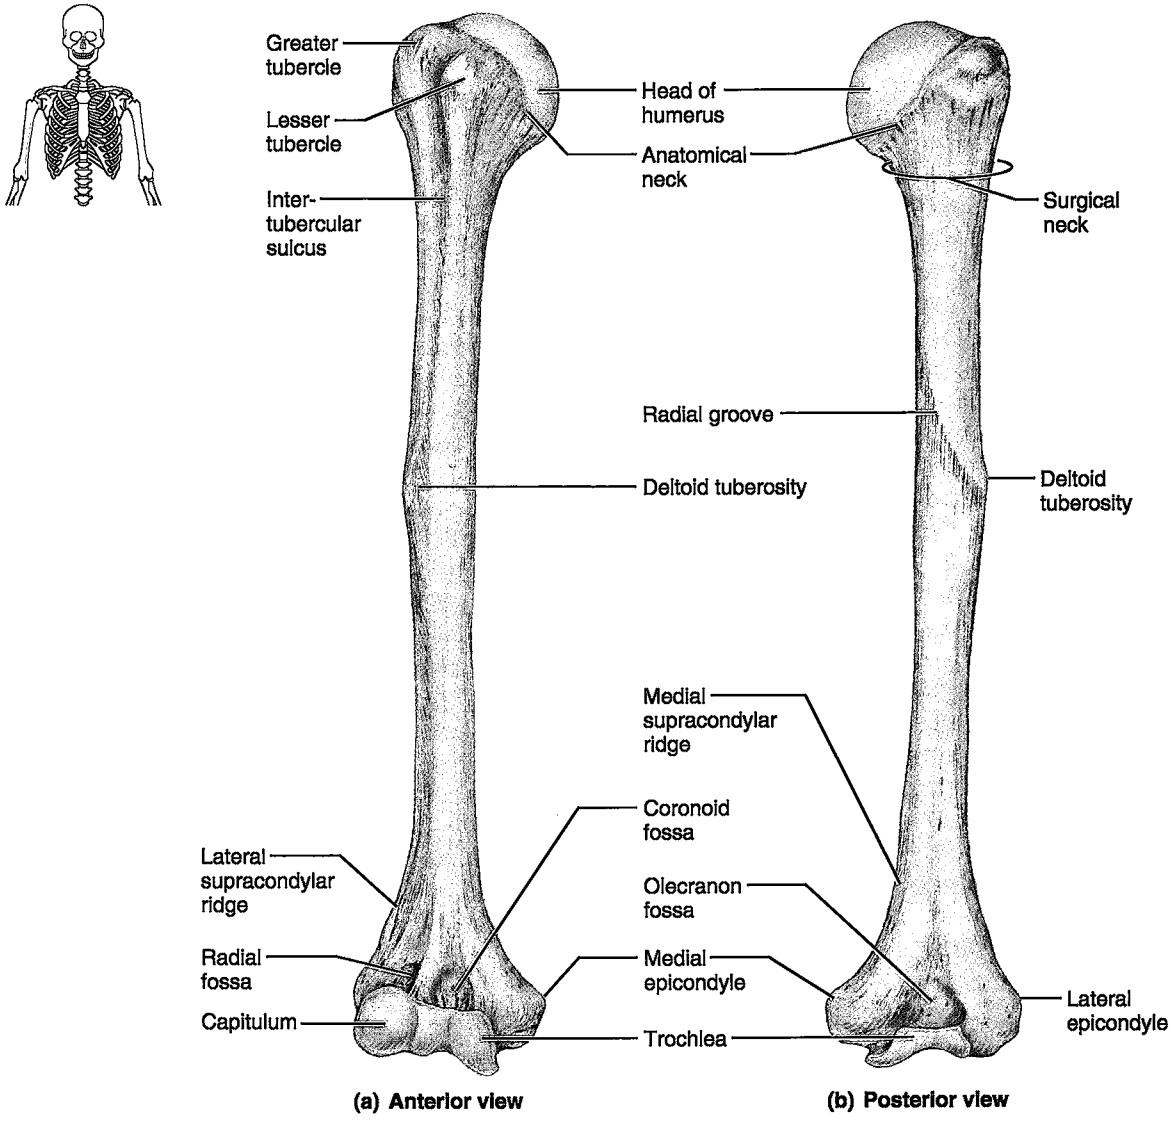

FIGURE 7.23 **The humerus of the right arm.** (See *A Brief Atlas of the Human Body*, Figure 25.)

enlarged, roughened triangular projection called the **acromion** (ah-kro'me-on; "point of the shoulder"). The acromion articulates with the acromial end of the clavicle, forming the **acromioclavicular joint.**

Projecting anteriorly from the superior scapular border is the **coracoid process** (kor'ah-coid); *corac* means "beaklike," but this process looks more like a bent little finger. The coracoid process helps anchor the biceps muscle of the arm. It is bounded by the **suprascapular notch** (a nerve passage) medially and by the glenoid cavity laterally.

Several large fossae appear on both sides of the scapula and are named according to location. The *infraspinous* and *supraspinous fossae* are respectively inferior and superior to the spine. The *subscapular fossa* is the shallow concavity formed by the entire anterior scapular surface.

The Upper Limb

Thirty separate bones form the bony framework of each upper limb (see Figures 7.23 to 7.26, and Table 7.3 on p. 236). Each of these bones may be described regionally as a bone of the arm, forearm, or hand. (Keep in mind that anatomically the "arm" is only that part of the upper limb between the shoulder and elbow.)

Arm

The **humerus** (hu'mer-us), the sole bone of the arm, is a typical long bone (Figures 7.23 and 7.25). The largest, longest bone of the upper limb, it articulates with the scapula at the shoulder and with the radius and ulna (forearm bones) at the elbow.

At the proximal end of the humerus is its smooth, hemispherical **head,** which fits into the

glenoid cavity of the scapula in a manner that allows the arm to hang freely at one's side. Immediately inferior to the head is a slight constriction, the **anatomical neck.** Just inferior to this are the lateral **greater tubercle** and the more medial **lesser tubercle,** separated by the **intertubercular sulcus,** or *bicipital groove* (bi-sip'ĭ-tal). The tubercles are sites of attachment of the rotator cuff muscles.The intertubercular sulcus guides a tendon of the biceps muscle of the arm to its attachment point at the rim of the glenoid cavity. Just distal to the tubercles is the **surgical neck,** so named because it is the most frequently fractured part of the humerus. About midway down the shaft on its lateral side is the **deltoid tuberosity,** the roughened attachment site for the deltoid muscle of the shoulder. Nearby, the **radial groove** runs obliquely down the posterior aspect of the shaft, marking the course of the radial nerve, an important nerve of the upper limb.

At the distal end of the humerus are two condyles, a medial **trochlea** (trok'le-ah; "pulley"), which looks like an hourglass tipped on its side, and the lateral ball-like **capitulum** (kah-pit'u-lum). These condyles articulate with the ulna and the radius, respectively. The condyle pair is flanked by the **medial** and **lateral epicondyles** (muscle attachment sites). Directly above these epicondyles are the **medial** and **lateral supracondylar ridges.** The ulnar nerve runs behind the medial epicondyle and is responsible for the painful, tingling sensation you experience when you hit your "funny bone."

Superior to the trochlea on the anterior surface is the **coronoid fossa;** on the posterior surface is the deeper **olecranon fossa** (o-lek'rah-non). These two depressions allow the corresponding processes of the ulna to move freely when the elbow is flexed and extended. A small **radial fossa,** lateral to the coronoid fossa, receives the head of the radius when the elbow is flexed.

Forearm

Two parallel long bones, the radius and the ulna, form the skeleton of the forearm, or *antebrachium* (an"te-bra'ke-um) (Figures 7.24 and 7.25). Unless a person's forearm muscles are very bulky, these bones are easily palpated along their entire length. Their proximal ends articulate with the humerus; their distal ends form joints with bones of the wrist. The radius and ulna articulate with each other both proximally and distally at small **radioulnar joints** (ra"de-o-ul'nar), and they are connected along their entire length by a flat, flexible ligament, the **interosseous membrane** (in"ter-os'e-us; "between the bones"). In the anatomical position, the radius lies laterally (on the thumb side) and the ulna medially. However, when you rotate your forearm so that the palm faces posteriorly (a movement called pronation), the distal end of the radius crosses over the ulna and the two bones form an X.

Ulna

The **ulna** (ul'nah; "elbow") is slightly longer than the radius. It has the main responsibility for forming the elbow joint with the humerus. Its proximal end looks like the adjustable end of a monkey wrench; it bears two prominent processes, the **olecranon** (elbow) and **coronoid processes,** separated by a deep concavity, the **trochlear notch** (see Figures 7.24 and 7.25). Together, these two processes grip the trochlea of the humerus, forming a hinge joint that allows the forearm to be bent upon the arm (flexed), then straightened again (extended). When the forearm is fully extended, the olecranon process "locks" into the olecranon fossa, keeping the forearm from hyperextending (moving posteriorly beyond the elbow joint). The posterior olecranon process forms the angle of the elbow when the forearm is flexed and is the bony part that rests on the table when you lean on your elbows. On the lateral side of the coronoid process is a small depression, the **radial notch,** where the ulna articulates with the head of the radius.

Distally the ulnar shaft narrows and ends in a knoblike **head.** Medial to the head is a **styloid process,** from which a ligament runs to the wrist. The ulnar head is separated from the bones of the wrist by a disc of fibrocartilage and plays little or no role in hand movements.

Radius

The **radius** ("rod") is thin at its proximal end and wide distally—the opposite of the ulna. The **head** of the radius is shaped somewhat like the head of a nail (see Figures 7.24 and 7.25). The superior surface of this head is concave, and it articulates with the capitulum of the humerus. Medially, the head articulates with the radial notch of the ulna. Just inferior to the head is the rough **radial tuberosity,** which anchors the biceps muscle of the arm. Distally, where the radius is expanded, it has a medial **ulnar notch,** which articulates with the ulna, and a lateral **styloid process** (an anchoring site for ligaments that run to the wrist). Between these two markings, the radius is concave where it articulates with carpal bones of the wrist. While the ulna contributes more heavily to the elbow joint, the radius is the major forearm bone contributing to the wrist joint. When the radius moves, the hand moves with it.

HOMEOSTATIC IMBALANCE

Colle's fracture is a break in the distal end of the radius. It is a common fracture when a falling person attempts to break his or her fall with outstretched hands (see Figure 7.24c). ●

Q *(1) Which of these bones "carries" the hand? (2) Which plays the major role in forming the elbow joint with the humerus?*

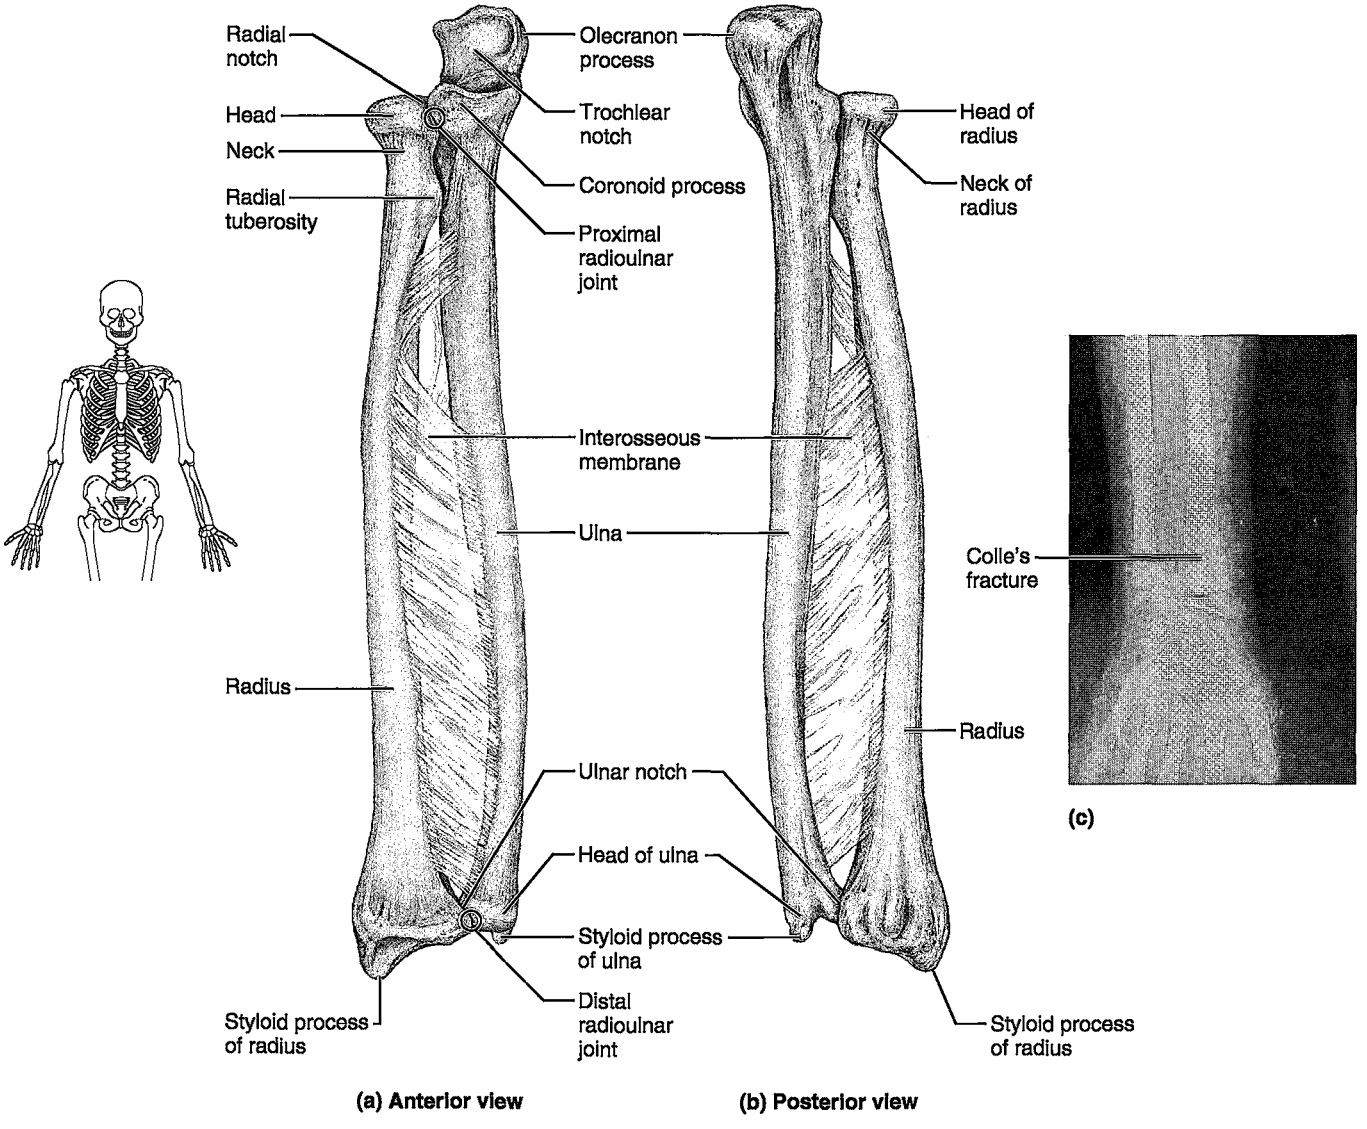

FIGURE 7.24 **Radius and ulna of the right forearm. (a, b)** Anterior and posterior views, respectively. **(c)** X ray of Colle's fracture of the radius. (See *A Brief Atlas of the Human Body*, Figure 26.)

Hand

The skeleton of the hand (Figure 7.26) includes the bones of the *carpus* (wrist); the bones of the *metacarpus* (palm); and the *phalanges* (bones of the fingers).

A *(1) The radius carries the hand. (2) The ulna forms the elbow joint with the humerus.*

Carpus (Wrist)

A "wrist" watch is actually worn on the distal forearm (over the lower ends of the radius and ulna), not on the wrist at all. The true wrist, or **carpus,** is the proximal part of the structure we generally call our "hand." The carpus consists of a group of eight marble-size short bones, or **carpals** (kar'palz), closely united by ligaments. Because gliding movements occur between these bones, the carpus as a whole is quite flexible. The carpals are arranged in two irregular rows of four bones each (Figure 7.26). In the proximal row (lateral to medial) are the **scaphoid** (skaf'oid; "boat-shaped"),

lunate (lu'nāt; "moonlike"), **triquetral** (tri-kwe'trul; "triangular"), and **pisiform** (pi'sĭ-form; "pea-shaped"). Only the scaphoid and lunate articulate with the radius to form the wrist joint. The carpals of the distal row (lateral to medial) are the **trapezium** (trah-pe'ze-um; "little table"), **trapezoid** (tra'peh-zoid; "four-sided"), **capitate** ("head-shaped"), and **hamate** (ham'āt; "hooked"). There are numerous memory-jogging phrases to help you recall the carpals in the order given above. If you don't have one, try: **S**ally **l**eft **t**he **p**arty **t**o **t**ake **C**athy **h**ome. As with all such memory jogs, the first letter of each word is the first letter of the term you need to remember.

HOMEOSTATIC IMBALANCE

The arrangement of its bones is such that the carpus is concave anteriorly and a ligament roofs over this concavity, forming the notorious *carpal tunnel.* Besides the median nerve (which supplies the lateral side of the hand), several long muscle tendons crowd into this tunnel. Overuse and inflammation of the tendons cause them to swell, compressing the median nerve, which causes tingling and numbness of the areas served. Pain is greatest at night. Those who repeatedly flex their wrists and fingers, such as those who work at computer keyboards all day, are particularly susceptible to this nerve impairment, called *carpal tunnel syndrome.* This condition is treated by splinting the wrist during sleep or by surgery. ◉

Metacarpus (Palm)

Five **metacarpal bones** radiate from the wrist like spokes to form the palm of the hand (*meta* = beyond). These small long bones are not named, but instead are numbered 1 to 5 from thumb to little finger. The **bases** of the metacarpals articulate with the carpals proximally and each other medially and laterally (see Figure 7.26). Their bulbous **heads** articulate with the proximal phalanges of the fingers. When you clench your fist, the heads of the metacarpals become prominent as your *knuckles.*

Metacarpal 1, associated with the thumb, is the shortest and most mobile. It occupies a more anterior position than the other metacarpals. Consequently, the

joint between metacarpal 1 and the trapezium is a unique saddle joint that allows *opposition*, the action of touching your thumb to the tips of your other fingers.

Phalanges (Fingers)

The **fingers,** or **digits** of the upper limb, are numbered 1 to 5 beginning with the thumb, or **pollex** (pol'eks). In most people, the third finger is the longest. Each hand contains 14 miniature long bones called **phalanges** (fah-lan'jēz). Except for the thumb, each finger has three phalanges: *distal, middle,* and *proximal.* The thumb has no middle phalanx. [Phalanx (fa'langks; "a closely knit row of soldiers") is the singular term for phalanges.]

The Pelvic (Hip) Girdle

The **pelvic girdle,** or **hip girdle,** attaches the lower limbs to the axial skeleton, transmits the weight of the upper body to the lower limbs, and supports the visceral organs of the pelvis (Figures 7.27 and 7.30 and Table 7.4, p. 240). Whereas the pectoral girdle is sparingly attached to the thoracic cage, the pelvic girdle is secured to the axial skeleton by some of the strongest ligaments in the body. And whereas the glenoid cavity of the scapula is shallow, the corresponding sockets of the pelvic girdle are deep and cuplike and firmly secure the head of the femur in place. Thus, even though both the shoulder and hip joints are ball-and-socket joints, very few of us can wheel or swing our legs about with the same degree of freedom as our arms. The pelvic girdle lacks the mobility of the pectoral girdle but is far more stable.

The pelvic girdle is formed by a pair of **hip bones** (Figure 7.27), each also called an **os coxae** (ahs kok'se), or **coxal bone** (*coxa* = hip). Each hip bone unites with its partner anteriorly and with the sacrum posteriorly. The deep, basinlike structure formed by the hip bones, together with the sacrum and coccyx, is called the **bony pelvis.**

Each large, irregularly shaped hip bone consists of three separate bones during childhood: the ilium, ischium, and pubis. In adults, these bones are firmly fused and their boundaries are indistinguishable. Their names are retained, however, to refer to different regions of the composite hip bone. At the point of fusion of the ilium, ischium, and pubis is a deep hemispherical socket called the **acetabulum** (as"ĕ-tab'u-lum; "wine cup") on the lateral surface of the pelvis (see Figure 7.27b). The acetabulum receives the head of the femur, or thigh bone, at this *hip joint.*

Ilium

The **ilium** (il'e-um; "flank") is a large flaring bone that forms the superior region of a coxal bone. It consists of a **body** and a superior winglike portion called the **ala** (a'lah). When you rest your hands on your hips, you are resting them on the thickened superior margins of the alae, the **iliac crests.** Thickest at the **tubercle of the iliac crest,** each iliac crest ends anteriorly in the blunt **anterior superior iliac spine** and posteriorly in the sharp **posterior superior iliac spine.** Located below these are the less prominent **anterior** and **posterior inferior iliac spines.** All of these spines are attachment points for the muscles of the trunk, hip, and thigh. The anterior superior iliac spine is an especially important anatomical landmark. It is easily felt through the skin and is visible in thin people. The posterior superior iliac spine is difficult to palpate, but its position is revealed by a skin dimple in the sacral region.

Just inferior to the posterior inferior iliac spine, the ilium indents deeply to form the **greater sciatic notch** (si-at'ik), through which the thick cordlike sciatic nerve passes to enter the thigh. The broad posterolateral surface of the ilium, the **gluteal surface** (gloo'te-al), is crossed by three ridges, the **posterior, anterior,** and **inferior gluteal lines,** to which the gluteal (buttock) muscles attach.

The internal surface of the iliac ala exhibits a concavity called the **iliac fossa.** Posterior to this, the roughened **auricular surface** (aw-rik'u-lar; "ear-shaped") articulates with the same-named surface of the sacrum, forming the *sacroiliac joint.* The weight of the body is transmitted from the spine to the pelvis through the sacroiliac joints. Running inferiorly and anteriorly from the auricular surface is a robust ridge called the **arcuate line** (ar'ku-at; "bowed"). The arcuate line helps define the **pelvic brim,** the superior margin of the *true pelvis,* which we will discuss shortly. Anteriorly, the body of the ilium joins the pubis; inferiorly it joins the ischium.

Ischium

The **ischium** (is'ke-um; "hip") forms the posteroinferior part of the hip bone (Figures 7.27 and 7.30). Roughly L- or arc-shaped, it has a thicker, superior **body** adjoining the ilium and a thinner, inferior **ramus** (*ramus* = branch). The ramus joins the pubis anteriorly. The ischium has three important markings. Its **ischial spine** projects medially into the pelvic cavity and serves as a point of attachment of the *sacrospinous ligament* running from the sacrum. Just inferior to the ischial spine is the **lesser sciatic notch.** A number of nerves and blood vessels pass through this notch to supply the anogenital area. The inferior surface of the ischial body is rough and grossly thickened as the **ischial tuberosity.** When we sit, our weight is borne entirely by the ischial tuberosities, which are the strongest parts of the hip bones. A massive ligament runs from the sacrum to

Q *What bone marking identified in Figure 7.27 allows passage of the sciatic nerve and artery?*

A Greater sciatic notch.

each ischial tuberosity. This *sacrotuberous ligament* (not illustrated) helps hold the pelvis together. The ischial tuberosity is also a site of attachment of the large hamstring muscles of the posterior thigh.

Pubis

The **pubis** (pu'bis; "sexually mature"), or **pubic bone,** forms the anterior portion of the hip bone (Figures 7.27 and 7.30). In the anatomical position, it lies nearly horizontally and the urinary bladder rests upon it. Essentially, the pubis is V shaped with **superior** and **inferior rami** issuing from a flattened medial **body.** The body of the pubis lies medially and its anterior border is thickened to form a **pubic crest.** At the lateral end of the pubic crest is the **pubic tubercle,** one of the attachments for the inguinal ligament. As the two rami of the pubic bone run laterally to join with the body and ramus of the ischium, they define a large opening in the hip bone, the **obturator foramen** (ob"tu-ra'tor), through which a few blood vessels and nerves pass. Although the obturator foramen is large, it is nearly closed by a fibrous membrane in life (*obturator* = closed up).

The bodies of the two pubic bones are joined by a fibrocartilage disc, forming the midline **pubic symphysis joint.** Inferior to this joint, the inferior pubic rami angle laterally, forming an inverted V-shaped arch called the **pubic arch** or **subpubic angle.** The acuteness of this arch helps to differentiate the male and female pelves.

Pelvic Structure and Childbearing

So striking are the differences between the male and female pelves that a trained anatomist can immediately determine the sex of a skeleton from a casual examination of the pelvis. The female pelvis is modified for childbearing: It tends to be wider, shallower, lighter, and rounder than that of a male. The female pelvis not only accommodates a growing fetus, but it must be large enough to allow the infant's relatively large head to exit at birth. The major differences between the typical male and female pelves are summarized and illustrated in Table 7.4.

The pelvis is said to consist of a false (greater) pelvis and a true (lesser) pelvis separated by the **pelvic brim,** a continuous oval ridge that runs from the pubic crest through the arcuate line and sacral promontory (Figure 7.27a). The false pelvis, that portion superior to the pelvic brim, is bounded by the alae of the ilia laterally and the lumbar vertebrae posteriorly. The **false pelvis** is really part of the abdomen and helps support the abdominal viscera. It does not restrict childbirth in any way. The **true pelvis** is the region inferior to the pelvic brim that is almost entirely surrounded by bone. It forms a deep bowl containing the pelvic organs. Its dimensions, particularly those of its *inlet* and *outlet,* are critical to the uncomplicated delivery of a baby, and they are carefully measured by an obstetrician.

The **pelvic inlet** *is* the pelvic brim, and its widest dimension is from right to left along the frontal plane. As labor begins, an infant's head typically enters the inlet with its forehead facing one ilium and its occiput facing the other. A sacral promontory that is particularly large can impair the infant's entry into the true pelvis. The **pelvic outlet,** illustrated in the photos at the bottom of Table 7.4, is the inferior margin of the true pelvis. It is bounded anteriorly by the pubic arch, laterally by the ischia, and posteriorly by the sacrum and coccyx. Both the coccyx and the ischial spines protrude into the outlet opening, so a sharply angled coccyx or unusually large spines can interfere with delivery. The largest dimension of the outlet is the anteroposterior diameter. Generally, after the baby's head passes through the inlet, it rotates so that the forehead faces posteriorly and the occiput anteriorly. Thus, during birth, the infant's head makes a quarter turn to follow the widest dimensions of the true pelvis.

The Lower Limb

The lower limbs carry the entire weight of the erect body and are subjected to exceptional forces when we jump or run. Thus, it is not surprising that the bones of the lower limbs are thicker and stronger than comparable bones of the upper limbs. The three segments of each lower limb are the thigh, the leg, and the foot (see Table 7.5 on p. 246).

Thigh

The **femur** (fe'mur; "thigh"), the single bone of the thigh (Figures 7.28 and 7.30), is the largest, longest, strongest bone in the body. Its durable structure reflects the fact that the stress on the femur during vigorous jumping can reach 280 kg/cm^2 (about 2 tons per square inch)! The femur is clothed by bulky muscles that prevent us from palpating its course down the length of the thigh. Its length is roughly one-quarter of a person's height.

Proximally, the femur articulates with the hip bone and then courses medially as it descends toward the knee. This arrangement allows the knee joints to be closer to the body's center of gravity and provides for better balance. The medial course of the two femurs is more pronounced in women because of their wider pelvis.

The ball-like **head** of the femur has a small central pit called the **fovea capitis** (fo've-ah kă'pĭ-tis; "pit of the head"). The short *ligament of the head of the femur* runs from this pit to the acetabulum, where it helps secure the femur. The head is carried on a *neck* that angles *laterally* to join the shaft. This

TABLE 7.4 Comparison of the Male and Female Pelves

CHARACTERISTIC	FEMALE	MALE
General structure and functional modifications	Tilted forward; adapted for childbearing; true pelvis defines the birth canal; cavity of the true pelvis is broad, shallow, and has a greater capacity	Tilted less far forward; adapted for support of a male's heavier build and stronger muscles; cavity of the true pelvis is narrow and deep
Bone thickness	Less; bones lighter, thinner, and smoother	Greater; bones heavier and thicker, and markings are more prominent
Acetabula	Smaller; farther apart	Larger; closer
Pubic arch/angle	Broader (80–90°); more rounded	More acute (50–60°)
Anterior view		
Sacrum	Wider; shorter; sacral curvature is accentuated	Narrow; longer; sacral promontory more ventral
Coccyx	More movable; straighter	Less movable; curves ventrally
Left lateral view		Pelvic inlet (brim)	Wider; oval from side to side	Narrow; basically heart shaped
Pelvic outlet	Wider; ischial tuberosities shorter, farther apart and everted	Narrower; ischial tuberosities longer, sharper, and point more medially
Posteroinferior view		

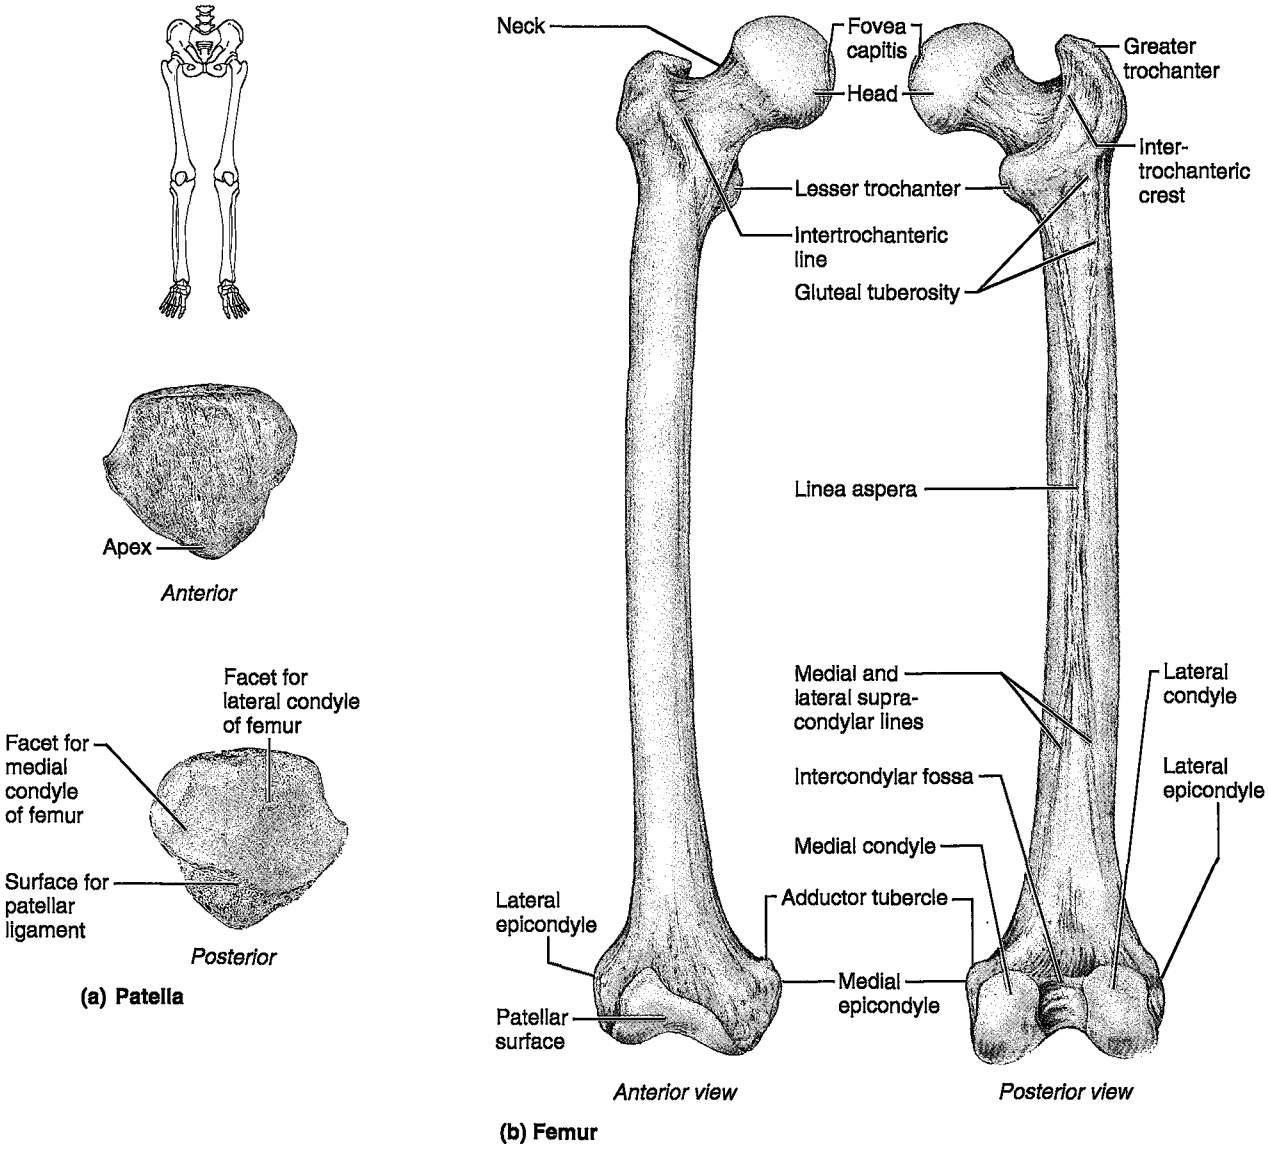

FIGURE 7.28 **Bones of the right thigh and knee. (a)** The patella (kneecap). **(b)** The femur (thigh bone). (See *A Brief Atlas of the Human Body*, Figure 29.)

arrangement reflects the fact that the femur articulates with the lateral aspect (rather than the inferior region) of the pelvis. The neck is the weakest part of the femur and is often fractured, an injury commonly called a broken hip. At the junction of the shaft and neck are the lateral **greater trochanter** (tro-kan'ter) and posteromedial **lesser trochanter.** These projections serve as sites of attachment for thigh and buttock muscles. The two trochanters are connected by the **intertrochanteric line** anteriorly and by the prominent **intertrochanteric crest** posteriorly.

Inferior to the intertrochanteric crest on the posterior shaft is the **gluteal tuberosity,** which blends into a long vertical ridge, the **linea aspera** (lin'e-ah as'per-ah; "rough line"), inferiorly. Distally, the linea aspera diverges, forming the **medial** and **lateral supracondylar lines.** All of these markings are sites of muscle attachment. Except for the linea aspera, the femur shaft is smooth and rounded.

Distally, the femur broadens and ends in the wheel-like **lateral** and **medial condyles,** which articulate with the tibia of the leg. The **medial** and **lateral epicondyles** (sites of muscle attachment) flank the condyles superiorly. On the superior part of the medial epicondyle is a bump, the **adductor tubercle.** The smooth **patellar surface,** between the condyles on the anterior femoral surface, articulates with the *patella* (pah-tel'ah), or kneecap (see Figures 7.28a, 7.30, and 7.21).

Between the condyles on the posterior aspect of the femur is the deep, U-shaped **intercondylar fossa,** and superior to that on the shaft is the smooth popliteal surface.

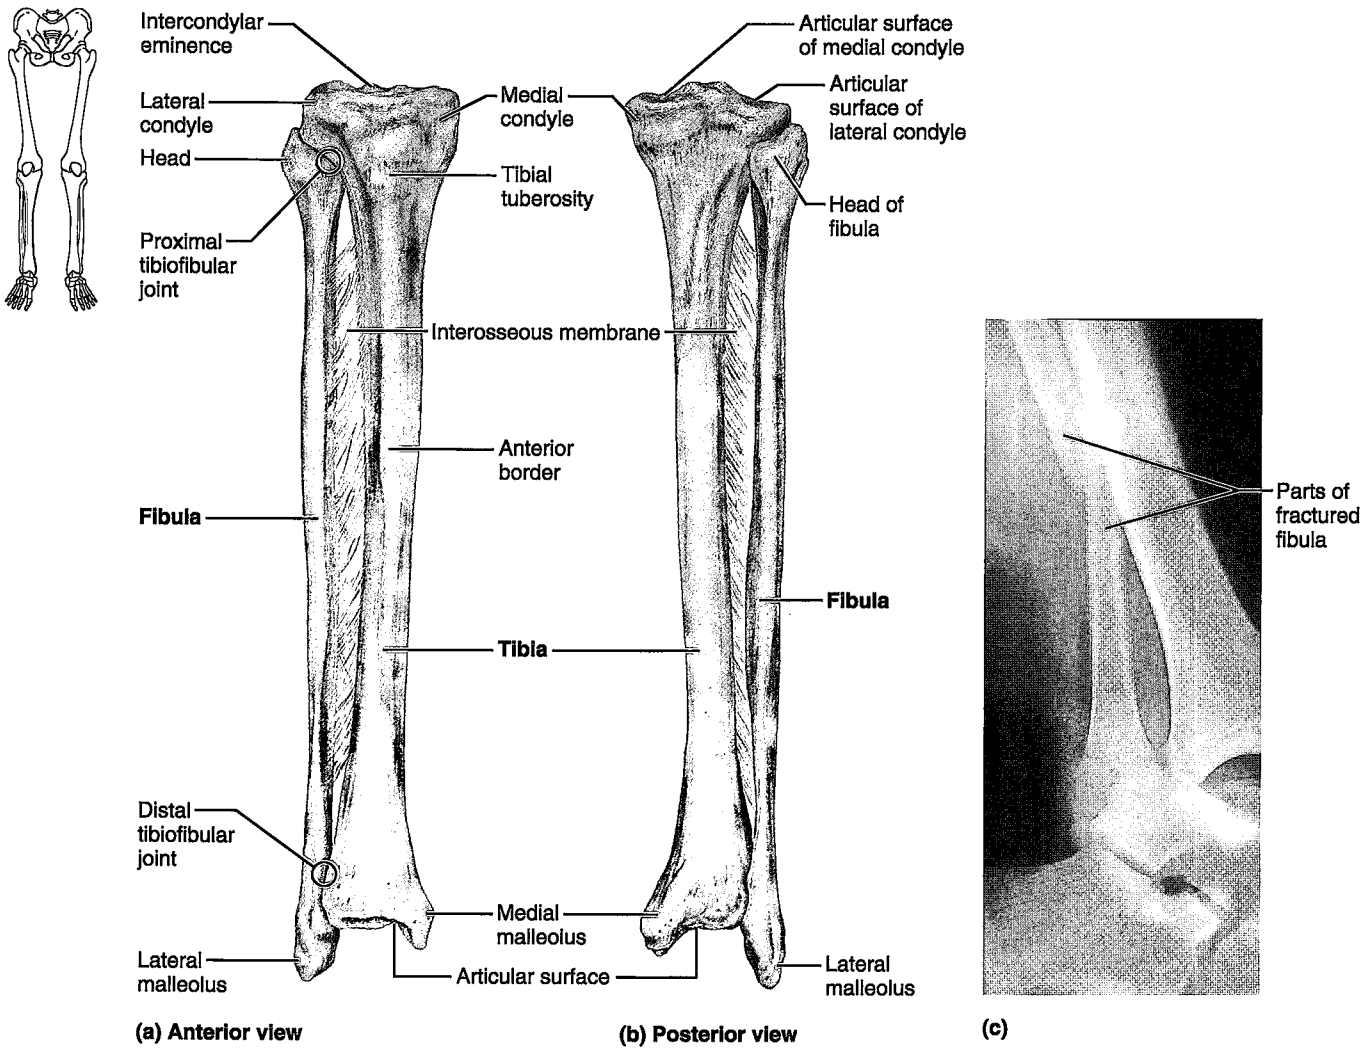

FIGURE 7.29 **The tibia and fibula of the right leg. (a)** Anterior view. **(b)** Posterior view. **(c)** X ray of Pott's fracture of the fibula. (See *A Brief Atlas of the Human Body*, Figure 30.)

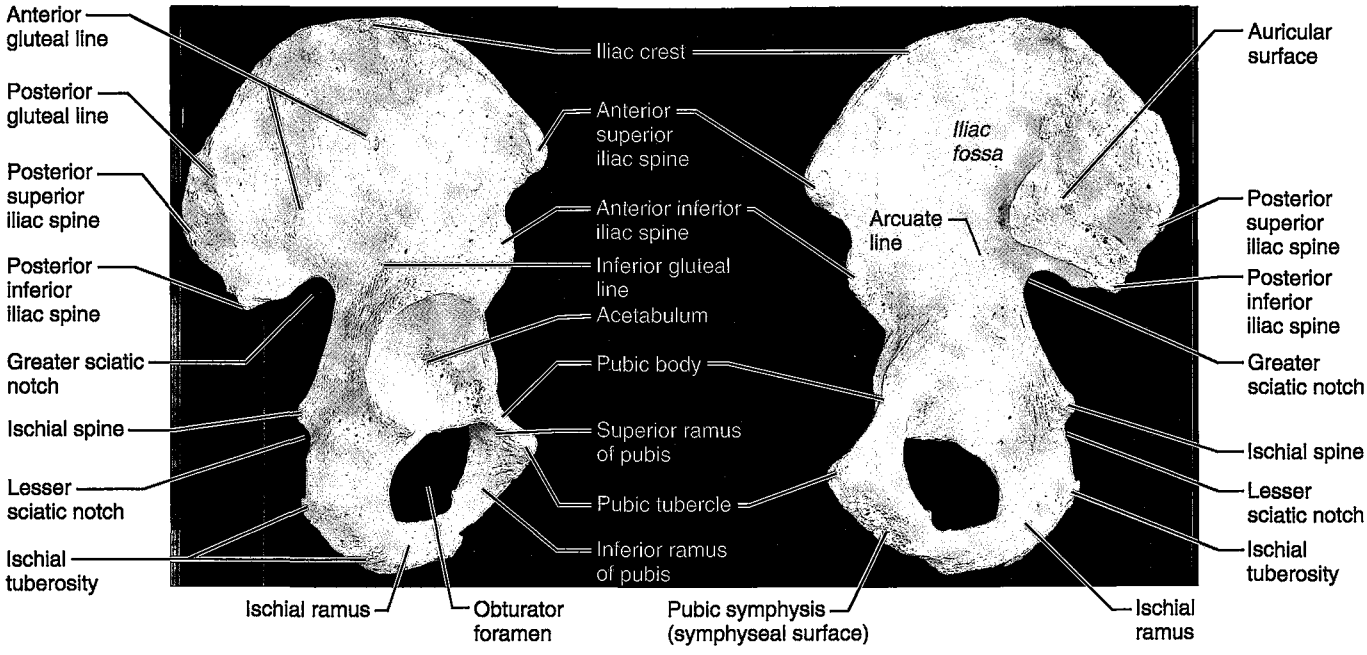
The **patella** ("small pan") is a triangular sesamoid bone enclosed in the (quadriceps) tendon that secures the anterior thigh muscles to the tibia. It protects the knee joint anteriorly and improves the leverage of the thigh muscles acting across the knee.

Leg

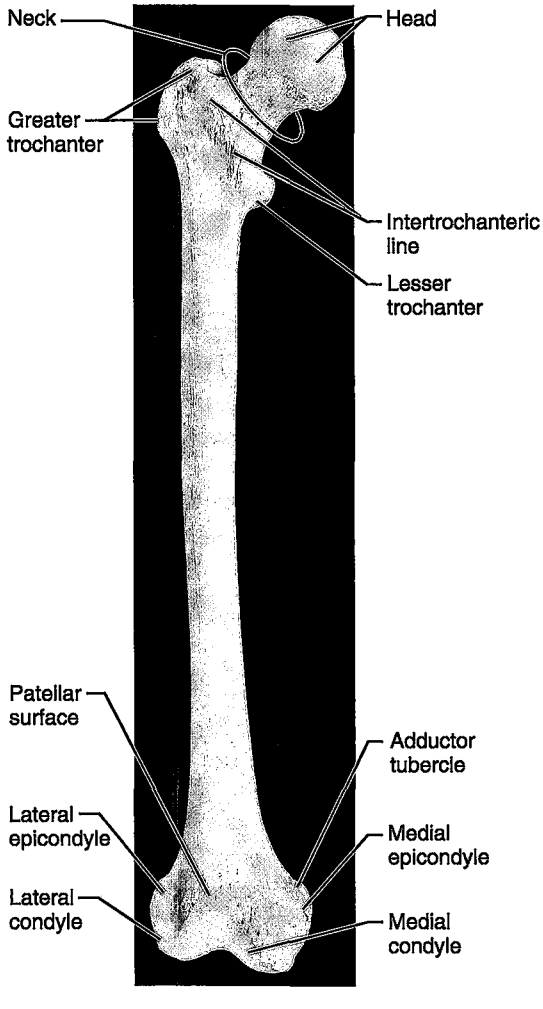
Two parallel bones, the tibia and fibula, form the skeleton of the leg, the region of the lower limb between the knee and the ankle (Figures 7.29 and 7.30). These two bones are connected by an *interosseous membrane* and articulate with each other both proximally and distally. However, unlike the joints between the radius and ulna of the forearm, the *tibiofibular joints* (tib"e-o-fib'u-lar) of the leg allow essentially no movement. The bones of the leg thus form a less flexible but stronger and more stable limb than those of the forearm. The medial tibia articulates proximally with the femur to form the modified hinge joint of the knee and distally with the talus bone of the foot at the ankle. The fibula, by contrast, does not contribute to the knee joint and merely helps stabilize the ankle joint.

Tibia

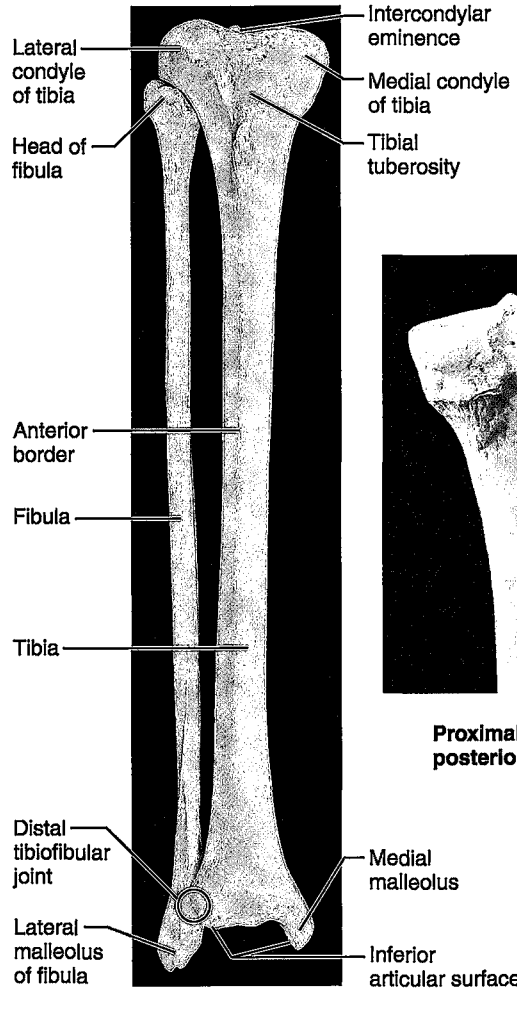
The **tibia** (tib'e-ah; "shinbone") receives the weight of the body from the femur and transmits it to the foot. It is second only to the femur in size and strength. At its broad proximal end are the concave **medial** and **lateral condyles,** which look like two huge checkers lying side by side. These are separated by an irregular projection, the **intercondylar eminence.** The tibial condyles articulate with the corresponding condyles of the femur. The inferior region of the lateral tibial condyle bears a facet that indicates the site of the *proximal tibiofibular joint.* Just inferior to the condyles, the tibia's anterior surface displays the rough **tibial tuberosity,** to which the patellar ligament attaches.



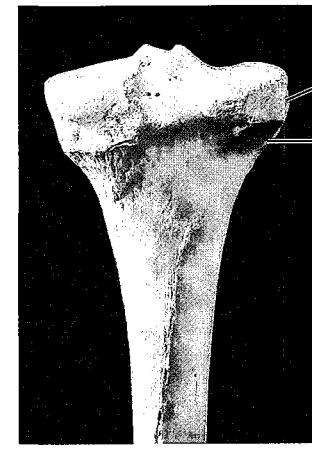
(a) Lateral view **Right hip bone** **(b) Medial view**



Right femur, anterior surface



Right tibia and fibula, anterior view



Proximal right tibia, posterior view

FIGURE 7.30 **Photographs of selected bones of the pelvic girdle and lower limb.** (See *A Brief Atlas of the Human Body*, Figures 28, 29, and 30.)

The tibial shaft is triangular in cross section. Neither the tibia's sharp **anterior border** nor its medial surface is covered by muscles, so they can be felt just deep to the skin along their entire length. The anguish of a "bumped" shin is an experience familiar to nearly everyone. Distally the tibia is flat where it articulates with the talus bone of the foot. Medial to that joint surface is an inferior projection, the **medial malleolus** (mah-le'o-lus; "little hammer"), which forms the medial bulge of the ankle. The **fibular notch,** on the lateral surface of the tibia, participates in the *distal tibiofibular joint.*

Fibula

The **fibula** (fib'u-lah; "pin") is a sticklike bone with slightly expanded ends. It articulates proximally and distally with the lateral aspects of the tibia. Its proximal end is its **head;** its distal end is the **lateral malleolus.** The lateral malleolus forms the conspicuous lateral ankle bulge and articulates with the talus. The fibular shaft is heavily ridged and appears to have been twisted a quarter turn. The fibula does not bear weight, but several muscles originate from it.

HOMEOSTATIC IMBALANCE

A *Pott's fracture* occurs at the distal end of the fibula, the tibia, or both. It is a common sports injury. (See Figure 7.29c.)

Foot

The skeleton of the foot includes the bones of the *tarsus,* the bones of the *metatarsus,* and the *phalanges,* or toe bones (Figure 7.31). The foot has two important functions: It supports our body weight, and it acts as a lever to propel the body forward when we walk and run. A single bone could serve both purposes, but it would adapt poorly to uneven ground. Segmentation makes the foot pliable, avoiding this problem.

Tarsus

The **tarsus** is made up of seven **tarsal bones** (tar'sal) that form the posterior half of the foot. It corresponds to the carpus of the hand. Body weight is carried primarily by the two largest, most posterior tarsals: the **talus** (ta'lus; "ankle"), which articulates with the tibia and fibula superiorly, and the strong **calcaneus** (kal-ka'ne-us; "heel bone"), which forms the heel of the foot and carries the talus on its superior surface. The thick *calcaneal,* or *Achilles, tendon* of the calf muscles attaches to the posterior surface of the calcaneus. The part of the calcaneus that touches the ground is the **calcaneal tuberosity,** and its shelflike projection that supports part of the talus is the **sustentaculum tali** (sus"ten-tak'u-lum ta'le; "supporter of the talus") or **talar shelf.** The tibia articulates with the talus at the *trochlea* of the talus. The remaining tarsals are the lateral **cuboid,** the medial **navicular** (nah-vik'u-lar), and the anterior **medial, intermediate,** and **lateral cuneiform bones** (ku-ne'i-form; "wedge-shaped"). The cuboid and cuneiform bones articulate with the metatarsal bones anteriorly.

Metatarsus

The **metatarsus** consists of five small, long bones called **metatarsal bones.** These are numbered 1 to 5 beginning on the medial (great toe) side of the foot. The first metatarsal is short and thick and its plantar surface rests on paired sesamoid bones (not shown), which play an important role in supporting body weight. The arrangement of the metatarsals is more parallel than that of the metacarpals of the hands. Distally, where the metatarsals articulate with the proximal phalanges of the toes, the enlarged head of the first metatarsal forms the "ball" of the foot.

Phalanges (Toes)

The 14 phalanges of the toes are a good deal smaller than those of the fingers and thus are less nimble. But their general structure and arrangement are the same. There are three phalanges in each digit except for the great toe, the **hallux.** The hallux has only two, proximal and distal.

Arches of the Foot

A segmented structure can hold up weight only if it is arched. The foot has three arches: two *longitudinal arches* (*medial* and *lateral*) and one *transverse arch* (Figure 7.32), which account for its awesome strength. These arches are maintained by the interlocking shapes of the foot bones, by strong ligaments, and by the pull of some tendons during muscle activity. The ligaments and muscle tendons provide a certain amount of springiness. In general, the arches "give" or stretch slightly when weight is applied to the foot and spring back when the weight is removed, which makes walking and running more economical in terms of energy use than would otherwise be the case.

If you examine your wet footprints, you will see that the medial margin from the heel to the head of the first metatarsal leaves no print. This is because the **medial longitudinal arch** curves well above the ground. The talus is the keystone of this arch, which originates at the calcaneus, rises to the talus, and then descends to the three medial metatarsals. The **lateral longitudinal arch** is very low. It elevates the lateral part of the foot just enough to redistribute some of the weight to the calcaneus and the head of the fifth metatarsal (to the ends of the arch). The cuboid is the keystone bone of this arch. The two longitudinal arches serve as pillars for the **transverse**

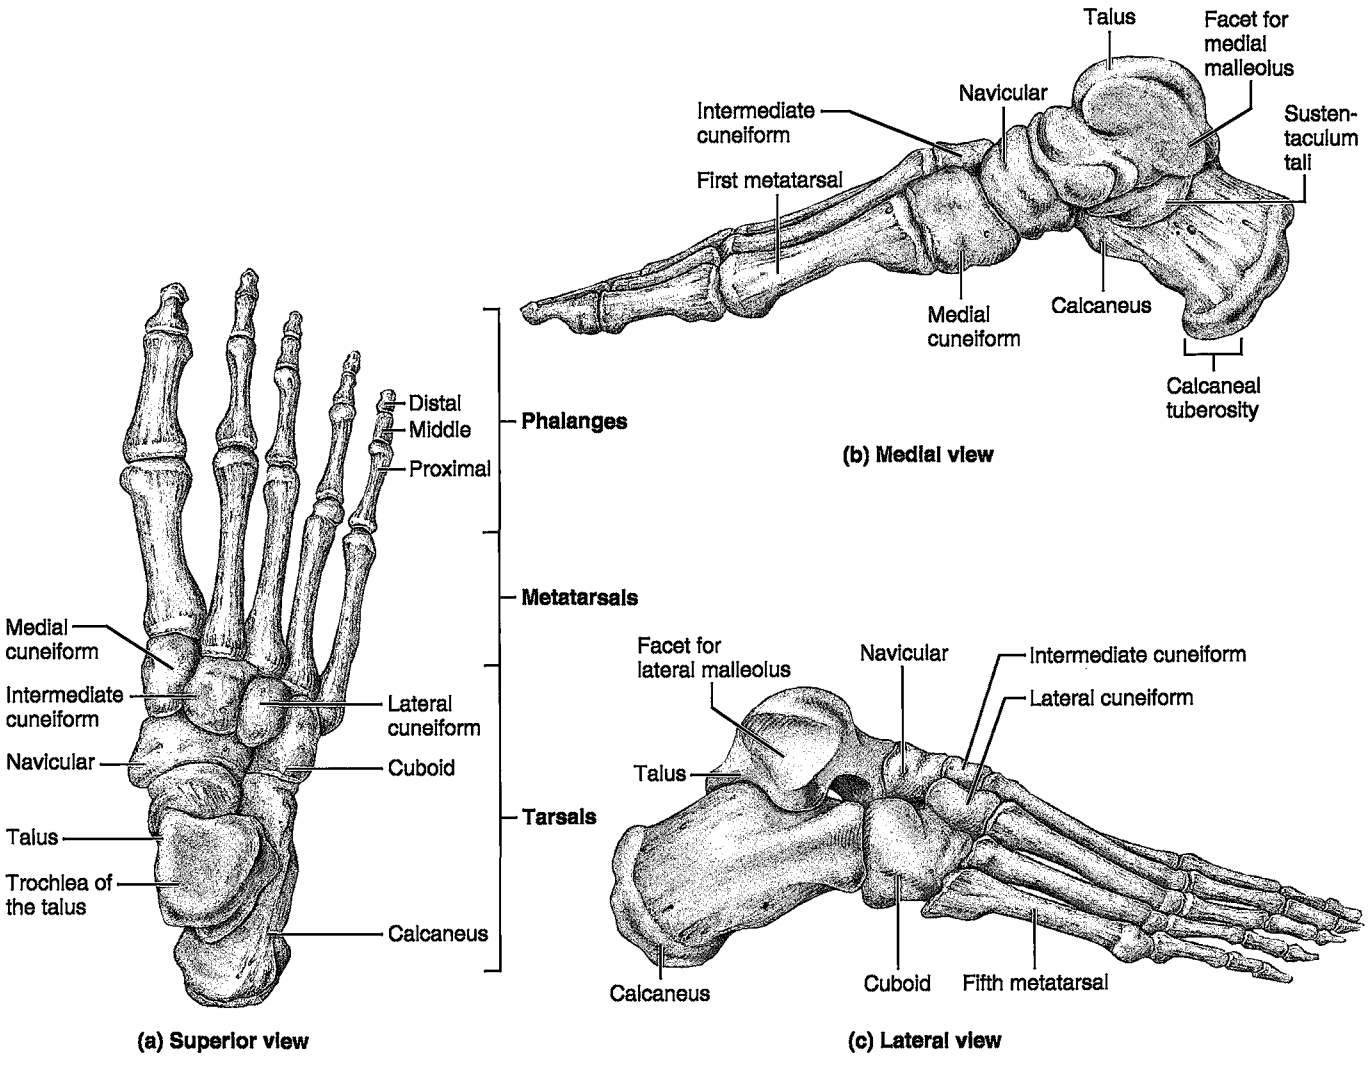


FIGURE 7.31 **Bones of the right foot.** (See *A Brief Atlas of the Human Body*, Figure 31a, c, and d.)

arch, which runs obliquely from one side of the foot to the other, following the line of the joints between the tarsals and metatarsals. Together, the arches of the foot form a half-dome that distributes about half of a person's standing and walking weight to the heel bones and half to the heads of the metatarsals.

HOMEOSTATIC IMBALANCE

Standing immobile for extended periods places excessive strain on the tendons and ligaments of the feet (because the muscles are inactive) and can result in fallen arches, or "flat feet," particularly if one is overweight. Running on hard surfaces can also cause arches to fall unless one wears shoes that give proper arch support. ●

■ ■ ■

The bones of the thigh, leg, and foot are summarized in Table 7.5.

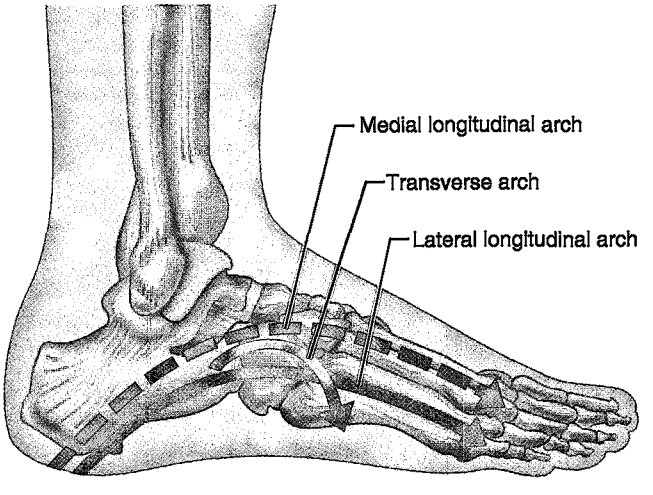

FIGURE 7.32 **Arches of the foot.**

TABLE 7.5 Bones of the Appendicular Skeleton Part 2: Pelvic Girdle and Lower Limb

BODY REGION	BONES*	ILLUSTRATION	LOCATION	MARKINGS
Pelvic girdle (Figures 7.27, 7.30)	Coxal (2) (hip)		Each hip bone is formed by the fusion of an ilium, an ischium, and a pubic bone; the hip bones fuse anteriorly at the pubic symphysis and form sacroiliac joints with the sacrum posteriorly; girdle consisting of both hip bones is basinlike	Iliac crest; anterior and posterior iliac spines; auricular surface; greater and lesser sciatic notches; obturator foramen; ischial tuberosity and spine; acetabulum; pubic arch; pubic crest; pubic tubercle
Free lower limb				
Thigh (Figures 7.28b, 7.30)	Femur (2)		Femur is the only bone of thigh; between hip joint and knee; largest bone of the body	Head; greater and lesser trochanters; neck; lateral and medial condyles and epicondyles; adductor tubercle; gluteal tuberosity; linea aspera
Kneecap (Figure 7.28a)	Patella (2)		Patella is a sesamoid bone lodged in the tendon of the quadriceps (anterior thigh) muscles	
Leg (Figures 7.29, 7.30)	Tibia (2)		Tibia is the larger and more medial bone of leg; between knee and foot	Medial and lateral condyles; tibial tuberosity; anterior border; medial malleolus
	Fibula (2)		Fibula is the lateral bone of leg; sticklike	Head; lateral malleolus
Foot (Figure 7.31)	7 Tarsals (14) • talus • calcaneus • navicular • cuboid • lateral cuneiform • intermediate cuneiform • medial cuneiform		Seven tarsal bones form the proximal part of the foot; the talus articulates with the leg bones at the ankle joint; the calcaneus, the largest tarsal, forms the heel	
	5 Metatarsals (10)		Metatarsals are five bones numbered 1–5 from the great toe	
	14 Phalanges (28) • distal • middle • proximal		Phalanges form the toes; three in digits 2–5, two in digit 1 (the great toe)	

Anterior view of pelvic girdle and left lower limb

*The number in parentheses ( ) following the bone name denotes the total number of such bones in the body.

Developmental Aspects of the Skeleton

The membrane bones of the skull start to ossify late in the second month of development. The rapid deposit of bone matrix at the ossification centers produces cone-shaped protrusions in the developing bones. At birth, the skull bones are still incomplete and are connected by as yet unossified remnants of fibrous membranes called **fontanels** (fon"tah-nelz') (Figure 7.33). The fontanels allow the infant's head to be compressed slightly during birth, and they accommodate brain growth in the fetus and infant. A baby's pulse can be felt surging in these "soft spots"; hence their name (*fontanel* = little fountain). The large, diamond-shaped *anterior fontanel* is palpable for 1½ to 2 years after birth. The others are replaced by bone by the end of the first year.

HOMEOSTATIC IMBALANCE

Several congenital abnormalities may distort the skull. Most common is *cleft palate,* a condition in which the right and left halves of the palate fail to

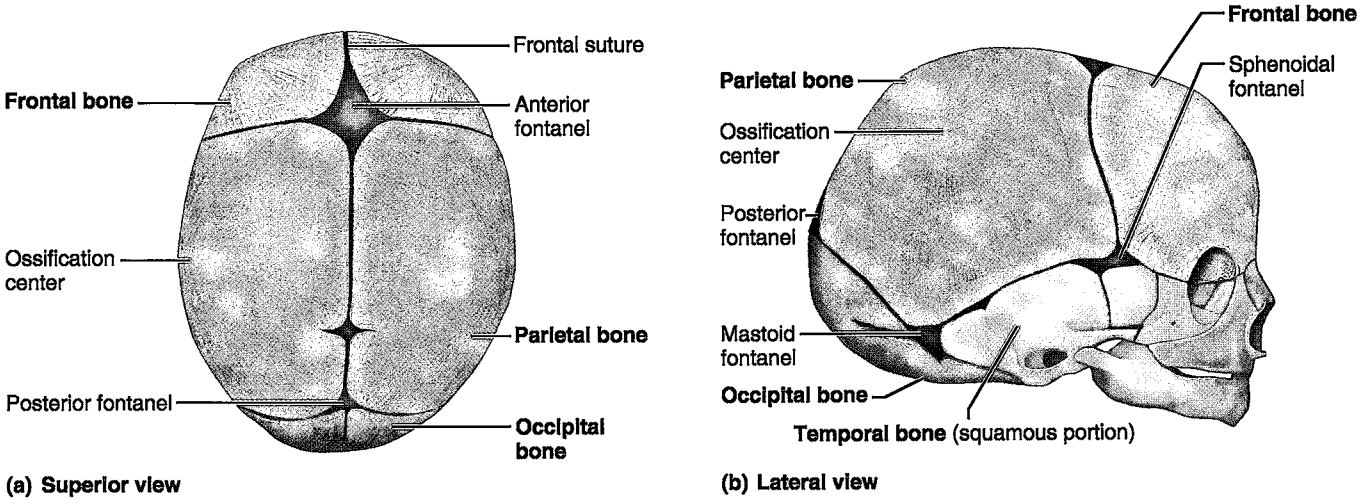

FIGURE 7.33 **The fetal skull.** Notice that the infant's skull has more bones than that of an adult. (See *A Brief Atlas of the Human Body*, Figure 16.)

fuse medially (Figure 7.34). The persistent opening between the oral and nasal cavities interferes with sucking and can lead to aspiration (inhalation) of food into the lungs and *aspiration pneumonia.*

The skeleton changes throughout life, but the changes in childhood are most dramatic. At birth, the baby's cranium is huge relative to its face, and several bones are still unfused (e.g., the mandible and frontal bones). The maxillae and mandible are foreshortened, and the contours of the face are flat (Figure 7.35). By 9 months after birth, the cranium is already half of its adult size (volume) because of the rapid growth of the brain. By 8 to 9 years, the cranium has almost reached adult proportions. Between the ages of 6 and 13, the head appears to enlarge substantially as the face literally grows out from the skull. The jaws, cheekbones, and nose become more prominent. These facial changes are correlated with the expansion of the nose and paranasal sinuses, and development of the permanent teeth. Figure 7.35 tracks how differential bone growth alters body proportions throughout life.

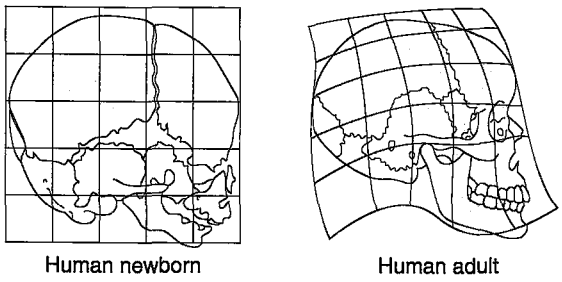
Only the thoracic and sacral curvatures are well developed at birth. These so-called **primary curvatures** are convex posteriorly, and an infant's spine arches, like that of a four-legged animal. The **secondary curvatures**—cervical and lumbar—are convex anteriorly and are associated with a child's development. They result from reshaping of the intervertebral discs rather than from modifications of the vertebrae. The cervical curvature is present before birth but is not pronounced until the baby starts to lift its head (at about 3 months). The lumbar curvature develops when the baby begins to walk (at about 12 months). The lumbar curvature positions the weight of the trunk over the body's center of gravity, providing optimal balance when standing.

Vertebral problems (scoliosis or lordosis) may appear during the early school years, when rapid growth of the limb bones stretches many muscles. During the preschool years, lordosis is often present, but this is usually rectified as the abdominal muscles become stronger and the pelvis tilts forward. The thorax grows wider, but a true "military posture" (head erect, shoulders back, abdomen in, and chest out) does not develop until adolescence.

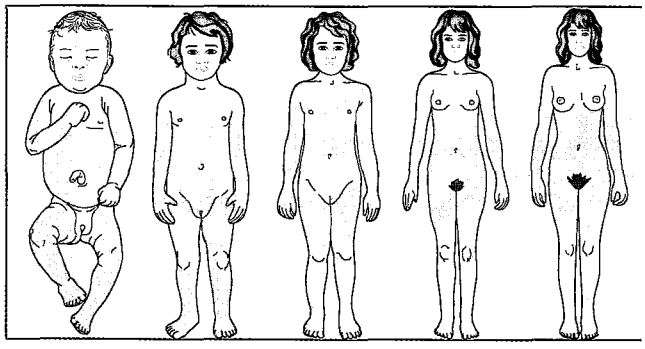
HOMEOSTATIC IMBALANCE

The appendicular skeleton can also suffer from a number of congenital abnormalities. One that is fairly common (4% of infants) and quite severe is *dysplasia of the hip* (dis-pla'ze-ah; "bad formation"). The acetabulum forms incompletely or the ligaments of the hip joint are loose, so the head of the femur slips out of its socket. Early treatment (a splint or harness to hold the femur in place or

FIGURE 7.34 **A baby born with a cleft lip and palate.**



(a)



(b)

FIGURE 7.35 **Different growth rates of body parts determine body proportions. (a)** Differential growth transforms the rounded, foreshortened skull of a newborn to the sloping skull characteristic of adults. **(b)** During growth of a human, the arms and legs grow faster than the head and trunk, as can be seen in this conceptualization of different-aged individuals all drawn at the same height.

surgery to tighten hip ligaments) is essential to prevent permanent crippling.

During youth, growth of the skeleton not only increases overall body height but also changes body proportions (Figure 7.35). At birth, the head and trunk are approximately 1½ times as long as the lower limbs. The lower limbs grow more rapidly than the trunk from this time on, and by the age of 10, the head and trunk are approximately the same height as the lower limbs, a condition that persists thereafter. During puberty, the female pelvis broadens in preparation for childbearing, and the entire male skeleton becomes more robust. Once adult height is reached, a healthy skeleton changes very little until late middle age.

Old age affects many parts of the skeleton, especially the spine. As the discs become thinner, less hydrated, and less elastic, the risk of disc herniation increases. By 55 years, a loss of several centimeters in stature is common. Further shortening can be produced by osteoporosis of the spine or by kyphosis (called "dowager's hump" in the elderly). What was done during youth may be undone in old age as the vertebral column gradually resumes its initial arc shape.

The thorax becomes more rigid with age, largely because the costal cartilages ossify. This loss of rib cage elasticity causes shallow breathing, which leads to less efficient gas exchange.

All bones, you will recall, lose mass with age. Cranial bones lose less mass than most, but changes in facial contours with age are common. As the bony tissue of the jaws declines, the jaws look small and child-like once again. If the elderly person loses his or her teeth, this loss of bone from the jaws is accelerated, because the alveolar region bone is resorbed. As bones become more porous, they are more likely to fracture, especially the vertebrae and the neck of the femur.

■ ■ ■

Our skeleton is a marvelous substructure, to be sure, but it is much more than that. It is a protector and supporter of other body systems, and without it (and the joints considered in Chapter 8), our muscles would be almost useless. The homeostatic relationships between the skeletal system and other body systems are illustrated in *Making Connections* in Chapter 6 (pp. 196–197).

Related Clinical Terms

Chiropractic (ki"ro-prak'tik) A system of treating disease by manipulating the vertebral column based on the theory that most diseases are due to pressure on nerves caused by faulty bone alignment; a specialist in this field is a chiropractor.

Clubfoot A relatively common congenital defect (1 in 700 births) in which the soles of the feet face medially and the toes point inferiorly; may be genetically induced or reflect an abnormal position of the foot during fetal development.

Laminectomy Surgical removal of a vertebral lamina; most often done to relieve the symptoms of a ruptured disc.

Orthopedist (or"tho-pe'dist) or **orthopedic surgeon** A physician who specializes in restoring lost skeletal system function or repairing damage to bones and joints.

Pelvimetry Measurement of the dimensions of the inlet and outlet of the pelvis, usually to determine whether the pelvis is of adequate size to allow normal delivery of a baby.

Spina bifida (spi'nah bĭ'fi-dah; "cleft spine") Congenital defect of the vertebral column in which one or more of the vertebral arches are incomplete; ranges in severity from inconsequential to severe conditions that impair neural functioning and encourage nervous system infections.

Spinal fusion Surgical procedure involving insertion of bone chips (or crushed bone) to immobilize and stabilize a specific region of the vertebral column, particularly in cases of vertebral fracture and herniated discs.

Chapter Summary

1. The axial skeleton forms the longitudinal axis of the body. Its principal subdivisions are the skull, vertebral column, and bony thorax. It provides support and protection (by enclosure).

2. The appendicular skeleton consists of the bones of the pectoral and pelvic girdles and the limbs. It allows mobility for manipulation and locomotion.

PART 1: THE AXIAL SKELETON

The Skull (pp. 203–218)

1. The skull is formed by 22 bones. The cranium forms the vault and base of the skull, which protect the brain. The facial skeleton provides openings for the respiratory and digestive passages and attachment points for facial muscles.

2. Except for the temporomandibular joints, all bones of the adult skull are joined by immovable sutures.

3. **Cranium.** The eight bones of the cranium include the paired parietal and temporal bones and the single frontal, occipital, ethmoid, and sphenoid bones (see Table 7.1, pp. 216–217).

4. **Facial bones.** The 14 bones of the face include the paired maxillae, zygomatics, nasals, lacrimals, palatines, and inferior conchae and the single mandible and vomer bones (Table 7.1).

5. **Orbits and nasal cavity.** Both the orbits and the nasal cavities are complicated bony regions formed of several bones.

6. **Paranasal sinuses.** Paranasal sinuses occur in the frontal, ethmoid, sphenoid, and maxillary bones.

7. **Hyoid bone.** The hyoid bone, supported in the neck by ligaments, serves as an attachment point for tongue and neck muscles.

The Vertebral Column (pp. 218–225)

1. **General characteristics.** The vertebral column includes 24 movable vertebrae (7 cervical, 12 thoracic, and 5 lumbar) and the sacrum and coccyx.

2. The fibrocartilage intervertebral discs act as shock absorbers and provide flexibility to the vertebral column.

3. The primary curvatures of the vertebral column are the thoracic and sacral; the secondary curvatures are the cervical and lumbar. Curvatures increase spine flexibility.

4. **General structure of vertebrae.** With the exception of C_1 and C_2, all vertebrae have a body, two transverse processes, two superior and two inferior articular processes, a spinous process, and a vertebral arch.

5. **Regional vertebral characteristics.** Special features distinguish the regional vertebrae (see Table 7.2, p. 224).

The Thoracic Cage (pp. 226–228)

1. The bones of the thoracic cage include the 12 rib pairs, the sternum, and the thoracic vertebrae. The thoracic cage protects the organs of the thoracic cavity.

2. **Sternum.** The sternum consists of the fused manubrium, body, and xiphoid process.

3. **Ribs.** The first seven rib pairs are called true ribs; the rest are called false ribs. Ribs 11 and 12 are floating ribs.

PART 2: THE APPENDICULAR SKELETON

The Pectoral (Shoulder) Girdle* (pp. 229–231)

1. Each pectoral girdle consists of one clavicle and one scapula. The pectoral girdles attach the upper limbs to the axial skeleton.

2. **Clavicles.** The clavicles hold the scapulae laterally away from the thorax. The sternoclavicular joints are the only attachment points of the pectoral girdle to the axial skeleton.

3. **Scapulae.** The scapulae articulate with the clavicles and with the humerus bones of the arms.

The Upper Limb* (pp. 231–237)

1. Each upper limb consists of 30 bones and is specialized for mobility.

2. **Arm/forearm/hand.** The skeleton of the arm is composed solely of the humerus; the skeleton of the forearm is composed of the radius and ulna; and the skeleton of the hand consists of the carpals, metacarpals, and phalanges.

The Pelvic (Hip) Girdle* (pp. 237–239)

1. The pelvic girdle, a heavy structure specialized for weight bearing, is composed of two hip bones that secure the lower limbs to the axial skeleton. Together with the sacrum, the hip bones form the basinlike bony pelvis.

2. Each hip bone consists of three fused bones: ilium, ischium, and pubis; the acetabulum occurs at the point of fusion.

3. **Ilium/ischium/pubis.** The ilium is the superior flaring portion of the hip bone. Each ilium forms a secure joint with the sacrum posteriorly. The ischium is a curved bar of bone; we sit on the ischial tuberosities. The V-shaped pubic bones articulate anteriorly at the pubic symphysis.

4. **Pelvic structure and childbearing.** The male pelvis is deep and narrow with larger, heavier bones than those of the female. The female pelvis, which forms the birth canal, is shallow and wide.

The Lower Limb* (pp. 239–246)

1. Each lower limb consists of the thigh, leg, and foot and is specialized for weight bearing and locomotion.

2. **Thigh.** The femur is the only bone of the thigh. Its ball-shaped head articulates with the acetabulum.

3. **Leg.** The bones of the leg are the tibia, which participates in forming both the knee and ankle joints, and the fibula.

4. **Foot.** The bones of the foot include the tarsals, metatarsals, and phalanges. The most important tarsals are the calcaneus (heel bone) and the talus, which articulates with the tibia superiorly.

5. The foot is supported by three arches (lateral, medial, and transverse) that distribute body weight to the heel and ball of the foot.

Developmental Aspects of the Skeleton (pp. 246–248)

1. Fontanels, which allow brain growth and ease birth passage, are present in the skull at birth. Growth of the cranium after birth is related to brain growth; increase in size of the facial skeleton follows tooth development and enlargement of nose and sinus cavities.

---

*For associated bone markings, see the pages indicated in the section heads.

2. The vertebral column is C shaped at birth (thoracic and sacral curvatures are present); the secondary curvatures form when the baby begins to lift its head and walk.

3. Long bones continue to grow in length until late adolescence. The head and torso, initially 1½ times the length of the lower limbs, equal their length by the age of 10.

4. Changes in the female pelvis (preparatory for childbirth) occur during puberty.

5. Once at adult height, the skeleton changes little until late middle age. With old age, the intervertebral discs thin; this, along with osteoporosis, leads to a gradual loss in height and increased risk of disc herniation. Loss of bone mass increases the risk of fractures, and thoracic cage rigidity promotes breathing difficulties.

Review Questions

Multiple Choice/Matching

(Some questions have more than one correct answer. Select the best answer or answers from the choices given.)

1. Using the letters from column B, match the bone descriptions in column A. (Note that some require more than a single choice.)

Column A	Column B
____ (1) connected by the coronal suture	(a) ethmoid
____ (2) keystone bone of cranium	(b) frontal
____ (3) keystone bone of the face	(c) mandible
____ (4) form the hard palate	(d) maxillary
____ (5) allows the spinal cord to pass	(e) occipital
____ (6) forms the chin	(f) palatine
____ (7) contain paranasal sinuses	(g) parietal
____ (8) contains mastoid sinuses	(h) sphenoid
	(i) temporal

2. Match the key terms with the bone descriptions that follow.

Key: (a) clavicle (b) ilium (c) ischium (d) pubis (e) sacrum (f) scapula (g) sternum

____ (1) bone of the axial skeleton to which the pectoral girdle attaches
____ (2) markings include glenoid cavity and acromion
____ (3) features include the ala, crest, and greater sciatic notch
____ (4) doubly curved; acts as a shoulder strut
____ (5) pelvic girdle bone that articulates with the axial skeleton
____ (6) the "sit-down" bone
____ (7) anteriormost bone of the pelvic girdle
____ (8) part of the vertebral column

3. Use key choices to identify the bone descriptions that follow.

Key: (a) carpals (b) femur (c) fibula (d) humerus (e) radius (f) tarsals (g) tibia (h) ulna

____ (1) articulates with the acetabulum and the tibia
____ (2) forms the lateral aspect of the ankle
____ (3) bone that "carries" the hand
____ (4) the wrist bones
____ (5) end shaped like a monkey wrench
____ (6) articulates with the capitulum of the humerus
____ (7) largest bone of this "group" is the calcaneus

Short Answer Essay Questions

4. Name the cranial and facial bones and compare and contrast the functions of the cranial and facial skeletons.

5. How do the relative proportions of the cranium and face of a fetus compare with those of an adult skull?

6. Name and diagram the normal vertebral curvatures. Which are primary and which are secondary curvatures?

7. List at least two specific anatomical characteristics each for typical cervical, thoracic, and lumbar vertebrae that would allow *anyone* to identify each type correctly.

8. (a) What is the function of the intervertebral discs? (b) Distinguish between the anulus fibrosus and nucleus pulposus regions of a disc. (c) Which provides durability and strength? (d) Which provides resilience? (e) Which part is involved in a "slipped" disc?

9. Name the major components of the thoracic cage.

10. (a) What is a true rib? A false rib? (b) Is a floating rib a true rib or a false rib? (c) Why are floating ribs easily broken?

11. The major function of the shoulder girdle is flexibility. What is the major function of the pelvic girdle? Relate these functional differences to anatomical differences seen in these girdles.

12. List three important differences between the male and female pelves.

13. Describe the function of the arches of the foot.

14. Briefly describe the anatomical characteristics and impairment of function seen in cleft palate and hip dysplasia.

15. Compare a young adult skeleton to that of an extremely aged person relative to bone mass in general and the bony structure of the skull, thorax, and vertebral column in particular.

16. Peter Howell, a teaching assistant in the anatomy class, picked up a hip bone and pretended it was a telephone. He held the big hole in this bone right up to his ear and said, "Hello, obturator, obturator (operator, operator)." Name the structure he was helping the student to learn.

Critical Thinking and Clinical Application Questions

1. Justiniano worked in a poultry-packing plant where his job was cutting open chickens and stripping out their visceral organs. After work, he typed for long hours on his computer keyboard, writing a book about his work in the plant. Soon, his wrist and hand began to hurt whenever he flexed it, and he began to awaken at night with pain and tingling on the thumb-half of his hand. What condition did he probably have?

2. Ralph had polio as a boy and was partially paralyzed in one lower limb for over a year. Although no longer paralyzed, he now has a severe lateral curvature of the lumbar spine. Explain what has happened and identify his condition.

3. Mary's grandmother slipped on a scatter rug and fell heavily to the floor. Her left lower limb was laterally rotated and noticeably shorter than the right, and when she attempted to get up, she winced with pain. Mary surmised that her grandmother might have "fractured her hip," which later proved to be true. What bone was probably fractured and at what site? Why is a "fractured hip" a common type of fracture in the elderly?

4. Mrs. Shea came up with what she considered to be a clever idea to bypass the long lines at Disney World. She had her husband rent a wheelchair and he wheeled her around from one exhibit to another for the better part of three days. As they sat on the plane, waiting to take off for Chicago, she complained to him that she had two sore spots on her buttocks. Why? What do you suppose would happen (to her buttocks) if she was wheeled around for a few more days?

CHAPTER

Joints

1. Define joint or articulation.

Classification of Joints (p. 253)

2. Classify joints structurally and functionally.

Fibrous Joints (pp. 253–254)

3. Describe the general structure of fibrous joints. Name and give an example of each of the three common types of fibrous joints.

Cartilaginous Joints (p. 255)

4. Describe the general structure of cartilaginous joints. Name and give an example of each of the two common types of cartilaginous joints.

Synovial Joints (pp. 255–272)

5. Describe the structural characteristics of synovial joints.
6. List three natural factors that stabilize synovial joints.
7. Compare the structures and functions of bursae and tendon sheaths.
8. Name and describe (or perform) the common body movements.
9. Name and provide examples of the six types of synovial joints based on the movement(s) allowed.
10. Describe the elbow, knee, hip, jaw, and shoulder joints relative to articulating bones, anatomical characteristics of the joint, movements allowed, and joint stability.

Homeostatic Imbalances of Joints (pp. 272–274, 276)

11. Name the most common joint injuries and discuss the symptoms and problems associated with each.
12. Compare and contrast the common types of arthritis.

Developmental Aspects of Joints (p. 276)

13. Discuss factors that promote or disturb joint homeostasis.

The graceful movements of ballet dancers and the rough-and-tumble grapplings of football players demonstrate the great variety of motion allowed by **joints,** or **articulations**—the sites where two or more bones meet. Our joints have two fundamental functions: They give our skeleton mobility, and they hold it together, sometimes playing a protective role in the process.

Joints are the weakest parts of the skeleton. Nonetheless, their structure resists various forces, such as crushing or tearing, that threaten to force them out of alignment.

Classification of Joints

Joints are classified by structure and by function. The *structural classification* focuses on the material binding the bones together and whether or not a joint cavity is present. Structurally, there are *fibrous, cartilaginous,* and *synovial joints* (Table 8.1 on p. 256).

The *functional classification* is based on the amount of movement allowed at the joint. On this basis, there are **synarthroses** (sin"ar-thro'sēz; *syn* = together, *arthro* = joint), which are immovable joints; **amphiarthroses** (am"fe-ar-thro'sēz; *amphi* = on both sides), slightly movable joints; and **diarthroses** (di"ar-thro'sēz; *dia* = through, apart), or freely movable joints. Freely movable joints predominate in the limbs; immovable and slightly movable joints are largely restricted to the axial skeleton.

In general, fibrous joints are immovable, and synovial joints are freely movable. However, cartilaginous joints have both rigid and slightly movable examples. Since the structural categories are more clear-cut, we will use the structural classification in this discussion, indicating functional properties where appropriate.

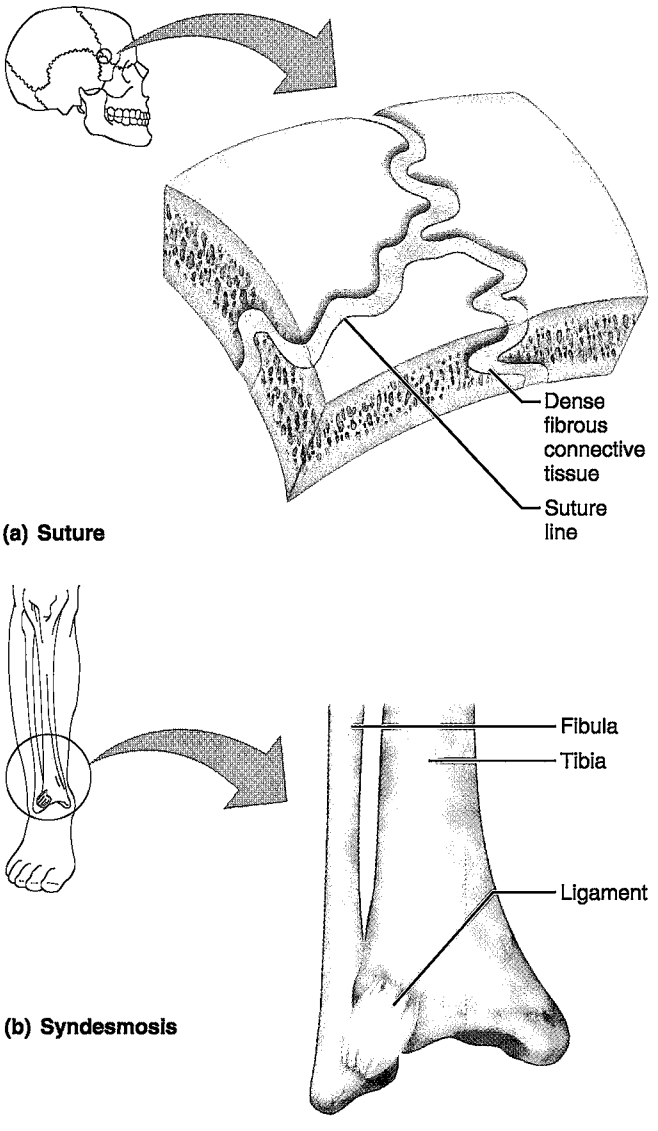

FIGURE 8.1 **Fibrous joints. (a)** Sutures of the skull have interconnecting connective tissue fibers that are very short, and the bone edges interlock so that the joint is immovable (synarthrotic). **(b)** In the syndesmosis at the distal tibiofibular joint, the fibrous tissue (ligament) connecting the bones is longer than that in sutures.

Fibrous Joints

In **fibrous joints,** the bones are joined by fibrous tissue; no joint cavity is present. The amount of movement allowed depends on the length of the connective tissue fibers uniting the bones. Although a few are slightly movable, most fibrous joints are immovable. The three types of fibrous joints are *sutures, syndesmoses,* and *gomphoses.*

Sutures

Sutures, literally "seams," occur only between bones of the skull (Figure 8.1a). The wavy articulating bone edges interlock, and the junction is completely filled by a minimal amount of very short connective tissue fibers that are continuous with the periosteum. The result is nearly rigid splices that bind the bones tightly together, yet allow the bones to grow at their edges during youth. During middle age, the fibrous tissue ossifies and the skull bones fuse into a single unit. At this stage, the sutures are more precisely called **synostoses** (sin"os-to'sēz), literally, "bony junctions." Because movement of the cranial bones would damage the brain, the immovable nature of sutures is a protective adaptation.

Syndesmoses

In **syndesmoses** (sin"des-mo'sēz), the bones are connected by a *ligament* (*syndesmos* = ligament), a cord

Q *Which one of the joint types shown here has the greatest flexibility and why?*

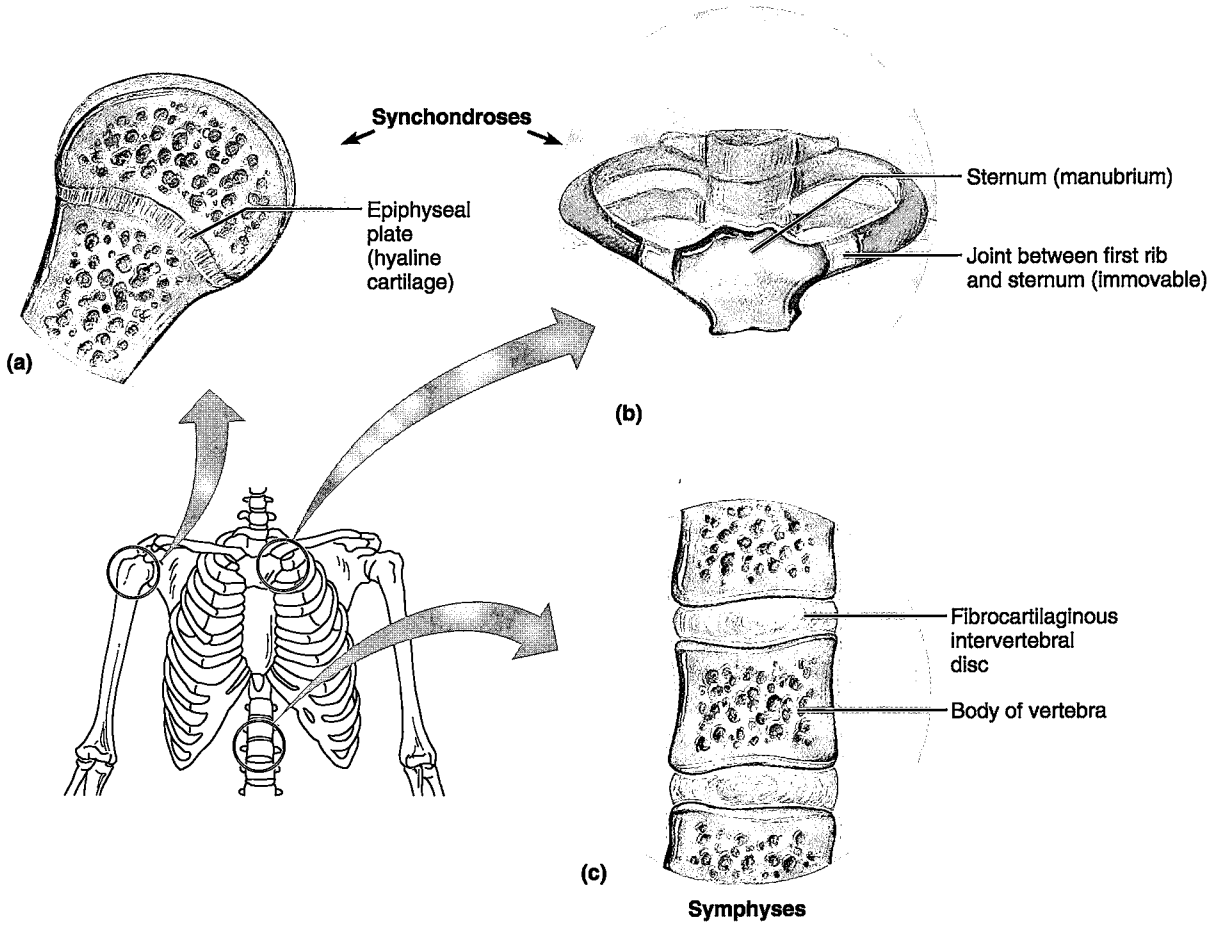

FIGURE 8.2 **Cartilaginous joints. (a)** The epiphyseal plate in a growing long bone is a temporary synchondrosis; the shaft and epiphysis are connected by hyaline cartilage that is later completely ossified. **(b)** The sternocostal joint between rib 1 and the manubrium of the sternum is an immovable hyaline cartilage joint, or synchondrosis. **(c)** The intervertebral joints, in which the vertebrae are connected by fibrocartilaginous discs, are symphyses.

or band of fibrous tissue. Although the connecting fibers are always longer than those in sutures, they vary quite a bit in length. The amount of movement allowed depends on the length of the connecting fibers, and slight to considerable movement is possible. For example, the ligament connecting the distal ends of the tibia and fibula is short (Figure 8.1b), and this joint allows only slightly more movement than a suture, a characteristic best described as "give." True movement is still prevented, so the joint is classed functionally as an immovable joint, or synarthrosis. (Note, however, that some authorities classify this joint as an amphiarthrosis.) On the other hand, the fibers of the ligament-like interosseous membrane connecting the radius and ulna along their length (Figure 7.24, p. 233) are long enough to permit rotation of the radius around the ulna.

A *The symphyses, represented by the intervertebral joints in (c), are most flexible because the uniting cartilage in this joint type is the resilient fibrocartilage, versus the hyaline cartilage seen in (a) and (b).*

Gomphoses

A **gomphosis** (gom-fo'sis) is a peg-in-socket fibrous joint. The only example is the articulation of a tooth with its bony alveolar socket. The term *gomphosis* comes from the Greek *gompho,* meaning "nail" or "bolt," and refers to the way teeth are embedded in their sockets (as if hammered in). The fibrous connection in this case is the short **periodontal ligament** (Figure 23.11, p. 894).

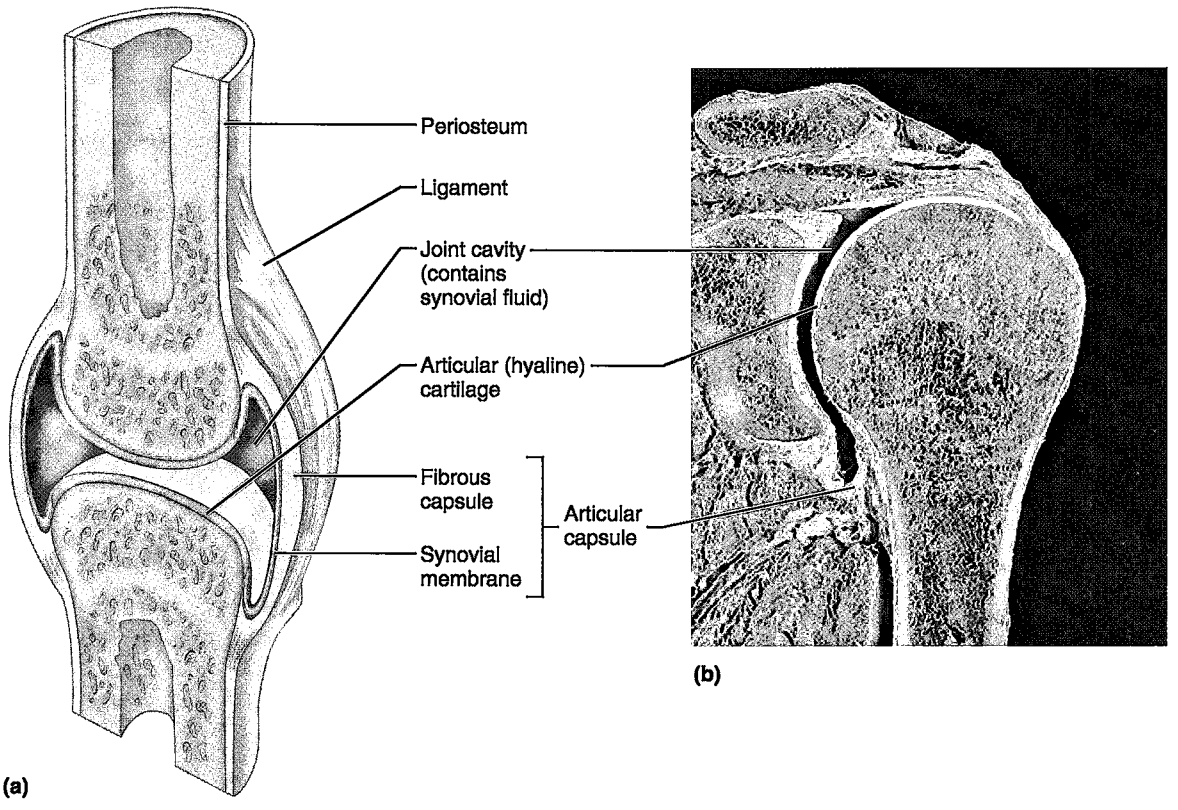

FIGURE 8.3 **General structure of a synovial joint. (a)** The articulating bone ends are covered with articular cartilage and enclosed within an articular capsule which is typically reinforced by ligaments externally. Internally, the fibrous capsule is lined with a smooth synovial membrane that secretes synovial fluid. **(b)** Photo of frontally sectioned shoulder joint.

Cartilaginous Joints

In **cartilaginous joints** (kar"ti-laj'ĭ-nus), the articulating bones are united by cartilage. Like fibrous joints, they lack a joint cavity. The two types of cartilaginous joints are *synchondroses* and *symphyses*.

Synchondroses

A bar or plate of *hyaline cartilage* unites the bones at a **synchondrosis** (sin"kon-dro'sis; "junction of cartilage"). Virtually all synchondroses are synarthrotic.

The most common examples of synchondroses are the epiphyseal plates connecting the diaphysis and epiphysis regions in long bones of children (Figure 8.2a). Epiphyseal plates are temporary joints and eventually become synostoses. Another example of a synchondrosis is the immovable joint between the costal cartilage of the first rib and the manubrium of the sternum (Figure 8.2b).

Symphyses

In **symphyses** (sim'fih-sēz; "growing together") the articular surfaces of the bones are covered with articular (hyaline) cartilage, which in turn is fused to an intervening pad, or plate, of *fibrocartilage*. Since fibrocartilage is compressible and resilient, it acts as a shock absorber and permits a limited amount of movement at the joint. Symphyses are amphiarthrotic joints designed for strength with flexibility. Examples include the intervertebral joints (Figure 8.2c) and the pubic symphysis of the pelvis (see Table 8.2 on p. 258).

Synovial Joints

Synovial joints are those in which the articulating bones are separated by a fluid-containing joint cavity. This arrangement permits substantial freedom of movement, and all synovial joints are freely movable diarthroses. All joints of the limbs—indeed, most joints of the body—fall into this class.

General Structure

Synovial joints have five distinguishing features (Figure 8.3a):

1. **Articular cartilage.** Glassy-smooth hyaline cartilage covers the opposing bone surfaces as **articular**

TABLE 8.1 Summary of Joint Classes

STRUCTURAL CLASS	STRUCTURAL CHARACTERISTICS	TYPES	MOBILITY
Fibrous	Bone ends/parts united by collagenic fibers	Suture (short fibers)	Immobile (synarthrosis)
		Syndesmosis (longer fibers)	Slightly mobile (amphiarthrosis) and immobile
		Gomphosis (periodontal ligament)	Immobile
Cartilaginous	Bone ends/parts united by cartilage	Synchondrosis (hyaline cartilage)	Immobile
		Symphysis (fibrocartilage)	Slightly movable
Synovial	Bone ends/parts covered with articular cartilage and enclosed within an articular capsule lined with synovial membrane	Plane, Hinge, Pivot, Condyloid, Saddle, Ball and socket	Freely movable (diarthrosis; movements depend on design of joint)

cartilage. These thin (1 mm or less) but spongy cushions absorb compression placed on the joint and thereby keep the bone ends from being crushed.

2. Joint (synovial) cavity. A feature unique to synovial joints, the **joint cavity** is really just a potential space that contains a small amount of synovial fluid.

3. Articular capsule. The joint cavity is enclosed by a two-layered **articular capsule,** or *joint capsule*. The external layer is a tough **fibrous capsule,** composed of dense irregular connective tissue, that is continuous with the periostea of the articulating bones. It strengthens the joint so that the bones are not pulled apart. The inner layer of the joint capsule is a **synovial membrane** composed of loose connective tissue. Besides lining the fibrous capsule internally, it covers all internal joint surfaces that are not hyaline cartilage.

4. Synovial fluid. A small amount of slippery **synovial fluid** occupies all free spaces within the joint capsule. This fluid is derived largely by filtration from blood flowing through the capillaries in the synovial membrane. Synovial fluid has a viscous, egg-white consistency (*synovi* = joint egg) due to hyaluronic acid secreted by cells in the synovial membrane, but it thins, becoming less viscous, as it warms during joint activity. Synovial fluid, which is also found *within* the articular cartilages, provides a slippery weight-bearing film that reduces friction between the cartilages. The synovial fluid is forced from the cartilages when a joint is compressed; then as pressure on the joint is relieved, synovial fluid seeps back into the articular cartilages like water into a sponge, ready to be squeezed out again the next time the joint is loaded (put under pressure). This mechanism, called *weeping lubrication,* lubricates the free surfaces of the cartilages and nourishes their cells. Synovial fluid also contains phagocytic cells that rid the joint cavity of microbes and cellular debris.

5. Reinforcing ligaments. Synovial joints are reinforced and strengthened by a number of band-like **ligaments.** Most often, these are **capsular,** or **intrinsic, ligaments;** that is, they are thickened parts of the fibrous capsule. In other cases, they remain distinct and are found outside the capsule **(extracapsular ligaments)** or deep to it **(intracapsular ligaments).** Since intracapsular ligaments are covered with synovial membrane, they do not actually lie *within* the joint cavity.

People said to be double-jointed amaze the rest of us by placing both heels behind their neck. However, they have the normal number of joints; it's just that their joint capsules and ligaments are more stretchy and looser than average.

The articular capsule and ligaments are richly supplied with sensory nerve endings that monitor joint position and help to maintain muscle tone. Stretching these structures sends nerve impulses to the central nervous system, resulting in reflexive contraction of muscles surrounding the joint. Synovial joints are also richly supplied with blood vessels, most of which supply the synovial membrane.

Besides the basic components described above, certain synovial joints have other structural features. Some, such as the hip and knee joints, have cushioning **fatty pads** between the fibrous capsule and the synovial membrane or bone. Others have discs or wedges of fibrocartilage separating the articular surfaces. Where present, these so-called **articular discs,** or **menisci** (mĕ-nis'ki; "crescents"), extend inward from the articular capsule and partially or completely divide the synovial cavity in two (see the menisci in Figure 8.8). Articular discs improve the fit between articulating bone ends, making the joint more stable and minimizing wear and tear on the joint surfaces. Articular discs occur in the knee, jaw, and a few other joints (see Table 8.2).

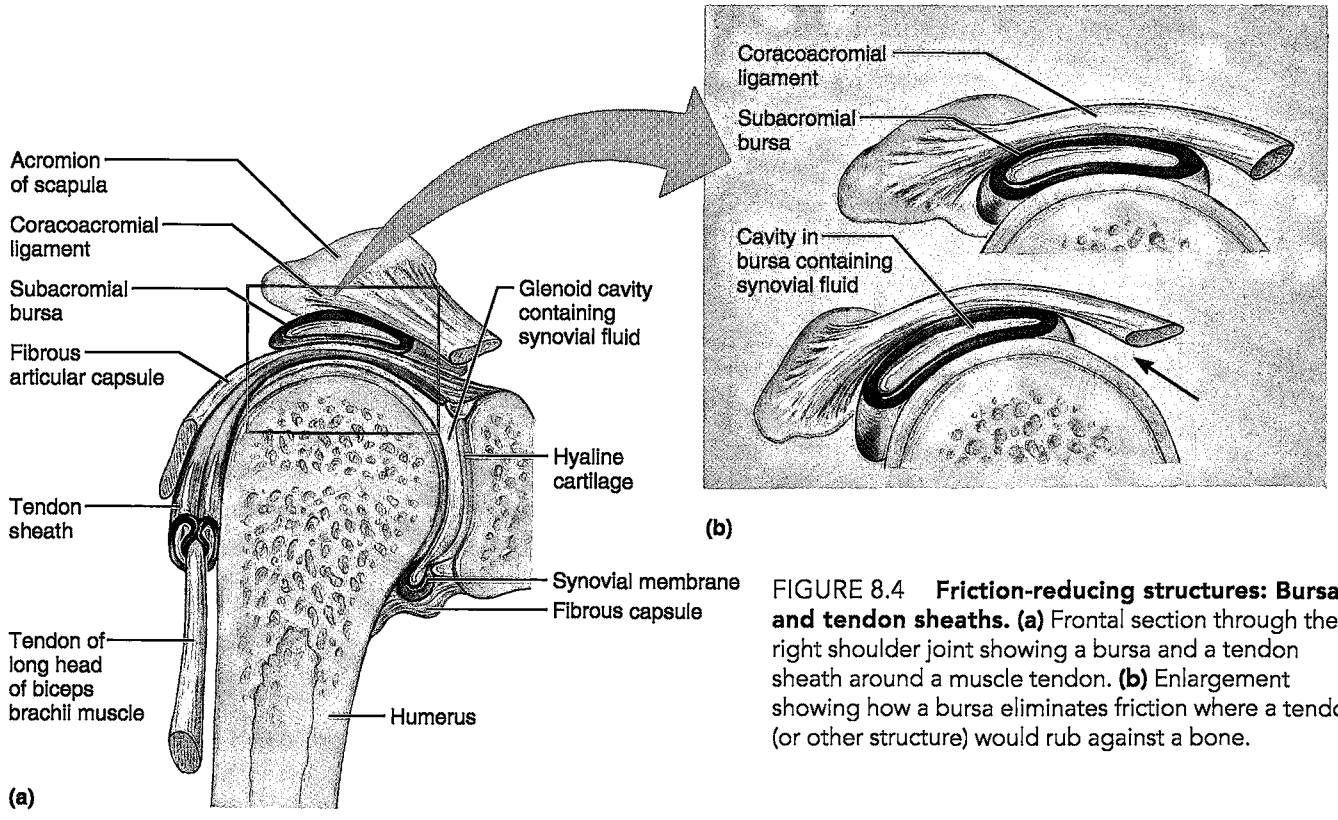

FIGURE 8.4 **Friction-reducing structures: Bursae and tendon sheaths. (a)** Frontal section through the right shoulder joint showing a bursa and a tendon sheath around a muscle tendon. **(b)** Enlargement showing how a bursa eliminates friction where a tendon (or other structure) would rub against a bone.

8

Bursae and Tendon Sheaths

Bursae and tendon sheaths are not strictly part of synovial joints, but they are often found closely associated with them (Figure 8.4). Essentially bags of lubricant, they act as "ball bearings" to reduce friction between adjacent structures during joint activity. **Bursae** (ber'se; "purse") are flattened fibrous sacs lined with synovial membrane and containing a thin film of synovial fluid. They are common where ligaments, muscles, skin, tendons, or bones rub together.

A **tendon sheath** is essentially an elongated bursa that wraps completely around a tendon subjected to friction, like a bun around a hot dog.

Factors Influencing the Stability of Synovial Joints

Because joints are constantly stretched and compressed, they must be stabilized so that they do not dislocate (come out of alignment). The stability of a synovial joint depends chiefly on three factors: the shapes of the articular surfaces; the number and positioning of ligaments; and muscle tone.

Articular Surfaces

The shapes of articular surfaces determine what movements are possible at a joint, but surprisingly, articular surfaces play only a minor role in joint stability. Many joints have shallow sockets or noncomplementary articulating surfaces ("misfits") that actually hinder joint stability. But when articular surfaces are large and fit snugly together, or when the socket is deep, stability is vastly improved. The ball and deep socket of the hip joint provide the best example of a joint made extremely stable by the shape of its articular surfaces.

Ligaments

The capsules and ligaments of synovial joints unite the bones and prevent excessive or undesirable motion. As a rule, the more ligaments a joint has, the stronger it is. However, when other stabilizing factors are inadequate, undue tension is placed on the ligaments and they stretch. Stretched ligaments stay stretched, like taffy, and a ligament can stretch only about 6% of its length before it snaps. Thus, when ligaments are the major means of bracing a joint, the joint is not very stable.

Muscle Tone

For most joints, the muscle tendons that cross the joint are the most important stabilizing factor. These tendons are kept taut at all times by the tone of their muscles. (Muscle tone is defined as low levels of contractile activity in relaxed muscles that keep the muscles healthy and ready to react to stimulation.) Muscle tone is extremely important in

TABLE 8.2 Structural and Functional Characteristics of Body Joints

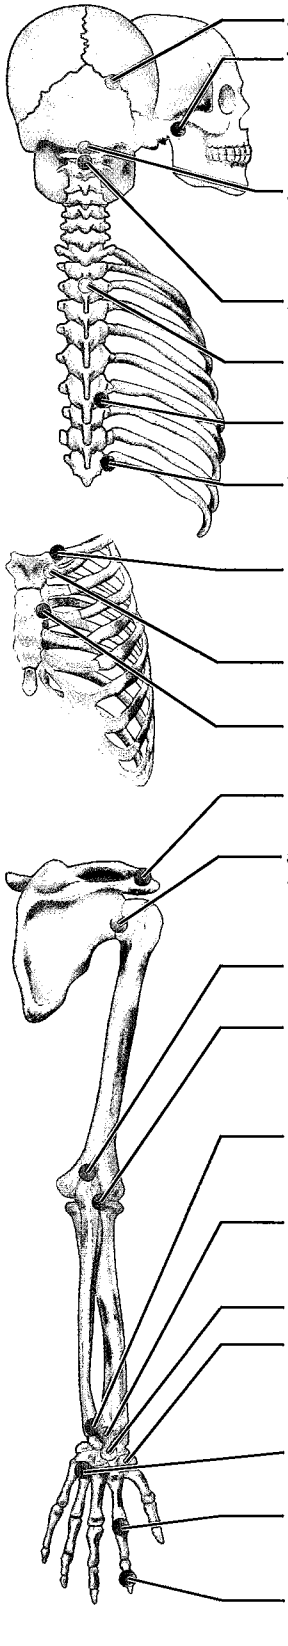

ILLUSTRATION	JOINT	ARTICULATING BONES	STRUCTURAL TYPE*	FUNCTIONAL TYPE; MOVEMENTS ALLOWED
	Skull	Cranial and facial bones	Fibrous; suture	Synarthrotic; no movement
	Temporo-mandibular	Temporal bone of skull and mandible	Synovial; modified hinge† (contains articular disc)	Diarthrotic; gliding and uniaxial rotation; slight lateral movement, elevation, depression, protraction, and retraction of mandible
	Atlanto-occipital	Occipital bone of skull and atlas	Synovial; condyloid	Diarthrotic; biaxial; flexion, extension, lateral flexion, circumduction of head on neck
	Atlantoaxial	Atlas (C_1) and axis (C_2)	Synovial; pivot	Diarthrotic; uniaxial; rotation of the head
	Intervertebral	Between adjacent vertebral bodies	Cartilaginous; symphysis	Amphiarthrotic; slight movement
	Intervertebral	Between articular processes	Synovial; plane	Diarthrotic; gliding
	Vertebrocostal	Vertebrae (transverse processes or bodies) and ribs	Synovial; plane	Diarthrotic; gliding of ribs
	Sternoclavicular	Sternum and clavicle	Synovial; shallow saddle (contains articular disc)	Diarthrotic; multiaxial (allows clavicle to move in all axes)
	Sternocostal	Sternum and rib 1	Cartilaginous; synchondrosis	Synarthrotic; no movement
	Sternocostal	Sternum and ribs 2–7	Synovial; double plane	Diarthrotic; gliding
	Acromio-clavicular	Acromion of scapula and clavicle	Synovial; plane (contains articular disc)	Diarthrotic; gliding and rotation of scapula on clavicle
	Shoulder (glenohumeral)	Scapula and humerus	Synovial; ball and socket	Diarthrotic; multiaxial; flexion, extension, abduction, adduction, circumduction, rotation of humerus
	Elbow	Ulna (and radius) with humerus	Synovial; hinge	Diarthrotic; uniaxial; flexion, extension of forearm
	Radioulnar (proximal)	Radius and ulna	Synovial; pivot	Diarthrotic; uniaxial; rotation of radius around long axis of forearm to allow pronation and supination
	Radioulnar (distal)	Radius and ulna	Synovial; pivot (contains articular disc)	Diarthrotic; uniaxial; rotation (convex head of ulna rotates in ulnar notch of radius)
	Wrist (radiocarpal)	Radius and proximal carpals	Synovial; condyloid	Diarthrotic; biaxial; flexion, extension, abduction, adduction, circumduction of hand
	Intercarpal	Adjacent carpals	Synovial; plane	Diarthrotic; gliding
	Carpometacarpal of digit 1 (thumb)	Carpal (trapezium) and metacarpal 1	Synovial; saddle	Diarthrotic; biaxial; flexion, extension, abduction, adduction, circumduction, opposition of metacarpal 1
	Carpometacarpal of digits 2–5	Carpal(s) and metacarpal(s)	Synovial; plane	Diarthrotic; gliding of metacarpals
	Knuckle (metacarpo-phalangeal)	Metacarpal and proximal phalanx	Synovial; condyloid	Diarthrotic; biaxial; flexion, extension, abduction, adduction, circumduction of fingers
	Finger (interphalangeal)	Adjacent phalanges	Synovial; hinge	Diarthrotic; uniaxial; flexion, extension of fingers

TABLE 8.2 *(continued)*

ILLUSTRATION	JOINT	ARTICULATING BONES	STRUCTURAL TYPE*	FUNCTIONAL TYPE; MOVEMENTS ALLOWED
	Sacroiliac	Sacrum and coxal bone	Synovial; plane in childhood, increasingly fibrous in adult	Diarthrotic in child; amphiarthrotic in adult; (more movement during pregnancy)
	Pubic symphysis	Pubic bones	Cartilaginous; symphysis	Amphiarthrotic; slight movement (enhanced during pregnancy)
	Hip (coxal)	Hip bone and femur	Synovial; ball and socket	Diarthrotic; multiaxial; flexion, extension, abduction, adduction, rotation, circumduction of thigh
	Knee (tibiofemoral)	Femur and tibia	Synovial; modified hinge† (contains articular discs)	Diarthrotic; biaxial; flexion, extension of leg, some rotation allowed
	Knee (femoropatellar)	Femur and patella	Synovial; plane	Diarthrotic; gliding of patella
	Tibiofibular	Tibia and fibula (proximally)	Synovial; plane	Diarthrotic; gliding of fibula
	Tibiofibular	Tibia and fibula (distally)	Fibrous; syndesmosis	Synarthrotic; slight "give" during dorsiflexion
	Ankle	Tibia and fibula with talus	Synovial; hinge	Diarthrotic; uniaxial; dorsiflexion, and plantar flexion of foot
	Intertarsal	Adjacent tarsals	Synovial; plane	Diarthrotic; gliding; inversion and eversion of foot
	Tarsometatarsal	Tarsal(s) and metatarsal(s)	Synovial; plane	Diarthrotic; gliding of metatarsals
	Metatarsophalangeal	Metatarsal and proximal phalanx	Synovial; condyloid	Diarthrotic; biaxial; flexion, extension, abduction, adduction, circumduction of great toe
	Toe (interphalangeal)	Adjacent phalanges	Synovial; hinge	Diarthrotic; uniaxial; flexion; extension of toes

reinforcing the shoulder and knee joints and the arches of the foot.

Movements Allowed by Synovial Joints

Every skeletal muscle of the body is attached to bone or other connective tissue structures at no fewer than two points. The muscle's **origin** is attached to the immovable (or less movable) bone. Its other end, the **insertion,** is attached to the movable bone. Body movement occurs when muscles contract across joints and their insertion moves toward their origin. The movements can be described in directional terms relative to the lines, or *axes,* around which the body part moves and the planes of space along which the movement occurs, that is, along the transverse, frontal, or sagittal plane. (These planes were described in Chapter 1.)

Range of motion allowed by synovial joints varies from **nonaxial movement** (slipping movements only, since there is no axis around which movement can occur) to **uniaxial movement** (movement in one plane) to **biaxial movement** (movement in two planes) to **multiaxial movement** (movement in or around all three planes of space and axes). Range of motion varies greatly in different people. In some, such as trained gymnasts or acrobats, range of joint movement may be extraordinary. The ranges of motion at the major joints are given in Table 8.2.

There are three general types of movements: *gliding, angular movements,* and *rotation.* The most common body movements allowed by synovial joints are described next and illustrated in Figure 8.5.

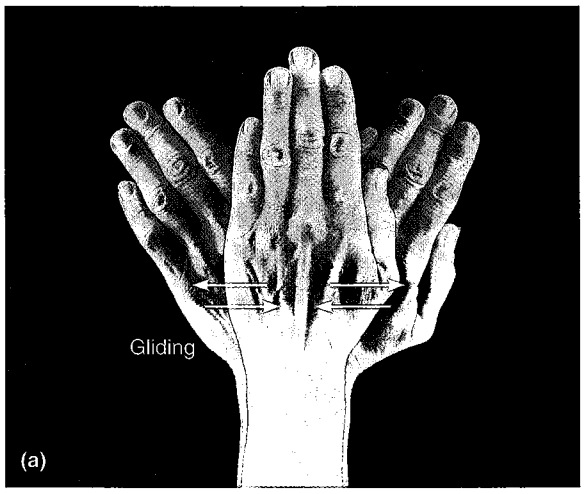

FIGURE 8.5 **Movements allowed by synovial joints.** **(a)** Gliding movements.

Gliding Movements

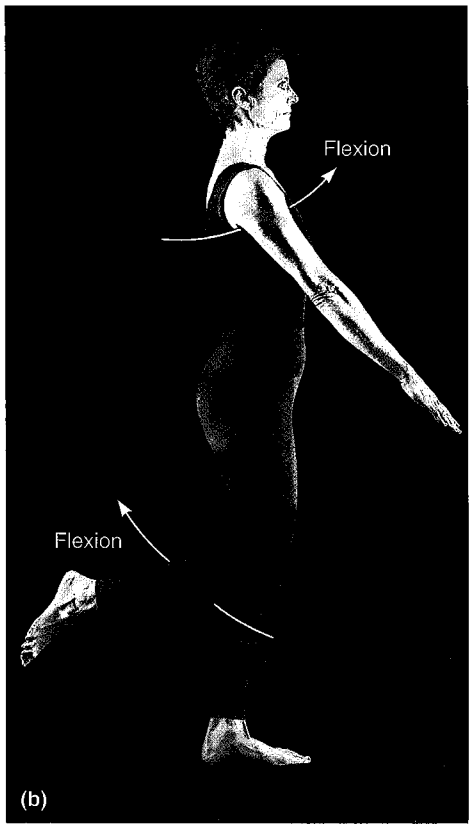
Gliding movements (Figure 8.5a), also known as *translation*, are the simplest joint movements. One flat, or nearly flat, bone surface glides or slips over another (back-and-forth and side-to-side) without appreciable angulation or rotation. Gliding movements occur at the intercarpal and intertarsal joints, and between the flat articular processes of the vertebrae, as well as in combination with other movements (see Table 8.2).

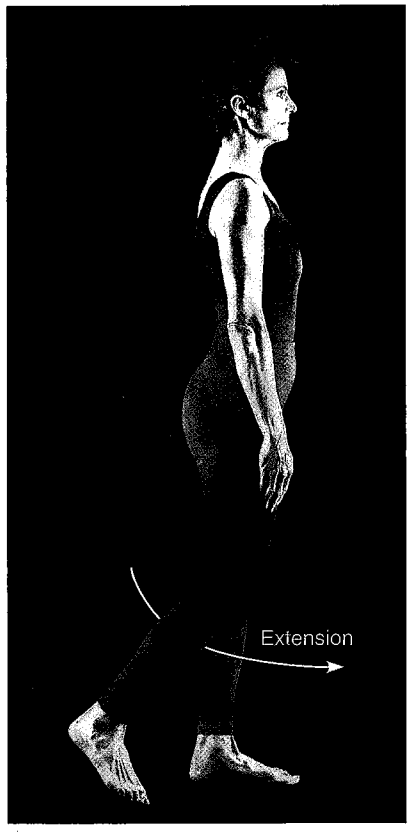
Angular Movements

Angular movements (Figure 8.5b–f) increase or decrease the angle between two bones. These movements may occur in any plane of the body and include flexion, extension, hyperextension, abduction, adduction, and circumduction.

Flexion **Flexion** (flek'shun) is a bending movement, usually along the sagittal plane, that *decreases the angle* of the joint and brings the articulating bones closer together. Examples include bending the head forward on the chest (Figure 8.5d) and bending the body trunk or the knee from a straight to an angled position (Figure 8.5b and c). As a less obvious example, the arm is flexed at the shoulder when the arm is lifted in an anterior direction (Figure 8.5b).

Extension **Extension** is the reverse of flexion and occurs at the same joints. It involves movement along the sagittal plane that *increases the angle* between the articulating bones, such as straightening a





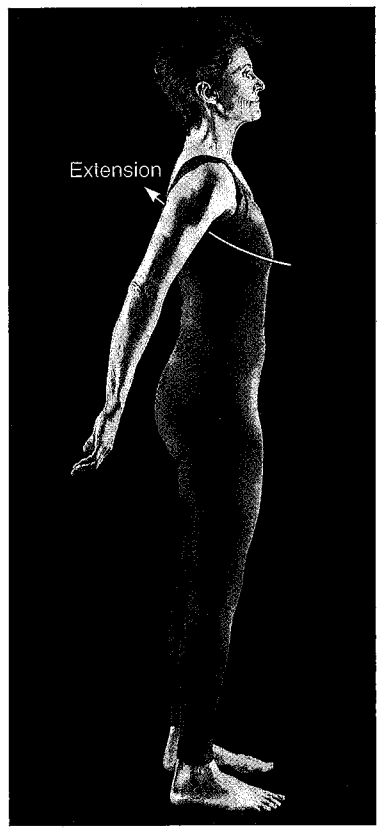


FIGURE 8.5 *(continued)* **Movements allowed by synovial joints. (b)** Angular movements.

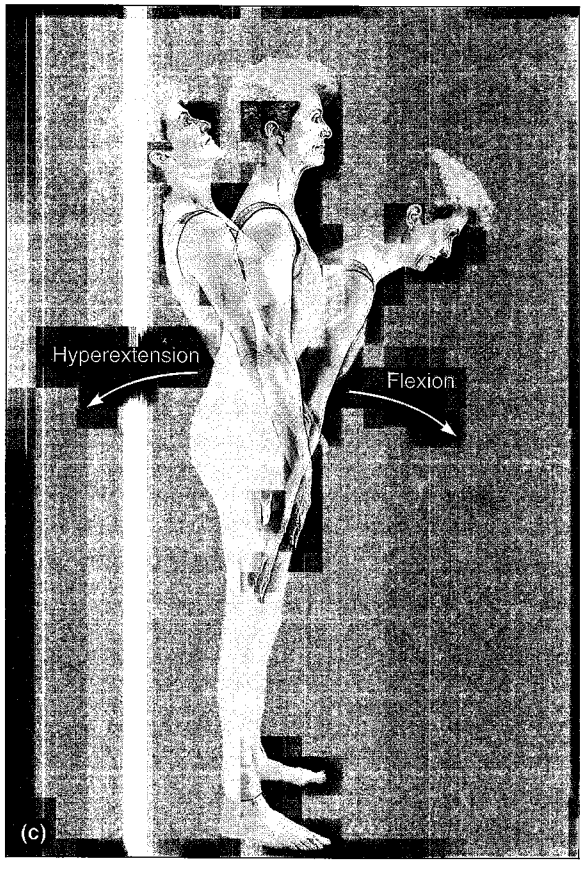

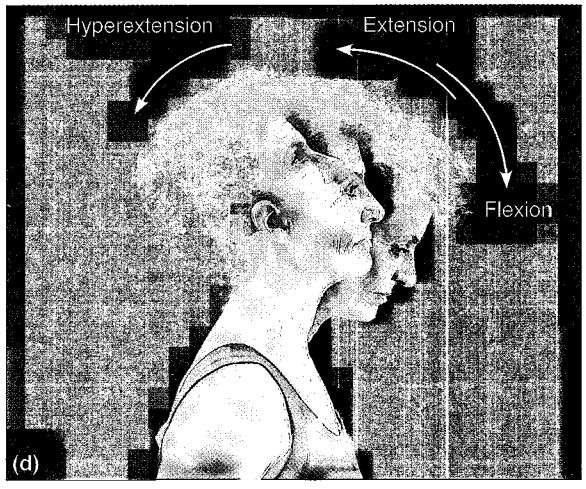

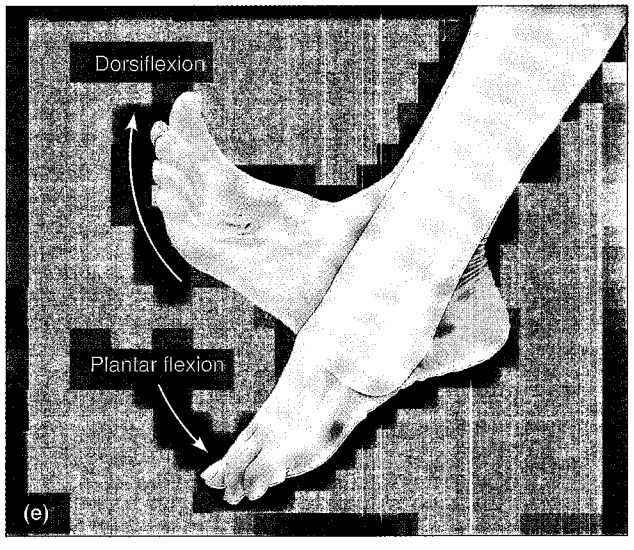

FIGURE 8.5 *(continued)* **Movements allowed by synovial joints. (c–e)** Angular movements

flexed neck, body trunk, elbow, or knee (Figure 8.5b–d). Bending the head backward beyond its straight (upright) position is called **hyperextension.** At the shoulder and hip, extension carries the limb to a point posterior to the shoulder joint.

Dorsiflexion and Plantar Flexion of the Foot The up-and-down movements of the foot at the ankle joint are given more specific names (Figure 8.5e). Lifting the foot so that its superior surface approaches the shin is **dorsiflexion** (corresponds to wrist extension), whereas depressing the foot (pointing the toes) is **plantar flexion** (corresponds to wrist flexion).

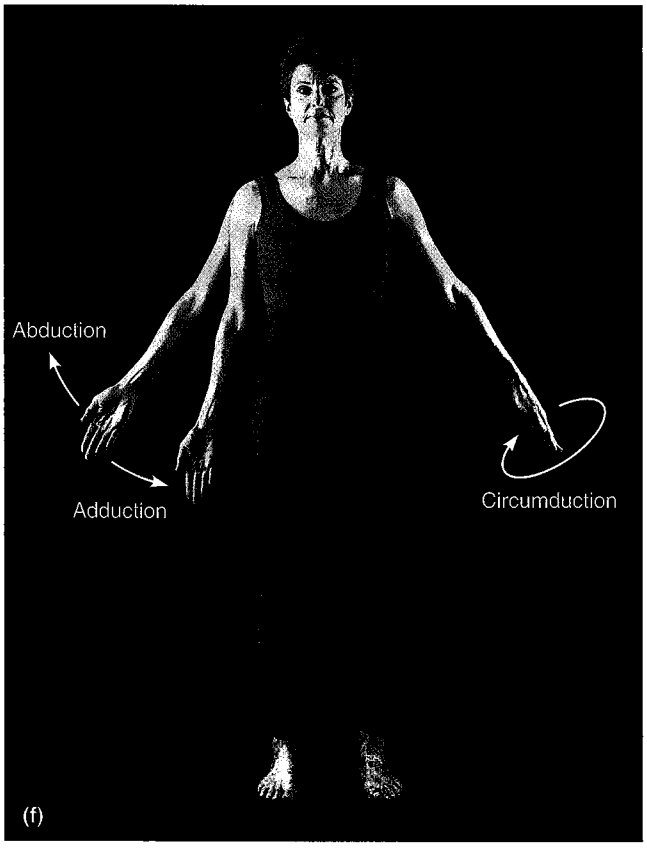
Abduction **Abduction** ("moving away") is movement of a limb *away* from the midline or median plane of the body, along the frontal plane. Raising the arm laterally is an example of abduction (Figure 8.5f). When the term is used to indicate the movement of the fingers or toes, it means spreading them apart. In this case "midline" is the longest digit: the third finger or second toe. Notice, however, that lateral bending of the trunk away from the body midline in the frontal plane is called *lateral flexion,* not abduction.

Adduction **Adduction** ("moving toward") is the opposite of abduction, so it is the movement of a limb *toward* the body midline or, in the case of the digits, toward the midline of the hand or foot (Figure 8.5f).

Circumduction **Circumduction** (Figure 8.5f) is moving a limb so that it describes a cone in space (*circum* = around; *duco* = to draw). The distal end of the limb moves in a circle, while the point of the cone (the shoulder or hip joint) is more or less stationary. A pitcher winding up to throw a ball is actually circumducting his or her pitching arm. Because circumduction consists of flexion, abduction, extension, and adduction performed in succession, it is the quickest way to exercise the many muscles that move the hip and shoulder ball-and-socket joints.

Rotation

Rotation is the turning of a bone around its own long axis. It is the only movement allowed between



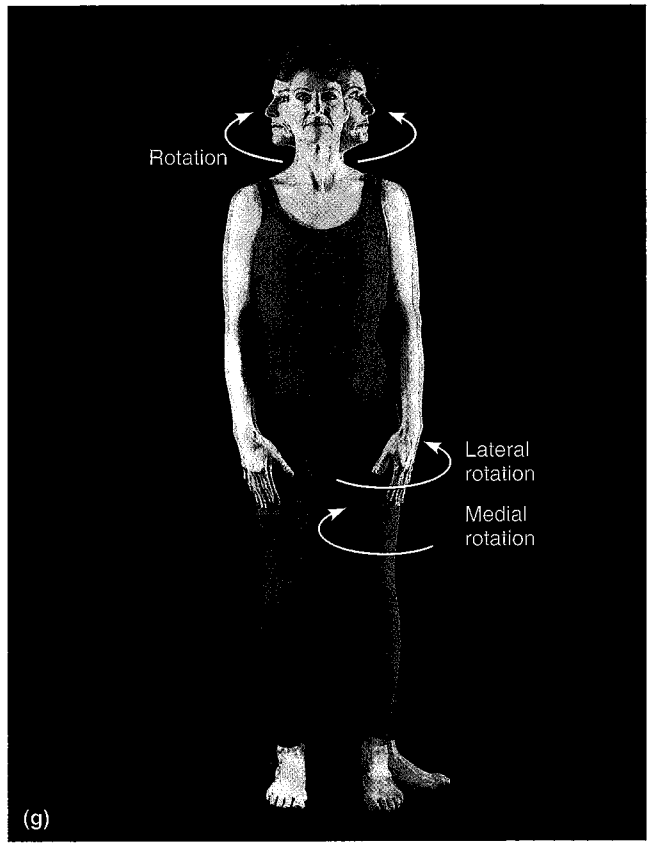


FIGURE 8.5 *(continued)* **Movements allowed by synovial joints. (f)** Angular movements, continued. **(g)** Rotation.

the first two cervical vertebrae and is common at the hip (Figure 8.5g) and shoulder joints. Rotation may be directed toward the midline or away from it. For example, in *medial rotation* of the thigh, the femur's anterior surface moves toward the median plane of the body; *lateral rotation* is the opposite movement.

Special Movements

Certain movements do not fit into any of the above categories and occur at only a few joints. Some of these special movements are illustrated in Figure 8.6.

Supination and Pronation The terms **supination** (soo″pĭ-na′shun; "turning backward") and **pronation** (pro-na′shun; "turning forward") refer to the movements of the radius around the ulna (Figure 8.6a). Rotating the forearm laterally so that the palm faces anteriorly or superiorly is supination. In the anatomical position, the hand is supinated and the radius and ulna are parallel. In pronation, the forearm rotates medially and the palm faces posteriorly or inferiorly. Pronation moves the distal end of the radius across the ulna so that the two bones form an X. This is the forearm's position when we are standing in a relaxed manner. Pronation is a much weaker movement than supination.

A trick to help you keep these terms straight: A *pro* basketball player pronates his or her forearm to dribble the ball.

Inversion and Eversion **Inversion** and **eversion** are special movements of the foot (Figure 8.6b). In inversion, the sole of the foot turns medially. In eversion, the sole faces laterally.

Protraction and Retraction Nonangular anterior and posterior movements in a transverse plane are called **protraction** and **retraction,** respectively (Figure 8.6c). The mandible is protracted when you jut out your jaw and retracted when you move it back to its original position.

Elevation and Depression **Elevation** means lifting a body part superiorly (Figure 8.6d). For example, the scapulae are elevated when you shrug your shoulders. Moving the elevated part inferiorly is **depression.** During chewing, the mandible is alternately elevated and depressed.

Opposition The saddle joint between metacarpal 1 and the carpals allows a movement called

Q *Which hand position—pronation or supination—is characteristic of the anatomical position?*

(e) Opposition

opposition of the thumb (Figure 8.6e). This movement is the action taken when you touch your thumb to the tips of the other fingers on the same hand. It is opposition that makes the human hand such a fine tool for grasping and manipulating objects.

Types of Synovial Joints

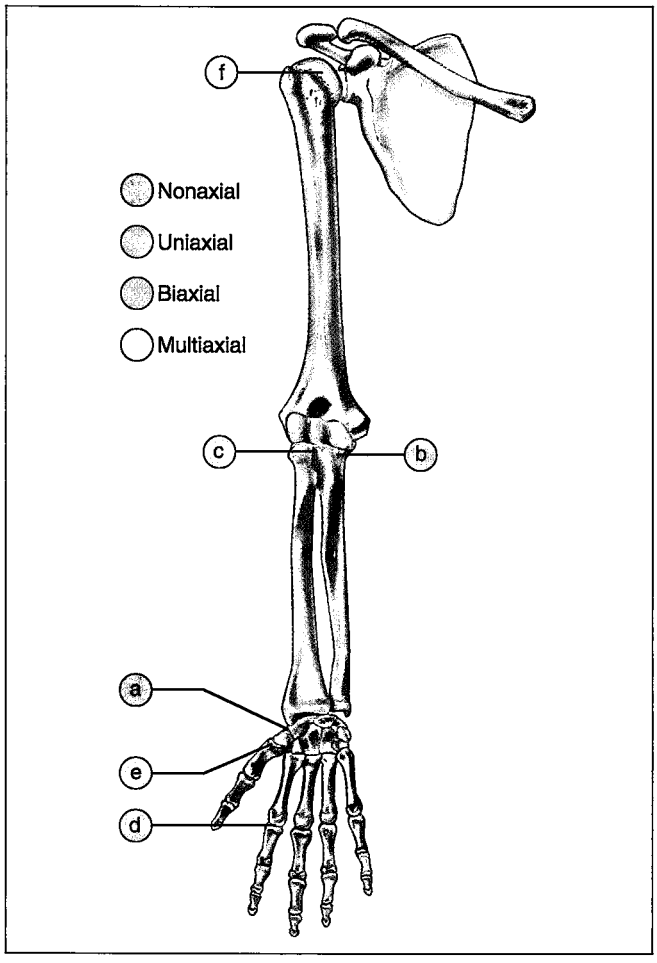
Although all synovial joints have structural features in common, they do not have a common structural plan. Based on the shape of their articular surfaces, which in turn determine the movements allowed, synovial joints can be classified further into six major categories—plane, hinge, pivot, condyloid, saddle, and ball-and-socket joints.

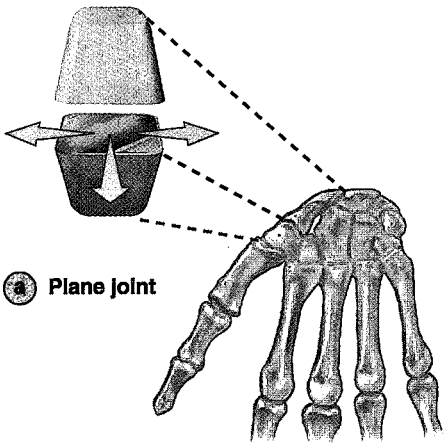
Plane Joints

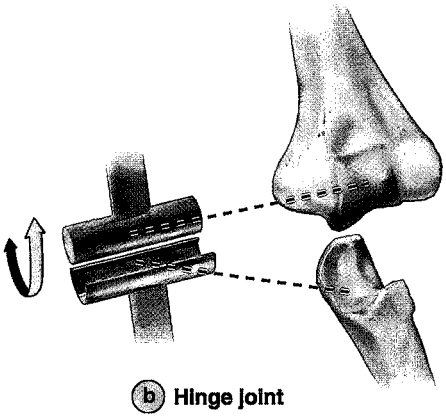
In **plane joints** (Figure 8.7a) the articular surfaces are essentially flat, and they allow only short gliding or translational movements. Examples are the gliding joints introduced earlier—the intercarpal and intertarsal joints, and the joints between vertebral

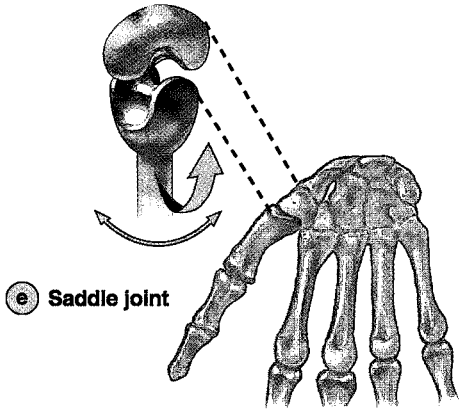
A Supination.

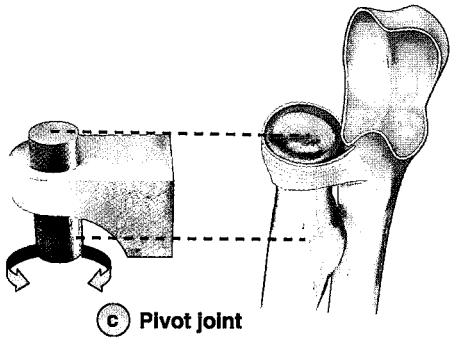
FIGURE 8.7 **Types of synovial joints.** Dashed lines indicate the articulating bones. **(a)** Plane joint (e.g., intercarpal and intertarsal joints). **(b)** Hinge joint (e.g., elbow joints and interphalangeal joints). **(c)** Pivot joint (e.g., proximal radioulnar joint). **(d)** Condyloid joint (e.g., metacarpophalangeal joints). **(e)** Saddle joint (e.g., carpometacarpal joint of the thumb). **(f)** Ball-and-socket joint (e.g., shoulder joint).

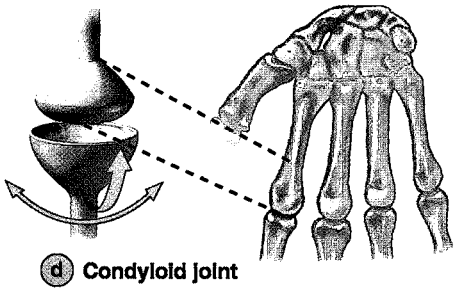


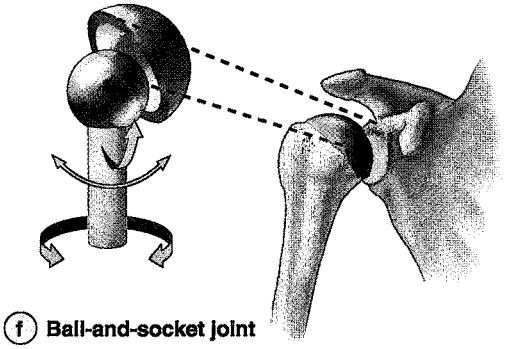












articular processes. Gliding does not involve rotation around any axis, and gliding joints are the only examples of nonaxial joints.

Hinge Joints

In **hinge joints** (Figure 8.7b), a cylindrical projection of one bone fits into a trough-shaped surface on another. Motion is along a single plane and resembles that of a mechanical hinge. The uniaxial hinge joints permit flexion and extension only, typified by bending and straightening the elbow and interphalangeal joints.

Pivot Joints

In a **pivot joint** (Figure 8.7c), the rounded end of one bone protrudes into a "sleeve" or ring composed of bone (and possibly ligaments) of another. The only movement allowed is uniaxial rotation of one bone around its own long axis. An example is the joint between the atlas and dens of the axis, which allows you to move your head from side to side to indicate "no." Another is the proximal radioulnar joint, where the head of the radius rotates within a ringlike ligament secured to the ulna.

Condyloid Joints

In **condyloid joints** (kon′dĭ-loid; "knuckle-like"), or **ellipsoidal joints,** the oval articular surface of one bone fits into a complementary depression in another (Figure 8.7d). The important characteristic is that both articulating surfaces are oval. The biaxial condyloid joints permit all *angular* motions, that is, flexion and extension, abduction and adduction, and circumduction. The radiocarpal (wrist) joints and the metacarpophalangeal (knuckle) joints are typical condyloid joints.

Saddle Joints

Saddle joints (Figure 8.7e) resemble condyloid joints, but they allow greater freedom of movement. Each articular surface has *both* concave and convex areas; that is, it is shaped like a saddle. The articular surfaces then fit together, concave to convex surfaces. The most clear-cut examples of saddle joints in the body are the carpometacarpal joints of the thumbs, and the movements allowed by these joints are clearly demonstrated by twiddling your thumbs.

Ball-and-Socket Joints

In **ball-and-socket joints** (Figure 8.7f), the spherical or hemispherical head of one bone articulates with the cuplike socket of another. These joints are multiaxial and the most freely moving synovial joints. Universal movement is allowed (that is, in all axes and planes, including rotation). The shoulder and hip joints are examples.

Selected Synovial Joints

In this section, we examine five joints [knee, shoulder, hip, elbow, and temporomandibular (jaw) joint] in detail. All of these joints have the five distinguishing characteristics of synovial joints, and we will not discuss these common features again. Instead, we will emphasize the unique structural features, functional abilities, and, in certain cases, functional weaknesses of each of these joints.

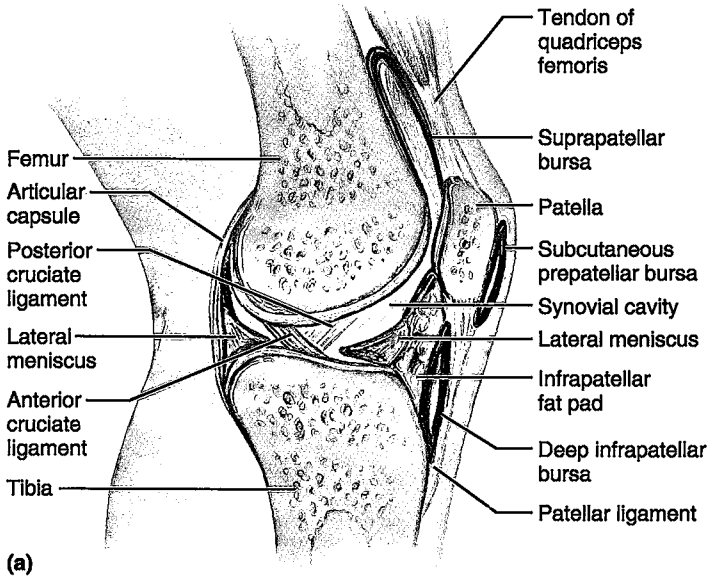
Knee Joint

The knee joint is the largest and most complex joint in the body (Figure 8.8). It allows extension, flexion, and some rotation. Despite its single joint cavity, the knee consists of three joints in one: an intermediate one between the patella and the lower end of the femur (the **femoropatellar joint**), and lateral and medial joints (collectively known as the **tibiofemoral joint**) between the femoral condyles above and the C-shaped **menisci,** or *semilunar cartilages,* of the tibia below. Besides deepening the shallow tibial articular surfaces, the menisci help prevent side-to-side rocking of the femur on the tibia and absorb shock transmitted to the knee joint. However, the menisci are attached only at their outer margins and are frequently torn free.

The tibiofemoral joint acts primarily as a hinge, permitting flexion and extension. However, structurally it is a bicondylar joint. Some rotation is possible when the knee is partly flexed, but when it is extended, side-to-side movements and rotation are strongly resisted by ligaments and the menisci. The femoropatellar joint is a plane joint, and the patella glides across the distal end of the femur during knee movements.

The knee joint is unique in that its joint cavity is only partially enclosed by a capsule. The relatively thin articular capsule is present only on the sides and posterior aspects of the knee, where it covers the bulk of the femoral and tibial condyles. Anteriorly, where the capsule is absent, three broad ligaments run from the patella to the tibia below. These are the **patellar ligament** flanked by the **medial** and **lateral patellar retinacula** (ret″ĭ-nak′u-lah; "retainers"), which merge imperceptibly into the articular capsule on each side (Figure 8.8c). The patellar ligament and retinacula are actually continuations of the tendon of the bulky quadriceps muscle of the anterior thigh. Physicians tap the patellar ligament to test the knee-jerk reflex.

The synovial cavity of the knee joint has a complicated shape, with several extensions that lead into "blind alleys." At least a dozen bursae are associated



(a)

with this joint, some of which are shown in Figure 8.8a. For example, notice the *subcutaneous prepatellar bursa,* which is often injured when the knee is bumped.

All three types of joint ligaments stabilize and strengthen the capsule of the knee joint. The ligaments of two of the types, capsular and extracapsular, all act to prevent hyperextension of the knee and are stretched taut when the knee is extended. These include the following:

1. The extracapsular **fibular** and **tibial collateral ligaments** are also critical in preventing lateral or medial rotation when the knee is extended. The broad, flat tibial collateral ligament runs from the medial epicondyle of the femur to the medial condyle of the tibial shaft below and is fused to the medial meniscus.
2. The **oblique popliteal ligament** (pop″lĭ-te′al) is actually part of the tendon of the semimembranosus muscle that fuses with the capsule and stabilizes the posterior aspect of the knee joint (Figure 8.8e).
3. The **arcuate popliteal ligament** arcs superiorly from the head of the fibula over the popliteus muscle and reinforces the joint capsule posteriorly.

The knee's *intracapsular ligaments* are called *cruciate ligaments* (kroo′she-āt) because they cross each other, forming an X (*cruci* = cross) in the notch between the femoral condyles. They help prevent anterior-posterior displacement of the articular surfaces and secure the articulating bones when we stand (see Figure 8.8b). Although these ligaments are in the joint capsule, they are *outside* the synovial cavity, and synovial membrane nearly covers their surfaces. Note that the two cruciate ligaments both run up to the femur and are named for their *tibial* attachment site. The **anterior cruciate ligament** attaches to the *anterior* intercondylar area of the tibia. From there it passes posteriorly, laterally, and upward to attach to the femur on the medial side of its lateral condyle. This ligament prevents forward sliding of the tibia on the femur and checks hyperextension of the knee. It is somewhat lax when the knee is flexed, and taut when the knee is extended. The stronger **posterior cruciate ligament** is attached to the *posterior* intercondylar area of the tibia and passes anteriorly, medially, and upward to attach to the lateral side of the medial femoral condyle. This ligament prevents backward displacement of the tibia or forward sliding of the femur.

The knee capsule is heavily reinforced by muscle tendons. Most important are the strong tendons of the quadriceps muscles of the anterior thigh and the tendon of the semimembranosus muscle posteriorly. The greater the strength and tone of these muscles, the less the chance of knee injury.

The knees have a built-in locking device that provides steady support for the body in the standing position. As we begin to stand up, the wheel-shaped femoral condyles roll like ball bearings across the flat condyles of the tibia and the flexed leg begins to extend at the knee. Because the lateral femoral condyle stops rolling before the medial condyle stops, the femur *spins* (rotates) medially on the tibia, until all major ligaments of the knee are twisted and taut and the menisci are compressed. The tension in the ligaments effectively locks the joint into a rigid structure that cannot be flexed again until it is unlocked. This unlocking is accomplished by the popliteus muscle (see Figure 8.8 and Table 10.15, p. 373), which rotates the femur laterally on the tibia, causing the ligaments to become untwisted and slack.

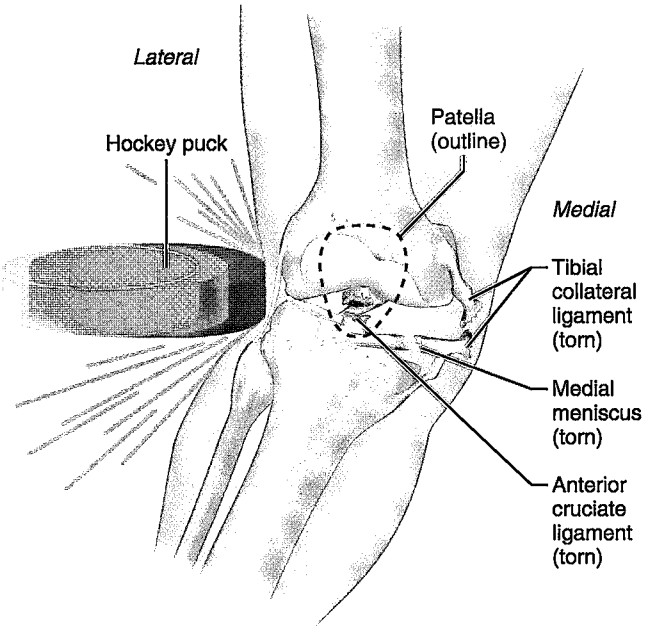

FIGURE 8.9 **A common knee injury.** Anterior view of a knee being hit by a hockey puck. By separating the femur from the tibia medially, such blows to the lateral side tear both the tibial collateral ligament and the medial meniscus because the two are attached. The anterior cruciate ligament also tears.

HOMEOSTATIC IMBALANCE

Of all body joints, the knees are most susceptible to sports injuries because of their high reliance on nonarticular factors for stability and the fact that they carry the body's weight. The knee can absorb a vertical force equal to nearly seven times body weight. However, it is very vulnerable to *horizontal* blows, such as those that occur during blocking and tackling in football. When thinking of common knee injuries, remember the 3 Cs: collateral ligaments, cruciate ligaments, and cartilages (menisci). Most dangerous are *lateral* blows to the extended knee. These forces tear the tibial collateral ligament and the medial meniscus attached to it, as well as the anterior cruciate ligament (Figure 8.9). It is estimated that 50% of all professional football players have serious knee injuries during their careers.

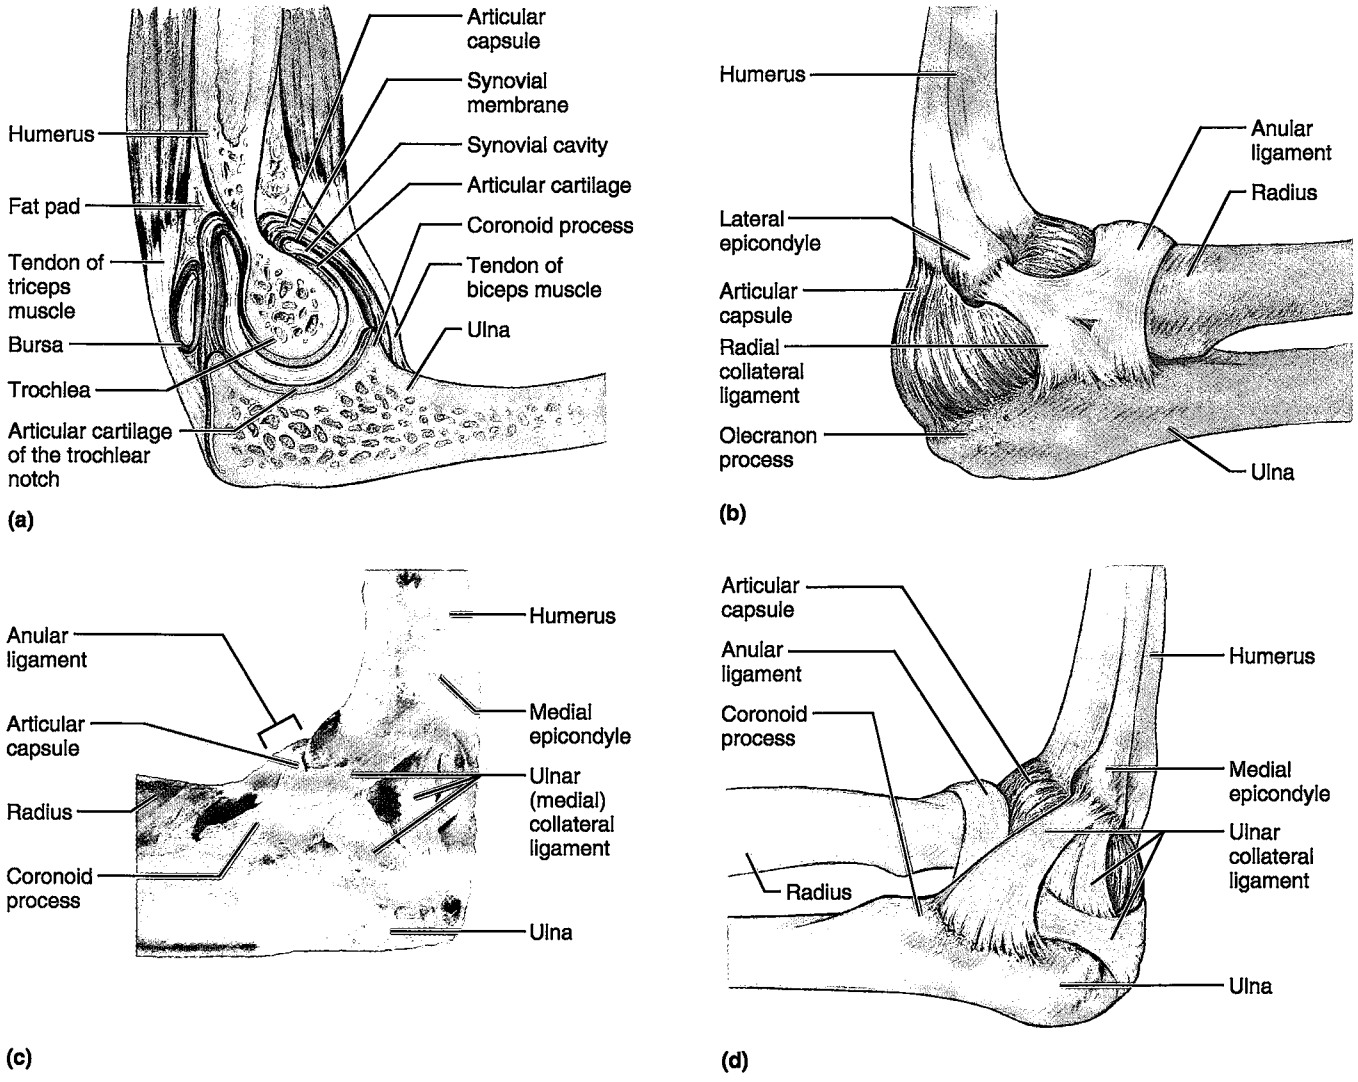

FIGURE 8.10 **The elbow joint. (a)** Midsagittal section of the right elbow joint. **(b)** Lateral view. **(c)** Cadaver photograph of the right elbow joint, medial view. **(d)** Diagram corresponding to view (c).

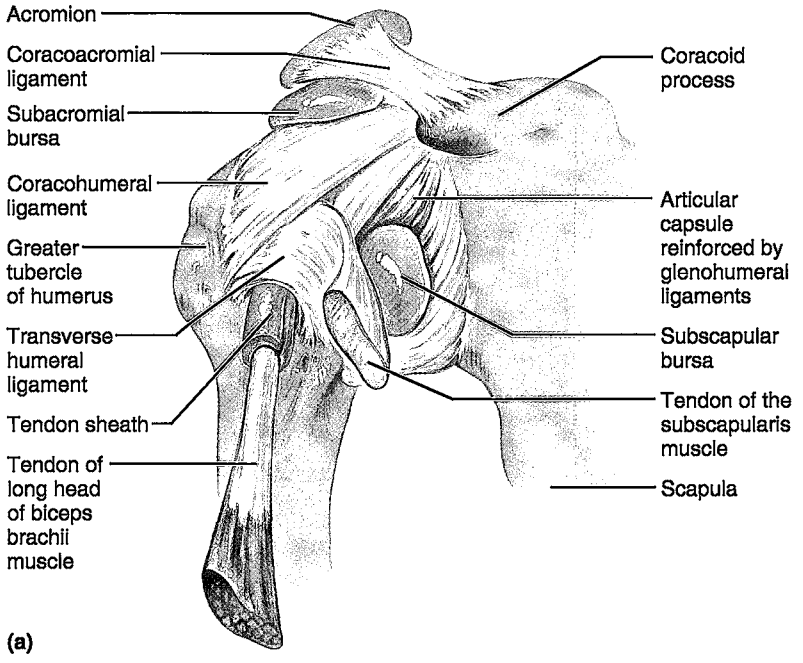
Although less devastating than the injury just described, injuries that affect only the anterior cruciate ligament (ACL) are becoming more common, particularly as women's sports become more vigorous and competitive. Most ACL injuries occur when a runner changes direction quickly, twisting a hyperextended knee. A torn ACL heals poorly, so repair usually requires a ligament graft using connective tissue taken from one of the larger ligaments (e.g., patellar, Achilles, or semitendinosus). ●

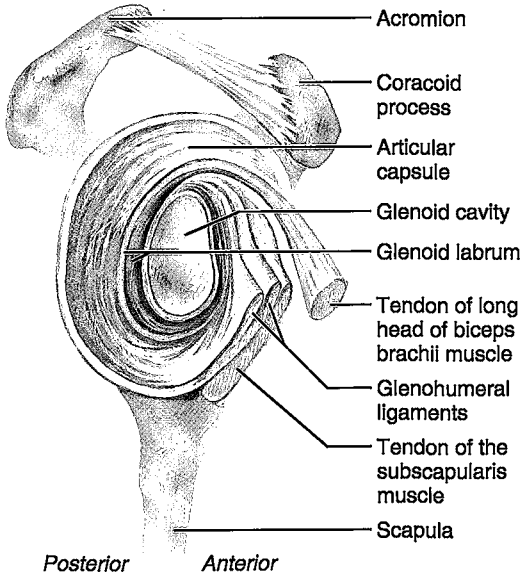
Elbow Joint

Our upper limbs are flexible extensions that permit us to reach out and manipulate things in our environment. Besides the shoulder joint, the most prominent of the upper limb joints is the elbow. The elbow joint provides a stable and smoothly operating hinge that allows flexion and extension only (Figure 8.10). Within the joint, both the radius and ulna articulate with the condyles of the humerus, but it is the close gripping of the trochlea by the ulna's trochlear notch that forms the "hinge" and stabilizes this joint. A relatively lax articular capsule extends inferiorly from the humerus to the ulna and to the **anular ligament** (an'u-lar) surrounding the head of the radius.

Anteriorly and posteriorly, the articular capsule is thin and allows substantial freedom for elbow flexion and extension. However, side-to-side movements are restricted by two strong capsular ligaments: the **ulnar collateral ligament** medially, and the **radial collateral ligament,** a triangular ligament on the lateral side. Additionally, tendons of several arm muscles, such as the biceps and triceps, cross the elbow joint and provide security.

The radius is a passive "onlooker" in the angular elbow movements. However, its head rotates within the anular ligament during supination and pronation of the forearm.





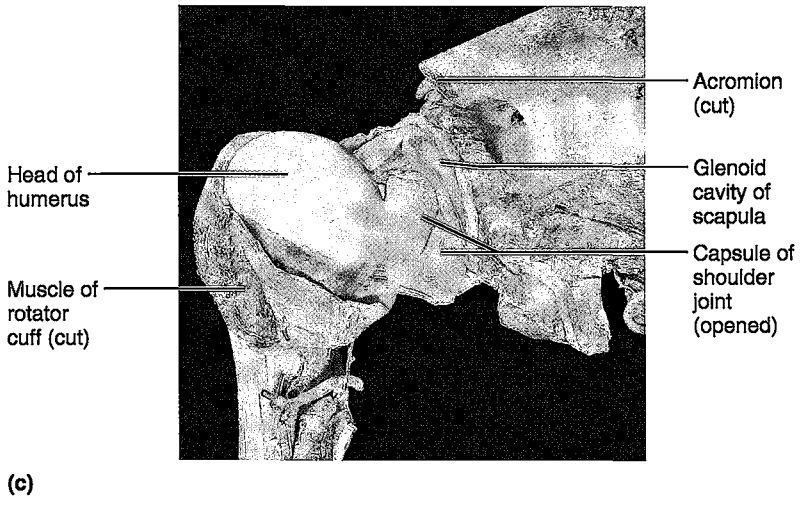


FIGURE 8.11 **The shoulder joint. (a)** Anterior superficial view of right shoulder joint. **(b)** The right shoulder joint, cut open and viewed from the lateral aspect; the humerus has been removed. **(c)** Photo of an opened shoulder joint, anterior view.

Shoulder (Glenohumeral) Joint

In the shoulder joint, stability has been sacrificed to provide the most freely moving joint of the body. The shoulder joint is a ball-and-socket joint. The large hemispherical head of the humerus fits in the small, shallow glenoid cavity of the scapula (Figures 8.4 and 8.11), like a golf ball sitting on a tee. Although the glenoid cavity is slightly deepened by a rim of fibrocartilage, the **glenoid labrum** (*labrum* = lip), it is only about one-third the size of the humeral head and contributes little to joint stability.

The articular capsule enclosing the joint cavity (from the margin of the glenoid cavity to the anatomical neck of the humerus) is remarkably thin and loose, qualities that contribute to this joint's freedom of movement. The few ligaments reinforcing the shoulder joint are located primarily on its anterior aspect. The superiorly located **coracohumeral ligament** (kor'ah-ko-hu'mer-ul) provides the only strong thickening of the capsule and helps support the weight of the upper limb. Three **glenohumeral ligaments** (glĕ"no-hu'mer-ul) strengthen the front of the capsule somewhat but are weak and may even be absent.

Muscle tendons that cross the shoulder joint contribute most to this joint's stability. The "superstabilizer" is the tendon of the long head of the biceps brachii muscle of the arm (Figure 8.11a). This tendon attaches to the superior margin of the glenoid labrum, travels through the joint cavity, and then runs within the intertubercular sulcus of the humerus. It secures the head of the humerus against the glenoid cavity. Four other tendons (and the associated muscles) make up the **rotator cuff.** This cuff encircles the shoulder joint and blends with the articular capsule. The muscles include the subscapularis, supraspinatus, infraspinatus, and teres minor. (The rotator cuff muscles are illustrated in Figure 10.14, p. 356.) The rotator cuff can be severely

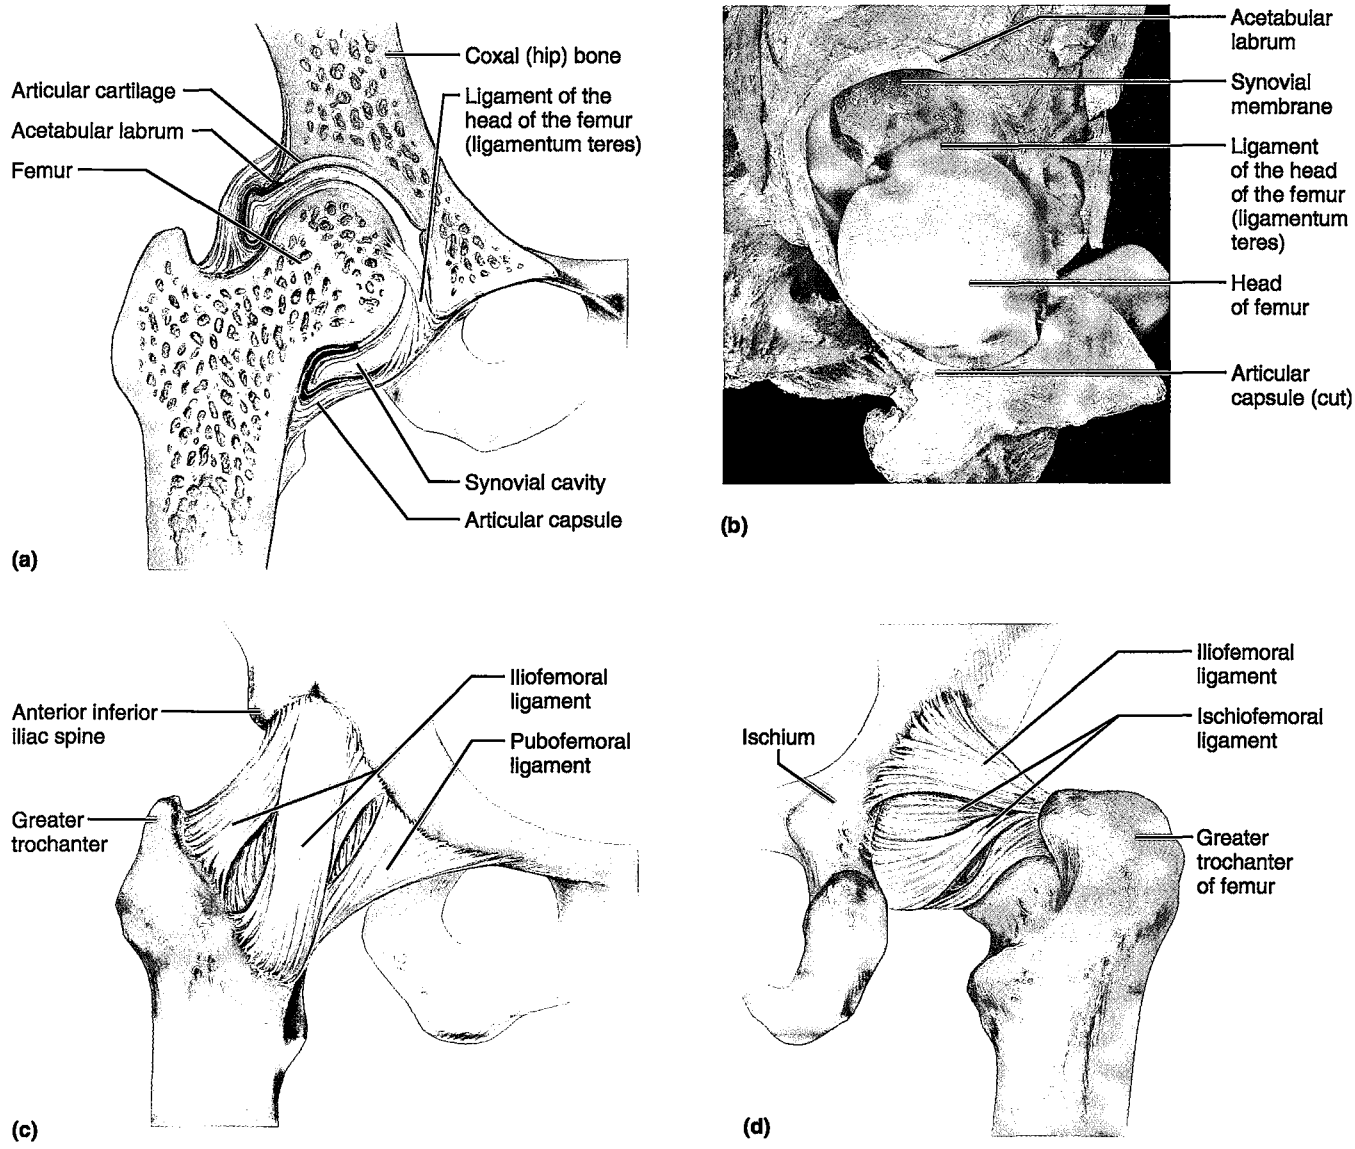

FIGURE 8.12 **The hip joint. (a)** Frontal section through the right hip joint. **(b)** Photograph of the joint, interior lateral view. **(c)** Anterior superficial view of the right hip joint. **(d)** Posterior superficial view.

stretched when the arm is vigorously circumducted; this is a common injury of baseball pitchers. As noted in Chapter 7, shoulder dislocations are fairly common. Because the shoulder's reinforcements are weakest anteriorly and inferiorly, the humerus tends to dislocate in the forward and downward direction.

Hip (Coxal) Joint

The hip joint, like the shoulder joint, is a ball-and-socket joint. It has a good range of motion, but not nearly as wide as the shoulder's range. Movements occur in all possible planes but are limited by the joint's strong ligaments and its deep socket. The hip joint is formed by the articulation of the spherical head of the femur with the deeply cupped acetabulum of the hip bone (Figure 8.12). The depth of the acetabulum is enhanced by a circular rim of fibrocartilage called the **acetabular labrum** (as″ĕ-tab′u-lar) (Figure 8.12a and b). The labrum's diameter is less than that of the head of the femur, and these articular surfaces fit snugly together, so hip joint dislocations are rare.

The thick articular capsule extends from the rim of the acetabulum to the neck of the femur and completely encloses the joint. Several strong ligaments reinforce the capsule of the hip joint. These include the **iliofemoral ligament** (il″e-o-fem′o-ral), a strong V-shaped ligament anteriorly; the **pubofemoral ligament** (pu″bo-fem′o-ral), a triangular thickening of the inferior part of the capsule; and the **ischiofemoral ligament** (is″ke-o-fem′o-ral), a spiraling

(a)** Location of the joint in the skull showing important surrounding structures. **(b)** Enlargement of a sagittal section through the joint, showing the articular disc, the superior and inferior compartments of the joint cavity, and two movements that occur (arrows). The inferior joint cavity allows the mandibular condyle to rotate in opening and closing the mouth, whereas the superior joint cavity lets the mandibular condyle move forward to brace against the articular tubercle when the mouth opens wide. **(c)** Lateral movements of the mandible.

posterior ligament. These ligaments are arranged in such a way that they "screw" the femur head into the acetabulum when a person stands up straight, thereby providing more stability.

The **ligament of the head of the femur,** also called the **ligamentum teres,** is a flat intracapsular band that runs from the femur head to the lower lip of the acetabulum. This ligament is slack during most hip movements, so it is not important in stabilizing the joint. In fact, its mechanical function (if any) is unclear, but it does contain an artery that helps supply the head of the femur. Damage to this artery may lead to severe arthritis of the hip joint.

Muscle tendons that cross the joint and the bulky hip and thigh muscles that surround it contribute to its stability and strength. However, the deep socket that securely encloses the femoral head and the strong ligaments contribute most to the stability of the hip joint.

Temporomandibular Joint

The **temporomandibular joint (TMJ),** or jaw joint, lies just anterior to the ear. At this joint, the mandibular condyle articulates with the inferior surface of the squamous temporal bone (Figure 8.13). The mandibular condyle is egg-shaped, whereas the articular surface of the temporal bone has a more complex shape. Posteriorly, it forms the concave mandibular fossa; anteriorly it forms a dense knob called the **articular tubercle.** The lateral aspect of the loose articular capsule that encloses the joint is

thickened into a **lateral ligament**. Within the capsule, an articular disc divides the synovial cavity into superior and inferior compartments (Figure 8.13).

