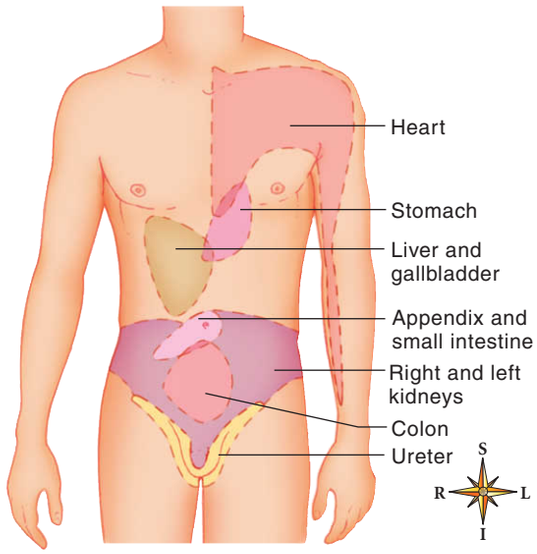
BY STRUCTURE	BY LOCATION AND TYPE	BY ACTIVATION STIMULUS	BY SENSATION OR FUNCTION
Free Nerve Endings			
Nociceptor 	Either exteroceptor or visceroceptor—most body tissues	Almost any noxious stimulus; temperature change; mechanical	Pain; temperature; itch; tickle
Tactile (Merkel) disk (meniscus) 	Exteroceptor	Light pressure; mechanical	Discriminative touch
Root hair plexus 	Exteroceptor	Hair movement; mechanical	Sense of "deflection" type of movement of hair

(continued on page 512)

Box 17-1 | FYI



Referred Pain

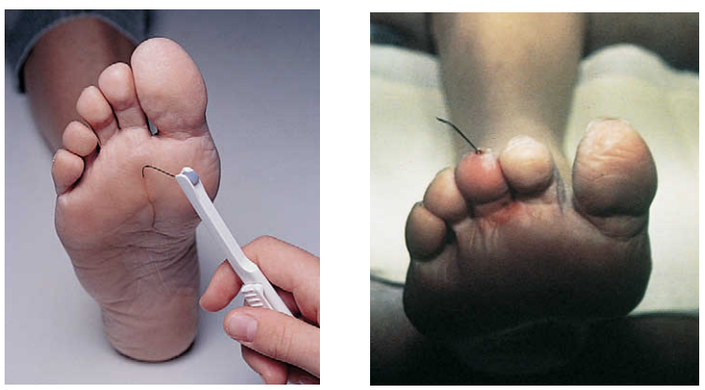
The stimulation of pain receptors in deep structures may be felt as pain in the skin that lies over the affected organ or in an area of skin on the body surface far removed from the site of disease or injury. **Referred pain** is the term for this phenomenon.

The cause of referred pain is related to a mixing or convergence of sensory nerve impulses from both the diseased organ and the skin in the area of referred pain. For example, pain originating in an organ deep in the abdominal cavity is often interpreted as coming from an area of skin whose sensory fibers enter the same segment of the spinal cord as the sensory fibers from the deep structure.

A classic example is the referred pain often associated with a heart attack. Sensory fibers from the skin on the chest over the heart and from the tissue of the heart itself enter the first to the fifth thoracic spinal cord segments and so do sensory fibers from the skin areas over the left shoulder and inner surface of the left arm. Sensory impulses from all these areas travel to the brain over a common pathway. Thus the brain may feel the pain of a heart attack in the shoulder or arm.

Misinterpretation in the brain in regard to the true location of sensory neurons being stimulated causes referred pain. In clinical medicine, an understanding of referred pain is often an important determinant in whether the correct diagnosis of disease is made (see figure).

gift that nobody wants." Individuals who are unable to adequately sense pain on the body surface tend to have other types of sensory loss as well. They are very much at risk for injury because they lack the ability to sense the "warning signs" that a normally functioning sensory system can provide.



Individuals with uncontrolled or poorly controlled diabetes often lose their ability to sense pain on certain areas of the body surface—especially on the skin of the feet. Other sensations are also frequently diminished or lost over time in diabetics because of nerve damage called **diabetic neuropathy.** For this reason physicians closely monitor the adequacy of cutaneous sensation on the bottom of the foot (Figure 17-2, A). Recognizing early signs of diabetic neuropathy can help prevent later injury. Figure 17-2, *B*, shows a foreign body (a piece of wire) protruding from the tip of the third toe in a diabetic patient. The individual lacked sensation in the feet and only after visually noticing it sought medical attention. This is just one example, but a common one, of a failure of "the gift of pain" to give an appropriate warning of an injury.

In a syndrome called **fibromyalgia (FM),** chronic and widespread musculoskeletal pain is usually accompanied by distress and a variety of other symptoms. The primary mechanism of FM seems to be an abnormal amplification of pain information processed in the central nervous system. However, other mechanisms are also being investigated as contributing factors. The drug *pregabalin (Lyrica)* reduces the pain of FM mainly by blocking calcium channels in the pain-pathway neurons of the spinal cord. Reducing calcium influx, as you probably recall (see Figure 13-27 on p. 402), inhibits the release of pain neurotransmitters.

Temperature Sensations

Free nerve endings called **thermoreceptors** mediate sensations of heat and cold. When small cold or warm probes are used to "map" the skin's sensitivity to temperature, small areas called "receptive fields" about 1 mm across can be identified on the skin surface as being sensitive to *either* cold or warmth, but not both. Research has shown that these receptive fields represent separate *warm receptors* and *cold receptors* that respond to different thermal sensations and are sensitive to a range of relatively hot or cold temperatures. Thermal maps have also shown that thermoreceptors, like other types of cutaneous receptors, are not spread uniformly across the skin surface.

Both types of thermoreceptors undergo rapid adaptation. As a result, the intensity of the warm or cold sensations they initially produce when activated soon fade. We adapt to the heat of a sauna or a cool shower in a short time.

A B

FIGURE 17-2

The importance of cutaneous sensation. A, Using a monofilament to check for sensation on the bottom of the foot. **B,** Foreign body (wire) in the toe of a diabetic patient may not trigger appropriate sensations of pain because of nerve damage (diabetic neuropathy).

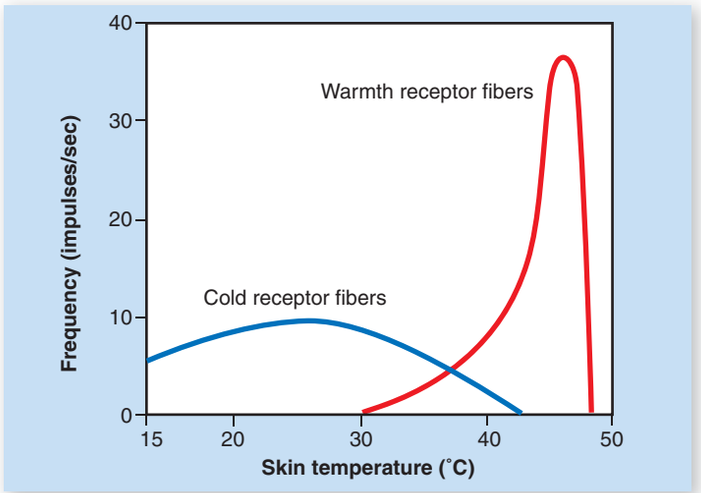


FIGURE 17-3

Range of temperature receptor sensitivity.

Warm receptors, which are located in the dermis, are activated above about 25° C (77° F) and increase their firing rate until the temperature reaches about 46° C (114° F). Figure 17-3 shows the range of temperature receptor sensitivity. Beyond a temperature of about 48° C (118° F) a sensation of burning pain begins.

Cold receptors, which are located in the deepest layer of the epidermis, have a broader temperature response than warm receptors (see Figure 17-3). They are most active between about 10° C (50° F) and 40° C (104° F). Below 10° C the firing of cold receptors decreases dramatically. The falling temperature first acts as a local anesthetic and then activates nociceptors resulting in a sensation of freezing pain. Between temperature extremes the brain senses a particular temperature sensation by integrating sensory inputs from both receptor types.

Tactile Sensations

In addition to their role in mediation of pain and temperature, free nerve endings and slightly modified free nerve endings are also involved in certain tactile sensations.

Skin Movement

Root hair plexuses are rapidly adapting free nerve endings that are activated when very slight skin movement bends or deforms a hair shaft or follicle surrounded by the receptor. When you feel a mosquito "bite," it may not be caused by the piercing of the skin by the mouth of the insect. Instead, it may be the movement of your own skin caused by the mosquito's activity that triggers or stimulates a root hair plexus. In any event, it's a good idea to swat the mosquito!

Itch

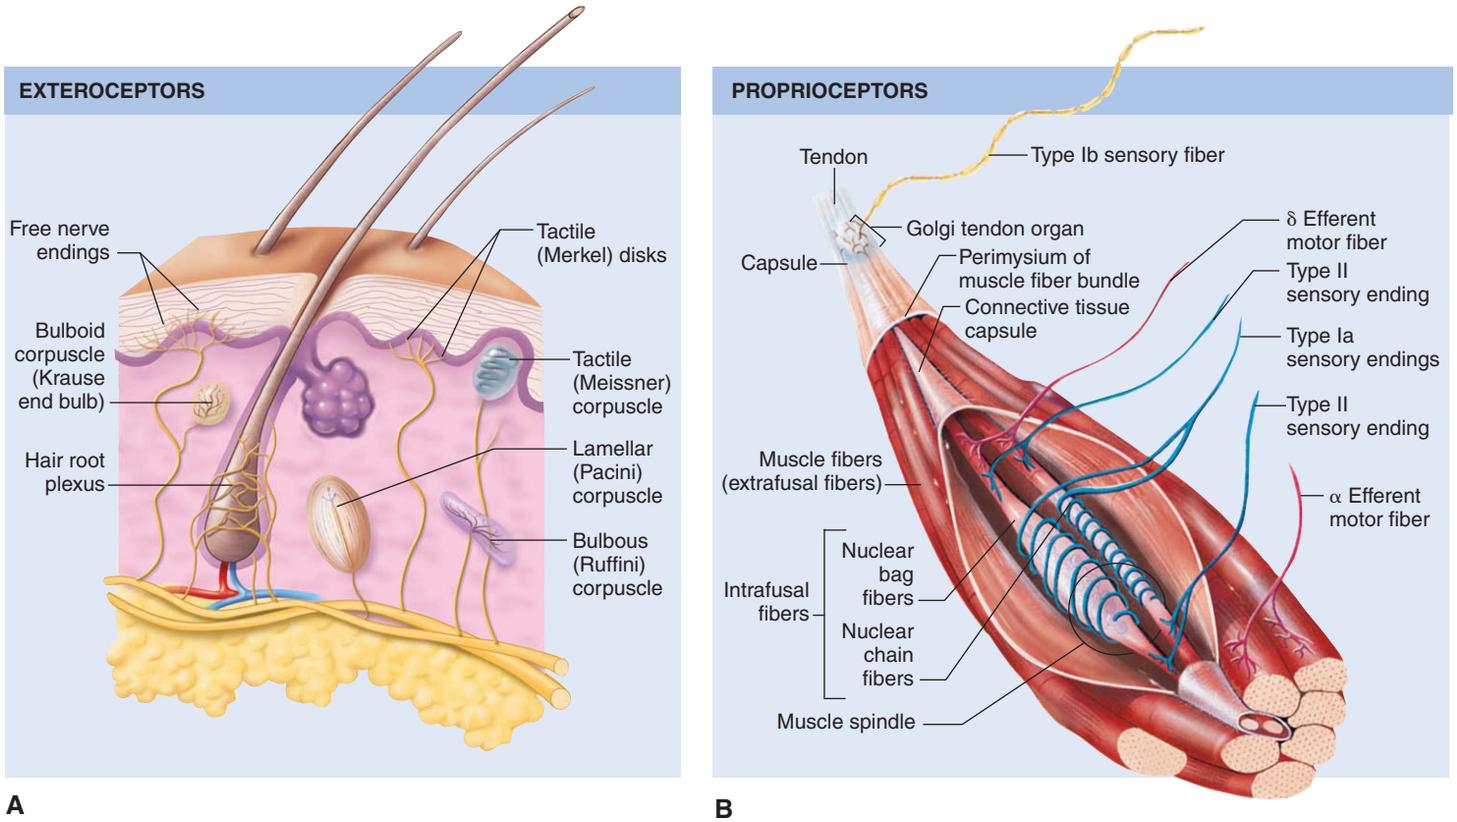
The term "itch" is used to describe several different tactile sensations mediated by free nerve endings. Most people would describe it as a sensation that makes you want to scratch. It can vary in intensity from almost imperceptible to intense and disabling. The cause is generally chemical irritation of free nerve endings by inflammatory chemicals, such as bradykinin or histamine. These types of chemicals are often released by injured tissue following insect bites, or during allergic reactions. But itches can also be induced by suggestion, like a yawn. Scientists are just now working out the types of itch that occur in humans and how these itch mechanisms work.

Tickle

Tickle is a unique sensation in that it most often results from tactile stimulation of the skin, not by you, but by someone else. It is mediated by free nerve endings and is a good but somewhat baffling example of how perception can alter the conscious

FIGURE 17-4

Discriminative touch. A, Normally, sensation can be elicited by a light stroke to the skin. **B,** Examples of specific sites used to verify sensation of discriminative touch.



interpretation of a nervous impulse when it reaches the brain. We know that neural pathways in tickle involve both the thalamus and cerebellum before the impulses reach the cerebral cortex. However, the circuits involved in the cerebral cortex and how these circuits interact with neurons in other areas of the brain are not well understood. Obviously, knowing consciously that a particular tactile sensation generally occurs only when you are touched by someone else requires complex nervous system involvement. What begins as a simple receptor potential in a free nerve ending ends in a complex, consciously interpreted tactile sensation.

Discriminative Touch

Discriminative touch, or "light touch," refers to an often very subtle sensation that can be located exactly in certain areas of the skin (Figure 17-4). It is mediated by a flattened or disk-shaped variation of a free nerve ending called a **tactile disk** or *Merkel disk*. It may also be called a *tactile meniscus*. This structure was first described by the German anatomist Friedrich Merkel (1885-1919) when he studied delicate nervous elements near the skin surface.

Structurally, the tactile receptor unit is made up of two cells. One is an epithelial cell called the *tactile epithelial cell*, located in the epidermis of the skin (see Figure 6-4, p. 138). The other cell is a sensory neuron called the *tactile disk*. The tactile epithelial cell is rather stiff and transmits compression of the outer layer of the skin to the tactile disk neuron. The tactile disk is a delicate mechanoreceptor that is not encapsulated and has a superficial placement in the epidermis of the skin (Figure 17-5, A). It is therefore easily "deformed" when pressed by the stiff tactile cell and capable of generating an action potential when exposed to very minimal stimulation. Tactile disks adapt slowly, thus maintaining information flow to the central nervous system for some time.

In addition to discriminative or light touch, the tactile receptor unit is also capable of detecting subtle changes in surface form and contours.

Somatic sensory receptors.

TABLE 17-1 Classification of Somatic Sensory Receptors *(continued from page 508)*

BY STRUCTURE	BY LOCATION AND TYPE	BY ACTIVATION STIMULUS	BY SENSATION OR FUNCTION
Encapsulated Nerve Endings			
Touch and Pressure Receptors			
Tactile (Meissner) corpuscle 	Exteroceptor; epidermis, hairless skin	Light pressure, mechanical	Touch; low-frequency vibration
Bulboid (Krause) corpuscle 	Exteroceptor; mucous membranes	Mechanical	Touch; low-frequency vibration; textural sensation
Bulbous (Ruffini) corpuscle 	Exteroceptor; dermis of skin	Mechanical	Crude and persistent touch
Lamellar (Pacini) corpuscle 	Exteroceptor; dermis of skin, joint capsules	Deep pressure, mechanical	Deep pressure; high-frequency vibration; stretch
Stretch Receptors			
Muscle spindles 	Interoceptor; skeletal muscle	Stretch; mechanical	Sense of muscle length
Golgi tendon receptors 	Interoceptor; tendon (near muscle tissue)	Force of contraction and tendon stretch; mechanical	Sense of muscle tension

ENCAPSULATED NERVE ENDINGS

The six types of encapsulated nerve endings have in common some type of connective tissue capsule that surrounds their terminal or dendritic end. In addition, most of the encapsulated receptors are primary mechanoreceptors. Thus they are most often activated by a mechanical or "deforming" type of stimulus. Encapsulated receptors vary in size and anatomical characteristics, as well as in numbers and distribution throughout the body (see Table 17-1).

Touch and Pressure Receptors

Tactile corpuscles are encapsulated tactile end organs, also called *Meissner corpuscles*, first described by the German physiologist George Meissner (1829-1905). Note in Figure 17-5, A, and Table 17-1 that they are superficially placed ovoid or egg-shaped mechanoreceptors that are larger than tactile disks. The encapsulated receptor fibers are coiled and enmeshed in connective tissue. They are located in or very close to the dermal papillae in hairless skin areas such as the fingertips, lips, nipples, and genitals.

Although their covering capsule requires slightly more of a "deforming" stimulus to generate an action potential than a tactile (Merkel) disk, they do mediate light touch in addition to textural sensations and low-frequency vibration.

Two important anatomical variants of tactile (Meissner) corpuscles also act as mechanoreceptors. One is called the **bulboid corpuscle** or *Krause end bulb*. Bulboid corpuscles are egg shaped, like tactile corpuscles, but they are somewhat smaller and have fewer and less tightly coiled dendritic endings within their covering capsule. These receptors are more numerous in mucous membranes than in skin and are sometimes called *mucocutaneous corpuscles*. They are involved in touch and low-frequency vibration.

The other variant of the tactile (Meissner) corpuscle is the **bulbous corpuscle,** also known as the *Ruffini corpuscle* (see Figure 17-5, *A*). Although considered to be a variant of the tactile corpuscle, it has a more flattened capsule and is more deeply located in the dermis of the skin. These receptors mediate sensations of crude, heavy, and persistent touch. Because they are slow adapting, they permit the skin of the fingers to remain sensitive to deep pressure for long periods. The ability to grasp an object, such as the steering wheel of a car, for long periods of time and still be able to "sense" its presence between the fingers depends on these receptors.

Lamellar corpuscles (*Pacini corpuscles*) are large mechanoreceptors, which, when sectioned, show thick laminated connective tissue capsules. They are found in the deep dermis of the skin—especially in the hands and feet—and are also numerous in joint capsules throughout the body (see Figure 17-5, *A*). Pacini, or lamellar, corpuscles respond quickly to sensations of deep pressure, high-frequency vibration, and stretch. Although sensitive and quick to respond, these receptors adapt quickly, and the sensations they evoke seldom last for long.

Stretch Receptors

The most important stretch receptors are associated with muscles and tendons and are classified as proprioceptors. Two types of stretch receptors, called **muscle spindles** and **Golgi tendon receptors,** operate to provide the body with information concerning muscle length and the strength of muscle contraction (see Figure 17-5, *B*).

Anatomically, each muscle spindle consists of a discrete grouping of about 5 to 10 modified muscle fibers called *intrafusal fibers*, which are surrounded by a delicate capsule. These fibers have striated ends that are capable of contraction but are devoid of contractile filaments in their central areas where, instead, there are several nuclei surrounded by clear cytoplasm and two types of sensory nerve fibers that are described below. The muscle spindles can be found lying between and parallel to the regular muscle fibers called *extrafusal fibers*. Both ends of each spindle are connected or anchored to connective tissue elements within the muscle mass.

Two types of sensory (afferent) nerve fibers are found encircling the central area of each spindle. Both large-diameter and rapidly conducting type Ia and slower-conducting, small-diameter type II fibers encircle the clear central area of each spindle. When stretching occurs, afferent impulses from these sensory neurons pass to the spinal cord and are relayed to the brain, providing a mechanism to monitor changes in muscle length.

The striated ends of the muscle spindle fibers (intrafusal fibers) are capable of contraction when stimulated by efferent impulses generated in **gamma motor neurons,** whereas regular muscle fibers (extrafusal fibers) are stimulated to contract by efferent impulses generated in **alpha motor neurons.** Both types of neurons are located in the anterior gray horn of the spinal cord.

Muscle spindles are stimulated if the length of a muscle is stretched and exceeds a certain limit. The result of stimulation is a **stretch reflex** that shortens a muscle or muscle group, thus aiding in the maintenance of posture or the positioning of the body or one of its extremities in a way that may be opposed by the force of gravity (see Figure 12-25, p. 366). We do this unconsciously, even though these receptors do contribute to conscious proprioception.

Golgi tendon organs, often called simply *tendon organs*, like muscle spindles, are proprioceptors. They are located at the point of junction between muscle tissue and tendon. Each Golgi tendon organ consists of dendrites *(Golgi tendon receptors)* of afferent (sensory) nerves called *type Ib nerve fibers*, which are associated with bundles of collagen fibers from the tendon and surrounded by a capsule. These sensory organs act in a way opposite that of muscle spindles. Golgi tendon organs are stimulated by excessive stretch of a tendon—as when pulling too great a load for the muscle to bear safely. When the Golgi tendon organ is activated, the skeletal muscle relaxes. This response, called a *Golgi tendon reflex*, protects muscles from tearing internally or pulling away from their tendinous points of attachment to bone because of excessive contractile force.

Table 17-1 summarizes the different types of somatic sense receptors, their locations, and their functions.

| QUICK CHECK |

1. Classify receptors into six groups based on the type of stimuli that activate them.
2. Distinguish between the special and the general, or somatic, senses.
3. Name the three types of sense receptors classified according to location in the body.
4. Name the receptors associated with pain, touch, pressure, and stretch responses.

SENSE OF SMELL

We begin our study of the special senses with olfaction. Olfaction is our sense of smell. It helps us interpret our environment by detecting molecules given off by organisms and substances around us.

Olfactory Receptors

The **olfactory** epithelium consists of yellow-colored **epithelial support cells, basal cells,** and bipolar-type **olfactory sensory neurons.** These neurons, also called *olfactory receptor neurons*, have unique *olfactory cilia*, which touch the surface of the

olfactory epithelium lining the upper surface of the nasal cavity. The olfactory sensory neurons are *chemoreceptors*. They are unique because they are replaced on a regular basis by **basal cells** in the olfactory epithelium.

Receptor potentials are generated in olfactory sensory neurons when gas molecules or chemicals dissolved in the mucus covering the olfactory epithelium (Figure 17-6) bind to protein "*odor receptors*" located in the membrane of the olfactory sensory neurons. Gentle, random movement of the cilia helps "mix" the covering mucus and increases its efficiency as a solvent.

The olfactory epithelium is located in the most superior portion of the nasal cavity (see Figure 17-6). Functionally, this is a poor location because a great deal of inspired air flows around and down the nasal passageways without contacting the protein odorant receptors located in the cell membranes of the olfactory receptor cells. The location of these receptor neurons explains the necessity for sniffing, or drawing air forcefully up into the nose, to smell delicate odors.

The olfactory receptors are extremely sensitive, that is, capable of being stimulated by even very slight odors caused by just a few molecules of a particular chemical. However, rapid adaptation of olfactory sensations in the face of continuous stimulation occurs. It is due to both the inhibition of action potentials by **granule cells** in the olfactory bulbs and by fatigue of odorant receptor function caused by ongoing stimulation of the olfactory sensory neurons.

Although humans have a sense of smell far less keen than many animals, some individuals can distinguish several thousand different odors, and most of us can easily identify at least several hundred. Examples of well-known primary scents include putrid, floral, peppermint, and musky odors. Many odors are combinations of primary scents.

In 2004 U.S. researchers Drs. Linda Buck and Richard Axel received the Nobel Prize in physiology or medicine for their pioneering work that explained for the first time how the sense of smell or olfaction in humans actually "works." Their research identified almost 1000 different types of odorant receptors in the cell membranes of human olfactory sensory neurons. All of them are G-protein–coupled receptors (GPCRs), which we encountered in an earlier chapter (see Figure 13-30 on p. 405).

In a series of sophisticated experiments, they were able to show that by stimulating the entire olfactory epithelium—or specific odorant receptors—or combinations or sequences of these receptor proteins—different odors could be identified. If the receptor proteins are compared to the letters of the alphabet, activation of specific letters, formation of different "words," or word sequences, will cause differing olfactory sensory neurons or groups of neurons to transmit impulses to the brain that are perceived as unique odors.

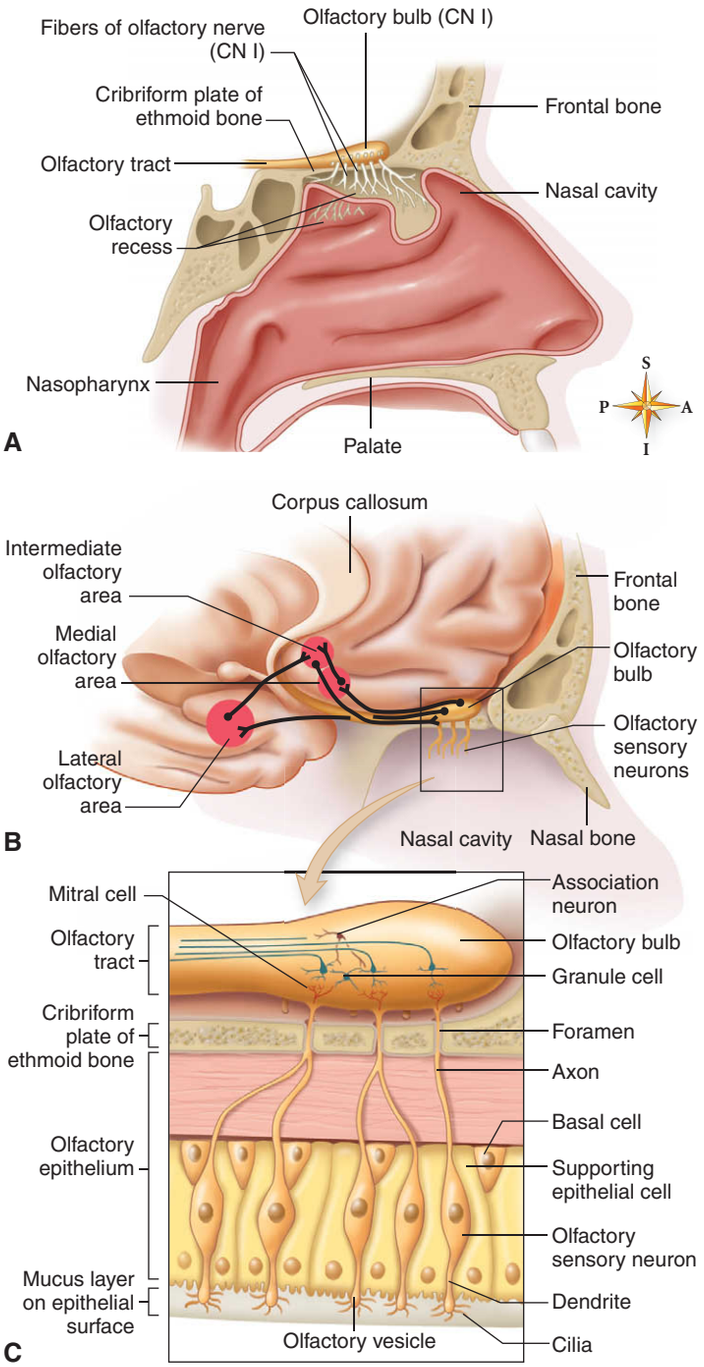

FIGURE 17-6

Olfaction. Location of olfactory epithelium, olfactory bulb, and neural pathways involved in olfaction. **A,** Midsagittal section of the nasal area shows the locations of major olfactory sensory structures. **B,** Major olfactory integration centers of the brain. **C,** Details of the olfactory bulb and olfactory epithelium.

Olfactory Pathway

If the level of odor-producing chemicals dissolved in the mucus surrounding the olfactory cilia reaches a threshold level, a receptor potential and then an action potential will be generated and passed to the olfactory nerves in the olfactory bulb. From there, the impulse passes through the olfactory tract and into the thalamic and olfactory centers of the brain for interpretation, integration, and memory storage.

The sense of smell can create powerful and long-lasting memories. Memories coupled with unique sensory inputs, especially distinctive odors, often persist from early childhood to death. Dental office smells, baby smells, kitchen smells, and new car smells are examples of olfactory "triggers" that often bring back memories of events that occurred years earlier. In addition to the olfactory cortex and thalamic areas of the brain, components of the limbic system, including the cingulate gyrus and hippocampus, play a key role in coupling olfactory sense inputs to both short- and long-term memory.

Not only can specific odors trigger long-term memory, they often allow the individual to recall emotions associated with the recalled experience as well. For example, the smell of an evergreen tree by a 90-year-old man may trigger both the memory of events and the recall of emotions he experienced at Christmas when he was a 9-year-old boy. The mechanism of such a complex association between the detection of a specific odor and recall of the actual emotions and ambiance surrounding a long-term memory remain unknown.

People who suffer from permanent **anosmia,** complete lack of smell, can suffer from serious depression. Apparently, the loss of smell can have more impact on our psychological health than the loss of any other sense.

Our senses of smell and taste are closely related. Note in Figure 17-7 that the neural inputs from both olfactory and gustatory (taste) receptors travel in several common areas of the brain. Ultimately, olfactory sensations are produced in the (smell) sensory cortex located in the temporal lobes, and taste sensations result from stimulation of the (taste) sensory cortex in the parietal lobes.

| A&P CONNECT |

A sense related to olfaction is our ability to detect *pheromones,* or sexual signal molecules, from other people. The receptors for pheromones are just inside our nose, near the olfactory receptors. Find out more about this sexual signaling in ***Pheromones and the Vomeronasal Organ*** online at ***A&P Connect.***

evolve

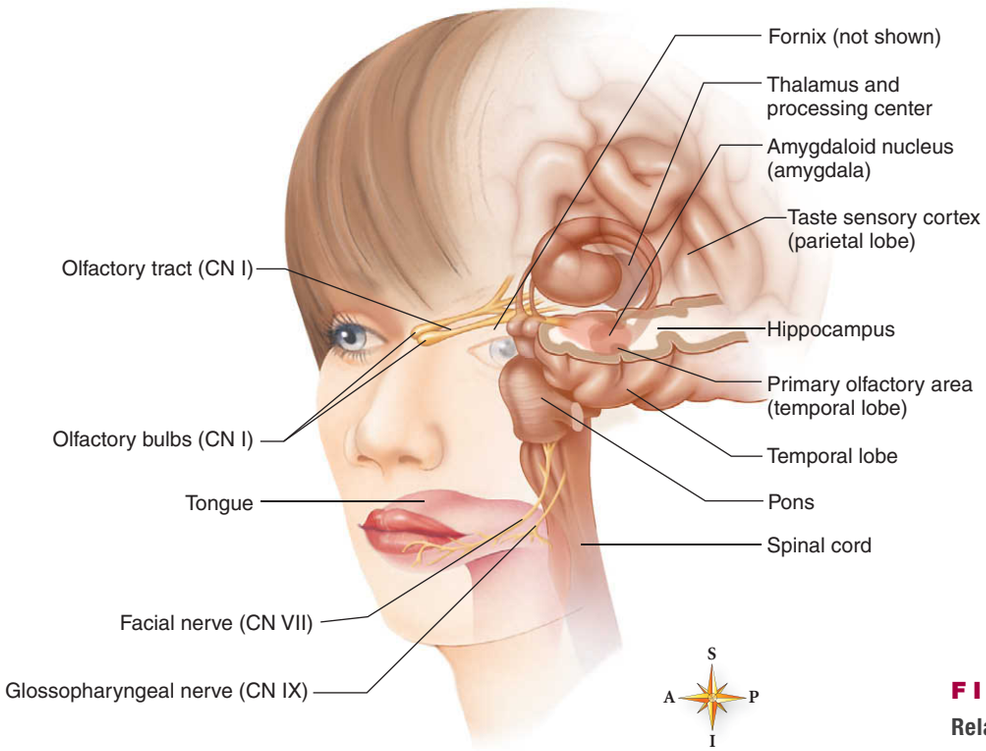

FIGURE 17-7
Relationship of olfactory and gustatory pathways.

UNIT 3

SENSE OF TASTE

Taste Buds

The **taste buds** are the sense organs that respond to **gustatory,** or taste, stimuli. Although a few taste buds are located in the lining of the mouth and on the soft palate, most are associated with small, elevated projections on the tongue, called **papillae** (Figure 17-8, *A* and *B*).

Tongue papillae are classified by their structure:

Fungiform papillae—large, mushroom-shaped bumps found in the anterior two thirds of the tongue surface; each one contains one or a few taste buds

Circumvallate papillae—huge, dome-shaped bumps that form a transverse row near the back of the tongue surface; each one contains thousands of taste buds

Foliate papillae—red, leaflike ridges of mucosa on the lateral edges of the posterior tongue surface; each contains about a hundred or so taste buds

Filiform papillae—bumps with tiny, threadlike projections; these papillae are scattered among the fungiform papillae; they do not contain taste buds but allow us to experience food texture and "feel"

Although the different varieties of papillae are distributed differently across the tongue surface, no regional difference exists in where a particular taste can be detected. For example, the long-held belief that bitter taste was localized at the back of the tongue with its high concentration of circumvallate papillae (see Figure 17-8, *A*) or that sweet taste is detected best at the tip of the tongue is simply not true. No tongue or taste "map" accurately indicates regional areas of particular sensitivity to different tastes. All tastes can be detected in all areas of the tongue that contain taste buds.

Taste buds house the chemoreceptors responsible for taste. They are stimulated by chemicals, called *tastants*, dissolved in the saliva. Each taste bud is like a banana cluster that contains 50 to 125 of these chemoreceptors, called **gustatory cells,** which are surrounded by a supportive epithelial cell capsule. Cilia, here called *gustatory hairs*, extend from each of the gustatory cells and project into an opening called the *taste pore*, which is bathed in saliva (see Figure 17-8, *C*).

The sense of taste depends on the creation of a receptor potential in gustatory cells. Only then can an action potential be generated and a nerve impulse relayed to the brain for interpretation. Generation of a receptor potential begins when G-protein–coupled receptors (GPCRs) or ion channels in the plasma membranes of gustatory hairs bind to taste-producing chemicals (tastants) in the saliva. See Figure 13-30 (p. 405) to review GPCRs and Figure 13-29 (p. 405) to review ion channels acting as receptors. The nature and concentration of the chemicals that bind to either the receptor sites or ion channels determine how fast the receptor potential is generated.

Taste cells appear similar structurally, and all of them can respond at least in some degree to most taste-producing chemicals. Each taste receptor cell, however, responds most effectively to only one of five "primary" taste sensations: sour, sweet, bitter, umami

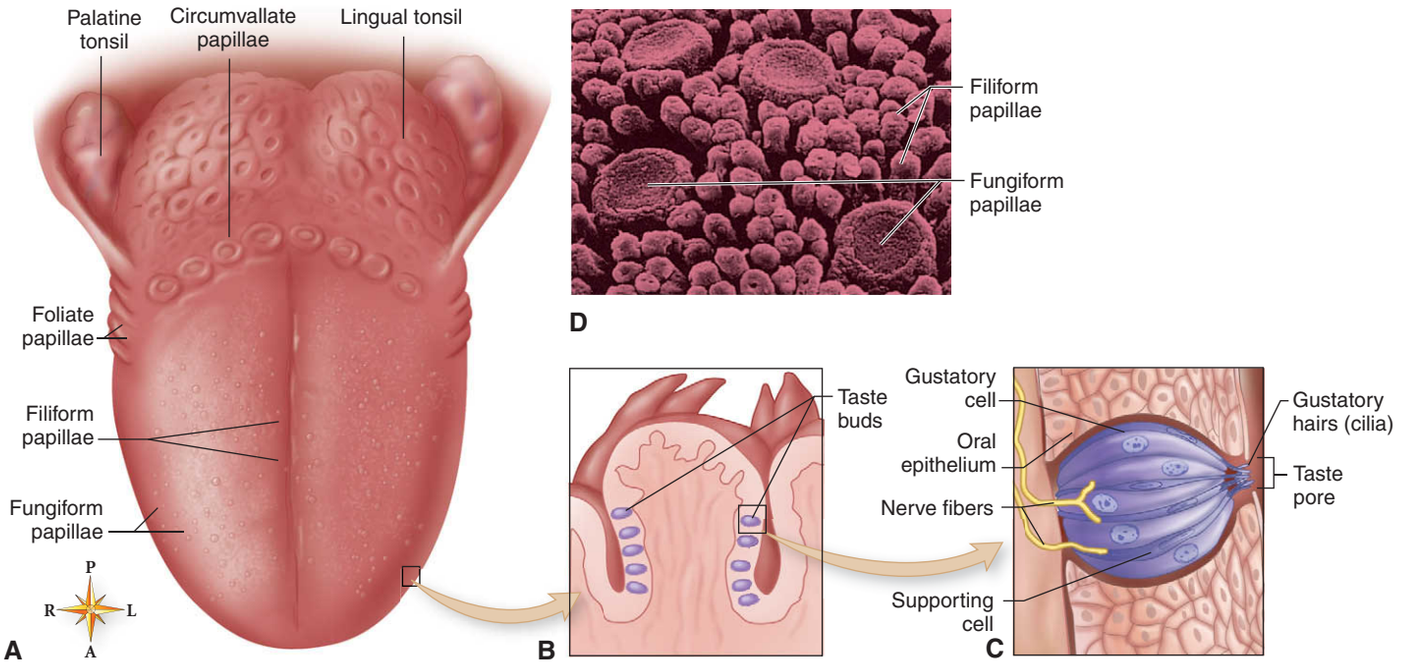

FIGURE 17-8

The tongue. A, Dorsal surface of tongue and adjacent structures. **B,** Section through a papilla with taste buds on the side. **C,** Enlarged view of a section through a taste bud. **D,** Scanning electron micrograph of the tongue surface showing the papillae in detail.

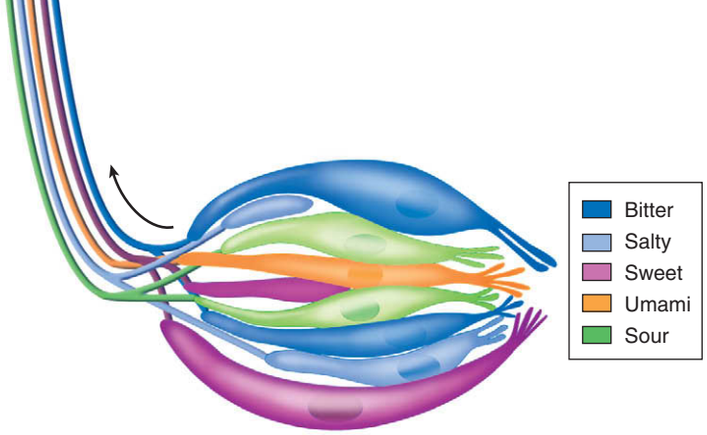

FIGURE 17-9

Taste receptors. The labeled-line model of gustation (taste) holds that each distinct taste has a separate group of taste receptors, with each group sending its impulses along a distinct "line" or neural pathway.

(savory), and salty. The *labeled-line model*, shown in Figure 17-9, holds that our brain can determine which taste we are detecting by the fact that signals from different types of receptors are conducted along different lines or neural pathways. Our ability to experience a larger variety of tastes results from combinations of the five primary sensations.

The exact mechanism by which a chemical tastant binds to a particular receptor site or ion channel on a gustatory hair is unknown. Chemical structure plays a part but is not the only factor involved, because substances that are very different chemically, such as artificial sweeteners, chloroform, and table sugar, produce a sweet taste. Some chemical compounds and specific ions, however, are definitely associated with specific tastes. Sour (H^+) and salty (Na^+) tastes activate ion channels, whereas sweet, umami, and bitter tastes result from stimulation of receptor sites. As chemoreceptors, the taste buds, like olfactory receptors, tend to be quite sensitive initially but fatigue easily. Very low levels of taste-producing chemicals are required to generate a receptor potential. However, adaptation often begins within a few seconds after a taste sensation is first noticed and is generally complete in a few minutes.

The adaptive value of our sense of taste is obvious: taste allows us to chemically test our food before swallowing it. We can then selectively eat salty foods when our body is low in sodium, or avoid foods that contain too much sodium. We can determine which foods are high in sugars when they taste sweet. Foods with a savory, or umami, taste are likely to be high in amino acids. Umami receptors detect *L-glutamate*, a form of the common amino acid *glutamic acid* released from proteins in cooked, fermented, and ripened foods. Bitter tastes, to which we have a natural aversion, signal a variety of toxins and other druglike chemicals such as caffeine that are sometimes present in plants. Research shows that there may be additional taste modalities such as "metallic" taste.

Neural Pathway for Taste

The taste sensation begins with creation of a receptor potential in the gustatory cells of a taste bud. The generation and propagation of an action potential, or nerve impulse, then transmits the sensory input to the brain.

Nerve impulses generated in the anterior two thirds of the tongue travel over the facial (CN VII) nerve, whereas those generated from the posterior one third are conducted by fibers of the glossopharyngeal (CN IX) nerve. A third cranial nerve, the vagus (CN X) nerve, plays a minor role in taste. It contains a few fibers that carry taste sensation from a limited number of taste buds located in the walls of the pharynx and on the epiglottis.

All three cranial nerves carry impulses into the medulla oblongata. The fact that, unlike any other special sense, taste has several different pathways to the brain is evidence that taste information is very important for survival. Once taste information is processed in the medulla, relays then carry the impulses into the thalamus and then into the taste, or gustatory, area of the cerebral cortex in the parietal lobe of the brain (see Figure 17-7).

We generally think of taste in terms of the "primary" sensations of sour, sweet, bitter, umami, and salty (and perhaps metallic). However, touch, texture, and temperature are also involved in taste and whether we sense it as pleasant, neutral, or unpleasant. Take the sensation of *flavor* as an example. Flavor, as the term is normally used, is a combined sense of smell, taste, and the so-called *trigeminal senses* (mediated by CN V) that detect irritants, textures, and other characteristics present in spices and most other foods. As we breathe out as we are chewing or savoring food in the mouth, olfactory receptors are triggered as the same time as receptors in taste buds and the rest of the oral mucosa. This information is integrated in the brain and we sense the combination of smells, tastes, heat (as in pepper), cold (as in mint), and texture as a single, complex flavor experience.

| QUICK CHECK |

5. List the special senses.
6. Discuss how a receptor potential is generated in olfactory cells.
7. Discuss how a receptor potential is generated in gustatory cells.
8. Trace the path of a nervous impulse carrying (1) olfactory and (2) gustatory sense information from its point of origin to that area of the brain where interpretation occurs.
9. List the five "primary" taste sensations.
10. Locate on the tongue where taste buds are detected.

SENSES OF HEARING AND BALANCE: THE EAR

The ear has dual sensory functions. In addition to its role in hearing, it also functions as the sense organ of balance, or equilibrium. The stimulation, or "trigger," responsible for hearing and balance involves activation of mechanoreceptors called *hair cells*. Sound waves and fluid movement are the physical forces that act on hair cells to generate receptor potentials and then nerve impulses, which are eventually perceived in the brain as sound or

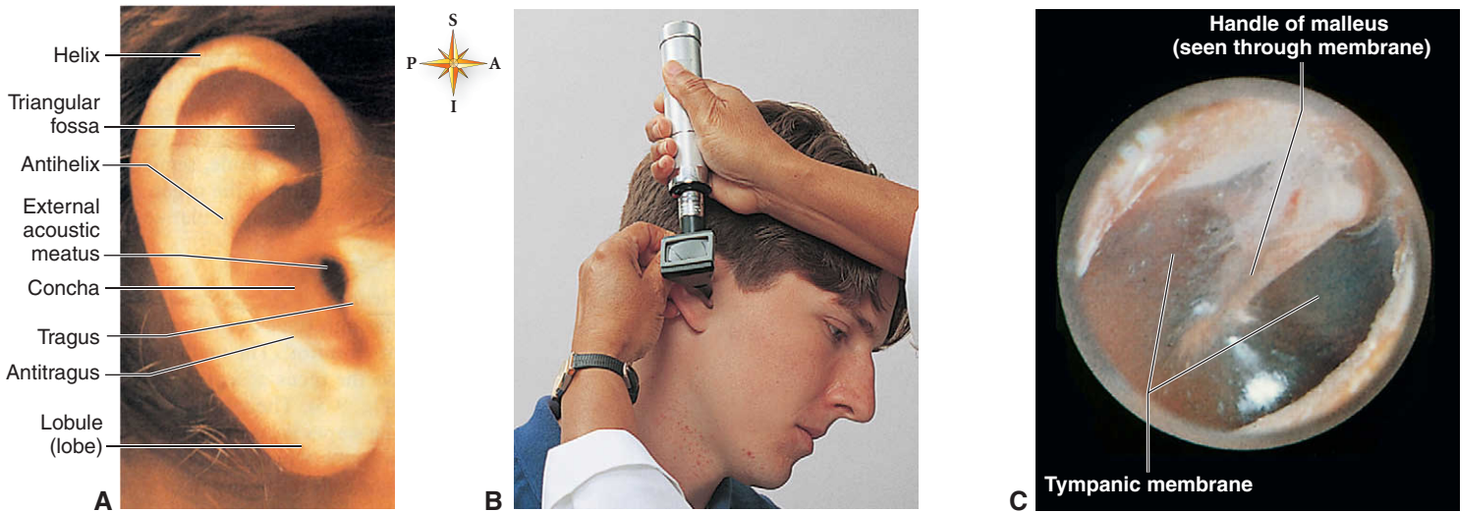

FIGURE 17-10

Examining the external ear, ear canal, and tympanic membrane. **A,** Anatomical structures of the auricle (external ear). **B,** Using a lighted otoscope to view the external ear canal and tympanic membrane. **C,** Note the translucent, pearly-grey appearance of a normal tympanic membrane. The "handle" of the malleus can be seen attaching near the center of the inner surface of the membrane.

balance. The ear is divided into three anatomical parts: **external ear, middle ear,** and **inner ear** (Figures 17-10 and 17-11).

The structures illustrated in Figure 17-11 are not drawn to scale. Instead, the smaller components of the middle and inner ear are enlarged so that they can be more easily identified. In addition, this type of artistic rendering makes it easier to see the anatomical relationships of these tiny elements to one another and to adjacent structures.

External Ear

The external ear has two divisions: the *auricle* or *pinna*, and the *external acoustic meatus* (ear canal). The auricle is the visible appendage on the side of the head surrounding the opening of the external acoustic meatus. A number of anatomical components of the auricle are identified in Figure 17-10.

Because it lies exposed against the bony surface of the skull, the auricle is frequently injured by blunt trauma. Bruising may then cause an accumulation of blood and tissue fluid between the skin and underlying cartilage. If bruising is left untreated, the dramatic swelling of "cauliflower ear" may develop and become permanent. The sun-exposed auricle, especially the tops of the helix, is also a frequent site for development of skin cancer, often squamous cell carcinoma (see Chapter 7).

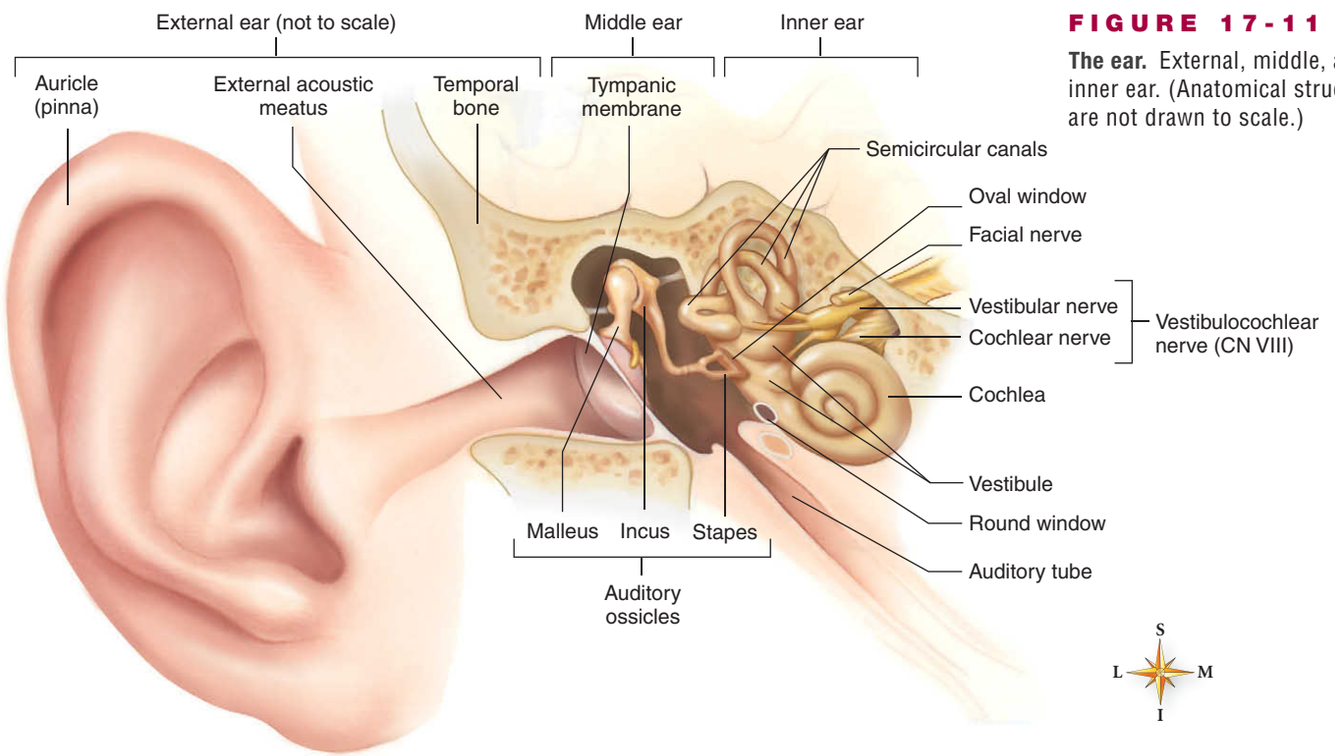

FIGURE 17-11

The ear. External, middle, and inner ear. (Anatomical structures are not drawn to scale.)

The *lobule* or lobe of the auricle is a frequent site of piercing for cosmetic reasons. Piercings of the cartilage in other areas of the auricle carry a higher risk of infection and slower healing because there is a better blood supply in the lobule.

Note in Figure 17-10 that the *tragus* of the auricle is located just in front of the opening to the ear in adults, this canal is about 3 cm long. Initially it slants upward a bit and then curves downward before traveling into the temporal bone in an inward and forward direction. It ends at the **tympanic membrane,** or **eardrum,** which stretches across the inner end of the canal, separating it from the middle ear.

A lighted instrument called an **otoscope** is used to examine the external ear canal and outer surface of the tympanic membrane (see Figure 17-10, *B*). Changes in the appearance of the ear canal and tympanic membrane can provide a skilled observer with a great deal of information. For example, middle ear infection, called **otitis media,** will cause the eardrum to become red and inflamed and to bulge outward into the ear canal as pus and other fluids accumulate in the middle ear (see Mechanisms of Disease, p. 534). Accumulation of the waxlike substance *cerumen*, which is secreted by modified sweat glands in the auditory canal, may cause pain and temporary deafness. It is easily identified during otoscopic examination of the ear canal.

Middle Ear

The middle ear (tympanic cavity), a tiny epithelial-lined cavity hollowed out of the temporal bone, contains the three **auditory ossicles:** the *malleus*, *incus*, and *stapes* (see Figure 17-11). The names of these very small bones describe their shapes (hammer, anvil, stirrup). The "handle" of the malleus is attached to the inner surface of the tympanic membrane, whereas the "head" attaches to the incus, which in turn attaches to the stapes. There are several openings into the middle ear cavity: one from the external acoustic meatus, covered with the tympanic membrane; two into the internal ear, the **oval window** (into which the stapes fits) and the **round window,** which is covered by a membrane; and one into the auditory (eustachian) tube.

Posteriorly the middle ear cavity is continuous with numerous mastoid air spaces in the temporal bone. The clinical importance of these middle ear openings is that they provide routes through which infection can travel. Head colds, for example, especially in children, may lead to middle ear or mastoid infections by way of the nasopharynx-auditory tube, middle ear–mastoid path.

The **auditory,** or **eustachian,** tube is composed partly of bone and partly of cartilage and fibrous tissue and is lined with mucosa. It extends downward, forward, and inward from the middle ear cavity to the nasopharynx, or pharyngotympanic tube (the part of the throat behind the nose). The auditory tube serves a useful function: it makes possible equalization of pressure against inner and outer surfaces of the tympanic membrane and therefore prevents membrane rupture and the discomfort that marked pressure differences produce. The way the auditory tube equalizes tympanic membrane pressure is this: when you swallow or yawn, air spreads rapidly through the open tube. Atmospheric pressure then presses against the inner surface of the tympanic membrane. Because atmospheric pressure is continually exerted against its outer surface, the pressures are equal.

Inner Ear

The inner ear is also called the **labyrinth** because of its complicated shape. It consists of two main parts, a bony labyrinth and, inside this, a membranous labyrinth. The bony labyrinth consists of three parts: the *vestibule*, *cochlea*, and *semicircular canals* (Figure 17-12). The membranous labyrinth consists of the *utricle*

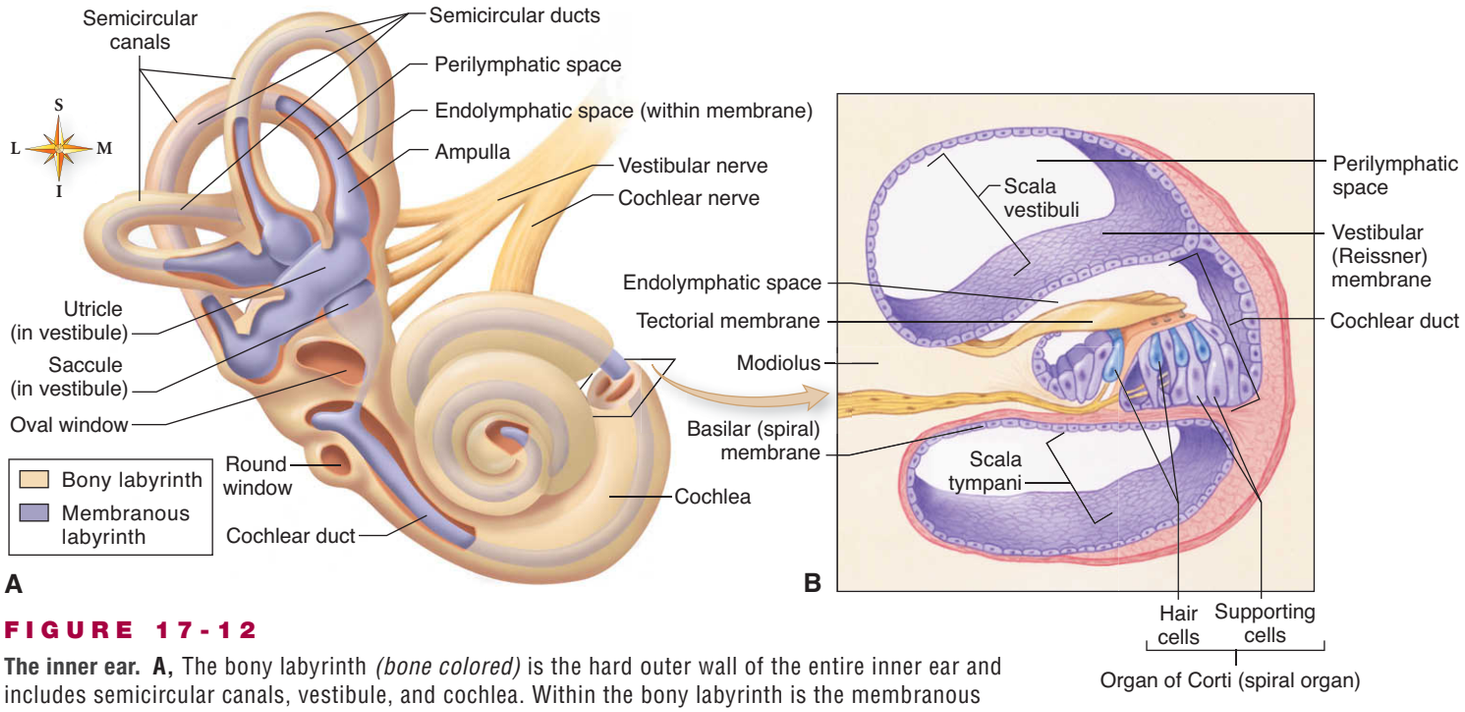

FIGURE 17-12

The inner ear. A, The bony labyrinth *(bone colored)* is the hard outer wall of the entire inner ear and includes semicircular canals, vestibule, and cochlea. Within the bony labyrinth is the membranous labyrinth *(purple),* which is surrounded by perilymph and filled with endolymph. Each ampulla in the vestibule contains a crista ampullaris that detects changes in head position and sends sensory impulses through the vestibular nerve to the brain. **B,** The inset shows a section of the membranous cochlea. Hair cells in the organ of Corti (spiral organ) detect sound and send the information through the cochlear nerve. The vestibular and cochlear nerves join to form the eighth cranial nerve.

and *saccule* inside the vestibule, the *cochlear duct* inside the cochlea, and the membranous *semicircular ducts* inside the bony ones. The vestibule (containing the membranous utricle and saccule) and the semicircular canals (and membranous ducts) are involved in balance; the cochlea (and membranous cochlear duct) is involved in hearing.

The term **endolymph** is used to describe the clear and potassium-rich fluid that fills the membranous labyrinth. **Perilymph,** a fluid similar to cerebrospinal fluid, surrounds the membranous labyrinth and therefore fills the space between this membranous tunnel and its contents and the bony walls that surround it (see Figure 17-12).

COCHLEA AND COCHLEAR DUCT

The word *cochlea*, which means "snail," describes the outer appearance of this part of the bony labyrinth. When sectioned, the cochlea resembles a tube wound spirally around a cone-shaped core of bone, the *modiolus*. The modiolus houses the spiral ganglion, which consists of cell bodies of the first sensory neurons in the auditory relay.

Inside the cochlea lies the membranous *cochlear duct*—the only part of the internal ear concerned with hearing. This structure is shaped like a somewhat triangular tube. It forms a shelf across the inside of the bony cochlea, dividing it into upper and lower sections all along its winding course (see Figure 17-12). The upper section (above the cochlear duct) is called the *scala vestibuli* (vestibular duct), whereas the lower section below the cochlear duct is called the *scala tympani* (tympanic duct). The roof of the cochlear duct is known as the **vestibular membrane** *(Reissner membrane)*. The **basilar membrane** is located on the floor of the cochlear duct. It is also called the *spiral membrane* and is supported by bony and fibrous projections from the wall of the cochlea. Perilymph fills the scala vestibuli and scala tympani, and endolymph fills the cochlear duct.

The hearing sense organ, named the **organ of Corti,** rests on the basilar membrane throughout the entire length of the cochlear duct. The organ of Corti is also called the *spiral organ* because of its spiraling curl within the cochlea. The structure of the organ of Corti consists of supporting cells, as well as important hair cells that project into the endolymph and are topped by an adherent gelatinous membrane called the **tectorial membrane.**

Dendrites of the sensory neurons, whose cell bodies lie in the spiral ganglion in the modiolus, have their beginnings around the bases of the inner row of ciliated hair cells of the organ of Corti. Axons of these neurons extend to form the cochlear nerve (a branch of the eighth cranial nerve) to the brain. They conduct impulses that produce the sensation of hearing.

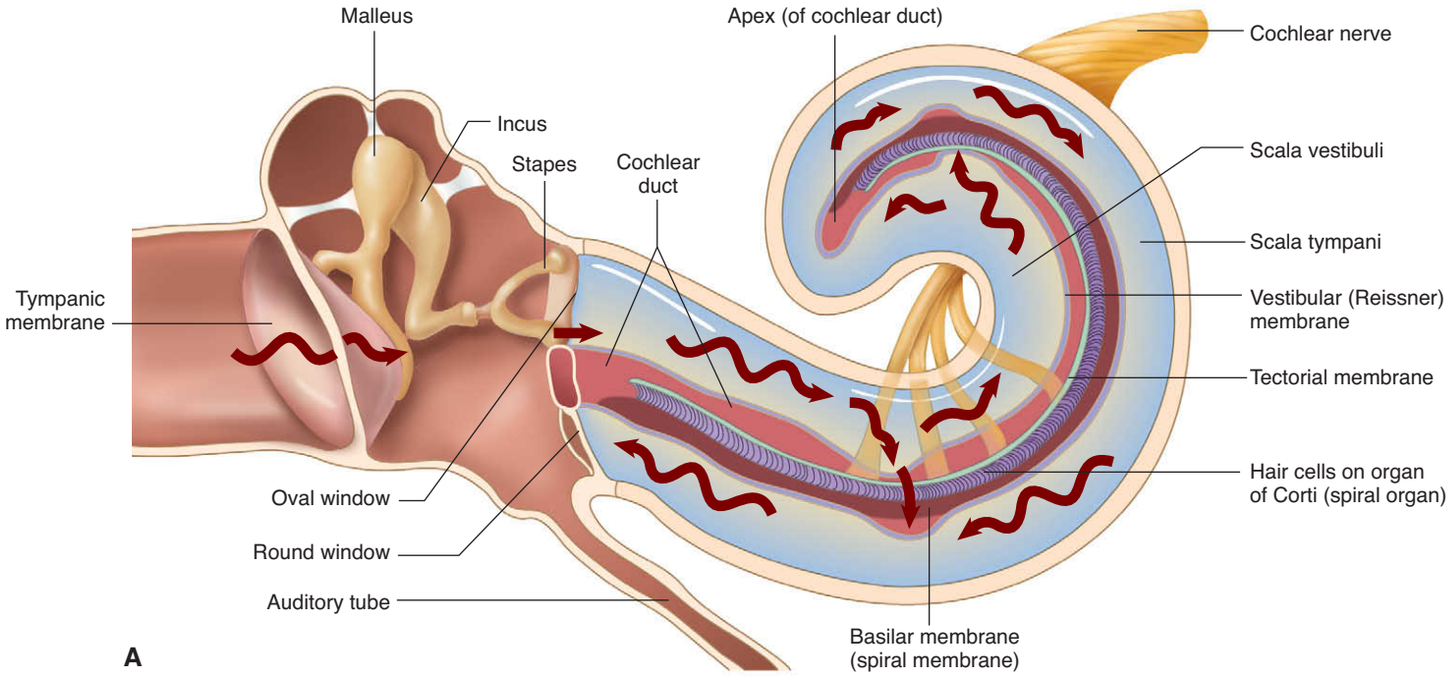
SENSE OF HEARING

Sound is created by vibrations that may occur in air, fluid, or solid material. When we speak, for example, the vibrating vocal cords create sound waves by producing vibrations in air passing over them.

Numerous terms are used to describe sound waves. The height, or amplitude, of a sound wave determines its perceived loudness, or **volume.** The number of sound waves that occur during a specific time unit (frequency) determines **pitch.** Our ability to hear sound waves depends in part on volume, pitch, and other acoustic properties. Sound waves must be of sufficient amplitude to initiate movement of the tympanic membrane and have a frequency that is capable of stimulating the hair cells in the organ of Corti at some point along the basilar membrane.

The basilar membrane is not the same width and thickness throughout its length. Because of this structural fact, different frequencies of sound will cause the basilar membrane to vibrate and bulge upward at different places along its length. Two bulges are shown in Figure 17-13, *A*.

High-frequency sound waves cause the narrow portion of the basilar membrane near the oval window to vibrate, whereas low frequencies vibrate the membrane near the apex of the cochlea, where it is considerably wider and thicker (Figure 17-13, *B*). This ability of sound waves of differing frequency to vibrate and cause a bulge, or displacement, of the basilar membrane at differing points along its length explains how specific groups of hair cells respond to specific frequencies of sound. When a particular portion of the basilar membrane bulges upward, the cilia on hair cells attached to that particular area are stimulated, and ultimately, sound of a particular pitch is perceived.



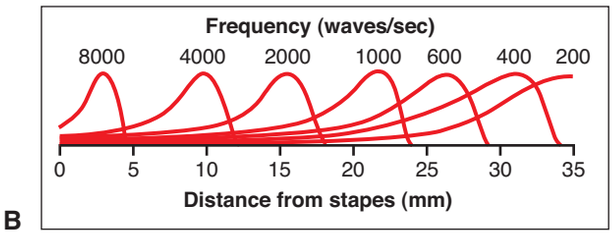
Our perception of different degrees of loudness of the same sound is determined by the amplitude, or movement, of the basilar membrane at any particular point along its length. The higher the upward bulge, the more the cilia on the attached hair cells are bent or stimulated. This causes an increase in perceived loudness. The moving wave of perilymph caused by upward displacement of the basilar membrane is soon dampened as it moves through the cochlea.

Hearing results from stimulation of the auditory area of the cerebral cortex. First, however, sound waves must be projected through air, bone, and fluid to stimulate nerve endings and set up impulse conduction over nerve fibers. Box 17-2 describes a method for artificially detecting sound and stimulating the neural pathways of hearing.

Pathway of Sound Waves

Sound waves in the air enter the external auditory canal with aid from the pinna. At the inner end of the canal, they strike against the tympanic membrane, causing it to vibrate. Vibrations of the tympanic membrane move the malleus, whose handle attaches to the membrane. The head of the malleus attaches to the incus, and the incus attaches to the stapes. So when the malleus vibrates, it moves the incus, which moves the stapes against the oval window into which it fits so precisely. At this point, fluid conduction of sound waves begins. When the stapes moves against the oval window, pressure is exerted inward into the perilymph in the scala vestibuli of the cochlea. This starts a "ripple" in the perilymph that is transmitted through the vestibular membrane (the roof of the cochlear duct) to endolymph inside the duct and then to the organ of Corti and to the basilar membrane that supports the organ of Corti and forms the floor of the cochlear duct. From the basilar membrane the ripple is next transmitted to and through the perilymph in the scala tympani and finally expends itself against the round window—like an ocean wave as it breaks against the shore, but on a much reduced scale.

Figure 17-13 summarizes the steps involved in detecting sound stimuli in the ear.



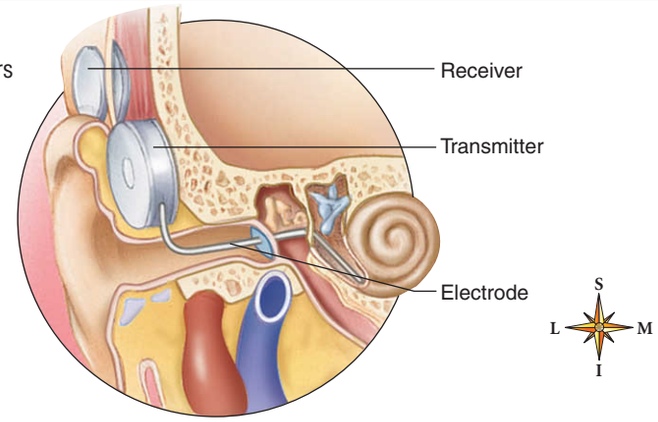


FIGURE 17-13

Effect of sound waves on cochlear structures. A, Sound waves strike the tympanic membrane and cause it to vibrate. This causes the membrane of the oval window to vibrate, which causes the perilymph in the bony labyrinth of the cochlea and the endolymph in the membranous labyrinth of the cochlea, or cochlear duct, to move. This movement of endolymph causes the basilar (spiral) membrane to vibrate, which in turn stimulates hair cells on the organ of Corti (spiral organ) to transmit nerve impulses along the cochlear nerve. Eventually, nerve impulses reach the auditory cortex and are interpreted as sound. **B,** High-frequency (high-pitch) waves stimulate hair cells nearer the stapes (oval window) and low-frequency (low-pitch) waves stimulate hair cells nearer the distal end of the cochlea. The location of peak stimulation of the hair cells allows the brain to interpret the pitch of the sound.

Box 17-2 | HEALTH matters

Cochlear Implants

Electronic devices can help correct some forms of nerve deafness. If the hairs on the organ of Corti (spiral organ) are damaged, nerve deafness results—even if the vestibulocochlear nerve is healthy. A surgically implanted device can improve this form of hearing loss by eliminating the need for the sensory hairs. As you can see in the figure, a transmitter just outside the scalp sends external sound information to a receiver under the scalp (behind the auricle). The receiver translates the information into an electrical code that is relayed down an electrode to the cochlea. The electrode, wired to the organ of Corti, stimulates the vestibulocochlear nerve endings directly. Thus even though the cochlear hair cells are damaged, sound can be perceived.

UNIT 3

Neural Pathway of Hearing

Dendrites of neurons whose cell bodies lie in the spiral ganglion and whose axons make up the cochlear nerve terminate around the bases of the hair cells of the organ of Corti, and the tectorial membrane adheres to their upper surfaces. The movement of the hair cells against the adherent tectorial membrane somehow stimulates these dendrites and initiates impulse conduction by the cochlear nerve to the brainstem. Before reaching the auditory area of the temporal lobe, impulses pass through "relay stations" in nuclei in the medulla, pons, midbrain, and thalamus.

| QUICK CHECK |

11. List the three anatomical divisions of the ear.
12. Identify the three auditory ossicles.
13. Name the divisions of both the membranous and bony labyrinths.
14. Name the specific sense organ responsible for hearing.

VESTIBULE AND SEMICIRCULAR CANALS

The vestibule constitutes the central section of the bony labyrinth. Look again at Figure 17-12, A. Note that the bony labyrinth opens into the oval and round windows from the middle ear, as well as the three semicircular canals of the internal ear. The utricle and saccule are the membranous structures within the vestibule. Both have walls of simple cuboidal epithelium and are filled with endolymph.

Three semicircular canals, each in a plane approximately at right angles to the others, are found in each temporal bone (see Figure 17-12, A). Within the bony semicircular canals and separated from them by perilymph are the membranous semicircular ducts. Each contains endolymph and connects with the utricle inside the bony vestibule. Near its junction with the utricle each canal enlarges into an *ampulla*.

SENSE OF BALANCE

The sense organs involved in the sense of balance, or **equilibrium**, are found in the vestibule and semicircular canals. The sense organs located in the utricle and saccule function in **static equilibrium**—a function needed to sense the position of the head relative to gravity or to sense acceleration or deceleration of the body, such as would occur when seated motionless in a vehicle that was increasing or decreasing in speed. The sense organs associated with the semicircular ducts function in **dynamic equilibrium**—a function needed to maintain balance when the head or body itself is rotated or suddenly moved.

Static Equilibrium

A small patchlike strip of epithelium called the **macula** is found within both the utricle and saccule (Figure 17-14, A). It is sensory

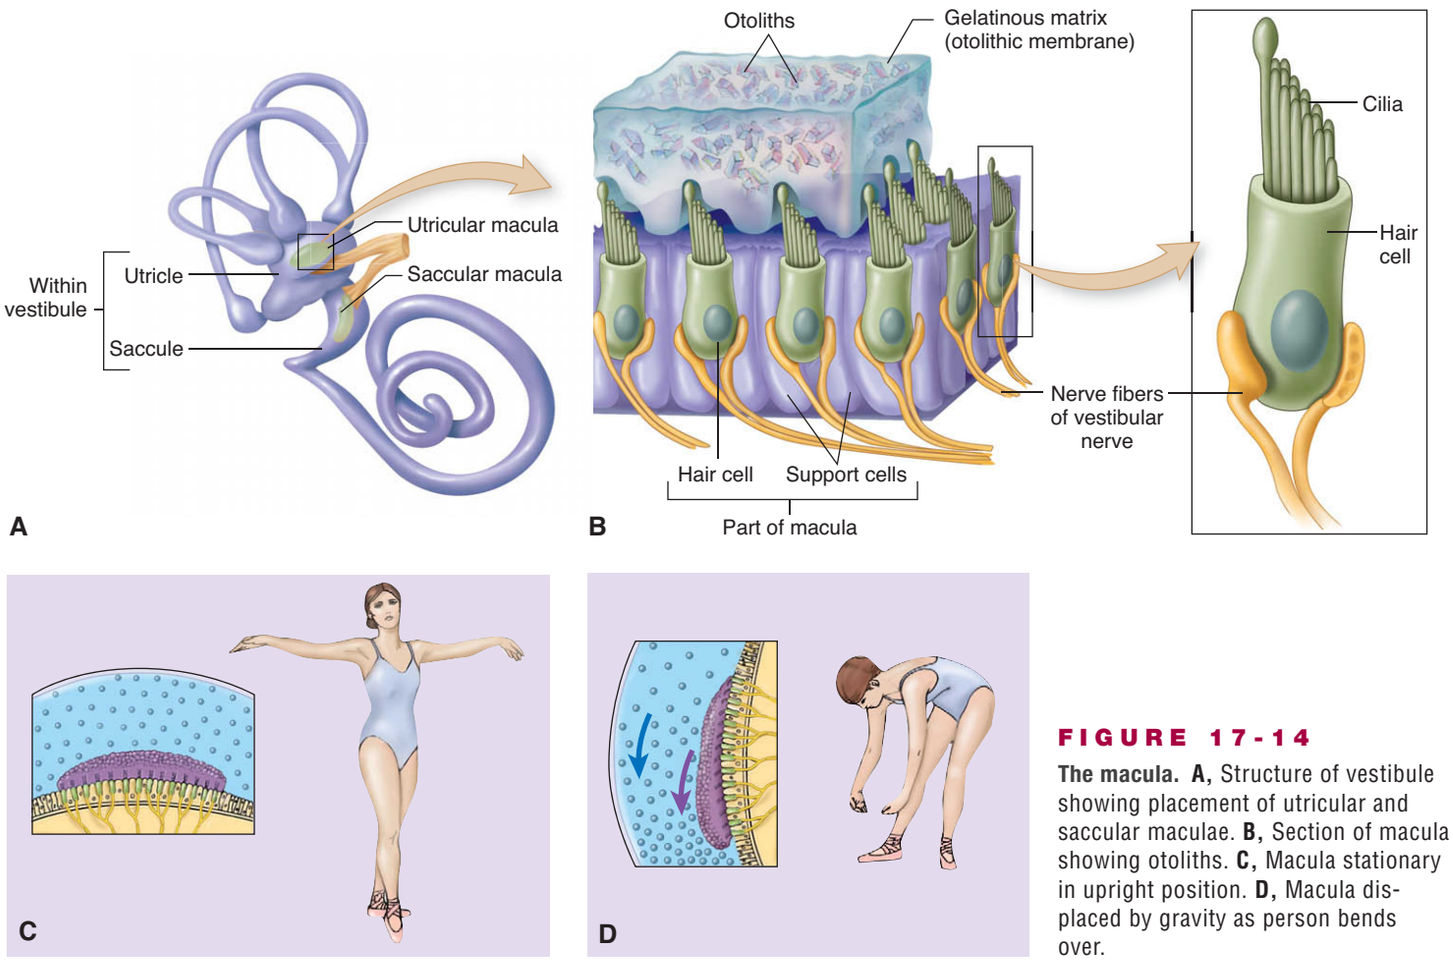

FIGURE 17-14

The macula. A, Structure of vestibule showing placement of utricular and saccular maculae. **B,** Section of macula showing otoliths. **C,** Macula stationary in upright position. **D,** Macula displaced by gravity as person bends over.

epithelium containing receptor hair cells and supporting cells covered with a gelatinous matrix. Movements of the macula provide information related to head position or acceleration. Action potentials are generated by movement of the hair cells, which occurs when the position of the head relative to gravity changes.

Otoliths—tiny "ear stones" composed of protein and calcium carbonate—are located within the matrix of the macula (Figure 17-14, *B*). Now note the relative positions of the utricular and saccular maculae in Figure 17-14, *A*. The two maculae are oriented almost at right angles to each other: the one in the utricle is parallel to the base of the skull, and the one in the saccule is perpendicular.

Changing the position of the head produces a change in the amount of pressure on the otolith-weighted matrix, which, in turn, stimulates the hair cells (Figure 17-14, *C* and *D*). This stimulates the adjacent receptors of the vestibular nerve. Its fibers conduct impulses to the brain that produce a sense of the position of the head and also a sensation of a change in the pull of gravity, for example, a sensation of acceleration.

In addition, stimulation of the macula evokes *righting reflexes*, muscular responses to restore the body and its parts to their normal position when they have been displaced. Impulses from proprioceptors and from the eyes also activate righting reflexes. Interruption of the vestibular, visual, or proprioceptive impulses that initiate these reflexes may cause disturbances of equilibrium, nausea, vomiting, and other symptoms.

Dynamic Equilibrium

Dynamic equilibrium depends on the functioning of the **crista ampullaris,** located in the ampulla of each semicircular duct. It is also called the *ampullary crest*. This unique structure is a form of sensory epithelium that is similar in many ways to the maculae. Each ridgelike crista is dotted with many hair cells, each with their processes embedded in a gelatinous flap called the **cupula** (Figure 17-15, *A* and *B*).

The cupula is not weighted with otoliths and does not respond to the pull of gravity. It serves, instead, much like a float that moves with the flow of endolymph in the semicircular ducts. Like the maculae, the semicircular ducts are placed nearly at right angles to each other. This arrangement enables detection of movement in all directions. As the cupula moves, it bends the hairs

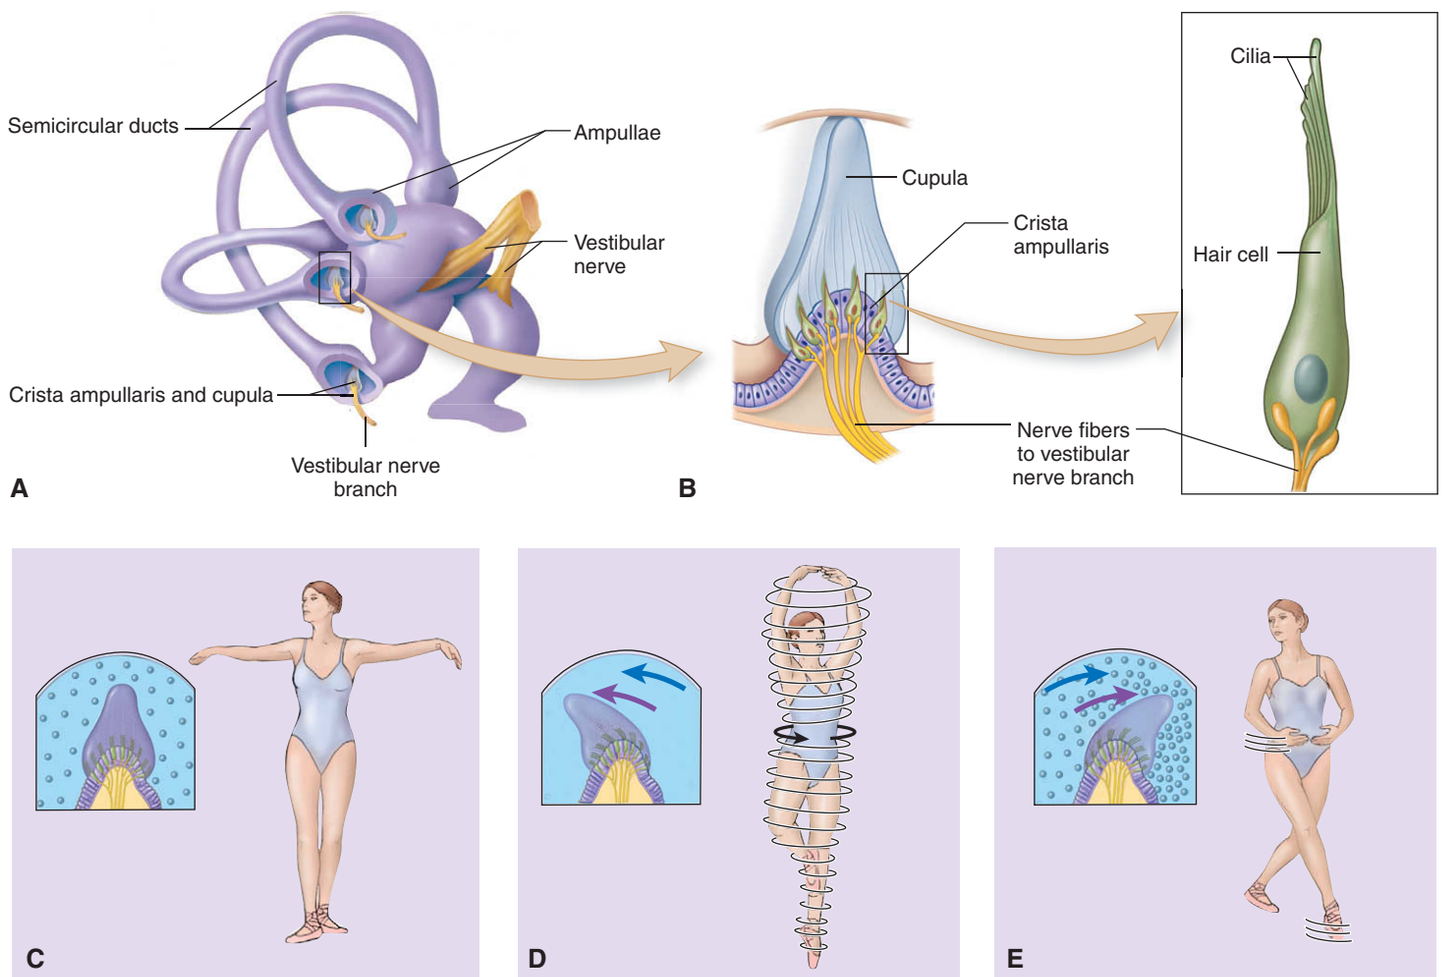

FIGURE 17-15

Structure and function of the crista ampullaris. A, Semicircular ducts showing location of the crista ampullaris in ampullae. **B,** Enlargement of crista ampullaris and cupula. **C,** When a person is at rest, the crista ampullaris does not move. **D** and **E,** As a person begins to spin, the crista ampullaris is displaced by the endolymph in a direction opposite to the direction of spin.

embedded in it, producing first a receptor and then an action potential that passes through the vestibular portion of the eighth cranial nerve to the medulla oblongata and, from there, to other areas of the brain and spinal cord for interpretation, integration, and response.

When a person spins (Figure 17-15, *C* to *E*), the semicircular ducts move with the body, but inertia keeps the endolymph in them from moving at the same rate. The cupula therefore moves in a direction opposite to head movement until after the initial movement stops. Dynamic equilibrium is thus able to detect changes in both the direction and the rate at which movement occurs.

| A&P CONNECT |

Vertigo involves a sensation of one's own body spinning in space or of the external world spinning around the individual. Vertigo can be a frightening and recurring problem often precipitated in affected individuals by sudden changes in body position that may occur when rolling over in bed, bending to pick up an object from the floor, or simply sitting up quickly. This condition is often related to the abnormal displacement of rocks in your head. Really! Want to know more about how "rocks in your head" occurs and how it can be fixed? Check out ***Vertigo and Ear Rocks*** online at ***A&P Connect.***

VISION: THE EYE

One of the most important sensations involved in maintaining homeostasis is vision, and the eye is the body's sense organ for this important function. Vision is a truly remarkable sensory ability and is used to guide almost all that we do. It allows us to activate and respond to a multitude of warning systems, and provides us with almost constant feedback on various types of form and movement in an ever-changing environment. It is the eye that uses as a stimulus the pervasive nature of light to convert stored photochemical energy into nervous impulses that are ultimately interpreted by the brain as sight.

The study of vision and the visual apparatus is an important area of ongoing research and clinical interest. Clinical **ophthalmology** is a medical practice specialty concerned with pathologic conditions of the eye and the diagnosis and treatment of eye disorders. A number of allied health professionals, including ophthalmic medical technologists, laboratory technicians, and opticians, work closely with ophthalmologists in administrative, research, and clinical environments.

We will first discuss the various structures of the eye and then move on to the ways in which these structures enable the eye to control the amount of light entering it and how the conversion to electrical stimuli actually occurs.

Structure of the Eye

EXTERNAL STRUCTURES

A number of the anatomical structures of the external eye are visible in Figure 17-16 and discussed in the sections that follow. Some of these structures, such as the sclera, iris, and pupil, are structures of the eye itself. Accessory structures of the eye discussed here include the eyebrows, eyelashes, eyelids, and lacrimal apparatus.

Eyebrows and Eyelashes

The eyebrows and eyelashes serve a cosmetic purpose and give some protection against foreign objects entering the eyes. They also help shade the eyes and provide at least minimal protection from direct light. Small glands located at the base of the lashes secrete a lubricating fluid. They frequently become infected, forming a *sty*.

Eyelids

The eyelids, or *palpebrae* (sing., *palpebra*), consist mainly of voluntary muscle and skin, with a border of thick connective tissue at the free edge of each lid, known as the *tarsal plate*. One can feel the tarsal plate as a ridge when turning back the eyelid to remove a foreign object. A lateral and medial angle or *canthus* forms where the superior and inferior eyelids meet. An additional fold of skin over the upper eyelid and medial angle of most infants and toddlers, and many adults, is called an epicanthal fold (Figure 17-16, *B*). The epicanthal fold is especially prominent in many people of Asian descent.

Mucous membrane, called *conjunctiva*, lines each lid (Figure 17-17). It continues over the surface of the eyeball, where it is modified to give transparency. Inflammation of the conjunctiva (conjunctivitis) is a fairly common infection. Because it produces a pinkish discoloration of the eye's surface, it is called *pinkeye* (Figure 17-18).

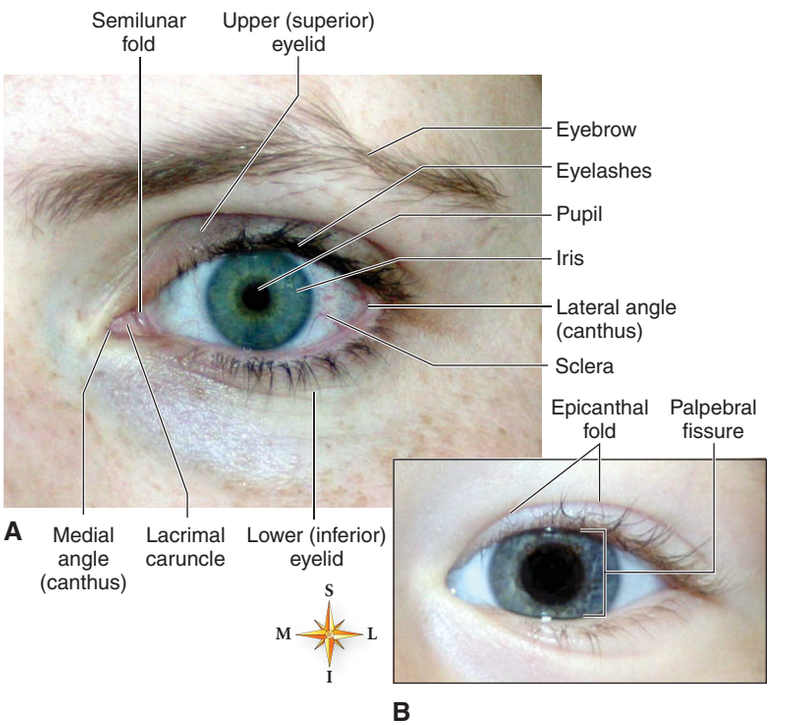

FIGURE 17-16

External eye structures. A, Visible portion of the adult eye and surrounding structures. **B,** Epicanthal fold in a toddler.

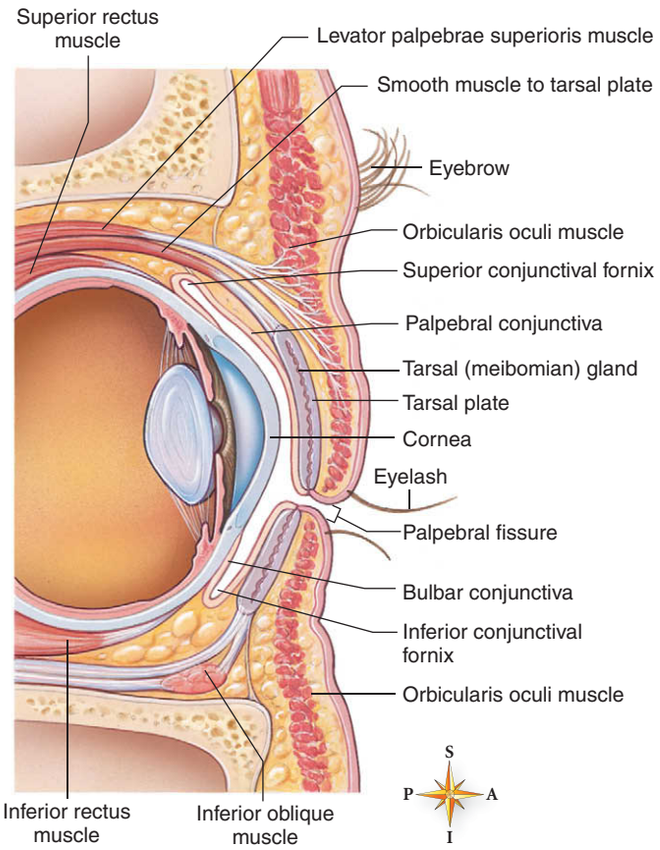

FIGURE 17-17

Accessory structures of the eye. Lateral view with eyelids closed.

The opening between the eyelids bears the technical name of *palpebral fissure*. The height of the fissure determines the apparent size of the eyes. If the eyelids are habitually held wide open, the eyes appear large, although the difference in eyeball size among most adults is not significant. Eyes appear small if the upper eyelids droop. Plastic surgeons can correct this common aging change with an operation called **blepharoplasty.**

FIGURE 17-18

Acute bacterial conjunctivitis. Note the discharge of pus characteristic of this highly contagious infection of the conjunctiva.

Lacrimal Apparatus

The *lacrimal apparatus* consists of the structures that secrete tears and drain them from the surface of the eyeball. They are the lacrimal glands, lacrimal ducts, lacrimal sacs, and nasolacrimal ducts (Figure 17-19).

The *lacrimal glands*, comparable in size and shape to a small almond, are located in a depression of the frontal bone at the upper outer margin of each orbit. Approximately a dozen small ducts lead from each gland, draining the tears onto the conjunctiva at the upper outer corner of the eye.

The *lacrimal canals* are small channels, one above and the other below each *caruncle* (small red body at the inner canthus). They empty into the lacrimal sacs. The openings into the canals are called *puncta* (sing., *punctum*) and can be seen as two small dots at the medial angle (inner canthus) of the eye. The *lacrimal sacs* are located in a groove in the lacrimal bone. The *nasolacrimal ducts* are small tubes that extend from the lacrimal sac into the inferior meatus of the nose.

All the tear ducts are lined with mucous membrane, an extension of the mucosa that lines the nose. When this membrane becomes inflamed and swollen, the nasolacrimal ducts become plugged, causing the tears to overflow from the eyes instead of draining into the nose as they do normally. Hence when we have a common cold, "watery" eyes add to our discomfort.

Muscles of the Eye

Eye muscles are of two types: *extrinsic* and *intrinsic*.

Extrinsic eye muscles are skeletal muscles that attach to the outside of the eyeball and to the bones of the orbit. They move the eyeball in any desired direction and are, of course, voluntary muscles. Four of them are straight muscles, and two are oblique. Their names describe their positions on the eyeball. They are the

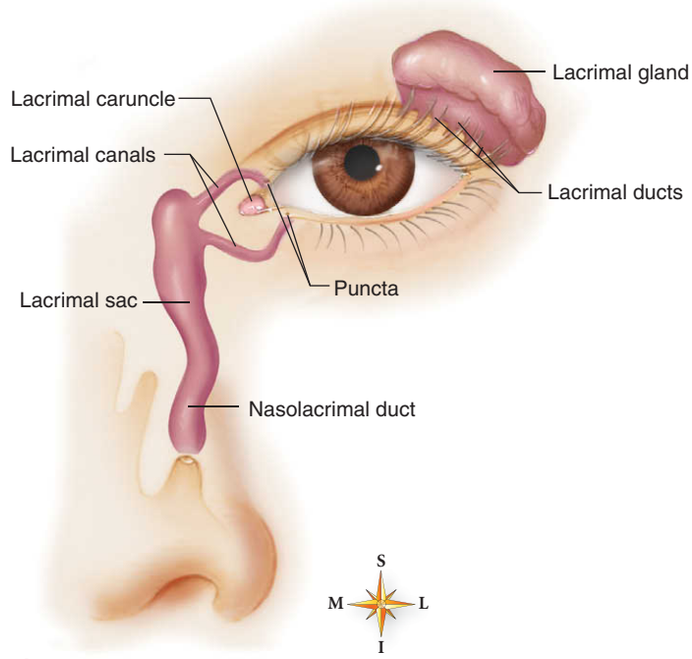

FIGURE 17-19

Lacrimal apparatus. Fluid produced by lacrimal glands (tears) streams across the eye surface, enters the canals, and then passes through the lacrimal sac and nasolacrimal duct to enter the nose.

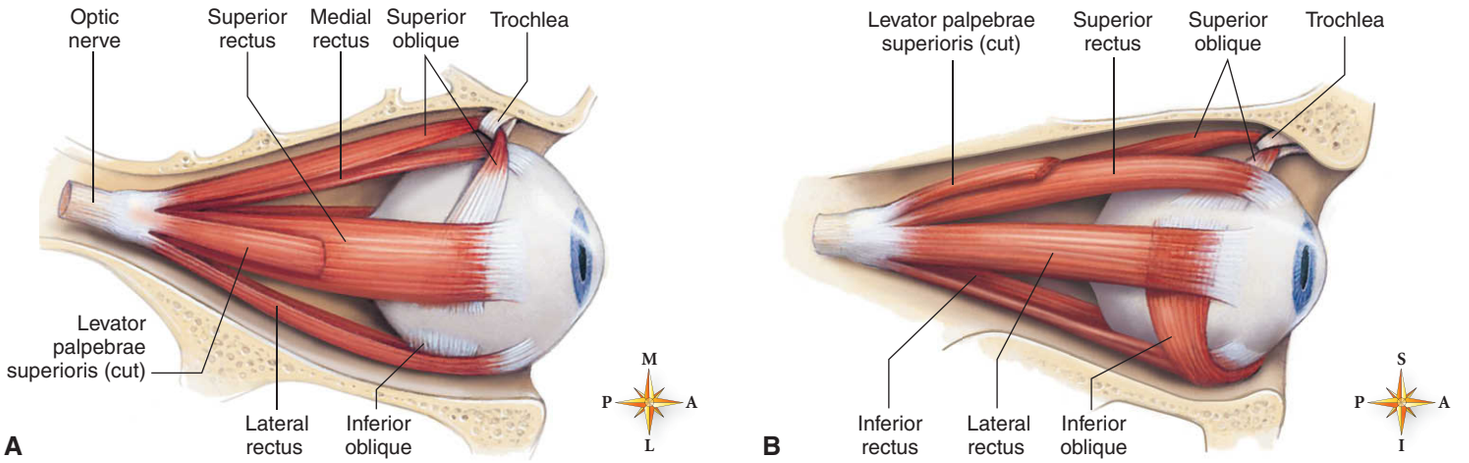

FIGURE 17-20

Extrinsic muscles of the right eye. A, Superior view. **B,** Lateral view.

superior, inferior, medial, and lateral rectus muscles and superior and inferior oblique muscles (Figure 17-20).

Intrinsic eye muscles are smooth, or involuntary, muscles located within the eye. These are called the *iris* and the *ciliary muscles.* Incidentally, the eye is one of only a few organs in the body in which both voluntary and involuntary muscles are found. The iris regulates the size of the pupil. The ciliary muscle controls the shape of the lens. As the ciliary muscle contracts, it releases the suspensory ligament from the backward pull usually exerted on it, and this allows the elastic lens, suspended in the ligament, to bulge, or become more convex. The role of both these muscles in vision is discussed later in this chapter.

LAYERS OF THE EYEBALL

Approximately five sixths of the eyeball, a spherelike globe about 22 to 25 mm in diameter, lies recessed in and is protected by the bony orbit or eye socket. Only the small anterior surface of the eyeball is exposed. Three layers of tissues compose the eyeball. From the outside in, the following three layers of tissues and their component parts or regions form the eyeball.

1. Fibrous layer
   - Sclera
   - Cornea
2. Vascular layer
   - Choroid
   - Ciliary body
   - Iris
3. Inner layer
   - Retina
   - Optic nerve
   - Retinal blood vessels

Refer to Figure 17-21 as you read the following paragraphs.

The anterior portion of the sclera is called the *cornea* and lies over the colored part of the eye, the *iris* (see Figures 17-16 and 17-21). The cornea is transparent, whereas the rest of the sclera is white and opaque, a fact that explains why the visible anterior surface of the sclera is usually spoken of as the "white" of the eye. No blood vessels are found in the cornea or in the lens. Deep within the anterior part of the sclera, at its junction with the cornea, is a ring-shaped *scleral venous sinus*, formerly called the *canal of Schlemm.* Corneas that have lost their transparency can sometimes be transplanted from a donor (Box 17-3).

As noted above, the vascular layer consists of three component parts or regions—the choroid, ciliary body, and iris. This layer is characterized by many blood vessels and a large amount of melanin pigment. Most of this layer, forming the middle and posterior coating just inside the fibrous coat, is the highly pigmented choroid.

Box 17-3 | HEALTH matters

Corneal Transplants

Surgical removal of an opaque or deteriorating cornea and replacement with a donor transplant is a common medical practice. Corneal tissue is avascular; that is, the cornea is free of blood vessels. Therefore corneal tissue is seldom rejected by the body's immune system. Antibodies carried in the blood have no way to reach the transplanted tissue, and therefore long-term success following implant surgery is excellent. The Figure is a photo of a patient with a recent corneal transplant. Note sutures and mild edema.

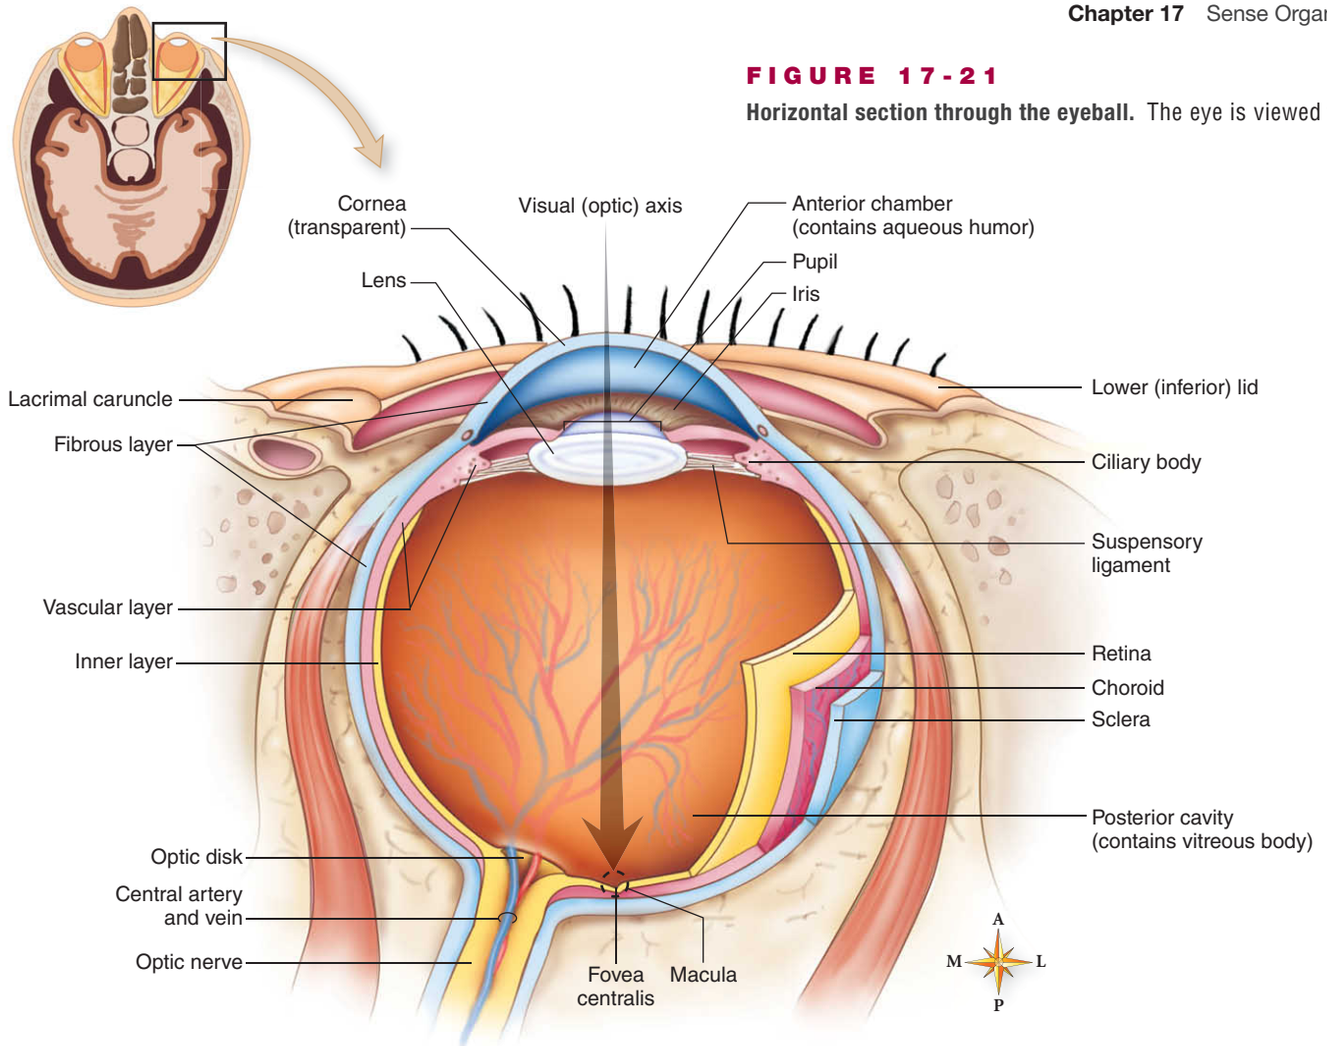

FIGURE 17-21

Horizontal section through the eyeball. The eye is viewed from above.

The **ciliary body** is formed by a thickening of the choroid and fits like a collar into the area between the anterior margin of the retina and the posterior margin of the iris (Figure 17-22). The small *ciliary muscle*, composed of both radial and circular smooth muscle fibers, lies in the anterior part of the ciliary body. Folds in the ciliary body are called *ciliary processes*, and attached to these are the *suspensory ligaments*, which blend with the elastic capsule of the *lens* and hold it suspended in place.

The **iris,** or the colored part of the eye, consists of circular and radial smooth muscle fibers arranged to form a doughnut-shaped structure. It attaches to the ciliary body. The hole-shaped opening in the middle of the iris is the **pupil.** By adjusting the diameter of the opening, the iris acts like the diaphragm of a camera. It controls the amount of light that enters the eye by adjusting the size of the pupil. Eye color is determined by the amount, placement, and type of melanin in the iris—and the reflection of light bouncing off the iris.

In *ocular albinism*, a genetic disorder, there is little or no pigmentation of the vascular layer, and thus light entering the eye passes through this layer and reflects off of the white fibrous coat. This both amplifies the light inside the eye and disrupts the formation of a clear image—often leading to full or partial blindness.

The **retina** is the incomplete innermost coat of the eyeball—incomplete in that it has no anterior portion. Melanin-containing epithelial cells form the layer of the retina next to the choroid coat. This part of the retina is called the *pigmented retina*.

Most of the retina, however, is made up of nervous tissue and is called the *sensory retina*. Three layers of neurons form the basic structure of the sensory retina. Named in the order in which they conduct impulses, these neurons are the *main photoreceptor*

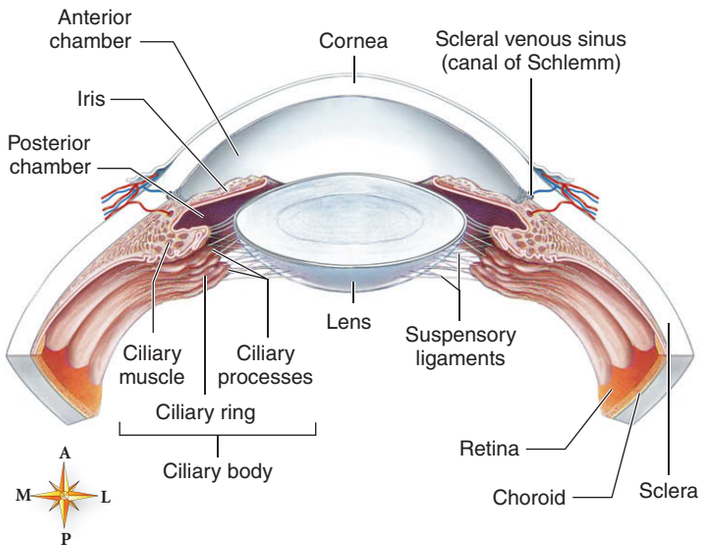

FIGURE 17-22

Lens, cornea, iris, and ciliary body. Note the suspensory ligaments that attach the lens to the ciliary body.

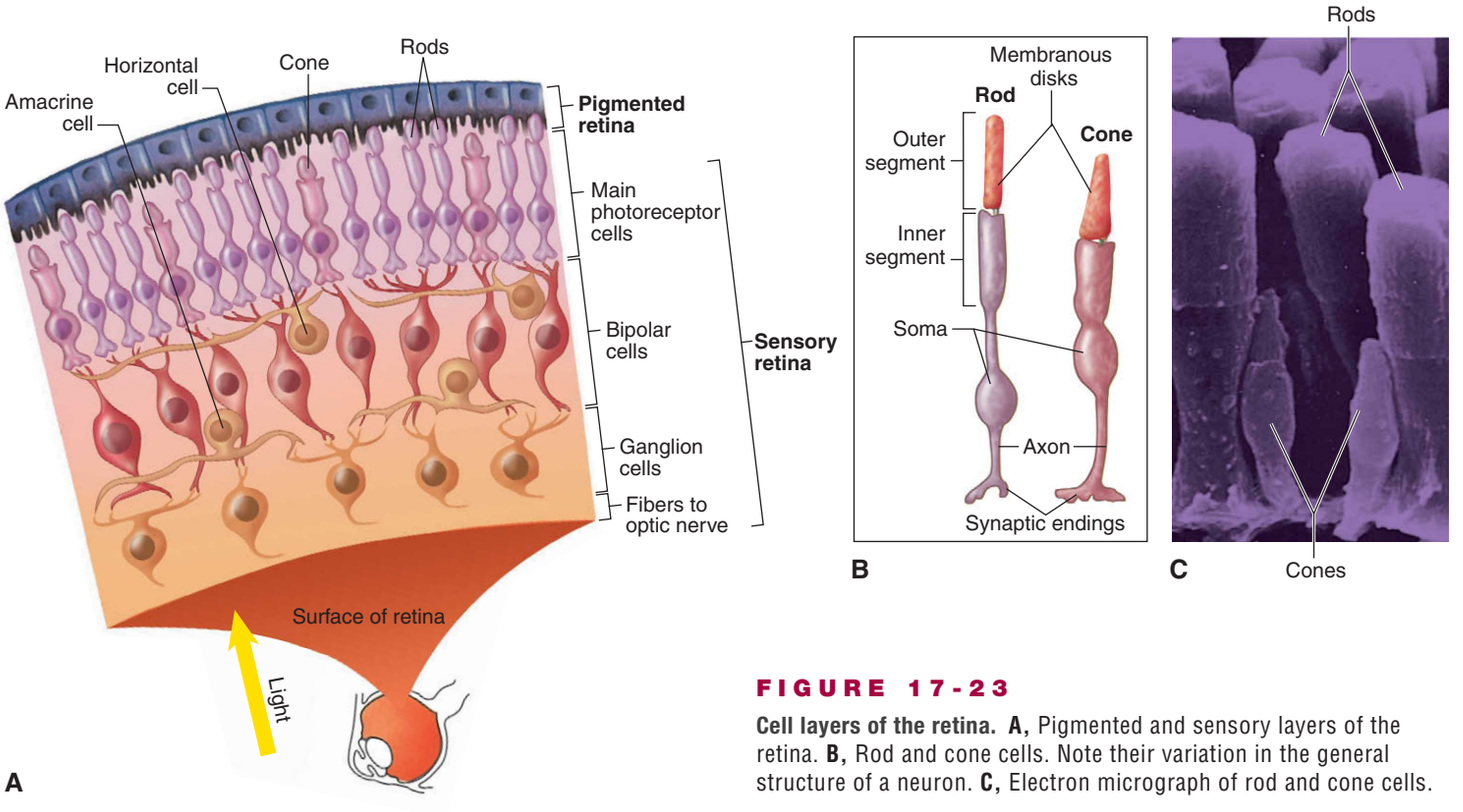

FIGURE 17-23

Cell layers of the retina. A, Pigmented and sensory layers of the retina. **B,** Rod and cone cells. Note their variation in the general structure of a neuron. **C,** Electron micrograph of rod and cone cells.

cells, *bipolar cells*, and *ganglion cells*. Identify each of these in Figure 17-23, *A*. Notice that the main photoreceptor cells are the deepest, then the bipolar cells, then the ganglion cells.

The distal ends of the dendrites of the main photoreceptor neurons have names that describe their shapes. Because some look like tiny rods and others look like cones, they are called **rods** and **cones,** respectively (Figure 17-23, *B* and *C*). Because they are sensitive to light rays, they act as our principal visual receptors. They differ in numbers, distribution, and function. Cones are less numerous than rods and are most densely concentrated in the **fovea centralis,** a small depression in the center of a yellowish area, the **macula lutea,** found near the center of the retina (see Figures 17-21 and 17-24). The macula lutea (Latin) is called simply the *macula* in English. The cones become less and less dense from the fovea outward. Rods, on the other hand, are absent entirely from the fovea and macula and increase in density toward the periphery of the retina. How these anatomical facts relate to rod and cone functions is discussed on pp. 529–530.

The bipolar cells are neurons that receive impulses from the rods and cones and pass these impulses to the ganglion neurons. Notice in Figure 17-23 that a bipolar neuron connects either to one cone or to many rods.

The ganglion neurons collect information from the primary photoreceptor neurons—the rods and cones. But they also act as photoreceptors themselves. Additional sets of neurons allow lateral connections among rods and cones (*horizontal cells*) and among bipolar and ganglion cells (*amacrine cells*). The lateral connecting cells are thought to help us detect patterns of movement.

All the axons of ganglion neurons extend back to a small circular area in the posterior part of the eyeball known as the *optic disk*. This part of the sclera contains perforations through which the fibers emerge from the eyeball as the **optic nerve** (second cranial nerve). The optic disk is also called the **blind spot** because light rays striking this area cannot be seen. Why? Because it contains no rods or cones, only nerve fibers. Box 17-4 shows you how to locate the blind spots in your own eyes.

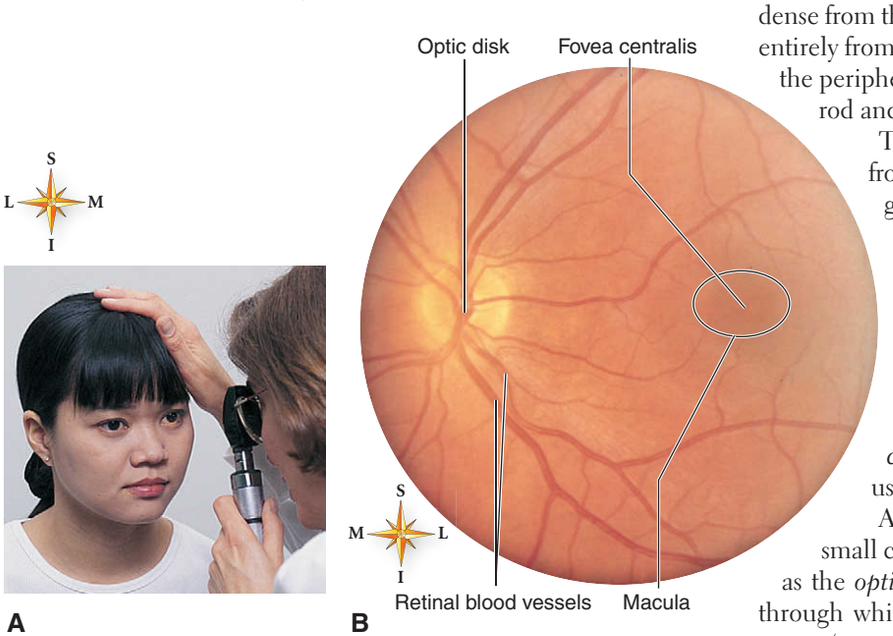

FIGURE 17-24

Examining the eye. A, Using the ophthalmoscope to view the retina. **B,** Ophthalmoscopic view of the retina as seen through the pupil.

Box 17-4 | FYI

Finding Your Blind Spot

Demonstrate the location of the blind spot in your visual field by covering your left eye and looking at the objects below. While staring at the square, begin about 30 cm (12 inches) from objects and slowly bring the figures closer to your eye. At one point, the circle will seem to disappear because its image has fallen on the blind spot.

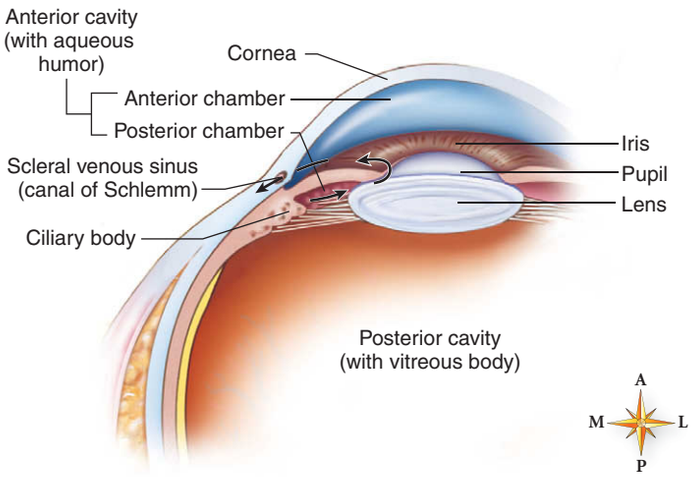

FIGURE 17-25

Formation of aqueous humor. Aqueous humor *(heavy arrows)* is believed to be formed mainly by secretion by the ciliary body into the posterior chamber. It passes into the anterior chamber through the pupil, from which it is drained away by the ring-shaped scleral venous sinus (canal of Schlemm), and finally into the anterior ciliary veins.

Just as an otoscope is used to view the external auditory canal and surface of the tympanic membrane, a lighted **ophthalmoscope** can be used to examine the retinal surface, called the *fundus*, and internal eye structures by viewing them through the pupil (see Figure 17-24, *A* and *B*). This noninvasive technique is a safe and effective aid in the diagnosis of many types of disease (see Mechanisms of Disease, p. 534). Locate the branching network of retinal blood vessels in Figure 17-24, *B*. These vessels supply the retinal tissues and are critical for normal visual function. Diseases such as diabetes mellitus and atherosclerosis can reduce blood flow to these vessels, causing loss of vision.

CAVITIES AND HUMORS

The eyeball is not a solid sphere; rather it contains a large interior space that is divided into two cavities: anterior and posterior.

The **anterior cavity** has two subdivisions, known as the *anterior* and *posterior chambers*. As Figure 17-21 shows, the entire anterior cavity lies in front of the **lens.** The posterior chamber of the anterior cavity consists of the small space directly posterior to the iris but anterior to the lens. And the anterior chamber of the anterior cavity is the space anterior to the iris but posterior to the cornea. *Aqueous humor* fills both chambers of the anterior cavity. This substance is clear and watery and often leaks out when the eye is injured.

The **posterior cavity** of the eyeball is considerably larger than the anterior, because it occupies the entire space posterior to the lens, suspensory ligament, and ciliary body (see Figure 17-21). It contains the *vitreous body*, which is a sac filled with a soft, watery gel. The thick fluid of the vitreous body, along with the aqueous humor, helps maintain sufficient intraocular pressure to prevent the eyeball from collapsing.

Aqueous humor forms from blood in capillaries (located mainly in the ciliary body). The ciliary body actively secretes aqueous humor into the posterior chamber, but passive filtration from capillary blood contributes also to aqueous humor formation. From the posterior chamber, aqueous humor moves from the area between the iris and the lens through the pupil into the anterior chamber. From here, it drains into the scleral venous sinus and moves into small veins (Figure 17-25). Normally, aqueous humor drains out of the anterior chamber at the same rate at which it enters the posterior chamber, so the amount of aqueous humor in the eye remains relatively constant—and so, too, does intraocular pressure. But sometimes something happens to upset this balance, and intraocular pressure increases above the normal level of about 20 to 25 mm Hg. The individual then has the eye disease known as *glaucoma*, which, if untreated, can lead to retinal damage and blindness. Either excess formation or, more often, decreased drainage is seen as an immediate cause of this condition, but underlying causes are unknown (see Mechanisms of Disease, p. 534).

An outline summary of the cavities of the eye appears in Table 17-2. The cavities and lens are not part of the layers of the eyeball.

The Process of Seeing

For vision to occur, the following conditions must be fulfilled: an image must be formed on the retina to stimulate its receptors (rods and cones), and the resulting nerve impulses must be conducted to the visual areas of the cerebral cortex for interpretation.

FORMATION OF RETINAL IMAGE

Four processes focus light rays so that they form a clear image on the retina: *refraction* of the light rays, *accommodation* of the lens, *constriction* of the pupil, and *convergence* of the eyes.

TABLE 17-2 Cavities of the Eye

CAVITY	DIVISIONS	LOCATION	CONTENTS
Anterior	Anterior chamber	Anterior to iris and posterior to cornea	Aqueous humor

Posterior	None	Posterior to lens	Vitreous body

Refraction of Light Rays

Refraction is the deflection, or bending, of light rays. It is produced by light rays passing obliquely from one transparent medium into another of different optical density; the more convex the surface of the medium, the greater its refractive power. The refracting media of the eye are the cornea, aqueous humor, lens, and vitreous body. Light rays are bent, or refracted, at the anterior surface of the cornea as they pass from the air into the denser cornea, at the anterior surface of the lens as they pass from the aqueous humor into the denser lens, and at the posterior surface of the lens as they pass from the lens into the less dense gel of the vitreous body.

When an individual goes to an optometrist or ophthalmologist for an eye examination, the doctor performs a "refraction." In other words, by various specially designed methods, the refractory, or light-bending, power of that person's eyes is determined. Tests of visual acuity also rely on a person's ability to refract light properly (Box 17-5).

In a relaxed normal eye, the four refracting media together bend light rays sufficiently to bring to a focus on the retina the parallel rays reflected from an object 20 or more feet (6 m) away. Of course a normal eye can also focus on objects located much nearer than 20 feet (6 m) from the eye. This is accomplished by a mechanism known as *accommodation* (discussed next).

Many eyes, however, show errors of refraction; that is, they are not able to focus the rays on the retina under the stated conditions. Some common errors of refraction that are discussed later in the chapter are nearsightedness (myopia), farsightedness (hyperopia), and astigmatism.

Accommodation for Near Vision

Accommodation for near vision necessitates three changes: (1) increase in the curvature of the lens, (2) constriction of the pupils, and (3) convergence of the two eyes. Light rays from objects 20 or more feet away are practically parallel. The normal eye, as previously noted, refracts such rays sufficiently to focus them clearly on the retina. However, light rays from nearer objects are divergent rather than parallel. So obviously they must be bent more acutely to bring them to a focus on the retina. Accommodation of the lens or, in other words, an increase in its curvature takes place to achieve this greater refraction.

Change in Lens Shape

Contraction of the ciliary muscle pulls the choroid layer closer to the lens (see Figure 17-22). This, in turn, loosens the tension of the suspensory ligaments, allowing the lens to bulge. For near vision, the ciliary muscle is contracted and the lens is bulging. For far vision, however, the ciliary muscle is relaxed and the lens is comparatively flat (Figure 17-26). Continual use of the eyes for near work produces eyestrain because of the prolonged contraction of the ciliary muscle. Some of the strain can be avoided by looking into the distance at intervals while doing close work.

As people grow older, they tend to become farsighted because lenses lose their elasticity and therefore lose their ability to bulge and to accommodate for near vision. This condition is called *presbyopia*.

Constriction of Pupil

The muscles of the iris play an important part in the formation of clear retinal images (Figure 17-27). Part of the accommodation mechanism consists of contraction of the inner circular smooth muscle fibers of the iris as the outer radial fibers relax, which constricts the pupil. Such constriction prevents divergent rays from the object from entering the eye through the periphery of the cornea and lens. Such peripheral rays could not be refracted sufficiently to be brought to a focus on the retina and therefore would cause a blurred image. Constriction of the pupil for near vision is called the *near reflex* of the pupil and occurs simultaneously with accommodation of the lens in near vision.

Box 17-5 | FYI

Visual Acuity

Visual *acuity* is the clearness or sharpness of visual perception. Acuity is affected by our focusing ability, the efficiency of the retina, and the proper function of the visual pathway and processing centers in the brain.

One common way to measure visual acuity for distant vision is to use the familiar test chart on which letters or other objects of various sizes and shapes are printed. The subject is asked to identify the smallest object that he or she can see from a distance of 20 feet (6.1 m). The resulting determination of visual acuity is expressed as a double number such as "20/20." The first number represents the distance (in feet) between the subject and the test chart; the standard is 20. The second number represents the number of feet a person with normal acuity would have to stand to see the same objects clearly. Thus a finding of 20/20 is normal because the subject can see at 20 feet what a person with normal acuity can see at 20 feet. A person with 20/100 vision can see objects at 20 feet that a person with normal vision can see at 100 feet.

Testing for near-vision acuity.

People whose distant-vision acuity is worse than 20/200 after correction are considered to be legally blind. Legal blindness is a designation that is used to identify the severity of a wide variety of visual disorders so that laws that involve visual acuity can be enforced. For example, laws that govern the awarding of driving licenses require that drivers have a minimum level of visual acuity.

The Figure shows a common test for near-vision acuity. A chart or sample of newsprint of different size fonts is held at a distance of 12 to 14 inches and the subject is asked to read it. In both near-vision and distant-vision acuity tests, the subject attempts the test with each eye separately, then both eyes together.

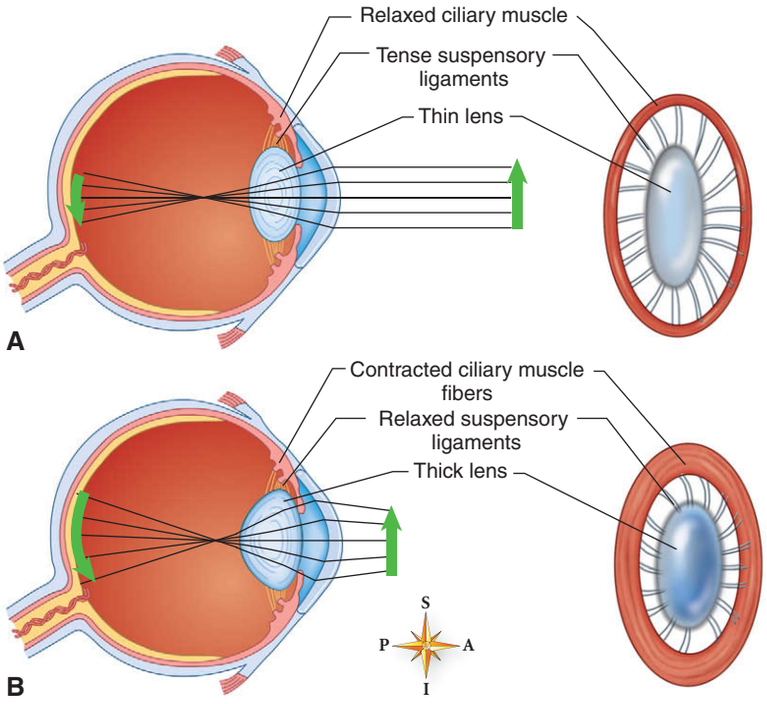

FIGURE 17-26

Accommodation of lens. A, Distant image: the lens is flattened (ciliary muscle relaxed), and the image is focused on the retina. **B,** Close image: the lens is rounded (ciliary muscle contracted), and the image is focused on the retina.

As Figure 17-27 shows, the pupil constricts in bright light (*photopupil reflex* or *pupillary light reflex*) to protect the retina from stimulation that is too intense or too sudden. As the same Figure also shows, relaxation of inner circular fibers and contraction of the outer radial fibers causes dilation of the pupil in dim light. Pupil dilation allows more light to enter and form a more intense image in low-light environments.

Convergence of Eyes

Single binocular vision (seeing only one object instead of two when both eyes are used) occurs when light rays from an object fall on corresponding points of the two retinas. The foveae and all points lying equidistant and in the same direction from the foveae are corresponding points. Whenever the eyeballs move in unison, either with the visual axes parallel (for far objects) or converging on a common point (for near objects), light rays strike corresponding points of the two retinas.

Convergence is the movement of the two eyeballs inward so that their visual axes come together, or converge, at the object viewed. The nearer the object is, the greater the degree of convergence necessary to maintain single vision. A simple procedure demonstrates the fact that single binocular vision results from stimulation of corresponding points on two retinas. Gently press one eyeball out of line while viewing an object. Instead of one object, you will see two. To achieve unified movement of the two eyeballs, a functional balance between the antagonistic extrinsic muscles must exist.

For clear distant vision, the muscles must hold the visual axes of the two eyes parallel. For clear near vision, the muscles must converge the eyes. These conditions cannot be met if, for

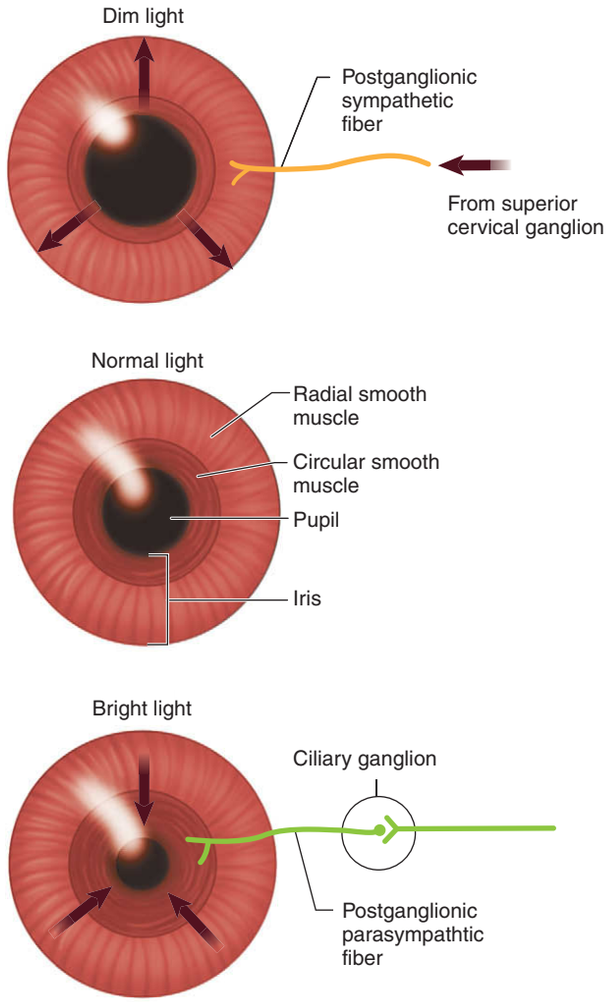

FIGURE 17-27

Constriction and dilation of pupil. Only the muscular part of the iris is shown.

example, the medial rectus muscle of one eye contracts more forcefully than its antagonist, the lateral rectus muscle. That eye is then pulled in toward the nose. The movement of its visual (optic) axis does not coordinate with that of the other eye. Light rays from an object then fall on noncorresponding points of the two retinas, and the object is seen double (**diplopia**). **Strabismus** (cross-eye or squint) is an exaggerated condition that cannot be overcome by neuromuscular effort (Figure 17-28). However, an individual with strabismus usually does not have double vision, as you might expect, because he or she learns to suppress one of the images.

FIGURE 17-28

Strabismus. This child exhibits convergent left eye strabismus.

THE ROLE OF PHOTOPIGMENTS

Rods and cones are our main photoreceptor cells. Both rods and cones contain *photopigments*, or light-sensitive pigmented compounds that are found in the outer (distal) area of both types of photoreceptors near the pigmented retina (see Figure 17-23). Chemically, all photopigments can be broken down into a glycoprotein called **opsin** and a vitamin A derivative called **retinal,** which acts as the light-absorbing portion of all photopigments.

Rods

The single photopigment found in rods is named **rhodopsin.** Rhodopsin is so highly light sensitive that even dim light causes a rapid breakdown of the photopigment into its opsin and retinal components. Light causes retinal to change its shape and the opsin molecule to expand, or open. When opsin and retinal open and separate in the presence of light (a process called **bleaching**), active sites for other chemical reactions are exposed and this triggers a change in the membrane potential of the rod cell (Figure 17-29). This neural membrane signal then travels to the brain for interpretation. Energy is required to bring opsin back to its original shape and reattach retinal to it. Until this occurs, the photopigment remains bleached and is unable to respond to light.

The color of light is measured in wavelengths (usually with the unit nanometer, abbreviated as nm). That is, we perceive different wavelengths of radiant energy (light) as different colors. Figure 17-30 shows that rods are most sensitive to light in the green range of wavelengths, peaking at about 500 nm. However, the brain perceives information from the rods only as intensity of light, not as a color. Thus the rods produce a kind of *monochrome*, or "black-and-white," vision.

Because rods are very sensitive to light, and thus not only become bleached easily but also remain bleached in bright light, they are used only for "dim light" vision.

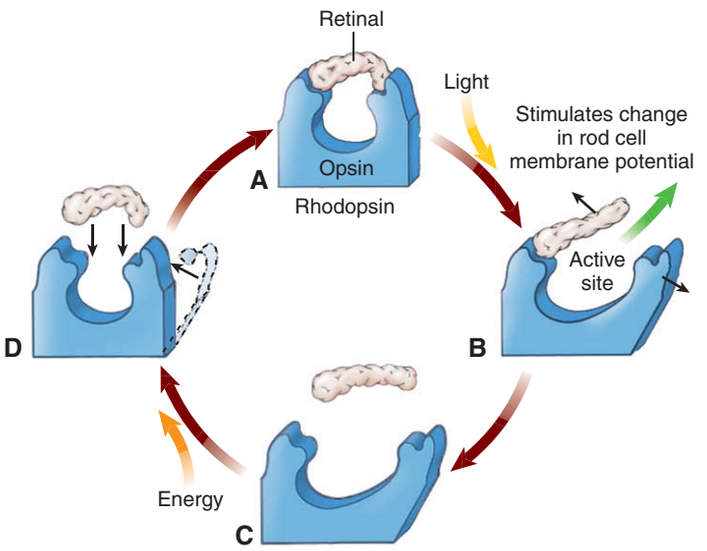

FIGURE 17-29

Rhodopsin cycle. A, Retinal is attached to opsin. **B,** Light causes retinal and opsin to change shape, causing change in rod cell membrane potential. **C,** Retinal separates from opsin (bleaching). **D,** Energy is required to bring opsin back to its original shape and to attach retinal to it.

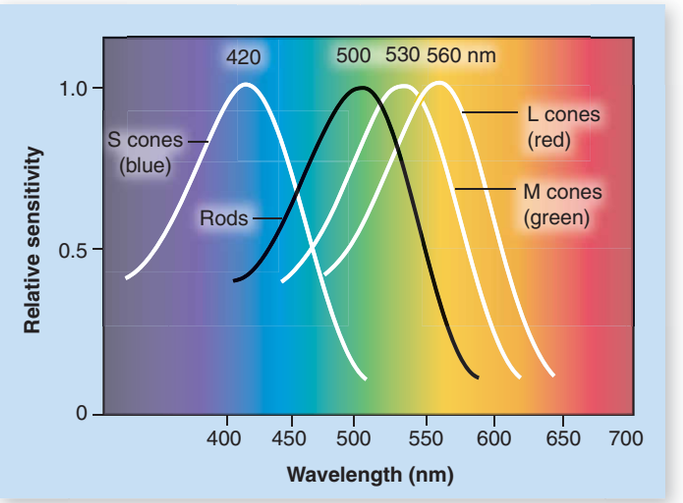

FIGURE 17-30

Color sensitivity of rods and cones. Rods *(black line)* are sensitive only in dim-light conditions in the range of greenish wavelengths—but their information is perceived only as light and dark, not green. Three types of cones *(white lines)* perceive colors in bright-light conditions. Blue (*S,* short-wave) cones are sensitive in the blue range, green (*M,* medium-wave) cones in the green range, and red (*L,* long-wave) cones in the red range. Information from all three cone types is combined to produce a large palette of color perception in the brain.

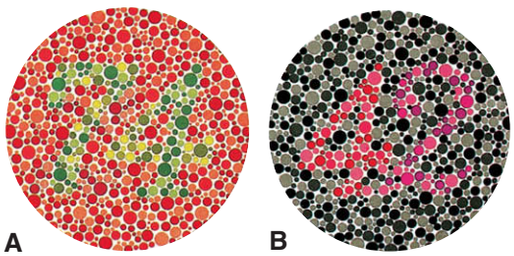
Cones

Three types of cones are present in the retina. Each contains its own version of the rhodopsin photopigment, different from the rhodopsin found in rod cells. Blue-sensitive cones are sensitive in the blue range of wavelengths (see Figure 17-30) and are often called *S cones* (for "short" wavelengths). Green-sensitive cones are often called *M cones* for "medium" wavelengths. Red-sensitive cones are called *L cones* for "long" wavelengths.

Our perception of a range of colors results from the combined neural input from varying numbers of the three different cone types. Abnormal function in any of the cones disrupts the normal perception of colors—a condition called *color-blindness* (Box 17-6).

Because cone photopigments are less sensitive to light than the rhodopsin in rods, brighter light is necessary for their breakdown. Cones therefore function to produce vision only in bright light.

In addition, cones contribute more than rods to the perception of sharp images. The reason for this difference involves the way in which information generated by the stimulation of rods and cones is "processed" before it reaches the brain. Look again at Figure 17-23. Note that information obtained by the bipolar cells is collated from many rods, whereas bipolar cells tend to synapse with only a single cone receptor. Recall that this property of combining input from several receptors is called *convergence.* The result of convergence is that, although the rods combine their input to make a bipolar cell fire in dimmer light, the brain is unable to determine exactly which rod was stimulated when a given bipolar or ganglion cell fires.



Convergence of impulses from cones is rare. There is almost a one-to-one relationship between cones and the ganglion cells that carry impulses toward the brain. Interpretation by the brain of sharp images is therefore much better as a result of cone stimulation.

Box 17-6 | FYI

Color Blindness

Color blindness, usually an inherited condition, is caused by mistakes in the functioning of the three *photopigments* in the cones. Each photopigment is sensitive to one of the three primary colors of light: green, blue, and red (see Figure 17-30). In many cases, the green-sensitive photopigment is missing or deficient; other times, the red-sensitive photopigment is abnormal. (Dysfunction of the blue-sensitive cone is rare.) Color-blind individuals see colors, but they cannot distinguish between them normally.

Figures such as parts *A* and *B* shown here are often used to screen individuals for color blindness. A person with red-green color blindness cannot see the *74* in part *A* of the figure, whereas a person with normal vision can. To determine which photopigment is deficient, a color-blind person may try a Figure similar to part *B*. Persons with a deficiency of red-sensitive photopigment can distinguish only the *2;* those deficient in green-sensitive photopigment can only see the *4.*

The fovea contains the greatest concentration of cones and is therefore the point of clearest vision in good light. For this reason, when we want to see an object clearly in the daytime, we look directly at it to focus the image on the fovea. But in dim light or darkness, we see an object better if we look slightly to the side of it, thereby focusing the image nearer the periphery of the retina, where the more plentiful rods can collate the lesser amount of light information and generate an image.

Ganglion Cells

Although the rods and cones are the dominant form of photoreceptor cell in the retina, and are entirely responsible for detecting visual images, some ganglion cells are now known to act in an additional visual system. The ganglion photoreceptors contain a photopigment called *melanopsin*. Melanopsin is sensitive to light in the blue range of wavelengths that seem to predominate at dawn and dusk. The light information from this system is not used to form an image but is instead needed to adjust our biological clock—a function involving the pineal body of the brain discussed in Chapter 14 (see Figure 14-14 on p. 424).

NEURAL PATHWAY OF VISION

Fibers that conduct impulses from the rods and cones reach the visual cortex in the occipital lobes by way of the optic nerves, optic chiasma, optic tracts, and optic radiations. "Relay stations" along the way include the superior colliculi and the lateral geniculate nuclei of the thalamus. Look closely at Figure 17-31. Note that each optic nerve contains fibers from only one retina but that the

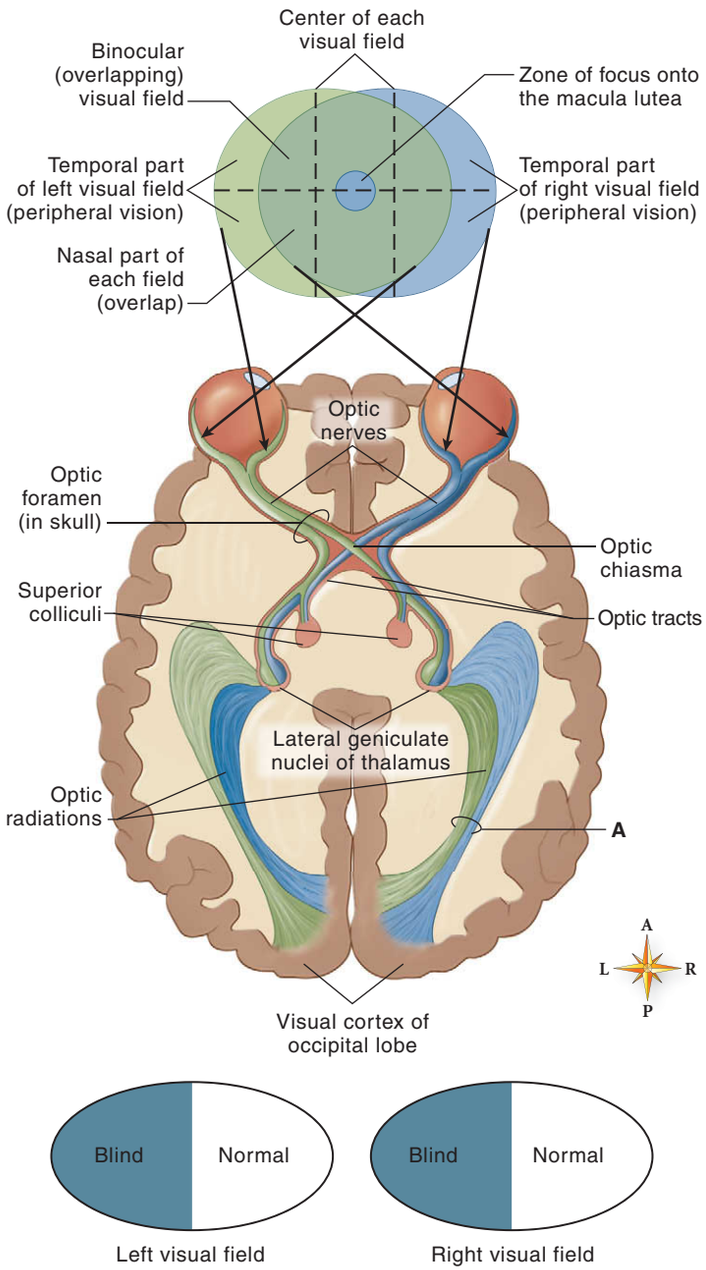


FIGURE 17-31

Visual fields and neural pathways of the eye. Note the structures that make up each pathway: optic nerve, optic chiasma, lateral geniculate body of thalamus, optic radiations, and visual cortex of occipital lobe. Fibers from the nasal portion of each retina cross over to the opposite side at the optic chiasma and terminate in the lateral geniculate nuclei. Location of a lesion in the visual pathway determines the resulting visual defect. Damage at point *A,* for example, would cause blindness in the right nasal and left temporal visual fields, as the ovals beneath indicate. (Trace the visual pathway from point *A* back to the visual field map to see why this is so.) What would be the effect of pressure on the optic chiasma—by a pituitary tumor, for instance? (*Answer:* It would produce blindness in both temporal visual fields. Why? Because it destroys fibers from the nasal side of both retinas.)

optic chiasma contains fibers from the nasal portions of both retinas. Each optic tract also contains fibers from both retinas.

These anatomical facts explain certain peculiar visual abnormalities that sometimes occur. Suppose a person's right optic tract were injured so that it could not conduct impulses—say, at point A in Figure 17-31. This person would be totally blind in neither eye but partially blind in both eyes. Specifically, this person would be blind in the right nasal and left temporal visual fields. Here are the reasons: the right optic tract contains fibers from the right retina's temporal area, the area that sees the right nasal visual field. In addition, the right optic tract contains fibers from the left retina's nasal area, the area that sees the left temporal visual field.

| QUICK CHECK |

15. Name the layers, or coats, of the eyeball.
16. Identify the layers of the retina.
17. Name the four processes that function to focus a clear image on the retina.
18. Outline the steps of the rhodopsin cycle.

Cycle of LIFE

Sense Organs

The ability of the sense organs to respond to stimuli caused by changes in the body's internal or external environment varies during life. Ultimately, all sensory information is acquired through depolarization of sensory nerve endings. Anything that interferes with the generation of a receptor potential or its transmission to and interpretation by areas of the central nervous system influences sensory acuity. Age, disease, structural defects, and lack of maturation all affect our ability to identify and respond to sensory input.

Structure and function response capabilities of the sense organs are related to developmental factors associated with age. For example, a newborn baby has limited sight, hearing, and tactile identification capabilities. As maturation occurs and normal development progresses, the senses become more acute. By late adulthood, presbyopia, progressive hearing loss, and a reduced sense of taste and smell are common.

Some loss of sensory capability in old age is directly related to structural change in receptor cells or other necessary sense organ structures. The lens of the eye becomes harder and less able to change shape, taste buds become less functional, and exteroceptors of all types become less responsive to stimuli because of structural deterioration.

the BIG picture

Sense Organs

Almost invariably, as you study the various organ systems of the body, seeing the "big picture" involves an understanding of how that organ system affects homeostasis. Both the structure and function of the body sense organs illustrate this relationship.

The somatic sense organs are widely distributed throughout the body, and they serve to provide the body with vital information related to both external and internal conditions that affect homeostasis. For example, pain—regardless of cause—is very often the first indicator of homeostatic imbalance. Further, the ability to sense touch, pressure, vibration, stretch, or temperature changes on or in the body before these stimuli reach levels that may cause injury is vital to survival.

The functioning of all the special senses also plays an important homeostatic role. Classic examples include vision and hearing that help us monitor our often hostile external environment and avoid or respond to dangers that might otherwise be life threatening. Also, consider the sensation of thirst. It helps us to regulate our water intake and thus avoid dehydration or the sensation or "craving" for salt, which may signal a dangerous loss of sodium from the body. Other examples include a bitter taste or offensive odor, which are sensations frequently associated with poisonous materials or toxic fumes and thus serve as important defense mechanisms. Take a few minutes to review each of the somatic and special senses by integrating their structure and functions with the "big picture" of homeostasis and survival.

MECHANISMS of DISEASE

DISORDERS OF THE SENSE ORGANS

Disorders of the Ear

Hearing problems can be divided into two basic categories: *conduction impairment* and *nerve impairment*. Conduction impairment refers to the blocking of sound waves as they are conducted through the external and middle ear to the sensory receptors of the inner ear (the conduction pathway). Nerve impairment results in insensitivity to sound because of inherited or acquired nerve damage.

The most obvious cause of conduction impairment is blockage of the external auditory canal. Waxy buildup of cerumen (Figure 17-32, C) commonly blocks conduction of sound toward the tympanic membrane. Foreign objects, tumors, and other matter can block conduction in the external or middle ear. An inherited bone disorder called **otosclerosis** impairs conduction by causing structural irregularities in the stapes. Otosclerosis usually first appears during childhood or early adulthood as **tinnitus,** or "ringing in the ear."

Temporary conduction impairment often results from ear infection, or **otitis.** The structure of the auditory tube, especially its connection with the nasopharynx, makes the middle ear prone to bacterial or viral *otitis media* (Figure 17-32, A). Otitis media often produces swelling and pus formation that block the conduction of sound through the middle ear. Surgical insertion of a *ventilation* or **tympanotomy tube** (Figure 17-32, *B*) is sometimes employed

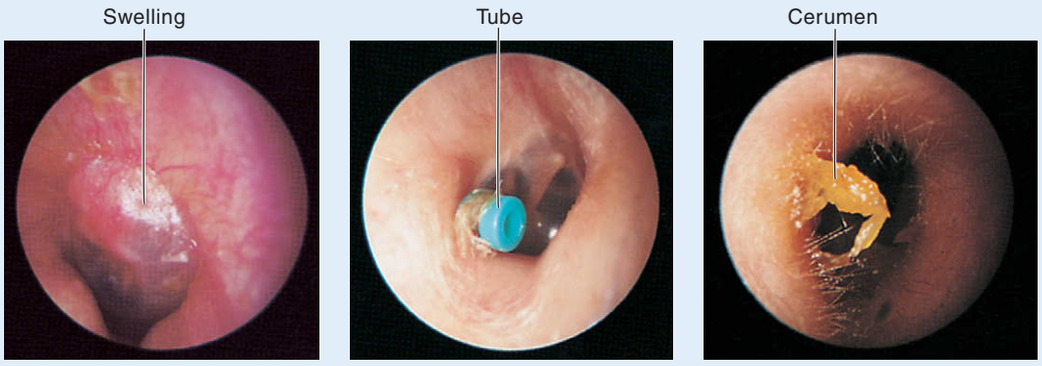

FIGURE 17-32

Disorders of the ear. A, Acute otitis media. Note the red, thickened, and bulging tympanic membrane. **B,** Ventilation or tympanotomy tube ("ear tube"). Inserted to relieve pressure and permit drainage in otitis media. **C,** Cerumen (earwax) in ear canal.

to relieve pressure and permit drainage. Permanent damage to structures of the middle ear occasionally occurs in severe cases.

Hearing loss because of nerve impairment is common in the elderly. Called **presbycusis,** this progressive hearing loss associated with aging results from degeneration of nerve tissue in the ear and the vestibulocochlear nerve. A similar type of hearing loss occurs after chronic exposure to loud noises that damages receptors in the organ of Corti. Because different sound *frequencies* (tones) stimulate different regions of the organ of Corti, hearing impairment is limited to only those frequencies associated with the portion of the organ of Corti that is damaged. For example, the portion of the organ of Corti that degenerates first in presbycusis is normally stimulated by high-frequency sounds. Thus the inability to hear high-pitched sounds is common among older adults.

Two small muscles, the *tensor tympani* and *stapedius*, help prevent damage to hearing caused by prolonged loud noise. The tensor tympani attaches to and limits movement of the eardrum, thus preventing excess displacement caused by prolonged loud sounds.

In addition, the smallest of all body muscles, the stapedius, limits excess movement of the stapes and thus protects the oval window from prolonged noise-related damage. Only protective devices, such as earplugs, can protect hearing from damage caused by very sudden loud noises, such as a gunshot.

Nerve damage can also occur in **Ménière disease,** a chronic inner ear disease of unknown cause. Ménière disease is characterized by tinnitus, progressive nerve deafness, and **vertigo** (sensation of spinning).

Disorders of the Eye

Healthy vision requires three basic processes: formation of an image on the retina (refraction), stimulation of rods and cones, and conduction of nerve impulses to the brain. Malfunction of any of these processes can disrupt normal vision.

Refraction Disorders

Focusing a clear image on the retina is essential for good vision. In the normal eye, light rays enter the eye and are focused into a clear, upside-down image on the retina (Figure 17-33, *A*). The brain can easily right the upside-down image in our conscious perception but cannot correct an image that is not sharply focused. If our eyes are elongated, the image focuses in front of the retina rather than on it. The retina receives only a fuzzy image. This condition, called **myopia** or *nearsightedness*, can be corrected by using concave

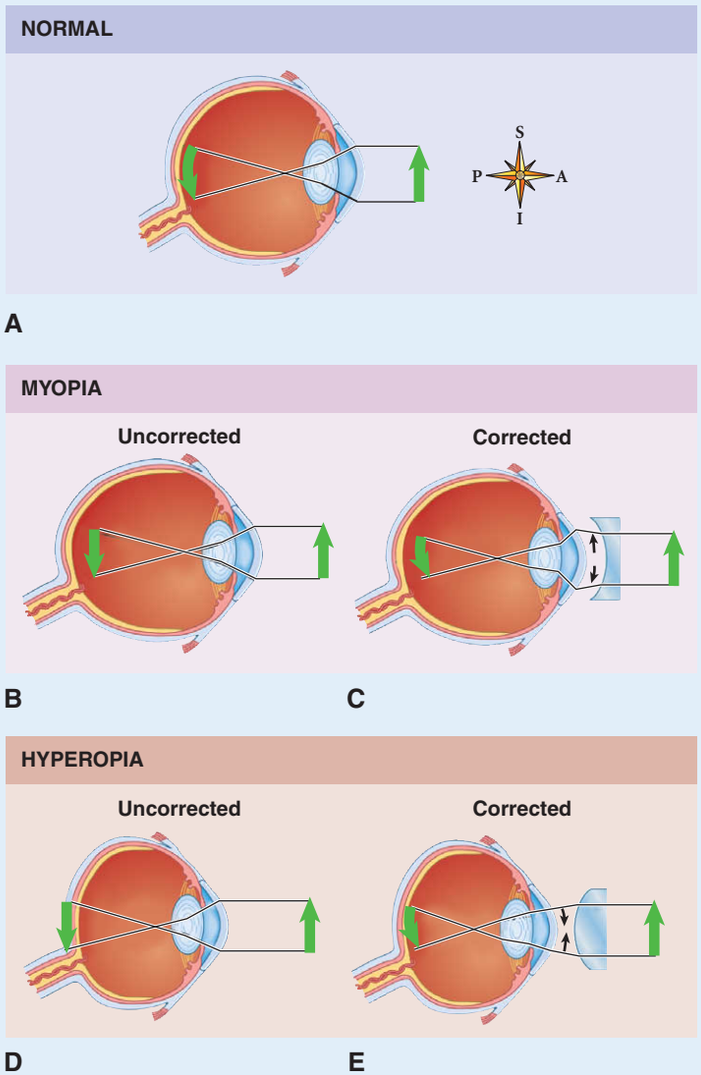

FIGURE 17-33

Correcting refraction disorders. A, Normal eye structure results in a well-focused retinal image. **B,** In myopia, an elongated eyeball causes the image to focus in front of the retina. **C,** An external lens can refocus the image on the retina, correcting the effects of myopia. **D,** In hyperopia, a flattened eyeball causes the image to focus behind the retina. **E,** An external lens can refocus the image on the retina.

(continued)

contact lenses or glasses or by performing refractive eye surgery (Figure 17-33, *B* and *C*). If our eyes are shorter than normal, the image focuses behind the retina, also producing a fuzzy image. This condition, called **hyperopia** or *farsightedness*, can also be corrected by convex lenses or refractive eye surgery (Figure 17-33, *D* and *E*).

| A&P CONNECT |

You have probably heard of eye surgeries such as RK, CK, PRK, or LASIK. But you may have wondered, *what is* a LASIK? Check out ***Refractive Eye Surgery*** online at ***A&P Connect*** to explore the common refractive eye surgeries and how they are done.

evolve

Various other conditions can prevent the formation of a clear image on the retina. For example, the inability to focus the lens properly as we age, or **presbyopia,** has already been mentioned. Older individuals can compensate for presbyopia by using reading glasses when near vision is needed. An irregularity in the curvature of the cornea or lens, a condition called **astigmatism,** can also be corrected with glasses or contact lenses that are formed with the opposite curvature. **Cataracts,** cloudy spots in the eye's lens that develop as we age, may also interfere with focusing (Figure 17-34). Cataracts are especially troublesome in dim light because weak beams of light cannot pass through the cloudy spots the way some brighter light can. This fact accounts for the trouble many older adults have with their night vision.

Infections of the eye also have the potential to impair vision, sometimes permanently. Most eye infections begin in the conjunctiva, producing an inflammation response known as "pink-eye," or **conjunctivitis.** Various pathogens can cause conjunctivitis. For example, the bacterium *Chlamydia trachomatis* that commonly infects the reproductive tract can cause a chronic infection called *chlamydial conjunctivitis*, or **trachoma.** Because *Chlamydia* and other pathogens often inhabit the birth canal, antibiotics are routinely applied to the eyes of newborns to prevent conjunctivitis. Highly contagious *acute bacterial conjunctivitis*, characterized by drainage of a mucous pus, is most commonly caused by bacteria such as *Staphylococcus* and *Haemophilus* (see Figure 17-18, p. 525). Conjunctivitis may produce lesions on the inside of the eyelid that can damage the cornea and thus impair vision. Occasionally infections of the conjunctiva spread to the tissues of the eye proper and cause permanent injury—even total blindness. Besides infection, conjunctivitis may also be caused by allergies. The red, itchy, watery eyes commonly associated with allergic reactions to pollen and other substances result from an allergic inflammatory response of the conjunctiva.

FIGURE 17-34

Cataract. Note the prominent cataract of the left eye.

Disorders of the Retina

Damage to the retina impairs vision because even a well-focused image cannot be perceived if some or all of the light receptors do not function properly. For example, in a condition called **retinal detachment,** part of the retina falls away from the tissue supporting it (Figure 17-35, *A*). This condition may result from aging, eye tumors, or blows to the head—as in a sporting injury. Common warning signs include the sudden appearance of floating spots that may decrease over a period of weeks and odd "flashes of light" that appear when the eye moves. If left untreated, the retina may detach completely and cause total blindness in the affected eye.

Diabetes mellitus, a disorder involving the hormone insulin, may cause a condition known as **diabetic retinopathy**. In this disorder the diabetes causes small hemorrhages in retinal blood vessels that disrupt the oxygen supply to the photoreceptors (Figure 17-35, *B*). The eye responds by building new, but abnormal, vessels that block vision and may cause detachment of the retina. Diabetic retinopathy is one of the leading causes of blindness in the United States. Diabetic retinopathy and other complications of diabetes are often associated with high blood pressure, or *hypertension*, which also causes retinal hemorrhages (Figure 17-35, *C*).

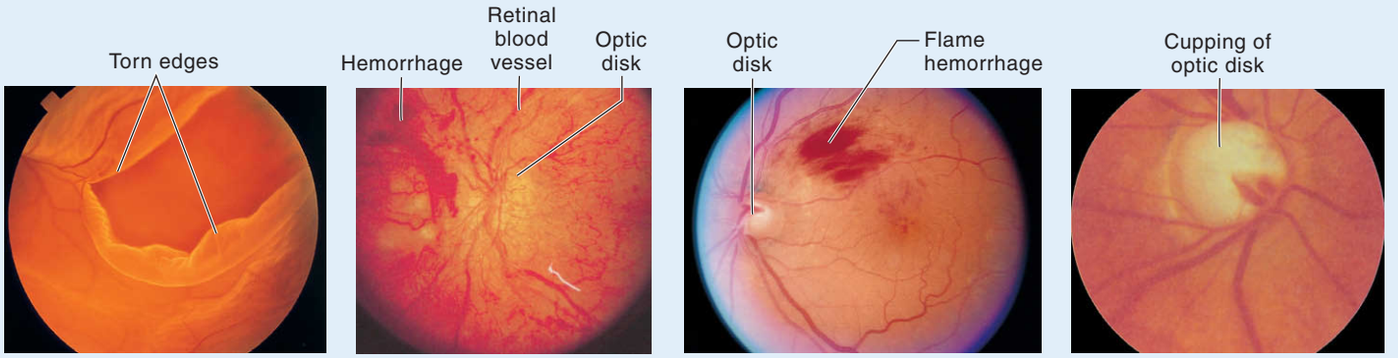

FIGURE 17-35

Retinal pathological conditions. A, Retina tear and detachment. **B,** Diabetic retinopathy. Note the abnormal blood vessels and hemorrhages in the retina caused by diabetes. **C,** Hypertensive retinopathy. Large "flame hemorrhages" in the retina are associated with high blood pressure. **D,** Glaucoma. Note "cupping" of the optic disk caused by increased intraocular pressure. (Compare to normal retina in Figure 17-24 on p. 528.)

Another condition that can damage the retina is **glaucoma.** Recall that glaucoma is excessive *intraocular* (in-trah-AHK-yoo-lar) *pressure* caused by abnormal accumulation of aqueous humor. As fluid pressure against the retina increases above normal, blood flow through the retina slows. Reduced blood flow causes degeneration of the retina and thus leads to loss of vision. Although acute forms of glaucoma can occur, most cases of glaucoma develop slowly over a period of years. This chronic form may not produce any symptoms, especially in its early stages. For this reason, routine eye examinations typically include a screening test for glaucoma. As chronic glaucoma progresses, damage first appears at the edges of the retina—causing a gradual loss of peripheral vision. Blurred vision and headaches may also occur. As the damage becomes more extensive, "halos" are seen around bright lights. If untreated, glaucoma eventually produces total, permanent blindness. One of the most common characteristic early retinal changes associated with glaucoma is swelling or "cupping" of the optic disk (Figure 17-35, *D*).

Degeneration of the retina can cause difficulty seeing at night or in dim light. This condition, called **nyctalopia,** or "night blindness," can also be caused by a deficiency of vitamin A. Recall that vitamin A is needed to make retinal, a component of rhodopsin. A deficiency of rhodopsin impairs the function of rod cells, which are needed for dim light vision.

Disorders of the Visual Pathway

Damage or degeneration in the optic nerve, the brain, or any part of the visual pathway between them, can impair vision. For example, the pressure associated with glaucoma can also damage the optic nerve. Diabetes, already cited as a cause of retina damage, can also cause degeneration of the optic nerve.

Damage to the visual pathway does not always result in total loss of sight. Depending on where the damage occurs, only a part of the visual field may be affected. For example, a certain form of neuritis (nerve inflammation), often associated with multiple sclerosis, can cause loss of only the center of the visual field—a condition called **scotoma.**

A stroke can cause vision impairment when the resulting tissue damage occurs in one of the regions of the brain that processes visual information. For example, damage to an area that processes information about colors may result in a rare condition called **acquired cortical color blindness.** This condition is characterized by difficulty in distinguishing any color—not just one or two colors as in the more common inherited forms of color blindness.

CASE study

Why were the headlights of the oncoming cars so bright, she wondered. Rita flashed her car lights as the next car approached, but when the driver flashed his lights in return, she saw his lights had been on the low setting all along. She noticed too that the street signs were difficult to read tonight. When she got to her daughter's house, Rita was quite relieved to be off the road! Over the years, her vision had always been excellent; not being able to see well was a new experience for her. Her daughter suggested she have her eyes checked as soon as possible.

The next week, as Rita tried to read one of the magazines in the optometrist's waiting room, she found that she could not get the letters to come into focus unless she held the magazine at arm's length—yet another sign of trouble with her eyesight.

1. What could be causing the inability to focus on close objects?
   a. Myopia
   b. Presbyopia
   c. Conjunctivitis
   d. Scotoma

In a few minutes, she heard, "Rita!" The receptionist was calling her back to the examination room.

2. What type of receptors in the ear responded to the receptionist's voice?
   a. Mechanoreceptors
   b. Photoreceptors
   c. Thermoreceptors
   d. Chemoreceptors

As the optometrist leaned closer to get a better look at her eyes, Rita could smell his cologne.

3. What type of receptors are responding to the cologne smell?
   a. Mechanoreceptors
   b. Photoreceptors
   c. Thermoreceptors
   d. Chemoreceptors

When the examination was completed, the optometrist told Rita that the lenses of her eyes had some cloudy spots on them. That would account for the vision problems she had when driving at night.

4. What condition could the spots indicate?
   a. Presbyopia
   b. Glaucoma
   c. Cataracts
   d. Myopia

SENSORY RECEPTORS

A. Sensory receptors make it possible for the body to respond to stimuli caused by changes occurring in our internal or external environment
B. Receptor response
   1. General function—responds to stimuli by converting them to nerve impulses
   2. Different types of receptors respond to different stimuli
   3. Receptor potential
      a. The potential that develops when an adequate stimulus acts on a receptor; it is a graded response
      b. When a threshold is reached, an action potential in the sensory neuron's axon is triggered
      c. Impulses travel over sensory pathways to the brain and spinal cord where either they are interpreted as a particular sensation or they initiate a reflex action
   4. Adaptation—a functional characteristic of receptors; receptor potential decreases over time in response to a continuous stimulus, which leads to a decreased rate of impulse conduction and a decreased intensity of sensation (Figure 17-1)
C. Distributions of receptors
   1. Receptors for special senses of smell, taste, vision, hearing, and equilibrium are grouped into localized areas or into complex organs
   2. General sense organs of somatic senses are microscopic receptors widely distributed throughout the body in the skin, mucosa, connective tissue, muscles, tendons, joints, and viscera

CLASSIFICATION OF RECEPTORS (TABLE 17-1)

A. Classification by location
   1. Exteroceptors
      a. On or near body surface
      b. Often called *cutaneous receptors;* examples: pressure, touch, pain, temperature
   2. Visceroceptors (interoceptors)
      a. Located internally—often within body organs, or viscera
      b. Provide body with information about internal environment; examples: pressure, stretch, chemical changes, hunger, thirst
   3. Proprioceptors—special type of visceroceptor
      a. Location limited to skeletal muscle, joint capsules, and tendons

b. Provide information on body movement, orientation in space, and muscle stretch
c. Two types—tonic and phasic proprioceptors provide positional information on body or body parts while at rest or during movement

B. Classification by stimulus detected
1. Mechanoreceptors—activated when "deformed" to generate receptor potential
2. Chemoreceptors—activated by amount or changing concentration of certain chemicals, for example, taste and smell
3. Thermoreceptors—activated by changes in temperature (Figure 17-3)
4. Nociceptors—activated by intense stimuli that may damage tissue; sensation produced in pain (Figure 17-2)
5. Photoreceptors—found only in the eye; respond to light stimuli if the intensity is great enough to generate a receptor potential
6. Osmoreceptors—concentrated in the hypothalamus; activated by changes in concentration of electrolytes (osmolarity) in extracellular fluids.

C. Classification by structure (Figure 17-5): divides sensory receptors into either those with free nerve endings or those with encapsulated nerve endings
1. Free nerve endings
a. Most widely distributed sensory receptor
b. Include both exteroceptors and visceroceptors
c. Called nociceptors—primary receptors for pain
d. Primary receptors for heat and cold
e. Pain sensations
(1) Acute (A) fibers—mediate sharp, intense, localized pain
(2) Chronic (B) fibers—mediate less intense but more persistent dull or aching pain
f. Tactile sensations—skin movement, itch, tickle, discriminative tough
(1) Root hair plexuses
(2) Tactile (Merkel) disks
2. Encapsulated nerve endings—six types; all have connective tissue capsules and are mechanoreceptors
a. Touch and pressure receptors
(1) Tactile corpuscle (Meissner corpuscle), relatively large and superficial in placement; mediates touch and low-frequency vibration; large numbers in hairless skin areas, such as nipples, fingertips, and lips; two anatomical variations of tactile (Meissner) corpuscle
(a) Bulboid corpuscles (Krause end bulbs)—small, with less tightly coiled dendritic endings within their capsule; involved in touch, low-frequency vibrations
(b) Bulbous (Ruffini) corpuscles, have a flattened capsule and are deeply located in the dermis; mediate crude and persistent touch
(2) Lamellar or Pacini corpuscles—large mechanoreceptors that respond quickly to sensations of deep pressure, high-frequency vibration, and stretch; found in deep dermis and in joint capsules—they adapt quickly, and sensations they evoke seldom last for long periods
b. Stretch receptors—two types; operate to provide body with information concerning muscle length and strength of muscle contraction
(1) Muscle spindle—composed of 5 to 10 intrafusal fibers lying between and parallel to regular (extrafusal) muscle fibers
(a) Large-diameter and rapid-conducting type Ia and smaller-diameter and slower-conducting type II afferent fibers carry messages to brain concerning changes in muscle length
(b) If the length of a muscle exceeds a certain limit, a stretch reflex is initiated to shorten the muscle, thus helping to maintain posture
(2) Golgi tendon organs—located at junction between muscle tissue and tendon; made up of encapsulated neuron endings associated with collagen bundles (Figure 17-5)
(a) Type Ib sensory neurons (Golgi tendon receptors) are stimulated by excessive contraction—when stimulated, they cause muscle to *relax*
(b) Golgi tendon reflex protects muscle from tearing internally because of excessive contractile force

SENSE OF SMELL

A. Olfactory receptors
1. Olfactory sense organs consist of epithelial support cells and olfactory sensory neurons (Figure 17-6)
a. Olfactory cilia—located on olfactory sensory neurons that touch the olfactory epithelium lining the upper surface of the nasal cavity
b. Olfactory cells—chemoreceptors; gas molecules or chemicals dissolved in the mucus covering the nasal epithelium stimulate the olfactory cells
c. Olfactory epithelium—located in most superior portion of the nasal cavity
d. Olfactory receptors—extremely sensitive and easily fatigued

B. Olfactory pathway—when the level of odor-producing chemicals reaches a threshold level, the following occurs (Figure 17-7):
1. Receptor potential and then action potential are generated and passed to the olfactory nerves in the olfactory bulb
2. The impulse then passes through the olfactory tract and into the thalamic and olfactory centers of the brain for interpretation, integration, and memory storage

SENSE OF TASTE

A. Taste buds—sense organs that respond to gustatory, or taste, stimuli
1. Associated with papillae
a. Fungiform—large, mushroom shaped; anterior two-thirds of tongue
b. Circumvallate—huge, dome-shaped; form row near back of tongue
c. Foliate—leaflike; lateral edges of posterior tongue

   d. Filiform—threadlike; scattered among fungiform papillae
2. Chemoreceptors that are stimulated by chemicals dissolved in the saliva
3. Gustatory cells—sensory cells in taste buds; gustatory hairs extend from each gustatory cell into the taste pore
4. Sense of taste depends on the creation of a receptor potential in gustatory cells because of taste-producing chemicals in the saliva
5. Taste buds are similar structurally; functionally, each taste bud responds most effectively to one of five primary taste sensations: sour, sweet, bitter, umami, and salty (and perhaps others, such as metallic) (Figure 17-8 and 17-9)
6. Adaptation and sensitivity thresholds differ for each of the primary taste sensations

B. Neural pathway for taste
1. Taste sensation begins with a receptor potential in the gustatory cells of a taste bud; generation and propagation of an action potential then transmits the sensory input to the brain
2. Nerve impulses from the anterior two thirds of the tongue travel over the facial nerve; those from the posterior one third of the tongue travel over the glossopharyngeal nerve; vagus nerve plays a minor role in taste
3. Nerve impulses are carried to the medulla oblongata, relayed into the thalamus, and then relayed into the gustatory area of the cerebral cortex in the parietal lobe of the brain
4. Flavor results from integration of taste, smell, and the trigeminal senses (textures and irritants)

SENSES OF HEARING AND BALANCE: THE EAR

A. External ear—two divisions (Figures 17-10 and 17-11)
1. Auricle, or pinna—the visible portion of the ear
2. External acoustic meatus—tube leading from the auricle into the temporal bone and ending at the tympanic membrane

B. Middle ear (Figure 17-11)
1. Tiny, epithelium-lined cavity hollowed out of the temporal bone
2. Contains three auditory ossicles
   a. Malleus (hammer)—attached to the inner surface of the tympanic membrane
   b. Incus (anvil)—attached to the malleus and stapes
   c. Stapes (stirrup)—attached to the incus
3. Openings into the middle ear cavity
   a. Opening from the external acoustic meatus covered with tympanic membrane
   b. Oval window—opening into inner ear; stapes fits here
   c. Round window—opening into inner ear; covered by a membrane
   d. Opening into the auditory (eustachian) tube

C. Inner ear (Figure 17-12, *A*)
1. Structure of the inner ear
   a. Bony labyrinth—made up of the vestibule, cochlea, and semicircular canals
   b. Membranous labyrinth—made up of utricle and saccule inside the vestibule, cochlear duct inside the cochlea, and membranous semicircular ducts inside the bony semicircular canals
   c. Vestibule and semicircular canal organs are involved with balance
   d. Cochlea—involved with hearing
   e. Endolymph—clear, potassium-rich fluid filling the membranous labyrinth
   f. Perilymph—similar to cerebrospinal fluid, surrounds the membranous labyrinth, filling the space between the membranous tunnel and its contents and the bony walls that surround it

D. Cochlea and cochlear duct (Figure 17-12, *B*)
1. Cochlea—bony labyrinth
2. Modiolus—cone-shaped core of bone that houses the spiral ganglion, which consists of cell bodies of the first sensory neurons in the auditory relay
3. Cochlear duct
   a. Lies inside the cochlea; only part of the internal ear concerned with hearing; contains endolymph
   b. Shaped like a triangular tube
   c. Divides the cochlea into the scala vestibuli, the upper section, and the scala tympani, the lower section; both sections filled with perilymph
   d. Vestibular membrane—the roof of the cochlear duct
   e. Basilar (spiral) membrane—floor of the cochlear duct
   f. Organ of Corti—rests on the basilar membrane; consists of supporting cells and hair cells; also called *spiral organ*
   g. Axons of the neurons that begin around the organ of Corti, extend in the cochlear nerve to the brain to produce the sensation of hearing

E. Sense of hearing
1. Sound is created by vibrations
2. Ability to hear sound waves depends on volume, pitch, and other acoustic properties
3. Sound waves must be of sufficient amplitude to move the tympanic membrane and have a frequency capable of stimulating the hair cells in the organ of Corti (spiral organ) (Figure 17-13, *A*)
4. Basilar membrane width and thickness varies throughout its length
   a. High-frequency sound waves vibrate the narrow portion near the oval window
   b. Low frequencies vibrate the wider, thicker portion near the apex of the cochlea
   c. Each frequency stimulates different hair cells and facilitates perception of different pitches (Figure 17-13, *B*)
   d. Perception of loudness is determined by movement amplitude; the greater the movement, the louder the perceived sound
   e. Hearing results from stimulation of the auditory area of the cerebral cortex
5. Pathway of sound waves (Figure 17-13)
   a. Enter external auditory canal
   b. Strike tympanic membrane, causing vibrations

c. Tympanic vibrations move the malleus, which in turn moves the incus and then the stapes
d. The stapes moves against the oval window, which begins the fluid conduction of sound waves
e. The perilymph in the scala vestibuli of the cochlea begins a "ripple" that is transmitted through the vestibular membrane to the endolymph inside the duct, to the basilar membrane, and then to the organ of Corti
f. From the basilar membrane, the ripple is transmitted through the perilymph in the scala tympani and then expends itself against the round window

6. Neural pathway of hearing
a. A movement of hair cells against the tectorial membrane stimulates the dendrites that terminate around the base of the hair cells and initiates impulse conduction by the cochlear nerve to the brainstem
b. Impulses pass through "relay stations" in the nuclei in the medulla, pons, midbrain, and thalamus before reaching the auditory area of the temporal lobe

F. Vestibule and semicircular canals (Figure 17-12, *A*)
1. Vestibule—the central section of the bony labyrinth; the utricle and saccule are the membranous structures within the vestibule
2. Three semicircular canals—found in each temporal bone
a. Each canal is at a right angle to the other
b. Membranous semicircular ducts, within the canals; each contains endolymph and connects with the utricle
c. Each canal enlarges into an ampulla near junction with utricle

G. Sense of balance
1. Static equilibrium—ability to sense the position of the head relative to gravity or to sense acceleration or deceleration (Figure 17-14)
a. Movements of the maculae, located in both the utricle and saccule almost at right angles to each other, provide information related to head position or acceleration
b. Otoliths are located within the matrix of the macula
c. Changing head position produces a change of pressure on the otolith-weighted matrix, which stimulates the hair cells that in turn stimulate the receptors of the vestibular nerve
d. Vestibular nerve fibers conduct impulses to the brain and produce a sensation of the position of the head and also a sensation of a change in the pull of gravity
e. Righting reflexes—muscular responses to restore the body and its parts to their normal position when they have been displaced; caused by stimuli of the macula and impulses from proprioceptors and from the eyes
2. Dynamic equilibrium—needed to maintain balance when the head or body is rotated or suddenly moved; able to detect changes both in direction and rate at which movement occurs (Figure 17-15)
a. Depends on the functioning of the cristae ampullaris, which are located in the ampulla of each semicircular duct
b. Cupula—gelatinous cap in which the hair cells of each crista are embedded
(1) Does not respond to gravity
(2) Moves with the flow of endolymph in the semicircular ducts
c. Semicircular ducts are arranged at nearly right angles to each other to detect movement in all directions
d. Hair cells bend as cupula moves, producing a receptor potential followed by an action potential
(1) Action potential passes through the vestibular portion of the eighth cranial nerve to the medulla oblongata
(2) Sent next to other areas of the brain and spinal cord for interpretation, integration, and response

VISION: THE EYE

A. Structure of the eye (Figures 17-16 through 17-25)
1. External structures (Figure 17-16 through 17-20)
a. Eyebrows and eyelashes—give some protection against foreign objects entering the eye; cosmetic purposes
b. Eyelids—consist of voluntary muscle and skin with a tarsal plate
(1) Lined with conjunctiva, a mucous membrane
(2) Palpebral fissure—opening between the eyelids
(3) Angle or canthus—where the upper and lower eyelids join
c. Lacrimal apparatus—structures that secrete tears and drain them from the surface of the eyeball (Figure 17-19)
(1) Lacrimal glands—size and shape of a small almond
(a) Located at the upper, outer margin of each orbit
(b) Approximately a dozen small ducts lead from each gland
(c) Drain tears onto the conjunctiva
(2) Lacrimal canals—small channels that empty into lacrimal sacs
(3) Lacrimal sacs—located in a groove in the lacrimal bone
(4) Nasolacrimal ducts—small tubes that extend from the lacrimal sac into the inferior meatus of the nose
2. Muscles of the eye
a. Extrinsic eye muscles (Figure 17-20)—skeletal muscles that attach to the outside of the eyeball and to the bones of the orbit
(1) Named according to their position on the eyeball
(2) Include the superior, inferior, medial, and lateral rectus muscles and superior and inferior oblique muscles
b. Intrinsic eye muscles—smooth muscles located within the eye
(1) Iris—regulates size of pupil
(2) Ciliary muscle—controls shape of lens
3. Layers of the eyeball—three coats of tissues compose the eyeball (Figure 17-21)
a. Fibrous layer—outer coat
(1) Sclera—tough, white, fibrous tissue

(2) Cornea—the transparent anterior portion that lies over the iris; no blood vessels found in the cornea or in the lens
(3) Scleral venous sinus (canal of Schlemm)—ring-shaped venous sinus found deep within the anterior portion of the sclera at its junction with the cornea

b. Vascular layer—middle coat
(1) Contains many blood vessels and a large amount of pigment
(2) Choroid—pigmented membrane lining more than two thirds of the posterior fibrous outer coat
(3) Anterior portion has three different structures (Figure 17-21)
(a) Ciliary body—thickening of choroid, fits between anterior margin of retina and posterior margin of iris; ciliary muscle lies in anterior part of ciliary body; ciliary processes—fold in the ciliary body
(b) Suspensory ligament—attached to the ciliary processes and blends with the elastic capsule of the lens, to hold it in place
(c) Iris—colored part of the eye; consists of circular and radial smooth muscle fibers that form a doughnut-shaped structure; attaches to the ciliary body

c. Inner layer—incomplete innermost coat of the eyeball
(1) Retina—made up of an outer layer of pigmented epithelium (pigmented retina) and an inner layer of nervous tissue (sensory retina) (Figure 17-23)
(2) Three layers of neurons make up the sensory retina
(a) Photoreceptor cells—visual receptors, sensitive to light rays
(i) Rods—absent from the fovea and macula; increased in density toward the periphery of the retina
(ii) Cones—less numerous than rods; most densely concentrated in the fovea centralis in the macula lutea
(b) Bipolar cells
(c) Ganglionic cells—all axons of these neurons extend back to the optic disk; part of the sclera, which contains perforations through which the fibers emerge from the eyeball as the optic nerve
(d) Horizontal and amacrine cells allow lateral connections within the sensory retina
(3) Optic nerve—second cranial nerve (CN II) extends from the eyeball to the brain
(4) Retinal blood vessels—critical to normal visual function (Figure 17-24)

4. Cavities and humors
a. Cavities—eyeball has a large interior space divided into two cavities
(1) Anterior cavity—lies in front of the lens; has two subdivisions
(a) Anterior chamber—space anterior to the iris and posterior to the cornea
(b) Posterior chamber—small space posterior to the iris and anterior to the lens
(2) Posterior cavity—larger than the anterior cavity; occupies all the space posterior to the lens, suspensory ligament, and ciliary body

b. Humors
(1) Aqueous humor—fills both chambers of the anterior cavity; clear, watery fluid that often leaks out when the eye is injured; formed from blood in capillaries located in the ciliary body (Figure 17-25)
(2) Vitreous body—gel-filled sac fills the posterior cavity; helps to maintain sufficient intraocular pressure, with aqueous humor, to give the eyeball its shape

B. The process of seeing
1. Formation of retinal image
a. Refraction of light rays—deflection, or bending, of light rays produced by light rays passing obliquely from one transparent medium into another of different optical density; cornea, aqueous humor, lens, and vitreous body are the refracting media of the eye
b. Accommodation for near vision requires three changes:
(1) Change of lens shape (Figure 17-26)
(a) Increase in curvature of the lens to achieve the greater refraction needed for near vision
(b) Contraction of ciliary muscle reduces tension in suspensory ligaments, allowing lens to bulge to better see near objects
(c) Relaxation of ciliary muscle increases tension in suspensory ligaments, flattening lens for distant vision
(2) Constriction of pupil—muscles of iris are important to formation of a clear retinal image (Figure 17-27)
(a) Pupil constriction prevents divergent rays from object from entering eye through periphery of the cornea and lens
(b) Near reflex—constriction of pupil that occurs with accommodation of the lens in near vision
(c) Photopupil reflex—pupil constricts in bright light
(3) Convergence of eyes—movement of the two eyeballs inward so that their visual axes come together at the object viewed
(a) The closer the object, the greater the degree of convergence necessary to maintain single vision
(b) For convergence to occur, a functional balance between antagonistic extrinsic muscles must exist
(c) Strabismus is abnormal convergence (Figure 17-28)

2. The role of photopigments—light-sensitive pigmented compounds undergo structural changes that result in

generation of nerve impulses, which are interpreted by the brain as sight
   a. Rods—photopigment in rods is rhodopsin
      (1) Highly light sensitive
      (2) Breaks down into opsin and retinal
      (3) Separation of opsin and retinal in the presence of light causes an action potential in rod cells
      (4) Energy is needed to re-form rhodopsin (Figure 17-29)
   b. Cones—three types of cones are present in the retina, with each having a different variation of the rhodopsin photopigment: blue (S) cones, green (M) cones, and red (L) cones
      (1) Perception of a large variety colors results from the combination of signals from different cone types
      (2) Cone pigments are less light sensitive than rhodopsin and need brighter light to break down (Figure 17-30)
   c. Ganglion cells—relay information from rods and cones (by way of bipolar cells) but also relay non-image light information to the body's biological clock; photopigment is melanopsin
3. Neural pathway of vision (Figure 17-31)
   a. Fibers that conduct impulses from the rods and cones reach the visual cortex in the occipital lobes by way of the optic nerves, optic chiasma, optic tracts, and optic radiations
   b. Optic nerve contains fibers from only one retina, but optic chiasma contains fibers from the nasal portion of both retinas; these anatomical facts explain peculiar visual abnormalities that sometimes occur

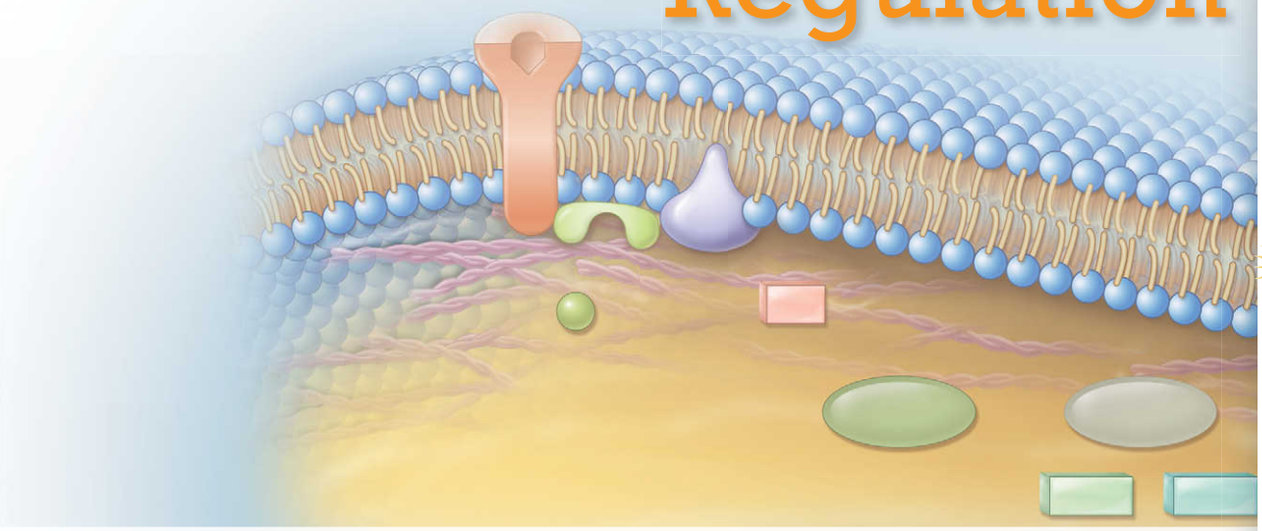
CYCLE OF LIFE: SENSE ORGANS

A. Sensory information is acquired through depolarization of sensory nerve endings
   1. Age, disease, structural defects, or lack of maturation affects ability to identify and respond
B. Structure and function response capabilities are related to developmental factors associated with age
C. Senses become more acute with maturation
D. Sensory capability loss in old age related to structural change in receptor cells or other sense organ structures

REVIEW QUESTIONS

Write out the answers to these questions after reading the chapter and reviewing the Chapter Summary. If you simply think through the answer without writing it down, you won't retain much of your new learning.

1. Define adaptation.
2. Describe each of the following: mechanoreceptors, chemoreceptors, thermoreceptors, nociceptors, photoreceptors.
3. Identify the pathway involved for the production of the sense of smell.
4. What are G-protein–mediated receptor sites?
5. Describe the main features of the middle ear.
6. Name the parts of the bony and membranous labyrinths and describe the relationship of those parts.
7. In what ear structure or structures is the hearing sense organ located? Location of the equilibrium sense organs?
8. What is the name of the hearing sense organ? Of the equilibrium sense organs?
9. Describe the path of sound waves as they enter the ear.
10. Define vertigo. How is vertigo treated?
11. Describe the role of the basilar (spiral) membrane in hearing.
12. What is the difference between static and dynamic equilibrium? Describe the general mechanisms by which each is maintained.
13. Name two involuntary muscles in the eye. Explain their functions.
14. Define the term *refraction*. Name the refractory media of the eye.
15. Explain briefly the mechanism for accommodation for near vision.
16. Name the photopigments present in rods and in cones. Explain their role in vision.
17. Explain why "night blindness" may occur in marked vitamin A deficiency.
18. Describe the phenomenon of referred pain.



CRITICAL THINKING QUESTIONS

After finishing the Review Questions, write out the answers to these more in-depth questions to help you apply your new knowledge. Go back to sections of the chapter that relate to concepts that you find difficult.

1. With regard to location, explain the difference between an above-threshold receptor potential and the sensation of that stimulus?
2. Which free nerve ending is able to respond to light touch? Name the free nerve ending that is the most common receptor in the brain.
3. Describe the neural pathways for taste and smell. What would be most likely to stimulate a memory: the taste of apple pie or the smell of apple pie? How can you explain your answer?
4. Identify the three coats of the eye. Include the specific functions of each within your answer.
5. How would you compare and contrast the receptors for vision in dim light and those for vision in bright light?
6. How is sensory response related to age?

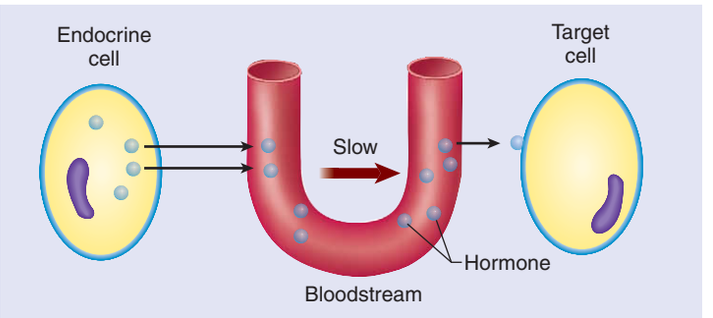
continued on p. 559

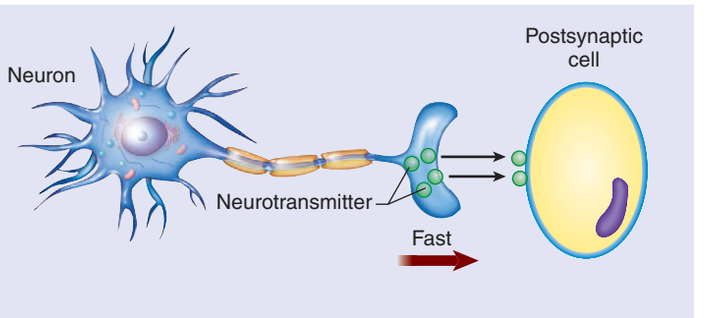
In the previous chapters we explored important sensory and regulatory mechanisms involving the nervous system. Our study of the regulation of body function continues in this chapter, in which we discuss the regulatory function of the endocrine system. The endocrine system uses signaling molecules called hormones, which are released by glands into the bloodstream and sent throughout the body. These hormones can thus affect any or all tissues of the body. As you learn concepts of hormone function, try to see them as part of an overall system of regulating the body's functions. In the next chapter, we continue the story of endocrine regulation by exploring specific endocrine glands and the hormones they produce.

ORGANIZATION OF THE ENDOCRINE SYSTEM



The endocrine system and nervous system both function to achieve and maintain stability of the internal environment. Each system may work alone or in concert with each other as a single **neuroendocrine system,** performing the same general functions within the body: communication, integration, and control.

Both the endocrine system and the nervous system perform their regulatory functions by means of chemical messengers sent to specific cells. In the nervous system, neurons secrete neurotransmitter molecules to signal nearby cells that have the appropriate receptor molecules. In the endocrine system, secreting cells send **hormone** (from the Greek *hormaein*, "to excite") molecules by way of the bloodstream to signal specific **target cells** throughout the body. Tissues and organs that contain endocrine target cells are called *target tissues* and *target organs*, respectively. As with postsynaptic cells, endocrine target cells must have the appropriate receptor to be influenced by the signaling chemical—a process called *signal transduction*. Many cells have receptors for neurotransmitters and hormones, so they can be influenced by both types of chemicals.



Whereas neurotransmitters are sent over very short distances across a synapse, hormones diffuse into the blood to be carried to nearly every point in the body. The nervous system can directly control only muscles and glands that are innervated with efferent fibers, whereas the endocrine system can regulate most cells in the body. The effects of neurotransmitters are rapid and short lived compared with the effects of hormones, which appear more slowly and last longer. Table 18-1 compares endocrine structure and function with nervous structure and function (Figure 18-1).

TABLE 18-1 Comparison of the Endocrine System and Nervous System

FEATURE	ENDOCRINE SYSTEM	NERVOUS SYSTEM
Overall Function	Regulation of effectors to maintain homeostasis	Regulation of effectors to maintain homeostasis
Control by regulatory feedback loops	Yes (endocrine reflexes)	Yes (nervous reflexes)
Effector tissues	Endocrine effectors: virtually all tissues	Nervous effectors: muscle and glandular tissue only
Effector cells	Target cells (throughout the body)	Postsynaptic cells (in muscle and glandular tissue only)
Chemical Messenger	Hormone	Neurotransmitter
Cells that secrete the chemical messenger	Glandular epithelial cells or neurosecretory cells (modified neurons)	Neurons
Distance traveled (and method of travel) by chemical messenger	Long (by way of circulating blood)	Short (across a microscopic synapse)
Location of receptor in effector cell	On the plasma membrane or within the cell	On the plasma membrane
Characteristics of regulatory effects	Slow to appear, long lasting	Appear rapidly, short lived

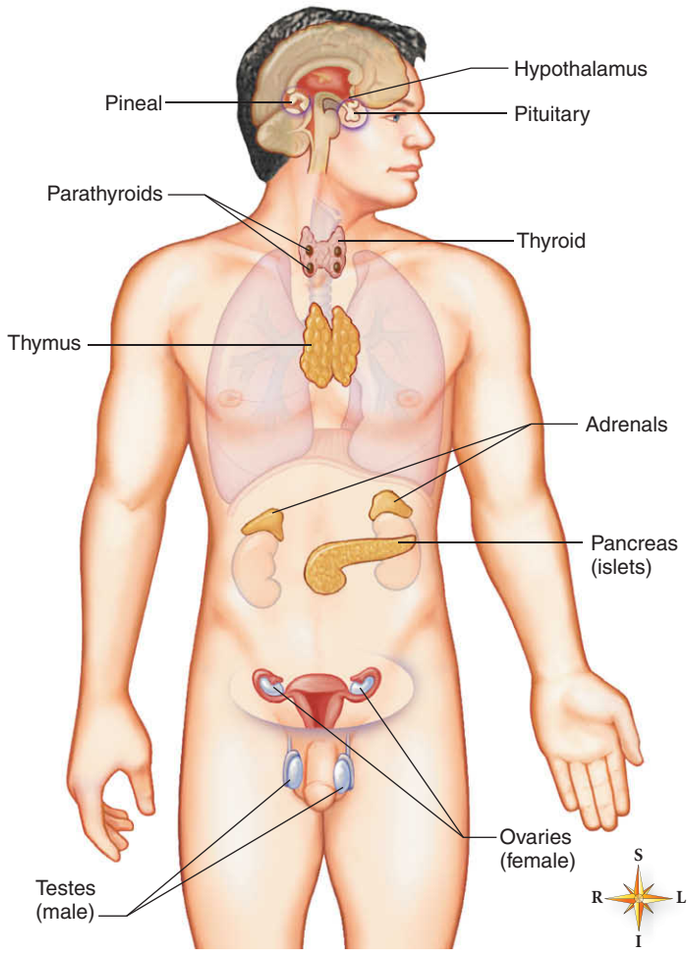

FIGURE 18-2
Locations of some major endocrine glands.

TABLE 18-2 Some of the Major Endocrine Glands

NAME	LOCATION
Hypothalamus	Cranial cavity (brain)
Pituitary gland	Cranial cavity
Pineal gland	Cranial cavity (brain)
Thyroid gland	Neck
Parathyroid glands	Neck
Thymus	Mediastinum
Adrenal glands	Abdominal cavity (retroperitoneal)
Pancreatic islets	Abdominal cavity (pancreas)
Ovaries	Pelvic cavity
Testes	Scrotum
Placenta	Pregnant uterus

Endocrine glands secrete their products, hormones, directly into the blood. Because they do not have ducts, they are often called "ductless glands." This characteristic distinguishes *endocrine glands* from *exocrine glands*, which secrete their products into ducts (see Chapter 6, p. 141). Many endocrine glands are made of glandular epithelium, whose cells manufacture and secrete hormones. However, a few endocrine glands are made of **neurosecretory tissue.** Neurosecretory cells are simply modified neurons that secrete chemical messengers that diffuse into the bloodstream rather than across a synapse. In such cases, the chemical messenger is called a *hormone* rather than a *neurotransmitter.* For example, when norepinephrine is released by neurons, diffuses across a synapse, and binds to an adrenergic receptor in a postsynaptic neuron, we call norepinephrine a *neurotransmitter.* On the other hand, we call norepinephrine a *hormone* when it diffuses into the blood (because no postsynaptic cell is present) and then binds to an adrenergic receptor in a distant target cell.

Glands of the endocrine system are widely scattered throughout the body. New discoveries in *endocrinology* continue to add to the long list of hormone-secreting tissues. However, even the most newly discovered endocrine tissues and their hormones operate according to some basic physiological principles.

In this chapter, we focus our discussion primarily on a few major endocrine glands and their principal hormones. Figure 18-2 and Table 18-2 summarize the names and locations of these representative endocrine glands. After you are familiar with the basic principles of endocrinology and the major examples of glands and their hormones, you will be prepared for additional examples that you will encounter as you continue your study of the human body.

| QUICK CHECK |

1. What is meant by the term *target cell?*
2. Describe how the nervous system and the endocrine system differ in the way they control effectors.

HORMONES

Classification of Hormones

Hormone molecules can be classified in various useful ways. For example, when classified by general function, hormones can be identified as **tropic hormones** (hormones that target other endocrine glands and stimulate their growth and secretion), **sex hormones** (hormones that target reproductive tissues), **anabolic hormones** (hormones that stimulate anabolism in their target cells), and many other functional names. Another useful way to classify hormones is by their chemical structure. Because this method of classifying hormones is so widely used, we will briefly describe it in the following paragraphs.

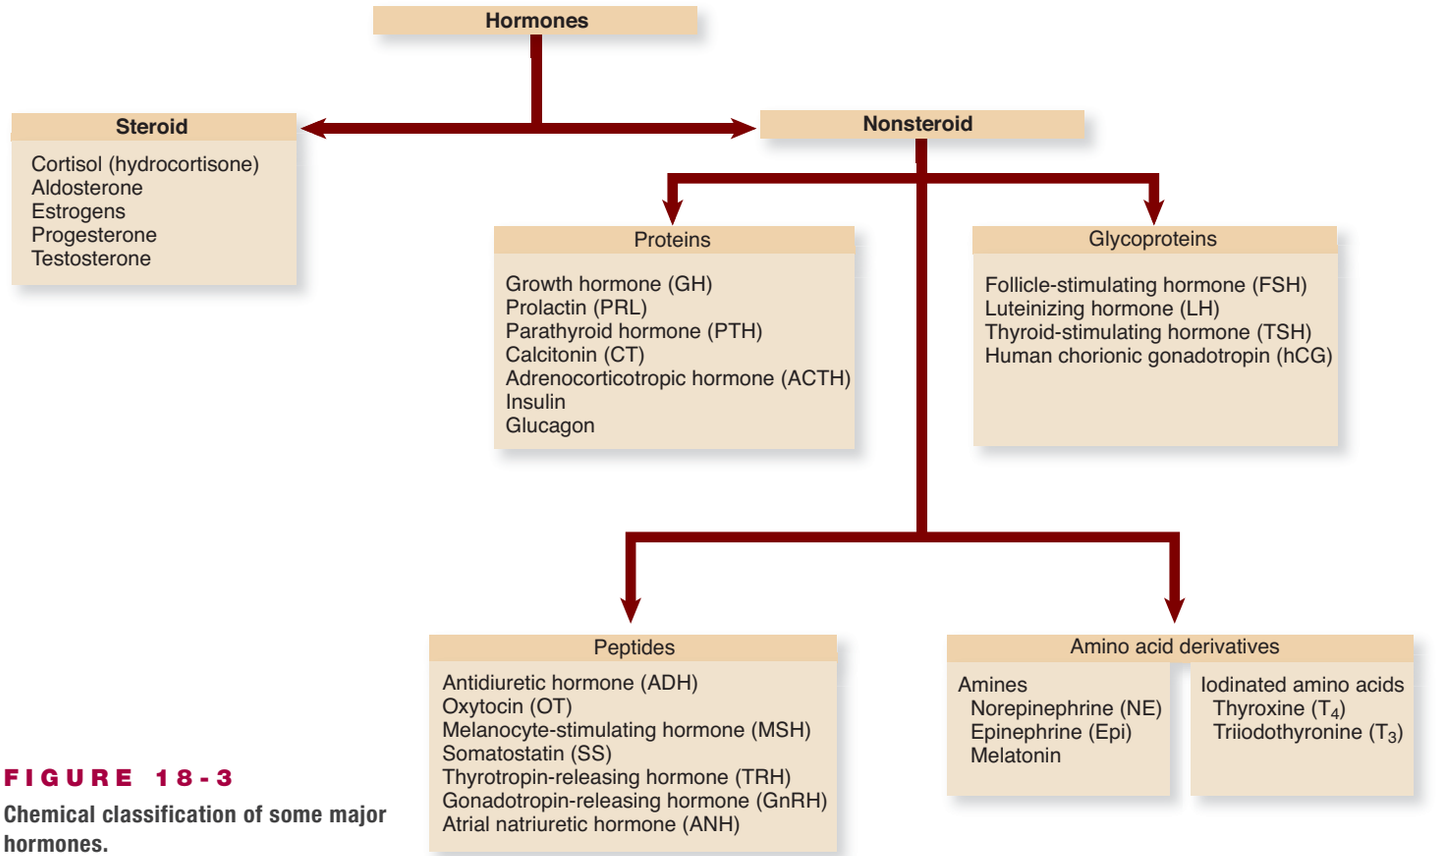

FIGURE 18-3

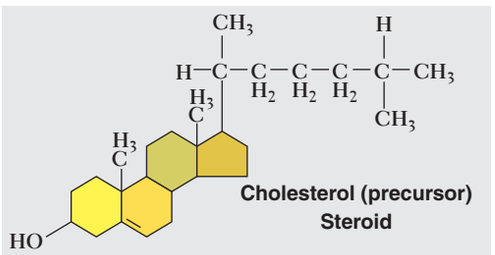
Chemical classification of some major hormones.

STEROID HORMONES

All of the many hormones secreted by endocrine tissues can be classified simply as **steroid** or **nonsteroid** (Figure 18-3). Steroid hormone molecules are manufactured by endocrine cells from cholesterol, an important type of lipid in the human body (see Chapter 2, p. 50). As Figure 18-4 shows, because all steroid hormones are derived from a common molecule, cholesterol, they have a characteristic chemical group at the core of each molecule. Because steroids are lipid soluble, they can easily pass through the phospholipid plasma membrane of target cells. Figure 18-5 outlines the metabolic pathways used by endocrine cells to convert cholesterol into steroid hormones. Examples of important steroid hormones include cortisol, aldosterone, estrogen, progesterone, and testosterone.

NONSTEROID HORMONES

Most nonsteroid hormones are synthesized primarily from amino acids rather than from cholesterol (Figure 18-6). Some nonsteroid hormones are **protein hormones.** These hormones are long,



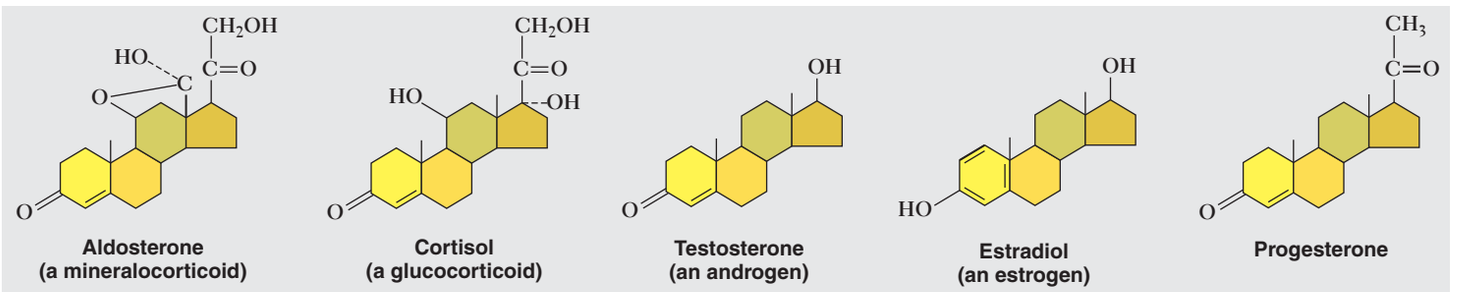


FIGURE 18-4

Steroid hormone structure. As these examples show, steroid hormone molecules are very similar in structure to cholesterol *(top left),* particularly in having a four-ring steroid nucleus at their core. Cholesterol is the precursor molecule from which the steroid hormones are all derived.

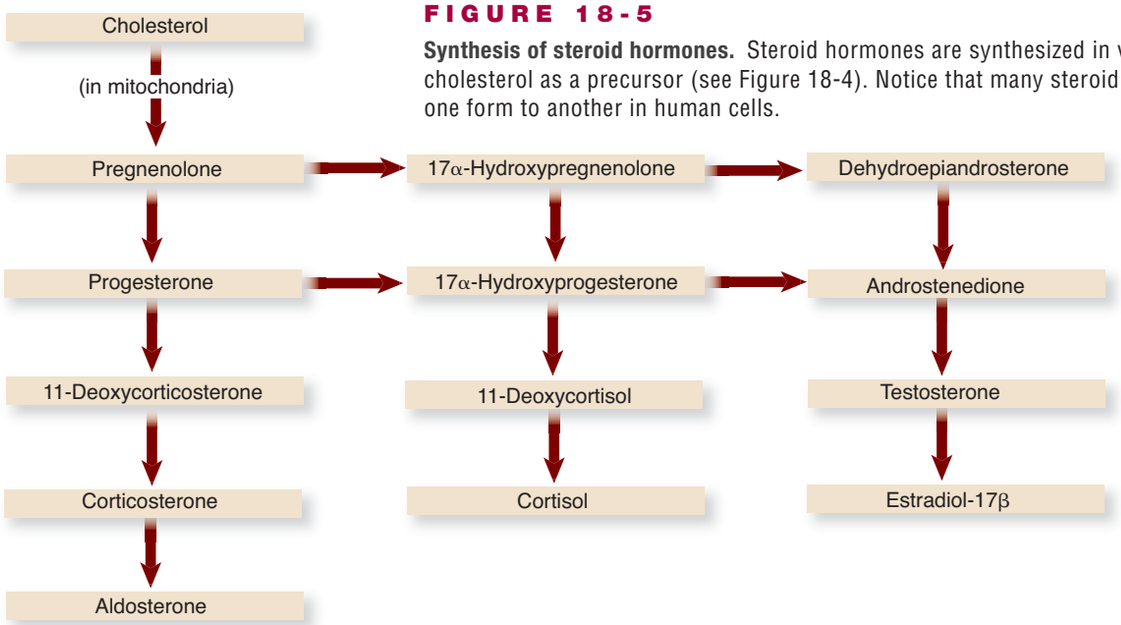

FIGURE 18-5

Synthesis of steroid hormones. Steroid hormones are synthesized in various endocrine tissues using cholesterol as a precursor (see Figure 18-4). Notice that many steroid hormones are converted from one form to another in human cells.

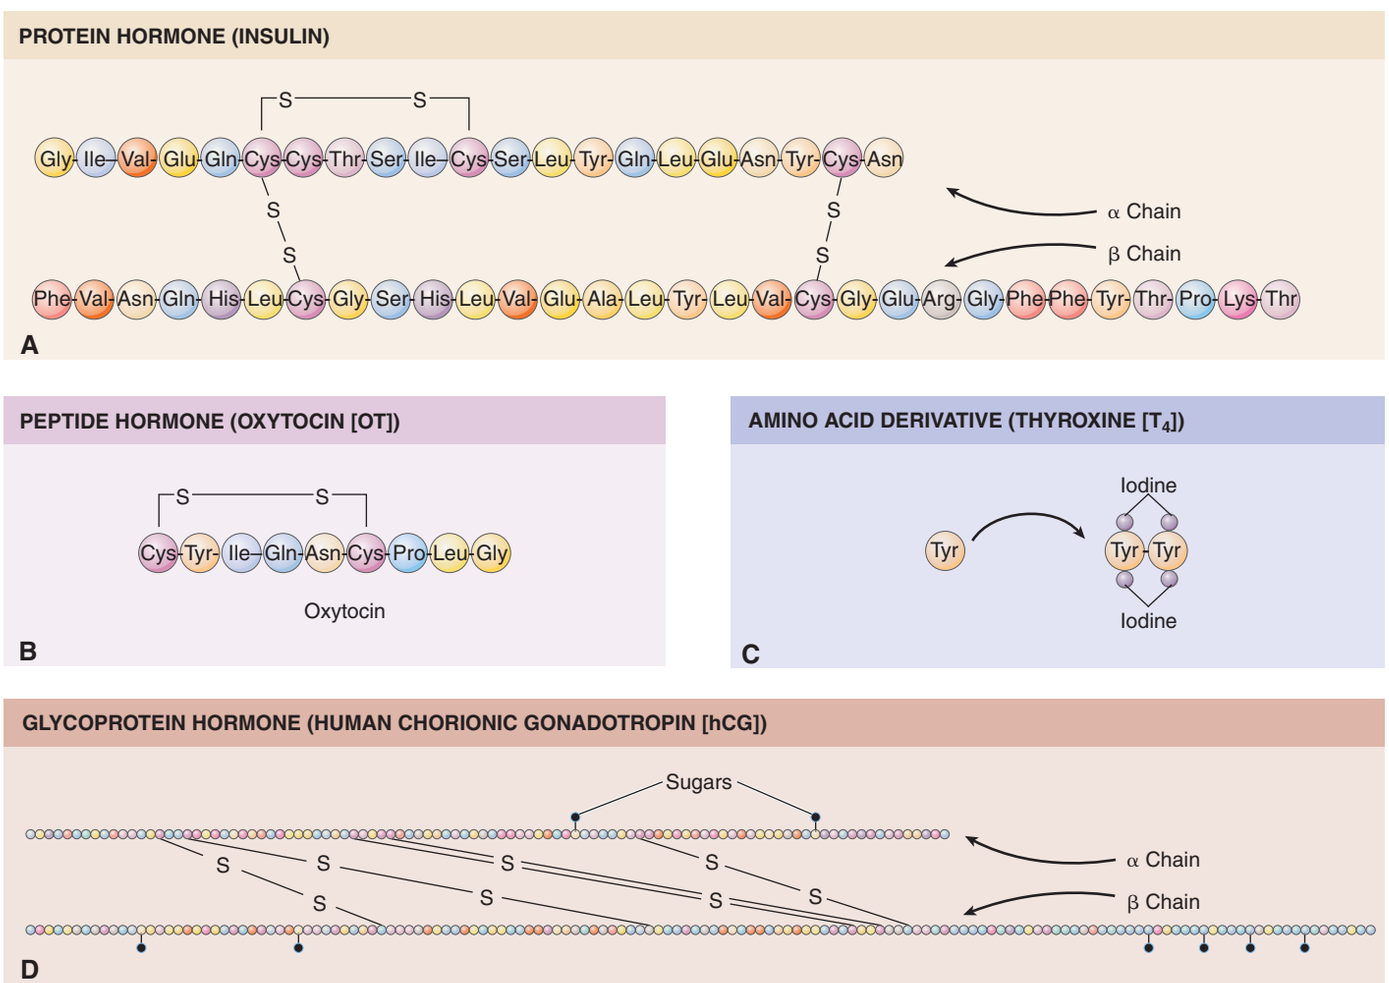

FIGURE 18-6

Nonsteroid hormone structure. **A,** Protein hormone molecules are made of long, folded strands of amino acids. **B,** Peptide hormone molecules are smaller strands of amino acids. **C,** Amino acid derivatives are, as their name implies, derived from a single amino acid. **D,** Glycoprotein hormones are long, folded strands of amino acids with attached sugar groups.

folded chains of amino acids, a structure typical of protein molecules of any sort (see Chapter 2, p. 52). Included among the protein hormones are insulin, parathyroid hormone, and others listed in Figure 18-3. Protein hormones that have carbohydrate groups attached to their amino acid chains are often classified separately as **glycoprotein hormones** (Figure 18-6, *D*).

Another major category of nonsteroid hormones consists of the peptide hormones. **Peptide hormones** such as oxytocin and antidiuretic hormone are smaller than the protein hormones. They are each made of a short chain of amino acids, as Figure 18-6, *B*, shows. Figure 18-3 lists examples of peptide hormones.

Yet another category of nonsteroid hormones consists of the **amino acid derivative hormones.** Each of these hormones is derived from only a single amino acid molecule. There are two major subgroups within this category. One subgroup, the *amine hormones*, is synthesized by modifying a single molecule of an amino acid—either tyrosine or tryptophan. Amine hormones such as epinephrine and norepinephrine are produced by neurosecretory cells (secreted as hormones) and by neurons (secreted as neurotransmitters). Another subgroup of amino acid derivatives produced by the thyroid gland are all synthesized by adding iodine (I) atoms to a tyrosine molecule (Figure 18-6, *C*). Figure 18-3 lists examples of hormones derived from single amino acids.

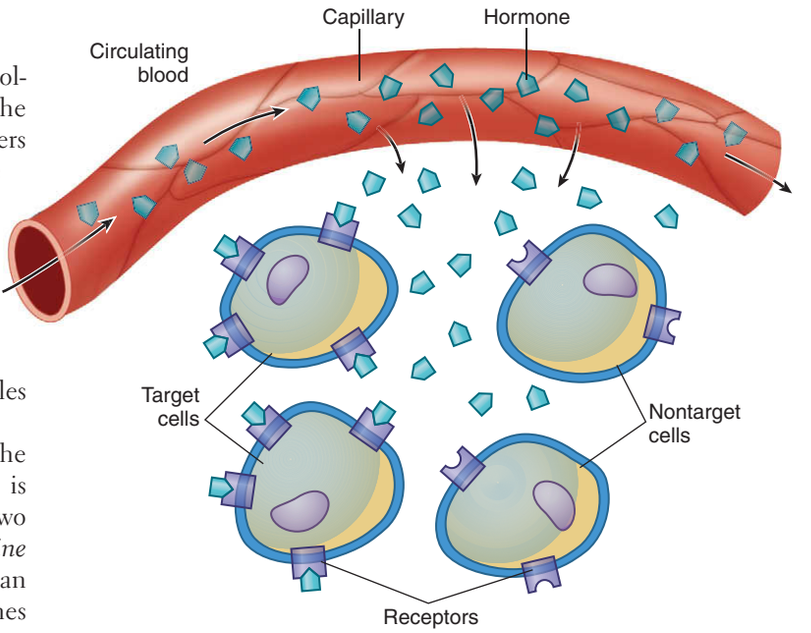

FIGURE 18-7

The target cell concept. A hormone acts only on cells that have receptors specific to that hormone because the shape of the receptor determines which hormone can react with it. This is an example of the lock-and-key model of biochemical reactions.

| QUICK CHECK |

3. How are steroid hormones able to pass through a cell's plasma membrane easily?
4. Name some of the different general types of nonsteroid hormones. Give an example of each.

How Hormones Work

GENERAL PRINCIPLES OF HORMONE ACTION

As previously stated, hormones signal a cell by binding to specific receptors on or in the cell. In a "lock-and-key" mechanism, hormones will bind only to receptor molecules that "fit" them exactly. Any cell with one or more receptors for a particular hormone is said to be a *target* of that hormone (Figure 18-7). Cells usually have many different types of receptors; therefore they are *target cells* of many different hormones.

In a complex process called *signal transduction*, each different hormone-receptor interaction produces different regulatory changes within the target cell. These cellular changes are usually accomplished by altering the chemical reactions within the target cell. For example, some hormone-receptor interactions initiate synthesis of new proteins. Other hormone-receptor interactions trigger the activation or inactivation of certain enzymes and thus affect the metabolic reactions regulated by those enzymes. Still other hormone-receptor interactions regulate cells by opening or closing specific ion channels in the plasma membrane. Specific mechanisms of signal transduction and endocrine effects in target cells are outlined in the next section.

Different hormones may work together to enhance each other's influence on a target cell. In a phenomenon called **synergism,** combinations of hormones have a greater effect on a target cell than the sum of the effects that each would have if acting alone. Combined hormone actions may exhibit instead the phenomenon of **permissiveness.** Permissiveness occurs when a small amount of one hormone allows a second hormone to have its full effect on a target cell; the first hormone "permits" the full action of the second hormone. A common type of combined action of hormones is seen in the phenomenon of **antagonism.** In antagonism, one hormone produces the opposite effect of another hormone. Antagonism between hormones can be used to "fine tune" the activity of target cells with great accuracy, signaling the cell exactly when (and by how much) to increase or decrease a certain cellular process.

Although our discussion is focused on the primary actions of only a few selected hormones, ongoing studies make it clear that hormones usually have many diverse secondary functions in the body. For example, prolactin (PRL) is a hormone with primary actions that regulate milk production (lactation) and reproduction, but it also has about 300 secondary actions in the body. Most secondary effects of hormones modulate, or influence, the activity of other regulatory mechanisms. The primary effect of a hormone, on the other hand, is a more direct regulatory mechanism.

As previously stated, hormones travel to their target cells by way of the circulating bloodstream. This means that all hormones travel throughout the body. Because they affect only their target cells, however, the effects of a particular hormone may be limited to specific tissues in the body. Some hormone molecules are attached to plasma proteins while they are carried along in the bloodstream. Such hormones must free themselves from the plasma protein to leave the blood and combine with their receptors. Because blood carries hormones nearly everywhere in the body, even where there are no target cells, not all hormone molecules produced by endocrine glands actually hit their target. Unused hormones usually are quickly excreted by the kidneys or broken down by metabolic processes.

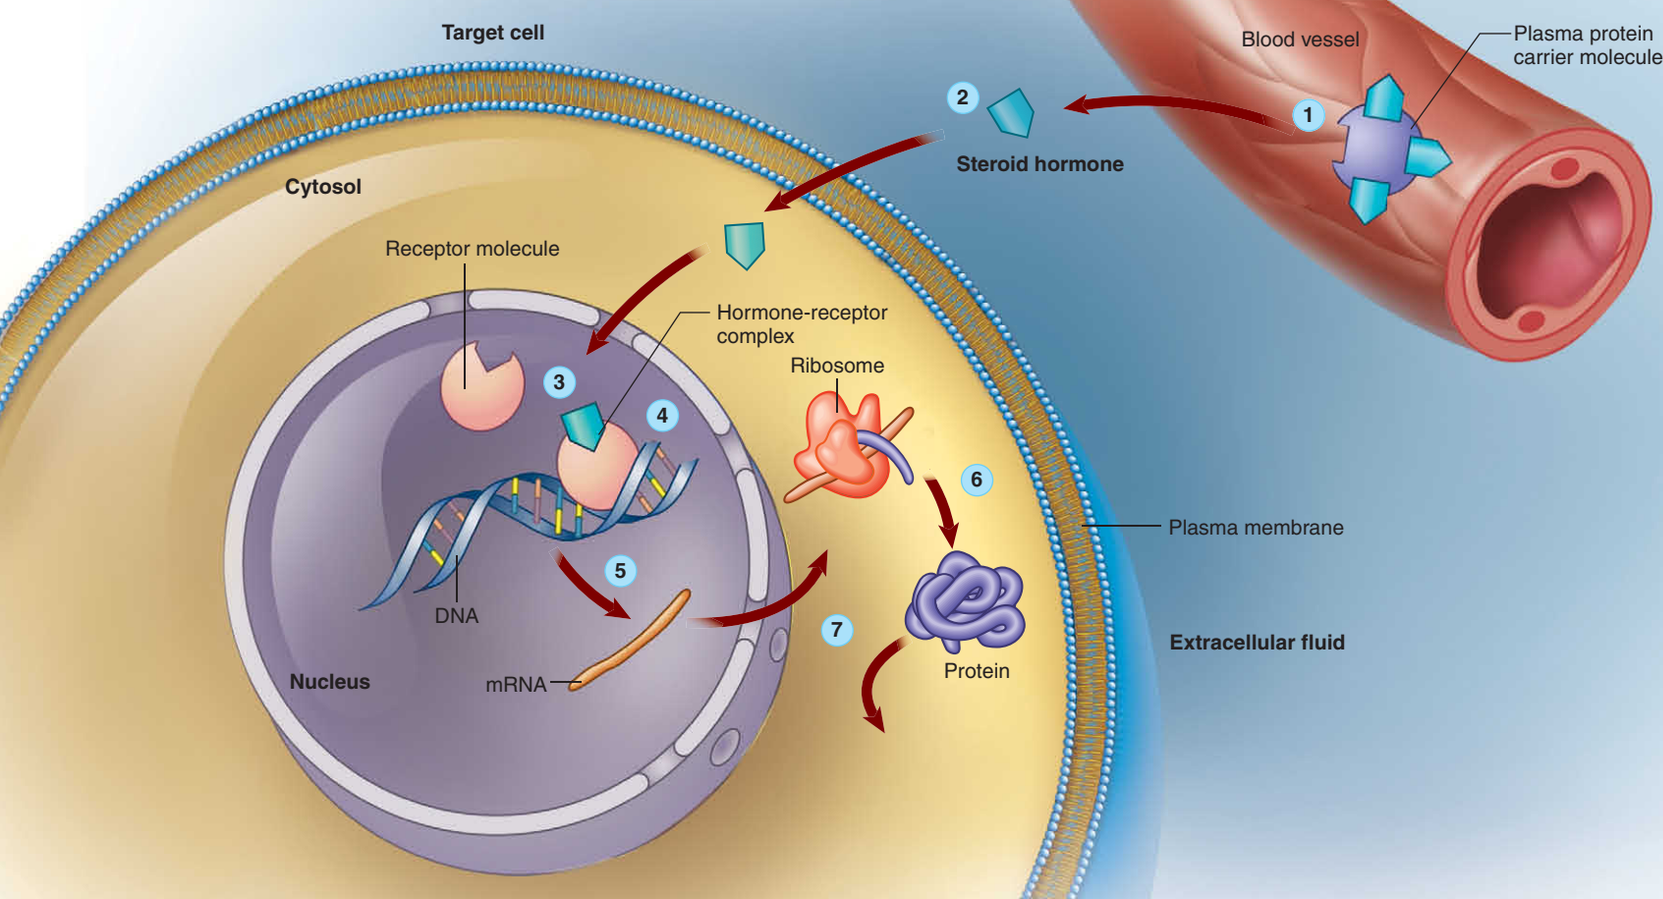
MECHANISM OF STEROID HORMONE ACTION

Steroid hormones are lipids and thus are not very soluble in blood plasma, which is mostly water. Instead of traveling in the plasma as free molecules, they attach to soluble plasma proteins. As you can see in Figure 18-8, a steroid hormone molecule dissociates from its carrier before approaching the target cell. Because steroid hormones are lipid soluble and thus can pass into cells easily, it is not surprising that many of their receptors are found inside the cell rather than on the surface of the plasma membrane. After a steroid hormone molecule has diffused into its target cell, it passes into the nucleus, where it binds to a mobile-receptor molecule to form a *hormone-receptor complex*. Some hormones must be activated by enzymes before they can bind to their receptors. Because steroid hormone receptors are not attached to the plasma membrane, but seem to move freely in the nucleoplasm, this model of hormone action has been called the **mobile-receptor model,** or the *nuclear-receptor model*.

Once formed, the hormone-receptor complex activates a certain gene sequence to begin transcription of messenger RNA (mRNA) molecules. The newly formed mRNA molecules then move out of the nucleus into the cytosol, where they associate with ribosomes and begin synthesizing protein molecules.

The new protein molecules synthesized by the target cell would not have been made if not for the arrival of the steroid hormone molecule. Steroid hormones regulate cells by regulating their production of certain critical proteins, such as enzymes that control intracellular reactions or integral membrane proteins that alter the permeability of a cell.

This mechanism of steroid hormone action implies several things about the effects of these hormones. For one thing, the more hormone-receptor complexes formed, the more mRNA molecules are transcribed, the more new protein molecules are formed, and thus the greater the magnitude of the regulatory effect. In short, the *amount* of steroid hormone present determines the magnitude of a target cell's response. Also, because transcription and protein synthesis take some time, responses to steroid hormones can be slow—from 45 minutes to several days before the full effect is seen.



MECHANISMS OF NONSTEROID HORMONE ACTION

The Second Messenger Mechanism

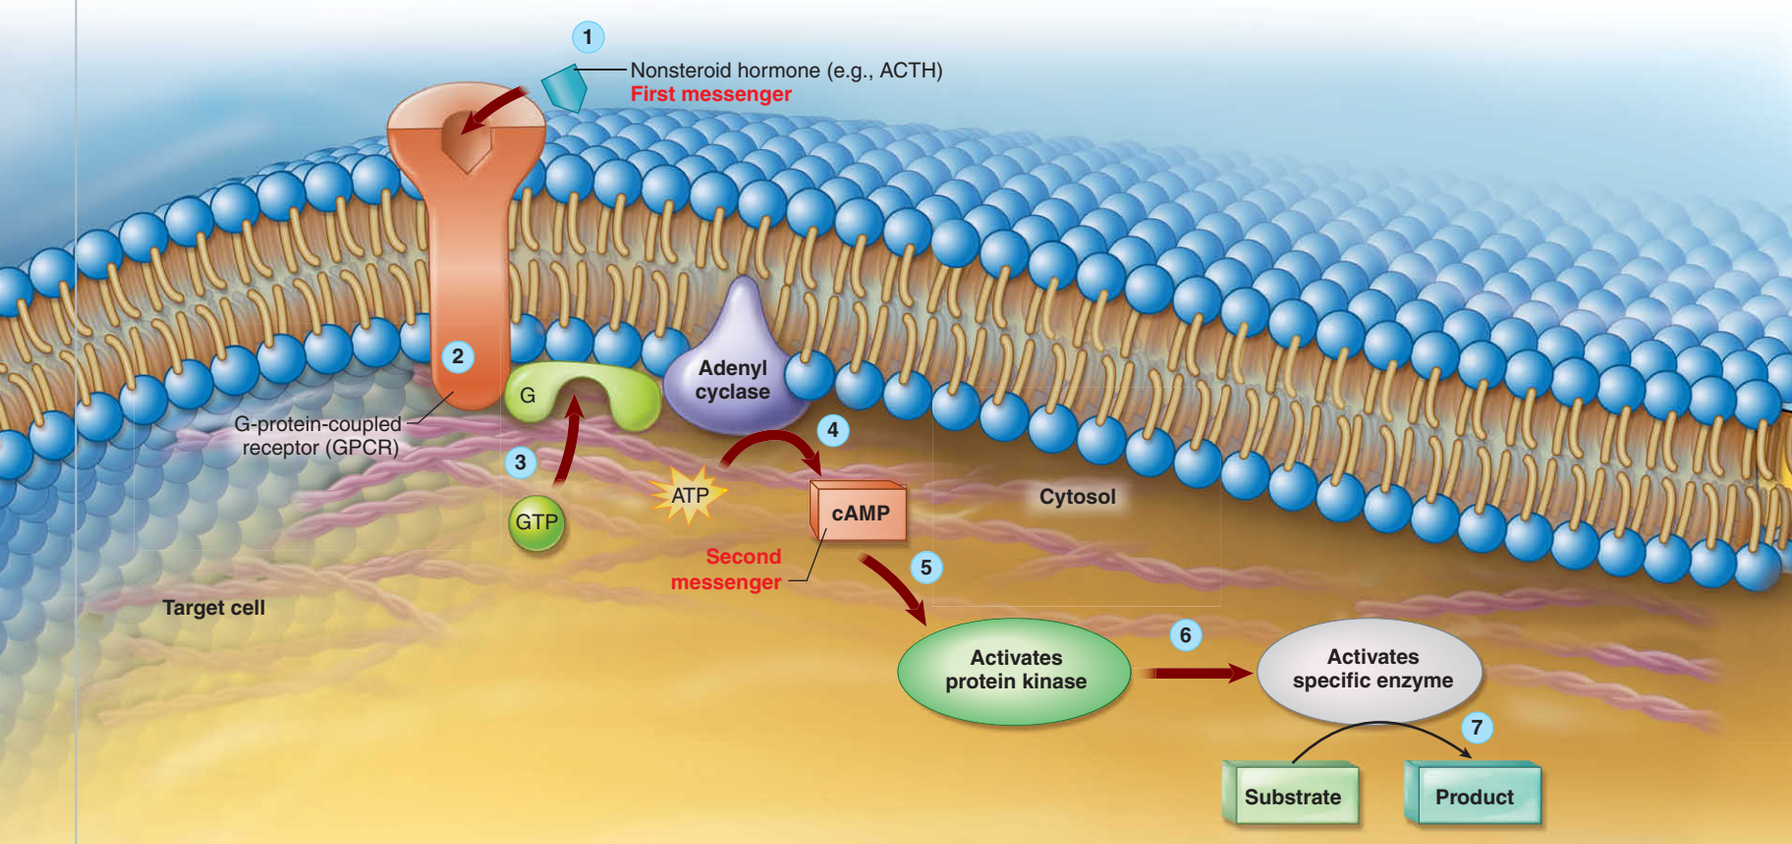
Nonsteroid hormones typically operate according to a mechanism originally called the **second messenger model.** This concept of hormone action—first proposed in the last century by Dr. Earl W. Sutherland—was a milestone in endocrinology for which he received the 1971 Nobel Prize in Medicine or Physiology. According

FIGURE 18-8

Steroid hormone mechanism. According to the mobile-receptor model, lipid-soluble steroid hormone molecules detach from a carrier protein **(1)** and pass through the plasma membrane **(2)**. The hormone molecules then pass into the nucleus where they bind with a mobile receptor to form a hormone-receptor complex **(3)**. This complex then binds to a specific site on a DNA molecule **(4)**, triggering transcription of the genetic information encoded there **(5)**. The resulting mRNA molecule moves to the cytosol, where it associates with a ribosome, initiating synthesis of a new protein **(6)**. This new protein—usually an enzyme or channel protein—produces specific effects in the target cell **(7)**. Some steroid hormones also have additional secondary effects such as influencing signal transduction pathways at the plasma membrane.

to this concept of signal transduction, a nonsteroid hormone molecule acts as a "first messenger," delivering its chemical message to fixed receptors in the target cell's plasma membrane. The "message" is then passed into the cell where a "second messenger" triggers the appropriate cellular changes. This concept of nonsteroid hormone action is also called the *fixed-membrane-receptor model.*

In the example illustrated in Figure 18-9, a nonsteroid hormone can trigger a **G-protein–coupled receptor (GPCR)** embedded in the membrane of a target cell. The activated GPCR causes an integral membrane protein, called the G *protein*, to bind to a nucleotide called *guanosine triphosphate (GTP)*. This in turn activates another membrane protein, *adenyl cyclase*. Adenyl cyclase is an enzyme that promotes the removal of two phosphate groups from adenosine triphosphate (ATP) molecules in the cytosol. The product thus formed is cyclic adenosine monophosphate *(cAMP)*. The cAMP molecule acts as a second messenger within the cell. cAMP activates *protein kinases*, a set of enzymes that activate other types of enzymes. It is this final set of specific enzymes, which are now activated, that catalyze the cellular reactions that characterize the target cell's response. In short, the hormone first messenger binds to a membrane receptor, triggering formation of an intracellular second messenger, which activates a cascade of chemical reactions that produces the target cell's response.



Since the time Sutherland first began his pioneering work, other second messenger systems for signal transduction have been discovered. As a matter of fact, the study of second messenger mechanisms is currently a central area of physiology research. Although many nonsteroid hormones seem to use cAMP as the second messenger, we now know that some hormones use nucleotides such as inositol triphosphate (IP_3) and cyclic guanosine monophosphate (cGMP) as the second messenger.

Still other hormones produce their effects by triggering the opening of calcium (Ca^{++}) channels in the target cell's membranes, as you can see in Figure 18-10. Binding of a hormone to a fixed membrane receptor (GPCR) activates a chain of integral membrane proteins (G protein and phosphatidylinositol 4,5-biphosphate, PIP_2) that in turn trigger the opening of calcium channels in the plasma membrane. Ca^{++} ions that enter the cytosol when the channels open bind to an intracellular molecule called *calmodulin*. The Ca^{++}-calmodulin complex thus formed acts as a second messenger, influencing the enzymes that produce the target cell's response.

Research findings also show that in second messenger systems, the hormone-receptor complexes may be taken into the cell by means of endocytosis. Although the purpose of this may be primarily to break down the complexes and recycle the receptors, the

FIGURE 18-9

Example of a second messenger mechanism. A nonsteroid hormone (first messenger) binds to a fixed G-protein–coupled receptor (GPCR) in the plasma membrane of the target cell **(1)**. The hormone-receptor complex activates the G protein **(2)**. The activated G protein reacts with GTP, which in turn activates the membrane-bound enzyme adenyl cyclase **(3)**. Adenyl cyclase removes phosphates from ATP, converting it to cAMP (second messenger) **(4)**. cAMP activates or inactivates protein kinases **(5)**. Protein kinases activate specific intracellular enzymes **(6)**. These activated enzymes then influence specific cellular reactions, thus producing the target cell's response to the hormone **(7)**. *GTP,* Guanosine triphosphate; *ATP,* adenosine triphosphate; *cAMP,* cyclic adenosine monophosphate.

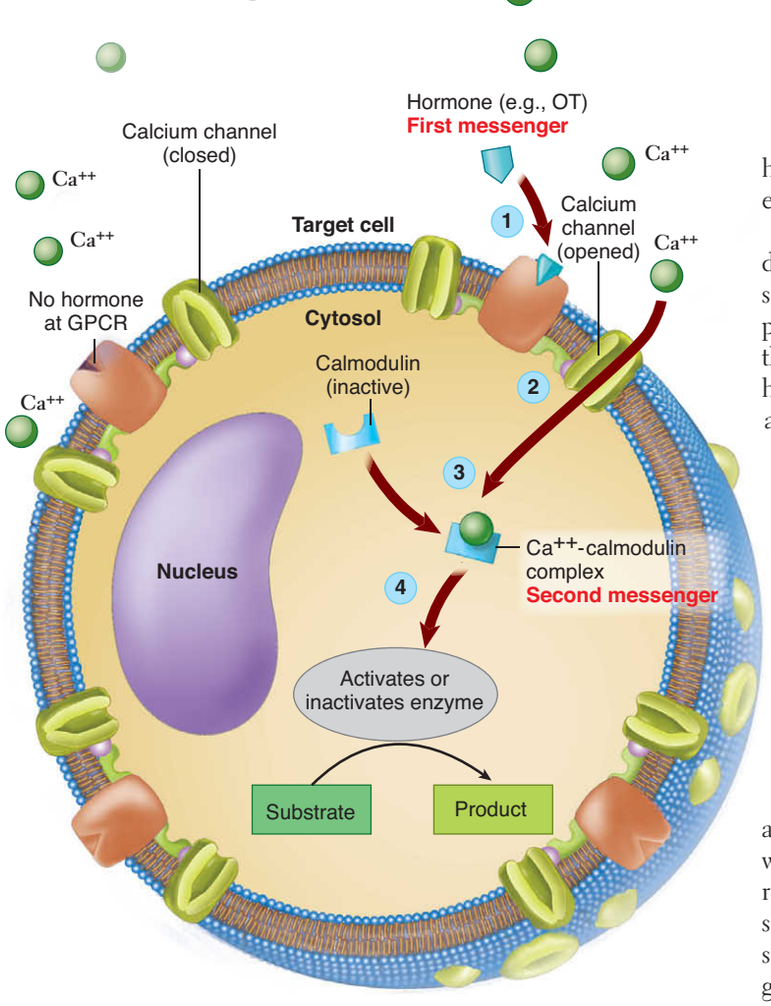


FIGURE 18-10

Calcium-calmodulin as a second messenger. In this example of a second messenger mechanism, a nonsteroid hormone (first messenger) first binds to a fixed receptor (G-protein–coupled receptor, GPCR) in the plasma membrane **(1)**, which activates membrane-bound proteins (G protein and PIP_2) that trigger the opening of calcium channels **(2)**. Calcium ions, which are normally at a higher concentration in the extracellular fluid, diffuse into the cell and bind to a calmodulin molecule **(3)**. The Ca^{++}-calmodulin complex thus formed is a second messenger that binds to an enzyme to produce an allosteric effect that promotes or inhibits the enzyme's regulatory effect in the target cell **(4)**. *PIP_2*, Phosphatidylinositol 4,5-biphosphate.

hormone-receptor complex may continue to have physiological effects after it is taken into the cell.

The second messenger mechanism of signal transduction produces target cell effects that differ from steroid hormone effects in several important ways (Table 18-3). First, the cascade of reactions produced in the second messenger mechanism greatly amplifies the effects of the hormone. Thus the effects of many nonsteroid hormones are disproportionately great when compared with the amount of hormone present. Recall that steroid hormones produce effects in proportion to the amount of hormone present. Also, the second messenger mechanism operates much more quickly than the steroid mechanism. Many nonsteroid hormones produce their full effects within seconds or minutes of initial binding to the target cell receptors—not the hours or days sometimes seen with steroid hormones.

The Nuclear-Receptor Mechanism

Not all nonsteroid hormones operate according to the second messenger model. The notable exception is the pair of thyroid hormones, thyroxine (T_4) and triiodothyronine (T_3). These small iodinated amino acids apparently enter their target cells and bind to receptors already associated with a DNA molecule within the nucleus of the target cell. Formation of a hormone-receptor complex triggers transcription of mRNA and the synthesis of new enzymes in a signal transduction system similar to the steroid mechanism. More information on thyroid hormones is given later in this chapter.

Regulation of Hormone Secretion

The control of hormonal secretion is usually part of a negative feedback loop. Recall from Chapter 1 (see Figure 1-13, p. 22) that negative feedback loops tend to reverse any deviation of the internal environment away from its stable point (the set point value). Rarely, a positive feedback loop controls the secretion of a hormone. Recall that in positive feedback control, deviation from the stable point is exaggerated rather than reversed. Responses that result from the operation of feedback loops within the endocrine system are called *endocrine reflexes*, just as responses to nervous feedback loops (reflex arcs) are called *nervous reflexes*.

TABLE 18-3 Comparison of Steroid and Nonsteroid Hormones

CHARACTERISTIC	STEROID HORMONES*	NONSTEROID HORMONES†
Chemical structure	Lipid	One or more amino acids, sometimes with added sugar groups
Stored in secretory cell	No	Yes; stored in secretory vesicles before release
Interaction with plasma membrane	No; simple diffusion through plasma membrane and into target cell	Yes; binds to specific plasma membrane receptor
Receptor	Mobile receptor in cytoplasm or nucleus	Embedded in plasma membrane
Action	Regulates gene activity (transcription of new proteins that eventually produce effects in the cell)	Triggers signal transduction cascade, producing internal "second messengers" that trigger rapid effects in the target cell
Response time	One hour to several days	Several seconds to a few minutes

*See Box 18-1 on p. 554 for additional emerging concepts of steroid hormone characteristics.
†Some nonsteroid hormones derived from amino acids (e.g., thyroid hormones T_3 and T_4) have gene-activating actions similar to steroid hormones.

Box 18-1 | Rapid Responses to Steroid Hormones

The conventional view of steroid hormone regulation of gene activity states that one or more hours pass before the effects of the hormone reach their peak. Steroid hormones, however, can also produce some rapid effects in target cells—in just seconds or minutes. How is this possible? We now know that additional steroid hormone receptors at the plasma membrane enable many steroid hormones to regulate signal transduction in target cells. That is, steroid hormones have a secondary effect that can change the messages sent by other regulatory molecules, such as other hormones or neurotransmitters.

The emerging view therefore is that steroid hormones produce both slow and rapid effects in target cells. Slow effects result from stimulating the transcription of specific genes in the target cell's nucleus—thus producing new proteins. Rapid effects result from altering signal transduction mechanisms in the plasma membrane of the target cell.

For a moment, let us focus our attention on the specific mechanisms that regulate the release of hormones from endocrine cells (Box 18-1). The simplest mechanism operates when an endocrine cell is sensitive to the physiological changes produced by its target cells (Figure 18-11). For example, parathyroid hormone (PTH) produces responses in its target cells that increase Ca^{++} concentration in the blood. When blood Ca^{++} concentration exceeds the set point value, parathyroid cells sense it and reflexively reduce their output of PTH. Secretion by many endocrine glands is regulated by a hormone produced by another gland. For example, the pituitary gland (specifically, the anterior portion) produces thyroid-stimulating hormone (TSH), which stimulates the thyroid gland to release its hormones. The anterior pituitary responds to changes in the controlled physiological variable and to changes in the blood concentration of hormones secreted by its target gland. Secretion by the anterior pituitary can in turn be regulated by *releasing hormones* or *inhibiting hormones* secreted by the hypothalamus. Hypothalamic secretion is responsive to changes in the controlled variable, as well as changes in the blood concentration of anterior pituitary and target gland hormones. Although the target gland may be able to adjust its own output, the additional controls exerted by long feedback loops involving the anterior pituitary and hypothalamus allow more precise regulation of hormone secretion—and thus more precise regulation of the internal environment.

Another mechanism that may influence the secretion of hormones by a gland is input from the nervous system. For example, secretion by the posterior pituitary is not regulated by releasing hormones but by direct nervous input from the hypothalamus. Likewise, sympathetic nerve impulses that reach the medulla of the adrenal glands trigger the secretion of epinephrine and norepinephrine. Many other glands, including the pancreas, are also influenced to some degree by nervous input. That the nervous system operates with hormonal mechanisms to produce endocrine

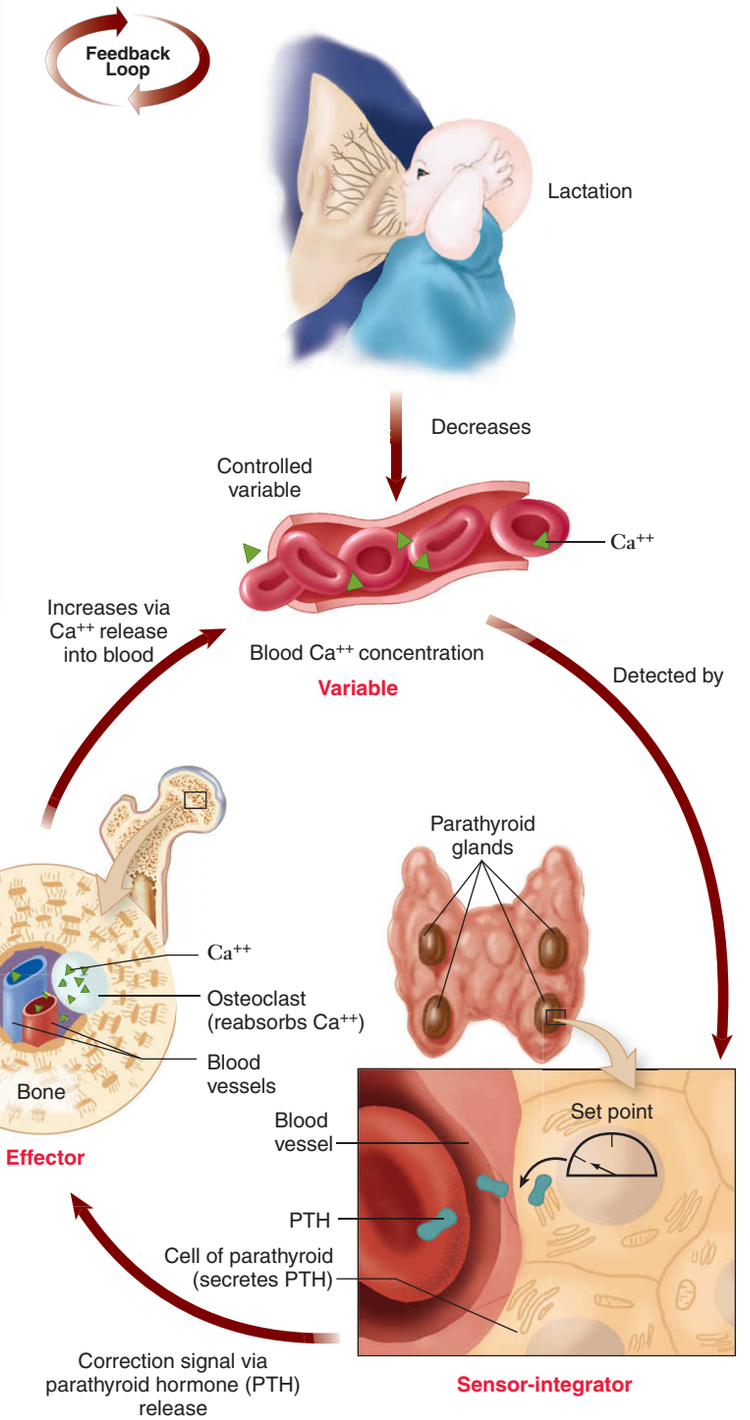

FIGURE 18-11

Endocrine feedback loop. In this example of a short feedback loop, each parathyroid gland is sensitive to changes in the physiological variable its hormone (parathyroid hormone [PTH]) controls—blood calcium (Ca^{++}) concentration. When lactation (milk production) in a breastfeeding woman consumes Ca^{++} and thus lowers blood Ca^{++} concentration, the parathyroids sense the change and respond by increasing their secretion of PTH. PTH stimulates osteoclasts in bone to release more Ca^{++} from storage in bone tissue (among other effects), which increases maternal blood Ca^{++} concentration to the set point level.

reflexes emphasizes the close functional relationship between these two systems.

Although the operation of long feedback loops tends to minimize wide fluctuations in secretion rates, the output of several hormones typically rises and falls dramatically within a short period. For example, the concentration of insulin—a hormone that can correct a rise in blood glucose concentration—increases to a high level just after a meal high in carbohydrates. The level of insulin decreases only after the blood glucose concentration returns to its set point value. Likewise, threatening stimuli can cause a sudden, dramatic increase in the secretion of epinephrine from the adrenal medulla as part of the fight-or-flight response.

Specific examples of feedback control of hormone secretion are given later in this chapter.

Regulation of Target Cell Sensitivity

The sensitivity of a target cell to any particular hormone partly depends on how many receptors for that hormone it has. The more receptors there are, the more sensitive is the target cell. Hormone receptors, as with other cell components, are constantly broken down by the cell and replaced with newly synthesized receptors. This mechanism not only ensures that all cell parts are "new" and working properly, but also provides a method by which the number of receptors can be changed from time to time.

If synthesis of new receptors occurs faster than degradation of old receptors, the target cell will have more receptors and thus be more sensitive to the hormone. This phenomenon, illustrated in Figure 18-12, *A*, is often called **up-regulation** because the number of receptors goes up. If, on the other hand, the rate of receptor degradation exceeds the rate of receptor synthesis, the target cell's number of receptors will decrease (Figure 18-12, *B*). Because the number of receptors, and thus the sensitivity of the target cell, go down, this phenomenon is often called **down-regulation.**

Of course, regulation of signal transduction mechanisms and gene transcription triggered by various hormones can also play a role in adjusting the sensitivity of target cells to a particular hormone at a particular time. For example, one hormone may affect the signal transduction of another hormone, thus inhibiting or enhancing the second hormone's effects (Box 18-2).

Endocrinologists are just now learning the mechanisms that control the process of receptor turnover and signal transduction in the cell and how this affects the functions of the target cell. Information uncovered so far has already led to a better understanding of important and widespread endocrine disorders such as diabetes mellitus.

8. Name some ways that the secretion of an endocrine cell can be controlled.

Box 18-2 | HEALTH matters

"Too Much or Too Little"

Diseases of the endocrine system are numerous, varied, and sometimes spectacular. Tumors or other abnormalities frequently cause the glands to secrete too much or too little of their hormones. Production of too much hormone by a diseased gland is called **hypersecretion.** If too little hormone is produced, the condition is called **hyposecretion.**

Various endocrine disorders that appear to result from hyposecretion are actually caused by a problem in the target cells. If the usual target cells of a particular hormone have damaged receptors, too few receptors, or some other abnormality, they will not respond to that hormone properly. In other words, lack of target cell response could be a sign of hyposecretion or a sign of target cell insensitivity. *Diabetes mellitus (DM),* for example, can result from insulin hyposecretion or from the target cells' insensitivity to insulin.