Two distinct kinds of movement occur at the TMJ. First, the concave inferior disc surface receives the mandibular condyle and allows the familiar hinge-like movement of depressing and elevating the mandible while opening and closing the mouth. Second, the superior disc surface glides anteriorly along with the mandibular condyle when the mouth is opened wide. This anterior movement braces the condyle against the articular tubercle, so that the mandible is not forced through the thin roof of the mandibular fossa when one bites hard foods such as nuts or hard candies. The superior compartment also allows this joint to glide from side to side. As the posterior teeth are drawn into occlusion during grinding, the mandible moves with a side-to-side movement called *lateral excursion* (Figure 8.13). This lateral jaw movement is unique to mammals and it is readily apparent in horses and cows as they chew.

HOMEOSTATIC IMBALANCE

Because of its shallow socket, the TMJ is the most easily dislocated joint in the body. Even a deep yawn can dislocate it. This joint almost always dislocates anteriorly, the mandibular condyle ending up in a skull region called the infratemporal fossa (see Figure 8.13a). In such cases, the mouth remains wide open. To realign a dislocated TMJ, the physician places his or her thumbs in the patient's mouth between the lower molars and the cheeks, and then pushes the mandible inferiorly and posteriorly.

At least 5% of Americans suffer from painful temporomandibular disorders, the most common symptoms of which are pain in the ear and face, tenderness of the jaw muscles, popping sounds when the mouth opens, and joint stiffness. Usually caused by painful spasms of the chewing muscles, TMJ disorders often afflict people who grind their teeth; however, it can also result from jaw trauma or from poor occlusion of the teeth. Treatment usually focuses on getting the jaw muscles to relax by using massage, applying moist heat or ice, muscle-relaxant drugs, and adopting stress reduction tehniques. For tooth grinders, use of a bite plate during sleep is generally recommended. ●

Homeostatic Imbalances of Joints

Few of us pay attention to our joints unless something goes wrong with them. Joint pain and malfunction can be caused by a number of factors, but most joint problems result from injuries and inflammatory or degenerative conditions.

Common Joint Injuries

For most of us, sprains and dislocations are the most common trauma-induced joint injuries, but cartilage injuries are equally threatening to athletes.

Sprains

In a **sprain,** the ligaments reinforcing a joint are stretched or torn. The lumbar region of the spine, the ankle, and the knee are common sprain sites. Partially torn ligaments will repair themselves, but they heal slowly because ligaments are so poorly vascularized. Sprains tend to be painful and immobilizing. Completely ruptured ligaments require prompt surgical repair because inflammation in the joint will break down the neighboring tissues and turn the injured ligament to "mush." Surgical repair can be difficult: A ligament consists of hundreds of fibrous strands, and sewing one back together has been compared to trying to sew two hairbrushes together.

When important ligaments are too severely damaged to be repaired, they must be removed and replaced with grafts or substitute ligaments. For example, a piece of tendon from a muscle, or woven collagen bands, can be stapled to the articulating bones.

Cartilage Injuries

Many aerobics devotees, encouraged to "feel the burn" during their workout, may feel the snap and pop of their overstressed cartilage instead. Although most cartilage injuries involve tearing of the knee menisci, overuse damage to the articular cartilages of other joints is becoming increasingly common in competitive young athletes.

Cartilage is avascular and it rarely can obtain sufficient nourishment to repair itself; thus, it usually stays torn. Cartilage fragments (called *loose bodies*) can interfere with joint function by causing the joint to lock or bind, so most sports physicians recommend that the central (nonvascular) part of a damaged cartilage be removed. Today, this can be done by **arthroscopic surgery** (ar-thro-skop'ik; "looking into joints"), a procedure that enables patients to be out of the hospital the same day. The arthroscope, a small instrument bearing a tiny lens and fiber-optic light source, enables the surgeon to view the joint interior (Figure 8.14), repair a ligament, or remove cartilage fragments through one or more tiny slits, minimizing tissue damage and scarring. Removal of part of a meniscus does not severely impair knee joint mobility, but the joint is definitely less stable.

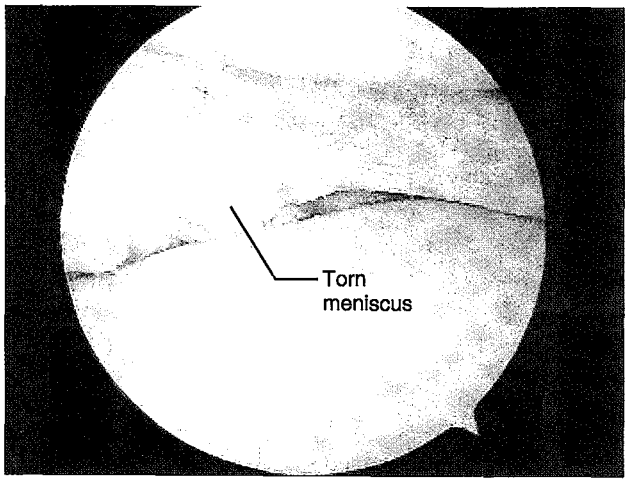

FIGURE 8.14 **Arthroscopic photograph of a torn medial meniscus** (Courtesy of the author's tennis game).

Dislocations

A **dislocation (luxation)** occurs when bones are forced out of alignment. It is usually accompanied by sprains, inflammation, and joint immobilization. Dislocations may result from serious falls and are common contact sports injuries. Joints of the jaw, shoulders, fingers, and thumbs are most commonly dislocated. Like fractures, dislocations must be *reduced;* that is, the bone ends must be returned to their proper positions by a physician. *Subluxation* is a partial dislocation of a joint.

Repeat dislocations of the same joint are common because the initial dislocation stretches the joint capsule and ligaments. The resulting loose capsule provides poor reinforcement for the joint.

Inflammatory and Degenerative Conditions

Inflammatory conditions that affect joints include bursitis, tendonitis, and various forms of arthritis.

Bursitis and Tendonitis

Bursitis is inflammation of a bursa and is usually caused by a blow or friction. Falling on one's knee may result in a painful bursitis of the prepatellar bursa, known as *housemaid's knee* or *water on the knee.* Prolonged leaning on one's elbows may damage the bursa close to the olecranon process, producing *student's elbow,* or *olecranon bursitis.* Severe cases are treated by injecting anti-inflammatory drugs into the bursa. If excessive fluid accumulates, removing some fluid by needle aspiration may relieve the pressure.

Tendonitis is inflammation of tendon sheaths, typically caused by overuse. Its symptoms (pain and swelling) and treatment (rest, ice, and anti-inflammatory drugs) mirror those of bursitis.

Arthritis

The term **arthritis** describes over 100 different types of inflammatory or degenerative diseases that damage the joints. In all its forms, arthritis is the most widespread crippling disease in the United States. One out of seven Americans suffers its ravages. To a greater or lesser degree, all forms of arthritis have the same initial symptoms: pain, stiffness, and swelling of the joint.

Acute forms of arthritis usually result from bacterial invasion and are treated with antibiotics. The synovial membrane thickens and fluid production decreases, causing increased friction and pain. Chronic forms of arthritis include osteoarthritis, rheumatoid arthritis, and gouty arthritis.

Osteoarthritis **Osteoarthritis (OA)** is the most common chronic arthritis. A chronic (long-term) degenerative condition, OA is often called "wear-and-tear arthritis." OA is most prevalent in the aged and is probably related to the normal aging process (although it is seen occasionally in younger people and some forms have a genetic basis). More women than men are affected, but 85% of all Americans develop this condition.

Current theory holds that normal joint use prompts the release of (metalloproteinase) enzymes that break down articular cartilage, especially its collagen fibrils. In healthy individuals, this damaged cartilage is eventually replaced, but in people with OA, more cartilage is destroyed than replaced. Although its specific cause is unknown, OA may reflect the cumulative effects of years of compression and abrasion acting at joint surfaces, causing excessive amounts of the cartilage-destroying enzymes to be released. The result is softened, roughened, pitted, and eroded articular cartilages. Because this process occurs most where an uneven orientation of forces cause extensive microdamage, badly aligned or overworked joints are likely to develop OA.

As the disease progresses, the exposed bone tissue thickens and forms bony spurs (osteophytes) that enlarge the bone ends and may restrict joint movement. Patients complain of stiffness on arising that lessens somewhat with activity. The affected joints may make a crunching noise, called *crepitus* (krep'ĭ-tus), as they move and the roughened articular surfaces rub together. The joints most often affected are those of the cervical and lumbar spine and the fingers, knuckles, knees, and hips.

The course of osteoarthritis is usually slow and irreversible. In many cases, its symptoms are controllable with a mild pain reliever like aspirin or acetaminophen, along with moderate activity to keep the joints mobile. Rubbing a hot-pepper-like substance

FIGURE 8.15 **X ray of a hand deformed by rheumatoid arthritis.**

called capsaicin on the skin over the painful joints helps lessen the pain of OA. Glucosamine and chondroitin sulfate, nutritional supplements consisting of macromolecules normally present in cartilage, appear to decrease pain and inflammation in some people and may help to preserve the articular cartilage. Osteoarthritis is rarely crippling, but it can be, particularly when the hip or knee joints are involved.

Rheumatoid Arthritis **Rheumatoid arthritis (RA)** (roo'mah-toid) is a chronic inflammatory disorder with an insidious onset. Though it usually arises between the ages of 40 and 50, it may occur at any age. It affects three times as many women as men. While not as common as osteoarthritis, rheumatoid arthritis causes disability in millions (Figure 8.15). It occurs in more than 1% of Americans.

In the early stages of RA, joint tenderness and stiffness are common. Many joints, particularly the small joints of the fingers, wrists, ankles, and feet, are afflicted at the same time and bilaterally. For example, if the right elbow is affected, most likely the left elbow is also affected. The course of RA is variable and marked by flare-ups (exacerbations) and remissions (*rheumat* = susceptible to change). Other manifestations may include anemia, osteoporosis, muscle atrophy, and cardiovascular problems.

RA is an *autoimmune disease*—a disorder in which the body's immune system attacks its own tissues. The initial trigger for this reaction is unknown, but the streptococcus bacterium and viruses have been suspect. Perhaps these microorganisms bear molecules similar to some naturally present in the joints (possibly glucosaminoglycans, complex carbohydrates found in cartilage, joint fluid, and other connective tissues) and the immune system, once activated, attempts to destroy both.

RA begins with inflammation of the synovial membrane (*synovitis*) of the affected joints. Inflammatory cells (lymphocytes, neutrophils, and others) migrate into the joint cavity from the blood and unleash a deluge of inflammatory chemicals that destroy body tissues when released inappropriately in large amounts as in RA. Synovial fluid accumulates, causing joint swelling and in time, the inflamed synovial membrane thickens into a **pannus** ("rag"), an abnormal tissue that clings to the articular cartilages. The pannus erodes the cartilage (and sometimes the underlying bone) and eventually scar tissue forms and connects the bone ends. Later this scar tissue ossifies and the bone ends fuse together, immobilizing the joint. This end condition, called *ankylosis* (ang"kĭ-lo'sis; "stiff condition"), often produces bent, deformed fingers (see Figure 8.15). Not all cases of RA progress to the severely crippling ankylosis stage, but all cases do involve restriction of joint movement and extreme pain.

A wonder drug for RA sufferers is still undiscovered. Currently the pendulum is swinging from conservative RA therapy utilizing aspirin, long-term antibiotic therapy, and physical therapy to a more progressive treatment course using immunosuppressants such as methotrexate, or anti-inflammatory drugs. Particularly promising are etanercept (Enbrel) and infliximab (Remicade), the first in a class of drugs called *biologic response modifiers* that neutralize some of the harmful properties of the inflammatory chemicals. Unexpected success has been achieved in clinical studies using a tandem drug therapy approach (methotrexate in combination with etanercept). The arthritis of 35% of those treated went into remission and the arthritic joints of some patients actually improved after a year of therapy. Joint prostheses, if available, are the last resort for severely crippled RA patients (see *A Closer Look*).

Gouty Arthritis Uric acid, a normal waste product of nucleic acid metabolism, is ordinarily excreted in urine without any problems. However, when blood levels of uric acid rise excessively (due to its excessive production or slow excretion), it may be deposited as needle-shaped urate crystals in the soft tissues of joints. An inflammatory response follows, leading into an agonizingly painful attack of **gouty arthritis** (gow'te), or gout. The initial attack typically affects one joint, often at the base of the great toe.

Gout is far more common in males than in females because males naturally have higher blood levels of uric acid (perhaps because estrogens increase the rate of its excretion). Because gout seems to run in families, genetic factors are definitely implicated.

Untreated gout can be very destructive; the articulating bone ends fuse and immobilize the joint. Fortunately, several drugs (colchicine, nonsteroidal

A CLOSER LOOK

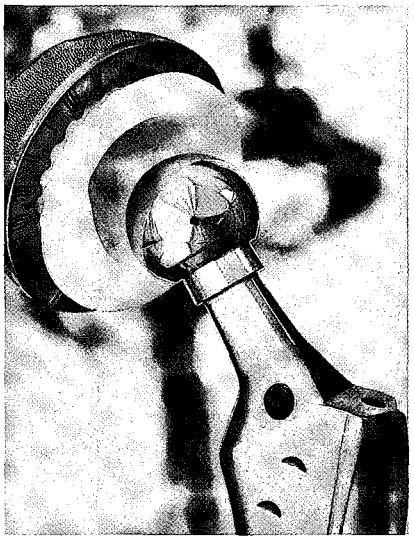
Joints: From Knights in Shining Armor to Bionic Humans

The technology for fashioning joints in medieval suits of armor developed over centuries. The technology for creating the prostheses (artificial joints) used in medicine today developed, in relative terms, in a flash. The history of joint prostheses dates to the 1940s and 1950s, when World War II and the Korean War left large numbers of wounded who needed artificial limbs. Today, over a third of a million Americans receive total joint replacements each year, mostly because of the destructive effects of osteoarthritis or rheumatoid arthritis.

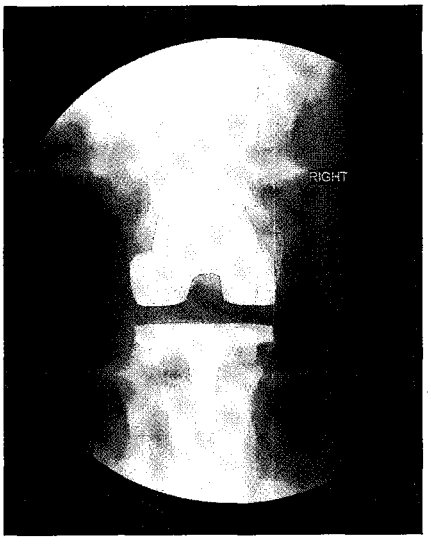
To produce durable, mobile joints requires a substance that is strong, nontoxic, and resistant to the corrosive effects of organic acids in blood. In 1963, Sir John Charnley, an English orthopedic surgeon, performed the first total hip replacement and revolutionized the therapy of arthritic hips. His device consisted of a metal ball on a stem and a cup-shaped polyethylene plastic socket anchored to the pelvis by methyl methacrylate cement. This cement proved to be exceptionally strong and relatively problem free. Hip prostheses were followed by knee prostheses, but not until ten years later did smoothly operating total knee joint replacements become a reality. Today, the metal parts of the prostheses are strong cobalt and titanium alloys, and the number of knee replacements equals the number of hip replacements.

Replacements are now available for many other joints, including fingers, elbows, and shoulders. Total hip and knee replacements last about 10 to 15 years in elderly patients who do not excessively stress the joint. Most such operations are done to reduce pain and restore about 80% of original joint function.

Replacement joints are not yet strong or durable enough for young, active people, but making them so is a major goal. The problem is that the prostheses work loose over time, so researchers are seeking to enhance the fit between implant and bone. One solution is to strengthen the cement that binds them (simply eliminating air bubbles from the cement increases its durability). Another solution currently being tested is a robotic surgeon, ROBODOC, to drill a better-fitting hole for the femoral prosthesis in hip surgery. In cementless prostheses, researchers are exploring ways to get the bone to grow so that it binds strongly to the implant. A supersmooth titanium coating seems to encourage direct bony on-growth.



A hip prosthesis.



X ray of right knee showing total knee replacement prosthesis (Co-designed by Kenneth Gustke M.D. of Florida Orthopedic Institute).

Dramatic changes are also occurring in the way artificial joints are made. CAD/CAM (computer-aided design and computer-aided manufacturing) techniques have significantly reduced the time and cost of creating individualized joints. Fed the patient's X rays and medical information, the computer draws from a database of hundreds of normal joints and generates possible designs and modifications for a prosthesis. Once the best design is selected, the computer produces a program to direct the machines that shape it.

Joint replacement therapy is coming of age, but equally exciting are techniques that call on the ability of the patient's own tissues to regenerate, such as

- Osteochondral grafting: Healthy bone and cartilage are removed from one part of the body and transplanted to the injured joint.
- Autologous chondrocyte implantation: Healthy chondrocytes are removed from the body, cultivated in the lab, and implanted at the damaged joint.
- Mesenchymal stem cell regeneration: Undifferentiated mesenchymal cells are removed from bone marrow and placed in a gel, which is packed into an area of eroded cartilage.

These techniques offer hope for younger patients, since they could stave off the need for a joint prosthesis for several years.

And so, through the centuries, the focus has shifted from jointed armor to artificial joints that can be put inside the body to restore lost function. Modern technology has accomplished what the armor designers of the Middle Ages never dreamed of. ■

anti-inflammatory drugs, glucocorticoids, and others) that terminate or prevent gout attacks are available. Patients are advised to drink plenty of water and to avoid alcohol excess (which promotes uric acid overproduction), and foods high in purine-containing nucleic acids, such as liver, kidneys, and sardines.

Developmental Aspects of Joints

As bones form from mesenchyme in the embryo, the joints develop in parallel. By week 8, the synovial joints resemble adult joints in form and arrangement.

Injuries aside, relatively few interferences with joint function occur until late middle age. Eventually advancing years take their toll and ligaments and tendons shorten and weaken. The intervertebral discs become more likely to herniate, and osteoarthritis rears its ugly head. Virtually everyone has osteoarthritis to some degree by the time they are in their 70s. The middle years also see an increased incidence of rheumatoid arthritis.

Exercise that coaxes joints through their full range of motion, such as regular stretching and aerobics, is the key to postponing the immobilizing effects of aging on ligaments and tendons, to keeping cartilages well nourished, and to strengthening the muscles that stabilize the joints. The key word for exercising is "prudently," because excessive or abusive use of the joints guarantees early onset of osteoarthritis. The buoyancy of water relieves much of the stress on weight-bearing joints, and people who swim or exercise in a pool often retain good joint function as long as they live. As with so many medical problems, it is easier to prevent joint problems than to cure or correct them.

■ ■ ■

The importance of joints is obvious: The skeleton's ability to protect other organs and to move smoothly reflects their presence. Now that we are familiar with joint structure and with the movements that joints allow, we are ready to consider how the muscles attached to the skeleton cause body movements by acting across its joints.

Related Clinical Terms

Ankylosing spondylitis (ang'kĭ-lōz"ing spon"dĭ-li'tis; *ankyl* = crooked, bent; *spondyl* = vertebra) A variant of rheumatoid arthritis that chiefly affects males; it usually begins in the sacroiliac joints and progresses superiorly along the spine. The vertebrae become interconnected by fibrous tissue, causing the spine to become rigid ("poker back").

Arthrology (ar-throl'o-je; *logos* = study) The study of joints.

Chondromalacia patellae (kon-dro-mal-a'sĭ-ah; "softening of cartilage by the patella") Damage and softening of the articular cartilages on the posterior patellar surface and the anterior surface of the distal femur; most often seen in adolescent athletes. Produces a sharp pain in the knee when the leg is extended (in climbing stairs, for example). May result when the quadriceps femoris, the main group of muscles on the anterior thigh, pulls unevenly on the patella, persistently rubbing it against the femur in the knee joint; often corrected by exercises that strengthen weakened parts of the quadriceps muscles.

Lyme disease An inflammatory disease caused by spirochetes, bacteria transmitted by the bites of ticks that live on mice and deer. It often results in joint pain and arthritis, especially in the knees, and is characterized by a skin rash, flulike symptoms, and foggy thinking. If untreated, neurological disorders and irregular heartbeat may ensue. Because symptoms vary from person to person, the disease is hard to diagnose. Antibiotic therapy is the usual treatment, but it takes a long time to kill the infecting bacteria.

Rheumatism A term used by laypeople to indicate disease involving muscle or joint pain; consequently may be used to apply to arthritis, bursitis, etc.

Synovitis (sin"o-vi'tis) Inflammation of the synovial membrane of a joint. In healthy joints, only small amounts of synovial fluid are present, but synovitis causes copious amounts to be produced, leading to swelling and limitation of joint movement.

Chapter Summary

1. Joints, or articulations, are sites where bones meet. Their functions are to hold bones together and to allow various degrees of skeletal movement.

Classification of Joints (p. 253)

1. Joints are classified structurally as fibrous, cartilaginous, or synovial. They are classed functionally as synarthrotic, amphiarthrotic, or diarthrotic.

Fibrous Joints (pp. 253–254)

1. Fibrous joints occur where bones are connected by fibrous tissue; no joint cavity is present. Nearly all fibrous joints are synarthrotic.

2. **Sutures/syndesmoses/gomphoses.** The major types of fibrous joints are sutures, syndesmoses, and gomphoses.

Cartilaginous Joints (p. 255)

1. In cartilaginous joints, the bones are united by cartilage; no joint cavity is present.

2. Synchondroses/symphyses. Cartilaginous joints include synchondroses and symphyses. Synchondroses are synarthrotic; all symphyses are amphiarthrotic.

Synovial Joints (pp. 255–272)

1. Most body joints are synovial joints, all of which are diarthrotic.

General Structure (pp. 255–256)

2. All synovial joints have a joint cavity enclosed by a fibrous capsule lined with synovial membrane and reinforced by ligaments; articulating bone ends covered with articular cartilage; and synovial fluid in the joint cavity. Some (e.g., the knee) contain fibrocartilage discs that absorb shock.

Bursae and Tendon Sheaths (p. 257)

3. Bursae are fibrous sacs lined with synovial membrane and containing synovial fluid. Tendon sheaths are similar to bursae but are cylindrical structures that surround muscle tendons. Both allow adjacent structures to move smoothly over one another.

Factors Influencing the Stability of Synovial Joints (pp. 257–259)

4. Articular surfaces providing the most stability have large surfaces and deep sockets and fit snugly together.

5. Ligaments prevent undesirable movements and reinforce the joint.

6. The tone of muscles whose tendons cross the joint is the most important stabilizing factor in many joints.

Movements Allowed by Synovial Joints (pp. 259–263)

7. When a skeletal muscle contracts, the insertion (movable attachment) moves toward the origin (immovable attachment). Three common types of movements can occur when muscles contract across joints: (a) gliding movements, (b) angular movements (which include flexion, extension, abduction, adduction, and circumduction), and (c) rotation.

8. Special movements include supination and pronation, inversion and eversion, protraction and retraction, elevation and depression, and opposition.

Types of Synovial Joints (pp. 263–265)

9. Synovial joints differ in their range of motion. Motion may be nonaxial (gliding), uniaxial (in one plane), biaxial (in two planes), or multiaxial (in all three planes).

10. The six major categories of synovial joints are plane joints (nonaxial movement), hinge joints (uniaxial), pivot joints (uniaxial, rotation permitted), condyloid joints (biaxial with angular movements in two planes), saddle joints (biaxial, like condyloid joints, but with freer movement), and ball-and-socket joints (multiaxial and rotational movement).

Selected Synovial Joints (pp. 265–272)

11. The knee joint is the largest joint in the body. It is a hinge joint formed by the articulation of the tibial and femoral condyles (and anteriorly by the patella and patellar surface of the femur). Extension, flexion, and (some) rotation are allowed. Its articular surfaces are shallow and condyloid. C-shaped menisci deepen the articular surfaces. The joint cavity is enclosed by a capsule only on the sides and posterior aspects. Several ligaments help prevent displacement of the joint surfaces. Muscle tone of the quadriceps and semimembranosus muscles is important in knee stability.

12. The elbow is a hinge joint in which the ulna (and radius) articulates with the humerus, allowing flexion and extension. Its articular surfaces are highly complementary and are the most important factor contributing to joint stability.

13. The shoulder joint is a ball-and-socket joint formed by the glenoid cavity of the scapula and the humeral head. The most freely movable joint of the body, it allows all angular and rotational movements. Its articular surfaces are shallow. Its capsule is lax and poorly reinforced by ligaments. The tendons of the biceps brachii and rotator cuff muscles help to stabilize it.

14. The hip joint is a ball-and-socket joint formed by the acetabulum of the coxal bone and the femoral head. It is highly adapted for weight bearing. Its articular surfaces are deep and secure. Its capsule is heavy and strongly reinforced by ligaments.

15. The temporomandibular joint is formed by (1) the mandibular condyle and (2) the mandibular fossa and articular tubercle of the temporal bone. This joint allows both a hingelike opening and closing of the mouth and an anterior gliding of the mandible. It often dislocates anteriorly and exhibits a number of TMJ disorders.

Homeostatic Imbalances of Joints (pp. 272–274, 276)

Common Joint Injuries (p. 272–273)

1. Sprains involve stretching or tearing of joint ligaments. Because ligaments are poorly vascularized, healing is slow.

2. Cartilage injuries, particularly of the knee, are common in contact sports and may result from excessive twisting or high pressure. The avascular cartilage is unable to repair itself.

3. Dislocations involve displacement of the articular surfaces of bones. They must be reduced.

Inflammatory and Degenerative Conditions (pp. 273–274, 276)

4. Bursitis and tendonitis are inflammations of a bursa and a tendon sheath, respectively.

5. Arthritis is joint inflammation or degeneration accompanied by stiffness, pain, and swelling. Acute forms generally result from bacterial infection. Chronic forms include osteoarthritis, rheumatoid arthritis, and gouty arthritis.

6. Osteoarthritis is a degenerative condition most common in the aged. Weight-bearing joints are most affected.

7. Rheumatoid arthritis, the most crippling arthritis, is an autoimmune disease involving severe inflammation of the joints.

8. Gouty arthritis, or gout, is joint inflammation caused by the deposit of urate salts in soft joint tissues.

Developmental Aspects of Joints (p. 276)

1. Joints form from mesenchyme and in tandem with bone development in the embryo.

2. Excluding traumatic injury, joints usually function well until late middle age, at which time symptoms of connective tissue stiffening and osteoarthritis begin to appear. Prudent exercise delays these effects, whereas excessive exercise promotes the early onset of arthritis.

Review Questions

Multiple Choice/Matching

(Some questions have more than one correct answer. Select the best answer or answers from the choices given.)

1. Match the key terms to the appropriate descriptions.

Key: (a) fibrous joints (c) synovial joints
(b) cartilaginous joints

____ (1) exhibit a joint cavity
____ (2) types are sutures and syndesmoses
____ (3) bones connected by collagen fibers
____ (4) types include synchondroses and symphyses
____ (5) all are diarthrotic
____ (6) many are amphiarthrotic
____ (7) bones connected by a disc of hyaline cartilage or fibrocartilage
____ (8) nearly all are synarthrotic
____ (9) shoulder, hip, jaw, and elbow joints

2. Freely movable joints are (a) synarthroses, (b) diarthroses, (c) amphiarthroses.

3. Anatomical characteristics of a synovial joint include (a) articular cartilage, (b) a joint cavity, (c) an articular capsule, (d) all of these.

4. Factors that influence the stability of a synovial joint include (a) shape of articular surfaces, (b) presence of strong reinforcing ligaments, (c) tone of surrounding muscles, (d) all of these.

5. The description "Articular surfaces deep and secure; capsule heavily reinforced by ligaments and muscle tendons; extremely stable joint" best describes (a) the elbow joint, (b) the hip joint, (c) the knee joint, (d) the shoulder joint.

6. Ankylosis means (a) twisting of the ankle, (b) tearing of ligaments, (c) displacement of a bone, (d) immobility of a joint due to fusion of its articular surfaces.

7. An autoimmune disorder in which joints are affected bilaterally and which involves pannus formation and gradual joint immobilization is (a) bursitis, (b) gout, (c) osteoarthritis, (d) rheumatoid arthritis.

Short Answer Essay Questions

8. Define joint.

9. Discuss the relative value (to body homeostasis) of immovable, slightly movable, and freely movable joints.

10. Compare the structure, function, and common body locations of bursae and tendon sheaths.

11. Joint movements may be nonaxial, uniaxial, biaxial, or multiaxial. Define what each of these terms means.

12. Compare and contrast the paired movements of flexion and extension with adduction and abduction.

13. How does rotation differ from circumduction?

14. Name two types of uniaxial, biaxial, and multiaxial joints.

15. What is the specific role of the menisci of the knee? of the anterior and posterior cruciate ligaments?

16. The knee has been called "a beauty and a beast." Provide several reasons that might explain the negative (beast) part of this description.

17. Why are sprains and cartilage injuries a particular problem?

18. List the functions of the following elements of a synovial joint: fibrous part of the capsule, synovial fluid, articular disc.

Critical Thinking and Clinical Application Questions

1. Sophie worked cleaning homes for 30 years so she could send her two children to college. Several times, she had been forced to call her employers to tell them she could not come in to work because one of her kneecaps was swollen and painful. What is Sophie's condition, and what probably caused it?

2. As Harry was jogging down the road, he tripped and his left ankle twisted violently to the side. When he picked himself up, he was unable to put any weight on that ankle. The diagnosis was severe dislocation and sprains of the left ankle. The orthopedic surgeon stated that she would perform a closed reduction of the dislocation and attempt ligament repair by using arthroscopy. (a) Is the ankle joint normally a stable joint? (b) What does its stability depend on? (c) What is a closed reduction? (d) Why is ligament repair necessary? (e) What does arthroscopy entail? (f) How will the use of this procedure minimize Harry's recuperation time (and suffering)?

3. Mrs. Bell, a 45-year-old woman, appeared at her physician's office complaining of unbearable pain in the distal interphalangeal joint of her right great toe. The joint was red and swollen. When asked about previous episodes, she recalled a similar attack two years earlier that disappeared as suddenly as it had come. Her diagnosis was arthritis. (a) What type? (b) What is the precipitating cause of this particular type of arthritis?

4. Grace heard on the evening TV news that the deer population in her state had been increasing rapidly in the past few years and it was common knowledge that deer walked the streets at night. After the program, she suddenly exclaimed, "So that's why those three boys in my son's class got Lyme disease last year." Explain what she meant by that comment.

5. Tony Bowers, an exhausted biology student, was attending a lecture. After 30 minutes or so, he lost interest and began to doze. As the lecture ended, the hubbub aroused him and he let go with a tremendous yawn. To his great distress, he couldn't close his mouth—his lower jaw was "stuck" open. What do you think had happened?

Muscles and Muscle Tissue

Overview of Muscle Tissues (pp. 280–281)

1. Compare and contrast the basic types of muscle tissue.
2. List four important functions of muscle tissue.

Skeletal Muscle (pp. 281–309)

3. Describe the gross structure of a skeletal muscle.
4. Describe the microscopic structure and functional roles of the myofibrils, sarcoplasmic reticulum, and T tubules of muscle fibers (cells).
5. Explain the sliding filament mechanism.
6. Define motor unit and explain how muscle fibers are stimulated to contract.
7. Define muscle twitch and describe the events occurring during its three phases.
8. Explain how smooth, graded contractions of a skeletal muscle are produced.
9. Differentiate between isometric and isotonic contractions.
10. Describe three ways in which ATP is regenerated during skeletal muscle contraction.
11. Define oxygen debt and muscle fatigue. List possible causes of muscle fatigue.
12. Describe factors that influence the force, velocity, and duration of skeletal muscle contraction.
13. Describe three types of skeletal muscle fibers and explain the relative value of each type.
14. Compare and contrast the effects of aerobic and resistance exercise on skeletal muscles and on other body systems.

Smooth Muscle (pp. 309–316)

15. Compare the gross and microscopic anatomy of smooth muscle cells to that of skeletal muscle cells.
16. Compare and contrast the contractile mechanisms and the means of activation of skeletal and smooth muscles.
17. Distinguish between single-unit and multiunit smooth muscle structurally and functionally.

Developmental Aspects of Muscles (pp. 316–318, 320)

18. Describe embryonic development of muscle tissues and the changes that occur in skeletal muscles with age.

Because flexing muscles look like mice scurrying beneath the skin, some scientist long ago dubbed them *muscles,* from the Latin *mus* meaning "little mouse." Indeed, the rippling muscles of professional boxers or weight lifters are often the first thing that comes to mind when one hears the word *muscle.* But muscle is also the dominant tissue in the heart and in the walls of other hollow organs. In all its forms, muscle tissue makes up nearly half the body's mass. The most distinguishing functional characteristic of muscles is their ability to transform chemical energy (ATP) into directed mechanical energy. In so doing, they become capable of exerting force.

Overview of Muscle Tissues

Types of Muscle Tissue

The three types of muscle tissue are *skeletal, cardiac,* and *smooth.* Before exploring their characteristics, however, let us introduce some terminology. First, skeletal and smooth muscle cells (but not cardiac muscle cells) are elongated and, for this reason, are called **muscle fibers.** Second, muscle contraction depends on two kinds of *myofilaments,* which are the muscle equivalents of the actin- or myosin-containing microfilaments described in Chapter 3. As you will recall, these two proteins play a role in motility and shape changes in virtually every cell in the body, but this property reaches its highest development in the contractile muscle fibers. Third, whenever you see the prefixes **myo** or **mys** (both are word roots meaning "muscle") or **sarco** (flesh), the reference is to muscle. For example, the plasma membrane of muscle fibers is called the *sarcolemma* (sar"ko-lem'ah), literally "muscle" (sarco) "husk" (lemma), and muscle fiber cytoplasm is called *sarcoplasm.* Now we are ready to describe the three types of muscle tissue.

Skeletal muscle tissue is packaged into the *skeletal muscles,* organs that attach to and cover the bony skeleton. Skeletal muscle fibers are the longest muscle cells; they have obvious stripes called *striations* and can be controlled voluntarily. Although it is often activated by reflexes, skeletal muscle is called **voluntary muscle** because it is the *only type subject to* conscious control. Therefore, when you think of skeletal muscle tissue, the key words to keep in mind are *skeletal, striated,* and *voluntary.* Skeletal muscle is responsible for overall body mobility. It can contract rapidly, but it tires easily and must rest after short periods of activity. Nevertheless, it can exert tremendous power, a fact revealed by reports of people lifting cars to save their loved ones. Skeletal muscle is also remarkably adaptable. For example, your hand muscles can exert a force of a fraction of an ounce to pick up a dropped paper clip and the same muscles can exert a force of about 70 pounds to pick up this book!

Cardiac muscle tissue occurs only in the heart (the body's blood pump), where it constitutes the bulk of the heart walls. Like skeletal muscle cells, cardiac muscle cells are striated, but cardiac muscle is not voluntary. Most of us have no conscious control over how fast our heart beats. Key words to remember for this muscle type are *cardiac, striated,* and *involuntary.* Cardiac muscle usually contracts at a fairly steady rate set by the heart's pacemaker, but neural controls allow the heart to "shift into high gear" for brief periods, as when you race across the tennis court to make that overhead smash.

Smooth muscle tissue is found in the walls of hollow visceral organs, such as the stomach, urinary bladder, and respiratory passages. Its role is to force fluids and other substances through internal body channels. It has no striations, and like cardiac muscle, it is not subject to voluntary control. We can describe smooth muscle tissue most precisely as *visceral, nonstriated,* and *involuntary.* Contractions of smooth muscle fibers are slow and sustained.

Skeletal and smooth muscles are discussed in this chapter. Cardiac muscle is discussed in Chapter 18 (The Heart). Table 9.3 on pp. 314–315 summarizes the most important characteristics of each type of muscle tissue.

Functional Characteristics of Muscle Tissue

Muscle tissue is endowed with some special functional properties that enable it to perform its duties.

Excitability, also termed **responsiveness** or **irritability,** is the ability to receive and respond to a stimulus, that is, any change in the environment whether inside or outside the body. In the case of muscle, the stimulus is usually a chemical—for example, a neurotransmitter released by a nerve cell, or a local change in pH. The response is generation of an electrical impulse that passes along the sarcolemma (plasma membrane) of the muscle cell and causes the cell to contract.

Contractility is the ability to shorten forcibly when adequately stimulated. This property sets muscle apart from all other tissue types.

Extensibility is the ability to be stretched or extended. Muscle fibers shorten when contracting, but they can be stretched, even beyond their resting length, when relaxed.

Elasticity is the ability of a muscle fiber to recoil and resume its resting length after being stretched.

Muscle Functions

Muscle performs four important functions for the body: It produces movement, maintains posture, stabilizes joints, and generates heat.

Producing Movement

Just about all movements of the human body and its parts are a result of muscle contraction. Skeletal muscles are responsible for all locomotion and manipulation. They enable you to respond quickly to changes in the external environment—for example, by jumping out of the way of a runaway car, directing your eyeballs, and smiling or frowning.

The coursing of blood through your body is evidence of the work of the rhythmically beating cardiac muscle of your heart and the smooth muscle in the walls of your blood vessels, which helps maintain blood pressure. Smooth muscle in organs of the digestive, urinary, and reproductive tracts propels, or squeezes, substances (foodstuffs, urine, a baby) through the organs and along the tract.

Maintaining Posture

We are rarely aware of the workings of the skeletal muscles that maintain body posture. Yet these muscles function almost continuously, making one tiny adjustment after another that enables us to maintain an erect or seated posture despite the never-ending downward pull of gravity.

Stabilizing Joints

Even as muscles pull on bones to cause movements, they stabilize and strengthen the joints of the skeleton (Chapter 8).

Generating Heat

Muscles generate heat as they contract. This heat is vitally important in maintaining normal body temperature. Because skeletal muscle accounts for at least 40% of body mass, it is the muscle type most responsible for generating heat.

Although not usually cited as a major muscle function, skeletal muscles also protect more fragile internal organs (the viscera) by enclosure. Also, smooth muscle, in particular, forms valves to regulate the passage of substances through internal body openings.

▪ ▪ ▪

In the following section, we examine the structure and function of skeletal muscle in detail. Then we consider smooth muscle more briefly, largely by comparing it with skeletal muscle. Because cardiac muscle is described in Chapter 18, its treatment in this chapter is limited to the summary of its characteristics provided in Table 9.3.

Skeletal Muscle

The levels of skeletal muscle organization, gross to microscopic, are summarized in Table 9.1.

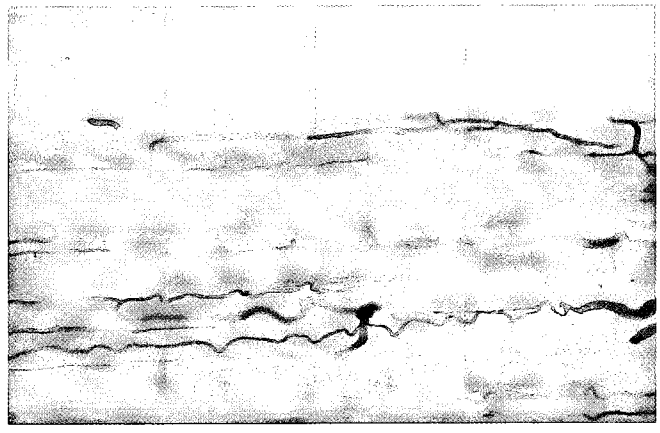

FIGURE 9.1 **Photomicrograph of the capillary network surrounding skeletal muscle fibers.** The arterial supply was injected with dark red gelatin to demonstrate the capillary bed. The long muscle fibers are stained orange (30×).

Gross Anatomy of a Skeletal Muscle

Each **skeletal muscle** is a discrete organ, made up of several kinds of tissues. Although skeletal muscle fibers predominate, blood vessels, nerve fibers, and substantial amounts of connective tissue are also present. A skeletal muscle's shape and its attachments in the body can be examined easily without the help of a microscope.

Nerve and Blood Supply

In general, each muscle is served by one nerve, an artery, and by one or more veins, all of which enter or exit near the central part of the muscle and branch profusely through its connective tissue sheaths (described below). Unlike cells of cardiac and smooth muscle tissues, which can contract in the absence of nerve stimulation, each skeletal muscle fiber is supplied with a nerve ending that controls its activity.

Contracting muscle fibers use huge amounts of energy, a situation that requires more or less continuous delivery of oxygen and nutrients via the arteries. Muscle cells also give off large amounts of metabolic wastes that must be removed through veins if contraction is to remain efficient. Muscle capillaries, the smallest of the body's blood vessels, are long and winding and have numerous cross-links, features that accommodate changes in muscle length (Figure 9.1). They straighten when the muscle is stretched and contort when the muscle contracts.

Connective Tissue Sheaths

In an intact muscle, the individual muscle fibers are wrapped and held together by several different connective tissue sheaths. Together these connective tissue sheaths support each cell and reinforce the muscle as

TABLE 9.1 Structure and Organizational Levels of Skeletal Muscle

STRUCTURE AND ORGANIZATIONAL LEVEL	DESCRIPTION	CONNECTIVE TISSUE WRAPPINGS
Muscle (organ)  	Consists of hundreds to thousands of muscle cells, plus connective tissue wrappings, blood vessels, and nerve fibers	Covered externally by the epimysium
Fascicle (a portion of the muscle)  	Discrete bundle of muscle cells, segregated from the rest of the muscle by a connective tissue sheath	Surrounded by a perimysium
Muscle fiber (cell)  	Elongated multinucleate cell; has a banded (striated) appearance	Surrounded by the endomysium
Myofibril or fibril (complex organelle composed of bundles of myofilaments)  	Rodlike contractile element; myofibrils occupy most of the muscle cell volume; composed of sarcomeres arranged end to end; appear banded, and bands of adjacent myofibrils are aligned	
Sarcomere (a segment of a myofibril)  	The contractile unit, composed of myofilaments made up of contractile proteins	
Myofilament or filament (extended macromolecular structure)  	Contractile myofilaments are of two types—thick and thin: the thick filaments contain bundled myosin molecules; the thin filaments contain actin molecules (plus other proteins); the sliding of the thin filaments past the thick filaments produces muscle shortening. Elastic filaments (not shown here) maintain the organization of the A band and provide for elastic recoil when muscle contraction ends	

Q *Consider the term* epimysium. *What is the meaning of* epi? *Of* mys? *How do these word stems relate to the role and position of this connective tissue sheath?*

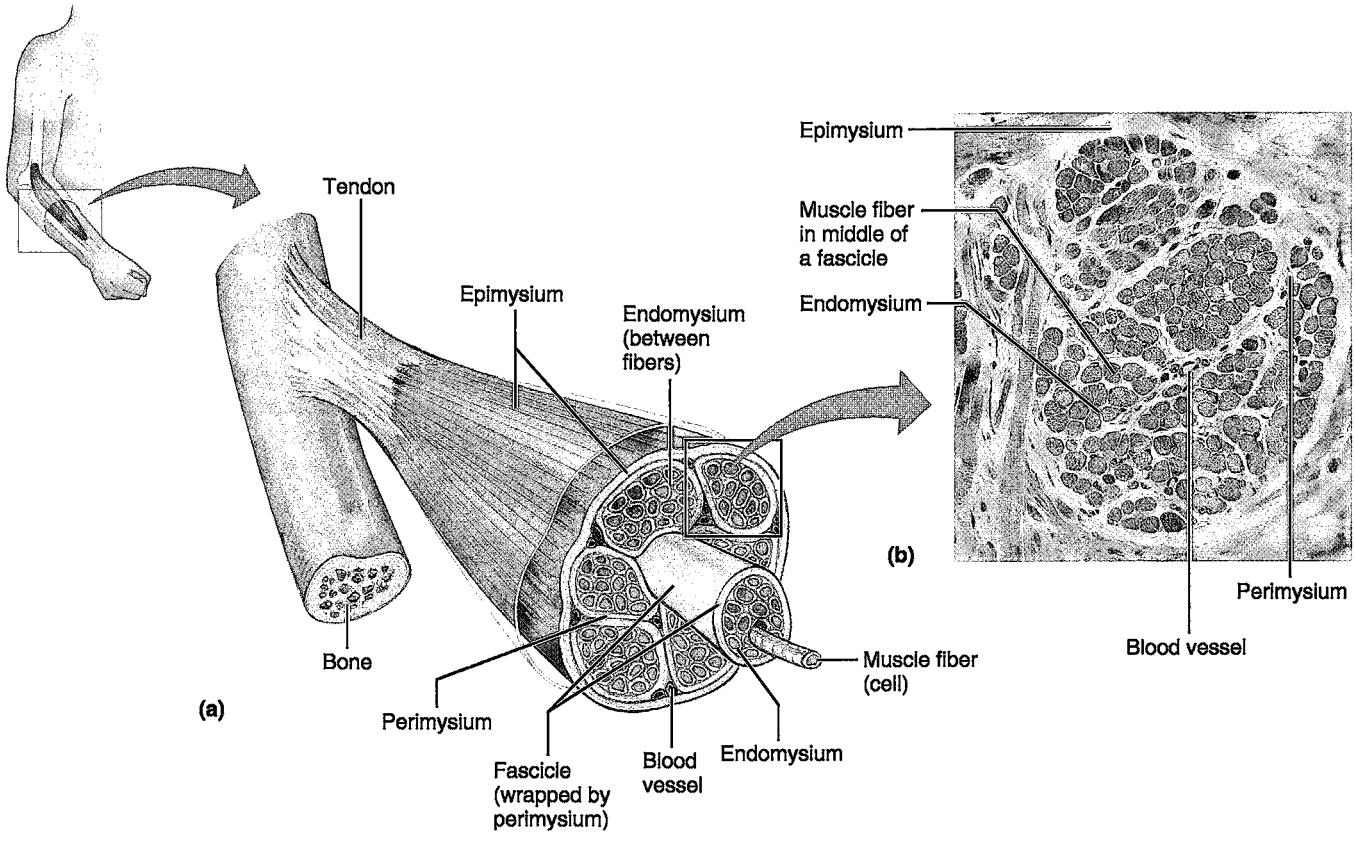

FIGURE 9.2 **Connective tissue sheaths of skeletal muscle. (a)** Each muscle fiber is wrapped with a delicate connective tissue sheath, the endomysium. Bundles, or fascicles, of muscle fibers are bound by a collagenic sheath called a perimysium. The entire muscle is strengthened and wrapped by a coarse epimysium sheath. **(b)** Photomicrograph of a cross section of part of a skeletal muscle (90×).

a whole, preventing the bulging muscles from bursting during exceptionally strong contractions. We will consider these from internal to external (Figure 9.2).

1. Endomysium. Each individual muscle fiber is surrounded by a fine sheath of connective tissue consisting of areolar and reticular fibers. This is the endomysium (en"do-mis'e-um; "within the muscle").

2. Perimysium and **fascicles.** Within each skeletal muscle, the endomysium-wrapped muscle fibers are grouped into fascicles (fas'i-klz; "bundles") that resemble bundles of sticks. Surrounding each fascicle is a layer of fibrous connective tissue called perimysium [per"i-mis'e-um; "around the muscle (fascicles)"].

3. Epimysium. An "overcoat" of dense irregular connective tissue surrounds the whole muscle. This coat is the epimysium (ep"i-mis'e-um), a name that means "outside the muscle." Sometimes the epimysium blends with the deep fascia that lies between neighboring muscles or the superficial fascia deep to the skin.

As shown in Figure 9.2, all of these connective tissue sheaths are continuous with one another as well as with the tendons that join muscles to bones. Therefore, when muscle fibers contract, they pull on these sheaths, which in turn transmit the pulling force to the bone to be moved. They also contribute to the natural elasticity of muscle tissue, and for this reason these elements are sometimes referred to collectively as the *series elastic components.* The wrappings also provide entry and exit routes for the blood vessels and nerve fibers that serve the muscle.

Attachments

Recall from Chapter 8 that (1) most skeletal muscles span joints and are attached to bones (or other structures) in at least two places and (2) when a muscle contracts, the movable bone, the muscle's **insertion,**

A Epi = outer; mys = muscle. The epimysium covers the external surface of the muscle.

moves toward the immovable or less movable bone, the muscle's **origin.** In the muscles of the limbs, the origin typically lies proximal to the insertion.

Muscle attachments, whether origin or insertion, may be direct or indirect. In **direct, or fleshy, attachments,** the epimysium of the muscle is fused to the periosteum of a bone or perichondrium of a cartilage. In **indirect attachments,** the muscle's connective tissue wrappings extend beyond the muscle either as a ropelike **tendon** or as a sheetlike **aponeurosis** (ap"o-nu-ro'sis). The tendon or aponeurosis anchors the muscle to the connective tissue covering of a skeletal element (bone or cartilage) or to the fascia of other muscles.

Of the two, indirect attachments are much more common because of their durability and small size. Tendons are mostly tough collagenic fibers so they can cross rough bony projections that would tear apart the more delicate muscle tissues. Because of their relatively small size, more tendons than fleshy muscles can pass over a joint—thus, tendons also conserve space.

Microscopic Anatomy of a Skeletal Muscle Fiber

Each skeletal muscle fiber is a long cylindrical cell with multiple oval nuclei arranged just beneath its **sarcolemma,** or plasma membrane (see Figure 9.3a). Skeletal muscle fibers are huge cells. Their diameter typically ranges from 10 to 100 μm—up to ten times that of an average body cell—and their length is phenomenal, some up to 30 cm long. Their large size and the fact that they are multinucleate are not surprising once you learn that each fiber is produced by the fusion of hundreds of embryonic cells.

The **sarcoplasm** of a muscle fiber is similar to the cytoplasm of other cells, but it contains unusually large amounts of *glycosomes* (granules of stored glycogen) and **myoglobin,** a red pigment that stores oxygen and is similar to hemoglobin, the pigment that transports oxygen in blood. The usual organelles are present, along with some that are highly modified in muscle fibers: myofibrils and the sarcoplasmic reticulum. T tubules are unique modifications of the sarcolemma. Let's look at these special structures more closely.

Myofibrils

Each muscle fiber contains many rodlike **myofibrils** that run parallel to its length (see Figure 9.3b). The myofibrils, each 1–2 μm in diameter, are so densely packed in the fiber that mitochondria and other organelles appear to be squeezed between them. Hundreds to thousands of myofibrils are in a single muscle fiber, depending on its size, and they account for about 80% of cellular volume. The myofibrils contain the contractile elements of skeletal muscle cells.

Striations, Sarcomeres, and Myofilaments

Striations, a repeating series of dark **A bands** and light **I bands,** are evident along the length of each myofibril. In an intact muscle fiber, the A and I bands are nearly perfectly aligned with one another, giving the cell as a whole its striped (striated) appearance.

As illustrated in Figure 9.3c, each A band has a lighter stripe in its midsection called the **H zone** (*H* for *helle;* "bright"). Each H zone is bisected vertically by a dark line called the **M line** (*M* for middle). The I bands also have a midline interruption, a darker area called the **Z disc** (or Z line). A **sarcomere** (sar'ko-mĕr; literally, "muscle segment") is the region of a myofibril between two successive Z discs, that is, it contains an A band flanked by half an I band at each end (see Figure 9.3c). Averaging 2 μm long, the sarcomere is the smallest contractile unit of a muscle fiber. Thus, the *functional units* of skeletal muscle are sarcomeres aligned end-to-end like boxcars in a myofibril "train."

If we examine the *banding pattern* of a myofibril at the molecular level, we see that it arises from an orderly arrangement of two types of even smaller structures, called **myofilaments** or **filaments,** within the sarcomeres (Figure 9.3d). The central **thick filaments** extend the entire length of the A band. The more lateral **thin filaments** extend across the I band and partway into the A band. The Z disc, a coin-shaped sheet composed largely of the protein alpha actinin, anchors the thin filaments. Intermediate (desmin) filaments extending from the Z disc connect each myofibril to the next throughout the width of the muscle cell. The H zone of the A band appears less dense because the thin filaments do not extend into this region. The M line in the center of the H zone is slightly darker because of the presence there of fine protein strands that hold adjacent thick filaments together. The third type of myofilament illustrated in Figure 9.3d, the *elastic*

filament, is described in the next section. The myofilaments are connected to the sarcolemma at the Z discs and the M lines.

A longitudinal view of the myofilaments, such as that in Figure 9.3d, is a bit misleading because it gives the impression that each thick filament interdigitates with only four thin filaments. In areas where thick and thin filaments overlap, each thick filament is actually surrounded by a hexagonal arrangement of six thin filaments, and each thin filament is enclosed by three thick filaments (Figure 9.3e).

Ultrastructure and Molecular Composition of the Myofilaments Thick filaments (about 16 nm in diameter) are composed primarily of the protein **myosin** (Figure 9.4a). Each myosin molecule has a rodlike *tail* terminating via a flexible hinge in two globular *heads.* The tail consists of two interwoven helical polypeptide chains. Its globular heads are the "business end" of myosin; they link the thick and thin filaments together (form **cross bridges**) and swivel around their point of attachment during contraction. As explained shortly, these cross bridges act as motors to generate the tension developed by a contracting muscle cell. Each thick filament contains about 300 myosin molecules bundled together with their tails forming the central part of the thick filament and their heads facing outward and in opposite directions at each end (Figure 9.4b and d). As a result, the central portion of a thick filament is smooth, but its ends are studded with a staggered array of myosin heads. Besides bearing actin binding sites, the heads contain ATPase enzymes that split ATP to generate energy for muscle contraction.

The thin filaments (7–8 nm thick) are composed chiefly of the protein **actin** (Figure 9.4c). The kidney-shaped polypeptide subunits of actin, called *globular actin* or *G actin,* bear the active sites to which the myosin heads attach during contraction. G actin monomers are polymerized into long actin filaments called *fibrous,* or *F, actin.* The backbone of each thin

FIGURE 9.4 **Composition of thick and thin filaments.** **(a)** An individual myosin molecule has a rodlike tail, from which two "heads" protrude. **(b)** Each thick filament consists of many myosin molecules, whose heads protrude at opposite ends of the filament, as shown in (d). **(c)** A thin filament contains two strands of actin subunits twisted into a helix. Tropomyosin molecules coil around the actin filaments, helping to reinforce them. A troponin complex is attached to each tropomyosin molecule. **(d)** Arrangement of the filaments in a sarcomere (longitudinal view). In the center of the sarcomere, the thick filaments are devoid of myosin heads, but at points of thick and thin filament overlap, myosin heads extend toward the actin, with which they interact during contraction. **(e)** Transmission electron micrograph of part of a sarcomere clearly showing the myosin heads forming cross bridges that generate the contractile force.

filament appears to be formed by two intertwined actin filaments that look like a twisted double strand of pearls.

Several regulatory proteins are also present in the thin filament. Two strands of **tropomyosin** (tro"po-mi'o-sin), a rod-shaped protein, spiral about the actin core and help stiffen it. Successive tropomyosin molecules are arranged end-to-end along the actin filaments, and in a relaxed muscle fiber, they block myosin binding sites on actin so that the myosin heads cannot bind to the thin filaments. The other major protein in the thin filament, **troponin** (tro'po-nin), is a three-polypeptide complex. One of these polypeptides (TnI) is an inhibitory subunit that binds to actin; another (TnT) binds to tropomyosin and helps position it on actin. The third (TnC) binds calcium ions. Both troponin and tropomyosin help control the myosin-actin interactions involved in contraction.

The discoveries of additional types of muscle filaments during the past decade or so demanded that the established view of striated muscle as a two-filament system be rewritten. One of these newly discovered filament types, the **elastic filament** referred to earlier, is composed of the giant protein **titin,** which extends from the Z disc to the thick filament, and then runs within the latter to attach to the M line. Acting as a kind of molecular ruler, it has two basic functions: (1) holding the thick filaments in place, thus maintaining the organization of the A band, and (2) assisting the muscle cell to spring back into shape after being stretched or shortening. (The part of the titin that spans the I bands is extensible, unfolding when the muscle is stretched and recoiling when the tension is released.) Titin does not resist stretching in the ordinary range of extension, but it stiffens as it uncoils, helping the muscle to resist excessive stretching, which might pull the sarcomeres apart. Another important structural protein is **dystrophin,** which links the thin filaments to the integral proteins of the sarcolemma (which in turn are anchored to the extracellular matrix). Other proteins that act to bind filaments or sarcomeres together include *nebulin, myomesin,* and *vimentin.*

Sarcoplasmic Reticulum and T Tubules

Skeletal muscle fibers (cells) contain two sets of intracellular tubules that participate in regulation of muscle contraction: (1) the sarcoplasmic reticulum and (2) the T tubules (Figure 9.5).

Sarcoplasmic Reticulum The **sarcoplasmic reticulum (SR)** is an elaborate smooth endoplasmic reticulum (see p. 88). Its interconnecting tubules surround each myofibril the way the sleeve of a loosely crocheted sweater surrounds your arm. Most of these tubules run longitudinally along the myofibril. Others form larger, perpendicular cross channels at the A band–I band junctions. These channels are called **terminal cisternae** ("end sacs") and they always occur in pairs.

The major role of the SR is to regulate intracellular levels of ionic calcium: It stores calcium and releases it on demand when the muscle fiber is stimulated to contract. As you will see, calcium provides the final "go" signal for contraction.

T Tubules At each A band–I band junction, the sarcolemma of the muscle cell penetrates into the cell interior, forming an elongated tube called the **T tubule** (T for "transverse"). Possibly the result of fusing tube-like caveolae (inpocketings of the sarcolemma), the lumen of the T tubule is continuous with the extracellular space. As each T tubule protrudes deep into the cell, it runs between the paired terminal cisternae of the SR so that **triads,** successive groupings of the three membranous structures (terminal cisterna, T tubule, and terminal cisterna), are formed (Figure 9.5). As they pass from one myofibril to the next, the T tubules also encircle each sarcomere.

Muscle contraction is ultimately controlled by nerve-initiated electrical impulses that travel along the sarcolemma. Because T tubules are continuations of the sarcolemma, they can and do conduct impulses to the deepest regions of the muscle cell and to every sarcomere. These impulses signal for the release of calcium from the adjacent terminal cisternae. Thus, the T tubules can be thought of as a rapid telegraph system that ensures that every myofibril in the muscle fiber contracts at virtually the same time.

Triad Relationships The roles of the T tubules and SR in providing signals for contraction are tightly linked. At the triads, where these organelles come into closest contact, something that resembles a *double zipper* of integral proteins protrudes into the intermembrane spaces. The protruding integral proteins of the T tubule (DHP receptors) act as voltage sensors; and those of the SR, called *foot proteins,* (or ryanodine receptors) form channels through which Ca^{2+} can be released from the SR cisternae. We will return to consider their interaction shortly.

Sliding Filament Model of Contraction

Although we almost always think "shortening" when we hear the word **contraction,** to physiologists the term refers only to the activation of myosin's cross bridges, which are the force-generating sites. Shortening occurs when the tension generated by the cross bridges on the thin filaments exceeds the forces opposing shortening. Contraction ends when the cross bridges become inactive and the tension generated declines, inducing *relaxation* of the muscle

Q *Which of the following structures shown in this diagram would contain the highest concentration of Ca^{2+} in a resting muscle cell: T tubule, mitochondrion, or SR?*

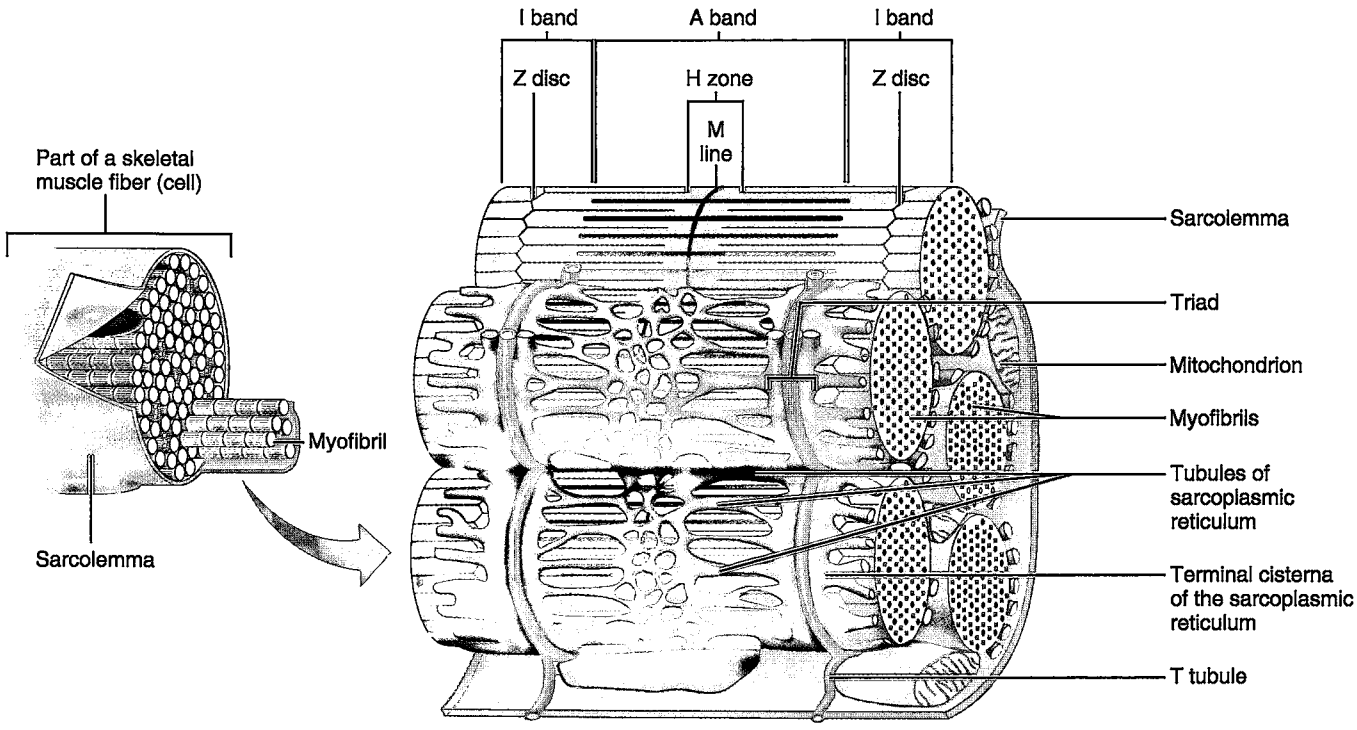

FIGURE 9.5 **Relationship of the sarcoplasmic reticulum and T tubules to myofibrils of skeletal muscle.** The tubules of the SR encircle each myofibril like a "holey" sleeve. The tubules fuse to form communicating channels at the level of the H zone and abutting the A-I junctions, where the saclike elements called terminal cisternae are formed. The T tubules, inward invaginations of the sarcolemma, run deep into the cell between the terminal cisternae. Sites of close contact of these three elements (terminal cisterna, T tubule, and terminal cisterna) are called triads.

fiber. The **sliding filament theory of contraction** states that during contraction the thin filaments slide past the thick ones so that the actin and myosin filaments overlap to a greater degree (Figure 9.6). In a relaxed muscle fiber, the thick and thin filaments overlap only at the ends of the A band. But when muscle fibers are stimulated by the nervous system, the myosin heads latch on to myosin binding sites on actin in the thin filaments, and the sliding begins. These cross bridge attachments are formed and broken several times during a contraction, acting like tiny ratchets to generate tension and propel the thin filaments toward the center of the sarcomere. As this event occurs simultaneously in sarcomeres throughout the cell, the muscle cell shortens. Notice that as the thin filaments slide centrally, the Z discs to which they are attached are pulled *toward* the thick filaments. Overall, the I bands shorten, the distance between successive Z discs is reduced, the H zones disappear, and the contiguous A bands move closer together but do not change in length.*

A The SR, which is a calcium storage depot.

Physiology of a Skeletal Muscle Fiber

For a skeletal muscle fiber to contract, it must be stimulated by a nerve ending and must propagate an electrical current, or **action potential,** along its sarcolemma. This electrical event causes the short-lived rise in intracellular calcium ion levels that is the final trigger for contraction. The series of events linking the electrical signal to contraction is called *excitation-contraction coupling.* Let's consider these events in order.

The Nerve Stimulus and Events at the Neuromuscular Junction

Skeletal muscle cells are stimulated by *motor neurons*† of the somatic nervous system. Although these motor neurons "reside" in the brain or spinal cord,

* These changes in the banding pattern apply to a muscle contraction that produces shortening (an isotonic contraction, not an isometric contraction; see p. 300).

† Somatic motor neurons are nerve cells that activate skeletal muscle cells.

their long threadlike extensions called *axons* travel, bundled within nerves, to the muscle cells they serve. The axon of each motor neuron divides profusely as it enters the muscle, and each axon ending gives off several short, curling branches that form an elliptical **neuromuscular junction** with a single muscle fiber (Figure 9.7). As a rule, each muscle fiber has only one neuromuscular junction, located approximately midway along the fiber's length. Although the axon terminal and the muscle fiber are exceedingly close (1–2 nm apart), they remain separated by a space, the **synaptic cleft,** which is filled with a gel-like extracellular substance rich in glycoproteins and collagen fibers. Within the flattened moundlike axon terminal are **synaptic vesicles,** small membranous sacs containing the neurotransmitter **acetylcholine** (as″ĕ-til-ko′lēn), or **ACh.** The **motor end plate,** the troughlike part of the muscle fiber's sarcolemma that helps form the neuromuscular junction, is highly folded. These *junctional folds* provide a large surface area for the millions of **ACh receptors** located there.

When a nerve impulse reaches the end of an axon, voltage-gated calcium channels in its membrane open, allowing Ca^{2+} (propelled by its electrochemical gradient) to flow in from the extracellular fluid. The presence of calcium inside the axon terminal causes some of the synaptic vesicles to fuse with the axonal membrane and release ACh into the synaptic cleft by *exocytosis.* ACh diffuses across the cleft and attaches to ACh receptors on the sarcolemma. The electrical events triggered in a sarcolemma when ACh binds are similar to those that take place in excited nerve cell membranes (see Chapter 11).

After ACh binds to the ACh receptors, it is swiftly broken down to its building blocks, acetic acid and choline, by **acetylcholinesterase** (as″ĕ-til-ko″lin-es′ter-ās), an enzyme located in the synaptic cleft (Figure 9.7c). This destruction of ACh prevents continued muscle fiber contraction in the absence of additional nervous system stimulation.

HOMEOSTATIC IMBALANCE

Many toxins, drugs, and diseases interfere with events at the neuromuscular junction. For example, *myasthenia gravis* (*asthen* = weakness; *gravi* = heavy), a disease characterized by drooping upper eyelids, difficulty swallowing and talking, and generalized muscle weakness, involves a shortage of ACh receptors. Serum analysis reveals antibodies to ACh receptors, suggesting that myasthenia gravis is an autoimmune disease. Although normal numbers of receptors are initially present, they appear to be destroyed as the disease progresses. ●

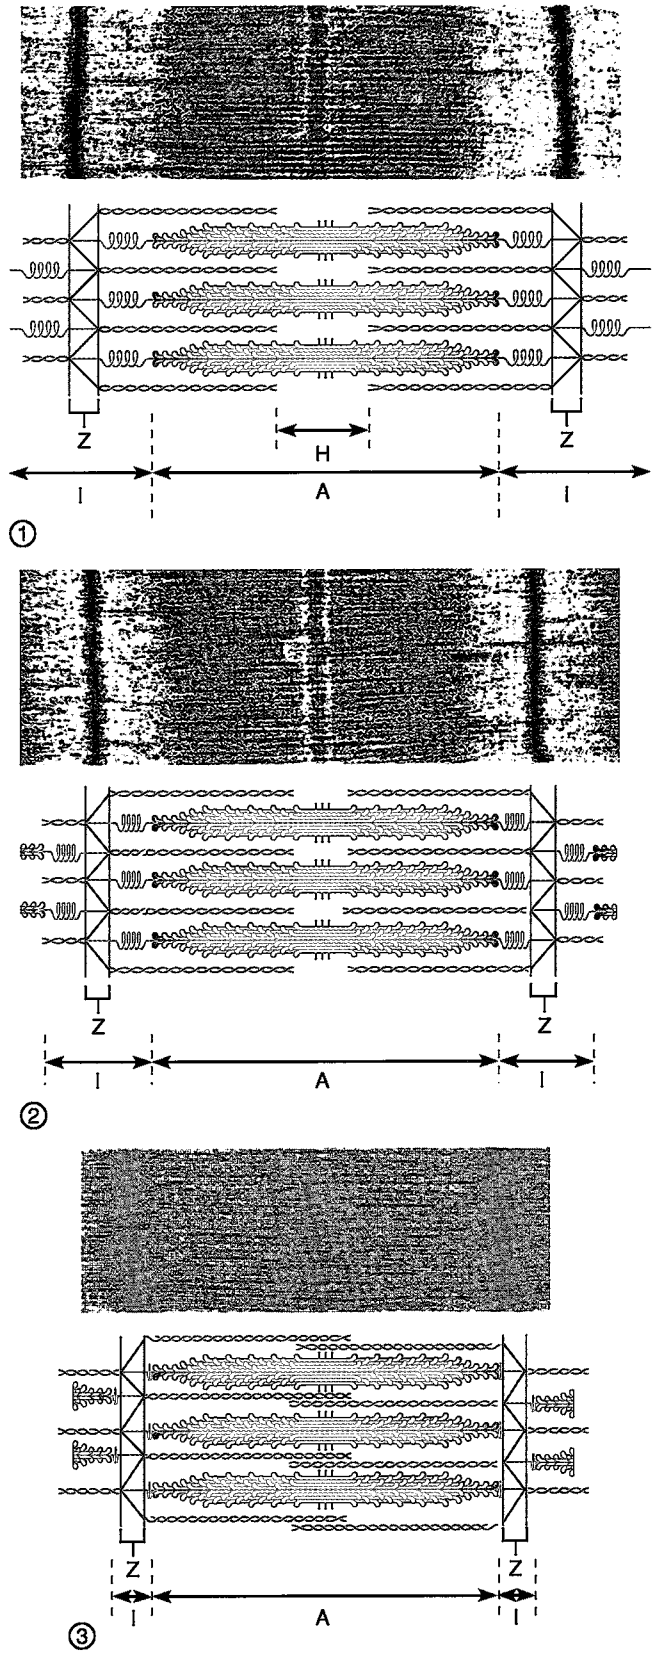

FIGURE 9.6 **Sliding filament model of contraction.** The numbers indicate a sequence of events, with ① being relaxed and ③ fully contracted. At full contraction, the Z discs abut the thick filaments and the thin filaments overlap each other. The photomicrographs (top view in each case) show enlargements of 25,000×.

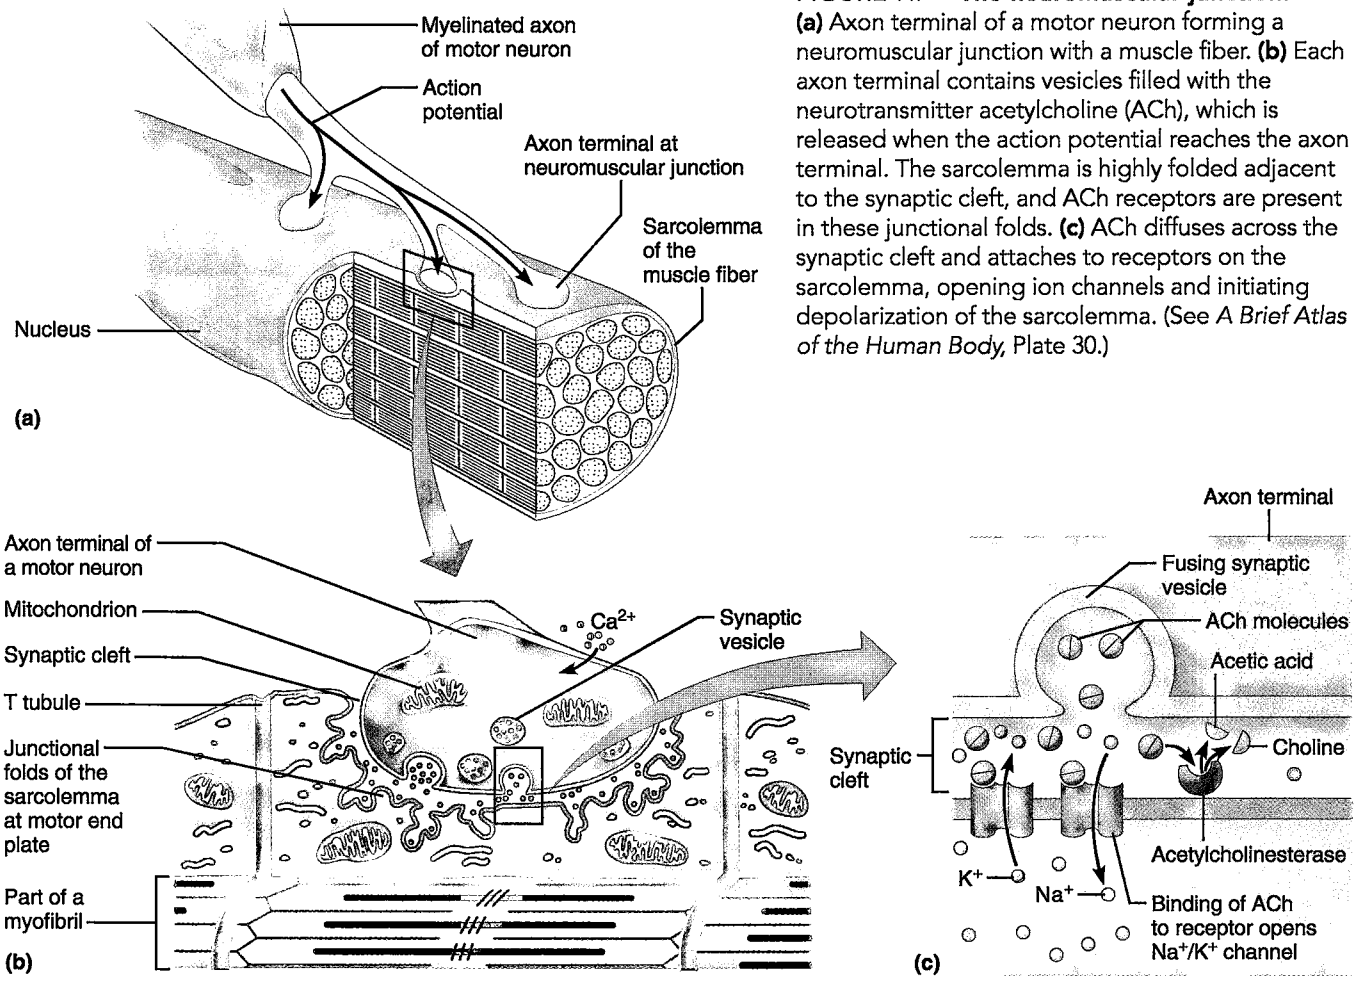

FIGURE 9.7 **The neuromuscular junction.** **(a)** Axon terminal of a motor neuron forming a neuromuscular junction with a muscle fiber. **(b)** Each axon terminal contains vesicles filled with the neurotransmitter acetylcholine (ACh), which is released when the action potential reaches the axon terminal. The sarcolemma is highly folded adjacent to the synaptic cleft, and ACh receptors are present in these junctional folds. **(c)** ACh diffuses across the synaptic cleft and attaches to receptors on the sarcolemma, opening ion channels and initiating depolarization of the sarcolemma. (See *A Brief Atlas of the Human Body*, Plate 30.)

Generation of an Action Potential Across the Sarcolemma

Like the plasma membranes of all cells, a resting sarcolemma is *polarized*. That is, a voltmeter would show there is a potential difference (voltage) across the membrane and the inside is negative relative to the outer membrane face. (The resting membrane potential is described in Chapter 3.) Binding of ACh molecules to ACh receptors at the motor end plate opens the *chemically (ligand) gated ion channels* (p. 83) housed in the ACh receptors and allows both Na^+ and K^+ to pass (Figure 9.7). Because more Na^+ diffuses in than K^+ diffuses out, a transient change in membrane potential occurs such that the interior of the sarcolemma becomes slightly less negative, an event called **depolarization.**

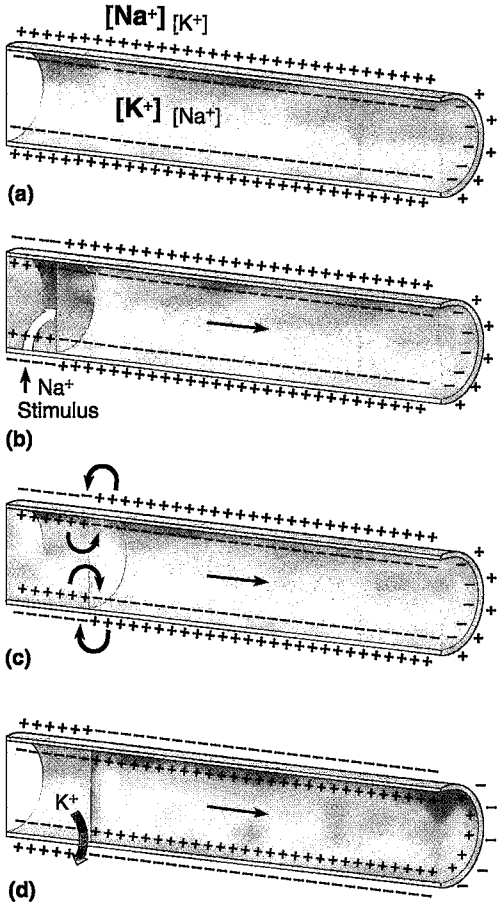
Initially, depolarization is a local electrical event called an *end plate potential,* but it ignites the action potential that spreads in all directions from the neuromuscular junction across the sarcolemma, just as ripples move away from pebbles dropped into a stream.

The action potential (AP) is the result of a predictable sequence of electrical changes that once initiated occurs along the entire length of the sarcolemma (Figure 9.8). Essentially three steps are involved.

1. First the membrane areas adjacent to the depolarized motor end plate are depolarized by local currents that spread to them from the neuromuscular junction. This opens *voltage-gated* (p. 84) sodium channels there, so Na^+ enters, following its electrochemical gradient, and initiates the action potential (Figure 9.9).

2. During step 2, the action potential is propagated (moves along the length of the sarcolemma) as the local depolarization wave spreads to adjacent areas of the sarcolemma and opens voltage-gated sodium channels there (see Figure 9.8c). Again, sodium ions, normally restricted from entering, diffuse into the cell following their electrochemical gradient.

3. Step 3 is **repolarization,** which restores the sarcolemma to its initial polarized state. The repolarization wave, which quickly follows the depolarization wave, is a consequence of Na^+ channels closing and voltage-gated K^+ channels opening. Since the potassium ion concentration is substantially higher inside the cell than in the extracellular fluid, K^+ diffuses rapidly out of the muscle fiber (Figures 9.8d and 9.9).



(a) Electrical conditions of a resting (polarized) sarcolemma. The outside face is positive, while the inside face is negative. The predominant extracellular ion is sodium (Na^+); the predominant intracellular ion is potassium (K^+). The sarcolemma is relatively impermeable to both ions.

(b) Step 1: Depolarization and generation of the action potential. Production of an end plate potential at the motor end plate causes adjacent areas of the sarcolemma to become permeable to sodium (voltage-gated sodium channels open). As sodium ions diffuse rapidly into the cell, the resting potential is decreased (i.e., depolarization occurs). If the stimulus is strong enough, an action potential is initiated.

(c) Step 2: Propagation of the action potential. The positive charge inside the initial patch of sarcolemma changes the permeability of an adjacent patch, opening voltage-gated Na^+ channels there. Consequently the membrane potential in that region decreases and depolarization occurs there as well. Thus, the action potential travels rapidly over the entire sarcolemma.

(d) Step 3: Repolarization. Immediately after the depolarization wave passes, the sarcolemma's permeability changes once again: Na^+ channels close and K^+ channels open, allowing K^+ to diffuse from the cell. This restores the electrical conditions of the resting (polarized) state. Repolarization occurs in the same direction as depolarization, and must occur before the muscle fiber can be stimulated again. The ionic concentrations of the resting state are restored later by the sodium-potassium pump.

FIGURE 9.8 **An action potential in a skeletal muscle fiber.** Events in the generation and propagation of an action potential are summarized.

During repolarization, a muscle fiber is said to be in a **refractory period,** because the cell cannot be stimulated again until repolarization is complete. Notice that repolarization restores only the *electrical conditions* of the resting (polarized) state. The ATP-dependent Na^+-K^+ pump restores the ionic conditions of the resting state, but hundreds of contractions can occur before ionic imbalances interfere with contractile activity.

Once initiated, the action potential is unstoppable and ultimately results in contraction of the muscle cell. Although the action potential itself is very brief [1–2 milliseconds (ms)], the contraction phase of a muscle fiber may persist for 100 ms or more and far outlasts the electrical event that triggers it because active transport of Ca^{2+} back into the SR takes substantially longer than its release.

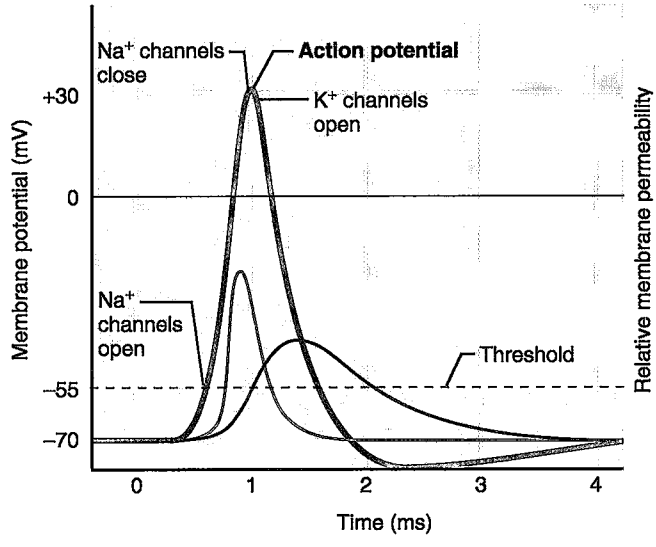


FIGURE 9.9 **Action potential scan showing changing sarcolemma permeability to Na^+ and K^+ ions.** (Na^+ permeability = yellow scan line; K^+ permeability = green scan line; action potential = blue scan line)

Excitation-Contraction Coupling

Excitation-contraction (E-C) coupling is the sequence of events by which transmission of an action potential along the sarcolemma leads to the sliding of myofilaments. The action potential is brief and

Q *(1) Why is Ca^{2+} called the final trigger for contraction?*
(2) What constitutes the initial trigger?

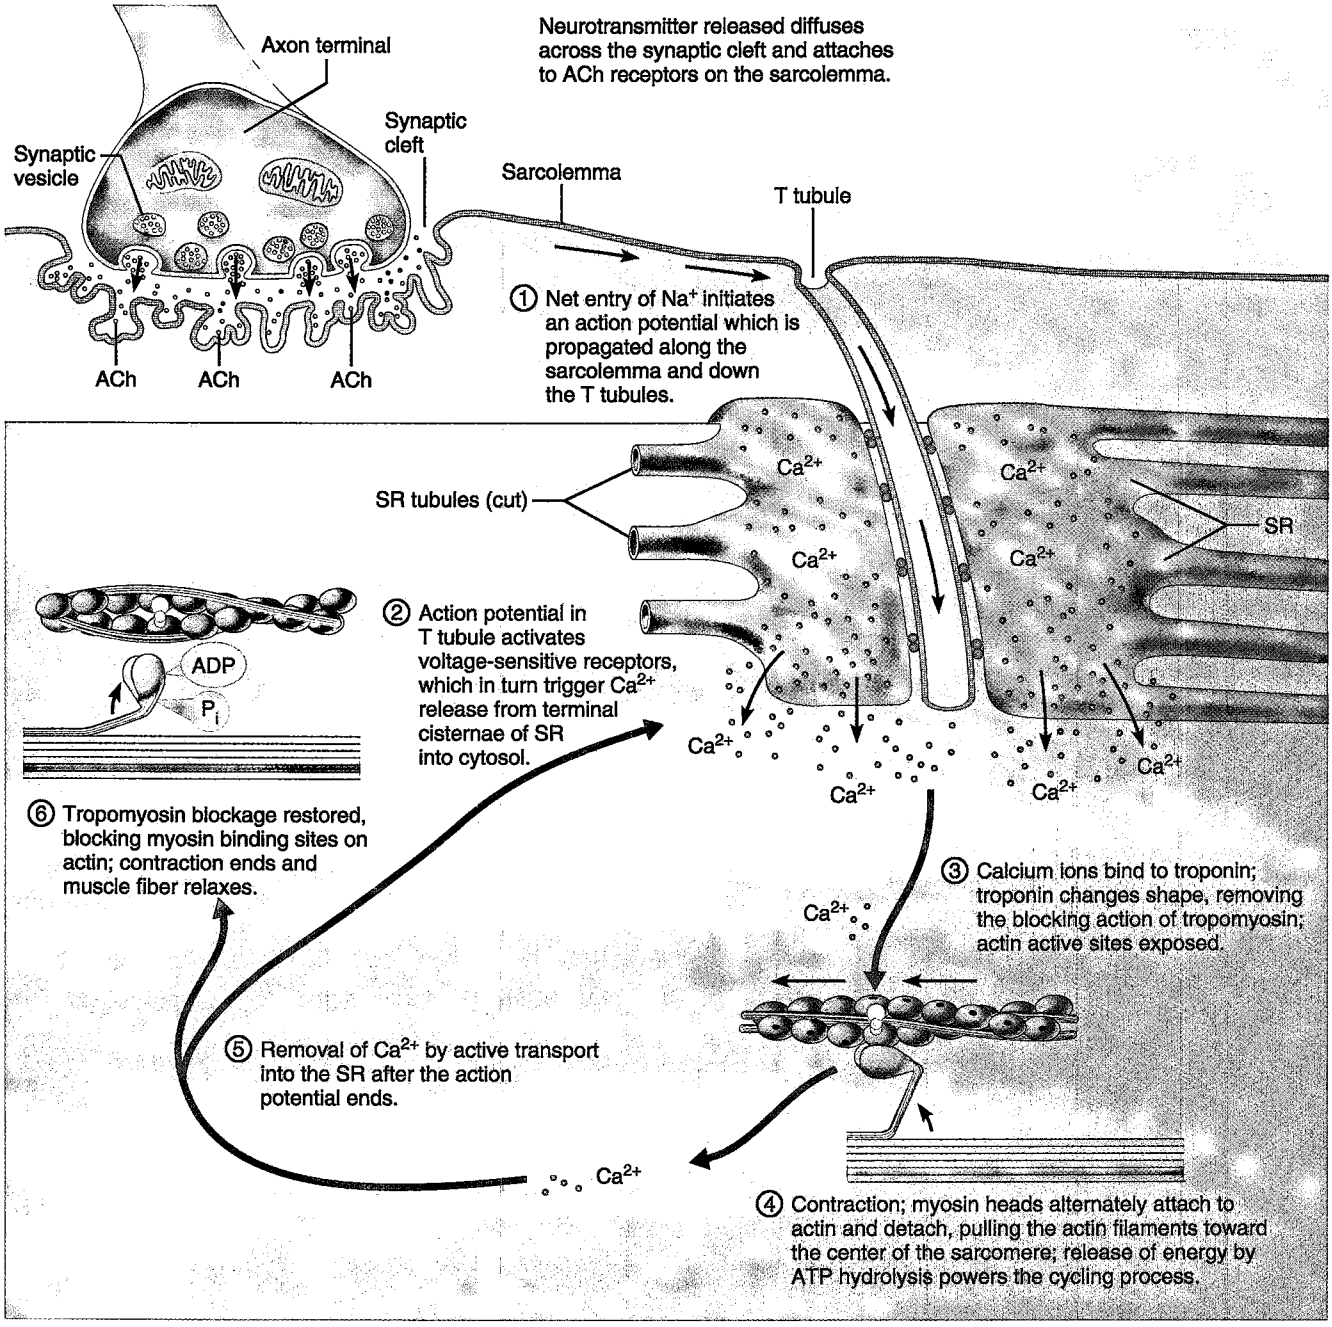

FIGURE 9.10 **Excitation-contraction coupling.** Events ① through ⑤ indicate the sequence of events in the coupling process. Contraction continues until ⑥ the calcium signal ends.

(1) Because calcium binding to troponin frees the actin active sites to bind with myosin heads. (2) The initial trigger is neurotransmitter binding, which initiates generation of an action potential along the sarcolemma.

ends well before any signs of contraction are obvious. The events of excitation-contraction coupling occur during the *latent period* (*laten* = hidden), between action potential initiation and the beginning of mechanical activity (shortening). As you will see, the electrical signal does not act directly on the myofilaments; rather, it causes the rise in intracellular

calcium ion concentration that allows the filaments to slide.

Excitation-contraction coupling consists of the following steps illustrated in (Figure 9.10):

① The action potential propagates along the sarcolemma and down the T tubules.

② Transmission of the action potential in the T tubules of the triads causes the terminal cisternae of the SR to release Ca^{2+} into the sarcoplasm, where it becomes available to the myofilaments. The "double zippers" (p. 287) at the T-SR junctions of the triads are involved in this action as follows: The T tubule proteins (DHP receptors) are sensitive to voltage and change shape in response to the arrival of the action potential. This voltage-regulated change is communicated to the linked SR foot proteins, which in turn undergo shape changes that open their calcium-release channels (and perhaps other mechanically linked Ca^{2+} channels nearby). Because these events occur at every triad in the cell, within 1 ms massive amounts of Ca^{2+} flood into the sarcoplasm from the SR cisternae.

③ Some of this calcium binds to troponin, which changes shape and removes the blocking action of tropomyosin.

④ When the intracellular calcium level is about 10^{-5} *M*, the myosin heads attach and pull the thin filaments toward the center of the sarcomere. At this point you can say the muscle cell is in the active state.

⑤ The short-lived Ca^{2+} signal ends, usually within 30 ms after the action potential is over. The fall in Ca^{2+} levels reflects the operation of a continuously active, ATP-dependent calcium pump that moves Ca^{2+} back into the SR to be stored once again.

⑥ The inactive state occurs when intracellular Ca^{2+} levels drop too low for the amount of Ca^{2+} needed for contraction to bind to troponin, so the tropomyosin blockade is reestablished, and myosin-actin interaction is inhibited. Cross bridge activity ends and relaxation occurs.

This sequence of events is repeated when another nerve impulse arrives at the neuromuscular junction. When the impulses are delivered rapidly, intracellular Ca^{2+} levels increase greatly due to successive "puffs" or rounds of Ca^{2+} released from the SR. In such cases, the muscle cells do not completely relax between successive stimuli and contraction is stronger and more sustained (within limits) until nervous stimulation ceases.

Summary of Roles of Ionic Calcium in Muscle Contraction

Except for the brief period following muscle cell excitation, calcium ion concentrations in the sarcoplasm are kept almost undetectably low. There is a reason for this: ATP provides the cell's energy source and its hydrolysis yields inorganic phosphate (P_i). If the intracellular level of Ca^{2+} were always high, calcium and phosphate ions would combine to form hydroxyapatite crystals, the stony-hard salts found in bone matrix. Such calcified cells would die. Also, because calcium's physiological roles are so vital (besides triggering neurotransmitter secretion and sliding of the myofilaments, it promotes breakdown of glycogen and ATP synthesis), its cytoplasmic concentration is exquisitely regulated by intracellular proteins. These include **calsequestrin** (found within the SR cisternae) and **calmodulin,** which can alternately bind and release calcium to provide a metabolic signal.

Muscle Fiber Contraction

As noted, cross bridge formation (attachment of myosin heads to actin) requires Ca^{2+}. When intracellular calcium levels are low, the muscle cell is relaxed, and the active (myosin binding) sites on actin are physically blocked by tropomyosin molecules (Figure 9.11a). As Ca^{2+} levels rise, the ions bind to regulatory sites on troponin TnC (Figure 9.11b), causing it to change shape. This event moves tropomyosin deeper into the groove of the actin helix and away from the myosin binding sites (Figure 9.11c and d). Thus, the tropomyosin "blockade" is removed when sufficient calcium is present.

Once binding sites on actin are exposed, the following events occur in rapid succession (Figure 9.12):

① **Cross bridge formation.** The activated myosin heads are strongly attracted to the exposed binding sites on actin, and cross bridges form.

② **The power (working) stroke.** As a myosin head binds, phosphate (P_i) generated during the prior contraction cycle is released, initiating the power stroke. During the power stroke the myosin head pivots (moves through an angle of about 70°), changing from its high-energy configuration to its bent, low-energy shape, which pulls on the thin filament, sliding it toward the center of the sarcomere. At the same time, ADP generated during the *prior* contraction cycle is released. Each working stroke of myosin produces a movement or step of 5–15 nm.

③ **Cross bridge detachment.** As a new ATP molecule binds to the myosin head, myosin's hold on actin loosens and the cross bridge detaches from actin.

④ **"Cocking" of the myosin head.** The ATPase in the myosin head hydrolyzes ATP to ADP and P_i which provides the energy needed to return the myosin head to its prestroke high-energy, or "cocked," position. This provides the potential energy needed for its *next* sequence of attachment and power stroke. (The ADP and P_i remain attached to the myosin head during this phase.)

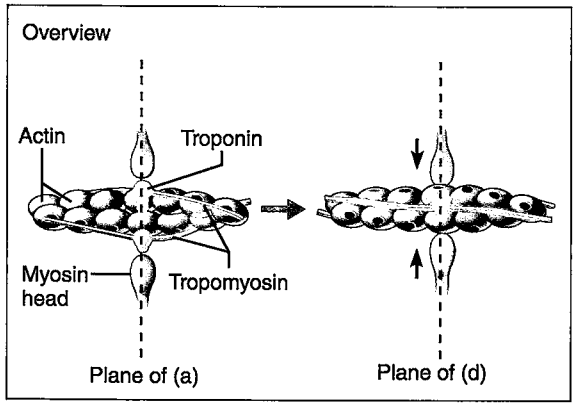

FIGURE 9.11 **Role of ionic calcium in the contraction mechanism.** Views (a–d) are cross-sectional views of the thin (actin) filament. **(a)** At low intracellular Ca^{2+} concentration, tropomyosin blocks the binding sites on actin, preventing attachment of myosin heads and enforcing the relaxed muscle state. **(b)** At higher intracellular Ca^{2+} concentrations, additional calcium binds to TnC of troponin. **(c)** Calcium-activated troponin undergoes a conformational change that moves the tropomyosin away from actin's binding sites. **(d)** This displacement allows the myosin heads to bind and cycle, and contraction (sliding of the thin filaments by the myosin cross bridges) begins.

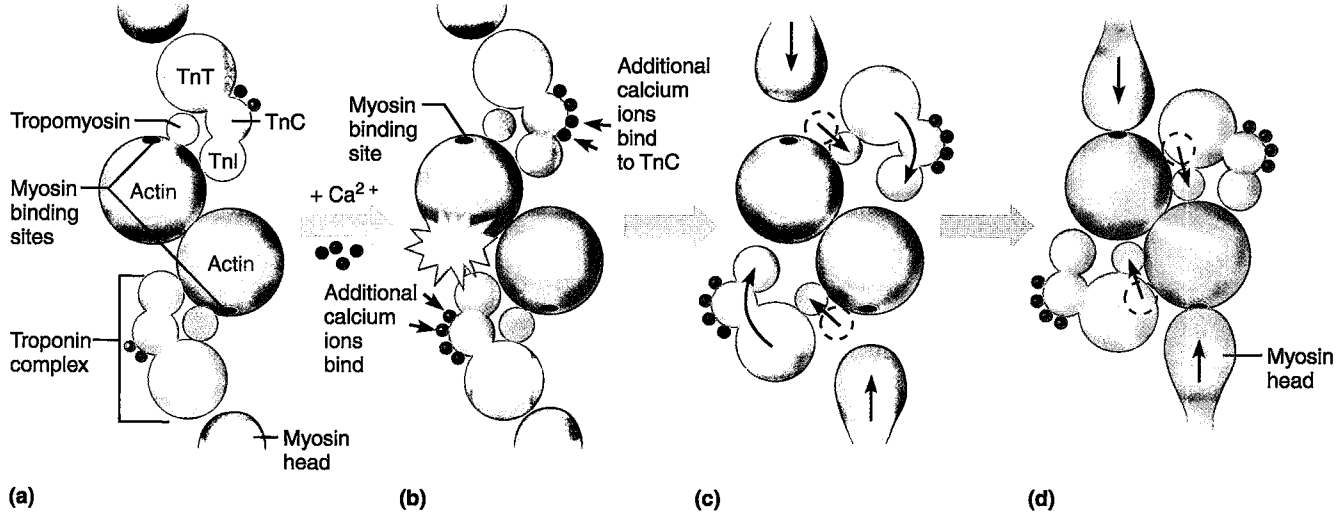

At this point, the cycle is back where it started. The myosin head is in its upright high-energy configuration, ready to take another "step" and attach to an actin site farther along the thin filament. This "walking" of the myosin heads along the adjacent thin filaments during muscle shortening is much like a centipede's gait. Because some myosin heads ("legs") are always in contact with actin (the "ground"), the thin filaments cannot slide backward as the cycle is repeated again and again.

A single power stroke of all the cross bridges in a muscle results in a shortening of only about 1%. Because contracting muscles routinely shorten by 30–35% of their total resting length, each myosin cross bridge must attach and detach many times during a single contraction. It is likely that only half of the myosin heads of a thick filament are pulling at the same instant; the balance are randomly seeking their next binding site. Sliding of thin filaments continues as long as the calcium signal and adequate ATP are present. As the Ca^{2+} pumps of the SR reclaim calcium ions from the sarcoplasm and troponin again changes shape, actin's myosin-binding sites are covered by tropomyosin, the contraction ends, and the muscle fiber relaxes.

HOMEOSTATIC IMBALANCE

Rigor mortis (death rigor) illustrates the fact that cross bridge detachment is ATP driven. Most muscles begin to stiffen 3 to 4 hours after death. Peak rigidity occurs at 12 hours and then gradually dissipates over the next 48 to 60 hours. Dying cells are unable to exclude calcium (which is in higher concentration in the extracellular fluid), and the calcium influx into muscle cells promotes formation of myosin cross bridges. Shortly after breathing stops, ATP synthesis ceases, but it continues to be consumed and cross bridge detachment is impossible. Actin and myosin become irreversibly cross-linked, producing the stiffness of rigor mortis, which gradually disappears as muscle proteins break down after death. ●

Q *What would happen if the muscle fiber suddenly ran out of ATP when the sarcomeres had only partially contracted?*

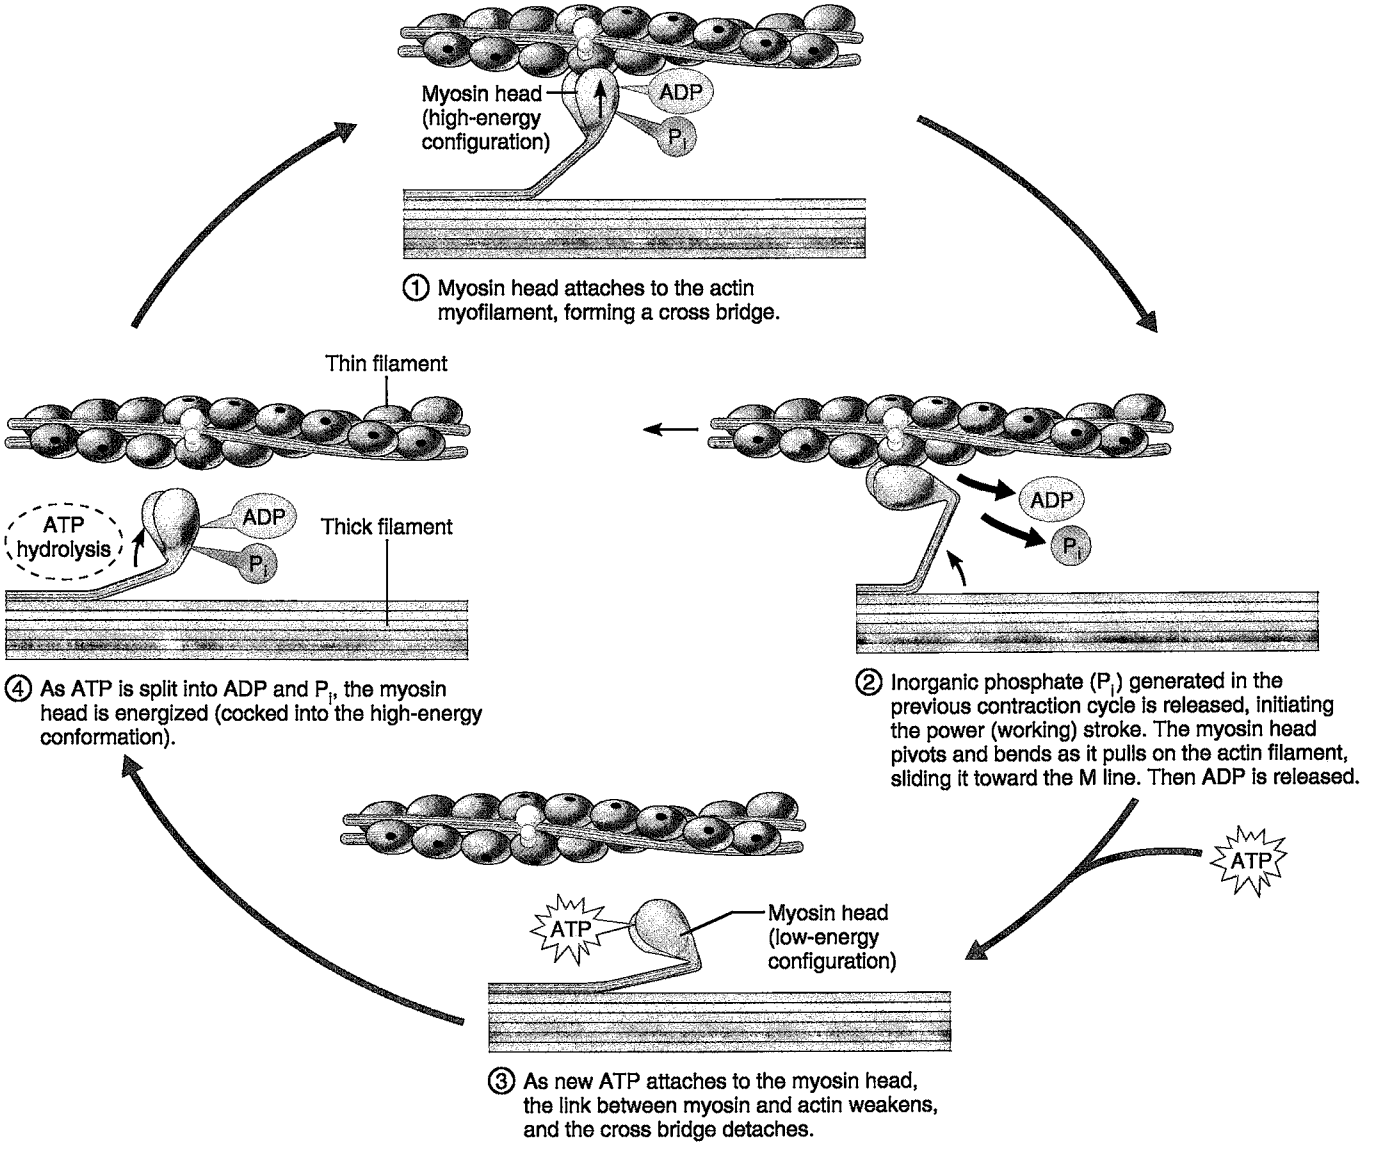

FIGURE 9.12 **The cross bridge cycle.** A small section of adjacent thick and thin filaments is used to illustrate the interactions between the two types of myofilaments during contraction. These events occur only in the presence of ionic calcium (Ca^{2+}), which releases tropomyosin's blockade of actin's active sites.

Contraction of a Skeletal Muscle

In its relaxed state, a muscle is soft and unimpressive; not what you would expect of a prime mover of the body. However, within a few milliseconds, it can contract to become a hard elastic structure with dynamic characteristics that intrigue not only biologists but engineers and physicists as well.

Before we consider muscle contraction on the organ level, let's review a few principles of muscle mechanics.

1. The principles governing contraction of a muscle fiber (cell) and of a skeletal muscle consisting of a huge number of cells are pretty much the same.
2. The force exerted by a contracting muscle on an object is called **muscle tension,** and the opposing

A *The sarcomeres would remain in their partially contracted state.*

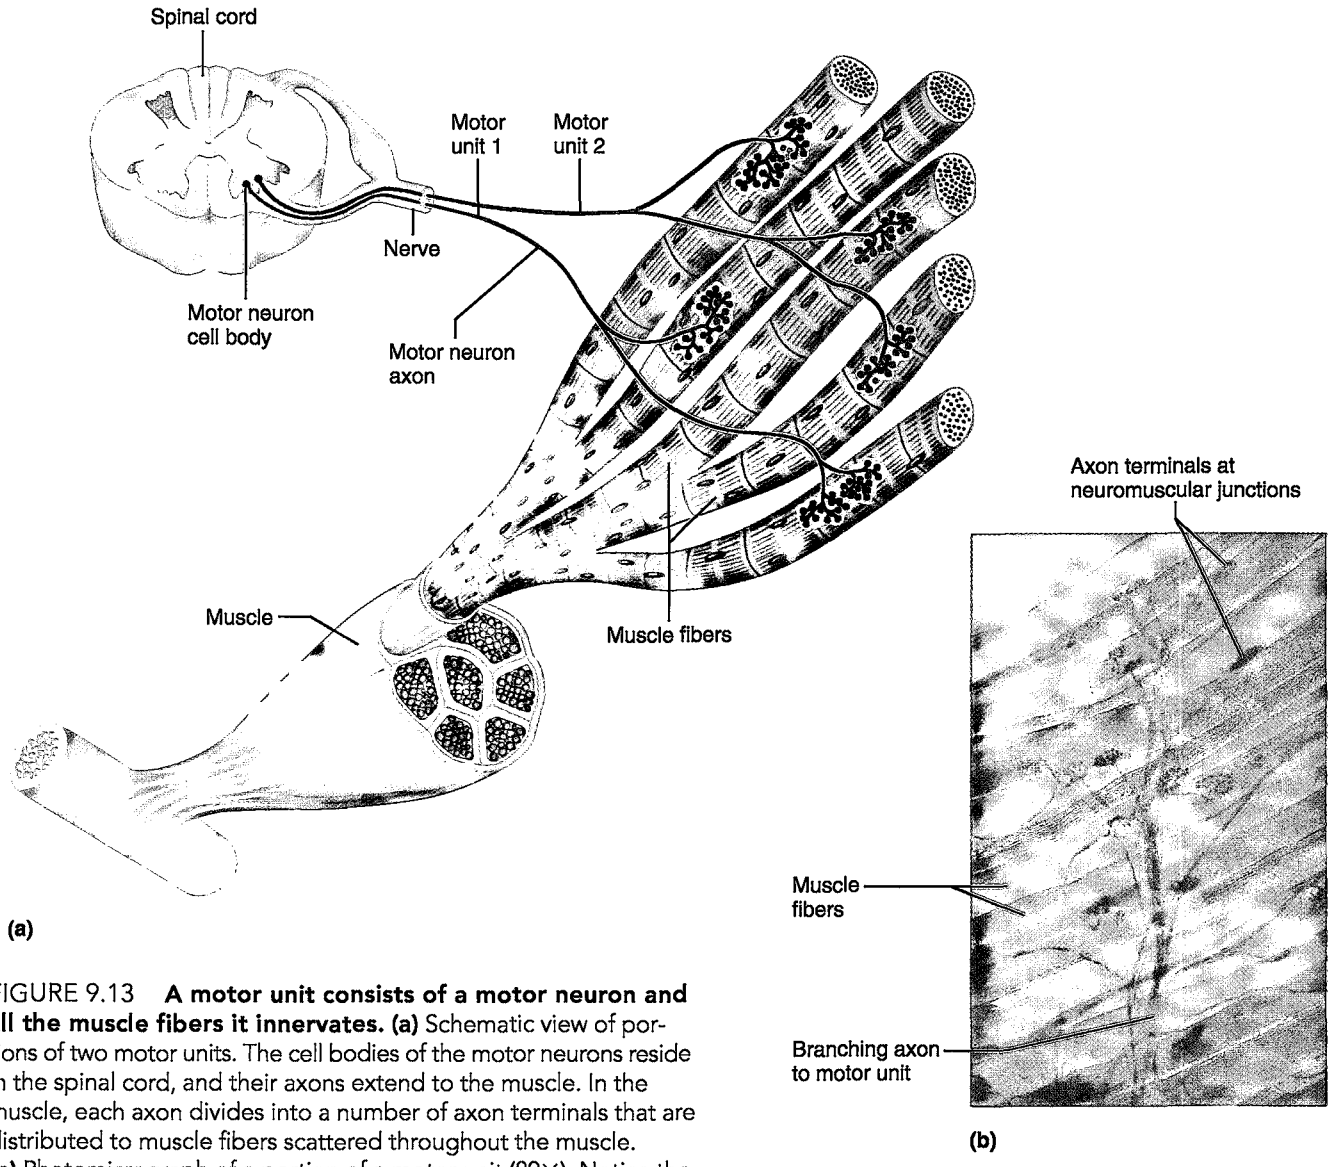

FIGURE 9.13 **A motor unit consists of a motor neuron and all the muscle fibers it innervates. (a)** Schematic view of portions of two motor units. The cell bodies of the motor neurons reside in the spinal cord, and their axons extend to the muscle. In the muscle, each axon divides into a number of axon terminals that are distributed to muscle fibers scattered throughout the muscle. **(b)** Photomicrograph of a portion of a motor unit (80×). Notice the diverging axon terminals and the neuromuscular junctions formed by the terminals and muscle fibers.

force exerted on the muscle by the weight of the object to be moved is called the **load.**

3. A contracting muscle does not always shorten and move the load. If muscle tension develops but the load is not moved, the contraction is called *isometric* ("same measure"). If the muscle tension developed overcomes the load and muscle shortening occurs, the contraction is *isotonic.* These major types of contraction will be described in detail shortly, but for now the important thing to remember when reading the accompanying graphs is that *increasing muscle tension* is measured in isometric contractions, whereas the *amount of shortening* (distance in millimeters) is measured in isotonic contractions.

4. A skeletal muscle contracts with varying force and for different periods of time in response to stimuli of varying frequencies and intensities. To understand how this occurs, we must first look at the nerve-muscle functional unit called a *motor unit.* This is our next topic.

The Motor Unit

Each muscle is served by at least one motor nerve, which contains axons (fibrous extensions) of up to hundreds of motor neurons. As an axon enters a muscle, it branches into a number of terminals, each of which forms a neuromuscular junction with a single muscle fiber. A motor neuron and all the muscle fibers it supplies is called a **motor unit** (Figure 9.13). When a motor neuron fires (transmits an electrical impulse), all the muscle fibers it innervates contract. The number of muscle fibers per motor unit may be

as high as several hundred or as few as four. Muscles that exert fine control (such as those controlling the fingers and eyes) have small motor units. By contrast, large, weight-bearing muscles, whose movements are less precise (such as the hip muscles), have large motor units. The muscle fibers in a single motor unit are not clustered together but are spread throughout the muscle. As a result, stimulation of a single motor unit causes a weak contraction of the *entire* muscle.

The Muscle Twitch

Muscle contraction is easily investigated in the laboratory using an isolated muscle. The muscle is attached to an apparatus that produces a **myogram,** a graphic recording of contractile activity. (The line recording the activity is called a *tracing.*)

The response of a motor unit to a single action potential of its motor neuron is called a **muscle twitch.** The muscle fibers contract quickly and then relax. Every twitch myogram has three distinct phases (Figure 9.14a).

1. Latent period. The **latent period** is the first few milliseconds following stimulation when excitation-contraction coupling is occurring. During this period, muscle tension is beginning to increase but no response is seen on the myogram.

2. Period of contraction. The period of contraction is when cross bridges are active, from the onset to the peak of tension development, and the myogram tracing rises to a peak. This period lasts 10–100 ms. If the tension (pull) becomes great enough to overcome the resistance of a load, the muscle shortens.

3. Period of relaxation. The period of contraction is followed by the period of relaxation. This final phase, lasting 10–100 ms, is initiated by reentry of Ca^{2+} into the SR. Because contractile force is no longer being generated, muscle tension decreases to zero and the tracing returns to the baseline. If the muscle shortened during contraction, it now returns to its initial length.

As you can see in Figure 9.14b, twitch contractions of some muscles are rapid and brief, as with the muscles controlling eye movements. In contrast, the fibers of fleshy calf muscles (gastrocnemius and soleus) contract more slowly and remain contracted for much longer periods. These differences between muscles reflect metabolic properties of the myofibrils and enzyme variations.

Graded Muscle Responses

Although *muscle twitches*—like those single, jerky contractions provoked in a laboratory—may result from certain neuromuscular problems, this is *not* the way our muscles normally operate. Instead, healthy muscle contractions are relatively smooth and vary in strength as different demands are placed

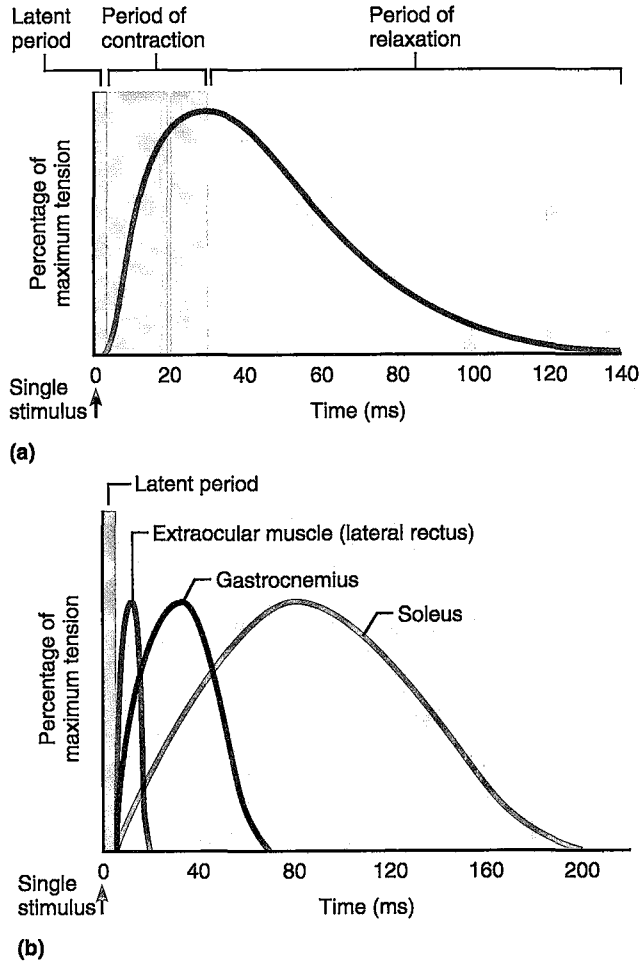

FIGURE 9.14 **The muscle twitch. (a)** Myogram of an isometric twitch contraction, showing its three phases: the latent period, the period of contraction, and the period of relaxation. **(b)** Comparison of the relative duration of twitch responses of extraocular, gastrocnemius, and soleus muscles.

on them. These variations (an obvious requirement for proper control of skeletal movement) are referred to as **graded muscle responses.** In general, muscle contraction can be graded in two ways: (1) by changing the frequency of stimulation and (2) by changing the strength of the stimulus.

Muscle Response to Changes in Stimulation Frequency The nervous system achieves greater muscular force by increasing the firing rate of motor neurons. For example, if two identical stimuli (electrical shocks or nerve impulses) are delivered to a muscle in rapid succession, the second twitch will be stronger than the first. On a myogram the second twitch will appear to ride on the shoulders of the first (Figure 9.15). This phenomenon, called **wave summation,** occurs because the second contraction occurs before the muscle has completely relaxed. Because the muscle is already partially contracted when the next

Q *If the second stimulus in part 2 was delayed by a few milliseconds, would the second peak be higher or lower? Why?*

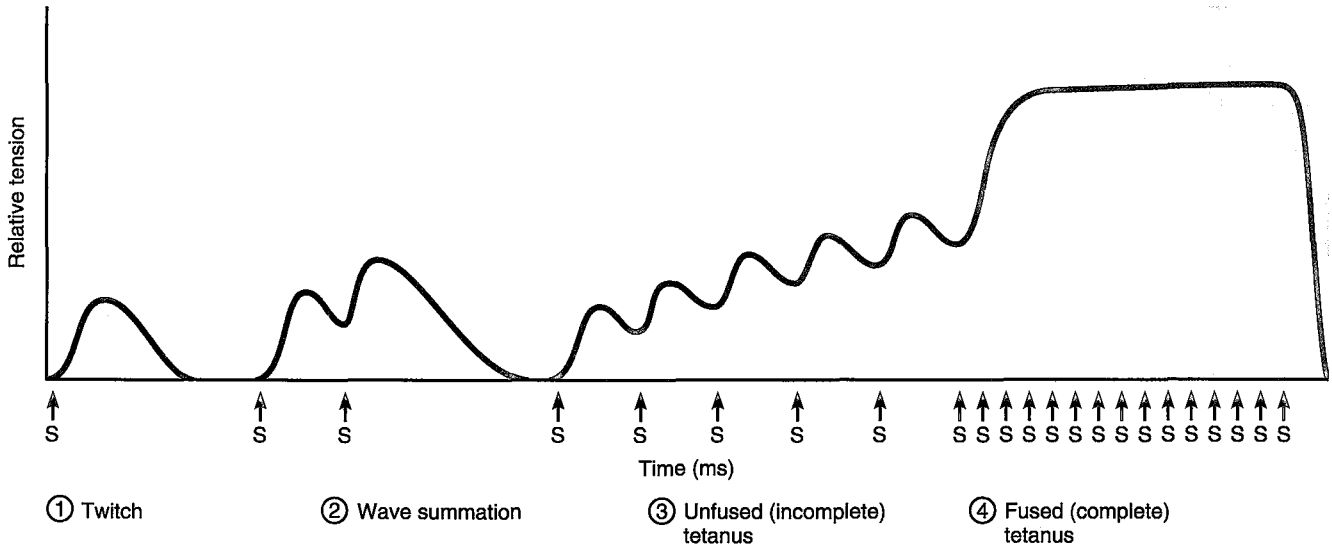

FIGURE 9.15 **Wave summation and tetanus in a whole muscle.** ① A single stimulus is delivered, and the muscle contracts and relaxes (twitch contraction). ② Stimuli are delivered more frequently, so that the muscle does not have adequate time to relax completely, and contraction force increases (wave summation). ③ More complete twitch fusion (unfused or incomplete tetanus) occurs as stimuli are delivered more rapidly. ④ In fused or complete tetanus, a smooth, continuous contraction without any evidence of relaxation occurs.

stimulus arrives and more calcium is being released to replace that being reclaimed by the SR, muscle tension produced during the second contraction causes more shortening than the first. In other words, the contractions are summed. (However, the refractory period is *always* honored. Thus, if a second stimulus is delivered before repolarization is complete, no summation occurs.) If the stimulus strength is held constant and the muscle is stimulated at an increasingly faster rate, the relaxation time between the twitches becomes shorter and shorter, the concentration of Ca^{2+} in the sarcoplasm higher and higher, and the degree of summation greater and greater, progressing to a sustained but quivering contraction referred to as **unfused** or **incomplete tetanus.** Finally, as the stimulation frequency continues to increase, muscle tension increases until a maximal tension is reached. At this point all evidence of muscle relaxation disappears and the contractions fuse into a smooth, sustained contraction plateau called **fused** or **complete tetanus** (tet'ah-nus; *tetan* = rigid, tense). (This term is often confused with the bacterial disease called tetanus that causes severe involuntary contractions.)

A The second peak would be lower, more like the first peak because more of the muscle cells would have had time to relax.

Vigorous muscle activity cannot continue indefinitely. Prolonged tetanus inevitably leads to *muscle fatigue,* a situation in which the muscle is unable to contract and its tension drops to zero.

Muscle Response to Stronger Stimuli Although wave summation contributes to contractile force, its primary function is to produce smooth, continuous muscle contractions by rapidly stimulating a specific number of muscle cells. The force of contraction is controlled more precisely by **recruitment,** also called **multiple motor unit summation** (Figure 9.16). In the laboratory this phenomenon is achieved by delivering shocks of increasing voltage to the muscle, calling more and more muscle fibers into play. The stimulus at which the first observable contraction occurs is called the **threshold stimulus.** Beyond this point, the muscle contracts more and more vigorously as the stimulus strength is increased (Figure 9.16). The **maximal stimulus** is the strongest stimulus that produces increased contractile force. It represents the point at which all the muscle's motor units are recruited. Increasing the stimulus intensity beyond the maximal stimulus does not produce a stronger contraction. In the body, the same phenomenon is caused by neural activation of an

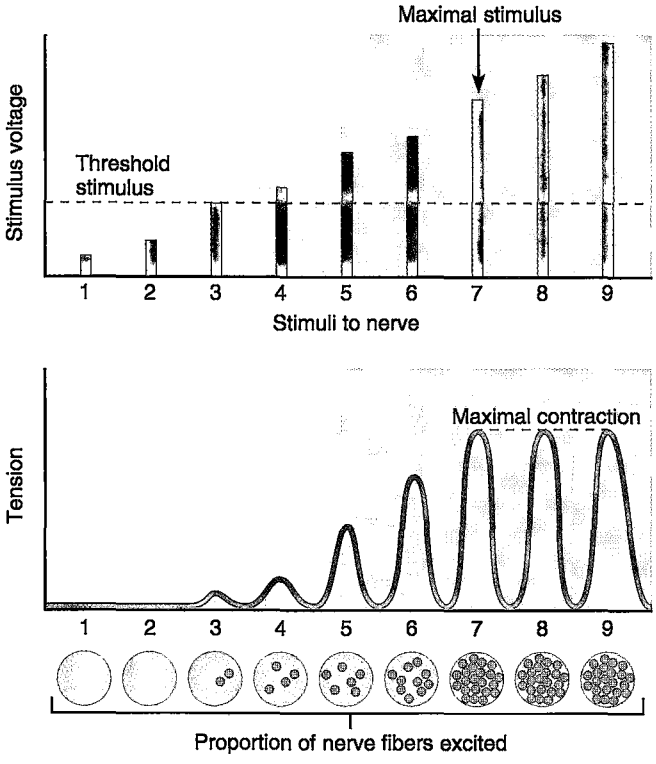

FIGURE 9.16 **Relationship between stimulus intensity (graph at top) and muscle tension (tracing below).** Below threshold voltage, no muscle response is seen on the tracing (1 and 2). Once threshold (3) is reached, increases in voltage excite (recruit) more and more motor units until the maximal stimulus is reached (7). Further increases in stimulus voltage produce no further increase in contractile strength.

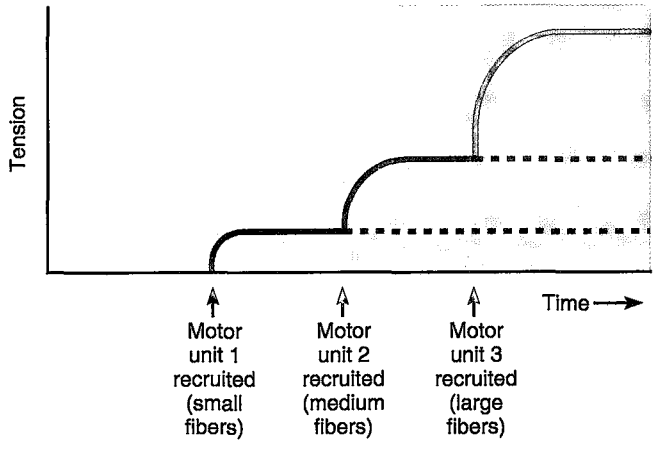

FIGURE 9.17 **The size principle.** Recruitment of motor neurons controlling skeletal muscle fibers is orderly—small motor neurons are generally recruited more readily than large ones. This phenomenon is referred to as the *size principle*. In weaker contractions, small motor neurons controlling motor units containing small-diameter muscle fibers are recruited. As contractile strength increases, larger and larger motor neurons are activated, which in turn stimulate motor units containing larger numbers of increasingly larger diameter muscle fibers. Consequently, the contractions get stronger and stronger in a disproportionate and predictable way.

increasingly large number of motor units serving the muscle.

The recruitment process is not random; instead it is dictated by the *size principle*. In any muscle, motor units with the smallest muscle fibers are controlled by small, highly excitable motor neurons, and these motor units tend to be activated first. As the contractile strength increases, motor units with larger and larger muscle fibers begin to be excited. The largest motor units, containing large, coarse muscle fibers have as much as 50 times the contractile force of the smallest ones. They are controlled by the largest, least excitable (highest-threshold) neurons and are activated only when the most powerful contraction is necessary (Figure 9.17). The size principle is important because it allows the increases in force during weak contractions (for example, those that maintain posture or slow movements) to occur in small steps, whereas gradations in muscle force are progressively greater when large amounts of force are needed for vigorous activities such as jumping or running. This explains how the same hand that pats your cheek can deliver a stinging slap.

Although *all* the motor units of a muscle may be recruited simultaneously to produce an exceptionally strong contraction, motor units are more commonly activated asynchronously in the body. At a given instant, some are in tetanus (usually unfused tetanus) while others are resting and recovering. This technique helps prolong a strong contraction by preventing or delaying fatigue. It also explains how weak contractions promoted by infrequent stimuli can remain smooth.

Treppe: The Staircase Effect When a muscle begins to contract after a long period of rest, its initial contractions may be only half as strong as those that occur later in response to stimuli of the same strength. During these periods, a tracing shows a staircase pattern called **treppe** (trep'ĕ) (Figure 9.18). Treppe probably reflects the increasing availability of Ca^{2+} in the sarcoplasm; more Ca^{2+} ions expose more active sites on the thin filaments for cross bridge attachment. Additionally, as the muscle begins to work and liberates heat, its enzymes become more efficient and the muscle becomes more pliable. Together, these factors produce a slightly stronger contraction with each successive stimulus during the initial phase of muscle activity. This is the basis of the warm-up period used by athletes.

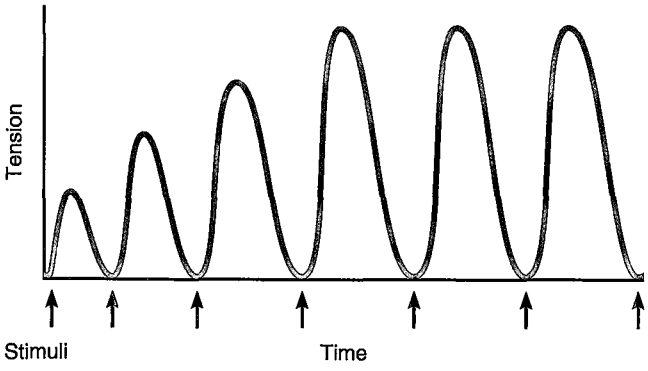

FIGURE 9.18 **Myogram of treppe.** Notice that although the stimuli are of the same intensity and the muscle is not being stimulated rapidly, the first few contractile responses get stronger and stronger.

Muscle Tone

Skeletal muscles are described as voluntary, but even relaxed muscles are almost always slightly contracted, a phenomenon called **muscle tone.** This is due to spinal reflexes that activate first one group of motor units and then another in response to activation of stretch receptors in the muscles. Muscle tone does not produce active movements, but it keeps the muscles firm, healthy, and ready to respond to stimulation. Skeletal muscle tone also helps stabilize joints and maintain posture.

Isotonic and Isometric Contractions

As noted earlier, there are two main categories of contractions—*isotonic* and *isometric*. In **isotonic contractions** (*iso* = same; *ton* = tension), muscle length changes (decreasing the angle at the joint) and moves the load. Once sufficient tension has developed to move the load, the tension remains relatively constant through the rest of the contractile period (Figure 9.19a).

Isotonic contractions come in two "flavors"—*concentric* and *eccentric*. **Concentric contractions** in which the muscle *shortens* and does work—picking up a book or kicking a ball, for instance—are probably more familiar. However, **eccentric contractions,** in which the muscle generates force as it *lengthens*, are equally important for coordination and purposeful movements. Eccentric contractions occur in your calf muscle, for example, as you walk up a steep hill. Eccentric contractions are about 50% more forceful than concentric ones at the same load and more often cause delayed-onset muscle soreness. (Consider how your calf muscles *feel* the day after hiking up that hill.) Just why this is so is unclear, but it may be that the muscle stretching that occurs during such contractions causes microtears in the muscles.

Squats, or deep knee bends, provide a simple example of how concentric and eccentric contractions work together in our everyday activities. As the knees flex, the powerful quadriceps muscles of the anterior thigh lengthen (are stretched), but at the same time they also contract (eccentrically) to counteract the force of gravity and control the descent of the torso ("muscle braking") and prevent joint injury. Raising the body back to its starting position requires that the same muscles contract concentrically as they shorten to extend the knees again. As you can see, eccentric contractions put the body in position to contract concentrically. All jumping and throwing activities involve both types of contraction.

In **isometric contractions** (*metric* = measure), tension may build to the muscle's peak tension-producing capacity, but the muscle *neither shortens nor lengthens* (Figure 9.19b). Isometric contractions occur when a muscle attempts to move a load that is greater than the force (tension) the muscle is able to develop—think of trying to lift a piano singlehandedly. Muscles contract isometrically when they act primarily to maintain upright posture or to hold joints in stationary positions while movements occur at other joints. In our knee bend example, the quadriceps muscles contract isometrically when the squat position is held for a few seconds to hold the knee in the flexed position. They also contract isometrically when we begin to rise to the upright position until their tension exceeds the load (weight of the upper body). At that point muscle shortening (concentric contraction) begins. So the quadriceps contractile sequence for a deep knee bend from start to finish is (1) flex knee (eccentric), (2) hold squat position (isometric), (3) extend knee (isometric, then concentric). Of course, this does not even begin to consider the isometric contractions of the posterior thigh muscles or of the trunk muscles that maintain a relatively erect trunk posture during the movement.

Electrochemical and mechanical events occurring within a muscle are identical in both isotonic and isometric contractions. However, the result is different. In isotonic contractions, the thin filaments are sliding; in isometric contractions, the cross bridges are generating force but are *not* moving the thin filaments, so there is no change in the banding pattern from that of the resting state. (You could say that they are "spinning their wheels" on the same actin binding sites.)

Muscle Metabolism

Providing Energy for Contraction

Now let's look at the mechanisms by which the body provides the energy needed for contraction.

Stored ATP As a muscle contracts, ATP provides the energy for cross bridge movement and detachment

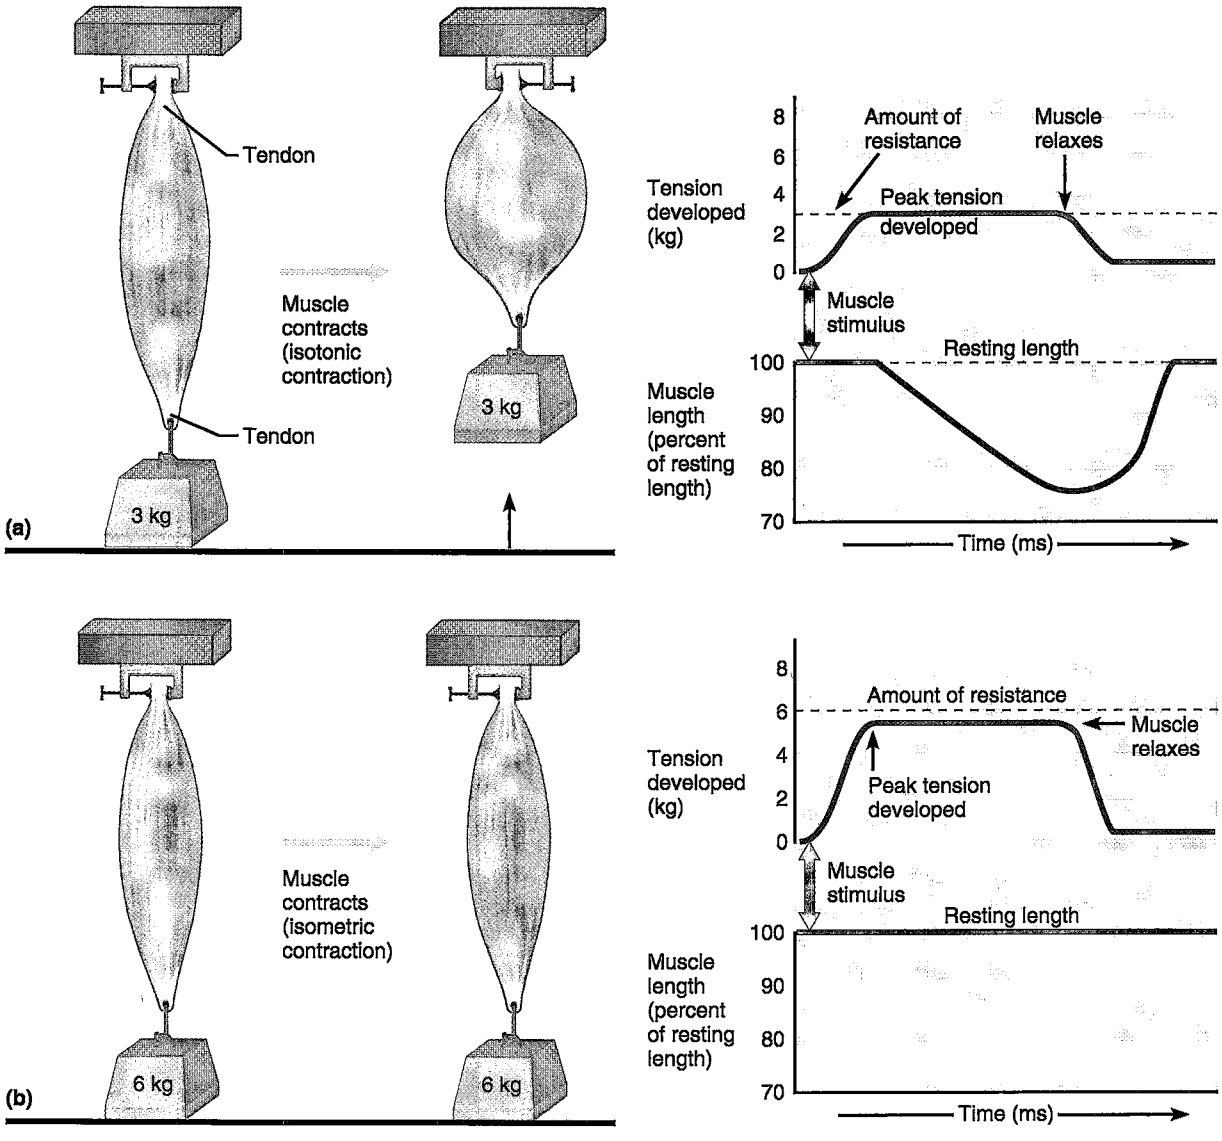

FIGURE 9.19 **Isotonic (concentric) and isometric contractions. (a)** On stimulation, this muscle develops enough tension (force) to lift the load (weight). Once the resistance is overcome, tension remains constant for the rest of the contraction and the muscle shortens. This is a concentric isotonic contraction. **(b)** This muscle is attached to a weight that exceeds the muscle's peak tension-developing capabilities. When stimulated, the tension increases to the muscle's peak tension-developing capability, but the muscle does not shorten. This is an isometric contraction.

and for operation of the calcium pump. Surprisingly, muscles store very limited reserves of ATP—4 to 6 seconds' worth at most, just enough to get you going.

Because ATP is the *only* energy source used directly for contractile activities, it must be regenerated as fast as it is broken down if contraction is to continue. Fortunately, after ATP is hydrolyzed to ADP and inorganic phosphate, it is regenerated within a fraction of a second by three pathways (Figure 9.20): (1) by interaction of ADP with creatine phosphate, (2) from stored glycogen via the anaerobic pathway called glycolysis, and (3) by aerobic respiration. The second and third of these metabolic pathways, which are used to produce ATP in all body cells, are just touched on here, as they are described in detail in Chapter 24.

Direct Phosphorylation of ADP by Creatine Phosphate As we begin to exercise vigorously, the demand for ATP soars and the ATP stored in working muscles is consumed within a few twitches. Then **creatine phosphate (CP)** (kre'ah-tin), a unique

high-energy molecule stored in muscles, is tapped to regenerate ATP while the metabolic pathways are adjusting to the suddenly higher demands for ATP. The result of coupling CP with ADP is almost instant transfer of energy and a phosphate group from CP to ADP to form ATP:

Creatine phosphate + ADP → creatine + ATP

Muscle cells store four to five times as much CP as ATP, and the CP-ADP reaction, catalyzed by the enzyme **creatine kinase,** is so efficient that the amount of ATP in muscle cells changes very little during the initial period of contraction.

Together, stored ATP and CP provide for maximum muscle power for 10–15 seconds—long enough to energize a 100-meter dash. The coupled reaction is readily reversible, and to keep CP "on tap," CP reserves are replenished during periods of inactivity.

Anaerobic Mechanism: Glycolysis and Lactic Acid Formation As stored ATP and CP are used, more ATP is generated by catabolism of glucose obtained from the blood or by breakdown of glycogen stored in the muscle. The initial phase of glucose respiration is **glycolysis** (gli-kol'ĭ-sis; "sugar splitting"). This pathway occurs in both the presence *and* the absence of oxygen, but because it does not *use* oxygen, it is an *anaerobic* (an-a'er-ob-ik; "without oxygen") pathway (see Figure 9.20b). During glycolysis, glucose is broken down to two *pyruvic acid* molecules, releasing enough energy to form small amounts of ATP (2 ATPs per glucose).

Ordinarily, pyruvic acid produced in glycolysis then enters the mitochondria and reacts with oxygen to produce still more ATP in the oxygen-using pathway called aerobic respiration, described shortly. But when muscles contract vigorously and contractile activity reaches about 70% of the maximum possible (e.g., running 600 meters with maximal effort), the bulging muscles compress the blood vessels within them, impairing blood flow and hence oxygen delivery. Under these anaerobic conditions, most of the pyruvic acid produced during glycolysis is converted into **lactic acid,** and the overall process is referred to as **anaerobic glycolysis.** Thus, during oxygen deficit, lactic acid is the end product of cellular metabolism of glucose. Most of the lactic acid diffuses out of the muscles into the bloodstream and is gone from the muscle tissue within 30 minutes after exercise stops. Subsequently, the lactic acid is picked up by liver, heart, or kidney cells, which can use it as an energy source. Additionally, liver cells can reconvert it to pyruvic acid or glucose and release it back into the bloodstream for muscle use, or convert it to glycogen for storage.

The anaerobic pathway harvests only about 5% as much ATP from each glucose molecule as the aerobic pathway; however, it produces ATP about 2½ times faster. Thus, when large amounts of ATP are needed for moderate periods (30–40 seconds) of strenuous muscle activity, glycolysis can provide most of the ATP needed as long as the required fuels and enzymes are available. Together, stored ATP and CP and the glycolysis–lactic acid system can support strenuous muscle activity for nearly a minute.

Although anaerobic glycolysis readily fuels spurts of vigorous exercise, it has shortcomings. Huge amounts of glucose are used to produce relatively small harvests of ATP, and the accumulating lactic acid contributes to muscle fatigue and is partially responsible for muscle soreness during intense exercise.

Aerobic Respiration During rest and light to moderate exercise, even if prolonged, 95% of the ATP used for muscle activity comes from aerobic respiration. **Aerobic respiration** occurs in the mitochondria, requires oxygen, and involves a sequence of chemical reactions in which the bonds of fuel molecules are broken and the energy released is used to make ATP.

During aerobic respiration, which includes glycolysis and the reactions that take place in the mitochondria, glucose is broken down entirely, yielding water, carbon dioxide, and large amounts of ATP as the final products (Figure 9.20c).

Glucose + oxygen → carbon dioxide + water + ATP

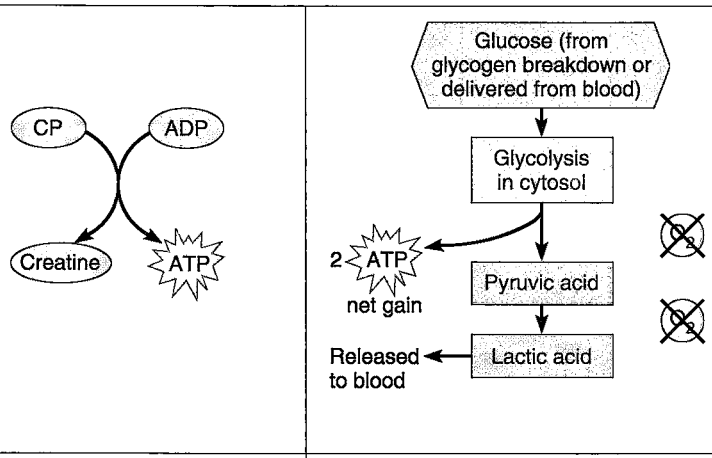
The carbon dioxide released diffuses out of the muscle tissue into the blood and is removed from the body by the lungs.

As exercise begins, muscle glycogen provides most of the fuel. Shortly thereafter, bloodborne glucose, pyruvic acid from glycolysis, and free fatty acids are the major sources of fuels for oxidation. After about 30 minutes, fatty acids become the major energy fuels. Aerobic respiration provides a high yield of ATP (about 38 ATPs per glucose), but it is relatively sluggish because of its many steps and it requires continuous delivery of oxygen and nutrient fuels to keep it going.

Energy Systems Used During Sports Activities

As long as it has enough oxygen, a muscle cell will form ATP by aerobic reactions. When ATP demands are within the capacity of the aerobic pathway, light to moderate muscular activity can continue for several hours in well-conditioned individuals. However, when exercise demands begin to exceed the ability of the muscle cells to carry out the necessary reactions quickly enough, glycolysis begins to contribute more

Q *Which of these energy-producing pathways would predominate in the leg muscles of a long-distance cyclist?*



(a) Direct phosphorylation [coupled reaction of creatine phosphate (CP) and ADP]	(b) Anaerobic mechanism (glycolysis and lactic acid formation)	(c) Aerobic mechanism (aerobic cellular respiration)
Energy source: CP	Energy source: glucose	Energy source: glucose; pyruvic acid; free fatty acids from adipose tissue; amino acids from protein catabolism
Oxygen use: None Products: 1 ATP per CP, creatine Duration of energy provision: 15 s.	Oxygen use: None Products: 2 ATP per glucose, lactic acid Duration of energy provision: 30–60 s.	Oxygen use: Required Products: 38 ATP per glucose, CO_2, H_2O Duration of energy provision: Hours

FIGURE 9.20 **Methods of regenerating ATP during muscle activity.** The fastest mechanism is direct phosphorylation **(a)**; the slowest is the aerobic mechanism **(c)**.

and more of the total ATP generated. The length of time a muscle can continue to contract using aerobic pathways is called **aerobic endurance,** and the point at which muscle metabolism converts to anaerobic glycolysis is called **anaerobic threshold.**

Exercise physiologists have been able to estimate the relative importance of each energy-producing system to athletic performance. Activities that require a surge of power but last only a few seconds, such as weight lifting, diving, and sprinting, rely entirely on ATP and CP stores. The more on-and-off or burstlike activities of tennis, soccer, and a 100-meter swim appear to be fueled almost entirely by anaerobic glycolysis. Prolonged activities such as marathon runs and jogging, where endurance rather than power is the goal, depend mainly on aerobic respiration.

Muscle Fatigue

Muscle fatigue is a state of *physiological inability to contract* even though the muscle still may be receiving stimuli. This is quite different from *psychological,* or *central, fatigue,* in which the flesh is still able to perform but we feel tired.

Although many factors appear to contribute to fatigue, its specific causes are not fully understood. Most experimental evidence indicates that fatigue is due to a problem in excitation-contraction coupling or within the muscle cells themselves. Hence, physiological fatigue is a peripheral mechanism (rather than a central mechanism). Availability of ATP declines during contraction and a total lack of ATP results in **contractures,** states of continuous contraction because the cross bridges are unable to detach (not unlike what happens in rigor mortis). Writer's cramp is a familiar example of temporary contractures. However, ATP is not a fatigue-producing limiting factor in moderate exercise.

Although excessive intracellular accumulation of lactic acid (which causes the muscles to ache and raises H^+) alters contractile proteins, it seems to be more important in provoking central fatigue than physiological fatigue. pH is normally regulated within normal limits in all but the greatest degree of exertion. Other ionic imbalances also contribute to muscle

(c) The aerobic pathway.

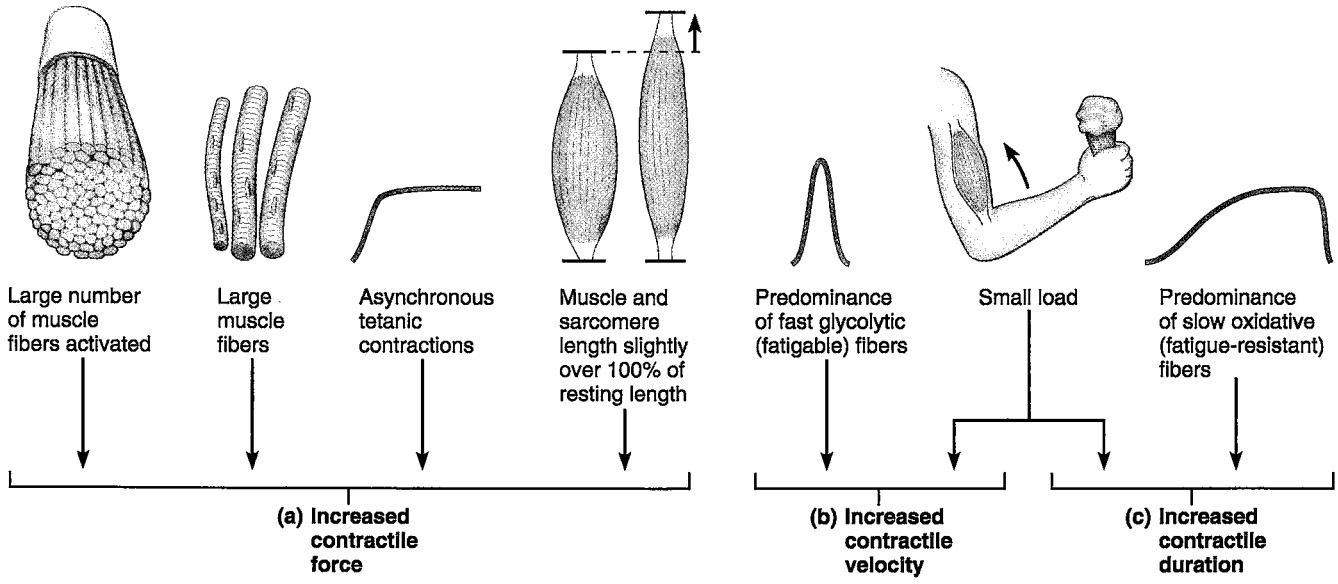


FIGURE 9.21 **Factors influencing force, velocity, and duration of skeletal muscle contraction.**

fatigue. As action potentials are transmitted, potassium is lost from the muscle cells, and the Na^+-K^+ pumps are insufficient to reverse the ionic imbalances quickly, so K^+ accumulates in the fluids of the T tubules. This disturbs the membrane potential of the muscle cell and halts Ca^{2+} release from the SR. Theoretically, an accumulation of inorganic phosphate (P_i) from CP and ATP breakdown may interfere with calcium release or alternatively with the release of P_i from myosin and thus hamper myosin's power strokes.

In general, intense exercise of short duration produces fatigue rapidly via ionic disturbances that alter E-C coupling, but recovery is also rapid. In contrast to short-duration exercise, the slow-developing fatigue of prolonged low-intensity exercise may require several hours for complete recovery. It appears that this type of exercise damages the SR, interfering with Ca^{2+} regulation and release, and therefore with muscle activation.

Oxygen Debt

Whether or not fatigue occurs, vigorous exercise causes a muscle's chemistry to change dramatically. For a muscle to return to its resting state, its oxygen reserves must be replenished, the accumulated lactic acid must be reconverted to pyruvic acid, glycogen stores must be replaced, and ATP and creatine phosphate reserves must be resynthesized. Additionally, the liver must convert any lactic acid persisting in blood to glucose or glycogen. During anaerobic muscle contraction, all of these oxygen-requiring activities occur more slowly and are (at least partially) deferred until oxygen is again available. Thus, we say an *oxygen debt* is incurred, which must be repaid.

Oxygen debt is defined as the extra amount of oxygen that the body must take in for these restorative processes. It represents the difference between the amount of oxygen needed for totally aerobic muscle activity and the amount actually used. All nonaerobic sources of ATP used during muscle activity contribute to this debt.

Heat Production During Muscle Activity

Only about 40% of the energy released during muscle contraction is converted to useful work (still, this is significantly higher than that of many mechanical devices). The rest is given off as heat, which has to be dealt with if body homeostasis is to be maintained. When you exercise vigorously, you start to feel hot as your blood is warmed by the liberated heat. Ordinarily, heat buildup is prevented from reaching dangerous levels by several homeostatic mechanisms, including sweating and radiation of heat from the skin surface. Shivering represents the opposite side of homeostatic balance, in which muscle contractions are used to produce more heat.

Force of Muscle Contraction

The force of muscle contraction is affected by (1) the number of muscle fibers stimulated, (2) the relative size of the fibers, (3) frequency of stimulation, and (4) the degree of muscle stretch (Figure 9.21a). Let's briefly examine the role of each of these factors.

Number of Muscle Fibers Stimulated

As already discussed, the more motor units that are recruited, the greater the muscle force will be.

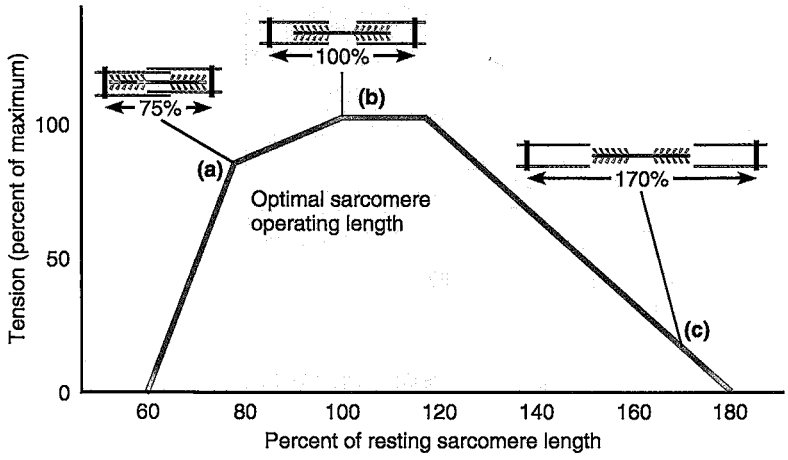

FIGURE 9.22 **Length-tension relationships in skeletal muscles.** Maximum force is generated when the muscle is between 80 and 120% of its resting length. Increases and decreases beyond this optimal range result in decreased force and inability to generate tension. Depicted here is the relative sarcomere length in a muscle that is **(a)** greatly shortened, **(b)** at normal resting length, and **(c)** excessively stretched.

Size of the Muscle Fibers Stimulated

The bulkier the muscle (the greater its cross-sectional area), the more tension it can develop and the greater its strength, but there is more to it than this. As noted earlier, the large fibers of large motor units are very effective in producing the most powerful movements. Regular exercise increases muscle force by causing muscle cells to *hypertrophy* (hi-per'tro-fe), or increase in size.

Frequency of Stimulation

As a muscle begins to contract, the force generated by the cross bridges (myofibrils)—the **internal tension**—stretches the series elastic (noncontractile) components. These in turn become taut and transfer their tension, called the **external tension,** to the load (muscle insertion), and when the contraction ends, their recoil helps to return the muscle to its resting length.

The point is that time is required to take up slack and stretch the series elastic components, and while this is happening, the internal tension is already declining. So, in brief twitch contractions, the external tension is always less than the internal tension. However, when a muscle is stimulated rapidly, contractions are summed up, becoming stronger and more vigorous and ultimately producing tetanus. During tetanic contractions more time is available to stretch the series elastic components, and external tension approaches the internal tension. So, the more rapidly a muscle is stimulated, the greater the force it exerts.

Degree of Muscle Stretch

The optimal resting length for muscle fibers is the length at which they can generate maximum force (Figures 9.21a and 9.22). Within a sarcomere, the ideal **length-tension relationship** occurs when a muscle is slightly stretched and the thin and thick filaments overlap optimally, because this permits sliding along nearly the entire length of the thin filaments. If a muscle fiber is stretched to the extent that the filaments do not overlap (Figure 9.22c), the myosin heads have nothing to attach to and cannot generate tension. Alternatively, if the sarcomeres are so compressed and cramped that the Z discs abut the thick myofilaments, and the thin filaments touch and interfere with one another (Figure 9.22a), little or no further shortening can occur.

Identical relationships exist in a whole muscle. If you stretch a muscle to various extents and then stimulate it tetanically, the active tension the muscle can generate varies with length as shown in Figure 9.22. A severely stretched muscle (say one at 180% of its optimal length) cannot develop tension. Likewise, at 75% of a muscle's resting length, force generation (or shortening) is limited. Muscles, like muscle fibers, are at optimal operational length from about 80% to about 120% of their normal resting length. In the body, skeletal muscles are maintained near that optimum by the way they are attached to bones; that is, the joints normally prevent bone movements that would stretch attached muscles beyond their optimal range.

Velocity and Duration of Contraction

Muscles vary in how fast they can contract and in how long they can continue to contract before they fatigue. These characteristics are influenced by muscle fiber type, load, and recruitment.

Muscle Fiber Type

There are several ways of classifying muscle fibers, but learning about these classes will be easier if you initially pay attention to just two major functional characteristics:

- **Speed of contraction.** On the basis of speed of shortening, or contraction, there are **slow fibers** and **fast fibers.** The difference in their speed reflects how fast their myosin ATPases split ATP, and on the pattern of electrical activity of their motor neurons.

TABLE 9.2 Structural and Functional Characteristics of the Three Types of Skeletal Muscle Fibers

	SLOW OXIDATIVE FIBERS	FAST OXIDATIVE FIBERS	FAST GLYCOLYTIC FIBERS
METABOLIC CHARACTERISTICS			
Speed of contraction	Slow	Fast	Fast
Myosin ATPase activity	Slow	Fast	Fast
Primary pathway for ATP synthesis	Aerobic	Aerobic (some anaerobic glycolysis)	Anaerobic glycolysis
Myoglobin content	High	High	Low
Glycogen stores	Low	Intermediate	High
Recruitment order	First	Second	Third
Rate of fatigue	Slow (fatigue-resistant)	Intermediate (moderately fatigue-resistant)	Fast (fatigable)
ACTIVITIES BEST SUITED FOR			
	Endurance-type activities—e.g., running a marathon; maintaining posture (antigravity muscles)	Sprinting, walking	Short-term intense or powerful movements, e.g., hitting a baseball
STRUCTURAL CHARACTERISTICS			
Color	Red	Red to pink	White (pale)
Fiber diameter	Small	Intermediate	Large
Mitochondria	Many	Many	Few
Capillaries	Many	Many	Few

- **The major pathways for forming ATP.** The cells that rely mostly on the oxygen-using aerobic pathways for ATP generation are **oxidative fibers;** those that rely more on anaerobic glycolysis are **glycolytic fibers.**

On the basis of these two criteria, we can classify skeletal muscle cells as being **slow oxidative fibers, fast oxidative fibers,** or **fast glycolytic fibers.** Details about each group are given in Table 9.2, but a word to the wise: Do not approach this information by rote memorization—you'll just get frustrated. Instead, start with what you know for any category and see how the characteristics listed support that. For example, a *slow oxidative fiber*

- Contracts relatively *slowly* because its myosin ATPases are slow (a criterion)
- Depends on oxygen delivery and aerobic mechanisms (*high oxidative capacity*—a criterion)
- Is fatigue resistant and has high endurance (typical of fibers that depend on aerobic metabolism)
- Is thin (a large amount of cytoplasm impedes diffusion of O_2 and nutrients from the blood)
- Has relatively little power (a thin cell can contain only a limited number of myofibrils)
- Has many mitochondria (actual sites of oxygen use)
- Has a rich capillary supply (the better to deliver bloodborne O_2)
- Is red (its color stems from an abundant supply of myoglobin, muscle's oxygen-binding pigment that stores O_2 reserves in the cell and aids diffusion of O_2 through the cell)

Conversely, a *fast glycolytic fiber* contracts rapidly (Figure 9.21b), depends on plentiful glycogen reserves for fuel rather than on a blood-delivered glucose or fatty acids, and does not use oxygen (Table 9.2). Compared to an oxidative cell, it has few mitochondria, little myoglobin and low capillary density (and so is white), and is a much larger cell (because it doesn't depend on continuous oxygen and nutrient diffusion from the blood). Because glycogen reserves are short-lived and lactic acid accumulates quickly in these cells, they tire quickly and hence are fatigable fibers. However, their large diameter reflects their plentiful contractile myofilaments that allow them to contract powerfully before they "poop out." Thus, the fast glycolytic fibers are best suited for short-term, rapid, intense movements (moving furniture across the room, for example). Intermediate muscle fiber types, called fast oxidative fibers, have many characteristics (fiber diameter and power for example)

intermediate between the other two types (Table 9.2). Like fast glycolytic fibers, they contract quickly; like slow oxidative fibers, they are oxygen dependent and have a rich supply of myoglobin and capillaries.

Although some muscles have a predominance of one fiber type, most contain a mixture of fiber types, which gives them a range of contractile speeds and fatigue resistance. For example, a calf muscle can propel us in a sprint (using mostly its white fast glycolytic fibers), or a long-distance race (making good use of its intermediate fast oxidative fibers), or may simply help maintain a standing posture (using slow oxidative fibers). As might be expected, all muscle fibers in a particular motor unit are of the same type.

Although everyone's muscles contain mixtures of the three fiber types, some people have relatively more of one variety. These differences are genetically initiated, but are modified by exercise and no doubt determine athletic capabilities (endurance versus strength) to a large extent. For example, muscles of marathon runners have a high percentage of slow oxidative fibers (about 80%), while those of sprinters contain a higher percentage (about 60%) of fast oxidative fibers. Weight lifters appear to have approximately equal amounts of both. However, fiber type interconversion of the "fast" fiber types does occur as a result of specific exercise regimes, as described below.

Load Because muscles are attached to bones, they are always pitted against some resistance, or load, when they contract. As you might expect, they contract fastest when there is no added load on them. The greater the load, the longer the latent period, the slower the contraction, and the shorter the duration of contraction (Figure 9.23). If the load exceeds the muscle's maximum tension, the speed of shortening is zero and the contraction is isometric.

Recruitment Just as many hands on a project can get a job done more quickly and also can keep working longer, the more motor units that are contracting, the faster and more prolonged the contraction.

Effect of Exercise on Muscles

The amount of work a muscle does is reflected in changes in the muscle itself. When used actively or strenuously, muscles may increase in size or strength or become more efficient and fatigue resistant. Muscle inactivity, on the other hand, *always* leads to muscle weakness and wasting.

Adaptations to Exercise

Aerobic, or **endurance, exercise** such as swimming, jogging, fast walking, and biking results in several recognizable changes in skeletal muscles. There is an increase in the number of capillaries surrounding the muscle fibers, and in the number of mitochondria within them, and the fibers synthesize more myoglobin. These changes occur in all fiber types, but are most dramatic in slow oxidative fibers, which depend primarily on aerobic pathways. The changes result in more efficient muscle metabolism and in greater endurance, strength, and resistance to fatigue. Additionally, regular endurance exercise may convert fast glycolytic fibers into fast oxidative fibers.

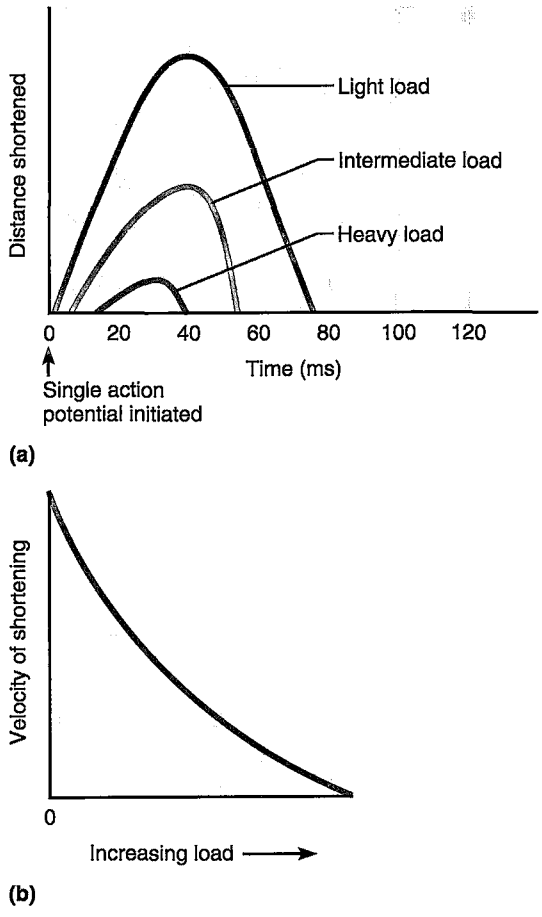

FIGURE 9.23 **Influence of load on contraction velocity and duration. (a)** Relationship of load to degree and duration of contraction (shortening). **(b)** Relationship of load to velocity of shortening. As the load increases, the velocity of shortening decreases.

The moderately weak but sustained muscle activity required for endurance exercise does not promote significant skeletal muscle hypertrophy, even though the exercise may go on for hours. Muscle hypertrophy, illustrated by the bulging biceps and chest muscles of a professional weight lifter, results mainly from high-intensity **resistance exercise** (typically under anaerobic conditions) such as weight lifting or isometric exercise, in which the muscles are pitted against high-resistance or immovable forces. Here strength, not stamina, is important; a few minutes every other day is sufficient to allow a

A CLOSER LOOK

Athletes Looking Good and Doing Better with Anabolic Steroids?

Society loves a winner and top athletes reap large social and monetary rewards. Thus, it is not surprising that some will grasp at anything that might increase their performance—including "juice" (anabolic steroids). Anabolic steroids, variants of the male sex hormone testosterone engineered by pharmaceutical companies, were introduced in the 1950s to treat anemia and certain muscle-wasting diseases and to prevent muscle atrophy in patients immobilized after surgery. Testosterone is responsible for the increase in muscle and bone mass and other physical changes that occur during puberty and converts boys into men.

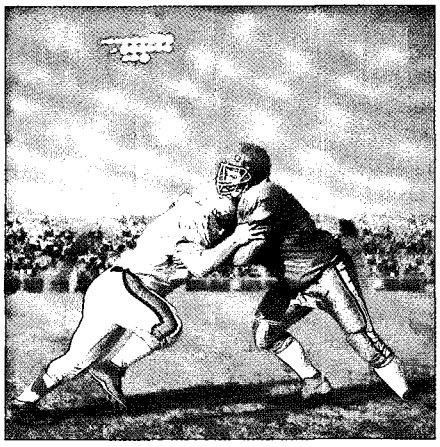
Convinced that megadoses of steroids could produce enhanced masculinizing effects in grown men, many athletes and bodybuilders were using them by the early 1960s, and this is still going on. Investigations of the so-called Balco Scandal have stunned fans of major league baseball players with revelations in 2004 of rampant steroid use by Barry Bonds, of the San Francisco Giants, and others. Steroid use today is not confined to athletes. Indeed, it is estimated that nearly one in every ten young men has tried them, and the practice is also growing rapidly among young women.

It is difficult to determine the extent of anabolic steroid use because most international competitions ban the use of drugs. Users (and prescribing physicians or drug dealers) are naturally reluctant to talk about it, and users stop doping before the event, aware that evidence of drug use is hard to find a week after its use is stopped. Additionally, "underground" suppliers of performance-enhancing drugs keep producing new versions of designer steroids that evade standard antidoping tests. Indeed, the Olympic Analytical Laboratory in Los Angeles rocked the sports world in November of 2003 when it revealed that a number of elite athletes tested positive for tetrahydrogestrinone (THG), a designer steroid not previously known or tested for. Nonetheless, there is little question that many professional bodybuilders and athletes competing in events that require muscle strength (e.g., shot put, discus throwing, and weight lifting) are heavy users. Sports figures such as football players have also admitted to using steroids as an adjunct to training, diet, and psychological preparation for games. These athletes claim that anabolic steroids enhance muscle mass and strength, and raise oxygen-carrying capability owing to greater red blood cell volume.

Typically, bodybuilders who use steroids combine high doses (up to 200 mg/day) via injection or transdermal skin patches with heavy resistance training. Intermittent use begins several months before an event, and commonly entails the use of many anabolic steroid supplements (a method called stacking). Doses are increased gradually as the competition nears.

Do the drugs do all that is claimed? Research studies report increased isometric strength and body weight in steroid users. While these are results weight lifters dream about, for runners and others requiring fine muscle coordination and endurance this may not translate into improved performance. The "jury is still out" on this question.

Do the alleged advantages of steroids outweigh their risks? Absolutely not. Physicians say they cause bloated faces (Cushingoid sign of steroid excess); acne and hair loss; shriveled testes and infertility; damage to the liver that promotes liver cancer; and changes in blood cholesterol levels that may predispose users to coronary heart disease. In addition, females can develop masculine characteristics such as smaller breasts, enlarged clitoris, excess body hair, and thinning scalp hair. The psychiatric hazards of anabolic steroid use may be equally threatening: Recent studies indicate that one-third of users suffer serious mental problems. Depression, delusions, and manic behavior—in which users undergo



Jekyll-and-Hyde personality swings and become extremely violent (termed *'roid rage*)—are all common.

A more recent arrival on the scene, sold over the counter as a "nutritional performance-enhancer," is androstenedione, which is converted to testosterone in the body. Though it is taken orally (and much of it is destroyed by the liver soon after ingestion), the few milligrams that survive temporarily boost testosterone levels. Reports of its use by baseball great Mark McGwire before he retired, and of athletic wanna-bes from the fifth grade up sweeping the supplement off the drugstore shelves, are troubling, particularly since it is not regulated by the U.S. Food and Drug Administration (FDA) and its long-term effects are unpredictable and untested. A study at Massachusetts General Hospital found that males who took androstenedione developed higher levels of the female hormone estrogen as well as testosterone, raising their risk of feminizing effects such as enlarged breasts. Youths with elevated levels of estrogen or testosterone may enter puberty early, stunting bone growth and leading to shorter-than-normal adult height. Some people admit to a willingness to try almost anything to win, short of killing themselves. Are they unwittingly doing this as well? ■

proverbial weakling to put on 50% more muscle within a year. The increased muscle bulk largely reflects increases in the size of individual muscle fibers (particularly the fast glycolytic variety) rather than an increased number of muscle fibers. [However, some of the increased muscle size may result either from longitudinal splitting or tearing of the fibers and subsequent growth of these "split" cells, or from the proliferation and fusion of satellite cells (see p. 317). The controversy is still raging.] Vigorously stressed muscle fibers contain more mitochondria, form more myofilaments and myofibrils, and store more glycogen. The amount of connective tissue between the cells also increases. Collectively these changes promote significant increases in muscle strength and size. Fast oxidative fibers can be shifted to fast glycolytic fibers in response to resistance activities. However, if the specific exercise routine is discontinued, the fibers previously converted revert to their original metabolic properties.

Resistance training can produce magnificently bulging muscles, but if done unwisely, some muscles may develop more than others. Because muscles work in antagonistic pairs (or groups), opposing muscles must be equally strong to work together smoothly. When muscle training is not balanced, individuals can become *muscle-bound,* which means they lack flexibility, have a generally awkward stance, and are unable to make full use of their muscles.

Whatever the activity, exercise gains adhere to the *overload principle.* Forcing a muscle to work hard promotes increased muscle strength and endurance, and as muscles adapt to the increased demands, they must be overloaded even more to produce further gains. To become faster, you must train at an increasingly fast pace. A heavy-workout day should be followed by one of rest or an easy workout to allow the muscles to recover and repair themselves. Doing too much too soon, or ignoring the warning signs of muscle or joint pain, increases the risk of **overuse injuries** that may prevent future sports activities, or even lead to lifetime disability.

Endurance and resistance exercises produce different patterns of muscular response, so it is important to know what your exercise goals are. Lifting weights will not improve your endurance for a triathlon. By the same token, jogging will do little to improve your muscle definition or to enhance your strength for moving furniture. A program that alternates aerobic activities with anaerobic ones provides the best program for optimal health.

HOMEOSTATIC IMBALANCE

To remain healthy, muscles must be active. Complete immobilization due to enforced bed rest or loss of neural stimulation results in *disuse atrophy* (degeneration and loss of mass), which begins almost as soon as the muscles are immobilized. Under such conditions, muscle strength can decrease at the rate of 5% per day!

As noted earlier, even at rest, muscles receive weak intermittent stimuli from the nervous system. When totally deprived of neural stimulation, a paralyzed muscle may atrophy to one-quarter of its initial size. Lost muscle tissue is replaced by fibrous connective tissue, making muscle rehabilitation impossible. Atrophy of a denervated muscle may be delayed by electrically stimulating the muscle periodically while waiting to see whether the damaged nerve fibers regenerate. ●

Smooth Muscle

Except for the heart, which is made of cardiac muscle, the muscle in the walls of all the body's hollow organs is almost entirely smooth muscle. Although the chemical and mechanical events of contraction are essentially the same in all muscle tissues, smooth muscle is distinctive in several ways (see Table 9.3).

Microscopic Structure of Smooth Muscle Fibers

Smooth muscle fibers are spindle-shaped cells, each with one centrally located nucleus (Figure 9.24). Typically, they have a diameter of 5–10 μm and are 30–200 μm long. Skeletal muscle fibers are some 10 times wider and thousands of times longer.

Smooth muscle lacks the coarse connective tissue sheaths seen in skeletal muscle. However, a small amount of fine connective tissue (endomysium), secreted by the smooth muscles themselves and containing blood vessels and nerves, is found between smooth muscle fibers. Most smooth muscle is organized into sheets of closely apposed fibers. These sheets occur in the walls of all but the smallest blood vessels and in the walls of hollow organs of the respiratory, digestive, urinary, and reproductive tracts. In most cases, two sheets of smooth muscle are present, with their fibers oriented at right angles to each other (Figure 9.24). In the *longitudinal layer,* the muscle fibers run parallel to the long axis of the organ. Consequently, when the muscle contracts, the organ dilates and shortens. In the *circular layer,* the fibers run around the circumference of the organ. Contraction of this layer constricts the lumen (cavity) of the organ and causes the organ to elongate. The alternating contraction and relaxation of these opposing layers mixes substances in the lumen and squeezes them through the organ's internal pathway. This phenomenon is called **peristalsis** (per"i-stal'sis; "around contraction"). Contraction of smooth muscle

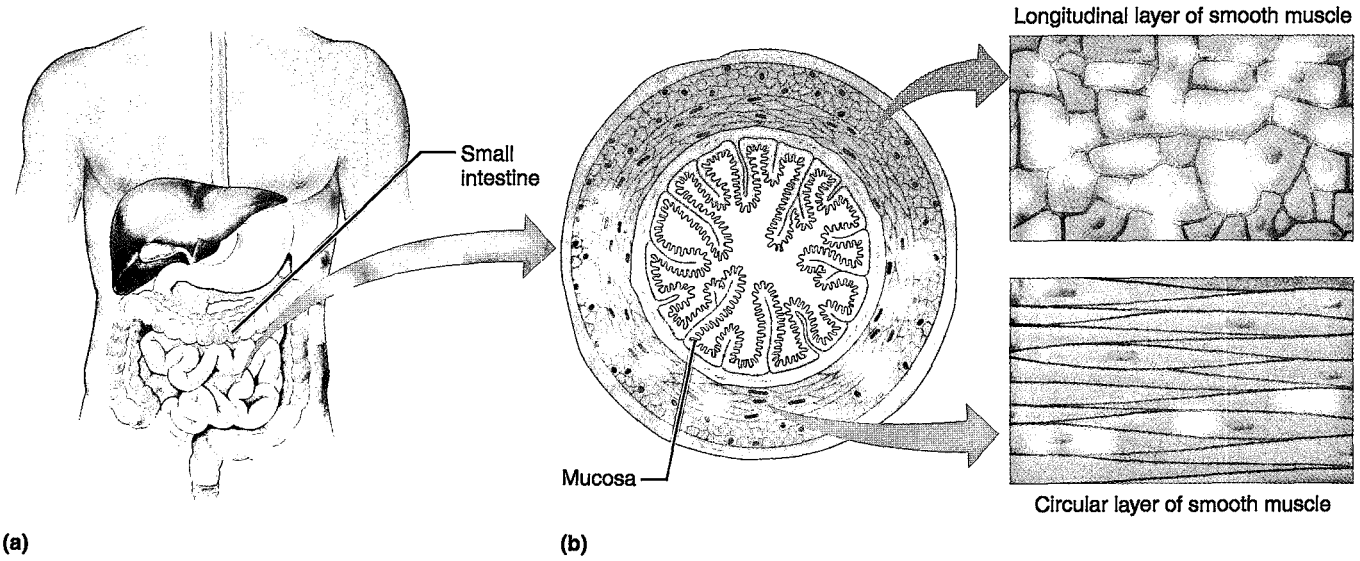


FIGURE 9.24 **Arrangement of smooth muscle in the walls of hollow organs.** Simplified cross-sectional view of the intestine showing two smooth muscle layers (one circular and the other longitudinal) running at right angles to each other.

in the rectum, urinary bladder, and uterus helps those organs to expel their contents. Smooth muscle contraction also accounts for the constricted breathing of asthma and for stomach cramps.

Smooth muscle lacks the highly structured, specific neuromuscular junctions of skeletal muscle. Instead, the innervating nerve fibers, which are part of the autonomic nervous system, have numerous bulbous swellings, called **varicosities** (Figure 9.25). The varicosities release neurotransmitter into a wide synaptic cleft in the general area of the smooth muscle cells. Such junctions are called **diffuse junctions.** Comparing the specificity of neural input to skeletal and smooth muscles, you could say that skeletal muscle gets priority mail while smooth muscle gets bulk mailings.

The sarcoplasmic reticulum of smooth muscle fibers is much less developed than that of skeletal muscle and lacks a specific pattern relative to the myofilaments. Some SR tubules of smooth muscle touch the sarcolemma at several sites, forming what resembles half-triads that may couple the action potential to calcium release from the SR. T tubules are notably absent, but the sarcolemma of the smooth muscle fiber has multiple caveolae, pouchlike infoldings that sequester bits of extracellular fluid containing a high concentration of Ca^{2+} close to the membrane. Consequently, when calcium channels open, Ca^{2+} influx occurs rapidly. Although the SR *does* release some of the calcium ions that trigger contraction, most gain entry via calcium channels directly from the extracellular space. Contraction ends when calcium is actively transported into the SR and out of the cell. This is quite different from what we see in skeletal muscle, which does not depend on extracellular Ca^{2+} for excitation-contraction coupling.

There are no striations, as the name *smooth muscle* indicates, and no sarcomeres. Smooth muscle fibers *do* contain interdigitating thick and thin filaments, but they are much longer than those in skeletal muscle and the type of myosin contained differs in smooth muscle. The proportion and organization of the myofilaments are also different:

1. The ratio of thick to thin filaments is much lower in smooth muscle than in skeletal muscle (1:13 compared to 1:2). However, thick filaments of smooth muscle contain actin-gripping heads along their *entire length,* a feature that allows smooth muscle to be as powerful as a skeletal muscle of the same size.
2. As opposed to skeletal muscle, no troponin complex is present in smooth muscle.
3. Smooth muscle thick and thin filaments are arranged diagonally within the cell so that they spiral down the long axis of the cell like the stripes on a barber pole. Because of this arrangement, the smooth muscle cells contract in a twisting way so that they look like tiny corkscrews (Figure 9.26b).
4. Smooth muscle fibers contain a lattice-like arrangement of noncontractile *intermediate filaments* that resist tension. These attach at regular intervals to structures called **dense bodies.** The dense bodies, which are also tethered to the sarcolemma, act as anchoring points for thin filaments and therefore correspond to Z discs of skeletal muscle. The intermediate filament–dense body network forms a strong, cablelike intracellular cytoskeleton that harnesses the pull generated by the sliding of the thick

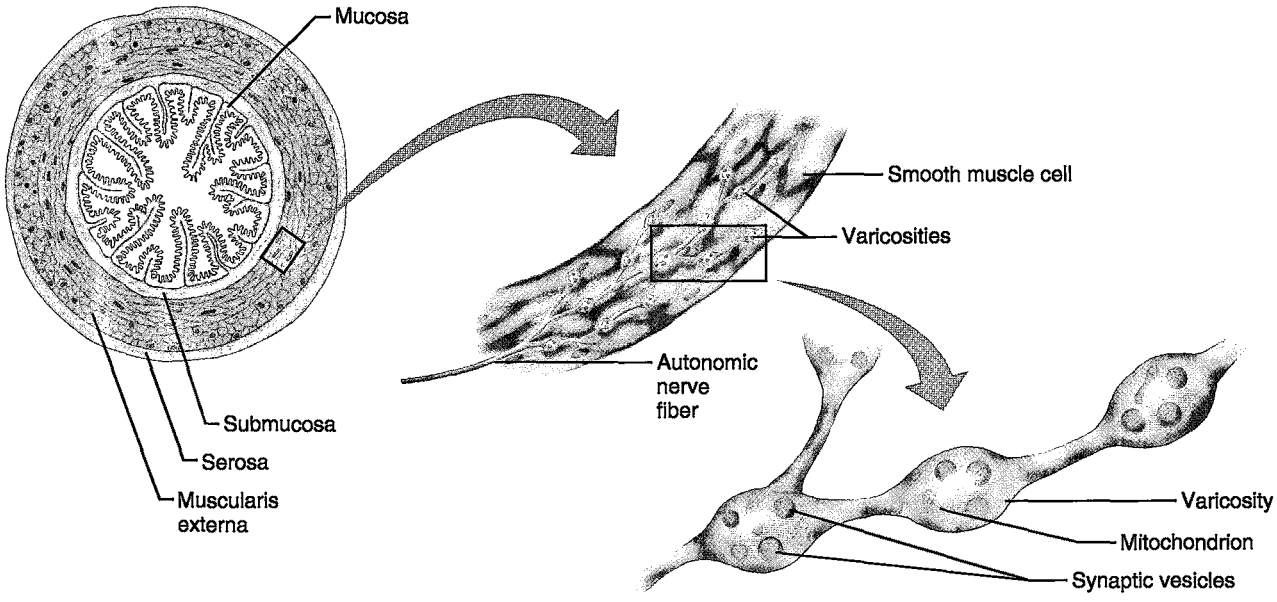

FIGURE 9.25 **Innervation of smooth muscle.** Most smooth muscle cells are innervated by autonomic nervous system fibers that release their neurotransmitters from varicosities into a wide synaptic cleft (a diffuse junction).

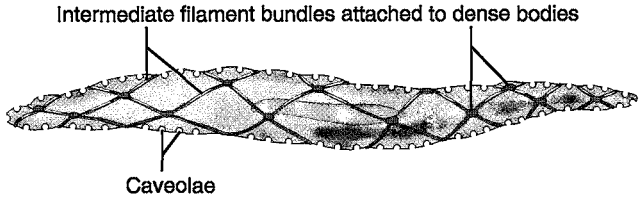
and thin filaments (Figure 9.26). During contraction, areas of the sarcolemma between the dense bodies bulge outward, giving the cell a puffy appearance (see Figure 9.26b). Dense bodies at the sarcolemma surface also bind the muscle cell to the connective tissue fibers outside the cell (endomysium) and to adjacent cells, an arrangement that transmits the pulling force to the surrounding connective tissue and that partly accounts for the synchronous contraction of most smooth muscle.

Contraction of Smooth Muscle

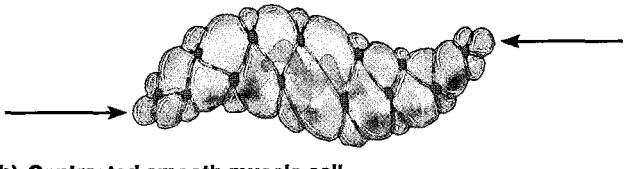
Mechanism and Characteristics of Contraction

In most cases, adjacent smooth muscle fibers exhibit slow, synchronized contractions, the whole sheet responding to a stimulus in unison. This phenomenon reflects electrical coupling of smooth muscle cells by *gap junctions*, specialized cell connections described in Chapter 3. Skeletal muscle fibers are electrically isolated from one another, each stimulated to contract by its own neuromuscular junction. By contrast, gap junctions allow smooth muscles to transmit action potentials from fiber to fiber. Some smooth muscle fibers in the stomach and small intestine are *pacemaker cells* and, once excited, act as "drummers" to set the contractile pace for the entire muscle sheet. Additionally, these pacemakers have fluctuating membrane potentials and are self-excitatory, that is, they depolarize spontaneously in the absence of external stimuli. However, both the rate and the intensity of smooth muscle contraction may be modified by neural and chemical stimuli.

The contraction mechanism in smooth muscle is like that in skeletal muscle in the following ways: (1) actin and myosin interact by the sliding filament mechanism; (2) the final trigger for contraction is a rise in the intracellular calcium ion level; and (3) the sliding process is energized by ATP.



(a) Relaxed smooth muscle cell



(b) Contracted smooth muscle cell

FIGURE 9.26 **Intermediate filaments and dense bodies of smooth muscle fibers harness the pull generated by the activity of myosin cross bridges.** Intermediate filaments attach to dense bodies scattered throughout the sarcoplasm and occasionally anchor to the sarcolemma. **(a)** A relaxed smooth muscle cell. **(b)** A contracted smooth muscle cell. [Caveolae are not illustrated in (b).]

During excitation-contraction coupling, Ca^{2+} is released by the tubules of the SR, but, as mentioned above, it also moves into the cell from the extracellular space. By binding to troponin, calcium ions trigger myosin activity in all striated muscle types, but in smooth muscle, they activate myosin by interacting with a regulatory molecule called **calmodulin,** a cytoplasmic calcium-binding protein. Calmodulin, in turn, interacts with a kinase enzyme called **myosin kinase** or **myosin light chain kinase** which phosphorylates the myosin heads. The thin filaments lack troponin and so are always ready for contraction. The sequence of events that occurs is depicted in Figure 9.27. [Note that this is just one mechanism of smooth muscle activation. There are others. For example, in some smooth muscles, regulatory proteins associated with actin (caldesmon and others) appear to play a role as well.]

As in skeletal muscle, smooth muscle relaxes when intracellular Ca^{2+} levels drop, but getting smooth muscle to cease its contractile activity is quite a bit more complex in smooth muscle. Events known to be involved include calcium detachment from calmodulin, active transport of Ca^{2+} into the SR and the extracellular fluid, and dephosphorylation of the myosin heads by a phosphorylase enzyme, which reduces the activity of the myosin ATPases.

Smooth muscle takes 30 times longer to contract and relax than does skeletal muscle and can maintain the same contractile tension for prolonged periods at less than 1% of the energy cost. If skeletal muscle is like a speedy windup car that quickly runs down, then smooth muscle is like a steady, heavy-duty engine that lumbers along tirelessly. Part of the striking energy economy of smooth muscle is the sluggishness of its ATPases compared to those in skeletal muscle. Moreover, smooth muscle myofilaments may latch together during prolonged contractions, saving energy in that way as well. Smooth muscle cells may maintain that *latch state* even after dephosphorylation of the myosin heads.

The ATP-efficient contraction of smooth muscle is extremely important to overall body homeostasis. The smooth muscle in small arterioles and other visceral organs routinely maintains a moderate degree of contraction, called *smooth muscle tone,* day in and day out without fatiguing. Smooth muscle has low energy requirements. Typically, enough ATP is made via aerobic pathways to keep up with the demand.

Regulation of Contraction

Neural Regulation In some cases, the activation of smooth muscle by a neural stimulus is identical to that in skeletal muscle: An action potential is generated by neurotransmitter binding, and is coupled to a rise in calcium ions in the sarcoplasm. However, some types of smooth muscle respond to neural stimulation with graded potentials (local electrical signals) only.

All somatic nerve endings, that is, nerve endings that serve skeletal muscle, release acetylcholine, which excites the skeletal muscle. However, different autonomic nerves serving the smooth muscle of visceral organs release different neurotransmitters, each of which may excite or inhibit a particular group of smooth muscle cells. The effect of a specific neurotransmitter on a given smooth muscle cell depends on the type of receptor molecules on its sarcolemma. For example, when acetylcholine binds to ACh receptors on smooth muscle in the bronchioles (small air passageways of the lungs), the muscle contracts strongly, narrowing the bronchioles. When norepinephrine, released by a different type of autonomic nerve fiber, binds to norepinephrine receptors on the *same* smooth muscle cells, the effect is inhibitory; the muscle relaxes, dilating the air passageways. However, when norepinephrine binds to smooth muscle in the walls of most blood vessels, it stimulates the smooth muscle cells to contract and constrict the vessel.

Hormones and Local Factors Not all smooth muscle activation results from neural signals. Some smooth muscle layers have no nerve supply at all; instead they depolarize spontaneously or in response to chemical stimuli that bind to G protein–linked receptors. Others respond to both neural and chemical stimuli. Chemical factors that cause smooth muscle contraction or relaxation without an action potential (by enhancing or inhibiting Ca^{2+} entry into the sarcoplasm) include certain hormones, lack of oxygen, histamine, excess carbon dioxide, and low pH. The direct response to these chemical stimuli alters smooth muscle activity according to local tissue needs and probably is most responsible for smooth muscle tone. For example, the hormone gastrin stimulates contraction of stomach smooth muscle so that it can churn foodstuffs more efficiently. We will consider how the smooth muscle of specific organs is activated as we discuss each organ in subsequent chapters.

Special Features of Smooth Muscle Contraction

Smooth muscle is intimately involved in the functioning of most hollow organs and has a number of unique characteristics. Some of these—smooth muscle tone; slow, prolonged contractile activity; and low energy requirements—have already been considered. But smooth muscle also responds differently to stretch and can shorten more than other muscle types. Let's take a look.

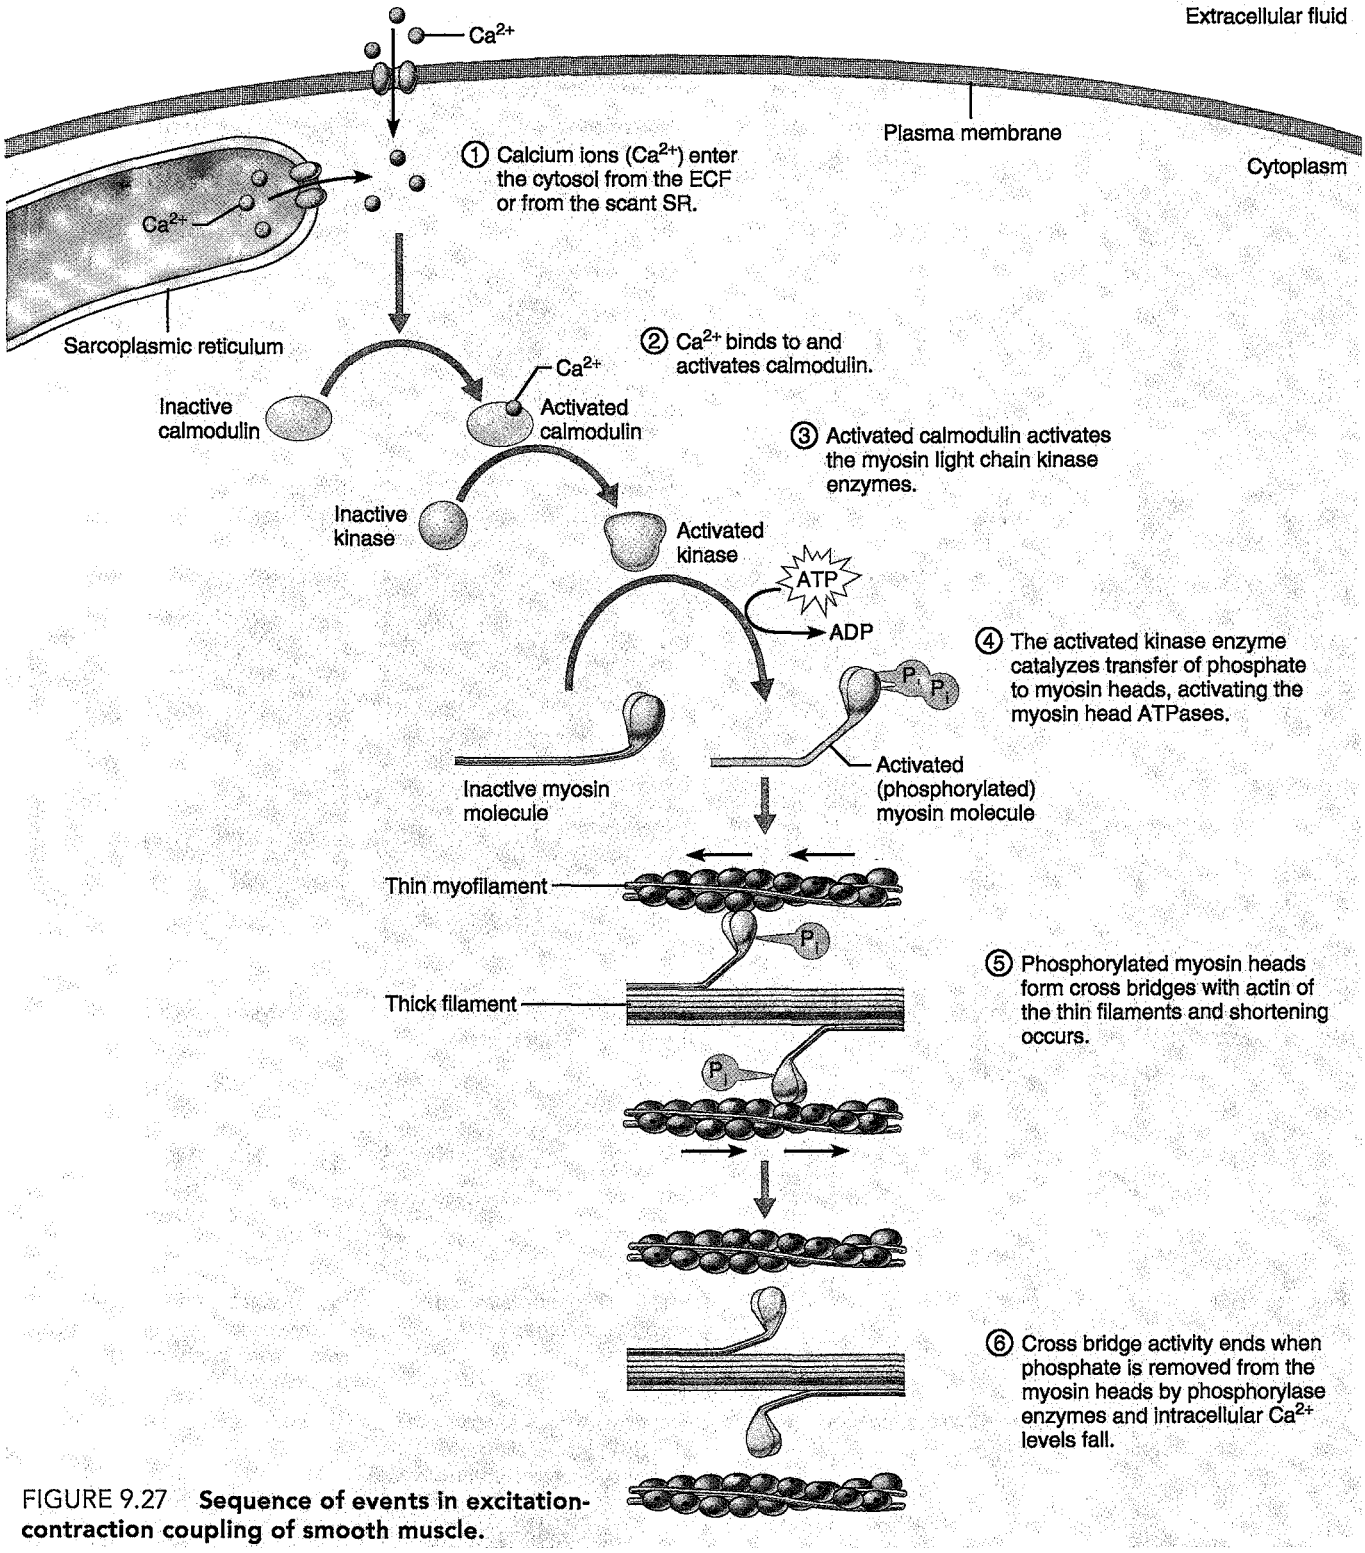


FIGURE 9.27 **Sequence of events in excitation-contraction coupling of smooth muscle.**

Response to Stretch When cardiac muscle is stretched, it responds with more vigorous contractions. So does skeletal muscle up to a point (about 120% of resting length). Stretching of smooth muscle also provokes contraction, which automatically moves substances along an internal tract. However, the increased tension persists only briefly; soon the muscle adapts to its new length and relaxes, while still retaining the ability to contract on demand. This **stress-relaxation response** allows a hollow organ to fill or expand slowly (within certain limits) to accommodate a greater volume without promoting

(Text continues on p. 316.)

TABLE 9.3 Comparison of Skeletal, Cardiac, and Smooth Muscle

CHARACTERISTIC	SKELETAL	CARDIAC	SMOOTH
Body location	Attached to bones or (some facial muscles) to skin 	Walls of the heart 	Single-unit muscle in walls of hollow visceral organs (other than the heart); multiunit muscle in intrinsic eye muscles, airways, large arteries Cell shape and appearance	Single, very long, cylindrical, multinucleate cells with obvious striations 	Branching chains of cells; uni- or binucleate; striations 	Single, fusiform, uninucleate; no striations Connective tissue components	Epimysium, perimysium, and endomysium 	Endomysium attached to fibrous skeleton of heart 	Endomysium Presence of myofibrils composed of sarcomeres	Yes	Yes, but myofibrils are of irregular thickness	No, but actin and myosin filaments are present throughout; dense bodies anchor actin filaments
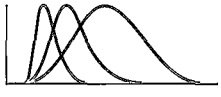
Presence of T tubules and site of invagination	Yes; two in each sarcomere at A-I junctions 	Yes; one in each sarcomere at Z disc; larger diameter than those of skeletal muscle 	No; only caveolae
Elaborate sarcoplasmic reticulum	Yes	Less than skeletal muscle (1–8% of cell volume); scant terminal cisternae	Equivalent to cardiac muscle (1–8% of cell volume); some SR contacts the sarcolemma

TABLE 9.3 *(continued)*

CHARACTERISTIC	SKELETAL	CARDIAC	SMOOTH
Presence of gap junctions	No	Yes; at intercalated discs	Yes; in single-unit muscle
Cells exhibit individual neuromuscular junctions	Yes	No	Not in single-unit muscle; yes in multiunit muscle
			Regulation of contraction	Voluntary via axon terminals of the somatic nervous system	Involuntary; intrinsic system regulation; also autonomic nervous system controls; hormones; stretch	Involuntary; autonomic nerves, hormones, local chemicals; stretch
			Source of Ca^{2+} for calcium pulse	Sarcoplasmic reticulum (SR)	SR and from extracellular fluid	SR and from extracellular fluid
Site of calcium regulation	Troponin on actin-containing thin filaments	Troponin on actin-containing thin filaments	Calmodulin in the sarcoplasm
			Presence of pacemaker(s)	No	Yes	Yes (in single-unit muscle only)
Effect of nervous system stimulation	Excitation	Excitation or inhibition	Excitation or inhibition
Speed of contraction	Slow to fast	Slow	Very slow
			


Rhythmic contraction	No	Yes	Yes in single-unit muscle
Response to stretch	Contractile strength increases with degree of stretch (to a point)	Contractile strength increases with degree of stretch	Stress-relaxation response
Respiration	Aerobic and anaerobic	Aerobic	Mainly aerobic

strong contractions that would expel its contents. This is an important attribute, because organs such as the stomach and intestines must be able to store their contents temporarily to provide sufficient time for digestion and absorption of the nutrients. Likewise, your urinary bladder must be able to store the continuously made urine until it is convenient to empty your bladder, or you would spend all your time in the bathroom.

Length and Tension Changes Smooth muscle stretches much more than skeletal muscle and generates more tension than skeletal muscles stretched to a comparable extent. As Figure 9.22c shows, precise, highly organized sarcomeres limit how far a skeletal muscle can be stretched before it is unable to generate force. In contrast, the lack of sarcomeres and the irregular, overlapping arrangement of smooth muscle filaments allow them to generate considerable force, even when they are substantially stretched. The total length change that skeletal muscles can undergo and still function efficiently is about 60% (from 30% shorter to 30% longer than resting length), but smooth muscle can contract when it is anywhere from twice to half its resting length—a total length change of 150%. This allows hollow organs to tolerate tremendous changes in volume without becoming flabby when they empty.

Hyperplasia Besides the ability to hypertrophy (increase in cell size), which is common to all muscle cells, certain smooth muscle fibers can divide to increase their numbers, that is, they undergo *hyperplasia* (hi"per-pla'ze-ah). One example is the response of the uterus to estrogen. At puberty, girls' plasma estrogen levels rise. As estrogen binds to uterine smooth muscle receptors, it stimulates the synthesis of more uterine smooth muscle, causing the uterus to grow to adult size. During pregnancy, high blood levels of estrogen stimulate uterine hyperplasia to accommodate the growing fetus.

Types of Smooth Muscle

The smooth muscle in different body organs varies substantially in its (1) fiber arrangement and organization, (2) responsiveness to various stimuli, and (3) innervation. For simplicity, however, smooth muscle is usually categorized into two major types: *single-unit* and *multiunit*.

Single-Unit Smooth Muscle

Single-unit smooth muscle, commonly called **visceral muscle** because it is in the walls of all hollow organs except the heart, is far more common. Its cells (1) contract rhythmically and as a unit, (2) are electrically coupled to one another by *gap junctions*, and (3) often exhibit spontaneous action potentials. All the smooth muscle characteristics described so far pertain to single-unit smooth muscle. Thus, the cells of single-unit smooth muscle are arranged in opposing sheets, exhibit the stress-relaxation response, and so on.

In single-unit smooth muscle, contractile force is related to the amount of calcium that enters the cells during excitation-contraction coupling. Because the cells are united by gap junctions, the number of muscle fibers activated is not variable. Thus, recruitment is not an option in this type of smooth muscle.

Multiunit Smooth Muscle

The smooth muscles in the large airways to the lungs and in large arteries, the arrector pili muscles attached to hair follicles, and the internal eye muscles that adjust pupil size and allow the eye to focus visually are all examples of **multiunit smooth muscle.**

In contrast to what we see in single-unit muscle, gap junctions are rare, and spontaneous synchronous depolarizations are infrequent. Like skeletal muscle, multiunit smooth muscle

1. Consists of muscle fibers that are structurally independent of one another
2. Is richly supplied with nerve endings, each of which forms a motor unit with a number of muscle fibers
3. Responds to neural stimulation with graded contractions that involve recruitment

However, while skeletal muscle is served by the somatic (voluntary) division of the nervous system, multiunit smooth muscle (like single-unit smooth muscle) is innervated by the autonomic (involuntary) division and is also responsive to hormonal controls.

Developmental Aspects of Muscles

With rare exceptions, all muscle tissues develop from embryonic mesoderm cells called **myoblasts.** Multinucleate skeletal muscle fibers form by the fusion of several myoblasts to form multinuclear *myotubes*, a process guided by the integrins (cell adhesion proteins) forming part of the myoblast membranes. Soon functional sarcomeres are present, and skeletal muscle fibers are contracting by week 7 when the embryo is only about 1 inch long. Initially, ACh receptors "sprout" over the entire surface of the developing myoblasts. As spinal nerves invade the muscle masses, the nerve endings target individual myoblasts and release the growth factor *agrin*, which stimulates

clustering and maintenance of ACh receptors at the newly forming motor end plate in each muscle fiber. Then, the nerve endings provide an independent chemical signal that disperses the receptor sites not innervated and stabilized by agrin. Electrical activity in the neurons serving the muscle fibers also plays a critical role in muscle fiber maturation. As the muscle fibers are brought under the control of the somatic nervous system, the number of fast and slow contractile fiber types is determined.

Myoblasts producing cardiac and smooth muscle cells do not fuse. However, both develop gap junctions at a very early embryonic stage. Cardiac muscle is pumping blood just 3 weeks after fertilization.

Specialized skeletal and cardiac muscle cells become amitotic early on but retain the ability to lengthen and thicken in a growing child and to hypertrophy in adults. However, *satellite cells*, myoblast-like cells associated with skeletal muscle, help repair injured fibers and allow *very limited* regeneration of dead skeletal muscle fibers. Cardiac muscle was thought to have no regenerative capability whatsoever, but recent studies suggest that cardiac cells do divide at a modest rate. Nonetheless, injured heart muscle is repaired mostly by scar tissue. Smooth muscles have a good ability to regenerate throughout life.

At birth, a baby's movements are uncoordinated and largely reflexive. Muscular development reflects the level of neuromuscular coordination, which develops in a head-to-toe and proximal-to-distal direction. In other words, a baby can lift its head before it can walk, and gross movements precede fine ones. All through childhood, our control of our skeletal muscles becomes more and more sophisticated. By midadolescence, we reach the peak of our *natural* neural control of muscles, and can either accept that level of development or improve it by athletic or other types of training.

A frequently asked question is whether the difference in strength between women and men has a biological basis. It does. Individuals vary, but on average, women's skeletal muscles make up approximately 36% of body mass, whereas men's account for about 42%. Men's greater muscular development is due primarily to the effects of testosterone on skeletal muscle, not to the effects of exercise. Body strength per unit muscle mass, however, is the same in both sexes. Strenuous muscle exercise causes more muscle enlargement in males than in females, again because of the influence of testosterone. Some athletes take large doses of synthetic male sex hormones ("steroids") to increase their muscle mass. This illegal and physiologically dangerous practice is discussed in *A Closer Look* (p. 308).

Because of its rich blood supply, skeletal muscle is amazingly resistant to infection throughout life and, given good nutrition and moderate exercise, relatively few problems afflict skeletal muscles. However, muscular dystrophy, the world's most common genetic disorder, is a serious condition that deserves more than a passing mention.

HOMEOSTATIC IMBALANCE

The term **muscular dystrophy** refers to a group of inherited muscle-destroying diseases that generally appear during childhood. The affected muscles initially enlarge due to fat and connective tissue deposit, but the muscle fibers atrophy and degenerate.

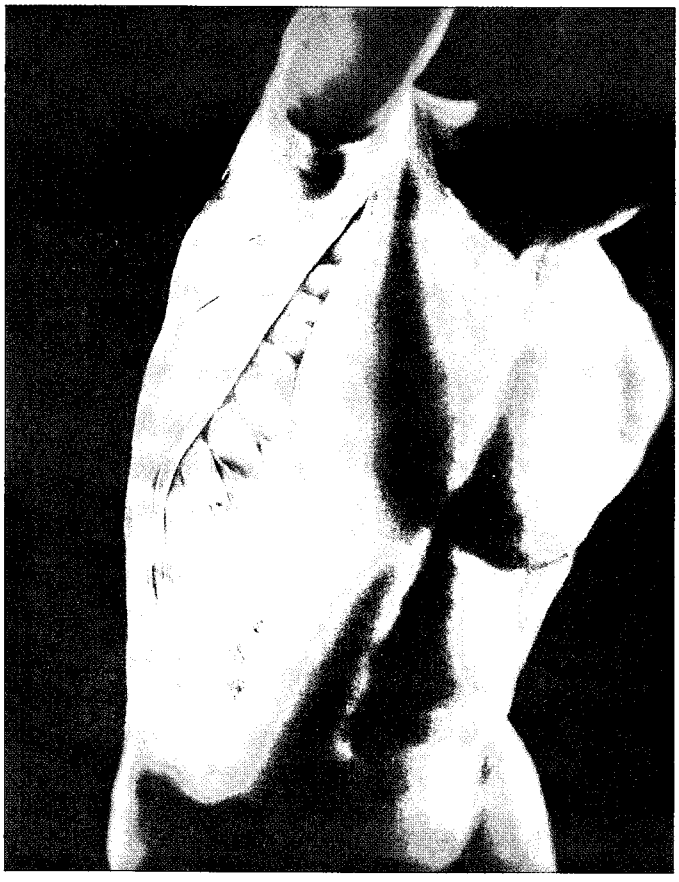
The most common and serious form is **Duchenne muscular dystrophy (DMD)**, which is inherited as a sex-linked recessive disease: Females carry and transmit the abnormal gene, but it is expressed almost exclusively in males (one in every 3500 births). This tragic disease is usually diagnosed when the boy is between 2 and 7 years old. Active, normal-appearing children become clumsy and fall frequently as their skeletal muscles weaken. The disease progresses relentlessly from the extremities upward, finally affecting the head and chest muscles and cardiac muscle of the heart. Victims rarely live beyond their early 20s, dying of respiratory failure.

Recent research has pinned down the cause of DMD: The diseased muscle fibers lack *dystrophin*, a cytoplasmic protein that links the cytoskeleton to the extracellular matrix and, like a girder, helps stabilize the sarcolemma. The fragile sarcolemma of DMD patients tears during contraction allowing entry of excess Ca^{2+}. The deranged calcium homeostasis damages the contractile fibers which then breakdown, and inflammatory cells (macrophages and lymphocytes) accumulate in the surrounding connective tissue. As the regenerative capacity of the muscle is lost, and damaged cells undergo apoptosis, muscle mass drops.

There is still no cure for DMD, and thus far the only medication that has improved muscle strength and function is the steroid prednisone. One initially promising technique, *myoblast transfer therapy*, involves injecting diseased muscle with healthy myoblast cells that fuse with the unhealthy ones. The idea is that the normal gene provided would allow the fiber to produce dystrophin and so to grow normally. The therapy has shown some success in mice but human trials have been disappointing. The large size of the dystrophin gene and of human muscles presents a huge challenge to that therapy. On the other hand, injection of adeno-associated viruses carrying pared-down microdystrophin genes has produced a striking reversal of disease symptoms in dystrophic mice. A different approach being tested is coaxing dystrophic muscles to produce more *utrophin*, a similar protein present in low amounts in adults but at much higher levels in fetal muscles. In mice at least, utrophin can compensate for dystrophin deficiency.

MAKING CONNECTIONS

SYSTEM CONNECTIONS: Homeostatic Interrelationships Between the Muscular System and Other Body Systems



Integumentary System

- Muscular exercise enhances circulation to skin and improves skin health
- Skin protects the muscles by external enclosure; helps dissipate heat generated by the muscles

Skeletal System

- Skeletal muscle activity maintains bone health and strength
- Bones provide levers for muscle activity

Nervous System

- Facial muscle activity allows emotions to be expressed
- Nervous system stimulates and regulates muscle activity

Endocrine System

- Growth hormone and androgens influence skeletal muscle strength and mass; other hormones help regulate cardiac and smooth muscle activity

Cardiovascular System

- Skeletal muscle activity increases efficiency of cardiovascular functioning; helps prevent atherosclerosis and causes cardiac hypertrophy
- Cardiovascular system delivers needed oxygen and nutrients to muscles

Lymphatic System/Immunity

- Physical exercise may enhance or depress immunity depending on its intensity
- Lymphatic vessels drain leaked tissue fluids; immune system protects muscles from disease

Respiratory System

- Muscular exercise increases respiratory capacity and efficiency of gas exchange
- Respiratory system provides oxygen and disposes of carbon dioxide

Digestive System

- Physical activity increases gastrointestinal motility and elimination when at rest
- Digestive system provides nutrients needed for muscle health; liver metabolizes lactic acid

Urinary System

- Physical activity promotes normal voiding behavior; skeletal muscle forms the voluntary sphincter of the urethra
- Urinary system disposes of nitrogenous wastes

Reproductive System

- Skeletal muscle helps support pelvic organs (e.g., uterus); assists erection of penis and clitoris
- Testicular androgen promotes increased skeletal muscle

As we age, the amount of connective tissue in our skeletal muscles increases, the number of muscle fibers decreases, and the muscles become stringier, or more sinewy. By the age of 30 even in healthy people, a gradual loss of muscle mass, called *sarcopenia* (sar-co-pe'ne-ah), begins to occur as muscle proteins start to degrade more rapidly than they can be replaced. Just why this happens is still a question, but apparently the same regulatory molecules (transcription factors, enzymes, hormones, and others) that promote muscle growth also oversee this type of muscle atrophy. Because skeletal muscles form so much of the body mass, body weight and muscle strength decline in tandem.

CLOSER CONNECTIONS

THE MUSCULAR SYSTEM and Interrelationships with the Cardiovascular, Endocrine, Lymphatic/Immunity, and Skeletal Systems

Our skeletal muscles are a marvel. In the well conditioned, they ripple with energy. In those of us who are less athletic, they enable us to perform the rather remarkable tasks of moving and getting around. No one would argue that the nervous system is indispensable for activating muscles to contract and for keeping them healthy via tone. Let's look at how skeletal muscle activity affects other body systems from the vantage point of overall health and disease prevention.

Cardiovascular System

The single most important barometer of how "well" we age is the health of our cardiovascular system. More than any other factor, regular exercise helps to maintain that health. Anything that gets you huffing and puffing on a regular basis, be it racquetball or a vigorous walk, helps to keep heart muscle healthy and strong. It also keeps blood vessels clear, delaying atherosclerosis and helping to prevent the most common type of high blood pressure and hypertensive heart disease—ailments that can lead to the deterioration of heart muscle and the kidneys. Uncluttered blood vessels also stave off painful or disabling intermittent claudication in which muscle pain due to ischemia hinders walking. Furthermore, regular exercise boosts blood levels of clot-busting enzymes, helping to ward off heart attacks and strokes, other scourges of old age.

Endocrine System

Muscle has a high rate of metabolism, and even at rest it uses much more energy than does fat. Consequently, exercise that builds moderate muscle mass helps to keep weight down and prevents obesity. Obesity is one of the risk factors for development of age-related diabetes mellitus—the metabolic disorder in which body cells are unresponsive to insulin (secreted by the pancreas) and, hence, unable to utilize glucose normally. Additionally, exercise helps to maintain normal cellular responses to insulin. On the other side of the coin, several hormones, including growth hormone, thyroid hormone, and sex hormones, are essential for normal development and maturation of the skeletal muscles.

Lymphatic System/Immunity

Physical exercise has a marked effect on immunity. Moderate or mild exercise causes a temporary rise in the number of phagocytes, T cells (a particular group of white blood cells), and antibodies, all of which populate lymphatic organs and mount the attack against infectious disease. By contrast, strenuous exercise depresses the immune system. The way in which exercise affects immunity—including these seemingly contradictory observations—is still a mystery, but the so-called stress hormones are definitely involved. Like major stressors such as surgery and serious burns, strenuous exercise increases blood levels of stress hormones such as epinephrine and glucocorticoids. These hormones depress the immune system during severe stress. This is thought to be a protective mechanism—a way of preventing large numbers of slightly damaged cells from being rejected.

Skeletal System

Last but not least, weight-bearing exercise of the skeletal muscles promotes skeletal strength and helps prevent osteoporosis. Since osteoporosis severely detracts from the quality of life by increasing risk of fractures, this is an extremely important interaction. But without their bony attachments, muscles would be ineffective in causing body movement.

CLINICAL CONNECTIONS

Muscular System

Case study: Let's continue our tale of Mrs. DeStephano's medical problems, this time looking at the notes made detailing observations of her skeletal musculature.

- Severe lacerations of the muscles of the right leg and knee
- Damage to the blood vessels serving the right leg and knee
- Transection of the sciatic nerve (the large nerve serving most of the lower limb), just above the right knee

Her physician orders daily passive range-of-motion (ROM) exercise and electrical stimulation for her right leg and a diet high in protein, carbohydrates, and vitamin C.

1. Describe the step-by-step process of wound healing that will occur in her fleshy (muscle) wounds, and note the consequences of the specific restorative process that occurs.
2. What complications in healing can be anticipated owing to vascular (blood vessel) damage in the right leg?
3. What complications in muscle structure and function result from transection of the sciatic nerve? Why are passive ROM and electrical stimulation of her right leg muscles ordered?
4. Explain the reasoning behind the dietary recommendations.

(Answers in Appendix G)

Muscle strength has usually decreased by about 50% by the age of 80 years. This "flesh wasting" condition has serious health implications for the elderly, particularly because falling becomes a common event. But we don't have to slow up during old age; muscle is responsive to exercise throughout life. Regular exercise helps reverse sarcopenia, and frail elders who begin to "pump iron" (lift leg and hand weights) can rebuild muscle mass and dramatically increase their strength. Performing those lifting exercises rapidly can improve one's ability to carry out the "explosive" movements needed to rise from a chair or catch one's balance. Even moderate activity, like taking a walk daily, results in improved neuromuscular functioning and enhances independent living.

Muscles can also suffer indirectly. Aging of the cardiovascular system affects nearly every organ in the body, and muscles are no exception. As atherosclerosis takes its toll and begins to block distal arteries, a circulatory condition called *intermittent claudication* (klaw"dĭ-ka'shun; "limping") occurs in some individuals. This condition restricts blood delivery to the legs, leading to excruciating pains in the leg muscles during walking, which forces the person to stop and rest to get relief.

Smooth muscle is remarkably trouble free. The few problems that impair its functioning stem from external irritants. In the gastrointestinal tract, irritation might result from ingestion of excess alcohol, spicy foods, or bacterial infection. Under such conditions, smooth muscle motility increases in an attempt to rid the body of irritating agents, and diarrhea or vomiting occurs.

■ ■ ■

The capacity for movement is a property of all cells but, with the exception of muscle, these movements are largely restricted to intracellular events. Skeletal muscles, the major focus of this chapter, permit us to interact with our external environment in an amazing number of ways, and they also contribute to our internal homeostasis as summarized in *Making Connections* (pp. 318–319). In this chapter we have covered muscle anatomy from the gross level to the molecular level and have considered muscle physiology in some detail. Chapter 10 continues from this point to explain how muscles interact with bones and with each other, and then describes the individual skeletal muscles that make up the muscular system of the body.

Related Clinical Terms

Fibromyositis (*fibro* = fiber; *itis* = inflammation) Also known as **fibromyalgia,** a group of conditions involving chronic inflammation of a muscle, its connective tissue coverings and tendons, and capsules of nearby joints. Symptoms are nonspecific and involve varying degrees of tenderness associated with specific trigger points, as well as fatigue and frequent awakening from sleep.

Hernia Protrusion of an organ through its body cavity wall; may be congenital (owing to failure of muscle fusion during development), but most often is caused by heavy lifting or obesity and subsequent muscle weakening.

Myalgia (mi-al'je-ah; *algia* = pain) Muscle pain resulting from any muscle disorder.

Myofascial pain syndrome Pain caused by a tightened band of muscle fibers, which twitch when the skin over them is touched. Mostly associated with overused or strained postural muscles.

Myopathy (mi-op'ah-the; *path* = disease, suffering) Any disease of muscle.

Myotonic dystrophy A form of muscular dystrophy that is less common than DMD; in the U.S. it affects about 14 of 100,000 people. Symptoms include a gradual reduction in muscle mass and control of the skeletal muscles, abnormal heart rhythm, and diabetes mellitus. May appear at any time; not sex-linked. Underlying genetic defect is multiple repeats of a particular gene on chromosome 19. Because the number of repeats tends to increase from generation to generation, subsequent generations develop more severe symptoms. No effective treatment.

RICE Acronym for *rest, ice, compression,* and *elevation,* the standard treatment for a pulled muscle, or excessively stretched tendons or ligaments.

Spasm A sudden, involuntary twitch in smooth or skeletal muscle ranging in severity from merely irritating to very painful; may be due to chemical imbalances. In spasms of the eyelid or facial muscles, called tics, psychological factors have been implicated. Stretching and massaging the affected area may help to end the spasm. A cramp is a prolonged spasm; usually occurs at night or after exercise.

Strain Commonly called a "pulled muscle," a strain is excessive stretching and possible tearing of a muscle due to muscle overuse or abuse; the injured muscle becomes painfully inflamed (myositis), and adjacent joints are usually immobilized.

Tetanus (1) A state of sustained contraction of a muscle that is a normal aspect of skeletal muscle functioning. (2) An acute infectious disease caused by the anaerobic bacterium *Clostridium tetani* and resulting in persistent painful spasms of some of the skeletal muscles. Progresses to fixed rigidity of the jaws (lockjaw) and spasms of trunk and limb muscles; usually fatal due to respiratory failure.

Chapter Summary

Media study tools that could provide you additional help in reviewing specific key topics of Chapter 9 are referenced below.
IP = *InterActive Physiology*

Overview of Muscle Tissues (pp. 280–281)

Types of Muscle Tissue (p. 280)

1. Skeletal muscle is attached to the skeleton, is striated, and can be controlled voluntarily.

2. Cardiac muscle forms the heart, is striated, and is controlled involuntarily.

3. Smooth muscle, located chiefly in the walls of hollow organs, is controlled involuntarily. Its fibers are not striated.

Functional Characteristics of Muscle Tissue (p. 280)

4. Special functional characteristics of muscle include excitability, contractility, extensibility, and elasticity.

Muscle Functions (pp. 280–281)

5. Muscles move internal and external body parts, maintain posture, stabilize joints, generate heat, and protect some visceral organs.

Skeletal Muscle (pp. 281–309)

Gross Anatomy of a Skeletal Muscle (pp. 281–284)

1. Skeletal muscle fibers (cells) are protected and strengthened by connective tissue coverings. Deep to superficial, these are endomysium, perimysium, and epimysium.

2. Skeletal muscle attachments (origins/insertions) may be direct or indirect via tendons or aponeuroses. Indirect attachments withstand friction better.

Microscopic Anatomy of a Skeletal Muscle Fiber (pp. 284–287)

3. Skeletal muscle fibers are long, striated, and multinucleate.

4. Myofibrils are contractile elements that occupy most of the cell volume. Their banded appearance results from a regular alternation of dark (A) and light (I) bands. Myofibrils are chains of sarcomeres; each sarcomere contains thick (myosin) and thin (actin) myofilaments arranged in a regular array. The heads of myosin molecules form cross bridges that interact with the thin filaments.

5. The sarcoplasmic reticulum (SR) is a system of membranous tubules surrounding each myofibril. Its function is to release and then sequester calcium ions.

6. T tubules are invaginations of the sarcolemma that run between the terminal cisternae of the SR. They allow the electrical stimulus to be delivered quickly to deep cell regions.

Sliding Filament Model of Contraction (pp. 287–288)

7. According to the sliding filament theory, the thin filaments are pulled toward the sarcomere centers by cross bridge (myosin head) activity of the thick filaments.

Physiology of a Skeletal Muscle Fiber (pp. 288–294)

8. Regulation of skeletal muscle cell contraction involves (a) generation and transmission of an action potential along the sarcolemma and (b) excitation-contraction coupling.

9. An end plate potential is set up when acetylcholine released by a nerve ending binds to ACh receptors on the sarcolemma, causing changes in membrane permeability which allow ion flows that depolarize the membrane at the motor end plate. Once initiated, the action potential is self-propagating and unstoppable.

10. Current flows from the motor end plate depolarize the adjacent area of the sarcolemma, opening voltage-gated Na^+ channels which allow Na^+ influx. Then Na^+ channels close and K^+ voltage-gated channels open, repolarizing the membrane. These events generate the action potential.

11. In excitation-contraction coupling, the action potential is propagated down the T tubules, causing calcium to be released from the SR into the cell interior.

12. Sliding of the filaments is triggered by a rise in intracellular calcium ion levels. Troponin binding of calcium moves tropomyosin away from myosin binding sites on actin, allowing cross bridge binding. Myosin ATPases split ATP, which energizes the power strokes and is necessary for cross bridge detachment. Cross bridge activity ends when calcium is pumped back into the SR.

IP Muscular System; Topic: Sliding Filament Theory, pp. 18–29.

Contraction of a Skeletal Muscle (pp. 295–300)

13. A motor unit is one motor neuron and all the muscle cells it innervates. The neuron's axon has several branches, each of which forms a neuromuscular junction with one muscle cell.

14. A motor unit's response to a single brief threshold stimulus is a twitch. A twitch has three phases: the latent period (preparatory events occurring), the period of contraction (the muscle tenses and may shorten), and the period of relaxation (muscle tension declines and the muscle resumes its resting length).

15. Graded responses of muscles to rapid stimuli are wave summation and unfused and fused tetanus. A graded response to increasingly strong stimuli is multiple motor unit summation or recruitment. The type and order of motor unit recruitment follows the size principle.

16. Isotonic contractions occur when the muscle shortens (concentric contraction) or lengthens (eccentric contraction) as the load is moved. Isometric contractions occur when muscle tension produces neither shortening nor lengthening.

IP Muscular System; Topic: Contraction of Motor Units, pp. 1–11.

Muscle Metabolism (pp. 300–304)

17. The energy source for muscle contraction is ATP, obtained from a coupled reaction of creatine phosphate with ADP and from aerobic and anaerobic metabolism of glucose.

18. When ATP is produced by nonaerobic pathways, lactic acid accumulates and ionic imbalances disturb the membrane potential; an oxygen debt occurs. To return the muscles to their resting state, ATP must be produced aerobically and used to regenerate creatine phosphate, glycogen reserves must be restored, and accumulated lactic acid must be oxidized.

19. Only about 40% of energy released during ATP hydrolysis powers contractile activity. The rest is liberated as heat.

IP Muscular System; Topic: Muscle Metabolism, pp. 1–7.

Force of Muscle Contraction (pp. 304–305)

20. The force of muscle contraction is affected by the number and size of contracting muscle cells (the more and the larger the cells, the greater the force), the frequency of stimulation, and the degree of muscle stretch.

21. In twitch contractions, the external tension exerted on the load is always less than the internal tension. When a muscle is tetanized, the external tension equals the internal tension.

22. When the thick and thin filaments are optimally overlapping, the muscle can generate maximum force. With excessive increase or decrease in muscle length, force declines.

Velocity and Duration of Contraction (pp. 305–307)

23. Factors determining the velocity and duration of muscle contraction include the load (the greater the load, the slower the contraction) and muscle fiber types.

24. There are three types of muscle fibers: (1) fast glycolytic (fatigable) fibers, (2) slow oxidative (fatigue-resistant) fibers, and (3) intermediate fast oxidative (fatigue-resistant) fibers. Most muscles contain a mixture of fiber types. The fast muscle fiber types are interconvertible with certain exercise regimens.

Effect of Exercise on Muscles (pp. 307–309)

25. Regular aerobic exercise results in increased efficiency, endurance, strength, and resistance to fatigue of skeletal muscles.

26. Resistance exercises cause skeletal muscle hypertrophy and large gains in skeletal muscle strength.

27. Immobilization of muscles leads to muscle weakness and severe atrophy.

28. Improper training and excessive exercise result in overuse injuries, which may be disabling.

Smooth Muscle (pp. 309–316)

Microscopic Structure of Smooth Muscle Fibers (pp. 309–311)

1. Smooth muscle fibers are spindle shaped and uninucleate; they display no striations.

2. Smooth muscle cells are most often arranged in sheets. They lack elaborate connective tissue coverings.

3. The SR is poorly developed; T tubules are absent. Actin and myosin filaments are present, but sarcomeres are not. Intermediate filaments and dense bodies form an intracellular network that harnesses the pull generated during cross bridge activity and transfers it to the extracellular matrix.

Contraction of Smooth Muscle (pp. 311–316)

4. Smooth muscle fibers may be electrically coupled by gap junctions, and the pace of contraction may be set by pacemaker cells.

5. Smooth muscle contraction is energized by ATP and is activated by a calcium pulse. However, calcium binds to calmodulin rather than to troponin (which is not present in smooth muscle fibers), and the myosin heads must be phosphorylated to become active in contraction.

6. Smooth muscle contracts for extended periods at low energy cost and without fatigue.

7. Neurotransmitters of the autonomic nervous system may inhibit or stimulate smooth muscle fibers. Smooth muscle contraction may also be initiated by pacemaker cells, hormones, or other local chemical factors that influence intracellular calcium levels, and by mechanical stretch.

8. Special features of smooth muscle contraction include the stress-relaxation response, the ability to generate large amounts of force when extensively stretched, and hyperplasia under certain conditions.

Types of Smooth Muscle (p. 316)

9. Single-unit smooth muscle has electrically coupled fibers that contract synchronously and often spontaneously.

10. Multiunit smooth muscle has independent, well-innervated fibers that lack gap junctions and pacemaker cells. Stimulation is via autonomic nerves (or hormones). Multiunit muscle contractions are rarely synchronous.

Developmental Aspects of Muscles (pp. 316–318, 320)

1. Muscle tissue develops from embryonic mesoderm cells called myoblasts. Skeletal muscle fibers are formed by the fusion of several myoblasts. Smooth and cardiac cells develop from single myoblasts and display gap junctions.

2. For the most part, specialized skeletal and cardiac muscle cells lose their ability to divide but retain the ability to hypertrophy. Smooth muscle regenerates well and undergoes hyperplasia.

3. Skeletal muscle development reflects maturation of the nervous system and occurs in cephalocaudal and proximal-to-distal directions. Peak development of natural neuromuscular control is achieved in midadolescence.

4. Women's muscles account for about 36% of their total body weight and men's for about 42%, a difference due chiefly to the effects of male hormones on skeletal muscle growth.

5. Skeletal muscle is richly vascularized and quite resistant to infection, but in old age, skeletal muscles become fibrous, decline in strength, and atrophy unless an appropriate exercise regimen is followed.

Review Questions

Multiple Choice/Matching

(Some questions have more than one correct answer. Select the best answer or answers from the choices given.)

1. The connective tissue covering that encloses the sarcolemma of an individual muscle fiber is called the (a) epimysium, (b) perimysium, (c) endomysium, (d) periosteum.

2. A fascicle is a (a) muscle, (b) bundle of muscle fibers enclosed by a connective tissue sheath, (c) bundle of myofibrils, (d) group of myofilaments.

3. Thick and thin myofilaments have different compositions. For each descriptive phrase, indicate whether the filament is (a) thick or (b) thin.

____ (1) contains actin
____ (2) contains ATPases
____ (3) attaches to the Z disc
____ (4) contains myosin
____ (5) contains troponin
____ (6) does not lie in the I band

4. The function of the T tubules in muscle contraction is to (a) make and store glycogen, (b) release Ca^{2+} into the cell interior and then pick it up again, (c) transmit the action potential deep into the muscle cells, (d) form proteins.

5. The sites where the motor nerve impulse is transmitted from the nerve endings to the skeletal muscle cell membranes are the (a) neuromuscular junctions, (b) sarcomeres, (c) myofilaments, (d) Z discs.

6. Contraction elicited by a single brief stimulus is called (a) a twitch, (b) wave summation, (c) multiple motor unit summation, (d) fused tetanus.

7. A smooth, sustained contraction resulting from very rapid stimulation of the muscle, in which no evidence of relaxation is seen, is called (a) a twitch, (b) wave summation, (c) multiple motor unit summation, (d) fused tetanus.

8. Characteristics of isometric contractions include all but (a) shortening, (b) increased muscle tension throughout the contraction phase, (c) absence of shortening, (d) use in resistance training.

9. During muscle contraction, ATP is provided by (a) a coupled reaction of creatine phosphate with ADP, (b) aerobic respiration of glucose, and (c) anaerobic glycolysis.

____ (1) Which provides ATP fastest?
____ (2) Which does (do) not require that oxygen be available?
____ (3) Which provides the highest yield of ATP per glucose molecule?
____ (4) Which results in the formation of lactic acid?
____ (5) Which has carbon dioxide and water products?
____ (6) Which is most important in endurance sports?

10. The neurotransmitter released by somatic motor neurons is (a) acetylcholine, (b) acetylcholinesterase, (c) norepinephrine.

11. The ions that enter the muscle cell during action potential generation are (a) calcium ions, (b) chloride ions, (c) sodium ions, (d) potassium ions.

12. Myoglobin has a special function in muscle tissue. It (a) breaks down glycogen, (b) is a contractile protein, (c) holds a reserve supply of oxygen in the muscle.

13. Aerobic exercise results in all of the following except (a) increased cardiovascular system efficiency, (b) more mitochondria in the muscle cells, (c) increased size and strength of existing muscle cells, (d) increased neuromuscular system coordination.

14. The smooth muscle type found in the walls of digestive and urinary system organs and that exhibits gap junctions and pacemaker cells is (a) multiunit, (b) single-unit.

Short Answer Essay Questions

15. Name and describe the four special functional characteristics of muscle that are the basis for muscle response.

16. Distinguish between (a) direct and indirect muscle attachments and (b) a tendon and an aponeurosis.

17. (a) Describe the structure of a sarcomere and indicate the relationship of the sarcomere to the myofilament. (b) Explain the sliding filament theory of contraction using appropriately labeled diagrams of a relaxed and a contracted sarcomere.

18. What is the importance of acetylcholinesterase in muscle cell contraction?

19. Explain how a slight (but smooth) contraction differs from a vigorous contraction of the same muscle; use the concepts of multiple motor unit summation.

20. Explain what is meant by the term excitation-contraction coupling.

21. Define motor unit.

22. Describe the three distinct types of skeletal muscle fibers.

23. True or false: Most muscles contain a predominance of one skeletal muscle fiber type. Explain the reasoning behind your choice.

24. Describe the cause(s) of muscle fatigue and define this term clearly.

25. Define oxygen debt.

26. Name four factors that influence contractile force and two that influence velocity and duration of contraction.

27. Smooth muscle has some unique properties, such as low energy usage, ability to maintain contraction over long periods, and the stress-relaxation response. Tie these properties to the function of smooth muscle in the body.

Critical Thinking and Clinical Application Questions

1. Diego was seriously out of shape the day he joined his friends for a game of touch football. While he was running pell-mell for the ball, his left calf began to hurt. He went to the clinic the next day and was told he had a strain. Diego insisted that this must be wrong, because his joints did not hurt. Clearly, Diego was confusing a *strain* with a *sprain*. Explain the difference.

2. Jim Fitch decided that his physique left much to be desired, so he joined a local health club and began to "pump iron" three times weekly. After three months of training, during which he was able to lift increasingly heavier weights, he noticed that his arm and chest muscles were substantially larger. Explain the structural and functional basis of these changes.

3. When a suicide victim was found, the coroner was unable to remove the drug vial clutched in his hand. Explain the reasons for this. If the victim had been discovered three days later, would the coroner have had the same difficulty? Explain.

4. Muscle-relaxing drugs are administered to a patient during major surgery. Which of the two chemicals described next would be a good skeletal muscle relaxant and why?
   - Chemical A binds to and blocks ACh receptors of muscle cells
   - Chemical B floods the muscle cells' cytoplasm with Ca^{2+}

5. When Eric returned from jogging, he was breathing heavily, sweating profusely, and complained that his legs ached and felt weak. His wife poured him a sports drink and urged him to take it easy until he could "catch his breath." On the basis of what you have learned about muscle energy metabolism, respond to the following questions.
   - Why is Eric breathing heavily?
   - What ATP harvesting pathway have his working muscles been using that leads to such a breathing pattern?
   - What metabolic product(s) might account for his sore muscles and his feeling of muscle weakness?

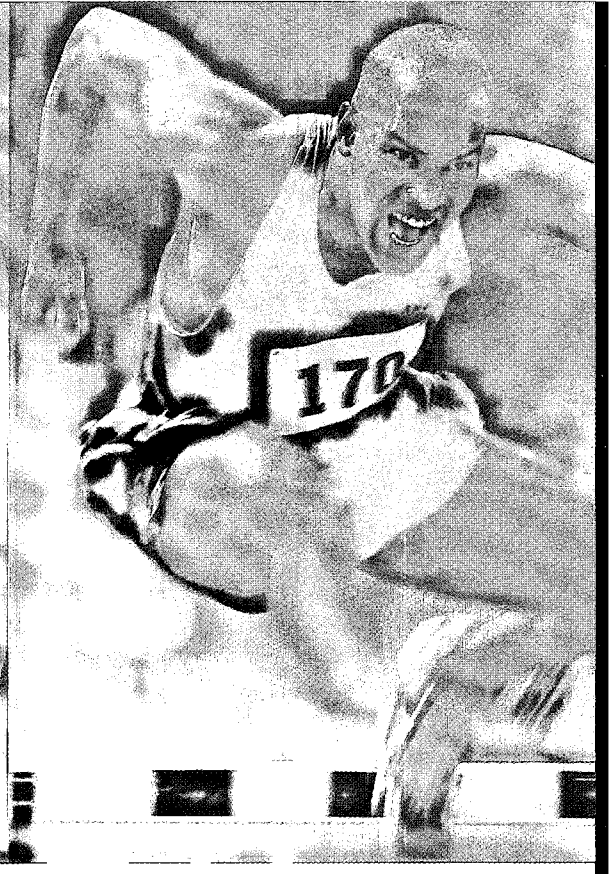
CHAPTER 10

The Muscular System



Interactions of Skeletal Muscles in the Body (p. 325)

1. Describe the function of prime movers, antagonists, synergists, and fixators.

Naming Skeletal Muscles (pp. 325–326)

2. List the criteria used in naming muscles. Provide an example to illustrate the use of each criterion.

Muscle Mechanics: Importance of Fascicle Arrangement and Leverage (pp. 326–330)

3. Name the common patterns of muscle fascicle arrangement and relate these to power generation.
4. Define lever, and explain how a lever operating at a mechanical advantage differs from one operating at a mechanical disadvantage.
5. Name the three types of lever systems and indicate the arrangement of effort, fulcrum, and load in each. Also note the advantages of each type of lever system.

Major Skeletal Muscles of the Body (pp. 330–383)

6. Name and identify the muscles described in Tables 10.1 to 10.17. State the origin, insertion, and action of each.

The human body enjoys an incredibly wide range of movements. The gentle blinking of your eye, standing on tiptoe, and wielding a sledgehammer are just a small sample of different activities promoted by the muscular system. Although muscle tissue includes all contractile tissues (skeletal, cardiac, and smooth muscle), when we study the muscular system, **skeletal muscles** take center stage. These muscular "machines" that enable us to perform so many different activities are the focus of this chapter. Before describing the individual muscles in detail, we will describe the manner in which muscles "play" with or against each other to bring about movements, consider the criteria used for naming muscles, and explain the principles of leverage.

Interactions of Skeletal Muscles in the Body

The arrangement of body muscles permits them to work either together or in opposition to achieve a wide variety of movements. As you eat, for example, you alternately raise your fork to your lips and lower it to your plate, and both sets of actions are accomplished by your arm and hand muscles. But muscles can only *pull;* they never *push.* Generally as a muscle shortens, its *insertion* (attachment on the movable bone) moves toward its *origin* (its fixed or immovable point of attachment). Thus, whatever one muscle or muscle group can do, there is another muscle or group of muscles that "undoes" the action.

Muscles can be classified into four *functional* groups: prime movers, antagonists, synergists, and fixators. A muscle that provides the major force for producing a specific movement is a **prime mover,** or **agonist** (ag'o-nist; "leader"), of that movement. The biceps brachii muscle, which fleshes out the anterior arm (and inserts on the radius), is a prime mover of elbow flexion.

Muscles that oppose, or reverse, a particular movement are called **antagonists** (an-tag'o-nists). When a prime mover is active, the antagonist muscles are often stretched and may be relaxed. Antagonists can also help to regulate the action of a prime mover by contracting to provide some resistance, thus helping to prevent overshoot or to slow or stop the movement. As you might expect, a prime mover and its antagonist are located on opposite sides of the joint across which they act. Antagonists can also be prime movers in their own right. For example, flexion of the forearm by the biceps brachii muscle of the arm is antagonized by the triceps brachii, the prime mover for extending the forearm.

In addition to agonists and antagonists, most movements involve the action of one or more **synergists** (sin'er-jists; *syn* = together, *erg* = work). Synergists help prime movers by (1) adding a little extra force to the same movement or (2) reducing undesirable or unnecessary movements that might occur as the prime mover contracts. This latter function deserves more explanation. When a muscle crosses two or more joints, its contraction causes movement at all of the spanned joints unless other muscles act as joint stabilizers. For example, the finger flexor muscles cross both the wrist and the phalangeal joints, but you can make a fist without bending your wrist because synergistic muscles stabilize the wrist. Additionally, as some flexors act, undesirable rotatory movements occur; synergists can prevent this, allowing all of the prime mover's force to be exerted in the desired direction.

When synergists immobilize a bone, or a muscle's origin, they are more specifically called **fixators** (fik'sa-terz). Recall from Chapter 7 that the scapula is held to the axial skeleton only by muscles and is quite freely movable. The fixator muscles that run from the axial skeleton to the scapula can immobilize the scapula so that only the desired movements occur at the mobile shoulder joint. Additionally, muscles that help to maintain upright posture are fixators.

In summary, although prime movers seem to get all the credit for causing certain movements, antagonistic and synergistic muscles are also important in producing smooth, coordinated, and precise movements. Furthermore, a muscle may act as a prime mover in one movement, an antagonist for another movement, a synergist for a third movement, and so on.

Naming Skeletal Muscles

Skeletal muscles are named according to a number of criteria, each of which describes the muscle in some way. Paying attention to these cues can simplify the task of learning muscle names and actions.

1. Location of the muscle. Some muscle names indicate the bone or body region with which the muscle is associated. For example, the temporalis (tem"porā'lis) muscle overlies the temporal bone, and intercostal (*costal* = rib) muscles run between the ribs.

2. Shape of the muscle. Some muscles are named for their distinctive shapes. For example, the deltoid (del'toid) muscle is roughly triangular (*deltoid* = triangle), and together the right and left trapezius (trah-pe'ze-us) muscles form a trapezoid.

3. Relative size of the muscle. Terms such as *maximus* (largest), *minimus* (smallest), *longus* (long), and *brevis* (short) are often used in muscle names—as in gluteus maximus and gluteus minimus (the large and small gluteus muscles, respectively).

4. Direction of muscle fibers. The names of some muscles reveal the direction in which their fibers (and

fascicles) run in reference to some imaginary line, usually the midline of the body or the longitudinal axis of a limb bone. In muscles with the term *rectus* (straight) in their names, the fibers run parallel to that imaginary line (axis), whereas the terms *transversus* and *oblique* indicate that the muscle fibers run respectively at right angles and obliquely to that line. Specific examples include the rectus femoris (straight muscle of the thigh, or femur) and transversus abdominis (transverse muscle of the abdomen).

5. Number of origins. When *biceps, triceps,* or *quadriceps* forms part of a muscle's name, you can assume that the muscle has two, three, or four origins, respectively. For example, the biceps brachii (bra'ke-i) muscle of the arm has two origins, or *heads.*

6. Location of the attachments. Some muscles are named according to their points of origin and insertion. The origin is always named first. For instance, the sternocleidomastoid (ster"no-kli"do-mas'toid) muscle of the neck has a dual origin on the sternum *(sterno)* and clavicle *(cleido),* and it inserts on the *mastoid* process of the temporal bone.

7. Action. When muscles are named for their action, action words such as *flexor, extensor,* or *adductor* appear in the muscle's name. For example, the adductor longus, located on the medial thigh, brings about thigh adduction, and the supinator (soo'pĭ-na"tor) muscle supinates the forearm.

Often, several criteria are combined in the naming of a muscle. For instance, the name *extensor carpi radialis longus* tells us the muscle's action (extensor), what joint it acts on (*carpi* = wrist), and that it lies close to the radius of the forearm (radialis); it also hints at its size (longus) relative to other wrist extensor muscles. Unfortunately, not all muscle names are this descriptive.

Muscle Mechanics: Importance of Fascicle Arrangement and Leverage

Most factors contributing to muscle force and speed (load, fiber type, etc.) have already been covered in Chapter 9 with two important exceptions—the patterns of fascicle arrangement in muscles and lever systems. These are attended to next.

Arrangement of Fascicles

All skeletal muscles consist of fascicles, but fascicle arrangements vary, resulting in muscles with different shapes and functional capabilities. The most common patterns of fascicle arrangement are parallel, pennate, convergent, and circular (Figure 10.1).

The fascicular pattern is **circular** when the fascicles are arranged in concentric rings (Figure 10.1a). Muscles with this arrangement surround external body openings, which they close by contracting. A general term for such muscles is *sphincters* ("squeezers"). Examples are the orbicularis muscles surrounding the eyes and the mouth.

A **convergent** muscle has a broad origin, and its fascicles *converge* toward a single tendon of insertion. Such a muscle is triangular or fan shaped like the pectoralis major muscle of the anterior thorax (Figure 10.1b).

In a **parallel** arrangement, the long axes of the fascicles run parallel to the long axis of the muscle. Such muscles are either *straplike* (Figure 10.1c), or spindle shaped with an expanded belly (midsection), like the biceps brachii muscle of the arm (Figure 10.1f). However, some authorities classify the spindle-shaped muscles into a separate class as **fusiform muscles.** This is the approach used here.

In a **pennate** (pen'āt) pattern, the fascicles are short and they attach obliquely (*penna* = feather) to a central tendon that runs the length of the muscle. If, as seen in the extensor digitorum muscle of the leg, the fascicles insert into only one side of the tendon, the muscle is *unipennate* (Figure 10.1d). If the fascicles insert into the tendon from opposite sides, so that the muscle's "grain" resembles a feather, the arrangement is *bipennate* (Figure 10.1g). The rectus femoris of the thigh is bipennate. A *multipennate* arrangement looks like many feathers situated side by side, with all their quills inserted into one large tendon. The deltoid muscle, which forms the roundness of the shoulder, is multipennate (Figure 10.1e).

The arrangement of a muscle's fascicles determines its range of motion and power. Because skeletal muscle fibers shorten to about 70% of their resting length when they contract, the longer and the more nearly parallel the muscle fibers are to a muscle's long axis, the more the muscle can shorten. Muscles with parallel fascicle arrangement shorten the most, but they are not usually very powerful. Muscle power depends more on the total number of muscle cells in the muscle; the greater the number, the greater the power. The stocky bipennate and multipennate muscles, which "pack in" the most fibers, shorten very little but are very powerful.

Lever Systems: Bone-Muscle Relationships

The operation of most skeletal muscles involves the use of leverage and **lever systems** (partnerships between the *muscular* and skeletal systems). A **lever** is a rigid bar that moves on a fixed point, or **fulcrum,** when a force is applied to it. The applied force, or **effort,** is used to move a resistance, or **load.** In your

Q *Of the muscles illustrated, which could shorten most? Which two would probably be most powerful? Why?*

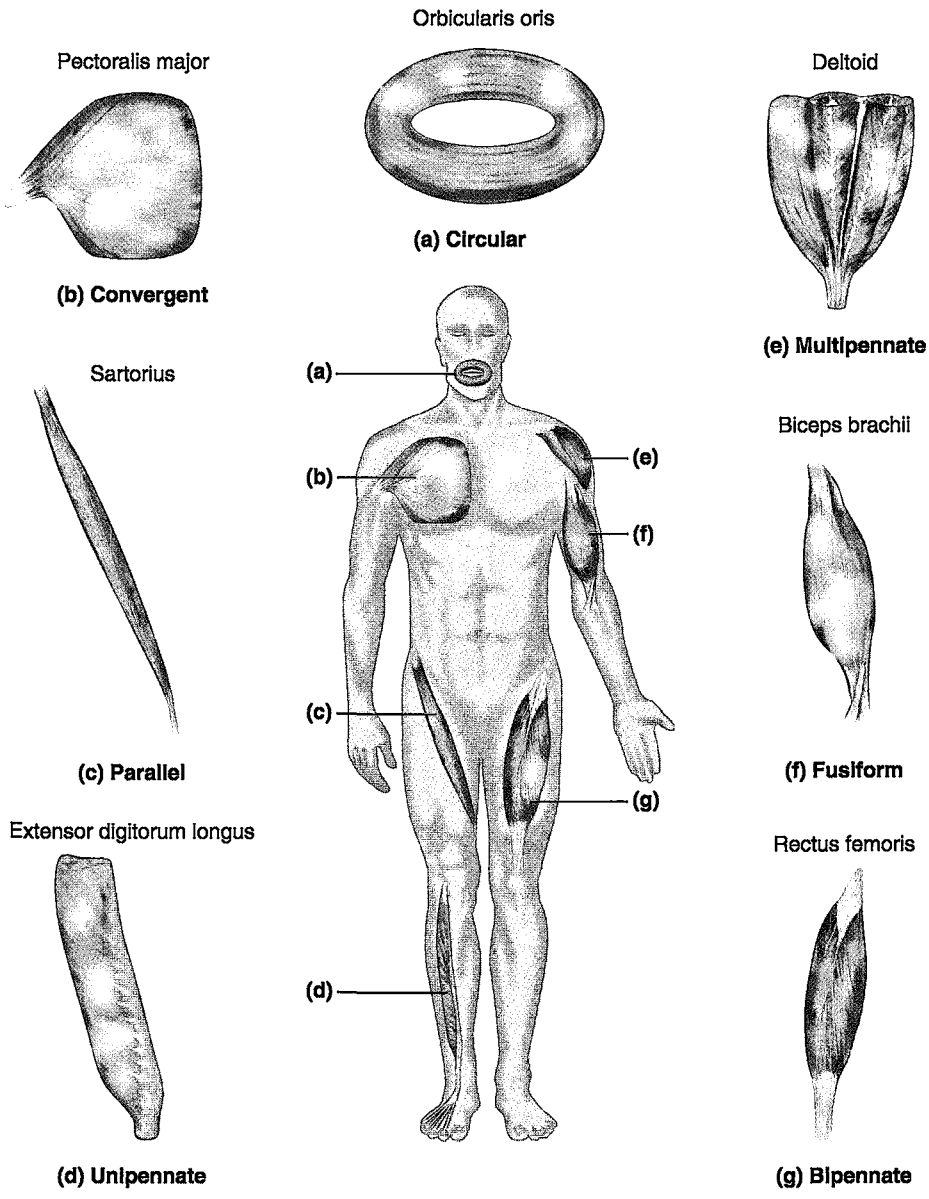


FIGURE 10.1 **Relationship of fascicle arrangement to muscle structure.**

body, your joints are the fulcrums, and your bones act as levers. Muscle contraction provides the effort which is applied at the muscle's insertion point on a bone. The load is the bone itself, along with overlying tissues and anything else you are trying to move with that lever.

A lever allows a given effort to move a heavier load, or to move a load farther or faster, than it otherwise could. If, as shown in Figure 10.2a, the load is close to the fulcrum and the effort is applied far from the fulcrum, a small effort exerted over a relatively large distance can be used to move a large load over a small distance. Such a lever is said to operate at a **mechanical advantage** and is commonly called a *power lever.* For example, as shown to the right in Figure 10.2a, a person can lift a car with such a lever, in this case, a jack. The car moves up only a small distance with each downward "push" of the jack handle, but relatively little muscle effort is needed. If, on the other

∀ *The biceps brachii and sartorius could shorten most because they have the longest fibers and fibers that run generally parallel to the long axis of the bone with which it is closely associated. The pectoralis major, deltoid, and rectus femoris would be the most powerful because they are the most fleshy.*

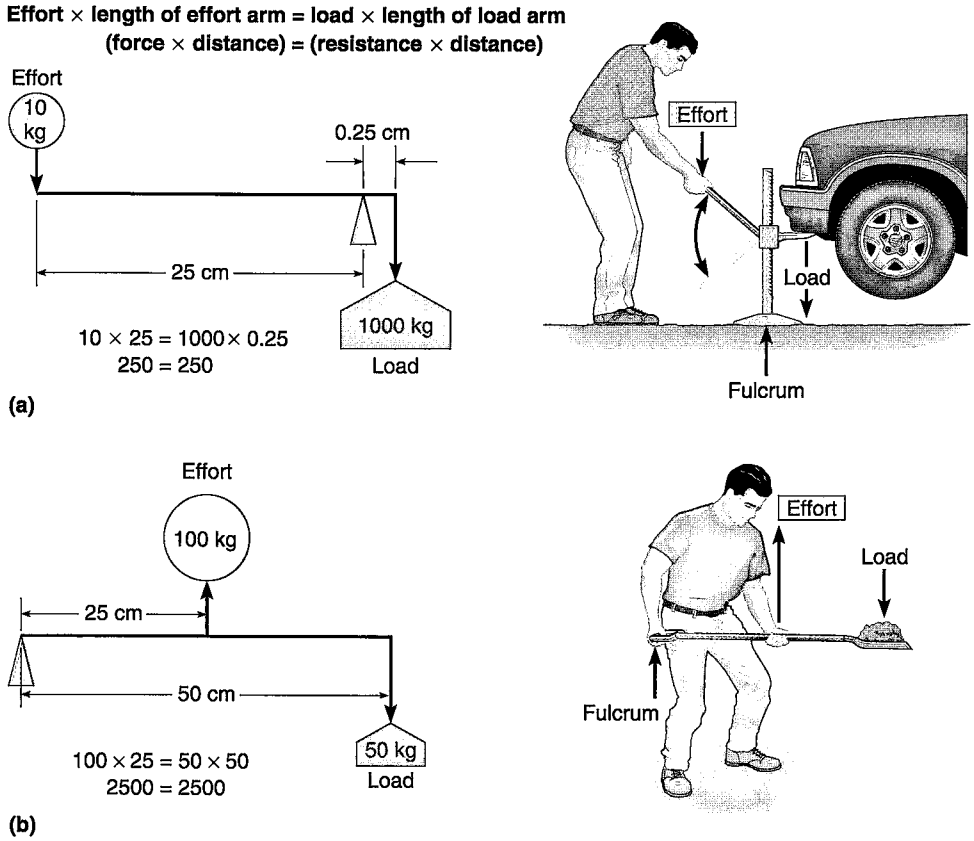

FIGURE 10.2 **Lever systems operating at a mechanical advantage and a mechanical disadvantage.** The equation at the top expresses the relationships among the forces and distances in any lever system. **(a)** 10 kg of force (the effort) is used to lift a 1000-kg car (the load). This lever system, which employs a jack, operates at a mechanical advantage: The load lifted is greater than the applied muscular effort. **(b)** Using a shovel to lift dirt is an example of a lever system that operates at a mechanical disadvantage. A muscular force (effort) of 100 kg is used to lift 50 kg of dirt (the load). Levers operating at a mechanical disadvantage are common in the body.

hand, the load is far from the fulcrum and the effort is applied near the fulcrum, the force exerted by the muscle must be greater than the load moved or supported (Figure 10.2b). This lever system operates at a **mechanical disadvantage** and is a *speed lever.* These levers are useful because they provide rapid contractions with a wide range of motion. Wielding a shovel is an example. As you can see, small differences in the site of a muscle's insertion (relative to the fulcrum or joint) can translate into large differences in the amount of force a muscle must generate to move a given load or resistance. Regardless of type, all levers follow the same basic principle: effort farther than load from fulcrum = mechanical advantage; effort nearer than load to fulcrum = mechanical disadvantage.

Depending on the relative position of the three elements—effort, fulcrum, and load—a lever belongs to one of three classes. In **first-class levers,** the effort is applied at one end of the lever and the load is at the other, with the fulcrum somewhere between (Figure 10.3a). Seesaws and scissors are first-class levers. First-class leverage also occurs when you lift your head off your chest. Some first-class levers in the body operate at a mechanical advantage, but others, such as the action of the triceps muscle in extending the forearm against resistance, operate at a mechanical disadvantage.

In a **second-class lever,** the effort is applied at one end of the lever and the fulcrum is located at the other, with the load between them (Figure 10.3b). A wheelbarrow demonstrates this type of lever system. Second-class levers are uncommon in the body; the best example is the act of standing on your toes. All second-class levers in the body work at a mechanical advantage because the muscle insertion is always farther from the fulcrum than is the load to be moved. Second-class levers are levers of strength, but speed and range of motion are sacrificed for that strength.

In **third-class levers,** the effort is applied between the load and the fulcrum (Figure 10.3c). These levers operate with great speed and *always* at a mechanical disadvantage. Tweezers or forceps provide this type of leverage. Most skeletal muscles of the body act in third-class lever systems; an example is the activity of the biceps muscle of the arm, lifting the distal forearm and anything carried in the hand. Third-class lever systems permit a muscle to be inserted very close to the joint across which movement occurs, which allows rapid, extensive movements with relatively little shortening of the muscle. Muscles involved in third-class levers tend to be thicker and more powerful.

In conclusion, differences in the positioning of the three elements modify muscle activity with respect to (1) speed of contraction, (2) range of movement, and (3) the weight of the load that can be lifted. In lever systems that operate at a mechanical disadvantage (speed levers), force is lost but speed and range of movement are gained, and this can be a

Q *Which of these lever systems as demonstrated at far left in the diagrams would be the fastest lever?*

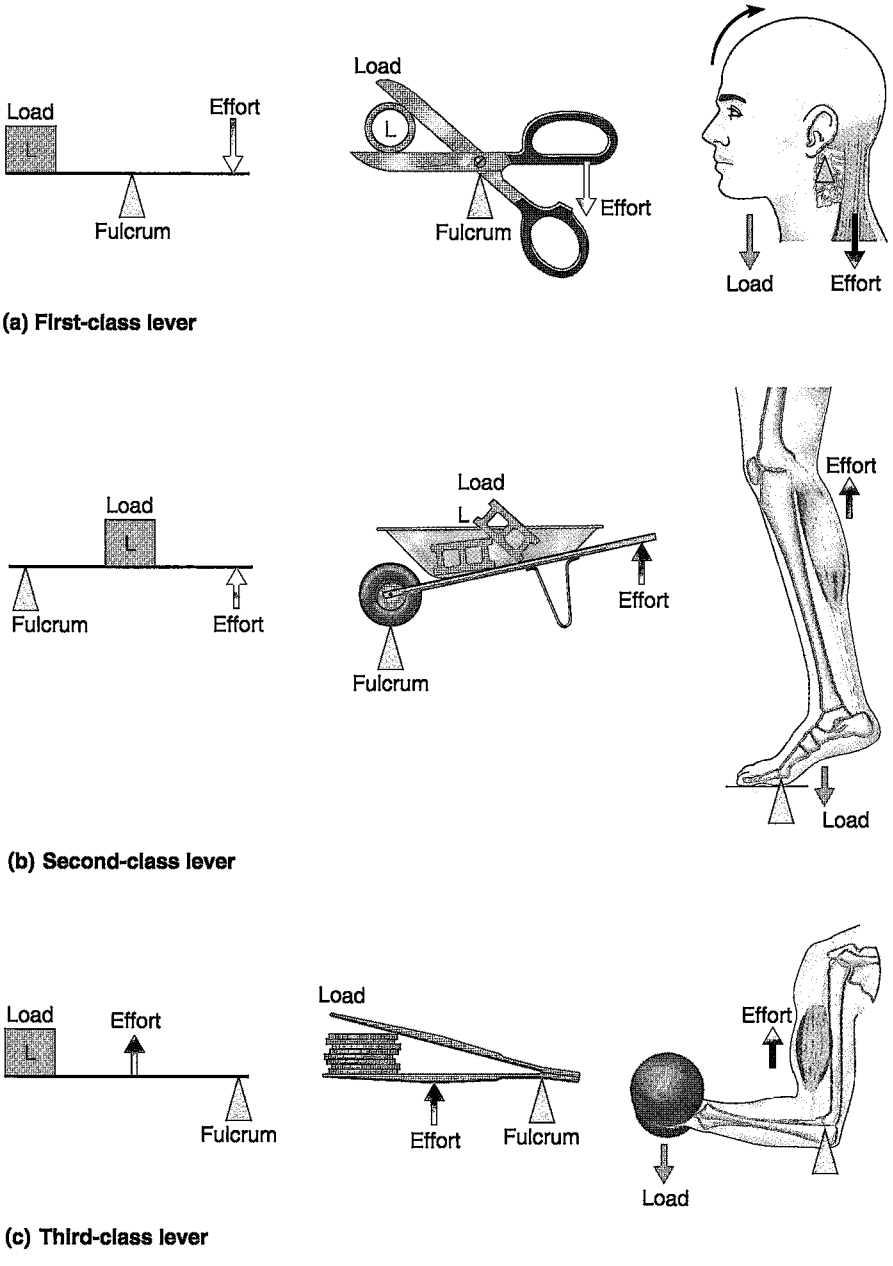

FIGURE 10.3 **Lever systems. (a)** In a first-class lever, the arrangement of the elements is load-fulcrum-effort. Scissors are in this lever class. In the body, a first-class lever system is activated when you raise your head off your chest. The posterior neck muscles provide the effort, the atlanto-occipital joint is the fulcrum, and the weight to be lifted is the facial skeleton. **(b)** In second-class levers, the arrangement is fulcrum-load-effort, as exemplified by a wheelbarrow. In the body, second-class leverage is exerted when you stand on tiptoe. The joints of the ball of the foot are the fulcrum, the weight of the body is the load, and the effort is exerted by the calf muscles pulling upward on the heel (calcaneus) of the foot. **(c)** In a third-class lever, the arrangement is load-effort-fulcrum. A pair of tweezers or forceps uses this type of leverage. The operation of the biceps brachii muscle in flexing the forearm exemplifies third-class leverage. The load is the hand and distal end of the forearm, the effort is exerted on the proximal radius of the forearm, and the fulcrum is the elbow joint.

A (c) The third-class lever.

Q *Which two muscles identified in (a) are used to do biceps curls (flex the elbow)? Which would be active during abdominal crunches (sit-ups)?*

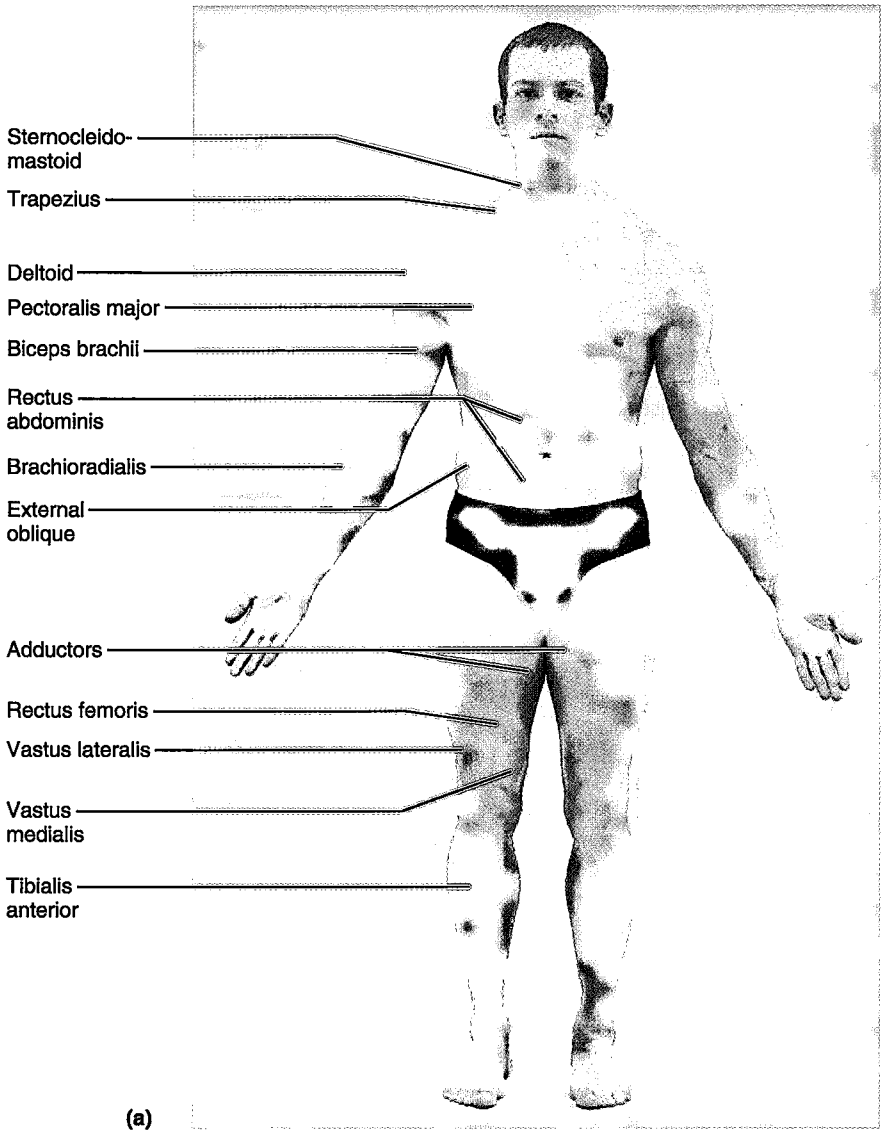

FIGURE 10.4 **Anterior view of superficial muscles of the body.** **(a)** Photograph of surface anatomy. **(b)** Diagrammatic view. The abdominal surface has been partially dissected on the right side to show somewhat deeper muscles. (See *A Brief Atlas of the Human Body*, Figure 33.)

distinct benefit. Systems that operate at a mechanical advantage (power levers) are slower, more stable, and used where strength is a priority.

Major Skeletal Muscles of the Body

The grand plan of the muscular system is all the more impressive because of the sheer number of skeletal muscles in the body—there are over 600 of them (many more than are shown in Figures 10.4 and 10.5 combined)! Obviously, trying to remember all the names, locations, and actions of these muscles is a monumental task. Take heart; only the principal muscles (approximately 125 pairs of them) are considered here. Although this number is far fewer than 600, the job of learning about all these muscles will still require a concerted effort on your part. Memorization will be easier if you can apply what you have learned in a practical, or clinical, way; that is, with a *functional anatomy focus*. Once you are satisfied that you have learned the name of a muscle and can identify it on a cadaver, model, or diagram, you must then flesh out your learning by asking yourself, "What does it do?" [It might be a good idea to review body movements (pp. 259–263) before you get to this point.]

A *Brachioradialis and biceps brachii would be used to do curls. The external obliques and rectus abdominis muscle would be working during crunches.*

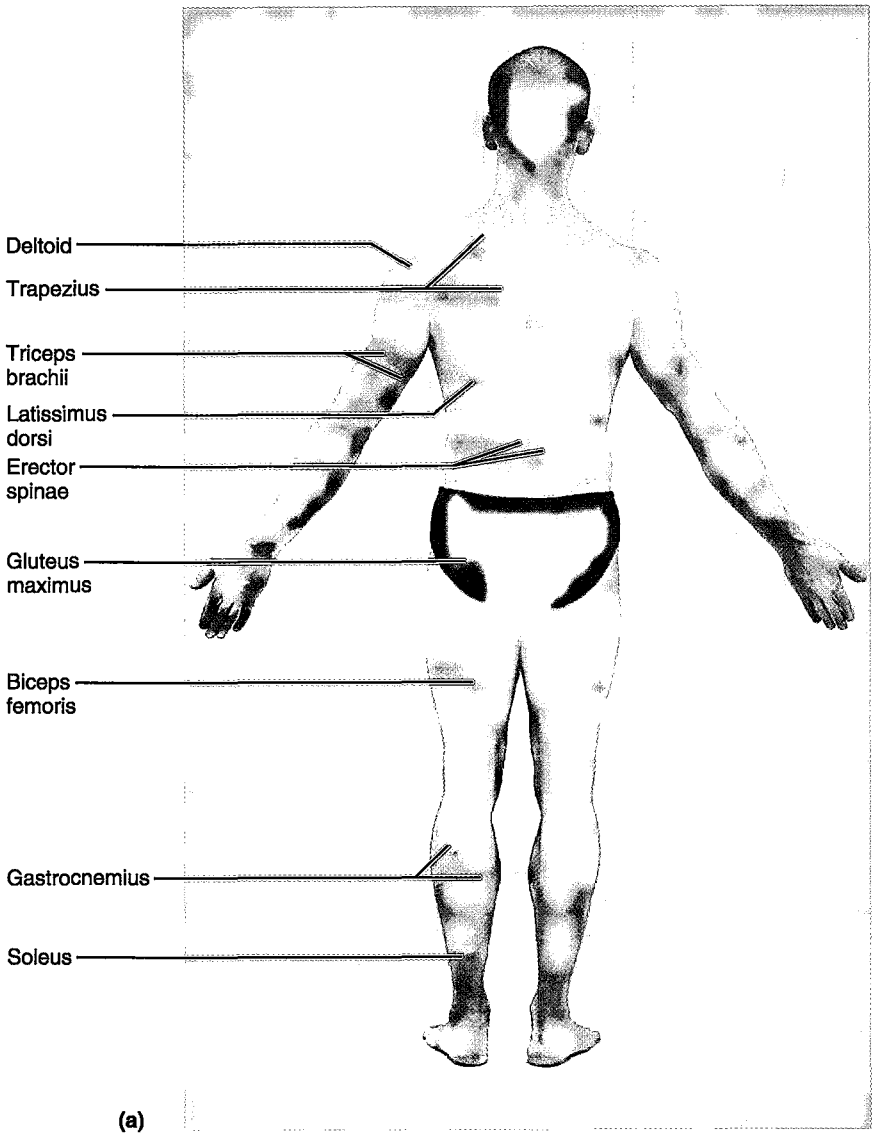

FIGURE 10.5 **Posterior view of superficial muscles of the body.** **(a)** Photograph of surface anatomy. **(b)** Diagrammatic view. (See *A Brief Atlas of the Human Body*, Figures 32, 35, and 36.)

In the tables that follow, the muscles of the body have been grouped by function and by location, roughly from head to foot. Each table is keyed to a particular figure or group of figures illustrating the muscles it describes. The legend at the beginning of each table provides an overview of the types of movements effected by the muscles listed and gives pointers on the way those muscles interact with one another. The table itself describes each muscle's shape, location relative to other muscles, origin and insertion, primary actions, and innervation. (Because some instructors want students to defer learning the muscle innervations until the nervous system has been studied, you might want to check on what is expected of you in this regard.)

As you consider each muscle, be alert to the information its name provides. After reading its entire description, identify the muscle on the corresponding figure and, in the case of superficial muscles, also on Figure 10.4 or 10.5. This will help you to link the descriptive material in the table to a visual image of the muscle's location in the body. Also try to relate a muscle's attachments and location to its actions. This will focus your attention on functional

(b)

details that often escape student awareness. For example, both the elbow and knee joints are hinge joints that allow flexion and extension. However, the knee flexes to the dorsum of the body (the calf moves toward the posterior thigh), whereas elbow flexion carries the forearm toward the anterior aspect of the arm. Therefore, leg flexors are located on the posterior thigh, while forearm flexors are found on the anterior aspect of the humerus.

Finally, keep in mind that the *best* way to learn muscle actions is to act out their movements yourself while feeling for the muscles contracting (bulging) beneath your skin.

The following list summarizes the organization and sequence of the tables in this chapter:

- **Table 10.1** Muscles of the Head, Part I: Facial Expression (Figure 10.6); pp. 335–337.
- **Table 10.2** Muscles of the Head, Part II: Mastication and Tongue Movement (Figure 10.7); pp. 338–339.
- **Table 10.3** Muscles of the Anterior Neck and Throat: Swallowing (Figure 10.8); pp. 340–341.
- **Table 10.4** Muscles of the Neck and Vertebral Column: Head and Trunk Movements (Figure 10.9); pp. 342–345.
- **Table 10.5** Muscles of the Thorax: Breathing (Figure 10.10); pp. 346–347.
- **Table 10.6** Muscles of the Abdominal Wall: Trunk Movements and Compression of Abdominal Viscera (Figure 10.11); pp. 348–349.
- **Table 10.7** Muscles of the Pelvic Floor and Perineum: Support of Abdominopelvic Organs (Figure 10.12); pp. 350–351.

- **Table 10.11** Muscles of the Forearm: Movements of the Wrist, Hand, and Fingers (Figures 10.15 and 10.16); pp. 358–361.
- **Table 10.12** Summary of Actions of Muscles Acting on the Arm, Forearm, and Hand (Figure 10.17); pp. 362–363.
- **Table 10.13** Intrinsic Muscles of the Hand: Fine Movements of the Fingers (Figure 10.18); pp. 364–366.
- **Table 10.14** Muscles Crossing the Hip and Knee Joints: Movements of the Thigh and Leg (Figures 10.19 and 10.20); pp. 367–372.
- **Table 10.15** Muscles of the Leg: Movements of the Ankle and Toes (Figures 10.21 to 10.23); pp. 373–378.
- **Table 10.16** Summary of Actions of Muscles Acting on the Thigh, Leg, and Foot (Figure 10.24); pp. 379–380.
- **Table 10.17** Intrinsic Muscles of the Foot: Toe Movement and Arch Support (Figure 10.25); pp. 381–383.

MUSCLE GALLERY TABLE 10.1 Muscles of the Head, Part I: Facial Expression (Figure 10.6)

The muscles that promote facial expression lie in the scalp and face just deep to the skin. They are thin and variable in shape and strength, and adjacent muscles tend to be fused. They are unusual muscles in that they insert into skin (or other muscles), not bones. In the scalp, the main muscle is the **epicranius,** which has distinct anterior and posterior parts; the lateral scalp muscles are vestigial in humans. Muscles clothing the facial bones lift the eyebrows, flare the nostrils, open and close the eyes and mouth, and provide one of the best tools for influencing others—the smile. The tremendous importance of facial muscles in nonverbal communication becomes especially clear when they are paralyzed, as in some stroke victims. All muscles listed in this table are innervated by *cranial nerve VII,* the *facial nerve* (see Table 13.2). The external muscles of the eyes, which act to direct the eyeballs, and the levator palpebrae superioris muscles that raise the eyelids are described in Chapter 15.

MUSCLE	DESCRIPTION	ORIGIN (O) AND INSERTION (I)	ACTION	NERVE SUPPLY
Muscles of the Scalp				
Epicranius (occipitofrontalis) (ep″ĭ-kra′ne-us; ok-sip″ĭ-to-fron-ta′lis) (*epi* = over; *cran* = skull)	Bipartite muscle consisting of the frontal and occipital bellies connected by a cranial aponeurosis, the galea aponeurotica; the alternate actions of these two muscles pull scalp forward and backward			
▪ **Frontal belly** (fron′tal) (*front* = forehead)	Covers forehead and dome of skull; no bony attachments	O—galea aponeurotica I—skin of eyebrows and root of nose	With aponeurosis fixed, raises the eyebrows (as in surprise); wrinkles forehead skin horizontally	Facial nerve (cranial VII)
▪ **Occipital belly** (ok-sip″ĭ-tal′) (*occipito* = base of skull)	Overlies posterior occiput; by pulling on the galea, fixes origin of frontalis	O—occipital and temporal bones I—galea aponeurotica	Fixes aponeurosis and pulls scalp posteriorly	Facial nerve
Muscles of the Face				
Corrugator supercilii (kor′ah-ga-ter soo″per-sĭ′le-i) (*corrugo* = wrinkle; *supercilium* = eyebrow)	Small muscle; activity associated with that of orbicularis oculi	O—arch of frontal bone above nasal bone I—skin of eyebrow	Draws eyebrows together and inferiorly; wrinkles skin of forehead vertically (as in frowning)	Facial nerve
Orbicularis oculi (or-bik′u-lar-is ok′u-li) (*orb* = circular; *ocul* = eye)	Thin, tripartite sphincter muscle of eyelid; surrounds rim of the orbit	O—frontal and maxillary bones and ligaments around orbit I—tissue of eyelid	Protects eyes from intense light and injury; various parts can be activated individually; produces blinking, squinting, and draws eyebrows inferiorly	Facial nerve

MUSCLE GALLERY TABLE 10.1 Muscles of the Head, Part I: Facial Expression (Figure 10.6) *(continued)*

MUSCLE	DESCRIPTION	ORIGIN (O) AND INSERTION (I)	ACTION	NERVE SUPPLY
Zygomaticus—major and minor (zi-go-mat'ĭ-kus) (*zygomatic* = cheekbone)	Muscle pair extending diagonally from cheekbone to corner of mouth	O—zygomatic bone I—skin and muscle at corner of mouth	Raises lateral corners of mouth upward (smiling muscle)	Facial nerve
Risorius (ri-zor'e-us) (*risor* = laughter)	Slender muscle inferior and lateral to zygomaticus	O—lateral fascia associated with masseter muscle I—skin at angle of mouth	Draws corner of lip laterally; tenses lips; synergist of zygomaticus	Facial nerve
Levator labii superioris (lĕ-va'tor la'be-i soo-per"e-or'is) (*leva* = raise; *labi* = lip; *superior* = above, over)	Thin muscle between orbicularis oris and inferior eye margin	O—zygomatic bone and infraorbital margin of maxilla I—skin and muscle of upper lip	Opens lips; raises and furrows the upper lip	Facial nerve
Depressor labii inferioris (de-pres'or la'be-i in-fer"e-or'is) (*depressor* = depresses; *infer* = below)	Small muscle running from mandible to lower lip	O—body of mandible lateral to its midline I—skin and muscle of lower lip	Draws lower lip inferiorly (as in a pout)	Facial nerve
Depressor anguli oris (ang'gu-li or-is) (*angul* = angle, corner; *or* = mouth)	Small muscle lateral to depressor labii inferioris	O—body of mandible below incisors I—skin and muscle at angle of mouth below insertion of zygomaticus	Zygomaticus antagonist; draws corners of mouth downward and laterally (as in a "tragedy mask" grimace)	Facial nerve
Orbicularis oris	Complicated, multilayered muscle of the lips with fibers that run in many different directions; most run circularly	O—arises indirectly from maxilla and mandible; fibers blended with fibers of other facial muscles associated with the lips I—encircles mouth; inserts into muscle and skin at angles of mouth	Closes lips; purses and protrudes lips; kissing and whistling muscle	Facial nerve
Mentalis (men-ta'lis) (*ment* = chin)	One of the muscle pair forming a V-shaped muscle mass on chin	O—mandible below incisors I—skin of chin	Protrudes lower lip; wrinkles chin	Facial nerve
Buccinator (bu'sĭ-na"ter) (*bucc* = cheek or "trumpeter")	Thin, horizontal cheek muscle; principal muscle of cheek; deep to masseter (see also Figure 10.7)	O—molar region of maxilla and mandible I—orbicularis oris	Draws corner of mouth laterally; compresses cheek (as in whistling and sucking); holds food between teeth during chewing; well developed in nursing infants	Facial nerve
Platysma (plah-tiz'mah) (*platy* = broad, flat)	Unpaired, thin, sheetlike superficial neck muscle; not strictly a head muscle, but plays a role in facial expression	O—fascia of chest (over pectoral muscles and deltoid) I—lower margin of mandible, and skin and muscle at corner of mouth	Helps depress mandible; pulls lower lip back and down, i.e., produces downward sag of mouth; tenses skin of neck (e.g., during shaving)	Facial nerve

MUSCLE GALLERY TABLE 10.1 *(continued)*

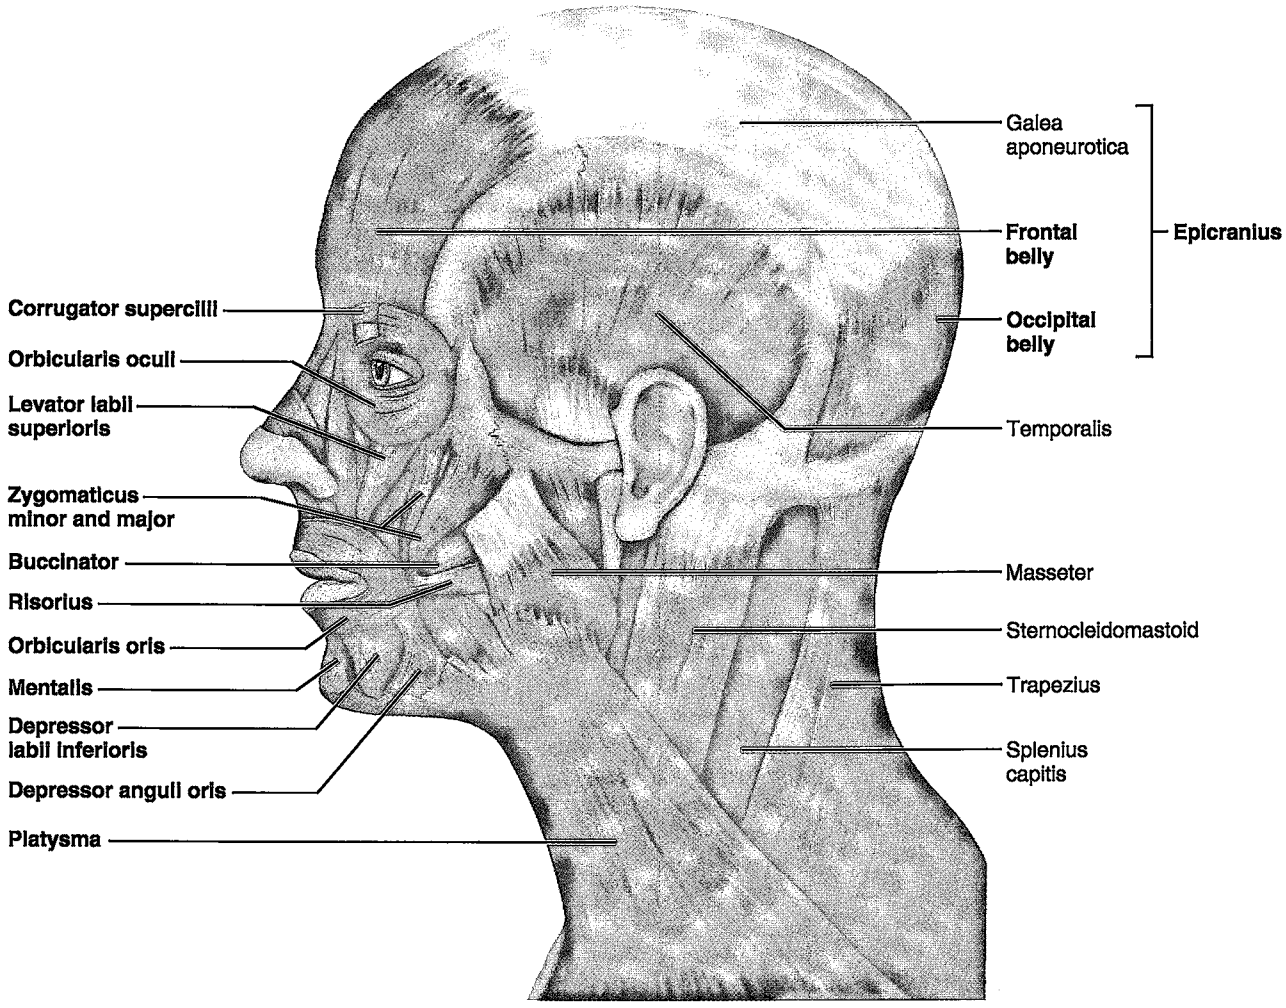

FIGURE 10.6 **Lateral view of muscles of the scalp, face, and neck.**

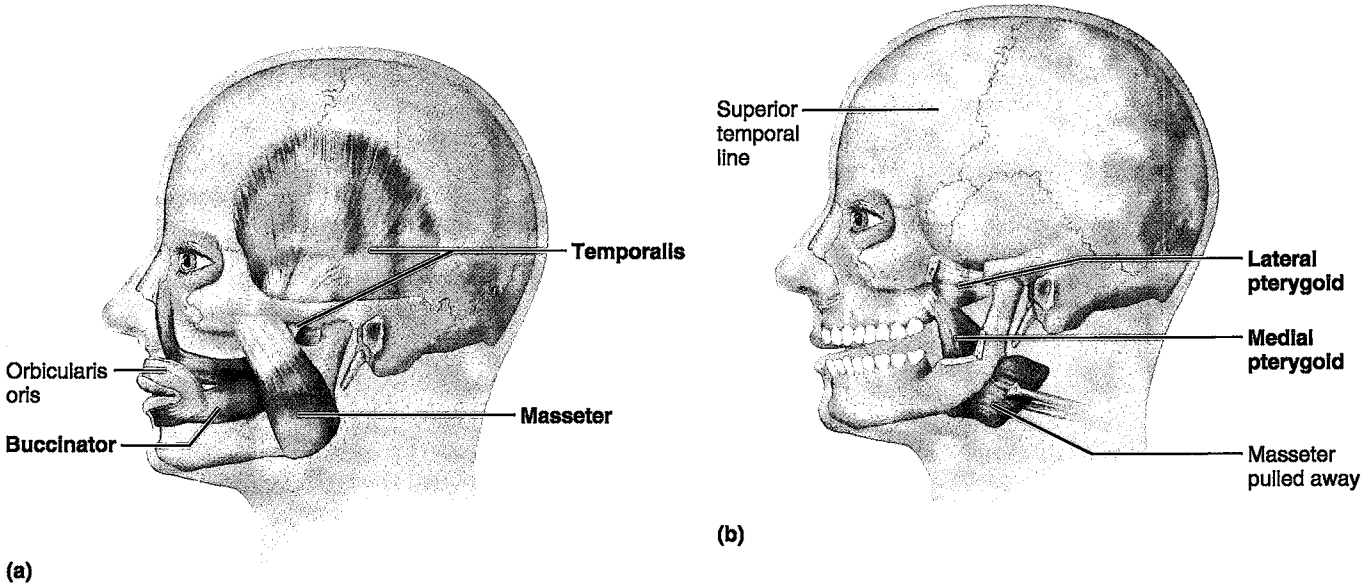
MUSCLE GALLERY TABLE 10.2 Muscles of the Head, Part II: Mastication and Tongue Movement (Figure 10.7)

Four pairs of muscles are involved in mastication (chewing and biting) activities, and all are innervated by the *mandibular branch* of *cranial nerve V* (the *trigeminal nerve*). The prime movers of jaw closure (and biting) are the powerful **masseter** and **temporalis** muscles, which can be palpated easily when the teeth are clenched. Grinding movements are brought about by the **pterygoid** muscles. The **buccinator** muscles (see Table 10.1) also play a role in chewing. Normally, gravity is sufficient to depress the mandible, but if there is resistance to jaw opening, neck muscles such as the digastric and mylohyoid muscles (see Table 10.3) are activated. In 1996, researchers claimed to have discovered a tiny new muscle (not illustrated) extending from the lateral sphenoid to the medial aspect of the mandibular ramus and coronoid process. It is still uncertain whether this *sphenomandibular muscle* is a chewing muscle or actually part of the temporalis or lateral pterygoid.

The tongue is composed of muscle fibers that curl, squeeze, and fold the tongue during speaking and chewing. These **intrinsic tongue muscles,** arranged in several planes, change the shape of the tongue and contribute to its exceptional nimbleness, but they do not really move the tongue. They are considered in Chapter 23 with the digestive system. Only the **extrinsic tongue muscles,** which anchor and move the tongue, are considered in this table. All extrinsic tongue muscles are innervated by *cranial nerve XII*, the *hypoglossal nerve* (see Table 13.2).

MUSCLE	DESCRIPTION	ORIGIN (O) AND INSERTION (I)	ACTION	NERVE SUPPLY
Muscles of Mastication				
Masseter (mah-se'ter) (*maseter* = chewer)	Powerful muscle that covers lateral aspect of mandibular ramus	O—zygomatic arch and maxilla I—angle and ramus of mandible	Prime mover of jaw closure; elevates mandible	Trigeminal nerve (cranial V)
Temporalis (tem"por-ă'lis) (*tempora* = time; pertaining to the temporal bone)	Fan-shaped muscle that covers parts of the temporal, frontal, and parietal bones	O—temporal fossa I—coronoid process of mandible via a tendon that passes deep to zygomatic arch	Closes jaw; elevates and retracts mandible; synergist of pterygoids (see below) in side-to-side movements; maintains position of the mandible at rest	Trigeminal nerve
Medial pterygoid (me'de-ul ter'ĭ-goid) (*medial* = toward median plane; *pterygoid* = winglike)	Deep two-headed muscle that runs along internal surface of mandible and is largely concealed by that bone	O—medial surface of lateral pterygoid plate of sphenoid bone, maxilla, and palatine bone I—medial surface of mandible near its angle	Synergist of temporalis and masseter muscles in elevation of the mandible; acts with the lateral pterygoid muscle to protrude mandible and to promote side-to-side side (grinding) movements	Trigeminal nerve
Lateral pterygoid (*lateral* = away from median plane)	Deep two-headed muscle; lies superior to medial pterygoid muscle	O—greater wing and lateral pterygoid plate of sphenoid bone I—condyle of mandible and capsule of temporomandibular joint	Protrudes mandible (pulls it anteriorly); provides forward sliding and side-to-side grinding movements of the lower teeth	Trigeminal nerve
Buccinator	See Table 10.1	See Table 10.1	Trampoline-like action of buccinator muscles helps keep food between grinding surfaces of teeth during chewing	Facial nerve (cranial VII)

MUSCLE	DESCRIPTION	ORIGIN (O) AND INSERTION (I)	ACTION	NERVE SUPPLY
Muscles Promoting Tongue Movements (Extrinsic Muscles)				
Genioglossus (je"ne-o-glah'sus) (*geni* = chin; *glossus* = tongue)	Fan-shaped muscle; forms bulk of inferior part of tongue; its attachment to mandible prevents tongue from falling backward and obstructing respiration	O—internal surface of mandible near symphysis I—inferior aspect of the tongue and body of hyoid bone	Primarily protrudes tongue, but can depress or act in concert with other extrinsic muscles to retract tongue	Hypoglossal nerve (cranial XII)
Hyoglossus (hi'o-glos"us) (*hyo* = pertaining to hyoid bone)	Flat, quadrilateral muscle	O—body and greater horn of hyoid bone I—inferolateral tongue	Depresses tongue and draws its sides downward	Hypoglossal nerve
Styloglossus (sti-lo-glah'sus) (*stylo* = pertaining to styloid process)	Slender muscle running superiorly to and at right angles to hyoglossus	O—styloid process of temporal bone I—inferolateral tongue	Retracts (and elevates) tongue	Hypoglossal nerve



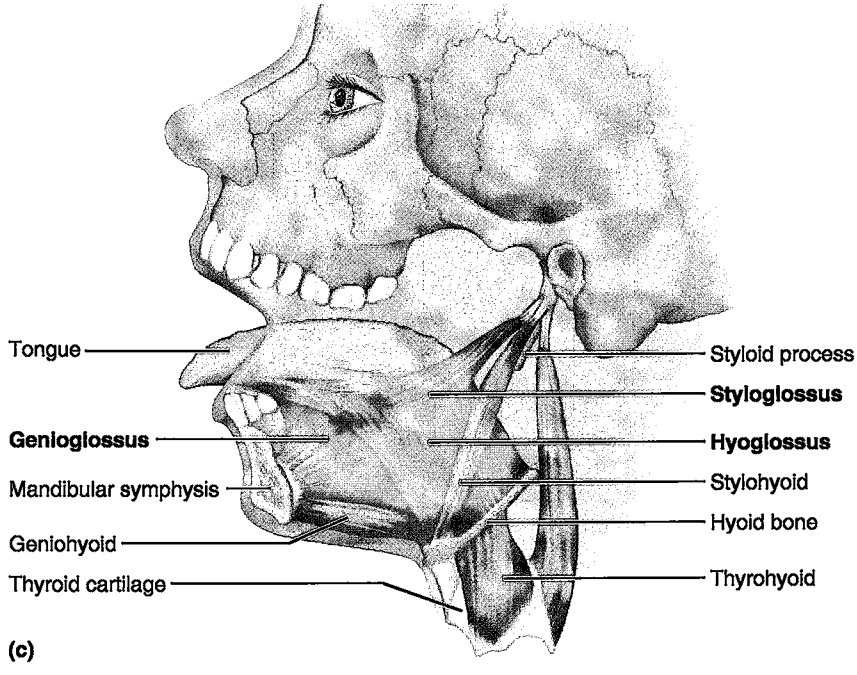


FIGURE 10.7 **Muscles promoting mastication and tongue movements.** **(a)** Lateral view of the temporalis, masseter, and buccinator muscles. **(b)** Lateral view of the deep chewing muscles, the medial and lateral pterygoid muscles. **(c)** Extrinsic muscles of the tongue. Some suprahyoid muscles of the throat are also illustrated.

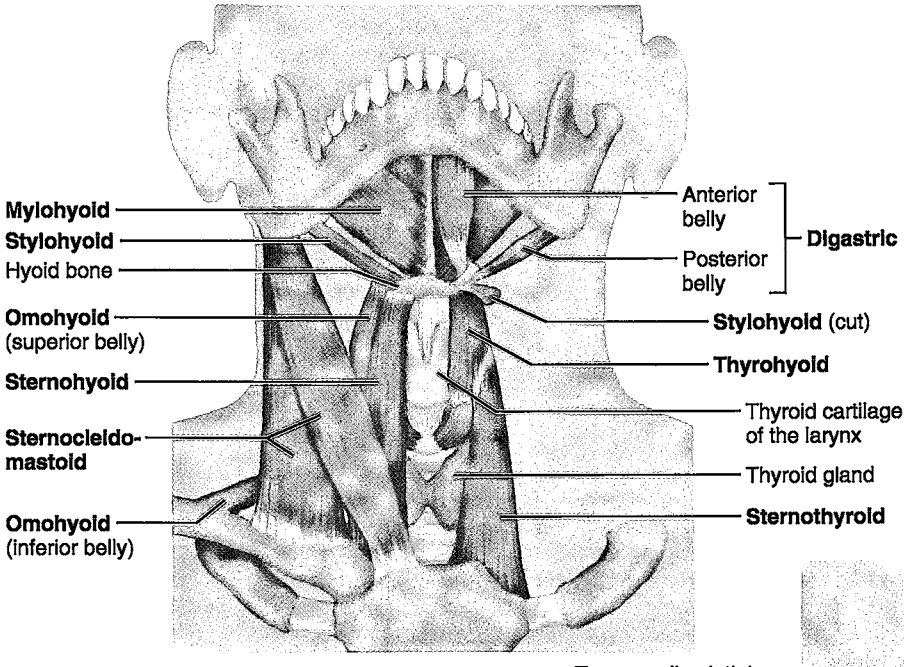
MUSCLE GALLERY TABLE 10.3 Muscles of the Anterior Neck and Throat: Swallowing (Figure 10.8)

The neck is divided into two triangles (anterior and posterior) by the sternocleidomastoid muscle (Figure 10.8a). This table considers the muscles of the *anterior* triangle, which are divided into **suprahyoid** and **infrahyoid muscles** (above and below the hyoid bone respectively). Most of these muscles are deep (throat) muscles involved in swallowing.

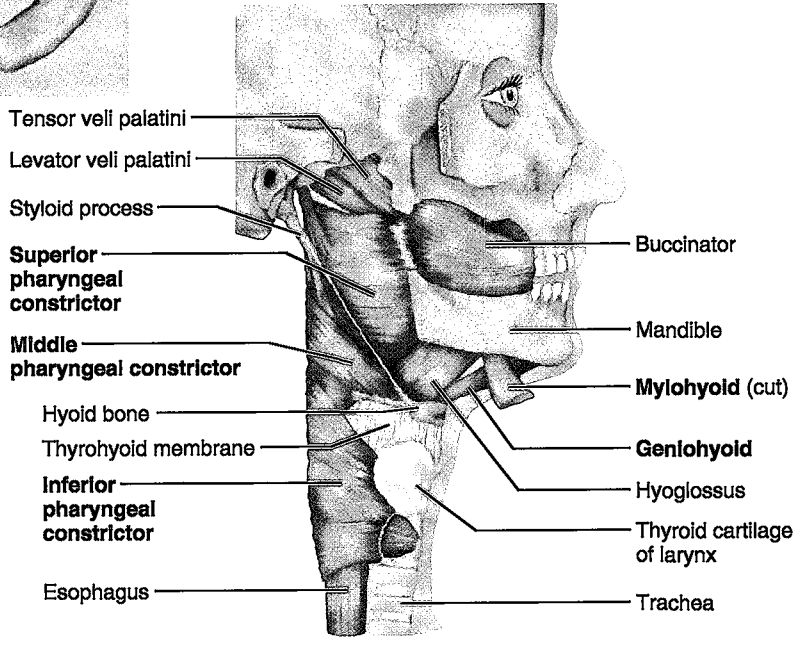
Swallowing begins when the tongue and buccinator muscles of the cheeks squeeze the food back along the roof of the mouth toward the pharynx. Then a rapid series of muscular movements in the posterior mouth and pharynx complete the process. Events of swallowing include: (1) Widening the pharynx to receive the food, and closing the respiratory passageway (larynx) anteriorly to prevent aspiration of food, is accomplished by the *suprahyoid muscles,* which pull the hyoid bone upward and forward toward the mandible. Since the hyoid bone is attached by the thyrohyoid membrane to the larynx, the larynx is also pulled upward and forward, a maneuver that widens the pharynx and closes the respiratory passageway. (2) Closing off the nasal passages to prevent food from entering the superior nasal cavity is accomplished by small muscles that elevate the soft palate. (These muscles, the *tensor* and *levator veli palatini,* are not described in the table but are illustrated in Figure 10.8b.) (3) Food is propelled through the pharynx into the esophagus inferiorly by the **pharyngeal constrictor muscles.** (4) Returning the hyoid bone and larynx to their more inferior positions after swallowing is promoted by the *infrahyoid muscles.*

MUSCLE	DESCRIPTION	ORIGIN (O) AND INSERTION (I)	ACTION	NERVE SUPPLY
Suprahyoid Muscles (soo"prah-hi'oid)	Muscles that help form floor of oral cavity, anchor tongue, elevate hyoid, and move larynx superiorly during swallowing; lie superior to hyoid bone			
Digastric (di-gas'trik) (*di* = two; *gaster* = belly)	Consists of two bellies united by an intermediate tendon, forming a V shape under the chin	O—lower margin of mandible (anterior belly) and mastoid process of the temporal bone (posterior belly) I—by a connective tissue loop to hyoid bone	Acting in concert, the digastric muscles elevate hyoid bone and steady it during swallowing and speech; acting from behind, they open mouth and depress mandible	Mandibular branch of trigeminal nerve (cranial V) for anterior belly; facial nerve (cranial VII) for posterior belly
Stylohyoid (sti"lo-hi'oid) (also see Figure 10.7)	Slender muscle below angle of jaw; parallels posterior belly of diagastric muscle	O—styloid process of temporal bone I—hyoid bone	Elevates and retracts hyoid, thereby elongating floor of mouth during swallowing	Facial nerve
Mylohyoid (mi"lo-hi'oid) (*myle* = molar)	Flat, triangular muscle just deep to digastric muscle; this muscle pair forms a sling that forms the floor of the anterior mouth	O—medial surface of mandible I—hyoid bone and median raphe	Elevates hyoid bone and floor of mouth, enabling tongue to exert backward and upward pressure that forces food bolus into pharynx	Mandibular branch of trigeminal nerve
Geniohyoid (je'ne-o-hy"oid) (also see Figure 10.7) (*geni* = chin)	Narrow muscle in contact with its partner medially; runs from chin to hyoid bone deep to mylohyoid	O—inner surface of mandibular symphysis I—hyoid bone	Pulls hyoid bone superiorly and anteriorly, shortening floor of mouth and widening pharynx for receiving food	First cervical spinal nerve via hypoglossal nerve (cranial XII)
Infrahyoid Muscles	Straplike muscles that depress the hyoid bone and larynx during swallowing and speaking (see also Figure 10.9c)			
Sternohyoid (ster"no-hi'oid) (*sterno* = sternum)	Most medial muscle of the neck: thin; superficial except inferiorly, where covered by sternocleidomastoid	O—manubrium and medial end of clavicle I—lower margin of hyoid bone	Depresses larynx and hyoid bone if mandible is fixed; may also flex skull	Cervical spinal nerves 1–3 (C_1–C_3) through ansa cervicalis (slender nerve root in cervical plexus)
Sternothyroid (ster"no-thi'roid) (*thyro* = thyroid cartilage)	Lateral and deep to sternohyoid	O—posterior surface of manubrium of sternum I—thyroid cartilage	Pulls thyroid cartilage (plus larynx and hyoid bone) inferiorly	As for sternohyoid

MUSCLE	DESCRIPTION	ORIGIN (O) AND INSERTION (I)	ACTION	NERVE SUPPLY
Omohyoid (o"mo-hi'oid) (*omo* = shoulder)	Straplike muscle with two bellies united by an intermediate tendon; lateral to sternohyoid	O—superior surface of scapula I—hyoid bone, lower border	Depresses and retracts hyoid bone	As for sternohyoid
Thyrohyoid (thi"ro-hi'oid) (also see Figure 10.7)	Appears as a superior continuation of sternothyroid muscle	O—thyroid cartilage I—hyoid bone	Depresses hyoid bone and elevates larynx if hyoid is fixed	First cervical nerve via hypoglossal
Pharyngeal constrictor muscles—superior, middle, and inferior (far-rin'je-al)	Composite of three paired muscles whose fibers run circularly in pharynx wall; superior muscle is innermost and inferior one is outermost; substantial overlap	O—attached anteriorly to mandible and medial pterygoid plate (superior), hyoid bone (middle), and laryngeal cartilages (inferior) I—posterior median raphe of pharynx	Working as a group and in sequence, all constrict pharynx during swallowing, which propels a food bolus to esophagus (via a massagelike action called peristalsis)	Pharyngeal plexus [branches of vagus (X)]



(a)



(b)

FIGURE 10.8 **Muscles of the anterior neck and throat that promote swallowing.** **(a)** Anterior view of the suprahyoid and infrahyoid muscles. The sternocleidomastoid muscle (not involved in swallowing) is shown on the left side of the illustration to provide an anatomical landmark. Deeper neck muscles are illustrated on the right side. (See *A Brief Atlas of the Human Body,* Figures 44 and 45.) **(b)** Lateral view of the constrictor muscles of the pharynx shown in their proper anatomical relationship to the buccinator (a chewing muscle) and the hyoglossus muscle (which promotes tongue movements).

MUSCLE GALLERY TABLE 10.4 Muscles of the Neck and Vertebral Column: Head and Trunk Movements (Figure 10.9)

Head movements. The head is moved by muscles originating from the axial skeleton. The major head flexors are the **sternocleidomastoid muscles,** but the suprahyoid and infrahyoid muscles described in Table 10.3 act as synergists in this action. Lateral head movements are effected by the sternocleidomastoids and a number of deeper neck muscles, including the **scalenes,** and by several straplike muscles of the vertebral column at the back of the neck. Head extension is aided by the superficial trapezius muscles of the back, but the **splenius** muscles deep to the trapezius muscles bear most of the responsibility for head extension.

Trunk movements. Trunk extension is effected by the *deep* or *intrinsic back muscles* associated with the bony vertebral column. As opposed to these deep back muscles, superficial back muscles are concerned primarily with movements of the shoulder girdle and upper limbs (see Tables 10.8 and 10.9).

The deep muscles of the back form a broad, thick column extending from the sacrum to the skull. Many muscles of varying length contribute to this mass. It helps to regard each of these individual muscles as a string that when pulled causes one or several vertebrae to extend or to rotate on the vertebrae below. The largest of the deep back muscle groups is the **erector spinae** ("spine erectors"). Since the origins and insertions of the different muscle groups overlap extensively, entire regions of the vertebral column can be moved simultaneously and smoothly. Acting in concert, the deep back muscles extend (or hyperextend) the spine, but contraction of the muscles on only one side causes lateral bending of the back, neck, or head. Lateral flexion is automatically accompanied by some degree of rotation of the vertebral column. During vertebral movements, the articular facets of the vertebrae glide on each other.

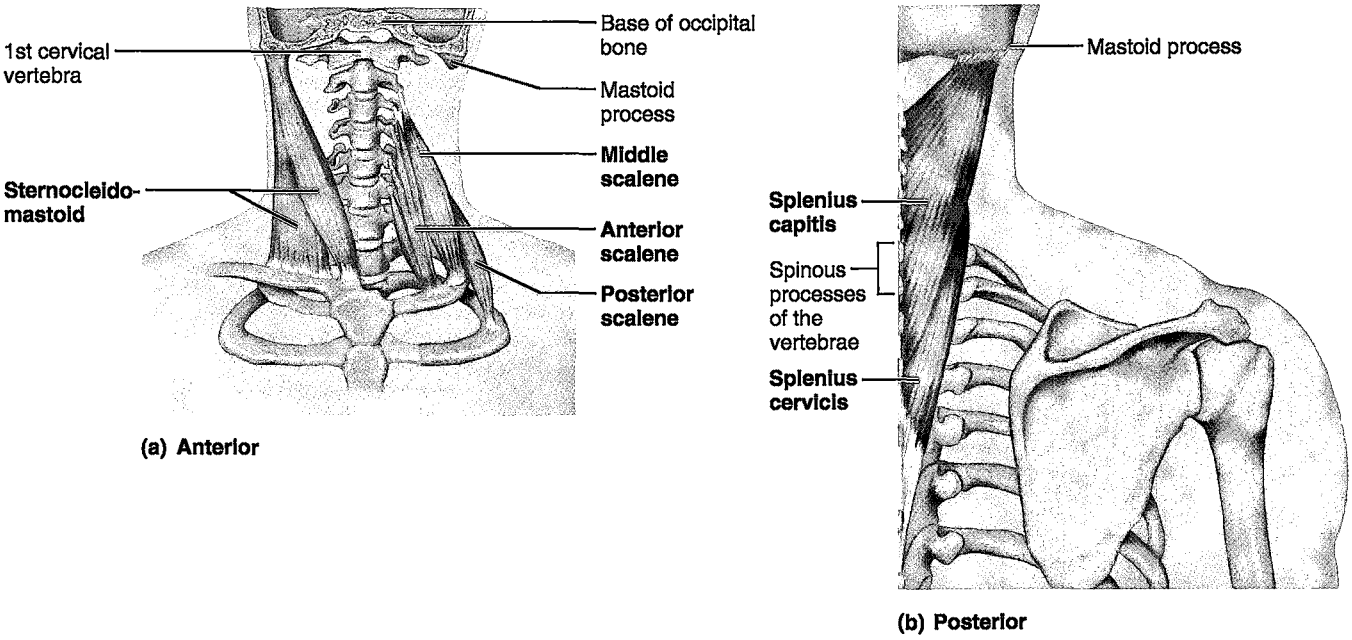
In addition to the long back muscles, a number of short muscles extend from one vertebra to the next (Figure 10.9e). These small muscles (the rotatores, multifidus, interspinales, and intertransversarii muscles) act primarily as synergists in extension and rotation of the spine and as spine stabilizers. They are not described in the table but you can deduce their actions by examining their origins and insertions in the figure.

Trunk muscles also maintain the normal curvatures of the spine, acting as postural muscles. It is these deep trunk *extensors* that are considered in this table. The more superficial muscles, which have other functions, are considered in subsequent tables. For example, the anterior muscles of the abdominal wall that cause trunk *flexion* are described in Table 10.6.

MUSCLE	DESCRIPTION	ORIGIN (O) AND INSERTION (I)	ACTION	NERVE SUPPLY
Anterolateral Neck Muscles (Figure 10.9a and c)				
Sternocleidomastoid (ster"no-kli"do-mas'toid) (*sterno* = breastbone; *cleido* = clavicle; *mastoid* = mastoid process)	Two-headed muscle located deep to platysma on anterolateral surface of neck; fleshy parts on either side of neck delineate limits of anterior and posterior triangles; key muscular landmark in neck; spasms of one of these muscles may cause torticollis (wryneck)	O—manubrium of sternum and medial portion of clavicle I—mastoid process of temporal bone and superior nuchal line of occipital bone	Prime mover of active head flexion; simultaneous contraction of both muscles causes neck flexion, generally against resistance as when one raises head when lying on back; acting alone, each muscle rotates head toward shoulder on opposite side and tilts or laterally flexes head to its own side	Accessory nerve (cranial nerve XI) and branches of cervical spinal nerves C_2 and C_3 (ventral rami)
Scalenes (ska'lēnz)—anterior, middle, and posterior (*scalene* = uneven)	Located more laterally than anteriorly on neck; deep to platysma and sternocleidomastoid	O—transverse processes of cervical vertebrae I—anterolaterally on first two ribs	Elevate first two ribs (aid in inspiration); flex and rotate neck	Cervical spinal nerves

MUSCLE GALLERY TABLE 10.4 *(continued)*

MUSCLE	DESCRIPTION	ORIGIN (O) AND INSERTION (I)	ACTION	NERVE SUPPLY
Intrinsic Muscles of the Back (Figure 10.9b, d, e)				
Splenius (sple'ne-us)—capitis and cervicis portions (kah-pit'us; ser-vis'us) (*splenion* = bandage; *caput* = head; *cervi* = neck) (Figures 10.9b and 10.6)	Broad bipartite superficial muscle (capitis and cervicis parts) extending from upper thoracic vertebrae to skull; capitis portion known as "bandage muscle" because it covers and holds down deeper neck muscles	O—ligamentum nuchae,* spinous processes of vertebrae C_7–T_6 I—mastoid process of temporal bone and occipital bone (capitis); transverse processes of C_2–C_4 vertebrae (cervicis)	Act as a group to extend or hyperextend head; when splenius muscles on one side are activated, head is rotated and bent laterally toward same side	Cervical spinal nerves (dorsal rami)



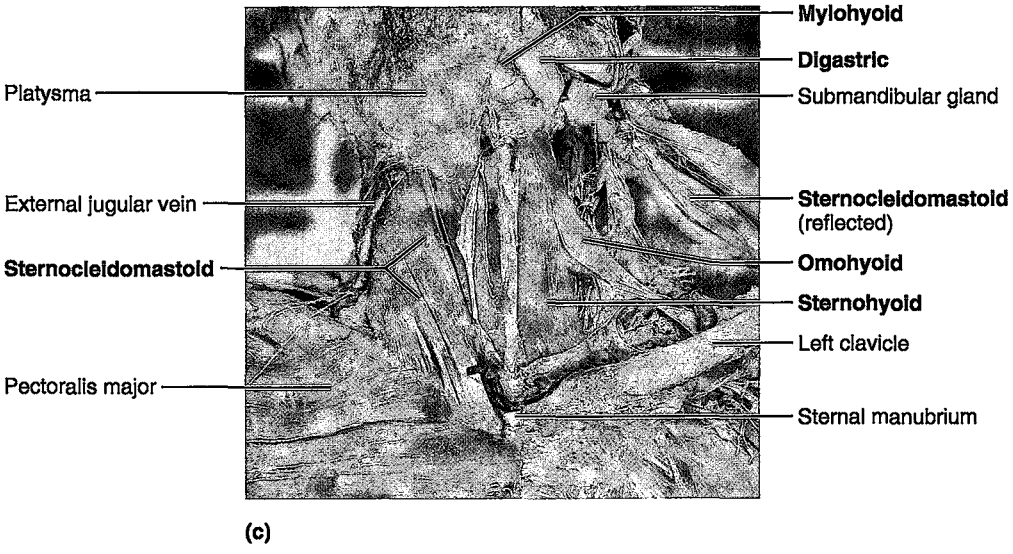


FIGURE 10.9 **Muscles of the neck and vertebral column causing movements of the head and trunk. (a)** Muscles of the anterolateral neck. The superficial platysma muscle and the deeper neck muscles have been removed to show the origins and insertions of the sternocleidomastoid and scalene muscles. **(b)** Deep muscles of the posterior neck; superficial muscles have been removed. **(c)** Photograph of the anterior and lateral regions of the neck. *(Figure continues on p. 345.)*

*The ligamentum nuchae (lig"ah-men'tum noo'ke) is a strong, elastic ligament extending from the occipital bone of the skull along the tips of the spinous processes of the cervical vertebrae. It binds the cervical vertebrae together and inhibits excessive head and neck flexion, thus preventing damage to the spinal cord in the vertebral canal.

MUSCLE GALLERY TABLE 10.4 Muscles of the Neck and Vertebral Column: Head and Trunk Movements (Figure 10.9) *(continued)*

MUSCLE	DESCRIPTION	ORIGIN (O) AND INSERTION (I)	ACTION	NERVE SUPPLY
Erector spinae (e-rek'tor spi'ne) Also called **sacrospinalis** (Figure 10.9d, left side)	Prime mover of back extension. Each side consists of three columns—the iliocostalis, longissimus, and spinalis muscles—forming intermediate layer of intrinsic back muscles. Erector spinae provide resistance that helps control action of bending forward at the waist and act as powerful extensors to promote return to erect position. During full flexion (i.e., when touching fingertips to floor), erector spinae are relaxed and strain is borne entirely by ligaments of back; on reversal of the movement, these muscles are initially inactive, and extension is initiated by hamstring muscles of thighs and gluteus maximus muscles of buttocks. As a result of this peculiarity, lifting a load or moving suddenly from a bent-over position is potentially dangerous (in terms of possible injury) to muscles and ligaments of back and intervertebral discs; erector spinae muscles readily go into painful spasms following injury to back structures.			
▪ **Iliocostalis** (il"e-o-kos-tă'lis)—lumborum, thoracis, and cervicis portions (lum'bor-um; tho-ra'sis) (*ilio* = ilium; *cost* = rib; *thorac* = *thorax*)	Most lateral muscle group of erector spinae muscles; extend from pelvis to neck	O—iliac crests (lumborum); inferior 6 ribs (thoracis); ribs 3 to 6 (cervicis) I—angles of ribs (lumborum and thoracis); transverse processes of cervical vertebrae C_6–C_4 (cervicis)	Extend vertebral column, maintain erect posture; acting on one side, bend vertebral column to same side	Spinal nerves (dorsal rami)
▪ **Longissimus** (lon-jis'ĭ-mus)—thoracis, cervicis, and capitis parts (*longissimus* = longest)	Intermediate tripartite muscle group of erector spinae; extend by many muscle slips from lumbar region to skull; mainly pass between transverse processes of the vertebrae	O—transverse processes of lumbar through cervical vertebrae I—transverse processes of thoracic or cervical vertebrae and to ribs superior to origin as indicated by name; capitis inserts into mastoid process of temporal bone	Thoracis and cervicis act together to extend vertebral column and acting on one side, bend it laterally; capitis extends head and turns the face toward same side	Spinal nerves (dorsal rami)
▪ **Spinalis** (spi-nă'lis)—thoracis and cervicis parts (*spin* = vertebral column, spine)	Most medial muscle column of erector spinae; cervicis usually rudimentary and poorly defined	O—spines of upper lumbar and lower thoracic vertebrae I—spines of upper thoracic and cervical vertebrae	Extends vertebral column	Spinal nerves (dorsal rami)
Semispinalis (sem'e-spĭ-nă'lis)—thoracis, cervicis, and capitis regions (*semi* = half) (Figure 10.9d, right side)	Composite muscle forming part of deep layer of intrinsic back muscles; extends from thoracic region to head	O—transverse processes of C_7–T_{12} I—occipital bone (capitis) and spinous processes of cervical (cervicis) and thoracic vertebrae T_1–T_4 (thoracis)	Extends vertebral column and head and rotates them to opposite side; acts synergistically with sternocleidomastoid muscles of opposite side	Spinal nerves (dorsal rami)
Quadratus lumborum (kwod-ra'tus lum-bor'um) (*quad* = four-sided; *lumb* = lumbar region) (See also Figure 10.19a)	Fleshy muscle forming part of posterior abdominal wall	O—iliac crest and lumbar fascia I—transverse processes of upper lumbar vertebrae and lower margin of 12th rib	Flexes vertebral column laterally when acting separately; when pair acts jointly, lumbar spine is extended and 12th rib is fixed; maintains upright posture; assists in forced inspiration	T_{12} and upper lumbar spinal nerves (ventral rami)

MUSCLE GALLERY TABLE 10.4 *(continued)*

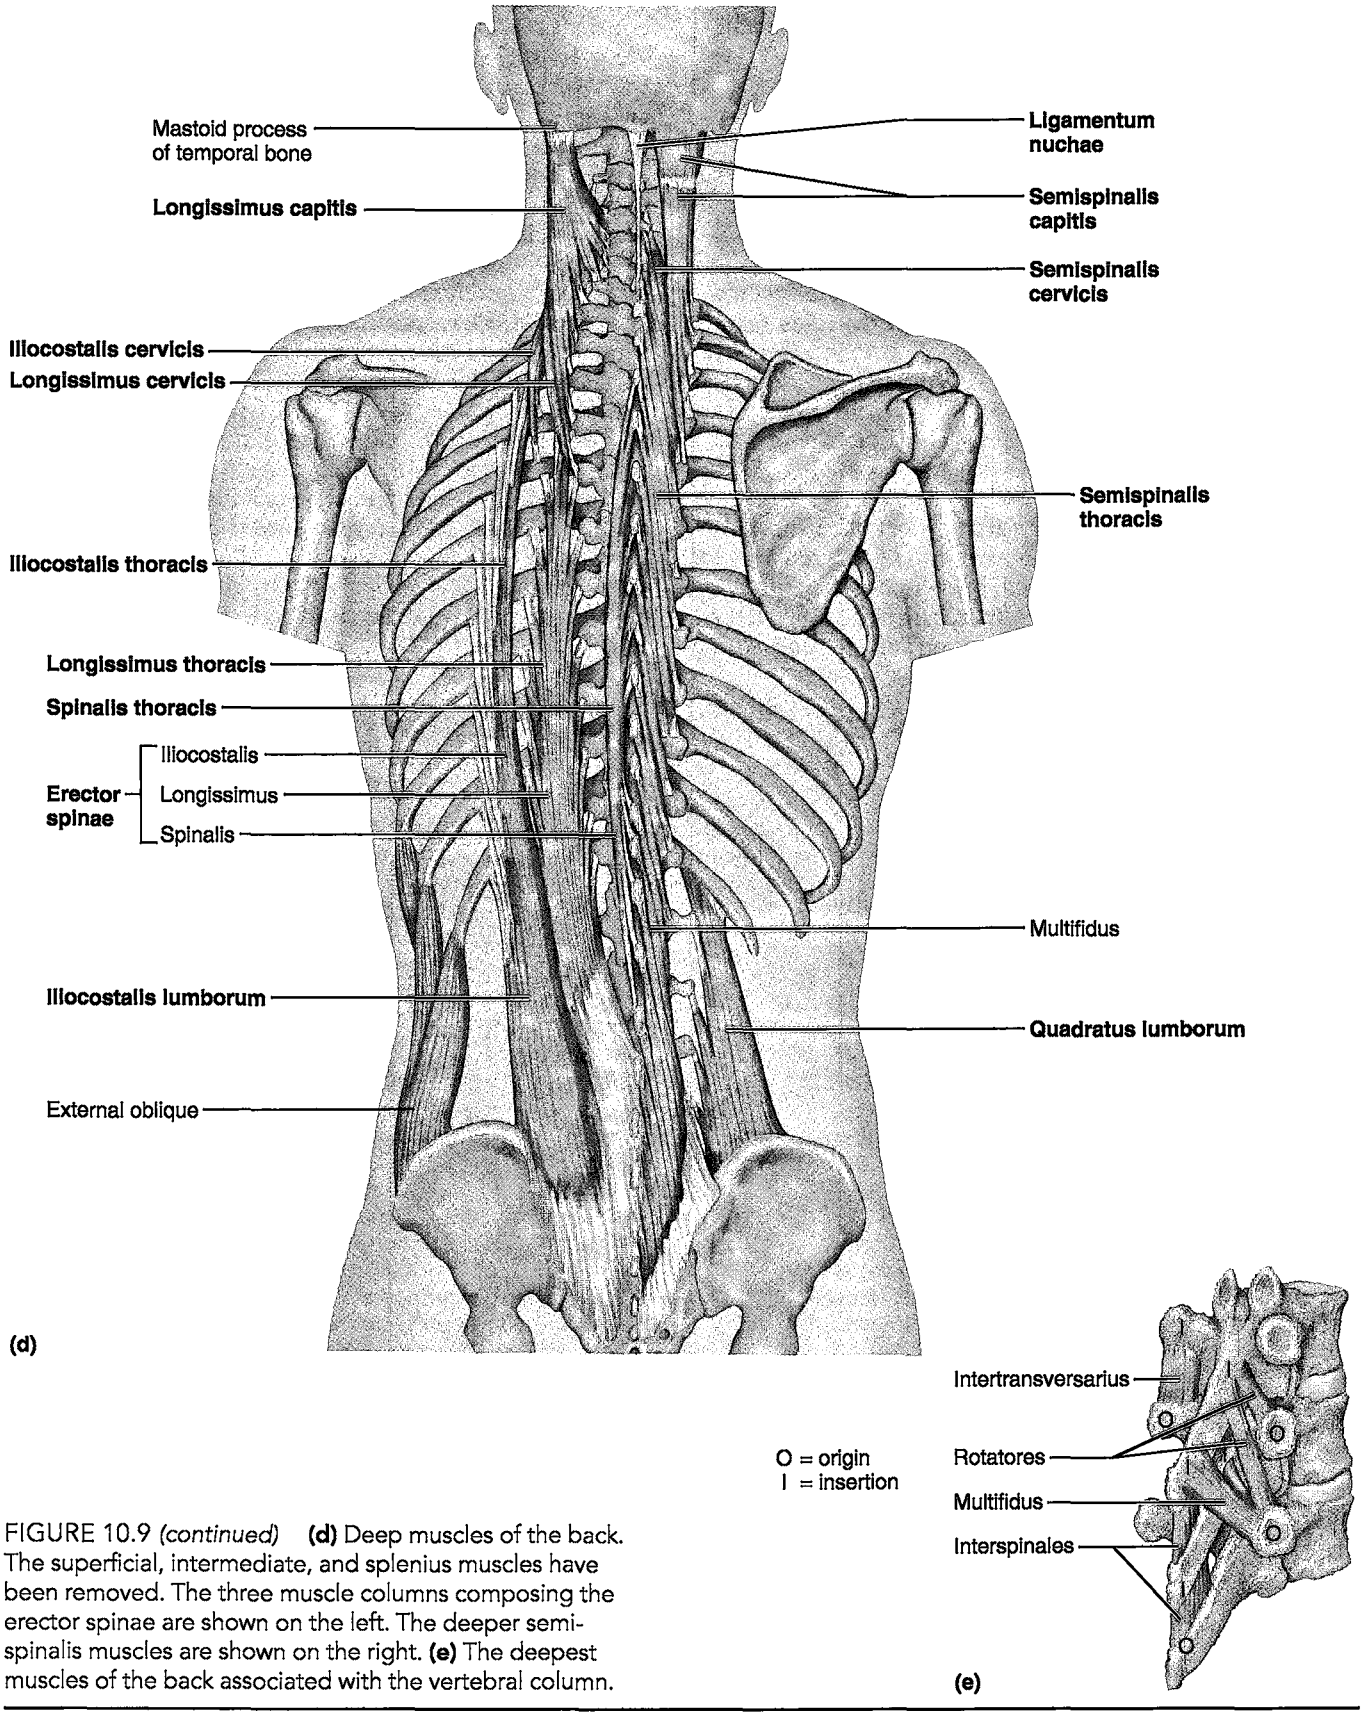

FIGURE 10.9 *(continued)* **(d)** Deep muscles of the back. The superficial, intermediate, and splenius muscles have been removed. The three muscle columns composing the erector spinae are shown on the left. The deeper semispinalis muscles are shown on the right. **(e)** The deepest muscles of the back associated with the vertebral column.

MUSCLE GALLERY TABLE 10.5 Muscles of the Thorax: Breathing (Figure 10.10)

The primary function of the deep muscles of the thorax is to promote movements necessary for breathing. Breathing consists of two phases—inspiration, or inhaling, and expiration, or exhaling—caused by cyclic changes in the volume of the thoracic cavity.

Two main layers of muscles help form the anterolateral wall of the thorax. The thoracic muscles are very short, most extending only from one rib to the next. On contraction, they draw the somewhat flexible ribs closer together. The **external intercostal muscles,** considered inspiratory muscles, form the more superficial layer. They lift the rib cage, an action that increases the anterior to posterior and side-to-side dimensions of the thorax. The **internal intercostal muscles** form the deeper layer and aid active (forced) expiration by depressing the rib cage. (However, quiet expiration is largely a passive phenomenon, resulting from relaxation of the external intercostals and diaphragm and elastic recoil of the lungs.)

The **diaphragm,** the most important muscle of inspiration, forms a muscular partition between the thoracic and abdominopelvic cavities. In the relaxed state, the diaphragm is dome shaped, but when it contracts it moves inferiorly and flattens, increasing the volume of the thoracic cavity. The alternating contraction and relaxation of the diaphragm causes pressure changes in the abdominopelvic cavity below that facilitate the return of blood to the heart. In addition to its rhythmic contractions during respiration, one can also contract the diaphragm voluntarily to push down on the abdominal viscera and increase the pressure in the abdominal cavity to help evacuate pelvic organ contents (urine, feces, or a baby) or during weight lifting. When one takes a deep breath to fix the diaphragm, the abdomen becomes a firm pillar that will not buckle under the weight being lifted. Needless to say, it is important to have good control of the bladder and anal sphincters during such maneuvers.

With the exception of the diaphragm, which is served by the *phrenic nerves,* the muscles listed in this table are served by the *intercostal nerves,* which run between the ribs.

Forced breathing calls into play a number of other muscles that insert into the ribs; e.g., during forced inspiration the scalene and sternocleidomastoid muscles of the neck help lift the ribs. Forced expiration is aided by muscles that pull the ribs inferiorly and those that push the diaphragm superiorly by compressing the abdominal contents (abdominal wall muscles).

MUSCLE	DESCRIPTION	ORIGIN (O) AND INSERTION (I)	ACTION	NERVE SUPPLY
External intercostals (in"ter-kos'talz) (*external* = toward the outside; *inter* = between; *cost* = rib)	11 pairs lie between ribs; fibers run obliquely (down and forward) from each rib to rib below; in lower intercostal spaces, fibers are continuous with external oblique muscle, forming part of abdominal wall	O—inferior border of rib above I—superior border of rib below	With first ribs fixed by scalene muscles, pull ribs toward one another to elevate rib cage; aid in inspiration; synergists of diaphragm	Intercostal nerves
Internal intercostals (*internal* = toward the inside, deep)	11 pairs lie between ribs; fibers run deep to and at right angles to those of external intercostals (i.e., run downward and posteriorly); lower internal intercostal muscles are continuous with fibers of internal oblique muscle of abdominal wall	O—superior border of rib below I—inferior border (costal groove) of rib above	With 12th ribs fixed by quadratus lumborum, muscles of posterior abdominal wall, and oblique muscles of the abdominal wall, they draw ribs together and depress rib cage; aid in forced expiration; antagonistic to external intercostals	Intercostal nerves
Diaphragm (di'ah-fram) (*dia* = across; *phragm* = partition)	Broad muscle pierced by the aorta, inferior vena cava, and esophagus, forms floor of thoracic cavity; in relaxed state is dome shaped; fibers converge from margins of thoracic cage toward a boomerang-shaped central tendon	O—inferior, internal surface of rib cage and sternum, costal cartilages of last six ribs and lumbar vertebrae I—central tendon	Prime mover of inspiration; flattens on contraction, increasing vertical dimensions of thorax; when strongly contracted, dramatically increases intra-abdominal pressure	Phrenic nerves

FIGURE 10.10 **Muscles of respiration. (a)** Deep muscles of the thorax. The external intercostals (inspiratory muscles) are shown on the left and the internal intercostals (expiratory muscles) are shown on the right. These two muscle layers run obliquely and at right angles to each other. **(b)** Inferior view of the diaphragm, the prime mover of inspiration. Notice that its muscle fibers converge toward a central tendon, an arrangement that causes the diaphragm to flatten and move inferiorly as it contracts. **(c)** Photograph of the diaphragm, superior view. MUSCLE GALLERY TABLE 10.6 Muscles of the Abdominal Wall: Trunk Movements and Compression of Abdominal Viscera (Figure 10.11)

Unlike the thorax, the anterior and lateral abdominal wall has no bony reinforcements (ribs). Instead, it is a composite of four paired muscles, their investing fasciae, and aponeuroses. Three broad flat muscle pairs, layered one atop the next, form the lateral abdominal walls: The fibers of the **external oblique muscle** run inferomedially and at right angles to those of the **internal oblique,** which immediately underlies it. The fibers of the deep **transversus abdominis muscle** run horizontally across the abdomen at an angle to both. This alternation of fascicle directions is similar to the construction of plywood (which is made of sheets with different grains) and provides great strength. These three muscles blend into broad insertion aponeuroses anteriorly. The aponeuroses, in turn, enclose a fourth muscle pair medially, the straplike **rectus abdominis muscles,** and then fuse, forming the **linea alba** ("white line"), a tendinous raphe (seam) that runs from the sternum to the pubic symphysis. Enclosure of the rectus abdominis muscles within the aponeuroses prevents them from "bowstringing" (protruding anteriorly). The quadratus lumborum muscles of the *posterior* abdominal wall are covered in Table 10.4.

The abdominal muscles protect and support the viscera most effectively when they are well toned. When weak or severely stretched (as during pregnancy), they allow the abdomen to become pendulous (i.e., to form a potbelly). Additional functions include lateral flexion and rotation of the trunk and anterior flexion of the trunk against resistance (as in sit-ups). During inspiration, the abdominal muscles relax, allowing the abdominal viscera to be pushed inferiorly by the descending diaphragm. When all these abdominal muscles contract in unison, several different activities may be effected. For example, when they contract simultaneously, the ribs are pulled inferiorly and the abdominal contents compressed. This pushes the visceral organs upward on the diaphragm, aiding forced expiration. When the abdominal muscles contract with the diaphragm and the glottis is closed (an action called the Valsalva maneuver), the increased intra-abdominal pressure helps to promote urination, defecation, childbirth, vomiting, coughing, screaming, sneezing, burping, and nose blowing. (Next time you perform one of these activities, feel your abdominal muscles contract under your skin.) These muscles also contract during heavy lifting—sometimes so forcefully that hernias result. Contraction of the abdominal muscles along with contraction of the deep back muscles helps prevent hyperextension of the spine and splints the entire body trunk.

MUSCLE	DESCRIPTION	ORIGIN (O) AND INSERTION (I)	ACTION	NERVE SUPPLY
Muscles of the Anterior and Lateral Abdominal Wall				
Rectus abdominis (rek'tus ab-dom'ĭ-nis) (*rectus* = straight; *abdom* = abdomen)	Medial superficial muscle pair; extend from pubis to rib cage; ensheathed by aponeuroses of lateral muscles; segmented by 3 tendinous intersections	O—pubic crest and symphysis I—xiphoid process and costal cartilages of ribs 5–7	Flex and rotate lumbar region of vertebral column; fix and depress ribs, stabilize pelvis during walking, increase intra-abdominal pressure; used in sit-ups, curls	Intercostal nerves (T_6 or T_7–T_{12})
External oblique (o-blēk') (*external* = toward outside; *oblique* = running at an angle)	Largest and most superficial of the three lateral muscles; fibers run downward and medially (same direction outstretched fingers take when hands put into pants pockets); aponeurosis turns under inferiorly, forming inguinal ligament	O—by fleshy strips from outer surfaces of lower eight ribs I—most fibers insert anteriorly via a broad aponeurosis into linea alba; some into pubic crest and tubercle and iliac crest	When pair contract simultaneously, aid rectus abdominis muscles in flexing vertebral column and in compressing abdominal wall and increasing intra-abdominal pressure; acting individually, aid muscles of back in trunk rotation and lateral flexion; used in oblique curls	Intercostal nerves (T_7–T_{12})
Internal oblique (*internal* = toward the inside; deep)	Most fibers run upward and medially; however, the muscle fans so its inferior fibers run downward and medially	O—lumbar fascia, iliac crest, and inguinal ligament I—linea alba, pubic crest, last three or four ribs, and costal margin	As for external oblique	Intercostal nerves (T_7–T_{12}) and L_1
Transversus abdominis (trans-ver'sus) (*transverse* = running straight across)	Deepest (innermost) muscle of abdominal wall; fibers run horizontally	O—inguinal ligament, lumbar fascia, cartilages of last six ribs; iliac crest I—linea alba, pubic crest	Compresses abdominal contents	Intercostal nerves (T_7–T_{12}) and L_1

MUSCLE GALLERY TABLE 10.6 *(continued)*

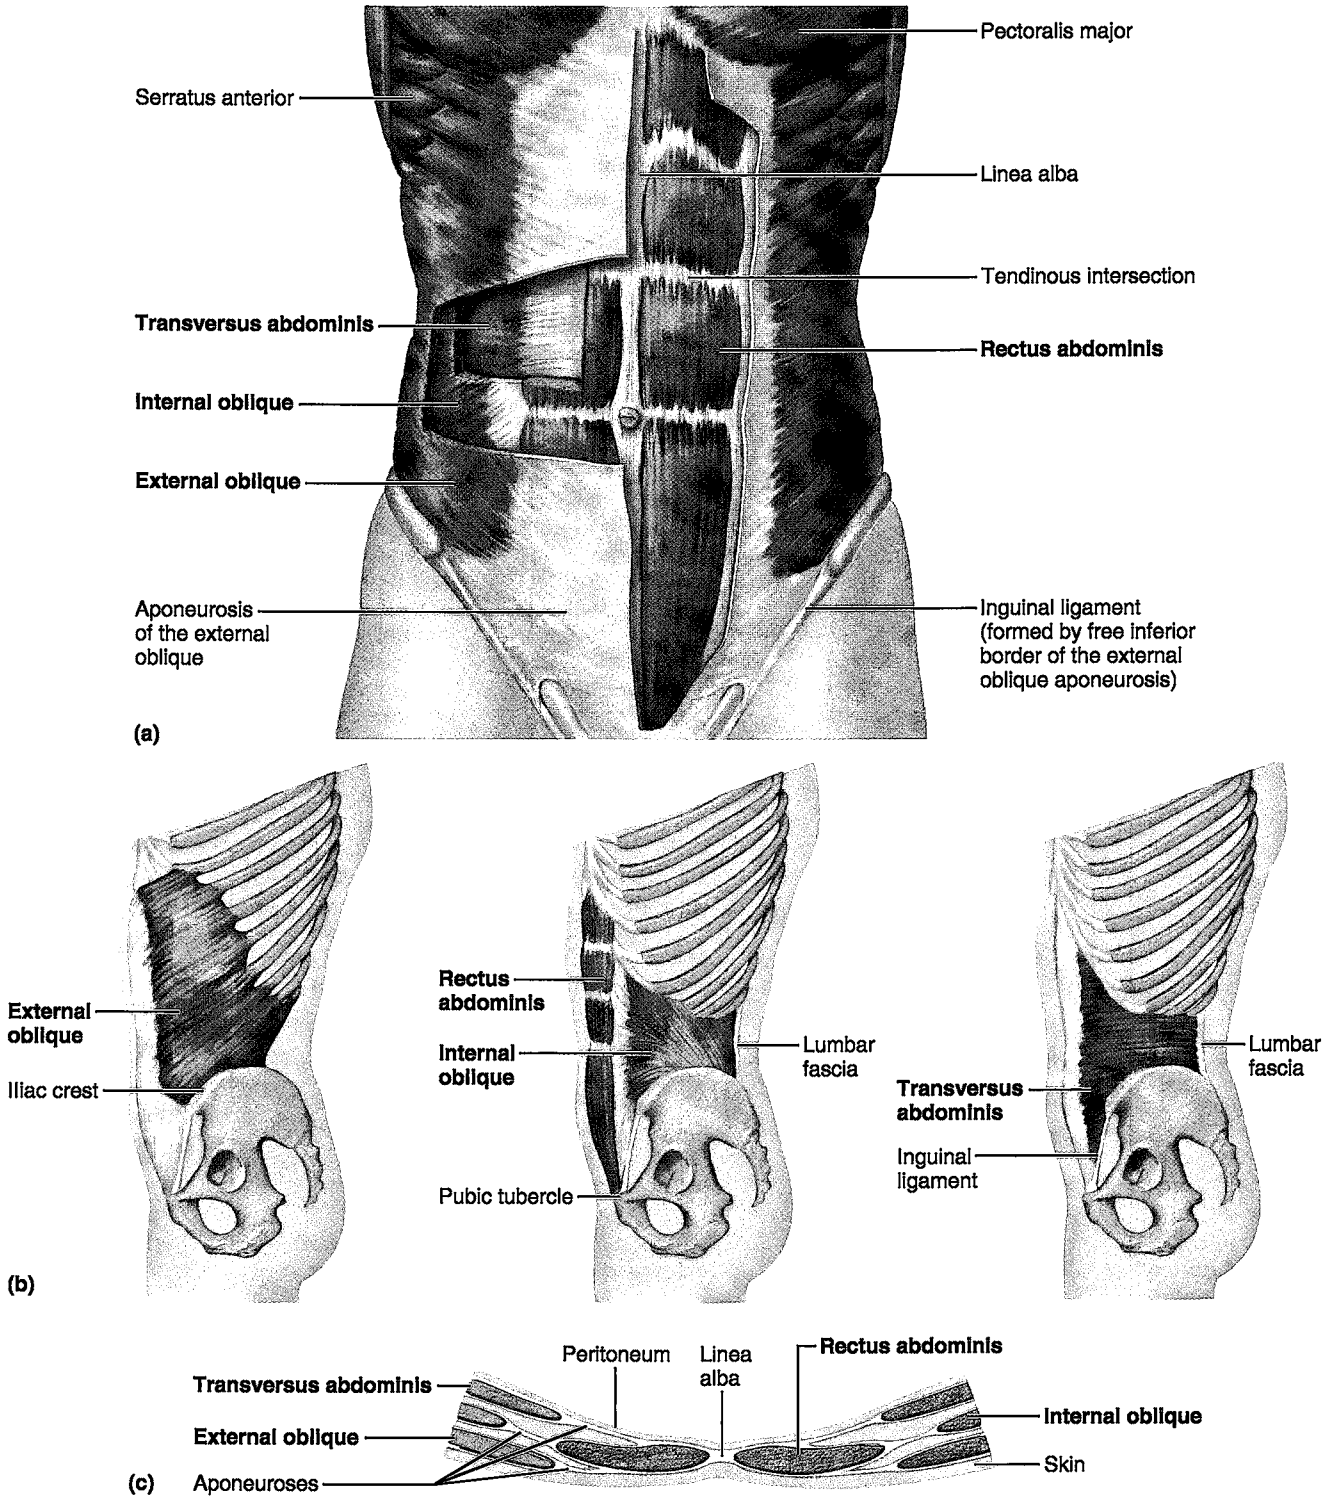

FIGURE 10.11 **Muscles of the abdominal wall. (a)** Anterior view of the muscles forming the anterolateral abdominal wall. The superficial muscles have been partially cut away to reveal the deeper muscles. **(b)** Lateral view of the trunk, illustrating the fiber direction and attachments of the external and internal obliques, and transversus abdominis muscles. Although shown in the same view, the rectus abdominis is deep to the fascia of the internal oblique muscle. **(c)** Transverse section through the anterolateral abdominal wall (midregion), showing how the aponeuroses of the lateral abdominal muscles contribute to the rectus abdominis sheath.

MUSCLE GALLERY TABLE 10.7 Muscles of the Pelvic Floor and Perineum: Support of Abdominopelvic Organs (Figure 10.12)

Two paired muscles, the **levator ani** and **coccygeus,** form the funnel-shaped pelvic floor, or **pelvic diaphragm.** These muscles (1) seal the inferior outlet of the pelvis, (2) support the pelvic floor and elevate it to release feces, and (3) resist increased intra-abdominal pressure (which would expel contents of the bladder, rectum, and uterus). The pelvic diaphragm is pierced by the rectum and urethra (urinary tube), and by the vagina in females. The body region inferior to the pelvic diaphragm is the *perineum*. The relationships of the perineum are worth explaining. Inferior to the muscles of the pelvic floor, and stretching between the two sides of the pubic arch in the anterior half of the perineum, is the **urogenital diaphragm.** This thin triangular sheet of muscle contains the **external urethral sphincter,** a sphincter muscle that surrounds the urethra and allows voluntary control of urination. Superficial to the urogenital diaphragm, and covered by the skin of the perineum, is the *superficial space,* which contains muscles (**ischiocavernosus** and **bulbospongiosus**) that help maintain erection of the penis and clitoris. In the posterior half of the perineum encircling the anus is the **external anal sphincter,** which allows voluntary control of defecation. Just anterior to this sphincter is the **central tendon of the perineum,** a strong tendon into which many of the perineal muscles insert.