Polyendocrine disorders are caused by hypersecretion and/or hyposecretion of more than one hormone. Often, an imbalance of one hormone will lead to an imbalance of other hormones as well.

TABLE 18-4 Prostaglandins and Related Hormones

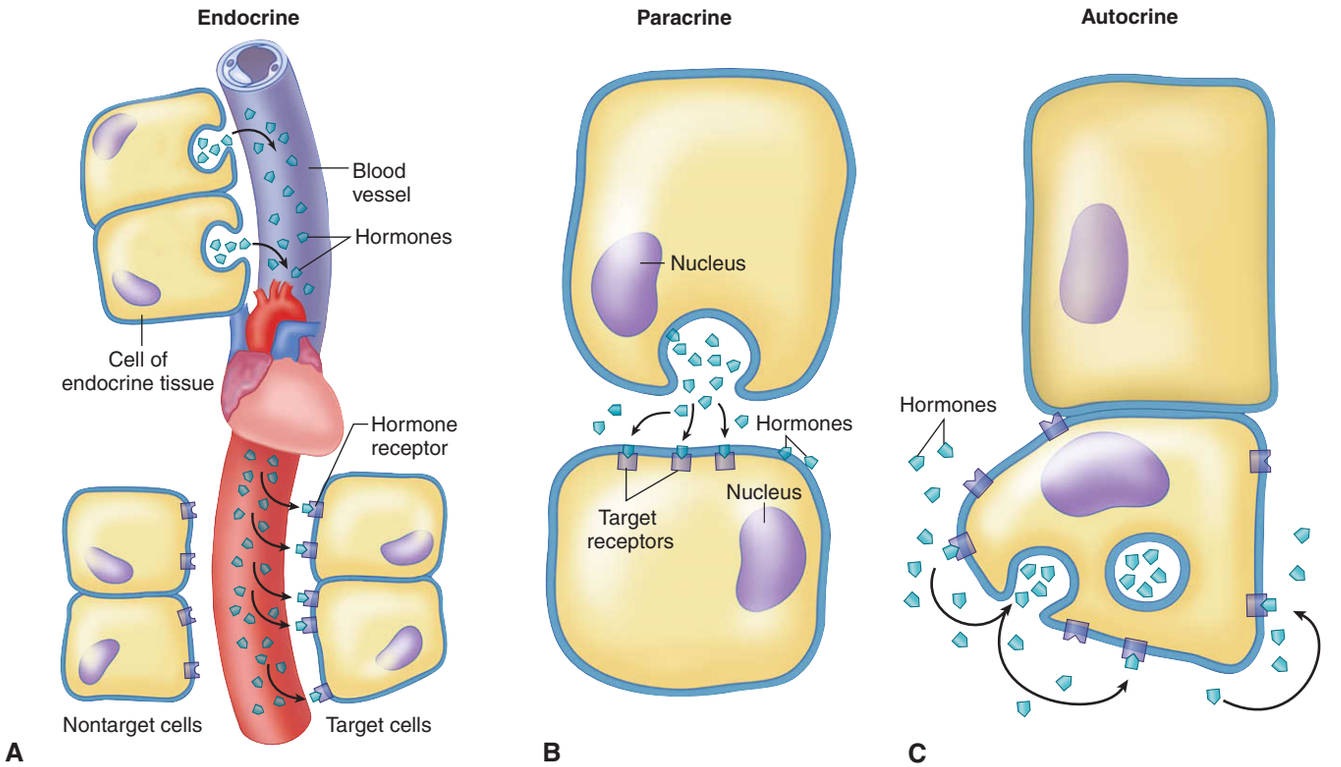
HORMONE	SOURCE	TARGET	PRINCIPAL ACTION
Prostaglandins (PGs)	Many diverse tissues of the body	Local cells within the source tissue	Diverse local (paracrine/autocrine) effects such as regulation of inflammation, muscle contraction in blood vessels
Thromboxanes (TXs)	Platelets	Other platelets; muscles in blood vessel walls	Increase stickiness of platelets; promote blood clotting; cause constriction of blood vessels
Leukotrienes	Several types of white blood cells (leukocytes)	Local cells of various types	Produce local inflammation triggered by allergens, including constriction of airways (as in asthma) and other inflammatory responses

PROSTAGLANDINS

Before continuing our discussion of endocrine glands and hormones, let us pause a moment to consider the **prostaglandins (PGs)** and related compounds (Table 18-4). The prostaglandins are a unique group of lipid molecules that serve important and widespread integrative functions in the body but do not meet the usual definition of a hormone (Box 18-3).

Prostaglandins are 20-carbon unsaturated fatty acids and contain a 5-carbon ring (Figure 18-13). Prostaglandins are made by cells throughout the body by breaking apart membrane

Box 18-3 | Local Hormones



The classical view of hormones is that they are secreted from a tissue into the bloodstream and have their effects in target cells at some distance from their source. This is the standard definition of an **endocrine hormone** (part *A* of figure). That is, hormones have "global" effects in the body.

However, some hormones and related agents have primarily local effects—that is, effects *within* the source tissue. To distinguish classical endocrine hormones from local regulators such as prostaglandins and related compounds, scientists often use more precise terms for "local" hormones. Here are examples of terms used to designate local regulators:

Paracrine hormones—hormones that regulate activity in nearby cells within the same tissue as their source (part *B* of figure)

Autocrine hormones—hormones that regulate activity in the secreting cell itself (part *C* of figure)

To avoid confusion, scientists most often refer only to endocrine hormones simply as "hormones." For local regulators, scientists use general terms such as "tissue hormone" or "local regulator"—or more specific terms such as "paracrine" or "autocrine" factor.

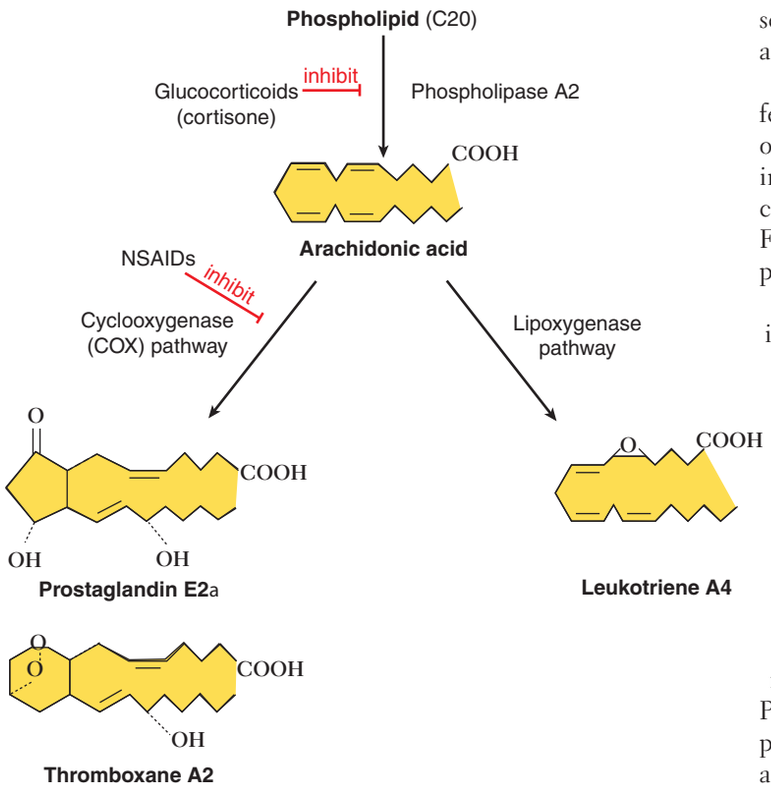


FIGURE 18-13

Formation of prostaglandin and related molecules. Membrane phospholipids containing the 20-carbon fatty acid arachidonic acid are enzymatically broken apart (C20, 20-carbon). Therapeutic use of glucocorticoids such as cortisone can inhibit this pathway, thus reducing the amount (and effects) of any of the resulting regulator molecules. Arachidonic acid is then converted by the COX pathway to either prostaglandins or thromboxanes (*left*). This step can be therapeutically inhibited by NSAIDs (nonsteroidal antiinflammatory drugs). Arachidonic acid may alternatively be converted by the lipoxygenase pathway to a leukotriene. See also Figure 2-24 on p. 51. *COX,* Cyclooxygenase.

phospholipids and using their fatty acid "tails" (specifically, *arachidonic acid*). Box 2-3 on p. 51 discusses one of the enzymes (*cyclooxygenase* or *COX*) used to convert arachidonic acid to prostaglandin.

Although prostaglandins may be secreted directly into the bloodstream, they are rapidly metabolized, so that circulating levels are extremely low. The term *tissue hormone* is appropriate because the secretion is produced in a tissue and diffuses only a short distance to other cells within the same tissue. Whereas typical hormones integrate activities of widely separated organs, prostaglandins tend to integrate activities of neighboring cells.

There are at least 16 different prostaglandins, falling into nine structural classes—prostaglandin A through prostaglandin I. Prostaglandins have been isolated and identified from a variety of tissues. The first prostaglandin was discovered in semen, so it was attributed to the prostate gland (hence the name, prostaglandin). Later, researchers found that the seminal vesicles, not the prostate, secreted the prostaglandin that they had found. Many other tissues are now known to secrete prostaglandins.

As a group, the prostaglandins have diverse physiological effects and are among the most varied and potent of any naturally occurring biological compounds. They are intimately involved in overall endocrine regulation by influencing adenyl cyclase–cAMP interaction within the cell's plasma membrane (see Figure 18-9). Specific biological effects depend on the class of prostaglandin.

Intraarterial infusion of prostaglandins A (PGAs) results in an immediate fall in blood pressure accompanied by an increase in regional blood flow to several areas, including the coronary and renal systems. PGAs apparently produce this effect by causing relaxation of smooth muscle fibers in the walls of certain arteries and arterioles.

Prostaglandins E (PGEs) have an important role in various vascular, metabolic, and gastrointestinal functions. Vascular effects include regulation of red blood cell deformability and platelet aggregation (see Chapter 20). PGEs also have a role in systemic inflammations, such as fever. Common antiinflammatory agents such as aspirin and ibuprofen produce some of their effects by inhibiting PGE synthesis. These drugs act by blocking one or more of the prostaglandin-producing *cyclooxygenase* enzymes such as *COX-1* and *COX-2*, as you may recall from Box 2-3 on p. 51. PGE also regulates hydrochloric acid secretion in the stomach, helping to prevent gastric ulcers.

Prostaglandins F (PGFs) have an especially important role in the reproductive system. They cause uterine muscle contractions, so they have been used to induce labor and thus accelerate delivery of a baby. PGFs also affect intestinal motility and are required for normal peristalsis.

In addition to prostaglandins, various tissues also synthesize other fatty acid compounds that are structurally and functionally similar to prostaglandins (see Figure 18-13). One example is **thromboxane,** a blood regulator important in blood clotting (discussed in Chapter 20). Another important example is a group called the **leukotrienes,** which are regulators of immunity (discussed in Chapter 24). As with prostaglandins, these compounds may also be referred to as "tissue hormones" because of their local, yet potent, regulatory effects.

The potential therapeutic use of prostaglandins and related compounds, which are found in almost every body tissue and are capable of regulating hormone activity on the cellular level, has been described as the most revolutionary development in medicine since the advent of antibiotics. They are likely to play increasingly important roles in the treatment of diverse conditions, such as hypertension, coronary thrombosis, asthma, and ulcers.

9. Why are prostaglandins sometimes called *tissue hormones?*
10. Why are prostaglandins considered to be important in clinical applications?

the BIG picture

Endocrine Regulation and the Whole Body

It is important to appreciate the precision of control afforded by the partnership of the two major regulatory systems: the endocrine system and the nervous system. Some of the more important endocrine glands and the actions of their hormones are summarized in the following chapter. However, we have already seen how the hormones interact with each other in functional teams, as well as how their functions complement those of the nervous system. Although there is still much to be learned, we can see that a basic understanding of hormonal regulatory mechanisms is required to fully appreciate the nature of homeostasis in the human organism. As we continue our study of human anatomy and physiology, we will often encounter the critical integrative role played by the endocrine system. Having explored the basic principles of hormonal regulation, we are now ready for the specific examples of important glands and hormones outlined in the next chapter.

MECHANISMS of DISEASE

ENDOCRINE DISORDERS

As we have stated throughout this chapter, endocrine disorders typically result from either elevated or depressed hormone levels (hypersecretion or hyposecretion). At first thought, this may seem very simple and straightforward. In reality, however, nothing could be further from the truth. A variety of specific mechanisms may produce hypersecretion or hyposecretion of hormones. A few of the more well-known mechanisms are briefly explained here.

Mechanisms of Hypersecretion

Excessively high blood concentration of a hormone—or any condition that mimics high hormone levels—is called *hypersecretion.* Specific types of hypersecretion are usually named by placing the prefix *hyper-* in front of the name of the source gland and the suffix *-ism* at the end. For example, hypersecretion of thyroid hormone—no matter what the specific cause—is called **hyperthyroidism.** Hyperthyroidism is not a disease itself but a condition that characterizes several different diseases (e.g., Graves disease, toxic nodular goiter).

Any of several different mechanisms may be responsible for a particular case of hypersecretion. For example, tumors are often responsible for an abnormal proliferation of endocrine cells and the resulting increase in hormone secretion. Pituitary adenomas, for example, are benign tumors that may cause **hyperpituitarism.** As many as one in five people may have pituitary adenomas, but the majority of tumors are microscopic and asymptomatic. Larger tumors may, however, cause hyperpituitarism with possible outcomes of **gigantism** and/or **acromegaly.**

Another cause of hypersecretion is a phenomenon called **autoimmunity.** In autoimmunity, the immune system functions abnormally. In **Graves disease,** for example, autoimmune antibodies against the TSH receptor actually stimulate the receptor and mimic the activity of TSH. As a result, the thyroid gland hypertrophies and excess thyroid hormone is produced.

Another possible cause of hypersecretion of a hormone is a failure of the feedback mechanisms that regulate secretion of a particular hormone. For example, a condition called **primary hyperparathyroidism** is characterized by a failure of the parathyroid gland to adjust its output to compensate for changes in blood calcium levels. Instead, the parathyroid gland seems to operate independently of the normal feedback loop and thus overproduces parathyroid hormone.

Mechanisms of Hyposecretion

Depressed blood hormone levels—or any condition that mimics low hormone levels—is termed *hyposecretion.* Specific types of hyposecretion are named in a manner similar to that in which hypersecretion disorders are named: by the addition of the *hypo-* prefix and the *-ism* suffix. For example, hyposecretion of thyroid hormone is called *hypothyroidism.*

Various different mechanisms have been shown to cause hyposecretion of hormones. For example, although most tumors cause oversecretion of a hormone, they may instead cause a gland to undersecrete its hormone or hormones. Tissue death, perhaps caused by a blockage or other failure of the blood supply, can also cause a gland to reduce its hormonal output. Hypopituitarism (hyposecretion by the anterior pituitary) can occur this way. Still another way in which a gland may reduce its secretion below normal levels is through abnormal operation of regulatory feedback loops. An example of this is in the case of hyposecretion of testosterone and gonadotropic hormones in males who abuse *anabolic steroids.* Men who take testosterone steroids increase their blood concentration of this hormone above set point levels. The body responds to this overabundance by reducing its own output of testosterone (i.e., gonadotropins). This may lead to sterility and other complications.

Abnormalities of immune function may also cause hyposecretion. For example, an autoimmune attack on glandular tissue sometimes has the effect of reducing hormone output. Some endocrinologists theorize that autoimmune destruction of pancreatic islet cells, perhaps in combination with viral and genetic mechanisms, is a culprit in many cases of *type 1 (insulin-dependent) diabetes mellitus (DM)*.

Many types of hyposecretion disorders have been shown to be caused by insensitivity of the target cells to tropic hormones rather than from actual hyposecretion. A few major types of abnormal responses in target cells are as follows:

- An abnormal decrease in the number of hormone receptors
- Abnormal function of hormone receptors, resulting in failure to bind to hormones properly
- Antibodies bind to hormone receptors, thus blocking binding of hormone molecules
- Abnormal metabolic response to the hormone-receptor complex by the target cell
- Failure of the target cell to produce enough second messenger molecules

For example, type 2 (non–insulin-dependent) diabetes mellitus is thought to be caused by target cell abnormalities that render the cells insensitive to insulin.

The next chapter will give several examples of many specific endocrine disorders. Apply the principles you have learned here to determine whether each primarily involves functional hyposecretion or functional hypersecretion of the hormone(s) involved.

HINT

Scan this summary after reading the chapter to help you reinforce the key concepts. Later, use the summary as a quick review before your class or before a test.

ORGANIZATION OF THE ENDOCRINE SYSTEM

A. The endocrine and nervous systems function to achieve and maintain homeostasis (Table 18-1)
B. When the two systems work together, referred to as the *neuroendocrine system*, they perform the same general functions: communication, integration, and control
C. In the endocrine system, secreting cells send hormone molecules by way of the blood to specific target cells contained in target tissues or target organs
D. Hormones—carried to almost every point in the body; can regulate most cells; effects work more slowly and last longer than those of neurotransmitters
E. Endocrine glands are "ductless glands"; many are made of glandular epithelium whose cells manufacture and secrete hormones; a few endocrine glands are made of neurosecretory tissue
F. Glands of the endocrine system are widely scattered throughout the body (Figure 18-2; Table 18-2)

HORMONES

A. Classification of hormones
  1. Classification by general function
    a. Tropic hormones—hormones that target other endocrine glands and stimulate their growth and secretion
    b. Sex hormones—hormones that target reproductive tissues
    c. Anabolic hormones—hormones that stimulate anabolism in target cells
  2. Classification by chemical structure (Figure 18-3; Table 18-3)
    a. Steroid hormones
    b. Nonsteroid hormones
  3. Steroid hormones (Figure 18-4)
    a. Synthesized from cholesterol (Figure 18-5)
    b. Lipid soluble and can easily pass through the phospholipid plasma membrane of target cells
    c. Examples of steroid hormones: cortisol, aldosterone, estrogen, progesterone, and testosterone
  4. Nonsteroid hormones (Figure 18-6)
    a. Synthesized primarily from amino acids
    b. Protein hormones—long, folded chains of amino acids; e.g., insulin, parathyroid hormone
    c. Glycoprotein hormones—protein hormones with carbohydrate groups attached to the amino acid chain
    d. Peptide hormones—smaller than protein hormones; short chain of amino acids; e.g., oxytocin, antidiuretic hormone (ADH)
    e. Amino acid derivative hormones—each is derived from a single amino acid molecule
      (1) Amine hormones—synthesized by modifying a single molecule of tyrosine or tryptophan; produced by neurosecretory cells and by neurons; e.g., epinephrine, norepinephrine
      (2) Amino acid derivatives produced by the thyroid gland; synthesized by adding iodine to tyrosine
B. How hormones work
  1. General principles of hormone action
    a. Hormones signal a cell by binding to the target cell's specific receptors in a "lock-and-key" mechanism (Figure 18-7)
    b. Different hormone-receptor interactions produce different regulatory changes within the target cell through chemical reactions
    c. Combined hormone actions
      (1) Synergism—combinations of hormones acting together have a greater effect on a target cell than the sum of the effects that each would have if acting alone
      (2) Permissiveness—when a small amount of one hormone allows a second one to have its full effects on a target cell
      (3) Antagonism—one hormone produces the opposite effects of another hormone; used to "fine tune" the activity of target cells with great accuracy
    d. Most hormones have primary effects that directly regulate target cells and many secondary effects that influence or modulate other regulatory mechanisms in target cells
    e. Endocrine glands produce more hormone molecules than actually are needed; the unused hormones are quickly excreted by the kidneys or broken down by metabolic processes
  2. Mechanism of steroid hormone action (Figure 18-8)
    a. Steroid hormones are lipid soluble, and their receptors are normally found in the target cell's cytosol
    b. After a steroid hormone molecule has diffused into the target cell, it binds to a receptor molecule to form a hormone-receptor complex
    c. Mobile-receptor model—the hormone passes into the nucleus, where it binds to a mobile receptor and activates a certain gene sequence to begin transcription of mRNA; newly formed mRNA molecules move into the cytosol, associate with ribosomes, and begin synthesizing protein molecules that produce the effects of the hormone

d. Steroid hormones regulate cells by regulating production of certain critical proteins
e. The amount of steroid hormone present determines the magnitude of a target cell's response
f. Because transcription and protein synthesis take time, responses to steroid hormones are often slow

3. Mechanisms of nonsteroid hormone action
   a. The second messenger mechanism—also known as the *fixed-membrane-receptor model* (Figure 18-9)
      (1) A nonsteroid hormone molecule acts as a "first messenger" and delivers its chemical message to fixed receptors in the target cell's plasma membrane
      (2) The "message" is then passed by way of a G-protein–coupled receptor (GPCR) into the cell where a "second messenger" triggers a G protein, which leads to the appropriate cellular changes
      (3) Second messenger mechanism—produces target cell effects that differ from steroid hormone effects in several important ways
         (a) The effects of the hormone are amplified by the cascade of reactions
         (b) There are a variety of second messenger mechanisms—e.g., IP_3, cGMP, calcium-calmodulin mechanisms (Figure 18-10)
         (c) The second messenger mechanism operates much more quickly than the steroid mechanism
   b. The nuclear-receptor mechanism—small iodinated amino acids (T_4 and T_3) enter the target cell and bind to receptors associated with a DNA molecule in the nucleus; this binding triggers transcription of mRNA and synthesis of new enzymes

C. Regulation of hormone secretion
1. Control of hormonal secretion is usually part of a negative feedback loop and is called *endocrine reflexes* (Figure 18-11)
2. Simplest mechanism—when an endocrine gland is sensitive to the physiological changes produced by its target cells
3. Endocrine gland secretion may also be regulated by a hormone produced by another gland
4. Endocrine gland secretions may be influenced by nervous system input; this fact emphasizes the close functional relationship between the two systems

D. Regulation of target cell sensitivity
1. Sensitivity of target cell depends in part on number of receptors (Figure 18-12)
   a. Up-regulation—increased number of hormone receptors increases sensitivity
   b. Down-regulation—decreased number of hormone receptors decreases sensitivity
2. Sensitivity of target cell may also be regulated by factors that affect signal transcription or gene transcription

PROSTAGLANDINS

A. Unique group of lipid hormones (20-carbon fatty acid with 5-carbon ring) that serve important and widespread integrative functions in the body but do not meet the usual definition of a hormone (Figure 18-13; Table 18-4)
B. Called *tissue hormones* because the secretion is produced in a tissue and diffuses only a short distance to other cells within the same tissue; PGs tend to integrate activities of neighboring cells
C. Many structural classes of prostaglandins have been isolated and identified
1. Prostaglandin A (PGA)—intraarterial infusion resulting in an immediate fall in blood pressure accompanied by an increase in regional blood flow to several areas
2. Prostaglandin E (PGE)—vascular effects: regulation of red blood cell deformability and platelet aggregation; inflammation (which can be blocked with drugs that inhibit PG-producing enzymes such as COX-1 and COX-2); gastrointestinal effects: regulates hydrochloric acid secretion
3. Prostaglandin F (PGF)—especially important in reproductive system, causing uterine contractions; also affects intestinal motility and is required for normal peristalsis

D. Many tissues are known to secrete PGs
E. PGs have diverse physiological effects

THE BIG PICTURE: THE ENDOCRINE SYSTEM AND THE WHOLE BODY

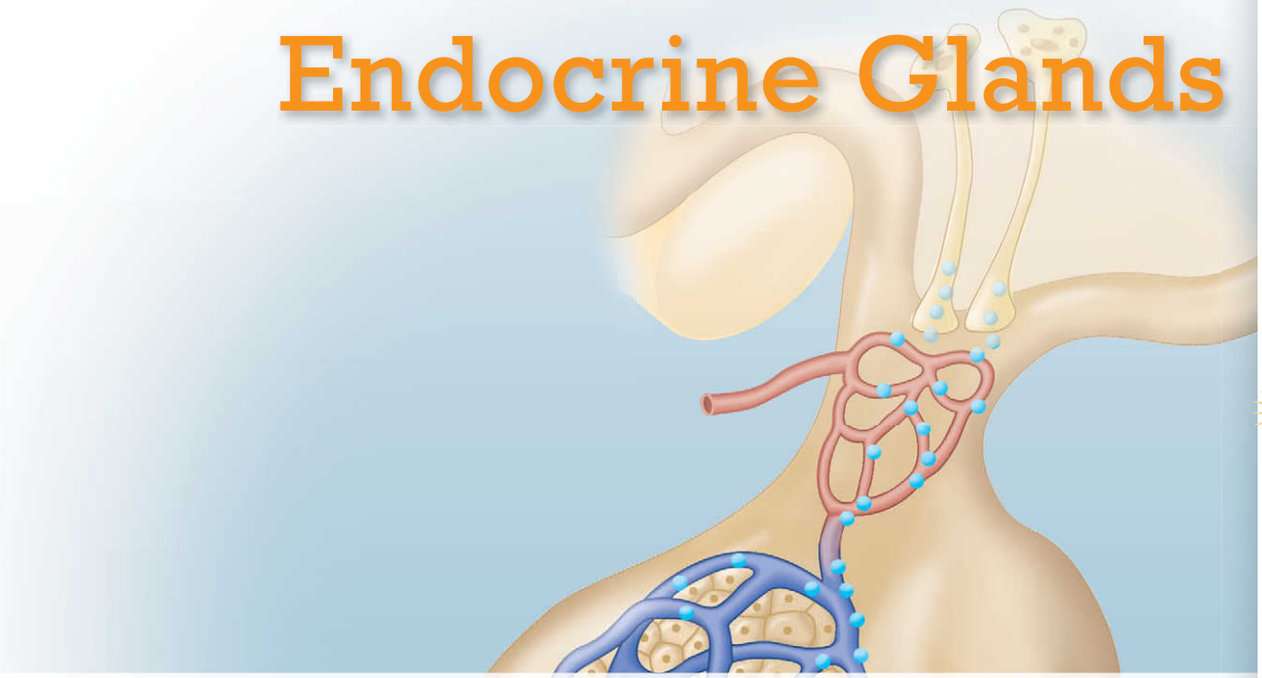
A. Nearly every process in the human organism is kept in balance by the intricate interaction of different nervous and endocrine regulatory chemicals
B. The endocrine system operates with the nervous system to finely adjust the many processes they regulate

REVIEW QUESTIONS

Write out the answers to these questions after reading the chapter and reviewing the Chapter Summary. If you simply think through the answer without writing it down, you won't retain much of your new learning.

1. Define the terms *hormone* and *target organ*.
2. Describe the characteristic chemical group found at the core of each steroid hormone.
3. Identify the major categories of nonsteroid hormones.
4. Identify the sequence of events involved in a second messenger mechanism.
5. What is the function of calmodulin?
6. List the classes of prostaglandins. Identify the functions of three of these classes.

CRITICAL THINKING QUESTIONS



After finishing the Review Questions, write out the answers to these more in-depth questions to help you apply your new knowledge. Go back to sections of the chapter that relate to concepts that you find difficult.

1. Driving a car requires rapid response of selected muscles. The regulation of blood sugar level requires regulating almost every cell in the body. Based on the characteristics of each system, explain why driving would be a nervous system function and blood sugar regulation would be an endocrine function.
2. How would you explain the ways in which one hormone interacts with another and its impact on the cell?
3. Compare and contrast the action mechanisms of steroid and nonsteroid hormones.
4. Why are thyroid hormones exceptions to the usual mode of nonsteroid hormone functioning?
5. What examples can you find that apply the concept of a negative feedback loop to the regulation of hormone secretion?

Endocrine Glands

continued on p. 588

In the previous chapter we outlined the basic mechanisms of endocrine regulation and its partnership with nervous regulation. We learned how hormones released from endocrine glands into the bloodstream can signal target tissues to alter their functions in ways that promote homeostasis. Our study of neuroendocrine regulation of body function continues in this chapter, in which we explore the structure and function of some of the major endocrine glands. By looking at a few of the important glands and their hormones, a clear picture emerges of how endocrine regulation works. As you learn the specific actions of the major hormones, think of them as part of an overall system of regulating the body's functions. In later chapters, we will encounter many of these hormones again as we explore the various body functions they regulate.

PITUITARY GLAND

Structure of the Pituitary Gland

The **pituitary gland** (formerly called the *hypophysis*) is a small but mighty structure. It measures only 1.2 to 1.5 cm (about ½ inch) across. By weight, it is even less impressive—only about 0.5 gram (⅑₀ ounce)! And yet so crucial are the functions of the anterior lobe of the pituitary gland that, in past centuries, it was referred to as the "master gland."

The pituitary gland has a well-protected location within the skull on the ventral surface of the brain (Figure 19-1). It lies in the *pituitary fossa* of the sella turcica and is covered by a portion of the dura mater called the *pituitary diaphragm*. The gland has a stemlike stalk, the **infundibulum,** which connects it to the hypothalamus of the brain.

Although the pituitary looks like one gland, it actually consists of two separate glands—the **adenohypophysis,** or anterior pituitary gland, and the **neurohypophysis,** or posterior pituitary gland. In the embryo, the adenohypophysis develops from an upward projection of the pharynx and is composed of regular endocrine tissue. The neurohypophysis, on the other hand, develops from a downward projection of the brain and is composed of neurosecretory tissue. These histological differences are incorporated into their names—*adeno* means "gland," and *neuro* means "nervous." As you may suspect, the hormones secreted by the adenohypophysis serve very different functions from those released by the neurohypophysis.

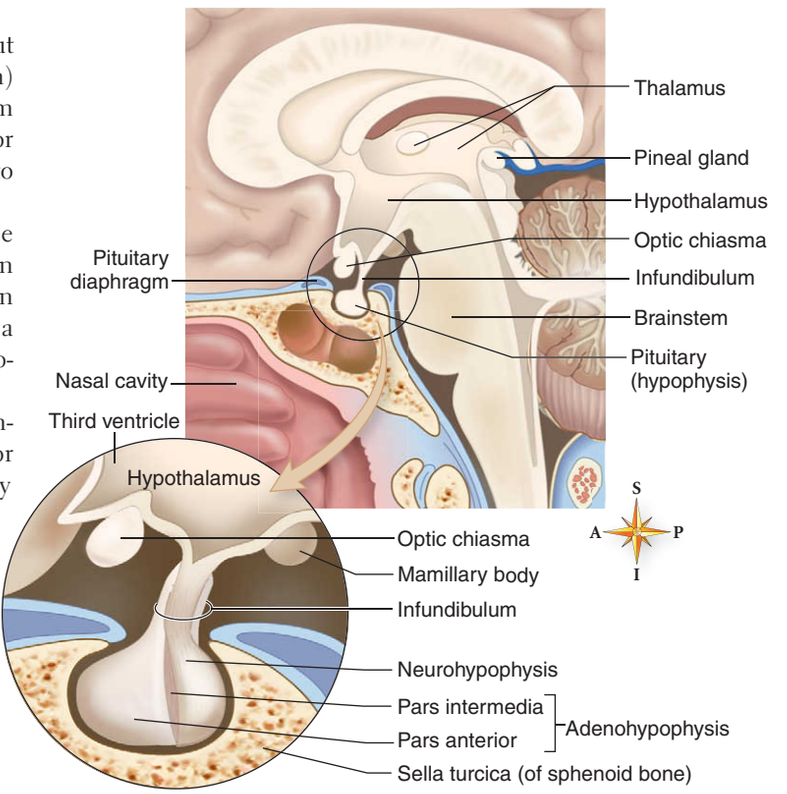

FIGURE 19-1

Location and structure of the pituitary gland. The pituitary gland is located within the sella turcica of the skull's sphenoid bone and is connected to the hypothalamus by a stalklike infundibulum. The infundibulum passes through a gap in the portion of the dura mater that covers the pituitary (the pituitary diaphragm). The inset shows that the pituitary is divided into an anterior portion, the adenohypophysis, and a posterior portion, the neurohypophysis. The adenohypophysis is further subdivided into the pars anterior and pars intermedia. The pars intermedia is almost absent in the adult pituitary.

Adenohypophysis (Anterior Lobe of Pituitary)

The **adenohypophysis,** the anterior portion of the pituitary gland, is divided into two parts—the *pars anterior* and the *pars intermedia*. The pars anterior forms the major portion of the adenohypophysis and is divided from the tiny pars intermedia by a narrow cleft and some connective tissue (see Figure 19-1).

The tissue of the adenohypophysis is composed of irregular clumps of secretory cells supported by fine connective tissue fibers and surrounded by a rich vascular network.

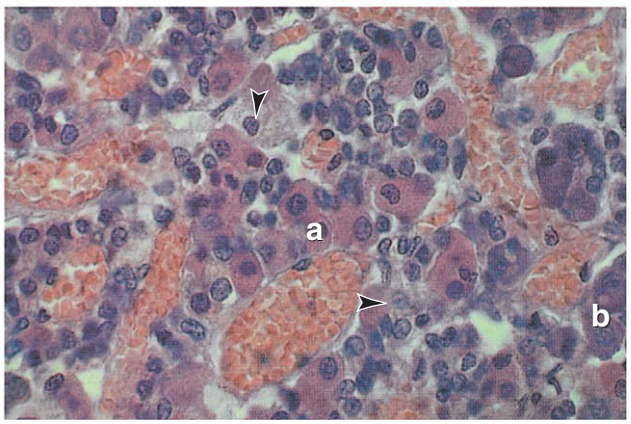

FIGURE 19-2

Histology of the adenohypophysis. In this light micrograph, nonstaining chromophobes are indicated by arrowheads. Examples of hormone-secreting cells are labeled *a* (acidophil) and *b* (basophil).

Traditionally, histologists have identified three types of cells according to their affinity for certain types of stains: *chromophobes* (literally "afraid of color"), *acidophils* ("acid [stain] lovers"), and *basophils* ("base [stain] lovers"). All three types are visible in the photomicrograph shown in Figure 19-2. Currently, however, cells of the adenohypophysis are more often classified by their secretions into five types:

1. **Somatotrophs**—secrete growth hormone (GH)
2. **Corticotrophs**—secrete adrenocorticotropic hormone (ACTH)
3. **Thyrotrophs**—secrete thyroid-stimulating hormone (TSH)
4. **Lactotrophs**—secrete prolactin (PRL)
5. **Gonadotrophs**—secrete luteinizing hormone (LH) and follicle-stimulating hormone (FSH)

Figure 19-3 summarizes the hormones of the adenohypophysis and shows the primary locations of their target cells.

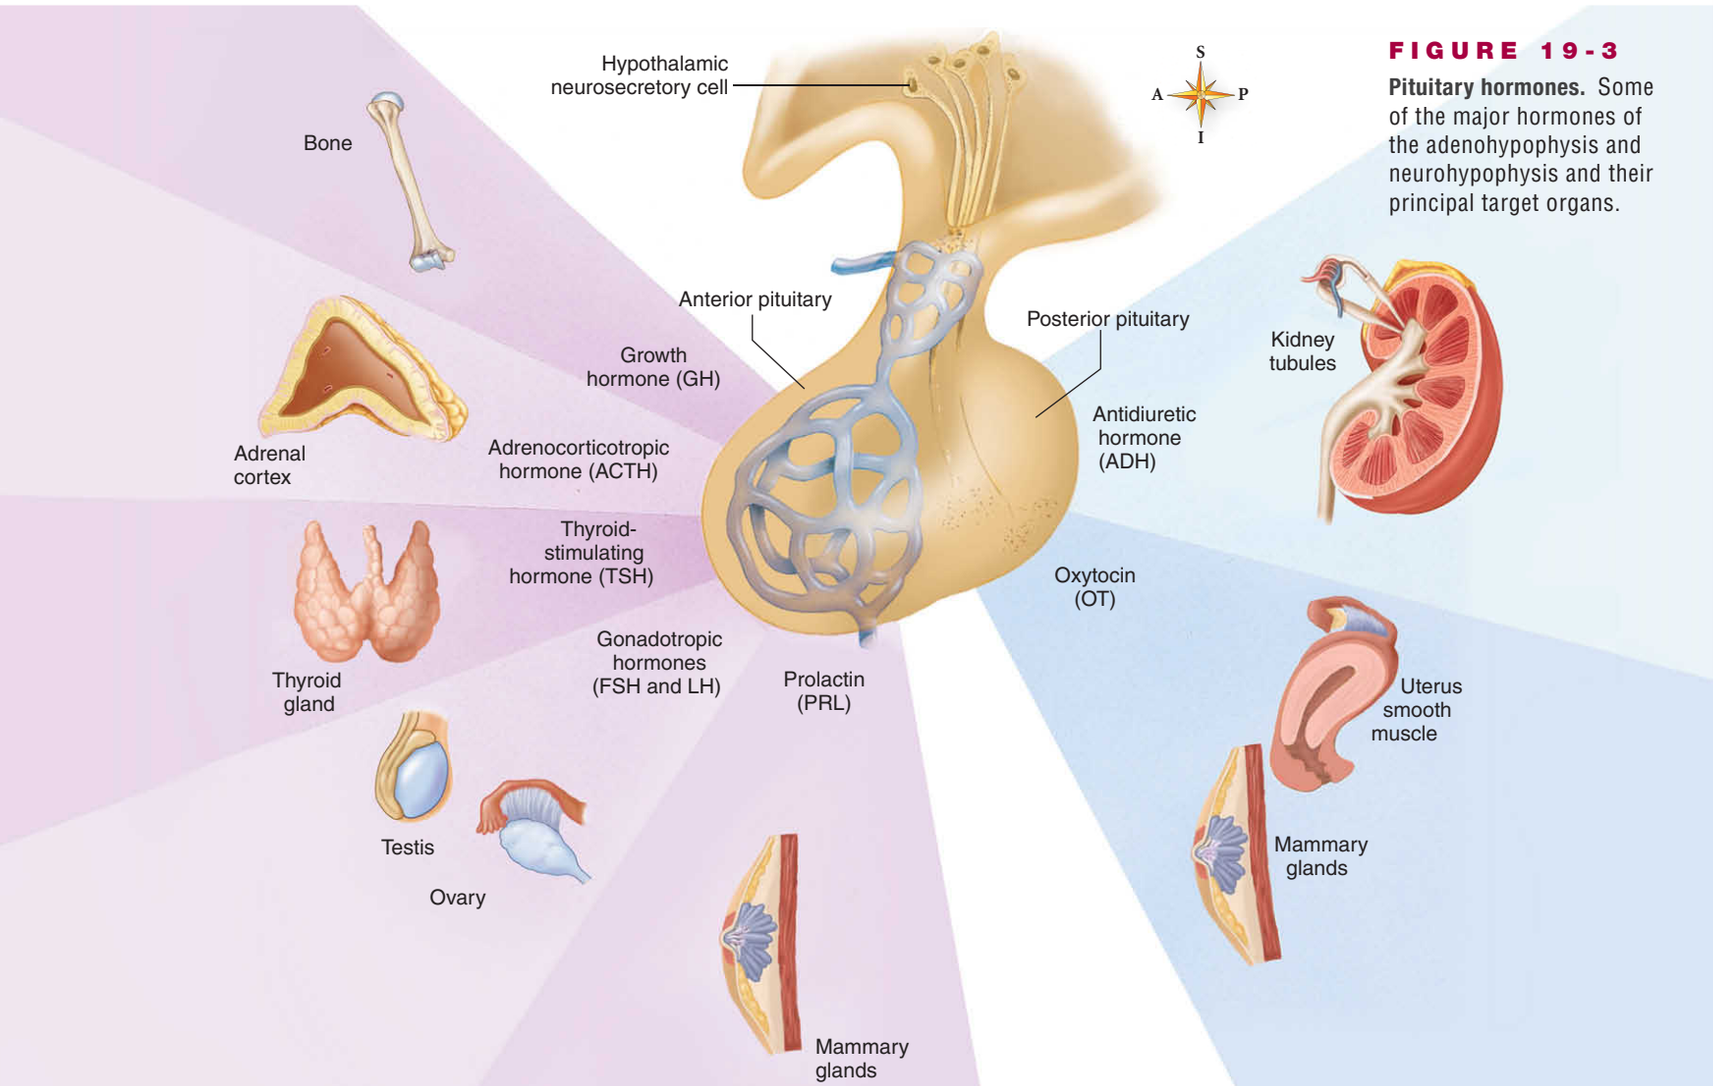

FIGURE 19-3

Pituitary hormones. Some of the major hormones of the adenohypophysis and neurohypophysis and their principal target organs.

GROWTH HORMONE

Growth hormone (GH), or **somatotropin (STH),** promotes bodily growth indirectly by stimulating the liver and other tissues to produce another hormone called *insulin-like growth factor 1 (IGF-1),* which, in turn, produces most of the effects attributed to GH.

One of the functions of the GH, by way of IGF-1, is to accelerate amino acid transport into cells. Rapid entrance of amino acids from the blood into the cells allows protein anabolism within the cells to accelerate. Increased protein anabolism allows an increased rate of growth. GH promotes the growth of bone, muscle, and other tissues (Box 19-1).

Box 19-1 | HEALTH matters

Growth Hormone Abnormalities

Hypersecretion of growth hormone (GH) during the growth years (before ossification of the epiphyseal plates) causes an abnormally rapid rate of skeletal growth. This condition is known as **gigantism** (see figure, *left*). Hypersecretion after skeletal fusion has occurred can result in **acromegaly,** a condition in which cartilage still left in the skeleton continues to form new bone. This abnormal growth may result in a distorted appearance because of the enlargement of the hands, feet, face, jaw (causing separation of the teeth), and other body parts. Overlying soft tissue may also be affected—for instance, the skin often thickens and the pores become more pronounced.

Hyposecretion of GH during growth years may result in stunted body growth, known as **pituitary dwarfism** (see figure, *right*). Formerly, patients were treated only with GH extracted from human tissues. Since 1987, the availability of human GH produced by genetically engineered bacteria has made the treatment obtainable for many more patients. However, continuing concerns have been raised about possible adverse side effects associated with human GH from bacterial sources.

Growth hormone abnormalities. The man on the left exhibits gigantism, and the man on the right exhibits pituitary dwarfism. The two men in the middle are of average height.

In addition to stimulating protein anabolism, GH also stimulates fat metabolism. GH accelerates mobilization of lipids from storage in adipose cells and also speeds up the catabolism of those lipids after they have entered another cell. In this way, GH tends to shift a cell's use of nutrients away from carbohydrate (glucose) catabolism and toward lipid catabolism as an energy source. Because less glucose is then removed from the blood by cells, the blood glucose levels tend to rise. Thus GH is said to have a *hyperglycemic effect.* Insulin (from the pancreas) has the opposite effect—it promotes glucose entry into cells, producing a *hypoglycemic effect.* Therefore GH and insulin function as antagonists. The balance between these two hormones is vital to maintaining a homeostasis of blood glucose levels.

GH affects metabolism in these ways:

- Promotes protein anabolism (growth, tissue repair)
- Promotes lipid mobilization and catabolism
- Indirectly inhibits glucose metabolism
- Indirectly increases blood glucose levels

PROLACTIN

Prolactin (PRL), produced by acidophils in the pars anterior, is also called *lactogenic hormone.* Both names of this hormone suggest its function in "generating" or initiating milk secretion (lactation). During pregnancy, a high level of PRL promotes the development of the breasts in anticipation of milk secretion. At the birth of an infant, PRL in the mother stimulates the mammary glands to begin milk secretion.

Hypersecretion of PRL may cause lactation in nonnursing women, disruption of the menstrual cycle, and impotence in men. **Hyposecretion** of PRL is usually insignificant except in women who want to nurse their children. Milk production cannot be initiated or maintained without PRL.

TROPIC HORMONES

Tropic hormones are hormones that have a stimulating effect on other endocrine glands. These hormones stimulate the development of their target glands and tend to stimulate synthesis and secretion of the target hormone (Box 19-2). Four principal tropic

Box 19-2 | HEALTH matters

Tropic Hormone Abnormalities

Hypersecretion of the tropic hormones may result from a pituitary tumor. The tropic hormones, produced at higher than normal levels, cause hypersecretion in their target glands. This may result in various effects throughout the body. Early hypersecretion of gonadotropins may lead to an abnormally early onset of puberty.

Hyposecretion of tropic hormones often causes their target glands to secrete less than a normal amount of their hormones. This may disrupt reproduction, kidney function, overall metabolism, and other processes.

hormones are produced and secreted by the basophils of the pars anterior:

1. **Thyroid-stimulating hormone (TSH),** or *thyrotropin*, promotes and maintains the growth and development of its target gland—the thyroid. TSH also causes the thyroid gland to secrete thyroid hormone.
2. **Adrenocorticotropic hormone (ACTH),** or *adrenocorticotropin*, promotes and maintains normal growth and development of the cortex of the adrenal gland. ACTH also stimulates the adrenal cortex to synthesize and secrete some of its hormones.
3. **Follicle-stimulating hormone (FSH)** stimulates structures within the ovaries, primary follicles, to grow toward maturity. Each follicle contains a developing egg cell (ovum), which is released from the ovary during ovulation. FSH also stimulates the follicle cells to synthesize and secrete estrogens (female sex hormones). In the male, FSH stimulates the development of the seminiferous tubules of the testes and maintains spermatogenesis (sperm production) by them.
4. **Luteinizing hormone (LH)** stimulates the formation and activity of the corpus luteum of the ovary. The corpus luteum (meaning "yellow body") is the tissue left behind when a follicle ruptures to release its egg during ovulation. The corpus luteum secretes progesterone and estrogens when stimulated by LH. LH also supports FSH in stimulating the maturation of follicles. In males, LH stimulates interstitial cells in the testes to develop and then synthesize and secrete testosterone (the male sex hormone).

FSH and LH are called **gonadotropins** because they stimulate the growth and maintenance of the gonads (ovaries and testes). During childhood the adenohypophysis secretes insignificant amounts of the gonadotropins. A few years before puberty, gonadotropin secretion is gradually increased. Then, suddenly, their secretion spurts, and the gonads are stimulated to develop and begin their normal functions.

In addition to those listed, the adenohypophysis produces many other hormones in small amounts. Many of these are also produced elsewhere in the body. For example, *α-MSH (alpha melanocyte-stimulating hormone)* and other melanocortins discussed in Chapter 7 (see p. 179) are produced in the skin and other tissues, with a relatively insignificant amount also produced in the adenohypophysis.

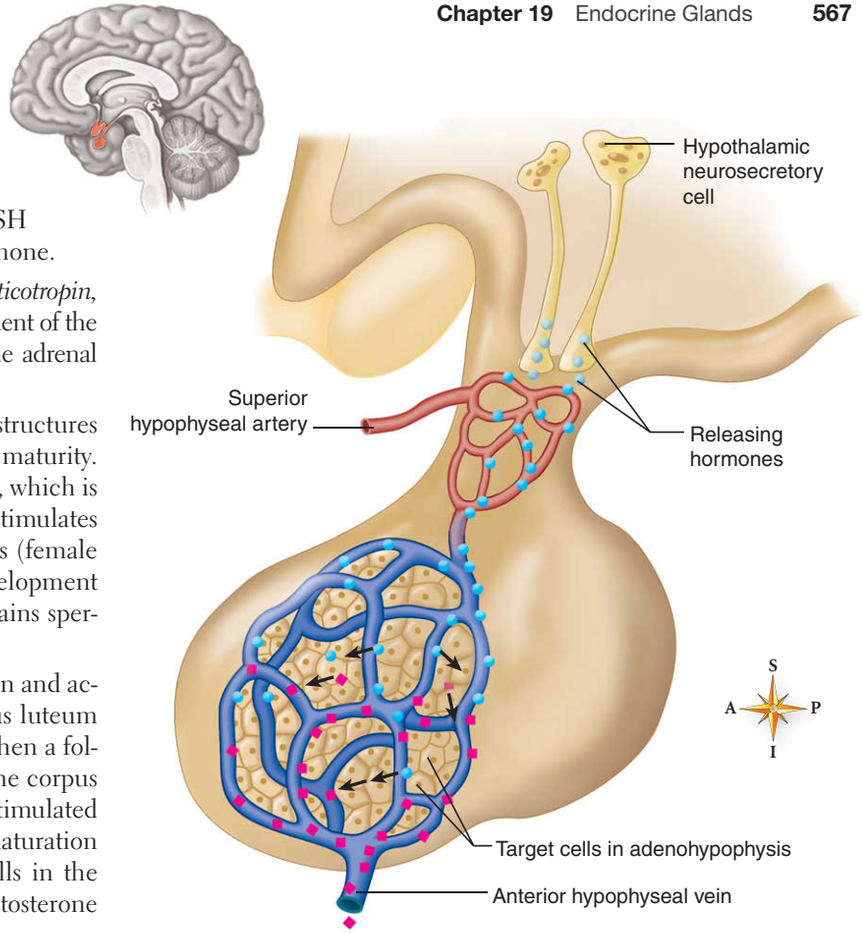

FIGURE 19-4

Hypophyseal portal system. Neurons in the hypothalamus secrete releasing hormones into veins that carry the releasing hormones directly to the vessels of the adenohypophysis, thus bypassing the normal circulatory route.

CONTROL OF SECRETION IN THE ADENOHYPOPHYSIS

The cell bodies of neurons in certain parts of the hypothalamus synthesize chemicals that their axons then secrete into the blood. These chemicals, generally called **releasing hormones,** travel through a complex of small blood vessels called the **hypophyseal portal system** (Figure 19-4). A *portal system* is an arrangement of blood vessels in which blood exiting one tissue is immediately carried to a second tissue before being returned to the heart and lungs for oxygenation and redistribution. The hypophyseal portal system carries blood from the hypothalamus directly to the adenohypophysis, where the target cells of the releasing hormones are located. The advantage of a portal system in the hypophysis is that a small amount of hormone can be delivered directly to its target tissue without the great dilution that would occur in the general circulation. The releasing hormones that arrive in the adenohypophysis by means of this portal system influence the secretion of hormones by acidophils and basophils. In this manner, the hypothalamus directly regulates the secretion of the adenohypophysis. You can see that the supposed "master gland" really has a master of its own—the hypothalamus.

The following is a list of some of the important hormones secreted by the hypothalamus into the hypophyseal portal system:

- Growth hormone–releasing hormone (GHRH)
- Growth hormone–inhibiting hormone (GHIH) (also called somatostatin [SS])
- Corticotropin-releasing hormone (CRH)
- Thyrotropin-releasing hormone (TRH)
- Gonadotropin-releasing hormone (GnRH)
- Prolactin-releasing hormone (PRH)
- Prolactin-inhibiting hormone (PIH)

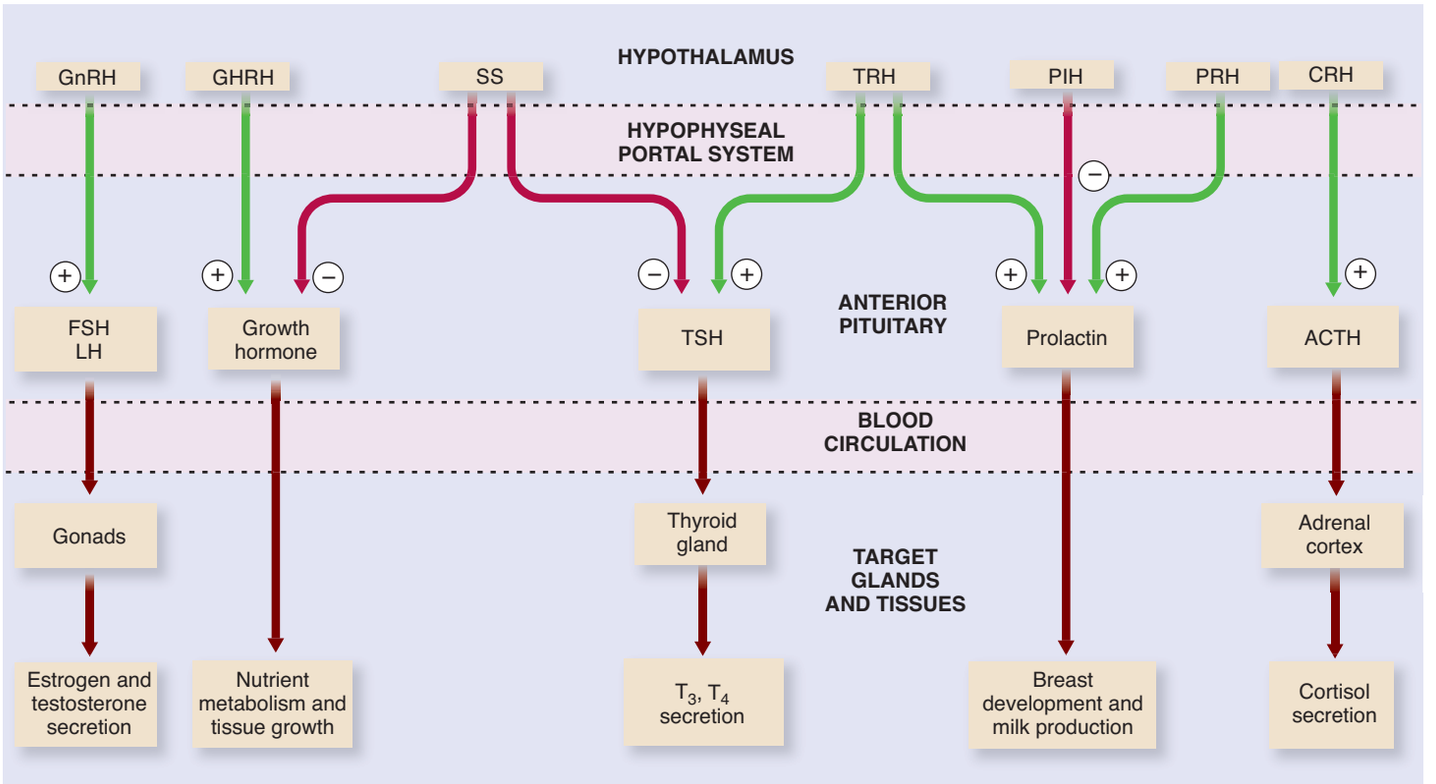

FIGURE 19-5

Action of hypothalamic hormones. Hypothalamic hormones have releasing or inhibiting effects on the various cells of the anterior pituitary, thus regulating anterior pituitary secretion—and thus ultimately regulating the effects of anterior pituitary hormones throughout the body. *GnRH,* Gonadotropin-releasing hormone; *GHRH,* growth hormone–releasing hormone; *SS,* somatostatin; *TRH,* thyroid-releasing hormone; *PIH,* prolactin-inhibiting hormone; *PRH,* prolactin-releasing hormone; *CRH,* corticotropin-releasing hormone; *FSH,* follicle-stimulating hormone; *LH,* luteinizing hormone; *TSH,* thyroid-stimulating hormone; *ACTH,* adrenocorticotropic hormone; T_3, triiodothyronine; T_4, thyroxine.

Figure 19-5 and Table 19-1 list functions of each releasing hormone. Before consulting the figure or table, try to deduce their functions from their names.

Through negative feedback mechanisms, the hypothalamus adjusts the secretions of the adenohypophysis, and the adenohypophysis adjusts the secretions of its target glands, which in turn adjust the activity of their target tissues (Box 19-3). For example, Figure 19-6 shows the negative feedback control of the secretion of TSH and thyroid hormone (T_3 and T_4).

Hormone secretion can occur in pulses or peaks, as we see in a graph of minute by minute variations in GH secretion (Figure 19-7). The peaks result from many somatotroph cells in the pituitary collectively increasing their rate of secretion of GH. Such increases result from pulses in GHRH secretion by the

TABLE 19-1 Hormones of the Hypothalamus

HORMONE	SOURCE	TARGET	PRINCIPAL ACTION
Growth hormone–releasing hormone (GHRH)	Hypothalamus	Adenohypophysis (somatotrophs)	Stimulates secretion (release) of growth hormone
Growth hormone–inhibiting hormone (GHIH), or somatostatin	Hypothalamus	Adenohypophysis (somatotrophs)	Inhibits secretion of growth hormone
Corticotropin-releasing hormone (CRH)	Hypothalamus	Adenohypophysis (corticotrophs)	Stimulates release of adrenocorticotropic hormone (ACTH)
Thyrotropin-releasing hormone (TRH)	Hypothalamus	Adenohypophysis (thyrotrophs)	Stimulates release of thyroid-stimulating hormone (TSH)
Gonadotropin-releasing hormone (GnRH)	Hypothalamus	Adenohypophysis (gonadotrophs)	Stimulates release of gonadotropins (FSH and LH)
Prolactin-releasing hormone (PRH)	Hypothalamus	Adenohypophysis (corticotrophs)	Stimulates secretion of prolactin
Prolactin-inhibiting hormones (PIH)	Hypothalamus	Adenohypophysis (corticotrophs)	Inhibits secretion of prolactin

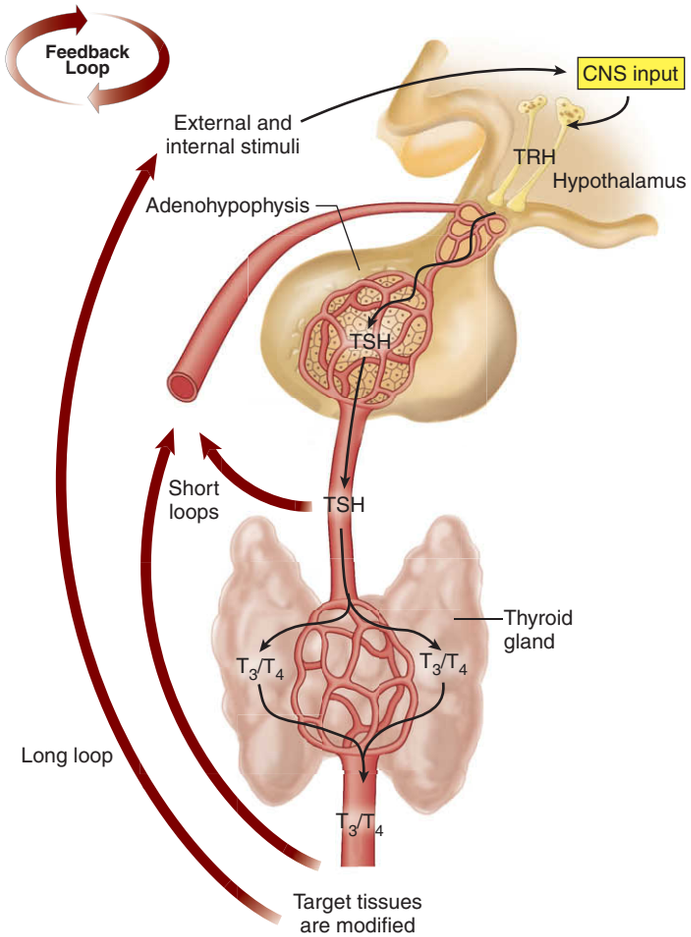

FIGURE 19-6

Negative feedback control by the hypothalamus. In this example, the secretion of thyroid hormone (T_3 and T_4) is regulated by a number of negative feedback loops. A long negative feedback loop *(long red arrow)* allows the central nervous system (CNS) to influence hypothalamic secretion of thyrotropin-releasing hormone (TRH) by nervous feedback from the targets of T_3/T_4 (and from other nerve inputs). The secretion of TRH by the hypothalamus and thyroid-stimulating hormone (TSH) by the adenohypophysis is also influenced by shorter feedback loops *(shorter red arrows),* allowing great precision in the control of this system.

hypothalamus (see Figure 19-5), which are especially large during sleep. Exercise, stress, and high-protein meals can cause an increase in the frequency of these peaks.

Before leaving the subject of control of pituitary secretion, we call your attention to another concept involving the hypothalamus. It functions as an important part of the body's complex machinery for responding to stress situations. For example, in severe pain or intense emotions, the cerebral cortex—especially the limbic area—sends impulses to the hypothalamus. The impulses stimulate the hypothalamus to secrete its releasing hormones into the hypophyseal portal veins. Circulating quickly to the adenohypophysis, they stimulate it to secrete more of its hormones. These in turn stimulate increased activity by the pituitary's target structures. In essence, what the hypothalamus does through its releasing of hormones is to translate nerve impulses into hormone secretion by endocrine glands. Thus the hypothalamus links the nervous system

Box 19-3 | HEALTH matters

Clinical Evidence of Feedback Control

Clinical facts provide interesting evidence about feedback control of hormone secretion by the anterior pituitary gland and its target glands. For instance, patients who have the pituitary gland removed **(hypophysectomy)** surgically or by radiation must be given hormone replacement therapy for the rest of their lives. If not, they will develop thyroid, adrenal cortical, and gonadotropic deficiencies—deficiencies of the anterior pituitary's target gland hormones. Another well-known clinical fact is that estrogen deficiency develops in women between 40 and 50 years of age. By then the ovaries seem to have tired of producing hormones and ovulating each month. They no longer respond to FSH stimulation, so estrogen deficiency develops, brings about menopause, and persists after menopause. What therefore would you deduce is true of the blood concentration of FSH after menopause? Apply the principle that a low concentration of a target gland hormone stimulates tropic hormone secretion by the anterior pituitary gland and you will understand that FSH levels rise, indeed, after menopause.

to the endocrine system. It integrates the activities of these two great integrating systems—particularly, it seems, in times of stress. When survival is threatened, the hypothalamus can take over the adenohypophysis and thus gain control of literally every cell in the body. We discuss stress in more detail in Chapter 25.

The mind-body link provided by the hypothalamus has tremendous implications. It means that the cerebrum can do more than just receive sensory impulses and send out impulses to muscles and glands. It means that our thoughts and emotions—our minds—can,

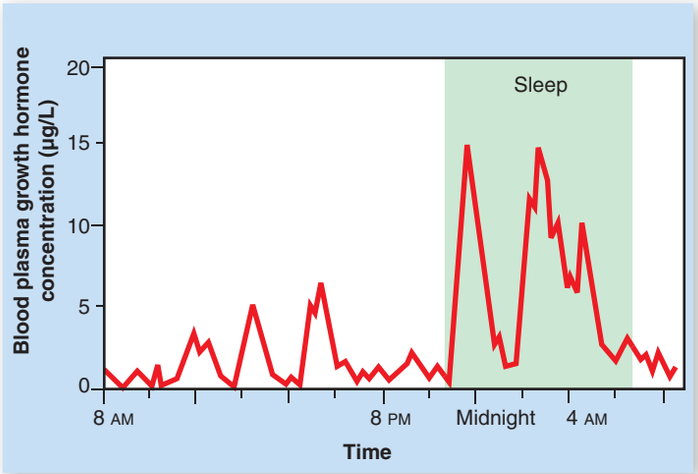

FIGURE 19-7

Secretion of growth hormone (GH). The amount of GH in the blood plasma of a 23-year-old woman was plotted on a graph every 5 minutes over the course of 24 hours. Note that GH fluctuates chaotically minute by minute, with occasional peaks that get larger after she falls asleep. The surges of GH result in part from pulses of GHRH (GH-releasing hormone) from the hypothalamus.

by way of the hypothalamus, influence the functions of all of our billions of cells. In short, the brain has two-way contact with every tissue of the body. Thus the state of the body can influence mental processes, and the state of the mind can affect the functioning of the body. Therefore both psychosomatic (mind influencing the body) and somatopsychic (body influencing the mind) relationships exist between human body systems and the brain.

| QUICK CHECK |

1. What are the two main divisions of the pituitary called? How are they distinguished by location and histology?
2. Name three hormones produced by the adenohypophysis, and give their main functions.
3. What is a tropic hormone? A releasing hormone?

Neurohypophysis (Posterior Lobe of Pituitary)

The **neurohypophysis** serves as a storage and release site for two hormones: **antidiuretic hormone (ADH)** and **oxytocin (OT).** The cells of the neurohypophysis do not themselves make these hormones. Instead, neurons whose bodies are in either the *supra-optic* or the *paraventricular nuclei* of the hypothalamus synthesize them (Figure 19-8).

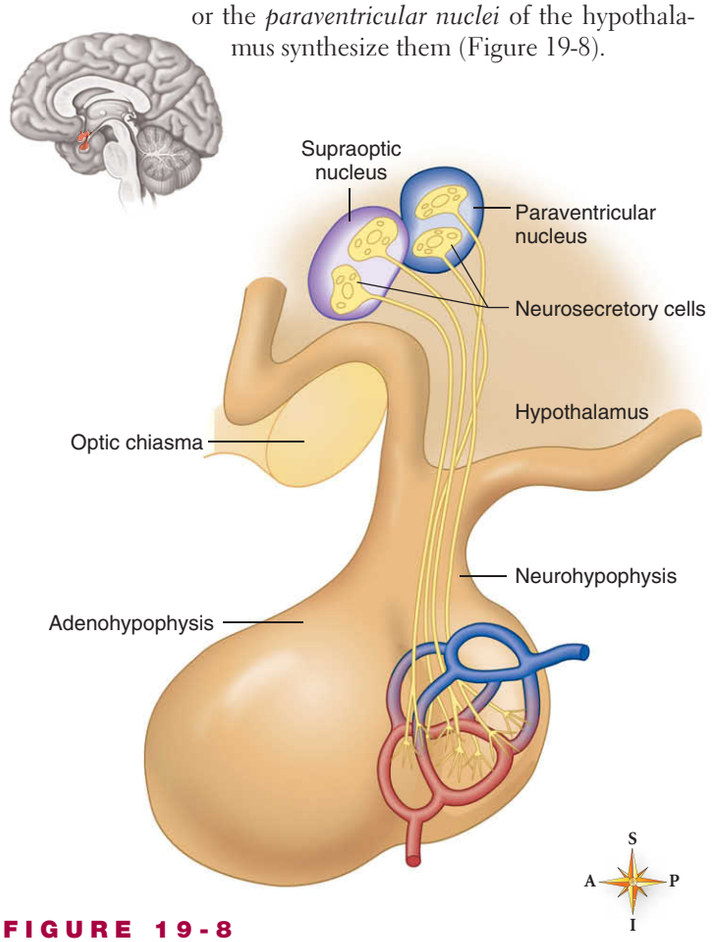

FIGURE 19-8

Relationship of the hypothalamus and neurohypophysis. Neurosecretory cells have their cell bodies in the hypothalamus and their axon terminals in the neurohypophysis. Thus hormones synthesized in the hypothalamus are actually released from the neurohypophysis.

From the cell bodies of these neurons in the hypothalamus, the hormones pass down along axons (in the hypothalamohypophyseal tract) into the neurohypophysis. Instead of the chemical-releasing factors that triggered secretion of hormones from the adenohypophysis, release of ADH and OT into the blood is controlled by nervous stimulation.

ANTIDIURETIC HORMONE

The term *antidiuresis* literally means "opposing the production of a large urine volume." And this is exactly what ADH does—it prevents the formation of a large volume of urine. In preventing large losses of fluid through the excretion of dilute urine, ADH helps the body conserve water. In other words, ADH maintains water balance in the body. When the body dehydrates, the increased osmotic pressure of the blood is detected by special *osmoreceptors* near the supraoptic nucleus. This triggers the release of ADH from the neurohypophysis. ADH causes water to be reabsorbed from the tubules of the kidney and returned to the blood (see Chapter 31). This increases the water content of the blood, restoring the osmotic pressure to its normal lower level.

ADH has many other effects in the body as well. One of the most well known is that ADH stimulates contraction of muscles in the walls of small arteries (blood vessels that supply tissues), thus increasing blood pressure. For that reason, ADH is also known as *vasopressin* (literally, "vessel pressure substance"). Human vasopressin contains the amino acid arginine, unlike the vasopressin of some other organisms, so it is called **arginine vasopressin (AVP).**

Box 19-4 discusses some abnormalities associated with ADH.

OXYTOCIN

Oxytocin has at least two primary actions: it stimulates rhythmic contraction of smooth muscles in the uterus and it causes milk ejection from the breasts of lactating women.

Under the influence of OT, muscle-like *myoepithelial* cells surrounding the milk-storing *alveoli* of the mammary glands squeeze milk into the ducts of the breast. Figure 35-17 on p. 1083 clearly shows the structures involved. This action is very important because milk cannot be removed by suckling unless it has first been ejected into the ducts. Throughout nursing, the mechanical and psychological stimulation of the baby's suckling action triggers the release of more OT. In other words, OT secretion is regulated by a *positive feedback* mechanism: the baby suckles, which increases OT levels, which provides more milk, so the baby continues to suckle, which increases OT levels, and so on.

Box 19-4 | HEALTH matters

Antidiuretic Hormone Abnormalities

Hyposecretion of antidiuretic hormone (ADH) can lead to **diabetes insipidus,** a condition in which the patient produces abnormally large amounts of urine. Drugs such as desmopressin, which mimic ADH, can alleviate this symptom. Studies have shown that ADH may be involved in learning and memory, so investigators are looking into the possibility of administering ADH to reverse the memory loss associated with senility.

OT, together with prolactin, ensures successful nursing. Prolactin prepares the breast for milk production and stimulates cells to produce milk. The milk is not released, however, until OT stimulates its release.

The other major action of OT—its stimulation of uterine contractions—is the source of its name: oxytocin (literally "swift childbirth"). OT stimulates the uterus to strengthen the strong, muscular labor contractions that occur during childbirth. OT secretion is regulated here again by means of a positive feedback mechanism. After they have begun, uterine contractions stimulate stretch receptors in the pelvis, which triggers the release of more OT, which again stretches the pelvic receptors, and so on. Review the diagram in Box 1-3 (p. 23) outlining this positive feedback loop.

The wavelike contractions continue to some degree after childbirth, which helps the uterus expel the placenta and then return to its unstretched shape. Commercial preparations of synthetic OT have been given to stimulate contractions after childbirth to lessen the danger of uterine hemorrhage.

OT rises during sexual arousal in both males and females. The increased OT is related to rhythmic smooth muscle contractions associated with sexual arousal and orgasm.

Interestingly, recent research shows that the smell of OT can increase the feeling of social connection to the person releasing it (perhaps in sweat). This may enhance a strong feeling of trust a newborn has for its mother. The role of oxytocin as a pheromone in social recognition and bonding is still being investigated—possibly leading to a better understanding of *autism* and other disorders that involve disruptions of social bonding.

Important characteristics of the hormones secreted by the pituitary—both the adenohypophysis and the neurohypophysis—are summarized in Table 19-2.

PINEAL GLAND

The **pineal gland,** or *pineal body*, is a tiny (1 cm [about .38 inches]) structure resembling a pine nut (or a large kernel of corn) located on the dorsal aspect of the brain's diencephalon region (see Figure 19-1). It is a member of two body systems because it acts as a part of the nervous system (because it receives and processes nerve stimuli relayed from other parts of the nervous system) and as a part of the endocrine system (because it secretes hormones).

The pineal gland produces small amounts of many different hormones, but the principal hormone is melatonin. As you recall from Chapter 14, melatonin is an altered form of serotonin that acts as a hormone because it is released by neurosecretory cells of the pineal gland into the blood to regulate functions throughout the body. Recall also that melatonin levels rise and fall in a cycle related to the changing levels of sunlight throughout the day—melatonin levels rise when sunlight is absent, triggering sleepiness. Thus the pineal gland and melatonin act as important parts of a person's *biological clock*—the timekeeping mechanism of the body.

Melatonin, whose secretion is inhibited by the presence of sunlight, may also affect a person's mood. This is not surprising, given melatonin's relationship to another mood-altering molecule—serotonin. Serotonin is a precursor of melatonin, making both molecules structurally similar. A mental disorder called *seasonal affective disorder (SAD)*, in which a patient suffers severe depression only in winter (when there are fewer hours of daylight), has been linked to the pineal gland. Patients suffering from this "winter depression" are often advised to expose themselves to special high-intensity lights for several hours each evening during the winter months. Apparently, light stimulates the pineal gland for a longer period, which shifts the phase of melatonin peaks in the bloodstream. For reasons not fully understood, this phase shift often reduces or eliminates

TABLE 19-2 Hormones of the Pituitary Gland

HORMONE	SOURCE	TARGET	PRINCIPAL ACTION
Growth hormone (GH) (somatotropin [STH])	Adenohypophysis (somatotrophs)	General	Promotes growth by stimulating protein anabolism and fat mobilization
Prolactin (PRL) (lactogenic hormone)	Adenohypophysis (lactotrophs)	Mammary glands (alveolar secretory cells)	Promotes milk secretion
Thyroid-stimulating hormone (TSH)*	Adenohypophysis (thyrotrophs)	Thyroid gland	Stimulates development and secretion in the thyroid gland
Adrenocorticotropic hormone (ACTH)*	Adenohypophysis (corticotrophs)	Adrenal cortex	Promotes development and secretion in the adrenal cortex
Follicle-stimulating hormone (FSH)*	Adenohypophysis (gonadotrophs)	Gonads (primary sex organs)	*Female:* promotes development of ovarian follicle; stimulates estrogen secretion *Male:* promotes development of testes; stimulates sperm production
Luteinizing hormone (LH)*	Adenohypophysis (gonadotrophs)	Gonads	*Female:* triggers ovulation; promotes development of corpus luteum *Male:* stimulates production of testosterone
Antidiuretic hormone (ADH), or arginine vasopressin (AVP)	Neurohypophysis	Kidney	Promotes water retention by kidney tubules; raises blood pressure by stimulating muscles in walls of small arteries
Oxytocin (OT)	Neurohypophysis	Uterus and mammary glands	Stimulates uterine contractions; stimulates ejection of milk into ducts of mammary glands; involved in social bonding

*Tropic hormones.

symptoms of depression. Apparently, keeping the body's clock well timed is important for maintaining a healthy mood.

| QUICK CHECK |

4. Where are the hormones of the neurohypophysis manufactured? From which location in the body are they released into the bloodstream?
5. Name the two hormones of the neurohypophysis.
6. How does the pineal gland adjust the body's biological clock?

THYROID GLAND

Structure of the Thyroid Gland

Two large **lateral lobes** and a narrow connecting isthmus make up the **thyroid gland** (Figure 19-9). Often a thin wormlike piece of thyroid tissue, called the *pyramidal lobe*, extends upward from the isthmus. The weight of the gland in the adult is variable, but it is around 30 grams (1 ounce). The thyroid is located in the neck, on the anterior and lateral surfaces of the trachea, just below the larynx.

Thyroid tissue is composed of tiny structural units called **follicles,** the site of thyroid hormone synthesis. Each follicle is a small hollow sphere with a wall of simple cuboidal glandular epithelium (Figure 19-10). The interior is filled with a thick fluid called **thyroid colloid.** The colloid is produced by the cuboidal cells of the follicle wall (**follicular cells**) and contains protein-iodine complexes known as **thyroglobulins**—the precursors of thyroid hormones. Scattered around the outside of the follicles are *parafollicular cells,* which produce a hormone called calcitonin (CT).

Thyroid Hormone

The substance that is often called *thyroid hormone* (TH) is actually two different hormones. The most abundant TH is **tetraiodothyronine (T_4),** or **thyroxine.** The other is called **triiodothyronine (T_3).** One molecule of T_4 contains four iodine atoms, and one molecule of T_3 contains three iodine atoms. After synthesizing a preliminary form of its hormones, the thyroid gland stores considerable amounts of them before secreting them (Figure 19-11). This is unusual because none of the other endocrine glands stores its hormones in another form for later release. T_3 and T_4 form in the colloid of the follicles on globulin molecules, forming thyroglobulin complexes. When they are to be released, T_3 and T_4 detach from the globulin and enter the blood. Once in the bloodstream, however, they attach to plasma proteins, principally a globulin called *thyroid-binding globulin* (TBG) and albumin, and circulate as a hormone-globulin complex. When they near their target cells, T_3 and T_4 detach from the plasma globulin.

Although the thyroid gland releases about 20 times more T_4 than T_3, T_3 is much more potent than T_4 and is considered by physiologists to be the principal thyroid hormone. Why is this? T_4 binds more strongly to plasma globulins than T_3, so T_4 is not removed from the blood by target cells as quickly as T_3. The small amount of T_4 that enters target tissues is usually converted to T_3. Add this to the fact that experiments have shown that T_3 binds more efficiently than T_4 to nuclear receptors in target cells, and the evidence is overwhelming that T_3 is the principal thyroid hormone. Although T_4 may influence target cells to some extent, its major importance is as a precursor to T_3. Such hormone precursors are often called *prohormones.*

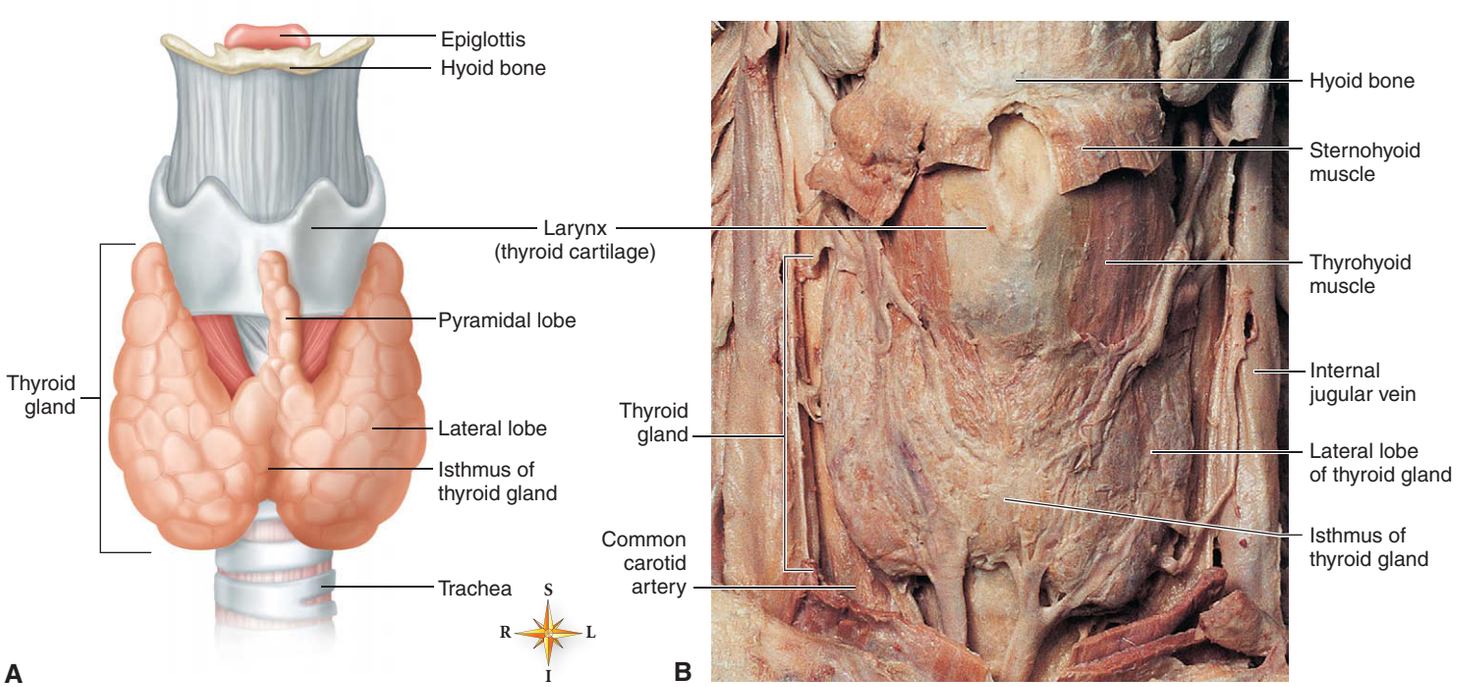

FIGURE 19-9

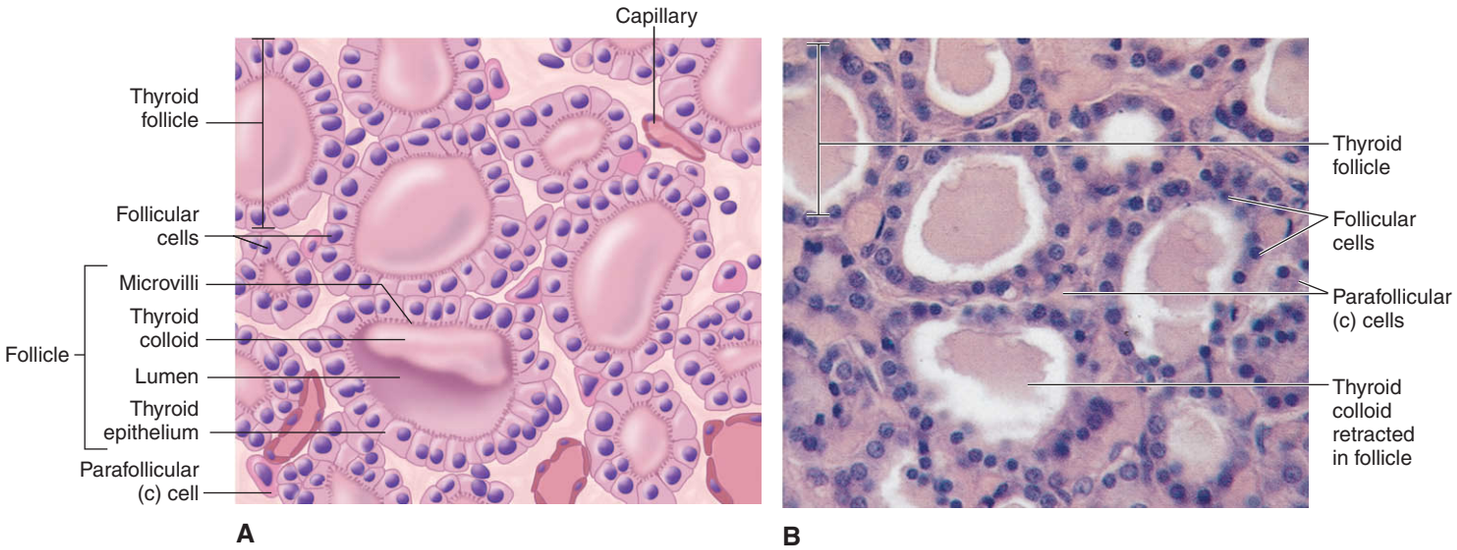
Thyroid gland. A, In this drawing, the relationship of the thyroid to the larynx (voice box) and to the trachea is easily seen. **B,** In this photo of a dissected cadaver, the location of the thyroid relative to the carotid arteries and jugular veins is seen.



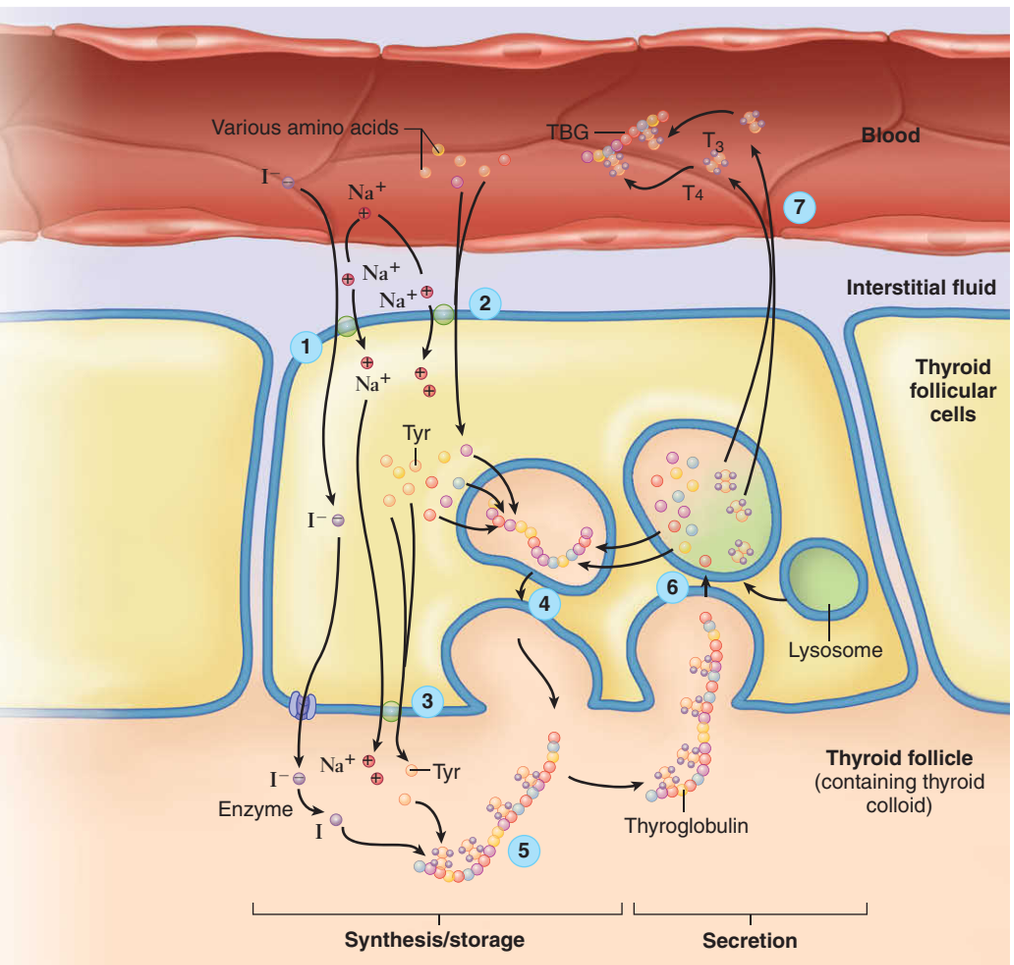


FIGURE 19-10

Thyroid gland tissue. In the drawing **(A)** and the photomicrograph **(B)** note that each of the thyroid follicles is filled with colloid. In the micrograph (×140), the thyroid colloid has separated from the follicular cells during preparation of the specimen.

1. **Step 1.** Iodide ions (I^-) present in the blood enter follicular cells in the thyroid by sodium cotransport (see Box 4-3, p. 96). I^- then moves into the thyroid follicle through an ion channel, after which it is converted to iodine (I).
2. **Step 2.** At the same time, various amino acids (including tyrosine) enter follicular cells by sodium cotransport.
3. **Step 3.** Tyrosine amino acids move into the follicle.
4. **Step 4.** Some of the amino acids form a polypeptide, which is released into the follicle to be used as a structural "backbone" for thyroglobulin.
5. **Step 5.** The iodine (I) and tyrosine (Tyr) molecules are added to the polypeptide backbone to form thyroglobulin.
6. **Step 6.** When needed, thyroglobulin molecules move into follicular cells by endocytosis, where they are digested and thus release "free" T_3 and T_4 molecules.
7. **Step 7.** Thyroid hormones (T_3 and T_4) are secreted into the bloodstream, where they bind to plasma proteins called *thyroid-binding globulins (TBGs)* and travel to other parts of the body.

FIGURE 19-11

Synthesis, storage, and release of thyroid hormone (T_3 and T_4).

UNIT 3

Thyroid hormone helps regulate the metabolic rate of all cells, as well as the processes of cell growth and tissue differentiation (Box 19-5). Because thyroid hormone can potentially interact with any cell in the body, it is said to have a "general" target.

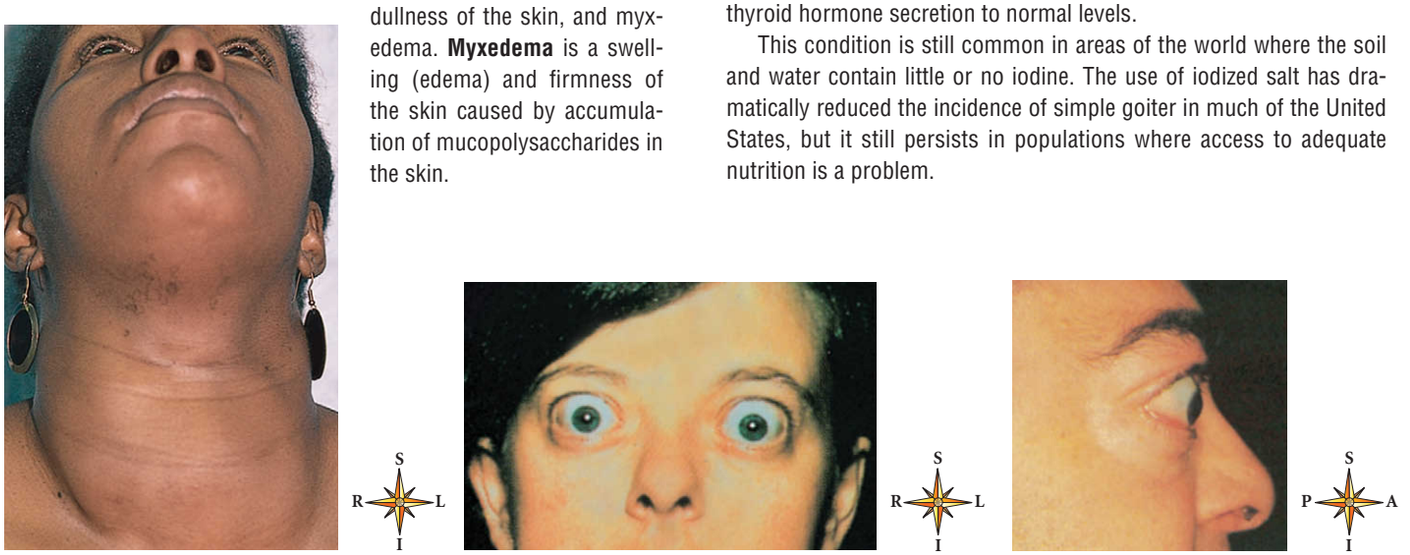
Calcitonin

Besides thyroid hormone (T_3 and T_4), the thyroid gland also produces a hormone called **calcitonin (CT).** You might wonder why some hormones of the thyroid qualify for the name "thyroid hormone," whereas calcitonin does not. The answer lies in the simple fact that for many years, we had no idea that a hormone other than thyroid hormone was produced by the thyroid gland. By the time calcitonin was discovered, and later shown to be made in the thyroid gland, the term *thyroid hormone* was too well established to change it easily.

Produced by *parafollicular cells* (cells associated with the thyroid follicles) called **C cells,** calcitonin influences the processing of calcium by bone cells. Calcitonin apparently controls calcium content of the blood by increasing bone formation by osteoblasts and inhibiting bone breakdown by osteoclasts. This

Box 19-5 | HEALTH matters

Thyroid Hormone Abnormalities



Hypersecretion of thyroid hormone occurs in **Graves disease,** which is thought to be an autoimmune condition. Graves disease patients may suffer from unexplained weight loss, nervousness, increased heart rate, and **exophthalmos** (protrusion of the eyeballs resulting, in part, from edema of tissue at the back of the eye socket; see parts *B* and *C* of the figure).

Hyposecretion of thyroid hormone during growth years may lead to **cretinism,** a condition characterized by a low metabolic rate, retarded growth and sexual development, and possibly mental retardation. People with profound manifestations of this condition are said to have deformed *dwarfism* (as opposed to the proportional dwarfism caused by hyposecretion of growth hormone). Hyposecretion later in life produces a condition characterized by decreased metabolic rate, loss of mental and physical vigor, gain in weight, loss of hair, yellow dullness of the skin, and myxedema. **Myxedema** is a swelling (edema) and firmness of the skin caused by accumulation of mucopolysaccharides in the skin.

In a condition called **simple goiter,** the thyroid enlarges when there is a lack of iodine in the diet (part *A* of figure). This condition is an interesting example of how the feedback control mechanisms illustrated in Figure 19-6 operate.

Because iodine is required for the synthesis of T_3 and T_4, lack of iodine in the diet results in a drop in the production of these hormones. When the reserve (in thyroid colloid) is exhausted, feedback informs the hypothalamus and adenohypophysis of the deficiency. In response, the secretion of thyrotropin-releasing hormone (TRH) and thyroid-stimulating hormone (TSH) increases in an attempt to stimulate the thyroid to produce more thyroid hormone. Because there is no iodine available to do this, the only effect is to increase the size of the thyroid gland. This information feeds back to the hypothalamus and adenohypophysis, and both increase their secretions in response. Thus the thyroid gets larger and larger and larger—all in a futile attempt to increase thyroid hormone secretion to normal levels.

This condition is still common in areas of the world where the soil and water contain little or no iodine. The use of iodized salt has dramatically reduced the incidence of simple goiter in much of the United States, but it still persists in populations where access to adequate nutrition is a problem.

TABLE 19-3 Hormones of the Thyroid and Parathyroid Glands

HORMONE	SOURCE	TARGET	PRINCIPAL ACTION
Triiodothyronine (T_3)	Thyroid gland (follicular cells)	General	Increases rate of metabolism
Tetraiodothyronine (T_4), or thyroxine	Thyroid gland (follicular cells)	General	Increases rate of metabolism (usually converted to T_3 first)
Calcitonin (CT)	Thyroid gland (parafollicular cells)	Bone tissue	Increases calcium storage in bone, lowering blood Ca^{++} levels
Parathyroid hormone (PTH), or parathormone	Parathyroid glands	Bone tissue and kidney	Increases calcium removal from storage in bone and produces the active form of vitamin D in the kidneys, increasing absorption of calcium by intestines and increasing blood Ca^{++} levels

Box 19-6 | FYI

Osteoporosis

Calcitonin contained in nasal spray can be used for the treatment of **osteoporosis.** This treatment is designed especially for patients who are unable to tolerate the more common estrogen replacement therapy. Osteoporosis is a condition that results in brittle and easily fractured bones and is a common disorder affecting millions of postmenopausal women (see Chapter 8, p. 216). The nasal spray delivery mechanism permits easier administration of the drug, called Miacalcin (synthetic calcitonin), to patients suffering from this often crippling disorder. By increasing calcium storage in bone, calcitonin can strengthen weakened bone tissue and help prevent spontaneous fractures, which can occur if the disease is allowed to progress without treatment.

means more calcium is removed from the blood by the osteoblasts, and less calcium is released into the blood by osteoclasts. Calcitonin in humans does not seem to have a great effect—but it may slightly decrease blood calcium levels and promote conservation of hard bone matrix (Box 19-6). Parathyroid hormone, discussed later, is an antagonist to calcitonin, because it has the opposite effect. Together, calcitonin and parathyroid hormone help maintain calcium homeostasis (look ahead to Figure 19-14 on p. 576).

Table 19-3 summarizes hormones of the thyroid gland.

PARATHYROID GLANDS

Structure of the Parathyroid Glands

There are usually four or five **parathyroid glands** embedded in the posterior surface of the thyroid's lateral lobes (Figure 19-12).

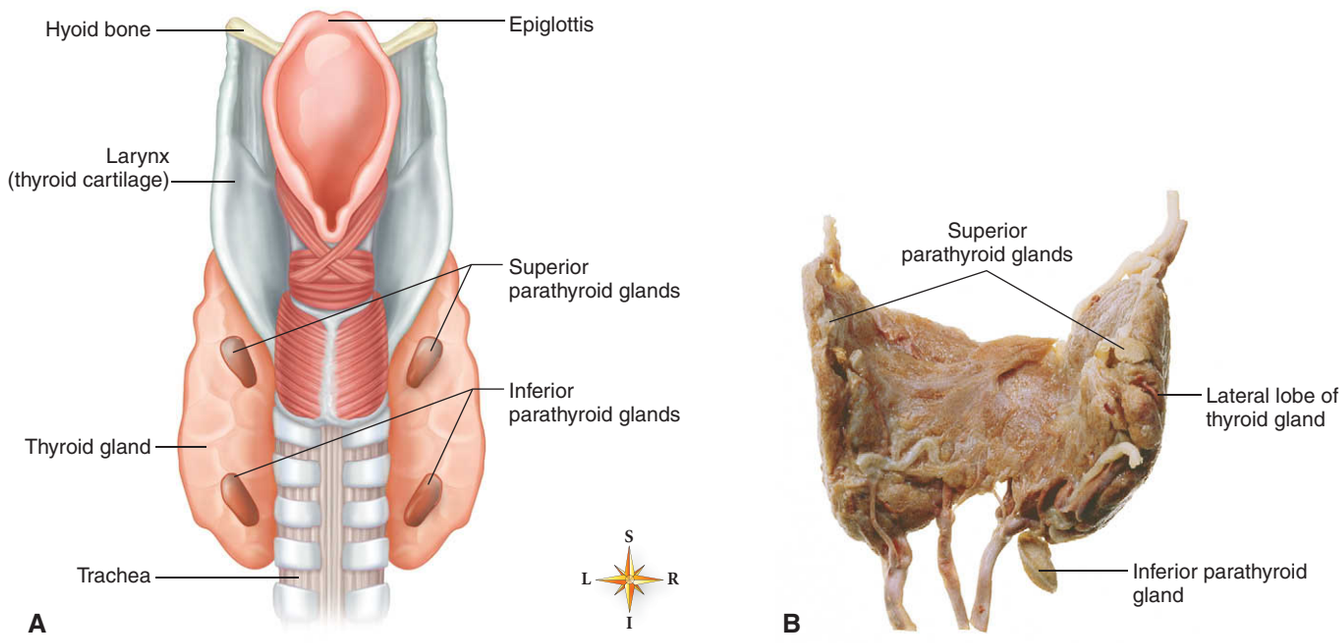

FIGURE 19-12

Parathyroid gland. A, In this drawing from a posterior view, note the relationship of the parathyroid glands to each other, to the thyroid gland, to the larynx (voice box), and to the trachea. **B,** Photo of a cadaver dissection (also from a posterior view) showing several parathyroid glands on the posterior surface of the lateral lobes of an isolated thyroid gland.

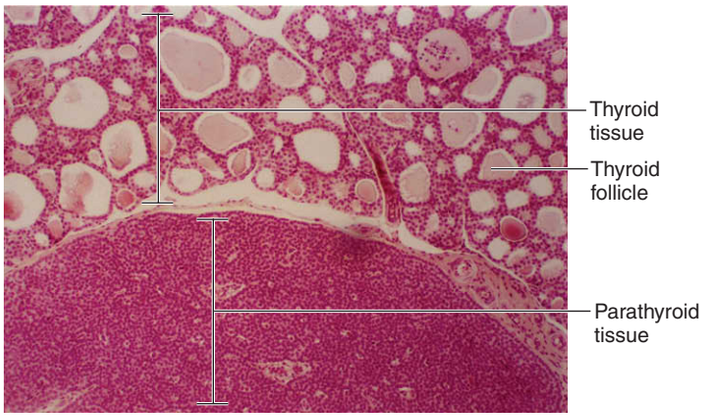

FIGURE 19-13

Parathyroid tissue. This microscopic specimen shows a portion of a parathyroid gland bordered by the surrounding thyroid tissue.

They appear as tiny rounded bodies within thyroid tissue formed by compact, irregular rows of cells (Figure 19-13).

Parathyroid Hormone

The parathyroid glands secrete **parathyroid hormone (PTH),** or *parathormone* (see Table 19-3). PTH is the main hormone the body uses to maintain calcium homeostasis. PTH acts on bone and kidney cells by increasing the release of calcium into the blood. The bone cells are especially affected, causing less new bone to be formed and more old bone to be dissolved, yielding calcium and phosphate. These minerals are then free to move into the blood, elevating blood levels of calcium and phosphate. In the kidney, however, only calcium is reabsorbed from urine into the blood. Under the influence of PTH, phosphate is secreted by kidney cells *out* of the blood and into the urine to be excreted. PTH also increases the body's absorption of calcium from food by activating **vitamin D** *(cholecalciferol)* in the kidney, which then permits Ca^{++} to be transported through intestinal cells and into the blood.

The maintenance of calcium homeostasis, achieved through the interaction of PTH and calcitonin, is very important for healthy survival (Figure 19-14). You learned in Chapter 8 that adequate calcium in the blood is needed to build and maintain a healthy skeleton. Normal neuromuscular excitability, blood clotting, cell membrane permeability, and normal functioning of certain enzymes all depend on the maintenance of normal levels of calcium in the blood. For example, hyposecretion of PTH can lead to hypocalcemia (Box 19-7). Hypocalcemia increases neuromuscular irritability—sometimes so much that it produces muscle spasms and convulsions. Conversely, high blood calcium levels decrease the irritability of muscle and nerve tissue so that constipation, lethargy, and even coma can result.

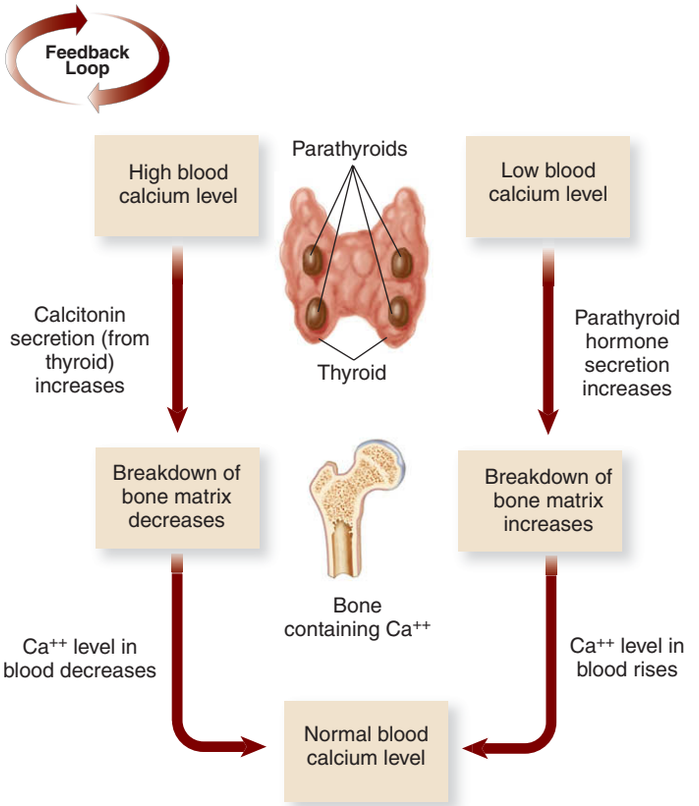

FIGURE 19-14

Regulation of blood calcium levels. Calcitonin and parathyroid hormones have antagonistic (opposite) effects on calcium concentration in the blood. (Also see Figure 18-11.)

| QUICK CHECK |

7. Where is the thyroid located? What does it look like?
8. Thyroid hormone is really two distinct compounds—what are they? Which of the two is considered more physiologically active?
9. How do calcitonin and parathyroid hormone act together to regulate homeostasis of blood calcium concentration?

Box 19-7 | HEALTH matters

Parathyroid Treatments

In cases of hyperparathyroidism, elevated parathyroid hormone (PTH) levels cause increases in blood calcium levels and possible development of osteoporosis and kidney stones. Treatment often involves surgical removal of one or more of the parathyroid glands.

However, knowing just how much parathyroid tissue to remove is a problem for the surgeon. If too much tissue is removed, the resulting drop in PTH below normal limits can result in **hypocalcemia** that requires a lifetime of *PTH replacement therapy.*

A special deep freezing technique permits **cryopreservation,** or frozen storage, of the removed parathyroid tissue for up to 1 year. If too much tissue was removed at the time of surgery, a "banked" portion can be reimplanted (generally below the skin in the forearm) and will function to restore normal blood PTH levels.

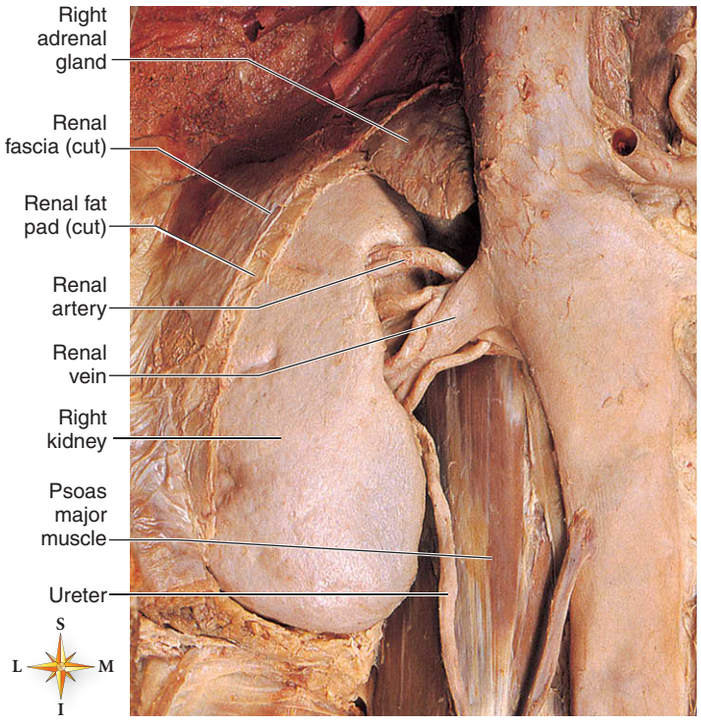

FIGURE 19-15

Location of the adrenal gland. Photograph of a cadaver dissection showing the location of the adrenal gland just superior to the kidney. Note that the adrenal glands are covered by the renal fascia but not the renal fat pad, both of which cover the kidney.

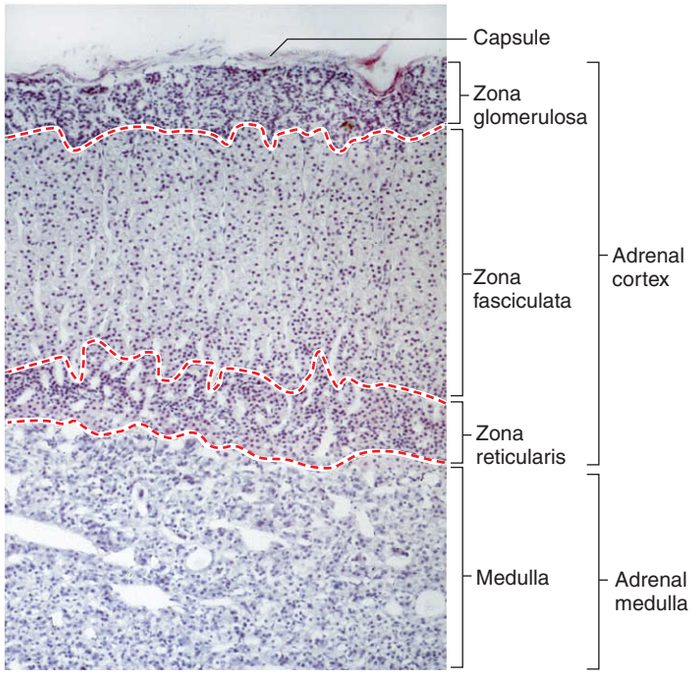

FIGURE 19-17

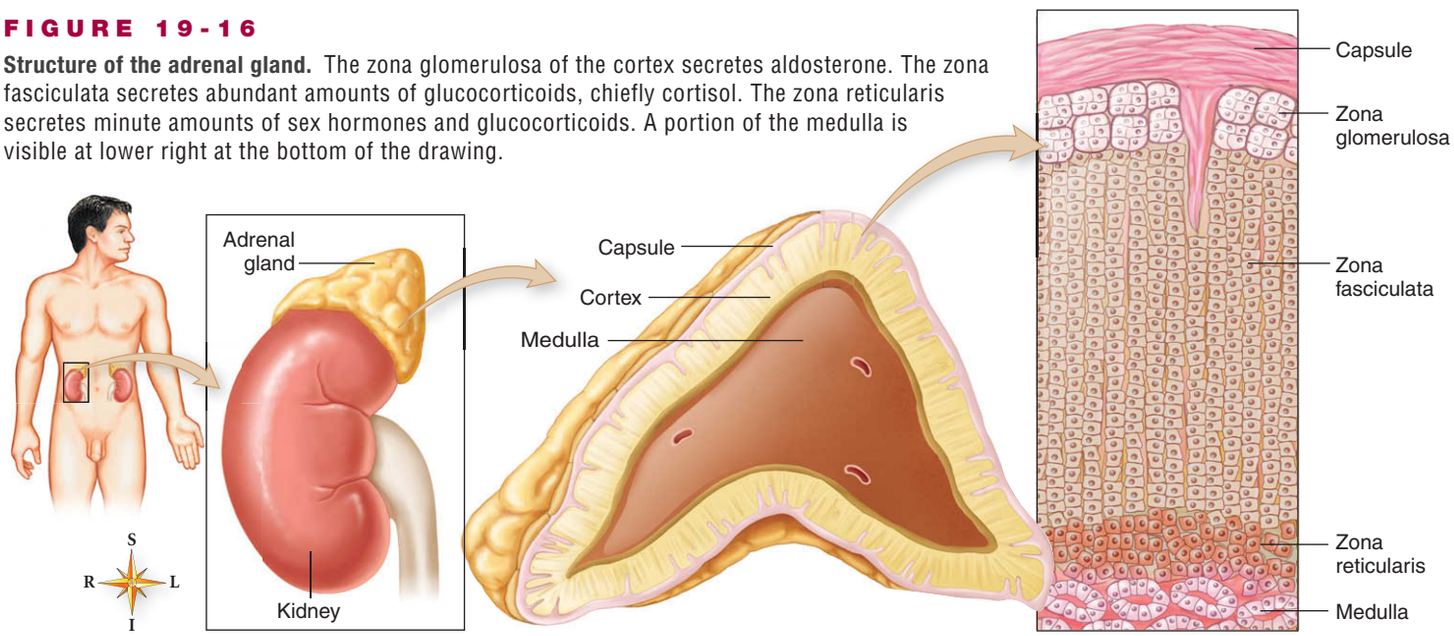
Adrenal tissue. The major regions of the adrenal gland are shown in a light micrograph of a stained specimen. The cortex is made up of epithelial endocrine tissue, and the medulla is instead made up of neurosecretory tissue. Compare with drawing in Figure 19-16.



ADRENAL GLANDS

Structure of the Adrenal Glands

The **adrenal glands,** or *suprarenal glands*, are located atop the kidneys, fitting like a cap over these organs (Figure 19-15). The outer portion of the gland is called the **adrenal cortex,** and the inner portion of the gland is called the **adrenal medulla** (Figure 19-16). Even though the adrenal cortex and adrenal medulla are part of the same organ, they have different embryological origins and are structurally and functionally so different that they are often spoken of as if they were separate glands. The adrenal cortex is composed of regular endocrine tissue, but the adrenal medulla is made of neurosecretory tissue (Figure 19-17). As you might guess, each of

FIGURE 19-16

Structure of the adrenal gland. The zona glomerulosa of the cortex secretes aldosterone. The zona fasciculata secretes abundant amounts of glucocorticoids, chiefly cortisol. The zona reticularis secretes minute amounts of sex hormones and glucocorticoids. A portion of the medulla is visible at lower right at the bottom of the drawing.

UNIT 3

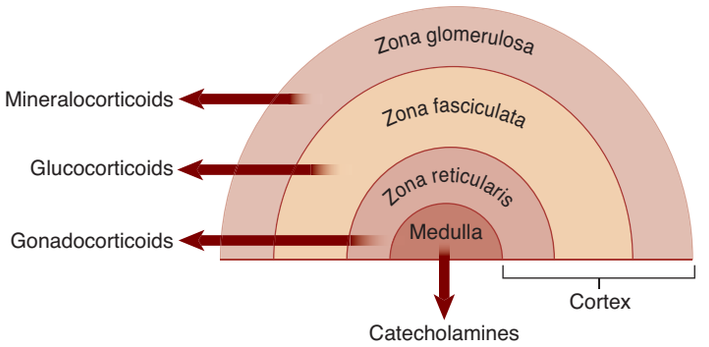


FIGURE 19-18
Adrenal hormones.

these tissues synthesizes and secretes a different set of hormones (Figure 19-18 and Table 19-4).

Adrenal Cortex

The adrenal cortex is composed of three distinct layers, or zones, of secreting cells (see Figures 19-16 to 19-18). Starting with the zone directly under the outer connective tissue capsule of the gland, they are the **zona glomerulosa, zona fasciculata,** and **zona reticularis.** Cells of the outer zone secrete a class of hormones called *mineralocorticoids.* Cells of the middle zone secrete *glucocorticoids.* The inner zone secretes small amounts of *glucocorticoids* and *gonadocorticoids* (sex hormones). All these cortical hormones are steroids, so together they are known as *corticosteroids.*

MINERALOCORTICOIDS

Mineralocorticoids, as their name suggests, have an important role in regulating how mineral salts (electrolytes) are processed in the body. In the human, **aldosterone** is the only physiologically important mineralocorticoid. Its primary function is the maintenance of sodium homeostasis in the blood. Aldosterone accomplishes this by increasing sodium reabsorption in the kidneys. Sodium ions are reabsorbed from the urine back into the blood in exchange for potassium or hydrogen ions. In this way, aldosterone not only adjusts blood sodium levels but also can influence potassium and pH levels in the blood.

Because the reabsorption of sodium ions causes water to also be reabsorbed (partly by triggering the secretion of ADH), aldosterone promotes water retention by the body. Altogether, aldosterone can increase sodium and water retention and promote the loss of potassium and hydrogen ions.

Aldosterone secretion is controlled mainly by the **renin-angiotensin-aldosterone system (RAAS)** and by blood potassium concentration. The RAAS (Figure 19-19) operates as indicated in this sequence of steps:

1. When the incoming blood pressure in the kidneys drops below a certain level, a piece of tissue near the vessels (the *juxtaglomerular apparatus*) secretes *renin* into the blood.
2. **Renin,** an enzyme, causes **angiotensinogen** (a normal constituent of blood) to be converted to *angiotensin I.*
3. **Angiotensin I** circulates to the lungs, where *angiotensin-converting enzyme (ACE)* in the capillaries splits the molecule, forming *angiotensin II.*
4. **Angiotensin II** circulates to the adrenal cortex, where it stimulates the secretion of aldosterone. (Some aldosterone is also synthesized in the heart and blood vessels.)
5. **Aldosterone** causes increased reabsorption of sodium, which causes increased water retention. As water is retained, the volume of blood increases. The increased volume of blood creates higher blood pressure—which then causes the renin-angiotensin-aldosterone system to stop.

The renin-angiotensin-aldosterone system is a negative feedback mechanism that helps maintain homeostasis of blood pressure. One way is to increase the overall volume of blood, a function of aldosterone. Another way is by the action of angiotensin II, which increases the tone of smooth muscle in the wall of arteries—thus increasing arterial blood pressure. A type of drug called an *ACE inhibitor* reduces abnormally high blood pressure by blocking the formation of angiotensin II (see step 3 above) and thus reducing both of these blood-pressure enhancing effects.

GLUCOCORTICOIDS

The chief glucocorticoids secreted by the zona fasciculata of the adrenal cortex are **cortisol** (also called *hydrocortisone*), *cortisone,* and

TABLE 19-4 Hormones of the Adrenal Glands

HORMONE	SOURCE	TARGET	PRINCIPAL ACTION
Aldosterone	Adrenal cortex (zona glomerulosa)	Kidney	Stimulates kidney tubules to conserve sodium, which in turn triggers the release of ADH and the resulting conservation of water by the kidney
Cortisol (hydrocortisone)	Adrenal cortex (zona fasciculata)	General	Influences metabolism of food molecules; in large amounts, it has an antiinflammatory effect
Adrenal androgens	Adrenal cortex (zona reticularis)	Sex organs, other effectors	Exact role uncertain but may support sexual function
Adrenal estrogens	Adrenal cortex (zona reticularis)	Sex organs	Thought to be physiologically insignificant
Epinephrine (Epi) (adrenaline)	Adrenal medulla	Sympathetic effectors	Enhances and prolongs the effects of the sympathetic division of the autonomic nervous system
Norepinephrine (NE)	Adrenal medulla	Sympathetic effectors	Enhances and prolongs the effects of the sympathetic division of the autonomic nervous system

ADH, Antidiuretic hormone.

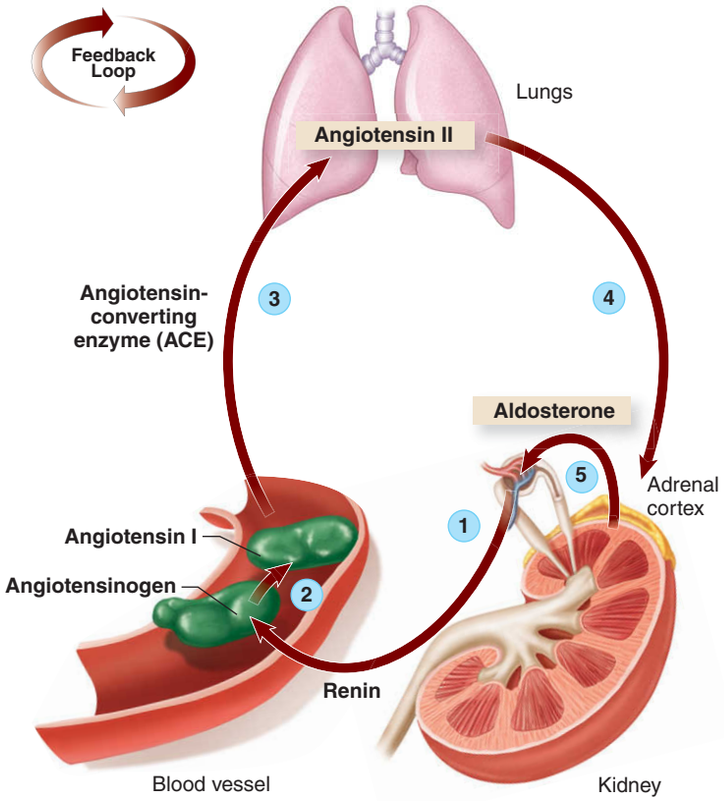

FIGURE 19-19

Renin-angiotensin-aldosterone system (RAAS) for regulating aldosterone secretion. The numbers correspond to the steps outlined in the text.

corticosterone. Of these, only cortisol is secreted in significant quantities in the human. Glucocorticoids affect every cell in the body. Although much remains to be discovered about their precise mechanisms of action, we do know enough to make some generalizations:

- Glucocorticoids accelerate the breakdown of proteins into amino acids (except in liver cells). These "mobilized" amino acids move out of the tissue cells and into the blood. From there, they circulate to the liver cells, where they are changed to glucose in a process called *gluconeogenesis*. A prolonged high blood concentration of glucocorticoids in the blood therefore results in a net loss of tissue proteins ("tissue wasting") and hyperglycemia (high blood glucose). Glucocorticoids are protein mobilizing, gluconeogenic, and hyperglycemic.
- Glucocorticoids tend to accelerate mobilization of both lipids from adipose cells and lipid catabolism by nearly every cell in the body. In other words, glucocorticoids tend to cause a shift from carbohydrate catabolism to lipid catabolism as an energy source. The mobilized lipids may also be used in the liver for gluconeogenesis. This effect contributes to the hyperglycemic effect already observed.
- Glucocorticoids are essential for maintaining a normal blood pressure. Without adequate amounts of glucocorticoids in the blood, the hormones norepinephrine and epinephrine cannot produce their vasoconstricting effect on blood vessels, and blood pressure falls. In other words, glucocorticoids exhibit *permissiveness* in that they permit norepinephrine and epinephrine to have their full effects. When glucocorticoids are present in high concentrations for a prolonged time, they may elevate blood pressure beyond normal (hypertension).
- A high blood concentration of glucocorticoids rather quickly causes a marked decrease in the number of white blood cells called *eosinophils* in the blood (eosinopenia) and marked atrophy of lymphatic tissues. The thymus gland and lymph nodes are particularly affected. This in turn leads to a decrease in the number of lymphocytes and plasma cells in the blood. Because of the decreased number of lymphocytes and plasma cells (antibody-processing cells), antibody formation decreases. Antibody formation is an important part of immunity—the body's defense against infection.
- Normal amounts of glucocorticoids act with epinephrine, a hormone secreted by the adrenal medulla, to bring about normal recovery from injury produced by inflammatory agents. How they act together to bring about this antiinflammatory effect is still uncertain.
- Glucocorticoid secretion increases as part of the stress response. One advantage gained by increased secretion may be the increase in glucose available for skeletal muscles needed in fight-or-flight responses. However, prolonged stress can lead to immune dysfunction, probably as a result of prolonged exposure to high levels of glucocorticoids (see Chapter 25).
- Except during the stress response, glucocorticoid secretion is controlled mainly by means of a negative feedback mechanism that involves ACTH from the adenohypophysis.
- As with many hormones, including all the adrenal cortical hormones, glucocorticoid secretion occurs in pulses and also shows a daily pattern of pulses of different amounts of hormone secretion (Figure 19-20).

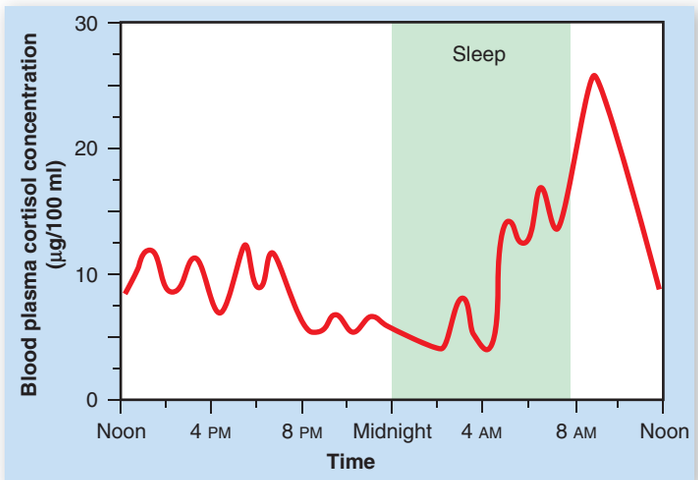

FIGURE 19-20

Secretion of cortisol. As with many hormones, the amount of cortisol secreted into the blood varies chaotically throughout the day. However, pulses of increased hormone secretion occur occasionally with the highest peaks shortly before and after waking. Pulsing secretion (in response to specific conditions in the body) with a daily, or *diurnal,* pattern is seen in many hormones—including all of the adrenal cortical hormones.

GONADOCORTICOIDS

The term *gonadocorticoid* refers to sex hormones that are released from the zona fasciculata and zona reticularis of the adrenal cortex rather than the gonads. The normal adrenal cortex secretes small amounts of male hormones (androgens). Normally, not enough androgen is produced to give women masculine characteristics, but it is sufficient to influence the appearance of pubic and axillary hair in both boys and girls.

Box 19-8 discusses some adrenal cortical hormone disorders.

Adrenal Medulla

The adrenal medulla is composed of neurosecretory tissue, that is, tissue composed of neurons adapted to secrete their products into the blood rather than across a synapse. Actually, the medullary cells are modified versions of sympathetic postganglionic fibers of the autonomic nervous system. They are innervated by sympathetic preganglionic fibers, so that when the sympathetic nervous system is activated (as in the stress response), the medullary cells secrete their hormones directly into the blood.

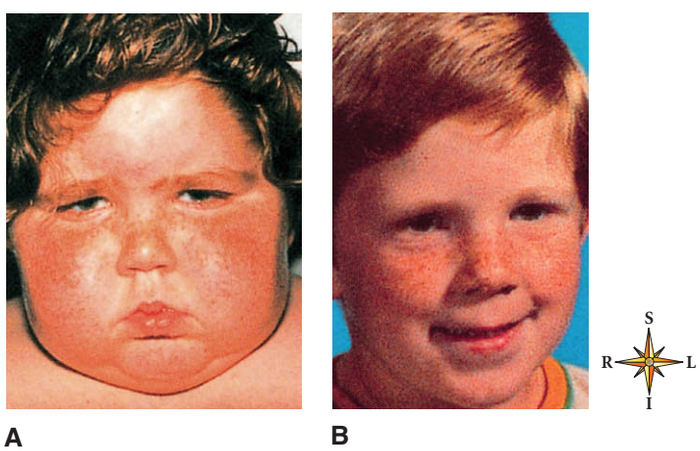
The adrenal medulla secretes two important hormones, both of which are in the class of nonsteroid hormones called catecholamines. **Epinephrine (Epi),** or *adrenaline*, accounts for about 80% of the medulla's secretion. The other 20% is **norepinephrine** (**NE** or **NR**). You may recall that norepinephrine is also the neurotransmitter produced by postganglionic sympathetic fibers. Sympathetic effectors such as the heart, smooth muscle, and glands have receptors for norepinephrine. Both epinephrine and norepinephrine produced by the adrenal medulla can bind to the receptors of sympathetic effectors to prolong and enhance the effects of sympathetic stimulation by the autonomic nervous system (Figure 19-21).

| QUICK CHECK |

10. Distinguish between the histology of the adrenal cortex and the adrenal medulla.
11. Name some effects of cortisol in the body.
12. How does the function of the adrenal medulla overlap with the function of the autonomic nervous system?

PANCREATIC ISLETS

Structure of the Pancreatic Islets



The pancreas is an elongated gland (12 to 15 cm [or about 5 to 6 inches] long) weighing up to 100 grams (3.5 ounces) (Figure 19-22). The "head" of the gland lies in the C-shaped beginning of the small intestine (duodenum), with its body extending horizontally behind the stomach and its tail touching the spleen

The tissue of the pancreas is composed of both endocrine and exocrine tissues. The endocrine portion is made up of scattered,

Box 19-8 | HEALTH matters

Adrenal Cortical Hormone Abnormalities

Hypersecretion of cortisol from the adrenal cortex often produces a collection of symptoms called **Cushing syndrome.** Hypersecretion of glucocorticoids results in a redistribution of body fat. The fatty "moon face" and thin, reddened skin characteristic of Cushing syndrome are shown in part *A* of the figure. Part *B* shows the face of the same boy 4 months after treatment. Hypersecretion of aldosterone, *aldosteronism,* leads to increased water retention and muscle weakness resulting from potassium loss. Hypersecretion of androgens can result from tumors of the adrenal cortex, called *virilizing tumors.* They are so called because the increased blood level of male hormones in women can cause them to acquire male characteristics, such as facial hair. People with Cushing syndrome may suffer from all the symptoms described above.

Cushing syndrome. A, Fatty "moon face" in a boy with Cushing syndrome. **B,** The face of the same boy 4 months after treatment.

Hyposecretion of mineralocorticoids and glucocorticoids, as in **Addison disease,** may lead to a drop in blood sodium and blood glucose, an increase in blood potassium levels, dehydration, and weight loss.

Pharmacological preparations of glucocorticoids have been used for many years to temporarily relieve the symptoms of severe inflammatory conditions such as rheumatoid arthritis. Over-the-counter creams and ointments containing hydrocortisone are widely available for use in treating the pain, itching, swelling, and redness of skin rashes.

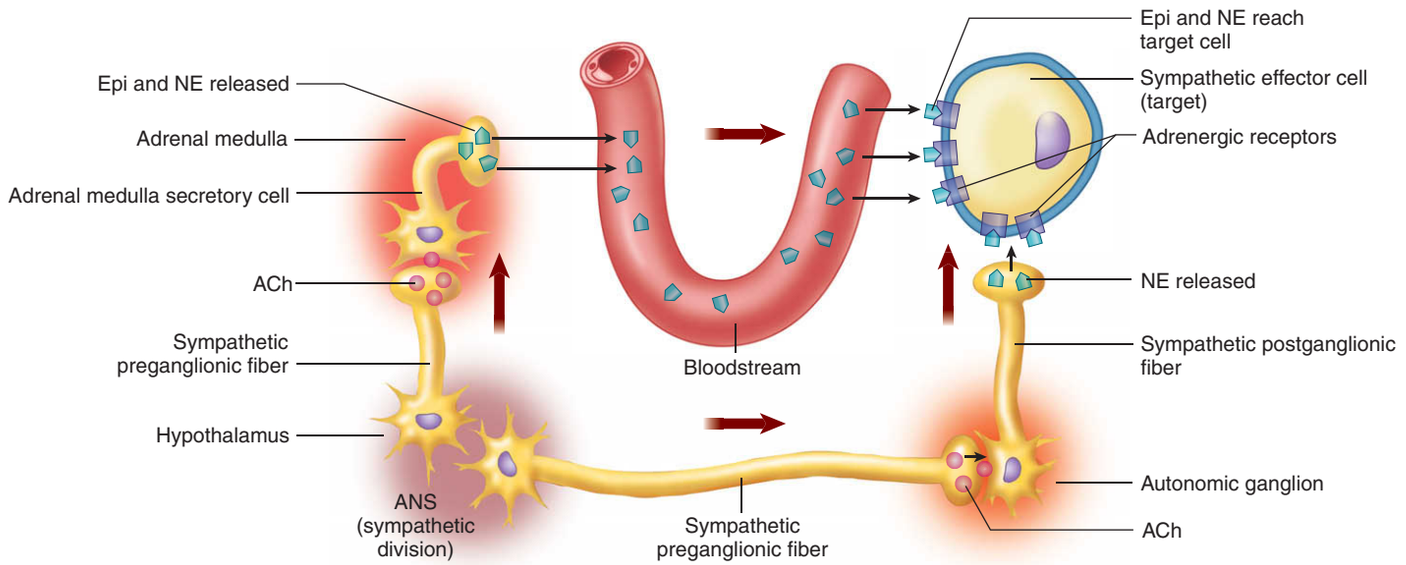


FIGURE 19-21

Combined nervous and endocrine influence on sympathetic effectors. A sympathetic center in the hypothalamus sends efferent impulses through preganglionic fibers. Some preganglionic fibers synapse with postganglionic fibers that deliver norepinephrine *(NE)* across a synapse with the effector cell. Other preganglionic fibers synapse with postganglionic neurosecretory cells in the adrenal medulla. These neurosecretory cells secrete epinephrine *(Epi)* and norepinephrine into the bloodstream, where they travel to the target cells (sympathetic effectors). Compare this figure with Figure 18-1. *ANS,* Autonomic nervous system; *ACh,* acetylcholine.

tiny islands of cells, called **pancreatic islets** *(islets of Langerhans)* that account for only about 2% or 3% of the total mass of the pancreas. These hormone-producing islets are surrounded by cells called *acini*, which secrete a serous fluid containing digestive enzymes into ducts that drain into the small intestine (see Figure 19-22). The digestive roles of the pancreas are discussed in Chapters 28 and 29. For the moment, we will concentrate on the endocrine part of this gland, the pancreatic islets.

Each of the 1 to 2 million pancreatic islets in the pancreas contains a combination of four primary types of endocrine cells, all joined to each other by gap junctions. Each type of cell secretes a different hormone, but the gap junctions may allow for some coordination of these functions as a single secretory unit. One type of pancreatic islet cell is the **alpha cell** (α or *A cell*), which secretes the hormone glucagon. **Beta cells** (β *or B cells*) secrete the hormone insulin; **delta cells** (δ *or D cells*) secrete the hormone somatostatin; **pancreatic polypeptide cells** *(F,* or *PP, cells)* secrete pancreatic polypeptide; and **epsilon cells** (ε *cells*) secrete the hormone ghrelin. Beta cells, which account for about three fourths of all the pancreatic islet cells, are usually found near the center of each islet, whereas cells of the other three types are

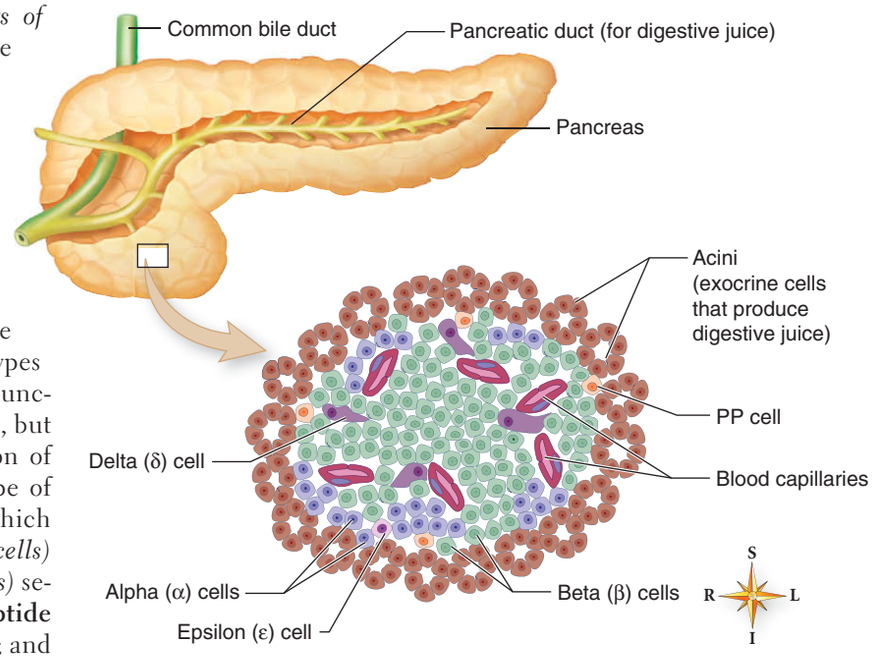

FIGURE 19-22

Pancreas. A pancreatic islet, or hormone-producing area, is evident among the pancreatic cells that produce the pancreatic digestive juice. The pancreatic islets are more abundant in the tail of the pancreas than in the body or head.

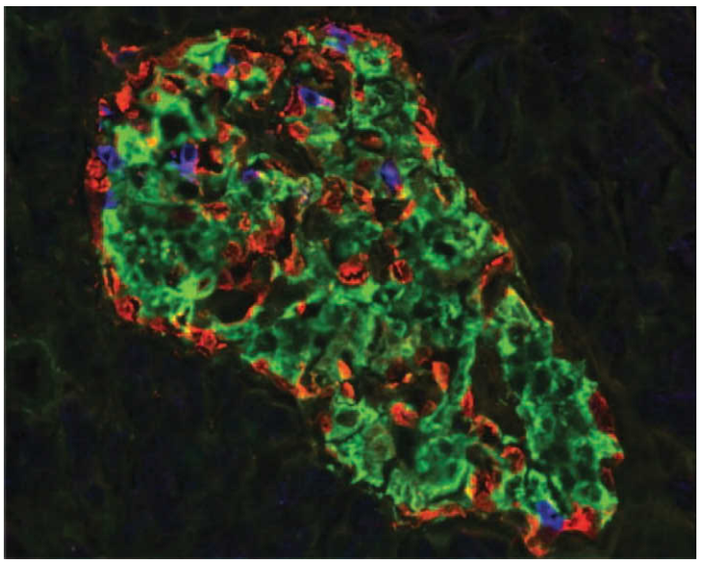

FIGURE 19-23

Cells of the pancreatic islet. A special technique of microscopy, called immunofluorescent staining, allows cells to be distinguished by the different molecules that they contain. Beta cells containing insulin appear green. Alpha cells containing glucagon appear red. Delta cells containing somatostatin appear blue.

more often found in the outer portion. Figure 19-23 shows how the different cell types can be distinguished by the microscope with special staining techniques.

Pancreatic Hormones

The pancreatic islets produce several hormones, the most important of which are described in Table 19-5 and in the following list:

Glucagon, produced by alpha cells, tends to increase blood glucose levels by stimulating the conversion of glycogen to glucose in liver cells. It also stimulates gluconeogenesis (transformation of fatty acids and amino acids into glucose) in liver cells. The glucose produced by way of the breakdown of glycogen and by gluconeogenesis is released into the bloodstream, producing a hyperglycemic effect.

Insulin, produced by beta cells, tends to promote the movement of glucose, amino acids, and fatty acids out of the blood and into tissue cells. Hence insulin tends to lower the blood concentrations of these food molecules and to promote their metabolism by tissue cells. The antagonistic effects that glucagon and insulin have on blood glucose levels are summarized in Figure 19-24 and discussed further in Chapter 30.

Somatostatin, produced by delta cells, may affect many different tissues in the body, but its primary role seems to be in regulating the other endocrine cells of the pancreatic islets. Somatostatin inhibits the secretion of glucagon, insulin, and pancreatic polypeptide. It also inhibits the secretion of growth hormone (somatotropin) from the anterior pituitary.

Pancreatic polypeptide is produced by PP (or F) cells in the periphery of pancreatic islets. Although much is yet to be learned about pancreatic polypeptide, we do know that it influences the digestion and distribution of food molecules to some degree.

Ghrelin (GHRL) is produced in tiny amounts by epsilon cells near the outer boundary of pancreatic islets. It acts by stimulating the hypothalamus to boost appetite. Since it also acts on other body tissues to slow metabolism and reduce fat burning, it may play an important role in contributing to obesity. GHRL is also secreted by the gastric mucosa.

All of the pancreatic hormones work together as a team to maintain a homeostasis of nutrient molecules (glucose, fatty acids, and amino acids). More about their respective roles in overall nutrient metabolism is discussed in Chapter 30.

TABLE 19-5 Hormones of the Pancreatic Islets

HORMONE	SOURCE	TARGET	PRINCIPAL ACTION
Glucagon	Pancreatic islets (alpha [α] cells, or A cells)	General	Promotes movement of glucose from storage and into the blood
Insulin	Pancreatic islets (beta [β] cells, or B cells)	General	Promotes movement of glucose out of the blood and into cells
Somatostatin (SS)	Pancreatic islets (delta [δ] cells, or D cells)	Pancreatic cells and other effectors	Can have general effects in the body, but primary role seems to be regulation of secretion of other pancreatic hormones
Pancreatic polypeptide (PP)	Pancreatic islets (pancreatic polypeptide [PP] or F cells)	Intestinal cells and other effectors	Exact function uncertain but seems to influence absorption in the digestive tract
Ghrelin (GHRL)	Stomach mucosa, pancreatic islets (epsilon [ε] cells)	Hypothalamus; other diverse tissues	Stimulates hypothalamus to boost appetite; affects energy balance in various tissues

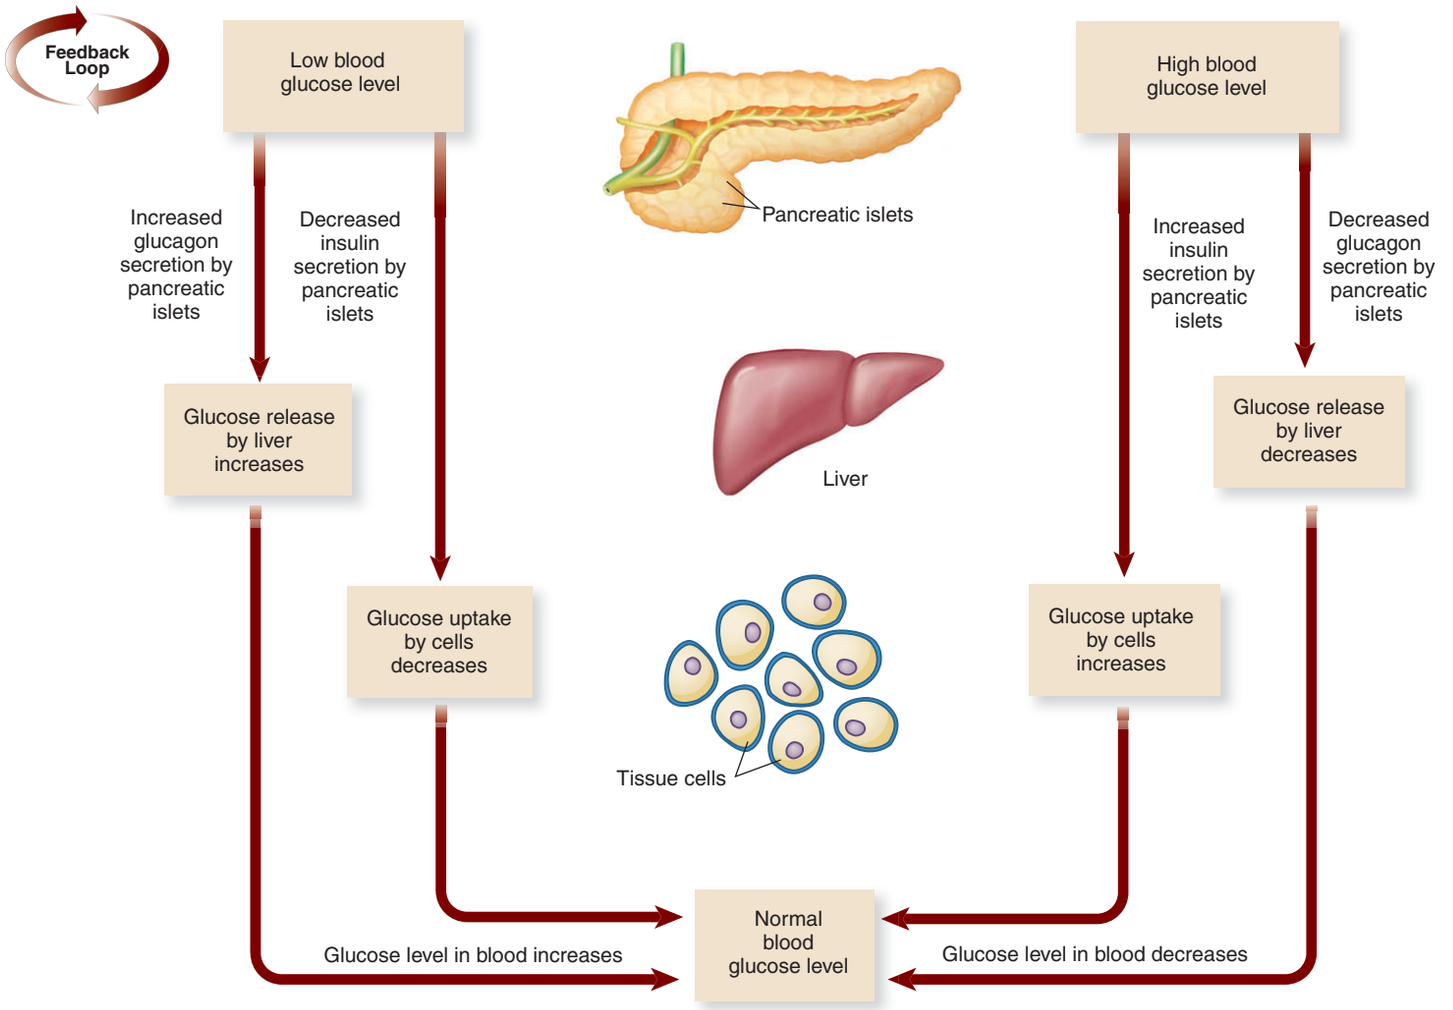

FIGURE 19-24

Regulation of blood glucose levels. Insulin and glucagon, two of the major pancreatic hormones, have antagonistic (opposite) effects on glucose concentration in the blood. Of course, many other hormones, such as GH, cortisol, and others, also influence blood glucose levels.

| A&P CONNECT |

Diabetes mellitus (DM) is one of the most common endocrine disorders. It involves a variety of abnormal effects in the body, all related to either hyposecretion of insulin or a reduction of insulin effects in target cells (or both). For a brief discussion of this disorder, and a chart showing the causes of the common symptoms of DM, check out ***Diabetes Mellitus*** online at ***A&P Connect.***

evolve

| QUICK CHECK |

13. Name two of the four principal hormones secreted by the pancreatic islets.
14. In what way do insulin and glucagon exert antagonistic influences on the concentration of glucose in the blood?

GONADS

Gonads are the primary sex organs in the male (*testes*; singular, *testis*) and in the female (*ovaries*). Each is structured differently, and each produces its own unique set of hormones (Table 19-6).

Testes

The testes are paired organs within a sac of skin called the *scrotum*, which hangs from the groin area of the trunk (see Figure 18-2 on p. 547). They are composed mainly of coils of sperm-producing

TABLE 19-6 Examples of Additional Hormones of the Body

HORMONE	SOURCE	TARGET	PRINCIPAL ACTION
Cholecalciferol (vitamin D_3)	Skin, liver, kidney (in progressive steps)	Intestines, bones, most other tissues	Promotes calcium absorption from food, regulates mineral balance in bones, regulates growth and differentiation of many cell types
Dehydroepiandrosterone (DHEA)	Adrenal gland, testis, ovary, other tissues	Converted to other hormones	Eventually converted to estrogens, testosterone, or both (see Figure 18-5)
Melatonin	Pineal gland	Timekeeping tissues of the nervous system	Helps "set" the biological clock mechanisms of the body by signaling light changes during the day, month, and seasons; may help induce sleep
Testosterone	Testis (small amounts in adrenal and ovary)	Sperm-producing tissues of testis, muscles, other tissues	Stimulates sperm production, stimulates growth and maintenance of male sexual characteristics, promotes muscle growth
Estrogen including estradiol (E_2) and estrone	Ovary and placenta (small amounts in adrenal and testis)	Uterus, breasts, other tissues	Stimulates development of female sexual characteristics, breast development, bone and nervous system maintenance
Progesterone	Ovary and placenta	Uterus, mammary glands, other tissues	Helps maintain proper conditions for pregnancy
Human chorionic gonadotropin (hCG)	Placenta	Ovary	Stimulates secretion of estrogen and progesterone during pregnancy
Human placental lactogens (hPLs)	Placenta	Mammary glands; pancreas and other tissues	Promote development of mammary glands during pregnancy; help regulate energy balance in fetus
Relaxin	Placenta	Uterus and joints	Inhibits uterine contractions during pregnancy and softens pelvic joints to facilitate childbirth
Thymosins and thymopoietins	Thymus gland	Certain lymphocytes (type of white blood cell)	Stimulate development of T lymphocytes, which are involved in immunity
Gastrin	Stomach mucosa	Exocrine glands of stomach	Triggers increased gastric juice secretion
Secretin	Intestinal mucosa	Stomach and pancreas	Increases alkaline secretions of the pancreas and slows emptying of stomach; helps regulate water homeostasis
Cholecystokinin (CCK)	Intestinal mucosa	Gallbladder and pancreas	Triggers the release of bile from gallbladder and enzymes from the pancreas
Atrial natriuretic hormone (ANH) and other atrial natriuretic peptides (ANPs)	Heart muscle	Kidney	Promotes loss of sodium from body into urine, thus promoting water loss from the body and a resulting decrease in blood volume and pressure
Inhibins	Ovary and testis	Hypothalamus Adenohypophysis (anterior pituitary)	Inhibit secretion of GnRH by hypothalamus and FSH by the anterior pituitary, thus helping to regulate the female reproductive cycle
Leptin	Adipose tissue	Hypothalamus; other diverse tissues	Affects energy balance, perhaps as a signal of how much fat is stored; affects various immune, neuroendocrine, and developmental functions throughout body
Resistin	Adipose tissue and macrophages	Liver and other tissues	Reduces sensitivity to insulin (a pancreatic islet hormone), thus increasing blood glucose levels
Insulin-like growth factor 1 (IGF-1)	Liver, kidney, and other tissues	Bone, muscle, and other tissues	Secreted in response to growth hormone (GH) IGF-1 carries out many of the functions attributed to GH

Box 19-9 | SPORTS and FITNESS

Steroid Abuse

Some steroid hormones are called **anabolic steroids** because they stimulate the building of large molecules (anabolism). Specifically, they stimulate the building of proteins in muscle and bone. Steroids such as testosterone and its synthetic derivatives may be abused by athletes and others who want to increase their muscle size, strength, or performance. The anabolic effects of the hormones increase the mass and strength of skeletal muscles.

Unfortunately, steroid abuse has other consequences. Prolonged use of testosterone will cause a negative feedback response of the adenohypophysis: gonadotropin levels will drop in response to high blood levels of testosterone. This may lead to atrophy of the testes and, possibly, permanent sterility. Many other adverse effects, including behavioral abnormalities, are known to result from steroid abuse.

seminiferous tubules with a scattering of endocrine *interstitial cells* found in areas between the tubules. These interstitial cells produce androgens (male sex hormones); the principal androgen is **testosterone.** Testosterone is responsible for the growth and maintenance of male sexual characteristics and for sperm production (Box 19-9). Testosterone secretion is regulated principally by gonadotropin (especially LH) levels in the blood.

Ovaries

Ovaries are a set of paired glands in the pelvis (see Figure 18-2 on p. 547) that produce several types of sex hormones, including those described briefly in the following list:

Estrogens, including estradiol and estrone, are steroid hormones secreted by the cells of the ovarian follicles that promote the development and maintenance of female sexual characteristics. With other hormones, they are responsible for breast development and the proper sequence of events in the female reproductive cycle (menstrual cycle). More details of their function are discussed in Chapter 35.

Progesterone is a hormone whose name, which means "pregnancy-promoting steroid," indicates its chief function. Secreted by the corpus luteum (the tissue left behind after the rupture of a follicle during ovulation), progesterone (along with estrogen) maintains the lining of the uterus necessary for successful pregnancy (gestation). This hormone, along with others, is discussed in detail in Chapter 35.

Regulation of ovarian hormone secretion is complex, to say the least, but basically depends on the changing levels of follicle-stimulating hormone (FSH) and LH (gonadotropins) from the adenohypophysis.

PLACENTA

Another reproductive tissue that functions as an important endocrine gland is the placenta. The **placenta,** the tissue that forms on the lining of the uterus as an interface between the circulatory systems of the mother and developing child, serves as a temporary endocrine gland.

The placenta produces **human chorionic gonadotropin (hCG).** This hormone is called "chorionic" because it is secreted by the chorion, a fetal tissue component of the placenta. It is called "gonadotropin" because, as with the gonadotropins of the adenohypophysis, it stimulates development and hormone secretion by maternal ovarian tissues. Chorionic gonadotropin secretion is high during the early part of pregnancy and serves as a signal to the mother's gonads to maintain the uterine lining rather than allow it to degenerate and fall away (as in menstruation).

The discovery of hCG many years ago led to the development of early pregnancy tests. The high levels of hCG in the urine of women who are in the early part of their pregnancies can be detected through several means. The most familiar test involves the use of an over-the-counter kit that tests for hCG in urine by means of an antigen-antibody reaction that can be easily interpreted.

As the placenta develops past the first trimester (3 months) of pregnancy, its production of hCG drops as its production of estrogens and progesterone increases. The placenta therefore more or less takes over the job of ovaries in producing these hormones necessary for a successful pregnancy.

The placenta also produces additional estrogen and progesterone during pregnancy, as well as several other hormones (see Table 19-6). These include **human placental lactogen (hPL)** and **relaxin.**

More about how placental hormones work is discussed in Chapter 36.

THYMUS

The **thymus** is a gland in the mediastinum, just beneath the sternum (see Figure 18-2 on p. 547). It is large in children until puberty, when it begins to atrophy. It continues to atrophy throughout adulthood, so that by the time an individual reaches old age, the gland is but a vestige of fat and fibrous tissue.

The anatomy of the thymus is described in Chapter 23.

Although it is considered to be primarily a lymphatic organ (see Chapter 23), the hormones **thymosin** and **thymopoietin** have been isolated from thymus tissue and are considered to be largely responsible for its endocrine activity (see Table 19-6). Thymosin and thymopoietin actually refer to two entire families of peptides that together have a critical role in the development of the immune system. Specifically, thymosin and thymopoietin are thought to stimulate the production of special lymphocytes involved in the immune response called *T cells.* The role of T cells in the immune system is discussed in Chapter 24.

GASTRIC AND INTESTINAL MUCOSA

The mucous lining of the gastrointestinal (GI) tract, like the pancreas, contains cells that produce both endocrine and exocrine secretions (see Table 19-6).

GI hormones such as **gastrin, secretin,** and **cholecystokinin (CCK)** have important regulatory roles in coordinating the secretory and motor activities involved in the digestive process. For example, secretin is released when acids make contact with the intestinal mucosa. Secretin carried by the blood triggers its target cells in the stomach to reduce acid secretion. Secretin also triggers its target cells in the pancreas to release an alkaline fluid, and it acts with CCK to trigger the pancreas to release digestive enzymes. CCK triggers the gallbladder to release more bile, which helps break up fat droplets. In effect, secretin and CCK are signals from the intestine to other parts of the digestive system that promote an effective coordination of GI functions.

The appetite-boosting hormone *ghrelin (GHRL)* is secreted by endocrine cells in the gastric mucosa as well as in the pancreatic islets.

Chapter 29 describes the hormonal control of digestion in the stomach and small intestine in more detail (see Table 29-5, p. 920).

HEART

The heart is another organ with a secondary endocrine role. Although the heart's main function is to pump blood, a specific area in its wall contains some hormone-producing cells. These cells produce several peptide hormones (see Table 19-6). This group of hormones is collectively called *atrial natriuretic peptide (ANP)*, and the principal hormone of the group is called **atrial natriuretic hormone (ANH).**

The name of ANH reveals much about its role in the body. The term *atrial* refers to the fact that ANH is secreted by cells in an upper chamber of the heart called an *atrium*. Atrial cells increase their secretion of ANH in response to an increase in the stretch of the atrial wall caused by abnormally high blood volume or blood pressure. The term *natriuretic* refers to the fact that its principal effect is to promote the loss of sodium (Latin, *natrium*) from the body by means of the urine. When sodium is thus lost from the internal environment, water follows. Water loss results in a decrease in blood volume (and thus a decrease in blood pressure). We can then state that the primary effect of ANH is to oppose increases in blood volume or blood pressure. We can also state that ANH is an antagonist to ADH and aldosterone.

ANH is also known by several other names, including *atrial natriuretic factor (ANF)*, *atrial natriuretic peptide*, and simply, *atrial peptide*.

OTHER ENDOCRINE GLANDS AND HORMONES

In this chapter, we have outlined the structure and function of only a few of the more central endocrine glands. And we have discussed only a few of their principal hormones. Many of the glands we have discussed in this chapter produce many more hormones, all of which are important to normal body function. For example, the ovaries produce the hormone **inhibin**—a glycoprotein hormone that helps to regulate FSH levels in women. And many hormones have additional effects besides the principal effects listed in this chapter (see Box 18-1, p. 554).

Many other tissues throughout the body produce hormones—perhaps all tissues in the body produce hormones. For example, adipose tissue has been shown to secrete **leptin,** a protein hormone that plays a role in energy balance, regulation of immunity and neuroendocrine function, and development. Another hormone secreted by adipose tissue and macrophages—*resistin*—reduces sensitivity to insulin and thus raises blood glucose levels. Table 19-6 summarizes a few additional examples of hormones that you are likely to encounter in your studies.

It is neither within the scope of this chapter—nor within the scope of this book—to discuss every known human hormone. Such a discussion would be longer than this *whole* book is now! Having had this brief preview, however, you will now be prepared for additional examples that you will encounter as you continue your study of the human body.

| QUICK CHECK |

15. What are the major hormones secreted by reproductive tissues (gonads and the placenta)?
16. Which gland produces a hormone that regulates the development of cells important to the immune system?
17. Secretin was the first substance in the body to be identified as a hormone. What structure produces secretin?
18. Which type of body tissue produces the hormone *leptin?*

Cycle of LIFE

Endocrine System

Endocrine regulation of body processes first begins during early development in the womb. By the time a baby is born, many of the hormones are already at work influencing the activity of target cells throughout the body. As a matter of fact, it is a hormonal signal from the fetus to the mother that signals the onset of labor and delivery. Many of the basic hormones are active from birth, but most of the hormones related to reproductive functions are not produced or secreted until puberty. Secretion of male reproductive hormones follows the same pattern as most nonreproductive hormones: continuous secretion from puberty until a slight tapering off occurs in late adulthood. The secretion of female reproductive hormones such as estrogens also declines late in life, but more suddenly and completely—often during or just at the end of middle adulthood.

the BIG picture

The Endocrine System and the Whole Body

In the previous chapter we identified the precision of control afforded by the partnership of the two major regulatory systems: the endocrine system and the nervous system. In this chapter we have encountered many examples of this partnership.

The neuroendocrine system is able to finely adjust the availability and processing of nutrients through a diverse array of mechanisms: growth hormone, thyroid hormone, cortisol, epinephrine, somatostatin, autonomic nervous regulation, and so on. The absorption, storage, and transport of calcium ions are kept in balance by the antagonistic actions of calcitonin and parathyroid hormone (and its effects on vitamin D). Reproductive ability is triggered, developed, maintained, and timed by the complex interaction of the nervous system with follicle-stimulating hormone, luteinizing hormone, estrogen, progesterone, testosterone, chorionic gonadotropin, prolactin, oxytocin, and melatonin. Nearly every process in the human organism is kept in balance by the incredibly complex, but precise, interaction of all these different nervous and endocrine regulatory chemicals.

In this chapter, we have also seen the many different structures and regulatory mechanisms that make up the endocrine system. Some of the more important hormones and their characteristics are summarized in tables throughout the chapter. As we continue our study of human anatomy and physiology, we will often encounter these hormones and the critical integrative role played by the endocrine system.

MECHANISMS of DISEASE

ENDOCRINE DISORDERS

In chapter 18 (see p. 546) we stated that nearly all endocrine disorders are caused by abnormal hormonal effects in target tissues. This could result from hypersecretion or hyposecretion of hormones. Or it could result from oversensitivity or undersensitivity in the target tissues, which can produce effects similar to hyper- or hyposecretion of hormones. Throughout this chapter, we have seen examples of many such disorders. Table 19-7 summarizes some important examples of endocrine disorders.

TABLE 19-7 Examples of Endocrine Conditions

CONDITION	MECHANISM	DESCRIPTION
Acromegaly	Hypersecretion of growth hormone (GH) during adulthood	Chronic metabolic disorder characterized by gradual enlargement or elongation of facial bones and extremities
Addison disease	Hyposecretion of adrenal cortical hormones (adrenal cortical insufficiency)	Caused by tuberculosis, autoimmunity, or other factors, this life-threatening condition is characterized by weakness, anorexia, weight loss, nausea, irritability, decreased cold tolerance, dehydration, increased skin pigmentation, and emotional disturbance; it may lead to an acute phase (adrenal crisis) characterized by circulatory shock
Aldosteronism	Hypersecretion of aldosterone	Often caused by adrenal hyperplasia, this condition is characterized by sodium retention and potassium loss—producing Conn syndrome: severe muscle weakness, hypertension (high blood pressure), kidney dysfunction, cardiac problems
Cretinism	Hyposecretion of thyroid hormone during early development	Congenital condition characterized by dwarfism, retarded mental development, facial puffiness, dry skin, umbilical hernia, lack of muscle coordination
Cushing disease	Hypersecretion of adrenocorticotropic hormone (ACTH)	Caused by adenoma of the anterior pituitary; increased ACTH causes hypersecretion of adrenal cortical hormones, producing *Cushing syndrome*
Cushing syndrome	Hypersecretion (or injection) of glucocorticoids	Metabolic disorder characterized by fat deposits on upper back, striated pad of fat on chest and abdomen, rounded "moon" face, muscular atrophy, edema, hypokalemia (low blood potassium level), possible abnormal skin pigmentation; occurs in Cushing disease
Diabetes insipidus	Hyposecretion of (or insensitivity to) antidiuretic hormone (ADH)	Metabolic disorder characterized by extreme polyuria (excessive urination) and polydipsia (excessive thirst) because of a decrease in the kidney's retention of water
Gestational diabetes mellitus (GDM)	Temporary decrease in blood levels of insulin during pregnancy	Carbohydrate-metabolism disorder occurring in some pregnant women; characterized by polydipsia, polyuria, overeating, weight loss, fatigue, irritability
Gigantism	Hypersecretion of GH before age 25 years	Condition characterized by extreme skeletal size caused by excess protein anabolism during skeletal development

(continued)

TABLE 19-7 Examples of Endocrine Conditions *(continued)*

CONDITION	MECHANISM	DESCRIPTION
Graves disease	Hypersecretion of thyroid hormone	Inherited, possibly autoimmune disease characterized by hyperthyroidism, exophthalmos (protruding eyes)
Hashimoto disease	Autoimmune damage to thyroid causing hyposecretion of thyroid hormone	Enlargement of thyroid (goiter) is sometimes accompanied by hypothyroidism, typically occurring between ages 30 and 50 years; 20 times more common in females than males
Hyperparathyroidism	Hypersecretion of parathyroid hormone (PTH)	Condition characterized by increased reabsorption of calcium from bone tissue and kidneys and increased absorption by the gastrointestinal tract; produces hypercalcemia, resulting in confusion, anorexia, abdominal pain, muscle pain, and fatigue, possibly progressing to circulatory shock, kidney failure, death
Hyperthyroidism (adult)	Hypersecretion of thyroid hormone	Condition characterized by nervousness, tremor, weight loss, excessive hunger, fatigue, heat intolerance, heart arrhythmia, and diarrhea; caused by a general acceleration of body function
Hypothyroidism (adult)	Hyposecretion of thyroid hormone	Condition characterized by sluggishness, weight gain, skin dryness, constipation, arthritis, and general slowing of body function; may lead to myxedema, coma, or death if untreated
Insulin shock	Hypersecretion (or overdose injection) of insulin, decreased food intake, excessive exercise	Hypoglycemic (low blood glucose) shock characterized by nervousness, sweating and chills, irritability, hunger, and pallor—progressing to convulsion, coma, and death if untreated
Myxedema	Extreme hyposecretion of thyroid hormone during adulthood	Severe form of adult hypothyroidism characterized by edema of the face and extremities; often progressing to coma and death
Osteoporosis	Hyposecretion of estrogen in postmenopausal women	Bone disorder characterized by loss of minerals and collagen from bone matrix, producing holes or porosities that weaken the skeleton
Pituitary dwarfism	Hyposecretion of GH before age 25 years	Condition characterized by reduced skeletal size caused by decreased protein anabolism during skeletal development
Simple goiter	Lack of iodine in diet	Enlargement of thyroid tissue results from the inability of the thyroid to make thyroid hormone because of a lack of iodine; a positive feedback situation develops in which low thyroid hormone levels trigger hypersecretion of thyroid-stimulating hormone (TSH) by pituitary—which stimulates thyroid growth
Sterility	Hyposecretion of sex hormones	Loss of reproductive function
Type 1 diabetes mellitus	Hyposecretion of insulin	Inherited condition with sudden childhood onset characterized by polydipsia, polyuria, overeating, weight loss, fatigue, and irritability, resulting from the inability of cells to secure and metabolize carbohydrates
Type 2 diabetes mellitus	Insensitivity of target cells to insulin	Carbohydrate-metabolism disorder with slow adulthood onset thought to be caused by a combination of genetic and environmental factors and characterized by polydipsia, polyuria, overeating, weight loss, fatigue, irritability
Winter (seasonal) depression	Hypersecretion of (or hypersensitivity to) melatonin	Abnormal emotional state characterized by sadness and melancholy resulting from exaggerated melatonin effects; melatonin levels are inhibited by sunlight so they increase when day length decreases during winter

CASE study

"Why are you so grumpy lately?" Sharon was the third person to ask that in the past week. When she stopped to think about it, Cara realized that she had been getting angry at what should be minor issues. "I just need to get more sleep," she thought. But that didn't really make sense either. She'd been getting about 9 hours of sleep each night, but could still barely keep her eyes open during dinner. Her annual check-up was coming up in a few days. She would ask her doctor about it then.

At the doctor's office, Cara filled out the usual paperwork, checking off symptoms that she had recently noted: fatigue, increased urination, irritability, back ache.

1. Increased urination is a symptom associated with which endocrine disorder?
   a. Diabetes mellitus
   b. Acromegaly
   c. Hyperthyroidism
   d. Cretinism

The nurse called Cara in to take her vital signs and weight. Cara was surprised to see that she had gained several pounds because her arms felt so thin. Her blood pressure was much higher than usual too. "How long have you had that cut on your hand?" the nurse asked. Cara

CASE study *(continued)*

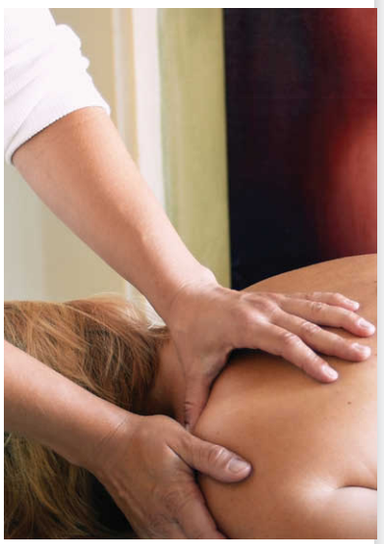
replied that she had cut her hand about 3 days before. She was a little concerned because it wasn't healing very quickly.

2. Which hormone alteration could possibly cause weight gain (in the trunk area), increased blood pressure, and slowed healing?
   a. Insulin
   b. Cortisol
   c. Thyroid hormone
   d. Testosterone
3. Which condition would you choose as a diagnosis?
   a. Addison disease
   b. Graves disease
   c. Hashimoto disease
   d. Cushing syndrome
4. One of the most common causes of Cara's condition is a tumor in the anterior pituitary gland. If this is the case for Cara, what will her blood levels show?
   a. Increased CRH; increased ACTH; increased cortisol
   b. Increased CRH; decreased ACTH; increased cortisol
   c. Decreased CRH; increased ACTH; increased cortisol
   d. Decreased CRH; decreased ACTH; increased cortisol

HINT *To solve a case study, you may have to refer to the glossary or index, other chapters in this textbook, **A&P Connect,** and other resources.*

CAREER choices

Mark Alderman, BS, DC



Chiropractor

Chiropractic is a holistic approach to health and illness (the absence of health), recognizing the body's inherent ability to heal itself during times of physical, mental, and environmental stress. I chose to be a Doctor of Chiropractic because I like the mind-body connection concept. I believe health comes from within, not from outside the body with potions and pills. Many chiropractic and medical studies have proven the effectiveness of chiropractic care. I was an athlete with many biomechanical problems, and traditional approaches did not help. Eventually I tried chiropractic, and it worked! Great thinkers such as Hippocrates wrote, "Look well to the spine for the cause of disease." Thomas Edison said, "The doctor of the future will give no medicines, but will interest his patients in the care of the human frame, in diet, and the cause and prevention of disease." I chose to practice in a small-town setting, in a suburb of Philadelphia called Media, Pennsylvania.

D.D. Palmer founded chiropractic back in 1885 in Davenport, Iowa. Chiropractic now enjoys worldwide acceptance by medical professionals. Chiropractic is the second largest health care profession in the world. Currently, there are more than 65,000 chiropractors worldwide. I feel chiropractic will continue to grow and be even further accepted as long as people understand that health does not come from a bottle or a pill but from within.

The reward of chiropractic is quite clear—it helps patients return to their optimum potential for health. Chiropractic is not a treatment for disease. The purpose of the chiropractic adjustment is to allow the inborn intelligence within the body to be more fully expressed. When the innate (inborn) intelligence within the body is fully expressed, the body functions at its maximum potential for health and healing. To see this occur is the biggest reward for me!

Chiropractors use anatomy and physiology in everyday practice. We use the five components of subluxation that affect the physiology of the body. **Kinesiopathology** deals with the biomechanics, *neuropathology* deals with the nerves, **myopathology** deals with the muscles, *histopathology* deals with the cells, and finally, we use the biochemical system. Chiropractic is concerned with the relationship of the spinal column and the musculoskeletal structures of the body to the nervous system. Proper alignment of the spinal column is essential for optimum health because the spine acts as a "switchboard" for the nervous system. When there is nerve interference caused by misalignment in the spine, known as subluxation, pain can occur, and the body's natural defenses are diminished. The chiropractor adjusts the spinal joints to remove subluxation and restore normal nerve function.

The education of the chiropractor is long and challenging. First you must go to undergraduate school to obtain a bachelor of science (B.S.) degree. Then you attend chiropractic school for another 4 years (8 years is a big commitment!). To receive a Doctor of Chiropractic, you have to take four national boards and a state board in the state in which you wish to practice.

HINT

Scan this summary after reading the chapter to help you reinforce the key concepts. Later, use the summary as a quick review before your class or before a test.

PITUITARY GLAND

A. Structure of the pituitary gland
   1. Formerly known as *hypophysis*
   2. Size: 1.2 to 1.5 cm (about 1.2 inches) across; weight: 0.5 gram (1.60 ounce)
   3. Located on the ventral surface of the brain within the skull (Figure 19-1)
   4. Infundibulum—stemlike stalk that connects pituitary to the hypothalamus
   5. Made up of two separate glands, the adenohypophysis (anterior pituitary gland) and the neurohypophysis (posterior pituitary gland)

B. Adenohypophysis (anterior lobe of pituitary)
   1. Divided into two parts
      a. Pars anterior—forms the major portion of the adenohypophysis
      b. Pars intermedia
   2. Tissue composed of irregular clumps of secretory cells supported by fine connective tissue fibers and surrounded by a rich vascular network
   3. Three types of cells can be identified according to their affinity for certain stains (Figure 19-2)
      a. Chromophobes—do not stain
      b. Acidophils—stain with acid stains
      c. Basophils—stain with basic stains
   4. Five functional types of secretory cells exist
      a. Somatotrophs—secrete GH
      b. Corticotrophs—secrete ACTH
      c. Thyrotrophs—secrete TSH
      d. Lactotrophs—secrete prolactin (PRL)
      e. Gonadotrophs—secrete LH and FSH
   5. Growth hormone (GH) (Figure 19-3; Table 19-2)
      a. Also known as somatotropin (STH)
      b. Promotes growth of bone, muscle, and other tissues by accelerating amino acid transport into the cells
      c. Stimulates fat metabolism by mobilizing lipids from storage in adipose cells and speeding up catabolism of the lipids after they have entered another cell
      d. GH tends to shift cell chemistry away from glucose catabolism and toward lipid catabolism as an energy source; this leads to increased blood glucose levels
      e. GH functions as an insulin antagonist and is vital to maintaining homeostasis of blood glucose levels
   6. Prolactin (PRL; Table 19-2)
      a. Produced by acidophils in the pars anterior
      b. Also known as *lactogenic hormone*
      c. During pregnancy, PRL promotes development of the breasts, anticipating milk secretion; after the baby is born, PRL stimulates the mother's mammary glands to produce milk
   7. Tropic hormones—hormones that have a stimulating effect on other endocrine glands; four principal tropic hormones are produced and secreted by the basophils of the pars anterior (Table 19-2)
      a. Thyroid-stimulating hormone (TSH), or thyrotropin—promotes and maintains the growth and development of the thyroid; also causes the thyroid to secrete its hormones
      b. Adrenocorticotropic hormone (ACTH), or adrenocorticotropin—promotes and maintains normal growth and development of the cortex of the adrenal gland; also stimulates the adrenal cortex to secrete some of its hormones
      c. Follicle-stimulating hormone (FSH)—in the female, stimulates primary follicles to grow toward maturity; also stimulates the follicle cells to secrete estrogens; in the male, FSH stimulates the development of the seminiferous tubules of the testes and maintains spermatogenesis
      d. Luteinizing hormone (LH)—in the female, stimulates the formation and activity of the corpus luteum of the ovary; corpus luteum secretes progesterone and estrogens when stimulated by LH; LH also supports FSH in stimulating maturation of follicles; in the male, LH stimulates interstitial cells in the testes to develop and secrete testosterone; FSH and LH are called *gonadotropins* because they stimulate the growth and maintenance of the gonads
   8. Control of secretion in the adenohypophysis
      a. Hypothalamus secretes releasing hormones into the blood, which are then carried to the hypophyseal portal system (Figure 19-5; Table 19-1)
      b. Hypophyseal portal system carries blood from the hypothalamus directly to the adenohypophysis, where the target cells of the releasing hormones are located (Figure 19-4)
      c. Releasing hormones influence the secretion of hormones by acidophils and basophils
      d. Through negative feedback, the hypothalamus adjusts the secretions of the adenohypophysis, which then adjusts the secretions of the target glands that in turn adjust the activity of their target tissues (Figure 19-6)
      e. Minute-by-minute variations in hormone secretion can exhibit occasional large peaks, caused by pulse in releasing hormone secretion by the hypothalamus (Figure 19-7)
      f. In stress, the hypothalamus translates nerve impulses into hormone secretions by endocrine glands, basically creating a mind-body link

C. Neurohypophysis (posterior lobe of pituitary)
   1. Serves as storage and release site for antidiuretic hormone (ADH) and oxytocin (OT), which are synthesized in the hypothalamus (Figure 19-8; Table 19-2)
   2. Release of ADH and OT into the blood is controlled by nervous stimulation

3. Antidiuretic hormone (ADH)
   a. Prevents the formation of a large volume of urine, thereby helping the body conserve water
   b. Causes a portion of each tubule in the kidney to reabsorb water from the urine it is forming
   c. Dehydration triggers the release of ADH
   d. Also called arginine vasopressin (AVP) because it stimulates a rise in blood pressure, partly by increasing contraction in small arteries
4. Oxytocin (OT)—has at least two primary actions
   a. Causes milk ejection from the lactating breast; regulated by positive feedback mechanism; PRL cooperates with oxytocin
   b. Stimulates contraction of uterine muscles that occurs during and after childbirth; regulated by positive feedback mechanism
   c. Involved in sexual arousal and social bonding

PINEAL GLAND

A. Tiny, pine cone–shaped structure located on the dorsal aspect of the brain's diencephalons
B. Member of the nervous system because it receives visual stimuli and also a member of the endocrine system because it secretes hormones
C. Pineal gland supports the body's biological clock
D. Principal pineal secretion is melatonin (Table 19-6)

THYROID GLAND

A. Structure of the thyroid gland
   1. Made up of two large lateral lobes and a narrow connecting isthmus (Figure 19-9)
   2. A thin, wormlike projection of thyroid tissue often extends upward from the isthmus
   3. Weight of the thyroid in an adult is approximately 30 grams (1 ounce)
   4. Located in the neck, on the anterior and lateral surfaces of the trachea, just below the larynx
   5. Composed of follicles (Figure 19-10)
      a. Small, hollow spheres
      b. Filled with thyroid colloid that contains thyroglobulins
B. Thyroid hormone (Figure 19-11; Table 19-3)
   1. Actually two different hormones
      a. Tetraiodothyronine (T_4), or thyroxine—contains four iodine atoms; approximately 20 times more abundant than T_3; major importance is as a precursor to T_3
      b. Triiodothyronine (T_3)—contains three iodine atoms; considered to be the principal thyroid hormone; T_3 binds efficiently to nuclear receptors in target cells
   2. Thyroid gland stores considerable amounts of a preliminary form of its hormones *before* secreting them
   3. Before being stored in the colloid of follicles, T_3 and T_4 are attached to globulin molecules, forming thyroglobin complexes
   4. Before release, T_3 and T_4 detach from globulin and enter the bloodstream
   5. Once in the blood, T_3 and T_4 attach to a plasma protein called *thyroid-binding globulins (TBGs)* and travel as a hormone-globulin complex
   6. T_3 and, to a lesser extent, T_4 detach from plasma globulin as they near the target cells
   7. Thyroid hormone—helps regulate the metabolic rate of all cells and cell growth and tissue differentiation; it is said to have a "general" target
C. Calcitonin (CT) (Table 19-3)
   1. Produced by thyroid gland in the parafollicular cells
   2. In humans, CT may subtly influence the processing of calcium by bone cells by decreasing blood calcium levels and promoting conservation of hard bone matrix
   3. Parathyroid hormone acts as antagonist to calcitonin to maintain calcium homeostasis

PARATHYROID GLANDS

A. Structure of the parathyroid glands
   1. Four or five parathyroid glands embedded in the posterior surface of the thyroid's lateral lobes (Figure 19-12)
   2. Tiny, rounded bodies within thyroid tissue formed by compact, irregular rows of cells (Figure 19-13)
B. Parathyroid hormone (PTH) (Table 19-3)
   1. PTH is an antagonist to calcitonin and is the primary hormone to maintain calcium homeostasis (Figure 19-14)
   2. PTH acts on bone and kidney
      a. Causes more bone to be dissolved, yielding calcium and phosphate, which enters the bloodstream
      b. Causes phosphate to be secreted by the kidney cells into the urine to be excreted
      c. Causes increased intestinal absorption of calcium by stimulating the kidney to produce active vitamin D, which increases calcium absorption in gut

ADRENAL GLANDS

A. Structure of the adrenal glands
   1. Located on top of the kidneys, fitting like caps (Figure 19-15)
   2. Made up of two portions (Figure 19-16; Table 19-4)
      a. Adrenal cortex—composed of endocrine tissue (Figure 19-17)
      b. Adrenal medulla—composed of neurosecretory tissue
B. Adrenal cortex—all cortical hormones are steroids and known as *corticosteroids* (Figure 19-18)
   1. Composed of three distinct layers of secreting cells
      a. Zona glomerulosa—outermost layer, directly under the outer connective tissue capsule of the adrenal gland; secretes mineralocorticoids
      b. Zona fasciculata—middle layer; secretes glucocorticoids
      c. Zona reticularis—inner layer; secretes small amounts of glucocorticoids and gonadocorticoids
   2. Mineralocorticoids
      a. Have an important role in the regulatory process of sodium in the body

b. Aldosterone
(1) Only physiologically important mineralocorticoid in the human; primary function is maintenance of sodium homeostasis in the blood by increasing sodium reabsorption in the kidneys
(2) Aldosterone also increases water retention and promotes the loss of potassium and hydrogen ions
(3) Aldosterone secretion is controlled by the renin-angiotensin-aldosterone system (RAAS) and by blood potassium concentration (Figure 19-19)

3. Glucocorticoids
a. Main glucocorticoids secreted by the zona fasciculata are cortisol, cortisone, and corticosterone, with cortisol the only one secreted in significant quantities
b. Affect every cell in the body
c. Are protein mobilizing, gluconeogenic, and hyperglycemic
d. Tend to cause a shift from carbohydrate catabolism to lipid catabolism as an energy source
e. Essential for maintaining normal blood pressure by aiding norepinephrine and epinephrine to have their full effect, causing vasoconstriction
f. High blood concentration causes eosinopenia and marked atrophy of lymphatic tissues
g. Act with epinephrine to bring about normal recovery from injury produced by inflammatory agents
h. Secretion increases in response to stress
i. Except during stress response, secretion is mainly controlled by a negative feedback mechanism involving ACTH from the adenohypophysis
j. Secretion is characterized by several large pulses of increased hormone levels throughout the day—the largest occurring just before waking (Figure 19-20)

4. Gonadocorticoids—sex hormones (androgens) that are released from the adrenal cortex

C. Adrenal medulla
1. Neurosecretory tissue—tissue composed of neurons that secrete their products into the blood
2. Adrenal medulla secretes two important hormones—epinephrine and norepinephrine; they are part of the class of nonsteroid hormones called *catecholamines*
3. Both hormones bind to the receptors of sympathetic effectors to prolong and enhance the effects of sympathetic stimulation by the ANS (Figure 19-21)

PANCREATIC ISLETS

A. Structure of the pancreatic islets (Figure 19-22)
1. Elongated gland, weighing approximately 100 grams (3.5 ounces); its head lies in the duodenum, extends horizontally behind the stomach, and, then, touches the spleen
2. Composed of endocrine and exocrine tissues
a. Pancreatic islets (islets of Langerhans)—endocrine portion
b. Acini—exocrine portion—secretes a serous fluid containing digestive enzymes into ducts draining into the small intestine
3. Pancreatic islets—each islet contains five primary types of endocrine cells joined by gap junctions (Figure 19-23)
a. Alpha cells (A cells)—secrete glucagon
b. Beta cells (B cells)—secrete insulin; account for up to 75% of all pancreatic islet cells
c. Delta cells (D cells)—secrete somatostatin
d. Pancreatic polypeptide cells (F, or PP, cells)—secrete pancreatic polypeptide
e. Epsilon cells (ε cells)—secrete ghrelin

B. Pancreatic hormones (Table 19-5)—work as a team to maintain homeostasis of food molecules (Figure 19-24)
1. Glucagon—produced by alpha cells; tends to increase blood glucose levels; stimulates gluconeogenesis in liver cells
2. Insulin—produced by beta cells; lowers blood concentration of glucose, amino acids, and fatty acids and promotes their metabolism by tissue cells
3. Somatostatin—produced by delta cells; primary role is regulating the other endocrine cells of the pancreatic islets
4. Pancreatic polypeptide—produced by F (PP) cells; influences the digestion and distribution of food molecules to some degree
5. Ghrelin (GHRL)—hormone secreted by epsilon cells at periphery of pancreatic islets; stimulates hypothalamus to boost appetite; slows metabolism and fat burning; may contribute to obesity

GONADS

A. Testes (Figure 18-2; Table 19-6)
1. Paired organs within the scrotum in the male
2. Composed of seminiferous tubules and a scattering of interstitial cells
3. Testosterone is produced by the interstitial cells and responsible for the growth and maintenance of male sexual characteristics
4. Testosterone secretion is mainly regulated by gonadotropin levels in the blood

B. Ovaries (Figure 18-2; Table 19-6)
1. Primary sex organs in the female
2. Set of paired glands in the pelvis that produce several types of sex hormones
a. Estrogens—steroid hormones secreted by ovarian follicles; promote development and maintenance of female sexual characteristics
b. Progesterone—secreted by corpus luteum; maintains the lining of the uterus necessary for successful pregnancy
c. Ovarian hormone secretion depends on the changing levels of FSH and LH from the adenohypophysis

PLACENTA

A. Tissues that form on the lining of the uterus as a connection between the circulatory systems of the mother and developing child
B. Serves as a temporary endocrine gland that produces human chorionic gonadotropin, estrogens, and progesterone (Table 19-6)

THYMUS

A. Gland located in the mediastinum just beneath the sternum (Figure 18-2)
B. Thymus is large in children, begins to atrophy at puberty, and by old age, is a vestige of fat and fibrous tissue
C. Considered to be primarily a lymphatic organ, but the hormone thymosin has been isolated from thymus tissue (Table 19-6)
D. Thymosin—stimulates development of T cells

GASTRIC AND INTESTINAL MUCOSA

A. The mucous lining of the GI tract contains cells that produce both endocrine and exocrine secretions (Table 19-6)
B. GI hormones, such as gastrin, secretin, and cholecystokinin (CCK), play regulatory roles in coordinating the secretory and motor activities involved in the digestive process
C. Ghrelin (GHRL)—appetite-boosting hormone secreted by endocrine cells in gastric mucosa as well as in pancreatic islets

HEART

A. The heart has a secondary endocrine role
B. Hormone-producing cells produce several atrial natriuretic peptides (ANPs), including atrial natriuretic hormone (ANH) (Table 19-6)
C. ANH's primary effect is to oppose increases in blood volume or blood pressure; also an antagonist to ADH and aldosterone

OTHER ENDOCRINE GLANDS AND ORGANS

A. Major endocrine glands produce more hormones than are outlined in this book (e.g., inhibin secreted by the ovaries) (Table 19-6)
B. Many tissues (perhaps all tissues) produce hormones, most of which are beyond the scope of this book (e.g., leptin and resistin secreted by adipose tissue).

CYCLE OF LIFE: ENDOCRINE SYSTEM

A. Endocrine regulation begins in the womb
B. Many active hormones are active from birth—evidence that a hormonal signal from fetus to mother signals the onset of labor
C. Hormones related to reproduction begin at puberty
D. Secretion of male reproductive hormones—continuous production from puberty, slight decline in late adulthood
E. Secretion of female reproductive hormones declines suddenly and completely in middle adulthood

THE BIG PICTURE: THE ENDOCRINE SYSTEM AND THE WHOLE BODY

A. The endocrine system operates with the nervous system to finely adjust the many processes they regulate
B. Neuroendocrine system adjusts nutrient supply
C. Calcitonin, parathyroid hormone, and vitamin D balance calcium ion use
D. The nervous system and hormones regulate reproduction

REVIEW QUESTIONS

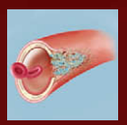
Write out the answers to these questions after reading the chapter and reviewing the Chapter Summary. If you simply think through the answer without writing it down, you won't retain much of your new learning.

1. Name the two subdivisions of the adenohypophysis.
2. Discuss and identify, by staining tendency and relative percentages, the cell types present in the anterior pituitary gland.
3. Discuss the functions of growth hormone.
4. What effect does growth hormone have on blood glucose concentration? Fat mobilization and catabolism? Protein anabolism?
5. List the four tropic hormones secreted by the basophils of the anterior pituitary gland. Which of the tropic hormones are also called *gonadotropins?*
6. How does antidiuretic hormone act to alter urine volume?
7. Describe the positive feedback associated with oxytocin.
8. Discuss the synthesis and storage of thyroxine and triiodothyronine. How are they transported in the blood?
9. Discuss the functions of parathyroid hormone.
10. List the hormones produced by each "zone" of the adrenal cortex, and describe the actions of these hormones.
11. Discuss the normal function of hormones produced by the adrenal medulla.
12. Identify the hormones produced by each of the cell types in the pancreatic islets.
13. Identify the "pregnancy-promoting" hormone.
14. Where is human chorionic gonadotropin produced? What does it do?
15. Describe the role of atrial natriuretic hormone.
16. Identify the conditions resulting from both hypersecretion and hyposecretion of growth hormone during growth years.
17. Describe the face of a patient with Cushing syndrome.
18. How does exercise affect diabetes mellitus?

CRITICAL THINKING QUESTIONS

After finishing the Review Questions, write out the answers to these more in-depth questions to help you apply your new knowledge. Go back to sections of the chapter that relate to concepts that you find difficult.

1. What examples can you find that apply the concept of a negative feedback loop to the regulation of hormone secretion?
2. A hyposecretion of which hormone would make it difficult for a mother to nurse her child? How would you summarize the effects of this hormone?
3. Why do you think the hypothalamus can be called the "mind-body link"?
4. How would you explain the hormonal interaction that helps maintain the set point value for the glucose in the blood?
5. Explain how the cell is able to become more or less sensitive to a specific hormone.
6. What is the relationship between increased blood level concentrations of FSH and menopause?
7. A lack of iodine in the diet will cause a simple goiter. Describe the feedback loop that will cause its formation.
8. A friend of yours is considering the use of anabolic steroids. Based on what you know of their effects, how would you explain why using these steroids could be harmful?



Unit Four

Transportation and Defense

The chapters in Unit Four are concerned with transportation, how the body defends itself, and stress. Blood (Chapter 20), a complex fluid tissue, is discussed and the text explains how blood serves to transport respiratory gases and key nutrients to cells and carry away wastes. The body's blood fills the cardiovascular system (Chapters 21 and 22) and is moved through a closed pathway, or circuit, of vessels by the pumping action of the heart.

The elements of the lymphatic system (Chapter 23) provide an open pathway for return of fluid and proteins from the interstitial spaces and for fats, which are absorbed from the intestine into the general circulation. The lymphatic system is also involved in immunity or resistance to disease and in the removal and destruction of dead red blood cells. The immune system is more fully discussed in Chapter 24. Elements of the immune system provide a multilayered defense mechanism, involving both phagocytic cells and defensive proteins called *antibodies.* Stress—and the body's frequently maladaptive response to it—is discussed in Chapter 25.

The Big Picture: Blood and the Whole Body, 619

Mechanisms of Disease, 619

Case Study, 625

Four chapters in this unit deal with transportation, one of the body's vital functions. Homeostasis of the internal environment—and therefore survival itself—depend on continual transportation to and from body cells. This chapter discusses the major transportation fluid, blood. Chapters 21 and 22 consider the major transportation system, the cardiovascular system, and Chapter 23 explains a supplementary drainage system, the lymphatic system.

COMPOSITION OF BLOOD

Blood is much more than the simple liquid it seems to be. It consists of not only a fluid but also cells, including *thrombocytes (platelets)*. The fluid portion of blood, that is, the **plasma,** is one of the three major body fluids (interstitial and intracellular fluids are the other two). As explained below, the quantity of whole blood found in the body (blood volume) is often expressed as a percent of total body weight. However, the measurement of the plasma and formed elements is generally expressed as a percent of the *whole blood volume*. Using these measurement criteria, whole blood constitutes about 8% of total body weight, plasma accounts for 55%, and the formed elements account for about 45% of the total blood volume (Figure 20-1). The term **formed elements** is used to designate the various kinds of blood cells that are normally present in blood.

Blood is a complex transport medium that performs vital pickup and delivery services for the body. It picks up food and oxygen from the digestive and respiratory systems and delivers them to cells while also picking up wastes from cells for delivery to excretory organs. Blood also transports hormones, enzymes, buffers, and various other biochemical substances that serve important functions. Blood serves another critical function. It is the keystone of the body's heat-regulating mechanism. Certain physical properties of blood make it especially effective in this role. Its high specific heat and conductivity enable this unique fluid to absorb large quantities of heat without an appreciable increase in its own temperature and to transfer this absorbed heat from the core of the body to its surface, where the heat can be more readily dissipated (see Figure 7-15, p. 183).

Blood Volume

How much blood does the body contain? The answer is about 8% of total body weight in average-sized adults. In a healthy young female, that amounts to about 4 to 5 liters and in a male about 5 to 6 liters. In addition to gender differences, blood volume varies with age, body composition, and method of measurement. A *unit* of blood is the amount (0.45 liter or just under 1 pint) that is collected from a blood donor for transfusion purposes. It constitutes about 10% of total blood volume in many adults.

Blood volume can be determined using direct methods or indirect methods of measurement. *Direct* measurement of total blood volume can be accomplished only by complete removal of all blood from an experimental animal. In humans, *indirect* methods of measurement that employ "tagging" of red blood cells or plasma components with radioisotopes are used. The principle is simply to introduce a known amount of radioisotope into the circulation, allow the material to be distributed uniformly

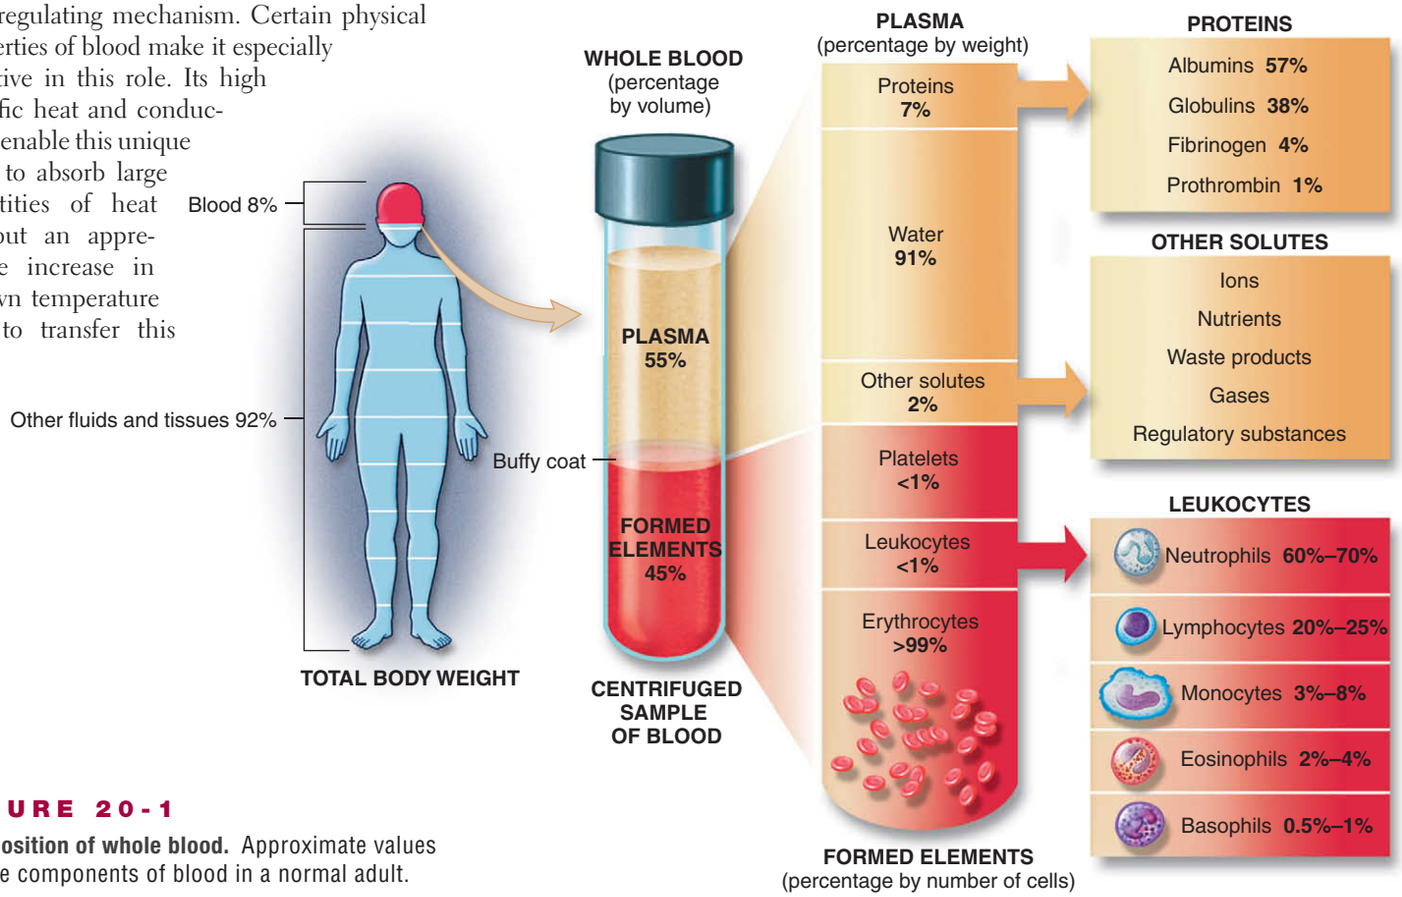

FIGURE 20-1

Composition of whole blood. Approximate values for the components of blood in a normal adult.

throughout the blood, and then analyze its concentration in a representative blood sample. Having an accurate measurement is important in replacing blood lost because of hemorrhage or in treating other serious conditions such as shock.

One of the chief variables influencing normal blood volume is the amount of body fat. Blood volume per kilogram of body weight varies inversely with the amount of excess body fat. This means that the less fat there is in your body, the more blood you have per kilogram of your body weight. Because females normally have a higher percent of body fat than males, they have less blood per kilogram of body weight and therefore a lower blood volume.

FORMED ELEMENTS OF BLOOD

Figure 20-2 illustrates the formed elements of blood. They are as follows:

- Red blood cells (RBCs) (erythrocytes)
- White blood cells (WBCs) (leukocytes)
- Platelets (thrombocytes)

Plasma, when separated from "whole blood," is a clear straw-colored fluid that consists of about 90% water and 10% solutes. *Blood transfusions* most often involve three major blood components—plasma, platelets, and red blood cells. In the United States, red blood cells constitute about 13.5 million transfusions compared with 1.75 million transfusions of platelets and 3.5 million transfusions of plasma each year.

evolve

If a tube of whole blood, that is, plasma and formed elements, is allowed to stand or is spun in a centrifuge, separation will occur. The term **packed cell volume (PCV),** or **hematocrit** (hee-MAT-oh-krit),

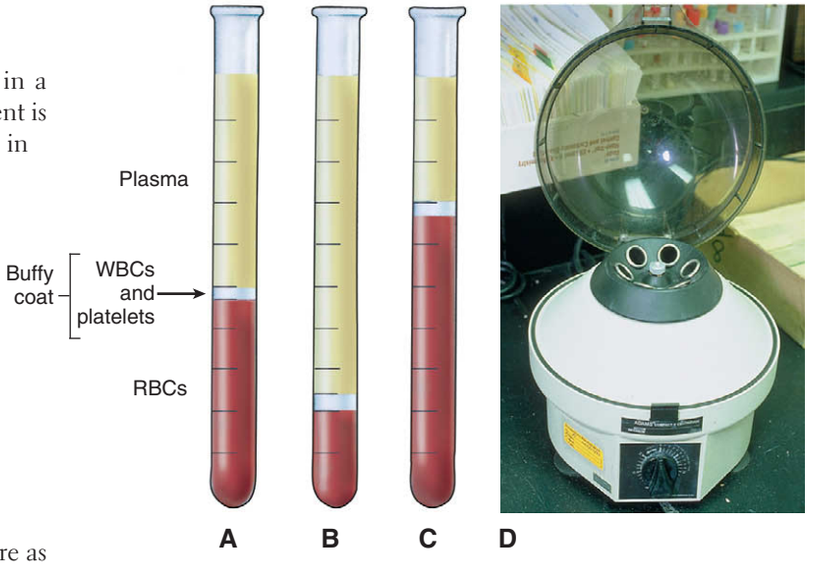

FIGURE 20-3

Hematocrit tubes showing normal blood, anemia, and polycythemia. Note the buffy coat located between the packed RBCs and the plasma. **A,** A normal percent of red blood cells. **B,** Anemia (a low percent of red blood cells). **C,** Polycythemia (a high percent of red blood cells). **D,** Centrifuge used to spin tubes of whole blood and thereby separate blood solids from plasma.

is used to describe the volume percent of red blood cells (RBCs) in whole blood. In Figure 20-3, *A*, a sample of normal whole blood has been separated by spinning in a centrifuge so that the formed elements are forced to the bottom. The percentage of plasma is about 55% of the total sample, whereas the packed cell volume, or hematocrit, is 45%. A hematocrit of 45% means that in every 100 ml of whole blood there are 45 ml of RBCs and 55 ml of fluid plasma.

Normally the average hematocrit for a man is about 45% (40% to 54%, normal range) and for a woman about 42% (38% to 47%, normal range). Conditions that result in decreased RBC numbers (Figure 20-3, *B*) are called **anemias** and are characterized by a reduced hematocrit value. Healthy individuals who live and work in high altitudes often have elevated RBC numbers and hematocrit values (Figure 20-3, *C*). The condition is called **physiological polycythemia** (from word parts meaning "condition of many blood cells").

Box 20-1 describes another clinical blood test that involves separating RBCs from plasma.

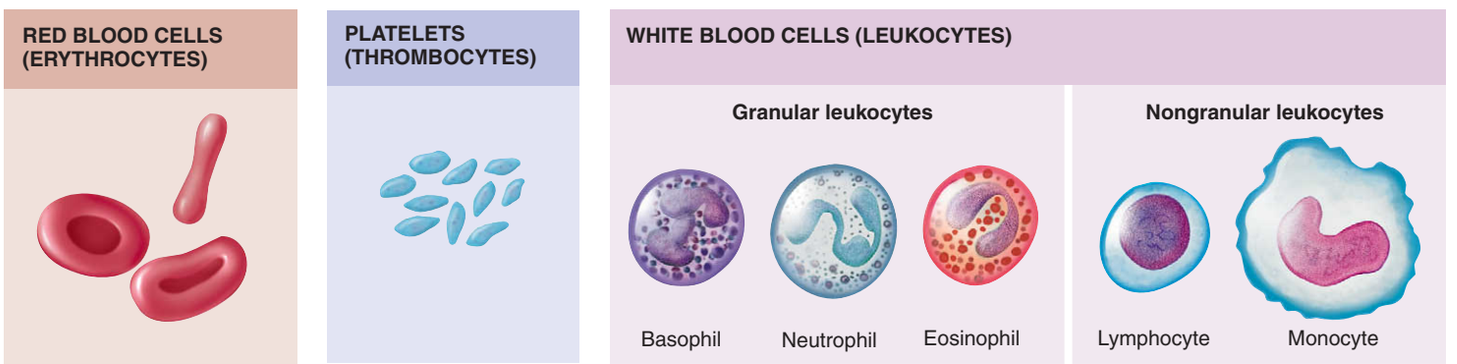

FIGURE 20-2

The formed elements of blood. Red blood cells (erythrocytes), white blood cells (leukocytes), and platelets (thrombocytes) constitute the formed elements of blood.

Box 20-1 | DIAGNOSTIC study

Erythrocyte Sedimentation Rate

If a tube of anticoagulated blood from a healthy individual is allowed to stand upright for an hour, gravity will cause sedimentation of the formed elements leaving a layer of clear plasma about 15 mm thick on top of the tube. The rate of fall in 1 hour is called the **erythrocyte sedimentation rate,** or **ESR.**

In individuals suffering from some type of inflammatory process, the clear layer on top of the ESR tube at the end of an hour is often over 40 mm thick. The increased ESR is due to the liver secreting into the circulation a number of large proteins that assist the body in responding to the inflammation. In addition to their large size and high molecular weight, these proteins also cause RBCs to "cluster," thus effectively increasing blood density. The result is an elevated ESR. The ESR is a "nonspecific" medical test because an increase will occur as a result of many different inflammatory conditions. Although the test cannot identify a specific disease, it is widely used by clinicians because it is a safe, easily performed, and cost-effective procedure that provides useful information early in the diagnostic process. For example, it is often used to make an initial determination concerning the possibility of inflammation as the cause of nonspecific complaints such as generalized fatigue, or weakness. If the presence of an inflammatory process is confirmed by an elevated ESR, more specific diagnostic tests can be used to identify the cause.

White blood cells (WBCs), or leukocytes, and platelets make up less than 1% of blood volume. Note in Figure 20-3 that a thin white layer of leukocytes and platelets, called the **buffy coat,** is present at the interface between the packed red cells and plasma.

1. Name the fluid portion of whole blood.
2. What constitutes the formed elements of blood?
3. What factors influence blood volume?
4. Identify the component percentages of the normal hematocrit.

Red Blood Cells (Erythrocytes)

A normal, mature RBC has no nucleus and is only about 7.5 µm in diameter. More than 1500 of them could be placed side by side in a 1 cm space. Before the cell reaches maturity and enters the bloodstream from the bone marrow, the nucleus is extruded. As you can see in Figure 20-4, normal, mature RBCs are shaped like tiny biconcave disks.

The mature **erythrocyte** is also unique in that it does not contain ribosomes, mitochondria, and other organelles typical of most body cells. Instead, the primary component of each RBC is the red protein pigment, **hemoglobin.** It accounts for more than one third of the cell volume and is critically important to its primary function.

The depression on each flat surface of the cell results in a thin center and thicker edges. This unique shape of the RBC gives it a very large surface area relative to its volume. The shape of erythrocytes can passively change as they forcibly pass through blood capillaries that often are smaller than the typical 7.5 µm diameter of an erythrocyte.

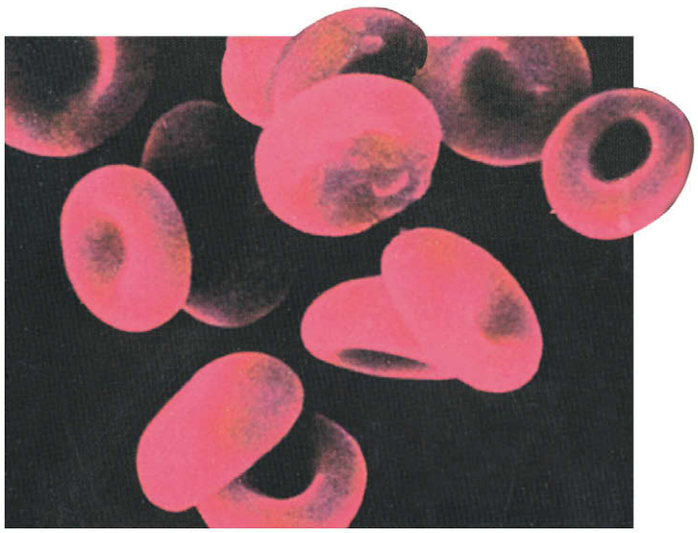

FIGURE 20-4

Erythrocytes. Color-enhanced scanning electron micrograph shows normal erythrocytes.

The flexibility of RBC shape is possible because of the presence of stretchable fibers composed of a unique protein called *spectrin.* These fibers, which are part of the cytoskeleton, adhere to the inside of the erythrocyte plasma membrane. It is the presence of flexible spectrin fibers that permits the plasma membrane surrounding the RBC to accommodate change from a more typical biconcave shape to a smaller cup-shaped cell size and then back to its normal size and appearance when deforming pressures are no longer being applied to the surface of the plasma membrane. This ability to change shape is necessary for the survival of RBCs, which are under almost constant mechanical shearing and bursting strains as they pass through the capillary system. In addition, the degree of cell deformity that is possible influences the speed of blood flow in the microcirculation.

RBCs are the most numerous of the formed elements in the blood. In men, RBC counts average about 5,500,000 per cubic millimeter (mm^3) of blood; in women, 4,800,000/mm^3. Gender differences in RBC numbers may be influenced by the stimulating effect of the male sex hormone testosterone on RBC production. RBC numbers in females are normally lower than those in males.

evolve

FUNCTION OF RED BLOOD CELLS

RBCs play a critical role in the transport of oxygen and carbon dioxide in the body. Chapter 27 includes a detailed discussion of how oxygen is transported from air in the lungs to the body

cells and how carbon dioxide moves from body cells to the lungs for removal. Both of these functions depend on hemoglobin. In addition to hemoglobin, the presence of an enzyme, **carbonic anhydrase (CA),** in RBCs catalyzes a reaction that joins carbon dioxide and water to form carbonic acid. Dissociation of the acid then generates **bicarbonate ions** (HCO_3^-) and hydrogen ions (H^+), which diffuse out of the RBCs. Because carbon dioxide (CO_2) is chemically incorporated into the newly formed bicarbonate ions, it can be transported in this new form in the blood plasma until it is excreted from the body. Bicarbonate ions also have an important role in maintaining normal blood pH levels (see Chapter 33).

Considered together, the total surface area of all the RBCs in an adult is enormous. It provides an area larger than a football field for the exchange of respiratory gases between hemoglobin found in circulating erythrocytes and interstitial fluid that bathes the body cells. This is an excellent example of the relationship between form and function.

HEMOGLOBIN

Packed within each RBC are an estimated 200 to 300 million molecules of hemoglobin, which make up about 95% of the dry weight of each cell. Each hemoglobin molecule is composed of four protein chains. Each chain, called a **globin,** is bound to a red pigment, identified in Figure 20-5, as a **heme** group. Each heme group contains one iron atom. Therefore one hemoglobin molecule contains four iron atoms. This structural fact enables one hemoglobin molecule to unite with four oxygen molecules to form *oxyhemoglobin* (a reversible reaction). Hemoglobin can also combine with carbon dioxide to form *carbaminohemoglobin* (also reversible). But in this reaction the structure of the globin part of the hemoglobin molecule, rather than its heme part, makes the combining possible.

A man's blood usually contains more hemoglobin than a woman's. In most normal men, 100 ml of blood contains 14 to 16 grams of hemoglobin. The normal hemoglobin content of a woman's blood is a little less—specifically, in the range of 12 to 14 grams/100 ml. Recall that testosterone in the male tends to stimulate erythrocyte production and cause an increase in RBC numbers. Increased levels of hemoglobin in males are directly related to increased erythrocyte numbers.

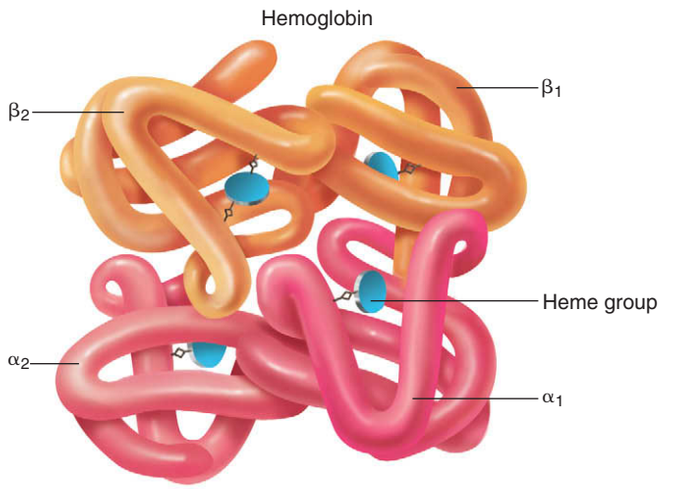

FIGURE 20-5

Hemoglobin. Four protein chains (globins), each with a heme group, form a hemoglobin molecule. Each heme contains one iron atom.

An adult who has a hemoglobin content of less than 10 grams/100 ml of blood is diagnosed as having **anemia.** If you dissect the word parts, you see that *anemia* literally means "lack of blood." The term *anemia* also may be used to describe a reduction in the number or volume of functional RBCs in a given unit of whole blood. Anemias are classified according to the size and hemoglobin content of RBCs. Box 20-2 describes a type of anemia that results from production of an abnormal type of hemoglobin.

FORMATION OF RED BLOOD CELLS

The entire process of RBC formation is called **erythropoiesis.** In the adult, erythrocytes begin their maturation sequence in the red bone marrow from nucleated cells known as **hematopoietic stem cells,** or adult blood-forming stem cells. *Adult stem cells* are cells that have the ability to maintain a constant population of newly differentiating cells of a specific type. These adult blood-forming stem cells divide by mitosis; some of the daughter cells remain as undifferentiated adult stem cells, whereas others go through several stages of development to become erythrocytes. Figure 20-6 shows

Box 20-2 | FYI

Sickle cell anemia.

Sickle cell anemia.

Sickle cell anemia is a severe, sometimes fatal, hereditary disease that is characterized by an abnormal type of hemoglobin. A person who inherits only one defective gene develops a form of the disease called *sickle cell trait,* in which red blood cells contain a small proportion of a hemoglobin type that is less soluble than normal. This hemoglobin forms solid crystals when the blood oxygen level is low, causing distortion and fragility of the red blood cell. If two defective genes are inherited (one from each parent), more of the defective hemoglobin is produced, and the distortion of red blood cells becomes severe. In the United States, about 1 in every 500 African-American and 1 in every 1000 Hispanic newborns are affected each year. In these individuals, the distorted red blood cell membranes can be damaged by drastic changes in shape. Red blood cells damaged in this way tend to stick to vessel walls, and if a blood vessel in the brain is affected, a stroke may occur because of the decrease in blood flow velocity or blockage of blood flow.

Stroke is one of the most devastating problems associated with sickle cell anemia in children and will affect about 10% of the 2500 youngsters who have the disease in the United States. Studies have shown that frequent blood transfusions in addition to standard care can dramatically reduce the risk of stroke in many children suffering from sickle cell anemia. Recent advances in bone marrow transplants in children and hemopoietic stem cell transplants in adults show the promise of long-term reversal of the effects of sickle cell anemia.

The illustration shows the characteristic shape of a red cell containing the abnormal hemoglobin.

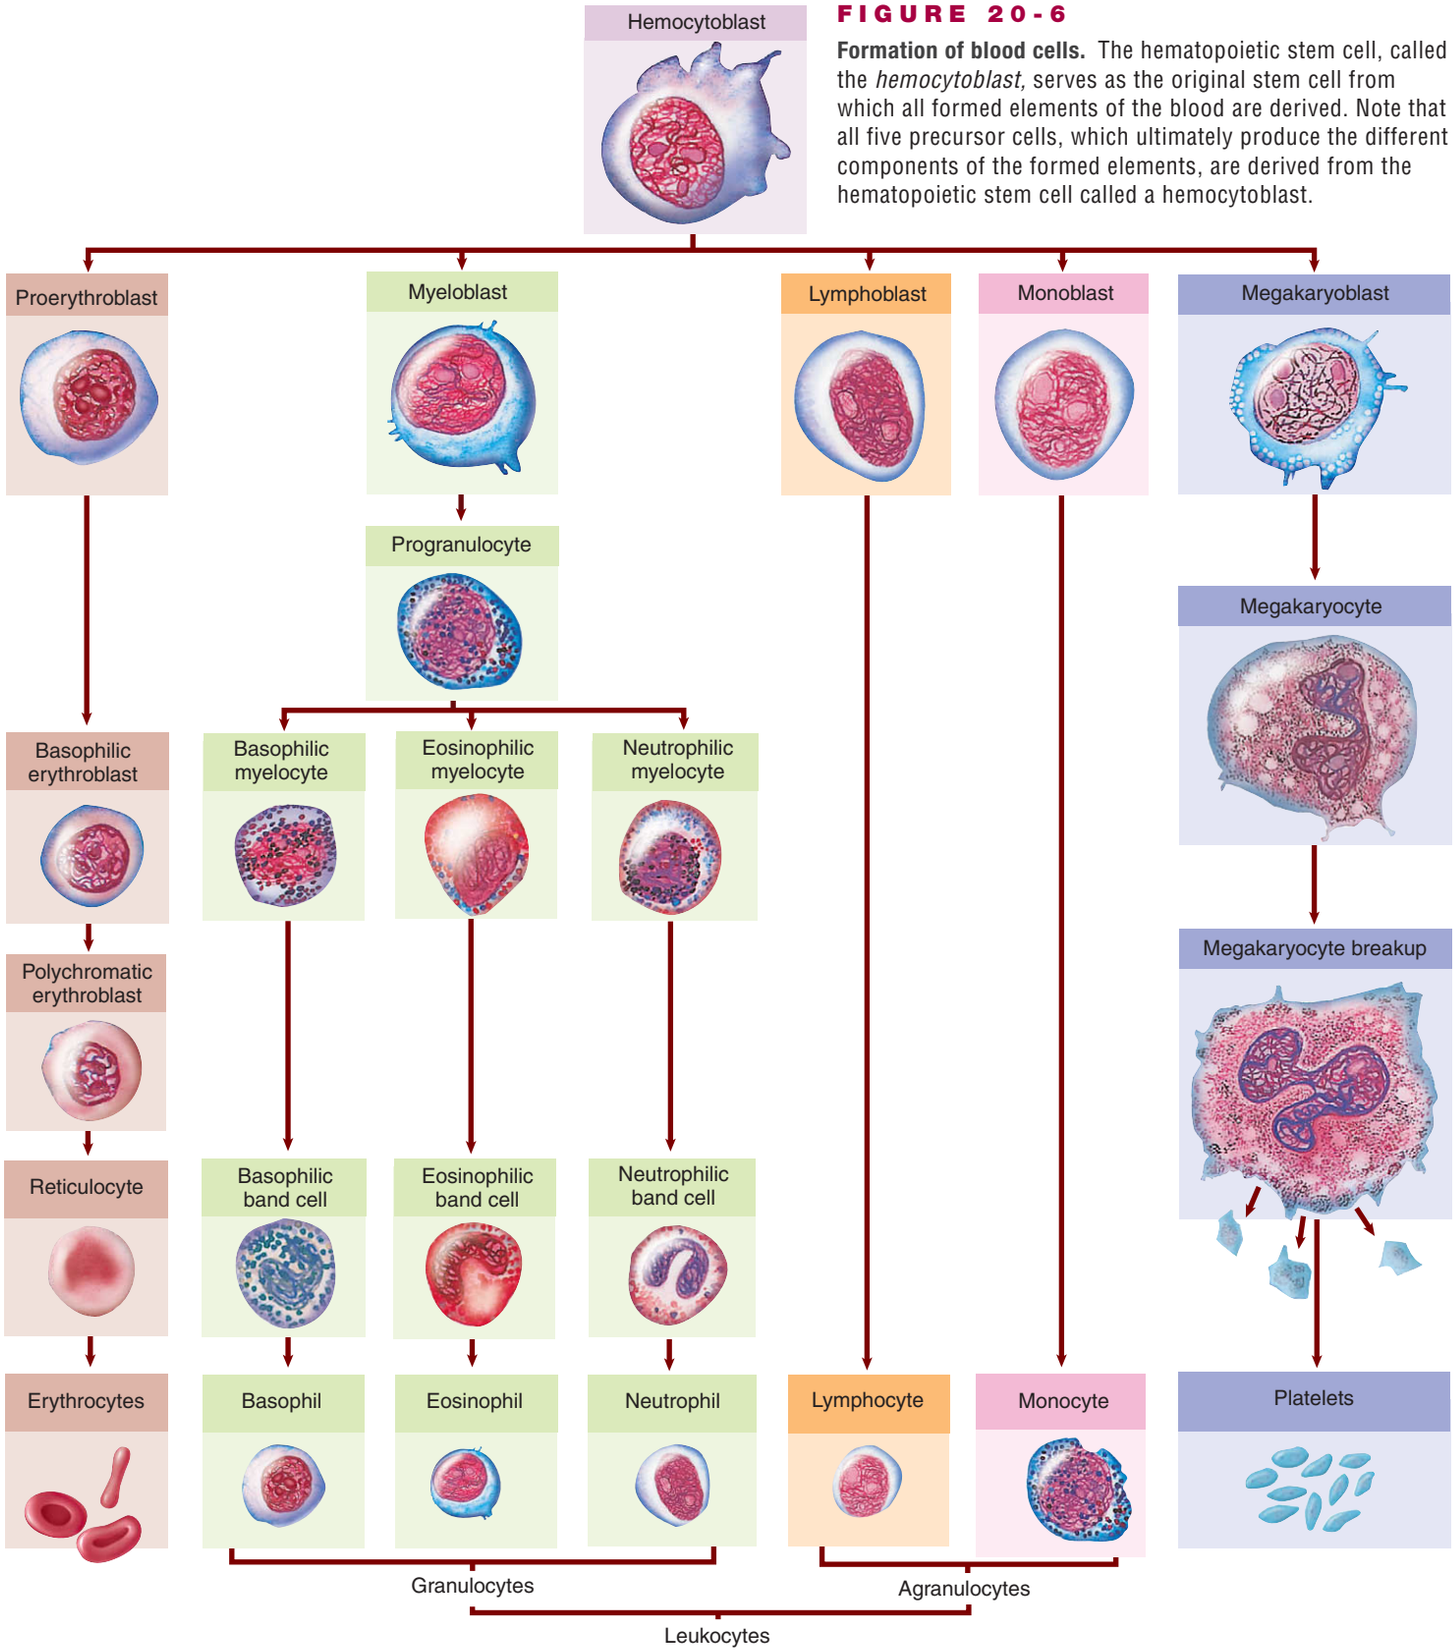

FIGURE 20-6

Formation of blood cells. The hematopoietic stem cell, called the *hemocytoblast,* serves as the original stem cell from which all formed elements of the blood are derived. Note that all five precursor cells, which ultimately produce the different components of the formed elements, are derived from the hematopoietic stem cell called a hemocytoblast.

the developmental stages that can be identified as transformation from the immature forms to the mature red blood cell occurs. The entire maturation process requires about 4 days and proceeds from step to step by gradual transition. Just what influences direct **embryonic stem cells** (found in the embryo and in umbilical cord blood) to develop into a specific type of **adult stem cell** (e.g., hematopoietic stem cells) and then eventually differentiate into a specific cell type, such as an RBC, is a topic of intense research.

As you can see in Figure 20-6, all blood cells are derived from hematopoietic stem cells. In RBCs, differentiation begins with the appearance of **proerythroblasts.** Mitotic divisions then produce

basophilic erythroblasts. The next maturation division produces **polychromatic erythroblasts,** which produce hemoglobin. These cells subsequently lose their nuclei and become **reticulocytes.** Once released into the circulating blood, reticulocytes lose their delicate reticulum and become mature erythrocytes in about 24 to 36 hours. Note in Figure 20-6 that overall cell size decreases as the maturation sequence progresses.

RBCs are formed and destroyed at a breathtaking rate. Every day of our adult lives we produce more than 200 billion RBCs to replace an equal number destroyed during that brief time. Because in health the number of RBCs remains relatively constant, efficient homeostatic mechanisms must operate to balance the number of cells formed against the number destroyed.

The rate of RBC production soon speeds up if blood oxygen levels reaching the tissues decrease. Oxygen deficiency increases RBC numbers by increasing the secretion of a glycoprotein hormone named **erythropoietin** (eh-RITH-roh-POY-eh-tin), or **EPO.** An inactive form of this hormone, called an *erythropoietinogen*, is released into the blood primarily from the liver on an ongoing basis. If oxygen levels decrease, the kidneys release increasing amounts of erythropoietin, which in turn stimulates bone marrow to accelerate its production of red blood cells. With increasing numbers of RBCs, oxygen delivery to tissues increases, and less erythropoietin is produced, and consequently less is available to stimulate RBC production in the red bone marrow. Figure 20-7 shows how erythropoietin production is controlled by a negative feedback loop that is activated by decreasing oxygen concentration in the tissues.

Box 20-3 discusses practices that boost RBC numbers artificially.

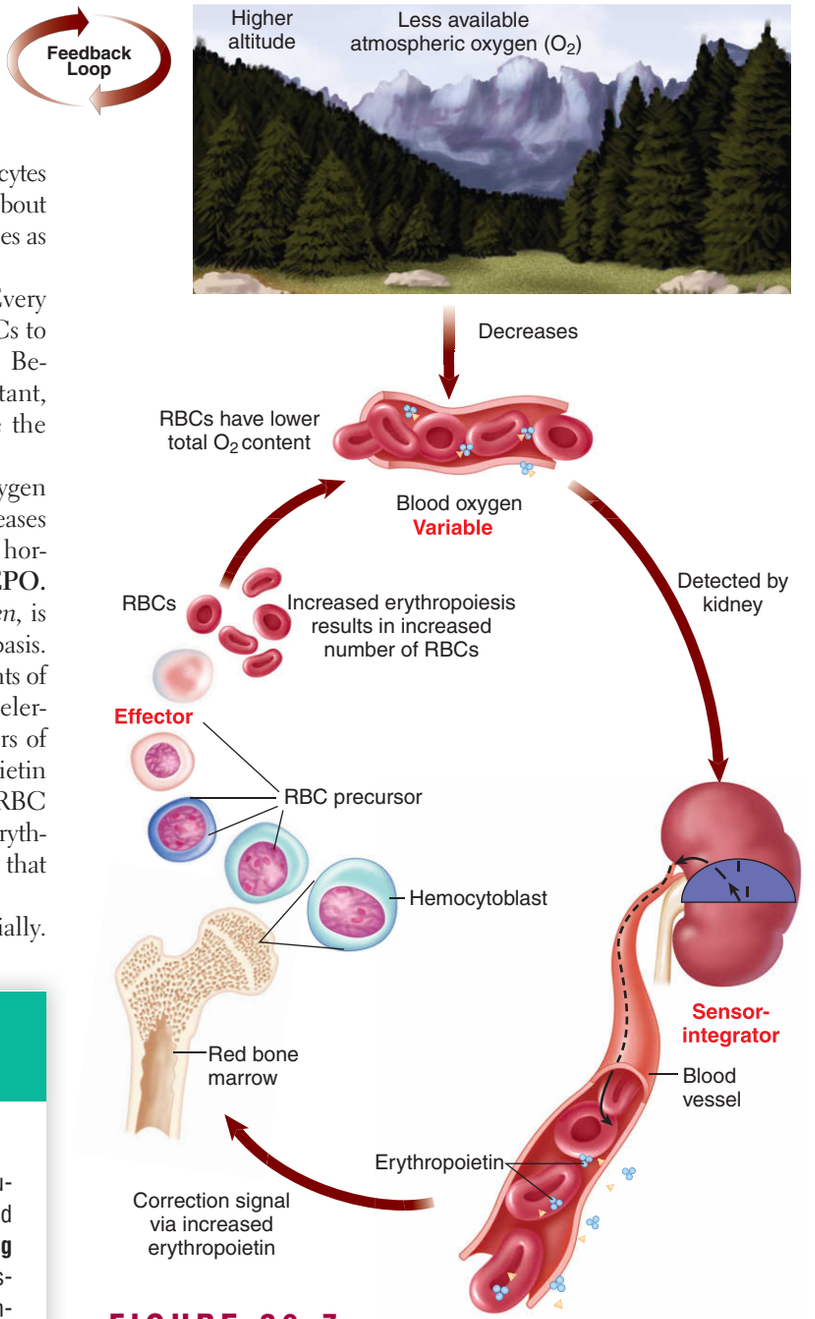

FIGURE 20-7

Erythropoiesis. In response to decreased blood oxygen, the kidneys release erythropoietin, which stimulates erythrocyte production in the red bone marrow.

Box 20-3 | SPORTS and FITNESS

Blood Doping

Reports that some Olympic and other elite athletes employ transfusions of their own blood to improve performance have surfaced repeatedly in the past 20 years. The practice—called **blood doping** or **blood boosting**—is intended to increase oxygen delivery to muscles. A few weeks before competition, blood is drawn from the athlete and the red blood cells (RBCs) are separated and frozen. Just before competition, the RBCs are thawed and injected. Theoretically, infused RBCs and elevation of hemoglobin levels after transfusion should increase oxygen consumption and muscle performance during exercise. In practice, however, the advantage appears to be minimal. All blood transfusions carry some risk, and unnecessary or questionably indicated transfusions are medically unacceptable.

In addition to blood transfusions, injection of substances that increase RBC levels in an attempt to improve athletic performance has also been condemned by leading authorities in the area of sports medicine and by athletic organizations around the world. "Doping" with either the naturally occurring hormone erythropoietin (EPO) or with synthetic drugs that have similar biological effects—such as Epogen and Procrit—can result in devastating medical outcomes. For example, EPO abuse can produce dangerously high blood pressure that may lead to a heart attack or stroke.

DESTRUCTION OF RED BLOOD CELLS

The life span of RBCs circulating in the bloodstream averages about 105 to 120 days. They often break apart, or fragment, in the capillaries as they age. Macrophage cells in the lining of blood vessels, particularly in the liver and spleen, phagocytose (ingest and destroy) the aged, abnormal, or fragmented red blood cells (Figure 20-8). The process results in breakdown of hemoglobin, with the release of amino acids, iron, and the pigment bilirubin. Iron is returned to the bone marrow for use in synthesis of new hemoglobin, and bilirubin is transported to the liver, where it is excreted into the intestine as part of bile. Amino acids, released

from the globin portion of the degraded hemoglobin molecule, are used by the body for energy or for synthesis of new proteins.

For the RBC homeostatic mechanism to succeed in maintaining a normal number of RBCs, the bone marrow must function adequately. To do this the blood must supply it with adequate amounts of several substances with which to form the new red blood cells—vitamin B_{12}, iron, and amino acids, for example, and also copper and cobalt to serve as catalysts. In addition, the gastric mucosa must provide some unidentified intrinsic factor necessary for absorption of vitamin B_{12} (also called **extrinsic factor** because it derives from external sources in foods and is not synthesized by the body; vitamin B_{12} is also called the **antianemic principle**).

| QUICK CHECK |

5. Name the red pigment found in RBCs, and list the normal range (in grams per 100 ml of blood) for women and men.
6. Trace the formation of an erythrocyte from stem cell precursor to a mature and circulating RBC.
7. Explain the negative feedback loop that controls erythropoiesis.
8. Discuss the destruction of RBCs in the body.

White Blood Cells (Leukocytes)

White blood cells, or **leukocytes,** do not contain pigments and thus these transparent cells appear white when collected together—just like clear snowflakes that appear white when grouped together. Because they are colorless WBCs can be seen easily under a microscope only when stained. Five general types of WBCS can be classified according to their staining characteristics, including the presence or absence of stained granules in their cytoplasm.

Granulocytes include the three WBCs that have large granules in their cytoplasm. They are named according to their cytoplasmic staining properties:

1. Neutrophils
2. Eosinophils
3. Basophils

Agranulocytes (WBCs without stained cytoplasmic granules) include the following:

1. Lymphocytes
2. Monocytes

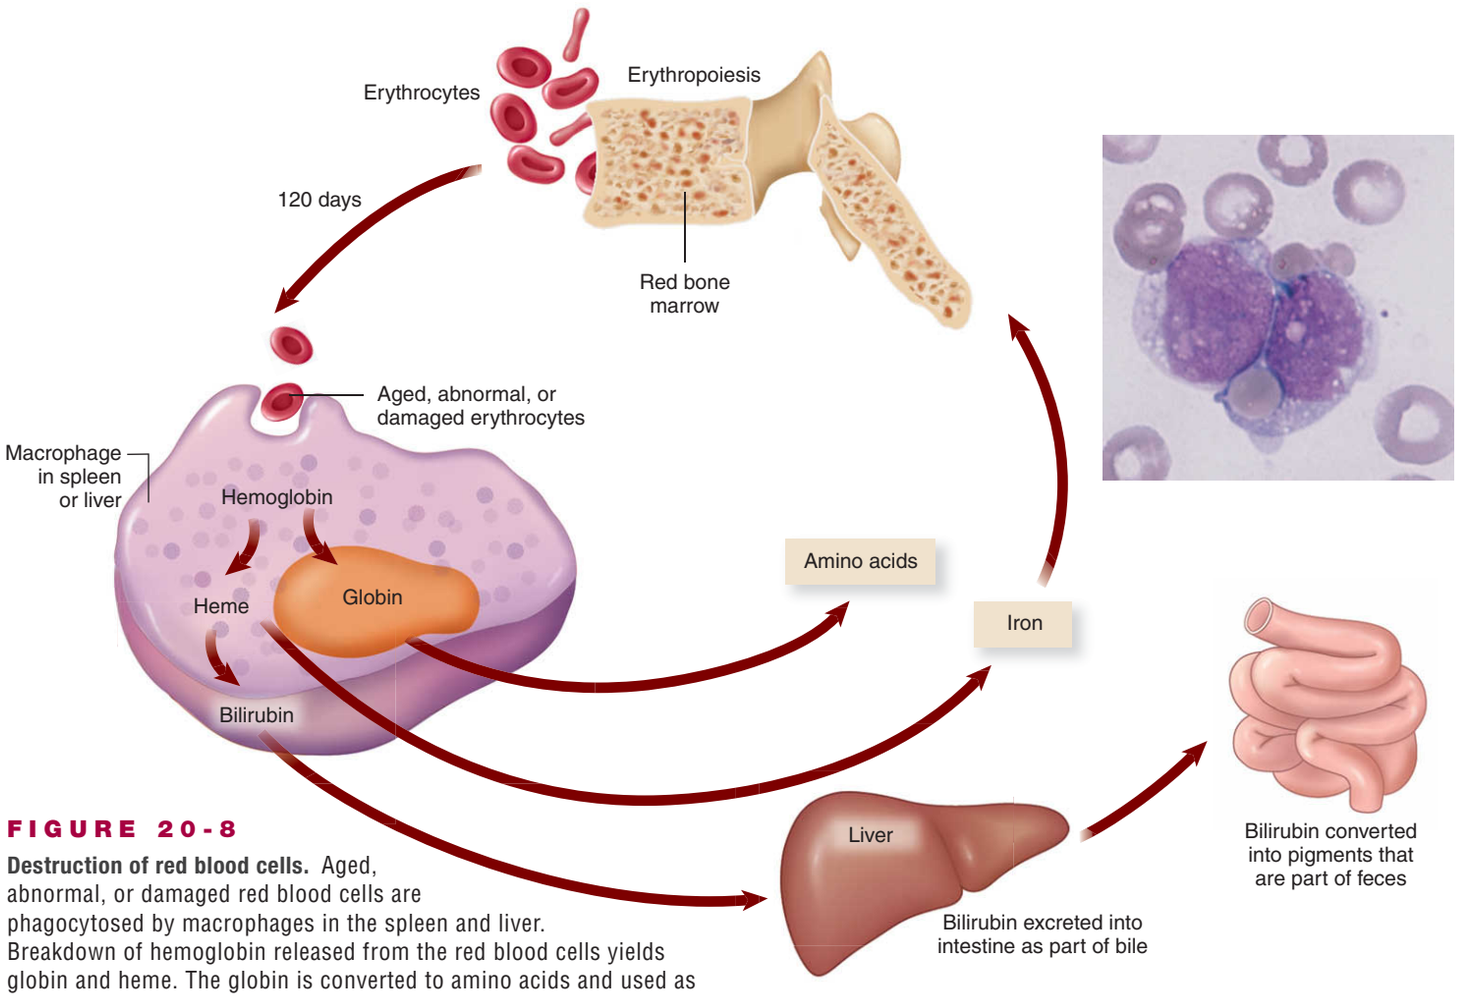

FIGURE 20-8

Destruction of red blood cells. Aged, abnormal, or damaged red blood cells are phagocytosed by macrophages in the spleen and liver. Breakdown of hemoglobin released from the red blood cells yields globin and heme. The globin is converted to amino acids and used as an energy source or for protein synthesis. Note that the released heme is further degraded into iron, which may be stored or used immediately to produce both new hemoglobin and bilirubin; the bilirubin is ultimately excreted in the bile. Photo inset shows phagocytosis of erythrocytes by macrophages in the liver.

WBCs have nuclei and are generally larger in size than RBCs. Table 20-1 illustrates the formed elements, provides a brief description of each cell type, and lists life span and primary functions. In Chapter 24 we more fully explore many of the defensive functions of leukocytes.

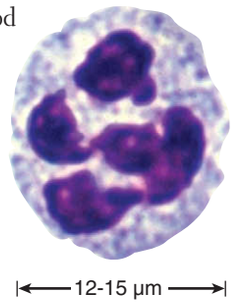
GRANULOCYTES

Neutrophils

Neutrophils (Figure 20-9) take their name from the fact that their cytoplasmic granules stain a very light purple with neutral dyes. The granules in these cells are small and numerous and tend to give the cytoplasm a coarse appearance. Because their nuclei have two, three, or more lobes, neutrophils are also called **polymorphonuclear leukocytes** or, to avoid that tongue twister, simply *polys*.

Neutrophil numbers average about 65% of the total WBC count in a normal blood sample. These leukocytes are highly mobile, active phagocytic cells that can migrate out of blood vessels and enter the tissue spaces. The process is called **diapedesis.** The cytoplasmic granules in neutrophils contain powerful lysosomes, the organelles with digestive-like enzymes that are capable of destroying bacterial cells.

Bacterial infections that produce an inflammatory response cause the release of chemicals from damaged cells that attract neutrophils and other phagocytic WBCs to the infection site. The process, called **chemotaxis,** helps the body concentrate phagocytic cells at focal points of infection.



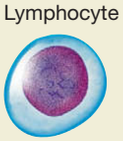


FIGURE 20-9
Neutrophil.

TABLE 20-1 Classes of Blood Cells

CELL TYPE	DESCRIPTION	FUNCTION	LIFE SPAN
Erythrocyte 	7 μm in diameter; concave disk shape; entire cell stains pale pink; no nucleus	Transportation of respiratory gases (O_2 and CO_2)	105–120 days
Neutrophil 	12-15 μm in diameter; spherical shape; multilobed nucleus; small, pink-purple–staining cytoplasmic granules	Cellular defense—phagocytosis of small pathogenic microorganisms	Hours to 3 days
Basophil 	11-14 μm in diameter; spherical shape; generally two-lobed nucleus; large purple-staining cytoplasmic granules	Secretes heparin (anticoagulant) and histamine (important in inflammatory response)	Hours to 3 days
Eosinophil 	10-12 μm in diameter; spherical shape; generally two-lobed nucleus; large, orange-red–staining cytoplasmic granule	Cellular defense—some phagocytosis; chemical attack of large pathogenic microorganisms (such as protozoa) and parasitic worms; helps regulate allergic reactions and other inflammatory responses	10–12 days
Lymphocyte 	6-9 μm in diameter; spherical shape; round (single-lobed) nucleus; small lymphocytes have scant cytoplasm	Humoral defense—secretes antibodies; involved in immune system response and regulation	Days to years
Monocyte 	12-17 μm in diameter; spherical shape; nucleus generally kidney-bean or horseshoe shaped with convoluted surface; ample cytoplasm often "steel blue" in color	Capable of migrating out of the blood to enter tissue spaces as a macrophage—an aggressive phagocytic cell capable of ingesting bacteria, cellular debris, and cancerous cells	Months
Platelet 	2-5 μm in diameter; irregularly shaped fragments; cytoplasm contains very small, pink-staining granules	Releases clot-activating substances and helps in formation of actual blood clot by forming platelet "plugs"	7–10 days

Eosinophils

Eosinophils (Figure 20-10) contain cytoplasmic granules that are large, are numerous, and stain orange with acid dyes such as eosin. Their nuclei generally have two lobes. Normally, eosinophils account for about 2% to 5% of circulating WBCs. They are also numerous in mucous membranes such as the lining of the respiratory and digestive tracts.

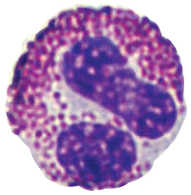

FIGURE 20-10
Eosinophil.

Although eosinophils are weak phagocytes, their major role is the release of chemicals from their granules. These immune chemicals include cell toxins and many regulators of the body's immune response. Perhaps their most important overall functions involve protection against infections caused by parasitic worms and involvement in regulating allergic reactions such as asthma.

Basophils

Basophils (Figure 20-11) have relatively large, but sparse, cytoplasmic granules that stain a dark purple with basic dyes. They are the least numerous of the WBCs, numbering only 0.5% to 1% of the total leukocyte count. Basophils are both motile and capable of diapedesis. They exhibit S-shaped, but indistinct, nuclei. The cytoplasmic granules of these WBCs contain *histamine* (an inflammatory chemical) and *heparin* (an anticoagulant).

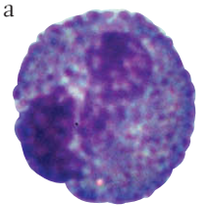

FIGURE 20-11
Basophil.

AGRANULOCYTES

Lymphocytes

Lymphocytes (Figure 20-12) found in the blood are the smallest of the leukocytes, averaging about 6 to 9 μm in diameter. They have large, spherical nuclei surrounded by a very limited amount of pale blue–staining cytoplasm. Next to neutrophils, lymphocytes are the most numerous WBCs. They account for about 25% of all the leukocyte population. Two types of lymphocytes, called *T lymphocytes* and *B lymphocytes*, have important roles in immunity. T lymphocytes function by directly attacking an infected or cancerous cell, whereas B lymphocytes produce antibodies against specific antigens. Activated B lymphocytes are also called *plasma cells*. The functions of both types of lymphocytes are fully discussed in Chapter 24.

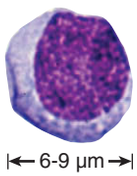

FIGURE 20-12
Lymphocyte.

Monocytes

Monocytes (Figure 20-13) are the largest of the leukocytes. They have dark, kidney bean–shaped nuclei surrounded by large quantities of distinctive blue-gray cytoplasm. Monocytes are motile and highly phagocytic cells capable of engulfing large bacterial organisms and viral-infected cells.

WHITE BLOOD CELL NUMBERS

One cubic millimeter of normal blood usually contains about 5000 to 9000 leukocytes, with different percentages of each type. Because these numbers change in certain abnormal conditions, they have clinical significance. In acute appendicitis, for example, the percentage of neutrophils increases and so, too, does the total WBC count. In fact, these characteristic changes may be the deciding points for surgery.

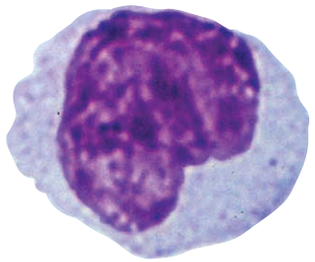

FIGURE 20-13
Monocyte.

An overall decrease in the number of WBCs is called **leukopenia.** An increase in the number of WBCs is **leukocytosis.**

A special type of white blood cell count called a **differential WBC count** reveals more information than simply the total number of all of the different types of WBCs in a blood sample. In a differential WBC count, a component test in the CBC or *complete blood count* (Box 20-4), the *proportions* of each type of white blood cell are reported as percentages of the total WBC count. Normal percentages are shown in Table 20-2. A lab technician may count

Box 20-4 | DIAGNOSTIC study

Complete Blood Cell Count

One of the most useful and frequently performed clinical blood tests is called the **complete blood cell count** or simply the **CBC.** The CBC is a collection of tests whose results, when interpreted as a whole, can yield an enormous amount of information regarding a person's health. Standard red blood cell, white blood cell, and thrombocyte counts, the differential white blood cell count, hematocrit, hemoglobin content, and other characteristics of the formed elements are usually included in this battery of tests.

TABLE 20-2 Differential Count of White Blood Cells

	DIFFERENTIAL COUNT*	
CLASS	NORMAL RANGE (%)	TYPICAL VALUE (%)†
Neutrophils	65-75	65
Lymphocytes (large and small)	20-25	25
Monocytes	3-8	6
Eosinophils	2-5	3
Basophils	½-1	1
TOTAL	100	100

*In any differential count the sum of the percentages of the different kinds of white blood cells (WBCs) must, of course, total 100%.
†The following mnemonic phrase may help you remember percent values in decreasing order by class of WBC: "**N**ever **L**et **M**onkeys **E**at **B**ananas."

the first 100 WBCs seen in a blood smear under a microscope to estimate the percentage of each type of WBC, but often this is done using advanced image-recognition computer technology (Figure 20-14).

Because all disorders do not affect each WBC type the same way, the differential WBC count is a valuable diagnostic tool. For example, although some parasite infestations do not cause an increase in the total WBC count, they often do cause an increase in the proportion of eosinophils that are present. The reason? This type of WBC specializes in defending against parasites (see Table 20-1).

FORMATION OF WHITE BLOOD CELLS

The hematopoietic stem cell serves as the precursor of not only the erythrocytes but also the leukocytes and platelets in blood. Figure 20-6, p. 603, shows the maturation sequence that results in formation of the granular and the agranular leukocytes from the undifferentiated hematopoietic stem cell (hemocytoblast).

Neutrophils, eosinophils, basophils, and a few lymphocytes and monocytes originate, as do erythrocytes, in red bone marrow (myeloid tissue). Most lymphocytes and monocytes derive from hematopoietic adult stem cells in lymphatic tissue. Although many lymphocytes are found in bone marrow, presumably most are formed in lymphatic tissues and carried to the bone marrow by the bloodstream.

Myeloid tissue (bone marrow) and lymphatic tissue together constitute the hematopoietic, or blood cell–forming, tissues of the body. Red bone marrow is myeloid tissue that actually produces blood cells. Its red color comes from the red blood cells it contains. Yellow marrow, on the other hand, is yellow because it stores a considerable amount of fat. It is not active in the business of blood cell formation as long as it remains yellow. Sometimes, however, it becomes active and then red in color when an extreme and prolonged need for red blood cell production occurs.

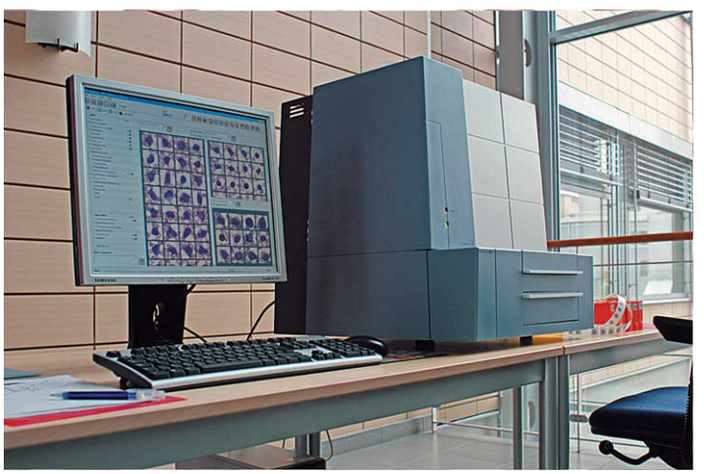

FIGURE 20-14

Differential WBC count. Automated microscope systems use advanced image-recognition technology to identify and count different WBC types in blood smear samples and produce the differential WBC count.

Platelets

To compare **platelets** with other blood cells in terms of appearance and size, see Figure 20-2. In circulating blood, platelets are small, nearly colorless bodies that usually appear as irregular spindles or oval disks about 2 to 4 μm in diameter.

Three important physical properties of platelets—namely, agglutination, adhesiveness, and aggregation—make attempts at classification on the basis of size or shape in dry blood smears all but impossible. As soon as blood is removed from a vessel, the platelets adhere to each other and to every surface they contact; in so doing, they assume various shapes and irregular forms.

Platelet counts in adults average about 250,000/mm^3 of blood. A range of 150,000 to 400,000/mm^3 is considered normal. Newborn infants often show reduced counts, but these rise gradually to reach normal adult values at about 3 months of age. There are no differences between the sexes in platelet count.

FUNCTIONS OF PLATELETS

Platelets play an important role in both **hemostasis** (from the Greek *stasis*, "a standing") and **blood clotting,** or **coagulation.** The two functions, although interrelated, are separate and distinct. Hemostasis refers to the stoppage of blood *flow* and may occur as an end result of any one of several body defense mechanisms. The role that platelets play in the operation of the blood-clotting mechanism is discussed on pp. 614–617.

Within 1 to 5 seconds after injury to a blood capillary, platelets will adhere to the damaged lining of the vessel and to each other to form a hemostatic **platelet plug** that helps stop the flow of blood into the tissues.

The formation of a temporary platelet plug is an important step in hemostasis. It generally follows vascular spasm, which is caused by constriction of smooth muscle fibers in the wall of damaged blood vessels. Vascular spasm can cause temporary closure of a damaged vessel and lessen blood loss until the platelet plug and subsequent coagulation effectively stop the hemorrhage.

The formation of a platelet plug results when platelets undergo a change caused by an encounter with a damaged capillary wall, or with underlying connective tissue fibers. The transformation results in the creation of *sticky platelets*, which bind to underlying tissues and each other. In addition to forming a physical plug at the site of injury, sticky platelets secrete several chemicals, including adenosine diphosphate (ADP), thromboxane, and a fatty acid (arachidonic acid), that are involved in the coagulation process. When released, these substances affect both local blood flow (by vasoconstriction) and platelet aggregation at the site of injury. If the injury is extensive, the blood-clotting mechanism is activated to assist in hemostasis.