MUSCLE	DESCRIPTION	ORIGIN (O) AND INSERTION (I)	ACTION	NERVE SUPPLY
Muscles of the Pelvic Diaphragm (Figure 10.12a)				
Levator ani (lĕ-va'tor a'ne) (*levator* = raises; *ani* = anus)	Broad, thin, tripartite muscle (pubococcygeus, puborectalis, and iliococcygeus parts); its fibers extend inferomedially, forming a muscular "sling" around male prostate (or female vagina), urethra, and anorectal junction before meeting in the median plane	O—extensive linear origin inside pelvis from pubis to ischial spine I—inner surface of coccyx, levator ani of opposite side, and (in part) into the structures that penetrate it	Supports and maintains position of pelvic viscera; resists downward thrusts that accompany rises in intrapelvic pressure during coughing, vomiting, and expulsive efforts of abdominal muscles; forms sphincters at anorectal junction and vagina; lifts anal canal during defecation	S_4 and inferior rectal nerve (branch of pudendal nerve)
Coccygeus (kok-sij'e-us) (*coccy* = coccyx)	Small triangular muscle lying posterior to levator ani; forms posterior part of pelvic diaphragm	O—spine of ischium I—sacrum and coccyx	Supports pelvic viscera; supports coccyx and pulls it forward after it has been reflected posteriorly by defecation and childbirth	S_4 and S_5
Muscles of the Urogenital Diaphragm (Figure 10.12b)				
Deep transverse perineal muscle (per"ĭ-ne'al) (*deep* = far from surface; *transverse* = across; *perine* = near anus)	Together the pair spans distance between ischial rami; in females, lies posterior to vagina	O—ischial rami I—midline central tendon of perineum; some fibers into vaginal wall in females	Supports pelvic organs; steadies central tendon	Pudendal nerve
External urethral sphincter (*sphin* = squeeze)	Muscle encircling urethra and vagina (female)	O—ischiopubic rami I—midline raphe	Constricts urethra; helps support pelvic organs	Pudendal nerve
Muscles of the Superficial Space (Figure 10.12c)				
Ischiocavernosus (is'ke-o-kav'ern-o'sus) (*ischi* = hip; *caverna* = hollow chamber)	Runs from pelvis to base of penis or clitoris	O—ischial tuberosities I—crus of corpus cavernosa of male penis or female clitoris	Retards venous drainage and maintains erection of penis or clitoris	Pudendal nerve
Bulbospongiosus (bul"bo-spun"je-o'sus) (*bulbon* = bulb; *spongio* = sponge)	Encloses base of penis (bulb) in males and lies deep to labia in females	O—central tendon of perineum and midline raphe of penis I—anteriorly into corpus cavernosa of penis or clitoris	Empties male urethra; assists in erection of penis and of clitoris	Pudendal nerve
Superficial transverse perineal muscles (*superficial* = closer to surface)	Paired muscle bands posterior to urethral (and in females, vaginal) opening; variable; sometimes absent	O—ischial tuberosity I—central tendon of perineum	Stabilizes and strengthens midline tendon of perineum	Pudendal nerve

MUSCLE GALLERY TABLE 10.7 *(continued)*

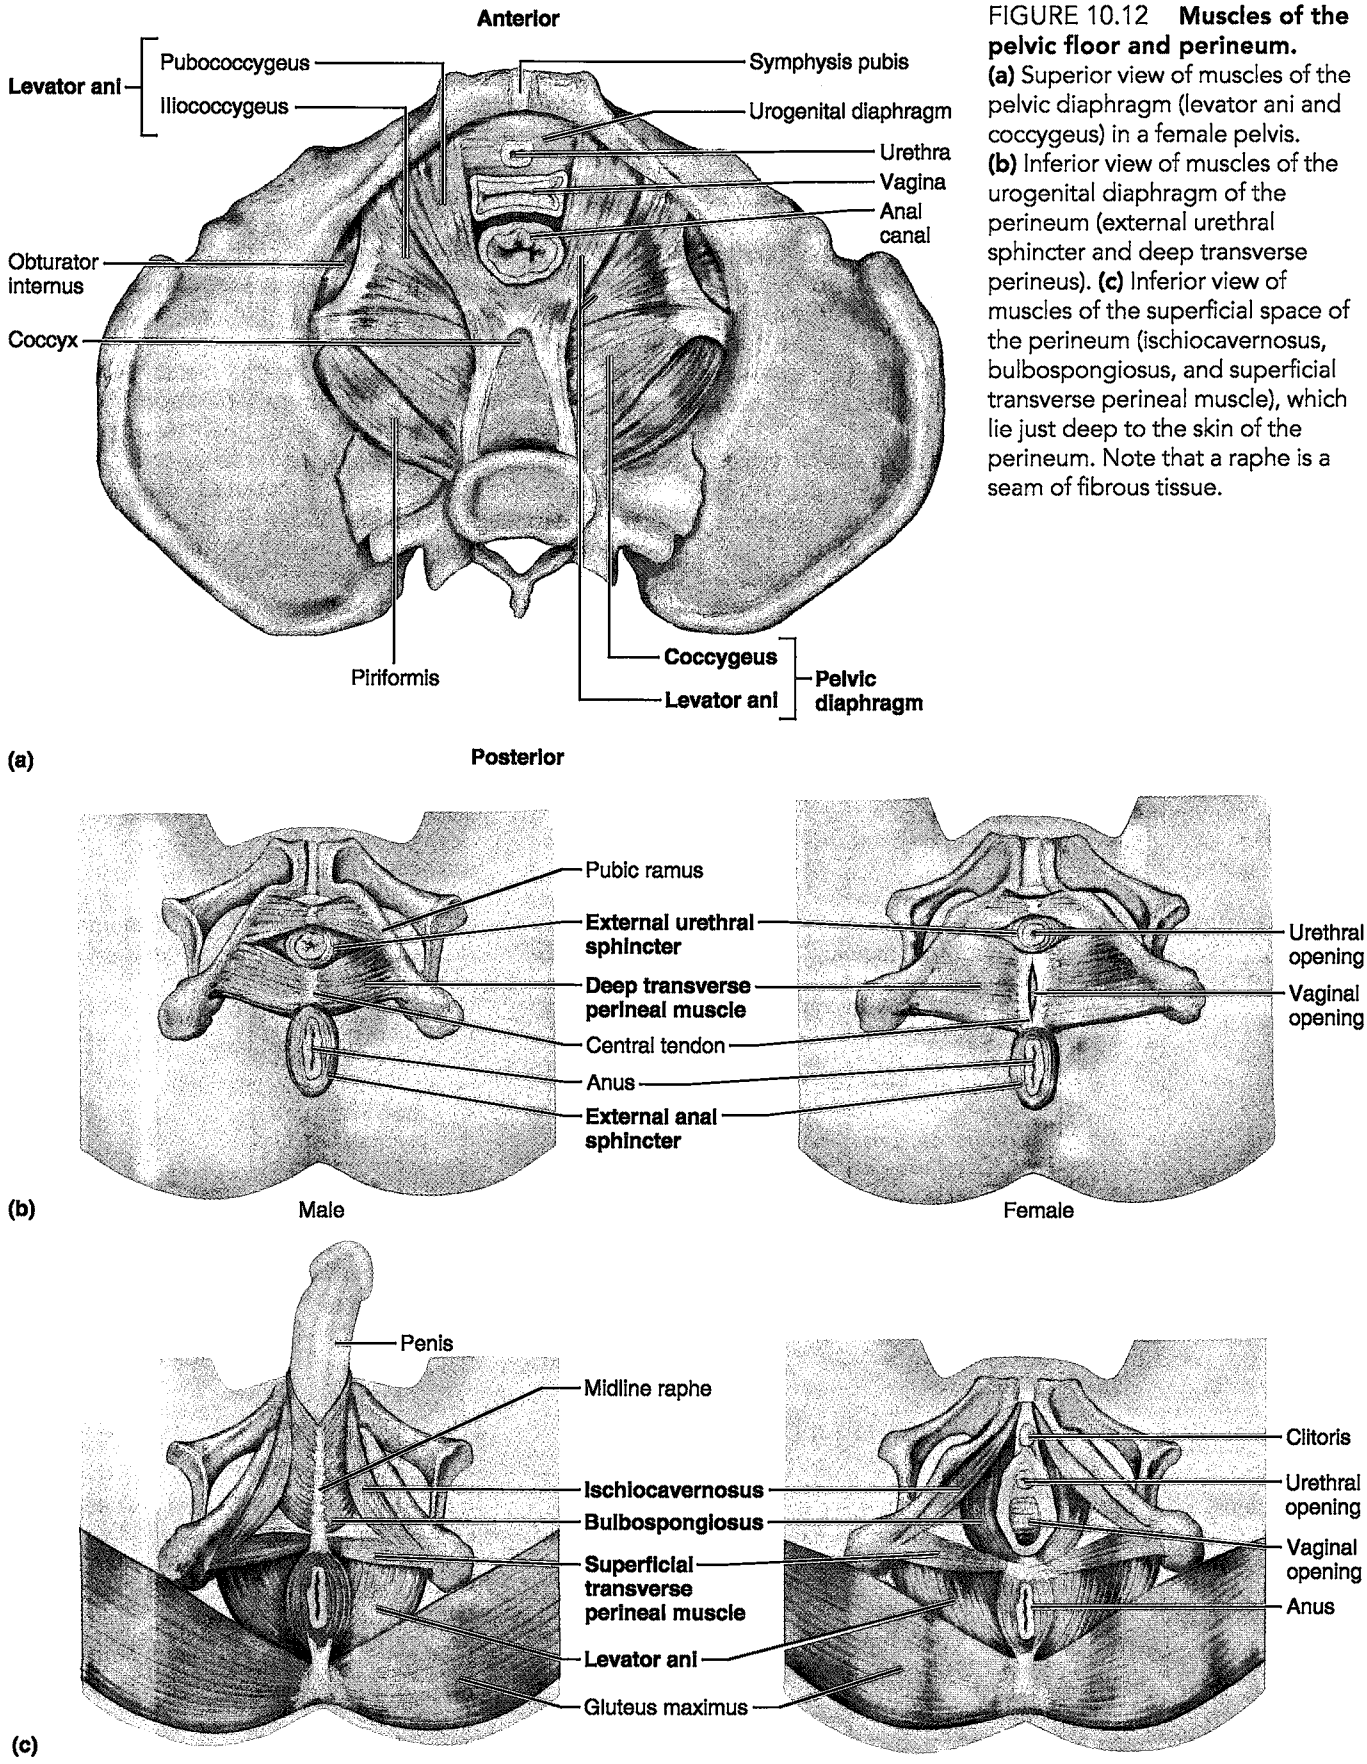

FIGURE 10.12 **Muscles of the pelvic floor and perineum.** **(a)** Superior view of muscles of the pelvic diaphragm (levator ani and coccygeus) in a female pelvis. **(b)** Inferior view of muscles of the urogenital diaphragm of the perineum (external urethral sphincter and deep transverse perineus). **(c)** Inferior view of muscles of the superficial space of the perineum (ischiocavernosus, bulbospongiosus, and superficial transverse perineal muscle), which lie just deep to the skin of the perineum. Note that a raphe is a seam of fibrous tissue.

MUSCLE GALLERY TABLE 10.8 Superficial Muscles of the Anterior and Posterior Thorax: Movements of the Scapula (Figure 10.13)

Most superficial thorax muscles are *extrinsic shoulder muscles*, which run from the ribs and vertebral column to the shoulder girdle. They fix the scapula to the wall of the thorax; they also move it to increase the range of arm movements. The muscles of the anterior thorax include the **pectoralis major, pectoralis minor, serratus anterior,** and **subclavius.** Except for the pectoralis major, which inserts into the humerus, all muscles of the anterior group insert into the pectoral girdle. Extrinsic muscles of the posterior thorax include the **latissimus dorsi** and **trapezius muscles** superficially and the underlying **levator scapulae** and **rhomboids.** The latissimus dorsi, like the pectoralis major muscles anteriorly, insert into the humerus and are more concerned with movements of the arm than of the scapula. We will defer consideration of these two muscle pairs to Table 10.9 (arm-moving muscles).

The important movements of the pectoral girdle involve displacements of the scapula, i.e., its elevation and depression, rotation, lateral (forward) movements, and medial (backward) movements. The clavicles rotate around their own axes to provide both stability and precision to scapular movements.

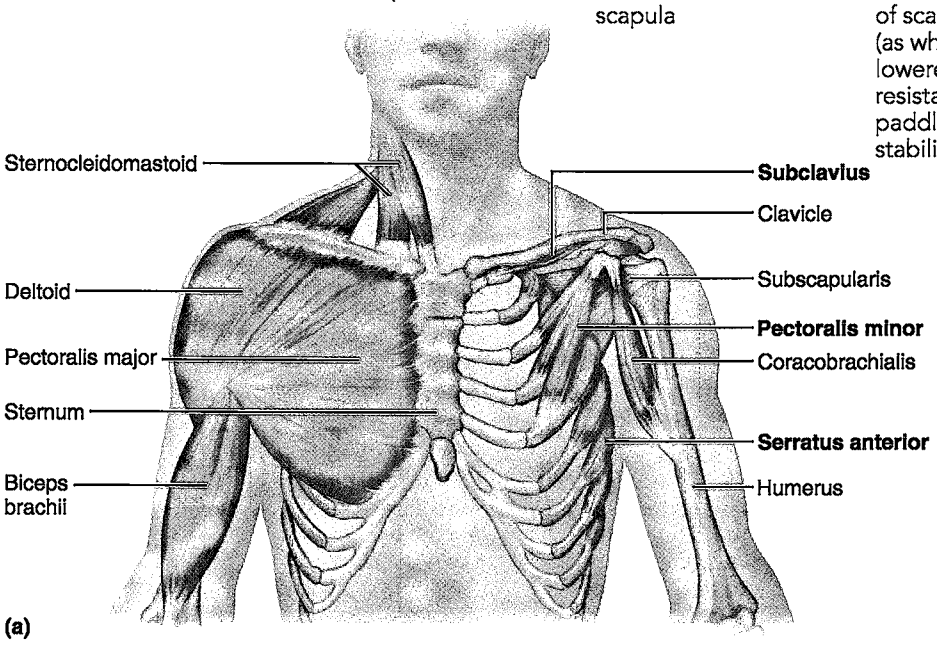
Except for the serratus anterior, the anterior muscles stabilize and depress the shoulder girdle. Thus, most scapular movements are promoted by the serratus anterior muscles anteriorly and by posterior muscles. The arrangement of muscle attachments to the scapula is such that one muscle cannot bring about a simple (linear) movement on its own. To effect scapular movements, several muscles must act in combination.

The prime movers of shoulder elevation are the trapezius and levator scapulae. When acting together to shrug the shoulder, their opposite rotational effects counterbalance each other. The scapula is depressed largely by gravity (weight of the arm), but when it is depressed against resistance, the trapezius and serratus anterior (along with the latissimus dorsi, Table 10.9) are active. Forward movements (abduction) of the scapula on the thorax wall, as in pushing or punching movements, mainly reflect serratus anterior activity. Retraction (adduction) of the scapula is effected by the trapezius and rhomboids. Although the serratus anterior and trapezius muscles are antagonists in forward/backward movements of the scapulae, they act together to coordinate *rotational* scapular movements.

MUSCLE	DESCRIPTION	ORIGIN (O) AND INSERTION (I)	ACTION	NERVE SUPPLY
Muscles of the Anterior Thorax (Figure 10.13a)				
Pectoralis minor (pek"to-ra'lis mi'nor) (*pectus* = chest, breast; *minor* = lesser)	Flat, thin muscle directly beneath and obscured by pectoralis major	O—anterior surfaces of ribs 3–5 (or 2–4) I—coracoid process of scapula	With ribs fixed, draws scapula forward and downward; with scapula fixed, draws rib cage superiorly	Medial and lateral pectoral nerves (C_6–C_8)
Serratus anterior (ser-a'tus) (*serratus* = saw)	Fan-shaped muscle; lies deep to scapula, beneath and inferior to pectoral muscles on lateral rib cage; forms medial wall of axilla; origins have serrated, or sawtooth, appearance; paralysis results in "winging" of vertebral border of scapula away from chest wall, making arm elevation impossible	O—by a series of muscle slips from ribs 1–8 (or 9) I—entire anterior surface of vertebral border of scapula	Prime mover to protract and hold scapula against chest wall; rotates scapula so that its inferior angle moves laterally and upward; raises point of shoulder; important role in abduction and raising of arm and in horizontal arm movements (pushing, punching); called "boxer's muscle"	Long thoracic nerve (C_5–C_7)
Subclavius (sub-kla've-us) (*sub* = under, beneath; *clav* = clavicle)	Small cylindrical muscle extending from rib 1 to clavicle	O—costal cartilage of rib 1 I—groove on inferior surface of clavicle	Helps stabilize and depress pectoral girdle	Nerve to subclavius (C_5 and C_6)
Muscles of the Posterior Thorax (Figure 10.13b)				
Trapezius (trah-pe'ze-us) (*trapezion* = irregular four-sided figure)	Most superficial muscle of posterior thorax; flat, and triangular in shape; upper fibers run inferiorly to scapula; middle fibers run horizontally to scapula; lower fibers run superiorly to scapula	O—occipital bone, ligamentum nuchae, and spines of C_7 and all thoracic vertebrae I—a continuous insertion along acromion and spine of scapula and lateral third of clavicle	Stabilizes, raises, retracts, and rotates scapula; middle fibers retract (adduct) scapula; superior fibers elevate scapula (as in shrugging the shoulders) or can help extend head with scapula fixed; inferior fibers depress scapula (and shoulder)	Accessory nerve (cranial nerve XI); C_3 and C_4

MUSCLE GALLERY TABLE 10.8 *(continued)*

MUSCLE	DESCRIPTION	ORIGIN (O) AND INSERTION (I)	ACTION	NERVE SUPPLY
Levator scapulae (skap'u-le) (*levator* = raises)	Located at back and side of neck, deep to trapezius; thick, straplike muscle border of scapula	O—transverse processes of C_1–C_4 I—medial border of the scapula, superior to the spine	Elevates/adducts scapula in concert with superior fibers of trapezius; tilts glenoid cavity downward when scapula is fixed, flexes neck to same side	Cervical spinal nerves and dorsal scapular nerve (C_3–C_5)
Rhomboids (rom'boidz)—major and minor (*rhomboid* = diamond shaped)	Two rectangular muscles lying deep to trapezius and inferior to levator scapulae; rhomboid minor is the more superior muscle	O—spinous processes of C_7 and T_1 (minor) and spinous processes of T_2–T_5 (major) I—medial border of scapula	Act together (and with middle trapezius fibers) to retract scapula, thus "squaring shoulders"; rotate glenoid cavity of scapula downward (as when arm is lowered against resistance; e.g., paddling a canoe); stabilize scapula	Dorsal scapular nerve (C_4 and C_5)



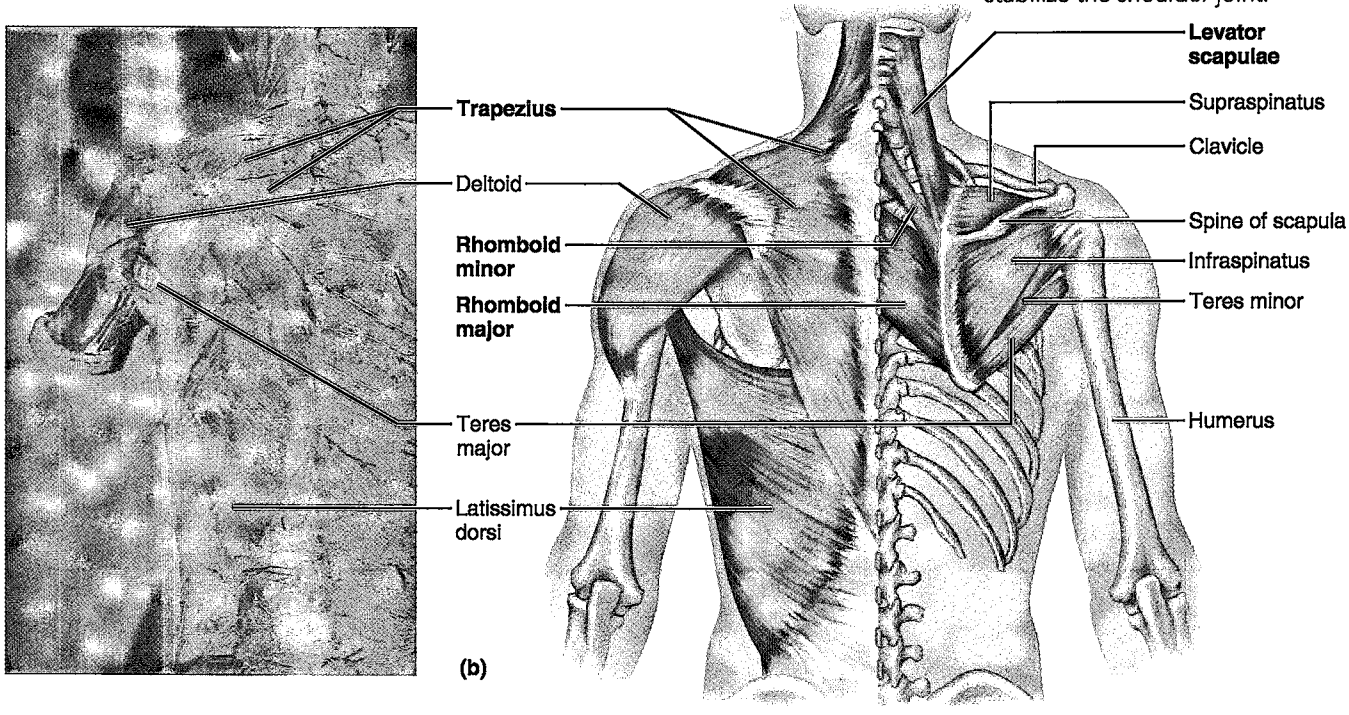


FIGURE 10.13 **Superficial muscles of the thorax and shoulder acting on the scapula and arm. (a)** Anterior view. The superficial muscles, which effect arm movements, are shown on the left side of the illustration. These muscles are removed on the right to show the muscles that stabilize or move the pectoral girdle. **(b)** Posterior view. The superficial muscles are shown for the left side of the illustration, with a corresponding photograph. The superficial muscles are removed on the right side to reveal the deeper muscles acting on the scapula, and the rotator cuff muscles that help stabilize the shoulder joint.

MUSCLE GALLERY TABLE 10.9 Muscles Crossing the Shoulder Joint: Movements of the Arm (Figure 10.14)

Recall that the ball-and-socket shoulder joint is the most flexible joint in the body, but pays the price of instability. A total of nine muscles cross each shoulder joint to insert on the humerus. All muscles acting on the humerus originate from the pectoral girdle; however, the latissimus dorsi and pectoralis major primarily originate on the axial skeleton.

Of these nine muscles, only the superficial **pectoralis major, latissimus dorsi,** and **deltoid muscles** are prime movers of arm movements. The remaining six are synergists and fixators. Four of these, the **supraspinatus, infraspinatus, teres minor,** and **subscapularis,** are known as *rotator cuff muscles.* They originate on the scapula, and their tendons blend with the fibrous capsule of the shoulder joint en route to the humerus. Although the rotator cuff muscles act as synergists in the angular and rotational movements of the arm, their main function is to reinforce the capsule of the shoulder joint to prevent dislocation of the humerus. The remaining two muscles, the small **teres major** and **coracobrachialis,** cross the shoulder joint but do not contribute to its reinforcement.

Generally speaking, muscles that originate *anterior* to the shoulder joint (pectoralis major, coracobrachialis, and anterior fibers of the deltoid) *flex* the arm, i.e., lift it anteriorly. The prime mover of arm flexion is the pectoralis major. The biceps brachii of the arm (see Table 10.10) also assists in this action. Muscles originating *posterior* to the shoulder joint extend the arm. These include the latissimus dorsi and posterior fibers of the deltoid muscles (both prime movers of arm extension) and the teres major. Thus, the latissimus dorsi and pectoralis muscles are *antagonists* of one another in the flexion-extension movements of the arm.

The middle region of the fleshy deltoid muscle of the shoulder is the prime mover of arm abduction. The main adductors are the pectoralis major anteriorly and latissimus dorsi posteriorly. The small muscles acting on the humerus promote lateral and medial rotation of the shoulder joint. Since the interactions of these nine muscles are complex and each muscle contributes to more than a single movement, a summary of muscles contributing to the various angular and rotational movements of the humerus is provided in Table 10.12 (Part I).

MUSCLE	DESCRIPTION	ORIGIN (O) AND INSERTION (I)	ACTION	NERVE SUPPLY
Pectoralis major (pek"to-ra'lis ma'jer) (*pectus* = breast, chest; *major* = larger)	Large, fan-shaped muscle covering upper portion of chest; forms anterior axillary fold; divided into clavicular and sternal parts	O—sternal end of clavicle, sternum, cartilage of ribs 1–6 (or 7), and aponeurosis of external oblique muscle I—fibers converge to insert by a short tendon into greater tubercle of humerus	Prime mover of arm flexion; rotates arm medially; adducts arm against resistance; with scapula (and arm) fixed, pulls rib cage upward, thus can help in climbing, throwing, pushing, and in forced inspiration	Lateral and medial pectoral nerves (C_5–C_8, and T_1)
Latissimus dorsi (lah-tis'ĭ-mus dor'si) (*latissimus* = widest; *dorsi* = back)	Broad, flat, triangular muscle of lower back (lumbar region); extensive superficial origins; covered by trapezius superiorly; contributes to the posterior wall of axilla	O—indirect attachment via lumbodorsal fascia into spines of lower six thoracic vertebrae, lumbar vertebrae, lower 3 to 4 ribs, and iliac crest I—spirals around teres major to insert in floor of intertubercular sulcus of humerus	Prime mover of arm extension; powerful arm adductor; medially rotates arm at shoulder; depresses scapula; because of its power in these movements, it plays an important role in bringing the arm down in a power stroke, as in striking a blow, hammering, swimming, and rowing; with arms fixed overhead, it pulls the rest of the body upward and forward	Thoracodorsal nerve (C_6–C_8)

MUSCLE	DESCRIPTION	ORIGIN (O) AND INSERTION (I)	ACTION	NERVE SUPPLY
Deltoid (del'toid)) (*delta* = triangular)	Thick, multipennate muscle forming rounded shoulder muscle mass; responsible for roundness of shoulder; a site commonly used for intramuscular injection, particularly in males, where it tends to be quite fleshy	O—embraces insertion of the trapezius; lateral third of clavicle; acromion and spine of scapula I—deltoid tuberosity of humerus	Prime mover of arm abduction when all its fibers contract simultaneously; antagonist of pectoralis major and latissimus dorsi, which adduct the arm; if only anterior fibers are active, can act powerfully in flexion and medial rotation of humerus, therefore synergist of pectoralis major; if only posterior fibers are active, effects extension and lateral rotation of arm; active during rhythmic arm swinging movements during walking	Axillary nerve (C_5 and C_6)
Subscapularis (sub-scap"u-lar'is) (*sub* = under; *scapular* = scapula)	Forms part of posterior wall of axilla; tendon of insertion passes in front of shoulder joint; a rotator cuff muscle	O—subscapular fossa of scapula I—lesser tubercle of humerus	Chief medial rotator of humerus; assisted by pectoralis major; helps to hold head of humerus in glenoid cavity, thereby stabilizing shoulder joint	Subscapular nerves (C_5–C_7)
Supraspinatus (soo"prah-spi-nah'tus) (*supra* = above, over; *spin* = spine)	Named for its location on posterior aspect of scapula; deep to trapezius; a rotator cuff muscle	O—supraspinous fossa of scapula I—superior part of greater tubercle of humerus	Stabilizes shoulder joint; helps to prevent downward dislocation of humerus, as when carrying a heavy suitcase; assists in abduction	Suprascapular nerve
Infraspinatus (in"frah-spi-nah'tus) (*infra* = below)	Partially covered by deltoid and trapezius; named for its scapular location; a rotator cuff muscle	O—infraspinous fossa of scapula I—greater tubercle of humerus posterior to insertion of supraspinatus	Helps to hold head of humerus in glenoid cavity, stabilizing the shoulder joint; rotates humerus laterally	Suprascapular nerve
Teres minor (te'rēz) (*teres* = round; *minor* = lesser)	Small, elongated muscle; lies inferior to infraspinatus and may be inseparable from that muscle; a rotator cuff muscle	O—lateral border of dorsal scapular surface I—greater tubercle of humerus inferior to infraspinatus insertion	Same action(s) as infraspinatus muscle; adducts arm	Axillary nerve
Teres major	Thick, rounded muscle; located inferior to teres minor; helps to form posterior wall of axilla (along with latissimus dorsi and subscapularis)	O—posterior surface of scapula at inferior angle I—intertubercular sulcus of the humerus; insertion tendon fused with that of latissimus dorsi	Posteromedially extends, medially rotates, and adducts humerus; synergist of latissimus dorsi	Lower subscapular nerve (C_6 and C_7)
Coracobrachialis (kor"ah-ko-bra"ke-al'is) (*coraco* = coracoid; *brachi* = arm)	Small, cylindrical muscle	O—coracoid process of scapula I—medial surface of humerus shaft	Flexion and adduction of the humerus; synergist of pectoralis major	Musculocutaneous nerve (C_5–C_7)

MUSCLE GALLERY TABLE 10.9 **Muscles Crossing the Shoulder Joint: Movements of the Arm (Figure 10.14)** *(continued)*

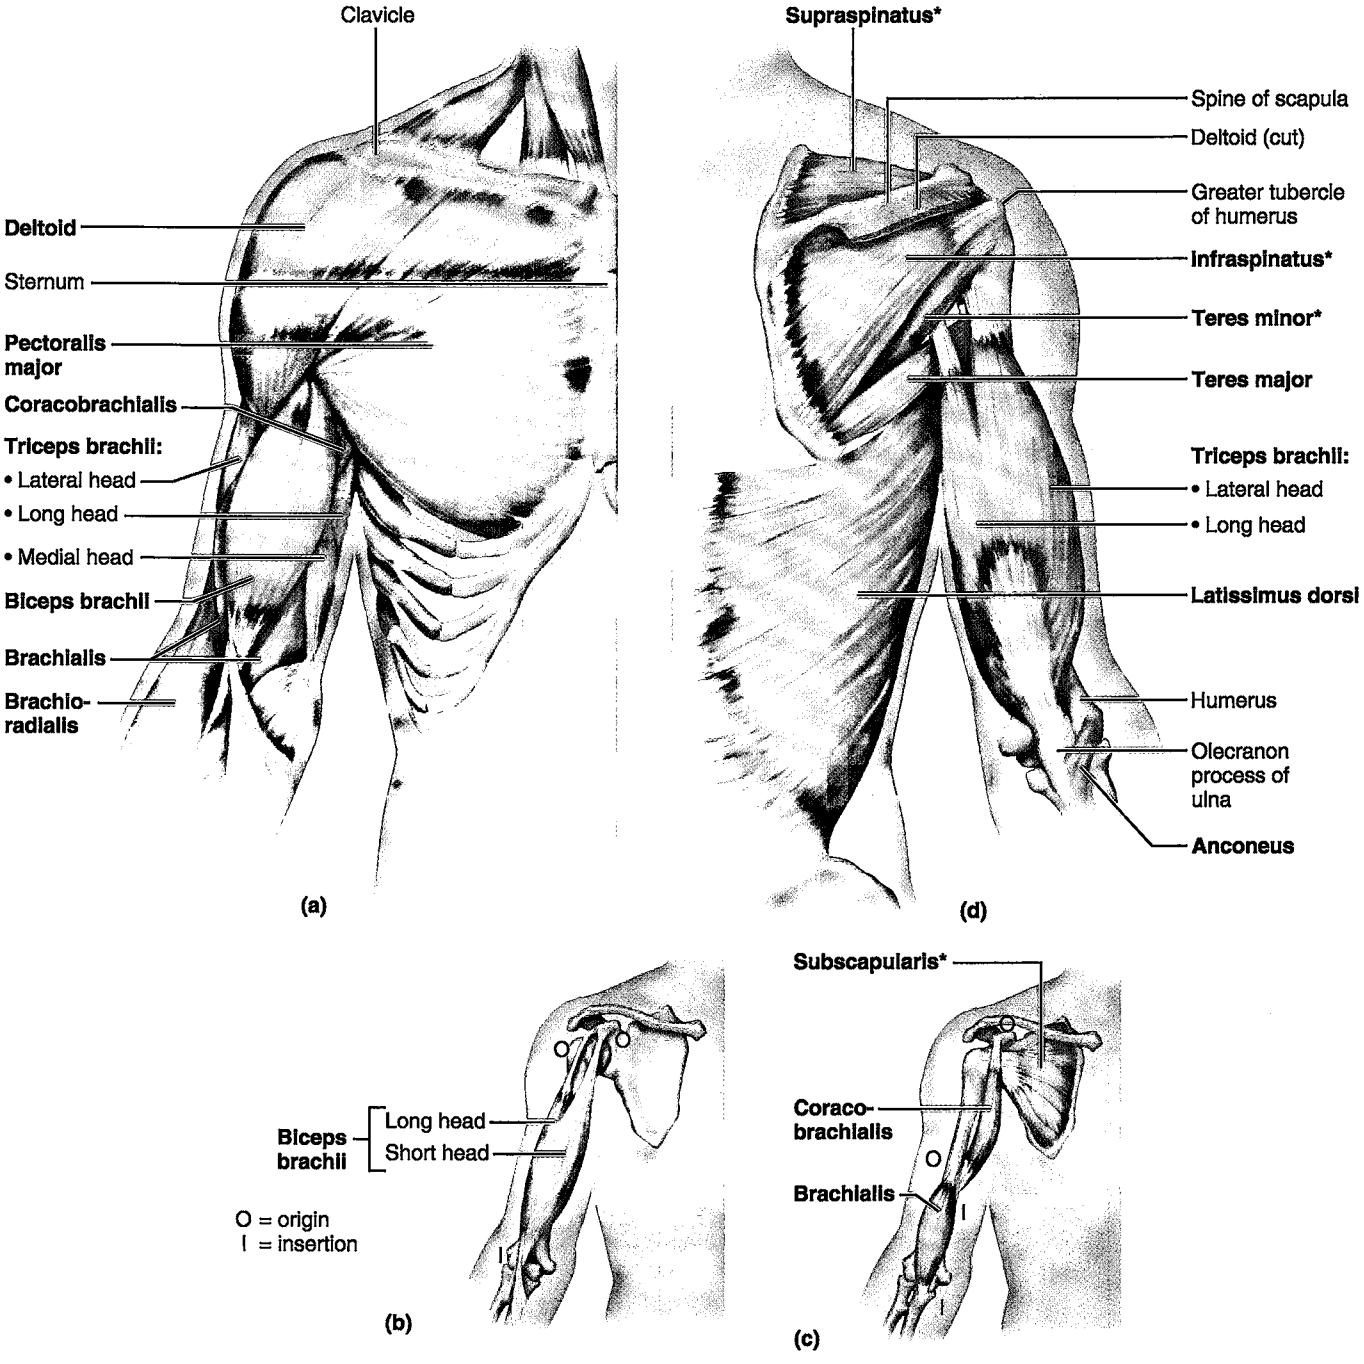

FIGURE 10.14 **Muscles crossing the shoulder and elbow joint, respectively causing movements of the arm and forearm. (a)** Superficial muscles of the anterior thorax, shoulder, and arm, anterior view. (See *A Brief Atlas of the Human Body,* Figures 35 and 36.) **(b)** The biceps brachii muscle of the anterior arm, shown in isolation. **(c)** The brachialis muscle and the coraco-brachialis and subscapularis muscles shown in isolation. **(d)** The extent of the triceps brachii muscle of the posterior arm, shown in relation to the deep scapular muscles. The deltoid muscle of the shoulder has been removed.

* Rotator cuff muscles

MUSCLE GALLERY TABLE 10.10 Muscles Crossing the Elbow Joint: Flexion and Extension of the Forearm (Figure 10.14)

Muscles fleshing out the arm cross the elbow joint to insert on the forearm bones. Since the elbow is a hinge joint, movements promoted by these muscles are limited almost entirely to flexion and extension of the forearm. Walls of fascia divide the arm into two muscle compartments—the *posterior extensors* and *anterior flexors*. The prime mover of forearm extension is the bulky **triceps brachii** muscle, which forms nearly the entire musculature of the posterior compartment. It is assisted (minimally) by the tiny **anconeus** muscle, which just about spans the elbow joint posteriorly.

All anterior arm muscles cause elbow flexion. In order of decreasing strength, these are the **brachialis, biceps brachii,** and **brachioradialis.** The brachialis and biceps insert (respectively) into the ulna and radius and contract simultaneously during flexion; they are the chief forearm flexors. The biceps brachii, a muscle that bulges when the forearm is flexed, is familiar to almost everyone; the brachialis, which lies deep to the biceps, is less known, but is as important in flexing the elbow. The biceps muscle also supinates the forearm and is ineffective in flexing the elbow when the forearm *must* stay pronated. (This is why doing chin-ups with palms facing anteriorly is harder than with palms facing posteriorly.) Since the brachioradialis arises from the distal humerus and inserts on the distal forearm, it resides mainly in the forearm (rather than in the arm). Because its force is exerted far from the fulcrum, the brachioradialis is a weak forearm flexor. It becomes active only when the elbow has been partially flexed and is semipronated.

The actions of the muscles described here are summarized in Table 10.12 (Part II).

MUSCLE	DESCRIPTION	ORIGIN (O) AND INSERTION (I)	ACTION	NERVE SUPPLY
Posterior Muscles				
Triceps brachii (tri'seps bra'ke-i) (*triceps* = three heads; *brachi* = arm)	Large fleshy muscle; the only muscle of posterior compartment of arm; three-headed origin; long and lateral heads lie superficial to medial head	O—long head: infraglenoid tubercle of scapula; lateral head: posterior shaft of humerus; medial head: posterior humeral shaft distal to radial groove I—by common tendon into olecranon process of ulna	Powerful forearm extensor (prime mover, particularly medial head); antagonist of forearm flexors; long and lateral heads mainly active in extension against resistance; long head tendon may help stabilize shoulder joint and assist in arm adduction	Radial nerve (C_6–C_8)
Anconeus (an-ko'ne-us) (*ancon* = elbow) (see Figure 10.16)	Short triangular muscle; closely associated (blended) with distal end of triceps on posterior humerus	O—lateral epicondyle of humerus I—lateral aspect of olecranon process of ulna	Abducts ulna during forearm pronation; synergist of triceps brachii in elbow extension	Radial nerve
Anterior Muscles				
Biceps brachii (bi'seps) (*biceps* = two heads)	Two-headed fusiform muscle; bellies unite as insertion point is approached; tendon of long head helps stabilize shoulder joint	O—short head: coracoid process; long head: tubercle above and lip of glenoid cavity; tendon of long head runs within capsule and into intertubercular sulcus of humerus I—by common tendon into radial tuberosity	Flexes elbow joint and supinates forearm; these actions usually occur at same time (e.g., when you open a bottle of wine, it turns the corkscrew and pulls the cork); weak flexor of arm at shoulder	Musculocutaneous nerve (C_5 and C_6)
Brachialis (bra'ke-al-is)	Strong muscle that is immediately deep to biceps brachii on distal humerus	O—front of distal humerus; embraces insertion of deltoid muscle I—coronoid process of ulna	A major forearm flexor (lifts ulna as biceps lifts the radius)	Musculocutaneous nerve
Brachioradialis (bra"ke-o-ra"de-al'is) (*radi* = radius, ray) (also see Figure 10.15)	Superficial muscle of lateral forearm; forms lateral boundary of antecubital fossa; extends from distal humerus to distal forearm	O—lateral supracondylar ridge at distal end of humerus I—base of styloid process of radius	Synergist in forearm flexion; acts to best advantage when forearm is partially flexed and semipronated; during rapid flexion *and* extension, stabilizes the elbow	Radial nerve (an important exception: the radial nerve typically serves extensor muscles)

MUSCLE GALLERY TABLE 10.11 Muscles of the Forearm: Movements of the Wrist, Hand, and Fingers (Figures 10.15 and 10.16)

The forearm muscles are functionally divided into two approximately equal groups: those causing wrist movements and those moving the fingers and thumb. In most cases, their fleshy portions contribute to the roundness of the proximal forearm and then they taper to long insertion tendons. Their insertions are securely anchored by strong ligaments called **flexor** and **extensor retinacula** ("retainers"). These "wrist bands" keep the tendons from jumping outward when tensed. Crowded together in the wrist and palm, the muscle tendons are surrounded by slippery tendon sheaths that minimize friction as they slide against one another.

Although many forearm muscles arise from the humerus (and thus cross both the elbow and wrist joints), their actions on the elbow are slight. Flexion and extension are the movements typically effected at both the wrist and finger joints. In addition, the wrist can be abducted and adducted.

The forearm muscles are subdivided by fascia into two main compartments (the *anterior flexors* and *posterior extensors*), each with superficial and deep muscle layers. Most flexors in the anterior compartment arise from a common tendon on the humerus and are innervated largely by the median nerve. Two anterior compartment muscles are not flexors but pronators, the **pronator teres** and **pronator quadratus.** Pronation is one of the most important forearm movements.

Muscles of the posterior compartment extend the wrist and fingers. An exception is the **supinator** muscle, which assists the biceps brachii muscle of the arm in supinating the forearm. (Also residing in the posterior compartment is the brachioradialis muscle, the weak elbow flexor considered in Table 10.10.) Like those of the anterior compartment, most muscles of the posterior compartment arise from a common origin tendon on the humerus. All posterior forearm muscles are supplied by the radial nerve.

As described above, most muscles that move the hand are located in the forearm and "operate" the fingers via their long tendons, like operating a puppet by strings. This design makes the hand less bulky and enables it to perform finer movements. The hand movements promoted by the forearm muscles are assisted and made more precise by the small *intrinsic* muscles of the hand (see Table 10.13). A summary of the actions of the forearm muscles is provided in Table 10.12 (Parts II and III).

MUSCLE	DESCRIPTION	ORIGIN (O) AND INSERTION (I)	ACTION	NERVE SUPPLY
Part I: Anterior Muscles (Figure 10.15)	These eight muscles of the anterior fascial compartment are listed from the lateral to the medial aspect. Most arise from a common flexor tendon attached to the medial epicondyle of the humerus and have additional origins as well. Most of the tendons of insertion of these flexors are held in place at the wrist by a thickening of deep fascia called the *flexor retinaculum.*			
Superficial Muscles				
Pronator teres (pro-na'tor te'rēz) (*pronation* = turning palm posteriorly, or down; *teres* = round)	Two-headed muscle; seen in superficial view between proximal margins of brachioradialis and flexor carpi radialis; forms medial boundary of antecubital fossa	O—medial epicondyle of humerus; coronoid process of ulna I—by common tendon into lateral radius, midshaft	Pronates forearm; weak flexor of elbow	Median nerve
Flexor carpi radialis (flek'sor kar'pe ra"de-a'lis) (*flex* = decrease angle between two bones; *carpi* = wrist; *radi* = radius)	Runs diagonally across forearm; midway, its fleshy belly is replaced by a flat tendon that becomes cordlike at wrist	O—medial epicondyle of humerus I—base of second and third metacarpals; insertion tendon easily seen and provides guide to position of radial artery (used for pulse taking) at wrist	Powerful flexor of wrist; abducts hand; weak synergist of elbow flexion	Median nerve
Palmaris longus (pahl-ma'ris lon'gus) (*palma* = palm; *longus* = long)	Small fleshy muscle with a long insertion tendon; often absent; may be used as guide to find median nerve that lies lateral to it at wrist	O—medial epicondyle of humerus I—palmar aponeurosis; skin and fascia of palm	Weak wrist flexor; tenses skin and fascia of palm during hand movements; weak synergist for elbow flexion	Median nerve
Flexor carpi ulnaris (ul-na'ris) (*ulnar* = ulna)	Most medial muscle of this group; two-headed; ulnar nerve lies lateral to its tendon	O—medial epicondyle of humerus; olecranon process and posterior surface of ulna I—pisiform and hamate bones and base of fifth metacarpal	Powerful flexor of wrist; also adducts hand in concert with extensor carpi ulnaris (posterior muscle); stabilizes wrist during finger extension	Ulnar nerve (C_7 and C_8)

MUSCLE	DESCRIPTION	ORIGIN (O) AND INSERTION (I)	ACTION	NERVE SUPPLY
Flexor digitorum superficialis (dĭ″ji-tor′um soo″per-fish″e-a′lis) (*digit* = finger, toe; *superficial* = close to surface)	Two-headed muscle; more deeply placed (therefore, actually forms an intermediate layer); overlain by muscles above but visible at distal end of forearm	O—medial epicondyle of humerus, coronoid process of ulna; shaft of radius I—by four tendons into middle phalanges of fingers 2–5	Flexes wrist and middle phalanges of fingers 2–5; the important finger flexor when speed and flexion against resistance are required	Median nerve (C_7, C_8, and T_1)
Deep Muscles				
Flexor pollicis longus (pah′lĭ-kis) (*pollix* = thumb)	Partly covered by flexor digitorum superficialis; parallels flexor digitorum profundus laterally	O—anterior surface of radius and interosseous membrane I—distal phalanx of thumb	Flexes distal phalanx of thumb	Branch of median nerve (C_8, T_1)
Flexor digitorum profundus (pro-fun′dus) (*profund* = deep)	Extensive origin; overlain entirely by flexor digitorum superficialis	O—coronoid process, anteromedial surface of ulna, and interosseous membrane I—by four tendons into distal phalanges of fingers 2–5	Slow-acting flexor of any or all fingers; assists in flexing wrist; the only muscle that can flex distal interphalangeal joints	Medial half by ulnar nerve; lateral half by median nerve

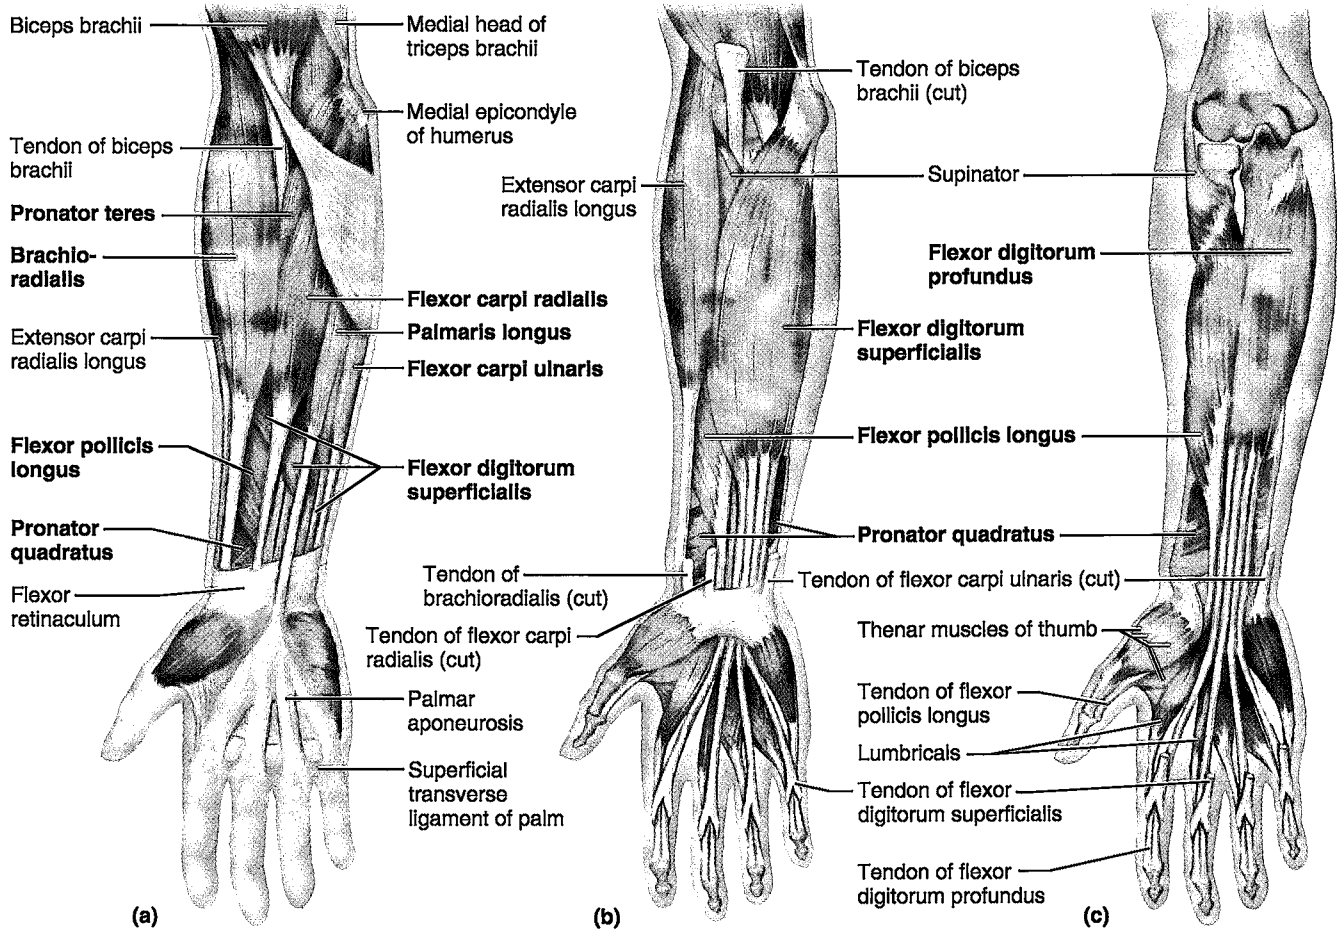

FIGURE 10.15 **Muscles of the anterior compartment of the forearm acting on the right wrist and fingers. (a)** Superficial view. **(b)** The brachioradialis, flexors carpi radialis and ulnaris, and palmaris longus muscles have been removed to reveal the position of the flexor digitorum superficialis. **(c)** Deep muscles of the anterior compartment. The lumbricals and thenar muscles (intrinsic hand muscles) are also illustrated. (See *A Brief Atlas of the Human Body*, Figure 37.)

MUSCLE GALLERY TABLE 10.11 Muscles of the Forearm: Movements of the Wrist, Hand, and Fingers (Figures 10.15 and 10.16) *(continued)*

MUSCLE	DESCRIPTION	ORIGIN (O) AND INSERTION (I)	ACTION	NERVE SUPPLY
Pronator quadratus (kwod-ra'tus) (*quad* = square, four-sided)	Deepest muscle of distal forearm; passes downward and laterally; only muscle that arises solely from ulna and inserts solely into radius	O—distal portion of anterior ulnar shaft I—distal surface of anterior radius	Prime mover of forearm pronation; acts with pronator teres; also helps hold ulna and radius together	Median nerve (C_8 and T_1)
Part II: Posterior Muscles (Figure 10.16)	These muscles of the posterior fascial compartment are listed from the lateral to the medial aspect. They are all innervated by the radial nerve or its branches. More than half of the posterior compartment muscles arise from a common extensor origin tendon attached to the posterior surface of the lateral epicondyle of the humerus and adjacent fascia. The extensor tendons are held in place at the posterior aspect of the wrist by the *extensor retinaculum*, which prevents "bowstringing" of these tendons when the wrist is hyperextended. The extensor muscles of the fingers end in a broad hood over the dorsal side of the digits, the extensor expansion.			
Superficial Muscles				
Brachioradialis (see Table 10.10)				
Extensor carpi radialis longus (ek-sten'sor) (*extend* = increase angle between two bones)	Parallels brachioradialis on lateral forearm, and may blend with it	O—lateral supracondylar ridge of humerus I—base of second metacarpal	Extends wrist in conjunction with the extensor carpi ulnaris and abducts wrist in conjunction with the flexor carpi radialis	Radial nerve (C_6 and C_7)
Extensor carpi radialis brevis (brē'vis) (*brevis* = short)	Somewhat shorter than extensor carpi radialis longus and lies deep to it	O—lateral epicondyle of humerus I—base of third metacarpal	Extends and abducts wrist; acts synergistically with extensor carpi radialis longus to steady wrist during finger flexion	Deep branch of radial nerve
Extensor digitorum	Lies medial to extensor carpi radialis brevis; a detached portion of this muscle, called *extensor digiti minimi*, extends little finger	O—lateral epicondyle of humerus I—by four tendons into extensor expansions and distal phalanges of fingers 2–5	Prime mover of finger extension; extends wrist; can abduct (flare) fingers	Posterior interosseous nerve, a branch of radial nerve (C_5 and C_6)
Extensor carpi ulnaris	Most medial of superficial posterior muscles; long, slender muscle	O—lateral epicondyle of humerus and posterior border of ulna I—base of fifth metacarpal	Extends wrist in conjunction with the extensor carpi radialis and adducts wrist in conjunction with flexor carpi ulnaris	Posterior interosseous nerve
Deep Muscles				
Supinator (soo"pĭ-na'tor) (*supination* = turning palm anteriorly or upward)	Deep muscle at posterior aspect of elbow; largely concealed by superficial muscles	O—lateral epicondyle of humerus; proximal ulna I—proximal end of radius	Assists biceps brachii to forcibly supinate forearm; works alone in slow supination; antagonist of pronator muscles	Posterior interosseous nerve
Abductor pollicis longus (ab-duk'tor) (*abduct* = movement away from median plane)	Lateral and parallel to extensor pollicis longus; just distal to supinator	O—posterior surface of radius and ulna; interosseous membrane I—base of first metacarpal and trapezium	Abducts and extends thumb; abducts wrist	Posterior interosseous nerve
Extensor pollicis brevis and longus	Deep muscle pair with a common origin and action; overlain by extensor carpi ulnaris	O—dorsal shaft of radius and ulna; interosseous membrane I—base of proximal (brevis) and distal (longus) phalanx of thumb	Extends thumb	Posterior interosseous nerve

MUSCLE	DESCRIPTION	ORIGIN (O) AND INSERTION (I)	ACTION	NERVE SUPPLY
Extensor indicis (in′dĭ-kis) (*indicis* = index finger)	Tiny muscle arising close to wrist	O—posterior surface of distal ulna; interosseous membrane I—extensor expansion of index finger; joins tendon of extensor digitorum	Extends index finger and assists in wrist extension	Posterior interosseous nerve

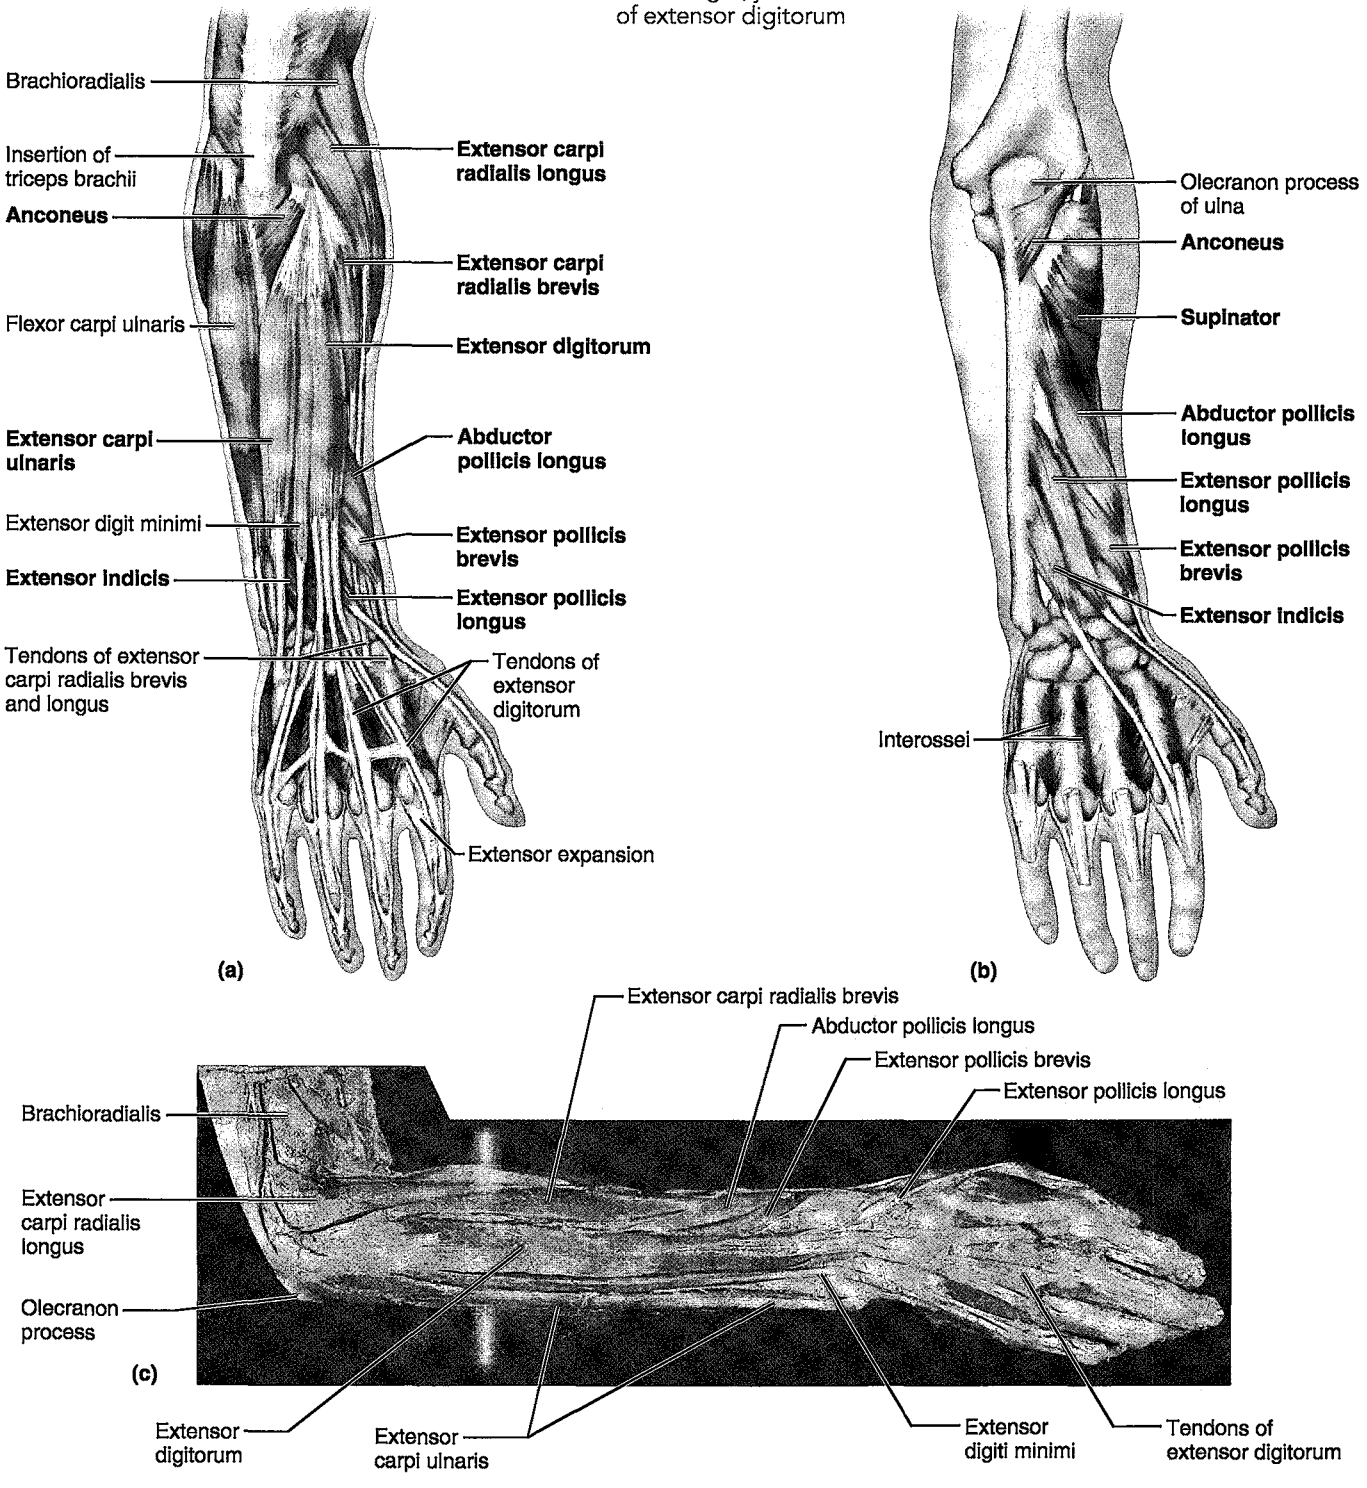

FIGURE 10.16 **Muscles of the posterior compartment of the right forearm acting on the wrist and fingers. (a)** Superficial muscles, posterior view. (See *A Brief Atlas of the Human Body*, Figure 37b.) **(b)** Deep posterior muscles, superficial muscles removed. The interossei, the deepest layer of intrinsic hand muscles, are also illustrated. **(c)** Photograph of the posterior muscles.

MUSCLE GALLERY TABLE 10.13 Intrinsic Muscles of the Hand: Fine Movements of the Fingers (Figure 10.18)

This table considers the small muscles that lie entirely in the hand. All are in the palm, none on the hand's dorsal side. All move the metacarpals and fingers. Small, weak muscles, they mostly control precise movements (such as threading a needle), leaving the powerful movements of the fingers ("power grip") to the forearm muscles.

The intrinsic muscles include the main abductors and adductors of the fingers, as well as muscles that produce the movement of opposition—moving the thumb toward the little finger—that enables one to grip objects in the palm (the handle of a hammer, for example). Many palm muscles are specialized to move the thumb, and surprisingly many move the little finger. Thumb movements are defined differently from movements of other fingers because the thumb lies at a right angle to the rest of the hand. The thumb flexes by bending medially along the palm, not anteriorly, as do the other fingers. (Start with your hand in the anatomical position or this will not be clear!) The thumb extends by pointing laterally (as in hitchhiking), not posteriorly, as do the other fingers. To abduct the fingers is to splay them laterally, but to abduct the thumb is to point it anteriorly. Adduction of the thumb brings it back posteriorly.

The intrinsic muscles of the palm are divided into three groups, those in (1) the *thenar eminence* (ball of the thumb); (2) the *hypothenar eminence* (ball of the little finger); and (3) the midpalm. Thenar and hypothenar muscles are almost mirror images of each other, each containing a small flexor, an abductor, and an opponens muscle. The midpalmar muscles, called **lumbricals** and **interossei,** extend our fingers at the interphalangeal joints. The interossei are also the main finger abductors and adductors.

MUSCLE	DESCRIPTION	ORIGIN (O) AND INSERTION (I)	ACTION	NERVE SUPPLY
Thenar Muscles in Ball of Thumb (the'nar) (*thenar* = palm)				
Abductor pollicis brevis (*pollex* = thumb)	Lateral muscle of thenar group; superficial	O—flexor retinaculum and nearby carpals I—lateral base of thumb's proximal phalanx	Abducts thumb (at carpometacarpal joint)	Median nerve (C_8, T_1)
Flexor pollicis brevis	Medial and deep muscle of thenar group	O—flexor retinaculum and trapezium I—lateral side of base of proximal phalanx of thumb	Flexes thumb (at carpometacarpal and metacarpophalangeal joints)	Median (or occasionally ulnar) nerve (C_8, T_1)
Opponens pollicis (o-pōn'enz) (*opponens* = opposition)	Deep to abductor pollicis brevis, on metacarpal 1	O—flexor retinaculum and trapezium I—whole anterior side of metacarpal 1	Opposition: moves thumb to touch tip of little finger	Median (or occasionally ulnar) nerve
Adductor pollicis	Fan-shaped with horizontal fibers; distal to other thenar muscles; oblique and transverse heads	O—capitate bone and bases of metacarpals 2–4; front of metacarpal 3 I—medial side of base of proximal phalanx of thumb	Adducts and helps to oppose thumb	Ulnar nerve (C_8, T_1)
Hypothenar Muscles in Ball of Little Finger				
Abductor digiti minimi (dĭ'jĭ-ti min'ĭ-mi) (*digiti minimi* = little finger)	Medial muscle of hypothenar group; superficial	O—pisiform bone I—medial side of proximal phalanx of little finger	Abducts little finger at metacarpophalangeal joint	Ulnar nerve
Flexor digiti minimi brevis	Lateral deep muscle of hypothenar group	O—hamate bone and flexor retinaculum I—same as abductor digiti minimi	Flexes little finger at metacarpophalangeal joint	Ulnar nerve
Opponens digiti minimi	Deep to abductor digiti minimi	O—same as flexor digiti minimi brevis I—most of length of medial side of metacarpal 5	Helps in opposition: brings metacarpal 5 toward thumb to cup the hand	Ulnar nerve

MUSCLE GALLERY TABLE 10.13 *(continued)*

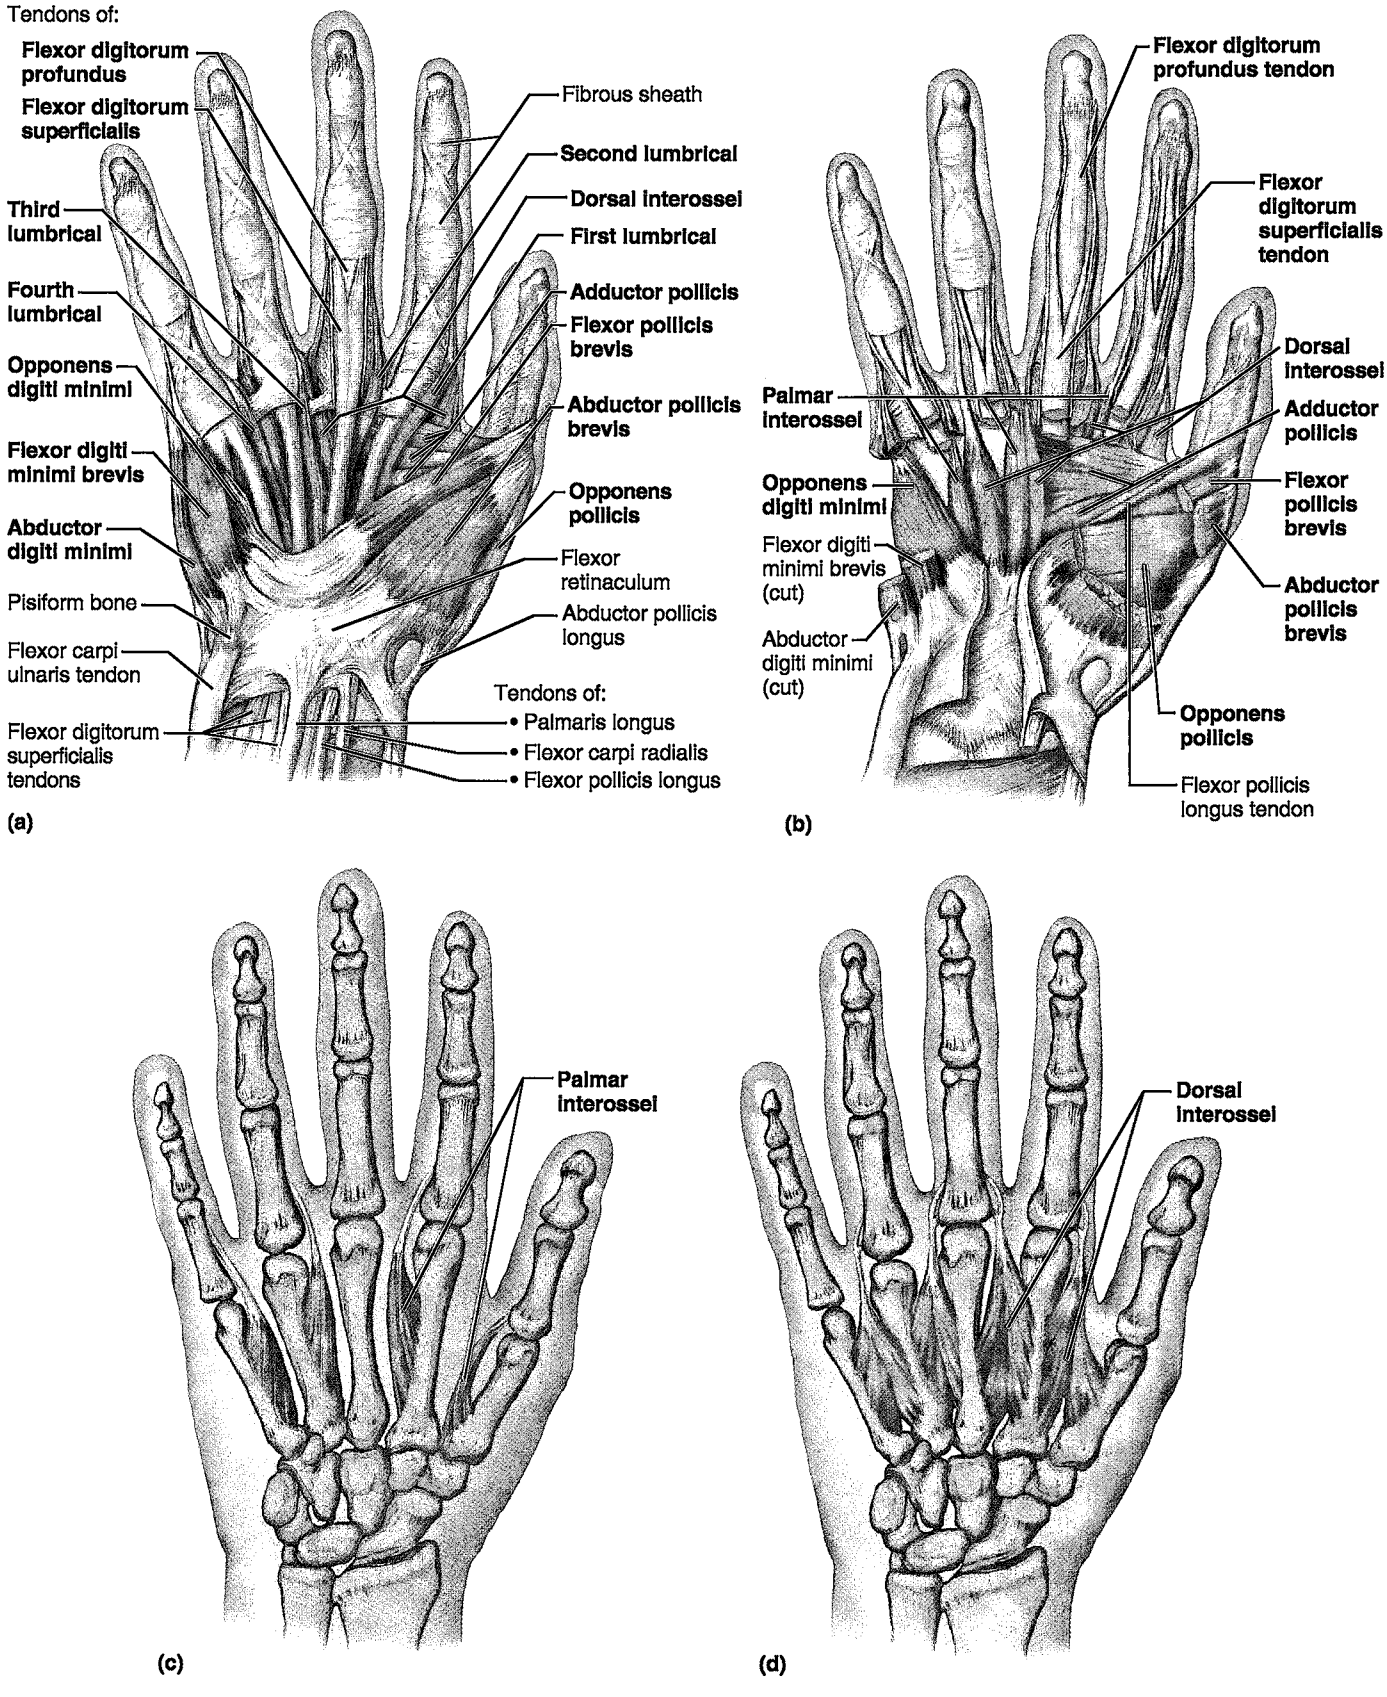

FIGURE 10.18 **Hand muscles, ventral views of right hand. (a)** First superficial layer. **(b)** Second layer. **(c)** Palmar interossei (isolated). **(d)** Dorsal interossei (isolated).

MUSCLE GALLERY TABLE 10.13 **Intrinsic Muscles of the Hand: Fine Movements of the Fingers (Figure 10.18)** *(continued)*

MUSCLE	DESCRIPTION	ORIGIN (O) AND INSERTION (I)	ACTION	NERVE SUPPLY
Midpalmar Muscles				
Lumbricals (lum′brĭ-klz) (*lumbric* = earthworm)	Four worm-shaped muscles in palm, one to each finger (except thumb); unusual because they originate from the tendons of another muscle	O—lateral side of each tendon of flexor digitorum profundus in palm I—lateral edge of extensor expansion on first phalanx of fingers 2–5	Flex fingers at metacarpophalangeal joints but extend fingers at interphalangeal joints	Median nerve (lateral two) and ulnar nerve (medial two)
Palmar interossei (in″ter-os′e-i) (*interossei* =between bones)	Four long, cone-shaped muscles in the spaces between the metacarpals; lie ventral to the dorsal interossei	O—the side of each metacarpal that faces the midaxis of the hand (metacarpal 3) but absent from metacarpal 3 I—extensor expansion on first phalanx of each finger (except finger 3), on side facing midaxis of hand	Adductors of fingers: pull fingers in toward third digit; act with lumbricals to extend fingers at interphalangeal joints and flex them at metacarpophalangeal joints	Ulnar nerve
Dorsal interossei	Four bipennate muscles filling spaces between the metacarpals; deepest palm muscles, also visible on dorsal side of hand (Figure 10.16b)	O—sides of metacarpals I—extensor expansion over first phalanx of fingers 2–4 on side opposite midaxis of hand (finger 3), but on *both* sides of finger 3	Abduct (diverge) fingers; extend fingers at interphalangeal joints and flex them at metacarpophalangeal joint	Ulnar nerve

MUSCLE GALLERY TABLE 10.14 Muscles Crossing the Hip and Knee Joints: Movements of the Thigh and Leg (Figures 10.19 and 10.20)

The muscles fleshing out the thigh are difficult to segregate into groups on the basis of action. Some thigh muscles act only at the hip joint, others only at the knee, while still others act at both joints. Attempts to classify these muscles solely on the basis of location are equally frustrating because different muscles in a particular location often have very different actions. However, the *most anterior* muscles of the hip and thigh flex the femur at the hip and extend the leg at the knee—producing the foreswing phase of walking. The *posterior* muscles of the hip and thigh, by contrast, mostly extend the thigh and flex the leg—the backswing phase of walking. The third group of muscles in this region, the *medial,* or *adductor,* muscles, all adduct the thigh; they have no effect on the leg. In the thigh, the anterior, posterior, and adductor muscles are separated by walls of fascia into *anterior, posterior,* and *medial compartments* (see Figure 10.24a). The deep fascia of the thigh, the *fascia lata,* surrounds and encloses all three groups of muscles like a support stocking.

Movements of the thigh (occurring at the hip joint) are accomplished largely by muscles anchored to the pelvic girdle. Like the shoulder joint, the hip joint is a ball-and-socket joint permitting flexion, extension, abduction, adduction, circumduction, and rotation. Muscles effecting these movements of the thigh are among the most powerful muscles of the body. For the most part, the thigh *flexors* pass in front of the hip joint. The most important of these are the **iliopsoas, tensor fasciae latae,** and **rectus femoris.** They are assisted in this action by the **adductor muscles** of the medial thigh and the straplike **sartorius.** The prime mover of thigh flexion is the iliopsoas.

Thigh *extension* is effected primarily by the massive **hamstring muscles** of the posterior thigh. However, during forceful extension, the **gluteus maximus** of the buttock is activated. Buttock muscles that lie lateral to the hip joint (**gluteus medius** and **minimus**) *abduct* the thigh. Thigh adduction is the role of the adductor muscles of the medial thigh. Abduction and adduction of the thighs are extremely important during walking to keep the body's weight balanced over the limb that is on the ground. Many different muscles bring about medial and lateral rotation of the thigh.

At the knee joint, flexion and extension are the main movements. The sole knee *extensor* is the **quadriceps femoris** muscle of the anterior thigh, the most powerful muscle in the body. The quadriceps is antagonized by the hamstrings of the posterior compartment, which are prime movers of knee flexion.

The actions of the muscles presented here are further summarized in Table 10.16 (Part I).

MUSCLE	DESCRIPTION	ORIGIN (O) AND INSERTION (I)	ACTION	NERVE SUPPLY
Part I: Anterior and Medial Muscles (Figure 10.19)				
Origin on the Pelvis				
Iliopsoas (il″e-o-so′us)	Iliopsoas is a composite of two closely related muscles (iliacus and psoas major) whose fibers pass under the inguinal ligament [see Table 10.6 (external oblique muscle) and Figure 10.11] to insert via a common tendon on the femur.			
■ **Iliacus** (il-e-ak′us) (*iliac* = ilium)	Large, fan-shaped, more lateral muscle	O—iliac fossa and crest, lateral sacrum I—femur on and immediately below lesser trochanter of femur via iliopsoas tendon	Iliopsoas is the prime mover for flexing thigh or for flexing trunk on thigh during a bow	Femoral nerve (L_2 and L_3)
■ **Psoas major** (so′us) (*psoa* = loin muscle; *major* = larger)	Longer, thicker, more medial muscle of the pair (butchers refer to this muscle as the tenderloin)	O—by fleshy slips from transverse processes, bodies, and discs of lumbar vertebrae and T_{12} I—lesser trochanter of femur via iliopsoas tendon	As above; also effects lateral flexion of vertebral column; important postural muscle	Ventral rami L_1–L_3
Sartorius (sar-tor′e-us) (*sartor* = tailor)	Straplike superficial muscle running obliquely across anterior surface of thigh to knee; longest muscle in body; crosses both hip and knee joints	O—anterior superior iliac spine I—winds around medial aspect of knee and inserts into medial aspect of proximal tibia	Flexes, abducts, and laterally rotates thigh; flexes knee (weak) as in a soccer kick; known as "tailor's muscle" because it helps effect cross-legged position in which tailors are often depicted	Femoral nerve

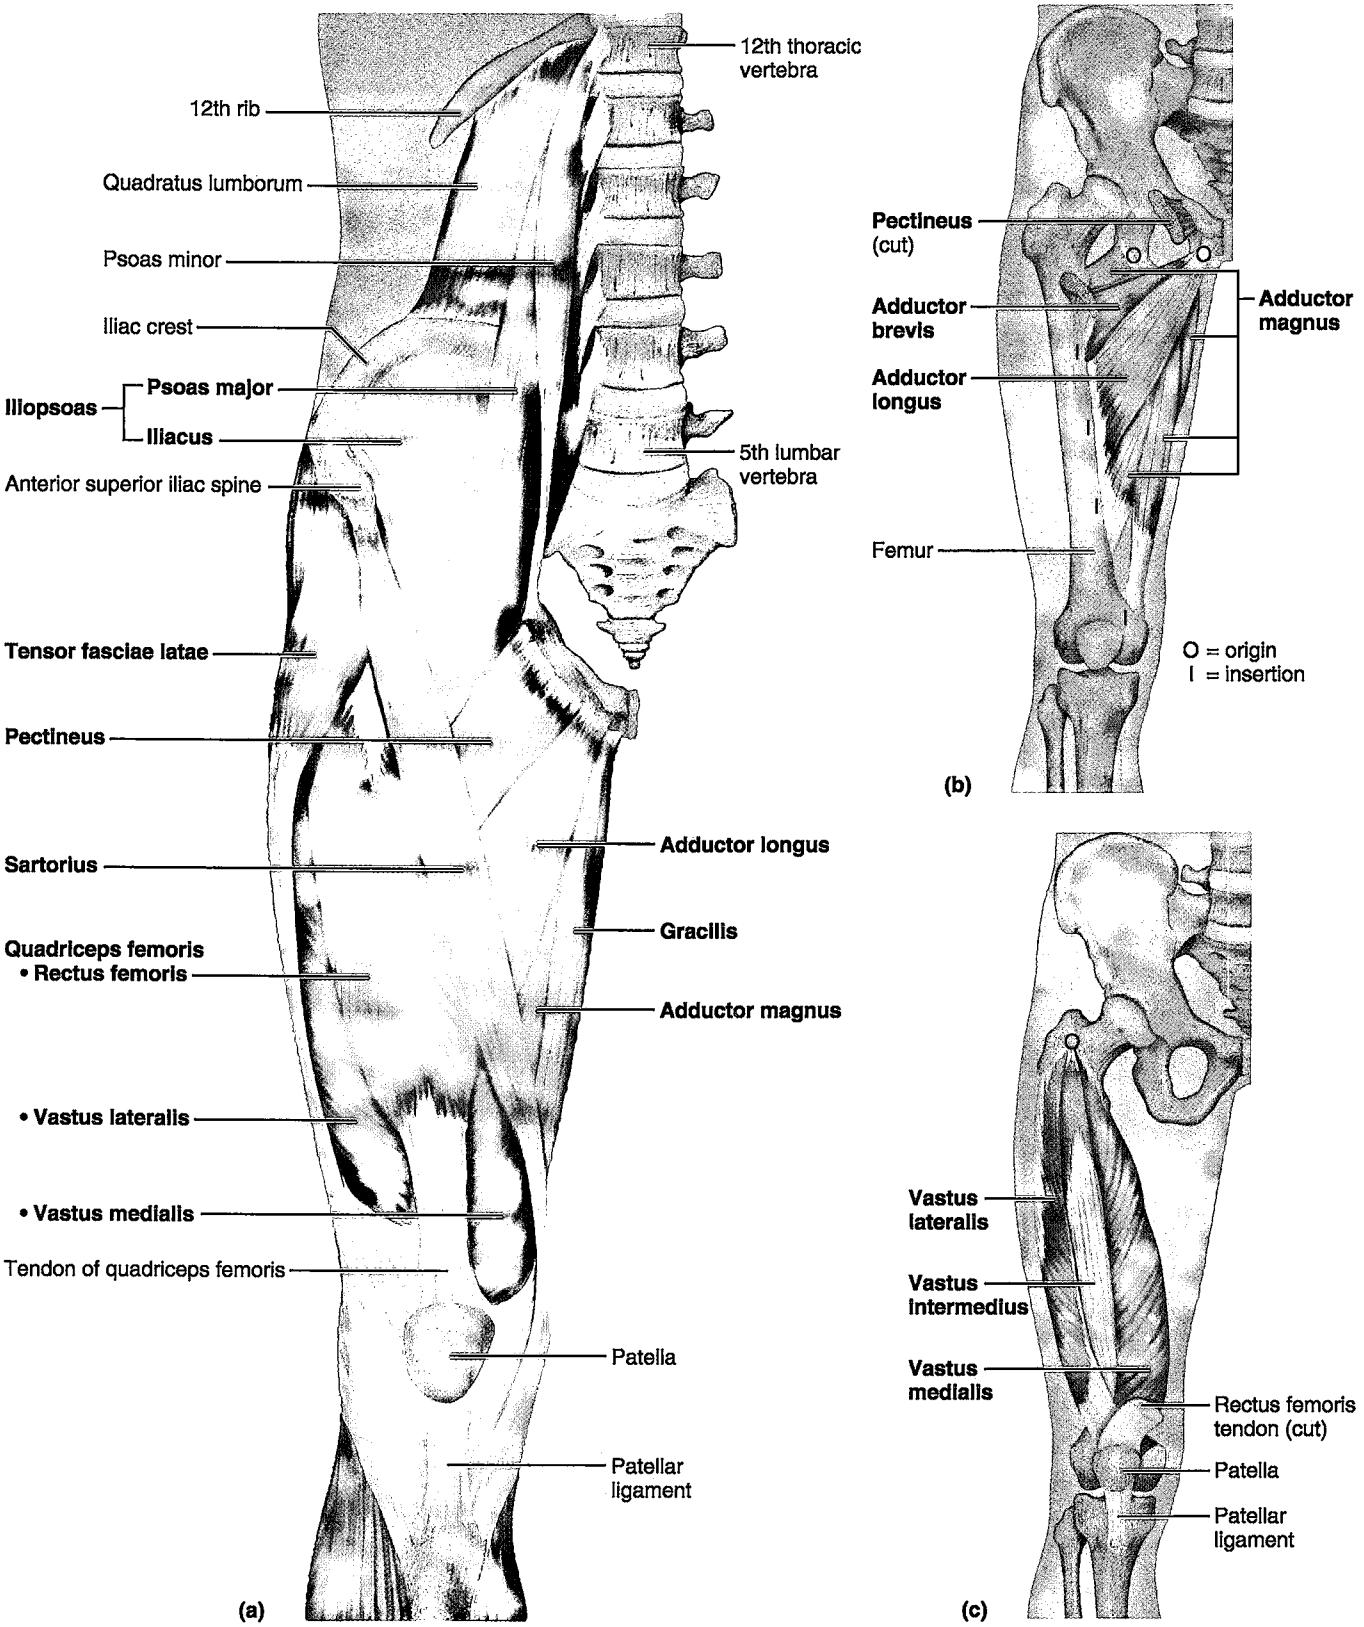

FIGURE 10.19 **Anterior and medial muscles promoting movements of the thigh and leg. (a)** Anterior view of the deep muscles of the pelvis and superficial muscles of the right thigh. (See *A Brief Atlas of the Human Body,* Figure 40.) **(b)** Adductor muscles of the medial compartment of the thigh isolated. **(c)** The vastus muscles of the quadriceps group. The rectus femoris muscle of the quadriceps group and surrounding muscles have been removed.

MUSCLE GALLERY TABLE 10.14 *(continued)*

MUSCLE	DESCRIPTION	ORIGIN (O) AND INSERTION (I)	ACTION	NERVE SUPPLY
Muscles of the Medial Compartment of the Thigh				
Adductors (ah-duk'torz)	Large muscle mass consisting of three muscles (magnus, longus, and brevis) forming medial aspect of thigh; arise from inferior part of pelvis and insert at various levels on femur; all used in movements that press thighs together, as when astride a horse; important in pelvic tilting movements that occur during walking and in fixing the hip when the knee is flexed and the foot is off the ground; entire group innervated by obturator nerve. Strain or stretching of this muscle group is called a "pulled groin."			
▪ **Adductor magnus** (mag'nus) (*adduct* = move toward midline; *magnus* = large)	A triangular muscle with a broad insertion; is a composite muscle that is part adductor and part hamstring in action	O—ischial and pubic rami and ischial tuberosity I—linea aspera and adductor tubercle of femur	Anterior part adducts and medially rotates and flexes thigh; posterior part is a synergist of hamstrings in thigh extension	Obturator nerve and sciatic nerve (L_2–L_4)
▪ **Adductor longus** (*longus* = long)	Overlies middle aspect of adductor magnus; most anterior of adductor muscles	O—Pubis near pubic symphysis I—linea aspera	Adducts, flexes, and medially rotates thigh	Anterior division of obturator nerve (L_2–L_4)
▪ **Adductor brevis** (*brevis* = short)	In contact with obturator externus muscle; largely concealed by adductor longus and pectineus	O—body and inferior ramus of pubis I—linea aspera above adductor longus	Adducts and medially rotates thigh	Obturator nerve
Pectineus (pek-tin'e-us) (*pecten* = comb)	Short, flat muscle; overlies adductor brevis on proximal thigh; abuts adductor longus medially	O—pectineal line of pubis (and superior ramus) I—inferior from lesser trochanter to the linea aspera of posterior aspect of femur	Adducts, flexes, and medially rotates thigh	Femoral and sometimes obturator nerve
Gracilis (grah-sĭ'lis) (*gracilis* = slender)	Long, thin, superficial muscle of medial thigh	O—inferior ramus and body of pubis and adjacent ischial ramus I—medial surface of tibia just inferior to its medial condyle	Adducts thigh, flexes and medially rotates thigh, especially during walking; flexes knee	Obturator nerve
Muscles of the Anterior Compartment of the Thigh				
Quadriceps femoris (kwod'rĭ-seps fem'o-ris)	Quadriceps femoris arises from four separate heads (*quadriceps* = four heads) that form the flesh of front and sides of thigh; these heads (rectus femoris, and lateral, medial, and intermediate vastus muscles) have a common insertion tendon, the quadriceps tendon, which inserts into the patella and then via the patellar ligament into tibial tuberosity. The quadriceps is a powerful knee extensor used in climbing, jumping, running, and rising from seated position; group is innervated by femoral nerve; the tone of quadriceps plays important role in strengthening knee joint.			
▪ **Rectus femoris** (rek'tus) (*rectus* = straight; *femoris* = femur)	Superficial muscle of anterior thigh; runs straight down thigh; longest head and only muscle of group to cross hip joint	O—anterior inferior iliac spine and superior margin of acetabulum I—patella and tibial tuberosity via patellar ligament	Extends knee and flexes thigh at hip	Femoral nerve (L_2–L_4)
▪ **Vastus lateralis** (vas'tus lat"er-a'lis) (*vastus* = large; *lateralis* = lateral)	Largest head of the group, forms lateral aspect of thigh; a common intramuscular injection site, particularly in infants (who have poorly developed buttock and arm muscles)	O—greater trochanter, intertrochanteric line, linea aspera I—as for rectus femoris	Extends and stabilizes knee	Femoral nerve
▪ **Vastus medialis** (me"de-a'lis) (*medialis* = medial)	Forms inferomedial aspect of thigh	O—linea aspera, intertrochanteric line I—as for rectus femoris	Extends knee; inferior fibers stabilize patella	Femoral nerve

MUSCLE GALLERY TABLE 10.14 **Muscles Crossing the Hip and Knee Joints: Movements of the Thigh and Leg (Figures 10.19 and 10.20)** *(continued)*

MUSCLE	DESCRIPTION	ORIGIN (O) AND INSERTION (I)	ACTION	NERVE SUPPLY
▪ **Vastus intermedius** (in"ter-me'de-us) (*intermedius* = intermediate)	Obscured by rectus femoris; lies between vastus lateralis and vastus medialis on anterior thigh	O—anterior and lateral surfaces of proximal femur shaft I—as for rectus femoris	Extends knee	Femoral nerve
Tensor fasciae latae (ten'sor fă'she-e la'te) (*tensor* = to make tense; *fascia* = band; *lata* = wide)	Enclosed between fascia layers of anterolateral aspect of thigh; functionally associated with medial rotators and flexors of thigh	O—anterior aspect of iliac crest and anterior superior iliac spine I—iliotibial tract*	Flexes and abducts thigh (thus a synergist of the iliopsoas and gluteus medius and minimus muscles); rotates thigh medially; steadies the knee and trunk on thigh by making iliotibial tract taut	Superior gluteal nerve (L_4 and L_5)
Part II: Posterior Muscles (Figure 10.20)				
Gluteal Muscles—Origin on Pelvis				
Gluteus maximus (gloo'te-us mak'sĭ-mus) (*glutos* = buttock; *maximus* = largest)	Largest and most superficial of gluteus muscles; forms bulk of buttock mass; fibers are thick and coarse; important site of intramuscular injection (dorsal gluteal site); overlies large sciatic nerve; covers ischial tuberosity only when standing; when sitting, moves superiorly, leaving ischial tuberosity exposed in the subcutaneous position	O—dorsal ilium, sacrum, and coccyx I—gluteal tuberosity of femur; iliotibial tract	Major extensor of thigh; complex, powerful, and most effective when thigh is flexed and force is necessary, as in rising from a forward flexed position and in thrusting the thigh posteriorly in climbing stairs and running; generally inactive during standing and walking; laterally rotates and abducts thigh	Inferior gluteal nerve (L_5, S_1, and S_2)
Gluteus medius (me'de-us) (*medius* = middle)	Thick muscle largely covered by gluteus maximus; important site for intramuscular injections (ventral gluteal site); considered safer than dorsal gluteal site because there is less chance of injuring sciatic nerve	O—between anterior and posterior gluteal lines on lateral surface of ilium I—by short tendon into lateral aspect of greater trochanter of femur	Abducts and medially rotates thigh; steadies pelvis; its action is extremely important in walking; e.g., muscle of limb planted on ground tilts or holds pelvis in abduction so that pelvis on side of swinging limb does not sag; the foot of swinging limb can thus clear the ground	Superior gluteal nerve (L_5, S_1)
Gluteus minimus (mĭ'nĭ-mus) (*minimus* = smallest)	Smallest and deepest of gluteal muscles	O—between anterior and inferior gluteal lines on external surface of ilium I—anterior border of greater trochanter of femur	As for gluteus medius	Superior gluteal nerve (L_5, S_1)
Lateral Rotators				
Piriformis (pir'ĭ-form-is) (*piri* = pear; *forma* = shape)	Pyramidal muscle located on posterior aspect of hip joint; inferior to gluteus minimus; issues from pelvis via greater sciatic notch	O—anterolateral surface of sacrum (opposite greater sciatic notch) I—superior border of greater trochanter of femur	Rotates extended thigh laterally; since inserted above head of femur, can also assist in abduction of thigh when hip is flexed; stabilizes hip joint	S_1 and S_2, L_5

*The iliotibial tract is a thickened lateral portion of the *fascia lata* (the fascia that ensheathes all the muscles of the thigh). It extends as a tendinous band from the iliac crest to the knee (see Figure 10.20a).

MUSCLE GALLERY TABLE 10.14 *(continued)*

MUSCLE	DESCRIPTION	ORIGIN (O) AND INSERTION (I)	ACTION	NERVE SUPPLY
Obturator externus (ob"tu-ra'tor ek-ster'-nus) (*obturator* = obturator foramen; *externus* = outside)	Flat, triangular muscle deep in superomedial aspect of thigh	O—outer surfaces of obturator membrane, pubis, and ischium, margins of obturator foramen I—by a tendon into trochanteric fossa of posterior femur	As for piriformis	Obturator nerve

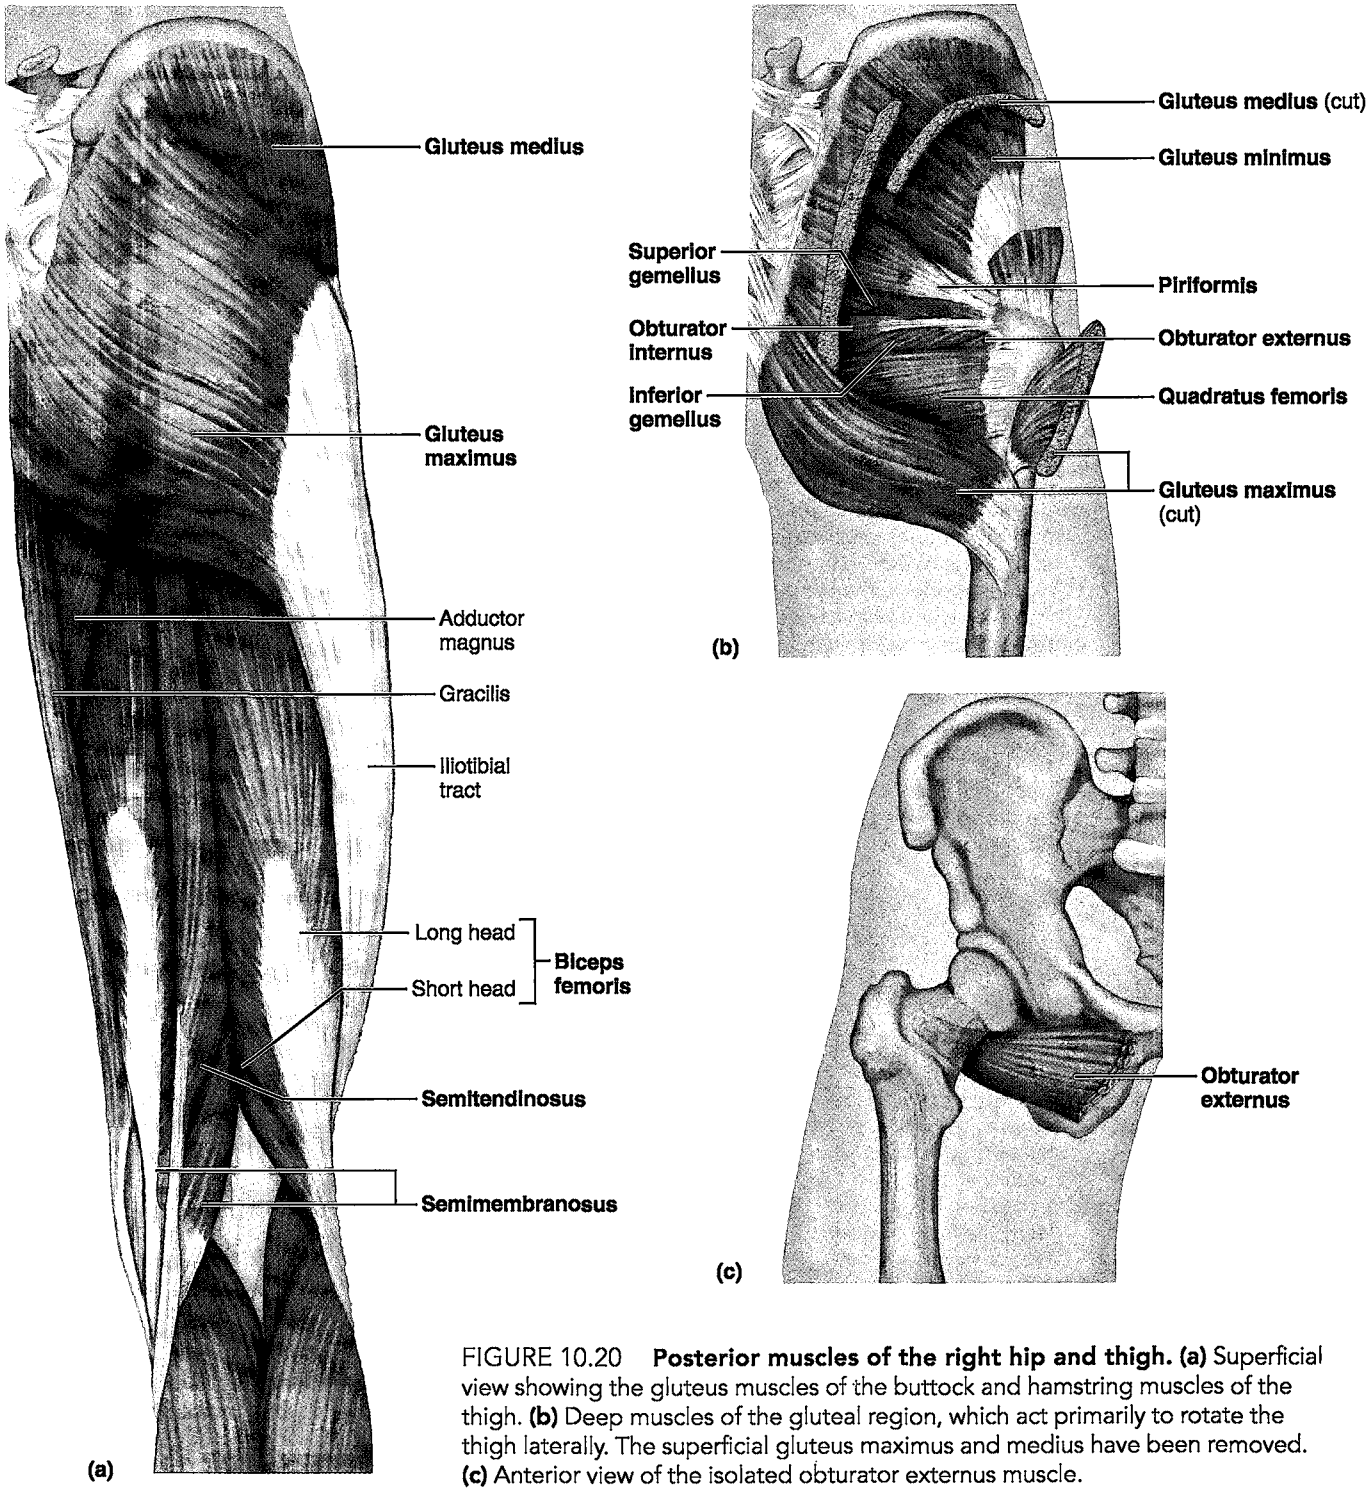

FIGURE 10.20 **Posterior muscles of the right hip and thigh. (a)** Superficial view showing the gluteus muscles of the buttock and hamstring muscles of the thigh. **(b)** Deep muscles of the gluteal region, which act primarily to rotate the thigh laterally. The superficial gluteus maximus and medius have been removed. **(c)** Anterior view of the isolated obturator externus muscle.

MUSCLE GALLERY TABLE 10.14 Muscles Crossing the Hip and Knee Joints: Movements of the Thigh and Leg (Figures 10.19 and 10.20) *(continued)*

MUSCLE	DESCRIPTION	ORIGIN (O) AND INSERTION (I)	ACTION	NERVE SUPPLY
Obturator internus (in-ter'nus) (*internus* = inside)	Surrounds obturator foramen within pelvis; leaves pelvis via lesser sciatic notch and turns acutely forward to insert in femur	O—inner surface of obturator membrane, greater sciatic notch, and margins of obturator foramen I—greater trochanter in front of piriformis	As for piriformis	L_5 and S_1
Gemellus (jĕ-mĕ'lis)—superior and inferior (*gemin* = twin, double; *superior* = above; *inferior* = below)	Two small muscles with common insertions and actions; considered extrapelvic portions of obturator internus	O—ischial spine (superior); ischial tuberosity (inferior) I—greater trochanter of femur	As for piriformis	L_5 and S_1
Quadratus femoris (*quad* = four-sided square)	Short, thick muscle; most inferior of lateral rotator muscles; extends laterally from pelvis	O—ischial tuberosity I—trochanteric crest of femur	Rotates thigh laterally and stabilizes hip joint	L_5 and S_1
Muscles of the Posterior Compartment of the Thigh				
Hamstrings	The hamstrings are fleshy muscles of the posterior thigh (biceps femoris, semitendinosus, and semimembranosus). They cross both the hip and knee joints and are prime movers of thigh extension and knee flexion. Group has a common origin site and is innervated by sciatic nerve (actually two nerves, the tibial and common fibular nerves wrapped in a common sheath). Ability of hamstrings to act on one of the two joints spanned depends on which joint is fixed; i.e., if knee is fixed (extended), they promote hip extension; if hip is extended, they promote knee flexion. However, when hamstrings are stretched, they tend to restrict full accomplishment of antagonistic movements; e.g., if knees are fully extended, it is difficult to flex the hip fully (and touch your toes), and when the thigh is fully flexed as in kicking a football, it is almost impossible to extend the knee fully at the same time (without considerable practice). Name of this muscle group comes from old butchers' practice of using their tendons to hang hams for smoking. "Pulled hamstrings" are common sports injuries in those who run very hard, e.g., football halfbacks.			
▪ **Biceps femoris** (*biceps* = two heads)	Most lateral muscle of the group; arises from two heads	O—ischial tuberosity (long head); linea aspera and distal femur (short head) I—common tendon passes downward and laterally (forming lateral border of popliteal fossa) to insert into head of fibula and lateral condyle of tibia	Extends thigh and flexes knee; laterally rotates leg, especially when knee is flexed	Sciatic nerve—tibial nerve to long head, common fibular nerve to short head (L_5–S_2)
▪ **Semitendinosus** (sem"e-ten"dĭ-no'sus) (*semi* = half; *tendinosus* = tendon)	Lies medial to biceps femoris; although its name suggests that this muscle is largely tendinous, it is quite fleshy; its long slender tendon begins about two-thirds of the way down thigh	O—ischial tuberosity in common with long head of biceps femoris I—medial aspect of upper tibial shaft	Extends thigh at hip; flexes knee; with semimembranosus, medially rotates leg	Sciatic nerve—tibial nerve portion (L_5–S_2)
▪ **Semimembranosus** (sem"e-mem"-brah-no'sus) (*membranosus* = membrane)	Deep to semitendinosus	O—ischial tuberosity I—medial condyle of tibia; via oblique popliteal ligament to lateral condyle of femur	Extends thigh and flexes knee; medially rotates leg	Sciatic nerve—tibial nerve portion (L_5–S_2)

MUSCLE GALLERY TABLE 10.15 Muscles of the Leg: Movements of the Ankle and Toes (Figures 10.21 to 10.23)

The deep fascia of the leg is continuous with the fascia lata that ensheathes the thigh. Like a snug knee sock beneath the skin, the leg fascia binds the leg muscles tightly, helping to prevent excessive swelling of muscles during exercise and aiding venous return. Its inward extensions segregate the leg muscles into *anterior, lateral,* and *posterior compartments* (see Figure 10.24b), each with its own nerve and blood supply. Distally the leg fascia thickens to form the **flexor, extensor,** and **fibular** (or **peroneal**) **retinaculae,** "ankle brackets" that hold the tendons in place where they run to the foot.

The various muscles of the leg promote movements at the ankle joint (dorsiflexion and plantar flexion), the intertarsal joints (inversion and eversion of the foot), and/or the toes (flexion and extension). Muscles in the *anterior extensor compartment of the leg*—**tibialis anterior, extensor digitorum longus, extensor hallucis longus,** and **fibularis tertius**—are primarily toe extensors and ankle dorsiflexors. Although dorsiflexion is not a powerful movement, it is important in preventing the toes from dragging during walking. Lateral compartment muscles are the **fibular,** formerly **peroneal** (*peron* = fibula), **muscles** that plantar flex and evert the foot. Muscles of the *posterior flexor compartment*—**gastrocnemius, soleus, tibialis posterior, flexor digitorum longus,** and **flexor hallucis longus**—primarily plantar flex the foot and flex the toes. Plantar flexion is the most powerful movement of the ankle (and foot) because it lifts the entire weight of our body. It is essential for standing on tiptoe and provides the forward thrust when walking and running. The **popliteus muscle,** which crosses the knee, "unlocks" the extended knee in preparation for flexion.

The tiny intrinsic muscles of the sole of the foot (lumbricals, interossei, and others) are considered separately in Table 10.17.

The actions of the muscles in this table are summarized in Table 10.16 (Part II).

MUSCLE	DESCRIPTION	ORIGIN (O) AND INSERTION (I)	ACTION	NERVE SUPPLY
Part I: Muscles of the Anterior Compartment (Figures 10.21 and 10.22)	All muscles of the anterior compartment are dorsiflexors of the ankle and have a common innervation, the deep fibular nerve. Paralysis of the anterior muscle group causes *foot drop,* which requires that the leg be lifted unusually high during walking to prevent tripping over one's toes. "Shin splints" is a painful inflammatory condition of the muscles of the anterior compartment.			
Tibialis anterior (tib"e-a'lis) (*tibial* = tibia; *anterior* = toward the front)	Superficial muscle of anterior leg; laterally parallels sharp anterior margin of tibia	O—lateral condyle and upper 2/3 of tibial shaft; interosseous membrane I—by tendon into inferior surface of medial cuneiform and first metatarsal bone	Prime mover of dorsiflexion; inverts foot; assists in supporting medial longitudinal arch of foot	Deep fibular nerve (L_4 and L_5)
Extensor digitorum longus (*extensor* = increases angle at a joint; *digit* = finger or toe; *longus* = long)	Unipennate muscle on anterolateral surface of leg; lateral to tibialis anterior muscle	O—lateral condyle of tibia; proximal 3/4 of fibula; interosseous membrane I—middle and distal phalanges of toes 2–5 via extensor expansion	Prime mover of toe extension (acts mainly at metatarsophalangeal joints); dorsiflexes foot (in conjunction with the tibialis anterior and extensor hallucis longus)	Deep fibular nerve (L_5 and S_1)
Fibularis (peroneus) tertius (fib-u-lar'ris ter'shus) (*fibular* = fibula; *tertius* = third)	Small muscle; usually continuous and fused with distal part of extensor digitorum longus; not always present	O—distal anterior surface of fibula and interosseous membrane I—tendon inserts on dorsum of fifth metatarsal	Dorsiflexes and everts foot	Deep fibular nerve (L_5 and S_1)
Extensor hallucis longus (hal'yu-kis) (*hallux* = great toe)	Deep to extensor digitorum longus and tibialis anterior; narrow origin	O—anteromedial fibula shaft and interosseous membrane I—tendon inserts on distal phalanx of great toe	Extends great toe; dorsiflexes foot	Deep fibular nerve (L_5 and S_1)

(See *A Brief Atlas of the Human Body*, Figure 42.)

MUSCLE GALLERY TABLE 10.15 Muscles of the Leg: Movements of the Ankle and Toes (Figures 10.21 to 10.23) *(continued)*

MUSCLE	DESCRIPTION	ORIGIN (O) AND INSERTION (I)	ACTION	NERVE SUPPLY
Part II: Muscles of the Lateral Compartment (Figures 10.22 and 10.23) These muscles have a common innervation, the superficial fibular nerve. Besides plantar flexion and foot eversion, these muscles stabilize the lateral ankle and lateral longitudinal arch of the foot.				
Fibularis (peroneus) longus (See also Figure 10.21)	Superficial lateral muscle; overlies fibula	O—upper portion of lateral fibula I—by long tendon that curves under foot to first metatarsal and medial cuneiform	Plantar flexes and everts foot; may help keep foot flat on ground	Superficial fibular nerve (L_5–S_2)
Fibularis (peroneus) brevis (*brevis* = short)	Smaller muscle; deep to fibularis longus; enclosed in a common sheath	O—distal fibula shaft I—by tendon running behind lateral malleolus to insert on proximal end of fifth metatarsal	Plantar flexes and everts foot	Superficial fibular nerve (L_5–S_2)
Part III: Muscles of the Posterior Compartment (Figure 10.23) The muscles of the posterior compartment have a common innervation, the tibial nerve. They act in concert to plantar flex the ankle.				
Superficial Muscles				
Triceps surae (tri"seps sur'e) (See also Figure 10.22)	Refers to muscle pair (gastrocnemius and soleus) that shapes the posterior calf and inserts via a common tendon into the calcaneus of the heel; this calcaneal or Achilles tendon is the largest tendon in the body. Prime movers of ankle plantar flexion.			
▪ **Gastrocnemius** (gas"truk-ne'me-us) (*gaster* = belly; *kneme* = leg)	Superficial muscle of pair; two prominent bellies that form proximal curve of calf	O—by two heads from medial and lateral condyles of femur I—posterior calcaneus via calcaneal tendon	Plantar flexes foot when knee is extended; since it also crosses knee joint, it can flex knee when foot is dorsiflexed	Tibial nerve (S_1, S_2)
▪ **Soleus** (so'le-us) (*soleus* = fish)	Broad, flat muscle, deep to gastrocnemius on posterior surface of calf	O—extensive origin from superior tibia, fibula, and interosseous membrane I—as for gastrocnemius	Plantar flexes foot; important locomotor and postural muscle during walking, running, and dancing	Tibial nerve
Plantaris (plan-tar'is) (*planta* = sole of foot)	Generally a small, feeble muscle, but varies in size and extent; may be absent	O—posterior femur above lateral condyle I—via a long, thin tendon into calcaneus or its tendon	Assists in knee flexion and plantar flexion of foot	Tibial nerve
Deep Muscles				
Popliteus (pop-lit'e-us) (*poplit* = back of knee)	Thin, triangular muscle at posterior knee; passes inferomedially to tibial surface	O—lateral condyle of femur and lateral meniscus I—proximal tibia	Flexes and rotates leg medially to unlock extended knee; with tibia fixed, rotates thigh laterally	Tibial nerve (L_4–S_1)
Flexor digitorum longus (*flexor* = decreases angle at a joint)	Long, narrow muscle; runs medial to and partially overlies tibialis posterior	O—extensive origin on the posterior tibia I—tendon runs behind medial malleolus and inserts into distal phalanges of toes 2–5	Plantar flexes and inverts foot; flexes toes; helps foot "grip" ground	Tibial nerve (S_2 and S_3)
Flexor hallucis longus (See also Figure 10.22)	Bipennate muscle; lies lateral to inferior aspect of tibialis posterior	O—midshaft of fibula; interosseous membrane I—tendon runs under foot to distal phalanx of great toe	Plantar flexes and inverts foot; flexes great toe at all joints; "push off" muscle during walking	Tibial nerve (S_2 and S_3)
Tibialis posterior (*posterior* = toward the back)	Thick, flat muscle deep to soleus; placed between posterior flexors	O—extensive origin from superior tibia and fibula and interosseous membrane I—tendon passes behind medial malleolus and under arch of foot; inserts into several tarsals and metatarsals 2–4	Prime mover of foot inversion; plantar flexes foot; stabilizes medial longitudinal arch of foot (as during ice skating)	Tibial nerve (L_4 and L_5)

MUSCLE GALLERY TABLE 10.17 Intrinsic Muscles of the Foot: Toe Movement and Arch Support (Figure 10.25)

The intrinsic muscles of the foot help to flex, extend, abduct, and adduct the toes. Collectively, along with the tendons of some leg muscles that enter the sole, the foot muscles help support the arches of the foot. There is a single muscle on the foot's dorsum (superior aspect), and several muscles on the plantar aspect (the sole). The plantar muscles occur in four layers, from superficial to deep. Overall, the foot muscles are remarkably similar to those in the palm of the hand.

MUSCLE	DESCRIPTION	ORIGIN (O) AND INSERTION (I)	ACTION	NERVE SUPPLY
Muscle on Dorsum of Foot				
Extensor digitorum brevis (Figures 10.21a and 10.22a)	Small, four-part muscle on dorsum of foot; deep to the tendons of extensor digitorum longus; corresponds to the extensor indicis muscle of forearm. Its most medial muscle slip corresponds to the extensor pollicis of the forearm and is sometimes called the extensor hallucis brevis.	O—anterior part of calcaneus bone; extensor retinaculum I—base of proximal phalanx of great toe; extensor expansions on toes 2–5	Helps extend toes at metatarsophalangeal joints	Deep fibular nerve (S_1 and S_2)
Muscles on Sole of Foot—First Layer (Most Superficial) (Figure 10.25)				
Flexor digitorum brevis	Bandlike muscle in middle of sole; corresponds to flexor digitorum superficialis of forearm and inserts into digits in the same way	O—calcaneal tuberosity I—middle phalanx of toes 2–4	Helps flex toes	Medial plantar nerve (S_2 and S_3)
Abductor hallucis (hal'yu-kis) (*hallux* = great toe)	Lies medial to flexor digitorum brevis (recall the similar thumb muscle, abductor pollicis brevis)	O—calcaneal tuberosity and flexor retinaculum I—proximal phalanx of great toe, medial side, in the tendon of flexor hallucis brevis (see below)	Abducts great toe	Medial plantar nerve
Abductor digiti minimi	Most lateral of the three superficial sole muscles; (recall similar abductor muscle in palm)	O—calcaneal tuberosity I—lateral side of base of little toe's proximal phalanx	Abducts and flexes little toe	Lateral plantar nerve (S_2 and S_3)
Muscles on Sole of Foot—Second Layer				
Flexor accessorius (quadratus plantae)	Rectangular muscle just deep to flexor digitorum brevis in posterior half of sole; two heads (see also Figure 10.25c)	O—medial and lateral sides of calcaneus I—tendon of flexor digitorum longus in midsole	Straightens out the oblique pull of flexor digitorum longus	Lateral plantar nerve
Lumbricals	Four little "worms" (like lumbricals in hand)	O—from each tendon of flexor digitorum longus I—extensor expansion on proximal phalanx of toes 2–5, medial side	By pulling on extensor expansion, flex toes at metatarsophalangeal joints and extend toes at interphalangeal joints	Medial plantar nerve (first lumbrical) and lateral plantar nerve (second to fourth lumbrical)

FIGURE 10.25 **Muscles of the right foot, plantar and medial aspects.**

MUSCLE GALLERY TABLE 10.17 *(continued)*

MUSCLE	DESCRIPTION	ORIGIN (O) AND INSERTION (I)	ACTION	NERVE SUPPLY
Muscles on Sole of Foot—Third Layer				
Flexor hallucis brevis	Covers metatarsal 1; splits into two bellies—recall flexor pollicis brevis of thumb	O—lateral cuneiform and cuboid bones I—via two tendons onto base of the proximal phalanx of great toe	Flexes great toe's metatarsophalangeal joint	Medial plantar nerve
Adductor hallucis	Oblique and transverse heads; deep to lumbricals (recall adductor pollicis in thumb)	O—from bases of metatarsals 2–4 and from fibularis longus tendon sheath (oblique head); from a ligament across metatarsophalangeal joints (transverse head) I—base of proximal phalanx of great toe, lateral side	Helps maintain the transverse arch of foot; weak adductor of great toe	Lateral plantar nerve (S_2 and S_3)
Flexor digiti minimi brevis	Covers metatarsal 5 (recall same muscle in hand)	O—base of metatarsal 5 and tendon sheath of fibularis longus I—base of proximal phalanx of toe 5	Flexes little toe at metatarsophalangeal joint	Lateral plantar nerve
Muscles on Sole of Foot—Fourth Layer (Deepest)				
Plantar (3) and dorsal interossei (4)	Similar to the palmar and dorsal interossei of hand in locations, attachments, and actions; however, the long axis of foot around which these muscles orient is the second digit, not the third	See palmar and dorsal interossei (Table 10.13)	See palmar and dorsal interossei (Table 10.13)	Lateral plantar nerve

Related Clinical Terms

Charley horse A muscle contusion, i.e., tearing of muscle followed by bleeding into the tissues (hematoma) and severe, prolonged pain; a common contact sports injury; a charley horse of the quadriceps muscle of the thigh occurs frequently in football players.

Electromyography Recording and interpretation of graphic records of the electrical activity of contracting muscles. Electrodes inserted into the muscles record the impulses that pass over muscle-cell membranes to stimulate contraction. The best and most important technique for determining the functions of muscles and muscle groups.

Hernia An abnormal protrusion of abdominal contents (typically coils of the small intestine) through a weak point in the muscles of the abdominal wall. Most often caused by increased intra-abdominal pressure during lifting or straining. The hernia penetrates the muscle wall but not the skin and so appears as a visible bulge in the body surface. Common abdominal hernias include the inguinal and umbilical hernias.

Quadriceps and hamstring strains Also called quad and hamstring pulls, these conditions involve tearing of these muscles or their tendons; happen mainly in athletes who do not warm up properly and then fully extend their hip (quad pull) or knee (hamstring pull) quickly or forcefully (e.g., sprinters, tennis players); not painful at first, but pain intensifies within three to six hours (30 minutes if the tearing is severe). After a week of rest, stretching is the best therapy.

Rupture of the calcaneal tendon Although the calcaneal (Achilles) tendon is the largest, strongest tendon in the body, its rupture is surprisingly common, particularly in older people as a result of stumbling and in young sprinters when the tendon is traumatized during the takeoff. The rupture is followed by abrupt pain; a gap is seen just above the heel, and the calf bulges as the triceps surae are released from their insertion. Plantar flexion is weak or impossible, but dorsiflexion is exaggerated. Surgical repair of the tendon is necessary.

Shin splints Common term for pain in the anterior compartment of the leg caused by irritation of the tibialis anterior muscle as might follow extreme or unusual exercise without adequate prior conditioning. Because it is tightly wrapped by fascia, the inflamed tibialis anterior cuts off its own circulation as it swells and presses painfully on its own nerves.

Tennis elbow Tenderness due to trauma or overuse of the tendon of origin of the forearm extensor muscles at the lateral epicondyle of the humerus. Caused and aggravated when these muscles contract forcefully to extend the hand at the wrist—as in executing a tennis backhand or lifting a loaded snow shovel. Despite its name, tennis elbow does not involve the elbow joint; most cases caused by work activities.

Torticollis (tor″tĭ-kol′is; *tort* = twisted) A twisting of the neck in which there is a chronic rotation and tilting of the head to one side, due to injury of the sternocleidomastoid muscle on one side; also called wryneck. Sometimes present at birth when the muscle fibers are torn during difficult delivery. Exercise that stretches the affected muscle is the usual treatment.

Chapter Summary

Interactions of Skeletal Muscles in the Body (p. 325)

1. Skeletal muscles are arranged in opposing groups across body joints so that one group can reverse or modify the action of the other.

2. Muscles are classified as prime movers, or agonists (bear the chief responsibility for producing movement); antagonists (reverse, or oppose, the action of another muscle); synergists (aid a prime mover by effecting the same action, stabilizing joints, or preventing undesirable movements); and fixators (function to immobilize a bone or a muscle's origin).

Naming Skeletal Muscles (pp. 325–326)

1. Criteria used to name muscles include a muscle's location, shape, relative size, fiber (fascicle) direction, number of origins, attachment sites (origin/insertion), and action. Several criteria are combined to name some muscles.

Muscle Mechanics: Importance of Fascicle Arrangement and Leverage (pp. 326–330)

1. Common patterns of fascicle arrangement are parallel, fusiform, pennate, convergent, and circular. Muscles with fibers that run parallel to the long axis of the muscle shorten most; stocky pennate muscles shorten little but are the most powerful muscles.

2. A lever is a bar that moves on a fulcrum. When an effort is applied to the lever, a load is moved. In the body, bones are the levers, joints are the fulcrums, and the effort is exerted by skeletal muscles at their insertions.

3. When the effort is farther from the fulcrum than is the load, the lever operates at a mechanical advantage (is slow and strong). When the effort is exerted closer to the fulcrum than is the load, the lever operates at a mechanical disadvantage (is fast and promotes a large degree of movement).

4. First-class levers (effort-fulcrum-load) may operate at a mechanical advantage or disadvantage. Second-class levers (fulcrum-load-effort) all operate at a mechanical advantage. Third-class levers (fulcrum-effort-load) always operate at a mechanical disadvantage.

Major Skeletal Muscles of the Body (pp. 330–383)

1. Muscles of the head that produce facial expression tend to be small and to insert into soft tissue (skin and other muscles) rather than into bone. These muscles open and close the eyes and mouth, compress the cheeks, allow smiling and other types of facial language (see Table 10.1*).

2. Muscles of the head involved in mastication include the masseter and temporalis that elevate the mandible and two deep muscle pairs that promote grinding and sliding jaw movements (see Table 10.2*). Extrinsic muscles of the tongue anchor the tongue and control its movements.

*See specific table cited for detailed description of each muscle in the group.

3. Deep muscles of the anterior neck promote swallowing movements, including elevation/depression of the hyoid bone, closure of the respiratory passages, and peristalsis of the pharynx (see Table 10.3*).

4. Neck muscles and deep muscles of the vertebral column promote head and trunk movements (see Table 10.4*). The deep muscles of the posterior trunk can extend large regions of the vertebral column (and head) simultaneously. Head flexion and rotation are effected by the anteriorly located sternocleidomastoid and scalene muscles.

5. Movements of quiet breathing are promoted by the diaphragm and the external intercostal muscles of the thorax (see Table 10.5*). Downward movement of the diaphragm increases intra-abdominal pressure.

6. The four muscle pairs forming the abdominal wall are layered like plywood to form a natural muscular girdle that protects, supports, and compresses abdominal contents. These muscles also flex and laterally rotate the trunk (see Table 10.6*).

7. Muscles of the pelvic floor and perineum (see Table 10.7*) support the pelvic viscera, resist increases in intra-abdominal pressure, inhibit urination and defecation, and aid erection.

8. Except for the pectoralis major and the latissimus dorsi, the superficial muscles of the thorax act to fix or promote movements of the scapula (see Table 10.8*). Scapular movements are effected primarily by posterior thoracic muscles.

9. Nine muscles cross the shoulder joint to effect movements of the humerus (see Table 10.9*). Of these, seven originate on the scapula and two arise from the axial skeleton. Four muscles contribute to the "rotator cuff" helping to stabilize the multiaxial shoulder joint. Generally speaking, muscles located anteriorly flex, rotate, and adduct the arm. Those located posteriorly extend, rotate, and adduct the arm. The deltoid muscle of the shoulder is the prime mover of shoulder abduction.

10. Muscles causing movements of the forearm form the flesh of the arm (see Table 10.10*). Anterior arm muscles are forearm flexors; posterior muscles are forearm extensors.

11. Movements of the wrist, hand, and fingers are effected mainly by muscles originating on the forearm (see Table 10.11*). Except for the two pronator muscles, the anterior forearm muscles are wrist and/or finger flexors; those of the posterior compartment are wrist and finger extensors.

12. The intrinsic muscles of the hand aid in precise movements of the fingers (Table 10.13*) and in opposition, which helps us grip things in our palms. These small muscles are divided into thenar, hypothenar, and midpalmar groups.

13. Muscles crossing the hip and knee joints effect thigh and leg movements (see Table 10.14*). Anteromedial muscles include thigh flexors and/or adductors and knee extensors. Muscles of the posterior gluteal region extend and rotate the thigh. Posterior thigh muscles extend the hip and flex the knee.

14. Muscles in the leg act on the ankle and toes (see Table 10.15*). Anterior compartment muscles are largely ankle dorsiflexors. Lateral compartment muscles are plantar flexors and foot everters. Those of the posterior leg are plantar flexors.

15. The intrinsic muscles of the foot (Table 10.17*) support the foot arches and help move the toes. Most occur in the sole, arranged in four layers. They resemble the small muscles in the palm of the hand.

*See specific table cited for detailed description of each muscle in the group.

Review Questions

Multiple Choice/Matching

(Some questions have more than one correct answer. Select the best answer or answers from the choices given.)

1. A muscle that assists an agonist by causing a like movement or by stabilizing a joint over which an agonist acts is (a) an antagonist, (b) a prime mover, (c) a synergist, (d) an agonist.

2. A muscle in which the fibers are arranged at an angle to a central longitudinal tendon has a _____ arrangement. (a) circular, (b) longitudinal, (c) pennate, (d) parallel.

3. Match the muscle names in column B to the facial muscles described in column A.

Column A	Column B
____ (1) squints the eyes	(a) corrugator supercilii
____ (2) raises the eyebrows	(b) depressor anguli oris
____ (3) smiling muscle	(c) frontal belly of epicranius
____ (4) puckers the lips	(d) occipital belly of epicranius
____ (5) pulls the scalp posteriorly	(e) orbicularis oculi
	(f) orbicularis oris
	(g) zygomaticus

4. The prime mover of inspiration is the (a) diaphragm, (b) internal intercostals, (c) external intercostals, (d) abdominal wall muscles.

5. The arm muscle that both flexes the elbow and supinates the forearm is the (a) brachialis, (b) brachioradialis, (c) biceps brachii, (d) triceps brachii.

6. The chewing muscles that protrude the mandible and produce side-to-side grinding movements are the (a) buccinators, (b) masseters, (c) temporalis, (d) pterygoids.

7. Muscles that depress the hyoid bone and larynx include all but the (a) sternohyoid, (b) omohyoid, (c) geniohyoid, (d) sternothyroid.

8. Intrinsic muscles of the back that promote extension of the spine (or head) include all but (a) splenius muscles, (b) semispinalis muscles, (c) scalene muscles, (d) erector spinae.

9. Several muscles act to move and/or stabilize the scapula. Which of the following are small rectangular muscles that square the shoulders as they act together to retract the scapula? (a) levator scapulae, (b) rhomboids, (c) serratus anterior, (d) trapezius.

10. The quadriceps include all but (a) vastus lateralis, (b) vastus intermedius, (c) vastus medialis, (d) biceps femoris, (e) rectus femoris.

11. A prime mover of hip flexion is the (a) rectus femoris, (b) iliopsoas, (c) vasti muscles, (d) gluteus maximus.

12. The prime mover of hip extension *against* resistance is the (a) gluteus maximus, (b) gluteus medius, (c) biceps femoris, (d) semimembranosus.

13. Muscles that cause plantar flexion include all but the (a) gastrocnemius, (b) soleus, (c) tibialis anterior, (d) tibialis posterior, (e) fibularis muscles.

14. In walking, which two lower limb muscles keep the forward-swinging foot from dragging on the ground? (a) pronator teres and popliteus, (b) flexor digitorum longus and popliteus, (c) adductor longus and abductor digiti minimi in foot, (d) gluteus medius and tibialis anterior.

15. What criterion (or criteria) are used in naming the gluteus medius? (a) relative size, (b) muscle location, (c) muscle shape, (d) action, (e) number of origins.

16. Which of the following is a large, deep muscle that protracts the scapula during punching? (a) serratus anterior, (b) rhomboids, (c) levator scapulae, (d) subscapularis.

Short Answer Essay Questions

17. Name four criteria used in naming muscles, and provide an example (other than those used in the text) that illustrates each criterion.

18. Differentiate between the arrangement of elements (load, fulcrum, and effort) in first-, second-, and third-class levers.

19. What does it mean when we say that a lever operates at a mechanical disadvantage, and what benefits does such a lever system provide?

20. What muscles act to propel a food bolus down the length of the pharynx to the esophagus?

21. Name and describe the action of muscles used to shake your head no. To nod yes.

22. (a) Name the four muscle pairs that act in unison to compress the abdominal contents. (b) How does their arrangement (fiber direction) contribute to the strength of the abdominal wall? (c) Which of these muscles can effect lateral rotation of the spine? (d) Which can act alone to flex the spine?

23. List all (six) possible movements that can occur at the shoulder joint and name the prime mover(s) of each movement. Then name their antagonists.

24. (a) Name two forearm muscles that are powerful extensors and abductors of the wrist. (b) Name the sole forearm muscle that can flex the distal interphalangeal joints.

25. Name the muscles usually grouped together as the lateral rotators of the hip.

26. Name three thigh muscles that help you keep your seat astride a horse.

27. (a) Name three muscles or muscle groups used as sites for intramuscular injections. (b) Which of these is used most often in infants, and why?

28. Name two muscles in each of the following compartments or regions: (a) thenar eminence (ball of thumb), (b) posterior compartment of forearm, (c) anterior compartment of forearm—deep muscle group, (d) anterior muscle group in the arm, (e) muscles of mastication, (f) third muscle layer of the foot, (g) posterior compartment of leg, (h) medial compartment of thigh, (i) posterior compartment of thigh.

Critical Thinking and Clinical Application Questions

1. Assume you have a 10-lb weight in your right hand. Explain why it is easier to flex the right elbow when your forearm is supinated than when it is pronated.

2. When Mrs. O'Brien returned to her doctor for a follow-up visit after childbirth, she complained that she was having problems controlling her urine flow (was incontinent) when she sneezed. The physician asked his nurse to give Mrs. O'Brien instructions on how to perform exercises to strengthen the muscles of the pelvic floor. To what muscles was he referring?

3. Mr. Ahmadi, an out-of-shape 45-year-old man, was advised by his physician to lose weight and to exercise on a regular basis. He followed his diet faithfully and began to jog daily. One day, while on his morning jog, he heard a snapping sound that was immediately followed by a severe pain in his right lower calf. When his leg was examined, a gap was seen between his swollen upper calf region and his heel, and he was unable to plantar flex that ankle. What do you think happened? Why was the upper part of his calf swollen?

4. As Peter watched Sue walk down the runway at the fashion show, he contracted his right orbicularis oculi muscle, raised his arm, and contracted his opponens pollicis. Was he pleased or displeased with her performance? How do you know?

5. What type of lever is described by the following activities? (a) The soleus muscle plantar flexes the foot. (b) The deltoid abducts the arm. (c) The triceps brachii is strained while doing pushups.

6. While riding an unusually large horse, Chao Jung had to spread her thighs widely to span its back and she pulled the muscles in her medial thighs. Which muscles were these and what might this condition be called?

CHAPTER 11

Fundamentals of the Nervous System and Nervous Tissue

1. List the basic functions of the nervous system.

Organization of the Nervous System (pp. 388–389)

2. Explain the structural and functional divisions of the nervous system.

Histology of Nervous Tissue (pp. 389–397)

3. List the types of neuroglia and cite their functions.
4. Define neuron, describe its important structural components, and relate each to a functional role.
5. Differentiate between a nerve and a tract, and between a nucleus and a ganglion.
6. Explain the importance of the myelin sheath and describe how it is formed in the central and peripheral nervous systems.
7. Classify neurons structurally and functionally.

Neurophysiology (pp. 397–421)

8. Define resting membrane potential and describe its electrochemical basis.
9. Compare and contrast graded and action potentials.
10. Explain how action potentials are generated and propagated along neurons.
11. Define absolute and relative refractory periods.
12. Define saltatory conduction and contrast it to conduction along unmyelinated fibers.
13. Define synapse. Distinguish between electrical and chemical synapses structurally and in their mechanisms of information transmission.
14. Distinguish between excitatory and inhibitory postsynaptic potentials.
15. Describe how synaptic events are integrated and modified.
16. Define neurotransmitter and name several classes of neurotransmitters.

Basic Concepts of Neural Integration (pp. 421–423)

17. Describe common patterns of neuronal organization and processing.
18. Distinguish between serial and parallel processing.

Developmental Aspects of Neurons (pp. 423–425)

19. Describe the role of astrocytes and nerve cell adhesion molecules in neuronal differentiation.

You are driving down the freeway, and a horn blares to your right. You immediately swerve to your left. Charlie leaves a note on the kitchen table: "See you later. Have the stuff ready at 6." You know the "stuff" is chili with taco chips. You are dozing but you awaken instantly as your infant son makes a soft cry. What do these three events have in common? They are all everyday examples of the functioning of your nervous system, which has your body cells humming with activity nearly all the time.

The **nervous system** is the master controlling and communicating system of the body. Every thought, action, and emotion reflects its activity. Its cells communicate by electrical and chemical signals, which are rapid and specific, and usually cause almost immediate responses.

The nervous system has three overlapping functions (Figure 11.1): (1) It uses its millions of sensory receptors to monitor changes occurring both inside and outside the body. The gathered information is called **sensory input.** (2) It processes and interprets sensory input and decides what should be done at each moment—a process called **integration.** (3) It causes a *response*, called **motor output,** by activating *effector organs*. For example, when you are driving and see a red light ahead (sensory input), your nervous system integrates this information (red light means "stop"), and your foot goes for the brake (motor output).

This chapter begins with a brief overview of the organization of the nervous system. It then focuses on the functional anatomy of nervous tissue, especially that of nerve cells, or *neurons*, which are the key to neural communication.

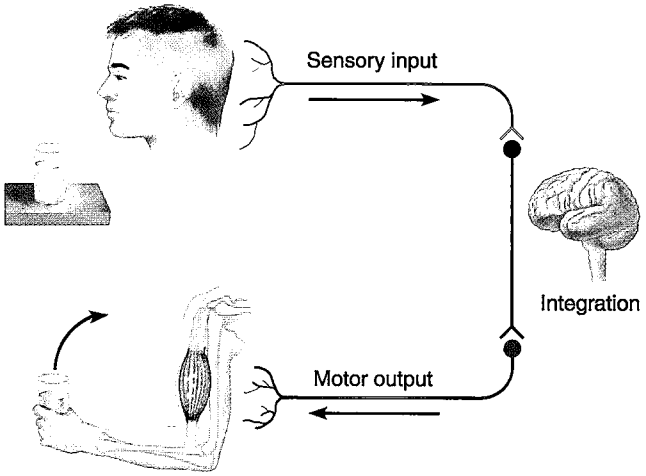

FIGURE 11.1 **The nervous system's functions.**

Organization of the Nervous System

We have only one highly integrated nervous system. However, for convenience, it can be divided into two principal parts (Figure 11.2). The **central nervous system (CNS)** consists of the *brain* and *spinal cord*, which occupy the dorsal body cavity. The CNS is the integrating and command center of the nervous system. It interprets sensory input and dictates motor responses based on past experience, reflexes, and current conditions. The **peripheral nervous system (PNS),** the part of the nervous system *outside* the CNS, consists mainly of the nerves (bundles of axons) that extend from the brain and spinal cord. *Spinal nerves* carry impulses to and from the spinal cord; *cranial nerves* carry impulses to and from the brain. These peripheral nerves serve as the communication lines that link all parts of the body to the CNS.

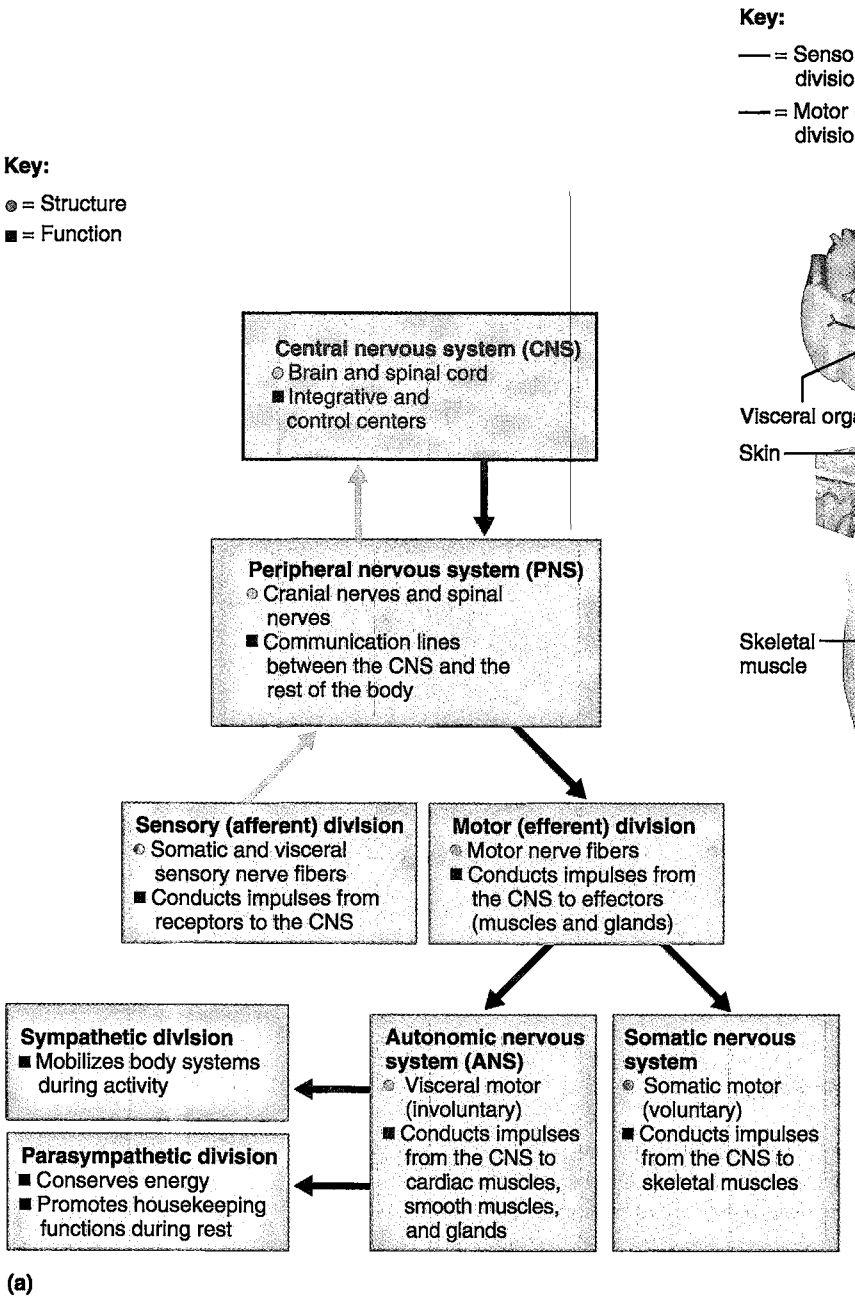
The PNS has two functional subdivisions (see Figure 11.2). The **sensory,** or **afferent, division** (af'er-ent; "carrying toward") consists of nerve fibers that convey impulses to the central nervous system from sensory receptors located throughout the body. Sensory fibers conveying impulses from the skin, skeletal muscles, and joints are called *somatic afferent fibers* (*soma* = body), and those transmitting impulses from the visceral organs (organs within the ventral body cavity) are called *visceral afferent fibers*. The sensory division keeps the CNS constantly informed of events going on both inside and outside the body.

The **motor,** or **efferent, division** (ef'er-ent; "carrying away") of the PNS transmits impulses *from* the CNS to effector organs, which are the muscles and glands. These impulses activate muscles to contract and glands to secrete; that is, they *effect* (bring about) a motor response.

The motor division also has two main parts:

1. The **somatic nervous system** is composed of somatic motor nerve fibers (axons) that conduct impulses from the CNS to skeletal muscles. It is often referred to as the **voluntary nervous system** because it allows us to consciously control our skeletal muscles.

2. The **autonomic nervous system (ANS)** consists of visceral motor nerve fibers that regulate the activity of smooth muscles, cardiac muscles, and glands. *Autonomic* means "a law unto itself," and because we generally cannot control such activities as the pumping of our heart or the movement of food through our digestive tract, the ANS is also referred to as the **involuntary nervous system.** As indicated in Figure 11.2 and described in Chapter 14, the ANS has two functional subdivisions, the **sympathetic**



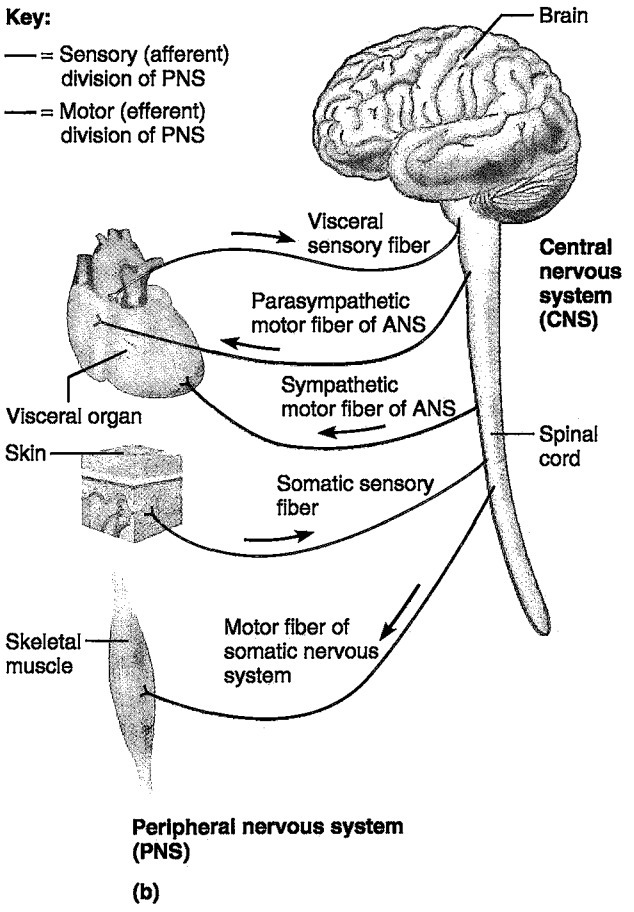


FIGURE 11.2 **Levels of organization in the nervous system. (a)** Organizational chart. **(b)** Visceral organs (primarily located in the ventral body cavity) are served by visceral sensory fibers and by motor fibers of the autonomic nervous system. The somata (limbs and body wall) are served by motor fibers of the somatic nervous system and by somatic sensory fibers. Arrows indicate the direction of nerve impulses.

and the **parasympathetic,** which typically work in opposition to each other—what one subdivision stimulates, the other inhibits.

Histology of Nervous Tissue

The nervous system consists mostly of nervous tissue, which is highly cellular. For example, less than 20% of the CNS is extracellular space, which means that the cells are densely packed and tightly intertwined. Although it is very complex, nervous tissue is made up of just two principal types of cells: (1) *supporting cells*, smaller cells that surround and wrap the more delicate neurons, and (2) *neurons*, the excitable nerve cells that transmit electrical signals.

Neuroglia

Neurons associate closely with much smaller cells called **neuroglia** (nu-rog'le-ah; "nerve glue") or simply **glial cells** (gle'al). There are six types of neuroglia—four in the CNS and two in the PNS (Figure 11.3). Each type has a unique function, but in general, these cells provide a supportive scaffolding for neurons. Some produce chemicals that guide young neurons to the proper connections, and

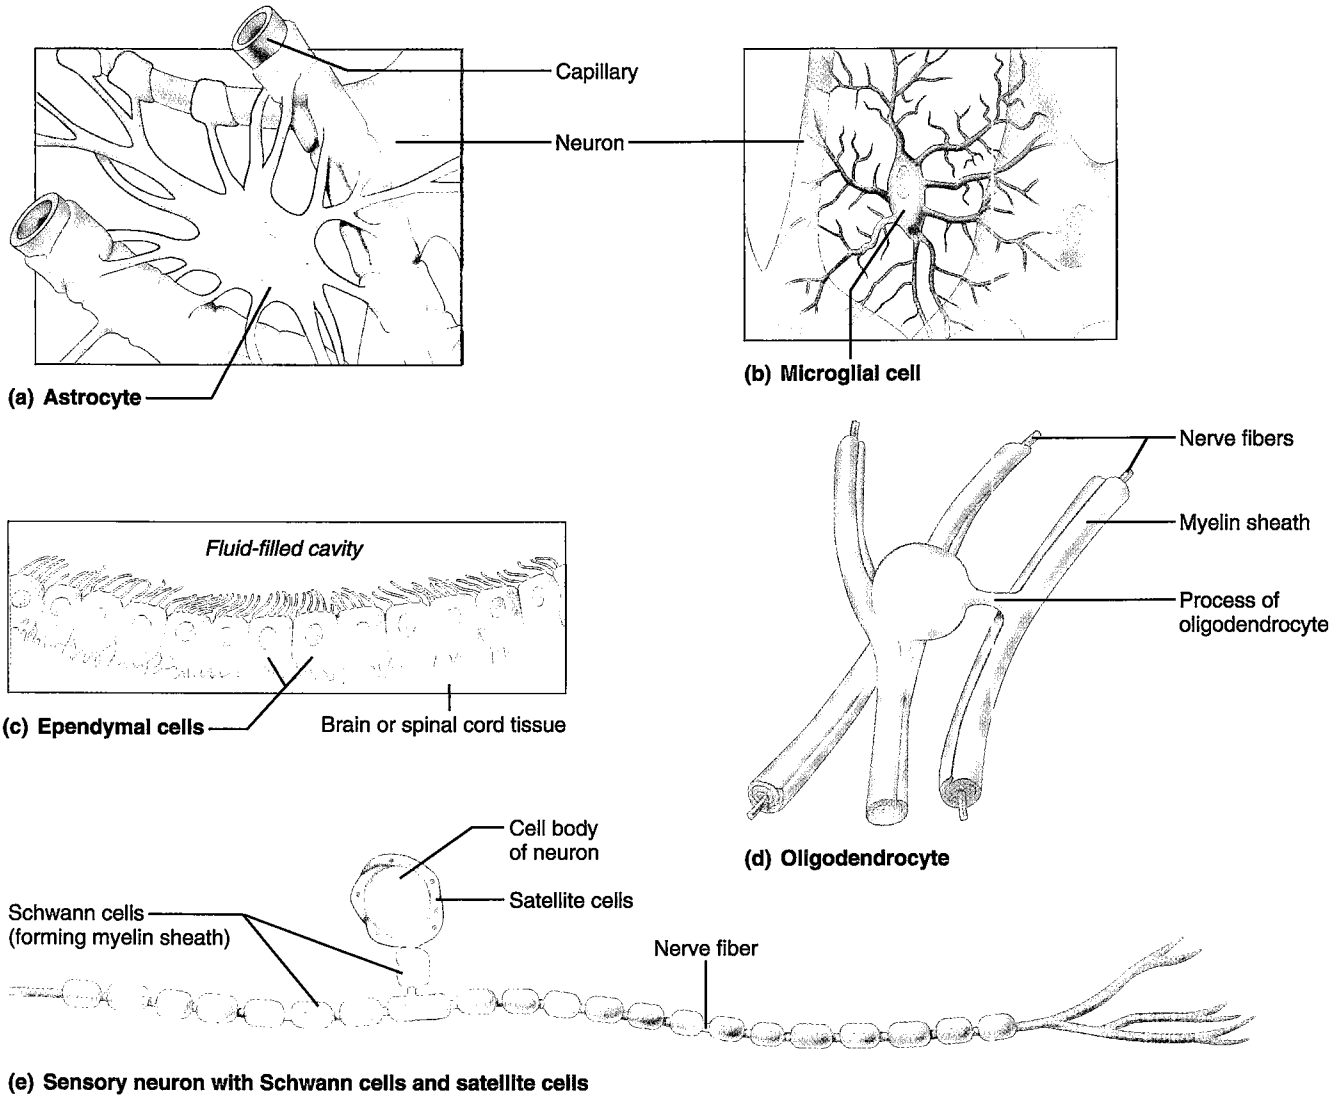

FIGURE 11.3 **Neuroglia. (a–d)** Types of neuroglia found in the CNS. Notice in (d) that it is the processes of the oligodendrocytes that form the myelin sheaths around CNS nerve fibers. **(e)** The relationships of Schwann cells (myelinating cells) and satellite cells to a sensory neuron (nerve cell) in the peripheral nervous system.

promote neuron health and growth. Others wrap around and insulate neuronal processes to speed up action potential conduction.

Neuroglia in the CNS

Neuroglia in the CNS include *astrocytes, microglia, ependymal cells,* and *oligodendrocytes*. Like neurons, most glial cells have branching processes (extensions) and a central cell body (Figure 11.3a–d). Neuroglia can be distinguished, however, by their much smaller size and by their darker-staining nuclei. They outnumber neurons in the CNS by about 10 to 1, and make up about half the mass of the brain.

Shaped like delicate branching sea anemones, **astrocytes** (as'tro-sītz; "star cells") are the most abundant and most versatile glial cells. Their numerous radiating processes cling to neurons and their synaptic endings, and cover nearby capillaries, supporting and bracing the neurons and anchoring them to their nutrient supply lines, the blood capillaries (Figure 11.3a). Astrocytes have a role in making exchanges between capillaries and neurons, in guiding the migration of young neurons, in synapse formation, and in helping to determine capillary permeability. They also control the chemical environment around neurons, where their most important job is "mopping up" leaked potassium ions and recapturing (and recycling) released neurotransmitters. Furthermore, astrocytes connected by gap junctions have been shown to respond to nearby nerve impulses and released

neurotransmitters by taking in calcium and signaling one another both by slow-paced intracellular calcium pulses (calcium sparks) and extracellular chemical messengers. According to recent research, astrocytes also influence neuronal functioning and therefore participate in information processing in the brain.

Microglia (mi-kro'gle-ah) are small ovoid cells with relatively long "thorny" processes (Figure 11.3b). Their processes touch nearby neurons, monitoring their health, and when they sense that certain neurons are injured or in other trouble, the microglia migrate toward them. Where invading microorganisms or dead neurons are present, the microglia transform into a special type of macrophage that phagocytizes the microorganisms or neuronal debris. This protective role of the microglia is important because cells of the immune system are denied access to the CNS.

Ependymal cells (ĕ-pen'dĭ-mul; "wrapping garment") range in shape from squamous to columnar, and many are ciliated. They line the central cavities of the brain and the spinal cord, where they form a fairly permeable barrier between the cerebrospinal fluid that fills those cavities and the tissue fluid bathing the cells of the CNS. The beating of their cilia helps to circulate the cerebrospinal fluid that cushions the brain and spinal cord (Figure 11.3c).

Though they also branch, the **oligodendrocytes** (ol"ĭ-go-den'dro-sīts) have fewer processes (*oligo* = few; *dendr* = branch) than astrocytes. Oligodendrocytes line up along the thicker neuron fibers in the CNS and wrap their processes tightly around the fibers, producing insulating coverings called *myelin sheaths* (Figure 11.3d).

Neuroglia in the PNS

The two kinds of PNS neuroglia—*satellite cells* and *Schwann cells*—differ mainly in location. **Satellite cells** surround neuron cell bodies located in the peripheral nervous system (Figure 11.3e), but their function is still largely unknown. Their name comes from a fancied resemblance to the moons (satellites) around a planet.

Schwann cells (also called *neurolemmocytes*) surround and form myelin sheaths around the larger nerve fibers in the peripheral nervous system (Figures 11.3e and 11.4b). Hence, they are functionally similar to oligodendrocytes. (The formation of myelin sheaths is described later in this chapter.) Schwann cells are vital to regeneration of damaged peripheral nerve fibers.

Neurons

The billions of **neurons,** also called **nerve cells,** are the structural units of the nervous system. They are highly specialized cells that conduct messages in the form of nerve impulses from one part of the body to another. Besides their ability to conduct nerve impulses, neurons have some other special characteristics:

1. They have *extreme longevity*. Given good nutrition, neurons can function optimally for a lifetime (over 100 years).
2. They are *amitotic*. As neurons assume their roles as communicating links of the nervous system, they lose their ability to divide. We pay a high price for this neuron feature because they cannot be replaced if destroyed. There *are* exceptions to this rule. For example, olfactory epithelium and some hippocampal regions contain stem cells that can produce new neurons throughout life. (The hippocampus is a brain region involved in memory.)
3. They have an exceptionally *high metabolic rate* and require continuous and abundant supplies of oxygen and glucose. Neurons cannot survive for more than a few minutes without oxygen.

Neurons are typically large, complex cells. Although they vary in structure, they all have a *cell body* from which one or more slender *processes* project (Figure 11.4). The plasma membrane of neurons is the site of electrical signaling, and it plays a crucial role in cell-to-cell interactions that occur during development.

Cell Body

The **neuron cell body** consists of a transparent, spherical nucleus with a conspicuous nucleolus surrounded by cytoplasm. Also called the **perikaryon** (*peri* = around, *kary* = nucleus) or **soma,** the cell body ranges in diameter from 5 to 140 μm. The cell body is the major *biosynthetic center* of a neuron. Except for centrioles, it contains the usual organelles. (Centrioles play an important role in forming the mitotic spindle. Their apparent absence reflects the amitotic nature of most neurons.)

The neuron cell body's protein- and membrane-making machinery, consisting of clustered free ribosomes and rough endoplasmic reticulum (ER), is probably the most active and best developed in the body. This rough ER, referred to as **Nissl bodies** (nis'l) or **chromatophilic substance** (*chromatophilic* = "color loving"), stains darkly with basic dyes. The Golgi apparatus is also well developed and forms an arc or a complete circle around the nucleus. Mitochondria are scattered among the other organelles. Microtubules and **neurofibrils,** bundles of intermediate filaments *(neurofilaments)*, which are important in maintaining cell shape and integrity, form a network throughout the cell body. The cell body of some neurons also contains pigment inclusions. For example, some contain a black melanin, a red iron-containing pigment, or a golden-brown pigment

Q Neurons with the longest axons tend to have large cell bodies, while those with short axons usually have small cell bodies. Can you think of an explanation for this relationship?

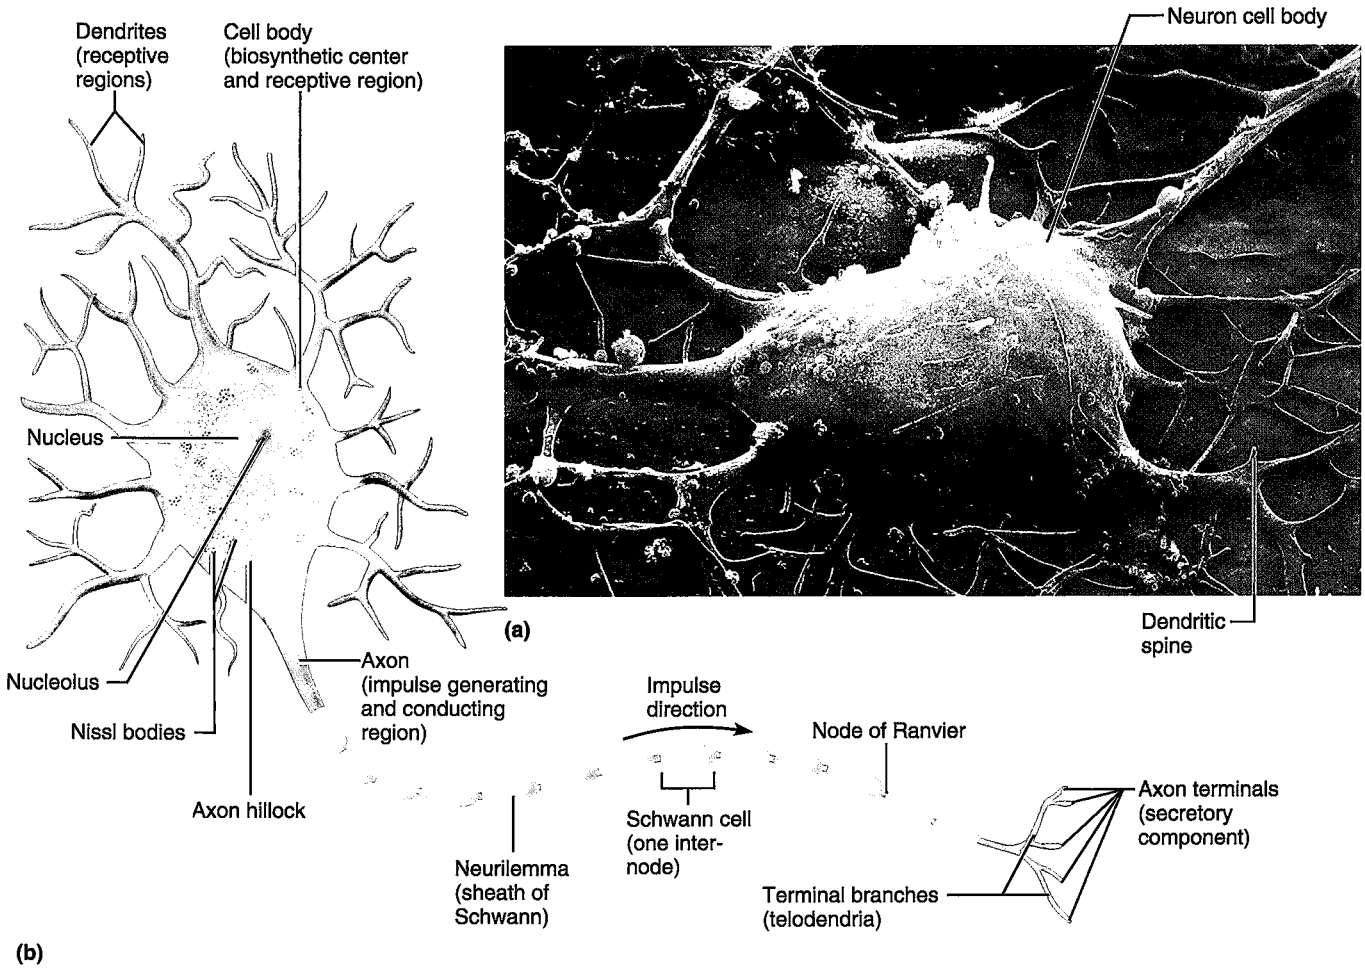

FIGURE 11.4 **Structure of a motor neuron. (a)** Scanning electron micrograph showing the cell body and dendrites with obvious dendritic spines (6000×). **(b)** Diagrammatic view.

called *lipofuscin* (lip"o-fu'sin). Lipofuscin, a harmless by-product of lysosomal activity, is sometimes called the "aging pigment" because it accumulates in neurons of elderly individuals.

The cell body is the focal point for the outgrowth of neuron processes during embryonic development. In most neurons, the plasma membrane of the cell body also acts as *part of the receptive region* (Table 11.1, pp. 396–397) that receives information from other neurons.

Most neuron cell bodies are located in the CNS, where they are protected by the bones of the skull and vertebral column. Clusters of cell bodies in the CNS are called **nuclei,** whereas those that lie along the nerves in the PNS are called **ganglia** (gang'gle-ah; *ganglion* = "knot on a string," "swelling").

Processes

Armlike **processes** extend from the cell body of all neurons. The brain and spinal cord (CNS) contain both neuron cell bodies and their processes. The PNS, for the most part, consists chiefly of neuron processes. Bundles of neuron processes are called **tracts** in the CNS and **nerves** in the PNS.

The two types of neuron processes, *dendrites* and *axons* (ak'sonz), differ from each other in the structure and function of their plasma membranes. The convention is to describe these processes using

A longer axon requires more supporting "machinery" in the cell body to service it.

a motor neuron as an example of a typical neuron. We shall follow this practice, but keep in mind that many sensory neurons and some tiny CNS neurons differ from the "typical" pattern we present here.

Dendrites **Dendrites** of motor neurons are short, tapering, diffusely branching extensions. Typically, motor neurons have hundreds of twiglike dendrites clustering close to the cell body. Virtually all organelles present in the cell body also occur in dendrites. Dendrites are the main **receptive** or **input regions** (see Table 11.1). They provide an enormous surface area for receiving signals from other neurons. In many brain areas, the finer dendrites are highly specialized for information collection. They bristle with thorny appendages having bulbous or spiky ends called *dendritic spines* (Figure 11.4a), which represent points of close contact (synapses) with other neurons. Dendrites convey incoming messages *toward* the cell body. These electrical signals are usually *not* action potentials (nerve impulses) but are short-distance signals called *graded potentials*, as described shortly.

The Axon Each neuron has a single **axon** (*axo* = axis, axle). The initial region of the axon arises from a cone-shaped area of the cell body called the **axon hillock** ("little hill") and then narrows to form a slender process that is uniform in diameter for the rest of its length (Figure 11.4). In some neurons, the axon is very short or absent; in others it is long and accounts for nearly the entire length of the neuron. For example, axons of the motor neurons controlling the skeletal muscles of your great toe extend from the lumbar region of your spine to your foot, a distance of a meter or more (3–4 feet), making them among the longest cells in the body. Any long axon is called a **nerve fiber.**

Each neuron has only one axon, but axons may have occasional branches along their length. These branches, called **axon collaterals,** extend from the axon at more or less right angles. Whether an axon is undivided or has collaterals, it usually branches profusely at its end (terminus): 10,000 or more **terminal branches,** or **telodendria,** per neuron is not unusual. The knoblike distal endings of the terminal branches are variously called **axon terminals, synaptic knobs,** or **boutons** (boo-tonz; "buttons"). Take your pick!

Functionally, the axon is the **conducting region** of the neuron (Table 11.1). It *generates nerve impulses* and *transmits them*, typically away from the cell body. In motor neurons, the nerve impulse is generated at the junction of the axon hillock and axon (which is therefore called the *trigger zone*) and conducted along the axon to the axon terminals, which are the **secretory region** of the neuron. When the impulse reaches the axon terminals, it causes *neurotransmitters*, signaling chemicals stored in vesicles there, to be released into the extracellular space. The neurotransmitters either excite or inhibit neurons (or effector cells) with which the axon is in close contact. Because each neuron both receives signals from and sends signals to scores of other neurons, it carries on "conversations" with many different neurons at the same time.

An axon contains the same organelles found in the dendrites and cell body with two important exceptions—it lacks Nissl bodies and a Golgi apparatus, the structures involved with protein synthesis and packaging. Consequently, an axon depends (1) on its cell body to renew the necessary proteins and membrane components, and (2) on efficient transport mechanisms to distribute them. Axons quickly decay if cut or severely damaged.

Because axons are often very long, moving molecules along their length might appear to be a problem. However, through the cooperative effort of several types of cytoskeletal elements (microtubules, actin filaments, and so on), substances travel continuously along the axon both away from and toward the cell body. Movement toward the axon terminals is *anterograde movement*, and that in the opposite direction is *retrograde movement*.

Substances moved in the anterograde direction include mitochondria, cytoskeletal elements, membrane components used to renew the axon plasma membrane, or **axolemma** (ak"so-lem'ah), and enzymes needed for synthesis of certain neurotransmitters. (Some neurotransmitters are synthesized in the cell body and then transported to the axon terminals.)

Substances transported through the axon in the retrograde direction are mostly organelles being returned to the cell body for degradation or recycling. Retrograde transport is also an important means of intracellular communication for "advising" the cell body of conditions at the axon terminals, and for delivering to the cell body vesicles containing signal molecules (like nerve growth factor, which activates certain nuclear genes promoting growth).

A single bidirectional transport mechanism appears to be responsible for axonal transport. It uses ATP-dependent "motor" proteins such as kinesin, dynein, and myosin. These proteins propel cellular components along the microtubules like trains along tracks at speeds up to 40 cm (15 inches) per day.

HOMEOSTATIC IMBALANCE

Certain viruses and bacterial toxins that damage neural tissues use retrograde axonal transport to reach the cell body. This transport mechanism has

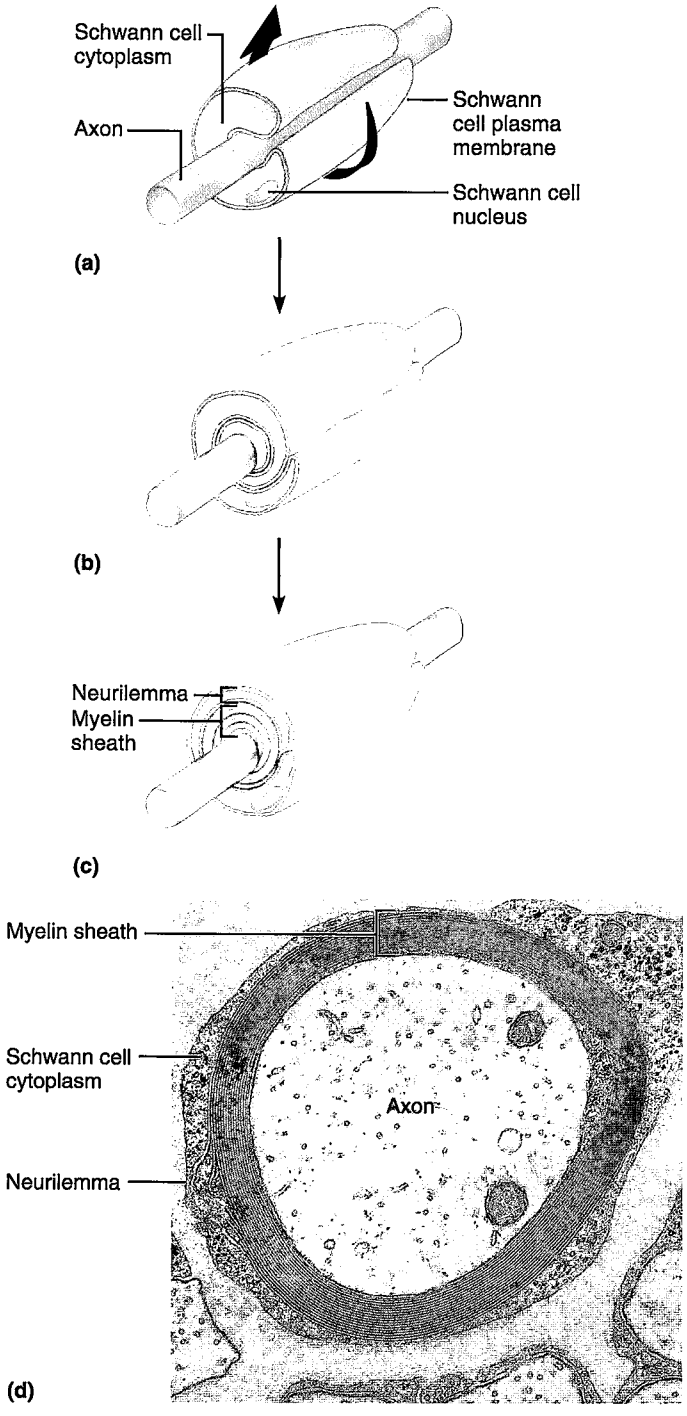

FIGURE 11.5 **Relationship of Schwann cells to axons in the PNS. (a–c)** Myelination of a nerve fiber (axon). As illustrated, a Schwann cell envelops an axon in a trough. It then rotates around the axon, enveloping the axon loosely in successive layers of its plasma membrane. Eventually, the Schwann cell cytoplasm is forced from between the membranes and comes to lie peripherally just beneath the exposed portion of the Schwann cell plasma membrane. The tight membrane wrappings surrounding the axon form the myelin sheath; the area of Schwann cell cytoplasm and its exposed membrane is referred to as the neurilemma. **(d)** Electron micrograph of a myelinated axon, cross-sectional view (20,000×).

been demonstrated for polio, rabies, and herpes simplex viruses and for tetanus toxin. Its use as a tool to treat genetic diseases by introducing viruses containing "corrected" genes is under investigation. ●

Myelin Sheath and Neurilemma Many nerve fibers, particularly those that are long or large in diameter, are covered with a whitish, fatty (protein-lipoid), segmented **myelin sheath** (mi'ĕ-lin). Myelin protects and electrically insulates fibers, and it increases the speed of transmission of nerve impulses. **Myelinated fibers** (axons bearing a myelin sheath) conduct nerve impulses rapidly, whereas **unmyelinated fibers** conduct impulses quite slowly. Note that myelin sheaths are associated only with axons. Dendrites are *always* unmyelinated.

Myelin sheaths in the PNS are formed by Schwann cells, which indent to receive an axon and then wrap themselves around it in a jelly roll fashion (Figure 11.5). Initially the wrapping is loose, but the Schwann cell cytoplasm is gradually squeezed from between the membrane layers. When the wrapping process is complete, many concentric layers of Schwann cell plasma membrane enclose the axon, much like gauze wrapped around an injured finger. This tight coil of wrapped membranes is the myelin sheath, and its thickness depends on the number of spirals. Plasma membranes of myelinating cells contain much less protein than the plasma membranes of most body cells. Channel and carrier proteins are notably absent, a characteristic that makes myelin sheaths exceptionally good electrical insulators. Another unique characteristic of these membranes is the presence of specific protein molecules that interlock to form a sort of molecular Velcro between adjacent myelin membranes.

The nucleus and most of the cytoplasm of the Schwann cell end up as a bulge just external to the myelin sheath. This portion of the Schwann cell, which includes the exposed part of its plasma membrane, is called the **neurilemma** ("neuron husk"). Adjacent Schwann cells along an axon do not touch one another, so there are gaps in the sheath. These gaps, called **nodes of Ranvier** (ran'vē-ā") or **neurofibril nodes,** occur at regular intervals (about 1 mm apart) along the myelinated axon. It is at these nodes that axon collaterals can emerge from the axon.

Sometimes Schwann cells surround peripheral nerve fibers but the coiling process does not occur. In such instances, a single Schwann cell can partially enclose 15 or more axons, each of which occupies a separate recess in the Schwann cell surface. Nerve fibers associated with Schwann cells in this manner are said to be *unmyelinated* and are typically thin fibers.

Both myelinated and unmyelinated axons are also found in the central nervous system. However, it is oligodendrocytes that form CNS myelin sheaths (Figure 11.3d). In contrast to Schwann cells, each of which forms only one segment (internode) of a myelin sheath, oligodendrocytes have multiple flat processes that can coil around as many as 60 axons at the same time. Nodes of Ranvier are present, but are more widely spaced than in the PNS. CNS myelin sheaths lack a neurilemma because cell extensions are doing the coiling and the squeezed-out cytoplasm is forced not peripherally but back toward the centrally located nucleus. As in the PNS, the smallest-diameter axons are unmyelinated. These unmyelinated axons are covered by the long extensions of adjacent glial cells.

Regions of the brain and spinal cord containing dense collections of myelinated fibers are referred to as **white matter** and are primarily fiber tracts. **Gray matter** contains mostly nerve cell bodies and unmyelinated fibers.

Classification of Neurons

Neurons are classified both structurally and functionally. We describe both classifications here but use the functional classification in most discussions.

Structural Classification Neurons are grouped structurally according to the number of processes extending from their cell body. Three major neuron groups make up this classification: multipolar (*polar* = end, pole), bipolar, and unipolar neurons (Table 11.1).

Multipolar neurons have three or more processes. They are the most common neuron type in humans (more than 99% of neurons belong to this class) and the major neuron type in the CNS.

Bipolar neurons have two processes—an axon and a dendrite—that extend from opposite sides of the cell body. These rare neurons are found in some of the special sense organs. Examples include some neurons in the retina of the eye and in the olfactory mucosa.

Unipolar neurons have a single short process that emerges from the cell body and divides T-like into proximal and distal branches. The more distal process, which is often associated with a sensory receptor, is the **peripheral process,** whereas that entering the CNS is the **central process** (Table 11.1). Unipolar neurons are more accurately called **pseudounipolar neurons** (*pseudo* = false) because they originate as bipolar neurons. Then, during early embryonic development, the two processes converge and partially fuse to form the short single process that issues from the cell body. Unipolar neurons are found chiefly in ganglia in the PNS, where they function as sensory neurons.

The fact that the fused peripheral and central processes of unipolar neurons are continuous and function as a single fiber might make you wonder whether they are axons or dendrites. The central process is definitely an axon because it conducts impulses away from the cell body (one definition of axon). However, the peripheral process is perplexing. Three facts favor classifying it as an axon: (1) it generates and conducts an impulse (functional definition of axon); (2) when large, it is heavily myelinated; and (3) it has a uniform diameter and is indistinguishable microscopically from an axon. However, the older definition of a dendrite as a process that transmits impulses *toward* the cell body interferes with that conclusion. So which is it? In this book, we have chosen to emphasize the newer definition of an axon as generating and transmitting an impulse. Hence, *for unipolar neurons*, we will refer to the combined length of the peripheral and central process as an axon. In place of "dendrites," unipolar neurons have *receptive endings* (sensory terminals) at the end of the peripheral process.

Functional Classification This scheme groups neurons according to the direction in which the nerve impulse travels relative to the central nervous system. Based on this criterion, there are sensory neurons, motor neurons, and interneurons (Table 11.1).

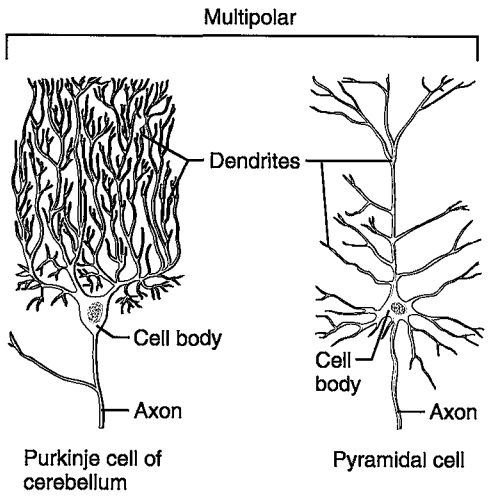
Sensory, or **afferent, neurons** transmit impulses from sensory receptors in the skin or internal organs *toward* or *into* the central nervous system. Except for certain neurons found in some special sense organs, virtually all sensory neurons are unipolar, and their cell bodies are located in sensory ganglia *outside* the CNS. Only the most distal parts of these unipolar neurons act as impulse receptor sites, and the peripheral processes are often very long. For example, fibers carrying sensory impulses from the skin of your great toe travel for more than a meter before they reach their cell bodies in a ganglion close to the spinal cord.