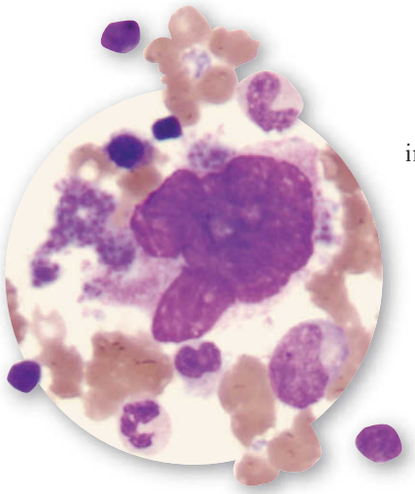

FIGURE 20-15

Megakaryocyte. Note the large size of the cell and multinucleated nucleus. This bone marrow smear also shows a number of WBCs scattered among more numerous RBCs.

Platelet plugs are extremely important in controlling so-called microhemorrhages, which may involve a break in a single capillary. Failure to arrest hemorrhage from these very minor but numerous and widespread capillary breaks can result in life-threatening blood loss.

Platelet plugs are also believed to be involved in causing intermittent arterial microvascular occlusion in certain types of peripheral vascular disease (see Box 20-5, p. 617).

FORMATION AND LIFE SPAN OF PLATELETS

Formation of platelets, sometimes called *thrombocytes*, is referred to as **thrombopoiesis.** It begins with stimulation of precursor cells called megakaryoblasts (see Figure 20-6), and is controlled by the hormone *thrombopoietin*. Mature megakaryocytes are huge cells (20 to 100 mm) with large nuclei containing as many as 20 lobes (Figure 20-15). They often have a bizarre shape. The cytoplasm of a stained specimen is blue to pink in color, is abundant, and contains a variable number of very fine granules. Mature megakaryocytes are largely confined to red bone marrow although some are located in the lungs and, to a lesser extent, the spleen. Between 2000 and more than 3000 platelets are released when the irregular cytoplasmic membrane surrounding the mature megakaryocyte ruptures. The resulting platelets have a limiting plasma membrane but, like RBCs, no nucleus. Platelets have a short life span, an average of about 7 days.

BLOOD TYPES (BLOOD GROUPS)

In 1902, the Austrian pathologist Karl Landsteiner announced his discovery of blood types, one of the most important medical discoveries of the time. The term *blood type* refers to the type of cell markers or antigens present on RBC membranes. (The concept of **antigens** and **antibodies** is discussed in detail in Chapter 24.) Landsteiner discovered the most important blood antigens: A and B. The presence or absence of these antigens determines a person's blood type in the ABO system. In 1940, Landsteiner found that a group of six Rh (or D) antigens previously found in rhesus monkeys was also found in humans. Continuing research by Landsteiner and others revealed nearly two dozen additional blood antigens that vary from person to person.

The fact that not everyone has the same blood antigens is very important. This means that our immune system may "attack" donated blood cells (from a transfusion) if they have antigens different than our own. Antigens A, B, and Rh are the most important blood antigens as far as transfusions and newborn survival are concerned. The other blood antigens are less important clinically but may still cause occasional problems.

Why do different people have different antigens on their RBCs? We do not have a complete answer to that question, but their presence or absence probably gives some biological advantage related to conditions within different human populations. For example, an antigen called *Duffy* (after the patient in whom it was first discovered) is often missing in populations that have lived with the threat of malaria for many generations. The Duffy antigen is used by the malaria parasite to enter RBCs, so its absence protects a person against developing malaria. However, we know very little about functions of the other antigens.

The term *agglutinins* is often used to describe the antibodies dissolved in plasma that react with specific blood group antigens or *agglutinogens*. We use the terms agglutinin and agglutinogen because when they combine and react, they cause the RBCs to clump together or agglutinate. It is the specific agglutinogens or antigens on red cell membranes that characterize the different ABO blood groups, which are described in the following paragraphs.

When a blood transfusion occurs, great care must be taken to prevent a mixture of agglutinogens (antigens) and agglutinins (antibodies) that would result in the agglutination of the donor and recipient blood—a potentially fatal event known as a **transfusion reaction.** Clinical laboratory tests, called *blood typing* and *cross-matching*, ensure the proper identification of blood group antigens and antibodies in both donor and recipient blood and demonstrate the lack of an agglutination reaction when they are mixed together.

The ABO System

Every person's blood belongs to one of the four ABO blood types (or groups). Blood types are named according to the antigens present (agglutinogens) on RBC membranes. Here, then, are the four ABO blood types:

1. Type A—antigen A on RBCs
2. Type B—antigen B on RBCs
3. Type AB—both antigen A and antigen B on RBCs
4. Type O—neither antigen A nor antigen B on RBCs

Blood plasma may or may not contain antibodies (agglutinins) that can react with red blood cell antigens A or B. An important principle related to this is that plasma never contains antibodies against the antigens present on its own red blood cells—for obvious reasons. If it did, the antibody would react with the antigen and thereby destroy the RBCs. However (and this is an equally important principle), plasma does contain antibodies against antigen

A or antigen B if they are *not* present on its RBCs. So by applying these two principles, we can deduce the following: In type A blood, antigen A is present on its RBCs; therefore its plasma contains no anti-A antibodies but does contain anti-B antibodies. In type B blood, antigen-B is present on its RBCs; therefore its plasma contains no anti-B antibodies but does contain anti-A antibodies (Figure 20-16).

Note in Figure 20-17, *A*, that type A blood donated to a type A recipient does not cause an agglutination transfusion reaction because the antiB antibodies in the recipient do not combine with the A antigens in the donated blood. However, type A blood donated to a type B recipient causes an agglutination reaction because the anti-A antibodies in the recipient combine with the A antigens in the donated blood (Figure 20-17, *B*). Figure 20-18 shows the results of different combinations of donor and recipient blood.

Because type O blood does not contain either antigen A or B, it has been referred to as *universal donor* blood, a term that implies that it can safely be given to any recipient. This, however, is not true because the recipient's plasma may contain agglutinins other than anti-A or anti-B antibodies. For this reason the recipient's and the donor's blood—even if it is type O—should be cross-matched; that is, mixed and observed for agglutination of the donor's red blood cells.

Universal recipient (type AB) blood contains neither anti-A nor anti-B antibodies, so it cannot agglutinate type A or type B donor red blood cells. This does not mean, however, that any type of donor blood may be safely given to an individual who has type AB blood without first cross-matching. Other agglutinins may be present in the so-called universal recipient blood and may clump unidentified antigens (agglutinogens) in the donor's blood.

Improperly typed and cross-matched blood given during a blood transfusion can cause a *transfusion reaction* in the recipient. Depending on the response of the recipient's immune system and the amount of mismatched blood given, such a reaction may range from mild to severe to life threatening. As the host antibodies attack the donor RBCs, the RBCs are broken apart—a process called *hemolysis*. Hemoglobin is thus released into the blood stream, which (if severe) may overload the kidney and cause kidney failure. Signs of this type of transfusion reaction include fever, difficulty breathing, and pink urine.

The Rh System

The term *Rh-positive blood* means that an Rh (or D) antigen is present on its RBCs. *Rh-negative blood*, on the other hand, is blood whose red cells have no Rh antigens present on them.

Blood does not normally contain anti-Rh antibodies. However, anti-Rh antibodies can appear in the blood of an Rh-negative person, provided Rh-positive RBCs have at some time entered the bloodstream. One way this can happen is by giving an Rh-negative person a transfusion of Rh-positive blood. In a short time, the person's body makes anti-Rh antibodies, and these remain in the blood. The other way in which Rh-positive RBCs can enter the bloodstream of an Rh-negative individual can happen only to a woman during pregnancy. In this fact lies the danger for a baby born to an Rh-negative mother and

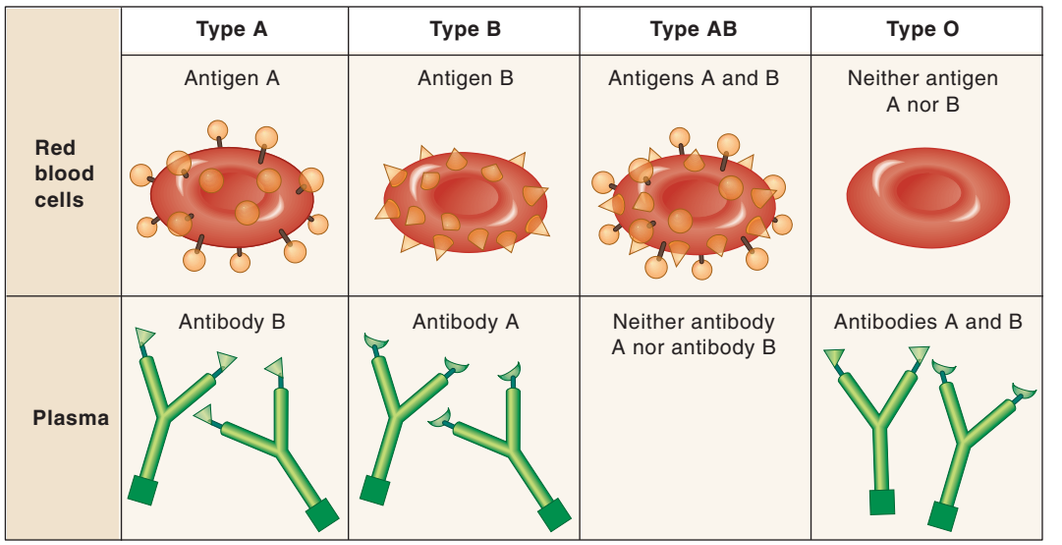

FIGURE 20-16

ABO blood types. Note that antigens characteristic of each blood type are bound to the surface of RBCs. The antibodies of each blood type are found in the plasma and exhibit unique structural features that permit agglutination to occur if exposure to the appropriate antigen occurs.

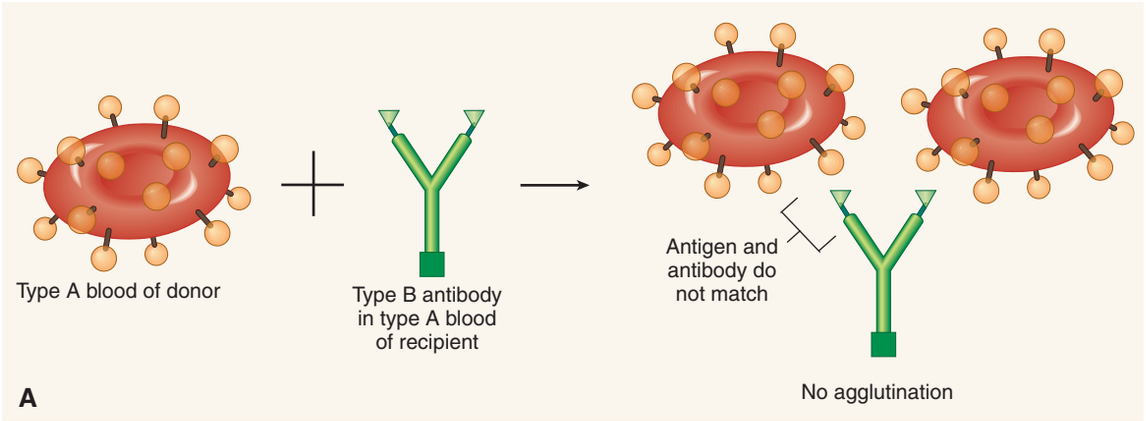

FIGURE 20-17

Agglutination. A, When mixing of donor and recipient blood of the same type *(A)* occurs, there is no agglutination because only anti-B antibodies are present. **B,** If type A donor blood is mixed with type B recipient blood, agglutination will occur because of the presence of anti-A antibodies in the type B recipient blood.

Recipient's blood		Reactions with donor's blood			
RBC antigens	Plasma antibodies	Donor type O	Donor type A	Donor type B	Donor type AB
None (Type O)	Anti-A Anti-B				
A (Type A)	Anti-B				
B (Type B)	Anti-A				
AB (Type AB)	(None)				

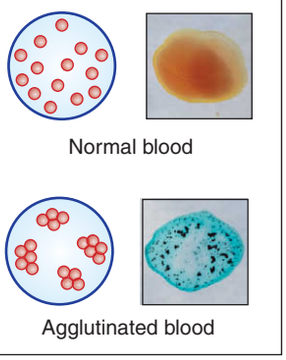

FIGURE 20-18

Results of (cross-matching) different combinations (types) of donor and recipient blood. The left columns show the antigen and antibody characteristics that define the recipient's blood type, and the top row shows the donor's blood type. Cross-matching identifies either a compatible combination of donor-recipient blood (no agglutination) or an incompatible combination (agglutinated blood). Photo inset shows drops of blood showing appearance of agglutinated and non-agglutinated red blood cells.

an Rh-positive father. If the baby inherits the Rh-positive trait from the father, the Rh factor on the RBCs may stimulate the mother's body to form anti-Rh antibodies. Then, if she later carries another Rh-positive fetus, the fetus may develop a disease called **erythroblastosis fetalis,** a hemolytic condition caused by the mother's Rh antibodies reacting with the baby's Rh-positive cells (Figure 20-19).

All Rh-negative mothers who carry an Rh-positive baby should be treated with an anti-Rh antibody marketed under the name RhoGAM (and others). RhoGAM stops the mother's body from forming anti-Rh antibodies and thus prevents the possibility of harm to the next Rh-positive baby she may have. Briefly, the only people who can ever have anti-Rh antibodies in their plasma are Rh-negative men or women who have been transfused with Rh-positive blood or Rh-negative women who have carried an Rh-positive fetus.

Table 20-3 summarizes the ABO and Rh blood types, including the frequency of each in the general population—that is, the human population as a whole. Of course the frequency of these and other blood types may be different within a family or ethnic group based on regional differences in the human gene pool.

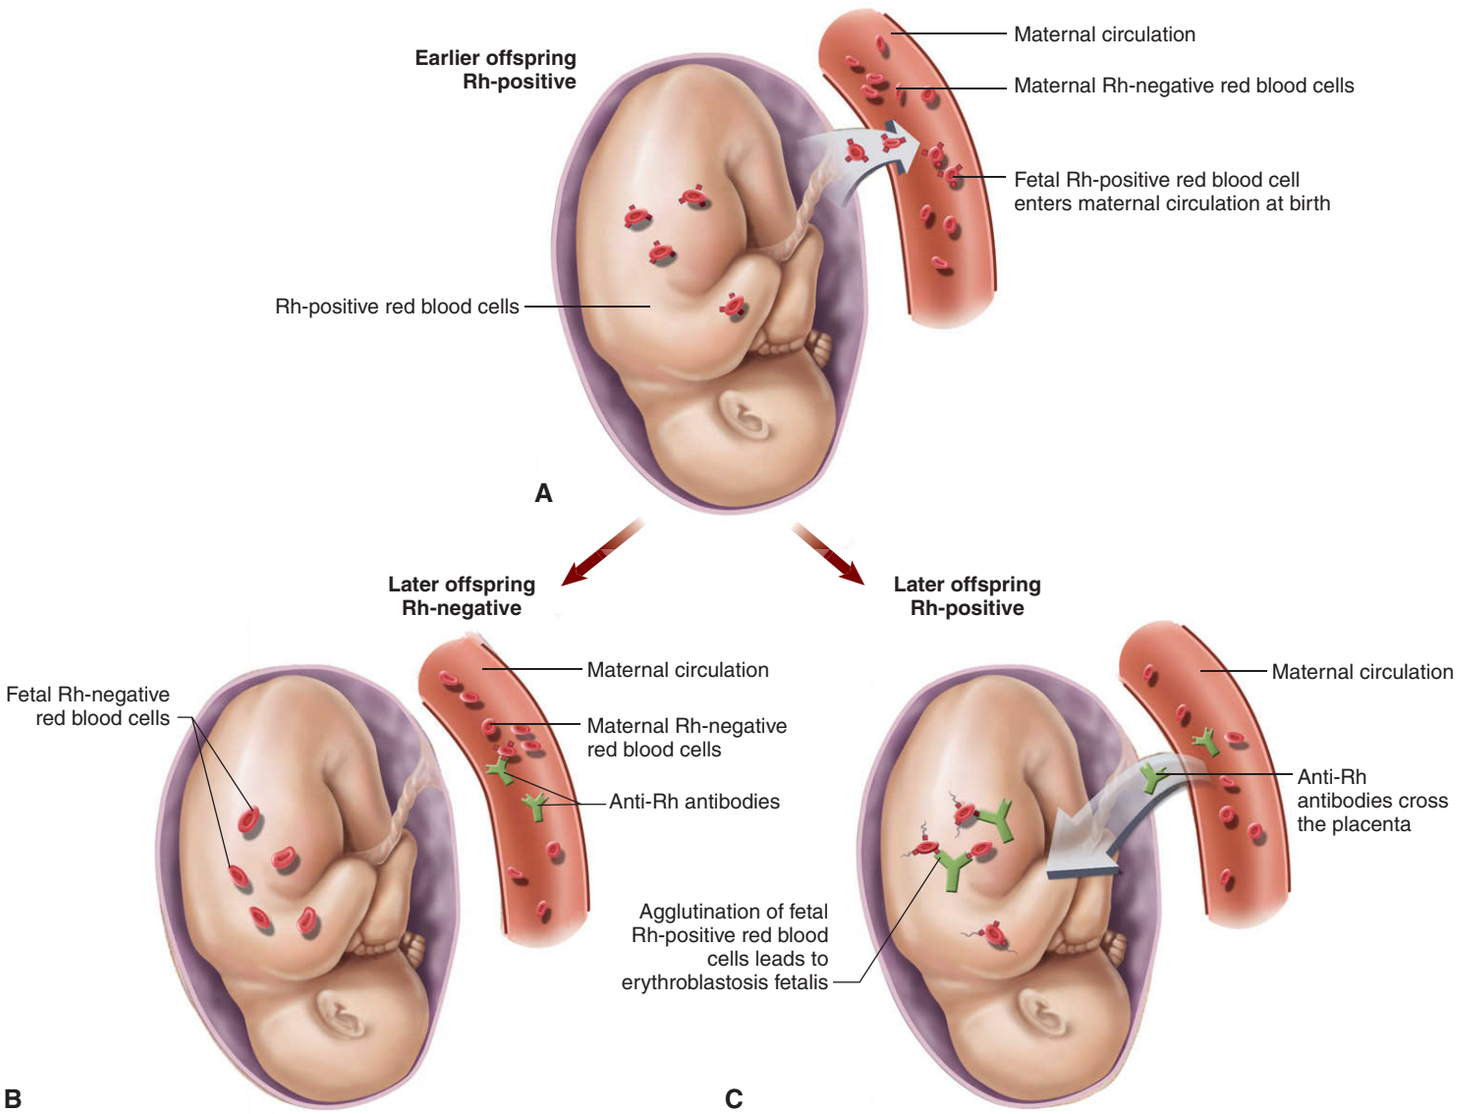

FIGURE 20-19

Erythroblastosis fetalis. A, Rh-positive blood cells enter the mother's bloodstream during delivery of an Rh-positive baby. If not treated, the mother's body will produce anti-Rh antibodies. **B,** A later pregnancy involving an Rh-negative baby is normal because there are no Rh antigens in the baby's blood. **C,** A later pregnancy involving an Rh-positive baby may result in erythroblastosis fetalis. Anti-Rh antibodies enter the baby's blood supply and cause agglutination of RBCs with the Rh antigen.

TABLE 20-3 Blood Typing

BLOOD TYPE (ABO AND RH)	ANTIGENS PRESENT*	ANTIBODIES PRESENT*	PERCENT OF GENERAL POPULATION
O+	Rh	anti-A, anti-B	35%
O–†	None	anti-A, anti-B, anti-Rh?	7%
A+	A, Rh	anti-B	35%
A–	A	anti-B, anti-Rh?	7%
B+	B, Rh	anti-A	8%
B–	B	anti-A, anti-Rh?	2%

BLOOD PLASMA

Plasma is the liquid part of blood—whole blood minus formed elements (Figure 20-20). In the laboratory, whole blood that has not clotted is centrifuged to form plasma. This consists of a rapid whirling process that hurls the blood cells to the bottom of the centrifuge tube. A clear, straw-colored fluid—blood plasma—lies above the cells.

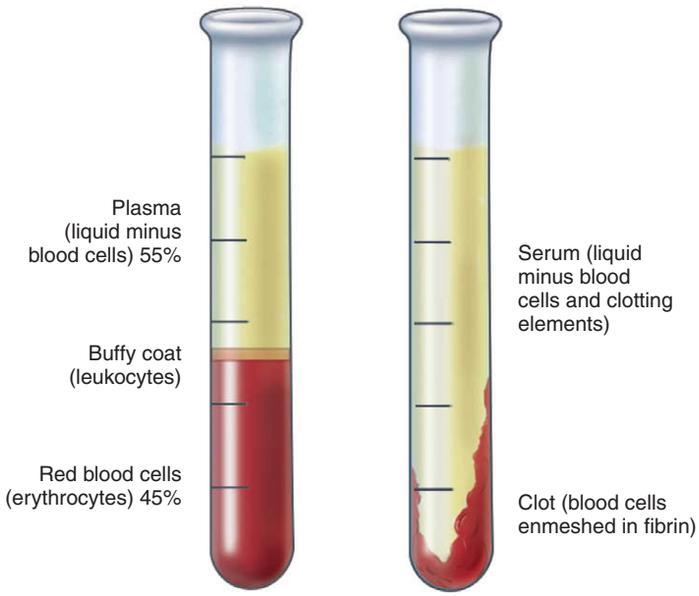

FIGURE 20-20

Difference between blood plasma and blood serum. Plasma is whole blood minus cells. Serum is whole blood minus the clotting elements. Plasma is prepared by centrifuging anticoagulated blood. Serum is prepared by allowing blood to clot.

Plasma consists of 90% water and 10% solutes. By far the largest quantity of these solutes is proteins; normally, they constitute about 6% to 8% of the plasma. Proteins such as factor VIII regulate blood clotting; and others such as gamma globulins, which are important in treating weakened immune systems, and albumin, a blood volume expander, are common transfusion products. Other solutes present in much smaller amounts in plasma are nutrient substances (principally glucose, amino acids, and lipids), compounds formed by metabolism (e.g., urea, uric acid, creatinine, and lactic acid), respiratory gases (oxygen and carbon dioxide), and regulatory substances (hormones, enzymes, and certain other substances).

Some solutes present in blood plasma are true solutes, or crystalloids. Others are colloids. *Crystalloids* are solute particles less than 1 nm in diameter (e.g., ions, glucose, and other small molecules). *Colloids* are solute particles from 1 to about 100 nm in diameter (e.g., proteins of all types). Blood solutes also may be classified as **electrolytes** (molecules that ionize in solution) or **nonelectrolytes**—examples: proteins and inorganic salts are electrolytes; glucose and lipids are nonelectrolytes.

The proteins in blood plasma consist of three main kinds of compounds: *albumins*, *globulins*, and clotting proteins, principally *fibrinogen*. Measuring the amounts of these compounds reveals that 100 ml of plasma contains a total of approximately 6 to 8 grams of protein. Albumins constitute about 55% of this total, globulins about 38%, and fibrinogen about 7%.

Plasma proteins are crucially important substances. Fibrinogen, for instance, and a clotting protein named prothrombin have key roles in the blood-clotting mechanism. Globulins function as essential components of the immunity mechanism. Many modified globulins, called gamma globulins, serve important roles as circulating antibodies (see also immunoglobulins, Chapter 24). All plasma proteins contribute to the maintenance of normal blood viscosity, blood osmotic pressure, and blood volume. Therefore plasma proteins have an essential part in maintaining normal circulation.

Synthesis of plasma proteins occurs in liver cells. They form all kinds of plasma proteins, except some of the gamma globulin antibodies synthesized by plasma cells. Plasma cells are a type of lymphocyte (WBC). Cancer of plasma cells, called *multiple myeloma*, results in production of an abnormal myeloma antibody—a gamma globulin—that results in numerous and very serious disease symptoms (see Mechanisms of Disease, p. 619).

BLOOD CLOTTING (COAGULATION)

The primary purpose of blood coagulation is obvious—to plug ruptured vessels to stop bleeding and prevent loss of a vital body fluid. Recall that this process is called *hemostasis*. A secondary and less well known function of the hemostasis mechanism is to help in defending us against infection. In an injury, bacteria may find an opportunity to invade our tissues. However, a blood clot will hopefully trap and bind enough of them to prevent such an invasion.

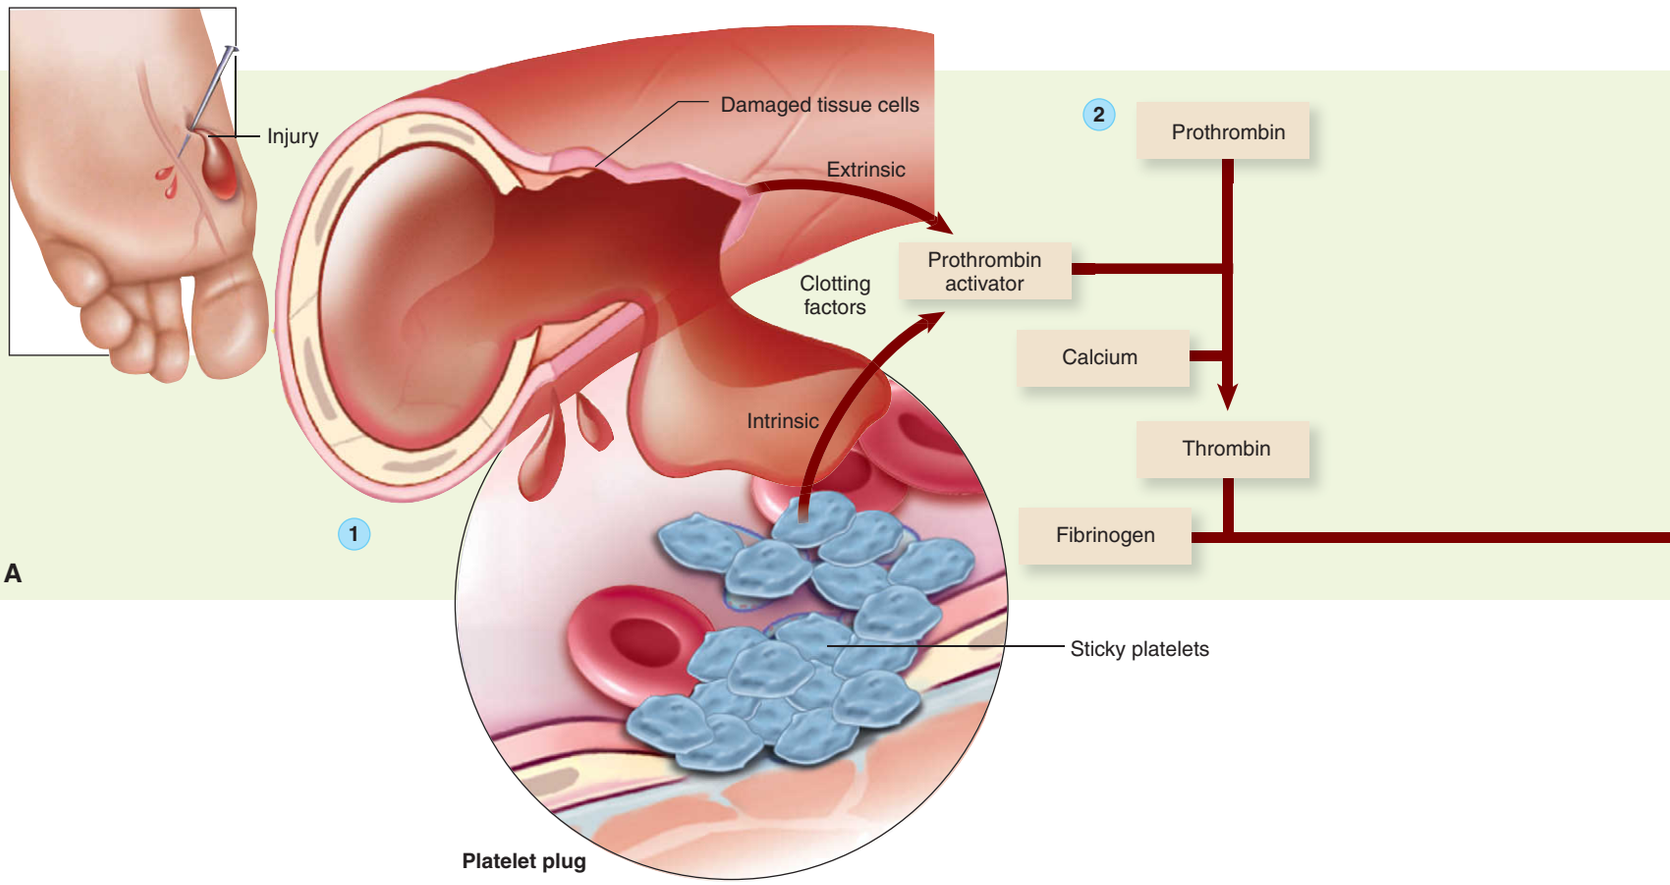
Mechanism of Blood Clotting

Because of the function of coagulation, the mechanism for producing it must be swift and sure when needed, such as when a vessel is cut or ruptured. Equally important, however, coagulation needs to be prevented from happening when it is not needed because clots can plug up vessels that must stay open if cells are to receive blood's life-sustaining cargo of oxygen.

What makes blood coagulate? Over many years a host of investigators have searched for the answer to this question. They have tried to find out what events make up the coagulation mechanism and what sets it in operation. They have succeeded in gathering an abundance of relevant information, but questions about this complicated and important process still outnumber answers.

The blood-clotting mechanism involves a series of chemical reactions that takes place in a definite and rapid sequence resulting in a net of fibers that traps red blood cells (Figure 20-21, *B*).

The so-called classic theory of coagulation was advanced in 1905 and dominated research efforts in this complex area for almost 50 years. It continues as the basis of our current understanding of coagulation. This theory has now been expanded and assumes (1) the interaction of numerous coagulation factors in the presence of calcium ions and (2) that the interaction between the components occurs in three stages.



Scientists working more than a century ago discovered that four components were critical to coagulation:

1. Prothrombin
2. Thrombin
3. Fibrinogen
4. Fibrin

These early studies in coagulation research suggested that interactions between these components occurred in what we now

FIGURE 20-21

Blood-clotting mechanism. A, The complex clotting mechanism can be distilled into three basic steps: *(1)* release of clotting factors from both injured tissue cells and sticky platelets at the injury site (which form temporary platelet plug); *(2)* series of chemical reactions that eventually result in the formation of thrombin; and *(3)* formation of fibrin and trapping of blood cells to form a clot. **B,** Photo inset is a colorized electron micrograph showing RBCs and platelets *(blue)* entrapped in a fibrin *(yellow)* mesh during clot formation.

designate as stage 2 and stage 3 of the blood-clotting process, which are simplified and illustrated in Figure 20-21:

Stage 2:

$$\text{Prothrombin} \xrightarrow[Ca^{++}]{\text{Prothrombin activator}} \text{Thrombin}$$

Stage 3:

$$\text{Fibrinogen} \xrightarrow[Ca^{++}]{\text{Thrombin}} \text{Fibrin}$$

It is interesting that basic reaction stages 2 and 3 have been modified only by the action of a host of additional coagulation factors discovered in recent decades (Table 20-4). In addition, the

TABLE 20-4 Coagulation Factors—Standard Nomenclature and Synonyms

FACTOR	COMMON SYNONYM(S)
Factor I	Fibrinogen
Factor II	Prothrombin
Factor III	Thromboplastin

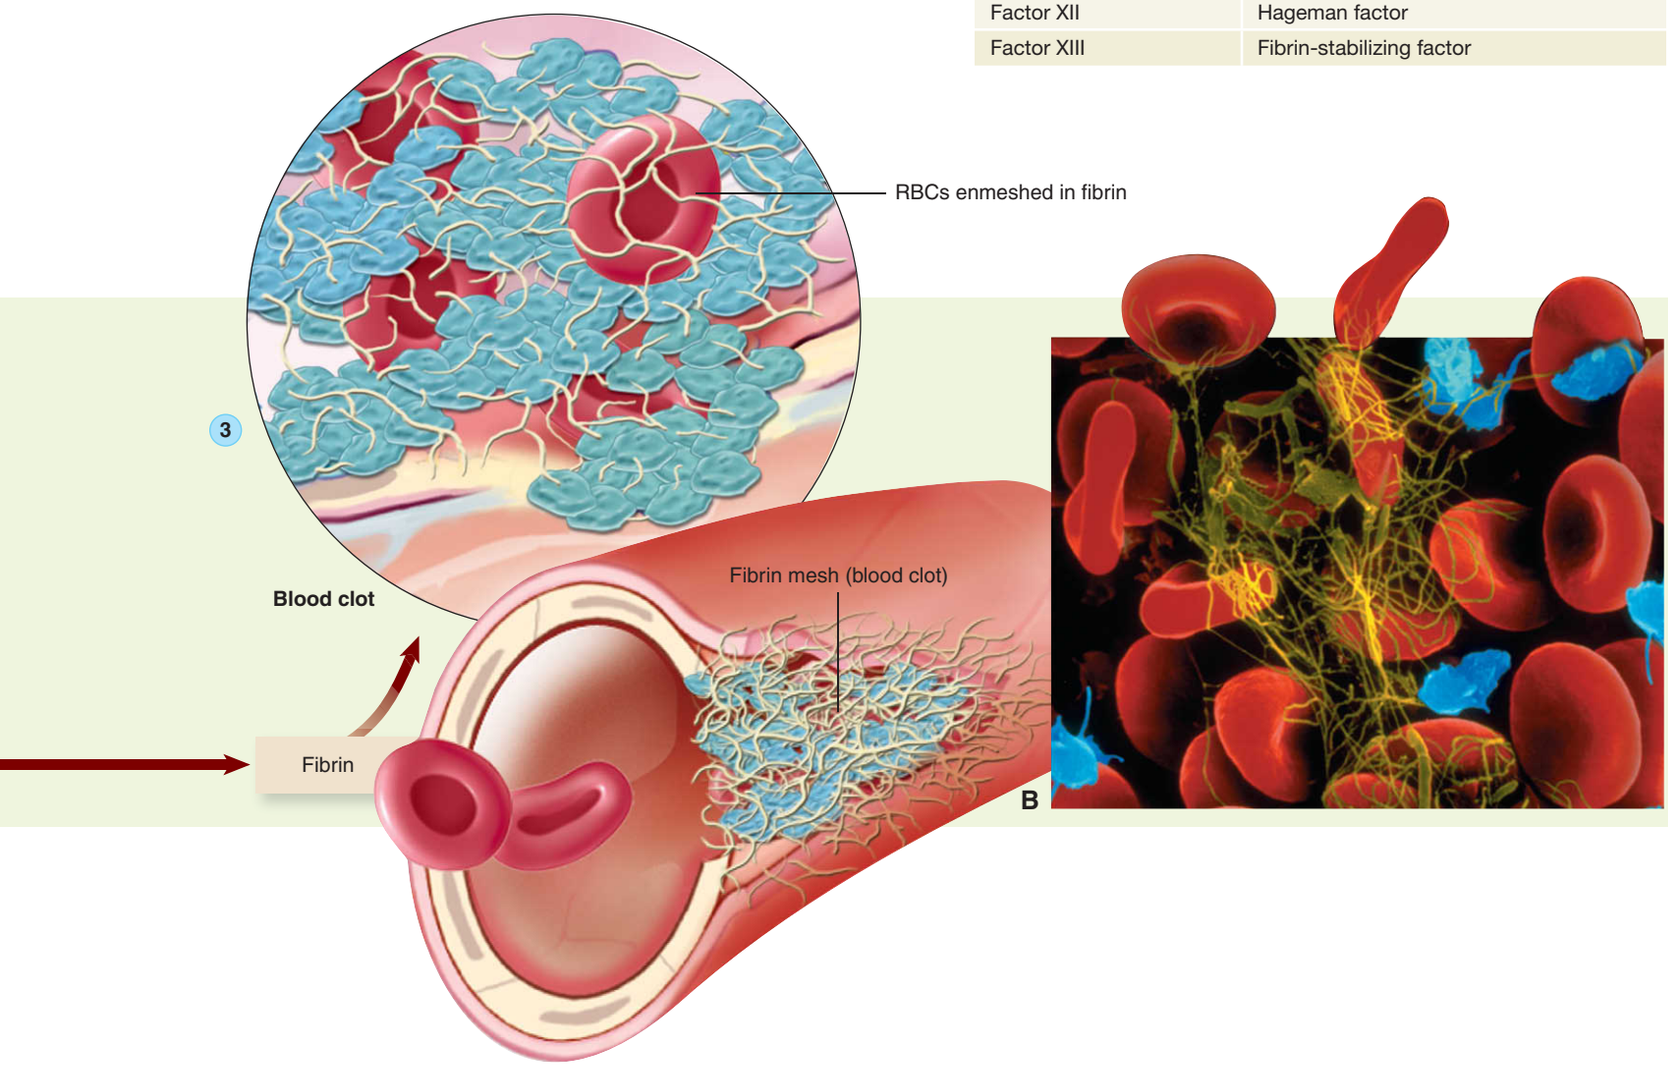
Factor XII	Hageman factor
Factor XIII	Fibrin-stabilizing factor



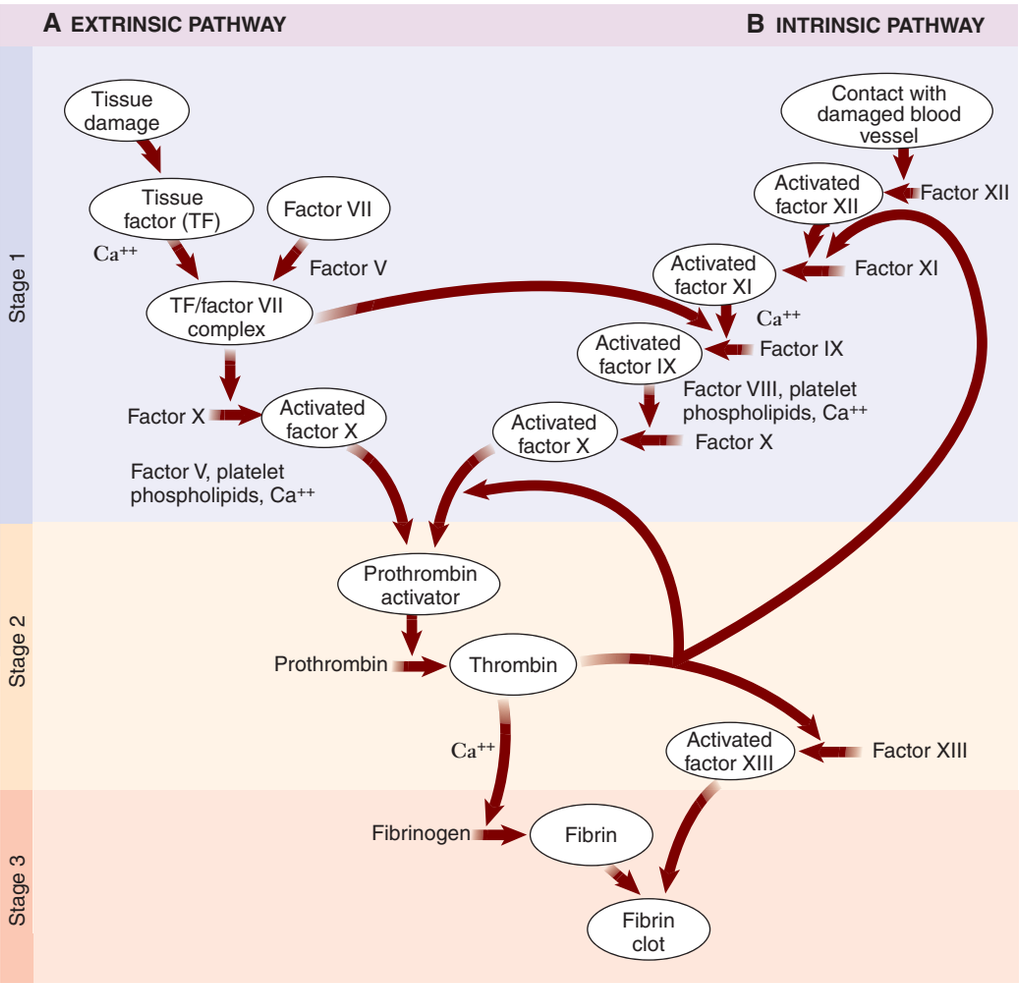


FIGURE 20-22

Clot formation. A, Extrinsic clotting pathway. *Stage 1:* Damaged tissue releases tissue factor, which with factor VII and calcium ions activates factor X. Activated factor X, factor V, phospholipids, and calcium ions form prothrombin activator (prothrombinase). *Stage 2:* Prothrombin is converted to thrombin by prothrombin activator. *Stage 3:* Fibrinogen is converted to fibrin by thrombin. Fibrin forms a clot. **B,** Intrinsic clotting pathway. *Stage 1:* Damaged vessels cause activation of factor XII. Activated factor XII activates factor XI, which activates factor IX. Factor IX, along with factor VIII and platelet phospholipids, activates factor X. Activated factor X, factor V, phospholipids, and calcium ions form prothrombin activator. Stages 2 and 3 take the same course as the extrinsic clotting pathway.

source of prothrombin activator at the end of stage 1 of the current coagulation theory mechanism is now used to divide this stage into *intrinsic* and *extrinsic* systems.

The three stages of coagulation described in the following paragraphs are illustrated in Figure 20-22.

Stage 1 of the clotting mechanism can be divided into two separate mechanisms called the **extrinsic clotting pathways** and **intrinsic clotting pathways.** In both pathways a sequential series of chemical reactions called a *clotting cascade* precedes the formation of prothrombin activator. This substance is the catalyst needed for conversion of prothrombin to thrombin in stage 2 of the clotting process (see Figure 20-22).

EXTRINSIC PATHWAY

In the extrinsic pathway, chemicals released from damaged tissues that are outside or extrinsic to the blood trigger the cascade of events that ultimately result in formation of prothrombin activator. Initially, tissue damage results in release of a mixture of lipoproteins and phospholipids called *tissue factor* or *factor III*. In the coordinated series of chemical reactions that follow, this factor, in the presence of calcium ions, factor V, and factor VII, forms a complex that in turn activates factor X and produces prothrombin activator (see Figure 20-22, A).

INTRINSIC PATHWAY

The intrinsic pathway involves a series of reactions that begin with factors normally present, or intrinsic to, the blood. Damage to the endothelial lining of blood vessels exposes collagen fibers, which in turn causes the activation of a number of coagulation factors present in plasma. When activated in this manner, factor XII (Hageman factor) then causes factor XI to activate factor IX. Sticky platelets participate in the intrinsic pathway by releasing a phospholipid called *platelet factor VIII*. This substance activates factor X, which then produces the prothrombin activator (prothrombinase) (see Figure 20-22, *B*).

STAGES 2 AND 3

Regardless of the pathway involved, after prothrombin activator is produced, stages 2 and 3 of the blood-clotting mechanism are initiated and a clot will form. Thrombin formed in stage 2 accelerates in stage 3 conversion of the soluble plasma protein fibrinogen to insoluble fibrin. The stage 3 polymerization of fibrin strands into a fibrin clot is accelerated by the presence of activated factor XIII. Fibrin appears in blood as fine threads all tangled together. Blood cells catch in the entanglement, and because most of the cells are RBCs, clotted blood has a red color. Note that several of the clotting factors require calcium ions as a co-factor. This explains the need

Box 20-5 | HEALTH matters

Anticoagulant and Antiplatelet Drug Treatments

Many types of drugs are now available to physicians that help prevent thrombosis and embolism. If an individual is at risk for thrombus formation, the selection of a so-called targeted or rational drug treatment may depend on the location in the vascular system in which the clots may form. Research has shown that venous thrombi consist mainly of fibrin and red blood cells, whereas arterial thrombi consist mainly of platelet aggregates. This information provides a theoretic basis for selecting different types of drug treatment for conditions caused by either venous or arterial thrombi.

For example, **anticoagulant drugs** such as aspirin, heparin, and warfarin (Coumadin) should be more effective in prevention of venous thrombi, and drugs that decrease the tendency for platelets to become sticky and form aggregates **(antiplatelet drugs)** should be more effective in preventing arterial thrombi.

A daily low dose of aspirin inhibits the COX-1 enzyme, thus blocking production of the platelet inhibitor thromboxane (see Figure 18-13 on p. 548). Daily low-dose (81 mg) aspirin therapy prevents thrombosis that can trigger a myocardial infarction (MI). A larger dose of aspirin taken during an MI can lessen its severity. Heparin is a naturally occurring "blood thinner" that can be used to prevent excessive clotting. Heparin inhibits the conversion of prothrombin to thrombin, preventing the formation of a thrombus. Warfarin (Coumadin), an oral anticoagulant, is also frequently used to prevent excessive clotting. It blocks the stimulating effect of vitamin K on the liver, and consequently the liver cells make less prothrombin. The prothrombin content soon falls low enough to prevent abnormal clotting.

Despite anticoagulant drugs being called "blood thinners," they do not really dilute the blood. They instead make blood less likely to clot and more likely to flow easily, just as adding "paint thinner" to paint prevents clumping and promotes the smooth flow of paint.

A number of antiplatelet drugs, such as cilostazol (Pletal) and ticlopidine (Ticlid), exert effects by inhibiting an enzyme called *phosphodiesterase,* which is involved in platelet aggregation activity. The mechanism of action of these drugs may explain why a condition such as **intermittent claudication,** which involves cramplike pain in the calves after walking that is caused by occasional arterial microvascular blockages by platelet plugs, often responds well to antiplatelet but not to anticoagulant drug therapy.

Another popular antiplatelet drug is clopidogrel (Plavix), which exerts its antiplatelet action by blocking adenosine diphosphate (ADP) receptors on the platelet membranes. This drug is used to prevent arterial clots that may cause an MI or stroke.

for the presence of adequate calcium levels in the blood for normal clotting to occur. The pale yellowish liquid left after a clot forms is **blood serum.** How do you think serum differs from plasma? What is plasma? To check your answers, see Figure 20-20.

Liver cells synthesize both prothrombin and fibrinogen as they do almost all other plasma proteins. For the liver to synthesize prothrombin at a normal rate, blood must contain an adequate amount of vitamin K. Vitamin K is absorbed into the blood from the intestine. Some foods contain this vitamin, but it is also synthesized in the intestine by certain bacteria (not present for a time in newborn infants). Because vitamin K is fat soluble, its absorption requires bile. Therefore if the bile ducts become obstructed and bile cannot enter the intestine, a vitamin K deficiency develops. The liver cannot then produce prothrombin at its normal rate, and the blood's prothrombin concentration soon falls below normal. A prothrombin deficiency gives rise to a bleeding tendency. As a preoperative safeguard, therefore, patients with obstructive jaundice are generally given some kind of vitamin K preparation.

Conditions That Oppose Clotting

Although blood clotting goes on continuously and concurrently with clot dissolution (fibrinolysis), several conditions operate to oppose clot formation in intact vessels. Most important by far is the perfectly smooth surface of the normal endothelial lining of blood vessels. Platelets do not adhere to healthy endothelium; consequently, they do not activate and release platelet factors into the blood. Therefore the blood-clotting mechanism does not begin in normal vessels.

As an additional deterrent to clotting, blood contains certain substances called *antithrombins.* The name suggests their function—they oppose (inactivate) thrombin. Thus antithrombins prevent thrombin from converting fibrinogen to fibrin. **Heparin,** a natural constituent of blood, acts as an antithrombin. It was first prepared from liver (hence its name), but other organs also contain heparin. Injections of heparin are used to prevent clots from forming in vessels. *Coumarin* compounds such as *warfarin* (Coumadin) impair the liver's use of vitamin K and thereby slow its synthesis of prothrombin and factors VII, IX, and X. Indirectly, therefore, coumarin compounds retard coagulation. Direct thrombin inhibitors such as dabigatron (Pradaxa) can be administered orally to prevent clotting. Citrates keep donor blood from clotting before transfusion. Aspirin and other drugs, such as clopidogrel (Plavix) or cilostazol (Pletal), that inhibit platelet aggregation also inhibit coagulation (Box 20-5).

Conditions That Hasten Clotting

Two conditions particularly favor thrombus formation: a rough spot in the endothelium (blood vessel lining) and abnormally slow blood flow. Atherosclerosis, for example, is associated with an increased tendency toward **thrombosis**, the abnormal formation of clots. It is endothelial rough spots in the form of plaques of accumulated cholesterol lipid material that could trigger abnormal clot formation. Body immobility, on the other hand, may lead to thrombosis

Box 20-6 | HEALTH matters

Clinical Methods of Hastening Clotting

One way of treating excessive bleeding is to speed up the blood-clotting mechanism. This can be accomplished by increasing any of the substances essential for clotting, for example:

- Applying a rough surface such as gauze or gently squeezing the tissues around a cut vessel causes more platelets to activate and release more platelet factors. This in turn accelerates the first of the clotting reactions.
- Applying purified thrombin (in the form of sprays or impregnated gelatin sponges that can be left in a wound) accelerates the third stage.
- Applying cold compresses, which causes vasoconstriction and slows blood flow, can stop some superficial bleeding.
- Applying new types of hemostatic materials made with shrimp shells (HemCon), purified algae derivatives (MDRH), or mineral dust (QuickClot), which incorporate a variety of mechanisms, can promote blood clotting of wounds by providing large surface areas to stimulate platelet stickiness and release of clotting factors.

because blood flow slows down as movements decrease. Incidentally, this fact is one of the major reasons why physicians insist that bed patients must either move or be moved frequently.

Once started, a clot tends to grow. Platelets enmeshed in the fibrin threads activate, releasing more thromboplastin, which, in turn, causes more clotting, which enmeshes more platelets, and so on, in a vicious circle. Clot-retarding substances have proved valuable for retarding this process. Box 20-6 discusses some methods for therapeutically hastening clotting to stop bleeding.

Clot Dissolution

The physiological mechanism that dissolves clots is known as **fibrinolysis** (Figure 20-23). Evidence indicates that the two opposing processes of clot formation and fibrinolysis go on continuously. Normal blood contains an inactive plasma protein called *plasminogen* that can be activated by several substances released from damaged cells. These converting substances include thrombin, factor XII, tissue plasminogen activator (t-PA), and lysosomal enzymes. Plasmin hydrolyzes fibrin strands and dissolves the clot (see Figure 20-23).

In today's clinical practice, several different kinds of proteins are used to dissolve blood clots that are causing an acute medical crisis. These are enzymes that generate plasmin when injected into patients. Streptokinase (SK) is a plasminogen-activating factor made by certain *Streptococci* bacteria. It and recombinant t-PA can be used to dissolve clots in the large arteries of the heart, which, when blocked, can result in myocardial infarction (heart attack). In addition, t-PA has been recognized as a promising drug for the early treatment of strokes. If given within the first 6 hours after a clot forms in a cerebral vessel, it can often improve blood flow and greatly reduce the serious after-effects of a stroke.

The fact that streptococcal bacteria can form blood-dissolving factors such as SK is an important one. Recall that a secondary function of blood clotting is to trap bacteria that attempt to enter our tissues. To make their attack more effective, many bacteria such as *Streptococcus* (strep), *Staphylococcus* (staph), *Escherichia coli* (*E. coli*), and others, release anticlotting agents to overcome our defenses. Such agents often activate plasminogen and thus disrupt formation of the initial blood clot. Some bacterial agents instead bind fibrinogen to disrupt normal clotting.

| QUICK CHECK |

9. List the granulocytic and agranulocytic leukocytes.
10. List the normal percentages of the different WBCs in a differential count.
11. List the four ABO blood groups, and identify the antigens and antibodies (if any) associated with each.
12. Identify the two basic coagulation steps.

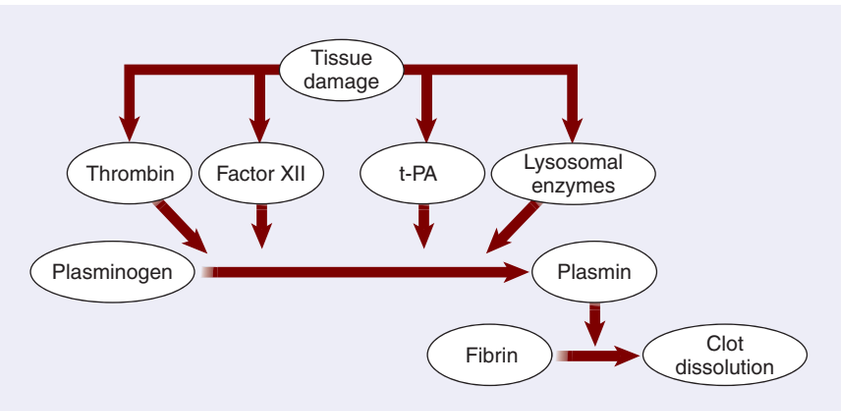

FIGURE 20-23

Fibrinolysis. Dissolution of a clot by fibrinolysis is triggered by the same events as those producing the clot but operates at a slower rate. Plasminogen is converted into the active enzyme plasmin by thrombin, factor XII, tissue plasminogen activator *(t-PA),* and lysosomal enzymes. Plasmin hydrolyzes fibrin strands and dissolves the clot.

the BIG picture

Blood and the Whole Body

In every chapter of this book we have referred to the notion that the whole body's function is geared toward maintaining stability of the internal fluid environment—that is, *homeostasis.* The fluid that makes up the internal environment in which cells are bathed—the fluid that must be kept stable—includes the plasma of the blood. As a matter of fact, it is the blood plasma that transports substances, and even heat, around the internal environment so that all body tissues are linked together. The various tissues of the body are linked by the plasma, which flows back and forth between any two points served by blood vessels. This, of course, means that substances such as nutrients, wastes, dissolved gases, water, antibodies, and hormones can be transported between almost any two points in the body.

Blood tissue is not just plasma, however. It contains the *formed elements*—the blood cells and platelets. The RBCs participate in the mechanisms that permit the efficient transport of the gases oxygen and carbon dioxide. WBCs are important in the defense mechanisms of the whole body. Their presence in blood ensures that they are available to all parts of the body, all of the time, to fight cancer, resist infectious agents, and clean up injured tissues. Platelets provide mechanisms for preventing loss of the fluid that constitutes our internal environment.

All other organs and systems of the body rely on blood to perform their many functions. No organ or system can maintain proper levels of nutrients, dissolved gases, or water without direct or indirect help from the blood. On the other hand, many other systems help blood do its job. For example, the respiratory system excretes carbon dioxide from the blood and picks up oxygen. Organs of the digestive system pick up nutrients, remove some toxins, and dispose of old blood cells. The endocrine system regulates the production of blood cells and the water content of the plasma. Besides removing toxic wastes such as urea, the urinary system has a vital role in maintaining homeostasis of plasma water concentration and pH.

Of course, blood is useless unless it continually and rapidly flows around the whole body—and continues to transport, defend, and maintain balance. The next several chapters outline the structures and functions that make this possible. Chapters 21 and 22 discuss the plan of the blood circulation and how adequate blood flow is maintained. Chapter 23 discusses the role of the lymphatic system in maintaining the fluid balance of the blood. Chapters 24 and 25 deal with the defensive mechanisms of blood and other tissues. As a matter of fact, most of the remaining chapters feature the role of blood in maintaining stability of the whole body.

MECHANISMS of DISEASE

BLOOD DISORDERS

Most blood diseases are disorders of the formed elements. Thus it is not surprising that the basic mechanism of many blood diseases is the failure of the blood-producing myeloid and lymphatic tissues to properly form blood cells. In many cases, this failure is the result of damage by drugs, toxic chemicals, or radiation. In other cases, it results from an inherited defect or even cancer.

If bone marrow failure is the suspected cause of a particular blood disorder, a sample of myeloid tissue may be drawn into a syringe. The bone marrow is obtained from inside the pelvic bone (iliac crest) or the sternum. This procedure, called **aspiration biopsy cytology** (ABC), allows examination of the tissue that may help confirm or reject a tentative diagnosis. If the bone marrow is severely damaged, the choice of a **bone marrow transplant** may be offered to the patient. In this procedure, myeloid tissue from a compatible donor is introduced into the recipient intravenously. If the recipient's immune system does not reject the new tissue, which is always a danger in this type of tissue transplant, the donor cells may establish a colony of new, healthy tissue in the bone marrow. In some cases, infusion of healthy marrow follows total body irradiation. This treatment destroys the diseased marrow, permitting the new tissue to grow.

Red Blood Cell Disorders

Anemia

The term **anemia** is used to describe different disease conditions caused by an inability of the blood to carry sufficient oxygen to the body cells. Anemias can result from inadequate numbers of RBCs or a deficiency of oxygen-carrying hemoglobin. Thus anemia can occur if the hemoglobin in RBCs is inadequate, even if normal numbers of RBCs are present.

Anemia Resulting from Changes in RBC Number

Anemias caused by an actual change in the number of RBCs can occur if blood is lost by hemorrhage, as with accidents or bleeding ulcers or if the blood-forming tissues cannot maintain normal numbers of blood cells. Such failures occur because of cancer, chemotherapy treatment, radiation (x-ray) damage, and certain types of infections. If bone marrow produces an excess of RBCs, the result is a condition called **polycythemia**. The blood in individuals suffering from this condition may contain so many RBCs that it may become too thick to flow properly.

One type of anemia characterized by an abnormally low number of red blood cells is **aplastic anemia.** Although idiopathic forms of this disease occur, most cases result from destruction of bone marrow by drugs, toxic chemicals, or radiation. Less commonly, aplastic anemia results from bone marrow destruction by cancer. Because tissues that produce other formed elements are also affected, aplastic anemia is usually accompanied by a decreased number of WBCs and platelets. Bone marrow transplants have been successful in treating some cases of aplastic anemia.

Pernicious anemia is another disorder characterized by a low number of RBCs. Pernicious anemia sometimes results from a dietary deficiency of vitamin B_{12}. Vitamin B_{12} is used in the formation of new RBCs in the bone marrow. In many cases, pernicious anemia results from the failure of the stomach lining to produce *intrinsic factor*—the substance that allows vitamin B_{12} to be absorbed. Pernicious anemia can be fatal if not successfully treated. One method of treatment involves intramuscular injections of vitamin B_{12}.

Folate deficiency anemia is similar to pernicious anemia because it also causes a decrease in the RBC count resulting from a vitamin deficiency. In this condition, it is *folic acid* (vitamin B_9) that is deficient. Folic acid deficiencies are common among individuals with alcoholism and other malnourished individuals. Treatment for folate deficiency **acute anemia** involves taking vitamin supplements until a balanced diet can be restored.

Of course, a significant reduction in the number of RBCs can occur as a result of blood loss**. Blood loss anemia** often occurs after hemorrhages associated with trauma, extensive surgeries, or other situations involving a sudden loss of blood. **Anemia of chronic disease** can be a serious complication of chronic inflammatory diseases and cancer; the cause is often unknown.

Changes in Hemoglobin

The amount and quality of hemoglobin within RBCs are just as important as the number of RBCs. In hemoglobin disorders, RBCs are sometimes classified as **hyperchromic** (abnormally high hemoglobin content) or hypochromic (abnormally low hemoglobin content).

Iron (Fe) is a critical component of the hemoglobin molecule, forming the central core of each heme group (see Figure 20-5). Without adequate iron in the diet, the body cannot manufacture enough hemoglobin. The result is **iron deficiency anemia**—a worldwide medical problem. Although the body carefully protects its iron reserves, they may be depleted through hemorrhage, increased requirements such as wound healing or pregnancy, or low intake. Unfortunately, iron deficiency is the most common nutritional deficiency in the world. The tragic result is that an estimated 10% of the population in some developed countries and up to 50% in developing countries suffers from iron deficiency anemia. Oral administration of iron-containing compounds, such as ferrous sulfate or ferrous gluconate, is very effective in treating the basic iron deficiency seen in the disease. Figure 20-24 shows a peripheral blood smear from an individual suffering from iron deficiency anemia. The numbers of RBCs are only slightly below normal. Note, however, that the cells are small and appear pale (hypochromic) because of the reduction in hemoglobin content.

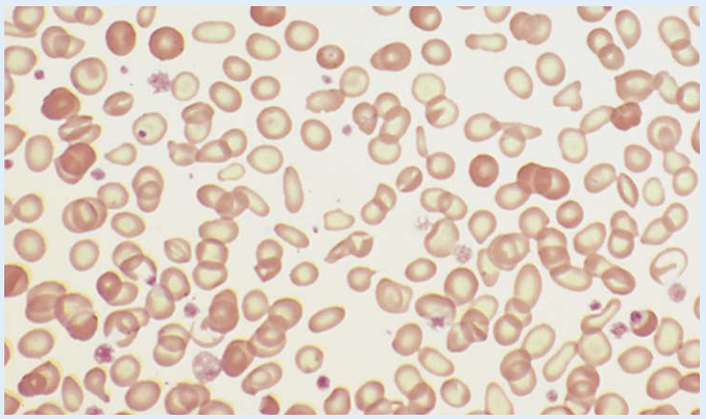

FIGURE 20-24

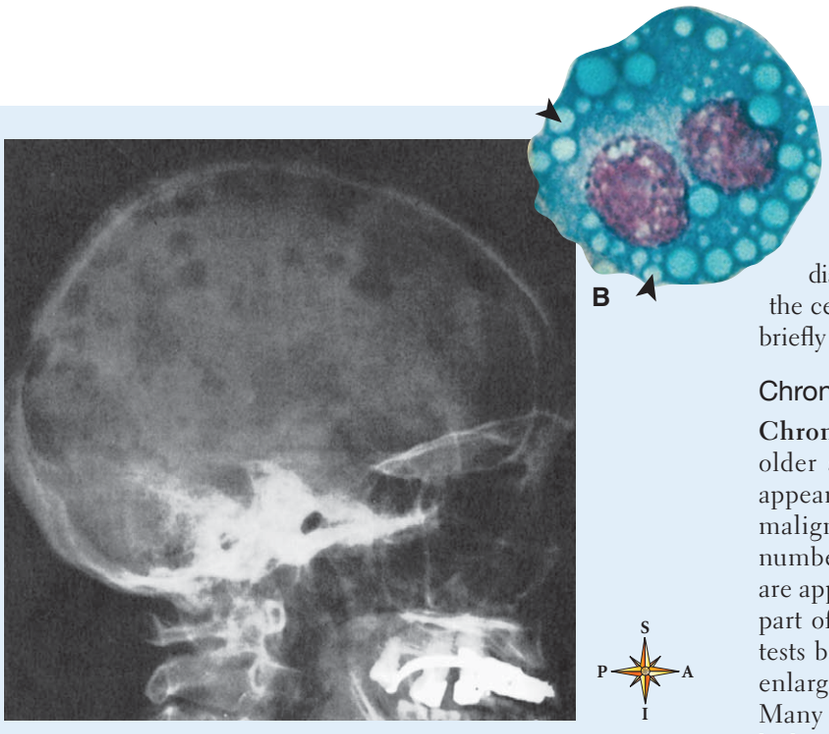
Iron deficiency anemia. Note the small, pale (hypochromic) red blood cells (RBCs). Lack of adequate color in the RBCs is due to reduced hemoglobin content.

The term **hemolytic anemia** applies to any of a variety of inherited blood disorders characterized by abnormal types of hemoglobin. The term *hemolytic* means "relating to blood breakage" and emphasizes the fact that abnormal hemoglobin often causes red blood cells to become distorted and easily broken. An example of a hemolytic anemia is **sickle cell anemia.** Another type of hemolytic anemia is **thalassemia**. As with sickle cell anemia, thalassemia is an inherited disorder, with both a mild and a severe form (*thalassemia minor* and *thalassemia major*).



White Blood Cell Disorders

The term **leukopenia** refers to an abnormally low WBC count (less than 5000 cells/mm^3 of blood). Various disease conditions may affect the immune system and decrease the amount of circulating WBCs. Acquired immunodeficiency syndrome, or AIDS, results in marked leukopenia. **Leukocytosis** refers to an abnormally high WBC count. It is a much more common problem than leukopenia, is seen in most types of leukemia, and almost always accompanies bacterial infections.

Two major groups of disease conditions constitute a majority of WBC and blood-related cancers, or malignant neoplasms. **Lymphoid neoplasms** arise from lymphoid precursor cells that normally produce B lymphocytes, T lymphocytes, or their descendent cell types. **Myeloid neoplasms** appear as a result of malignant transformation of myeloid stem or precursor cells that normally produce granulocytic WBCs, monocytes, RBCs, and platelets.

Multiple Myeloma

Multiple myeloma is cancer of antibody-secreting B lymphocytes called *plasma cells* (Figure 20-25, *B*). It is one of the most common and one of the most deadly forms of blood-related cancers in people older than 65 years of age. The cancerous transformation of plasma cells results in impairment of bone marrow function, production of defective antibodies, recurrent infections (from neutropenia), anemia, and the painful destruction and fracture

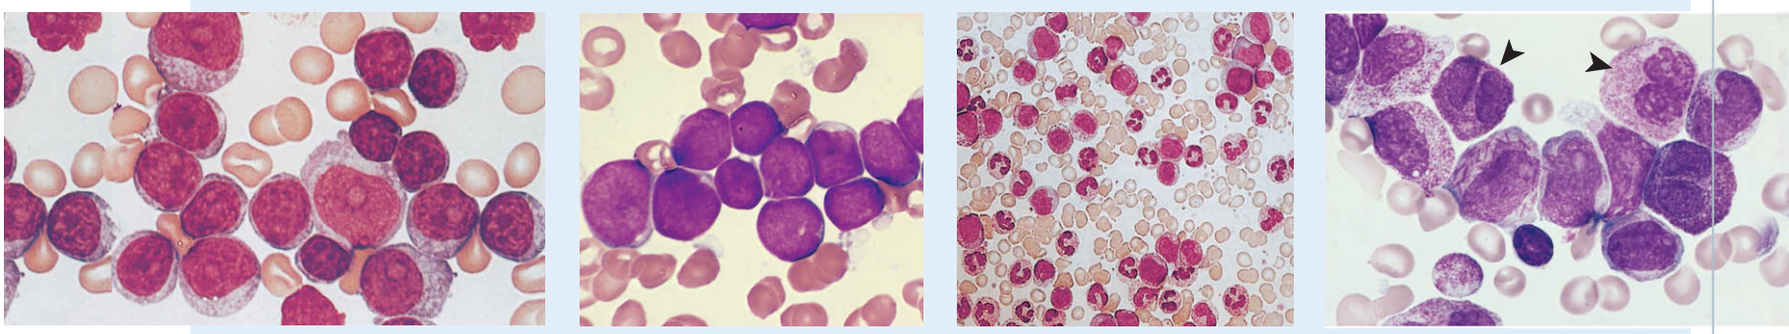
A B

FIGURE 20-25

Multiple myeloma. A, x ray of skull showing "honeycomb" or "punched-out" appearance of bones caused by defective antibodies from plasma cells. Normal skull bones would instead have a more uniform (less mottled) appearance in an x ray. **B,** Malignant plasma cell. Vesicles *(arrowheads)* contain defective antibodies.

of bones in the skull and throughout the skeletal system. The x-ray photo in Figure 20-25, *A*, shows the typical "honeycomb" or "punched-out" defects in skull bones caused by the defective myeloma antibody.

Leukemia



Leukemia is the term used to describe a number of blood cancers affecting the WBCs. In almost every form of leukemia, marked leukocytosis occurs. Leukocyte counts in excess of 100,000/mm^3 in circulating blood are common. The different types of leukemia are identified as either *acute* or *chronic*, based on how quickly symptoms appear after the disease begins, and as *lymphocytic* or *myeloid*, depending on the cell type involved. Four of the most common leukemias are briefly described here.

Chronic Lymphocytic Leukemia (CLL)

Chronic lymphocytic leukemia (CLL) most often affects older adults. Average age of onset is about 65 years, and it appears more often in men than women. In those with CLL, malignant precursor B lymphocytes are produced in great numbers (Figure 20-26, *A*). Early in the disease few symptoms are apparent, and many patients are diagnosed inadvertently as part of a routine physical examination when results of blood tests become available. When symptoms such as lymph node enlargement and fatigue do appear, they are often quite mild. Many patients with CLL live many years after diagnosis with little or no treatment.

Acute Lymphocytic Leukemia (ALL)

Acute lymphocytic leukemia (ALL) is primarily a disease of children and constitutes the most common form of "blood cancer" in children between 3 and 7 years of age (Figure 20-26, *B*). Fully 80% of all children who develop leukemia have this form of the disease. Although always a serious condition, it is highly curable in children but less so when it occurs in adults. As the name implies, onset of the disease is sudden. Symptoms include fever, bone pain, and increased rates of infection. Cancerous cells crowd out other bone marrow cells and decrease the production of RBCs and platelets as well as other nonmalignant lymphocyte cells. Anemia and swelling of lymph nodes, spleen, and liver are common symptoms. Treatment may involve chemotherapy, irradiation, and bone marrow or stem cell transplants.

A B C D

FIGURE 20-26

Types of leukemia. A, Chronic lymphocytic leukemia (CLL)—peripheral blood smear showing large numbers of diseased B lymphocytes. **B,** Acute lymphocytic leukemia (ALL)—appearance of B lymphocytes in ALL. **C,** Chronic myeloid leukemia (CML)—note severe granulocytic leukocytosis. **D,** Acute myeloid leukemia (AML)—note large numbers of myelocytic precursor cells *(arrowheads)*.

Chronic Myeloid Leukemia (CML)

Chronic myeloid leukemia (CML) accounts for about 20% of all cases of leukemia and occurs most often in adults between 25 and 60 years of age. CML results from cancerous transformation of granulocytic (neutrophil, eosinophil, and basophil) precursor cells in the bone marrow. Onset is slow, and once the disease is established, it progresses slowly. Diagnosis is often made by discovery of marked elevations of granulocytic WBCs in peripheral blood (Figure 20-26, *C*) and by extreme spleen enlargement. The drug imatinib (Gleevec) specifically seeks out and blocks the flawed signals in CML cancer cells that cause runaway proliferation (Box 20-7).

Acute Myeloid Leukemia (AML)

Acute myeloid leukemia (AML) is caused by pathologic transformation of myeloid stem cells (Figure 20-26, *D*). It accounts for 80% of all cases of acute leukemia in adults and 20% of acute leukemia cases in children. Onset is sudden, and once symptoms appear the disease progresses rapidly. The most common symptoms include anemia and fatigue, recurrent infections, bone and joint pain, and spongy bleeding gums. The prognosis of AML is poor, with only about 50% of children and 30% of adults achieving long-term survival. However, advances in bone marrow and stem cell transplantation have increased cure rates in selected patients.

Infectious Mononucleosis

Infectious mononucleosis is a common noncancerous WBC disorder appearing most often in adolescents and young adults between 15 and 25 years of age. It is caused by a virus found in the saliva of infected individuals. Leukocytosis is common early in the disease with total WBC counts averaging between 12,000 and 18,000/mm^3. More than 60% of the leukocytes can be identified in a differential WBC count as large, *atypical* (abnormal) lymphocytes that have abundant cytoplasm and a large nucleus (Figure 20-27). Symptoms vary greatly, but, in addition to the leukocytosis and atypical lymphocytes seen in peripheral blood, fever, sore throat, rash, severe fatigue, and enlargement of lymph nodes and the spleen are common findings. Infectious "mono" is generally self-limited and resolves without complications in about 4 to 6 weeks, although fatigue may last for longer periods.

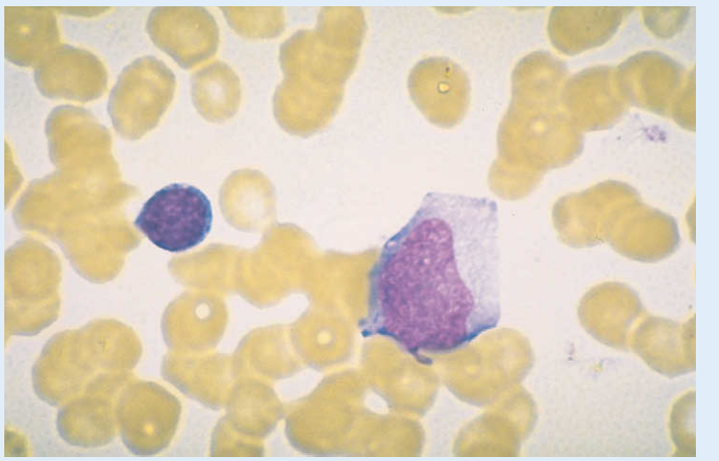


FIGURE 20-27

Infectious mononucleosis. The cell on the left is a typical small lymphocyte with the nucleus almost filling the cell. The larger atypical lymphocyte on the right has much more cytoplasm and a larger nucleus.

Box 20-7 | HEALTH matters

Treating Chronic Myeloid Leukemia

Scientists have known for a number of years now that a pathologic transformation of the gene that controls the production of an intracellular protein called *tyrosine kinase* is associated with development of **chronic myeloid leukemia (CML)**—a common and deadly form of blood cancer.

One type of treatment for CML is a tyrosine kinase **signal transduction inhibitor** drug called imatinib (Gleevec). It acts by seeking out and breaking up the signal transduction between the abnormal tyrosine kinase being produced and the specific receptor sites for this enzyme on the CML cancer cells that send the signal causing runaway proliferation. It is a "rational" drug that acts to treat CML at the molecular level. By doing so, it blocks some of the most serious functional effects of the genetic flaw that causes the disease—not just the symptoms resulting from expression of the genetic defect.

Clotting Disorders

Unfortunately, clots sometimes form in unbroken blood vessels of the heart, brain, lungs, or other organs—a dreaded thing because clots may produce sudden death by shutting off the blood supply to a vital organ. When a clot stays in the place where it formed, it is called a **thrombus**, and the condition itself is spoken of as **thrombosis**. If all or part of a clot dislodges and circulates through the bloodstream, it is called an, and the condition is called an **embolism**.

Thrombosis and embolism cause most myocardial infarctions (MIs or "heart attacks") and cerebrovascular accidents (CVAs or "strokes"), making them the leading cause of death in developed countries. Box 20-5 on p. 617 discusses various therapies to prevent the dangers of thrombus formation.

Hemophilia is an X-linked inherited disorder that affects 1 in every 10,000 males worldwide. It results from a failure to produce one or more plasma proteins responsible for blood clotting—a process illustrated in Figure 20-21. Thus hemophilia is characterized by a relative inability to form blood clots. Because minor blood vessel injuries are common in ordinary life, hemophilia can be a life-threatening condition. The most common form is called *hemophilia* A. It is caused by

absence of factor VIII protein and affects more than 300,000 people around the world.

Historically, factor VIII was obtained by plasma fractionation. This method cannot meet demand given the shortage of available donated blood. Currently, recombinant methods are used to produce enough recombinant antihemophilic factor VIII (rAHF) to meet the therapeutic needs of the world's hemophiliac population. Increasing amounts are needed to meet the larger quantities required as adolescent patients mature and as physicians prescribe more factor VIII to prevent as well as to treat bleeding episodes. The blood's ability to clot can be determined by tests such as prothrombin time (PT), discussed in Box 20-8, which help monitor the success of antihemophilia therapies.

A more common type of clotting disorder results from a decrease in the platelet count—a condition called **thrombocytopenia.** This condition is characterized by bleeding from many small blood vessels throughout the body, most visibly in the skin and mucous membranes. If the number of thrombocytes falls to 20,000/mm^3 or less (normal range is 150,000 to 400,000/mm^3), catastrophic bleeding may occur. Although a number of different mechanisms can result in thrombocytopenia, the usual cause is bone marrow destruction by drugs or an immune system disease, chemicals, radiation, or cancer. Drugs may cause thrombocytopenia as a side effect. In such cases, stopping the drug usually solves the problem.

Box 20-8 | HEALTH matters

Prothrombin Time

A laboratory test called the *prothrombin time (PT)* is often used to assess the body's ability to form blood clots. This can be useful to find the cause of abnormal bruising or bleeding, regulate dosage of anticoagulant drugs (see Box 20-5 on p. 617), check levels of clotting factors, or assess liver function (where prothrombin is produced).

In this test, thromboplastin (a blood clotting factor) and calcium are added simultaneously to a tube of the patient's plasma and a tube containing a normal control solution, and the time required for clot formation in both tubes is determined.

A patient prothrombin time in excess of the standard control value (11 to 12.5 seconds) indicates reduced clotting. Unfortunately, PT test results may vary between different clinical laboratories. Variability is often caused by differing techniques or differences in the sensitivity of reagents used. To minimize the effects of these and other variables and standardize the results of anticoagulation testing, a system called the *INR* (abbreviation for *International Normalized Ratio*) has been developed. PT is reported in seconds. The INR is a mathematical calculation and is reported as a number. An INR of 0.8 to 1.2 is considered normal—and values above the normal range indicate reduced clotting ability.

CASE study

Duncan was slicing a bagel to put in the toaster. When the microwave beeped, he glanced in that direction, taking his eyes off the bagel for a split second. In that split second, the knife slipped and cut deeply into his finger. Immediately blood started spurting out of the damaged blood vessels.

Duncan grabbed a towel and wrapped it tightly around the cut, while holding his hand above his heart.

1. What is the main component of the blood coming out of Duncan's finger?
   a. Erythrocytes
   b. Leukocytes
   c. Plasma
   d. Thrombocytes

Because of the damage to his blood vessels, Duncan's body will immediately start the blood clotting process.

2. What's the first step in hemostasis (stopping bleeding)?
   a. Vascular spasm
   b. Platelet plug
   c. Coagulation
   d. Leukocytic plug

3. What is the last step in clot formation?
   a. Fibrinogen converted to fibrin
   b. Prothrombin converted to thrombin
   c. Profibrin converted to fibrin
   d. Factor VIII converted to factor IX

4. If Duncan were missing factor VIII, what condition would he have?
   a. Thrombocytopenia
   b. Pernicious anemia
   c. Polycythemia
   d. Hemophilia

COMPOSITION OF BLOOD

A. Introduction (Figure 20-1)
   1. Blood—made up of plasma and formed elements
   2. Blood—complex transport medium that performs vital pickup and delivery services for the body
   3. Blood—keystone of body's heat-regulating mechanism

B. Blood volume
   1. Young adult male has approximately 5 liters of blood
   2. Blood volume varies according to age, body type, sex, and method of measurement

FORMED ELEMENTS OF BLOOD

A. Red blood cells (RBCs; erythrocytes)
   1. Description of mature RBCs (Figure 20-4)
      a. Have no nucleus and shaped like tiny biconcave disks
      b. Do not contain ribosomes, mitochondria, and other organelles typical of most body cells
      c. Primary component is hemoglobin
      d. Most numerous of the formed elements
   2. Function of RBCs
      a. RBCs' critical role in the transport of oxygen and carbon dioxide depends on hemoglobin
      b. Carbonic anhydrase (CA)—enzyme in RBCs that catalyzes a reaction that joins carbon dioxide and water to form carbonic acid
      c. Carbonic acid—dissociates and generates bicarbonate ions, which diffuse out of the RBC and serve to transport carbon dioxide in the blood plasma
   3. Hemoglobin (Figure 20-5)
      a. Within each RBC are approximately 200 to 300 million molecules of hemoglobin

b. Hemoglobin is made up of four globin chains, with each attached to a heme group
c. Hemoglobin is able to unite with four oxygen molecules to form oxyhemoglobin to allow RBCs to transport oxygen where it is needed
d. A male has a greater amount of hemoglobin than a female
e. Anemia—a decrease in number or volume of functional RBCs in a given unit of whole blood

4. Formation of RBCs (review Figures 20-6 and 20-7)
a. Erythropoiesis—entire process of RBC formation
b. RBC formation begins in the red bone marrow as hematopoietic stem cells and goes through several stages of development to become erythrocytes; entire maturation process requires approximately 4 days
c. RBCs are created and destroyed at approximately 200 billion per day in an adult; homeostatic mechanisms operate to balance the number of cells formed against the number of cells destroyed

5. Destruction of RBCs (Figure 20-8)
a. Life span of a circulating RBC averages 105 to 120 days
b. Macrophage cells phagocytose the aged, abnormal, or fragmented RBCs
c. Hemoglobin is broken down, and amino acids, iron, and bilirubin are released

B. White blood cells (leukocytes; WBCs) (review Table 20-1)
1. Granulocytes
a. Neutrophils (review Figure 20-9)—make up approximately 65% of total WBC count in a normal blood sample; highly mobile and very active phagocytic cells; capable of diapedesis; cytoplasmic granules contain lysosomes
b. Eosinophils (review Figure 20-10)—account for 2% to 5% of circulating WBCs; numerous in mucous lining of respiratory and digestive tracts; weak phagocytes; release chemicals of immunity; provide protection against infections caused by parasitic worms and help regulate allergic reactions
c. Basophils (review Figure 20-11)—account for only 0.5% to 1% of circulating WBCs; motile and capable of diapedesis; cytoplasmic granules contain histamine and heparin

2. Agranulocytes (Figures 20-12 and 20-13)
a. Lymphocytes—smallest of the WBCs; second most numerous WBC; account for approximately 25% of circulating WBCs; T lymphocytes and B lymphocytes have an important role in immunity—T lymphocytes directly attack an infected or cancerous cell, and B lymphocytes produce antibodies against specific antigens
b. Monocytes—largest leukocytes; mobile and highly phagocytic cells

3. WBC numbers—1 mm^3 of normal blood usually contains 5000 to 9000 leukocytes, with different percentages for each type; WBC numbers have clinical significance because they change with certain abnormal conditions (Figure 20-14)

4. Formation of WBCs (review Figure 20-6)
a. Granular and agranular leukocytes mature from the undifferentiated hematopoietic stem cell
b. Neutrophils, eosinophils, basophils, and a few lymphocytes and monocytes originate in red bone marrow; most lymphocytes and monocytes develop from hematopoietic stem cells in lymphatic tissue

C. Platelets (review Figure 20-2)
1. Structure
a. In circulating blood, platelets are small, pale bodies that appear as irregular spindles or oval disks
b. Three important properties are agglutination, adhesiveness, and aggregation
c. Platelet counts in adults average 250,000/mm^3 of blood; normal range is 150,000 to 400,000/mm^3

2. Functions of platelets
a. Important role in hemostasis and blood coagulation; secondary role in defending against bacterial attacks
b. Hemostasis—refers to stoppage of blood flow; however, if injury is extensive, the blood-clotting mechanism is activated to assist

3. Platelet plug formation
a. Platelets adhere to damaged endothelial lining and to each other 1 to 5 seconds after injury to vessel wall, forming a platelet plug
b. Temporary platelet plug is an important step in hemostasis
c. "Sticky platelets" form physical plug and secrete several chemicals involved in the coagulation process

4. Formation and life span of platelets (average of 7 days)—formed in red bone marrow, lungs, and spleen by fragmentation of megakaryocytes

BLOOD TYPES (BLOOD GROUPS)

A. The ABO system (Figures 20-16 to 20-18)
1. Every person's blood belongs to one of four ABO blood groups
2. Named according to antigens present on RBC membranes
a. Type A—antigen A on RBCs
b. Type B—antigen B on RBCs
c. Type AB—both antigen A and antigen B on RBCs; known as universal recipient
d. Type O—neither antigen A nor antigen B on RBCs; known as universal donor

B. The Rh system (Figure 20-19)
1. Rh-positive blood—Rh antigen is present on the RBCs
2. Rh-negative—RBCs have no Rh antigen present
3. Anti-Rh antibodies are not normally present in blood; anti-Rh antibodies can appear in Rh-negative blood if it has come in contact with Rh-positive RBCs

BLOOD PLASMA

A. Plasma—liquid part of blood; clear, straw-colored fluid; made up of 90% water and 10% solutes (Figure 20-20)
B. Solutes—6% to 8% of plasma solutes are proteins, consisting of three main compounds
   1. Albumins—help maintain osmotic balance of the blood
   2. Globulins—essential component of the immunity mechanism
   3. Fibrinogen—key role in blood clotting
C. Plasma proteins have an essential role in maintaining normal blood circulation

BLOOD CLOTTING (COAGULATION)

A. Mechanism of blood clotting—goal of coagulation is to stop bleeding and prevent loss of vital body fluid in a swift and sure method; the classic theory (Figure 20-21) is as follows:
   1. Classic theory of coagulation advanced in 1905; identified four components critical to coagulation
      a. Prothrombin
      b. Thrombin
      c. Fibrinogen
      d. Fibrin
   2. Current explanation of coagulation involves three stages (Figure 20-22)
      a. Stage 1—production of thromboplastin activator by *either* of the following:
         (1) Chemicals released from damaged tissues (extrinsic pathway)
         (2) Chemicals present in the blood (intrinsic pathway)
      b. Stage II—conversion of prothrombin to thrombin
      c. Stage III—conversion of fibrinogen to fibrin and production of fibrin clot
B. Conditions that oppose clotting
   1. Clot formation in intact vessels is opposed
   2. Several factors oppose clotting
      a. Perfectly smooth surface of the normal endothelial lining of blood vessels does not allow platelets to adhere
      b. Antithrombins—substances in the blood that oppose or inactivate thrombin; prevent thrombin from converting fibrinogen to fibrin; for example, heparin
C. Conditions that hasten clotting
   1. Rough spot in the endothelium
   2. Abnormally slow blood flow
D. Clot dissolution (Figure 20-23)
   1. Fibrinolysis—physiological mechanism that dissolves the clot once it has formed
   2. Plasmin—enzyme in the blood that catalyzes the hydrolysis of fibrin, causing it to dissolve; it is activated by chemicals released from damaged cells and acts slowly to dissolve the clot
   3. Substances that generate plasmin can be used as a therapy to dissolve blood clots

THE BIG PICTURE: BLOOD AND THE WHOLE BODY

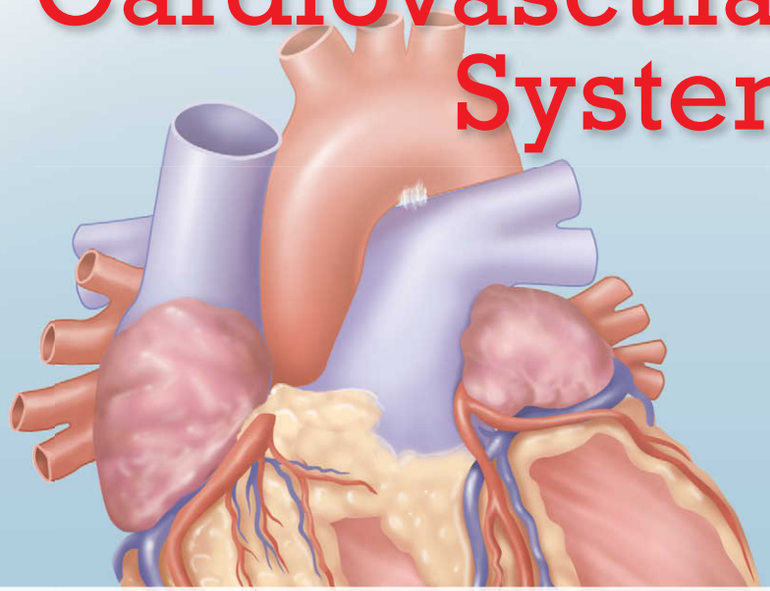
A. Blood plasma transports substances, including heat, around the body, linking all body tissues together
B. Blood tissue contains formed elements—blood cells and platelets
   1. RBCs assist in the transport of oxygen and carbon dioxide
   2. WBCs assist in the defense mechanisms of the whole body
   3. Platelets prevent loss of the fluid that constitutes the internal environment
C. Blood is needed by all organs and body systems to function properly, just as many body systems aid the functions of blood.
D. Blood is useless to the body unless it continues to flow around the body and performs its functions of transport, defense, and balance (or homeostasis).

REVIEW QUESTIONS

Write out the answers to these questions after reading the chapter and reviewing the Chapter Summary. If you simply think through the answer without writing it down, you won't retain much of your new learning.

1. What are the formed elements of blood?
2. What is the function of carbonic anhydrase?
3. Describe the structure of hemoglobin.
4. How does the structure of hemoglobin allow it to combine with oxygen?
5. Discuss the steps involved in erythropoiesis.
6. What is the average life span of a circulating red blood cell?
7. How are granulocytes similar to agranulocytes? How do they differ?
8. Define the term *chemotaxis*.
9. List the important physical properties of platelets.
10. Explain what is meant by *type AB blood*. Explain Rh-negative blood.
11. Which organ is responsible for the synthesis of most plasma proteins?
12. What is the normal plasma protein concentration?
13. What are some functions served by plasma proteins?
14. Describe the role of platelets in hemostasis and blood clotting.
15. What triggers blood clotting?
16. Identify factors that oppose blood clotting. Do the same for factors that hasten blood clotting.
17. Describe the physiological mechanism that dissolves clots.
18. Describe the hemoglobin in a person with sickle cell trait.
19. List and describe three blood disorders.

CRITICAL THINKING QUESTIONS



After finishing the Review Questions, write out the answers to these more in-depth questions to help you apply your new knowledge. Go back to sections of the chapter that relate to concepts that you find difficult.

1. A modern hospital laboratory has machines that can automatically do blood cell counts based on the size of cells. If the lab technician did not want to count erythrocytes, for what size range would the machine be set? What white blood cells would be missed? What would be the classes, functions, and life spans of the white blood cells that were counted?
2. A friend received a report detailing the laboratory results related to his recent physical examination and noted that his hematocrit was below normal. Because he knows you are taking anatomy and physiology, he has come to you for an explanation. Based on what you know, explain to him what a hematocrit value is, how it is determined, and what value would put him below normal.
3. You are a medical examiner and are asked to determine the cause of death of a body brought to the morgue. You find a very large agglutination (not a clot) in a major vein. Based on this, what judgment would you make regarding the cause of death?
4. Suppose a person had a thyroid disorder that caused the production of calcitonin to be many times higher than it should be. Elaborate on why a possible side effect of this condition might be a very slow blood-clotting time.
5. A patient comes into the emergency room with severe bleeding. What can be done to speed the formation of a clot?
6. Some athletes, seeking a competitive edge, may resort to blood doping. How would you explain blood doping? What information would you use to discourage athletes from participating in the practice of blood doping?
7. How would you summarize the condition *erythroblastosis fetalis*?

Anatomy of the Cardiovascular System

The cardiovascular system is sometimes called simply the circulatory system. *It consists of the heart, which is a muscular pumping device, and a closed system of vessels called* arteries, capillaries, *and* veins. *As the name implies, blood contained in the circulatory system is pumped by the heart around a closed circle or circuit of vessels as it passes again and again through the various circulations of the body (see p. 648).*

As in the adult, survival of the developing embryo depends on the circulation of blood to maintain homeostasis and a favorable cellular environment. In response to this need, the cardiovascular system makes its appearance early in development and reaches a functional state long before any other major organ system. Incredible as it seems, the heart begins to beat regularly early in the fourth week after fertilization.

HEART

Location of the Heart

The human heart is a four-chambered muscular organ, shaped and sized roughly like a person's closed fist (Figure 21-1). It lies in the mediastinum, or middle region of the thorax, just behind the body of the sternum between the points of attachment of the second through the sixth ribs. Approximately two thirds of the heart's mass is to the left of the midline of the body, and one third is to the right (Figure 21-2).

Posteriorly the heart rests against the bodies of the fifth to the eighth thoracic vertebrae. Because of its placement between the sternum in front and the bodies of the thoracic vertebrae behind, it can be compressed by application of pressure to the lower portion of the body of the sternum using the heel of the hand (Figure 21-2, *E*). Rhythmic compression of the heart in this way can maintain blood flow in cases of cardiac arrest and, if combined with effective artificial respiration, the resulting procedure, called *cardiopulmonary resuscitation* (CPR), can be life saving.

The anatomical position of the heart in the thoracic cavity is shown in Figure 21-2. The lower border of the heart, which forms a blunt point known as the *apex*, lies on the diaphragm, pointing toward the left. To count the apical beat, one must place a stethoscope directly over the apex, that is, in the space between the fifth and sixth ribs (fifth intercostal space) on a line with the midpoint of the left clavicle.

The upper border of the heart, that is, its base, lies just below the second rib. The boundaries, which indicate its size, have considerable clinical importance, because a marked increase in heart size accompanies certain types of heart disease. Therefore, when diagnosing heart disorders, the physician charts the boundaries of the heart. The "normal" boundaries of the heart are, however, influenced by factors such as age, body build, and state of contraction.

Size and Shape of the Heart

At birth the heart is said to be transverse (wide) in type and appears large in proportion to the diameter of the chest cavity. In the infant, it is 1/130 of the total body weight compared with about 1/300 in the adult. Between puberty and 25 years of age the heart attains its adult shape and weight—about 310 grams is average for the male and 225 grams for the female.

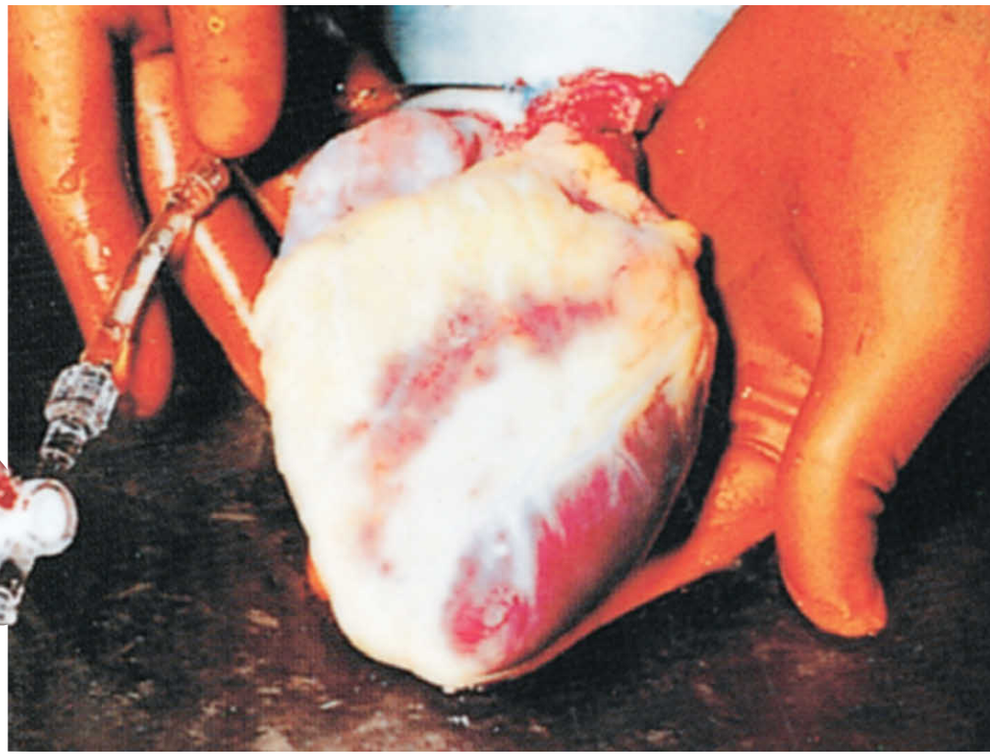

FIGURE 21-1

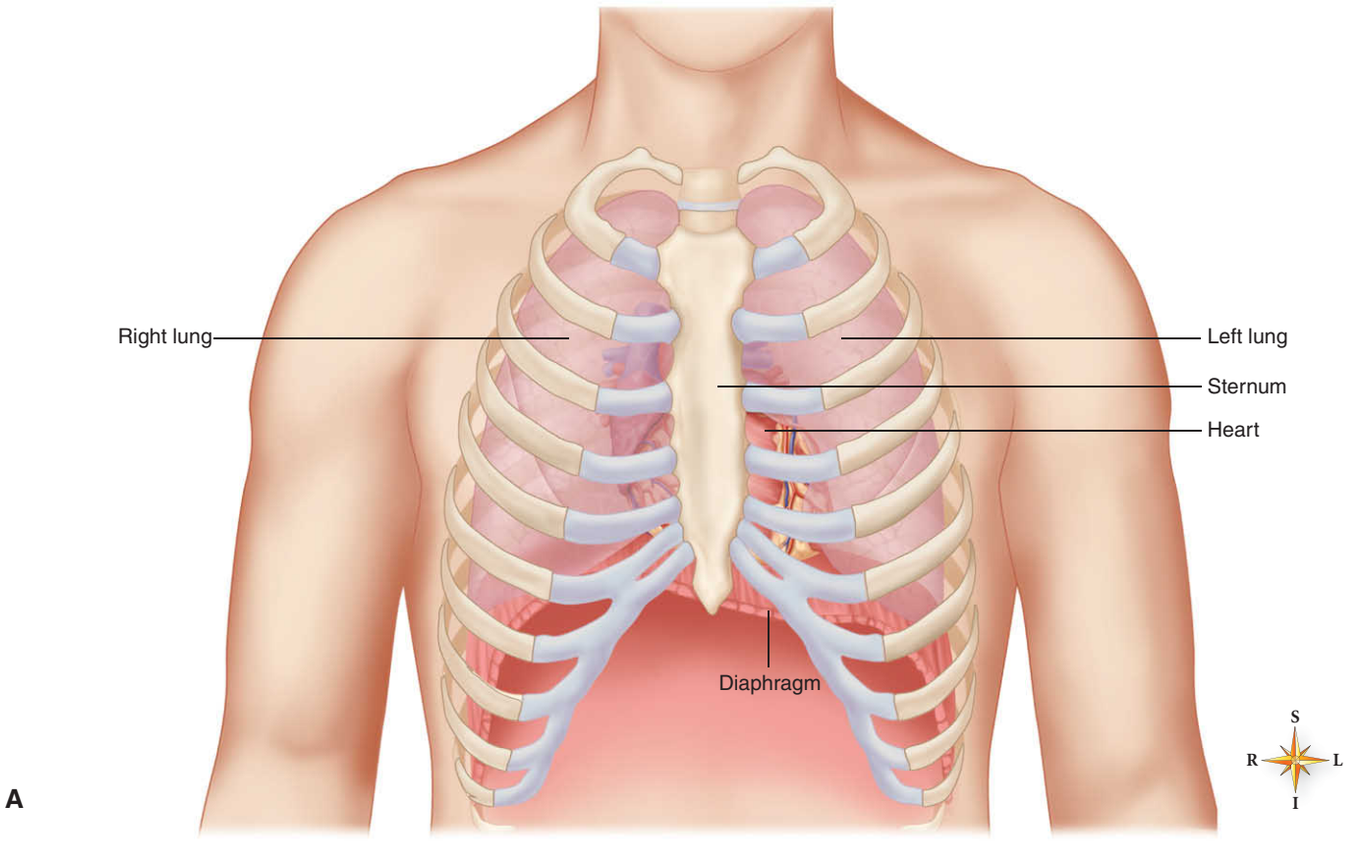
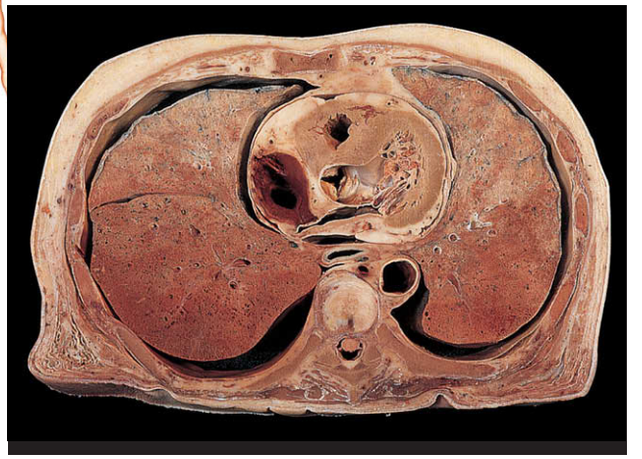
Appearance of the heart. This photograph shows a living human heart prepared for transplantation into a patient. Note its size relative to the hands that are holding it.

In the adult the shape of the heart tends to resemble that of the chest. In tall, thin individuals the heart is frequently described as elongated, whereas in short, stocky individuals it has greater width and is described as transverse. In individuals of average height and weight it is neither long nor transverse but somewhat intermediate between the two. Its approximate dimensions are 12 cm (4¾ inches) long, 9 cm (3½ inches) wide, and 6 cm (2½ inches) deep. Figure 21-3 shows details of the heart and great vessels in external views.

| QUICK CHECK |

1. In anatomical terms, where is the heart located?
2. Describe the shape of the heart.
3. When does the heart attain its adult shape and weight?





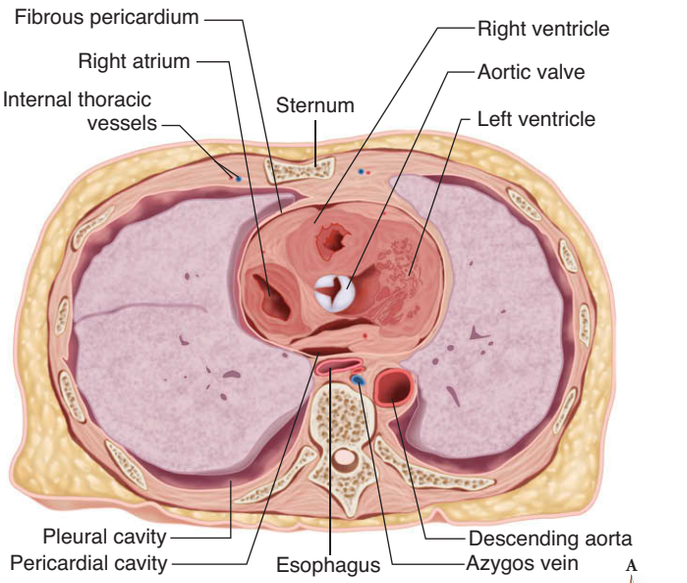


FIGURE 21-2

Coverings of the Heart

STRUCTURE OF THE HEART COVERINGS

The heart has its own special covering, a loose-fitting inextensible sac called the **pericardium.** The pericardial sac, with the heart removed, can be seen in Figure 21-4. The pericardium consists of two parts: a fibrous portion and a serous portion (Figure 21-5). The sac itself is made of tough white fibrous tissue but is lined with smooth, moist serous membrane—the parietal layer of the serous pericardium. The same kind of membrane covers the entire outer surface of the heart. This covering layer is known as the *visceral layer* of the serous pericardium or the **epicardium.** The fibrous sac attaches to the large blood vessels emerging from the top of the heart but not to the heart itself (see Figure 21-4). Therefore it fits loosely around the heart, with a slight space between the visceral layer adhering to the heart and the parietal layer adhering to the inside of the fibrous sac. This space is called the **pericardial space.** It contains 10 to 15 ml of **pericardial fluid**, a lubricating fluid secreted by the serous membrane.

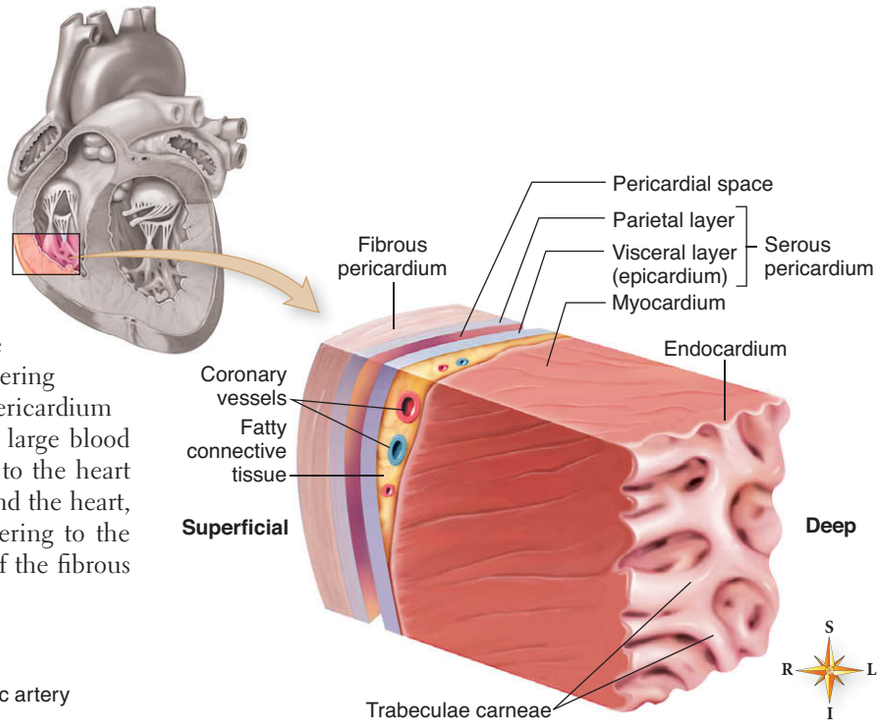

FIGURE 21-5

Wall of the heart. The cutout section of the heart wall shows the outer fibrous pericardium and the parietal and visceral layers of the serous pericardium (with the pericardial space between them). Note that a layer of fatty connective tissue is located between the visceral layer of the serous pericardium (epicardium) and the myocardium. Note also that the endocardium covers beamlike projections of myocardial muscle tissue, called *trabeculae carneae.*

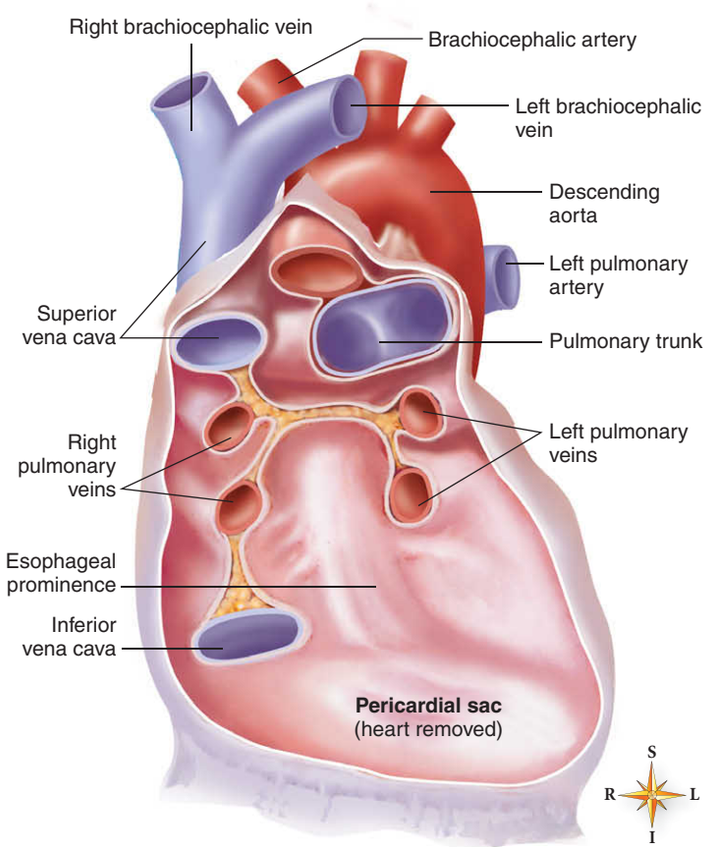

FIGURE 21-4

Pericardium. Frontal view diagram showing cut pericardial sac with heart removed. Notice that the pericardial sac attaches to the large vessels that enter and exit the heart, not to the heart itself. For a different view of the pericardium, see Figure 21-2, *C.*

Fibrous pericardium—tough, loose-fitting, and inelastic sac around the heart

Serous pericardium—consisting of two layers

1. *Parietal layer*—lining inside the fibrous pericardium
2. *Visceral layer (epicardium)*—adhering to the outside of the heart; between visceral and parietal layers is a space, the pericardial space, that contains a few drops of pericardial fluid

FUNCTION OF THE HEART COVERINGS

The fibrous pericardial sac with its smooth, well-lubricated lining provides protection against friction. The heart moves easily in this loose-fitting jacket with no danger of irritation from friction between the two surfaces, as long as the serous pericardium remains normal and continues to produce lubricating serous fluid.

Structure of the Heart

WALL OF THE HEART

Three distinct layers of tissue make up the heart wall (see Figure 21-5) in both the atria and the ventricles: the epicardium, myocardium, and endocardium.

Epicardium

The outer layer of the heart wall is called the **epicardium,** a name that literally means "on the heart." The epicardium is actually the visceral layer of the serous pericardium already described. In other words, the same structure has two different names: epicardium and serous pericardium.

Myocardium

The bulk of the heart wall is the thick, contractile, middle layer of specially constructed and arranged cardiac muscle cells called the **myocardium.** The minute structure of cardiac muscle has been described in Chapters 5 and 12. Review Table 6-7 on p. 152 for a brief overview of cardiac muscle.

Recall that cardiac muscle tissue is composed of many branching cells that are joined into a continuous mass by end-to-end junctions called *intercalated disks* (see Figure 6-35 on p. 153). Because each intercalated disk includes many gap junctions, large areas of cardiac muscle are electrically coupled into a single functional unit called a *syncytium* (meaning "joined cells"). Figure 13-23 on p. 400 shows how such electrical connections work. Because they form an electrically coupled syncytium, cardiac muscle cells can pass an action potential from fiber to fiber along a large area of the heart wall—thus stimulating contraction in each muscle fiber of the syncytium.

Another advantage of the linked structure of myocardial cells is that the cardiac fibers form a continuous sheet of muscle that wraps entirely around the cavities within the heart. Thus the encircling myocardium can compress the heart cavities, and the blood within them, with great force.

Recall also that cardiac muscles are *autorhythmic*, meaning that they can contract on their own in a slow, steady rhythm. As we explained in Chapter 12, cardiac muscle cells cannot summate contractions to produce tetanus and thus do not fatigue—a useful characteristic for muscle tissue that must maintain a continuous cycle of alternating contraction and relaxation for the entire span of life. Because the muscular myocardium can contract powerfully and rhythmically, without fatigue, the heart is an efficient and dependable pump for blood.

If the myocardium is damaged, as it may be in a "heart attack" or myocardial infarction (MI), then it will not pump as efficiently—which may quickly lead to death if the damage is severe. Such damage can be diagnosed by analyzing cardiac marker molecules released into the blood by damaged cardiac muscle fibers (Box 21-1).

Box 21-1 | DIAGNOSTIC study

Cardiac Marker Studies

When the heart muscle is damaged, molecules contained within the muscle cells are released into the bloodstream, causing increased plasma levels of these molecules. Blood tests (see figure) for these "marker" molecules are useful in confirming a *myocardial infarction (MI),* or "heart attack." The **troponins test** is very sensitive and is often the first choice in determining whether damage to the cardiac muscle has occurred. The two types of markers measured by this test are *cardiac-derived troponin I (cTnI) and troponin T (cTnT).* These troponins often increase to 20-fold their normal level within a few hours of an MI and remain high for several days.

A cardiac enzyme called *creatine kinase (CK)* is also often used as a cardiac marker. The ratio of the MB type of creatine kinase, or *CK-MB,* to standard CK increases within a few hours after an MI. The total CK/CK-MB released helps determine the size of the infarct. The CK-MB test is often used to confirm an MI when the results of the troponins test are confusing.

Cardiac marker determinations are also useful in observing the course of a myocardial infarction once it has occurred and in detecting an extension of it.

C-reactive protein (CRP) is a well-known blood marker for inflammation. Research has now confirmed that elevated levels of this blood protein are highly suggestive of either active cardiac disease (including MI) or early stages of progressive risk factor development. Many cardiologists are now measuring C-reactive protein levels in their heart patients as often as they check blood lipid levels or follow other known risk factors. The intent is to actively treat the disease before it becomes symptomatic or a heart attack actually occurs (also see Box 20-1 on erythrocyte sedimentation rate, p. 601).

Endocardium

The lining of the interior of the myocardial wall is a delicate layer known as the **endocardium.** The endocardium is made of a type of tissue called endothelial tissue, or simply **endothelium.** Endothelium lines the heart (where it is called the *endocardium*) and continues on to line all of the blood vessels. Endothelium is a specialized type of simple squamous epithelium.

Note in Figure 21-5 that the endocardium covers beamlike projections of myocardial tissue. These muscular projections are called *trabeculae carneae* (meaning "fleshy beams") and help to add force to the inward contraction of the heart wall.

Inward folds or pockets formed by the endocardium and supporting connective tissue make up the flaps or cusps of the major heart valves. These valves ensure the one-way flow of blood through the chambers of the heart, thus enabling the heart to act as a pump.

CHAMBERS OF THE HEART

The interior of the heart is divided into four cavities, or heart chambers (Figure 21-6). The two upper chambers are called *atria* (singular, *atrium*), and the two lower chambers are called *ventricles.* The left chambers are separated from the right chambers by an extension of the heart wall called the *septum.*

Atria

The two superior chambers of the heart—the **atria**—are separated into left and right chambers by the *interatrial septum.* Atria are often called the "receiving chambers" because they receive blood from vessels called *veins.* **Veins** are the large blood vessels that return blood from various tissues to the heart so that the blood can be pumped out to tissues again.

Figure 21-7 shows how the atria alternately relax and contract to receive blood, then push it into the lower chambers. Because the atria need not generate great pressure to move blood such a small distance, the myocardial wall of each atrium is not very thick.

If you look at Figures 21-2, C, and 21-3, A, you will notice that part of each atrium is labeled as an *auricle.* The term *auricle* (meaning "little ear") refers to the earlike flap protruding from each atrium. Thus the auricles are *part of* the atria. The terms *auricles* and *atria* should not be used synonymously.

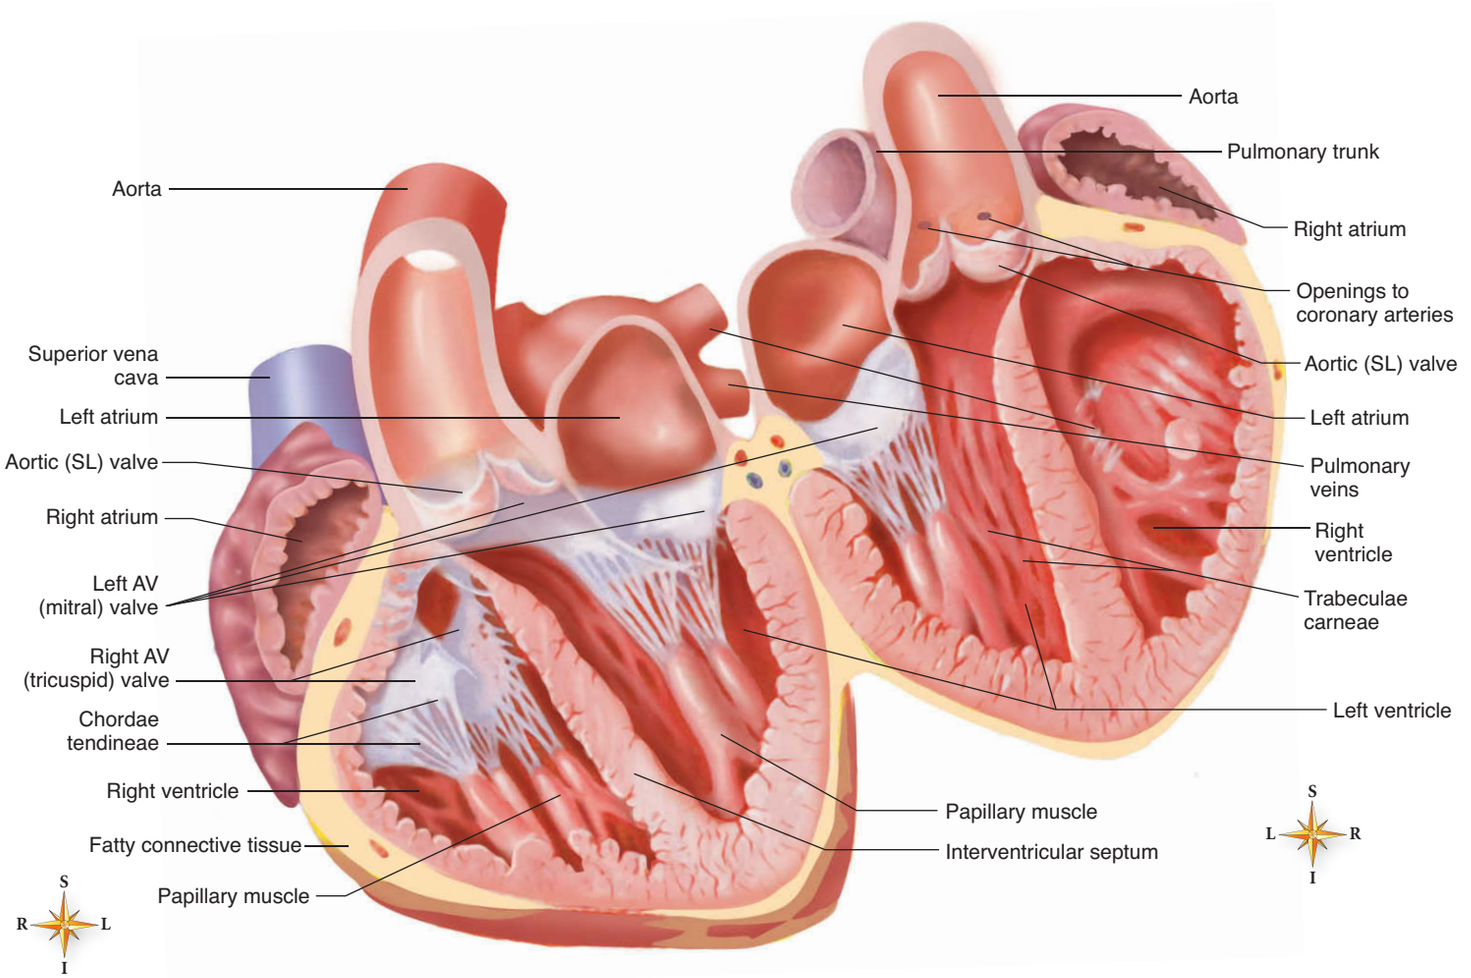

FIGURE 21-6

Interior of the heart. This illustration shows the heart as it would appear if it were cut along a frontal plane and opened like a book. The front portion of the heart lies to the reader's right; the back portion of the heart lies to the reader's left. (Note each portion has a separate anatomical rosette to facilitate orientation.) The four chambers of the heart—two atria and two ventricles—are easily seen. *AV,* Atrioventricular; *SL,* semilunar.

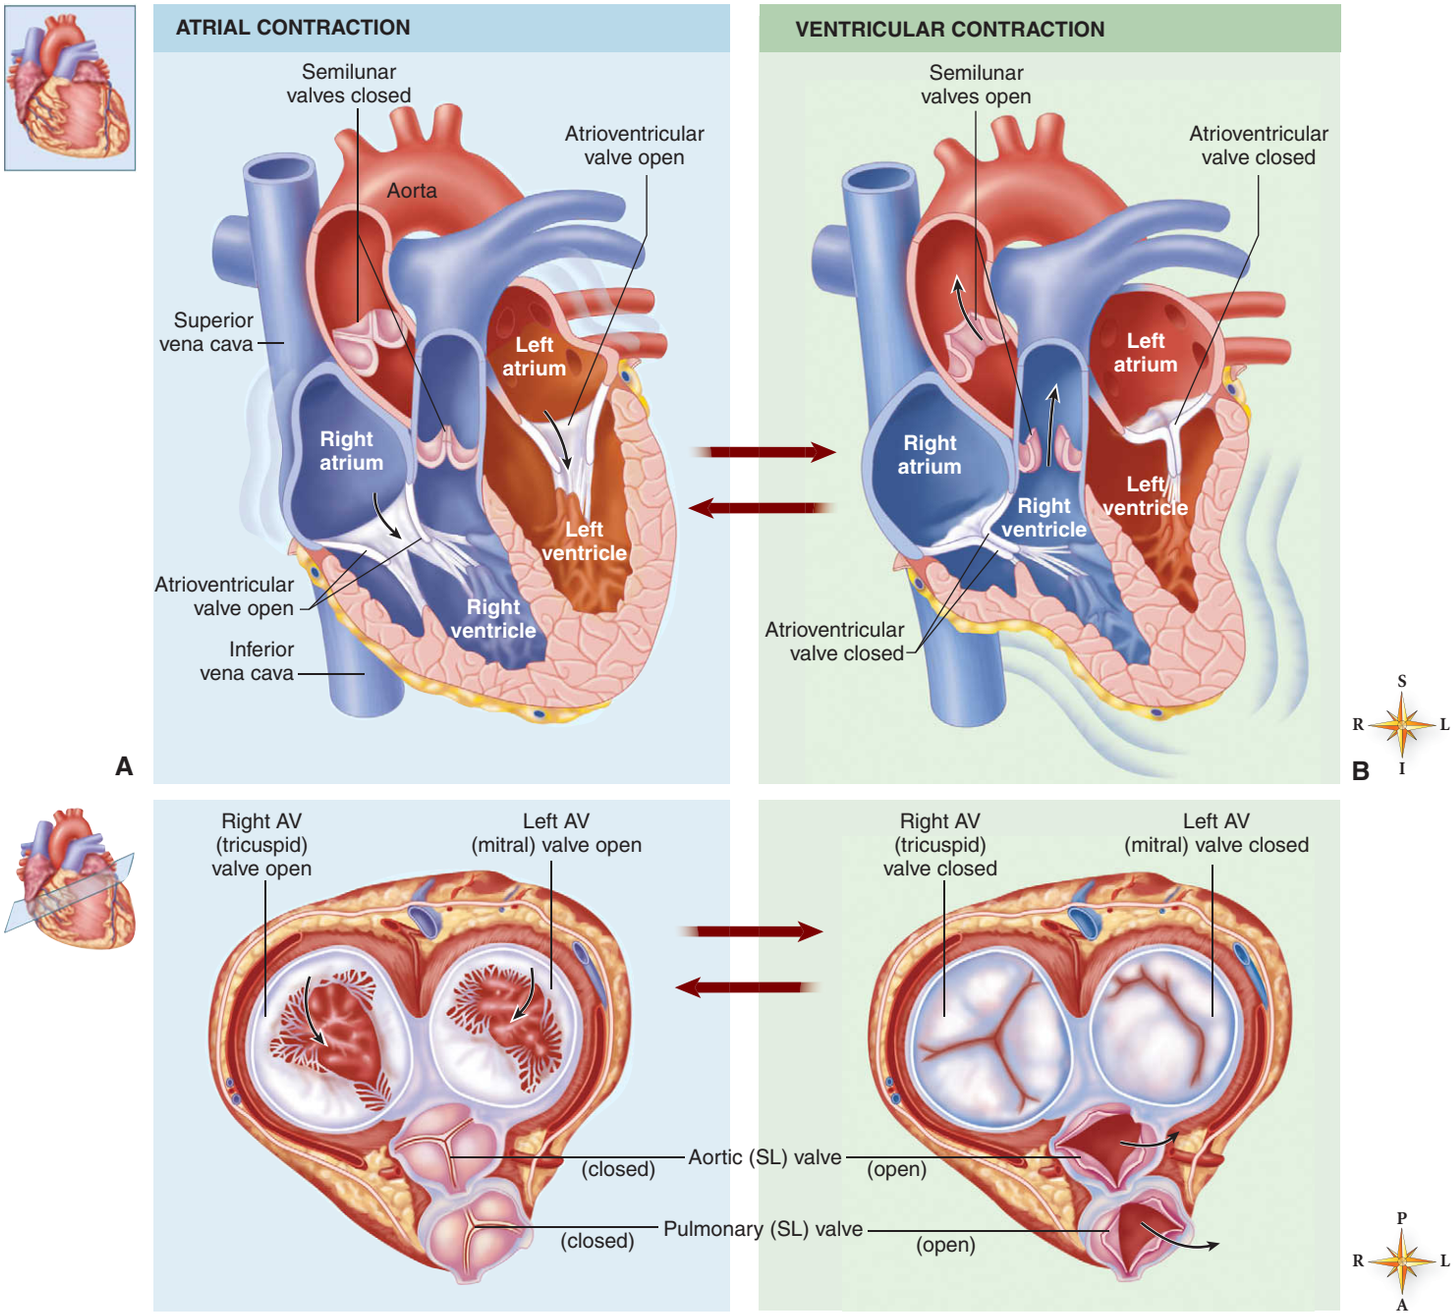

FIGURE 21-7

Chambers and valves of the heart. A, During atrial contraction cardiac muscle in the atrial wall contracts, forcing blood through the atrioventricular (AV) valves and into the ventricles. Bottom illustration shows superior view of all four valves, with semilunar (SL) valves closed and AV valves open. **B,** During ventricular contraction that follows, the AV valves close and the blood is forced out of the ventricles through the SL valves and into the arteries. Bottom illustration shows superior view of SL valves open and AV valves closed.

Ventricles

The **ventricles** are the two lower chambers of the heart. The ventricles are separated into left and right chambers by the *interventricular septum*. Because the ventricles receive blood from the atria and pump blood out of the heart into arteries, the ventricles are considered to be the primary "pumping chambers" of the heart.

Because more force is needed to pump blood a farther distance from the ventricles than from the atria, the myocardium of each ventricle is thicker than the myocardium of either atrium. The myocardium of the left ventricle is thicker than that of the right ventricle because the left ventricle pushes blood through most vessels of the body, whereas the right ventricle pushes blood only

through the nearby pulmonary vessels that serve the gas exchange tissues of the lungs.

The pumping action of the heart chambers is summarized in Figure 21-7 and described further in Chapter 22.

VALVES OF THE HEART

The heart valves are structures that permit the flow of blood in one direction only—allowing the heart to act as a pump that forces the continuous flow of blood in one direction.

Four valves are of importance to the normal functioning of the heart (Figure 21-8; see Figure 21-7). Because they guard the openings between the atria and the ventricles, two of the valves are called the **atrioventricular (AV) valves.** The atrioventricular valves have pointed leaflets or flaps called *cusps* and are therefore also called **cuspid valves.** The other two heart valves, the heart's **semilunar (SL) valves,** are located where the trunk of the pulmonary artery joins the right ventricle (pulmonary valve) and where the aorta joins the left ventricle (aortic valve).

Atrioventricular Valves

The atrioventricular valve regulating flow through the right atrioventricular opening consists of three flaps (cusps) of endocardium. The free edge of each flap is anchored to the *papillary muscles* of the right ventricle by several *tendinous cords* that are more often called **chordae tendineae.**

Because the right atrioventricular valve has three flaps or cusps, it is also called the **tricuspid valve.** The valve that guards the left atrioventricular opening is similar in structure to the right atrioventricular valve, except that it has only two flaps and is therefore also called the **bicuspid valve.** Most commonly, however, the left AV valve is called the **mitral valve**—a name it gets from its resemblance to the miter, a double-cusp hat worn by bishops.

The construction of both atrioventricular valves allows blood to flow from the atria into the ventricles but prevents it from flowing back up into the atria from the ventricles. When ventricles are relaxed, blood can flow through the AV valve from the atrium by simply pushing the flimsy valve cusps aside, into the ventricle.

Ventricular contraction forces the blood in the ventricles hard against the valve flaps, closing the valves. The papillary muscles contract along with the rest of the ventricular myocardium, thus pulling on the edges of the cusps by way of the chordae tendineae. By holding the edges of the cusps firmly during ventricular contraction, the chordae tendinae prevent the edges of the flaps from bending backwards and allowing blood to flow back into the atria. The harder the ventricular myocardium contracts, the more strongly it pushes against the AV valve—and the more strongly the papillary muscles pull on the chordae tendineae to hold the AV valves shut. This mechanism thus prevents backflow, no matter how strongly the heart ventricles contract. Keeping the AV valves closed during ventricular contraction ensures the movement of the blood upward into the pulmonary trunk and aorta as the ventricles contract (see Figure 21-7).

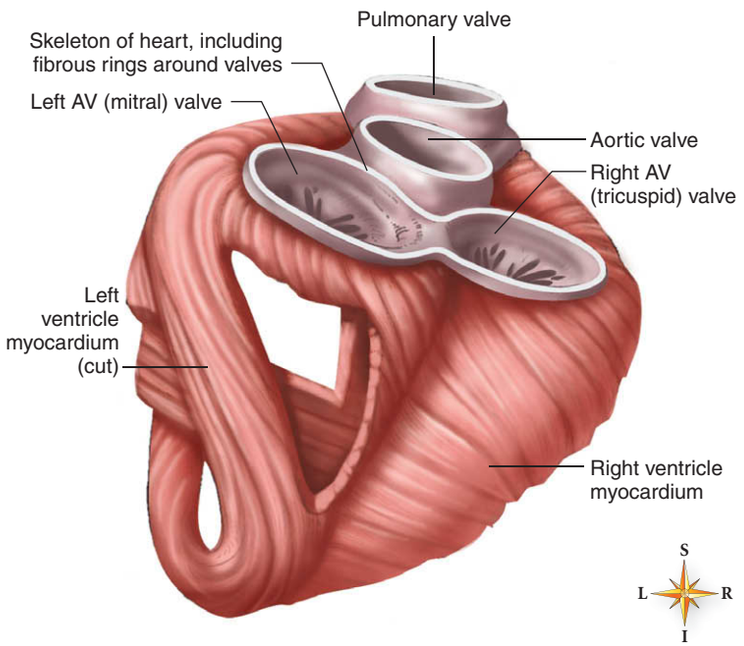

FIGURE 21-8

Skeleton of the heart. This posterior view shows part of the ventricular myocardium with the heart valves still attached. The rim of each heart valve is supported by a fibrous structure, called the skeleton of the heart, that encircles all four valves.

Semilunar Valves

The *semilunar (SL) valves* of the heart consist of pocket-like flaps (leaflets) extending inward from the lining of the trunk of the pulmonary artery and aorta. Semilunar, which literally means "half moon," refers to the crescent shape of the valve cusps visible in a frontal section of the heart.

The semilunar valve at the entrance of the pulmonary trunk is called the *pulmonary valve*. The semilunar valve at the entrance of the aorta is called the *aortic valve*. When the pulmonary and aortic valves are closed, as in Figures 21-7, *A*, blood fills the spaces between the leaflets and the vessel wall. Each leaflet then looks like a tiny, filled bucket. Inflowing blood smoothes the leaflets against the blood vessel walls, collapsing the buckets and thereby opening the valves (see Figures 21-7, *B*). Closure of the semilunar valves, as of the atrioventricular valves, simultaneously prevents backflow and ensures forward flow of blood in places where there would otherwise be considerable backflow.

Whereas the atrioventricular valves prevent blood from flowing back up into the atria from the ventricles, the semilunar valves prevent it from flowing back down into the ventricles from the aorta and pulmonary trunk.

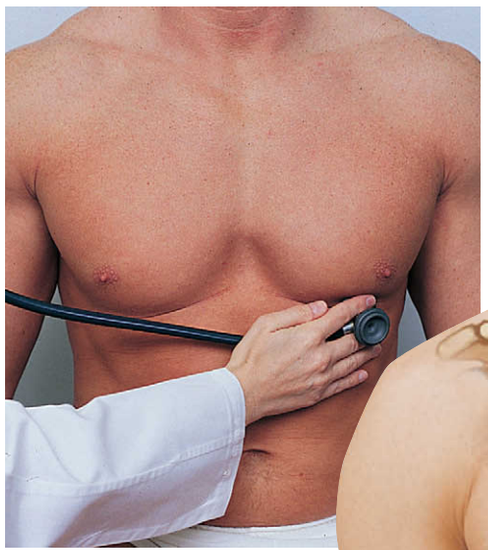
Skeleton of the Heart

Figure 21-8 shows the fibrous structure that is often called the *skeleton of the heart*. It is a set of connected rings that serve as a semirigid support for the heart valves (on the inside of the rings) and for the attachment of cardiac muscle of the myocardium (on the outside of the rings).

The skeleton of the heart also serves as an electrical barrier between the myocardium of the atria and the myocardium of the ventricles. This arrangement allows the ventricles to contract separately from the atria, thus ensuring effective pumping of blood.

Surface Projection

When listening to the sounds of the heart on the body surface, as with a stethoscope, one must have an idea of the relationship between the valves of the heart and the surface of the thorax. Figure 21-9 indicates the surface relationship of the four heart valves and other features of the heart. It is important to remember, however, that considerable variation within the normal range makes a precise "surface projection" outline of the heart's structure on the chest wall difficult.



Flow of Blood Through the Heart

To understand the functional anatomy of the heart and the rest of the cardiovascular system, one should be able to trace the flow of blood through the heart. As we take you through one complete pass through the right side of the heart, then the left side of the heart, trace the path of blood flow with your finger, using Figure 21-7. We can trace the path of blood flow through the right side of the heart by beginning in the right atrium. From the right atrium, blood flows through the right atrioventricular (tricuspid) valve into the right ventricle. From the right ventricle, blood flows through the pulmonary semilunar valve into the first portion of the pulmonary artery, the pulmonary trunk. The pulmonary trunk branches to form the left and right pulmonary arteries, which conduct blood to the gas exchange tissues of the lung. From there, blood flows through pulmonary veins into the left atrium.

We can begin to trace the path of blood flow through the left side of the heart from the left atrium. From the left atrium, blood flows through the left atrioventricular (mitral) valve into the left ventricle. From the left ventricle, blood flows through the aortic semilunar valve into the aorta. Branches of the aorta supply all the tissues of the body except the gas-exchange tissues of the lungs. Blood leaving the head, neck, and upper extremities empties into the superior vena cava. Blood leaving the lower body empties into the inferior vena cava. Both large vessels conduct blood into the right atrium, bringing us back to the point where we began.

BLOOD SUPPLY OF HEART TISSUE

Coronary Arteries

Myocardial cells receive blood by way of two small vessels, the right and left **coronary arteries**. *Coronary* means "crown"—an apt name when you visualize the position of the left and right coronary arteries encircling the myocardium, much as a crown encircles the head (Figure 21-10, *A*). Because the openings into these vitally important vessels lie behind leaflets of the aortic semilunar valve, they come off the aorta at its very beginning and are its first branches.

Figure 21-10, *B*, shows that the placement of the openings of the coronary arteries behind the leaflets or flaps of the aortic valve permits an unusual and necessary method of arterial filling. Ordinarily, arteries that branch from the aorta fill during ventricular contraction when the great force of ventricular pressure pushes blood into the arteries. However, the coronary arteries are squeezed during ventricular contraction and could not fill during this time. Because the coronary artery openings are placed behind the leaflets of the aortic valve, blood flow is diverted from these openings during ventricular contraction when the valve leaflets are against the wall of the aorta. During ventricular relaxation, when the coronary arteries expand somewhat, blood flow is diverted into the coronary artery openings by the closing of the aortic valve—allowing the coronary arteries to fill.

Both right and left coronary arteries have two main branches, as shown in Figures 21-10 and 21-11.

More than one-half million Americans die every year from coronary disease, and another 3.5 million or more are estimated to suffer some degree of incapacitation. Knowledge about the distribution of coronary artery branches therefore has great practical importance. Here, then, are some principles related to the heart's own blood supply that are worth noting:

- Both ventricles receive their blood supply from branches of the right and left coronary arteries.
- Each atrium, in contrast, receives blood only from a small branch of the corresponding coronary artery.
- The most abundant blood supply goes to the myocardium of the left ventricle—an appropriate amount—because the left ventricle does the most work and so needs the most oxygen and nutrients delivered to it.
- The right coronary artery is dominant in about 50% of all hearts; the left coronary artery is dominant in about 20%; and in about 30%, neither right nor left coronary artery dominates.

Another fact about the heart's own blood supply—one of life-and-death importance—is that only a few connections, or anastomoses, exist between the larger branches of the coronary arteries. An **anastomosis** consists of one or more branches from the proximal part of an artery to a more distal part of itself or of another artery. Thus anastomoses provide detours in which arterial blood

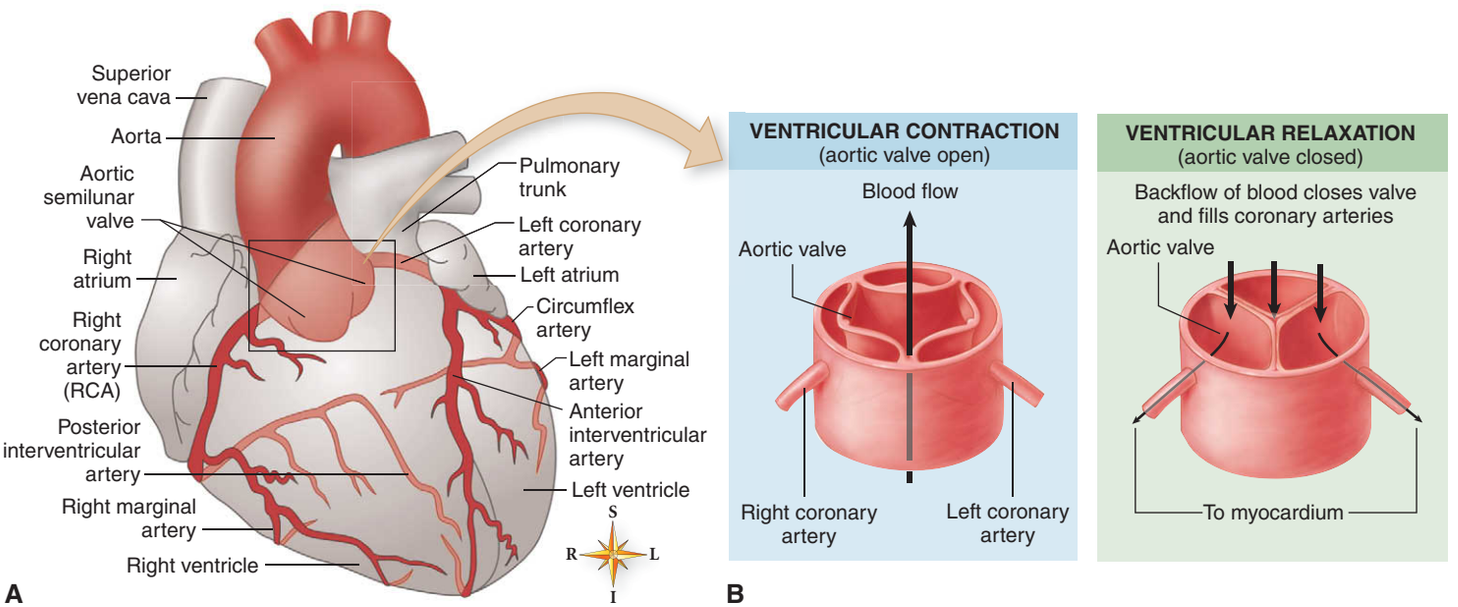

FIGURE 21-10

Coronary arteries. A, Diagram showing the major coronary arteries (anterior view). Clinicians often refer to the interventricular arteries as *descending* arteries. Thus a cardiologist would refer to the *left anterior descending (LAD) artery* and an anatomist would refer to the same vessel as the *anterior interventricular artery.* **B,** The unusual placement of the coronary artery opening behind the leaflets of the aortic valve allows the coronary arteries to fill during ventricular relaxation.

can travel if the main route becomes obstructed. In short, they provide collateral circulation to a part. This explains why the scarcity of anastomoses between larger coronary arteries looms so large as a threat to life.

If, for example, a blood clot plugs one of the larger coronary artery branches, as it frequently does in coronary thrombosis or embolism, too little or possibly no blood at all can reach some of the heart muscle cells. They become ischemic, in other words. Deprived of oxygen, metabolic function is impaired and cell survival is threatened. **Myocardial infarction (MI)**—death of ischemic heart muscle cells—soon results.

Another anatomical fact, however, brightens the picture somewhat: although few anastomoses exist between the larger coronary arteries, many anastomoses do exist between the very small arterial vessels in the heart. Given time, new anastomoses between the very small coronary arteries develop and provide collateral circulation to ischemic areas. Several surgical procedures have been devised to aid this process (see Mechanisms of Disease, p. 669).

Box 21-2 discusses a method for visualizing blood channels through the coronary arteries.

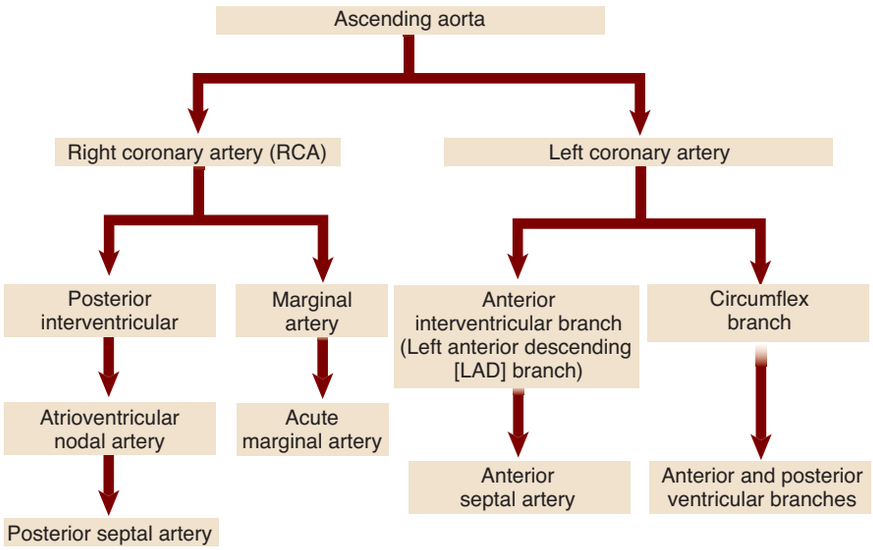

FIGURE 21-11

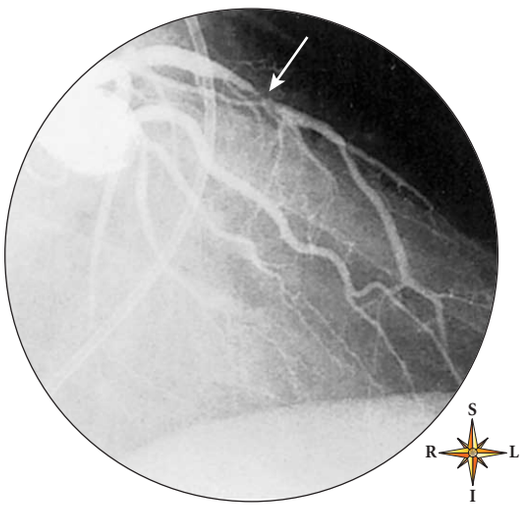
Blood flow through the coronary arteries. Blood leaves the ascending aorta and flows through the myocardium of the heart. Compare to Figure 21-10.

Cardiac Veins

After blood has passed through **capillary** networks in the myocardium, it enters a series of cardiac veins before draining into the right atrium through a common venous channel called the *coronary sinus.* Several veins that collect blood from a small area of the right ventricle do not end in the coronary sinus but instead drain directly into the right atrium. As a rule, the cardiac veins

Box 21-2 | DIAGNOSTIC study

Angiography



A special type of radiography called **angiography** (an-jee-AH-gra-fee) is often used to visualize arteries. A radiopaque dye—a substance that cannot be penetrated by x rays—is injected into an artery to better visualize vessels that would otherwise be invisible in a radiograph. This dye is often called *contrast medium.*

Sometimes the dye is released through a long, thin tube called a catheter—a procedure called *catheterization.* The catheter can be pushed through arteries until its tip is in just the right location to release the dye. As the dye begins to circulate, an *angiogram* (radiograph) will show the outline of the arteries as clearly as if they were made of bone or other dense material (see figure).

An angiogram of an artery is often called an *arteriogram.* An angiogram of veins can be called a *venogram* or *phlebogram.*

Widow Maker. Coronary arteriogram of the coronary arteries shows a narrowing *(arrow)* of the channel in the left anterior descending (LAD) artery of the heart. Partial or complete occlusion of the LAD coronary artery is sometimes called the "widow maker" because complete occlusion of this artery results in a massive heart attack and sudden death—often occuring in men in their 50s.

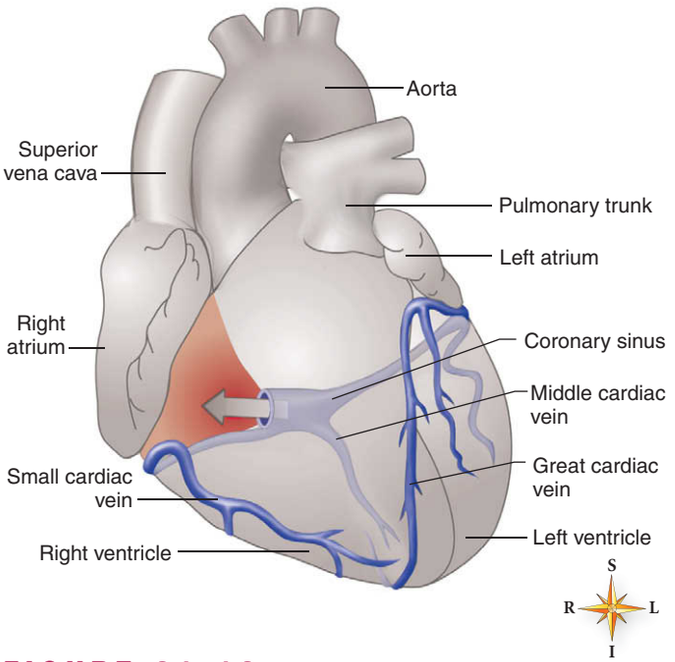

FIGURE 21-12

Coronary veins. Diagram showing the major veins of the coronary circulation (anterior view). Vessels near the anterior surface are more darkly colored than vessels of the posterior surface seen through the heart.

(Figure 21-12) follow a course that closely parallels that of the coronary arteries.

NERVE SUPPLY OF THE HEART

The myocardium is autorhythmic and can thus produce its own action potentials without the influence of afferent nerve signals. To coordinate effective self-activation, the heart has a system of myocardial fibers specialized for rapid electrical conduction along a pathway extending from the top to the bottom of the heart. The myocardial structures that generate and conduct action potentials are called the *conduction system of the heart*. The structure and function of this important system are discussed in Chapter 22.

Although the heart can generate its own rhythm of impulses (action potentials) and thus generate its own pumping contractions, the body sometimes has need to increase or decrease that rhythm. For example, when you increase the use of skeletal muscles and thus use oxygen more rapidly, your heart must increase its rate of pumping to keep the blood oxygen level near the set point. So it is no surprise that the heart receives efferent (motor) nerves that permit such regulation of the contractions of the heart.

Both divisions of the autonomic nervous system send fibers to the heart. Sympathetic fibers (contained in the middle, superior, and inferior cardiac nerves) and parasympathetic fibers (in branches of the vagus nerve) combine to form cardiac plexuses located close to the arch of the aorta. From the cardiac plexuses, fibers accompany the right and left coronary arteries to enter the heart. Here most of the fibers terminate in the *sinoatrial (SA) node* near the junction of the superior vena cava and right atrial wall. The SA node acts as the heart's *pacemaker* and is part of the heart's own conduction system, a concept we explore in Chapter 22 (see Figure 22-2 on p. 683).

However, some of the fibers end in the *atrioventricular (AV) node* (another part of the heart's conduction system) and in the atrial myocardium. A few parasympathetic fibers extend to the ventricular part of the heart's conduction system. Because they increase the heart rate by stimulating the heart's built-in pacemaker, sympathetic nerves to the heart are also called *accelerator nerves*. Vagus fibers to the heart instead serve as *inhibitory* or *depressor nerves*.

BLOOD VESSEL TYPES

There are nearly 100,000 km—more than 60,000 miles—of vessels carrying blood through your body right now. These vessels developed through the complex process of **angiogenesis** (*angi* means "vessel") that begins during embryonic development and continues through the lifespan. As scientists work out how angiogenesis is guided by chemical signals, they also develop new therapies to promote angiogenesis after tissue injury and to inhibit the accelerated angiogenesis in tumors that allows them to spread as cancer.

You have already been introduced to the different roles that blood vessels play in the body: *arteries* conduct blood away from the heart, *capillaries* conduct blood through tissues and permit exchange of materials, and *veins* conduct blood back toward the heart. In the following sections, we explore a few important details of blood vessel anatomy.

Arteries

An **artery** is a vessel that carries blood away from the heart. There are several types of arteries in the cardiovascular system.

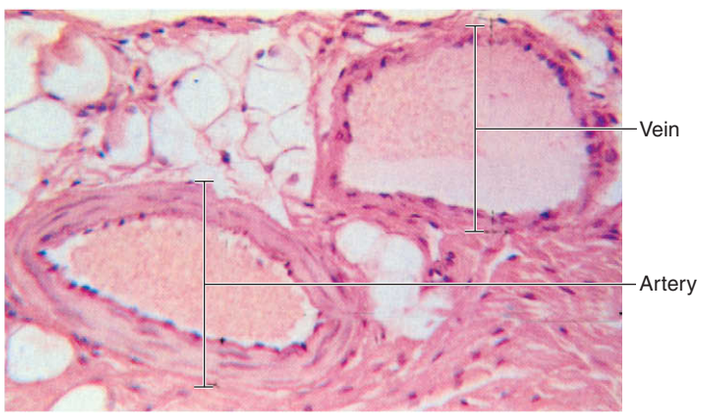

FIGURE 21-13

Artery and vein. Light micrograph of a cross section of similar-sized artery *(left)* and vein *(right)*. Notice the thick muscular wall of the artery as compared to the thin-walled vein.

Elastic arteries (also called *conducting arteries*) are the largest in the body and include the aorta and some of its major branches. As the name implies, elastic arteries can stretch without causing injury to accommodate the surge of blood that is forced into them when the ventricles contract and then recoil when the ventricles relax.

Muscular arteries (also called *distributing arteries*) carry blood farther away from the heart to specific organs and areas of the body. They are smaller in diameter than elastic arteries. However, the muscular layer in the wall of these vessels is proportionately thicker. Because of the thick muscle layer, muscular arteries have a thicker vessel wall than similar-sized veins (Figure 21-13). Like elastic arteries, muscular arteries are given names. Examples include the brachial, gastric, and superior mesenteric arteries.

Arterioles, also called *resistance vessels*, are the smallest arteries. Figure 21-14 shows the structure of arterioles in comparison to muscular and elastic arteries. Arterioles are not named individually, but as a group, they are critically important in regulating blood flow throughout the body. They function in this way by variable contraction of smooth muscle in their walls, which in turn increases resistance to blood flow and helps regulate blood

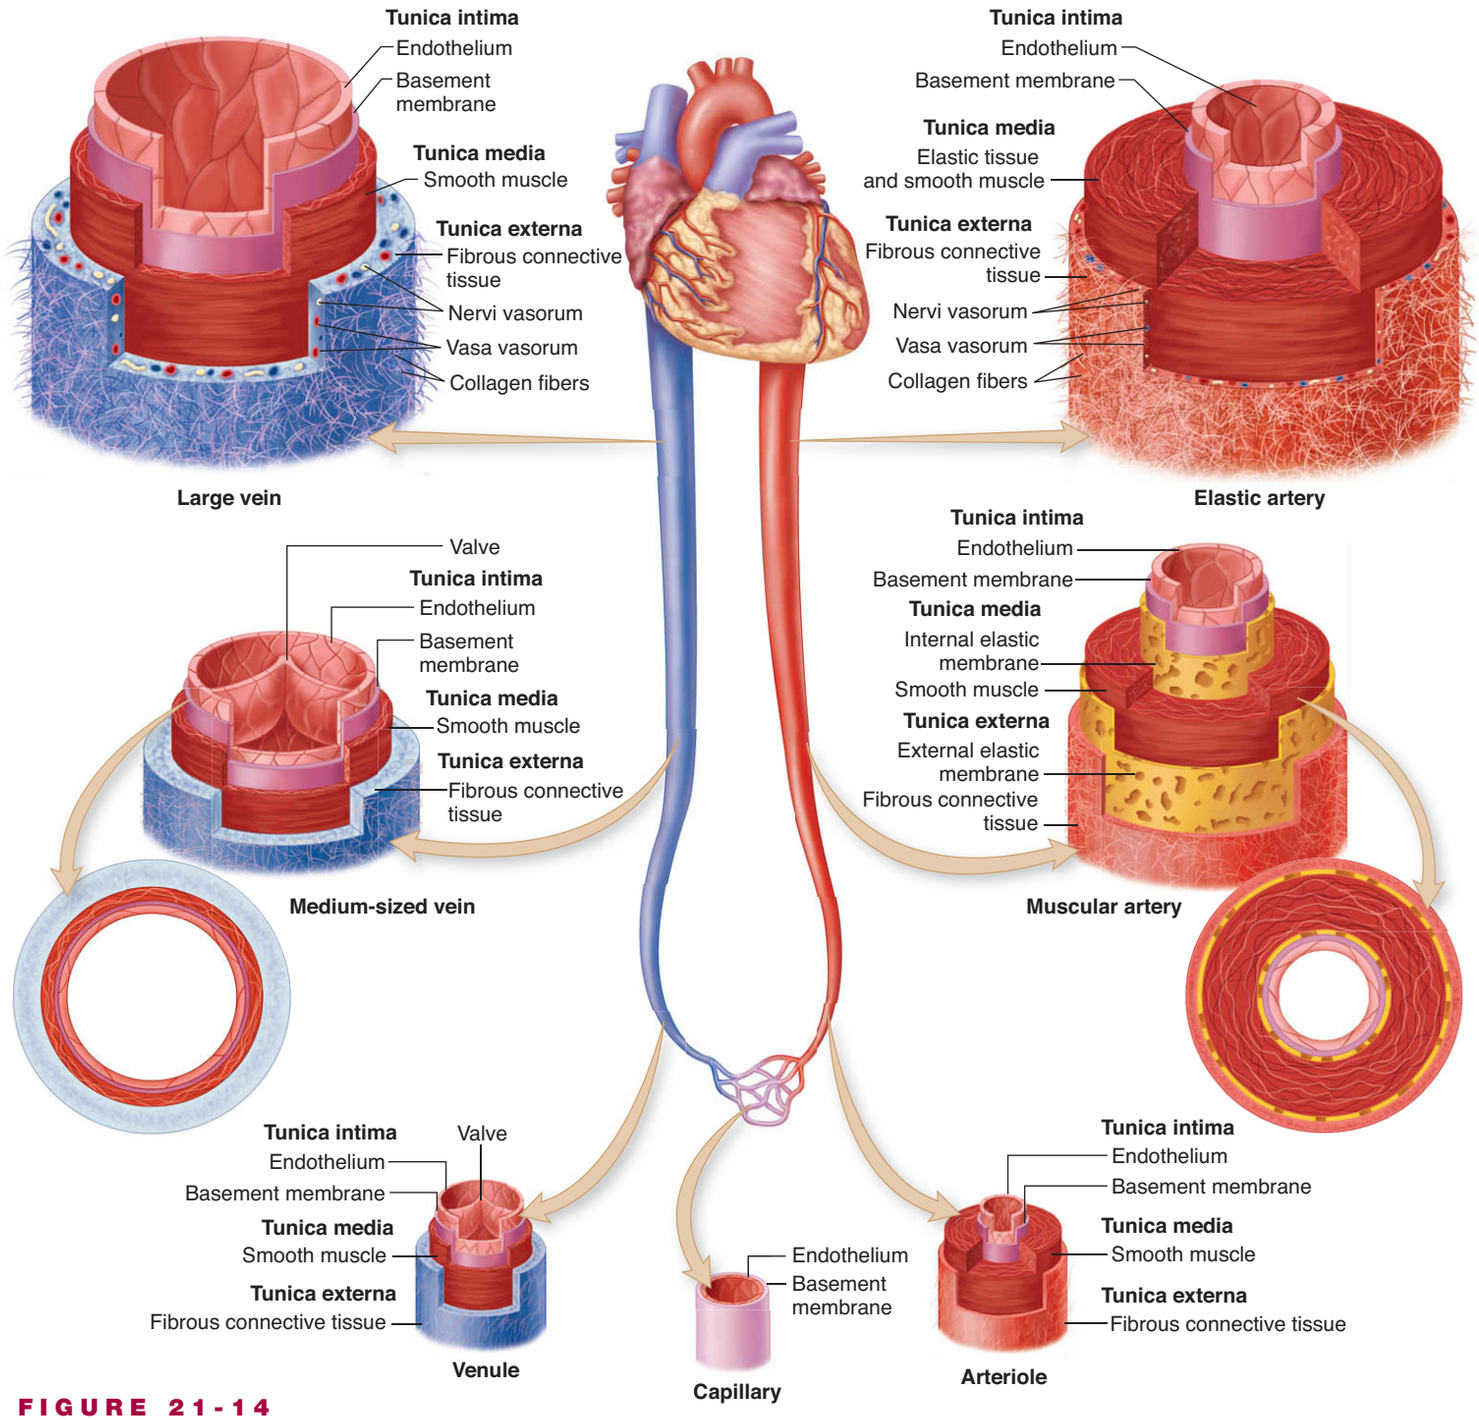

FIGURE 21-14

Structure of blood vessels. The tunica externa of the veins are color-coded blue and the arteries red.

pressure as well as determine the quantity of blood that enters a particular organ. The concept of flow resistance and its relationship to blood vessel diameter are discussed further in Chapter 22.

Metarteriole is the term used to describe the short connecting vessel that connects a true arteriole with the proximal end of between 20 and 100 capillaries and then extends through the capillary bed (Figure 21-15). The proximal ends of metarterioles are encircled by special "regulatory valves"—smooth muscle cells called *precapillary sphincters*. Because each precapillary sphincter wraps around the entrance to a capillary, it can relax or contract to increase or decrease blood flow into specific capillary networks. The distal end of a metarteriole is devoid of precapillary sphincters and is called a *thoroughfare channel*. It is possible for blood passing directly through a metarteriole into a thoroughfare channel to bypass the intervening capillary bed. After birth all arteries except the pulmonary artery and its branches carry oxygenated blood.

Capillaries

Capillaries are the microscopic vessels that carry blood from arterioles to venules. Blood flow through the arterioles, venules, and capillaries is called the *microcirculation* (see Figure 21-15). Transfer of nutrients and other vital substances between blood and tissue cells occurs at or very near a capillary—in so-called capillary beds or networks. It is for this reason that capillaries are sometimes known as the *primary exchange vessels* of the cardiovascular system. So vital is this function that no cell in the body is far removed from a capillary.

Although capillaries are small in size, the number of them in the body is estimated to be in excess of 1 billion. They are not, however, uniformly distributed. Some body tissues, such as liver or cardiac muscle, have high metabolic rates and require large numbers of capillary vessels. Other tissues, such as cartilage and epithelium, are avascular and lack capillary networks altogether.

True capillaries receive blood flowing out of metarterioles or other small arterioles. Precapillary sphincters regulate the volume of inflow of blood and its rate of passage through a true capillary. If the sphincter is "open," blood flows into the capillary; and if the sphincter is closed or partially closed, blood flow into the capillary bed decreases (see Figure 21-15). Capillaries are often categorized into three groups by the ease of passage of substances through their walls or by structural differences that affect their permeability.

Continuous capillaries have a continuous lining of endothelial cells with only small openings called *intercellular clefts* between them (Figure 21-16). This type of capillary is typically found in skeletal muscle, lung, and many types of connective tissue. **Fenestrated capillaries** also have intercellular clefts between their lining endothelial cells. But, in addition, they also have small "holes" or fenestrations through the plasma membrane of the endothelial cell itself. This unique structural adaptation allows for special function. Understanding the anatomy of these tiny vessels will be helpful in understanding the function of a number of major organs, such as the kidneys and small intestines, discussed later in the text.

Sinusoid is the term used to describe a type of capillary that has a much larger lumen and more winding or tortuous course than other capillary vessels. The basement membrane that completely covers other capillaries is either absent or incomplete in sinusoids. In addition, the fenestrations present both between and within the endothelial lining cells are much larger than in other capillary types. The result is great porosity. Because of this structural

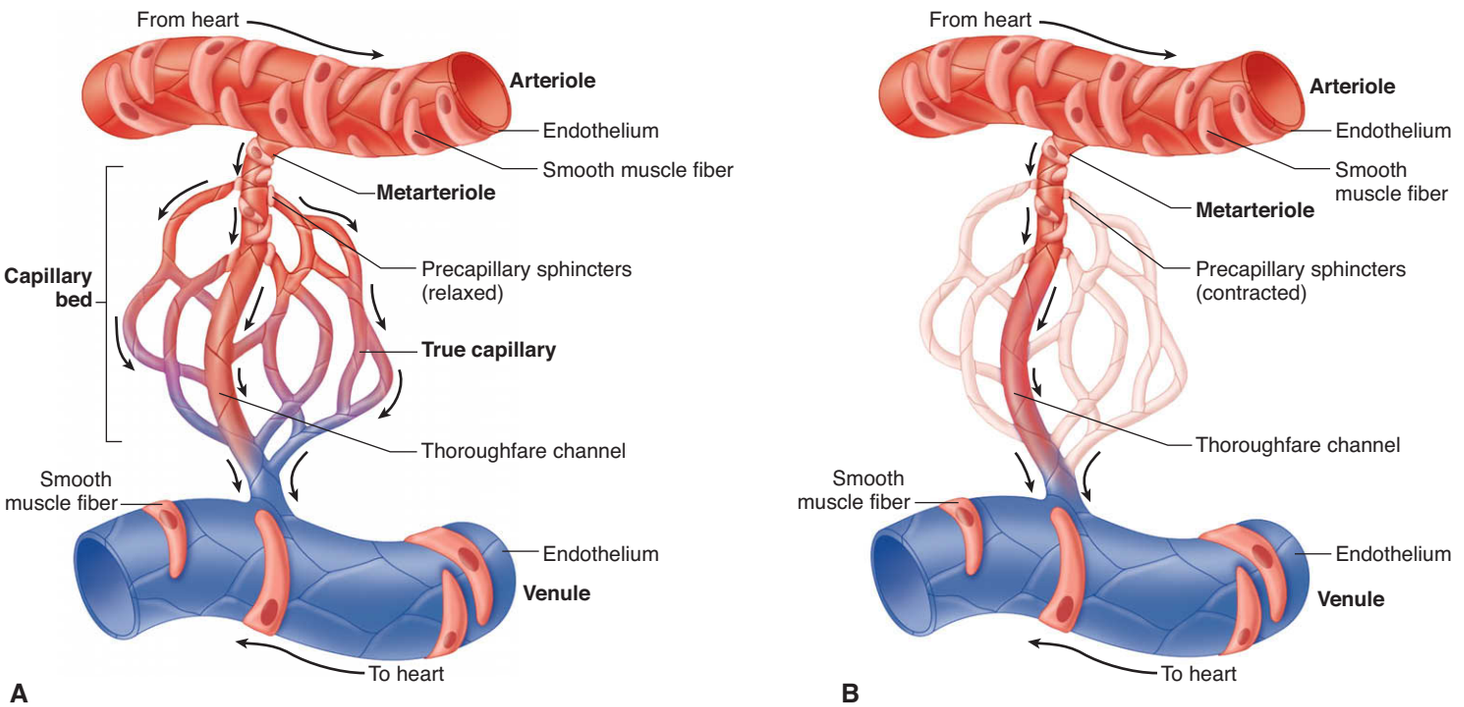

FIGURE 21-15

Microcirculation. Control of blood flow through a capillary network is regulated by the relative contraction of precapillary sphincters surrounding arterioles and metarterioles. **A,** Sphincters are relaxed, permitting blood flow to enter the capillary bed. **B,** With sphincters contracted blood flows from metarteriole directly into thoroughfare channel, bypassing the capillary bed.

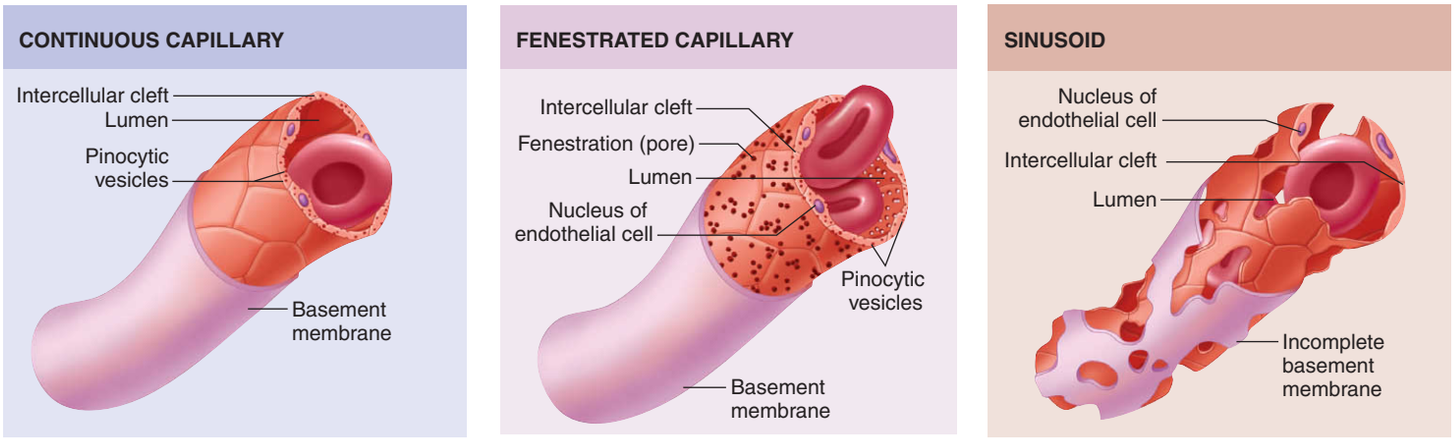

FIGURE 21-16

Types of capillaries. A, Continuous capillary. Note the presence of clefts only between adjacent endothelial cells. **B,** Fenestrated capillary. In addition to intercellular clefts, fenestrations (pores) exist in the plasma membranes of endothelial cells. **C,** Sinusoid. In addition to large intercellular clefts and cellular fenestrations, the basement membrane is incomplete or absent.

adaptation, sinusoids in the bone marrow and liver, for example, are able to permit migration of blood cells from the intravascular space into surrounding tissues.

Veins

A **vein** is a vessel that carries blood toward the heart. After passing through the complex capillary network of vessels, blood from several capillaries flows into the distal end of the metarteriole, the thoroughfare channel, or directly enters the first of a series of vessels that will eventually return it to the heart.

The first venous structures are small diameter vessels called **venules.** Initially, these tiny veins, especially those closest to the capillary bed, have very narrow lumens and porous, thin walls. As in capillaries, fluid can be exchanged between blood in the smallest venules and the tissue spaces. Their walls consist of little more than endothelial cells, a few smooth muscle cells and an occasional fibroblast. In addition to movement of fluid through the wall of the venule, phagocytic white blood cells (WBCs) also move out of the cardiovascular system and into areas of inflamed tissue by passing through the pores in walls of venules (see discussion of diapedesis on pp. 606 and 752).

As blood exits the smaller venules it enters progressively larger venous channels—the veins. Their names correspond to their arterial counterparts. However, whereas arteries become progressively smaller as blood flows away from the heart and into branches feeding other areas of the body, named veins become progressively larger as additional blood flows into them as they approach the heart. Structural changes occur in the walls of veins as they grow in size to accommodate and regulate additional blood volume and flow.

Veins can accommodate varying amounts of blood with almost no change in blood pressure. This results from their great ability to stretch. Ease of stretch is also called *capacitance*. Therefore, the veins are often referred to as the *capacitance vessels* of the cardiovascular system. High capacitance permits veins to serve as reservoirs for blood as well as conduits for its passage back to the heart.

Another structural adaptation in veins that has an important functional significance is the presence of one-way valves similar to the heart's semilunar valves. These valves develop from the thin membrane (endothelium) that lines the lumen of these vessels. The peripheral veins in the extremities have more valves than other veins of the body. Valves keep blood moving toward the heart and prevent its potential backflow.

The term **venous sinus** is used to describe large venous structures that have very thin endothelial walls. Since no smooth muscle cells or other support tissues found in the outer layers of typical large veins are located in the walls of venous sinuses, they cannot change their shape and thus depend on surrounding structures for support. Examples of venous sinuses include the dural venous sinuses of the brain (look ahead to Figure 21-28 on p. 660) and the coronary sinus of the heart (see Figure 21-12). After birth, all the veins except the pulmonary veins contain deoxygenated blood.

Structure of Blood Vessels

COMPONENTS OF THE BLOOD VESSEL WALL

Differences in the amounts of the tissue components present in blood vessel walls occur in different types of arteries and veins (see Figure 21-14). Regardless of how thick a vessel wall might be, four types of "fabrics" that make up a vessel wall are commonly present: (1) lining *endothelial tissue*, (2) *collagen fibers*, (3) *elastic fibers*, and (4) *smooth muscle tissue*.

Endothelial Tissue

Endothelial tissue or *endothelium* is a specific type of simple squamous epithelium. Recall from Chapter 6 (see Figure 6-2 on p. 136) that this tissue forms a thin, smooth membrane made up of flattened cells. The endothelial membrane that lines the entire vascular tree exhibits specific features and performs a number of different functions in different regions of the vascular system. By providing a smooth luminal surface, endothelium influences blood flow and inhibits intravascular coagulation.

Intercellular clefts between adjacent endothelial cells and the presence, size, and number of pores or fenestrations in their cytoplasmic membranes influence diffusion and movement of substances or cells out of and into the circulating blood (see Figure 21-16). Endothelial cells are also capable of transporting substances rapidly across their boundaries by using pinocytic vesicles (see Box 3-1, p. 71).

Cellular reproduction provides new cells to increase blood vessel size, replace damaged cells, and provide growing cords of cells that are forerunners of new blood vessels. Besides producing several important growth factors, endothelium releases a variety of signaling molecules that play important roles in maintaining cardiovascular health.

Collagen Fibers

Collagen fibers in the vascular wall are woven together much like the reinforcing strands found in the wall of a tire or hose. They form from fibrous protein molecules that aggregate into fibers several micrometers in diameter and are clearly visible with a light microscope (see Figure 6-13 on p. 143 and Figure 6-15 on p. 145).

Under physiological conditions collagen fibers are very flexible—but far less extensible than the elastic fibers described later. They do not stretch more than 2% to 3%. The collagen fibers function more to keep the lumen of the vessel open and strengthen the wall than to contribute to overall tension or recoil ability.

Elastic Fibers

Individual elastic fibers are composed largely of an insoluble protein polymer called *elastin* and are quite small (0.1 to 1 μm in diameter). Once secreted into the extracellular matrix, they form into a rubberlike network that is highly elastic and capable of stretching more than 100% under physiological conditions (see Figure 6-14 on p. 143).

In large elastic arteries, especially, wavy elastic fibers are organized or arranged in concentric, almost circular patterns. Elastic fibers allow for recoil after distention. This property of elastic fibers plays an important role in maintaining *passive tension* in the vessels of the cardiovascular system. This type of tension is required to maintain normal blood pressure levels throughout the cardiac cycle—a process that is discussed in Chapter 22.

Smooth Muscle Tissue

Smooth muscle cells are found in the wall of all segments of the vascular system except capillaries. Recall from Chapters 6 and 11 that smooth muscle is an involuntary muscle found in the wall of most hollow organs of the body.

Smooth muscle cells are most numerous in elastic and muscular arteries and exert *active tension* in these vessels when contracting.

LAYERS OF THE BLOOD VESSEL WALL

The walls of arteries and veins consist of three separate layers or "coats" called the *tunica externa*, *tunica media*, and *tunica intima*. These layers are arranged in sequence from the outside, to the middle, and then to the interior, or luminal, surface of the vessel. As blood vessels decrease in diameter, the relative thickness of their walls also decreases.

When considering the general structure of the walls of vessels in the circulatory system, capillaries are the exception. They consist of only a single layer of endothelial cells (tunica intima) surrounded by a basement membrane (see Figure 21-16).

Outer Layer

The walls of the larger blood vessels, the arteries and veins, have three layers (see Figure 21-14 and Table 21-1). The outermost layer is called the **tunica externa.** This Latin name literally means "outside coat." The tunica externa, also called *tunica adventitia*, is made of strong, flexible fibrous connective tissue. This layer prevents tearing of the vessel walls during body movements. Collagen fibers extend outward from this layer to connect to nearby structures—anchoring the vessel and helping to hold it open. In veins, the tunica externa is the thickest of the three layers of the venous wall. In arteries, it is usually a little thinner than the middle layer of the arterial wall.

Middle Layer

The middle layer, or **tunica media** (Latin for "middle coat"), is made of a layer of smooth muscle tissue sandwiched together with

TABLE 21-1 Structure of Blood Vessels

	TYPICAL DIAMETER	TYPICAL WALL THICKNESS	TUNICA INTIMA	TUNICA MEDIA	TUNICA EXTERNA
Typical histology			Endothelium	Smooth muscle; elastic fibers	Collagen fibers
Arteries	Aorta: 25 mm Small artery: 4 mm Arteriole: 30 μm	Aorta: 2 mm Small artery: 1 mm Arteriole: 8 μm	Smooth lining	Allows constriction and dilation of vessels; thicker than in veins; muscle innervated by autonomic fibers	Provides flexible support that resists collapse or injury; thicker than in veins; thinner than tunica media
Veins	Vena cava: 30 mm Vein: 5 mm Venule: 20 μm	Vena cava: 1.5 mm Vein: 0.5 mm Venule: 1μm	Smooth lining with valves to ensure one-way flow	Allows constriction and dilation of vessels; thinner than in arteries; muscle innervated by autonomic fibers	Provides flexible support that resists collapse or injury; thinner than in arteries; thicker than tunica media
Capillaries	5 μm	0.5 μm	Makes up entire wall of capillary; thinness permits ease of transport across vessel wall	(Absent)	(Absent)

a layer of elastic connective tissue. Some anatomists consider the elastic portion of the tunica media to be distinct enough to call it a separate *external elastic membrane* of the wall. The encircling smooth muscles of the tunica media permit changes in blood vessel diameter. The smooth muscle tissue of the tunica media is innervated by autonomic nerves called *nervi vasorum* ("nerves of the vessel") and supplied with blood by tiny *vasa vasorum* ("vessels of the vessel") that extend inward from the tunica externa. As a rule, arteries have a thicker layer of smooth muscle than do veins.

Inner Layer

The innermost layer of a blood vessel is called the **tunica intima**—Latin for "inside coat." The tunica intima is made up of endothelium that is continuous with the endothelium that lines the heart. The endothelium has a basement membrane to support it. Elastic arteries also have an *internal elastic membrane*.

In arteries, the endothelium provides a completely smooth lining. In veins, however, the endothelium also forms valves that help maintain the one-way flow of blood. The smallest of the vessels, the capillaries, have only one thin coat: the endothelium. This structural feature is important because the thinness of the capillary wall allows for efficient exchange of materials between the blood plasma and the interstitial fluid of the surrounding tissues.

| QUICK CHECK |

13. Name the three major types of blood vessels.
14. How does the structure of each major type of vessel differ from the other types?
15. How does the function of capillaries relate to the structure of their walls?

MAJOR BLOOD VESSELS

Circulatory Routes

The term *circulation of blood* suggests its meaning, namely, blood flow through vessels arranged to form a circuit or circular pattern.

The **systemic circulation** route conducts blood flow from the heart (left ventricle) through blood vessels to all parts of the body (except the gas-exchange tissues in the lungs) and back to the heart (to the right atrium) (Figure 21-17). The left ventricle pumps blood into the ascending aorta. From here it flows into arteries that carry it into the various tissues and organs of the body. Within each structure, blood moves, as indicated in Figure 21-17, from arteries to arterioles to capillaries. Here the vital two-way exchange of substances occurs between the blood and cells. Blood flows next out of each organ by way of its venules and then its veins to drain eventually into the inferior or superior vena cava. These two great veins of the body return venous blood to the right atrium of the heart to complete the systemic circulation. But the blood does not quite come full circle back to its starting point, the left ventricle.

To start on its way again, blood must first flow through another circuit, the **pulmonary circulation** route. Observe in Figure 21-17 that deoxygenated blood moves from the right atrium to the right ventricle to the pulmonary artery to lung arterioles and capillaries. Here, exchange of gases between blood and air takes place, converting

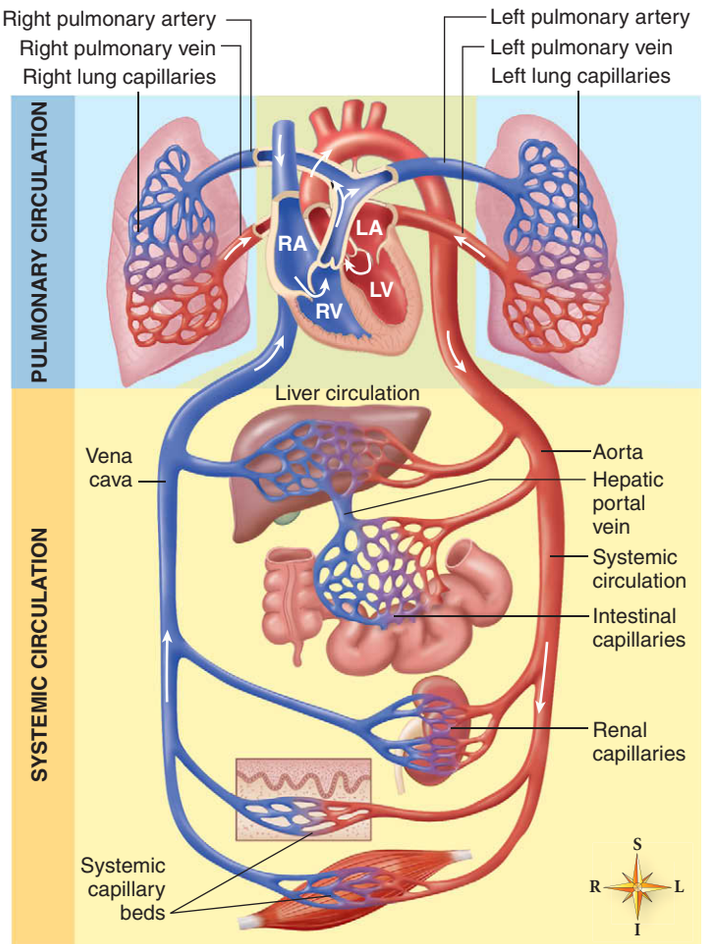

FIGURE 21-17

Circulatory routes. The pulmonary circulation routes blood flow to and from the gas-exchange tissues of the lungs. The systemic circulation, on the other hand, routes blood flow to and from the oxygen-consuming tissues of the body.

deoxygenated blood to oxygenated blood. This oxygenated blood then flows on through lung venules into four pulmonary veins and returns to the left atrium of the heart. From the left atrium it enters the left ventricle to be pumped again through the systemic circulation.

Movement of blood as shown in Figure 21-17 follows a general rule of thumb often used when studying the circulatory system, namely, that blood passes through only one capillary network in the systemic circulation from the time it leaves the heart until it returns. Although this is certainly true in most instances, two important exceptions to the rule do occur. In a **portal system,** blood flowing through the systemic circulation passes through two consecutive capillary beds rather than one. For example, notice in Figure 21-17 that blood coming from the digestive organs passes through a second capillary network in the liver before returning to the heart. The liver's portal circulation is discussed later in this chapter.

The term **vascular anastomosis** is used to describe a second type of exception. It involves the direct connection or merger of blood vessels to one another. In vascular anastomoses, blood moves from veins to other veins or arteries to other arteries without passing through an intervening capillary network.

Arterial anastomoses involve the merger of one artery directly into another artery and may develop in response to disease. Such an anastomosis may permit "bypass" of a partially blocked artery, thus allowing blood to flow into a capillary network and an area of tissue that would otherwise be deprived of an adequate supply of oxygen and nutrients. As stated earlier, arterial anastomoses between the smaller coronary arteries may permit development of "collateral circulation" and movement of blood into areas of ischemic cardiac muscle tissue. However, since very few natural arterial anastomoses exist between the larger coronary arteries, surgical arterial bypass procedures are often required to correct inadequate blood flow to heart muscle (see discussion of myocardial infarction in Mechanisms of Disease, p. 669).

Venous anastomoses, which are much more common, involve direct linkage between different veins. Multiple venous drainage routes from an organ or body area provide a safety mechanism if occlusion of one venous return route should occur. This is especially true of the deep veins. Catastrophic consequences from a so-called *deep venous thrombosis (DVT)* may be prevented or lessened because of these anastomoses.

Arteriovenous anastomoses, or **shunts,** occur when blood flows from an artery directly into a vein without passing through a capillary bed. Heat loss occurs when blood passes through capillary beds in the skin. In cases of hypothermia, heat loss can be avoided by shunting of blood directly from skin arteries to veins without permitting it to pass through capillary beds near the skin surface (see Figure 7-15 on p. 183).

Systemic Circulation

The systemic circulatory route includes most of the vessels of the body. The following paragraphs, tables, and illustrations outline some of the major vessels of the systemic circulation and give tips for understanding this circulatory route.

SYSTEMIC ARTERIES

Locate the arteries listed in Table 21-2 (see also Figures 21-18 to 21-26). You may find it easier to learn the names of blood vessels and the relation of the vessels to each other from diagrams and tables than from narrative descriptions.

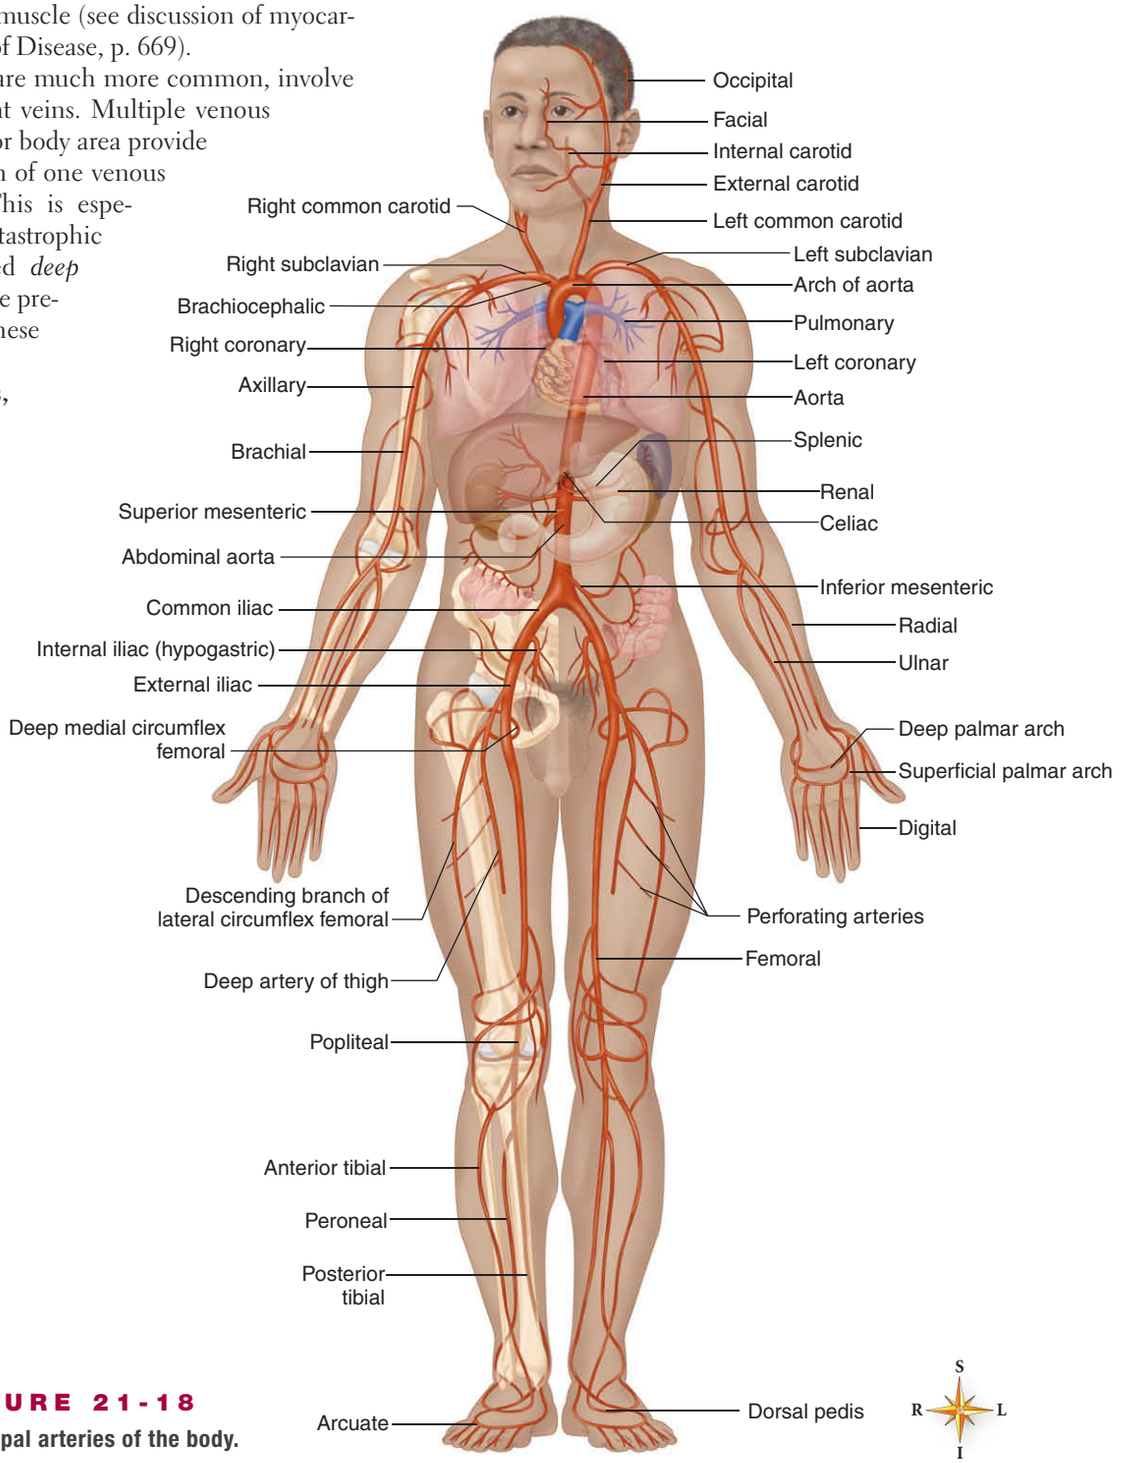

FIGURE 21-18
Principal arteries of the body.

TABLE 21-2 Major Systemic Arteries

ARTERY*	REGION SUPPLIED
Ascending Aorta	
Coronary arteries	Myocardium
Arch of Aorta	
Brachiocephalic (Innominate)	Head, upper extremity
Right common carotid	Head, neck
Right internal carotid†	Brain, eye, forehead, nose
Right external carotid†	Thyroid, tongue, tonsils, ear, etc.
Right subclavian	Head, upper extremity
Right vertebral†	Spinal cord, brain
Right axillary (continuation of subclavian)	Shoulder, chest, axillary region
Right brachial (continuation of axillary)	Arm, hand
Right radial	Forearm, hand (lateral)
Right ulnar	Forearm, hand (medial)
Superficial and deep palmar arches (formed by anastomosis of branches of radial and ulnar)	Hand, fingers
Digital	Fingers
Left Common Carotid	Head, neck
Left internal carotid†	Brain, eye, forehead, nose
Left external carotid†	Thyroid, tongue, tonsils, ear, etc.
Left Subclavian	Head, upper extremity
Left vertebral†	Spinal cord, brain
Left axillary (continuation of subclavian)	Shoulder, chest, axillary region
Left brachial (continuation of axillary)	Arm, hand
Left radial	Forearm, hand (lateral)
Left ulnar	Forearm, hand (medial)
Superficial and deep palmar arches (formed by anastomosis of branches of radial and ulnar)	Hand, fingers
Digital	Fingers
Descending Thoracic Aorta	
Visceral Branches	Thoracic viscera
Bronchial	Lungs, bronchi
Esophageal	Esophagus
Parietal Branches	Thoracic walls
Intercostal	Lateral thoracic walls (rib cage)
Superior phrenic	Superior surface of diaphragm
Descending Abdominal Aorta	
Visceral Branches	Abdominal viscera
Celiac artery (trunk)	Abdominal viscera
Left gastric	Stomach, esophagus
Visceral Branches (continued)	
Common hepatic	Liver
Splenic	Spleen, pancreas, stomach
Superior mesenteric	Pancreas, small intestine, colon
Inferior mesenteric	Descending colon, rectum
Suprarenal	Adrenal (suprarenal) gland
Renal	Kidney
Ovarian	Ovary, uterine tube, ureter
Testicular	Testis, ureter
Parietal Branches	Walls of abdomen
Inferior phrenic	Inferior surface of diaphragm, adrenal gland
Lumbar	Lumbar vertebrae, muscles of back
Median sacral	Lower vertebrae
Common Iliac (formed by terminal branches of aorta)	Pelvis, lower extremity
External Iliac	Thigh, leg, foot
Femoral (continuation of external iliac)	Thigh, leg, foot
Popliteal (continuation of femoral)	Leg, foot
Anterior tibial	Leg, foot
Posterior tibial	Leg, foot
Plantar arch (formed by anastomosis of branches of anterior and posterior tibial arteries)	Foot, toes
Digital	Toes
Internal Iliac	Pelvis
Visceral branches	Pelvic viscera
Middle rectal	Rectum
Vaginal	Vagina, uterus
Uterine	Uterus, vagina, uterine tube, ovary
Parietal branches	Pelvic wall, external regions
Lateral sacral	Sacrum
Superior gluteal	Gluteal muscles
Obturator	Pubic region, hip joint, groin
Internal pudendal	Rectum, external genitals, floor of pelvis
Inferior gluteal	Lower gluteal region, coccyx, upper thigh

*Branches of each artery are indented below its name.
†See text and/or figures for branches of the artery.

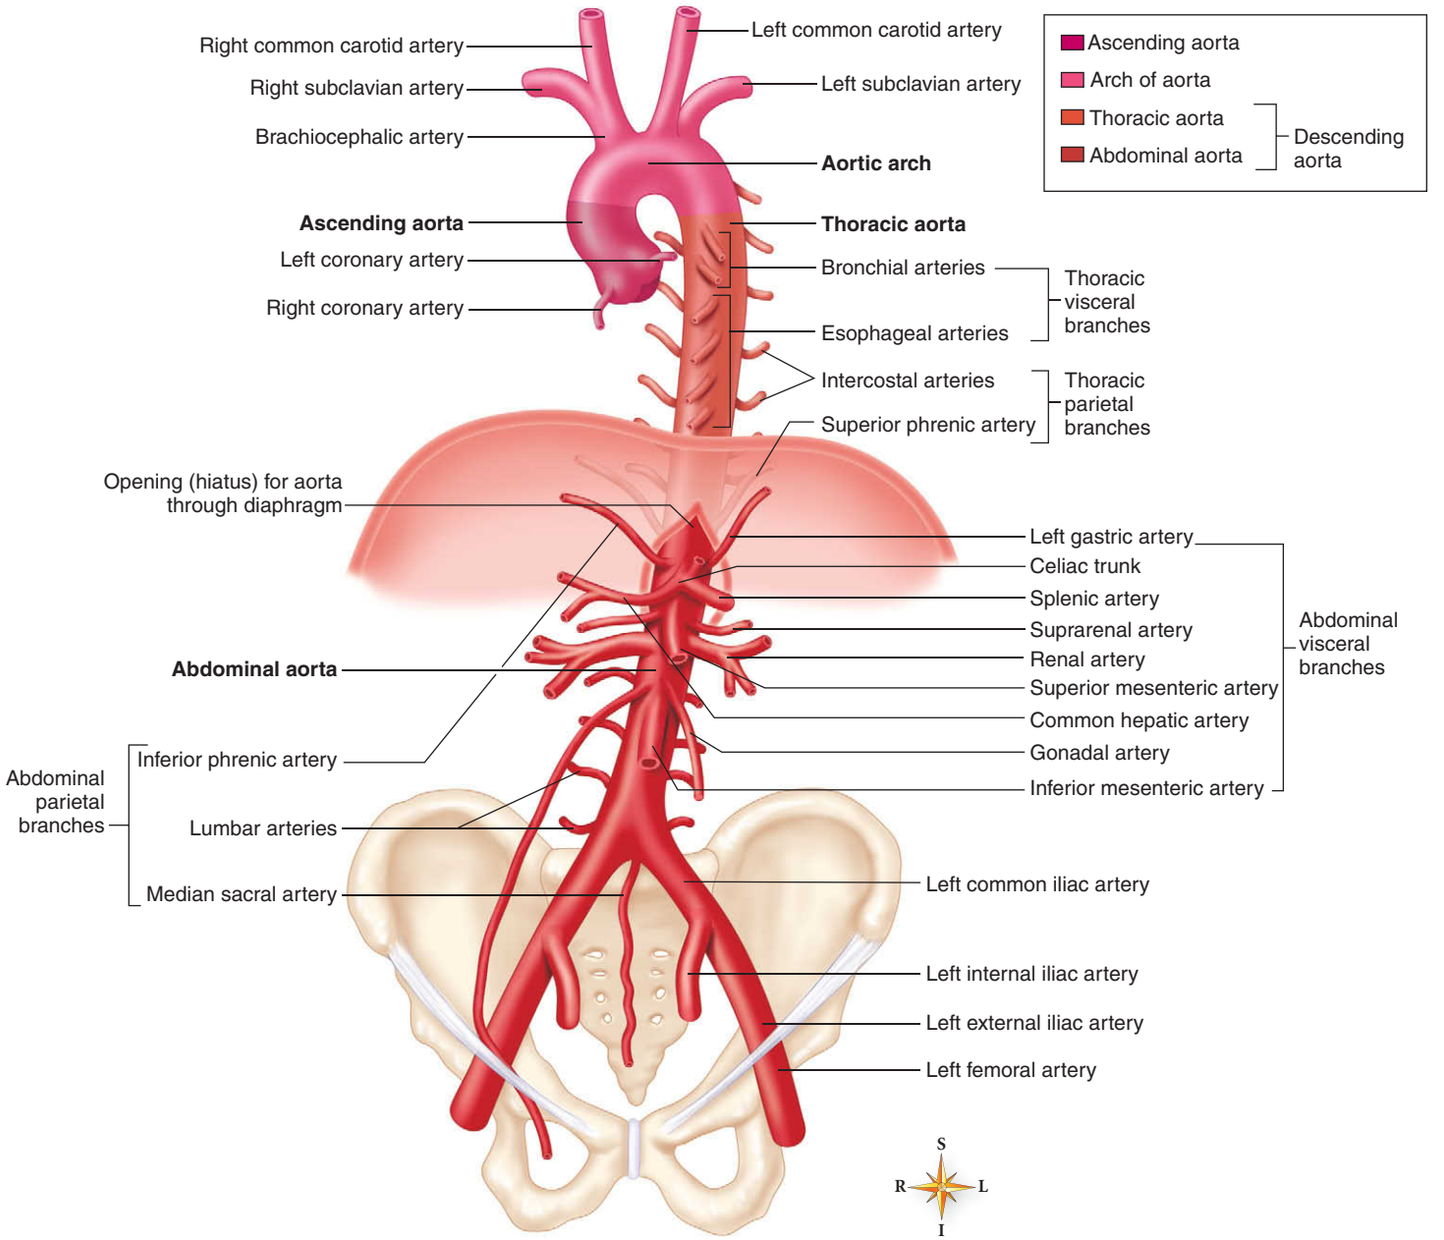

FIGURE 21-19

Divisions and primary branches of the aorta (anterior view). The aorta is the main systemic artery, serving as a trunk from which other arteries branch. Blood is conducted from the heart first through the ascending aorta, then through the arch of the aorta, and then through the thoracic and abdominal segments of the descending aorta. Note the designation of visceral and parietal branches in the thoracic and abdominal aortic divisions. Table 21-2 and the flow charts showing branches of the aortic divisions in Figures 21-22, 21-24, and 21-26 are intended to assist you in interpreting the artist's depiction of arterial vessels.

General Principles Concerning Arteries

As you learn the names of the main arteries, keep in mind that these are only the major pipelines distributing blood from the heart to the various organs and that, in each organ, the main artery resembles a tree trunk in that it gives off numerous branches that continue to branch and rebranch, forming ever-smaller vessels (arterioles), which also branch, forming microscopic vessels, the capillaries. In other words, most arteries eventually diverge into capillaries. Arteries of this type are called **end-arteries.** Important organs or areas of the body supplied by end-arteries are subject to serious damage or death in occlusive arterial disease. As an example, permanent blindness results when the central artery of the

retina, an end-artery, is occluded. Therefore arterial disease that occludes (blocks) blood flow, such as atherosclerosis, is of clinical concern when it affects important organs having an end-arterial blood supply.

A few arteries open into other branches of the same or other arteries. Such a communication was described earlier as an **arterial anastomosis.** Anastomoses, we have already noted, fulfill an important protective function in that they provide detour routes for blood to travel through in the event of obstruction of a main artery. The incidence of arterial anastomoses increases as distance from the heart increases, and smaller arterial branches tend to anastomose more often than larger vessels. Examples of arterial anastomoses are the palmar and plantar arches and the cerebral arterial circle (of Willis) at the base of the brain (look ahead to Figure 21-22 on p. 653). Other examples are found around several joints, as well as in other locations.

Another general principle to remember as you study the systemic arteries is that the **aorta** is the major artery that serves as the main trunk of the entire systemic arterial system. Notice in Figures 21-18 and 21-19 that different segments of the aorta are known by different names. Because the first few centimeters of the aorta conduct blood upward out of the left ventricle, this region is known as the **ascending aorta.** The coronary arteries are branches of the ascending aorta (look back to Figures 21-10 and 21-11). The aorta then turns 180 degrees, forming a curved segment called the *arch of the aorta* or simply **aortic arch.** Arterial blood is conducted downward from the arch of the aorta through the **descending aorta.** The descending aorta passes through the thoracic cavity, where it is known as the **thoracic aorta,** to the abdominal cavity, where it is known as the **abdominal aorta.**

If you check Table 21-2 or Figure 21-18, you will notice that all systemic arteries branch from the aorta or one of its branches.

Look again at Figures 21-18 and 21-19. Notice how the main branches from the arch of the aorta are different on the right compared with the left. The right side of the head and neck are supplied by the **brachiocephalic artery,** which branches to become the right **subclavian artery** and right **common carotid artery.** On the left, however, the left subclavian artery and the left common carotid artery branch directly from the arch of the aorta—without an intervening brachiocephalic artery.

Arteries of the Head and Neck

Figure 21-20 shows the major arteries of the head, neck, and face. Trace the branching of arteries in the figure with your finger as you read through Table 21-2. Notice in this figure how the right and left vertebral arteries extend from their origin as branches of the subclavian arteries up the neck, through foramina in the transverse processes of the cervical vertebrae, through the foramen magnum, and into the cranial cavity.

Next, take a look at Figure 21-21, which shows the arteries at the base of the brain. Note how the vertebral arteries unite on the undersurface of the brainstem to form the *basilar artery*, which

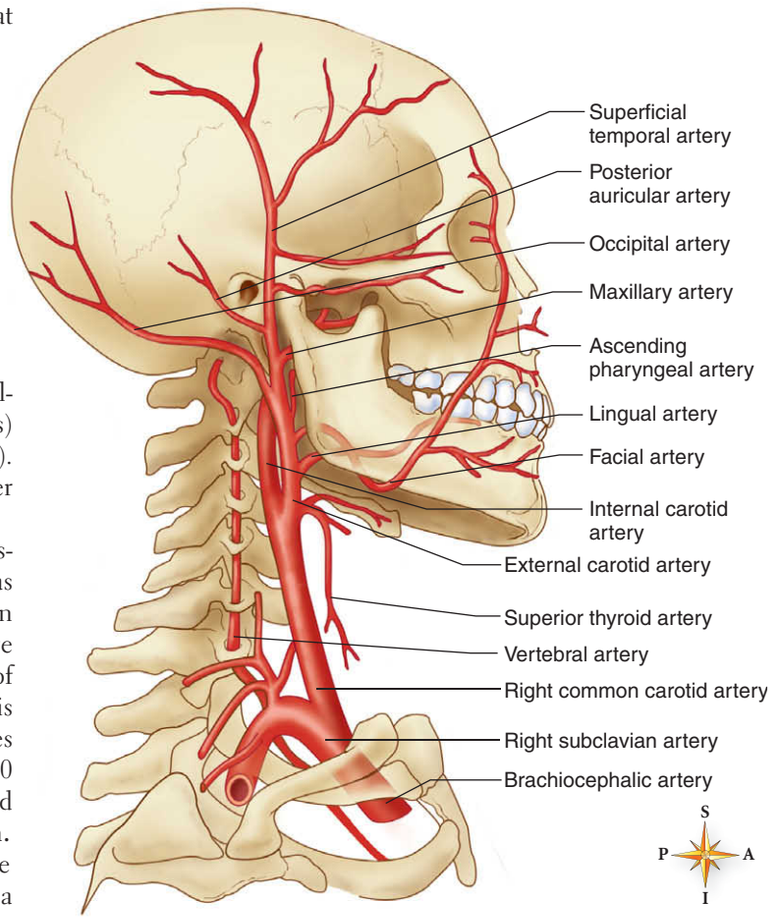

FIGURE 21-20

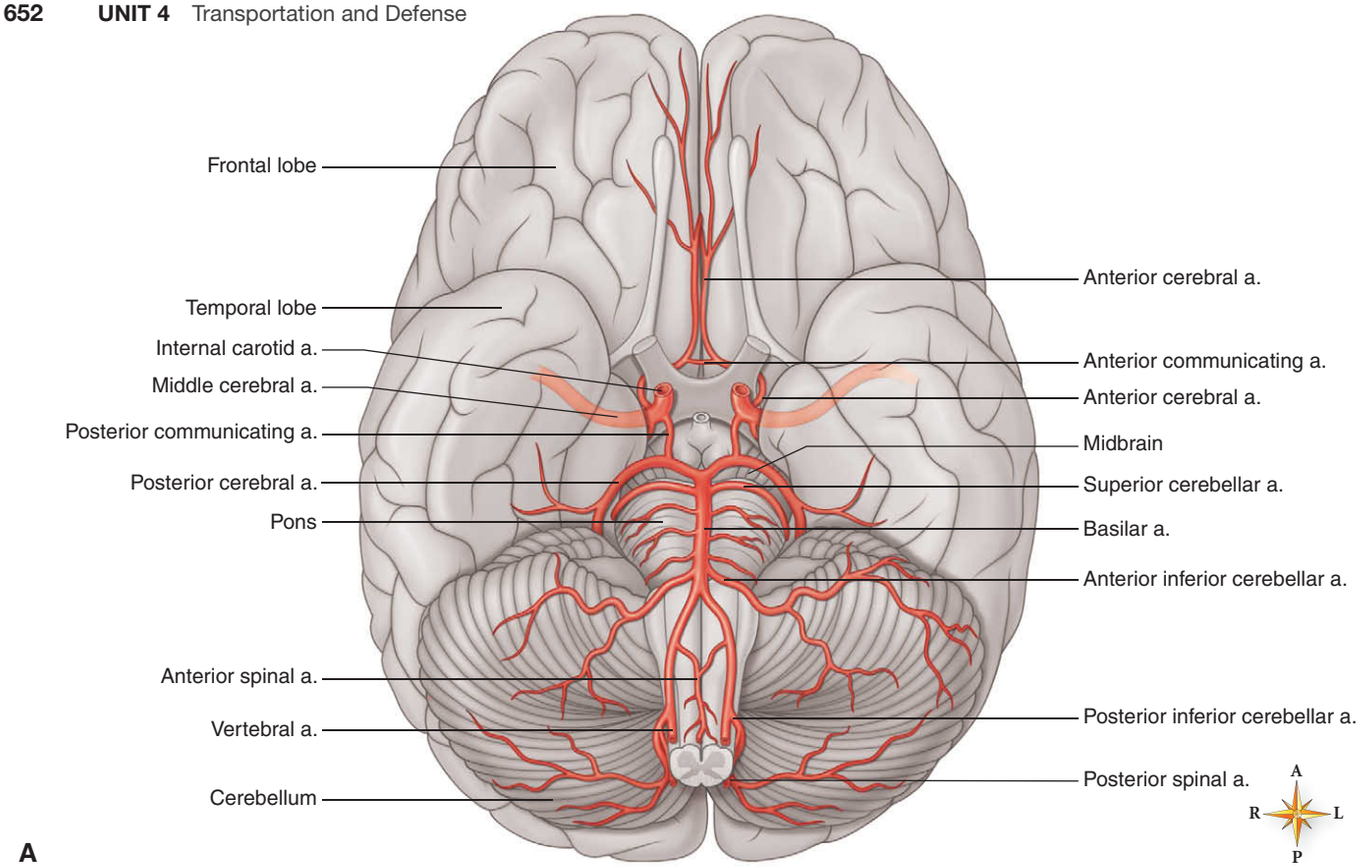
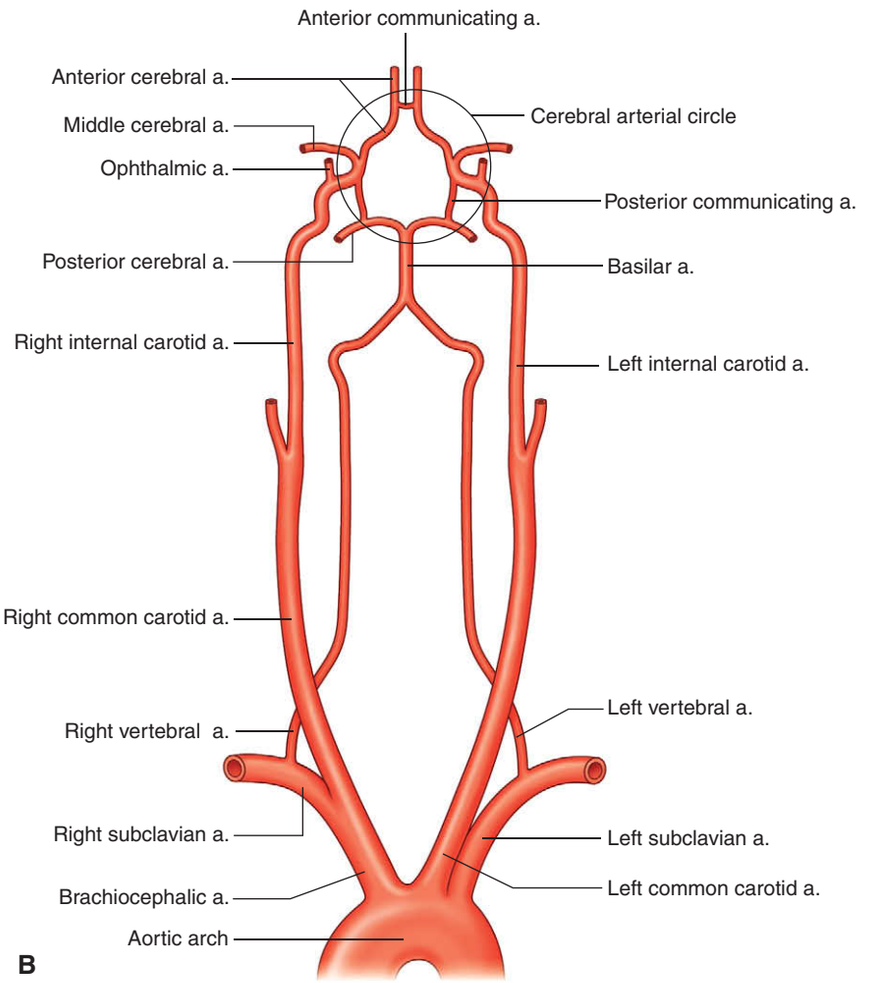


Major arteries of the head and neck. See Figure 21-21 for arteries at the base of the brain.



shortly branches into the right and left *posterior cerebral arteries* (see Figure 21-21). The basilar artery also braches to the pons and cerebellum (see Table 21-2). The internal carotid arteries enter the cranial cavity in the mid part of the cranial floor, where they become known as the *anterior cerebral arteries.* Small vessels, the *communicating arteries,* join the anterior and posterior cerebral arteries in such a way as to form the *cerebral arterial circle (of Willis)* at the base of the brain, a good example of arterial anastomosis (see Figure 21-21).

Arteries of the Trunk

The arch of the aorta continues downward as the **thoracic aorta.** It begins at the level of the fifth thoracic vertebra and ends at the diaphragm. *Parietal* branches of the thoracic aorta (posterior intercostal, superior phrenic, and subcostal arteries) supply blood to the body wall. Four *visceral* branches (mediastinal, bronchial, esophageal, and pericardial) provide arterial blood to internal thoracic structures.

Just as the thoracic aorta is a downward continuation of the aortic arch so, too, is the **abdominal aorta** a downward continuation

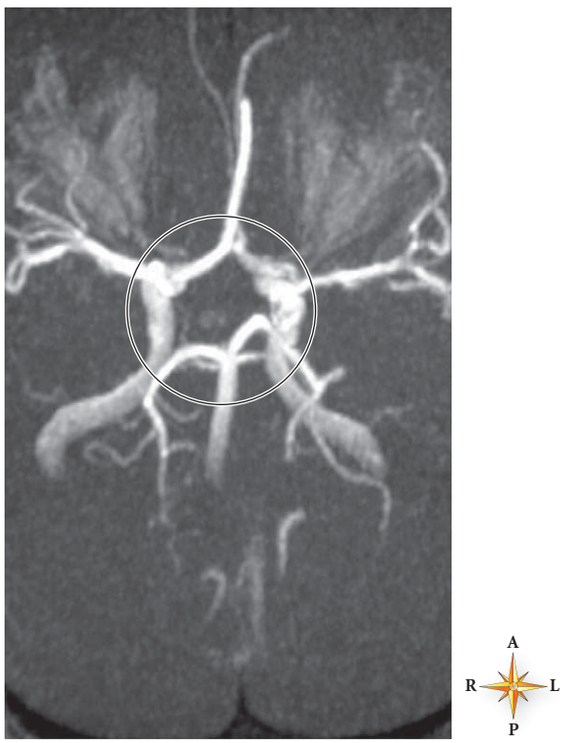


FIGURE 21-21

Arteries at the base of the brain. A, Diagram shows the cerebral arterial circle (of Willis) and related structures on the base of the brain. Note the arterial anastomoses. **B,** Origins of blood vessels that form the cerebral arterial circle. **C,** Magnetic resonance image of the cerebral arterial circle.

of the thoracic portion above it. It extends from the diaphragm above to the point where it divides into the right and left common iliac arteries at the level of the fourth lumbar vertebra. Note in Figure 21-20 that this segment of the aorta lies just anterior to the vertebral bodies. As a result, a physician can feel the aortic pulse during deep palpation of the abdomen when the vessel is compressed against the underlying vertebrae. The presence of a pulsating swelling along the aorta—an aortic aneurysm—is often diagnosed in this way.

Major abdominal and pelvic branches of the abdominal aorta may also be described as parietal or visceral depending on the location of the end organ or structures they supply with blood. Branches of this segment of the aorta are illustrated in Figures 21-18 and 21-20 and shown in schematic form in Figure 21-22.

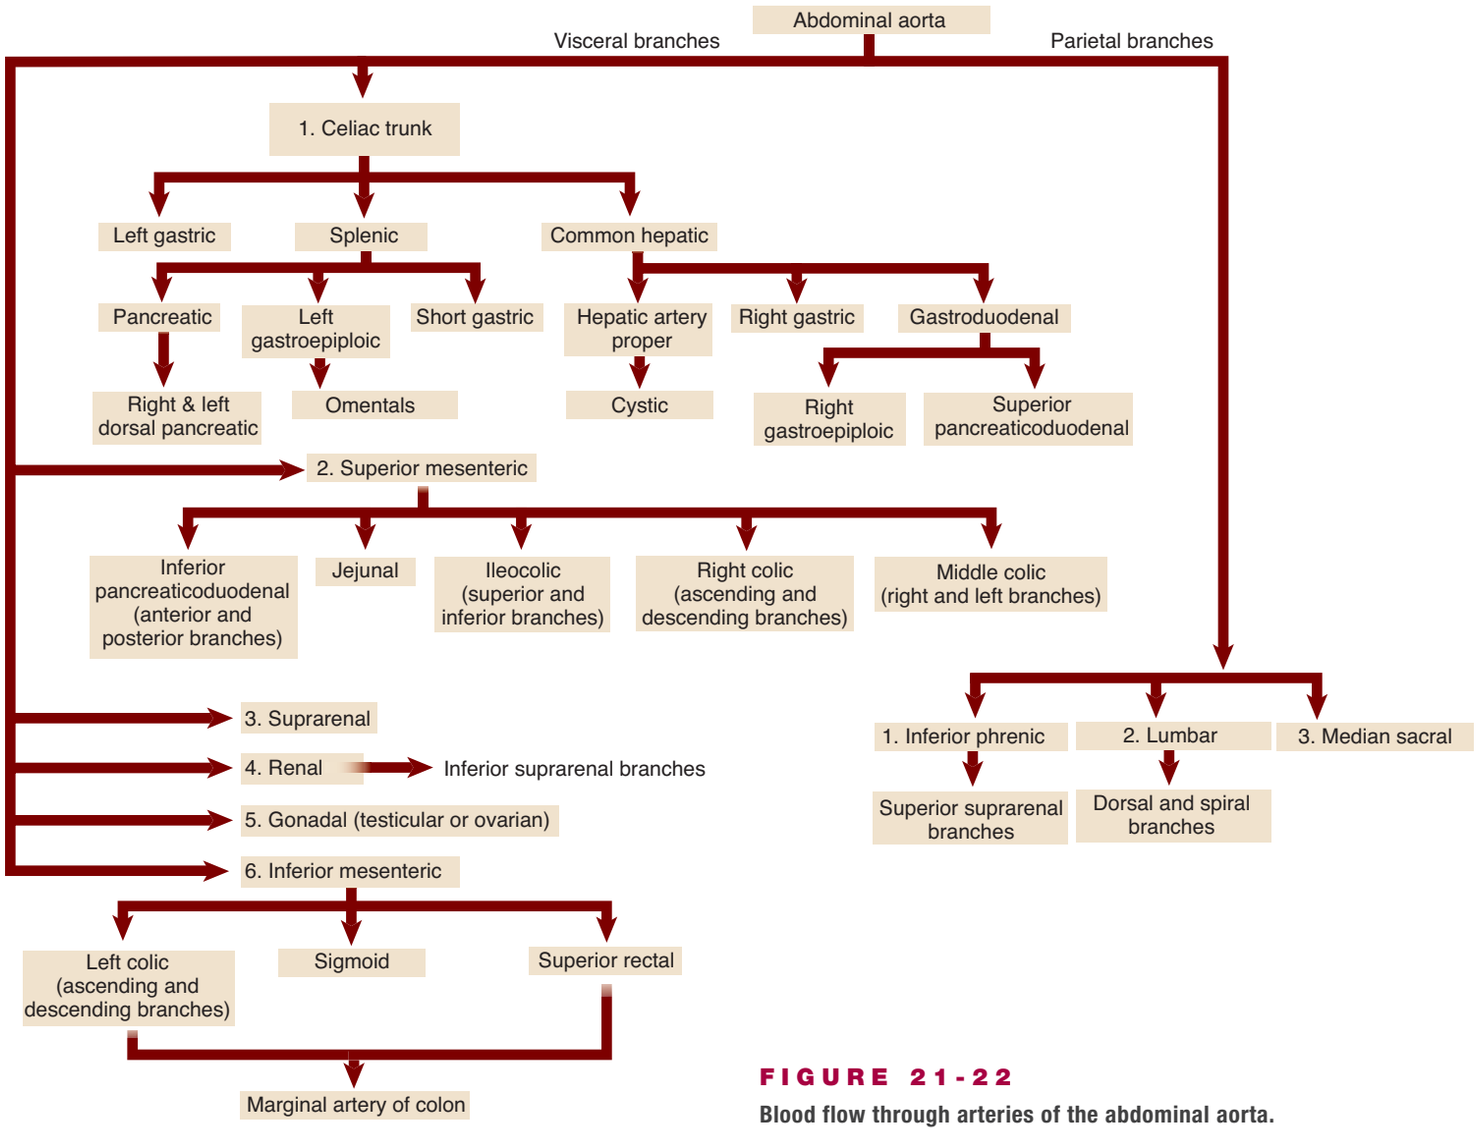

FIGURE 21-22

Blood flow through arteries of the abdominal aorta.

Arteries of the Extremities

Next, take a look at Figures 21-23 and 21-24, which outline the arteries of the upper extremity. Then take a look at Figures 21-25 and 21-26, which outline the arteries of the lower extremity. Trace these arteries with your finger as you compare each figure to Table 21-2. Because of differences in orientation, not every artery listed in the table appears in every illustration.

SYSTEMIC VEINS

Locate the veins listed in Table 21-3 (see also Figures 21-27 to 21-34). As with the arteries, you may find it easier to learn the names of veins and their anatomical relation to each other from diagrams and tables than from narrative descriptions.

General Principles Concerning Veins

The following facts should be borne in mind while learning the names and locations of veins:

- Veins are the ultimate extensions of capillaries, just as capillaries are the eventual extensions of arteries. Whereas arteries

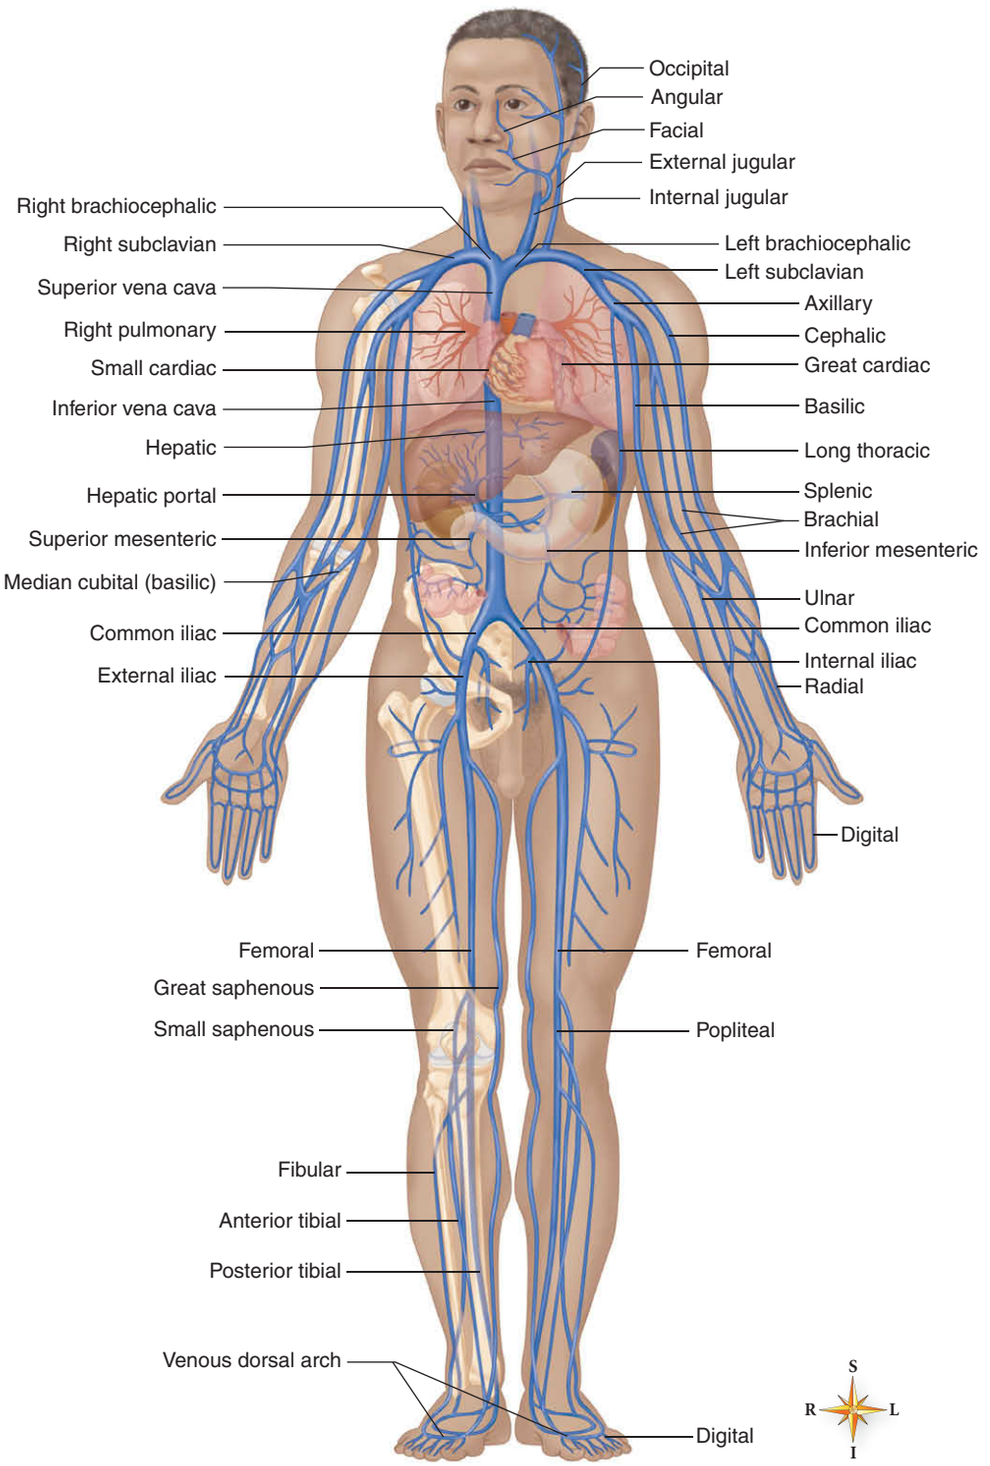

FIGURE 21-27

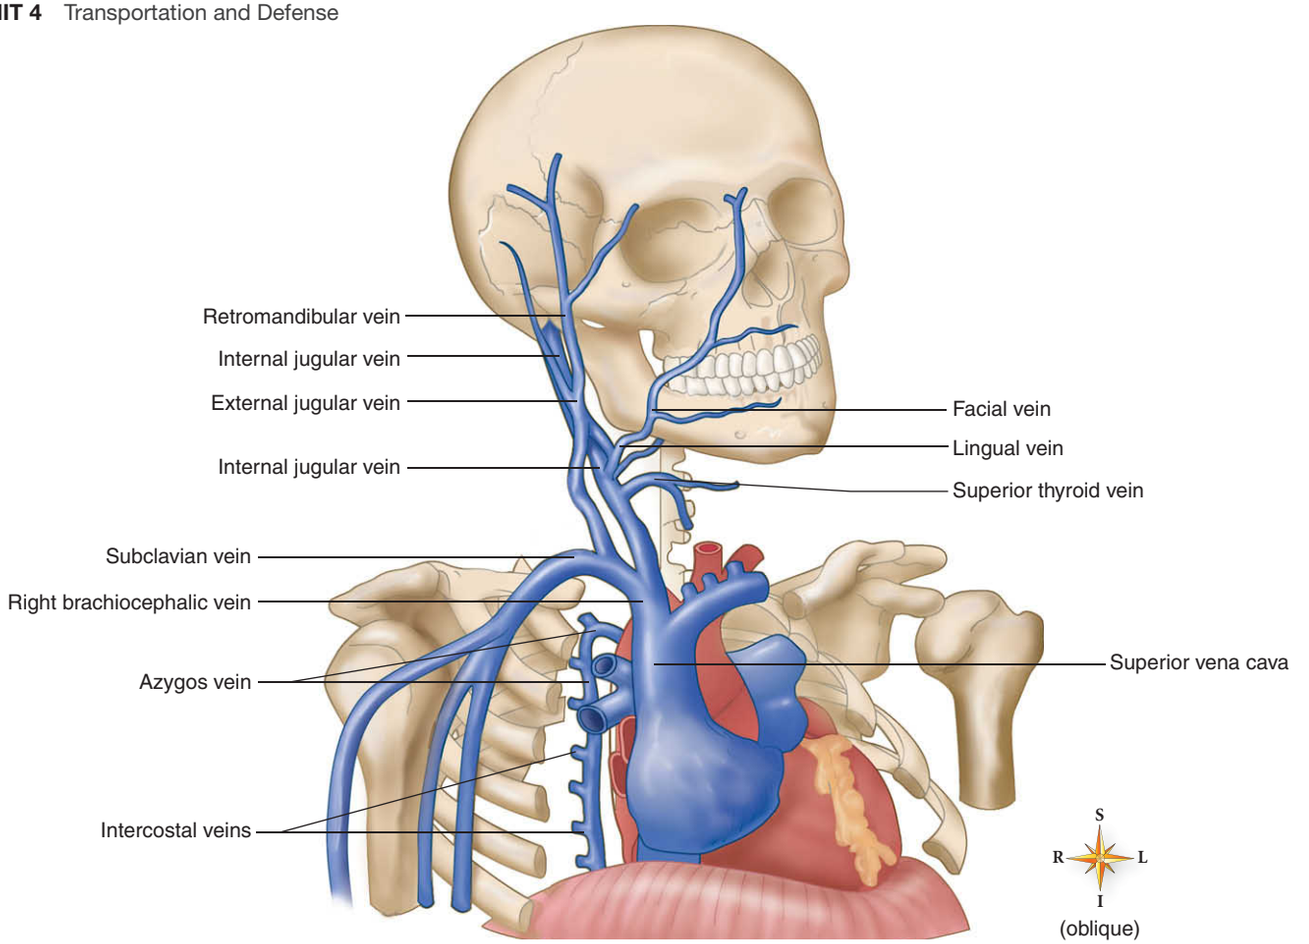

Principal veins of the body.

TABLE 21-3 Major Systemic Veins

VEIN*	REGION DRAINED
SUPERIOR VENA CAVA	Head, neck, thorax, upper extremity
Brachiocephalic (Innominate)	Head, neck, upper extremity
Internal jugular (continuation of sigmoid sinus)	Brain
Lingual	Tongue, mouth
Superior thyroid	Thyroid, deep face
Facial	Superficial face
Sigmoid sinus (continuation of transverse sinus; direct tributary of internal jugular)	Brain, meninges, skull
Superior and inferior petrosal sinuses	Anterior brain, skull
Cavernous sinus	Anterior brain, skull
Ophthalmic veins	Eye, orbit
Transverse sinus (direct tributary of sigmoid sinus)	Brain, meninges, skull
Occipital sinus	Inferior, central region of cranial cavity
Straight sinus	Central region of brain, meninges
Inferior sagittal sinus	Central region of brain, meninges
Superior sagittal (longitudinal) sinus	Superior region of cranial cavity
External jugular	Superficial, posterior head, neck
Subclavian (continuation of axillary; direct tributary of brachiocephalic)	Axilla, lower extremity
Cephalic	Lateral arm and forearm, hand
Axillary (continuation of basilic; direct tributary of subclavian)	Axilla, lower extremity
Brachial	Deep arm
Radial	Deep lateral forearm
Ulnar	Deep medial forearm
Basilic (direct tributary of axillary)	Medial arm and forearm, hand
Median cubital (formed by anastomosis of cephalic and basilic)	Forearm, hand
Deep and superficial palmar venous arches (formed by anastomosis of cephalic and basilic)	Hand
Digital	Fingers
Azygos (anastomoses with right ascending lumbar)	Right posterior wall of thorax and abdomen, esophagus, bronchi, pericardium, mediastinum
Hemiazygos (anastomoses with left renal)	Left inferior posterior wall of thorax and abdomen, esophagus, mediastinum
Accessory hemiazygos	Left superior posterior wall of thorax

VEIN*	REGION DRAINED
INFERIOR VENA CAVA	Lower trunk and extremity
Phrenic	Diaphragm
Hepatic portal system	Upper abdominal viscera
Hepatic veins (continuations of liver venules and sinusoids and ultimately the hepatic portal vein)	Liver
Hepatic portal vein	Gastrointestinal organs, pancreas, spleen, gallbladder
Cystic	Gallbladder
Gastric	Stomach
Splenic	Spleen
Inferior mesenteric	Descending colon, rectum
Pancreatic	Pancreas
Superior mesenteric	Small intestine, most of colon
Gastroepiploic	Stomach
Renal	Kidneys
Suprarenal	Adrenal (suprarenal) gland
Left ovarian	Left ovary
Left testicular	Left testis
Left ascending lumbar (anastomoses with hemiazygos)	Left lumbar region
Right ovarian (gonadal)	Right ovary
Right testicular (gonadal)	Right testis
Right ascending lumbar (anastomoses with azygos)	Right lumbar region
Common iliac (continuation of external iliac; common iliacs unite to form inferior vena cava)	Lower extremity
External iliac (continuation of femoral direct tributary of common iliac)	Thigh, leg, foot
Femoral (continuation of popliteal direct tributary of external iliac)	Thigh, leg, foot
Popliteal	Leg, foot
Small (external, short) saphenous	Superficial posterior leg, lateral foot
Dorsal veins of foot (also drain into great saphenous)	Anterior (dorsal) foot, toes
Medial and lateral plantar	Sole of foot
Anterior tibial	Anterior leg, foot
Fibular (peroneal)	Lateral and anterior leg, foot
Posterior tibial	Deep posterior leg
Great (internal, long) saphenous	Superficial medial and anterior thigh, leg, foot
Dorsal veins of foot	Anterior (dorsal) foot, toes
Dorsal venous arch	Anterior (dorsal) foot, toes
Digital	Toes
Internal iliac (unites with external iliac to form common iliac)	Pelvic region

*Tributaries of each vein are identified below its name; deep veins are printed in dark blue, and superficial veins are printed in light blue.

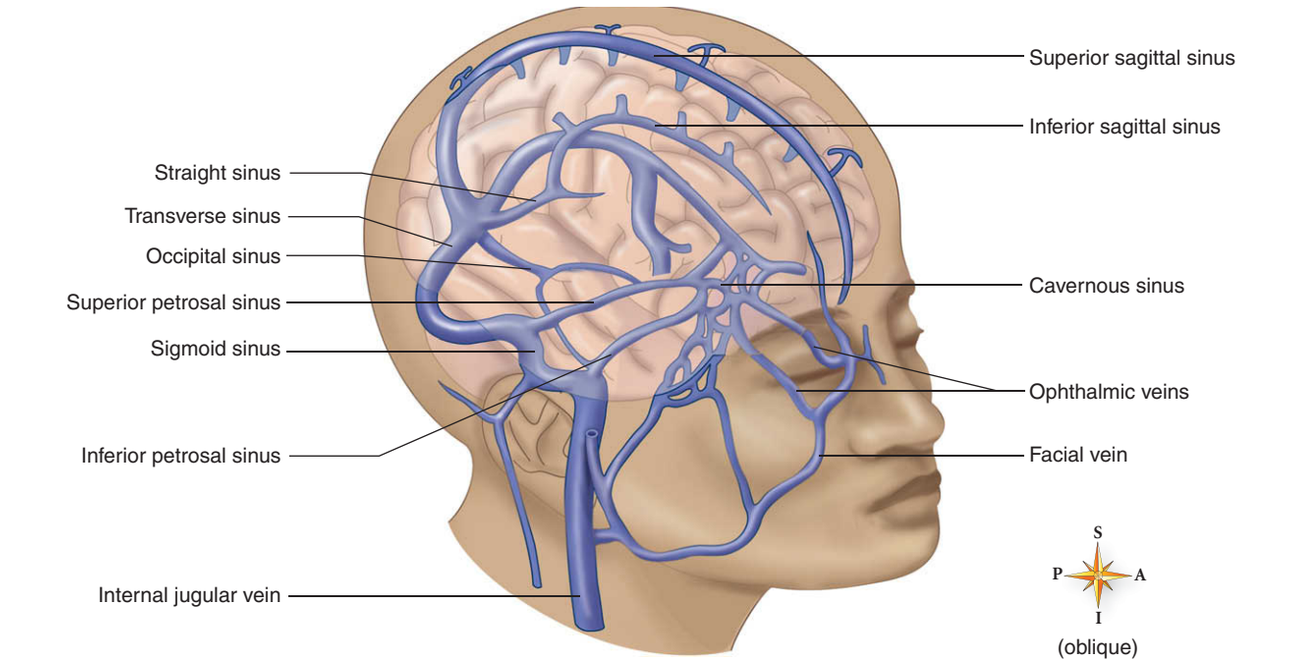

FIGURE 21-28

Major veins of the head and neck. A, Anterior view showing veins on the right side of the head and neck. **B,** Lateral, superior view showing the position of major veins relative to the brain. The venous sinuses shown here are within the dura mater and are thus called *dural sinuses*.

branch into vessels of decreasing size to form arterioles and eventually capillaries, capillaries unite into vessels of increasing size to form venules and, eventually, veins.

- Although all vessels vary considerably in location and branches—and whether or not they are even present—the veins are especially variable. For example, the **median cubital vein** in the forearm is absent in many individuals.
- Many of the main arteries have corresponding veins bearing the same name and are located alongside or near the arteries. These veins, like the arteries, lie in deep, well-protected areas, for the most part, close along the bones. Examples include the femoral artery and femoral vein, both located along the femur bone.
- Veins found in the deep parts of the body are called **deep veins** in contrast to **superficial veins,** which lie near the surface. The latter are the veins that can be seen through the skin.
- The large veins of the cranial cavity, formed by the dura mater, are not usually called veins but are instead called *dural sinuses,* or, simply, **sinuses.** They should not be confused with the bony, air-filled sinuses of the skull.
- Veins communicate (anastomose) with each other in the same way as arteries. In fact, the venous portion of the systemic circulation has even more anastomoses than the arterial portion. Such venous anastomoses provide for collateral return blood flow in cases of venous obstruction.
- Venous blood from the head, neck, upper extremities, and thoracic cavity, with the exception of the lungs, drains into the superior vena cava. Blood from the lower extremities and abdomen enters the inferior vena cava.

Table 21-3 identifies the major systemic veins. Locate each one as you read the table and trace them with your finger on Figures 21-27 to 21-34.

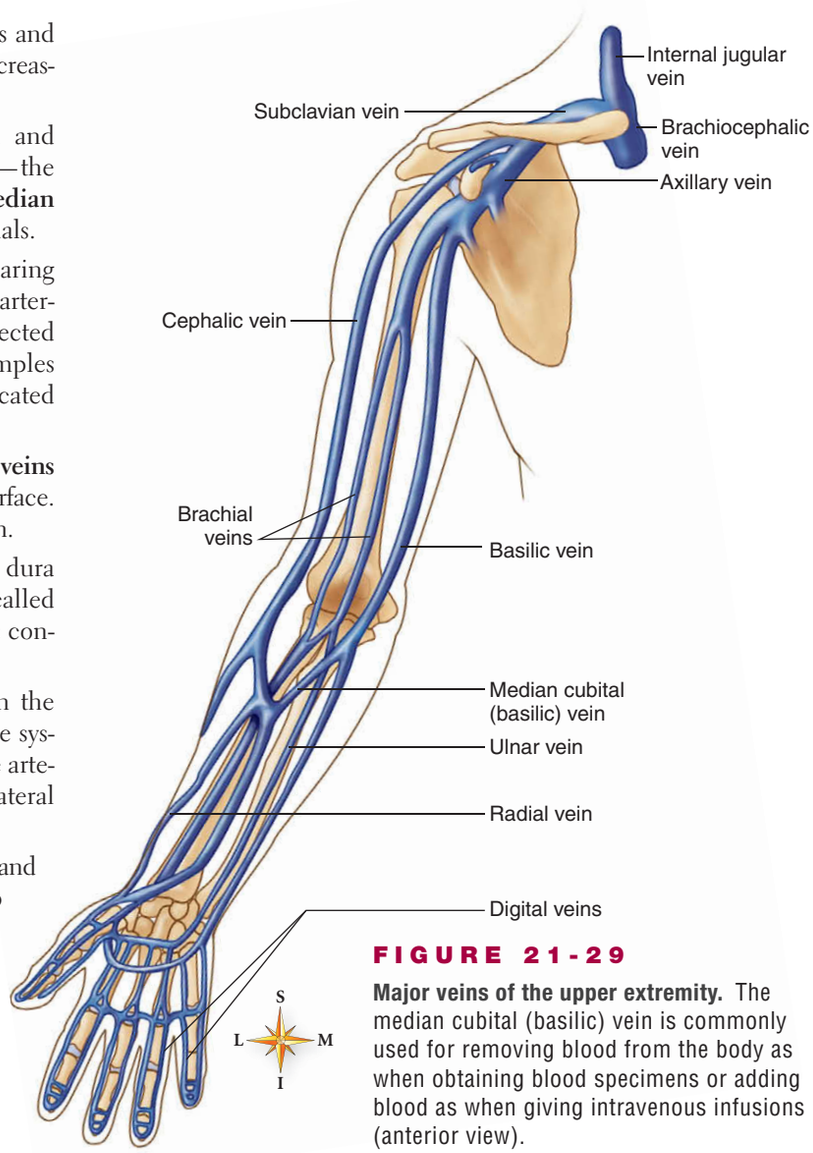

FIGURE 21-29

Major veins of the upper extremity. The median cubital (basilic) vein is commonly used for removing blood from the body as when obtaining blood specimens or adding blood as when giving intravenous infusions (anterior view).

Veins of the Head and Neck

The deep veins of the head and neck lie mostly within the cranial cavity (see Figure 21-28). These are mainly dural sinuses and other veins that drain into the **internal jugular vein.** The internal jugular vein also receives blood from superficial veins of the face and neck.

The superficial veins that lie over the cranium drain into the right and left **external jugular veins** in the neck. The external jugular veins also receive blood from deep veins of the face. Each external jugular vein terminates in a *subclavian vein.* Small emissary veins connect veins of the scalp and face with blood sinuses of the cranial cavity, a fact of clinical interest as a possible avenue for infections to enter the cranial cavity.

Veins of the Upper Extremity

Deep veins of the upper extremity drain into the **brachial vein,** which in turn drain into the **axillary vein** and then the **subclavian vein** before joining the **brachiocephalic vein,** a major tributary of the **superior vena cava.** The major veins of the upper extremity are shown in Figures 21-29 and 21-30. At this point, it is interesting to note that the tributaries of the superior vena cava are more symmetric from left to right than the nearby branches of the aorta. Compare Figures 21-18 and 21-27 to verify this point.

Superficial veins of the hand form the **palmar venous arches,** which, together with a complicated network of superficial veins of the forearm, finally pour their blood into two large veins: the **cephalic vein** (thumb side) and **basilic vein** (little finger side). These two veins empty into the deep **axillary vein.**

Veins of the Thorax

Several small veins—such as the **bronchial vein, esophageal vein,** and **pericardial vein**—return blood from thoracic organs (except gas exchange tissues in the lungs) directly into

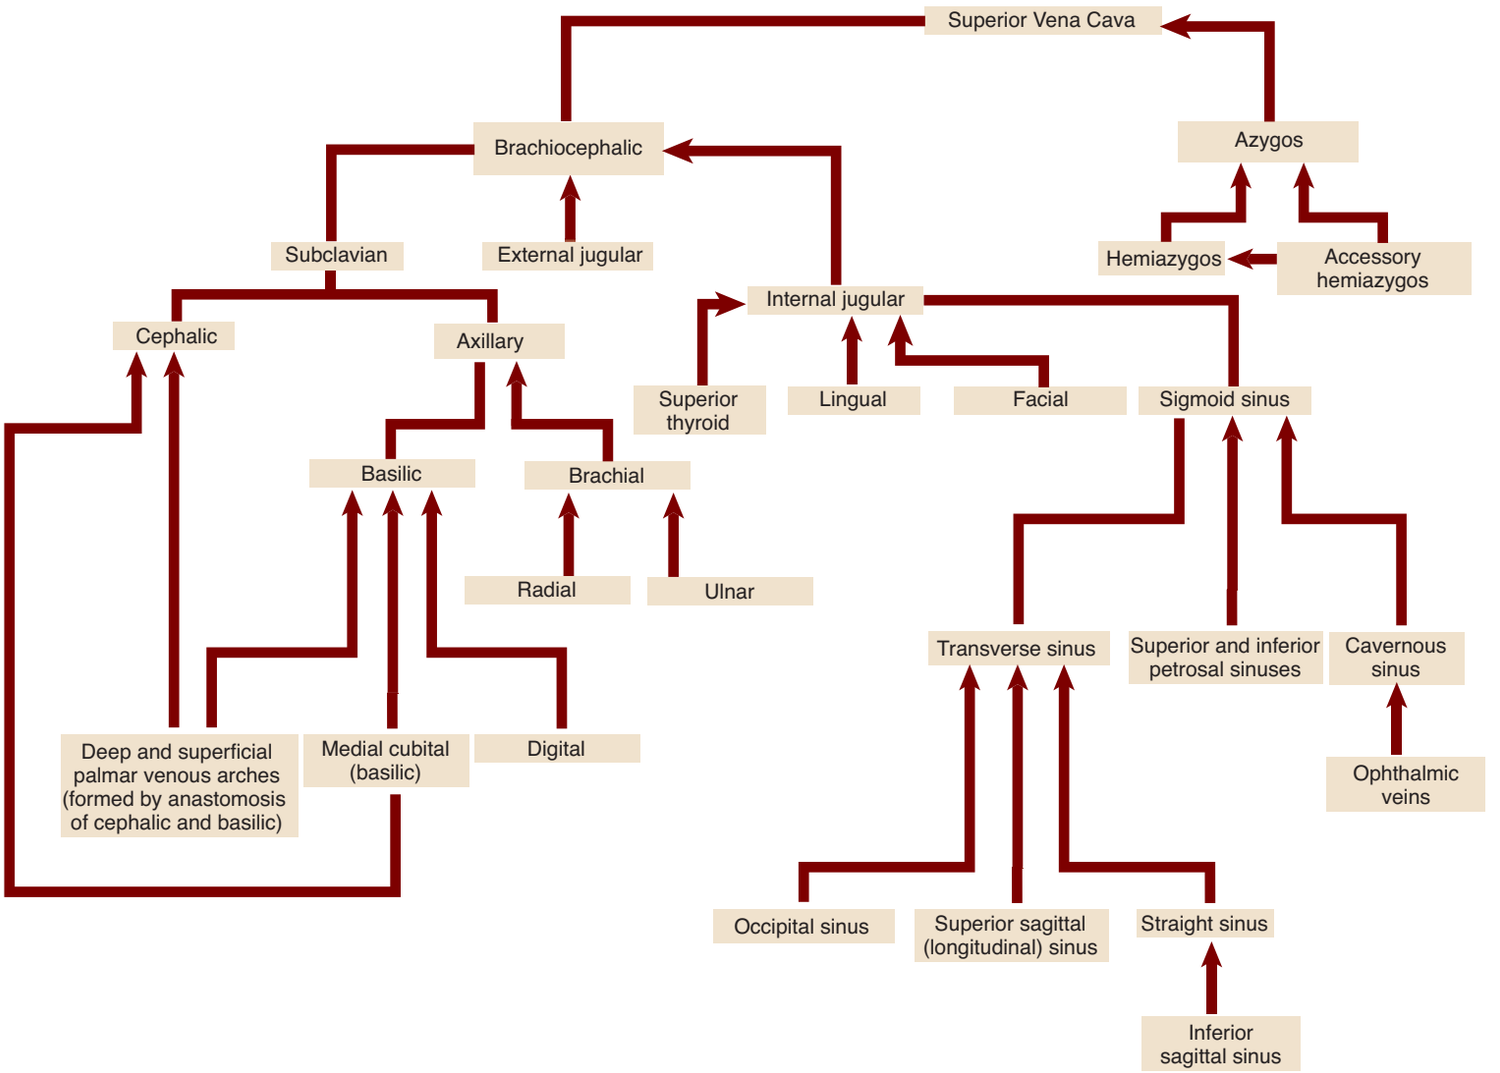

FIGURE 21-30

Blood flow into the superior vena cava from its major tributaries. Keep in mind that venous pathways show great variability among individuals.

the **superior vena cava** or **azygos vein.** Refer to Figure 21-31 to see how these veins are arranged. The azygos vein lies to the right of the spinal column and extends from the inferior vena cava (at the level of the first or second lumbar vertebra) through the diaphragm to the terminal part of the superior vena cava. The **hemiazygos vein** lies to the left of the spinal column, extending from the lumbar level of the inferior vena cava through the diaphragm to terminate in the azygos vein. The **accessory hemiazygos vein** connects some of the **superior intercostal veins** with the azygos or hemiazygos vein.