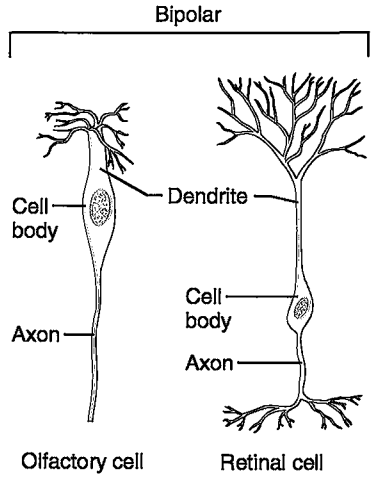
Although the receptive endings of some sensory neurons are naked, in which case those terminals themselves function as sensory receptors, many bear receptors that include other cell types. The various types of general sensory receptor end organs, such as those of the skin, are described in Chapter 13. The special sensory receptors (of the ear, eye, etc.) are the topic of Chapter 15.

Motor, or **efferent, neurons** carry impulses *away from* the CNS to the effector organs (muscles and glands) of the body periphery. Motor neurons are multipolar, and except for some neurons of the autonomic nervous system, their cell bodies are located in the CNS.

Interneurons, or **association neurons,** lie between motor and sensory neurons in neural

TABLE 11.1 Comparison of Structural Classes of Neurons

	NEURON TYPE		
	MULTIPOLAR	**BIPOLAR**	**UNIPOLAR (PSEUDOUNIPOLAR)**
STRUCTURAL CLASS: NEURON TYPE ACCORDING TO THE NUMBER OF PROCESSES EXTENDING FROM THE CELL BODY			
	Many processes extend from the cell body; all are dendrites except for a single axon.	Two processes extend from the cell body: one is a fused dendrite, the other is an axon.	One process extends from the cell body and forms central and peripheral processes, which together comprise an axon.
			RELATIONSHIP OF ANATOMY TO THE THREE FUNCTIONAL REGIONS			
	☐ = Receptive region (receives stimulus). Plasma membrane exhibits chemically gated ion channels.	☐ = Conducting region (generates/transmits action potential). Plasma membrane exhibits voltage-gated Na^+ and K^+ channels.	☐ = Secretory region (axon terminals release neurotransmitters). Plasma membrane exhibits voltage-gated Ca^+ channels.
					(Many bipolar neurons do not generate action potentials and, in those that do, the location of the trigger zone is not universal.)	
RELATIVE ABUNDANCE AND LOCATION IN HUMAN BODY			
	Most abundant in body. Major neuron type in the CNS.	Rare. Found in some special sensory organs (olfactory mucosa, eye, ear).	Found mainly in the PNS. Common only in dorsal root ganglia of the spinal cord and sensory ganglia of cranial nerves.
STRUCTURAL VARIATIONS			
			




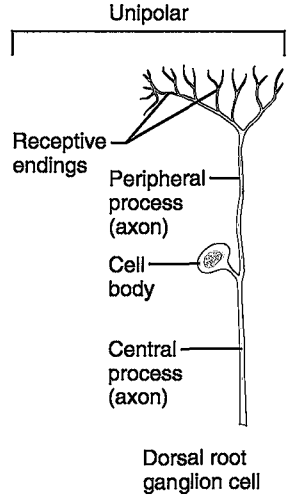


TABLE 11.1 (continued)

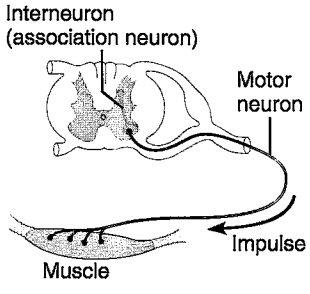
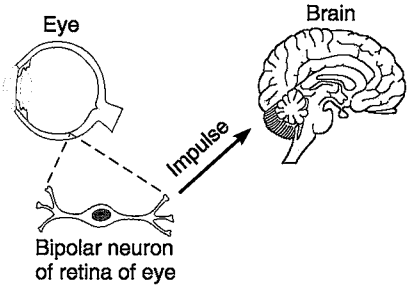
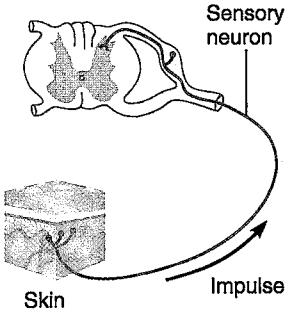
NEURON TYPE		
MULTIPOLAR	**BIPOLAR**	**UNIPOLAR (PSEUDOUNIPOLAR)**
FUNCTIONAL CLASS: NEURON TYPE ACCORDING TO DIRECTION OF IMPULSE CONDUCTION		
1. Most multipolar neurons are **interneurons (association neurons)** that conduct impulses within the CNS, integrating sensory input or motor output; may be one of a chain of CNS neurons, or a single neuron connecting sensory and motor neurons. **2.** Some multipolar neurons are **motor neurons** that conduct impulses along the efferent pathways from the CNS to an effector (muscle/gland).	Essentially all bipolar neurons are **sensory neurons** that are located in some special sense organs. For example, bipolar cells of the retina are involved with the transmission of visual inputs from the eye to the brain (via an intermediate chain of neurons).	Most unipolar neurons are **sensory neurons** that conduct impulses along afferent pathways to the CNS for interpretation. (These sensory neurons are called primary or first-order sensory neurons.)
		






pathways and shuttle signals through CNS pathways where integration occurs. Most interneurons are confined within the CNS. They make up over 99% of the neurons of the body, including most of those in the CNS. Almost all interneurons are multipolar, but there is considerable diversity in both size and fiber-branching patterns. The Purkinje and pyramidal cells illustrated as structural variations in Table 11.1 are just two examples of their variety.

Neurophysiology

Neurons are highly *irritable* (responsive to stimuli). When a neuron is adequately stimulated, an electrical impulse is generated and conducted along the length of its axon. This response, called the *action potential (nerve impulse)*, is always the same, regardless of the source or type of stimulus, and it underlies virtually all functional activities of the nervous system.

In this section, we will consider how neurons become excited or inhibited and how they communicate with other cells. First, however, we need to explore some basic principles of electricity and revisit the resting membrane potential.

Basic Principles of Electricity

The human body is electrically neutral; it has the same number of positive and negative charges. However, there are areas where one type of charge predominates, making such regions positively or negatively charged. Because opposite charges attract each other, energy must be used (work must be done) to separate them. On the other hand, the coming together of opposite charges liberates energy that can be used to do work. Thus, situations in which there are separated electrical charges of opposite sign have potential energy.

Some Definitions: Voltage, Resistance, Current

The measure of potential energy generated by separated charge is called **voltage** and is measured in either *volts* or *millivolts* (1 mV = 0.001 V). Voltage is always measured between two points and is called the **potential difference** or simply the **potential** between the points. The greater the difference in charge between two points, the higher the voltage.

The flow of electrical charge from one point to another is called a **current,** and it can be used to do

work—for example, to power a flashlight. The amount of charge that moves between the two points depends on two factors: voltage and resistance. **Resistance** is the hindrance to charge flow provided by substances through which the current must pass. Substances with high electrical resistance are called *insulators;* those with low resistance are called *conductors*.

The relationship between voltage, current, and resistance is given by **Ohm's law:**

$$\text{Current } (I) = \frac{\text{voltage } (V)}{\text{resistance } (R)}$$

which tells us that current (I) is directly proportional to voltage: The greater the voltage (potential difference), the greater the current. This relationship also tells us there is no net current flow between points that have the same potential, as you can see by inserting a value of 0 V into the equation. A third thing Ohm's law tells us is that current is inversely related to resistance: The greater the resistance, the smaller the current.

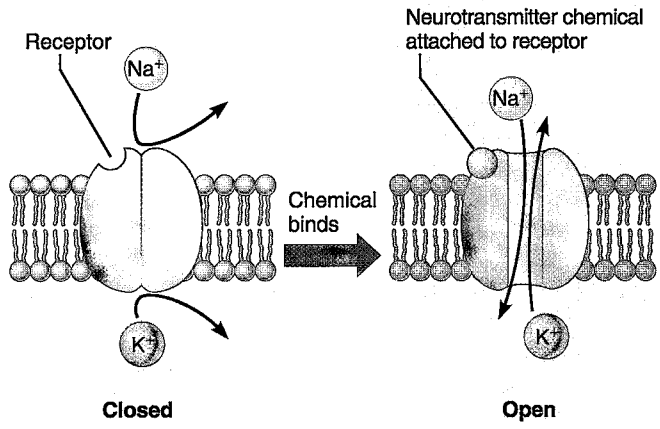
In the body, electrical currents reflect the flow of ions (rather than free electrons) across cellular membranes. (Unlike the electrons flowing along your house wiring, there are no free electrons "running around" in a living system.) As described in Chapter 3, there is a slight difference in the numbers of positive and negative ions on the two sides of cellular plasma membranes (there is a charge separation), so there is a potential across those membranes. The resistance to current flow is provided by the plasma membranes.

Role of Membrane Ion Channels

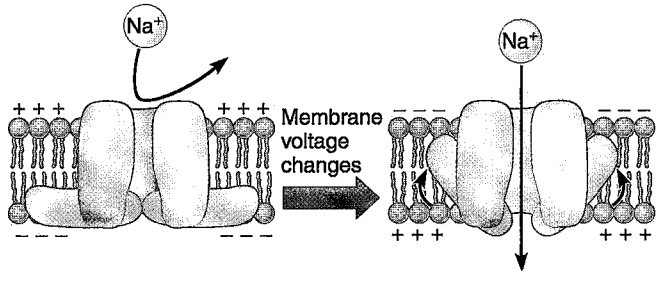
Plasma membranes are peppered with a variety of membrane proteins that act as *ion channels*. These channels are large proteins, often with several subunits, whose amino acid chains snake back and forth across the membrane. In many channels, part of the protein forms a molecular "gate" that changes shape to open and close the channel in response to specific signals. These are called *gated* channels (Figure 11.6). **Chemically gated,** or **ligand-gated, channels** open when the appropriate chemical (in this case a neurotransmitter) binds. **Voltage-gated channels** open and close in response to changes in the membrane potential. **Mechanically gated channels** open in response to physical deformation of the receptor (seen in sensory receptors for touch and pressure)—more on this later. Other channels, **leakage** or **nongated channels,** do not respond to these signals and are always open. Each type of channel is selective as to the type of ion (or ions) it allows to pass. For example, a potassium ion channel allows only potassium ions to pass.

When gated ion channels are open, ions diffuse quickly across the membrane following their electrochemical gradients, creating electrical currents and

Q *For an open channel, what factors determine in which direction ions will flow through that channel?*



(a) Chemically gated ion channel



(b) Voltage-gated ion channel

FIGURE 11.6 **Operation of gated channels.** **(a)** Chemically (ligand) gated channels (a Na^+-K^+ channel in this example) open when the appropriate neurotransmitter binds to the receptor, allowing simultaneous movement of Na^+ and K^+ through the channel. **(b)** Voltage-gated channels open or close in response to changes in membrane voltage. In this example, a Na^+ channel opens as the membrane interior changes from negative to positive.

voltage changes across the membrane according to the rearranged Ohm's law equation:

$$\text{Voltage } (V) = \text{current } (I) \times \text{resistance } (R)$$

Ions move along chemical *concentration gradients* when they diffuse passively from an area of their higher concentration to an area of lower concentration,

A *The concentration gradient and the electrical gradient—together called the electrochemical gradient.*

and along *electrical gradients* when they move toward an area of opposite electrical charge. Together, electrical and concentration gradients constitute the **electrochemical gradient.** It is ion flows along electrochemical gradients that underlie all electrical phenomena in neurons.

The Resting Membrane Potential

The potential difference between two points is measured with a voltmeter (Figure 11.7). When one microelectrode of the voltmeter is inserted into the neuron and the other is in the extracellular fluid, a voltage across the membrane of approximately −70 mV is recorded. The minus sign indicates that the cytoplasmic side (inside) of the membrane is negatively charged relative to the outside. This potential difference in a resting neuron (V_r) is called the **resting membrane potential,** and the membrane is said to be **polarized.** The value of the resting membrane potential varies (from −40 mV to −90 mV) in different types of neurons.

The resting potential exists only across the membrane; that is, the bulk solutions inside and outside the cell are electrically neutral. As shown in Figure 11.8, the resting membrane potential is generated by differences in the ionic makeup of the intracellular and extracellular fluids and the differential permeability of the plasma membrane to those ions. The cell cytosol contains a lower concentration of Na^+ and a higher concentration of K^+ than the extracellular fluid. In the extracellular fluid, the positive charges of sodium and other cations are balanced chiefly by chloride ions (Cl^-). Negatively charged (anionic) proteins (A^-) help to balance the positive charges of intracellular cations (primarily K^+). Although there are many other solutes (glucose, urea, and other ions) in both fluids, potassium plays the most important role in generating the membrane potential.

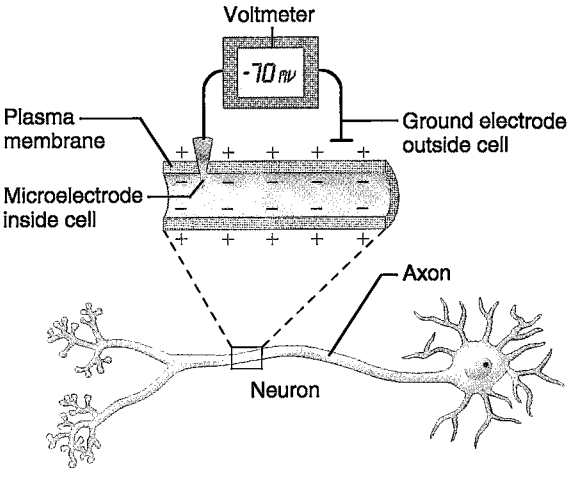


FIGURE 11.7 **Measuring membrane potential in neurons.** The potential across the membrane of a neuron (membrane potential) can be recorded by inserting an electrode inside a neuron. The potential difference between this electrode and the ground electrode outside the cell is approximately −70 mV (inside negative).

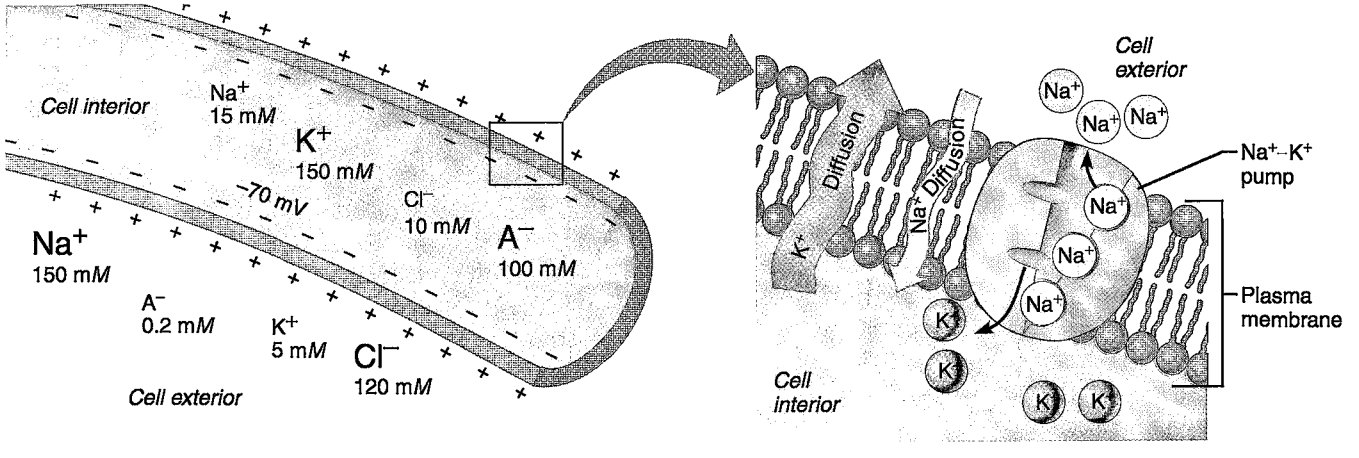

FIGURE 11.8 **The basis of the resting membrane potential.** Approximate concentrations of major ions in mammalian cells are indicated in millimoles per liter (mM). Steady diffusion of K^+ to the cell exterior through leakage channels is strongly promoted by its concentration gradient. Na^+ is strongly attracted to the cell interior by its concentration gradient, but it is far less able to cross the cell membrane because of the near lack of Na^+ leakage channels. The relative membrane permeability to Na^+ and K^+ through such leakage channels is indicated by diffusion arrows of different thickness. The resulting net outward diffusion of positive charge (K^+) leads to a state of relative negativity on the inner membrane face. This membrane potential (−70 mV, inside negative) is maintained indirectly by the sodium-potassium pump, which transports three Na^+ out of the cell for each two K^+ transported back into the cell. The electrochemical gradient thus maintained resists K^+ efflux but enhances the drive for Na^+ influx.

Q Hyper *means greater than or more than. When we say the membrane becomes hyperpolarized, what value has increased or become greater?*

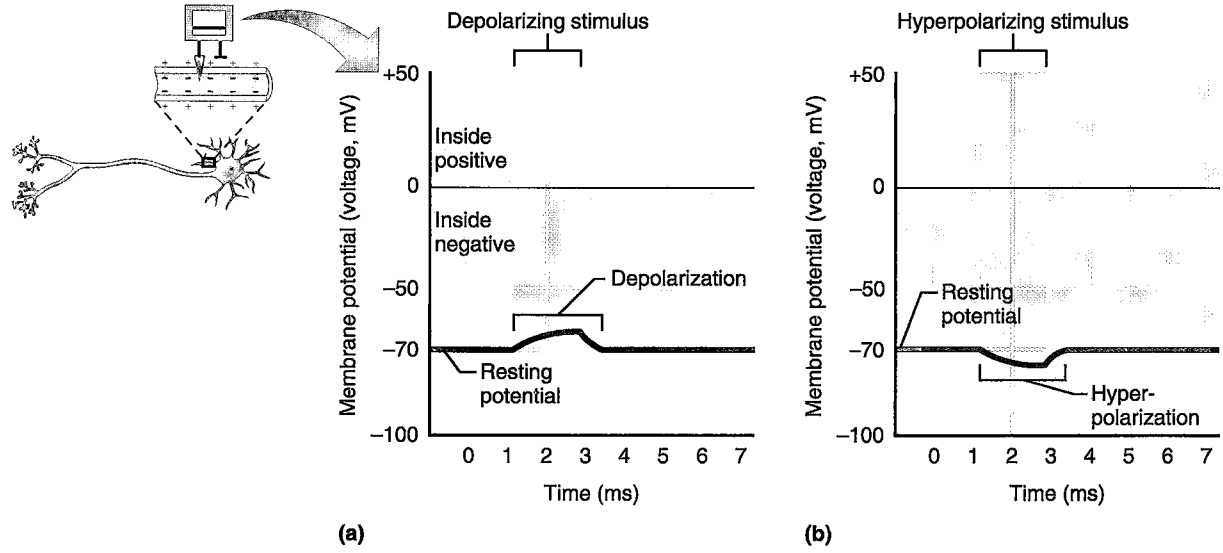

FIGURE 11.9 **Depolarization and hyperpolarization of the membrane.** The resting membrane potential is approximately −70 mV (inside negative) in neurons. Changes in this potential are called depolarization or hyperpolarization of the membrane. **(a)** In depolarization, the membrane potential moves toward 0 mV, the inside becoming less negative (more positive). **(b)** In hyperpolarization, the membrane potential increases, the inside becoming more negative.

11

At rest the membrane is impermeable to the large anionic cytoplasmic proteins, very slightly permeable to sodium, approximately 75 times more permeable to potassium than to sodium, and quite freely permeable to chloride ions. These resting permeabilities reflect the properties of the leakage ion channels in the membrane. Potassium ions diffuse out of the cell along their *concentration gradient* much more easily than sodium ions can enter the cell along theirs. K^+ flowing out of the cell causes the cell to become more negative inside. Na^+ trickling into the cell makes the cell just slightly more positive than it would be if only K^+ flowed. Therefore, at resting membrane potential, the negative interior of the cell is due to much greater diffusion of K^+ out of the cell than Na^+ diffusion into the cell.

Because some K^+ is always leaking out of the cell and some Na^+ is always leaking in, you might think that the concentration gradients would eventually "run down," resulting in equal concentrations of Na^+ and K^+ inside and outside the cell. This does not happen, because the ATP-driven sodium-potassium pump first ejects three Na^+ from the cell and then transports two K^+ back into the cell. Thus, the sodium-potassium pump stabilizes the resting membrane potential by maintaining the concentration gradients for sodium and potassium.

A *The negativity of the internal membrane surface.*

Membrane Potentials That Act as Signals

Neurons use changes in their membrane potential as communication signals for receiving, integrating, and sending information. A change in membrane potential can be produced by (1) anything that changes membrane permeability to any ion or (2) anything that alters ion concentrations on the two sides of the membrane. However, only permeability changes are important for information transfer. Two types of signals are produced by a change in membrane potential: *graded potentials*, which are usually incoming signals operating over short distances, and *action potentials*, which are long-distance signals of axons.

The terms *depolarization* and *hyperpolarization* are used in the following sections to describe membrane potential changes *relative to resting membrane potential*, so it is important to understand these terms clearly. **Depolarization** is a reduction in membrane potential: The inside of the membrane becomes *less negative* (moves closer to zero) than the resting potential (Figure 11.9a). For instance, a

change in resting potential from −70 mV to −65 mV is a depolarization. By convention, depolarization also includes events in which the membrane potential reverses and moves above zero to become positive.

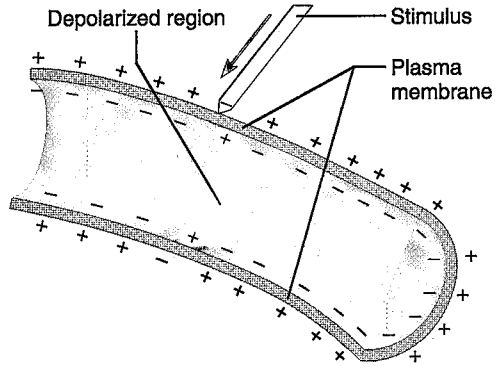
Hyperpolarization occurs when the membrane potential increases, becoming *more negative* than the resting potential. For example, a change from −70 mV to −75 mV is hyperpolarization (Figure 11.9b). As described shortly, depolarization increases the probability of producing nerve impulses, whereas hyperpolarization reduces this probability.

Graded Potentials

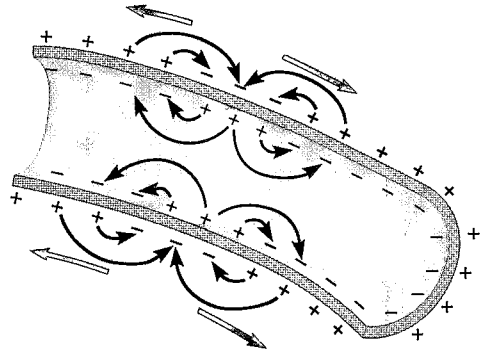
Graded potentials are short-lived, localized changes in membrane potential that can be either depolarizations or hyperpolarizations. These changes cause current flows that decrease in magnitude with distance. Graded potentials are called "graded" because their magnitude varies directly with stimulus strength. The stronger the stimulus, the more the voltage changes and the farther the current flows.

Graded potentials are triggered by some change (a stimulus) in the neuron's environment that causes gated ion channels to open. Graded potentials are given different names, depending on where they occur and the functions they perform. When the receptor of a sensory neuron is excited by some form of energy (heat, light, or other), the resulting graded potential is called a *receptor potential* or *generator potential*. These types of graded potentials are considered in Chapter 13. When the stimulus is a neurotransmitter released by another neuron, the graded potential is called a *postsynaptic potential*, because the neurotransmitter is released into a fluid-filled gap called a synapse and influences the neuron beyond (post) the synapse.

Fluids inside and outside cells are fairly good conductors, and current, carried by ions, flows through these fluids whenever voltage changes occur. Let us assume that a small area of a neuron's plasma membrane has been depolarized by a stimulus (Figure 11.10a). Current will flow on both sides of the membrane between the depolarized (active) membrane area and the adjacent polarized (resting) areas. Positive ions migrate toward more negative areas (the direction of cation movement is the direction of current flow), and negative ions simultaneously move toward more positive areas (Figure 11.10b). Thus, inside the cell, positive ions (mostly K^+) move away from the depolarized area and accumulate on the neighboring membrane areas, where they neutralize negative ions. Meanwhile, positive ions on the outer membrane face are moving toward the region of reversed membrane polarity (the depolarized region), which is momentarily less positive. As these positive ions move, their "places" on the membrane become occupied by negative ions (such as Cl^- and HCO_3^-), sort of like ionic



(a) Depolarization



(b) Spread of depolarization

FIGURE 11.10 **The mechanism of a graded potential.** **(a)** A small patch of the membrane has become depolarized, resulting in a change in polarity at that point. **(b)** As positive ions flow toward negative areas (and negative ions flow toward adjacent more positive areas), local currents are created that depolarize adjacent membrane areas and allow the wave of depolarization to spread.

musical chairs. Thus, at regions abutting the depolarized region, the inside becomes less negative and the outside becomes less positive; that is, the neighboring membrane is, in turn, depolarized.

To simplify the explanation, virtually all diagrams that illustrate local currents give the impression that the circuit is completed by ions passing into and out of the cell through the membrane. This is *not* the case. Only the inward current across the membrane is caused by the flow of ions through gated channels. The outward current, the so-called *capacitance current*, reflects changes in the charge distribution as the ions migrate *along* the two membrane faces as described above. The capacitance current reflects the fact that the fatty membrane interior is a poor conductor of current. That is, it is a *capacitor* (an insulating element surrounded by a conducting surface) that *temporarily* stores the charge, forcing the ions of opposite charge to

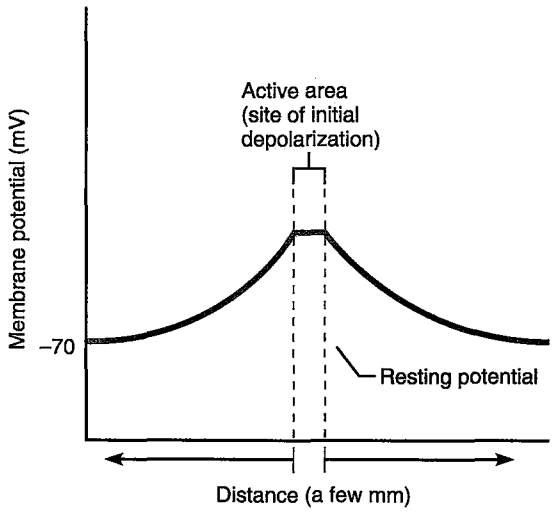


FIGURE 11.11 **Changes in membrane potential produced by a depolarizing graded potential.** Such voltage changes are decremental because the current is quickly dissipated by loss of ions through the "leaky" plasma membrane. Consequently, graded potentials are short-distance signals.

accumulate opposite one another on either side of the membrane.

As just explained, the flow of current to adjacent membrane areas changes the membrane potential there as well. However, the plasma membrane is permeable like a leaky water hose, and most of the charge is quickly lost through leakage channels. Consequently, the current is *decremental*; that is, it dies out within a few millimeters of its origin (Figure 11.11). Because the current dissipates quickly and dies out with increasing distance from the site of initial depolarization, graded potentials can act as signals only over very short distances. Nonetheless, they are essential in initiating action potentials, the long-distance signals.

Action Potentials

The principal way neurons send signals over long distances is by generating and propagating **action potentials (APs)**, and for the most part, only cells with *excitable membranes*—neurons and muscle cells—can generate action potentials. As illustrated in the graph in Figure 11.12, an action potential is a brief reversal of membrane potential with a total amplitude (change in voltage) of about 100 mV (from −70 mV to +30 mV). A depolarization phase is followed by a repolarization phase and often a short period of hyperpolarization. The whole event is over in a few milliseconds. Unlike graded potentials, action potentials do not decrease in strength with distance.

The events of action potential generation and transmission are identical in skeletal muscle cells and neurons. In a neuron, an AP is also called a **nerve impulse,** and is typically generated *only in axons*. A neuron transmits a nerve impulse only when it is adequately stimulated. The stimulus changes the permeability of the neuron's membrane by opening specific voltage-gated channels on the axon. These channels open and close in response to changes in the membrane potential and are activated by local currents (graded potentials) that spread toward the axon along the dendritic and cell body membranes. In many neurons, the transition from local graded potential to action potential takes place at the axon hillock. In sensory neurons, the action potential is generated by the peripheral (axonal) process just proximal to the receptor region. However, for simplicity, we will just use the term *axon* in our discussion.

Generation of an Action Potential Generating an action potential involves three consecutive but overlapping changes in membrane permeability resulting from the opening and closing of voltage-gated ion channels, all induced by depolarization of the axon membrane (Figure 11.12). These permeability changes are a transient increase in Na^+ permeability, followed by restoration of Na^+ impermeability, and then a short-lived increase in K^+ permeability. The first two permeability changes mark the beginning and the end of the *depolarization phase* of action potential generation, indicated by the upward-rising part of the AP curve or spike of Figure 11.12. The third permeability change is responsible for both the *repolarization* (the downward part of the AP spike) and *hyperpolarization phases* shown in the Figure 11.12 graph. Let's examine each of these phases more carefully, starting with a neuron in the resting (polarized) state.

① **Resting state: Voltage-gated channels closed.** Virtually all the voltage-gated Na^+ and K^+ channels are closed. Only the leakage channels are open, maintaining resting membrane potential.

Each Na^+ channel has two gates: a voltage-sensitive *activation gate* that is closed at rest and responds to depolarization by opening, and an *inactivation gate* that blocks the channel once it is open. Thus, *depolarization opens and then inactivates sodium channels*. Both gates must be open in order for Na^+ to enter, but the closing of *either* gate effectively closes the channel. By contrast, each active potassium channel has a single voltage-sensitive gate; it is closed in the resting state and opens slowly in response to depolarization.

② **Depolarizing phase: Increase in Na^+ permeability and reversal of membrane potential.** As the axon membrane is depolarized by local currents, the sodium channels open and Na^+ rushes into the cell. This influx of positive charge depolarizes that local

Q *The green line on the graph, representing K^+ permeability, starts to increase at about the peak of the action potential. Relative to channels, what does an increase in K^+ permeability mean?*

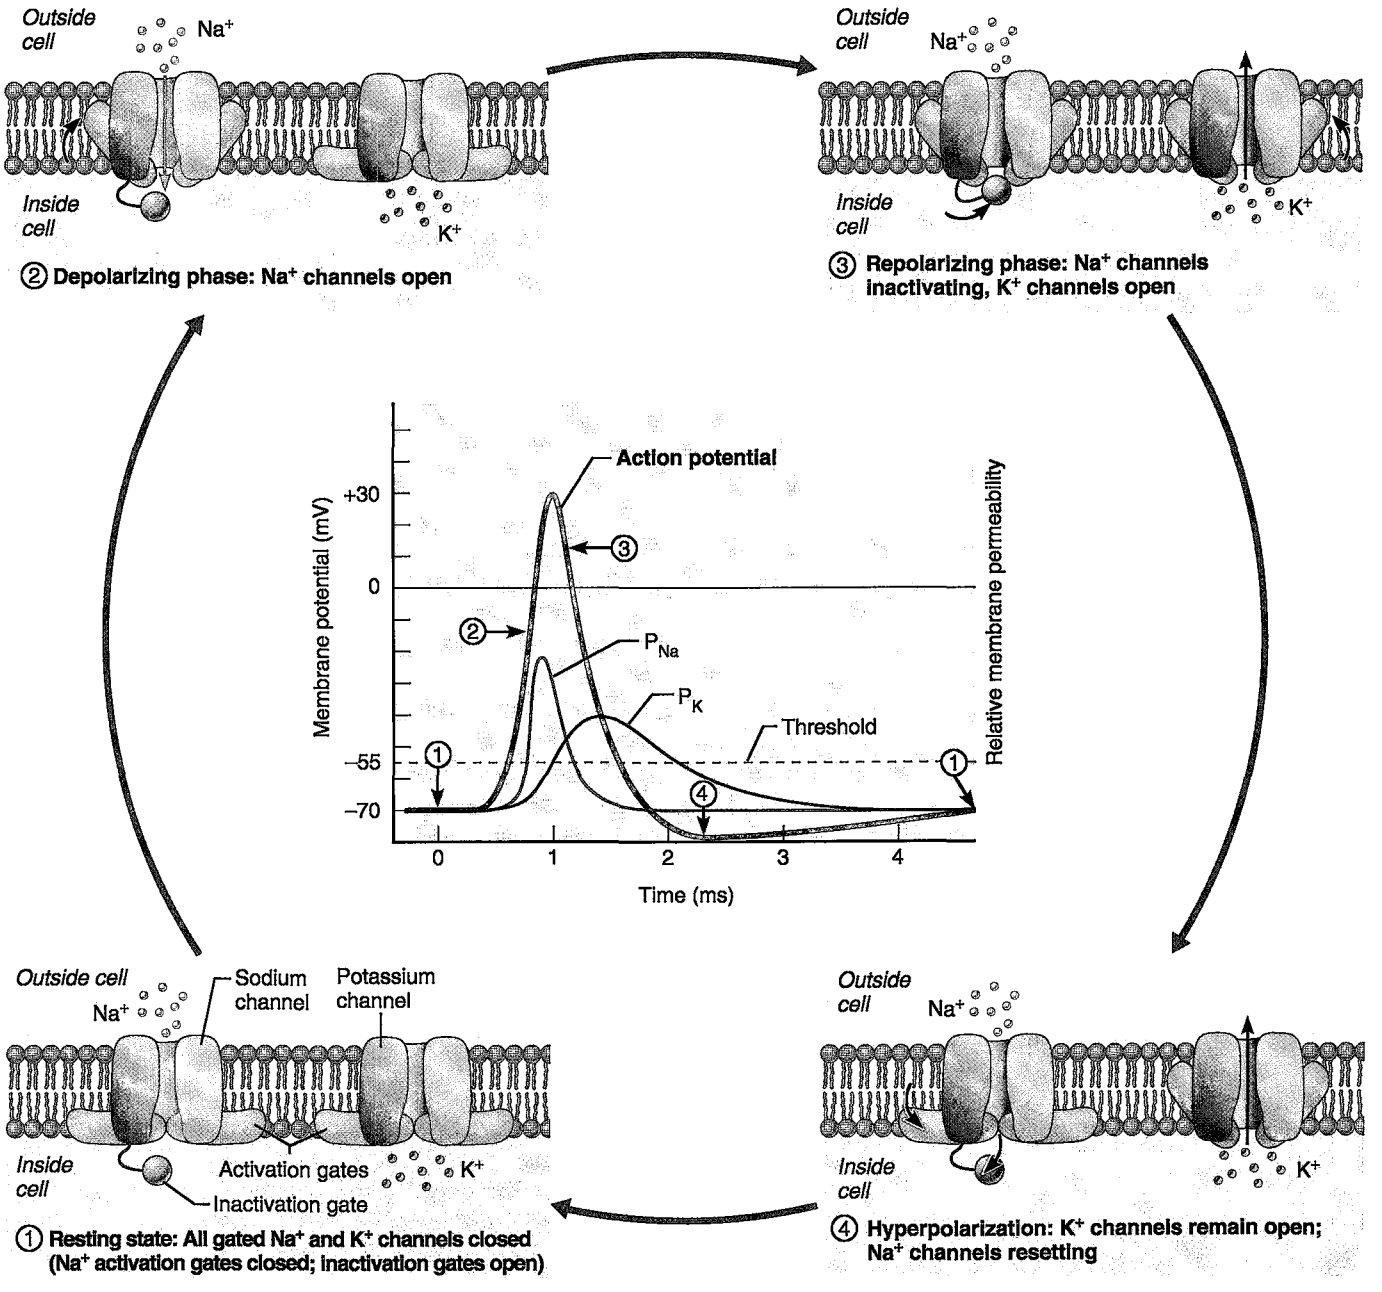

FIGURE 11.12 **Phases of the action potential and the role of voltage-gated ion channels.** The center graph shows the intracellular voltage during the action potential (red) together with the membrane permeability changes to Na^+ (P_{Na}, orange) and K^+ (P_K, green) which underlie the voltage changes during the action potential. The outer diagrams show the motion of the gates within the voltage-gated channels during the course of the action potential. In each case, the arrows show the gate movement just completed. ① Resting state: Neither channel is open. (Sodium inactivation gates are open, but activation gates are closed.) ② Depolarizing phase of the action potential: Sodium activation gates open, but potassium channels remain closed. ③ Repolarizing phase of the action potential: Sodium inactivation gates block the sodium channels, and potassium channels open. ④ Hyperpolarization: Potassium channels remain open temporarily because they have not had time to respond to repolarization. Sodium channels begin resetting, opening their inactivation gates and closing their activation gates. Within another millisecond or two, the resting state ① is restored, and the system is ready to respond to the next stimulus.

▲ *An increase in K^+ permeability means that K^+ channels have opened.*

"patch" of membrane further, opening more Na^+ channels so that the cell interior becomes progressively less negative. When depolarization at the stimulation site reaches a certain critical level called **threshold** (often between −55 and −50 mV), depolarization becomes self-generating, urged on by positive feedback. That is, after being initiated by the stimulus, depolarization is driven by the ionic currents created by Na^+ influx. As more Na^+ enters, the membrane depolarizes further and opens still more channels until all Na^+ channels are open. At this point, Na^+ permeability is about 1000 times greater than in a resting neuron. As a result, the membrane potential becomes less and less negative and then overshoots to about +30 mV as Na^+ rushes in along its electrochemical gradient. This rapid depolarization and polarity reversal produces the sharply upward *spike* of the action potential (see the Figure 11.12 graph).

Earlier, we stated that membrane potential depends on membrane permeability, but here we are saying that membrane permeability depends on membrane potential. Can both statements be true? Yes, because these two relationships establish a *positive feedback* cycle (increased Na^+ permeability due to increased channel openings leads to greater depolarization, which leads to increased Na^+ permeability, and so on). It is this explosive positive feedback cycle that is responsible for the rising (depolarizing) phase of action potentials and is the property that puts the "action" in the action potential.

③ **Repolarizing phase: Decrease in Na^+ permeability.** The explosively rising phase of the action potential persists for only about 1 ms. It is self-limiting because the slow inactivation gates of the Na^+ channels begin to close at this point. As a result, the membrane permeability to Na^+ declines to resting levels, and the net influx of Na^+ stops completely. Consequently, the AP spike stops rising and reverses direction.

Repolarizing phase: Increase in K^+ permeability. As Na^+ entry declines, the slow voltage-gated K^+ channels open and K^+ rushes out of the cell, following its electrochemical gradient. Consequently, internal negativity of the resting neuron is restored, an event called **repolarization** (see the Figure 11.12 graph). Both the abrupt decline in Na^+ permeability and the increased permeability to K^+ contribute to repolarization.

④ **Hyperpolarization: K^+ permeability continues.** The period of increased K^+ permeability typically lasts longer than needed to restore the resting state. As a result of the excessive K^+ efflux, an **afterhyperpolarization**, also called the *undershoot*, is seen on the AP curve as a slight dip following the spike (and before the potassium gates close). Also at this point, the Na^+ channels begin to reset back to their original position by changing shape to reopen their inactivation gates and close their activation gates.

Although repolarization restores resting electrical conditions, it does *not* restore resting ionic conditions. The ion redistribution is accomplished by the **sodium-potassium pump** following repolarization. While it might appear that tremendous numbers of Na^+ and K^+ ions change places during action potential generation, this is not the case. Only small amounts of sodium and potassium cross the membrane. (The Na^+ influx required to reach threshold produces only a 0.012% change in intracellular Na^+ concentration.) Because an axon membrane has thousands of Na^+-K^+ pumps, these small ionic changes are quickly corrected.

Propagation of an Action Potential If it is to serve as the neuron's signaling device, an AP must be **propagated** (sent or transmitted) along the axon's entire length (Figure 11.13). As we have seen, the AP is generated by the influx of Na^+ through a given area of the membrane. This establishes local currents that depolarize adjacent membrane areas in the forward direction (away from the origin of the nerve impulse), which opens voltage-gated channels and triggers an action potential there. Because the area where the AP originated has just generated an AP, the sodium channels in that area are inactivated and no new AP is generated there. Thus, the AP propagates away from its point of origin. (If an *isolated* axon is stimulated by an electrode, the nerve impulse will move away from the point of stimulus in *all* directions along the membrane.) In the body, APs are initiated at one end of the axon and conducted away from that point toward the axon's terminals. Once initiated, an AP is *self-propagating* and continues along the axon at a constant velocity—something like a domino effect.

Following depolarization, each segment of axon membrane repolarizes, which restores the resting membrane potential in that region. Because these electrical changes also set up local currents, the repolarization wave chases the depolarization wave down the length of the axon. The propagation process just described occurs on unmyelinated axons. Propagation that occurs along myelinated axons, called *saltatory conduction*, is described shortly.

Although the phrase *conduction of a nerve impulse* is commonly used, nerve impulses are not really conducted in the same way that an insulated wire conducts current. In fact, neurons are fairly poor conductors, and as noted earlier, local current flows decline with distance because the charges leak through the membrane. The expression *propagation of a nerve impulse* is more accurate, because the AP

Q *The action potential shown will not get smaller as it propagates along the axon. Why not?*

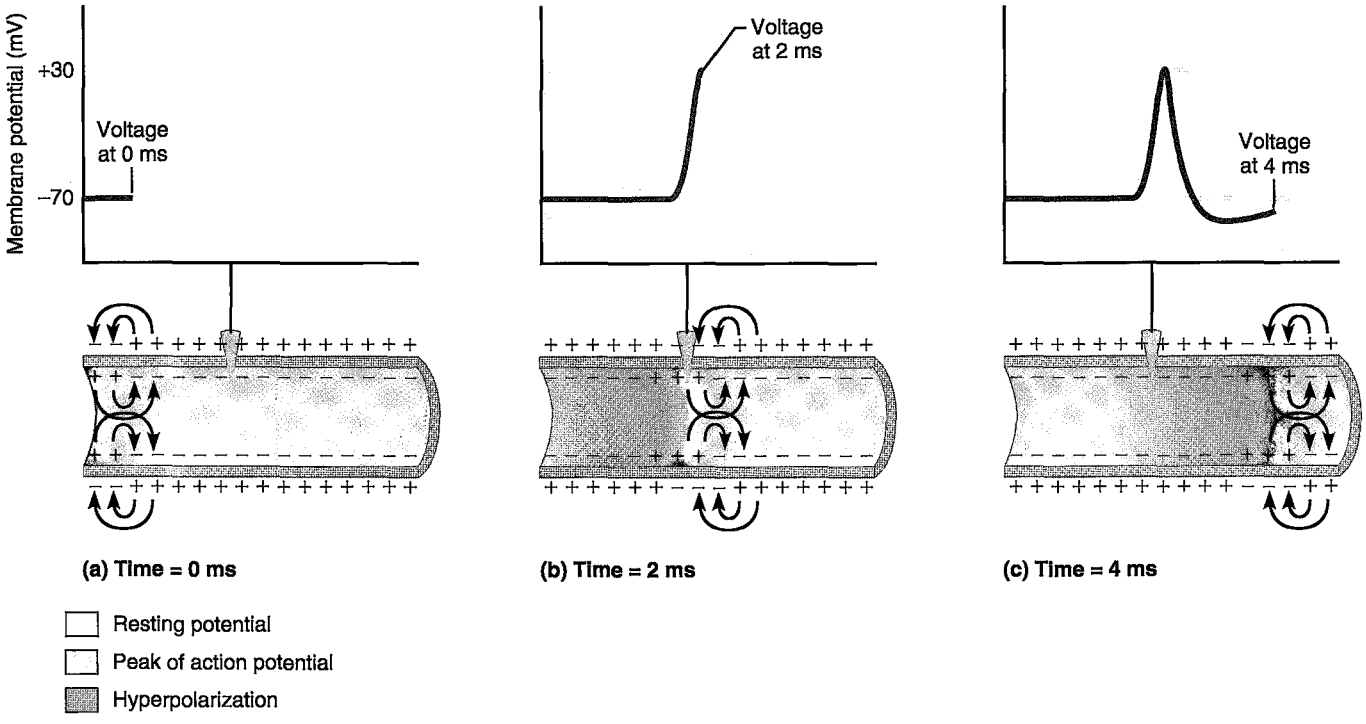

FIGURE 11.13 **Propagation of an action potential (AP).** Recordings at three successive times as an AP propagates along an axon (from left to right). The arrows show the direction of local current flow generated by the movement of positive ions. This current brings the resting membrane at the leading edge of the AP to threshold, propagating the AP forward. Local current flow at the trailing edge of the AP (not shown) does not initiate another AP because the voltage-gated Na^+ channels there are inactivated.

11

is *regenerated anew* at each membrane patch, and every subsequent AP is identical to that generated initially.

Threshold and the All-or-None Phenomenon

Not all local depolarization events produce APs. The depolarization must reach threshold values if an axon is to "fire." What determines the *threshold point*? One explanation is that threshold is the membrane potential at which the outward current created by K^+ movement is exactly equal to the inward current created by Na^+ movement. Threshold is typically reached when the membrane has been depolarized by 15 to 20 mV from the resting value. This depolarization status seems to represent an unstable equilibrium state at which one of two things can happen. If one more Na^+ enters, further depolarization occurs, opening more Na^+ channels and allowing more Na^+ entry. If, on the other hand, one more K^+ leaves, the membrane potential is driven away from threshold, Na^+ channels close, and K^+ continues to diffuse outward until the potential returns to its resting value.

Recall that local depolarizations are graded potentials and that their magnitude increases with increasing stimulus intensity. Brief weak stimuli (*subthreshold stimuli*) produce subthreshold depolarizations that are not translated into nerve impulses. On the other hand, stronger *threshold stimuli* produce depolarizing currents that push the membrane potential toward and beyond the threshold voltage. As a result, Na^+ permeability is increased to such an extent that entering sodium ions "swamp" (exceed) the outward movement of K^+, allowing the positive feedback cycle to become established and generating an AP. The critical factor here is the total amount of current that flows through the membrane during a stimulus (electrical charge × time). Strong stimuli depolarize

A Once the membrane reaches threshold, a positive feedback cycle is initiated that results in all available Na^+ channels opening, and this is true for each new piece of membrane that depolarizes.

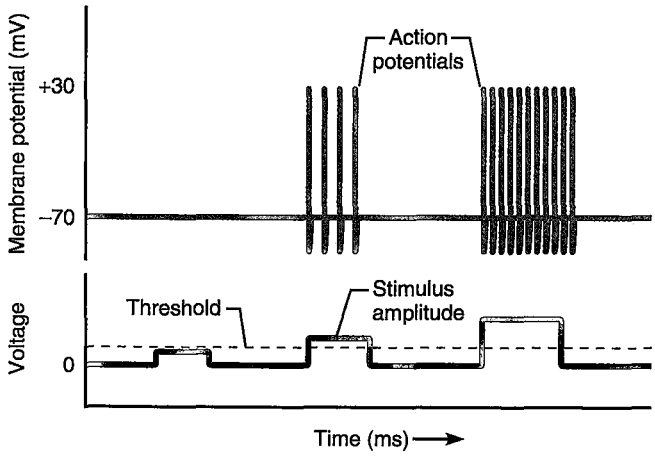

FIGURE 11.14 **Relationship between stimulus strength and action potential frequency.** APs are shown as vertical lines in the upper trace. The lower trace shows the intensity of the applied stimulus. A subthreshold stimulus does not generate an AP, but once threshold voltage is reached, the stronger the stimulus, the more frequently APs are generated.

the membrane to threshold quickly. Weaker stimuli must be applied for longer periods to provide the crucial amount of current flow. Very weak stimuli do not trigger an AP because the local current flows they produce are so slight that they dissipate long before threshold is reached.

The AP is an **all-or-none phenomenon;** it either happens completely or doesn't happen at all. Generation of an AP can be compared to lighting a match under a small dry twig. The changes occurring where the twig is heated are analogous to the change in membrane permeability that initially allows more Na^+ to enter the cell. When that part of the twig becomes hot enough (when enough Na^+ has entered the cell), the flash point (threshold) is reached and the flame consumes the entire twig, even if you blow out the match (the AP is generated and propagated whether or not the stimulus continues). But if the match is extinguished just before the twig has reached the critical temperature, ignition will not take place. Likewise, if the number of Na^+ entering the cell is too low to achieve threshold, no AP will occur.

Coding for Stimulus Intensity Once generated, all APs are independent of stimulus strength, and all APs are alike. So how can the CNS determine whether a particular stimulus is intense or weak—information it needs to initiate an appropriate response? The answer is really quite simple: Strong stimuli cause nerve impulses to be generated more *often* in a given time interval than do weak stimuli (Figure 11.14). Thus, stimulus intensity is coded for

What causes after-hyperpolarization?

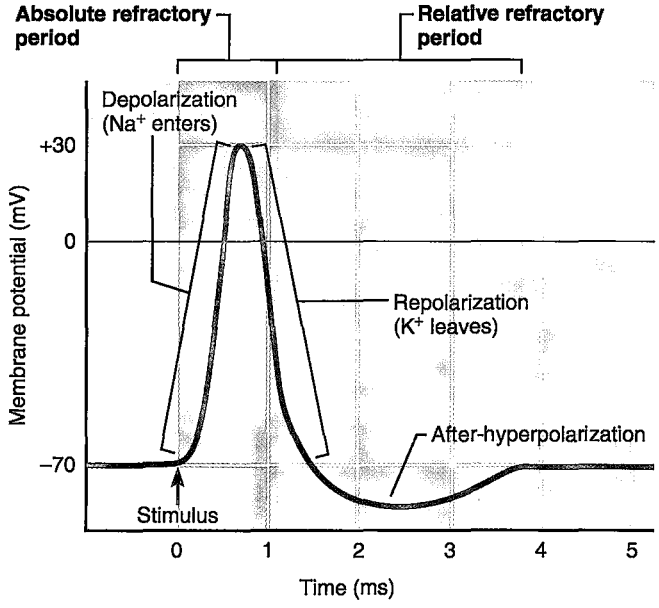

FIGURE 11.15 **Refractory periods in an AP.** This recording of an action potential indicates the timing of the absolute and relative refractory periods.

by the number of impulses generated per second—that is, by the *frequency of action potentials*—rather than by increases in the strength (amplitude) of the individual APs.

Refractory Periods When a patch of neuron membrane is generating an AP and its voltage-gated sodium channels are open, the neuron cannot respond to another stimulus, no matter how strong. This period from the opening of the Na^+ channels until the Na^+ channels begin to reset to their original resting state, called the **absolute refractory period** (Figure 11.15), ensures that each AP is a separate, *all-or-none event* and enforces one-way transmission of the AP.

The **relative refractory period** is the interval following the absolute refractory period. During the relative refractory period, most Na^+ channels have returned to their resting state, some K^+ channels are still open, and repolarization is occurring. During this time, the axon's threshold for AP generation is substantially elevated. A stimulus that would normally have generated an AP is no longer sufficient, but an exceptionally strong stimulus can reopen the Na^+

After-hyperpolarization occurs because potassium channel gates are slow to respond to changes in the membrane voltage. Hence more K^+ leaves the cell than is absolutely necessary to restore the neuron to its resting membrane potential.

Q *How does the location of voltage-gated Na^+ channels differ in a myelinated axon (as depicted here) and in an unmyelinated axon?*

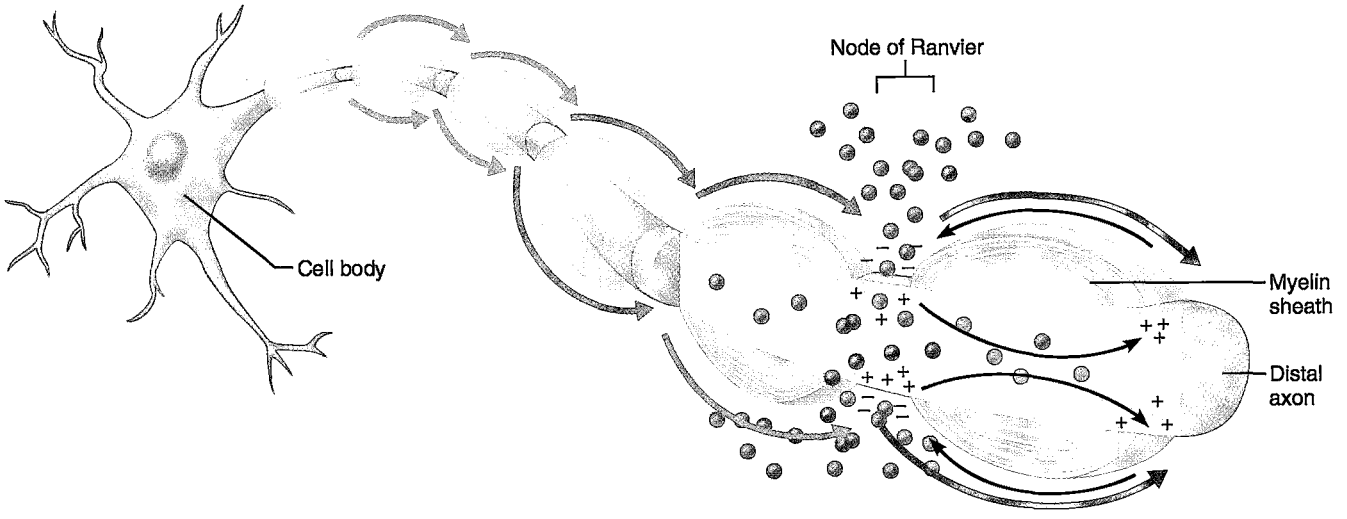

FIGURE 11.16 **Saltatory conduction in a myelinated axon.** In myelinated nerve fibers, local currents (thin black arrows) give rise to a propagated AP (pink and red arrows) that appears to jump from node to node. Notice that while APs are generated only at the nodes, the current flows along the axon from node to node.

channels that have already returned to their resting state and allow another AP to be generated. Thus, by intruding into the relative refractory period, strong stimuli cause more frequent generation of APs.

Conduction Velocity Conduction velocities of neurons vary widely. Nerve fibers that transmit impulses most rapidly (100 m/s or more) are found in neural pathways where speed is essential, such as those that mediate some postural reflexes. Axons that conduct impulses more slowly typically serve internal organs (the gut, glands, blood vessels), where slower responses are not a handicap. The rate of impulse propagation depends largely on two factors:

1. **Axon diameter.** Axons vary considerably in diameter and, as a rule, the larger the axon's diameter, the faster it conducts impulses. This is because larger axons offer less resistance to the flow of local currents, and so adjacent areas of the membrane can more quickly be brought to threshold.

2. **Degree of myelination.** On unmyelinated axons, APs are generated at sites immediately adjacent to each other and conduction is relatively slow, a type of AP propagation called **continuous conduction.** The presence of a myelin sheath dramatically increases the rate of AP propagation because myelin acts as an insulator, both preventing almost all leakage of charge from the axon and allowing the membrane voltage to change more rapidly. Current can pass through the membrane of a myelinated axon *only* at the nodes of Ranvier, where the myelin sheath is interrupted and the axon is bare, and essentially all the voltage-gated Na^+ channels are concentrated at the nodes. Thus, when an AP is generated in a myelinated fiber, the local depolarizing current does not dissipate through the adjacent (nonexcitable) membrane regions but instead is maintained and moves rapidly to the next node, a distance of approximately 1 mm, where it triggers another AP. Consequently, APs are triggered only at the nodes, a type of conduction called **saltatory conduction** (*saltare* = to leap) because the electrical signal jumps from node to node along the axon (Figure 11.16). Saltatory conduction is about 30 times faster than continuous conduction.

A *In a myelinated axon, voltage-gated sodium channels are located only at the nodes of Ranvier, instead of along the entire length of an unmyelinated axon.*

HOMEOSTATIC IMBALANCE

The importance of myelin to nerve transmission is painfully clear to those with demyelinating diseases such as **multiple sclerosis (MS).** This autoimmune disease affects mostly young adults. Common symptoms are visual disturbances (including blindness), problems controlling muscles (weakness, clumsiness,

and ultimately paralysis), speech disturbances, and urinary incontinence. In this disease, myelin sheaths in the CNS are gradually destroyed, reduced to nonfunctional hardened lesions called *scleroses*. The loss of myelin (a result of the immune system's attack on myelin proteins) causes such substantial shunting and short-circuiting of the current that successive nodes are excited more and more slowly, and eventually impulse conduction ceases. However, the axons themselves are not damaged and growing numbers of Na^+ channels appear spontaneously in the demyelinated fibers. This may account for the remarkably variable cycles of relapse (disability) and remission (symptom-free periods) typical of this disease.

Until a few years ago, little could be done to help MS victims. This situation is changing with the advent of the so-called disease-modifying drugs including interferons and glatiramer (Copaxone). These drugs seem to hold the symptoms at bay, reducing complications and the disability that often occurs with MS. ●

Nerve fibers may be classified based on diameter, degree of myelination, and conduction speed. **Group A fibers** are mostly somatic sensory and motor fibers serving the skin, skeletal muscles, and joints. They have the largest diameter and thick myelin sheaths, and conduct impulses at speeds ranging up to 150 m/s (over 300 miles per hour). Autonomic nervous system motor fibers serving the visceral organs; visceral sensory fibers; and the smaller somatic sensory fibers transmitting afferent impulses from the skin (such as pain and small touch fibers) belong in the B and C fiber groups. **Group B fibers,** lightly myelinated fibers of intermediate diameter, transmit impulses at an average rate of 15 m/s (about 40 mi/h). **Group C fibers** have the smallest diameter and are unmyelinated. Hence, they are incapable of saltatory conduction and conduct impulses at a leisurely pace—1 m/s (2 mi/h) or less.

HOMEOSTATIC IMBALANCE

A number of chemical and physical factors impair impulse propagation. Local anesthetics like those used by your dentist act by blocking voltage-gated Na^+ channels. As we have seen, no Na^+ entry—no AP.

Cold and continuous pressure interrupt blood circulation (and hence the delivery of oxygen and nutrients) to neuron processes, impairing their ability to conduct impulses. For example, your fingers get numb when you hold an ice cube for more than a few seconds, and your foot "goes to sleep" when you sit on it. When you remove the cold object or pressure, impulses are transmitted again, leading to an unpleasant prickly feeling. ●

The Synapse

The operation of the nervous system depends on the flow of information through chains of neurons functionally connected by synapses. A **synapse** (sin'aps), from the Greek *syn*, "to clasp or join," is a junction that mediates information transfer from one neuron to the next or from a neuron to an effector cell—it's where the action is.

Synapses between the axon endings of one neuron and the dendrites of other neurons are **axodendritic synapses** (Figure 11.17). Those between axon endings of one neuron and cell bodies of other neurons are **axosomatic synapses.** Less common (and far less understood) are synapses between axons *(axoaxonic)*, between dendrites *(dendrodendritic)*, or between dendrites and cell bodies *(dendrosomatic)*.

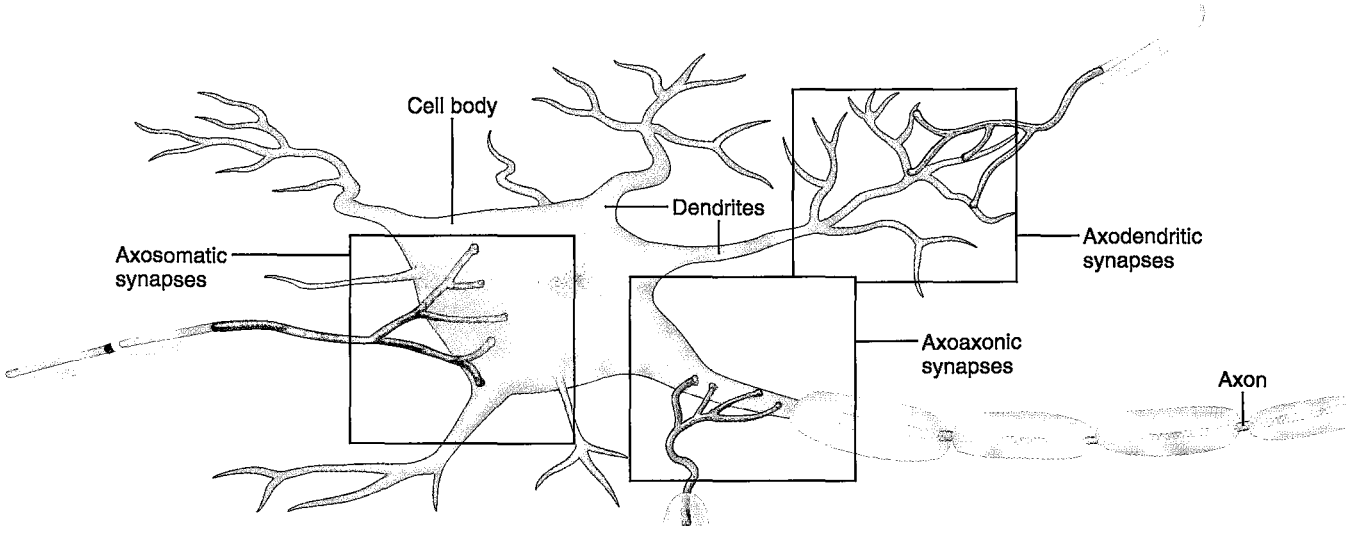
The neuron conducting impulses toward the synapse is the **presynaptic neuron,** and the neuron transmitting the electrical signal away from the synapse is the **postsynaptic neuron.** At a *given* synapse, the presynaptic neuron is the information sender, and the postsynaptic neuron is the information receiver. As you might anticipate, most neurons function as both presynaptic and postsynaptic neurons. Neurons have anywhere from 1000 to 10,000 axon terminals making synapses and are stimulated by an equal number of other neurons. In the body periphery, the postsynaptic cell may be either another neuron or an effector cell (a muscle cell or gland cell).

There are two varieties of synapses: *electrical* and *chemical*. These are described next.

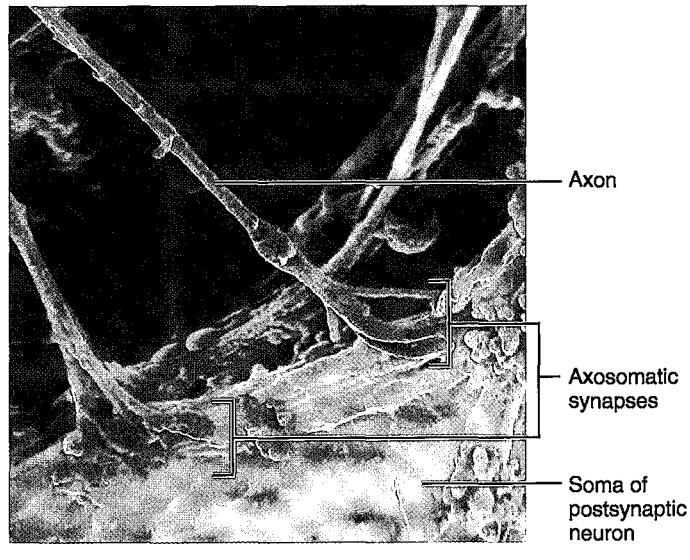
Electrical Synapses

Electrical synapses, the less common variety, correspond to the gap junctions found between certain other body cells. They contain protein channels, made of connexin subunits, that intimately connect the cytoplasm of adjacent neurons and allow ions and small molecules to flow directly from one neuron to the next. Neurons joined in this way are said to be *electrically coupled*, and transmission across these synapses is very rapid. Depending on the nature of the synapse, communication may be unidirectional or bidirectional.

A key feature of electrical synapses between neurons is that they provide a simple means of synchronizing the activity of all interconnected neurons. In adults, electrical synapses are found in regions of the brain responsible for certain stereotyped movements, such as the normal jerky movements of the eyes, and in axoaxonic synapses in the hippocampus, a region intimately involved in emotions and memory. They are far more abundant in embryonic nervous tissue, where they permit exchange of guiding clues during early neuronal development so that neurons can connect properly with one another. As



(a)



(b)

FIGURE 11.17 **Synapses. (a)** Axodendritic, axosomatic, and axoaxonic synapses. **(b)** Scanning electron micrograph of incoming fibers at axosomatic synapses (4000×).

the nervous system develops, some electrical synapses are replaced by chemical synapses. Gap junctions also exist between glial cells of the CNS.

Chemical Synapses

In contrast to electrical synapses, which are specialized to allow the flow of ions between neurons, **chemical synapses** are specialized for release and reception of chemical neurotransmitters. A typical chemical synapse is made up of two parts: (1) a knoblike *axon terminal* of the presynaptic neuron, which contains many tiny, membrane-bounded sacs called **synaptic vesicles,** each containing thousands of neurotransmitter molecules; and (2) a neurotransmitter *receptor region* on the membrane of a dendrite or the cell body of the postsynaptic neuron.

Although close to each other, presynaptic and postsynaptic membranes are always separated by the **synaptic cleft,** a fluid-filled space approximately 30 to 50 nm (about one-millionth of an inch) wide. (If an electrical synapse is like the threshold of a doorway between neurons, a synaptic cleft is like a good-size lake intervening between them.) Because the current from the presynaptic membrane dissipates in the fluid-filled cleft, chemical synapses effectively prevent a nerve impulse from being *directly* transmitted from one neuron to another. Instead, transmission of signals across these synapses is a *chemical event* that depends on the release, diffusion, and receptor binding of neurotransmitter molecules and results in *unidirectional communication* between neurons. Thus, while transmission of nerve impulses along an axon and across electrical synapses is a purely electrical event, chemical synapses convert the electrical signals to chemical signals (neurotransmitters) that travel across the synapse to the postsynaptic cells, where they are converted back into electrical signals.

Information Transfer Across Chemical Synapses

When a nerve impulse reaches the axon terminal, it sets into motion a chain of events that triggers neurotransmitter release. The neurotransmitter crosses the synaptic cleft and, on binding to receptors on the postsynaptic membrane, causes changes in the postsynaptic membrane permeability. The steps are shown in Figure 11.18:

① **Calcium channels open in the presynaptic axon terminal.** When the nerve impulse reaches the axon terminal, membrane depolarization opens not only Na^+ channels but voltage-gated Ca^{2+} channels as well. During the brief time the Ca^{2+} channels are open, Ca^{2+} floods down its electrochemical gradient into the terminal from the extracellular fluid.

Q *Why may such axon terminals be referred to as "biological transducers"?*

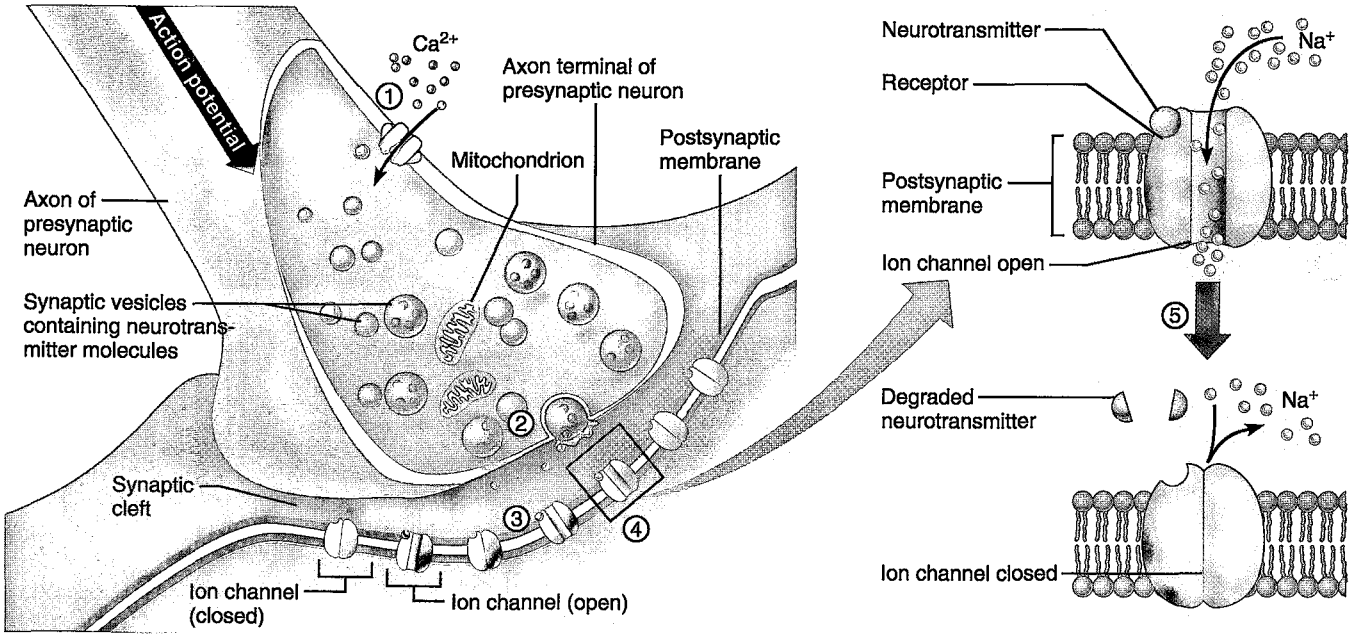


FIGURE 11.18 **Events at a chemical synapse in response to depolarization.** ① Arrival of the depolarization wave (action potential) opens voltage-gated calcium channels and allows Ca^{2+} influx into the axon terminal. ② Synaptic vesicles fuse with the presynaptic membrane and neurotransmitter is released into the synapse. ③ The neurotransmitter diffuses across the synaptic cleft and attaches to receptors on the postsynaptic membrane. ④ Binding of neurotransmitter opens ion channels in the postsynaptic membrane, resulting in graded potentials in that membrane. In this example of an excitatory synapse, chemically gated ion channels are opened, leading to depolarization. ⑤ Neurotransmitter is quickly destroyed by enzymes present at the synapse or taken back into the presynaptic terminal; depletion of neurotransmitter closes the ion channels and terminates the synaptic response.

11

② **Neurotransmitter is released.** The surge of Ca^{2+} into the axon terminal acts as an intracellular messenger, directing synaptic vesicles to fuse with the axon membrane and empty their contents by exocytosis into the synaptic cleft. Ca^{2+} is then quickly removed from the terminal, either taken up into the mitochondria or ejected from the neuron by an active Ca^{2+} pump. The precise Ca^{2+} sensor that initiates neurotransmitter exocytosis is still a question, but a Ca^{2+}-binding protein called *synaptotagmin* found in the synaptic vesicles seems a likely candidate.

③ **Neurotransmitter binds to postsynaptic receptors.** The neurotransmitter diffuses across the synaptic cleft and binds reversibly to specific protein receptors clustered on the postsynaptic membrane.

④ **Ion channels open in the postsynaptic membrane.** When neurotransmitter binds to the receptor protein, this receptor changes its three-dimensional shape. This in turn causes ion channels to open and creates graded potentials. Postsynaptic membranes often contain receptor proteins and ion channels packaged together as chemically gated ion channels. Depending on the receptor protein to which the neurotransmitter binds and the type of channel the receptor controls, the postsynaptic neuron may be either excited or inhibited.

For each nerve impulse reaching the presynaptic terminal, many vesicles (perhaps 300) are emptied into the synaptic cleft. The higher the impulse frequency (that is, the more intense the stimulus), the greater the number of synaptic vesicles that fuse and spill their contents, and the greater the effect on the postsynaptic cell.

⑤ **Neurotransmitter effects are terminated.** As long as it is bound to a postsynaptic receptor, a neurotransmitter continues to affect membrane permeability and to block reception of additional signals from presynaptic neurons. Thus, some means of "wiping the postsynaptic slate clean" is necessary.

∀ *Because they change the signal from an electrical current to a chemical signal (neurotransmitter), which in turn initiates an electrical current in the postsynaptic neuron.*

The effects of neurotransmitters generally last a few milliseconds before being terminated by one of three mechanisms. Depending on the particular neurotransmitter, the terminating mechanism may be

1. Degradation by enzymes associated with the postsynaptic membrane or present in the synapse, as with acetylcholine
2. Reuptake by astrocytes or the presynaptic terminal, where the neurotransmitter is stored or destroyed by enzymes, as with norepinephrine
3. Diffusion away from the synapse

Synaptic Delay Although an impulse may travel at speeds of up to 150 m/s (300 mi/h) down an axon, neural transmission across a chemical synapse is comparatively slow and reflects the time required for neurotransmitter release, diffusion across the synapse, and binding to receptors. Typically, this **synaptic delay,** which lasts 0.3–5.0 ms, is the *rate-limiting* (slowest) step of neural transmission. Synaptic delay helps explain why transmission along neural pathways involving only two or three neurons occurs rapidly, but transmission along multisynaptic pathways typical of higher mental functioning occurs much more slowly. However, in practical terms these differences are not noticeable.

Postsynaptic Potentials and Synaptic Integration

Many receptors present on postsynaptic membranes at chemical synapses are specialized to open ion channels, thereby converting chemical signals to electrical signals. Unlike the voltage-gated ion channels responsible for APs, however, these chemically gated channels are relatively insensitive to changes in membrane potential. Consequently, channel opening at postsynaptic membranes cannot possibly become self-amplifying or self-generating. Instead, neurotransmitter receptors mediate graded potentials—local changes in membrane potential that are *graded* according to the amount of neurotransmitter released and the time it remains in the area. APs are compared with postsynaptic potentials in Table 11.2.

Chemical synapses are either excitatory or inhibitory, depending on how they affect the membrane potential of the postsynaptic neuron.

Excitatory Synapses and EPSPs

At excitatory synapses, neurotransmitter binding causes depolarization of the postsynaptic membrane. However, in contrast to what happens on axon membranes, a single type of *chemically gated* ion channel opens on postsynaptic membranes (those of dendrites and neuronal cell bodies). This channel allows Na^+ and K^+ to diffuse *simultaneously* through the membrane in opposite directions. Although this two-way cation flow may appear to be self-defeating when depolarization is the goal, remember that the electrochemical gradient for sodium is much steeper than that for potassium. Hence, Na^+ influx is greater than K^+ efflux, and *net* depolarization occurs.

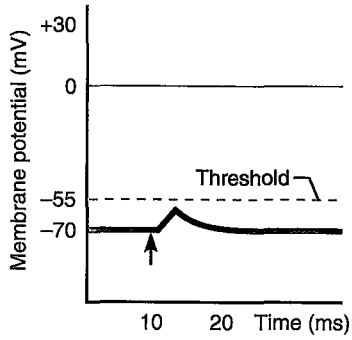
If enough neurotransmitter binds, depolarization of the postsynaptic membrane can successfully reach 0 mV, which is well above an axon's threshold (about −50 mV) for "firing off" an AP. However, *postsynaptic membranes generally do not generate APs; axons* (with their voltage-gated channels) *do have this capability.* The dramatic polarity reversal seen in axons never occurs in membranes containing *only* chemically gated channels because the opposite movements of K^+ and Na^+ prevent accumulation of excessive positive charge inside the cell. Hence, instead of APs, local graded depolarization events called **excitatory postsynaptic potentials (EPSPs)** occur at excitatory postsynaptic membranes (Figure 11.19a). Each EPSP lasts a few milliseconds and then the membrane returns to its resting potential. The only function of EPSPs is to help trigger an AP distally at the axon hillock of the postsynaptic neuron. Although currents created by individual EPSPs decline with distance, they can and often *do* spread all the way to the axon hillock. If currents reaching the hillock are strong enough to depolarize the axon to threshold, axonal voltage-gated channels open and an AP is generated.

Inhibitory Synapses and IPSPs

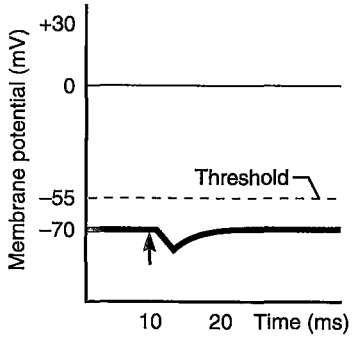
Binding of neurotransmitters at inhibitory synapses *reduces* a postsynaptic neuron's ability to generate an AP. Most inhibitory neurotransmitters induce hyperpolarization of the postsynaptic membrane by making the membrane more permeable to K^+ or Cl^-. Sodium ion permeability is not affected. If K^+ channels are opened, K^+ moves out of the cell; if Cl^- channels are opened, Cl^- moves in. In either case, the charge on the inner face of the membrane becomes more negative. As the membrane potential increases and is driven farther from the axon's threshold, the postsynaptic neuron becomes less and less likely to "fire" and larger depolarizing currents are required to induce an AP. Such changes in potential are called **inhibitory postsynaptic potentials (IPSPs)** (Figure 11.19b).

Integration and Modification of Synaptic Events

Summation by the Postsynaptic Neuron A single EPSP cannot induce an AP in the postsynaptic neuron. But if thousands of excitatory axon terminals are firing on the same postsynaptic membrane,



(a) Excitatory postsynaptic potential (EPSP)



(b) Inhibitory postsynaptic potential (IPSP)

FIGURE 11.19 **Postsynaptic potentials. (a)** An excitatory postsynaptic potential (EPSP) is a local depolarization of the postsynaptic membrane that brings the neuron closer to threshold for AP generation. It is mediated by neurotransmitter binding that opens chemically gated channels allowing the simultaneous passage of Na^+ and K^+ through the postsynaptic membrane. **(b)** An inhibitory postsynaptic potential results in hyperpolarization of the postsynaptic neuron and drives the neuron away from the threshold for firing. It is mediated by neurotransmitter binding that opens K^+ or Cl^- channels. The red vertical arrows represent stimulation.

or if a smaller number of terminals are delivering impulses rapidly, the probability of reaching threshold depolarization increases greatly. Thus, EPSPs can add together, or **summate,** to influence the activity of a postsynaptic neuron (Figure 11.20). Nerve impulses would never be initiated if this were not so.

Two types of summation occur. **Temporal summation** (*temporal* = time) occurs when one or more presynaptic neurons transmit impulses in rapid-fire order and bursts of neurotransmitter are released in quick succession. The first impulse produces a small EPSP, and before it dissipates, successive impulses trigger more EPSPs. These summate, producing a much greater depolarization of the postsynaptic membrane than would result from a single EPSP.

Spatial summation occurs when the postsynaptic neuron is stimulated at the same time by a large number of terminals from the same or, more commonly, different neurons. Huge numbers of its receptors bind neurotransmitter and simultaneously initiate EPSPs, which summate and dramatically enhance depolarization.

Although we have focused on EPSPs here, IPSPs also summate, both temporally and spatially. In this case, the postsynaptic neuron is inhibited to a greater degree.

Most neurons receive both excitatory and inhibitory inputs from thousands of other neurons. Additionally, the same fiber may form different types of synapses (in terms of biochemical and electrical characteristics) with different types of target neurons. How is all this conflicting information sorted out? Each neuron's axon hillock keeps a running account of all the signals it receives (Figure 11.20d). Not only do EPSPs summate and IPSPs summate, but also EPSPs summate with IPSPs. If the stimulatory effects of EPSPs dominate the membrane potential enough to reach threshold, the neuron will fire. If summation yields only subthreshold depolarization or hyperpolarization, the neuron fails to generate an AP. However, partially depolarized neurons are **facilitated**—that is, more easily excited by successive depolarization events—because they are already near threshold. Thus, axon hillock membranes function as *neural integrators,* and their potential at any time reflects the sum of all incoming neural information.

Because EPSPs and IPSPs are graded potentials that diminish in strength the farther they spread, this means that the most effective synapses are those closest to the axon hillock. As a result, inhibitory synapses are most effective when placed between the site of excitatory inputs and the site of action potential generation (the axon hillock). In general, inhibitory synapses occur most often on the cell body and excitatory synapses occur most often on the dendrites.

Synaptic Potentiation Repeated or continuous use of a synapse (even for short periods) enhances the presynaptic neuron's ability to excite the postsynaptic neuron, producing larger-than-expected postsynaptic potentials. This phenomenon is called **synaptic potentiation.** The presynaptic terminals at such synapses contain relatively high Ca^{2+} concentrations, a condition that (presumably) triggers the release of more neurotransmitter, which in turn produces larger EPSPs. Furthermore, synaptic potentiation brings about Ca^{2+} influx via dendritic spines into the postsynaptic neuron as well. Brief high-frequency stimulation partially depolarizes the postsynaptic membrane. This causes certain chemically gated channels called *NMDA (N-methyl-D-aspartate)*

Q *Graphs b and c show an action potential on the axon of this neuron. Why don't APs generally occur on neuronal cell bodies and dendrites?*

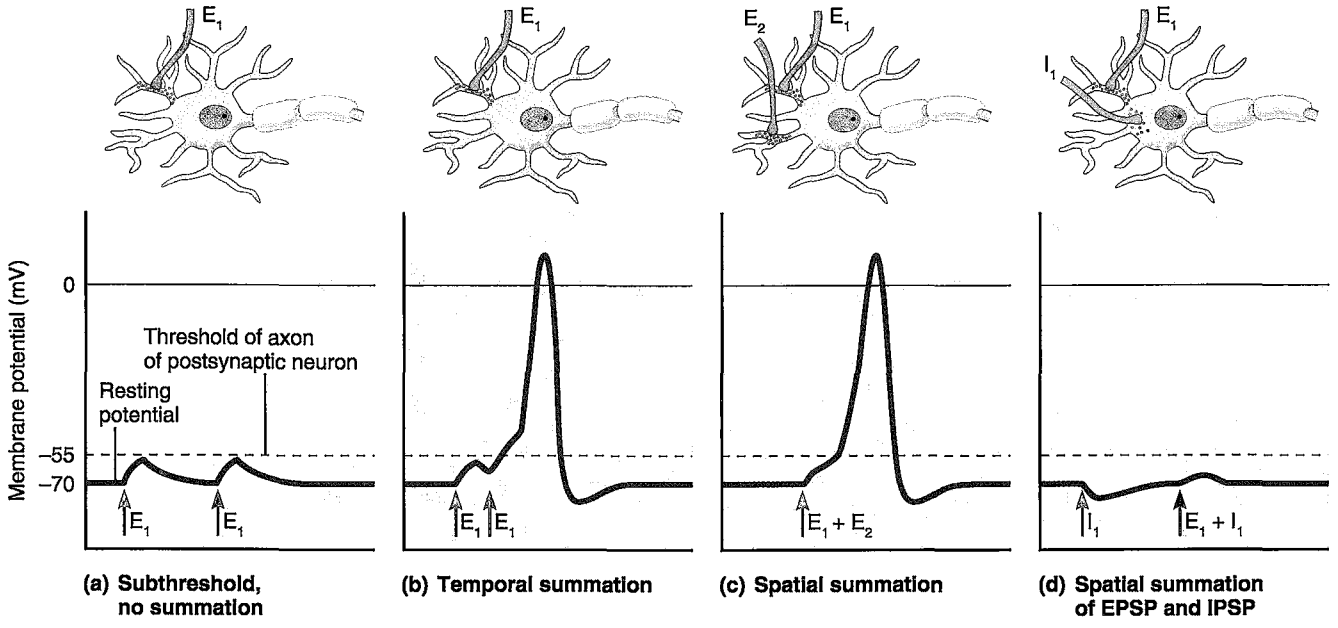


FIGURE 11.20 **Neural integration of EPSPs and IPSPs.** Synapses E_1 and E_2 are excitatory; synapse I_1 is inhibitory. Each individual impulse is subthreshold. **(a)** Synapse E_1 is stimulated and then stimulated again shortly thereafter. The two EPSPs do not overlap in time, so no summation occurs; threshold is not reached in the axon of the postsynaptic neuron. **(b)** Synapse E_1 is stimulated a second time before the initial EPSP has died away; temporal summation occurs, and the axon's threshold is reached, causing an AP to be generated. **(c)** Synapses E_1 and E_2 are stimulated simultaneously (spatial summation), resulting in a threshold depolarization. **(d)** Synapse I_1 is stimulated, resulting in a short-lived IPSP (hyperpolarization). When E_1 and I_1 are simultaneously stimulated, the changes in potential cancel each other.

11

receptors to allow Ca^{2+} entry, something that only happens when the membrane is depolarized. As Ca^{2+} floods into the cell, it activates certain kinase enzymes that promote changes that result in more effective responses to subsequent stimuli. In some neurons, APs generated at the axon hillock propagate back up into the dendrites. This current flow may alter the effectiveness of synapses by causing voltage-gated Ca^{2+} channels to open, again allowing Ca^{2+} into the dendrites and promoting synaptic potentiation.

Synaptic potentiation can be viewed as a learning process that increases the efficiency of neurotransmission along a particular pathway. Indeed, the hippocampus of the brain, which plays a special role in memory and learning, exhibits an important type of synaptic plasticity called *long-term potentiation* (LTP).

A Cell bodies and dendrites generally don't have enough voltage-gated Na^+ channels to generate APs.

Presynaptic Inhibition Postsynaptic activity can also be influenced by events occurring at the presynaptic membrane. **Presynaptic inhibition** occurs when the release of excitatory neurotransmitter by one neuron is inhibited by the activity of another neuron via an axoaxonic synapse. More than one mechanism is involved, but the end result is that less neurotransmitter is released and bound, and smaller EPSPs are formed. Notice that this is the opposite of what we see with synaptic potentiation. In contrast to postsynaptic inhibition by IPSPs, which decreases the excitability of the postsynaptic neuron, presynaptic inhibition is more like a functional synaptic "pruning." Events at the presynaptic neuron reduce excitatory stimulation of the postsynaptic neuron.

Neurotransmitters and Their Receptors

Neurotransmitters, along with electrical signals, are the "language" of the nervous system—the means by which each neuron communicates with others to

TABLE 11.2 Comparison of Action Potentials with Postsynaptic Potentials

		POSTSYNAPTIC POTENTIAL (A TYPE OF GRADED POTENTIAL)	
CHARACTERISTIC	ACTION POTENTIAL (AP)	EXCITATORY (EPSP)	INHIBITORY (IPSP)
Function	Long-distance signaling; constitutes the nerve impulse	Short-distance signaling; depolarization that spreads to axon hillock; moves membrane potential *toward* threshold for generation of AP	Short-distance signaling; hyperpolarization that spreads to axon hillock; moves potential *away from* threshold for generation of AP
Stimulus for opening of ionic gates	Voltage (depolarization)	Chemical (neurotransmitter)	Chemical (neurotransmitter)
Initial effect of stimulus	First opens Na^+ channels, then K^+ channels	Opens channels that allow simultaneous Na^+ and K^+ fluxes	Opens K^+ or Cl^- channels
Repolarization	Voltage-regulated; inactivation of Na^+ channels together with opening of K^+ channels	Voltage independent; occurs when neurotransmitter is no longer present	
Conduction distance	Not conducted by local current flows; continually regenerated (propagated) along entire axon; intensity does not decline with distance	0.1–1 mm; local electrical events; intensity declines with distance	
Positive feedback cycle	Present	Absent	Absent
Peak membrane potential	+30 to +50 mV	Becomes depolarized; moves toward 0 mV	Becomes hyperpolarized; moves toward −90 mV
Summation	None; an all-or-none phenomenon	Present; temporal or spatial	Present; temporal or spatial
Refractory period	Present	Absent	Absent

process and send messages to the rest of the body. Sleep, thought, rage, hunger, memory, movement, and even your smile reflect the "doings" of these versatile molecules. Most factors that affect synaptic transmission do so by enhancing or inhibiting neurotransmitter release or destruction, or by blocking their binding to receptors. Just as speech defects may hinder interpersonal communication, interferences with neurotransmitter activity may short-circuit the brain's "conversations" or internal talk (see *A Closer Look* on pp. 424–425).

At present, more than 50 neurotransmitters or neurotransmitter candidates have been identified. Although some neurons produce and release only one kind of neurotransmitter, most make two or more and may release any one or all of them. It appears that in most cases, different neurotransmitters are released at different stimulation frequencies, a restriction that avoids producing a jumble of nonsense messages. However, co-release of two neurotransmitters from the same vesicles has been documented. The coexistence of more than one neurotransmitter in a single neuron makes it possible for that cell to exert several influences rather than one discrete effect.

Neurotransmitters are classified chemically and functionally. Table 11.3 provides a fairly detailed overview of neurotransmitters, some of which are described here. No one expects you to memorize this table at this point, but it will be a handy reference for you to look back at when neurotransmitters are mentioned in subsequent chapters.

Classification of Neurotransmitters by Chemical Structure

Neurotransmitters fall into several chemical classes based on molecular structure.

Acetylcholine **Acetylcholine (ACh)** (as″ĕ-til-ko′lēn) was the first neurotransmitter identified. It is still the best understood because it is released at

TABLE 11.3 Neurotransmitters and Neuromodulators

NEUROTRANSMITTER	FUNCTIONAL CLASSES	SITES WHERE SECRETED	COMMENTS
ACETYLCHOLINE			
▪ At *nicotinic ACh receptors* (on skeletal muscles, autonomic ganglia, and in the CNS) ▪ At *muscarinic ACh receptors* (on visceral effectors and in the CNS) 	Excitatory Direct action Excitatory or inhibitory depending on subtype of muscarinic receptor Indirect action via second messengers	CNS: widespread throughout cerebral cortex, hippocampus, and brain stem PNS: all neuromuscular junctions with skeletal muscle; some autonomic motor endings (all preganglionic and parasympathetic postganglionic fibers)	Effects prolonged, leading to tetanic muscle spasms, when AChE blocked by nerve gas and organophosphate insecticides (malathion). Release inhibited by botulinum toxin; binding to nicotinic ACh receptors inhibited by curare (a muscle paralytic agent) and some snake venoms, and to muscarinic ACh receptors by atropine. ACh levels decreased in certain brain areas in Alzheimer's disease; nicotinic ACh receptors destroyed in myasthenia gravis. Binding of nicotine to nicotinic receptors in the brain enhances dopamine release, which may account for the behavioral effects of nicotine in smokers
BIOGENIC AMINES			
Norepinephrine 	Excitatory or inhibitory, depending on receptor type bound Indirect action via second messengers	CNS: brain stem, particularly in the locus coeruleus of the midbrain; limbic system; some areas of cerebral cortex PNS: main neurotransmitter of ganglion neurons in the sympathetic nervous system	A "feeling good" neurotransmitter; release enhanced by amphetamines; removal from synapse blocked by tricyclic antidepressants [amitriptyline (Elavil) and others] and cocaine; brain levels reduced by reserpine (an antihypertensive drug), leading to depression
Dopamine 	Excitatory or inhibitory depending on the receptor type bound Indirect action via second messengers	CNS: substantia nigra of midbrain; hypothalamus; is the principal neurotransmitter of extrapyramidal system PNS: some sympathetic ganglia	A "feeling good" neurotransmitter; release enhanced by L-dopa and amphetamines; reuptake blocked by cocaine; deficient in Parkinson's disease; may be involved in pathogenesis of schizophrenia
Serotonin (5-HT) 	Mainly inhibitory Indirect action via second messengers; direct action at 5-HT_3 receptors	CNS: brain stem, especially midbrain; hypothalamus; limbic system; cerebellum; pineal gland; spinal cord	Activity blocked by LSD and enhanced by ecstasy (MDMA); may play a role in sleep, appetite, nausea, migraine headaches, and regulation of mood; drugs that block its uptake [fluoxetine (Prozac)] relieve anxiety and depression
Histamine 	Indirect action via second messengers	CNS: hypothalamus	Increases acid secretion in the stomach; acid secretion blocked by histamine H_2 receptor blockers (cimetidine); also released by mast cells during inflammation and acts as powerful vasodilator

TABLE 11.3 Neurotransmitters and Neuromodulators *(continued)*

NEUROTRANSMITTER	FUNCTIONAL CLASSES	SITES WHERE SECRETED	COMMENTS
PURINES			
ATP	Excitatory or inhibitory depending on receptor type bound Direct and indirect actions via second messengers	CNS: basal nuclei, induces Ca^{2+} wave propagation in astrocytes PNS: dorsal root ganglion neurons	ATP released by sensory neurons (as well as that released by injured cells) provokes pain sensation
Adenosine  	Inhibitory neuromodulator Indirect action via second messengers	Throughout CNS	Caffeine (coffee), theophylline (tea), and theobromine (chocolate) stimulate by blocking brain adenosine receptors; may be involved in sleep-wake cycle and terminating seizures. Dilates arterioles, increasing blood flow to heart and other tissues as needed
AMINO ACIDS			
GABA (γ-aminobutyric acid) 	Generally inhibitory Direct and indirect actions via second messengers	CNS: cerebral cortex, hypothalamus, Purkinje cells of cerebellum, spinal cord, granule cells of olfactory bulb, retina	Principal inhibitory neurotransmitter in the brain; important in presynaptic inhibition at axoaxonic synapses. GABA-dependent neural communication declines with age in visual and auditory systems. Inhibitory effects augmented by alcohol, antianxiety drugs of the benzodiazepine class (e.g., Valium), and barbiturates, resulting in impaired motor coordination. Substances that block its synthesis, release, or action induce convulsions
Glutamate 	Generally excitatory Direct action	CNS: spinal cord; widespread in brain where it represents the major excitatory neurotransmitter	Important in learning and memory. The "stroke neurotransmitter": excessive release produces excitotoxicity—neurons literally stimulated to death; most commonly caused by ischemia (oxygen deprivation, usually due to a blocked blood vessel). When released by gliomas, aids tumor advance
Glycine 	Generally inhibitory Direct action	CNS: spinal cord and brain stem, retina	Principal inhibitory neurotransmitter of the spinal cord. Strychnine blocks glycine receptors, resulting in uncontrolled convulsions and respiratory arrest

NEUROTRANSMITTER	FUNCTIONAL CLASSES	SITES WHERE SECRETED	COMMENTS
PEPTIDES			
Endorphins, e.g., dynorphin, enkephalins (illustrated) 	Generally inhibitory Indirect action via second messengers	CNS: widely distributed in brain; hypothalamus; limbic system; pituitary; spinal cord	Natural opiates; inhibit pain by inhibiting substance P; effects mimicked by morphine, heroin, and methadone
Tachykinins: Substance P (illustrated), neurokinin A (NKA) 	Excitatory Indirect action via second messengers	CNS: basal nuclei, midbrain, hypothalamus, cerebral cortex PNS: certain sensory neurons of dorsal root ganglia (pain afferents)	Substance P mediates pain transmission in the PNS; in the CNS tachykinins are involved in respiratory and cardiovascular controls and in mood
Somatostatin 	Generally inhibitory Indirect action via second messengers	CNS: hypothalamus, retina, and other parts of brain Pancreas	Inhibits release of growth hormone; a gut-brain peptide
Cholecystokinin (CCK) 	Possible neurotransmitter	Cerebral cortex Small intestine	May be related to feeding behaviors; a gut-brain peptide
DISSOLVED GASES			
Nitric oxide (NO)	Excitatory Indirect action via second messengers	CNS: brain, spinal cord PNS: adrenal gland; nerves to penis	Its release potentiates stroke damage; some types of male impotence treated by enhancing NO action [e.g., with sildenafil (Viagra)]
Carbon monoxide (CO)	Excitatory Indirect action via second messengers	Brain and some neuromuscular and neuroglandular synapses	

neuromuscular junctions, which are much easier to study than synapses buried in the CNS. ACh is synthesized and enclosed in synaptic vesicles in axon terminals in a reaction catalyzed by the enzyme *choline acetyltransferase*. Acetic acid is bound to coenzyme A (CoA) to form acetyl CoA, which then combines with choline. Then coenzyme A is released.

$$\text{Acetyl CoA} + \text{choline} \xrightarrow[\text{acetyltransferase}]{\text{choline}} \text{ACh} + \text{CoA}$$

Once released by the presynaptic terminal, ACh binds to the postsynaptic receptors briefly. Then it is released and degraded to acetic acid and choline by the enzyme **acetylcholinesterase (AChE)**, located in the synaptic cleft and on postsynaptic membranes. The released choline is recaptured by the presynaptic terminals and reused to synthesize more ACh.

ACh is released by all neurons that stimulate skeletal muscles and by some neurons of the autonomic nervous system. ACh-releasing neurons are also found in the CNS.

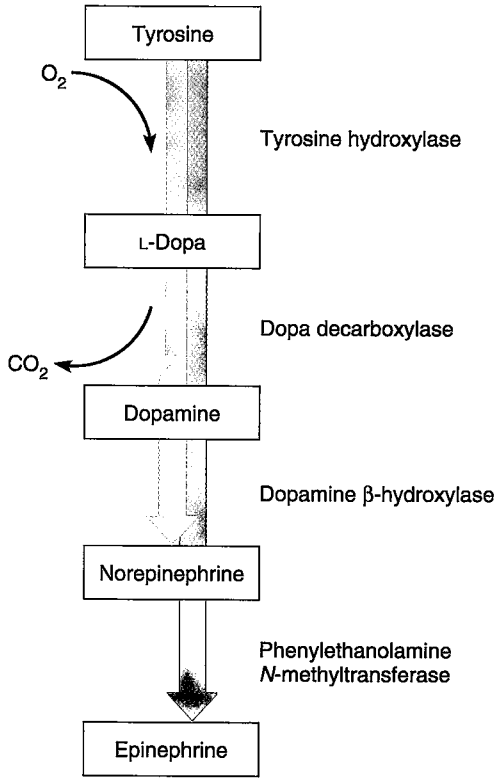

FIGURE 11.21 **Common pathway for synthesis of dopamine, norepinephrine, and epinephrine.** How far synthesis proceeds along the pathway depends on the enzymes present in the cell.

Biogenic Amines The **biogenic amines** (bi″o-jen′ik) include the **catecholamines** (kat″ĕ-kol′ah-mēnz), such as dopamine, norepinephrine (NE), and epinephrine, and the **indolamines,** which include serotonin and histamine. As illustrated in Figure 11.21, *dopamine* and *NE* are synthesized from the amino acid tyrosine in a common pathway consisting of several steps. Apparently, neurons contain only the enzymes needed to produce their own neurotransmitter(s). Thus, the sequence stops at dopamine in dopamine-releasing neurons but continues on to NE in NE-releasing neurons. The same pathway is used by the epinephrine-releasing cells of the brain and the adrenal medulla. *Serotonin* is synthesized from the amino acid tryptophan. *Histamine* is synthesized from the amino acid histidine.

Biogenic amine neurotransmitters are broadly distributed in the brain, where they play a role in emotional behavior and help regulate the biological clock. Additionally, catecholamines (particularly NE) are released by some motor neurons of the autonomic nervous system. Imbalances of these neurotransmitters are associated with mental illness; for example, overactive dopamine signaling occurs in schizophrenia. Additionally, certain psychoactive drugs (LSD and mescaline) can bind to biogenic amine receptors and induce hallucinations.

Amino Acids It is difficult to prove a neurotransmitter role when the suspect is an *amino acid,* because amino acids occur in all cells of the body and are important in many biochemical reactions. The amino acids for which a neurotransmitter role is certain include **gamma (γ)-aminobutyric acid (GABA), glycine, aspartate,** and **glutamate,** but there may be others.

Peptides The **neuropeptides,** essentially strings of amino acids, include a broad spectrum of molecules with diverse effects. For example, a neuropeptide called **substance P** is an important mediator of pain signals. By contrast, **endorphins,** which include **beta endorphin, dynorphin,** and **enkephalins** (en-kef′ah-linz), act as natural opiates, reducing our perception of pain under certain stressful conditions. Enkephalin activity increases dramatically in pregnant women in labor. Endorphin release is enhanced when an athlete gets a so-called second wind and is probably responsible for the "runner's high." Additionally, some researchers claim that the placebo effect is due to endorphin release. These painkilling neurotransmitters remained undiscovered until investigators began to ask why morphine and other opiates reduce anxiety and pain, and found that these drugs attach to the same receptors that bind natural opiates, producing similar but stronger effects.

Some neuropeptides, such as somatostatin and cholecystokinin, are also produced by nonneural body tissues and are widespread in the gastrointestinal tract. Such peptides are commonly referred to as **gut-brain peptides.**

Purines Like amino acids, another ubiquitous cellular component, **adenosine triphosphate** (**ATP,** the universal form of energy), is now recognized as a major neurotransmitter (perhaps the most primitive one) in both the CNS and PNS. Like glutamate and acetylcholine, it produces a fast excitatory response at certain receptors. Depending on the ATP receptor type it binds to, ATP can mediate fast excitatory responses or trigger slow, second-messenger responses. Upon binding to receptors in astrocytes, it mediates Ca^{2+} influx.

In addition to the neurotransmitter action of extracellular ATP, **adenosine,** a part of ATP, also acts outside of cells on adenosine receptors. Adenosine is a potent inhibitor in the brain. Caffeine's well-known stimulatory effects result from its block of these adenosine receptors. Four subtypes of adenosine receptors have now been recognized, all of which act indirectly via second messengers.

Dissolved Gases Just a short while ago, it would have been scientific suicide to suggest that nitric oxide and carbon monoxide—two ubiquitous molecules—might be neurotransmitters. Nonetheless, the discovery of these unlikely messengers has opened up a whole new chapter in the story of neurotransmission.

Nitric oxide (NO), a short-lived toxic gas, defies all the official descriptions of neurotransmitters in that rather than being stored in vesicles and released by exocytosis, it is synthesized on demand and diffuses out of the cells making it. Instead of attaching to surface receptors, it zooms through the plasma membrane of nearby cells to bind with a peculiar intracellular receptor—iron in *guanylyl cyclase*, the enzyme that makes the second messenger *cyclic GMP*. The precise role of NO in the brain has been hard to pin down, but when the neurotransmitter glutamate binds to NMDA receptors, Ca^{2+} channels open to allow an influx of Ca^{2+} into the cell. The Ca^{2+} triggers reactions that activate *nitric oxide synthase (NOS)*, the enzyme needed for NO synthesis. Many believe NO is the retrograde messenger involved in long-term potentiation (learning and memory)—that is, it may travel back from the postsynaptic neuron to the presynaptic neuron where it activates guanylyl cyclase. Excessive release of NO contributes to much of the brain damage seen in stroke patients (see pp. 468–469). In the myenteric plexus of the intestine, NO causes intestinal smooth muscle to relax.

It may be that NO is just the first of a soon-to-be-discovered class of signaling gases that pass swiftly into cells, bind briefly to metal-containing enzymes, and then vanish. **Carbon monoxide (CO)**, another airy messenger, also stimulates synthesis of cyclic GMP, and some researchers speculate that CO is the main regulator of cyclic GMP levels in the brain. Though NO and CO are found in different brain regions and appear to act in different pathways, their mode of action is similar.

Classification of Neurotransmitters by Function

This text cannot begin to describe the incredible diversity of functions that neurotransmitters mediate. Therefore, we limit our discussion to two broad ways of classifying neurotransmitters according to function; more details will be added as appropriate in subsequent chapters.

Effects: Excitatory Versus Inhibitory We can summarize this classification scheme by saying that some neurotransmitters are excitatory (cause depolarization), some are inhibitory (cause hyperpolarization), and others exert both effects, depending on the specific receptor types with which they interact. For example, the amino acids GABA and glycine are usually inhibitory, whereas glutamate is typically excitatory (see Table 11.3). On the other hand, ACh and NE each bind to at least two receptor types that cause opposite effects. For example, acetylcholine is excitatory at neuromuscular junctions in skeletal muscle and inhibitory in cardiac muscle.

Mechanism of Action: Direct Versus Indirect Neurotransmitters that bind to and open ion channels are said to act *directly*. These neurotransmitters provoke rapid responses in postsynaptic cells by promoting changes in membrane potential. ACh and the amino acid neurotransmitters typically act as direct-acting neurotransmitters.

Neurotransmitters that act *indirectly* tend to promote broader, longer-lasting effects by acting through intracellular *second-messenger* molecules [typically via G protein mechanisms (see Figure 3.16)]. In this way their mechanism of action is similar to that of many hormones. The biogenic amines, neuropeptides, and the dissolved gases are indirect neurotransmitters.

Neuromodulator is a term used to describe a chemical messenger released by a neuron that does not directly cause EPSPs or IPSPs but does affect the strength of synaptic transmission. A neuromodulator may act presynaptically to influence the synthesis, release, degradation, or reuptake of neurotransmitter. Alternatively, a neuromodulator may act postsynaptically by altering the sensitivity of the postsynaptic membrane to neurotransmitter. Receptors for neuromodulators are not necessarily found at a synapse. Instead, a neuromodulator may be released from one cell to act at many cells in its vicinity in the manner typical of paracrines (chemical messengers that act locally and are quickly destroyed). The distinction between neurotransmitters and neuromodulators is fuzzy, but chemical messengers such as NO and a number of neuropeptides are often referred to as neuromodulators.

Neurotransmitter Receptors

In Chapter 3, we introduced the various receptors involved in cell signaling. Now we are ready to pick up that thread again as we examine the action of receptors that bind neurotransmitters. For the most part, neurotransmitter receptors are either channel-linked receptors, which mediate fast synaptic transmission, or G protein–linked receptors, which oversee slow synaptic responses.

Mechanism of Action of Channel-Linked Receptors **Channel-linked receptors** are ligand-gated ion channels that mediate direct transmitter action.

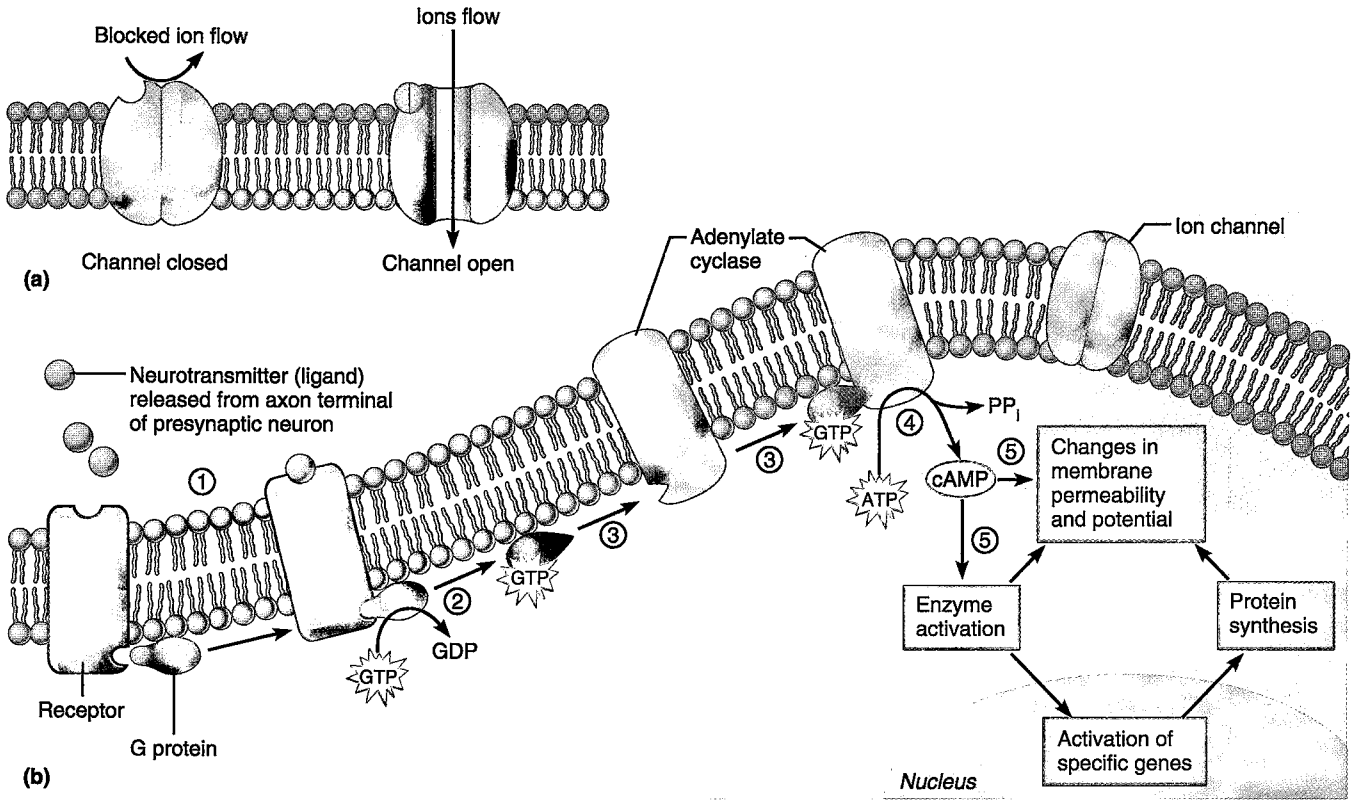

FIGURE 11.22 **Neurotransmitter receptor mechanism. (a)** Channel-linked receptors open in response to binding of ligand (ACh in this case). When no ligand is bound, the channel is closed and no current passes through it. As soon as ligand binds, the channel opens and ions flow through it. The precise ion current is determined by the structure and charge of the channel proteins. (In ACh channels, Na^+, K^+, and Ca^{2+} pass, resulting in a depolarizing current.) **(b)** A G protein–linked receptor. ① A neurotransmitter (ligand, first messenger) binds to its receptor. ② Binding of the neurotransmitter to the receptor results in receptor–G protein interaction and activation of the G protein. Once GTP replaces GDP in the G protein complex, ③ the G protein can interact with and activate adenylate cyclase. ④ Activated adenylate cyclase catalyzes the formation of cyclic AMP (cAMP) from ATP. ⑤ cAMP, acting as an intracellular second messenger, mediates events which activate enzymes that bring about the postsynaptic neuron's response (changes in membrane potential, protein synthesis, etc.).

Also called *ionotropic receptors*, they are composed of several protein subunits arranged in a "rosette" around a central pore. As the ligand binds to one (or more) receptor subunits, the proteins change shape. This event opens the central channel and allows ions to pass (Figure 11.22a), altering the membrane potential of the target cell. Channel-linked receptors are always located precisely opposite sites of neurotransmitter release, and their ion channels open instantly upon ligand binding and remain open 1 ms or less while the ligand is bound. At excitatory receptor sites (nicotinic ACh channels and receptors for glutamate, aspartate, and ATP), the channel-linked receptors are cation channels that allow small cations (Na^+, K^+, Ca^{2+}) to pass, but Na^+ entry contributes most to membrane depolarization. Channel-linked receptors that respond to GABA and glycine, and allow Cl^- to pass, mediate fast inhibition (hyperpolarization).

Mechanism of Action of G Protein–Linked Receptors Unlike responses to neurotransmitter binding at channel-linked receptors, which are immediate, simple, and brief, the activity mediated by **G protein–linked receptors** is indirect, slow (hundreds of milliseconds or more), complex, and often prolonged—ideal as a basis for some types of learning. Receptors that fall into this class are transmembrane protein complexes and include muscarinic ACh receptors and those that bind the biogenic amines and neuropeptides. When a neurotransmitter binds to a G protein–linked receptor, the G protein is activated (Figure 11.22b). (You might like to refer back to the simpler G protein explanation in Figure 3.16 on p. 84 to orient yourself.) Activated G proteins typically work by controlling the production of second messengers such as **cyclic AMP, cyclic GMP, diacylglycerol,** or **Ca^{2+}.** These, in turn, act as go-betweens to regulate

(open or close) ion channels or activate kinase enzymes that initiate a cascade of enzymatic reactions in the target cells. Some of these second messengers modify (activate or inactivate) other proteins, including channel proteins, by attaching phosphate groups to them. Others interact with nuclear proteins that activate genes and induce synthesis of new proteins in the target cell. Because the effects produced tend to bring about widespread metabolic changes, G protein–linked receptors are commonly called *metabotropic receptors*.

Basic Concepts of Neural Integration

Until now, we have been concentrating on the activities of individual neurons; however, neurons function in groups, and each group contributes to still broader neural functions. Thus, the organization of the nervous system is hierarchical, or ladderlike.

Any time you have a large number of *anything*—people included—there must be *integration*; that is, the parts must be fused into a smoothly operating whole. In this section, we begin to ascend the ladder of **neural integration,** dealing only with the first rung, *neuronal pools* and their patterns of communicating with other parts of the nervous system. Chapter 13 picks up the thread of neural integration to examine how sensory inputs interface with motor activity. The highest levels of neural integration—how we think and remember—are discussed in Chapter 12.

Organization of Neurons: Neuronal Pools

The millions of neurons in the CNS are organized into **neuronal pools,** functional groups of neurons that integrate incoming information received from receptors or different neuronal pools and then forward the processed information to other destinations.

In a simple type of neuronal pool, shown in Figure 11.23, one incoming presynaptic fiber branches profusely as it enters the pool and then synapses with several different neurons in the pool. When the incoming fiber is excited, it will excite some postsynaptic neurons and facilitate others. Neurons most likely to generate impulses are those closely associated with the incoming fiber, because they receive the bulk of the synaptic contacts. Those neurons are said to be in the *discharge zone* of the pool. Neurons farther from the center are not usually excited to threshold by EPSPs induced by the incoming fiber, but they are facilitated and can easily be brought to threshold by stimuli from another source. Thus, the periphery of the pool is the *facilitated zone*. Keep in mind, however, that our figure is a gross oversimplification. Most neuronal pools consist of thousands of neurons and include inhibitory as well as excitatory neurons.

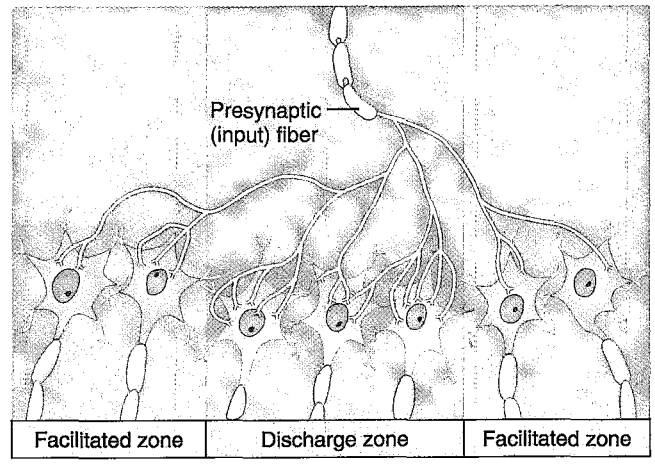

FIGURE 11.23 **Simple neuronal pool.** This simplified representation shows the relative position of postsynaptic neurons in the discharge and facilitated zones. Notice that the presynaptic fiber makes more synapses per neuron with neurons in the discharge zone.

Types of Circuits

Individual neurons in a neuronal pool both send and receive information, and synaptic contacts may cause either excitation or inhibition. The patterns of synaptic connections in neuronal pools are called **circuits**, and they determine the pool's functional capabilities. Four basic circuit patterns are shown in simplified form in Figure 11.24.

In **diverging circuits,** one incoming fiber triggers responses in ever-increasing numbers of neurons farther and farther along in the circuit. Thus, diverging circuits are often *amplifying* circuits. Divergence can occur along a single pathway or along several (Figure 11.24a and b). These circuits are common in both sensory and motor systems. For example, impulses traveling from a single neuron of the brain can activate a hundred or more motor neurons in the spinal cord and, consequently, thousands of skeletal muscle fibers.

The pattern of **converging circuits** is opposite that of diverging circuits, but they too are common in both sensory and motor pathways. In a converging circuit, the pool receives inputs from several presynaptic neurons, and the circuit has a funneling, or *concentrating*, effect. Incoming stimuli may converge from one area or from many different

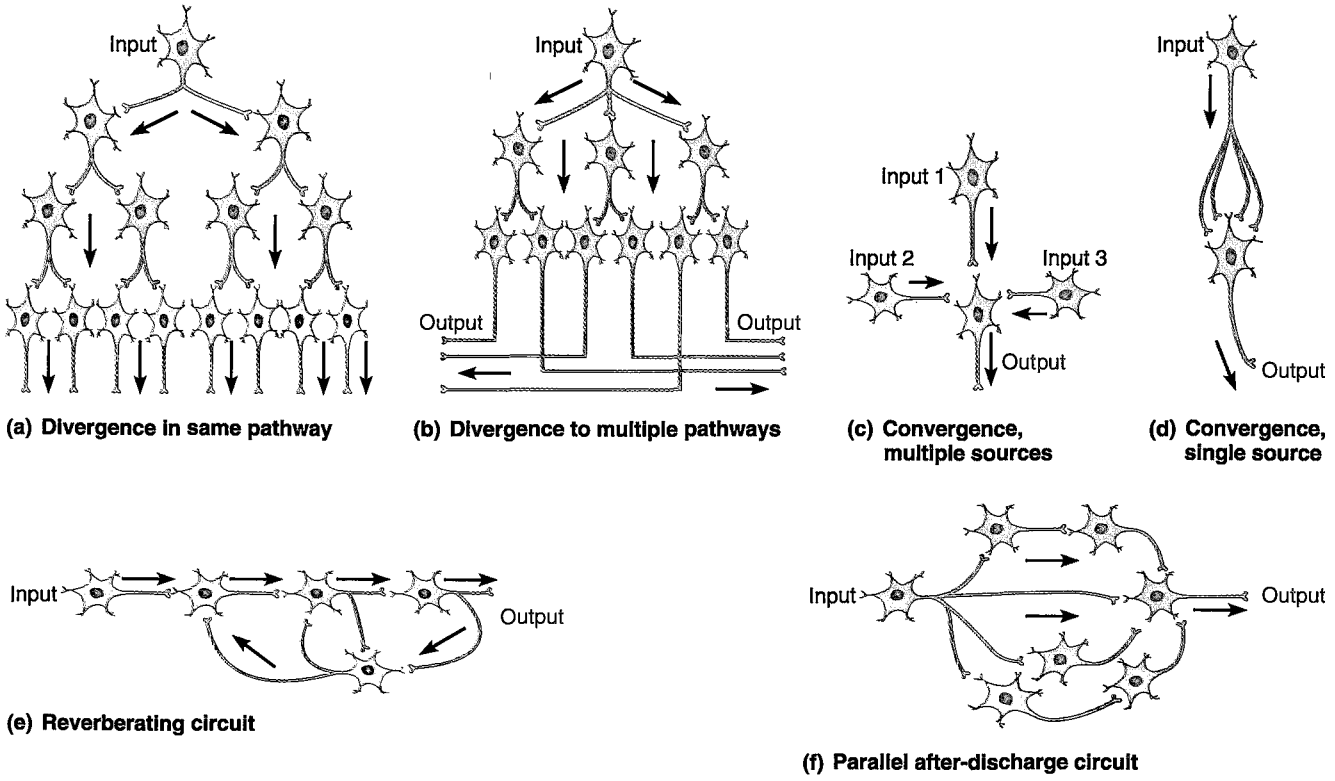

FIGURE 11.24 **Types of circuits in neuronal pools.**

areas (Figure 11.24c and d), which results in strong stimulation or inhibition. The former condition helps explain how different types of sensory stimuli can have the same ultimate effect. For instance, seeing the smiling face of their infant, smelling the baby's freshly powdered skin, or hearing the baby gurgle can all trigger a flood of loving feelings in parents.

In **reverberating,** or **oscillating, circuits** (Figure 11.24e), the incoming signal travels through a chain of neurons, each of which makes collateral synapses with neurons in a previous part of the pathway. As a result of the positive feedback, the impulses *reverberate* (are sent through the circuit again and again), giving a continuous output signal until one neuron in the circuit fails to fire. Reverberating circuits are involved in control of rhythmic activities, such as the sleep-wake cycle, breathing, and certain motor activities (such as arm swinging when walking). Some researchers believe that such circuits underlie short-term memory. Depending on the specific circuit, reverberating circuits may continue to oscillate for seconds, hours, or (in the case of the circuit controlling the rhythm of breathing) a lifetime.

In **parallel after-discharge circuits,** the incoming fiber stimulates several neurons arranged in parallel arrays that eventually stimulate a common output cell (Figure 11.24f). Impulses reach the output cell at different times, creating a burst of impulses called an *after-discharge* that lasts 15 ms or more after the initial input has ended. This type of circuit has no positive feedback, and once all the neurons have fired, circuit activity ends. Parallel after-discharge circuits may be involved in complex, exacting types of mental processing.

Patterns of Neural Processing

Input processing is both *serial* and *parallel*. In serial processing, the input travels along one pathway to a specific destination. In parallel processing, the input travels along several different pathways to be integrated in different CNS regions. Each mode has unique advantages in the overall scheme of neural functioning, but as an information processor, the brain derives its power from its ability to process in parallel.

Serial Processing

In **serial processing,** the whole system works in a predictable all-or-nothing manner. One neuron stimulates the next, which stimulates the next, and so on, eventually causing a specific, anticipated response. The most clear-cut examples of serial processing are spinal reflexes, but straight-through

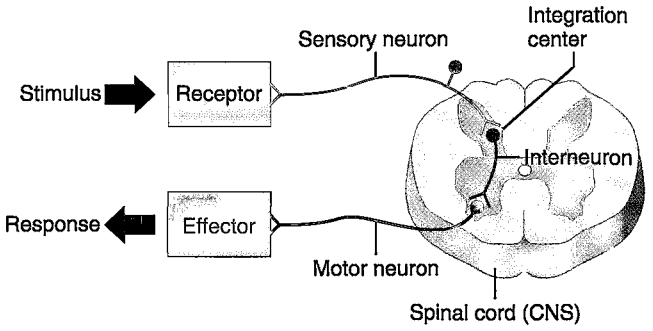

FIGURE 11.25 **A simple reflex arc.** Receptors detect changes in the internal or external environment. Effectors are muscles or glands.

sensory pathways from receptors to the brain are also examples. Because reflexes are the functional units of the nervous system, it is important that you understand them early on.

Reflexes are rapid, automatic responses to stimuli, in which a particular stimulus always causes the *same* response. Reflex activity, which produces the simplest of behaviors, is stereotyped and dependable. For example, jerking away your hand after touching a hot object is the norm, and an object approaching the eye triggers a blink. Reflexes occur over neural pathways called **reflex arcs** that have five essential components—receptor, sensory neuron, CNS integration center, motor neuron, and effector (Figure 11.25).

Parallel Processing

In **parallel processing,** inputs are segregated into many pathways, and information delivered by each pathway is dealt with simultaneously by different parts of the neural circuitry. For example, smelling a pickle (the input) may cause you to remember picking cucumbers on a farm; or it may remind you that you don't like pickles or that you must buy some at the market; or perhaps it will call to mind *all* these thoughts. For each person, parallel processing triggers some pathways that are unique. The same stimulus—pickle smell, in our example—promotes many responses beyond simple awareness of the smell. Parallel processing is not repetitious because the circuits do different things with the information, and each "channel" is decoded in relation to all the others to produce a total picture.

Think, for example, about what happens when you step on something sharp while walking barefoot. The serially processed withdrawal reflex causes instantaneous removal of your injured foot from the sharp object (painful stimulus). At the same time, pain and pressure impulses are speeding up to the brain along parallel pathways that allow you to decide whether to simply rub the hurt spot to soothe it or to seek first aid.

Parallel processing is extremely important for higher level mental functioning—for putting the parts together to understand the whole. For example, you can recognize a dollar bill in a split second, a task that takes a serial-based computer a fairly long time. This is because you use parallel processing, which allows a single neuron to send information along several pathways instead of just one, so a large amount of information is processed much more quickly.

Developmental Aspects of Neurons

The nervous system is covered in several chapters, so we limit our attention here to the development of neurons, beginning with the questions, How do nerve cells originate? and How do they mature?

The nervous system originates from a dorsal *neural tube* and the *neural crest* (see Figure 12.1, p. 431), formed from surface ectoderm. The neural tube, whose walls begin as a layer of *neuroepithelial* cells, becomes the CNS. The neuroepithelial cells then begin a three-phase process of differentiation, which occurs largely in the second month of development. (1) They *proliferate* to produce the appropriate number of cells needed for nervous system development. (2) The potential neurons, **neuroblasts,** become amitotic and *migrate* externally into their characteristic positions. (3) The neuroblasts sprout axons to *connect with* their functional targets and in so doing become neurons.

How does a neuroblast's growing axon "know" where to go—and once it gets there, where to make the proper connection? This question has been a topic of intense research over the past decade. We now know a great deal about how axons find their correct targets. The growth of an axon toward an appropriate target requires multiple steps and is guided by multiple signals. The growing tip of an axon, called a **growth cone,** is a prickly, fanlike structure that gives an axon the ability to interact with its environment. Extracellular and cell surface adhesion proteins such as laminin, integrin, and *nerve cell adhesion molecule (N-CAM)* provide anchor points for the growth cone, saying, "It's okay to grow here." *Neurotropins* are chemicals that signal to the growth cone "come this way" (netrin) or "go away" (ephrin) or "stop here" (semaphorin). Throughout this growth and development, neurotrophic factors such as *nerve growth factor (NGF)* must be present to keep the neuroblast alive. Failure of any of these guiding signals results in catastrophic developmental problems. For example, lack of N-CAM action causes developing

A CLOSER LOOK

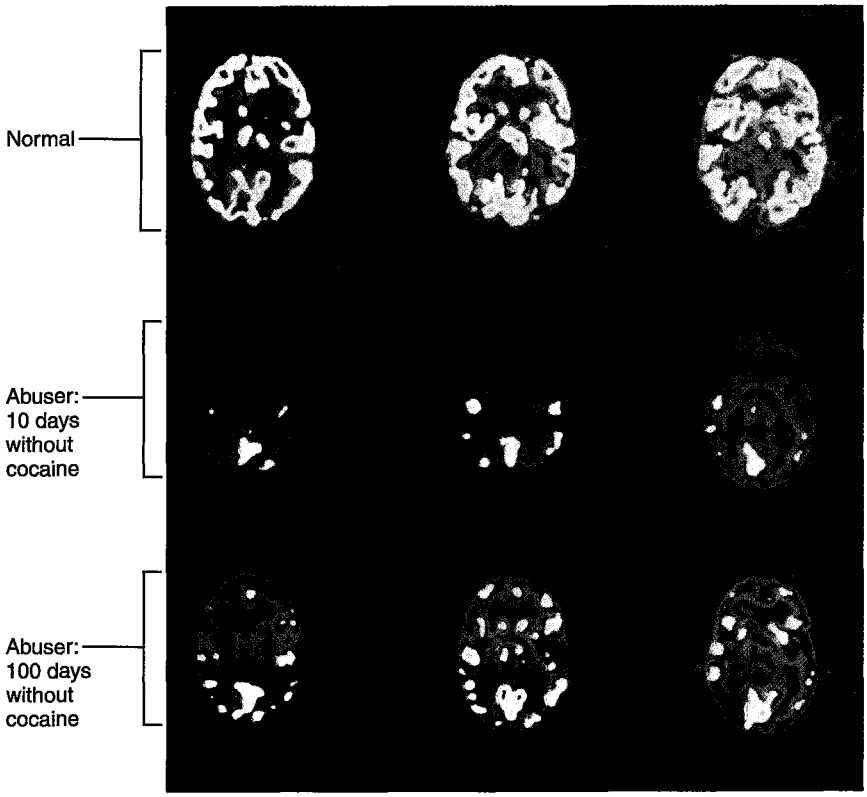
Pleasure Me, Pleasure Me!

Sex! Drugs! Rock 'n' roll! Eat, drink and be merry! Why do we find these activities so compelling? Our brains are wired to give us pleasurable rewards when we engage in behavior that is necessary for our own and our species' survival. This reward system consists of dopamine-releasing neurons in areas of the brain called the *ventral tegmental area* (VTA), the *nucleus accumbens,* and the *amygdala.*

Our ability to "feel good" involves brain neurotransmitters in this reward system. For example, the ecstasy of romantic love may be just a brain bath of glutamate and norepinephrine, which act on the reward system to release dopamine. Cole Porter knew what he was talking about when he wrote "I get a kick out of you," because these neurotransmitters are chemical cousins of the amphetamines. People who use "crystal meth" (methamphetamine) artificially stimulate their brains to provide their highly addictive pleasure flush. However, their pleasure is short-lived, because when the brain is flooded with neurotransmitter-like chemicals from the outside, it makes less of its own (why bother?).

Unfortunately, this powerful system can be subverted by drugs of abuse. Cocaine, another reward system titillater, has been around since ancient times. Once a toy of the rich, its granular form is inhaled, or "snorted." The laws of supply and demand have now brought cheaper cocaine to the masses, notably "crack"—a cheaper, more potent, smokable form of cocaine. For ten dollars or so, a novice user can experience a rush of intense pleasure. But crack is treacherous and intensely addictive. It produces not only a higher high than the inhaled form of cocaine, but also a deeper crash that leaves the user desperate for more.

How does cocaine produce its effects? Basically, the drug stimulates the reward system and then "squeezes it dry." Cocaine produces its rush by hooking up to the dopamine reuptake transporter protein, thus blocking the reabsorption of dopamine. The neurotransmitter remains in the synapse and stimulates the postsynaptic receptor cells again and again, allowing the body to feel its effects over a prolonged period. This sensation is accompanied by increases in heart rate, blood pressure, and sexual appetite. As dopamine uptake continues to be blocked by repeated doses of cocaine, the system releases less and less dopamine and the reward system effectively goes dry. The cocaine user becomes anxious and, in a very real



PET scans show that normal levels of brain activity (yellow and red) are depressed in cocaine users long after drug use has stopped.

11

neural tissue to fall into a tangled, spaghetti-like mass and hopelessly impairs neural function.

The growth cone gropes along like an amoeba, with oozing processes called *filopodia* which detect the guiding signals in the surrounding environment. Receptors for these signals generate various second messengers that cause the filopodia to move by rearranging their actin protein cores. Once the axon has reached its target area, it must select the right site on the target cell to form a synapse, an event that requires signaling by both presynaptic and postsynaptic cells. This process is not yet well understood, but involves clustering postsynaptic neurotransmitter receptors while the postsynaptic cell tells the presynaptic cell what neurotransmitters to make. In the brain and spinal cord, astrocytes seem to provide both physical support and the cholesterol essential for constructing synapses. Both dendrites and astrocytes are active partners in the process of synapse formation. In the presence of thrombospondin released by astrocytes,

sense, unable to experience pleasure without the drug. Consequently, the postsynaptic cells become hypersensitive and sprout new receptors in a desperate effort to pick up dopamine signals. A vicious cycle of addiction begins: Cocaine is needed to experience pleasure, but using it suppresses dopamine release even more.

The dopamine effect alone is not enough to establish addiction. Another neurotransmitter, glutamate, which plays an important role in learning, is required to maintain addiction. Glutamate signaling seems to cause more permanent changes in the brain (synaptic potentiation) that lead to compulsive drug-seeking behaviors elicited by external cues. Take, for example, mice genetically engineered to lack a particular glutamate receptor (GluR5). These mice are perfectly willing to try cocaine but never become addicted. (Of course, they're none too bright, either.)

Current thinking, then, is that the rush of pleasure on taking cocaine is due to dopamine. Glutamate, on the other hand, is thought to be responsible for the learning that makes true the perception "once an addict, always an addict." So strong is the combined dopamine and glutamate system that, even years later, certain settings can trigger intense cravings for the drug.

These out-of-control, desperate cravings are notoriously difficult to manage. Drug abusers call it "jonesing." Traditional antiaddiction drugs take so long to reduce the cravings that users commonly drop out of treatment programs. How can we break this cycle of addiction? One way is to prevent cocaine from ever reaching the brain. Researchers have created a vaccine that prevents cocaine from entering the brain, and clinical trials on this vaccine are ongoing. Another approach to breaking the addiction cycle is to even out the highs and lows experienced by the drug user. Clinical trials are under way with a drug (vanoxerine) that slowly binds the dopamine reuptake transporter and inhibits it in a more long-lasting manner than cocaine does. This results in a leveling-out of brain dopamine levels and keeps the user from "crashing" so badly. A final approach to breaking the addiction cycle is to interrupt the learned reinforcement that brings on cravings. An effective ancient African folk remedy called ibogaine may do exactly this. However, ibogaine itself is too toxic for clinical use, as some unfortunate "underground" users have discovered. A close synthetic cousin, 18-methoxycoronaridine (18-MC) is much less toxic and promises to be effective against not only cocaine but also a number of other abused drugs. Future studies will show if it is truly effective.

The craving for drugs has made some who depend on them into very creative home pharmacologists, willing to experiment with practically anything, no matter how toxic or dangerous, to get the "buzz" they need. A cheap mixture of cold medications, match heads, and iodine in acetone yields crystal meth—the highly addictive and once-again popular drug that wrecks people's lives and often explodes their home laboratories. Another creative mixture, with the street name of "ill face" or "illy," involves dipping marijuana in formaldehyde, drying and then smoking it. Other remarkable combinations are the "H-bomb" (ecstasy mixed with heroin), "A-bomb" (marijuana with heroin or opium), "sextasy" [ecstasy mixed with sildenafil (Viagra)], "octane" (PCP laced with gasoline), and "ozone" (marijuana, PCP, and crack in a cigarette). Formaldehyde is a known cancer-causing agent and gasoline damages the liver, but the real damage comes from the drugs themselves. Take, for example, ecstasy, a drug that many of its users believe to be innocuous. In reality, ecstasy (MDMA) targets serotonin-releasing neurons. The "rush" of pleasure and energy that users feel is due to release of serotonin and other neurotransmitters. However, it damages and may destroy these neurons, causing the loss of verbal and spatial memory. Depression, sleeplessness, and memory problems may be permanent consequences—a high price for a few moments of pleasure!

People who want pure, effective, and "safe" drugs of abuse don't get them on the street. They get them from doctors or "pill ladies" [female senior citizens who sell oxycodone (OxyContin), a powerful prescription opioid with effects similar to heroin]. Even those who would never dream of taking the illicit drugs can be caught in the addictive cycle of prescription drugs. Prescribed legitimately to relieve severe pain, oxycodone is meant to be swallowed whole. Abusers crush the tablets and snort the powder or dissolve it in water and inject the solution. Oxycodone abuse is spreading rapidly. Medical examiners across North America report soaring rates of oxycodone-related emergency room visits and deaths.

The brain, with its complex biochemistry, always circumvents attempts to keep it in a euphoric haze. Perhaps this means that pleasure must be transient by nature, experienced only against a background of its absence. ■

dendrites actually reach out and grasp migrating axons, and synapses begin sprouting.

Neurons that fail to make appropriate or functional synaptic contacts act as if they have been deprived of some essential nutrient and die. Besides cell death resulting from unsuccessful synapse formation, *apoptosis* (programmed cell death) also appears to be a normal part of the developmental process. Of the neurons formed during the embryonic period, perhaps two-thirds die before we are born. Those that remain constitute most of our neural endowment for life. The generally amitotic nature of neurons is important because their activity depends on the synapses they've formed; if neurons were to divide, their connections might be hopelessly disrupted. This aside, there *do* appear to be some specific neuronal populations where stem cells are found and new neurons can be formed—notably olfactory neurons and some cells of the hippocampus, a brain region involved in learning and memory.

■ ■ ■

In this chapter, we have examined how the amazingly complex neurons, via electrical and chemical signals, serve the body in a variety of ways: Some serve as "lookouts," others process information for immediate use or for future reference, and still others stimulate the body's muscles and glands into activity. With this background, we are ready to study the most sophisticated mass of neural tissue in the entire body—the brain (and its continuation, the spinal cord), the focus of Chapter 12.

Related Clinical Terms

Neuroblastoma (nu"ro-blas-to'mah; *oma* = tumor) A malignant tumor in children; arises from cells that retain a neuroblast-like structure. These tumors sometimes arise in the brain, but most occur in the peripheral nervous system.

Neurologist (nu-rol'o-jist) A medical specialist in the study of the nervous system, its functions, and its disorders.

Neuropathy (nu-rop'ah-the) Any disease of nervous tissue, but particularly degenerative disease of nerves.

Neuropharmacology (nu"ro-far"mah-kol'o-je) Scientific study of the effects of drugs on the nervous system.

Neurotoxin Substance that is poisonous or destructive to nervous tissue, e.g., botulinum and tetanus toxins.

Rabies (*rabies* = madness) A viral infection of the nervous system transmitted by the bite of an infected mammal (such as a dog, bat, or skunk). After entry, the virus travels via axonal transport in peripheral nerve axons to the CNS, where it causes brain inflammation, delirium, and death. A vaccine- and antibody-based treatment is effective if given before symptoms appear; rabies in humans is very rare in the United States.

Shingles (herpes zoster) A viral infection of sensory neurons serving the skin. Characterized by scaly, painful blisters usually confined to a narrow strip of skin, often on one side of the body trunk. Caused by the varicella-zoster virus, which causes chicken pox (generally during childhood); during this initial infection the virus is transported from the skin lesions to the sensory cell bodies in the sensory ganglia. Typically, the virus is held in check by the immune system and remains dormant until the immune system is weakened, often by stress. Then viral particles multiply and travel back to the skin, producing the characteristic rash. Attacks last several weeks, alternating between periods of healing and relapse. Seen mostly in those over 50 years old.

Chapter Summary

11

Media study tools that could provide you additional help in reviewing specific key topics of Chapter 11 are referenced below.

IP = *InterActive Physiology*

1. The nervous system bears a major responsibility for maintaining body homeostasis. Its chief functions are to monitor, integrate, and respond to information in the environment.

Organization of the Nervous System (pp. 388–389)

1. The nervous system is divided anatomically into the central nervous system (brain and spinal cord) and the peripheral nervous system (cranial and spinal nerves).

2. The major functional divisions of the nervous system are the sensory (afferent) division, which conveys impulses to the CNS, and the motor (efferent) division, which conveys impulses from the CNS.

3. The efferent division includes the somatic (voluntary) system, which serves skeletal muscles, and the autonomic (involuntary) system, which innervates smooth and cardiac muscle and glands.

Histology of Nervous Tissue (pp. 389–397)

Neuroglia (pp. 389–391)

1. Neuroglia (supporting cells) segregate and insulate neurons and assist neurons in various other ways.

2. CNS neuroglia include astrocytes, microglia, ependymal cells, and oligodendrocytes. Schwann cells and satellite cells are neuroglia found in the PNS.

Neurons (pp. 391–397)

3. Neurons have a cell body and cytoplasmic processes called axons and dendrites.

4. A bundle of nerve fibers is called a tract in the CNS and a nerve in the PNS. A collection of cell bodies is called a nucleus in the CNS and a ganglion in the PNS.

5. The cell body is the biosynthetic (and receptive) center of the neuron. Except for those found in ganglia, cell bodies are found in the CNS.

6. Some neurons have many dendrites, receptive sites that conduct signals from other neurons toward the nerve cell body. With few exceptions, all neurons have one axon, which generates and conducts nerve impulses away from the nerve cell body. Terminal endings of axons release neurotransmitter.

7. Bidirectional transport along axons uses ATP-dependent motor proteins "walking" along microtubule tracks. It moves vesicles, mitochondria, and cytosolic proteins toward the axon terminals and conducts substances destined for degradation back to the cell body. It involves microtubules and motor proteins.

8. Large nerve fibers (axons) are myelinated. The myelin sheath is formed in the PNS by Schwann cells and in the CNS by oligodendrocytes. The sheath has gaps called nodes of Ranvier. Unmyelinated fibers are surrounded by supporting cells, but the membrane-wrapping process does not occur.

9. Anatomically, neurons are classified according to the number of processes issuing from the cell body as multipolar, bipolar, or unipolar.

10. Functionally, neurons are classified according to the direction of nerve impulse conduction. Sensory neurons conduct impulses toward the CNS, motor neurons conduct away from the CNS, and interneurons (association neurons) lie between sensory and motor neurons in the neural pathways.

Nervous System I; Topic: Anatomy Review, pp. 1–12.

Neurophysiology (pp. 397–421)

Basic Principles of Electricity (pp. 397–399)

1. The measure of the potential energy of separated electrical charges is called voltage (*V*) or potential. Current (*I*) is the flow of electrical charge from one point to another. Resistance (*R*) is hindrance to current flow. The relationship among these is given by Ohm's law: $I = V/R$.

2. In the body, electrical charges are provided by ions; cellular plasma membranes provide resistance to ion flow. The membranes contain leakage channels (nongated, always open) and gated channels.

Nervous System I; Topic: Ion Channels, pp. 1–10.

The Resting Membrane Potential (pp. 399–400)

3. A resting neuron exhibits a resting membrane potential, which is −70 mV (inside negative). It is due to both differences in sodium and potassium ion concentrations inside and outside the cell and differences in permeability of the membrane to these ions.

4. The ionic concentration differences result from the operation of the sodium-potassium pump, which ejects $3Na^+$ from the cell for each $2K^+$ transported in.

Nervous System I; Topic: The Membrane Potential, pp. 1–16.

Membrane Potentials That Act as Signals (pp. 400–408)

5. Depolarization is a reduction in membrane potential (inside becomes less negative); hyperpolarization is an increase in membrane potential (inside becomes more negative).

6. Graded potentials are small, brief, local changes in membrane potential that act as short-distance signals. The current produced dissipates with distance.

7. An action potential (AP), or nerve impulse, is a large, but brief, depolarization signal (and polarity reversal) that underlies long-distance neural communication. It is an all-or-none phenomenon.

8. An AP has three underlying changes in membrane permeability: (1) Increase in sodium permeability: Local depolarization opens voltage-gated Na^+ channels; at threshold, depolarization becomes self-generating (driven by Na^+ influx). The membrane potential is reversed to approximately +30 mV (inside positive). (2) Decrease in sodium permeability. (3) Increase in potassium permeability. Repolarization occurs during phases 2 and 3.

9. In nerve impulse propagation, each AP provides the depolarizing stimulus for triggering an AP in the next membrane patch. Regions that have just generated APs are refractory; hence, the nerve impulse is propagated in one direction only.

10. If threshold is reached, an AP is generated; if not, depolarization remains local.

11. APs are independent of stimulus strength: strong stimuli cause APs to be generated more frequently but not with greater amplitude.

12. During the absolute refractory period, a neuron cannot respond to another stimulus because it is already generating an AP. During the relative refractory period the neuron's threshold is elevated because repolarization is ongoing.

13. In unmyelinated fibers, APs are produced in a wave all along the axon, that is, by continuous conduction. In myelinated fibers, APs are generated only at nodes of Ranvier and are propagated more rapidly by saltatory conduction.

Nervous System I; Topic: The Action Potential, pp. 1–18.

The Synapse (pp. 408–411)

14. A synapse is a functional junction between neurons. The information-transmitting neuron is the presynaptic neuron; the information-receiving neuron is the postsynaptic neuron.

15. Electrical synapses allow ions to flow directly from one neuron to another; the cells are electrically coupled.

16. Chemical synapses are sites of neurotransmitter release and binding. When the impulse reaches the presynaptic axon terminals, voltage-gated Ca^{2+} channels open, and Ca^{2+} enters the cell and mediates neurotransmitter release. Neurotransmitters diffuse across the synaptic cleft and attach to postsynaptic membrane receptors, opening ion channels. After binding, the neurotransmitters are removed from the synapse by enzymatic breakdown or by reuptake into the presynaptic terminal or astrocytes.

Nervous System II; Topics: Anatomy Review, pp. 1–9, Ion Channels, pp. 1–8, Synaptic Transmission, pp. 1–7.

Postsynaptic Potentials and Synaptic Integration (pp. 411–413)

17. Binding of neurotransmitter at excitatory chemical synapses results in local graded potentials called EPSPs, caused by the opening of channels that allow simultaneous passage of Na^+ and K^+.

18. Neurotransmitter binding at inhibitory chemical synapses results in hyperpolarizations called IPSPs, caused by the opening of K^+ or Cl^- channels. IPSPs drive the membrane potential farther from threshold.

19. EPSPs and IPSPs summate temporally and spatially. The membrane of the axon hillock acts as a neuronal integrator.

20. Synaptic potentiation, in which the postsynaptic neuron's response is enhanced, is produced by intense repeated stimulation. Ionic calcium appears to mediate such effects, which may be the basis of learning.

21. Presynaptic inhibition is mediated by axoaxonic synapses that reduce the amount of neurotransmitter released by the inhibited neuron.

Nervous System II; Topic: Synaptic Potentials and Cellular Integration, pp. 1–10.

Neurotransmitters and Their Receptors (pp. 413–421)

22. The major classes of neurotransmitters based on chemical structure are acetylcholine, biogenic amines, amino acids, peptides, purines, and dissolved gases.

23. Functionally, neurotransmitters are classified as (1) inhibitory or excitatory (or both) and (2) direct or indirect. Direct-acting neurotransmitters bind to and open ion channels. Indirect-acting neurotransmitters act through second messengers. Neuromodulators also act indirectly presynaptically or postsynaptically to change synaptic strength.

24. Neurotransmitter receptors are either channel-linked receptors that open ion channels, leading to fast changes in membrane potential, or G protein–linked receptors that oversee slow synaptic responses mediated by G proteins and intracellular second messengers. Second messengers most often activate kinases, which in turn act on ion channels or activate other proteins.

Nervous System II; Topic: Synaptic Transmission pp. 6–15.

Basic Concepts of Neural Integration (pp. 421–423)

Organization of Neurons: Neuronal Pools (p. 421)

1. CNS neurons are organized into several types of neuronal pools, each with distinguishing patterns of synaptic connections called circuits.

Types of Circuits (pp. 421–422)

2. The four basic circuit types are diverging, converging, reverberating, and parallel after-discharge.

Patterns of Neural Processing (pp. 422–423)

3. In serial processing, one neuron stimulates the next in sequence, producing specific, predictable responses, as in spinal reflexes. A reflex is a rapid, involuntary motor response to a stimulus.

4. Reflexes are mediated over neural pathways called reflex arcs. The minimum number of elements in a reflex arc is five: receptor, sensory neuron, integration center, motor neuron, and effector.

5. In parallel processing, which underlies complex mental functions, impulses are sent along several pathways to different integration centers.

Developmental Aspects of Neurons (pp. 423–425)

1. Neuron development involves proliferation, migration, and cellular differentiation. Cellular differentiation entails neuron specialization, specific neurotransmitter synthesis, and synapse formation.

2. Axon outgrowth and synapse formation are guided by other neurons, glial fibers, and chemicals (such as N-CAM and nerve growth factor). Neurons that do not make appropriate synapses die, and approximately two-thirds of neurons formed in the embryo undergo programmed cell death before birth.

Review Questions

Multiple Choice/Matching

(Some questions have more than one correct answer. Select the best answer or answers from the choices given.)

1. Which of the following structures is not part of the central nervous system? (a) the brain, (b) a nerve, (c) the spinal cord, (d) a tract.

2. Match the names of the supporting cells found in column B with the appropriate descriptions in column A.

Column A	Column B
____ (1) myelinates nerve fibers in the CNS	(a) astrocyte
____ (2) lines brain cavities	(b) ependymal cell
____ (3) myelinates nerve fibers in the PNS	(c) microglia
____ (4) CNS phagocytes	(d) oligodendrocyte
____ (5) helps regulate the ionic composition of CNS extracellular fluid	(e) satellite cell
	(f) Schwann cell

3. What type of current flows through the axolemma during the steep phase of repolarization? (a) chiefly a sodium current, (b) chiefly a potassium current, (c) sodium and potassium currents of approximately the same magnitude.

4. Assume that an EPSP is being generated on the dendritic membrane. Which will occur? (a) specific Na^+ channels will open, (b) specific K^+ channels will open, (c) a single type of channel will open, permitting simultaneous flow of Na^+ and K^+, (d) Na^+ channels will open first and then close as K^+ channels open.

5. The velocity of nerve impulse conduction is greatest in (a) heavily myelinated, large-diameter fibers, (b) myelinated, small-diameter fibers, (c) unmyelinated, small-diameter fibers, (d) unmyelinated, large-diameter fibers.

6. Chemical synapses are characterized by all of the following except (a) the release of neurotransmitter by the presynaptic membranes, (b) postsynaptic membranes bearing receptors that bind neurotransmitter, (c) ions flowing through protein channels from the presynaptic to the postsynaptic neuron, (d) a fluid-filled gap separating the neurons.

7. Biogenic amine neurotransmitters include all but (a) norepinephrine, (b) acetylcholine, (c) dopamine, (d) serotonin.

8. The neuropeptides that act as natural opiates are (a) substance P, (b) somatostatin, (c) cholecystokinin, (d) enkephalins.

9. Inhibition of acetylcholinesterase by poisoning blocks neurotransmission at the neuromuscular junction because (a) ACh is no longer released by the presynaptic terminal, (b) ACh synthesis in the presynaptic terminal is blocked, (c) ACh is not degraded, hence prolonged depolarization is enforced on the postsynaptic neuron, (d) ACh is blocked from attaching to the postsynaptic ACh receptors.

10. The anatomical region of a multipolar neuron that has the lowest threshold for generating an AP is the (a) soma, (b) dendrites, (c) axon hillock, (d) distal axon.

11. An IPSP is inhibitory because (a) it hyperpolarizes the postsynaptic membrane, (b) it reduces the amount of neurotransmitter released by the presynaptic terminal, (c) it prevents calcium ion entry into the presynaptic terminal, (d) it changes the threshold of the neuron.

12. Identify the neuronal circuits described by choosing the correct response from the key.

Key: (a) converging
(b) diverging
(c) parallel after-discharge
(d) reverberating

____ (1) Impulses continue around and around the circuit until one neuron stops firing.
____ (2) One or a few inputs ultimately influence large numbers of neurons.
____ (3) Many neurons influence a few neurons.
____ (4) May be involved in exacting types of mental activity.

Short Answer Essay Questions

13. Explain both the anatomical and functional divisions of the nervous system. Include the subdivisions of each.

14. (a) Describe the composition and function of the cell body. (b) How are axons and dendrites alike? In what ways (structurally and functionally) do they differ?

15. (a) What is myelin? (b) How does the myelination process differ in the CNS and PNS?

16. (a) Contrast unipolar, bipolar, and multipolar neurons structurally. (b) Indicate where each is most likely to be found.

17. What is the polarized membrane state? How is it maintained? (Note the relative roles of both passive and active mechanisms.)

18. Describe the events that must occur to generate an AP. Relate the sequence of changes in permeability to changes in the ion channels, and explain why the AP is an all-or-none phenomenon.

19. Since all APs generated by a given nerve fiber have the same magnitude, how does the CNS "know" whether a stimulus is strong or weak?

20. (a) Explain the difference between an EPSP and an IPSP. (b) What specifically determines whether an EPSP or IPSP will be generated at the postsynaptic membrane?

21. Since at any moment a neuron is likely to have thousands of neurons releasing neurotransmitters at its surface, how is neuronal activity (to fire or not to fire) determined?

22. The effects of neurotransmitter binding are very brief. Explain.

23. During a neurobiology lecture, a professor repeatedly refers to group A and group B fibers, absolute refractory period, and nodes of Ranvier. Define these terms.

24. Distinguish between serial and parallel processing.

25. Briefly describe the three stages of neuron development.

26. What factors appear to guide the outgrowth of an axon and its ability to make the "correct" synaptic contacts?

Critical Thinking and Clinical Application Questions

1. Mr. Miller is hospitalized for cardiac problems. Somehow, medical orders are mixed up and Mr. Miller is infused with a K^+-enhanced intravenous solution meant for another patient who is taking potassium-wasting diuretics (i.e., drugs that cause excessive loss of potassium from the body in urine). Mr. Miller's potassium levels are normal before the IV is administered. What do you think will happen to Mr. Miller's resting membrane potentials? To his neurons' ability to generate APs?

2. Local anesthetics block voltage-gated Na^+ channels. General anesthetics are thought to activate chemically gated Cl^- channels, thereby rendering the nervous system quiescent while surgery is performed. What specific process do anesthetics impair, and how does this interfere with nerve transmission?

3. When admitted to the emergency room, John was holding his right hand, which had a deep puncture hole in its palm. He explained that he had fallen on a nail while exploring a barn. John was given an antitetanus shot to prevent neural complications. Tetanus bacteria fester in deep, dark wounds, but how do they travel in neural tissue?

4. Rochelle developed multiple sclerosis when she was 27. After eight years she had lost a good portion of her ability to control her skeletal muscles. How did this happen?

5. In the Netherlands a young man named Jan was admitted to the emergency room. He and his friends had been to a rave. His friends say he started twitching and having muscle spasms which progressed until he was "stiff as a board." On examination, staff found a marked increase in muscle tone and hyperreflexia involving facial and limb muscles. In his pocket, he had unmarked dark yellow tablets with dark flecks. Analysis of the tablets showed them to contain a mixture of ecstasy and strychnine. Ecstasy would not cause this clinical picture, but strychnine, which blocks glycine receptors, could. Explain how.

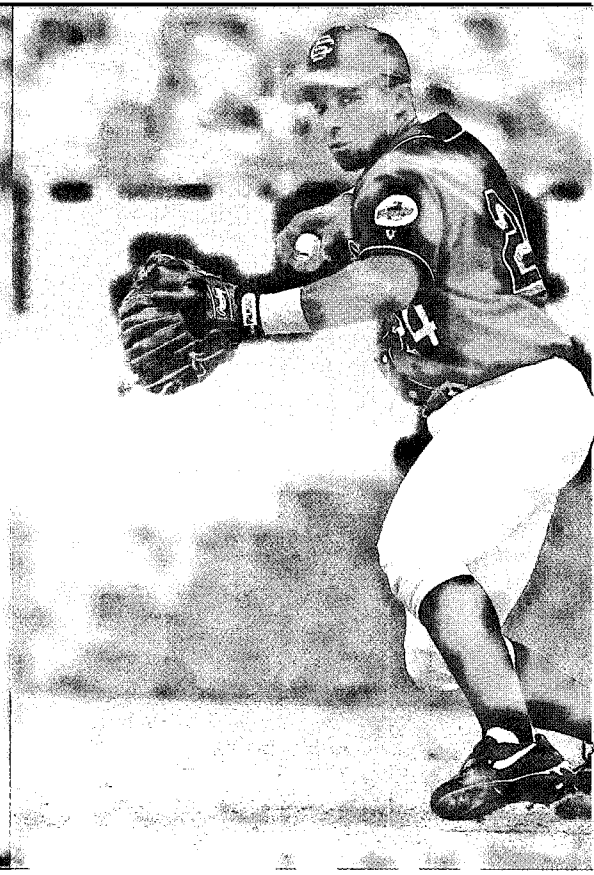
CHAPTER

The Central Nervous System



The Brain (pp. 431–456)

1. Describe the process of brain development.
2. Name the major regions of the adult brain.
3. Name and locate the ventricles of the brain.
4. List the major lobes, fissures, and functional areas of the cerebral cortex.
5. Explain lateralization of hemisphere function.
6. Differentiate between commissures, association fibers, and projection fibers.
7. Describe the general function of the basal nuclei (basal ganglia).
8. Describe the location of the diencephalon, and name its subdivisions.
9. Identify the three major regions of the brain stem, and note the functions of each area.
10. Describe the structure and function of the cerebellum.
11. Locate the limbic system and the reticular formation, and explain the role of each functional system.

Higher Mental Functions (pp. 456–463)

12. Define EEG and distinguish between alpha, beta, theta, and delta brain waves.
13. Compare and contrast the events and importance of slow-wave and REM sleep, and indicate how their patterns change through life.
14. Describe consciousness clinically.
15. Compare and contrast the stages and categories of memory.
16. Describe the relative roles of the major brain structures believed to be involved in declarative and procedural memories.

Protection of the Brain (pp. 463–470)

17. Describe how meninges, cerebrospinal fluid, and the blood-brain barrier protect the CNS.
18. Describe the formation of cerebrospinal fluid, and follow its circulatory pathway.
19. Describe the cause (if known) and major signs and symptoms of cerebrovascular accidents, Alzheimer's disease, Huntington's disease, and Parkinson's disease.

The Spinal Cord (pp. 470–481)

20. Describe the embryonic development of the spinal cord.
21. Describe the gross and microscopic structure of the spinal cord.
22. List the major spinal cord tracts, and classify each as a motor or sensory tract.
23. Distinguish between flaccid and spastic paralysis and between paralysis and paresthesia.

Diagnostic Procedures for Assessing CNS Dysfunction (p. 481)

24. List and explain several techniques used to diagnose brain disorders.

Developmental Aspects of the Central Nervous System (pp. 481–484)

25. Indicate several maternal factors that can impair development of the nervous system in an embryo.
26. Explain the effects of aging on the brain.

Historically, the **central nervous system (CNS)**—brain and spinal cord—has been compared to the central switchboard of a telephone system that interconnects and directs a dizzying number of incoming and outgoing calls. Nowadays, many people compare it to a supercomputer. These analogies may explain some workings of the spinal cord, but neither does justice to the fantastic complexity of the human brain. Whether we view the brain as an evolved biological organ, an impressive computer, or simply a miracle, it is one of the most amazing things known.

During the course of animal evolution, **cephalization** (sĕ"fah-lĭ-za'shun) has occurred. That is, there has been an elaboration of the rostral ("toward the snout"), or anterior, portion of the CNS, along with an increase in the number of neurons in the head. This phenomenon reaches its highest level in the human brain.

In this chapter, we examine the structure of the CNS and the functions associated with its various regions. Complex integrative functions, such as sleep-wake cycles and memory, are also touched on.

The Brain

The unimpressive appearance of the human **brain** gives few hints of its remarkable abilities. It is about two good fistfuls of quivering pinkish gray tissue, wrinkled like a walnut, and somewhat the consistency of cold oatmeal. The average adult man's brain has a mass of about 1600 g (3.5 lb); that of a woman averages 1450 g (3.2 lb). In terms of brain mass per body mass, however, males and females have equivalent brain sizes.

Embryonic Development

We begin our study of the brain with brain embryology, as the terminology used for the structural divisions of the adult brain is easier to follow when you understand brain development.

The earliest phase of brain development is shown in Figure 12.1. Starting in the three-week-old embryo, the ectoderm (cell layer at the dorsal surface) thickens along the dorsal midline axis of the embryo to form the **neural plate.** The neural plate then invaginates, forming a groove flanked by **neural folds.** As this **neural groove** deepens, the superior edges of the neural folds fuse, forming the **neural tube,** which soon detaches from the surface ectoderm and sinks to a deeper position. The neural tube, formed by the fourth week of pregnancy, differentiates rapidly into the CNS. The brain forms anteriorly (rostrally) and the spinal cord develops from the caudal ("toward the tail") or posterior portion of the neural tube. Small

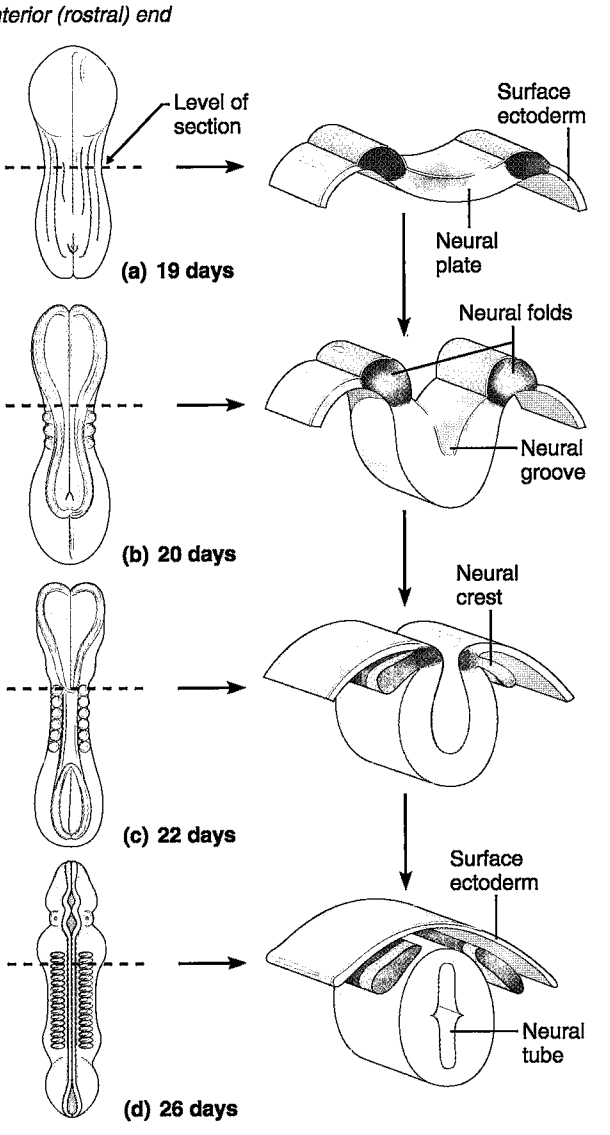


FIGURE 12.1 **Development of the neural tube from embryonic ectoderm.** Left: dorsal surface views of the embryo; right: transverse sections. **(a)** Formation of the neural plate from surface ectoderm. **(b–d)** Development of neural plate into neural groove (flanked by neural folds) and then neural tube. The neural tube forms CNS structures; neural crest cells form some PNS structures.

groups of neural fold cells migrate laterally from between the surface ectoderm and the neural tube, forming the **neural crest** (Figure 12.1c). Neural crest cells give rise (among other things) to some neurons destined to reside in ganglia.

As soon as the neural tube forms, its anterior end immediately begins to expand and constrictions appear that mark off the three **primary brain vesicles** (Figure 12.2): the **prosencephalon** (pros"en-sef'ah-lon), or **forebrain;** the **mesencephalon** (mes"en-sef'ah-lon), or **midbrain;** and the **rhombencephalon** (romb"en-sef'ah-lon), or **hindbrain.** (Note

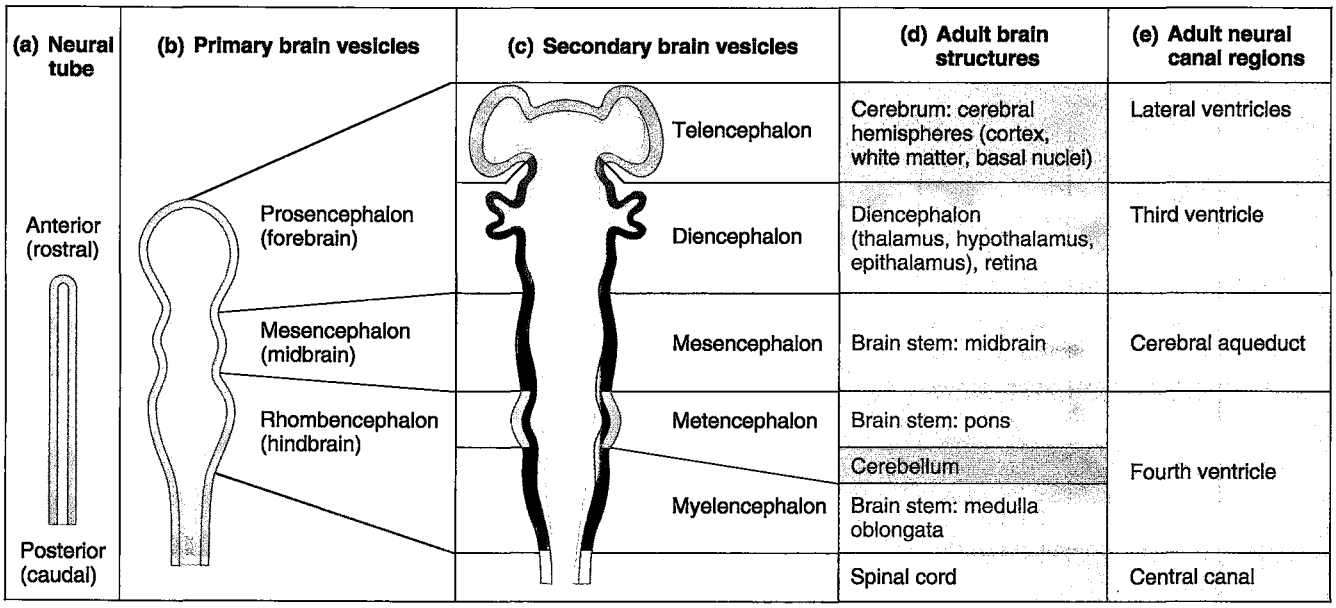

FIGURE 12.2 **Embryonic development of the human brain.** **(a)** Formed by week 4, the neural tube quickly subdivides into **(b)** the primary brain vesicles, which subsequently form **(c)** the secondary brain vesicles by week 5. These five vesicles differentiate into **(d)** the adult brain structures. **(e)** The adult structures derived from the neural canal.

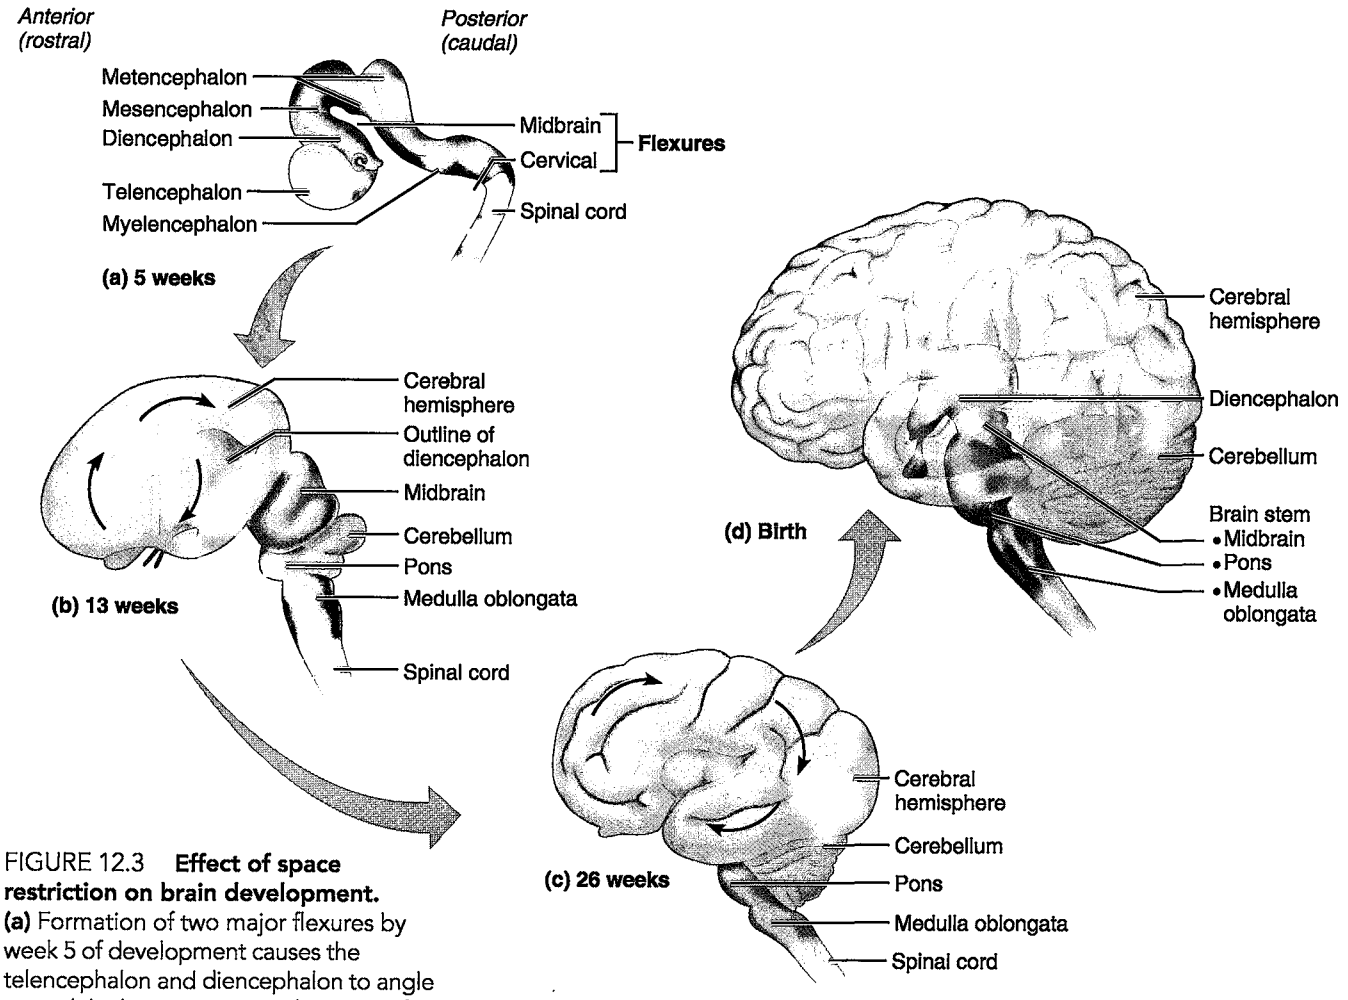

FIGURE 12.3 **Effect of space restriction on brain development.** **(a)** Formation of two major flexures by week 5 of development causes the telencephalon and diencephalon to angle toward the brain stem. Development of the cerebral hemispheres at **(b)** 13 weeks, **(c)** 26 weeks, and **(d)** birth. Initially, the cerebral surface is smooth; the folding begins in month 6, and convolutions become more obvious as development continues. The posterolateral growth of the cerebral hemispheres ultimately encloses the diencephalon and superior aspect of the brain stem (seen through the cerebral hemispheres in this see-through view).

that *encephalo* means "brain.") The remainder of the neural tube becomes the spinal cord (discussed later in the chapter).

In week 5, the primary vesicles give rise to the **secondary brain vesicles.** The forebrain divides into the **telencephalon** ("endbrain") and **diencephalon** ("interbrain"), and the hindbrain constricts, forming the **metencephalon** ("afterbrain") and **myelencephalon** ("spinal brain"). The midbrain remains undivided. Each of the five secondary vesicles then develops rapidly to produce the major structures of the adult brain (Figure 12.2d). The greatest change occurs in the telencephalon, which sprouts two lateral swellings that look like Mickey Mouse's ears. These become the two *cerebral hemispheres,* referred to collectively as the **cerebrum** (ser'ĕ-brum). The diencephalon part of the forebrain specializes to form the *hypothalamus* (hi"po-thal'ah-mus), *thalamus, epithalamus,* and *retina* of the eye. Less dramatic changes occur in the mesencephalon, metencephalon, and myelencephalon as these regions are transformed into the *midbrain,* the *pons* and *cerebellum,* and the *medulla oblongata,* respectively. All these midbrain and hindbrain structures, except the cerebellum, form the **brain stem.** The central cavity of the neural tube remains continuous and enlarges in four areas to form the fluid-filled *ventricles* (*ventr* = little belly) of the brain. The ventricles are described shortly.

Because the brain grows more rapidly than the membranous skull that contains it, two major flexures develop—the *midbrain* and *cervical flexures*—which bend the forebrain toward the brain stem (Figure 12.3a). A second consequence of restricted space is that the cerebral hemispheres are forced to take a horseshoe-shaped course and grow posteriorly and laterally (indicated by black arrows in Figure 12.3b and c). As a result, they grow back over and almost completely envelop the diencephalon and midbrain. By week 26, the continued growth of the cerebral hemispheres causes their surfaces to crease and fold (Figure 12.3c and d), producing *convolutions* and increasing their surface area, which allows more neurons to occupy the limited space.