Veins of the Abdomen

The abdominal tributaries offer another opportunity to see a slight difference between the left and right portions of the systemic venous circulation. For example, Figure 21-31 shows that the gonadal veins—*ovarian vein* or *testicular (spermatic) vein*—and left **suprarenal vein** usually drain into the left **renal vein** instead of into the **inferior vena cava.** This is the opposite of the arrangement of these veins on the right. For a description of the return of blood from the abdominal digestive organs, see the subsequent discussion of the **hepatic portal circulation.**

Hepatic Portal Circulation

Veins from the spleen, stomach, pancreas, gallbladder, and intestines do not pour their blood directly into the inferior vena cava, as do the veins from other abdominal organs. They send their blood to the liver by means of the hepatic portal vein. Here the blood mingles with the arterial blood in the capillaries and is eventually drained from the liver by the hepatic veins that join the inferior vena cava. Any arrangement in which venous blood flows through

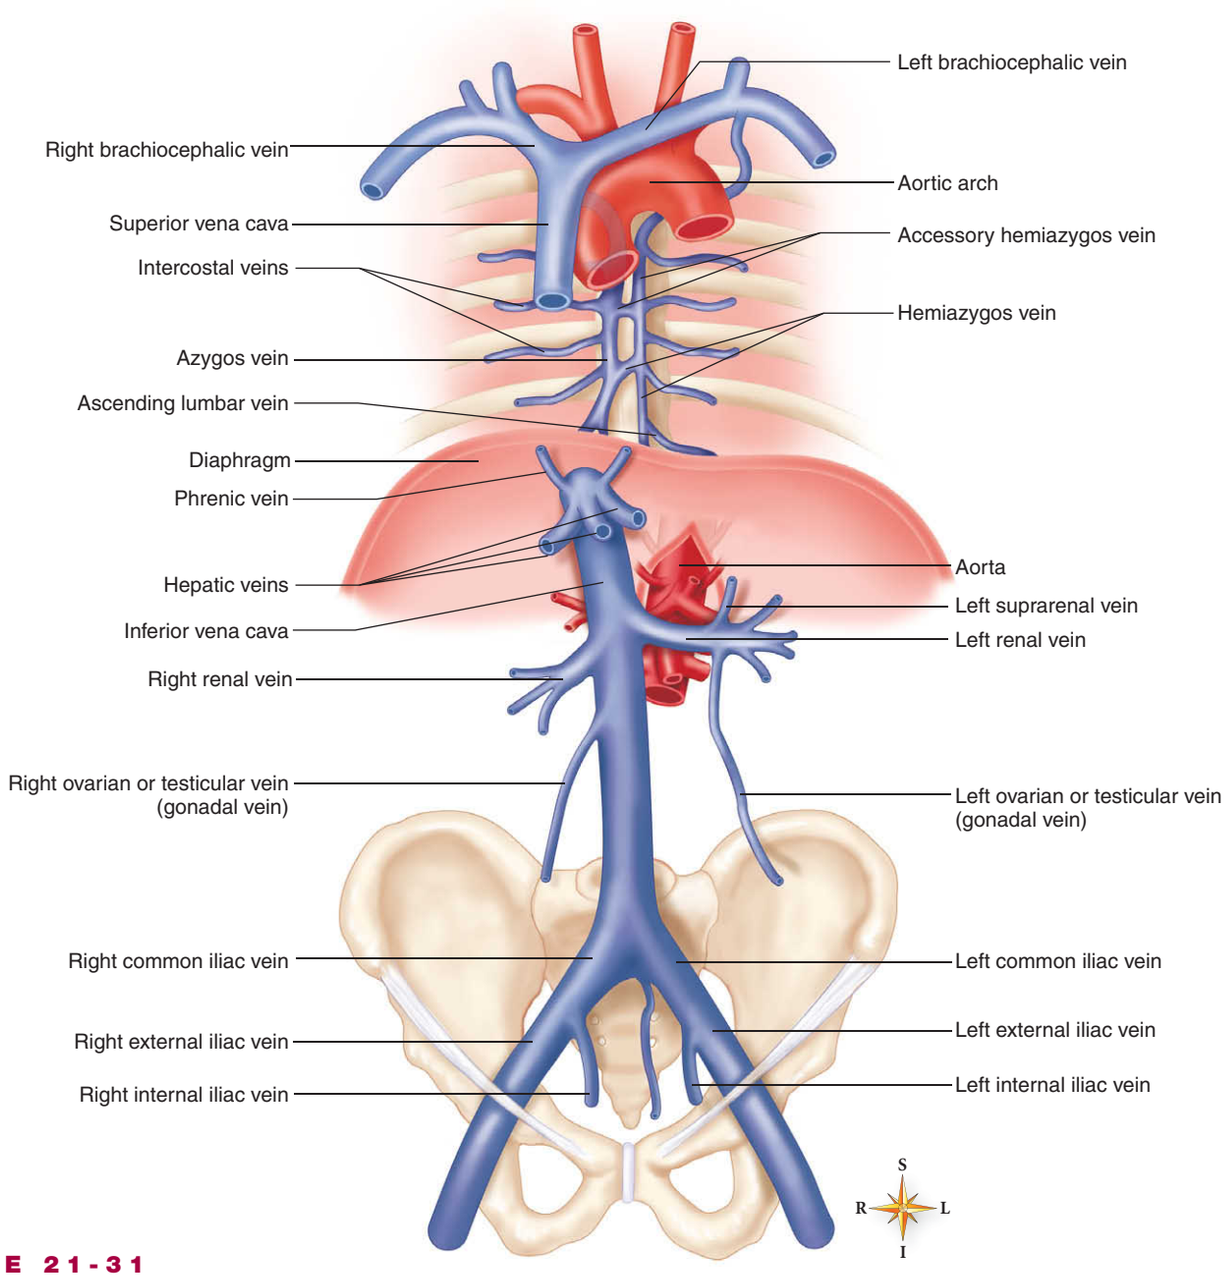

FIGURE 21-31

Inferior vena cava and its abdominopelvic tributaries. Anterior view of ventral body cavity with many of the viscera removed. Note the close anatomical relationship between the inferior vena cava and the descending aorta. Smaller veins of the thorax drain blood into the inferior vena cava or into the azygos vein—both are shown here. The hemiazygos vein and accessory hemiazygos vein on the left drain into the azygos vein on the right.

a second capillary network before returning to the heart is called a *portal* circulatory route. Portal comes from the Latin *porta*, meaning "gateway," and is used here because the liver is a gateway through which blood returning from the digestive tract must pass before it returns to the heart.

There are several advantages to detouring blood from the digestive tract through the liver before it returns to the heart. Shortly after a meal, blood flowing through digestive organs begins absorbing glucose and other simple nutrients. The result is a tremendous increase in the blood glucose level. As the blood travels through the liver, however, excess glucose is removed from the blood and stored in liver cells as glycogen. Thus blood returned to the heart carries only a moderate level of glucose. Many hours after food has yielded its nutrients,

low-glucose blood coming from the digestive organs can pick up glucose released from the glycogen stores held in the liver cells before returning to the heart.

Another advantage of the hepatic portal scheme is that toxic molecules such as alcohol can be partially removed or detoxified before the blood is distributed to the rest of the body. Additional information regarding the role of the liver, and the advantages of the portal circulation through the liver, is discussed in Chapters 28 and 29.

Figure 21-17 (p. 647) shows the plan of the hepatic portal system in relation to the overall scheme of circulation. Figure 21-32 shows the details of the veins involved in the hepatic portal circulation. In most individuals the hepatic portal vein is formed by the union of the splenic and superior mesenteric veins, but blood from the gastric, pancreatic, and inferior mesenteric veins drains into the splenic vein before it merges with the superior mesenteric vein.

If either hepatic portal circulation or venous return from the liver is interfered with (as often occurs in certain types of liver disease or heart disease), venous drainage from most of the other abdominal organs is necessarily obstructed also. The accompanying increased capillary pressure accounts, at least in part, for the occurrence of abdominal bloating, or *ascites* (ah-SITE-eez), under these conditions.

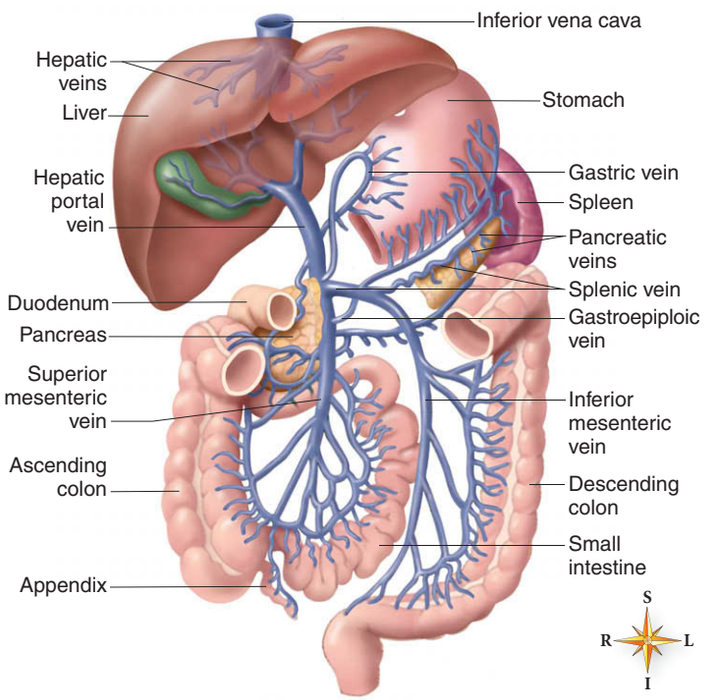

FIGURE 21-32

Hepatic portal circulation. In this unusual circulatory route, a vein is located between two capillary beds (see Figure 21-17). The hepatic portal vein collects blood from capillaries in visceral structures located in the abdomen and empties it into the liver. Hepatic veins return blood to the inferior vena cava.

Veins of the Lower Extremity

As Figure 21-33 shows, deep veins of the leg drain from the **anterior tibial vein,** the **fibular (peroneal) vein,** and the **posterior tibial vein.** These veins join the **popliteal vein,** which runs behind the knee joint and continues up along the femur as the deep femoral vein. The **femoral vein** continues as the **external iliac**

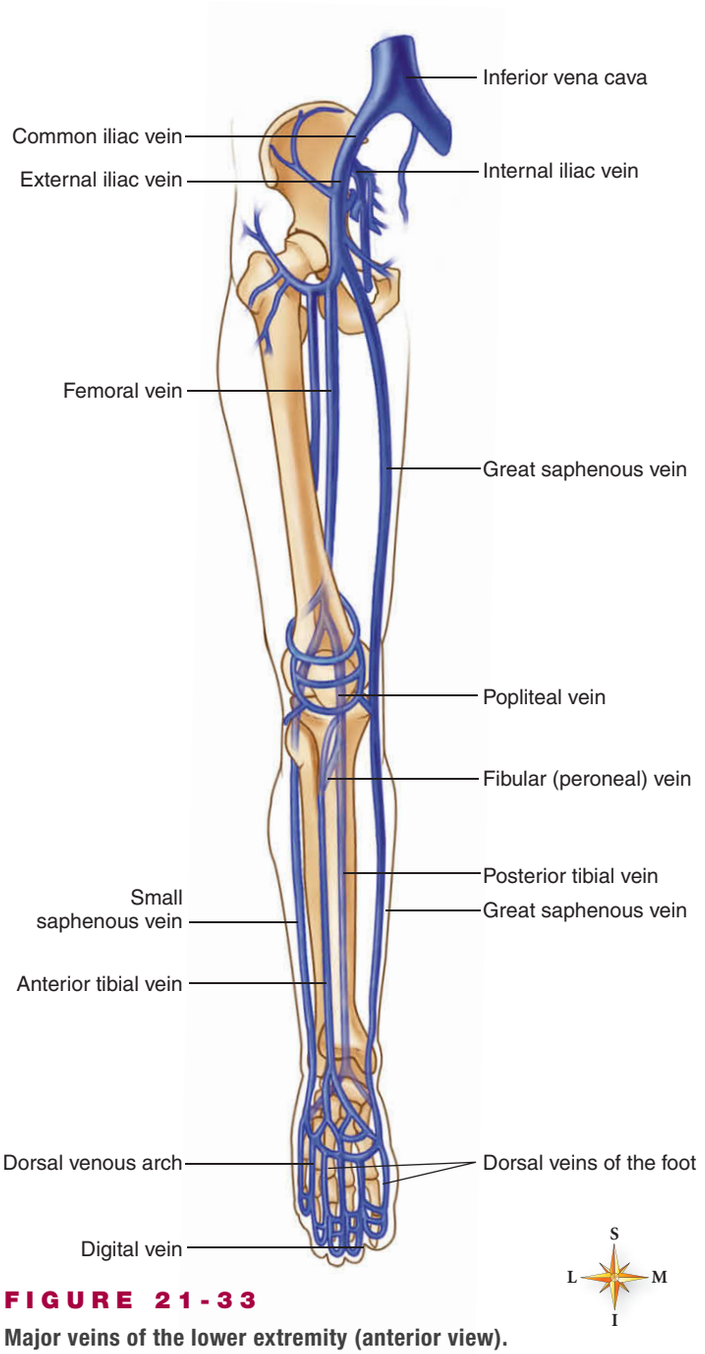

FIGURE 21-33

Major veins of the lower extremity (anterior view).

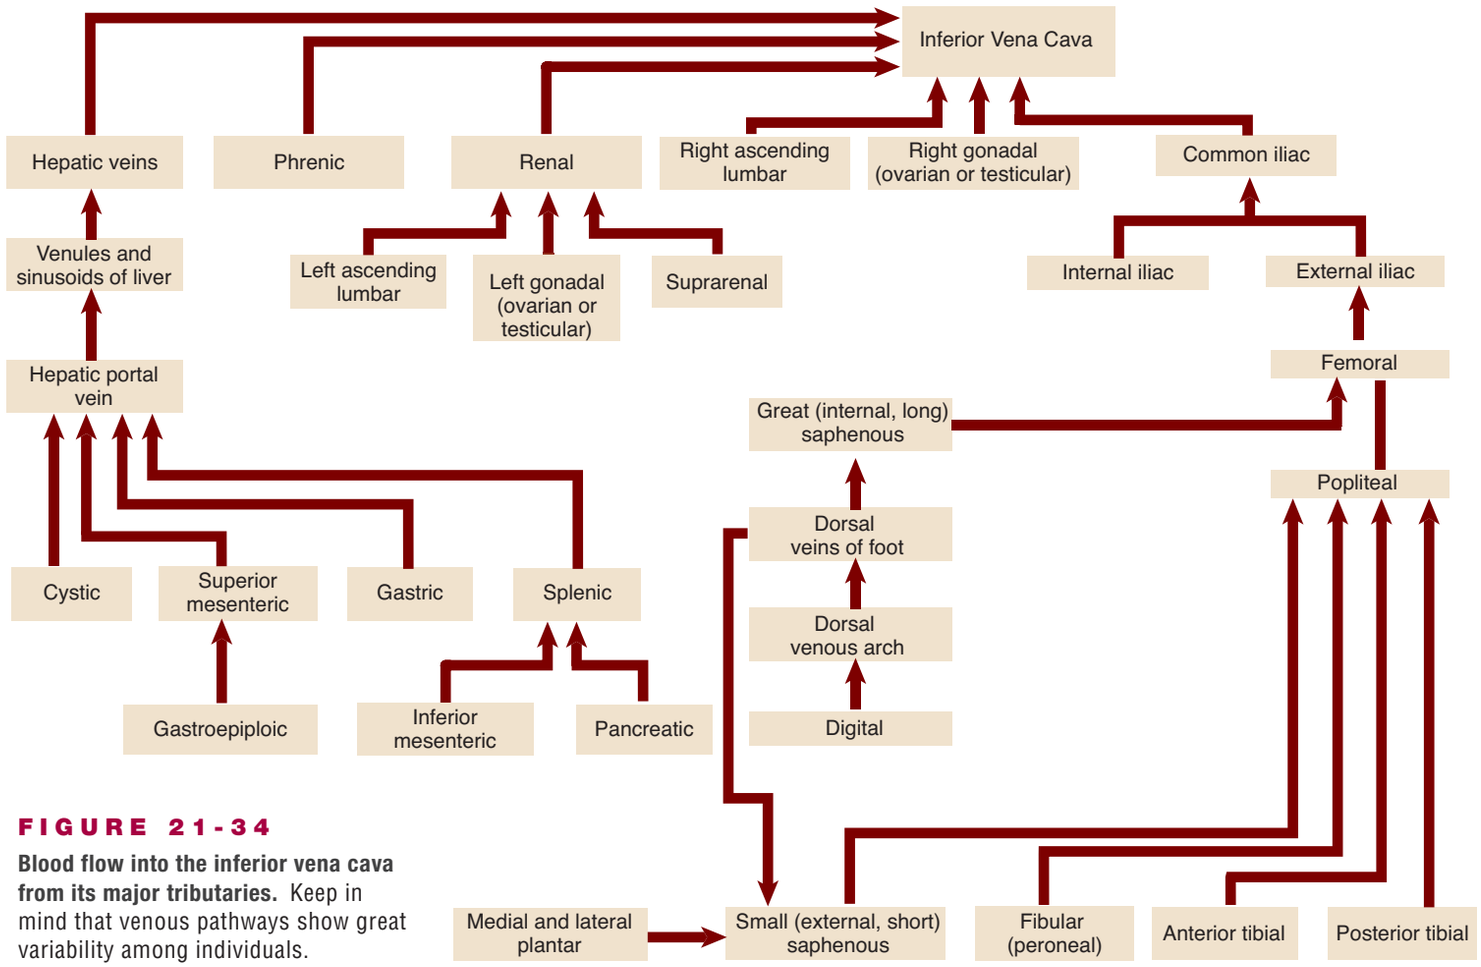

FIGURE 21-34

Blood flow into the inferior vena cava from its major tributaries. Keep in mind that venous pathways show great variability among individuals.

vein, draining into the common iliac vein and from there into the **inferior vena cava.**

Superficial veins of the lower extremity include the **small saphenous vein,** a tributary of the popliteal vein, and the **great saphenous vein,** which drains much of the superficial leg and foot. The name *saphenous* is from the Greek *saphenes,* a word that means "apparent"—an appropriate name for these visible, superficial veins.

Figure 21-34 summarizes blood flow from the abdomen and lower extremities into the inferior vena cava.

A valuable skill is the ability to trace the flow of blood completely through the normal adult circulatory route. Check out ***How to Trace the Flow of Blood*** online at ***A&P Connect*** for some tips and a handy diagram of the route of blood flow through the body.

evolve

FETAL CIRCULATION

The Basic Plan of Fetal Circulation

Circulation in the body before birth necessarily differs from circulation after birth for one main reason—fetal blood secures oxygen and food from maternal blood instead of from fetal lungs and digestive organs. Obviously, then, there must be additional blood vessels in the fetus to carry the fetal blood into close approximation with the maternal blood and to return it to the fetal body. These structures are the two **umbilical arteries,** the **umbilical vein,** and the **ductus venosus.**

Also, some structure must function as the lungs and digestive organs do after birth, that is, provide a place where an exchange of gases, foods, and wastes between the fetal and maternal blood can occur. This structure is the *placenta* (Figure 21-35). The exchange of substances occurs without any actual mixing of maternal and fetal blood, because each flows in its own separate space.

In addition to the placenta and umbilical vessels, three structures located within the fetus's own body play an important part in fetal circulation. One of them (the ductus venosus) serves as a detour by which most of the blood returning from the placenta bypasses the fetal liver. The other two (the foramen ovale and ductus arteriosus) provide detours by which blood bypasses the lungs. A brief description of each of the six structures necessary for fetal circulation follows (Figure 21-36):

1. The two **umbilical arteries** are branches of the internal iliac (hypogastric) arteries and carry fetal blood to the placenta.
2. The **placenta** is a structure attached to the uterine wall. Exchange of oxygen and other substances between maternal and fetal blood takes place in the placenta, although no mixing of maternal and fetal blood occurs. Box 21-3 discusses how alcohol from the maternal blood can damage developing fetal tissues.
3. The **umbilical vein** returns oxygenated blood from the placenta, enters the fetal body through the umbilicus, extends up to the undersurface of the liver where it gives off two or three branches to the liver, and then continues on as the ductus venosus. Two umbilical arteries and the umbilical vein together constitute the umbilical cord; these are shed at birth along with the placenta.
4. The **ductus venosus** is a continuation of the umbilical vein along the undersurface of the liver and drains into the inferior vena cava. Most of the blood returning from the placenta bypasses the liver. Only a relatively small amount of blood enters the liver by way of the branches from the umbilical vein into the liver.
5. The **foramen ovale** is an opening in the septum between the right and left atria. A valve at the opening of the inferior vena cava into the right atrium directs most of the blood through

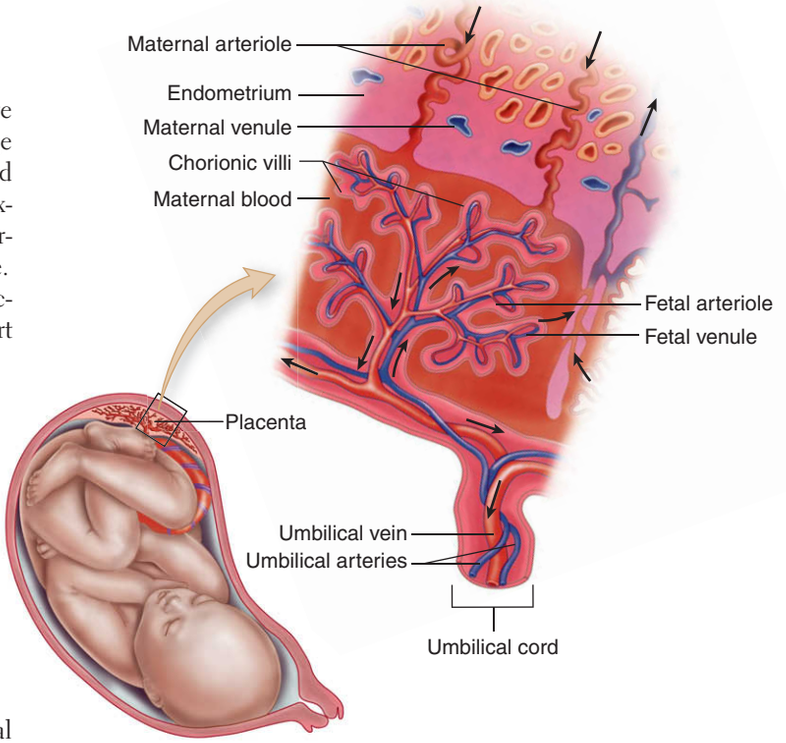

FIGURE 21-35

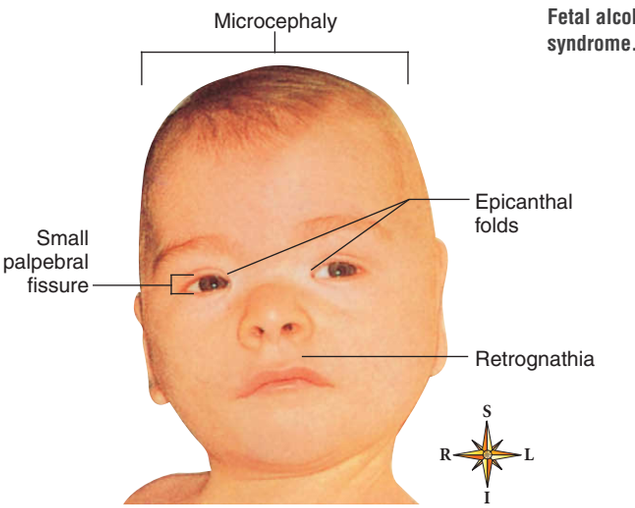
Placental circulation. The placenta is an organ that permits exchange of blood gases (O^2 and CO^2), nutrients, and wastes between fetal blood and maternal blood. Fetal capillaries found within branched villi are bathed in maternal blood. Note that fetal and maternal blood is separated by a membranous barrier. Other special features of fetal circulation are shown in Figures 21-36 and 21-37.



Box 21-3 | HEALTH matters

Fetal Alcohol Syndrome

Consumption of alcohol by a woman during her pregnancy can have tragic effects on the developing fetus. Educational efforts to inform pregnant women about the dangers of alcohol are now receiving national attention. Even very limited consumption of alcohol during pregnancy poses significant hazards to the developing fetus because alcohol can easily cross the placental barrier and enter the fetal bloodstream.

When alcohol enters the fetal blood, the potential result, called **fetal alcohol syndrome (FAS),** can cause tragic congenital abnormalities such as "small head," or *microcephaly* (my-kro-SEF-ah-lee); low birth weight; cardiovascular defects; developmental disabilities such as physical and mental retardation; and even fetal death.

The photograph shows the small head, thinned upper lip, horizontally narrow eye openings (palpebral fissures), epicanthal folds, and receded upper jaw (retrognathia) typical of infants born with fetal alcohol syndrome.

Fetal alcohol syndrome.

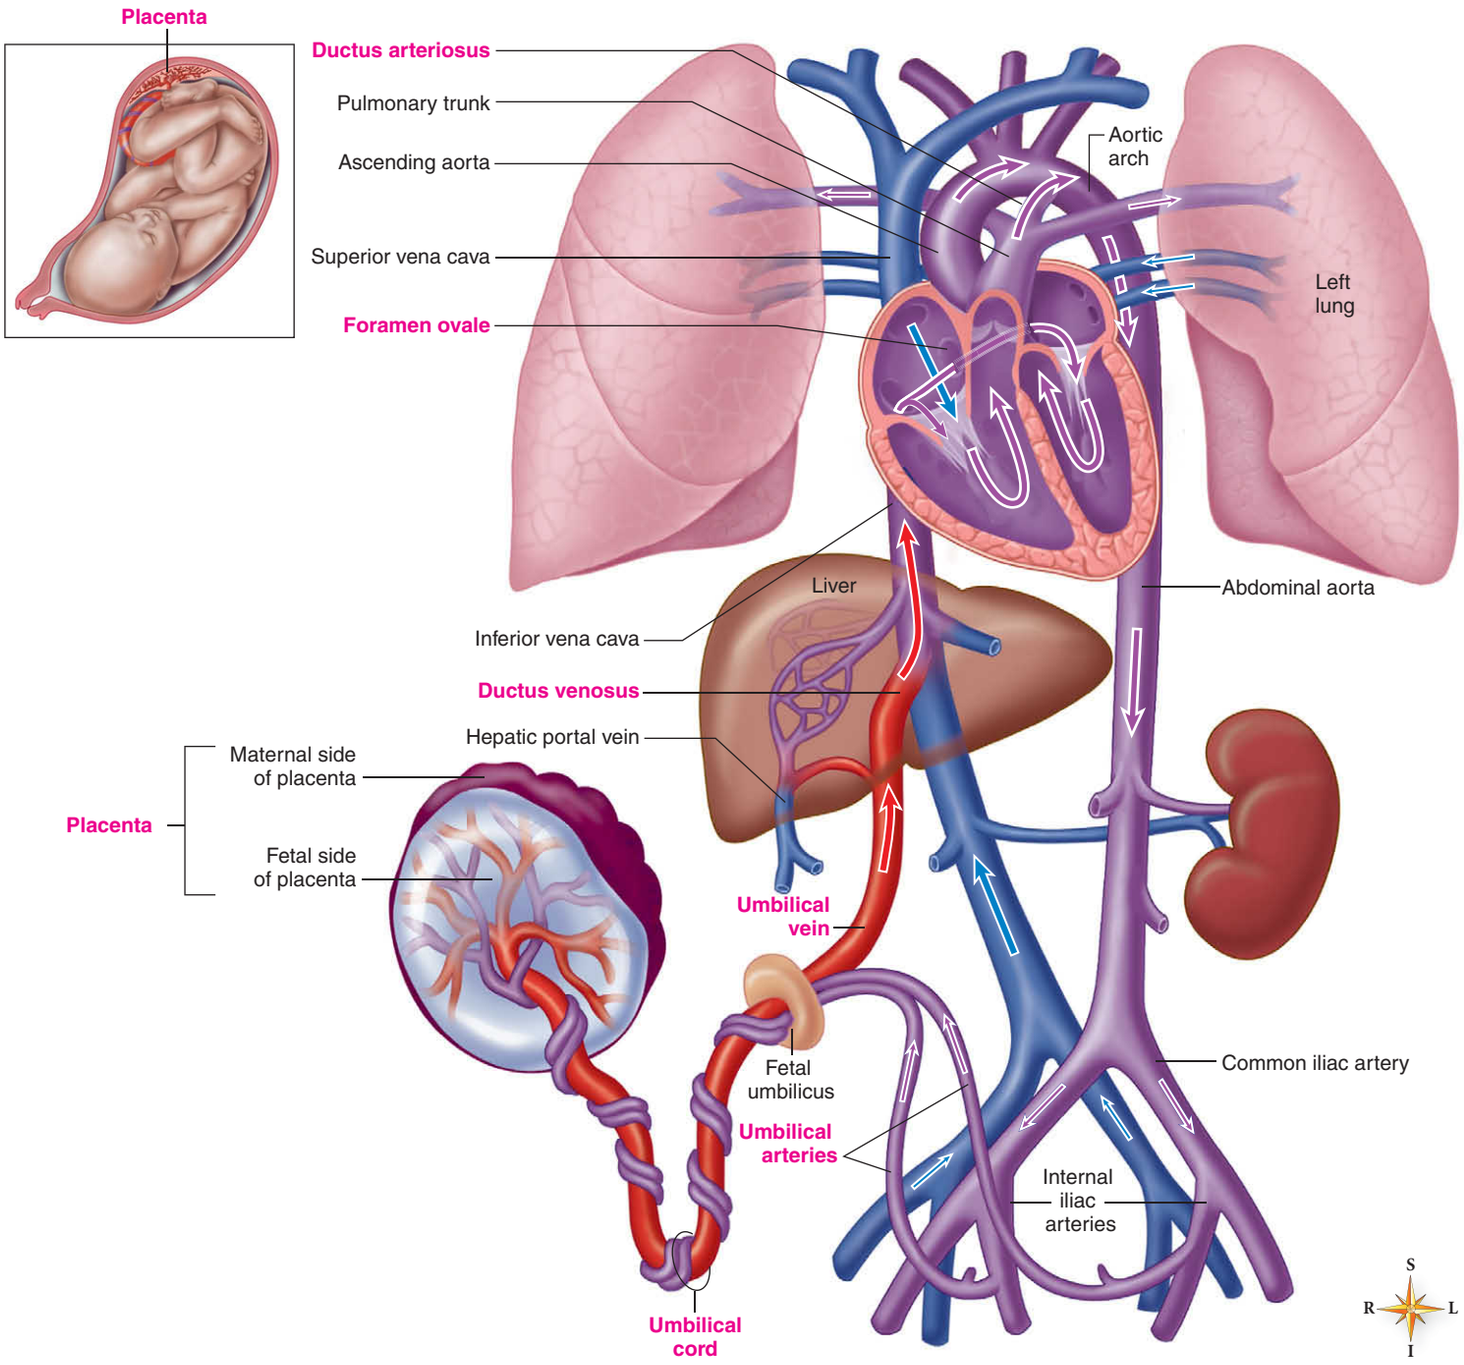


FIGURE 21-36

Plan of fetal circulation. Before birth, the human circulatory system has several special features that adapt the body to life in the womb. These features *(labeled in red type)* include two umbilical arteries, one umbilical vein, ductus venosus, foramen ovale, ductus arteriosus, and umbilical cord. The placenta, another essential feature of the fetal circulatory plan, is shown in Figure 21-35.

the foramen ovale into the left atrium so that it bypasses the fetal lungs. A small percentage of the blood leaves the right atrium for the right ventricle and pulmonary trunk. But most of this blood does not flow on into the lungs. Still another detour, the ductus arteriosus, diverts it.

6. The **ductus arteriosus** is a small vessel connecting the pulmonary trunk with the aortic arch. It therefore enables another portion of the blood to detour into the systemic circulation without going through the lungs.

Almost all fetal blood is a mixture of oxygenated and deoxygenated blood. Examine Figure 21-36 carefully to determine why this is so. What happens to the oxygenated blood returned from the placenta by way of the umbilical vein? Note that it flows into the inferior vena cava.

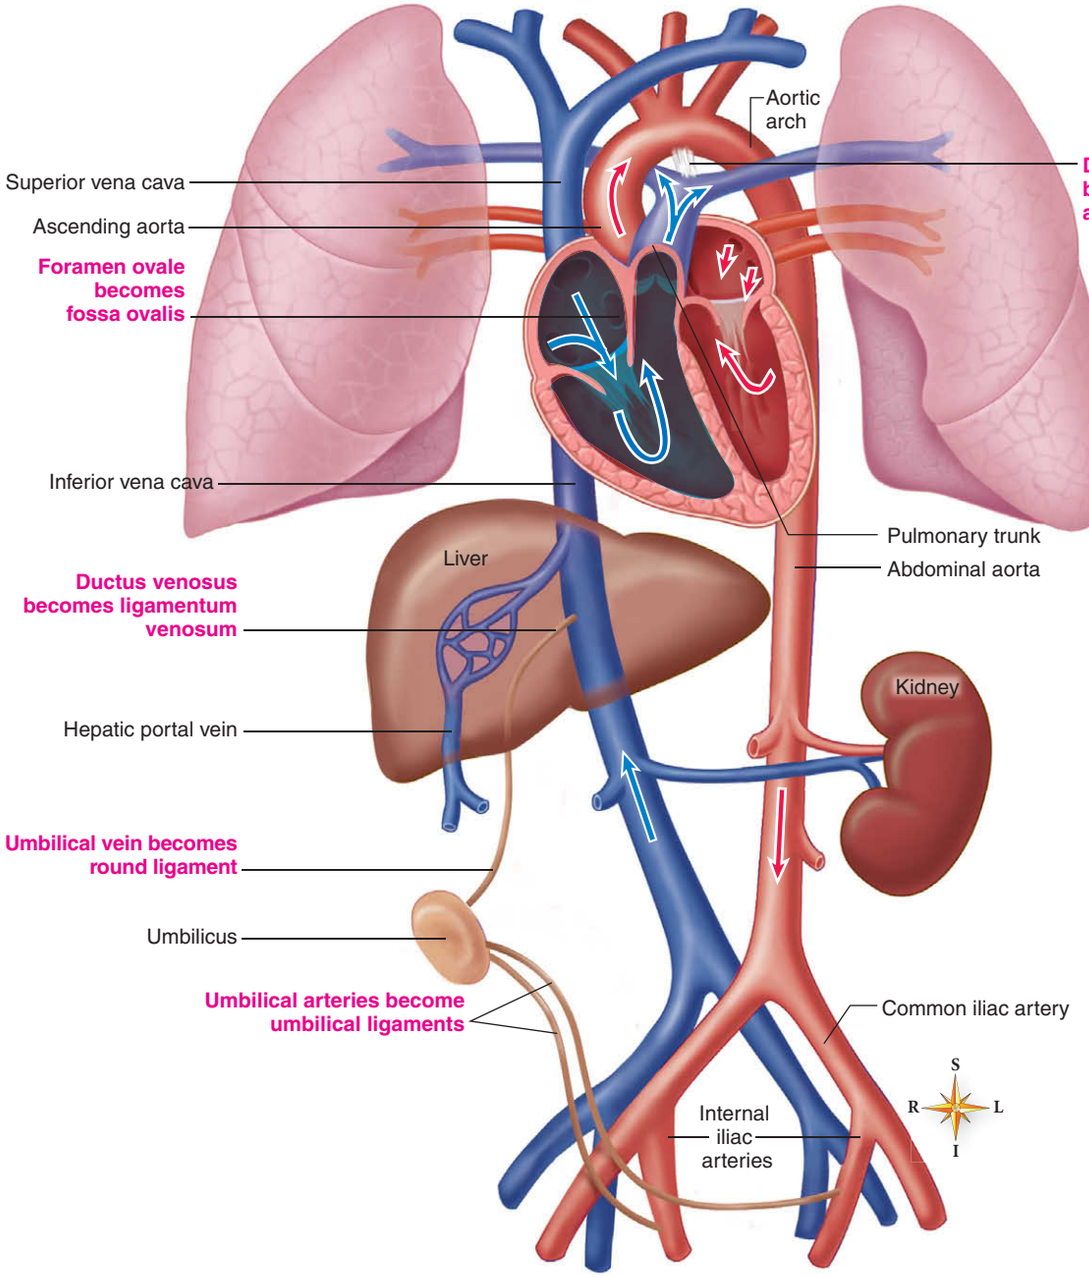

FIGURE 21-37

Changes in circulation after birth. Within the first year after the time of birth, certain changes in the circulatory plan occur to adapt the body to life outside the womb. The placenta and portions of the umbilical vessels outside the infant's body are removed or fall off at, or shortly after, the time of birth. The internal portion of the umbilical vein constricts and becomes fibrous, eventually forming the round ligament of the liver. Likewise, the internal umbilical arteries become umbilical ligaments, the ductus venosus becomes the ligamentum venosum, and the ductus arteriosus becomes the ligamentum arteriosum. The foramen ovale closes, forming a thin region of the atrial wall called the *fossa ovalis*.

Changes in Circulation at Birth

Because the six structures that serve fetal circulation are no longer needed after birth, several changes take place (Figure 21-37). As soon as the umbilical cord is cut, the two umbilical arteries, the placenta, and the umbilical vein obviously no longer function. The placenta is shed from the mother's body as the *afterbirth* with part of the umbilical vessels attached. The sections of these vessels remaining in the infant's body eventually become fibrous cords, which remain throughout life (the umbilical vein becomes the round ligament of the liver).

The ductus venosus, no longer needed to bypass blood around the liver, eventually becomes the ligamentum venosum of the liver.

The foramen ovale normally becomes functionally closed soon after a newborn takes the first breath and full circulation through the lungs becomes established. Complete structural closure, however, usually requires 9 months or more. Eventually, the foramen ovale becomes a mere depression (fossa ovalis) in the wall of the right atrial septum.

The ductus arteriosus contracts as soon as respiration is established. Eventually, it also turns into a fibrous cord, the ligamentum arteriosum. Compare the blood flow in Figures 21-36 and 21-37. Notice how separation of oxygenated and deoxygenated blood occurs *after* birth.

| QUICK CHECK |

20. Name some structures of the fetal circulation that are not part of the adult circulation.
21 What is the function of the placenta and umbilical vessels?
22. What changes in the circulatory system occur at the time of birth?

Cycle of LIFE

Cardiovascular Anatomy

As with all body structures, the heart and blood vessels undergo profound anatomical changes during early development in the womb. At birth, the switch from a placenta-dependent system causes another set of profound anatomical changes. Throughout childhood, adolescence, and adulthood, the heart and blood vessels normally maintain their basic structure and function—permitting continued survival of the individual. Perhaps the only apparent normal changes in these structures occur as a result of regular exercise. The myocardium thickens and the supply of blood vessels in skeletal muscle tissues increases in response to increased oxygen and glucose use during prolonged exercise.

As we pass through adulthood, especially later adulthood, various degenerative changes can occur in the heart and blood vessels. For example, a type of "hardening of the arteries," called **atherosclerosis,** can result in blockage or weakening of critical arteries—perhaps causing a myocardial infarction or stroke. The heart valves and myocardial tissues often degenerate with age, becoming hardened or fibrotic and less able to perform their functions properly. This reduces the heart's pumping efficiency and therefore threatens homeostasis of the entire internal environment.

the BIG picture

Cardiovascular Anatomy and the Whole Body

In this chapter, we have briefly outlined the functional anatomy of many different structures: the heart, major arteries and veins, and even the tiny arterioles, venules, and capillaries.

In essence, we have described a complex, interconnected network of transport pipes for blood. Part of what you learned from this description is how each component of this blood-transporting network is constructed and just a little bit about how each works as an individual unit. Step back from this collection of facts for a moment, and think about how each component of the heart works with the other components to keep blood flowing continuously through the heart. Broaden the picture now in your mind's eye to include each of the other components of the network: the arteries, the veins, and the capillaries. As you continue to study this chapter, keep this "big picture" in mind and add to it your deepening understanding of where each vessel and chamber gets its blood and where it delivers the blood. Before long, you will have a useful understanding of how the entire network functions as a system.

In the next chapter, we build on your understanding of the functional anatomy of the cardiovascular system by discussing mechanisms of blood flow. In other words, all of the next chapter deals with issues relating to the "big picture" of cardiovascular function and its importance to survival.

MECHANISMS of DISEASE

DISORDERS OF THE CARDIOVASCULAR SYSTEM

Disorders of Heart Structure

Disorders Involving the Pericardium

If the pericardium becomes inflamed, a condition called **pericarditis** results. Pericarditis may be caused by various factors: trauma, viral or bacterial infection, tumors, and other factors. The pericardial edema that characterizes this condition often causes the visceral and parietal layers of the serous pericardium to rub together—causing severe chest pain. Pericardial fluid, pus, or blood (in the case of an injury) may accumulate in the space between the two pericardial layers and impair the pumping action of the heart. This is termed **pericardial effusion** and may develop into a serious compression of the heart called **cardiac tamponade.**

Pericarditis may be acute or chronic, depending on the rate, severity, and duration of symptoms. Clinical manifestations include pericardial pain that increases with respirations or coughing, a "friction rub" (a grating, scratching sound heard over the left sternal border and upper ribs) resulting from the swollen pericardial layers rubbing against each other, difficulty breathing, restlessness, and an accumulation of pericardial fluid. Cardiac tamponade requires immediate pericardial drainage **(pericardiocentesis).** Antibiotics are usually prescribed to treat the causative organism, and nonsteroidal antiinflammatory agents such as aspirin are prescribed to reduce the inflammation and thus control the symptoms.

Disorders Involving Heart Valves

Disorders of the cardiac valves can have several effects. For example, a congenital defect in valve structure can result in mild to severe pumping inefficiency. Incompetent valves leak, allowing some blood to flow back into the chamber from which it came. **Stenosed valves** are valves that are narrower than normal, slowing blood flow from a heart chamber (Figure 21-38).

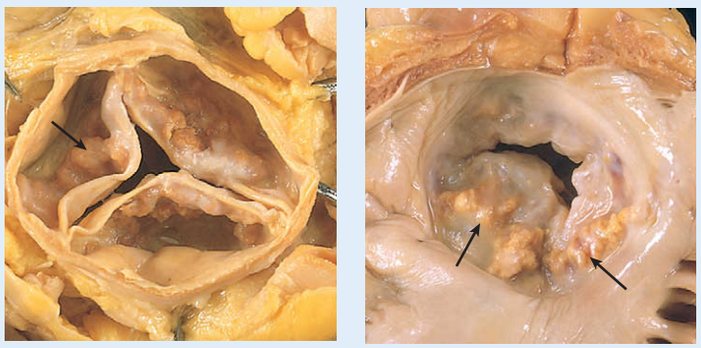

FIGURE 21-38

Stenosed mitral valve. Note the calcific nodules *(arrows)* attached to the cusps, thus narrowing the opening and slowing blood flow.

UNIT 4

Rheumatic heart disease results from a delayed inflammatory response to streptococcal infection that occurs most often in children. A few weeks after an improperly treated streptococcal infection, the cardiac valves and other tissues in the body may become inflamed—a condition called **rheumatic fever.** If severe, the inflammation can result in stenosis or other deformities of the valves, chordae tendineae, or myocardium.

Mitral valve prolapse (MVP), a condition affecting the bicuspid or mitral valve, has a genetic basis in some cases but can result from rheumatic fever or other factors. A prolapsed mitral valve is one whose flaps extend back into the left atrium, causing incompetence (leaking) of the valve (Figure 21-39). Although this condition is common, occurring in up to 1 in every 20 people, most cases are asymptomatic. In severe cases, patients suffer chest pain and fatigue.

Aortic regurgitation is a condition in which blood not only ejects forward into the aorta but also regurgitates back into the left ventricle because of a leaky aortic semilunar valve. This causes a volume overload on the left ventricle, with subsequent hypertrophy and dilation of the left ventricle. The left ventricle attempts to compensate for the increased load by increasing its strength of contraction—which may eventually stress the heart to the point of causing myocardial ischemia.

Damaged or defective cardiac valves can often be replaced surgically—a procedure called **valvuloplasty.** Artificial valves made from synthetic materials, as well as valves taken from other mammals such as swine, are frequently used in these valve replacement procedures.

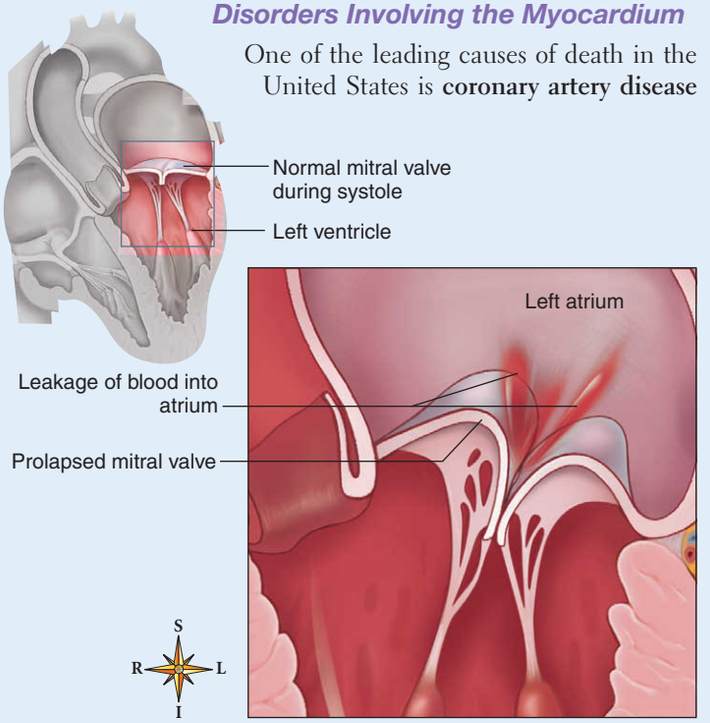

FIGURE 21-39

Mitral valve prolapse. The normal mitral valve *(left)* prevents backflow of blood from the left ventricle into the left atrium during ventricular systole (contraction). The prolapsed mitral valve *(inset)* permits leakage because the valve flaps billow backward, parting slightly.

Disorders Involving the Myocardium

One of the leading causes of death in the United States is **coronary artery disease (CAD).** This condition can result from many causes, all of which somehow reduce the flow of blood to the vital myocardial tissue. For example, in both coronary thrombosis and coronary embolism, a blood clot occludes, or plugs, some part of a coronary artery. Blood cannot pass through the occluded vessel and so cannot reach the heart muscle cells it normally supplies. Deprived of oxygen, these cells soon die or are damaged. In medical terms, a **myocardial infarction (MI),** or tissue death, occurs.

A myocardial infarction (heart attack) is a common cause of death during middle and late adulthood. Recovery from a myocardial infarction is possible if the amount of heart tissue damaged is small enough that the remaining undamaged heart muscle can pump blood effectively enough to supply the needs of the rest of the heart, as well as the body.

How does a heart attack develop? Take a tour through an illustrated description of the process of an MI in ***Heart Attack!*** online at ***A&P Connect.***

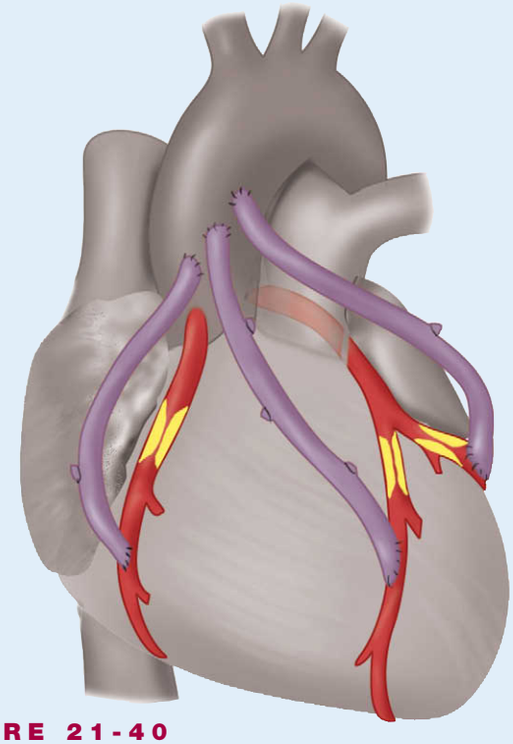
evolve

Coronary arteries may also become blocked as a result of **atherosclerosis,** a type of "hardening of the arteries" in which lipids and other substances build up within the wall of blood vessels and eventually calcify, making the vessel wall hard and brittle. Mechanisms of atherosclerosis are discussed elsewhere in this chapter. Coronary atherosclerosis has increased dramatically over the last half century to become the leading cause of death in western countries. Many pathophysiologists believe this increase results from a change in lifestyle. They cite several important risk factors associated with coronary atherosclerosis: cigarette smoking, high-fat and high-cholesterol diets, diabetes, and hypertension (high blood pressure).

The term **angina pectoris** is used to describe the severe chest pain that occurs when the myocardium is deprived of adequate oxygen. It is often a warning that the coronary arteries are no longer able to supply enough blood and oxygen to the heart muscle. **Coronary bypass surgery** is a frequent treatment for those who suffer from severely restricted coronary artery blood flow. In this procedure, veins and sometimes arteries are "harvested" from other areas of the body and used to bypass partial blockages in coronary arteries (Figure 21-40).

Congestive heart failure (CHF), or simply, *left-side heart failure,* is the inability of the left ventricle to pump blood effectively. Most often, such failure results from chronic systemic hypertension (high blood pressure) or from myocardial infarction caused by coronary artery disease (Figure 21-41, A). It is called *congestive heart failure* because it decreases pumping pressure in the systemic circulation, which in turn causes the body to retain fluids. Portions of the systemic circulation thus become congested with extra fluid. Left-side heart failure also causes congestion of blood in the pulmonary circulation, termed **pulmonary edema**—possibly leading to right-side heart failure and pulmonary hypertension (Figure 21-41, *B*).

The term **cardiomyopathy** is used to describe a number of different types of heart diseases that result in abnormal enlargement.



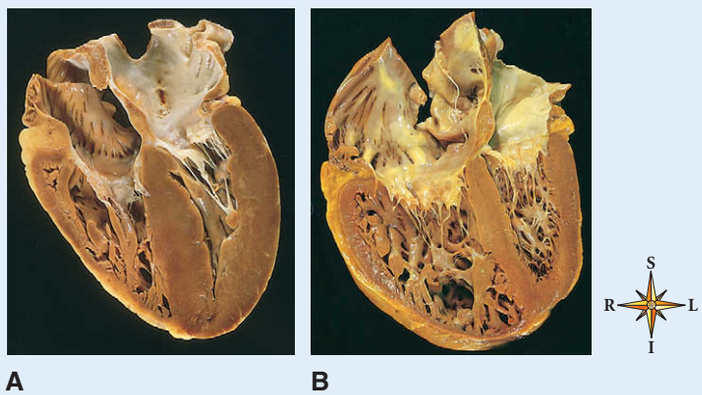


FIGURE 21-40

Coronary bypass. In coronary bypass surgery, blood vessels are "harvested" or "rerouted" from other parts of the body and used to construct detours around blocked coronary arteries. Artificial vessels can also be used.

In addition to left and right ventricular hypertrophy, another form of enlargement is called **hypertrophic cardiomyopathy** and is caused by a genetic defect. Figure 21-42 shows the appearance of the heart in this condition. It is one of the most common causes of sudden unexplained death in young athletes.

Patients in danger of death because of heart failure may be candidates for heart *transplants* or heart *implants*. Heart transplants are surgical procedures in which healthy hearts from recently deceased donors replace the hearts of patients with heart disease. Unfortunately, a continuing problem with this procedure is the tendency of the body's immune system to reject the new heart—perceiving it as a foreign tissue. More details about the rejection of transplanted tissues are found in Chapter 24.

A B

FIGURE 21-41

Congestive heart failure. A, Left ventricle hypertrophy (left-sided heart failure). Note the hypertrophy of the left ventricle often caused by chronic systemic hypertension. **B,** Right ventricular hypertrophy (right-sided heart failure or *cor pulmonale*). Note the right ventricular hypertrophy and dilation caused by pulmonary hypertension.

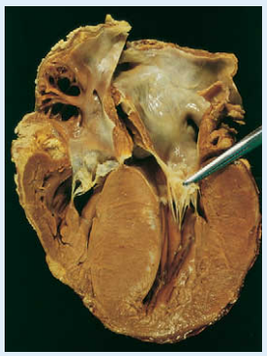

FIGURE 21-42

Hypertrophic cardiomyopathy. Note the dramatic increase of myocardial tissue. This genetic condition may cause sudden heart failure in the apparent absence of warning symptoms.

Heart implants are artificial hearts that are made of biologically inert synthetic materials. On July 3, 2001, the first artificial heart was successfully implanted into Robert Tools by University of Louisville researchers. The 1-kg (2-pound) *AbioCor Implantable Replacement Heart* ("artificial heart") allowed the patient to move about freely without any external pumps. Portable external battery packs are used to recharge the small internal battery that powers the internal pumping unit. The success of the AbioCor unit and other artificial heart models gives hope that artificial hearts will one day be a commonplace and effective treatment for patients with severe heart disease.

Disorders of Blood Vessels

Disorders of Arteries

As mentioned earlier in this chapter, arteries contain blood that is maintained at a relatively high pressure. This means the arterial walls must be able to withstand a great deal of force or they will burst. The arteries must also stay free of obstruction; otherwise they cannot deliver their blood to the capillary beds (and thus the tissues they serve).

A common type of vascular disease that occludes (blocks) arteries and weakens arterial walls is called **arteriosclerosis,** or *hardening of the arteries*. Arteriosclerosis is characterized by thickening of arterial walls that eventually progresses to hardening as calcium deposits form. The thickening and calcification reduce the flow of blood to the tissues. If blood slows in peripheral tissues such as the hands, legs, or feet, the condition is often referred to as **peripheral vascular disease (PVD)** or **peripheral arterial disease (PAD)** and the result is ischemia.

Ischemia, or decreased blood supply to a tissue, involves the gradual death of cells and may lead to complete tissue death—a condition called **necrosis.** If a large section of tissue becomes necrotic, it may begin to decay because of bacterial action. Necrosis that has progressed this far is called **gangrene.** Gangrene is a very serious consequence of ischemia or blocked blood flow in

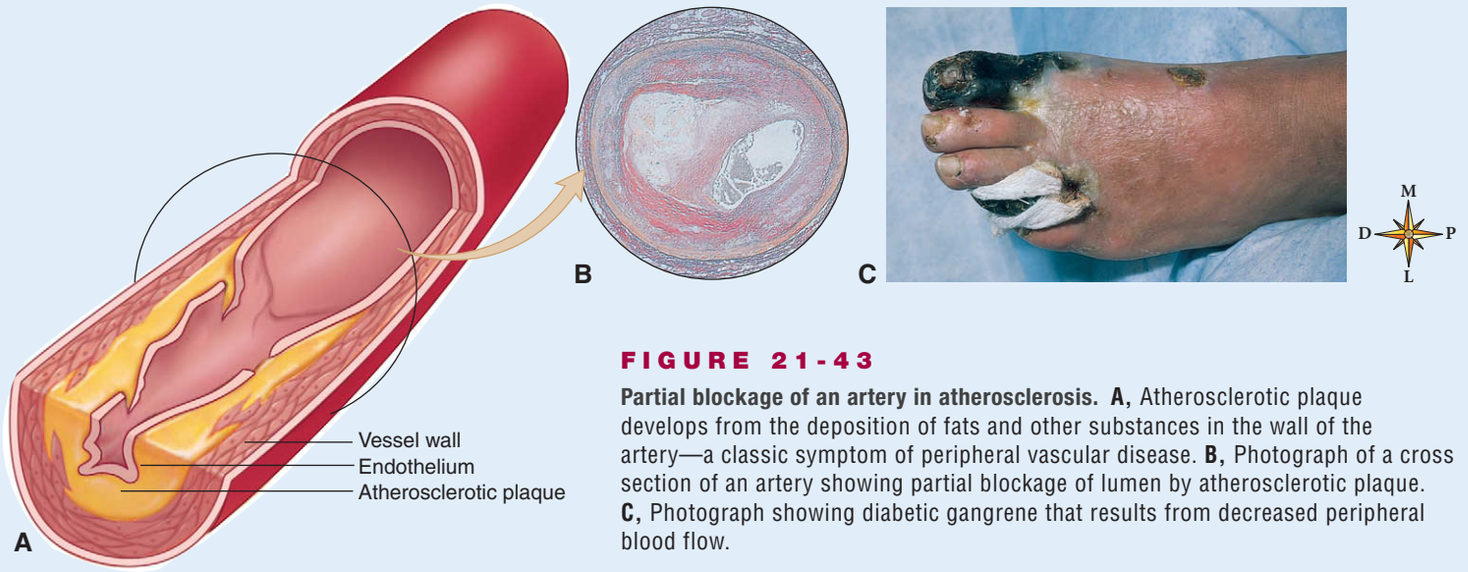

FIGURE 21-43

Partial blockage of an artery in atherosclerosis. A, Atherosclerotic plaque develops from the deposition of fats and other substances in the wall of the artery—a classic symptom of peripheral vascular disease. **B,** Photograph of a cross section of an artery showing partial blockage of lumen by atherosclerotic plaque. **C,** Photograph showing diabetic gangrene that results from decreased peripheral blood flow.

PVD and is, unfortunately, a common problem in uncontrolled diabetes (Figure 21-43). PVD may also cause occasional pain, cramping, or weakness in the extremities—a condition called *intermittent claudication* (see Box 20-5 on p. 617).

Because of the tissue damage involved, arteriosclerosis is not only painful—it is life threatening. As we have previously stated, ischemia of heart muscle can lead to *myocardial infarction* and death.

There are several types of arteriosclerosis, but perhaps the most well known is *atherosclerosis*—described earlier as the blockage of arteries by lipids and other matter (see Figure 21-43). Eventually, the fatty deposits in the arterial walls become fibrous and perhaps calcified—resulting in sclerosis (hardening). High blood levels of triglycerides and cholesterol, which may be caused by a high-fat and high-cholesterol diet, smoking, and a genetic predisposition, are associated with atherosclerosis.

In general, arteriosclerosis develops with advanced age, diabetes, high-fat and high-cholesterol diets, hypertension (high blood pressure), and smoking. Arteriosclerosis can be treated by drugs, called **vasodilators,** that trigger the smooth muscles of the arterial walls to relax, thus causing the arteries to dilate (widen).

Some cases of atherosclerosis are treated by mechanically opening the affected area of an artery in a type of procedure called **percutaneous coronary intervention (PCI).** In one PCI procedure called **angioplasty,** a deflated balloon attached to a long, thin tube called a **catheter** is inserted into a partially blocked artery and then inflated (Figure 21-44). As the balloon inflates, the *atherosclerotic plaque* (fatty deposits and tissue) is pushed outward, and the artery widens to allow near-normal blood flow. In a similar procedure, metal springs or mesh tubes, called **stents**, are inserted in affected arteries to hold them open.

Similar types of PCIs called **atherectomies** use lasers, drills, or spinning loops of wire to clear the way for normal blood flow. Severely affected arteries can also be surgically bypassed or replaced.

Damage to arterial walls caused by arteriosclerosis or other factors may lead to the formation of an **aneurysm.** An aneurysm is a section of an artery that has become abnormally widened because of a weakening of the arterial wall. Aneurysms sometimes form a saclike extension of the arterial wall. One reason aneurysms are dangerous is because they, like atherosclerotic plaques, promote the formation of thrombi (abnormal clots). A thrombus may cause an embolism (blockage) in the heart or some other vital tissue. Another reason aneurysms are dangerous is their tendency to burst, causing severe hemorrhaging that may result in death.

A brain aneurysm may lead to a **stroke,** or **cerebrovascular accident (CVA).** A stroke results from ischemia of brain tissue caused by an embolism or ruptured aneurysm. Depending on the amount of tissue affected and the place in the brain the CVA occurs, effects of a stroke may range from hardly noticeable to crippling to fatal.

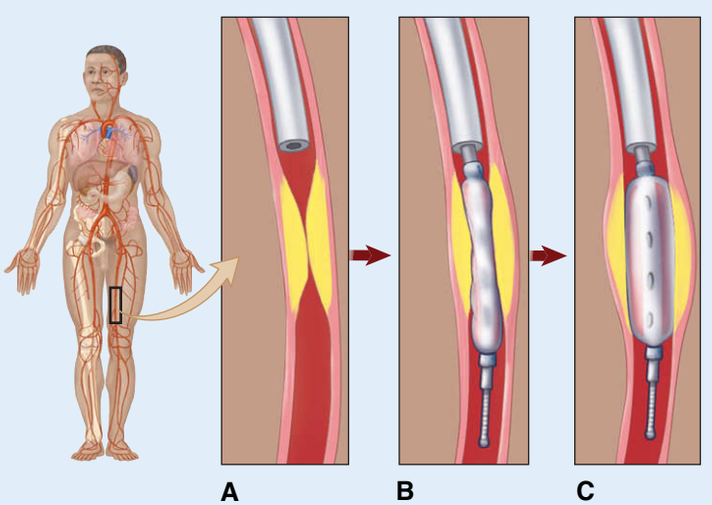

FIGURE 21-44

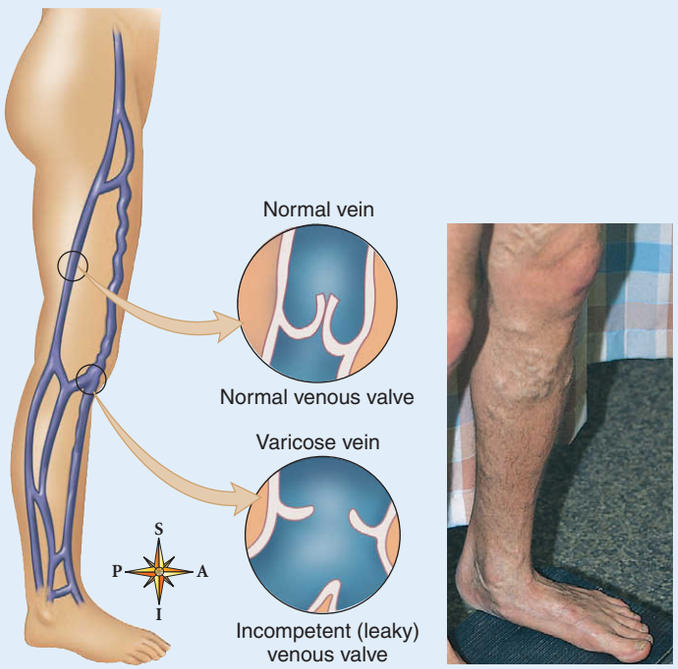
Balloon angioplasty. A, A catheter is inserted into the vessel until it reaches the affected region. **B,** A probe with a metal tip is pushed out the end of the catheter into the blocked region of the vessel. **C,** The balloon is inflated, pushing the walls of the vessel outward. Sometimes metal coils or tubes, called "stents," are inserted to keep the vessel open. Drug-coated stents may further reduce delayed scarring and reclogging of arteries following angioplasty in many patients.

Disorders of Veins

Varicose veins are enlarged veins in which blood tends to pool rather than continue on toward the heart. Varicose veins, also called *varices* (*singular*, **varix**), commonly occur in *superficial veins* near the surface of the body. The *great saphenous vein*, the largest superficial vein of the leg (see Figure 21-33), often becomes varicose in people who stand for long periods. The force of gravity slows the return of venous blood to the heart in such cases, causing blood-engorged veins to dilate. As the veins dilate, the distance between the flaps of venous valves widens—eventually making them incompetent (leaky) (Figure 21-45). Incompetence of valves causes even more pooling in affected veins—a positive feedback phenomenon.

Hemorrhoids, or *piles*, are varicose veins in the anal canal (look ahead to Figure 28-30 on p. 889). Excessive straining during defecation can create pressures that cause hemorrhoids. The unusual pressures of carrying a child during pregnancy predispose expectant mothers to hemorrhoids and other varicosities.



Varicose veins in some parts of the body can be treated by supporting the dilated veins from the outside. For instance, support stockings can reduce blood pooling in the great saphenous vein. Surgical removal of varicose veins can be performed in severe cases. Advanced cases of hemorrhoids are often treated by this type of surgery. Symptoms of milder cases of varicose veins can be relieved by removing the pressure that caused the condition.

Several factors can cause **phlebitis,** or vein inflammation. Irritation by an intravenous catheter, for example, is a common cause of vein inflammation. **Thrombophlebitis** is acute phlebitis caused by clot (thrombus) formation. Veins are more likely sites of thrombus formation than arteries because venous blood moves more slowly and is under less pressure.

A *deep vein thrombosis (DVT)* is a clot that has formed in a deep vein, especially in the legs, and is particularly dangerous. If a piece of a clot breaks free from a DVT, it may cause an embolism when it blocks a blood vessel. **Pulmonary embolism,** for example, could result when an embolus lodges in the circulation of the lung (Figure 21-46). Pulmonary embolism can lead to death quickly if too much blood flow is blocked.

Heart Medication

Although numerous drugs are used in the treatment of heart disease, the following have proven to be basic tools of the cardiologist: **anticoagulants** prevent clot formation; **beta-adrenergic blockers** block norepinephrine receptors and thus reduce the strength and rate of heart beats; **calcium channel blockers** reduce heart contractions by preventing the flow of Ca^{++} into cardiac muscle cells; **digitalis** slows and increases the strength of cardiac contractions; **nitroglycerin** dilates coronary blood vessels and thus improves O^2 supply to myocardium; and **tissue plasminogen activator (t-PA)** helps dissolve clots.

CASE study

Kyle (45 years old) finally gave in to his wife's insistence and stopped by his doctor's office. After all, it was in the same building where he was working on a construction job. He had been having some minor chest pain for a couple of days. But, he'd been telling himself the pain was just sore muscles caused by his recent weight-lifting. Kyle was expecting the receptionist to make an appointment for him. However, as he described his symptoms (chest pain, some sweating, slight nausea), she interrupted him and called over her shoulder to the triage nurse. As soon as the nurse was made aware of his symptoms, Kyle was rushed into an exam room, where his heart rate and blood pressure were checked and then the electrical activity of his heart was measured (by performing an ECG).

"What's going on?" he asked the doctor a few minutes later. The doctor replied, "Based on your symptoms, we think you may have some blockage in your coronary arteries. We'd like to do an angiogram to see what's going on."

1. The doctor suspects the potential blockage is in what part of Kyle's body?
   a. His brain
   b. His liver
   c. His neck
   d. His heart

"Let's take him over to the Cath Lab," ordered the doctor. Kyle said, "I've heard of a cath lab, but I'm not sure what that means." "Cardiac

catheterization lab," clarified the nurse. "We're going to insert a small tube…" She kept talking, but Kyle couldn't concentrate on her words. He was suddenly feeling a little anxious. He signed the consent form without really reading it.

In the lab, Kyle changed into a hospital gown as instructed; next he was asked to lie on the table. A nurse began cleaning a spot on his thigh

CASE study *(continued)*

in preparation for inserting a catheter. Kyle was confused—why were they cleaning his leg when it seemed like his heart was the problem?

2. Into which artery will the catheter be inserted?
   a. Brachial
   b. Popliteal
   c. Femoral
   d. Tibial

3. From this artery, the catheter will be moved toward the heart through which path?
   a. External iliac artery, abdominal aorta, descending aorta, aortic arch, ascending aorta
   b. Internal iliac artery, abdominal aorta, ascending aorta, aortic arch, descending aorta
   c. Abdominal aorta, descending aorta, aortic arch, ascending aorta
   d. Popliteal artery, external iliac artery, abdominal aorta, thoracic aorta, aortic arch

After some dye was injected, the screen monitor showed that Kyle's right coronary artery was partially blocked. The surgeon inserted a balloon through the catheter, which was then inflated to press against the sides of the artery and enlarge its diameter. Next she inserted a metal stent to keep the artery open.

4. The coronary arteries supply oxygen and nutrients for cardiac muscle contraction. The myocardium of which heart chamber receives the most abundant blood supply from the coronary arteries?
   a. Left atrium
   b. Left ventricle
   c. Right atrium
   d. Right ventricle

HINT *Scan this summary after reading the chapter to help you reinforce the key concepts. Later, use the summary as a quick review before your class or before a test.*

HEART

A. Location of the heart (Figure 21-2)
   1. Lies in the mediastinum, behind the body of the sternum between the points of attachment of ribs two through six; approximately two thirds of its mass is to the left of the midline of the body, and one third is to the right
   2. Posteriorly the heart rests on the bodies of thoracic vertebrae five through eight
   3. Apex lies on the diaphragm, pointing to the left
   4. Base lies just below the second rib
   5. Boundaries of the heart are clinically important as an aid in diagnosing heart disorders

B. Size and shape of the heart (Figures 21-1 and 21-2)
   1. At birth, the heart is transverse and appears large in proportion to the diameter of the chest cavity
   2. Between puberty and 25 years of age, the heart attains its adult shape and weight
   3. In adults, the shape of the heart tends to resemble that of the chest

C. Coverings of the heart
   1. Structure of the heart coverings
      a. Pericardium (Figure 21-4)
         (1) Fibrous pericardium—tough, loose-fitting inextensible sac
         (2) Serous pericardium—parietal layer lies inside the fibrous pericardium, and visceral layer (epicardium) adheres to the outside of the heart
         (3) Pericardial space—lies between visceral and parietal layers and contains 10 to 15 ml of pericardial fluid
   2. Function of the heart coverings—provides protection against friction

D. Structure of the heart
   1. Wall of the heart—made up of three distinct layers (Figure 21-5)
      a. Epicardium—outer layer of heart wall
      b. Myocardium—thick, contractile middle layer of heart wall; compresses the heart cavities, and the blood within them, with great force
      c. Endocardium—delicate inner layer of endothelial tissue
   2. Chambers of the heart—divided into four cavities with the right and left chambers separated by the septum (Figures 21-6 and 21-7)
      a. Atria
         (1) Two superior chambers known as "receiving chambers" because they receive blood from veins
         (2) Atria alternately relax to receive blood and then contract to push blood into ventricles
         (3) Myocardial wall of each atrium is not very thick, because little pressure is needed to move blood such a small distance
         (4) Auricle—earlike flap protruding from each atrium
      b. Ventricles
         (1) Two lower chambers known as "pumping chambers" because they push blood into the large network of vessels

UNIT 4

(2) Ventricular myocardium is thicker than the myocardium of the atria because great force must be generated to pump the blood a large distance; myocardium of left ventricle is thicker than the right, because it must push blood much farther

3. Valves of the heart—mechanical devices that permit the flow of blood in one direction only (Figure 21-8)
   a. Atrioventricular (AV) valves—prevent blood from flowing back into the atria from the ventricles when the ventricles contract
      (1) Tricuspid valve (right AV valve)—guards the right atrioventricular orifice; free edges of three flaps of endocardium are attached to papillary muscles by chordae tendineae
      (2) Bicuspid, or mitral, valve (left AV valve)—similar in structure to tricuspid valve except has only two flaps
   b. Semilunar (SL) valves—half-moon–shaped flaps growing out from the lining of the pulmonary trunk and aorta; prevent blood from flowing back into the ventricles from the aorta and pulmonary trunk
      (1) Pulmonary valve—valve at entrance of the pulmonary trunk
      (2) Aortic valve—valve at entrance of the aorta
   c. Skeleton of the heart
      (1) Set of connected rings that serve as a semirigid support for the heart valves and for the attachment of cardiac muscle of the myocardium
      (2) Serves as an electrical barrier between the myocardium of the atria and that of the ventricles
   d. Surface projection (review Figure 21-9)
   e. Flow of blood through heart (review Figure 21-7)
4. Coronary circulation—blood supply of heart tissue (Figures 21-10, 21-11, and 21-12)
   a. Coronary arteries—myocardial cells receive blood from the right and left coronary arteries
      (1) First branches to come off the aorta
      (2) Ventricles receive blood from branches of both right and left coronary arteries
      (3) Each ventricle receives blood only from a small branch of the corresponding coronary artery
      (4) Most abundant blood supply goes to the myocardium of the left ventricle
      (5) Right coronary artery is dominant in approximately 50% of all hearts and the left in about 20%; in approximately 30%, neither coronary artery is dominant
      (6) Few anastomoses exist between the larger branches of the coronary arteries
   b. Cardiac veins
      (1) As a rule, veins follow a course that closely parallels that of coronary arteries
      (2) After going through cardiac veins, blood enters the coronary sinus to drain into the right atrium
      (3) Several veins drain directly into the right atrium
5. Nerve supply of the heart
   a. Conduction system of the heart—made up of modified cardiac muscle, it generates and distributes the heart's own rhythmic contractions; can be regulated by afferent nerves
   b. Cardiac plexuses—located near the arch of the aorta, made up of the combination of sympathetic and parasympathetic fibers
   c. Fibers from the cardiac plexus accompany the right and left coronary arteries to enter the heart
   d. Most fibers end in the SA node, but some end in the AV node and in the atrial myocardium; the SA node acts as the heart's pacemaker (Chapter 22)
   e. Sympathetic nerves—accelerator nerves
   f. Vagus fibers—inhibitory, or depressor, nerves

BLOOD VESSEL TYPES

A. Types of blood vessels (Figures 21-13 and 21-14)
   1. Angiogenesis—formation of new blood vessels
   2. Arteries
      a. Carry blood away from heart—all arteries except pulmonary artery carry oxygenated blood
      b. Elastic (conducting) arteries—largest in body
         (1) Examples: aorta and its major branches
         (2) Able to stretch without injury
         (3) Accommodate surge of blood when heart contracts and able to recoil when ventricles relax
      c. Muscular (distributing) arteries
         (1) Smaller in diameter than elastic arteries
         (2) Muscular layer is thick
         (3) Examples: brachial, gastric, superior mesenteric
      d. Arterioles (resistance vessels)
         (1) Smallest arteries
         (2) Important in regulating blood flow to end organs
      e. Metarterioles
         (1) Short connecting vessel between true arteriole and 20 to 100 capillaries
         (2) Encircled by precapillary sphincters
         (3) Distal end called *thoroughfare channel*, which is free of precapillary sphincters
   3. Capillaries—primary exchange vessels
      a. Microscopic vessels
      b. Carry blood from arterioles to venules—together, arterioles, capillaries, and venules constitute the microcirculation (Figure 21-15)
      c. Not evenly distributed—highest numbers in tissues with high metabolic rate; may be absent in some "avascular" tissues, such as cartilage
      d. Types of capillaries (Figure 21-16)
         (1) True capillaries—receive blood flowing from metarteriole with input regulated by precapillary sphincters
         (2) Continuous capillaries
            (a) Continuous lining of endothelial cells
            (b) Openings called *intercellular clefts* exist between adjacent endothelial cells
         (3) Fenestrated capillaries
            (a) Have both intercellular clefts and "holes" or fenestrations through plasma membrane to facilitate exchange functions

(4) Sinusoids
(a) Large lumen and tortuous course
(b) Absent or incomplete basement membrane
(c) Very porous—permit migration of cells into or out of vessel lumen

4. Veins
a. Carry blood toward the heart
b. Act as collectors and as reservoir vessels; called *capacitance vessels*

B. Structure of blood vessels (Figure 21-13 and 21-14)
1. Components or "building blocks" commonly present
a. Lining endothelial tissue—one layer of squamous endothelial cells
(1) Only lining found in capillary
(2) Lines entire vascular tree
(3) Provides a smooth luminal surface—protects against intravascular coagulation
(4) Intercellular clefts, cytoplasmic pores, and fenestrations in cells allow exchange to occur between blood and tissue fluid
(5) Capable of secreting a number of substances
(6) Capable of reproduction
b. Collagen fibers
(1) Exhibit woven appearance
(2) Formed from protein molecules that aggregate into fibers
(3) Visible with light microscope
(4) Have only a limited ability to stretch (2% to 3%) under physiological conditions
(5) Function to strengthen and keep lumen of vessel open
c. Elastic fibers
(1) Composed of insoluble protein called *elastin*
(2) Form highly elastic networks
(3) Wavy fibers can stretch more than 100% under physiological conditions
(4) Play important role in creating passive tension to help regulate blood pressure throughout the cardiac cycle
d. Smooth muscle tissue
(1) Present in all segments of vascular system except capillaries
(2) Most abundant in elastic and muscular arteries
(3) Exerts active tension in vessels when contracting

2. Layers
a. Tunica externa—found in arteries and veins (tunica adventitia)
b. Tunica media—found in arteries and veins
c. Tunica intima—found in all blood vessels; only layer present in capillaries

MAJOR BLOOD VESSELS

A. Circulatory routes (Figure 21-17)
1. Systemic circulation—blood flows from the left ventricle of the heart through blood vessels to all parts of the body (except gas exchange tissues of lungs) and back to the right atrium
2. Pulmonary circulation—deoxygenated blood moves from right atrium to right ventricle to pulmonary artery to lung arterioles and capillaries, where gases are exchanged; oxygenated blood returns to left atrium by way of pulmonary veins; from left atrium, blood enters the left ventricle

B. Systemic circulation
1. Systemic arteries (review Table 21-2 and Figures 21-18 to 21-26)
a. Main arteries give off branches, which continue to rebranch, forming arterioles and then capillaries
b. End-arteries—arteries that eventually diverge into capillaries
c. Arterial anastomosis—arteries that open into other branches of the same or other arteries; incidence of arterial anastomoses increases as distance from the heart increases
d. Arteriovenous anastomoses or shunts occur when blood flows from an artery directly into a vein

2. Systemic veins (review Table 21-3 and Figures 21-27 to 21-34)
a. Veins are the ultimate extensions of capillaries; unite into vessels of increasing size to form venules and then veins
b. Large veins of the cranial cavity are called *dural sinuses*
c. Veins anastomose the same as arteries
d. Venous blood from the head, neck, upper extremities, and thoracic cavity (except lungs) drains into superior vena cava
e. Venous blood from thoracic organs drains directly into superior vena cava or azygos vein
f. Hepatic portal circulation (Table 21-34 and Figures 21-17 and 21-32)
(1) Veins from the spleen, stomach, pancreas, gallbladder, and intestines send their blood to the liver by way of the hepatic portal vein
(2) In the liver the venous blood mingles with arterial blood in the sinusoids and is eventually drained from the liver by hepatic veins that join the inferior vena cava
g. Venous blood from the lower extremities and abdomen drains into the inferior vena cava

C. Fetal circulation
1. Basic plan of fetal circulation—additional vessels needed to allow fetal blood to secure oxygen and nutrients from maternal blood at the placenta (Figure 21-36)
a. Two umbilical arteries—extensions of the internal iliac arteries; carry fetal blood to the placenta
b. Placenta—attached to uterine wall; where exchange of oxygen and other substances between the separated maternal and fetal blood occurs (Figure 21-35)
c. Umbilical vein—returns oxygenated blood from the placenta to the fetus; enters body through the umbilicus and goes to the undersurface of the liver where it gives off two or three branches and then continues as the ductus venosus
d. Ductus venosus—continuation of the umbilical vein and drains into inferior vena cava

e. Foramen ovale—opening in septum between the right and left atria
f. Ductus arteriosus—small vessel connecting the pulmonary trunk with the aortic arch

2. Changes in circulation at birth (compare Figures 21-36 and 21-37)
   a. When umbilical cord is cut, the two umbilical arteries, the placenta and umbilical vein, no longer function
   b. Umbilical vein within the baby's body becomes the round ligament of the liver
   c. Ductus venosus becomes the ligamentum venosum of the liver
   d. Foramen ovale—functionally closed shortly after a newborn's first breath and pulmonary circulation is established; structural closure takes approximately 9 months
   e. Ductus arteriosus—contracts with establishment of respiration, becomes ligamentum arteriosum

CYCLE OF LIFE: CARDIOVASCULAR ANATOMY

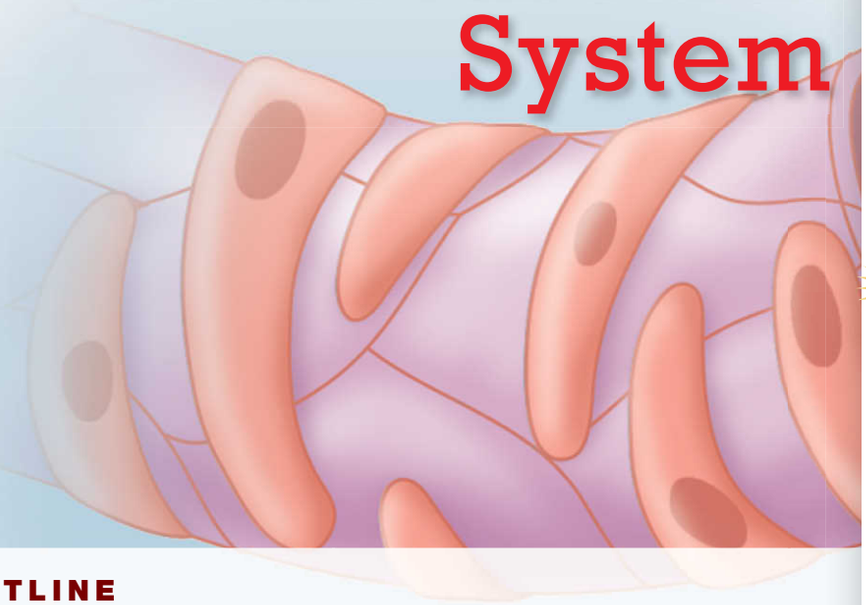
A. Birth—change from placenta-dependent system
B. Heart and blood vessels maintain basic structure and function from childhood through adulthood
C. Only apparent normal changes occur as a result of exercise
   1. Exercise thickens myocardium
   2. Exercise increases the supply of blood vessels in skeletal muscle tissue
D. Adulthood through later adulthood—degenerative changes
   1. Atherosclerosis—blockage or weakening of critical arteries (Figure 21-43)
   2. Heart valves and myocardial tissue degenerate—reduces pumping efficiency

REVIEW QUESTIONS

Write out the answers to these questions after reading the chapter and reviewing the Chapter Summary. If you simply think through the answer without writing it down, you won't retain much of your new learning.

1. Discuss the size, position, and location of the heart in the thoracic cavity.
2. Describe the pericardium, differentiating between the fibrous and serous portions.
3. Exactly where is pericardial fluid found? Explain its function.
4. Define the following terms: *intercalated disks, syncytium, autorhythmic.*
5. Name and locate the chambers and valves of the heart.
6. Trace the flow of blood through the heart.
7. Identify, locate, and describe the functions of each of the following structures: SA node, AV node, AV bundle.
8. Identify the vessels that join to form the hepatic portal vein.
9. Describe the six unique structures necessary for fetal circulation.
10. Explain how the separation of oxygenated and deoxygenated blood occurs after birth.
11. Explain the purpose of echocardiography.
12. Identify the clinical significance of cardiac markers.
13. How might a jugular vein spread infection?
14. Briefly define the following terms: *aneurysm, atherosclerosis, phlebitis.*
15. Identify possible causes of coronary artery disease.
16. Define congestive heart failure.
17. Explain how hemorrhoids develop.

CRITICAL THINKING QUESTIONS



After finishing the Review Questions, write out the answers to these more in-depth questions to help you apply your new knowledge. Go back to sections of the chapter that relate to concepts that you find difficult.

1. How is CPR accomplished? What is the significance of the placement of the heart in the thoracic cavity and successful CPR?
2. What would result if there were a lack of anastomosis in the arteries of the heart?
3. The general public thinks the most important structure in the cardiovascular system is the heart. Anatomists know it is the capillary. What information would you use to support this view?
4. Compare and contrast arterial blood in systemic circulation and arterial blood in pulmonary circulation.
5. Explain the distinction between an occlusion of an end-artery and an occlusion of other small arteries?
6. Determine which of the following veins drain into the superior vena cava and which drain into the inferior vena cava: longitudinal sinus, great saphenous, basilic, internal jugular, azygos, popliteal, and hepatic portal.
7. Describe the functional advantage of a portal system.
8. Naming the vessels and organs involved, trace the path taken by a single RBC. Begin at the right atrium, proceed to the left great toe, and return to the right atrium.
9. Explain the changes that occur in the cardiovascular system during the normal cycle of one's life.

Physiology of the Cardiovascular System

22

UNIT 4

The vital role of the cardiovascular system in maintaining homeostasis depends on the continuous and controlled movement of blood through the thousands of miles of capillaries that permeate every tissue and reach every cell in the body. It is in the microscopic capillaries that blood performs its ultimate transport function. Nutrients and other essential materials pass from capillary blood into fluids surrounding the cells as waste products are removed. Blood must not only be kept moving through its closed circuit of vessels by the pumping activity of the heart, but also must be directed and delivered to those capillary beds surrounding cells that need it most. Blood flow to cells at rest is minimal. In contrast, blood is shunted to the digestive tract after a meal or to skeletal muscles during exercise. The thousands of miles of capillaries could hold far more than the body's total blood volume if it were evenly distributed. Because variations in cellular activity require uneven distribution of blood, regulation of blood pressure and flow must change in response to cellular activity.

Numerous control mechanisms help regulate and integrate the diverse functions and component parts of the cardiovascular system to supply blood to specific body areas according to need. These mechanisms ensure a constant ***milieu intérieur,*** *that is, a constant internal environment surrounding each body cell regardless of differing demands for nutrients or production of waste products. This chapter explores the control mechanisms that regulate the pumping activity of the heart and the smooth and directed flow of blood through the complex channels of the circulation.*

HEMODYNAMICS

Hemodynamics is a term used to describe a collection of mechanisms that influence the active and changing—or dynamic—circulation of blood (Figure 22-1). Circulation is, of course, a vital function. It constitutes the only means by which cells can receive materials needed for their survival and can have their wastes removed. Circulation is necessary, and circulation of different volumes of blood per minute at different times is also essential for healthy survival. For example, more active cells need more blood per minute than less active cells. The reason underlying this principle is obvious. The more work cells do, the more energy they use, and the more oxygen and nutrients they remove from the blood. Because blood circulates, it can continually bring in more oxygen and nutrients to replace what is consumed. The greater the activity of any part of the body, the greater the volume of blood circulating through it. This requires that circulation control mechanisms accomplish two functions: maintain circulation (keep blood flowing) and vary the volume and distribution of the blood circulated. Therefore as any structure increases its activity, an increased volume of blood must be distributed to it; that is, blood must be shifted from the less active tissues to the more active tissues.

To achieve these two ends, a great many factors must operate together as one smooth-running, although complex, machine. Incidentally, this is an important physiological principle that you have no doubt observed by now—that every body function depends on many other functions. A constellation of separate processes or mechanisms acts as a single integrated mechanism.

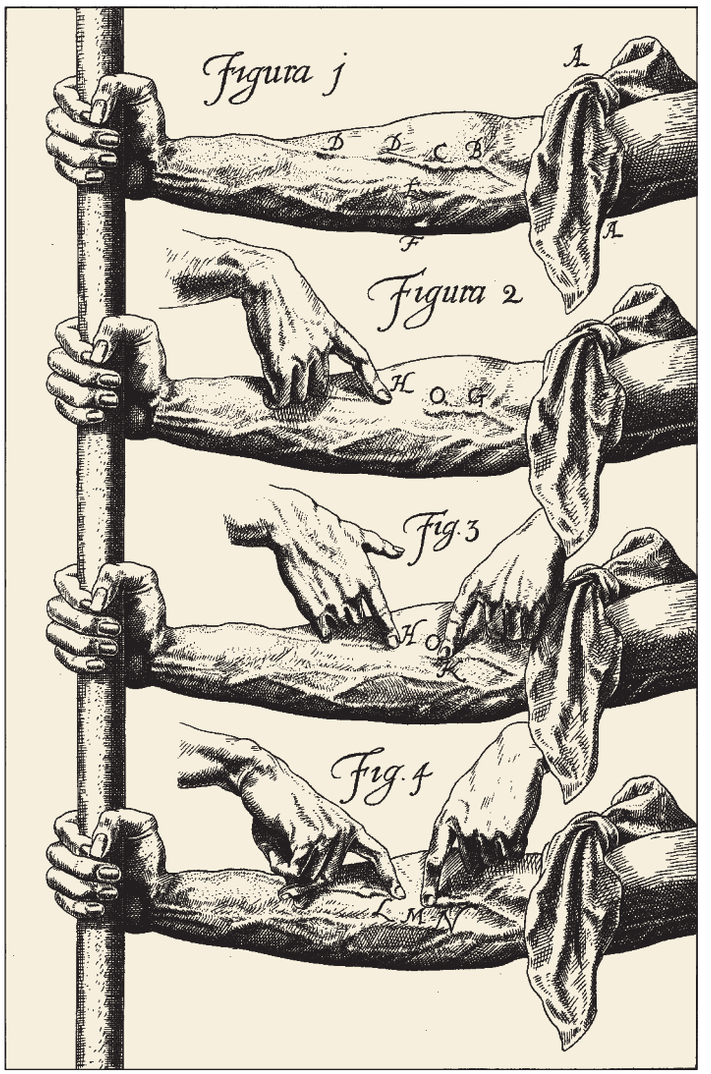

FIGURE 22-1

Hemodynamics. An illustration of a famous experiment in hemodynamics conducted by English scientist William Harvey in the early seventeenth century. Through a series of such experiments, Harvey finally proved that blood flows in a circuit out through the arteries and back through the veins—a concept on which most other hemodynamic concepts are based.

Together, these separate mechanisms perform one large function. For example, many mechanisms together accomplish the large function we call *circulation*.

This chapter is about hemodynamics—the mechanisms that keep blood flowing properly. We begin with a discussion of the heart as a pump and then move on to the even bigger picture of blood flow through the entire cardiovascular system.

THE HEART AS A PUMP

In Chapter 21 we discussed the functional anatomy of the heart. Its four chambers and their valves make up two pumps: a left pump and a right pump. The left pump (left side of the heart) helps move blood through the systemic circulation, and the right pump (right side of the heart) helps move blood through the pulmonary circulation. We will now step back from our previous discussion of the valves and chambers of the heart to look at the bigger picture and see how these two linked pumps function together as a single unit. First, we will discuss the role of the electrical conduction system of the heart in coordinating heart contractions. Then we will discuss how these coordinated contractions produce the pumping cycle of the heart.

Conduction System of the Heart

For the heart to pump effectively, the impulses (action potentials) that trigger myocardial contraction must be coordinated carefully. This requires a system for generating rhythmic impulses and distributing them quickly to the different regions of the myocardium along impulse-conducting pathways. Without such a system, different regions of the myocardium would be contracting too slowly and at slightly different rates.

Four structures make up the core of the electrical conduction system of the heart:

1. **Sinoatrial (SA) node**
2. **Atrioventricular (AV) node**
3. **AV bundle** (bundle of His)
4. **Subendocardial branches** (Purkinje fibers)

These structures are represented in Figure 22-2 and described in the following paragraphs.

Each of the structures of the heart's conduction system consists of cardiac muscle modified enough in structure to differ in function from ordinary cardiac muscle. The specialty of ordinary cardiac muscle is contraction. In this, it is like all muscle, and like all muscle, ordinary cardiac muscle can also conduct impulses. However, the myocardial fibers of the conduction system are more highly specialized, both structurally and functionally, than ordinary cardiac muscle tissue. They are not contractile. Instead, they permit only generation or rapid conduction of an action potential through the heart.

The normal cardiac impulse that initiates mechanical contraction of the heart arises in the SA node (or **pacemaker**), located just beneath the right atrial epicardium at its junction with the superior vena cava (Figure 22-2, A). Pacemaker cells in the node possess an *intrinsic rhythm*. This means that without any stimulation by nerve impulses from the brain and cord, they themselves initiate impulses at regular intervals. Even if pacemaker cells are removed from the

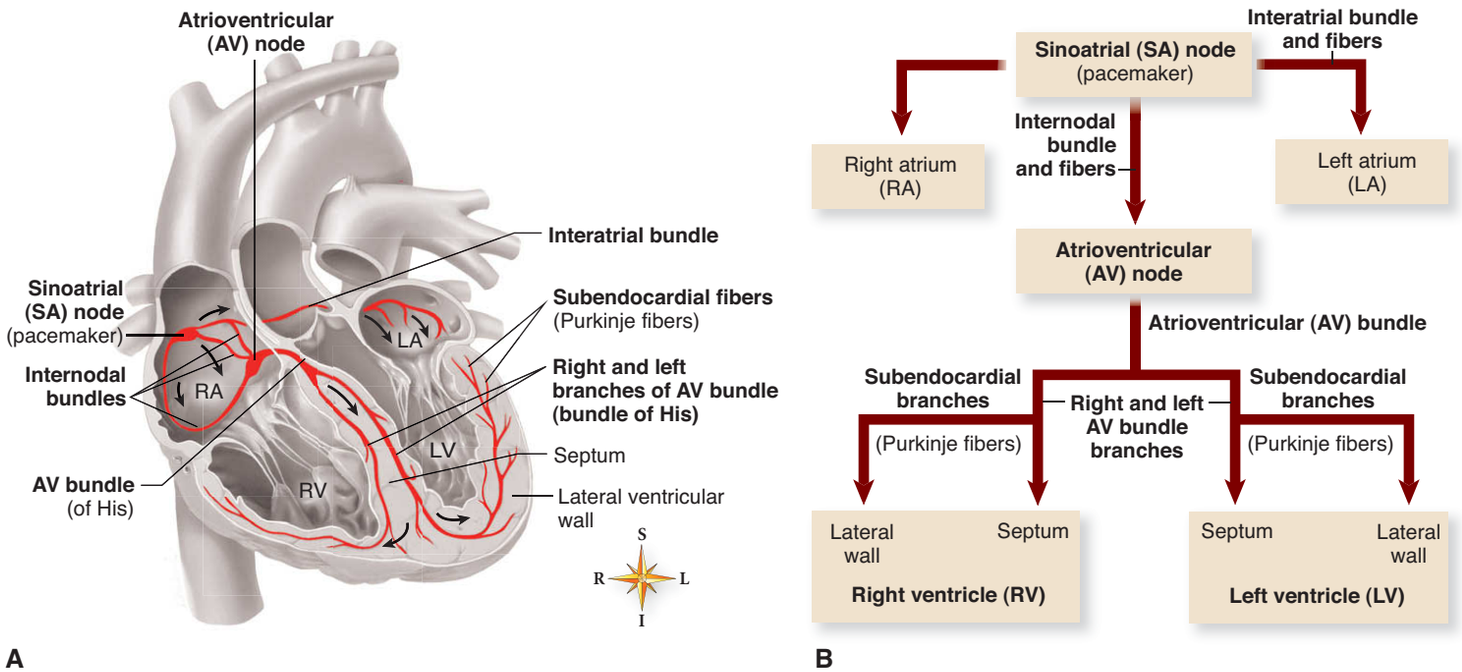

FIGURE 22-2

Conduction system of the heart. Specialized cardiac muscle cells *(boldface type)* in the wall of the heart rapidly initiate or conduct an electrical impulse throughout the myocardium. Both the sketch of the conduction system **(A)** and the flowchart **(B)** show the origin and path of conduction. The signal is initiated by the SA node (pacemaker) and spreads to the rest of the right atrial myocardium directly, to the left atrial myocardium by way of a bundle of interatrial conducting fibers, and to the AV node by way of three internodal bundles. The AV node then initiates a signal that is conducted through the ventricular myocardium by way of the AV bundle (of His) and subendocardial branches (Purkinje fibers).

body and placed in a nutrient solution, completely separated from all nervous and hormonal control, they will continue to beat! In an intact living heart, of course, nervous and hormonal regulation does occur and the SA node generates a pace accordingly.

Each impulse generated at the SA node travels swiftly throughout the muscle fibers of both atria. An **interatrial bundle** of conducting fibers facilitates rapid conduction to the left atrium. Thus stimulated, the atria begin to contract. As the action potential enters the AV node by way of three **internodal bundles** of conducting fibers, its conduction slows markedly, thus allowing for complete contraction of both atrial chambers before the impulse reaches the ventricles.

After passing slowly through the AV node, conduction velocity increases as the impulse is relayed through the AV bundle (bundle of His) into the ventricles. Here, right and left *bundle branches* and the subendocardial branches (Purkinje fibers) in which they terminate conduct the impulses throughout the muscle of both ventricles, stimulating them to contract almost simultaneously.

Thus the SA node initiates each heartbeat and sets its pace—it is the heart's own natural *pacemaker.* Under the influence of autonomic and endocrine control, the SA node will normally "discharge," or "fire," at an intrinsic rhythmical rate of 70 to 75 beats/min under resting conditions. However, if for any reason the SA node loses its ability to generate an impulse, pacemaker activity will shift to another excitable component of the conduction system, such as the AV node or the subendocardial branches (Purkinje fibers). Pacemakers other than the SA node are abnormal and are usually **ectopic pacemakers.** Ectopic is a word that means "out of place." Although ectopic pacemakers fire rhythmically, their rate of discharge is generally much slower than that of the SA node. For example, a pulse of 40 to 60 beats/min would result if the AV node were forced to assume pacemaker activity.

| A&P CONNECT |

If the heart's own pacemaker fails to maintain a healthy heart rhythm, an artificial pacemaker can be implanted to restore normal function. Check out ***Artificial Cardiac Pacemakers*** online at ***A&P Connect*** to see how this is done.

Electrocardiogram (ECG)

ELECTROCARDIOGRAPHY

Impulse conduction generates tiny electrical currents in the heart that spread through surrounding tissues to the surface of the body.

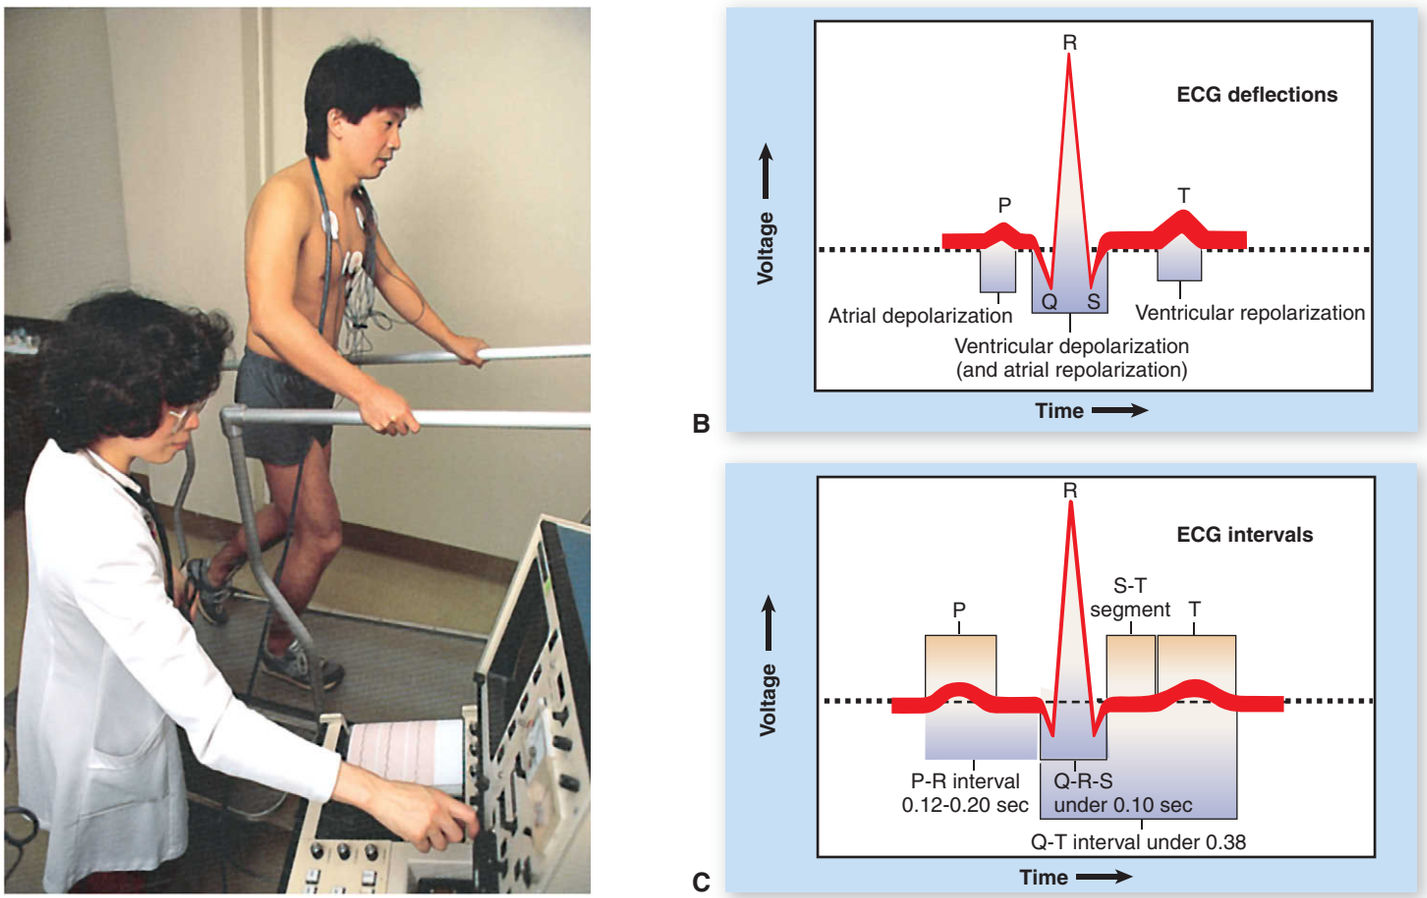

FIGURE 22-3

Electrocardiogram. A, A nurse monitors a patient's ECG as he exercises on a treadmill. **B,** Idealized ECG deflections represent depolarization and repolarization of cardiac muscle tissue. **C,** Principal ECG intervals between P, QRS, and T waves. Note that the P-R interval is measured from the start of the P wave to the start of the Q wave.

This fact has great clinical importance. Why? Because from the skin, visible records of the heart's electrical activity can be made with an instrument called an *electrocardiograph*. Skilled interpretation of these records may sometimes make the difference between life and death.

The **electrocardiogram** (**ECG** when written or **EKG** when spoken) is a graphic record of the heart's electrical activity, its conduction of impulses. It is not a record of the heart's contractions but of the *electrical events* that precede them. To produce an electrocardiogram, electrodes of a recording voltmeter (electrocardiograph) are attached to the limbs and/or chest of the subject (Figure 22-3, A). Changes in voltage, which represent changes in the heart's electrical activity, are observed as deflections of a line drawn on paper or traced on a video monitor.

Figure 22-4 explains the basic theory behind **electrocardiography.** To keep things simple, a single cardiac muscle fiber is shown with the two electrodes of a recording voltmeter nearby. Before the action potential reaches either electrode, there is no difference in charge between the electrodes, and thus no change in voltage is recorded on the voltmeter graph (Figure 22-4, step *1*). As an action potential reaches the first electrode, the external surface of the sarcolemma becomes relatively negative and so the voltmeter records a difference in charge between the two electrodes as an upward deflection of the pen on the recording chart (Figure 22-4, step 2). When the action potential also reaches the second electrode, the pen returns to the zero baseline because there is no difference in charge between the two electrodes (Figure 22-4, step 3). As the end of the action potential passes the first electrode, the sarcolemma

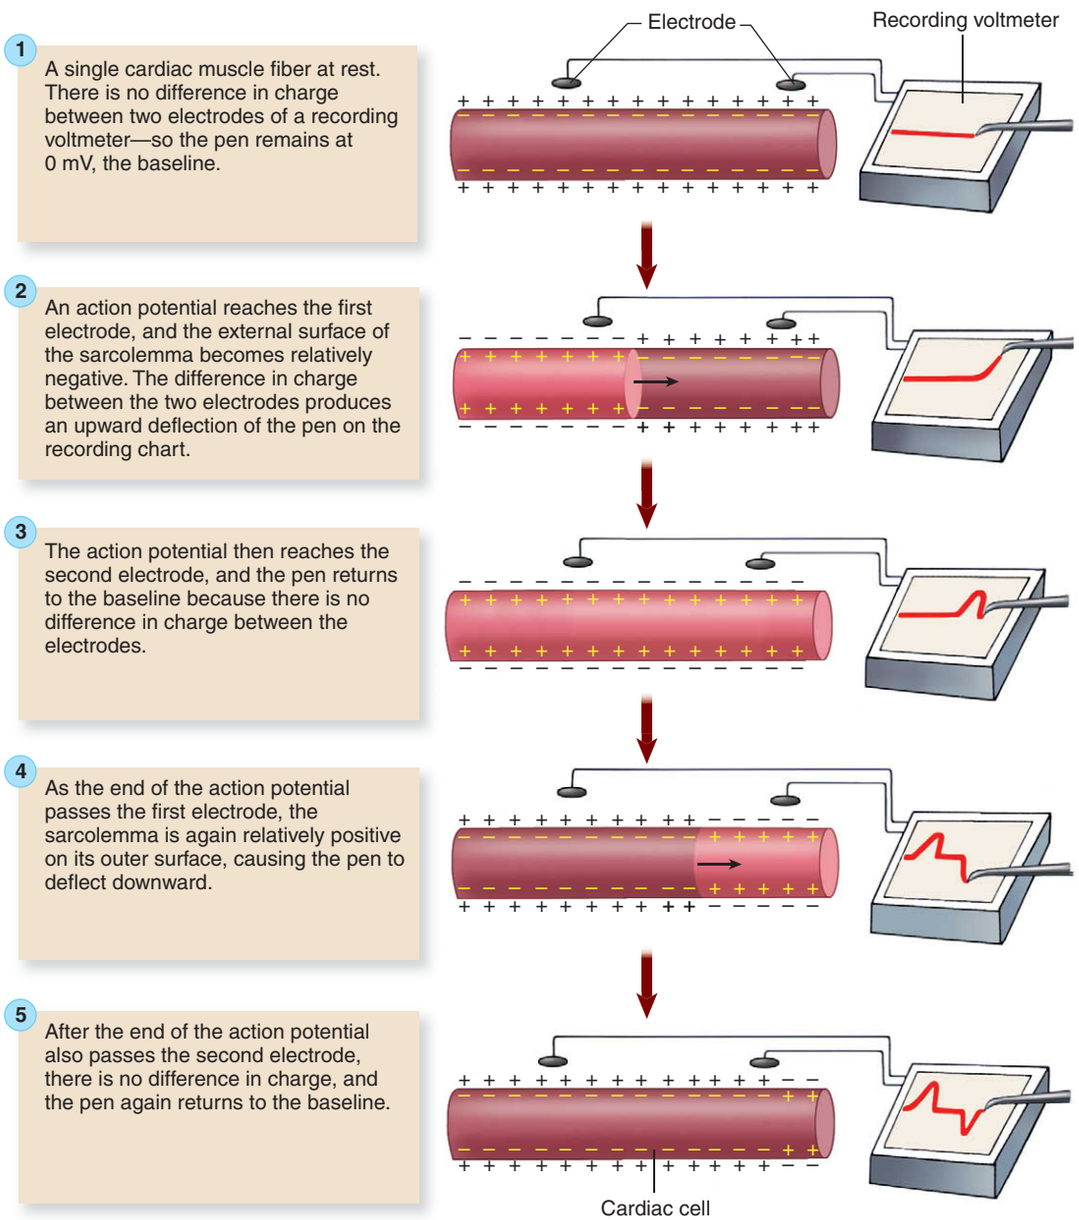

FIGURE 22-4

The basic theory of electrocardiography.

is again relatively positive on its outer surface, causing the pen to again deflect away from the baseline. This time, because the direction of the negative and positive electrodes is reversed, the pen deflects downward rather than upward (Figure 22-4, step 4). After the end of the action potential also passes the second electrode, the pen again returns to the zero baseline (Figure 22-4, step 5). In short, depolarization of cardiac muscle causes a deflection of the graphed line; repolarization causes a deflection in the opposite direction.

Electrocardiography electrodes are normally quite some distance from myocardial tissue, but, given the massive size of the myocardial syncytium, it should not be surprising that even cutaneous electrodes can detect changes in the heart's polarity.

| A&P CONNECT |

There are a number of locations and patterns of attaching ECG leads. Different ECG setups produce different results—thus allowing physicians to "see" the electrical activity of the heart from different angles. See how this is done in ***Electrocardiography*** online at ***A&P Connect.***

evolve

ECG WAVES

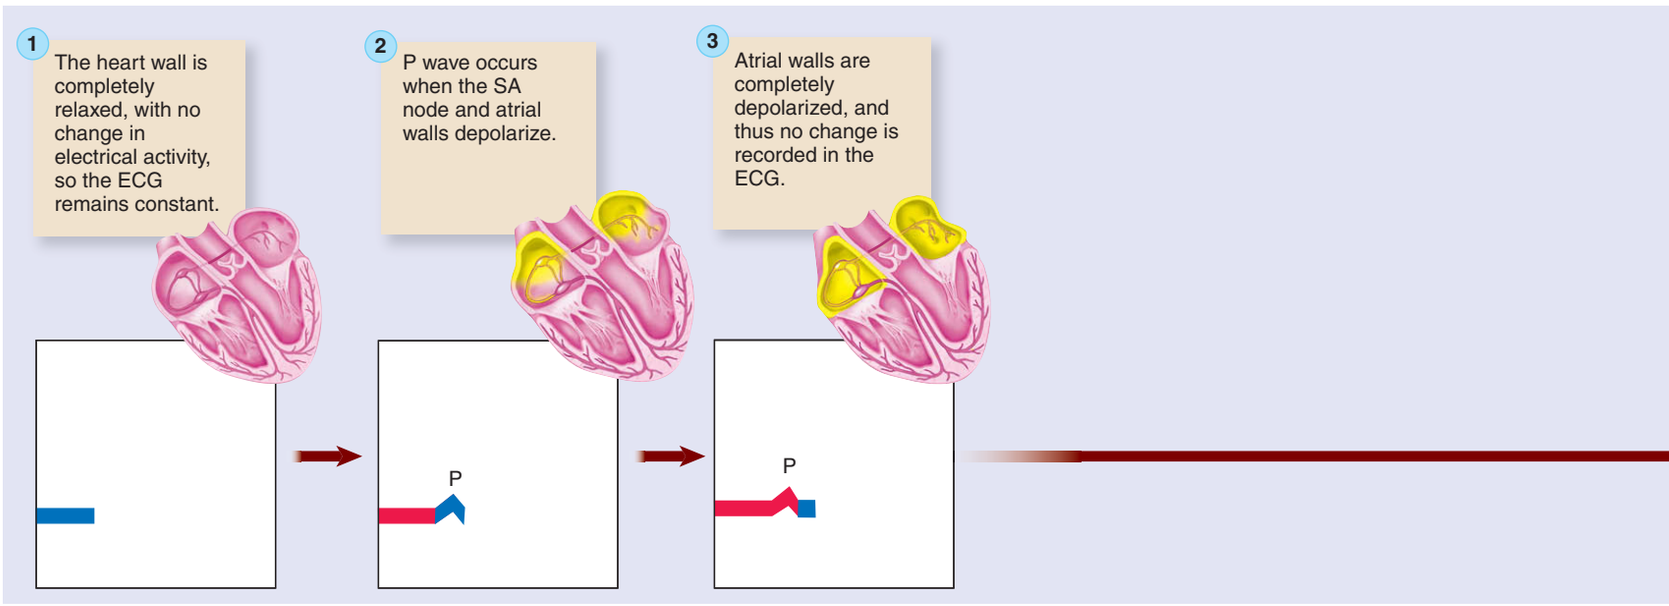
Because electrocardiography is far too complex a subject to explain fully here, normal ECG *deflection waves* and the *ECG intervals* between them shall be discussed only briefly. As shown in Figures 22-3, *B*, and 22-5, the normal ECG is composed of deflection waves called the *P wave*, *QRS complex*, and *T wave*. (The letters do not represent any words; they are simply an arbitrarily chosen sequence of letters of the alphabet.)

P Wave

The **P wave** represents depolarization of the atria. That is, the P wave is the deflection caused by the passage of an electrical impulse from the SA node through the musculature of both atria. P wave abnormalities often reflect atrial enlargement.

QRS Complex

The **QRS complex** represents depolarization of the ventricles. Depolarization of the ventricles is a complex process, involving depolarization of the interventricular septum and the subsequent spread of depolarization by the subendocardial branches (Purkinje fibers) through the lateral ventricular walls. Rather than getting mired in a detailed explanation, let us simplify matters by stating that the combined duration of all three deflections of the QRS complex (Q, R, and S) represent the time required (0.07–0.11 seconds) for ventricular depolarization. (See Figure 22-2, C.)



At the same time that the ventricles are depolarizing, the atria are repolarizing. As we explained earlier, we should expect to see a deflection that is opposite in direction to the P wave that represented depolarization. However, the massive ventricular depolarization that is occurring at the same time overshadows the voltage fluctuation produced by atrial repolarization. Thus we can say that the QRS complex represents both ventricular depolarization and atrial repolarization. If the QRS duration is prolonged, ventricular conduction delay is probably occurring.

T Wave

The **T wave** reflects repolarization of the ventricles. In atria, the first part of the myocardium to depolarize is the first to

FIGURE 22-5

Events represented by the electrocardiogram (ECG). It is impossible to illustrate the invisible, dynamic events of heart conduction in a few cartoon panels or "snapshots," but the sketches here give you an idea of what is happening in the heart as an ECG is recorded. Note that depolarization triggers contraction in the affected muscle tissue. Thus cardiac muscle contraction occurs *after* depolarization begins.

repolarize. In ventricles, on the other hand, the first part of the myocardium to depolarize is the last to repolarize. Thus ECG deflections for both depolarization and repolarization are in the same direction. An inverted T wave is often seen following myocardial muscle damage.

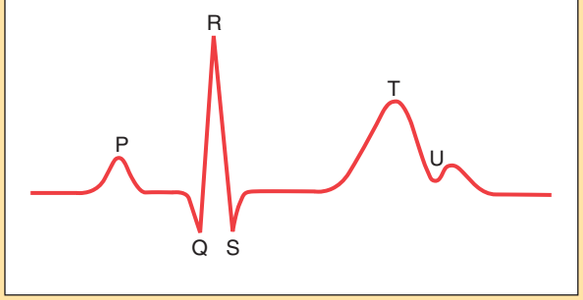
Sometimes, an additional **U wave** may be seen in the electrocardiogram (Figure 22-6). The U wave, when visible, appears as a tiny "hump" at the end of the T wave. The U wave is thought to represent late repolarization of subendocardial branches (Purkinje fibers) in the papillary muscle of the ventricular myocardium. However, some cardiologists believe it is simply a two-part T wave resulting from longer duration of the action potential in some ventricular myocardial cells. If not too big, U waves are usually considered to be normal. Sometimes, however, U waves can be a sign of **hypokalemia** (low blood potassium) or too much **digoxin** (a heart medication).

ECG INTERVALS

The principal ECG intervals between P, QRS, and T waves are shown in Figure 22-3, *C*. Measurement of these intervals can provide valuable information concerning the rate of conduction of an action potential through the heart, as we shall see later in this chapter. Figure 22-5 summarizes the relationship between the electrical events of the myocardium and the ECG recordings.

| QUICK CHECK |

1. List the principal structures of the heart's conduction system.
2. What are the three deflection waves seen in a typical ECG?
3. What event does each ECG wave represent?



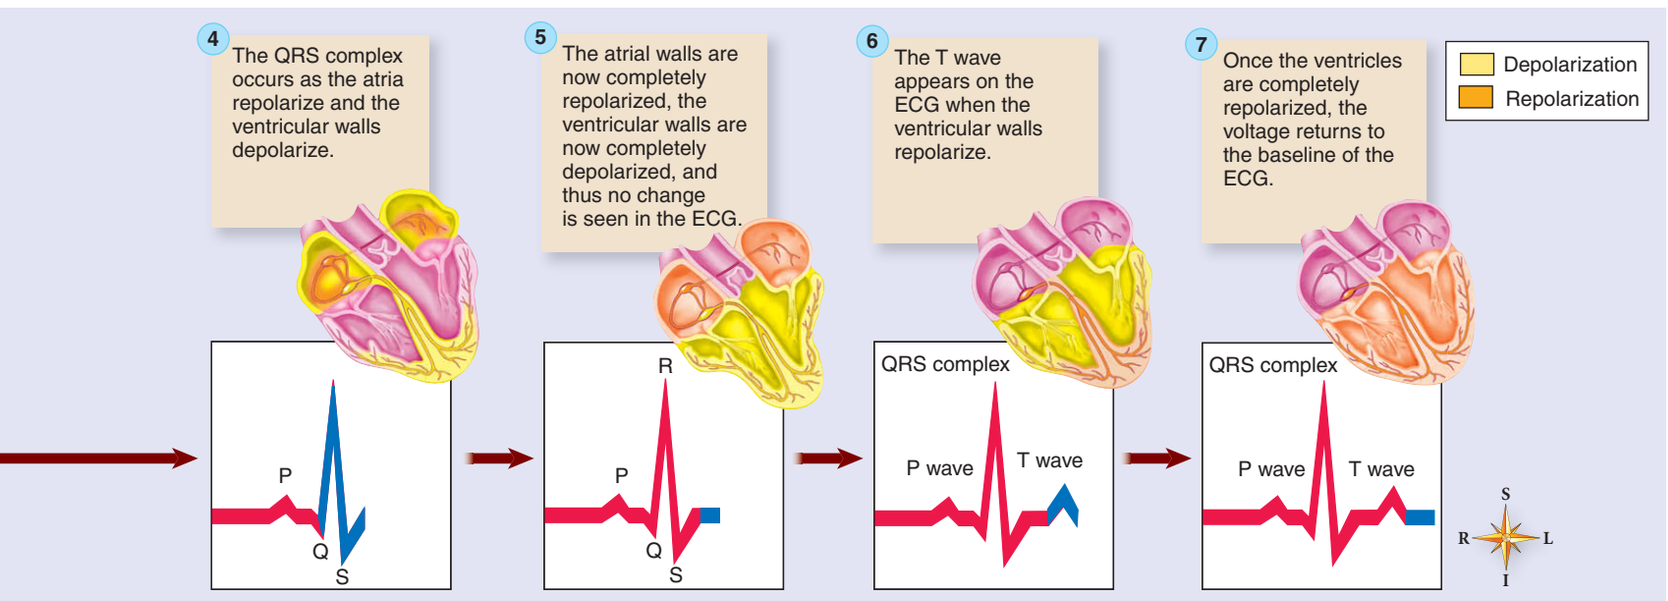


FIGURE 22-6

The U wave. This ECG recording shows the presence of a U wave, which follows the T wave—or appears as a "hump" on the back of the T wave. The U wave represents a sudden, late repolarization of subendocardial branches (Purkinje fibers) in the papillary muscle.

Cardiac Cycle

The term **cardiac cycle** means a complete heartbeat, or pumping cycle, consisting of contraction (**systole**) and relaxation (**diastole**) of both atria and both ventricles. The two atria contract simultaneously. Then, as the atria relax, the two ventricles contract and relax, instead of the entire heart contracting as a unit. This gives a kind of pumping action to the movements of the heart. The atria remain relaxed during part of the ventricular relaxation and then start the cycle over again. The cycle as a whole is often divided into time intervals for discussion and study. The following sections describe several of the important events of the cardiac cycle. As you read through these sections, refer frequently

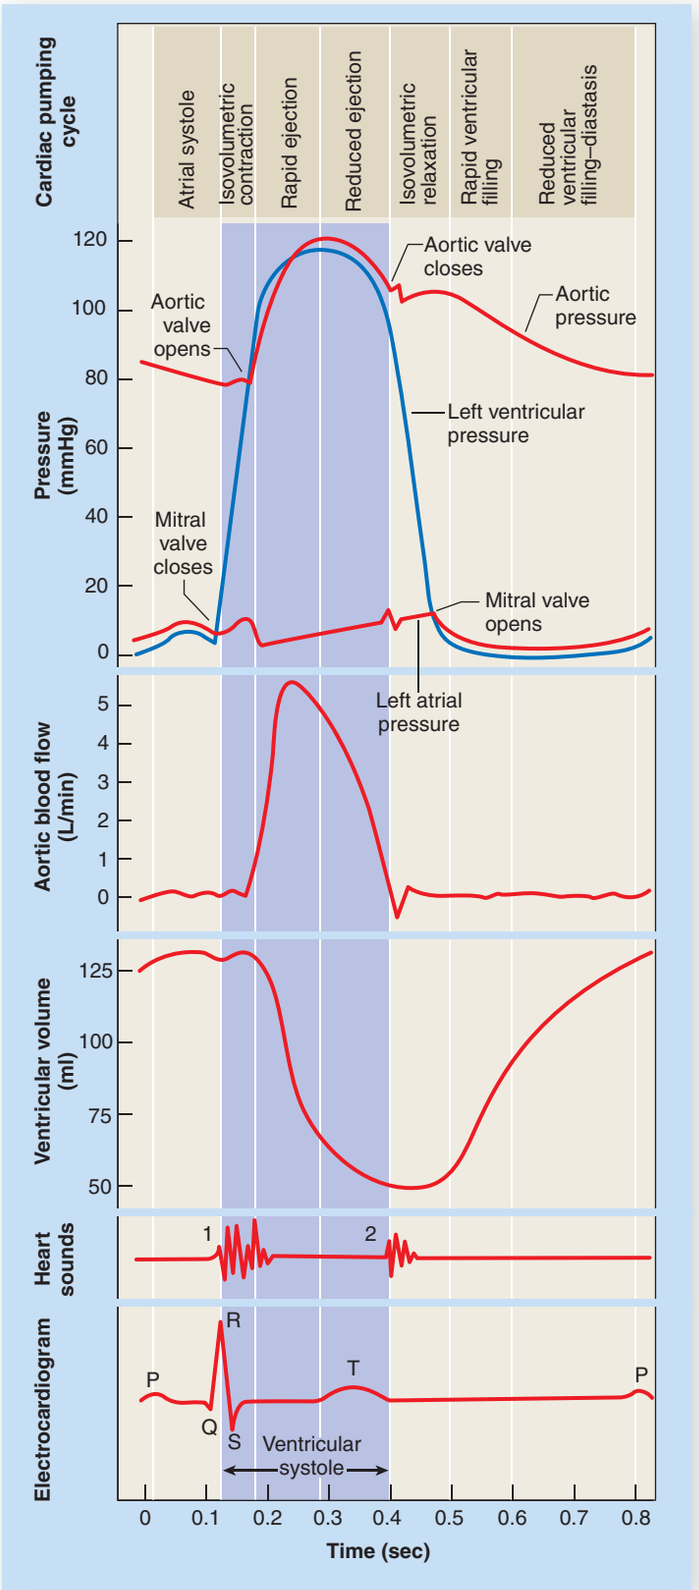

FIGURE 22-7

Composite chart of heart function. This chart is a composite of several diagrams of heart function (cardiac pumping cycle, blood pressure, blood flow, volume, heart sounds, and ECG), all adjusted to the same time scale. Although it appears daunting at first glance, you will find it a valuable reference tool as you proceed through this chapter.

to Figure 22-7, which is a composite chart that graphically illustrates and integrates changes in pressure gradients in the left atrium, left ventricle, and aorta with ECG and heart sound recordings. Aortic blood flow and changes in ventricular volume are also shown. Refer also to Figure 22-8, which shows the major phases of the cardiac cycle.

Recall that damage to the myocardium that sometimes affects the heart's ECG and pumping cycle may result from a heart attack. Review the illustrated walk-through of a ***Heart Attack!*** online at ***A&P Connect.***

evolve

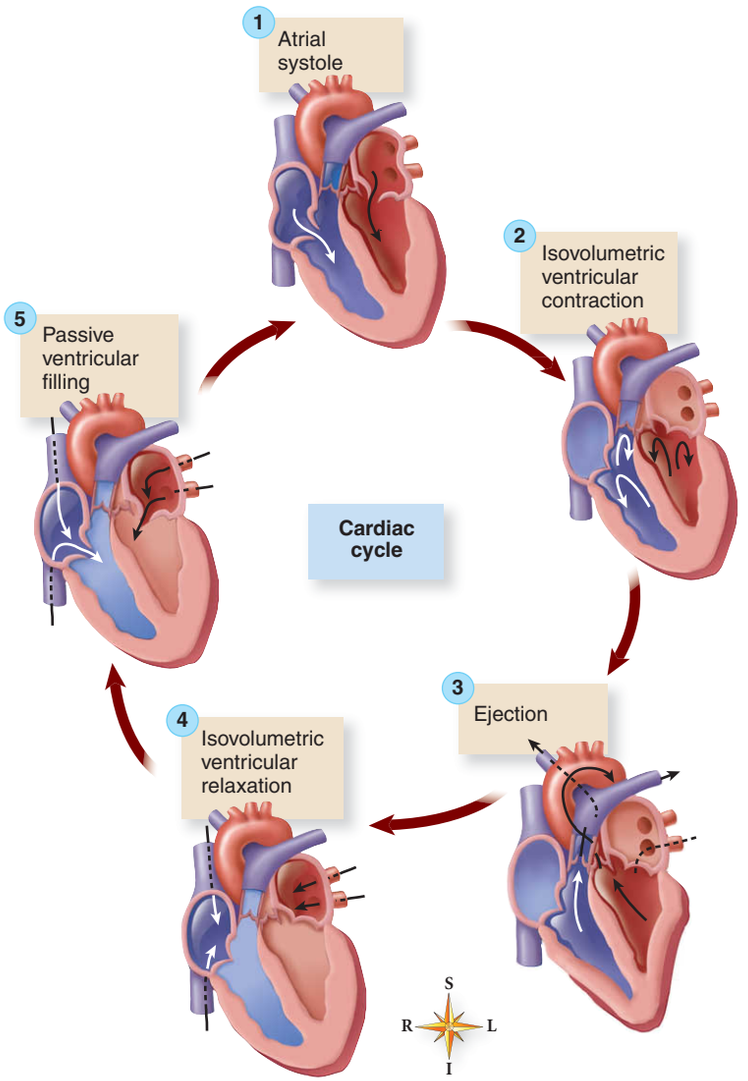

FIGURE 22-8

The cardiac cycle. The five steps of the heart's pumping cycle described in the text are shown as a series of changes in the heart wall and valves.

ATRIAL SYSTOLE

This phase of the cardiac cycle begins with the P wave of the ECG. Passage of the electrical wave of depolarization is then followed almost immediately by actual contraction (systole) of the atrial musculature.

The contracting force of the atria creates a pressure gradient that pushes blood out of the atria into the relaxed ventricles. Keep in mind that fluid moves from an area of high pressure toward an area of lower pressure—an important principle of hemodynamics that helps explain how the heart functions as a pump. Because of the high pressure of atrial blood during atrial systole, blood moves into the relaxed ventricles, where the pressure is lower.

The pressure gradient not only drives the movement of blood from the atria into the ventricles, it also keeps the atrioventricular (or cuspid) valves open during this phase. The ventricles are relaxed and rapidly filling with blood. The semilunar valves are closed because during this phase the arterial pressure is higher than pressure in the relaxed ventricles. This pressure gradient pushes blood against the semilunar valves and thereby prevents reentry of blood from the pulmonary artery or aorta.

ISOVOLUMETRIC VENTRICULAR CONTRACTION

The onset of ventricular systole coincides with the R wave of the ECG and the appearance of the first heart sound.

Iso- is a combining form denoting equality or uniformity, and *volumetric* denotes measurement of volume. Thus *isovolumetric* is a term that means "having the same measured volume." During the brief period of isovolumetric ventricular contraction the intraventricular pressure begins to increase. This is enough of a pressure increase in the ventricles to overcome atrial pressure and close the atrioventricular valves—producing the first heart sound—but not enough to overcome arterial pressure and open the semilunar valves. This phase occurs between the start of ventricular systole and the opening of the semilunar valves, during which ventricular volume remains constant as the pressure increases rapidly.

EJECTION

The semilunar valves open and blood is ejected from the heart when the pressure in the ventricles exceeds the pressure in the pulmonary artery and aorta. An initial, shorter phase, called *rapid ejection*, is characterized by a marked increase in ventricular and aortic pressure and in aortic blood flow. The T wave of the ECG appears during the later, longer phase of *reduced ejection* (characterized by a less abrupt decrease in ventricular volume). A considerable quantity of blood, called the **residual volume,** normally remains in the ventricles at the end of the ejection period. In heart failure the residual volume remaining in the ventricles may greatly exceed that ejected during systole.

ISOVOLUMETRIC VENTRICULAR RELAXATION

Ventricular diastole, or relaxation, begins with the isovolumetric ventricular relaxation period of the cardiac cycle. It is the period between closure of the semilunar valves and opening of the atrioventricular valves. At the end of ventricular ejection, the semilunar valves close when the ventricular pressure drops below arterial pressure and pushes the valve flaps closed. As the valves snap shut, they produce the second heart sound. Closure of the semilunar valves prevents blood from reentering the ventricular chambers from the pulmonary trunk and aorta. Both sets of valves are closed, and the ventricles are relaxing.

Ventricular relaxation causes a dramatic fall in intraventricular pressure but not enough to open the atrioventricular valves. Because the valves are closed, there is no change in volume. The atrioventricular valves do not open until the pressure in the atrial chambers increases above that in the relaxing ventricles.

PASSIVE VENTRICULAR FILLING

As the ventricles continue to relax, the intraventricular pressure continues to drop. That, along with rising intraatrial pressure produced by return of venous blood, produces a pressure gradient sufficient to force open the atrioventricular valves. Blood then rushes into the relaxing ventricles.

The rapid influx of blood into the ventricles lasts about 0.1 second and results in a dramatic increase in ventricular volume. The term *diastasis* is often used to describe a later, longer period of slow ventricular filling as ventricular diastole ends. The abrupt inflow of blood that occurred immediately after opening of the atrioventricular valves is followed by a slow but continuous flow of venous blood into the atria and then through the open atrioventricular valves into the ventricles. Diastasis lasts about 0.2 second and is characterized by a gradual increase in ventricular pressure and volume.

At the end of this phase of the cardiac cycle, a new P wave triggers the contraction of atria that marks the beginning of another *atrial systole* phase—and new cardiac cycle.

Review ***Echocardiography*** online at ***A&P Connect*** to learn how sound waves are used to visualize the events of the cardiac cycle.

evolve

Heart Sounds

The heart makes certain typical sounds during each cardiac cycle that are described as sounding like "lubb-dupp" when heard through a stethoscope.

The first, or systolic, sound is caused primarily by the contraction (systole) of the ventricles and also by vibrations of the closing atrioventricular, or cuspid, valves. It is longer and lower than the second, or diastolic, sound, which is short and sharp and is caused by vibrations of the closing semilunar valves as the ventricles relax (diastole) (see Figure 22-7).

Heart sounds have clinical significance because they provide information about the valves of the heart. Any variation from normal in the sounds indicates imperfect functioning of the valves. **Heart murmur** is one type of abnormal heart sound heard frequently. It is sometimes described as a "swishing" sound that may signify incomplete closing of the valves (valvular insufficiency) or stenosis (constriction, or narrowing) of them.

| QUICK CHECK |

4. Using Figure 22-8 as a guide, describe the major events of the cardiac cycle.
5. As the ventricles contract, their volume remains constant for a period of time. Explain why the volume does not begin to decrease immediately.

PRIMARY PRINCIPLE OF CIRCULATION

Blood circulates for the same reason that any fluid flows—whether it is water in a river, water in a garden hose, fluid in hospital tubing, or blood in vessels. A fluid flows because a pressure gradient exists between different parts of its volume (Figure 22-9).

This primary fluid flow principle derives from Newton's first and second laws of motion. In essence, these laws state the following principles:

1. A fluid does not flow when the pressure is the same throughout.
2. A fluid flows only when its pressure is higher in one area than in another, and it flows always from its higher pressure area toward its lower pressure area.

Thus the primary principle about circulation is this: blood flows because of a pressure gradient. We have already seen this principle operate to drive the flow of blood through the heart during the cardiac cycle (see pp. 687–689). It also applies to a whole circulatory loop—blood circulates from the left ventricle and returns to the right atrium of the heart because a blood pressure gradient exists between these two structures. Likewise, blood circulates from the right ventricle and returns to the left atrium because of a pressure gradient. By blood pressure gradient, we mean the difference between the blood pressure in one structure and the blood pressure in another.

An example of a normal blood pressure measurement in the aorta, as the left ventricle contracts and thereby pumps blood into it, is 120 mmHg; as the left ventricle relaxes, blood pressure decreases to 80 mmHg. The midpoint of aortic pressure in this instance is 100 mmHg. Figure 22-9 shows the systolic and diastolic pressures in the arterial system and illustrates the progressive fall in pressure from a midpoint of 100 mmHg in the aorta down to 0 mmHg by the time blood reaches the venae cavae and right atrium. The progressive fall in pressure as blood passes through the circulatory system is directly related to flow resistance. Resistance to blood flow in the aorta is almost zero. Although the pumping action of the heart causes fluctuations in aortic blood pressure (systolic 120 mmHg; diastolic 80 mmHg), the midpoint of pressure remains almost constant, dropping perhaps only 1 or 2 mmHg. The greatest drop in pressure (about 50 mmHg) occurs as blood goes through the arterioles because they present the greatest resistance to blood flow. The importance of flow resistance to maintaining a healthy pressure gradient is explored further in the next part of the chapter.

P_1–P_2 is often used to represent a pressure gradient, with P_1 the symbol for the higher pressure and P_2 the symbol for the lower pressure. For example, blood enters the arterioles at 85 mmHg and leaves at 35 mmHg. Which measurement is P_1? P_2? What is the blood pressure gradient? It would cause blood to flow through the arterioles toward the capillaries.

Of course, this principle applies to local blood flow as well as an entire circulatory loop. For example, pressure in the arteries and arterioles of the kidney must be higher than the blood pressure in the capillaries and veins of the kidney in order for blood to flow through the tissues of the kidney. This local pressure gradient needed to maintain blood flow in a tissue is called **perfusion pressure** (*perfusion* means "flow through").

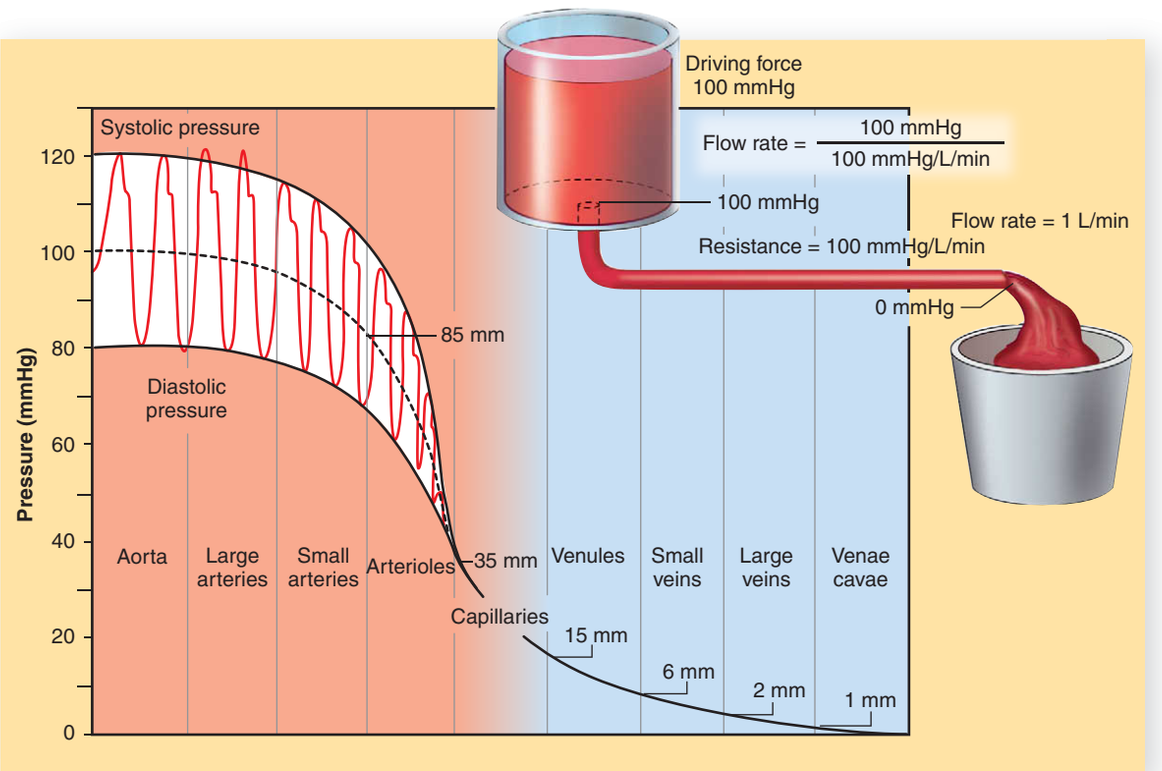

FIGURE 22-9

The primary principle of circulation. Fluid always travels from an area of high pressure to an area of low pressure. Water flows from an area of high pressure in the tank (100 mmHg) toward the area of low pressure above the bucket (0 mmHg). Blood tends to move from an area of high pressure at the beginning of the aorta (100 mmHg) toward the area of lowest pressure at the end of the venae cavae (0 mmHg). Blood flow between any two points in the circulatory system can always be predicted by the pressure gradient.

ARTERIAL BLOOD PRESSURE

According to the primary principle of circulation, high pressure in the arteries must be maintained to keep blood flowing through the cardiovascular system. The chief determinant of arterial blood pressure is the volume of blood in the arteries. Arterial blood pressure is directly proportional to arterial blood volume. This means that an increase in arterial blood volume tends to increase arterial pressure, and conversely, a decrease in arterial volume tends to decrease arterial pressure.

Many factors determine arterial pressure through their influence on arterial volume. Two of the most important—**cardiac output** and **peripheral resistance**—are directly proportional to blood volume (Figure 22-10).

Cardiac Output

Cardiac output (CO) is the amount of blood that flows out of a ventricle of the heart per unit of time. The resting cardiac output from the left ventricle into the systemic arteries is roughly 5000 ml/min, for example. As Figure 22-11 shows, the cardiac output influences the flow rate to the various organs of the body. For the sake of discussion, we focus mainly on cardiac output from the left ventricle into the systemic loop—but the same principles apply to cardiac output from either the left or the right ventricle.

Cardiac output is determined by the volume of blood pumped out of a ventricle by each beat (**stroke volume,** or **SV**) and by heart rate (HR). Because contraction of the heart is called *systole*, the volume of blood pumped by one contraction is known as *systolic discharge*. Stroke volume means the same thing, the amount of blood pumped by one stroke (contraction) of the ventricle.

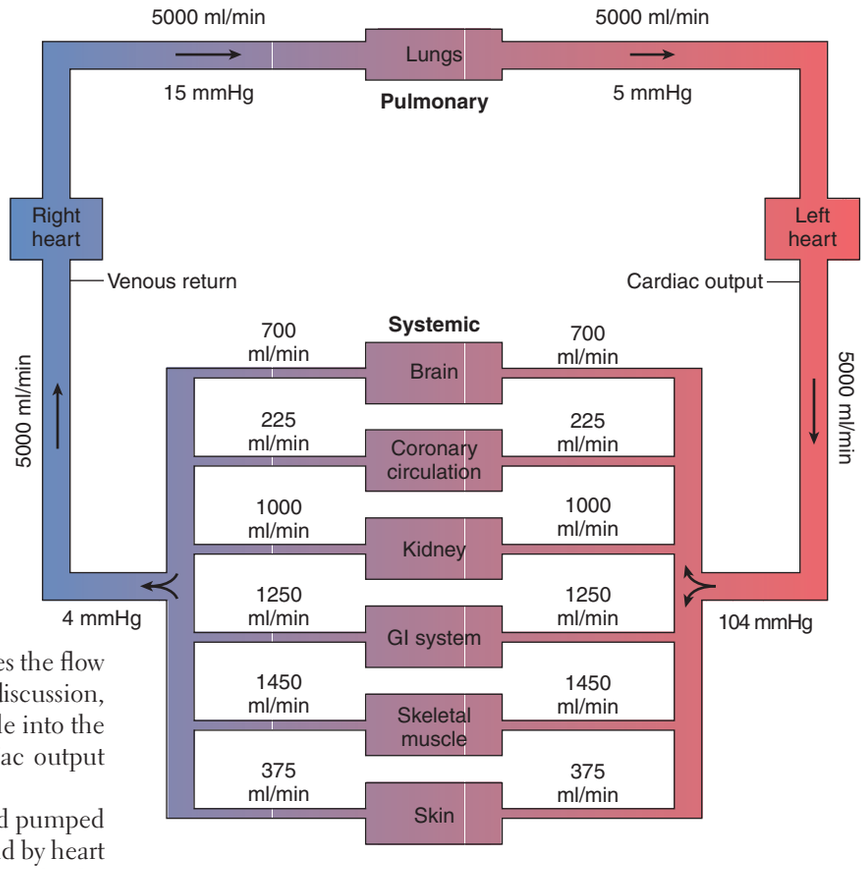

FIGURE 22-11

Cardiac output. This diagram shows that a typical resting cardiac output (CO) of 5000 ml/min (or 5 L/min) is distributed among the various systems and organs of the body. *GI,* Gastrointestinal.

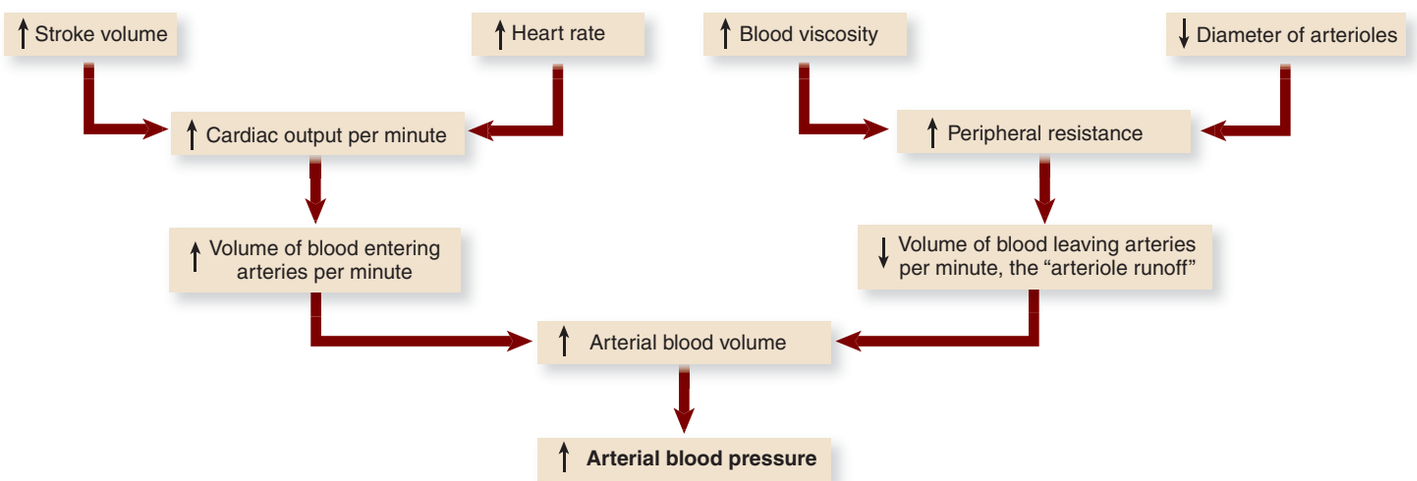

FIGURE 22-10

Relationship between arterial blood volume and blood pressure. Arterial blood pressure is directly proportional to arterial blood volume. Cardiac output (CO) and peripheral resistance (PR) are directly proportional to arterial blood volume, but for opposite reasons: CO affects blood *entering* the arteries, and PR affects blood *leaving* the arteries. If cardiac output increases, the amount of blood entering the arteries increases and tends to increase the volume of blood in the arteries. If peripheral resistance increases, it decreases the amount of blood leaving the arteries, which tends to increase the amount of blood left in them. Thus an increase in either CO or PR results in an increase in arterial blood volume, which increases arterial blood pressure.

Stroke volume, or volume pumped per heartbeat, is one of two major factors that determine CO. CO can be computed by the following simple equation:

SV (volume/beat) × HR (beat/min) = CO (volume/min)

Thus the greater the stroke volume, the greater the CO (but only if the heart rate remains constant). In practice, computing the CO is far from simple. It requires introducing a catheter into the right side of the heart (cardiac catheterization) and solving a computation known as *Fick's formula.*

Because the heart's rate and stroke volume determine its output, anything that changes the rate of the heartbeat or its stroke volume tends to change CO, arterial blood volume, and blood pressure in the same direction. In other words, anything that makes the heart beat faster or anything that makes it beat stronger (increases its stroke volume) *tends* to increase CO and therefore arterial blood volume and pressure. Conversely, anything that causes the heart to beat more slowly or more weakly tends to decrease CO, arterial volume, and blood pressure.

Do not overlook the word *tends* in the preceding sentences. A change in heart rate or stroke volume does not *always* change the heart's output, or the amount of blood in the arteries, or the blood pressure. To see whether this is true, do the following arithmetic calculation, using the simple formula for computing CO. Assume a normal rate of 72 beats/min and a normal stroke volume of 70 ml. Next, suppose the rate drops to 60 and the stroke volume increases to 100. Does the decrease in heart rate actually cause a decrease in CO in this case? Clearly not—the CO increases. Do you think it is valid, however, to say that a slower rate tends to decrease the heart's output? By itself, without any change in any other factor, would not a slowing of the heartbeat cause CO volume, arterial volume, and blood pressure to fall?

FACTORS THAT AFFECT STROKE VOLUME

Mechanical, neural, and chemical factors regulate the strength of the heartbeat and therefore its stroke volume. One mechanical factor that helps determine stroke volume is the length of myocardial fibers at the beginning of ventricular contraction.

Many years ago, an English physiologist named Ernest Starling described a principle that later became known as **Starling's law of the heart.** Because the principle was partly based on the earlier work of Otto Frank, it is sometimes called the *Frank-Starling mechanism.* In this principle, Starling stated the factor he had observed as the main regulator of heartbeat strength in experiments performed on denervated animal hearts. Starling's law of the heart is this: within limits, the longer, or more stretched, the heart fibers at the beginning of contraction, the stronger is their contraction. Compare this concept with the length-tension relationship in skeletal muscle described in Chapter 12 (p. 365).

The factor determining how stretched the animal hearts were at the beginning of contractions was, as you might deduce, the amount of blood in the hearts at the end of diastole—the **end-diastolic volume (EDV).** The more blood returned to the heart per minute, the more stretched were their fibers, the stronger were their contractions, and the larger was the volume of blood they ejected with each contraction. If, however, too much blood stretched the hearts beyond a certain critical point, they seemed to lose their elasticity. They then contracted less vigorously, similar to how a band of elastic, stretched too much, rebounds with less force (Figure 22-12).

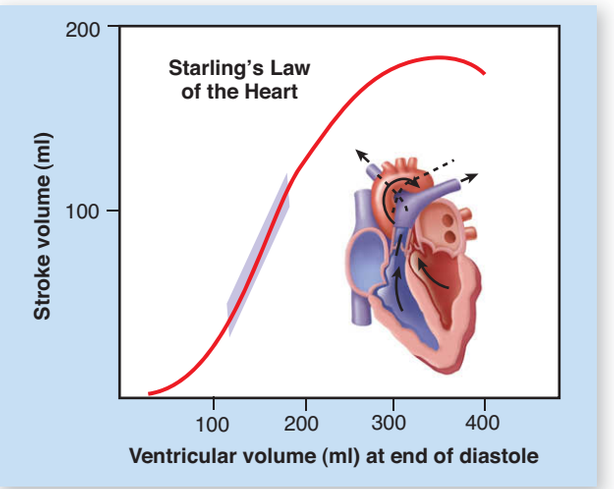

FIGURE 22-12

Starling's law of the heart. This curve represents the relationship between the stroke volume and the ventricular volume at the end of diastole. The range of values observed in a typical heart is shaded. Note that if the ventricle has an abnormally large volume at the end of diastole *(far right portion of the curve),* the stroke volume cannot compensate.

Thus, according to Starling's law of the heart, the heart pumps out what it receives. That is, within certain limits, the strength of myocardial contraction matches the pumping load—unlike mechanical pumps that do not adjust themselves to their input with every stroke.

Although Starling's law of the heart was first described in animal experiments, most physiologists agree that it operates in humans as a major regulator of stroke volume under ordinary conditions. Operation of Starling's law of the heart ensures that increased amounts of blood returned to the heart will be pumped out of it. It automatically adjusts CO to venous return under usual conditions. Factors that influence the amount of blood returned to the heart—venous return—are discussed in a later section.

Other factors that influence stroke volume are neural and endocrine chemical factors. You already know from our discussions in earlier chapters that norepinephrine (NE) released by sympathetic fibers in the cardiac nerve and epinephrine released into the blood by the adrenal medulla can both increase the strength of contraction, or *contractility*, of the myocardium. This increased contractility of heart muscle pushes more blood out of the heart per cardiac stroke—thus increasing the stroke volume. As Figure 22-13 shows, both the increased contractility from these chemical factors and the effects of Starling's law of the heart can change the stroke volume—and therefore also cardiac output. Factors such as the stress of exercise can trigger these neural and endocrine responses.

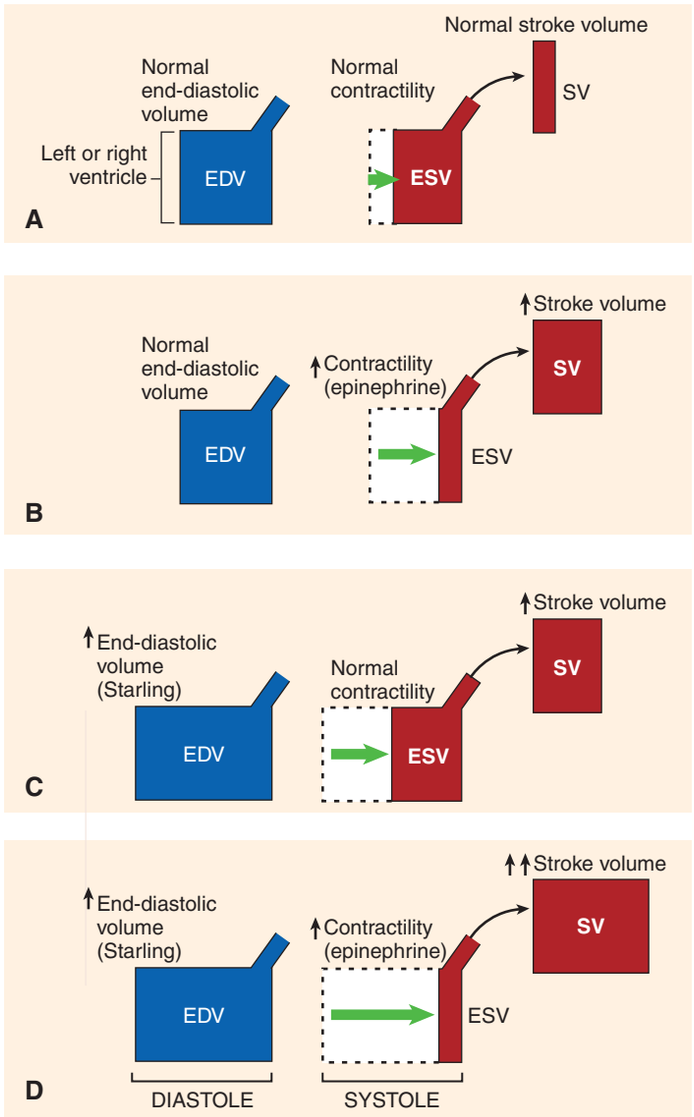

FIGURE 22-13

Stroke volume. Changes in stroke volume caused by increasing the end-diastolic volume (EDV) and/or contractility. **A,** Normal stroke volume (no external influences). **B,** When EDV remains constant and contractility increases (from epinephrine), then the stroke volume increases. **C,** When contractility remains constant and EDV increases, then the stroke volume increases (Starling's law of the heart). **D,** When both EDV and contractility increase, a combined effect increases the stroke volume even more. *EDV,* End-diastolic volume; *ESV,* end-systolic volume; *SV,* stroke volume.

The **ejection fraction (EF)** is related to the stroke volume. The ejection fraction is the ratio of the stroke volume (SV) to the end-diastolic volume (EDV), often expressed as a percentage. Expressed as a formula, EF = (SV/EDV) × 100. Thus as SV goes up, EF goes up—and as SV goes down, EF also goes down. An EF of 55% or higher is typical in healthy adults. The EF declines when the myocardium fails to function properly and cannot contract strongly enough to eject a normal amount of blood—as sometimes happens after a myocardial infarction (MI). The EF is usually measured by echocardiography, a procedure described in *Echocardiography* online at *A&P Connect.*

FACTORS THAT AFFECT HEART RATE

Although the sinoatrial node normally initiates each heartbeat, the rate it sets is not an unalterable one. Various factors can and do change the rate of the heartbeat. One major modifier of sinoatrial node activity—and therefore of the heart rate—is the ratio of sympathetic and parasympathetic impulses conducted to the node per minute. Autonomic control of heart rate is the result of opposing influences between parasympathetic (chiefly vagus) and sympathetic (cardiac nerve) stimulation. The results of parasympathetic stimulation on the heart are inhibitory and are mediated by vagal release of acetylcholine, whereas sympathetic (stimulatory) effects result from the release of norepinephrine at the distal end of the cardiac nerve.

Cardiac Pressoreflexes

Receptors sensitive to changes in pressure (**baroreceptors**) are located in two places near the heart (Figure 22-14). Called

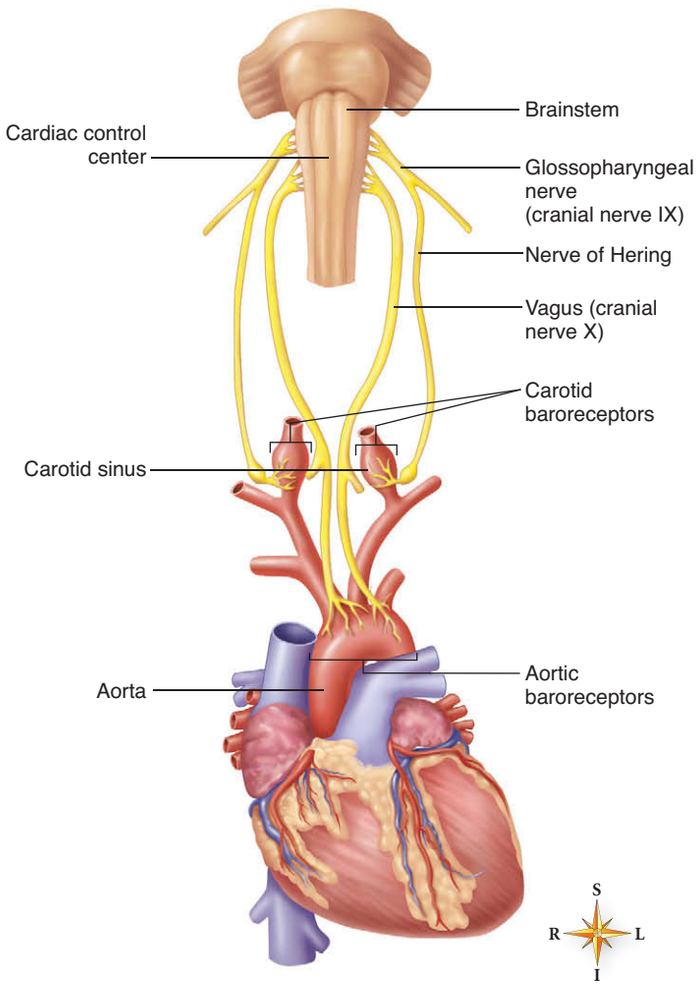

FIGURE 22-14

Cardiac baroreceptors. Location of aortic and carotid baroreceptors and the sensory nerves that carry feedback information about blood pressure back to the central nervous system.

the *aortic baroreceptors* and *carotid baroreceptors*, they send afferent nerve fibers to cardiac control centers in the medulla oblongata. These stretch receptors, located in the aorta and carotid sinus, constitute a very important heart rate control mechanism because of their effect on the autonomic cardiac control centers—and therefore on parasympathetic and sympathetic outflow. Baroreceptors operate with integrators in the cardiac control centers in negative feedback loops called **pressoreflexes** or *baroreflexes* that oppose changes in pressure by adjusting heart rate.

Carotid Sinus Reflex

The carotid sinus is a small dilation at the beginning of the internal carotid artery just above the branching of the common carotid artery to form the internal and external carotid arteries (see Figure 22-14).

The sinus lies just under the sternocleidomastoid muscle at the level of the upper margin of the thyroid cartilage. Sensory (afferent) fibers from carotid sinus baroreceptors (pressure sensors) run through the carotid sinus nerve (of Hering) and on through the glossopharyngeal (or ninth cranial) nerve. These nerves relay feedback information to an integrator area of the medulla called the *cardiac control center*. If the integrators in the cardiac control center detect an increase in blood pressure above the set point, then a correction signal is sent to the SA node by way of efferent parasympathetic fibers in the vagus (tenth cranial) nerve. Acetylcholine released by vagal fibers decreases the rate of SA node firing, thus decreasing the heart rate back toward the set point. The vagus is said to act as a "brake" on the heart—a situation called *vagal inhibition*. Figure 22-15 summarizes this negative feedback loop, which is often called the **carotid sinus reflex.**

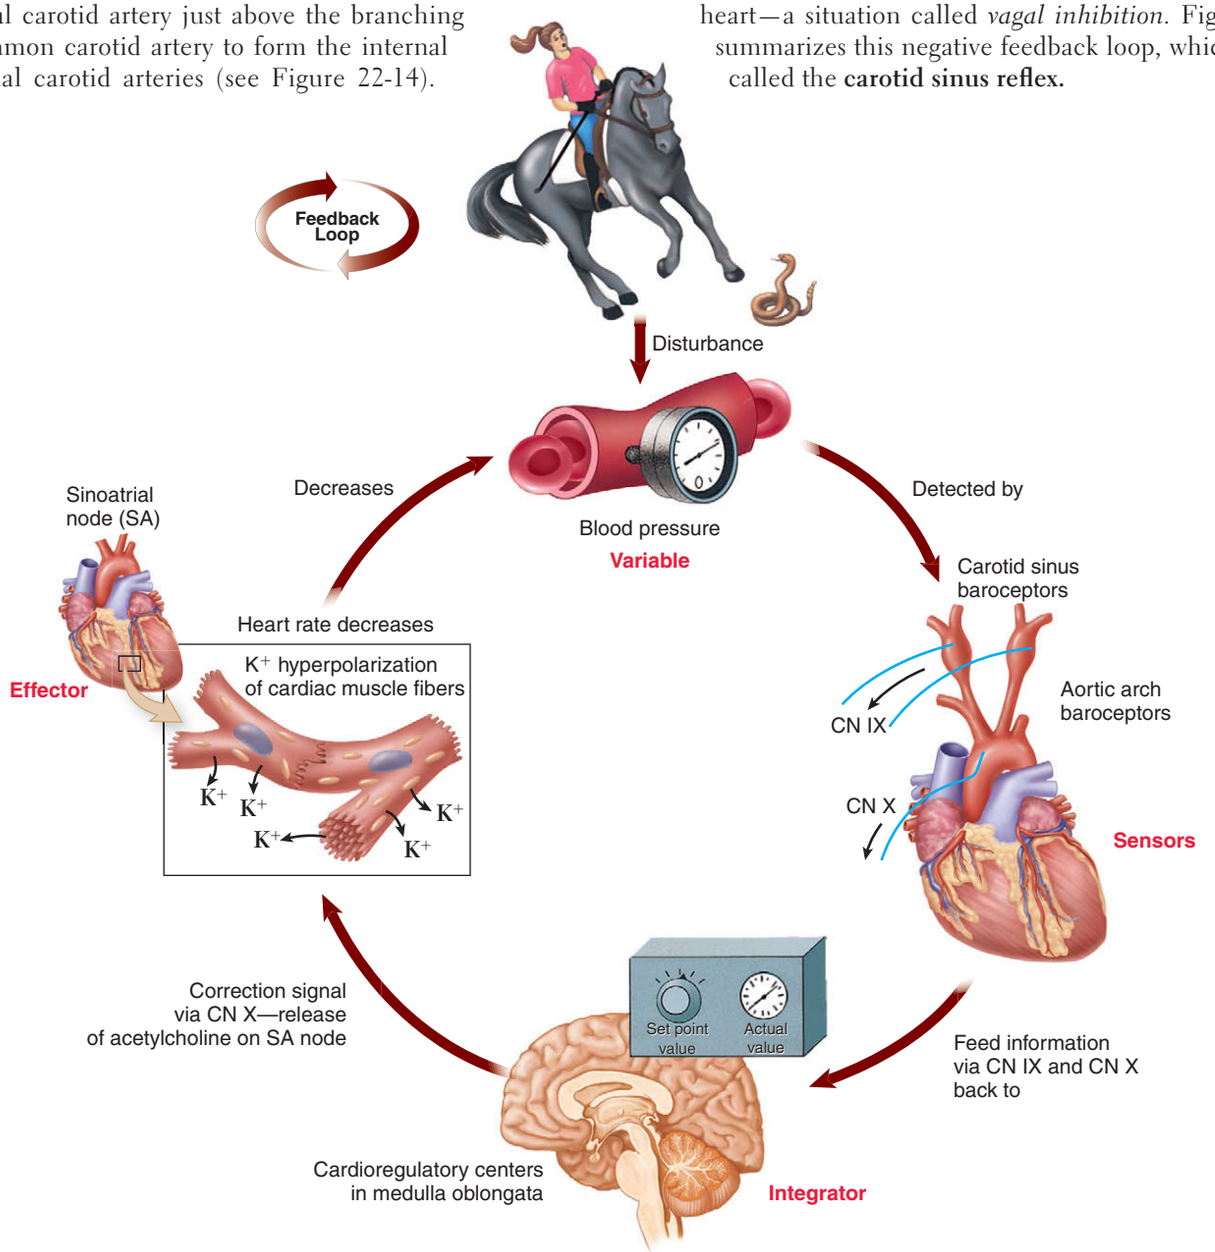

FIGURE 22-15

Aortic and carotid sinus pressoreflexes. These pressoreflexes operate in a feedback loop that maintains the homeostasis of blood pressure by decreasing the heart rate when the blood pressure surpasses the set point—as when recovering from a stress event after being startled.

Aortic Reflex

Sensory (afferent) nerve fibers also extend from baroreceptors located in the wall of the arch of the aorta through the aortic nerve and then through the vagus (tenth cranial) nerve to terminate in the cardiac control center of the medulla (see Figure 22-14).

If blood pressure within the aorta or carotid sinus suddenly increases beyond the set point, it stimulates the aortic or carotid baroreceptors, as shown in Figure 22-15. Stimulation of these stretch receptors causes the cardiac control center to increase vagal inhibition, thus slowing the heart and returning blood pressure back toward the normal set point. A decrease in aortic or carotid blood pressure usually allows some acceleration of the heart by way of correction signals through the cardiac nerve. Because it involves receptors located in the wall of the aorta, this feedback loop is called the **aortic reflex.**

More details of pressoreflex activity are included later in the chapter as part of a mechanism that tends to maintain or restore homeostasis of arterial blood pressure.

Other Reflexes That Influence Heart Rate

Reflexes involving important factors such as emotions, exercise, hormones, blood temperature, pain, and stimulation of various exteroceptors also influence heart rate. Anxiety, fear, and anger often make the heart beat faster. Grief, in contrast, tends to slow it. Emotions produce changes in the heart rate through the influence of impulses from the "higher centers" in the cerebrum by way of the hypothalamus. Such impulses can influence activity of the cardiac control centers.

During exercise the heart normally accelerates. The mechanism for this acceleration is not definitely known, but it is thought to include impulses from the cerebrum through the hypothalamus to the cardiac center. Epinephrine is the hormone most noted as a cardiac accelerator.

Increased blood temperature or stimulation of skin heat receptors tends to increase the heart rate, and decreased blood temperature or stimulation of skin cold receptors tends to slow it. Sudden, intense stimulation of pain receptors in visceral structures such as the gallbladder, ureters, or intestines can result in such slowing of the heart that fainting may result.

Reflexive increases in heart rate often result from an increase in sympathetic stimulation of the heart. Sympathetic impulses originate in the cardiac control center of the medulla and reach the heart by way of sympathetic fibers (contained in the middle, superior, and inferior cardiac nerves). Norepinephrine released as a result of sympathetic stimulation increases heart rate and strength of cardiac muscle contraction.

7. Relate stroke volume and heart rate to cardiac output.
8. If the amount of blood returned to the heart increases, what happens to the stroke volume? What principle explains this?
9. How does the body use a pressoreflex to counteract an abnormal increase in heart rate? An abnormal decrease in heart rate?

Peripheral Resistance

HOW RESISTANCE INFLUENCES BLOOD PRESSURE

Peripheral resistance means the resistance to blood flow imposed by the force of friction between blood and the walls of its vessels. Friction develops partly because of a characteristic of blood—its **viscosity,** or stickiness—and partly from the small diameter of arterioles and capillaries. The resistance offered by arterioles, in particular, accounts for almost one half of the total resistance in systemic circulation.

Peripheral resistance in arterioles helps determine arterial blood pressure because the more resistance there is in the arterioles, the more blood "backs up" in the arteries to increase fluid pressure. This mechanism can help maintain the pressure gradient needed to keep blood flowing (review again Figure 22-9 on p. 690). Think of what happens when you pinch off the end of a garden hose. The water backs up in the hose and the increased pressure gradient gives more force to the water flowing out of the hose.

Blood viscosity stems mainly from the proportion of red blood cells (hematocrit) but also partly from the protein molecules present in blood. An increase in either blood protein concentration or hematocrit tends to increase viscosity, and a decrease in either tends to decrease it (Figure 22-16). Under normal circumstances, blood viscosity changes very little. But under certain abnormal conditions, such as marked anemia or hemorrhage, a decrease in blood viscosity may be the crucial factor lowering peripheral resistance and arterial pressure, even to the point of circulatory failure.

The muscular coat of the arterioles allows them to constrict or dilate and thus change the amount of resistance to blood flow. This muscular mechanism in the vessels is called the **vasomotor mechanism.** Reduction in vessel diameter caused by increased contraction of the muscular coat, or **vasoconstriction,** increases

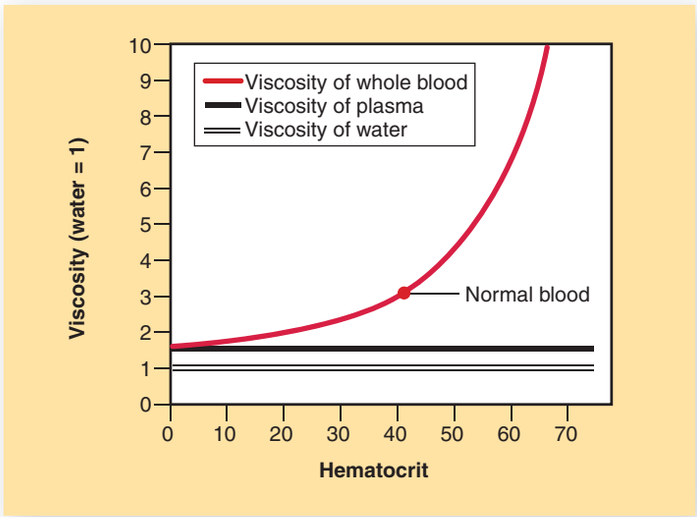

FIGURE 22-16

Blood viscosity. The effect of a changing hematocrit (% RBCs in blood) on blood viscosity is shown here. As hematocrit increases (horizontal axis of graph), the viscosity increases. Water is the reference value at viscosity = 1. Plasma is slightly more viscous than water—at approximately 1.5. As the total viscosity of blood increases, the resistance to blood flow increases.

resistance to blood flow, and thus blood flow into the tissue decreases. **Vasodilation,** the increase in vessel diameter caused by relaxation of vascular muscles, decreases resistance to blood flow, and thus blood flow into the tissue increases. As Figure 22-17 shows, small changes in diameter can cause proportionally large changes in resistance—and therefore large changes in local blood flow. This makes the vasomotor mechanism well suited for quickly and dramatically changing blood flow under varying conditions in the body, as we shall see.

Peripheral resistance helps determine arterial pressure by controlling the rate of "arteriole runoff," the amount of blood that runs out of the arteries into the arterioles (Figure 22-18). The greater the resistance, the less the arteriole runoff, or outflow, tends to be—and therefore the more blood left in the arteries, the higher the arterial pressure tends to be. This can occur locally, within a particular tissue or organ, or it can occur throughout the systemic loop when enough arterioles constrict and increase the **total peripheral resistance (TPR).**

VASOMOTOR CONTROL MECHANISM

Blood distribution patterns, as well as blood pressure, can be influenced by factors that control changes in the diameter of arterioles. Such factors might be said to constitute the vasomotor control mechanism. Like most physiological control mechanisms, it consists of many parts. An area in the medulla called the *vasomotor center*, or *vasoconstrictor center*, will, when stimulated, initiate an impulse outflow by way of sympathetic fibers that ends in the smooth muscle surrounding resistance vessels, arterioles, venules, and veins of the "blood reservoirs," causing their constriction. Thus the vasomotor control mechanism plays a role both in the maintenance of the general blood pressure and in the distribution of blood to areas of special need.

The main blood reservoirs are the venous plexuses and sinuses in the skin and abdominal organs (especially in the liver and spleen). In other words, blood reservoirs are the venous networks in most parts of the body—all but those in the skeletal muscles, heart, and brain. Figure 22-19 shows that the volume of blood in the systemic

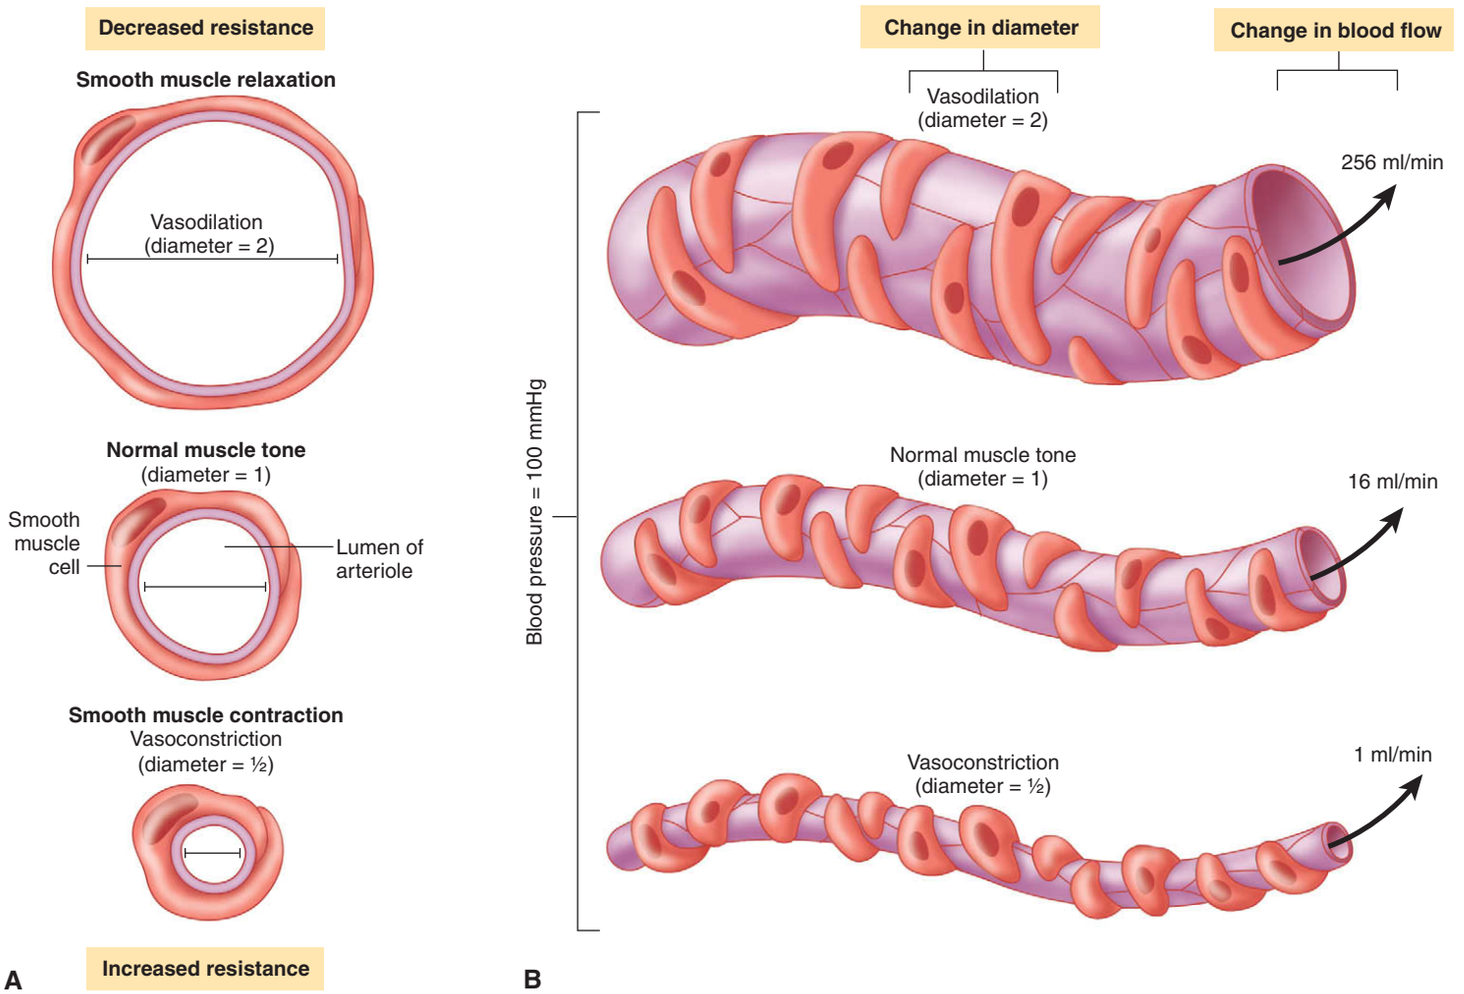

FIGURE 22-17

Vessel diameter. The effect of changing diameter of arterioles on peripheral resistance and blood flow. **A,** Cross sections of an arteriole showing vasodilation *(top),* normal diameter *(center),* and vasoconstriction *(bottom)* as tension in smooth muscle fibers changes. **B,** Diagram showing that relatively small changes from the normal diameter of an arteriole (normal = 1) cause very large changes in peripheral resistance to blood flow. For example, reducing diameter to one half of normal reduces blood flow to $^{1}/_{16}$ of normal. Likewise, doubling the vessel diameter does not double the blood flow—it increases blood flow 16 times the normal flow!

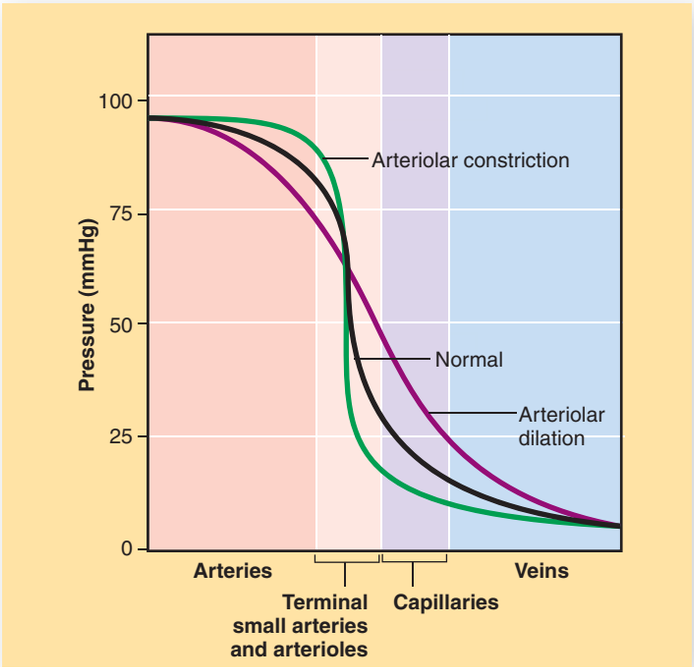

FIGURE 22-18

Vasomotor effects on blood pressure. The normal blood pressures in various vessels are shown by the black line. The green line shows a shift in blood pressures during vasoconstriction of the arterioles. Note that because there is more resistance in the arterioles, blood flow in the arteries backs up and thus increases arterial blood pressure. The purple line shows that vasodilation of the arterioles increases blood flow from the arteries and therefore reduces arterial blood pressure.

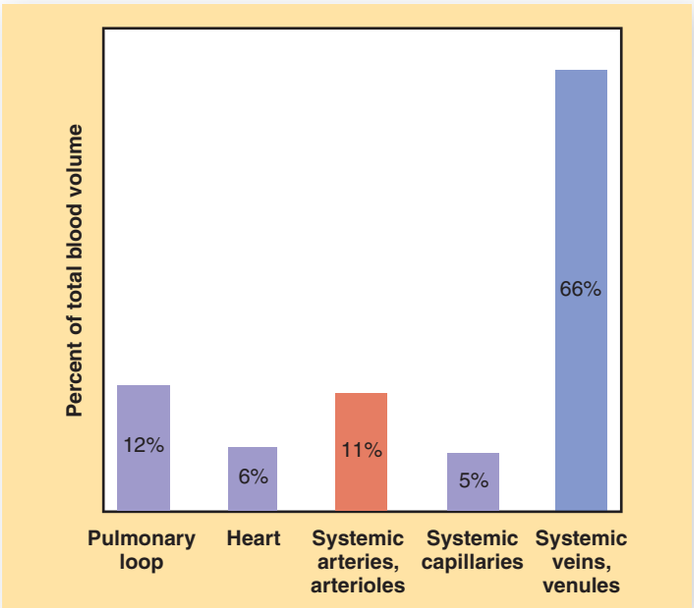

FIGURE 22-19

Relative blood volumes. The relative volumes of blood at rest in different parts of the adult cardiovascular system expressed as percentages of total blood volume. Note that at rest most of the body's blood supply is in the systemic veins and venules.

veins and venules in a resting adult is extremely large compared with the volume in other vessels of the body. The term *reservoir* is apt, because the systemic veins and venules serve as a kind of slowly moving stockpile or reserve of blood. Blood can quickly be moved out of blood reservoirs and "shifted" to arteries that supply heart and skeletal muscles when increased activity demands (Figure 22-20). A change in either arterial blood's oxygen or carbon dioxide content sets a chemical vasomotor control mechanism in operation. A change in arterial blood pressure initiates a **vasomotor pressoreflex.**

Vasomotor Pressoreflexes

A sudden increase in arterial blood pressure stimulates aortic and carotid baroreceptors—the same ones that initiate cardiac reflexes. Not only does this stimulate the cardiac control center to reduce heart rate (see Figure 22-15), but also it inhibits the vasoconstrictor center. More impulses per second go out over parasympathetic fibers to the heart. As a result, the heartbeat slows. Because sympathetic vasoconstrictor impulses predominate at normal arterial pressures, inhibition of these is considered the major mechanism

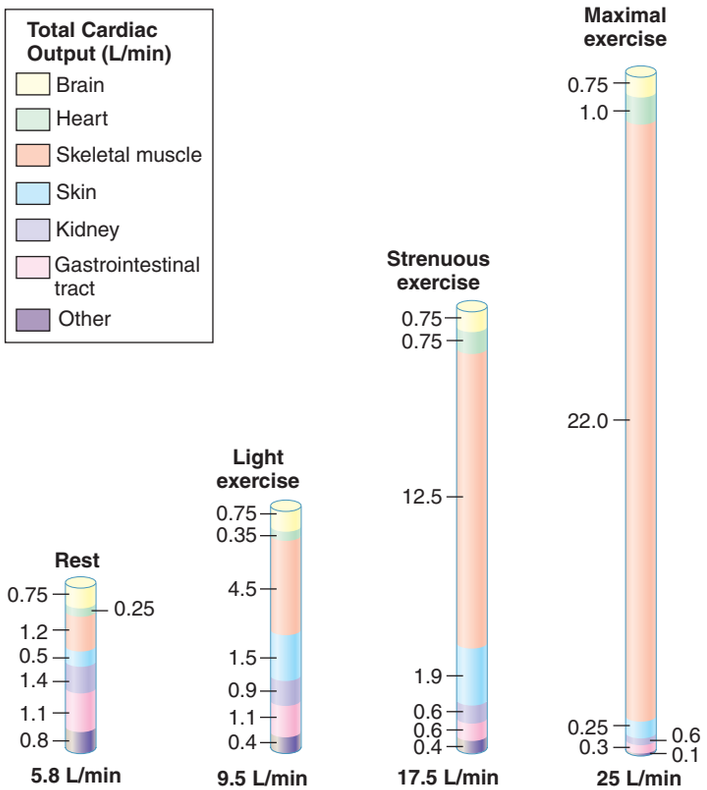

FIGURE 22-20

Changes in local blood flow during exercise. Graphic representation of blood flow (L/min) in an individual in various circumstances: at rest and during light, strenuous, and maximal exercise. During exercise, the vasomotor center of the medulla sends sympathetic signals to certain blood vessels to change diameter and thus shunt blood away from "maintenance" organs, such as the digestive organs in the abdomen, and toward the skeletal muscles. Local regulators of blood flow add to this effect. Note that blood flow in the brain is held constant. Note also that the total blood flow (cardiac output) in this individual increases from 5.8 L/min (rest) to 25 L/min—a fivefold increase in cardiac output—as the intensity of exercise increases.

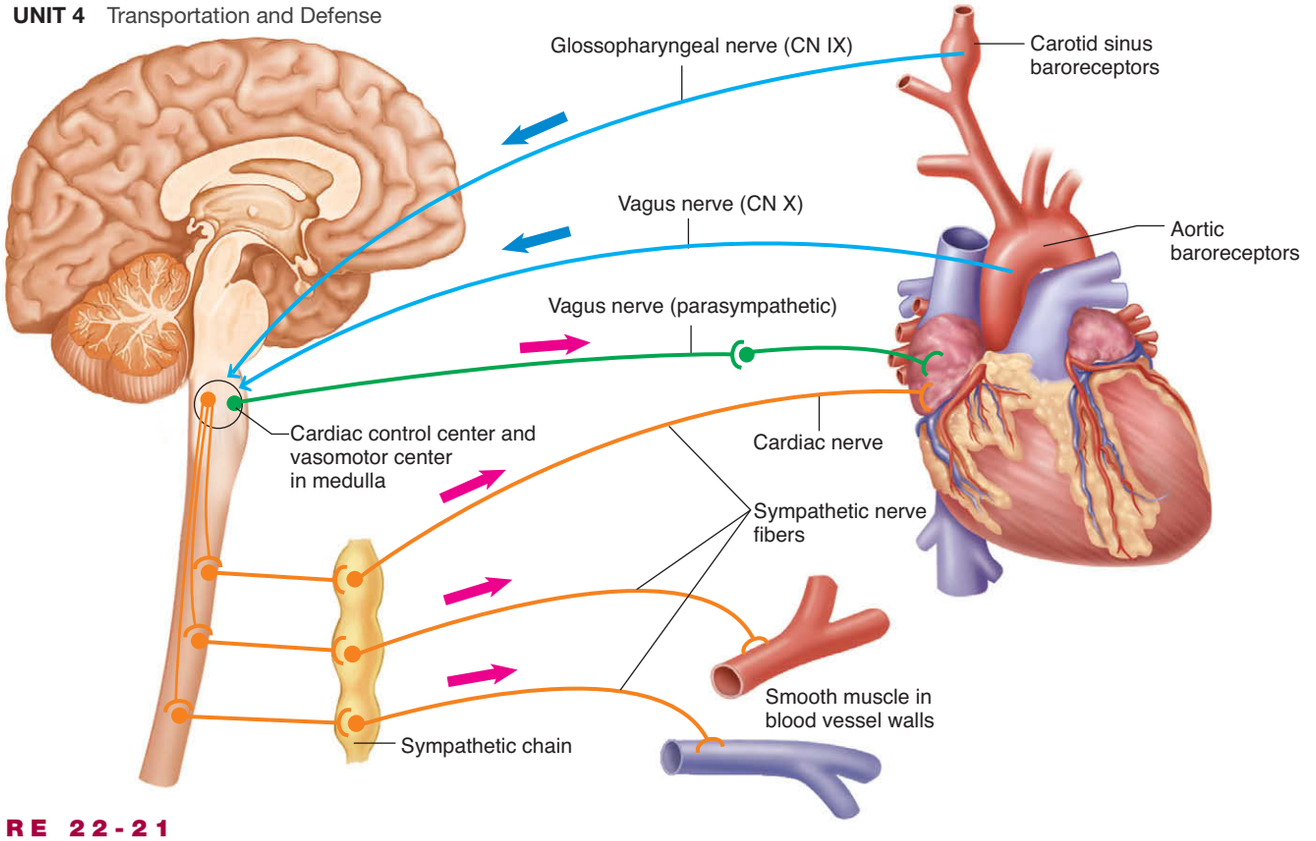

FIGURE 22-21

Vasomotor pressoreflexes. Carotid sinus and aortic baroreceptors detect changes in blood pressure and feed the information back to the cardiac control center and the vasomotor center in the medulla. In response, these control centers alter the ratio between sympathetic and parasympathetic output. If the pressure is too high, increased parasympathetic impulses and reduced sympathetic impulses will reduce it by slowing heart rate, reducing stroke volume, and dilating blood "reservoir" vessels. If the pressure is too low, an increase in sympathetic impulses will increase it by increasing heart rate and stroke volume and constricting arterioles and reservoir vessels.

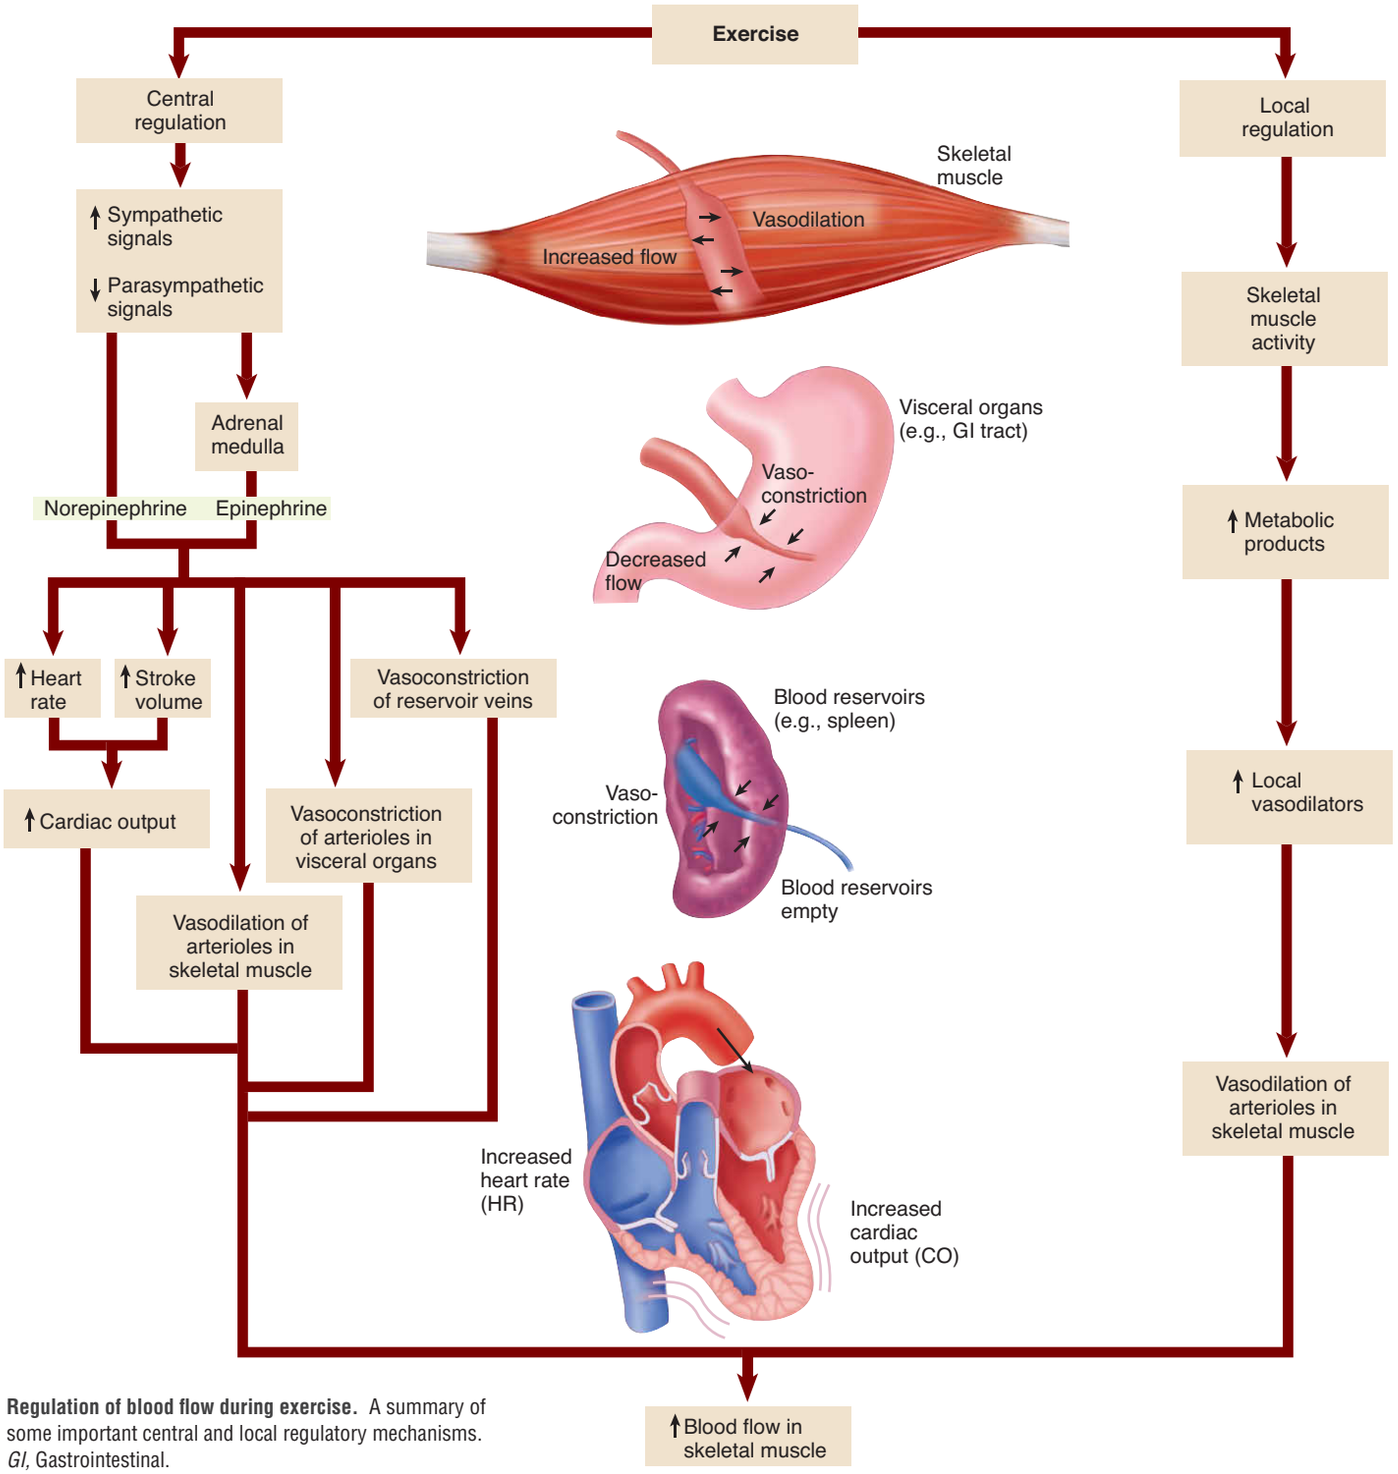
of vasodilation. The nervous pathways involved in this mechanism are illustrated in Figure 22-21.

A decrease in arterial pressure causes the aortic and carotid baroreceptors to send more impulses to the medulla's vasoconstrictor centers, thereby stimulating them. These centers then send more impulses by way of the sympathetic fibers to stimulate vascular smooth muscle and cause vasoconstriction. When arterioles constrict, it "backs up" arterial blood and increases aterial blood pressure. Vasoconstriction also squeezes more blood out of the blood reservoirs, increasing the amount of venous blood return to the heart.

During exercise, blood from reservoirs is redistributed to more active structures such as skeletal muscles and heart because their arterioles become dilated largely from the operation of a local mechanism (discussed later). Thus the vasoconstrictor pressoreflex and the local vasodilating mechanism together serve as an important device for shifting blood from reservoirs to tissues that need it during exercise (see Figure 22-20 and Box 22-1).

Box 22-1 | SPORTS and FITNESS

The Cardiovascular System and Exercise



Exercise produces short-term and long-term changes in the cardiovascular system.

Short-term changes involve negative feedback mechanisms that maintain set point levels of blood oxygen and glucose, as well as other physiological variables. Because moderate to strenuous use of skeletal muscles greatly increases the body's overall rate of metabolism, oxygen and glucose are used up at a faster rate. This requires an increase in transport of oxygen and glucose by the cardiovascular system to maintain normal set point levels of these substances. One response by the cardiovascular system is to increase the cardiac output (CO) from 5 to 6 L/min at rest to up to 30 to 40 L/min during strenuous exercise. This represents a fivefold to eightfold increase in the blood output of the heart! Such an increase is accomplished by a reflexive increase in heart rate (see Figure 22-15) coupled with an increase in stroke volume (see Figures 22-12 and 22-13). Exercise can also trigger a reflexive change in local distribution of blood flow to various tissues, shown in Figure 22-20, that results in a larger share of blood flow going to the skeletal muscles than to some other tissues. A number of central and local regulatory effects that operate during exercise are summarized in the figure.

Long-term changes in the cardiovascular system come only when moderate to strenuous exercise occurs regularly over a long period.

Box 22-1 | SPORTS and FITNESS

Evidence indicates that 20 to 30 minutes of moderate aerobic exercise such as cycling or running three times per week produces profound, health-promoting changes in the cardiovascular system. Among these long-term cardiovascular changes are an increase in the mass and contractility of the myocardial tissue, an increase in the number of capillaries in the myocardium, a lower resting heart rate, and decreased peripheral resistance during rest. The lower resting heart rate coupled with the increase in stroke volume possible with increased myocardial mass and contractility produce a greater range of CO, and coupled with the other listed effects, a greater maximum CO. Exercise is also known to decrease the risk of various cardiovascular disorders, including arteriosclerosis, hypertension, and heart failure.

Regulation of blood flow during exercise. A summary of some important central and local regulatory mechanisms. *GI,* Gastrointestinal.

Vasomotor Chemoreflexes

Chemoreceptors located in the aortic and carotid bodies are particularly sensitive to excess blood carbon dioxide (**hypercapnia**) and somewhat less sensitive to a deficiency of blood oxygen (**hypoxia**) and to decreased arterial blood pH. When one or more of these conditions stimulates the chemoreceptors, their fibers transmit more impulses to the medulla's vasoconstrictor centers, and vasoconstriction of arterioles and venous reservoirs soon follows (Figure 22-22). This **chemoreceptor reflex** functions as an emergency mechanism when hypoxia or hypercapnia endangers the stability of the internal environment.

Medullary Ischemic Reflex

The **medullary ischemic reflex** mechanism is said to exert powerful control of blood vessels during emergency situations when blood flow to the brain drops below normal. When the blood supply to the medulla becomes inadequate (**ischemic**), its neurons suffer from both oxygen deficiency and carbon dioxide excess. But, presumably, it is hypercapnia that intensely and directly stimulates the vasoconstrictor centers to bring about marked arteriole and venous constriction (see Figure 22-22). If the oxygen supply to the medulla decreases below a certain level, its neurons, of course, cannot function, and the medullary ischemic reflex cannot operate.

Vasomotor Control by Higher Brain Centers

Impulses from centers in the cerebral cortex and in the hypothalamus are believed to be transmitted to the vasomotor centers in the medulla and to thereby help control vasoconstriction and dilation. Evidence supporting this view is that vasoconstriction and a rise in arterial blood pressure characteristically accompany emotions of intense fear or anger. Also, laboratory experiments on animals in which stimulation of the posterior or lateral parts of the hypothalamus leads to vasoconstriction support the belief that higher brain centers influence the vasomotor centers in the medulla.

LOCAL CONTROL OF ARTERIOLES

Several kinds of local mechanisms operate to produce vasodilation in localized areas. Although not all these mechanisms are clearly understood, they are known to function in times of increased tissue activity. For example, they probably account for the increased blood flow into skeletal muscles during exercise. They also operate in ischemic tissues, serving as a homeostatic mechanism that tends to restore normal blood flow. Some locally produced substances, such as nitric oxide, activate the local vasodilator mechanism, whereas others, such as *endothelin*, constrict the arterioles. Local vasodilation is also referred to as *active hyperemia*.

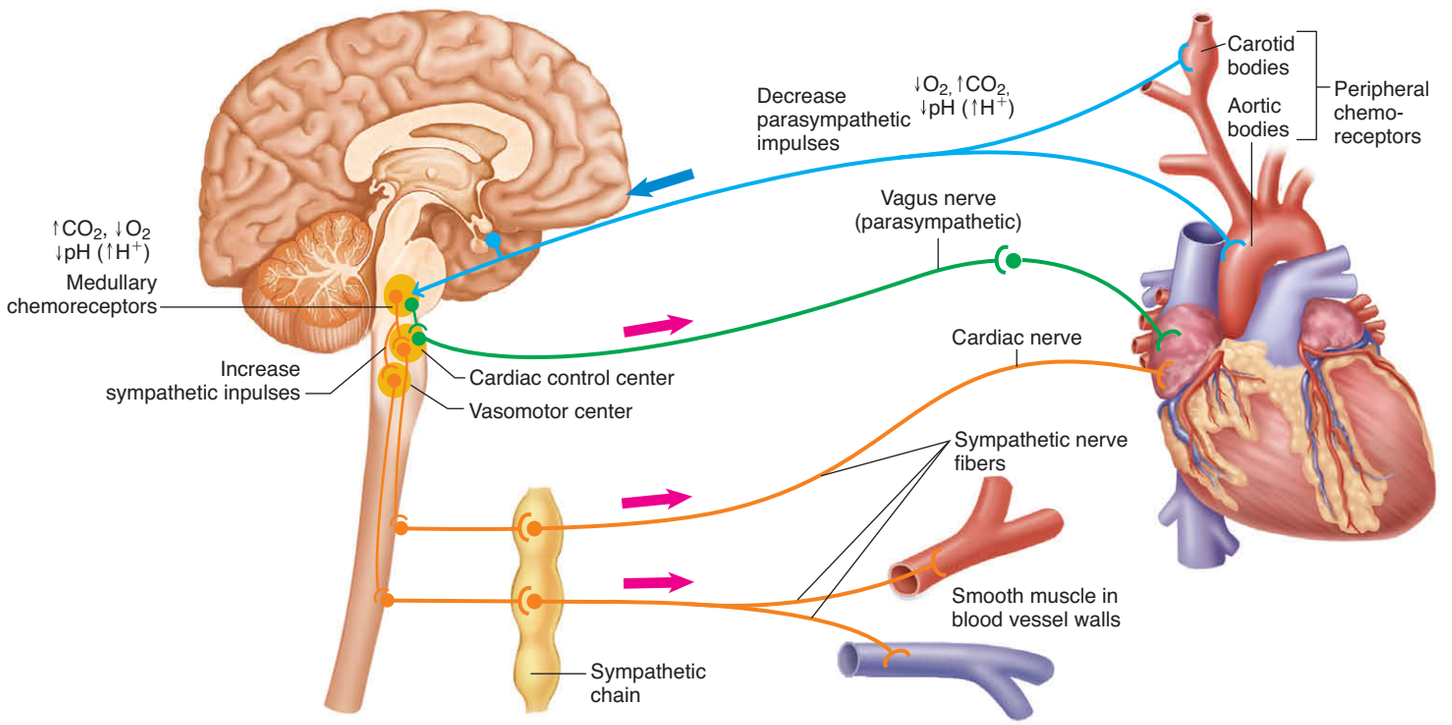


FIGURE 22-22

Vasomotor chemoreflexes. Chemoreceptors in the carotid and aortic bodies, as well as chemoreceptive neurons in the vasomotor center of the medulla itself, detect increases in carbon dioxide (CO_2), decreases in blood oxygen (O_2), and/or decreases in pH (which is really an increase in H^+). This information feeds back to the cardiac control center and the vasomotor control center of the medulla, which in turn alter the ratio of parasympathetic and sympathetic output. When O_2 drops, CO_2 increases, and/or pH drops, a dominance of sympathetic impulses increases heart rate and stroke volume and constricts reservoir vessels in response.

11. If the diameter of the arteries decreases, what effect does it have on peripheral resistance?
12. In general, how do vasomotor pressoreflexes affect the flow of blood?
13. What is a chemoreflex? How do chemoreflexes affect the flow of blood?

VENOUS RETURN TO THE HEART

Venous return refers to the amount of blood that is returned to the heart by way of the veins. Various factors influence venous return, including the reservoir function of veins, which occurs whenever blood pressure drops and the elasticity of the venous walls adapts the diameter of veins to the lower pressure, thus maintaining blood flow and venous return to the heart. Likewise, when overall blood pressure rises, the elastic nature of blood vessels allows them to expand and adapt to the higher pressure to maintain normal blood flow. This effect, which occurs in all blood vessels to some degree (with certain limitations to its adaptability), is often called the **stress-relaxation effect.**

Another factor that influences venous return is gravity. Figure 22-23 shows that when a person is reclining, the force of gravity is not pulling blood downward toward the legs. However, when a person is sitting or standing, the blood *is* pulled by gravity toward the legs. Because the venous blood is already at a low blood pressure and because the venous walls are compliant (easily stretched), it is easy for the force of gravity to work against venous return back to the heart and cause some blood to remain in the veins of the limbs. The shift of the blood reservoir to the veins in the legs when standing is often called the **orthostatic effect** because *orthostasis* means "standing upright."

A factor that can help to overcome the influence of gravity is the operation of **venous pumps** that maintain the pressure gradients necessary to keep blood moving into the central veins (e.g., venae cavae) and from there into the atria of the heart. Changes in the total volume of blood in the vessels can also alter venous return. Venous return and total blood volume are discussed in the paragraphs that follow.

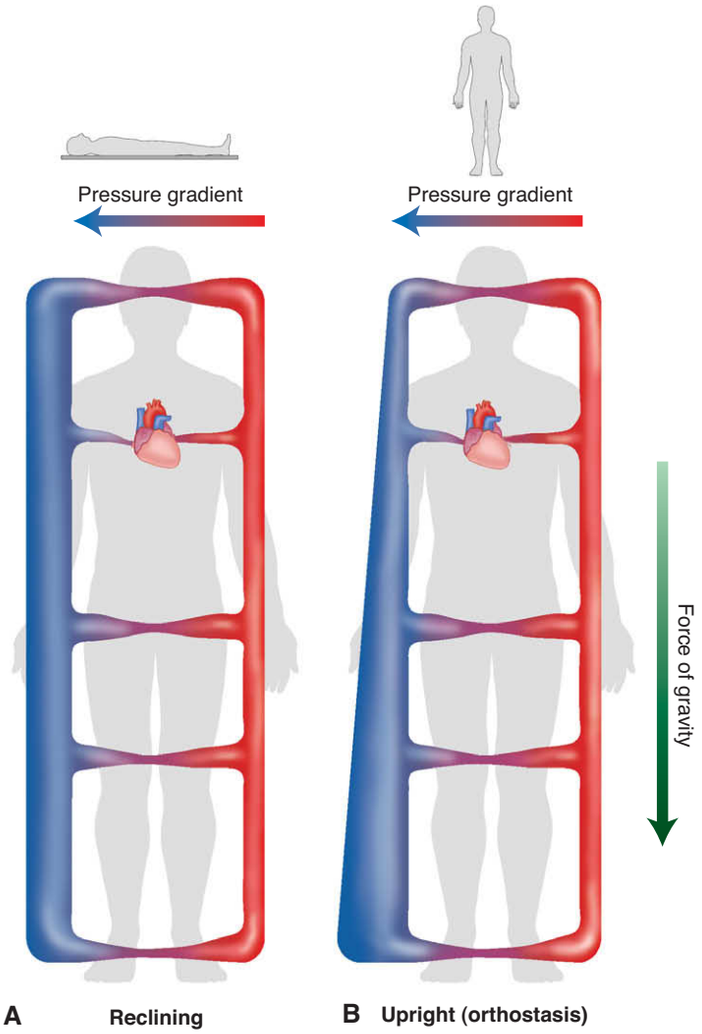

FIGURE 22-23

Influence of gravity on blood distribution in veins. A, When a person is lying flat, the pull of gravity is equal above and below the heart. **B,** When a person stands upright (orthostasis), the pull of gravity combined with the compliance (ease of stretch) of the veins causes a redistribution of venous blood to the lower limbs. This *orthostatic effect* can reduce venous return to the heart if not counteracted by other forces.

Venous Pumps

One important factor that promotes the return of venous blood to the heart is the blood-pumping action of respirations and skeletal muscle contractions. Both actions produce their facilitating effect on venous return by increasing the pressure gradient between the peripheral veins and the venae cavae (central veins).

The process of inspiration increases the pressure gradient between peripheral and central veins by decreasing central venous pressure and also by increasing peripheral venous pressure. Each time the diaphragm contracts, the thoracic cavity necessarily becomes larger and the abdominal cavity smaller. Therefore the pressures in the thoracic cavity, in the thoracic portion of the vena cava, and in the atria decrease, and those in the abdominal cavity and the abdominal veins increase. As Figure 22-24, A, shows, this change in pressure between expiration and inspiration acts as a "respiratory pump" that moves blood along the venous route.

Deeper respirations intensify these effects and therefore tend to increase venous return to the heart more than normal respirations. This is part of the reason the principle is true—increased respirations and increased circulation tend to go hand in hand.

Skeletal muscle contractions serve as "booster pumps" for the heart. The skeletal muscle pump promotes venous return in

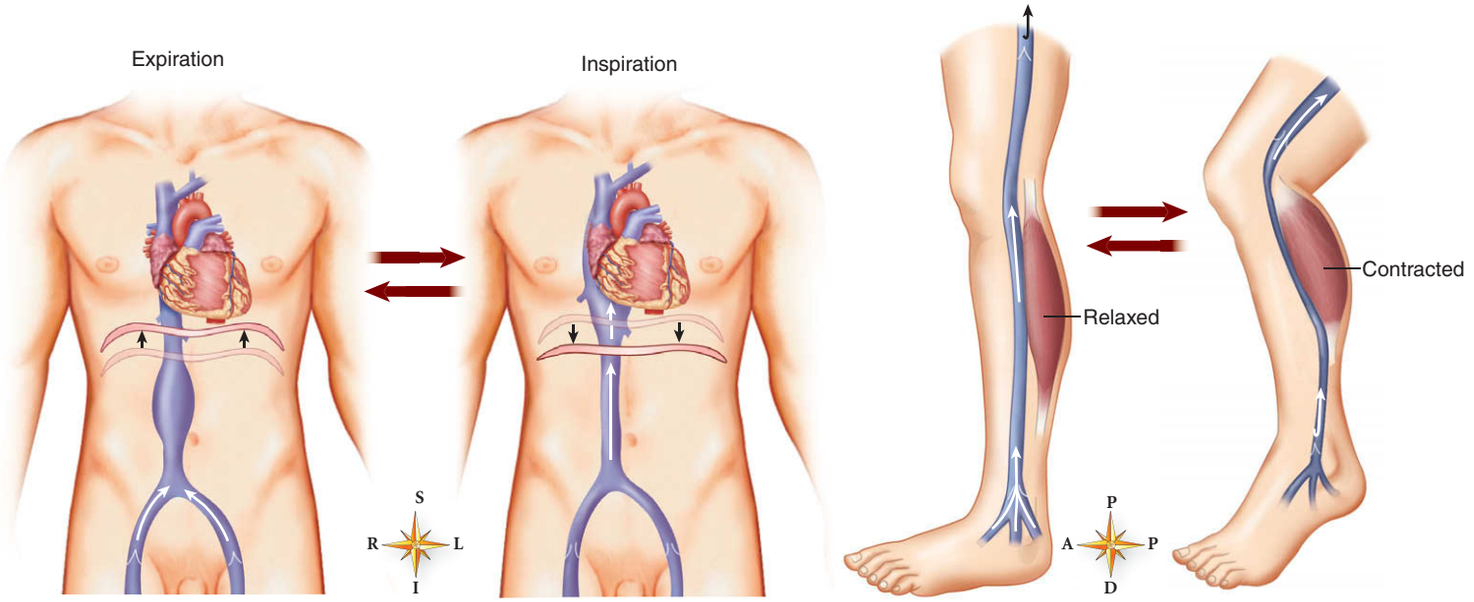

FIGURE 22-24

Venous pumping mechanisms. A, The respiratory pump operates by alternately increasing pressure in the thorax during expiration (thus pushing central venous blood into the heart) and decreasing thoracic pressure during inspiration (thus pulling venous blood into the central veins). **B,** The skeletal muscle pump operates by the alternate increase and decrease in peripheral venous pressure that normally occurs when the skeletal muscles are used for the activities of daily living. Both pumping mechanisms rely on the presence of one-way valves in the veins to prevent backflow during the low-pressure points in the pumping cycle (see Figure 22-25).

the following way. As each skeletal muscle contracts, it squeezes the soft veins scattered through its interior, thereby "milking" the blood in them upward, or toward the heart (Figure 22-24, *B*). The closing of the one-way valves present in veins prevents blood from falling back as the muscle relaxes. Their flaps catch the blood as gravity pulls backward on it (Figure 22-25). The net effect of skeletal muscle contraction plus venous valvular action therefore is to move venous blood toward the heart, to increase the venous return.

The value of skeletal muscle contractions in moving blood through veins is illustrated by a common experience. Who has not noticed how much more uncomfortable and tiring standing still is than walking? After several minutes of standing quietly, the feet and legs feel "full" and swollen. Blood has accumulated in the veins because the skeletal muscles are not contracting and squeezing it upward. The repeated contractions of the muscles when walking naturally in comfortable shoes, on the other hand, keep the blood moving in the veins and prevent the discomfort of distended veins.

Total Blood Volume

The return of venous blood to the heart can be influenced by factors that change the total volume of blood in the closed circulatory pathway. Stated simply, the more the total volume of blood, the greater the volume of blood returned to the heart. What mechanisms can increase or decrease the total volume of

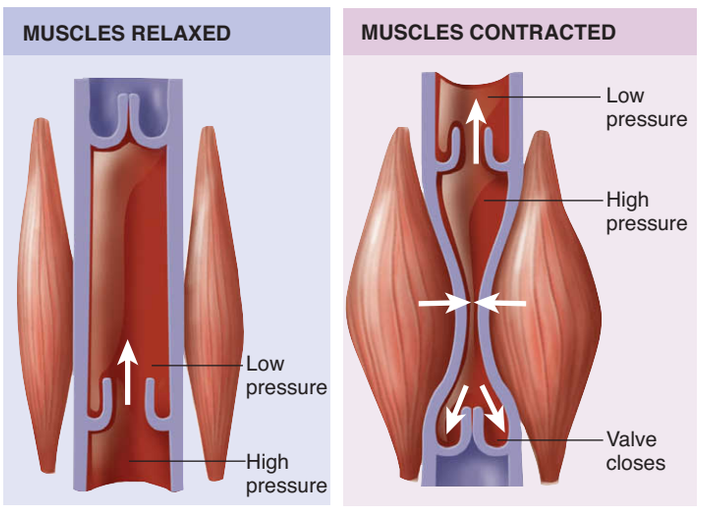

FIGURE 22-25

Venous valves. In veins, one-way valves aid circulation by preventing backflow of venous blood when pressure in a local area is low. **A,** Local high blood pressure pushes the flaps of the valve to the side of the vessel, allowing easy flow. **B,** When pressure below the valve drops, blood begins to flow backward but fills the "pockets" formed by the valve flaps, pushing the flaps together and thus blocking further backward flow.

blood? The mechanisms that change total blood volume most quickly, making them most useful in maintaining constancy of blood flow, are those that cause water to quickly move into the plasma (increasing total blood volume) or out of the plasma (decreasing total blood volume). Most mechanisms that accomplish such changes in plasma volume operate by altering the body's retention of water.

CAPILLARY EXCHANGE AND TOTAL BLOOD VOLUME

We begin our discussion of fluid movement into and out of the blood plasma with a brief overview of **capillary exchange**—the exchange of materials between plasma in the capillaries and the surrounding interstitial fluid of the systemic tissues.

According to a principle first proposed by Ernest Starling, several factors govern the movement of fluid (and solutes contained in the fluid) back and forth across a capillary wall—a principle now known as **Starling's law of the capillaries.** These factors, illustrated in Figure 22-26, include inwardly directed forces and outwardly directed forces. It is the balance between these forces that determines whether fluids will move into or out of the plasma at any particular point.

One type of force, osmotic pressure, tends to promote diffusion of fluid into the plasma. Osmotic pressure generated by blood colloids (large solute particles such as plasma proteins) in the plasma that cannot cross the vessel wall tends to draw water osmotically into the plasma. At the arterial end of a capillary (and in some thin-walled arterioles) the potential osmotic pressure is small and thus generates only a small, inwardly directed force. However, a much larger, outwardly directed force is operating at the arterial end of a capillary, namely, a hydrostatic pressure gradient. Recall from Chapter 4 that hydrostatic pressure gradients promote filtration across a barrier with filtration pores, such as the capillary wall. At the arterial end of a capillary, the blood pressure in the vessel is much greater than the hydrostatic pressure of the interstitial fluid (IF), thus generating a very large, outwardly directed force. In short, the stronger, outwardly directed forces at the arterial end of a capillary drive fluids out of the blood vessel and into the surrounding IF—producing a net loss of blood volume.

At the venous end of the capillary, however, the loss of water has increased the blood colloid osmotic pressure—promoting osmosis of water back into the plasma. This inwardly directed force is much larger than the hydrostatic pressure gradient, which has dissipated somewhat with the loss of water at the arterial end of the vessel. In short, the capillary recovers much of the fluid it lost—recovering some of the previously lost blood volume.

If you look carefully at Figure 22-26, A, you will notice that about 10% of the fluid lost at the arterial end of a capillary is not recovered by the forces operating in Starling's law of the capillaries. Does that mean that there is a constant loss of blood volume? No. Notice that the 10% fluid loss is recovered by the lymphatic system and returned to the venous blood before it reaches the heart. Details of how the lymphatic system accomplishes this fluid recovery are discussed in the next chapter. For now, we will simply state that if the lymphatic system operates normally and the

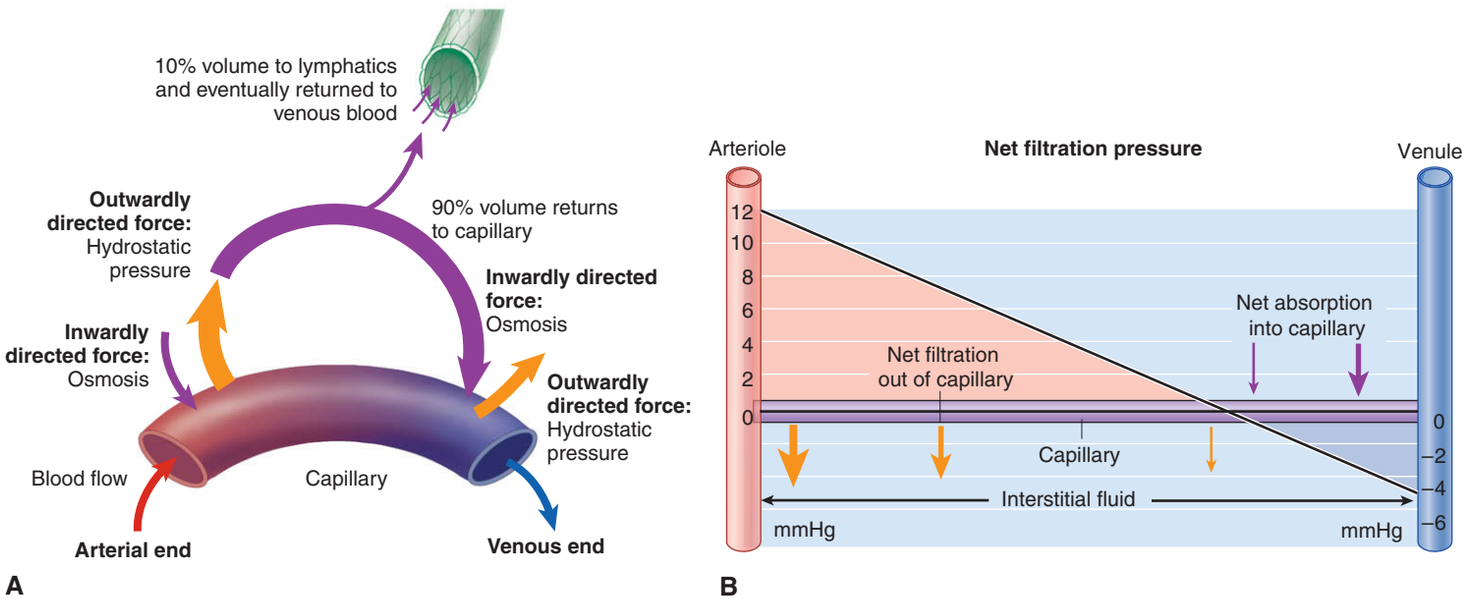

FIGURE 22-26

Starling's law of the capillaries. A, At the arterial end of a capillary the outward driving force of blood pressure (hydrostatic pressure of blood) is larger than the inwardly directed force of osmosis—thus fluid moves out of the vessel. At the venous end of a capillary the inward driving force of osmosis is greater than the outwardly directed force of hydrostatic pressure—thus fluid enters the vessel. About 90% of the fluid leaving the capillary at the arterial end is recovered by the blood before it leaves the venous end. The remaining 10% is recovered by the venous blood eventually, by way of the lymphatic vessels (see Chapter 23). **B,** Graph showing the shift in net filtration force along the length of a capillary, according to Starling's law of the capillaries. At the arterial end, net movement of fluid is *out of* the capillary; at the venous end, net movement of fluid shifts *into* the capillary.

osmotic and hydrostatic pressure gradients remain relatively constant, there is no net loss of blood volume resulting from capillary exchange. If any of these factors change, however, fluid retention by the blood will be affected.

CHANGES IN TOTAL BLOOD VOLUME

You have already studied the primary mechanisms for altering water retention in the body—they are the endocrine reflexes previewed in Chapter 19.

ADH Mechanism

One endocrine reflex that regulates total blood volume is the *ADH mechanism.* Recall that ADH (antidiuretic hormone) is released by the neurohypophysis (posterior pituitary) and acts on the kidneys in a way that reduces the amount of water lost by the body. ADH does this by increasing the amount of water that the kidneys reabsorb from urine before the urine is excreted from the body. The more ADH is secreted, the more water will be reabsorbed into the blood from the urine, and the greater the blood plasma volume will become. The ADH mechanism can be triggered by various factors, such as input from baroreceptors and input from osmoreceptors (which detect the balance between water and solutes in the internal environment).

Renin-angiotensin-aldosterone System (RAAS)

Another mechanism that changes blood plasma volume is the *renin-angiotensin mechanism* of aldosterone secretion—the **renin-angiotensin-aldosterone system, RAAS.** You may want to turn back to Figure 19-19 (p. 579) to see that the enzyme renin is released when blood pressure in the kidney is low. Renin triggers a series of events that leads to the secretion of aldosterone, a hormone of the adrenal cortex. Aldosterone promotes sodium retention by the kidney, which in turn stimulates the osmotic flow of water from kidney tubules back into the blood plasma—but only when ADH is present to permit the movement of water. Thus low blood pressure increases the secretion of aldosterone, which in turn stimulates retention of water and thus an increase in blood volume.

Another effect of the renin-angiotensin mechanism is the vasoconstriction of blood vessels caused by an intermediate compound called *angiotensin II.* This complements the volume-increasing effects of the mechanism and thus also promotes an increase in overall blood flow. Because ACE (angiotensin-converting enzyme) regulates the amount of available angiotensin II, drugs that act as ACE inhibitors can reduce angiotensin II and thus block vasoconstriction—an effect that is useful in reducing abnormally high blood pressure (hypertension).

ANH Mechanism

Yet another mechanism that can change blood plasma volume and thus venous return of blood to the heart is the *ANH mechanism.* Recall that ANH (atrial natriuretic hormone) is secreted by specialized cells in the atrial wall in response to overstretching. Overstretching of the atrial wall, of course, occurs when venous return to the heart is abnormally high. ANH adjusts venous return back down to its set point value by promoting the loss of water from the plasma and the resulting decrease in blood volume. ANH accomplishes this feat by increasing urine sodium loss, which causes water to follow osmotically. Sodium loss also inhibits the secretion of ADH. ANH may also have other complementary effects, such as promoting vasodilation of blood reservoirs.

Balance of Regulation

Thus various mechanisms influence blood volume and therefore venous return. These primary mechanisms are summarized in Figure 22-27. The ANH mechanism opposes ADH, renin-angiotensin, and aldosterone mechanisms to produce a balanced, precise control of blood volume. Precision of blood volume control contributes to precision in controlling venous return, which in turn contributes to precision in the overall control of blood circulation.

In summary, many different factors help regulate blood pressure and therefore regulate blood flow. Figure 22-28 summarizes some of the rapidly acting, intermediate, and long-term responses that can return blood pressure and blood flow back to normal after a sudden change. Most of these responses have been discussed in this chapter and Chapter 21, but some will be explored further in later chapters.

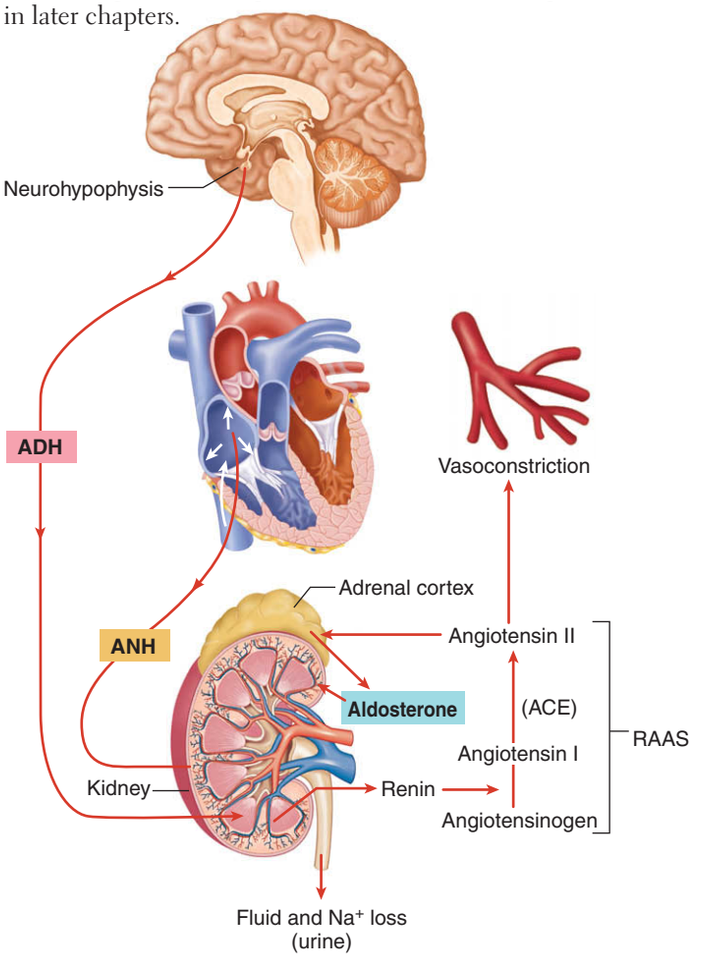

FIGURE 22-27

Three mechanisms that influence total plasma volume. The antidiuretic hormone (ADH) mechanism and renin-angiotensin-aldosterone system (RAAS) tend to increase water retention and thus increase total plasma volume. The atrial natriuretic hormone (ANH) mechanism antagonizes these mechanisms by promoting water loss and thus promoting a decrease in total plasma volume. *ACE,* Angiotensinogen-converting enzyme.

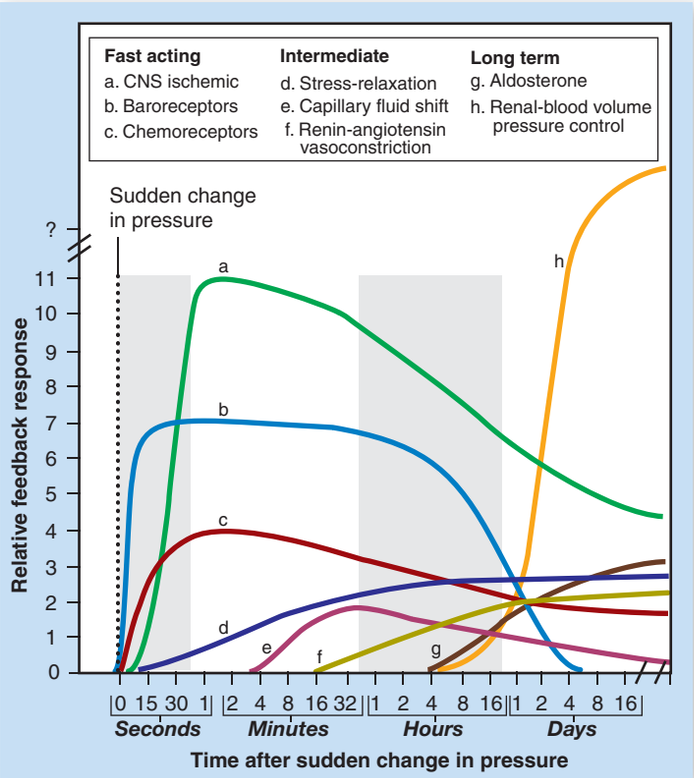

FIGURE 22-28

Feedback responses of various arterial pressure mechanisms. This composite graph shows the relative regulatory shifts that can be carried out by different regulatory mechanisms in response to a sudden shift in blood pressure—all with the outcome of moving arterial blood pressure back to its set point value. Note that some responses have their maximum effect within a few seconds or minutes. Other responses take longer to reach their maximum effect. *CNS,* Central nervous system.

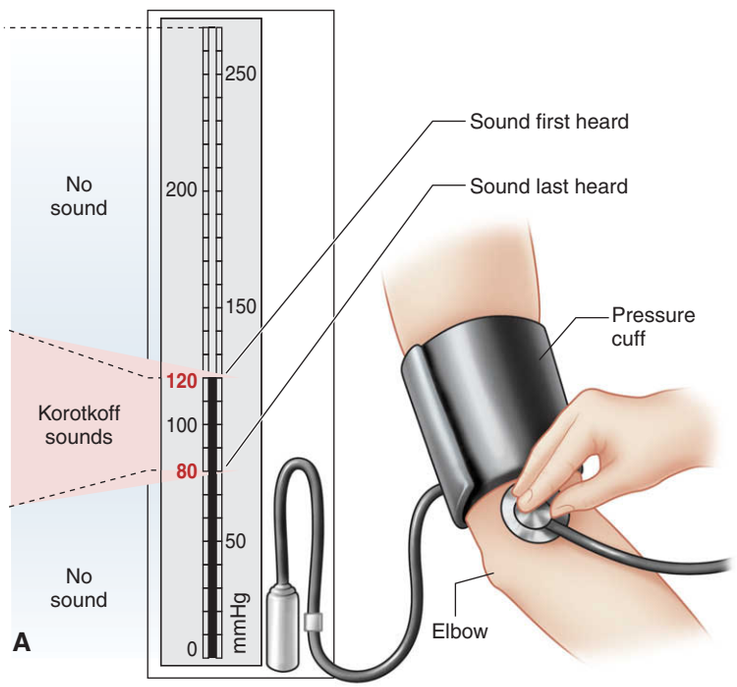
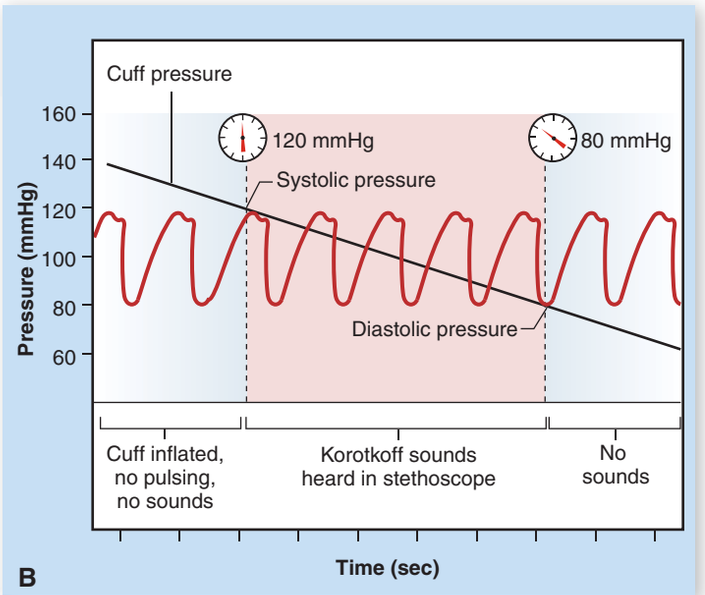
MEASURING BLOOD PRESSURE



Arterial Blood Pressure



Blood pressure is measured with the aid of an apparatus known as a **sphygmomanometer,** which makes it possible to measure the amount of air pressure equal to the blood pressure in an artery. The measurement is made in terms of how many millimeters (mm) high the air pressure raises a column of mercury (Hg) in a glass tube.

Sphygmomanometers originally consisted of a rubber cuff attached by a rubber tube to a compressible bulb and by another tube to a column of mercury that was marked off in millimeters (Figure 22-29). Pressure in the cuff and rubber tube pushes the

FIGURE 22-29

Sphygmomanometer. This mercury-filled pressure sensor is used in clinical and research settings to quickly and accurately measure arterial blood pressure. **A,** The pressure cuff is pumped with air until the pressure inside the cuff exceeds the expected systolic pressure of the large arteries of the arm. No sound caused by pulsing of blood in the arteries can then be heard with a stethoscope. As the pressure inside the cuff is slowly released from a valve, the air pressure equals the maximum pressure of the pulse waves in the artery—thus the pulsing sounds can then be heard. **B,** The sounds of pulsing (Korotkoff sounds) continue as long as the cuff pressure is equal to pressures of the pulse wave. The sounds disappear at the point that cuff pressure drops below the minimum pulse pressure in the arteries.

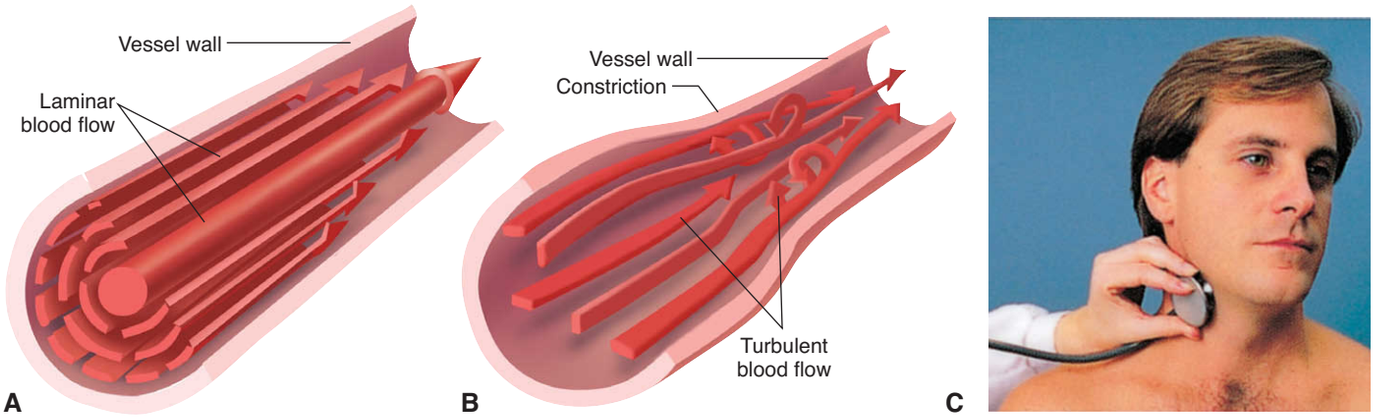
column of mercury to a new height. Therefore, pressure can be expressed as *millimeters of mercury (mmHg)*. Because of the hazardous nature of mercury, many sphygmomanometers in use today have mercury-free mechanical or electronic pressure sensors that are calibrated to the mercury scale.

The cuff of the sphygmomanometer is wrapped around the arm over the brachial artery, and air is pumped into the cuff by means of the bulb. In this way, air pressure is exerted against the outside of the artery. Air is added until the air pressure exceeds the blood pressure within the artery or, in other words, until it compresses the artery. At this time, no pulse can be heard through a stethoscope placed over the brachial artery at the bend of the elbow along the inner margin of the biceps muscle.

By slowly releasing the air in the cuff, the air pressure is decreased until it approximately equals the blood pressure within the artery. At this point, the vessel opens slightly and a small spurt of blood comes through, producing sharp "tapping" sounds. This is followed by increasingly louder sounds that change suddenly. They become more muffled, then disappear altogether. These sounds are called *Korotkoff sounds* (Box 22-2). Health professionals train themselves to hear these different sounds and simultaneously read the column of mercury, because the first tapping sound appears when the column of mercury indicates the **systolic blood pressure.** Systolic pressure is the force with which the blood is pushing against the artery walls at its highest pressure—during the ejection phase of the cardiac cycle when the ventricles are contracting. The lowest point at which the sounds can be heard, just before they disappear, is approximately equal to the **diastolic blood pressure,** or the force of the blood against the arterial walls when the ventricles are relaxed. Diastolic pressure is observed at the end of ventricular relaxation,

Box 22-2 | DIAGNOSTIC study

Focus on Turbulent Blood Flow



Understanding the mechanics of fluid flow through blood vessels facilitates comprehension of the bigger picture of hemodynamics.

Normally, blood flows through vessels with smooth walls that taper or enlarge only slightly, if at all. The manner in which a fluid, in this case blood, flows through a smooth vessel is termed **laminar flow.** The Latin word *lamina* means layer, an apt description of the way fluids flow through tubes in concentric, cylindrical layers—as you can see in part *A* of the figure. Because of friction against the inner face of the vessel wall, the outer layers of blood flow more slowly than the inner layers. Laminar flow is the normal pattern of blood flow in most healthy vessels.

When smooth, laminar flow is disrupted by branching or narrowing of a vessel, a sharp turn, or a sudden constriction or obstruction, the flow of blood becomes turbulent. **Turbulent flow,** shown in part *B* of the figure, occurs normally at heart valves and contributes to the first and second heart sounds described on p. 689.

However, significant turbulent flow in most vessels is not normal. If the sounds of turbulence are detected in a peripheral vessel, an abnormal or unusual constriction may exist. Such constrictions could be temporary and intentional, as in the case of an inflated blood pressure cuff pressing on an artery and creating turbulence. The sounds of turbulence generated by such blood pressure measurements are called **Korotkoff sounds** (see Figure 22-29). These sounds are named for Nicolai Korotkoff, the Russian surgeon who in 1905 developed the method for using these sounds to indirectly measure arterial blood pressure.

Some sounds of turbulence are caused by constrictions that are a serious threat to one's health. For example, in Chapter 21 we discussed the fact that arteriosclerosis can cause such a narrowing of a vessel's channel and can ultimately lead to death by ischemia, thrombosis, or other mechanisms (see Figure 21-44). Part *C* of the figure shows a stethoscope being used to listen for low-pitched blowing sounds called **bruits** (BROO-eez) that can occur in the carotid arteries. Bruits may result from obstruction caused by arteriosclerosis or abnormally increased pulse pressure. A usually benign, but abnormal, condition known as venous hum produces a humming noise in the internal jugular vein. Venous hum is common in children and probably results from vigorous myocardial contraction.

Turbulent blood flow. A, Laminar blood flow (no turbulence). **B,** Turbulent blood flow. **C,** Listening for bruits.

and as isovolumetric contraction of the ventricle occurs, as you can see near the top of the diagram in Figure 22-7 (p. 688).

Systolic pressure gives valuable information about the force of the left ventricular contraction, and diastolic pressure gives valuable information about the resistance of the blood vessels.

Blood in the arteries of an adult with a blood pressure reading at the high end of the normal range exerts a pressure equal to that required to raise a column of mercury about 120 mm (or a column of water more than 5 feet) high in a glass tube during systole of the ventricles and 80 mm high during diastole. For the sake of brevity, this is expressed as a blood pressure of "120 over 80" or 120/80. The first, or upper, figure represents systolic pressure, and the second represents diastolic pressure.

From the figures just given, we observe that blood pressure fluctuates considerably during each heartbeat. During ventricular systole, the force is great enough to raise the mercury column 40 mm higher than during ventricular diastole. This difference between systolic and diastolic pressure is called **pulse pressure.** It characteristically increases in arteriosclerosis, mainly because systolic pressure increases more than diastolic pressure. Pulse pressure increases even more markedly in aortic valve insufficiency because of both a rise in systolic pressure and a fall in diastolic pressure.

Be aware that although the classic method of indirect arterial blood pressure assessment involves a column of mercury, and the units in which blood pressure is expressed are based on the height of a mercury column, very few modern sphygmomanometers actually use mercury. The reason is twofold. First, mercury is a very hazardous substance and should the mercury column break, an environmental health hazard would be created. Second, it is much more cost effective to use inexpensive and durable electronic pressure sensors that are calibrated to the mercury scale than to construct fragile columns of mercury in glass.

Blood pressure can also be measured directly in various ways. For example, a small tube called a *cannula* with a removable pointed insert can be pushed directly into a vessel, the insert withdrawn, and the cannula connected to a manometer or electronic pressure sensor. A long, flexible tube called a *catheter* can likewise be placed in a blood vessel or even into a chamber of the heart. These techniques can be used in critical care, but the more indirect methods described previously are more practical for routine screening and clinical evaluation.

Blood Pressure and Bleeding

Because blood exerts a comparatively high pressure in arteries and a very low pressure in veins, it gushes forth with considerable force from a cut artery but seeps in a slow, steady stream from a vein. As we have just seen, each ventricular contraction raises arterial blood pressure to the systolic level, and each ventricular relaxation lowers it to the diastolic level. As the ventricles contract, the blood spurts forth forcefully because of the increased pressure in the artery, but as the ventricles relax, the flow ebbs to almost nothing because of the fall in pressure. In other words, blood escapes from an artery in spurts because of the alternate raising and lowering of arterial blood pressure but flows slowly and steadily from a vein because of the low, practically constant pressure. A uniform, instead of a pulsating, pressure exists in the capillaries and veins. Why? Because the arterial walls, being elastic, continue to squeeze the blood forward while the ventricles are in diastole. Therefore blood enters capillaries and veins under a relatively steady pressure (see Figure 22-9).

MINUTE VOLUME OF BLOOD

The volume of blood circulating through the body per minute **(minute volume)** is determined by the magnitude of the blood pressure gradient and the peripheral resistance (Figure 22-30).

A nineteenth century physiologist and physicist, Jean Poiseuille (pwah-SWEE), described the relation between these three factors—pressure gradient, resistance, and minute volume—with a mathematical equation known as **Poiseuille's law.** In general, but with certain modifications, it applies to blood circulation. We can state the law in a simplified form as follows: the volume of blood circulated per minute is directly related to mean arterial pressure minus central venous pressure and is inversely related to resistance:

$$\text{Volume of blood circulated per minute} = \frac{\text{Mean arterial pressure} - \text{Central venous pressure}}{\text{Resistance}}$$

$$\text{Minute volume} = \frac{\text{Pressure gradient}}{\text{Resistance}}$$

This mathematical relationship needs qualifying with regard to the influence of peripheral resistance on circulation. For instance, according to the equation, an increase in peripheral resistance tends to decrease blood flow. (Why? Increasing peripheral resistance increases the denominator of the fraction in the preceding equation. Increasing the denominator of any fraction necessarily does what to its value? It decreases the value of the fraction.)

Increased peripheral resistance, however, has a secondary action that opposes its primary tendency to decrease blood flow. An increase in peripheral resistance hinders or decreases arteriole runoff. This, of course, tends to increase the volume of blood left in the arteries and so tends to increase arterial pressure. Note also that increasing arterial pressure tends to increase the value of the fraction in Poiseuille's equation. Therefore it tends to increase circulation. In short, to say unequivocally what the effect of an increased peripheral resistance will be on circulation is impossible. It depends also on arterial blood pressure—whether it increases, decreases, or stays the same when peripheral resistance increases. The clinical condition *arteriosclerosis with hypertension* (high blood pressure) illustrates this point. Both peripheral resistance and arterial pressure are increased in this condition. If resistance were to increase more than arterial pressure, circulation (i.e., volume of blood flow per minute) would decrease. But if arterial pressure increases proportionately to resistance, circulation remains normal.

19. How is minute volume related to peripheral resistance?

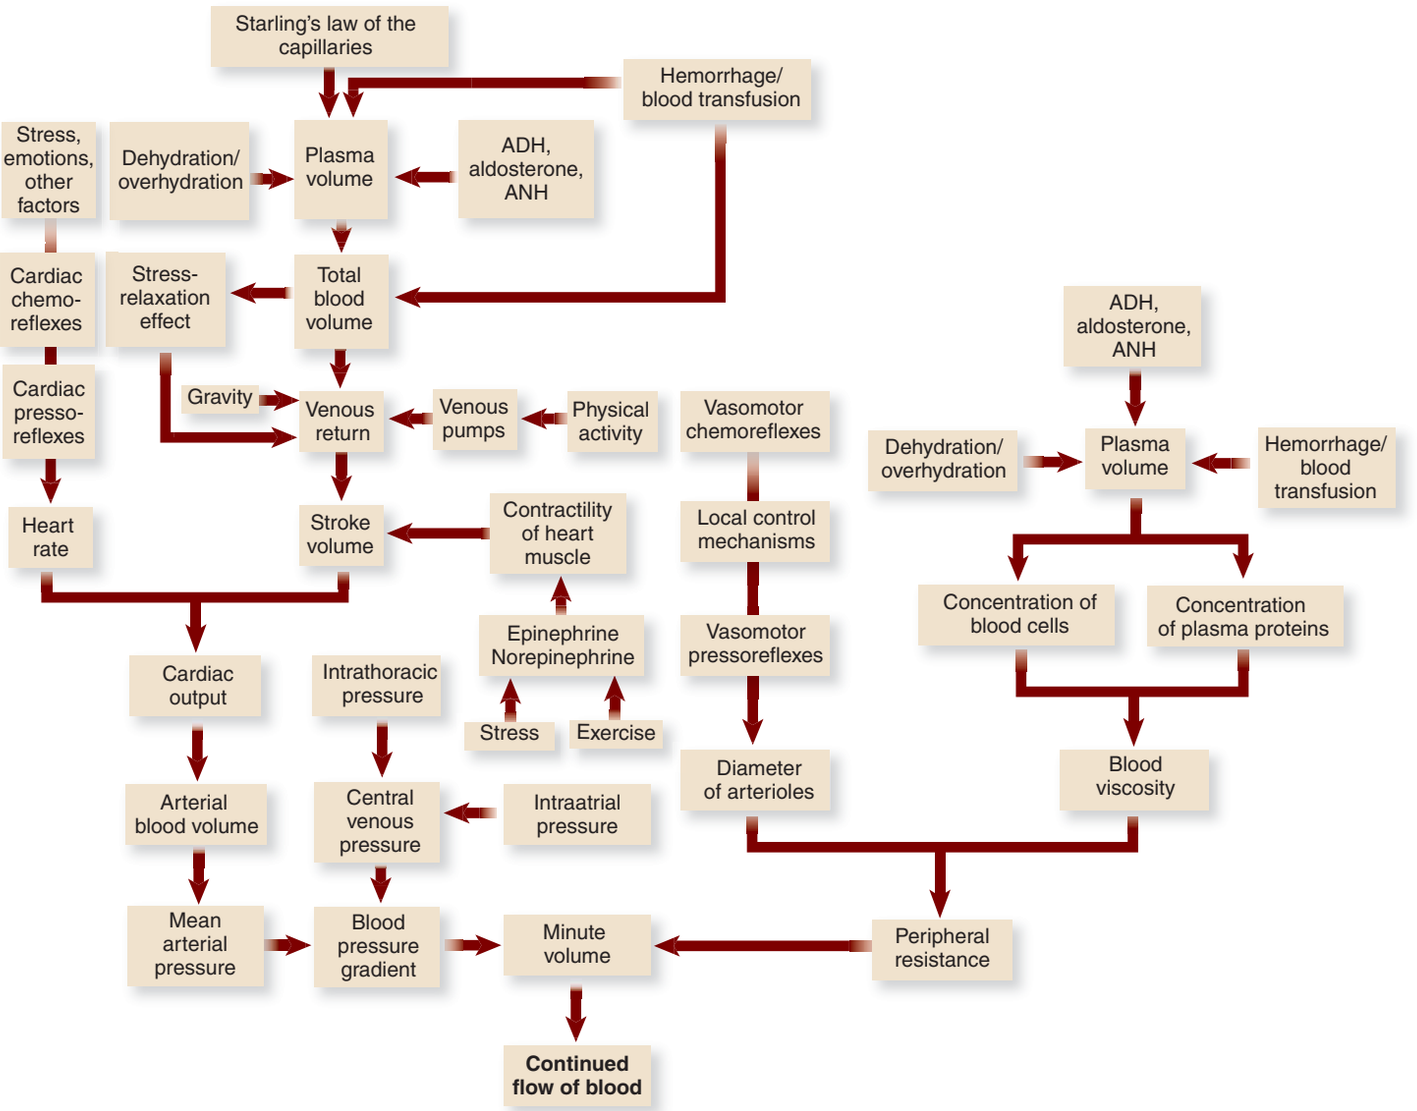

FIGURE 22-30

Factors that influence the flow of blood. The flow of blood, expressed as volume of blood flowing per minute (or *minute volume*), is determined by various factors. This chart shows only some of the major factors that influence blood flow. Note that some factors appear more than once in the chart, indicating that they can influence blood flow in several ways. *ADH,* Antidiuretic hormone; *ANH,* atrial natriuretic hormone.

VELOCITY OF BLOOD FLOW

The speed with which the blood flows, that is, distance per minute, through its vessels is governed in part by the physical principle that when a liquid flows from an area of one cross-sectional size to an area of larger size, its velocity slows in the area with the larger cross section (Figure 22-31). For example, a narrow river whose bed widens flows more slowly through the wide section than through the narrow section. In terms of the blood vascular system, the total cross-sectional area of all arterioles together is greater than that of the arteries. Therefore blood flows more slowly through arterioles than through arteries. Likewise, the total cross-sectional area of all capillaries together is greater than that of all arterioles, and therefore capillary flow is slower than arteriole flow. The venule cross-sectional area, on the other hand, is smaller than the capillary cross-sectional area. Therefore blood velocity increases in venules and again in veins, which have a still smaller cross-sectional area. In short, the most rapid blood flow takes place in arteries and the slowest in capillaries. Can you think of a valuable effect stemming from the fact that blood flows most slowly through the capillaries?

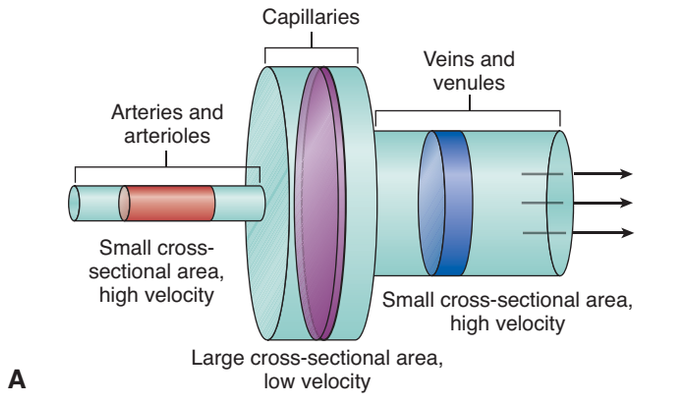

FIGURE 22-31

Relationship between cross-sectional area and velocity of blood flow. As you can see in the simple diagram **(A)** and the blood vessel chart **(B)**, blood flows with great speed in the large arteries. However, branching of arterial vessels increases the total cross-sectional area of the arterioles and capillaries, reducing the flow rate. When capillaries merge into venules and venules merge into veins, the total cross-sectional area decreases, causing the flow rate to increase.

PULSE

Mechanism

Pulse is defined as the alternate expansion and recoil of an artery. Two factors are responsible for the existence of a pulse that can be felt:

1. Intermittent injections of blood from the heart into the aorta, which alternately increase and decrease the pressure in that vessel. If blood poured steadily out of the heart into the aorta, the pressure there would remain constant, and there would be no pulse.
2. The elasticity of the arterial walls, which allows them to expand with each injection of blood and then recoil. If the vessels were fashioned from rigid material such as glass, there would still be an alternate raising and lowering of pressure within them with each systole and diastole of the ventricles, but the walls could not expand and recoil, and therefore no pulse could be felt.

Pulse Wave

Each ventricular systole starts a new pulse that proceeds as a wave of expansion throughout the arteries and is known as the pulse wave. It gradually dissipates as it travels, disappearing entirely in the capillaries. The pulse wave felt at the common carotid artery in the neck is large and powerful, rapidly following the first heart sound. Figure 22-32 shows that the carotid pulse wave begins during ventricular systole. Note that the closure of the aortic valve produces a detectable *dicrotic notch* in the pulse wave. However, the pulse felt in the radial artery at the wrist does not coincide with the contraction of the ventricles. It follows each contraction by an appreciable interval (the length of time required for the pulse wave to travel from the aorta to the radial artery). The farther from the heart the pulse is taken, therefore, the longer that interval is.

Almost everyone is aware of the diagnostic importance of the pulse. It reveals important information about the cardiovascular system, heart action, blood vessels, and circulation.

Not everyone is aware of the basic functional role of the pulse wave, however. The pulse wave actually conserves energy produced by the pumping action of the heart (Figure 22-33). The great force of pressure with which blood is ejected from the heart during ventricular systole expands the wall of the aorta. At that point, the stretched aortic wall has potential energy stored in it—just as a stretched rubber band has potential energy. During ventricular diastole, the elastic nature of the aortic wall allows it to recoil. This recoil exerts pressure on the blood and thus keeps it moving. If the wall of the aorta were inelastic, it would not alternately expand and recoil—and would thus not keep blood moving continuously. Instead, arterial blood would simply spurt, then stop, then spurt, then stop, and so on.

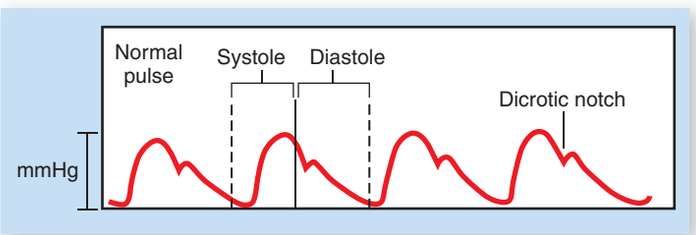

FIGURE 22-32

Normal carotid pulse wave. This series of pulse waves shows rhythmic increases and decreases in pressure as measured at the common carotid artery in the neck. The dicrotic notch represents the pressure fluctuation generated by closure of the aortic valve.

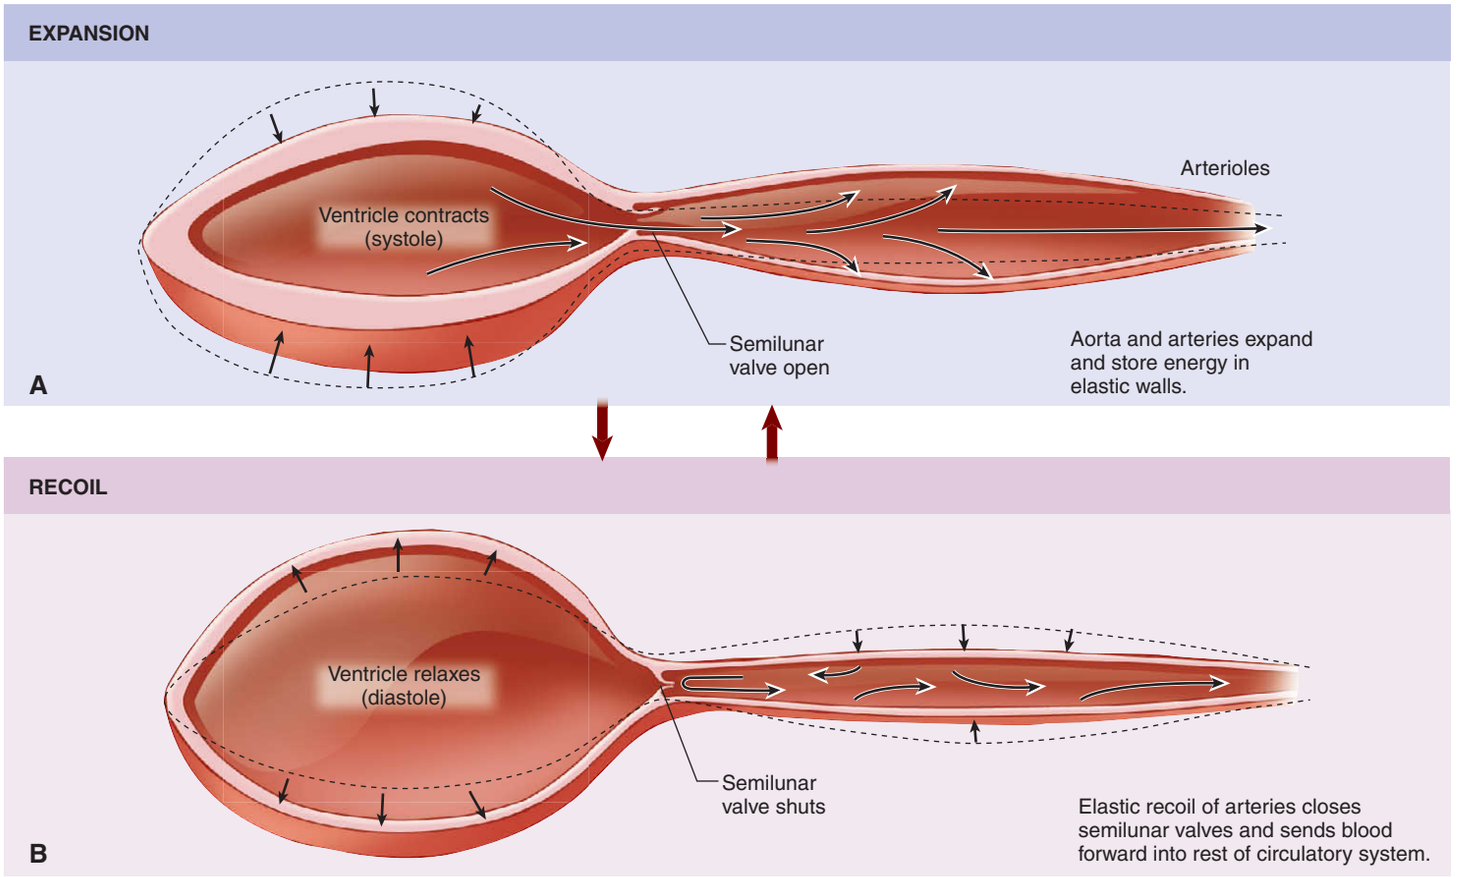

FIGURE 22-33

Functional role of the pulse wave. The arterial pulse conserves energy by absorbing and storing force from the ventricular contraction by causing elastic expansion of the arterial wall. The energy is used to maintain continued blood flow during ventricular relaxation by elastic recoil of the arterial wall—thus producing enough arterial pressure to keep blood flowing.

Where the Pulse Can Be Felt

The pulse can be felt wherever an artery lies near the surface and over a bone or other firm background. Some specific locations where the pulse point is most easily felt are listed here and shown in Figure 22-34:

Radial artery—at wrist
Temporal artery—in front of ear or above and to outer side of eye
Common carotid artery—along anterior edge of sternocleidomastoid muscle at level of lower margin of thyroid cartilage
Facial artery—at lower margin of lower jawbone on a line with corners of mouth and in groove in mandible about one third of the way forward from angle
Brachial artery—at bend of elbow along inner margin of biceps muscle
Femoral artery—in middle of groin, where artery passes over pelvic bone
Popliteal artery—behind the knee
Posterior tibial artery—behind the medial malleolus (inner "ankle bone")
Dorsalis pedis artery—on dorsum (upper surface) of foot

Six important pressure points can be used to stop arterial bleeding:

1. **Temporal artery**—in front of ear
2. **Facial artery**—same place at which pulse is taken
3. **Common carotid artery**—point where pulse is taken, with pressure back against spinal column
4. **Subclavian artery**—behind medial third of clavicle, pressing against first rib
5. **Brachial artery**—few inches above elbow on inside of arm, pressing against humerus
6. **Femoral artery**—in middle of groin, where artery passes over pelvic bone; pulse can also be felt here

In trying to stop arterial bleeding by pressure, one must always remember to apply the pressure at the pulse point, or *pressure point*, that lies between the bleeding part and the heart. Why? Blood flows from the heart through the arteries to the affected part. Pressure between the heart and bleeding point therefore cuts off the source of the blood flow to that point.

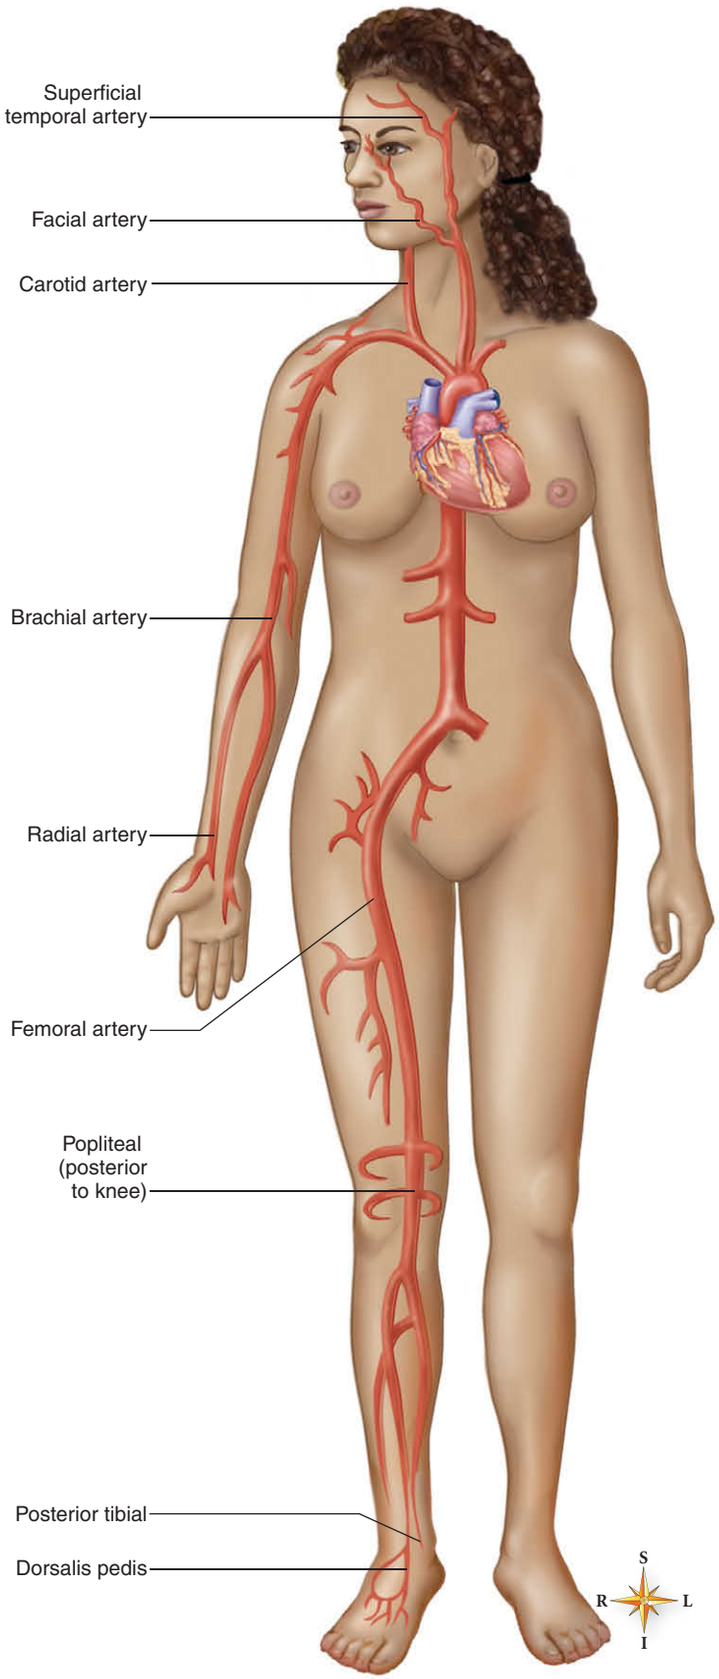

FIGURE 22-34

Pulse points. Each pulse point is named after the artery with which it is associated. (Some arteries in the figure have been enlarged to clarify the location of pulse points.)

Venous Pulse

A detectable pulse exists in the large veins only. It is most prominent in the veins near the heart because of changes in venous blood pressure brought about by alternate contraction and relaxation of the atria of the heart. The clinical significance of venous pulse is not as great as that of arterial pulse, and thus it is less often measured.

| QUICK CHECK |

20. What device is used in clinical settings to measure arterial blood pressure?
21. Which is more important for assessing health—the systolic pressure or the diastolic pressure?
22. In which type of vessel is blood most likely to be flowing at a very slow rate—an artery, a capillary, or a vein?
23. Without being specific, where are pulse points normally located in the body?

Cycle of LIFE

Cardiovascular Physiology

Changes in the function of the heart and blood vessels usually parallel the structural changes in these organs over the life span. For example, changes at the time of birth that adapt the circulatory system to life outside the womb cause changes in the blood pressure gradients that alter the flow of blood in many parts of the body. Likewise, the degenerative changes associated with aging reduce the heart's ability to maintain cardiac output and the ability of arteries to withstand high pressure.

Changes in arterial blood pressure are among the most apparent changes in the function of the cardiovascular system associated with the progression through the life cycle. In a newborn, normal arterial blood pressure is only about 90/55 mmHg—much lower than the arterial pressure of just under 120/80 mmHg in most healthy young adults. In older adults hypertension can develop—with arterial blood pressures commonly reaching 150/90 mmHg.

Another commonly observed change in cardiovascular function relates to heart rate. The heart rates of infants and children typically vary more than those in adults. Compared with adults, children often exhibit very large increases in heart rate in response to stressors such as illness, pain, tension, and exercise. Whereas a typical resting heart rate for adults is about 72 beats/min, the resting heart rate of a newborn can range from 120 to 170 beats/ min, and the resting heart rate of a preschooler can range from 80 to 160 beats/min. In older adults, resting heart rates range from lows of around 40 beats/min to 100 beats/min.

the BIG picture

Blood Flow and the Whole Body

As stated in this chapter and many times throughout this book, one of the essential concepts of homeostasis is the renewable fluid that makes up our internal environment. If we were not able to maintain the chemical nature and other physical characteristics of our internal fluid environment, we would not survive. To maintain the constancy of the internal fluid, we must be able to shift nutrients, gases, hormones, waste products, agents of immunity, and other materials around in the body. As certain materials are depleted in one tissue and new materials enter the internal environment in another tissue, redistribution must occur. What better way than through a system of circulating fluid? This fluid shifts materials from place to place and also redistributes heat and pressure. Recall from your study of the integumentary and muscular systems that shifting the flow of blood to or away from warm tissues at the proper time is essential to maintaining the homeostasis of body temperature. As we will learn in Chapter 31, the ability of our blood to increase or decrease blood pressure in the kidney has a great impact on that organ's vital function of filtering the internal environment. Understanding the basic mechanisms of almost any system in the body requires an understanding of the dynamics of blood flow.

What we have seen in this chapter is a wonderfully complex array of mechanisms that work together in concert with the actions of other systems to maintain the constancy of the *milieu intérieur*—the internal environment.

MECHANISMS of DISEASE

DISORDERS OF CARDIOVASCULAR PHYSIOLOGY

Cardiac Dysrhythmia

Various conditions such as inflammation of the endocardium (endocarditis) or myocardial infarction (heart attack) can damage the heart's conduction system and thereby disturb the normal rhythmical beating of the heart (Figure 22-35, *A*). The term **dysrhythmia** refers to an abnormality of heart rhythm. Dysrhythmia may also be called *arrhythmia*.

One kind of dysrhythmia is called a **heart block.** In AV node block, impulses are blocked from getting through to the ventricular myocardium, resulting in the ventricles contracting at a much slower rate than normal. On an ECG, there may be a large interval between the P wave and the R peak of the QRS complex (Figure 22-35, *B*). *Complete heart block* occurs when the P waves do not match up at all with the QRS complexes—as in an ECG that shows two or more P waves for every QRS complex. A physician may treat heart block by implanting in the heart an *artificial pacemaker.*

Bradycardia is a slow heart rhythm—below 60 beats/min (Figure 22-35, *C*). Slight bradycardia is normal during sleep and in conditioned athletes while they are awake (but at rest). Abnormal bradycardia can result from improper autonomic nervous control of the heart or from a damaged SA node. If the problem is severe, artificial pacemakers can be used to increase the heart rate by taking the place of the SA node.

Tachycardia is a very rapid heart rhythm—more than 100 beats/min (Figure 22-35, *D*). Tachycardia is normal during and just after exercise and during the stress response. Abnormal tachycardia can result from improper autonomic control of the heart, blood loss or shock, the action of drugs and toxins, fever, and other factors.

Sinus dysrhythmia is a variation in heart rate during the breathing cycle. Typically, the rate increases during inspiration and decreases during expiration. The causes of sinus dysrhythmia are not clear. This phenomenon is common in young people and usually does not require treatment.

Premature contractions, or *extrasystoles,* are contractions that occur before the next expected contraction in a series of cardiac cycles. For example, *premature atrial contractions (PACs)* may occur shortly after the ventricles contract—seen as early P waves on the ECG (Figure 22-35, *E*). Premature atrial contractions often occur with lack of sleep, too much caffeine or nicotine, alcoholism, or heart damage. Ventricular depolarizations that appear earlier than expected are called *premature ventricular contractions* (PVCs). PVCs appear on the ECG as early, wide QRS complexes without a preceding related P wave. PVCs are caused by a variety of circumstances that include stress, electrolyte imbalance, acidosis, hypoxemia, ventricular enlargement, or drug reactions. Occasional PVCs are not clinically significant in otherwise healthy individuals. However, in people with heart disease they may reduce cardiac output.

Frequent premature contractions can lead to fibrillation, a condition in which cardiac muscle fibers contract out of step with each other. This event can be seen in an ECG as the absence of regular P waves or abnormal QRS and T waves. In fibrillation, the affected heart chambers do not effectively pump blood.

Atrial fibrillation (A-fib or AF) occurs commonly in mitral stenosis, rheumatic heart disease, and infarction of the atrial myocardium (Figure 22-35, *F*). This condition can be treated with drugs such as digoxin (a **digitalis** preparation) or by *cardioversion*—the application of carefully timed electrical shocks to restore the normal myocardial rhythm.

Ventricular fibrillation (V-fib or VF) is an immediately life-threatening condition in which the lack of ventricular pumping suddenly stops the flow of blood to vital tissues (Figure 22-35, *G*). Ventricular fibrillation is often treated by *defibrillation*—application of electrical shock to force cardiac muscle fibers to contract in unison (Figure 22-36). Unless ventricular fibrillation is corrected immediately by defibrillation or some other method, death may occur within minutes.

Other types of defibrillators, besides those used by health professionals in emergency situations, also save lives. For example, *automatic internal cardiac defibrillators (AICDs)* are preprogrammed devices placed inside the body of a patient who is at a high risk for fibrillation. An AICD will automatically fire a

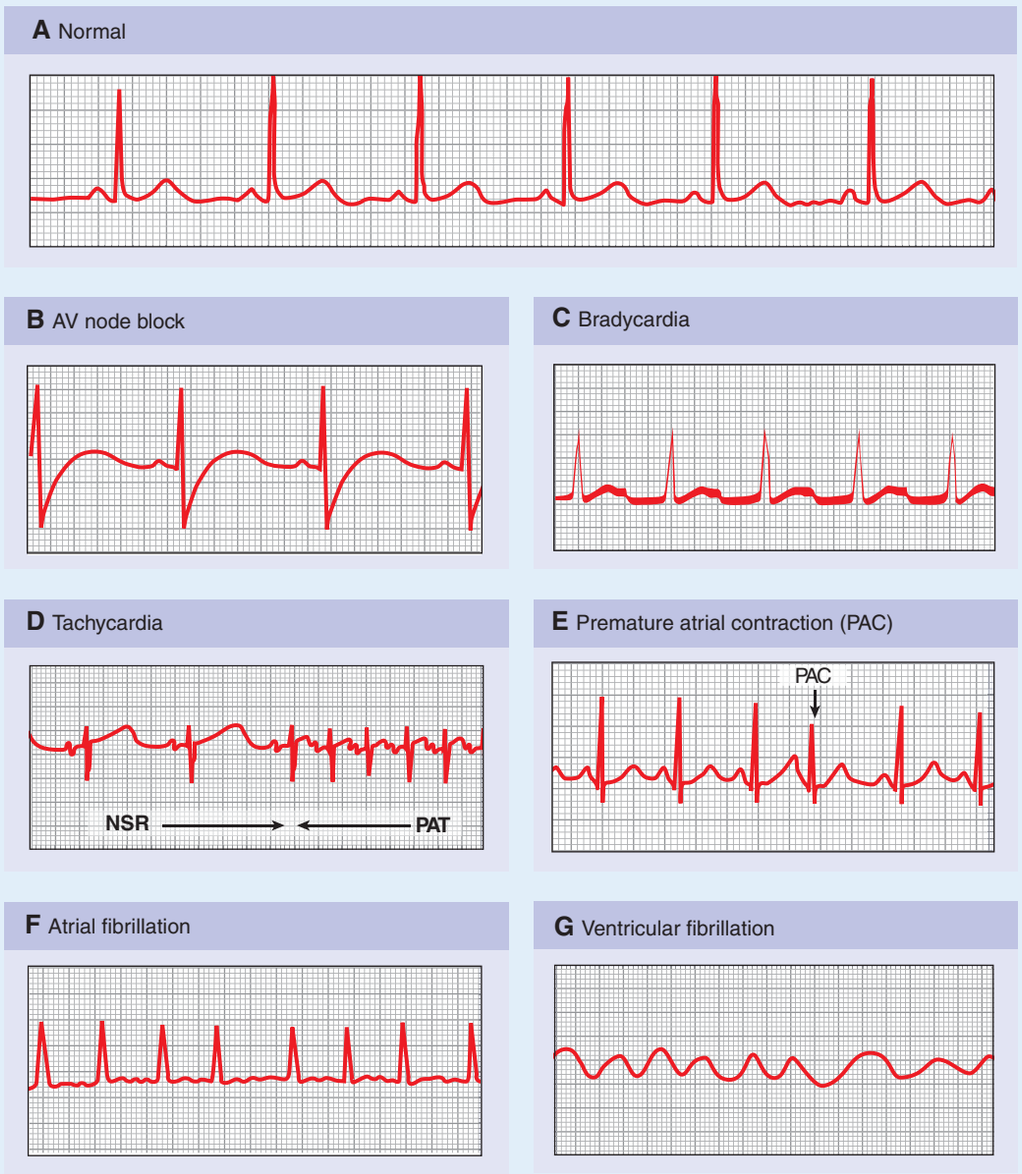

FIGURE 22-35

ECG strip chart recordings. A, Normal ECG. **B,** AV node block. Very slow ventricular contraction (25 to 45 beats/min at rest); P waves widely separated from peaks of QRS complexes. **C,** Bradycardia. Slow heart rhythm (less than 60 beats/min); no disruption of normal rhythm pattern. **D,** Tachycardia. Rapid heart rhythm (greater than 100 beats/min); no disruption of normal rhythm pattern. *NSR,* Normal sinus rhythm; *PAT,* paroxysmal (sudden) atrial tachycardia. **E,** Premature atrial contraction (PAC). Unexpected, early P wave that differs from normal P waves; PR interval may be shorter or longer than normal; normal QRS complex; more than 6 PACs per minute may precede atrial fibrillation. **F,** Atrial fibrillation. Irregular, rapid atrial depolarizations; P wave rapid (greater than 300/min) with irregular QRS complexes (150 to 170 beats/min). **G,** Ventricular fibrillation. Complete disruption of normal heart rhythm.

defibrillating shock as needed. Increasingly, *automatic external defibrillators (AEDs)* that can be used by nearly anyone have become available in public areas or for private use (see Figure 22-36).

Heart Failure

Heart failure is the inability of the heart to pump enough blood to sustain life. Heart failure is often measured as a decline in the *ejection fraction (EF)* below normal. The lower the EF, the more severe the heart failure.

Heart failure can result from many different heart diseases. Valve disorders can reduce the pumping efficiency of the heart enough to cause heart failure. **Cardiomyopathy** (kar-dee-oh-my-OP-ah-thee), or disease of the myocardial tissue, may reduce pumping effectiveness. A specific event such as myocardial infarction can result in myocardial damage that causes heart failure. Dysrhythmias such as complete heart block or ventricular fibrillation can also impair the pumping effectiveness of the heart and thus cause heart failure.

Congestive heart failure (CHF), or simply, *left-side heart failure,* is the inability of the left ventricle to pump blood

FIGURE 22-36

Defibrillation. Application of electrical shock to force cardiac muscle fibers to contract in unison, as with this *AED (automatic external defibrillator),* has saved many lives by correcting fibrillation of the atria and/or ventricles.

effectively. Most often, such failure results from myocardial infarction caused by coronary artery disease. It is called *congestive heart failure* because it decreases pumping pressure in the systemic circulation, which in turn causes the body to retain fluids. Portions of the systemic circulation thus become congested with extra fluid. As previously stated, left-side heart failure also causes congestion of blood in the pulmonary circulation (termed *pulmonary edema*)—possibly leading to right-side heart failure.

Failure of the right side of the heart, or *right-side heart failure*, accounts for about one fourth of all cases of heart failure. Right-side heart failure often results from the progression of disease that begins in the left side of the heart. Failure of the left side of the heart results in reduced pumping of blood returning from the lungs. Blood backs up into the pulmonary circulation and then into the right side of the heart—causing an increase in pressure that the right side of the heart simply cannot overcome. Right-side heart failure can also be caused by lung disorders that obstruct normal pulmonary blood flow and thus overload the right side of the heart—a condition called **cor pulmonale** (kohr pul-mah-NAL-ee). (See also Mechanisms of Disease section in Chapter 21.)

Circulatory Shock

The term **circulatory shock** refers to the failure of the circulatory system to adequately deliver oxygen to the tissues, resulting in the impairment of cell function throughout the body. If left untreated, circulatory shock may lead to death. Circulatory failure has many causes, all of which somehow reduce the flow of blood through the blood vessels of the body. Because of the variety of causes, circulatory shock is often classified into the following types:

Cardiogenic shock results from any type of heart failure, such as that after severe myocardial infarction (heart attack), heart infections, and other heart conditions. Because the heart can no longer pump blood effectively, blood flow to the tissues of the body decreases or stops.

Hypovolemic shock results from the loss of blood volume in the blood vessels (hypovolemia means "low blood volume"). Reduced blood volume results in low blood pressure and reduced flow of blood to tissues. Hemorrhage is a common cause of blood volume loss leading to hypovolemic shock. Hypovolemia can also be caused by loss of interstitial fluid, causing a drain of blood plasma out of the vessels and into the tissue spaces. Loss of interstitial fluid is common in chronic diarrhea or vomiting, dehydration, intestinal blockage, severe or extensive burns, and other conditions.

Neurogenic shock results from widespread dilation of blood vessels caused by an imbalance in autonomic stimulation of smooth muscle in vessel walls. It is also sometimes called **vasodilatory shock.** You may recall from Chapter 16 that autonomic effectors such as smooth muscle tissues are controlled by a balance of stimulation from the sympathetic and parasympathetic divisions of the autonomic nervous system. Normally, sympathetic stimulation maintains the muscle tone that keeps blood vessels at their usual diameter. If sympathetic stimulation is disrupted by an injury to the spinal cord or medulla, depressive drugs, emotional stress, or some other factor, blood vessels dilate significantly. Widespread vasodilation reduces blood pressure, thus reducing blood flow.

Anaphylactic shock results from an acute allergic reaction called *anaphylaxis*. Anaphylaxis causes the same kind of blood vessel dilation characteristic of neurogenic shock.

Septic shock results from complications of septicemia, a condition in which infectious agents release toxins into the blood. The toxins often dilate blood vessels, thereby causing shock. The situation is usually made worse by the damaging effects of the toxins on tissues combined with the increased cell activity caused by the accompanying fever. One type of septic shock is *toxic shock syndrome* (TSS), which usually results from staphylococcal infections that begin in the vagina of menstruating women and spread to the blood.

The body has numerous mechanisms that compensate for the changes that occur during shock. However, these mechanisms may fail to compensate for changes that occur in severe cases, and this failure often results in death.

Hypertension

The largest number of office visits to physicians is due to a condition called **hypertension (HTN),** or high blood pressure. More than 60 million cases of HTN have been diagnosed in the United States. This condition occurs when the force of blood exerted by the arterial blood vessel exceeds a blood pressure of 140/90 mmHg. Ninety percent of HTN cases are classified as *primary-essential*, or idiopathic, with no single known causative etiology. Another classification, *secondary HTN*, is caused by kidney disease or hormonal problems or induced by oral contraceptives, pregnancy, or other causes.

Another way of classifying hypertension is illustrated in the accompanying chart adapted from the National High Blood Pressure Education Program (Figure 22-37). This system uses systolic and diastolic blood pressure values to classify hypertension into stages according to severity. The guidelines that accompany this scheme emphasize the belief that there is no precise distinction between normal and abnormal values—thus even those in the high-normal range or the *prehypertension* range may be treated as having HTN.

Many risk factors have been identified in the development of HTN. Genetic factors play a large role. There is an increased susceptibility or predisposition with a family history of HTN. Men experience higher rates of HTN at an earlier age than women, and HTN in African Americans far exceeds that of Caucasians in the United States. There is also a direct relationship between age and high blood pressure. This is because as age advances, the blood vessels become less compliant and there is a higher incidence of atherosclerotic plaque buildup. HTN can also be fatal if undetected in women taking oral contraceptives. Risk factors include high stress levels, obesity, calcium deficiencies, high levels of alcohol and caffeine intake, smoking, and lack of exercise.

Untreated HTN has many potential complications. Ischemic heart disease and heart failure, kidney failure, and stroke are some examples. As many as 400,000 people per year experience a stroke. Because HTN manifests minimal or no overt signs, it is known as the "silent killer." Headaches, dizziness, and fainting have been

Blood Pressure (BP) Classification

Classification	Systolic BP		Diastolic BP
Normal	<120	and	<80
Prehypertension	120-139	or	80-89
	High BP		
Stage 1 hypertension	140-159	or	90-99
Stage 2 hypertension	≥160	or	≥100

FIGURE 22-37

Classification of hypertension. This chart is adapted from the National High Blood Pressure Education Program.

reported but are not always symptomatic of HTN. Regular screenings at the worksite and screening booths in malls and in hospitals often help to identify asymptomatic HTN.

Hypotension

Blood pressure that is lower than normal is called **hypotension,** or low blood pressure. Hypotension may be temporary, as in *orthostatic hypotension* when a person stands up suddenly (see Figure 22-23 on p. 701) or when blood pressure drops because of a sudden loss of blood. Unexplained or *essential* hypotension is generally chronic and may result from heart disease or genetic influences. Whether acute or chronic, hypotension may cause rapid heart rate and pulse as the body attempts to maintain constant blood pressure for good circulation. Rapid heart rate may, in turn, lead to heart rhythm or other cardiac problems. If normal circulation cannot be maintained, reduced blood flow in local areas may cause damage or dysfunction in the affected areas. For example, hypotension in the elderly may cause cognitive impairment when proper blood flow to the brain cannot be maintained.

CASE study

Bobby was in a hurry to finish the last job of the day. Being an electrician, he had been called in to help complete and inspect the wiring in a museum that was due to open the next week. Bobby called to his coworker, Jerry, to confirm the current was off to the electrical box on which he was working. When he heard a positive response, he climbed the ladder and reached up to tighten a few loose screws. As he was tightening the screws with his right hand, he lost his balance and reached up with his left hand to catch hold of the ladder . . . but instead caught a live wire that sent a jolt of electricity through his body. Jerry came running and knocked the ladder out from under Bobby so he would fall to the floor, breaking the electric arc. "Are you okay?" he asked Bobby, who appeared dazed, but was conscious. "I don't feel so great," he replied, smiling weakly. Then he collapsed. Jerry yelled at the other workers in the room to call 911, checked Bobby's pulse, and started CPR. The foreman rushed in with an AED (automated external defibrillator) and attached the electrodes to Bobby's chest. The AED's mechanical voice said, "V-fib. Recommend shock. Press button when clear."

1. What is this V-fib that the AED registered?
   a. Ventricular fibrosis
   b. Venous fibrillation
   c. Ventricular fibrillation
   d. Vasomotor fibrosis

CASE study

When activated, the AED shocks the heart—the intended purpose being electrical stimulation of the cardiac muscle cells to elicit a response from the heart's pacemaker that will cause the cells to contract in unison to effectively pump blood.

2. What bundle of cells in Bobby's heart (and yours) is known as the pacemaker?
   a. SV node
   b. SA node
   c. AV node
   d. AV bundle

When the paramedics arrive, they rush Bobby to the hospital. "Let's get an EKG!" the attending physician calls out.

3. What is an EKG?
   a. Electrocardiogram
   b. Electrocirculogram
   c. Encephalocardiogram
   d. Enhancercardiogram

4. Ventricular depolarization is shown as which part of the EKG?
   a. V wave
   b. P wave
   c. T wave
   d. QRS complex

INTRODUCTION

A. Vital role of the cardiovascular system in maintaining homeostasis depends on the continuous and controlled movement of blood through the capillaries
B. Numerous control mechanisms help regulate and integrate the diverse functions and component parts of the cardiovascular system to supply blood in response to specific body area needs

HEMODYNAMICS

A. Hemodynamics—collection of mechanisms that influence the dynamic (active and changing) circulation of blood (Figure 22-1)
B. Circulation of different volumes of blood per minute is essential for healthy survival
C. Circulation control mechanisms must accomplish two functions
   1. Maintain circulation
   2. Vary volume and distribution of the blood circulated

THE HEART AS A PUMP

A. Conduction system of the heart (Figure 22-2)
   1. Composed of four major structures
      a. Sinoatrial node (SA node)
      b. Atrioventricular (AV) node
      c. AV bundle (bundle of His)
      d. Subendocardial branches (Purkinje fibers)
   2. Conduction system structures are more highly specialized than ordinary cardiac muscle tissue and permit rapid conduction of an action potential through the heart
   3. SA node (pacemaker)
      a. Initiates each heartbeat and sets its pace
      b. Specialized pacemaker cells in the node possess an intrinsic rhythm
   4. Sequence of cardiac stimulation
      a. After being generated by the SA node, each impulse travels throughout the muscle fibers of both atria and the atria begin to contract
      b. As the action potential enters the AV node from the right atrium, its conduction slows to allow complete contraction of both atrial chambers before the impulse reaches the ventricles
      c. After the AV node, conduction velocity increases as the impulse is relayed through the AV bundle into the ventricles
      d. Right and left branches of the bundle fibers and subendocardial branches (Purkinje fibers) conduct the impulses throughout the muscles of both ventricles, stimulating them to contract almost simultaneously
B. Electrocardiogram (ECG or EKG)
   1. Graphic record of the heart's electrical activity, its conduction of impulses; a record of the electrical events that precede the contractions of the heart
   2. Production of an ECG (Figure 22-3)
      a. Electrodes are attached to the subject
      b. Voltage changes that represent the heart's electrical activity are sensed by electrodes and recorded on paper (Figure 22-4)
   3. Composition (ECG waves) of normal ECG recording (Figures 22-3 and 22-5) is composed of:
      a. P wave—represents depolarization of the atria
      b. QRS complex—represents depolarization of the ventricles and repolarization of the atria

c. T wave—represents repolarization of the ventricles
d. U wave—tiny "hump" at end of T wave—represents repolarization of the papillary muscle (or a two-part T wave) and may appear on ECG as well (Figure 22-6)
(1) Absent or small U waves usually considered normal
(2) U waves may be a sign of hypokalemia or too much digoxin
e. ECG intervals between P, QRS, and T waves can provide information about rate of conduction of an action potential through the heart

C. Cardiac cycle—a complete heartbeat
1. Consists of contraction (systole) and relaxation (diastole) of both atria and both ventricles
2. Cycle is often divided into time intervals (Figures 22-7 and 22-8)
3. Atrial systole
a. This cycle begins with the P wave of the ECG, which triggers atrial contraction
b. Contraction of atria creates a pressure gradient that pushes blood out of the atria into the relaxed ventricles
c. Due to pressure gradients, AV valves are open; SL valves are closed
d. Ventricles are relaxed and filling with blood from atria
4. Isovolumetric ventricular contraction
a. Onset of ventricular systole coincides with the R wave of the ECG and the appearance of the first heart sound
b. Occurs between the start of ventricular systole and the opening of the SL valves
c. Ventricular volume remains constant as the pressure increases rapidly
(1) Intraventricular pressure rises enough to close AV valves, producing the first heart sound
(2) Intraventricular pressure is not yet high enough to open the SL valves
5. Ejection
a. SL valves open and blood is ejected from the ventricles when the intraventricular pressure exceeds the pressure in the pulmonary artery and aorta
b. Rapid ejection—initial short phase characterized by a marked increase in ventricular and aortic pressure and in aortic blood flow
c. Reduced ejection—characterized by a less abrupt decrease in ventricular volume; coincides with the T wave of the ECG
6. Isovolumetric ventricular relaxation
a. Ventricular diastole begins with this phase
b. Occurs between closure of the SL valves and opening of the AV valves
c. A dramatic fall in intraventricular pressure but not enough to open the AV valves, thus no change in volume
d. Second heart sound is heard during this period
7. Passive ventricular filling
a. Continued ventricular relaxation reduces intraventricular pressure and returning venous blood increases intraatrial pressure, producing enough of a pressure gradient to push open the AV valves
b. Blood rushes into the relaxing ventricles; influx lasts approximately 0.1 second and results in a dramatic increase in ventricular volume
c. Diastasis—later longer period of slow ventricular filling near end of ventricular diastole lasting approximately 0.2 second; characterized by a gradual increase in ventricular pressure and volume
d. The cardiac cycle then begins again with a new atrial systole

D. Heart sounds
1. Systolic sound—first sound, believed to be caused primarily by contraction of the ventricles and by vibrations of the closing AV valves
2. Diastolic sound—short, sharp sound; thought to be caused by vibrations of the closing of SL valves
3. Heart sounds have clinical significance because they provide information about the functioning of the valves of the heart

PRIMARY PRINCIPLE OF CIRCULATION

A. Blood flows because a pressure gradient exists between different parts of its volume; this is based on Newton's first and second laws of motion (Figure 22-9)
B. For example, blood circulates from the left ventricle to the right atrium of the heart because a blood pressure gradient exists between these two structures; likewise, a blood pressure gradient drives blood flow from the right ventricle to the left atrium
C. P_1–P_2 is the symbol used to represent a pressure gradient, with P_1 representing the higher pressure and P_2 the lower pressure
D. Perfusion pressure—the pressure gradient needed to maintain blood flow through a local tissue

ARTERIAL BLOOD PRESSURE

A. Primary determinant of arterial blood pressure is the volume of blood in the arteries; a direct relationship exists between arterial blood pressure and arterial blood volume (Figure 22-10)
B. Cardiac output (CO)—volume of blood pumped out of the heart per unit of time (ml/min or L/min) (Figure 22-11)
1. General principles and definitions
a. Cardiac output (CO)—determined by stroke volume and heart rate
b. Stroke volume (SV)—volume pumped per heartbeat
c. CO (volume/min) = SV (volume/beat) × HR (beats/min)
d. In practice, CO is computed by Fick's formula
e. Heart rate and stroke volume determine CO, so anything that changes either also tends to change CO, arterial blood volume, and blood pressure in the same direction
2. Stroke volume
a. Starling's law of the heart (Frank-Starling mechanism) (Figure 22-12)

(1) Within limits, the longer, or more stretched, the heart fibers at the beginning of contraction, the stronger the contraction
(2) The amount of blood in the heart at the end of diastole determines the amount of stretch placed on the heart fibers
(3) The myocardium contracts with enough strength to match its pumping load (within certain limits) with each stroke—unlike mechanical pumps

b. Contractility (strength of contraction) can also be influenced by chemical factors (Figure 22-13)
(1) Neural—norepinephrine; endocrine—epinephrine
(2) Triggered by stress, exercise

c. Ejection fraction (EF)—the ratio of stroke volume (SV) to end-diastolic volume (EDV)
(1) Usually expressed as a percentage: EF = (SV/EDV) × 100
(2) Healthy adults have EFs of at least 55%
(3) EF goes down as the myocardium fails

3. Factors that affect heart rate—SA node normally initiates each heartbeat; however, various factors can and do change the rate of the heartbeat
a. Cardiac pressoreflexes
(1) Aortic baroreceptors and carotid baroreceptors, located in the aorta and carotid sinus
(2) Extremely important because they affect the autonomic cardiac control center, and therefore parasympathetic and sympathetic outflow, to aid in control of blood pressure (Figures 22-14 and 22-15)

b. Carotid sinus reflex
(1) Located at the beginning of the internal carotid artery
(2) Sensory fibers from carotid sinus baroreceptors run through the carotid sinus nerve and the glossopharyngeal nerve to the cardiac control center
(3) Parasympathetic impulses leave the cardiac control center, travel through the vagus nerve to reach the SA node

c. Aortic reflex
(1) Sensory fibers extend from baroreceptors located in the wall of the arch of the aorta through the aortic nerve and through the vagus nerve to terminate in the cardiac control center
(2) Stimulation causes cardiac control center to increase vagal inhibition, thus slowing the heart

d. Other reflexes that influence heart rate
(1) Anxiety, fear, and anger often increase heart rate
(2) Grief tends to decrease heart rate
(3) Emotions produce changes in heart rate through the influence of impulses from the cerebrum by way of the hypothalamus
(4) Exercise normally increases heart rate
(5) Increased blood temperature or stimulation of skin heat receptors increases heart rate
(6) Decreased blood temperature or stimulation of skin cold receptors decreases heart rate

C. Peripheral resistance—resistance to blood flow imposed by the force of friction between blood and the walls of its vessels
1. Factors that influence peripheral resistance
a. Blood viscosity—the thickness of blood as a fluid (Figure 22-16)
(1) High plasma protein concentration can slightly increase blood viscosity
(2) High hematocrit (% RBC) can increase blood viscosity
(3) Anemia, hemorrhage, or other abnormal conditions may also affect blood viscosity

b. Diameter of arterioles (Figure 22-17)
(1) Vasomotor mechanism—muscles in walls of arteriole may constrict vessel (vasoconstriction) or dilate vessel (vasodilation), thus changing diameter of arteriole
(2) Small changes in blood vessel diameter cause large changes in resistance, making the vasomotor mechanism ideal for regulating blood pressure and blood flow

2. How resistance influences blood pressure
a. Arterial blood pressure tends to vary directly with peripheral resistance
b. Friction caused by viscosity and small diameter of arterioles and capillaries
c. Muscular coat of arterioles allows them to constrict or dilate and change the amount of resistance to blood flow
d. Peripheral resistance helps determine arterial pressure by controlling the amount of blood that runs from the arteries to the arterioles (Figure 22-18)
(1) Increased resistance and decreased arteriole runoff lead to higher arterial pressure
(2) Can occur locally (in one organ), or the total peripheral resistance (TPR) may increase, thus generally raising systemic arterial pressure

3. Vasomotor control mechanism—controls changes in the diameter of arterioles; plays role in maintenance of the general blood pressure and in distribution of blood to areas of special need (Figures 22-19 and 22-20)
a. Vasomotor pressoreflexes (Figure 22-21)
(1) Sudden increase in arterial blood pressure stimulates aortic and carotid baroreceptors; results in arterioles and venules of the blood reservoirs dilating
(2) Decrease in arterial blood pressure results in stimulation of vasoconstrictor centers, causing vascular smooth muscle to constrict

b. Vasomotor chemoreflexes (Figure 22-22)—chemoreceptors located in aortic and carotid bodies are sensitive to hypercapnia, hypoxia, and decreased arterial blood pH

c. Medullary ischemic reflex—acts during emergency situation when there is decreased blood flow to the medulla; causes marked arteriole and venous constriction

d. Vasomotor control by higher brain centers—impulses from centers in cerebral cortex and hypothalamus are transmitted to vasomotor centers in medulla to help control vasoconstriction and dilation

4. Local control of arterioles—several local mechanisms produce vasodilation in localized areas; referred to as *active hyperemia*

VENOUS RETURN TO THE HEART

A. Venous return—amount of blood returned to the heart by the veins

B. Stress-relaxation effect—occurs when a change in blood pressure causes a change in vessel diameter (because of elasticity) that accommodates the new pressure and thereby keeps blood flowing (works only within certain limits)

C. Gravity—the pull of gravity on venous blood while sitting or standing tends to cause a decrease in venous return (orthostatic effect) (Figure 22-23)

D. Venous pumps—blood-pumping action of respirations and skeletal muscle contractions facilitate venous return by increasing pressure gradient between peripheral veins and venae cavae (Figure 22-24)

1. Respirations—inspiration increases the pressure gradient between peripheral and central veins by decreasing central venous pressure and also by increasing peripheral venous pressure
2. Skeletal muscle contractions—promote venous return by squeezing veins through a contracting muscle and milking the blood toward the heart
3. One-way valves in veins prevent backflow (Figure 22-25)

E. Total blood volume—changes in total blood volume change the amount of blood returned to the heart

1. Capillary exchange—governed by Starling's law of the capillaries (Figure 22-26)
   a. At arterial end of capillary, outward hydrostatic pressure is strongest force; moves fluid out of plasma and into IF
   b. At venous end of capillary, inward osmotic pressure is strongest force; moves fluid into plasma from IF; 90% of fluid lost by plasma at arterial end is recovered
   c. Lymphatic system recovers fluid not recovered by capillary and returns it to the venous blood before it is returned to the heart
2. Changes in total blood volume—mechanisms that change total blood volume most quickly are those that cause water to quickly move into or out of the plasma (Figure 22-27)
   a. ADH mechanism—decreases the amount of water lost by the body by increasing the amount of water that kidneys resorb from urine before the urine is excreted from the body; triggered by input from baroreceptors and osmoreceptors
   b. Renin-angiotensin-aldosterone system (RAAS)—decreases water loss
      (1) Renin—released when blood pressure in kidney is low; leads to increased secretion of aldosterone, which stimulates retention of sodium, causing increased retention of water and an increase in blood volume
      (2) Angiotensin II—intermediate compound that causes vasoconstriction, which complements the volume-increasing effects of renin and promotes an increase in overall blood flow
   c. ANH mechanism—adjusts venous return from an abnormally high level by promoting the loss of water from plasma, causing a decrease in blood volume; increases urine sodium loss, which causes water to follow osmotically

F. A variety of feedback responses restore normal blood pressure after a sudden change in pressure (Figure 22-28)

MEASURING BLOOD PRESSURE

A. Arterial blood pressure

1. Measured with the aid of a sphygmomanometer and stethoscope; listen for Korotkoff sounds as the pressure in the cuff is gradually decreased (Figure 22-29)
2. Systolic blood pressure—force of the blood pushing against the artery walls while ventricles are contracting
3. Diastolic blood pressure—force of the blood pushing against the artery walls when ventricles are relaxed and during isovolumetric ventricular contraction
4. Pulse pressure—difference between systolic and diastolic blood pressure

B. Relation to arterial and venous bleeding

1. Arterial bleeding—blood escapes from artery in spurts because of alternating increase and decrease of arterial blood pressure
2. Venous bleeding—blood flows slowly and steadily because of low, practically constant pressure

MINUTE VOLUME OF BLOOD (FIGURE 22-30)

A. Minute volume—determined by the magnitude of the blood pressure gradient and peripheral resistance

B. Poiseuille's law—Minute volume = Pressure gradient ÷ Resistance

VELOCITY OF BLOOD FLOW

A. Governed by the physical principle that when a liquid flows from an area of one cross-sectional size to an area of larger size, its velocity decreases in the area with the larger cross section (Figure 22-31)

B. Blood flows more slowly through arterioles than arteries because total cross-sectional area of arterioles is greater than that of arteries, and capillary blood flow is slower than arteriole blood flow

C. Venule cross-sectional area is smaller than capillary cross-sectional area, causing blood velocity to increase in venules and then veins with a still smaller cross-sectional area

PULSE

A. Mechanism

1. Pulse—alternate expansion and recoil of an artery (Figure 22-32)

   a. Clinical significance: reveals important information regarding the cardiovascular system, blood vessels, and circulation
   b. Physiological significance: expansion stores energy released during recoil, conserving energy generated by the heart and maintaining relatively constant blood flow (Figure 22-33)
2. Existence of pulse is due to two factors
   a. Alternating increase and decrease of pressure in the vessel
   b. Elasticity of arterial walls allows walls to expand with increased pressure and recoil with decreased pressure

B. Pulse wave
1. Each pulse starts with ventricular contraction and proceeds as a wave of expansion throughout the arteries
2. Gradually dissipates as it travels, disappearing in the capillaries

C. Where the pulse can be felt—wherever an artery lies near the surface and over a bone or other firm background (Figure 22-34)

D. Venous pulse—detectable pulse exists only in large veins; most prominent near the heart; not of clinical importance

THE BIG PICTURE: BLOOD FLOW AND THE WHOLE BODY

A. Blood flow shifts materials from place to place and redistributes heat and pressure

B. Vital to maintaining homeostasis of internal environment

REVIEW QUESTIONS

Write out the answers to these questions after reading the chapter and reviewing the Chapter Summary. If you simply think through the answer without writing it down, you won't retain much of your new learning.

1. Identify, locate, and describe the function of each of the following structures: SA node, AV node, AV bundle, and subendocardial branches (Purkinje fibers).
2. What does an electrocardiogram measure and record? List the normal ECG deflection waves and intervals. What do the various ECG waves represent?
3. What is meant by the term *cardiac cycle*?
4. List the "phases" of the cardiac cycle and briefly describe the events that occur in each.
5. What is meant by the term *residual volume* as it applies to the heart?
6. Describe and explain the origin of the heart sounds.
7. Which blood vessels present the greatest resistance to blood flow?
8. What is the primary determinant of arterial blood pressure?
9. List the two most important factors that indirectly determine arterial pressure by their influence on arterial volume.
10. How is cardiac output determined?
11. List and give the effect of several factors, such as grief or pain, on heart rate.
12. What mechanisms control peripheral resistance? Cite an example of the operation of one or more parts of this mechanism to increase resistance and to decrease it.
13. What are the components of the vasomotor control mechanism?
14. Explain how antidiuretic hormone can change the total blood volume.
15. What is the effect of low blood pressure in relation to aldosterone and antidiuretic hormone secretion?
16. Describe the measurement of arterial blood pressure.
17. Identify the eight locations where the pulse point is most easily felt. List the six pressure points at which pressure can be applied to stop arterial bleeding distal to that point.
18. Describe the various types of cardiac dysrhythmias.

CRITICAL THINKING QUESTIONS

After finishing the Review Questions, write out the answers to these more in-depth questions to help you apply your new knowledge. Go back to sections of the chapter that relate to concepts that you find difficult.

1. What is an ectopic pacemaker? What would be the effect on the heart rate if an ectopic pacemaker took over for the SA node?
2. State in your own words the primary principle of circulation. How does it govern the various mechanisms involved in blood flow?
3. What is Starling's law of the heart? What role does *venous return* play in Starling's law?
4. Explain how the heart rate is a good example of dual innervation in the autonomic nervous system. Include the nerves and neurotransmitters involved.
5. Explain how blood pressure in the brain is prevented from getting too high.
6. What is arterial runoff? What is the relationship of arteriole runoff and peripheral resistance?
7. Explain what occurs when the carbon dioxide level in the medulla rises above set point.
8. By the time blood gets to the veins, almost all the pressure from the contracting ventricles has been lost. What mechanisms does the body use to assist in returning blood to the heart?
9. Explain the forces that act on capillary exchange on both the arterial and venous ends of the capillary. Is the recovery of fluid at the venous end 100% effective?
10. State in your own words Poiseuille's law. What equation expresses this law? According to the equation, an increase in resistance would lower the minute volume. Give an example of where this would not be the case.
11. What two factors determine blood viscosity? What does viscosity mean? Give an example of a condition in which blood viscosity decreases. Explain its effects on resistance, arterial pressure, and circulation.

Mechanisms of Disease, 738

Case Study, 741

The lymphatic system serves various functions in the body. The two most important functions of this system are maintenance of fluid balance in the internal environment and immunity. Although both of these important functions are discussed in this chapter, details of immunity are discussed more fully in Chapter 24. A third, somewhat less important, function of the lymphatic system is the absorption of lipids from digested food in the small intestine and its transport to the large systemic veins. This fat-transport function of the lymphatic system is discussed in Chapter 29.

OVERVIEW OF THE LYMPHATIC SYSTEM

The importance of the lymphatic system in maintaining a balance of fluid in the internal environment is best explained by the diagram in Figure 23-1. As this figure shows, plasma filters into interstitial spaces from blood flowing through capillaries. Most of this interstitial fluid (IF) is absorbed by tissue cells or reabsorbed by the blood before it flows out of the tissue. However, a small percentage of the interstitial fluid remains behind (review Figure 22-26, *A*, on p. 703). If this continued for even a brief period, the increased interstitial fluid would cause massive edema (swelling) of the tissue. The high fluid pressure from this edema could cause tissue destruction or perhaps even death as normal functions became disrupted. Such a problem is avoided by the presence of lymphatic vessels that act as "drains" to collect the excess tissue fluid and return it to the venous blood just before it reaches the heart.

The lymphatic system is a component of the circulatory system because it consists of a moving fluid (lymph) derived from the blood and tissue fluid and a group of vessels (lymphatics) that return the lymph to the blood. In general, the lymphatic vessels that drain the peripheral areas of the body parallel the venous return.

In addition to lymph and the lymphatic vessels, the system includes various structures that contain **lymphoid tissue**—a type of reticular tissue (see Chapter 6) that contains lymphocytes and other defensive cells. For example, lymph nodes are located along the paths of the collecting lymphatic vessels. Isolated nodules of lymphatic tissue, such as the **aggregated lymphoid nodules** called *Peyer patches* in the intestinal wall or the nodules of the vermiform appendix of the large intestine, are other examples. Additional lymphoid structures include the tonsils, thymus, spleen, and bone marrow (Figure 23-2).

Although it serves a unique transport function by returning tissue fluid, proteins, fats, and other substances to the general circulation, lymph flow differs from the true "circulation" of blood seen in the cardiovascular system. Unlike vessels in the blood vascular system, lymphatic vessels do not form a closed ring, or circuit, but instead begin blindly in the intercellular spaces of the soft tissues of the body (see Figure 23-1).

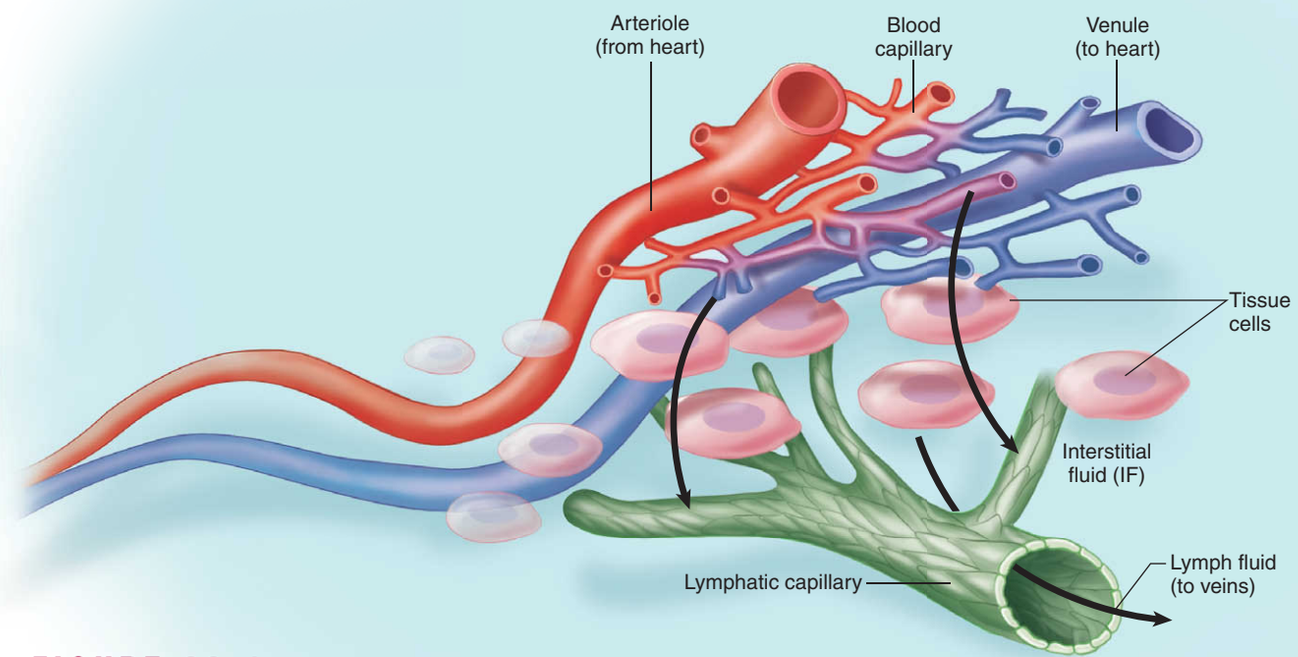

FIGURE 23-1

Role of the lymphatic system in fluid balance. Fluid from plasma flowing through the capillaries moves into interstitial spaces. Although *most* of this interstitial fluid is either absorbed by tissue cells or resorbed by blood capillaries, *some* of the fluid tends to accumulate in the interstitial spaces. As this fluid builds up, it tends to drain into lymphatic vessels (green) that eventually return the fluid to the venous blood. Lymphatic structures are not actually green. Green is used in diagrams to contrast lymphatic structures with nearby blood vessels (red, blue) or nerves (yellow).

LYMPH AND INTERSTITIAL FLUID

Lymph (or *lymphatic fluid*) is the clear, watery-appearing fluid found in the lymphatic vessels. **Interstitial fluid (IF),** which fills the spaces between the cells, is not the simple fluid it seems to be. Studies show that it is an important and complex part of the *ECM (extracellular matrix)*. Interstitial fluid and blood plasma together constitute the extracellular fluid compartment of the body, or in the words of Claude Bernard, the "internal environment of the body"—the fluid environment of cells in contrast to the atmosphere, or external environment, of the body.

Both lymph and interstitial fluid closely resemble blood plasma in composition. The main difference is that they contain a lower percentage of proteins than does plasma. Lymph is isotonic and almost identical in chemical composition to interstitial fluid when comparisons are made between the two fluids taken from the same area of the body. However, the average concentration of protein (4 grams/100 ml) in lymph taken from the thoracic duct (see Figure 23-2) is about twice that found in most interstitial fluid samples.

The elevated protein level of thoracic duct lymph (a mixture of lymph from all areas of the body) results from protein-rich lymph flowing into the duct from the liver and small intestine. A little more than one half of the 2800 to 3000 ml total daily lymph flowing through the thoracic duct is derived from these two organs.

Box 23-1 discusses the effects of abnormal loss of lymphatic fluid.

Box 23-1 | HEALTH matters

Loss of Lymphatic Fluid

Lymph does not clot. Therefore, if damage to the main lymphatic trunks in the thorax occurs as a result of penetrating injury, the flow of lymph must be stopped surgically or death ensues. It is impossible to maintain adequate plasma protein concentration by dietary means if significant loss of lymph continues over time. As lymph is lost, rapid emaciation occurs, with a progressive and eventually fatal decrease in total blood fat and protein concentration.

LYMPHATIC VESSELS

Distribution of Lymphatic Vessels

Lymphatic vessels—often simply called *lymphatics*—originate as microscopic blind-end vessels called *lymphatic capillaries.* (Those originating in the villi of the small intestine are called *lacteals*; see Chapter 29.) The wall of each **lymphatic capillary** consists of a single layer of flattened endothelial cells. Each blindly ending capillary is attached, or fixed, to surrounding cells by tiny connective tissue filaments. Networks of lymphatic capillaries branch and anastomose extensively. Lymphatic networks are located in the intercellular (interstitial) spaces and are widely distributed throughout the body. As a rule, lymphatic and blood capillary networks lie side by side but are always independent of each other.

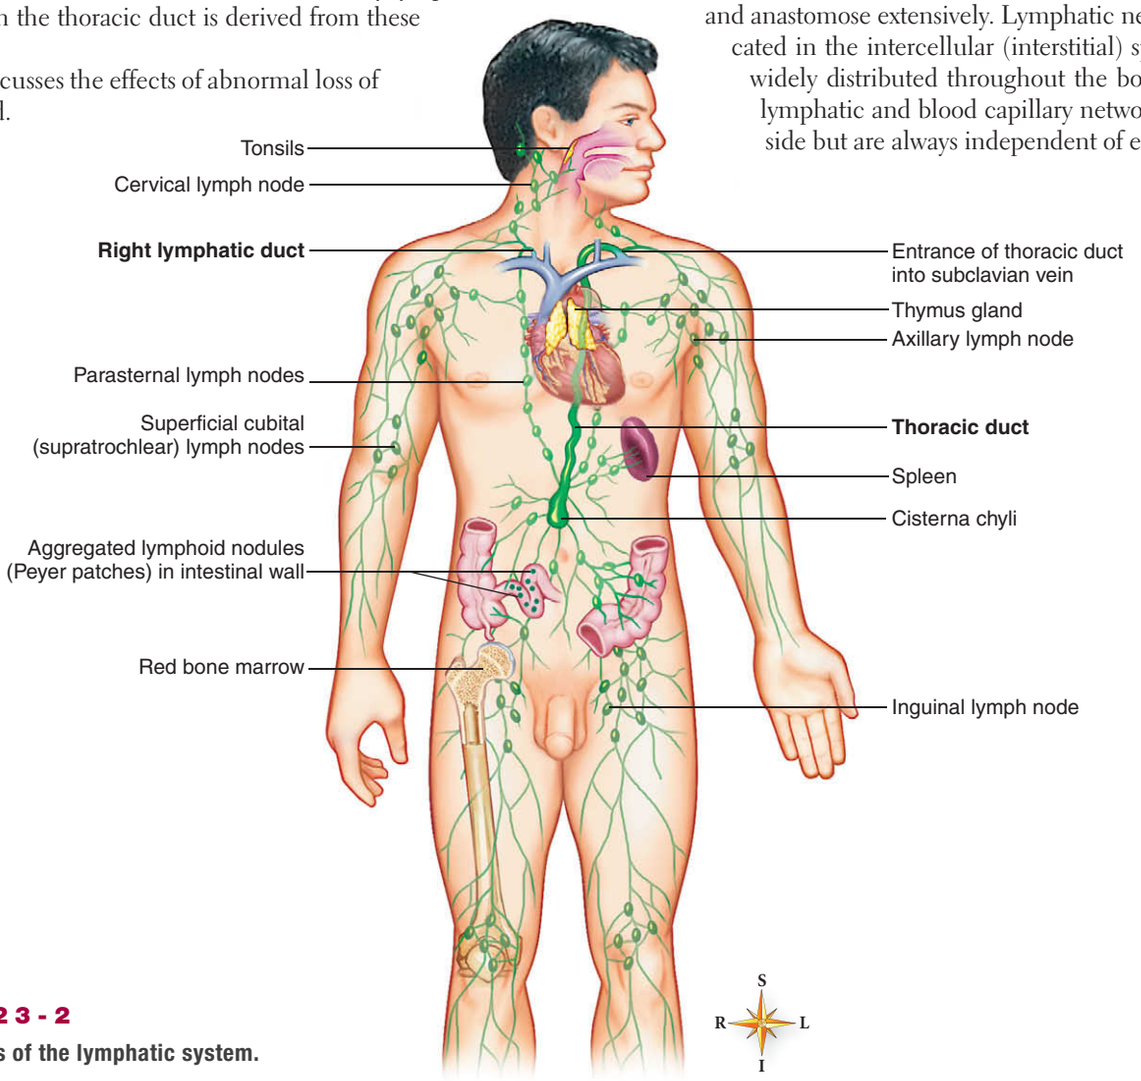

FIGURE 23-2
Principal organs of the lymphatic system.

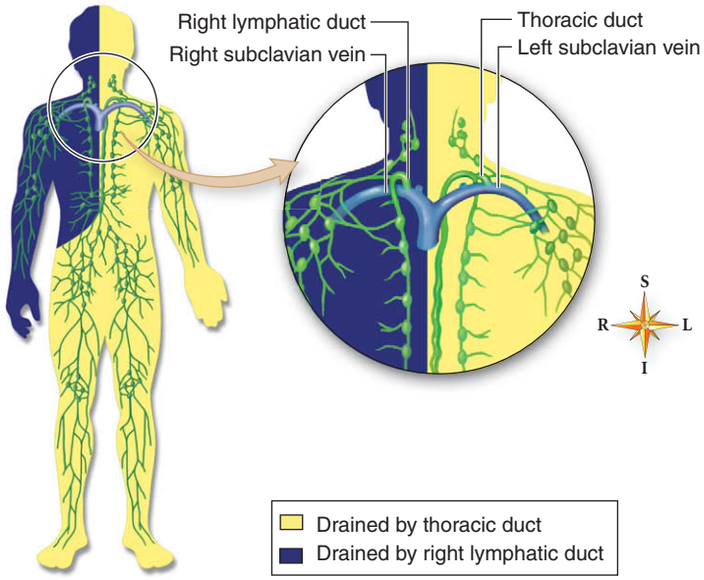

FIGURE 23-3

Lymphatic drainage. The right lymphatic duct drains lymph from the upper right quadrant *(dark blue)* of the body into the right subclavian vein. The thoracic duct drains lymph from the rest of the body *(green)* into the left subclavian vein. The lymphatic fluid is thus returned to the systemic blood just before entering the heart.

As twigs of a tree join to form branches, branches join to form larger branches, and larger branches join to form the tree trunk, so do lymphatic capillaries merge, forming slightly larger lymphatics that join other lymphatics to form still larger vessels, which merge to form the main lymphatic trunks: the **right lymphatic duct** and the **thoracic duct** (see Figure 23-2).

Lymph from the entire body, except for the upper right quadrant, drains eventually into the thoracic duct, which drains into the left subclavian vein at the point where it joins the left internal jugular vein (Figure 23-3). Lymph from the upper right quadrant of the body empties into the right lymphatic duct and then into the right subclavian vein. However, this structure can be vary among individuals. For example, in most people there are three separate lymphatic ducts that drain into the right subclavian vein rather than a single right lymphatic duct.

Because most of the lymph of the body returns to the bloodstream by way of the thoracic duct, this vessel is considerably larger than the other main lymph channels, the right lymphatic ducts, but is much smaller than the large veins, which it resembles in structure. It has an average diameter of about 5 mm (1.5 inches) and a length of about 40 cm (16 inches). It originates as a dilated structure, the **cisterna chyli** or *chyle cistern*, in the lumbar region of the abdominal cavity—where fatty lymph called *chyle* from the intestinal tract collects. The thoracic duct then ascends a curving pathway to the root of the neck, where it joins the subclavian vein as just described (see Figures 23-2 and 23-3).

Structure of Lymphatic Vessels

Lymphatics resemble veins in structure with these exceptions:

- Lymphatics have thinner walls.
- Lymphatics contain more valves.
- Lymphatics contain lymph nodes located at certain intervals along their course.

The lymphatic capillary wall is formed by a single layer of large but very thin and flat endothelial cells (Figure 23-4). Although the openings (clefts) between endothelial cells of lymphatic capillary walls are small, they are larger than those found in blood capillaries—a fact that explains the remarkable permeability of this system.

As lymph flows from the thin-walled capillaries into vessels with a larger diameter (0.2 to 0.3 mm), the walls become thicker and exhibit the three coats, or layers, typical of arteries and veins (see Table 21-1, p. 646). Interlacing elastic fibers and several strata of circular smooth muscle bundles are found in both the tunica media and the tunica externa of the large lymphatic vessel wall. Boundaries between layers are less distinct in the thinner lymphatic vessel walls than in arteries or veins.

One-way valves are extremely numerous in lymphatics of all sizes and give the vessels a somewhat varicose and beaded appearance. Valves are present every few millimeters in large lymphatics and are even more numerous in the smaller vessels. Formed from folds of the tunica intima, each valve projects into the vessel lumen in a slightly expanded area circled by bundles of smooth muscle fibers.

Experimental evidence suggests that most lymph vessels have the capacity for repair or regeneration when damaged. Formation of new lymphatic vessels occurs by extension of solid cellular cores, or sprouts, formed by mitotic division of endothelial cells in existing vessels, which later become "canalized."

Functions of Lymphatic Vessels

The lymphatics play a critical role in numerous interrelated homeostatic mechanisms. The high degree of permeability of the lymphatic capillary wall permits very large molecules and even

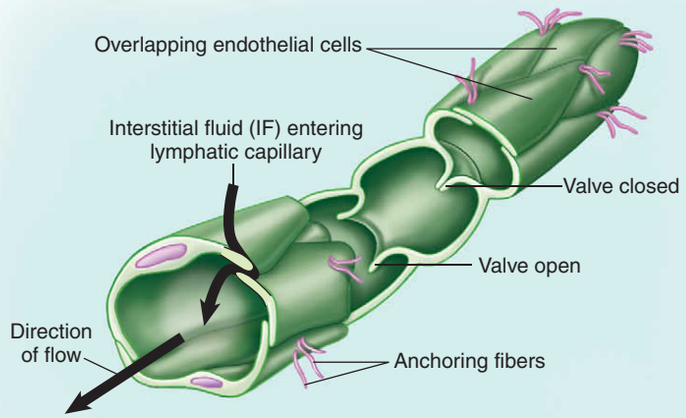

FIGURE 23-4

Structure of a typical lymphatic capillary. Notice that interstitial fluid enters through clefts between overlapping endothelial cells that form the wall of the vessel. Valves ensure one-way flow of lymph out of the tissue. Small fibers anchor the wall of the lymphatic capillary to the surrounding ECM (extracellular matrix) and cells, thus holding it open to allow entry of fluids and small particles.

particulate matter, which cannot be absorbed into a blood capillary, to be removed from the interstitial spaces. Proteins that accumulate in the tissue spaces can return to blood only by way of lymphatics. This fact has great clinical importance. For instance, if anything blocks lymphatic return, blood protein concentration and blood osmotic pressure soon fall below normal, and fluid imbalance and death will result (discussed in Chapter 32).

Lacteals (lymphatics in the villi of the small intestine) serve an important function in the absorption of fats and other nutrients. The milky lymph found in lacteals after digestion contains 1% to 2% fat and is called **chyle.** Interstitial fluid has a much lower lipid content than chyle (see Chapter 29).

CIRCULATION OF LYMPH

Water and solutes continually filter out of capillary blood into the interstitial fluid (see Figure 23-1). To balance this outflow, fluid continually reenters blood from the interstitial fluid. Newer evidence has disproved the old idea that healthy capillaries do not "leak" proteins. In truth, each day about 50% of the total blood proteins leak out of the capillaries into the tissue fluid and return to the blood by way of the lymphatic vessels. For more details about fluid exchange between blood and interstitial fluid, see Chapter 32. From lymphatic capillaries, lymph flows through progressively larger lymphatic vessels to eventually reenter blood at the junction of the internal jugular and subclavian veins (Figure 23-5).

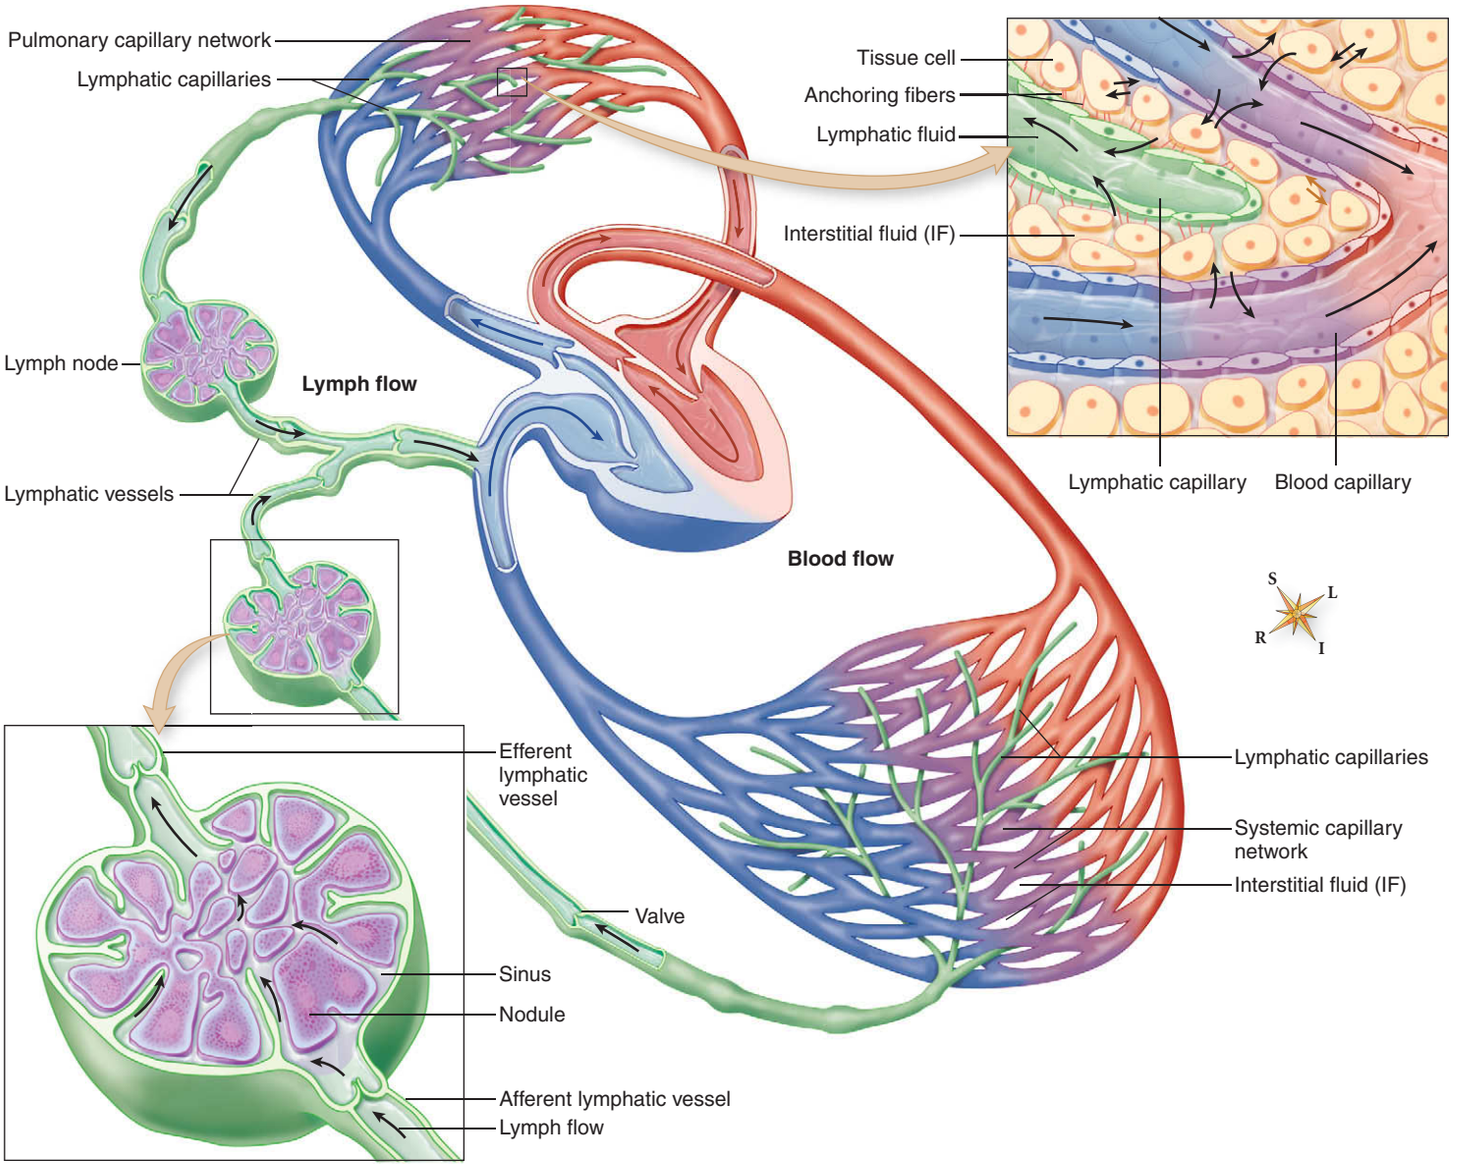

FIGURE 23-5

Circulation plan of lymphatic fluid. This diagram outlines the general scheme for lymphatic circulation. Fluids from the systemic and pulmonary capillaries leave the bloodstream and enter the interstitial space, thus becoming part of the IF (interstitial fluid). The IF also exchanges materials with the surrounding tissues. Often, because less fluid is returned to the blood capillary than had left it, IF pressure increases—causing IF to flow into the lymphatic capillary. The fluid is then called *lymph* (lymphatic fluid) and is carried through one or more lymph nodes and finally to large lymphatic ducts. The lymph enters a subclavian vein, where it is returned to the systemic blood plasma. Thus fluid circulates through blood vessels, tissues, and lymphatic vessels in a sort of "open circulation."

The Lymphatic Pump

Although there is no muscular pumping organ connected with the lymphatic vessels to force lymph onward as the heart forces blood, lymph still moves slowly and steadily along in its vessels. Lymph flows through the thoracic duct and reenters the general circulation at the rate of about 3 liters per day. This occurs despite the fact that most of the flow is against gravity, or "uphill." It moves through the system in the right direction because of the large number of valves that permit fluid flow only in the central direction.

What mechanisms establish the pressure gradient required by the basic law of fluid flow? Two of the same mechanisms that contribute to the blood pressure gradient in veins also establish a lymph pressure gradient. These are breathing movements and skeletal muscle contractions (see Figure 22-24, p. 702). Box 23-2 explains one of many reasons a working knowledge of lymphatic flow is important.

Activities that result in central movement, or flow, of lymph are called *lymphokinetic* actions (from the Greek *kinetos*, "movable"). Thus the flow of lymph may be called **lymphokinesis.** X-ray films taken after radiopaque material is injected into the lymphatics show that lymph pours into the central veins most rapidly at the peak of inspiration. This method of visualizing lymphatic vessels is called **lymphangiography** (Figure 23-6).

The mechanism of inspiration, resulting from the descent of the diaphragm, causes intraabdominal pressure to increase as intrathoracic pressure decreases. This simultaneously causes pressure to increase in the abdominal portion of the thoracic duct and to decrease in the thoracic portion. In other words, the process of inspiring establishes a pressure gradient in the thoracic duct that causes lymph to flow upward through it.

Research studies have shown that thoracic duct lymph is literally "pumped" into the venous system during the inspiration phase of pulmonary ventilation. The rate of flow, or ejection, of lymph into the venous circulation is proportional to the depth of inspiration. The total volume of lymph that enters the central veins during a given period depends on the depth of the inspiration phase and the overall breathing rate.

Most lymph flow in the body is the result of contracting skeletal muscles. As muscles contract, they "milk" the lymphatic vessels and push the lymph forward (Figure 23-7). The actual pressure

Box 23-2 | HEALTH matters

Lymphatic Drainage and Artificial Limbs

An understanding of the anatomy of lymphatic drainage of the skin is critically important in surgical amputation of an extremity. A majority of the lymphatics draining the skin are located in plexus-like networks lying on the deep fascia. To prevent stasis of lymph in the stump following amputation, the surgeon retains the deep fascia and its lymphatic vessels with the skin flaps that are used to cover the cut end of the extremity. This procedure results in minimal edema and swelling—a matter of obvious importance to the patient and artificial-limbfitter.

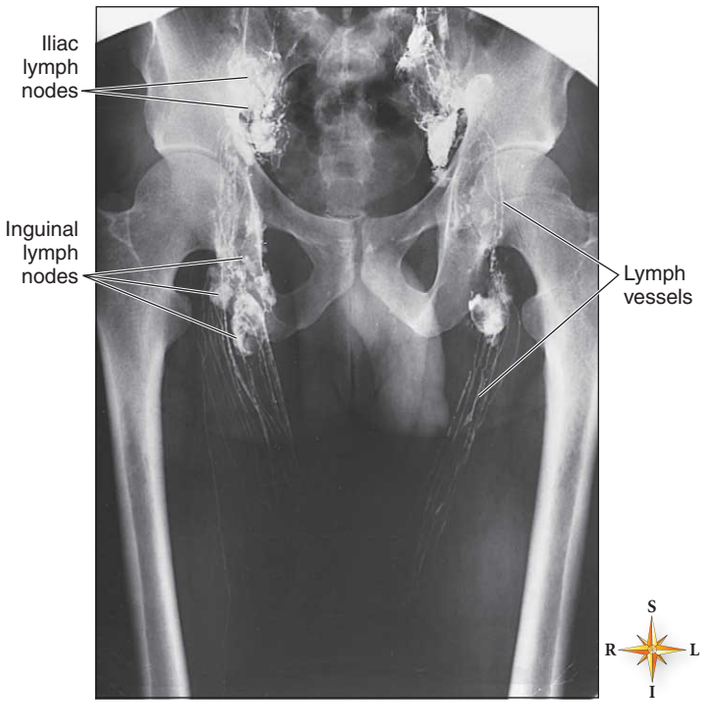

FIGURE 23-6

Lymphangiogram. A dye that is radiopaque (blocks x rays) is injected into the interstitial fluid that eventually drains into nearby lymphatic pathways. There the dye is seen as bright areas outlining the location of pelvic (iliac) and inguinal lymphatic vessels and lymph nodes.

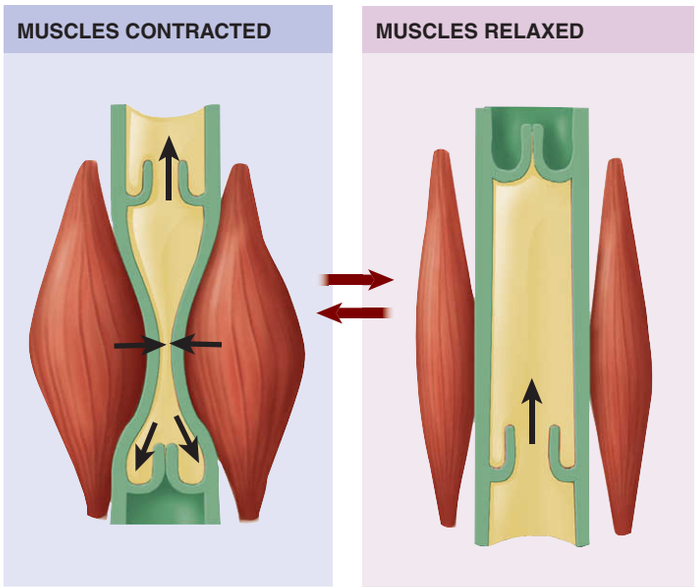

FIGURE 23-7

Lymphatic pump. The diagram shows a "muscle pump" in a lymphatic vessel similar to that which moves blood through the veins. Increased external pressure from muscle contraction also increases lymphatic pressure, pushing it past one-way lymphatic valves. Because the valves prevent backflow, the system becomes a pump that keeps lymph moving in one direction (toward a subclavian vein).

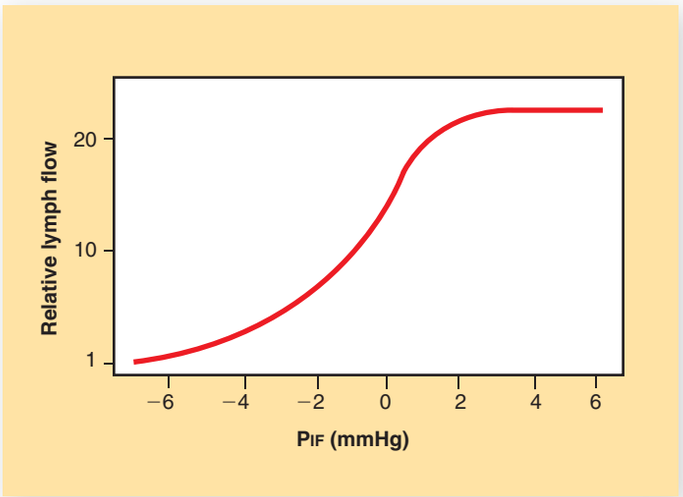

FIGURE 23-8

Lymph flow and interstitial fluid (IF) pressure. As the pressure of IF increases, the flow of lymph increases. Muscle pumps can increase IF pressure, as can other factors, such as accumulation of additional interstitial fluid volume within a tissue.

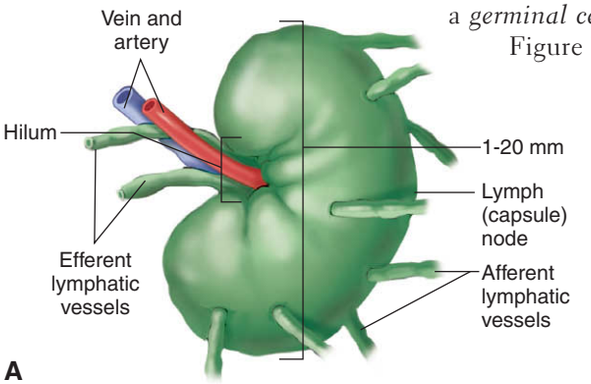
generated in the system remains very low, and movement of lymph proceeds quite slowly when compared with the circulation of blood. During exercise, lymph flow may increase as much as 10 to 15 times. In addition to lymph flow caused by skeletal muscle contractions, a very limited amount of smooth muscle exists in the walls of the large lymphatic trunks. Contraction of the smooth muscle in the thoracic vessel walls permits lymphatic vessels to pulse rhythmically and thus help move lymph from one valved segment to the next.

Other pressure-generating factors that can compress the lymphatics also contribute to the effectiveness of the "lymphatic pump." Examples of such lymphokinetic factors include interstitial fluid pressure (Figure 23-8), arterial pulsations, postural changes, and passive compression (massage) of the body soft tissues.

Although the overall volume of lymph that enters the bloodstream during each 24-hour period averages about 3 L, it may enter the system at different rates during the day. The rate of return varies, depending on the level of generalized physical activity and other factors, including changes in the interstitial fluid pressure and the rate and depth of respiration. As physical activity increases, so does the outflow of fluid from blood capillaries into the tissue spaces of the body. The increased flow of lymph that occurs with increased physical activity helps return this fluid to the cardiovascular system and thus serves as an important balancing or homeostatic mechanism.

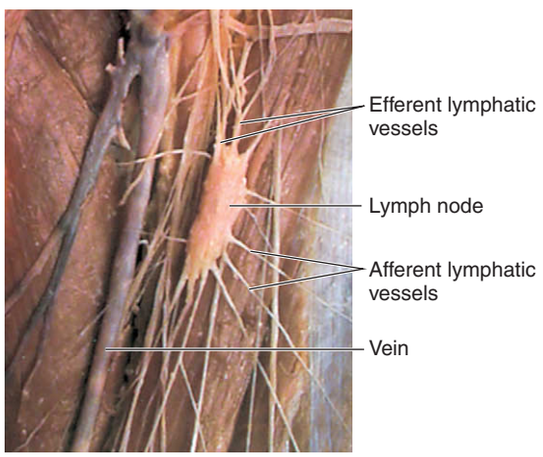
| QUICK CHECK |

1. What is the overall function of the lymphatic system?
2. What is the origin of lymph?
3. Compare lymphatic vessels with blood vessels.



LYMPH NODES

Structure of Lymph Nodes



Lymph nodes, or *lymph glands,* as some people call them, are oval-shaped or bean-shaped structures (Figure 23-9). Some are as small as a pinhead, and others are as large as a lima bean. Each lymph node (from 1 mm to more than 20 mm in diameter) is enclosed by a fibrous capsule. Note in Figure 23-10 that lymph moves into a node by way of *afferent* lymphatic vessels and emerges by one or more *efferent* vessels.

Think of a lymph node as a biological filter placed in the channel of several afferent lymph vessels (as you saw in Figure 23-5). Once lymph enters the node, it "percolates" slowly through the spaces known as sinuses before draining into the single efferent exit vessel. One-way valves in both the afferent and efferent vessels keep lymph flowing in one direction.

Fibrous septa, or *trabeculae,* extend from the covering capsule toward the center of the node. **Cortical nodules** within sinuses along the periphery, or cortex, of the node are separated from each other by these connective tissue trabeculae. Each cortical nodule is composed of packed lymphocytes that surround a less dense area called a *germinal center* (see Figure 23-10).

A

B

FIGURE 23-9

External structure of a lymph node. A, A lymph node is typically a small structure into which afferent lymphatic ducts empty their lymph and out of which efferent lymphatic ducts drain the lymph. An outer fibrous capsule maintains the structural integrity of the node. **B,** Photograph of a dissected cadaver shows a lymph node and its associated lymphatic vessels, along with nearby muscles, nerves, and blood vessels.

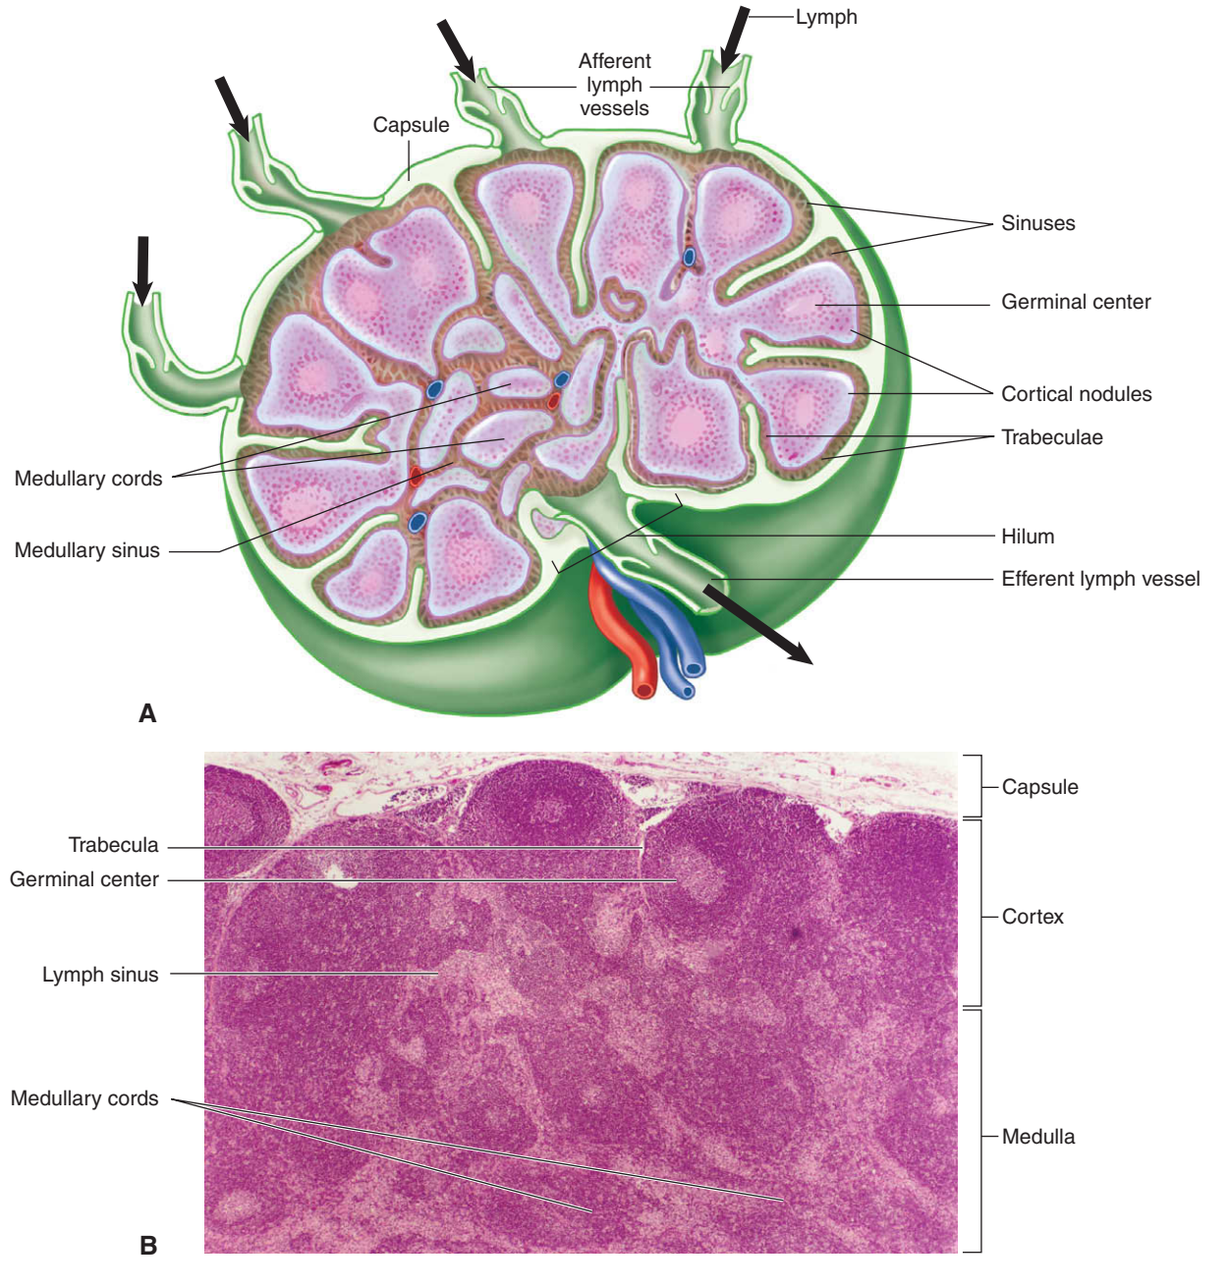


FIGURE 23-10

Internal structure of a lymph node. A, Several afferent valved lymphatics bring lymph to the node. In this example, a single efferent lymphatic leaves the node at a concave area called the *hilum.* Note that the artery and vein also enter and leave at the hilum. Arrows show direction of lymph flow. **B,** Photomicrograph and drawing showing a portion of the cortex and medulla of a lymph node.

Figure 23-10, *B*, is a low-power (×35) light micrograph of a portion of a typical lymph node. When an infection is present, germinal centers form and the node begins to release lymphocytes. B lymphocytes (B cells) begin their final stages of maturation within the less dense germinal center of the nodule and then are pushed to the more densely packed outer layers as they mature to become antibody-producing plasma cells. The center, or medulla, of a lymph node is composed of sinuses and medullary cords (see Figure 23-10). Both the cortical and medullary sinuses are lined with reticuloendothelial cells (macrophages) capable of phagocytosis.

Locations of Lymph Nodes

With the exception of comparatively few single nodes, most lymph nodes occur in groups, or clusters, in certain areas. The group locations of greatest clinical importance are as follows:

Preauricular lymph nodes—located just in front of the ear; these nodes drain the superficial tissues and skin on the lateral side of the head and face (Figure 23-11).

Submental group and **submandibular group** *(submaxillary)*—in the floor of the mouth; lymph from the nose, lips, and teeth drains through these nodes (see Figure 23-11).

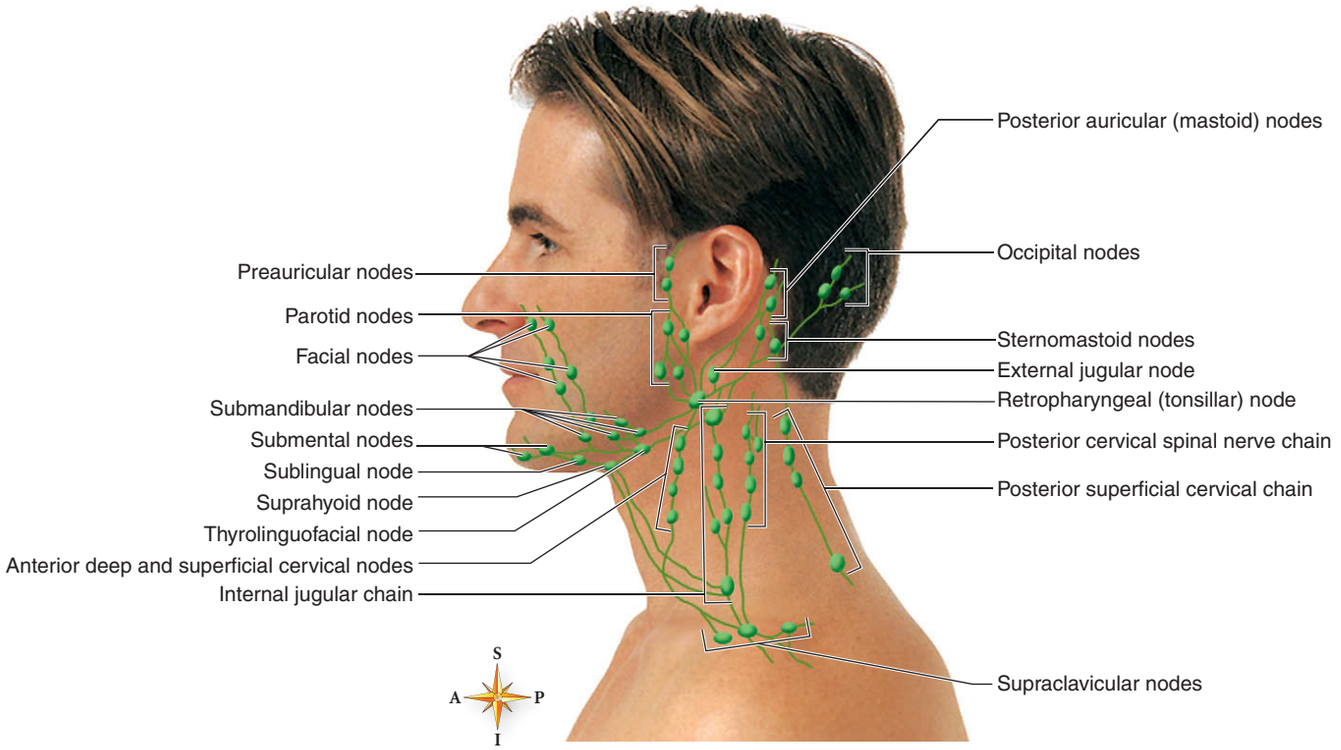

FIGURE 23-11

Lymphatic drainage of the head and neck. The head and neck contain many lymph nodes (and associated lymphatic vessels) that are often of clinical significance in certain infections and cancers.

Superficial cervical lymph nodes—in the neck along the sternocleidomastoid muscle, these nodes drain lymph (which has already passed through other nodes) from the head and neck (see Figures 23-11 and 23-12).

Superficial cubital lymph nodes (supratrochlear lymph nodes)—located just above the bend of the elbow; lymph from the forearm passes through these nodes (see Figure 23-2).

Axillary lymph nodes—(20 to 30 large nodes clustered deep within the underarm and upper chest regions); lymph from the arm and upper part of the thoracic wall, including the breast, drains through these nodes (see Figure 23-2).

Iliac lymph nodes and **inguinal lymph nodes**—in the pelvis and groin; lymph from the pelvic organs, legs, and external genitals drains through these nodes (Figures 23-6 and 23-13).

Functions of Lymph Nodes

Lymph nodes perform at least two distinct functions: defense and hematopoiesis.

DEFENSE FUNCTIONS: FILTRATION AND PHAGOCYTOSIS

The structure of the sinus channels within lymph nodes slows the lymph flow through them. This gives the reticuloendothelial cells that line the channels time to remove the microorganisms and other injurious particles—soot, for example—from the lymph

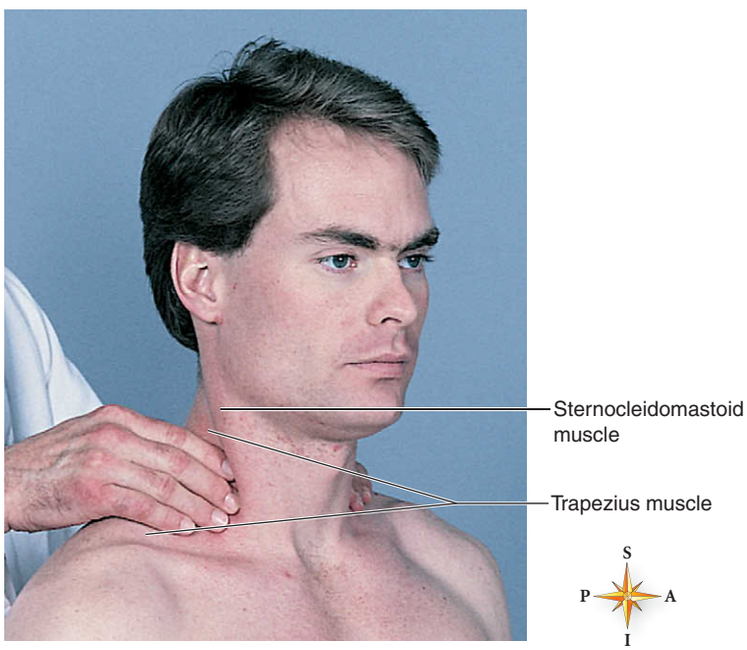

FIGURE 23-12

Palpation of the posterior cervical lymph nodes. The pads of the fingertips are used to palpate (feel) along the anterior surface of the trapezius muscle and then moved slowly in a circular motion to the posterior surface of the sternocleidomastoid muscle. Swollen lymph nodes may be a sign of infection, cancer, blocked lymphatic drainage, or some other abnormal condition.

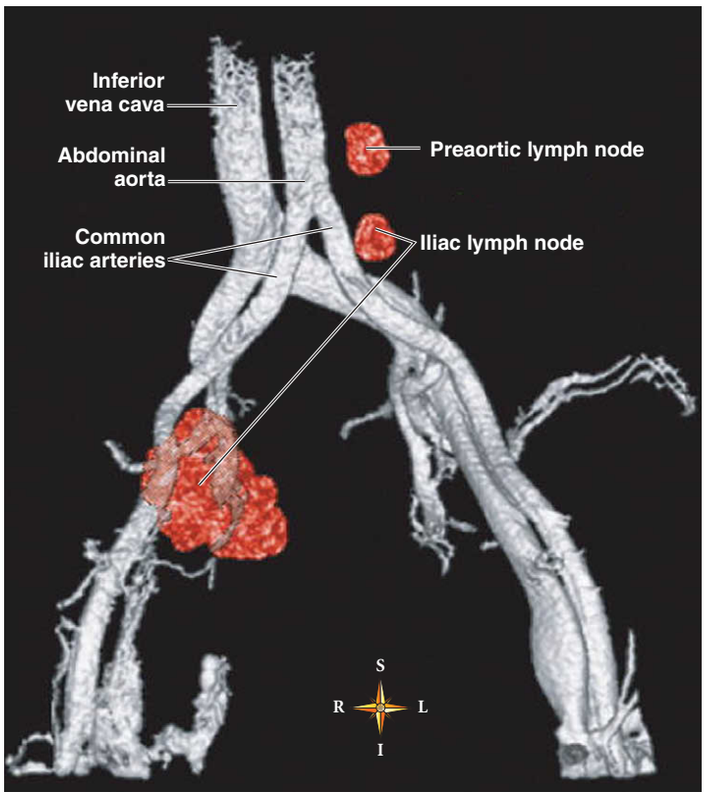

FIGURE 23-13

MRI of lymph nodes. This three-dimensional MRI (magnetic resonance image) has been enhanced by the use of specially engineered nanoparticles that are injected into the blood and then later ingested by macrophages in the lymphoid tissue of the lymph nodes. In lymphoid tissue containing metastasized cancer cells, there is a recognizable, abnormal pattern calculated in the MRI software (color-coded red in this image). Thus cancerous lymph nodes can be identified and accurately located for surgical removal or other therapy.

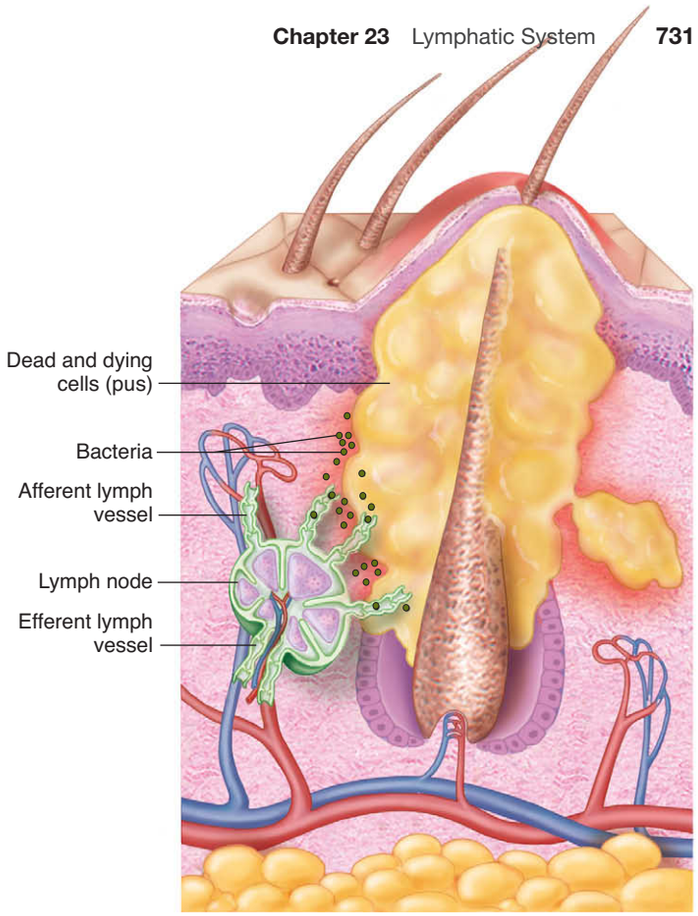

FIGURE 23-14

Role of a lymph node in a skin infection. Leukocytes phagocytose many bacteria in tissue spaces. Others may enter the lymph nodes by way of afferent lymphatics. The nodes filter out these bacteria; reticuloendothelial cells within the nodes usually destroy all the bacteria by phagocytosis. (Lymph node is shown smaller than actual size.)

and phagocytose them (Figure 23-14). Lymph nodes physically stop particles from progressing farther in the body—a process called *mechanical filtration*. Because lymph nodes also make use of biological processes such as phagocytosis to destroy particles, *biological filtration* also occurs here.

Sometimes, however, such hordes of microorganisms enter the nodes that the phagocytes cannot destroy enough of them to prevent injury to the node. An infection of the node, *adenitis*, then results. Also, because cancer cells often break away from a malignant tumor and enter lymphatics, they travel to the lymph nodes, where they may set up new growths and block flow of lymph. This may leave too few channels for lymph to return to the blood. For example, if tumors block axillary node channels, fluid accumulates in the interstitial spaces of the arm, causing the arm to become markedly swollen. Even viruses such as HIV (human immunodeficiency virus) and other types of pathogens can infect or infest lymph nodes, as seen in Figure 23-15.

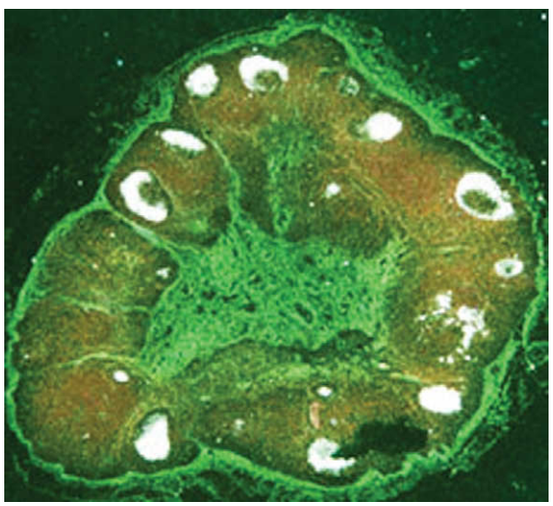

FIGURE 23-15

Infected lymph node. This lymph node is infected with HIV (human immunodeficiency virus), seen in this specially stained micrograph as white areas. Researchers at the National Institute of Allergy and Infectious Disease (NIAID) found that lymphoid tissue is a major reservoir for HIV, thus providing a sanctuary for viral replication while the virus is being cleared from the bloodstream by the immune system.

HEMATOPOIESIS

The lymphoid tissue of lymph nodes serves as the site of the final stages of maturation for some types of lymphocytes and monocytes that have migrated from the bone marrow. In addition to lymph nodes and the major lymphatic organs described later in the chapter, small aggregates of diffuse lymphoid tissue and other lymphatic cell types are found throughout the body—especially in connective tissues and under mucous membranes.

LYMPHATIC DRAINAGE OF THE BREAST

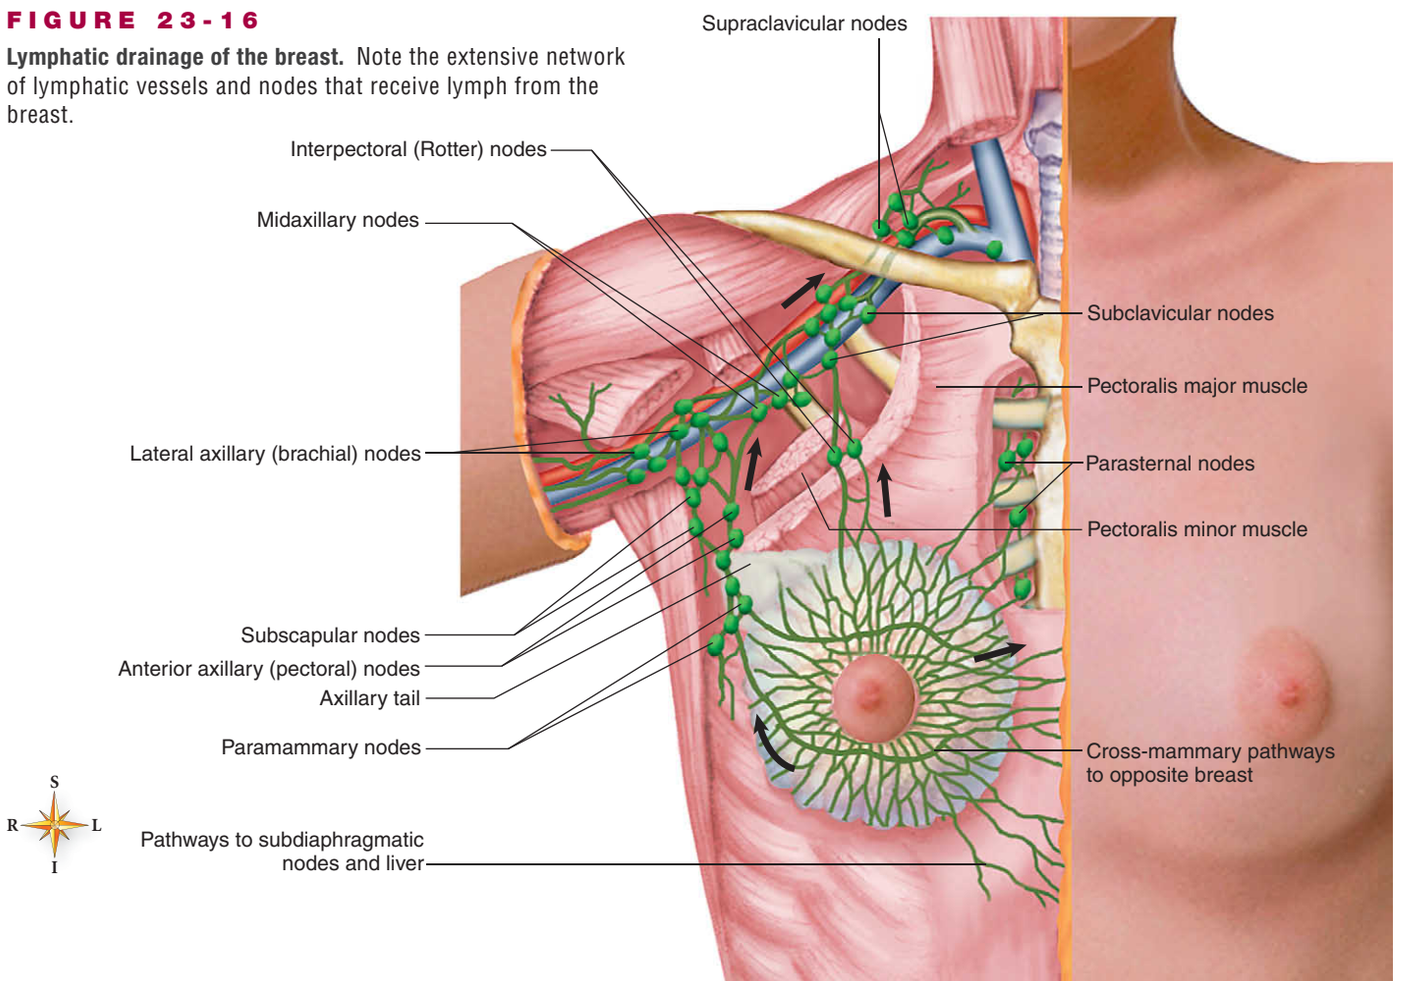
Cancer of the breast is one of the most common forms of malignancy in women. Unfortunately, cancerous cells from a single "primary" tumor in the breast often spread to other areas of the body through the lymphatic system. An understanding of the lymphatic drainage of the breast is therefore of particular importance in the diagnosis and treatment of this type of malignancy (Box 23-3).

Breast infections (**mastitis**) are also a serious health concern, especially among women who are nursing infants. Breast infections, like cancer, can also spread easily through lymphatic pathways associated with the breast. Refer to Figure 23-16 as you study the lymphatic drainage of the breast.

Box 23-3 | HEALTH matters

Lymphedema After Breast Surgery

Surgical procedures called *mastectomies,* in which some or all of the breast tissues are removed, are sometimes performed to treat breast cancer. Because cancer cells can spread so easily through the extensive network of lymphatic vessels associated with the breast (see Figure 23-16), the lymphatic vessels and their nodes are sometimes also removed. Occasionally, such procedures interfere with the normal flow of lymph fluid from the arm. When this happens, tissue fluid may accumulate in the arm—resulting in swelling, or **lymphedema.** Fortunately, adequate lymph drainage is almost always restored by the reestablishment of new lymphatic vessels, which grow back into the area.



Distribution of Lymphatics in the Breast

The breast—mammary gland and surrounding tissues—is drained by the following two sets of lymphatic vessels:

1. Lymphatics that originate in and drain the skin over the breast with the exception of the areola and nipple
2. Lymphatics that originate in and drain the underlying substance of the breast itself, as well as the skin of the areola and nipple

FIGURE 23-16

Lymphatic drainage of the breast. Note the extensive network of lymphatic vessels and nodes that receive lymph from the breast.

Superficial vessels that drain lymph from the skin and surface areas of the breast converge to form a diffuse *cutaneous lymphatic plexus*. Communication between the cutaneous plexus and large lymphatics that drain the secretory tissue and ducts of the breast occurs in the *subareolar plexus (plexus of Sappey)* located under the areola surrounding the nipple.

Box 23-4 discusses the numerous connections of the breast lymphatic pathways.

Lymph Nodes Associated with the Breast

More than 85% of the lymph from the breast enters the lymph nodes of the axillary region (see Figure 23-16). Most of the remainder enters lymph nodes along the lateral edges of the sternum.

Several very large nodes in the axillary region are in actual physical contact with an extension of breast tissue called the *axillary tail (tail of Spence)*. Because of the physical contact between these nodes and breast tissue, cancerous and infectious cells may spread by both lymphatic extension and contiguity of tissue. Other nodes in the axilla or chest wall will enlarge and swell after being "seeded" with malignant cells or bacteria as lymph from a cancerous or infected breast flows through them. For example, interpectoral (Rotter) nodes found between the pectoralis major and minor muscles often contain metastases from mammary cancer.

A **sentinel lymph node (SLN)** is the first lymph node to which a cancerous tumor can spread. When a tumor is detected, the nearby SLN may be examined in a biopsy to determine whether cancer cells are present—showing that the cancer has metastasized.

| QUICK CHECK |

4. Describe the overall structure of a typical lymph node.
5. Where are lymph nodes usually found?
6. What functions are carried out by lymph nodes?
7. How do the lymphatic structures of the breast relate to breast cancer?

Box 23-4 | HEALTH matters

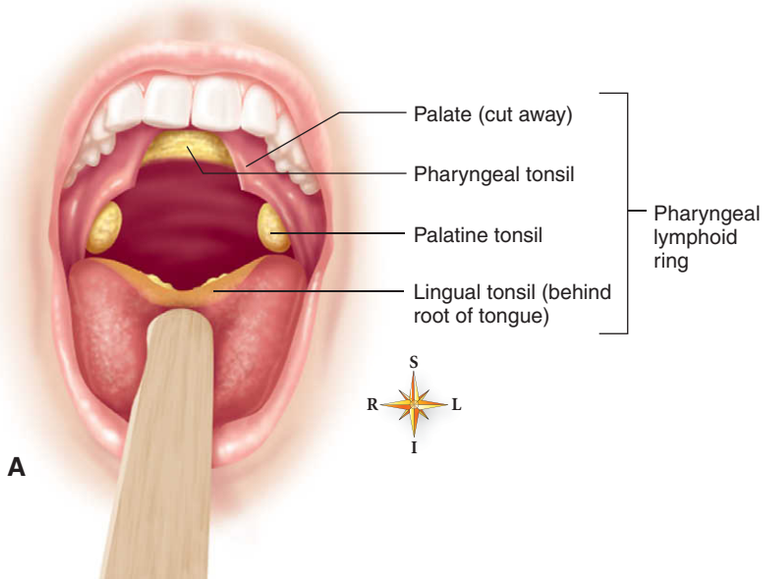
Lymphatic Anastomoses and Breast Cancer

Anastomoses (connections) occur between superficial lymphatics from both breasts across the middle line. Such communication can result in the spread of cancerous cells in one breast to previously healthy tissue in the other breast.

Both superficial and deep lymphatic vessels also communicate with lymphatics in the fascia of the pectoralis major muscle. Removal of a wide area of deep fascia is therefore required in surgical treatment of advanced or diffuse breast malignancy (radical mastectomy). In addition, cancer cells from a breast tumor sometimes reach the abdominal cavity because of lymphatic communication through the upper part of the linea alba.

A more thorough discussion of breast cancer is found in Chapter 35, beginning on p. 1090.

TONSILS



Masses of lymphoid tissue, called **tonsils,** are located in a protective ring under the mucous membranes in the mouth and back of the throat (Figure 23-17, A). This ring is called the *pharyngeal lymphoid ring*. The ring of tonsils helps protect against bacteria that may invade tissues in the area around the openings between the nasal and oral cavities.

The **palatine tonsils** are located on each side of the throat. The **pharyngeal tonsils,** known as *adenoids* when they become swollen, are near the posterior opening of the nasal cavity. A third type of tonsil, the **lingual tonsils,** is near the base of the tongue. A fourth type of tonsil, the *tubal tonsils*, are located near the opening of the auditory (eustachian) tube. Each of the tonsils has deep recesses called *tonsillar crypts* that trap bacteria and put them in close contact with cells of the immune system.

The tonsils serve as the first line of defense from the exterior and as such are subject to chronic infection, or tonsillitis

FIGURE 23-17

Location of the tonsils. A, Small segments of the roof and floor of the mouth have been removed to show the protective ring of tonsils (pharyngeal lymphoid ring) around the internal openings of the nose and throat. Tubal tonsils are not visible in this view. **B,** Tonsillitis. Note the swelling and presence of a white coating (exudate) indicating an infection.

UNIT 4

(Figure 23-17, *B*). They are sometimes removed surgically if antibiotic therapy is not successful or if swelling impairs breathing. This procedure, called **tonsillectomy,** has become controversial because of the critical immunological role played by the lymphoid tissue.

| A&P CONNECT |

Because it is exposed to the external environment, the respiratory tract could be extremely vulnerable. Look at the structure of a tonsil and learn about its defensive role in ***Protective Strategies of the Respiratory Tract*** online at ***A&P Connect.***

evolve

THYMUS

Location and Appearance of the Thymus

Intensive study and experimentation have identified the **thymus** as a primary organ of the lymphatic system. It is an unpaired organ consisting of two pyramidal lobes with delicate and finely lobulated surfaces. The thymus is located in the mediastinum, extending up into the neck as far as the lower edge of the thyroid gland and inferiorly as far as the fourth costal cartilage (Figure 23-18, A). Its size relative to the rest of the body is largest in a child about 2 years old. Its absolute size is largest at puberty, when its weight ranges between 35 and 40 grams. From then on, it gradually atrophies until, in advanced old age, it may be largely replaced by fat, weigh less than 10 grams, and be barely recognizable. The process of shrinkage of an organ in this manner is called **involution.** The thymus is pinkish gray in color early in childhood but, with advancing age, becomes yellowish as lymphoid tissue is replaced by fat.

Structure of the Thymus

The lobes of the thymus are subdivided into small (1- to 2-mm) lobules by connective tissue septa that extend inward from a fibrous covering capsule. Each lobule is composed of a dense cellular cortex and an inner, less dense medulla (Figure 23-18, *B*). Both cortex and medulla are composed of lymphocytes in an epithelial framework quite different from the supporting connective tissue seen in other lymphoid organs.

In stained histological sections of thymus, medullary tissue can be identified by the presence of rather large (30- to 150-mm) laminated spherical structures called **thymic corpuscles,** or *Hassall corpuscles.* Composed of concentric layers of keratinized epithelial cells, thymic corpuscles have a unique onionlike appearance. These corpuscles may serve as a place to break down dead, keratinized epithelial cells migrating inward from the outer parts of each lobule. They also secrete some of the regulatory molecules that affect white blood cell (WBC) development described in the next section.

Function of the Thymus

One of the body's best-kept secrets has been the function of the thymus. Before 1961 there were no significant clues as to its role. Then a young Briton, Dr. Jacques F.A.P. Miller, removed the thymus glands from newborn mice. His findings proved startling and crucial. Almost like a chain reaction, further investigations followed, leading to the gradual uncovering of the thymus's long-held secrets. It is now clear that this small structure plays a critical part in the body's defenses against infections—in its vital immunity mechanism (see Chapter 24).

The thymus performs at least two important functions. First, it serves as the final site of lymphocyte development before birth. (The fetal bone marrow forms immature lymphocytes, which then move to the thymus.) Many lymphocytes leave the thymus and circulate to the spleen, lymph nodes, and other lymphoid tissues. Second, soon after birth the thymus begins secreting a group of hormones (collectively called

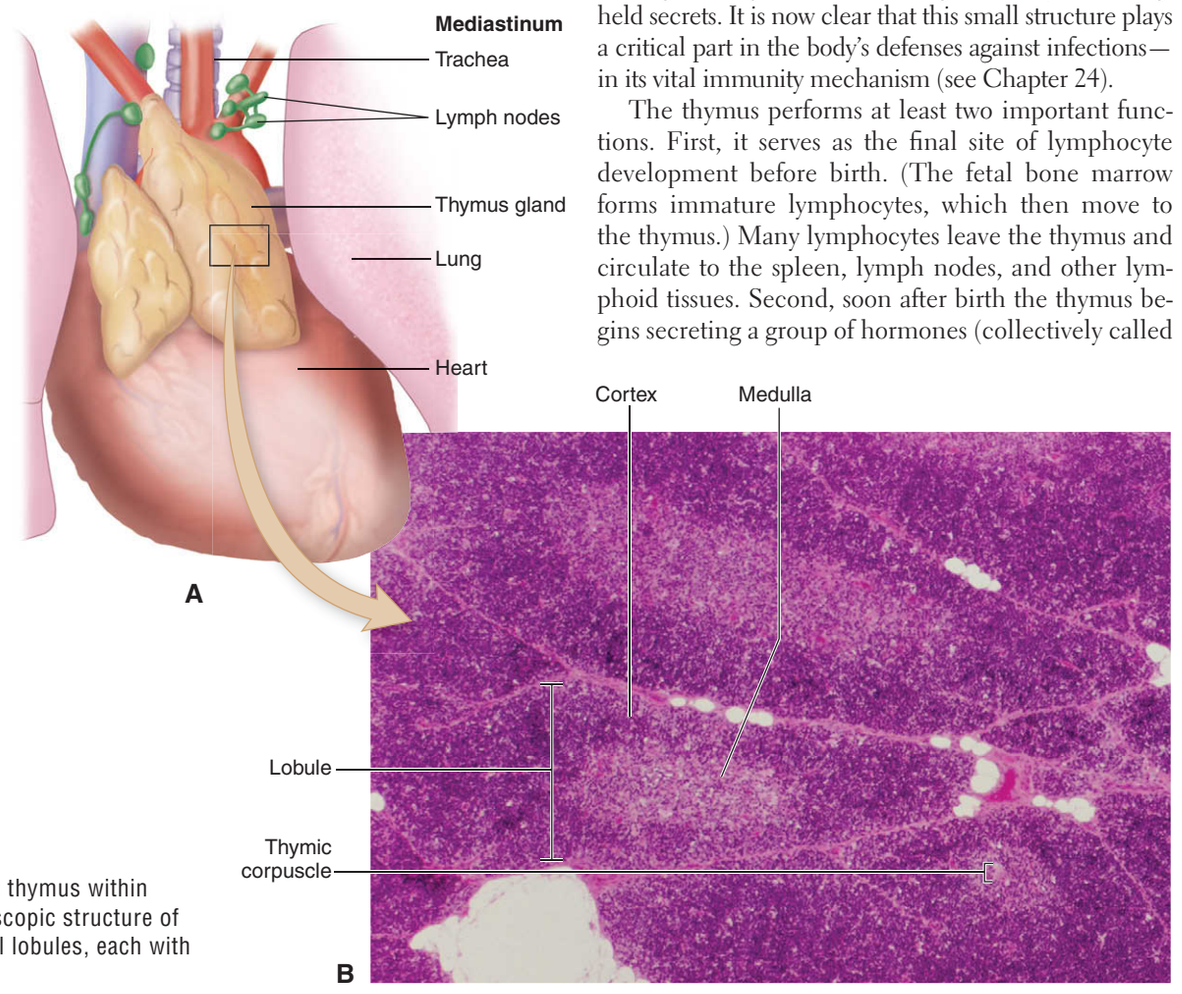


FIGURE 23-18

Thymus. A, Location of the thymus within the mediastinum. **B,** Microscopic structure of the thymus showing several lobules, each with a cortex and a medulla.

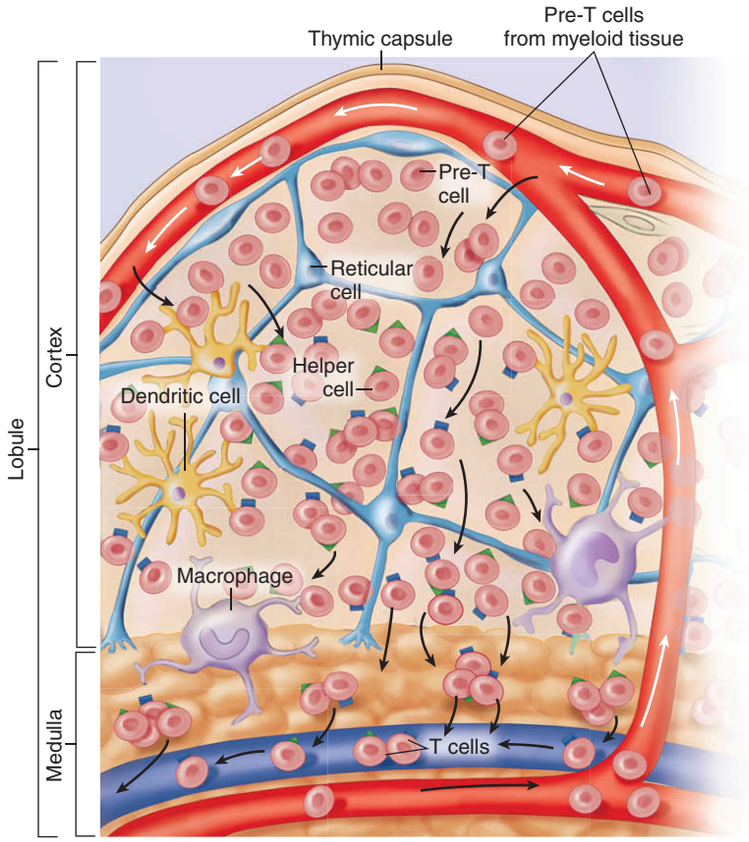

FIGURE 23-19

T-cell development in the thymus. This diagram shows part of a lobule, with the cortex at the top and the medulla at the bottom. Pre–T cells derived from hematopoietic stem cells in red bone marrow (myeloid tissue) travel through the bloodstream to the cortex of the thymus. Under the influence of thymosin and other regulators, the pre–T cells divide and mature as they migrate toward the medulla. Along the way, the developing T cells (T lymphocytes) are tested for immune capability against various lymphoid immune cells, such as dendritic cells and macrophages. Only about 5% of the cells pass these tests and are released into the bloodstream to defend the body.

thymosin) and other regulators that enable lymphocytes to develop into mature T cells. Only T cells (T lymphocytes) that pass immunological testing by lymphoid cells such as *macrophages* and *dendritic cells*—only about 5% of the cells that mature each day—are released into the bloodstream. Figure 23-19 outlines some essential steps in T cell development within the thymus.

Because T cells attack foreign or abnormal cells and also serve as regulators of immune function, the thymus functions as an important part of the immune mechanism. It is most active in childhood. Beginning at puberty, involution of the thymus reduces its function gradually through adulthood. By time a person is 50, only 10% of functional thymus tissue remains. Elderly people have virtually no functional thymus tissue left, a factor that contributes to reduced immune function associated with aging.

SPLEEN

Location of the Spleen

The **spleen** is located in the left hypochondrium of the abdominopelvic cavity, directly below the diaphragm. The spleen is just above most of the left kidney and the descending colon and behind the fundus of the stomach (Figures 23-2 and 23-20). In addition, it is common to find small *accessory spleens* embedded in the double fold of serous membrane that connects the spleen and stomach.

Structure of the Spleen

As Figures 23-20 and 23-21 show, the spleen is roughly ovoid in shape. Its size varies in different individuals and in the same individual at different times (Box 23-5). For example, it hypertrophies during infectious diseases and atrophies in old age.

Like other lymphoid organs, the spleen is surrounded by a fibrous capsule with inward extensions that roughly divide the organ into compartments. One such compartment is shown in Figure 23-21, *B*. Arteries leading into each compartment are surrounded by dense masses (nodules) of developing lymphocytes. Because of its whitish appearance, this tissue is called *white pulp*.

Near the outer regions of each compartment is tissue called *red pulp*, made up of a network of fine reticular fibers submerged in blood that comes from the nearby arterioles. The red pulp network supports cords of WBCs and related cells surrounded by blood-filled sinusoids. After passing through the reticular meshwork, blood collects in venous sinuses and then returns to the heart through veins.

Functions of the Spleen

The spleen has many and sundry functions, including defense, hematopoiesis, and red blood cell and platelet destruction; it also serves as a reservoir for blood.

Defense. As blood passes through the sinusoids of the spleen, reticuloendothelial cells (macrophages) lining these venous spaces remove microorganisms from the blood and destroy

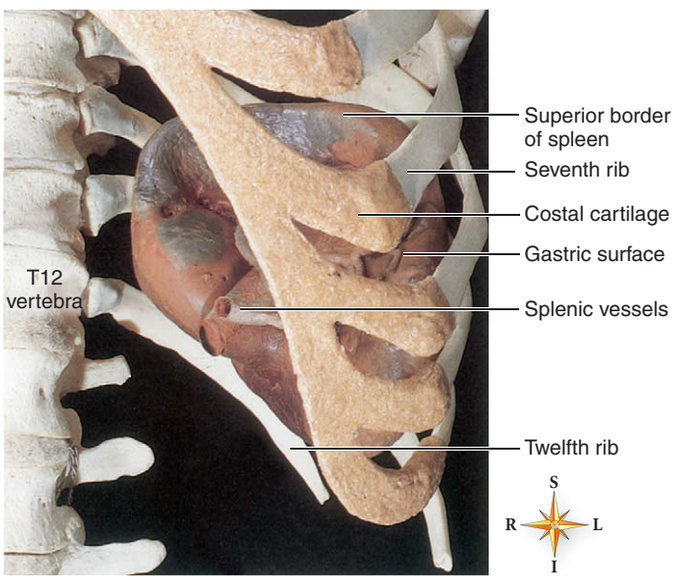

FIGURE 23-20

Location of the spleen. The spleen is located in the left hypochondrium of the abdominopelvic cavity, just inferior to the diaphragm and just deep to the lower portion of the rib cage.

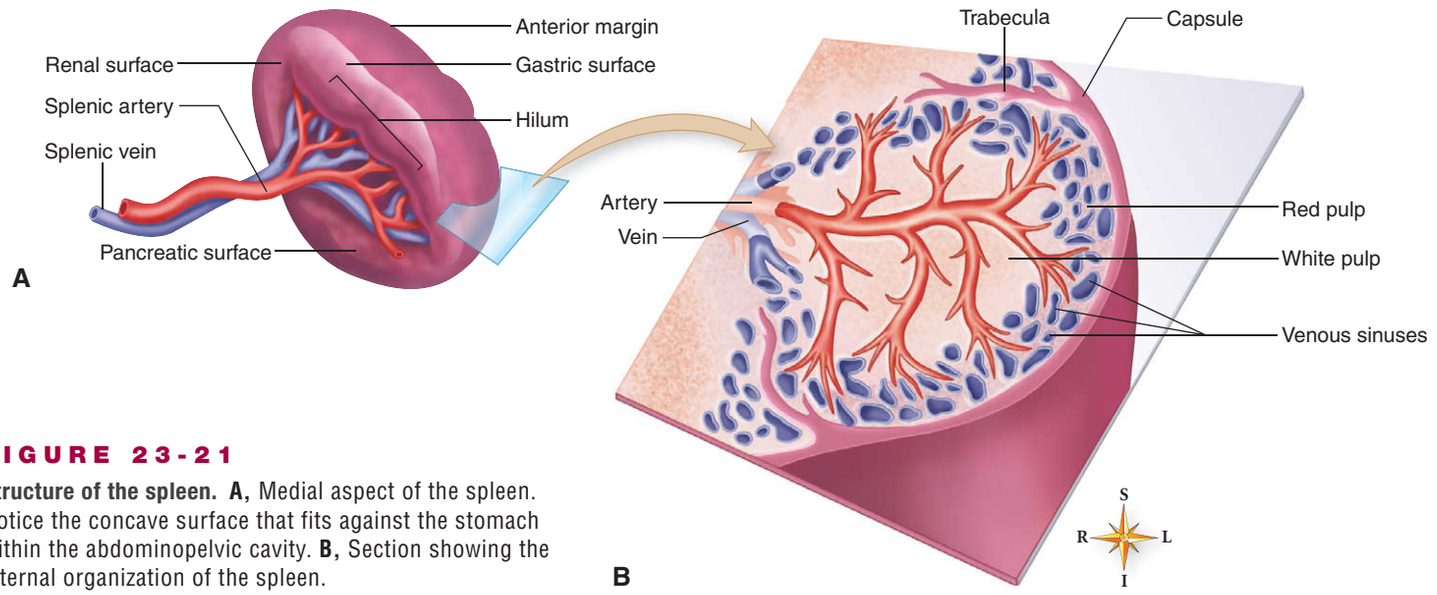

FIGURE 23-21

Structure of the spleen. A, Medial aspect of the spleen. Notice the concave surface that fits against the stomach within the abdominopelvic cavity. **B,** Section showing the internal organization of the spleen.

them by phagocytosis. Therefore the spleen plays a part in the body's defense against microorganisms.

Tissue repair. Monocytes found in the cords of WBCs in red pulp just under the spleen's outer capsule are mobilized when significant tissue damage occurs, such as in an MI (myocardial infarction or "heart attack"). A large number of monocytes migrate quickly to the injured tissue and assist in healing and repair.

Hematopoiesis. Nongranular leukocytes, that is, monocytes and lymphocytes, complete their development and become activated in the spleen. Before birth, red blood cells are also formed in the spleen, but after birth, the spleen forms red blood cells only in cases of extreme hemolytic anemia.

Red blood cell destruction *and* ***platelet destruction.*** Macrophages lining the spleen's sinusoids remove worn out red blood cells and imperfect platelets from the blood and destroy them by phagocytosis. They also break apart the hemoglobin molecules from the destroyed red blood cells and salvage their iron and globin content by returning them to the bloodstream for storage in bone marrow and liver.

Blood reservoir. At any given point in time the pulp of the spleen and its venous sinuses contain a considerable amount of blood. Although continually moving slowly through the spleen, blood can rapidly be added back into the circulatory system from this functional reservoir if needed. Its normal volume of about 350 ml is said to decrease by about 200 ml in less than 1 minute following sympathetic stimulation that produces marked constriction of its smooth-muscle capsule. This "self-transfusion" occurs, for example, as a response to the stress imposed by hemorrhage.

Although the spleen's functions make it a most useful organ, it is not a vital one. Dr. Charles Austin Doan in 1933 took the daring step of performing the first **splenectomy.** He removed the spleen from a 4-year-old girl who was dying of hemolytic anemia. Presumably, he justified his radical treatment on the basis of what was then merely conjecture, that is, that the spleen destroys red blood cells. The child recovered, and Dr. Doan's operation proved to be a landmark. It created a great upsurge of interest in the spleen and led to many investigations of this organ.

Because of its role as a blood reservoir, the spleen contains a high volume of blood at any one time—especially during rest. If the spleen is accidentally ruptured, as it might when the ribs are broken and pushed into the spleen, significant internal bleeding could occur. If the blood loss is rapid and is not stopped in time, death could result. Surgical repair or removal of the spleen can stop the blood loss and save a life.

Table 23-1 summarizes the essential characteristics of the major types of lymphatic organs.

Box 23-5 | HEALTH matters

Splenomegaly

Splenomegaly, or abnormal spleen enlargement, is observed in various disorders. For example, infectious conditions such as scarlet fever, syphilis, and typhoid fever may be characterized by splenomegaly. Spleen enlargement sometimes accompanies hypertension. Splenomegaly also accompanies some forms of hemolytic anemia in which red blood cells appear to be broken apart at an abnormally fast rate. Surgical removal of the spleen often prevents death in such cases.

| QUICK CHECK |

8. Where are the major tonsils located? What is their role?
9. What major role does the thymus play in immunity?
10. What are the major functions of the spleen?

TABLE 23-1 Major Lymphatic Organs

ORGAN	STRUCTURE	FUNCTION
Lymphatic vessels	Thin-walled vessels with numerous valves that ensure one-way flow of lymphatic fluid (lymph); larger vessels have three layers (similar to veins)	Collect fluids draining from tissues of the body (lymph) and return it to the blood circulation
Lymphatic capillaries	Microscopic, blind-end vessels, made up of single endothelial layer having many gaps	Collect tissue fluid (forming lymph) Transport lymph to larger lymphatic vessels
Lymphatic ducts	Large lymphatic vessels formed by many tributaries throughout the body; connect to the subclavian veins	Collect lymph from network of lymphatic vessels and drain it into the blood circulation
Lymphoid organs	Have a significant component of lymphoid tisse (developing white blood cells)	Hematopoiesis (WBCs) Immunity Filter body fluids
Lymph nodes	Fibrous capsule surrounding a maze of sinuses, each with lymphoid tissue nodule suspended by reticular fibers	Filtration of lymph before it enters bloodstream Mechanical filtration: removing particles Biological filtration: cells destroy and remove particles
Aggregated lymph nodules (tonsils, Peyer patches)	Groupings of nodules (lumps of lymphoid tissue) embedded in mucous membranes	Immunity at common points of entry for pathogenic microbes
Thymus	Two pyramid-shaped lobes subdivided into smaller lobules containing lymphoid tissue	Hematopoiesis—site of T-lymphocyte (T-cell) development Hormone production—thymosin regulates T-cell development
Spleen	Ovoid fibrous capsule with internal maze of sinuses containing dense lymphoid tissue (white pulp) surrounded by blood sinusoids having cords of lymphoid tissue (red pulp)	Hematopoiesis (WBCs) Immunity Filtration of blood Tissue repair Destruction of old RBCs, platelets Blood reservoir

RBC, red blood cell
WBC, white blood cell

Cycle of LIFE
Lymphatic System

Many of the structural features of the lymphatic system exhibit dramatic changes as a person progresses through a life span. Most of the organs containing masses of developing lymphocytes appear before birth and continue growing through most of childhood until just before puberty. After puberty, these lymphoid organs typically begin to slowly atrophy until they reach much smaller size by late adulthood. These organs—including the thymus, lymph nodes, tonsils, and other lymphoid structures—shrink in size and become fatty or fibrous. The notable exception to this principle is the spleen, which develops early in life and remains intact until very late adulthood.

Despite the fact that lymphocyte-producing lymphoid tissues decline after puberty, the overall function of the immune system is maintained until late adulthood. During the late adult years, deficiency of the immune system permits a greater risk of infections and cancer, and hypersensitivity of the immune system may make autoimmune conditions more likely to occur.

the BIG picture

Lymphatic System and the Whole Body

One way to imagine the role of the lymphatic system in the "society of cells" that makes up the human body is as a sort of waste-water system. Like waste-water systems used in the cities of human society, the lymphatic system drains away excess, or "runoff," water from large areas. After collecting the body's runoff, or lymph, the lymphatic system conducts it through a network of lymphatic vessels, or "drain pipes," to miniature "treatment facilities" called *lymph nodes.* Contaminants are there removed from lymph, just as contaminants are removed in a waste-water treatment plant. The "clean" fluid is then returned to the bloodstream much as clean waste water is returned to a nearby river or lake. Like municipal waste-water systems, the lymphatic system not only prevents dangerous fluid buildups, or "floods," but also prevents the spread of disease.

All systems of the body benefit from the fluid-balancing and immune functions of the lymphatic system. Some parts of the body such as the digestive and respiratory tracts make special use of the defensive capacities of lymphatic organs such as aggregated lymph nodules (Peyer patches) and tonsils. Likewise, body structures such as the breasts and limbs make more use of the fluid-draining capacities of the lymphatic system than do other regions of the body. Overall, however, the entire body benefits from the fluid balance and freedom from disease conferred by the proper functioning of this important body system.

MECHANISMS of DISEASE

DISORDERS OF THE LYMPHATIC SYSTEM

Disorders Associated with Lymphatic Vessels

Lymphedema is an abnormal condition in which swelling of tissues in the extremities occurs because of an obstruction of the lymphatics and accumulation of lymph (Figure 23-22). The most common type of lymphedema is *congenital lymphedema* (lymphedema praecox), more often seen in women between the ages of 15 and 25 years. The obstruction in lymphedema can be in both the lymphatic vessels and lymph nodes themselves. Initially, the swelling, or edema, in the extremity will be soft, but as the condition progresses, it becomes firm, painful, and unresponsive to treatment. Frequent infections, involving high fever and chills, may occur with chronic lymphedema. Diuretics (agents that cause water loss) to reduce the swelling have been shown to be effective, along with strict bed rest, massage, and elevation of the involved extremities. If the edema is severe and unresponsive to these measures, or infection has occurred, or the person's mobility is severely compromised, surgical removal of the involved subcutaneous tissue and fascia may be required. Other procedures involving surgically "shunting" of superficial lymphatic drainage into the deep lymphatic system have been tried.

Lymphedema may be caused by small parasitic worms (nematodes) called **filaria** that infest the lymph vessels. This condition is rare in most of North America and is more often seen in the tropics. The flow of lymph is blocked, causing edema in the affected extremities that, in severe cases, become so swollen that they resemble an elephant's limbs (Figure 23-23). For this reason, the condition is referred to as **elephantiasis**—literally "condition of being an elephant." Chronic swelling, thickening of the subcutaneous tissue, and frequent bouts of infections are common in this condition.

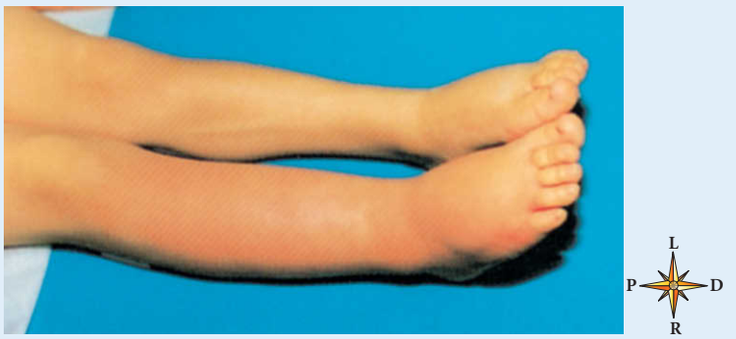

FIGURE 23-22

Lymphedema. Notice the significant swelling in the subject's right leg and foot.

FIGURE 23-23

Elephantiasis. Prolonged infestation of the lymphatic system by *Filaria* worms produces so much swelling (lymphedema) that the affected limbs begin to resemble those of an elephant!

Lymphangitis, an acute inflammation of the lymphatic vessels, stems from invasion of an infectious organism. This condition is characterized by thin, red streaks extending from an infected region up the arm or leg (Figure 23-24). The lymph nodes also become enlarged, tender, and reddened. Necrosis, or tissue death, along with development of an abscess (collection of fluid and pus) can occur, leading to a condition known as *suppurative lymphadenitis*. The lymph nodes commonly involved are in the groin, axilla, and cervical regions. The infectious agents that cause lymphangitis may eventually spread into the bloodstream, causing *septicemia* (blood poisoning) and possible death from septic shock, but this is rare if the proper antibiotic therapy is initiated.

Disorders Associated with Lymph Nodes and Other Lymphatic Organs

Tonsillitis

The tonsils, composed of lymphoid tissue, serve as the first line of defense from the exterior and also are subject to acute or chronic

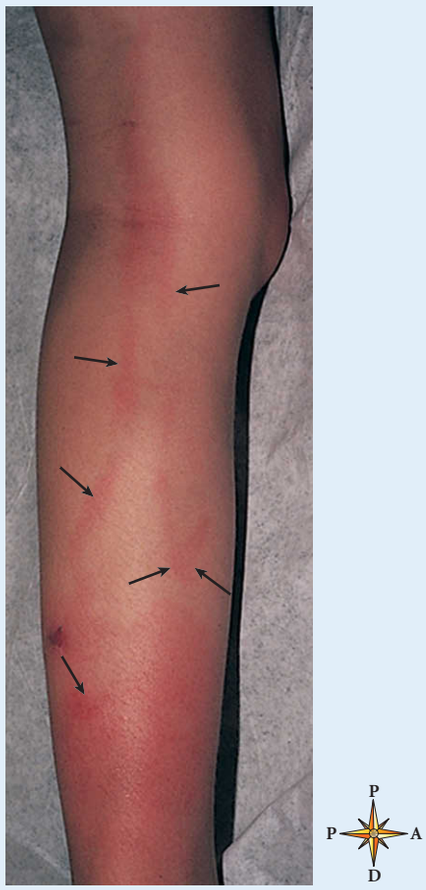

FIGURE 23-24

Lymphangitis. Red streaks mark the location of inflamed lymphatic vessels in this leg. Arrows highlight some of the red streaks.

infection, known as **tonsillitis.** Fever, sore throat, and difficulty swallowing are common signs and symptoms. Enlarged pharyngeal tonsils *(adenoids)* may cause nasal obstruction. The infection may extend to the middle ear by way of the auditory (eustachian) tubes, causing *acute otitis media* (middle ear infection) and possible deafness if left untreated. Antibiotics are usually initiated after diagnosis of tonsillitis. If these are unsuccessful, and swelling has endangered the airway and breathing, a *tonsillectomy*, or surgical removal of the tonsils, may be performed.

Lymphoma

Lymphoma is a term that refers to a tumor of the cells of lymphoid tissue. Lymphomas are often malignant but, in rare cases, can be benign. They usually originate in isolated lymph nodes but can involve lymphoid tissue in the liver, spleen, and gastrointestinal tract. Widespread involvement is common because the disease spreads from node to node through the many anastomoses of the lymphatic vessels throughout the body. The exact cause of these neoplasms is unknown.

Two principal categories of lymphomas are *Hodgkin lymphoma (HL)* and *non-Hodgkin lymphoma (NHL)*. Hodgkin lymphoma (or **Hodgkin disease**) is a malignancy with an uncertain etiology. Some pathophysiologists believe that it originates as a pathogen-induced tumor of T cells, although there is currently no evidence to support this conclusively. Other factors such as exposure to chemicals or other environmental hazards may also be involved. This condition usually begins as painless, nontender, enlarged lymph nodes in the neck or axilla (Figure 23-25). Soon, lymph nodes in other regions enlarge in the same manner. If they involve the trachea or esophagus, pressure results in difficulty breathing or swallowing. HL is considered to be one of the most curable forms of cancer if detected early.

Lymphedema caused by blockage of lymph nodes may cause enlargement of the extremities. Occasionally the disease may obstruct flow into or out of the liver, leading to liver enlargement and failure. Anemia, leukocytosis, fever, and weight loss occur as the condition progresses. Hodgkin lymphoma is potentially curable with radiation therapy, provided it has not spread beyond the lymphatic system. Chemotherapy is used in addition to radiation therapy in more advanced cases. Infection, from both the disease and the treatments, is a common complication.

Non-Hodgkin lymphoma is the name given to a malignancy of lymphoid tissue other than Hodgkin lymphoma. Again, the etiology is uncertain but has been hypothesized to be caused by a virus. Patients with immunodeficiencies such as AIDS often develop this condition. Manifestations are similar to Hodgkin lymphoma, but there is usually a more generalized involvement of lymph nodes. The central nervous system is also often involved. Radiation and chemotherapy are treatments of choice.

CASE study

Courtney, a dental hygiene student, was in Ghana with several of her classmates. Each summer, the students had an opportunity to combine study abroad with volunteering at a dental clinic in Accra. On their second day at the clinic, Courtney met Juba, a local farmer's daughter. Juba's right foot and leg below the knee were extremely swollen, seemingly blown up like a balloon. In contrast, Juba's left leg had no swelling at all and appeared quite normal. One of the local dentists told Courtney that Juba had elephantiasis, a type of lymphedema caused by a blockage.

1. With Juba's condition, what vessels are blocked?
   a. Arteries
   b. Veins
   c. Capillaries
   d. Lymphatic vessels

2. Which of the following is NOT a function of the lymphatic system?
   a. Removing excess fluid from the blood
   b. Absorbing lipids from the small intestines
   c. Returning fluid from the interstitial areas back to the bloodstream
   d. Filtering lymph to remove foreign organisms and particulates

3. What helps circulate the lymph (fluid) through the lymph vessels?
   a. Ventricular contraction
   b. Skeletal muscle contractions
   c. Exhalation
   d. Lymphatic vessel contraction

4. Before Juba's leg became affected by this disorder, the lymph would have passed first through which nodes?
   a. Cervical
   b. Axillary
   c. Inguinal
   d. Mediastinal

CHAPTER SUMMARY

*To download an MP3 version of the chapter summary for use with your iPod or portable media player, access the **Audio Chapter Summaries** online at evolve.elsevier.com.*

HINT *Scan this summary after reading the chapter to help you reinforce the key concepts. Later, use the summary as a quick review before your class or before a test.*

OVERVIEW OF THE LYMPHATIC SYSTEM

A. Two most important functions—maintain fluid balance in the internal environment and immunity; a third function is to collect absorbed fat from the intestines and transport it to the systemic veins
B. Lymph vessels act as "drains" to collect excess tissue fluid and return it to the venous blood just before it returns to the heart (Figure 23-1)
C. Lymphatic system—component of the circulatory system; made up of lymph, lymphatic vessels, and isolated structures containing lymphoid tissue: lymph nodes, aggregated lymphoid nodules, tonsils, thymus, spleen, and bone marrow (Figure 23-2)
D. Transports tissue fluid, proteins, fats, and other substances to the general circulation
E. Lymphatic vessels begin blindly in the intercellular spaces of the soft tissues; do not form a closed circuit

LYMPH AND INTERSTITIAL FLUID

A. Lymph (lymphatic fluid)
   1. Clear, watery-appearing fluid found in the lymphatic vessels
   2. Closely resembles blood plasma in composition but has a lower percentage of protein; isotonic
   3. Elevated protein concentration in thoracic duct lymph because of protein-rich lymph from the liver and small intestine

B. Interstitial fluid (IF)
   1. Complex, organized fluid that fills the spaces between the cells and is part of the ECM (extracellular matrix)
   2. Resembles blood plasma in composition with a lower percentage of protein
   3. Along with blood plasma, constitutes the extracellular fluid

LYMPHATIC VESSELS

A. Distribution of lymphatic vessels (lymphatics) (Figures 23-2 and 23-3)
   1. Lymphatic capillaries—microscopic blind-end vessels where lymphatic vessels originate; wall consists of a single layer of flattened endothelial cells; networks branch and anastomose freely
   2. Lymphatic capillaries merge to form larger lymphatics and eventually form the main lymphatic trunks, the right lymphatic ducts, and the thoracic duct

3. Lymph from upper right quadrant empties into right lymphatic duct and then into right subclavian vein
4. Lymph from rest of the body empties into the thoracic duct, which then drains into the left subclavian vein; thoracic duct originates as the cisterna chyli (chyle cistern)

B. Structure of lymphatic vessels (Figure 23-4)
1. Similar to veins except lymphatic vessels have thinner walls, have more valves, and contain lymph nodes
2. Lymphatic capillary wall is formed by a single layer of thin, flat endothelial cells
3. As the diameter of lymphatic vessels increases from capillary size, the walls become thicker and have three layers
4. One-way valves are present every few millimeters in large lymphatics and even more frequently in smaller lymphatics

C. Functions of the lymphatic vessels
1. Remove high–molecular-weight substances and even particulate matter from interstitial spaces
2. Lacteals absorb fats and other nutrients from the small intestine

CIRCULATION OF LYMPH

A. From lymphatic capillaries, lymph flows through progressively larger lymphatic vessels to eventually reenter blood at the junction of the internal jugular and subclavian veins (Figure 23-5).

B. The lymphatic pump
1. Lymphokinesis—the movement (flow) of lymph; can be visualized in a lymphangiogram (Figure 23-6)
2. Lymph moves through the system in the right direction because of the large number of valves
3. Breathing movements and skeletal muscle contractions (Figure 23-7) establish a fluid pressure gradient, as they do with venous blood
4. Other factors, such as IF pressure, also drive lymphokinesis (Figure 23-8)
5. Lymphokinetic actions—activities that result in a central flow of lymph

LYMPH NODES

A. Structure of lymph nodes
1. Lymph nodes are oval-shaped structures enclosed by a fibrous capsule (Figure 23-9)
2. Nodes are a type of biological filter
3. Once lymph enters a node, it moves slowly through sinuses to drain into the efferent exit vessel (Figure 23-10)
4. Trabeculae extend from the covering capsule toward the center of the node
5. Cortical and medullary sinuses are lined with reticuloendothelial cells capable of phagocytosis

B. Locations of lymph nodes
1. Most lymph nodes occur in groups
2. Groups with greatest clinical importance are preauricular lymph nodes, submental and submaxillary groups, and superficial cervical, superficial cubital, axillary, iliac, and inguinal lymph nodes (Figures 23-11 through 23-13)

C. Functions of lymph nodes—perform two distinct functions
1. Defense functions
   a. Filtration
      (1) Mechanical filtration—physically stopping particles from progressing further in the body
      (2) Biological filtration—biological activity of cells destroys and removes particles
   b. Phagocytosis—reticuloendothelial cells remove microorganisms and other injurious particles from lymph and phagocytose them (biological filtration)
   c. If overwhelmed, lymph nodes can become infected or damaged (Figures 23-14 and 23-15)
2. Hematopoiesis—lymphoid tissue is the site for the final stages of maturation of some lymphocytes and monocytes

LYMPHATIC DRAINAGE OF THE BREAST

A. Clinically important because cancer cells and infections can spread along lymphatic pathways to lymph nodes and other organs of the body

B. Distribution of lymphatics in the breast (Figure 23-16)
1. Drained by two sets of lymphatic vessels
   a. Lymphatics that drain the skin over the breast with the exception of the areola and nipple
   b. Lymphatics that drain the underlying substance of the breast, as well as the skin of the areola and nipple
2. Superficial vessels converge to form a diffuse, cutaneous lymphatic plexus
3. Subareolar plexus—located under the areola surrounding the nipple; where communication between the cutaneous plexus and large lymphatics that drain the secretory tissue and ducts of the breast occurs

C. Lymph nodes associated with the breast
1. More than 85% of the lymph from the breast enters the lymph nodes of the axillary region
2. Remainder of lymph enters lymph nodes along the lateral edges of the sternum

TONSILS

A. Form a broken ring under the mucous membranes in the mouth and back of the throat—the pharyngeal lymphoid ring (Figure 23-17)
1. Palatine tonsils—located on each side of the throat
2. Pharyngeal tonsils—located near the posterior opening of the nasal cavity
3. Lingual tonsils—located near the base of the tongue
4. Tubal tonsils—located near the openings of the auditory (eustachian) tubes

B. Protect against bacteria that may invade tissues around the openings between the nasal and oral cavities; bacteria are trapped in tonsillar crypts and put in close contact with immune system cells

THYMUS

A. Location and appearance of the thymus (Figure 23-18)
   1. Primary organ of lymphatic system
   2. Single, unpaired organ located in the mediastinum, extending upward to the lower edge of the thyroid and inferiorly as far as the fourth costal cartilage
   3. Thymus is pinkish gray in childhood; with advancing age, becomes yellowish as lymphoid tissue is replaced by fat

B. Structure of the thymus
   1. Two pyramid-shaped lobes are subdivided into small lobules
   2. Each lobule is composed of a dense cellular cortex and an inner, less dense medulla
   3. Medullary tissue can be identified by presence of thymic corpuscles

C. Function of the thymus
   1. Plays vital role in immunity mechanism
   2. Source of lymphocytes before birth
   3. Shortly after birth, thymus secretes thymosin and other regulators, which enables lymphocytes to develop into T cells (Figure 23-19)

SPLEEN

A. Location of the spleen—in the left hypochondrium, directly below the diaphragm, above the left kidney and descending colon, and behind the fundus of the stomach (Figures 23-2 and 23-20)

B. Structure of the spleen (Figure 23-21)
   1. Ovoid in shape
   2. Surrounded by fibrous capsule with inward extensions that divide the organ into compartments
   3. White pulp—dense masses of developing lymphocytes
   4. Red pulp—near outer regions, made up of a network of fine reticular fibers submerged in blood that comes from nearby arterioles; made up of cords of WBCs and related cells surrounded by sinusoids

C. Functions of the spleen
   1. Defense—macrophages lining the sinusoids of the spleen remove microorganisms from the blood and phagocytose them
   2. Tissue repair—the spleen holds a reservoir of monocytes that migrate in a large mass to sites of injury to help with tissue healing and repair
   3. Hematopoiesis—monocytes and lymphocytes complete their development in the spleen
   4. Red blood cell and platelet destruction—macrophages remove worn-out RBCs and imperfect platelets and destroy them by phagocytosis; also salvage iron and globin from destroyed RBCs
   5. Blood reservoir—pulp of spleen and its sinuses store blood

CYCLE OF LIFE: LYMPHATIC SYSTEM

A. Dramatic changes throughout life

B. Organs with lymphocytes appear before birth and grow until puberty

C. Postpuberty
   1. Organs atrophy through late adulthood
      a. Shrink in size
      b. Become fatty or fibrous
   2. Spleen—develops early, remains intact

D. Overall function maintained until late adulthood
   1. Later adulthood
      a. Deficiency permits risk of infection and cancer
      b. Hypersensitivity—likelihood of autoimmune conditions

THE BIG PICTURE: THE LYMPHATIC SYSTEM AND THE WHOLE BODY

A. Lymphatic system drains away excess water from large areas

B. Lymph is conducted through lymphatic vessels to nodes, where contaminants are removed

C. Lymphatic system benefits the whole body by maintaining fluid balance and freedom from disease

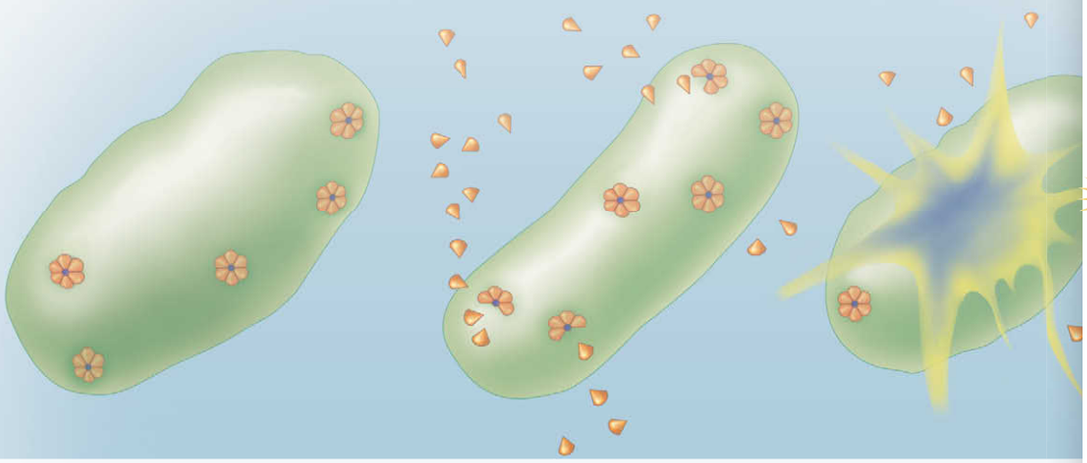
REVIEW QUESTIONS

Write out the answers to these questions after reading the chapter and reviewing the Chapter Summary. If you simply think through the answer without writing it down, you won't retain much of your new learning.

1. List the anatomical components of the lymphatic system.
2. How do interstitial fluid and lymph differ from blood plasma?
3. How do lymphatic vessels originate?
4. Briefly describe the anatomy of the lymphatic capillary wall.
5. Lymph from what body areas enters the general circulation by way of the thoracic duct? By way of the right lymphatic ducts?
6. What is the cisterna chyli?
7. Where does lymph enter the blood vascular system?
8. In general, lymphatics resemble veins in structure. List three exceptions to this general rule.
9. What are the unique lymphatic vessels that originate in the villi of the small intestine called?
10. What is chyle? Where is it formed?
11. Give examples of lymphokinetic factors and explain how they contribute to the "lymphatic pump."
12. List several important groups, or clusters, of lymph nodes.
13. Explain how lymph nodes function in body defense and hematopoiesis.
14. If cancer cells from breast cancer enter the lymphatics of the breast, where are they likely to lodge and start new growths? Explain why, using your knowledge of the anatomy of the lymphatic and circulatory systems.
15. Locate the thymus, and describe its appearance and size at birth, at maturity, and in old age.
16. Explain the function of the thymus.
17. Describe the location and functions of the spleen.

18. What happens when there is a loss of lymphatic fluid?
19. Explain why lymphedema may occur after breast surgery.

CRITICAL THINKING QUESTIONS



After finishing the Review Questions, write out the answers to these more in-depth questions to help you apply your new knowledge. Go back to sections of the chapter that relate to concepts that you find difficult.

1. Even though the lymphatic system is a component of the circulatory system, why is the term *circulation* not the most appropriate term to describe the flow of lymph?
2. Explain how lymph is formed. What would be the impact on lymph formation if the osmotic force at the venous end of the capillary was more successful at recovering fluid lost at the arterial end?
3. Discuss the importance of valves in the lymphatic system.
4. Explain the role of the lymphatic system in the spread of breast cancer and its surgical treatment.

Immune System

continued on p. 776

Enemies of many kinds and in great numbers assault the body during a lifetime. Among the most threatening are hordes of microorganisms. We live our lives in a virtual sea of protozoa, fungi, bacteria, viruses, and other pathogens. So ever-present and potentially lethal are these small but formidable foes that no newborn could live through infancy, much less survive to adulthood or old age, without effective defenses against them. We also are threatened by enemies from within. Inside the body, abnormal cells appear on an irregular but continual basis. If allowed to survive, these abnormal cells reproduce and form a tumor. At the very least, a tumor alone can damage surrounding tissues and can be life threatening as it continues to enlarge, and there is always the possibility that a tumor could become cancerous and spread (metastasize) to many other locations within the body. Without an internal "security force" to deal with such abnormal cells when they first appear, we would live very short lives. This chapter presents a brief overview of the system that provides defenses against both external and internal enemies—the immune system.

ORGANIZATION OF THE IMMUNE SYSTEM

Like any security force, the components and mechanisms of the immune system are organized in an efficient—almost military-like—manner. They are not just ready on a moment's notice; they are *continually* patrolling the body for foreign or internal enemies and shoring up the various lines of defense to fend off a possible attack. Before we begin studying the specifics of immunity, we will spend a moment mapping out the overall defensive strategy of the immune system.

First, it is important to recognize that cells, viruses, and other particles have unique molecules and groups of molecules on their surfaces that can be used to identify them. These molecular markers visible to the immune system are called **antigens.** This is similar to military operations in which enemy aircraft, vehicles, or soldiers can be identified by their distinctive insignia that are different from the insignia seen on "our side." Likewise, our own cells have unique cell markers embedded in our plasma membranes that identify each of our cells as **self**—that is, belonging to us as an individual. And foreign cells or particles have **nonself** molecules that serve as recognition markers for our immune system. The ability of our immune system to attack abnormal or foreign cells but spare our own normal cells is called **self-tolerance.**

In human society, any good security force employs numerous and varied strategies to guard its territory and take action if necessary. So, too, does the body's "society of cells" employ a system that uses many different kinds of mechanisms to ensure the integrity and survival of the internal environment. All of these defense mechanisms can be categorized into one of two major categories of immune mechanisms: **innate immunity** and **adaptive immunity.**

Innate immunity is called such because it is "in place" before a person is exposed to a particular harmful particle or condition. The word *innate* refers to something that is already present naturally at birth. Because it includes mechanisms that resist a wide variety of threatening agents or conditions, innate immunity is also called **nonspecific immunity.** The term *nonspecific* implies that these immune mechanisms do not act on only one or two specific invaders but rather provide a more general defense by simply acting against a wide variety of particles recognized as *nonself.*

Adaptive immunity, on the other hand, involves mechanisms that recognize *specific* threatening agents and then *adapt,* or respond, by targeting their activity against these agents—and these agents only. Because it targets only specific harmful particles, adaptive immunity is also called **specific immunity.** Adaptive immune mechanisms often take some time to recognize their targets and react with sufficient force to overcome the threat, at least on their first exposure to a specific kind of threatening agent. Innate mechanisms, because they are already in place, have the advantage of being able to meet an enemy as soon as it presents itself. As we discuss examples of each major type of immunity, you will come to understand how each type works and appreciate the distinction between them. You will also come to appreciate the value in having two complementary strategies for defending the body.

As in any body system, the work of the immune system is done by cells or substances made by cells. The primary types of cells involved in innate immunity are these: epithelial barrier cells, phagocytic cells (neutrophils, macrophages), and aptly named *natural killer (NK) cells.* The primary types of cells involved in adaptive immunity are two types of lymphocytes called *T cells* and *B cells.*

Cytokines, which are chemicals released from cells to trigger or regulate innate and adaptive immune responses, also participate in innate immunity. Examples of cytokines include *interleukins (ILs), leukotrienes,* and *interferons (IFNs)*—all of which are described later in this chapter. Other chemicals, in addition to cytokines, play a regulatory role in immunity—these include *complements,* other enzymes, and the amine *histamine.*

Awesome indeed is the army of cells and molecules that make up the immune system. Over one trillion lymphocytes, for example, and 100 million trillion (10^{20}) plasma protein molecules (antibodies) are a few of the many agents that help your body resist damage and disease. Figure 24-1 and Table 24-1 summarize some of the essential characteristics of innate and adaptive immunity that we discuss in this chapter.

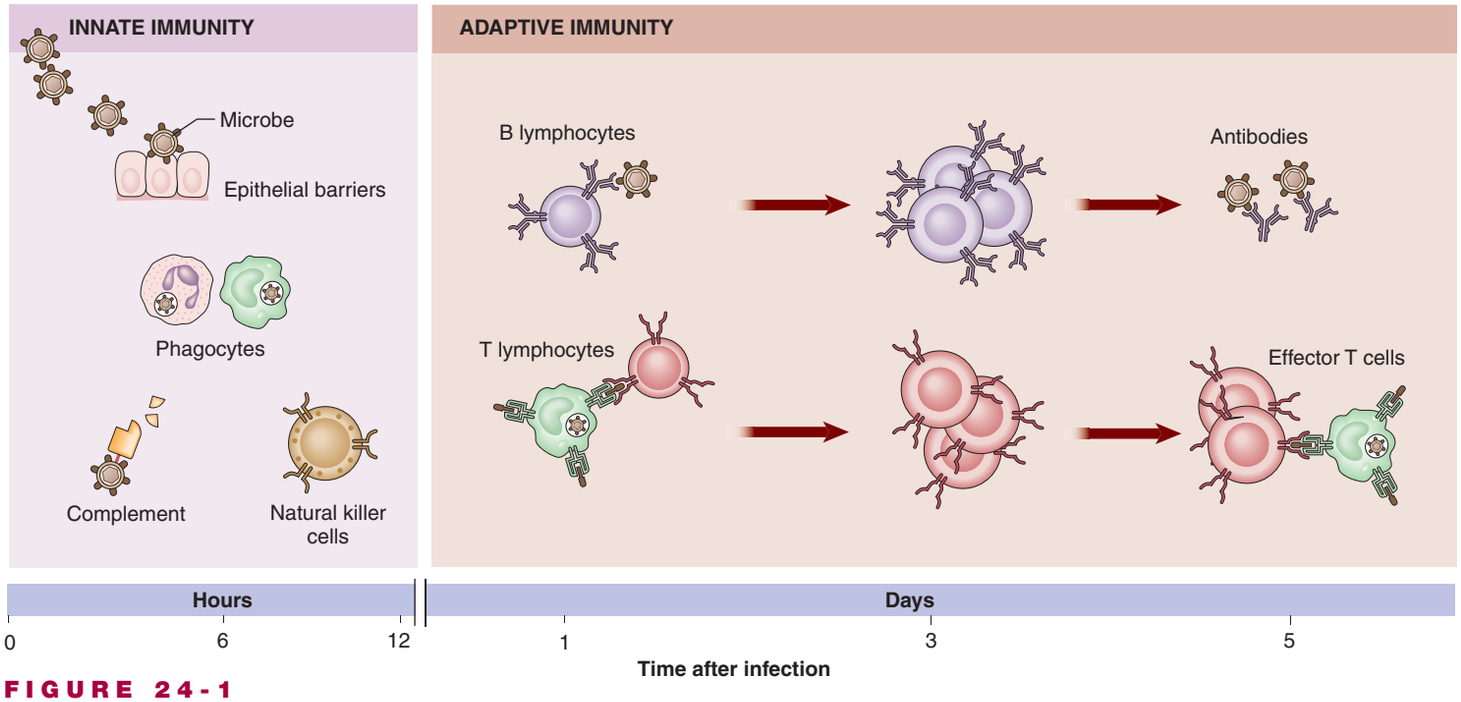

FIGURE 24-1

Innate and adaptive immunity. Innate (nonspecific) immune mechanisms are "built in" and ready for action—thus providing the initial defense against infections and other assaults on the body. Adaptive (specific) immune mechanisms develop later, as lymphocytes are activated to work against specific foreign or abnormal cells and particles. The timeframes are generalizations.

TABLE 24-1 Innate and Adaptive Immunity

		INNATE IMMUNITY	ADAPTIVE IMMUNITY
Synonyms	Frequently used alternate terminology	Nonspecific immunity, native immunity, genetic immunity	Specific immunity, acquired immunity
Characteristics			
Specificity	Unique antigens produce unique responses of the immune system	Not specific—recognizes variety of different groups of foreign cells or particles	Specific—recognizes specific antigens on specific cells or particles
Speed of reaction	Reaction time of the immune responses	Rapid: immediate up to several hours	Slower: several hours to several days
Memory	Enhanced responses to repeated exposures to the same antigen	None	Yes
Does not react to self	Prevents injury to the individual's own cells*	Yes	Yes
Components			
Barriers	Prevent entry of harmful particles	Skin, mucosa, antimicrobial chemicals	Lymphocytes in epithelia; antibodies released at epithelial surfaces
Blood proteins	Circulate throughout body, providing wide area of protection	Complement, interferon (IFN), others	Antibodies
Cells	Types of leukocytes involved in immunity	Phagocytes (macrophages, neutrophils), natural killer (NK) cells	Lymphocytes (B cells and T cells)

*Assumes healthy function. Anti-self immunity (autoimmunity) is a characteristic of many disorders.

| QUICK CHECK |

1. What is the difference between *self* and *nonself?*
2. What is the difference between *adaptive* and *innate* immunity?
3. What is a *cytokine?* What are some examples of cytokines?

INNATE IMMUNITY

The general, innate defensive mechanisms of the body are many and varied (Table 24-2). Only the major types of innate immune mechanisms are listed here; many other examples appear in other chapters throughout this book. You will probably recognize examples in this chapter that you have encountered already in previous chapters. Phagocytes are a good example. They are often referred to by different names when identified in specific body areas. For example, phagocytic cells in the skin were identified as *dendritic cells (DCs)* of the epidermis (Langerhans cells; Chapter 7, p. 173).

Species Resistance

Species resistance refers to a phenomenon in which the genetic characteristics common to a particular kind of organism, or *species*, provide defense against certain *pathogens* (disease-causing agents). The human species *(Homo sapiens)*, for example, is resistant to many life-threatening infections and infestations that often spread easily among plants and other animals. For example, humans do not have to worry about getting Dutch elm disease, a fungal infection that nearly eradicated the American elm tree, or becoming infected with canine viral distemper, a virus to which young dogs are susceptible. Usually, species resistance in humans results from the fact that our internal environment is not suitable for certain pathogens. We may also have resistance because a particular microbe may not be biochemically compatible with the various molecules on our cell membranes that the microbes would need to gain entry into a host cell.

Mechanical and Chemical Barriers

The internal environment of the human body is protected by a continuous mechanical barrier formed by the cutaneous membrane (skin) and mucous membranes (see Figure 6-39, p. 155).

TABLE 24-2 Mechanisms of Innate Defense

MECHANISM	DESCRIPTION
Species Resistance	Genetic characteristics of the human species protect the body from certain pathogens
Mechanical and Chemical Barriers	Physical impediments to the entry of foreign cells or substances
Skin and mucosa	Forms a continuous wall that separates the internal environment from the external environment, preventing the entry of pathogens
Secretions	Secretions such as sebum, mucus, acids, and enzymes chemically inhibit the activity of pathogens
Inflammation	The inflammatory response isolates the pathogens and stimulates the speedy arrival of large numbers of immune cells
Fever	Fever may enhance immune reactions and inhibit pathogens
Phagocytosis	Ingestion and destruction of pathogens by phagocytic cells
Neutrophils	Granular leukocytes that are usually the first phagocytic cell to arrive at the scene of an inflammatory response
Macrophages	Monocytes that have enlarged to become giant phagocytic cells capable of consuming many pathogens; often called by other, more specific names when found in specific tissues of the body
Natural Killer (NK) Cells	Group of lymphocytes that kill many different types of cancer cells and virus-infected cells
Interferon	Protein produced by cells after they become infected by a virus; inhibits the spread or further development of a viral infection
Complement	Group of plasma proteins (inactive enzymes) that produce a cascade of chemical reactions that ultimately causes lysis (rupture) of a foreign cell; the complement cascade can be triggered by adaptive or innate immune mechanisms
Toll-like Receptors (TLRs)	Membrane receptors that recognize nonspecific patterns in microbial molecules (not human molecules) and trigger a variety of innate immune responses (many of those listed in this table)

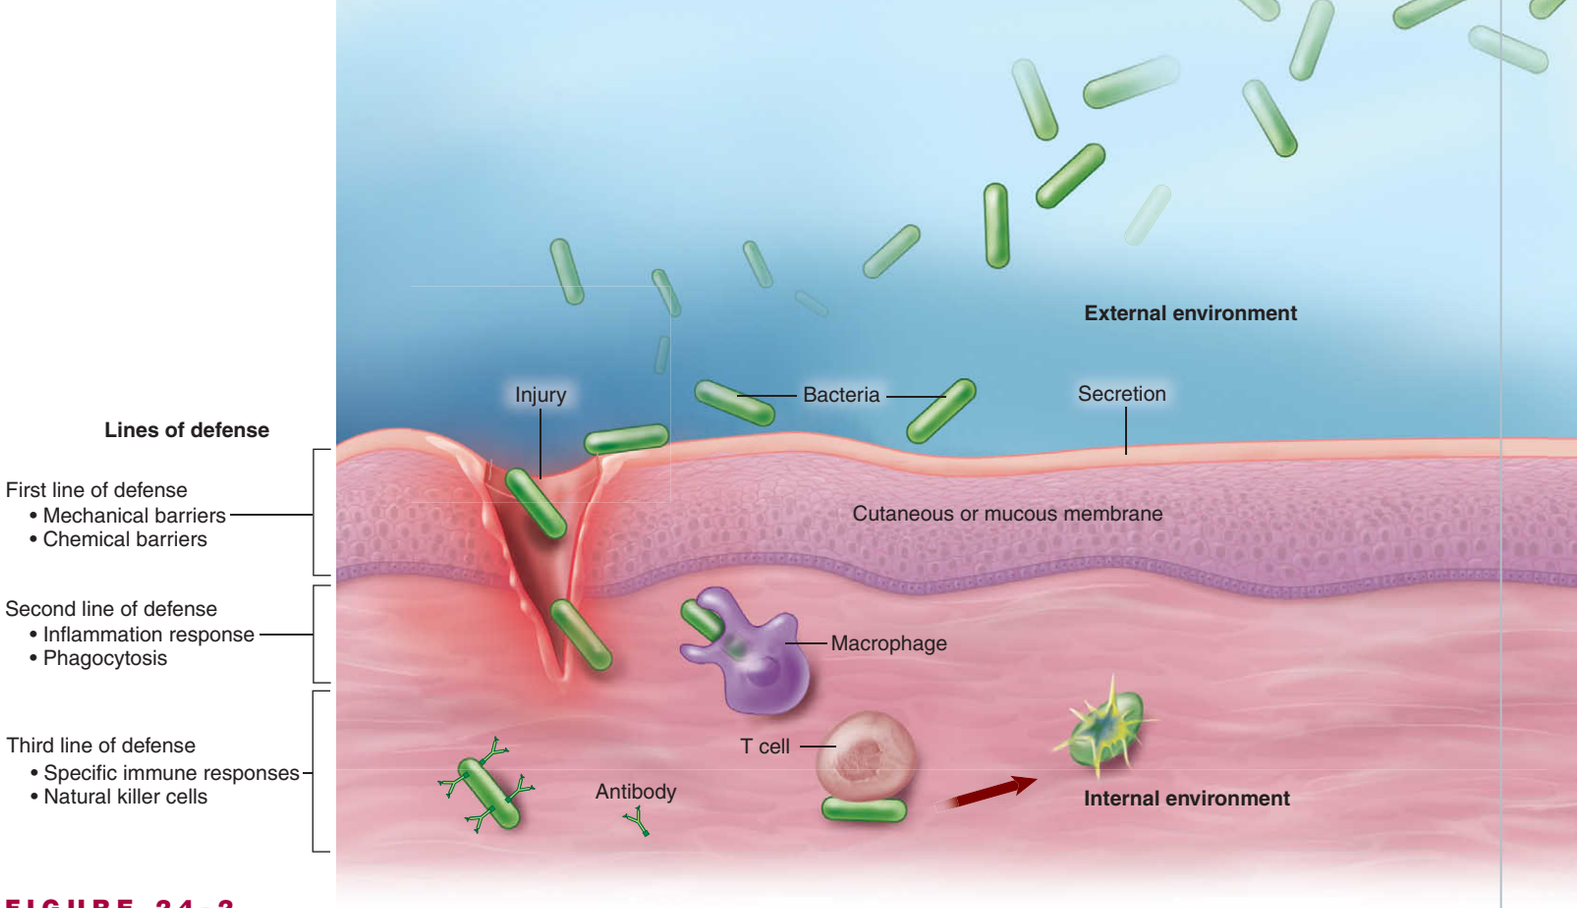

FIGURE 24-2

Lines of defense. Immune function, that is, defense of the internal environment against foreign cells, proteins, and viruses, includes three layers of protection. The first line of defense is a set of barriers between the internal and external environments, the second involves the innate inflammatory response (including phagocytosis), and the third includes the adaptive immune responses and the innate defense offered by natural killer cells. Of course, tumor cells that arise within the body are not affected by the first two lines of defense and must be attacked by the third line of defense. This diagram is a simplification of the complex function of the immune system; in reality, a great deal of crossover of mechanisms occurs between these "lines of defense."

Often called the *first line of defense*, these membranes provide several layers of densely packed cells and other materials—forming a sort of "castle wall"—that protects the internal environment from invasion by foreign cells (Figure 24-2).

Besides forming a protective wall, the skin and mucous membranes operate various additional immune mechanisms. For example, substances such as *sebum* (which contains pathogen-inhibiting agents), *mucus* (in which pathogens become stuck and are then swept away), enzymes (which may hydrolyze pathogens), and hydrochloric acid in gastric mucosa (which may destroy pathogens) also may be present to act as innate defense mechanisms. These chemical barriers act as a sort of moat around the castle wall formed by the membranes.

The epithelial barriers of the body are essentially innate, nonspecific defenses. However, the protective epithelial membranes also have adaptive (specific) defenses that reinforce them. The combined innate and adaptive immune functions of protective mucous membranes are discussed later in the chapter in a separate boxed essay (see Box 24-8 on p. 771).

Inflammation and Fever

THE INFLAMMATORY RESPONSE

If bacteria or other invaders break through the chemical and mechanical barriers formed by the membranes and their secretions, the body has a *second line of defense* at the ready: the inflammatory response (see Figure 24-2). The **inflammatory response** has already been discussed in some detail in Chapter 6 (see Box 6-3 on p. 146 and ***A&P Connect: Inflammation*** online). For the purpose of a quick review, recall that tissue damage elicits a host of responses that counteract the injury and promote a return to normal. An example of how local inflammation works is illustrated

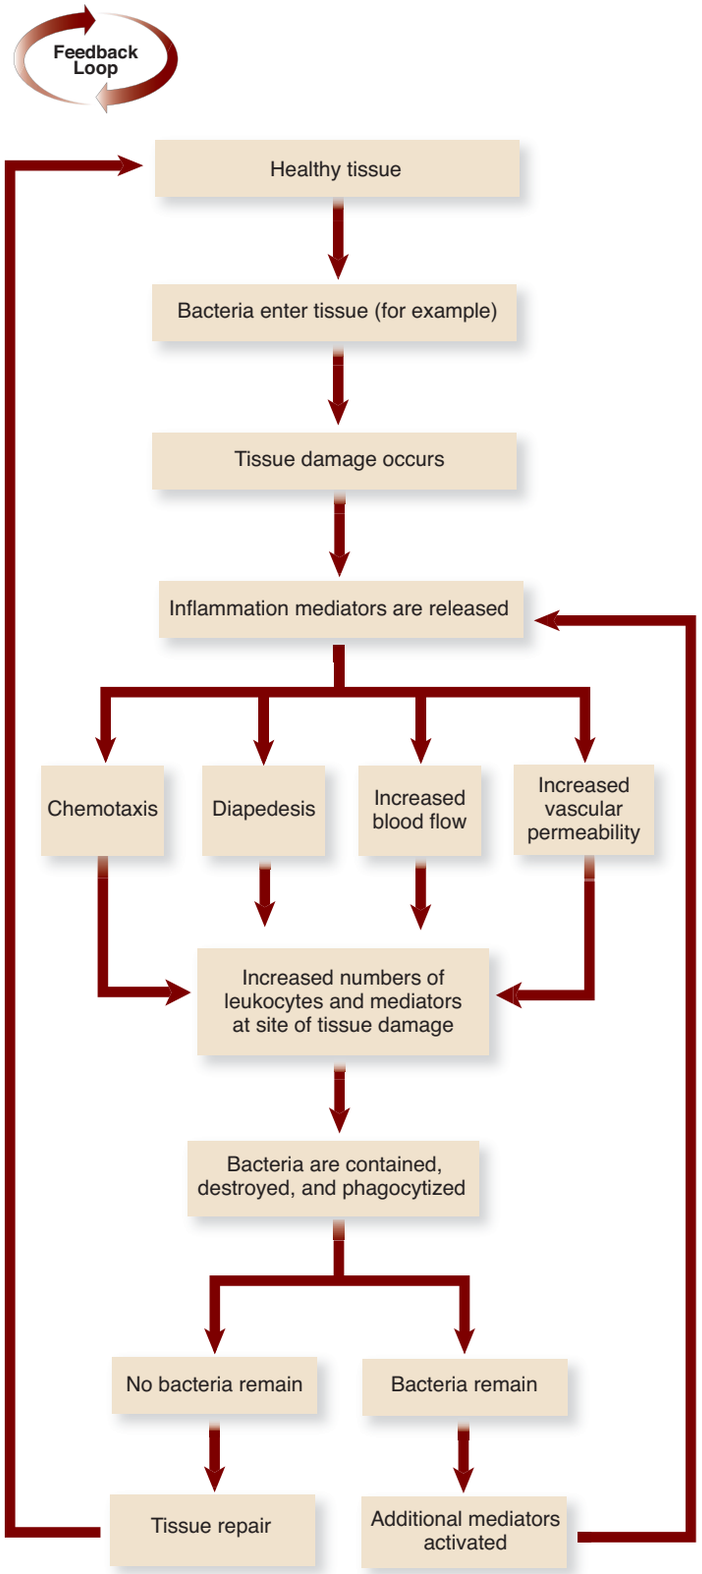

FIGURE 24-3

Example of the inflammatory response. Tissue damage caused by bacteria triggers a series of events that produces the inflammatory response and promotes phagocytosis at the site of injury. These responses tend to inhibit or destroy the bacteria, eventually bringing the tissue back to its healthy state. Similar reactions will occur in the presence of other abnormal or injurious particles or conditions.

in Figure 24-3. In the example, bacteria cause tissue damage that, in turn, triggers the release of various inflammation mediators from cells such as the *mast cells* found in connective tissues (Figure 24-4). These inflammation mediators include *histamine*, *kinins*, *prostaglandins*, *leukotrienes*, *interleukins (ILs)*, and related compounds. Many of these mediators are chemotactic factors, that is, substances that attract white blood cells to the area in a process called **chemotaxis.** As Figure 24-5 shows, chemotaxis is the process by which a cell navigates toward the source of the **chemotactic factor** *(chemotaxin)* by way of detecting and then moving toward higher concentrations of the factor.

Additionally, many of the factors released from tissue cells and phagocytes, such as the peptide fragment called *C5a* from complement, produce the mechanisms that cause characteristic signs of inflammation: heat, redness, pain, and swelling (Figure 24-6). These signs result from increased blood flow and vascular permeability in the affected region, which help phagocytic white blood cells reach the general area and then enter the affected tissue. Also, some inflammation mediators trigger fibroblasts to grow and produce more collagen fibers to promote repair and regeneration.

| A&P CONNECT |

Inflammation is an important defensive reaction in the body's tissues. Check out ***Inflammation*** online at ***A&P Connect*** for a brief review of the inflammatory response and its effects on the tissues of your body.

evolve

FEVER

Besides local inflammation, systemic inflammation may occur when the inflammation mediators trigger responses that occur on a body-wide basis. A body-wide inflammatory response may be manifested by a **fever**—a state of abnormally high body temperature. For example, bacterial infections that spread widely throughout the body may produce *systemic inflammatory response syndrome (SIRS)*. SIRS involves an abnormally high neutrophil (phagocytic white blood cell [WBC]) count and fever. Viral infections, tumors, allergies, and other abnormal conditions also can cause fevers.

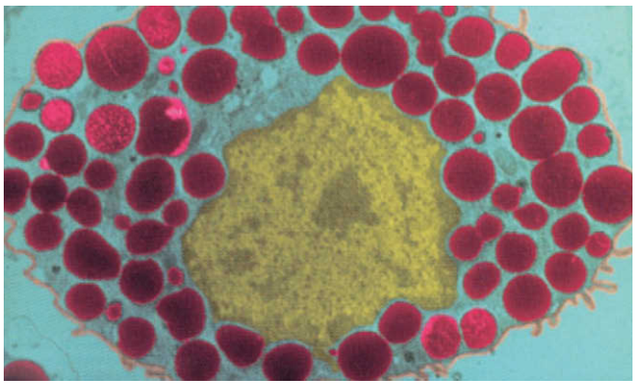

FIGURE 24-4

Mast cell. This colorized micrograph shows a mast cell filled with dense red granules of the inflammation mediator called *histamine.*

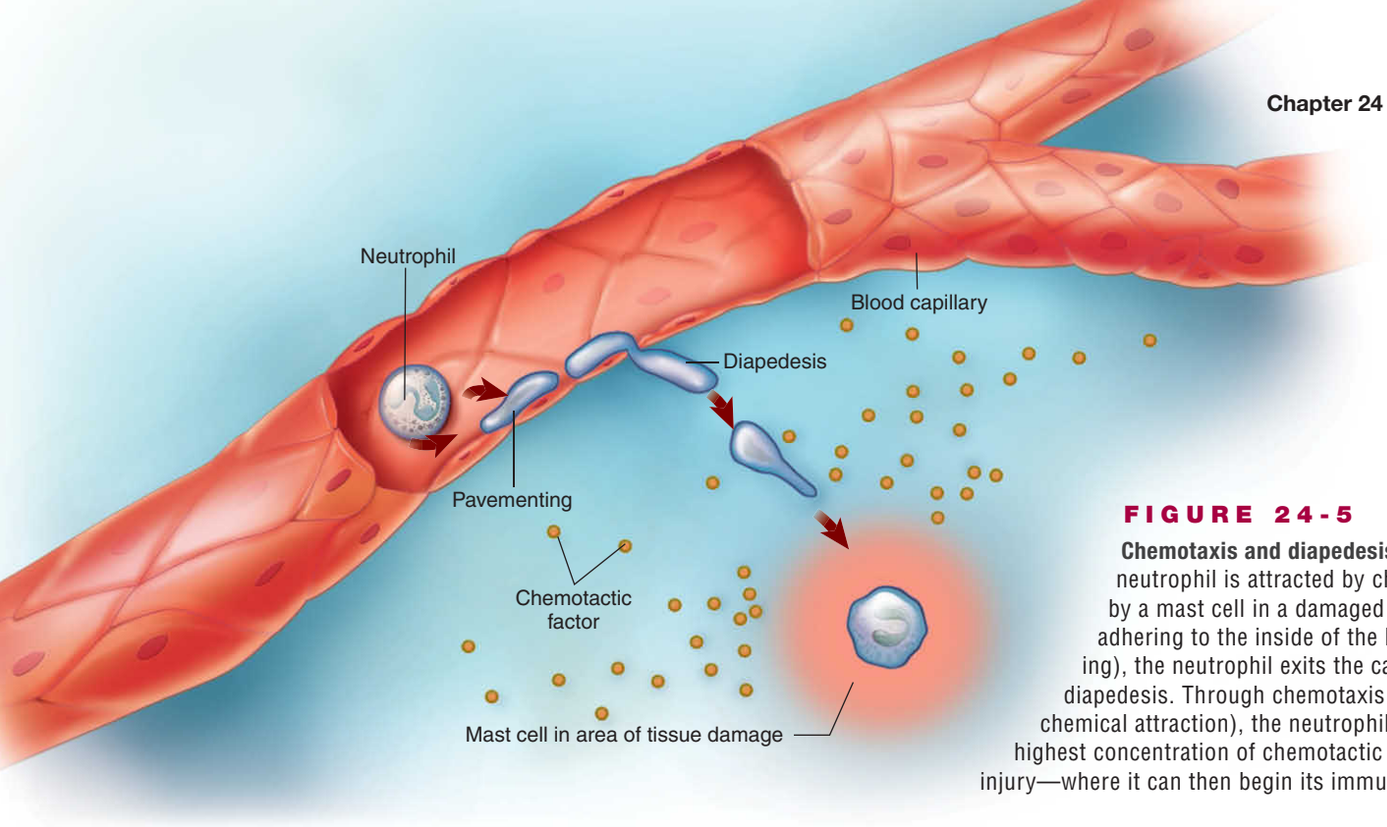

FIGURE 24-5

Chemotaxis and diapedesis. In this example, a neutrophil is attracted by chemotactic agents released by a mast cell in a damaged or infected tissue. After adhering to the inside of the blood capillary (pavementing), the neutrophil exits the capillary by the process of diapedesis. Through chemotaxis (movement directed by chemical attraction), the neutrophil migrates toward the highest concentration of chemotactic factor—the site of the injury—where it can then begin its immune functions.

Recall from Box 1-2 on p. 21 that fevers result from a "reset" of the body's thermostat in the hypothalamus, which temporarily increases the set point or target temperature to a higher-than-normal value. The body then shivers or we cover ourselves and otherwise seek heat until the new set point temperature—a fever—is reached.

As we have already learned in earlier chapters, *pyrogen* molecules trigger the fever response by promoting production of prostaglandins (PGs), which then reset the body's thermostat in the hypothalamus. Aspirin and other cyclooxygenase (COX) inhibitors reduce the activity of the COX enzymes (COX-1 and COX-2) that produces these prostaglandins—thus having a fever-reducing effect (see Figure 18-13 on p. 557). Pyrogens can be released from damaged cells (endogenous pyrogens) or could be introduced from outside the body (exogenous pyrogens).

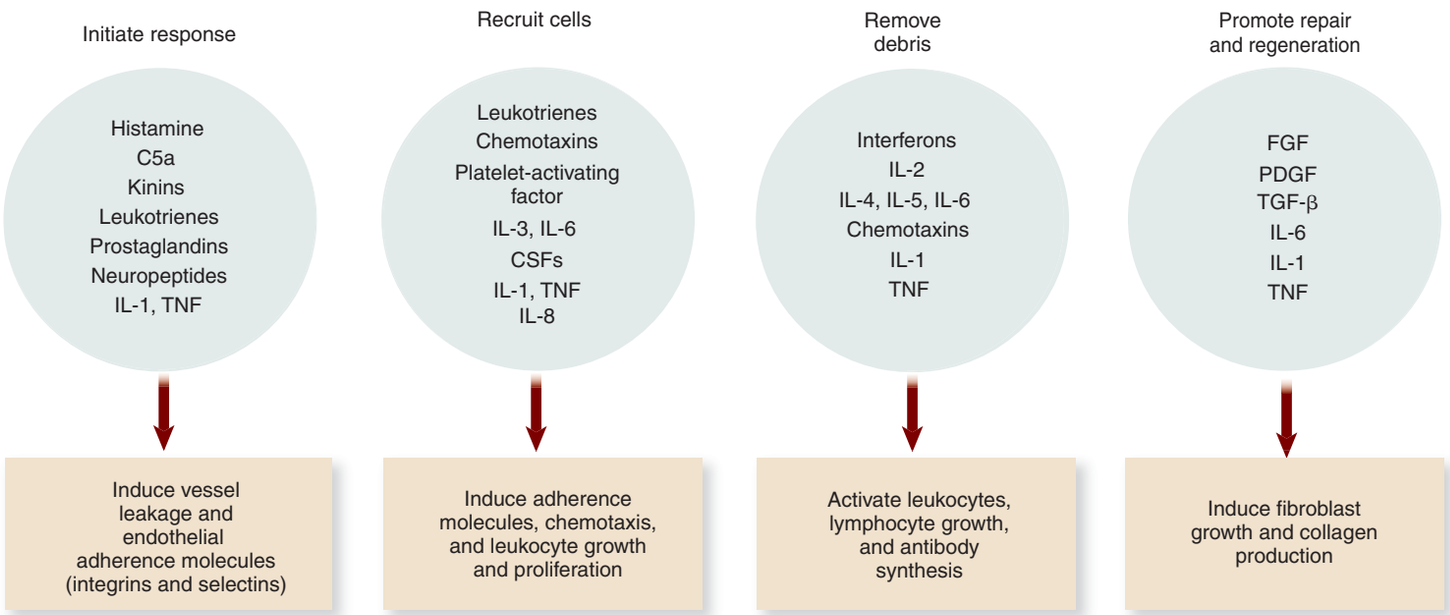

FIGURE 24-6

Inflammation mediators. A wide variety of chemical mediators help regulate the immune response, as this generalized chart shows. Some of the processes shown overlap in time and are thus sometimes concurrent.

The elevated temperature of a fever may facilitate some immune reactions and may also inhibit the reproduction of some microbial pathogens. However, immunologists still debate the role of fever in protecting the body.

Phagocytosis

A major component of the body's second line of defense is the mechanism of **phagocytosis**—the ingestion and destruction of microorganisms or other small particles. There are many types of *phagocytes*, that is, cells capable of phagocytosis, in the body. As Figure 24-7 shows, when phagocytes approach a microorganism, they extend footlike projections (pseudopods) toward it. Soon the pseudopods encircle the organism and form a complete sac, called a *phagosome*, around it. The phagosome then moves into the interior of the cell, where a lysosome fuses with it. The contents of the lysosome, chiefly digestive enzymes and hydrogen peroxide, drain into the phagosome and destroy the microorganisms within it.

Because phagocytosis defends us against various kinds of agents, it is classified as an *innate defense*. However, phagocytes also "cross over" to play an important role in adaptive immunity as well. After digesting the offending particle, a phagocyte will often process the proteins and display bits of the protein—peptides—on the surface of the phagocyte. These peptides are then recognized by cells of the adaptive immune system as antigens, thus possibly triggering an adaptive immune response. Cells that perform this function are called *antigen-presenting cells (APCs)*.

You learned in Chapter 20 that the most numerous type of phagocyte is the *neutrophil*, a granular, neutral-staining type of WBC. After being released at a site of inflammation or tissue damage, chemotactic factors diffuse into adjoining capillaries. Once in the bloodstream, they cause neutrophils and other phagocytes to adhere to the vessel's endothelial lining in a process called **pavementing** (see Figure 24-5). Numbers of these adherent phagocytes pass between the endothelial cells that form the capillary wall, dissolve the underlying basement membrane, and then exit through the vessel wall in the inflamed area. The movement of phagocytes from blood vessel to inflammation site is called **diapedesis.** Phagocytes have a very short life span, and thus dead cells tend to "pile up" at the inflammation site—forming most of the white substance called **pus.**

Another common type of phagocyte is the **macrophage** (meaning "large eater"). Macrophages are phagocytic monocytes (nongranular WBCs) that have grown to several times their original size after migrating out of the bloodstream. Macrophages are important APCs.

Yet another important type of phagocyte is the **dendritic cell (DC)** found in many tissues of the body that are in contact with the external environment, such as the skin and mucous membranes (Figure 24-8). This type of phagocytic APC is called *dendritic* because of its many branches (*dendr-* branch). Dendritic cells are also sometimes called *stellate* ("star shaped") *cells*.

Phagocytic APCs of various types are present in many areas of the body, even on the outside surface of some mucous membranes (e.g., in the respiratory tract). Phagocyte types are often known by

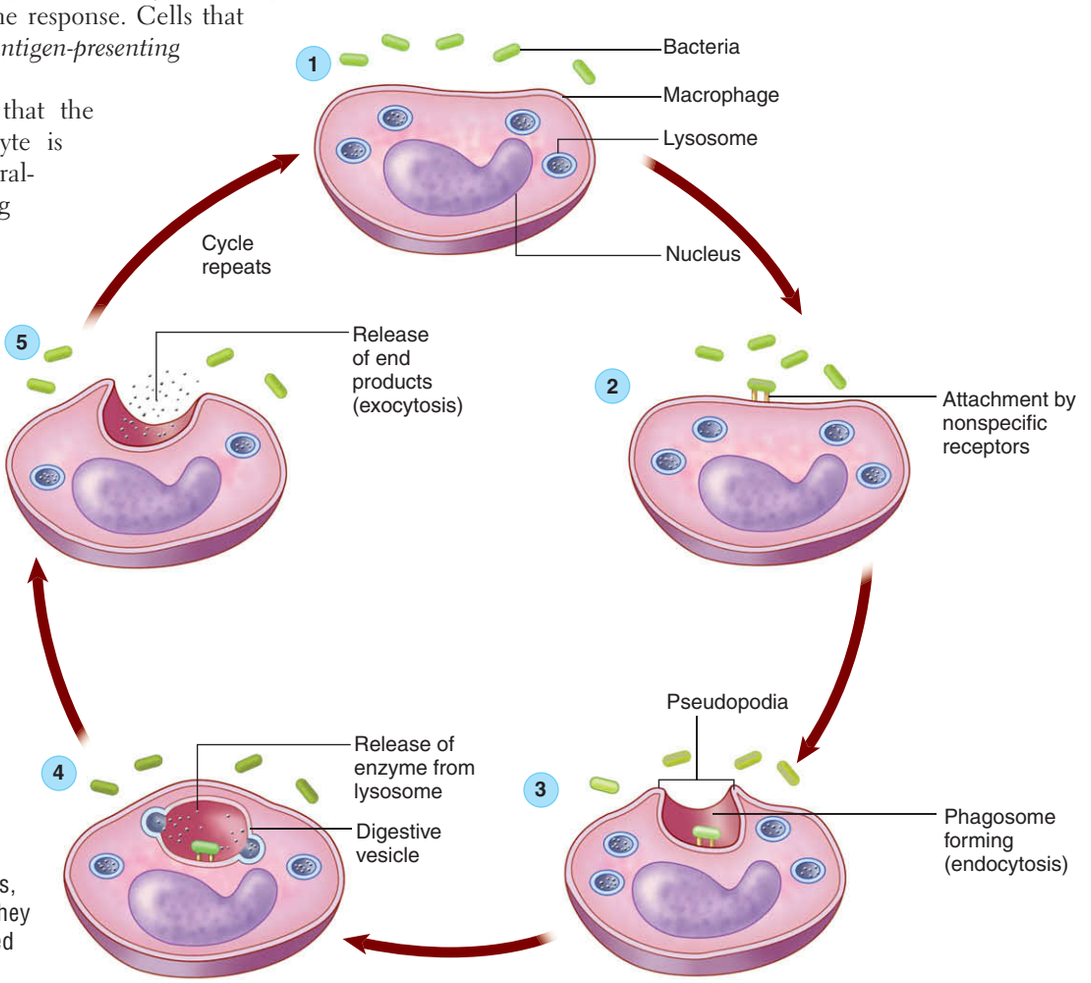

FIGURE 24-7

Phagocytosis of bacteria. Drawing shows sequence of steps in phagocytosis of bacteria. The plasma membrane extends (as a pseudopod) toward the bacterial cells, then envelops them. Once trapped, they are engulfed by the cell and destroyed by lysosomal enzymes.

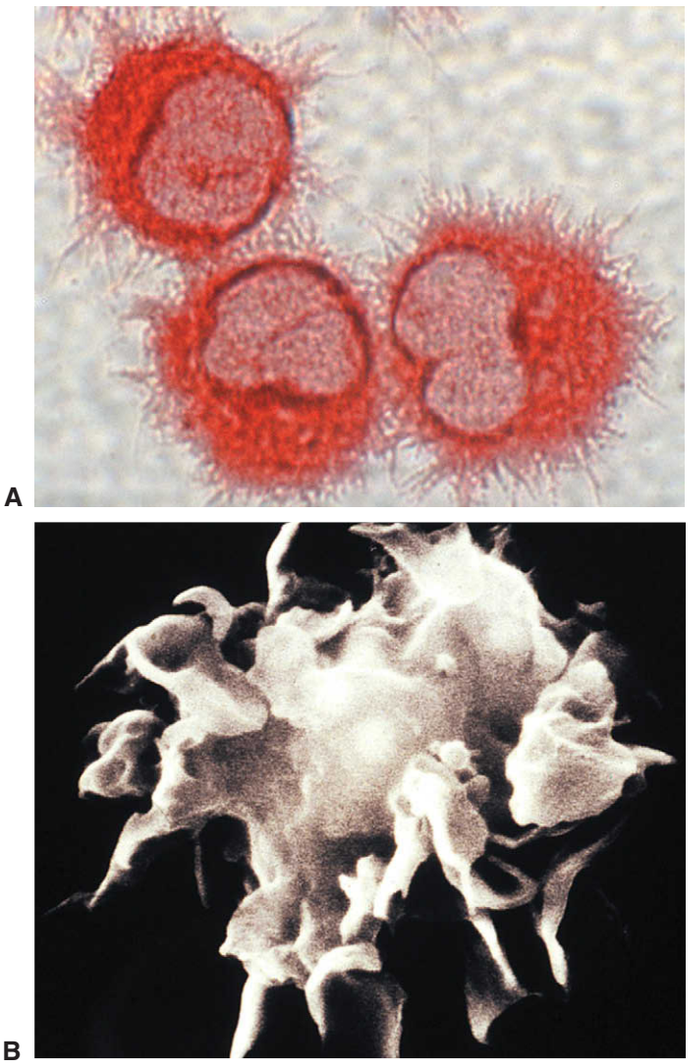

FIGURE 24-8

Dendritic cells (DCs). DCs, also called *stellate (star-shaped) cells,* are phagocytic antigen-presenting cells (APCs) that are found in many areas of the body. **A,** Light micrograph of DCs from the bone marrow. **B,** Scanning electron micrograph showing the detail of projections of the plasma membrane in DCs (see also Figure 24-15).

specific names that designate their location (Table 24-3). The importance of phagocytes to our overall defense of the body is made clear by the fact that 10% to 15% (by number) of all cells in any organ of the body are phagocytic cells!

Natural Killer Cells

Besides phagocytes, the body has another important set of cells that provides innate defense of the body. These are the **natural killer (NK) cells.** NK cells are a group of lymphocytes that kill many types of tumor cells and cells infected by different kinds of viruses. As a group they are produced in the red bone marrow and constitute about 15% of the total lymphocyte cell numbers. NK cells are neither T cells nor B cells, as described later under the topic of adaptive immunity. Because they have such a broad action and do not have to be activated by a specific foreign antigen to become active, they are usually included among the innate immune strategies.

TABLE 24-3 Examples of Phagocyte Locations

PHAGOCYTES	LOCATION
Circulating phagocytes	Bloodstream
Osteoclasts; bone marrow (fixed) phagocytes	Bone and bone marrow
Microglia	Central nervous system
Histiocytes	Connective tissues
Epidermal dendritic cells	Epidermis
Kupffer cells	Liver
Alveolar macrophages (dust cells); dendritic cells	Lung
Fixed and free lymphoid macrophages; dendritic cells	Lymph nodes
Pleural macrophages; peritoneal macrophages	Serous fluids
Splenic macrophages	Spleen

NK cells recognize abnormal cells by using two different recognition receptors: a killer-activating receptor and a killer-inhibiting receptor (Figure 24-9). The killer-activating receptor binds to any

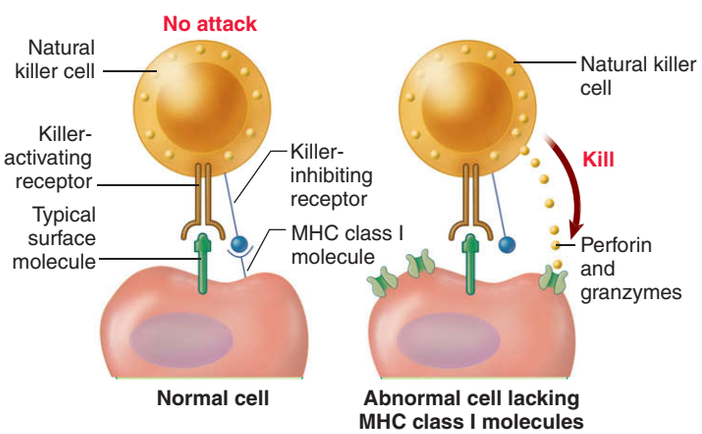

FIGURE 24-9

Natural killer (NK) cells. NK cells are a type of lymphocyte distinct from B cells and T cells. NK cells have killer-activating receptors that recognize any of several molecules commonly found in plasma membranes. NK cells also have killer-inhibiting receptors that recognize major histocompatibility complex (MHC) class I surface molecules, which act as "self" markers (see Box 24-1 on p. 754). If both the NK receptors bind, as they would in a normal cell with the proper MHC class I surface molecule, then the killing action of the cell is inhibited and the target cell remains alive. However, if the MHC class I marker is absent—as would happen with a foreign cell or a virus-infected cell—then the killer-inhibiting receptor has nothing to bind. Thus the killing action of the NK cell is not inhibited and the target cell is destroyed by chemicals released from the NK cell.

of several common surface molecules found in cells. Thus the NK cell can bind to any cell of the body as well as any foreign cells. However, if the killer-inhibiting receptor happens to bind to an MHC (major histocompatibility complex) protein also, then the killing action is stopped. Box 24-1 explains that MHCs are surface proteins on all normal cells and are unique to each individual person. Thus only abnormal and foreign cells fail to bind to the killer-inhibitor centers—and therefore are killed by the NK cell.

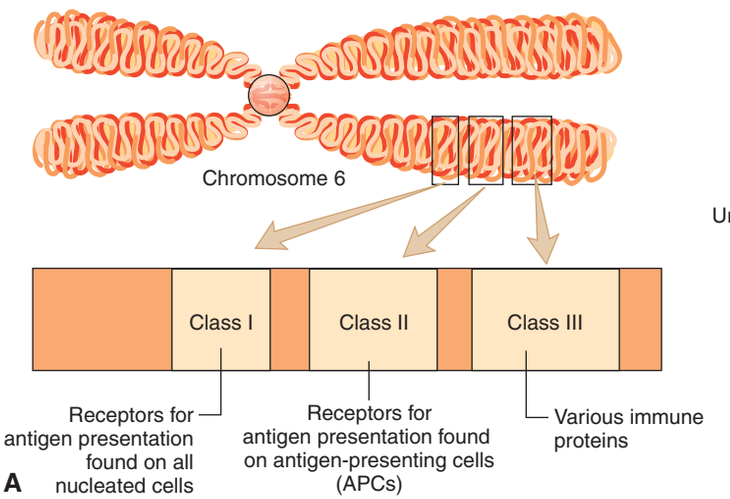
The NK cells use several different methods for killing cells, most of which involve chemically triggering apoptosis (programmed

Box 24-1 | FYI

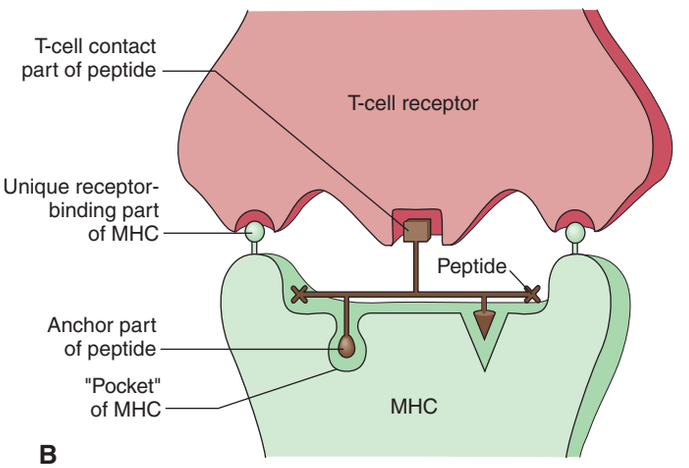
Major Histocompatibility Complex

The **major histocompatibility complex (MHC)** is a set of genes in chromosome 6 that all code for antigen-presenting proteins and other immune system proteins (part *A* of figure). Antigens are proteins that potentially trigger a specific immune response. The MHC proteins produced by MHC genes in class I and class II also are called *human leukocyte antigens (HLAs).* Their function is to present different protein fragments (peptides) at the surface of the cell for possible recognition as either self or nonself antigens by immune system cells.

The MHC class I proteins, or HLAs, are present in every nucleated cell of the body. Their function is to present protein fragments from within the cell at the surface as antigens. An immune cell will then recognize the presented antigen as a *self-antigen* or as a *nonself-antigen* (part *B* of figure). Self-antigens are normally ignored by the immune cell. Nonself-antigens are instead recognized as abnormal and attacked by the mechanisms described later in this chapter. If a normal cell becomes infected with a virus or becomes cancerous, it may present some abnormal antigens on the surface and thus be identified by the immune system.



MHC class I proteins are also involved in the mechanism by which natural killer (NK) cells recognize abnormal cells. As Figure 24-9 shows, the absence of MHC class I proteins fails to inhibit the killing action of the NK cell. Cells from outside the body are likely to have no MHC class I proteins or have a different version of the MHC class I proteins. Infected or damaged cells are also likely to have missing or damaged MHC class I surface proteins.



MHC class II proteins are expressed in immune cells that specialize in presenting antigens. These "professional" **antigen-presenting cells (APCs)** include macrophages, dendritic cells (DCs), and B cells, for example. The APCs use their MHC class II proteins to present fragments of proteins that they've brought in from outside the cell—perhaps from a bacterial cell. Thus they alert the immune system to the presence of these invaders and trigger certain adaptive (specific) immune responses.

MHC class III proteins include a wide variety of different immune-related proteins such as complement components, some cytokines, and a number of immune and nonimmune proteins.

The major histocompatibility complex (MHC) first came to the attention of researchers trying to find out why transplants and tissue grafts were often rejected by the recipient. They found that individuals with different MHC genes rejected tissues transplanted from one to the other. Thus they coined the term "histocompatibility" for this set of genes because the genes seemed to regulate the compatibility of transplants and grafts.

There are hundreds of different versions or alleles of the principal MHC genes—far more genetic variability than in any other group of genes in the human genome! Scientists are still trying to find a satisfactory explanation for this tremendous variation.

A, Major histocompatibility complex (MHC). The MHC is a region of chromosome 6 that codes for proteins important in immune system function. MHC class I proteins present antigens on the surfaces of all cells of the body that possess a nucleus—which is most cells. MHC class II proteins present antigens on the surfaces of cells that specialize in presenting antigens—the antigen-presenting cells (APCs). MHC class III proteins include complement, cytokines, and other proteins of the immune system. **B, MHC function.** This simplified diagram shows that the MHC protein displays an antigen (protein fragment or peptide) on the surface of the cell. A receptor on the surface of a T cell may then bind to the unique receptor-binding part of the MHC and to a complementary part of the T cell. Antigens (peptides) presented this way can then be recognized by immune cells as being "self" or "nonself."

cell death) that progresses to lysis (breaking apart). NK cells must engage their target cells by direct contact (binding of receptors) to cause cell destruction.

Interferon

Several types of cells, if invaded by viruses, respond rapidly by synthesizing the protein **interferon (IFN)** and releasing some of it into the circulation. As the name suggests, interferon proteins interfere with the ability of viruses to cause disease. One way that they do this is by preventing viruses from multiplying in cells. IFN production is triggered by viral infection in a cell, probably by the presence of viral dsRNA (double-strand RNA). The IFN is then released to nearby cells, where it triggers signal transduction that activates antiviral genes in the neighboring cells. These genes produce an "antiviral state" by producing several enzymes that block viral replication if the cell becomes infected. Thus IFN acts as a paracrine (local) hormone that allows virus-infected cells to send an "alarm" to nearby cells that protects the uninfected cells.

Some interferons also promote synthesis of more MHC proteins, thus allowing them to present viral antigens and promote immune destruction of infected cells (see Box 24-1). By promoting the destruction of cells that are already infected, the chance of the virus spreading to other cells is reduced.

Interferon comes in several varieties, each with somewhat different antiviral actions. Leukocyte interferon (β), fibroblast interferon (α), and immune interferon (γ) are the three major types of interferon proteins. All three have now been produced by using gene-splicing techniques. Studies exploring antiviral and anticancer activities of interferons are currently under way (Box 24-2).

Box 24-2 | HEALTH matters

Interferon Therapy

Although interferon (IFN) has not proven to be the "magic bullet" cure researchers may have once hoped, some useful therapies have emerged from ongoing research into clinical uses of this protein. Several types of leukocyte interferon, including *IFN alpha-2a* and *IFN alpha-2b,* are approved by the FDA for therapeutic use in viral hepatitis C. Interferons can be manufactured by splicing human genes that encode the amino acid sequence for this protein into the DNA of a common type of bacterium called *Escherichia coli.* These easily cultured bacteria, which normally would not make interferon, are thus converted into miniature "interferon factories." Interferon is often combined with polyethylene glycol to make it last longer in the body—and thus reduce the number of injections needed from three per week to just one per week.

Having both anticancer and antiviral properties, interferons are sometimes used with other therapies in the treatment of AIDS-related Kaposi sarcoma (see Fig. 7-28, p. 191), hairy-cell leukemia, other cancers, and genital warts. A type of interferon called *IFN beta* has also been used to treat multiple sclerosis (MS).

Complement

Complement is the name given to each of a group of about 20 inactive enzymes in the plasma and on cell surfaces. Individual complement proteins are often designated by C (for complement) followed by a number, such as C1, C2, C3, and so on. Subtypes of each complement are usually identified by a lower-case letter, such as C4b or C5a—or by Greek letters, as in C5bα or C8β.

Complement molecules are activated in a cascade of chemical reactions triggered by either adaptive or innate mechanisms. Ultimately, the complement cascade causes lysis (rupture) of the foreign cell that triggered the response. Complement also marks microbes for destruction by phagocytic cells—a process called *opsonization*—and it promotes the inflammatory response. Some of these functions of complement are discussed in more detail later in this chapter (Figure 24-10).

Toll-like Receptors

Triggering of many of the innate responses already mentioned requires action by **Toll-like receptors (TLRs)** in the membranes of host cells. They get their odd name from *Toll* (German for "weird"), the name of a gene for this receptor family that was first discovered to cause strange body shapes in fruit flies when damaged. Later, the proteins produced by the gene were also found to have a primitive immune function.

Each of the many types of TLRs present in membranes of human cells can recognize the general pattern of a whole group of molecules that originate in microbes (but not in human cells). That is, they are *pattern-recognition receptors (PRRs)* and thus do not identify specific antigens. Instead, they have a *nonspecific* ability to identify a large variety of different bacterial molecules such as toxins and flagella proteins, viral RNA and glycoproteins, and fungal molecules.

When triggered, TLRs facilitate many of the nonspecific immune mechanisms described earlier. For example, they help initiate the inflammatory response, antigen presentation to immune

cells, phagocytosis, release of cytokines and interferon—and even apoptosis of an infected host cell. TLRs are key facilitators of the overall innate immune response of the body.

6. What is the role of macrophages in the defense of the body?
7. How do *interferons* and *complement* protect the body?

OVERVIEW OF ADAPTIVE IMMUNITY

Unlike the innate, nonspecific mechanisms of immunity, the various types of adaptive immune mechanisms attack *specific* agents that the body recognizes as abnormal or nonself. Adaptive immunity, part of the body's *third line of defense*, is orchestrated by two different classes of a type of white blood cell called the *lymphocyte* (Figure 24-11).

Originally, lymphocytes are formed in the red bone marrow of the fetus. They, like all blood cells, derive from primitive cells known as *hematopoietic stem cells* (see Chapter 20). The stem cells destined to become lymphocytes of the adaptive immune system follow two developmental paths and differentiate into two major classes of lymphocytes—*B lymphocytes* and *T lymphocytes*, or simply **B cells** and **T cells** (Figure 24-12).

B cells do not attack pathogens themselves but instead produce molecules called **antibodies** that attack the pathogens or direct other cells, such as phagocytes, to attack them. B cell mechanisms are therefore often classified as **antibody-mediated immunity.** Because antibodies disperse freely in the blood plasma, where they accomplish their immune functions, this type of immunity is sometimes also called **humoral immunity.** The word *humoral* refers to body fluids, especially blood plasma. Many of these terms are further explained in Box 24-3.

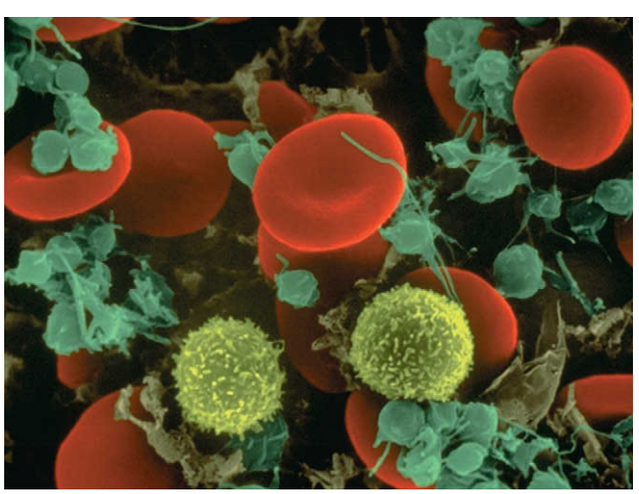

FIGURE 24-11

Lymphocytes. Color-enhanced scanning electron micrograph showing lymphocytes in yellow, red blood cells in red, and platelets in green.

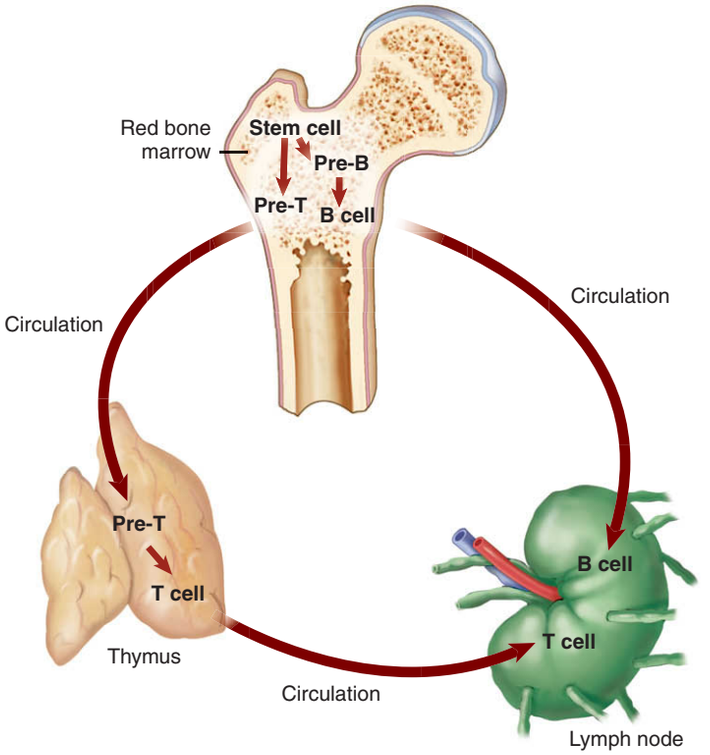

FIGURE 24-12

Development of B cells and T cells. Both types of lymphocytes originate from stem cells in the red bone marrow. Pre–B cells that are formed by dividing stem cells develop in the "bursa-equivalent" tissues in the yolk sac, fetal liver, and bone marrow. Likewise, pre–T cells migrate to the thymus, where they continue developing. Once they are formed, B cells and T cells circulate to the lymph nodes and spleen.

Because T cells attack pathogens more directly, T cell immune mechanisms are classified as **cell-mediated immunity** or, more simply, **cellular immunity** (Figure 24-13).

Lymphocytes express proteins on their surfaces known as *surface markers*. Some of these proteins are unique to lymphocytes; some are shared by other types of cells. B cells and T cells each have some unique surface markers that not only distinguish B cells from T cells but also subdivide these categories into *subsets*. Lymphocyte subsets are clinically meaningful. For example, the condition of a patient's T-cell subsets is very important in understanding AIDS. The international system for naming surface markers on blood cells is the **CD system** (CD stands for cluster of differentiation; the number after "CD" refers to a single, defined surface marker protein). For example, the T-cell subsets that are clinically important in diagnosing and assessing AIDS or other immune deficiencies are the CD4 and CD8 T-cell subsets.

Adaptive immunity requires activation of lymphocyte populations, which then begin their immune attack of specific antigens (or cells or viruses bearing those antigens). Such activation requires two activating signals: a specific antigen and a chemical signal (Figure 24-14). Each lymphocyte has receptors both for antigens and for signaling chemicals. Both receptors must be activated for the lymphocyte to begin its active immune function.

Box 24-3 | FYI

The Language of Adaptive Immunity

Learning the mechanisms of adaptive (specific) immunity will be easier if you first become familiar with the following terms:

Antigens—macromolecules (large molecules) that induce the immune system to make certain responses. Most antigens are foreign proteins. Some, however, are polysaccharides, and some are nucleic acids. *Haptens,* sometimes called "incomplete antigens," are very small molecules that must first bind to a protein before they can induce an immune response. Many antigens that enter the body are macromolecules located in the walls or outer membranes of microorganisms or the outer coats of viruses. Of course, antigens on the surfaces of some tumor cells (tumor markers) are not really from outside the body but are "foreign" in the sense that they are recognized as "not belonging." The membrane molecules that identify all the normal cells of the body are called *self-antigens* or *major histocompatibility complex (MHC) antigens* (see Box 24-1 on p. 754). Foreign and tumor cell antigens can be called *nonself-antigens.*

Antigenic determinants—variously shaped, small regions on the surface of an antigen molecule; a less cumbersome name is *epitopes.* In a protein molecule, for instance, an epitope consists of a sequence of only about 10 amino acids that are part of a much longer, folded chain of amino acids. The sequence of the amino acids in an epitope determines its shape. Because the sequence differs in different kinds of antigens, each kind of antigen usually has specific and uniquely shaped epitopes.

Antibodies—plasma proteins of the class called *immunoglobulins.* Unlike most antigens, all antibodies are native molecules, that is, they are normally present in the body.

Combining sites—two small concave regions on the surface of an antibody molecule. Like epitopes, combining sites have specific and unique shapes. An antibody's combining sites are shaped so that an antigen's epitope that has a complementary shape can fit into the combining site and thereby bind the antigen to the antibody to form an **antigen-antibody complex.** Because combining sites receive and bind antigens, they are also called *antigen receptors* and *antigen-binding sites.*

Clone—family of cells, all of which have descended from one cell.

Complement—a group of proteins that, when activated, work together to destroy foreign cells.

Effector cell—a B cell or T cell that is actively producing an immune response, such as secreting antibodies (effector B cells) or directly attacking other cells (effector T cells); effector cells usually die during or just after their immune response; effector B cells are also called *plasma cells.*

Memory cell—a B or T cell that has been activated (no longer naïve) but is not an effector cell producing an active response; rather, a memory cell survives for a long period in the lymph nodes and if later exposed to the same specific antigen, forms a clone of cells that rapidly produce a specific immune response.

Naïve—refers to a B or T cell that is inactive, has not yet been exposed to (or had an opportunity to react with) a specific antigen; synonymous with "inactive" or "virgin."

	Antibody-mediated (humoral) immunity	Cell-mediated immunity	
Microbe	Extracellular microbes	Phagocytosed microbes in macrophage	Intracellular microbes (e.g., viruses) replicating within infected cell
Responding lymphocytes	B lymphocyte	Helper T lymphocyte	Cytotoxic T lymphocyte
Effector mechanism	Secreted antibody		
Distributed by	Blood plasma (antibodies)	Cells (T lymphocytes)	Cells (T lymphocytes)
Main functions	**Block infections and eliminate extracellular microbes**	**Activate macrophages to kill phagocytosed microbes**	**Kill infected cells and eliminate reservoirs of infection**

FIGURE 24-13

Two strategies of adaptive immunity. Simplified summary of antibody-mediated (humoral) immunity and cell-mediated (cellular) immunity.

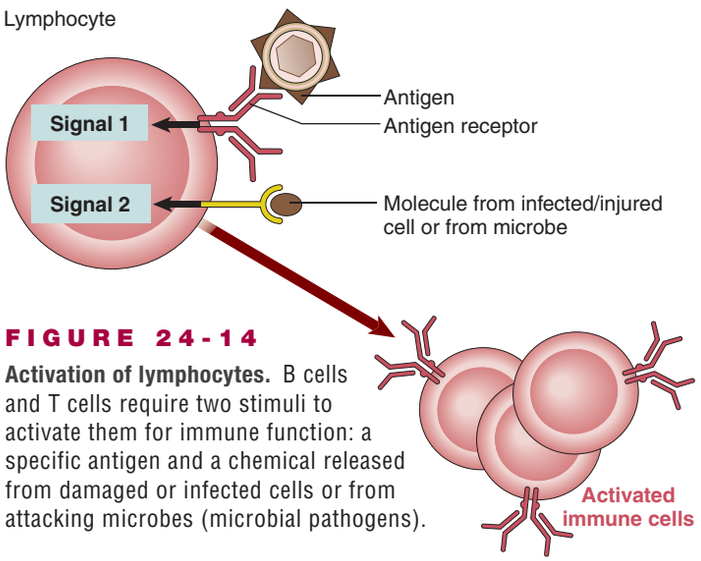

FIGURE 24-14

Activation of lymphocytes. B cells and T cells require two stimuli to activate them for immune function: a specific antigen and a chemical released from damaged or infected cells or from attacking microbes (microbial pathogens).

Chemicals required to stimulate immune function may come from injured/infected cells or from microbes themselves.

The densest populations of lymphocytes occur in the bone marrow, thymus gland, lymph nodes, and spleen (Figure 24-15). From these structures, lymphocytes pour into the blood and then distribute themselves throughout the tissues of the body. After wandering through the tissue spaces, they eventually find their way into lymphatic capillaries. Lymph flow transports the lymphocytes through a succession of lymph nodes and lymphatic vessels and empties them by way of the thoracic and right lymphatic ducts into the subclavian veins. Thus returned to the blood, the lymphocytes embark on still another long journey—through blood, tissue spaces, and lymph and then back to blood. The survival value of the continued recirculation of lymphocytes and of their widespread distribution throughout body tissues seems apparent. It provides these major cells of the immune system ample opportunity to perform their functions of searching out, recognizing, and destroying foreign invaders.

Before reading further, please review the basic terminology used to explain adaptive immunity, which is presented in Box 24-3.

| QUICK CHECK |

8. What is an antigen? What is the difference between a *self-antigen* and a *nonself-antigen?*
9. What is meant by the term *clone?*

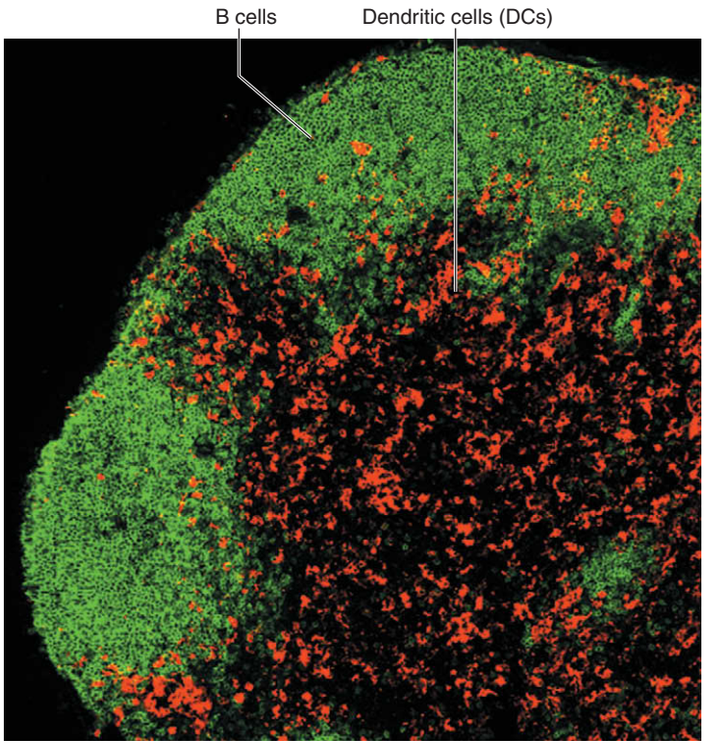

FIGURE 24-15

B cells in a lymph node. This micrograph of a lymph node shows fluorescent green stain in B cells, which are densely packed in the nodules of the lymph node. The cells marked by the red stain are a type of macrophage called *dendritic cells* (see Figure 24-8).

B CELLS AND ANTIBODY-MEDIATED IMMUNITY

Development and Activation of B Cells

The development of the lymphocytes called *B cells* occurs in two stages (Figure 24-16). In chickens the first stage of B-cell development occurs in the *bursa of Fabricius*—hence the name *B cells.* Because humans do not have a bursa of Fabricius, another organ must serve as the site for the first stage of B-cell development. The bursa-equivalent tissue in humans is the yolk sac and fetal liver during early development and then later the red marrow. After completing their first developmental stage, the B cells are then known as **naïve B cells,** or sometimes *inactive* or *virgin* B cells.

Naïve B cells synthesize antibody molecules but secrete few if any of them. Instead, they insert on the surface of their plasma membranes perhaps 100,000 antibody molecules. The combining sites of these surface antibody molecules serve as receptors for a specific antigen if encountered. After being released from the bone marrow, naïve B cells circulate to the lymph nodes, spleen, and other lymphoid structures.

The second major stage of B-cell development occurs when the naïve B cells become activated. Activation of a B cell must be initiated by an encounter between a naïve B cell and its specific antigen, that is, one whose epitopes fit the combining sites of the B cell's surface antibodies (see Figure 24-16).

The antigen binds to these antibodies on the B cell's surface. Antigen-antibody binding activates the B cell, triggering a rapid series of mitotic divisions. By dividing repeatedly, a single B cell produces a clone, or family, of identical B cells. Some of them differentiate to form **effector B cells** or **plasma cells.** Others do not differentiate completely but remain in the lymphatic tissue as the so-called **memory B cells.**

Plasma cells synthesize and secrete huge amounts of antibody. A single plasma cell, according to one estimate, secretes 2000 antibody molecules per second during the few days that it lives. All the cells in a clone of plasma cells secrete identical antibodies because they have all descended from the same B cell.

Memory B cells do not themselves secrete antibodies, but if they are later exposed to the antigen that triggered their formation, memory B cells then rapidly divide to produce more plasma cells and memory cells. The newly formed plasma cells then quickly secrete antibodies that can combine with the initiating antigen (see Figure 24-16)—thus quickly combating the antigen. Thus the ultimate function of B cells is to serve as ancestors of antibody-secreting plasma cells (effector B cells).

Antibodies (Immunoglobulins)

STRUCTURE OF ANTIBODY MOLECULES

Antibodies are proteins of the family called **immunoglobulin (Ig).** Like all proteins, antibodies are very large molecules and are composed of long chains of amino acids (polypeptides). Each immunoglobulin molecule consists of four polypeptide chains—two heavy chains and two light chains. Each polypeptide chain is intricately folded to form globular regions that are joined together in such a way that the immunoglobulin molecule as a whole is Y-shaped. Look now at Figure 24-17, A. The twisted strands of red

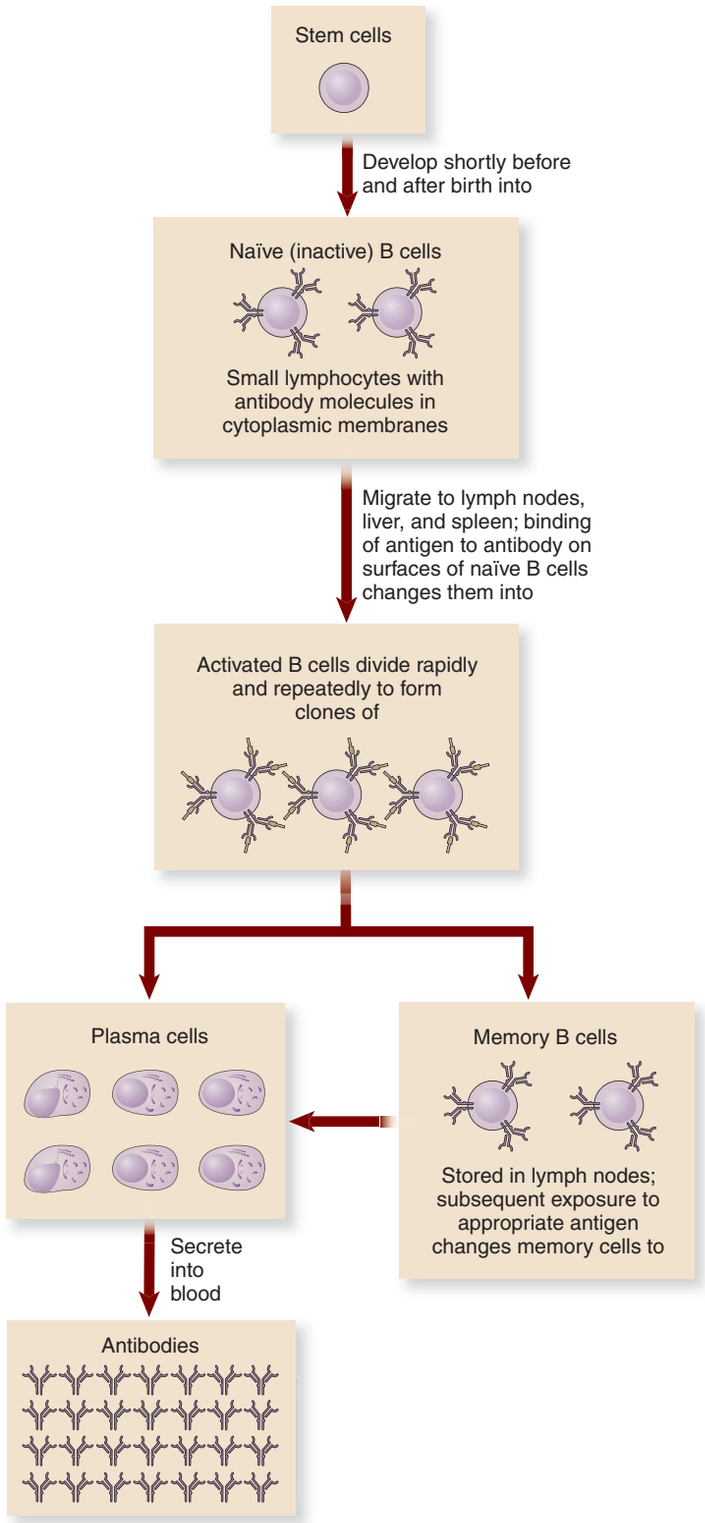

FIGURE 24-16

B cell development. B cell development takes place in two stages. *First stage:* shortly before and after birth, stem cells develop into naïve B cells. *Second stage* (occurs only if naïve B cell contacts its specific antigen): naïve B cell develops into activated B cell, which divides rapidly and repeatedly to form a clone of plasma cells and a clone of memory cells. Plasma cells secrete antibodies capable of combining with specific antigens that cause naïve B cell to develop into active B cell. Stem cells maintain a constant population of newly differentiating cells.

spheres (amino acids) in the diagram represent the light chains, and the two twisted strands of blue spheres represent the heavy chains. Each heavy chain consists of 446 amino acids. Heavy chains therefore are about twice as long and weigh about twice as much as light chains.