Regions and Organization

Some textbooks discuss brain anatomy in terms of the *embryonic scheme* (see Figure 12.2c), but in this text, we will consider the brain in terms of the medical scheme and the adult brain regions shown in Figure 12.3d: (1) cerebral hemispheres, (2) diencephalon, (3) brain stem (midbrain, pons, and medulla), and (4) cerebellum.

The basic pattern of the CNS consists of a central cavity surrounded by a gray matter core, external to which is white matter (myelinated fiber tracts).

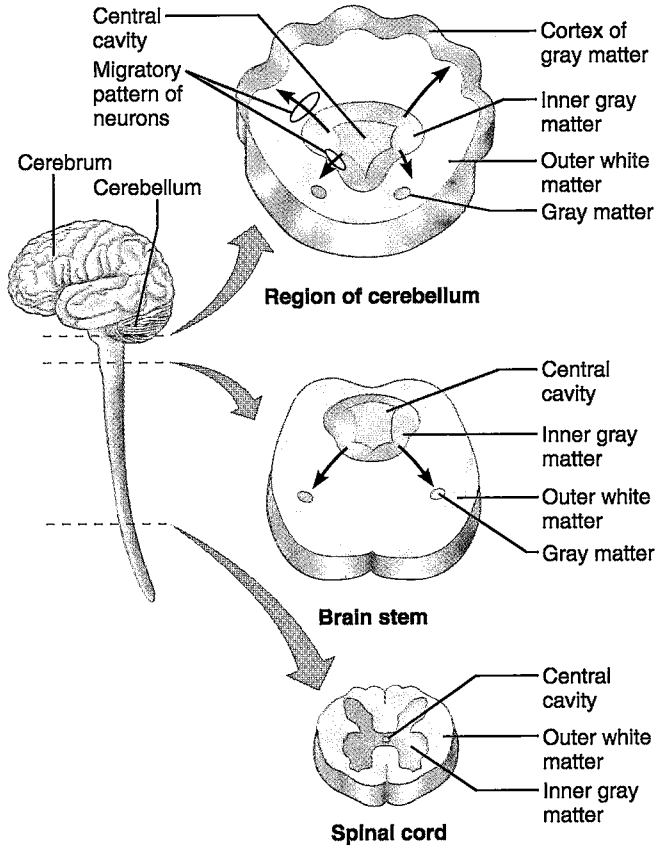

FIGURE 12.4 **Arrangement of gray and white matter in the CNS (highly simplified).** Cross sections at three CNS levels. In each section, the dorsal aspect is at the top. In general, white matter lies external to gray matter; however, collections of gray matter migrate externally into the white matter in the developing brain (see black arrows). The cerebrum resembles the cerebellum in its external cortex of gray matter.

The brain exhibits this basic design but has additional regions of gray matter not present in the spinal cord (Figure 12.4). Both the cerebral hemispheres and the cerebellum have an outer layer or "bark" of gray matter consisting of neuron cell bodies called a *cortex.* This pattern changes with descent through the brain stem—the cortex disappears, but scattered gray matter nuclei are seen within the white matter. At the caudal end of the brain stem, the basic pattern is evident.

Ventricles

As noted earlier, the brain **ventricles** arise from expansions of the lumen of the embryonic neural tube. They are continuous with one another and with the central canal of the spinal cord (Figure 12.5). The hollow ventricular chambers are filled with cerebrospinal fluid and lined by *ependymal cells,* a type of neuroglia (see Figure 11.3c on p. 390).

Q *Why are the lateral ventricles horn-shaped rather than vertically erect like the third and fourth ventricles?*

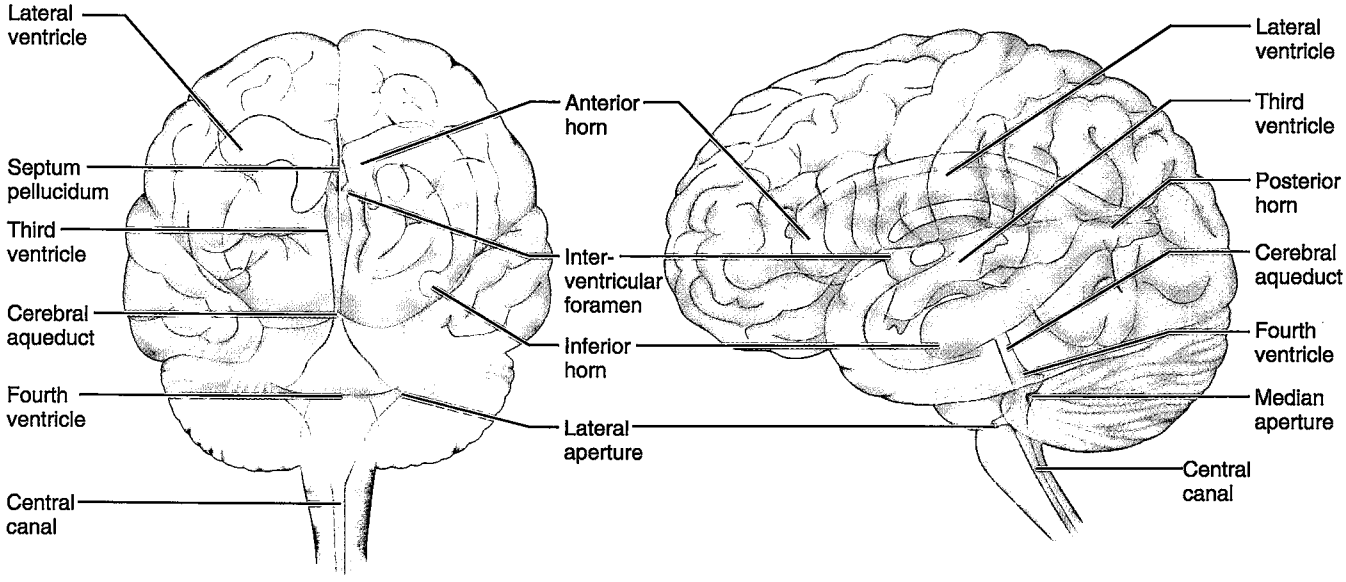

FIGURE 12.5 **Ventricles of the brain.** Note that different regions of the large lateral ventricles are indicated by the terms anterior horn, posterior horn, and inferior horn.

12

The paired **lateral ventricles,** one deep within each cerebral hemisphere, are large C-shaped chambers that reflect the pattern of cerebral growth. Anteriorly, the lateral ventricles lie close together, separated only by a thin median membrane called the **septum pellucidum** (pĕ-lu'sid-um; "transparent wall"). (See Figure 12.12, p. 445.) Each lateral ventricle communicates with the narrow **third ventricle** in the diencephalon via a channel called an **interventricular foramen** (*foramen of Monro*). The third ventricle is continuous with the **fourth ventricle** via the canal-like **cerebral aqueduct** that runs through the midbrain. The fourth ventricle lies in the hindbrain dorsal to the pons and superior medulla. It is continuous with the central canal of the spinal cord inferiorly. Three openings mark the walls of the fourth ventricle: the paired **lateral apertures** in its side walls and the **median aperture** in its roof. These apertures connect the ventricles to the *subarachnoid space* (sub"ah-rak'noid), a fluid-filled space surrounding the brain.

A Because their growth is restricted by the forming embryonic skull, the cerebral hemispheres are forced to grow posteriorly and inferiorly. Hence their cavities (ventricles) become horn-shaped.

Cerebral Hemispheres

The **cerebral hemispheres** form the superior part of the brain (Figure 12.6). Together they account for about 83% of total brain mass and are the most conspicuous parts of an intact brain. Picture how a mushroom cap covers the top of its stalk, and you have a fairly good idea of how the paired cerebral hemispheres cover and obscure the diencephalon and the top of the brain stem (see Figure 12.3d).

Nearly the entire surface of the cerebral hemispheres is marked by elevated ridges of tissue called **gyri** (ji'ri; "twisters"), separated by shallow grooves called **sulci** (sul'ki; "furrows"). The singular forms of these terms are *gyrus* and *sulcus*. Deeper grooves, called **fissures,** separate large regions of the brain. The more prominent gyri and sulci are similar in all people and are important anatomical landmarks. The median **longitudinal fissure** separates the cerebral hemispheres (Figure 12.6c). Another large fissure, the **transverse cerebral fissure,** separates the cerebral hemispheres from the cerebellum below (see Figure 12.6a).

Several sulci divide each hemisphere into five lobes—frontal, parietal, temporal, occipital, and insula—all but the last named for the cranial bones that overlie them (Figure 12.6a). The **central sulcus,**

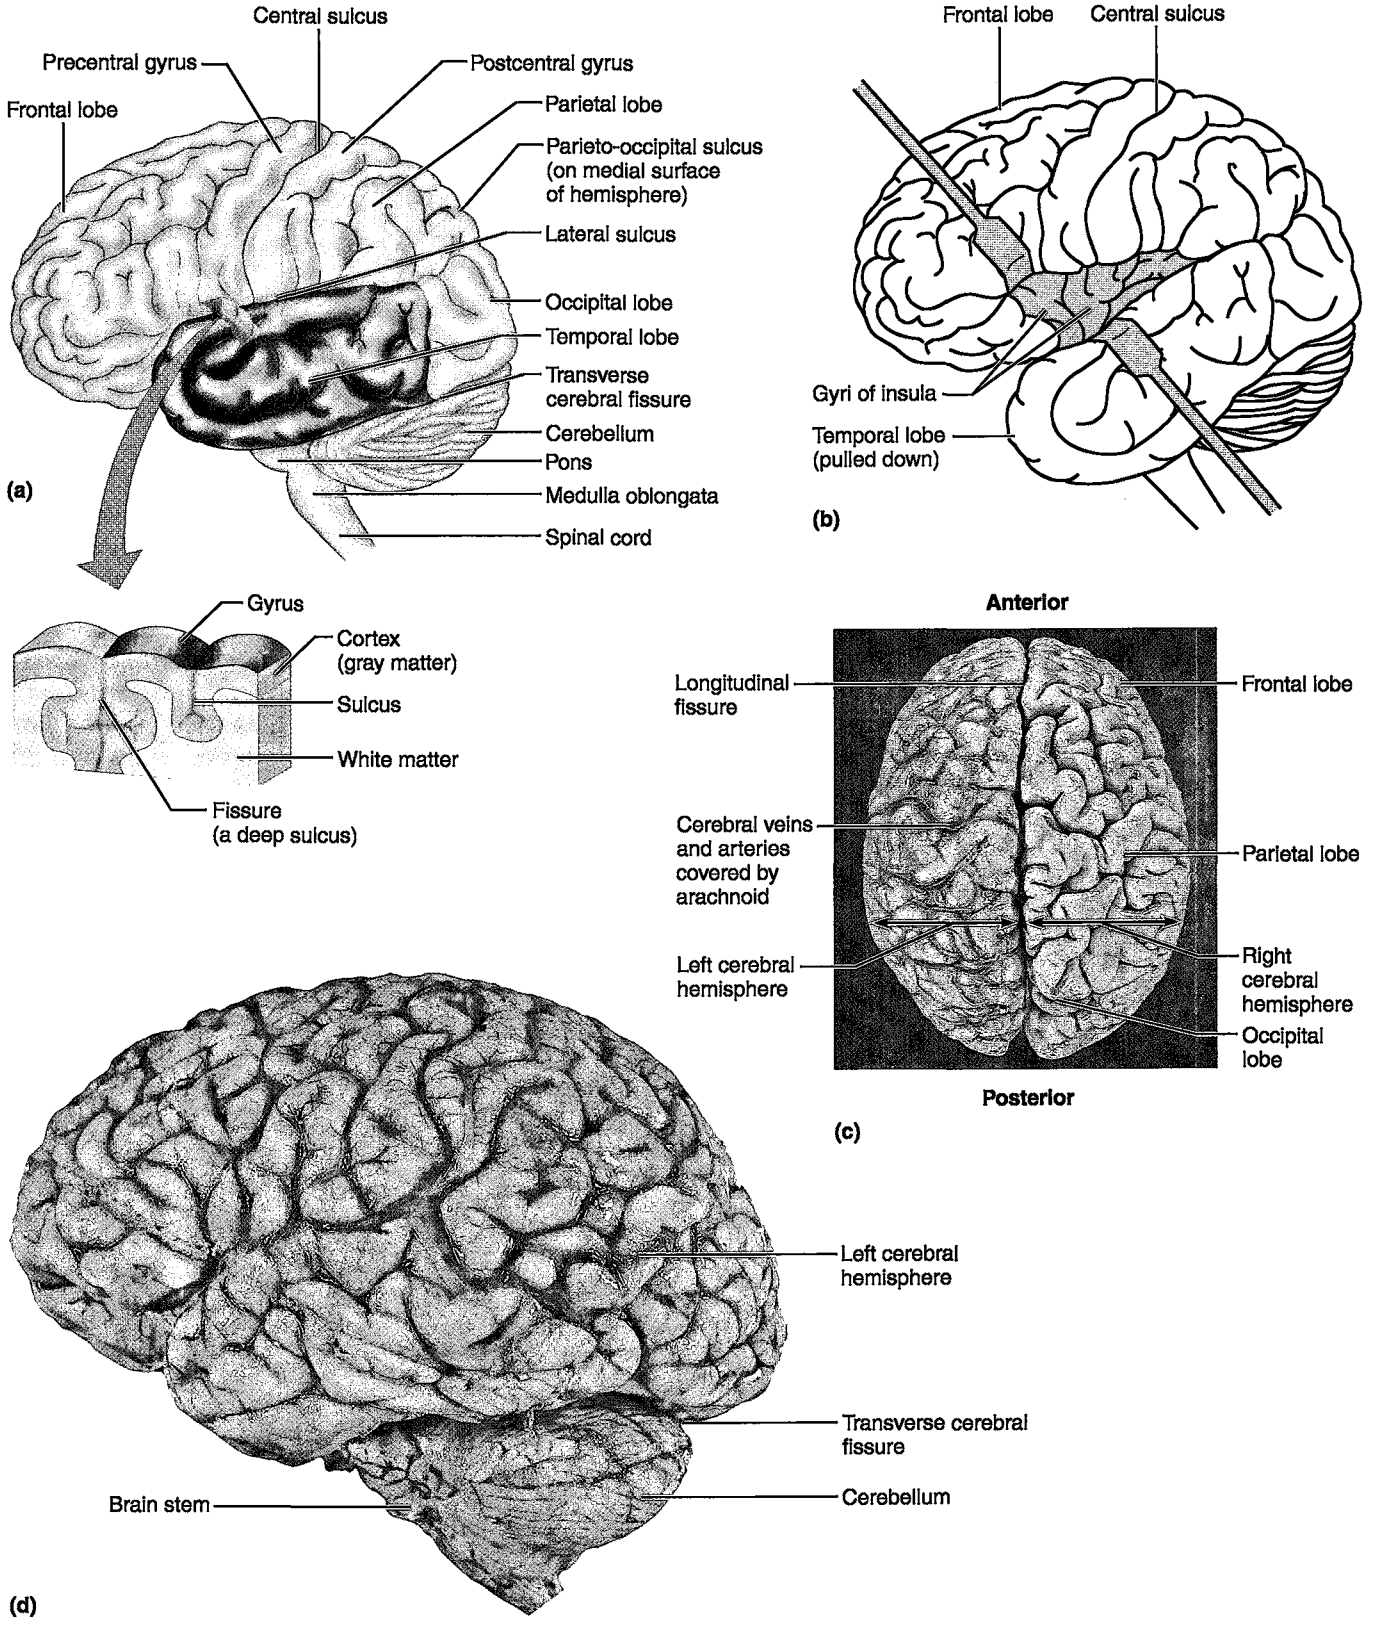

FIGURE 12.6 **Lobes and fissures of the cerebral hemispheres. (a)** Diagram of the lobes and major sulci and fissures of the brain. **(b)** The frontal and temporal lobes have been pulled back (retracted) to reveal the cortex of the insula below. **(c)** Superior surface of the cerebral hemispheres. Arachnoid has been removed on right half of the brain. **(d)** Photograph of the left lateral view of the brain. (See *A Brief Atlas of the Human Body,* Figure 48.)

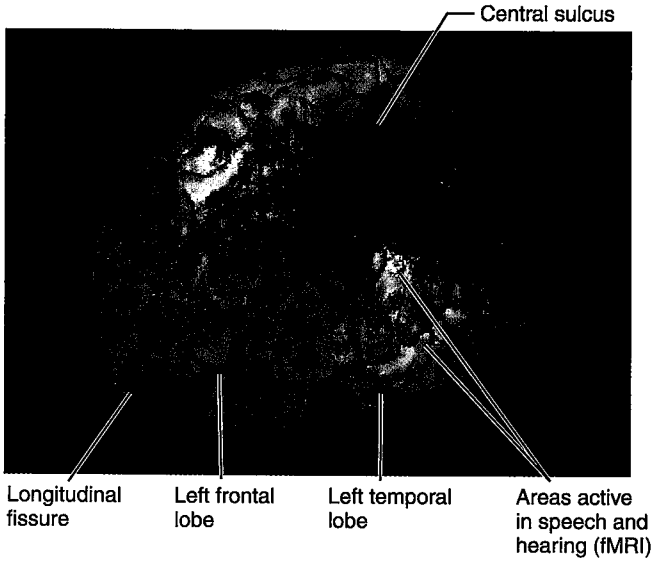

FIGURE 12.7 **Functional neuroimaging of the cerebral cortex.** The rostral direction is to the left. Functional magnetic resonance image (fMRI) of the cerebral cortex of a person speaking and hearing reveals activity (blood flow) in the posterior frontal and superior temporal lobes, respectively.

which lies in the frontal plane, separates the **frontal lobe** from the **parietal lobe.** Bordering the central sulcus are the **precentral gyrus** anteriorly and the **postcentral gyrus** posteriorly. More posteriorly, the **occipital lobe** is separated from the parietal lobe by the **parieto-occipital sulcus** (pah-ri″ĕ-to-ok-sip′ĭ-tal), located on the medial surface of the hemisphere.

The deep **lateral sulcus** outlines the flaplike **temporal lobe** and separates it from the parietal and frontal lobes. A fifth lobe of the cerebral hemisphere, the **insula** (in′su-lah; "island"), is buried deep within the lateral sulcus and forms part of its floor (Figure 12.6b). The insula is covered by portions of the temporal, parietal, and frontal lobes.

The cerebral hemispheres fit snugly in the skull. Rostrally, the frontal lobes lie in the anterior cranial fossa. The anterior parts of the temporal lobes fill the middle cranial fossa. The posterior cranial fossa, however, houses the brain stem and cerebellum; the occipital lobes are located well superior to that cranial fossa.

Each cerebral hemisphere has three basic regions: a superficial *cortex* of gray matter, which looks gray in fresh brain tissue; an internal *white matter;* and the *basal nuclei,* islands of gray matter situated deep within the white matter. We consider these regions next.

Cerebral Cortex

The **cerebral cortex** is the "executive suite" of the nervous system, where our *conscious mind* is found. It enables us to be aware of ourselves and our sensations, to communicate, remember, and understand, and to initiate voluntary movements. The cerebral cortex is composed of gray matter: neuron cell bodies, dendrites, associated glia and blood vessels, but no fiber tracts. It contains billions of neurons arranged in six layers. Although it is only 2–4 mm (about 1/8 inch) thick, it accounts for roughly 40% of total brain mass. Its many convolutions effectively triple its surface area.

In the late 1800s, anatomists mapped subtle variations in the thickness and structure of the cerebral cortex. Most successful in these efforts was K. Brodmann, who in 1906 produced an elaborate numbered mosaic of 52 cortical areas, now called **Brodmann areas.** With a structural map emerging, early neurologists were eager to localize *functional* regions of the cortex as well. Modern imaging techniques—PET scans to show maximal metabolic activity in the brain, or functional MRI scans to reveal blood flow (Figure 12.7)—have shown that specific motor and sensory functions are localized in discrete cortical areas called *domains*. However, many higher mental functions, such as memory and language, appear to have overlapping domains and are spread over large areas of the cortex. Some of the most important Brodmann areas are numbered in Figure 12.8.

Before we examine the functional regions of the cerebral cortex, let's consider some generalizations about this region of the brain:

1. The cerebral cortex contains three kinds of functional areas: *motor areas, sensory areas,* and *association areas*. As you read about these areas, do not confuse the sensory and motor areas of the cortex with sensory and motor neurons. All neurons in the cortex are interneurons.

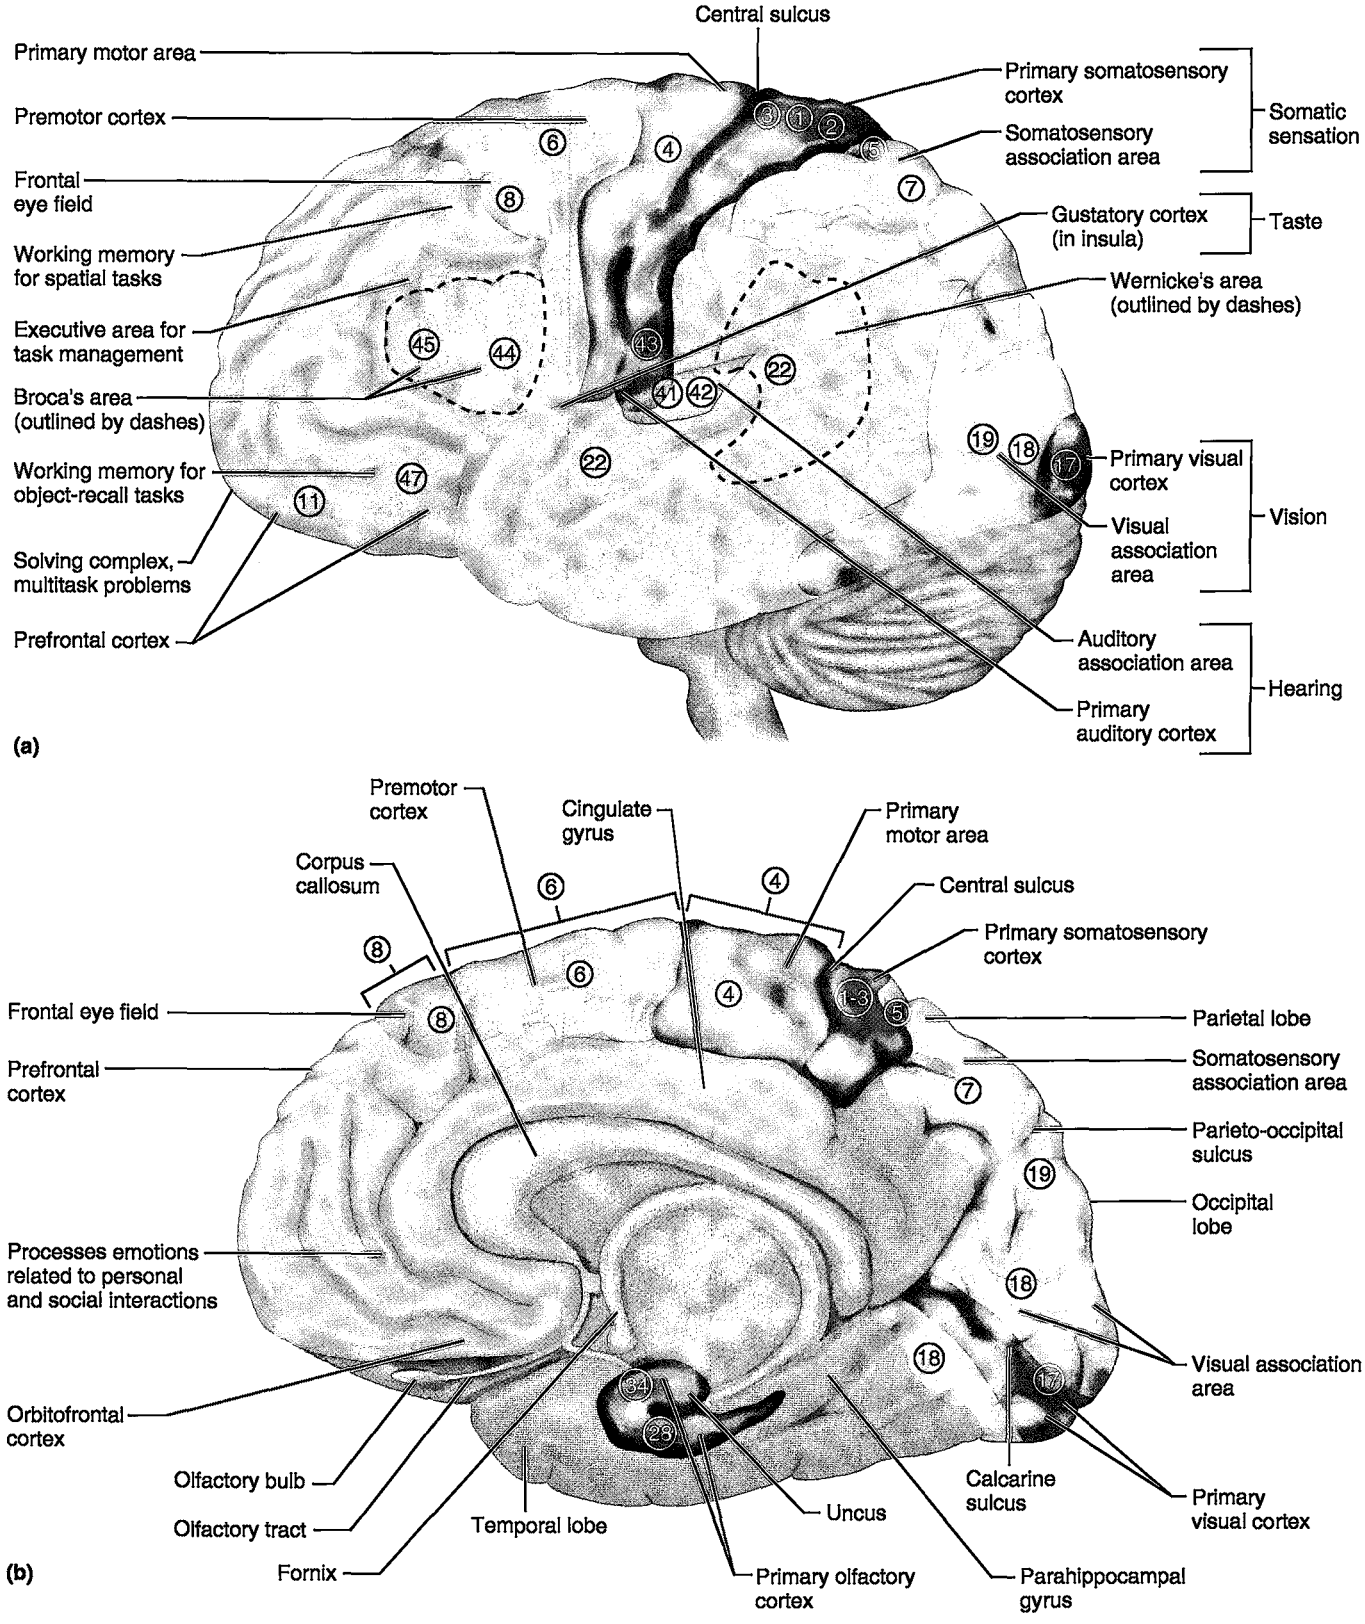
2. Each hemisphere is chiefly concerned with the sensory and motor functions of the opposite (contralateral) side of the body.

3. Although largely symmetrical in structure, the two hemispheres are not entirely equal in function. Instead, there is a lateralization (specialization) of cortical functions.

4. The final, and perhaps most important, generalization to keep in mind is that our approach is a gross oversimplification; no functional area of the cortex acts alone, and conscious behavior involves the entire cortex in one way or another.

Motor Areas As shown in Figure 12.8a, the following **motor areas** of the cortex, which control voluntary movement, lie in the posterior part of the frontal lobes: primary motor cortex, premotor cortex, Broca's area, and the frontal eye field.

Q *What anatomical landmark separates motor areas of the cerebral cortex from sensory areas?*



A Central sulcus.

FIGURE 12.8 **Functional and structural areas of the cerebral cortex. (a)** Lateral view, left cerebral hemisphere. Different colors define functional regions of the cortex. Dark colors show primary motor (red) or sensory (blue) cortex and lighter colors show association cortices. Violet shows multimodal association cortex. The olfactory area, which is deep to the temporal lobe on the medial hemispheric surface, is not identified. Numbers indicate Brodmann structural areas. **(b)** Parasagittal view, right hemisphere.

Q *Why are the motor and sensory homunculi anatomically "deformed"?*

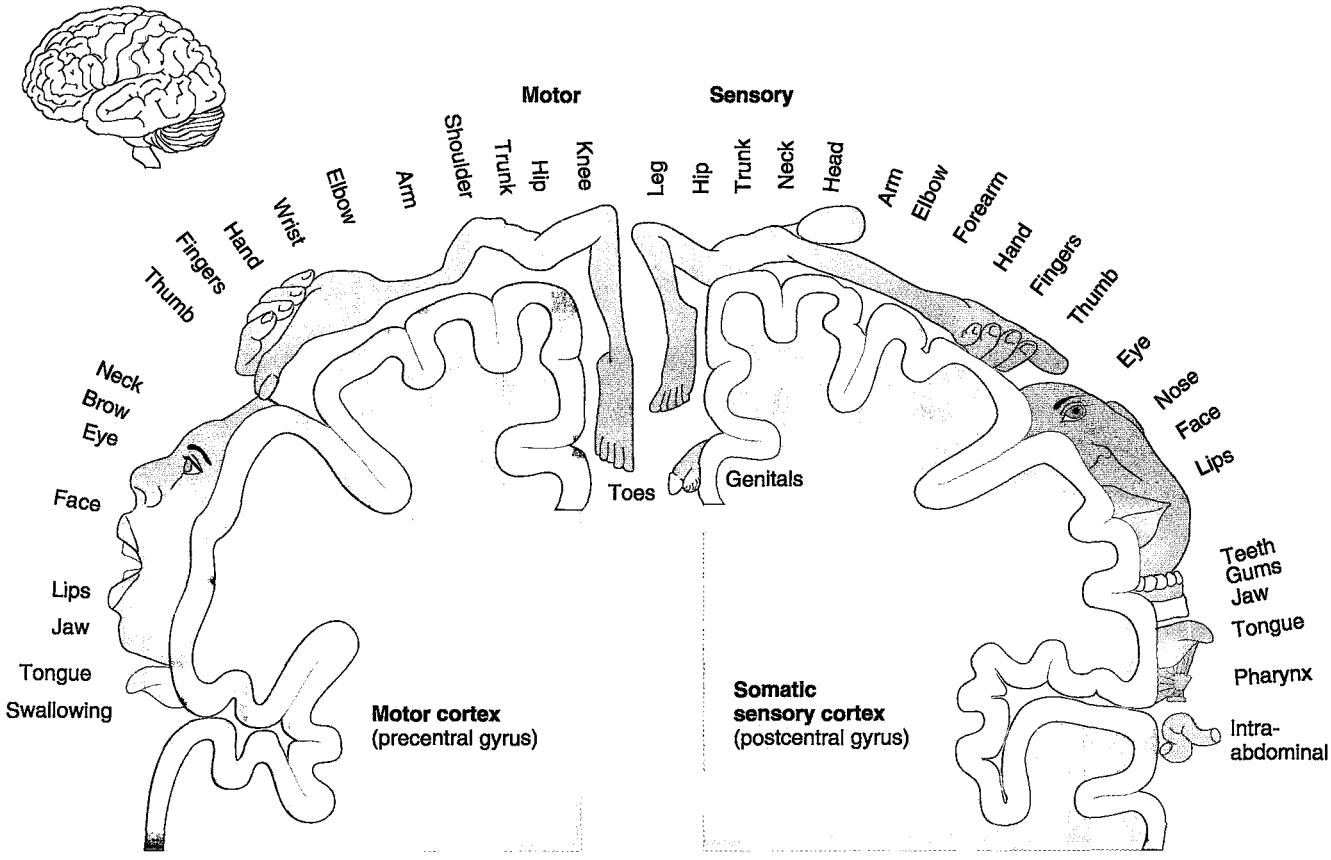


FIGURE 12.9 **Motor and sensory areas of the cerebral cortex.** The relative amount of cortical tissue devoted to each function is indicated by the amount of the gyrus occupied by the body diagrams. The primary motor cortex in the precentral gyrus is represented on the left, and the somatic sensory cortex in the postcentral gyrus is represented on the right.

1. Primary (somatic) motor cortex. The primary motor cortex is located in the precentral gyrus of the frontal lobe of each hemisphere (Brodmann area 4). Large neurons, called **pyramidal cells,** in these gyri allow us to consciously control the precise or skilled voluntary movements of our skeletal muscles. Their long axons, which project to the spinal cord, form the massive voluntary motor tracts called the **pyramidal tracts,** or **corticospinal tracts** (kor"tĭ-ko-spi'nal). All other descending motor tracts issue from brain stem nuclei and consist of chains of two or more neurons.

The entire body is represented spatially in the primary motor cortex of each hemisphere. In other words, the pyramidal cells that control foot movements are in one place and those that control hand movements are in another. Such a mapping of the body in CNS structures is called **somatotopy** (so"mah-to-to'pe). As illustrated in Figure 12.9, the body is typically represented upside down—with the head at the inferolateral part of the precentral gyrus, and the toes at the superomedial end. Most of the neurons in these gyri control muscles in body areas having the most precise motor control—that is, the face, tongue, and hands. Consequently, these regions of the caricature-like **motor homunculi** (ho-mung'ku-li; singular: homunculus; "little man") drawn in Figure 12.9 are disproportionately large. The motor innervation of the body is contralateral; that is, the left primary motor gyrus controls muscles on the right side of the body, and vice versa.

A *Because the relative size of each body area in the drawing represents the relative amount of the cerebral cortex dedicated to that body area.*

The *motor homunculus* view of the primary motor cortex, shown at the left in Figure 12.9, implies a one-to-one correspondence between certain cortical neurons and the muscles they control, but this is somewhat misleading. Current research indicates that a given muscle is controlled by multiple spots on the cortex and that individual cortical neurons actually send impulses to more than one muscle. In other words, individual pyramidal motor neurons control muscles that work together in a synergistic way to perform a given movement. For example, reaching forward with one arm involves some muscles acting at the shoulder and some acting at the elbow. Thus, instead of the discrete map offered by the motor homunculus, the primary motor cortex map is an orderly but fuzzy map with neurons arranged in useful ways to control and coordinate sets of muscles. Neurons controlling the arm, for instance, are intermingled and overlap with those controlling the hand and shoulder. However, neurons controlling unrelated movements, such as those controlling the arm and those controlling body trunk muscles, do not cooperate in motor activity. Thus, the motor homunculus is useful to show that broad areas of the primary cortex are devoted to the leg, arm, torso, and head, but neuron organization within those broad areas is much more diffuse than initially imagined.

2. Premotor cortex. Just anterior to the precentral gyrus in the frontal lobe (Brodmann area 6) is the premotor cortex (see Figure 12.8). This region controls learned motor skills of a repetitious or patterned nature, such as playing a musical instrument and typing. The premotor cortex coordinates the movement of several muscle groups either simultaneously or sequentially, mainly by sending activating impulses to the primary motor cortex. However, the premotor cortex also influences motor activity more directly by supplying about 15% of pyramidal tract fibers. Think of this region as the memory bank for skilled motor activities.

This region also appears to be involved in planning movements. Using highly processed sensory information received from other cortical areas, it can control voluntary actions that depend on sensory feedback, such as moving an arm through a maze to grasp a hidden object.

3. Broca's area (bro'kahz). Broca's area lies anterior to the inferior region of the premotor area and overlaps Brodmann areas 44 and 45. It has long been considered to be (1) present in one hemisphere only (usually the left) and (2) a special *motor speech area* that directs the muscles involved in speech production. However, recent studies using PET scans to watch active areas of the brain "light up" indicate that Broca's area also becomes active as we prepare to speak and even as we think about (plan) many voluntary motor activities other than speech.

4. Frontal eye field. The frontal eye field is located partially in and anterior to the premotor cortex and superior to Broca's area. This cortical region controls voluntary movement of the eyes.

HOMEOSTATIC IMBALANCE

Damage to localized areas of the *primary motor cortex* (as from a stroke) paralyzes the body muscles controlled by those areas. If the lesion is in the right hemisphere, the left side of the body will be paralyzed. Only *voluntary* control is lost, however, as the muscles can still contract reflexively.

Destruction of the *premotor cortex,* or part of it, results in a loss of the motor skill(s) programmed in that region, but muscle strength and the ability to perform the discrete individual movements are not hindered. For example, if the premotor area controlling the flight of your fingers over a computer keyboard were damaged, you couldn't type with your usual speed, but you could still make the same movements with your fingers. Reprogramming the skill into another set of premotor neurons would require practice, just as the initial learning process did. ●

Sensory Areas Areas concerned with conscious awareness of sensation, the **sensory areas** of the cortex, occur in the parietal, insular, temporal, and occipital lobes (see Figure 12.8).

1. Primary somatosensory cortex. This cortex resides in the postcentral gyrus of the parietal lobe, just posterior to the primary motor cortex (Brodmann areas 1–3). Neurons in this gyrus receive information from the general (somatic) sensory receptors in the skin and from proprioceptors (position sense receptors) in skeletal muscles, joints, and tendons. The neurons then identify the body region being stimulated, an ability called **spatial discrimination.** As with the primary motor cortex, the body is represented spatially and upside-down according to the site of stimulus input, and the right hemisphere receives input from the left side of the body. The amount of sensory cortex devoted to a particular body region is related to that region's sensitivity (that is, to how many receptors it has), not to the size of the body region. In humans, the face (especially the lips) and fingertips are the most sensitive body areas; hence these are the largest parts of the **somatosensory homunculus** shown in the right half of Figure 12.9.

2. Somatosensory association cortex. The somatosensory association cortex lies just posterior to the primary somatosensory cortex and has many connections with it. The major function of this area

is to integrate sensory inputs (temperature, pressure, and so forth) relayed to it via the primary somatosensory cortex to produce an understanding of an object being felt: its size, texture, and the relationship of its parts. For example, when you reach into your pocket, your somatosensory association cortex draws upon stored memories of past sensory experiences to perceive the objects you feel as coins or keys. Someone with damage to this area could not recognize these objects without looking at them.

3. Visual areas. The **primary visual (striate) cortex** is seen on the extreme posterior tip of the occipital lobe, but most of it is buried deep in the *calcarine sulcus* (Figure 12.8b) in the medial aspect of the occipital lobe. The largest of all cortical sensory areas, the primary visual cortex receives visual information that originates on the retina of the eye. There is a contralateral map of visual space on the primary visual cortex, analogous to the body map on the somatosensory cortex.

The **visual association area** surrounds the primary visual cortex and covers much of the occipital lobe. Communicating with the primary visual cortex, the visual association area uses past visual experiences to interpret visual stimuli (color, form, and movement), enabling us to recognize a flower or a person's face and to appreciate what we are seeing. We do our "seeing" with these cortical neurons. However, recent experiments on monkeys indicate that complex visual processing involves the entire posterior half of the cerebral hemispheres. Particularly important are two visual "streams"—one running along the top of the brain and handling spatial relationships and object location, the other taking the lower road and focusing on object identity (recognizing faces, words, and objects).

4. Auditory areas. Each **primary auditory cortex** is located in the superior margin of the temporal lobe abutting the lateral sulcus. Sound energy exciting the inner ear hearing receptors causes impulses to be transmitted to the primary auditory cortex, where they are interpreted as pitch, loudness, and location.

The more posterior **auditory association area** then permits the perception of the sound stimulus, which we "hear" as speech, a scream, music, thunder, noise, and so on. Memories of sounds heard in the past appear to be stored here for reference. Wernicke's area, described later, includes parts of the auditory cortex.

5. Olfactory (smell) cortex. The primary olfactory cortex lies on the medial aspect of the temporal lobe in a small region called the *piriform lobe* which is dominated by the hooklike *uncus* (Figure 12.8b). Afferent fibers from smell receptors in the superior nasal cavities send impulses along the olfactory tracts that are ultimately relayed to the olfactory cortices. The outcome is conscious awareness of different odors.

The olfactory cortex is part of the primitive **rhinencephalon** (ri"nen-sef'ah-lon; "nose brain"), which includes all parts of the cerebrum that receive olfactory signals—the orbitofrontal cortex, the uncus and associated regions located on or in the medial aspects of the temporal lobes, and the protruding olfactory tracts and bulbs that extend to the nose. During the course of evolution, most of the "old" rhinencephalon has taken on new functions concerned chiefly with emotions and memory. This "newer" emotional brain, called the *limbic system*, is considered later in this chapter. The only portions of the human rhinencephalon still devoted to smell are the olfactory bulbs and tracts (described in Chapter 13) and the greatly reduced olfactory cortices.

6. Gustatory (taste) cortex. The gustatory cortex (gus'tah-tor-e) (see Figure 12.8a), a region involved in the perception of taste stimuli, is located in the insula just deep to the temporal lobe.

7. Visceral sensory area. The cortex of the insula just posterior to the gustatory cortex is involved in conscious perception of visceral sensations. These include upset stomach, full bladder, and the feeling that your lungs will burst when you hold your breath too long.

8. Vestibular (equilibrium) cortex. It has been difficult to pin down the part of the cortex responsible for conscious awareness of balance, that is, of the position of the head in space. However, medical imaging studies now locate this region in the posterior part of the insula, deep to the temporal lobe.

HOMEOSTATIC IMBALANCE

Damage to the primary visual cortex (Figure 12.8) results in functional blindness. By contrast, those with damage to the visual association area can see, but they do not comprehend what they are looking at. ●

Multimodal Association Areas The association areas that you have considered so far (colored light red or blue in Figure 12.8) have all been tightly tied to one kind of primary sensory or motor cortex (colored dark red or blue). Most of the cortex, though, is more complexly connected, receiving inputs from multiple senses and sending outputs to multiple areas. We call these areas **multimodal association areas** (colored violet in Figure 12.8).

In general, information flows from sensory receptors to the appropriate primary sensory cortex, then to a sensory association cortex and then on to the multimodal association cortex. Multimodal association cortex allows us to give meaning to the information that we receive, store it in memory if

needed, tie it to previous experience and knowledge, and decide what action to take. Once the course of action has been decided, those decisions are relayed to the premotor cortex, which in turn communicates with the motor cortex. The multimodal association cortex seems to be where sensations, thoughts, and emotions become conscious and is what makes us who we are.

Suppose, for example, you drop a bottle of acid in the chem lab and it splashes on you. You see the bottle shatter; hear the crash; feel your skin burning; and smell the acid fumes. These individual perceptions come together in the multimodal association areas. Along with feelings of panic, these perceptions are woven into a seamless whole, which (hopefully) recalls instructions about what to do in this situation. As a result your premotor and primary motor cortices direct your legs to propel you to the safety shower. The multimodal association areas can be broadly divided into three parts, which are described next.

1. Anterior association area. The anterior association area in the frontal lobe (Figure 12.8b), also called the **prefrontal cortex,** is the most complicated cortical region of all. It is involved with intellect, complex learning abilities (called cognition), recall, and personality. It contains working memory, necessary for the production of abstract ideas, judgment, reasoning, persistence, and planning. That these qualities develop slowly in children implies that the prefrontal cortex matures slowly and is heavily dependent on positive and negative feedback from one's social environment.

2. Posterior association area. The posterior association area is a large region encompassing parts of the temporal, parietal, and occipital lobes. This area plays a role in recognizing patterns and faces, localizing us and our surroundings in space, and in binding different sensory inputs into a coherent whole. In the spilled acid example above, your awareness of the entire scene originates from this area. Attention to an area of space or an area of one's own body is also a function of this part of the brain. This is strikingly demonstrated by the experiences of some patients with lesions in the right posterior parietal region of this area who refuse to wash or dress the left side of their body because "that doesn't belong to me." Many parts of this area (including Wernicke's area, Figure 12.8a) are also involved in understanding written and spoken language.

3. Limbic association area. The limbic association area, which includes the cingulate gyrus, the parahippocampal gyrus, and the hippocampus, is part of the limbic system (described later). The limbic association area provides the emotional impact, which makes a scene important to us. In our example above, it provides the sense of "danger" when the acid splashes on our legs. The hippocampus (Figure 12.18) establishes memories that allow us to remember this incident. More on this later.

Lateralization of Cortical Functioning We use both cerebral hemispheres for almost every activity, and the hemispheres appear nearly identical. Nonetheless, there is a division of labor, and each hemisphere has unique abilities not shared by its partner. This phenomenon is called **lateralization.** Although one cerebral hemisphere or the other "dominates" each task, the term **cerebral dominance** designates the hemisphere that is *dominant for language*. In most people (about 90%), the left hemisphere has greater control over language abilities, math, and logic. This so-called dominant hemisphere is working when we compose a sentence, balance a checkbook, and memorize a list. The other hemisphere (usually the right) is more free-spirited, involved in visual-spatial skills, intuition, emotion, and artistic and musical skills. It is the poetic, creative, and the "Ah-ha!" (insightful) side of our nature, and it is far better at recognizing faces. Most individuals with left cerebral dominance are right-handed.

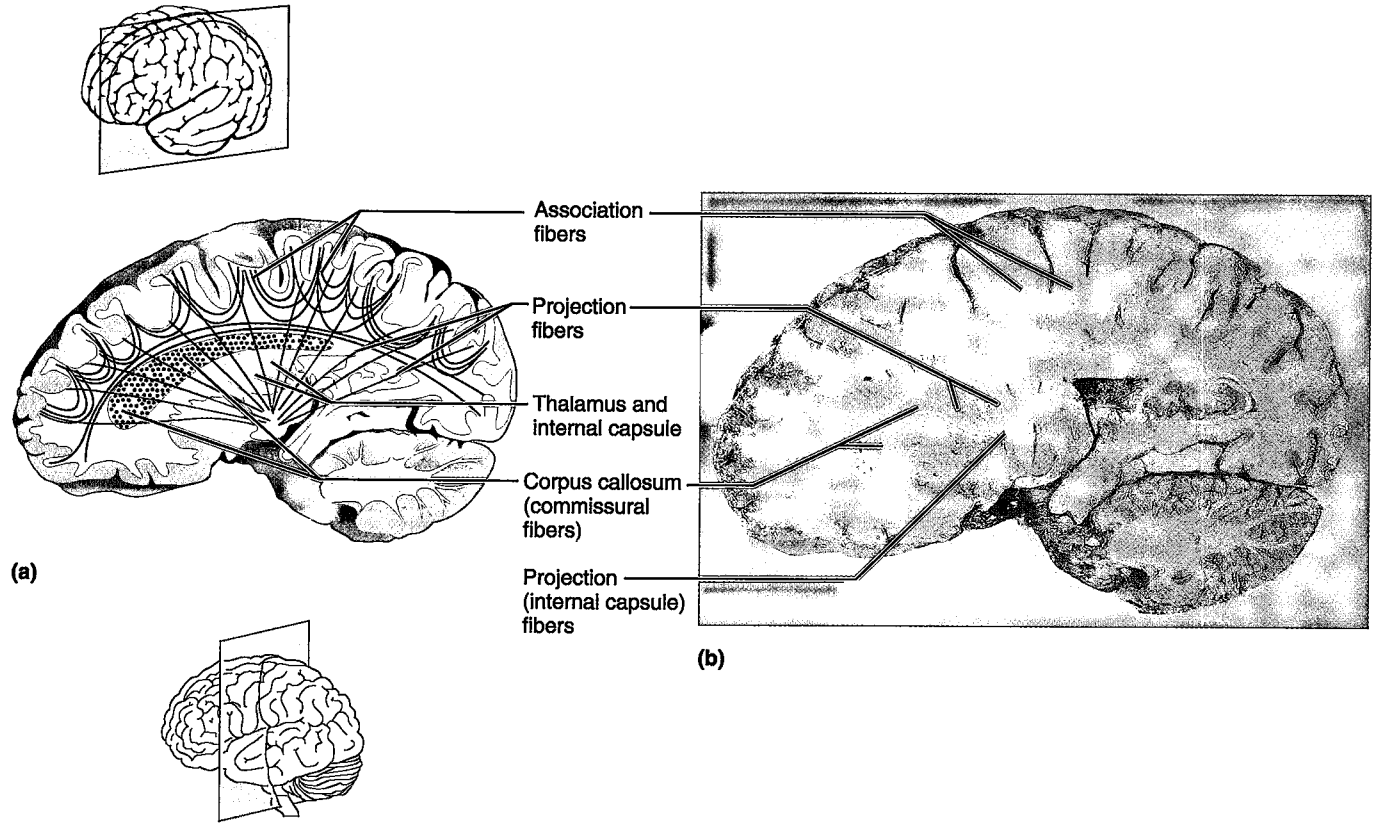
In the remaining 10% of people, the roles of the hemispheres are reversed or the hemispheres share their functions equally. Typically, right-cerebral-dominant people are left-handed and male. Some "lefties" who have a cerebral cortex that functions bilaterally are ambidextrous. In other cases, however, this phenomenon may also result in cerebral confusion ("Is it your turn, or mine?") and learning disabilities, such as the reading disorder *dyslexia,* in which otherwise intelligent people reverse the order of letters in words (and the order of words in sentences).

The two cerebral hemispheres have perfect and almost instantaneous communication with one another via connecting fiber tracts, as well as complete functional integration. Furthermore, although lateralization means that each hemisphere is better than the other at certain functions, neither side is better at everything.

Cerebral White Matter

The second of the three basic regions of each cerebral hemisphere is the internal **cerebral white matter.** From what has already been described, it is clear that communication within the brain is extensive. The white matter (Figure 12.10) deep to the cortical gray matter is responsible for communication between cerebral areas and between the cerebral cortex and lower CNS centers. White matter consists largely of myelinated fibers bundled into large tracts. These fibers and tracts are classified according to the

Q *How can you explain the observation that the two cerebral hemispheres have instantaneous communication with each other when it is obvious from diagram (c) that the projection fibers are part of crossed pathways and that information flows from each side of the body to only one (the opposite) hemisphere?*



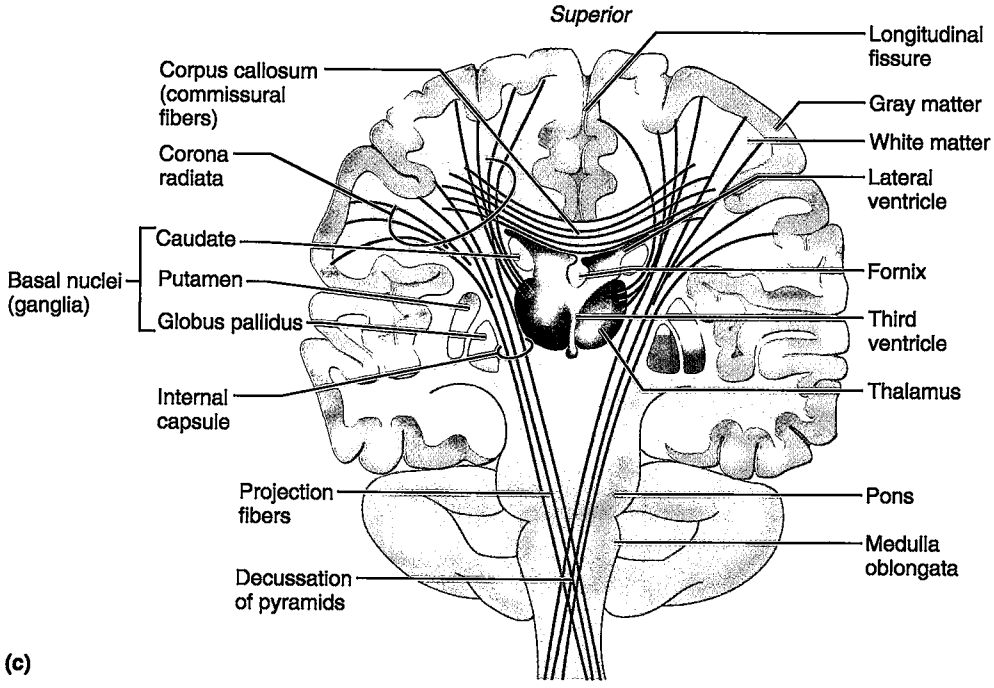


FIGURE 12.10 **Types of fiber tracts in white matter. (a)** Parasagittal view of the right cerebral hemisphere showing the association tract fibers (tracts connecting different parts of the same hemisphere), and the corpus callosum, a commissure that connects the hemispheres. **(b)** Photo of the same view as (a). **(c)** Frontal section showing commissural fibers and projection fibers running between the cerebrum and lower CNS centers. Notice the tight band of projection fibers called the internal capsule that passes between the thalamus and the basal nuclei, and then fans out as the corona radiata.

A Commissures allow the cerebral hemispheres to "talk to each other."

direction in which they run as *commissural, association,* or *projection*.

Commissures (kom'ĭ-shūrz), composed of **commissural fibers,** connect corresponding gray areas of the two hemispheres, enabling them to function as a coordinated whole. The largest commissure is the **corpus callosum** (kah-lo'sum; "thickened body"), which lies superior to the lateral ventricles, deep within the longitudinal fissure. Less prominent examples are the **anterior** and **posterior commissures** (see Figure 12.12, p. 445).

Association fibers connect different parts of the same hemisphere. Short association fibers connect adjacent gyri. Long association fibers are bundled into tracts and connect different cortical lobes.

Projection fibers are those that enter the cerebral hemispheres from lower brain or cord centers, and those that leave the cortex to travel to lower areas. They tie the cortex to the rest of the nervous system and to the body's receptors and effectors. In contrast to commissural and association fibers, which run horizontally, projection fibers run vertically as Figure 12.10c shows.

At the top of the brain stem, the projection fibers on each side form a compact band, the **internal capsule,** that passes between the thalamus and some of the basal nuclei. Beyond that point, the fibers radiate fanlike through the cerebral white matter to the cortex. This distinctive arrangement of projection tract fibers is known as the **corona radiata** ("radiating crown").

Basal Nuclei

Deep within the cerebral white matter is the third basic region of each hemisphere, a group of subcortical nuclei called the **basal nuclei** or **basal ganglia.*** Although the definition of the precise structures forming the basal nuclei is controversial, most anatomists agree that the **caudate nucleus** (kaw'dāt), **putamen** (pu-ta'men), and **globus pallidus** (glo'bis pal'ĭ-dus) constitute most of the mass of each group of basal nuclei (Figure 12.11). Together, the putamen ("pod") and globus pallidus ("pale globe") form a lens-shaped mass, the **lentiform nucleus,** that flanks the internal capsule laterally. The comma-shaped caudate nucleus arches superiorly over the diencephalon. Collectively, the lentiform and caudate nuclei are called the **corpus striatum** (stri-a'tum) because the fibers of the internal capsule that course past and through them give them a striped appearance. The basal nuclei are functionally associated with the *subthalamic nuclei* (located in the lateral "floor" of the diencephalon) and the *substantia nigra* of the midbrain (see Figure 12.16a).

The nuclei of the corpus striatum receive input from the entire cerebral cortex, as well as from other subcortical nuclei and each other. Via relays through the thalamus, the output nuclei of the basal nuclei (globus pallidus and the substantia nigra) project to the premotor and prefrontal cortices and so influence muscle movements directed by the primary motor cortex. The basal nuclei have no direct access to motor pathways.

The precise role of the basal nuclei has been elusive because of their inaccessible location and because their functions overlap with those of the cerebellum. Their role in motor control is complex and there is evidence they play a part in regulating attention and in cognition. The basal nuclei are particularly important in starting, stopping, and monitoring the intensity of movements executed by the cortex, especially those that are relatively slow or stereotyped, such as arm-swinging during walking. Additionally, they inhibit antagonistic or unnecessary movements; thus their input seems necessary to our ability to perform several activities at once. Disorders of the basal nuclei result in either too much or too little movement as exemplified by Huntington's chorea and Parkinson's disease, respectively (see pp. 469–470).

Diencephalon

Forming the central core of the forebrain and surrounded by the cerebral hemispheres, the **diencephalon** consists largely of three paired structures—the thalamus, hypothalamus, and epithalamus. These gray matter areas collectively enclose the third ventricle (Figure 12.12).

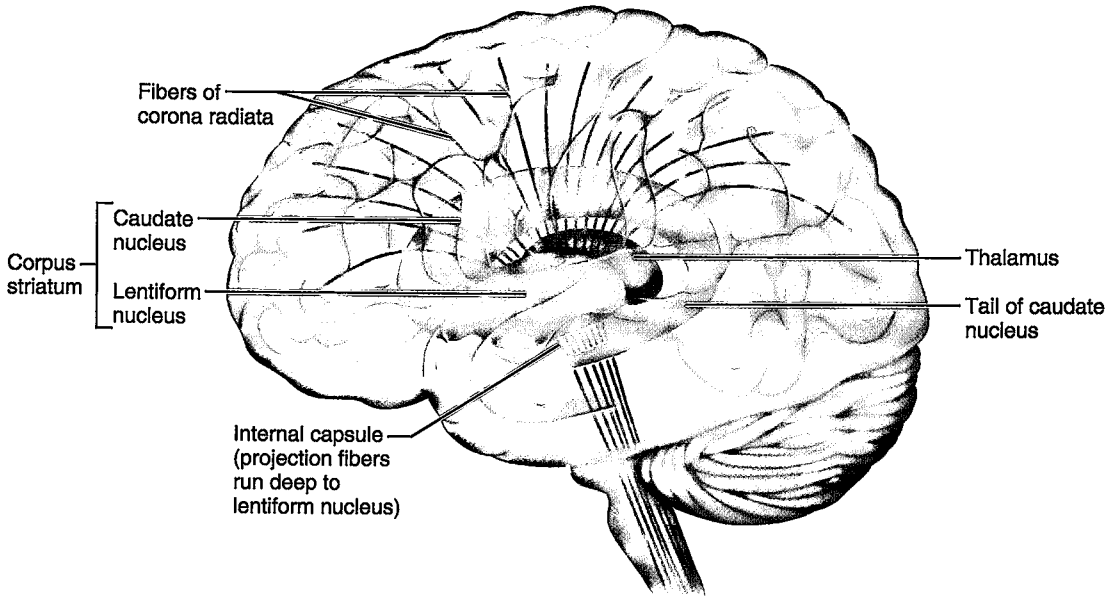
Thalamus

The **thalamus** consists of bilateral egg-shaped nuclei, which form the superolateral walls of the third ventricle (Figures 12.10 and 12.12). In most people, the nuclei are connected at the midline by an **interthalamic adhesion (intermediate mass).** *Thalamus* is a Greek word meaning "inner room," which well describes this deep, well-hidden brain region that makes up 80% of the diencephalon.

The thalamus contains a large number of nuclei, most named according to their relative location (Figure 12.13a). Each nucleus has a functional specialty, and each projects fibers to and receives fibers from a specific region of the cerebral cortex. Afferent impulses from all senses and all parts of

* Because a nucleus is a collection of nerve cell bodies within the CNS, the term *basal nuclei* is technically correct. The more frequently used but misleading historical term *basal ganglia* is a misnomer and should be abandoned, because ganglia are PNS structures.

Q *Why are the lentiform nucleus and caudate nucleus collectively referred to as the corpus striatum?*



(a)

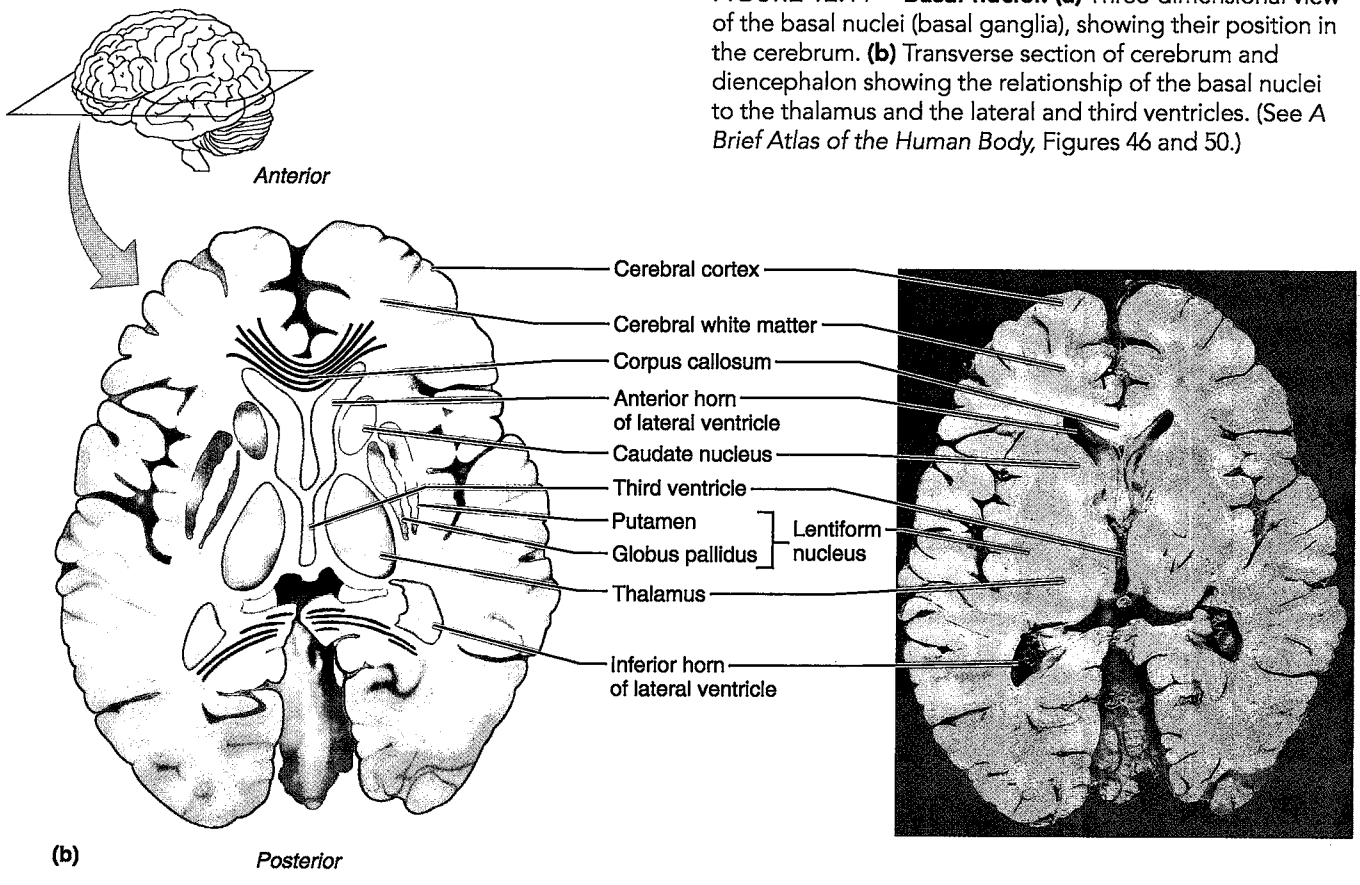


FIGURE 12.11 **Basal nuclei. (a)** Three-dimensional view of the basal nuclei (basal ganglia), showing their position in the cerebrum. **(b)** Transverse section of cerebrum and diencephalon showing the relationship of the basal nuclei to the thalamus and the lateral and third ventricles. (See *A Brief Atlas of the Human Body,* Figures 46 and 50.)

12

A *Because the fibers of the corona radiata running through them make them appear striped.*

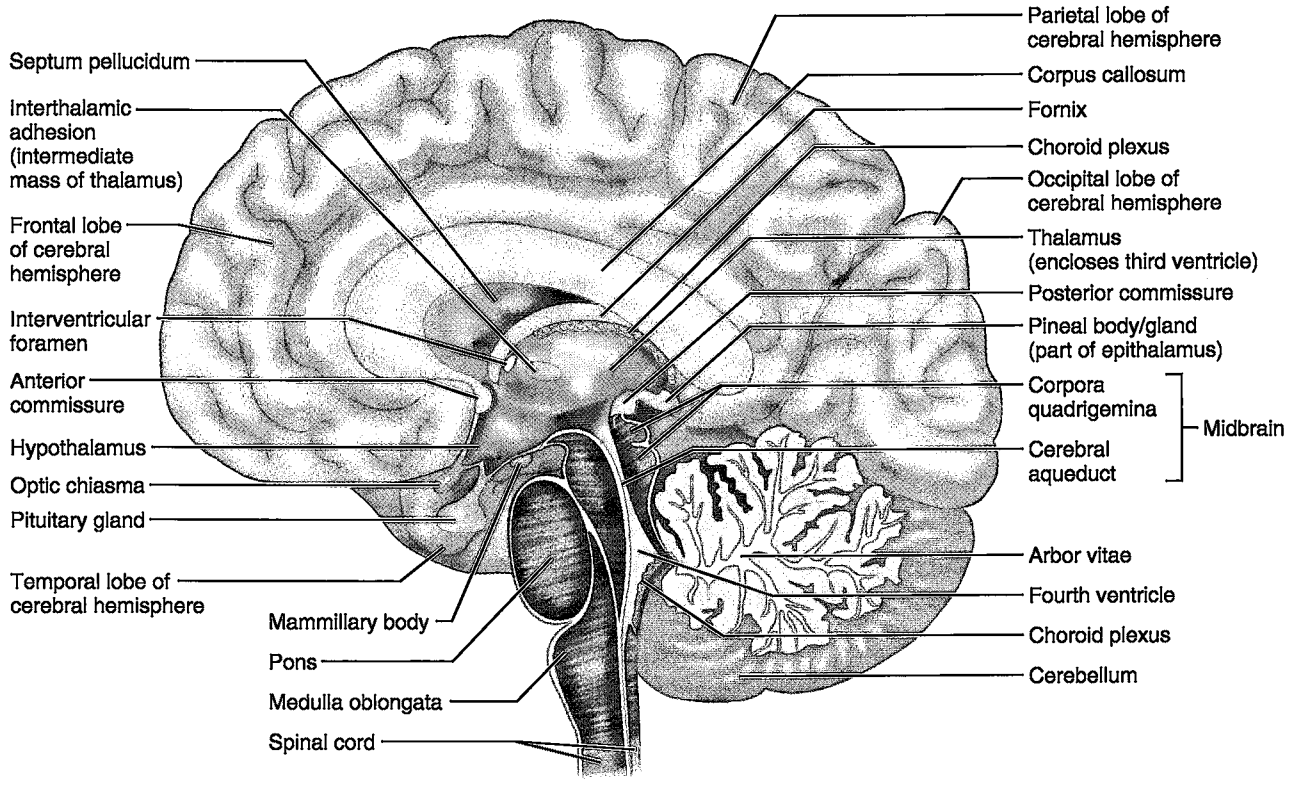

FIGURE 12.12 **Midsagittal section of the brain illustrating the diencephalon and brain stem.**

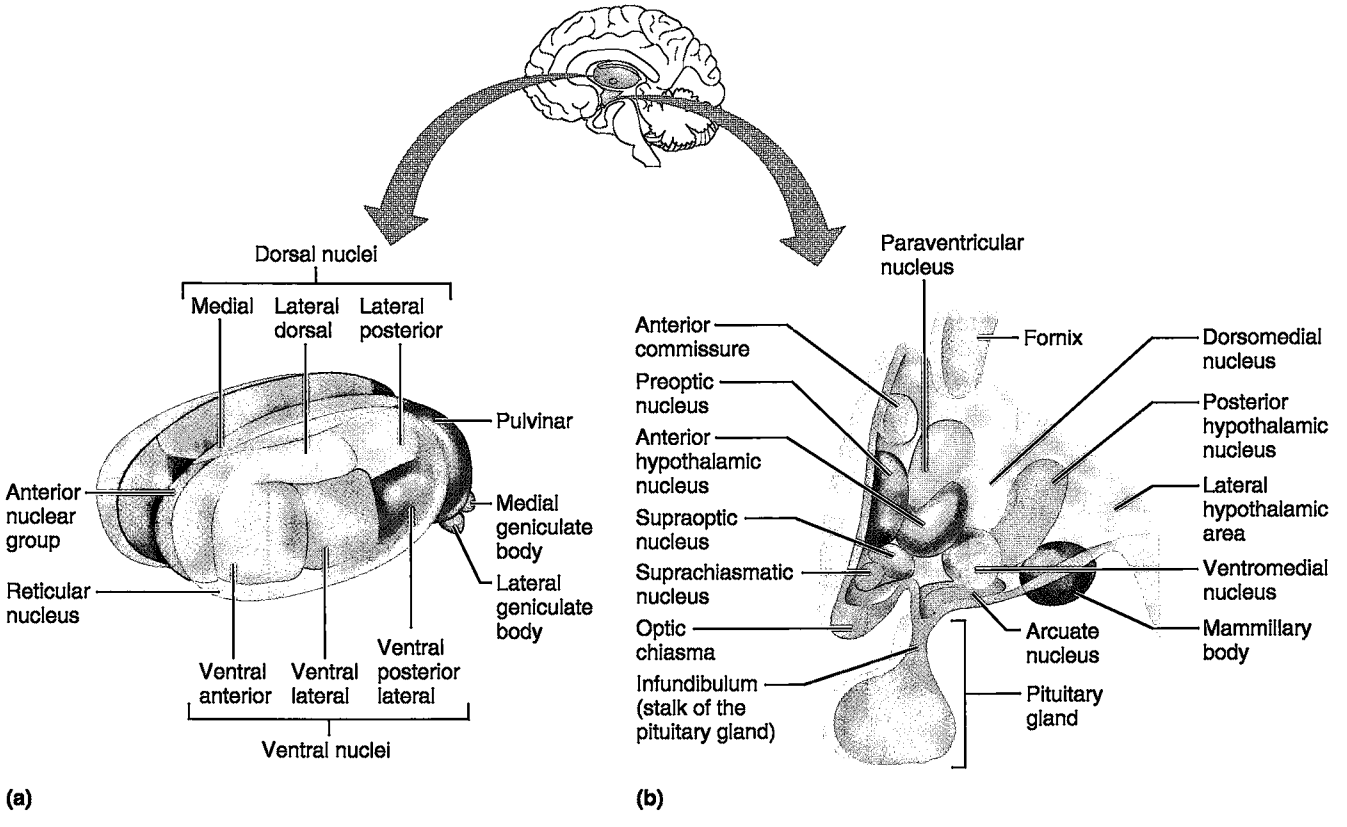

FIGURE 12.13 **Selected structures of the diencephalon. (a)** Thalamus showing the main thalamic nuclei. (The reticular nuclei that "cap" the thalamic nuclei laterally are depicted as curving translucent structures.) **(b)** Main hypothalamic nuclei.

the body converge on the thalamus and synapse with at least one of its nuclei. For example, the *ventral posterior lateral nucleus* receives impulses from the general somatic sensory receptors (touch, pressure, pain, etc.), and the *lateral* and *medial geniculate bodies* (jĕ-nik'u-lāt; "knee shaped") are important visual and auditory relay centers, respectively. Within the thalamus, information is sorted out and "edited." Impulses having to do with similar functions are relayed as a group via the internal capsule to the appropriate area of the sensory cortex as well as to specific cortical association areas. As the afferent impulses reach the thalamus, we have a crude recognition of the sensation as pleasant or unpleasant. However, specific stimulus localization and discrimination occur in the cerebral cortex.

In addition to sensory inputs, virtually *all* other inputs ascending to the cerebral cortex funnel through thalamic nuclei. These include impulses participating in the regulation of emotion and visceral function from the hypothalamus (via the anterior nuclei), and impulses that help direct the activity of the motor cortices from the cerebellum and basal nuclei (via the ventral lateral and ventral anterior nuclei, respectively). Several thalamic nuclei (pulvinar, lateral dorsal, and lateral posterior nuclei) are involved in integration of sensory information and project to specific association cortices. Thus the thalamus plays a key role in mediating sensation, motor activities, cortical arousal, learning, and memory. It is truly the gateway to the cerebral cortex.

12

Hypothalamus

Named for its position below (*hypo*) the thalamus, the **hypothalamus** caps the brain stem and forms the inferolateral walls of the third ventricle (Figure 12.12). Merging into the midbrain inferiorly, the hypothalamus extends from the optic chiasma (crossover point of the optic nerves) to the posterior margin of the mammillary bodies. The **mammillary bodies** (mam'mil-er-e; "little breast"), paired pealike nuclei that bulge anteriorly from the hypothalamus, are relay stations in the olfactory pathways. Between the optic chiasma and mammillary bodies is the **infundibulum** (in"fun-dib'u-lum), a stalk of hypothalamic tissue that connects the **pituitary gland** to the base of the hypothalamus. Like the thalamus, the hypothalamus contains many functionally important nuclei (Figure 12.13b).

Despite its small size, the hypothalamus is the main visceral control center of the body and is vitally important to overall body homeostasis. Few tissues in the body escape its influence. Its chief homeostatic roles are summarized next.

1. Autonomic control center. As you will remember, the autonomic nervous system (ANS) is a system of peripheral nerves that regulates cardiac and smooth muscle and secretion by the glands. The hypothalamus regulates ANS activity by controlling the activity of centers in the brain stem and spinal cord. In this role, the hypothalamus influences blood pressure, rate and force of heartbeat, digestive tract motility, eye pupil size, and many other visceral activities.

2. Center for emotional response. The hypothalamus lies at the "heart" of the limbic system (the emotional part of the brain). Nuclei involved in the perception of pleasure, fear, and rage, as well as those involved in biological rhythms and drives (such as the sex drive), are found in the hypothalamus.

The hypothalamus acts through ANS pathways to initiate most physical expressions of emotion. For example, a fearful person has a pounding heart, high blood pressure, pallor, sweating, and a dry mouth.

3. Body temperature regulation. The body's thermostat is in the hypothalamus. Hypothalamic neurons monitor blood temperature and receive input from other thermoreceptors in the brain and body periphery. Accordingly, the hypothalamus initiates cooling (sweating) or heat-generating mechanisms (shivering) as needed to maintain a relatively constant body temperature.

4. Regulation of food intake. In response to changing blood levels of certain nutrients (glucose and perhaps amino acids) or hormones [cholecystokinin (CCK) and others], the hypothalamus regulates feelings of hunger and satiety.

5. Regulation of water balance and thirst. When body fluids become too concentrated, hypothalamic neurons called *osmoreceptors* are activated. These neurons excite hypothalamic nuclei that trigger the release of antidiuretic hormone (ADH) from the posterior pituitary. ADH causes the kidneys to retain water. The same conditions also stimulate hypothalamic neurons in the *thirst center,* causing us to feel thirsty and, therefore, to drink more fluids.

6. Regulation of sleep-wake cycles. Acting with other brain regions, the hypothalamus helps regulate sleep. Through the operation of its *suprachiasmatic nucleus* (our biological clock), it sets the timing of the sleep cycle in response to daylight-darkness cues received from the visual pathways.

7. Control of endocrine system functioning. The hypothalamus acts as the helmsman of the endocrine system in two important ways. First, its *releasing hormones* control the secretion of hormones by the anterior pituitary gland. Second, its *supraoptic* and *paraventricular nuclei* produce the hormones ADH and oxytocin.

What part of the brain lies between the optic chiasma and the mammillary bodies?

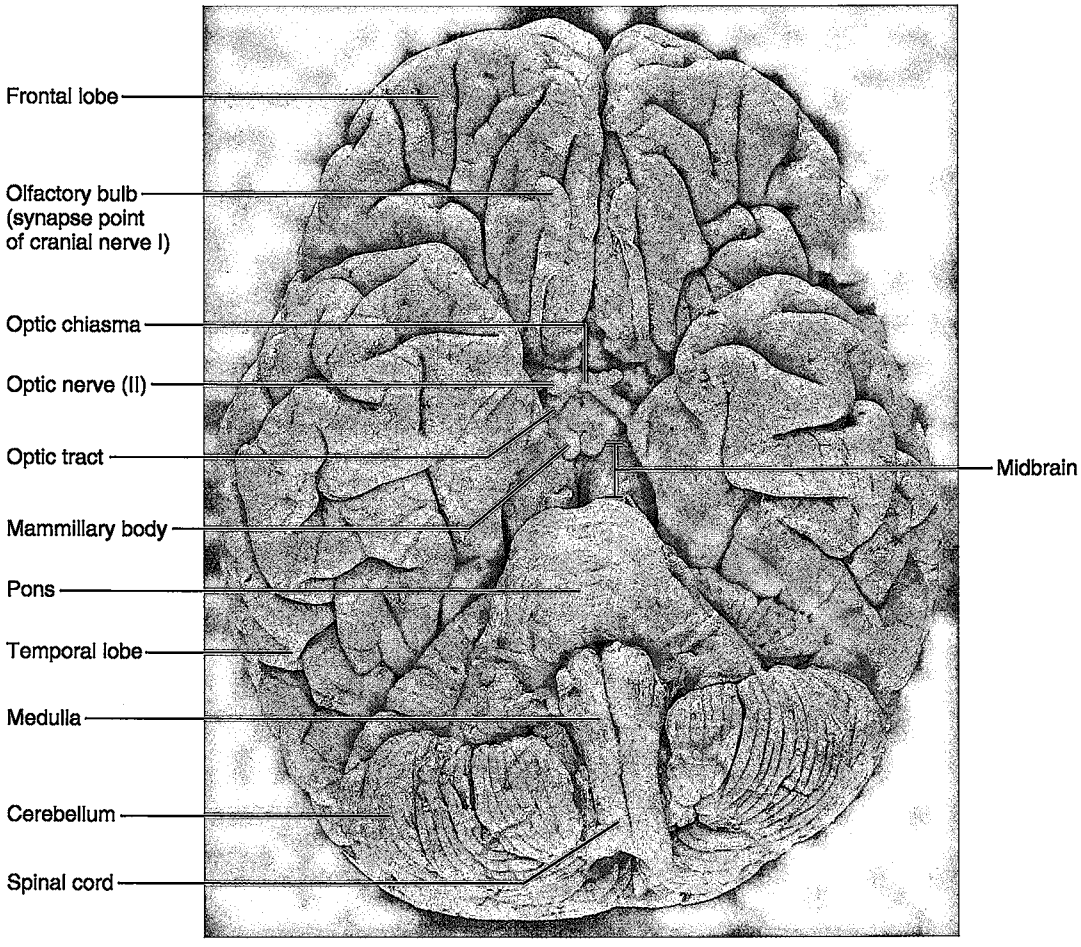

FIGURE 12.14 **Ventral aspect of the human brain, showing the three regions of the brain stem.** Only a small portion of the midbrain can be seen; the rest is surrounded by other brain regions.

HOMEOSTATIC IMBALANCE

Hypothalamic disturbances cause a number of disorders including severe body wasting, obesity, sleep disturbances, dehydration, and a broad range of emotional imbalances. For example, infants deprived of a warm, nurturing relationship may develop *failure to thrive*, a clinical term describing a delay in a child's growth or development. ●

Epithalamus

The **epithalamus** is the most dorsal portion of the diencephalon and forms the roof of the third ventricle. Extending from its posterior border and visible externally is the **pineal gland** or **body** (pin'e-al; "pine cone shaped") (see Figures 12.12 and 12.15). The pineal gland secretes the hormone *melatonin* (a sleep-inducing signal and antioxidant; see Chapter 16) and, along with hypothalamic nuclei, helps regulate the sleep-wake cycle.

Brain Stem

From superior to inferior, the brain stem regions are midbrain, pons, and medulla oblongata (Figures 12.12, 12.14, and 12.15). Each roughly an inch long, collectively they account for only 2.5% of total brain mass. Histologically, the organization of the brain stem is similar (but not identical) to that of the spinal cord—deep gray matter surrounded by white matter fiber tracts (see Figure 12.4). However, the brain stem has nuclei of gray matter embedded in the white matter, a feature not found in the spinal cord.

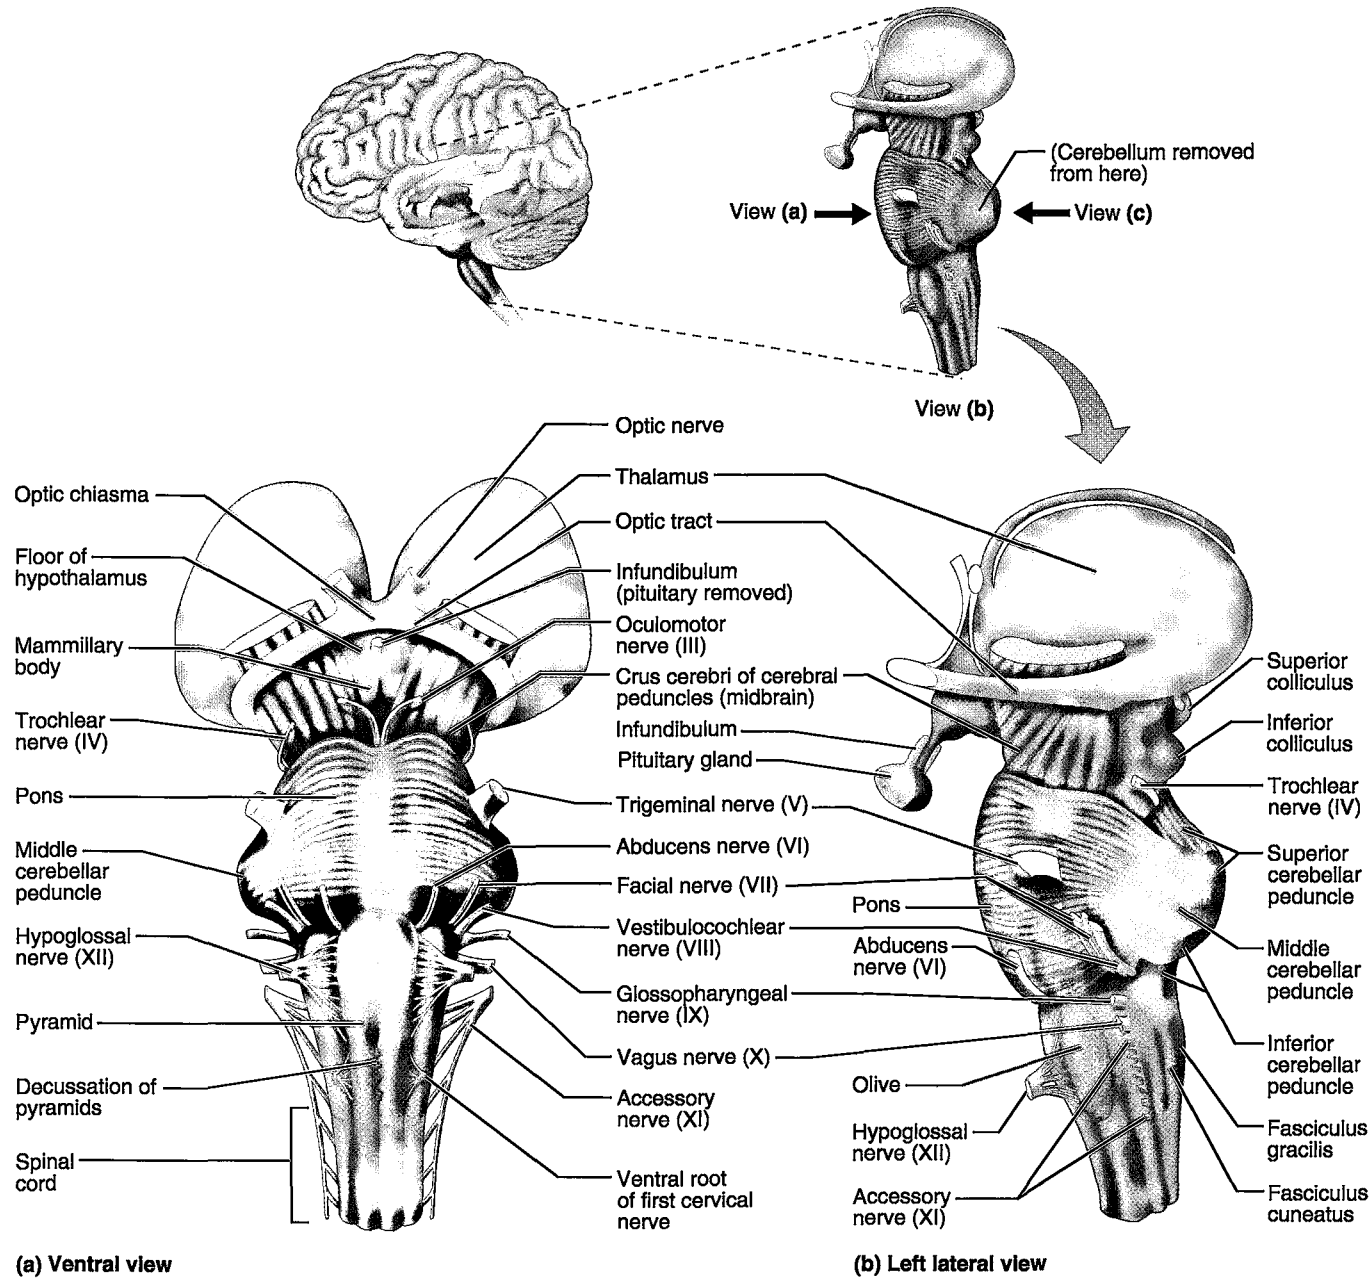

FIGURE 12.15 **Relationship of the brain stem and the diencephalon.**
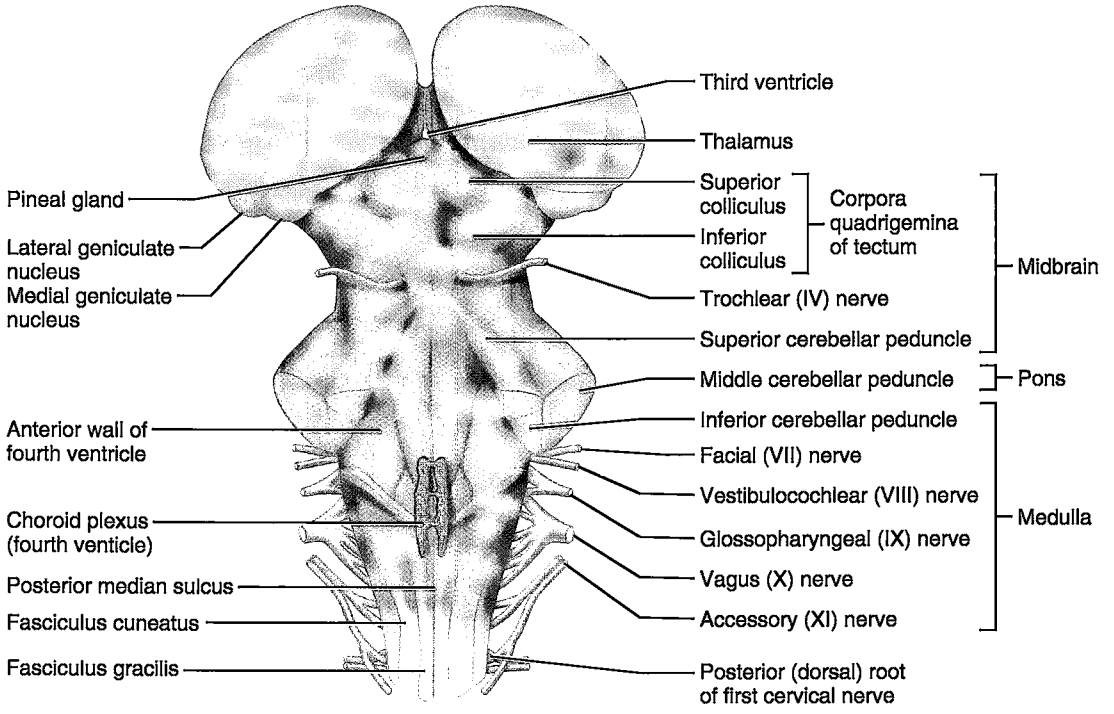
(a) Ventral view. **(b)** Lateral view.

Brain stem centers produce the rigidly programmed, automatic behaviors necessary for survival. Positioned between the cerebrum and the spinal cord, the brain stem also provides a pathway for fiber tracts running between higher and lower neural centers. Additionally, brain stem nuclei are associated with 10 of the 12 pairs of cranial nerves (described in Chapter 13), so it is heavily involved with innervation of the head.

Midbrain

The **midbrain** is located between the diencephalon and the pons (Figures 12.14 and 12.15). On its ventral aspect two bulging **cerebral peduncles** (pĕ-dung'klz) form vertical pillars that seem to hold up the cerebrum, hence their name meaning "little feet of the cerebrum." These peduncles contain the large pyramidal (corticospinal) motor tracts descending toward the spinal cord. The *superior cerebellar peduncles*, also fiber tracts, connect the midbrain to the cerebellum dorsally.

Running through the midbrain is the hollow *cerebral aqueduct* (Figures 12.12 and 12.16a), which connects the third and fourth ventricles, and delineates the cerebral peduncles ventrally from the *tectum*, the midbrain's roof. Surrounding the



(c) Dorsal view

FIGURE 12.15 *(continued)* **Relationship of the brain stem and the diencephalon. (c)** Dorsal view. Cerebral hemispheres have been removed.

aqueduct is the *periaqueductal gray matter,* which is involved in pain suppression and serves as the link between the fear-perceiving amygdala and ANS pathways that control the "fight-or-flight" response. The periaqueductal gray matter also includes nuclei that control two cranial nerves, the *oculomotor* and the *trochlear nuclei* (trok'le-ar).

Nuclei are also scattered in the surrounding white matter of the midbrain. The largest of these are the **corpora quadrigemina** (kor'por-ah kwod"ri-jem'i-nah; "quadruplets"), which raise four dome-like protrusions on the dorsal midbrain surface (Figures 12.12 and 12.15). The superior pair, the **superior colliculi** (kŏ-lik'u-li), are visual reflex centers that coordinate head and eye movements when we visually follow a moving object, even if we are not consciously looking at the object. The **inferior colliculi** are part of the auditory relay from the hearing receptors of the ear to the sensory cortex. They also act in reflexive responses to sound, such as in the *startle reflex,* which causes you to turn your head toward an unexpected sound.

Also embedded in each side of the midbrain white matter are two pigmented nuclei, the substantia nigra and red nucleus (Figure 12.16a). The band-like **substantia nigra** (sub-stan'she-ah ni'grah) is located deep to the cerebral peduncle. Its dark (*nigr* = black) color reflects a high content of melanin pigment, a precursor of the neurotransmitter (dopamine) released by these neurons. The substantia nigra is functionally linked to the basal nuclei (its axons project to the globus pallidus), and is considered part of the basal nuclear complex by many authorities. Degeneration of the dopamine-releasing neurons of the substantia nigra is the ultimate cause of Parkinson's disease.

The oval **red nucleus** lies deep to the substantia nigra. Its reddish hue is due to its rich blood supply and to the presence of iron pigment in its neurons. The red nuclei are relay nuclei in some descending motor pathways that effect limb flexion, and they are embedded in the *reticular formation,* a system of small nuclei scattered through the core of the brain stem (see pp. 455–456).

Pons

The **pons** is the bulging brain stem region wedged between the midbrain and the medulla oblongata (see Figures 12.12, 12.14, and 12.15). Dorsally, it forms part of the anterior wall of the fourth ventricle.

As its name suggests (*pons* = bridge), the pons is chiefly composed of conduction tracts that course in two directions. The deep projection fibers run longitudinally and complete the pathway between higher brain centers and the spinal cord. The more superficial ventral fibers issue from numerous *pontine nuclei,* which act as relays for "conversations" between

Q *Just what are the pyramids of the medulla?*

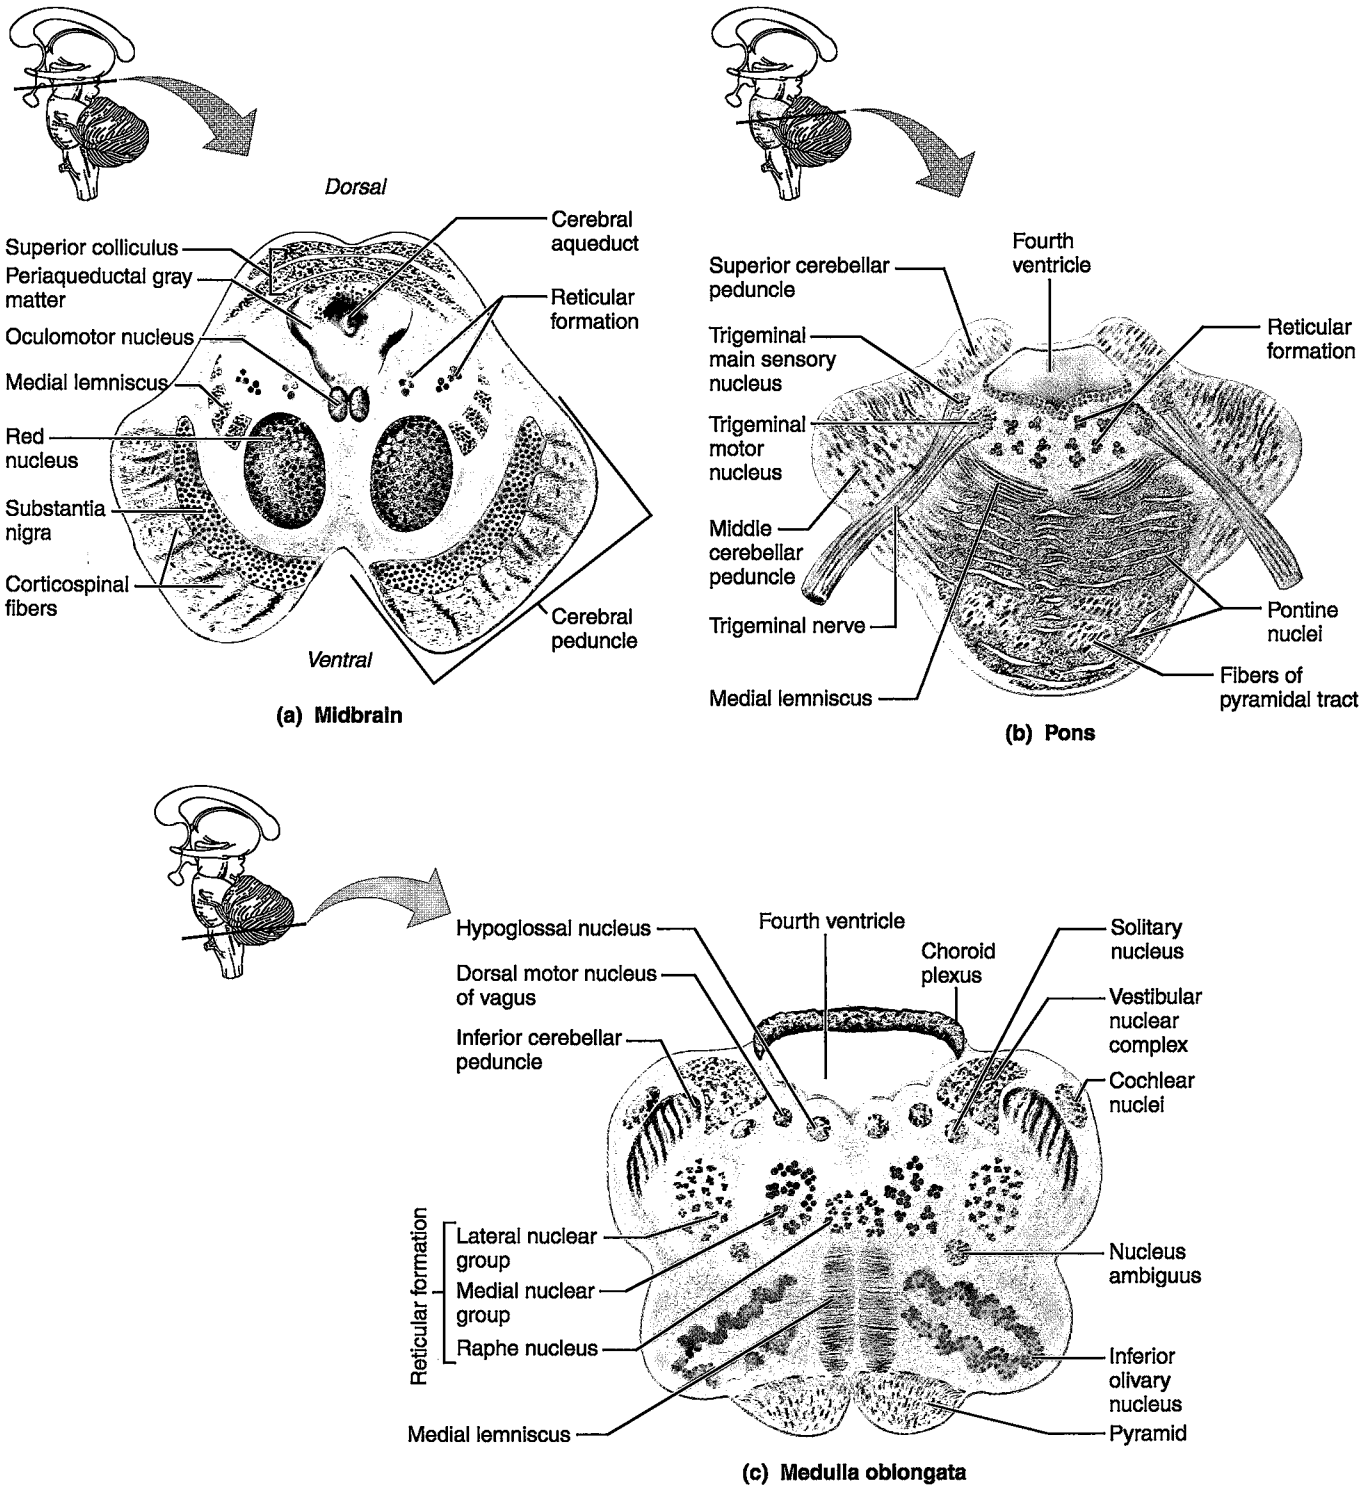


FIGURE 12.16 **Important brain stem nuclei.** Horizontal sections through **(a)** midbrain at the level of superior colliculi, **(b)** pons at the level of its trigeminal nerve nuclei, **(c)** superior medulla oblongata.

A *The corticospinal (pyramidal) tracts. The large voluntary motor tracts descending from the motor cortex.*

the motor cortex and cerebellum. These fibers are oriented transversely and dorsally as the *middle cerebellar peduncles* (Figure 12.15) and connect the pons bilaterally with the two sides of the cerebellum dorsally.

Several cranial nerve pairs issue from pons nuclei (Figure 12.16b), including the *trigeminal* (trijem'ĭ-nal), the *abducens* (ab-du'senz), and *facial nerves*. The cranial nerves and their functions are discussed in Chapter 13. Other important pons nuclei are part of the reticular formation and some help the medulla maintain the normal rhythm of breathing.

Medulla Oblongata

The conical **medulla oblongata** (me-dul'ah ob"long-gah'tah), or simply **medulla,** is the most inferior part of the brain stem. It blends imperceptibly into the spinal cord at the level of the foramen magnum of the skull (Figures 12.12 and 12.14). The central canal of the spinal cord continues upward into the medulla, where it broadens out to form the cavity of the fourth ventricle. Thus, both the medulla and the pons help form the ventral wall of the fourth ventricle. [The dorsal ventricular wall is formed by a thin capillary-rich membrane called a choroid plexus which abuts the cerebellum dorsally (Figure 12.12).]

Flanking the midline on the medulla's ventral aspect are two longitudinal ridges called **pyramids,** formed by the large pyramidal (corticospinal) tracts descending from the motor cortex (Figure 12.16c). Just above the medulla–spinal cord junction, most of these fibers cross over to the opposite side before continuing into the spinal cord. This crossover point is called the **decussation of the pyramids** (de"kus-sa'shun; "a crossing"). As mentioned earlier, the consequence of this crossover is that each cerebral hemisphere chiefly controls the voluntary movements of muscles on the opposite side of the body.

Also obvious externally are several other structures. The *inferior cerebellar peduncles* are fiber tracts that connect the medulla to the cerebellum dorsally. Situated lateral to the pyramids, the **olives** are oval swellings (which *do* resemble olives) produced mainly by the underlying **inferior olivary nuclei,** wavy folds of gray matter (Figure 12.16c). These nuclei relay sensory information on the state of stretch of muscles and joints to the cerebellum. The rootlets of the *hypoglossal nerves* emerge from the groove between the pyramid and olive on each side of the brain stem. Other cranial nerves associated with the medulla are the *glossopharyngeal nerves* and *vagus nerves,* and portions of the accessory nerves. Additionally, the fibers of the *vestibulocochlear nerves* (ves-tib"u-lo-kok'le-ar) synapse with the **cochlear nuclei** (auditory relays), and with numerous vestibular nuclei in both the pons and medulla. Collectively, the vestibular nuclei, called the **vestibular nuclear complex,** mediate responses that maintain equilibrium.

Also housed in the medulla are several nuclei associated with ascending sensory tracts. The most prominent are the dorsally located **nucleus gracilis** (grah-sĭ'lis) and **nucleus cuneatus** (ku'ne-āt-us), associated with the *medial lemniscal tract*. These serve as relay nuclei in a pathway by which general somatic sensory information ascends from the spinal cord to the somatosensory cortex.

The small size of the medulla belies its crucial role as an autonomic reflex center involved in maintaining body homeostasis. Important visceral motor nuclei found in the medulla include the following:

1. **Cardiovascular center.** This includes the *cardiac center,* which adjusts the force and rate of heart contraction to meet the body's needs, and the *vasomotor center,* which changes blood vessel diameter to regulate blood pressure.
2. **Respiratory centers.** These control the rate and depth of breathing and (in concert with pons centers) maintain respiratory rhythm.
3. **Various other centers.** Additional centers regulate such activities as vomiting, hiccuping, swallowing, coughing, and sneezing.

Notice that many functions listed above were also attributed to the hypothalamus (p. 446). The overlap is easily explained. The hypothalamus exerts its control over many visceral functions by relaying its instructions through medullary reticular centers, which carry them out.

Cerebellum

The cauliflower-like **cerebellum** (ser"ĕ-bel'um; "small brain"), exceeded in size only by the cerebrum, accounts for about 11% of total brain mass. The cerebellum is located dorsal to the pons and medulla (and to the intervening fourth ventricle). It protrudes under the occipital lobes of the cerebral hemispheres, from which it is separated by the transverse cerebral fissure (see Figure 12.6d).

By processing inputs received from the cerebral motor cortex, various brain stem nuclei, and sensory receptors, the cerebellum provides the precise timing and appropriate patterns of skeletal muscle contraction for smooth, coordinated movements and agility needed for our daily living—driving, typing, and for some of us, playing the tuba. Cerebellar activity occurs subconsciously; that is, we have no awareness of its functioning.

The cerebellum is primarily involved in motor control. What type of sensory information do you think is relayed to the sensory areas of the cerebellum?

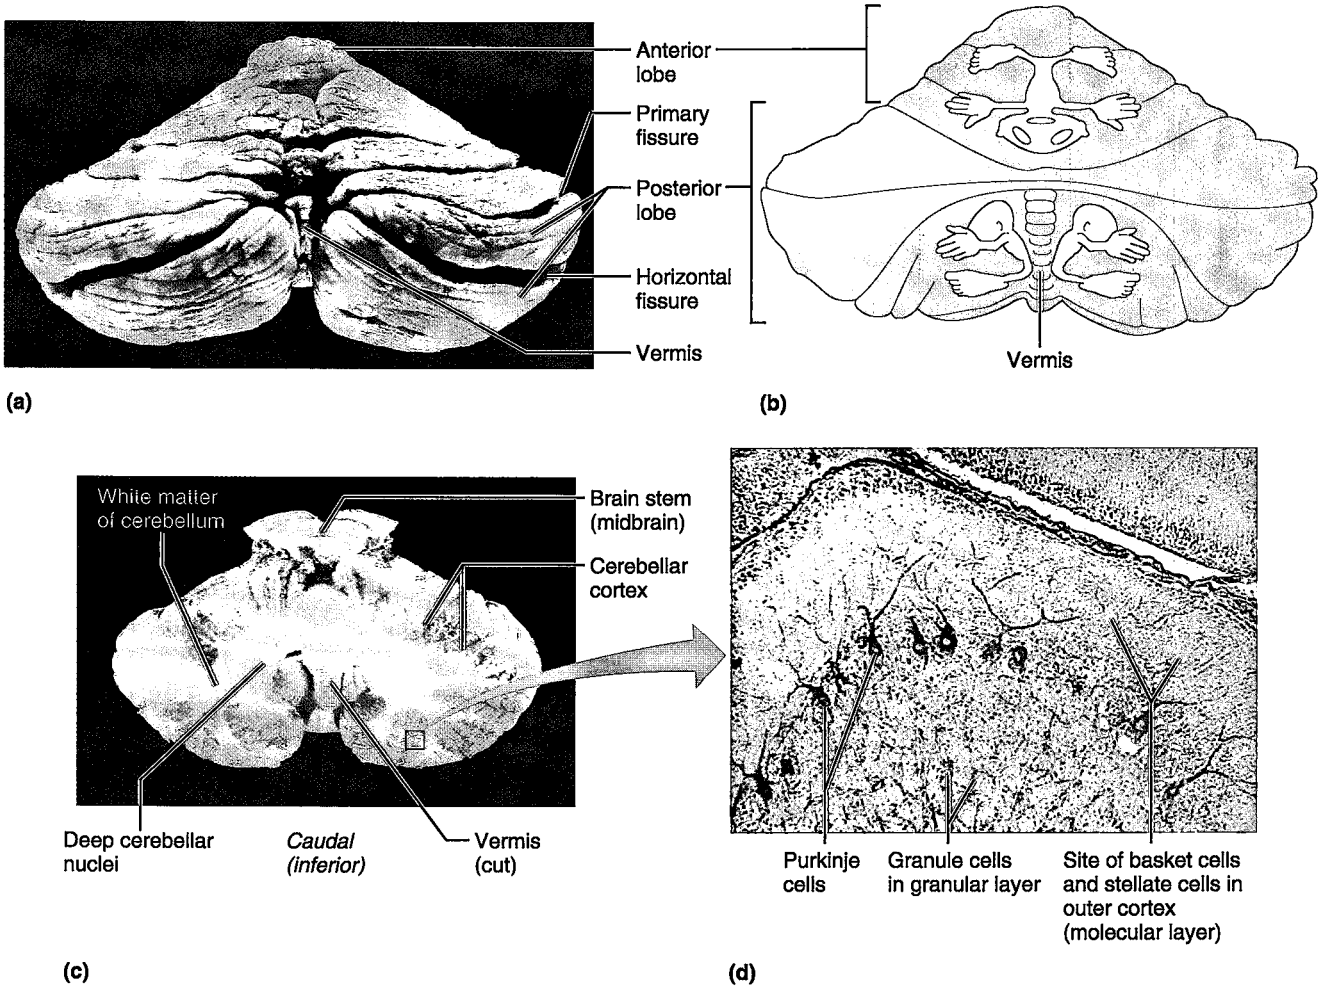

FIGURE 12.17 **Cerebellum. (a)** Photograph of the posterior aspect of the cerebellum. The flocculonodular lobe, which lies deep to the vermis, is not visible in this view. **(b)** Positioning of overlapping motor and sensory maps of the body (in the form of three homunculi). **(c)** Posterior view sectioned frontally to reveal the three cerebellar layers. **(d)** Photomicrograph of a small portion of the cerebellar cortex showing the relative positions of granule cells, Purkinje cells, and stellate and basket cells (200×).

Anatomy

The cerebellum is bilaterally symmetrical; its two apple-sized **cerebellar hemispheres** are connected medially by the wormlike **vermis** (Figure 12.17). Its surface is heavily convoluted, with fine, transversely oriented pleatlike gyri known as **folia** ("leaves"). Deep fissures subdivide each hemisphere into **anterior, posterior,** and **flocculonodular lobes** (flok"u-lo-nod'u-lar). The small propeller-shaped flocculonodular lobes, situated deep to the vermis and posterior lobe, cannot be seen in a surface view.

Like the cerebrum, the cerebellum has a thin outer cortex of gray matter, internal white matter, and small, deeply situated, paired masses of gray matter, the most familiar of which are the *dentate nuclei*. Several types of neurons populate the cerebellar cortex, including stellate, basket, granule, and Purkinje cells (Figure 12.17d). Of these, the large **Purkinje cells,** with their extensively branched dendrites, are the only cortical neurons that send axons through the white matter to synapse with the central nuclei of the cerebellum. TABLE 12.1 Functions of Major Brain Regions

REGION	FUNCTION
CEREBRAL HEMISPHERES (pp. 434–443)	
	Cortical gray matter localizes and interprets sensory inputs, controls voluntary and skilled skeletal muscle activity, and functions in intellectual and emotional processing; basal nuclei (ganglia) are subcortical motor centers important in initiation of skeletal muscle movements
DIENCEPHALON (pp. 443–447)	
	Thalamic nuclei are relay stations in conduction of (1) sensory impulses to cerebral cortex for interpretation, and (2) impulses to and from cerebral motor cortex and lower (subcortical) motor centers, including cerebellum; thalamus is also involved in memory processing Hypothalamus is chief integration center of autonomic (involuntary) nervous system; it functions in regulation of body temperature, food intake, water balance, thirst, and biological rhythms and drives; regulates hormonal output of anterior pituitary gland and is an endocrine organ in its own right (produces ADH and oxytocin); part of limbic system
Limbic system (pp. 454–455)	A functional system involving cerebral and diencephalon structures that mediates emotional response; also involved in memory processing
BRAIN STEM (pp. 447–451)	
	Midbrain: Conduction pathway between higher and lower brain centers (e.g., cerebral peduncles contain the fibers of the pyramidal tracts); its superior and inferior colliculi are visual and auditory reflex centers; substantia nigra and red nuclei are subcortical motor centers; contains nuclei for cranial nerves III and IV Pons: Conduction pathway between higher and lower brain centers; pontine nuclei relay information from the cerebrum to the cerebellum; its respiratory nuclei cooperate with the medullary respiratory centers to control respiratory rate and depth; houses nuclei of cranial nerves V–VII Medulla oblongata: Conduction pathway between higher brain centers and spinal cord; site of decussation of the pyramidal tracts; houses nuclei of cranial nerves VIII–XII; contains nuclei cuneatus and gracilis (synapse points of ascending sensory pathways transmitting sensory impulses from skin and proprioceptors), and visceral nuclei controlling heart rate, blood vessel diameter, respiratory rate, vomiting, coughing, etc.; its inferior olivary nuclei provide the sensory relay to the cerebellum
Reticular formation (pp. 455–456)	A functional brain stem system that maintains cerebral cortical alertness (reticular activating system) and filters out repetitive stimuli; its motor nuclei help regulate skeletal and visceral muscle activity
CEREBELLUM (pp. 451–454)	
	Processes information from cerebral motor cortex and from proprioceptors and visual and equilibrium pathways, and provides "instructions" to cerebral motor cortex and subcortical motor centers that result in proper balance and posture and smooth, coordinated skeletal muscle movements

white matter in the cerebellum resembles a branching tree, a pattern fancifully called the **arbor vitae** (ar'bor vi'te; "tree of life").

The anterior and posterior lobes of the cerebellum, which coordinate body movements, have completely overlapping sensory and motor maps of the entire body as indicated by the three homunculi in Figure 12.17b. The medial portions influence the motor activities of the trunk and girdle muscles. The intermediate parts of each hemisphere are more concerned with the distal parts of the limbs and skilled movements. The lateralmost parts of each

hemisphere integrate information from the association areas of the cerebral cortex and appear to play a role in planning rather than executing movements. The flocculonodular lobes receive inputs from the equilibrium apparatus of the inner ears, and adjust posture to maintain balance.

Cerebellar Peduncles

As noted earlier, three paired fiber tracts—the cerebellar peduncles—connect the cerebellum to the brain stem (see Figure 12.15). Unlike the contralateral fiber distribution to and from the cerebral cortex, virtually all fibers entering and leaving the cerebellum are **ipsilateral** (*ipsi* = same)—from and to the same side of the body. The **superior cerebellar peduncles** connecting cerebellum and midbrain carry instructions from neurons in the deep cerebellar nuclei to the cerebral motor cortex via thalamic relays. Like the basal nuclei, the cerebellum has no *direct* connections to the cerebral cortex.

The **middle cerebellar peduncles** carry one-way communication from the pons to the cerebellum, advising the cerebellum of voluntary motor activities initiated by the motor cortex (via relays in the pontine nuclei). The **inferior cerebellar peduncles** connect medulla and cerebellum. These peduncles convey sensory information to the cerebellum from (1) muscle proprioceptors throughout the body and (2) the vestibular nuclei of the brain stem, which are concerned with equilibrium and balance.

Cerebellar Processing

The functional scheme of cerebellar processing for motor activity seems to be as follows:

1. The motor areas of the cerebral cortex, via relay nuclei in the brain stem, notify the cerebellum of their intent to initiate voluntary muscle contractions.
2. At the same time, the cerebellum receives information from proprioceptors throughout the body (regarding tension in the muscles and tendons, and joint position) and from visual and equilibrium pathways. This information enables the cerebellum to evaluate body position and momentum, that is, where the body is and where it is going.
3. The cerebellar cortex calculates the best way to coordinate the force, direction, and extent of muscle contraction to prevent overshoot, maintain posture, and ensure smooth, coordinated movements.
4. Then, via the superior peduncles, the cerebellum dispatches to the cerebral motor cortex its "blueprint" for coordinating movement. Cerebellar fibers also send information to brain stem nuclei, which in turn influence motor neurons of the spinal cord.

Just as its automatic pilot compares a plane's instrument settings with the planned course, the cerebellum continually compares the higher brain's intention with the body's performance and sends out messages to initiate the appropriate corrective measures. Cerebellar injury results in loss of muscle tone and clumsy, unsure movements.

Cognitive Function of the Cerebellum

Functional imaging studies indicate that the cerebellum plays a role in cognition. The cerebellum recognizes and predicts sequences of events so that it may adjust for the multiple forces exerted on a limb during complex movements involving several joints. Some nonmotor functions, including word association and puzzle solving, also appear to involve the cerebellum.

Functional Brain Systems

Functional brain systems are networks of neurons that work together but span relatively large distances in the brain, so they cannot be localized to specific brain regions. The *limbic system* and the *reticular formation* are excellent examples (Table 12.1).

The Limbic System

The **limbic system** is a group of structures located on the medial aspect of each cerebral hemisphere and diencephalon. Its cerebral structures encircle (*limbus* = ring) the upper part of the brain stem (Figure 12.18), and include parts of the rhinencephalon (*septal nuclei, cingulate gyrus, parahippocampal gyrus, dentate gyrus,* and C-shaped *hippocampus*), and the **amygdala** (ah-mig'dah-lah), an almond-shaped nucleus that sits on the tail of the caudate nucleus. In the diencephalon, the main limbic structures are the *hypothalamus* and the *anterior thalamic nuclei*. The **fornix** ("arch") and other fiber tracts link these limbic system regions together.

The limbic system is our *emotional,* or *affective* (feelings), *brain*. Two parts seem especially important in emotions—the amygdala and the anterior part of the **cingulate gyrus.** The former recognizes angry or fearful facial expressions, assesses danger, and elicits the fear response. The latter plays a role in expressing our emotions through gestures and in resolving mental conflicts when we are frustrated.

Odors often trigger emotional reactions and memories; this reflects the origin of much of the limbic system in the primitive "smell brain" (rhinencephalon). Our reactions to odors are rarely neutral (a skunk smells *bad* and repulses us), and odors often recall memories of emotion-laden events.

Extensive connections between the limbic system and lower and higher brain regions allow the system to integrate and respond to a variety of environmental stimuli. Most limbic system output is relayed through the hypothalamus. Because the

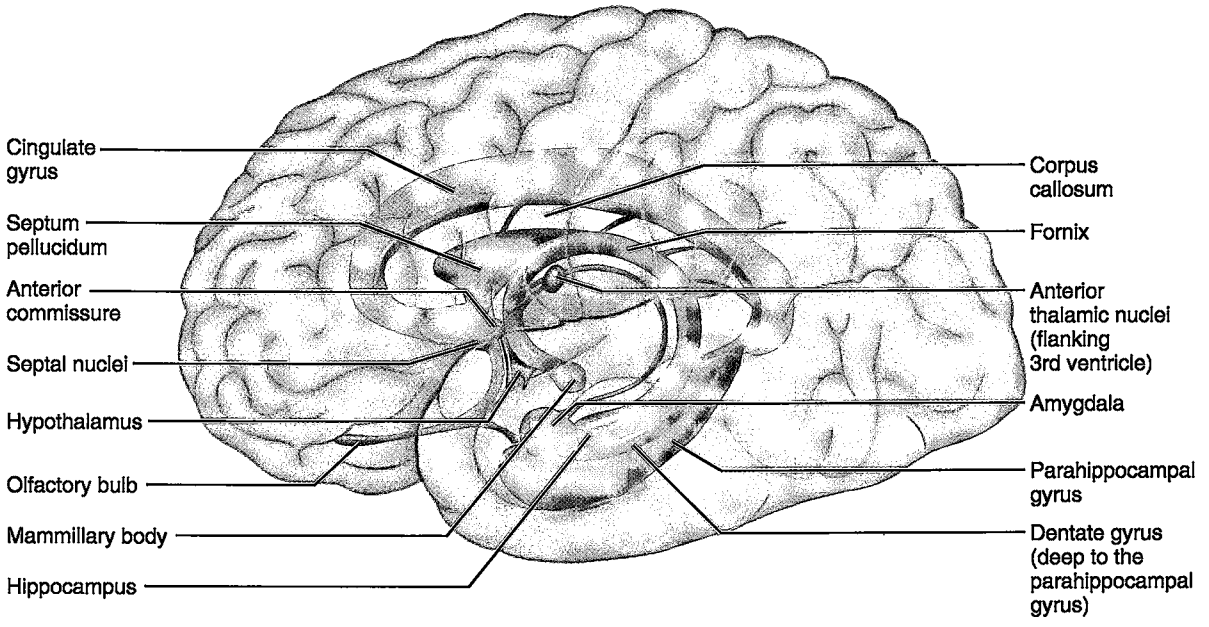

FIGURE 12.18 **The limbic system.** Lateral view of the brain, showing some of the structures of the limbic system, the emotional-visceral brain. The brain stem is not illustrated.

hypothalamus is the neural clearinghouse for both autonomic (visceral) function and emotional response, it is not surprising that some people under acute or unrelenting emotional stress fall prey to visceral illnesses, such as high blood pressure and heartburn. Such emotion-induced illnesses are called **psychosomatic illnesses.**

Because the limbic system interacts with the prefrontal lobes, there is an intimate relationship between our feelings (mediated by the emotional brain) and our thoughts (mediated by the cognitive brain). As a result, we (1) react emotionally to things we consciously understand to be happening, and (2) are consciously aware of the emotional richness of our lives. Communication between the cerebral cortex and limbic system explains why emotions sometimes override logic and, conversely, why reason can stop us from expressing our emotions in inappropriate situations. Particular limbic system structures—the **hippocampus** and amygdala—also play a role in memory.

The Reticular Formation

The **reticular formation** extends through the central core of the medulla oblongata, pons, and midbrain (Figure 12.19). It is composed of loosely clustered neurons in what is otherwise white matter. These neurons form three broad columns along the length of the brain stem (Figure 12.16c): (1) the midline **raphe nuclei** (ra'fe; *raphe* = seam or crease), which are flanked laterally by (2) the **medial (large cell) group** and then (3) the **lateral (small cell) group of nuclei.**

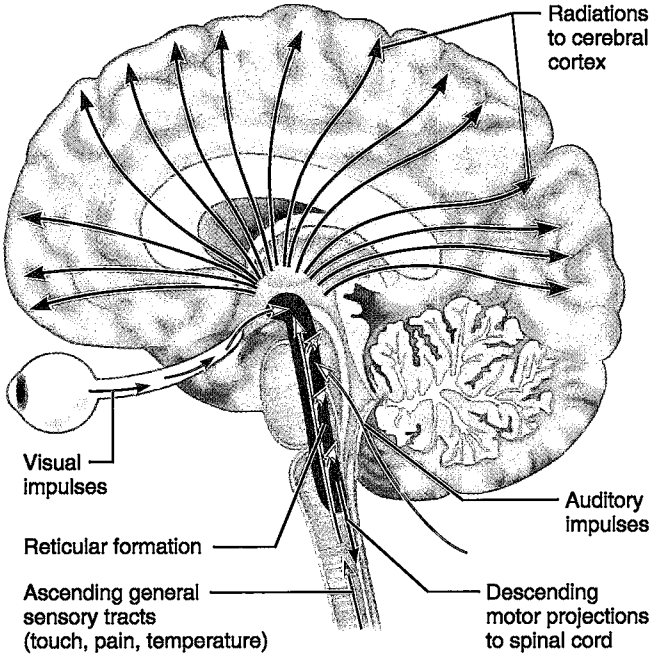

FIGURE 12.19 **The reticular formation.** The reticular formation extends the length of the brain stem. A portion of this formation, the reticular activating system, maintains alert wakefulness of the cerebral cortex. Ascending arrows indicate input of sensory systems to the RAS and then reticular output (some via thalamic relays) to the cerebral cortex. Other reticular nuclei are involved in muscle coordination. Their output is indicated by the red arrow descending the brain stem.

The outstanding feature of the reticular neurons is their far-flung axonal connections. Individual reticular neurons project to the hypothalamus, thalamus, cerebellum, and spinal cord, making reticular neurons ideal for governing the arousal of the brain as a whole. For example, certain reticular neurons, unless inhibited by other brain areas, send a continuous stream of impulses (via thalamic relays) to the cerebral cortex, which keeps the cortex alert and conscious and enhances its excitability. This arm of the reticular formation is known as the **reticular activating system (RAS).** Impulses from all the great ascending sensory tracts synapse with RAS neurons, keeping them active and enhancing their arousing effect on the cerebrum. (This may explain why many students, stimulated by a bustling environment, like to study in a crowded cafeteria.) The RAS also acts like a filter for this flood of sensory inputs. Repetitive, familiar, or weak signals are filtered out, but unusual, significant, or strong impulses do reach consciousness. For example, you are probably unaware of your watch encircling your wrist, but would immediately notice it if the clasp broke. Between them, the RAS and the cerebral cortex disregard perhaps 99% of all sensory stimuli as unimportant. If this did not occur, the sensory overload would drive us crazy. The drug LSD interferes with these sensory dampers, promoting an often overwhelming sensory overload.

- Take a moment to become aware of all the stimuli in your environment. Notice all the colors, shapes, odors, sounds, and so on. How many of these sensory stimuli are you usually aware of?

The RAS is inhibited by sleep centers located in the hypothalamus and other neural regions, and is depressed by alcohol, sleep-inducing drugs, and tranquilizers. Severe injury to this system, as might follow a knockout punch that twists the brain stem, results in permanent unconsciousness (irreversible *coma*). Although the RAS is central to wakefulness, some of its nuclei are also involved in sleep, which we will discuss later in this chapter.

The reticular formation also has a *motor* arm. Some of its motor nuclei project to motor neurons in the spinal cord via the *reticulospinal tracts*, and help control skeletal muscles during coarse limb movements. Other reticular motor nuclei, such as the vasomotor, cardiac, and respiratory centers of the medulla, are autonomic centers that regulate visceral motor functions.

Higher Mental Functions

During the last four decades, an exciting exploration of our "inner space," or what we commonly call *the mind*, has been going on. But researchers in the field of cognition are still struggling to understand how the mind's presently incomprehensible qualities might spring from living tissue and electrical impulses. Souls and synapses are hard to reconcile!

Because brain waves reflect the electrical activity on which higher mental functions are based, we will consider them first, along with the related topics of consciousness and sleep. We will then examine language and (hesitantly) memory, an area in which we are still forced to hypothesize or speculate about what must (or should) happen.

Brain Wave Patterns and the EEG

Normal brain function involves continuous electrical activity of neurons. An **electroencephalogram** (e-lek"tro-en-sef'ah-lo-gram), or **EEG,** records some aspects of this activity. An EEG is made by placing electrodes on the scalp and then connecting the electrodes to an apparatus that measures electrical potential differences between various cortical areas (Figure 12.20a). The patterns of neuronal electrical activity recorded, called **brain waves,** are generated by synaptic activity at the surface of the cortex, rather than by action potentials in the white matter.

Each of us has a brain wave pattern that is as unique as our fingerprints. For simplicity, however, we can group brain waves into the four frequency classes shown in Figure 12.20b. Each wave is a continuous train of peaks and troughs, and the wave frequency, expressed in hertz (Hz), is the number of peaks in one second. A frequency of 1 Hz means that one peak occurs each second.

- **Alpha waves** (8–13 Hz) are relatively regular and rhythmic, low-amplitude, synchronous waves. In most cases, they indicate a brain that is "idling"—a calm, relaxed state of wakefulness.
- **Beta waves** (14–30 Hz) are also rhythmic, but they are not as regular as alpha waves and have a higher frequency. Beta waves occur when we are mentally alert, as when concentrating on some problem or visual stimulus.
- **Theta waves** (4–7 Hz) are still more irregular. Though common in children, theta waves are abnormal in awake adults.
- **Delta waves** (4 Hz or less) are high-amplitude waves seen during deep sleep and when the reticular activating system is damped, such as during anesthesia. In awake adults, they indicate brain damage.

The amplitude or intensity of any wave is represented by how high the wave peaks rise and how low the troughs dip. The amplitude of brain waves reflects the synchronous activity of many neurons and not the degree of electrical activity of individual neurons. Usually, brain waves are complex and low amplitude. During some stages of sleep, neurons tend to fire synchronously, producing similar, high-amplitude brain waves.

FIGURE 12.20 **Electroencephalography and brain waves. (a)** To obtain a recording of brain wave activity (an EEG), electrodes are positioned on the patient's scalp and attached to a recording device called an electroencephalograph. **(b)** Typical EEGs. Alpha waves are typical of the awake but relaxed state; beta waves occur in the awake, alert state; theta waves are common in children but not adults; delta waves occur during deep sleep.

Brain waves change with age, sensory stimuli, brain disease, and the chemical state of the body. EEGs are used for research on sleep, and for diagnosing epilepsy and many types of brain lesions. Interference with cerebral cortical functions is suggested when brain waves are too fast or too slow, and unconsciousness occurs at both extremes. Because spontaneous brain waves are always present, even during unconsciousness and coma, their absence—called a "flat EEG"—is clinical evidence of brain death.

HOMEOSTATIC IMBALANCE

Almost without warning, a victim of epilepsy may lose consciousness and fall stiffly to the ground, body wracked by uncontrollable jerking. These **epileptic seizures** reflect a torrent of electrical discharges of groups of brain neurons, and while their uncontrolled activity is occurring, no other messages can get through. Epilepsy, manifested by one out of 100 of us, is not associated with, nor does it cause, intellectual impairment. Some cases of epilepsy are induced by genetic factors, but it can also result from brain injuries caused by blows to the head, stroke, infections, high fever, or tumors.

Epileptic seizures can vary tremendously in their expression and severity. *Absence seizures,* formerly known as *petit mal,* are mild forms in which the expression goes blank for a few seconds as consciousness disappears. These are typically seen in young children and usually disappear by the age of 10. In the most severe, convulsive form of epileptic seizures, *tonic-clonic* (formerly called *grand mal*), the person loses consciousness. Bones are often broken during the intense convulsions, showing the incredible strength of the muscle contractions that occur. Loss of bowel and bladder control and severe biting of the tongue are common. The seizure lasts for a few minutes, then the muscles relax and the person awakens but remains disoriented for several minutes. Many seizure sufferers experience a sensory hallucination, such as a taste, smell, or flashes of light, just before the seizure begins. This phenomenon, called an **aura,** is helpful because it gives the person time to lie down and avoid falling to the floor.

Epilepsy can usually be controlled by anticonvulsive drugs. Newer on the scene is the *vagus nerve stimulator,* which is implanted under the skin of the chest and delivers pulses via the vagus nerve to the brain at predetermined intervals to keep the electrical activity of the brain from becoming chaotic. A current line of research seeks to use implanted electrodes programmed to detect coming seizures in time to deliver customized drug or shock therapy. ●

Consciousness

Consciousness encompasses conscious perception of sensations, voluntary initiation and control of movement, and capabilities associated with higher mental processing (memory, logic, judgment, perseverance, and so on). Clinically, consciousness is defined on a

continuum that grades behavior in response to stimuli as (1) *alertness,* (2) *drowsiness* or *lethargy* (which proceeds to sleep), (3) *stupor,* and (4) *coma*. Alertness is the highest state of consciousness and cortical activity, and coma the most depressed. Consciousness is difficult to define. And to be perfectly frank, reducing our response to the palette of a Key West sunset to a series of interactions between dendrites, axons, and neurotransmitters does not capture what makes that event so special. A sleeping person obviously lacks something that he or she has when awake, and we call this "something" consciousness. The current suppositions about consciousness are as follows:

1. It involves simultaneous activity of large areas of the cerebral cortex.

2. It is superimposed on other types of neural activity. At any time, specific neurons and neuronal pools are involved both in localized activities (such as motor control) and in cognition.

3. It is holistic and totally interconnected. Information for "thought" can be claimed from many locations in the cerebrum simultaneously. For example, retrieval of a specific memory can be triggered by several routes—a smell, a place, a particular person, and so on.

HOMEOSTATIC IMBALANCE

Except when a person is sleeping, unconsciousness is always a signal that brain function is impaired. A brief loss of consciousness is called **fainting** or **syncope** (sing'ko-pe; "cut short"). Most often, it indicates inadequate cerebral blood flow due to low blood pressure, as might follow hemorrhage or sudden emotional stress.

Total unresponsiveness to sensory stimuli for an extended period is called **coma.** Coma is *not* deep sleep. During sleep, the brain is active and oxygen consumption resembles that of the waking state. In coma patients, in contrast, oxygen use is always below normal resting levels.

Blows to the head may induce coma by causing widespread cerebral or brain stem trauma. Coma may also be produced by tumors or infections that invade the brain stem. Metabolic disturbances such as hypoglycemia (abnormally low blood sugar levels), drug overdose, or liver or kidney failure interfere with overall brain function and can result in coma. Cerebral infarctions, unless massive and accompanied by extreme swelling of the brain, rarely cause coma.

When the brain has suffered irreparable damage, irreversible coma occurs, even though life-support measures may have restored vitality to other body organs. The result is **brain death,** a dead brain in an otherwise living body. Because life support can be removed only after death, physicians must determine whether a patient in an irreversible coma is legally alive or dead. ●

Sleep and Sleep-Wake Cycles

Sleep is defined as a state of partial unconsciousness from which a person can be aroused by stimulation. This distinguishes sleep from *coma,* a state of unconsciousness from which a person *cannot* be aroused by even the most vigorous stimuli. For the most part, cortical activity is depressed during sleep, but brain stem functions, such as control of respiration, heart rate, and blood pressure, continue. Even environmental monitoring continues to some extent, as illustrated by the fact that strong stimuli ("things that go bump in the night") immediately arouse us. In fact, people who sleepwalk can avoid objects and navigate stairs while truly asleep.

Types of Sleep

The two major types of sleep, which alternate through most of the sleep cycle, are **non–rapid eye movement (NREM) sleep** and **rapid eye movement (REM) sleep,** defined in terms of their EEG patterns. During the first 30 to 45 minutes of the sleep cycle, we pass through the four stages of NREM sleep (Figure 12.21), culminating in **slow-wave sleep.** As we pass through these stages and slip into deeper and deeper sleep, the frequency of the EEG waves declines, but their amplitude increases.

About 90 minutes after sleep begins, once NREM stage 4 has been achieved, the EEG pattern changes abruptly. It becomes very irregular and appears to backtrack quickly through the stages until alpha waves (more typical of the awake state) appear, indicating the onset of REM sleep. This brain wave change is coupled with increases in heart rate, respiratory rate, and blood pressure and a decrease in gastrointestinal motility. Oxygen use by the brain is tremendous during REM—greater than during the awake state.

Although the eyes move rapidly under the lids during REM, most of the body's skeletal muscles are actively inhibited and go limp. This temporary paralysis prevents us from acting out our dreams. Most dreaming occurs during REM sleep, and some suggest that the flitting eye movements are following the visual imagery of our dreams. (Note, however, that most nightmares and night terrors occur during NREM stages 3 and 4.) In adolescents and adults, REM episodes are frequently associated with erection of the penis or engorgement of the clitoris.

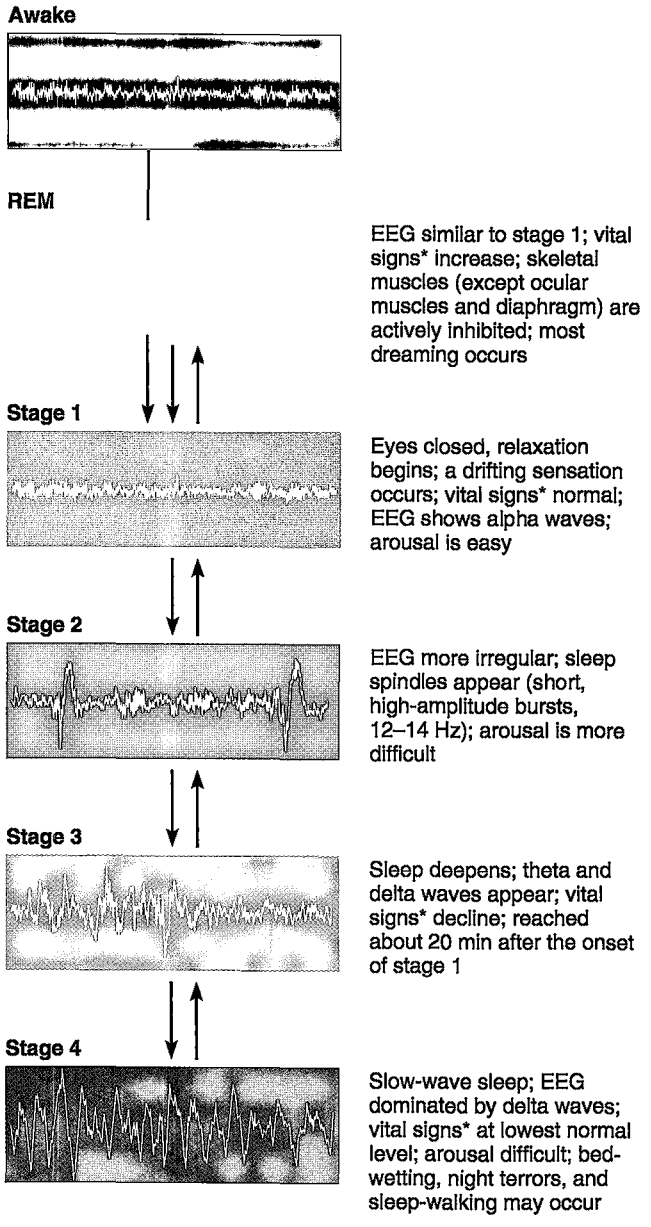

FIGURE 12.21 **Types and stages of sleep. (a)** The progression from the waking state through the four stages of non–rapid eye movement (NREM) sleep and REM sleep is shown. Each stage is characterized by a particular EEG pattern. **(b)** The bar graph shows the time spent during each of these stages in a typical 7½-hour sleep period for a young adult.

*Vital signs refer to heart rate and blood pressure only.

Sleep Patterns

The alternating cycles of sleep and wakefulness reflect a natural *circadian*, or 24-hour, *rhythm*. In the awake state, alertness of the cerebral cortex is mediated by the RAS (see Figure 12.19). When RAS activity declines, cerebral cortical activity declines as well; thus, lesions of the RAS nuclei result in unconsciousness. However, sleep is much more than simply turning off the arousal (RAS) mechanism. RAS centers not only help maintain the awake state but also mediate some sleep stages, especially dreaming sleep. The hypothalamus is responsible for the timing of the sleep cycle: Its *suprachiasmatic nucleus* (a biological clock) regulates its *preoptic nucleus* (a sleep-inducing center).

In young and middle-aged adults, a typical night's sleep alternates between REM and NREM sleep with occasional partial arousals. Following each REM episode, the sleeper descends to stage 4 again. REM recurs about every 90 minutes, with each REM period getting longer. The first REM of the night lasts 5–10 minutes and the final one 20 to 50 minutes (Figure 12.21). Hence, our longest dreams occur just before we wake. When certain neurons of the midbrain reticular formation fire at maximal rates, we awaken for the day.

The slow theta and delta waves of deep sleep are the result of synchronized firing of thalamic neurons that is normally inhibited during wakefulness by the RAS of the pons. Some pontine neurons of the reticular formation control the transition from NREM sleep to REM sleep, and others suppress motor activity, inducing paralysis. A large number of chemical substances in the body cause sleepiness, but the relative importance of these various sleep-inducing substances is not known.

Importance of Sleep

Slow-wave (NREM stage 4) and REM sleep seem to be important in different ways. Slow-wave sleep is presumed to be restorative—the time when most neural mechanisms can wind down to basal levels. When deprived of sleep, we spend more time than usual in slow-wave sleep during the next sleep episode.

A person persistently deprived of REM sleep becomes moody and depressed, and exhibits various personality disorders. REM sleep may give the brain an opportunity to analyze the day's events and to work through emotional problems in dream imagery.

Another idea is that REM sleep is reverse learning. According to this hypothesis, accidental, repetitious, and meaningless communications continually occur, and they must be eliminated from the neural networks by dreaming if the cortex is to remain a well-behaved and efficient thinking system. In other words, we dream to forget.

Alcohol and some sleep medications (barbiturates and others) suppress REM sleep but not slow-wave sleep. On the other hand, certain tranquilizers, such as diazepam (Valium) reduce slow-wave sleep much more than REM sleep.

Whatever its importance, the daily sleep requirement declines steadily from 16 hours or so in infants to approximately 7½ to 8½ hours in early adulthood. It then levels off before declining once again in old age. Sleep patterns also change throughout life. REM sleep occupies about half the total sleeping time in infants and then declines until the age of 10 years, when it stabilizes at about 25%. In contrast, stage 4 sleep declines steadily from birth and often disappears completely in those over 60.

HOMEOSTATIC IMBALANCE

People with **narcolepsy** lapse abruptly into REM sleep from the awake state. These sleep episodes last about 15 minutes, can occur without warning at any time, and are often triggered by a pleasurable event—a good joke, a game of poker. In most patients with narcolepsy, an emotionally intense experience can also trigger *cataplexy,* a sudden loss of voluntary muscle control similar to that seen during REM sleep. During cataplectic attacks, lasting seconds to minutes, the patient remains fully conscious but unable to move. Obviously this can be extremely hazardous when one is driving a car or swimming! It appears that the brains of patients with narcolepsy have fewer cells in the hypothalamus that secrete chemicals called hypocretins. This finding may be a key to future treatments.

Insomnia is a chronic inability to obtain the *amount* or *quality* of sleep needed to function adequately during the day. Sleep requirements vary from four to nine hours a day in healthy people, so there is no way to determine the "right" amount. Insomniacs tend to overestimate the extent of their sleeplessness, and some come to rely on hypnotics (sleep medications), which can exacerbate the problem.

True insomnia often reflects normal age-related changes, but perhaps the most common cause is psychological disturbance. We have difficulty falling asleep when we are anxious or upset, and depression is often accompanied by early awakening.

Sleep apnea, a temporary cessation of breathing during sleep, is scary. The victim awakes abruptly due to hypoxia (lack of oxygen)—a condition that may occur repeatedly throughout the night. Obstructive sleep apnea, the most common form, occurs when the loss of muscle tone during sleep allows excess fatty tissue or other structural abnormalities to block the upper airway. It is associated with obesity and made worse by alcohol and other depressants. Aside from weight loss, effective treatments are either a mask that allows air to be blown in through the nose, keeping the airway open, or surgery to correct the problem.

Language

Language is such an important part of the brain that practically all of the association cortex on the left side is involved in one way or another. Pioneering studies of patients with *aphasias* (the loss of language abilities due to damage to specific areas of the brain) pointed to two regions that are critically important for language, Broca's area and Wernicke's area. Patients with lesions involving **Broca's area** (Figure 12.8a) can understand language but have difficulty speaking (and sometimes cannot write or type or use sign language). On the other hand, patients with lesions involving **Wernicke's area** (Figure 12.8a) are able to speak but produce a type of nonsense often referred to as a "word salad." They also have great difficulty understanding language. Recent functional studies of the brain indicate that this picture is clinically useful, but oversimplified. In fact, Broca's and Wernicke's areas together with the basal nuclei form a single system that analyzes incoming and produces outgoing word sounds and grammatical structures. A surrounding set of cortical areas forms a bridge between this language implementation system and the regions of cortex that hold concepts and ideas, which are distributed throughout the remainder of the association cortices.

The corresponding areas in the right or nonlanguage-dominant hemisphere are involved in "body language"—the nonverbal emotional (affective) components of language. These areas allow the lilt or tone of our voice and our gestures to express our emotions when we speak, and permit us to comprehend the emotional content of what we hear. For example, a soft, melodious response to your question conveys quite a different meaning than a sharp reply.

Memory

Memory is the storage and retrieval of information. Memories are essential for learning and incorporating our experiences into behavior and are part and parcel of our consciousness. Stored somewhere in your 3 pounds of wrinkled brain are zip codes, the face of your grandfather, and the taste of yesterday's pizza. Your memories reflect your lifetime.

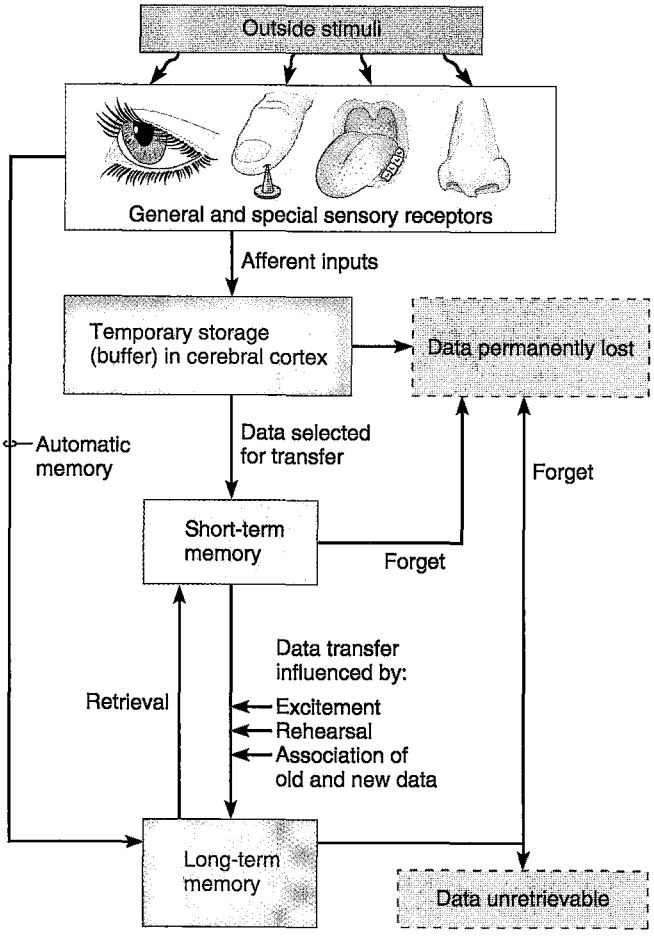

FIGURE 12.22 **Memory processing.** Sensory inputs are processed by the cerebral cortex (indicated as the temporary storage area), which selects what is to be sent to short-term memory. Rehearsal and other factors help the transfer of information from short-term memory to long-term memory. For long-term memory to become permanent, consolidation must occur. Some information not consciously attended to goes directly into long-term memory (automatic memory).

Stages of Memory

Memory storage involves two distinct stages: short-term memory and long-term memory (Figure 12.22). **Short-term memory (STM)**, also called *working memory*, is the preliminary step, as well as the power that lets you look up a telephone number, dial it, and then never think of it again. The capacity of STM is limited to seven or eight chunks of information, such as the digits of a telephone number or the sequence of words in an elaborate sentence.

In contrast to STM, **long-term memory (LTM)** seems to have a limitless capacity. Although our STM devices cannot recall numbers much longer than a telephone number, we can remember scores of telephone numbers by committing them to LTM. However, our ability to store and to retrieve information declines with aging. Thus, long-term memories too can be forgotten, and our memory bank continually changes with time.

We do not remember or even consciously notice much of what is going on around us. As sensory inputs flood into our cerebral cortex, they are processed, and some 5% of this information is selected for transfer to STM (Figure 12.22). STM serves as a sort of temporary holding bin for data that we may or may not want to retain. The transfer of information from STM to LTM is affected by many factors, including

1. **Emotional state.** We learn best when we are alert, motivated, surprised, and aroused. For example, when we witness shocking events, transferal is almost immediate. Norepinephrine, a neurotransmitter involved in memory processing of emotionally charged events, is released when we are excited or "stressed out," which helps to explain this phenomenon.
2. **Rehearsal.** Rehearsal or repetition of the material enhances memory.
3. **Association.** Tying "new" information to "old" information already stored in LTM appears to be important in remembering facts.
4. **Automatic memory.** Not all impressions that become part of LTM are consciously formed. A student concentrating on a lecturer's speech may record an automatic memory of the pattern of the lecturer's tie.

Memories transferred to LTM take time to become permanent. The process of **memory consolidation** apparently involves fitting new facts into the various categories of knowledge already stored in the cerebral cortex.

Categories of Memory

The brain distinguishes between factual knowledge and skills, and we process and store these different kinds of information in different ways. **Declarative (fact) memory** entails learning explicit information, such as names, faces, words, and dates. It is related to our conscious thoughts and our ability to manipulate symbols and language. When fact memories are committed to LTM, they are usually filed along with the context in which they were learned. For instance, when you think of your new acquaintance Joe, you probably picture him at the basketball game where you met him.

Nondeclarative memory is less conscious or even unconscious learning. Categories of nondeclarative memory are **procedural (skills) memory** (piano playing), **motor memory** (riding a bike), and **emotional memory** (your pounding heart when you hear a rattlesnake nearby). These kinds of memory are acquired through experience and usually repetition. They do not preserve the circumstances of learning; in fact, they are best remembered in the doing. You do not have to think through how to tie

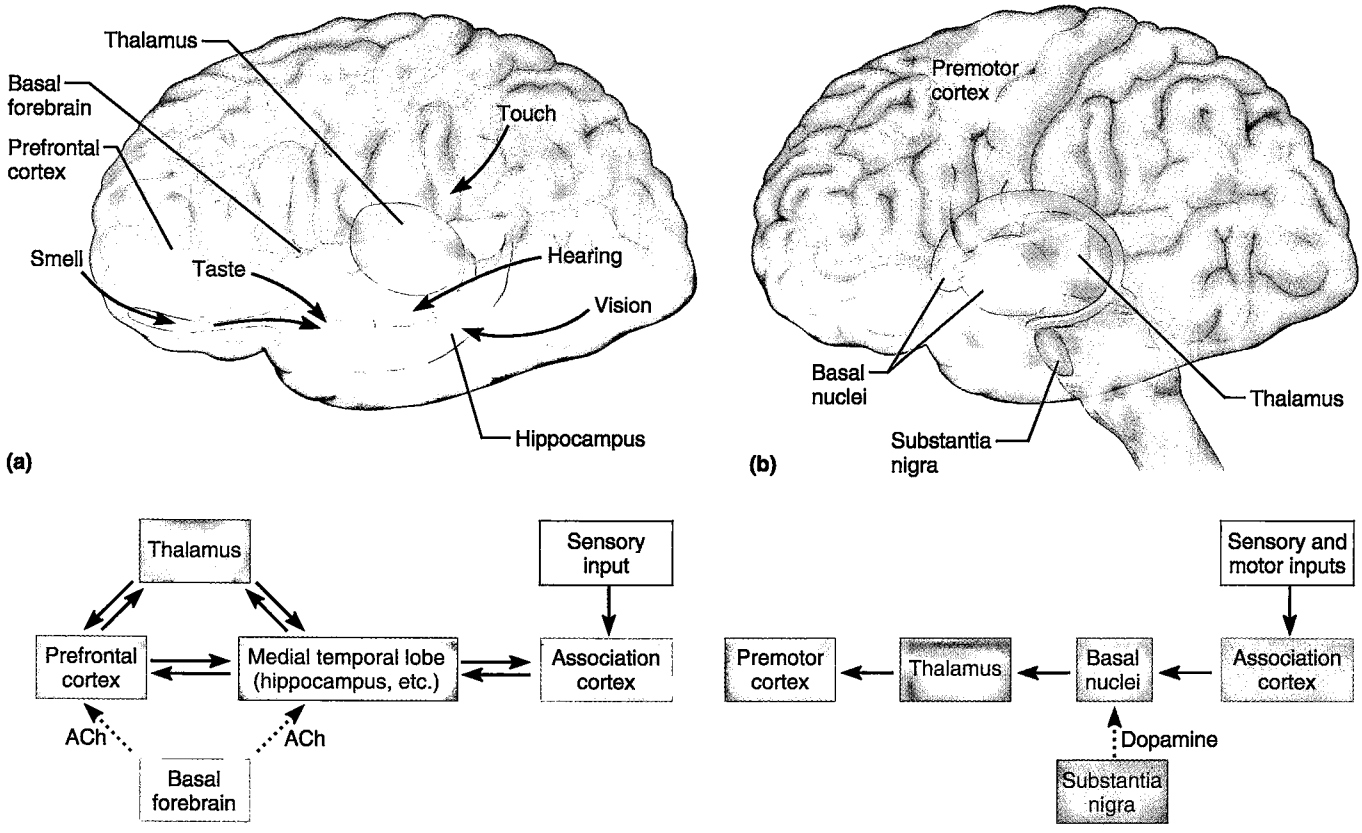

FIGURE 12.23 **Proposed memory circuits. (a)** Essential structures of declarative memory circuits. The flowchart below indicates how these structures may interact in memory formation. Information from association cortices flows to the medial temporal lobe (including the hippocampus), which communicates with the thalamus and prefrontal cortex. The medial temporal lobe structures then feed back to the association cortices. Acetylcholine, released from the basal forebrain, is necessary for this circuit to function. **(b)** Essential structures of procedural (skills) memory. Sensory and motor input flows through the association cortices and is relayed via the basal nuclei through the thalamus to the premotor cortex. Dopamine, released from the substantia nigra, is necessary for this circuit to function.

your shoes. Once learned, nondeclarative memories are hard to unlearn.

Brain Structures Involved in Memory

Much of what scientists know about learning and memory comes from experiments with macaque monkeys, and studies of amnesia and functional imaging in humans. Such studies have revealed that different brain structures are involved in the two categories of memory.

It appears that specific pieces of each memory are stored near regions of the brain that need them so that new inputs can be quickly associated with the old. Accordingly, visual memories are stored in the occipital cortex, memories of music in the temporal cortex, and so on.

But how do we create new memories? It seems that different types of memory are created in different parts of the brain. A proposed scheme of information flow for declarative memory is shown in Figure 12.23a. When sensory input is processed in the association cortices, the cortical neurons dispatch impulses to the medial temporal lobe, which includes the hippocampus and surrounding temporal cortical areas. These temporal lobe areas play a major role in memory consolidation and memory access by communicating with the thalamus and the prefrontal cortex. The prefrontal cortex and medial temporal lobe receive input from acetylcholine-releasing neurons in the basal forebrain. The sprinkling of acetylcholine onto these structures is thought to prime them to allow the formation of memories. The loss of this cholinergic input, for example in Alzheimer's disease, seems to disrupt both the formation of new memories and the retrieval of old ones. Memories are retrieved when the same sets of neurons that were initially involved in memory formation are stimulated.

HOMEOSTATIC IMBALANCE

Damage to the hippocampus and surrounding medial temporal lobe structures on either side results in only slight memory loss, but bilateral destruction causes widespread amnesia. Consolidated memories are not lost, but new sensory inputs cannot be associated with old, and the person lives in the here and now from that point on. This phenomenon is called *anterograde amnesia* (an'ter-o-grād"), in contrast to *retrograde amnesia*, which is the loss of memories formed in the distant past. You could carry on an animated conversation with a person with anterograde amnesia, excuse yourself, return five minutes later, and that person would not remember you. ●

Individuals suffering from anterograde amnesia can still learn skills such as drawing, which means a different learning circuit must be used for procedural memory (Figure 12.23b). Like the medial temporal lobe for declarative memory, the basal nuclei are the key players for procedural memory. Sensory and motor inputs passing through the cortex to the basal nuclei are then relayed via the thalamus back to the premotor cortex. The basal nuclei receive input from dopamine-releasing neurons in the substantia nigra of the midbrain. Just as acetylcholine is necessary for declarative memory, dopamine appears to be necessary for this procedural memory circuit to function. The loss of this dopamine input, as in Parkinson's disease, interferes with procedural memory.

The two other kinds of nondeclarative memory involve yet other brain regions. The cerebellum is involved in motor memory, while the amygdala (see Figure 12.18) is crucial for emotional memory. These will not be described further here.

Mechanisms of Memory

Human memory is notoriously difficult to study. Animal experimental studies reveal that during learning, (1) neuronal RNA content is altered and newly synthesized mRNAs are delivered to axons and dendrites, (2) dendritic spines change shape, (3) unique extracellular proteins are deposited at synapses involved in LTM, (4) the number and size of presynaptic terminals may increase, and (5) more neurotransmitter is released by the presynaptic neurons.

Each one of these changes is an aspect of *long-term potentiation (LTP)*, which has been shown to be crucial for memory formation. LTP refers to a persistent increase in synaptic strength, first identified in hippocampal neurons that use the amino acid glutamate as a neurotransmitter. One kind of glutamate receptor, the **NMDA receptor,** can act as a calcium channel and initiate the cellular changes that bring about LTP.

Normally, NMDA receptors are blocked so that calcium entry is prevented. When the postsynaptic terminal is depolarized by binding of glutamate to different receptors, as would happen upon the rapid arrival of action potentials at the synapse, this NMDA block is removed and calcium flows into the postsynaptic cell. Calcium influx triggers activation of enzymes that carry out two main tasks. First, they modify the proteins in the postsynaptic terminal, and also in the presynaptic terminal via retrograde messengers such as nitric oxide, which strengthens the response to subsequent stimuli. Second, they cause the activation of genes in the postsynaptic neuron's nucleus, which leads to synthesis of synaptic proteins. The molecular messenger that brings the news to the nucleus that more protein is needed is a molecule called CREB (cAMP response-element binding protein). A neurotrophic factor called BDNF (brain-derived neurotrophic factor) is required for the protein synthesis phase of LTP. These changes create long-lasting increases in synaptic strength that are believed to underlie memory.

The mechanisms underlying memory at a cellular level suggest several approaches to enhancing memory acquisition. Currently several drugs to improve memory are undergoing clinical trials. Among these are drugs that enhance CREB production—the more CREB, the more protein synthesis and the stronger the synapse becomes.

Protection of the Brain

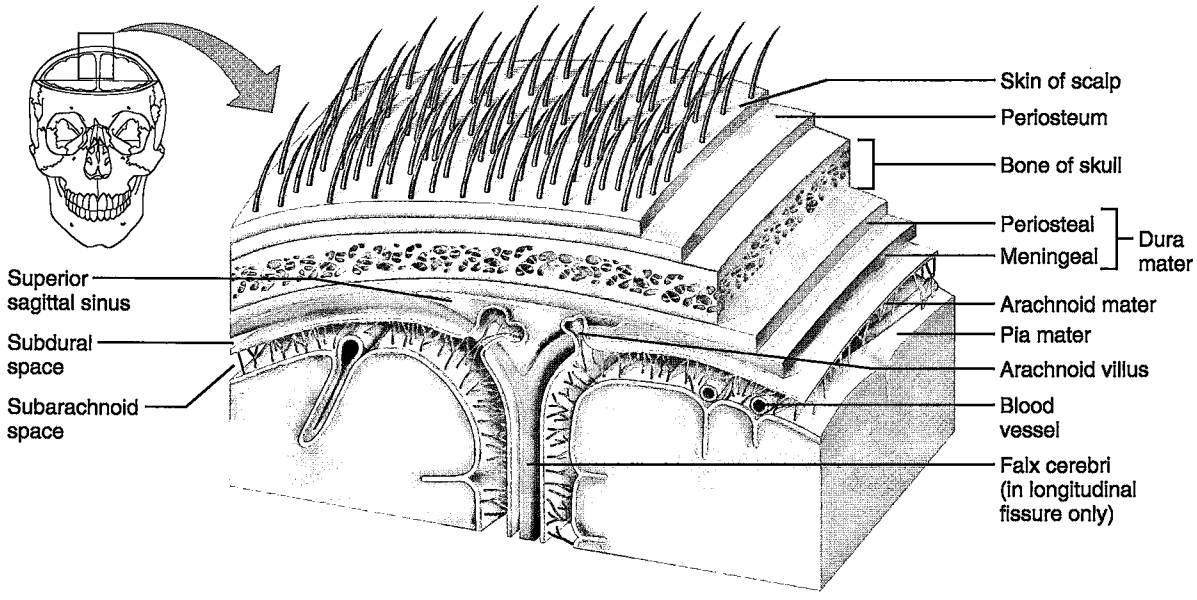
Nervous tissue is soft and delicate, and neurons are injured by even slight pressure. However, the brain is protected by bone (the skull), membranes (the meninges), and a watery cushion (cerebrospinal fluid). Furthermore, the brain is protected from harmful substances in the blood by the blood-brain barrier. We described the cranium, the brain's bony encasement, in Chapter 7. Here we will attend to the other protective devices.

Meninges

The **meninges** (mĕ-nin'jēz; *mening* = membrane) are three connective tissue membranes that lie just external to the CNS organs. They (1) cover and protect the CNS, (2) protect blood vessels and enclose venous sinuses, (3) contain cerebrospinal fluid, and (4) form partitions in the skull. From external to internal, the meninges (singular: **meninx**) are the dura mater, arachnoid mater, and pia mater (Figure 12.24).

Dura Mater

The leathery **dura mater** (du'rah ma'ter), meaning "tough mother," is the strongest meninx. Where it



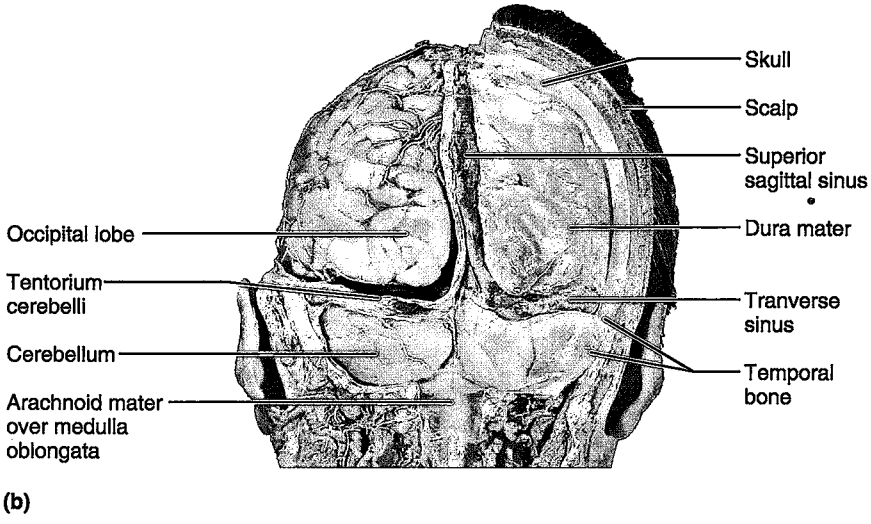


FIGURE 12.24 **Meninges. (a)** Frontal section showing the relationship of the dura mater, arachnoid, and pia mater. The meningeal dura forms the falx cerebri fold. A dural sinus, the superior sagittal sinus, is enclosed by the dural membranes superiorly. Arachnoid villi, which return cerebrospinal fluid to the dural sinus, are also shown. **(b)** Posterior view of the brain in place, surrounded by the dura mater and sinuses.

surrounds the brain, it is a two-layered sheet of fibrous connective tissue. The more superficial *periosteal layer* is attached to the inner surface of the skull (the periosteum). (There is no dural periosteal layer surrounding the spinal cord.) The deeper *meningeal layer* forms the true external covering of the brain and continues caudally in the vertebral canal as the dural sheath of the spinal cord. The brain's two dural layers are fused together except in certain areas, where they separate to enclose **dural sinuses** that collect venous blood from the brain and direct it into the internal jugular veins of the neck.

In several places, the meningeal dura mater extends inward to form flat partitions that subdivide the cranial cavity. These **dural septa,** which limit excessive movement of the brain within the cranium, include the following (Figure 12.25):

- **Falx cerebri** (falks ser'ĕ-bri). A large sickle-shaped (*falks* = sickle) fold that dips into the longitudinal fissure between the cerebral hemispheres. Anteriorly, it attaches to the crista galli of the ethmoid bone.
- **Falx cerebelli** (ser"ĕ-bel'i). Continuing inferiorly from the posterior falx cerebri, this small midline partition runs along the vermis of the cerebellum.
- **Tentorium cerebelli** (ten-to're-um; "tent"). Resembling a tent over the cerebellum, this nearly horizontal dural fold extends into the transverse fissure between the cerebral hemispheres (which it helps to support) and the cerebellum.

Arachnoid Mater

The middle meninx, the **arachnoid mater,** or simply the **arachnoid** (ah-rak'noid), forms a loose brain covering, never dipping into the sulci at the cerebral surface. It is separated from the dura mater by a

narrow serous cavity, the **subdural space,** which contains a film of fluid. Beneath the arachnoid membrane is the wide **subarachnoid space.** Weblike extensions span this space and secure the arachnoid mater to the underlying pia mater. (*Arachnida* means "spider," and this membrane was named for its weblike extensions.) The subarachnoid space is filled with cerebrospinal fluid and also contains the largest blood vessels serving the brain. Because the arachnoid is fine and elastic, these blood vessels are poorly protected.

Knoblike projections of the arachnoid mater called **arachnoid villi** (vil'i) protrude superiorly through the dura mater and into the superior sagittal sinus (see Figure 12.24a). Cerebrospinal fluid is absorbed into the venous blood of the sinus by these valvelike villi.

Pia Mater

The **pia mater** (pi'ah), meaning "gentle mother," is composed of delicate connective tissue and is richly invested with tiny blood vessels. It is the only meninx that clings tightly to the brain, following its every convolution. Small arteries entering the brain tissue carry ragged sheaths of pia mater inward with them for short distances.

HOMEOSTATIC IMBALANCE

Meningitis, inflammation of the meninges, is a serious threat to the brain because a bacterial or viral meningitis may spread to the CNS. This condition of brain inflammation is called *encephalitis* (en'sef-ah-li'tis). Meningitis is usually diagnosed by obtaining a sample of cerebrospinal fluid via a lumbar tap (see Figure 12.30) and examining it for microbes.

Cerebrospinal Fluid

Cerebrospinal fluid (CSF), found in and around the brain and spinal cord, forms a liquid cushion that gives buoyancy to the CNS structures. By floating the jellylike brain, the CSF effectively reduces brain weight by 97% and prevents the brain from crushing under its own weight. CSF also protects the brain and spinal cord from blows and other trauma. Additionally, although the brain has a rich blood supply, CSF helps nourish the brain, and there is some evidence that it carries chemical signals (such as hormones and sleep- and appetite-inducing molecules) from one part of the brain to another.

CSF is a watery "broth" similar in composition to blood plasma, from which it is formed. However, it contains less protein than plasma and its ion concentrations are different. For example, CSF contains more Na^+, Cl^-, and H^+ than does blood plasma, and less Ca^{2+} and K^+. CSF composition, particularly its pH, is important in the control of cerebral blood flow and breathing.

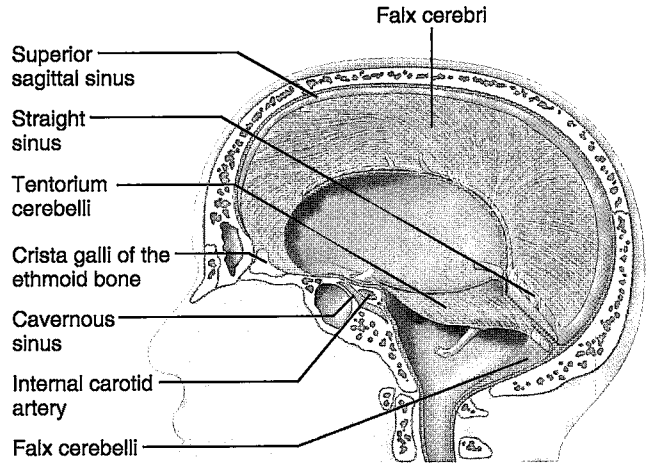

FIGURE 12.25 **Partitioning folds of dura mater in the cranial cavity.** Some dural sinuses are also shown.

The **choroid plexuses** that hang from the roof of each ventricle form CSF (Figure 12.26a). These plexuses are frond-shaped clusters of broad, thin-walled capillaries (*plex* = interwoven) enclosed first by pia mater and then by a layer of ependymal cells lining the ventricles. These capillaries are fairly permeable, and tissue fluid filters continuously from the bloodstream. However, the choroid plexus ependymal cells are joined by tight junctions and have ion pumps that allow them to modify this filtrate by actively transporting only certain ions across their membranes into the CSF pool. This sets up ionic gradients that cause water to diffuse into the ventricles as well. In adults, the total CSF volume of about 150 ml (about half a cup) is replaced every 8 hours or so; hence about 500 ml of CSF is formed daily. The choroid plexuses also help cleanse the CSF by removing waste products and unnecessary solutes.

Once produced, CSF moves freely through the ventricles. Some CSF circulates into the central canal of the spinal cord, but most enters the subarachnoid space via the lateral and median apertures in the walls of the fourth ventricle (Figure 12.26b). The constant motion of the CSF is aided by movement of the long cilia of the ependymal cells lining the ventricles. In the subarachnoid space, CSF bathes the outer surfaces of the brain and spinal cord and then returns to the blood in the dural sinuses via the arachnoid villi.

HOMEOSTATIC IMBALANCE

Ordinarily, CSF is produced and drained at a constant rate. However, if something (such as a tumor)

Q *What structures return CSF to the bloodstream?*

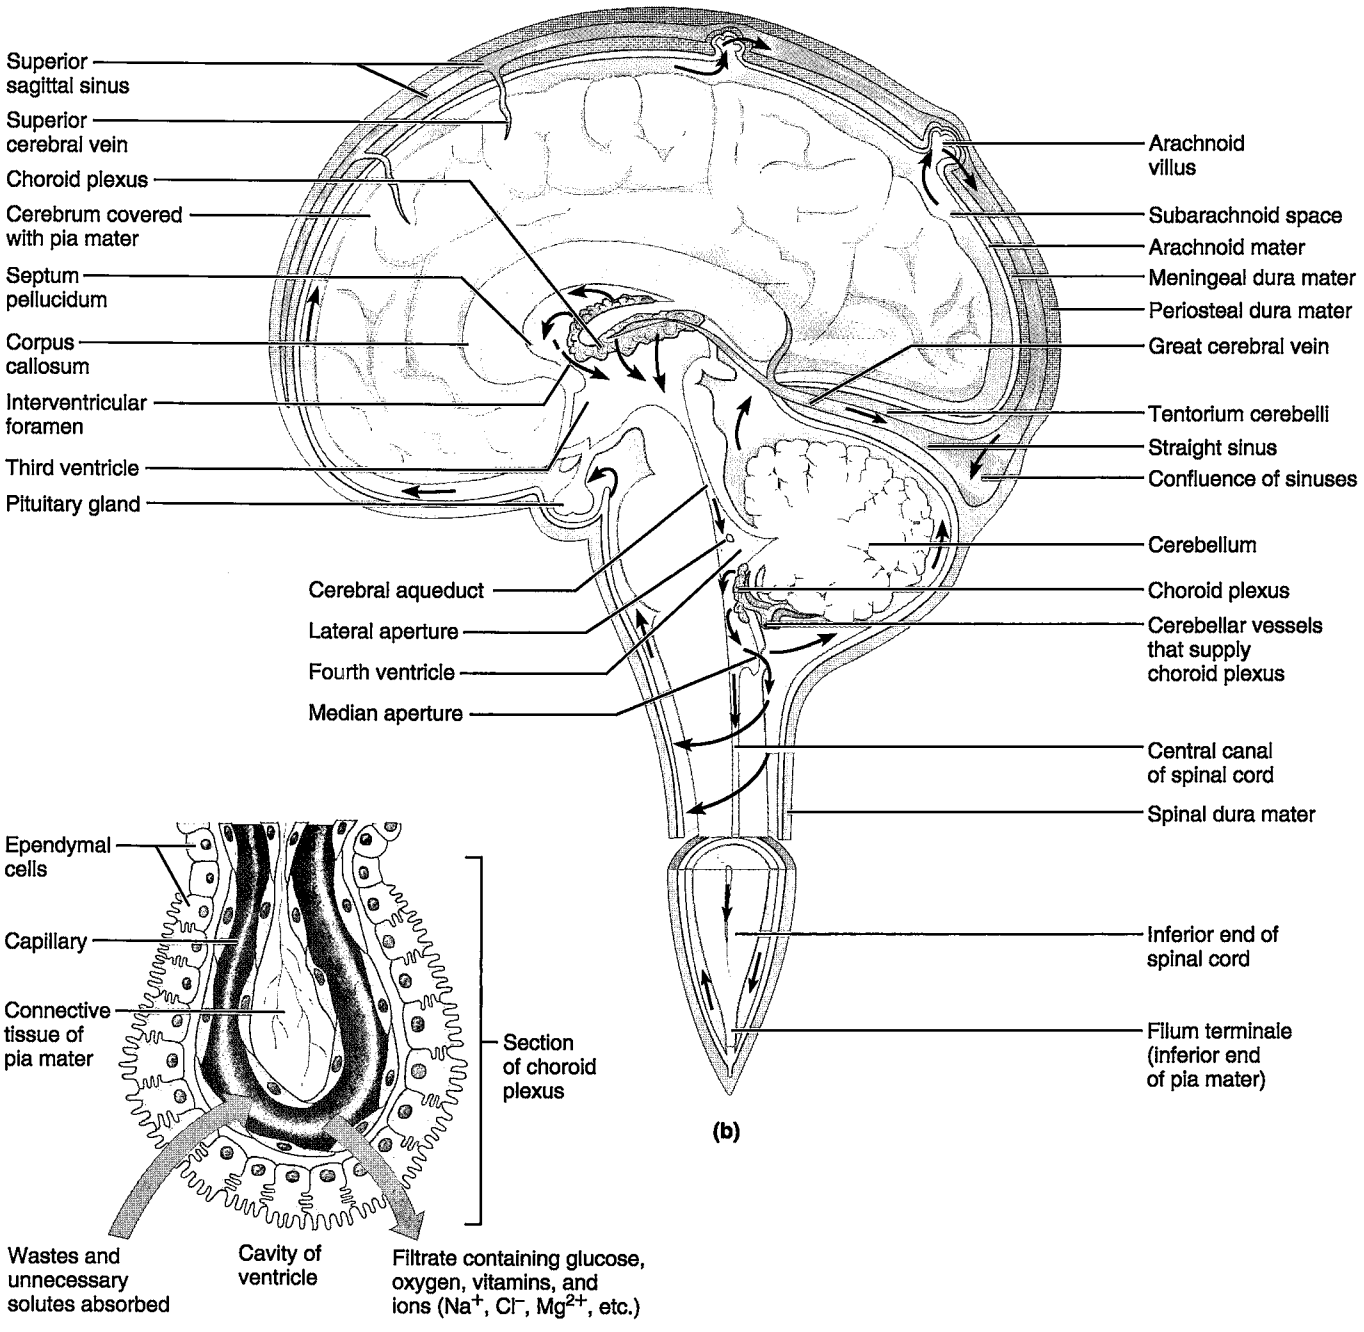

FIGURE 12.26 **Formation, location, and circulation of CSF. (a)** Choroid plexuses form CSF. Each choroid plexus consists of a knot of porous capillaries surrounded by a single layer of ependymal cells joined by tight junctions and bearing long cilia with blunted ends. Although the filtrate moves easily from the capillaries, it must move through and be processed by the ependymal cells before it is allowed to enter the ventricles as cerebrospinal fluid. **(b)** Location and circulatory pattern of CSF. Direction of circulation is indicated by the arrows. (The relative position of the right lateral ventricle is indicated by the pale bluish green area deep to the corpus callosum and septum pellucidum.)