The regions with colored bars seen in Figure 24-17, *B*, represent *variable regions*, that is, regions in which the sequence of amino acids varies in different antibody molecules. Note the relative positions of the variable regions of the light and heavy chains; they lie directly opposite each other. Because the amino acid sequence determines conformation or shape, and because different sequences of amino acids occur in the variable regions of different antibodies, the shapes of the sites between the variable regions also differ. At the end of each "arm" of the Y-shaped antibody molecule, the unique shapes of the variable regions form a cleft that serves as the antibody's combining sites, or antigen-binding sites. It is this structural

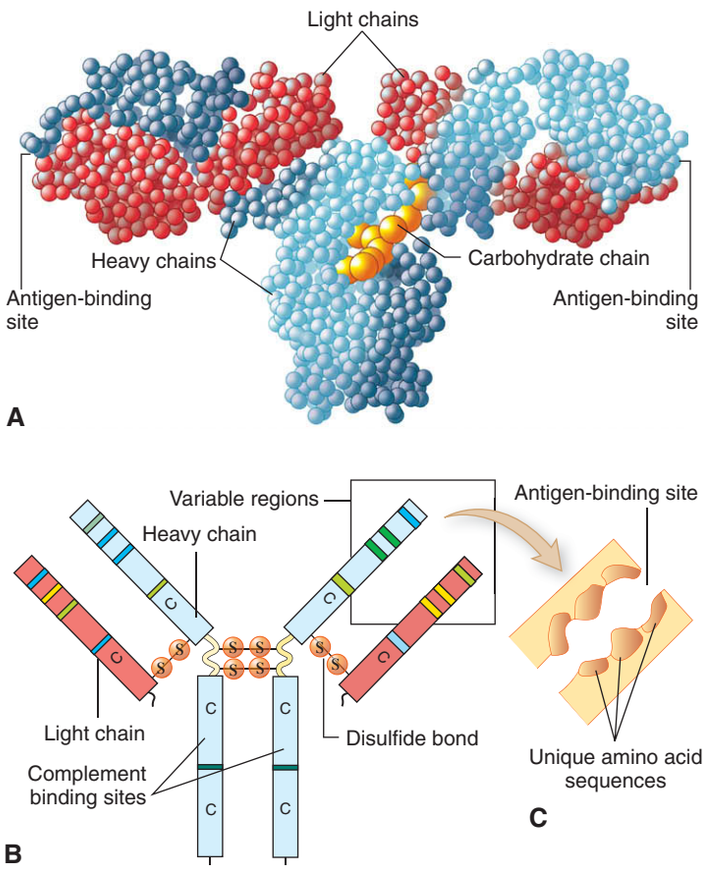

FIGURE 24-17

Structure of the antibody molecule. A, In this molecular model of a typical antibody molecule, the light chains are represented by strands of red spheres (each represents an individual amino acid). Heavy chains are represented by strands of blue spheres. Notice that the heavy chains can complex with a carbohydrate chain. **B,** This simplified diagram shows the variable regions, highlighted by colored bars, that represent amino acid sequences unique to that molecule. Constant regions of the heavy and light chains are marked. **C.** The inset shows that the variable regions at the end of each arm of the molecule form a cleft that serves as an antigen-binding site.

feature that enables antibodies to recognize and combine with specific antigens, both of which are crucial first steps in the body's defense against invading microorganisms and other foreign cells.

In addition to its variable region, each light chain in an antibody molecule also has a constant region. The constant region consists of 106 amino acids whose sequence is identical in all antibody molecules. Each heavy chain of an antibody molecule consists of three constant regions in addition to its one variable region. Identify the constant and variable regions of the light and heavy chains in Figure 24-17. Note the location of two *complement-binding sites* on the antibody molecule (one on each heavy chain).

In summary, an immunoglobulin, or antibody molecule, consists of two heavy and two light polypeptide chains. Each light chain consists of one variable region and one constant region. Each heavy chain consists of one variable region and three constant regions. Disulfide bonds join the two heavy chains to each other; they also bind each heavy chain to its adjacent light chain. An antibody has two antigen-binding sites—one at the top of each pair of variable regions—and two complement-binding sites located as shown in Figure 24-17.

DIVERSITY OF ANTIBODIES

Every normal baby is born with an enormous number of different clones of B cells populating his or her bone marrow, lymph nodes, and spleen. All the cells of each clone are committed to synthesizing a specific antibody with a sequence of amino acids in its variable regions that is different from the sequence synthesized by any other of the innumerable clones of B cells.

How does this astounding diversity originate? One suggested answer is called the *somatic recombination hypothesis*. According to this explanation, our chromosomes do not contain whole genes for producing the heavy and light polypeptide chains that make up each antibody molecule. Instead, the genetic code is a set of separate sequences that are assembled into whole genes as a B cell develops. Because the separate sequences can be assembled in an astounding number of different combinations to form each whole gene, and because several different polypeptides are needed to make one antibody, any particular B cell is not likely to synthesize *exactly* the same antibody as any other B cell. Thus somatic recombination is a sort of "genetic lottery" that produces millions of unique genes by combining different gene segments and millions of unique antibodies by combining different polypeptides.

Antibody diversity may also be influenced by occasional mutations in the gene segments used to form the genes needed to produce antibodies. Evidence from several different studies shows that random genetic mutations—slight changes in the master DNA code—result in slight differences in the variable regions of antibodies.

If these hypotheses about antibody diversity are correct, it is possible to produce B cells that make antibodies against self-antigens. It is thought that although most such B cells are eliminated early in their development, before they produce antibodies that would attack a person's own cells, all humans have some "anti-self" B cells in their bodies.

CLASSES OF ANTIBODIES

There are five classes of antibodies, identified by letter names as immunoglobulins M, G, A, E, and D (Figure 24-18). *IgM* (abbreviation for immunoglobulin M) is the antibody that immature B cells synthesize and insert into their plasma membranes. It is also the predominant class of antibody produced after initial contact with an antigen. The most abundant circulating antibody, the one that normally makes up about 75% of all the antibodies in the blood, is *IgG*. It is the predominant antibody of the secondary antibody response—that is, following subsequent contacts with a given antigen. The IgG antibodies are those that cross the placental barrier during pregnancy to impart natural passive immunity to the offspring (see Table 24-4 and Box 24-7). *IgA* is the major class of antibody present in the mucous membranes of the body, in saliva, and in tears (see Box 24-8). *IgE*, although minor in amount, can produce major harmful effects, such as those associated with allergies. *IgD* is present in the blood in very small amounts, and its precise function is as yet unknown. As Figure 24-18 shows, some immunoglobulin molecules are formed by the joining of several basic antibody units.

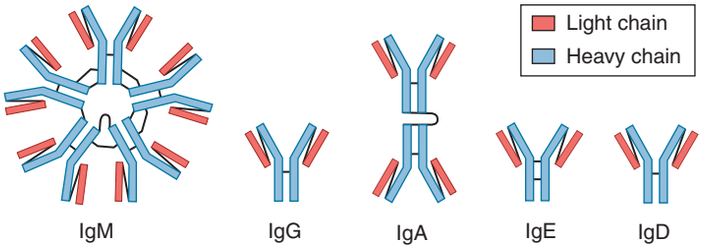

FIGURE 24-18

Classes of antibodies. Antibodies are classified into five major groups: immunoglobulin M (IgM), immunoglobulin G (IgG), immunoglobulin A (IgA), immunoglobulin E (IgE), and immunoglobulin D (IgD). Notice that each IgM molecule has five Y-shaped basic antibody units and most of the others have a single basic antibody unit. IgA is shown here with two antibody units, which is the form found in mucous secretions. But IgA also has a single-unit form found in the blood plasma.

FUNCTIONS OF ANTIBODIES

The function of antibody molecules—some 100 million trillion of them—is to produce **antibody-mediated immunity.** As we stated earlier, this type of immunity is also called *humoral immunity* because it occurs within plasma, which is one of the humors, or fluids, of the body.

TABLE 24-4 Types of Adaptive Immunity

TYPE	DESCRIPTION OR EXAMPLE
Natural Immunity	Exposure to the causative agent is not deliberate
Active (exposure)	A child develops measles and acquires an immunity to a subsequent infection
Passive (exposure)	A fetus receives protection from the mother through the placenta, or an infant receives protection through the mother's milk
Artificial Immunity	Exposure to the causative agent is deliberate
Active (exposure)	Injection of the causative agent, such as a vaccination against polio, confers immunity
Passive (exposure)	Injection of protective material (antibodies) that was developed by another individual's immune system

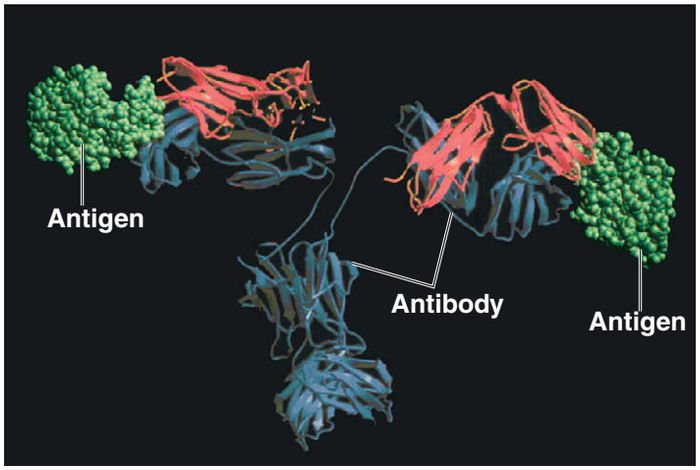

FIGURE 24-19

Binding of antigen by an antibody. This ribbon model of an antibody shows the heavy chains in blue and the light chains in red. Note the green antigen molecules bound to each antigen-binding site.

Antigen-Antibody Reactions

Antibodies fight disease first by recognizing substances that are foreign or abnormal. In other words, they distinguish nonself-antigens from self-antigens. Recognition occurs when an antigen's epitopes (small regions on its surface) fit into and bind to an antibody molecule's antigen-binding sites (Figure 24-19). The binding of the antigen to antibody forms an antigen-antibody complex that may produce one or more effects. For example, it transforms antigens that are toxins (chemicals poisonous to cells) into harmless substances. It agglutinates antigens that are molecules on the surface of microorganisms. In other words, it makes them stick together in clumps, and this in turn makes it possible for macrophages and other phagocytes to dispose of them more rapidly by ingesting and digesting large numbers of them at one time. The binding of antigens to antibodies frequently produces still another effect—it alters the shape of the antibody molecule, not very much, but enough to expose the molecule's previously hidden complement-binding sites. This seems a trivial enough change, but it is not so. It initiates an astonishing series of reactions that culminate in the destruction of microorganisms and other foreign cells (Figure 24-20).

Complement

Complement is a component of blood plasma that consists of about 20 protein compounds. They are inactive enzymes that become activated in a definite sequence to catalyze a series of intricately linked reactions. The binding of an antibody to an antigen located on the surface of a cell alters the shape of the antibody molecule in a way that exposes its complement-binding sites. By binding to these sites, complement protein 1 becomes activated and touches off the catalytic activity of the next complement protein in the series. A rapid sequence, or cascade, of activity by the next protein, then the next, and the next, follows until the entire series of enzymes has functioned. The end result of this rapid-fire

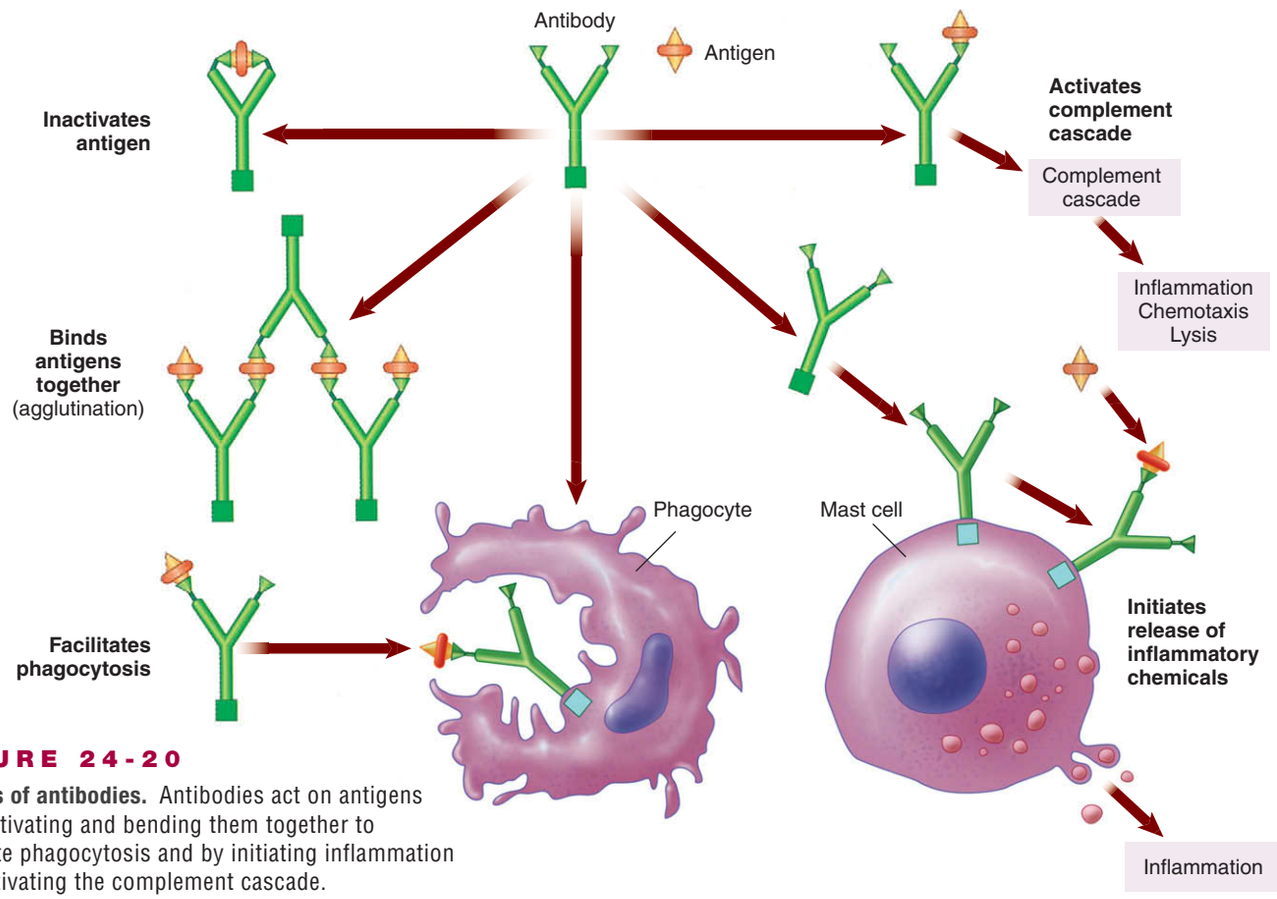

FIGURE 24-20

Actions of antibodies. Antibodies act on antigens by inactivating and bending them together to facilitate phagocytosis and by initiating inflammation and activating the complement cascade.

activity challenges the imagination. Some of the resulting reactions were summarized in Figure 24-10 (p. 755).

One of the more spectacular results of the complement cascade is the formation of **membrane attack complexes (MACs).** Molecules formed by the reactions of the complement cascade assemble themselves on the enemy cell's surface in such a way as to form a doughnut-shaped structure—complete with a hole in the middle (Figure 24-21). In effect, the complement has drilled a hole through the foreign cell's surface membrane. Ions and water rush into the cell through the MAC; consequently, it swells and bursts (Figure 24-22). **Cytolysis** is the technical name for this process. Nucleated cells usually resist cytolysis, but the influx of ions triggers apoptosis and thus kills the target cell another way.

Briefly, then, complement functions to kill foreign cells by cytolysis. In addition, various complement proteins serve other functions. Some, for example, cause vasodilation in the invaded area, and some attract neutrophils to the site and enhance phagocytosis.

The complement cascade can also be initiated by innate immune mechanisms. Complement protein 3 (C3) can become activated without any stimulation by an antigen. C3 is normally inactivated by enzymes, but it can produce the full complement effect if it binds to bacteria or viruses in the presence of a protein called *properdin*. Thus lysis of various foreign cells and viruses by complement can occur even when antibodies are not involved. This method of activating the complement cascade is often called the "alternate pathway" to distinguish it from the "classical pathway" involving antibodies.

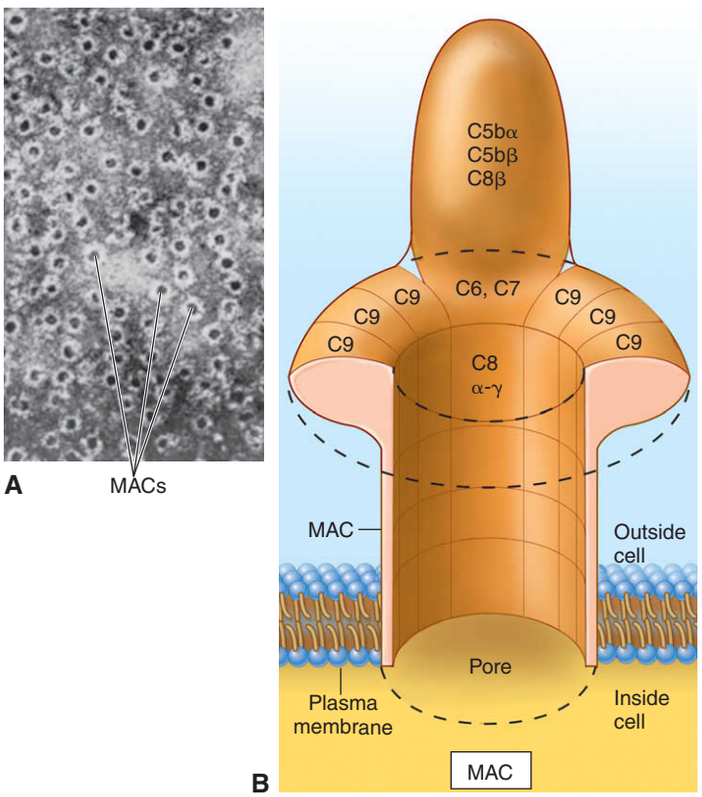

FIGURE 24-21

Membrane attack complex (MAC). Complement components assemble to form a ringlike complex that forms a pore in the membrane of a cell. **A,** Electron micrograph showing numerous MAC pores, each about 100 Å in diameter. **B,** Diagram of the structure of a MAC embedded in a plasma membrane.

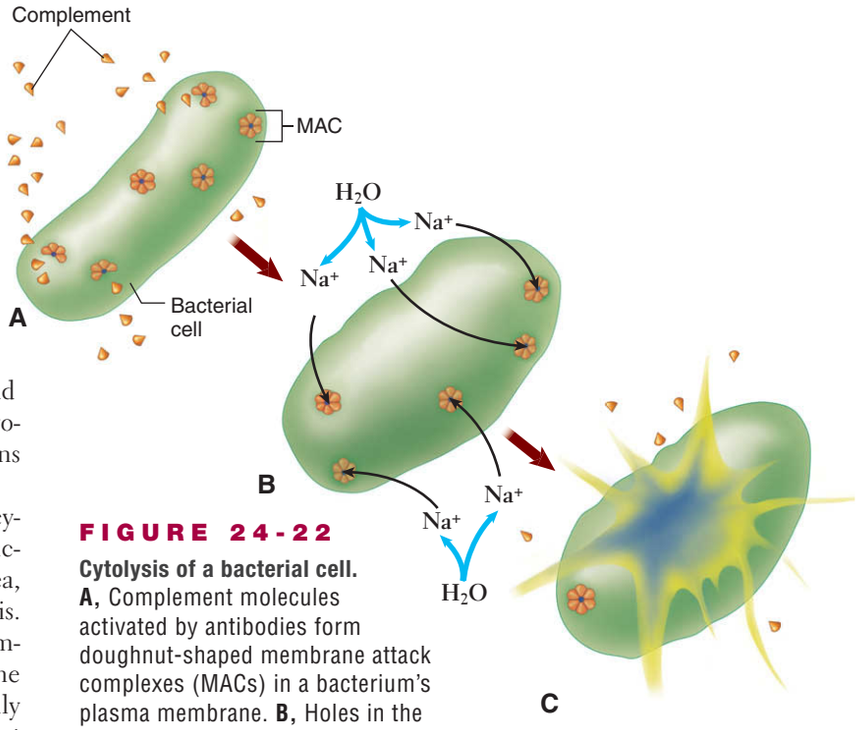

FIGURE 24-22

Cytolysis of a bacterial cell. **A,** Complement molecules activated by antibodies form doughnut-shaped membrane attack complexes (MACs) in a bacterium's plasma membrane. **B,** Holes in the complement complex allow sodium (Na^+) and then water (H_2O) to diffuse into the bacterium. **C,** After enough water has entered, the swollen bacterium bursts. In nucleated cells that resist cytolysis, the influx of calcium ions triggers apoptosis and thus kills the target cell another way.

Primary and Secondary Responses

As Figure 24-23 shows, an initial encounter with a specific antigen produces a *primary response* of increased antibody production in a few days. As the antigen is dealt with, the antibody levels decrease to their normal baseline levels. However, memory B cells that can respond to the triggering antigen have also been produced and wait for another encounter with the antigen. A later encounter with the same antigen triggers the waiting memory B cells and thus produces a secondary response in much less time. The memory B cells quickly divide to form more memory cells and a large number of plasma cells that produce antibodies against the known antigen. Thus the secondary response can be quicker and thus more effective. The strength of the secondary response can be used to boost the effectiveness of immunizations (Box 24-4).

| A&P CONNECT |

Techniques that permit biologists to produce and isolate large quantities of pure and very specific antibodies called monoclonal antibodies (MAbs) and tiny antibody fragments called nanobodies have resulted in dramatic advances in medicine. Learn how this works in ***Monoclonal Antibodies and Nanobodies*** online at ***A&P Connect.***

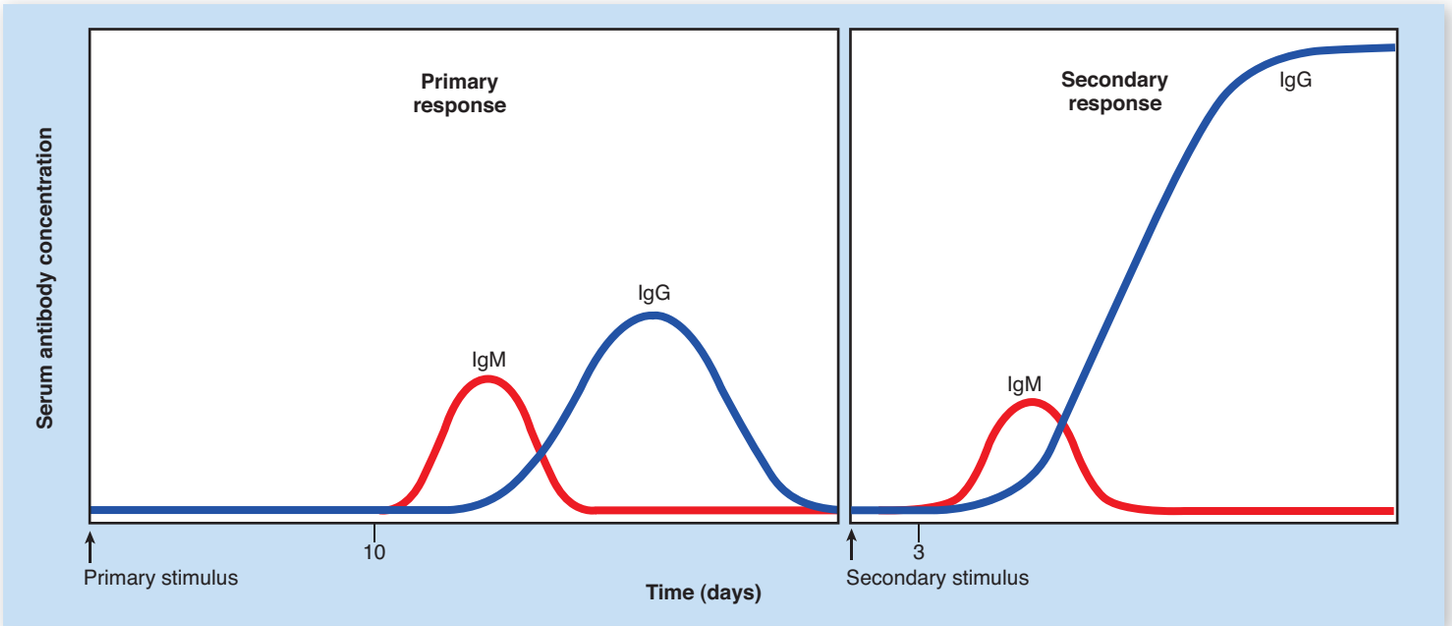

FIGURE 24-23

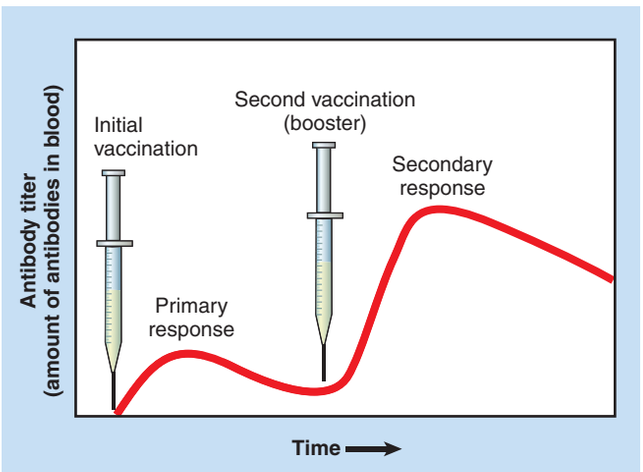
Antibody response times. The initial encounter with a specific antigen (primary stimulus) produces a primary response (increased production of IgM and IgG) in a few days. A later encounter (secondary stimulus) produces a secondary response in much less time. Note that both IgM production and IgG production occur more quickly in the secondary response—and IgG production also increases in the total amount of antibody produced.

Box 24-4 | HEALTH matters



Immunization

Active immunity can be established artificially by using a technique called **vaccination.** The first vaccine was a live cowpox virus that was injected into healthy people to cause a mild cowpox infection. The term *vaccine* literally means "cow substance." Because the cowpox virus is similar to the deadly *smallpox virus,* vaccinated individuals developed antibodies that imparted immunity against both cowpox and smallpox viruses.

Modern vaccines work on a similar principle; substances that trigger the formation of antibodies against specific pathogens are introduced orally or by injection. Some of these vaccines are killed pathogens or live, *attenuated* (weakened) pathogens. Such pathogens still have their specific antigens intact, so they can trigger formation of the proper antibodies, but they are no longer *virulent* (able to cause disease). Although rare, these vaccines sometimes backfire and actually cause an infection. Many of the newer vaccines avoid this potential problem by using only the part of the pathogen that contains antigens. Because the disease-causing portion is missing, such vaccines cannot cause infection.

The amount of antibodies in a person's blood produced in response to vaccination or an actual infection is called the **antibody titer.** As you can see in the figure, the initial injection of vaccine triggers a rise in the antibody titer that gradually diminishes. Often, a **booster shot,** or second injection, is given to keep the antibody titer high or to raise it to a level that is more likely to prevent infection. The secondary response is more intense than the primary response because memory B cells are ready to produce a large number of antibodies at a moment's notice. A later accidental exposure to the pathogen will trigger an even more intense response—thus preventing infection.

Toxoids are similar to vaccines but use an altered form of a bacterial toxin to stimulate production of antibodies. Injection of toxoids imparts protection against toxins, whereas administration of vaccines imparts protection against pathogenic organisms and viruses.

Changes in blood antibody titers following primary and secondary (booster) vaccinations.

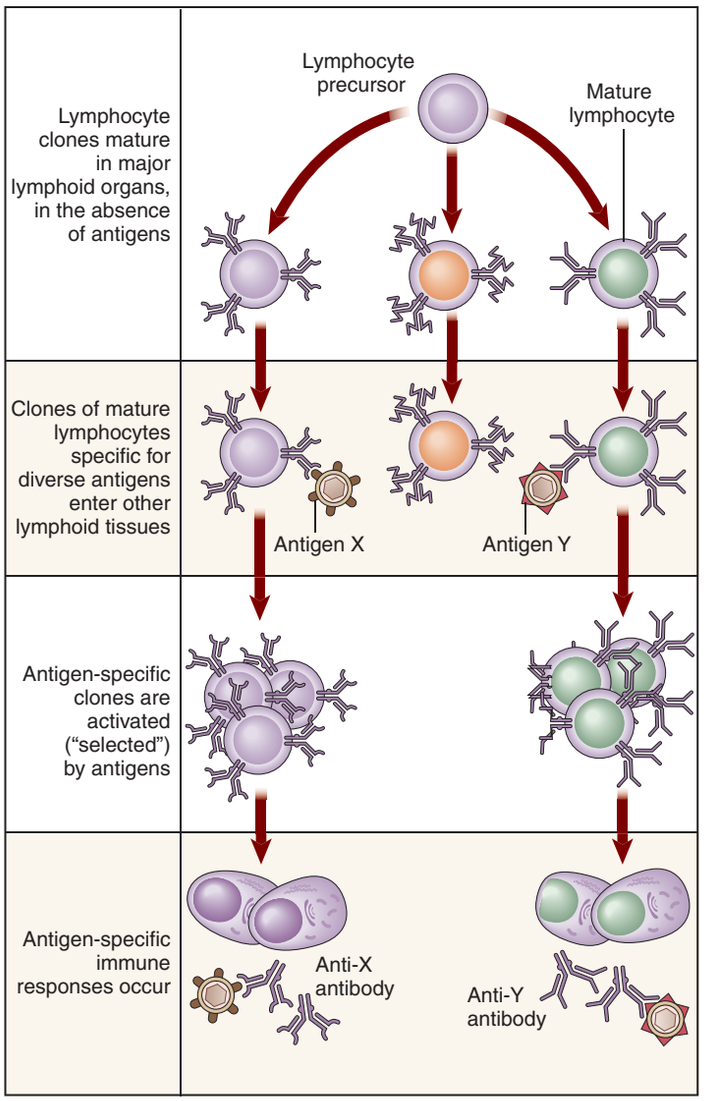


FIGURE 24-24

The clonal selection theory. This theory of immunity states that each specific antigen (here shown as X and Y) activates—selects—a previously produced clone of lymphocytes. The clone is "selected" because it is specifically targeted at the selecting antigen. The clone, when thus activated, produces effector cells that attack the antigen. B cells are shown here, but the same principle also applies to T cells.

Clonal Selection Theory

The *clonal selection theory*, which deals with antigen destruction, was first proposed in 1959 by Sir Macfarlane Burnet (Figure 24-24). It has two basic tenets. First, it holds that the body contains an enormous number of diverse clones of cells, each committed by certain of its genes to synthesize a different antibody. Second, the clonal selection theory postulates that when an antigen enters the body, it selects the clone whose cells are committed to synthesizing its specific antibody and stimulates these cells to proliferate and to thereby produce more antibodies. We now know that the clones selected by antigens consist of lymphocytes. We also know how antigens select lymphocytes—by the shape of antigen receptors on the lymphocyte's plasma membrane. An antigen recognizes receptors that fit its epitopes and combines with them. By thus selecting the precise clone committed to making its specific antibody, each antigen provokes its own destruction.

T CELLS AND CELL-MEDIATED IMMUNITY

Development of T Cells

T cells, by definition, are lymphocytes that have made a detour through the thymus gland before migrating to the lymph nodes and spleen (see Figure 24-12). During their residence in the thymus, pre–T cells develop into **thymocytes,** cells that proliferate as rapidly as any in the body. Thymocytes divide up to three times each day, and, as a result, their numbers increase enormously in a relatively short time. They stream out of the thymus into the blood and find their way to a new home in areas of the lymph nodes and spleen called *T-dependent zones.* From this time on, they are known as T cells.

Activation and Functions of T Cells

Each T cell, like each B cell, displays antigen receptors on its surface membrane. They are not immunoglobulins as are B-cell receptor molecules but are proteins similar to them. When an antigen (preprocessed and presented by phagocytes) encounters a naïve T cell whose surface receptors fit the antigen's epitopes, the antigen binds to the T cell's receptors. Here is where we see one of several differences between antibody-mediated immunity and cell-mediated immunity: antibodies can react to soluble antigens dissolved in the plasma, but T cells can only react to protein fragments presented on the surfaces of APCs (antigen-presenting cells) or infected cells. Thus T cells react to cells that are already infected—or have otherwise engulfed the antigen. B cells, on the other hand, react mainly to antigens that are in the plasma.

The presentation of an antigen by an antigen-presenting cell activates or sensitizes the T cell. The T cell then divides repeatedly to form a clone of identical *sensitized T cells* that form **effector T cells** and **memory T cells.** Effector T cells include **cytotoxic T cells,** which cause contact killing of a target cell. Cytotoxic T cells are also called *cytolytic T lymphocytes (CDLs)* or *killer T cells.* Memory T cells remain in red bone marrow until they ultimately produce additional active T cells when

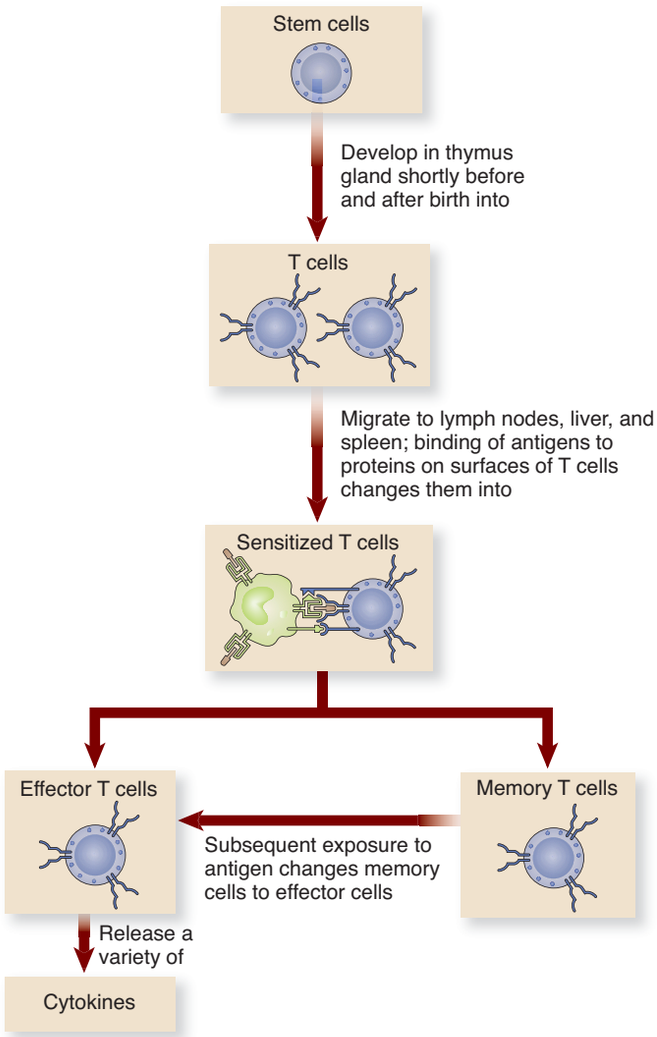

FIGURE 24-25

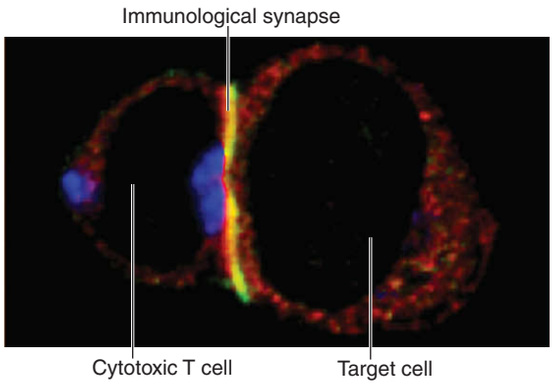

T cell development. The *first stage* occurs in the thymus gland shortly before and after birth. Stem cells maintain a constant population of newly differentiating cells as they are needed. The *second stage* occurs only if a T cell is presented an antigen, which combines with certain proteins on the T cell's surface.

Box 24-5 | FYI

Immunological Synapses

Immune cells often make contact with other immune cells or their target cells so that they can carry out their various functions. Their contact points are similar in many ways to the neurological synapse that you learned about in Chapter 13 (see Figure 13-25 on p. 401). Therefore, these contact points made by immune cells are called **immunological synapses (ISs).**

Some ISs are temporary junctions formed when an antigen-presenting cell (APC) connects to an effector cell, such as a cytotoxic T cell. For example, see the effector mechanisms for cell-mediated immunity in Figure 24-13. ISs also form when natural killer (NK) cells or cytotoxic T cells temporarily attach to a target cell to destroy it (see the figure). The junctions seen in Figures 24-9 and 24-26 are examples. ISs also form a temporary junction between immune cells to allow cytokines to pass efficiently from one cell to another. The junctions seen in the effector functions of helper T cells are shown in Figure 24-27.

Immunological synapses (IS). Fluorescence micrograph that highlights integral membrane proteins involved in the formation of a temporary junction—immunological synapse—between a cytotoxic T cell and the target cell it is about to destroy. Other types of ISs permit efficient communication between two or more immune cells.

needed. The process of T-cell development and activation is summarized in Figure 24-25.

The effector T cells then travel to the site where the antigens originally entered the body. There, in the inflamed tissue, the sensitized T cells bind to antigens of the same kind that led to their formation. However, T cells bind to their specific antigen only if the antigen is presented by an APC such as a macrophage or dendritic cell. The T cell and APC form a temporary junction called an **immunological synapse (IS),** as explained in Box 24-5. The antigen-bound sensitized T cells then release chemical messengers into the inflamed tissues.

The chemical messengers released by T cells, as we have stated earlier in this chapter, are called **cytokines.** Because some cytokines are secreted mainly by lymphocytes, such cytokines are sometimes called *lymphokines.* Names of a few individual cytokines are chemotactic factor, migration inhibition factor, macrophage activating factor, interleukin, and lymphotoxin.

Chemotactic factors attract macrophages, causing hundreds of them to migrate into the vicinity of the antigen-bound, sensitized T cell. *Migration inhibition factor* halts macrophage migration. *Macrophage activating factor* prods the assembled macrophages to destroy antigens by phagocytosing them at a rapid rate. **Interleukins (ILs)** are a class of about a dozen different cytokines that are involved in regulating a wide variety of immune functions in different cell types. **Lymphotoxin** is a powerful poison that acts more directly, quickly killing any cell it attacks.

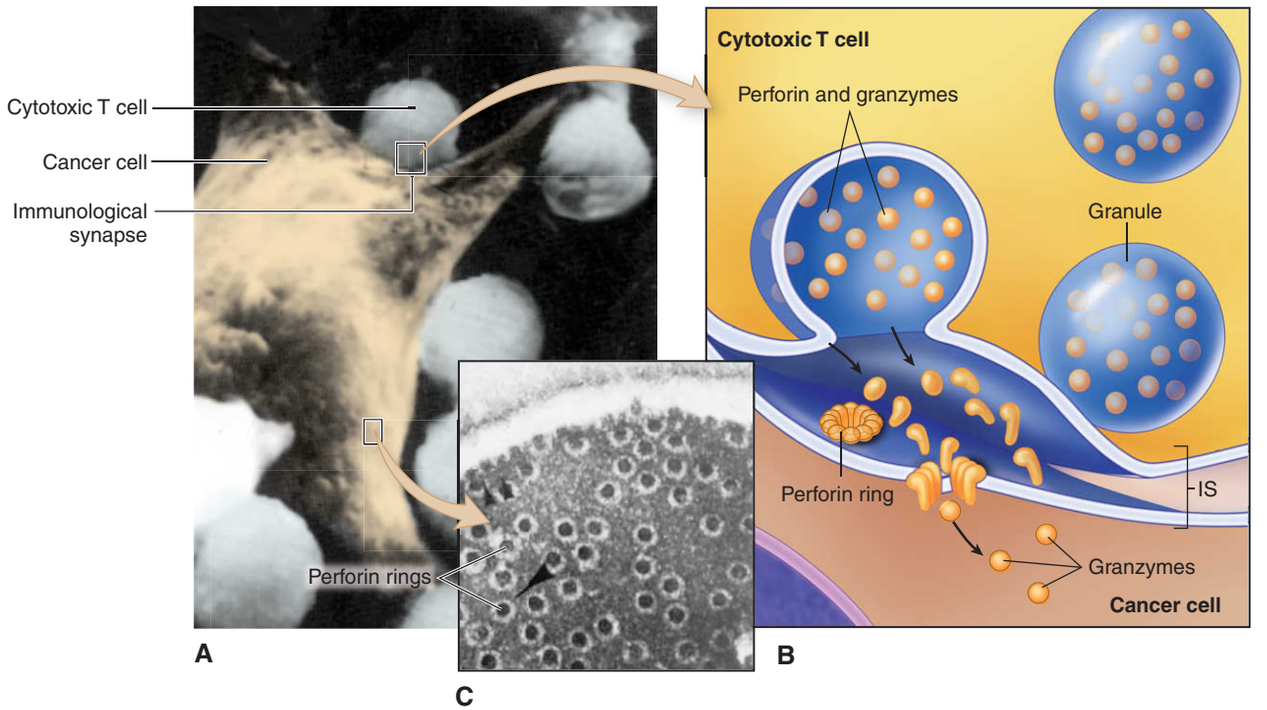

FIGURE 24-26

Killing by cytotoxic T cells. A, The blue spheres seen in this scanning electron microscope view are cytotoxic T cells attacking a much larger cancer cell. T cells are a significant part of our defense against cancer and other abnormal or foreign cells. **B,** After forming an immunological synapse (IS) with the tumor cell, the cytotoxic T cell releases perforin, which forms ringlike holes in the tumor cell's membrane, and granzymes, which pass through the perforin rings to trigger apoptosis (programmed cell death) in the tumor cell. **C,** Electron micrograph showing perforin rings with an average diameter of about 160 Å, which is much larger than the major histocompatibility complex (MHC) rings formed by complement (compare with Figure 24-21).

Effector T cells that release lymphotoxin are the *cytotoxic T cells*. Figure 24-26 shows how lymphotoxins work in killing a cell—a cancer cell in this case. After having been activated by the presentation of tumor cell antigens by an APC such as a dendritic cell, the cytotoxic T cell then becomes active and finds a tumor cell bearing that antigen. The cytotoxic T cell binds directly to the surface of the tumor cell and releases two kinds of molecules: perforin and granzymes. The lymphotoxins called *perforin* produce a ringlike hole in the plasma membrane of the target cell, similar to the one produced by the MAC formed by complement (see Figure 24-26). The *granzymes* enter the target cell through the perforin-ring hole and trigger apoptosis of the cell—thus killing it.

Besides cytotoxic T cells, at least two other populations of effector T cells are found in the body: **helper T cells (T_H cells)** and **suppressor T cells.** Both types of cells help regulate adaptive immune function by regulating B-cell and T-cell function. Helper T cells help other lymphocytes by secreting cytokines

Box 24-6 | HEALTH matters

Immunity and Cancer

One of the many functions of the immune system is to constantly guard against the development of cancer. Cell mutations occur frequently in the normal body, and many of the mutated cells formed are cancer cells. Cancer cells, you may recall, are cells capable of forming tumors in many different parts of the body—unless they are destroyed before this can happen. Abnormal antigens presented on cancer cells, called **tumor-specific antigens,** are present in the plasma membranes of some cancer cells in addition to self-antigens. Lymphocytes, in their continual wanderings through body tissues, are almost sure to come in contact with newly formed cancer cells. Hopefully, the lymphocytes recognize these cells by their abnormal antigens and quickly initiate reactions that kill the cancer cells. Abnormal antigens on cancer cells, called tumor-specific antigens or **tumor markers,** are present in the plasma membranes of some cancer cells in addition to self-antigens or major histocompatibility complex (MHC) antigens. Examples of cancer markers include (1) **carcinoembryonic antigen (CEA)**—found normally in the fetus and elevated in colorectal and other adult cancers; (2) **alpha-fetoprotein (AFP)**—normal fetal protein, whose presence in the adult strongly suggests liver or germ cell cancer; (3) **CA-125**—tumor antigen associated with ovarian cancer; and (4) **prostate-specific antigen (PSA),** which is elevated in both benign and malignant prostate disease. The relationship between cancer and the immune system continues to be an area of intense research by scientists looking for effective cancer treatments.

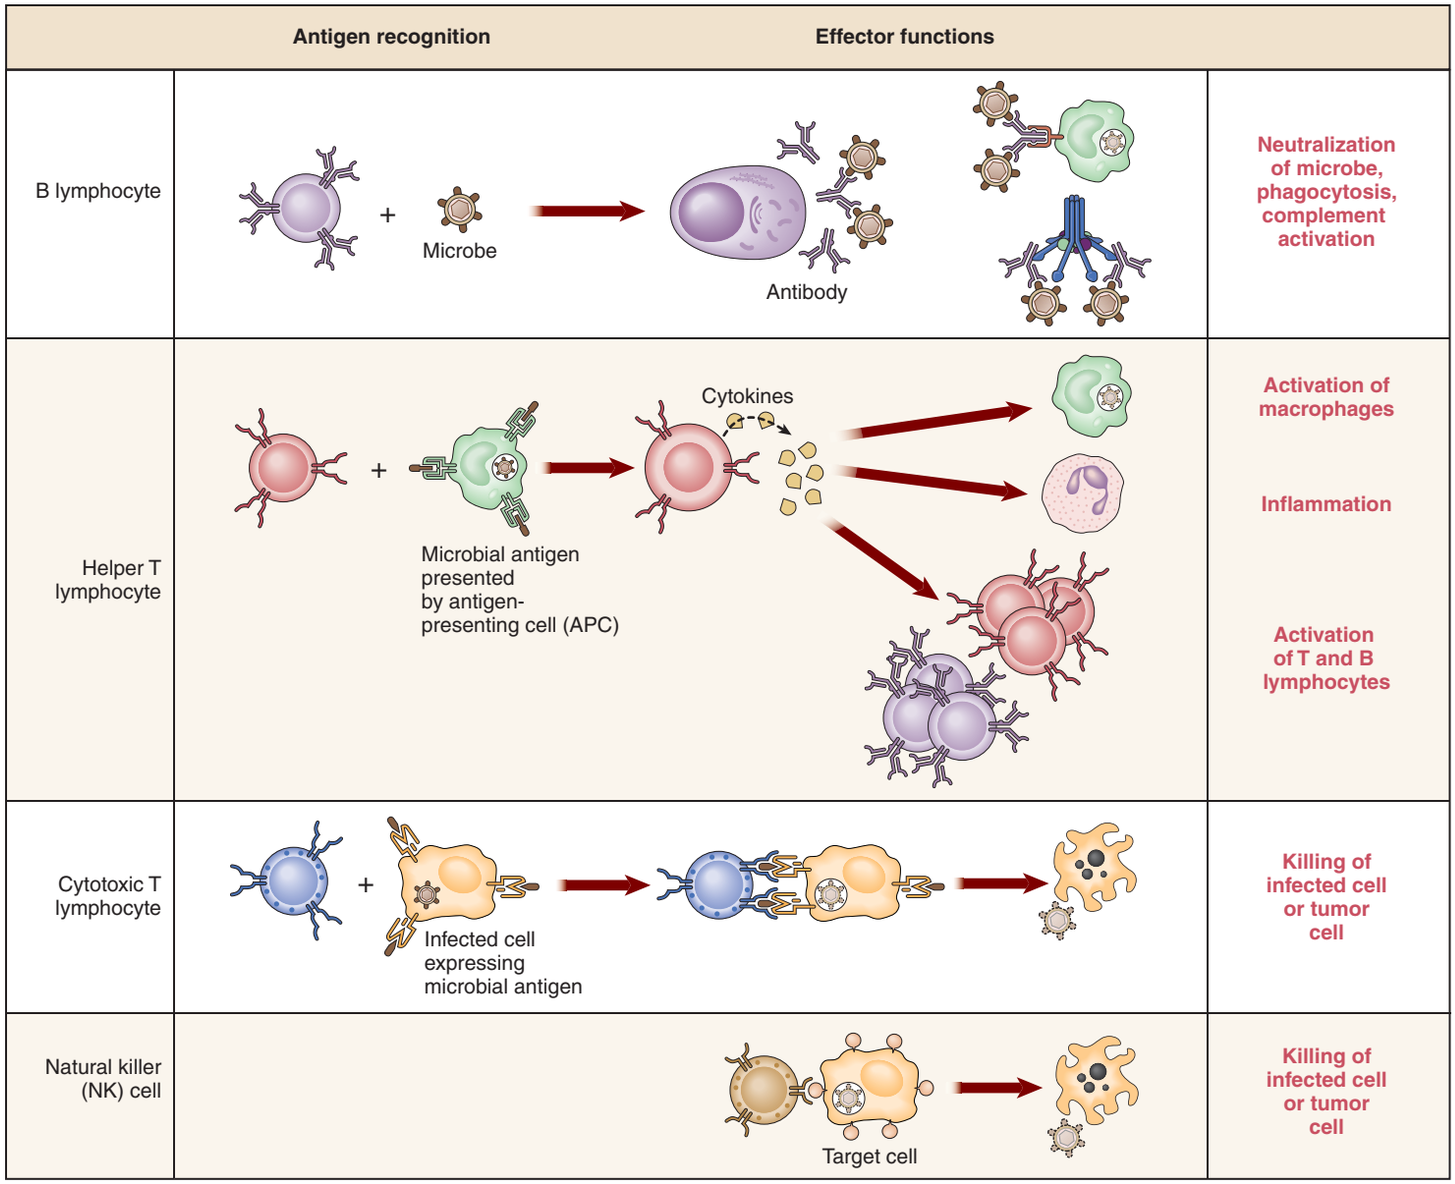

FIGURE 24-27

Lymphocyte functions. This diagram summarizes, in a simplified way, the main functions of the major classes of lymphocytes. B and T lymphocytes participate in adaptive immunity and NK cells participate in innate immunity.

that stimulate B cells and cytotoxic T cells. T_H cytokines also stimulate phagocytes and other leukocytes (Figure 24-27). These cytokines include *interleukin-2 (IL-2)* and *interleukin-4* (IL-4 or B-cell differentiating factor). Like other effector T cells, naïve T_H cells are activated by antigens presented on the surfaces of APCs and form a clone that differentiates into *effector T_H cells* and *memory T_H cells*.

Suppressor T cells, often called *regulator T cells (T-regs)*, act to suppress B-cell differentiation into plasma cells. The antagonistic action allows the immune system to finely tune its antibody-mediated response. Suppressor T cells also regulate other T cells, helping "turn off" an immune response to restore homeostasis, for example. Suppressor T cells help maintain self-tolerance by reducing T-cell reactions to self-antigens. For this reason, researchers are trying to find ways to enhance suppressor T-cell function to treat autoimmunity (see p. 772) or in organ transplants to prevent rejection of donor tissue.

Summarizing briefly, the function of T cells is to produce cell-mediated immunity. They search out, recognize, and bind to appropriate antigens located on the surfaces of cells. This kills the cells—the ultimate function of killer T cells. Usually these are not the body's own normal cells but are cells that have been invaded by viruses, that have become malignant (Box 24-6), or that have been transplanted into the body. Killer T cells therefore function to defend us from viral diseases and cancer, but they also bring about rejection of transplanted tissues or organs. T cells also serve as overall regulators of adaptive immune mechanisms.

15. What causes a T cell to become sensitized or activated?
16. How do cytotoxic T cells destroy pathogens?

TYPES OF ADAPTIVE IMMUNITY

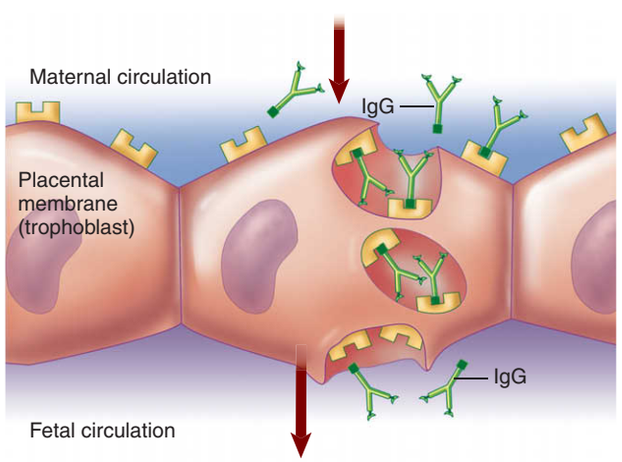
B-cell immunity and T-cell immunity, the two major types of adaptive immunity, can be further classified according to the manner in which they develop.

Recall that innate immunity, also called *inborn* or *inherited immunity*, occurs when nonspecific immune mechanisms are put in place by genetic mechanisms during the early stages of human development in the womb (see Table 24-2).

Adaptive immunity, our focus here, is instead a specific kind of resistance that develops after we are born. Acquired immunity may be further classified as either *natural immunity* or *artificial immunity*, depending on how the body is exposed to the antigen.

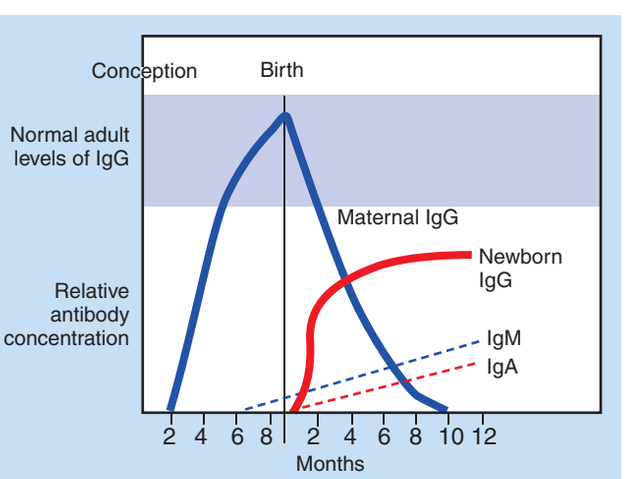
Natural exposure is not deliberate and occurs in the course of everyday living. We are naturally exposed to many disease-causing agents on a regular basis. Artificial, or deliberate, exposure to potentially harmful antigens is called *immunization*.

Natural and artificial immunity may be "active" or "passive." Active immunity occurs when an individual's own immune system responds to a harmful agent, regardless of whether that agent was naturally or artificially encountered. Passive immunity results when immunity to a disease that has developed in another individual or animal is transferred to an individual who was not previously immune. For example, antibodies in a mother's milk confer passive immunity to her nursing infant (see also Box 24-7). Active



Box 24-7 | FYI

Prenatal Immunity



Without direct access to external antigens, it is no wonder that the immune system is not very capable (on its own) of a vigorous defense during its maturation process before birth (prenatal development). However, as part *A* of the figure shows, certain antibodies from the mother (maternal antibodies) can be actively transported across the maternal-fetal blood barrier (trophoblast). Only IgG antibodies in the mother's blood can bind to the receptors, which then trigger endocytosis and transport each IgG antibody across to the fetal bloodstream. This mechanism provides passive natural immunity before and shortly after birth.

Part *B* of the figure shows that at birth, the newborn has adult levels of IgG—but nearly all of it came from the mother (maternal IgG, *black line*). Shortly after birth, the maternal IgG is broken down *(black line)* and replaced with new IgG made by the newborn's own immune system *(purple line)*.

Note also in part *B* of the figure that the concentration of IgM *(broken black line)* is only about 20% of the adult level at birth but steadily increases after birth. IgM reaches adult levels in about 2 years. IgA, an important component of the mucosal immune system (see Box 24-8), also begins to rise at birth. IgA reaches adult levels in just a few months. All three types of antibody are also found in breast milk, providing another avenue of passive immunity after birth.

A

B

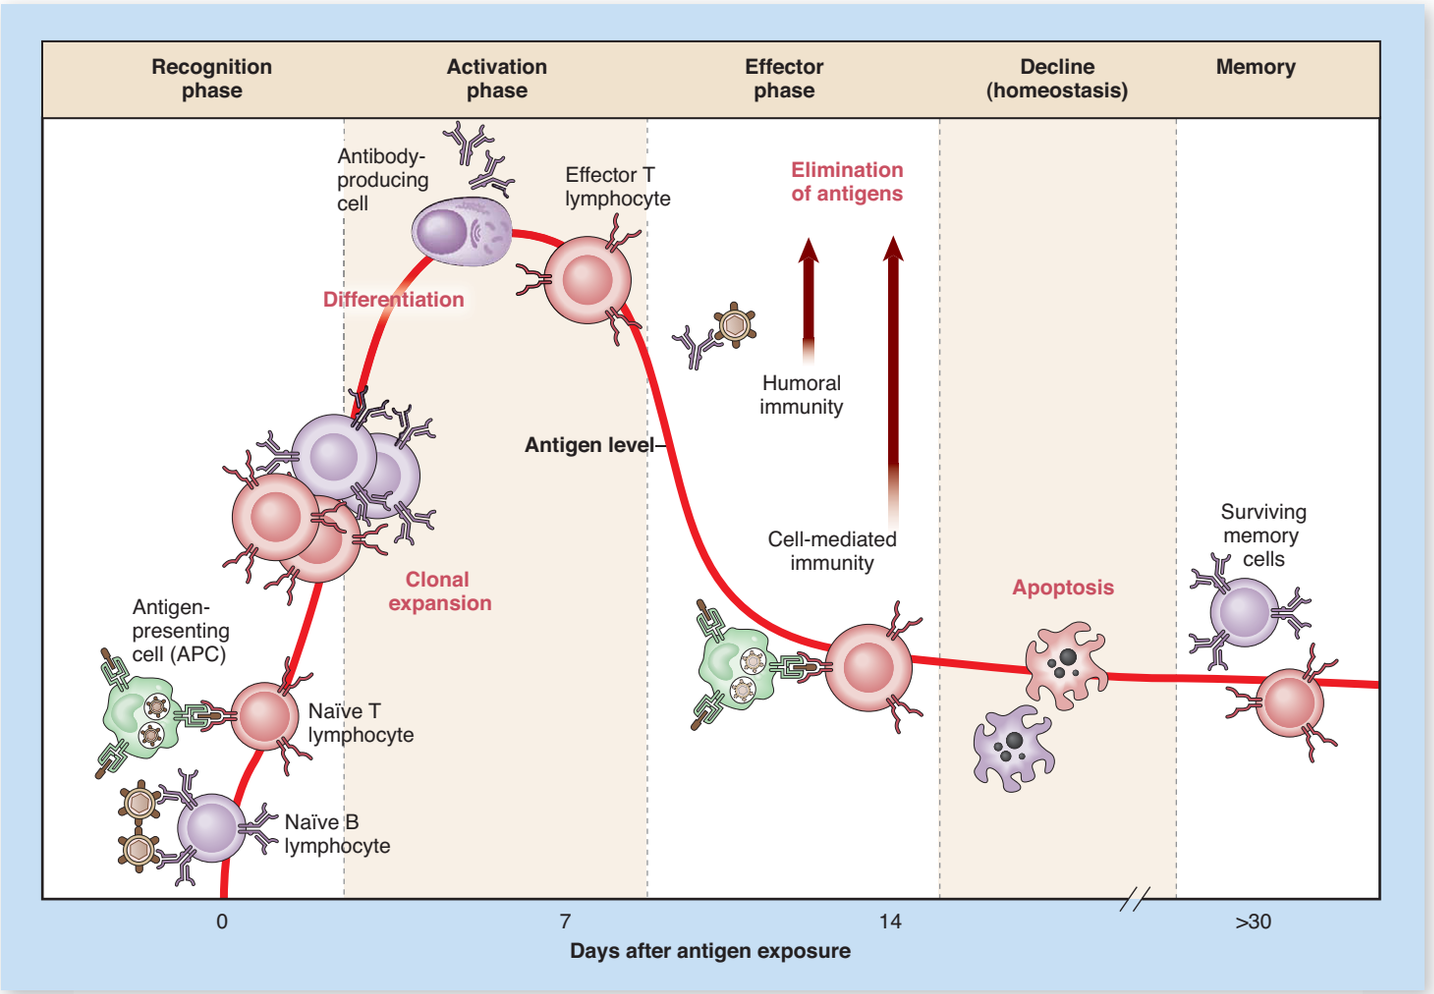
A, Transport of antibodies across the placenta. B, Antibody concentrations before and after birth.

immunity generally lasts longer than passive immunity. Passive immunity, although temporary, provides immediate protection. Table 24-4 lists the various forms of adaptive immunity.

SUMMARY OF ADAPTIVE IMMUNITY

Adaptive immunity is specific immunity—that is, it targets specific antigens. Two special types of lymphocytes play a major role in immunity: B cells and T cells. As Figure 24-27 shows, B cells recognize specific antigens and produce specific antibodies (immunoglobulins) to destroy the antigen—antibody-mediated or humoral immunity. T cells recognize antigens presented on cell surfaces to attack infected and abnormal cells in several ways—cell-mediated or cellular immunity.

Adaptive immunity progresses along a pathway of stages outlined in Figure 24-28. First, B cells and T cells recognize a specific antigen. Next, the B and T cells are activated—expanding their population (a clone) and thus producing effector cells and memory cells. Then, the effector cells get to work attacking the source or sources of the antigen. When there are no longer enough antigens to continue stimulating these immune responses, the effector B and effector T cells die off through the process of apoptosis. This represents a return to a homeostatic balance after the immune response. However, a number of memory cells



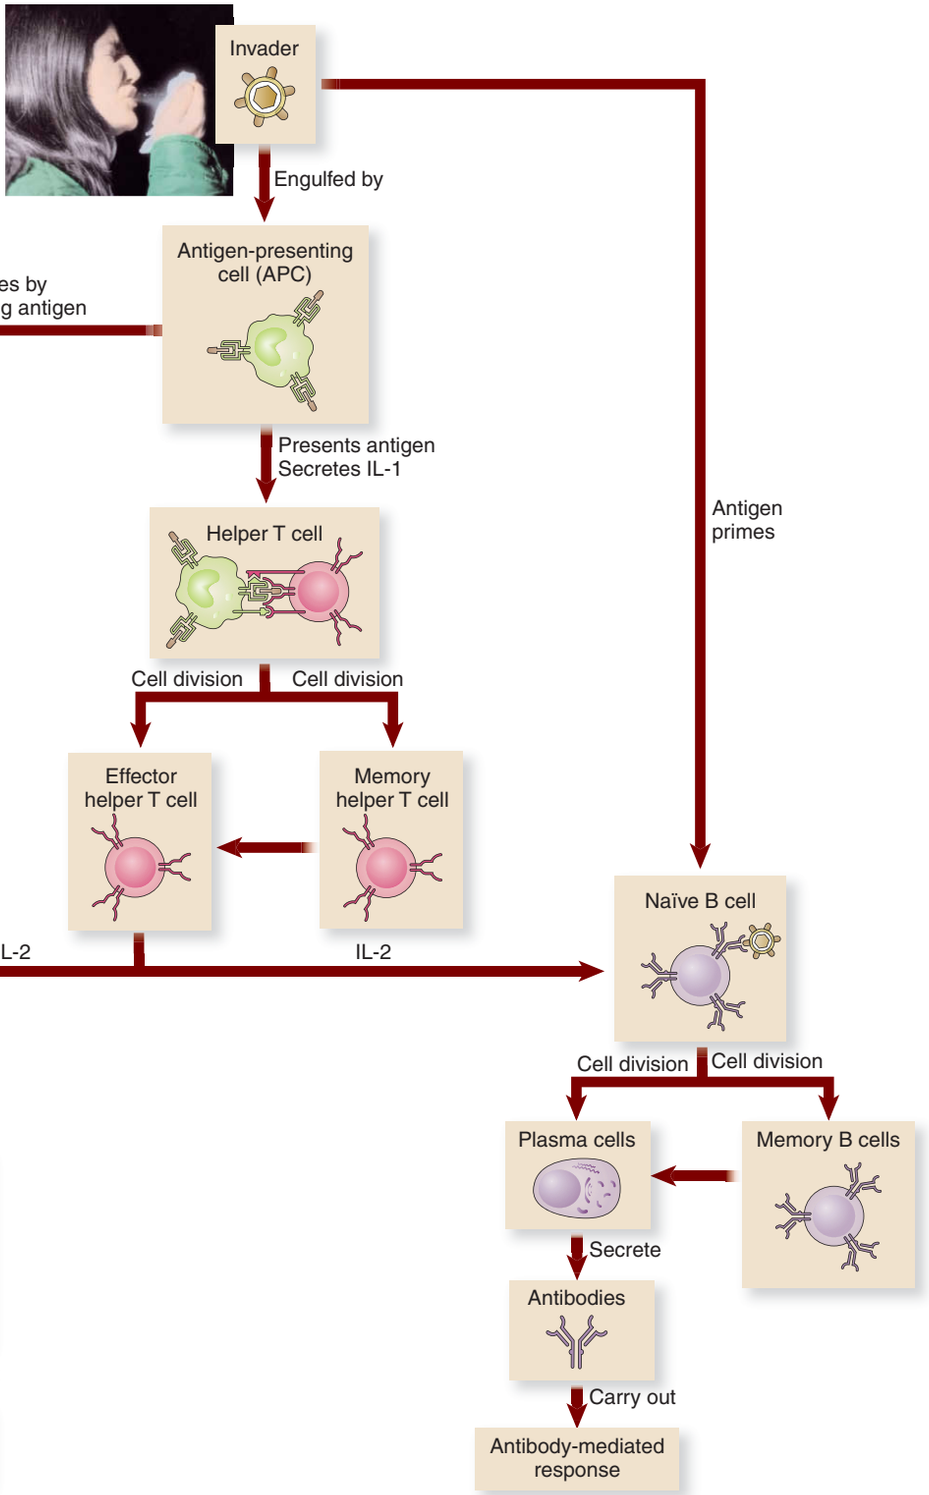


FIGURE 24-28

Stages of adaptive immune response. First, B cells and T cells recognize a specific antigen. Next, the B and T cells are activated—expanding their population (clonal expansion) while differentiating into effector cells and memory cells. Then the effector cells get to work attacking the source or sources of the antigen—humoral (antibody-mediated) immunity and cell-mediated immunity. As antigen levels decline, effector cells die off (apoptosis). Memory cells then remain—ready to quickly engage the antigen again later.

FIGURE 24-29

Summary of adaptive immunity. Flowchart summarizing an example of adaptive immune response when exposed to a microbial pathogen.

remain—ready to quickly engage the antigen again should it reappear later.

Figure 24-29 summarizes the activity of the adaptive immune system in a different way. This figure shows the interaction of different cells and cytokines (in this case, interleukins) in a simplified model of the cooperative nature of the adaptive immune responses.

Box 24-8 explores an additional immune system of the body found in the mucosa.

19. What is the difference between active and passive immunity?

Box 24-8 | FYI

Mucosal Immunity

The **mucosal immune system** is a complex system of defense distinct from the systemic (internal) immune system that we have been discussing in most of this chapter. It is an innate and adaptive system that is localized to the mucous barriers of the body: digestive tract, urinary/reproductive tracts, respiratory tract, exocrine ducts, conjunctiva, middle ear, and so on. The immune cells that make up the mucosal immune system are located mainly in or near **mucosal-associated lymphoid tissue (MALT).**

The main functions of the mucosal immune system involve preventing pathogens from colonizing the mucous surfaces of the body, preventing the accidental absorption of antigens from outside the body, and preventing inappropriate or intense responses of the systemic immune system to these external antigens.

As the figure shows, there are several components of the mucosal immune system. Large numbers of IgA antibodies are secreted by effector B cells (plasma cells) into the mucous layer lining the mucosal surfaces of the body. These secretory IgA molecules are dimers (double molecules) that resist being broken down by digestive and other enzymes (see Figure 24-18). Secretory IgA protects against a diverse group of pathogens such as viruses, bacteria, fungi, and animal parasites, thus forming an effective first line of defense.

Besides B cells, T cells also make up part of the mucosal immune system. T cells are located in both the epithelial layer and connective layer (lamina propria) of the mucous membrane, as well as in organized *regional lymphoid nodules* such as the aggregated lymphoid nodules (Peyer patches) of the intestines, the appendix, and the tonsils. Most of these T cells have distinctive structural and functional characteristics that distinguish them from the T cells of the systemic immune system. The mucosal T cells may be activated by antigens presented by APCs such as dendritic cells (DCs) present in the mucous membrane. Some antigens are processed by special *M (membrane) cells* in the surface of the epithelial layer and sent to lymphoid nodules, where APCs can present them to T cells. Interestingly, T cells activated in one mucosal membrane can migrate directly to mucous membranes in other parts of the body. They accomplish this through special "homing" receptors on the surface of each mucosal T cell.

Understanding the mucosal immune system and its cooperation with the systemic (internal) immune system promises to reveal new strategies of immunization. For example, researchers have found that immunizing through the bloodstream activates only the internal (systemic) B cells and T cells. Thus a pathogen would have to actually enter the internal environment before this type of specific immunity could protect us. Immunization of the mucosal lymphocytes, however, can activate both mucosal and systemic lymphocytes—providing a more thorough type of protection. Another advantage of mucosal immunization is that it is easier to administer to patients than immunizations injected under the skin or into the bloodstream. For example, immunization can be delivered by nasal sprays or drops instead of "shots."

Understanding how the mucosal immune system cooperates with microbes within the various microbiomes inhabiting our body's mucous membranes also promises to provide new strategies of preventing or managing infections. For example, scientists have already observed how *probiotic* (protective) bacteria found in yogurt can help stimulate mucosal immunity in ways that prevent infection by pathogenic bacteria.

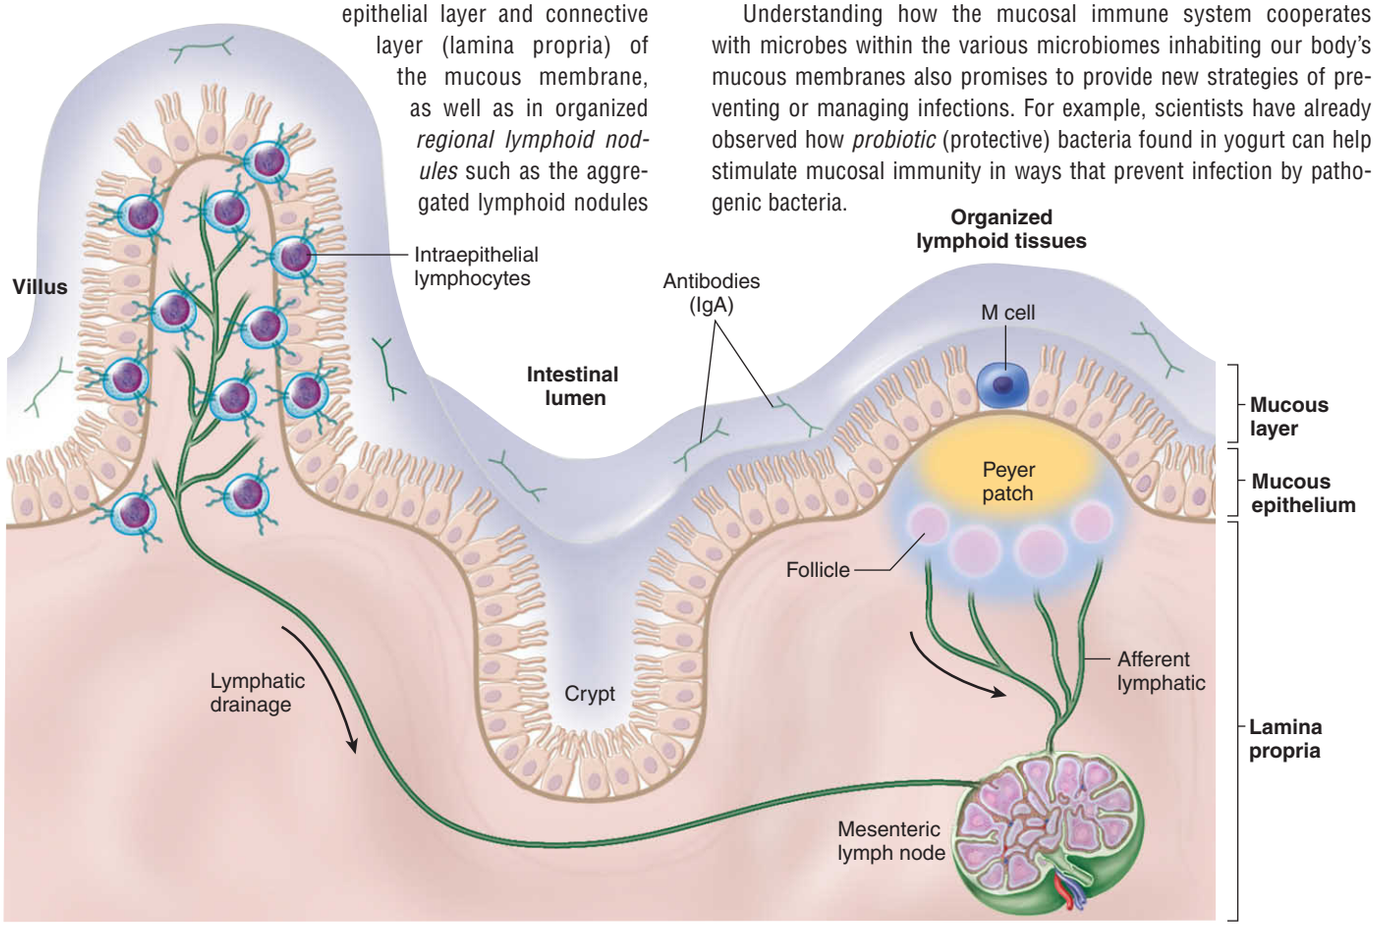

Diagram of the mucosal immune system. Lymphoid tissue associated with mucous membranes is called mucosal-associated lymphoid tissue (MALT).

the BIG picture

Immune System and the Whole Body

The "big picture" of the immune system's role in maintaining the relative constancy of the internal environment is probably easier to "see" than any other system. After all, its agents—antibodies, lymphocytes, and other substances and cells—are everywhere in the body. They even stand guard on the outside surface of the body. Without the defensive activity of the immune system, our internal constancy would be decimated by cancer, infections, and even minor injuries.

In describing the various mechanisms of the immune system, we have used the analogy of a militaristic-style security force. As useful as this analogy might be, it may mislead us into believing that the immune system is a completely independent group of defensive agents. Nothing could be further from the truth.

First of all, evidence shows that the immune system is regulated to some degree by the nervous and endocrine systems—triggering the development of the emerging field of *neuroimmunology.* These systems, as you already know, are in turn influenced by feedback from all parts of the body.

Second, the agents of the immune system are not a separate, distinct group of cells and substances. They include blood cells, skin cells, mucosal cells, brain cells, liver cells, and many other types of cells and their secretions. Thus the immune system is more like a self-defense force made up of ordinary citizens who work shoulder-to-shoulder with military specialists.

MECHANISMS of DISEASE

DISORDERS OF THE IMMUNE SYSTEM

There are two basic mechanisms for disorders of immunity. The immune defenses can either overreact to antigens or fail to react to an antigen and thus produce disease. A few examples of each of these mechanisms are briefly described in the paragraphs that follow.

Hypersensitivity of the Immune System

Hypersensitivity is a type of inappropriate or excessive response of the immune system. The three major types of immune hypersensitivity discussed in the following sections are allergy, autoimmunity, and isoimmunity.

Allergy

The term **allergy** is used to describe hypersensitivity of the immune system to relatively harmless environmental antigens. Antigens that trigger an allergic response are often called **allergens** (AL-er-jens). One in six Americans has a genetic predisposition to an allergy of some kind.

Immediate allergic responses involve antigen-antibody reactions, mainly IgE. Before such a reaction occurs, a susceptible person must be exposed repeatedly to an allergen—triggering the production of antibodies. After a person is thus *sensitized,* exposure to an allergen causes antigen-antibody reactions that trigger the release of histamine, kinins, and other inflammatory substances. These responses usually cause typical allergy symptoms such as runny nose, conjunctivitis, and *urticaria* (hives). In some cases, however, these substances may cause constriction of the airways, relaxation of blood vessels, and irregular heart rhythms that can progress to a life-threatening condition called **anaphylactic shock** (see Chapter 22, p. 714). Drugs called **antihistamines** are sometimes used to relieve the symptoms of this type of allergy.

Delayed allergic responses, on the other hand, involve cell-mediated immunity. In **contact dermatitis,** for example, T cells trigger events that lead to local skin inflammation a few hours or days after initial exposure to an antigen. Exposure to poison ivy, soaps, and certain cosmetics may cause contact dermatitis in this manner. Hypersensitive individuals may use **hypoallergenic** products (products without common allergens) to avoid such allergic reactions.

Autoimmunity

Autoimmunity is an inappropriate and excessive response to self-antigens. Disorders that result from autoimmune responses are called **autoimmune diseases.** Table 24-5 gives examples of autoimmune diseases. Self-antigens are molecules that are native to a person's body and that are used by the immune system to identify components of "self." In autoimmunity, the immune system inappropriately attacks these antigens.

A common autoimmune disease is **systemic lupus erythematosus (SLE),** or simply *lupus.* Lupus is a chronic inflammatory disease that affects many tissues in the body: joints, blood vessels, kidney, nervous system, and skin. The name *lupus erythematosus* refers to the red rash that often develops on the faces of those afflicted with SLE. The "systemic" part of the name comes from the fact that the disease affects many systems throughout the body. The systemic nature of SLE results from the production of IgG antibodies against a person's own DNA.

Isoimmunity

Isoimmunity is a normal but often undesirable reaction of the immune system to antigens from a different individual of the same

TABLE 24-5 Examples of Autoimmune Diseases

DISEASE	POSSIBLE SELF-ANTIGEN	DESCRIPTION
Addison disease	Surface antigens on adrenal cells	Hyposecretion of adrenal hormones, resulting in weakness, reduced blood sugar, nausea, loss of appetite, and weight loss
Cardiomyopathy	Cardiac muscle	Disease of cardiac muscle (i.e., the myocardium), resulting in loss of pumping efficiency (heart failure)
Diabetes mellitus (type 1)	Pancreatic islet cells, insulin, insulin receptors	Hyposecretion of insulin by the pancreas, resulting in extremely elevated blood glucose levels (in turn causing a host of metabolic problems, even death if untreated)
Glomerulonephritis	Blood antigens that form immune complexes that deposit in kidney	Disease of the filtration apparatus of the kidney (renal corpuscle), resulting in fluid and electrolyte imbalance and possibly total kidney failure and death
Graves disease (type of hyperthyroidism)	TSH receptors on thyroid cells	Hypersecretion of thyroid hormone and resulting increase in metabolic rate
Hemolytic anemia	Surface antigens on RBCs	Condition of low RBC count in the blood resulting from excessive destruction of mature RBCs (hemolysis)
Hypothyroidism	Antigens in thyroid cells	Hyposecretion of thyroid hormone in adulthood, causing decreased metabolic rate and characterized by reduced mental and physical vigor, weight gain, hair loss, and edema
Multiple sclerosis (MS)	Antigens in myelin sheaths of nervous tissue	Progressive degeneration of myelin sheaths, resulting in widespread impairment of nerve function (especially muscle control)
Myasthenia gravis	Antigens at neuromuscular junction	Muscle disorder characterized by progressive weakness and chronic fatigue
Pernicious anemia	Antigens on parietal cells, intrinsic factor	Abnormally low RBC count resulting from the inability to absorb vitamin B_{12}, a substance critical to RBC production
Reproductive infertility	Antigens on sperm or tissue surrounding ovum (egg)	Inability to produce offspring (in this case, resulting from destruction of gametes)
Rheumatic fever	Cardiac cell membranes (cross reaction with group A streptococcal antigen)	Rheumatic heart disease; inflammatory cardiac damage (especially to the endocardium/valves)
Rheumatoid arthritis (RA)	Collagen	Inflammatory joint disease characterized by synovial inflammation that spreads to other fibrous tissues
Systemic lupus erythematosus (SLE)	Numerous	Chronic inflammatory disease with widespread effects and characterized by arthritis, a red rash on the face, and other signs
Ulcerative colitis	Mucous cells of colon	Chronic inflammatory disease of the colon characterized by watery diarrhea containing blood, mucus, and pus

RBC, Red blood cell; *TSH,* thyroid-stimulating hormone.

species. Isoimmunity is important in two situations: pregnancy and tissue transplants.

During pregnancy, antigens from the fetus may enter the mother's blood supply and sensitize her immune system. Antibodies that are formed as a result of this sensitization may enter the fetal circulation and cause an inappropriate immune reaction. One example, erythroblastosis fetalis, was discussed in Chapter 20. Other pathological conditions may also be caused by damage to developing fetal tissues resulting from attack by the mother's immune system. Examples include congenital heart defects, Graves disease, and myasthenia gravis.

Tissue or organ **transplants** are medical procedures in which tissue from a donor is surgically *grafted* into the body. For example, skin grafts are often performed to repair damage caused by burns. Donated whole blood tissue is often transfused into a recipient after massive hemorrhaging. A kidney is sometimes removed from a living donor or cadaver and grafted into a person suffering from kidney failure. Unfortunately, the immune system sometimes reacts against foreign antigens in the grafted tissue, causing what is often called a **rejection syndrome.** The antigens commonly involved in transplant rejection are called MHC proteins—or **human leukocyte antigens (HLAs).**

Rejection of grafted tissues can occur in two ways: (1) **host-versus-graft rejection**—the recipient's immune system recognizes foreign HLAs and attacks them, destroying the donated tissue, and (2) **graft-versus-host rejection**—the donated tissue (e.g., bone marrow) attacks the recipient's HLAs, destroying tissue throughout the recipient's body. Graft-versus-host rejection may lead to death.

There are two ways to prevent rejection syndrome. One strategy is called *tissue typing* in which HLAs and other antigens of a potential donor and recipient are identified. If they match, tissue rejection is unlikely to occur. Another strategy is the use of **immunosuppressive drugs** in the recipient. Immunosuppressive drugs such as *cyclosporine* and *prednisone* suppress the immune system's ability to attack the foreign antigens in the donated tissue.

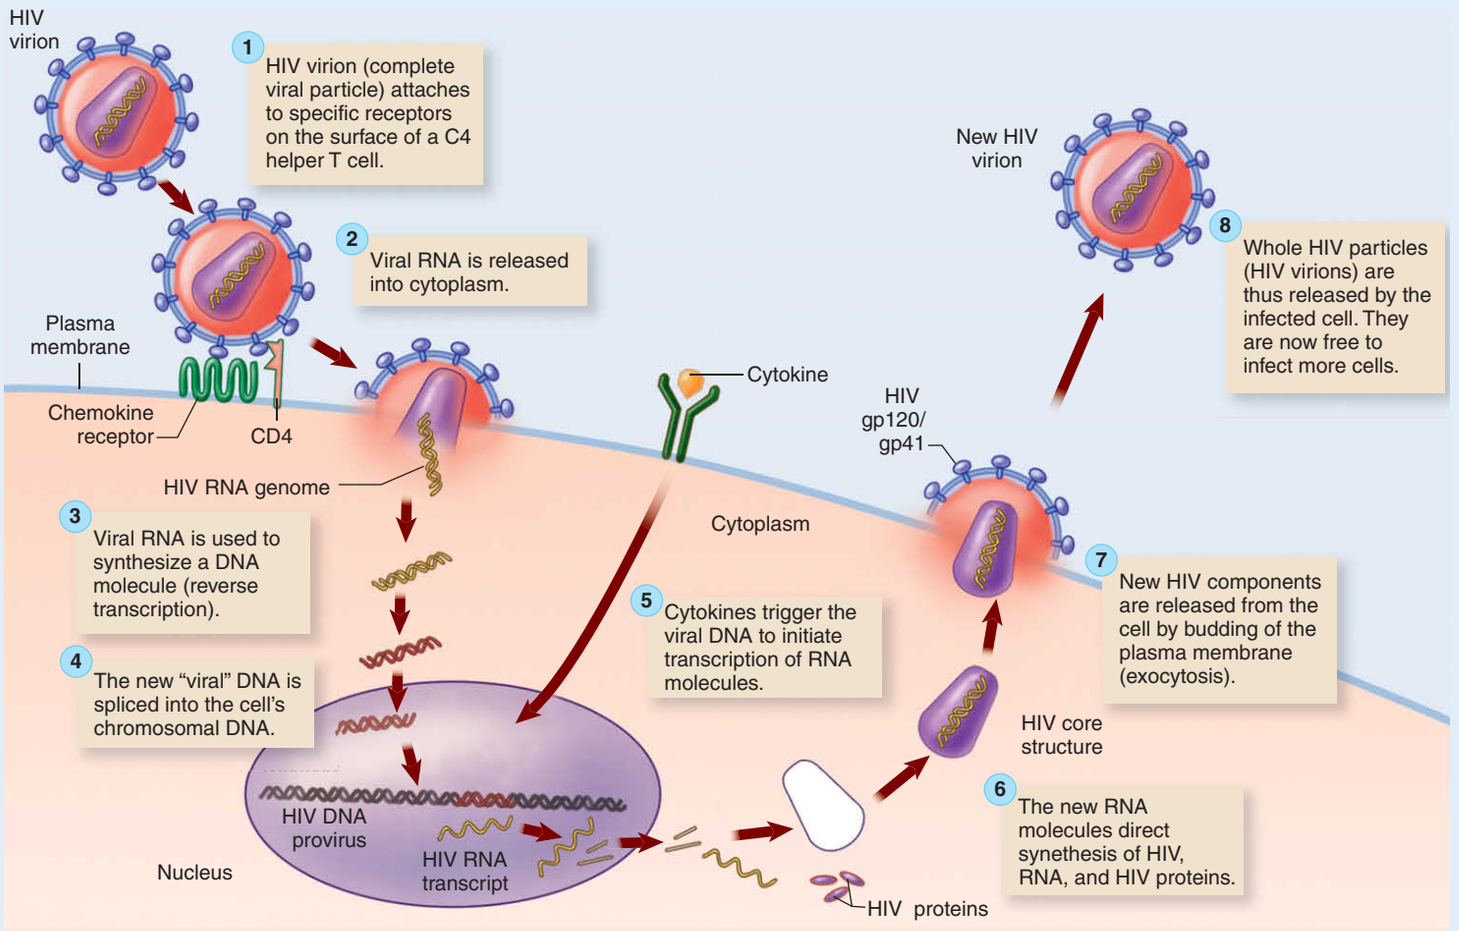
Deficiency of the Immune System

Immune deficiency, or *immunodeficiency*, is the failure of immune system mechanisms to defend against pathogens. Immune system failure usually results from disruption of lymphocyte (B cell or T cell) function. The chief characteristic of immune deficiency is the development of unusual or recurring severe infections or cancer. Although immune deficiency by itself does not cause death, the resulting infections or cancer can.

The two broad categories of immune deficiencies, based on the mechanism of lymphocyte dysfunction, are *congenital* and *acquired*. Each of these types is outlined in the following discussion.

Congenital Immune Deficiency

Congenital immune deficiency, which is rare, results from improper lymphocyte development before birth. Depending on which stage of the development of stem cells, B cells, or T cells the defect occurs, different diseases can result. For example, improper B-cell development can cause insufficiency or absence of antibodies in the blood. If stem cells are missing or are unable to grow properly, a condition called **severe combined immune deficiency (SCID)** occurs. In most forms of SCID, both humoral immunity and cell-mediated immunity are defective. Temporary immunity can be imparted to children with SCID by injecting them with a preparation of antibodies (gamma globulin). Bone marrow transplants, which replace the defective stem cells with healthy donor cells, have proven effective in treating some cases of SCID.



Acquired Immune Deficiency

Acquired immune deficiency develops after birth (and is not related to genetic defects). Many factors can contribute to acquired immune deficiency: nutritional deficiencies, immunosuppressive drugs or other medical treatments, trauma, stress, and viral infection.

One of the best known examples of acquired immune deficiency is **acquired immune deficiency syndrome (AIDS).** AIDS affects millions of people worldwide. This syndrome is caused by the **human immunodeficiency virus,** or **HIV.** HIV, a retrovirus, contains RNA that produces its own DNA inside infected cells. The viral DNA often becomes part of the cell's DNA (Figure 24-30). When the viral DNA is activated by cytokines, it directs the cell to synthesize viral RNA and viral proteins—producing new retroviruses. HIV thus "steals" raw materials from the cell. When this

FIGURE 24-30

Mechanisms of HIV infection. HIV is an RNA-containing virus *(retrovirus)* that appears to infect T cells by way of the mechanism described in the diagram and simplified into 8 steps.

occurs in the CD4 subset of T cells (helper T cells), the cell is destroyed and immunity is seriously impaired.

As the T cell dies, it releases new retroviruses that can spread the HIV infection. As the HIV infection progresses, more and more CD4 lymphocytes are lost. This change in CD4 lymphocyte number is one of the principal clinical methods for monitoring AIDS (Figure 24-31, *A*).

HIV can invade several types of human cells, including brain cells. However, when CD4 T-cell (helper T-cell) function is impaired, infectious organisms and cancer cells can grow and spread much more easily than normal. Infections and tumors that rarely occur in healthy people, such as *Pneumocystis jiroveci pneumonia* (a protozoal infection) and *Kaposi sarcoma* (a type of skin cancer), frequently are seen in AIDS patients. Because their immune system is deficient, AIDS patients usually die from one of these infections or cancers.

After they are infected with HIV, T cells may not show signs of AIDS for years. This is because the immune system can hold the infection at bay for a long time before finally succumbing to it. Figure 24-31, *B*, shows the progression of HIV infection to AIDS.

There are several strategies for controlling AIDS and related conditions. Many agencies are trying to slow the spread of AIDS by educating people about how to avoid contact with the HIV retrovirus. HIV is spread by direct contact with body fluids, so preventing such contact reduces HIV transmission. Sexual relations, blood transfusions, breastfeeding, and intravenous use of contaminated needles are the usual modes of HIV transmission.

Most patients with AIDS have an abundance of antibodies against the HIV in their blood. This is another important clinical test for diagnosing and monitoring AIDS patients (frequently referred to as a *Western blot*). Unfortunately, for the majority of patients, the antibody response to HIV is not sufficient to suppress the disease. However, a few patients who demonstrated a strong antibody response were able to shed the virus completely. Studies of these few cases are fueling an intensive, worldwide research effort to develop a vaccine for treating AIDS. The fast rate at which these viruses mutate (change their protein structure), however, is making vaccine development an extremely difficult challenge.

A drug called Fuzeon (enfuvirtide) can disrupt the HIV particle's ability to fuse with a host cell—the first drug in a class called *fusion inhibitors*. Inhibition of fusion can stop HIV from infecting cells that are not yet infected.

A way to inhibit symptoms of the disease is by means of chemicals such as zidovudine (Azidothymidine [AZT]) and ritonavir (Norvir) that block HIV's ability to reproduce within infected cells.

A breakthrough in the treatment of HIV occurred when it was discovered that a "cocktail" of several antiviral drugs working together greatly reduces the number of virus particles in a patient's blood. More than 100 such compounds in various combinations are being evaluated for use in halting the progress of HIV infections. Currently, the recommended treatment for HIV infection is a combination of at least three medications in an individually tailored regimen called *highly active antiretroviral therapy (HAART)*.

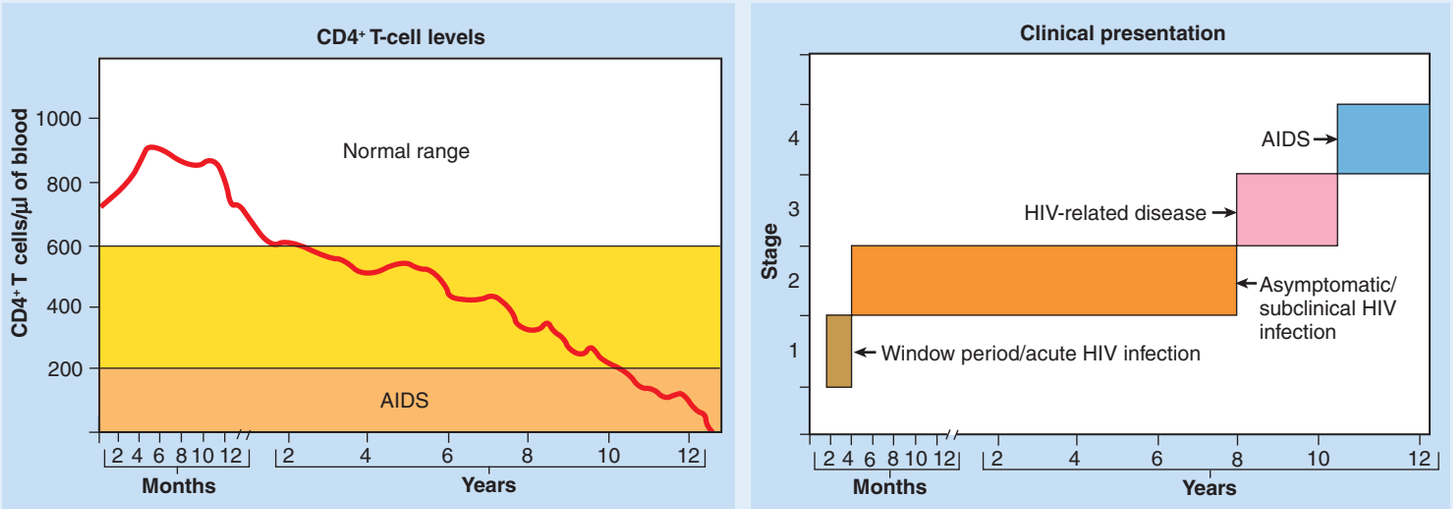


FIGURE 24-31

Clinical progression of HIV/AIDS. A, Changing numbers of CD4 T cells as an HIV infection progresses to AIDS. **B,** Progression from initial HIV infection to full-blown AIDS is usually described in four stages: (1) Acute viral infection with common viral symptoms; called "window period" because anti-HIV antibodies are not yet detectable by laboratory tests. (2) Subclinical stage in which there are often no (or minor) symptoms—but the virus is replicating. (3) HIV-related disease, with symptoms of acute viral infection and high levels of anti-HIV antibodies found in laboratory tests. (4) AIDS, including opportunistic infections and cancers.

CASE study

Kostas remembered getting the flu (influenza) last winter: coughing, fever, achiness all over his body, watery eyes, and fatigue. He felt awful! But he argued, "What's the point of a flu shot, when all it does is give you the flu?" Kostas did not understand that the flu vaccine is a combination of several *inactivated* (killed) viruses injected into muscles in your body (usually in your arm). No live viruses are injected. So, as for the injected form of the vaccine "causing" the flu—people who claim that could already have been exposed to a flu virus before the vaccination or could have been exposed to one of the strains not included in that year's vaccine. Some people produce a mild immune reaction that can be mistaken for the flu. In the end, Kostas relented and got his flu shot!

1. Which of Kostas' cells will respond to the flu antigens introduced by the vaccine?
   a. Erythrocytes
   b. Thrombocytes
   c. Lymphocytes
   d. Platelets

2. Which specific cell types will begin producing antibodies to the antigens?
   a. Z cells
   b. T cells
   c. A cells
   d. B cells

3. Which antibody is primarily involved in this response to vaccine?
   a. IgM
   b. IgE
   c. IgG
   d. IgD

4. Kostas' fever during the previous winter's flu was caused by the release of _____, molecules that help increase his body's "set point" to higher than normal.
   a. Vulcanogens
   b. Histamine
   c. Pyrogens
   d. Nanobodies

5. What would you call the specific type of immunity Kostas developed as a result of the vaccination?
   a. Natural active immunity
   b. Artificial active immunity
   c. Natural passive immunity
   d. Artificial passive immunity

INTRODUCTION

A. The immune system protects against assaults on the body
   1. External assaults include microorganisms—protozoans, bacteria, and viruses
   2. Internal assaults—abnormal cells reproduce and form tumors that may become cancerous and spread

ORGANIZATION OF THE IMMUNE SYSTEM

A. Immune system continually patrols and protects the body
B. Identification of cells and other particles
   1. Markers, or antigens, are unique molecules recognized by the immune system
   2. Self markers—molecules on the surface of our cells that are unique to an individual, thus identifying the cell as "self" to the immune system
   3. Nonself markers—molecules on the surface of foreign or abnormal cells or particles that identify the particle as "nonself" to the immune system
   4. Self-tolerance—the ability of our immune system to attack abnormal or foreign cells but spare our own normal cells
C. Two major categories of immune mechanisms—innate immunity and adaptive immunity (Figure 24-1; Table 24-1)
   1. Innate immunity provides a general, nonspecific defense against anything that is not "self"
   2. Adaptive immunity acts as a specific defense against specific threatening agents
   3. Primary cells of innate immunity—epithelial barrier cells, phagocytes (neutrophils, macrophages, DCs), and natural killer cells; chemicals used in innate immunity—complement and interferon
   4. Primary cells of adaptive immunity—lymphocytes called T cells and B cells
   5. Cytokines—chemicals released from cells to promote or trigger innate and adaptive immune responses (e.g., interleukin, interferon, leukotriene)
   6. Other chemicals (e.g., complement, other enzymes, histamine) also play regulatory roles in immunity

INNATE IMMUNITY (TABLE 24-2)

A. Species resistance—genetic characteristics of an organism or species defend against pathogens
B. Mechanical and chemical barriers—first line of defense (Figure 24-2)
   1. Internal environment of the body is protected by a barrier formed by the skin and the mucous membranes
   2. Skin and mucous membranes provide additional immune mechanisms—sebum, mucus, enzymes, and hydrochloric acid in the stomach
C. Inflammation and fever—second line of defense (Figure 24-3)
   1. Inflammatory response—tissue damage elicits responses to counteract injury and promote normalcy
      a. Inflammation mediators include histamine, kinins, prostaglandins, and related compounds (Figure 24-4)
      b. Chemotactic factors—substances that attract white blood cells to area of injury in a process called *chemotaxis* (Figure 24-6)
      c. Characteristic signs of inflammation—heat, redness, pain, and swelling
      d. Systemic inflammation—occurs from a body-wide inflammatory response
   2. Fever—abnormally high body temperature triggered by inflammation mediators
      a. Triggered in SIRS (systemic inflammatory response syndrome) and other events such as viral infections, tumors, allergies
      b. Pyrogens released from damaged tissues (endogenous) or introduced into the body (exogenous)
         (1) Promote prostaglandin (PG) production
         (2) PGs reset the hypothalamic "thermostat" to a higher temperature
         (3) Aspirin and other COX inhibitors interfere with PG production
      c. Fever is thought to increase immune function and inhibit pathogens
D. Phagocytosis—ingestion and destruction of microorganisms or other small particles by phagocytes (Figure 24-7)
   1. Phagocytes—many types capable of phagocytosis (Table 24-3)
   2. Antigen-presenting cells (APCs)—phagocytes that ingest foreign particles, isolate protein segments (peptides), and display them as antigens on their surface to trigger an immune response when recognized by a specific (adaptive) immune cell
      a. Neutrophil—most numerous phagocyte; usually first to arrive at site of injury; migrates out of bloodstream during diapedesis; forms pus
      b. Diapedesis—process by which immune cells squeeze through the wall of a blood vessel to get to the site of injury or infection (Figure 24-5)
      c. Macrophage—large phagocytic monocyte cells that grow to several times original size after migrating out of bloodstream; important APCs
      d. Dendritic cell (DC)—type of APC with long branches or extensions (Figure 24-8)
      e. Phagocytes often identified by location—histiocytes in connective tissue, microglia in nervous system, and Kupffer cells in liver
E. Natural killer (NK) cells—lymphocytes that kill tumor cells and cells infected by viruses (Figure 24-9)
   1. Method of recognizing abnormal or nonself cells—target cell is killed if killer-inhibiting receptor on NK cell does not bind to a proper MHC surface protein

2. Method of killing cells—lysing cells by damaging plasma membranes

F. Interferon (IFN)—protein synthesized and released into circulation by certain cells if invaded by viruses to signal other nearby cells to enter a protective antiviral state

G. Complement—group of enzymes that produce a cascade of reactions resulting in a variety of immune responses (Figure 24-10)
1. Lyse cells when activated by either adaptive or innate mechanisms
2. Opsonization—process that marks cells for destruction by phagocytes
3. Variety of other immune responses (Figure 24-10)

H. Toll-like receptors (TLRs)—pattern-recognition receptors in the membranes of host cells; when triggered, TLRs stimulate many different kinds of innate immune responses

OVERVIEW OF ADAPTIVE IMMUNITY

A. Adaptive immunity
1. Part of the third line of defense consisting of lymphocytes
2. Two different classes of a white blood cell (lymphocyte) involved (Figure 24-11)

B. Classes of lymphocytes (Figure 24-12)—B lymphocytes (B cells) and T lymphocytes (T cells)
1. B-cell mechanisms—antibody-mediated immunity (humoral immunity); produce antibodies that attack pathogens (Figure 24-13)
2. T cell mechanisms—attack pathogens more directly—classified as cell-mediated immunity (cellular immunity)
3. Lymphocytes have protein markers on their surfaces
   a. Surface markers named using the CD (cluster of differentiation) system
   b. Examples include CD4 and CD8 cells, clinically important in diagnosing AIDS
4. Activation of lymphocytes require two stimuli: a specific antigen and activating chemicals (Figure 24-14)
5. Lymphocytes are densest where they develop—in bone marrow, thymus gland, lymph nodes, and spleen (Figure 24-15)
6. Lymphocytes flow through the bloodstream, become distributed in tissues, and return to the bloodstream in a continuous recirculation

B CELLS AND ANTIBODY-MEDIATED IMMUNITY

A. Development and activation of B cells
1. Development occurs in two stages (Figure 24-16)
a. Pre–B cells develop in red bone marrow (prenatal, in the yolk sac and fetal liver)
b. Second stage occurs in lymph nodes and spleen—activation of a naïve B cell after it binds to a specific antigen
c. B cells divide repeatedly—serve as ancestors to antibody-secreting plasma cells
   (1) Some of the clone cells differentiate to form B cells or plasma cells
   (2) Others remain in lymphatic tissue and become memory B cells

B. Antibodies—proteins (immunoglobulins) secreted by activated B cell (Figure 24-16)
1. Structure of antibody molecules
   a. An antibody molecule consists of two heavy and two light polypeptide chains
   b. Each molecule has two antigen-binding sites and two complement-binding sites (Figure 24-17)
2. Diversity of antibodies
   a. Babies are born with different clones of B cells in bone marrow, lymph nodes, and spleen
   b. Cells of the clone synthesize a specific antibody with a sequence of amino acids in its variable region that differs from the sequence synthesized by other clones
3. Classes of antibodies (Figure 24-18)—immunoglobulins M, G, A, E, and D
   a. IgM—antibody that naïve B cells synthesize and insert into their own plasma membranes; the predominant class produced after initial contact with an antigen
   b. IgG—makes up 75% of antibodies in the blood; predominant antibody of the secondary antibody response
   c. IgA—major class of antibody in the mucous membranes, in saliva and tears (also found in plasma)
   d. IgE—small amount; produces harmful effects such as allergies
   e. IgD—small amount in blood; precise function unknown
4. Functions of antibodies (Figure 24-19)
   a. Antigen-antibody reactions
      (1) Transforms toxic antigens into harmless substances
      (2) Agglutinates antigens to make disposal by phagocytes more rapid
      (3) Alters the shape of antigen molecule to expose complement-binding sites (Figure 24-20)
   b. Complement—a component of blood plasma consisting of several protein compounds (inactive enzymes)
      (1) Antibodies can activate complement after binding to an antigen by exposing complement-binding sites that trigger a cascade of linked chemical reactions to produce a variety of immune effects
         i. Membrane attack complex (MAC)—complement cascade can form doughnut-shaped structures that produce a hole in a foreign cell's membrane, causing cytolysis (cell rupture) (Figures 24-21 and 24-22)
         ii. Complement can also cause vasodilation, enhances phagocytosis, and other effects
      (2) Complement activity can also be initiated by innate immune mechanisms
         i. Complement protein 3 (C3)—activated without antigen stimulation—produces full complement effect by binding to bacteria or viruses in presence of properdin
         ii. Complement activation by innate immunity is called the alternate pathway
   c. Primary and secondary responses (Figure 24-23)
      (1) Primary response—initial encounter with a specific antigen triggers the formation and release

of specific antibodies that reaches its peak in a few days
(2) Secondary response—a later encounter with the same antigen triggers a much quicker response; B memory cells rapidly divide, producing more plasma cells and thus more antibodies

C. Clonal selection theory (Figure 24-24)
1. Two basic tenets
a. Body contains many diverse clones of cells, each committed by its genes to synthesize a different antibody
b. When an antigen enters the body, it selects the clone whose cells are synthesizing its antibody and stimulates them to proliferate and create more antibody
2. The clones selected by antigens consist of lymphocytes and are selected by the shape of antigen receptors on the lymphocyte's plasma membrane

T CELLS AND CELL-MEDIATED IMMUNITY

A. Development of T cells
1. T cells are lymphocytes that go through the thymus gland before migrating to the lymph nodes and spleen
2. Pre–T cells develop into thymocytes while in the thymus
3. Thymocytes stream into the blood and are carried to the T-dependent zones in the spleen and the lymph nodes

B. Activation of T cells
1. T cells display antigen receptors on their surface membranes that are similar to antibodies
2. A T cell is activated when an antigen (in an infected cell or presented by an APC) binds to its receptors (at an IS), causing the T cell to divide repeatedly to form a clone of identical T cells (Figure 24-25)
a. Cells of the clone differentiate into effector T cells and memory T cells
b. Effector T cells go to the site where the antigen entered, bind to antigens, and begin their attack
c. Memory T cells remain in bone marrow until needed later to produce more effector T cells and memory T cells

C. Functions of T cells
1. Cytotoxic T cells—T cells release lymphotoxin to kill cells (Figure 24-26)
2. Helper T cells (T_H cells)—regulate the function of B cells, T cells, phagocytes, and other leukocytes (Figure 24-27)
3. Suppressor T cells—regulatory T cells that suppress lymphocyte function, thus regulating immunity and promoting self tolerance
4. T cells function to produce cell-mediated immunity and help to regulate adaptive immunity in general

TYPES OF ADAPTIVE IMMUNITY (TABLE 24-4)

A. Innate immunity (inborn or inherited immunity)—genetic mechanisms put innate immune mechanisms in place during development in the womb

B. Adaptive or acquired immunity; resistance developed after birth; two types:
1. Natural immunity results from nondeliberate exposure to antigens
2. Artificial immunity results from deliberate exposure to antigens, called *immunization*

C. Natural and artificial immunity may be active or passive
1. Active immunity—when the immune system responds to a harmful agent regardless of whether it was natural or artificial; lasts longer than passive
2. Passive immunity—immunity developed in another individual is transferred to an individual who was not previously immune; it is temporary but provides immediate protection

SUMMARY OF ADAPTIVE IMMUNITY

A. Adaptive immunity is specific immunity—targeting specific antigens

B. Adaptive immunity involves two classes of lymphocyte: B cells and T cells (Figure 24-27)
1. B cells—antibody-mediated (humoral) immunity
2. T cells—cell-mediated (cellular) immunity

C. Adaptive immunity occurs in a series of stages (Figure 24-28)
1. Recognition of antigen
2. Activation of lymphocytes
3. Effector phase (immune attack)
4. Decline of antigen causes lymphocyte death (homeostatic balance)
5. Memory cells remain for later response if needed

D. B cells and T cells work together in a coordinated system of adaptive immunity (Figure 24-29)

THE BIG PICTURE: IMMUNE SYSTEM AND THE WHOLE BODY

A. Immune system regulated to some degree by nervous and endocrine systems

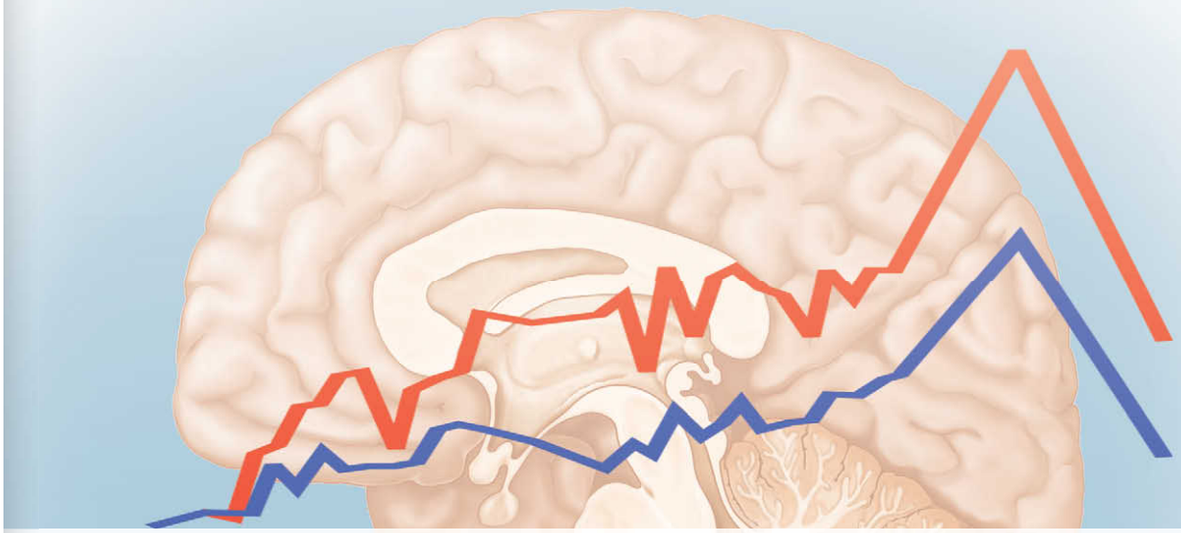
B. Agents of the immune system include blood cells, skin cells, mucosal cells, brain cells, liver cells, and other types of cells and their secretions

REVIEW QUESTIONS

Write out the answers to these questions after reading the chapter and reviewing the Chapter Summary. If you simply think through the answer without writing it down, you won't retain much of your new learning.

1. Define the term *innate immunity*.
2. List several mechanisms of innate defense, and give a brief description of each one.
3. Identify the body's first line of defense.
4. Describe chemotactic factors released from the mast cell.
5. What is the function of interferon?
6. Define the following terms: antigens, antibodies, antigenic determinants, combining sites, clone.
7. What two terms are synonyms for combining sites?

8. When an antigen-antibody complex is formed, what region on the antigen molecule fits into what region on the antibody molecule?
9. Activated B cells develop into clones of what two kinds of cells?
10. What cells synthesize and secrete copious amounts of antibodies?
11. Explain the function of memory cells.
12. Antibodies belong to what class of compounds? Diagram and describe the structure of an antibody.
13. Explain the two basic tenets of Burnet's clonal selection theory.
14. What are cytokines? Lymphotoxins?
15. Differentiate between the classifications of natural and artificial immunity.
16. Describe the process behind the functioning of modern vaccines.
17. What are monoclonal antibodies, and how do they function?



CRITICAL THINKING QUESTIONS

After finishing the Review Questions, write out the answers to these more in-depth questions to help you apply your new knowledge. Go back to sections of the chapter that relate to concepts that you find difficult.

1. The causative organism of tuberculosis has a coat around it that makes it much more resistant than other bacteria to digestive enzymes and hydrogen peroxide. What can you say about this characteristic, and why is it more difficult for the body to fight off these bacteria?
2. If a person had a mutation that prevented the formation of the complement proteins, what capabilities would be lessened in the immune system?
3. How would you explain how the various types of T cells can fine-tune the immune system?
4. Why do you think the development of cancer can be seen as a failure of the immune system?
5. Explain the distinction between inherited immunity and acquired immunity?
6. One of the best-known examples of acquired immune deficiency is acquired immune deficiency syndrome (AIDS). The human immunodeficiency virus (HIV) causes this syndrome. How would you summarize the mechanism of HIV infection?
7. If the genes that produce Toll-like receptors (TLRs) were abnormal, what effect might that have on a person's immunity?

25 Stress

The Big Picture: Stress and the Whole Body, 793

Case Study, 794

Stress affects people of all ages and in all walks of life. Children at play, students preparing for an examination, workers on the job, and even a baby before birth are all subject to stress. Although some stress can result in beneficial outcomes, excessive and long-term stress often has disastrous consequences for the health and quality of life of many people.

People experiencing severe stress are often overwhelmed by tension, anger, fear, and frustration. As a result, adrenaline levels rise, blood pressure and heart rate increase, and breathing patterns change. Blood levels of nutrients such as glucose and fatty acids deviate from their normal set points and the immune system becomes less effective. People who have difficulty in dealing with stress over time suffer from a number of stress-related illnesses. Every individual responds somewhat differently to stress, making diagnosis and treatment difficult. There is often a decrease in efficiency of study habits or job-related problem-solving skills; susceptibility to infections increases; and complaints of stomach pains, heart palpitations, fatigue, and muscle aches are common. Sleep disorders and depression frequently accompany stress, and affected individuals often have difficulty in staying with tasks.

Contemporary medicine now recognizes excessive and long-term stress as a critically important and widespread cause of disease. It causes disruption in the homeostasis of numerous physiological control systems in the body and must be controlled to ensure good health.

Our current concept of stress extends beyond the nonspecific physiological responses suggested by researchers nearly 70 years ago. However, the pioneering and classic research on stress by Hans Selye (described in the next section) continues to provide a scientific basis for ongoing work in this complex and important area.

A growing understanding of stress has resulted from insights and research data from diverse disciplines such as molecular genetics, neurobiology, psychology, endocrinology, immunology, and sociology. The result is a holistic model of stress—one that affirms the importance of mind-body interactions in both health and disease.

SELYE'S CONCEPT OF STRESS

In 1935, Hans Selye of McGill University in Montreal made an accidental discovery that launched him on a lifelong career and led him to conceive the idea of stress. This chapter tells briefly the story of how Selye developed his stress concept and also describes the mechanism of stress that he postulated. It then presents some current ideas about stress.

Development of the Stress Concept

Selye made his accidental discovery when he was trying to determine whether there was another sex hormone besides those already known. He injected rats with various extracts derived from ovaries and placenta, expecting to find different changes had occurred in animals injected with different hormonal preparations. But to his surprise and puzzlement, he found the same three changes in all the animals. The cortices of their adrenal glands were enlarged, but their lymphatic organs—thymus glands, spleens, and lymph nodes—were atrophied, and bleeding ulcers of the stomach and duodenum had developed in every animal. Next he injected many other substances, for example, extracts from pituitary glands, kidneys, and spleens and even a poison, formaldehyde. Every time he found the same three changes in the animal subjects: enlarged adrenals, shrunken lymphatic organs, and bleeding gastrointestinal ulcers. Selye believed that these symptoms were a specific syndrome.

A syndrome, according to the classical definition, is a set of signs and symptoms that occur together and that characterize one particular disease. The three changes, or "stress triad," Selye had observed occurred together, but they seemed to characterize not any one particular kind of injury but instead all kinds of harmful stimuli. More experiments using various chemicals and injurious agents confirmed for him that the three changes truly were a syndrome of injury. His first publication on the subject was a short paper entitled "A Syndrome Produced by Diverse Nocuous Agents"; it appeared in the July 1936 issue of the British journal *Nature*. Years later, in 1956, he published his monumental technical treatise, *The Stress of Life*.

Although a majority of the current literature credits Hans Selye with the first published reports on stress, Walter B. Cannon used the term "emotional stress" much earlier (1914) when discussing his theory of homeostasis. It seems Cannon was also convinced stress had both a psychological (emotional) and a physiological origin. It was Selye, however, who brought our knowledge of stress and its importance in health and disease into the forefront of modern medicine.

Definitions

Stress, according to Selye's use of the word, is a state, or condition, of the body produced by "diverse nocuous agents" and manifested by a syndrome of changes. We know as well that stress and its negative effects can also be caused by a wide variety of mental, emotional, and other psychological events that an individual may perceive as threatening or undesirable. Selye named the agents that produce stress *stressors* and coined a name—*general adaptation syndrome (GAS)*—for the syndrome or group of changes that make the presence of stress in the body known.

Stressors

A **stressor** is any agent or stimulus that produces stress. However, just how an individual interacts with or relates to a particular type of physiological or cognitive situation may well determine whether that particular event is stressful or not. Even the same intensity of a particular physiological stressor, such as temperature change, may be perceived as a threat and activate a stress response in one individual and not another.

In addition to variances in ability to handle physiological stress, some people have the ability to cope better than others when faced with difficult events in life, such as divorce or bereavement. As a result, they suffer less from negative stress-related symptoms or illness.

Clearly, a precise classification of stimuli as stressors or nonstressors is not possible. We can, however, make these five generalizations about the character of stressors.

1. Stressors are extreme stimuli—too much or too little of almost anything. The *perception* of the individual is critical. A particular event or circumstance that is viewed as undesirable or goes beyond what the individual is capable of coping with may be viewed as "extreme" and cause one or more of the psychological or physiological responses associated with stress. In contrast, almost anything in moderation or that engenders only mild stimuli are nonstressors. Thus coolness, warmth, and soft sounds are nonstressors, whereas extreme cold, extreme heat, and extremely loud sounds almost always act as stressors. Not only extreme excesses but also extreme deficiencies may be perceived as stressors. One example of this kind of stressor is an extreme lack of social contact stimuli. Solitary confinement in a prison, space travel, social isolation because of blindness or deafness, and in some cases, old age have all been identified as stressors. But the opposite extreme, an excess of social contact stimuli (e.g., caused by overcrowding), also acts as a stressor (Figure 25-1). We now know that various types of stress in young children and even prenatal infants may occur as a result of negative stimuli that are experienced by a parent. For example, severe psychological or physical trauma, environmental hazards, and nutritional deficiencies or abuses, when encountered by a pregnant or nursing woman, can all have a stress-related impact on her child that may result in immediate or delayed behavioral, physiological, or anatomical anomalies. Intrauterine stress is discussed in detail later in the chapter. Poverty and illness, typically associated with stress, are often coupled with alcoholism, drug abuse, and malnutrition. These conditions often result either directly or indirectly in premature births, developmental anomalies, increased susceptibility to many types of mental and physical diseases, and a myriad of other physical defects that may occur immediately in the children involved or these conditions may develop later in life.
2. Stressors very often are injurious, unpleasant, or painful stimuli—but not always. "A painful blow and a passionate kiss," Selye wrote, "can be equally stressful."
3. Anything that an individual perceives as a threat, whether real or imagined, arouses fear or anxiety. These emotions act as stressors. So, too, does the emotion of grief.
4. The reaction to stressors differs in different individuals and in one individual at different times. A stimulus that is a stressor for you may not be a stressor for me. A stimulus that is a stressor for you today may not be a stressor for you tomorrow and might not have been a stressor for you yesterday. Many factors—including one's physical and mental health, heredity, past experiences, coping habits, and even diet—determine which stimuli are stressors for each individual.
5. Stress can occur even in a developing fetus—a circumstance called *prenatal stress*. In many instances prenatal stress will result from a physical or nutritional stressor experienced by the mother. For example, in the United States alone, fetal alcohol syndrome (FAS) affects more than 40,000 infants each year (see Box 18-3 on p. 556). FAS involves signs ranging from poor prenatal and infant growth to mental retardation. In this context, alcohol consumed during pregnancy is a dangerous stressor. Even in small amounts it can produce prenatal brain damage that may permanently affect the ability of the child to concentrate, think abstractly, use appropriate judgment, or learn effectively. When a woman consumes alcohol during pregnancy, real or perceived stress is often the impetus for such behavior. Education that promotes healthy habits and teaches coping strategies must be a part of any social programs intended to eliminate alcohol consumption during pregnancy and the incidence of FAS.

| QUICK CHECK |

1. Define the terms *stress syndrome* and *stress.*
2. Identify the three changes Hans Selye called the "stress triad."
3. List four characteristics of stressors.

General Adaptation Syndrome

MANIFESTATIONS

Stress, like health or any other state or condition, is an intangible phenomenon. It cannot be seen, heard, tasted, smelled, felt, or measured directly. How, then, can we know that stress exists? It can be inferred to exist when certain visible, tangible, and

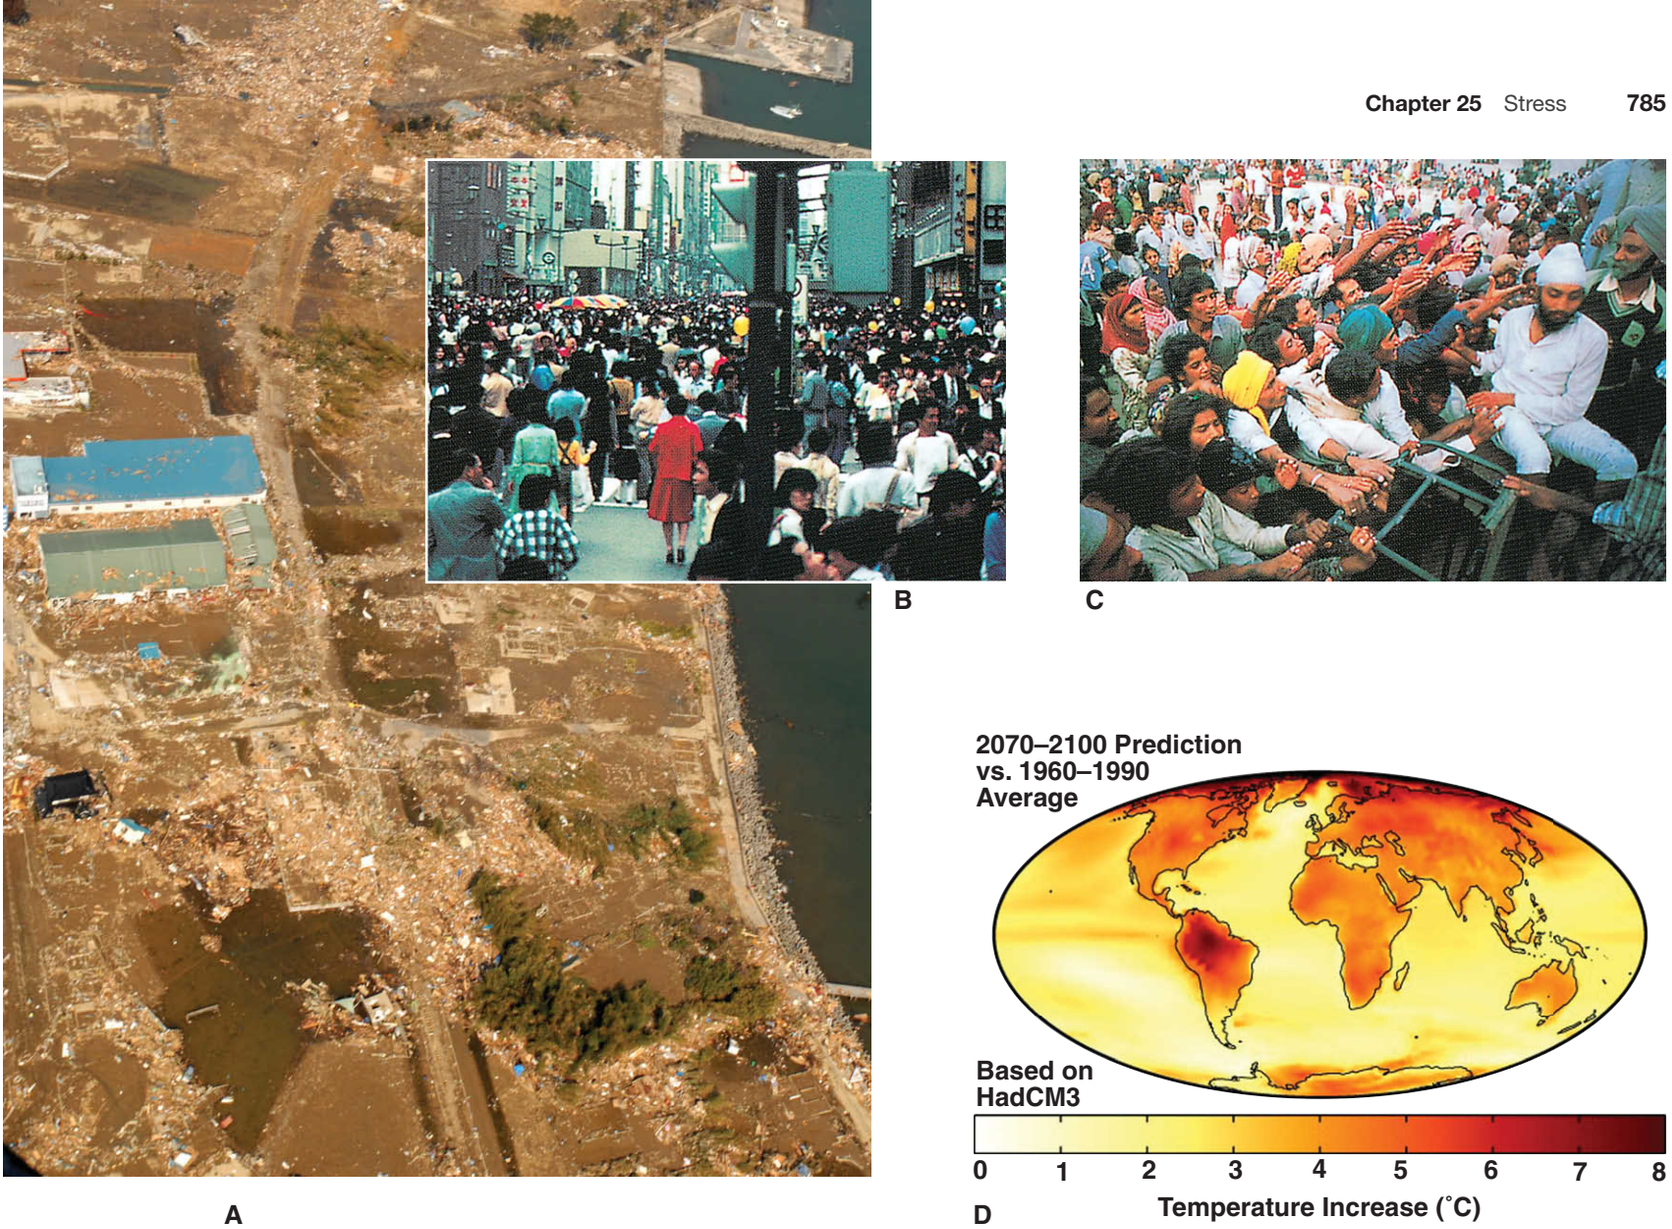

FIGURE 25-1

Causes of stress. A, Natural disaster (Japan tsunami). **B,** Overcrowding (Asia). **C,** Food shortages (refugee camp, New Delhi, India). **D,** Environmental dangers (climate change).

measurable responses occur. Selye, for example, inferred that the animals on which he experimented were in a state of stress when he found the syndrome of the three changes previously noted—hypertrophied adrenals, atrophied lymphatic organs, and bleeding gastrointestinal ulcers. Because this syndrome indicated the presence of stress and consisted of three changes, he called them the "**stress triad.**"

Eventually he found that many other changes also took place as a result of stress. He named the entire group of changes or responses the **general adaptation syndrome (GAS).** In coining this term, he reasoned that the word *general* suggested that the syndrome was "produced only by agents that have a general effect on large portions of the body." The word **adaptation** was meant to imply that the syndrome of changes made it possible for the body to adapt, to cope successfully with stress. Selye thought that these responses seemed to protect the animals from serious damage by extreme stimuli and to promote their healthy survival. He looked on the general adaptation syndrome as a crucial part of the body's complex defense mechanism.

STAGES

Changes that make up the general adaptation syndrome do not all take place simultaneously but over time in three stages. Selye named these stages: (1) the alarm reaction, (2) the stage of resistance or adaptation, and (3) the stage of exhaustion. A different syndrome of changes, he noted, characterized each stage.

Among the responses characteristic of the **alarm reaction,** for example, were the stress triad already described—hypertrophied adrenal cortex, atrophied lymphatic organs (thymus, spleen, lymph nodes), and bleeding gastric and duodenal ulcers. In

addition, the adrenal cortex increased its secretion of glucocorticoids, the number of lymphocytes decreased markedly, and so, too, did the number of eosinophils. Also, the sympathetic nervous system and the adrenal medulla greatly increased their activity (Figure 25-2). Each of these changes, in turn, produced other widespread changes. Figure 25-3 indicates some of the changes stemming from adrenal cortical hypertrophy. Figure 25-4 shows responses produced by increased sympathetic activity and increased secretion by the adrenal medulla of its hormone, epinephrine (adrenaline).

Quite different responses characterize the **stage of resistance.** For instance, the adrenal cortex and medulla return to their normal rates of hormone secretion. The changes that take place during the alarm stage as a result of increased corticoid secretion disappear during the stage of resistance. All of us go through the first and second stages of the stress syndrome many times in our lifetimes. Stressors of one kind or another act on most of us every day. They may upset or alarm us, but we soon resist them successfully. In short, we adapt; we cope.

The **stage of exhaustion** develops only when stress is extremely severe or when it continues over long periods. Otherwise, when stress is mild and of short duration, it ends with a successful stage of resistance and adaptation to the stressor. If stress continues until the body reaches the stage of exhaustion, corticoid secretion and adaptation eventually decrease markedly. The body can no longer cope successfully with the stressor and death may ensue as a result. For a brief summary of the changes characteristic of the three stages of the general adaptation syndrome, see Table 25-1.

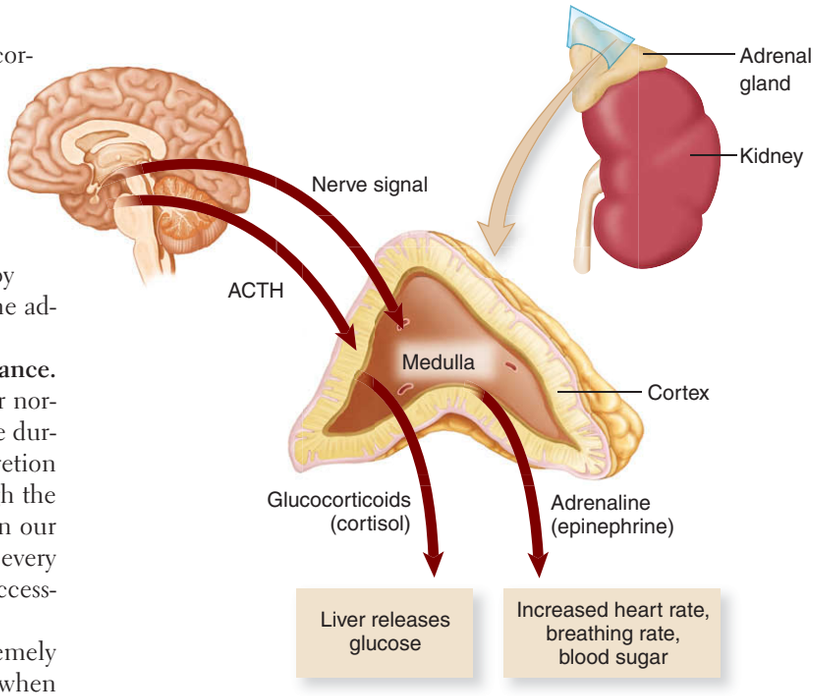

FIGURE 25-2

The alarm reaction. Note the interaction of nervous and hormonal responses. *ACTH,* Adrenocorticotropic hormone.

Mechanism of Stress

Stressors produce a state of stress. A state of stress in turn inaugurates a series of responses that Selye called the *general adaptation syndrome.* More simply, a state of stress turns on the stress response mechanism. It activates the organs that produce the responses that make up the general adaptation syndrome; but just how stress—a state of the body—does this is not clear. Selye could only guess about it, and his terms were vague. For instance, he postulated that, by some unknown "alarm signals," stress "acted through the floor of the brain" (presumably the hypothalamus) to stimulate the sympathetic nervous system and the pituitary gland.

TABLE 25-1 The Three Stages of the General Adaptation Syndrome

ALARM	RESISTANCE	EXHAUSTION
Increased secretion of glucocorticoids and resultant changes (see Figure 25-2)	Glucocorticoid secretion returns to normal	Initially increased glucocorticoid secretion but eventually markedly decreased secretion
Increased activity of sympathetic nervous system	Sympathetic activity returns to normal	Stress triad (hypertrophied adrenals, atrophied thymus and lymph nodes, bleeding ulcers in stomach and duodenum)
Increased norepinephrine secretion by adrenal medulla	Norepinephrine secretion returns to normal	
Fight-or-flight reaction (see Figure 25-4)	Fight-or-flight reaction disappears	
Low resistance to stressors	High resistance (adaptation) to stressor	Loss of resistance to stressor; may lead to death

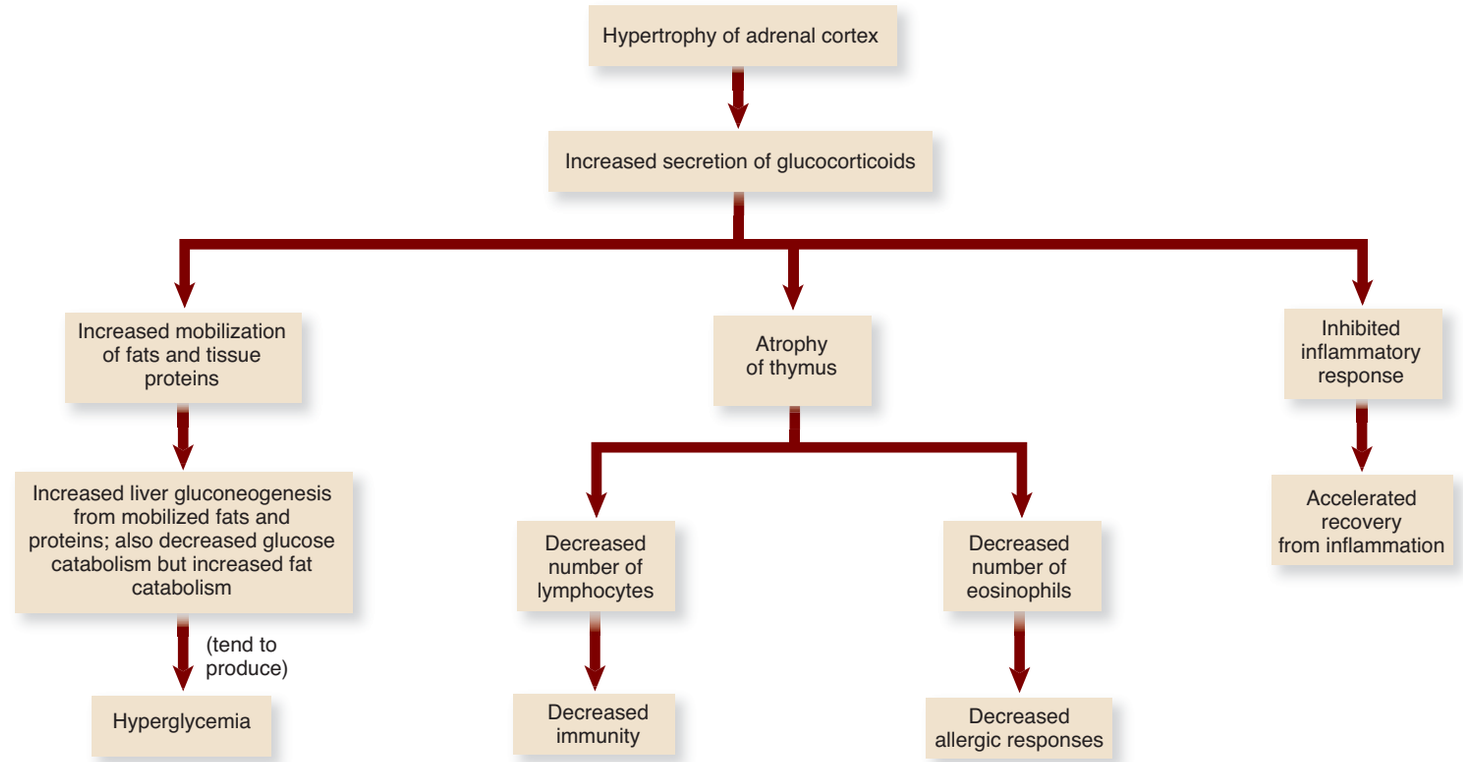

FIGURE 25-3

Alarm reaction responses resulting from hypertrophy of adrenal cortex.

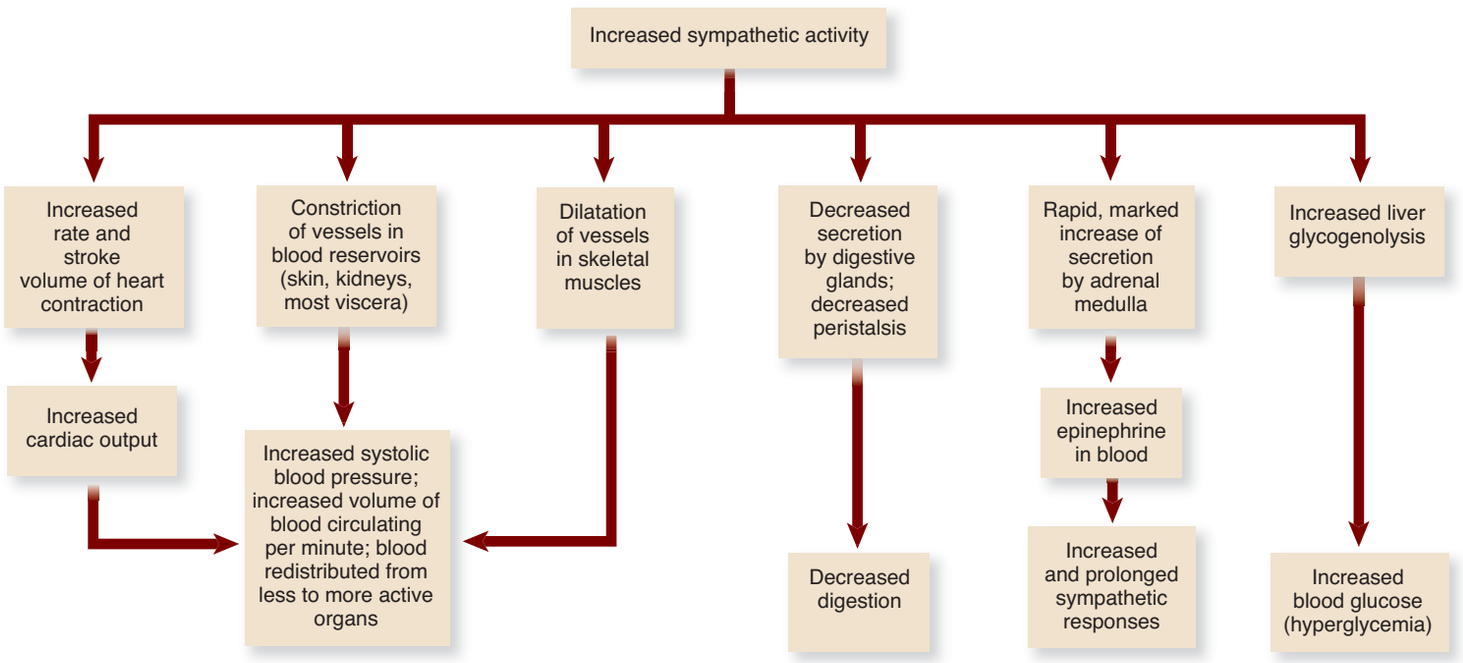

FIGURE 25-4

Alarm reaction responses resulting from increased sympathetic activity. Note that these are the responses commonly referred to as the "fight-or-flight" reaction.

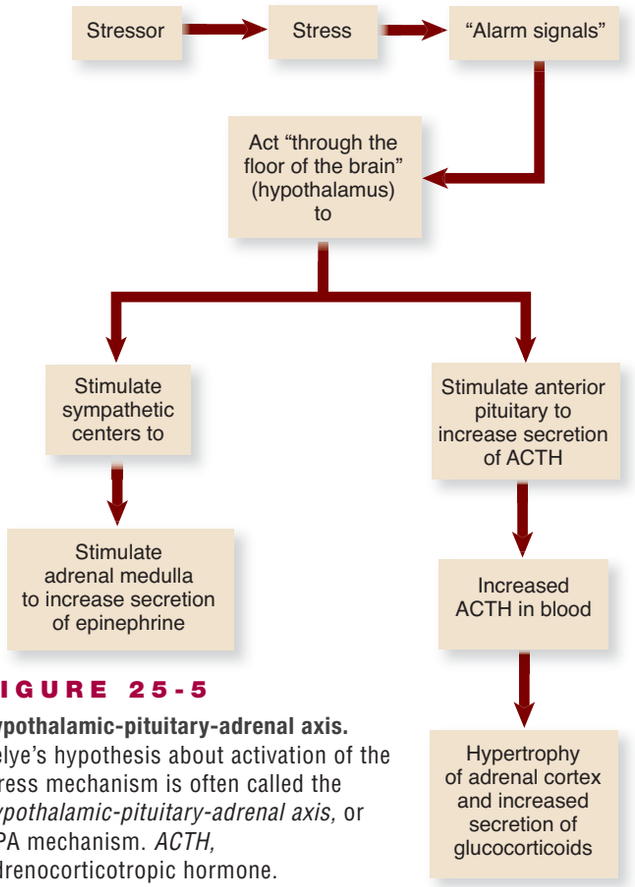

FIGURE 25-5

Hypothalamic-pituitary-adrenal axis. Selye's hypothesis about activation of the stress mechanism is often called the *hypothalamic-pituitary-adrenal axis,* or HPA mechanism. *ACTH,* Adrenocorticotropic hormone.

In Figure 25-5 you can see Selye's hypothesis in diagram form. Many scientists refer to this process as the **hypothalamic-pituitary-adrenal "axis,"** or **HPA** mechanism.

| QUICK CHECK |

4. What is the general adaptation syndrome?
5. Identify the three stages of the general adaptation syndrome. How do they differ?
6. Discuss the types of responses produced in the body by increased sympathetic activity.

SOME CURRENT CONCEPTS ABOUT STRESS

Definitions

Some of today's physiologists use the terms *stressors* and *stress* as Selye did—that is, they define stressors as stimuli that produce stress, a state (or condition) of the body. In contrast, many physiologists now use the word *stress* to mean something much more specific than a state of the body. **Stress,** according to their operational definition, is any stimulus that directly or indirectly stimulates neurons of the hypothalamus to release corticotropin-releasing hormone (CRH). CRH acts as a trigger that initiates many diverse changes in the body. Together, these changes constitute a syndrome now commonly called the **stress syndrome,** or simply, the **stress response.**

The term **allostasis** is sometimes used to refer to the stress syndrome, or the body's attempts to reestablish homeostatic balance while under stress. The word part *allo-* means "different." One can think of allostasis as the body's coping mechanisms when things are different. *Allostatic load* refers to the broad effects of allostasis on the body, such as increased energy expenditure, alterations of neural and endocrine mechanisms, and changes in behavior. One can think of allostatic load as the physiological load placed on the body by stress.

Stress Syndrome

Look now at Figure 25-6. It summarizes some current major ideas about the syndrome of stress responses. Beginning at the top of the diagram, note that the initiator of the stress syndrome is stress—any factor that stimulates the hypothalamus to release CRH. Most often, stress consists of injurious or extreme stimuli. These may act directly on the hypothalamus to stimulate it. Instead, or in addition, they may act indirectly on the hypothalamus.

An example of stress that stimulates the hypothalamus directly is hypoglycemia. A lower than normal concentration of glucose in the blood circulating to the hypothalamus stimulates it to release CRH.

Indirect stimulation of the hypothalamus occurs in this way: stress stimulates the cerebral part of the brain's limbic system—the so-called *emotional brain*—and other parts of the cerebral cortex, and these regions then send stimulating impulses to the hypothalamus (also part of the limbic system). The hypothalamus releases CRH in response.

In addition to releasing CRH, note in Figure 25-6 that the stress-stimulated hypothalamus sends stimulating impulses to sympathetic centers and to the posterior pituitary gland.

CRH stimulates the anterior pituitary gland to secrete increased amounts of adrenocorticotropic hormone (ACTH). ACTH stimulates the adrenal cortex to secrete greatly increased amounts of cortisol and more moderately increased amounts of aldosterone. These two hormones induce various stress responses. Some important ones worth remembering are listed in Figure 25-6 under cortisol effects and aldosterone effects.

Recall from Chapter 16 that stimulation of sympathetic centers by impulses from the stress-stimulated hypothalamus leads to many stress responses, known collectively as the **fight-or-flight reaction.** These *adrenergic responses* include important changes such as an increase in the rate and strength of the heartbeat, a rise in blood pressure, and hyperglycemia. Other sympathetic stress responses are pallor and coolness of the skin, sweaty palms, and dry mouth. Review Table 16-4 on p. 500 for a listing of the adrenergic effects observed in the fight-or-flight reaction.

Water retention and an increase in blood volume are common stress responses. They stem, as you can see in Figure 25-6, from increased ADH and increased aldosterone secretion.

Evidence also suggests that prolonged stress produces yet another hormone, called **neuropeptide Y,** that is secreted from the sympathetic nerves and adrenal medulla. This stress-related hormone causes vasoconstriction, platelet aggregation, and over time, hypertrophy of vascular smooth muscle.

Stress and Disease

Stress, as we have observed several times, produces different results in different individuals and different results in the same individual at different times. In one person, a certain amount of stress

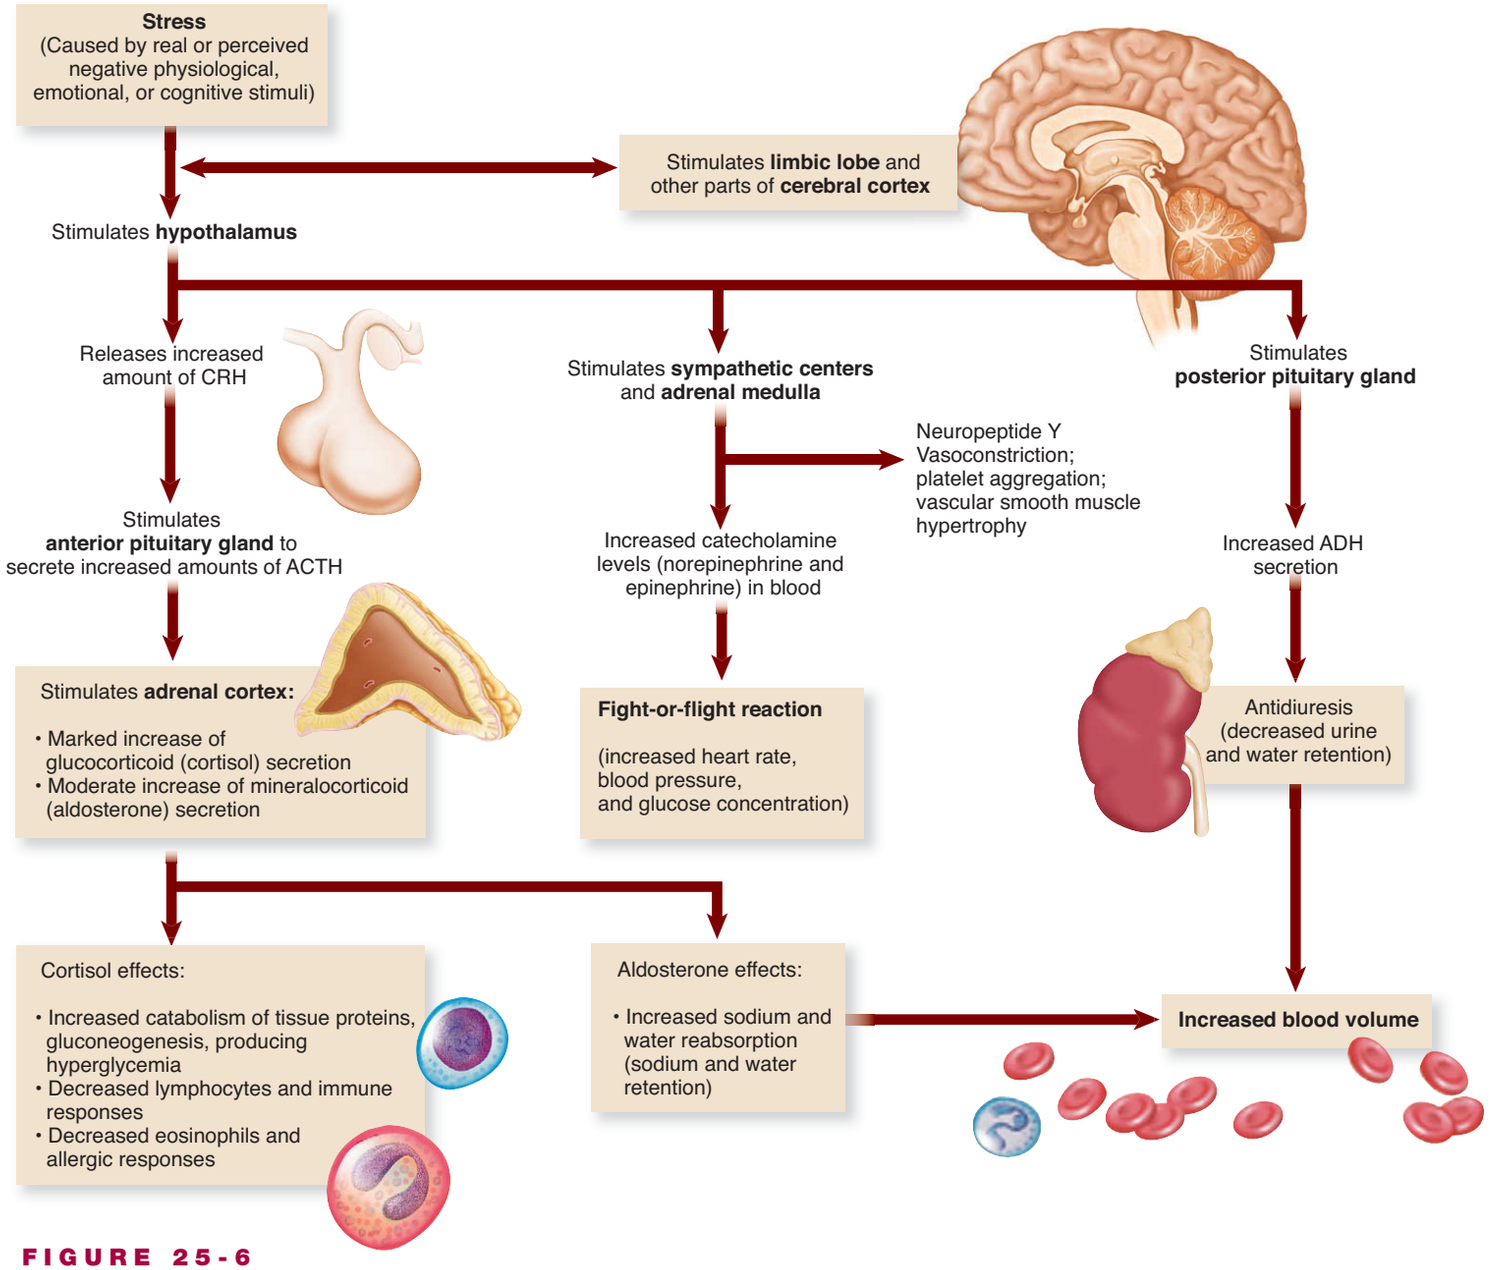

FIGURE 25-6

Current concepts of the stress syndrome. Some effects are immediate, such as the sympathetic fight-or-flight reaction, and some effects are longer term, such as the hormonal effects. CRH, Corticotropin-releasing hormone; ACTH, adrenocorticotropic hormone; ADH, antidiuretic hormone.

may induce responses that maintain or even enhance health. But in another person the same amount of stress appears to cause sickness. Whether stress is "good" or "bad" for you seems to depend more on your own body's responses to it than on the severity of the stressors inducing it.

You may recall that Selye emphasized the adaptive nature of stress responses. He coined the term *general adaptation syndrome* because he believed that stress responses usually enable the body to adapt successfully to the many stressors that assail it. He held that the state of stress activates physiological mechanisms to meet the challenge imposed by stressors. But a challenge issued does not necessarily mean a challenge successfully met. Selye proposed that sometimes the body's adaptive mechanisms fail to meet the challenge issued by stressors and that when they fail, disease results—diseases of adaptation, he called them. In today's terms, we might say that when the allostatic load becomes high, fatigue or disease may result.

Around the middle of the last century, one of the problems studied was the relationship of blood glucocorticoid concentration to disease. If stress is adaptive, the investigators reasoned, and helps the body combat the effects of many kinds of stressors (e.g., infection, injury, and burns), then possibly various diseases might be treated by adding to the body's natural output of glucocorticoids (cortisone).

Indicators of Stress

Whether an individual's body is responding to stress stimuli can be determined by certain measurements and observations (Figure 25-7). Some examples follow: an increase in the rate and force of heartbeat, a rise in systolic blood pressure, an increase in blood and urine concentration of epinephrine and norepinephrine, sweating of the palms of the hands, and dilation of pupils. The heart rate has been shown to increase in response to varied stress stimuli, such as anesthesia and annoying sounds. Even anticipation by patients in a coronary care unit of their upcoming transfer to a less closely supervised convalescent unit has been identified as a stress stimulus that causes the heart rate to speed up.

A decrease in the number of eosinophils and lymphocytes in the blood indicates that the individual is responding to stress stimuli. Soldiers stressed by prolonged marching, for example, have been found to have fewer circulating eosinophils than normal. This same stress indicator has been observed in college athletes when they were anticipating performing in an important event. It has also been observed in heart patients when they were anticipating the various types of procedures required to treat their illness.

The amount of urinary adrenocorticoids is often used as a measure of stress. It has been found to increase in depressed persons feeling hopeless and doomed, in test pilots anticipating a scheduled flight, and in college students taking examinations or watching exciting movies. In contrast, urinary corticoids were found to drop markedly in persons watching boring films.

The level of adrenocorticoids in the blood plasma of disturbed patients having acute psychotic episodes has been found to be 70% higher than that in normal individuals or in calm patients. Another study showed that the plasma corticoid levels of chronically depressed patients were significantly lower than those of acutely anxious patients. Smoking and exposure to nicotine have also been shown to be stressors that caused a marked rise in plasma adrenocorticoids—by as much as 77% in humans and in experimental animals.

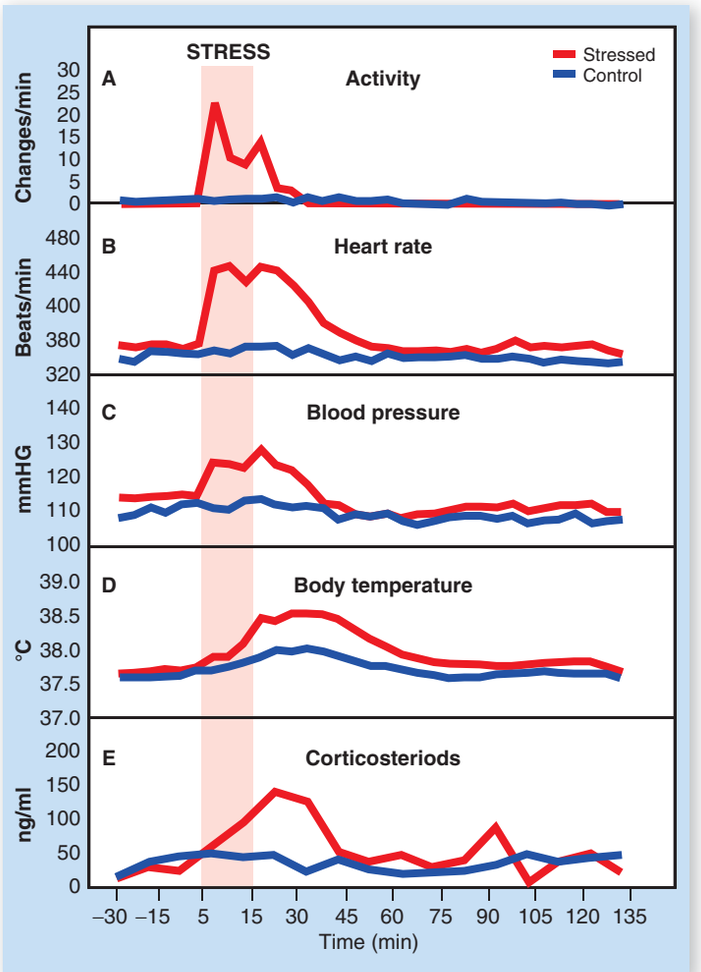

FIGURE 25-7

Stress indicators. Graphs showing a variety of physiological changes in mice when presented with a stressor: increased movements **(A)**, elevated heart rate **(B)**, elevated blood pressure **(C)**, elevated body temperature **(D)**, and increased plasma corticosteroids **(E)**. Similar stress responses occur in all mammals.

Corticoids and Resistance to Stress

Selye thought that the increase in **corticoids** that occurred in his stressed animals enabled them to adapt to and resist stress. Today many physiologists doubt this. No one questions that adrenal cortical hormones increase during stress. That fact has been clearly established. But what many question is how essential this increase is for *resisting stress.*

No one has proved by an unequivocal experiment that a higher than normal blood level of corticoids increases an animal's ability to adapt to stress, and increasing corticoid levels may in themselves be problematic—especially in the developing fetus. Some clinical evidence, however, seems to indicate that it does increase a human's coping ability. For instance, patients who have been taking cortisol for some time are known to require increased doses of this hormone to successfully resist stresses such as surgery or severe injury.

Psychological Stress

Stress as defined by Selye is physiological stress, that is, a state of the body. Psychological stress, in contrast, might be defined as a state of the mind. It is caused by psychological stressors and manifested by a syndrome.

A **psychological stressor** is anything that an individual perceives as a threat—a threat to survival or to self-image. Moreover, the threat does not need to be real—it needs only to be real to the individual, who must see it as a threat, although in truth, it may not be so. The ability to recognize threats is vital to the survival of any animal, including humans (Figure 25-8). But perceiving nonharmful stimuli as stressors will also produce stress effects in the body.

Psychological stressors produce a syndrome of subjective and objective responses. Dominant among the subjective reactions is a feeling of anxiety. Other emotional reactions, such as anger, hate, depression, fear, and guilt, are also common subjective responses to psychological stressors.

Some characteristic objective responses are restlessness, fidgeting, criticizing, quarreling, lying, and crying. Another objective indicator of psychological stress is that the concentration of lactate in the blood increases. Lactate, a molecule related to glucose, is released by glia to nourish nearby neurons. Increased blood lactate is an indicator of tissue hypoxia. Hypoxia may result from changes in breathing patterns.

Does psychological stress relate to physiological stress? The answer is clearly "yes." Physiological stress usually is accompanied by

FIGURE 25-8

Psychological stress. For any animal, a stressor is a perceived threat to survival. The threat may be real (pictured) or imagined. Regardless, it will produce protective stress responses in the body.

some degree of psychological stress. And conversely, in most people, psychological stress produces some physiological stress responses. Ancient peoples intuitively recognized this fact. For example, it is said that in ancient times when the Chinese suspected a person of lying, they made that person chew rice powder and then spit it out. If the powder came out dry, not moistened by saliva, they judged the suspect guilty. They seemed to know that lying makes a person nervous—and that nervousness makes a person's mouth dry. We "moderns" also know these facts, but we describe them with more technical language. Lying, we might say, induces psychological stress, and psychological stress acts in some way to cause the physiological stress response of decreased salivation.

Within recent decades, a scientific discipline called *psychophysiology* has come into being. Psychophysiologists, using accepted research methods, blood analyses, and sophisticated instruments—including polygraphs designed especially for this type of research—have investigated various physiological responses made by individuals subjected to psychological stressors. Their findings amply confirm the principle that psychological stressors often produce physiological stress responses in all age-groups.

Especially apparent are the links between the immune, nervous, and endocrine systems. Table 25-2 lists a number of stress-related diseases and conditions. Psychophysiologists have found, however, that identical psychological stressors do not necessarily induce identical physiological responses in different individuals. For example, stress may result in heart rate and blood pressure changes in one individual and changes in breathing patterns in another. Another of their interesting discoveries is that some organ systems become less responsive after they have been stimulated a number of times. We now know that infancy and early childhood, once overlooked

TABLE 25-2 Stress-Related Diseases and Conditions

TARGET ORGAN OR SYSTEM	DISEASE OR CONDITION
Cardiovascular system	Coronary artery disease
	Hypertension
	Stroke
	Disturbances of heart rhythm
Muscles	Tension headaches
	Muscle contraction backache
Connective tissues	Rheumatoid arthritis (autoimmune disease)
	Related inflammatory diseases of connective tissue
Pulmonary system	Asthma (hypersensitivity reaction)
	Hay fever (hypersensitivity reaction)
	Changes in breathing patterns
Immune system	Immunosuppression or immune deficiency
	Autoimmune diseases
Gastrointestinal system	Ulcer
	Irritable bowel syndrome
	Diarrhea
	Nausea and vomiting
	Ulcerative colitis
Genitourinary system	Diuresis
	Impotence (erectile dysfunction)
	Loss of libido (sexual desire)
Skin	Eczema
	Neurodermatitis
	Acne
Endocrine system	Diabetes mellitus
	Amenorrhea
Central nervous system	Fatigue and lethargy
	Type A behavior
	Overeating
	Depression
	Insomnia

as potentially stressful periods in life, do indeed present youngsters with challenges that result in stress. The result is often manifested by physical or behavioral adaptations intended to assist in coping. As young children mature, they continue to face multiple periods of often stressful transition to new roles in social relationships, self-concept, personal identity, and later, sexual identity and behavior. These challenges are highly individualistic and often temporary—existing for only short periods during childhood and adolescence.

In the adult years, the types of stressors characteristic of earlier periods of development, such as the transition from childhood to sexual maturity, will often change and maladaptive responses will vary. Adults often face higher levels of ongoing stress than do children because of the many complex social interactions they must deal with day in and day out, including the need to make ethical judgments and decisions related to standards of conduct.

Maladaptive responses to chronic stress in adults often affect not only their physical health but also the emotional, social, and

intellectual aspects of their lives. Living with chronic stress as an adult often leads to a decreased quality of life. Ulcers, hypertension, chemical dependency, impaired relationships, and even loss of contact with reality may occur. Adults struggling with unhealthy levels of stress over time often develop multiple problems that limit their ability to function in society as their general level of both physical and psychological health deteriorates.

Teaching these individuals how to manage stress is an important component of holistic treatment programs designed to improve both their physical and psychological health. In addition to specific drugs and counseling, such programs may include use of relaxation techniques, such as massage, meditation, and positive imagery, and educational components that focus on development of coping strategies.

Elderly people are at high risk for stress-related illness (Box 25-1). It is estimated that the U.S. population of very elderly individuals (80 years or older) will increase from a current number of about 31 million to more than 65 million by 2030. These individuals must deal with unique and very significant stressors during their later years. Unfortunately, loss of health and general well-being, fear of death or dying, a sense of abandonment and social isolation, poverty, and often the death of a spouse result in frequent maladaptive responses to stress in this age-group. Family support and societal support are particularly important for elderly individuals struggling with stress.

In summary, here are some principles to remember about psychological stress:

- Physiological stress almost always is accompanied by some degree of psychological stress.
- In most people, psychological stress leads to some physiological stress responses. Many of these are measurable autonomic responses, for example, accelerated heart rate and increased systolic blood pressure (Box 25-2).
- Identical psychological stressors do not always induce identical physiological responses in different individuals.
- In any one individual, certain autonomic responses are better indicators of psychological stress than others.

Box 25-1 | FYI

The Stress-Age Syndrome

The **stress-age syndrome** refers to a group of anatomical, neurohormonal, and immune system changes related to aging that influence both physiological and psychological stress responses. The syndrome includes a wide array of changes, including:

- Decrease in coping skills
  - Alteration of limbic system and hypothalamus excitability
  - Increases in catecholamines, adrenocorticotropic hormone (ACTH), and cortisol
  - Decreases in testosterone, estrogen, thyroxine, and other hormones
  - Immunodepression
  - Decreases in neuromuscular transmitter chemicals resulting in chronic fatigue and reduced physical strength
  - Changes in blood lipid profile
  - Increased potential for hypercoagulation of the blood
- Disturbances of the sleep/wake cycle

Although not all age-related changes connected with stress are damaging, a majority result in a lower potential for positive adaptation to change.

Effects of Intrauterine Stress

We now know that a fetus develops both short-term and long-term responses to stress experienced during intrauterine development.

Maternal malnutrition is one of the most common "stressors" experienced by a pregnant woman and her unborn child. In malnourished women who smoke, oxygen delivery to the fetus will also decrease. The result is hypoxic as well as nutritional stress. Physicians have known for years that when a fetus is stressed by toxins such as alcohol (see generalization #5 on p. 784) or by a lack of necessary nutrients or oxygen during development, the immediate outcome for the fetus is often preterm delivery and low birth weight. Both of these outcomes are associated with potential problems, including developmental delays, anatomical (congenital) anomalies, functional deficits, and overt disease.

The fetus is not simply a passive recipient of the negative results of maternal stress during pregnancy. And early delivery, low birth weight, or both are not the only outcomes related to fetal stress. Stress-related changes in the intrauterine environment may also trigger numerous development problems that may become apparent during gestation or at the time of delivery. Many are related to oversecretion of endocrine secretions, especially cortisol, by both mother and developing baby (Figure 25-9). Intrauterine levels of cortisol are influenced by the maternal-fetoplacental unit and by the shared maternal-fetal hypothalamic-pituitary-adrenal axis, or HPA mechanism (review Figure 25-5).

Not only do abnormal increases in the intrauterine level of cortisol have an immediate impact on the fetus or newborn infant, they also produce intermediate and long-term effects on the individual over a lifetime. The process is now called **fetal programming.** It refers to the relationship between events occurring during the course of fetal development and the appearance of specific anatomical, physiological, or disease states that develop later in life. Early research in the area of fetal programming focused on trying to explain the relationship known to exist between the stress of inadequate fetal nutrition, low birth weight, and adult rates of cardiovascular disease and its precursors—including elevated cholesterol levels, high blood pressure, and diabetes.

Fetal programming is strongly influenced by elevated intrauterine levels of cortisol and other stress hormones, and it affects not only the cardiovascular system but also many other body systems and physiological variables over a lifetime. Cortisol-induced fetal programming

Box 25-2 | FYI

Type A Behavior and Stress

Hard-driving, competitive type A individuals who put themselves in high-stress situations have been found to be at a somewhat greater risk of elevated systolic blood pressure and coronary disease than individuals with the more relaxed and less impatient type B personality. Studies show that type A behavior patterns can be reduced by psychological guidance. Counseling of type A individuals helps them reduce stress and may cut in half their chances of suffering a heart attack (myocardial infarction, or MI) because of stress.

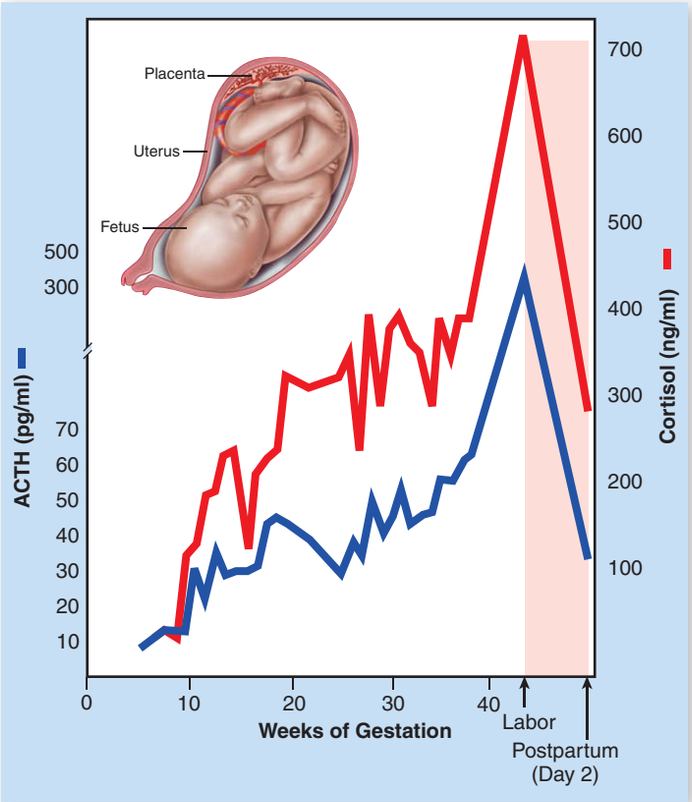

FIGURE 25-9

Stress hormones during pregnancy. The graph shows increasing levels of maternal stress hormones cortisol and ACTH during pregnancy. Notice that they decrease dramatically after birth (shaded area).

changes are known to influence body composition; growth rates; age at maturity; the functioning of the adult immune, endocrine, renal, and reproductive systems; the aging process; and even life expectancy.

Although sophisticated experimental work has shown that fetal programming does indeed occur and that it is often influenced by stress before birth, the mechanism that would explain exactly how it works has yet to be discovered. Fully understanding the role of cortisol in regulating the "partitioning" or allocation of energy (nutrients) available for use by different organ systems during intrauterine development will most certainly be important in solving the puzzle.

Many scientists believe the answer will be related to what are described as *biological tradeoffs*. For example, for a developing fetus, the "tradeoff" of simply surviving a dangerous pregnancy caused by the stress of maternal malnutrition might be to "accept" the dangers associated with preterm delivery and low birth weight. Or, diverting very limited nutrients to support central nervous system development required to sustain life at birth rather than using the same amount of energy resource to protect future reproductive system function might be another "acceptable" biological tradeoff. In a biological sense, in the cycle of life, the "big picture" focuses on survival. It is therefore appropriate to state that stress plays an important role in the health of an individual in every stage of the cycle of life from conception to death.

New research data related to fetal programming and its relationship to stress experienced by the fetus during development have dramatically increased interest in this area in both the scientific and medical communities. For example, knowing that a particular disease or condition is caused by prenatal stress related to a nutritional deficiency in the maternal diet, and not by genetic susceptibility, will drastically change public health and disease prevention strategies intended to reduce the incidence of that disease or condition in the population. A good example is prevention of certain congenital defects in the central nervous system by addition of an important micronutrient, folic acid, to the diet of pregnant women.

Expanding our knowledge about prenatal stress has resulted in new commitments being made to improve nutrition for women during pregnancy and to increase access to educational programs intended to decrease smoking and alcohol consumption.

| QUICK CHECK |

7. What is meant by the phrase "diseases of adaptation"?
8. What is the fight-or-flight reaction?
9. List four indicators of stress.
10. What is the difference between physiological and psychological stress?

the BIG picture

Stress and the Whole Body

Although our understanding of physiological and psychological stress is still evolving, we are certain of this: stress affects the entire body. Stress responses involve numerous physiological mechanisms, many of which are suspected to occur but are as yet unproven.

So far, we understand that stress responses involve nearly every system of the body. The nervous system detects and integrates the factors, or stressors, that trigger the stress responses. Physiological stress responses result from signals sent from the nervous system directly—or by way of the endocrine system. Many of these "stress signals" have been discovered in recent decades. Many different kinds of neurotransmitters, hormones, and perhaps other regulatory chemicals influence the function of the skeletal muscles, the digestive system, the urinary system, the reproductive system, the respiratory system, the cardiovascular system, the integumentary system—perhaps every system, organ, and tissue in the body.

Because the regulatory agents associated with stress influence the function of blood cells, stress can have a profound effect on the function of the immune system. Although the fact that stress inhibits immune function has been known for some time, many of the exact mechanisms that accomplish this have been discovered only in the past few decades. Biologists now better appreciate the link between the mind and the immune system and thus are better able to explain how stress causes disease—and even death. In fact, an emerging field within human biology is devoted to studying the mind-immunity link—the field of neuroimmunology. Some researchers in this emerging field have found their studies tend to incorporate diverse fields such as endocrinology, psychology, and hematology.

Considering the effect that stress can have on the entire internal environment—the whole body—and the high levels of stress that characterize the modern cultures in which many of us live and work, advancements in stress research hold the promise of improving the length and quality of our lives.

CASE study

"What's going on with me?" Jiang-Mei thought. Her palms were sweaty; her heart was racing; her mouth felt dry. She was finding it difficult to concentrate on the physiology test sitting on her desk. No matter how many times she told herself to calm down, the symptoms continued. She glanced over at her friend, who was taking the same test. Her friend seemed perfectly calm!

1. Which stage of the general adaptation syndrome is Jiang-Mei experiencing?
   a. Alert reaction
   b. Stage of resistance
   c. Stage of exhaustion
   d. Alarm reaction
2. If we were to do a blood test on Jiang-Mei at this moment, the levels of which hormone would be elevated?
   a. TRH
   b. CRH
   c. TSH
   d. Melatonin
3. Which of the following is not included in the "stress triad"?
   a. Enlarged lymphatic organs
   b. Increased size of adrenal glands
   c. Gastrointestinal ulcers
   d. Decreased size of lymphatic organs
4. All of the following statements are FALSE, except which one?
   a. Stressors are perceived in an infant before and after birth
   b. All stressors have the same effect on all people
   c. Stressors are always intensely negative experiences
   d. Stressors cannot be an imagined threat; they must be a real, physical threat

CAREER choices

Dominic Steward, NREMT-P

Paramedic

As a paramedic my primary function is to maintain life in critically ill or injured people, often during transport to a care facility.

My involvement with the profession came about while serving as a safety and security specialist at a mental health facility. I found that, in order to do my job effectively, I needed to know more about medical matters. I enrolled in an Emergency Medical Technician (EMT) course, and became a full-time EMT. I've had a lifelong interest in science and technology, so the next natural step was to further my education and become an EMT-Paramedic (EMT-P), eventually obtaining National Registry status (NREMT-P).

Paramedics are trained as generalists, and our scope of practice is expanding yearly. I have medic friends who have chosen to leave "the street" to work in hospital emergency departments, in hyperbaric chambers, and in flight medicine. Continuing education is mandatory to maintain state and national certification, and many paramedics choose to further their careers in other medical fields. I know of one paramedic who is currently completing her residency to become a physician's assistant, and many of us are taking courses to become registered nurses. Credentialing, with the goal of national certification, is becoming key. This will allow lateral (i.e., from state to state) mobility for paramedics. Pay and benefits are increasing, in part because of shortages. There is also a trend for colleges to offer associates' or bachelors' degrees in conjunction with paramedic training. This will allow the profession to grow and mature.

My profession is rewarding in several tangible ways. It's important to me to have the opportunity to help people in need. And, especially since recent national events, paramedics have received public appreciation and recognition. It is an honorable way to make a living, although you won't get rich!

A paramedic's effectiveness hinges on knowledge of the anatomy and physiology of the human body. One of my responsibilities is to precept new paramedics, and those who do not have a broad foundation in A&P do not go on the street. The laboratory component of the course was key to my comprehension of the text content. If you have

CAREER choices

the chance, try to attend a dissection. I was once in a laboratory where we learned about the components of the heart by dissecting a cow's heart in a carcass obtained from a local meat market. The organ was four times the size of a human heart, so it was easy to see the various features. Pharmacology was integrated into the class, and I had the opportunity to inject multiple doses of epinephrine into the tissue. This caused the long-dead organ to begin to beat. To this day I remember all of my heart A&P!

CHAPTER SUMMARY

To download an MP3 version of the chapter summary for use with your iPod or portable media player, access the ***Audio Chapter Summaries*** *online at evolve.elsevier.com.*

HINT

Scan this summary after reading the chapter to help you reinforce the key concepts. Later, use the summary as a quick review before your class or before a test.

SELYE'S CONCEPT OF STRESS

A. Development of the stress concept
   1. Selye found that animals exposed to noxious agents all responded with the same syndrome of changes, or "stress triad"
   2. Changes included enlarged adrenal glands, atrophied lymphatic organs, and bleeding ulcers of the stomatch and duodeum

B. Definitions
   1. Stress—a state, or condition, of the body produced by "diverse nocuous agents" and manifested by a syndrome of changes
   2. Stressors—agents that produce stress
   3. General adaptation syndrome—group of changes that manifest the presence of stress

C. Stressors
   1. Stressors are extreme stimuli—too much or too little of almost anything
   2. Stressors are very often injurious or painful stimuli
   3. Anything an individual perceives as a threat is a stressor for that individual
   4. Reaction to stressors differ for different individuals and for one individual at different times
   5. Physical or nutritional stressors experienced by a pregnant woman can cause her fetus to develop prenatal stress

D. General adaptation syndrome
   1. Manifestations
      a. Stress is intangible but can be inferred by physiological changes
      b. Three changes initially noted by Selye named *stress triad;* subsequently, many other changes were noted
      c. Entire group of changes or responses were named *general adaptation syndrome (GAS)*
   2. Stages
      a. Changes occur in stages over time, not simultaneously
      b. Three successive stages: alarm reaction, stage of resistance, stage of exhaustion
      c. Each stage characterized by different syndrome of changes (Table 25-1)

E. Mechanism of stress
   1. State of stress turns on stress response mechanism—general adaptation syndrome
   2. Stimulus that produces stress and thereby activates stress mechanism is nonspecific or variable
   3. Stress mechanism often referred to as hypothalamic-pituitary axis (HPA mechanism) (Figure 25-5)

SOME CURRENT CONCEPTS ABOUT STRESS

A. Definitions
   1. Stress—any stimulus that directly or indirectly stimulates the hypothalamus to release CRH
   2. Stress syndrome—also called the *stress response;* many diverse changes initiated by stress
   3. Allostasis—term sometimes used instead of stress syndrome to describe the body's attempts to restore homeostasis during stress
   4. Allostatic load—the effect of allostasis on the body (stress effects)

B. Stress syndrome—see Figure 25-6
   1. Direct or indirect stress stimulation of hypothalamus triggers release of CRH and stimulation of sympathetic centers and posterior pituitary gland
      a. CRH triggers release of adrenocortitropic hormone (ACTH), which in turn triggers release of cortisol and aldosterone from adrenal cortex
      b. Sympathetic activation produces collection of adrenergic effects called the fight-or-flight reaction (e.g., increased heart rate and blood pressure); review Table 16-4 on p. 500
   2. Additional hormones such as neuropeptide Y may produce additional stress responses

C. Stress and disease—Selye held that stress could result in disease instead of adaptation; in today's terms: high allostatic load can produce fatigue or disease

D. Indicators of stress (Figure 25-7)
   1. Stress response determined by physiological measurements and observations—faster, stronger heartbeat; higher blood pressure; sweaty palms; dilated pupils

2. Laboratory tests reveal decreased eosinophils and lymphocytes; increased level of adrenocorticoids

E. Corticoids and resistance to stress
   1. Increase in corticoids when experiencing stress is proved reaction to stress
   2. Role of higher levels of corticoids in helping body resist stress not yet proven

F. Psychological stress
   1. Psychological stressors—anything that an individual perceives as a threat to survival or self-image (Figure 25-8)
   2. A syndrome of subjective and objective responses characterizes the mental state of psychological stress including anxiety (dominant subjective response) restlessness, irritability, lying, crying
   3. Psychological stressors produce physiological stress (see summary of principles on p. 792)

G. Effects of intrauterine stress
   1. Fetus develops short- and long-term responses to stress experienced during intrauterine development (Figure 25-9)
      a. Frequent stressors include maternal malnutrition, hypoxia, and exposure to toxins such as alcohol
      b. Low birth weight and preterm delivery are common immediate responses to intrauterine stress
   2. Maternal-fetal blood levels of cortisol, important mediators of stress, are influenced by endocrine secretory activity of maternal-fetoplacental unit and the shared maternal-fetal hypothalamic-pituitary-adrenal (HPA) mechanism
   3. Fetal programming responses to stress often result in negative outcomes later in life and affect many organ systems and even life expectancy
   4. Concept of *biological tradeoffs* may be involved in fetal programming outcomes; for example, low birth weight and preterm delivery may be tradeoffs for stress of maternal malnutrition by the fetus to ensure survival

THE BIG PICTURE: STRESS AND THE WHOLE BODY

A. Stress affects the entire body
B. Nervous system detects and integrates stressors that trigger stress responses
C. Stress can have profound affect on immune system
D. Emerging field of neuroimmunology studies mind-immunity link

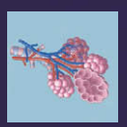
REVIEW QUESTIONS

Write out the answers to these questions after reading the chapter and reviewing the Chapter Summary. If you simply think through the answer without writing it down, you won't retain much of your new learning.

1. Define the terms *stress*, *stressor*, and *general adaptation syndrome*.
2. Describe a few generalizations about the kinds of stimuli that constitute stressors.
3. What three stages make up the general adaptation syndrome? What changes characterize each stage?
4. What changes constitute the "stress triad"?
5. An increase in what three hormones brought about the changes that Selye named the general adaptation syndrome?
6. What function, according to Selye, does the general adaptation syndrome serve?
7. Stress, according to Selye, is a state, or condition, of the body. According to a current operational definition, what is stress?
8. What part of the brain, according to current ideas, plays the key role in initiating stress syndrome responses?
9. What parts of the nervous system other than that named in question 8 are involved in inducing the stress syndrome?
10. Briefly, what role, if any, does each of the following hormones play when the body is subjected to stress: ACTH, ADH, aldosterone, cortisol, CRH, epinephrine, and norepinephrine?
11. What has been proven about corticoids in relation to stress?
12. What issue is considered controversial regarding corticoids as they relate to stress?
13. Cite several examples of psychological stressors.
14. Are psychological stressors the same for all individuals? Give an example.
15. Give some examples of subjective indicators of psychological stress.
16. Give some examples of objective responses that are part of psychological stress.

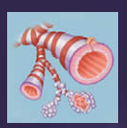
CRITICAL THINKING QUESTIONS

After finishing the Review Questions, write out the answers to these more in-depth questions to help you apply your new knowledge. Go back to sections of the chapter that relate to concepts that you find difficult.



1. Based on what you know regarding Selye's experimental results, how would you explain why stress could be described as a nonspecific response?
2. What is the relationship between stress and disease? If stress levels were high in a person, how might age and personality type affect the risk for specific diseases?
3. What observations and clinical test results would indicate an individual was under stress?
4. How would you use psychophysiology to explain the Chinese rice powder test?
5. Compare and contrast psychological stress and physiological stress. What is the relationship between physiological stress and psychological stress?

Unit Five



Respiration, Nutrition, and Excretion

The chapters in Unit Five provide a discussion of respiration, digestion, processing of nutrients, and excretion of wastes by the urinary system. The concluding chapters of this unit discuss fluid and electrolyte balance and acid-base balance. Ultimately, all homeostatic mechanisms function to maintain what can best be described as a "dynamic constancy" at the cellular level. For example, although under normal conditions the oxygen (O_2) and carbon dioxide (CO_2) content of blood does not change much over time, the quantity of O_2 and CO_2 that enters and exits the blood can vary widely with exercise. Delivery of oxygen and elimination of carbon dioxide and other wastes resulting from the metabolism of nutrients must be regulated within narrow limits so that cellular function remains normal. Maintaining the dynamic constancy of fluid and electrolyte balance and acid-base balance at the cellular level is also required for survival. The anatomical structures and functional control mechanisms discussed in this unit all relate, in the last analysis, to cellular homeostasis.

Cycle of Life: Respiratory System, 816

The Big Picture: Anatomy of the Respiratory System, 816

Mechanisms of Disease, 816

Case Study, 820

The respiratory system functions as an air distributor and a gas exchanger so that oxygen can be supplied to and carbon dioxide removed from the body's cells. Because most of our trillions of cells lie too far from air to exchange gases directly with it, air must first exchange gases with blood, blood must circulate, and finally, blood and cells must exchange gases. These events require the functioning of two systems, namely, the respiratory system and the circulatory system. All parts of the respiratory system—except its microscopic-sized sacs called alveoli*—function as air distributors. Only the alveoli and the tiny alveolar ducts that open into them serve as gas exchangers.*

In addition to air distribution and gas exchange, the respiratory system effectively filters, warms, and humidifies the air we breathe. Respiratory organs also help produce sounds, including speech used in communicating oral language. Special sensory epithelium in the respiratory tract makes the sense of smell (olfaction) possible. The respiratory system also plays an important role in the regulation, or homeostasis, of pH in the body.

In this chapter, we explore the structural aspects of the respiratory system and in Chapter 27 we explore the functional aspects.

STRUCTURAL PLAN OF THE RESPIRATORY SYSTEM

For purposes of study, the respiratory system may be divided into upper and lower tracts, or structural divisions. The organs of the upper respiratory tract are located outside the thorax, or chest cavity, whereas those in the lower tract, or division, are located almost entirely within it (Figure 26-1).

The **upper respiratory tract** is composed of the nose, nasopharynx, oropharynx, laryngopharynx, and larynx. The **lower respiratory tract,** or division, consists of the trachea, all segments of the bronchial tree, and the lungs. Functionally, the respiratory system also includes several accessory structures, such as the oral cavity, rib cage, and respiratory muscles including the diaphragm. Together, these structures constitute the lifeline, the air supply line of the body. This chapter describes the functional anatomy of these organs. The physiology of the respiratory system as a whole is discussed in Chapter 27. Cells require a constant supply of oxygen for the vital energy conversion process carried out within each cell's mitochondria—a process called *cellular respiration* (Chapter 30). Cellular respiration produces carbon dioxide (CO_2) as a waste product, which must be removed before it accumulates to dangerously high levels.

Box 26-1 | FYI

Danger Area of the Face

The fact that the skin of the external nose contains many sebaceous glands has great clinical significance. If these glands become infected, it is possible for infectious material to enter and pass from facial veins near the nose to one of the intracranial venous sinuses (see Chapter 21). For this reason, the triangle-shaped zone surrounding the external nose is often known as the "danger area of the face."

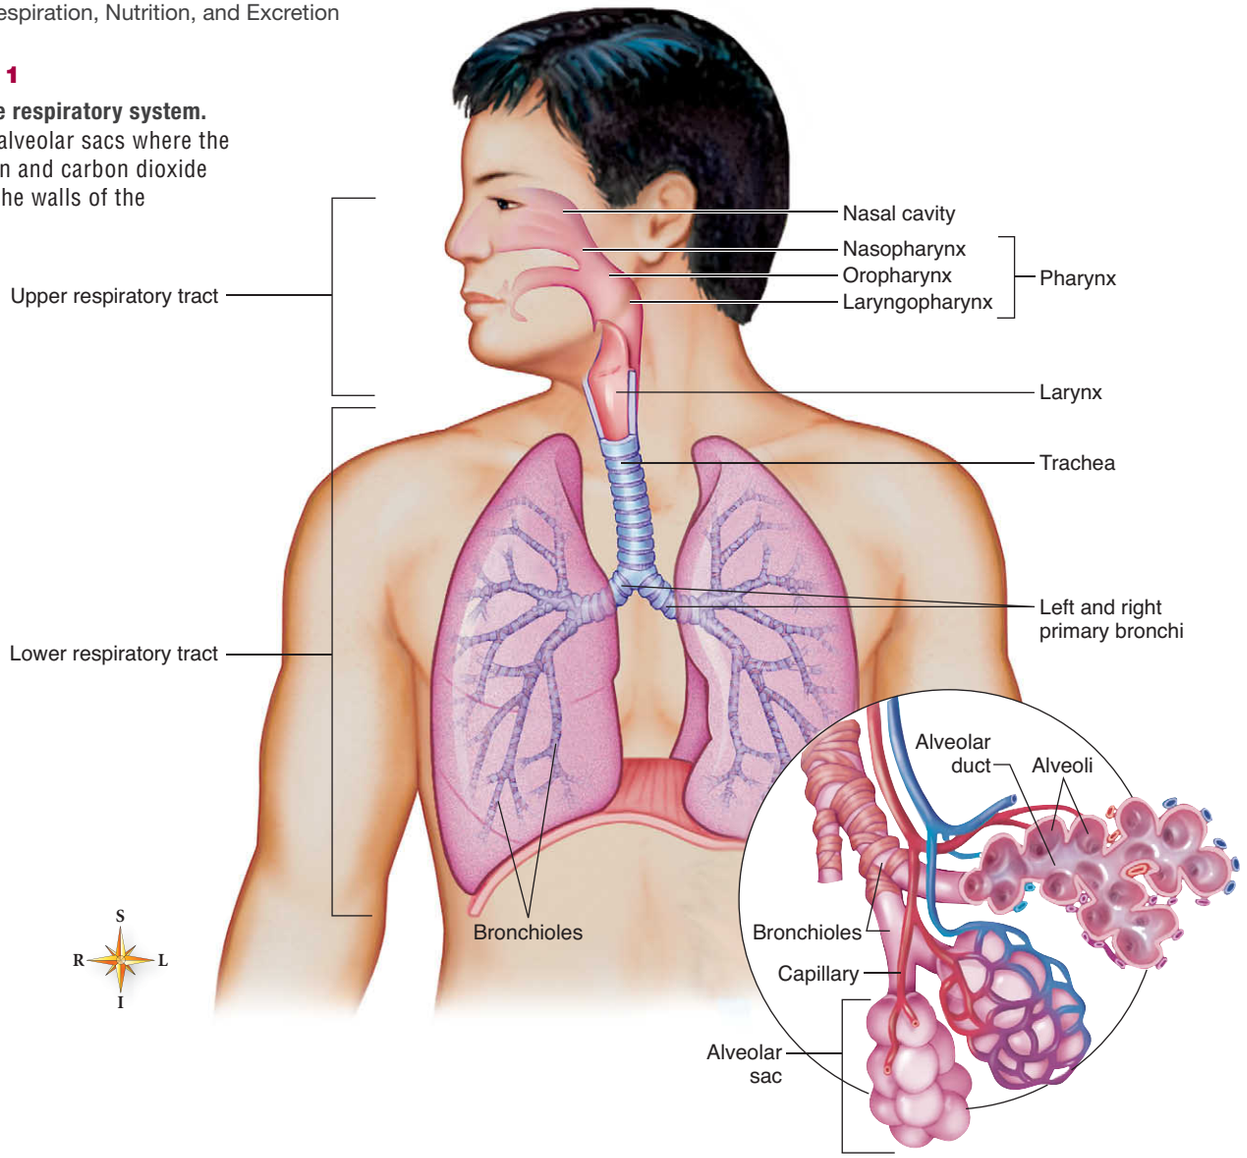
UPPER RESPIRATORY TRACT

Nose

STRUCTURE OF THE NOSE

The nose has external and internal structures. The external portion, that is, the part that protrudes from the face, consists of a bony and cartilaginous framework overlaid by skin containing many sebaceous glands (Box 26-1). The two nasal bones meet in the center of the face just below the forehead, where they are surrounded by the frontal bone to form the root of the nose. The nose is surrounded by the maxilla laterally and inferiorly at its base. The flaring cartilaginous expansion forming and supporting the outer side of each oval nostril opening is called the *ala*.

The internal portion of the nose, or nasal cavity, lies over the roof of the mouth where the palatine bones, which form the floor of the nose and the roof of the mouth, separate the nasal cavities from the mouth cavity. Sometimes the palatine bones fail to unite completely and produce a condition known as **cleft palate.** When this abnormality exists, the mouth is only partially separated from the nasal cavity, and consequently, difficulties arise in swallowing and speaking.



The roof of the nose is separated from the cranial cavity by a portion of the ethmoid bone called the **cribriform plate** (Figures 26-2 and 26-3). The cribriform plate is perforated by many small openings that permit branches of the olfactory nerve responsible for the special sense of smell to enter the cranial cavity and reach the brain.

Separation of the nasal and cranial cavities by a thin, perforated plate of bone presents real hazards. If the cribriform plate is damaged as a result of trauma to the nose, it is possible for potentially infectious material to pass directly from the nasal cavity into the cranial fossa and infect the brain and its covering membranes.

The hollow nasal cavity is separated by a midline partition, the **septum** (see Figure 26-2), into right and left cavities. Note in Figure 26-2 that the nasal septum is made up of four main structures: the perpendicular plate of the ethmoid bone above, the vomer bone, and the septal nasal and vomeronasal cartilages below. In the adult the nasal septum is frequently deviated to one

FIGURE 26-1

Structural plan of the respiratory system. The inset shows the alveolar sacs where the interchange of oxygen and carbon dioxide takes place through the walls of the grapelike alveoli.

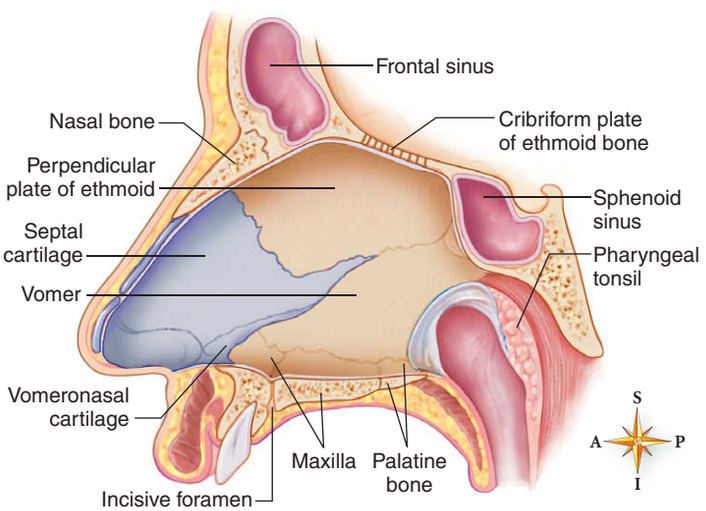


FIGURE 26-2

Nasal septum. The nasal septum consists of the perpendicular plate of the ethmoid bone, the vomer, and the septal and vomeronasal cartilages.

side or the other, interfering with respiration and with drainage of the nose and sinuses. The nasal septum has a rich blood supply. Nosebleeds, or *epistaxis*, often occur as a result of septal contusions caused by a direct blow to the nose. Epistaxis may also result from weak blood vessels combined with high blood pressure. Though seemingly dramatic, nosebleeds are seldom a serious health problem.

Each nasal cavity is divided into three passageways named the *superior*, *middle*, and *inferior meatuses*. These incomplete tubes are formed by the projection of the **conchae,** or **turbinates,** curving from the lateral walls of the internal portion of the nose (see Figure 26-3). The superior and middle conchae are processes of the ethmoid bone, whereas the inferior conchae are separate bones.

The external openings into the nasal cavities, commonly referred to as nostrils, have the technical name of *anterior nares*

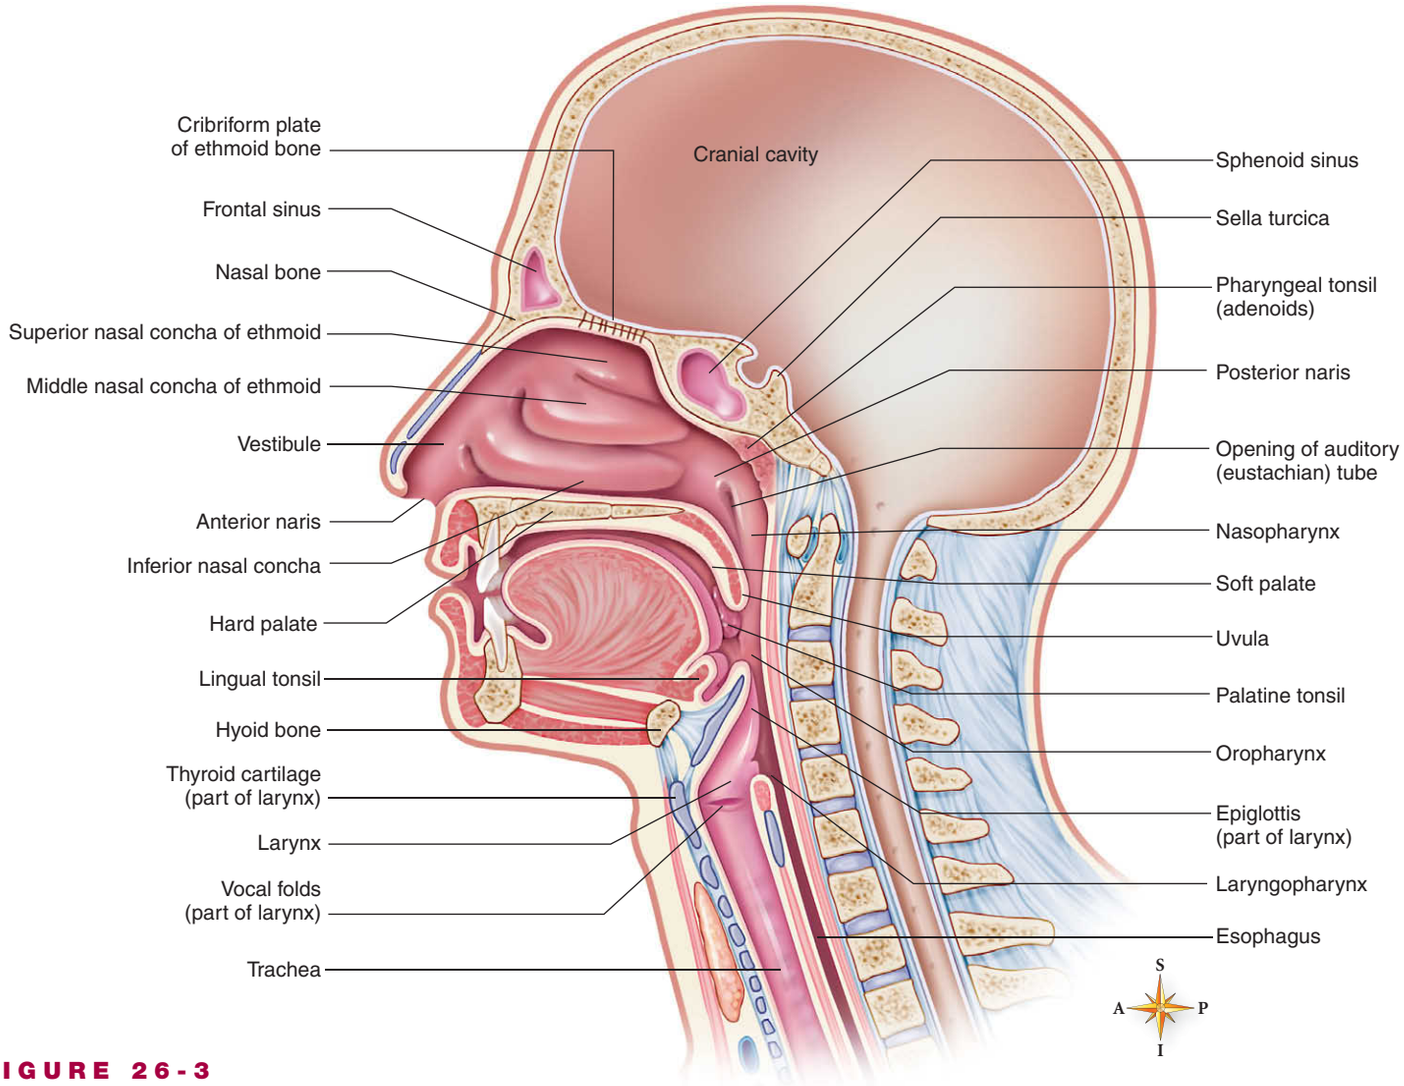

FIGURE 26-3

Upper respiratory tract. In this midsagittal section through the upper respiratory tract, the nasal septum has been removed to reveal the turbinates (nasal conchae) of the lateral wall of the nasal cavity. The three divisions of the pharynx (nasopharynx, oropharynx, and laryngopharynx) are also visible.

(singular, *naris*). They are sometimes called *external nares*. The anterior nares open into an area covered by skin that is reflected from the wings (ala) of the nose. This area, called the **vestibule,** is located just inside the nasal cavity below the inferior meatus. The vestibule is lined with skin. Coarse hairs called **vibrissae,** sebaceous glands, and numerous sweat glands are found in the skin of the vestibule. Once air has passed over the skin of the vestibule, it enters the **respiratory portion** of each nasal passage. This area extends from the inferior meatus to the small funnel-shaped orifices of the *posterior (internal) nares*. The posterior nares are openings that allow air to pass from the nasal cavity into the next major segment of the upper respiratory tract—the pharynx.

If one were to "trace" the movement of air through the nose into the pharynx, it would be found that air passes through several structures on the way. The sequence is as follows:

1. Anterior (external) nares
2. Vestibule
3. Inferior, middle, and superior meatuses, simultaneously
4. Posterior (internal) nares

Nasal Mucosa

Once air has passed over the skin of the vestibule and enters the respiratory portion of the nasal passage, it passes over the **respiratory mucosa.** This mucous membrane has a pseudostratified ciliated columnar epithelium rich in goblet cells (Figure 26-4). The respiratory mucosa possesses a rich blood supply, especially over the inferior turbinate, and is bright pink or red. Near the roof of the nasal cavity and over the superior turbinate and opposing portion of the septum, the mucosa turns pale and has a yellowish tint. In this area it is referred to as the **olfactory epithelium.** This membrane contains many olfactory nerve cells and has a rich lymphatic plexus. Ciliated mucous membrane lines the rest of the respiratory tract down as far as the smaller bronchioles.

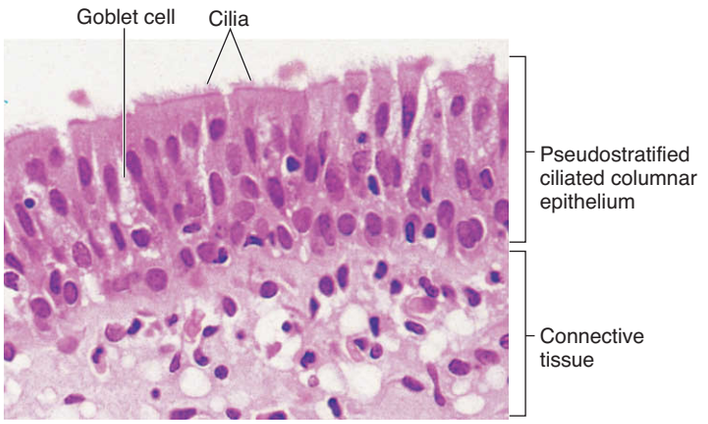

FIGURE 26-4

Respiratory mucosa. This epithelium is typically ciliated and exhibits numerous goblet cells that produce and release mucus.

| A&P CONNECT |

Besides the olfactory sensory neurons imbedded in the nasal mucosa, a structure called the *vomeronasal organ (VNO)* is located in the mucosa of the inferior nasal septum. The VNO is thought to be involved in sensing pheromones, which are sex signaling chemicals. Want to know more? Check out ***Pheromones and the Vomeronasal Organ*** and ***Nerve Zero*** online at ***A&P Connect.***

evolve

Paranasal Sinuses

The four pairs of **paranasal sinuses** are air-containing spaces that lighten the weight of the skull and open, or drain, into the nasal cavity. They take their names from the skull bones in which they are located (see Chapter 9). These paranasal sinuses are the frontal, maxillary, ethmoid, and sphenoid sinuses (Figure 26-5). Like the nasal cavity, each paranasal sinus is lined by respiratory mucosa. The mucous secretions produced in the sinuses are continually being swept into the nose by the ciliated surface of the respiratory membrane.

The right and left frontal sinuses are located just above the corresponding orbit, whereas the maxillary, the largest of the sinuses, extends into the maxilla on either side of the nose. The sphenoid sinuses lie in the body of the sphenoid bone on either side of the midline in close proximity to the optic nerves and pituitary gland.

Note in Figure 26-5 that the ethmoid sinuses are not single large cavities but a collection of small air cells divided into anterior, middle, and posterior groups that open independently into the upper part of the nasal cavity (Box 26-2). The paranasal sinuses drain as follows:

- Into the middle meatus (passageway below the middle concha)—frontal, maxillary, anterior, and middle ethmoidal sinuses
- Into the superior meatus—posterior ethmoidal sinuses
- Into the space above the superior conchae (sphenoethmoidal recess)—sphenoid sinuses

Box 26-2 | FYI

Development of the Paranasal Sinuses

The paired and often asymmetrical sinuses are small or rudimentary at birth but increase in size with growth of the skull. Although fairly well developed by 7 years of age, they do not reach maximal size until after puberty. In adults, the sinuses are subject to considerable variation in size and shape.

FUNCTIONS OF THE NOSE

The nose serves as a passageway for air going to and from the lungs. However, if the nasal passages are obstructed, it is possible for air to bypass the nose and enter the respiratory tract directly through the mouth.

Air that enters the system through the nasal cavity is filtered of impurities, warmed, moistened, and chemically examined (by olfaction) to detect substances that might prove irritating to the delicate lining of the respiratory tract. The vibrissae, or *nasal hairs*, in the vestibule serve as an initial "filter" that screens particulate matter from air that is entering the system. The conchae, or turbinates, then serve as baffles to slow and stir the air—as well as provide a large mucus-covered surface area over which air must pass before reaching the pharynx. The respiratory membrane produces copious quantities of mucus and possesses a rich blood supply, especially over the inferior conchae, which permits rapid warming and moistening of the dry inspired air. Mucous secretions provide the final "trap" where some of the remaining particulate matter from air is removed as it travels through the nasal passages. Fluid from the lacrimal glands (see Figure 17-19 on p. 525) and additional mucus produced in the paranasal sinuses also help trap particulate matter and moisten air passing through the nose.

In addition, the hollow sinuses act to lighten the bones of the skull and serve as resonating chambers for speech. Swirling of air by the middle and superior conchae over the olfactory epithelium makes the special sense of olfaction possible.

| QUICK CHECK |

1. What are the overall functions of the respiratory system? Which other body system is involved in accomplishing these functions?
2. Name the principal organs of the upper respiratory tract. Name the principal organs of the lower respiratory tract.
3. Describe the paranasal sinuses. What is their anatomical relationship to the nose?

Pharynx

STRUCTURE OF THE PHARYNX

Another name for the **pharynx** is the throat. It is a tubelike structure about 12.5 cm (5 inches) long that extends from the base of the skull to the esophagus and lies just anterior to the cervical vertebrae. It is made of muscle and is lined with mucous membrane.

The pharynx has three anatomical divisions. The **nasopharynx** is located behind the nose and extends from the posterior nares to the

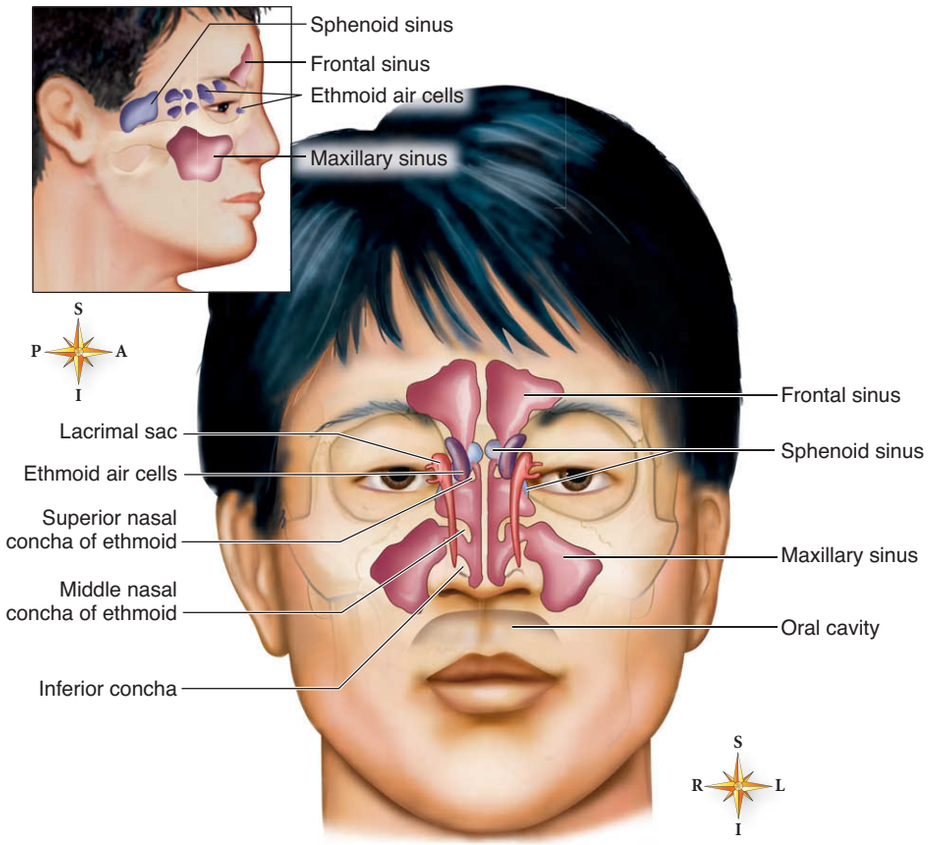

FIGURE 26-5

The paranasal sinuses. The anterior view shows the anatomical relationship of the paranasal sinuses to each other and to the nasal cavity. The inset is a lateral view of the position of the sinuses.

level of the soft palate. The **oropharynx** is located behind the mouth from the soft palate above to the level of the hyoid bone below. Finally, the **laryngopharynx** extends from the hyoid bone to the esophagus. Figure 26-3 shows the divisions of the pharynx.

Seven openings are found in the pharynx (see Figure 26-3):

- Right and left auditory (eustachian) tubes opening into the nasopharynx
- Two posterior nares opening into the nasopharynx
- The opening from the mouth, known as the fauces, into the oropharynx
- The opening into the larynx from the laryngopharynx
- The opening into the esophagus from the laryngopharynx

The **pharyngeal tonsils** are located in the nasopharynx on its posterior wall opposite the posterior nares. The pharyngeal tonsils are referred to as *adenoids* when they are enlarged. Although the cavity of the nasopharynx differs from the oral and laryngeal divisions in that it does not collapse, it still may become obstructed. If these tonsils enlarge to become adenoids, they may fill the space behind the posterior nares and make it difficult or even impossible for air to travel from the nose into the throat. You may want to review details of the structure and function of tonsils in Chapter 23.

Two pairs of organs are found in the oropharynx: the **palatine tonsils,** located behind and below the pillars of the fauces, and the **lingual tonsils,** located at the base of the tongue. The palatine tonsils are the ones most commonly removed in the procedure referred to as a tonsillectomy. Only rarely are the lingual tonsils also removed.

FUNCTIONS OF THE PHARYNX

The pharynx serves as a common pathway for the respiratory and digestive tracts, because both air and food must pass through this structure before reaching the appropriate tubes—the trachea (air) and esophagus (food). It also affects phonation (speech production). For example, only by changing the shape of the pharynx can the different vowel sounds of speech be formed.

Larynx

LOCATION OF THE LARYNX

The **larynx,** or voice box, lies between the root of the tongue and the upper end of the trachea just below and in front of the lowest part of the pharynx (see Figure 26-1). It might be described as a vestibule opening into the trachea from the pharynx. It normally extends between the third, fourth, fifth, and sixth cervical vertebrae but is often positioned somewhat higher in females and during childhood for both genders. The lateral lobes of the thyroid gland and the carotid artery within its covering sheath touch the sides of the larynx.

STRUCTURE OF THE LARYNX

The triangle-shaped larynx consists largely of cartilages that are attached to one another and to surrounding structures by muscles or

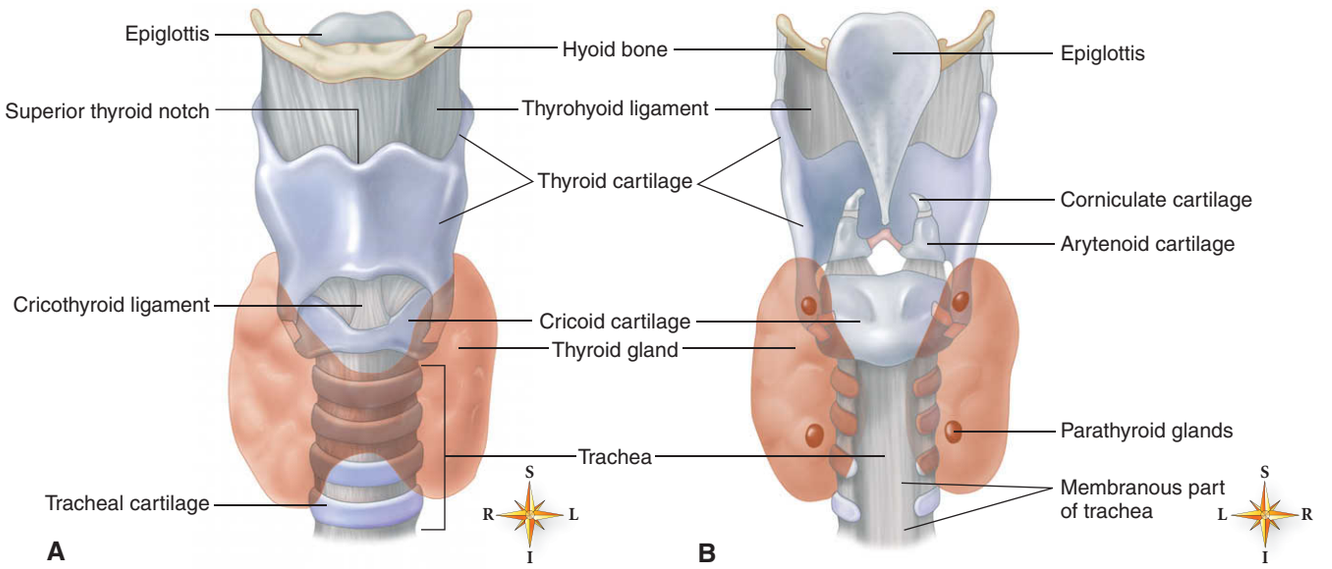

FIGURE 26-6

Laryngeal cartilages. Some softer tissues of the larynx and surrounding structures have been removed to make it possible to see the cartilages of the larynx. Note the position of the nearby thyroid gland. **A,** Anterior view. **B,** Posterior view.

by fibrous and elastic tissue components (Figure 26-6). It is lined by a ciliated mucous membrane. The cavity of the larynx extends from its triangle-shaped inlet at the epiglottis to the circular outlet at the lower border of the cricoid cartilage, where it is continuous with the lumen of the trachea (Figure 26-7).

The larynx is lined primarily with respiratory mucosa—pseudostratified ciliated columnar epithelium. The mucous membrane lining the larynx forms two pairs of lateral folds that jut inward into its cavity. The upper folds are called the **vestibular folds.** They are also sometimes called the *false vocal folds* for the rather obvious reason that they play no part in vocalization. The lower pair serves as the **vocal folds,** which produce sounds needed for speech and other vocalizations. The vocal folds are sometimes called the *true vocal folds* or simply *vocal cords.* Each vocal fold is covered with nonkeratinized stratified squamous epithelium and supported at its medial edge by a strong *vocal ligament.* The slitlike space between the left and right vocal folds, called the *rima glottidis,* is the narrowest part of the larynx.

The vocal folds and the space between them (rima glottidis) are together designated as the **glottis.** An endoscopic view of the vocal folds and related structures is shown in Figure 26-8, *B*.

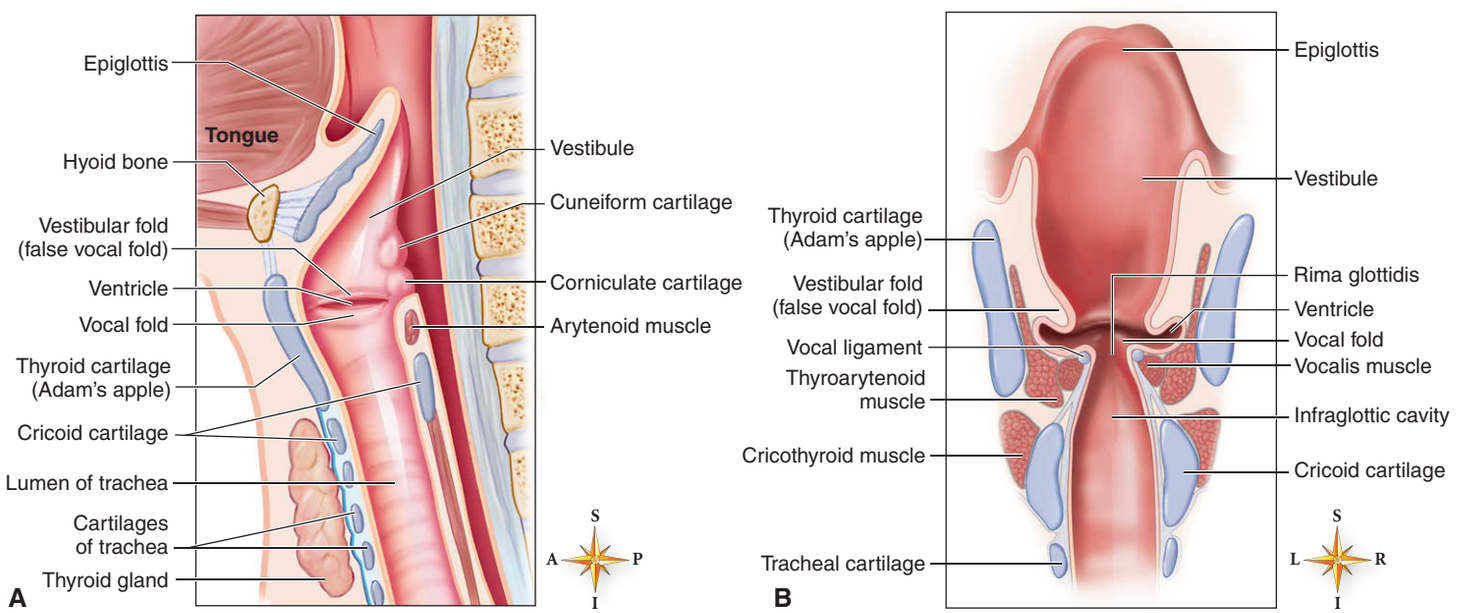

FIGURE 26-7

Larynx. These illustrations depict the mucosal lining of the larynx, with its folds and underlying muscles and ligaments visible. **A,** Sagittal section. **B,** Frontal section, viewed from behind.

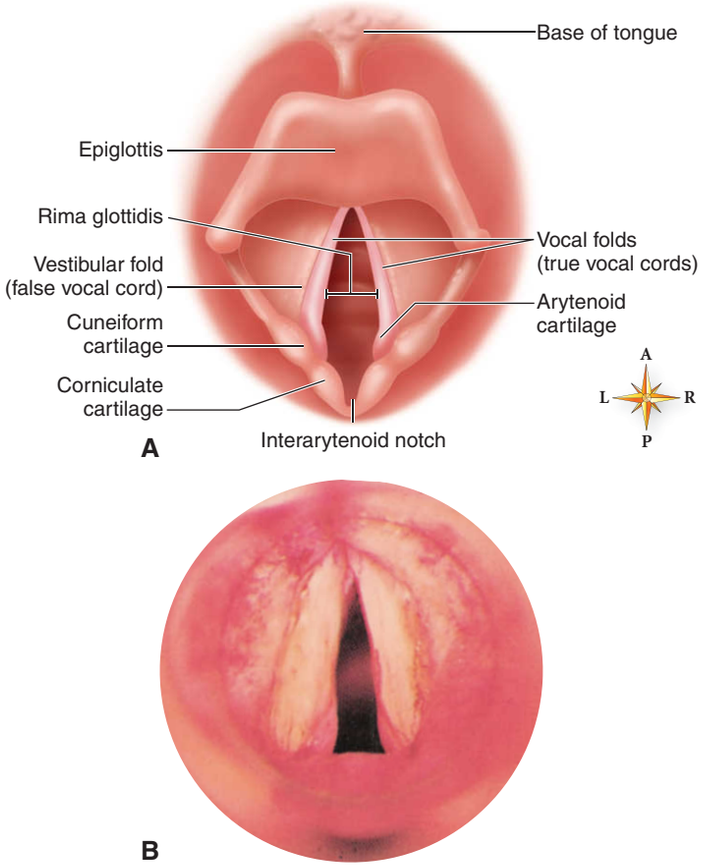

FIGURE 26-8

Vocal folds. A, Vocal folds viewed from above. **B,** Photograph taken with an endoscope showing the vocal folds in the open position.

The laryngeal cavity above the vestibular folds is called the **vestibule.** The very short middle portion of the cavity between the vestibular and vocal folds is the **ventricle** of the larynx, or *laryngeal ventricle.* The *infraglottic cavity* is the open space below the glottis.

CARTILAGES OF THE LARYNX

Nine cartilages form the framework of the larynx. The three largest—the thyroid cartilage, the epiglottis, and the cricoid cartilage—are single structures. The other six are three pairs of smaller accessory cartilages, namely, the arytenoid, corniculate, and cuneiform cartilages.

- The **thyroid cartilage** (Adam's apple) is the largest cartilage of the larynx and is the one that gives the characteristic triangular shape to its anterior wall. It is usually larger in men than in women and has less of a fat pad lying over it—two reasons that a man's thyroid cartilage protrudes more than a woman's.
- The **epiglottis** is a small leaf-shaped cartilage that projects upward behind the tongue and hyoid bone. It is attached below to the thyroid cartilage, but its free superior border can flex to move up and down during swallowing to prevent food or liquids from entering the trachea (see Figures 26-6 and 26-7). The epiglottis is covered with nonkeratinized stratified squamous epithelium.
- The pyramid-shaped **arytenoid** cartilages are the most important of the paired laryngeal cartilages. The base of each cartilage articulates with the superior border of the cricoid cartilage (see Figure 26-6). The anterior angles of these cartilages serve as points of attachment for the vocal folds.

MUSCLES OF THE LARYNX

The muscles of the larynx are often divided into intrinsic and extrinsic groups. Intrinsic muscles have both their origin and insertion on the larynx. They are important in controlling vocal fold length and tension and in regulating the shape of the laryngeal inlet. Extrinsic muscles insert on the larynx but have their origin on some other structure—such as the hyoid bone. Therefore, contraction of the extrinsic muscles actually moves or displaces the larynx as a whole. Muscles in both groups play important roles in respiration, vocalization, and swallowing. During swallowing, for example, contraction of the intrinsic aryepiglottic muscles (those that connect the arytenoid cartilages with the epiglottis) prevents entry of food or fluid into the trachea by squeezing the laryngeal inlet shut.

Two other pairs of intrinsic laryngeal muscles function to open and close the glottis by adducting or abducting the vocal folds. These events are crucial to both respiration and voice production. Certain other intrinsic muscles of the larynx function to influence the pitch of the voice by either lengthening and tensing or shortening and relaxing the vocal folds.

FUNCTIONS OF THE LARYNX

The larynx functions in respiration because it constitutes part of the vital airway to the lungs. This unique passageway, like the other components of the upper respiratory tract, is lined with a ciliated mucous membrane that helps in removal of dust particles and in warming and humidification of inspired air. In addition, it protects the airway against the entrance of solids or liquids during swallowing.

It also serves as the organ of voice production—hence its popular name, the *voice box.* Air being expired through the glottis, narrowed by partial adduction of the vocal folds, causes them to vibrate. Their vibration produces the voice. Several other structures besides the larynx contribute to the sound of the voice by acting as sounding boards or resonating chambers. Thus the size and shape of the nose, mouth, pharynx, and bony sinuses help determine the quality of the voice.

| A&P CONNECT |

Edema (swelling) of the mucosa covering the vocal folds and other laryngeal tissues can be a potentially lethal condition. Even a moderate amount of swelling can obstruct the glottis so much that air cannot get through and asphyxiation results. To find out more, check out ***Swollen Larynx*** online at ***A&P Connect.***

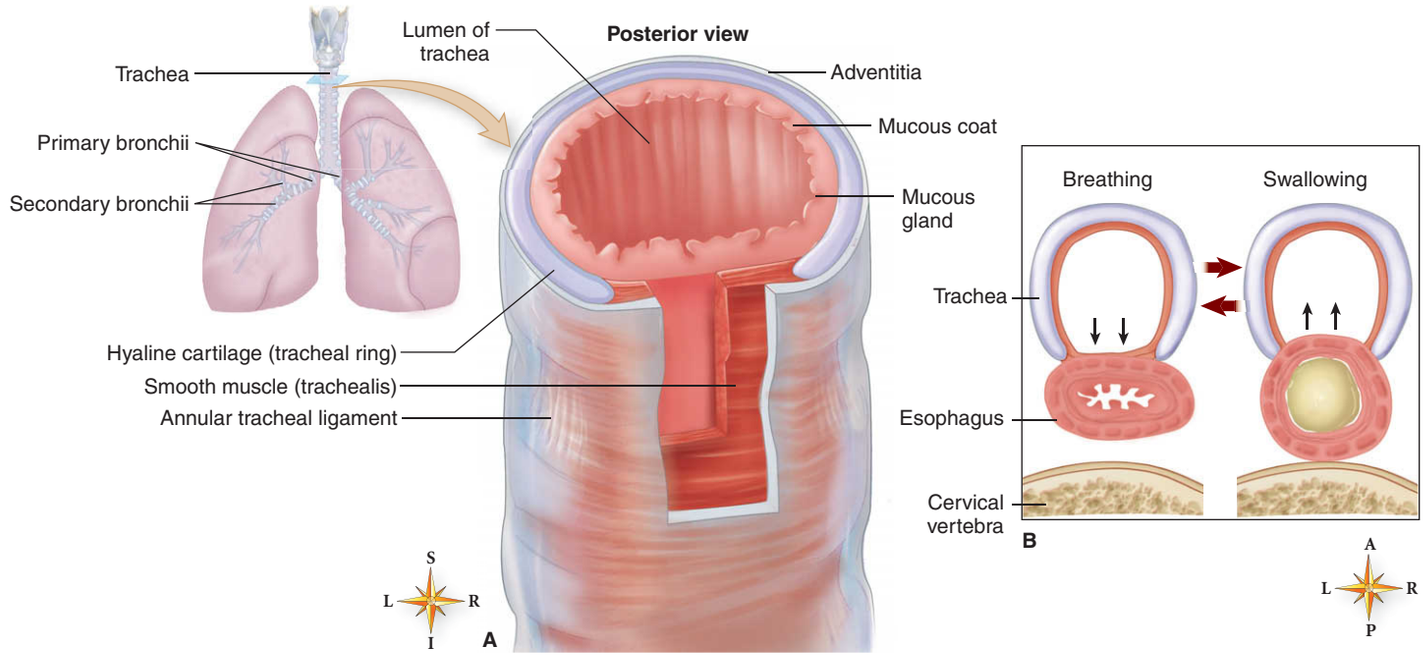

FIGURE 26-10

Cross section of the trachea. The inset at the top shows where the section was cut. **A,** Structure of the trachea. **B,** Incomplete tracheal rings and elasticity of posterior tracheal wall allow the esophagus to expand during swallowing.

LOWER RESPIRATORY TRACT

Trachea

STRUCTURE OF THE TRACHEA

The **trachea,** or windpipe, is a tube about 11 cm (4.5 inches) long that extends from the larynx in the neck to the primary bronchi in the thoracic cavity (Figure 26-9). Its diameter measures about 2.5 cm (1 inch).

The outside of the tracheal wall is covered in a fibrous *adventitia*. Smooth muscle, in which are embedded C-shaped rings of cartilage at regular intervals, makes up most of the wall of the trachea (Figure 26-10, A). The posterior wall also contains many elastic fibers.

The cartilaginous rings are incomplete on the posterior surface (look back at Figure 26-6, *B*). They give firmness to the wall and tend to prevent it from collapsing and shutting off the vital airway. The fact that the rings are incomplete allows the esophagus, which runs just posterior to the trachea, to expand as food moves toward the stomach during swallowing (Figure 26-10, *B*).

The trachea is lined with *respiratory mucosa*. This type of mucosa is characterized by pseudostratified ciliated columnar epithelium and is typical of the respiratory tract as a whole (Figure 26-11).

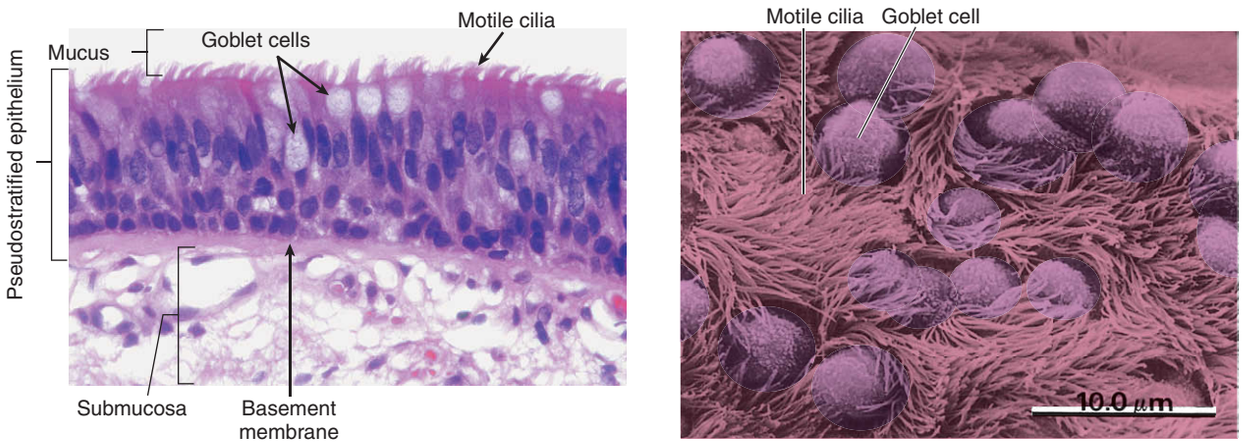

FIGURE 26-11

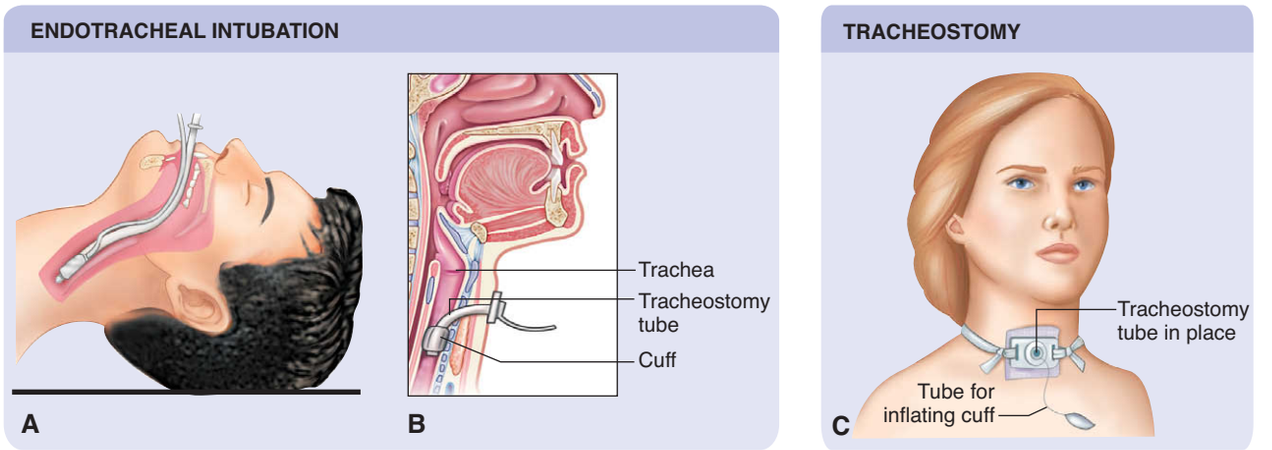

Respiratory mucosa. **A,** Light micrograph (×200) and **B,** Scanning electron micrograph (×2000) of respiratory mucosa. Note the numerous motile (moving) cilia and mucus-producing goblet cells.

Box 26-3 | HEALTH matters

Keeping the Trachea Open

Often, a tube is placed through the mouth, pharynx, and larynx into the trachea before patients leave the operating room, especially if they have been given a muscle relaxant. This procedure is called **endotracheal intubation.** The purpose of the tube is to ensure an open airway (see parts *A* and *B* of the figure). To ensure that the tube enters the trachea rather than the nearby esophagus (which leads to the stomach), anatomical landmarks such as the vocal folds are visualized. Likewise, the distinct feel of the V-shaped groove called the *interarytenoid notch* (see Figure 26-8, *A*) can help guide the proper insertion of the tube.

Another procedure done frequently in today's modern hospitals is a **tracheostomy,** that is, the cutting of an opening into the trachea (part *C* of the figure). A surgeon may perform this procedure so that a suction device can be inserted to remove secretions from the bronchial tree or so that mechanical ventilation can be used to improve ventilation of the lungs.

FUNCTION OF THE TRACHEA

The trachea performs a simple, but vital function—it furnishes part of the open passageway through which air can reach the lungs from the outside. Obstruction of this airway for even a few minutes causes death from asphyxiation (Box 26-3).

Bronchi and Alveoli

STRUCTURE OF THE BRONCHI

The trachea divides at its lower end into two **primary bronchi,** the right bronchus being slightly larger and more vertical than the left. This anatomical fact helps explain why aspirated foreign objects frequently lodge in the right bronchus.

In structure the bronchi resemble the trachea. The bronchi walls have incomplete cartilaginous rings in the sections superior to the lungs, but have complete rings in the sections within the lungs. Ciliated mucosa lines the bronchi, as it does the trachea.

Each primary bronchus enters the lung on its respective side and there immediately divides into smaller branches called **secondary bronchi.** The secondary bronchi continue to branch and form tertiary bronchi and then small **bronchioles.** The trachea and the two primary bronchi and their many branches resemble an inverted tree trunk with its branches and are therefore spoken of as the **bronchial tree** (Figure 26-12).

There are 23 levels of branching in the bronchial tree, producing a huge number of tiny bronchioles. As these bronchioles subdivide into smaller and smaller tubes, they eventually terminate in microscopic branches sometimes called *terminal bronchioles.* The terminal bronchioles are the last branches that serve solely to conduct air.

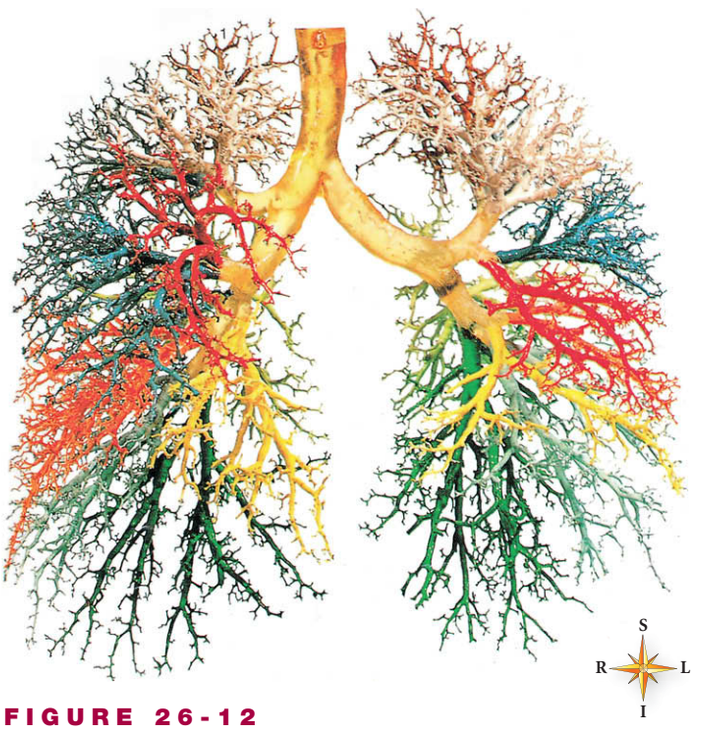

FIGURE 26-12

Plastic cast of air spaces of the lungs. The cast was prepared by pouring liquid plastic into the airways of a human lung—a different color for each bronchopulmonary segment supplied by its own tertiary bronchus. After the plastic hardened, the soft tissue was removed, leaving the branched form of the lower respiratory tract that is pictured here (compare with Figure 26-17).

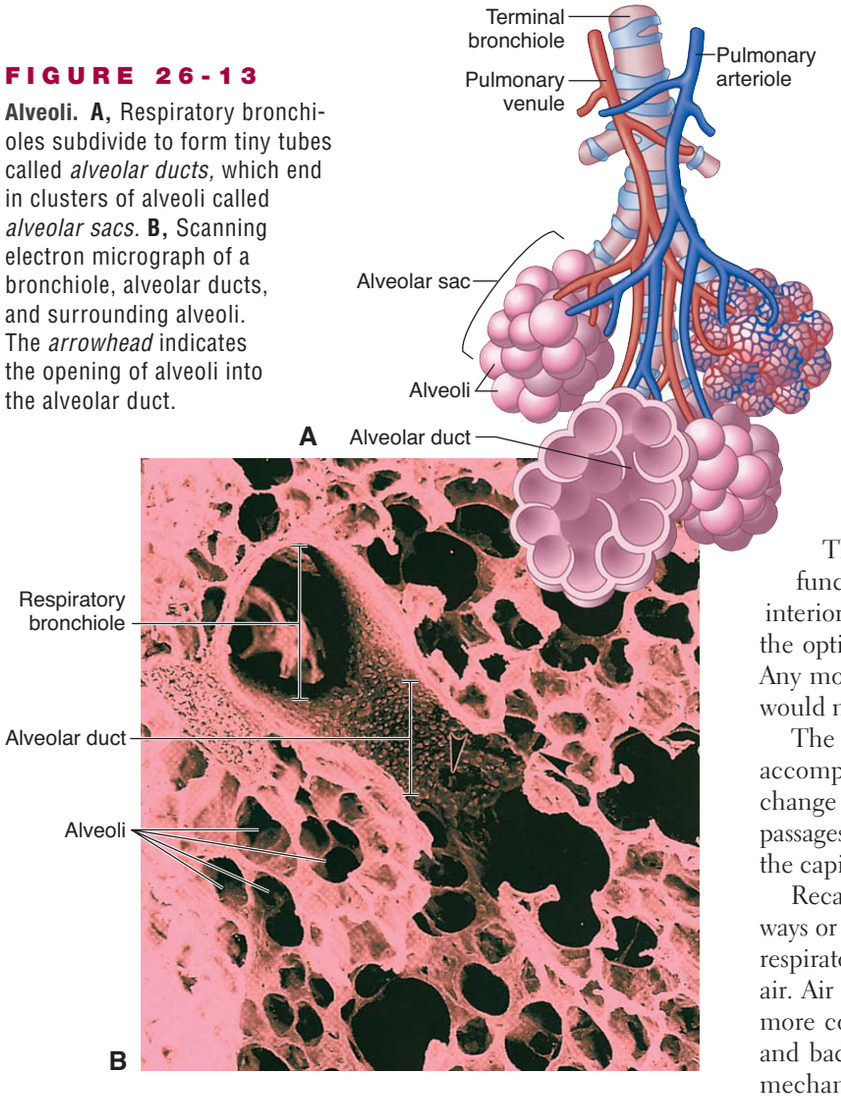

FIGURE 26-13

Alveoli. A, Respiratory bronchioles subdivide to form tiny tubes called *alveolar ducts,* which end in clusters of alveoli called *alveolar sacs.* **B,** Scanning electron micrograph of a bronchiole, alveolar ducts, and surrounding alveoli. The *arrowhead* indicates the opening of alveoli into the alveolar duct.

The terminal bronchioles divide into *respiratory bronchioles* that have thin, gas-exchanging walls. The respiratory bronchioles proceed onward into **alveolar ducts,** which end in one or more alveolar sacs, the walls of which consist of numerous **alveoli** grouped together like a bunch of hollow grapes (Figure 26-13; see also Figure 26-1). Some 300 million alveoli are estimated to be present in our two lungs.

The structure of the secondary and tertiary bronchi and bronchioles shows some modification of the primary bronchial structure. The cartilaginous rings become irregular and disappear entirely into the smaller bronchioles. By the time the branches of the bronchial tree dwindle to form the respiratory bronchioles, alveolar ducts and sacs, and the alveoli, only the internal surface layer of cells remains. In other words, the walls of these microscopic structures consist of a single layer of simple, squamous epithelial tissue (Figures 26-13 and 26-14). As we shall see, this structural fact makes it possible for them to perform their functions.

STRUCTURE OF THE ALVEOLI

The alveoli are the primary gas exchange structures of the respiratory tract (Figures 26-14 and 26-15). Alveoli are very effective in exchanging carbon dioxide (CO_2) and oxygen (O_2) because each alveolus is extremely thin walled, each alveolus lies in contact with blood capillaries, and there are millions of alveoli in each lung.

The barrier across which gases are exchanged between alveolar air and blood is called the **respiratory membrane** (see Figure 26-15, *inset*). The respiratory membrane consists of the alveolar epithelium, the capillary endothelium, and their joined basement membranes.

The surface of the respiratory membrane inside each alveolus is coated with a fluid containing **surfactant** produced by *type II cells* of the alveolar wall. Surfactant helps reduce surface tension—the force of attraction between water molecules—of the fluid. Thus it helps prevent each alveolus from collapsing and "sticking shut" as air moves in and out during respiration. In the next chapter, we explore this important role of surfactant further.

FUNCTIONS OF THE BRONCHI AND ALVEOLI

The tubes composing the bronchial tree perform the same function as the trachea—that of distributing air to the lung's interior. Calculations show that 23 levels of branching produce the optimum ability to transfer oxygen to the pulmonary blood. Any more or any fewer levels of branching in the bronchial tree would not be as efficient for oxygen exchange in the lungs.

The alveoli, enveloped as they are by networks of capillaries, accomplish the lung's main and vital function, that of gas exchange between air and blood. It has been observed that "the lung passages all serve the alveoli" just as "the circulatory system serves the capillaries."

Recall that in addition to serving as air distribution passageways or gas exchange surfaces, the anatomical components of the respiratory tract and lungs cleanse, warm, and humidify inspired air. Air entering the nose is generally contaminated with one or more common irritants; examples include insects, dust, pollen, and bacterial organisms. A remarkably effective air purification mechanism removes almost every form of contaminant before inspired air reaches the alveoli or terminal air sacs in the lungs.

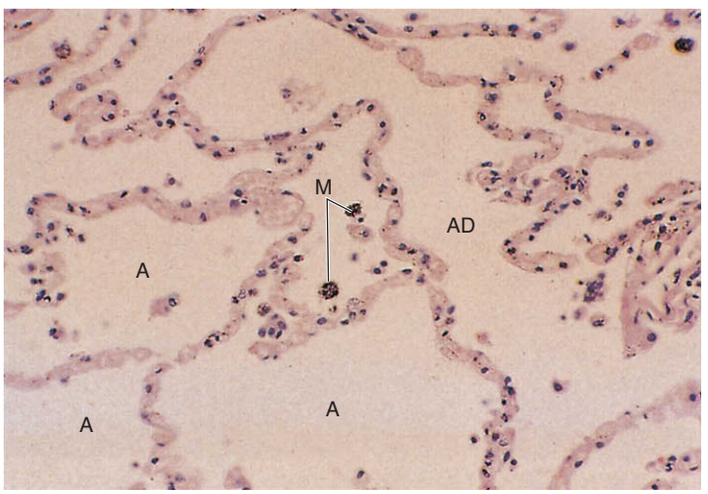

FIGURE 26-14

Micrograph of alveoli. Note the thin alveolar walls and open alveolar spaces **(A)**. An occasional macrophage **(M)**, which provides immune defense, can be seen in several of the alveolar spaces. **AD,** Alveolar duct.

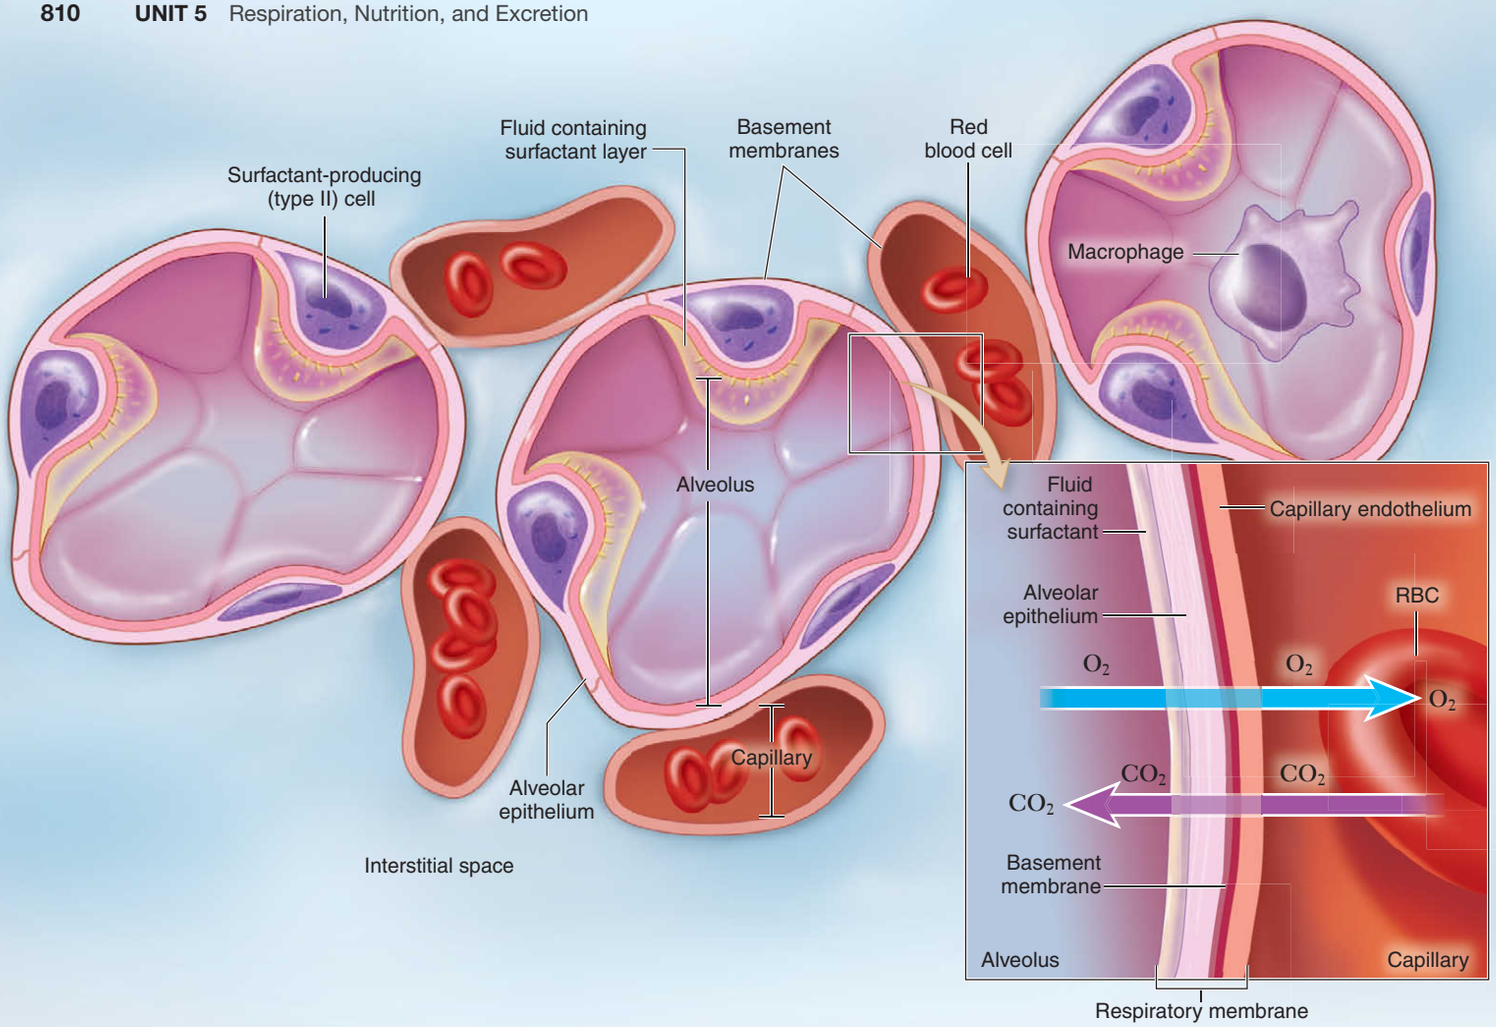

FIGURE 26-15

Gas exchange structures of the lung. Each alveolus is continually ventilated with fresh air. The inset shows a magnified view of the respiratory membrane composed of the alveolar wall (fluid coating, epithelial cells, and basement membrane), interstitial fluid, and the wall of a pulmonary capillary (basement membrane and endothelial cells). The gases—CO_2 (carbon dioxide) and O_2 (oxygen)—diffuse across the respiratory membrane.

The layer of protective mucus that covers a large portion of the membrane that lines the respiratory tree serves as the most important air purification mechanism. More than 125 ml of respiratory mucus is produced daily. It forms a continuous sheet, called a *mucus blanket*, that covers the lining of the air distribution tubes in the respiratory tree. This layer of cleansing mucus moves upward to the pharynx from the lower portions of the bronchial tree on millions of hairlike cilia that cover the epithelial cells in the respiratory mucosa (see Figure 26-11). The microscopic cilia that cover epithelial cells in the respiratory mucosa are motile, beating or moving in only one direction. The result is movement of mucus toward the pharynx—a mechanism sometimes called the *ciliary escalator*.

Respiratory cilia can "taste" bitter toxins and respond by moving more rapidly in an effort to clear the toxin molecules from the airway. Prolonged exposure to toxins, as with cigarette smoke, can paralyze the cilia. Eventually, the ciliary escalator begins to fail and accumulations of mucus trigger the typical smoker's cough, an effort to clear the secretions.

Additional information about the functional anatomy of each section of the respiratory tract can be found in Table 26-1.

| A&P CONNECT |

Because it is exposed to the external environment, the respiratory tract could be extremely vulnerable. Visualize how the respiratory tract defends itself in ***Protective Strategies of the Respiratory Tract*** online at ***A&P Connect.***

evolve

| QUICK CHECK |

7. How are the trachea and primary bronchi held open so that they do not collapse during inspiration?
8. What is meant by the term *bronchial tree?*
9. What characteristics of alveoli enable them to efficiently exchange gases with blood?

TABLE 26-1 Summary of Respiratory Tract Structures*

STRUCTURE	DESCRIPTION	FUNCTION
Upper respiratory tract	Portion of the respiratory tract outside the thoracic cavity	Processing of incoming air Conducts air to/from lungs Vocalization and phonation Olfaction
Nasal cavity	Lumen of nose, separated into left and right portions by nasal septum supported by cartilage, vomer, and perpendicular plate of ethmoid; supported laterally by nasal conchae	Conducts air between atmosphere (external environment) and pharynx Warms, humidifies, cleans inspired air
Anterior nares (external nares)	Nostrils External openings of nasal cavity	Boundary between external environment and nasal cavity
Vestibule	Extends from the anterior nares to the inferior meatus Supported by cartilage of septum and ala Lined with skin epidermis (keratinized stratified squamous epithelium) with vibrissae (hairs)	Conducts air between external environment and respiratory portion of nasal cavity Vibrissae prevent entry of large contaminants
Respiratory portion	Extends from vestibule to posterior nares Supported by bones of septum and nasal conchae, which curve to form meatuses Lined with highly vascular respiratory mucosa (pseudostratified ciliated columnar epithelium) Olfactory epithelium in superior lining contains numerous sensory receptors	Conducts air between vestibule and pharynx Meatuses create turbulence to assist processing of inspired air Mucosa warms, humidifies, and cleans inspired air Olfaction
Paranasal sinuses	Four pair of air-filled spaces within frontal, maxillary, ethmoid, and sphenoid bones of skull Lined with pseudostratified ciliated columnar epithelium Drain into the nasal cavity	Reduce weight of skull Help warm and humidify air
Posterior nares (internal nares)	Openings from the nasal cavity into the pharynx	Boundary between nasal cavity and pharynx
Pharynx	Throat Extends from posterior nares to the esophagus Supported by occipital bone and skeletal muscle Lined with mucous membrane (nonkeratinized stratified squamous epithelium)	Conducts air between nasal cavity and larynx
Nasopharynx	Segment of pharynx posterior to nasal cavity Pharyngeal tonsils in posterior wall	Conducts air between posterior nares and oropharynx
Oropharynx	Segment of pharynx posterior to oral cavity Pair of palatine tonsils in lateral walls Lingual tonsils in anterior wall, at base of tongue	Conducts air between nasopharynx and/or oral cavity and laryngopharynx
Laryngopharynx	Segment of pharynx posterior to opening of larynx and superior to opening of esophagus	Conducts air between oropharynx and larynx
Tonsils	Ring of individual aggregations of lymphoid nodules	Immune protection of respiratory and digestive mucosa (see Chapters 23 and 24)
Larynx	Voicebox Extends from laryngopharynx to trachea Supported by nine cartilages connected by muscle and ligaments Lined with mucosa (pseudostratified ciliated columnar epithelium, except epiglottis and vocal folds)	Conducts air between the pharynx and trachea Prevents food from entering lower airways Vocalization Ciliary escalator removes contaminants
Epiglottis	Flexible "lid" of larynx Covered/lined with nonkeratinized stratified squamous, transitioning through simple columnar to pseudostratified ciliated columnar epithelium at border with vestibule	Flexes during swallowing to cover larynx and prevent food from entering lower airways (see Chapter 29)
Vestibule	Extends from base of epiglottis to vestibular folds	Conducts air between pharynx and vestibular folds
Vestibular folds (false vocal folds)	Superior pair of lateral mucosal folds	Slow contaminants dripping toward lower airways
Ventricle (laryngeal ventricle)	Space between the vestibular folds and vocal folds	Conducts air between mucosal folds of larynx

*Listed in order of air flow during inspiration

(continued)

TABLE 26-1 Summary of Respiratory Tract Structures* *(continued)*

STRUCTURE	DESCRIPTION	FUNCTION
Upper respiratory tract (continued)		
Larynx *(continued)*		
Vocal folds (true vocal folds or vocal cords)	Inferior pair of lateral mucosal folds Each fold supported by skeletal muscle and strong *vocal ligament* at medial edge Covered with nonkeratinized stratified squamous epithelium Glottis: vocal folds and space between them (rima glottidis)	Prevent contaminants from entering lower airways Produce vibrations when pulled together during expiration (vocalization)
Infraglottic cavity	Segments below glottis, between vocal folds and trachea	Conducts air between vocal folds and trachea
Lower respiratory tract	Portion of respiratory tract within the thoracic cavity Also called *bronchial tree*	Conducts air to/from gas-exchange tissues of lungs
Trachea	Windpipe Extends from larynx to primary bronchi Supported by C-shaped cartilage rings Lined with respiratory mucosa (pseudostratified ciliated columnar epithelium)	Conduct air between the larynx and bronchi Ciliary escalator removes contaminants
Bronchi	Treelike branching of airways 23 levels of branching, producing a huge number of individual airways Supported by cartilage rings (incomplete outside lungs; complete inside lungs) Lined with respiratory mucosa (pseudostratified ciliated columnar epithelium)	Conduct air between trachea and lungs Ciliary escalator removes contaminants
Primary bronchi	Left and right branch from trachea, one to each lung	Conduct air to/from the lungs
Secondary bronchi (lobar bronchi)	Branches of the primary bronchi; three from the right, two from the left	Conduct air to/from the lobes of lungs
Tertiary bronchi (segmental bronchi)	Branches of the secondary bronchi	Conduct air to/from the various bronchopulmonary segments of lungs
Bronchioles	Smallest branches (20 levels of branching)	Conduct air to/from alveoli
Alveoli	Microscopic air spaces at terminals of bronchial tree Lined with simple squamous epithelium that joins with pulmonary capillary endothelium to form the respiratory membrane	Exchange of gases (CO_2, O_2) between air and pulmonary blood Surfactant lining alveoli prevents collapse of air spaces

*Listed in order of air flow during inspiration

Lungs

STRUCTURE OF THE LUNGS

The lungs are cone-shaped organs, large enough to fill the pleural portion of the thoracic cavity completely (see Figure 26-9). They extend from the diaphragm to a point slightly above the clavicles and lie against the ribs both anteriorly and posteriorly. The medial surface of each lung is roughly concave to allow room for the mediastinal structures and for the heart, but the concavity is greater on the left than on the right because of the position of the heart. The primary bronchi and pulmonary blood vessels (bound together by connective tissue to form what is known as the **root** of the lung) enter each lung through a slit on its medial surface called the **hilum.**

The broad inferior surface of the lung, which rests on the diaphragm, constitutes the **base,** whereas the pointed upper margin is the **apex** (Figure 26-16). Each apex projects above a clavicle (Figure 26-9, A). The **costal surface** of each lung lies against the ribs and is rounded to match the contours of the thoracic cavity.

Each lung is divided into lobes by fissures. The left lung is partially divided into two lobes (superior and inferior) and the

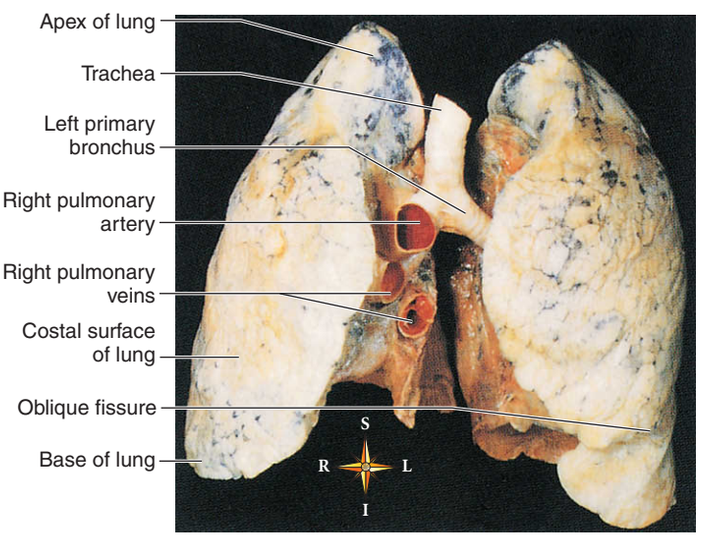

FIGURE 26-16

Anterior view of trachea, bronchi, and lungs. The lower respiratory tract has been dissected from a cadaver and its organs separated to show them clearly.

right lung into three lobes (superior, middle, and inferior). Note in Figure 26-17, *A*, that an **oblique fissure** is present in both lungs. In the right lung a **horizontal fissure** is also present that separates the superior from the middle lobe. After the primary bronchi enter the lungs, they branch into *secondary*, or *lobar*, bronchi that enter each lobe. Thus, in the right lung, three secondary bronchi are formed that enter the superior, middle, and inferior lobes. Each secondary bronchus is named for the lung lobe that it enters; for example, the superior secondary bronchus enters the superior lobe. The left primary bronchus divides into two secondary bronchi entering the superior and inferior lobes of that lung.

The lobes of the lung can be further subdivided into functional units called bronchopulmonary segments (see Figure 26-17, *B*). These segments may be called by their anatomically descriptive names (for example, *anterior segment of superior lobe*) or by Roman numerals. Both systems of naming the segments are shown in Figure 26-17, *B*.

Each bronchopulmonary segment is served by a separate *tertiary*, or *segmental*, bronchus. The interior of each bronchopulmonary segment consists of almost innumerable tubes of dwindling diameter that make up the bronchial tree and serve as air distributors. The smallest tubes terminate in the smallest, but

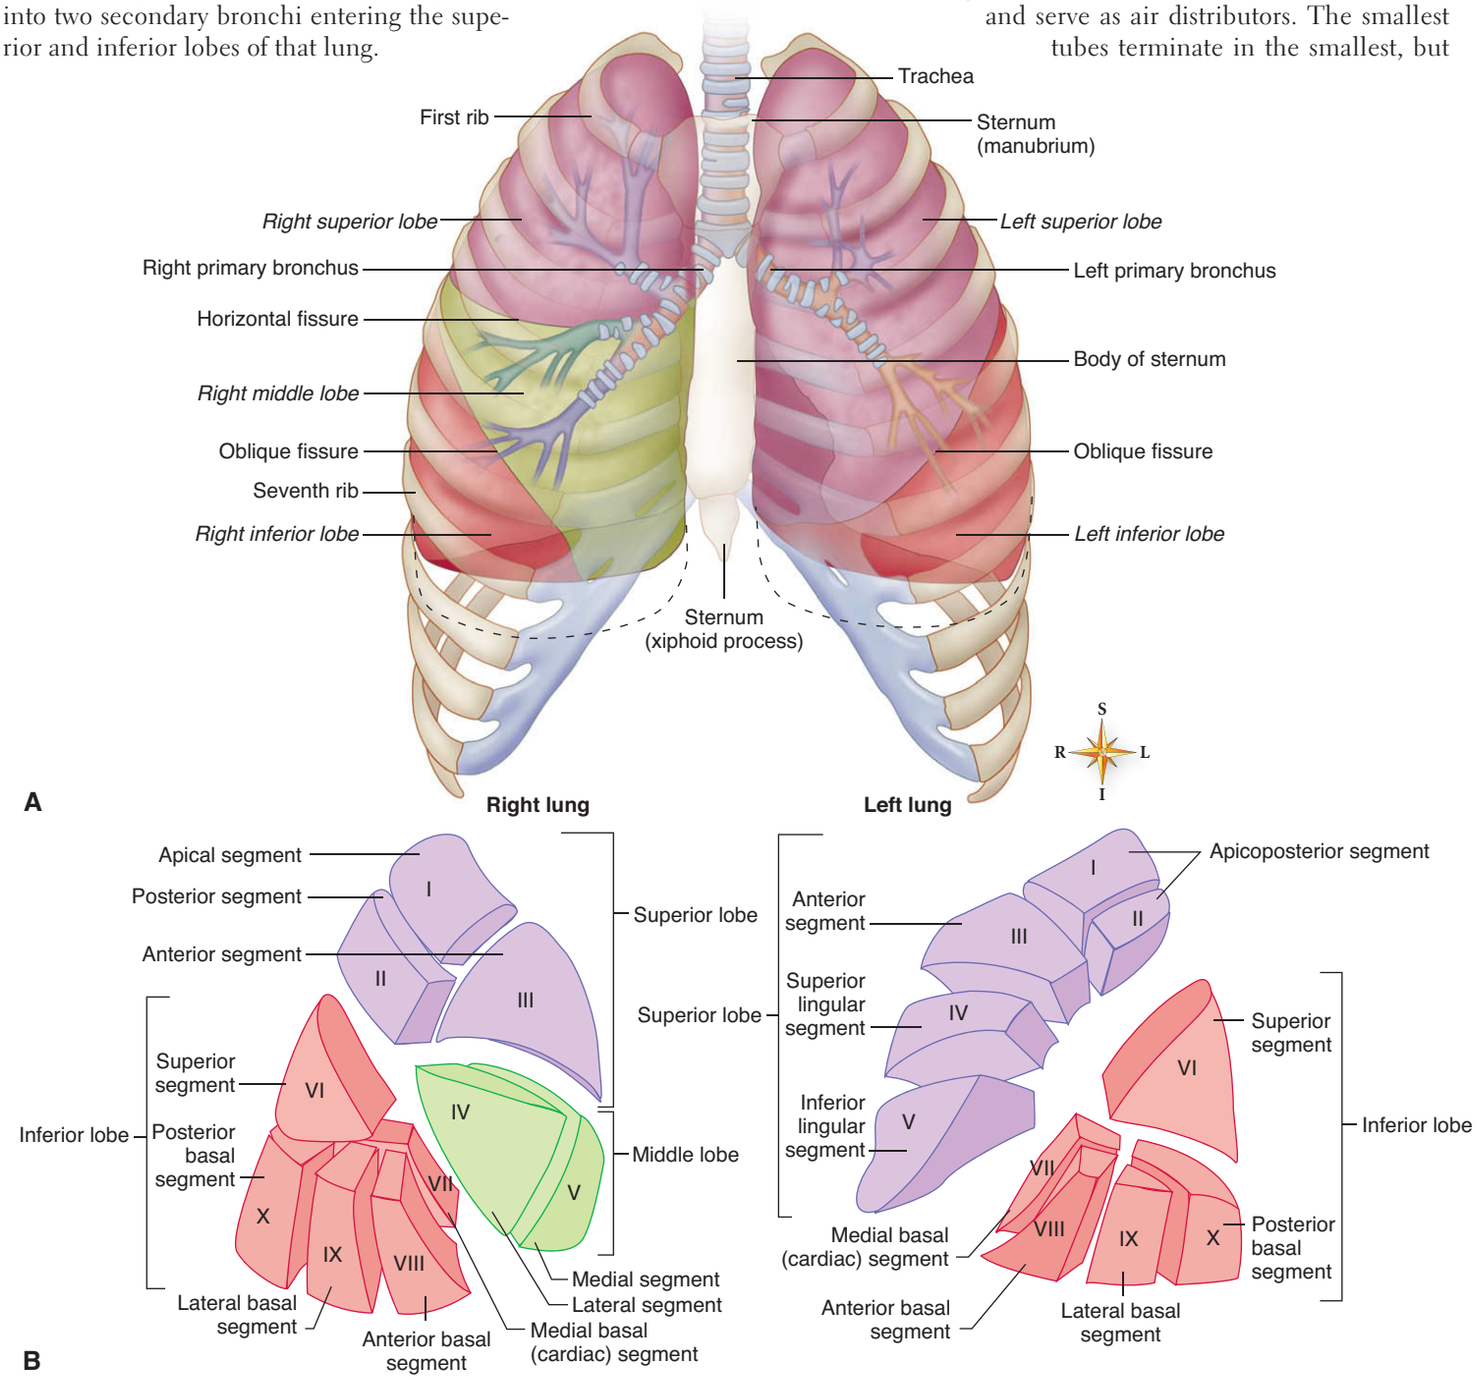

FIGURE 26-17

Lobes and segments of the lungs. **A,** Anterior view of the lungs, bronchi, and trachea. **B,** Expanded diagram showing the bronchopulmonary segments.

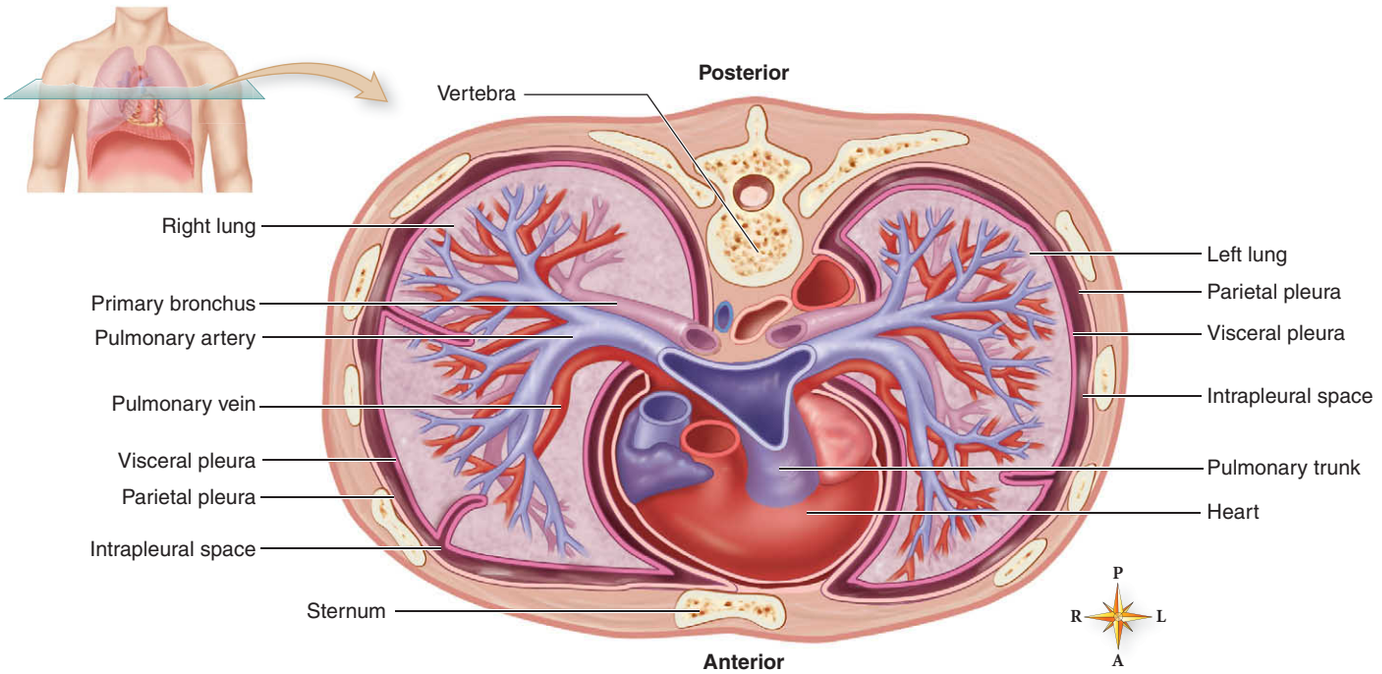

FIGURE 26-18

Lungs and pleura (transverse section). Note the parietal pleura lining the right and left pleural divisions of the thoracic cavity before folding inward near the bronchi to cover the lungs as the visceral pleura. The intrapleural space separates the parietal and visceral pleura. The heart, esophagus, and aorta are shown in the central mediastinum.

functionally most important, structures of the lung—the alveoli, or "gas exchangers."

Visceral pleura covers the outer surfaces of the lungs and adheres to them much as the skin of an apple adheres to the apple (Figure 26-18).

FUNCTIONS OF THE LUNGS

The lungs perform two functions—air distribution and gas exchange. Air distribution to the alveoli is the function of the tubes of the bronchial tree. Gas exchange between air and blood is the joint function of the alveoli and the networks of blood capillaries that envelop them. These two structures—one part of the respiratory system and the other part of the circulatory system—together serve as highly efficient gas exchangers. Why? Because together they provide an enormous surface area, the **respiratory membrane,** where the very thin-walled alveoli and equally thin-walled pulmonary capillaries come in contact (see Figures 26-14 and 26-15). This makes possible extremely rapid diffusion of gases between alveolar air and pulmonary capillary blood. It has been estimated that if the lungs' 300 million or so alveoli could be opened up flat, they would form a surface about the size of a tennis court, that is, about 85 square meters, or more than 40 times the surface area of the entire body! No wonder such large amounts of oxygen can be so quickly loaded into the blood while large amounts of carbon dioxide are rapidly unloaded from it.

Box 26-4 discusses the surgical removal of portions of the lung.

Thorax

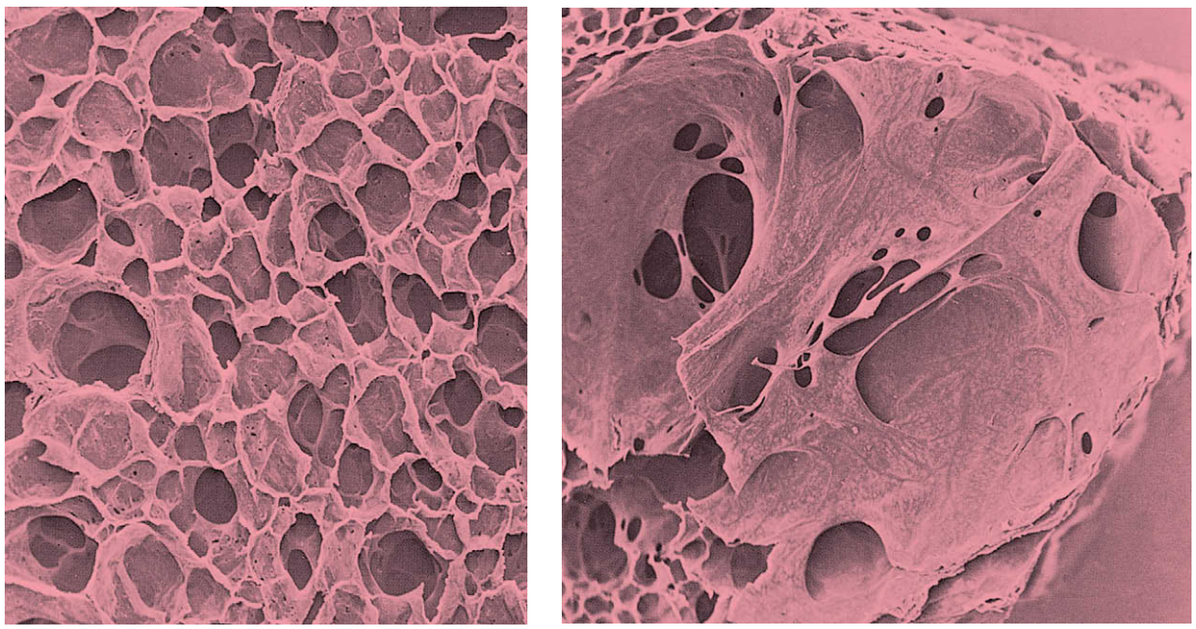
STRUCTURE OF THE THORACIC CAVITY

As described in Chapter 1, the thoracic cavity has three divisions, separated from each other by partitions of **pleura.** The parts of the cavity occupied by the lungs are the *pleural divisions.* The space between the lungs occupied mainly by the esophagus, trachea, large blood vessels, and heart is the *mediastinum* (see Figure 26-18).

The **parietal pleura** lines the entire thoracic cavity. It adheres to the internal surface of the ribs and the superior surface of the diaphragm, and it partitions off the mediastinum. A separate pleural sac thus encases each lung. Because the outer surface of each lung is covered by the visceral layer of the pleura, the **visceral pleura** lies against the parietal pleura, separated only by a potential space (pleural space) that contains just enough pleural fluid for lubrication (see Figure 26-18). Thus, when the lungs inflate with air, the smooth, moist visceral pleura coheres to the smooth, moist parietal pleura. Friction is thereby avoided, and respirations are painless. In *pleurisy* (pleuritis), on the other hand, the pleura is inflamed and respirations become painful.

FUNCTIONS OF THE THORACIC CAVITY

The thorax plays a major role in respiration. Because of the elliptical shape of the ribs and the angle of their attachment to the spine, the thorax becomes larger when the chest is raised and smaller when it is lowered. Lifting up the chest raises the ribs so that they no longer slant downward from the spine, and because of their elliptical shape, both the depth (from front to back) and the width of



Box 26-4 | HEALTH matters

Lung Volume Reduction Surgery

Lung volume reduction surgery (LVRS) is a "treatment of last resort" for severe cases of emphysema. It involves the removal of 20% to 30% of each lung. Diseased tissue is generally removed from the upper or apical areas of the superior lobes. Evidence from a number of large clinical trials has now shown that the LVRS procedure may benefit or at least help stabilize selected emphysema patients whose lung function continues to decline despite aggressive pulmonary rehabilitation efforts and other more conservative forms of treatment.

More than 2 million Americans, most of whom are older than age 50 and are current or former smokers, have emphysema—a major cause of disability and death in the United States. Emphysema is one of a number of conditions discussed in Chapter 27 and classified as a **chronic obstructive pulmonary disease,** or **COPD.** Although lung damage caused by emphysema is irreversible, in some cases the disease may be halted or its progression slowed by LVRS. In the end stages of this chronic disease, breathing becomes labored as the lungs fill with large irregular spaces resulting from the enlargement and rupture of many alveoli (see illustration). The LVRS procedure removes part of the diseased lung tissue and increases available space in the pleural cavities. As a result, the diaphragm and other respiratory muscles can more effectively move air into and out of the remaining lung tissue, thereby improving pulmonary function and making breathing easier.

LVRS may reduce the need for lung transplantation procedures and augment the effectiveness of such supporting medical treatments as nutritional supplementation and exercise training in the treatment of selected late-stage emphysema patients. Newer and less invasive techniques involving smaller incisions and tiny video equipment inserted into the thoracic cavity (video-assisted thoracic surgery) are now being used for many LVRS procedures. As a result, the relatively long hospital stays and home recovery periods previously required after more traditional open-chest surgery have been shortened.

A B

Emphysema. A, Scanning electron micrograph (SEM) of normal lung with many small alveoli. **B,** SEM of lung tissue affected by emphysema. Alveoli have merged into large air spaces, thereby reducing the surface area available for gas exchange.

the thorax are enlarged. (If this does not sound convincing to you, examine a skeleton to see why it is so.) An even greater change in thoracic volume occurs when the diaphragm contracts and relaxes. When the diaphragm contracts, it flattens out and thus pulls the floor of the thoracic cavity downward—thereby enlarging the volume of the thorax. When the diaphragm relaxes, it returns to its resting, domelike shape—thus reducing the volume of the thoracic cavity. It is these changes in thorax size that bring about inspiration and expiration (discussed on pp. 828–830 in Chapter 27).

| QUICK CHECK |

10. What is meant by the term *lobe of the lung?* What is a bronchopulmonary segment?
11. How does the structure of the diaphragm enable it to participate in breathing movements?

Cycle of LIFE

Respiratory System

Respiration involves the exchange of O_2 and CO_2 between the organism and its environment. The exchange must occur between air in the lungs and blood and, then, between blood and every body cell. In addition to the structural components of the body through which the respiratory gases must pass, hemoglobin plays a vital role in the respiration process. Each component of the system may be affected by developmental defects, by age-related structural changes, or by loss of function during the life cycle.

Premature birth can cause potentially fatal respiratory problems. A very low–birth-weight baby may have inadequate blood flow to the lungs, an inability to ventilate properly, and inadequate quantities of surfactant. Other diseases that cause serious respiratory problems are also associated with specific age-groups. Examples include cystic fibrosis and asthma in children and certain types of obstructive pulmonary disease and emphysema in older adults. Pneumothorax occurs more frequently in young adult females.

Numerous age-related changes affect lung capacity, make ventilation difficult, or reduce the oxygen- or carbon dioxide–carrying capacity of blood. For example, in older adulthood the ribs and sternum tend to become more fixed and less able to expand during inspiration, the respiratory muscles are less effective, and hemoglobin levels are often reduced. The result is a general reduction in respiratory efficiency in old age.

the BIG picture

Anatomy of the Respiratory System

Understanding the relationship of structure to function is critical to an understanding of homeostasis in all of the body organ systems. The anatomy of the respiratory system components permits the distribution of air and the exchange of respiratory gases. This dual function ultimately allows for both exchange of gases between environmental air and blood in the lungs and, finally, gas exchange between blood and individual body cells. In addition to delivery of air to the tiny terminal air passageways and alveoli for gas exchange with blood, components of the upper respiratory tract effectively filter, warm, and humidify the air we breathe.

Respiratory functions are dependent on the structural organization of the system parts and on the interrelationship of those components with other body systems, including the nervous, cardiovascular, muscular, and immune systems. For example, nerves regulate the thoracic and abdominal muscles that drive breathing, as well as the smooth muscles that regulate airflow through the bronchial tree. The immune system guards against airborne pathogens and irritants. Understanding the proper functioning and regulation of the physiology of the respiratory system, discussed in Chapter 27, depends on your understanding of its structural components and their relationships to one another and to other body organ systems—the "big picture" of total-body homeostasis.

MECHANISMS of DISEASE

DISORDERS ASSOCIATED WITH RESPIRATORY ANATOMY

Disorders of the Upper Respiratory Tract

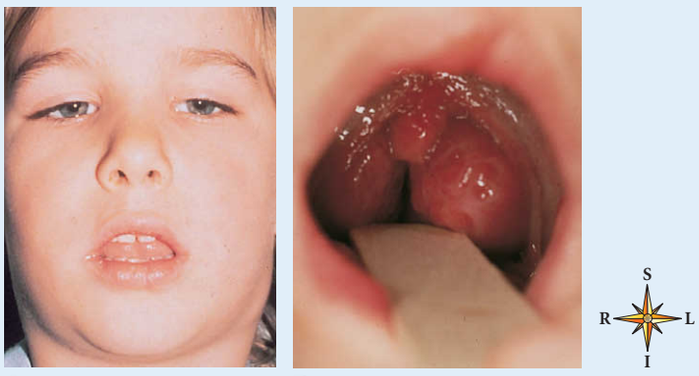
Inflammation and Infection

Any infection localized in the mucosa of the upper respiratory tract (nose, pharynx, and larynx) can be called an **upper respiratory infection (URI)** and is often named for the specific structure involved.

Rhinitis (from the Greek *rhinos*, "nose") is an inflammation of the mucosa of the nasal cavity. It is commonly caused by a viral infection, as in the common cold (caused by rhinoviruses) or flu (caused by influenza viruses). Rhinitis can also be caused by nasal irritants or an allergic reaction to airborne allergens. Allergic rhinitis, or "hay fever," occurs in sensitive people in a seasonal pattern, depending on the allergens involved (e.g., pollen). The excessive mucus production that results from the inflammatory response involved in rhinitis can cause fluid to drip down the pharynx and into the esophagus and lower respiratory tract. This dripping may cause sore throat, coughing, and upset stomach. Irritation of the **nasal mucosa** itself often triggers the sneeze reflex. Elimination of the causative factor, rest, and the use of antihistamines and decongestants usually relieve these symptoms.

Pharyngitis is inflammation or infection of the pharynx. Commonly referred to as a "sore throat," it is often due to viral invasion. Bacterial infection by *Streptococcus* bacteria is termed "strep throat." The common complaint is a sore throat, but redness and difficulty swallowing (dysphagia) often accompany it. Throat lozenges, rest, and fluid intake are encouraged, and antibiotics are prescribed for severe infections.

Laryngitis, or inflammation of the mucous lining of the larynx, is characterized by edema of the vocal folds, resulting in hoarseness (dysphonia) or loss of voice. Besides infections, inhalation of toxic or irritating fumes (i.e., smoking), endotracheal intubation, vocal abuse (i.e., public speaking), and alcohol ingestion can precipitate laryngitis. In children younger than 5 years, it may cause difficulty breathing, a condition often called **croup.** Conservative treatment, including limiting speech, is usually effective. A rare, but much more severe and rapidly progressing viral form of laryngeal edema called **epiglottitis** is always treated as a medical



emergency because of the potential for airway obstruction (see ***Swollen Larynx*** online at ***A&P Connect***).

Tonsillitis is inflammation of one or more of the masses of lymphatic tissue embedded in the mucous membrane of the pharynx (see pp. 733–734). Most cases of tonsillitis result in inflammation and swelling of the palatine tonsils in the oropharynx and the pharyngeal tonsils or adenoids in the nasopharynx. Repeated episodes of infection and chronic swelling of these tonsillar tissues require aggressive antibiotic therapy and, in severe cases, even surgical removal.

However, **tonsillectomy,** the surgical procedure used to remove inflamed and/or enlarged tonsillar tissue, is no longer considered a "first-choice" treatment option in routine cases of tonsillitis. As a result, the number of tonsillectomies performed each year continues to decrease. Physicians now recognize the value of lymphatic tissue in the body's defense mechanism and delay tonsillectomy with its rare, but potentially serious complications—including severe hemorrhage—until more conservative treatment options have proved ineffective.

Occasionally, surgical removal may be required, especially in children, if adenoidal and tonsillar infection and hypertrophy do not respond to antibiotic therapy. In these cases, sleep disturbance, fatigue, and other potentially serious complications involving the heart and lungs can result from progressive upper airway obstruction over time. Figure 26-19, *A*, shows the fatigued facial appearance of a child with severely enlarged tonsils who must keep his mouth open to breathe. In Figure 26-19, *B*, note how the enlarged tonsils in this child have all but filled the pharynx and are nearly meeting in the midline, thus seriously limiting airflow.

Because the upper respiratory mucosa is continuous with the mucous lining of the sinuses, auditory or eustachian tube, middle ear, and lower respiratory tract, URIs have the unfortunate tendency to spread. It is not unusual to see a common cold progress to **sinusitis** (sinus infection) or **otitis media** (middle ear infection).

A B

FIGURE 26-19

Tonsillitis. A, Facial appearance of a child with marked enlargement of the tonsils and adenoids. He must keep his mouth open to breathe and shows signs of fatigue. **B,** Enlarged tonsils can be seen meeting in the midline of the pharynx.

Anatomical Disorders

Nasal obstruction can be caused by displacement of the nasal septum from the midline of the nasal cavity, called a **deviated septum.** Most individuals have a small amount of septal cartilage protruding into one nasal passage; however, some are born with a congenital defect that results in various degrees of blockage on one or both sides of the nasal cavity. Damage from injury or infection may also cause a deviated septum. If breathing is impaired, surgical intervention is required to correct the deformity.

A frequent problem associated with a deviated septum is snoring. Pronounced snoring may be a symptom of **sleep apnea.** In these individuals there is a transition during sleep from loud snoring to variable periods of complete cessation of breathing. These periods of apnea are characterized by restlessness and often end in a loud "snort" before a normal breathing pattern resumes. Sleep apnea may be repeated many times each night and cause excessive daytime sleepiness and other symptoms related to chronic lack of oxygen.

Trauma to the nose can occur because the nose projects some distance from the front of the head. Usually, however, common bumps and other injuries cause little, if any, serious damage. **Epistaxis,** or nosebleed, can be caused by violent sneezing or nose blowing, chronic infection or inflammation (as in rhinitis), hypertension, or a strong bump or blow to the nose. Immediate direct pressure with an ice pack will often slow or stop the bleeding.

Disorders of the Lower Respiratory Tract

A range of conditions can interfere with the lower respiratory tract functions of gas exchange and ventilation. Some of these disorders, such as restrictive and obstructive conditions, are discussed in Chapter 27. For now, we concentrate on infections and lung cancer.

| A&P CONNECT |

Bronchial and lung disorders are often detected and monitored by chest x-ray imaging. Find out more in ***Pulmonary Radiology*** online at ***A&P Connect.***

evolve

Lower Respiratory Infection

Acute bronchitis is a common condition characterized by acute inflammation of the tracheobronchial tree, most commonly caused by infection. Part of or preceded by an acute URI, it is most prevalent in winter. Predisposing factors include chilling, fatigue, malnutrition, and exposure to air pollutants. The protective functions of the bronchial epithelium are disturbed and excessive fluid accumulates in the bronchi. Acute bronchitis often begins with a nonproductive cough, but malaise, slight fever, back and muscle pain, and a sore throat occur if a URI is present. Rest is indicated until the fever subsides, and cough suppressants may be used if the cough is troublesome.

Pneumonia is a common condition characterized by acute inflammation of the lungs. Depending on the cause, the alveoli and bronchi become swollen and plugged with mucous secretions. In

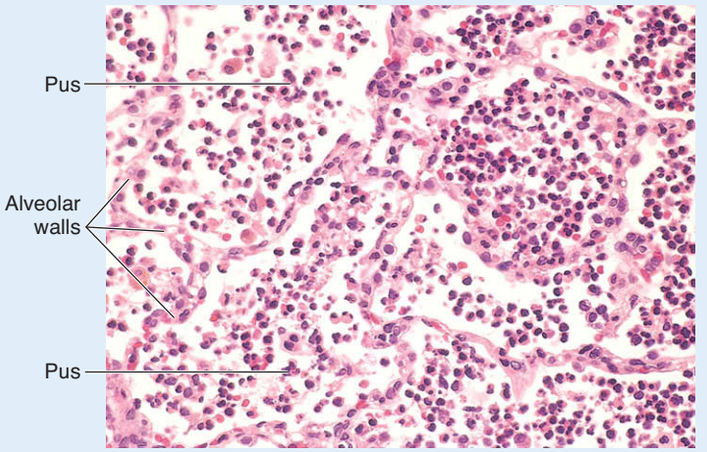


FIGURE 26-20

Acute bacterial pneumonia. The alveolar walls are thickened and the spaces filled with a fibrin exudate and neutrophils (pus)—a classic finding in acute pneumonia caused by bacterial infection.

bacterial pneumonia, a thick fibrin and neutrophil (pus)-containing exudate forms (Figure 26-20).

The vast majority of pneumonia cases result from infection by *Streptococcus pneumoniae* bacteria (see Figure 26-20), but pneumonia can also be caused by several other bacteria, viruses, and fungi. For example, **legionnaires' disease** is a form of bacterial pneumonia caused by infection with the *Legionella pneumophila* organism. Contaminated air conditioning cooling towers and whirlpool spas are sources of infection.

Viral infections can produce pneumonia as well. A dramatic example is the 2003 outbreak of *severe acute respiratory syndrome (SARS)* caused by the SARS-associated coronavirus (SARS-CoV). Unless treated very early, most SARS cases progress to pneumonia. SARS, like most viral infections responsible for pneumonia, is transmitted by close contact of individuals.

The term *aspiration pneumonia* is used to describe lung infections caused by the inhalation of vomit or other infective material. It is common in acute alcohol intoxication and as a complication of anesthesia.

Pneumonia is often associated with a high fever, chills, headache, cough, and chest pain. Increases in white blood cell (WBC) numbers (leukocytosis) and depressed blood oxygen levels (hypoxia) are common findings. The fact that each day over 10,000 liters of potentially contaminated air enters the respiratory system helps explain why pneumonia is such a common illness—especially in individuals with lowered resistance or impaired immune systems.

Types include *lobar pneumonia*, which typically affects an entire lobe of the lung (Figure 26-21), and *bronchopneumonia*, in which patches of infection are scattered along portions of the bronchial tree and generally involve more than one lobe (see Figure 26-20). Treatment involves antimicrobial drugs to control the infection and supportive therapy, including the administration of supplemental oxygen. Removal of tracheobronchial secretions may be necessary to maintain airway integrity.

Tuberculosis (TB) is a chronic bacillus infection caused by *Mycobacterium tuberculosis*. It is a highly contagious disease, transmitted by airborne mechanisms (i.e., inhalation of infectious

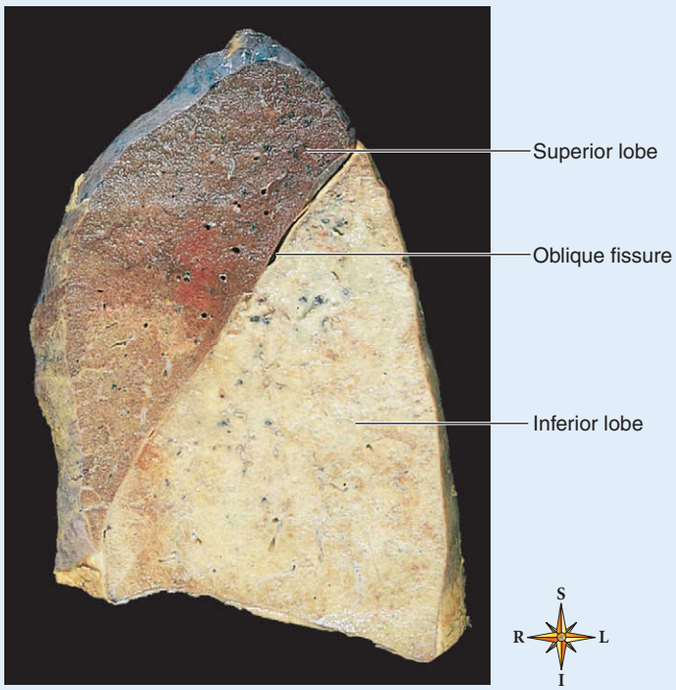

FIGURE 26-21

droplets). Inflammatory lesions called "tubercles" form around colonies of TB bacilli in the lung and produce the characteristic symptoms of cough, fatigue, chest pain, weight loss, and fever. As TB progresses, lung hemorrhage and dyspnea (labored breathing) may develop. If large areas of the lung are infected and tissue is destroyed, scar tissue may develop and cause reduced lung volume and restrictive lung disease. TB can invade other tissues or organs such as the lymphatic system, genitourinary system, and bone tissue. Because of the advancement of modern antimicrobial agents, the incidence of TB in the United States dropped dramatically in the last half century. However, various factors have allowed some highly resistant strains of TB to emerge once again as a major health threat in the United States. Although the incidence of TB has not yet reached epidemic proportions, health authorities in many large cities are working hard to prevent a major health crisis.

Lung Cancer

Lung cancer is a malignancy of pulmonary tissue that not only destroys the vital gas exchange tissues of the lungs, but like other cancers, may also invade other parts of the body (metastasis). Lung cancer most often develops in damaged or diseased lungs (see Figure 26-21). The most common predisposing condition associated with lung cancer is cigarette smoking (accounting for about 75% of lung cancer cases). In 1950, British epidemiologist Sir Richard Doll published the results of a groundbreaking scientific study that established for the first time the deadly link between smoking and lung cancer. His pioneering research was uniquely important in medical history. At the time of his death in 2005 at age 92, Doll was regarded as one of the most eminent scientists of his generation and one whose work will ultimately prevent tens of millions of

premature tobacco-related deaths around the world. Other factors thought to cause lung cancer include exposure to "second-hand" cigarette smoke, asbestos, chromium, coal products, petroleum products, rust, and ionizing radiation (as in radon gas).

Lung cancer may be arrested if detected early on routine chest x-ray films or by other diagnostic procedures such as bronchoscopy. Depending on the size, location, and exact type of malignancy involved, several strategies are available for treatment. Surgery is perhaps the most effective single treatment for most localized lung cancers. In a lobectomy, only the affected lobe of a lung is removed. **Pneumonectomy** is the surgical removal of an entire lung. Chemotherapy can also cause a cure or remission in selected cases, as can radiation therapy or concurrent (combination) chemotherapy and radiation treatment.

Unfortunately, in about 40% of patients diagnosed with the most common type of lung cancer, called "non–small cell" lung cancer, the disease has already spread, or metastasized, to lymph nodes and other organs by the time a diagnosis is made. Non–small cell lung cancer accounts for over 85% of cancer diagnoses in the United States.

Results of a National Cancer Institute study has shown that lobectomy combined with concurrent chemotherapy and radiation treatment can significantly increase survival time in cases of non–small cell lung cancer. Patients in the study who received either surgery or standard concurrent therapy—but not both—had less favorable survival rates 3 and 5 years after diagnosis.

So called "small cell" lung cancers usually appear first in the lining of the respiratory passageways. Curable if detected very early, this type of cancerous lesion is often treated by surgical removal, with **photodynamic therapy (PDT),** or both. This deadly form of the disease spreads very rapidly and is usually not effectively treated in its later stages with either standard concurrent radiation plus chemotherapy or by the standard treatment options followed by operation.

CASE study

Sharon looked away from her toddler for just a second. Her 2-year-old daughter, Zoe, was playing on the floor next to her desk. When Sharon glanced down again, Zoe was squirming, holding her throat and making little squeaking sounds. Zoe looked up at her Mom with scared eyes. "She's choking!" Sharon's voice screamed in her head. She first thought about performing the Heimlich maneuver on Zoe, but then remembered that was not the correct action because the child was still able to breathe a little (as evidenced by the squeaking sound). She didn't want to cause whatever had been swallowed to block Zoe's airway completely. Sharon grabbed the phone and dialed 911. The EMTs were there in minutes, but it seemed like hours. They took Zoe to the hospital. Based on Zoe's symptoms, the doctors immediately scheduled a bronchoscopy. In this procedure, a thin tube (with a camera) is inserted through the mouth and down the throat.

1. What is the correct sequence of structures through which the bronchoscope will pass?
   a. Nasopharynx, laryngopharynx, trachea, larynx
   b. Oropharynx, laryngopharynx, larynx, trachea
   c. Laryngopharynx, oropharynx, larynx, trachea
   d. Trachea, larynx, oropharynx, laryngopharynx

After finding nothing in the trachea, the doctor focused attention on the first tube to the right (after the trachea).

2. What is the name of this tube?
   a. Primary bronchiole
   b. Tracheal limb
   c. Primary bronchus
   d. Alveolar duct

3. What type of epithelium lines both this tube and the trachea?
   a. Stratified squamous
   b. Simple cuboidal
   c. Simple columnar
   d. Pseudostratified ciliated columnar

And there it was! Zoe had attempted to swallow a small magnetic ball, one of her older brother's toys. The toy had gone into her respiratory tract instead of her esophagus. The doctor inserted forceps through the bronchoscope, clamped onto the ball, and pulled it out.

4. What structure usually directs material into the esophagus when we swallow (instead of the air passages)?
   a. Epiglottis
   b. Glottis
   c. Concha
   d. Vocal fold

To solve a case study, you may have to refer to the glossary or index, other chapters in this textbook, ***A&P Connect,*** *and other resources.*

CHAPTER SUMMARY

STRUCTURAL PLAN OF THE RESPIRATORY SYSTEM

A. Structure determined by respiratory system functions of air distributor and gas exchanger—supplying oxygen and removing carbon dioxide from cells (Figure 26-1)
   1. Alveoli—sacs that serve as gas exchangers; all other parts of respiratory system serve as air distributors
   2. The respiratory system also warms, filters, and humidifies air
   3. Respiratory organs involved in speech, homeostasis of body pH, and olfaction

B. The respiratory system is divided into two structural divisions
   1. Upper respiratory tract—the organs are located outside the thorax and consist of the nose, nasopharynx, oropharynx, laryngopharynx, and larynx
   2. Lower respiratory tract—the organs are located within the thorax and consist of the trachea, the bronchial tree, and the lungs
   3. Accessory structures include the oral cavity, rib cage, and diaphragm

UPPER RESPIRATORY TRACT

A. Nose
   1. Structure of the nose—external portion consists of a bony and cartilaginous frame covered by skin containing sebaceous glands
      a. The two nasal bones meet and are surrounded by the frontal bone to form the root
      b. The nose is surrounded by the maxilla (Figure 26-2)
   2. Internal portion of the nose (nasal cavity) lies over the roof of the mouth, separated by the palatine bones
      a. Cleft palate—condition in which the palatine bones fail to unite completely and only partially separate the nose and the mouth, thereby producing difficulty swallowing
      b. Cribriform plate—separates the roof of the nose from the cranial cavity
      c. Septum—separates the nasal cavity into right and left cavities; it consists of four structures: the perpendicular plate of the ethmoid bone, the vomer bone, the vomeronasal cartilages, and the septal nasal cartilage
   3. Each nasal cavity is divided into three passageways: superior, middle, and inferior meatuses (Figure 26-3)
   4. Anterior (external) nares—external openings to the nasal cavities; open into the vestibule
   5. Sequence of airflow through the nose into the pharynx—anterior nares to the vestibule to all three meatuses simultaneously and then to the posterior (internal) nares
   6. Nasal mucosa
      a. Air passes over respiratory mucosa, which contains a rich blood supply (Figure 26-4)
      b. Olfactory epithelium—special sensory membrane containing many olfactory nerve cells and a rich lymphatic plexus
   7. Paranasal sinuses
      a. Four pairs of air-containing spaces that open or drain into the nasal cavity
      b. Each is lined with respiratory mucosa (Figure 26-5)
   8. Functions of the nose
      a. Provides a passageway for air traveling to and from the lungs
      b. Filters the air, aids speech, and makes possible the sense of smell

B. Pharynx (throat)
   1. Structure of pharynx
      a. Tubelike structure extending from the base of the skull to the esophagus
      b. Made of muscle and divided into three parts (Figure 26-3)—nasopharynx, oropharynx, and laryngopharynx
   2. Pharyngeal tonsils
      a. Located in the nasopharynx
      b. Called *adenoids* when they become enlarged
   3. Oropharynx contains two pair of organs—the palatine tonsils (most commonly removed in tonsillectomy) and the lingual tonsils (rarely removed)
   4. Functions of the pharynx—pathway for the respiratory and digestive tracts

C. Larynx (Figures 26-6 and 26-7)
   1. Location of larynx—positioned between the root of the tongue and the upper end of the trachea
   2. Structure of larynx
      a. Consists of cartilages attached to each other by muscle
      b. Lined by a ciliated mucous membrane, which forms two pairs of folds (Figure 26-8)—vestibular folds (false vocal folds) and vocal folds
   3. Cartilages (framework) of the larynx—formed by nine cartilages
      a. Single laryngeal cartilages—the three largest cartilages: the thyroid cartilage, the epiglottis, and the cricoid cartilages
      b. Paired laryngeal cartilages—three pairs of smaller cartilages: the arytenoid, the corniculate, and the cuneiform cartilages
   4. Muscles of the larynx
      a. Intrinsic muscles both insert and originate within the larynx
      b. Extrinsic muscles insert in the larynx but originate on some other structure
   5. Functions of the larynx—forms part of the airway to the lungs and produces the voice

D. Additional information is found in Table 26-1

LOWER RESPIRATORY TRACT

A. Trachea—often called "windpipe" (Figure 26-10)
   1. Structure of trachea
      a. Extends from the larynx to the primary bronchi
      b. Wall composed of (outer) adventitia, (middle) smooth muscle and C-shaped cartilage rings, (inner) respiratory mucosa; posterior wall is very elastic (Figure 26-11)

c. Incomplete rings and posterior elasticity allows esophagus to expand into trachea during swallowing
2. Functions of trachea—furnishes part of the open airway to the lungs; obstruction causes death

B. Bronchi and alveoli
1. Structure of bronchi
a. Lower end of the trachea divides into two primary bronchi, one on the right and one on the left; right one is larger and more vertical than left
b. Primary bronchi enter the lung and divide into secondary bronchi, which branch into bronchioles and eventually divide into alveolar ducts and alveoli
c. 23 levels of branching (Figure 26-12)
2. Structure of alveoli—the primary gas exchange structures
a. Respiratory membrane—the barrier between which gases are exchanged by alveolar air and blood (Figure 26-15)
b. Respiratory membrane consists of the alveolar epithelium, the capillary endothelium, and their joined basement membranes
c. Surfactant—a component of the fluid coating the respiratory membrane that reduces surface tension; produced by type II cells
3. Functions of bronchi and alveoli
a. Distribute air to the lung's interior; 23 levels of branching are optimal for oxygen transfer to the blood
b. Mucus blanket cleans the airways as it is moved upward by the ciliary escalator

C. Lungs
1. Structure of the lungs—cone-shaped organs extending from the diaphragm to above the clavicles (Figure 26-17)
a. Hilum—slit on the lung's medial surface where the primary bronchi and pulmonary blood vessels enter
b. Base—the inferior surface of the lung that rests on the diaphragm
c. Costal surface—lies against the ribs
d. Left lung is divided into two lobes—superior and inferior
e. Right lung is divided into three lobes—superior, middle, and inferior
f. Lobes are further divided into functional units—bronchopulmonary segments
(1) Ten segments in the right lung
(2) Eight segments in the left lung
2. Functions of the lungs—air distribution and gas exchange

D. Thorax (Figure 26-18)
1. Structure of the thoracic cavity—three divisions divided by the pleura
a. Pleural divisions—the part occupied by the lungs
b. Mediastinum—part occupied by the esophagus, trachea, large blood vessels, and heart
2. Functions of the thorax—brings about inspiration and expiration

E. Additional information is found in Table 26-1

CYCLE OF LIFE: RESPIRATORY SYSTEM

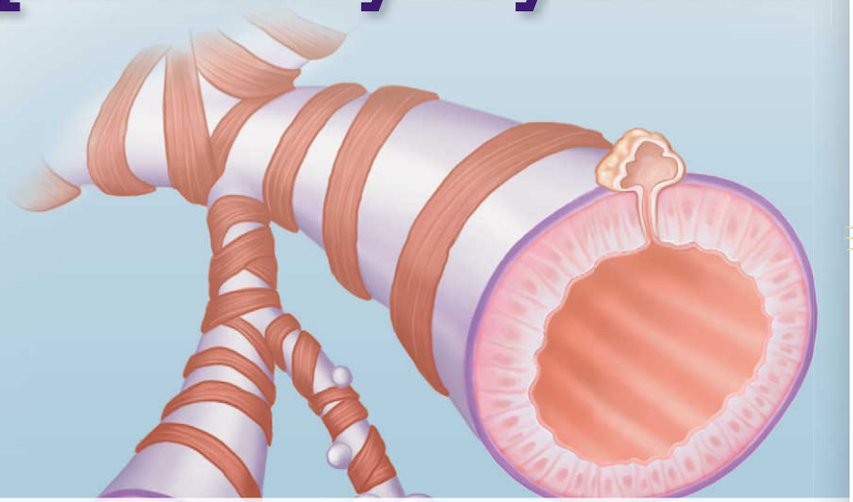
A. Respiration may be affected by developmental defects, age-related structural changes, or loss of function throughout the life cycle
B. Age-related changes affect lung capacity, make ventilation difficult, or reduce the oxygen- or carbon dioxide–carrying capacity of blood
C. Respiratory efficiency is reduced in old age as a result of changes in ribs, respiratory muscles, and hemoglobin levels

REVIEW QUESTIONS

Write out the answers to these questions after reading the chapter and reviewing the Chapter Summary. If you simply think through the answer without writing it down, you won't retain much of your new learning.

1. Identify the major anatomical structures of the nose.
2. How are the conchae arranged in the nose? What are they?
3. Describe the draining of the paranasal sinuses.
4. What organs are found in the nasopharynx?
5. What tubes open into the nasopharynx?
6. The pharynx is common to what two systems?
7. List the divisions of the larynx.
8. What is the voice box? Of what is it composed? What is the Adam's apple?
9. What is the epiglottis? What is its function?
10. What are the vocal folds? What name is given to the opening between the folds?
11. Describe the structure and function of the trachea.
12. Discuss the component parts of the bronchial tree.
13. Make a diagram showing the termination of a bronchiole in an alveolar duct with alveoli.
14. How many lobes are in the right lung? The left? What are the bronchopulmonary segments?
15. Describe the changes in thorax size during respiration.
16. List the organs that are included in the upper respiratory tract. Do the same for the lower respiratory tract.
17. What is the role of the vomeronasal organ?

CRITICAL THINKING QUESTIONS



After finishing the Review Questions, write out the answers to these more in-depth questions to help you apply your new knowledge. Go back to sections of the chapter that relate to concepts that you find difficult.

1. How would you describe the structure and function of the respiratory mucosa? Include the types of cells it contains and where these cells are located in the respiratory system.
2. Why do you think mucus production is especially important in the olfactory epithelium?
3. What are the features of the pharynx? Include in your answer the location of the openings in the pharynx, location of the tonsils, and the role of the pharynx in phonation.
4. Which of the paired laryngeal cartilages are the most important? What evidence can you cite to support your answer?
5. Identify which single cartilage is associated with a life-threatening condition in children. What are the symptoms of this condition?
6. In an earlier chapter the characteristic of water called *polarity* was described as the attraction water molecules have for each other. Why is this a problem in the respiratory system, and how is it solved?
7. Make the distinction between air distribution and gas exchange in the respiratory system. Identify the organs that serve as air distributors and gas exchangers.

continued on p. 856

In Chapter 26 the anatomy of the respiratory system was presented as a basis for understanding the physiological principles that regulate air distribution and gas exchange. This chapter deals with ***respiratory physiology****—a complex series of interacting and coordinated processes that have a critical role in maintaining the stability, or constancy, of our internal environment. The proper functioning of the respiratory system ensures the tissues of an adequate oxygen supply and prompt removal of carbon dioxide. This process is complicated by the fact that control mechanisms must permit maintenance of homeostasis throughout a wide range of ever-changing environmental conditions and body demands. Adequate and efficient regulation of gas exchange between body cells and circulating blood under changing conditions is the essence of respiratory physiology. This complex function would not be possible without integration of numerous physiological control systems, including acid-base, water, and electrolyte balance, circulation, and metabolism.*

RESPIRATORY PHYSIOLOGY

Functionally, the respiratory system is composed of an integrated set of regulated processes that include the following:

- External respiration: pulmonary ventilation (breathing) and gas exchange in the pulmonary capillaries of the lungs
- Transport of gases by the blood
- Internal respiration: gas exchange in the systemic blood capillaries and cellular respiration
- Overall regulation of respiration

Figure 27-1 summarizes the essential processes of pulmonary function. We will use this set of processes as a general framework for this chapter. Cellular respiration has already been covered in Chapter 4 and will be reviewed again in greater detail in Chapter 30.

PULMONARY VENTILATION

Pulmonary ventilation is a technical term for what most of us call breathing. One phase of it, inspiration, moves air into the lungs and the other phase, expiration, moves air out of the lungs.

Mechanism of Pulmonary Ventilation

Air moves in and out of the lungs for the same basic reason that any fluid (a liquid or a gas) moves from one place to another—briefly, because its pressure in one place is different from that in the other place. Or stated differently, the existence of a pressure gradient (a pressure difference) causes fluids to move. A fluid always moves *down* its pressure gradient. This means that a fluid moves from the area where its pressure is higher to the area where its pressure is lower. When applied to the flow of air in the pulmonary airways, we can call this central idea the **primary principle of ventilation.**

Under standard conditions, air in the atmosphere exerts a pressure of 760 mmHg. Air in the alveoli at the end of one **expiration** and before the beginning of another **inspiration** also exerts a pressure of 760 mmHg. This explains why, at that moment, air is neither entering nor leaving the lungs. The mechanism that produces pulmonary ventilation is one that establishes a gas pressure gradient between the atmosphere and the alveolar air.

When atmospheric pressure is greater than pressure within the lung, air flows down this gas pressure gradient. Then air moves from the atmosphere into the lungs. In other words, inspiration occurs. When pressure in the lungs becomes greater than atmospheric pressure, air again moves down a gas pressure gradient. But this time, the air moves in the opposite direction. That is, air moves out of the lungs into the atmosphere. The pulmonary ventilation mechanism, therefore, must somehow establish these two gas pressure gradients—one in which alveolar pressure (P_A, pressure within the alveoli of the lungs) is lower than atmospheric pressure (or barometric pressure, P_B) to produce inspiration and one in which it is higher than atmospheric pressure to produce expiration. See Figures 27-2 and 27-3.

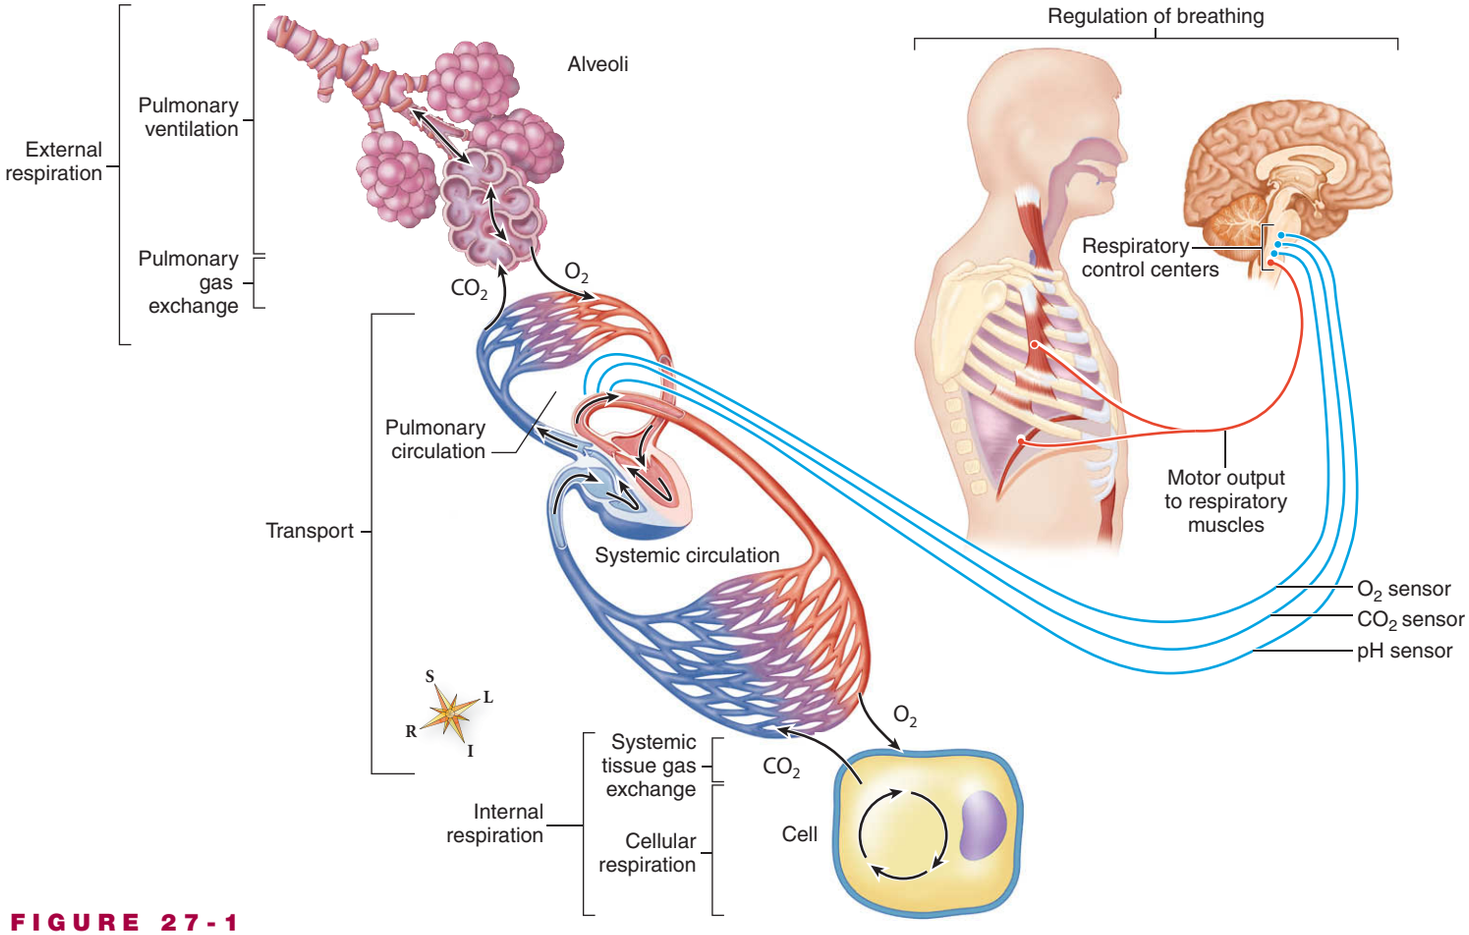

FIGURE 27-1

Overview of respiratory physiology. This chapter is organized around the principle that respiratory function includes external respiration (ventilation and pulmonary gas exchange), transport of gases by blood, and internal respiration (systemic tissue gas exchange and cellular respiration). Cellular respiration is discussed separately (see Chapters 4 and 30). Regulatory mechanisms centered in the brainstem use feedback from blood gas sensors to regulate ventilation.

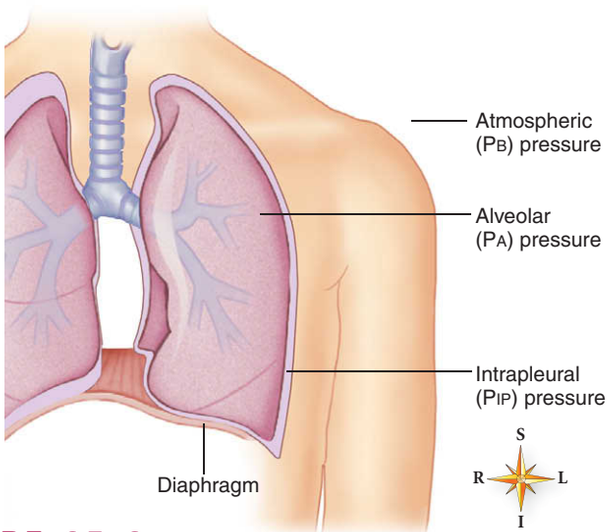

FIGURE 27-2

Pressures important in ventilation. This diagram shows the locations of pressures involved in the pressure gradients needed for ventilation (see Figure 27-3). Atmospheric pressure (P_B) is the air pressure of the atmosphere outside the body's airways. Alveolar pressure (P_A) is intrapulmonary pressure—the pressure at the far end of the internal airways. Intrapleural pressure (P_{IP}) is the fluid pressure of the pleural fluid between the parietal pleura and visceral pleura—or intrathoracic pressure (pressure in the thorax).

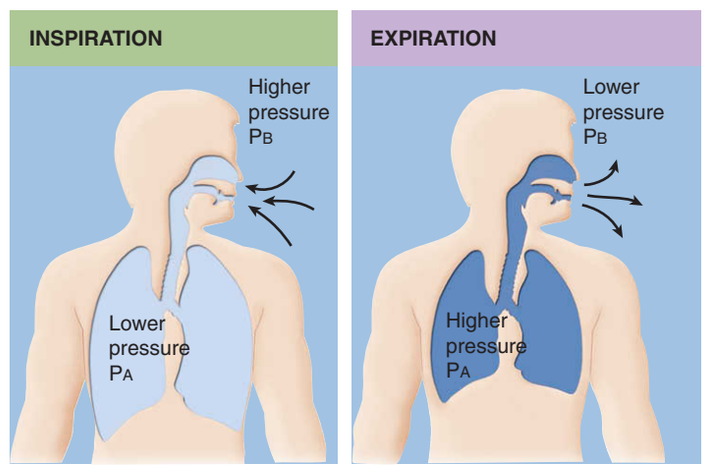

FIGURE 27-3

Primary principle of ventilation. Put simply, air moves down its pressure gradient—that is, it always moves from an area of high pressure to an area of lower pressure. To achieve inspiration, the higher pressure must be outside the body. To achieve expiration, the higher pressure must be inside the body's airways. P_B, Atmospheric [barometric] pressure; P_A, alveolar pressure. (See Figure 27-2.)

These pressure gradients are established by changes in the size of the thoracic cavity, which in turn are produced by contraction and relaxation of respiratory muscles. An understanding of *Boyle's law* is important for understanding the pressure changes that occur in the lungs and thorax during the breathing cycle. It is a familiar principle, stating that the volume of a gas varies inversely with pressure at a constant temperature (Box 27-1). One application of this principle is as follows: expansion of the thorax (increase in volume) results in a decreased intrapleural (intrathoracic) pressure. This leads to a decreased intraalveolar pressure that causes air to move from the outside into the lungs.

The mechanics of ventilation are often modeled using a balloon in a jar, as you can see in Figure 27-4. The bell-shaped jar represents the rib cage (thoracic cavity), and a rubber sheet across the open bottom of the bell jar represents the diaphragm. A balloon represents the lungs. The space between the balloon and the jar represents the intrapleural space. Expanding the thorax by pulling the diaphragm downward increases thoracic volume—thus decreasing intrapleural pressure (P_{IP}). Because the balloon is compliant (stretchable), the decrease in P_{IP} causes a similar decrease in the balloon pressure (alveolar pressure, P_A). This creates a pressure gradient that results in flow of air into the balloon. The opposite occurs when the elastic diaphragm recoils, decreasing

Box 27-1 | Gas Laws

A true understanding of respiratory function requires some familiarity with some of what physical scientists call the "gas laws." The gas laws are simply statements of what we have come to understand about the physical nature of gases. The gas laws are based on the concept of an **ideal gas,** that is, a gas whose molecules are so far apart that the molecules rarely collide with one another.

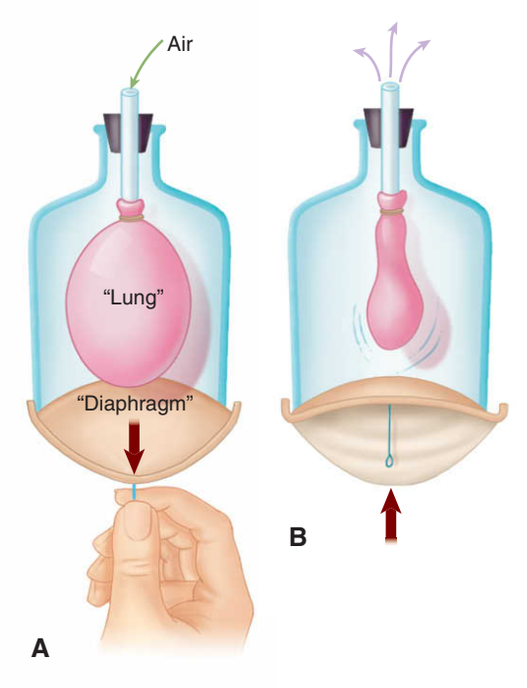
The gas laws are also based on the premise that gas molecules continually collide with the walls of their container and thus produce a force against it called the *gas pressure.* Pressure exerted by a gas depends on several factors. One factor is the frequency of collisions, which is proportional to the concentration of the gas: the higher the gas concentration, the higher the number of collisions with the wall of the container and thus the higher the gas pressure. **Boyle's law** sums up this principle very neatly by stating that a gas's volume is inversely proportional to its pressure (see figure, part *A*). When the volume of a container increases, the pressure of the gas inside it decreases, and when the volume decreases, the gas pressure increases. In this chapter, Boyle's law has been applied to ventilation: when thoracic volume increases, air pressure in the airways decreases (allowing air to move inward), and when thoracic volume decreases, air pressure in the airways increases (allowing air to move outward).

Another factor that affects an ideal gas is its temperature. Temperature is really a measurement of the motion of molecules. Thus an increase in temperature signals an increase in the average velocity of gas molecules. It follows that all other things remaining the same, an increase in the temperature of a gas will increase its pressure. However, if the container is expandable, as it is in part *B* of the figure, and thus the pressure is held constant, the volume increases. This principle is summed up in **Charles's law,** which states that volume is directly proportional to temperature ($V \propto T$) when pressure is held constant (see figure, part *B*). One could extend this notion to state that pressure is proportional to temperature ($P \propto T$) when volume is held constant. One can assume, then, that during inspiration, air expands in volume as it is warmed by the respiratory mucosa.

Dalton's law takes things a step further by stating the situation when the gas in question is actually a *mixture* of different kinds of gas molecules, as in air (part *C* of the figure). Dalton's law states that the total pressure exerted by a mixture of gases is the sum of the pressure of each individual gas. That is, the collision force created by all of one type of molecule accounts for only a part of the total pressure—the collision forces of all the other types of molecules in the mixture must be included to arrive at the total gas pressure. Dalton's law, also known as the **law of partial pressures,** is used to determine the partial pressure of oxygen (P_{O_2}) in air, for example. Because the partial pressure of a gas is determined by its relative concentration in the mixture of gases, partial pressure values can be used in much the same way as concentration values in determining the direction of net diffusion.

Another gas law, **Henry's law,** describes how the pressure of a gas relates to the concentration of that gas in a liquid solution (part *D* of the figure). If you have a beaker of water surrounded by air, which contains the oxygen, the concentration of oxygen dissolved in the water will be proportional by the partial pressure of oxygen in the air. Henry's law further states that the concentration of the gas in solution is also a function of the gas's **solubility,** or its relative ability to dissolve. Thus Henry's law states that the concentration of a gas in a solution depends on the partial pressure of the gas and the solubility of the gas, as long as the temperature remains constant. This principle explains how the plasma concentration of a gas such as oxygen relates to its partial pressure.

Also see Box 27-6, which discusses Fick's law.



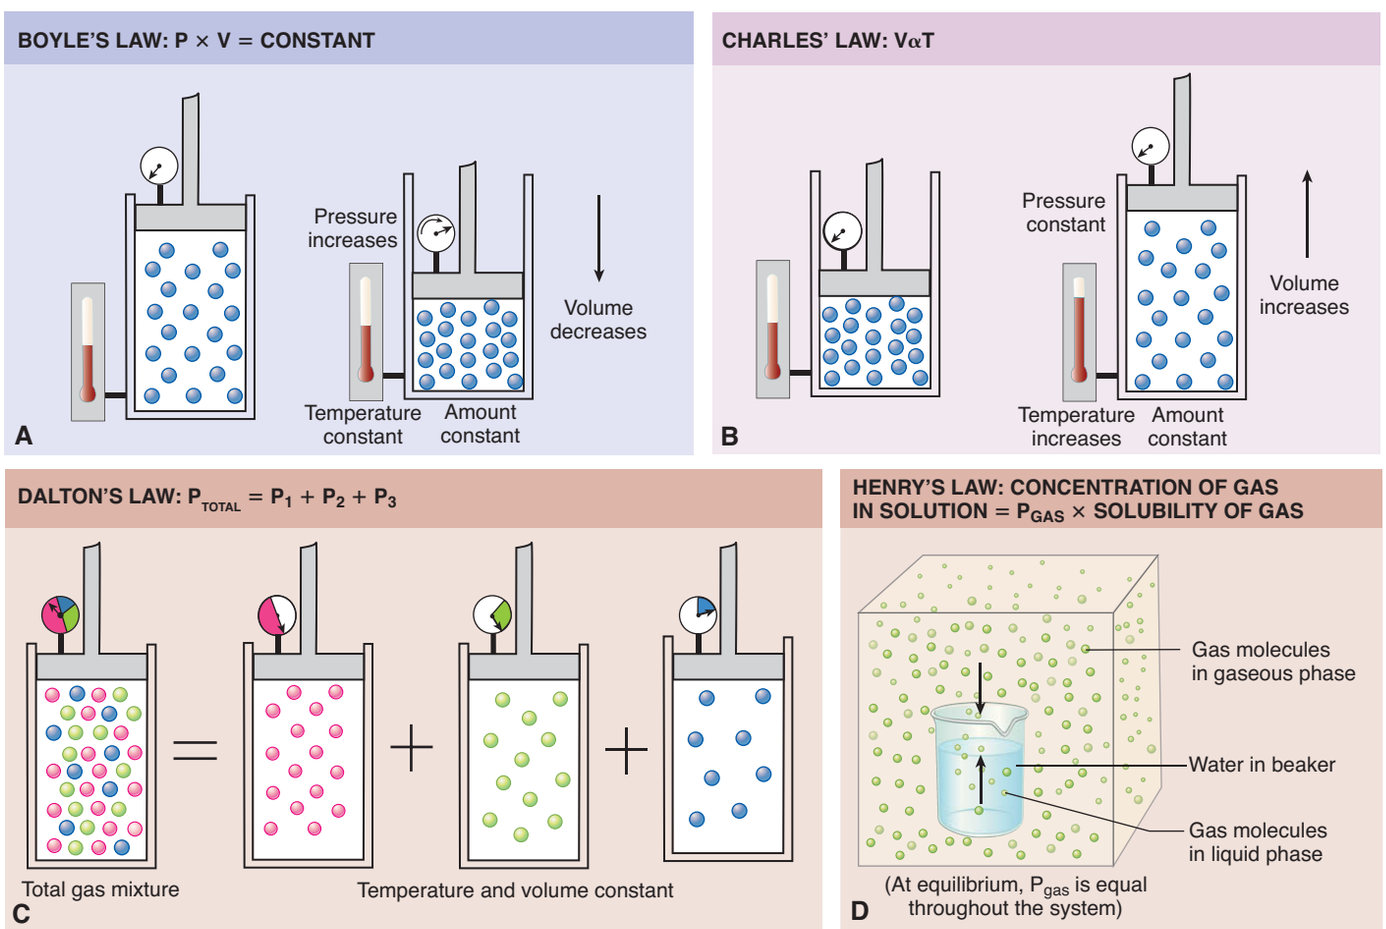


FIGURE 27-4

Balloon model of ventilation. The cartoons show a classic model in which a jar represents the rib cage (thoracic cavity), a rubber sheet represents the diaphragm, and a balloon represents the alveoli of the lungs. The space between the jar and balloon represents the intrapleural space. **A,** Inspiration, caused by downward movement of the diaphragm. **B,** Expiration, caused by elastic recoil of the diaphragm upward.

The gas laws. **A,** Boyle's law. **B,** Charles's law. **C,** Dalton's law. **D,** Henry's law.

internal air volumes (thus increasing internal air pressure) and forcing air out of the balloon.

Figure 27-5 applies the same principles of the balloon model to the human airways to demonstrate the mechanics of ventilation. The constant alternation between inspiration and expiration is called the **respiratory cycle.** The specific mechanics of the respiratory cycle are outlined in the following sections and in Table 27-1.

INSPIRATION

Contraction of the diaphragm alone, or contraction of both the diaphragm and the external intercostal muscles, produces quiet inspiration. As the diaphragm contracts, it descends, and this makes the thoracic cavity longer. Contraction of the external intercostal muscles pulls the anterior end of each rib up and out (Figure 27-6, *A*). This also elevates the attached sternum and enlarges the thorax from front to back and from side to side (Figure 27-6, *B*). In addition, contraction of the sternocleidomastoid, pectoralis minor, and serratus anterior muscles can aid in elevation of the sternum and rib cage during forceful inspiration.

As the size of the thorax increases, the intrapleural (intrathoracic) and alveolar pressure decreases (Boyle's law) and inspiration occurs.

At the beginning of each inspiration, intrapleural pressure (P_{IP}) is about 758 mmHg. Thus the P_{IP} is about 2 mmHg less than atmospheric pressure (frequently written −2 mmHg). During normal quiet inspiration, P_{IP} decreases further to 756 mmHg (−4 mmHg) or

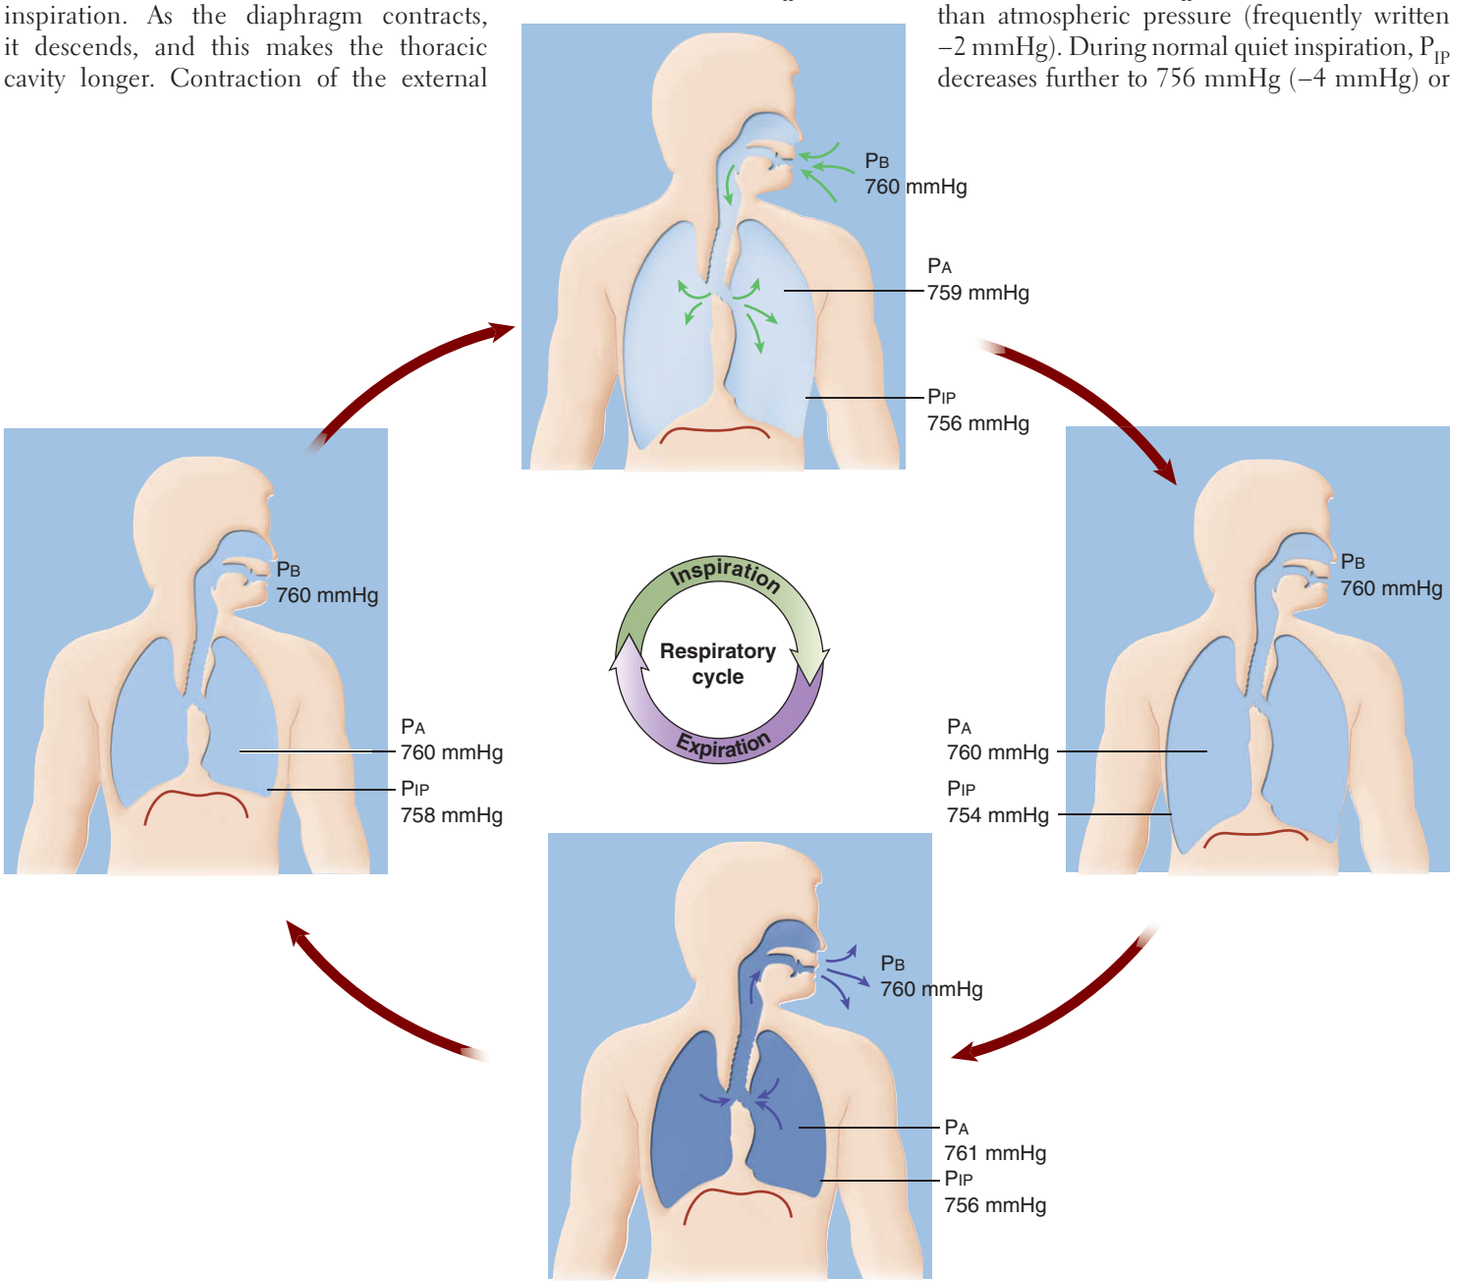

FIGURE 27-5

The respiratory cycle. During *inspiration,* the diaphragm contracts, increasing the volume of the thoracic cavity. This increase in volume results in a decrease in pressure, which causes air to rush into the lungs. During *expiration,* the diaphragm returns to an upward position, reducing the volume in the thoracic cavity. Air pressure thus increases, forcing air out of the lungs. See Table 27-1 for additional details. P_A, Alveolar pressure; P_B, barometric pressure; P_{IP}, intrapleural pressure.

TABLE 27-1 The Respiratory Cycle*

P_{IP}	P_A	P_B	DESCRIPTION
Inspiration			
758	760	760	The diaphragm is relaxed, putting the thoracic cavity at low volume. At the beginning of inspiration $P_{IP} < P_A$, keeping alveoli open. Since $P_A = P_B$, no air is flowing yet.
756	759	760	The diaphragm contracts, increasing the thoracic volume and reducing P_{IP}. A decrease in P_{IP} causes a decrease in P_A. Now $P_A < P_B$, and air flows down the pressure gradient (into the lungs).
754	760	760	Eventually, the alveoli fill with air and P_A equilibrates with P_B. Inward airflow stops. The cycle is now ready to shift to the expiration phase. Note that P_{IP} is still dropping but P_A has not yet "caught up" with the drop.
Expiration			
754	760	760	As expiration is about to begin, the diaphragm is contracted maximally. Since $P_A = P_B$, there is no airflow.
756	761	760	The diaphragm relaxes, and elastic recoil of the thoracic walls and alveoli increases P_{IP} and P_A. Now, $P_A > P_B$. Air moves (outward) down the pressure gradient.
758	760	760	The diaphragm eventually relaxes fully, so the decrease in volume stops. P_A equilibrates with P_B, and airflow ceases. The system is now ready for another inspiration phase.

*All P values are expressed in *mmHg* and are examples only.
P_{IP} = Intrapleural pressure (air pressure in the intrapleural space); P_A = alveolar pressure (air pressure inside the alveoli); P_B = atmospheric (barometric) pressure (air pressure of the external environment [atmosphere]).

less. As the thorax enlarges, it pulls the lungs along with it because of cohesion between the moist pleura covering the lungs and the moist pleura lining the thorax. Thus the lungs expand and the pressure in their tubes and alveoli necessarily decreases. Alveolar pressure decreases from an atmospheric level to a subatmospheric level—typically a drop of about 1 to 3 mmHg. The moment that alveolar pressure becomes less than atmospheric pressure, a pressure gradient exists between the atmosphere and the interior of the lungs. According to the primary principle of ventilation, air moves into the lungs. Eventually, enough air moves out of the lungs to establish a pressure equilibrium between the atmosphere and the alveoli—and the flow of air then stops.

The ability of the lungs and thorax to stretch, referred to as **compliance,** is essential to normal respiration. If the compliance

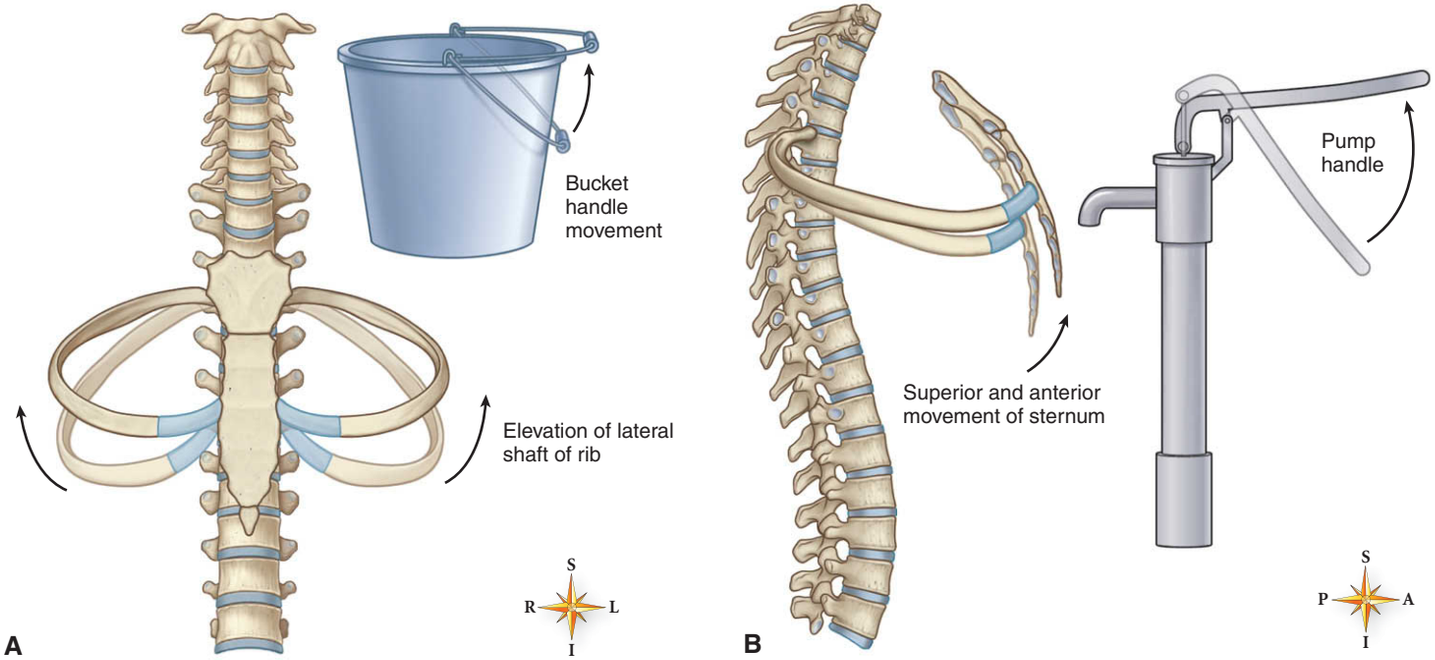

FIGURE 27-6

Movement of the rib cage during breathing. A, Inspiratory muscles pull the ribs upward and thus outward, as illustrated by lifting a bucket handle. **B,** Inspiratory muscles pull the sternum upward and thus outward, as when pulling upward on the handle of a water pump.

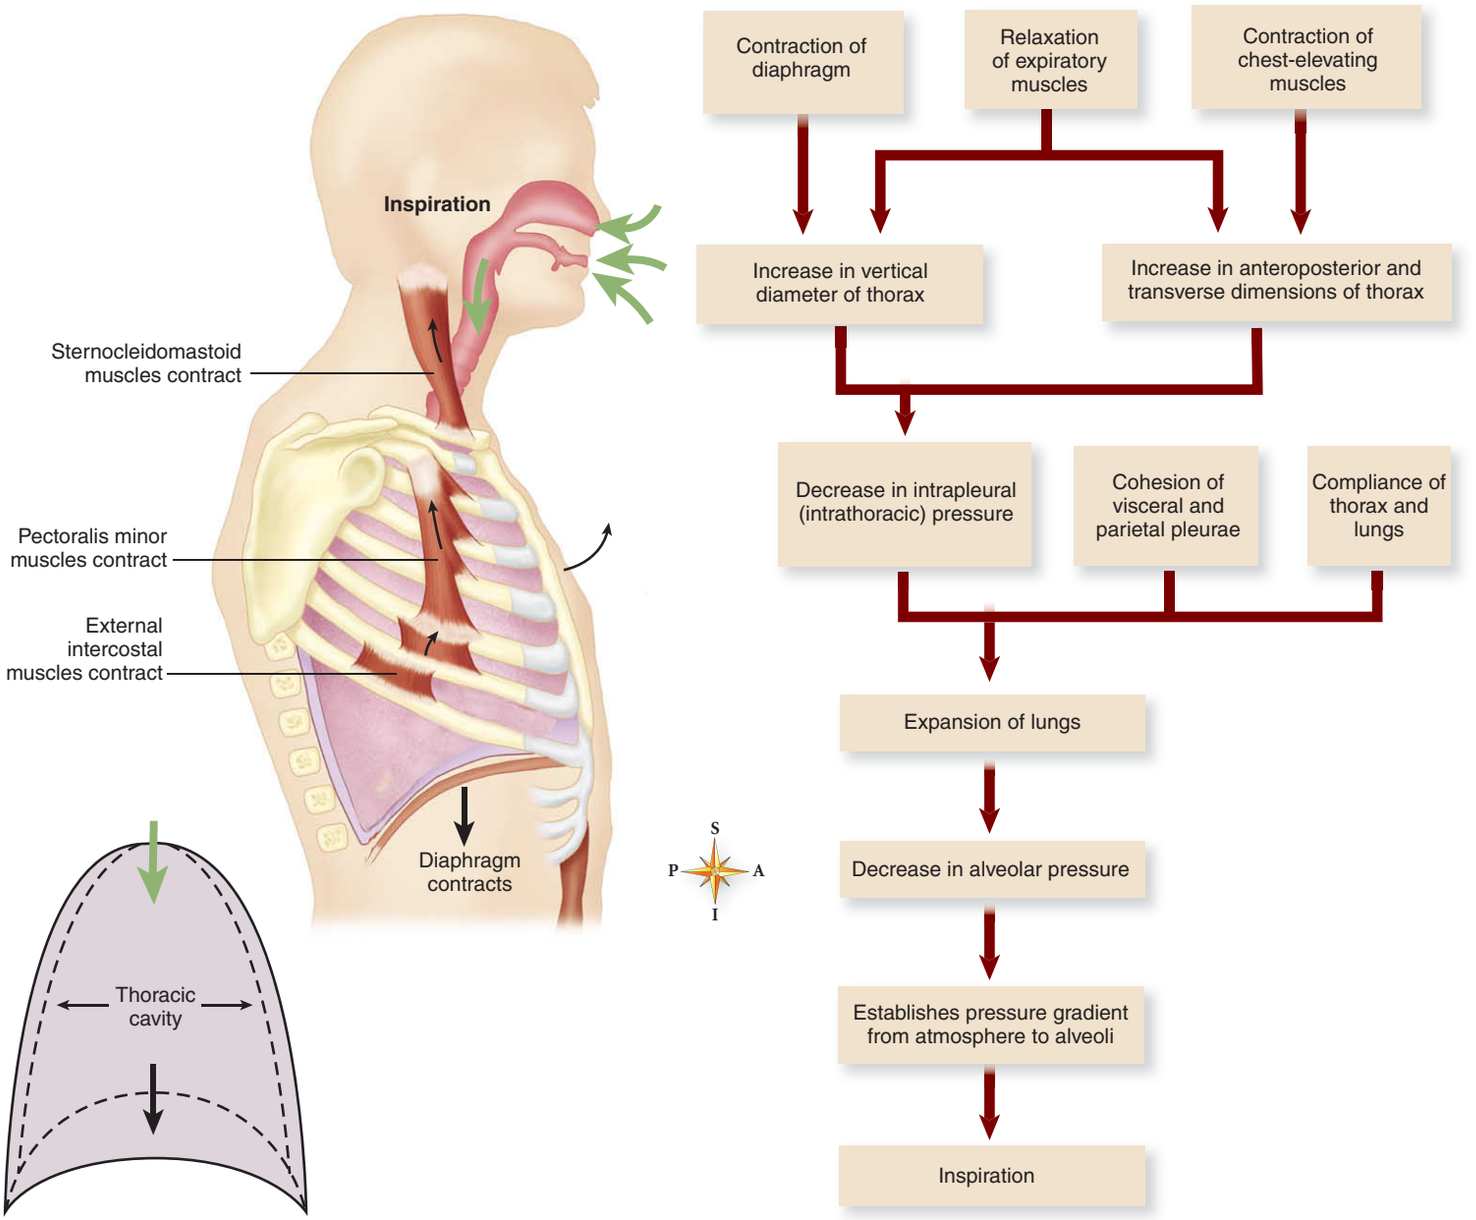

FIGURE 27-7

Mechanism of inspiration. Note the role of the diaphragm and the chest-elevating muscles (pectoralis minor and external intercostals) in increasing thoracic volume, which decreases pressure in the lungs and thus draws air inward.

of these structures is reduced by injury or disease, inspiration becomes difficult—or even impossible (Box 27-2 on p. 848).

For a summary of the mechanism of inspiration just described, see Figures 27-5 and 27-7.

EXPIRATION

Quiet expiration is ordinarily a passive process that begins when the pressure gradients that resulted in inspiration are reversed. The inspiratory muscles relax, causing a decrease in the size of the thorax and an increase in intrapleural pressure from about 754 mmHg (–6 mmHg) before expiration to about 756 mmHg (–4 mmHg) or more during respiration. It is important to understand that this pressure between the parietal and visceral pleura is always negative, that is, less than atmospheric pressure and less than alveolar pressure. The negative intrapleural pressure is required to overcome the so-called "collapse tendency of the lungs" caused by surface tension of the fluid lining the alveoli and the stretch of elastic fibers that are constantly attempting to recoil.

As alveolar pressure increases, a positive-pressure gradient is established from alveoli to atmosphere—and thus expiration occurs

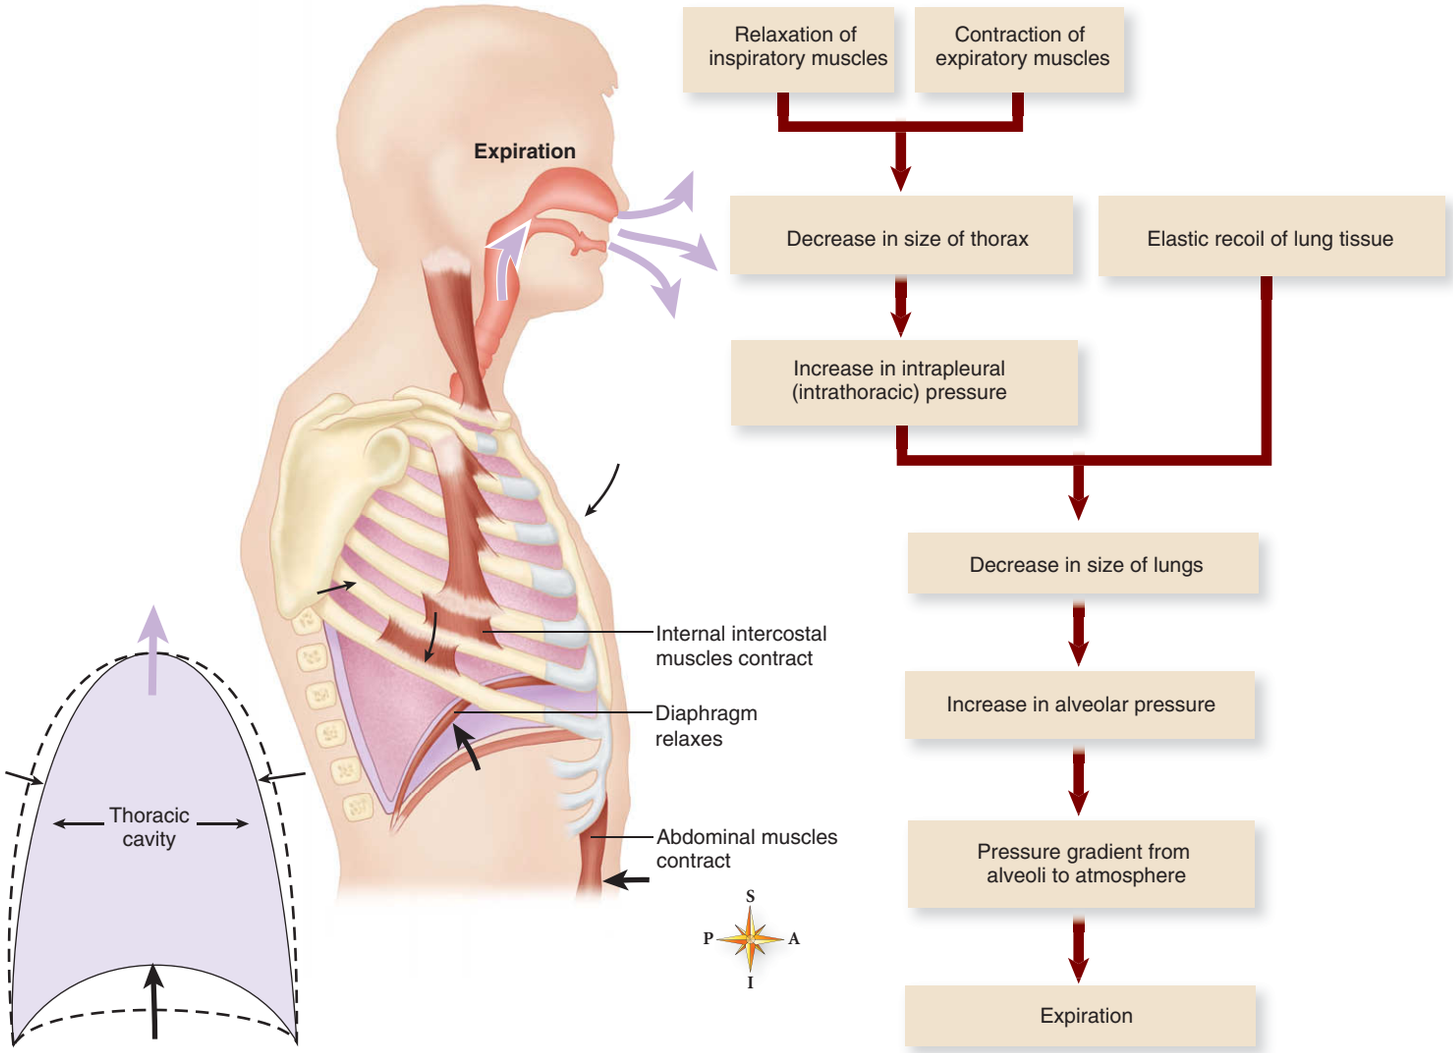

FIGURE 27-8

Mechanism of expiration. Note that relaxation of the diaphragm plus contraction of chest-depressing muscles (internal intercostals) reduces thoracic volume, which increases pressure in the lungs and thus pushes air outward.

as air flows outward through the respiratory passageways. In forced expiration, contraction of the abdominal and internal intercostal muscles can increase alveolar pressure tremendously—creating a very large air pressure gradient.

The tendency of the thorax and lungs to return to their preinspiration volume is a physical phenomenon called **elastic recoil.** If a disease condition reduces the elasticity of pulmonary tissues, expirations must become forced even at rest.

Figures 27-5 and 27-8 summarize the mechanism of expiration just described.

Look for a moment at Figure 27-9. This figure shows the repeating respiratory cycle mapped out as changes in pressures and volumes. Note that intrapleural pressure is always less than alveolar pressure. This difference ($P_{IP} - P_A$) is called the **transpulmonary pressure.** Intrapleural pressure is always "negative" with respect to alveolar pressure. Transpulmonary pressure must be negative to maintain inflation of the lungs, as stated previously.

| QUICK CHECK |

1. What is meant by the term *pulmonary ventilation?*
2. What effect does enlargement of the thoracic cavity have on the air pressure inside the lungs?
3. Which requires more expenditure of energy during normal, quiet breathing—inspiration or expiration?

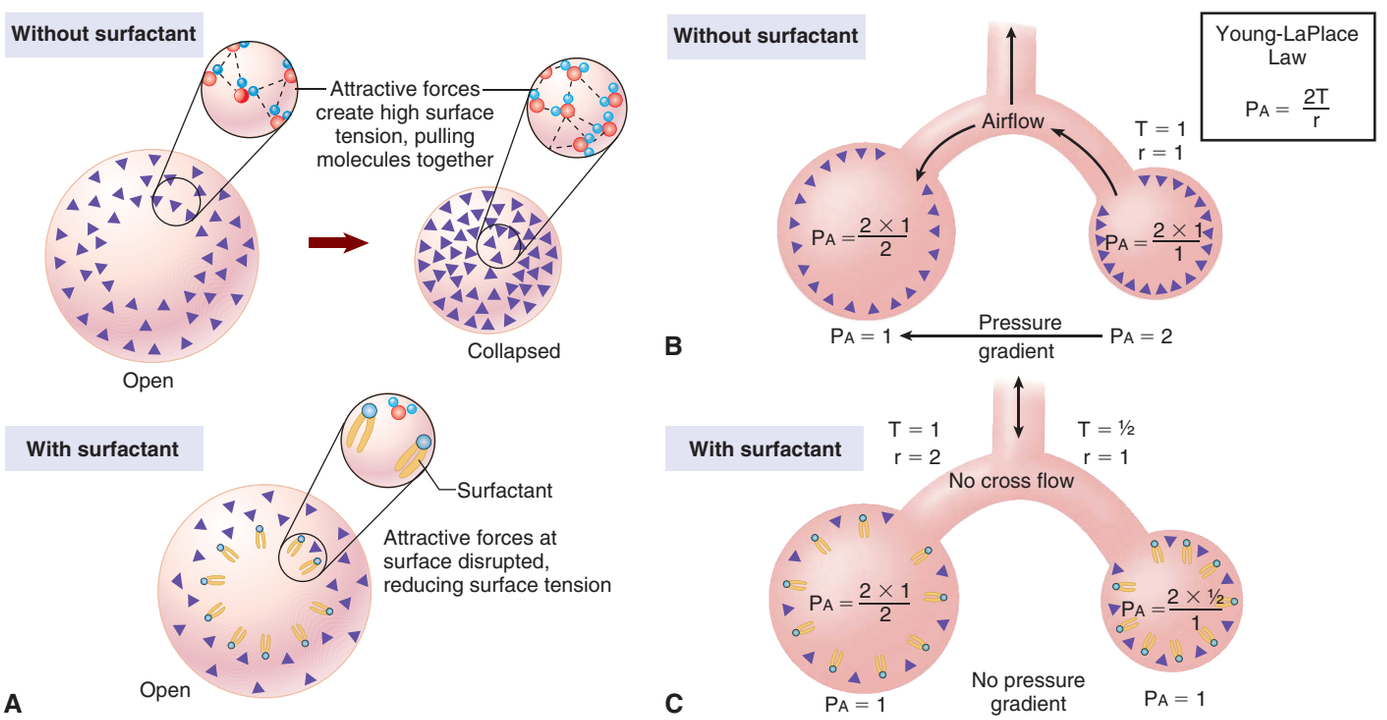
Pulmonary Volumes and Capacities

The volumes of air moved in and out of the lungs and the volume remaining in them are matters of great importance. They must be normal so that normal exchange of oxygen and carbon dioxide can occur between alveolar air and pulmonary capillary blood.

PULMONARY VOLUMES

An apparatus called a **spirometer** is used to measure the volume of air exchanged in breathing (Figure 27-10). A graphic recording

Box 27-2 | Surfactant and Lung Compliance



As we have discussed already, inspiration cannot occur without the lungs and thorax having the ability to stretch—a characteristic called *compliance.* Of course, the natural "stretchiness" of the alveolar walls is important in determining lung compliance. Conditions that cause thickening, or fibrosis, of lung tissues reduce the ease of stretch and thus reduce lung compliance. A greater impact on lung compliance is made by **surface tension** in the fluid film that lines the alveoli.

Surface tension in an aqueous (water-based) solution results from the attractive forces between water molecules in the solution. Recall from Chapter 2 that water molecules are polar and thus are electrically attracted to one another—as though they are weak magnets. Surface tension is high as the water molecules try to move toward one another, thereby contracting the fluid. The fluid lining of each alveolus would thus tend to collapse under this contracting force. However, as we discussed in Chapter 26 (see p. 809), the presence of surfactant prevents such collapse of alveoli. Surfactant is formed from the protein and phospholipid secretions of **type II cells** in the wall of each alveolus. Surfactant reduces surface tension and thus prevents fluid contraction and alveolar collapse. The role of surfactant in preventing alveolar collapse is illustrated in Figure *A.*

The pressure created by the force of surface tension is greater in smaller alveoli than in larger alveoli, according to the **Young-LaPlace law**. This means that smaller alveoli would tend to have a higher pressure (P_A) than larger alveoli would. Thus air would move from the smaller alveoli into larger alveoli. However, because the surfactant on the surface of the fluid that lines the smaller alveoli is more concentrated than that on larger alveoli, surface tension is reduced proportionally. In this way, the pressure in large alveoli is equal to that in smaller alveoli. In theory, all alveoli—no matter what their size—are ventilated equally. Figure *B* summarizes the Young-LaPlace law.

Surfactant is present in most newborns. However, because surfactant formation is not fully under way until the seventh or eighth month of prenatal development, premature infants often do not have enough surfactant. The deficiency of surfactant in premature infants is called **hyaline membrane disease (HMD).** Because lack of surfactant decreases lung compliance, a premature infant will try to inflate the alveoli by increasing effort of the inspiratory muscles. Such great effort is needed to maintain normal ventilation that the baby may die of exhaustion. The effects of such alveolar collapse and ventilation difficulty are collectively called **respiratory distress syndrome (RDS).** In infants, it is more specifically called *infant respiratory distress syndrome (IRDS).* See Figure *C.*

One way to treat IRDS is to use a special type of mechanical respirator with **continuous positive airway pressure** (**CPAP,** pronounced "SEE-pap"). The respirator artificially inflates the baby's lungs and then maintains enough pressure during expiration to prevent collapse—thus relieving the baby's inspiratory muscles. Synthetic surfactants are also used frequently to prevent or treat IRDS. The surfactant is delivered through a tube directly into the airways—a method called **intratracheal injection.**

A, Role of surfactant. The surface of the water that lines the small alveoli tends to contract because of its high surface tension, thereby collapsing the entire alveolus. Surfactant disrupts some of the attractive forces and thus reduces surface tension—and the risk of alveolar collapse. **B, Young-LaPlace law.** Also called the *law of LaPlace,* this principle states that alveolar pressure (P_A) is directly proportional to surface tension (T) and inversely proportional to the radius (r) of the alveolus. Without surfactant, the pressure gradient would cause air to flow from the small alveoli to the larger alveoli—thus triggering collapse of the smaller alveoli. When surfactant is present, the concentration of the surfactant is higher as the alveolus gets smaller. Because small alveoli have less surface tension than larger alveoli do (as a result of more concentrated surfactant), the effect of the Young-LaPlace law is counterbalanced. Because P_A thus remains about the same in all alveoli, regardless of size, ventilation is not disrupted. **C, Microscopic effects of respiratory distress syndrome (RDS).** The light micrograph on the left shows normal lung structure, with many open alveoli. The right image is from an infant who died of RDS. Note the collapse of the alveoli.

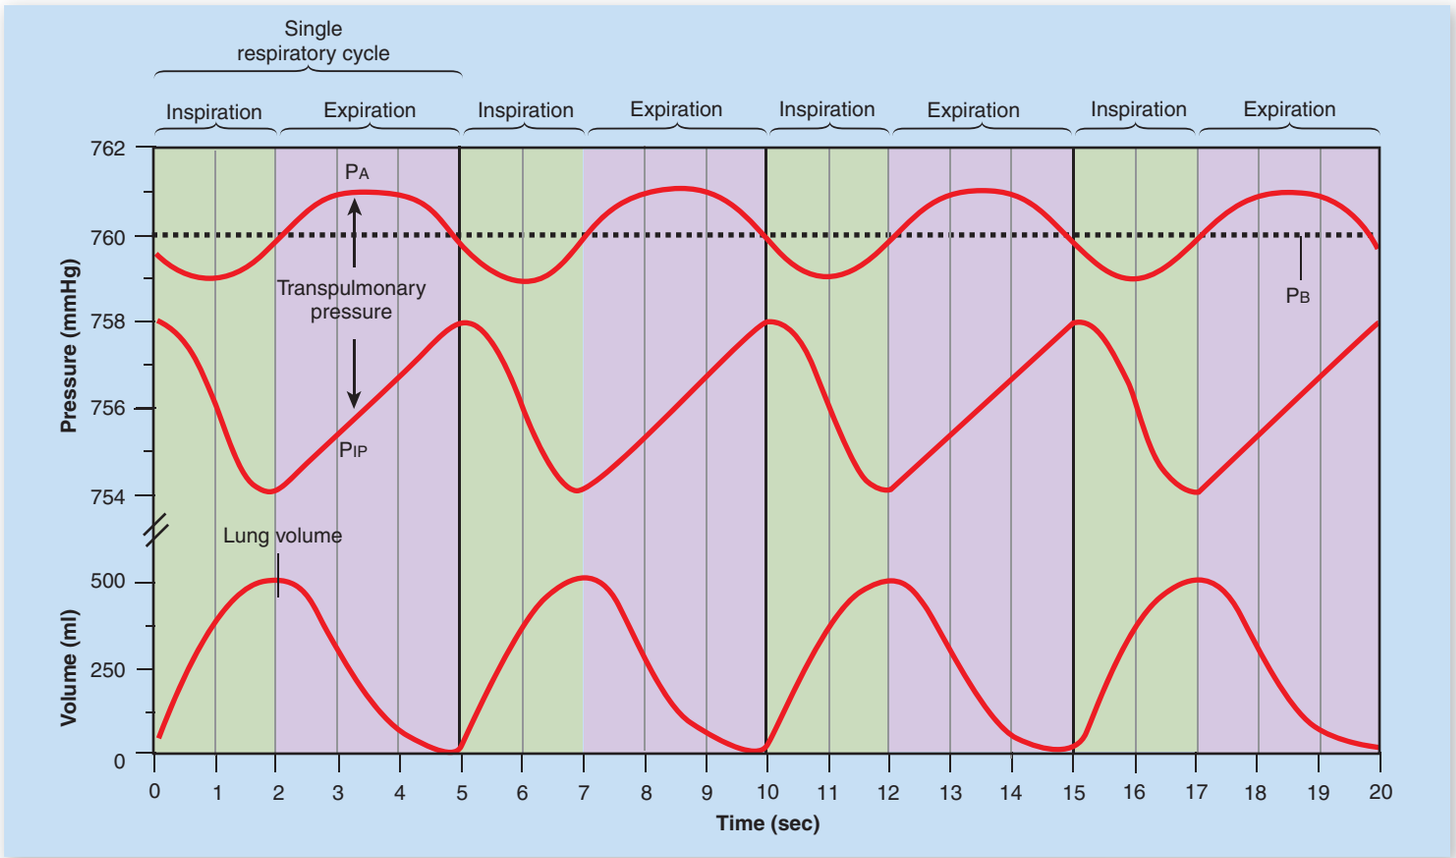


FIGURE 27-9

Rhythm of ventilation. Respiratory cycles repeat continuously in normal, quiet breathing. Notice the rhythmic rise and fall of the intrapleural pressure (P_{IP}) and alveolar pressure (P_A). You can easily see that P_{IP} is always lower than P_A (negative transpulmonary pressure), which helps keep the alveoli inflated. The lowest line shows the change in air volumes during the respiratory cycle.

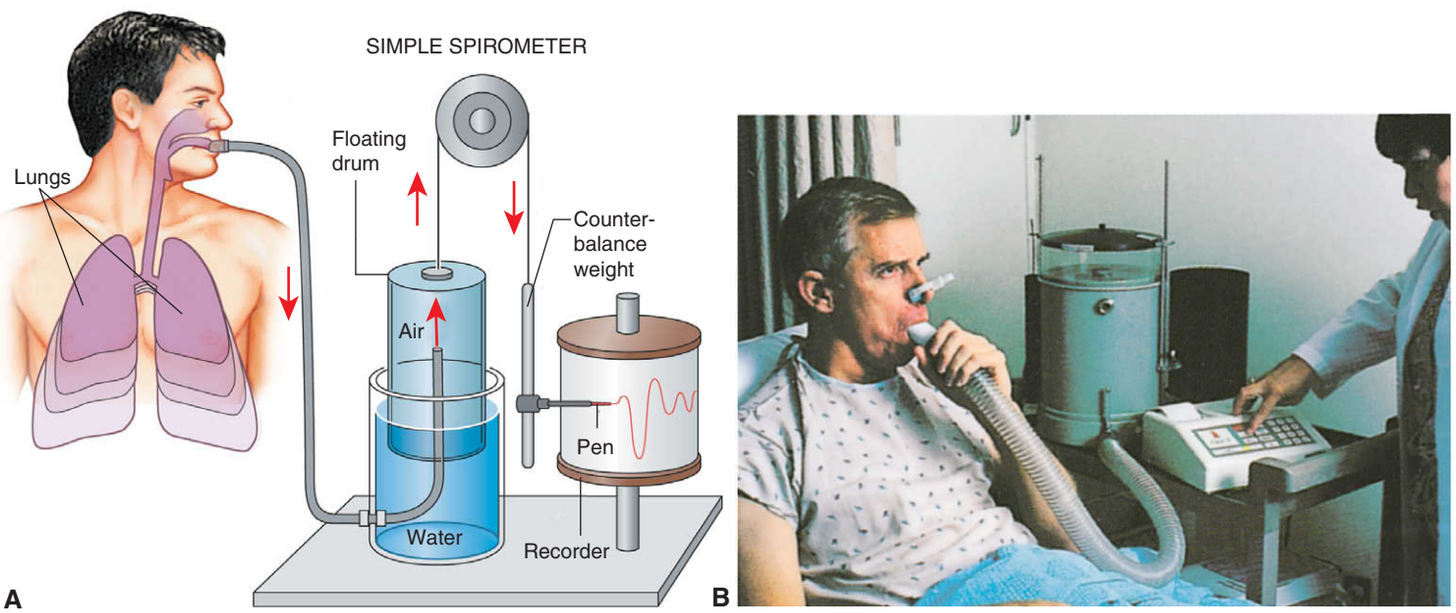

FIGURE 27-10

Spirometer. Spirometers are devices that measure the volume of gas that the lungs inhale and exhale, usually as a function of time. **A,** Diagram of a classic spirometer design showing how the volume of air exhaled and inhaled is recorded as a rising and falling line. **B,** A simple spirometer attached to a computerized recording device. This apparatus is used frequently for routine assessment of ventilation.

of the changing pulmonary volumes observed during breathing is called a **spirogram** (Figure 27-11, A). The volume of air exhaled normally after a typical inspiration is termed **tidal volume (TV).** As you can see in Figure 27-11, the normal volume of tidal air for an adult at rest is approximately 500 ml (or 0.5 L).

After expiration of tidal air, an individual can force still more air out of the lungs. The largest additional volume of air that one can forcibly expire after expiring tidal air is called the **expiratory reserve volume (ERV).** An adult, as Figure 27-11 shows, normally has an ERV of between 1000 and 1200 ml (1.0 to 1.2 L). **Inspiratory reserve volume (IRV)** is the amount of air that can be forcibly inspired over and above a normal inspiration. It is measured by having the individual exhale normally after a forced inspiration. The normal IRV is about 3300 ml (3.3 L). No matter how forcefully one exhales, one cannot squeeze all the air out of the lungs. Some of it remains trapped in the alveoli. This amount of air that cannot be forcibly expired is known as **residual volume (RV)** and amounts to about 1200 ml (1.2 L). Between breaths, an exchange of oxygen and carbon dioxide occurs between the trapped residual air in the alveoli and the blood. This process helps "level off" the amounts—or maintain the set point values—of oxygen and carbon dioxide in the blood during the breathing cycle. Have you ever had "the wind knocked out of you" by a sudden impact to the thorax or a series of deep coughs? In such a case, your expiratory reserve is forced out of your airways, as well as some of your residual volume. A few alveoli collapse as a result. It may take a moment or two, and some effort on your part, to reinflate the collapsed alveoli and reestablish normal breathing.

In *pneumothorax* (Box 27-3), the RV is eliminated when the lung collapses. Even after the RV is forced out, the collapsed lung has a porous, spongy texture and floats in water because of trapped air called the *minimal volume*, which is about 40% of the RV.

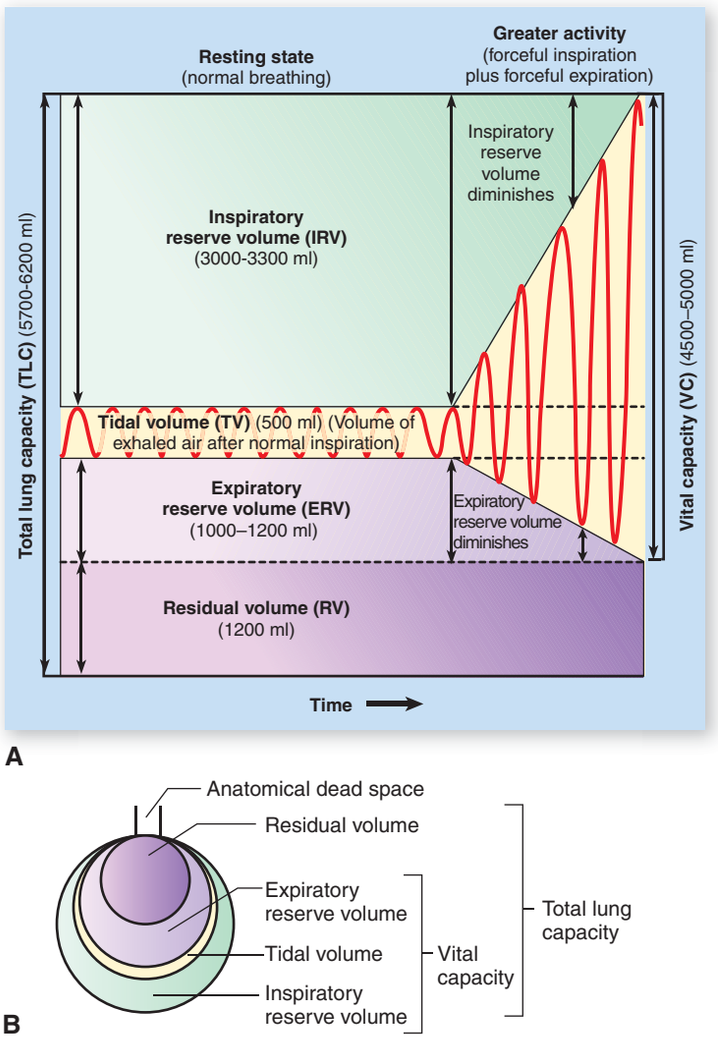

FIGURE 27-11

Pulmonary ventilation volumes and capacities. A, Spirogram. **B,** Pulmonary volumes (at rest) represented as relative proportions of an inflated balloon. During normal, quiet respirations, the atmosphere and lungs exchange about 500 ml of air (TV). With forcible inspiration, about 3300 ml more air can be inhaled (IRV). After a normal inspiration and normal expiration, approximately 1000 ml more air can be forcibly expired (ERV). Vital capacity is the amount of air that can be forcibly expired after a maximal inspiration and therefore indicates the largest amount of air that can enter and leave the lungs during respiration. Residual volume is the air that remains trapped in the alveoli.

PULMONARY CAPACITIES

A pulmonary "capacity" is the sum of two or more pulmonary "volumes." Notice in Figure 27-11 that **vital capacity (VC)** is the sum of:

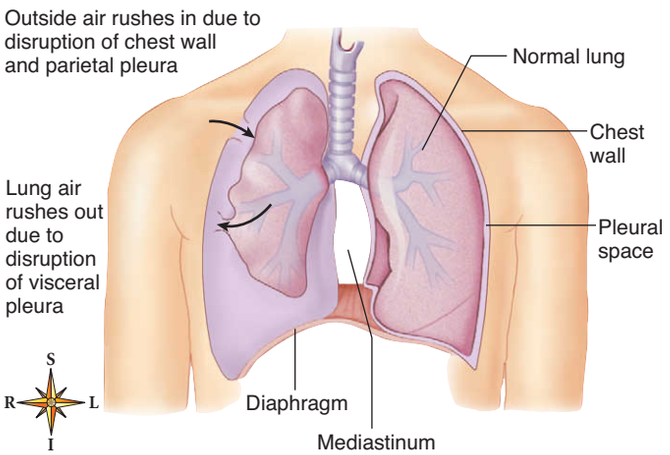
$$IRV + TV + ERV$$

The vital capacity represents the largest volume of air an individual can move in and out of the lungs. It is determined by measuring the largest possible expiration after the largest possible inspiration. How large a vital capacity a person has depends on many factors—the size of the thoracic cavity, posture, and various other factors. In general, a larger person has a larger vital capacity than a smaller person does. An individual has a larger vital capacity when standing erect than when stooped over or lying down. The volume of blood in the lungs also affects the vital capacity. If the lungs contain more blood than normal, the alveolar air space is encroached on and vital capacity accordingly decreases. This becomes a very important factor in congestive heart disease.

Excess fluid in the pleural or abdominal cavities also decreases vital capacity. So, too, does the disease *emphysema*. In emphysema, the alveolar walls become stretched—that is, lose their elasticity—and are unable to recoil normally for expiration. This leads to an increased RV. In severe emphysema, the RV may increase so much that the chest occupies the inspiratory position even at rest. Excessive muscular effort is therefore necessary for inspiration, and because of the loss of elasticity of lung tissue, greater effort is required, too, for expiration.

In diagnosing lung disorders a physician may need to know the inspiratory capacity and the functional residual capacity of the patient's lungs. **Inspiratory capacity (IC)** is the maximal amount of air an individual can inspire after a normal expiration. From Figure 27-11, you can deduce that:

$$IC = TV + IRV$$



Box 27-3 | HEALTH matters

Pneumothorax

Air in the pleural space may accumulate when the visceral pleura ruptures and air from the lung rushes out or when atmospheric air rushes in through a wound in the chest wall and parietal pleura. In either case, the lung collapses and normal respiration is impaired. Air in the thoracic cavity is a condition known as **pneumothorax** (see figure). To apply some of the information you have learned about the respiratory mechanism, let us suppose that a surgeon makes an incision through the chest wall into the pleural space, as is done in one of the dramatic, modern open-chest operations. What change, if any, can you deduce takes place in respirations? Compare your deductions with those in the next paragraph.

Intrapleural pressure, of course, immediately increases from its normal subatmospheric level to the atmospheric level. More pressure than normal is therefore exerted on the outer surface of the punctured lung and causes it to collapse. It could even collapse the other lung. Why? Because the mediastinum is a mobile rather than a rigid partition between the two pleural sacs. This anatomical fact allows the increased pressure in the side of the chest that is open to push the heart and other mediastinal structures over toward the intact side, where they would exert pressure on the other lung. Pneumothorax can also result from disruption of the visceral pleura and the resulting flow of pulmonary air into the pleural space.

Pneumothorax results in many respiratory and circulatory changes. They are of great importance in determining medical and nursing care but lie beyond the scope of this book.

Pneumothorax. Diagram showing air entering the thoracic cavity, causing lung collapse.

Using the volumes given in the figure, how many milliliters is the IC? Check your answer in Table 27-2, which summarizes pulmonary volumes and capacities. **Functional residual capacity (FRC)** is the amount of air left in the lungs at the end of a normal expiration. Therefore, as Figure 27-11 implies,

$$FRC = ERV + RV$$

Using the volumes given, the functional residual capacity is 2200 to 2400 ml (2.2 to 2.4 L). The total volume of air a lung can hold is called the **total lung capacity (TLC).** It is, as Figure 27-11 indicates, the sum of all four lung volumes.

The term **alveolar ventilation** refers to the volume of inspired air that actually reaches, or "ventilates," the alveoli. Only this volume of air takes part in the exchange of gases between air and blood. (Alveolar air exchanges some of its oxygen for some of the blood's carbon dioxide.) With every breath we take, part of the entering air necessarily fills our air passageways—nose, pharynx, larynx, trachea, and bronchi. This portion of air does not descend into any alveoli and therefore cannot take part in gas exchange. In this sense, it is "dead air." Appropriately, the larger air passageways this air occupies are said to constitute the **anatomical dead space.** Figure 27-11, *B*, relates the volume of the anatomical dead space

TABLE 27-2 Pulmonary Volumes and Capacities

VOLUME	DESCRIPTION	TYPICAL VALUE	CAPACITY	FORMULA	TYPICAL VALUE
Tidal volume (TV)	Volume moved into or out of the respiratory tract during a normal respiratory cycle	500 ml (0.5 L)	Vital capacity (VC)	TV + IRV +ERV	4500-5000 ml (4.5-5.0 L)
Inspiratory reserve volume (IRV)	Maximum volume that can be moved into the respiratory tract after a normal inspiration	3000-3300 ml (3.0-3.3 L)	Inspiratory capacity (IC)	TV + IRV	3500-3800 ml (3.5-3.8 L)
Expiratory reserve volume (ERV)	Maximum volume that can be moved out of the respiratory tract after a normal expiration	1000-1200 ml (1.0-1.2 L)	Functional residual capacity (FRC)	ERV + RV	2200-2400 ml (2.2-2.4 L)
Residual volume (RV)	Volume remaining in the respiratory tract after maximum expiration	1200 ml (1.2 L)	Total lung capacity (TLC)	TV + IRV + ERV + RV	5700-6200 ml (5.7-6.2 L)

to the major pulmonary volumes. In disorders such as **chronic obstructive pulmonary disease (COPD)**, some alveoli are not able to perform gas exchange and are therefore also "dead space." The anatomical dead space plus any alveolar dead space together make up the **physiological dead space.**

One rule of thumb estimates the volume of air in the anatomical dead space to be the same number of milliliters as the individual's weight in pounds. Another generalization says that the anatomical dead space approximates 30% of the TV. TV – dead space volume = alveolar ventilation volume. Suppose you have a normal TV of 500 ml and that 30% of this, or 150 ml, fills the anatomical dead space. The amount of air reaching your alveoli—your alveolar ventilation volume—is then 350 ml per breath, or 70% of your TV.

Emphysema and certain other abnormal conditions, in effect, increase the amount of dead space air or physiological dead space. Consequently, alveolar ventilation decreases, and this in turn decreases the amount of oxygen that can enter blood and the amount of carbon dioxide that can leave it. Inadequate air-blood gas exchange, therefore, is the inevitable result of inadequate alveolar ventilation. Stated differently, the alveoli must be adequately ventilated for an adequate gas exchange to take place in the lungs.

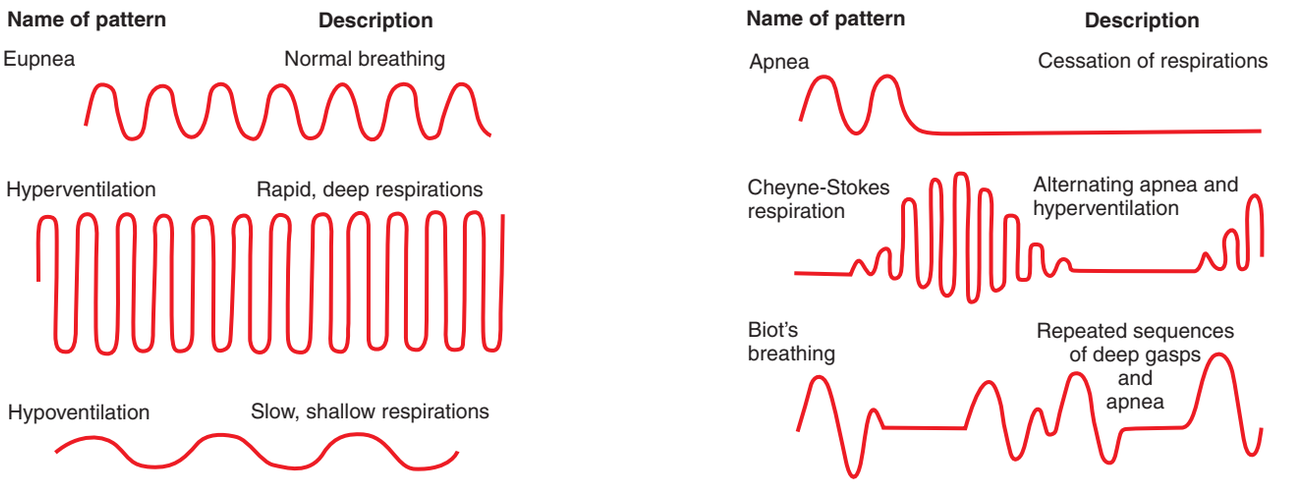
Box 27-4 summarizes some abnormal breathing patterns seen in spirometry.

Box 27-4 | Types of Breathing

The alternate movement of air into and out of the lungs that we call breathing can occur in distinctive patterns that can be recognized and designated by name (see figure).

Eupnea is the term used to describe normal quiet breathing. During eupnea, the need for oxygen and carbon dioxide exchange is being met, and the individual is not usually conscious of the breathing pattern. Ventilation occurs spontaneously at the rate of 12 to 17 breaths per minute.

Hyperpnea means increased breathing that is regulated to meet an increased demand by the body for oxygen. During hyperpnea, there is always an increase in pulmonary ventilation. The hyperpnea caused by exercise may meet the need for increased oxygen by an increase in tidal volume alone or by an increase in both tidal volume and breathing frequency.



Hyperventilation is characterized by an increase in pulmonary ventilation in excess of the need for oxygen. It sometimes results from a conscious voluntary effort preceding exertion or from psychogenic factors (hysterical hyperventilation). **Hypoventilation** is a decrease in pulmonary ventilation that results in elevated blood levels of carbon dioxide.

Dyspnea refers to labored or difficult breathing and is often associated with hypoventilation. A person suffering from dyspnea is aware, or conscious, of the breathing pattern and is generally uncomfortable and in distress. **Orthopnea** refers to dyspnea while lying down. It is relieved by sitting or standing up. This condition is common in patients with heart disease.

Several terms are used to describe the cessation of breathing. **Apnea** refers to the temporary cessation of breathing at the end of a normal expiration. It may occur during sleep or when swallowing. **Apneusis** is the cessation of breathing in the inspiratory position. Failure to resume breathing following a period of apnea, or apneusis, is called **respiratory arrest.**

Cheyne-Stokes respiration is a periodic type of abnormal breathing often seen in terminally ill or brain-damaged patients. It is characterized by cycles of gradually increasing tidal volume for several breaths followed by several breaths with gradually decreasing tidal volume. These cycles repeat in a type of crescendo-decrescendo pattern.

Biot's breathing is characterized by repeated sequences of deep gasps and apnea. This type of abnormal breathing pattern is seen in individuals suffering from increased intracranial pressure.

Examples of breathing patterns and spirograms.

PULMONARY AIRFLOW

Various applications of spirometry can be used to generate additional information about airflow in an individual. For example, spirometry can be used to determine pulmonary airflow as the rate of pulmonary ventilation, or **total minute volume** (volume moved per minute). Tidal volume (ml/cycle) multiplied by respiration rate (cycles per minute) yields the total minute volume (ml/min). The total minute volume of a person at rest is about 6000 ml (500 ml/cycle × 12 cycles/min). Box 27-5 discusses the concept of *maximum oxygen consumption*.

Yet another application of spirometry is the **forced expiratory volume (FEV)** test. The FEV test can determine the presence of respiratory obstruction by measuring the volume of air expired per second during forced expiration. The volume forcefully expired during the first second, the FEV_1, is normally about 83% of the vital capacity (Figure 27-12). FEV_2, the total volume expired during the first 2 seconds, is about 94% of the VC. By the end of the third second, FEV_3, 97% of the vital capacity should have been expired. The FEV test is also sometimes called the *FVC (forced vital capacity) test.*

Some spirometers are capable of producing a graph called the **flow-volume loop.** This type of graph shows a forced expiration (forced vital capacity) as a loop rather than the peaks and valleys of the classic spirogram. In Figure 27-13 you can see that the top portion of the loop represents expiratory airflow (liters per second) along the vertical axis and expiratory volume (liters) along the horizontal axis. The inspiratory airflow and volume are represented by the bottom portion of the loop.

Notice in Figure 27-13 that the top of the flow-volume loop represents the peak expiratory flow, or more simply the *peak flow.* The peak flow is easy to measure even with simple hand-held spirometers. It is no wonder, then, that peak flow measurements are

Box 27-5 | SPORTS and FITNESS

Maximum Oxygen Consumption

Exercise physiologists use **maximum oxygen consumption** ($Vo_{2\ max}$) as a predictor of a person's capacity to do aerobic exercise. An individual's $Vo_{2\ max}$ represents the amount of oxygen taken up by the lungs, transported to the tissues, and used to do work. $Vo_{2\ max}$ is determined largely by hereditary factors, but aerobic (endurance) training can increase it by as much as 35%. Many endurance athletes are now using $Vo_{2\ max}$ measurements to help them determine and then maintain their peak condition.

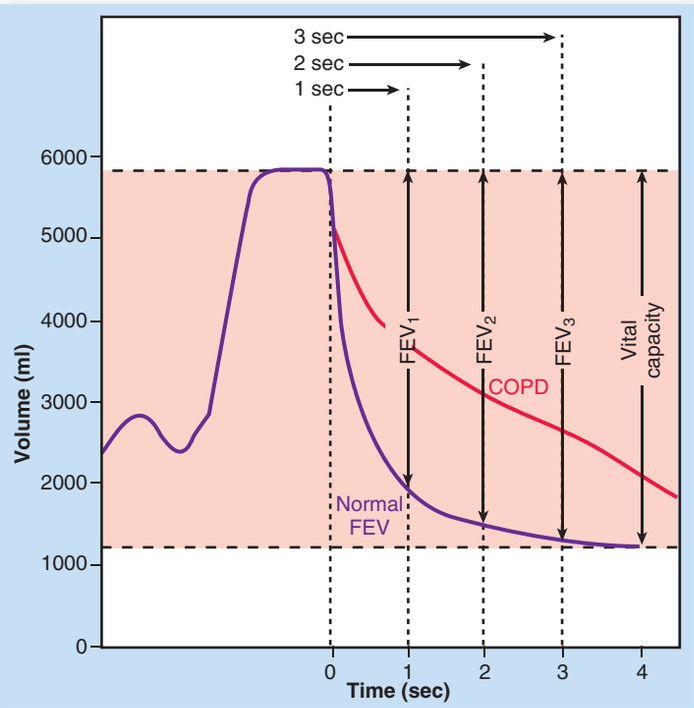


FIGURE 27-12

Forced expiratory volume (FEV). A normal individual forcefully exhales about 83% of the vital capacity (VC) during the first second, 94% at the end of 2 seconds, and 97% by the end of 3 seconds. The red line shows the results from a person with COPD (chronic obstructive pulmonary disease) who cannot forcefully exhale a large percentage of the vital capacity as quickly as a person without pulmonary obstruction.

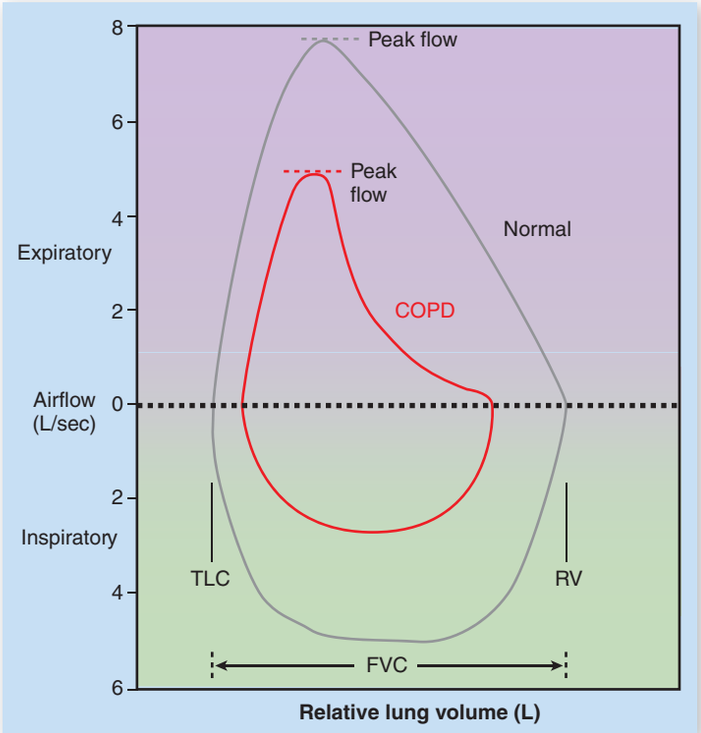

FIGURE 27-13

Flow-volume loops. The top of the loop represents expiratory flow (vertically) and volume (horizontally). The bottom of the loop represents inspiratory flow and volume. Notice that a person with COPD (chronic obstructive pulmonary disease) will produce a smaller loop with a "scooped-out" shape at the end of the expiratory curve. *FVC,* Forced vital capacity.

often used at home by asthma patients to keep a diary of airflow function. The flow-volume loop is especially useful in assessing such obstructive disorders because of the characteristic "scooped-out" shape of the expiratory part of the loop. In obstructive disorders, the inspiratory portion of the loop has a normal curve, but is smaller than normal.

| QUICK CHECK |

4. What is the difference between a pulmonary *volume* and a pulmonary *capacity?*
5. The volume of air that is expired after a normal inspiration during normal, quiet breathing is referred to by what name?
6. What is meant by the term *vital capacity?*
7. What is the *total minute volume?* How can it be calculated from a spirogram?

PULMONARY GAS EXCHANGE

Partial Pressure

Before discussing the exchange of gases across the respiratory membranes, we need to understand the law of partial pressures (Dalton's law). The term **partial pressure** means the pressure exerted by any one gas in a mixture of gases or in a liquid. According to the law of partial pressures, the partial pressure of a gas in a mixture of gases is directly related to the concentration of that gas in the mixture and to the total pressure of the mixture. Figure 27-14 shows how each gas in atmospheric air contributes to the total atmospheric pressure. The partial pressure of each gas is directly related to its concentration in the total mixture. Suppose we apply this principle to compute the partial pressure of oxygen in the atmosphere. The concentration of oxygen in the atmosphere is about 21%, and the total pressure of the atmosphere is 760 mmHg under standard conditions. Therefore:

$$\text{Atmospheric } P_{O_2} = 21\% \times 760 = 159.6 \text{ mmHg}$$

The symbol used to designate partial pressure is the capital letter *P* preceding the chemical symbol for the gas. Examples: alveolar air P_{O_2} is about 100 mmHg, arterial blood P_{O_2} is also about 100 mmHg, and venous blood P_{O_2} is about 37 mmHg. The word **tension** is often used as a synonym for the term *partial pressure*—oxygen tension means the same thing as P_{O_2}.

The partial pressure of a gas in a liquid is directly determined by the amount of that gas dissolved in the liquid, which in turn is determined by the partial pressure of the gas in the environment of the liquid. Gas molecules diffuse into a liquid from its environment and dissolve in the liquid until the partial pressure of the gas in solution becomes equal to its partial pressure in the environment of the liquid. Alveolar air constitutes the environment

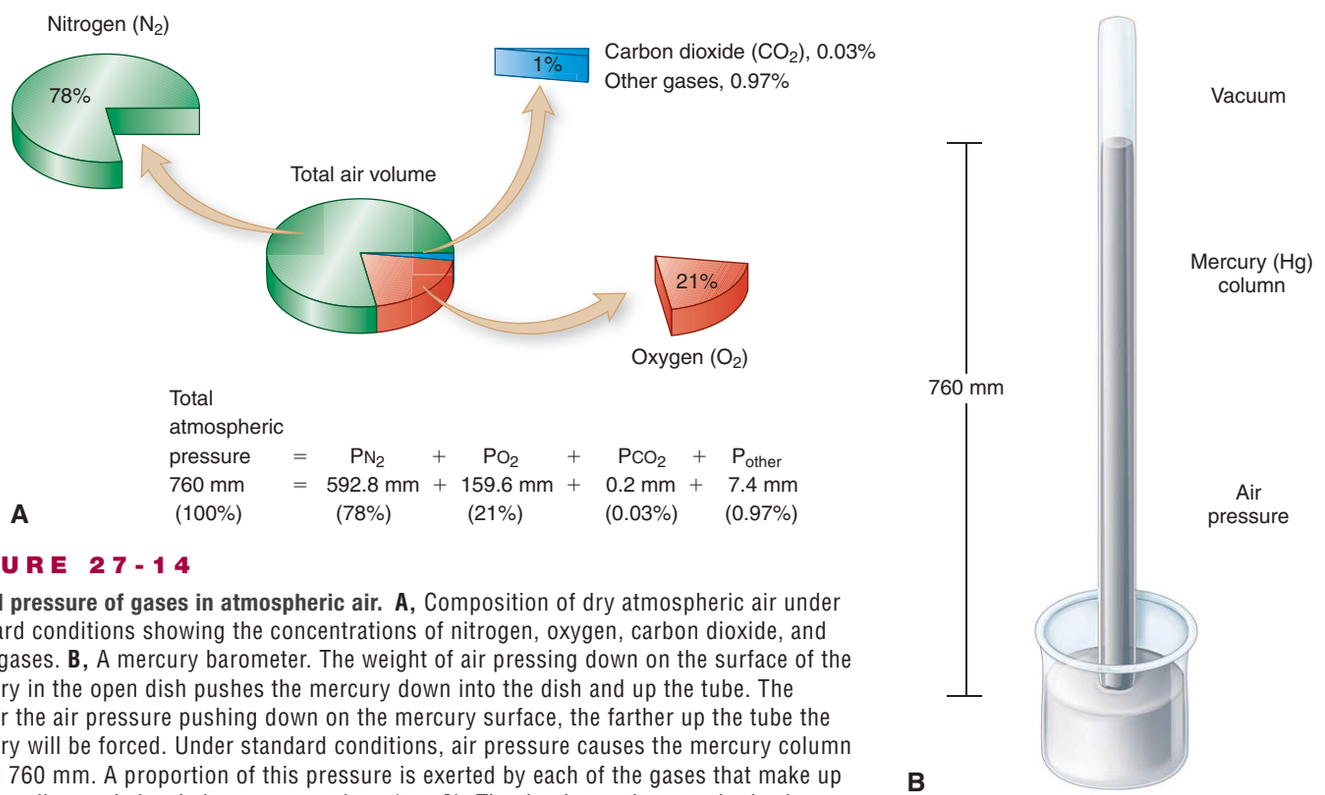

FIGURE 27-14

Partial pressure of gases in atmospheric air. A, Composition of dry atmospheric air under standard conditions showing the concentrations of nitrogen, oxygen, carbon dioxide, and other gases. **B,** A mercury barometer. The weight of air pressing down on the surface of the mercury in the open dish pushes the mercury down into the dish and up the tube. The greater the air pressure pushing down on the mercury surface, the farther up the tube the mercury will be forced. Under standard conditions, air pressure causes the mercury column to rise 760 mm. A proportion of this pressure is exerted by each of the gases that make up air, according to their relative concentrations (see **A**). That is, the total atmospheric air pressure is the sum of the partial pressures of nitrogen, oxygen, carbon dioxide, water vapor, and other gases.

TABLE 27-3 Oxygen and Carbon Dioxide Pressure Gradients*

	ATMOSPHERE	ALVEOLAR AIR	SYSTEMIC ARTERIAL BLOOD	SYSTEMIC VENOUS BLOOD
P_{O_2}	160	100	100	40
P_{CO_2}	0.2	40	40	46

*Values indicate approximate mmHg pressure under usual conditions.

surrounding blood moving through pulmonary capillaries. Standing between the blood and the air are only the very thin alveolar and capillary membranes, and both of these membranes are highly permeable to oxygen and carbon dioxide. By the time blood leaves the pulmonary capillaries as arterial blood, diffusion and approximate equilibration of oxygen and carbon dioxide across the membranes have occurred. Arterial blood P_{O_2} and P_{CO_2} therefore usually equal or very nearly equal alveolar P_{O_2} and P_{CO_2} (Table 27-3).

Exchange of Gases in the Lungs

Exchange of gases in the lungs takes place between alveolar air and blood flowing through lung capillaries. It is important to realize that physiologically speaking, air in the lung is not part of our body. That is, inspired air is not part of the internal environment. As Figure 27-15 shows, the airways are merely inward extensions of the external environment. Before oxygen can enter our internal environment, and before carbon dioxide can leave our internal environment, these gases must cross the barrier between the external world and the internal world.

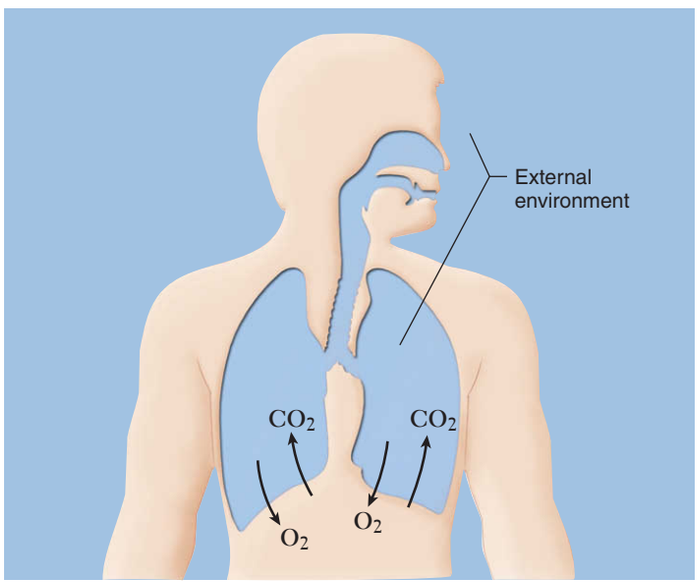

FIGURE 27-15

External-internal barrier. The respiratory membranes of the lung represent an interface or barrier that gases must cross to enter or exit the body's internal environment. The pulmonary airway is merely an extension of the external environment.

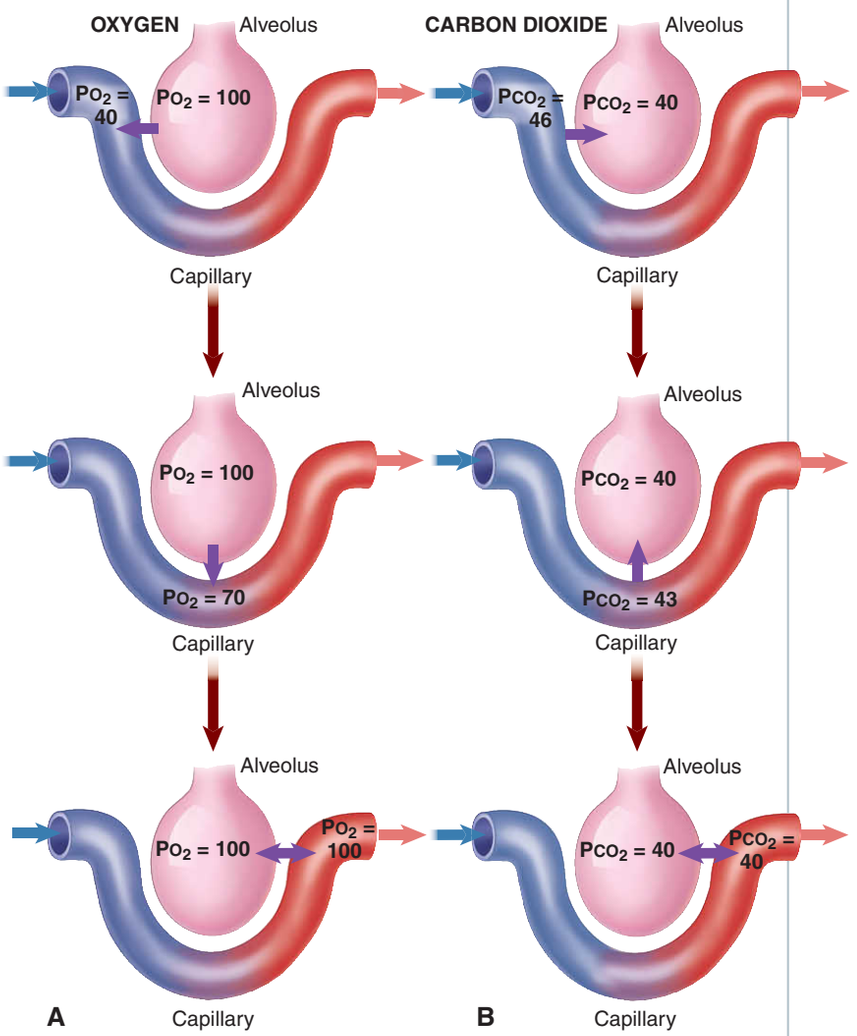

FIGURE 27-16

Pulmonary gas exchange. A, As blood enters a pulmonary capillary, oxygen diffuses down its pressure gradient (into the blood). Oxygen continues diffusing into the blood until equilibration has occurred (or until the blood leaves the capillary). **B,** As blood enters a pulmonary capillary, carbon dioxide diffuses down its pressure gradient (out of the blood). As with oxygen, carbon dioxide continues diffusing as long as there is a pressure gradient. P_{O_2} and P_{CO_2} remain relatively constant in a continually ventilated alveolus.

Gases move in both directions through the respiratory membrane (see Figure 26-15 on p. 810). Oxygen enters blood from the alveolar air because the P_{O_2} of alveolar air is greater than the P_{O_2} of incoming blood. Another way of saying this is that oxygen diffuses "down" its pressure gradient. Simultaneously, carbon dioxide molecules exit from the blood by diffusing down the carbon dioxide pressure gradient out into the alveolar air. The P_{CO_2} of venous blood is much higher than the P_{CO_2} of alveolar air. This two-way exchange of gases between alveolar air and pulmonary blood converts deoxygenated blood to oxygenated blood (Figure 27-16).

When you look at Figure 27-16, you might wonder why the partial pressures of gases in the alveoli remain constant, whereas

the partial pressures of gases in the blood change to equilibrate with alveolar partial pressures. The answer to this question lies in the fact that the alveoli are more or less continually ventilated. That is, there is always new air moving into the alveoli at a relatively low, stable velocity (Figure 27-17). Therefore, the average partial pressures of gases in the alveoli as a group are relatively constant.

The amount of oxygen that diffuses into blood each minute depends on several factors, notably the following four:

1. The oxygen pressure gradient between alveolar air and incoming pulmonary blood (alveolar Po_2 – blood Po_2)
2. The total functional surface area of the respiratory membrane
3. The respiratory minute volume (respiratory rate per minute times volume of air inspired per respiration)
4. Alveolar ventilation (discussed on p. 835)

All four of these factors bear a direct relation to oxygen diffusion. Anything that decreases alveolar Po_2, for instance, tends to decrease the alveolar-blood oxygen pressure gradient and therefore tends to decrease the amount of oxygen entering the blood. An application of this is as follows: Alveolar air Po_2 decreases as altitude increases, and thus less oxygen enters the blood at high altitudes. At a certain high altitude, alveolar air Po_2 equals the Po_2 of blood entering the pulmonary capillaries. How would this affect oxygen diffusion into blood?

Anything that decreases the total functional surface area of the respiratory membrane also tends to decrease oxygen diffusion into the blood (functional surface area is meant as that which is freely permeable to oxygen). An application of this is as follows: In emphysema the total functional area decreases and is one of the factors responsible for poor blood oxygenation in this condition. Surfactant disorders (Box 27-2) and pneumothorax (Box 27-3) can also decrease total functional area by collapsing alveoli.

Anything that decreases the respiratory minute volume also tends to decrease blood oxygenation. Application: Morphine slows respirations and therefore decreases the respiratory minute volume (volume of air inspired per minute) and tends to lessen the amount of oxygen entering the blood.

Several times we have stated the principle that structure determines function. This principle applies to gas exchange in the lungs. Several structural facts facilitate oxygen diffusion from the alveolar air into the blood in lung capillaries:

- The walls of the alveoli and the capillaries together form a very thin barrier for the gases to cross (estimated at not more than 0.004 mm thick—see Figure 26-15, p. 810).
- Alveolar and capillary surfaces are both extremely large (Box 27-6).

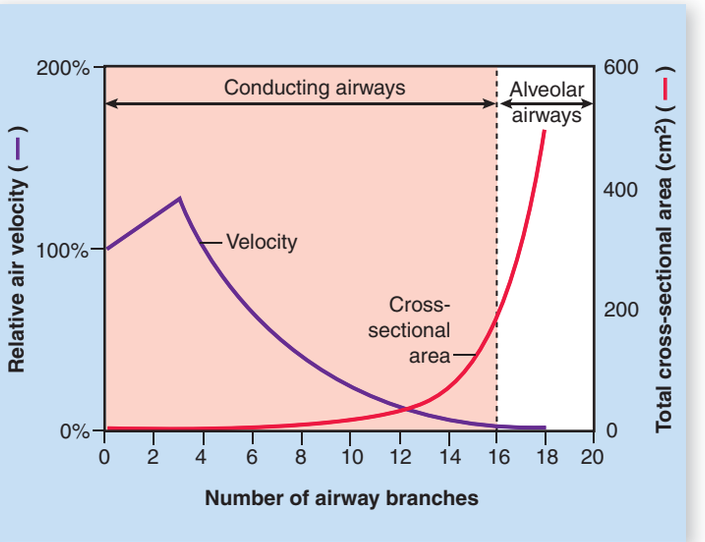

FIGURE 27-17

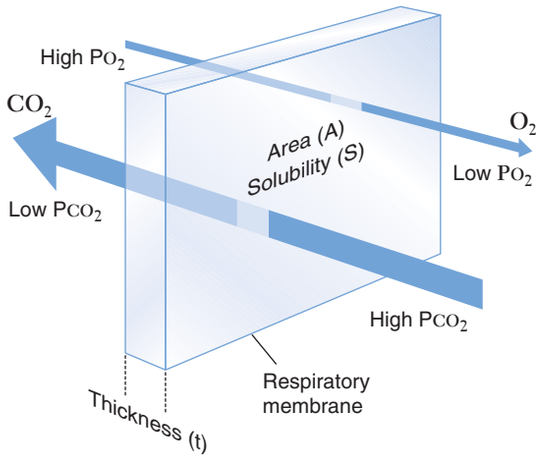
Airflow in airways. Air velocity (speed of flow) is high in the upper respiratory tract, where the total cross-sectional area is very low. As you can see on the left of the graph, however, the airflow slows down considerably in the alveolar airways because of the high total cross-sectional area of all of the alveoli. This accounts for the fact that ventilation of the alveoli is slow and relatively steady whereas ventilation of the upper airways is characterized by high-speed, alternating rushes of air.

- Lung capillaries accommodate a large amount of blood at one time. The lung capillaries of a small individual—one who has a body surface area of 1.5 square meters—contain about 90 ml of blood at one time under resting conditions (Figure 27-18).
- Blood is distributed through the capillaries in a layer so thin (equal only to the diameter of one red blood cell) that each red blood cell comes close to alveolar air.



| QUICK CHECK |

8. How does the partial pressure of a gas relate to its concentration?
9. What determines the direction in which oxygen will diffuse across the respiratory membrane?
10. List two of the four major factors that influence how much oxygen diffuses into pulmonary blood per minute.

Box 27-6 | Fick's Law

Fick's law is a principle that describes the diffusion of carbon dioxide (CO_2) and oxygen (O_2) across the respiratory membrane, including the fluid film on the surface of the alveoli. As you can see in the figure, the principle illustrates common sense: each gas diffuses more efficiently (faster) if the surface area *(A)* is large, if the thickness of the membrane *(t)* is small, if the solubility of the gas *(S)* is high, and if the partial pressure *(Po_2* or *Pco_2)* gradient is high. Another way of stating Fick's law is that the net gas diffusion rate across a fluid membrane is proportional to the membrane surface area *(A)*, solubility of the gas in the membrane *(S)*, and partial pressure *(P)* difference—and inversely proportional to the membrane thickness *(t)*.

The human respiratory system takes advantage of this principle by improving what it can in the equation to maximize the rate of gas diffusion. The body builds its respiratory membrane of material with as much solubility to CO_2 and O_2 as possible and makes it as thin as possible. The large number of alveoli in a fractal-like arrangement ensure a very large surface area, and a high partial pressure gradient is maintained across the respiratory membrane.

Rate of diffusion of a gas through a membrane. According to Fick's law, the membrane diffusion rate is affected by surface area (A), solubility (S) of the gas, membrane thickness (t), and the partial pressure (P) gradient.

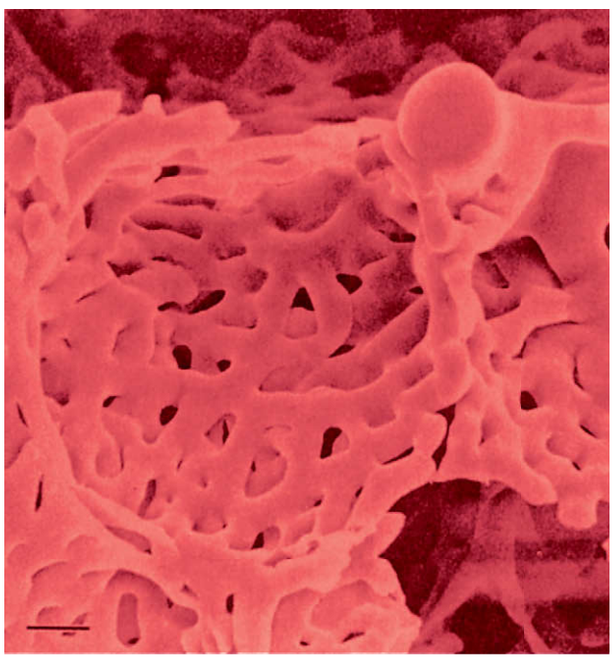


FIGURE 27-18

Alveolar blood supply. Scanning electron micrograph showing the rich blood supply to alveoli (which have been removed). The numerous, narrow branches ensure that each red blood cell is exposed to the alveolar air. (Black bar in lower left represents 10 μm.)

HOW BLOOD TRANSPORTS GASES

Blood transports oxygen and carbon dioxide either as solutes or combined with other chemicals. Immediately on entering the blood, both oxygen and carbon dioxide dissolve in the plasma, but because fluids can hold only small amounts of gas in solution, most of the oxygen and carbon dioxide rapidly form a chemical union with some other molecule—such as hemoglobin, a plasma protein, or water. Once gas molecules are bound to another molecule, their plasma concentration decreases and more gas can diffuse into the plasma. In this way, comparatively large volumes of the gases can be transported.

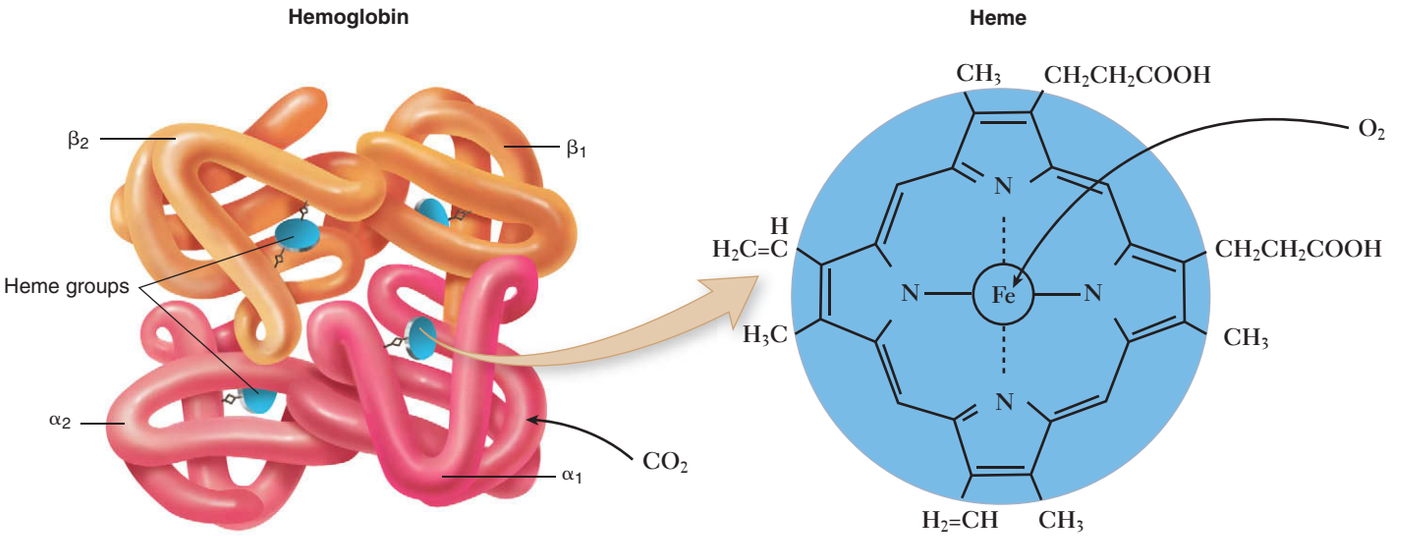

FIGURE 27-19

Hemoglobin. Sketch showing that hemoglobin is a quaternary protein consisting of four different tertiary (folded) polypeptide chains—two alpha (α) chains and two beta (β) chains. Each chain has an associated iron-containing heme group, as seen in detail in the inset. Oxygen (O_2) can bind to the iron (Fe) of the heme group, or carbon dioxide (CO_2) can bind to amine groups of the amino acids in the polypeptide chains.

Hemoglobin

Before we begin our discussion of transport of gases in the blood, we will pause and briefly review some facts about **hemoglobin (Hb)** (Figure 27-19). As we outlined in Chapter 20, hemoglobin is a reddish protein pigment found only inside red blood cells.

Hemoglobin is a quaternary protein made of four different polypeptide chains—two alpha chains and two beta chains—each associated with an iron-containing **heme group.** If you look at Figure 27-19, you will see that an oxygen molecule (O_2) can combine with the iron atom (Fe) in each heme group. Thus hemoglobin can act as a kind of oxygen sponge that chemically absorbs oxygen molecules from the surrounding solution. Notice also in this figure that carbon dioxide (CO_2) molecules can combine with the amino acids of the alpha and beta polypeptide chains. Thus hemoglobin can also act as a carbon dioxide sponge and absorb carbon dioxide molecules from a solution. Hemoglobin, then, has exactly the chemical characteristics needed to pick up and transport gases that enter the blood. As you will learn in the following paragraphs, hemoglobin also has the chemical characteristics needed to unload these gases. Box 27-7 explains how carbon monoxide interferes with hemoglobin's function.

Transport of Oxygen

Because oxygenated blood has a Po_2 of 100 mmHg, it contains only about 0.3 ml of dissolved O_2 per 100 ml of blood. Many times that amount, however, combines with the hemoglobin in 100 ml of blood to form **oxyhemoglobin.** Because each gram of hemoglobin can unite with 1.34 ml of oxygen, the exact amount of oxygen in blood depends mainly on the amount of hemoglobin present. Normally, 100 ml of blood contains about 15 grams of hemoglobin. If 100% of it combines with oxygen, 100 ml of blood will contain 15 × 1.34, or 20.1 ml, of oxygen in the form of oxyhemoglobin. Figure 27-20 shows how hemoglobin increases the oxygen-carrying capacity of blood.

Perhaps a more common way of expressing blood oxygen content is in terms of volume percent. Normal arterial blood, with a Po_2 of 100 mmHg, contains about 20 vol% O_2 (meaning 20 ml of oxygen in each 100 ml of blood).

Blood that contains more hemoglobin can, of course, transport more oxygen. Thus blood that contains less hemoglobin can transport less oxygen. Therefore hemoglobin deficiency anemia decreases oxygen transport and may produce marked cellular hypoxia (inadequate oxygen supply).

To combine with hemoglobin, oxygen must, of course, diffuse from plasma into the red blood cells where millions of hemoglobin molecules are located. Several factors influence the rate at which hemoglobin combines with oxygen in lung capillaries. For

Box 27-7 | Carbon Monoxide Poisoning

Gases other than O_2 and CO_2 can bind to the hemoglobin (Hb) molecule. **Carbon monoxide (CO)** is a molecule produced by incomplete combustion in furnaces, engines, and other circumstances. This invisible, odorless gas binds to Hb more than 200 times more strongly than O_2 does. That means that CO "knocks out" O_2 from HbO_2 and forms HbCO. As more and more HbCO is formed, less and less oxygen is being carried by your blood—a life-threatening situation. Because CO binds so strongly, it is hard to remove it from Hb. One strategy to remove CO is to place a person in a pressure chamber where the Po_2 can be driven so high that it "knocks off" the CO from the Hb, allowing O_2 to form HbO_2.

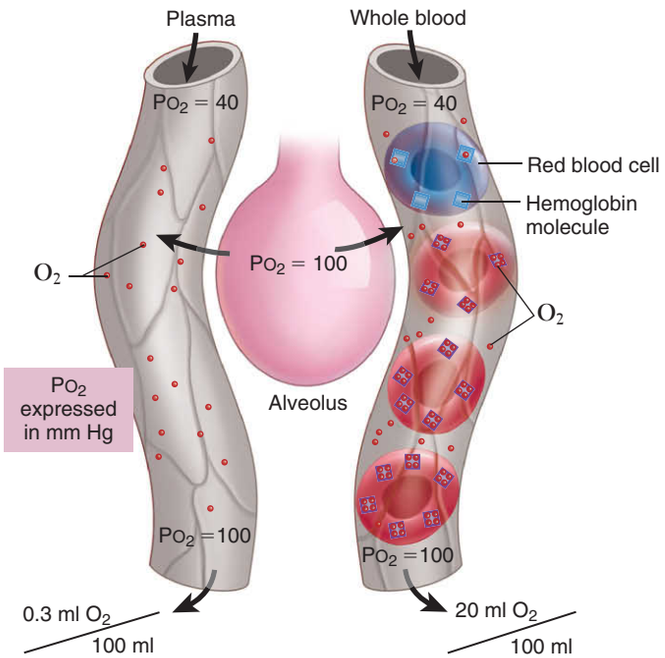

FIGURE 27-20

Oxygen-carrying capacity of blood. If blood consisted only of plasma, the maximum oxygen that could be transported would be only about 0.3 ml of O_2 per 100 ml of blood. Because the red blood cells contain hemoglobin molecules, which act as "oxygen sponges," the blood can actually carry up to 20 ml of dissolved O_2 per 100 ml of blood.

instance, as the following equation and the **oxygen-hemoglobin dissociation curve** (Figure 27-21) show, an increasing blood Po_2 accelerates hemoglobin association with oxygen:

$$Hb + O_2 \xrightarrow{\text{Increasing } Po_2} HbO_2$$

Decreasing Po_2, on the other hand, accelerates oxygen dissociation from oxyhemoglobin, that is, the reverse of the preceding equation. Oxygen associates with hemoglobin rapidly—so rapidly, in fact, that about 97% of the blood's hemoglobin has united with oxygen by the time the blood leaves the lung capillaries to return to the heart. In other words, the average oxygen saturation of hemoglobin in oxygenated blood is about 97%.

Summing up, we can say that oxygen travels in two forms: as dissolved O_2 in the plasma and as O_2 associated with hemoglobin (oxyhemoglobin). Of these two forms of transport, oxyhemoglobin carries the vast majority of the total oxygen transported by the blood.

| A&P CONNECT |

Variations of hemoglobin exist in the body to temporarily store or carry oxygen. Find out why we need more than one type of oxygen carrier in the body in ***Oxygen-binding Proteins*** online at ***A&P Connect.***

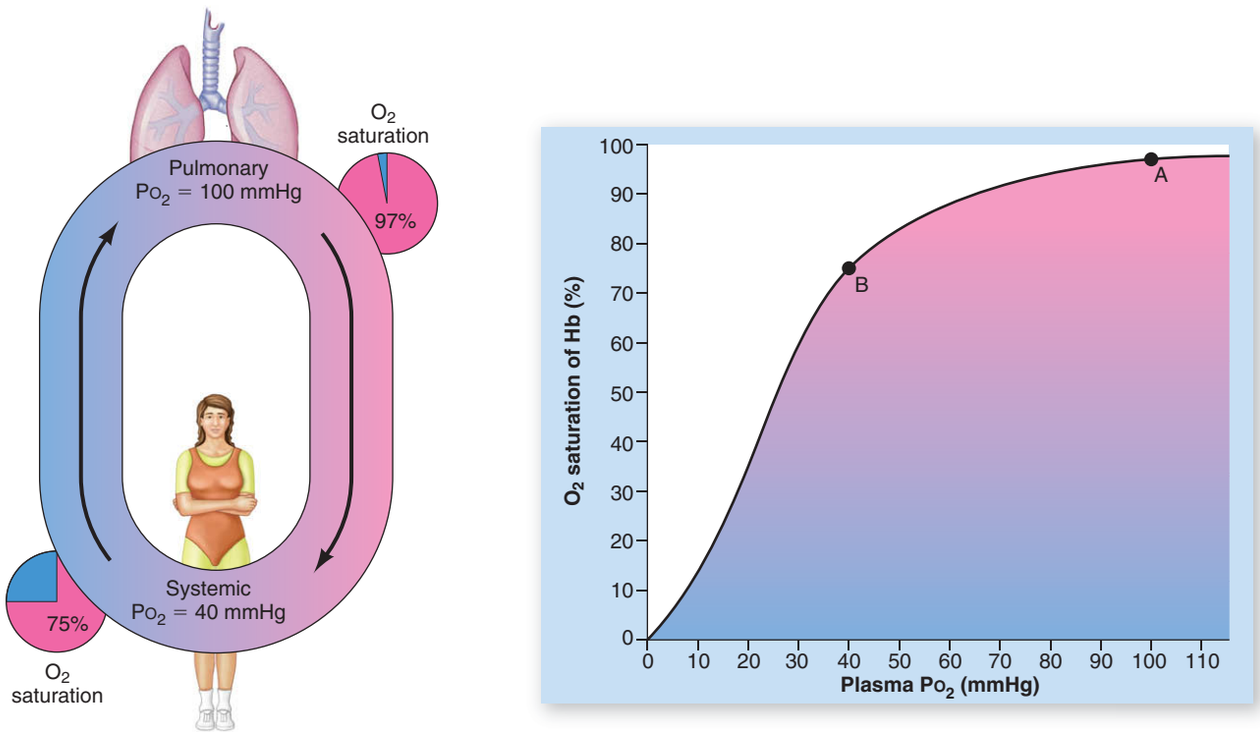

FIGURE 27-21

Oxygen-hemoglobin dissociation curve. The graph represents the relationship between Po_2 and O_2 saturation of hemoglobin (Hb-O_2 affinity). The inset shows how the graphed curve relates to oxygen transport by the blood. Notice that at high plasma Po_2 values (point *A*), hemoglobin (Hb) is fully loaded with oxygen. At low plasma Po_2 values (point *B*), Hb is only partially loaded with oxygen.

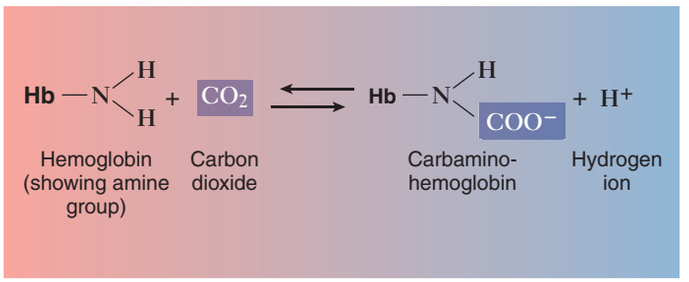

FIGURE 27-22

Carbon dioxide–hemoglobin reaction. Carbon dioxide can bind to an amine group (NH_2) in an amino acid within a hemoglobin (Hb) molecule to form carbaminohemoglobin ($HbNCOOH^-$) and a hydrogen ion. The highlighted areas show where the original carbon dioxide molecule is in each part of the equation.

Transport of Carbon Dioxide

Carbon dioxide is carried in the blood in several ways, the most important of which are described briefly in the following paragraphs.

DISSOLVED CARBON DIOXIDE

A small amount of CO_2 dissolves in plasma and is transported as a solute. About 10% of the total amount of carbon dioxide carried by the blood is carried in the dissolved form. It is this dissolved CO_2 that produces the P_{CO_2} of blood plasma.

CARBAMINO COMPOUNDS

One fifth to one quarter of the carbon dioxide in blood unites with the NH_2 (amine) groups of the amino acids that make up the polypeptide chains of hemoglobin and various plasma proteins. When carbon dioxide binds to amine groups, it forms *carbamino compounds*. Because hemoglobin is the main protein that combines with carbon dioxide, most carbamino molecules are formed and transported in the red blood cells. The compound formed when carbon dioxide combines with hemoglobin has a tongue-twisting name—**carbaminohemoglobin.** The following chemical equation, amplified in Figure 27-22, shows how carbon dioxide combines with amine (NH_2) in hemoglobin's polypeptide chains to produce carbaminohemoglobin (HbNCOOH) and H^+:

$$Hb{-}N\begin{matrix}H\\H\end{matrix} + CO_2 \rightleftharpoons Hb{-}N\begin{matrix}H\\COO^-\end{matrix} + H^+$$

Notice that the arrows in this equilibrium point in both directions. This means that under any given conditions, some carbon dioxide will be associated with hemoglobin and some will not—the reaction is moving in both directions at the same time. The rate of both forward and reverse reactions—carbon dioxide association with and dissociation from hemoglobin—can shift with changes in carbon dioxide concentration. This principle is sometimes called the **rate law** of chemistry. The addition of more carbon dioxide to blood, therefore, will increase the rate of formation of carbaminohemoglobin. Another way to state this principle is to say that the association of carbon dioxide with hemoglobin is accelerated by an increase in P_{CO_2} and is slowed by a decrease in P_{CO_2}. Figure 27-23, which shows the carbon dioxide dissociation curve, illustrates that the CO_2-carrying capacity of blood increases as plasma P_{CO_2} increases.

BICARBONATE

More than two-thirds of the CO_2 carried by blood is carried in the form of **bicarbonate** ions (HCO_3^-). When CO_2 dissolves in water (as in blood plasma), some of the CO_2 molecules associate with H_2O to form carbonic acid (H_2CO_3). Once formed, some of the H_2CO_3 molecules dissociate to form H^+ and bicarbonate (HCO_3^-) ions. This process, which is catalyzed by an enzyme present in red blood cells called *carbonic anhydrase (CA)*, is summarized by the following chemical equation:

$$CO_2 + H_2O \rightleftharpoons H_2CO_3 \rightleftharpoons H + HCO_3$$

Figure 27-24 amplifies this equation. According to the rate law of chemistry we stated earlier, as more CO_2 is added to the plasma, more will be converted to carbonic acid. Because the carbonic anhydrase enzyme in the blood is facilitating the conversion of carbon dioxide and water to carbonic acid, this reaction occurs very rapidly as CO_2 is added to the plasma. Carbonic acid concentration increases as a result, "pulling" the system toward the bicarbonate side, thus increasing the rate of bicarbonate formation. The end result is that CO_2 molecules diffusing into plasma will continually be removed from the solution and converted into bicarbonate. This allows room for even more CO_2 to dissolve in the plasma—thus increasing the CO_2-carrying capacity of the blood.

Figure 27-25, which summarizes all three forms of CO_2 transport, shows that once bicarbonate ions are formed, they diffuse down their concentration gradient into the plasma. The exit of this negative ion (HCO_3^-) from the red blood cell is balanced by the inward transport of another negative ion, chloride (Cl^-). This countertransport of negative ions is often called the **chloride shift.**

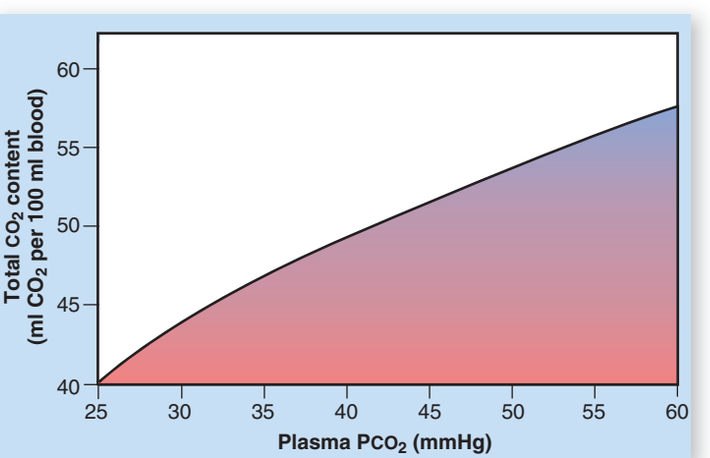

FIGURE 27-23

Carbon dioxide dissociation curve. The relationship between P_{CO_2} and total CO_2 content (ml CO_2 per 100 ml blood) is graphed as a nearly straight line. Notice that the CO_2-carrying capacity of blood increases as the plasma P_{CO_2} increases.

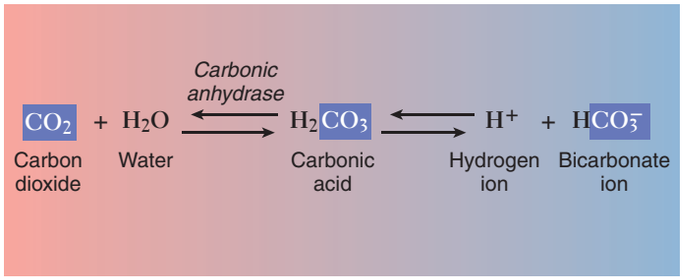

FIGURE 27-24

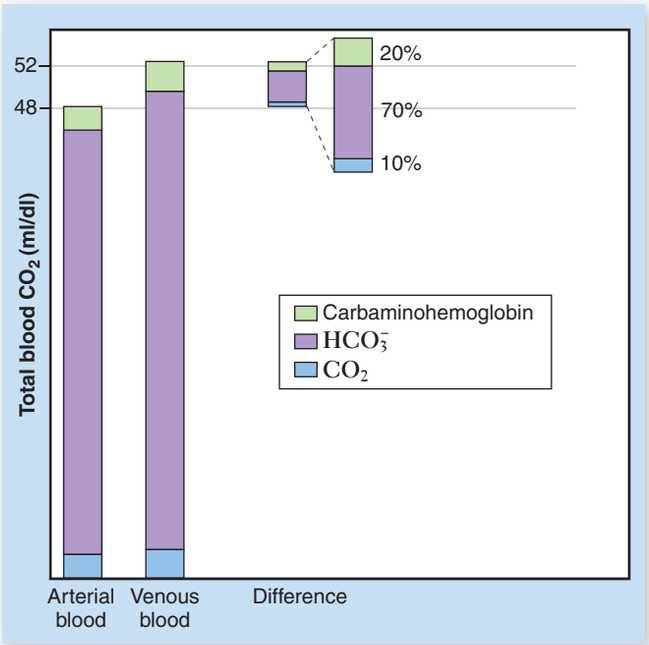
Formation of bicarbonate. Carbon dioxide can react with water to form carbonic acid, a reaction catalyzed by the red blood cell (RBC) enzyme carbonic anhydrase. Carbonic acid then dissociates to form bicarbonate and a hydrogen ion. The highlighted areas show where the original carbon dioxide molecule is in each part of the equation. The double arrows show that each reaction is reversible, the actual rate in each direction governed by the relative concentration of each molecule.

According to the rate law of chemistry described earlier, when CO_2 is removed from the plasma, the entire system, illustrated in Figures 27-24 and 27-25, shifts in the opposite direction. Thus the reaction that converts carbonic acid to free CO_2 becomes dominant. The declining concentration of carbonic acid then forces a shift in favor of the conversion of bicarbonate to carbonic acid. In short, CO_2 is unloaded from bicarbonate.

The relative proportions of the three different forms of carbon dioxide carried in the blood are summarized in Figure 27-26.



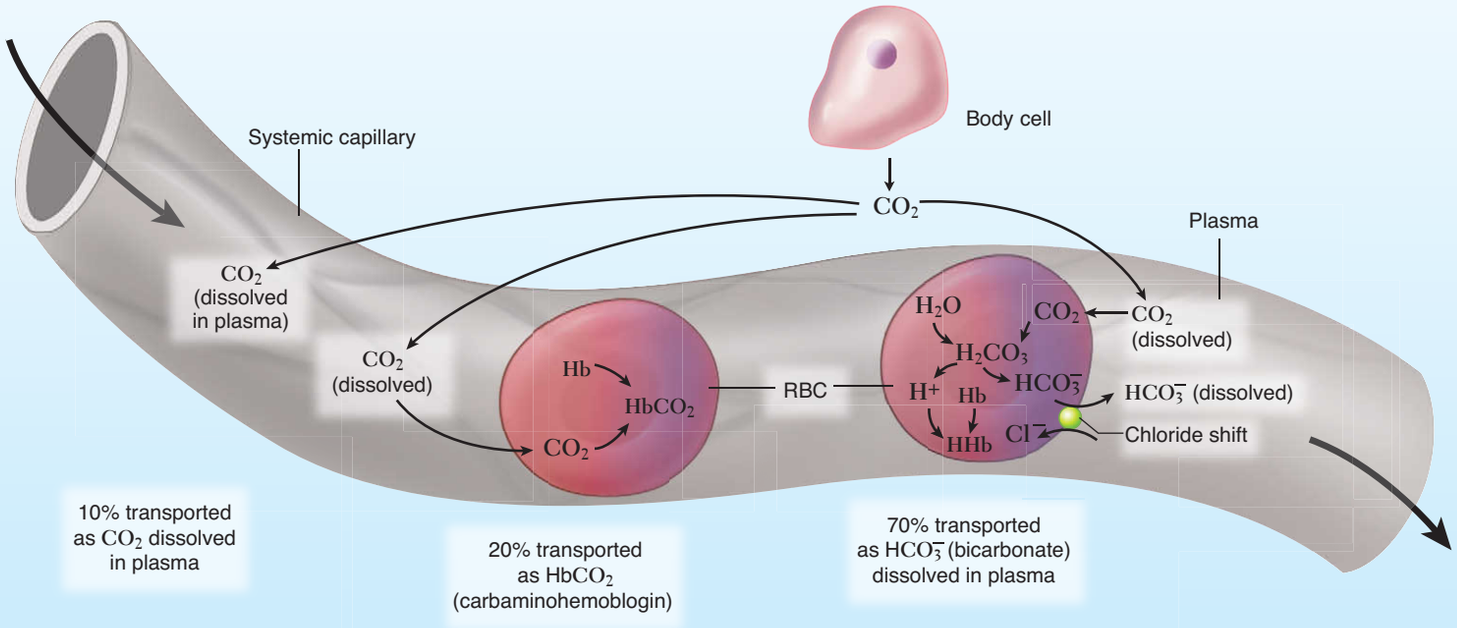


FIGURE 27-26

Proportions of carbon dioxide transported in the blood. This graph shows that systemic venous blood carries more carbon dioxide than systemic arterial blood does. The difference, shown in the upper left, represents the total amount of carbon dioxide loaded into the blood in the systemic tissues. Or it could be viewed as the total amount of carbon dioxide unloaded from the blood in the lungs. Note that most of the carbon dioxide is carried in the form of HCO_3^- (bicarbonate).

FIGURE 27-25

Carbon dioxide transport in the blood. As the illustration shows, CO_2 dissolves in the plasma. Some of the dissolved CO_2 enters red blood cells (RBCs) and combines with hemoglobin (Hb) to form carbaminohemoglobin ($HbCO_2$). Some of the CO_2 entering RBCs combines with H_2O to form carbonic acid (H_2CO_3), a process facilitated by the enzyme carbonic anhydrase (CA) present inside each cell. Carbonic acid then dissociates to form H^+ and bicarbonate (HCO_3^-). The H^+ combines with Hb, whereas the HCO_3^- diffuses down its concentration gradient into the plasma. As HCO_3^- leaves each RBC, Cl^- enters and prevents an imbalance in charge—a phenomenon called the *chloride shift,* which is discussed in Chapter 33.

CARBON DIOXIDE AND PH

You may have noticed by now that when carbon dioxide enters the blood, most of it is converted to carbaminohemoglobin and hydrogen ions (H^+) or to bicarbonate and hydrogen ions. In other words, have you noticed that increasing the carbon dioxide content of the blood also increases its H^+ concentration? Thus an increase in carbon dioxide in the blood causes an increase in the acidity, or a drop in pH, in the blood. This is a very important principle in understanding how and why respiration is regulated in the manner that it is. We will discuss these matters later in this chapter. This principle is also important to the understanding of acid-base balance in the body—a topic discussed thoroughly in Chapter 33.

SYSTEMIC GAS EXCHANGE

Exchange of gases in tissues takes place between arterial blood flowing through tissue capillaries and cells (Figure 27-27). It occurs because of the principle already noted—that gases move down a gas pressure gradient. More specifically, in the tissue capillaries, oxygen diffuses out of arterial blood because the oxygen pressure gradient favors its outward diffusion (see Figure 27-27). Arterial blood P_{O_2} is about 100 mmHg, interstitial fluid P_{O_2} is considerably lower, and intracellular fluid P_{O_2} is still lower. Although interstitial fluid and intracellular fluid P_{O_2} are not definitely established, they are thought to vary considerably—perhaps from around 60 mmHg down to about 1 mmHg.

As activity increases in any tissue, its cells necessarily use oxygen more rapidly. This decreases intracellular and interstitial P_{O_2}, which in turn tends to increase the oxygen pressure gradient between blood and tissues and to accelerate oxygen diffusion out of the tissue capillaries. In this way, the rate of oxygen use by cells automatically tends to regulate the rate of oxygen delivery to cells. As dissolved oxygen diffuses out of arterial blood, blood P_{O_2} decreases, and this accelerates oxyhemoglobin dissociation to release more oxygen into the plasma for diffusion out to cells, as indicated in Figure 27-28 and the following equation:

$$HbO_2 \xrightarrow{\text{Decreasing } P_{O_2}} Hb + O_2$$

Because of oxygen release to tissues from tissue capillary blood, P_{O_2}, oxygen saturation, and total oxygen content are less in venous blood than in arterial blood, as shown in Table 27-4. Carbon dioxide exchange between tissues and blood takes place in the opposite direction from oxygen exchange. Catabolism produces large amounts of CO_2 inside cells. Therefore, intracellular and interstitial P_{CO_2} are higher than arterial blood P_{CO_2}. This means that the CO_2 pressure gradient causes diffusion of CO_2 from the tissues into the blood flowing along through tissue capillaries (see Figure 27-27). Consequently, the P_{CO_2} of blood increases in tissue capillaries from its arterial level of about 40 mmHg to its venous level of about 46 mmHg.

TABLE 27-4 Blood Oxygen

	SYSTEMIC VENOUS BLOOD	SYSTEMIC ARTERIAL BLOOD
P_{O_2}	40 mmHg	100 mmHg
Oxygen saturation	75%	97%
Oxygen content	15 ml O_2 per 100 ml blood	20 ml O_2 per 100 ml blood*

*Oxygen use by tissues = difference between the oxygen content of arterial and venous blood (20-15) = 5 ml O_2 per 100 ml blood circulated per minute.

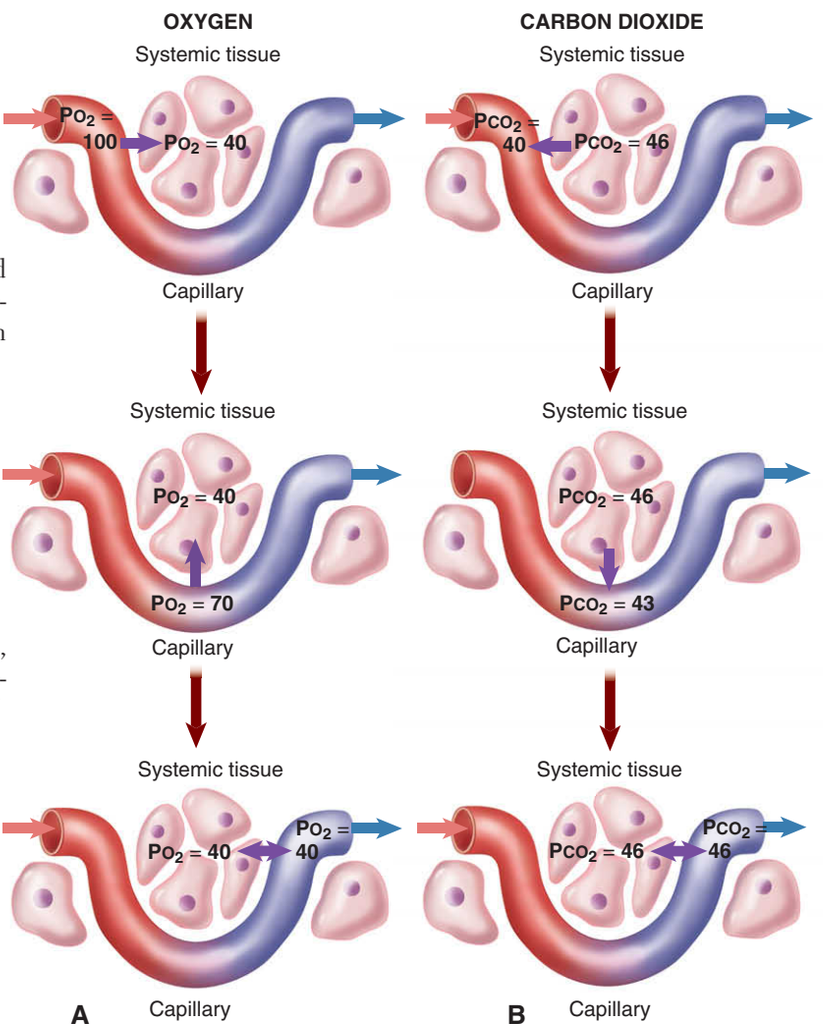

FIGURE 27-27

Systemic gas exchange. A, As blood enters a systemic capillary, O_2 diffuses down its pressure gradient (out of the blood). O_2 continues diffusing out of the blood until equilibration has occurred (or until the blood leaves the capillary). **B,** As blood enters a systemic capillary, CO_2 diffuses down its pressure gradient (into the blood). As with O_2, CO_2 continues diffusing as long as there is a pressure gradient.

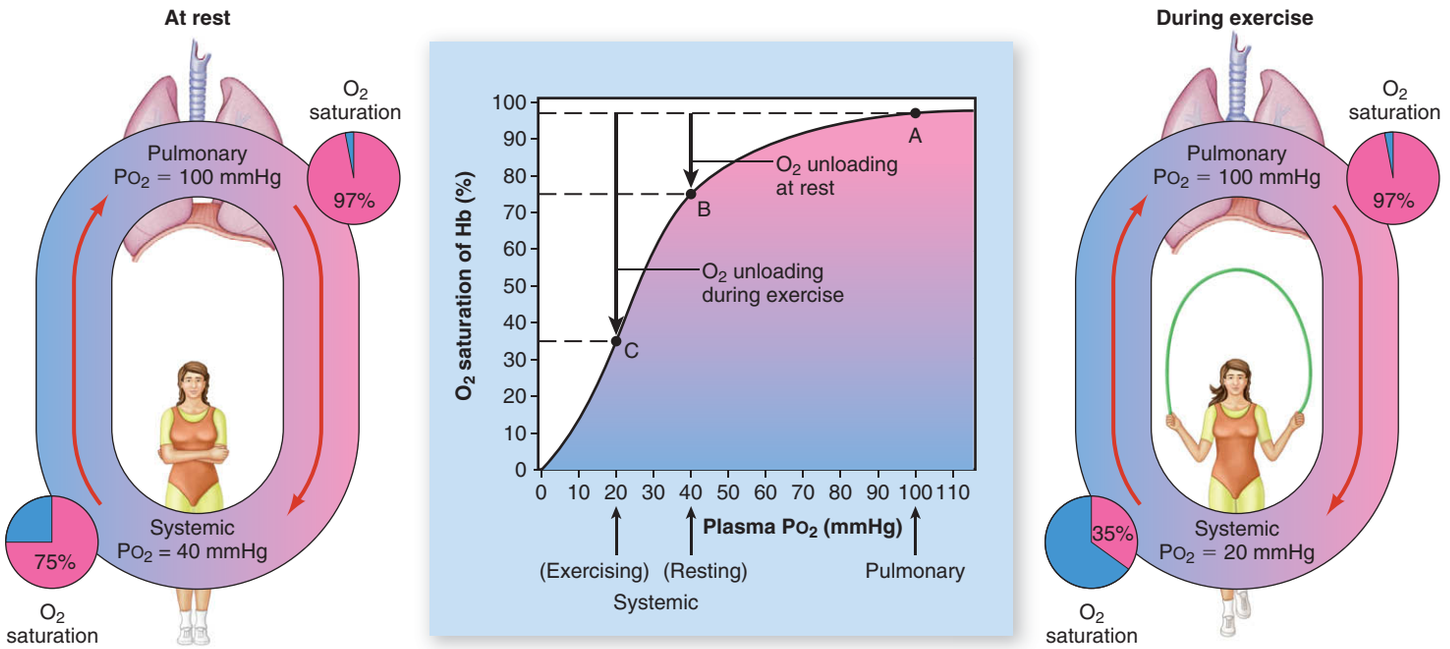

FIGURE 27-28

Oxygen unloading at rest and during exercise. At rest, fully saturated Hb unloads almost 25% of its O_2 load when it reaches the low-P_{O_2} (40 mmHg) environment in systemic tissues *(left inset)*. During exercise, the tissue P_{O_2} is even lower (20 mmHg)—thus causing fully saturated Hb to unload about 70% of its O_2 load *(right inset)*. As you can see in the graph, a slight drop in tissue P_{O_2}—from point *B* to point *C*—causes a large increase in O_2 unloading.

This increasing P_{CO_2} and decreasing P_{O_2} together produce two effects—they favor oxygen dissociation from oxyhemoglobin and carbon dioxide association with hemoglobin to form carbaminohemoglobin. This reciprocal interrelationship between oxygen and carbon dioxide transport mechanisms is contrasted in Figure 27-29. Note that increased P_{CO_2} decreases the affinity between hemoglobin and oxygen—this is called a "right shift." A right shift of the oxygen-hemoglobin dissociation curve resulting from increased P_{CO_2} is also known as the **Bohr effect,** named for Christian Bohr, who along with other scientists, discovered this phenomenon in 1904. A drop in plasma pH, which normally accompanies an increase in blood P_{CO_2}, also causes a right shift. The **Haldane effect** refers to the increased CO_2 loading caused by a decrease in P_{O_2}. This phenomenon is named for its discoverer John Scott Haldane.

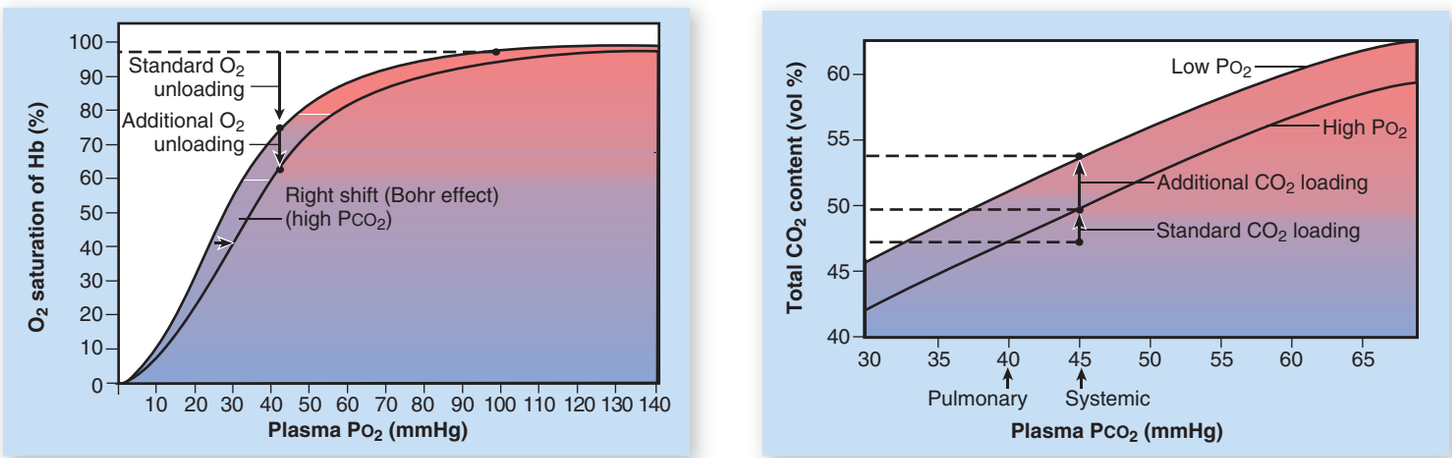

FIGURE 27-29

Interaction of P_{O_2} and P_{CO_2} on gas transport by the blood. A, The increased plasma P_{CO_2} in systemic tissues decreases the affinity between Hb and O_2, shown as a right shift of the oxygen-hemoglobin dissociation curve. This phenomenon is known as the *Bohr effect.* A right shift can also be caused by a decrease in plasma pH. **B,** At the same time, the decreased plasma P_{O_2} commonly observed in systemic tissues increases the CO_2 content of the blood, shown as a left shift of the CO_2 dissociation curve. This phenomenon is known as the *Haldane effect.*

16. What factors can cause an increase in the amount of carbon dioxide loaded into the systemic blood?

REGULATION OF PULMONARY FUNCTION

Respiratory Control Centers

Various mechanisms operate to maintain relative constancy of the blood P_{O_2} and P_{CO_2}. This homeostasis of blood gases is maintained primarily by means of changes in ventilation—the rate and depth of breathing. The main integrators that control the nerves that affect the inspiratory and expiratory muscles are located within the brainstem and are together simply called the *respiratory centers* (Figure 27-30).

The basic rhythm of the respiratory cycle of inspiration and expiration seems to be generated by the **medullary rhythmicity area.** This area of the medulla consists of two regions of interconnected control centers: the *dorsal respiratory group (DRG)* and the *ventral respiratory group (VRG)*. The VRG seems to be the basic rhythm generator in animal models and thus may also serve this function in human beings. Normal, quiet breathing rhythm is generated by alternating patterns of stimulation and inhibition of motor neurons that signal the muscles of the diaphragm. The DRG integrates information from chemoreceptors for P_{CO_2} and signals the VRG to alter the breathing rhythm to restore homeostasis.

A current hypothesis suggests that the basic breathing rhythm can be altered by different inputs to the medullary rhythmicity area. For example, input from the **apneustic center** in the pons regulates the length and depth of inspiration. Damage to the

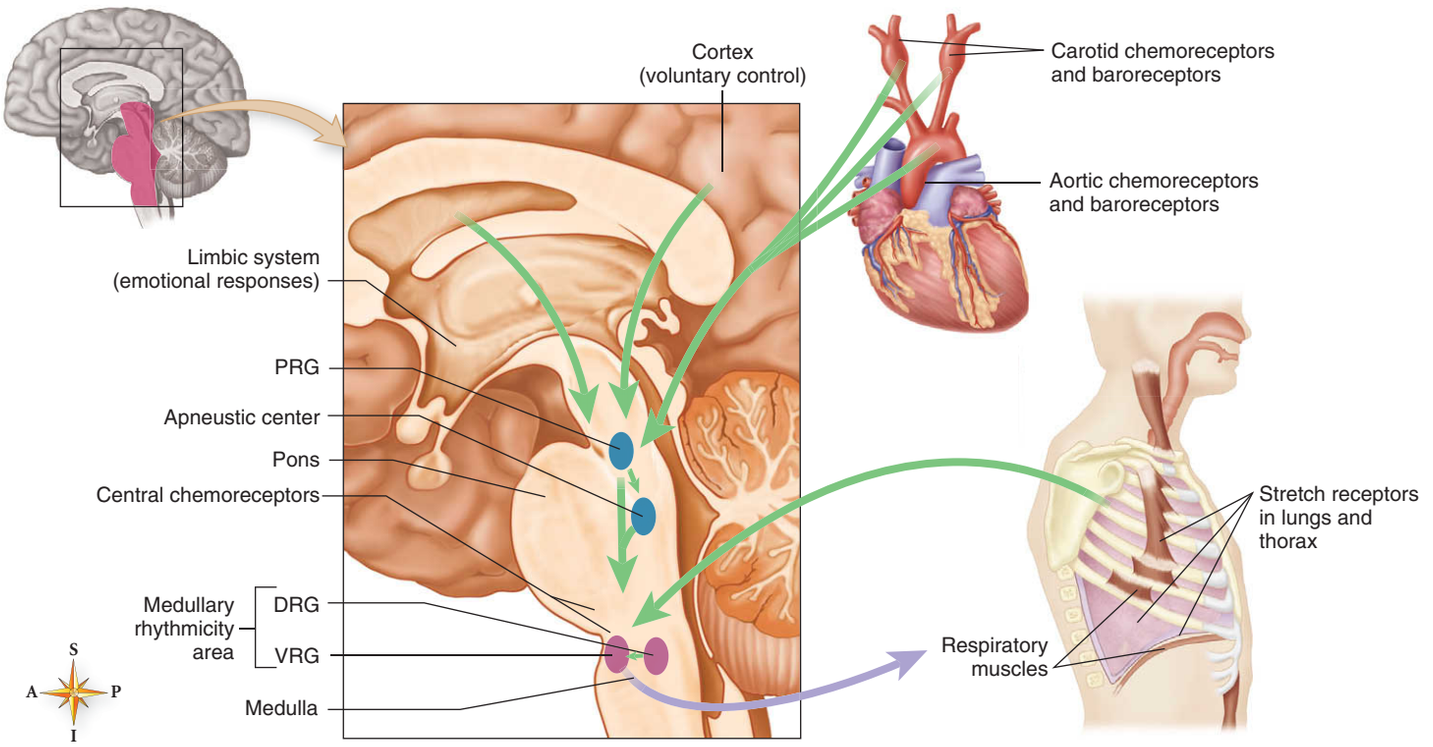

FIGURE 27-30

Regulation of breathing. The dorsal respiratory group (DRG) and ventral respiratory group (VRG) of the medulla represent the medullary rhythmicity area. The pontine respiratory group (PRG, or pneumotaxic center) and apneustic center of the pons influence the basic respiratory rhythm by means of neural input to the medullary rhythmicity area. The brainstem also receives input from other parts of the body; information from chemoreceptors, baroreceptors, and stretch receptors can alter the basic breathing pattern, as can emotional (limbic) and sensory input. Despite these subconscious reflexes, the cerebral cortex can override the "automatic" control of breathing to some extent to do such activities as sing or blow up a balloon. Green arrows show flow of information to the respiratory control centers. The purple arrow shows the flow of information from the control centers to the respiratory muscles that drive breathing.

Box 27-8 | FYI

Unusual Breathing Reflexes

The **cough reflex** is stimulated by foreign matter in the trachea or bronchi. The epiglottis and glottis reflexively close, and contraction of the expiratory muscles causes air pressure in the lungs to increase. The epiglottis and glottis then open suddenly, resulting in an upward burst of air that removes the offending contaminants—a cough.

The **sneeze reflex** is similar to the cough reflex, except that it is stimulated by contaminants in the nasal cavity. A burst of air is directed through the nose and mouth, forcing the contaminants (and mucus) out of the respiratory tract. Droplets from a sneeze can travel more than 161 km/hr (100 miles/hr) and travel 3 m (12 ft). Research suggests that many pathogenic microbes produce symptoms that trigger sneezing in order to spread themselves to other people. Scientists call this *altered host behavior* and identify it as a mechanism of microbes to efficiently spread themselves to additional human hosts.

The term **hiccup** is used to describe an involuntary, spasmodic contraction of the diaphragm. When such a contraction occurs, generally at the beginning of an inspiration, the glottis suddenly closes, producing the characteristic sound. Hiccups lasting for extended periods can be disabling. They may be produced by irritation of the phrenic nerve or the sensory nerves in the stomach or by direct injury or pressure on certain areas of the brain. Fortunately, most cases of hiccups last only a few minutes and are harmless.

A **yawn** is slow, deep inspiration through an unusually widened mouth. Yawns were once thought to be reflexes that increase ventilation when blood oxygen content is low, but newer evidence suggests that this is unlikely. A current theory states that we yawn for the same reason we occasionally stretch—to prepare our muscles and our circulatory system for action. Alternate hypotheses suggest that yawning cools the brain or otherwise regulates body temperature—or that yawning is triggered by neurotransmitters related to mood. The variety of hypotheses show one thing for certain: *we do not currently understand the physiology of yawning!*

A protective physiological response called the **diving reflex** is responsible for the astonishing recovery of apparent drowning victims—including some who may have been submerged for more than 40 minutes! Survivors are most often preadolescent children who have been immersed in water below 20° C (68° F). Apparently, the colder the water, the better the chance of survival. Victims initially appear dead when pulled from the water. Breathing has stopped; they have fixed, dilated pupils; they are cyanotic; and their pulse has stopped.

Studies have shown that when the head and face are immersed in ice-cold water, there is immediate shunting of blood to the core body areas with peripheral vasoconstriction and slowing of the heart (bradycardia). Metabolism is slowed, and tissue requirements for oxygen and nutrients decrease. The diving reflex is a protective response of the body to cold water immersion and is a function of such physiological and environmental parameters as water temperature, age, lung volume, and posture.

nerves from the apneustic center results in breathing characterized by abnormally long, deep inspirations, which is sometimes called "apneustic breathing." The **pontine respiratory group** (PRG; formerly called the *pneumotaxic center*), also in the pons, normally regulates both the apneustic center and the medullary rhythmicity area. Thus a network of interconnected centers in the brainstem regulates the rhythm of breathing. Box 27-8 discusses some unusual breathing reflexes such as coughing and sneezing.

Factors That Influence Breathing

Feedback information to the medullary rhythmicity area comes from sensors throughout the nervous system, as well as from other control centers. For example, changes in the P_{CO_2}, P_{O_2}, and pH of systemic arterial blood all influence the medullary rhythmicity area. The P_{CO_2} acts on chemoreceptors located in the medulla. Chemoreceptors, in this case, are cells that are sensitive to changes in the CO_2 and hydrogen ion concentration (pH) of arterial blood. The normal range for arterial P_{CO_2} is about 38 to 40 mmHg. When it increases even slightly above this value, it has a stimulating effect, mainly on *central chemoreceptors* (present throughout the brainstem).

Large increases in arterial P_{CO_2} also stimulate *peripheral chemoreceptors* in the carotid bodies and aorta. Stimulation of chemoreceptors by increased arterial P_{CO_2} results in faster breathing, with a greater volume of air moving in and out of

the lungs per minute. Figure 27-31 summarizes this negative feedback response. Decreased arterial P_{CO_2} produces opposite effects—it inhibits central and peripheral chemoreceptors, which leads to inhibition of the medullary rhythmicity area and slower respirations. In fact, breathing stops entirely for a few moments (apnea) when arterial P_{CO_2} drops moderately—to about 35 mmHg, for example. Recall that increases in the CO_2 content of plasma are accompanied by a proportional decrease in plasma pH. A decrease in arterial blood pH (increase in acid), within certain limits, has a stimulating effect on chemoreceptors located in the carotid and aortic bodies. Central chemoreceptors are more sensitive to changes in pH than are peripheral chemoreceptors. This increased sensitivity results from the fact that cerebrospinal fluid (CSF) and interstitial fluid (IF) of the brain is protected by the BBB (blood-brain barrier) from the buffers present in the blood. Thus, when blood P_{CO_2} increases in the blood, it is partially buffered in the blood—but the CO_2 is

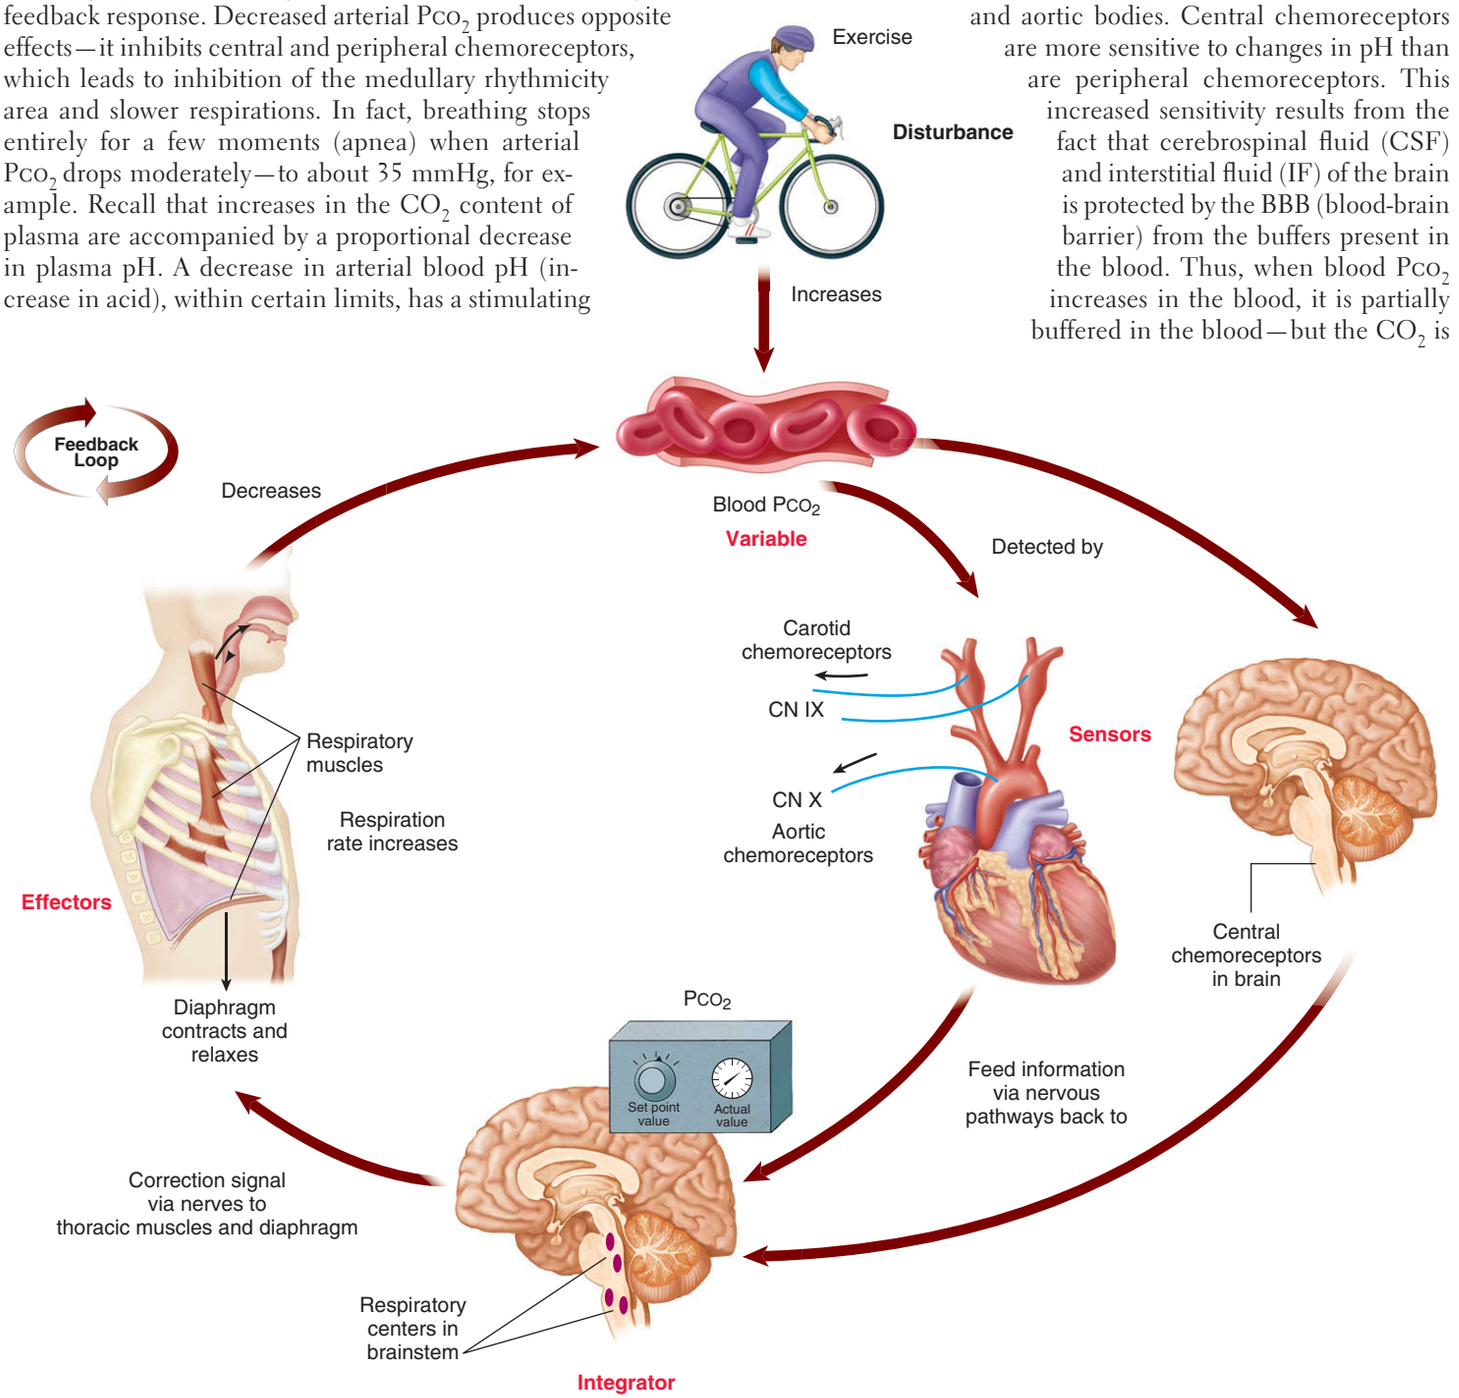

FIGURE 27-31

Negative feedback control of respiration. This diagram summarizes the feedback loop that operates to increase the respiratory rate in response to high plasma P_{CO_2}. Increased cellular respiration during exercise causes a rise in plasma P_{CO_2}—which is detected by central chemoreceptors in the brain and perhaps peripheral chemoreceptors in the carotid sinus and aorta. Feedback information is relayed to integrators in the brainstem that respond to the increase in P_{CO_2} above the set point value by sending nervous correction signals to the respiratory muscles, which act as effectors. The effector muscles increase their alternate contraction and relaxation, thus increasing the rate of respiration. As the respiration rate increases, the rate of CO_2 loss from the body increases and P_{CO_2} drops accordingly. This brings the plasma P_{CO_2} back to its set point value.

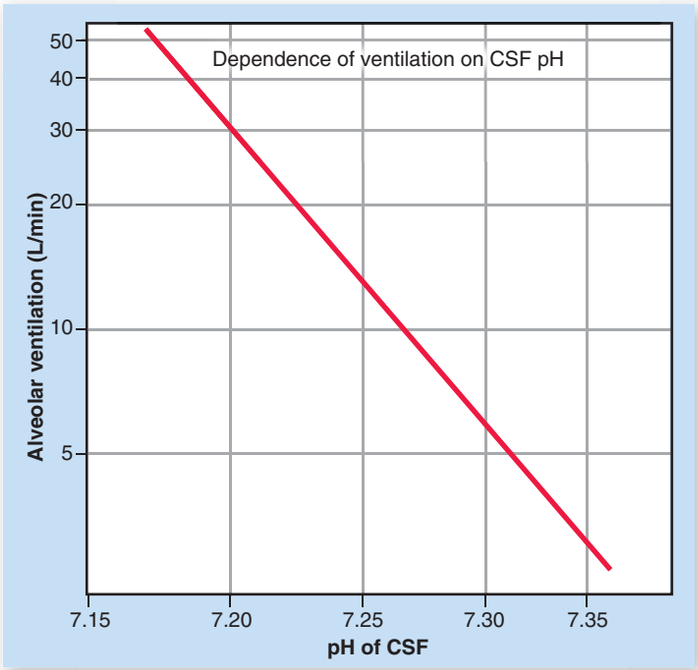

FIGURE 27-32

Regulatory effect of pH of cerebrospinal fluid. As P_{CO_2} of arterial blood increases, the pH of the cerebrospinal fluid (CSF) decreases, as does the brainstem's interstitial fluid (IF). As the graph shows, the lower the pH goes, the higher the ventilation rate rises. Higher ventilation results in increased rate of CO_2 loss from the body, eventually returning the body to a homeostatic balance.

not buffered in the brain's CSF and IF. The brain then senses unbuffered changes in pH (Figure 27-32).

The role of **arterial blood P_{O_2}** in controlling respirations is not entirely clear. Presumably, it has little influence as long as it stays above a certain level. But neurons of the respiratory centers, like all body cells, require adequate amounts of oxygen to function optimally. Consequently, if they become hypoxic, they become depressed and send fewer impulses to respiratory muscles. Respirations then decrease or fail entirely. This principle has important clinical significance. For example, the respiratory centers cannot respond to stimulation by an increasing blood CO_2 if, at the same time, blood P_{O_2} falls below a critical level—a fact that may become life or death important during anesthesia.

However, a decrease in arterial blood P_{O_2} below 70 mmHg, but not so low as the critical level, stimulates chemoreceptors in the carotid and aortic bodies and causes reflex stimulation of the inspiratory neurons of the medullary rhythmicity area. This constitutes an emergency respiratory control mechanism. It does not help regulate respirations under usual conditions when arterial blood P_{O_2} remains considerably higher than 70 mmHg, which is the level necessary to stimulate the chemoreceptors.

Arterial blood pressure helps control breathing through the respiratory pressoreflex mechanism. A sudden rise in arterial pressure, by acting on aortic and carotid baroreceptors, results in reflex slowing of respirations. A sudden drop in arterial pressure brings about a reflex increase in the rate and depth of respirations. The pressoreflex mechanism is probably not of great importance in the control of respirations. It is, however, of major importance in the control of circulation.

The **Hering-Breuer reflexes** also help control respirations, particularly their depth and rhythmicity when the tidal volume is high. It is believed they regulate the depth of respirations (extent of lung expansion)—and therefore the volume of tidal air—in the following way. Presumably, when a large tidal volume of air has been inspired, the lungs are expanded enough to stimulate stretch receptors located within them. The stretch receptors then send inhibitory impulses to the inspiratory neuron, relaxation of inspiratory muscles occurs, and expiration follows the Hering-Breuer expiratory reflex. Then, when a large tidal volume of air has been expired, the lungs are sufficiently deflated to inhibit the lung stretch receptors and allow inspiration to start again—the Hering-Breuer inspiratory reflex. Evidence suggests that these reflexes do not play a significant role in resting (low tidal volume) breathing, except perhaps in newborns.

The **cerebral cortex** also influences breathing. Impulses to the respiratory center from the motor area of the cerebrum may either increase or decrease the rate and strength of respirations. In other words, an individual may voluntarily speed up or slow down the breathing rate. This voluntary control of respirations, however, has certain limitations. For example, one may stop breathing and do so for a few minutes, but holding the breath results in an increase in the CO_2 content of the blood because it is not being removed by respirations. CO_2 is a powerful respiratory stimulant. So when arterial blood P_{CO_2} increases to a certain level, it stimulates the inspiratory neuron (directly and reflexively) to send motor impulses to the respiratory muscles, and breathing is resumed, even though the individual may still will contrarily.

Miscellaneous factors may also influence breathing. Among these are blood temperature and sensory impulses from skin thermal receptors and from superficial or deep pain receptors:

Sudden painful stimulation produces a reflex apnea, but continued painful stimuli cause faster and deeper respirations.

Sudden cold stimuli applied to the skin cause reflex apnea.

Stimulation of the pharynx or larynx by irritating chemicals or by touch causes a temporary apnea. This is the choking reflex, a valuable protective device. It operates, for example, to prevent aspiration of food or liquids during swallowing.

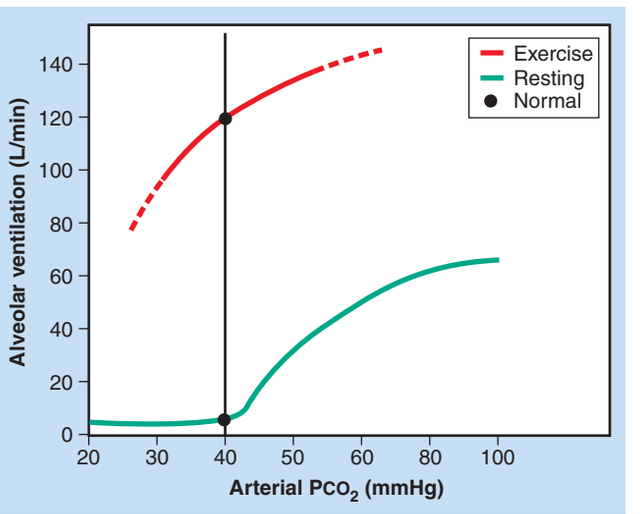
The major factors that influence breathing are summarized in Figure 27-30. Some factors that affect breathing during exercise are mentioned in Box 27-9.

Ventilation and Perfusion

Alveolar ventilation, as we already know, is airflow to the alveoli (see Figure 27-1). Alveolar perfusion is blood flow to the alveoli (see Figure 27-18). Matching ventilation and perfusion is important for efficient gas exchange in the lungs. If a poorly ventilated alveolus is well perfused, blood flow is being "wasted" on an inefficient alveolus. It is more efficient to detour some of the blood flow away from the poorly ventilated alveolus and toward a well-ventilated alveolus.

Figure 27-33 shows that perfusion can be matched—within very limited boundaries—to the ventilation status of individual groups of alveoli. As you have probably already deduced, this is accomplished through vasoconstriction (narrowing) of certain pulmonary arterioles to reduce perfusion to poorly ventilated alveoli. Such ventilation-perfusion matching in various regions of each lung can increase the overall efficiency of gas exchange.

| QUICK CHECK |



17. Where are the chief regulatory centers of the respiratory function located?
18. Name several factors that can influence the breathing rate of an individual; tell whether each triggers an increase or a decrease in breathing rate.

Box 27-9 | SPORTS and FITNESS

Control of Respirations During Exercise

Respirations increase abruptly at the beginning of exercise and decrease even more markedly as it ends. This much is known. The mechanism that accomplishes this increased ventilation rate, however, is not known. It is not identical to the one that produces moderate increases in breathing. Numerous studies have shown that arterial blood P_{CO_2}, P_{O_2}, and pH do not change enough during exercise to produce the degree of hyperpnea (faster, deeper respirations) observed. Presumably, many chemical and nervous factors and temperature changes operate as a complex, but still unknown, mechanism for regulating respirations during exercise.

Normal effects of maximum exercise in an athlete. This graph shows that the breathing rate (vertical axis) is much higher in an athlete exercising maximally than would be expected for any given blood carbon dioxide pressure (P_{CO_2}) (horizontal axis). As you can see at the normal points of a P_{CO_2} of 40 mmHg, the exercising athlete's breathing (ventilation) rate is 120 L/min. However, at rest the athlete's breathing rate is only about 5 or 6 L/min at the same P_{CO_2}—thus showing that P_{CO_2} is not the major factor causing an increased rate of breathing during exercise.

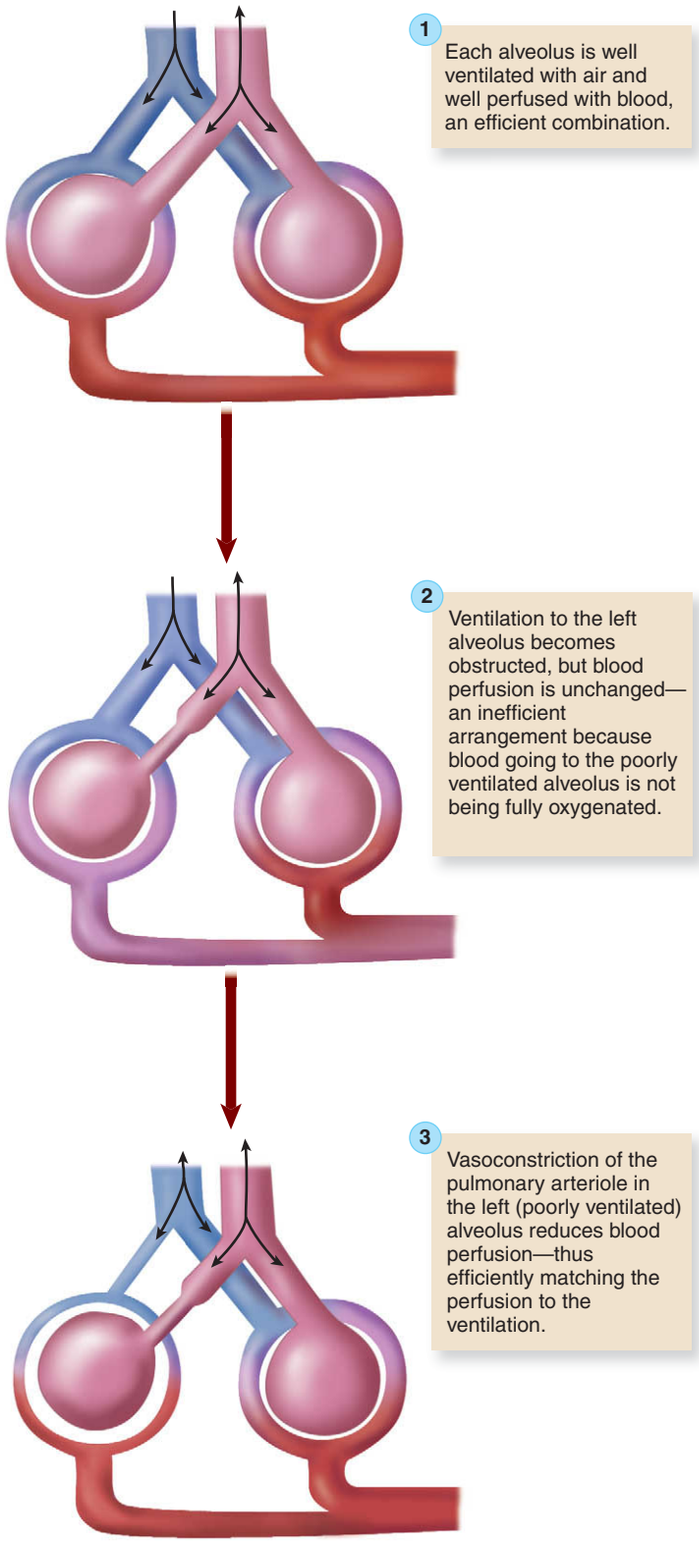


FIGURE 27-33

Ventilation and perfusion of the alveoli. Here, two alveoli represent typical alveoli in the lungs.

the BIG picture

Respiratory Physiology and the Whole Body

The homeostatic balance of the entire body, and thus the survival of each and every cell, depends on the proper functioning of the respiratory system. Because the mitochondria in each cell require oxygen for their energy conversions, and because each cell produces toxic carbon dioxide as a waste product of the very same energy conversions, the internal environment must continually acquire new oxygen and discard carbon dioxide. If each cell were immediately adjacent to the external environment—that is, atmospheric air—this would require no special system. However, because almost every one of the 100 trillion cells that make up the body are far removed from the outside air, another method of satisfying this condition must be employed—this is where the respiratory system comes in. By the process of ventilation, fresh external air continually flows less than a hair's breadth away from the circulating fluid of the body—the blood. By means of diffusion, oxygen enters the internal environment and carbon dioxide leaves. The efficiency of this process is enhanced by the presence of "oxygen sponges," called *hemoglobin molecules,* which immediately take oxygen molecules out of solution in the plasma so that more oxygen can rapidly diffuse into the blood. The blood, the circulating fluid tissue of the cardiovascular system, carries the blood gases throughout the body—picking up gases where there is an excess and unloading them where there is a deficiency. In this manner, each cell of the body is continually bathed in a fluid environment that offers a constant supply of oxygen and an efficient system for removing carbon dioxide.

Specific mechanisms involved in respiratory function show the interdependence between body systems observed throughout our study of the human body. For example, without blood and the maintenance of blood flow by the cardiovascular system, blood gases could not be transported between the gas exchange tissues of the lungs and the various systemic tissues of the body. Without regulation by the nervous system, ventilation could not be adjusted to compensate for changes in the oxygen or carbon dioxide content of the internal environment. Without the skeletal muscles of the thorax, the airways could not maintain the flow of fresh air that is so vital to respiratory function. The skeleton itself provides a firm outer housing for the lungs and has an arrangement of bones that facilitates the expansion and recoil of the thorax, which is needed to accomplish inspiration and expiration. Without the immune system, pathogens from the external environment could easily colonize the respiratory tract and possibly cause a fatal infection.

Even more subtle interactions between the respiratory system and other body systems can be found. For example, the language function of the nervous system is limited without the speaking ability provided by the larynx and other structures of the respiratory tract. The homeostasis of pH, which is regulated by a variety of systems, is influenced by the respiratory system's ability to adjust the body's carbon dioxide levels (and thus the levels of carbonic acid).

MECHANISMS of DISEASE

DISORDERS ASSOCIATED WITH RESPIRATORY FUNCTION

Many things can interfere with the functions of gas exchange and ventilation and cause respiratory failure. A few of the more important disorders are briefly described here.

Restrictive Pulmonary Disorders

Restrictive pulmonary disorders involve restriction of the alveoli, or reduced compliance, leading to decreased lung inflation. The hallmark of these disorders, regardless of their cause, is decreased lung volumes and capacities such as inspiratory reserve volume and vital capacity. Factors that restrict breathing can originate either within the lung or outside of it. Causes of restrictive lung disorders include alveolar fibrosis (scarring) secondary to occupational exposure to asbestos, toxic fumes, coal dust, or other contaminants; immunological diseases, as in rheumatoid lung; obesity; and metabolic disorders such as uremia. Restriction of breathing can also be caused by pain that accompanies pleurisy (inflammation of the pleurae) or mechanical injuries (such as a fractured or bruised rib). Patients with restrictive lung disease classically experience **dyspnea** (labored breathing) and are not able to tolerate increased activity, which reduces their ability to work or perform normal daily activities. Therapy involves eliminating the cause of the restriction, ensuring adequate gas exchange, and improving exercise tolerance.

Obstructive Pulmonary Disorders

A variety of conditions may cause obstruction of the airways. Exposure to cigarette smoke and other common air pollutants can trigger a reflexive constriction of bronchial airways. Obstructive disorders may obstruct inspiration and expiration, whereas restrictive disorders mainly restrict inspiration.

Chronic Obstructive Pulmonary Disease

Chronic obstructive pulmonary disease (COPD) is a broad term used to describe conditions of progressive irreversible obstruction of expiratory airflow. People with COPD have chronic difficulties with breathing, mainly emptying their lungs, and have visibly hyperinflated chests. Figures 27-12 and 27-13 (p. 837) show the effects of COPD compared to normal breathing patterns. Those with COPD often have a productive cough and intolerance of activity. The major disorders observed in people with COPD are chronic bronchitis and emphysema.

In North America, tobacco use is the primary cause of COPD, but air pollution, asthma, and respiratory infections also play a role. COPD is a leading cause of death—one that has been *increasing* over recent years! Until a few years ago, more men had COPD than women. However, the increase of smoking among women is thought to account for the fact that the rate for female COPD is growing rapidly.

Acute respiratory failure can occur when any of the disorders that produce COPD become intense. Heart failure resulting from the pulmonary disease and the vascular resistance that develops with COPD is another possible outcome. Although there is no cure for chronic obstructive respiratory conditions, limiting symptoms can improve quality of life. Bronchodilators and corticosteroids have been used to relieve some of the airway obstruction involved in COPD.

Acute obstruction of the airways, as when a piece of food blocks airflow, requires immediate action to avoid death from suffocation.

| A&P CONNECT |

Knowledge of the physical principles of ventilation can have lifesaving applications in medical emergencies involving acute airway obstruction caused by foreign material. Learn about how these procedures can help choking victims in ***Heimlich Maneuver*** online at ***A&P Connect.***

evolve

Bronchitis

In chronic **bronchitis,** the person produces excessive tracheobronchial secretions that obstruct airflow, and the bronchial mucous glands are enlarged (Figure 27-34, *B*). Risk factors include cigarette smoking (accounting for 80% to 90% of the risk of developing COPD), a normal decline in pulmonary function as a result of age, and environmental exposure to dust and chemicals. With impairment of the alveoli and loss of capillary beds, gas exchange is inefficient, which in turn produces hypoxia.

Emphysema

In **emphysema,** the air spaces distal to the terminal bronchioles are enlarged as a result of damage to lung connective tissue. As the bronchioles collapse and the alveoli enlarge, the alveolar walls rupture and fuse into large irregular spaces, and gas exchange units are destroyed (Figure 27-34, *D*). Although the etiology is not fully understood, this condition is believed to be caused by proteolytic enzymes that destroy lung tissue. Hypoxia often develops in emphysema victims.

Asthma

Asthma is an obstructive lung disorder characterized by recurring inflammation of mucous membranes and spasms of the smooth muscles in the walls of the bronchial air passages. The inflammation (edema and excessive mucus production) and contractions narrow airways, making breathing difficult (Figure 27-34, *C*). Initial onset of asthma can occur in children or adults. Acute episodes of asthma—so-called "asthma attacks"—can be triggered by stress, heavy exercise, infection, or exposure to allergens or other irritants such as dust, vapor, or fumes. Many patients with asthma have a family history of allergies.

Dyspnea is the major symptom of asthma, but hyperventilation, headaches, numbness, and nausea can occur. One way to treat asthma is by using inhaled or systemic bronchodilators that

reduce muscle spasms and thus open the airways. Other types of treatment involve the use of antiinflammatory medications including leukotriene modifiers to reduce the inflammation associated with asthma. (Recall from Chapter 24 that leukotrienes are cytokines released by immune cells to regulate the inflammation response.)