A Arachnoid villi.

FIGURE 12.27 **Hydrocephalus in a newborn.**

obstructs its circulation or drainage, it accumulates and exerts pressure on the brain. This condition is called *hydrocephalus* ("water on the brain"). Hydrocephalus in a newborn baby causes its head to enlarge (Figure 12.27); this is possible because the skull bones have not yet fused. In adults, however, hydrocephalus is likely to result in brain damage because the skull is rigid and hard, and accumulating fluid compresses blood vessels serving the brain and crushes the soft nervous tissue. Hydrocephalus is treated by inserting a shunt into the ventricles to drain the excess fluid into a vein in the neck.

Blood-Brain Barrier

The **blood-brain barrier** is a protective mechanism that helps maintain a stable environment for the brain. No other body tissue is so absolutely dependent on a constant internal milieu as is the brain. In other body regions, the extracellular concentrations of hormones, amino acids, and ions are in constant flux, particularly after eating or exercise. If the brain were exposed to such chemical variations, the neurons would fire uncontrollably, because some hormones and amino acids serve as neurotransmitters and certain ions (particularly K^+) modify the threshold for neuronal firing.

Bloodborne substances in the brain's capillaries are separated from the extracellular space and neurons by (1) the continuous endothelium of the capillary wall, (2) a relatively thick basal lamina surrounding the external face of each capillary, and (3) the bulbous "feet" of the astrocytes clinging to the capillaries. The capillary endothelial cells are almost seamlessly joined all around by *tight junctions* (Chapter 19), making them the least permeable capillaries in the body, a characteristic that constitutes most (if not all) of the blood-brain barrier. Although the astrocytes' feet contribute to the blood-brain barrier, it now appears that their major role is to provide the signals that stimulate the capillary endothelial cells to *form* the tight junctions characteristic of the blood-brain barrier.

The blood-brain barrier is selective, rather than absolute. Nutrients such as glucose, essential amino acids, and some electrolytes move passively by facilitated diffusion through the endothelial cell membranes. Bloodborne metabolic wastes, proteins, certain toxins, and most drugs are denied entry to brain tissue. Small nonessential amino acids and potassium ions not only are prevented from entering the brain, but also are actively pumped from the brain across the capillary endothelium.

The barrier is ineffective against fats, fatty acids, oxygen, carbon dioxide, and other fat-soluble molecules that diffuse easily through all plasma membranes. This explains why bloodborne alcohol, nicotine, and anesthetics can affect the brain.

The structure of the blood-brain barrier is not completely uniform. The capillaries of the choroid plexuses are very porous, but the ependymal cells surrounding them have tight junctions. In some brain areas surrounding the third and fourth ventricles, the blood-brain barrier is entirely absent and the capillary endothelium is quite permeable, allowing bloodborne molecules easy access to the neural tissue. One such region is the vomiting center of the brain stem, which monitors the blood for poisonous substances. Another is in the hypothalamus, which regulates water balance, body temperature, and many other metabolic activities; lack of a blood-brain barrier here is essential to allow the hypothalamus to sample the chemical composition of the blood. The barrier is incomplete in newborn and premature infants, and potentially toxic substances can enter the CNS and cause problems not seen in adults.

Injury to the brain, whatever the cause, may result in a localized breakdown of the blood-brain barrier. Most likely, this reflects some change in the capillary endothelial cells or their tight junctions.

Homeostatic Imbalances of the Brain

Brain dysfunctions are unbelievably varied and extensive. We have mentioned some of them already, and one family of transmissible brain disorders is

described in *A Closer Look* on p. 482. Here, we will focus on traumatic brain injuries, cerebrovascular accidents, and degenerative brain disorders.

Traumatic Brain Injury

Head injuries are a leading cause of accidental death in North America. Consider, for example, what happens if you forget to fasten your seat belt and then rear-end another car. Your head is moving and then is suddenly stopped as it hits the windshield. Brain damage is caused not only by localized injury at the site of the blow (the *coup* injury), but also by the ricocheting effect as the brain hits the opposite end of the skull (the *contrecoup* injury).

A **concussion** is an alteration in brain function, usually temporary, following a blow to the head. The victim may be dizzy or lose consciousness. Although typically mild and short lived, even a seemingly mild concussion can be damaging, and multiple concussions over time have been shown to produce cumulative damage. More serious concussions can cause bruising of the brain and permanent neurological damage, a condition called a **contusion.** In cortical contusions, the individual may remain conscious, but severe brain stem contusions always cause coma, lasting from hours to a lifetime because of injury to the reticular activating system.

Following a head blow, death may result from **subdural** or **subarachnoid hemorrhage** (bleeding from ruptured vessels into those spaces). Individuals who are initially lucid and then begin to deteriorate neurologically are, in all probability, hemorrhaging intracranially. Blood accumulating in the skull increases intracranial pressure and compresses brain tissue. If the pressure forces the brain stem inferiorly through the foramen magnum, control of blood pressure, heart rate, and respiration is lost. Intracranial hemorrhages are treated by surgical removal of the hematoma (localized blood mass) and repair of the ruptured vessels.

Another consequence of traumatic head injury is **cerebral edema,** swelling of the brain. Anti-inflammatory drugs are routinely administered to head injury patients in an attempt to prevent cerebral edema from aggravating brain injury.

Cerebrovascular Accidents

The single most common nervous system disorder and the third leading cause of death in North America are **cerebrovascular accidents (CVAs)** (ser″ĕ-bro-vas′ku-lar), also called *strokes*. CVAs occur when blood circulation to a brain area is blocked and brain tissue dies. [Deprivation of blood supply to any tissue is called **ischemia** (is-ke′me-ah; "to hold back blood") and results in deficient oxygen and nutrient delivery to cells.] The most common cause of CVA is blockage of a cerebral artery by a blood clot. Other causes include compression of brain tissue by hemorrhage or edema and narrowing of brain vessels by atherosclerosis.

Those who survive a CVA are typically paralyzed on one side of the body *(hemiplegia)*. Many exhibit sensory deficits or have difficulty in understanding or vocalizing speech. Whatever the cause, fewer than 35% of patients who survive a CVA are alive three years later. Even so, the picture is not hopeless. Some patients recover at least part of their lost faculties, because undamaged neurons sprout new branches that spread into the injured area and take over some lost functions. Physical therapy is usually started as soon as possible to prevent muscle contractures (abnormal shortening of muscles due to differences in strength between opposing muscle groups).

Not all strokes are "completed." Temporary episodes of reversible cerebral ischemia, called **transient ischemic attacks (TIAs),** are common. TIAs last from 5 to 50 minutes and are characterized by temporary numbness, paralysis, or impaired speech. While these deficits are not permanent, TIAs do constitute "red flags" that warn of impending, more serious CVAs.

CVAs are like undersea earthquakes. It's not the initial temblor that does most of the damage, it's the tsunami that floods the coast later. Similarly, the initial vascular blockage during a stroke is not usually disastrous because there are many blood vessels in the brain that can pick up the slack; it's the events that lead to killing of neurons not in the initial ischemic zone that wreak the most havoc.

Experimental evidence indicates that the main culprit is *glutamate,* an excitatory neurotransmitter also involved in learning and memory. Normally, glutamate binding to NMDA receptors opens NMDA channels that allow Ca^{2+} to enter the stimulated neuron. After brain injury, neurons totally deprived of oxygen begin to disintegrate, unleashing the cellular equivalent of "buckets" of glutamate. Under these conditions, glutamate acts as an *excitotoxin,* literally exciting surrounding cells to death. The initial events in excitotoxicity are identical to those in LTP—Ca^{2+} flows in through NMDA receptor channels (see p. 463). In excitotoxicity, however, the amount of Ca^{2+} swamps the cell's ability to cope and Ca^{2+} homeostasis breaks down. High levels of Ca^{2+} lead to cell death in two ways. First, Ca^{2+} damages mitochondria, causing them to produce the free radical superoxide, which can damage cells directly and also cause programmed cell death (apoptosis). Second, Ca^{2+} turns on the synthesis of certain proteins. Some of these promote apoptosis while others are enzymes that produce the free radical NO and other powerful inflammatory agents.

Although the NMDA receptor and the enzyme that makes NO are attractive targets for drug therapies to decrease damage around the stroke epicenter, clinical trials so far have all failed. At present, the only approved treatment for stroke is tissue plasminogen activator (tPA), which dissolves blood clots in the brain. Various mechanical devices to retrieve clots are currently undergoing clinical trials, and two other approaches are being studied. One method implants immature neurons into stroke-damaged brain regions in the hope that they will take on properties of the nearby mature neurons. Another tries to coax adult brain stem cells to replace damaged neurons. Mice with strokes can generate new tissue and recover motor function when treated with a combination of growth factors during a critical time following injury. Hopefully, this will be true for humans, too.

Degenerative Brain Disorders

Alzheimer's Disease **Alzheimer's disease (AD)** (altz'hi-merz) is a progressive degenerative disease of the brain that ultimately results in dementia (mental deterioration). Alzheimer's patients represent nearly half of the people living in nursing homes. Between 5 and 15% of people over 65 develop this condition, and for up to half of those over 85 it is a major contributing cause in their deaths.

Its victims exhibit memory loss (particularly for recent events), shortened attention span, disorientation, and eventual language loss. Over a period of several years, formerly good-natured people may become irritable, moody, and confused. Ultimately, hallucinations occur.

Examinations of brain tissue reveal senile plaques littering the brain like shrapnel between the neurons. The plaques consist of extracellular aggregations of *beta amyloid peptide,* which has been cut from a normal membrane precursor protein (APP) by enzymes. One form of Alzheimer's disease is caused by an inherited mutation in APP, which suggests that beta amyloid may be toxic. Some researchers believe that small clusters of these protein fragments kill cells by forming holes in their plasma membranes. Unfortunately, clinical trials of vaccines to stimulate an immune response to clear away beta amyloid protein have not been successful.

Another hallmark of Alzheimer's disease is the presence of *neurofibrillary tangles* inside neurons. These involve a protein called tau, which functions like railroad ties to bind microtubule "tracks" together. In the brains of AD victims, tau abandons its microtubule-stabilizing role and grabs onto other tau molecules, forming spaghetti-like neurofibrillary tangles, which kill the neurons by disrupting their transport mechanisms.

As the brain cells die, the brain shrinks. Particularly vulnerable brain areas include the hippocampus and the basal forebrain, regions involved in thinking and memory (Figure 12.23). Loss of neurons in the basal forebrain is associated with a shortage of the neurotransmitter acetylcholine, and drugs that inhibit breakdown of acetylcholine slightly enhance cognitive function in AD patients. Interestingly, a drug that blocks NMDA receptors, memantine, also seems to improve thinking in AD victims, suggesting that glutamate excitotoxicity is also involved in this disease.

Parkinson's Disease Typically striking people in their 50s and 60s, **Parkinson's disease** results from a degeneration of the dopamine-releasing neurons of the substantia nigra. As those neurons deteriorate, the dopamine-deprived basal nuclei they target become overactive, causing the well-known symptoms of the disease. Afflicted individuals have a persistent tremor at rest (exhibited by head nodding and a "pill-rolling" movement of the fingers), a forward-bent walking posture and shuffling gait, and a stiff facial expression, and they are slow in initiating and executing movement.

The cause of Parkinson's disease is still unknown, although recent evidence points to mitochondrial malfunction leading to the death of dopamine-releasing neurons. The drug *L-dopa* often helps to alleviate some symptoms; it passes through the blood-brain barrier and is then converted into dopamine. However, it is not curative, and as more and more neurons die off, L-dopa becomes ineffective. Mixing L-dopa with drugs that inhibit the breakdown of dopamine (for example, deprenyl), can prolong the effectiveness of L-dopa. In addition, deprenyl by itself, early in the disease, slows the neurological deterioration to some extent and delays the need to administer L-dopa for up to 18 months.

Deep brain stimulation via implanted electrodes shuts down abnormal brain activity and has proved helpful in alleviating tremors. This treatment (for patients who no longer respond to drug therapy) is delicate, expensive, and risky. Another possibility is to use gene therapy to insert genes into adult brain cells, causing them to secrete the inhibitory neurotransmitter GABA. GABA then inhibits the abnormal brain activity just as the electrical stimulation does. In the past, implantation of embryonic or fetal cells has shown limited success. However, the use of embryonic or fetal tissue is controversial and riddled with ethical and legal roadblocks.

Huntington's Disease **Huntington's disease** is a fatal hereditary disorder that strikes during middle age. Mutant *huntingtin* protein accumulates in brain

cells and the tissue dies, leading to massive degeneration of the basal nuclei and later of the cerebral cortex. Its initial symptoms in many are wild, jerky, almost continuous "flapping" movements called *chorea* (Greek for "dance"). Although the movements appear to be voluntary they are not. Late in the disease, marked mental deterioration occurs. Huntington's disease is progressive and usually fatal within 15 years of onset of symptoms.

The hyperkinetic manifestations of Huntington's disease are essentially the opposite of those of Parkinson's disease (overstimulation rather than inhibition of the motor drive), and Huntington's is usually treated with drugs that block, rather than enhance, dopamine's effects. As with Parkinson's disease, fetal tissue implants may provide promise for its treatment in the future.

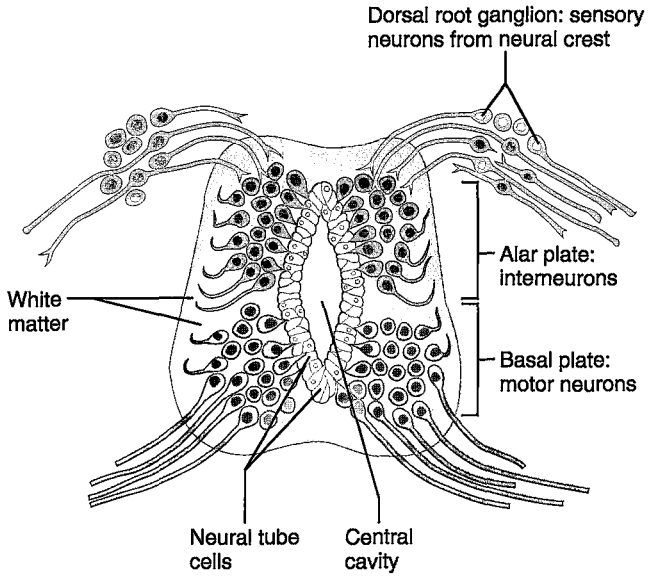

FIGURE 12.28 **Structure of the embryonic spinal cord.** At six weeks of development, aggregations of gray matter called the alar plates (future interneurons) and basal plates (future motor neurons) have formed, and dorsal root ganglia (future sensory neurons) have arisen from neural crest cells.

The Spinal Cord

Embryonic Development

The spinal cord develops from the caudal portion of the embryonic neural tube (see Figure 12.2 on p. 432). By the sixth week, each side of the developing cord has two recognizable clusters of neuroblasts that have migrated outward from the original neural tube: a dorsal **alar plate** (a'lar) and a ventral **basal plate** (Figure 12.28).

Alar plate neuroblasts become interneurons. The basal plate neuroblasts develop into motor neurons and sprout axons that grow out to the effector organs. Axons that emerge from alar plate cells (and some basal plate cells) form the white matter of the cord by growing along the length of the cord. As development progresses, these plates expand dorsally and ventrally to produce the H-shaped central mass of gray matter of the adult spinal cord. Neural crest cells that come to lie alongside the cord form the *dorsal root ganglia* containing sensory neuron cell bodies; these send their axons into the dorsal aspect of the cord.

Gross Anatomy and Protection

The spinal cord, enclosed in the vertebral column, extends from the foramen magnum of the skull to the level of the first or second lumbar vertebra, just inferior to the ribs (Figure 12.29). About 42 cm (17 inches) long and 1.8 cm (3/4 of an inch) thick, the glistening-white **spinal cord** provides a two-way conduction pathway to and from the brain. It is a major reflex center: Spinal reflexes are initiated and completed at the spinal cord level. We discuss reflex functions and motor activity of the cord in subsequent chapters. In this section we focus on the anatomy of the cord and on the location and naming of its ascending and descending tracts.

Like the brain, the spinal cord is protected by bone, meninges, and cerebrospinal fluid. The single-layered **spinal dura mater** (Figure 12.26) is not attached to the bony walls of the vertebral column. Between the bony vertebrae and the dural sheath is an **epidural space** filled with a soft padding of fat and a network of veins (see Figure 12.31a). Cerebrospinal fluid fills the subarachnoid space between the *arachnoid* and *pia mater* meninges. Inferiorly, the dural and arachnoid membranes extend to the level of S_2, well beyond the end of the spinal cord. The spinal cord typically ends between L_1 and L_2 (Figure 12.29a). Thus, the subarachnoid space within the meningeal sac inferior to that point provides a nearly ideal spot for removing cerebrospinal fluid for testing, a procedure called a **lumbar puncture** or **tap** (Figure 12.30). Because the spinal cord is absent there and the delicate nerve roots drift away from the point of needle insertion, there is little or no danger of damaging the cord (or spinal roots) beyond L_3.

Inferiorly, the spinal cord terminates in a tapering cone-shaped structure called the **conus medullaris** (ko'nus me"dul-ar'is). The **filum terminale** (fi'lum ter"mĭ-nah'le; "terminal filament"), a fibrous extension of the conus covered by pia mater, extends inferiorly from the conus medullaris to the posterior surface of the coccyx, where it anchors the spinal cord in place so it is not jostled by body movements (Figure 12.29d). Furthermore, the spinal cord is

Q *What is the explanation for the cervical and lumbar enlargements of the cord?*

The dura mater and arachnoid mater are cut open and reflected laterally. **(b)** Cervical part of the spinal cord. **(c)** Enlargement of thoracic spinal cord, showing denticulate ligaments. **(d)** Inferior end of spinal cord, showing conus medullaris, cauda equina, and filum terminale.

A *The nerves serving the limbs arise in these areas.*

Q *What information would you get by performing a lumbar tap?*

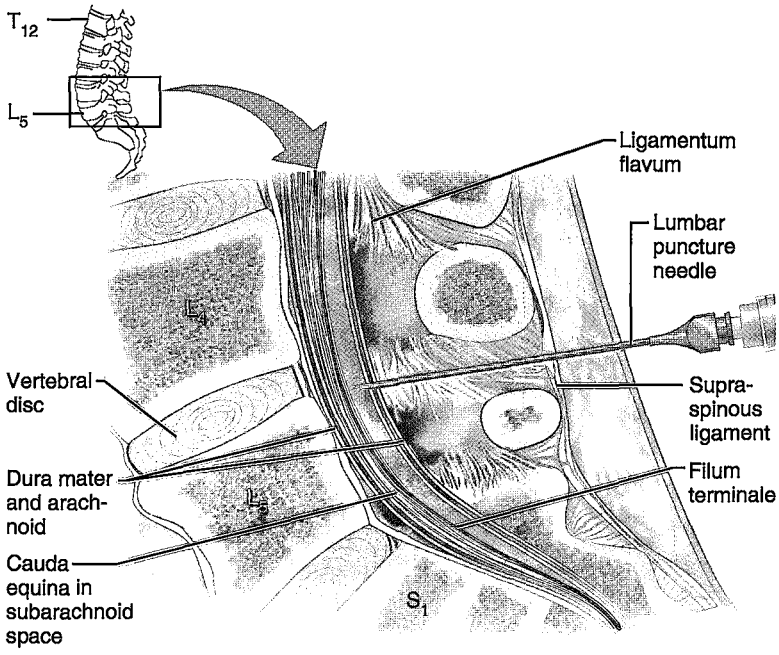

FIGURE 12.30 **Diagrammatic view of a lumbar tap.**

secured to the tough dura mater meninx throughout its length by saw-toothed shelves of pia mater called **denticulate ligaments** (den-tik'u-lāt; "toothed") (Figure 12.29c).

In humans, 31 pairs of *spinal nerves* attach to the cord by paired roots. Each nerve exits from the vertebral column by passing superior to its corresponding vertebra via the intervertebral foramina, and travels to the body region it serves. While each nerve pair defines a segment of the cord, the spinal cord is, in fact, continuous throughout its length and its internal structure changes gradually.

The spinal cord is about the width of a thumb for most of its length, but it has obvious enlargements in the cervical and lumbosacral regions, where the nerves serving the upper and lower limbs arise. These enlargements are the **cervical** and **lumbar enlargements,** respectively (Figure 12.29a). Because the cord does not reach the end of the vertebral column, the lumbar and sacral spinal nerve roots angle sharply downward and travel inferiorly through the vertebral canal for some distance before reaching their intervertebral foramina. The collection of nerve roots at the inferior end of the vertebral canal is named the **cauda equina** (kaw'da e-kwi'nuh) because of its resemblance to a horse's tail. This strange arrangement reflects the fact that during fetal development, the vertebral column grows faster than the spinal cord, forcing the lower spinal nerve roots to "chase" their exit points inferiorly through the vertebral canal.

A *Obtaining a sample of CSF allows you to check for CNS infection, inflammation, or the presence of abnormal cells.*

Cross-Sectional Anatomy

The spinal cord is somewhat flattened from front to back and two grooves mark its surface: the **anterior median fissure** and the shallower **posterior median sulcus** (see Figure 12.31b). These grooves run the length of the cord and partially divide it into right and left halves. The gray matter of the cord is located in its core, the white matter outside.

Gray Matter and Spinal Roots

In cross section the gray matter of the cord looks like the letter H or like a butterfly (Figure 12.31b). It consists of mirror-image lateral gray masses connected by a cross-bar of gray matter, the **gray commissure,** that encloses the central canal. The two posterior projections of the gray matter are the **dorsal (posterior) horns;** the anterior pair are the **ventral (anterior) horns.** In 3-D, these horns form columns of gray matter that run the entire length of the spinal cord. An additional pair of gray matter columns, the small **lateral horns,** is present in the thoracic and superior lumbar segments of the cord.

All neurons whose cell bodies are in the spinal cord gray matter are multipolar. The dorsal horns consist entirely of interneurons. The ventral horns have some interneurons but mainly house cell bodies of somatic motor neurons. These send their axons out via the **ventral roots** of the spinal cord (Figure 12.31b) to the skeletal muscles (their effector organs). The amount of ventral gray matter present at a given level of the spinal cord reflects the amount of skeletal muscle innervated at that level. Thus, the ventral horns are largest in the limb-innervating cervical and lumbar regions of the cord and are responsible for the cord enlargements seen in those regions.

Q *Which spaces in this figure are filled with CSF?*

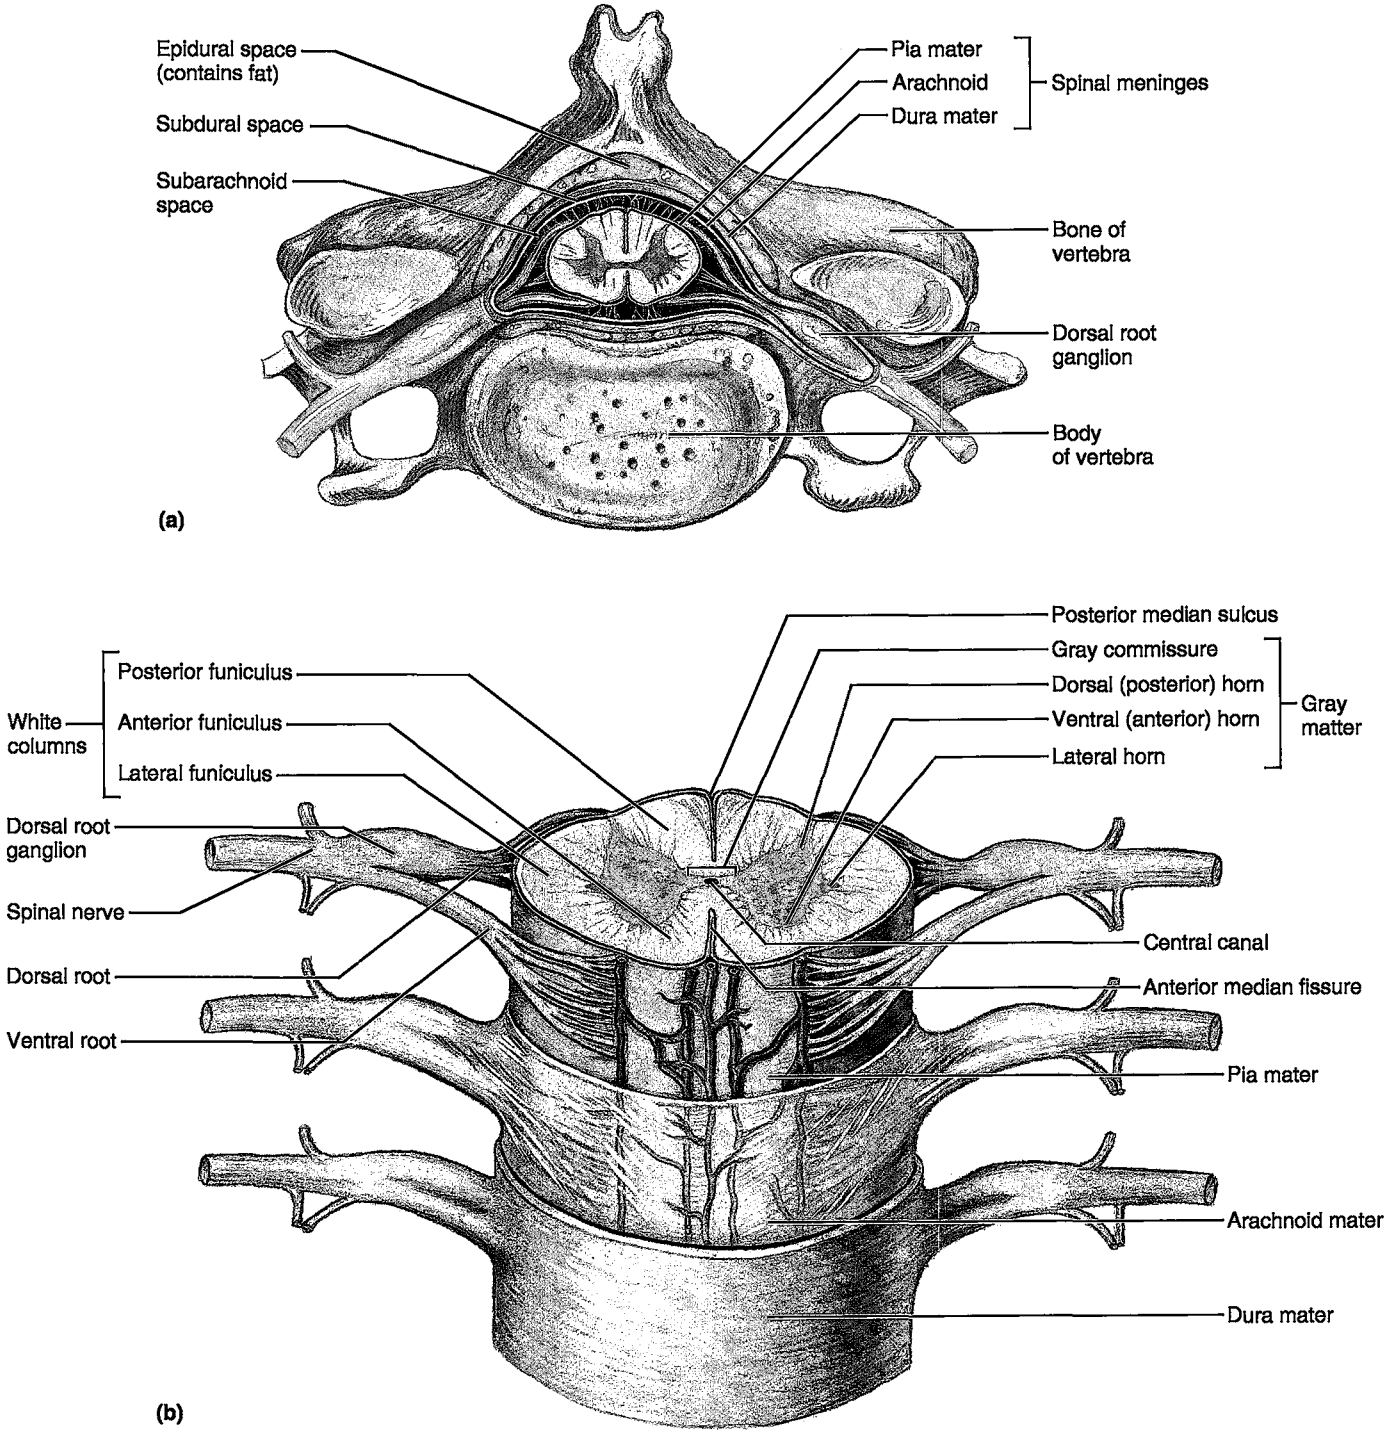

FIGURE 12.31 **Anatomy of the spinal cord. (a)** Cross section through the spinal cord illustrating its relationship to surrounding vertebral column. (See *A Brief Atlas of the Human Body,* Plate 36.) **(b)** Three-dimensional view of the adult spinal cord and its meningeal coverings.

A Subarachnoid space and central canal of the spinal cord.

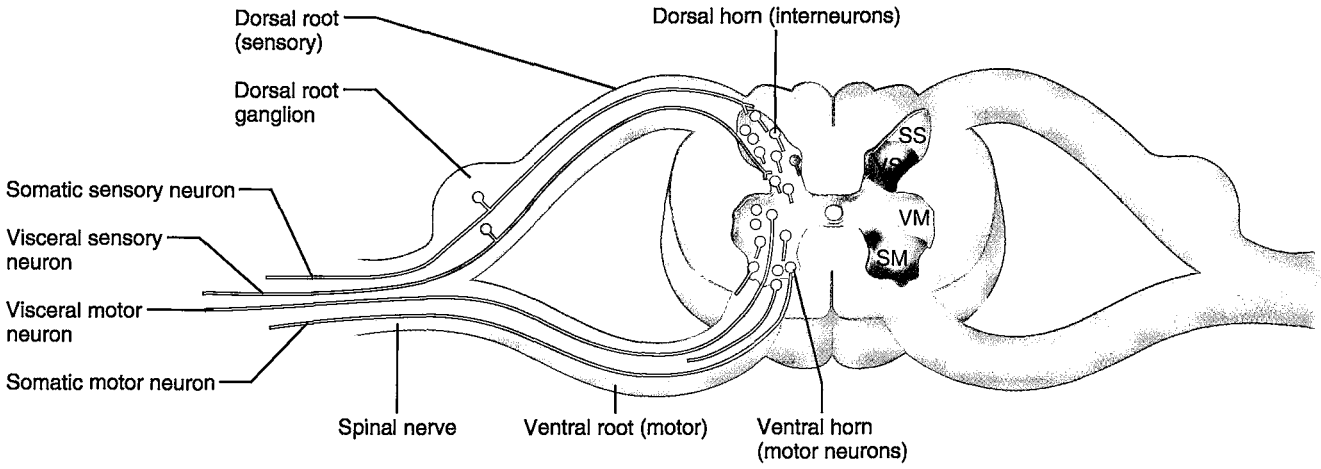

FIGURE 12.32 **Organization of the gray matter of the spinal cord.** The gray matter of the spinal cord is divided into a sensory half dorsally and a motor half ventrally. SS: interneurons receiving input from somatic sensory neurons. VS: interneurons receiving input from visceral sensory neurons. VM: visceral motor (autonomic) neurons. SM: somatic motor neurons. Note that the dorsal and ventral roots are part of the PNS, not of the spinal cord.

The lateral horn neurons are autonomic (sympathetic division) motor neurons that serve visceral organs. Their axons leave the cord via the ventral root along with those of the somatic motor neurons. Because the ventral roots contain both somatic and autonomic efferents, they serve both motor divisions of the peripheral nervous system (Figure 12.32).

Afferent fibers carrying impulses from peripheral sensory receptors form the **dorsal roots** of the spinal cord (Figure 12.31). The cell bodies of the associated sensory neurons are found in an enlarged region of the dorsal root called the **dorsal root ganglion** or **spinal ganglion.** After entering the cord, the axons of these neurons may take a number of routes. Some enter the posterior white matter of the cord directly and travel to synapse at higher cord or brain levels. Others synapse with interneurons in the dorsal horns of the spinal cord gray matter at their entry level.

The dorsal and ventral roots are very short and fuse laterally to form the **spinal nerves.** The spinal nerves, which are part of the peripheral nervous system, are considered further in Chapter 13.

The spinal gray matter can be divided further according to its neurons' relative involvement in the innervation of the somatic and visceral regions of the body. The following four zones are evident within this gray matter (Figure 12.32): **somatic sensory (SS), visceral** (autonomic) **sensory (VS), visceral motor (VM), somatic motor (SM).**

White Matter

The white matter of the spinal cord is composed of myelinated and unmyelinated nerve fibers that allow communication between different parts of the spinal cord and between the cord and brain. These fibers run in three directions: (1) *ascending*—up to higher centers (sensory inputs), (2) *descending*—down to the cord from the brain or within the cord to lower levels (motor outputs), and (3) *transversely*—across from one side of the cord to the other (commissural fibers). Ascending and descending tracts make up most of the white matter.

The white matter on each side of the cord is divided into three **white columns,** or **funiculi** (funik'u-li; "long ropes"), named according to their position as **posterior, lateral,** and **anterior funiculi** (Figure 12.31b). Each funiculus contains several fiber tracts, and each tract is made up of axons with similar destinations and functions. With a few exceptions, the names of the spinal tracts reveal both their origin and destination. The principal ascending and descending tracts of the spinal cord are illustrated schematically in the cross-sectional view of the spinal cord in Figure 12.33.

All major spinal tracts are *part of multineuron pathways* that connect the brain to the body periphery. These great ascending and descending pathways contain not only spinal cord neurons but also parts of peripheral neurons and neurons in the brain. Before we get specific about the individual tracts, we will make some generalizations about them and the pathways to which they contribute:

1. Most pathways cross from one side of the CNS to the other (decussate) at some point along their journey.
2. Most consist of a chain of two or three neurons that contribute to successive tracts of the pathway.

Q *What is a tract?*

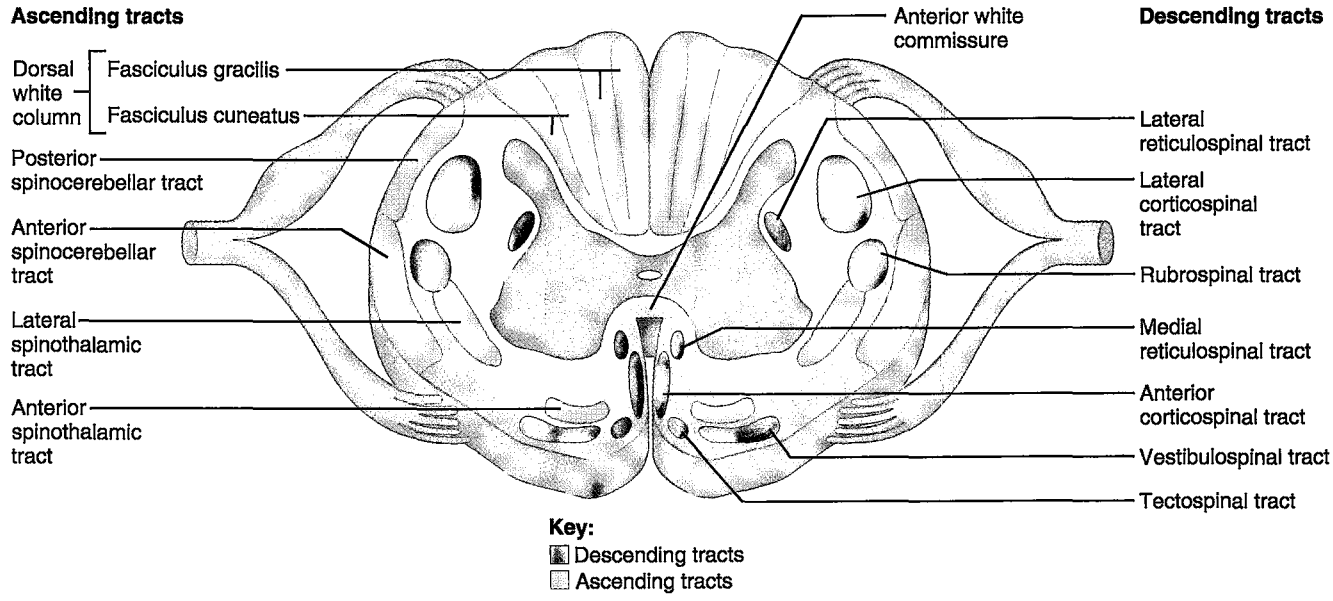

FIGURE 12.33 **Major ascending (sensory) and descending (motor) tracts of the spinal cord, cross-sectional view.**

3. Most exhibit *somatotopy,* a precise spatial relationship among the tract fibers that reflects the orderly mapping of the body. For example, in an ascending sensory tract, somatotopy refers to the fact that fibers transmitting inputs from sensory receptors in the superior parts of the body lie lateral to those conveying sensory information from inferior body regions.

4. All pathways and tracts are paired (right and left) with a member of the pair present on each side of the spinal cord or brain.

Ascending Pathways to the Brain

Neuronal Composition The ascending pathways conduct sensory impulses upward, typically through chains of three successive neurons (first-, second-, and third-order neurons) to various areas of the brain (Figure 12.34). (Note that both second- and third-order neurons are interneurons.)

- **First-order neurons,** whose cell bodies reside in a ganglion (dorsal root or cranial), conduct impulses from the cutaneous receptors of the skin and from proprioceptors to the spinal cord or brain stem, where they synapse with second-order neurons. Impulses from the facial area are transmitted by cranial nerves; spinal nerves conduct somatic sensory impulses from the rest of the body to the CNS.
- **Second-order neurons,** whose cell bodies reside in the dorsal horn of the spinal cord or in medullary nuclei, transmit impulses to the thalamus or to the cerebellum where they synapse.
- **Third-order neurons,** whose cell bodies reside in the thalamus, conduct impulses to the somatosensory cortex of the cerebrum. (There are no third-order neurons in the cerebellum.)

The Main Ascending Pathways In general, somatosensory information is conveyed along three main pathways on each side of the spinal cord. Two of these pathways (the *nonspecific* and *specific ascending pathways*) transmit impulses to the sensory cortex. Collectively the inputs of these sister tracts provide *discriminative touch* and *conscious proprioception*. Both pathways decussate—the first in the spinal cord and the second in the medulla.

The third pathway, consisting of the *spinocerebellar tracts,* tracks to the cerebellum, and hence does not contribute to sensory perception. Let's examine these pathways more closely.

1. **Nonspecific ascending pathways.** The evolutionarily older **nonspecific ascending pathways** receive inputs from many different types of sensory receptors and make multiple synapses in the brain stem. These pathways, also called the **anterolateral pathways** (because they are located in the anterior

A collection of axons in the CNS, having the same origin and termination.

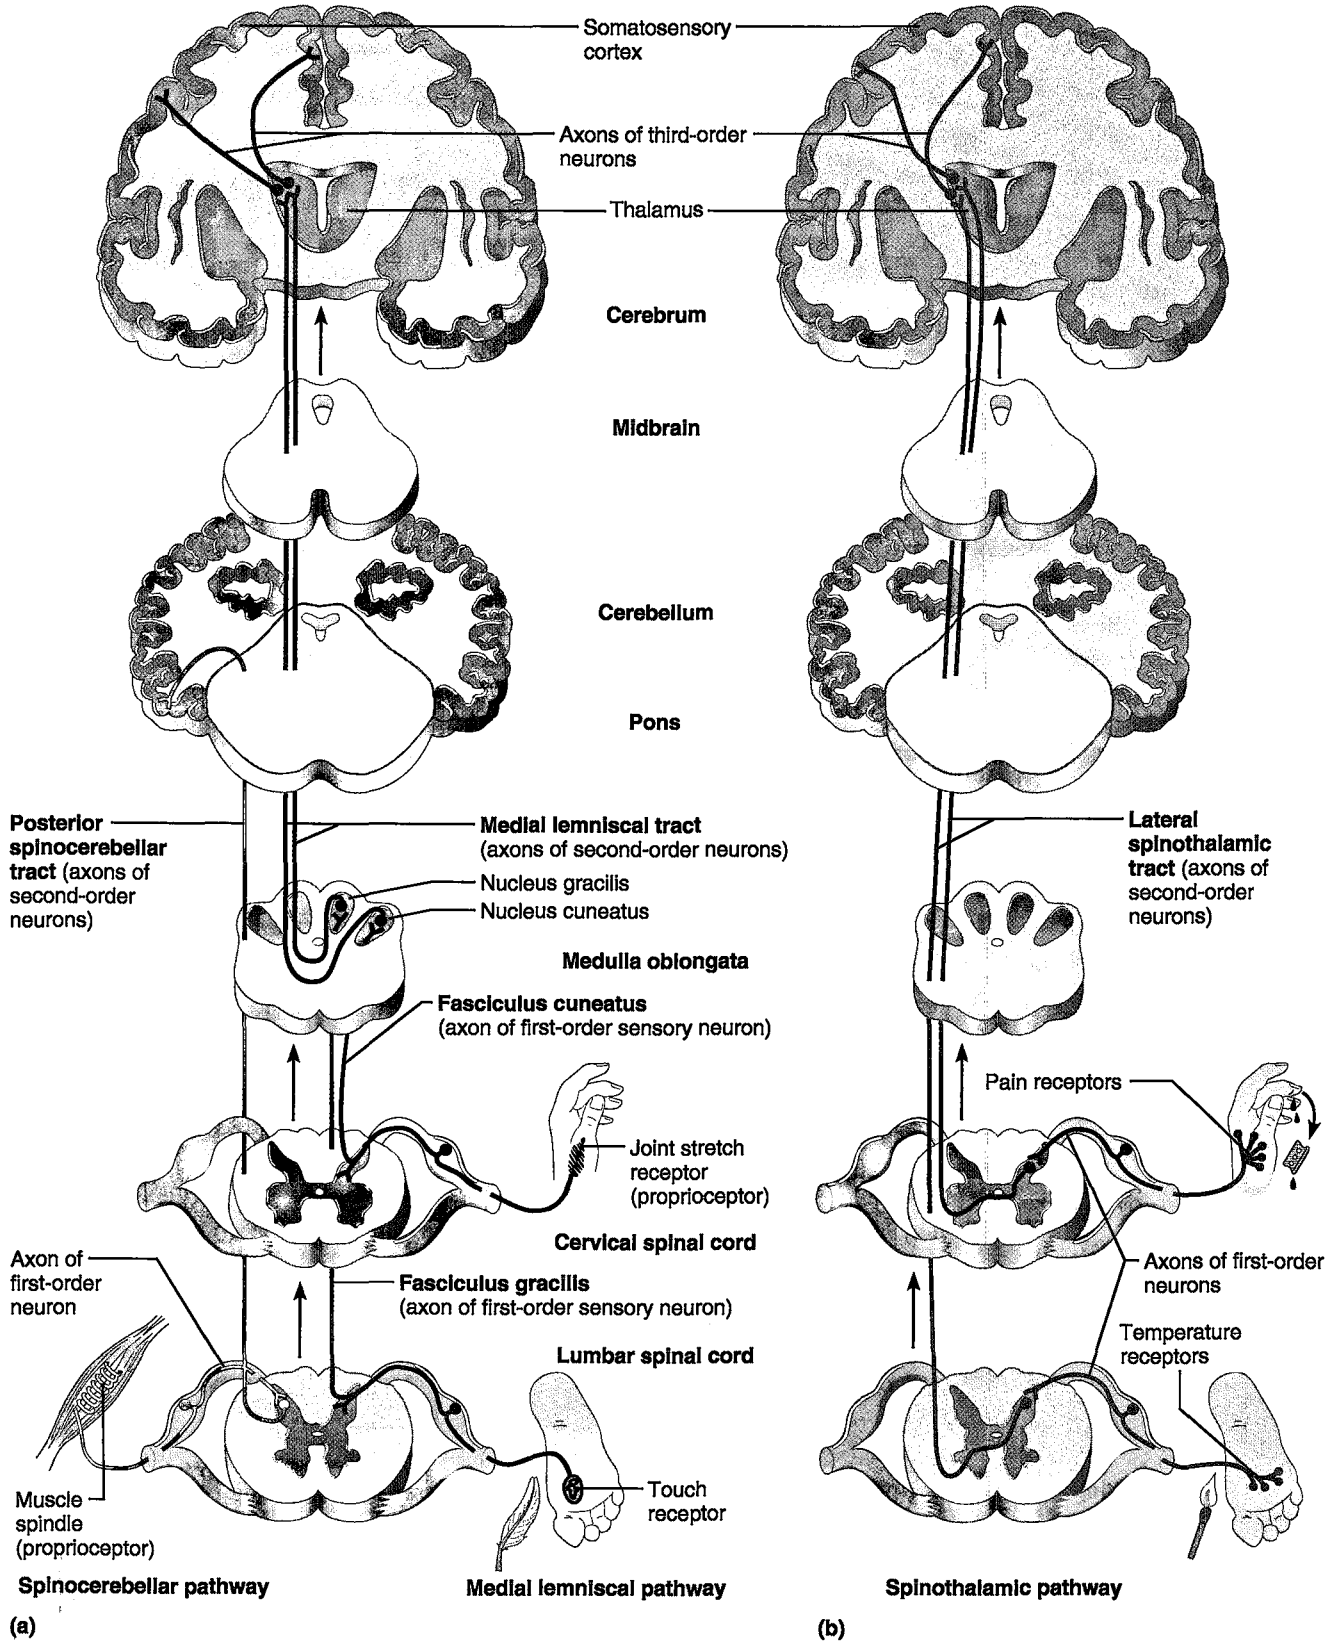

FIGURE 12.34 **Pathways of selected ascending spinal cord tracts.** Cross sections up to the cerebrum, which is shown in frontal section. **(a)** Right: Specific pathways for discriminative touch and conscious proprioception in the fasciculus gracilis and fasciculus cuneatus tracts and their continuation, the medial lemniscal tracts. Left: Posterior spinocerebellar tract (extends only to cerebellum). **(b)** Nonspecific pathways for pain, temperature, and crude touch in the lateral spinothalamic tract of the anterolateral pathways. The entire ascending pathway is shown in each case.

TABLE 12.2 Major Ascending (Sensory) Pathways and Spinal Cord Tracts

SPINAL CORD TRACT	LOCATION (FUNICULUS)	ORIGIN	TERMINATION	FUNCTION
SPECIFIC ASCENDING (LEMNISCAL) PATHWAYS				
Fasciculus cuneatus and fasciculus gracilis (dorsal white column)	Posterior	Central axons of sensory (first-order) neurons enter dorsal root of the spinal cord and branch; branches enter dorsal white column on same side without synapsing	By synapse with second-order neurons in nucleus cuneatus and nucleus gracilis in medulla; fibers of medullary neurons cross over and ascend in medial lemniscal tracts to thalamus, where they synapse with third-order neurons; thalamic neurons then transmit impulses to somatosensory cortex	Both tracts transmit sensory impulses from general sensory receptors of skin and proprioceptors, which are interpreted as discriminative touch, pressure, and "body sense" (limb and joint position) in opposite somatosensory cortex. Cuneatus transmits afferent impulses from upper limbs, upper trunk, and neck; it is not present in spinal cord below level of T_6. Gracilis carries impulses from lower limbs and inferior body trunk
NONSPECIFIC ASCENDING (ANTEROLATERAL) PATHWAYS				
Lateral spinothalamic	Lateral	Interneurons (second-order neurons) of dorsal horn; fibers cross to opposite side before ascending	By synapse with third-order neurons in thalamus; impulses then conveyed to somatosensory cortex by thalamic neurons	Transmits impulses concerned with pain and temperature to opposite side of brain; eventually interpreted in somatosensory cortex
Anterior spinothalamic	Anterior	Interneurons (second-order neurons) in dorsal horns; fibers cross to opposite side before ascending	By synapse with third-order neurons in thalamus; impulses eventually conveyed to somatosensory cortex by thalamic neurons	Transmits impulses concerned with crude touch and pressure to opposite side of brain for interpretation by somatosensory cortex
SPINOCEREBELLAR PATHWAYS				
Posterior spinocerebellar*	Lateral (posterior part)	Interneurons (second-order neurons) in dorsal horn on same side of cord; fibers ascend without crossing	By synapse in cerebellum	Transmits impulses from trunk and lower limb proprioceptors on one side of body to same side of cerebellum; subconscious proprioception
Anterior spinocerebellar*	Lateral (anterior part)	Interneurons (second-order neurons) of dorsal horn; contains crossed fibers that cross back to the opposite side in the pons	By synapse in cerebellum	Transmits impulses from the trunk and lower limb on the same side of body to cerebellum; subconscious proprioception

*The posterior and anterior spinocerebellar tracts carry information from the lower limbs and trunk only. The corresponding tracts for the upper limb and neck (rostral spinocerebellar and others) are beyond the scope of this book.

and lateral white columns of the spinal cord), are largely formed by the **lateral** and **anterior spinothalamic tracts** (see Figure 12.34b and Table 12.2). Crossover of fibers occurs in the spinal cord.

Most of the fibers in these pathways transmit pain, temperature, and coarse touch impulses, sensations that we are aware of but have difficulty localizing precisely on the body surface.

2. Specific ascending pathways. Also called the **medial lemniscal system** (lem-nis'kul; *lemnisc* = a ribbon), the **specific ascending pathways** mediate precise, straight-through transmission of inputs from a single type (or a few related types) of sensory receptor that *can* be localized precisely on the body surface, such as discriminative touch and vibrations. These pathways are formed by the paired tracts of the **dorsal white column—fasciculus cuneatus** and **fasciculus gracilis**—of the spinal cord and the **medial lemniscal tracts.** The latter arise in the medulla and terminate in the *ventral posterior nuclei* of the thalamus (see Figure 12.34a and Table 12.2). From the thalamus, impulses are forwarded to specific areas of the somatosensory cortex.

3. Spinocerebellar tracts. The last pair of ascending pathways, the **anterior** and **posterior spinocerebellar tracts,** convey information about muscle or tendon stretch to the cerebellum, which uses this information to coordinate skeletal muscle activity. As noted earlier, these pathways do not contribute to conscious sensation. The fibers of the spinocerebellar pathways either do not decussate or else cross over twice (thus "undoing" the decussation).

Descending Pathways and Tracts

The descending tracts that deliver efferent impulses from the brain to the spinal cord are divided into two groups: (1) the *direct pathways* equivalent to the pyramidal tracts and (2) the *indirect pathways,* essentially all others. Motor pathways involve two neurons, referred to as the upper and lower motor neurons. The pyramidal cells of the motor cortex, as well as the neurons in subcortical motor nuclei that give rise to other descending motor pathways, are called *upper motor neurons*. The ventral horn motor neurons, which actually innervate the skeletal muscles (their effectors), are called *lower motor neurons*. These tracts are briefly overviewed here; more information is provided in Table 12.3.

The Direct (Pyramidal) System The direct pathways originate mainly with the pyramidal neurons located in the precentral gyri. These neurons send impulses through the brain stem via the large **pyramidal (corticospinal) tracts** (Figure 12.35a). The direct pathways are so called because their axons descend without synapsing from the pyramidal neurons to the spinal cord. There they synapse either with interneurons or with ventral horn motor neurons. Stimulation of the ventral horn neurons activates the skeletal muscles with which they are associated. The direct pathway primarily regulates fast and fine (or skilled) movements such as doing needlework and writing.

The Indirect (Extrapyramidal) System The indirect system includes brain stem motor nuclei and *all motor pathways except* the pyramidal pathways. These tracts were formerly lumped together as the **extrapyramidal system** because their nuclei of origin were presumed to be independent of ("extra to") the pyramidal tracts. This term is still widely used clinically; however, pyramidal tract neurons are now known to project to and influence the activity of most "extrapyramidal" nuclei, so modern anatomists prefer to use the term **indirect,** or **multineuronal, pathways,** or even just the names of the individual motor pathways.

These motor pathways are complex and multisynaptic. They are most involved in regulating (1) the axial muscles that maintain balance and posture, (2) the muscles controlling coarse limb movements, and (3) head, neck, and eye movements that follow objects in the visual field. Many of the activities controlled by subcortical motor nuclei are heavily dependent on reflex activity. One of these tracts, the rubrospinal tract, is illustrated in Figure 12.35b.

Overall, the **reticulospinal** and **vestibulospinal tracts** (see Table 12.3) maintain balance by varying the tone of postural muscles. The **rubrospinal tracts** control flexor muscles, whereas the **tectospinal tracts** and the *superior colliculi* mediate head movements in response to visual stimuli.

Spinal Cord Trauma and Disorders

Spinal Cord Trauma

The spinal cord is elastic, stretching with every turn of the head or bend of the trunk, but it is exquisitely sensitive to direct pressure. Any localized damage to the spinal cord or its roots leads to some functional loss, either **paralysis** (loss of motor function) or sensory loss. Severe damage to ventral root or ventral horn cells results in a **flaccid paralysis** (flak'sid) of the skeletal muscles served. Nerve impulses do not reach these muscles, which consequently cannot move either voluntarily or involuntarily. Without stimulation, the muscles atrophy. When only the upper motor neurons of the primary motor cortex are damaged, **spastic paralysis** occurs. In this case, the spinal motor neurons remain intact and the muscles continue to be stimulated irregularly by spinal reflex activity. Thus, the muscles remain healthy longer, but their movements are no longer subject to voluntary control. In many such cases, the muscles become permanently shortened.

Transection (cross sectioning) of the spinal cord at any level results in total motor and sensory loss in body regions inferior to the site of damage. If the transection occurs between T_1 and L_1, both lower limbs are affected, resulting in **paraplegia**

TABLE 12.3 Major Descending (Motor) Pathways and Spinal Cord Tracts

SPINAL CORD TRACT	LOCATION (FUNICULUS)	ORIGIN	TERMINATION	FUNCTION
DIRECT (PYRAMIDAL)				
Lateral corticospinal	Lateral	Pyramidal neurons of motor cortex of the cerebrum; decussate in pyramids of medulla	By synapse directly with ventral horn motor neurons and with ventral horn interneurons that influence motor neurons	Transmits motor impulses from cerebrum to spinal cord motor neurons (which activate skeletal muscles on opposite side of body); voluntary motor tract
Anterior corticospinal	Anterior	Pyramidal neurons of motor cortex; fibers cross over at the spinal cord level	Ventral horn (as above)	Same as lateral corticospinal tract
INDIRECT (EXTRAPYRAMIDAL) PATHWAYS				
Tectospinal	Anterior	Superior colliculus of midbrain of brain stem (fibers cross to opposite side of cord)	By synapse with ventral horn interneurons that influence motor neurons	Transmits motor impulses from midbrain that are important for coordinated movement of head and eyes toward visual targets
Vestibulospinal	Anterior	Vestibular nuclei in medulla of brain stem (fibers descend without crossing)	By synapse, directly with ventral horn motor neurons and with ventral horn interneurons that influence motor neurons	Transmits motor impulses that maintain muscle tone and activate ipsilateral limb and trunk extensor muscles and muscles that move head; in this way helps maintain balance during standing and moving
Rubrospinal	Lateral	Red nucleus of midbrain of brain stem (fibers cross to opposite side just inferior to the red nucleus)	Ventral horn (as above)	In experimental animals, transmits motor impulses concerned with muscle tone of distal limb muscles (mostly flexors) on opposite side of body; in humans, functions largely assumed by corticospinal tracts except for some upper limb movement
Reticulospinal (anterior, medial, and lateral)	Anterior and lateral	Reticular formation of brain stem (medial nuclear group of pons and medulla); both crossed and uncrossed fibers	Ventral horn (as above)	Transmits impulses concerned with muscle tone and many visceral motor functions; may control most unskilled movements

(par"ah-ple'je-ah; *para* = beside, *plegia* = a blow). If the injury occurs in the cervical region, all four limbs are affected and the result is **quadriplegia.** *Hemiplegia,* paralysis of one side of the body, usually reflects brain injury rather than spinal cord injury.

Anyone with traumatic spinal cord injury must be watched for symptoms of **spinal shock,** a transient period of functional loss that follows the injury. Spinal shock results in immediate depression of all reflex activity caudal to the lesion site. Bowel and bladder reflexes stop, blood pressure falls, and all muscles (somatic and visceral alike) below the injury are paralyzed and insensitive. Neural function usually returns within a few hours following injury. If function does not resume within 48 hours, paralysis is permanent in most cases.

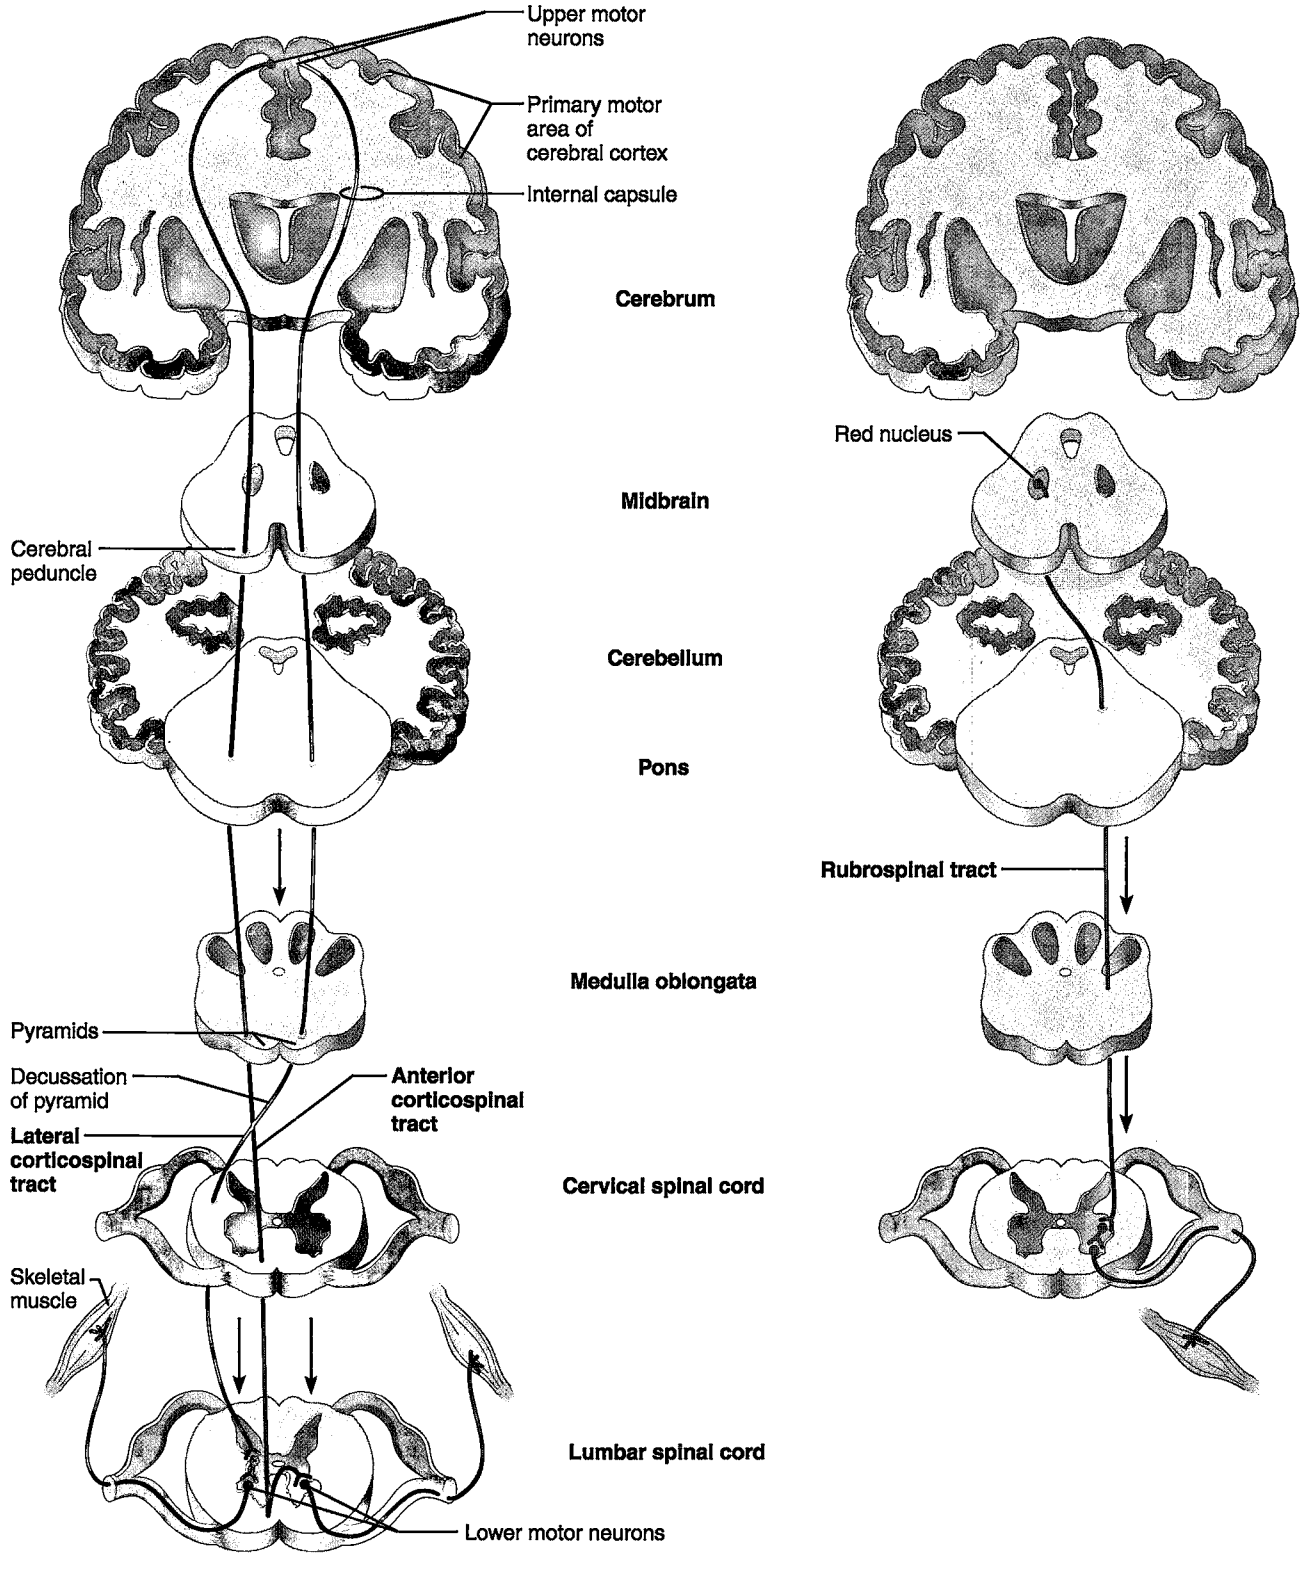

FIGURE 12.35 **Pathways of selected descending spinal cord tracts.** Cross sections up to the cerebrum, which is shown in frontal section. **(a)** Direct pathways, that is, the pyramidal tracts (lateral and anterior corticospinal tracts), carrying motor impulses to skeletal muscles. **(b)** The rubrospinal tract, one of the indirect or extrapyramidal tracts, helps regulate tone of muscles on opposite side of body.

Poliomyelitis

Poliomyelitis (po"le-o-mi"ĕ-li'tis; *polio* = gray matter; *myelitis* = inflammation of the spinal cord) results from destruction of ventral horn motor neurons by the poliovirus. Early symptoms include fever, headache, muscle pain and weakness, and loss of certain somatic reflexes. Later, paralysis develops and the muscles served atrophy. The victim may die from paralysis of the respiratory muscles or from cardiac arrest if neurons in the medulla oblongata are destroyed. In most cases, the poliovirus enters the body in feces-contaminated water (such as might occur in a public swimming pool), and the incidence of the disease has traditionally been highest in children and during the summer months. Fortunately, vaccines have nearly eliminated this disease and a global effort is ongoing to eradicate it completely from the world.

However, many of the "recovered" survivors of the great polio epidemic of the late 1940s and 1950s have begun to experience extreme lethargy, sharp burning pains in their muscles, and progressive muscle weakness and atrophy. Initially dismissed as the flu or psychosomatic illness, these disturbing symptoms are now referred to as **postpolio syndrome.** The cause of postpolio syndrome is not known, but a likely explanation is that its victims, like the rest of us, continue to lose neurons throughout life. While a healthy nervous system can recruit nearby neurons to compensate for the losses, polio survivors have already drawn on that "pool" and have few neurons left to take over. Ironically, those who worked hardest to overcome their disease are its newest victims.

Amyotrophic Lateral Sclerosis

Amyotrophic lateral sclerosis (ALS) (ah-mi"o-trof'ik), also called Lou Gehrig's disease, is a devastating neuromuscular condition that involves progressive destruction of ventral horn motor neurons and fibers of the pyramidal tract. As the disease progresses, the sufferer loses the ability to speak, swallow, and breathe. Death typically occurs within five years. For 90% of cases, the cause of ALS is unknown, although ALS patients appear to have excess extracellular glutamate. Researchers now believe that motor neurons are killed as a result of glutamate excitotoxicity, attack by the immune system, or possibly a combination of the two. Riluzole, the only advance in pharmacological treatment of ALS in 50 years, prolongs life, apparently by inhibiting glutamate release.

Diagnostic Procedures for Assessing CNS Dysfunction

Anyone who has had a routine physical examination is familiar with the reflex tests done to assess neural function. A tap with a reflex hammer stretches your quadriceps tendon and your anterior thigh muscles contract, which results in the knee-jerk response. This response shows that the spinal cord and upper brain centers are functioning normally. Abnormal reflex test responses may indicate such serious disorders as intracranial hemorrhage, multiple sclerosis, or hydrocephalus and suggest that more sophisticated neurological tests are needed to identify the problem.

New imaging techniques have revolutionized the diagnosis of brain lesions (see *A Closer Look*, pp. 20–21). Together the various *CT* and *MRI scanning techniques* allow most tumors, intracranial lesions, multiple sclerosis plaques, and areas of dead brain tissue (infarcts) to be identified quickly. PET scans can localize brain lesions that generate seizures (epileptic tissue) and diagnose Alzheimer's disease.

Take, for example, a patient arriving in emergency with a stroke. A race against time to save the affected area of the patient's brain begins. The first step is to determine if the stroke is due to a clot or a bleed by imaging the brain, most often with CT. If the stroke is due to a clot, then the clot-busting drug tPA can be used, but only within the first hours. tPA is usually given intravenously, but a longer time window can be obtained if tPA is applied directly to the clot using a catheter guided into position. In order to visualize the location of the catheter with respect to the clot, dye is injected to make arteries stand out in an X ray, a procedure called *cerebral angiography*.

Cerebral angiography is also used for patients who have had a warning stroke or TIA. The carotid arteries of the neck feed most of the cerebral vessels and often become narrowed with age, which can lead to strokes. Cheaper and less invasive than angiography, ultrasound can be used to quickly examine the carotid arteries and even measure the flow of blood through them.

Developmental Aspects of the Central Nervous System

Induced by several organizer centers and established during the first month of development, the brain and spinal cord continue to grow and mature throughout the prenatal period. During development, gender-specific areas appear in both the brain and the spinal cord. For example, certain hypothalamic nuclei concerned with regulating typical male sexual behavior and clusters of neurons in the spinal cord that serve the external genitals are much larger in males. Females have a larger corpus callosum, and gender differences are seen in the language and auditory area of the cerebral cortex. The key to this CNS gender-specific development is whether or not testosterone is being secreted by the fetus. If it is, the male pattern develops.

A CLOSER LOOK

How Now Mad Cow

Sarah, a 19-year-old from Carlisle, U.K., was first in her high school graduating class of 1996. She loved the university, but during her second term she began having problems. During the Easter break, her parents were distressed by her slovenly appearance and by the amount of time she spent in her room crying. She complained of being persecuted, had trouble remembering things, and lashed out angrily at her younger brother. Her doctor diagnosed depression and prescribed an antidepressant. Sarah did not return to the university and over the next several months, she became increasingly withdrawn. She grew uncharacteristically aggressive, pushing and swearing at her parents, and was admitted to the psychiatric ward of the district hospital. When she developed difficulty in walking, the medical staff attributed it to "acting out" or a side effect of the various psychiatric medications that had been tried. Confined to a wheelchair, she had lost bowel and bladder control and could no longer speak or feed herself. Her parents feared a brain tumor and insisted on a neurological consultation. Over the next months, many tests were done while her condition steadily deteriorated. Finally, spinal fluid was obtained and abnormal proteins, called **prion proteins** (prē'on), were found. Sarah had **variant Creutzfeldt-Jakob disease (vCJD).** She died shortly thereafter.

On autopsy, Sarah's brain was found to be riddled with sponge-like holes (see photomicrograph), characteristic of a group of diseases called **transmissible spongiform encephalopathies (TSEs).** TSEs include bovine spongiform encephalopathy (BSE, mad cow disease), scrapie in sheep, and a number of conditions in humans, most notably kuru. Kuru ("to tremble with fear") was a mysterious disease that threatened the survival of the Fore people in Papua New Guinea in the 1960s.

Kuru was transmitted from person to person primarily by the ritual cannibalistic practice of eating the brains of affected relatives. Similarly, vCJD seems to be acquired by eating beef contaminated with neural tissue from "mad" cows. What factor is transmitted to cause this disease? The most likely candidates were thought to be viruses or bacteria, but these were ruled out by treating brain extracts with agents that destroy DNA and RNA. Stanley Prusiner (Nobel Prize, 1997) proposed that the infectious factor is in fact a protein, for which he coined the name "prion" (**pr**oteinaceous **in**fectious particle). The idea that a protein, all by itself, could cause an infection was at first viewed with great skepticism. How could a protein possibly cause infection?

Prions are unusual proteins—they are almost indestructible. Cooking, digestion with protein-hydrolyzing enzymes (proteases), even autoclaving, does not destroy them; formaldehyde just makes them more stable. In fact, not even burning to ash at 600°C or burying in the ground for up to three years completely destroys them. Infectious prions are extremely stable, which explains why cooking meat did not protect victims of vCJD and kuru.

Unlike viruses, which take over the cell's protein-making machinery to make more viruses, prions can't program our cells to make new protein. So how do they wreak such havoc in our brains? Prions are, in fact, abnormally folded versions of proteins that are normally found throughout the animal kingdom, and even in yeasts. The function of the normally folded protein, abundant in brain synapses, is still unknown. We do know that it is a glycoprotein attached to the outside of plasma membranes and that it binds copper, suggesting that it plays a role in copper metabolism. To find out what prion protein does, researchers have genetically engineered a strain of mice without it. These mice survive, but some reports show subtle abnormalities in synaptic function and circadian rhythm. They are also completely immune to infection by infectious prions.

Although the amino acid sequence of the normally folded protein and the infectious prion are the same, the molecules have very different shapes. The prion is thought to act as a template that catalyzes a shape conversion in the normal protein, resulting in a shape with many more beta sheets than alpha helices (see p. 50). Once a normal protein has taken on the abnormal shape, it can convert many more of the normal proteins into the abnormal prion shape.

Not all prions are identical. Differences in amino acid sequences between species can make it difficult for prions infecting one species to successfully infect another species. In fact, the prion that causes scrapie in sheep has never been transmitted to humans

12

Maternal exposure to radiation, various drugs (alcohol, opiates, and others), and infections can harm a developing infant's nervous system, particularly during the initial formative stages. For example, rubella (German measles) often leads to deafness and other types of CNS damage in the newborn. Smoking decreases the amount of oxygen in the blood, and lack of oxygen for even a few minutes causes death of neurons. Hence, a smoking mother may be sentencing her infant to some degree of brain damage.

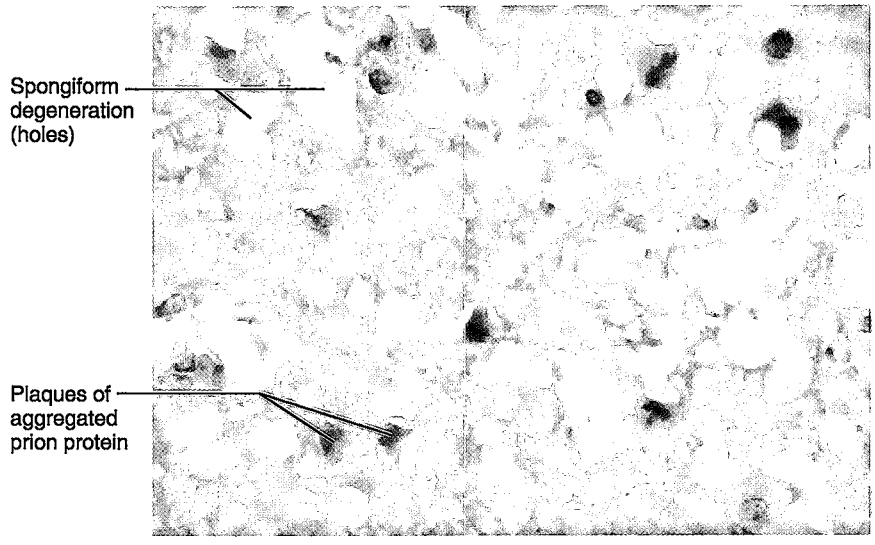
HOMEOSTATIC IMBALANCE

In difficult deliveries, a temporary lack of oxygen may lead to **cerebral palsy,** but any of the factors listed above may also be a cause. Cerebral palsy is a neuromuscular disability in which the voluntary muscles are poorly controlled or paralyzed as a result of brain damage. In addition to spasticity, speech difficulties, and other motor impairments, about half of cerebral palsy victims have seizures, half are mentally retarded,

even though it has been around for at least 200 years. Within a species, different strains of prions cause different clinical manifestations. A strain is determined by exactly how the protein is misfolded and how many sugars it has attached to it. In humans, these differences between strains gives rise to a number of distinct diseases: Creutzfeldt-Jakob disease (CJD), vCJD, kuru, Gerstmann-Sträussler-Scheinker disease (GSS), and fatal familial insomnia (FFI).

CJD and other TSEs are unique in that they can be acquired in three different ways: spontaneously (*sporadic* CJD), by inheritance (*familial* CJD), or by infection. The sporadic form of this disease occurs in people with no family history of the illness and no exposure to infected meat. Occurring in about one per million people per year, *sporadic* CJD is thought to arise from a spontaneous conversion of prion protein from the normal to the infective shape, which then alters the shape of its neighbors, and so on. CJD can also be inherited. This *familial* form of CJD arises from mutations in the gene which codes for the prion protein, making it more susceptible to misfolding. Tissue from a person with either one of these forms of CJD can *infect* another person. Infection via exposure to human tissue has occurred via corneal transplants, dural meningeal patches, contaminated surgical instruments, and of course, by eating as in kuru.

Some people appear to be more prone to acquiring the infective form of CJD than others. Like all proteins, prion protein in a human population exhibits a certain amount of normal variability in its amino acid sequence. Some of these variants make the protein more susceptible to conversion to the abnormal shape. Unfortunately, Sarah and all of the other victims of vCJD diagnosed so far, had a particular sequence of prion protein that left them vulnerable to the abnormal prion from cows with BSE.



Brain tissue affected by variant Creutzfeldt-Jakob disease. *Photomicrograph of human brain showing spongiform degeneration (holes) associated with vCJD (200×). Prions, once formed, tend to aggregate, forming protein plaques.*

Although there is no cure or even an approved treatment for prion diseases, a treatment being used on an emergency basis in the U.K. may prove helpful. Direct injection of pentosan polysulfate into the brain is thought to block conversion of the prion protein to its abnormal form. Another approach, still at the research stage, is to create small protein fragments called "beta breakers" that destabilize the beta sheet conformation of the abnormal protein, making it less likely to convert normal proteins. Genetically engineered dimers of the normal prion protein seem able, at least in mice, to "soak up" abnormal prion proteins and slow the onset of neuronal damage.

Sarah and others like her were infected with vCJD by eating meat from a cow with BSE. Cows acquired BSE from eating infected feed containing the rendered remains of other cows and sheep. Cannibalistic cows don't roam the range, but it was once common practice to use rendered animal carcasses as a cheap source of feed protein, allowing cows to grow bigger, faster, cheaper. Recent laws in countries around the world have abolished the practice of supplementing feed of ruminants in this way. In the Fore people kuru virtually disappeared one generation after they stopped their cannibalistic rituals. We can hope the same will be true for vCJD. ■

and about a third have some degree of deafness. Visual impairments are also common. Cerebral palsy does not get worse over time, but its deficits are irreversible. It is the largest single cause of physical disability in children, affecting three out of every thousand births.

The CNS is plagued by a number of other congenital malformations triggered by genetic or environmental factors during early development. The most serious are congenital hydrocephalus (discussed previously), anencephaly, and spina bifida.

In **anencephaly** (an"en-sef'ah-le; "without brain") the cerebrum and part of the brain stem never develop, presumably because the neural folds fail to fuse rostrally. The child is totally vegetative, unable to see, hear, or process sensory inputs. Muscles are flaccid, and no voluntary movement is possible. Mental life as we know it does not exist. Mercifully, death occurs soon after birth.

Spina bifida (spi'nah bif'ĭ-dah; "forked spine") results from incomplete formation of the vertebral

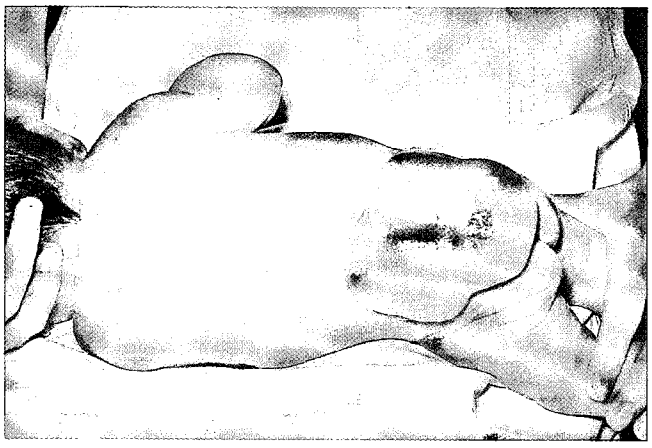


FIGURE 12.36 **Newborn with a lumbar myelomeningocele.**

arches and typically involves the lumbosacral region. The technical definition is that laminae and spinous processes are missing on at least one vertebra. If the condition is severe, neural deficits occur as well. *Spina bifida occulta,* the least serious type, involves one or only a few vertebrae and causes no neural problems. Other than a small dimple or tuft of hair over the site of nonfusion, it has no external manifestations. In the more common and severe form, *spina bifida cystica,* a saclike cyst protrudes dorsally from the child's spine. The cyst may contain meninges and cerebrospinal fluid [a *meningocele* (mĕ-ning'go-sēl)], or even portions of the spinal cord and spinal nerve roots [a *myelomeningocele,* "spinal cord in a meningeal sac," see Figure 12.36]. The larger the cyst and the more neural structures it contains, the greater the neurological impairment. In the worst case, where the inferior spinal cord is functionless, bowel incontinence, bladder muscle paralysis (which predisposes the infant to urinary tract infection and renal failure), and lower limb paralysis occur. Problems with infection are continual because the cyst wall is thin and porous and tends to rupture or leak. Spina bifida cystica is accompanied by hydrocephalus in 90% of all cases.

Up to 70% of cases of spina bifida are caused by inadequate amounts of the B vitamin folate in the maternal diet, a finding that has led to folate supplementation of all bread, flour, and pasta products sold in the United States. ●

One of the last CNS areas to mature is the hypothalamus. Since the hypothalamus contains body temperature regulatory centers, premature babies have problems controlling their loss of body heat and must be kept in temperature-controlled environments. PET scans have revealed that the thalamus and somatosensory cortex are active in a 5-day-old baby, but that the visual cortex is not. This explains why infants of this age respond to touch but have poor vision. By 11 weeks, more of the cortex is active, and the baby can reach for a rattle. By 8 months, the cortex is very active and the child can think about what he or she sees. Growth and maturation of the nervous system continue throughout childhood and largely reflect progressive myelination. As described in Chapter 9, neuromuscular coordination progresses in a superior-to-inferior direction and in a proximal-to-distal direction, and we know that myelination also occurs in this sequence.

The brain reaches its maximum weight in the young adult. Over the next 60 years or so, neurons are damaged and die, and brain weight and volume steadily decline. However, the number of neurons lost over the decades is normally only a small percentage of the total, and the remaining neurons can change their synaptic connections, providing for continued learning throughout life.

Although age brings some cognitive declines in spatial ability, speed of perception, decision making, reaction time, and working memory, these losses are not significant in the *healthy individual* until after the seventh decade. Then the brain becomes increasingly fragile, presumably due to an increase in the density of Ca^{2+} channels in aging neurons (as we have seen, elevated Ca^{2+} levels are neurotoxic), and a fairly rapid decline occurs in some, but not all, of these abilities. Ability to build on experience, mathematical skills, and verbal fluency do not decline with age, and many people continue to enjoy intellectual lives and to work at mentally demanding tasks their entire life. Fewer than 5% of people over 65 demonstrate true dementia. Sadly, many cases of "reversible dementia" are caused by prescription drug effects, low blood pressure, poor nutrition, hormone imbalances, depression, and/or dehydration that go undiagnosed. The best way to maintain one's mental abilities in old age may be to seek regular medical checkups throughout life.

Although eventual shrinking of the brain is normal and accelerates in old age, alcoholics and professional boxers hasten the process. Whether a boxer wins the match or not, the likelihood of brain damage and atrophy increases with every blow. Everyone recognizes that alcohol profoundly affects both the mind and the body. CT scans of alcoholics reveal a reduction in brain size and density appearing at a fairly early age. Both boxers and alcoholics exhibit signs of mental deterioration unrelated to the aging process.

■ ■ ■

The human cerebral hemispheres—our "thinking caps"—are awesome in their complexity. But no less amazing are the brain regions that oversee our subconscious, autonomic body functions—the diencephalon and brain stem—particularly when you consider their relatively insignificant size. The spinal

cord, which acts as a reflex center and a communication link between the brain and body periphery, is equally important to body homeostasis.

A good deal of new terminology has been introduced in this chapter, and much of it will come up again in one or more of the remaining nervous system chapters. Chapter 13, your next challenge, considers the structures of the peripheral nervous system that work hand in hand with the CNS to keep it informed and to deliver its orders to the effectors of the body.

Related Clinical Terms

Autism A complex developmental neurological disorder that typically appears in the first three years of life and is characterized by difficulty in communicating, forming relationships with others, and responding appropriately to the environment. No single cause has been determined although a number of genes are thought to play a role and structural brain abnormalities are present. Occurs in about 2 per 1000 people, and early behavioral intervention is beneficial.

Cordotomy (kor-dot'o-me) A procedure in which a tract in the spinal cord is severed surgically; usually done to relieve unremitting pain.

Encephalopathy (en-sef"ah-lop'ah-the; *enceph* = brain; *path* = disease) Any disease or disorder of the brain.

Functional brain disorders Psychological disorders for which no structural cause can be found; include *neuroses* and *psychoses* (see entries in this list).

Hypersomnia (*hyper* = excess; *somnus* = sleep) A condition in which affected individuals sleep as much as 15 hours daily.

Microcephaly (mi"kro-sef'ah-le; *micro* = small) Congenital condition involving the formation of a small brain, as evidenced by reduced skull size; most microcephalic children are retarded.

Myelitis (mi"ĕ-li'tis; *myel* = spinal cord; *itis* = inflammation) Inflammation of the spinal cord.

Myelogram (*gram* = recording) X ray of the spinal cord after injection of a contrast medium.

Myoclonus (mi"o-klo'nus; *myo* = muscle; *clon* = violent motion, tumult) Sudden contraction of a muscle or muscle part, usually involving muscles of the limbs. Myoclonal jerks occurring in normal individuals as they are falling asleep are thought to reflect a fleeting reactivation of the RAS; others may be due to diseases of the reticular formation or cerebellum.

Neuroses (nu-ro'sēs) A less debilitating class of mental illness; examples include severe anxiety (panic attacks), phobias (irrational fears), and obsessive-compulsive behaviors (e.g., washing one's hands every few minutes); the affected individual, however, retains contact with reality.

Pallidectomy ("cutting the pallidus") Surgically lesioning part of the globus pallidus of the basal nuclei to relieve some symptoms of Parkinson's disease.

Psychoses (si-ko'sēs) A class of severe mental illness in which affected individuals lose touch with reality and exhibit bizarre behaviors; the *legal* word for psychotic behavior is *insanity*; the psychoses include *schizophrenia* (skit-so-fre'ne-ah), *manic-depressive disease,* and some forms of *depression*.

Chapter Summary

The Brain (pp. 431–456)

1. The brain provides for voluntary movements, interpretation and integration of sensation, consciousness, and cognitive function.

Embryonic Development (pp. 431–433)

2. The brain develops from the rostral portion of the embryonic neural tube.

3. Early brain development yields the three primary brain vesicles: the prosencephalon (cerebral hemispheres and diencephalon), mesencephalon (midbrain), and rhombencephalon (pons, medulla, and cerebellum).

4. Cephalization results in the envelopment of the diencephalon and superior brain stem by the cerebral hemispheres.

Regions and Organization (p. 433)

5. In a widely used system, the adult brain is divided into the cerebral hemispheres, diencephalon, brain stem, and cerebellum.

6. The cerebral hemispheres and cerebellum have gray matter nuclei surrounded by white matter and an outer cortex of gray matter. The diencephalon and brain stem lack a cortex.

Ventricles (pp. 433–434)

7. The brain contains four ventricles filled with cerebrospinal fluid. The lateral ventricles are in the cerebral hemispheres; the third ventricle is in the diencephalon; the fourth ventricle is in the brain stem and connects with the central canal of the spinal cord.

Cerebral Hemispheres (pp. 434–443)

8. The two cerebral hemispheres exhibit gyri, sulci, and fissures. The longitudinal fissure partially separates the hemispheres; other fissures or sulci subdivide each hemisphere into lobes.

9. Each cerebral hemisphere consists of the cerebral cortex, the cerebral white matter, and basal nuclei (ganglia).

10. Each cerebral hemisphere receives sensory impulses from, and dispatches motor impulses to, the opposite side of the body. The body is represented in an upside-down fashion in the sensory and motor cortices.

11. Functional areas of the cerebral cortex include (1) motor areas: primary motor and premotor areas of the frontal lobe, the frontal eye field, and Broca's area in the frontal lobe of one hemisphere (usually the left); (2) sensory areas: primary somatosensory cortex and somatosensory association cortex in the parietal lobe; visual areas in the occipital lobe; olfactory and auditory areas in the temporal lobe; gustatory, visceral, and vestibular areas in the insula; (3) association areas: anterior association area in the frontal lobe, and posterior and limbic association areas spanning several lobes.

12. The cerebral hemispheres show lateralization of cortical function. In most people, the left hemisphere is dominant (i.e., specialized for language and mathematical skills); the right hemisphere is more concerned with visual-spatial skills and creative endeavors.

13. Fiber tracts of the cerebral white matter include commissures, association fibers, and projection fibers.

14. The paired basal nuclei (also called basal ganglia) include the lentiform nucleus (globus pallidus and putamen) and caudate nucleus. The basal nuclei are subcortical nuclei that help control muscular movements. Functionally they are closely associated with the substantia nigra of the midbrain.

Diencephalon (pp. 443–447)

15. The diencephalon includes the thalamus, hypothalamus, and epithalamus and encloses the third ventricle.

16. The thalamus is the major relay station for (1) sensory impulses ascending to the sensory cortex, (2) inputs from subcortical motor nuclei and the cerebellum traveling to the cerebral motor cortex, and (3) impulses traveling to association cortices from lower centers.

17. The hypothalamus is an important autonomic nervous system control center and a pivotal part of the limbic system. It maintains water balance and regulates thirst, eating behavior, gastrointestinal activity, body temperature, and the activity of the anterior pituitary gland.

18. The epithalamus includes the pineal gland, which secretes the hormone melatonin.

Brain Stem (pp. 447–451)

19. The brain stem includes the midbrain, pons, and medulla oblongata.

20. The midbrain contains the corpora quadrigemina (visual and auditory reflex centers), the red nucleus (subcortical motor centers), and the substantia nigra. The periaqueductal gray matter is involved in pain suppression and contains the motor nuclei of cranial nerves III and IV. The cerebral peduncles on its ventral face house the pyramidal fiber tracts. The midbrain surrounds the cerebral aqueduct.

21. The pons is mainly a conduction area. Its nuclei contribute to regulation of respiration and cranial nerves V–VII.

22. The pyramids (descending corticospinal tracts) form the ventral face of the medulla oblongata; these fibers cross over (decussation of the pyramids) before entering the spinal cord. Important nuclei in the medulla regulate respiratory rhythm, heart rate, and blood pressure and serve cranial nerves VIII–XII. The olivary nuclei and cough, sneezing, swallowing, and vomiting centers are also in the medulla.

Cerebellum (pp. 451–454)

23. The cerebellum consists of two hemispheres, marked by convolutions and separated by the vermis. It is connected to the brain stem by superior, middle, and inferior peduncles.

24. The cerebellum processes and interprets impulses from the motor cortex and sensory pathways and coordinates motor activity so that smooth, well-timed movements occur. It also plays a poorly understood role in cognition.

Functional Brain Systems (pp. 454–456)

25. The limbic system consists of numerous structures that encircle the brain stem. It is the "emotional-visceral brain." It also plays a role in memory.

26. The reticular formation is a diffuse network of neurons and nuclei spanning the length of the brain stem. It maintains the alert state of the cerebral cortex (RAS), and its motor nuclei serve both somatic and visceral motor activities.

Higher Mental Functions (pp. 456–463)

Brain Wave Patterns and the EEG (pp. 456–457)

1. Patterns of electrical activity of the brain are called brain waves; a record of this activity is an electroencephalogram (EEG). Brain wave patterns, identified by their frequencies, include alpha, beta, theta, and delta waves.

2. Epilepsy results from abnormal electrical activity of brain neurons. Involuntary muscle contractions and sensory auras are typical during such seizures.

Consciousness (pp. 457–458)

3. Consciousness is described clinically on a continuum from alertness to drowsiness to stupor and finally to coma.

4. Human consciousness is thought to involve holistic information processing, which is (1) not localizable, (2) superimposed on other types of neural activity, and (3) totally interconnected.

5. Fainting (syncope) is a temporary loss of consciousness that usually reflects inadequate blood delivery to the brain. Coma is loss of consciousness in which the victim is unresponsive to stimuli.

Sleep and Sleep-Wake Cycles (pp. 458–460)

6. Sleep is a state of partial consciousness from which one can be aroused by stimulation. The two major types of sleep are non–rapid eye movement (NREM) sleep and rapid eye movement (REM) sleep.

7. During stages 1–4 of NREM sleep, brain wave frequency decreases and amplitude increases until delta wave sleep (stage 4) is achieved. REM sleep is indicated by a return to a stage 1 EEG. During REM, the eyes move rapidly under the lids. NREM and REM sleep alternate throughout the night.

8. Slow-wave sleep (stage 4 of NREM) appears to be restorative. REM sleep is important for emotional stability.

9. REM occupies half of an infant's sleep time and then declines to about 25% of sleep time by the age of 10 years. Time spent in slow-wave sleep declines steadily throughout life.

10. Narcolepsy is involuntary lapses into REM sleep that occur without warning during waking periods. Insomnia is a chronic inability to obtain the amount or quality of sleep needed to function adequately. Sleep apnea is a temporary cessation of breathing during sleep, causing hypoxia.

Language (p. 460)

11. In most people language is controlled by the left hemisphere. The language implementation system, which includes Broca's and Wernicke's areas and the basal nuclei, analyzes incoming and produces outgoing language. The opposite hemisphere deals with the emotional content of language.

Memory (pp. 460–463)

12. Memory is the ability to recall one's thoughts. It is essential for learning and is part of consciousness.

13. Memory storage has two stages: short-term memory (STM) and long-term memory (LTM). Transfer of information from STM to LTM takes minutes to hours, but more time is required for LTM consolidation.

14. Declarative memory is the ability to learn and consciously remember information. Procedural memory is the learning of motor skills, which are then performed without conscious thought.

15. Declarative memory appears to involve the medial temporal lobe (hippocampus and surrounding temporal cortical areas), thalamus, basal forebrain, and prefrontal cortex. Skill memory (a type of procedural memory) relies on the basal nuclei.

16. The nature of memory traces in the human brain is not fully known, but NMDA receptors (essentially calcium channels), activated by depolarization and glutamate binding, play a major role in long-term potentiation (LTP). The calcium influx that follows NMDA receptor activation mobilizes enzymes that mediate events necessary for memory consolidation.

Protection of the Brain (pp. 463–470)

Meninges (pp. 463–465)

1. The brain is protected by bone, meninges, cerebrospinal fluid, and the blood-brain barrier.

2. The meninges from superficial to deep are the dura mater, the arachnoid mater, and the pia mater. They enclose the brain and spinal cord and their blood vessels. Inward folds of the inner layer of the dura mater secure the brain to the skull.

Cerebrospinal Fluid (pp. 465–467)

3. Cerebrospinal fluid (CSF), formed by the choroid plexuses from blood plasma, circulates through the ventricles and into the subarachnoid space. It returns to the dural venous sinuses via the arachnoid villi. CSF supports and cushions the brain and cord and helps to nourish them.

Blood-Brain Barrier (p. 467)

4. The blood-brain barrier reflects the relative impermeability of the epithelium of capillaries of the brain. It allows water, respiratory gases, essential nutrients, and fat-soluble molecules to enter the neural tissue, but prevents entry of other, water-soluble, potentially harmful substances.

Homeostatic Imbalances of the Brain (pp. 467–470)

5. Head trauma may cause brain injuries called concussions or, in severe cases, contusions (bruising). When the brain stem is affected, unconsciousness (temporary or permanent) occurs. Trauma-induced brain injuries may be aggravated by intracranial hemorrhage or cerebral edema, both of which compress brain tissue.

6. Cerebrovascular accidents (strokes) result when blood circulation to brain neurons is impaired and brain tissue dies. The result may be hemiplegia, sensory deficits, or speech impairment.

7. Alzheimer's disease is a degenerative brain disease in which beta amyloid peptide deposits and neurofibrillary tangles appear. Marked by a deficit of ACh, it results in slow, progressive loss of memory and motor control and increasing dementia.

8. Parkinson's disease and Huntington's disease are neurodegenerative disorders of the basal nuclei. Both involve abnormalities of the neurotransmitter dopamine (too little or too much secreted) and are characterized by abnormal movements.

The Spinal Cord (pp. 470–481)

Embryonic Development (p. 470)

1. The spinal cord develops from the neural tube. Its gray matter forms from the alar and basal plates. Fiber tracts form the outer white matter. The neural crest forms the sensory (dorsal root) ganglia.

Gross Anatomy and Protection (pp. 470–472)

2. The spinal cord, a two-way impulse conduction pathway and a reflex center, resides within the vertebral column and is protected by meninges and cerebrospinal fluid. It extends from the foramen magnum to the end of the first lumbar vertebra.

3. Thirty-one pairs of spinal nerve roots issue from the cord. The cord is enlarged in the cervical and lumbar regions, where spinal nerves serving the limbs arise.

Cross-Sectional Anatomy (pp. 472–478)

4. The central gray matter of the cord is H shaped. Ventral horns mainly contain somatic motor neurons. Lateral horns contain visceral (autonomic) motor neurons. Dorsal horns contain interneurons.

5. Axons of neurons of the lateral and ventral horns emerge in common from the cord via the ventral roots. Axons of sensory neurons (with cell bodies located in the dorsal root ganglion) enter the posterior aspect of the cord and form the dorsal roots. The ventral and dorsal roots combine to form the spinal nerves.

6. Each side of the white matter of the cord has posterior, lateral, and anterior columns (funiculi), and each funiculus contains a number of ascending and descending tracts. All tracts are paired and most decussate.

7. Ascending (sensory) tracts include the fasciculi gracilis and cuneatus, spinothalamic tracts, and spinocerebellar tracts.

8. The specific sensory pathway consists of the dorsal white column (fasciculus cuneatus, fasciculus gracilis) and the medial lemniscal tracts, which are concerned with straight-through, precise transmission of one or a few related sensory modalities. The nonspecific pathway (the spinothalamic tracts) is a multimodal pathway that permits brain stem processing of ascending impulses. The spinocerebellar tracts, which terminate in the cerebellum, serve muscle sense, not conscious sensory perception.

9. Descending tracts include the pyramidal tracts (anterior and lateral corticospinal tracts) and a number of motor tracts originating from subcortical motor nuclei. These descending fibers issue from the brain stem motor areas [indirect (extrapyramidal) system] and cortical motor areas [direct (pyramidal) system].

Spinal Cord Trauma and Disorders (pp. 478–481)

10. Injury to the ventral horn neurons or the ventral roots results in flaccid paralysis. (Injury to the upper motor neurons in the brain results in spastic paralysis.) If the dorsal roots or sensory tracts are damaged, paresthesias occur.

11. Poliomyelitis results from inflammation and destruction of the ventral horn neurons by the poliovirus. Paralysis and muscle atrophy ensue.

12. Amyotrophic lateral sclerosis results from destruction of the ventral horn neurons and the pyramidal tract. The victim eventually loses the ability to swallow, speak, and breathe. Death generally occurs within five years.

Diagnostic Procedures for Assessing CNS Dysfunction (p. 481)

1. Diagnostic procedures used to assess neurological condition and function range from routine reflex testing to sophisticated techniques such as cerebral angiography, CT scans, MRI scans, and PET scans.

Developmental Aspects of the Central Nervous System (pp. 481–484)

1. Maternal and environmental factors may impair embryonic brain development, and oxygen deprivation destroys brain cells. Severe congenital brain diseases include cerebral palsy, anencephaly, hydrocephalus, and spina bifida.

2. Premature babies have trouble regulating body temperature because the hypothalamus is one of the last brain areas to mature prenatally.

3. Development of motor control indicates progressive myelination and maturation of a child's nervous system.

4. Brain growth ends in young adulthood. Neurons die throughout life and most are not replaced; thus, brain weight and volume decline with age.

5. Healthy elders maintain nearly optimal intellectual function. Disease—particularly cardiovascular disease—is the major cause of declining mental function with age.

Review Questions

Multiple Choice/Matching

(Some questions have more than one correct answer. Select the best answer or answers from the choices given.)

1. The primary motor cortex, Broca's area, and the premotor area are located in which lobe? (a) frontal, (b) parietal, (c) temporal, (d) occipital.

2. The innermost layer of the meninges, delicate and closely apposed to the brain tissue, is the (a) dura mater, (b) corpus callosum, (c) arachnoid, (d) pia mater.

3. Cerebrospinal fluid is formed by (a) arachnoid villi, (b) the dura mater, (c) choroid plexuses, (d) all of these.

4. A patient has suffered a cerebral hemorrhage that has caused dysfunction of the precentral gyrus of his right cerebral cortex. As a result, (a) he cannot voluntarily move his left arm or leg, (b) he feels no sensation on the left side of his body, (c) he feels no sensation on his right side.

5. Choose the proper term from the key to respond to the statements describing various brain areas.

Key:

(a) cerebellum	**(d)** corpus striatum	**(g)** midbrain
(b) corpora quadrigemina	**(e)** hypothalamus	**(h)** pons
(c) corpus callosum	**(f)** medulla	**(i)** thalamus

____ **(1)** basal nuclei involved in fine control of motor activities
____ **(2)** region where there is a gross crossover of fibers of descending pyramidal tracts
____ **(3)** control of temperature, autonomic nervous system reflexes, hunger, and water balance
____ **(4)** houses the substantia nigra and cerebral aqueduct
____ **(5)** relay stations for visual and auditory stimuli input; found in midbrain
____ **(6)** houses vital centers for control of the heart, respiration, and blood pressure
____ **(7)** brain area through which all the sensory input is relayed to get to the cerebral cortex
____ **(8)** brain area most concerned with equilibrium, body posture, and coordination of motor activity

6. Which of the following tracts convey vibration and other specific sensations that can be precisely localized? (a) pyramidal tract, (b) medial lemniscal tract, (c) lateral spinothalamic tract, (d) reticulospinal tract.

7. Destruction of the ventral horn cells of the spinal cord results in loss of (a) integrating impulses, (b) sensory impulses, (c) voluntary motor impulses, (d) all of these.

8. Fiber tracts that allow neurons within the same cerebral hemisphere to communicate are (a) association tracts, (b) commissures, (c) projection tracts.

9. A number of brain structures are listed below. If an area is primarily gray matter, write **a** in the answer blank; if mostly white matter, respond with **b.**

____ **(1)** cerebral cortex
____ **(2)** corpus callosum and corona radiata
____ **(3)** red nucleus
____ **(4)** medial and lateral nuclear groups
____ **(5)** medial lemniscal tract
____ **(6)** cranial nerve nuclei
____ **(7)** spinothalamic tract
____ **(8)** fornix
____ **(9)** cingulate and precentral gyri

10. A professor unexpectedly blew a loud horn in his anatomy and physiology class. The students looked up, startled. The reflexive movements of their eyes were mediated by the (a) cerebral cortex, (b) inferior olives, (c) raphe nuclei, (d) superior colliculi, (e) nucleus gracilis.

11. Identify the stage of sleep described by using choices from the key. (Note that responses a–d refer to NREM sleep.)

Key: **(a)** stage 1 **(b)** stage 2 **(c)** stage 3 **(d)** stage 4 **(e)** REM

____ **(1)** the stage when vital signs (blood pressure and heart rate) reach their lowest levels
____ **(2)** indicated by movement of the eyes under the lids; dreaming occurs
____ **(3)** when sleepwalking is likely to occur
____ **(4)** when the sleeper is very easily awakened; EEG shows alpha waves

Short Answer Essay Questions

12. Make a diagram showing the three primary (embryonic) brain vesicles. Name each and then use clinical terminology to name the resulting adult brain regions.

13. (a) What is the advantage of having a cerebrum that is highly convoluted? (b) What term is used to indicate its grooves? Its outward folds? (c) What groove divides the cerebrum into two hemispheres? (d) What divides the parietal from the frontal lobe? The parietal from the temporal lobe?

14. (a) Make a rough drawing of the lateral aspect of the left cerebral hemisphere. (b) You may be thinking, "But I just can't draw!" So, name the hemisphere involved with most people's ability to draw. (c) On your drawing, locate the following areas and provide the major function of each: primary motor cortex, premotor cortex, somatosensory association area, primary sensory area, visual and auditory areas, prefrontal cortex, Wernicke's and Broca's areas.

15. (a) What does lateralization of cortical functioning mean? (b) Why is the term cerebral dominance a misnomer?

16. (a) What is the function of the basal nuclei? (b) Which basal nuclei form the lentiform nucleus? (c) Which arches over the diencephalon?

17. (a) Explain how the cerebellum is physically connected to the brain stem. (b) List ways in which the cerebellum is very similar to the cerebrum.

18. Describe the role of the cerebellum in maintaining smooth, coordinated skeletal muscle activity.

19. (a) Where is the limbic system located? (b) What structures make up this system? (c) How is the limbic system important in behavior?

20. (a) Localize the reticular formation in the brain. (b) What does RAS mean, and what is its function?

21. What is an aura?

22. How do sleep patterns, extent of sleeping time, and amount of time spent in REM and NREM sleep change through life?

23. Compare and contrast short-term memory (STM) and long-term memory (LTM) relative to storage capacity and duration of the memory.

24. (a) Name several factors that can enhance transfer of information from STM to LTM. (b) Define memory consolidation.

25. Compare and contrast declarative and procedural memory relative to the types of things remembered and the importance of conscious retrieval.

26. List four ways in which the CNS is protected.

27. (a) How is cerebrospinal fluid formed and drained? Describe its pathway within and around the brain. (b) What happens if CSF is not drained properly? Why is this consequence more harmful in adults?

28. What constitutes the blood-brain barrier?

29. A brain surgeon is about to make an incision. Name all the tissue layers that she cuts through from the skin to the brain.

30. (a) Define concussion and contusion. (b) Why does severe brain stem injury result in unconsciousness?

31. Describe the spinal cord, depicting its extent, its composition of gray and white matter, and its spinal roots.

32. All of the following descriptions refer to specific ascending pathways except one: (a) they include the fasciculus gracilis and fasciculus cuneatus, which terminate in the thalamus; (b) they include a chain of three neurons; (c) their connections are diffuse and polymodal; (d) they are concerned with precise transmission of one or a few related sensory modalities.

33. Describe the functional problems that would be experienced by a person in which these fiber tracts have been cut: (a) lateral spinothalamic, (b) anterior and posterior spinocerebellar, (c) tectospinal.

34. Differentiate between spastic and flaccid paralysis.

35. How do the conditions paraplegia, hemiplegia, and quadriplegia differ?

36. (a) Define cerebrovascular accident or CVA. (b) Describe its possible causes and consequences.

37. (a) What factors account for brain growth after birth? (b) List some structural brain changes observed with aging.

Critical Thinking and Clinical Application Questions

1. A 10-month-old infant has an enlarging head circumference and delayed overall development. She has a bulging anterior fontanel and her CSF pressure is elevated. Based on these findings, answer the following questions: (a) What are the possible cause(s) of an enlarged head? (b) What tests might be helpful in obtaining information about this infant's problem? (c) Assuming the tests conducted showed the cerebral aqueduct to be constricted, which ventricles or CSF-containing areas would you expect to be enlarged? Which would likely not be visible? Respond to the same questions based on a finding of obstructed arachnoid villi.

2. Mrs. Jones has had a progressive decline in her mental capabilities in the last five or six years. At first her family attributed her occasional memory lapses, confusion, and agitation to grief over her husband's death six years earlier. When examined, Mrs. Jones was aware of her cognitive problems and was shown to have an IQ score approximately 30 points less than would be predicted by her work history. A CT scan showed diffuse cerebral atrophy. The physician prescribed an acetylcholinesterase inhibitor and Mrs. Jones showed slight improvement. What is Mrs. Jones's problem? Why did the acetylcholinesterase inhibitor help?

3. Robert, a brilliant computer analyst, suffered a blow to his anterior skull from a falling rock while mountain climbing. Shortly thereafter, it was obvious to his co-workers that his behavior had undergone a dramatic change. Although previously a smart dresser, he was now unkempt. One morning, he was observed defecating into the wastebasket. His supervisor ordered Robert to report to the company's doctor immediately. What region of Robert's brain was affected by the cranial blow?

4. Mrs. Adams is ready to deliver her first baby. Unfortunately, the baby appears to have a myelomeningocele. Would a vaginal or surgical (C-section) delivery be more appropriate and why?

5. The medical chart of a 68-year-old man includes the following notes: "Slight tremor of right hand at rest; stony facial expression; difficulty in initiating movements." (a) Based on your present knowledge, what is the diagnosis? (b) What brain areas are most likely involved in this man's disorder, and what is the deficiency? (c) How is this condition currently treated?

6. Cynthia, a 16-year-old girl, was rushed to the hospital after taking a bad spill off the parallel bars. After she had a complete neurological workup, her family was told that she would be permanently paralyzed from the waist down. The neurologist then outlined for Cynthia's parents the importance of preventing complications in such cases. Common complications include urinary infection, bed sores, and muscular spasms. Using your knowledge of neuroanatomy, explain the underlying reasons for these complications.

7. Mrs. Herrera suffered a stroke two weeks ago. Initially she was unable to move her right arm and the right side of her face, but her paralysis has decreased markedly. However, she still has a great deal of difficulty speaking. Mrs. Herrera's speech consists of very few words. She struggles to produce these words and they are distorted and separated by long pauses. Her comprehension of written and spoken language is unaltered. She is fully aware of what happened to her and is tearful much of the time. Which side of the brain and which particular area of the brain was affected by Mrs. Herrera's stroke?

8. Five-year-old Amy wakes her parents up at 3 AM crying and complaining of a sore neck, a severe headache, and feeling sick to her stomach. She has a temperature of 40°C (104°F) and hides her eyes, saying that the lights are too bright. The emergency physician suspects meningitis and performs a lumbar tap. Using your knowledge of neuroanatomy, explain into which space and at what level of the vertebral column the needle will be inserted to perform this test. Which fluid is being obtained and why?

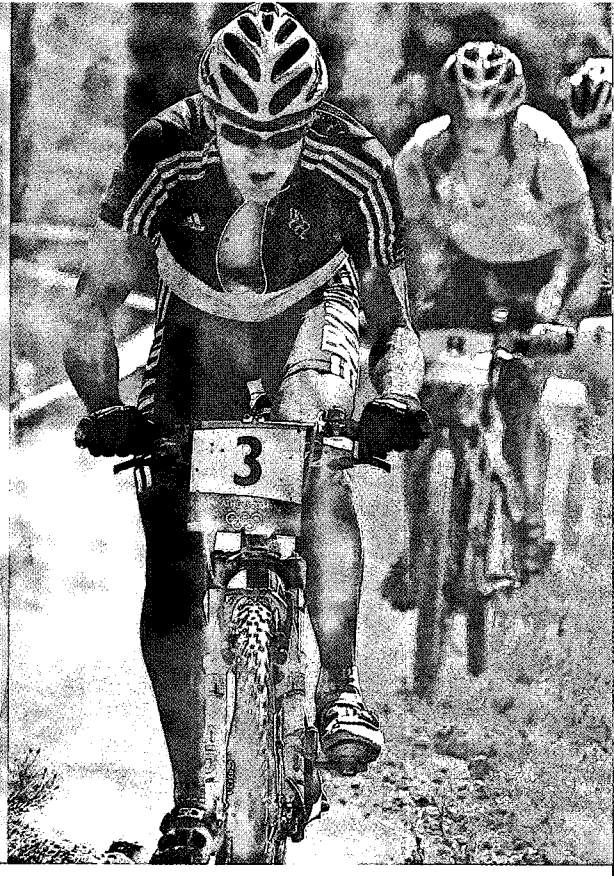
13 The Peripheral Nervous System and Reflex Activity



1. Define peripheral nervous system and list its components.

PART 1: SENSORY RECEPTORS AND SENSATION

Sensory Receptors (pp. 491–494)

2. Classify general sensory receptors by structure, stimulus detected, and body location.

Overview: From Sensation to Perception (pp. 494–498)

3. Outline the events that lead to sensation and perception.
4. Describe receptor and generator potentials and sensory adaptation.
5. Describe the main aspects of sensory perception.

PART 2: TRANSMISSION LINES: NERVES AND THEIR STRUCTURE AND REPAIR

Nerves and Associated Ganglia (pp. 498–500)

6. Define ganglion and indicate the general body location of ganglia.
7. Describe the general structure of a nerve, and follow the process of nerve regeneration.

Cranial Nerves (pp. 500–508)

8. Name the 12 pairs of cranial nerves; indicate the body region and structures innervated by each.

Spinal Nerves (pp. 508–518)

9. Describe the formation of a spinal nerve and the general distribution of its rami.
10. Define plexus. Name the major plexuses and describe the distribution and function of the peripheral nerves arising from each plexus.

PART 3: MOTOR ENDINGS AND MOTOR ACTIVITY

Peripheral Motor Endings (p. 519)

11. Compare and contrast the motor endings of somatic and autonomic nerve fibers.

Overview of Motor Integration: From Intention to Effect (pp. 519–521)

12. Outline the three levels of the motor hierarchy.
13. Compare the roles of the cerebellum and basal nuclei in controlling motor activity.

PART 4: REFLEX ACTIVITY

The Reflex Arc (pp. 521–522)

14. Name the components of a reflex arc and distinguish between autonomic and somatic reflexes.

Spinal Reflexes (pp. 522–527)

15. Compare and contrast stretch, flexor, crossed-extensor, and Golgi tendon reflexes.

Developmental Aspects of the Peripheral Nervous System (p. 527)

16. List changes that occur in the sensory system with aging.
17. Describe the developmental relationship between the segmented arrangement of peripheral nerves, skeletal muscles, and skin dermatomes.

The human brain, for all its sophistication, would be useless without its links to the outside world. In one experiment that illustrates this point, blindfolded volunteers suspended in warm water in a sensory deprivation tank (a situation that limits sensory inputs) hallucinated. One saw charging pink and purple elephants. Another heard a chorus, still others had taste hallucinations. Our very sanity depends on a continuous flow of information from the outside.

No less important to our well-being are the orders sent from the CNS to voluntary muscles and other effectors of the body, which allow us to move and to take care of our own needs. The **peripheral nervous system (PNS)** provides these links from and to the world outside our bodies. Ghostly white nerves thread through virtually every part of the body, enabling the CNS to receive information and to carry out its decisions.

The PNS includes all neural structures outside the brain and spinal cord, that is, the *sensory receptors*, peripheral *nerves* and their associated *ganglia*, and efferent *motor endings*. Its basic components are diagrammed in Figure 13.1. The first portion of this chapter deals with the functional anatomy of each PNS element. Then we consider the components of reflex arcs and some important somatic reflexes, played out almost entirely in PNS structures, that help to maintain homeostasis.

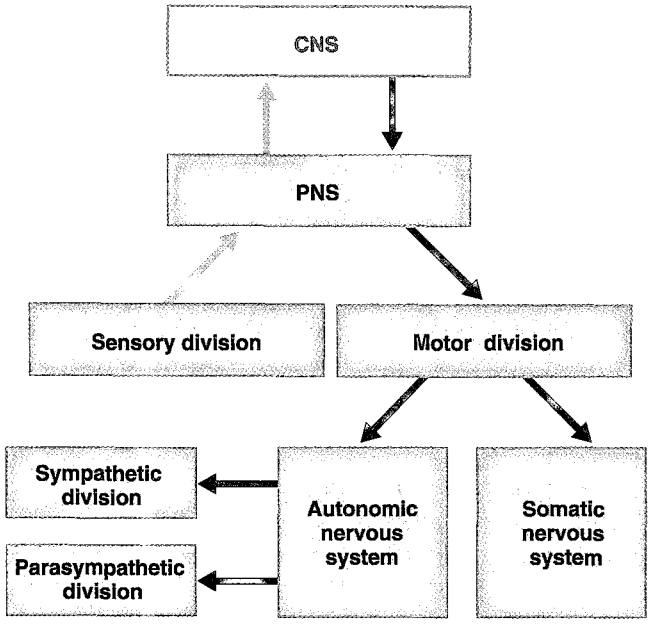


FIGURE 13.1 **Place of the PNS in the structural organization of the nervous system.**

PART 1: SENSORY RECEPTORS AND SENSATION

Sensory Receptors

Sensory receptors are specialized to respond to changes in their environment; such environmental changes are called **stimuli.** Typically, activation of a sensory receptor by an adequate stimulus results in graded potentials that in turn trigger nerve impulses along the afferent PNS fibers coursing to the CNS. *Sensation* (awareness of the stimulus) and *perception* (interpretation of the meaning of the stimulus) occur in the brain. But we are getting ahead of ourselves here. For now, let us just examine how sensory receptors are classified. Basically, there are three ways to classify sensory receptors: (1) by the type of stimulus they detect; (2) by their body location; and (3) by their structural complexity.

Classification by Stimulus Type

The receptor classes named according to the activating stimulus are easy to remember because the class name usually indicates the stimulus.

1. **Mechanoreceptors** generate nerve impulses when they, or adjacent tissues, are deformed by a mechanical force such as touch, pressure (including blood pressure), vibration, and stretch.
2. **Thermoreceptors** are sensitive to temperature changes.
3. **Photoreceptors,** such as those of the retina of the eye, respond to light energy.
4. **Chemoreceptors** respond to chemicals in solution (molecules smelled or tasted, or changes in blood or interstitial fluid chemistry).
5. **Nociceptors** (no"se-sep'torz; *noci* = harm) respond to potentially damaging stimuli that result in pain. For example, searing heat, extreme cold, excessive pressure, and inflammatory chemicals are all interpreted as painful. These signals stimulate subtypes of thermoreceptors, mechanoreceptors, and chemoreceptors.

Classification by Location

Three receptor classes are recognized according to either their location or the location of the activating stimulus.

1. **Exteroceptors** (ek"ster-o-sep'torz) are sensitive to stimuli arising outside the body (*extero* = outside), so most exteroceptors are near or at the body surface. They include touch, pressure, pain, and temperature receptors in the skin and most receptors of the

special senses (vision, hearing, equilibrium, taste, smell).

2. Interoceptors (in"ter-o-sep'torz), also called **visceroceptors,** respond to stimuli within the body (*intero*=inside), such as from the internal viscera and blood vessels. They monitor a variety of stimuli, including chemical changes, tissue stretch, and temperature. Sometimes their activity causes us to feel pain, discomfort, hunger, or thirst. However, we are usually unaware of their workings.

3. Proprioceptors (pro"pre-o-sep'torz), like interoceptors, respond to internal stimuli; however, their location is much more restricted. Proprioceptors occur in skeletal muscles, tendons, joints, and ligaments and in connective tissue coverings of bones and muscles. (Some authorities include the equilibrium receptors of the inner ear in this class.) Proprioceptors constantly advise the brain of our body movements (*propria* = one's own) by monitoring how much the organs containing these receptors are stretched.

Classification by Structural Complexity

On the basis of overall receptor structure, there are **simple** and **complex receptors,** but the overwhelming majority are simple. The simple receptors are modified dendritic endings of sensory neurons. They are found throughout the body and monitor most types of general sensory information. Complex receptors are actually **sense organs,** localized collections of cells (usually of many types) associated with the **special senses** (vision, hearing, equilibrium, smell, and taste). For example, the sense organ we know as the eye is composed not only of sensory neurons but also of nonneural cells that form its supporting wall, lens, and other associated structures. Though the complex sense organs are most familiar to us, the simple sensory receptors associated with the **general senses** are no less important, and we will concentrate on their structure and function in this chapter. The special senses are the topic of Chapter 15.

Simple Receptors of the General Senses

The widely distributed **general sensory receptors** are involved in tactile sensation (a mix of touch, pressure, stretch, and vibration), temperature monitoring, and pain, as well as the "muscle sense" provided by proprioceptors. Anatomically, these receptors are either *unencapsulated (free) nerve endings* or *encapsulated nerve endings.* The general sensory receptors are illustrated and classified in Table 13.1.

Unencapsulated Dendritic Endings **Free,** or **naked, nerve endings** of sensory neurons are present nearly everywhere in the body, but they are particularly abundant in epithelia and connective tissues. Most of these sensory fibers are unmyelinated, small-diameter C fibers, and their distal endings (the sensory terminals) usually have small knoblike swellings. They respond chiefly to temperature and painful stimuli, but some respond to tissue movements caused by pressure as well. Nerve endings that respond to cold (10–40°C) are located in the superficial dermis; those responding to heat (32–48°C) are found deeper in the dermis.

Heat or cold outside the range of thermoreceptors activates nociceptors and is perceived as painful. Nociceptors also respond to pinch and chemicals released from damaged tissue. A recently discovered receptor *(vanilloid receptor)* in the plasma membrane of nociceptive free nerve endings is an ion channel that is opened by heat, low pH, and the substance found in red peppers called capsaicin.

Another sensation mediated by free nerve endings is itch. Located in the dermis, the itch receptor escaped detection until 1997 because of its thin diameter. A number of chemicals—notably histamine—present at inflamed sites activate these nerve endings.

Certain free nerve endings associate with enlarged, disc-shaped epidermal cells *(Merkel cells)* to form **Merkel (tactile) discs,** which lie in the deeper layers of the epidermis and function as light touch receptors. **Hair follicle receptors,** free nerve endings that wrap basketlike around hair follicles, are light touch receptors that detect bending of hairs. The tickle of a mosquito landing on your skin is mediated by hair follicle receptors.

Encapsulated Dendritic Endings All **encapsulated dendritic endings** consist of one or more fiber terminals of sensory neurons enclosed in a connective tissue capsule. Virtually all the encapsulated receptors are mechanoreceptors; however, they vary greatly in shape, size, and distribution in the body.

The encapsulated receptors known as **Meissner's corpuscles** (mīs'nerz kor'pus"lz) are small receptors in which a few spiraling sensory terminals are surrounded by Schwann cells and then by a thin egg-shaped connective tissue capsule. Meissner's corpuscles are found just beneath the epidermis in the dermal papillae and are especially numerous in sensitive and hairless skin areas such as the nipples, fingertips, and soles of the feet. Also called **tactile corpuscles,** they are receptors for discriminative touch, and apparently play the same role in light touch reception in hairless skin as do the hair follicle receptors in hairy skin.

Pacinian corpuscles, also called **lamellated corpuscles,** are scattered deep in the dermis, and in subcutaneous tissue underlying the skin. Although they are mechanoreceptors stimulated by deep pressure, they respond only when the pressure is first applied,

TABLE 13.1 General Sensory Receptors Classified by Structure and Function

STRUCTURAL CLASS	ILLUSTRATION	FUNCTIONAL CLASSES ACCORDING TO LOCATION (L) AND STIMULUS TYPE (S)	BODY LOCATION
UNENCAPSULATED			
Free nerve endings of sensory neurons		L: Exteroceptors, interoceptors, and proprioceptors S: Thermoreceptors (warm and cool), chemoreceptors (itch, pH, etc.), mechanoreceptors (pressure), nociceptors (pain, hot, cold, pinch, and chemicals)	Most body tissues; most dense in connective tissues (ligaments, tendons, dermis, joint capsules, periostea) and epithelia (epidermis, cornea, mucosae, and glands)
Modified free nerve endings: Merkel discs (tactile discs)		L: Exteroceptors S: Mechanoreceptors (light pressure); slowly adapting	Basal layer of epidermis of skin
Hair follicle receptors		L: Exteroceptors S: Mechanoreceptors (hair deflection); rapidly adapting	In and surrounding hair follicles
ENCAPSULATED			
Meissner's corpuscles (tactile corpuscles)		L: Exteroceptors S: Mechanoreceptors (light pressure, discriminative touch, vibration of low frequency); rapidly adapting	Dermal papillae of hairless skin, particularly nipples, external genitalia, fingertips, soles of feet, eyelids
Pacinian corpuscles (lamellated corpuscles)		L: Exteroceptors, interoceptors, and some proprioceptors S: Mechanoreceptors (deep pressure, stretch, vibration of high frequency); rapidly adapting	Dermis and hypodermis; periostea, mesentery, tendons, ligaments, joint capsules; most abundant on fingers, soles of feet, external genitalia, nipples
Ruffini endings		L: Exteroceptors and proprioceptors S: Mechanoreceptors (deep pressure and stretch); slowly or nonadapting	Deep in dermis, hypodermis, and joint capsules
Muscle spindles		L: Proprioceptors S: Mechanoreceptors (muscle stretch, length)	Skeletal muscles, particularly those of the extremities
Golgi tendon organs		L: Proprioceptors S: Mechanoreceptors (tendon stretch, tension)	Tendons
Joint kinesthetic receptors		L: Proprioceptors S: Mechanoreceptors and nociceptors	Joint capsules of synovial joints

and thus are best suited to monitoring vibration (an "on/off" pressure stimulus). They are the largest corpuscular receptors. Some are over 3 mm long and half as wide and are visible to the naked eye as white, egg-shaped bodies. In section, a Pacinian corpuscle resembles a cut onion. Its single dendrite is surrounded by a capsule containing up to 60 layers of collagen fibers and flattened supporting cells.

Ruffini endings, which lie in the dermis, subcutaneous tissue, and joint capsules, contain a spray of receptor endings enclosed by a flattened capsule. They bear a striking resemblance to Golgi tendon organs (which monitor tendon stretch) and probably play a similar role in other dense connective tissues where they respond to deep and *continuous* pressure.

Muscle spindles are fusiform (spindle-shaped) proprioceptors found throughout the perimysium of a skeletal muscle. Each muscle spindle consists of a bundle of modified skeletal muscle fibers, called *intrafusal fibers* (in"trah-fu'zal), enclosed in a connective tissue capsule (Table 13.1). They detect muscle stretch and initiate a reflex that resists the stretch. Details of muscle spindle innervation are considered later when the stretch reflex is described (see pp. 523–525).

Golgi tendon organs are proprioceptors located in tendons, close to the skeletal muscle insertion. They consist of small bundles of tendon (collagen) fibers enclosed in a layered capsule, with sensory terminals coiling between and around the fibers. When the tendon fibers are stretched by muscle contraction, the nerve endings are activated by compression. When Golgi tendon organs are activated, the contracting muscle is inhibited, which causes it to relax.

Joint kinesthetic receptors (kin"es-thet'ik) are proprioceptors that monitor stretch in the articular capsules that enclose synovial joints. At least four receptor types (Pacinian corpuscles, Ruffini endings, free nerve endings, and receptors resembling Golgi tendon organs) contribute to this receptor category. Together these receptors provide information on joint position and motion (*kines* = movement), a sensation of which we are highly conscious.

- Close your eyes and flex and extend your fingers—you can *feel* exactly which joints are moving.

Overview: From Sensation to Perception

Our survival depends not only on **sensation** (awareness of changes in the internal and external environments) but also on **perception** (conscious interpretation of those stimuli). For example, a pebble kicked up into my shoe causes the *sensation* of localized deep pressure, but my *perception* of it is an awareness of discomfort. Perception in turn determines how we will respond to stimuli. In the case of the pebble-in-my-shoe example, I'm taking off my shoe to get rid of the pesky pebble in a hurry.

General Organization of the Somatosensory System

The **somatosensory system,** or that part of the sensory system serving the body wall and limbs, receives inputs from exteroceptors, proprioceptors, and interoceptors; consequently, it transmits information about several different sensory modalities.

There are three main levels of neural integration in the somatosensory (or any sensory) system (Figure 13.2):

① **Receptor level:** sensory receptors

② **Circuit level:** ascending pathways

③ **Perceptual level:** neuronal circuits in the cerebral cortex

Although sensory input is generally relayed toward the head, it is also processed along the way.

Let's examine the events that must occur at each level along the pathway.

Processing at the Receptor Level

For sensation to occur, a stimulus must excite a receptor. For this to happen:

- The stimulus energy must match the *specificity* of the receptor. For example, a given touch receptor may be sensitive to mechanical pressure, stretch, and vibration, but not to light energy (which is the province of receptors in the eye). The more complex the sensory receptor, the greater its specificity.
- The stimulus must be applied within a sensory receptor's *receptive field,* the particular area monitored by the receptor. Typically, the smaller the receptive field, the greater the ability of the brain to accurately localize the stimulus site.
- The stimulus energy must be converted into the energy of a *graded potential* called a **receptor potential,** a process called **transduction.** This may be a depolarizing or hyperpolarizing graded potential similar to the EPSPs or IPSPs generated at postsynaptic membranes in response to neurotransmitter binding. Membrane depolarizations that summate and directly lead to generation of action potentials in an afferent fiber are called **generator potentials.** When the receptor region is part of a sensory neuron (as with free dendrites or the encapsulated receptors of most general sense receptors), the terms receptor potential and generator potential are synonymous. When the receptor is a separate (nonneuron) cell, the receptor and generator potentials are completely separate events. Upon stimulation, such a depolarizing receptor cell produces a receptor potential, which (if strong

enough) causes it to release a neurotransmitter that in turn excites the associated afferent neuron.

- A generator potential in the associated sensory neuron (a first-order neuron) must reach threshold so that voltage-gated sodium channels on the axon (these are usually just proximal to the receptor membrane, often at the first node of Ranvier) are opened and nerve impulses are generated and propagated to the CNS.

Information about the stimulus—its strength, duration, and pattern—is encoded in the frequency of nerve impulses (the greater the frequency, the stronger the stimulus). Many but not all sensory receptors exhibit **adaptation,** a change in sensitivity (and nerve impulse generation) in the presence of a constant stimulus. For example, when you step into bright sunlight from a darkened room, your eyes are initially dazzled, but your photoreceptors rapidly adapt, allowing you to see both bright areas and dark areas in the scene. **Phasic receptors** are *fast adapting* often giving bursts of impulses at the beginning and at the end of the stimulus. These act mainly to report changes in the internal or external environment. Examples of phasic receptors are Pacinian and Meissner's corpuscles. **Tonic receptors** provide a sustained response with little or no adaptation. Nociceptors and most proprioceptors are tonic receptors because of the protective importance of their information. Pain and its modulation are discussed in more detail in *A Closer Look* (pp. 496–497).

Processing at the Circuit Level

The task at the circuit level is to deliver impulses to the appropriate region of the cerebral cortex for stimulus localization and perception. Recall from Chapter 12 (p. 475) that ascending sensory pathways typically consist of a chain of three neurons called first-, second-, and third-order sensory neurons. The axons of first-order sensory neurons, whose cell bodies are in the dorsal root or cranial ganglia, link the receptor and circuit levels of processing. Central processes of first-order neurons branch diffusely when they enter the spinal cord. Some branches take part in local spinal cord reflexes; others synapse with second-order sensory neurons, which then synapse with the third-order sensory neurons that take the message to the cortex of the cerebrum.

Impulses ascending in the specific and nonspecific ascending pathways (see p. 476) reach conscious awareness in the sensory cortex. In general, fibers in the nonspecific ascending pathways transmit pain, temperature, and coarse touch impulses. They give off numerous branches to the reticular formation and thalamus on the way up; and information sent to "headquarters" is fairly general, nondiscriminatory, and heavily involved in emotional aspects of perception (pleasure, pain, etc.).

Q *Identify the neurons in this figure as first-, second-, and third-order sensory neurons.*

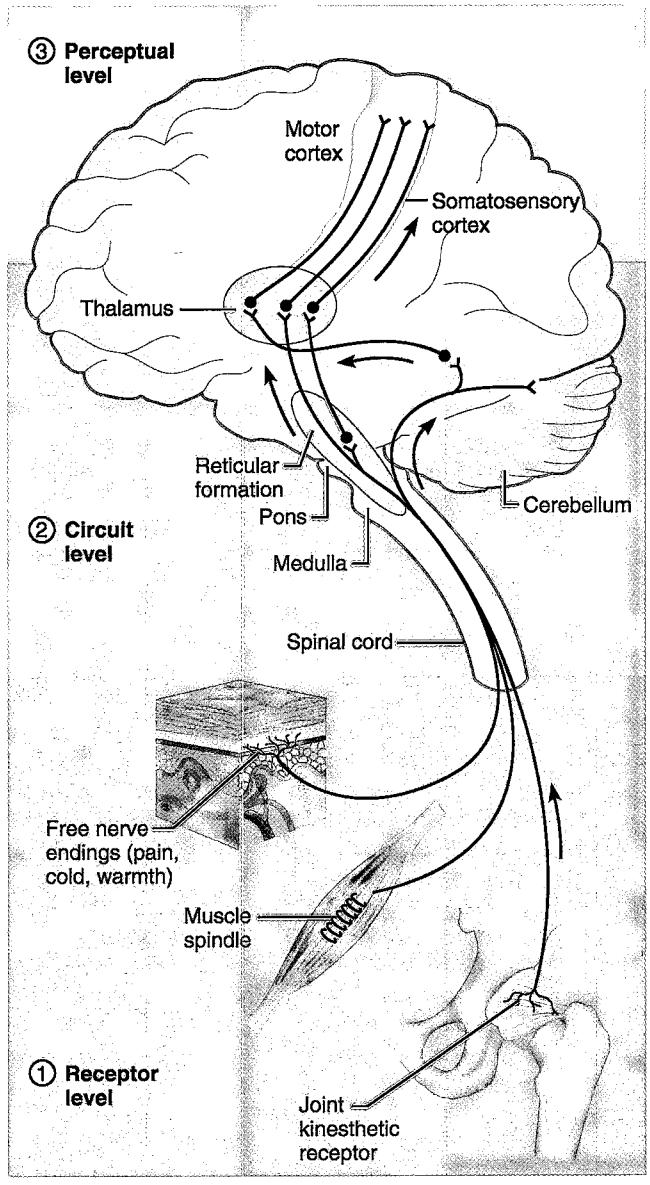

FIGURE 13.2 **General organization of the somatosensory system.** The three basic levels of neural integration are ① the receptor level, ② the circuit level, and ③ the perceptual level. The circuit level involves noncortical CNS centers, while the perceptual level involves cortical sensory centers.

The specific ascending pathways are more involved in the discriminative aspects of touch (tactile discrimination), vibration, pressure, and conscious proprioception (limb and joint position).

A *The first-order neurons are at the bottom of the figure and include the sensory receptors. The third-order neurons are the uppermost neurons in the figure, with cell bodies in the thalamus and terminals in the somatosensory cortex. Second-order neurons connect the first- and third-order neurons.*

A CLOSER LOOK

Pain: Sound the Alarm, But Pain Me Not!

Pain is a four-letter word that means suffering. It is also a primitive experience that we humans share with nearly all animals. Almost everyone has suffered the smart of a bee sting and the cruel persistence of a headache. Although pain warns of actual or impending tissue damage, its protective value is difficult to appreciate when we are its victims.

Clinically, pain is measured by roundabout techniques, such as tapping the painful spot and observing the patient's degree of wincing. This seems a bit strange, given that the other most common sign of disease or injury—fever—is readily measured with a thermometer.

Pain Reception

The principal pain receptors are the several million bare sensory nerve endings that weave through all the tissues and organs of the body (except the brain) and respond to noxious stimuli—a catchall term for anything damaging to tissues. Wherever body tissue is injured, the damaged cells release an "inflammatory soup" of chemicals including prostaglandins and bradykinins, among the most potent pain-producing chemicals known. This begins an avalanche of inflammatory chemicals, such as histamine, potassium, and ATP, that ubiquitous energy source for all cells. These chemicals activate specific receptors on small-diameter C fibers, thus initiating pain signals.

Pain Transmission and Perception

Clinically, pain is classified as *somatic* or *visceral*. Somatic pain, arising from the skin, muscles, or joints, can be either superficial or deep. Superficial somatic pain is a sharp, pricking pain that often causes us to cry out. Localizable to the skin epidermis or mucosae, it tends to be brief. This type of pain is transmitted along finely myelinated A delta (δ) fibers at the rate of 4–36 m/s (up to 120 ft/s). Deep somatic pain is more likely to burn or ache; it results from stimulation of pain receptors in joints, muscles, or deep skin layers. Deep somatic pain is more diffuse than superficial somatic pain, lasts longer, and *always* indicates tissue destruction. Impulses from the deep pain receptors are transmitted slowly (from 0.4 to more than 1 m/s, or up to 3.5 ft/s) along the small, unmyelinated C fibers.

Visceral pain results from noxious stimulation of receptors in the organs of the thorax and abdominal cavity. Like deep somatic pain, it is usually a sensation of dull aching, gnawing, or vague burning. Important stimuli for visceral pain are extreme stretching of tissue, ischemia, irritating chemicals, and muscle spasms. Because visceral pain inputs follow the same pathways as somatic pain (convergence), projection by the brain may cause visceral pain to be perceived as somatic in origin. Chapter 14 describes this phenomenon of *referred pain*.

Both the superficial somatic pain fibers and deep somatic/visceral pain fibers synapse with interneurons in the dorsal horns of the spinal cord (see the figure). Transmission of pain impulses to the CNS along the sensory neurons causes release of glutamate and *substance P*, the pain neurotransmitter, into the synaptic cleft. Glutamate, of course, depolarizes the postsynaptic neurons, relaying the pain message to the brain. Substance P, on the other hand, acts more diffusely as a neuromodulator to sensitize adjacent neurons.

The axons of most pain-relaying interneurons cross the cord and enter ventrolateral ascending tracts. Some fibers form an "express" pathway (the lateral spinothalamic tract) that ascends directly to the thalamus, which relays to the cortex. This allows the sensory cortex to rapidly analyze exactly what hurts and how much. Other pain messages "take the local," a set of smaller-diameter, slower fibers that make abundant synapses in the brain stem, hypothalamus, and other limbic system structures before reaching the thalamus. This second set of pathways mediates arousal and emotional reactions to pain, and has longer-lasting effects on the CNS.

We all have the same **pain threshold;** that is, we perceive it at the same stimulus intensity. For example, heat is perceived as painful at 44–46°C, the range at which it begins to damage tissue. However, reactions to pain, or pain tolerance, vary widely and are heavily influenced by persistent pain stimuli (they decrease it) as well as cultural and psychological factors. When we say that someone is "sensitive to pain," we are referring to that person's **pain tolerance** rather than pain threshold. Pain tolerance seems to increase with age, and is modified by emotions and mental state. In a disaster, many who feel no pain while struggling to help others may actually be severely injured.

Normally a steady state is maintained that correlates injury and pain. However, long-lasting or very intense pain inputs, such as limb amputation,

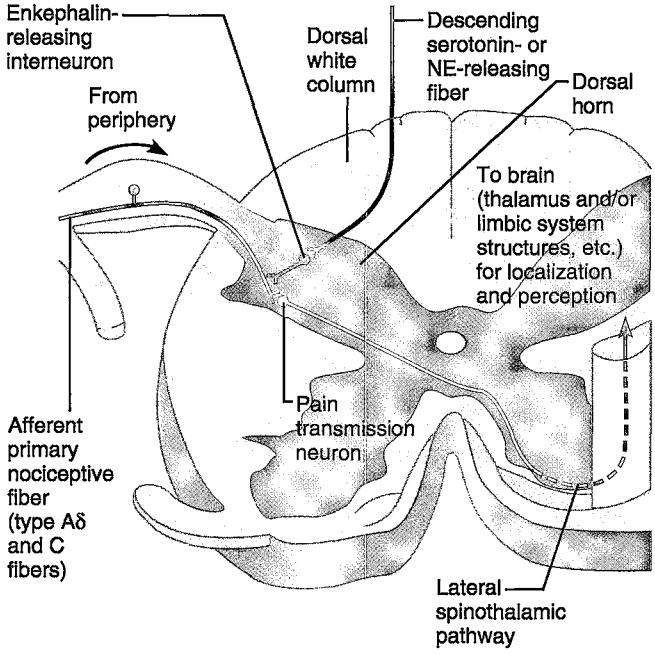
13

Proprioceptive impulses conducted via the *spinocerebellar tracts* end at the cerebellum, which uses this information to coordinate skeletal muscle activity. These tracts do not contribute to conscious sensation.

Processing at the Perceptual Level

Interpretation of sensory input occurs in the cerebral cortex. The ability to identify and appreciate sensations depends on the specific location of the target neurons in the sensory cortex, not on the nature of the message (which is, after all, just an action potential). Each sensory fiber is analogous to a "labeled line" that tells the brain "who" is calling—a taste bud or a pressure receptor—and from "where." The brain always interprets the activity of a specific sensory receptor ("who") as a specific sensation, no matter how it is activated. For example, pressing on your eyeball activates photoreceptors, but what you "see" is light.

can disrupt this system, leading to **hyperalgesia** (pain amplification), chronic pain, and phantom limb pain. Intense or long-duration pain causes activation of **NMDA receptors,** the same receptors that strengthen neural connections during certain kinds of learning. Essentially, the spinal cord *learns* hyperalgesia. In light of this, it is crucial that pain is effectively managed early to prevent the establishment of chronic pain. *Phantom limb pain* (pain perceived in tissue that is no longer present) is a curious example of hyperalgesia. Until recently, surgical limb amputations were conducted under general anesthesia only and the spinal cord still experienced the pain of amputation. Blocking neurotransmission in the spinal cord by additionally using epidural anesthetics greatly reduces the incidence of phantom limb pain.



Pain signals and analgesia. *When group A delta and group C pain fibers transmit via interneurons to the spinothalamic pathway, pain impulses travel to the cerebral cortex. Descending control of pain transmission (analgesia) is mediated by descending CNS fibers which synapse with small enkephalin-releasing interneurons in the dorsal horn that make inhibitory synapses with the afferent pain fibers, preventing their release of substance P.*

Pain Modulation and Analgesia

As everyone knows, rubbing that aching knee somehow makes it feel better. The body has its own mechanisms for modulating the intensity of pain. Massage, acupuncture, and transcutaneous electrical nerve stimulation (TENS) activate larger-diameter touch fibers that interfere with pain transmission in the spinal cord. These phenomena underlie the *gate control theory of pain* developed by Melzack and Wall in 1965. Threshold stimulation of the large touch fibers (as in massaging your knee) causes a burst of firing in certain dorsal horn cells, followed by a brief period of inhibited pain transmission, essentially closing the "gate" on pain.

Descending projections from the brain also modulate pain. When we're in pain, the brain activates these pathways to dull our pain perception. The periaqueductal gray matter, a crucial way station in this descending control of pain, contains many receptors for the body's own opiates called *endorphins* and *enkephalins*. Together with the periventricular nucleus of the hypothalamus, it oversees descending pain suppressor fibers that synapse in the dorsal horns. Hypnosis, natural childbirth techniques, morphine, and electrical stimulation of the periaqueductal gray matter all tap into these natural opiate pathways.

Descending pain suppressor fibers don't release opiates. Instead, they release either norepinephrine or serotonin onto dorsal horn neurons, either inhibiting pain transmission directly or activating enkephalin-releasing interneurons (see the diagram). This released enkephalin acts both presynaptically on synaptic terminals of nociceptor fibers to decrease their release of substance P (a pain neurotransmitter), and postsynaptically to inhibit action potential generation. For centuries physicians have made use of the juice of the opium poppy to relieve pain. Now we know that opiates such as morphine work because of their ability to mimic the actions of our own endorphins and enkephalins. You could say that such pain-reducing techniques—drugs, electrical stimulation, and massage—work because the body allows it! ▩

The exact point in the cortex that is activated always refers to the same "where," regardless of how it is activated, a phenomenon called **projection.** Electrically stimulating a particular spot in the visual cortex causes you to "see" light in a particular place.

The main aspects of sensory perception include the following:

- **Perceptual detection** is the ability to detect that a stimulus has occurred; this is the simplest level of perception. As a general rule, several receptor impulses must be summed for perceptual detection to occur.
- **Magnitude estimation** is the ability to detect how *intense* the stimulus is. Because of frequency coding, perception increases as stimulus intensity increases (see Figure 11.14).
- **Spatial discrimination** allows us to identify the site or pattern of stimulation. A common tool for studying this quality in the laboratory is the

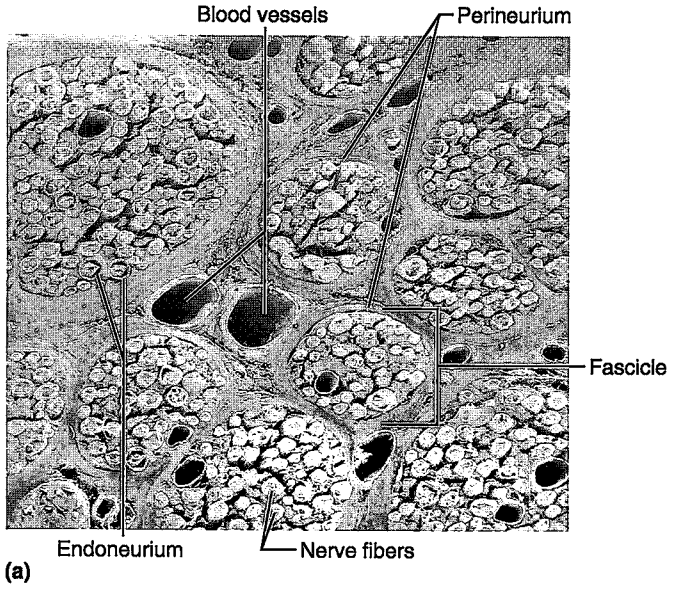


FIGURE 13.3 **Structure of a nerve. (a)** Scanning electron micrograph of a cross section of a portion of a nerve (500×). (© R. G. Kessel and R. H. Kardon, *Tissues and Organs: A Text-Atlas of Scanning Electron Microscopy*, W. H. Freeman and Company, 1979, all rights reserved.) (See *A Brief Atlas of the Human Body*, Plate 34.) **(b)** Three-dimensional view of a portion of a nerve, showing connective tissue wrappings.

two-point discrimination test. The test determines how close together two points on the skin can be and still be perceived as two points rather than as one. This test provides a crude map of the density of tactile receptors in the various regions of the skin. The distance between perceived points varies from less than 5 mm on highly sensitive body areas (tip of the tongue) to more than 50 mm on less sensitive areas (back).

- **Feature abstraction** is the mechanism by which a neuron or circuit is tuned to one feature in preference to others. Sensation usually involves an interplay of several stimulus properties or features. For example, one touch tells us that velvet is warm, compressible, and smooth but not completely continuous, each a feature that contributes to our perception of "velvet." Feature abstraction enables us to identify more complex aspects of a sensation.
- **Quality discrimination** is the ability to differentiate the submodalities of a particular sensation. Each sensory modality has several **qualities,** or submodalities. For example, the submodalities of taste include sweet and bitter.
- **Pattern recognition** is the ability to take in the scene around us and recognize a familiar pattern, an unfamiliar one, or one that has special significance for us. For example, a figure made of dots may be recognized as a familiar face, and when we listen to music, we hear the melody, not just a string of notes.

PART 2: TRANSMISSION LINES: NERVES AND THEIR STRUCTURE AND REPAIR

Nerves and Associated Ganglia

Structure and Classification

A **nerve** is a cordlike organ that is part of the peripheral nervous system. Nerves vary in size, but every nerve consists of parallel bundles of peripheral axons (some myelinated and some not) enclosed by successive wrappings of connective tissue (Figure 13.3).

Within a nerve, each axon is surrounded by **endoneurium** (en"do-nu're-um), a delicate layer of loose connective tissue that also encloses the fiber's associated myelin sheath or neurilemma. Groups of fibers are bound into bundles or **fascicles** by a coarser connective tissue wrapping, the **perineurium.** Finally, all the fascicles are enclosed by a tough fibrous sheath, the **epineurium,** to form the nerve. Axons constitute only a small fraction of a nerve's bulk. The balance consists chiefly of myelin, the protective connective tissue wrappings, blood vessels, and lymphatic vessels.

Recall that the PNS is divided into *sensory* (afferent) and *motor* (efferent) divisions. Hence, nerves are classified according to the direction in which they transmit impulses. Nerves containing both sensory and motor fibers and transmitting impulses both to and from the central nervous system are called **mixed nerves.** Those that carry impulses only toward the CNS are **sensory (afferent) nerves;** and those carrying impulses only away from the CNS are **motor (efferent) nerves.** Most nerves are mixed. Pure sensory or motor nerves are rare.

Because mixed nerves often carry both somatic and autonomic (visceral) nervous system fibers, the fibers in them may be classified according to the region they innervate as *somatic afferent, somatic efferent, visceral afferent,* and *visceral efferent.*

For convenience, the peripheral nerves are classified as *cranial* or *spinal* depending on whether they arise from the brain or the spinal cord. Although autonomic efferents of cranial nerves are mentioned, this chapter focuses on somatic functions. The discussion of the autonomic nervous system and the visceral functions it serves is deferred to Chapter 14.

Ganglia are collections of neuron cell bodies associated with nerves in the PNS. Ganglia associated with *afferent* nerve fibers contain cell bodies of sensory neurons. (These are the *dorsal root ganglia* studied in Chapter 12.) Ganglia associated with *efferent* nerve fibers mostly contain cell bodies of autonomic motor neurons. These more complicated ganglia are described in Chapter 14.

Regeneration of Nerve Fibers

Damage to nervous tissue is serious because, as a rule, mature neurons do not divide. If the damage is severe or close to the cell body, the entire neuron may die, and other neurons that are normally stimulated by its axon may die as well. However, if the cell body remains intact, cut or compressed axons of peripheral nerves can regenerate successfully.

Almost immediately after a peripheral axon has been severed or crushed, the separated ends seal themselves off and then swell as substances being transported along the axon begin to accumulate in the sealed ends (Figure 13.4a). Within a few hours, the axon and its myelin sheath distal to the injury site begin to disintegrate because they cannot receive nutrients from the cell body. This process, **Wallerian degeneration,** spreads distally from the injury site, completely fragmenting the axon (Figure 13.4b). Generally, the entire axon distal to the injury is degraded by phagocytes within a week, but the neurilemma remains intact within the endoneurium. After the debris has been disposed of, surviving Schwann cells proliferate in response to mitosis-stimulating chemicals released by the macrophages, and migrate into the injury site. Once

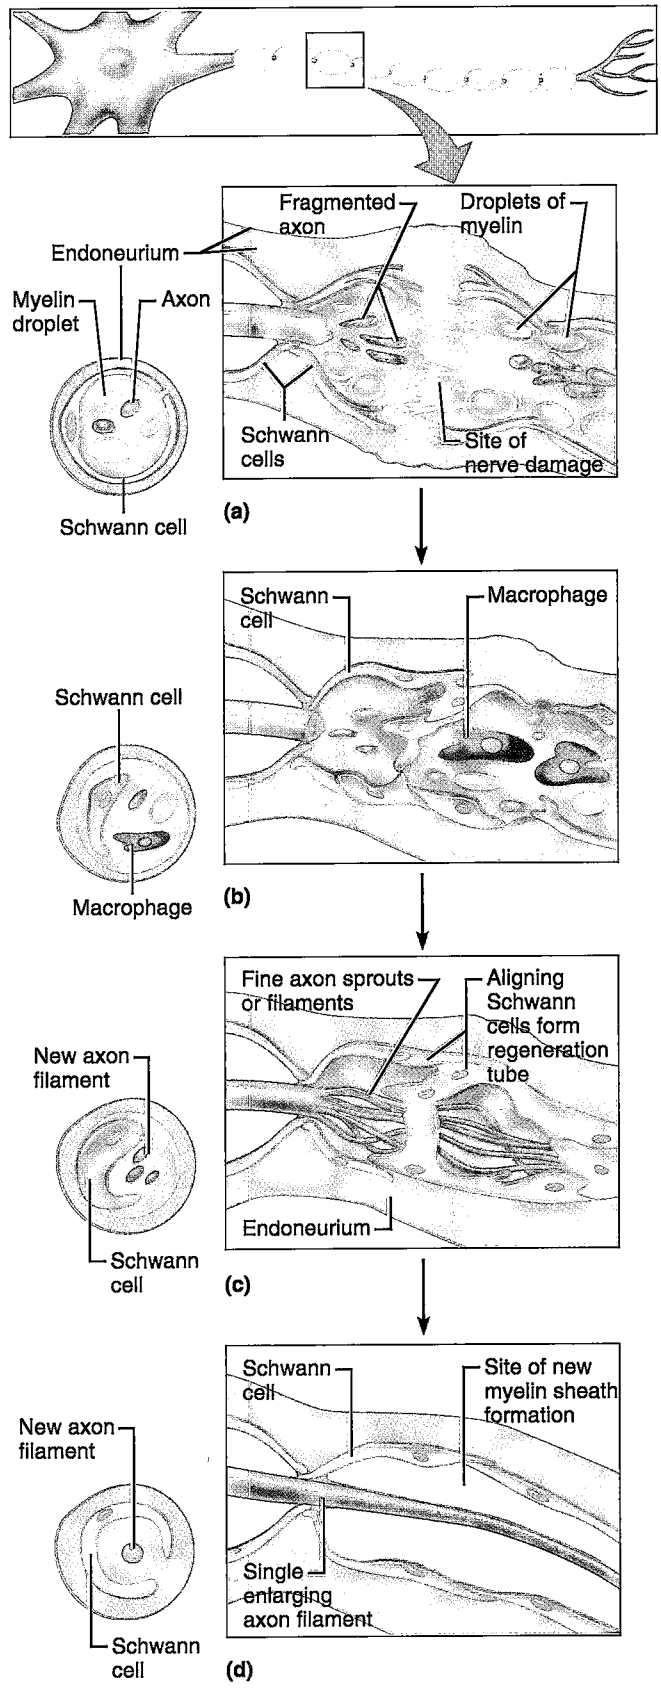

FIGURE 13.4 **Regeneration of a nerve fiber in a peripheral nerve. (a)** Fragmentation of the axon at the injury site. **(b)** Macrophages destroy the axon distal to the injury. **(c)** Axon filaments grow within a regeneration tube formed by Schwann cells. **(d)** Regenerated axon and the formation of a new myelin sheath.

there, they release growth factors and begin to express cell adhesion molecules (CAMs) that encourage axonal growth. Additionally, they form a *regeneration tube,* a system of cellular cords that guide the regenerating axon "sprouts" across the gap and to their original contacts (Figure 13.4c and d). The same Schwann cells protect, support, and remyelinate the regenerating axons.

Changes also occur in the neuronal cell body after axonal destruction. Within two days, its chromatophilic substance breaks apart, and then the cell body swells as protein synthesis revs up to support regeneration of its axon.

Axons regenerate at the approximate rate of 1.5 mm a day. The greater the distance between the severed endings, the less the chance of recovery because adjacent tissues block growth by protruding into the gaps, and axonal sprouts fail to find the regeneration tube. Neurosurgeons align cut nerve endings surgically to enhance the chance of successful regeneration, and scaffolding devices have been successful in guiding axon growth. Whatever the measures taken, post-trauma axon regrowth never exactly matches what existed before the injury, and much of the recovery protocol involves retraining the nervous system to respond appropriately so that stimulus and response are coordinated.

Unlike peripheral nerve fibers, most CNS fibers never regenerate. Consequently, damage to the brain or spinal cord has been viewed as irreversible. This difference in regenerative capacity seems to have less to do with the neurons themselves than with the "company they keep"—their supporting cells. After CNS injury, "cleanup" is much slower. Moreover, the oligodendrocytes surrounding the injured fibers fail to guide fiber regrowth. Indeed, the oligodendrocytes are studded with growth-inhibiting proteins (Nogo and others) that act on neuronal receptors, causing growth cone collapse and repulsion. Experiments neutralizing the myelin-bound growth inhibitors with antibodies or blocking their receptors have resulted in useful fiber regeneration.

Cranial Nerves

Twelve pairs of **cranial nerves** are associated with the brain (Figure 13.5). The first two pairs attach to the forebrain; the rest originate from the brain stem. Other than the vagus nerves, which extend into the abdomen, cranial nerves serve only head and neck structures.

In most cases, the names of the cranial nerves reveal either the structures they serve or their functions. The nerves are also numbered (using Roman numerals) from the most rostral to the most caudal. A mini-introduction to the cranial nerves follows.

I. Olfactory. These are the tiny sensory nerves (filaments) of smell, which run from the nasal mucosa to synapse with the olfactory bulbs. Note that the olfactory bulbs and tracts, shown in Figure 13.5a, are brain structures and not part of cranial nerve I. (See Table 13.2 art for the olfactory nerve filaments.)

II. Optic. Because this sensory nerve of vision develops as an outgrowth of the brain, it is really a brain tract.

III. Oculomotor. This nerve has a name meaning "eye mover" because it supplies four of the six extrinsic muscles that move the eyeball in the orbit.

IV. Trochlear. This nerve's name means "pulley" and it innervates an extrinsic eye muscle that loops through a pulley-shaped ligament in the orbit.

V. Trigeminal. Three *(tri)* branches spring from this, the largest of the cranial nerves. It supplies sensory fibers to the face and motor fibers to the chewing muscles.

VI. Abducens. This nerve controls the extrinsic eye muscle that *abducts* the eyeball (turns it laterally).

VII. Facial. A large nerve that innervates muscles of *facial* expression (among other things).

VIII. Vestibulocochlear. This sensory nerve for hearing and balance was formerly called the *auditory nerve.*

IX. Glossopharyngeal. Its name, meaning "tongue and pharynx," reveals the structures it helps to innervate.

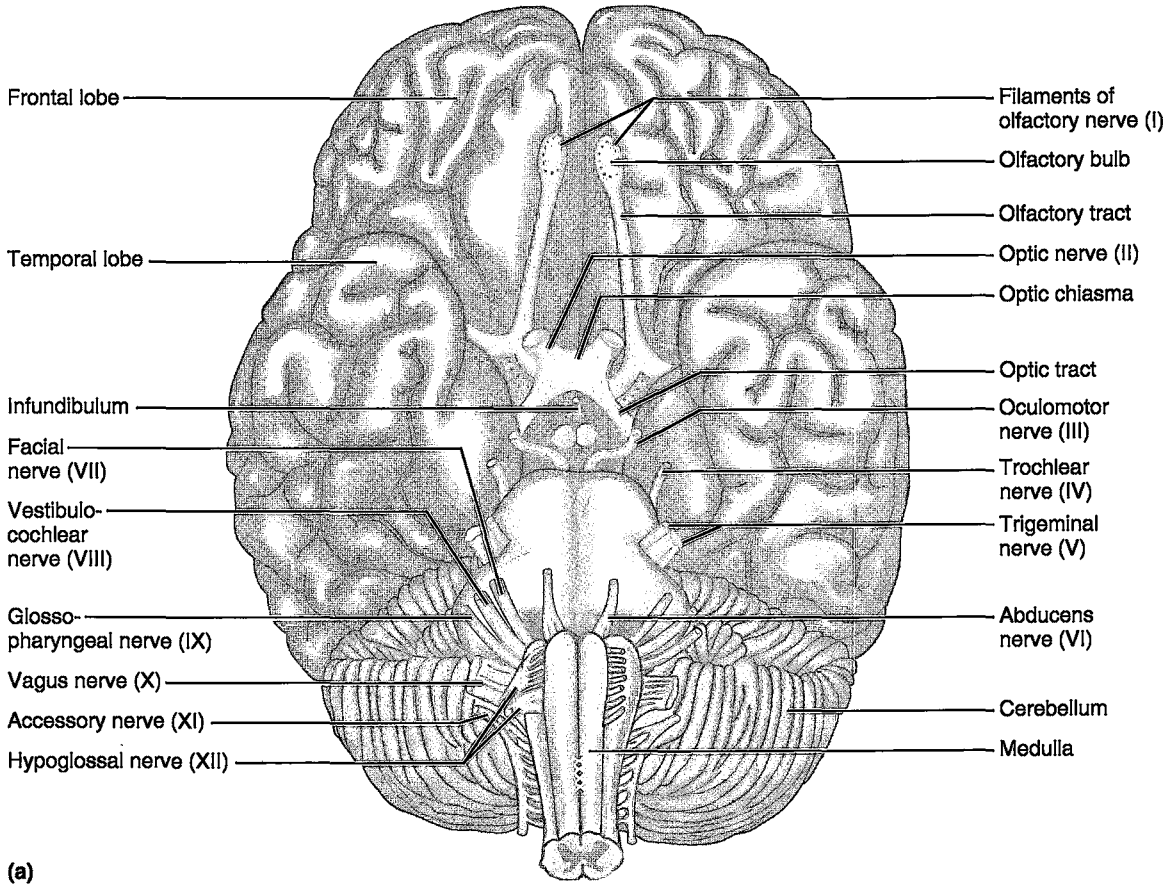
X. Vagus. This nerve's name means "wanderer" or "vagabond," and it is the only cranial nerve to extend beyond the head and neck to the thorax and abdomen.

XI. Accessory. Considered an *accessory* part of the vagus nerve, this nerve was formerly called the *spinal accessory nerve.*

XII. Hypoglossal. This nerve runs inferior to the tongue and innervates some tongue-moving muscles, as reflected by its name meaning "under the tongue."

You might make up your own saying to remember the first letters of the cranial nerves in order, or use the following memory jog sent to me by a student: "**O**n **o**ccasion, **o**ur **t**rusty **t**ruck **a**cts **f**unny—very **g**ood **v**ehicle **a**nyhow."

In the last chapter, we described how spinal nerves are formed by the fusion of ventral (motor) and dorsal (sensory) roots. Cranial nerves, on the other hand, vary markedly in their composition. Most cranial nerves are mixed nerves as shown in Figure 13.5b. However, two nerve pairs (the olfactory and optic) associated with special sense organs, are



(a)

Cranial nerves I – VI	Sensory function	Motor function	PS* fibers
I Olfactory	Yes (smell)	No	No
II Optic	Yes (vision)	No	No
III Oculomotor	No	Yes	Yes
IV Trochlear	No	Yes	No
V Trigeminal	Yes (general sensation)	Yes	No
VI Abducens	No	Yes	No

Cranial nerves VII – XII	Sensory function	Motor function	PS* fibers
VII Facial	Yes (taste)	Yes	Yes
VIII Vestibulocochlear	Yes (hearing and balance)	Some	No
IX Glossopharyngeal	Yes (taste)	Yes	Yes
X Vagus	Yes (taste)	Yes	Yes
XI Accessory	No	Yes	No
XII Hypoglossal	No	Yes	No

(b) *PS = parasympathetic

FIGURE 13.5 **Location and function of cranial nerves. (a)** Ventral view of the human brain, showing the cranial nerves. **(b)** Summary of cranial nerves by function. Two cranial nerves (I and II) have sensory function only, no motor function. Four nerves (III, VII, IX, and X) carry parasympathetic fibers that serve visceral muscles and glands. All cranial nerves that innervate muscles also carry afferent fibers from proprioceptors in the muscles served; only sensory functions other than proprioception are indicated.

generally considered purely sensory. The cell bodies of the sensory neurons of the olfactory and optic nerves are located *within* their respective special sense organs. In other cases of sensory neurons contributing to cranial nerves (V, VII, IX, and X) the cell bodies are located in **cranial sensory ganglia** just outside the brain. Some cranial nerves have a single sensory ganglion, others have several, and still others have none.

Several of the mixed cranial nerves contain both somatic and autonomic motor fibers and hence serve both skeletal muscles and visceral organs. Except for some autonomic motor neurons located in ganglia, the cell bodies of motor neurons contributing to the cranial nerves are located in the ventral gray matter regions (nuclei) of the brain stem.

Having read this overview, you are now ready to tackle Table 13.2, which provides a more detailed

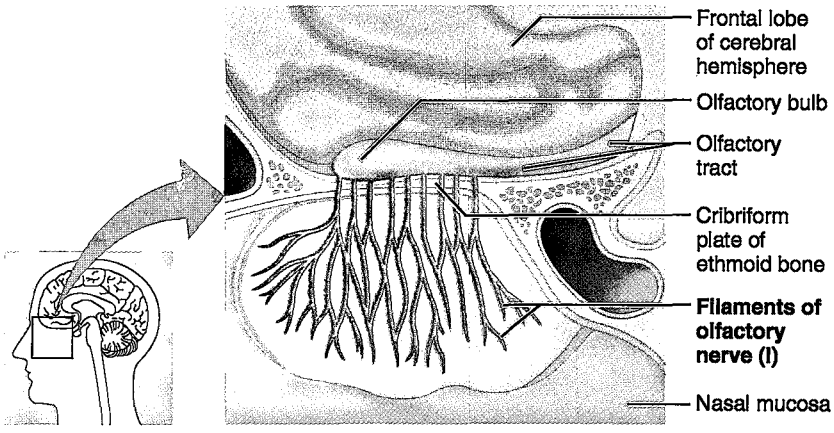
(Text continues on p. 508.)

TABLE 13.2 Cranial Nerves

I THE OLFACTORY NERVES (ol-fak'to-re)

Origin and course: Olfactory nerve fibers arise from olfactory receptor cells located in olfactory epithelium of nasal cavity and pass through cribriform plate of ethmoid bone to synapse in olfactory bulb. Fibers of olfactory bulb neurons extend posteriorly as olfactory tract, which runs beneath frontal lobe to enter cerebral hemispheres and terminates in primary olfactory cortex. See also Figure 15.21.
Function: Purely sensory; carry afferent impulses for sense of smell
Clinical testing: Person is asked to sniff aromatic substances, such as oil of cloves and vanilla, and to identify each.

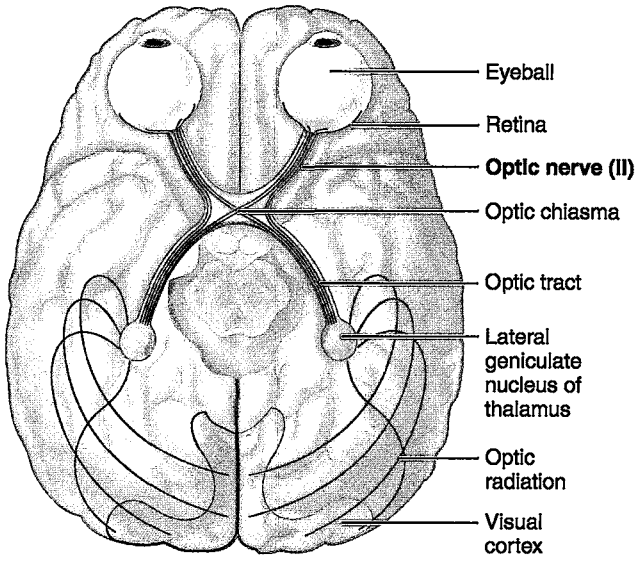
Homeostatic imbalance: Fracture of ethmoid bone or lesions of olfactory fibers may result in partial or total loss of smell, a condition known as *anosmia* (an-oz'me-ah). ●



II THE OPTIC NERVES

Origin and course: Fibers arise from retina of eye to form optic nerve, which passes through optic canal of orbit. The optic nerves converge to form the optic chiasma (ki-az'mah) where fibers partially cross over, continue on as optic tracts, enter thalamus, and synapse there. Thalamic fibers run (as the optic radiation) to occipital (visual) cortex, where visual interpretation occurs. See also Figure 15.19.
Function: Purely sensory; carry afferent impulses for vision
Clinical testing: Vision and visual field are determined with eye chart and by testing the point at which the person first sees an object (finger) moving into the visual field. Fundus of eye viewed with ophthalmoscope to detect papilledema (swelling of optic disc, the site where the optic nerve leaves the eyeball), as well as for routine examination of the optic disc and retinal blood vessels.

Homeostatic imbalance: Damage to optic nerve results in blindness in eye served by nerve; damage to visual pathway beyond the optic chiasma results in partial visual losses; visual defects are called *anopsias* (ah-nop'se-ahz). ●



13

TABLE 13.2 *(continued)*

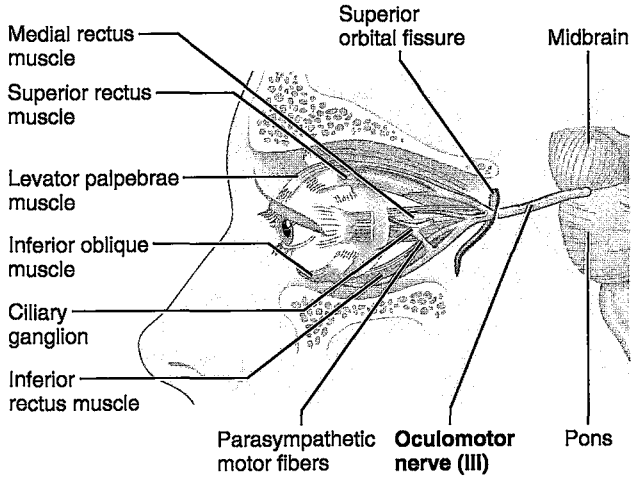
III THE OCULOMOTOR NERVES (ok"u-lo-mo'tor)

Origin and course: Fibers extend from ventral midbrain (near its junction with pons) and pass through bony orbit, via superior orbital fissure, to eye.
Function: Chiefly motor nerves (*oculomotor* = motor to the eye); contain a few proprioceptive afferents; each nerve includes

- Somatic motor fibers to four of the six extrinsic eye muscles (inferior oblique and superior, inferior, and medial rectus muscles) that help direct eyeball, and to levator palpebrae superioris muscle, which raises upper eyelid
- Parasympathetic (autonomic) motor fibers to sphincter pupillae (circular muscles of iris), which cause pupil to constrict, and to ciliary muscle, controlling lens shape for visual focusing; some parasympathetic cell bodies are in the ciliary ganglia
- Sensory (proprioceptor) afferents, which run from same four extrinsic eye muscles to midbrain

Clinical testing: Pupils are examined for size, shape, and equality. Pupillary reflex is tested with penlight (pupils should constrict when illuminated). Convergence for near vision is tested, as is subject's ability to follow objects with the eyes.

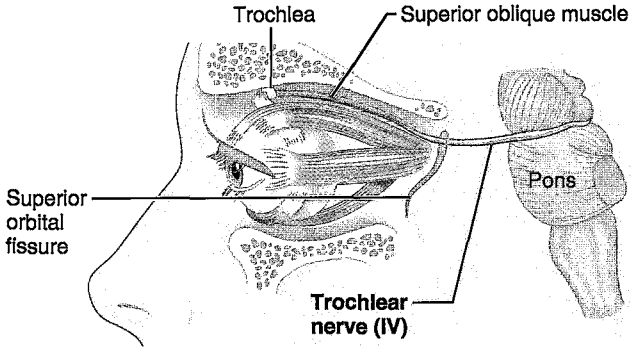
Homeostatic imbalance: In oculomotor nerve paralysis, eye cannot be moved up, down, or inward, and at rest, eye rotates laterally [*external strabismus* (strah-biz'mus)] because the actions of the two extrinsic eye muscles not served by cranial nerve III are unopposed; upper eyelid droops *(ptosis)*, and the person has double vision and trouble focusing on close objects.



IV THE TROCHLEAR NERVES (trok'le-ar)

Origin and course: Fibers emerge from dorsal midbrain and course ventrally around midbrain to enter orbit through superior orbital fissure along with oculomotor nerves.
Function: Primarily motor nerves; supply somatic motor fibers to (and carry proprioceptor fibers from) one of the extrinsic eye muscles, the superior oblique muscle
Clinical testing: Tested in common with cranial nerve III.

Homeostatic imbalance: Trauma to, or paralysis of, a trochlear nerve results in double vision and reduced ability to rotate eye inferolaterally.



V THE TRIGEMINAL NERVES

Largest of cranial nerves; fibers extend from pons to face, and form three divisions (*trigemina* = threefold): ophthalmic, maxillary, and mandibular divisions. As major general sensory nerves of face, transmit afferent impulses from touch, temperature, and pain receptors. Cell bodies of sensory neurons of all three divisions are located in large *trigeminal* (also called *semilunar* or *gasserian*) *ganglion.*

The mandibular division also contains motor fibers that innervate chewing muscles.

Dentists desensitize upper and lower jaws by injecting local anesthetic (such as Novocain) into alveolar branches of maxillary and mandibular divisions, respectively; since this blocks pain-transmitting fibers of teeth, the surrounding tissues become numb.

	Ophthalmic division (V_1)	Maxillary division (V_2)	Mandibular division (V_3)
Origin and course	Fibers run from face to pons via superior orbital fissure	Fibers run from face to pons via foramen rotundum	Fibers pass through skull via foramen ovale
Function	Conveys sensory impulses from skin of anterior scalp, upper eyelid, and nose, and from nasal cavity mucosa, cornea, and lacrimal gland	Conveys sensory impulses from nasal cavity mucosa, palate, upper teeth, skin of cheek, upper lip, lower eyelid	Conveys sensory impulses from anterior tongue (except taste buds), lower teeth, skin of chin, temporal region of scalp; supplies motor fibers to, and carries proprioceptor fibers from, muscles of mastication
Clinical testing	Corneal reflex tested: touching cornea with wisp of cotton should elicit blinking	Sensations of pain, touch, and temperature are tested with safety pin and hot and cold objects	Motor branch assessed by asking person to clench his teeth, open mouth against resistance, and move jaw side to side

Homeostatic imbalance: *Tic douloureux* (tik doo"loo-roo'; *tic* = twitch, *douloureux* = painful), or *trigeminal neuralgia* (nu-ral'je-ah), caused by inflammation of trigeminal nerve, is widely considered to produce most excruciating pain known; the stabbing pain lasts for a few seconds to a minute, but it can be relentless, occurring a hundred times a day. Usually provoked by some sensory stimulus, such as brushing teeth or even a passing breeze hitting the face. It seems to be caused by pressure on the trigeminal nerve root. Analgesics and carbamazepine (an anticonvulsant) are only partially effective. In severe cases, nerve is cut proximal to trigeminal ganglion; this relieves the agony, but also results in loss of sensation on that side of face. ●

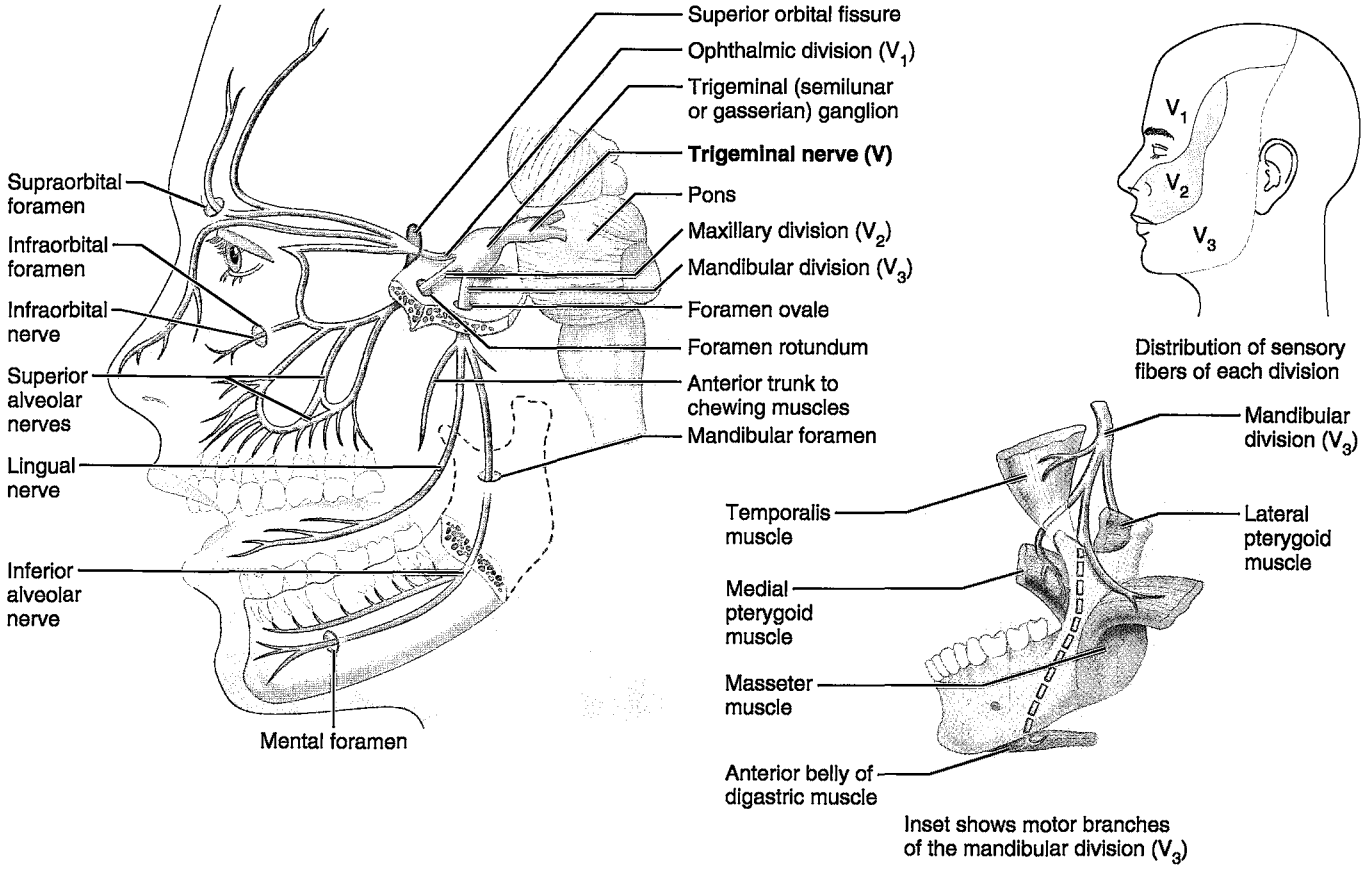


TABLE 13.2 *(continued)*

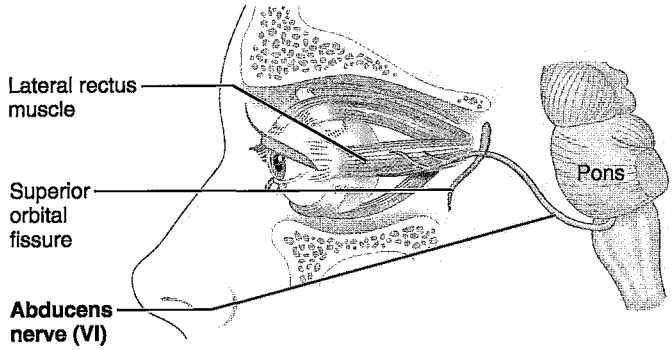
VI THE ABDUCENS NERVES (ab-du'senz)

Origin and course: Fibers leave inferior pons and enter orbit via superior orbital fissure to run to eye.
Function: Primarily motor; supply somatic motor fibers to lateral rectus muscle, an extrinsic muscle of the eye; convey proprioceptor impulses from same muscle to brain.
Clinical testing: Tested in common with cranial nerve III.

Homeostatic imbalance: In abducens nerve paralysis, eye cannot be moved laterally; at rest, affected eyeball rotates medially *(internal strabismus)*.



VII THE FACIAL NERVES

Origin and course: Fibers issue from pons, just lateral to abducens nerves (see Figure 13.5), enter temporal bone via *internal acoustic meatus,* and run within bone (and through inner ear cavity) before emerging through *stylomastoid foramen;* nerve then courses to lateral aspect of face.
Function: Mixed nerves that are the chief motor nerves of face; have five major branches: temporal, zygomatic, buccal, mandibular, and cervical (see **c**)

- Convey motor impulses to skeletal muscles of face (muscles of facial expression), except for chewing muscles served by trigeminal nerves, and transmit proprioceptor impulses from same muscles to pons (see **b**)
- Transmit parasympathetic (autonomic) motor impulses to lacrimal (tear) glands, nasal and palatine glands, and submandibular and sublingual salivary glands. Some of the cell bodies of these parasympathetic motor neurons are in *pterygopalatine* (ter"eh-go-pal'ah-tīn) and *submandibular ganglia* on the trigeminal nerve (see **a**)
- Convey sensory impulses from taste buds of anterior two-thirds of tongue; cell bodies of these sensory neurons are in *geniculate ganglion* (see **a**)

Clinical testing: Anterior two-thirds of tongue is tested for ability to taste sweet (sugar), salty, sour (vinegar), and bitter (quinine) substances. Symmetry of face is checked. Subject is asked to close eyes, smile, whistle, and so on. Tearing is assessed with ammonia fumes.

Homeostatic imbalance: *Bell's palsy,* characterized by paralysis of facial muscles on affected side and partial loss of taste sensation, may develop rapidly (often overnight). Most often caused by herpes simplex I viral infection, which causes swelling and inflammation of facial nerve. Lower eyelid droops, corner of mouth sags (making it difficult to eat or speak normally), tears drip continuously from eye and eye cannot be completely closed (conversely, dry-eye syndrome may occur). Condition may disappear spontaneously without treatment.

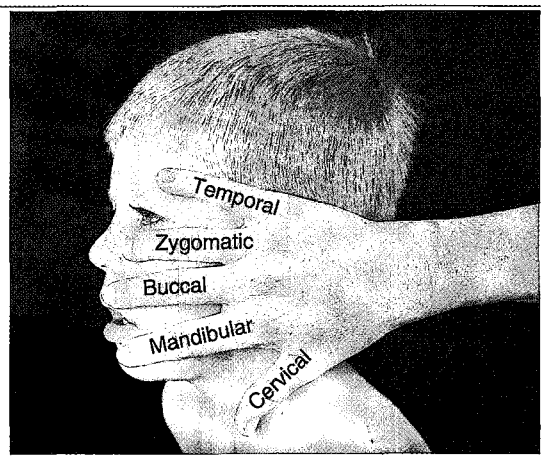
(b) Motor branches to muscles of facial expression and scalp muscles

13

TABLE 13.2 Cranial Nerves *(continued)*

VII THE FACIAL NERVES *(continued)*

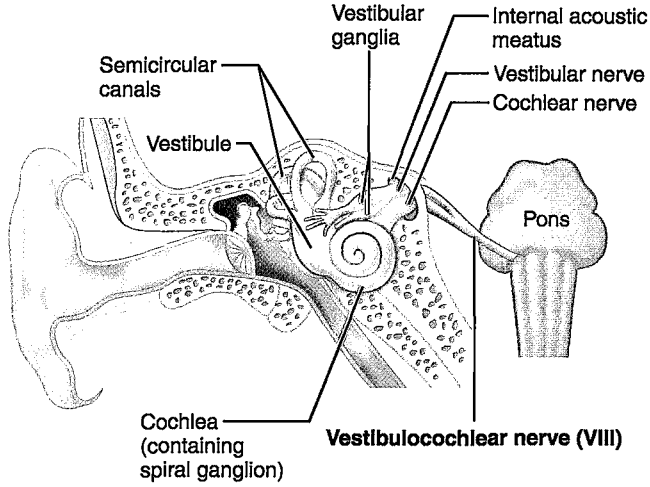


(c) A simple method of remembering the courses of the five major motor nerves of the face

VIII THE VESTIBULOCOCHLEAR NERVES (ves-tib"u-lo-kok'le-ar)

Origin and course: Fibers arise from hearing and equilibrium apparatus located within inner ear of temporal bone and pass through internal acoustic meatus to enter brain stem at pons-medulla border. Afferent fibers from hearing receptor in cochlea form the *cochlear division;* those from equilibrium receptors in semicircular canals and vestibule form the *vestibular division* (vestibular nerve); the two divisions merge to form vestibulocochlear nerve. See also Figure 15.27.
Function: Mostly sensory. Vestibular branch transmits afferent impulses for sense of equilibrium, and sensory nerve cell bodies are located in *vestibular ganglia.* Cochlear branch transmits afferent impulses for sense of hearing, and sensory nerve cell bodies are located in *spiral ganglion* within cochlea. Some motor fibers from the pons innervate the outer hair cells of the cochlea. See also Figure 15.28c
Clinical testing: Hearing is checked by air and bone conduction using tuning fork.

Homeostatic imbalance: Lesions of cochlear nerve or cochlear receptors result in *central* or *nerve deafness,* whereas damage to vestibular division produces dizziness, rapid involuntary eye movements, loss of balance, nausea, and vomiting.



IX THE GLOSSOPHARYNGEAL NERVES (glos"o-fah-rin'je-al)

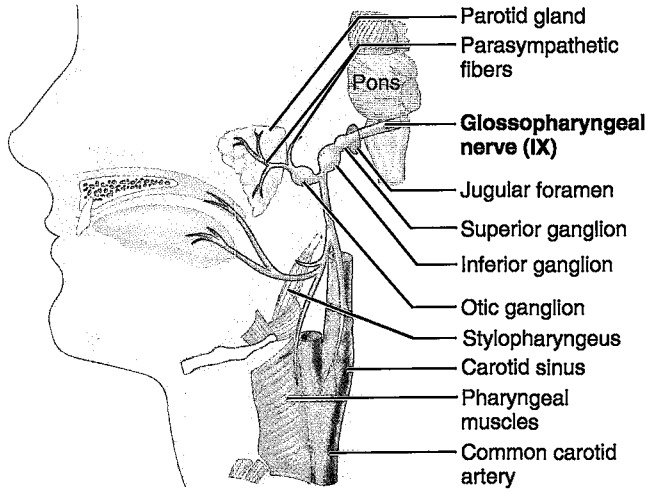
Origin and course: Fibers emerge from medulla and leave skull via *jugular foramen* to run to throat.
Function: Mixed nerves that innervate part of tongue and pharynx. Provide somatic motor fibers to, and carry proprioceptor fibers from, a superior pharyngeal muscle called the *stylopharyngeus,* which elevates the pharynx in swallowing. Provide parasympathetic motor fibers to parotid salivary glands (some of the nerve cell bodies of these parasympathetic motor neurons are located in *otic ganglion*).

TABLE 13.2 *(continued)*

IX THE GLOSSOPHARYNGEAL NERVES *(continued)*

Sensory fibers conduct taste and general sensory (touch, pressure, pain) impulses from pharynx and posterior tongue, from chemoreceptors in the carotid body (which monitor O_2 and CO_2 levels in the blood and help regulate respiratory rate and depth), and from baroreceptors of carotid sinus (which monitor blood pressure). Sensory neuron cell bodies are located in *superior* and *inferior ganglia*.
Clinical testing: Position of the uvula is checked. Gag and swallowing reflexes are checked. Subject is asked to speak and cough. Posterior third of tongue may be tested for taste.

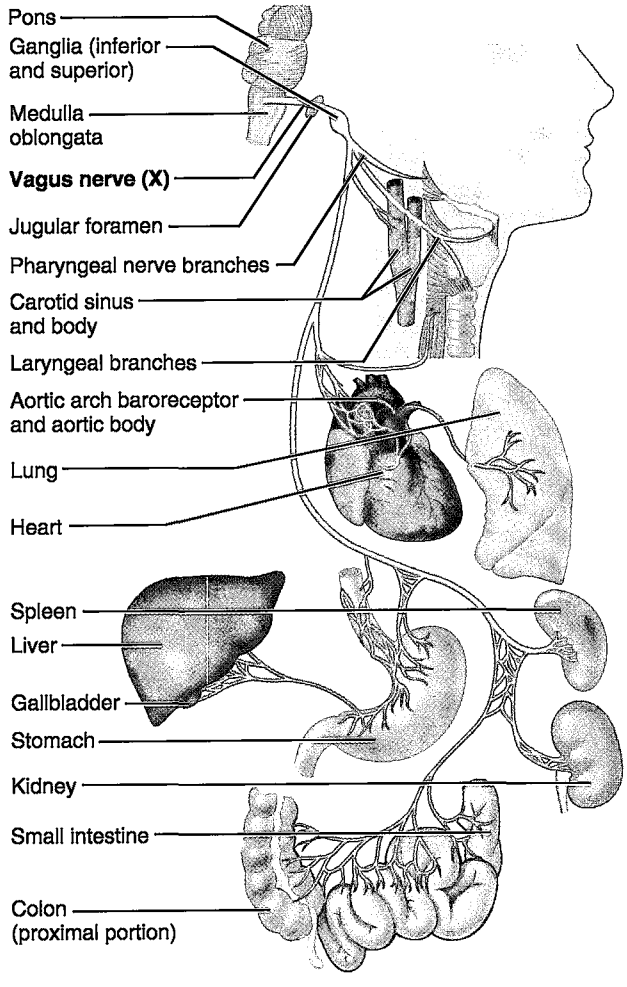
Homeostatic imbalance: Injury or inflammation of glossopharyngeal nerves impairs swallowing and taste.



X THE VAGUS NERVES (va'gus)

Origin and course: The only cranial nerves to extend beyond head and neck region. Fibers emerge from medulla, pass through skull via jugular foramen, and descend through neck region into thorax and abdomen. See also Figure 14.4.
Function: Mixed nerves; nearly all motor fibers are parasympathetic efferents, except those serving skeletal muscles of pharynx and larynx (involved in swallowing). Parasympathetic motor fibers supply heart, lungs, and abdominal viscera and are involved in regulation of heart rate, breathing, and digestive system activity. Transmit sensory impulses from thoracic and abdominal viscera, from the aortic arch baroreceptors (for blood pressure) and the carotid and aortic bodies (chemoreceptors for respiration), and taste buds of posterior tongue and pharynx. Carry proprioceptor fibers from muscles of larynx and pharynx.
Clinical testing: As for cranial nerve IX (IX and X are tested in common, since they both innervate muscles of throat and mouth).

Homeostatic imbalance: Since nearly all muscles of the larynx ("voice box") are innervated by laryngeal branches of the vagus, vagal nerve paralysis can lead to hoarseness or loss of voice; other symptoms are difficulty swallowing and impaired digestive system motility. Total destruction of both vagus nerves is incompatible with life, because these parasympathetic nerves are crucial in maintaining normal state of visceral organ activity; without their influence, the activity of the sympathetic nerves, which mobilize and accelerate vital body processes (and shut down digestion), would be unopposed.



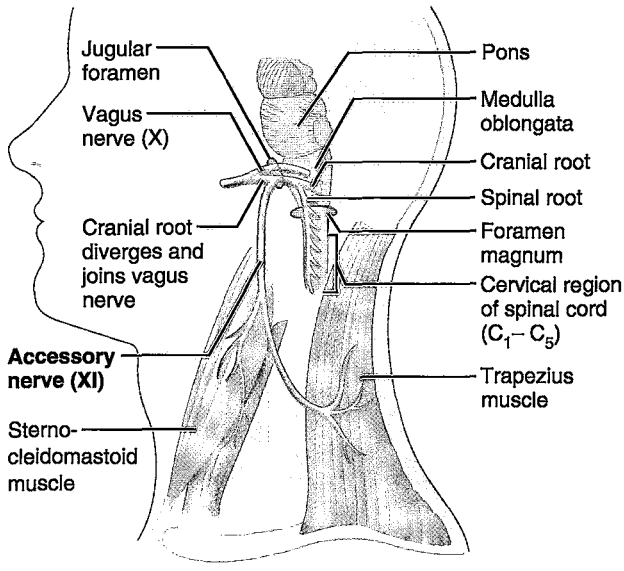
13

TABLE 13.2 **Cranial Nerves** *(continued)*

XI THE ACCESSORY NERVES

Origin and course: Unique in that they are formed by union of a *cranial root* and a *spinal root.* Cranial root emerges from lateral aspect of medulla of brain stem; spinal root arises from superior region (C_1–C_5) of spinal cord. Spinal portion passes upward along spinal cord, enters skull via foramen magnum, and temporarily joins cranial root; the resulting accessory nerve exits from skull through *jugular foramen.* Cranial and spinal fibers then diverge; cranial root fibers join vagus nerve, and spinal root runs to the largest neck muscles.
Function: Mixed nerves, but primarily motor in function. Cranial division joins with fibers of vagus nerve (X) to supply motor fibers to larynx, pharynx, and soft palate. Spinal root supplies motor fibers to trapezius and sternocleidomastoid muscles, which together move head and neck, and conveys proprioceptor impulses from same muscles.
Clinical testing: Sternocleidomastoid and trapezius muscles are checked for strength by asking person to rotate head and shrug shoulders against resistance.

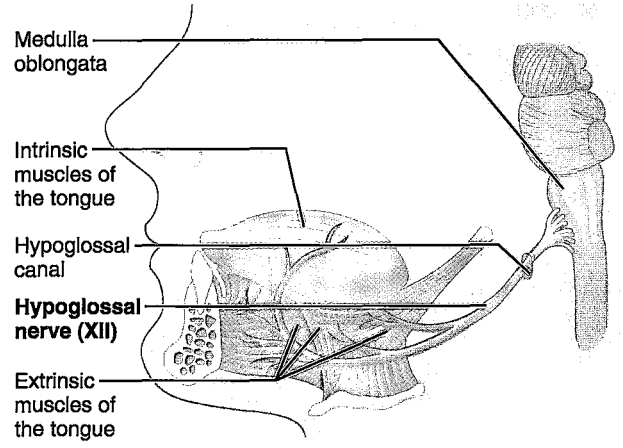
Homeostatic imbalance: Injury to the spinal root of one accessory nerve causes head to turn toward injury side as result of sternocleidomastoid muscle paralysis; shrugging of that shoulder (role of trapezius muscle) becomes difficult.



XII THE HYPOGLOSSAL NERVES (hi"po-glos'al)

Origin and course: As their name implies (*hypo* = beneath; *glossal* = tongue), hypoglossal nerves mainly serve the tongue. Fibers arise by a series of roots from medulla and exit from skull via *hypoglossal canal* to travel to tongue. See also Figure 13.5.
Function: Mixed nerves, but primarily motor in function. Carry somatic motor fibers to intrinsic and extrinsic muscles of tongue, and proprioceptor fibers from same muscles to brain stem. Hypoglossal nerve control allows not only food mixing and manipulation by tongue during chewing, but also tongue movements that contribute to swallowing and speech.
Clinical testing: Person is asked to protrude and retract tongue. Any deviations in position are noted.

Homeostatic imbalance: Damage to hypoglossal nerves causes difficulties in speech and swallowing; if both nerves are impaired, the person cannot protrude tongue; if only one side is affected, tongue deviates (points) toward affected side; eventually paralyzed side begins to atrophy.



13

description of the origin, course, and function of the cranial nerves. Notice that the pathways of the purely or mostly sensory nerves (I, II, and VIII) are described from the receptors to the brain, while those of the other nerves are described in the opposite direction (from the brain distally). Remembering the primary functions of the cranial nerves (as sensory, motor, or both) can be a problem; this sentence might help: "Some say marry money, but my brother believes (it's) bad business (to) marry money."

Spinal Nerves

General Features

Thirty-one pairs of **spinal nerves,** each containing thousands of nerve fibers, arise from the spinal cord and supply all parts of the body except the head and some areas of the neck. All are mixed nerves. As illustrated in Figure 13.6, these nerves are named according to their point of issue from the spinal cord.

Q *Why are the lumbar and cervical regions of the spinal cord enlarged?*

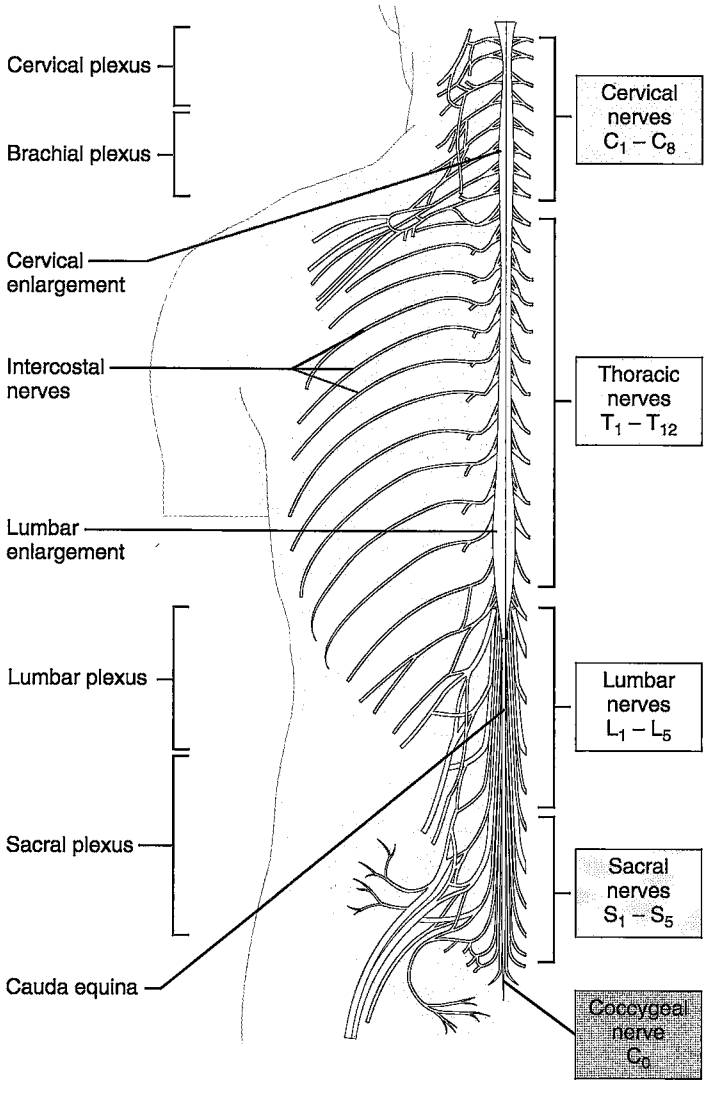


FIGURE 13.6 **Distribution of spinal nerves.** Distribution of spinal nerves, posterior view. Note that the spinal nerves are named according to their points of issue.

There are 8 pairs of cervical spinal nerves (C_1–C_8), 12 pairs of thoracic nerves (T_1–T_{12}), 5 pairs of lumbar nerves (L_1–L_5), 5 pairs of sacral nerves (S_1–S_5), and 1 pair of tiny coccygeal nerves (C_0).

Notice that there are eight pairs of cervical nerves but only seven cervical vertebrae. This "discrepancy" is easily explained. The first seven pairs exit the vertebral canal *superior to* the vertebrae for which they are named, but C_8 emerges *inferior to* the seventh cervical vertebra (between C_7 and T_1). Below the cervical level, each spinal nerve leaves the vertebral column *inferior to* the same-numbered vertebra.

As mentioned in Chapter 12, each spinal nerve connects to the spinal cord by a dorsal root and a ventral root. Each root forms from a series of **rootlets** that attach along the length of the corresponding spinal cord segment (Figure 13.7). The **ventral roots** contain *motor* (efferent) fibers that arise from ventral horn motor neurons and extend to and innervate the skeletal muscles. (Autonomic nervous system efferents also contained in the ventral roots are described in Chapter 14.) **Dorsal roots** contain *sensory* (afferent) fibers that arise from sensory neurons in the dorsal root ganglia and conduct impulses from peripheral receptors to the spinal cord.

The spinal roots pass laterally from the cord and unite just distal to the dorsal root ganglion to form a spinal nerve before emerging from the vertebral column via their respective intervertebral foramina. Because motor and sensory fibers mingle in a spinal nerve, it contains both efferent and afferent fibers. The length of the spinal roots increases progressively from the superior to the inferior aspect of the cord. In the cervical region, the roots are short and run horizontally, but the roots of the lumbar and sacral nerves extend inferiorly for some distance through the lower vertebral canal as the *cauda equina* before exiting the vertebral column (Figure 13.6).

A spinal nerve is quite short (only 1–2 cm) because almost immediately after emerging from its foramen, it divides into a small **dorsal ramus,** a larger **ventral ramus** (ra'mus; "branch"), and a tiny **meningeal branch** (mĕ-nin'je-al) that reenters the vertebral canal to innervate the meninges and blood vessels within. Each ramus, like the spinal nerve itself, is mixed. Finally, joined to the base of the ventral rami of the thoracic spinal nerves are special rami called **rami communicantes,** which contain autonomic (visceral) nerve fibers.

Innervation of Specific Body Regions

The spinal nerve rami and their main branches supply the entire somatic region of the body (voluntary muscles and skin) from the neck down. The dorsal rami supply the posterior body trunk. The thicker ventral rami supply the rest of the trunk and the limbs. To be clear, let's review the difference between roots and rami: Roots lie medial to and form the spinal nerves, and each root is strictly sensory *or* motor. Rami lie distal to and are lateral branches of the spinal nerves and, like spinal nerves, carry both sensory and motor fibers.

Before getting into the specifics of how the body is innervated, some important points about the ventral rami of the spinal nerves need to be understood.

A The peripheral nerves serving the limbs arise in the lumbar and cervical regions.

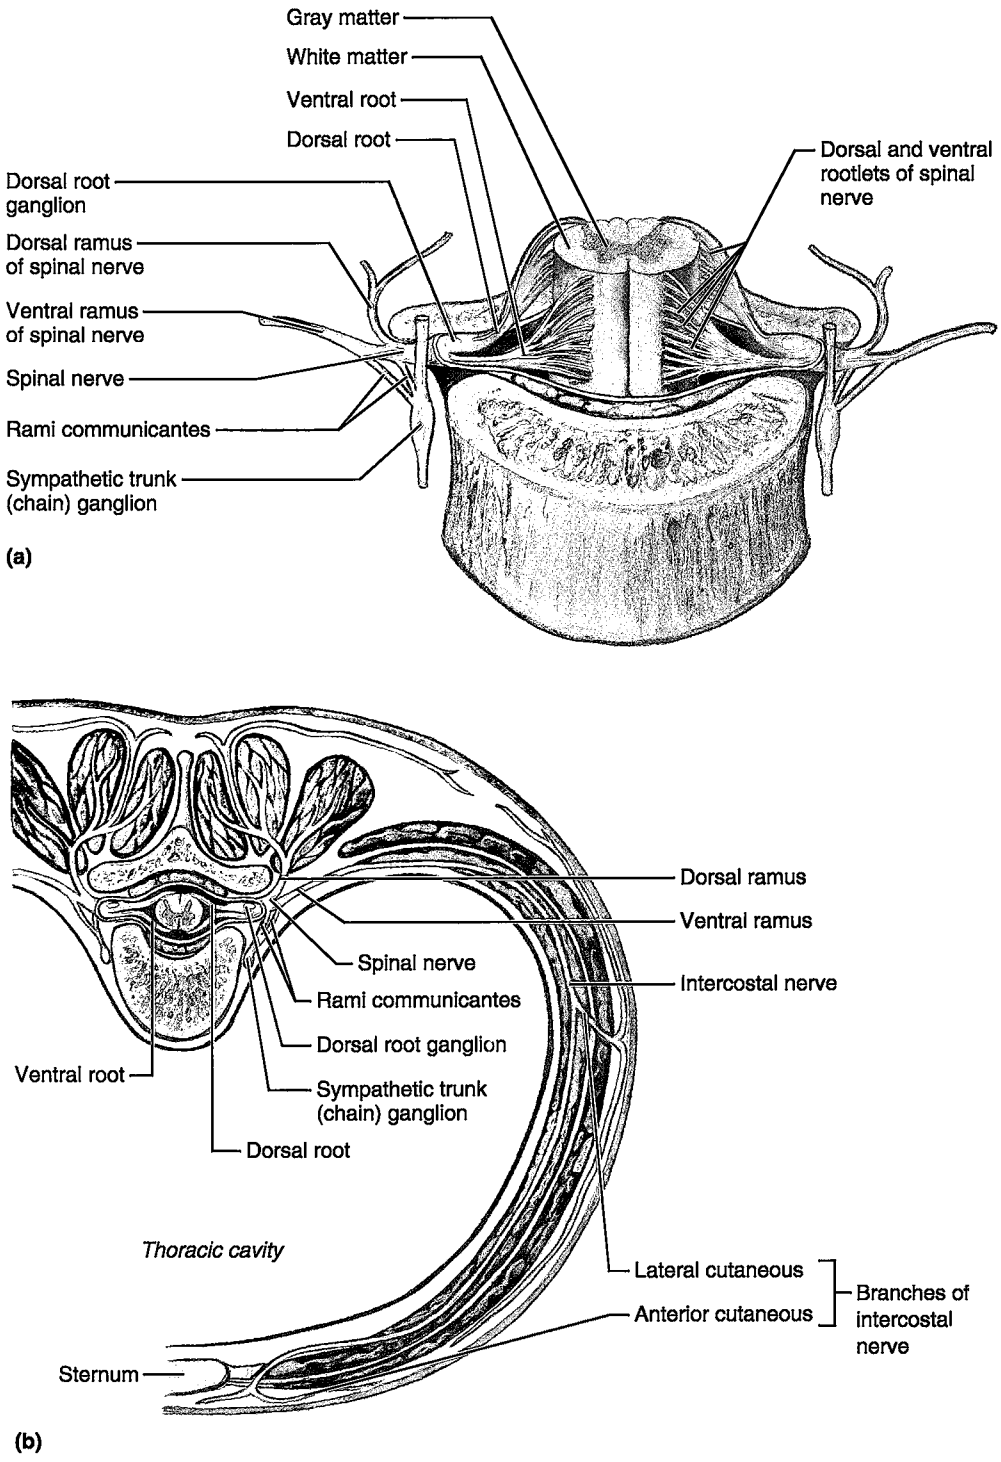

FIGURE 13.7 **Formation of spinal nerves and rami distribution. (a)** A diagrammatic view of a spinal cord segment, illustrating the formation of one pair of spinal nerves by the union of the ventral and dorsal roots of the spinal cord. **(b)** Cross-sectional view of the left side of the body at the level of the thorax, showing the distribution of the dorsal and ventral rami of the spinal nerve. In the thorax, each ventral ramus continues as an intercostal nerve. Notice also the rami communicantes branches of the spinal nerve. (The small meningeal branch is not illustrated.)

Except for T_2–T_{12}, all ventral rami branch and join one another lateral to the vertebral column, forming complicated **nerve plexuses** (Figure 13.6). Such interlacing nerve networks occur in the cervical, brachial, lumbar, and sacral regions and primarily serve the limbs. Notice that *only ventral rami form plexuses*. Within a plexus, fibers from the various ventral rami crisscross one another and become redistributed so that (1) each resulting branch of the plexus contains fibers from several spinal nerves and (2) fibers from each ventral ramus travel to the body periphery via several routes. Thus, each muscle in a limb receives its nerve supply from more than one spinal nerve. An advantage of this fiber regrouping is that damage to one spinal segment or root cannot completely paralyze any limb muscle.

Throughout this section, we mention major groups of skeletal muscles served. For more specific information on muscle innervations, see Tables 10.1–10.17.

TABLE 13.3 Branches of the Cervical Plexus (See Figure 13.8)

NERVES	SPINAL ROOTS (VENTRAL RAMI)	STRUCTURES SERVED
CUTANEOUS BRANCHES (SUPERFICIAL)		
Lesser occipital	C_2 (C_3)	Skin on posterolateral aspect of neck
Greater auricular	C_2, C_3	Skin of ear, skin over parotid gland
Transverse cutaneous (cervical)	C_2, C_3	Skin on anterior and lateral aspect of neck
Supraclavicular (medial, intermediate, and lateral)	C_3, C_4	Skin of shoulder and clavicular region
MOTOR BRANCHES (DEEP)		
Ansa cervicalis (superior and inferior roots)	C_1–C_3	Infrahyoid muscles of neck (omohyoid, sternohyoid, and sternothyroid)
Segmental and other muscular branches	C_1–C_5	Deep muscles of neck (geniohyoid and thyrohyoid) and portions of scalenes, levator scapulae, trapezius, and sternocleidomastoid muscles
Phrenic	C_3–C_5	Diaphragm (sole motor nerve supply)

Back

The innervation of the posterior body trunk by the dorsal rami follows a neat, segmented plan. Via its several branches (see Figure 13.7), each dorsal ramus innervates the narrow strip of muscle (and skin) in line with its emergence point from the spinal column.

Anterolateral Thorax and Abdominal Wall

Only in the thorax are the ventral rami arranged in a simple segmental pattern corresponding to that of the dorsal rami. The ventral rami of T_1–T_{12} mostly course anteriorly, deep to each rib, as the **intercostal nerves.** Along their course, these nerves give off *cutaneous branches* to the skin (Figures 13.6 and 13.7b). Two thoracic nerves are unusual: the tiny T_1 (most fibers enter the brachial plexus) and T_{12}, which lies inferior to the twelfth rib, making it a **subcostal nerve.** The intercostal nerves and their branches supply the intercostal muscles lying between the ribs, the muscle and skin of the anterolateral thorax, and most of the abdominal wall.

Cervical Plexus and the Neck

Buried deep in the neck under the sternocleidomastoid muscle, the looping **cervical plexus** is formed by the ventral rami of the first four cervical nerves (Figure 13.8). Its branches are summarized in Table 13.3. Most branches are **cutaneous nerves** (nerves that supply only the skin) that transmit sensory impulses from the skin of the neck, the ear area, the back of the head, and the shoulder. Other branches innervate muscles of the anterior neck.

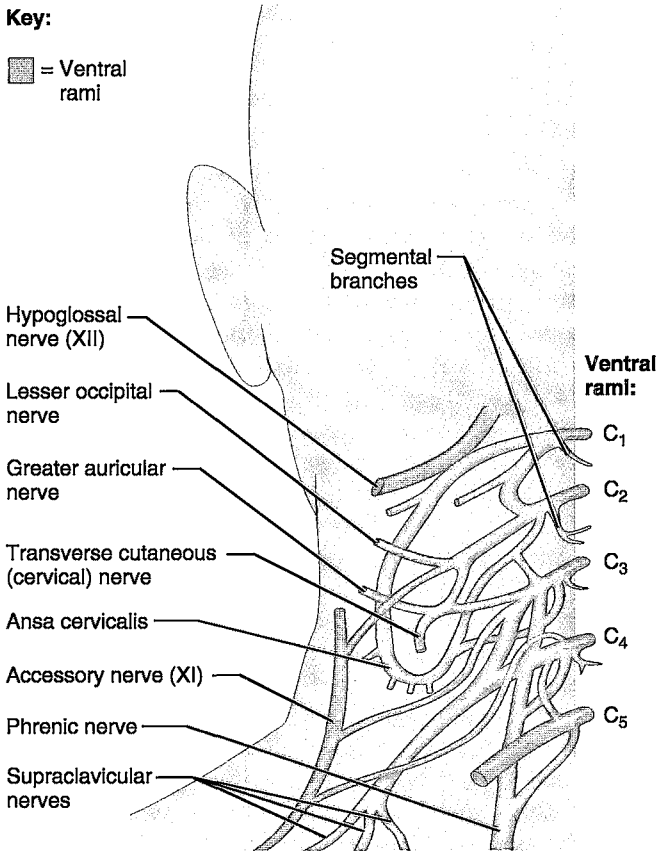

FIGURE 13.8 **The cervical plexus.** The nerves colored gray connect to the plexus but do not belong to it. See Table 13.3 for structures served. (See *A Brief Atlas of the Human Body,* Figure 45.)

The single most important nerve from this plexus is the **phrenic nerve** (fren'ik) (which receives its major input from C_3 and C_4). The phrenic nerve runs inferiorly through the thorax and supplies both motor and sensory fibers to the diaphragm (*phren* = diaphragm), which is the chief muscle causing breathing movements.

HOMEOSTATIC IMBALANCE

Irritation of the phrenic nerve causes spasms of the diaphragm, or hiccups. If both phrenic nerves are severed, or if the C_3–C_5 region of the spinal cord is crushed or destroyed, the diaphragm is paralyzed and respiratory arrest occurs. Victims are kept alive by mechanical respirators that force air into their lungs and do their breathing for them.

Brachial Plexus and Upper Limb

The large, important **brachial plexus,** situated partly in the neck and partly in the axilla, gives rise to virtually all the nerves that innervate the upper limb (Table 13.4). It can be palpated (felt) in a living person just superior to the clavicle at the lateral border of the sternocleidomastoid muscle.

This plexus is formed by intermixing of ventral rami of C_5–C_8 and most of the T_1 ramus. Additionally, it often receives fibers from C_4 or T_2 or both.

The brachial plexus is very complex (some consider it to be the anatomy student's nightmare). Perhaps the simplest approach is to master the terms used for its four major groups of branches (Figure 13.9). From medial to lateral, these are (1) the ventral rami, misleadingly called *roots,* which form (2) *trunks,* which form (3) *divisions,* which form (4) *cords.* You might want to use the saying "**R**eally **t**ired? **D**rink **c**offee" to help you remember this branching sequence.

The five **roots** (ventral rami C_5–T_1) of the brachial plexus lie deep to the sternocleidomastoid muscle. At the lateral border of that muscle, these roots unite to form **upper, middle,** and **lower trunks,** each of which divides almost immediately into an **anterior** and a **posterior division.** These divisions, which generally indicate which fibers serve the front or back of the limb, pass deep to the clavicle and enter the axilla, where they give rise to three large fiber bundles called the **lateral, medial,** and **posterior cords.** (The cords are named for their relationship to the axillary artery, which runs through the axilla; see Figure 19.22.) All along the plexus, small nerves branch off. These supply the muscles and skin of the shoulder and superior thorax.

HOMEOSTATIC IMBALANCE

Injuries to the brachial plexus are common; when severe, they cause weakness or paralysis of the entire upper limb. Such injuries may occur when the upper limb is pulled hard and the plexus is stretched (as when a football tackler yanks the arm of the running back), and by blows to the top of the shoulder that force the humerus inferiorly (as when a cyclist is pitched headfirst off a motorcycle and his shoulder grinds into the pavement).

The brachial plexus ends in the axilla, where its three cords wind along the axillary artery and then give rise to the main nerves of the upper limb (Figure 13.9c). Five of these nerves are especially important: the axillary, musculocutaneous, median, ulnar, and radial nerves. Their distribution and targets are described briefly here, and in more detail in Table 13.4.

The **axillary nerve** branches off the posterior cord and runs posterior to the surgical neck of the humerus. It innervates the deltoid and teres minor muscles and the skin and joint capsule of the shoulder.

The **musculocutaneous nerve,** the major end branch of the lateral cord, courses inferiorly in the anterior arm, supplying motor fibers to the biceps brachii and brachialis muscles. Distal to the elbow, it provides for cutaneous sensation of the lateral forearm.

The **median nerve** descends through the arm to the anterior forearm, where it gives off branches to the skin and to most flexor muscles. On reaching the hand, it innervates five intrinsic muscles of the lateral palm. The median nerve activates muscles that pronate the forearm, flex the wrist and fingers, and oppose the thumb.

HOMEOSTATIC IMBALANCE

Median nerve injury makes it difficult to use the pincer grasp (opposed thumb and index finger) to pick up small objects. Because this nerve runs down the midline of the forearm and wrist, it is a frequent casualty of wrist-slashing suicide attempts. In carpal tunnel syndrome (see p. 235), the median nerve is compressed.

The **ulnar nerve** branches off the medial cord of the plexus. It descends along the medial aspect of the arm toward the elbow, swings behind the medial epicondyle, and then follows the ulna along the medial forearm. There it supplies the flexor carpi ulnaris and the medial part of the flexor digitorum profundus (the flexors not supplied by the median nerve). It continues into the hand, where it innervates most intrinsic hand muscles and the skin of the medial aspect of the hand. It produces wrist and finger flexion

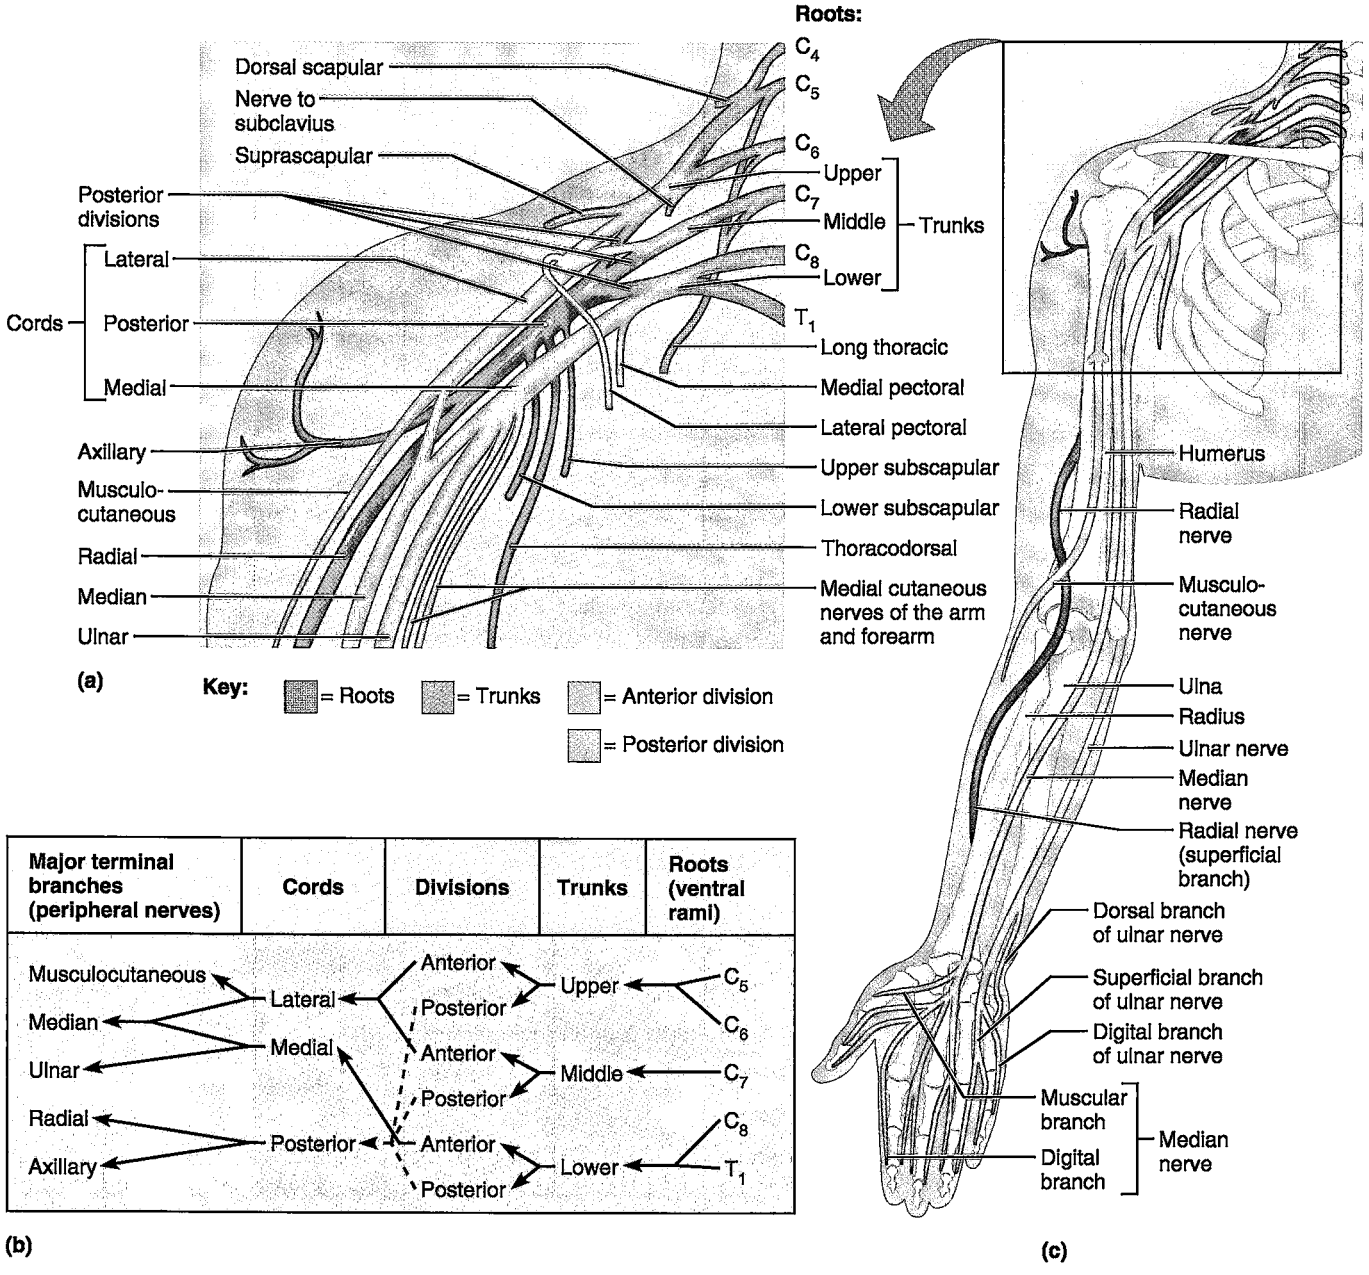

FIGURE 13.9 **The brachial plexus. (a)** Roots, trunks, divisions, and cords. **(b)** Flowchart of consecutive branches formed in the brachial plexus from the spinal roots (ventral rami) to the major nerves formed from the cords. **(c)** Distribution of the major peripheral nerves of the upper limb. (See Table 13.4.)

and (with the median nerve) adduction and abduction of the medial fingers.

HOMEOSTATIC IMBALANCE

Where it takes a superficial course, the ulnar nerve is very vulnerable to injury. Striking the "funny bone"—the spot where this nerve rests against the medial epicondyle—causes tingling of the little finger. Severe or chronic damage can lead to sensory loss, paralysis, and muscle atrophy. Affected individuals have trouble making a fist and gripping objects. As the little and ring fingers become hyperextended at the knuckles and flexed at the distal interphalangeal joints, the hand contorts into a *clawhand*. ●

The **radial nerve,** the largest branch of the brachial plexus, is a continuation of the posterior cord. This nerve wraps around the humerus (in the radial groove), and then runs anteriorly around the lateral epicondyle at the elbow. There it divides into a superficial branch that follows the lateral edge of the radius to the hand

TABLE 13.4 Branches of the Brachial Plexus (See Figure 13.9)

NERVES	CORD AND SPINAL ROOTS (VENTRAL RAMI)	STRUCTURES SERVED
Musculocutaneous	Lateral cord (C_5–C_7)	Muscular branches: flexor muscles in anterior arm (biceps brachii, brachialis, coracobrachialis) Cutaneous branches: skin on anterolateral forearm (extremely variable)
Median	By two branches, one from medial cord (C_8, T_1) and one from the lateral cord (C_5–C_7)	Muscular branches to flexor group of anterior forearm (palmaris longus, flexor carpi radialis, flexor digitorum superficialis, flexor pollicis longus, lateral half of flexor digitorum profundus, and pronator muscles); intrinsic muscles of lateral palm and digital branches to the fingers Cutaneous branches: skin of lateral two-thirds of hand, palm side and dorsum of fingers 2 and 3
Ulnar	Medial cord (C_8, T_1)	Muscular branches: flexor muscles in anterior forearm (flexor carpi ulnaris and medial half of flexor digitorum profundus); most intrinsic muscles of hand Cutaneous branches: skin of medial third of hand, both anterior and posterior aspects
Radial	Posterior cord (C_5–C_8, T_1)	Muscular branches: posterior muscles of arm, forearm, and hand (triceps brachii, anconeus, supinator, brachioradialis, extensors carpi radialis longus and brevis, extensor carpi ulnaris, and several muscles that extend the fingers) Cutaneous branches: skin of posterolateral surface of entire limb (except dorsum of fingers 2 and 3)
Axillary	Posterior cord (C_5, C_6)	Muscular branches: deltoid and teres minor muscles Cutaneous branches: some skin of shoulder region
Dorsal scapular	Branches of C_5 rami	Rhomboid muscles and levator scapulae
Long thoracic	Branches of C_5–C_7 rami	Serratus anterior muscle
Subscapular	Posterior cord; branches of C_5 and C_6 rami	Teres major and subscapular muscles
Suprascapular	Upper trunk (C_5, C_6)	Shoulder joint; supraspinatus and infraspinatus muscles
Pectoral (lateral and medial)	Branches of lateral and medial cords (C_5–T_1)	Pectoralis major and minor muscles

and a deep branch (not illustrated) that runs posteriorly. It supplies the posterior skin of the limb along its entire course. Its motor branches innervate essentially all the extensor muscles of the upper limb. The radial nerve produces elbow extension, forearm supination, wrist and finger extension, and thumb abduction.

HOMEOSTATIC IMBALANCE

Trauma to the radial nerve results in *wrist drop,* an inability to extend the hand at the wrist. Improper use of a crutch or "Saturday night paralysis," in which an intoxicated person falls asleep with an arm draped over the back of a chair or sofa edge, causes radial nerve compression and ischemia (deprivation of blood supply). ●

Lumbosacral Plexus and Lower Limb

The sacral and lumbar plexuses overlap substantially, and because many fibers of the lumbar plexus contribute to the sacral plexus via the **lumbosacral trunk,** the two plexuses are often referred to as the **lumbosacral plexus.** Although the lumbosacral plexus serves mainly the lower limb, it also sends some branches to the abdomen, pelvis, and buttock.

Lumbar Plexus The **lumbar plexus** arises from the spinal nerves L_1–L_4 (Figure 13.10) and lies within the psoas major muscle. Its proximal branches innervate parts of the abdominal wall muscles and the psoas muscle, but its major branches descend to innervate the anterior and medial thigh. The **femoral nerve,** the largest terminal nerve of this plexus, runs deep to the inguinal ligament to enter the thigh and then divides into several large branches. The motor branches innervate anterior thigh muscles (quadriceps), which are the principal thigh flexors and knee extensors. The cutaneous branches serve the skin of the anterior thigh and the medial surface of the leg from knee to foot. The **obturator nerve** (ob"tu-ra'tor) enters the medial thigh via the obturator foramen and innervates the adductor muscles. These and other smaller branches of the lumbar plexus are summarized in Table 13.5.

TABLE 13.5 Branches of the Lumbar Plexus (See Figure 13.10)

NERVES	SPINAL ROOTS (VENTRAL RAMI)	STRUCTURES SERVED
Femoral	L_2–L_4	Skin of anterior and medial thigh via *anterior femoral cutaneous* branch; skin of medial leg and foot, hip and knee joints via *saphenous* branch; motor to anterior muscles (quadriceps and sartorius) of thigh and to pectineus, iliacus
Obturator	L_2–L_4	Motor to adductor magnus (part), longus, and brevis muscles, gracilis muscle of medial thigh, obturator externus; sensory for skin of medial thigh and for hip and knee joints
Lateral femoral cutaneous	L_2, L_3	Skin of lateral thigh; some sensory branches to peritoneum
Iliohypogastric	L_1	Skin of lower abdomen, lower back, and hip; muscles of anterolateral abdominal wall (obliques and transversus) and pubic region
Ilioinguinal	L_1	Skin of external genitalia and proximal medial aspect of the thigh; inferior abdominal muscles
Genitofemoral	L_1, L_2	Skin of scrotum in males, of labia majora in females, and of anterior thigh inferior to middle portion of inguinal region; cremaster muscle in males

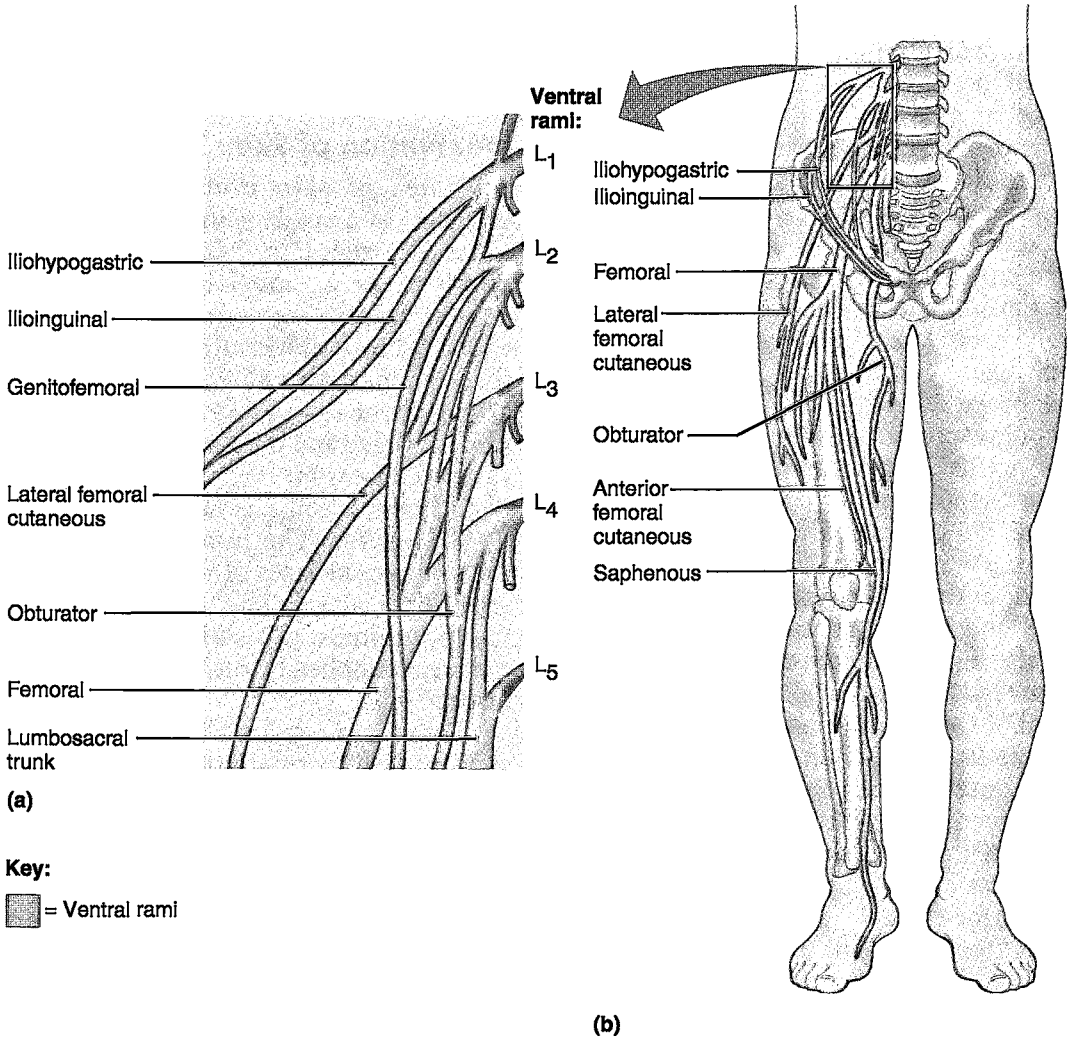

FIGURE 13.10 **The lumbar plexus. (a)** Spinal roots (ventral rami) and major branches. **(b)** Distribution of the major peripheral nerves in the lower limb (anterior view). (See Table 13.5.)

HOMEOSTATIC IMBALANCE

Compression of the spinal roots of the lumbar plexus, as by a herniated disc, results in gait problems because the femoral nerve serves the prime movers of both hip flexion and knee extension. Anesthesia of the anterior thigh and pain in the medial thigh occur if the obturator nerve is impaired. ●

Sacral Plexus The **sacral plexus** arises from spinal nerves L_4–S_4 and lies immediately caudal to the lumbar plexus (Figure 13.11). Some fibers of the lumbar plexus contribute to the sacral plexus via the *lumbosacral trunk,* as mentioned earlier. The sacral plexus has about a dozen named branches. About half of these serve the buttock and lower limb; the others innervate pelvic structures and the perineum. The most important branches are described here. Table 13.6 summarizes all but the smallest ones.

The largest branch of the sacral plexus is the **sciatic nerve** (si-at'ik), the thickest and longest nerve in the body. It supplies the entire lower limb, except the anteromedial thigh.

Actually two nerves (the tibial and common fibular) wrapped in a common sheath, the sciatic nerve leaves the pelvis via the greater sciatic notch. It courses deep to the gluteus maximus muscle and enters the posterior thigh just medial to the hip joint (*sciatic* = of the hip). There it gives off motor branches to the hamstring muscles (all thigh extensors and knee flexors) and to the adductor magnus. Immediately above the knee, the two divisions of the sciatic nerve diverge.

The **tibial nerve** courses through the popliteal fossa (the region just posterior to the knee joint) and supplies the posterior compartment muscles of the leg and the skin of the posterior calf and sole of the foot. In the vicinity of the knee, the tibial nerve gives off the **sural nerve,** which serves the skin of the posterolateral leg, and at the ankle the tibial nerve divides into the **medial** and **lateral plantar nerves,** which serve most of the foot. The **common fibular (peroneal) nerve** descends from its point of origin, wraps around the head of the fibula (fibula = *perone*), and then divides into superficial and deep branches. These branches innervate the knee joint, skin of the lateral calf and dorsum of the foot, and muscles of the anterolateral leg (the extensors that dorsiflex the foot).

The next largest sacral plexus branches are the **superior** and **inferior gluteal nerves.** Together, they innervate the buttock (gluteal) and tensor fasciae latae muscles. The **pudendal nerve** (pu-den'dal; "shameful") innervates the muscles and skin of the perineum, mediates the act of erection, and is involved in voluntary control of urination (see Table 10.7). Other branches of the sacral plexus supply the thigh rotators and muscles of the pelvic floor.

HOMEOSTATIC IMBALANCE

Injury to the proximal part of the sciatic nerve, as might follow a fall, disc herniation, or improper administration of an injection into the buttock, results in a number of lower limb impairments, depending on the precise nerve roots injured. *Sciatica* (si-at'ĭ-kah), characterized by stabbing pain radiating over the course of the sciatic nerve, is common. When the nerve is transected, the leg is nearly useless. The leg cannot be flexed (because the hamstrings are paralyzed), and all foot and ankle movement is lost. The foot drops into plantar flexion (it dangles), a condition called *footdrop.* Recovery from sciatic nerve injury is usually slow and incomplete.

If the lesion occurs below the knee, thigh muscles are spared. When the tibial nerve is injured, the paralyzed calf muscles cannot plantar flex the foot and a shuffling gait develops. The common fibular nerve is susceptible to injury largely because of its superficial location at the head and neck of the fibula. Even a tight leg cast, or remaining too long in a side-lying position on a firm mattress, can compress this nerve and cause footdrop. ●

Innervation of Skin: Dermatomes

The area of skin innervated by the cutaneous branches of a single spinal nerve is called a **dermatome** (der'mah-tōm; "skin segment"). Every spinal nerve except C_1 innervates dermatomes. Adjacent dermatomes on the body trunk are fairly uniform in width, almost horizontal, and in direct line with their spinal nerves (Figure 13.12). The dermatome arrangement in the limbs is less obvious. (It is also more variable and different clinicians have mapped a variety of areas for the same dermatomes.) The skin of the upper limbs is supplied by ventral rami of C_5–T_1 (or T_2). The lumbar nerves supply most of the anterior surfaces of the thighs and legs, and the sacral nerves serve most of the posterior surfaces of the lower limbs. (This distribution basically reflects the areas supplied by the lumbar and sacral plexuses, respectively.)

Dermatome regions are not as cleanly separated as a typical dermatome map indicates. Because those of the trunk overlap considerably (about 50%), destruction of a single spinal nerve will not result in complete numbness anywhere. In the limbs, the overlap is less complete and some skin regions are innervated by just one spinal nerve.

Innervation of Joints

The easiest way to remember which nerves serve which synovial joint is to use **Hilton's law,** which says: *Any nerve serving a muscle that produces movement at a joint also innervates the joint and*

TABLE 13.6 Branches of the Sacral Plexus (See Figure 13.11)

NERVES	SPINAL ROOTS (VENTRAL RAMI)	STRUCTURES SERVED
Sciatic nerve	L_4, L_5, S_1–S_3	Composed of two nerves (tibial and common fibular) in a common sheath; they diverge just proximal to the knee
▪ Tibial (including sural, medial and lateral plantar, and medial calcaneal branches)	L_4–S_3	Cutaneous branches: to skin of posterior surface of leg and sole of foot Motor branches: to muscles of back of thigh, leg, and foot [hamstrings (except short head of biceps femoris), posterior part of adductor magnus, triceps surae, tibialis posterior, popliteus, flexor digitorum longus, flexor hallucis longus, and intrinsic muscles of foot]
▪ Common fibular (superficial and deep branches)	L_4–S_2	Cutaneous branches: to skin of anterior surface of leg and dorsum of foot Motor branches: to short head of biceps femoris of thigh, fibular muscles of lateral compartment of leg, tibialis anterior, and extensor muscles of toes (extensor hallucis longus, extensors digitorum longus and brevis)
Superior gluteal	L_4, L_5, S_1	Motor branches: to gluteus medius and minimus and tensor fasciae latae
Inferior gluteal	L_5–S_2	Motor branches: to gluteus maximus
Posterior femoral cutaneous	S_1–S_3	Skin of buttock, posterior thigh, and popliteal region; length variable; may also innervate part of skin of calf and heel
Pudendal	S_2–S_4	Supplies most of skin and muscles of perineum (region encompassing external genitalia and anus and including clitoris, labia, and vaginal mucosa in females, and scrotum and penis in males); external anal sphincter

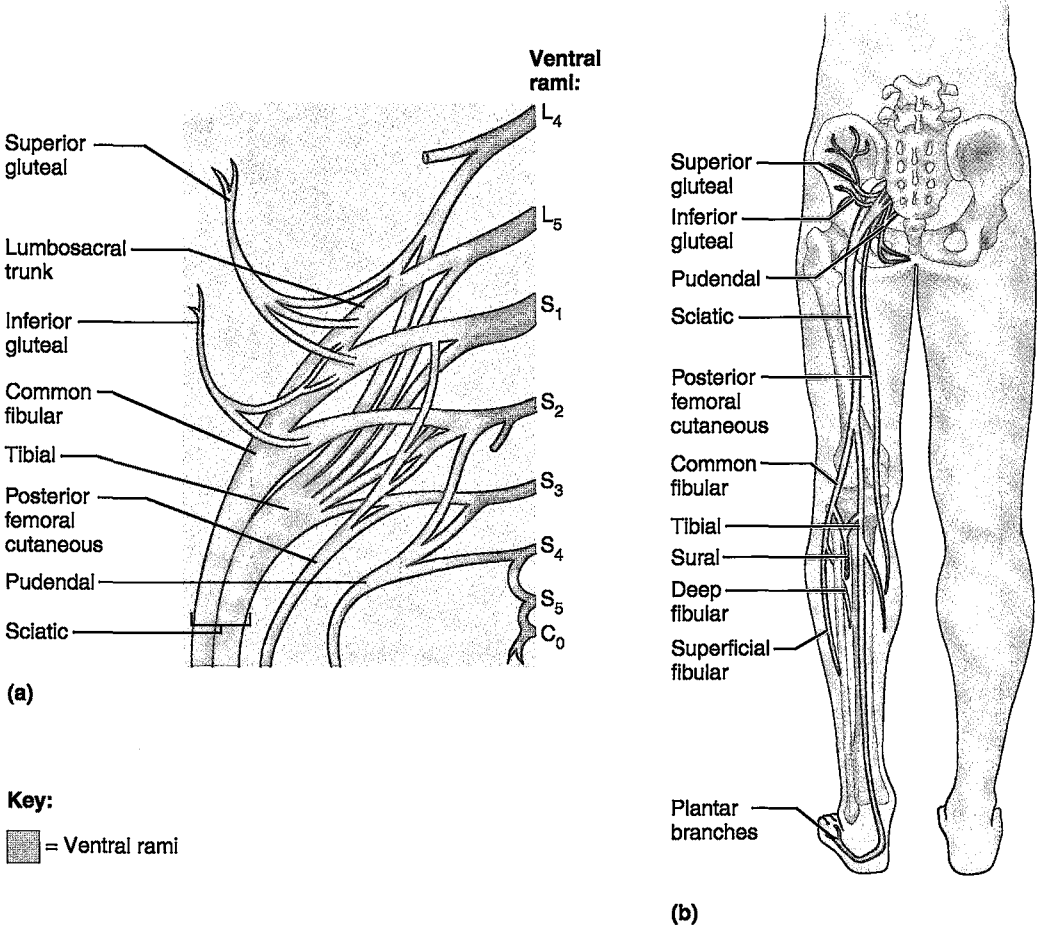

FIGURE 13.11 **The sacral plexus. (a)** The spinal roots (ventral rami) and major branches. **(b)** Distribution of the major peripheral nerves in the lower limb (posterior view). (See Table 13.6.)

Q *In what way are dermatomes clinically significant in patients with spinal cord injury?*

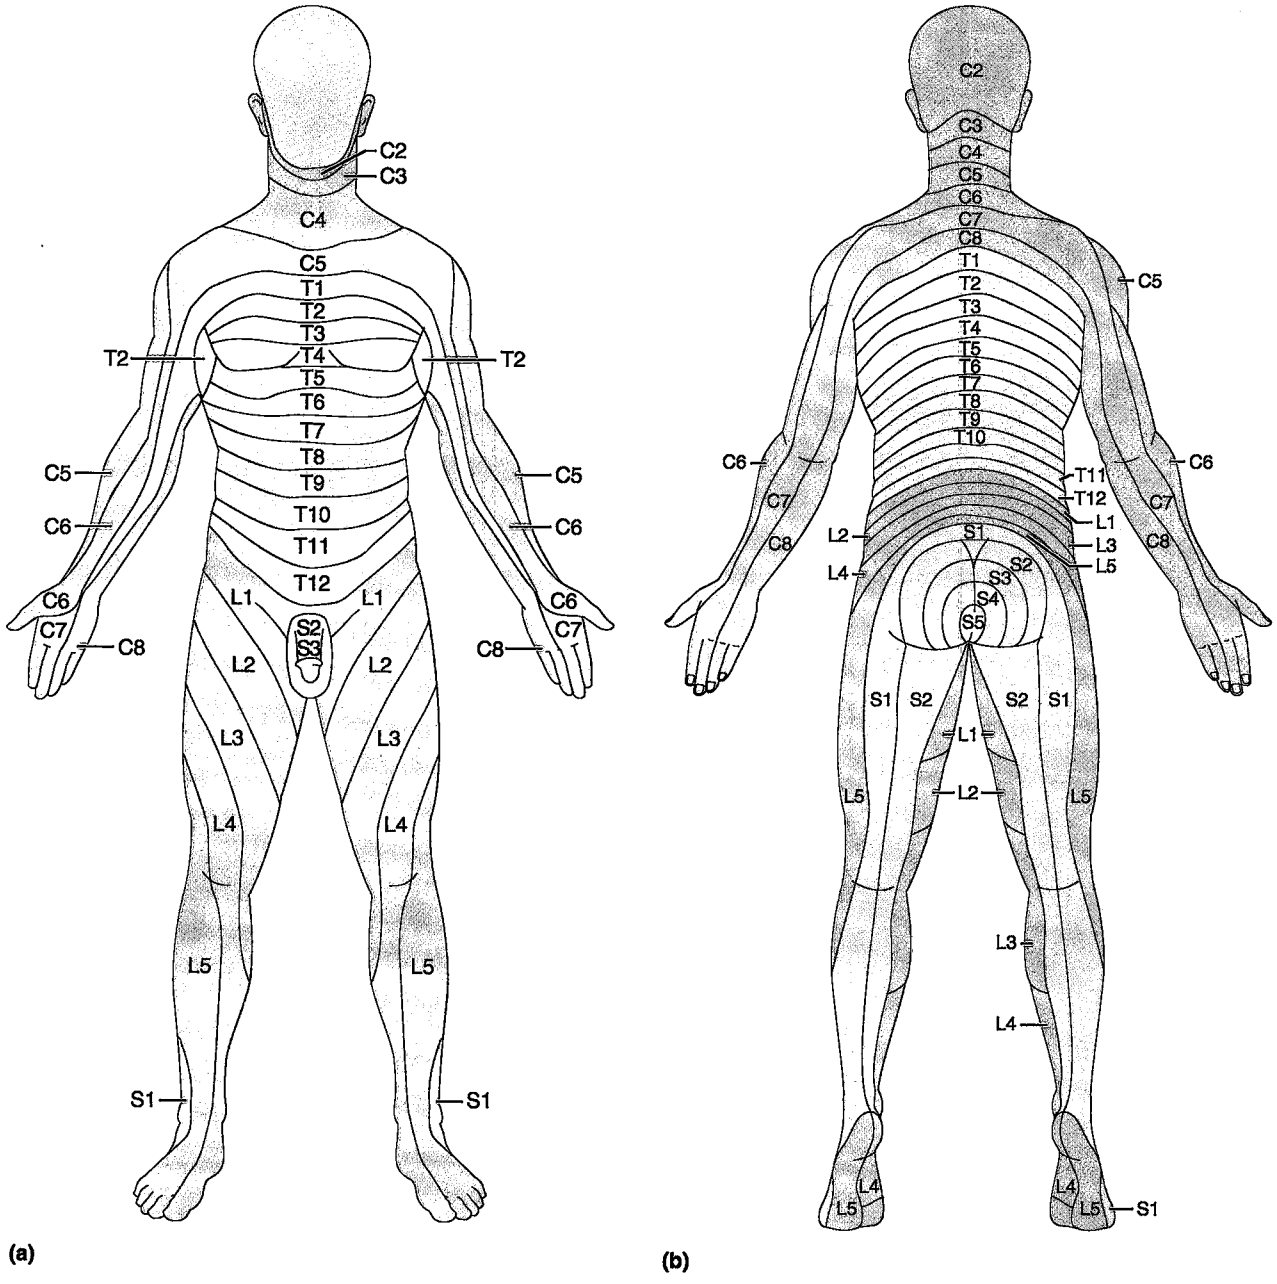

FIGURE 13.12 **Dermatomes.** Each dermatome is the skin segment innervated by the cutaneous sensory branches of a single spinal nerve. All spinal nerves but C_1 participate in the innervation of the dermatomes/**(a)** Anterior view. **(b)** Posterior view.

the skin over the joint. Hence, once you learn which nerves serve the various major muscles and muscle groups, no *new* learning is necessary. For example, the knee is crossed by the quadriceps, gracilis, and hamstring muscles. The nerves to these muscles are the femoral nerve anteriorly and branches of the sciatic and obturator nerves posteriorly. Consequently, these nerves innervate the knee joint as well.

A *The distribution of dermatomes affected can help the physician determine which nerves are damaged and localize the injured region of the spinal cord.*

PART 3: MOTOR ENDINGS AND MOTOR ACTIVITY

Peripheral Motor Endings

So far we have covered the structure of sensory receptors that detect stimuli, and that of nerves containing the afferent and efferent fibers that deliver impulses to and from the CNS. We now turn to **motor endings,** the PNS elements that activate effectors by releasing neurotransmitters. Because we discussed that topic earlier with the innervation of body muscles, all we need to do here is recap. To balance the overview of sensory function provided earlier in the chapter, this will be followed by a brief overview of motor integration.

Innervation of Skeletal Muscle

As illustrated in Figure 9.7 (p. 290), the terminals of somatic motor fibers that innervate voluntary muscles form elaborate **neuromuscular junctions** with their effector cells. As each axon branch reaches its target, a single muscle fiber, the ending splits into a cluster of *axon terminals (boutons)* that branch treelike over the motor end plate of the muscle fiber. The axon terminals contain mitochondria and synaptic vesicles filled with the neurotransmitter acetylcholine (ACh). When a nerve impulse reaches an axon terminal, ACh is released by exocytosis, diffuses across the fluid-filled synaptic cleft (about 50 nm wide), and attaches to ACh receptors on the highly infolded sarcolemma at the junction. ACh binding results in the opening of ligand-gated channels that allow both Na^+ and K^+ to pass. Because more Na^+ enters the cell than K^+ leaves, the muscle cell interior at that point depolarizes, producing a type of graded potential called an end plate potential. The end plate potential spreads to adjacent areas of the membrane where it triggers the opening of voltage-gated sodium channels. This event leads to propagation of an action potential along the sarcolemma that stimulates the muscle fiber to contract. The synaptic cleft at somatic neuromuscular junctions is filled with a glycoprotein-rich basal lamina (a structure not seen at other synapses). The basal lamina contains *acetylcholinesterase,* the enzyme that breaks down ACh almost immediately after it binds.

Innervation of Visceral Muscle and Glands

The junctions between autonomic motor endings and their effectors (which are smooth and cardiac muscle and glands) are much simpler than the junctions formed between somatic fibers and skeletal muscle cells. The autonomic motor axons branch repeatedly, each branch forming *synapses en passant* with its effector cells. Instead of a cluster of bulblike terminals, an axon ending serving smooth muscle or a gland (but not cardiac muscle) has a series of **varicosities,** knoblike swellings containing mitochondria and synaptic vesicles, that make it look like a string of beads (see Figure 9.25). The autonomic synaptic vesicles typically contain either acetylcholine or norepinephrine, both of which act indirectly on their targets via second messengers. Consequently, the visceral motor responses tend to be slower than those induced by somatic motor fibers, which directly open ion channels.

Overview of Motor Integration: From Intention to Effect

In the motor system, we have motor endings serving effectors (muscle fibers) instead of sensory receptors, descending efferent circuits instead of ascending afferent circuits, and motor behavior instead of perception. However, like sensory systems, the basic mechanisms of motor systems operate at three levels.

Levels of Motor Control

The cerebral cortex is at the highest level of the conscious motor pathways, but it is *not* the ultimate planner and coordinator of complex motor activities. The cerebellum and basal nuclei (ganglia) play this role and are therefore put at the top of the motor control hierarchy. Motor control exerted by lower levels is mediated by *reflex arcs* in some cases, but complex motor behavior, such as walking and swimming, appears to depend on more complex patterns. Currently, we define three levels of motor control: the *segmental level,* the *projection level,* and the *precommand level* (Figure 13.13).

The Segmental Level

The lowest level of the motor hierarchy, the **segmental level,** consists of the spinal cord circuits. A segmental circuit activates a network of ventral horn neurons in a group of cord segments, causing them to stimulate specific groups of muscles. Those circuits that control locomotion and other specific and oft-repeated motor activities are called **central pattern generators (CPGs).** CPGs consist of networks of oscillating inhibitory and excitatory neurons, which set crude rhythms and alternating patterns of movement.

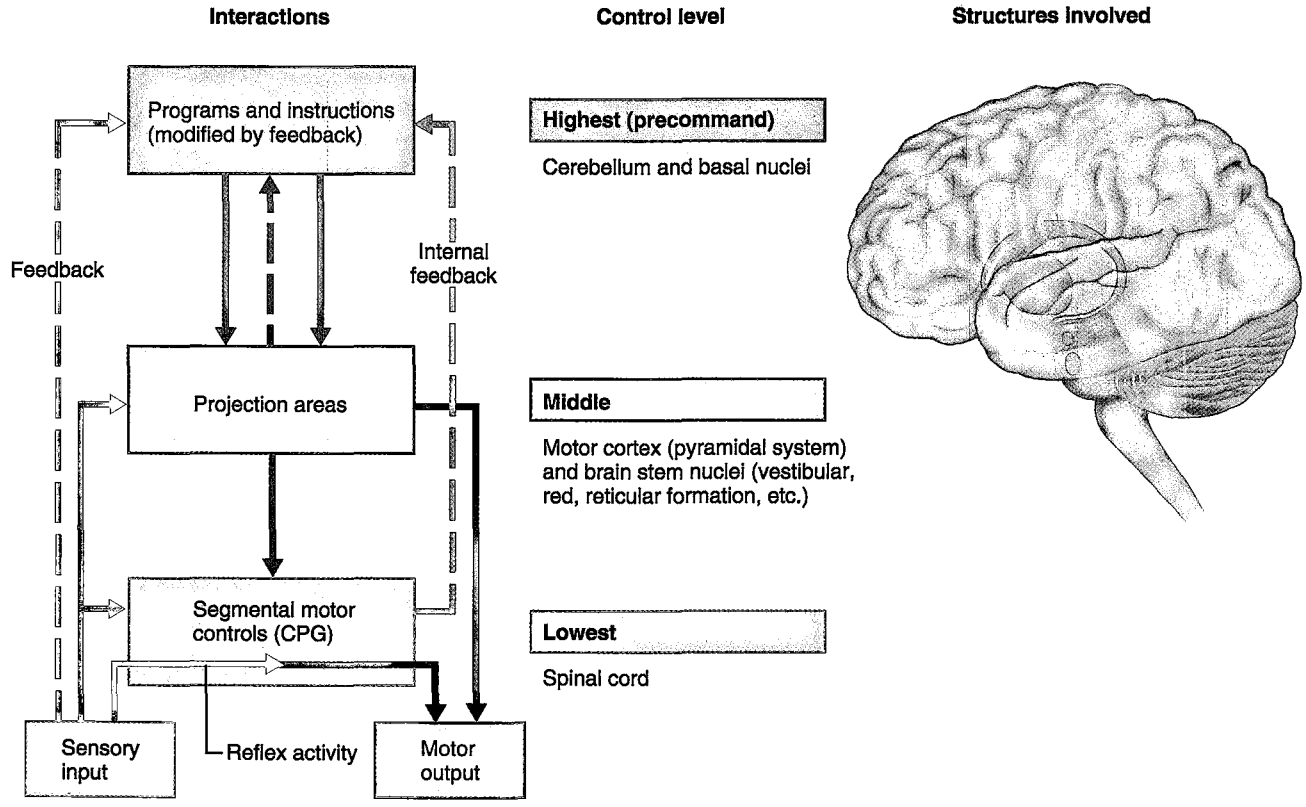

FIGURE 13.13 **Hierarchy of motor control.**

The Projection Level

The spinal cord is under the direct control of the **projection level** of motor control. The projection level consists of *upper motor neurons* of the motor cortex, which initiate the *direct (pyramidal) system*, and of brain stem motor areas, which oversee the *indirect (multineuronal) system* (see Table 12.3 and p. 478). Axons of the direct system neurons produce discrete voluntary movements of the skeletal muscles. Axons of the indirect system help control reflex and CPG-controlled motor actions, modifying and controlling the activity of the segmental apparatus.

Projection motor pathways convey information to lower motor neurons, and send a copy of that information *(internal feedback)* back to higher command levels, continually informing them of what is happening. The direct and indirect systems provide separate and parallel pathways for controlling the spinal cord, but these systems are interrelated at all levels.

The Precommand Level

Two other systems of brain neurons, located in the cerebellum and basal nuclei, regulate motor activity. They precisely start or stop movements, coordinate movements with posture, block unwanted movements, and monitor muscle tone. Collectively called **precommand areas,** these systems *control the outputs* of the cortex and brain stem motor centers and stand at the highest level of the motor hierarchy.

The key center for "online" sensorimotor integration and control is the **cerebellum.** Remember the cerebellum is a target of ascending proprioceptor, tactile, equilibrium, and visual inputs—feedback that it needs for rapid correction of "errors" in motor activity. It also receives information via branches from descending pyramidal tracts, and from various brain stem nuclei. The cerebellum lacks direct connections to the spinal cord; it acts on motor pathways through the projection areas of the brain stem and on the motor cortex via the thalamus to fine-tune motor activity.

The **basal nuclei** receive inputs from *all* cortical areas and send their output back mainly to premotor and prefrontal cortical areas via the thalamus. Compared to the cerebellum, the basal nuclei appear to be involved in more complex aspects of motor control. Under resting conditions, the basal nuclei inhibit various motor centers of the brain, but when the motor centers are released from inhibition, coordinated motions can begin. Cells in both the basal nuclei and the cerebellum are involved in this unconscious planning and discharge *in advance* of willed movements. When you actually move your fingers, both the precommand areas and the primary motor cortex

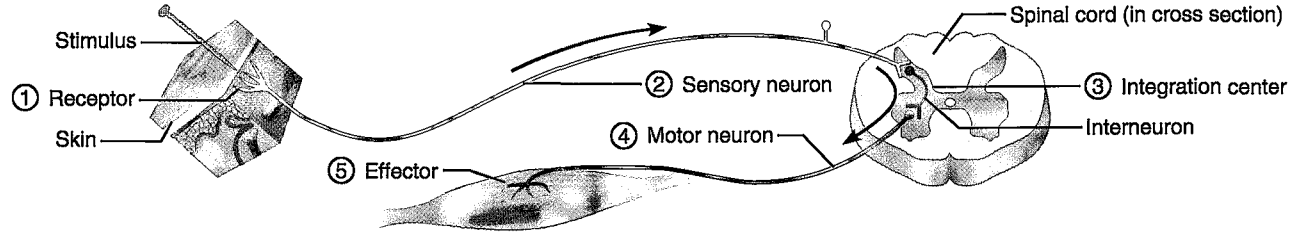

FIGURE 13.14 **The basic components of all human reflex arcs.** The reflex arc illustrated is polysynaptic.

are active. At the risk of oversimplifying, it appears that the cortex says, "I want to do this," and then lets the precommand areas take over to provide the proper timing and patterns to execute the movements desired. The precommand areas control the motor cortex and provide its readiness to initiate a voluntary act. The conscious cortex then chooses to act or not act, but the groundwork has already been laid.

PART 4: REFLEX ACTIVITY

The Reflex Arc

Many of the body's control systems belong to a general category known as reflexes, which can be either inborn or learned. In the most restricted sense, an *inborn,* or *intrinsic, reflex* is a rapid, predictable motor response to a stimulus. It is unlearned, unpremeditated, and involuntary, and may be considered as built into our neural anatomy. Reflexes prevent us from having to *think* about all the little details of staying upright, intact, and alive—helping us maintain posture, avoid pain, and control visceral activites.

One example of an inborn reflex is what happens when you splash a pot of boiling water on your arm; you are likely to drop the pot instantly and involuntarily even before feeling any pain. This response is triggered by a spinal reflex without any help from the brain. In many cases we are aware of the final response of a basic reflex activity (you know you've dropped the pot of boiling water). In other cases, reflex activities go on without any awareness on our part. This is typical of many visceral reflexes, which are regulated by the subconscious lower regions of the CNS, specifically the brain stem and spinal cord.

In addition to these basic, inborn types of reflexes, there are *learned,* or *acquired, reflexes* that result from practice or repetition. Take, for instance, the complex sequence of reactions that occurs when an experienced driver drives a car. The process is largely automatic, but only because substantial time and effort were expended to acquire the driving skill. In reality, the distinction between inborn and learned reflexes is not clear-cut and most inborn reflex actions are subject to modification by learning and conscious effort. For instance, if a 3-year-old child was standing by your side when you scalded your arm, you most likely would set the pot down (rather than just letting go) because of your conscious recognition of the danger to the child.

Recall the discussion in Chapter 11 about serial and parallel processing of sensory input. What happens when you scald your arm is a good example of how these two processing mechanisms work together. You drop the pot before feeling any pain, but the pain signals picked up by the interneurons of the spinal cord are quickly transmitted to the brain, so that within the next few seconds you *do* become aware of pain, and you also know what happened to cause it. The withdrawal reflex is serial processing mediated by the spinal cord, and pain awareness reflects simultaneous parallel processing of the sensory input.

Components of a Reflex Arc

As you learned in Chapter 11, reflexes occur over highly specific neural paths called **reflex arcs,** all of which have five essential components (Figure 13.14):

① **Receptor:** Site of the stimulus action.

② **Sensory neuron:** Transmits afferent impulses to the CNS.

③ **Integration center:** In simple reflex arcs, may be a single synapse between a sensory neuron and a motor neuron **(monosynaptic reflex).** More complex reflex arcs involve multiple synapses with chains of interneurons **(polysynaptic reflex).** The integration center is always within the CNS.

④ **Motor neuron:** Conducts efferent impulses from the integration center to an effector organ.

⑤ **Effector:** Muscle fiber or gland cell that responds to the efferent impulses (by contracting or secreting).

Reflexes are classified functionally as **somatic reflexes** if they activate skeletal muscle, or as **autonomic (visceral) reflexes** if they activate visceral

Q *There is a major difference in the functions of the intrafusal and extrafusal muscle fibers. What is it?*

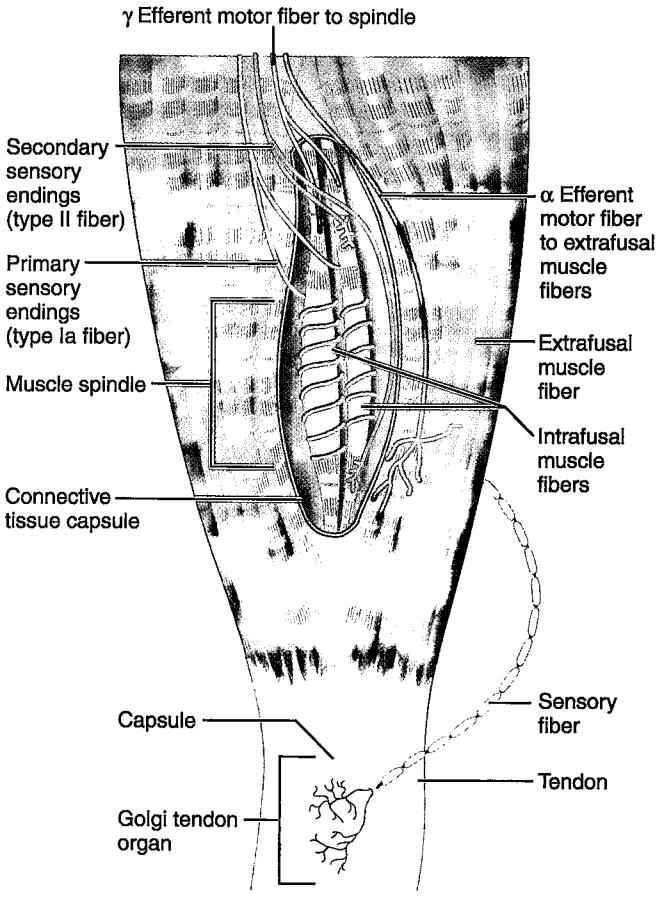

FIGURE 13.15 **Anatomy of the muscle spindle and Golgi tendon organ.** Notice the afferent fibers from and efferent fibers to the muscle spindle.

effectors (smooth or cardiac muscle or glands). Here we describe some common somatic reflexes mediated by the spinal cord. Autonomic reflexes are considered in later chapters with the visceral processes they help to regulate.

Spinal Reflexes

Somatic reflexes mediated by the spinal cord are called **spinal reflexes.** Many spinal reflexes occur without the direct involvement of higher brain centers. Generally, these reflexes are present in decerebrate animals (those in which the brain has been destroyed) as long as the spinal cord is functional. However, the brain is "advised" of most spinal reflex activity and can facilitate, inhibit, or adapt it, depending on the circumstances (as described in the above example of the hot water–filled pot). Moreover, continuous facilitating signals from the brain are required for normal spinal reflex activity because, as noted in Chapter 12, if the spinal cord is transected, *spinal shock* occurs (all functions controlled by the cord are immediately depressed).

Testing of somatic reflexes is important clinically to assess the condition of the nervous system. Exaggerated, distorted, or absent reflexes indicate degeneration or pathology of specific nervous system regions, often before other signs are apparent.

Stretch and Golgi Tendon Reflexes

In order to smoothly coordinate skeletal muscular activity, your nervous system needs two types of information about the current state of a muscle. First, it needs to know the amount of tension in the muscle and its associated tendons. This information is provided by the *Golgi tendon organs*. Second, it needs to know the length of the muscle. This information is provided by the *muscle spindles*. These two types of proprioceptors play an important role in spinal reflexes and also provide essential feedback to the cerebral cortex and cerebellum.

Functional Anatomy of Muscle Spindles

Each muscle spindle consists of three to ten **intrafusal muscle fibers** (*intra* = within; *fusal* = the spindle) enclosed in a connective tissue capsule (Figure 13.15). These modified skeletal muscle fibers are less than one-quarter the size of **extrafusal muscle fibers** (the effector fibers of the muscle). The central regions of the intrafusal fibers, which lack myofilaments and are noncontractile, are the receptive surfaces of the spindle. These regions are wrapped by two types of afferent endings that send sensory inputs to the CNS. The **primary sensory endings** of large **type Ia fibers,** which innervate the spindle center, are stimulated by both the rate and degree of stretch. The **secondary sensory endings** of small **type II fibers** supply the spindle ends and are stimulated only by degree of stretch. The contractile regions of the intrafusal muscle fibers are limited to their ends because these are the only areas that contain actin and myosin myofilaments. These regions are innervated by **gamma (γ) efferent fibers** that arise from small motor neurons in the ventral horn of the spinal cord. These γ motor fibers, which maintain spindle sensitivity (as described shortly), are distinct from the **alpha (α) efferent fibers** of the large **alpha (α) motor neurons** that stimulate the extrafusal muscle fibers to contract.

A *The extrafusal muscle fibers are effectors; when adequately stimulated, they contract, shortening the muscle. The intrafusal fibers are part of a receptor apparatus that provides input for regulation of the activity of the muscle.*

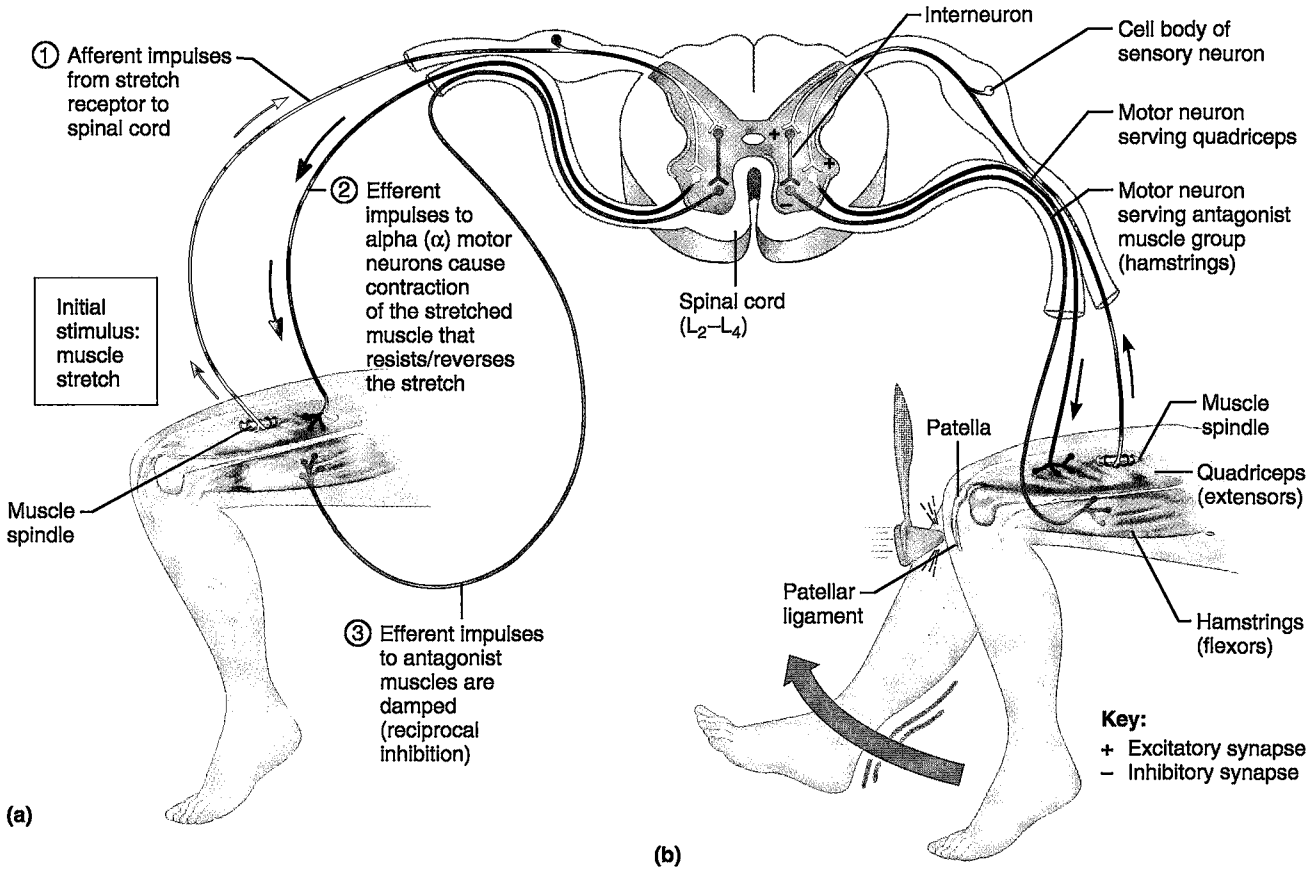

FIGURE 13.16 **The stretch reflex.** **(a)** Events of the stretch reflex by which muscle stretch is damped. The events are shown in circular fashion. **(b)** The patellar reflex. Tapping the patellar tendon excites muscle spindles in the quadriceps muscle. Afferent impulses travel to the spinal cord, where synapses occur with motor neurons and interneurons. The motor neurons send activating impulses to the quadriceps causing it to contract, which causes extension of the knee and forward movement of the foot, counteracting the initial stretch. The interneurons make inhibitory synapses with ventral horn neurons that serve the antagonistic muscle group (hamstrings), thus preventing the hamstrings from resisting the contraction.

The muscle spindle is stretched (and excited) in one of two ways: (1) by applying an external force that lengthens the entire muscle, such as occurs when we carry a heavy weight or when antagonistic muscles contract (external stretch); or (2) by activating the γ motor neurons that stimulate the distal ends of the intrafusal fibers to contract, thus stretching the middle of the spindle (internal stretch).

The Stretch Reflex

By sending commands to the motor neurons, the brain essentially sets a muscle's length. The **stretch reflex** makes sure that the muscle stays at that length (Figure 13.16). For example, the **patellar** (pah-tel'ar) or **knee-jerk reflex** (Figure 13.16b) helps keep your knees from buckling when you are standing upright. As your knees begin to buckle and the quadriceps lengthens, the stretch reflex causes the quadriceps to contract without your having to think about it. The stretch reflex is important for maintaining muscle tone and adjusting it reflexively. It is most important in the large extensor muscles that sustain upright posture and in postural muscles of the trunk. For example, contractions of the postural muscles of the spine are almost continuously regulated by stretch reflexes initiated first on one side of the spine and then on the other.

Let's look at how the stretch reflex works. When muscle spindles are activated by stretch, the associated sensory neurons transmit impulses at a higher frequency to the spinal cord (Figure 13.17b). There the sensory neurons synapse directly with α motor neurons, which rapidly excite the extrafusal muscle fibers of the stretched muscle (Figure 13.16a). The reflexive muscle contraction that follows (an example of serial processing) resists further muscle

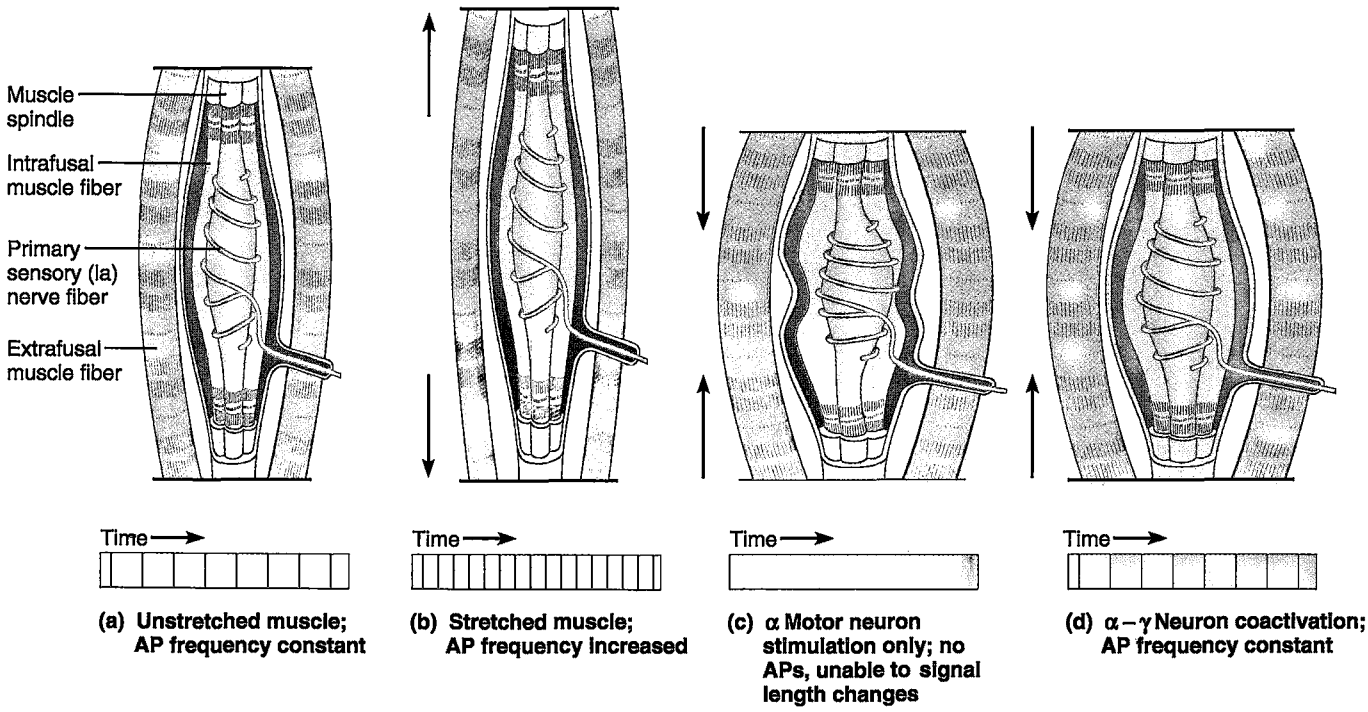

FIGURE 13.17 **Operation of the muscle spindle. (a)** Action potentials (APs) in unstretched muscle are generated at a constant rate in the associated sensory (Ia) fiber. **(b)** Stretching the muscle activates the muscle spindle, increasing the rate of AP generation. **(c)** Activation of α motor neurons alone causes contraction of extrafusal muscle fibers only. The muscle spindle becomes slack and unable to signal further length changes. **(d)** Coactivation of both α and γ motor neurons causes contraction of both extrafusal and intrafusal muscle fibers, maintaining tension on the muscle spindle. The muscle spindle can still signal changes in muscle length.

13

stretching. Branches of the afferent fibers also synapse with interneurons that inhibit motor neurons controlling antagonistic muscles (parallel processing), and the resulting inhibition is called **reciprocal inhibition.** Consequently, the stretch stimulus causes the antagonists to relax so that they cannot resist the shortening of the "stretched" muscle caused by the main reflex arc. While this spinal reflex is occurring, information on muscle length and the speed of muscle shortening is being relayed (mainly via the dorsal white columns) to higher brain centers (more parallel processing).

The most familiar clinical example of a stretch reflex is the knee-jerk reflex we have just described. Stretch reflexes can be elicited in any skeletal muscle by a sudden jolt to the tendon or the muscle itself. All stretch reflexes are **monosynaptic** and **ipsilateral;** that is, they involve a single synapse and motor activity on the same side of the body. Although stretch reflexes *themselves* are monosynaptic, the reflex arcs that inhibit the motor neurons serving the antagonistic muscles are polysynaptic.

A positive knee jerk (or a positive result for any other stretch reflex test) provides two important pieces of information. First, it proves that the sensory and motor connections between that muscle and the spinal cord are intact. Second, the vigor of the response indicates the degree of excitability of the spinal cord. When the spinal motor neurons are highly facilitated by impulses descending from higher centers, just touching the muscle tendon produces a vigorous reflex response. On the other hand, when the lower motor neurons are bombarded by inhibitory signals, even pounding on the tendon may fail to cause the reflex response.

HOMEOSTATIC IMBALANCE

Stretch reflexes tend to be either hypoactive or absent in cases of peripheral nerve damage or ventral horn injury involving the tested area. These reflexes are absent in those with chronic diabetes mellitus or neurosyphilis and during coma. However, they are hyperactive when lesions of the corticospinal tract reduce the inhibitory effect of the brain on the spinal cord (as in stroke patients). ●

Adjusting Muscle Spindle Sensitivity

During voluntary skeletal muscle contraction, the muscle shortens. If the intrafusal muscle fibers didn't contract along with the extrafusal fibers, then

the muscle spindle would go slack and cease generating action potentials (Figure 13.17c). At this point it would be unable to signal further changes in muscle length, so it would be useless. Fortunately, **α-γ coactivation** prevents this from happening. Descending fibers of motor pathways synapse with both α and γ motor neurons, and motor impulses are simultaneously sent to the large extrafusal fibers and to muscle spindle intrafusal fibers. Stimulating the intrafusal fibers maintains the spindle's tension (and sensitivity) during muscle contraction, so that the brain continues to be notified of conditions in the muscle. Without such a system, information on changes in muscle length would cease to flow from contracting muscles.

The motor supply to the muscle spindle also allows the brain to voluntarily modify the stretch reflex response and the firing rate of α motor neurons. When the γ neurons are vigorously stimulated by impulses from the brain, the spindle is stretched and highly sensitive, and muscle contraction force is maintained or increased. When the γ motor neurons are inhibited, the spindle resembles a loose rubber band and is nonresponsive, and the extrafusal muscles relax.

The ability to modify the stretch reflex is important in many situations. As the speed and difficulty of a movement increases, the brain increases γ motor output to increase the sensitivity of the muscle spindles. For example, a gymnast on a balance beam needs to have highly sensitive muscle spindles or she'll fall off. On the other hand, if you want to wind up to pitch a baseball, it is essential to suppress the stretch reflex so that your muscles can produce a large degree of motion (i.e., circumduct your pitching arm). Other athletes who require movements of maximum force learn to stretch muscles as much and as quickly as possible just before the movement. This advantage is demonstrated by the crouch that athletes assume just before jumping or running.

As we have seen, muscle tone and smooth coordination of movement depends upon having intact stretch reflex pathways. Both afferent and efferent fibers to the muscle spindle are vitally important. If either afferent or efferent fibers are cut, the muscle immediately loses its tone and becomes flaccid.

The Golgi Tendon Reflex

Whereas stretch reflexes cause muscle contraction in response to increased muscle length (stretch), the polysynaptic **Golgi tendon reflexes** produce exactly the opposite effect: muscle relaxation and lengthening in response to tension (Figure 13.18). When muscle tension increases substantially during contraction or passive stretching, high-threshold Golgi tendon organs in the tendon may be activated, and afferent impulses are transmitted to the spinal cord,

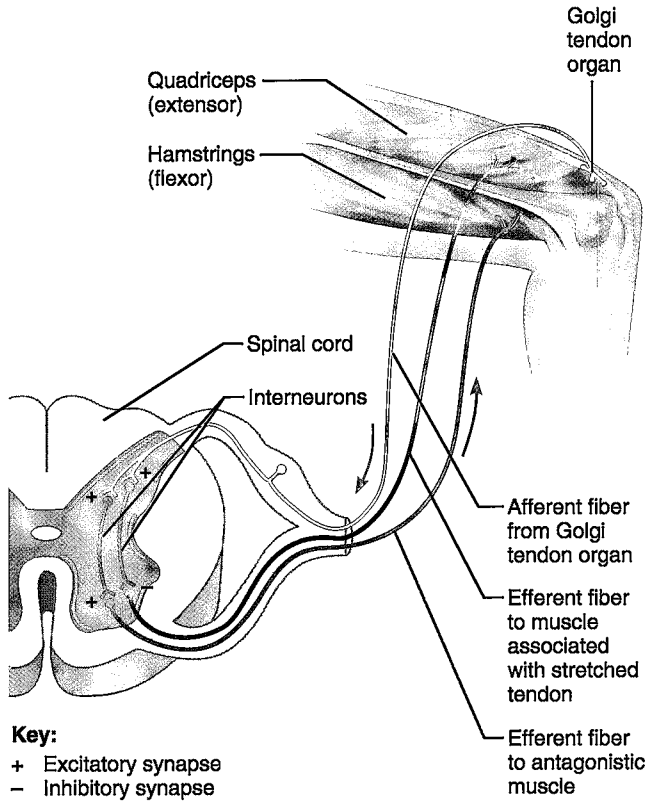

FIGURE 13.18 **The Golgi tendon reflex.** When the quadriceps muscle of the thigh contracts strongly, the tension in the patellar region increases, activating Golgi tendon organs in the tendon. Afferent neurons associated with the Golgi tendon organs synapse with interneurons in the spinal cord that inhibit motor neurons serving the contracting muscle and stimulate motor neurons activating the antagonistic muscle groups (the hamstrings). As a result, the contracting muscle relaxes and lengthens as the antagonist contracts and shortens.

and then to the cerebellum, where the information is used to adjust muscle tension. Simultaneously, motor neurons in spinal cord circuits supplying the contracting muscle are inhibited and antagonist muscles are activated, a phenomenon called **reciprocal activation.** As a result, the contracting muscle relaxes as its antagonist is activated.

Golgi tendon organs help avoid tearing of muscles and tendons subjected to possibly damaging stretching force. Golgi tendon organs also function at normal muscle tensions. In the normal range, Golgi tendon organs help to ensure smooth onset and termination of muscle contraction.

The Flexor and Crossed-Extensor Reflexes

The **flexor,** or **withdrawal, reflex** is initiated by a painful stimulus and causes automatic withdrawal of the threatened body part from the stimulus

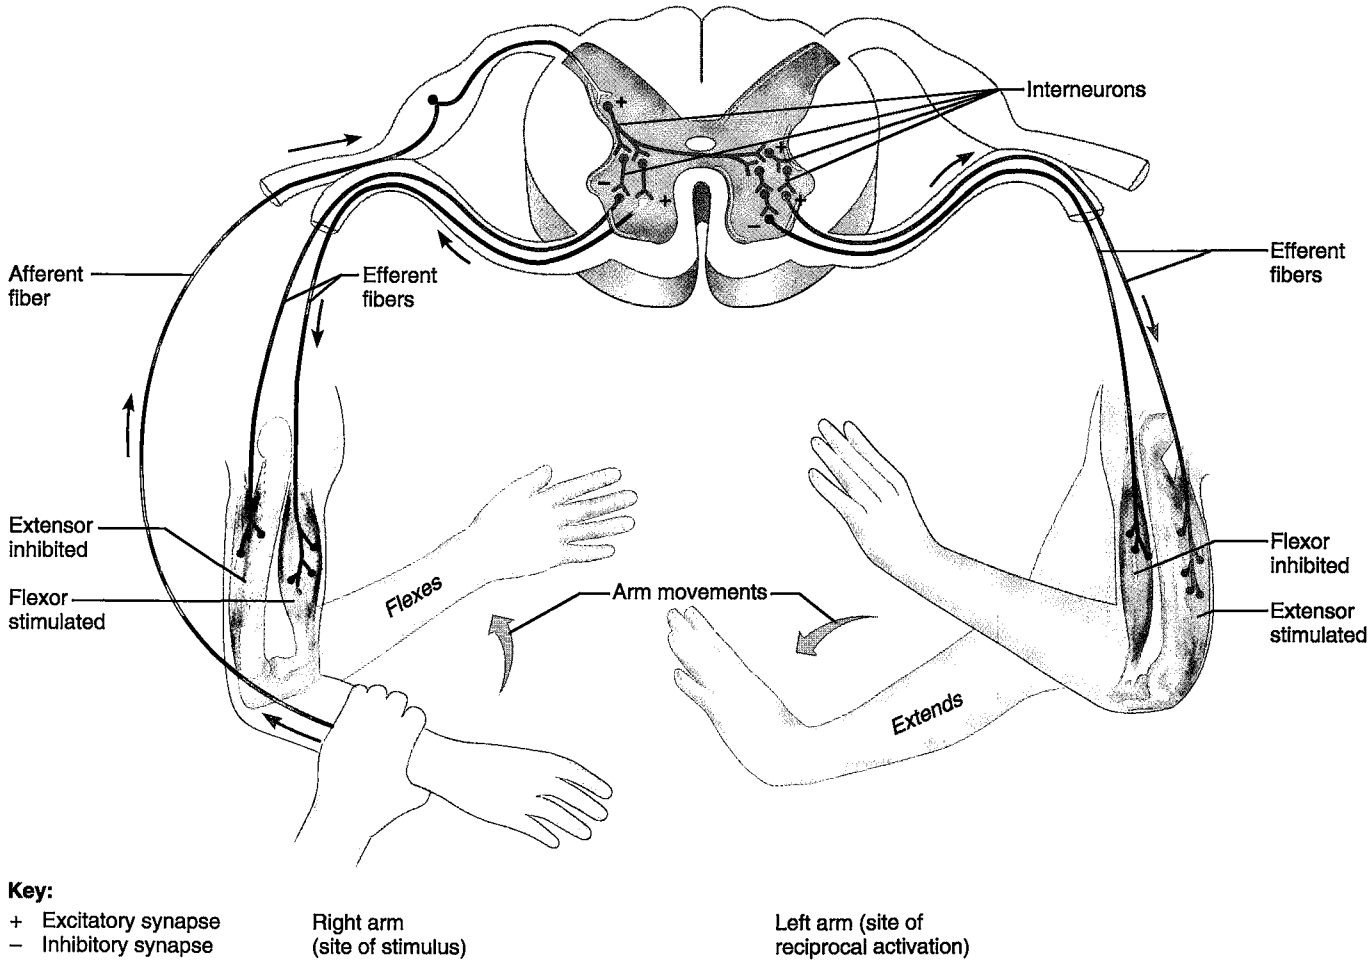

FIGURE 13.19 **The crossed-extensor reflex.** A noxious stimulus causes a flexor reflex on the same side, withdrawing that limb, as shown on the left side of the diagram. At the same time, the extensor muscles on the opposite side are activated. In the example illustrated, a stranger suddenly grasps one arm, which is reflexively withdrawn while the opposite arm reflexively extends and pushes the stranger away.

(Figure 13.19). The response that occurs when you prick your finger is a good example. Flexor reflexes are ipsilateral and polysynaptic, the latter a necessity when several muscles must be recruited to withdraw the injured body part. Because flexor reflexes are protective reflexes important to our survival, they override the spinal pathways and prevent any other reflexes from using them at the same time. However, this reflex, like other spinal reflexes, can be overridden by descending signals from the brain. This happens when you are expecting a painful stimulus, for example a skin prick as a lab technician prepares to draw blood from a vein.

The **crossed-extensor reflex** often accompanies the flexor reflex in weight-bearing limbs and is particularly important in maintaining balance. It is a complex spinal reflex consisting of an ipsilateral withdrawal reflex and a contralateral extensor reflex. Incoming afferent fibers synapse with interneurons that control the flexor withdrawal response on the same side of the body and with other interneurons that control the extensor muscles on the opposite side. This reflex is obvious when you step barefoot on broken glass. The ipsilateral response causes rapid lifting of the cut foot, while the contralateral response activates the extensor muscles of the opposite leg to support the weight suddenly shifted to it. The withdrawal reflex is also seen when someone unexpectedly grabs your arm. The grasped arm is withdrawn as the opposite arm pushes you away from the attacker (Figure 13.19).

Superficial Reflexes

Superficial reflexes are elicited by gentle cutaneous stimulation, such as that produced by stroking the skin with a tongue depressor. These clinically important reflexes depend both on functional upper motor pathways and on cord-level reflex arcs. The best known of these are the plantar and abdominal reflexes.

The **plantar reflex** tests the integrity of the spinal cord from L_4 to S_2 and indirectly determines if the corticospinal tracts are functioning properly. It is elicited by drawing a blunt object downward along the lateral aspect of the plantar surface (sole) of the foot. The normal response is a downward flexion (curling) of the toes. However, if the primary motor cortex or corticospinal tract is damaged, the plantar reflex is replaced by an abnormal reflex called **Babinski's sign,** in which the great toe dorsiflexes and the smaller toes fan laterally. Infants exhibit Babinski's sign until they are about a year old because their nervous systems are incompletely myelinated. Despite its clinical significance, the physiological mechanism of Babinski's sign is not understood.

Stroking the skin of the lateral abdomen above, to the side, or below the umbilicus induces a reflex contraction of the abdominal muscles in which the umbilicus moves toward the stimulated site. These reflexes, called **abdominal reflexes,** check the integrity of the spinal cord and ventral rami from T_8 to T_{12}. The abdominal reflexes vary in intensity from one person to another. They are absent when corticospinal tract lesions are present.

Developmental Aspects of the Peripheral Nervous System

Most skeletal muscles derive from paired blocks of mesoderm (somites) distributed segmentally down the posteromedial aspect of the embryo. The spinal nerves branch from the developing spinal cord and adjacent neural crest and exit between the forming vertebrae, and each nerve becomes associated with the adjacent muscle mass. The spinal nerves supply both sensory and motor fibers to the developing muscles and help direct their maturation. Cranial nerves innervate muscles of the head in a comparable manner.

The distribution of cutaneous nerves to the skin follows a similar pattern. Most of the scalp and facial skin is innervated by the trigeminal nerves. Spinal nerves supply cutaneous branches to specific (adjacent) dermatomes that eventually become dermal segments. Thus, the distribution and growth of the spinal nerves correlate with the segmented body plan, which is established by the fourth week of embryonic development.

Growth of the limbs and unequal growth of other body areas result in an adult pattern of dermatomes with unequal sizes and shapes and varying degrees of overlap. Because embryonic muscle cells migrate extensively, much of the early segmental pattern is lost. Understanding the general pattern of sensory nerve distribution is critical for physicians. For example, in areas of substantial dermatome overlap, two or three spinal nerves must be blocked to perform local surgery.

Sensory receptors atrophy to some degree with age, and there is some lessening of muscle tone in the face and neck. Reflexes occur a bit more slowly during old age. This deterioration seems to reflect a general loss of neurons, fewer synapses per neuron, and a slowdown in central processing rather than any major changes in the peripheral nerve fibers. In fact, the peripheral nerves remain viable and normally functional throughout life unless subjected to traumatic injury or ischemia. The most common symptom of ischemia is a tingling sensation or numbness in the affected region.

■ ■ ■

The PNS is an essential part of any functional nervous system. Without it, the CNS would lack its rich bank of information about events of the external and internal environments. Now that we have connected the CNS to both of these environments, we are ready to consider the autonomic nervous system, the topic of Chapter 14.

Related Clinical Terms

Analgesia (an"al-je'zeah; *an* = without; *algos* = pain) Reduced ability to feel pain, not accompanied by loss of consciousness. An analgesic is a pain-relieving drug.

Dysarthria (dis-ar'thre-ah) Difficulty in speech articulation due to motor pathway disorders that result in weakness, uncoordinated motion, or altered respiration or rhythm. For example, lesions of cranial nerves IX, X, and XII result in nasal, breathy speech, and lesions in upper motor pathways produce a hoarse, strained voice. Not to be confused with *dysphasia* or *aphasia*, which are disorders of language processing.

Dystonia (dis-to'ne-ah) Impairment of muscle tone.

Nerve conduction studies Diagnostic tests that assess nerve integrity as indicated by their conduction velocities; the nerve is stimulated at one point, activity is recorded at a second point a known distance away, and the time required for the response to reach the recording electrode is measured; used to assess suspected peripheral neuropathies.

Neuralgia (nu-ral'je-ah; *neuro* = nerve) Sharp spasmlike pain along the course of one or more nerves; may be caused by inflammation or injury to the nerve(s) (for example, trigeminal neuralgia).

Neuritis (nu-ri'tis) Inflammation of a nerve; there are many forms with different effects (e.g., increased or decreased nerve sensitivity, paralysis of structure served, and pain).

Paresthesia (par"es-the'ze-ah) An abnormal sensation (burning, numbness, tingling) in the absence of stimuli; caused by a sensory nerve disorder.

Tabes dorsalis (ta'bēz dor-sa'lis) A slowly progressive condition caused by deterioration of the posterior tracts (gracilis and cuneatus) and associated dorsal roots; a late sign of the neurological damage caused by the syphilis bacterium. Because joint proprioceptor tracts are destroyed, affected individuals have poor muscle coordination and an unstable gait. Bacterial invasion of the sensory (dorsal) roots results in pain, which ends when dorsal root destruction is complete.

Chapter Summary

1. The peripheral nervous system consists of sensory receptors, nerves conducting impulses to and from the CNS, their associated ganglia, and motor endings.

PART 1: SENSORY RECEPTORS AND SENSATION

Sensory Receptors (pp. 491–494)

1. Sensory receptors are specialized to respond to environmental changes (stimuli).

2. Sensory receptors include the simple (general) receptors for pain, touch, pressure, and temperature found in the skin, as well as those found in skeletal muscles and tendons and in the visceral organs. Complex receptors (sense organs), consisting of sensory receptors and other cells, serve the special senses (vision, hearing, equilibrium, smell, and taste).

3. Receptors are classified according to stimulus detected as mechanoreceptors, thermoreceptors, photoreceptors, chemoreceptors, and nociceptors, and according to location as exteroceptors, interoceptors, and proprioceptors.

4. The general sensory receptors are classified structurally as free or encapsulated nerve (receptor) endings of sensory neurons. The free endings are mainly receptors for temperature and pain, although two are for light touch (Merkel discs and hair follicle receptors). The encapsulated endings, which are mechanoreceptors, include Meissner's corpuscles, Pacinian corpuscles, Ruffini endings, muscle spindles, Golgi tendon organs, and joint kinesthetic receptors.

Overview: From Sensation to Perception (pp. 494–498)

1. Sensation is awareness of internal and external stimuli; perception is conscious interpretation of those stimuli.

2. The three levels of sensory integration are the receptor, circuit, and perceptual levels. These levels are functions of the sensory receptors, the ascending pathways, and the cerebral cortex, respectively.

3. Sensory receptors transduce (convert) stimulus energy via receptor or generator potentials into action potentials. Stimulus strength is frequency coded. Adaptation (decreased response to a continuous or unchanging stimulus) is seen in all general receptors except pain and proprioceptors.

4. Some sensory fibers entering the spinal cord act in local reflex arcs. Some synapse with the dorsal horn neurons (nonspecific ascending pathways), and others continue upward to synapse in medullary nuclei (specific ascending pathways). Second-order neurons of both specific and nonspecific ascending pathways terminate in the thalamus.

5. Perception—the internal, conscious image of the stimulus that serves as the basis for response—is the result of cortical processing.

6. The main aspects of sensory perception are detection, magnitude estimation, spatial discrimination, feature abstraction, quality discrimination, and pattern recognition.

PART 2: TRANSMISSION LINES: NERVES AND THEIR STRUCTURE AND REPAIR

Nerves and Associated Ganglia (pp. 498–500)

1. A nerve is a bundle of axons in the PNS. Each fiber is enclosed by an endoneurium, fascicles of fibers are wrapped by a perineurium, and the whole nerve is bundled by the epineurium.

2. Nerves are classified according to the direction of impulse conduction as sensory, motor, or mixed; most nerves are mixed. The efferent fibers may be somatic or autonomic.

3. Ganglia are collections of neuron cell bodies associated with nerves in the PNS. Examples are the dorsal root (sensory) ganglia and autonomic (motor) ganglia.

4. Injured PNS fibers may regenerate if macrophages enter the area, phagocytize the debris, and promote Schwann cell proliferation. Schwann cells then form a channel and secrete chemicals to guide axon sprouts to their original contacts. Fibers in the CNS do not normally regenerate because the oligodendrocytes inhibit axonal sprouting and regrowth.

Cranial Nerves (pp. 500–508)

1. Twelve pairs of cranial nerves originate from the brain and issue through the skull to innervate the head and neck. Only the vagus nerves extend into the thoracic and abdominal cavities.

2. Cranial nerves are numbered from anterior to posterior in order of emergence from the brain. Their names reflect structures served or function or both. The cranial nerves include

- The olfactory nerves (I): purely sensory; concerned with the sense of smell.
- The optic nerves (II): purely sensory; transmit visual impulses from the retina to the thalamus.
- The oculomotor nerves (III): primarily motor; emerge from the midbrain and serve four extrinsic eye muscles, the levator palpebrae superioris of the eyelid, and the intrinsic ciliary muscle of the eye and constrictor fibers of the iris. Also carry proprioceptive impulses from the skeletal muscles served.
- The trochlear nerves (IV): primarily motor; emerge from the dorsal midbrain and carry motor and proprioceptor impulses to and from superior oblique muscles of the eyeballs.
- The trigeminal nerves (V): mixed nerves; emerge from the lateral pons as the major general sensory nerves of the face. Each has three sensory divisions: ophthalmic, maxillary, and mandibular; the mandibular branch also contains motor fibers that innervate the chewing muscles.

- The abducens nerves (VI): primarily motor; emerge from the pons and serve the motor and proprioceptive functions of the lateral rectus muscles of the eyeballs.
- The facial nerves (VII): mixed nerves; emerge from the pons as the major motor nerves of the face. Also carry sensory impulses from the taste buds of anterior two-thirds of the tongue.
- The vestibulocochlear nerves (VIII): mostly sensory; transmit impulses from the hearing and equilibrium receptors of the inner ears.
- The glossopharyngeal nerves (IX): mixed nerves; issue from the medulla. Transmit sensory impulses from the taste buds of the posterior tongue, from the pharynx, and from chemo- and baroreceptors of the carotid bodies and sinuses. Innervate some pharyngeal muscles and parotid glands.
- The vagus nerves (X): mixed nerves; arise from the medulla. Almost all motor fibers are autonomic parasympathetic fibers; motor efferents to, and sensory fibers from, the pharynx, larynx, and visceral organs of the thoracic and abdominal cavities.
- The accessory nerves (XI): primarily motor; consist of a cranial root arising from the medulla and a spinal root arising from the cervical spinal cord. Cranial root supplies motor fibers to the pharynx and larynx; spinal root supplies somatic efferents to the trapezius and sternocleidomastoid muscles of the neck and carries proprioceptor afferents from the same muscles.
- The hypoglossal nerves (XII): primarily motor; issue from the medulla and carry somatic motor efferents to, and proprioceptive fibers from, the tongue muscles.

Spinal Nerves (pp. 508–518)

1. The 31 pairs of spinal nerves (all mixed nerves) are numbered successively according to the region of the spinal cord from which they issue.

2. Spinal nerves are formed by the union of dorsal and ventral roots of the spinal cord and are short, confined to the intervertebral foramina.

3. Branches of each spinal nerve include dorsal and ventral rami, and a meningeal branch, and in the thoracic region, rami communicantes (ANS branches).

4. Ventral rami, except T_2–T_{12}, form plexuses that serve the limbs.

5. Dorsal rami serve the muscles and skin of the posterior body trunk. T_1–T_{12} ventral rami give rise to intercostal nerves that serve the thorax wall and abdominal surface.

6. The cervical plexus (C_1–C_4) innervates the muscles and skin of the neck and shoulder. Its phrenic nerve serves the diaphragm.

7. The brachial plexus serves the shoulder, some thorax muscles, and the upper limb. It arises primarily from C_5–T_1. Proximal to distal, the brachial plexus has roots, trunks, divisions, and cords. The main nerves arising from the cords are the axillary, musculocutaneous, median, radial, and ulnar nerves.

8. The lumbar plexus (L_1–L_4) provides the motor supply to the anterior and medial thigh muscles and the cutaneous supply to the anterior thigh and part of the leg. Its chief nerves are the femoral and obturator.

9. The sacral plexus (L_4–S_4) supplies the posterior muscles and skin of the lower limb. Its principal nerve is the large sciatic nerve composed of the tibial and common fibular nerves.

10. Joints are innervated by the same nerves that serve the muscles acting at the joint. All spinal nerves except C_1 innervate specific segments of the skin called dermatomes.

PART 3: MOTOR ENDINGS AND MOTOR ACTIVITY

Peripheral Motor Endings (p. 519)

1. Motor endings of somatic nerve fibers (axon terminals) help to form elaborate neuromuscular junctions with skeletal muscle cells. Axon terminals contain synaptic vesicles filled with acetylcholine, which (when released) signals the muscle cell to contract. An elaborate basal lamina fills the synaptic cleft.

2. Autonomic motor endings, called varicosities, are functionally similar, but structurally simpler, beaded terminals that innervate smooth muscle and glands. They do not form specialized neuromuscular junctions and generally a wider synaptic cleft separates them from their effector cells.

Overview of Motor Integration: From Intention to Effect (pp. 519–521)

1. Motor mechanisms operate at the level of the effectors (muscle fibers), descending circuits, and control levels of motor behavior.

2. The motor control hierarchy consists of the segmental level, the projection level, and the precommand level.

3. The segmental level is the spinal cord circuitry that activates ventral horn motor neurons to stimulate the muscles. It consists of reflexes and central pattern generators (CPGs), segmental circuits controlling locomotion.

4. The projection level consists of descending fibers that project to and control the segmental level. These fibers issue from the brain stem motor areas [indirect (extrapyramidal) system] and cortical motor areas [direct (pyramidal) system]. Command neurons in the brain stem appear to turn CPGs on and off, or to modulate them.

5. The cerebellum and basal nuclei constitute the precommand areas that subconsciously integrate mechanisms mediated by the projection level.

PART 4: REFLEX ACTIVITY

The Reflex Arc (pp. 521–522)

1. A reflex is a rapid, involuntary motor response to a stimulus. The reflex arc has five elements: receptor, sensory neuron, integration center, motor neuron, and effector.

Spinal Reflexes (pp. 522–527)

1. Testing of somatic spinal reflexes provides information on the integrity of the reflex pathway and the degree of excitability of the spinal cord.

2. Somatic spinal reflexes include stretch, Golgi tendon, flexor, crossed-extensor, and superficial reflexes.

3. A stretch reflex, initiated by stretching of muscle spindles, causes contraction of the stimulated muscle and inhibits its antagonist. It is monosynaptic and ipsilateral. Stretch reflexes maintain muscle tone and body posture.

4. Golgi tendon reflexes, initiated by stimulation of Golgi tendon organs by excessive muscle tension, are polysynaptic reflexes. They cause relaxation of the stimulated muscle and contraction of its antagonist to prevent muscle and tendon damage.

5. Flexor reflexes are initiated by painful stimuli. They are polysynaptic, ipsilateral reflexes that are protective in nature.

6. Crossed-extensor reflexes consist of an ipsilateral flexor reflex and a contralateral extensor reflex.

7. Superficial reflexes (e.g., the plantar and abdominal reflexes) are elicited by cutaneous stimulation. They require functional cord reflex arcs and corticospinal pathways.

Developmental Aspects of the Peripheral Nervous System (p. 527)

1. Each spinal nerve provides the sensory and motor supply of an adjacent muscle mass (destined to become skeletal muscles) and the cutaneous supply of a dermatome (skin segment).

2. Reflexes decline in speed with age; this probably reflects neuronal loss or sluggish CNS integration circuits.

Review Questions

Multiple Choice/Matching

(Some questions have more than one correct answer. Select the best answer or answers from the choices given.)

1. The large onion-shaped receptors that are found deep in the dermis and in subcutaneous tissue and that respond to deep pressure are (a) Merkel discs, (b) Pacinian corpuscles, (c) free nerve endings, (d) muscle spindles.

2. Proprioceptors include all of the following except (a) muscle spindles, (b) Golgi tendon organs, (c) Merkel discs, (d) joint kinesthetic receptors.

3. The aspect of sensory perception by which the cerebral cortex identifies the site or pattern of stimulation is (a) perceptual detection, (b) feature abstraction, (c) pattern recognition, (d) spatial discrimination.

4. The neural machinery of the spinal cord is at the (a) precommand level, (b) projection level, (c) segmental level.

5. Dorsal root ganglia contain (a) cell bodies of somatic motor neurons, (b) axon terminals of somatic motor neurons, (c) cell bodies of autonomic motor neurons, (d) axon terminals of sensory neurons, (e) cell bodies of sensory neurons.

6. The connective tissue sheath that surrounds a fascicle of nerve fibers is the (a) epineurium, (b) endoneurium, (c) perineurium, (d) neurilemma.

7. Match the receptor type from column B to the correct description in column A.

Column A	Column B
____ (1) pain, itch, and temperature receptors	(a) Ruffini endings
____ (2) contains intrafusal fibers and type Ia and II sensory endings	(b) Golgi tendon organ
____ (3) discriminative touch receptor in hairless skin (fingertips)	(c) muscle spindle
____ (4) contains receptor endings wrapped around thick collagen bundles	(d) free nerve endings
____ (5) rapidly adapting deep-pressure receptor	(e) Pacinian corpuscle
____ (6) slowly adapting deep-pressure receptor	(f) Meissner's corpuscle

8. Match the names of the cranial nerves in column B to the appropriate description in column A.

Column A	Column B
____ (1) causes pupillary constriction	(a) abducens
____ (2) is the major sensory nerve of the face	(b) accessory
____ (3) serves the sternocleidomastoid and trapezius muscles	(c) facial
____ (4) are purely sensory (two nerves)	(d) glossopharyngeal
____ (5) serves the tongue muscles	(e) hypoglossal
____ (6) allows you to chew your food	(f) oculomotor
____ (7) is impaired in Bell's palsy	(g) olfactory
____ (8) helps to regulate heart activity	(h) optic
____ (9) helps you to hear and to maintain your balance	(i) trigeminal
	(j) trochlear
	(k) vagus
	(l) vestibulocochlear

____, ____, ____, ____ (10) contain parasympathetic motor fibers (four nerves)

9. For each of the following muscles or body regions, identify the plexus and the peripheral nerve(s) (or branch of one) involved. Use choices from keys A and B.

	Key A: Plexuses
____; ____ (1) the diaphragm	(a) brachial
____; ____ (2) muscles of the posterior leg	(b) cervical
____; ____ (3) anterior thigh muscles	(c) lumbar
____; ____ (4) medial thigh muscles	(d) sacral
____; ____ (5) anterior arm muscles that flex the forearm	**Key B: Nerves**
____; ____ (6) muscles that flex the wrist and digits (two nerves)	(1) common fibular
____; ____ (7) muscles that extend the wrist and digits	(2) femoral
____; ____ (8) skin and extensor muscles of the posterior arm	(3) median
____; ____ (9) fibularis muscles, tibialis anterior, and toe extensors	(4) musculocutaneous
	(5) obturator
	(6) phrenic
	(7) radial
	(8) tibial
	(9) ulnar

____; ____, ____, ____, ____ (10) elbow joint

10. Characterize each receptor activity described below by choosing the appropriate letter and number(s) from keys A and B.

____, ____ (1) You are enjoying an ice cream cone.
____, ____ (2) You have just scalded yourself with hot coffee.
____, ____ (3) The retinas of your eyes are stimulated.
____, ____ (4) You bump (lightly) into someone.
____, ____ (5) You are in a completely dark room and reaching toward the light switch.
____, ____ (6) You feel uncomfortable after a large meal.

Key A:
(a) exteroceptor
(b) interoceptor
(c) proprioceptor

Key B:
(1) chemoreceptor
(2) mechanoreceptor
(3) nociceptor
(4) photoreceptor
(5) thermoreceptor

11. A reflex that causes reciprocal activation of the antagonist muscle is the (a) crossed-extensor, (b) flexor, (c) Golgi tendon, (d) muscle stretch.

Short Answer Essay Questions

12. What is the functional relationship of the peripheral nervous system to the central nervous system?

13. List the structural components of the peripheral nervous system, and describe the function of each component.

14. Differentiate clearly between sensation and perception.

15. Central pattern generators (CPGs) are found at the segmental level of motor control. (a) What is the job of the CPGs? (b) What controls them, and where is this control localized?

16. Make a diagram of the hierarchy of motor control. Position the CPGs, the command neurons, and the cerebellum and basal nuclei in this scheme.

17. How do the types of motor activity controlled by the direct (pyramidal) and indirect systems differ?

18. Describe the functional problems that would be experienced by a person in which these fiber tracts have been cut: (a) lateral spinothalamic, (b) anterior and posterior spinocerebellar, (c) tectospinal.

19. Why are the cerebellum and basal nuclei called *pre*command areas?

20. Explain why damage to peripheral nerve fibers is often reversible, whereas damage to CNS fibers rarely is.

21. (a) Describe the formation and composition of a spinal nerve. (b) Name the branches of a spinal nerve (other than the rami communicantes), and indicate their distribution.

22. (a) Define plexus. (b) Indicate the spinal roots of origin of the four major nerve plexuses, and name the general body regions served by each.

23. Differentiate between ipsilateral and contralateral reflexes.

24. What is the homeostatic value of flexor reflexes?

25. Compare and contrast flexor and crossed-extensor reflexes.

26. Explain how a crossed-extensor reflex exemplifies both serial and parallel processing.

27. What clinical information can be gained by conducting somatic reflex tests?

28. What is the structural and functional relationship between spinal nerves, skeletal muscles, and dermatomes?

Critical Thinking and Clinical Application Questions

1. In 1962 a boy playing in a train yard fell under a train. His right arm was cut off cleanly by the train wheel. Surgeons reattached the arm, sewing nerves and vessels back together. The boy was told he should eventually regain the use of his arm but that it would never be strong enough to pitch a baseball. Explain why full recovery of strength was unlikely.

2. Jefferson, a football quarterback, suffered torn menisci in his right knee joint when tackled from the side. The same injury crushed his common fibular nerve against the head of the fibula. What locomotor problems did Jefferson have after this?

3. As Harry fell off a ladder, he grabbed a tree branch with his right hand, but unfortunately lost his grip and fell heavily to the ground. Days later, Harry complained that his upper limb was numb. What was damaged in his fall?

4. Mr. Frank, a former stroke victim who had made a remarkable recovery, suddenly began to have problems reading. He complained of seeing double and also had problems navigating steps. He was unable to move his left eye downward and laterally. What cranial nerve was the site of lesion? (Right or left?)

5. One of a group of rabbit hunters was accidentally sprayed with buckshot in both of his gluteal prominences. When his companions saw that he would survive, they laughed and joked about where he had been shot. They were horrified and ashamed a week later when it was announced that their friend would be permanently paralyzed and without sensation in both legs from the knee down, as well as on the back of his thighs. What had happened?

6. You are at a party at Mary's house. After you are blindfolded, an object (a key *or* a rabbit's foot) is placed in your hand. What spinal tracts carry the signals to the cortex that will allow you to differentiate between these objects, and what aspects of sensory perception are operating?

7. Fumiko, a 19-year-old nursing student, had had a runny nose and sore throat for several days. Upon waking, her face felt "twisted." When she examined her face in the mirror, she noticed that the right side looked "droopy" and she was unable to move the facial muscles on that side. This made it difficult to eat or speak clearly. Which cranial nerve was affected and on which side? What is a common cause of this condition?

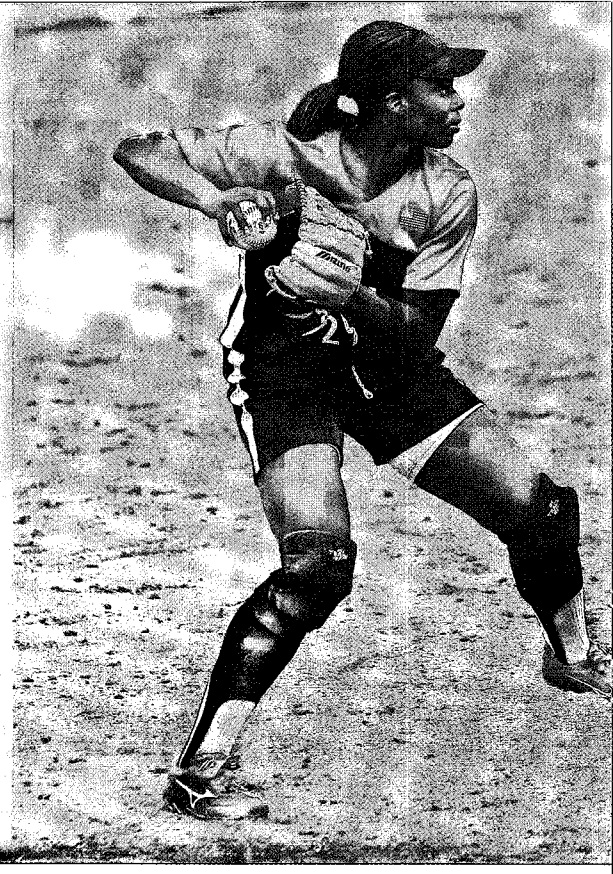
CHAPTER

The Autonomic Nervous System



Introduction (pp. 533–535)

1. Define autonomic nervous system and explain its relationship to the peripheral nervous system.
2. Compare the somatic and autonomic nervous systems relative to effectors, efferent pathways, and neurotransmitters released.
3. Compare and contrast the functions of the parasympathetic and sympathetic divisions.

ANS Anatomy (pp. 535–543)

4. For the parasympathetic and sympathetic divisions, describe the site of CNS origin, locations of ganglia, and general fiber pathways.

ANS Physiology (pp. 543–547, 550)

5. Define cholinergic and adrenergic fibers, and list the different types of their receptors.
6. Describe the clinical importance of drugs that mimic or inhibit adrenergic or cholinergic effects.
7. State the effects of the parasympathetic and sympathetic divisions on the following organs: heart, blood vessels, gastrointestinal tract, lungs, adrenal medulla, and external genitalia.
8. Describe autonomic nervous system controls.

Homeostatic Imbalances of the ANS (pp. 550–551)

9. Explain the relationship of some types of hypertension, Raynaud's disease, and autonomic dysreflexia to disorders of autonomic functioning.

Developmental Aspects of the ANS (p. 551)

10. Describe some effects of aging on the autonomic nervous system.

The human body is exquisitely sensitive to changes in its internal environment, and engages in a lifelong struggle to balance competing demands for resources under ever-changing conditions. Although all body systems contribute, the stability of our internal environment depends largely on the **autonomic nervous system (ANS),** the system of motor neurons that innervates smooth and cardiac muscle and glands (Figure 14.1). At every moment, signals stream from visceral organs into the CNS, and autonomic nerves make adjustments as necessary to ensure optimal support for body activities. In response to changing conditions, the ANS shunts blood to "needy" areas, speeds or slows heart rate, adjusts blood pressure and body temperature, and increases or decreases stomach secretions.

Most of this fine-tuning occurs without our awareness or attention. Can you tell when your arteries are constricting or when your pupils are dilating? Probably not, but if you've ever been stuck in a checkout line, and your full bladder was contracting as if it had a mind of its own, you've been very aware of a visceral activity. These functions, both those we're aware of and those that occur without our awareness or attention, are controlled by the ANS. Indeed, as the term *autonomic* (*auto* = self; *nom* = govern) implies, this motor subdivision of the peripheral nervous system has a certain amount of functional independence. The ANS is also called the **involuntary nervous system,** which reflects its subconscious control, or the **general visceral motor system,** which indicates the location of most of its effectors.

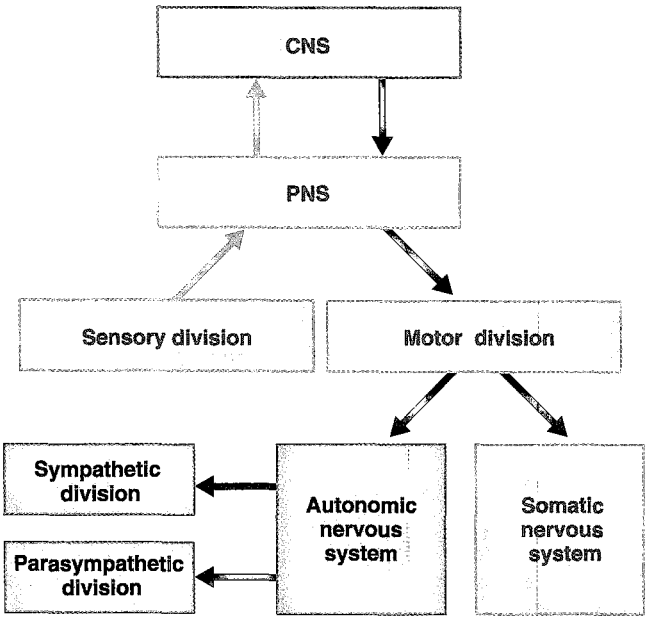


FIGURE 14.1 **Place of the ANS in the structural organization of the nervous system.**

Introduction

Comparison of the Somatic and Autonomic Nervous Systems

Our previous discussions of motor nerves have focused largely on the activity of the somatic nervous system. So, before describing autonomic nervous system anatomy, we will point out the major differences between the somatic and autonomic systems as well as some areas of functional overlap. Although both systems have motor fibers, the somatic and autonomic nervous systems differ (1) in their effectors, (2) in their efferent pathways, and (3) to some degree in target organ responses to their neurotransmitters. The differences are summarized in Figure 14.2.

Effectors

The somatic nervous system stimulates skeletal muscles, whereas the ANS innervates cardiac and smooth muscle and glands. Differences in the physiology of the effector organs account for most of the remaining differences between somatic and autonomic effects on their target organs.

Efferent Pathways and Ganglia

In the somatic nervous system, the motor neuron cell bodies are in the CNS, and their axons extend in spinal or cranial nerves all the way to the skeletal muscles they activate. Somatic motor fibers are typically thick, heavily myelinated group A fibers that conduct nerve impulses rapidly.

In contrast, the ANS uses a *two-neuron chain* to its effectors. The cell body of the first neuron, the **preganglionic neuron,** resides in the brain or spinal cord. Its axon, the **preganglionic axon,** synapses with the second motor neuron, the **ganglionic neuron,** in an **autonomic ganglion** outside the CNS. The axon of the ganglionic neuron, called the **postganglionic axon,** extends to the effector organ. If you think about the meanings of all these terms while referring to Figure 14.2, understanding the rest of the chapter will be much easier. Preganglionic axons are lightly myelinated, thin fibers; postganglionic axons are even thinner and are unmyelinated. Consequently, conduction through the autonomic efferent chain is slower than conduction in the somatic motor system. For most of their course, many pre- and postganglionic fibers are incorporated into spinal or cranial nerves.

Keep in mind that autonomic ganglia are *motor* ganglia, containing the cell bodies of motor neurons. Technically, they are sites of synapse and information transmission from preganglionic to ganglionic neurons. Also, remember that the somatic motor

Q *Why are the axons of the first and second neurons of the two-neuron motor autonomic chain named the preganglionic and postganglionic axons respectively?*

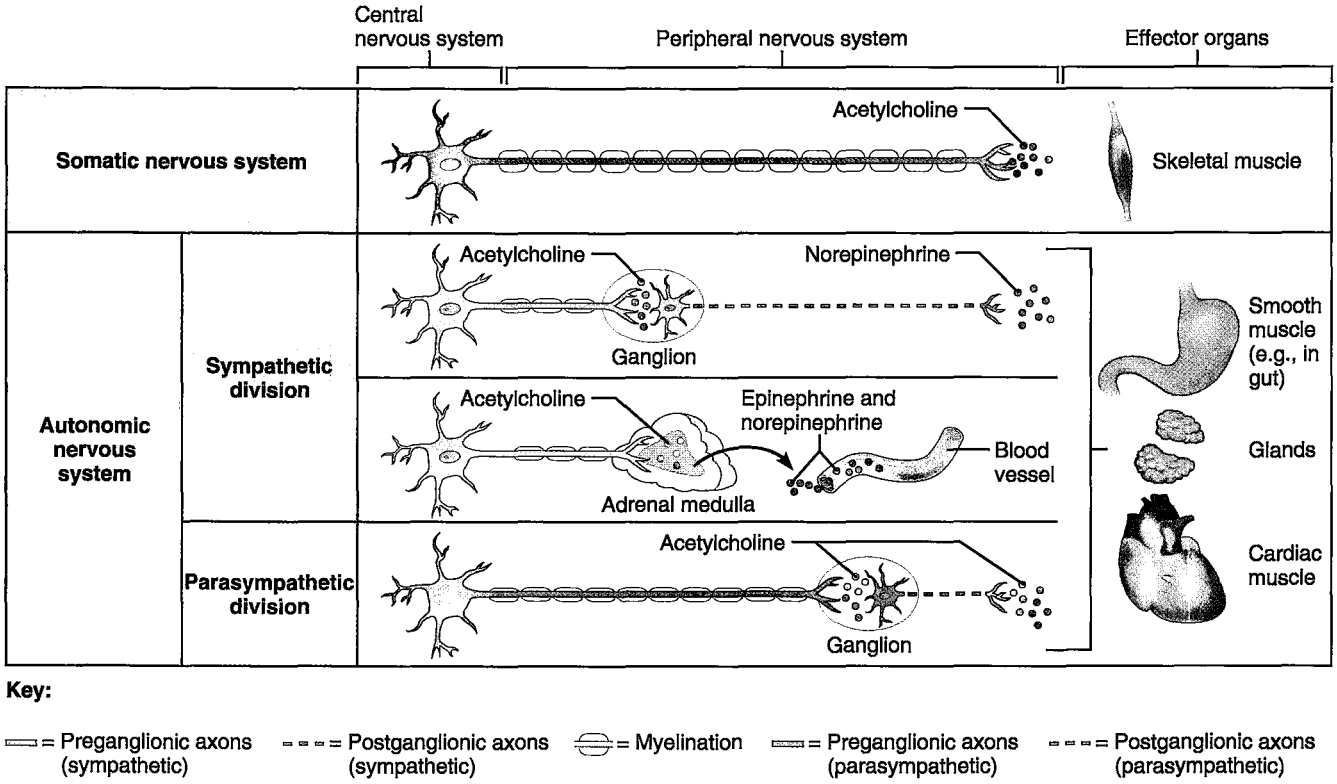

FIGURE 14.2 **Comparison of somatic and autonomic nervous systems.** *Somatic Division:* Axons of somatic motor neurons extend from the CNS to their effectors (skeletal muscle cells). These axons are typically heavily myelinated. Somatic motor neurons release acetylcholine, and the effect is always stimulatory.
Autonomic Division: Axons of most preganglionic neurons run from the CNS to synapse in a peripheral autonomic ganglion with a ganglionic neuron. A few sympathetic preganglionic axons synapse with cells of the adrenal medulla. Postganglionic axons run from the ganglion to effectors (cardiac and smooth muscle fibers and glands). Preganglionic axons are lightly myelinated; postganglionic axons are unmyelinated. All preganglionic fibers release acetylcholine; all parasympathetic postganglionic fibers release acetylcholine; most sympathetic postganglionic fibers release norepinephrine. Stimulated adrenal medullary cells release norepinephrine and epinephrine into the blood. Autonomic effects are stimulatory or inhibitory, depending on the postganglionic neurotransmitter released and the receptor types on the effector organs.

division *lacks* ganglia entirely. The dorsal root ganglia are part of the sensory, not the motor, division of the PNS.

Neurotransmitter Effects

All somatic motor neurons release **acetylcholine (ACh)** at their synapses with skeletal muscle fibers. The effect is always *excitatory,* and if stimulation reaches threshold, the muscle fibers contract.

Neurotransmitters released onto visceral effector organs by postganglionic autonomic fibers include **norepinephrine (NE)** secreted by most sympathetic fibers, and ACh released by parasympathetic fibers. Depending on the type of receptors present on the target organ (Figure 14.2 and Table 14.3 on p. 544), the organ's response may be either excitation or inhibition.

Overlap of Somatic and Autonomic Function

Higher brain centers regulate and coordinate both somatic and autonomic motor activities, and nearly all spinal nerves (and many cranial nerves) contain

A *The axon of the preganglionic neuron spans the distance between the CNS and the autonomic ganglion, whereas the ganglionic neuron's axon lies distal to ("post") the ganglion.*

both somatic and autonomic fibers. Moreover, most of the body's adaptations to changing internal and external conditions involve both skeletal muscle activity and enhanced responses of certain visceral organs. For example, when skeletal muscles are working hard, they need more oxygen and glucose and so autonomic control mechanisms speed up heart rate and dilate airways to meet these needs and maintain homeostasis. The ANS is only one part of our highly integrated nervous system, but according to convention we will consider it an individual entity and describe its role in isolation in the sections that follow.

ANS Divisions

The two arms of the ANS, the *parasympathetic* and *sympathetic divisions*, generally serve the same visceral organs but cause essentially opposite effects. If one division stimulates certain smooth muscles to contract or a gland to secrete, the other division inhibits that action. Through this **dual innervation,** the two divisions counterbalance each other's activities to keep body systems running smoothly. The sympathetic division mobilizes the body during activity, whereas the parasympathetic arm promotes maintenance functions and conserves body energy. Let's elaborate on these functional differences by focusing briefly on extreme situations in which each division is exerting primary control.

Role of the Parasympathetic Division

The **parasympathetic division,** sometimes called the "resting and digesting" system, keeps body energy use as low as possible, even as it directs vital "housekeeping" activities like digestion and elimination of feces and urine. (This explains why it is a good idea to relax after a heavy meal: so that digestion is not interfered with by sympathetic activity.) Parasympathetic activity is best illustrated in a person who relaxes after a meal and reads the newspaper. Blood pressure and heart rate are regulated at low normal levels, and the gastrointestinal tract is actively digesting food. In the eyes, the pupils are constricted and the lenses are accommodated for close vision to improve the clarity of the close-up image.

Role of the Sympathetic Division

The **sympathetic division** is often referred to as the "fight-or-flight" system. Its activity is evident when we are excited or find ourselves in emergency or threatening situations, such as being frightened by street toughs late at night. A rapidly pounding heart; deep breathing; dry mouth; cold, sweaty skin; and dilated eye pupils are sure signs of sympathetic nervous system mobilization. Not as obvious, but equally characteristic, are changes in brain wave patterns and in the electrical resistance of the skin (galvanic skin resistance)—events that are recorded during lie detector examinations.

During any type of vigorous physical activity, the sympathetic division also promotes a number of other adjustments. Visceral (and sometimes cutaneous) blood vessels are constricted, and blood is shunted to active skeletal muscles and the vigorously working heart. The bronchioles in the lungs dilate, increasing ventilation (and ultimately increasing oxygen delivery to body cells), and the liver releases more glucose into the blood to accommodate the increased energy needs of body cells. At the same time, temporarily nonessential activities, such as gastrointestinal tract motility, are damped. If you are running from a mugger, digesting lunch can wait! It is far more important that your muscles be provided with everything they need to get you out of danger.

In such active situations, the sympathetic division generates a head of steam that enables the body to cope with situations that threaten homeostasis. Its function is to provide the optimal conditions for an appropriate response to some threat, whether that response is to run, to see better, or to think more clearly.

We have just looked at two extreme situations in which one or the other branch of the ANS dominates. An easy way to remember the most important roles of the two ANS divisions is to think of the parasympathetic division as the **D** division [digestion, defecation, and diuresis (urination)], and the sympathetic division as the **E** division (exercise, excitement, emergency, embarrassment). A more detailed summary of the effects of each division is presented in Table 14.5 (p. 546). Remember, however, while it is easiest to think of the two ANS divisions as working in an all-or-none fashion as described above, this is rarely the case. A dynamic antagonism exists between the divisions, and fine adjustments are made continuously by both.

ANS Anatomy

The sympathetic and parasympathetic divisions are distinguished by

1. Their unique origin sites: Parasympathetic fibers emerge from the brain and sacral spinal cord (are craniosacral); sympathetic fibers originate in the thoracolumbar region of the spinal cord.

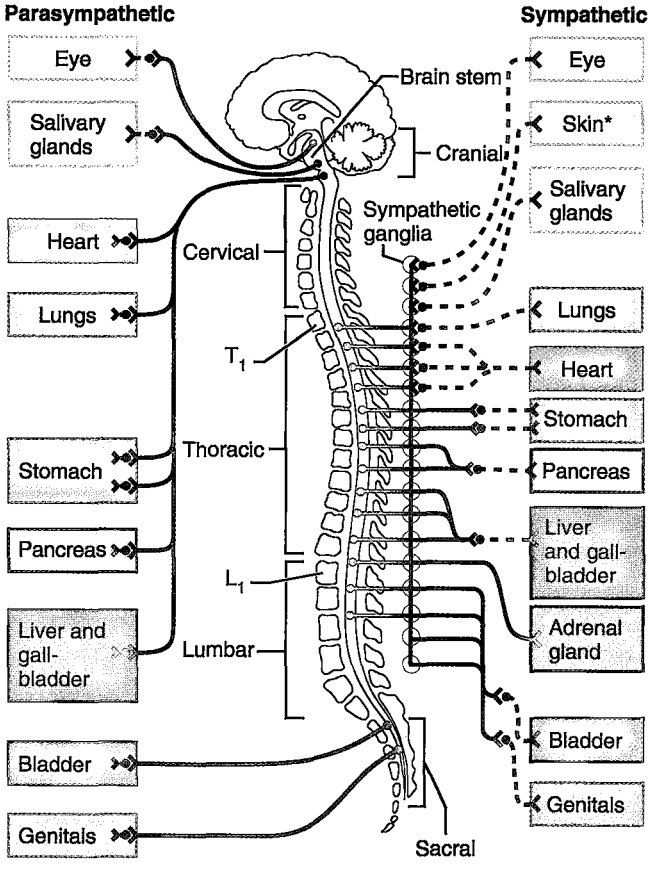
2. The relative lengths of their fibers: The parasympathetic division has long preganglionic and short postganglionic fibers; the sympathetic division has the opposite condition.

3. The location of their ganglia: Most parasympathetic ganglia are located in the visceral effector organs; sympathetic ganglia lie close to the spinal cord.

These and other differences are summarized in Table 14.1 and illustrated in Figure 14.3.

TABLE 14.1 Anatomical and Physiological Differences Between the Parasympathetic and Sympathetic Divisions

CHARACTERISTIC	PARASYMPATHETIC	SYMPATHETIC
Origin	Craniosacral outflow: brain stem nuclei of cranial nerves III, VII, IX, and X; spinal cord segments S_2–S_4	Thoracolumbar outflow: lateral horn of gray matter of spinal cord segments T_1–L_2
Location of ganglia	Ganglia in (intramural) or close to visceral organ served	Ganglia within a few centimeters of CNS: alongside vertebral column (sympathetic trunk, or chain, ganglia) and anterior to vertebral column (collateral, or prevertebral, ganglia)
Relative length of pre- and postganglionic fibers	Long preganglionic; short postganglionic	Short preganglionic; long postganglionic
Rami communicantes	None	Gray and white rami communicantes. White rami contain myelinated preganglionic fibers; gray contain unmyelinated postganglionic fibers
Degree of branching of preganglionic fibers	Minimal	Extensive
Functional role	Maintenance functions; conserves and stores energy	Prepares body for activity
Neurotransmitters	All fibers release ACh (cholinergic fibers)	All preganglionic fibers release ACh; most postganglionic fibers release norepinephrine (adrenergic fibers); postganglionic fibers serving sweat glands and some blood vessels of skeletal muscles release ACh; neurotransmitter activity augmented by release of adrenal medullary hormones (norepinephrine and epinephrine)



Parasympathetic (Craniosacral) Division

We begin our exploration of the ANS with the anatomically simpler parasympathetic division. Because its preganglionic fibers spring from opposite ends of the CNS—the brain stem and the sacral region of the spinal cord—the parasympathetic division is also called the **craniosacral division** (Figure 14.4). The preganglionic axons extend from the CNS nearly all the way to the structures to be innervated. There the axons synapse with ganglionic neurons located in **terminal ganglia** that lie very close to or within the target organs. Very short postganglionic axons issue from the terminal ganglia and synapse with effector cells in their immediate area.

FIGURE 14.3 **Overview of the subdivisions of the ANS.** Sites of origin of their nerves and major organs served are indicated. Synapse sites indicate the relative locations of the sympathetic and parasympathetic ganglia.

*Although sympathetic innervation to the skin is mapped to the cervical region here, all nerves to the periphery carry postganglionic sympathetic fibers.

Cranial Outflow

Preganglionic fibers run in the oculomotor, facial, glossopharyngeal, and vagus cranial nerves. Their cell bodies lie in associated motor cranial-nerve nuclei in the brain stem (see Figures 12.15 and 12.16). The precise locations of the neurons of the cranial parasympathetics are described next.

1. Oculomotor nerves (III). The parasympathetic fibers of the oculomotor nerves innervate smooth muscles in the eyes that cause the pupils to constrict and the lenses to bulge—actions needed to focus on close objects. The preganglionic axons found in the oculomotor nerves issue from the *accessory oculomotor (Edinger-Westphal) nuclei* in the midbrain. The cell bodies of the ganglionic neurons are in the **ciliary ganglia** within the eye orbits (see Table 13.2, p. 503).

2. Facial nerves (VII). The parasympathetic fibers of the facial nerves stimulate many large glands in the head. Fibers that activate the nasal glands and the lacrimal glands of the eyes originate in the *lacrimal nuclei* of the pons. The preganglionic fibers synapse with ganglionic neurons in the **pterygopalatine ganglia** (ter"eh-go-pal'ah-tīn) just posterior to the maxillae. The preganglionic neurons that stimulate the submandibular and sublingual salivary glands originate in the *superior salivatory nuclei* of the pons and synapse with ganglionic neurons in the **submandibular ganglia,** deep to the mandibular angles (see Table 13.2, p. 505).

3. Glossopharyngeal nerves (IX). The parasympathetics in the glossopharyngeal nerves originate in the *inferior salivatory nuclei* of the medulla and synapse in the **otic ganglia,** located just inferior to the foramen ovale of the skull. The postganglionic fibers course to and activate the parotid salivary glands anterior to the ears (see Table 13.2, p. 507).

Cranial nerves III, VII, and IX supply the entire parasympathetic innervation of the head; however, only the *preganglionic fibers* lie within these three pairs of cranial nerves—postganglionic fibers do not. The distal ends of the preganglionic fibers "jump over" to branches of the *trigeminal nerves (V)* to synapse; then the postganglionic fibers travel in the trigeminal nerves to reach the face. This "hitchhiking" takes advantage of the fact that the trigeminal nerves have the broadest facial distribution of all the cranial nerves and are well suited for this "delivery" role to the widely separated glands and smooth muscles in the head.

4. Vagus nerves (X). The remaining and major portion of the parasympathetic cranial outflow is via the vagus (X) nerves. Between them, the two vagus nerves account for about 90% of all preganglionic parasympathetic fibers in the body. They provide fibers to the

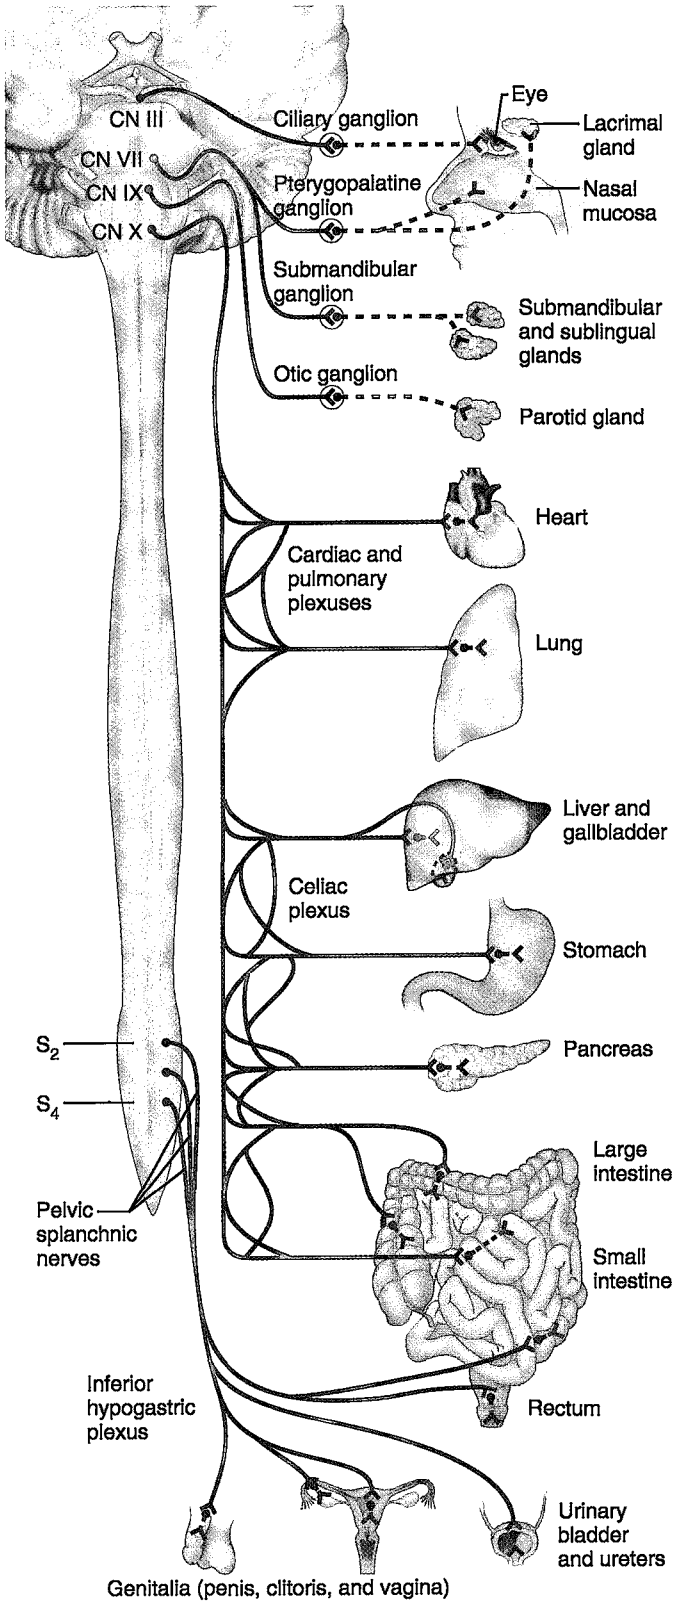


FIGURE 14.4 **Parasympathetic (craniosacral) division of the ANS.** Solid lines indicate preganglionic nerve fibers. Dashed lines indicate postganglionic fibers. Terminal ganglia of the vagus and pelvic splanchnic nerve fibers are not shown; most of these ganglia are located in or on the target organ. (Note: CN = cranial nerve.)

neck and to nerve plexuses (interweaving networks of nerves) that serve virtually every organ in the thoracic and abdominal cavities. The vagal nerve fibers (preganglionic axons) arise mostly from the *dorsal motor nuclei* of the medulla and synapse in terminal ganglia usually located in the walls of the target organ. Most terminal ganglia are not individually named; instead they are collectively called *intramural ganglia*, literally, "ganglia within the walls." As the vagus nerves pass into the thorax, they send branches to the **cardiac plexuses** supplying fibers to the heart that slow heart rate, the **pulmonary plexuses** serving the lungs and bronchi, and the **esophageal plexuses** (ĕ-sof″ah-je′al) supplying the esophagus.

When the main trunks of the vagus nerves reach the esophagus, their fibers intermingle, forming the **anterior** and **posterior vagal trunks,** each containing fibers from both vagus nerves. These vagal trunks then "ride" the esophagus down to the abdominal cavity. There they send fibers *through* the large **aortic plexus** [formed by a number of smaller plexuses (e.g., *celiac, superior mesenteric,* and *hypogastric*) that run along the aorta] before giving off branches to the abdominal viscera. The vagus nerves innervate the liver, gallbladder, stomach, small intestine, kidneys, pancreas, and the proximal half of the large intestine.

Sacral Outflow

The rest of the large intestine and the pelvic organs are served by the sacral outflow, which arises from neurons located in the lateral gray matter of spinal cord segments S_2–S_4. Axons of these neurons run in the ventral roots of the spinal nerves to the ventral rami and then branch off to form the **pelvic splanchnic nerves** (Figure 14.4), which pass through the **inferior hypogastric (pelvic) plexus** in the pelvic floor. Some preganglionic fibers synapse with ganglia in this plexus, but most synapse in intramural ganglia in the walls of the following organs: distal half of the large intestine, urinary bladder, ureters, and reproductive organs.

Sympathetic (Thoracolumbar) Division

The sympathetic division is more complex than the parasympathetic division, partly because it innervates more organs. It supplies not only the visceral organs in the internal body cavities but also all visceral structures in the superficial (somatic) part of the body. This sounds impossible, but there is an explanation—some glands and smooth muscle structures in the soma (sweat glands and the hair-raising arrector pili muscles of the skin) require autonomic innervation and are served only by sympathetic fibers. Moreover, all arteries and veins (be they deep or superficial) have smooth muscle in their walls that is innervated by sympathetic fibers. But these matters will be explained later—let us get on with the anatomy of the sympathetic division.

All preganglionic fibers of the sympathetic division arise from cell bodies of preganglionic neurons in spinal cord segments T_1 through L_2 (Figure 14.5). For this reason, the sympathetic division is also referred to as the **thoracolumbar division** (tho″rah-ko-lum′bar). The presence of numerous preganglionic sympathetic neurons in the gray matter of the spinal cord produces the **lateral horns**—the so-called **visceral motor zones** (see Figures 12.31b, p. 473, and 12.32, p. 474). The lateral horns are just posterolateral to the ventral horns that house somatic motor neurons. (Parasympathetic preganglionic neurons in the sacral cord are far less abundant than the comparable sympathetic neurons in the thoracolumbar regions, and *lateral horns are absent* in the sacral region of the spinal cord. This is a major anatomical difference between the two divisions.)

After leaving the cord via the ventral root, preganglionic sympathetic fibers pass through a **white ramus communicans** [plural: **rami communicantes** (kom-mu′nĭ-kan″tēz)] to enter an adjoining **sympathetic trunk (chain) ganglion** forming part of the **sympathetic trunk** or **chain** (Figure 14.6). Looking like strands of glistening white beads, the sympathetic trunks flank each side of the vertebral column. These ganglia are also called *paravertebral ganglia*, named for their location.

Although the sympathetic *trunks* extend from neck to pelvis, sympathetic *fibers* arise only from the thoracic and lumbar cord segments, as shown in Figure 14.5. The ganglia vary in size, position, and number, but typically there are 23 in each sympathetic trunk—3 cervical, 11 thoracic, 4 lumbar, 4 sacral, and 1 coccygeal.

Once a preganglionic axon reaches a trunk ganglion, one of three things can happen to the axon, as shown by the three numbered pathways in Figure 14.6:

① It can synapse with a ganglionic neuron in the same trunk ganglion.

② It can ascend or descend the sympathetic trunk to synapse in another trunk ganglion. (It is these fibers running from one ganglion to another that connect the ganglia into the sympathetic trunk.)

③ It can pass through the trunk ganglion and emerge from the sympathetic trunk without synapsing.

Preganglionic fibers following pathway ③ help form the **splanchnic nerves** (splank′nik) that synapse in **collateral, or prevertebral, ganglia** located anterior to the vertebral column. Unlike sympathetic trunk (chain) ganglia, the prevertebral ganglia are neither paired nor segmentally arranged and occur only in the abdomen and pelvis.