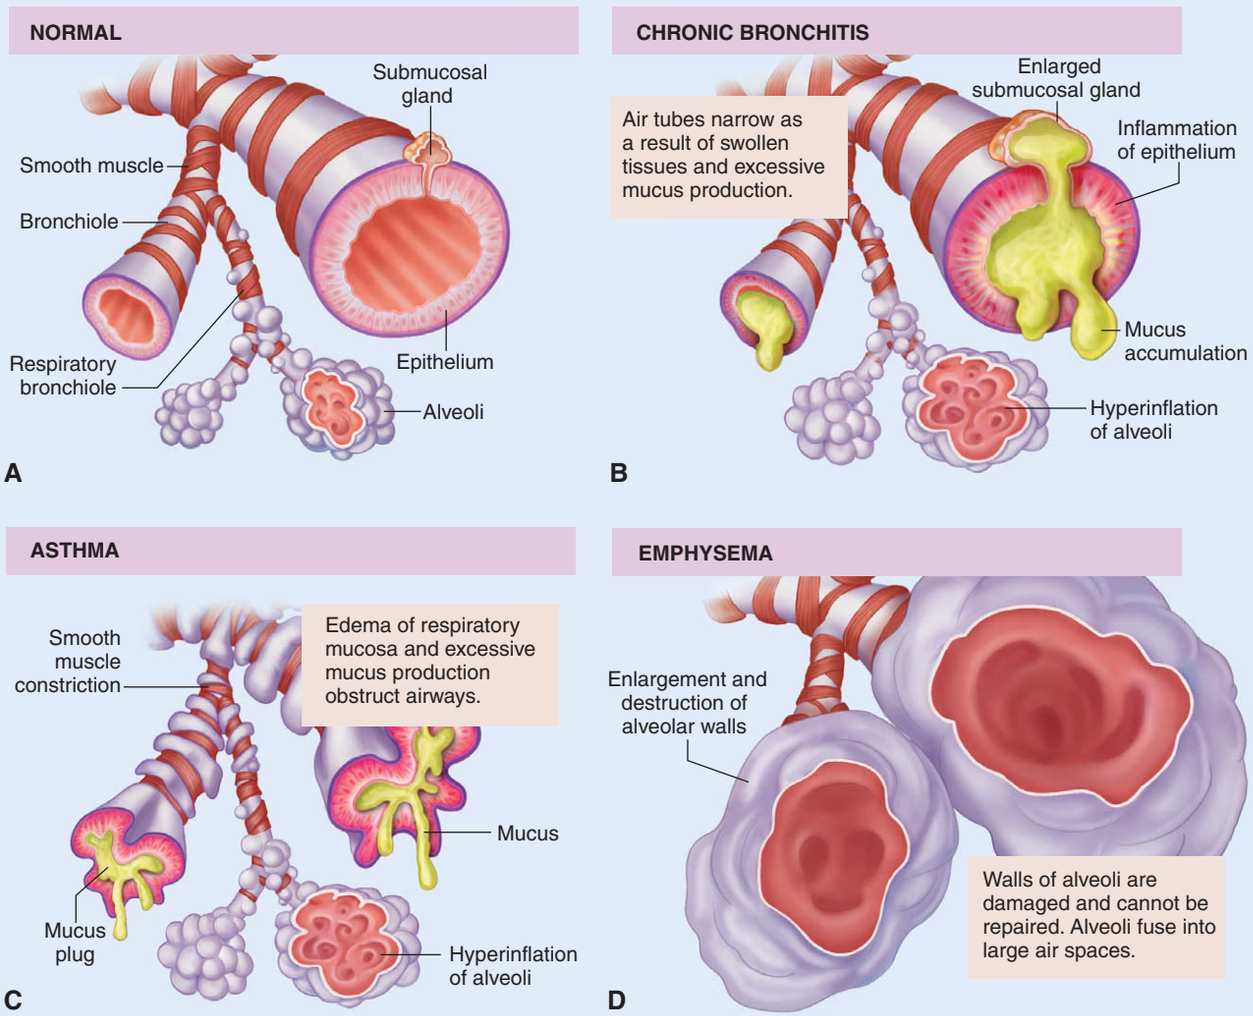

FIGURE 27-34

Obstructive pulmonary disorders. Examples of chronic disorders involving pulmonary obstruction.

HEALTH matters

Sudden Infant Death Syndrome (SIDS)

Sudden infant death syndrome (SIDS) is the third-ranking cause of infant death and accounts for about 1 in 9 of the nearly 30,000 infant deaths reported each year in the United States. Sometimes called "crib-death," SIDS occurs most frequently in babies with no obvious medical problems who are younger than 3 months of age. The exact cause of death can seldom be determined even after extensive testing and autopsy.

SIDS occurs at a higher rate in African-American and Native American babies than in white, Hispanic, or Asian infants, although the reasons remain a mystery. Regardless of infant ethnicity, data suggest that certain precautions, such as having babies sleep only on their backs and keeping cribs free of pillows or plush toys that might partially cover the nose or mouth, may reduce the incidence of SIDS. Also important is the elimination of smoking during pregnancy and protecting infants from exposure to "second-hand" cigarette smoke after birth.

Although the exact cause of SIDS remains unknown, genetic defects involving the structure and function of the respiratory system or unusual physiological responses to common flu or cold viruses may also play a role in this tragic problem.

CASE study

After having surgery to remove a stomach tumor, Derrick woke up in the recovery room in extreme pain. It hurt to move; it hurt to blink; it hurt to take even a little breath, and here was this nurse demanding that he take a deep breath and cough. Was she crazy?

1. Which of these muscles would **not** contract when Derrick complied with his nurse's instructions?
   a. Diaphragm
   b. Serratus anterior
   c. Rectus abdominis
   d. External intercostals
2. Which statement best describes the "mechanics" of Derrick's inhalations?
   a. The thoracic cavity decreases in size, lowering the alveolar pressure, and air flows from high (atmosphere) pressure to low (alveolar) pressure.
   b. The thoracic cavity increases in size, lowering the alveolar pressure, and air flows from high (atmospheric) pressure to low (alveolar) pressure.
   c. Air flows from high (atmospheric) pressure to low (alveolar) pressure and expands the thoracic cavity.
   d. Air flows from high (intrapleural) pressure to low (alveolar) pressure and expands the thoracic cavity.

What Derrick didn't realize was that his shallow respirations were not getting rid of as much carbon dioxide as usual. As a result, the concentration of CO_2 in his bloodstream was building to a level that would negatively affect homeostasis.

3. This increased carbon dioxide will make Derrick's blood _____.
   a. More acidic
   b. More basic
   c. More neutral
   d. None of the above

4. How is carbon dioxide transported in Derrick's blood?
   a. Dissolved in the plasma
   b. Bound to hemoglobin
   c. In the form of bicarbonate
   d. All of the above

RESPIRATORY PHYSIOLOGY (FIGURE 27-1)

A. Definition—complex, coordinated processes that help maintain homeostasis
B. External respiration
   1. Pulmonary ventilation (breathing)
   2. Pulmonary gas exchange
C. Transport of gases by the blood
D. Internal respiration
   1. Systemic tissue gas exchange
   2. Cellular respiration
E. Regulation of respiration

PULMONARY VENTILATION

A. Respiratory cycle (ventilation; breathing)
   1. Inspiration—moves air into the lungs
   2. Expiration—moves air out of the lungs
B. Mechanism of pulmonary ventilation
   1. Pulmonary ventilation mechanism must establish two gas pressure gradients (Figures 27-2 and 27-3)
      a. One in which the pressure within the alveoli of the lungs is lower than atmospheric pressure to produce inspiration
      b. One in which the pressure in the alveoli of the lungs is higher than atmospheric pressure to produce expiration
   2. Pressure gradients are established by changes in the size of the thoracic cavity that are produced by contraction and relaxation of muscles (Figures 27-4 and 27-5)
   3. Boyle's law—the volume of gas varies inversely with pressure at a constant temperature
   4. Inspiration—contraction of the diaphragm produces inspiration—as it contracts, it makes the thoracic cavity larger (Figures 27-6 and 27-7)
      a. Expansion of the thorax results in decreased intrapleural pressure (P_{IP}), leading to decreased alveolar pressure (P_A)
      b. Air moves into the lungs when alveolar pressure (P_A) drops below atmospheric pressure (P_B)
      c. Compliance—ability of pulmonary tissues to stretch, thus making inspiration possible
   5. Expiration—a passive process that begins when the inspiratory muscles are relaxed, which decreases the size of the thorax (Figures 27-8 and 27-9)
      a. Increasing thoracic volume increases the intrapleural pressure and thus increases alveolar pressure above the atmospheric pressure
      b. Air moves out of the lungs when alveolar pressure exceeds the atmospheric pressure
      c. Pressure between parietal and visceral pleura is always less than alveolar pressure and less than atmospheric pressure; the difference between P_{IP} and P_A is called *transpulmonary pressure*
      d. Elastic recoil—tendency of pulmonary tissues to return to a smaller size after having been stretched; occurs passively during expiration
C. Pulmonary volumes—normal exchange of oxygen and carbon dioxide depends on the presence of normal volumes of air moving in and out and the remaining volume (Figure 27-11)
   1. Spirometer—instrument used to measure the volume of air (Figure 27-10)
   2. Tidal volume (TV)—amount of air exhaled after normal inspiration
   3. Expiratory reserve volume (ERV)—largest volume of additional air that can be forcibly exhaled (between 1.0 and 1.2 liters is normal ERV)
   4. Inspiratory reserve volume (IRV)—amount of air that can be forcibly inhaled after normal inspiration (normal IRV is 3.3 liters)
   5. Residual volume—amount of air that cannot be forcibly exhaled (1.2 liters)
D. Pulmonary capacities—the sum of two or more pulmonary volumes
   1. Vital capacity (VC)—the sum of IRV + TV + ERV
   2. Minimal volume—the amount of air remaining after RV
   3. A person's vital capacity depends on many factors, including the size of the thoracic cavity and posture
   4. Inspiratory capacity (IC)—maximal amount of air that can be inspired after a normal expiration
   5. Functional residual capacity (FRC)—the amount of air at the end of a normal respiration
   6. Total lung capacity (TLC)—the sum of all four lung volumes—the total amount of air a lung can hold
   7. Alveolar ventilation—volume of inspired air that reaches the alveoli
   8. Anatomical dead space—passageways occupied by air that does not participate in gas exchange (Figure 27-6)
   9. Physiological dead space—anatomical dead space plus any alveoli not able to perform gas exchange (as in pulmonary disease)
   10. Alveoli must be properly ventilated for adequate gas exchange
E. Pulmonary airflow—rates of airflow into/out of the pulmonary airways
   1. Total minute volume—volume moved per minute (ml/min)
   2. Forced expiratory volume (FEV) or forced vital capacity (FVC)—volume of air expired per second during forced expiration (as a percentage of VC) (Figure 27-12)
   3. Flow-volume loop—graph that shows flow (vertically) and volume (horizontally), with the top of the loop representing expiratory flow-volume and the bottom of the loop representing inspiratory flow-volume relationships (Figure 27-13)

PULMONARY GAS EXCHANGE

A. Partial pressure of gases—pressure exerted by a gas in a mixture of gases or a liquid (Figure 27-14)
   1. Law of partial pressures (Dalton's law)—the partial pressure of a gas in a mixture of gases is directly related to the concentration of that gas in the mixture and to the total pressure of the mixture
   2. Arterial blood P_{O_2} and P_{CO_2} equal alveolar P_{O_2} and P_{CO_2}
B. Exchange of gases in the lungs—takes place between alveolar air and blood flowing through lung capillaries (Figures 27-15, 27-16, and 27-17)
   1. Four factors determine the amount of oxygen that diffuses into blood
      a. The oxygen pressure gradient between alveolar air and blood
      b. The total functional surface area of the respiratory membrane
      c. The respiratory minute volume
      d. Alveolar ventilation
   2. Structural facts that facilitate oxygen diffusion from the alveolar air to the blood
      a. The walls of the alveoli and capillaries form only a very thin barrier for gases to cross
      b. The alveolar and capillary surfaces are large
      c. The blood is distributed through the capillaries in a thin layer so that each red blood cell comes close to alveolar air (Figure 27-18)

HOW BLOOD TRANSPORTS GASES

A. Oxygen and carbon dioxide are transported as solutes and as parts of molecules of certain chemical compounds
B. Hemoglobin (Hb)
   1. Made up of four polypeptide chains (two alpha chains, two beta chains), each with an iron-containing heme group
   2. Carbon dioxide can bind to amino acids in the chains and oxygen can bind to iron in the heme groups (Figure 27-19)
C. Transport of oxygen
   1. Oxygenated blood contains about 0.3 ml of dissolved O_2 per 100 ml of blood
   2. Hemoglobin increases the oxygen-carrying capacity of blood (Figure 27-20)
   3. Oxygen travels in two forms: as dissolved O_2 in plasma and as being associated with hemoglobin (oxyhemoglobin)
      a. Increasing blood P_{O_2} accelerates hemoglobin association with oxygen (Figure 27-21)
      b. Oxyhemoglobin carries the majority of the total oxygen transported by blood
D. Transport of carbon dioxide
   1. A small amount of CO_2 dissolves in plasma and is transported as a solute (10%)
   2. Less than one-fourth of blood carbon dioxide combines with NH_2 (amine) groups of hemoglobin and other proteins to form carbaminohemoglobin (20%) (Figure 27-22)
   3. Carbon dioxide's association with hemoglobin is accelerated by an increase in blood P_{CO_2} (Figure 27-23)
   4. More than two-thirds of the carbon dioxide is carried in plasma as bicarbonate ions (70%) (Figures 27-24, 27-25, and 27-26)

SYSTEMIC GAS EXCHANGE

A. Exchange of gases in tissues takes place between arterial blood flowing through tissue capillaries and cells (Figure 27-27)
   1. Oxygen diffuses out of arterial blood because the oxygen pressure gradient favors its outward diffusion
   2. As dissolved oxygen diffuses out of arterial blood, blood P_{O_2} decreases, which accelerates oxyhemoglobin dissociation to release more oxygen to plasma for diffusion to cells (Figure 27-28)
B. Carbon dioxide exchange between tissues and blood takes place in the opposite direction from oxygen exchange
   1. Bohr effect—increased P_{CO_2} decreases the affinity between oxygen and hemoglobin (Figure 27-29, *A*)
   2. Haldane effect—increased carbon dioxide loading caused by a decrease in P_{O_2} (Figure 27-29, *B*)

REGULATION OF PULMONARY FUNCTION

A. Respiratory control centers—the main integrators controlling the nerves that affect the inspiratory and expiratory muscles are located in the brainstem (Figure 27-30)
   1. Medullary rhythmicity center—generates the basic rhythm of the respiratory cycle
      a. Consists of two interconnected control centers
         (1) Dorsal respiratory group (DRG)—integrates information from chemoreceptors to regulate the VRG pattern
         (2) Ventral respiratory group (VRG)—generates basic pattern of breathing rhythm
   2. The basic breathing rhythm can be altered by different inputs to the medullary rhythmicity center (Figure 27-30)
      a. Input from the apneustic center in the pons regulates the medullary rhythmicity area
      b. Pontine respiratory group (PRG, or pneumotaxic center)—in the pons—inhibits the apneustic center and medullary rhythmicity area to prevent overinflation of the lungs
B. Factors that influence breathing—sensors from the nervous system provide feedback to the medullary rhythmicity center (Figure 27-31)
   1. Changes in the P_{O_2}, P_{CO_2}, and pH of arterial blood influence the medullary rhythmicity area
      a. P_{CO_2} acts on central chemoreceptors throughout the brainstem—if it increases, the result is faster breathing; if it decreases, the result is slower breathing
      b. A decrease in blood pH stimulates peripheral chemoreceptors in the carotid and aortic bodies and, even more so, stimulates the central chemoreceptors (because they are surrounded by unbuffered fluid) (Figure 27-32)

   c. Arterial blood Po_2 presumably has little influence if it stays above a certain level
2. Arterial blood pressure controls breathing through the respiratory pressoreflex mechanism
3. Hering-Breuer reflexes help control respirations by regulating depth of respirations and the volume of tidal air
4. Cerebral cortex influences breathing by increasing or decreasing the rate and strength of respirations

C. Ventilation and perfusion (Figure 27-33)
1. Alveolar ventilation—airflow to the alveoli
2. Alveolar perfusion—blood flow to the alveoli
3. Efficiency of gas exchange can be maintained by limited ability to match perfusion to ventilation—for example, vasoconstricting arterioles that supply poorly ventilated alveoli and allow full blood flow to well-ventilated alveoli

THE BIG PICTURE: RESPIRATORY PHYSIOLOGY AND THE WHOLE BODY

A. The internal system must continually acquire new oxygen and rid itself of carbon dioxide because each cell requires oxygen and produces carbon dioxide as a result of energy conversion

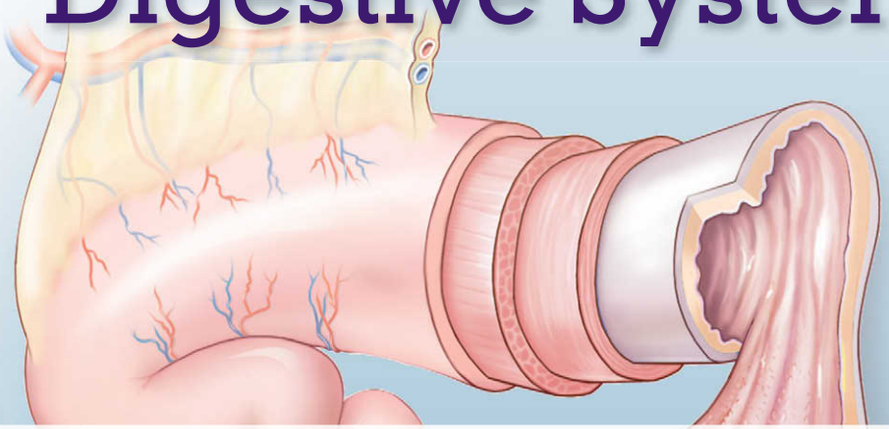
B. Specific mechanisms involved in respiratory function
1. Blood gases need blood and the cardiovascular system to be transported between gas exchange tissues of the lungs and various systemic tissues of the body
2. Regulation by the nervous system adjusts ventilation to compensate for changes in oxygen or carbon dioxide in the internal environment
3. The skeletal muscles of the thorax aid the airways in maintaining the flow of fresh air
4. The skeleton houses the lungs, and the arrangement of bones facilitates the expansion and recoil of the thorax
5. The immune system prevents pathogens from colonizing the respiratory tract and causing infection

REVIEW QUESTIONS

Write out the answers to these questions after reading the chapter and reviewing the Chapter Summary. If you simply think through the answer without writing it down, you won't retain much of your new learning.

1. Define respiratory physiology.
2. What is the main inspiratory muscle?
3. Identify the separate volumes that make up the total lung capacity.
4. Normally, about what percentage of the tidal volume fills the anatomical dead space?
5. Normally, about what percentage of the tidal volume is useful air, that is, ventilates the alveoli?
6. One gram of hemoglobin combines with how many milliliters of oxygen?
7. What factors influence the amount of oxygen that diffuses into the blood from the alveoli?
8. Identify the major factors that influence breathing.
9. Orthopnea is a symptom of what type of disease?
10. Dyspnea is often associated with what type of breathing?
11. Define the diving reflex and explain its physiological importance.
12. Describe four other unusual reflexes that indirectly affect breathing.
13. Describe the changes in respirations during a period of exercise.

CRITICAL THINKING QUESTIONS



After finishing the Review Questions, write out the answers to these more in-depth questions to help you apply your new knowledge. Go back to sections of the chapter that relate to concepts that you find difficult.

1. The proper functioning of the respiratory system allows what to occur in the body? What other control system has an impact on this function?
2. Can you identify the various processes that allow the respiratory system to accomplish its function?
3. What is pulmonary ventilation? What evidence can you find to describe whether the lungs are active or passive during this process?
4. How would you compare and contrast inspiration and expiration? Include the importance of elastic recoil and compliance to these processes.
5. How would you summarize the interaction of oxygen and carbon dioxide on gas transport in the blood? Include the Bohr and Haldane effects in your explanation.
6. Suppose your blood has a hemoglobin content of 15 grams/100 dl and an oxygen saturation of 97%. How many milliliters of oxygen would 100 ml of your arterial blood contain?
7. Compare and contrast infant and adult forms of respiratory distress syndrome.
8. After strenuous exercise, inexperienced athletes will quite often attempt to recover and resume normal breathing by bending over or sitting down. Using the mechanics of ventilation, how would you modify the recovery practices of these athletes?

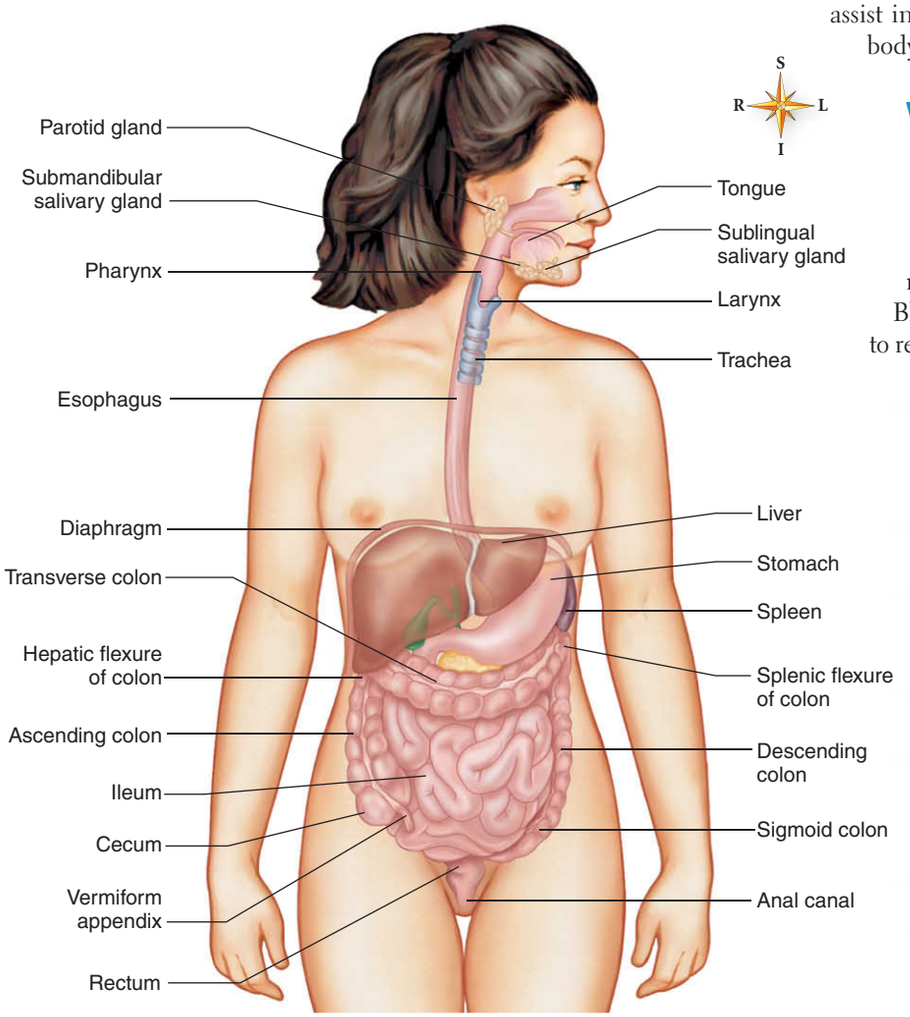
continued on p. 895

This chapter deals with the anatomy of the digestive system. The organs of the digestive system together perform a vital function—that of preparing food for absorption and for use by the millions of body cells. Most food when eaten is in a form that cannot reach the cells (because it cannot pass through the intestinal mucosa into the bloodstream), nor could it be used by the cells even if it could reach them. It must therefore be modified in both chemical composition and physical state so that nutrients can be absorbed and used by the body cells. The complete process of altering the physical and chemical composition of ingested food material so that it can be absorbed and used by the body cells is called ***digestion.*** *This complex process is the function of both the digestive tract and accessory organs that make up the digestive system. The physiology of the digestive system is discussed in Chapter 29.*

ORGANIZATION OF THE DIGESTIVE SYSTEM

Organs of Digestion



The main organs of the digestive system (Figure 28-1) form a tube that goes all the way through the ventral cavities of the body. It is open at both ends. This tube is usually referred to as the **alimentary canal** (tract). The term **gastrointestinal (GI) tract** refers only to the stomach and intestines but is sometimes used in reference to the entire alimentary canal.

It is important to realize that ingested food material passing through the lumen of the GI tract is actually outside the internal environment of the body, even though the tube itself is inside the ventral body cavity.

Box 28-1 lists the main organs of the digestive system, that is, the segments of the alimentary canal, and the accessory organs located in the main digestive organs or opening into them. Organs such as the larynx, trachea, diaphragm, and spleen are labeled in Figure 28-1, but they are not digestive organs. They are shown to assist in orienting the digestive organs to other important body structures.

Wall of the GI Tract

The GI tract is essentially a tube with walls fashioned of four layers of tissues: a mucous lining, a submucous coat of connective tissue in which are embedded the main blood vessels of the tract, a muscular layer, and a fibroserous layer (Figure 28-2). Blood vessels and nerves travel through the mesentery to reach the digestive tube throughout most of its length.

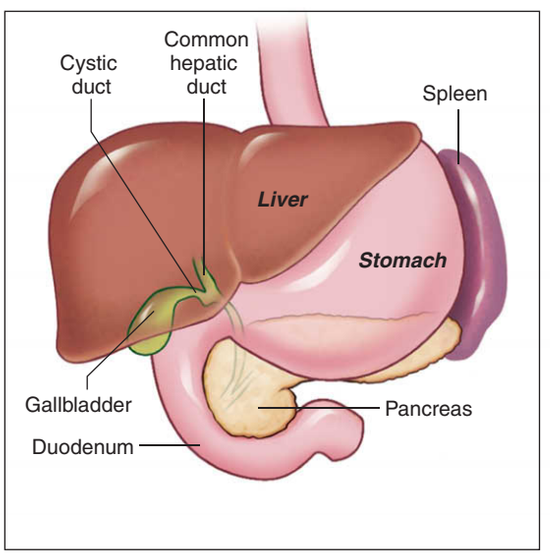


FIGURE 28-1
Location of the digestive organs.

MUCOSA

The innermost layer of the GI wall—the layer facing the lumen, or open space, of the tube—is called the **mucosa** or *mucous layer.* Note in Figure 28-2 that the mucosa is made up of three layers—an inner *mucous epithelium*, a layer of loose fibrous connective tissue called the *lamina propria*, and a thin layer of smooth muscle called the *muscularis mucosae*.

SUBMUCOSA

The **submucosa** layer of the digestive tube is composed of connective tissue that is thicker than the mucosal layer. It contains numerous small glands, blood vessels, and parasympathetic nerves that form the *submucosal plexus* (Meissner plexus).

MUSCULARIS

The **muscularis**—or *muscular layer*—is a thick layer of muscle tissue that wraps around the submucosa. This portion of the wall is characterized by an inner layer of circular and an outer layer of longitudinal smooth muscle. Like the submucosa, the muscularis contains nerves organized into a plexus called the *myenteric plexus* (Auerbach plexus). This plexus lies between the two muscle layers. Note in Figure 28-2 that the term **intramural plexus** is used to describe both plexuses. Together they play an important role in the regulation of digestive tract movement and secretion.

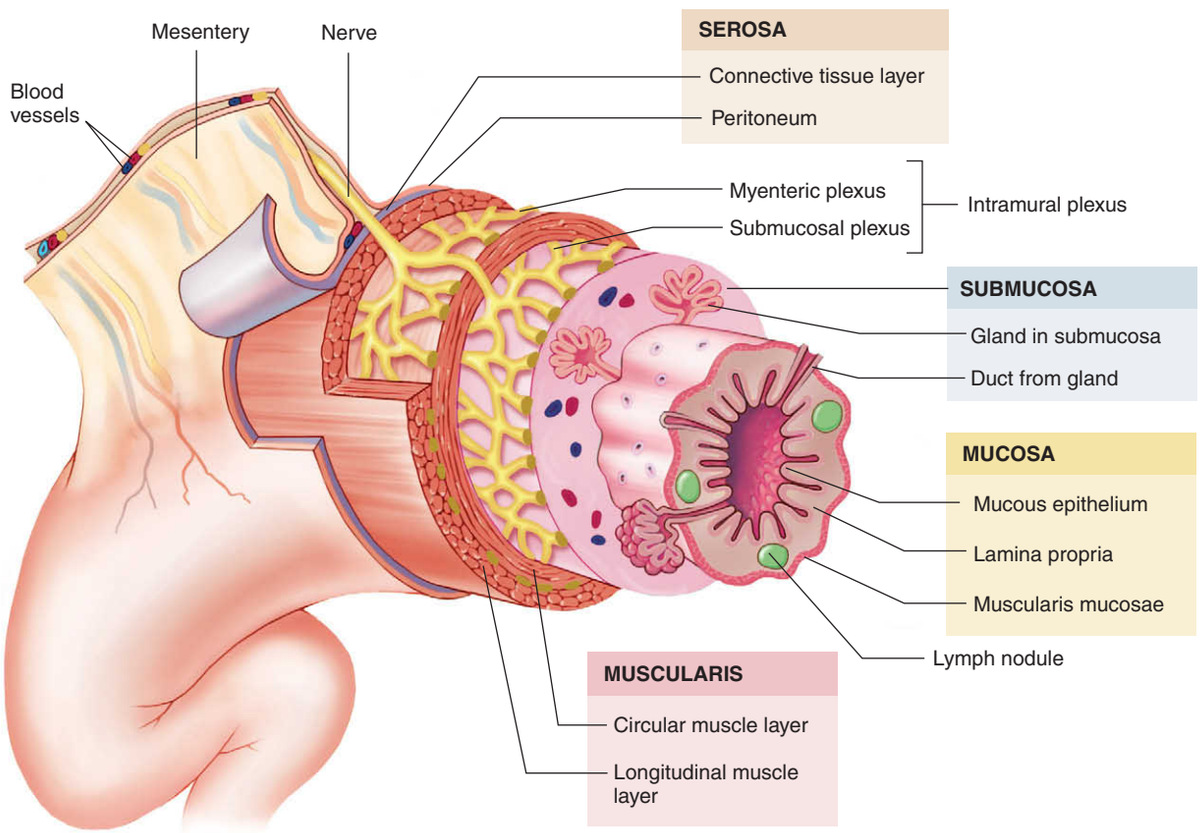

FIGURE 28-2

Wall of the GI tract. The wall of the gastrointestinal (GI) tract is made up of four layers, shown here in a generalized diagram of a segment of the GI tract. Notice that the serosa is continuous with a fold of serous membrane called a *mesentery.* Notice also that digestive glands may empty their products into the lumen of the GI tract by way of ducts.

SEROSA

The **serosa**—or *serous layer*—is the outermost layer of the GI wall. It is made up of serous membrane (see Figures 6-39 and 6-40 on pp. 639 and 640). The serosa is actually the *visceral layer* of the peritoneum—the serous membrane that lines the abdominopelvic cavity and covers its organs. The lining attached to and covering the walls of the abdominopelvic cavity is called the *parietal layer* of the peritoneum. The fold of serous membrane shown in Figure 28-2 that connects the parietal and visceral portions is called a *mesentery*.

MODIFICATIONS OF LAYERS

Although the same four tissue layers form the various organs of the GI tract, their structures vary in different regions of the tube throughout its length. Variations in the epithelial layer of the mucosa, for example, range from stratified layers of squamous cells that provide protection from abrasion in the upper part of the esophagus to the simple columnar epithelium, designed for absorption and secretion, which is found throughout most of the tract. Notice in Figure 28-2 that exocrine glands empty their secretions into the lumen of the GI tract through ducts. Some of these modifications are listed in Table 28-1; refer back to this table when each of these organs is studied in detail.

| QUICK CHECK |

1. What is another name for the digestive tract?
2. Name the four layers of the digestive tract wall.

MOUTH

Structure of the Oral Cavity

The mouth is also called the *oral cavity*. The following structures form the oral cavity *(buccal cavity)*: the lips, which surround the orifice of the mouth and form the anterior boundary of the oral cavity, the cheeks (side walls), the tongue and its muscles (floor), and the hard palate and soft palate (roof) (Figure 28-3).

LIPS

The **lips** are covered externally by skin and internally by mucous membrane that continues into the oral cavity and lines the mouth. The junction between skin and mucous membrane is highly sensitive and easily irritated. The upper lip is marked near the midline by a shallow vertical groove called the *philtrum*, which ends

TABLE 28-1 Modifications of Layers of the Digestive Tract Wall

ORGAN	MUCOSA	MUSCULARIS	SEROSA
Esophagus	Stratified squamous epithelium resists abrasion	Two layers—inner one of circular fibers and outer one of longitudinal fibers; striated muscle in the upper part and smooth muscle in the lower part of the esophagus and in the rest of the tract	Outer layer, fibrous (adventitia); serous around part of the esophagus in the thoracic cavity
Stomach	Arranged in flexible longitudinal folds called *rugae;* allow for distention; contains gastric pits with microscopic gastric glands	Has three layers instead of the usual two—circular, longitudinal, and oblique fibers; two sphincters—lower esophageal sphincter at the entrance of the stomach and pyloric sphincter at its exit, formed by circular fibers	Outer layer, visceral peritoneum; hangs in a double fold from the lower edge of the stomach over the intestines and forms an apronlike structure; greater omentum; lesser omentum connects the stomach to the liver
Small intestine	Contains permanent circular folds, plicae circulares Microscopic fingerlike projections, villi with brush border Crypts (of Lieberkühn) Microscopic duodenal (Brunner) mucous glands Aggregated lymphoid nodules (Peyer patches) Numerous single lymphoid nodules called *solitary nodules*	Two layers—inner one of circular fibers and outer one of longitudinal fibers	Outer layer, visceral peritoneum, continuous with the mesentery
Large intestine	Solitary lymph nodes Intestinal mucous glands Anal columns form in the anal region	Outer longitudinal layer condensed to form three tapelike strips (taeniae coli); small sacs (haustra) give the rest of the wall of the large intestine a puckered appearance; internal anal sphincter formed by circular smooth fibers; external anal sphincter formed by striated fibers	Outer layer, visceral peritoneum, continuous with mesocolon

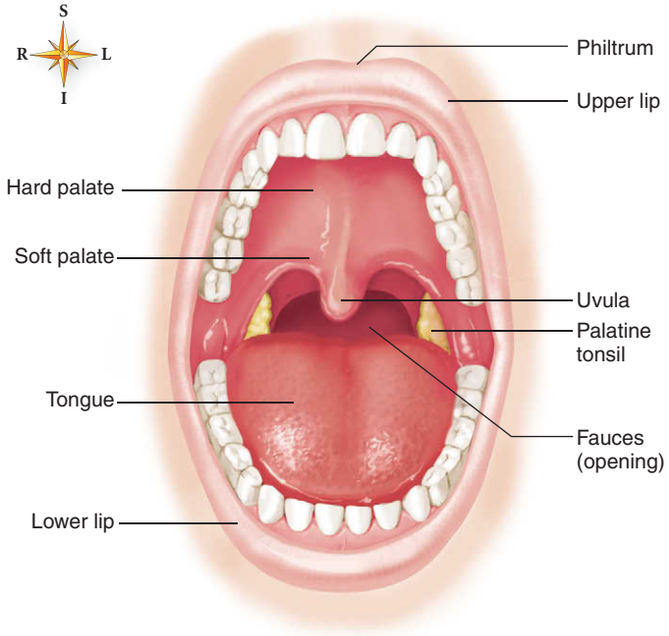

FIGURE 28-3
The oral cavity.

at the junction between skin and mucous membrane in a slight prominence called the *tubercle*. The term *fissure* is often used to describe a cleft or groove between or separating anatomical structures. Therefore, when the lips are closed, the line of contact between them is called the *oral fissure*. Besides keeping food in the mouth while it is being chewed, the lips help sense the temperature and texture of food before it enters the mouth. The lips are also needed to form many speech sounds (syllables).

CHEEKS

The **cheeks** form the lateral boundaries of the oral cavity. They are continuous with the lips in front and are lined by mucous membrane that is reflected onto the gingiva, or gums, and the soft palate. The cheeks are formed in large part by the buccinator muscle, which is sandwiched with a considerable amount of adipose, or fat, tissue between the outer skin and mucous membrane lining. Numerous small mucus-secreting glands are located between the mucous membrane and the buccinator muscle; their ducts open opposite the last molar teeth.

HARD PALATE AND SOFT PALATE

The **hard palate** consists of portions of four bones: two maxillae and two palatines (see Figure 8-5. *B* on p. 205). The **soft palate,** which forms a partition between the mouth and nasopharynx (see Figure 26-3), is fashioned of muscle arranged in the shape of an arch. The opening in the arch leads from the mouth into the oropharynx and is named the *fauces.* Suspended from the midpoint of the posterior border of the arch is a small cone-shaped process, the *uvula.*

TONGUE

The **tongue** is a solid mass of skeletal muscle components (intrinsic muscles) covered by a mucous membrane.

Note in Figure 28-4, A, that the tongue has a blunt *root*, a *tip*, and a central *body*. The upper, or dorsal, surface of the tongue is normally moist, pink, and covered by rough elevations, called *papillae* (Figure 28-4, *B*). Recall from Chapter 17 that papillae possess sensory organs called *taste buds.*

The four types of papillae—circumvallate, fungiform, foliate, and filiform—are all located on the sides or upper surface (dorsum) of the tongue. Note in Figure 28-4, A, that the large circumvallate papillae form an inverted V-shaped row extending from a

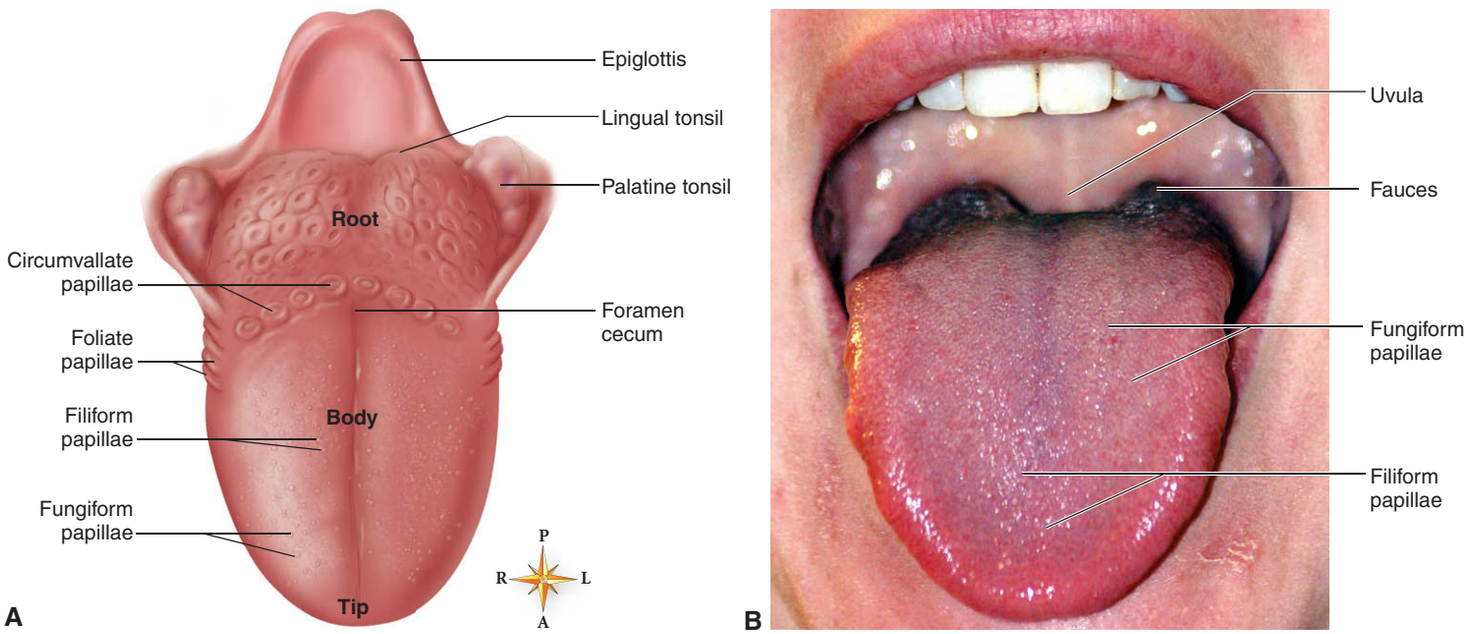

FIGURE 28-4

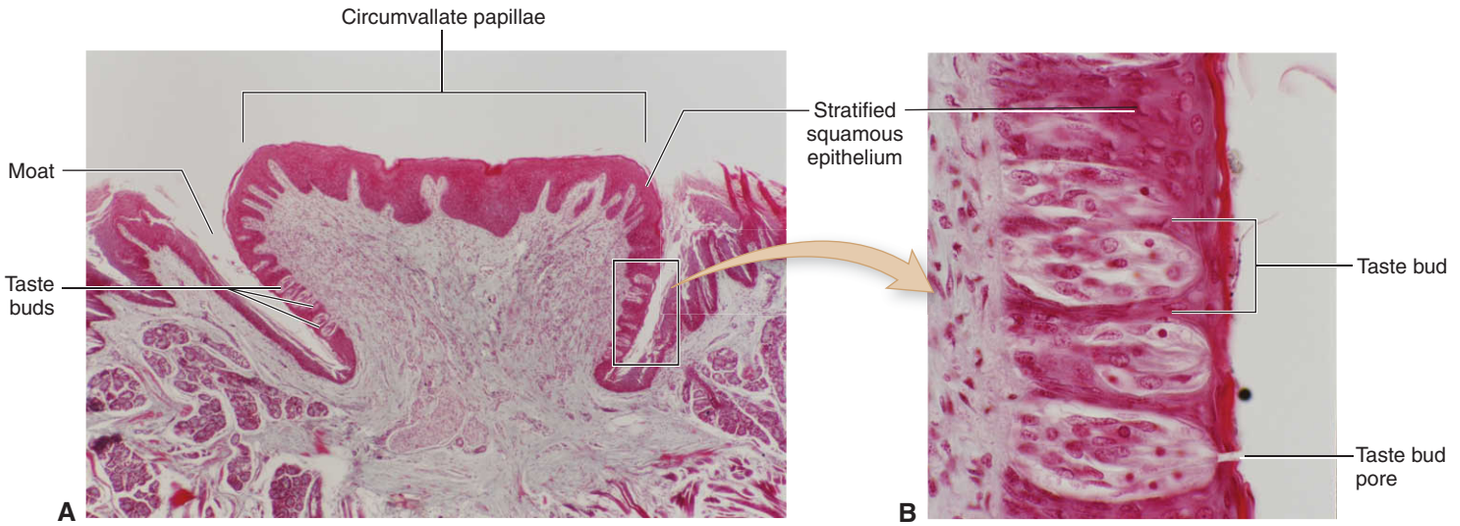

FIGURE 28-5

Circumvallate papillae on the surface of the tongue. A, Taste buds are located on the lateral surfaces of the papillae. Several taste buds can be seen opening into the moat from the sides of the papillae. (×35.) **B,** Enlargement of the photomicrograph of taste buds in **A.** The arrow points to a pore in the outer surface of the taste bud. (×40.) Compare to Figure 17-8 on p. 516.

median pit named the *foramen cecum* on the posterior part of the tongue. There are 10 to 14 of these large, mushroomlike papillae. You can readily distinguish them if you look at your own tongue. Figure 28-5 shows two micrographs of circumvallate papillae. To be tasted, a dissolved substance must enter a moatlike depression surrounding the papillae where it contacts taste buds located on the lateral surface.

Taste buds are also located on the sides of the fungiform papillae, which are found chiefly on the sides and tip of the tongue. Foliate papillae are leaflike ridges on the posterior, lateral edges of the tongue that also posses taste buds. The numerous filiform papillae are filamentous and threadlike in appearance. They have a whitish coloration and are distributed over the anterior two thirds of the tongue. Filiform papillae do not contain taste buds. Refer back to Chapter 17, p. 516, for more discussion of papillae and taste buds.

The *lingual frenulum* (Figure 28-6, A) is a fold of mucous membrane in the midline of the undersurface of the tongue that helps anchor the tongue to the floor of the mouth. If the frenulum is too short and hinders tongue movement—a congenital condition called *ankyloglossia*—the individual is said to be tongue-tied; this causes faulty speech (Figure 28-6, *B*).

A fold of mucous membrane called the *fimbriated fold* (or *plica fimbriata*) (see Figure 28-6, A) extends toward the apex of the tongue on either side of the lingual frenulum. The floor of the mouth and

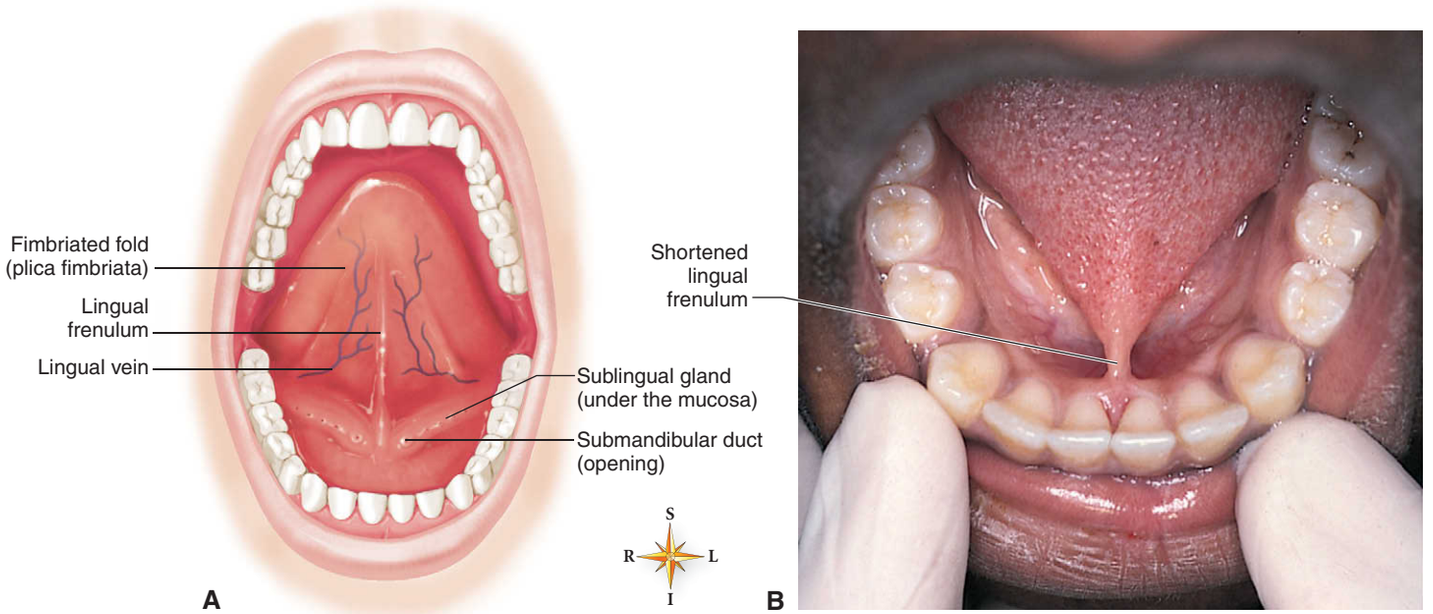

FIGURE 28-6

Floor of mouth. A, Floor of mouth and ventral surface of tongue. **B,** Photo showing ankyloglossia—characterized by an abnormally short lingual frenulum.

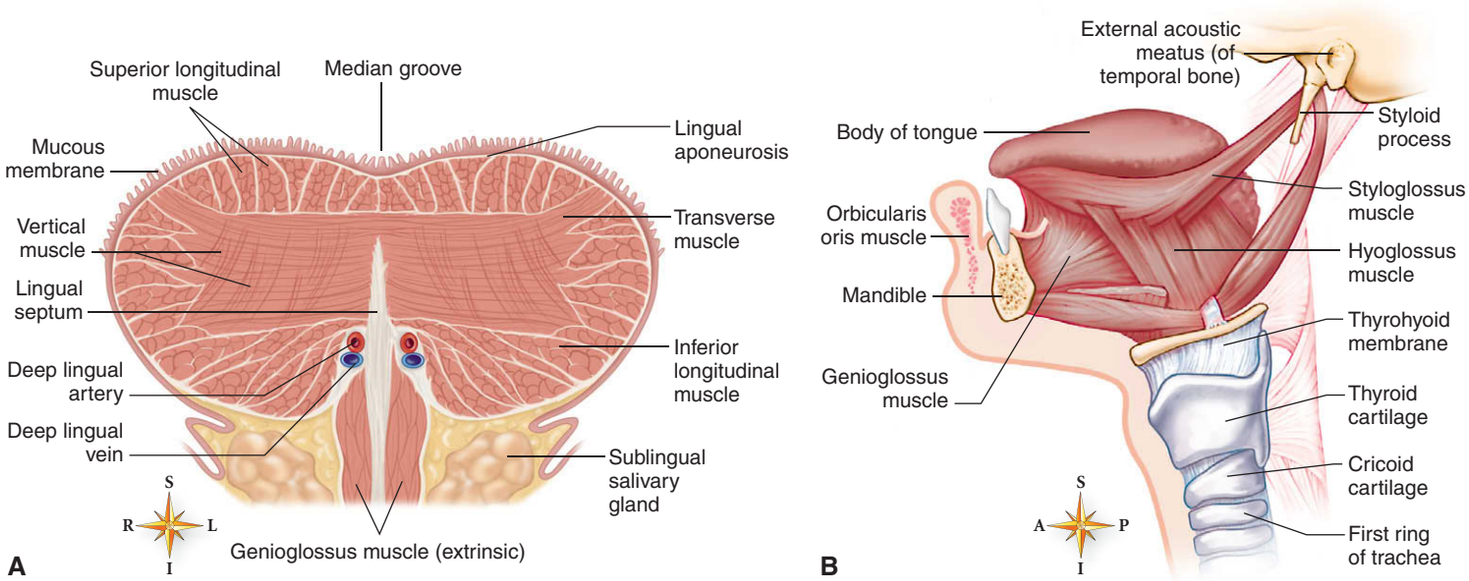

FIGURE 28-7

Muscles of the tongue. A, Intrinsic muscles of the tongue shown in a frontal section. **B,** Extrinsic muscles of the tongue.

undersurface of the tongue are richly supplied with blood vessels. The deep lingual vein can be seen (see Figure 28-6, *A*) shining through the mucous membrane between the lingual frenulum and fimbriated fold. In this region many vessels are extremely superficial and are covered only by a very thin layer of mucosa. Soluble drugs, such as aspirin or nitroglycerin used during a heart attack, are absorbed into the circulation rapidly if placed under the tongue.

The intrinsic muscles of the tongue have, by definition, both their origin and their insertion in the tongue itself. As you can see in Figure 28-7, *A*, intrinsic muscles have their fibers oriented in all directions, thus providing a basis for extreme maneuverability. Changes in the size and shape of the tongue caused by intrinsic muscle contraction assist in placement of food material between the teeth during **mastication** (chewing). Such movements are also necessary for forming speech syllables properly.

Extrinsic tongue muscles are those that insert into the tongue but have their origin on some other structure, such as the hyoid bone or one of the bones of the skull. Examples of extrinsic tongue muscles are the genioglossus, which protrudes the tongue, and the hyoglossus, which depresses it (see Figure 28-7, *B*). Contraction of the extrinsic muscles is important during **deglutition,** or swallowing, and speech.

Salivary Glands

The salivary glands are typical of the accessory glands associated with the digestive system. They are located outside the alimentary canal and convey their exocrine secretions by way of ducts from the glands into the lumen of the tract (Figure 28-8, *A*). The mucous and serous cells seen in the compound tubuloalveolar gland pictured in Figure 28-8, *B*, together secrete a mixture of fluids that are then

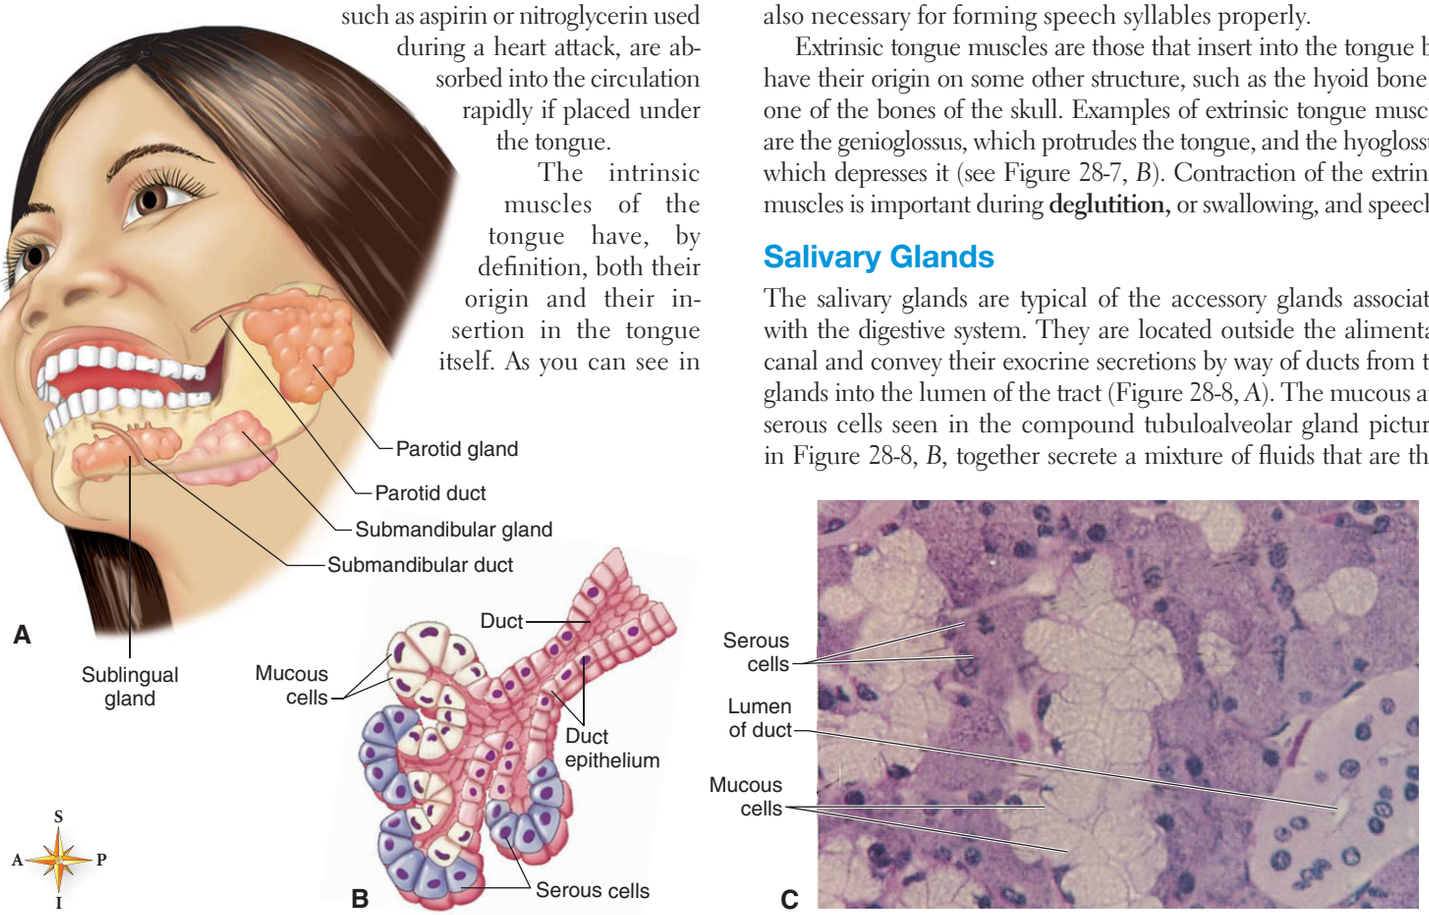

FIGURE 28-8

Salivary glands. A, Location of the salivary glands. **B** and **C,** Detail of submandibular salivary gland. This mixed- or compound-type gland produces mucus from mucous cells and enzymatic secretion from serous cells. Duct cross sections are also visible. (×140.)

modified by the duct cells on their way out of the salivary gland. The functions of saliva in the digestive process are discussed in Chapter 29.

Three pairs of major salivary glands (see Figure 28-8)—the parotid, submandibular, and sublingual glands—secrete a major amount (about 1 liter) of the saliva produced each day. The minor salivary glands (*buccal glands*) that occur in the mucosa lining the cheeks and mouth contribute less than 5% of the total salivary volume. Buccal gland secretion is important, however, to the hygiene and comfort of the mouth tissues.

PAROTID GLANDS

The pyramidal **parotids** are the largest of the paired salivary glands (see Figure 28-8, *A*). They are located between the skin and underlying masseter muscle in front of and below the external ear. The parotids produce a watery, or serous, type of saliva containing enzymes but not mucus. The parotid (Stensen) ducts are about 5 cm (2 inches) long. They penetrate the buccinator muscle on each side and open into the mouth through the *parotid papilla* opposite the upper second molars. Inflammation of the parotids is called **mumps** or **parotitis** and is caused by *paramyxovirus* (see Mechanisms of Disease, p. 888).

SUBMANDIBULAR GLANDS

Submandibular glands (see Figure 28-8, A) are called *mixed* or *compound glands* because they contain both serous (enzyme) and mucus-producing elements (see Figure 28-8, *B* and *C*). These glands are located just below the mandibular angle. You can feel the gland by placing your index finger on the posterior part of the floor of the mouth and your thumb medial to and just in front of the angle of the mandible. The gland is irregular in form and about the size of a walnut. The ducts of the submandibular glands (Wharton ducts) open into the mouth on either side of the lingual frenulum.

SUBLINGUAL GLANDS

Sublingual glands are the smallest of the main salivary glands (see Figure 28-8, A). They lie in front of the submandibular glands, under the mucous membrane covering the floor of the mouth. Each sublingual gland is drained by 8 to 20 ducts (ducts of Rivinus) that open into the floor of the mouth. Unlike the other salivary glands, the sublingual glands produce only a mucous type of saliva.

Teeth

The teeth are the organs of *mastication*, or chewing. They are designed to cut, tear, and grind ingested food so that it can be mixed with saliva and swallowed. During the process of mastication, food is ground into small bits. This increases the surface area that can be acted on by the digestive enzymes.

TYPICAL TOOTH

A typical tooth (Figure 28-9) can be divided into three main parts: crown, neck, and root. The **crown** is the exposed portion of a tooth. It is covered by enamel—the hardest and chemically most stable tissue in the body. Enamel consists of approximately 97% calcified (inorganic) material and only 3% organic material and water. It is ideally suited to withstand the very abrasive process of mastication. The *neck* of a tooth is the narrow portion shown in Figure 28-9 that is surrounded by the gingivae, or gums. It joins the crown of the tooth to the root. It is the **root** that fits into the socket of the alveolar process of either the upper or lower jaw.

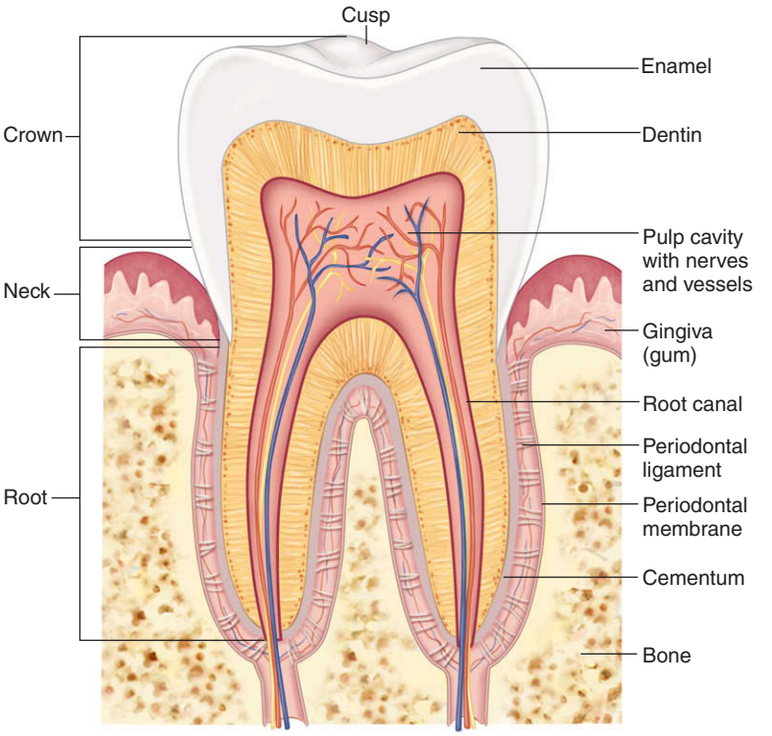

FIGURE 28-9

Typical tooth. A molar tooth sectioned to show its bony socket and details of its three main parts: crown, neck, and root. Enamel (over the crown) and cementum (over the neck and root) surround the dentin layer. The pulp contains nerves and blood vessels.

The root of a tooth may be a single peglike structure or consist of two or three separate conical projections. The root is not rigidly anchored to the alveolar process by cement but is suspended in the socket by the fibrous *periodontal membrane* (see Figure 28-9).

In addition to enamel, the outer shell of each tooth is composed of two additional dental tissues—*dentin* and *cementum* (see Figure 28-9). Dentin makes up the greatest proportion of the tooth shell. It is covered by enamel in the crown and by cementum in the neck and root area. The dentin contains a **pulp cavity** consisting of connective tissue, blood and lymphatic vessels, and sensory nerves.

TYPES OF TEETH

Dentition is the type, number, and arrangement of teeth in the jaws.

Twenty primary or **deciduous teeth,** or so-called *baby teeth,* appear early in life and are later replaced by 32 **permanent teeth** (Figure 28-10). The names and numbers of teeth in both sets are given in Table 28-2. The first deciduous tooth usually erupts at about 6 months of age. The remainder follow at the rate of one or more a month until all 20 have appeared. There is, however, great individual variation in the age at which teeth erupt. Deciduous teeth are generally shed between the ages of 6 and 13 years. The third molars (wisdom teeth) are the last to appear, and usually erupt sometime after 17 years of age.

Teeth in the upper jaw are called *maxillary teeth* because they are in the maxilla bone of the skull. Teeth in the lower jaw are called *mandibular teeth* because they are anchored in the mandible bone. Deciduous teeth are identified by either name or capital Roman letters (A, B, C, etc.) applied in a clockwise direction, as you can see in Figure 28-10. Permanent teeth are likewise identified by name or by Arabic numeral (1, 2, 3, etc.) in a clockwise direction.

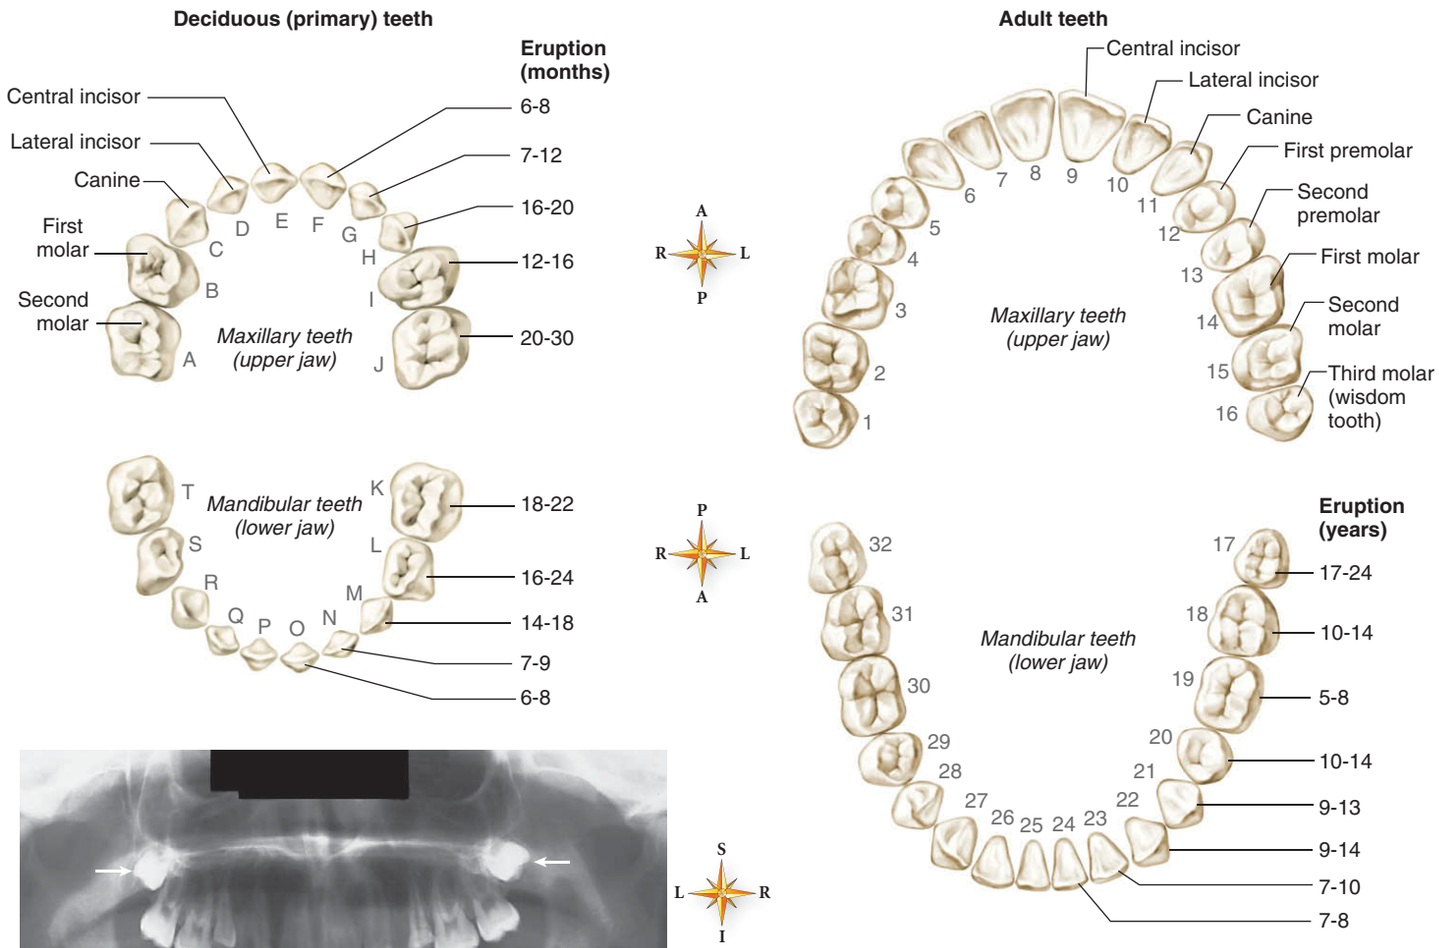

FIGURE 28-10

Dentition. In the deciduous set, where letters are used in place of numbers, there are no premolars and only two pairs of molars in each jaw. Generally, the lower teeth erupt before the corresponding upper teeth. The photo inset is a "Panorex" dental x ray. It displays the full dentition in a single "flattened-out" image. Arrows show the third molars or "wisdom teeth" that have not yet erupted.

| A&P CONNECT |

An epidemic of methamphetamine abuse has resulted in a number of health problems including "meth mouth." See an example of this disorder and learn about its causes in ***Meth Mouth*** online at ***A&P Connect.***

| QUICK CHECK |

3. What are the boundaries of the oral cavity?
4. Describe the location of the taste buds in the mouth.
5. What are the names of the three types of salivary glands?
6. How do the names of the salivary glands describe their locations?
7. What are the three main parts of a typical tooth?

TABLE 28-2 Dentition

	NUMBER PER JAW (UPPER OR LOWER)	
NAME OF TOOTH	DECIDUOUS SET	PERMANENT SET
Central incisors	2	2
Lateral incisors	2	2
Canines (cuspids)	2	2
Premolars (bicuspids)	0	4
First molars (tricuspids)	2	2
Second molars	2	2
Third molars (wisdom teeth)	0	2
TOTAL (per jaw)	10	16
TOTAL (per set)	20	32

PHARYNX

The act of swallowing, or **deglutition,** moves a rounded mass of food, called a *bolus*, from the mouth to the stomach. As the food bolus passes from the mouth, it enters the oropharynx by passing through a constricted, archlike opening called the *fauces*. The oropharynx is the second division of the pharynx (see Figure 26-3). During respiration, air passes through all three pharyngeal divisions. However, only the terminal portions of the pharynx serve the digestive system. Once a bolus has passed through the pharynx, it enters the digestive tube proper—the portion of the digestive tract that serves only the digestive system. The anatomy of the pharynx is discussed in more detail in Chapter 26 on pp. 802–803.

| A&P CONNECT |

The ring of tonsils in the pharynx defends both the digestive tract and respiratory tract from infection. Visualize the tonsils and review their defensive role in ***Protective Strategies of the Respiratory Tract*** online at ***A&P Connect.***

ESOPHAGUS

The **esophagus** (eh-SOFF-ah-gus), a collapsible, muscular, mucosa-lined tube about 25 cm (10 inches) long, extends from the pharynx to the stomach and pierces the diaphragm in its descent from the thoracic cavity to the abdominal cavity (Figure 28-11). It lies posterior to the trachea and heart and serves as a dynamic passageway for food, pushing the food toward the stomach. The short portion of the esophagus in the neck is called the *cervical part*, the portion in the thorax is called the *thoracic part*, and the short portion in the abdomen is called the *abdominal part*.

The esophagus is the first segment of the digestive tube proper, and the four layers that form the wall of the GI tract organs can be identified there (Figure 28-12, A). The esophagus is normally flattened, and thus the lumen is practically nonexistent in the resting state. The stratified squamous epithelium of the esophageal mucosa seen in Figure 28-12 provides a thick, abrasion-resistant lining that protects the esophagus from injury. The inner circular and outer longitudinal layers of the muscular layer are striated (voluntary) in the upper third, mixed (striated and smooth) in the middle third, and smooth (involuntary) in the lower third of the tube.

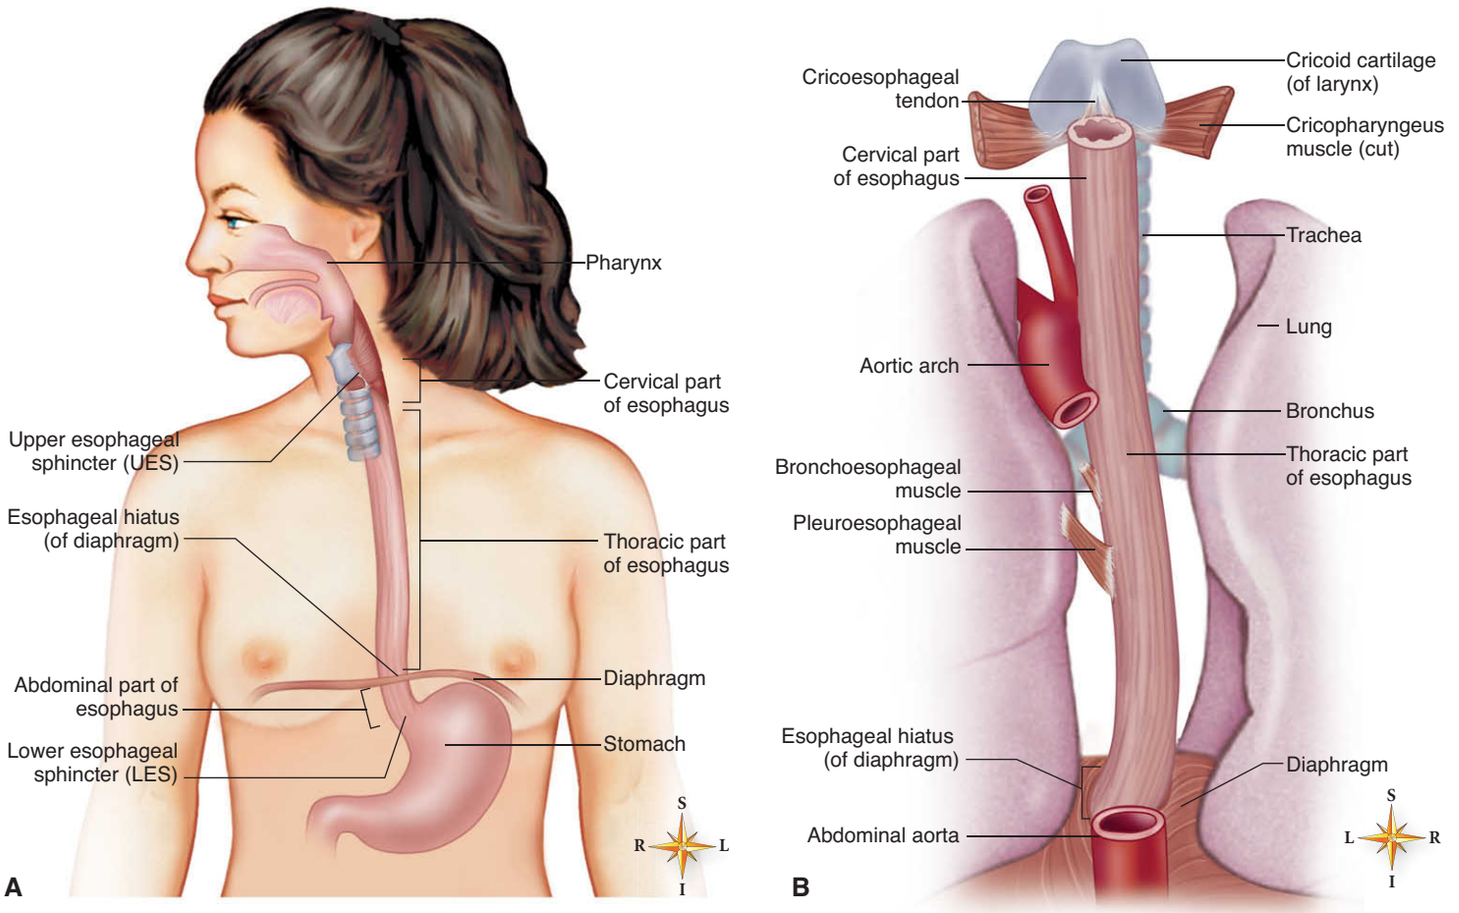

FIGURE 28-11

Esophagus. A, Diagram showing the major features of the esophagus. **B,** View of the muscular wall of the esophagus from behind, showing its position relative to other structures.

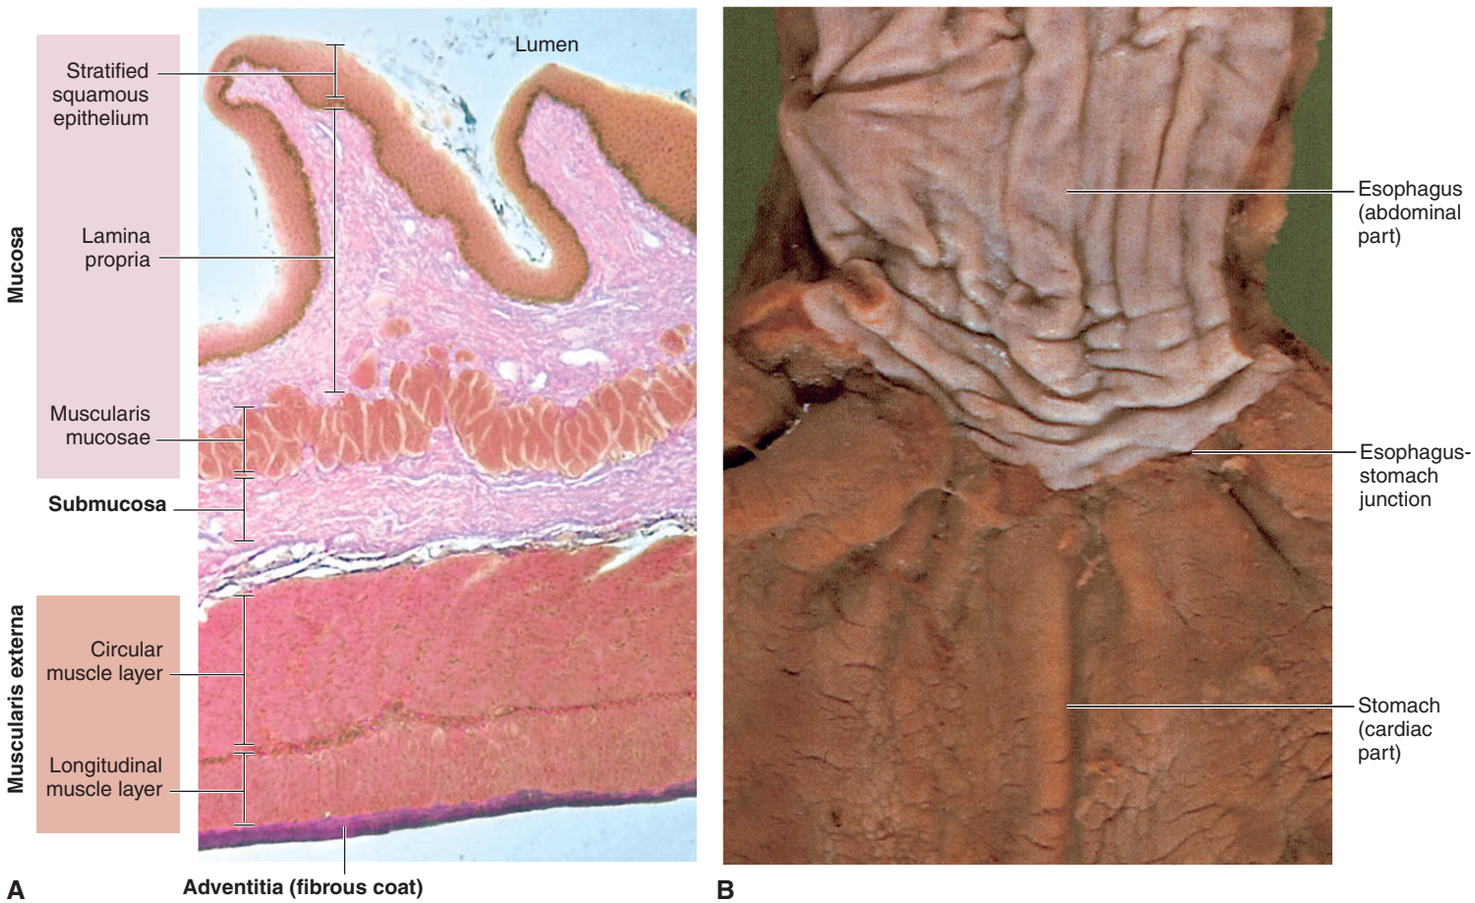

FIGURE 28-12

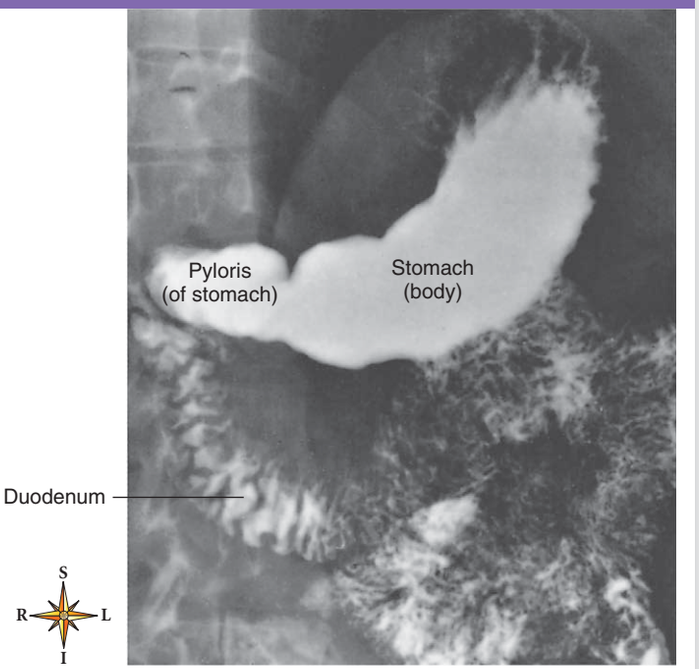
Wall of esophagus. A, The four layers of the gastrointestinal (GI) wall are easily identified in this microscopic cross section of the esophagus (see Table 28-1). **B,** Cadaver dissection photograph of the mucosal lining at the junction between the lower part of the esophagus and the stomach—a frequent site of irritation caused by reflux of acidic gastric secretions.

Each end of the esophagus is encircled by muscular sphincters that act as valves to regulate passage of material. The **upper esophageal sphincter (UES)** in the cervical part of the esophagus helps prevent air from entering the esophagus during respiration. The UES is made up of several muscles, but the *cricopharyngeus muscle* (see Figure 28-11, *B*) that wraps around the back of the cervical esophagus plays the primary role. Relaxation of the UES is what permits *belching* (or *burping*), which is the sudden escape of air trapped in the stomach and esophagus.

The **lower esophageal sphincter (LES)** is also called the *cardiac sphincter* or *cardial sphincter.* The intrinsic part of the LES is located at the junction with the stomach and is made up of layers of circular muscle that are thicker than in other parts of the esophagus. Slinglike oblique muscles from the stomach wall also form part of the LES, adding to its strength in containing the stomach contents while the stomach is full and churning. The muscles of the diaphragm at the *esophageal hiatus*—an opening in the diaphragm located near the junction between the terminal portion of the esophagus and the stomach—form the extrinsic part of the LES.

The esophageal hiatus in the diaphragm, which permits passage of the esophagus into the abdomen, may become stretched or otherwise enlarged. Such enlargement may permit bulging of the lower segment of the esophagus and intrinsic LES and part or even all of the stomach upward through the diaphragm and into the chest. The condition is called a **hiatal** (hye-AYT-al) **hernia.**



Gastroesophageal reflux disease, or **GERD,** is the term used to describe the backward flow of stomach acid up through the LES and into the lower part of the esophagus. It often causes a painful sensation called *heartburn.* Being a potentially serious medical condition, GERD is treated by elimination of the underlying causes, such as a hiatal hernia, by drugs to reduce excess

Box 28-2 | DIAGNOSTIC study

Upper Gastrointestinal X Ray Study

An upper GI (UGI) study consists of a series of x rays of the lower part of the esophagus, stomach, and duodenum, usually with barium sulfate used as the contrast medium. The test is used to detect ulcerations, tumors, inflammation, or anatomical malpositions such as *hiatal hernia* (distention of the diaphragm that allows the stomach to protrude). Obstruction of the upper GI tract is also easily detected.

In this test the patient is asked to drink a flavored liquid containing barium sulfate. As the contrast medium travels through the system, the lower portion of the esophagus, gastric wall, pyloric channel, and duodenum are each evaluated for defects. Benign peptic ulcer is a common pathological condition affecting these areas. Tumors, cysts, or enlarged organs near the stomach can also be identified by an anatomical distortion of the outline of the upper GI tract. Can you identify the outline of the stomach in the figure?

X ray film of the lower part of the esophagus, stomach, and duodenum.

stomach acid, or by surgery to reduce the lumen size or strengthen the LES (see Mechanisms of Disease on p. 890). Box 28-2 describes a method for imaging a hiatal hernia and other problems of the esophagus and stomach.

The junction between the lower part of the esophagus and stomach (see Figure 28-12, *B*) is an important site for a number of pathologic conditions, many associated with repeated exposure to acid gastric secretions. In the last 1- to 1.5-cm-long abdominal part of the esophagus below the diaphragm, stratified squamous epithelium is replaced by columnar epithelium. It is this area of transition that is often damaged by exposure to acid and digestive enzymes from the stomach. The area of transition between the lower part of the esophagus and stomach is clearly visible in Figure 28-12, *B*. The stratified squamous epithelial lining of the esophagus appears pale, whereas the columnar gastric epithelium appears brown.

STOMACH

Size and Position of the Stomach

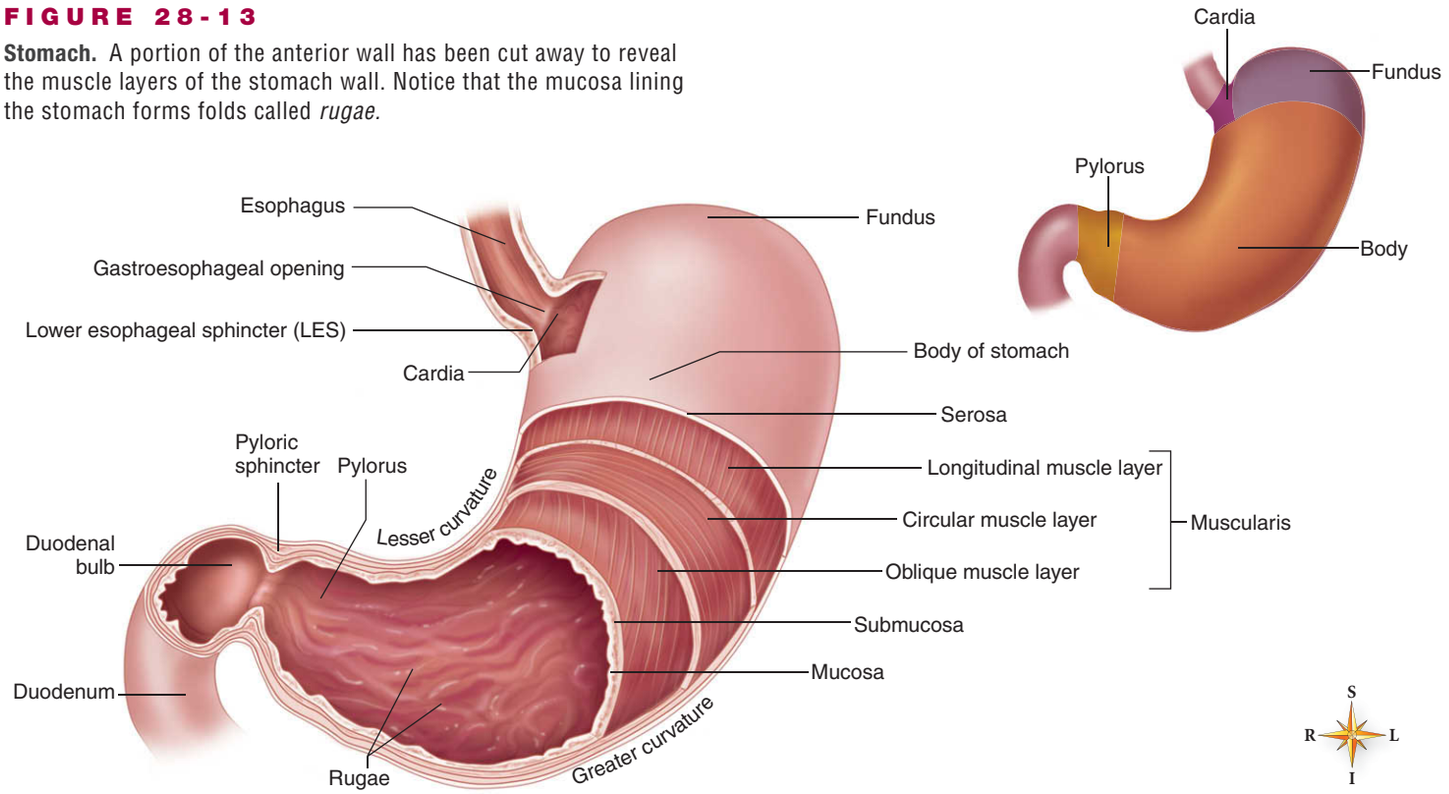
Just below the diaphragm, the digestive tube dilates into an elongated pouchlike structure, the stomach (Figure 28-13), the size of which varies according to several factors, notably the amount of distention. For some time after a meal, the stomach is enlarged because of distention of its walls, but as food passes out of the stomach, the walls partially collapse, leaving the organ about the size of a large sausage. In adults, the stomach usually holds a volume of up to 1 to 1.5 liters.

The stomach lies in the upper part of the abdominal cavity under the liver and diaphragm, with approximately five sixths of its mass to the left of the median line (see Figure 28-1). In other words, it is described as lying in the *epigastrium* and left *hypochondrium* (see Figure 1-7, p. 14). Its position, however, alters frequently. For example, it is pushed downward with each inspiration and upward with each expiration. When it is greatly distended from an unusually large meal, its size interferes with descent of the diaphragm on inspiration, thereby producing the familiar feeling of *dyspnea* (breathing difficulty) that accompanies overeating. In this state, the stomach also pushes upward against the heart and may give rise to the sensation that the heart is being crowded.

Divisions of the Stomach

The **fundus, body,** and **pylorus** are the major divisions of the stomach. The fundus is the enlarged portion to the left and above the opening of the esophagus into the stomach. The body is the central part of the stomach, and the pylorus is its lower portion (see Figure 28-13). The small collar or margin of the stomach at its junction with the esophagus is often called the **cardia** or *cardiac part* (or *cardial part*).

Curves of the Stomach



The curve formed by the upper right surface of the stomach is known as the *lesser curvature;* the curve formed by the lower left surface is known as the *greater curvature* (see Figure 28-13).

Sphincter Muscles

Sphincter muscles regulate passage of material at both stomach openings. A sphincter muscle, as you know, consists of circular fibers arranged to form an opening in the center of them (like the

FIGURE 28-13

Stomach. A portion of the anterior wall has been cut away to reveal the muscle layers of the stomach wall. Notice that the mucosa lining the stomach forms folds called *rugae.*

hole in a doughnut) when they are relaxed and no opening when they are fully contracted.

The *lower esophageal sphincter (LES)*, or *cardiac sphincter*, controls the opening of the esophagus into the stomach, and the **pyloric sphincter** controls the opening from the pyloric portion of the stomach into the first part of the small intestine (duodenum).

Stomach Wall

Each of the four layers of the stomach wall suits the function of this organ, as summarized in Table 28-1 (p. 863) and shown in Figures 28-13 and 28-14. Of particular interest are the modifications to the stomach mucosa and muscularis, both of which are briefly described below.

GASTRIC MUCOSA

The epithelial lining of the stomach is thrown into folds, called *rugae*, and marked by depressions called *gastric pits*. Numerous coiled

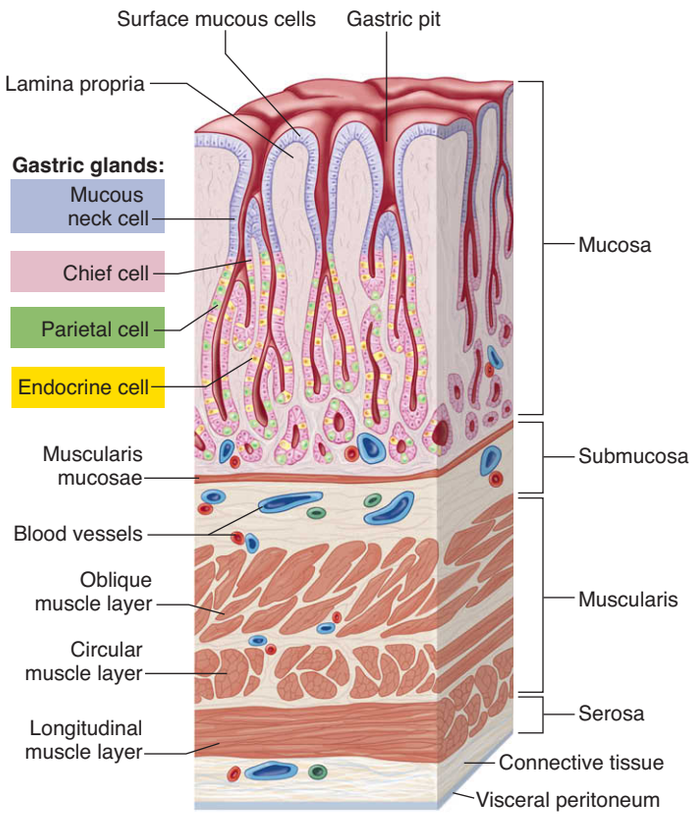


FIGURE 28-14

Gastric pits and gastric glands. Gastric pits are depressions in the epithelial lining of the stomach. At the bottom of each pit is one or more tubular *gastric glands.* Chief cells produce the enzymes of gastric juice, and parietal cells produce stomach acid. Endocrine cells secrete the appetite-boosting hormone ghrelin.

tubular-type glands, *gastric glands*, are found below the level of the pits, particularly in the fundus and body of the stomach. Figure 28-14 illustrates the anatomical relationship of the gastric pits and gastric glands. The glands secrete most of the gastric juice, a mucous fluid containing digestive enzymes and hydrochloric acid (HCl). Figure 28-15, *A*, a low-power micrograph of the mucosal lining in the body of the stomach, shows numerous gastric pits and a uniform underlying layer of coiled gastric glands. The mucosal lining is easily differentiated from the deeper submucosal layer in this section. Figure 28-15, *B*, shows an enlarged view of gastric pits and gastric glands isolated from the submucosa and surrounding tissues.

In addition to the mucus-producing cells that cover the entire surface of the stomach and line the pits, the gastric glands contain three major secretory cells—**chief cells, parietal cells,** and **endocrine cells** (see Figure 28-14). Chief cells (zymogenic cells) secrete the enzymes of gastric juice. Parietal cells secrete hydrochloric acid and are also thought to produce the important substance known as *intrinsic factor*. Intrinsic factor binds to vitamin B_{12} molecules to protect them from digestive juices until they reach the small intestine—and then facilitates the absorption of B_{12}. Endocrine cells secrete *ghrelin (GHRL)*—a hormone that stimulates the hypothalamus to secrete growth hormone and increase appetite—and *gastrin*, which influences digestive functions. The roles of the gastric secretory cells are explored further in Chapter 29.

GASTRIC MUSCLE

The thick layer of muscle in the stomach wall—the **muscularis**—is made of three distinct sublayers of smooth muscle tissue. As Figure 28-13 shows, there is the usual layer of longitudinal muscles and circular muscles, as well as an additional, underlying oblique layer. The crisscrossing pattern of smooth muscle fibers formed by this arrangement gives the stomach wall the ability to contract strongly at many angles—thus making the mixing action of this organ very efficient.

Functions of the Stomach

The stomach performs the following functions:

- Serves as a food reservoir, its main function; food is stored in the stomach until it can be partially digested and moved farther along the gastrointestinal tract.

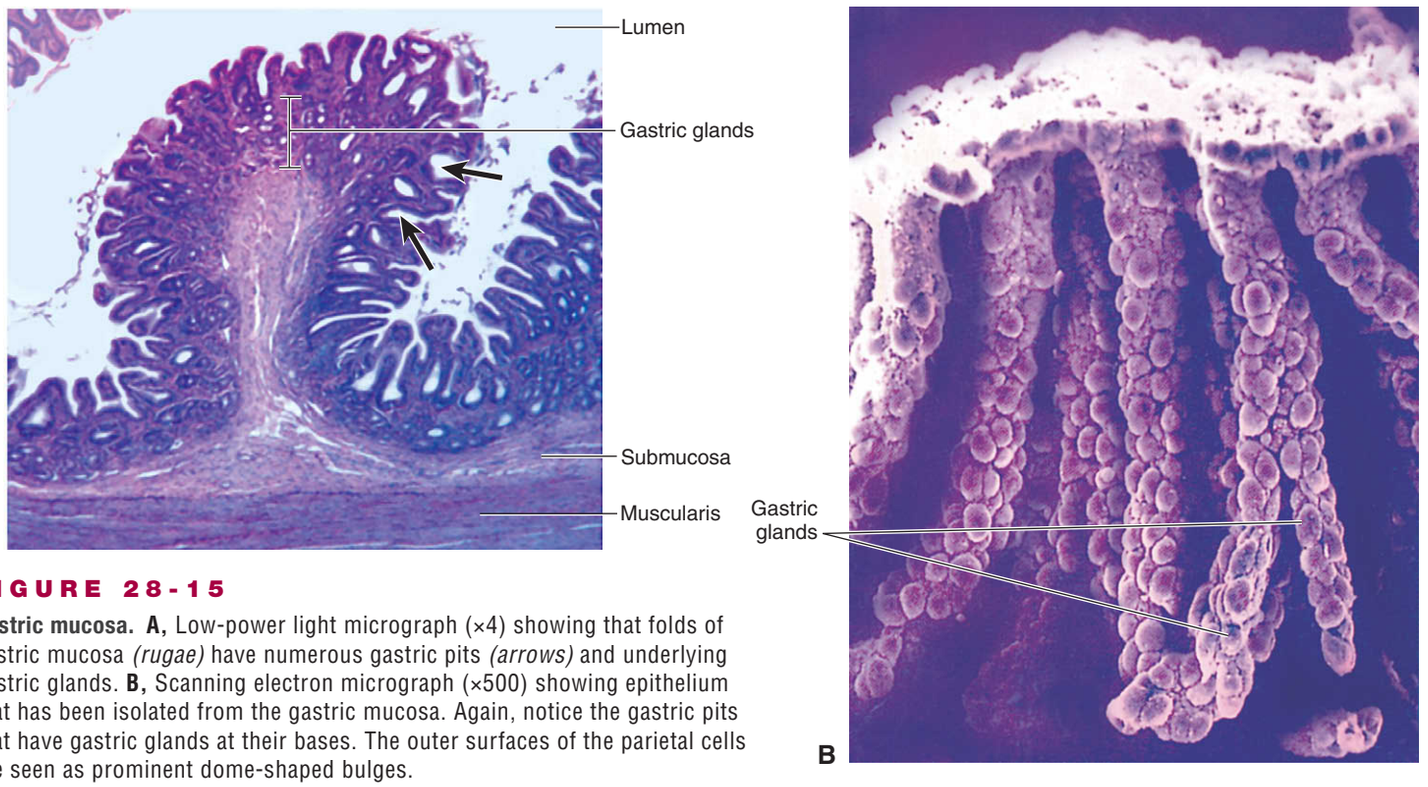

FIGURE 28-15

Gastric mucosa. A, Low-power light micrograph (×4) showing that folds of gastric mucosa *(rugae)* have numerous gastric pits *(arrows)* and underlying gastric glands. **B,** Scanning electron micrograph (×500) showing epithelium that has been isolated from the gastric mucosa. Again, notice the gastric pits that have gastric glands at their bases. The outer surfaces of the parietal cells are seen as prominent dome-shaped bulges.

- Secretes *gastric juice*, which contains acid and enzymes that aid in the digestion of food.
- Churns the food (by contractions of its muscular coat), breaking it into small particles and mixing them well with the gastric juice; in time, gastric contents are moved along into the duodenum.
- Secretes *intrinsic factor.*
- Performs a limited amount of absorption; absorbed substances include certain drugs, some water, alcohol, and some short-chain fatty acids found in butter or milk fat.
- Produces the hormones *gastrin*, which helps regulate digestive functions, and *ghrelin (GHRL)*, which increases appetite.
- Helps protect the body by destroying pathogenic bacteria swallowed with food or with mucus from the respiratory tract.

The digestive functions of the stomach are discussed further in Chapter 29.

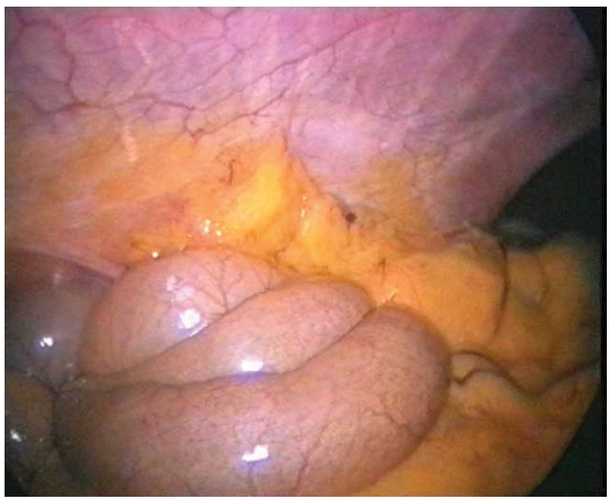
SMALL INTESTINE

Size and Position of the Small Intestine



The small intestine is a tube measuring about 2.5 cm (1 inch) in diameter and 6 m (20 feet) in length. Its coiled loops fill most of the abdominal cavity (see Figures 28-1 and 28-16).

Divisions of the Small Intestine

The small intestine consists of three divisions: the duodenum, the jejunum, and the ileum. The **duodenum** is the uppermost division and the part to which the pyloric end of the stomach attaches. It is about 25 cm (10 inches) long and is shaped roughly like the letter C. The name *duodenum*, meaning "12 fingerbreadths," refers to the short length of this intestinal division. The duodenum becomes **jejunum** at the point where the tube turns abruptly forward and downward. The jejunal portion continues for approximately the next 2.5 m (8 feet), at the end of which it becomes the **ileum,** but without any clear line of demarcation between the two divisions. The ileum is about 3.5 m (12 feet) long.

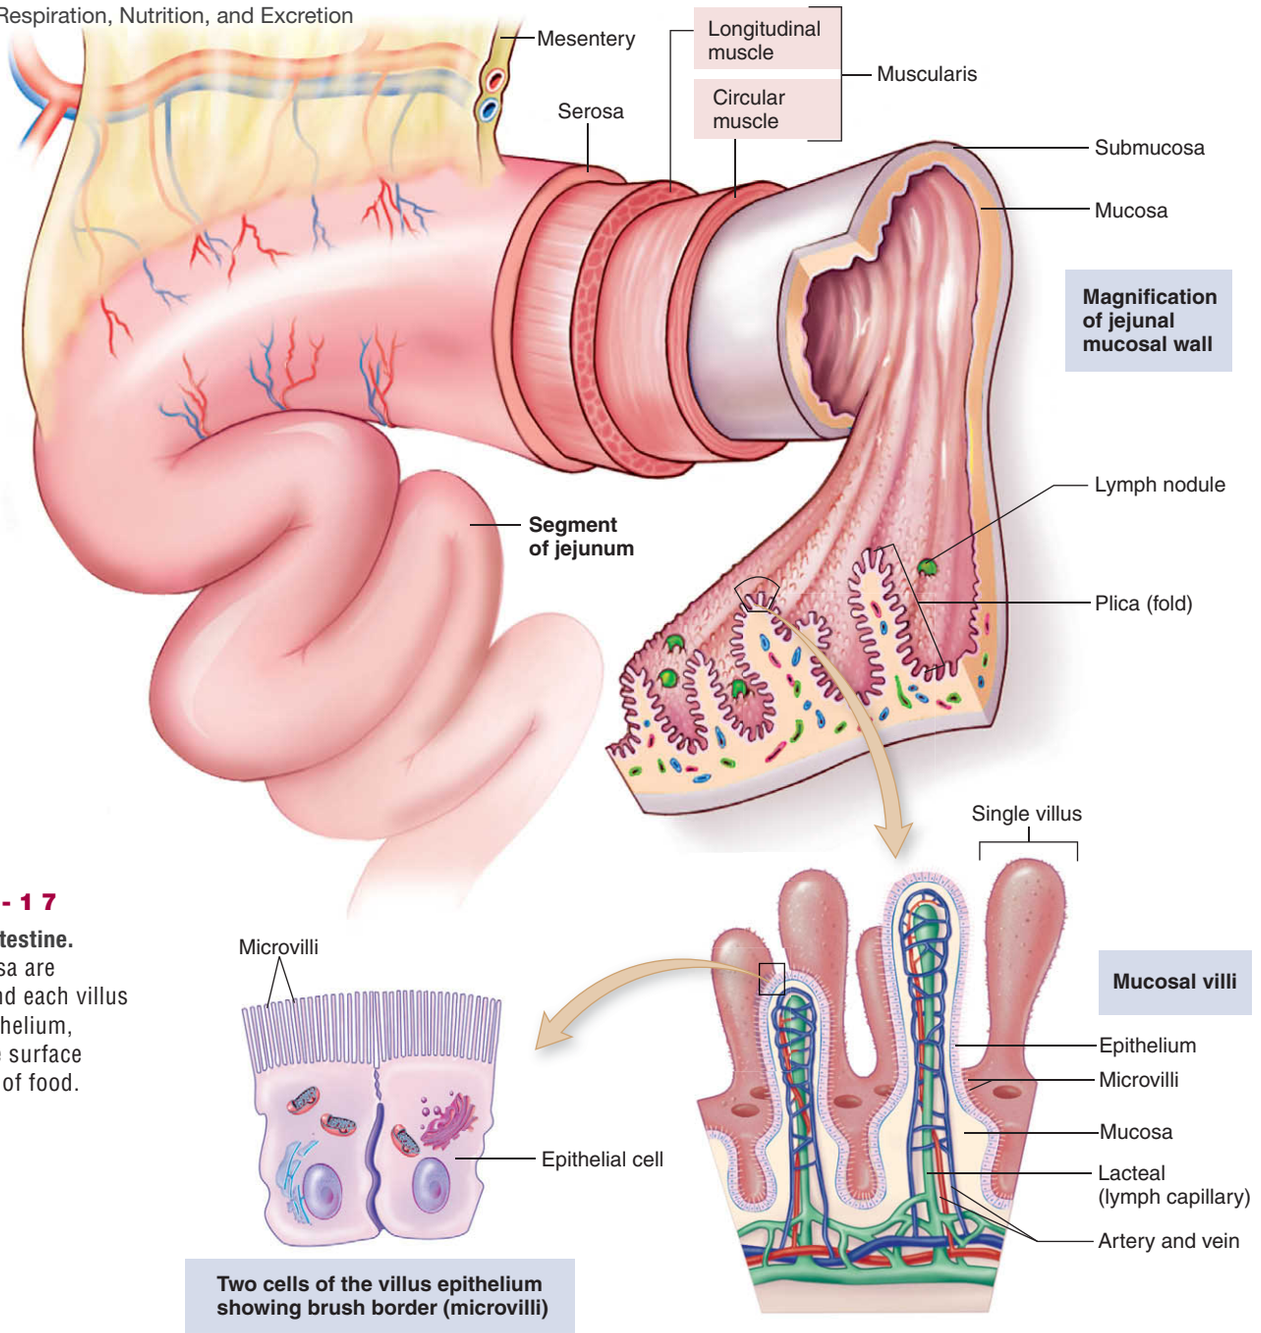

FIGURE 28-17

Wall of the small intestine. Note folds of mucosa are covered with villi and each villus is covered with epithelium, which increases the surface area for absorption of food.

Wall of the Small Intestine

Notice in Figure 28-17 that the intestinal lining has circular *plicae* (folds) that have many tiny projections called **villi.** Villi are important modifications of the mucosal layer of the small intestine. Millions of these projections, each about 1 mm in height, give the intestinal mucosa a velvety appearance. Each **villus** contains an arteriole, venule, and lymph vessel (lacteal) (see Figure 28-17). Box 28-3 identifies the fractal-like structure of the intestinal lining.

Absorptive epithelial cells called *enterocytes* on the surface of villi can be seen by microscopy to have a surface resembling a fine brush. This so-called *brush border* is formed by about 1700 ultrafine *microvilli* per cell. Intestinal digestive enzymes are imbedded in the brush border of these cells. The presence of villi and microvilli increases the surface area of the small intestine hundreds of times, thus making this organ the main site of digestion and absorption.

Box 28-3 | FYI

Fractal Geometry of the Body

Biologists are now applying the principles of the new field of **fractal geometry** to human anatomy. Specialists in fractal geometry often study surfaces with a seemingly infinite area, such as the lining of the small intestine. Fractal surfaces have bumps that have bumps that have bumps, and so on. The fractal-like nature of the intestinal lining is represented in Figure 28-17. The plicae (folds) have villi, the villi have microvilli, and even the microvilli have bumps that cannot be seen in the figure. Thus the absorptive surface area of the small intestine is almost limitless.

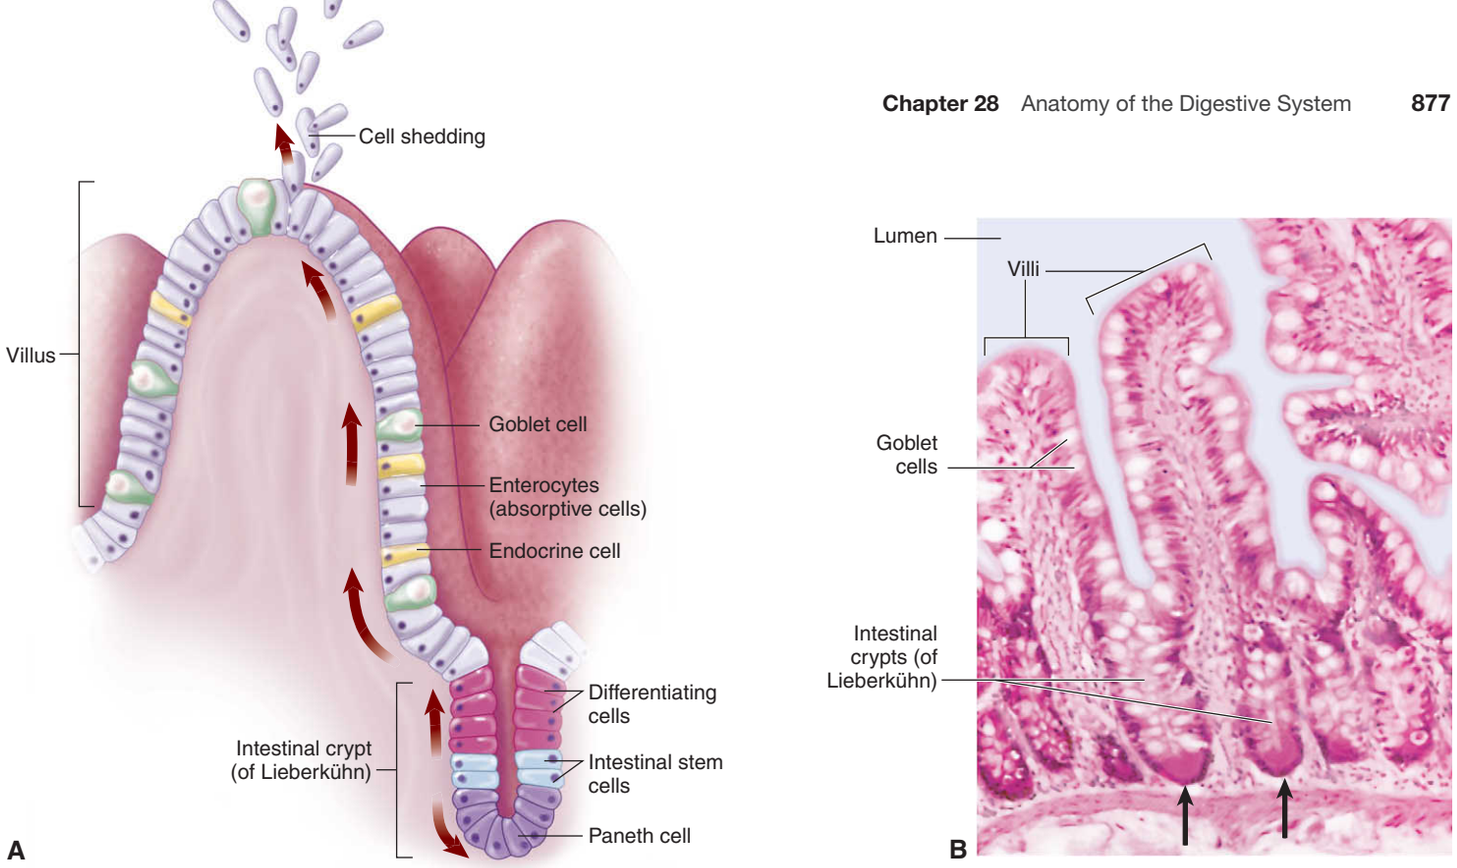

FIGURE 28-18

Intestinal villi and crypts. A, Stem cells near the bottom of each intestinal crypt divide to form daughter cells that move upward and differentiate into mucus-producing goblet cells, hormone-producing endocrine cells, and absorptive enterocytes. Eventually these cells are pushed to the top of the villus, where they are shed. Stem cells also produce Paneth cells, which move deeper into the crypt where they produce bactericidal secretions. **B,** This micrograph shows a section of the ileum wall with several villi and the intestinal crypts between them. Protective Paneth cells at the base of each crypt are marked by arrows.

Mucus-secreting goblet cells are found in large numbers on villi (Figure 28-18). Endocrine cells that produce intestinal hormones (to be discussed in Chapter 29) are also found in the villi.

Intestinal crypts serve as a site of rapid mitotic cell division. Stem cells near the bottom of each crypt keep the intestinal mucosa continuously supplied with fresh cells. New differentiating daughter cells are produced by the stem cells and pushed upward toward the mouth of the crypt. As they differentiate into enterocytes, goblet cells, and endocrine cells, the older cells are pushed up and out of each crypt, eventually moving to the distal end of a villus, where they are shed. Thus the intestinal mucosa is continually renewed. At the base of each crypt, protective *Paneth cells* produce enzymes and other molecules that inhibit bacterial growth in the small intestine. The location of the Paneth cells makes them especially useful in protecting the vital stem cells. See Table 28-1 and Figure 28-17 for more information on the layers of the small intestine.

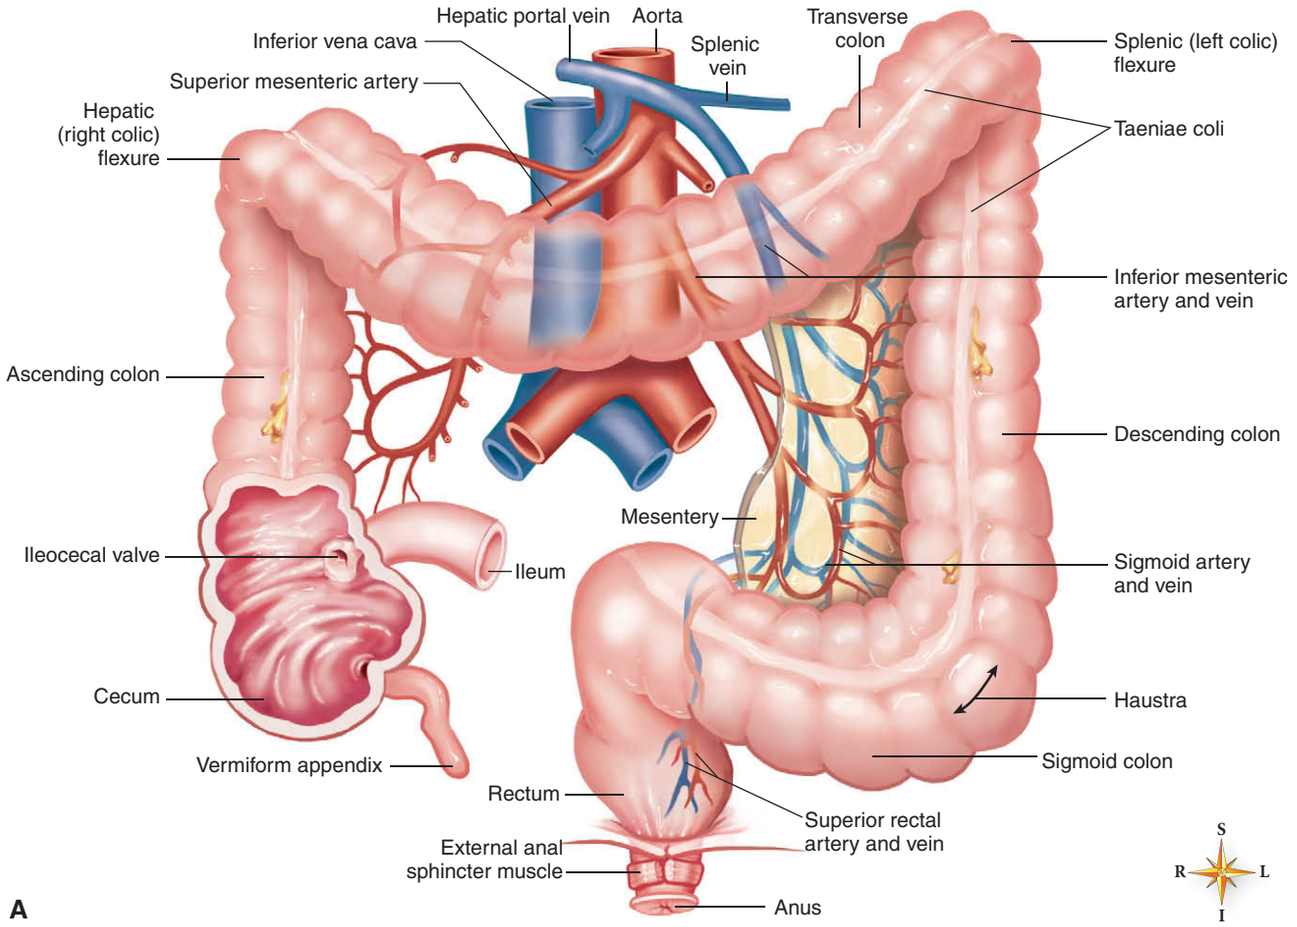
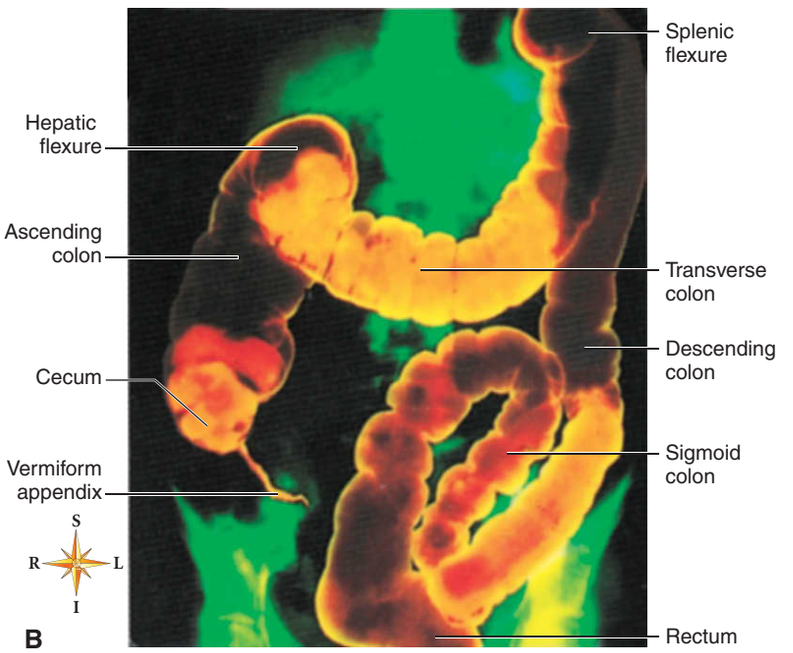
12. What are the three main divisions of the small intestine?
13. What are intestinal villi? What is their function?

LARGE INTESTINE

Size of the Large Intestine



The lower part of the alimentary canal bears the name *large intestine* because its diameter is noticeably larger than that of the small intestine. Its length, however, is much less, being about 1.5 to 1.8 m (5 or 6 feet). Its average diameter is approximately 6 cm (2½ inches), but the diameter decreases toward the lower end of the tube. Box 28-4 describes a common method for imaging the large intestine.



Box 28-4 | DIAGNOSTIC study

Barium Enema Study

The barium enema (BE) study, or lower GI series, consists of a series of x ray films of the colon that are used to detect and locate polyps, tumors, and diverticula (abnormal "pouches" in the lining of the intestine). Abnormalities in organ position can also be detected.

The test begins with the rectal instillation (enema) of approximately 500 to 1500 ml of fluid containing barium sulfate. The patient is placed in various positions, and the progress of the barium's flow through the intestine is monitored on a fluoroscope. Small polyps and early changes in ulcerative colitis are more easily detected with an *air-contrast barium enema study.* In this study, after the bowel is outlined with a thin coat of barium, air is added to enhance the contrast and outline of small lesions. After the x ray films are taken (see Figure 28-19), the patient is allowed to expel the barium.

Divisions of the Large Intestine

The large intestine is divided into the cecum, colon, and rectum (Figure 28-19).

CECUM

The first 5 to 8 cm (2 or 3 inches) of the large intestine is named the *cecum*. It is a blind pouch located in the lower right quadrant of the abdomen (see Figure 28-1).

COLON

The **colon** is divided into the following portions: ascending, transverse, descending, and sigmoid (see Figure 28-19).

- The **ascending colon** lies in a vertical position, on the right side of the abdomen, and extends up to the lower border of the liver. The ileum joins the large intestine

FIGURE 28-19

Divisions of the large intestine. A, Illustration showing divisions of the large intestine and adjacent vascular structures. **B,** Colorized x ray film taken after a barium enema (see Box 28-4).

at the junction of the cecum and ascending colon, the place of attachment resembling the letter T (see Figure 28-19). The *ileocecal valve* permits material to pass from the ileum into the large intestine, but not usually in the reverse direction.

- The **transverse colon** passes horizontally across the abdomen, below the liver, stomach, and spleen. Note that this part of the colon is above the small intestine (see Figure 28-1). The transverse colon extends from the *hepatic flexure* to the *splenic flexure*, the two points at which the colon bends on itself to form 90-degree angles.
- The **descending colon** lies in the vertical position, on the left side of the abdomen, and extends from a point below the stomach and spleen to the level of the iliac crest.
- The **sigmoid colon** is the portion of the large intestine that courses downward below the iliac crest. It is called *sigmoid* (meaning "S-shaped") because it forms an S-shaped curve. The lower part of the curve, which joins the rectum, bends toward the left, the anatomical reason for placing a patient on the left side when giving an enema. In this position, gravity aids the flow of enema fluid from the rectum into the sigmoid flexure.

RECTUM

The last 17 to 20 cm (7 or 8 inches) of the intestinal tube is called the **rectum** (Figure 28-20). Crescent-shaped *transverse rectal folds*, also called *rectal valves*, help slow down the flow of feces as it enters the rectum and hold the feces in place until defecation occurs. In an empty rectum, these folds may overlap and make it difficult to insert instruments during a **colonoscopy.**

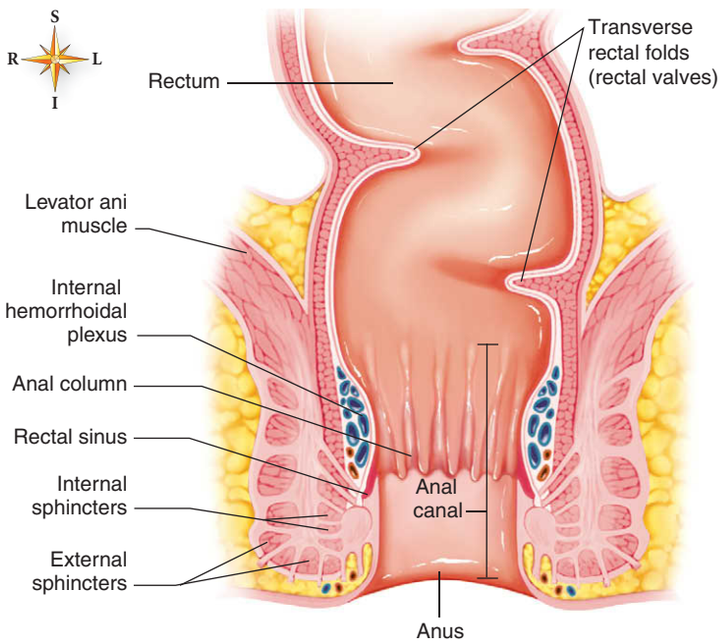


FIGURE 28-20
The rectum and anus.

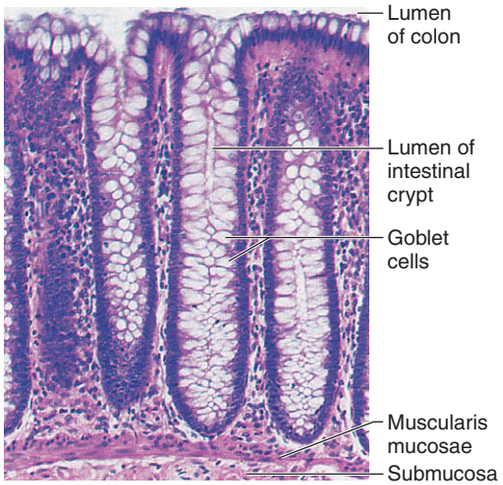

FIGURE 28-21
Wall of the colon. Note the straight nature of the intestinal glands of the colon. Many of the columnar epithelial cells are mucus-producing goblet cells.

The terminal inch of the rectum is called the **anal canal.** Its mucous lining is arranged in numerous vertical folds known as *anal columns*, each of which contains an artery and a vein. The opening of the canal to the exterior is guarded by two sphincter muscles—an internal one of smooth muscle and an external one of striated muscle. The opening itself is called the *anus*. The anus is directed slightly posteriorly and is therefore at almost a right angle to the rectum (see Figure 28-22).

Wall of the Large Intestine

Table 28-1 (see p. 863) summarizes modifications of the GI wall seen in the large intestine. One of the most notable of these modifications is the presence of intestinal mucous glands, which produce the lubricating mucus that coats the feces as they are formed (Figure 28-21). Although cells lining the large intestine have microvilli, the cells do not form villi like those that appear in the lining of the small intestine.

Another notable feature of the wall of the colon is the uneven distribution of fibers in the muscle layer. The longitudinal muscles are grouped into tapelike strips called *taeniae coli*, and the circular muscles are grouped into rings that produce pouchlike *haustra* between them (see Figure 28-19). In the rectum, rings of circular muscle form the rectal valves seen in Figure 28-20.

VERMIFORM APPENDIX

The **vermiform appendix** (from *vermis* "worm," *form* "shape") is, as the name implies, a wormlike tubular organ. It averages 8 to

10 cm (3 to 4 inches) in length and is most often found just behind the cecum or over the pelvic rim. The lumen of the appendix communicates with the cecum 3 cm (about 1 inch) below the ileocecal valve, thus making it an accessory organ of the digestive system (see Figure 28-19).

The appendix serves as a sort of "breeding ground" for the nonpathogenic intestinal bacteria found throughout the colon. The normal microbiome of the colon contributes to the digestive process by digesting unused nutrients and producing essential molecules such as vitamins K and B_7 (biotin). Some bacteria also produce gases that escape from the colon through the anus—a phenomenon called flatulence or *flatus*. Maintaining a normal intestinal microbiome also helps prevent pathogenic bacteria from becoming established. When the normal microbiome of the gut is disrupted by infection or antibiotics, for example, bacteria hidden away in the appendix can migrate into the colon to restore the normal ecological balance. The ecology of the human gut's microbiome is a very active field of research.

Lymph nodules appear in the wall of the appendix shortly after birth, become more prominent during the first 10 years of life, and then progressively disappear. The normal adult appendix shows only traces of lymphoid tissue. The function of lymphatic tissue present in the appendix of young children is not fully understood but may involve regulating the gut's microbial communities.

Inflammation of the appendix, or **appendicitis,** is a common and potentially very serious medical problem (see Mechanisms of Disease, pp. 893–894. The lifetime risk for appendicitis in the United States is 7%. A site on the surface of the anterior abdominal wall is often used to help in the diagnosis of appendicitis and to estimate the location of the appendix internally. It is called *McBurney's point* and is located in the right lower quadrant of the abdomen about a third of the way along a line from the right anterior superior iliac spine to the umbilicus. Extreme sensitivity and pain are common when the abdomen of persons with acute appendicitis is palpated over this point.

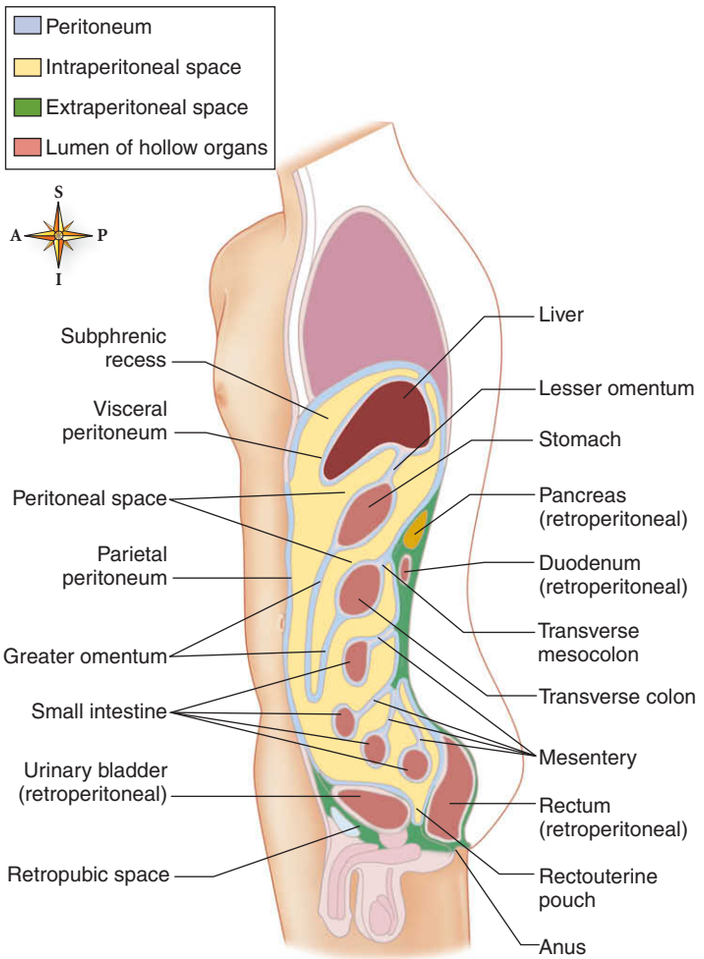

FIGURE 28-22

Peritoneum. Sagittal view of the abdomen showing the peritoneum and its reflections. *Intraperitoneal* spaces are shown in yellow and *extraperitoneal* spaces in green. The portion of the extraperitoneal space along the posterior wall of the abdomen is often called the *retroperitoneal space.*

PERITONEUM

Now that we have described the entire length of the digestive tube from one end to the other, let's focus on the membrane covering most of these organs and holding them loosely in place. The **peritoneum** is a large, continuous sheet of serous membrane. It lines the walls of the entire abdominal cavity (parietal layer) and also forms the serous outer coat of the organs (visceral layer) as you can see in Figure 28-22. All the space outside the parietal peritoneum is called *extraperitoneal space.* The extraperitoneal space along the posterior and bottom of the abdominopelvic cavity is most often identified as *retroperitoneal* ("behind the peritoneum"). Retroperitoneal organs include the pancreas (except the tail), kidneys and adrenal glands, ureters and bladder, aorta and inferior vena cava, part of the esophagus, part of the duodenum, ascending and descending colon, and the rectum.

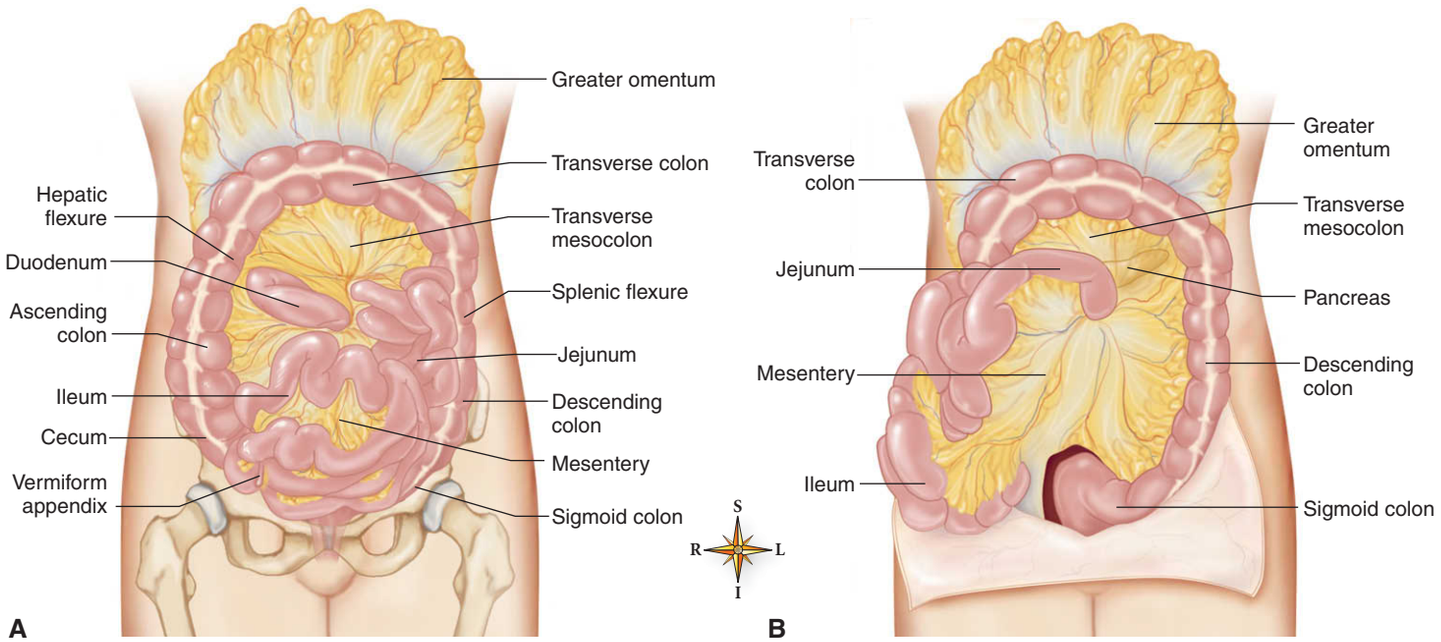

FIGURE 28-23

Projections of the peritoneum. A, Abdominal viscera from the front. The transverse colon and the greater omentum are elevated to reveal the flexures of the colon and the loops of the small intestine. **B,** The transverse colon and greater omentum are raised and the small intestine is pulled to the side to show the transverse mesocolon and mesentery.

In several places the peritoneum forms reflections, or extensions, that bind the abdominal organs together (Figures 28-22 and 28-23). The **mesentery** is a fan-shaped projection of the parietal peritoneum that extends from the lumbar region of the posterior abdominal wall. The attached posterior border of this great fan is just 15 to 20 cm (6 to 8 inches) long, yet the loose outer edge enclosing the jejunum and ileum is 6 m (over 9 feet) long. The mesentery allows free movement of each coil of the intestine and helps prevent strangulation of the long tube. A similar, but less extensive fold of peritoneum, called the **transverse mesocolon,** attaches the transverse colon to the posterior abdominal wall.

The **greater omentum** is a continuation of the serosa of the greater curvature of the stomach and the first part of the duodenum to the transverse colon. Spotty deposits of fat accumulate in the omentum and give it the appearance of a lace apron hanging down loosely over the intestines. In cases of localized abdominal inflammation such as appendicitis, the greater omentum envelops the inflamed area, walling it off from the rest of the abdomen. The **lesser omentum** attaches from the liver to the lesser curvature of the stomach and the first part of the duodenum. The falciform ligament extends from the liver to the anterior abdominal wall. Examine the relationships of peritoneal extensions in Figure 28-22.

LIVER

Location and Size of the Liver

The liver is the largest gland in the body. It weighs about 1.5 kg (3 to 4 pounds), lies immediately under the diaphragm, and occupies most of the right hypochondrium and part of the epigastrium (see Figure 28-1).

Liver Lobes and Lobules

The liver consists of two lobes separated by the falciform ligament (Figure 28-24). The **left lobe** forms about one sixth of the liver, and the **right lobe** makes up the remainder. The right lobe has three parts designated the *right lobe proper*, the *caudate lobe* (a small oblong area on the posterior surface), and the *quadrate lobe* (a four-sided section on the undersurface). Each lobe is divided into numerous lobules by small blood vessels and by fibrous strands that form a supporting framework for them called the *perivascular fibrous capsule*. The perivascular fibrous capsule—also called *capsule of Glisson*—is an extension of the heavy connective tissue capsule that envelops the entire liver.

The **hepatic lobules** (Figure 28-25), the anatomical units of the liver, are tiny hexagonal or pentagonal cylinders about 2 mm high and 1 mm in diameter. A small branch of the hepatic vein extends through the center of each lobule. Around this central (intralobular) vein, in plates or irregular walls radiating outward, are arranged the hepatic cells. On the outer corners of each lobule, several sets of tiny tubes—branches of the hepatic artery, the portal vein (interlobular veins), and the hepatic duct (interlobular bile ducts)—are arranged. From these, irregular branches (sinusoids) of the interlobular veins extend between the radiating plates of hepatic cells to join the central vein. Minute bile canaliculi are formed by the spaces around each cell that collect bile secreted by the hepatic cells.

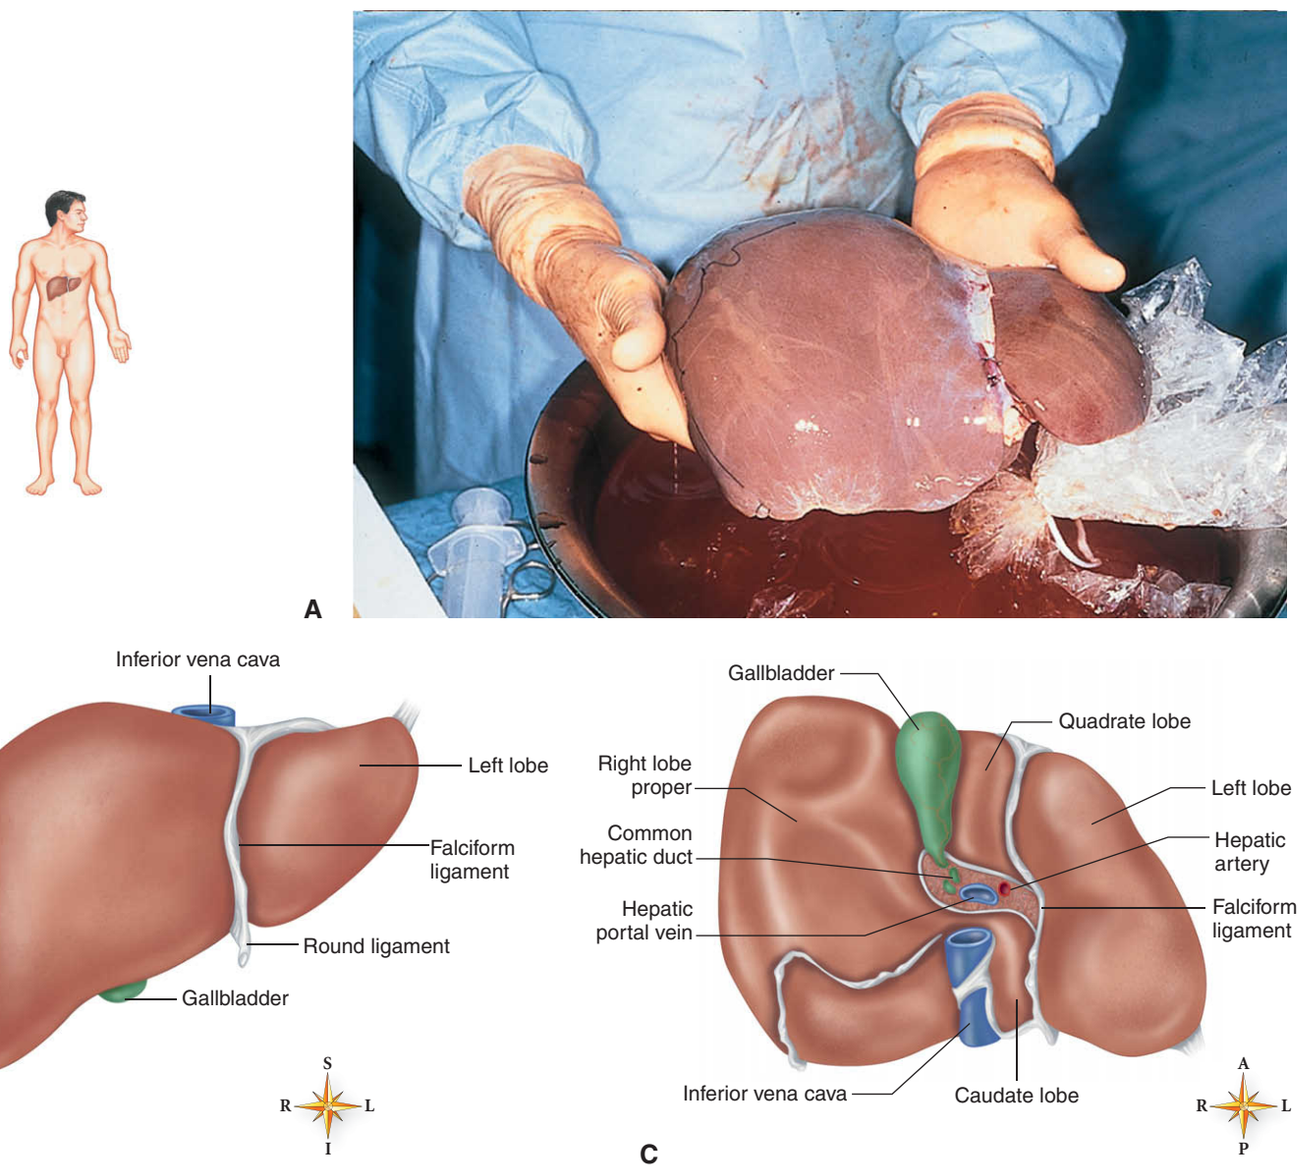

FIGURE 28-24

Gross structure of the liver. A, Normal liver prepared for organ transplantation. Diagrams of a normal liver—**B,** anterior view; **C,** inferior view.

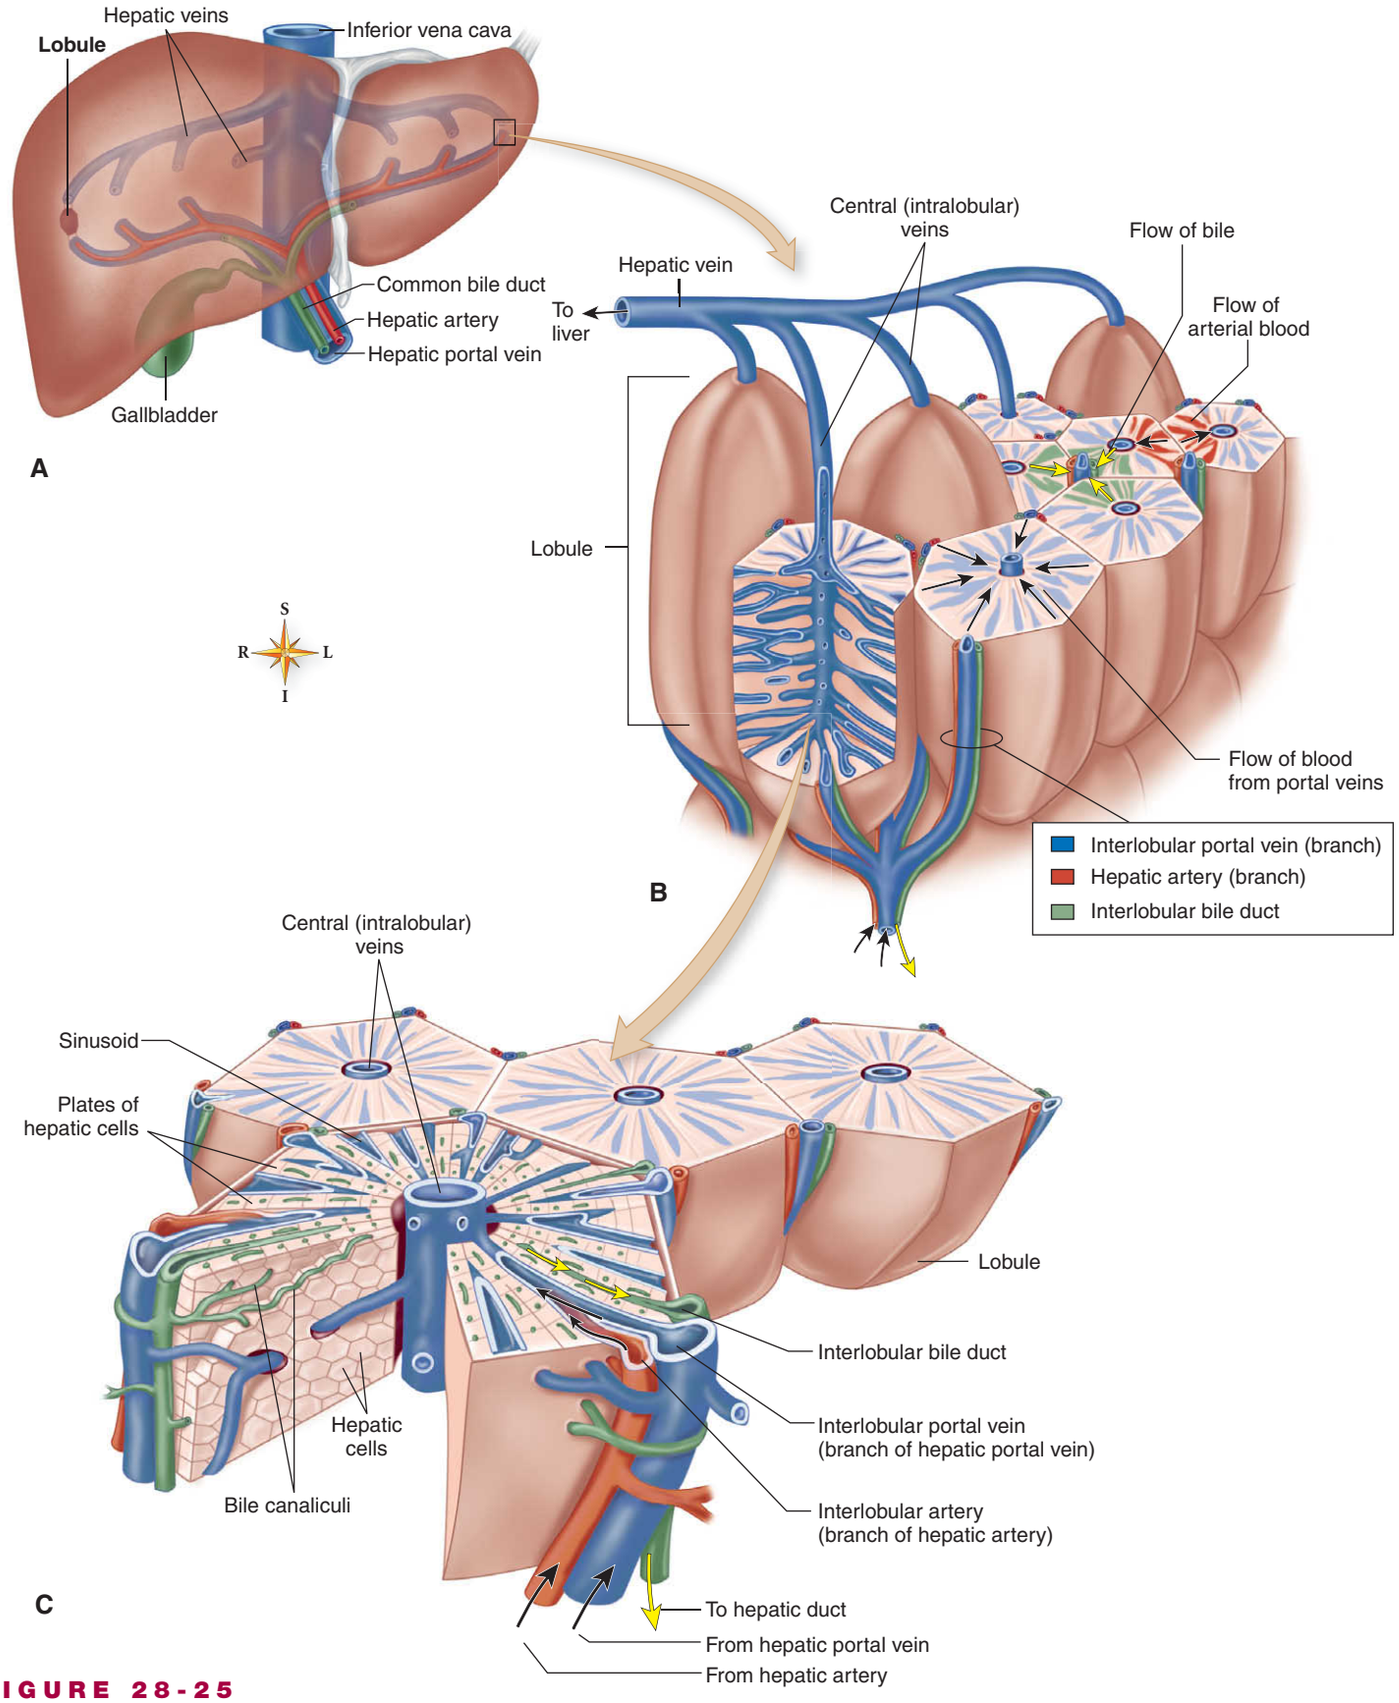

FIGURE 28-25

Microscopic structure of the liver. A, This diagram shows the location of liver lobules relative to the overall circulatory scheme of the liver. **B** and **C,** Enlarged views of several lobules show how blood from the hepatic portal veins and hepatic arteries flows through sinusoids and thus past plates of hepatic cells toward a central vein in each lobule *(black arrows)*. Hepatic cells form bile, which flows through bile canaliculi toward hepatic ducts that eventually drain the bile from the liver *(yellow arrows)*.

Consider the function of the hepatic lobule while carefully examining Figures 28-25 and 28-26. Blood enters a lobule from branches of the hepatic artery and portal vein. Arterial blood oxygenates the hepatic cells, whereas blood from the portal system simply passes through the liver for "inspection." Sinusoids in the lobule have many reticuloendothelial cells (mainly *Kupffer cells*) along their lining. These phagocytic cells can remove bacteria, worn red blood cells (RBCs), and other particles from the bloodstream. Ingested vitamins and other nutrients to be stored or metabolized by liver cells enter the hepatic cells that form radiating walls of the lobule. Dissolved toxins in the blood are also absorbed into hepatic cells, where they are detoxified (rendered harmless). Blood continues along the sinusoids to a vein at the center of the lobule. Such central, intralobular veins eventually lead to the main hepatic veins that drain into the inferior vena cava. **Bile** formed by hepatic cells passes through canaliculi to the periphery of the lobule to join small bile ducts.

Bile Ducts

The small bile ducts within the liver join to form two larger ducts that emerge from the undersurface of the organ as the *right* and *left hepatic ducts*. These ducts immediately join to form one common hepatic duct. The common hepatic duct merges with the *cystic duct* from the gallbladder to form the *common bile duct* (Figure 28-27), which opens into the duodenum in a small raised area called the *major duodenal papilla*. This papilla is located 7 to 10 cm (2 to 4 inches) below the pyloric opening from the stomach.

The inset in Figure 28-27 shows an x ray taken during a procedure with a tongue-twister name—*endoscopic cholangiography* (koh-lan-jee-OG-rah-fee). During this procedure, x rays are taken to visualize the gallbladder and ducts that carry bile. The process begins with passage of a flexible endoscope tube surrounding a hollow catheter and other laparoscopic instruments through the mouth, esophagus, and stomach into the duodenum. Once in the duodenum, the catheter is introduced into the major duodenal papilla, and contrast material is injected into the biliary tract. This procedure can also be used to fill the pancreatic duct and its branches with contrast material to obtain very high-quality x ray images.

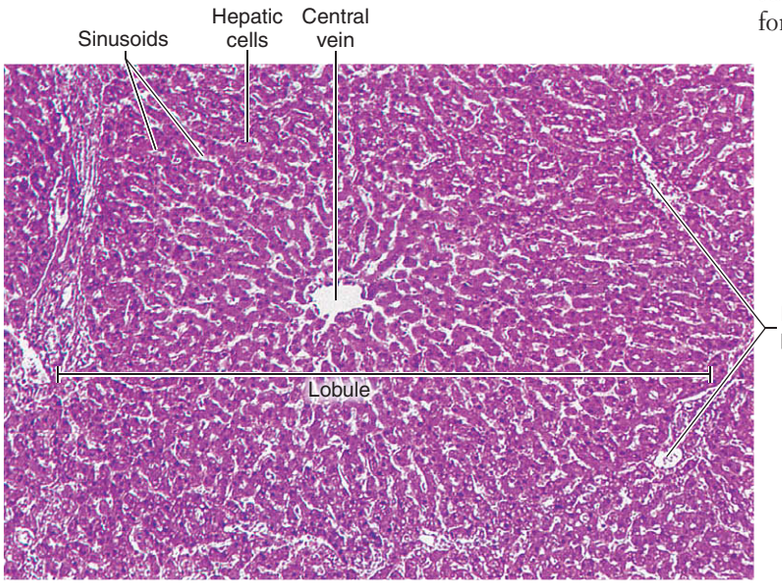

FIGURE 28-26

Liver tissue. This cross section of a hepatic lobule shows the sinusoids that permit passage of blood from the interlobular portal veins toward the central vein. The glandular epithelium (hepatic cells) forms plates between the sinusoids.

Functions of the Liver

The liver is one of the most vital organs of the body. Here, in brief, are its main functions:

- Liver cells detoxify various substances.
- Liver cells secrete approximately half a liter (about a pint) of bile a day.
- Liver cells carry on numerous important steps in the metabolism of all three kinds of foods—proteins, fats, and carbohydrates.
- Liver cells store several substances—iron, for example, and vitamins A, B_{12}, and D.
- The liver produces important plasma proteins and serves as a site of hematopoiesis (blood cell production) during fetal development.

DETOXIFICATION BY LIVER CELLS

Numerous poisonous substances enter blood from the intestines. They circulate to the liver, where, through a series of chemical reactions, they may be changed into nontoxic compounds. Ingested substances—alcohol, acetaminophen, and various other drugs, for example—and toxic substances formed in the intestines can be detoxified in the liver.

BILE SECRETION BY THE LIVER

The main components of bile are bile salts, bile pigments, and cholesterol. Bile salts (formed in the liver from cholesterol) are the most essential part of bile. They aid in the digestion and absorption of fats and then are themselves absorbed in the ileum. Eighty percent of bile salts are recycled in the liver to again become part of bile. Bile also serves as a pathway for elimination of certain breakdown products of RBCs. When aged and fragile erythrocytes are destroyed in the spleen, the heme portion of the released hemoglobin molecule is converted into bilirubin and transported by blood to the liver. Liver cells extract the bilirubin and excrete it into bile. Because it secretes bile into ducts, the liver qualifies as an exocrine gland.

LIVER METABOLISM

Although all liver functions are important for healthy survival, some of its metabolic processes are crucial for survival itself. A fairly detailed description of the role of the liver in metabolism is given in Chapter 30.

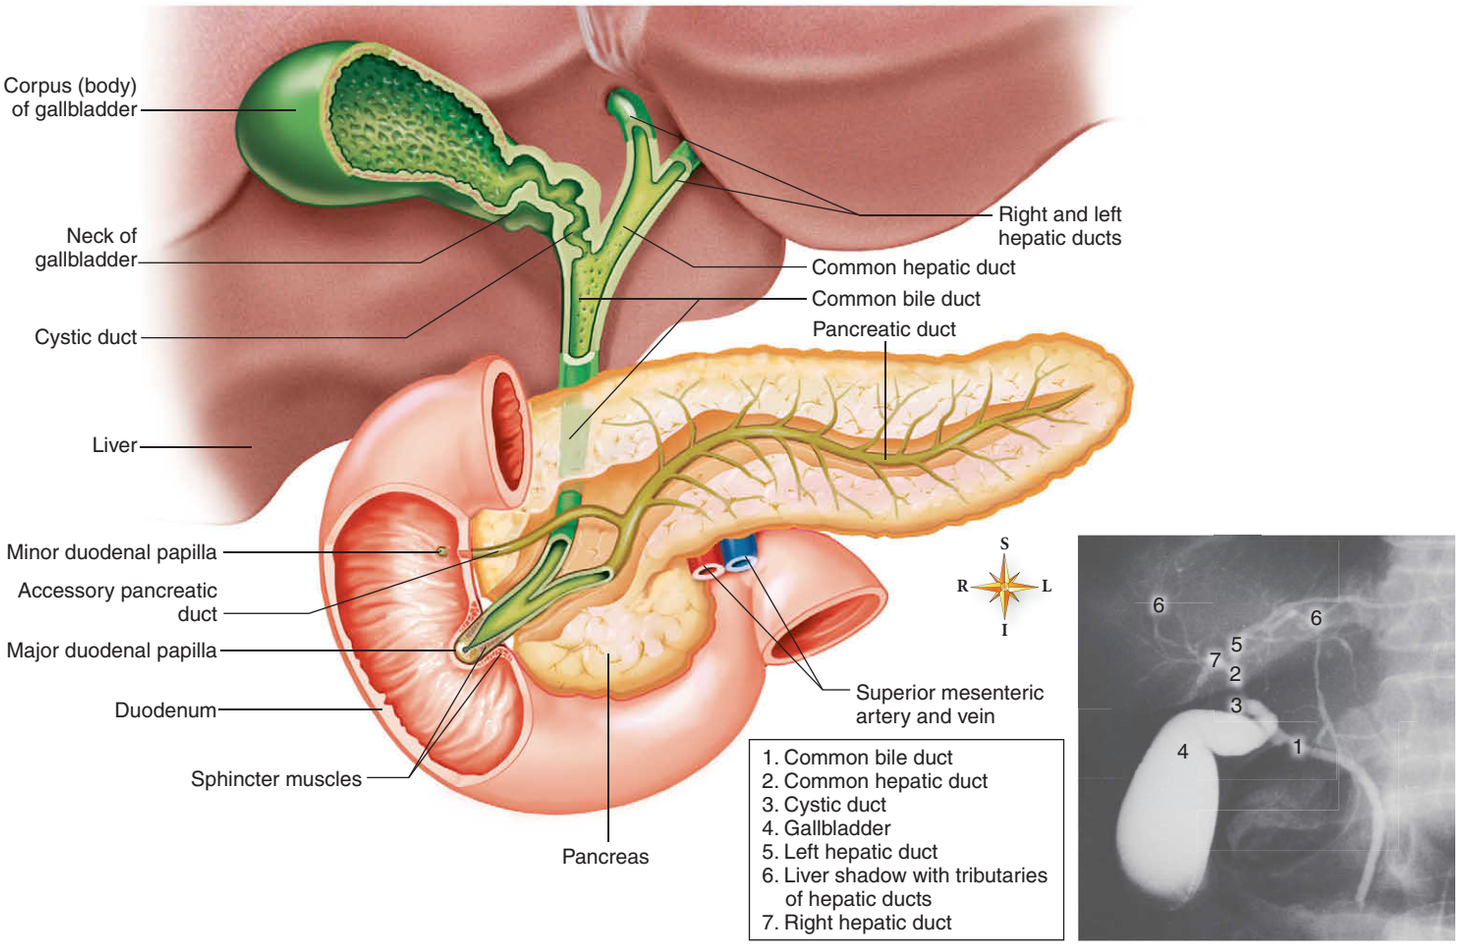

FIGURE 28-27

Ducts that carry bile from the liver and gallbladder. Bile exits the liver through the left and right hepatic ducts, which join to form the common hepatic duct. The common hepatic duct joins the cystic duct from the gallbladder to form the common bile duct, which enters the duodenum at the major duodenal papilla (regulated by sphincter muscles). When sphincter muscles contract, bile backs up into the gallbladder where it is stored and concentrated. Obstruction of either the common hepatic or the common bile duct by a stone or muscle spasm prevents bile from being ejected into the duodenum. The inset shows an x ray of the gallbladder and the ducts that carry bile taken during a procedure called *endoscopic cholangiography.*

GALLBLADDER

Size and Location of the Gallbladder

The gallbladder is a pear-shaped sac 7 to 10 cm (3 to 4 inches) long and 3 cm broad at its widest point (see Figure 28-27). The gallbladder lies on the undersurface of the liver and is attached there by areolar connective tissue.

Structure of the Gallbladder

Serous, muscular, and mucous layers compose the wall of the gallbladder. The mucosal lining is arranged in folds called *rugae*, similar in structure to those of the stomach. These rugae allow the gall bladder to expand as it receives bile that backs up into it when the sphincters of the major duodenal papilla contract. The gall bladder can hold 30 to 50 ml of bile.

Functions of the Gallbladder

The gallbladder stores bile that backs up into it. The gallbladder concentrates bile fivefold to tenfold as it is stored. When partially digested material exits the stomach, the gallbladder contracts and ejects the concentrated bile into the duodenum.

Jaundice, a yellow discoloration of the skin and mucosa, results when obstruction of bile flow into the duodenum occurs. Bile is thereby denied its normal exit from the body in feces. Instead, it is absorbed into the blood, and an excess of bile pigments with a yellow hue enters the blood and is deposited in tissues.

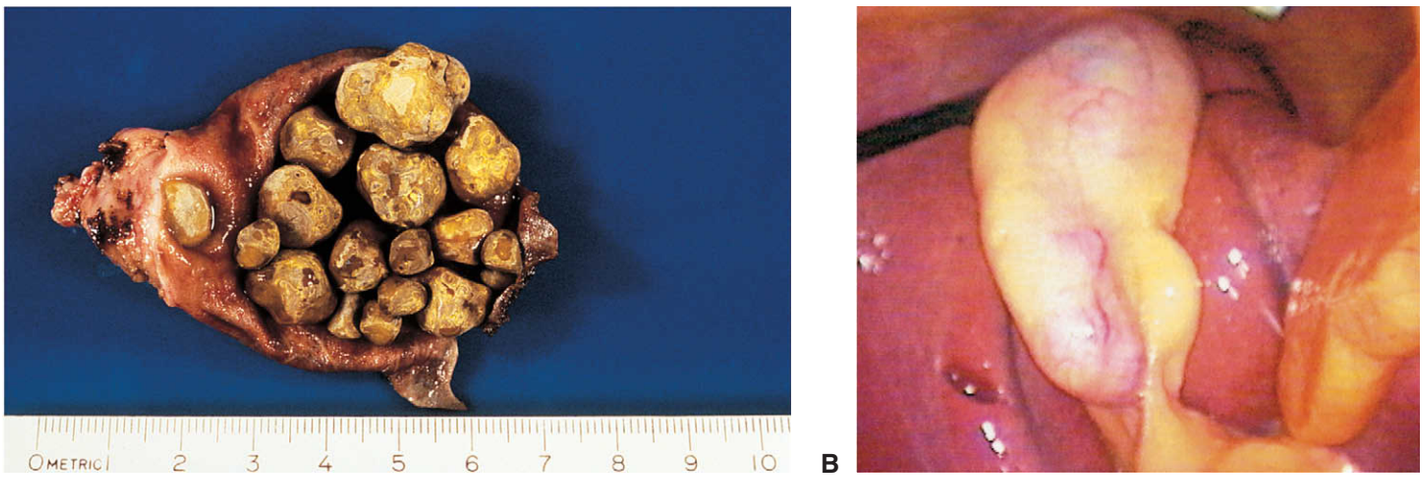

FIGURE 28-28

Gallbladder and gallstones. A, Gallbladder filled with yellow cholesterol gallstones. **B,** Laparoscopic view of the gallbladder before removal.

Inflammation of the gallbladder is called **cholecystitis** (koh-leh-sis-TYE-tis). It is often caused by gallstone formation or **cholelithiasis** (koh-leh-lih-THEE-ah-sis) (Figure 28-28, *A*). Inflammation and stone formation may require surgical removal in a procedure called **cholecystectomy** (koh-leh-sis-TEK-toh-mee). Surgical removal is now commonly performed laparoscopically, a procedure less invasive than traditional surgery (Figure 28-28, *B*). However, efforts to eliminate stones with drugs or nonsurgical methods, such as *ultrasound lithotripsy*, are often the treatment of choice initially.

Did you know that the formation of gallstones may be related to weight loss and dieting? Find out how, and see some dramatic medical images, in ***Gallstones and Weight Loss*** online at ***A&P Connect.***

PANCREAS

Size and Location of the Pancreas

The pancreas is a grayish pink–colored gland about 12 to 15 cm (6 to 9 inches) long, weighing about 60 grams. It resembles a fish with its head and neck in the C-shaped curve of the duodenum, its body extending horizontally behind the stomach, and its tail touching the spleen (Figure 28-29; see Figure 28-1). According to an old anatomical witticism, the "romance of the abdomen" is the pancreas lying "in the arms of the duodenum."

Structure of the Pancreas

The pancreas is composed of two different types of glandular tissue, one exocrine and one endocrine. Most of the tissue is exocrine, with a compound acinar arrangement. The word *acinar* means that the cells are in a grapelike formation and that they release their secretions into a microscopic duct within each unit (see Figure 28-29, *B*). The word *compound* indicates that the ducts have branches. These tiny ducts unite to form larger ducts that eventually join the main pancreatic duct, which extends throughout the length of the gland from its tail to its head.

The pancreatic duct empties into the duodenum at the same point as the common bile duct at the *major duodenal papilla*. An accessory duct is frequently found extending from the head of the pancreas into the duodenum, opening at the *minor duodenal papilla* about 2 cm above the major papilla (see Figure 28-29, *A*).

Embedded between the exocrine units of the pancreas, like so many little islands, lie clusters of endocrine cells called **pancreatic islets** (see Figure 28-29). Although there are about a million of these tiny islands, they constitute only about 2% of the total mass of the pancreas. Special staining techniques have revealed that several kinds of cells—mainly alpha cells and beta cells—make up the islets. They are secreting cells, but their secretion passes into blood capillaries rather than into ducts. Thus the pancreas is a dual gland—an exocrine, or duct, gland because of the acinar units and an endocrine, or ductless, gland because of the pancreatic islets.

Functions of the Pancreas

The acinar units that comprise most of the pancreatic tissue secrete pancreatic juice. This digestive juice is made up mostly of water but also contains sodium bicarbonate ($NaHCO_3$) and various digestive enzymes. Hence the exocrine part of the pancreas plays an important part in digestion (Chapter 29).

The endocrine functions of the pancreas were introduced in Chapter 19 (see p. 581) and will be discussed further in subsequent chapters. Recall that *beta cells* of the pancreatic islets secrete **insulin,** a hormone that exerts a major control over carbohydrate metabolism (see Figure 28-29, *B*). *Alpha cells* secrete **glucagon.** It is interesting to note that glucagon, which is produced so close to where insulin is produced, has an opposite effect on carbohydrate metabolism.

| A&P CONNECT |

An abnormal decrease in insulin effects can have dramatic consequence for a person's health. To see a flowchart of how these effects create disease and possibly death, check out ***Diabetes Mellitus*** online at your ***A&P Connect.***

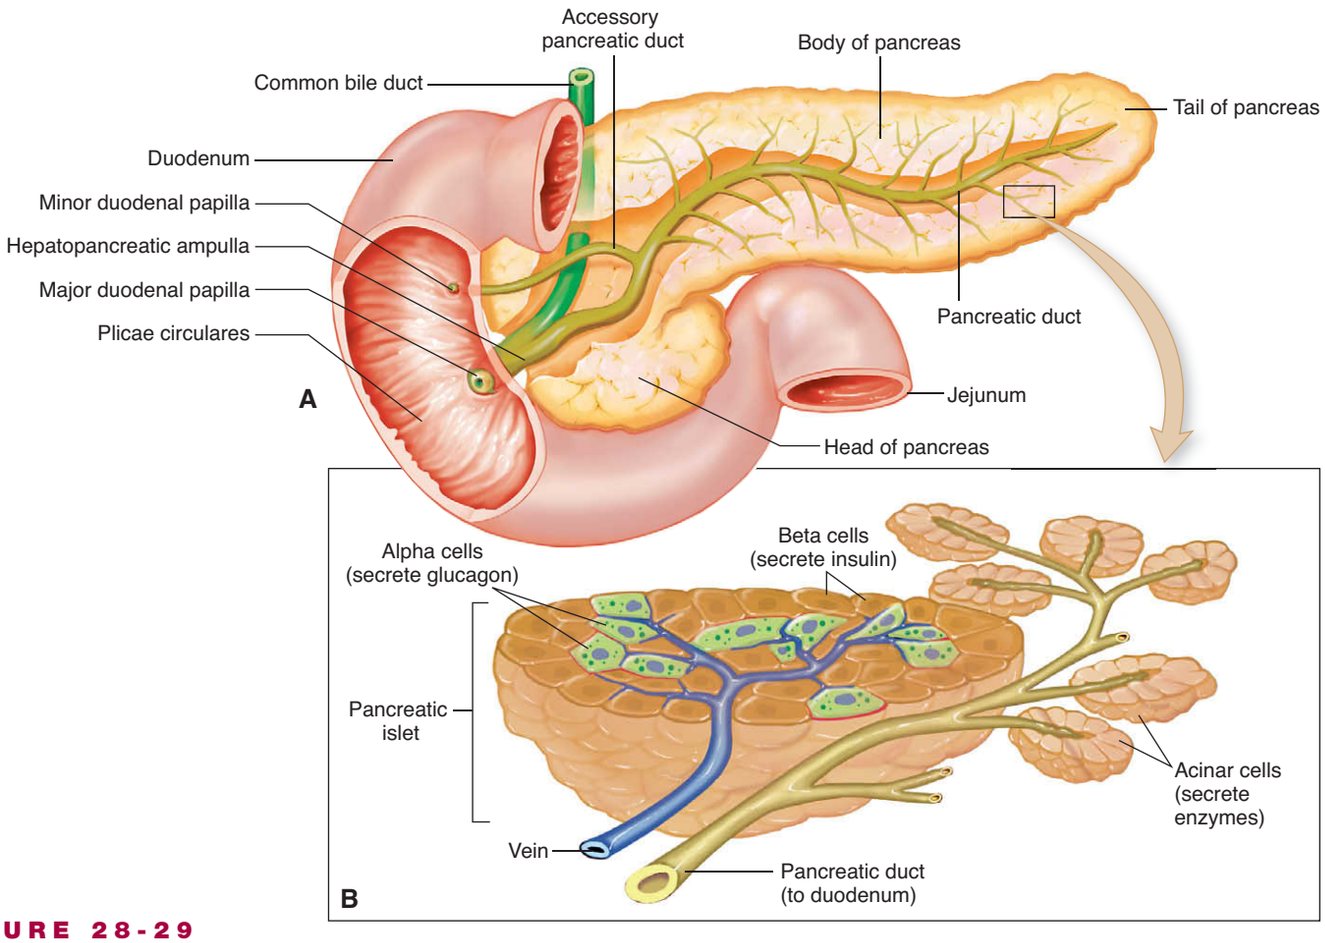

FIGURE 28-29

Pancreas. A, Pancreas dissected to show the main and accessory ducts. The main duct may join the common bile duct, as shown here, to enter the duodenum by a single opening at the major duodenal papilla (see Figure 28-27), or the two ducts may have separate openings. The accessory pancreatic duct is usually present and has a separate opening into the duodenum. **B,** Exocrine glandular cells (around small pancreatic ducts) and endocrine glandular cells of the pancreatic islets (adjacent to blood capillaries). Exocrine pancreatic cells secrete pancreatic juice, alpha endocrine cells secrete glucagon, and beta cells secrete insulin.

20. Trace the route of bile from the gallbladder to the duodenum.
21. What is the function of the acinar units of the pancreas?

Cycle of LIFE

Digestive System

Significant changes in both the structure and function of the digestive system can occur at different times in the human life cycle. Such changes result in numerous diseases or pathological conditions and may occur in any segment of the intestinal tract from the mouth to the anus. In addition, life cycle changes also involve the accessory organs of digestion, such as the teeth, salivary glands, liver, gallbladder, and pancreas.

Because of the immaturity of intestinal mucosa in young infants, some types of intact proteins can pass through the epithelial cells that line the tract. The result may be an early allergic response caused by the protein triggering the baby's immune system. Lactose intolerance is another age-related example of a common digestive system problem. Intestinal lactase, needed for the digestion of lactose, or milk sugar, is almost always present at the time of birth. Levels may rapidly diminish in some babies, however, and such individuals soon become unable to digest lactose.

Inflammation of the parotid salivary gland (mumps) is a common disease of children, whereas appendicitis occurs more frequently in adolescents. The incidence of appendicitis then decreases with age because the size of the opening between the appendix and the intestinal lumen decreases. Gallbladder disease and ulcers are primarily problems of middle age. In more elderly individuals, a decrease in volume of digestive fluids coupled with a slowing of peristalsis and reduced physical activity often results in constipation and diverticulosis.

the BIG picture

Anatomy of the Digestive System

The process of digestion, which is discussed in the next chapter, is structure dependent. It is the normal interrelationships of the anatomical components of the digestive system coupled with the functioning of other body organ systems that permit the highly regulated processes that result in digestion and absorption of nutrients. For example, breaking down of food involves not only the grinding action of the teeth but also the mechanical mixing of food as it passes through the GI tract. Nervous involvement in this process requires the conscious control of mastication and the parasympathetic regulation of smooth muscle contraction mediated through the intramural plexus. Furthermore, the structural adaptations of the GI tract that increase the surface area for better absorption (rugae, villi, brush borders) increase overall digestive efficiency. Involvement of the nervous, endocrine, circulatory, and muscular systems is obvious. Fluid balance, maintenance of core body temperature, numerous circadian rhythms, and regulation of pH, metabolic rates, and blood nutrient concentrations are less obvious, but nonetheless critically important components of the big picture as it relates to the anatomy of the digestive system.

MECHANISMS of DISEASE

DISORDERS OF THE DIGESTIVE SYSTEM

Disorders of the digestive system are described here rather than at the end of Chapter 29 because they will help you both apply the concepts of this chapter and prepare you for the concepts of the next chapter.

Disorders of the Mouth and Esophagus

Infections, cancer, congenital defects, and other disorders of the mouth and teeth can result in a variety of serious complications. Such conditions may cause pain or damage to the mouth and teeth that makes chewing and swallowing difficult. Mouth infections or cancer may also spread to nearby tissues: the nasal cavity (then on to the sinuses, middle ear, and brain) or pharynx (and on to the esophagus, larynx, and thoracic and other body organs).

Diseases of the salivary glands, including problems that affect their sympathetic and parasympathetic innervation, may alter both the chemical composition and the amount of saliva produced, about 1 liter per day on average. Inadequate saliva inhibits proper mixing and mastication of food, decreases production of salivary amylase (ptyalin) that initiates digestion in the mouth, and causes an imbalance in salivary pH (normally about 7.4).

Sjögren Syndrome

Sjögren syndrome is an autoimmune disease in which the body's immune system targets the salivary and tear glands for destruction. One to two million persons in the U.S. are affected. The condition results in a dramatic reduction in both the production of saliva, causing dry mouth (**xerostomia**), and tears, which produces dry eyes (**xerophthalmia**). Symptoms of dry mouth and dry eyes, which cause a feeling of irritation and grittiness, becomes progressively worse over time. The syndrome affects many more women than men and usually begins around age 50. Among other symptoms, the lack of saliva makes chewing and swallowing difficult and contributes to a higher incidence of tooth decay. Drugs used to treat the altered immune response and stimulate saliva production such as cyclosporine (Restasis) and the use of artificial tears and saliva help people with Sjögren syndrome cope with symptoms.

Mumps

Mumps is an acute viral disease characterized by swelling and inflammation of the parotid gland *(parotitis)*. Both parotid glands are involved in about 70% of individuals with mumps. It is caused by a paramyxovirus. Initial symptoms include fever, loss of appetite, and a generalized feeling of weakness and discomfort. Within a few hours, swelling of the parotid gland and spasm of the jaw muscles cause pain when the mouth is opened or during chewing movements. As swelling of the parotid gland becomes more pronounced, it extends over the ramus and fills the hollow behind the angle of the mandible to produce the classic "puffy" facial appearance of mumps (Figure 28-30). Another helpful diagnostic sign is redness of the parotid papilla on the inside of the cheek opposite the second molar tooth on one or both sides of the upper jaw.

Most of us think of mumps as a childhood disease because it most often affects children between the ages of 5 and 15 years. However, it can occur in adults—often producing a more severe infection. The mumps infection can affect other tissues in addition to the parotid gland, including the joints, pancreas, myocardium, and kidneys. In about 25% of infected men, mumps causes inflammation of the testes, or **orchitis.** Of the 25% of men in whom mumps-related orchitis develops, only about half experience atrophy of testicular tissue. Furthermore, since the problem is usually unilateral and involves only one testis, sterility rarely results, although some reduction in fertility may occur.

FIGURE 28-30

Mumps. This young boy with mumps has unilateral parotid swelling on the right side.

Tooth Decay

Tooth decay, or dental **caries** (KAIR-ees), is a common disease throughout the world. It is a disease of the enamel, dentin, and cementum of teeth that results in the formation of a permanent defect called a *cavity*. Most people living in the United States, Canada, and Europe are significantly affected by the disease.

Decay refers to demineralization of the hard tissues of the tooth caused by acids produced by *Streptococcus mutans* bacteria. These bacteria survive on sugars from food debris that collects around teeth, forming an acid-producing biofilm called *plaque*.

If the disease goes untreated, tooth decay results in infection, loss of teeth, and inflammation of the soft tissues in the mouth. Bacteria may also invade the paranasal sinuses or extend to the surface of the face and neck, causing even more serious complications.

Gingivitis (jin-ji-VYE-tis) is the general term for inflammation or infection of the gums. Most cases of gingivitis result from poor oral hygiene—inadequate brushing and no flossing. Gingivitis may also be a complication of other conditions such as diabetes mellitus, vitamin deficiency, or pregnancy.

Periodontitis (pair-ee-oh-don-TYE-tis) is inflammation of the periodontal membrane, or *periodontal ligament*, that anchors the tooth to the bone of the jaw. Periodontitis is often a complication of advanced or untreated gingivitis and may spread to the surrounding bony tissue. Destruction of periodontal membrane and bone results in loosening and eventually complete loss of teeth. Periodontitis is the leading cause of tooth loss in adults.

Leukoplakia (loo-koh-PLAY-kee-ah) of the mouth is a precancerous change in the mucous membrane characterized by thickened, white, and slightly raised patches of tissue. Leukoplakia often develops in the fold between the "cheek and gum" in users of smokeless tobacco. The condition, called *snuff dipper's pouch*, may lead to tooth and gum disease, as well as oral cancer.

Malocclusion

Malocclusion of the teeth occurs when missing teeth create wide spaces in the dentition, when teeth overlap, or when malposition of one or more teeth prevents correct alignment of the maxillary and mandibular dental arches (Figure 28-31, *A* and *B*). Malocclusion that results in protrusion of the upper front teeth so that they hang over the lower front teeth is called *overbite (A)*, whereas positioning of the lower front teeth outside the upper front teeth is called *underbite (B)*.

Dental malocclusion may cause chronic pain and significant problems in functioning of the temporomandibular joint, contribute to the generation of headaches, or complicate routine mastication of food. Fortunately, even severe malocclusion problems can be corrected by the use of braces and other dental appliances. **Orthodontics** (or-thoh-DON-tiks) is the branch of dentistry that deals with the prevention and correction of positioning irregularities of the teeth and malocclusion.

FIGURE 28-31

Malocclusion. A, Overbite. **B,** Underbite.

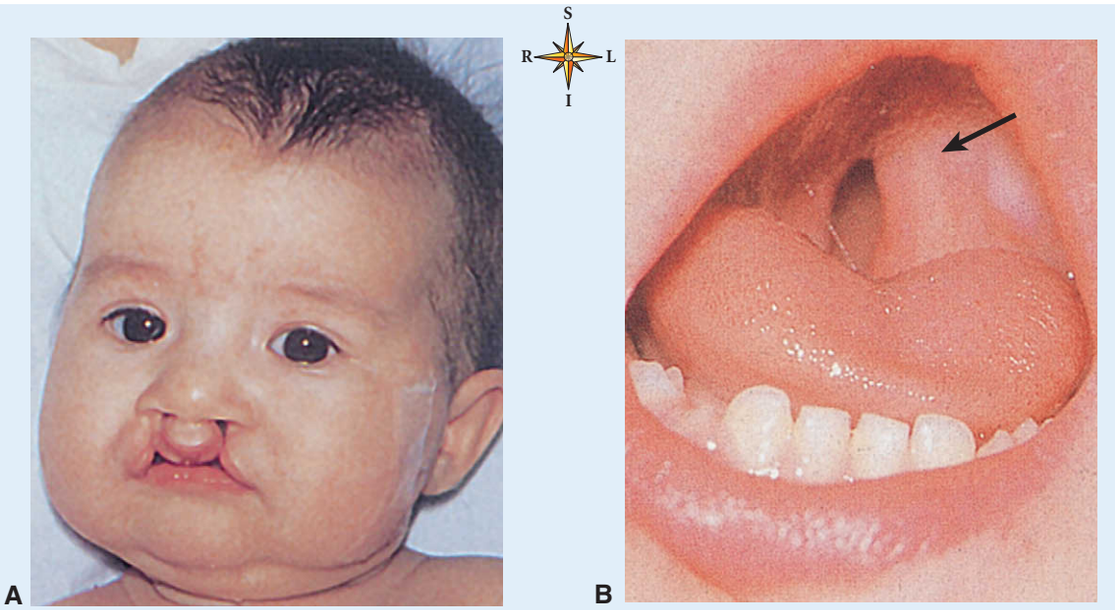

FIGURE 28-32

Congenital defects of the mouth. A, Bilateral cleft lip in an infant. **B,** Cleft palate (*arrow*). Modern reconstructive surgery techniques are extremely effective in minimizing the cosmetic, anatomical, and functional problems associated with these defects.

Cleft lip and *cleft palate* (Figure 28-32) are the most common *congenital defects* affecting the mouth. They may occur alone or together and are caused by failure of structures in the upper lip or palate to fuse or close properly during embryonic development. Cleft lip, which may occur on one or both sides, is typically repaired soon after birth. Surgical repair of cleft palate is usually done later—but generally in the first or second year of life.

Gastroesophageal Reflux Disease (GERD)

The terms *heartburn* or *acid indigestion* are often used to describe a number of unpleasant symptoms experienced by more than 60 million Americans each month. Backward flow of stomach acid up into the esophagus causes these symptoms, which typically include burning and pressure behind the breastbone. The term **gastroesophageal reflux disease (GERD)** is now used to better describe this common and sometimes serious medical condition.

In its simplest form, GERD symptoms are mild and occur only infrequently (twice a week or less). In these cases, avoiding problem foods or beverages, stopping smoking, or losing weight if needed may solve the problem. Additional treatment with over-the-counter antacids or nonprescription-strength acid-blocking medications called H_2-receptor antagonists (famotidine [Pepcid], others) may also be used. More severe and frequent episodes of GERD can trigger asthma attacks, cause severe chest pain, result in bleeding, or promote a narrowing (stricture) or chronic irritation of the esophagus called **erosive esophagitis** (Figure 28-33, *D*). In these cases, more powerful inhibitors of stomach acid production called *proton pump inhibitors* (esomeprazole [Nexium], others) may be added to the treatment prescribed. Drugs called *promotility agents*, which strengthen the lower esophageal sphincter and thus reduce backflow of stomach acid, are also used in moderate to severe cases of GERD.

Two minimally invasive procedures for treating serious cases of GERD are now available (Figure 28-33, *B* and *C*). One, called the *Stretta procedure*, uses radiofrequency energy emitted by a special electrode to produce small burns that tighten the muscular wall of the lower esophageal sphincter and reduce acid reflux from the stomach. The other procedure, called the *Bard endoscopic suturing system*, uses a miniature sewing machine–like device to place two or more stitches in the muscular wall of the lower esophageal sphincter, which are then pulled together to narrow the lumen. In both procedures, which are done on an outpatient basis, a flexible tube called an **esophageal endoscope** is used to insert and then remove the necessary electrode or suturing device required for treatment. As a last resort, a surgical procedure called *fundoplication* is performed to strengthen the sphincter. The procedure involves wrapping a layer of the upper stomach wall around the sphincter and terminal esophagus to lessen the possibility of acid reflux. If GERD is left untreated, serious pathological (precancerous) changes in the esophageal lining may develop—a condition called *Barrett esophagus*.

Gastroesophageal reflux disease (GERD). **A,** Reflux of gastric acid up into the esophagus through the lower esophageal sphincter. **B,** Stretta procedure. **C,** Bard endoscopic suturing system. **D,** Endoscopic view of esophageal inflammation *(esophagitis)* caused by "splashing back" of acids from the stomach in a patient with GERD.

Disorders of the GI Tract

Gastroenterology (gas-troh-en-ter-AHL-oh-jee) is the study of the stomach *(gastro-)* and intestines *(entero-)* and their diseases. The gastrointestinal tract is the potential site of numerous diseases and conditions, some of which are briefly described in this section. Many of these disorders, particularly those that primarily affect the stomach or duodenum, are characterized by one or more of the following signs and symptoms:

Gastroenteritis — stomach inflammation (gastritis) and intestinal inflammation (enteritis)

Anorexia — chronic loss of appetite

Nausea — unpleasant feeling that often leads to vomiting

Emesis — vomiting (Figure 28-34)

Diarrhea — elimination of liquid feces, perhaps accompanied by abdominal cramps

Constipation — decreased motility of colon, resulting in difficulty in defecation

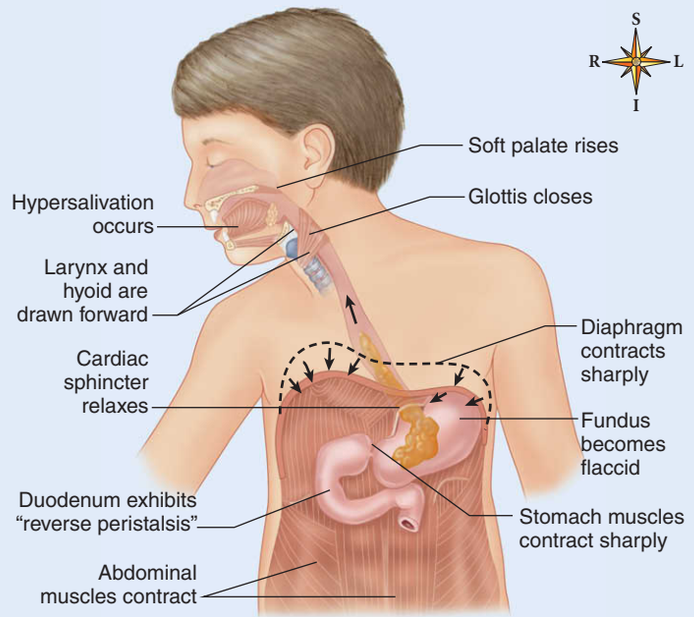

FIGURE 28-34

Emesis (vomiting). Summary of components of the vomiting reflex.

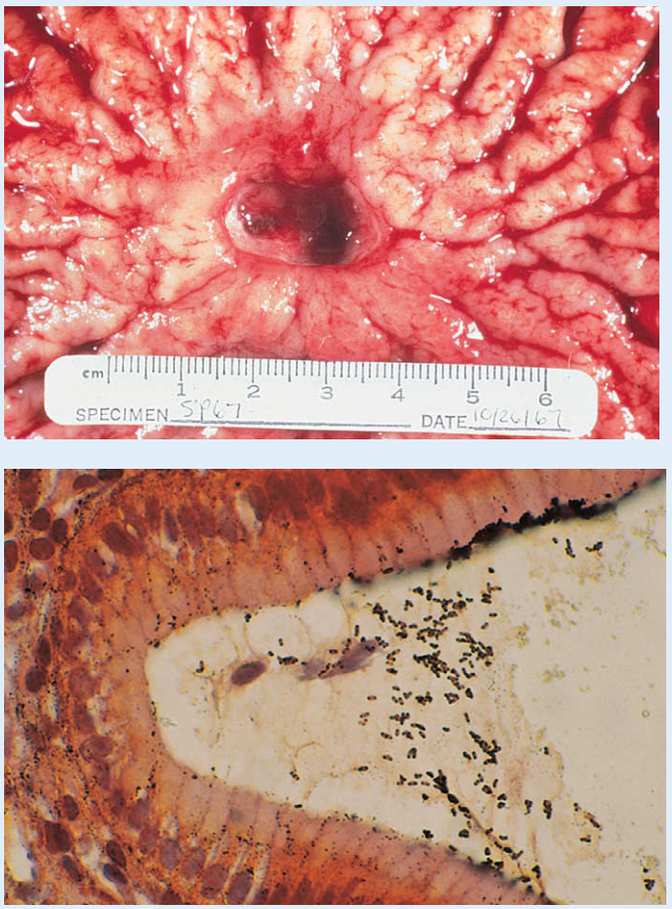

FIGURE 28-35

Ulcer. A, Gastric ulcer (actual size). **B,** Micrograph of *H. pylori (black particles)* infecting the stomach mucosa *(pink)*.

An **ulcer** is a craterlike wound or sore in a membrane caused by tissue destruction (Figure 28-35). Current statistics show that about 1 in 10 individuals in the United States will suffer from either a gastric (stomach) or duodenal ulcer in his or her lifetime. Ulcers cause disintegration, loss, and death of tissue as they erode the layers of the wall of the stomach or duodenum. These crater-like lesions cause gnawing or burning pain and may ultimately result in hemorrhage, perforation, widespread inflammation, scarring, and other very serious medical complications. Usually, perforation does not occur, but small, repeated hemorrhages over long periods can cause anemia.

Two Australian scientists, Dr. Barry Marshall (a microbiologist) and Dr. J. Robin Warren (a pathologist) were awarded the 2005 Nobel Prize in Physiology or Medicine for ulcer research. In 1979 they discovered that infection with a spiral-shaped bacterium called *Helicobacter pylori (H. pylori)*—and not excessive acid secretion—was the primary cause of most ulcers. The two scientists were quick to report the relationship they observed between inflammation, lack of protective mucus, and tissue erosion around areas of bacterial colonization by *H. pylori* in tissue biopsies obtained from many ulcer patients. However, many in the medical community were initially slow to accept their research results linking *H. pylori* to ulcer development as valid. At the time, it was difficult for many clinicians to accept that ulcers were caused by a bacterium and were, therefore, more like an infectious disease than an illness caused by excess acid. Initial skepticism decreased when Marshall publicly swallowed a culture of *H. pylori* and then developed a severe case of gastritis that was successfully treated with antibiotics!

Marshall and Warren not only identified a bacterium as the cause of ulcers, their work also suggested that the time-honored and traditional use of antacid treatment for ulcers be abandoned and replaced by antibiotic therapy. In awarding the Nobel, the committee described the research of Marshall and Warren as producing "one of the most radical and important changes in the last 50 years in the perception of a medical condition." What was once considered a radical new explanation for the cause of ulcers is now a proven fact. And, antibiotic treatment is now an important part of the accepted standard of care for most ulcer patients. *H. pylori* infection in ulcer patients can be diagnosed by biopsy, breath, or blood antibody tests.

Long-term use of certain pain medications such as aspirin and ibuprofen, called *nonsteroidal antiinflammatory drugs (NSAIDs)*, can also cause ulcers. These drugs interfere with prostaglandins that regulate the mucus lining of the GI tract. NSAID-induced ulcers can be treated by stopping NSAID use and taking acid-reducing drugs until the ulcer heals.

Stomach cancer (Figure 28-36) has been linked to *H. pylori* infection, excessive alcohol consumption, use of chewing tobacco, and eating smoked or heavily preserved food. Most stomach cancers, usually *adenocarcinomas*, have already metastasized before they are found because patients treat themselves for the early warning signs of heartburn, belching, and nausea. Later warning signs of stomach cancer include chronic indigestion, vomiting, anorexia, stomach pain, and blood in the feces. Surgical removal of the malignant tumors has been the most successful method of treating stomach cancer.

The pyloric sphincter is of clinical importance because **pylorospasm** is a fairly common condition in infants. The pyloric fibers do not relax normally to allow food to leave the stomach, and

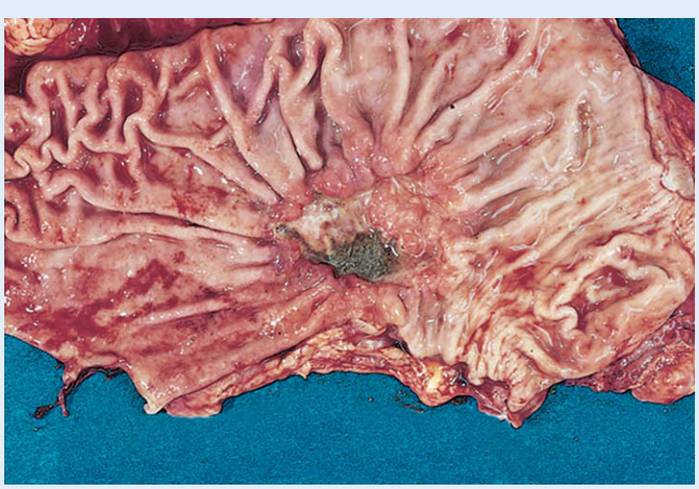

FIGURE 28-36

Stomach cancer. The abnormal tissue near the center of this opened stomach is gastric carcinoma, or "stomach cancer." Note the distinct, normal rugae (folds) that surround the tumor tissue.

consequently, the infant vomits food instead of digesting and absorbing it. The condition is relieved by the administration of a drug that relaxes smooth muscles. Another abnormality of the pyloric sphincter is **pyloric stenosis,** an obstructive narrowing of its opening.

Malabsorption syndrome is a general term referring to a group of symptoms resulting from the failure of the small intestine to absorb nutrients properly. These symptoms include anorexia, abdominal bloating, cramps, anemia, and fatigue. Numerous underlying conditions can cause malabsorption syndrome. For example, certain enzyme deficiencies can result in an absorption failure because there are no digested nutrients to absorb. Cystic fibrosis and other genetic conditions can also cause malabsorption syndrome.

Diverticulosis is the presence of abnormal saclike outpouchings of the intestinal wall called *diverticula* (Figure 28-37). Diverticula often develop in adults older than 50 years who eat low-fiber foods. Diverticulosis is usually asymptomatic. If the diverticula become inflamed, however, the condition is called **diverticulitis.** Diverticulitis is characterized by pain, tenderness, and fever.

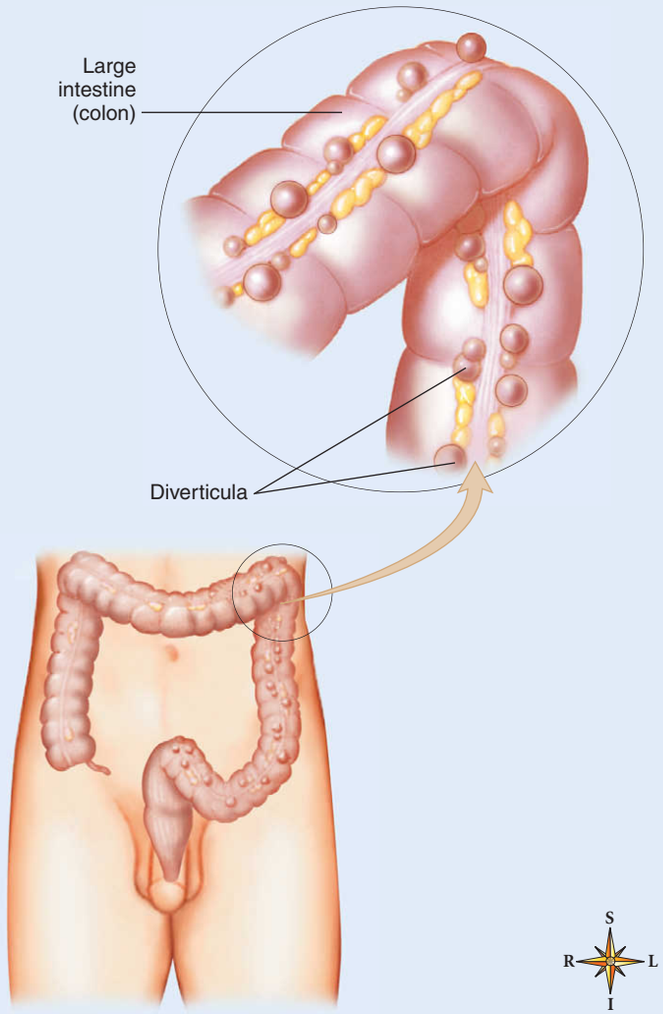

FIGURE 28-37

Diverticula. Abnormal outpouchings of the colon are called *diverticula.* When they become inflamed, the condition is called *diverticulitis.* Diverticula occur mainly in the descending colon and only very rarely in the transverse colon.

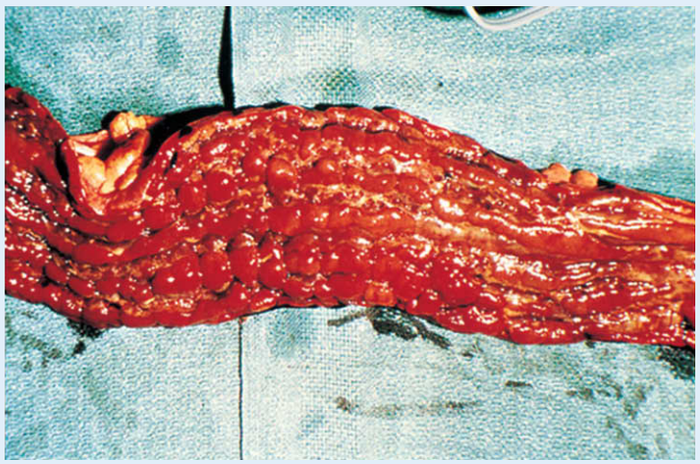

FIGURE 28-38

Crohn disease. Crohn disease, an autoimmune form of colitis, is characterized by severe inflammation that gives a sort of "cobblestone" appearance to the intestinal lining.

Colitis refers to any inflammatory condition of the large intestine. Symptoms of colitis include diarrhea and abdominal cramps or constipation. Some forms of colitis may also produce bleeding and intestinal ulcers. It may also result from an autoimmune disease, as in *ulcerative colitis.* Another type of colitis can occur in those with **Crohn disease.** Crohn disease results from an abnormal inflammatory response. Although it can occur in any part of the alimentary canal, it most often affects the small intestine and the colon (Figure 28-38). If more conservative treatments fail, colitis may be corrected by surgical removal of the affected portions of the colon.

Irritable bowel syndrome, or *spastic colon,* is a common chronic noninflammatory condition that is often caused by stress. Irritable bowel syndrome is characterized by diarrhea or constipation with or without pain.

Colorectal cancer is a malignancy, usually an *adenocarcinoma,* of the colon or rectum. Colorectal cancer occurs most often after the age of 50, and a low-fiber, high-fat diet and genetic predisposition are known risk factors. Early warning signs of this common type of cancer include changes in bowel habits, fecal blood, rectal bleeding, abdominal pain, unexplained anemia or weight loss, and fatigue. Screening for colorectal cancer may be done by checking for occult (hidden) blood in the feces or by examining the rectum and colon with a flexible scope during a *colonoscopy.*

If the mucous lining of the appendix becomes inflamed, the resulting condition is the well-known affliction **appendicitis.** As you can see in Figure 28-19, the appendix is very close to the rectal wall. For patients with suspected appendicitis, a physician often evaluates the appendix by performing a digital rectal examination.

The opening between the lumen of the appendix and the cecum is quite large in children and young adults—a fact of clinical significance because food, fecal material, or calcified, stonelike concrections called *appendicoliths* (ah-pen-DIK-oh-liths) may become trapped in the opening, block the lumen, and cause irritation and inflammation resulting in appendicitis. If calcification within the appendix is visible on an x ray in a patient with pain in the lower

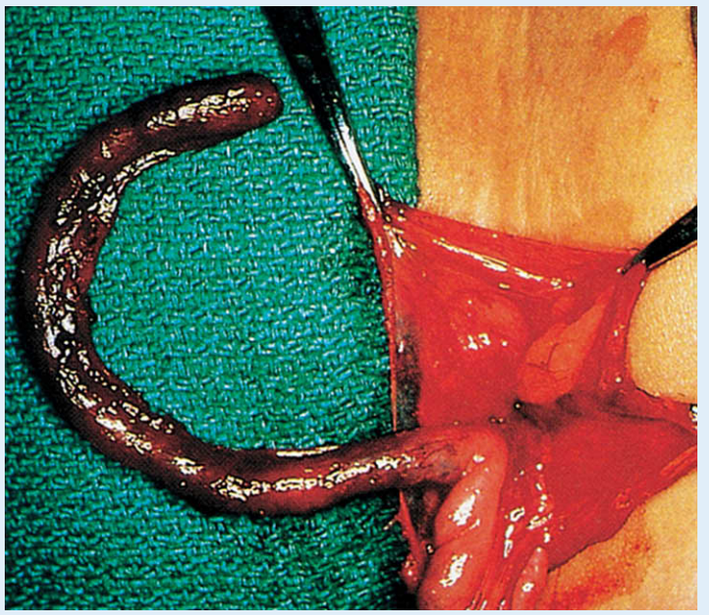

FIGURE 28-39

Acute appendicitis. Note the inflamed tissue surrounding the base of a gangrenous appendix.

right abdominal quadrant, there is an extremely high probability—physicians call it "clinical suspicion"—of acute appendicitis.

The opening between the appendix and the cecum is often completely obliterated in elderly persons, which explains the low incidence of appendicitis in this population.

If infectious material becomes trapped in an inflamed appendix (Figure 28-39), the appendix may rupture and release the material into the abdominal cavity. Infection of the peritoneum and other abdominal organs may result—with sometimes tragic consequences.

Rectal bleeding is a symptom that should always be investigated. Although it may signal a serious disease problem, such as cancer, most instances of this common problem are indicators of less serious and non–life-threatening conditions (Figure 28-40).

Hemorrhoids are dilated veins that result from direct irritation or from increases in venous pressure that often accompany pregnancy or result from constipation and the subsequent straining required to pass compact and hardened stools. Hemorrhoids most commonly develop near the anal opening or on the wall of the anal canal. Though often painful and irritating, hemorrhoids generally respond readily to treatment and are seldom a serious health concern.

Proctitis, or inflammation of the rectal mucosa, is another frequent cause of rectal bleeding and related symptoms such as mucus discharge or increased frequency of bowel movements. The condition may result from direct irritation or infection. In most cases, proctitis responds quickly to the administration of antiinflammatory drugs and treatment of the underlying problem.

Anal fissures are generally minor lacerations in the lining of the anus or anal canal that result in rectal bleeding. They are caused by direct irritation—often the result of passing a hardened stool. An **anal fistula** is a more serious problem that may require surgical repair. A fistula is a passageway that often develops between the rectal wall and the skin surrounding the anus. Fistulas occur in Crohn disease, an inflammatory bowel disease.

Disorders of the Liver and Pancreas

Hepatitis is a general term referring to inflammation of the liver. Hepatitis is characterized by jaundice (yellowish discoloration of body tissues), liver enlargement, anorexia, abdominal discomfort, gray-white feces, and dark urine. Various conditions can produce hepatitis. Alcohol, drugs, or other toxins may cause hepatitis. It may also be a complication of bacterial or viral infection or parasite infestation. *Hepatitis A,* for example, results from infection by the hepatitis A virus. Contaminated food is often a source of infection. Hepatitis A occurs commonly in young people and ranges in severity from mild to life threatening. Another viral hepatitis, *hepatitis B,* is usually more severe. It is also called *serum hepatitis* because it is often transmitted by contaminated blood serum (plasma). The *hepatitis C virus (HCV),* causes a viral form of hepatitis that can also be transmitted by contaminated blood. Although *hepatitis C* does not always produce symptoms or liver disease, it can in many individuals lead to various liver disorders. Other viral forms of hepatitis include the D, E, and G types.

Hepatitis, chronic alcohol abuse, malnutrition, infection, or *nonalcoholic fatty liver disease* may lead to a degenerative liver condition known as **cirrhosis.** The liver's ability to regenerate damaged tissue is well known, but it has its limits. For example, when the toxic effects of alcohol accumulate faster than the liver can regenerate itself, damaged tissue is replaced with fibrous scar tissue instead of normal tissue (Figure 28-41). *Cirrhosis* is the name given to such degeneration.

Besides the endocrine disorders such as diabetes mellitus discussed in Chapter 19, the pancreas may be involved in numerous other diseases. For example, **pancreatitis,** or inflammation of the

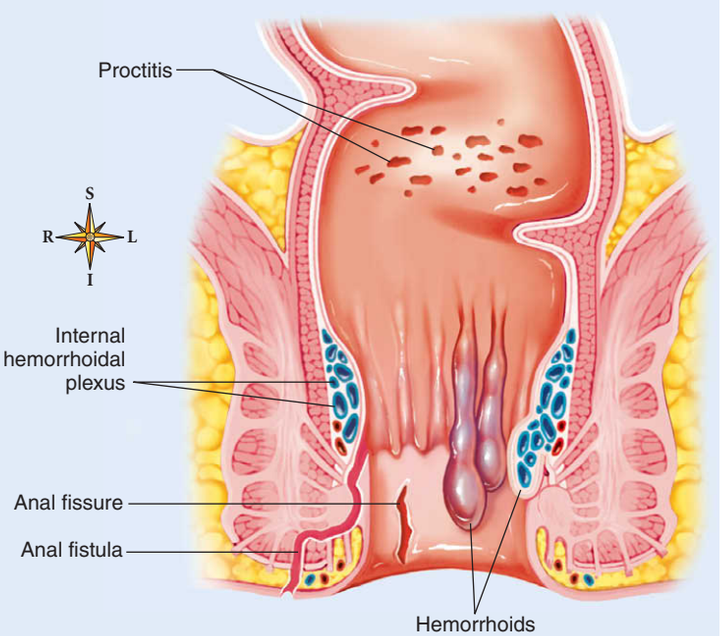

FIGURE 28-40

Causes of rectal bleeding.

pancreas, can be caused by various factors. *Acute pancreatitis* usually results from blockage of the pancreatic duct. The blockage causes pancreatic enzymes to "back up" into the pancreas and digest it. Another condition that blocks the flow of pancreatic enzymes is *cystic fibrosis (CF)*. You may recall from Chapter 4 that this inherited disorder disrupts cell transport and causes exocrine glands to produce excessively thick secretions. Thick pancreatic secretions may build up and block pancreatic ducts, disrupting the flow of pancreatic enzymes and damaging the pancreas.

Another serious pancreatic disorder is **pancreatic cancer.** Usually a form of *adenocarcinoma*, pancreatic cancer claims the lives of nearly all its victims within 5 years after diagnosis.

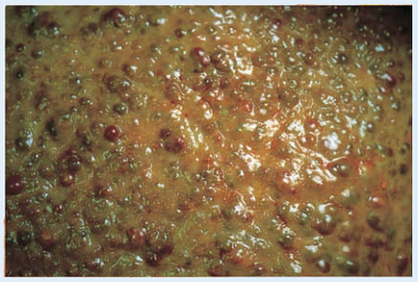

FIGURE 28-41

Cirrhosis. Alcoholic cirrhosis is characterized by hardness of the liver caused by fibrous tissue and by nodules—which can be seen clearly in this photograph of the surface of a cirrhotic liver.

colorectal cancer
(koh-loh-REK-tal KAN-ser)
[*colo-* **colon,** *-rect-* **straight,** *-al* **relating to,** *cancer* **crab or malignant tumor**]

constipation
(kon-sti-PAY-shun)
[*constipa-* **crowd together,** *-ation* **process**]

Crohn disease
(krohn)
[*Burrill B. Crohn* **American physician**]

diarrhea
(dye-ah-REE-ah)
[*dia-* **through,** *-rrhea* **flow**]

diverticulitis
(dye-ver-tik-yoo-LYE-tis)
[*diverticul-* **turn aside,** *-itis* **inflammation**]

diverticulosis
(dye-ver-tik-yoo-LOH-sis)
[*diverticul-* **turn aside,** *-osis* **condition**]

emesis
(EM-eh-sis)
[*emesis* **vomiting**]

erosive esophagitis
(eh-ROH-siv eh-SOF-ah-jye-tis)
[*es-* **will carry,** *-phag-* **food (eat),** *-itis* **inflammation**]

esophageal endoscope
(eh-sof-ah-JEE-ul EN-doh-skohp)
[*es-* **will carry,** *-phag-* **food (eat),** *-al* **relating to,** *endo-* **within,** *-scop-* **see**]

gastroenteritis
(gas-troh-en-ter-EYE-tis)
[*gastr-* **stomach,** *-enter-* **intestine,** *-itis* **inflammation**]

gastroenterology
(gas-troh-en-ter-AHL-oh-jee)
[*gastr-* **stomach,** *-entero-* **intestine,** *-o-* **combining form,** *-log-* **words (study of),** *-y* **activity**]

gastroesophageal reflux disease (GERD)
(gas-troh-eh-sof-eh-JEE-all REE-fluks)
[*gastro-* **stomach,** *-es-* **will carry,** *-phag-* **food (eat),** *-al* **relating to,** *re-* **again or back,** *-flux* **flow**]

gingivitis
(jin-ji-VYE-tis)
[*gingiv-* **gum,** *-itis* **inflammation**]

hemorrhoid
(HEM-eh-royd)
[*hemo-* **blood,** *- rrhoi-* **flow**]

hepatitis
(hep-ah-TYE-tis)
[*hepat-* **liver,** *-itis* **inflammation**]

hiatal hernia
(hye-AY-tal HER-nee-ah)
[*hiat-* **gap,** *-al* **relating to,** *hernia* **rupture**] *pl.,* herniae or hernias

irritable bowel syndrome
(IR-i-tah-bul BOW-uhl SIN-drohm)
[*irrita-* **tease,** *-ble* **able or tending to,** *bowel* **sausage,** *syn-* **together,** *-drome* **running or (race)course**]

jaundice
(JAWN-dis)
[*jaun-* **yellow,** *-ice* **state**]

leukoplakia
(loo-koh-PLAY-kee-ah)
[*leuko-* **white,** *-plak-* **flat area,** *-ia* **condition**]

malabsorption syndrome
(mal-ab-SORP-shun SIN-drohm)
[*mal-* **bad,** *-absorp-* **swallow,** *-tion* **process,** *syn-* **together,** *-drome* **running or (race)course**]

malocclusion
(mal-oh-CLEW-zhun)
[*mal-* **bad,** *-occlu-* **close up,** *-sion* **state**]

mumps
[*mumps* **grimace**]

nausea
(NAW-zee-ah)
[*nausea* **seasickness**]

orchitis
(or-KYE-tis)
[*orchi-* **testis,** *-itis* **inflammation**]

orthodontics
(or-thoh-DON-tiks)
[*ortho-* **straight or upright,** *-odont-* **tooth,** *-ic* **relating to**]

pancreatic cancer
(pan-kree-AT-ik KAN-ser)
[*pan-* **all,** *-creat-* **flesh,** *-ic* **relating to,** *cancer* **crab or malignant tumor**]

pancreatitis
(pan-kree-ah-TYE-tis)
[*pan-* **all,** *-creat-* **flesh,** *-itis* **inflammation**]

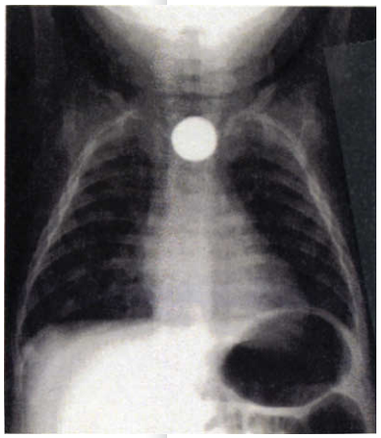
parotitis
(pair-oh-TYE-tis)
[*par-* **beside,** *-ot-* **ear (parotid salivary gland),** *-itis* **inflammation**]

periodontitis
(pair-ee-oh-don-TYE-tis)
[*peri-* **around,** *-odont-* **tooth,** *-itis* **inflammation**]

proctitis
(prok-TYE-tis)
[*proct-* **anus,** *-itis* **inflammation**]

pyloric stenosis
(pye-LOR-ik steh-NO-sis)
[*pyl-* **gate,** *-or-* **guard,** *-ic* **relating to,** *stenos-* **narrow,** *-osis* **condition**]
pl., stenoses

pylorospasm
(pye-LOHR-oh-spaz-um)
[*pyl-* **gate,** *-or-* **guard,** *-spasm* **twitch or involuntary contraction**]



Sjögren syndrome
(SHOW-grin SIN-drohm)
[*Henrik S.C. Sjögren* **Swedish ophthalmologist,** *syn-* **together,** *-drome* **running or (race)course**]

ulcer
(UL-ser)
[*ulc-* **sore**]

xerophthalmia
(zee-rof-THAL-mee-ah)
[*xero-* **dryness,** *-opth-* **eye,** *-thalm-* **inner chamber,** *-ia* **condition**]

xerostomia
(zee-roh-STOH-mee-ah)
[*xero-* **dryness,** *-stom-* **mouth,** *-ia* **condition**]

CASE study

It only took 3 seconds. Sangetha turned away from her sewing basket to pick up her cell phone. When she looked back, she saw a handful of buttons disappear into her 24-month-old daughter's mouth. She quickly dropped down and removed the buttons from her daughter Jinder's mouth—but Sangetha had no way of knowing how many had gone in. Had any already gone down Jinder's throat? She was coughing slightly and drooling. Sangetha immediately took Jinder to the emergency department, thankfully a very short drive away, where they took x rays of Jinder's neck and chest. On the x ray film, they found one button in Jinder's upper esophagus.

1. With what layer of the esophageal lining would the button be in contact?
- a. Serosa
- b. Muscularis
- c. Submucosa
- d. Mucosa

Because the button was rounded, with no sharp points, the decision was made to let it "pass" through Jinder's system naturally.

2. As the button makes its way through Jinder's alimentary tract, it will go through which sequence of sphincters and valves?
- a. Lower esophageal, pyloric, ileocecal, anal
- b. Anal, pyloric, lower esophageal, ileocecal
- c. Lower esophageal, ileocecal, pyloric, anal
- d. Pyloric, ileocecal, anal, lower esophageal

3. Imagine a camera is attached to the button. As the button travels through Jinder's small intestines, the viewing monitor shows many tiny projections that look like gently moving brush bristles in the lining of the small intestine. What are these projections?
- a. Plicae
- b. Rugae
- c. Villi
- d. Crowns

HINT *To solve a case study, you may have to refer to the glossary or index, other chapters in this textbook,* ***A&P Connect,*** *and other resources.*

CHAPTER SUMMARY

To download an MP3 version of the chapter summary for use with your iPod or portable media player, access the ***Audio Chapter Summaries*** *online at evolve.elsevier.com.*

HINT *Scan this summary after reading the chapter to help you reinforce the key concepts. Later, use the summary as a quick review before your class or before a test.*

ORGANIZATION OF THE DIGESTIVE SYSTEM

A. Organs of digestion (Figure 28-1)
   1. Main organs of the digestive system form the GI tract that extends through the abdominopelvic cavity
   2. Ingested food material passing through the lumen of the GI tract is outside the internal environment of the body

B. Wall of the GI tract (Figure 28-2)
   1. Mucosa—innermost layer
   2. Submucosa—contains numerous glands, blood vessels, and parasympathetic nerves
   3. Muscularis—thick layer of muscle tissue
   4. Serosa—outermost layer
   5. Modifications of layers—structure of layers varies in different regions throughout length of GI tract (Table 28-1)

MOUTH

A. Structure of the oral cavity (buccal cavity) (Figure 28-3)
   1. Lips
      a. Covered externally by skin and internally by mucous membrane
      b. Junction between skin and mucous membrane is highly sensitive
      c. Line of contact between closed lips forms the oral fissure
   2. Cheeks
      a. Lateral boundaries of the oral cavity, continuous with the lips and lined by mucous membrane
      b. Formed in large part by the buccinator muscle covered by adipose tissue
      c. Contain mucus-secreting glands
   3. Hard palate and soft palate
      a. Hard palate consists of portions of four bones: two maxillae and two palatines
      b. Soft palate forms the partition between the mouth and nasopharynx and is made of muscle arranged in an arch
      c. Suspended from the midpoint of the posterior border of the arch is the uvula
   4. Tongue—solid mass of skeletal muscle covered by a mucous membrane; extremely maneuverable
      a. Has three parts: root, tip, and body (Figure 28-4)

b. Papillae located on the dorsal and lateral surfaces of the tongue (Figure 28-5)
c. Lingual frenulum anchors the tongue to the floor of the mouth (Figure 28-6)
d. Intrinsic muscles important for speech and mastication; extrinsic muscles important for deglutition and speech (Figure 28-7)

B. Salivary glands
1. Three main pairs of compound tubuloalveolar glands (Figure 28-8)
a. Secrete approximately 1 liter of saliva each day
b. Additional small buccal glands contribute less than 5% of the total salivary volume but provide for hygiene and comfort of oral tissues
2. Parotid glands—largest of the paired salivary glands; produce watery saliva containing enzymes
3. Submandibular glands—compound glands that contain enzyme- and mucus-producing elements
4. Sublingual glands—smallest of the salivary glands; produce a mucous type of saliva

C. Teeth—organs of mastication
1. Typical tooth (Figure 28-9)
a. Crown—exposed portion of a tooth, covered by enamel; ideally suited to withstand abrasion during mastication
b. Neck—narrow portion that joins the crown to the root; surrounded by gingivae
c. Root—fits into the socket of the alveolar process; suspended by a fibrous periodontal membrane
d. Outer shell contains two additional tissues: dentin and cementum
(1) Dentin—greatest portion of the tooth shell; at the crown, covered by enamel, and at the neck and root, covered by cementum
(2) Pulp cavity—located in dentin, contains connective tissue, blood, and lymphatic vessels and sensory nerves
2. Types of teeth (Figure 28-10)
a. Deciduous teeth—20 baby teeth, which appear early in life
b. Permanent teeth—32 teeth, which replace the deciduous teeth

PHARYNX

A. Tube through which a food bolus passes when moved from the mouth to the esophagus by the process of deglutition
B. Air passes through all three divisions of the pharynx; only terminal portion involved in digestive system

ESOPHAGUS

A. Tube that extends from the pharynx to the stomach; first segment of the digestive tube (Figure 28-11)
B. Lined with stratified squamous epithelium (Figure 28-12)
C. Each end encircled by muscular sphincters

STOMACH

A. Size and position of the stomach
1. Size varies according to factors such as gender and amount of distention
a. When no food is in the stomach, it is about the size of a large sausage
b. In adults, its capacity ranges from 1.0 to 1.5 liters
2. Stomach location: upper part of the abdominal cavity under the liver and diaphragm

B. Divisions of the stomach (Figure 28-13)
1. Cardia—collarlike region at junction with esophagus
2. Fundus—enlarged portion to the left and above the opening of the esophagus into the stomach
3. Body—central portion of the stomach
4. Pylorus—lower part of the stomach

C. Curves of the stomach
1. Lesser curvature—upper right curve of the stomach
2. Greater curvature—lower left curve of the stomach

D. Sphincter muscles—circular fibers arranged so that there is an opening in the center when relaxed and no opening when contracted
1. Lower esophageal sphincter (LES), or cardiac sphincter, controls the opening of the esophagus into the stomach
2. Pyloric sphincter controls the outlet of the pyloric portion of the stomach into the duodenum

E. Stomach wall (Figure 28-14)
1. Gastric mucosa
a. Epithelial lining has rugae marked by gastric pits (Figure 28-15)
b. Gastric glands—found below the level of the pits; secrete most of the gastric juice
c. Chief cells—secretory cells found in the gastric glands; secrete the enzymes of gastric juice
d. Parietal cells—secretory cells found in the gastric glands; secrete hydrochloric acid; thought to produce intrinsic factor needed for vitamin B_{12} absorption
e. Endocrine cells—secrete gastrin and ghrelin
2. Gastric muscularis
a. Thick layer of muscle with three distinct sublayers of smooth muscle tissue arranged in a crisscrossing pattern
b. This pattern allows the stomach to contract strongly at many angles

F. Functions of the stomach
1. Reservoir for food until it is partially digested and moved further along the GI tract
2. Secretes gastric juice to aid in digestion of food
3. Breaks food into small particles and mixes them with gastric juice
4. Secretes intrinsic factor
5. Performs limited absorption
6. Produces gastrin and ghrelin
7. Helps protect the body from pathogenic bacteria swallowed with food

SMALL INTESTINE

A. Size and position of the small intestine
1. Tube approximately 2.5 cm in diameter and 6 m in length
2. Coiled loops fill most of the abdominal cavity (Figure 28-16)

B. Divisions of the small intestine
   1. Duodenum—uppermost division; approximately 25 cm long, shaped roughly like the letter C
   2. Jejunum—approximately 2.5 m long
   3. Ileum—approximately 3.5 m long
C. Wall of the small intestine (Figure 28-17)
   1. Intestinal lining has plicae with villi
   2. Villi—important modifications of the mucosal layer
      a. Each villus contains an arteriole, venule, and lacteal vessel
      b. Covered by a brush border made up of 1700 ultrafine microvilli per cell
      c. Villi and microvilli increase the surface area of the small intestine hundreds of times
   3. Crypts—located between villi; contain stem cells from which other cell types are produced and then migrate upward to cover the villi, where they eventually slough off (Figure 28-18)

LARGE INTESTINE

A. Size of the large intestine
   1. Average diameter, 6 cm
   2. Length, approximately 1.5 to 1.8 m
B. Divisions of the large intestine (Figure 28-19)
   1. Cecum—first 5 to 8 cm of the large intestine; blind pouch located in the lower right quadrant of the abdomen
   2. Colon
      a. Ascending colon—vertical position on the right side of the abdomen; the ileocecal valve prevents material from passing from the large intestine into the ileum
      b. Transverse colon—passes horizontally across the abdomen, above the small intestine; extends from the hepatic flexure to the splenic flexure
      c. Descending colon—vertical position on left side of the abdomen
      d. Sigmoid colon joins the descending colon to the rectum
   3. Rectum
      a. Last 7 or 8 inches of the intestinal tube
      b. Terminal inch is the anal canal with the opening called the *anus* (Figure 28-20)
C. Wall of the large intestine (Figure 28-21)
   1. Intestinal mucous glands produce lubricating mucus that coats feces as they are formed
   2. Uneven distribution of fibers in the muscle coat

VERMIFORM APPENDIX

A. Accessory organ of digestive system
B. 8 to 10 cm in length; communicates with the cecum
C. Serves as reservoir for beneficial gut bacteria

PERITONEUM

A. Large, continuous sheet of serous membrane (Figure 28-22)
   1. Many organs are covered with visceral peritoneum; parietal peritoneum then lines the wall of the abdominopelvic cavity
   2. Extraperitoneal space is outside the parietal layer of the peritoneum; retroperitoneal identifies the extraperitoneal space along the posterior and bottom of the abdominopelvic cavity.
B. Mesentery—projection of the parietal peritoneum; allows free movement of each coil of the intestine and helps prevent strangulation of the long tube (Figure 28-23)
C. Transverse mesocolon—extension of the peritoneum that supports the transverse colon

LIVER

A. Location and size of the liver (Figure 28-24)
   1. Largest gland in the body, weighs approximately 1.5 kg
   2. Lies under the diaphragm; occupies most of the right hypochondrium and part of the epigastrium
B. Liver lobes and lobules—two lobes separated by the falciform ligament
   1. Left lobe—forms about one sixth of the liver
   2. Right lobe—forms about five sixths of the liver; divides into right lobe proper, caudate lobe, and quadrate lobe
   3. Hepatic lobules—anatomical units of the liver; a small branch of the hepatic vein extends through the center of each lobule (Figures 28-25 and 28-26)
C. Bile ducts (Figure 28-27)
   1. Small bile ducts form right and left hepatic ducts
   2. Right and left hepatic ducts immediately join to form one hepatic duct
   3. Hepatic duct merges with the cystic duct to form the common bile duct, which opens into the duodenum
D. Functions of the liver
   1. Detoxification by liver cells—ingested toxic substances and toxic substances formed in the intestines may be changed to nontoxic substances
   2. Bile secretion by liver—bile salts are formed in the liver from cholesterol and are the most essential part of bile; liver cells secrete approximately 1 pint of bile per day
   3. Liver metabolism—carries out numerous important steps in metabolizing proteins, fats, and carbohydrates
   4. Storage of substances such as iron and some vitamins
   5. Production of important plasma proteins

GALLBLADDER

A. Size and location of the gallbladder
   1. Pear-shaped sac 7 to 10 cm long and 3 cm wide at its broadest point
   2. Lies on the undersurface of the liver (Figure 28-27)
B. Structure of the gallbladder
   1. Serous, muscular, and mucous layers compose the gallbladder wall
   2. The mucosal lining has rugae that expand to allow storage of bile; holds 30 to 50 ml of bile
C. Functions of the gallbladder
   1. Storage of bile
   2. Concentration of bile fivefold to tenfold
   3. Ejection of the concentrated bile into the duodenum
D. Gallstones—often made of cholesterol; can form when bile becomes concentrated (Figure 28-28)

PANCREAS

A. Size and location of the pancreas
   1. Grayish pink–colored gland; 12 to 15 cm long; weighs approximately 60 grams
   2. Runs from the duodenum, behind the stomach, to the spleen
B. Structure of the pancreas (Figure 28-29)—composed of endocrine and exocrine glandular tissue
   1. Exocrine portion makes up the majority of the pancreas; has a compound acinar arrangement; tiny ducts unite to form the main pancreatic duct, which empties into the duodenum
   2. Endocrine portion—embedded between exocrine units; called *pancreatic islets*; constitute only 2% of the total mass of the pancreas; made up of alpha cells and beta cells; pass secretions into capillaries
C. Functions of the pancreas
   1. Acinar units secrete digestive enzymes
   2. Beta cells secrete insulin
   3. Alpha cells secrete glucagon

CYCLE OF LIFE: DIGESTIVE SYSTEM

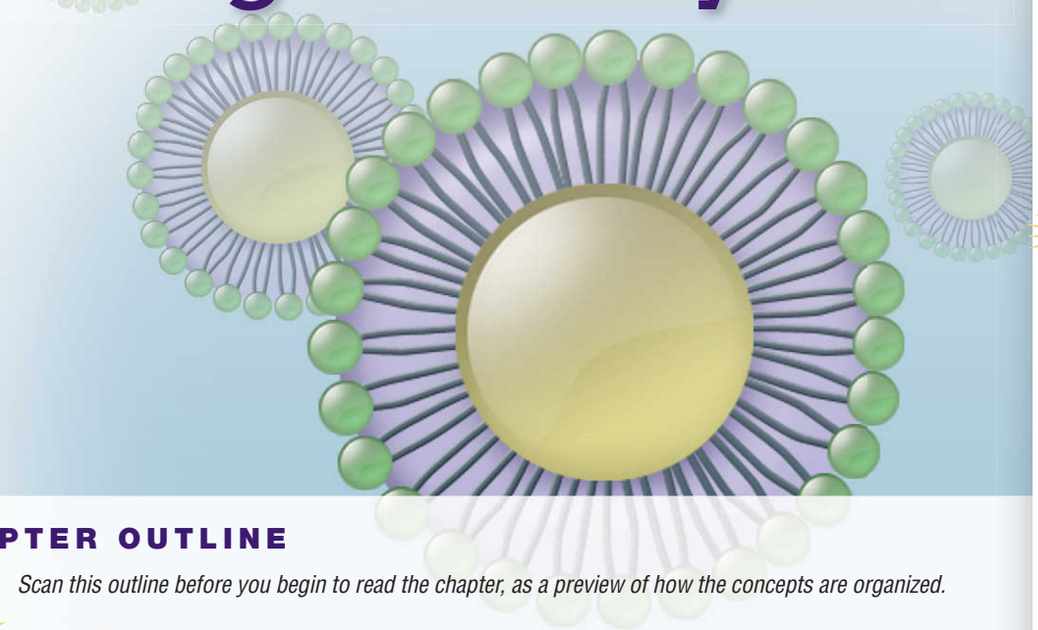
A. Changes in digestive function and structure are age related
   1. Result in diseases or pathological conditions
   2. May occur in any segment of the intestinal tract
   3. Changes involve accessory organs: teeth, salivary glands, liver, gallbladder, and pancreas
B. Infants have immature intestinal mucosa
   1. Intact proteins can pass through epithelial cells lining the tract and trigger an allergic response
   2. Lactose intolerance affects infants who lack the enzyme lactase
C. Mumps common in children; appendicitis more common in adolescents and then incidence decreases with advancing age
E. Ulcers and gallbladder disease common in middle age
F. Decreased digestive fluids, slowing of peristalsis, and reduced physical activity lead to constipation and diverticulosis in the elderly

REVIEW QUESTIONS

Write out the answers to these questions after reading the chapter and reviewing the Chapter Summary. If you simply think through the answer without writing it down, you won't retain much of your new learning.

1. List the component parts or segments of the GI tract and the accessory organs of digestion.
2. Name and describe the four tissue layers that form the wall of GI tract organs.
3. Identify the structures that form the mouth.
4. Define the following terms associated with the mouth and pharynx: *philtrum, oral fissure, hard palate and soft palate, fauces, uvula, foramen cecum, lingual frenulum.*
5. What is ankyloglossia?
6. Identify the types of tongue papillae. What is the relationship between papillae and taste buds?
7. List and give the location of the paired salivary glands. Identify by name the ducts that drain the saliva from these glands into the mouth.
8. What type of saliva is produced by the parotid glands? What is meant by the term *mixed* or *compound salivary gland?*
9. Describe a typical tooth. Name the specific types of teeth.
10. Compare and contrast deciduous and permanent teeth.
11. What is meant by the term *deglutition?*
12. List the divisions of the stomach. What is the difference between gastric pits and gastric glands?
13. Identify the three major cell types of the gastric glands. What cell type produces hydrochloric acid? Gastric enzymes? Gastrin? Ghrelin?
14. Describe the seven functions of the stomach.
15. List the divisions of the small intestine from proximal to distal.
16. In what area of the GI tract do you find villi? Haustra? Taeniae coli?
17. List the divisions of the large intestine.
18. What is believed to be the function of the vermiform appendix?
19. Discuss the peritoneum and its reflections.
20. Discuss the anatomy of a typical liver lobule.
21. Identify the ducts of the liver and gallbladder.
22. Explain the functions of the gallbladder.
23. Differentiate between endocrine and exocrine functions of the pancreas.
24. Identify the condition that can develop in men who are infected with mumps.
25. What is the difference between dental caries and periodontitis?
26. What is pyloric stenosis?
27. Define cholelithiasis.

CRITICAL THINKING QUESTIONS



After finishing the Review Questions, write out the answers to these more in-depth questions to help you apply your new knowledge. Go back to sections of the chapter that relate to concepts that you find difficult.

1. Explain the role of the tongue's intrinsic and extrinsic muscles.
2. Describe the unique muscular layer of the esophagus.
3. Increasing the interior surface area of the small intestine allows it to absorb nutrients more efficiently. What examples can you find that add to the interior surface area of the small intestine?
4. Explain the x ray procedure used to diagnose a hiatal hernia. What procedure would be used to diagnose an intestinal diverticulum?
5. If an elderly patient had abdominal pain, why would it be unlikely that it is caused by appendicitis?

Physiology of the Digestive System

continued on p. 926

Now that we are familiar with the structural organization of the digestive system (Chapter 28), we are ready to understand the physiological organization of this system. The primary function of the digestive system is to bring essential nutrients into the internal environment so that they are available to each cell of the body. This chapter lays out the essential processes of digestion and absorption. Later, in Chapter 30, you will learn about how the body manages the nutrients after they have been absorbed into the internal environment.

OVERVIEW OF DIGESTIVE FUNCTION

To accomplish the function of making nutrients available to each cell of the body, the digestive system uses various mechanisms (Table 29-1). For example, complex foods must first be taken in—a process called **ingestion.** Then, complex nutrients are broken down into simpler nutrients in the process that gives this system its name: **digestion.** To physically break large chunks of food into smaller bits and to move it along the tract, movement (or **motility**) of the gastrointestinal (GI) wall is required. Chemical digestion—that is, breakdown of large molecules into small molecules—requires **secretion** of digestive enzymes into the lumen of the GI tract. After being digested, nutrients are ready for the process of **absorption,** or movement through the GI mucosa into the internal environment. The material that is not absorbed must then be excreted to make room for more material—a process known as **elimination.** Of course, all these activities must be coordinated, which we have already learned is the process of *regulation*. Some of the major digestive processes are summarized in Figure 29-1. Digestive regulation is introduced in Box 29-1.

Note that Figure 29-1 also illustrates that from a functional perspective, the lumen of the alimentary canal is really a tubelike extension of the external environment that goes right through the middle of the body. Thus digested materials are not truly "part of the body" until they've been absorbed into the internal environment.

After we have explored the various mechanisms of the digestive process in this chapter, we will be ready for Chapter 30, which discusses the assimilation of nutrients after they have been absorbed.

TABLE 29-1 Primary Mechanisms of the Digestive System

MECHANISM	DESCRIPTION
Ingestion	Process of taking food into the mouth, starting it on its journey through the digestive tract
Digestion	A group of processes that break complex nutrients into simpler ones, thus facilitating their absorption; mechanical digestion physically breaks large chunks into small bits; chemical digestion breaks molecules apart
Motility	Movement by the muscular components of the digestive tube, including processes of mechanical digestion; examples include peristalsis and segmentation
Secretion	Release of digestive juices (containing enzymes, acids, bases, mucus, bile, or other products that facilitate digestion); some digestive organs also secrete endocrine hormones that regulate digestion or metabolism of nutrients
Absorption	Movement of digested nutrients through the gastrointestinal (GI) mucosa and into the internal environment
Elimination	Excretion of the residues of the digestive process (feces) from the rectum, through the anus; defecation
Regulation	Coordination of digestive activity (motility, secretion, etc.)

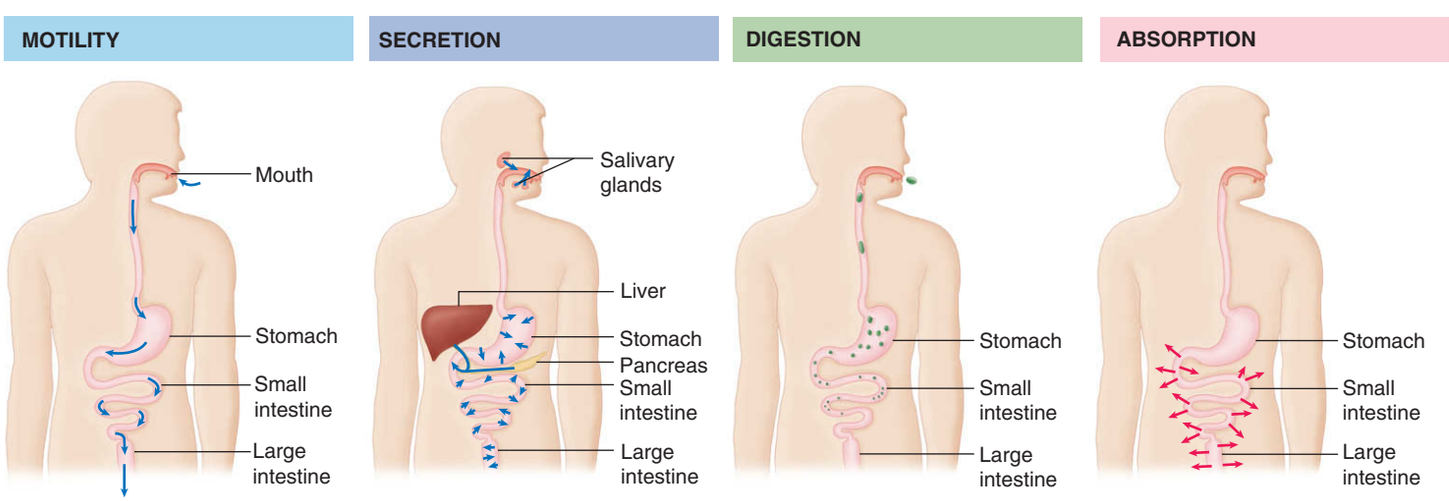

FIGURE 29-1

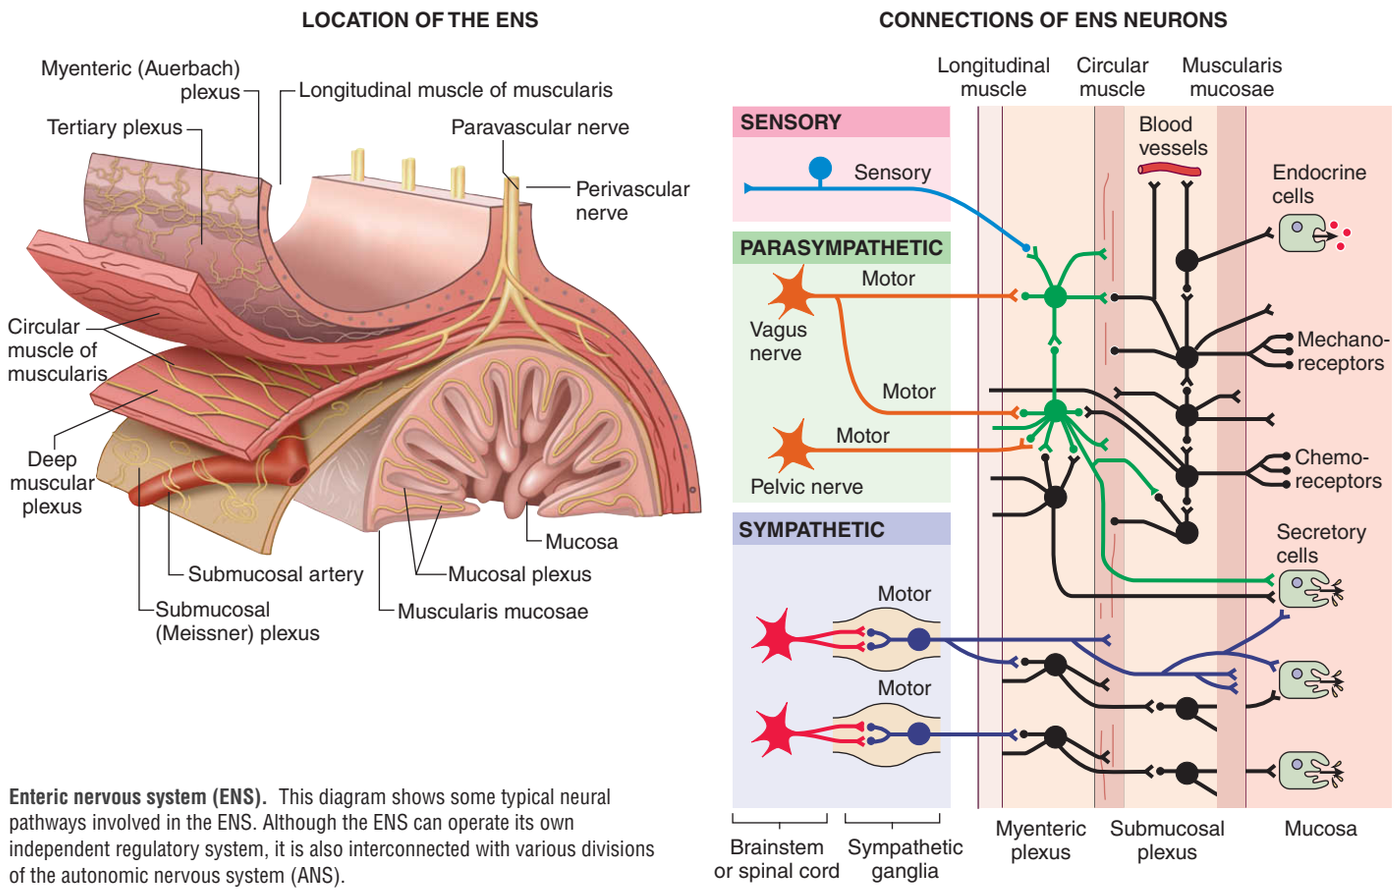
Overview of digestive functions. Several important digestive functions are summarized in these diagrams. Note that the digestive tract is an extension of the external environment—extending like a tunnel through the body.

Box 29-1 | The ENTERIC Nervous System

As we discussed in Chapter 28, the gastrointestinal (GI) wall includes an *intramural plexus* of nerve pathways. This complex arrangement of neurons is made up largely of the submucosal plexus (of Meissner) and the myenteric plexus (of Auerbach). Figure 28-2 on p. 863 clarifies the locations of these two structures and also shows that they are connected not only to each other but also to the CNS (central nervous system) and the GI muscles and mucous membrane. All of these structures work together in a coordinated system called the **enteric nervous system (ENS).**



The ENS is often called a "mini brain" or "second brain" because it includes afferent neurons, interneurons, and efferent neurons that independently operate their own nervous reflexes. Thus the ENS can act as "its own brain" in many ways. However, the ENS is certainly influenced by the CNS—as you can see in the diagram here. Because it operates as an involuntary, autonomic system, many physiologists consider the ENS to be another division of the autonomic nervous system (ANS). As the diagram shows, there is certainly communication between the ENS and the various divisions of the ANS.

Operation of the ENS, like the brain, seems to involve the storage and retrieval of memories and the establishment of repeating patterns of response.

Of course, this "second brain" has a complete set of different neurotransmitters that help carry out the complex functions of coordinating enteric reflexes. The list of major ENS neurotransmitters includes some familiar names: acetylcholine (ACh), enkephalins, substance P, serotonin, and nitric oxide (NO). Also on the list is an important peptide neurotransmitter, vasoactive intestinal peptide (VIP). Like other peptide neurotransmitters, VIP helps modulate neuron function—in this case, involving inhibition of intestinal smooth muscle or stimulation of intestinal secretions.

The ENS also helps establish a nervous-immune connection (*neuroimmune* function). For example, neurotransmitters from the ANS and from the ENS can stimulate mast cells in the wall of the GI tract to release histamine and other regulatory molecules. Histamine, for example, stimulates acid secretion in the stomach, besides having the immune functions previously discussed (see Chapter 24).

As we shall see throughout this chapter, the ENS works with other divisions of the nervous system, with the endocrine system, and with local regulatory mechanisms to achieve the coordination of incredibly complex, finely tuned mechanisms of motility (movement), secretion, digestion, and other functions.

Enteric nervous system (ENS). This diagram shows some typical neural pathways involved in the ENS. Although the ENS can operate its own independent regulatory system, it is also interconnected with various divisions of the autonomic nervous system (ANS).

DIGESTION

After food is ingested (taken into the mouth), the process of digestion begins immediately. Digestion is the overall name for all the processes that chemically and mechanically break complex foods into simpler nutrients that can be easily absorbed. We begin our discussion with a brief overview of *mechanical digestion* and then move on to a discussion of *chemical digestion*.

Mechanical Digestion

Mechanical digestion consists of all movement (motility) of the digestive tract that brings about the following:

- Change in the physical state of ingested food from comparatively large solid pieces into minute particles, thereby facilitating chemical digestion
- Churning of the contents of the GI lumen in such a way that they become well mixed with the digestive juices and all parts of them come in contact with the surface of the intestinal mucosa, thereby facilitating absorption
- Propelling the food forward along the digestive tract, and finally eliminating the digestive wastes from the body

MASTICATION

Mechanical digestion begins in the mouth when the particle size of ingested food material is reduced by chewing movements, or **mastication.** The tongue, cheeks, and lips play an important role in keeping food material between the cutting or grinding surfaces of the teeth when a person is biting off or chewing food. In addition to reducing particle size, chewing movements serve to mix food with saliva in preparation for swallowing.

DEGLUTITION

The process of swallowing, or **deglutition,** involves three main steps, or stages, that may be divided into the formation and then movement of a food bolus from the mouth to the stomach (Figure 29-2):

1. Oral stage (mouth to oropharynx)
2. Pharyngeal stage (oropharynx to esophagus)
3. Esophageal stage (esophagus to stomach)

The first step, which is voluntary and under control of the cerebral cortex, involves the formation of a food bolus that is to be swallowed by means of a depression or groove in the middle of the tongue. During the oral stage, the bolus is pressed against the palate by the tongue and then moved back into the oropharynx. The pharyngeal and esophageal stages, both involuntary, consist of movement of food from the pharynx into the esophagus and, finally, into the stomach.

To propel food from the pharynx into the esophagus, three openings must be blocked: mouth, nasopharynx, and larynx. Continued elevation of the tongue seals off the mouth. The soft palate, including the uvula, is elevated and tensed, causing the nasopharynx to be closed off. Food is prevented from entering the larynx by muscle action that causes the epiglottis to block this opening. The mechanism involves raising of the larynx, a process easily noted by palpation of the thyroid cartilage during swallowing. As a result, the bolus slips over the back of the epiglottis to enter the laryngopharynx.

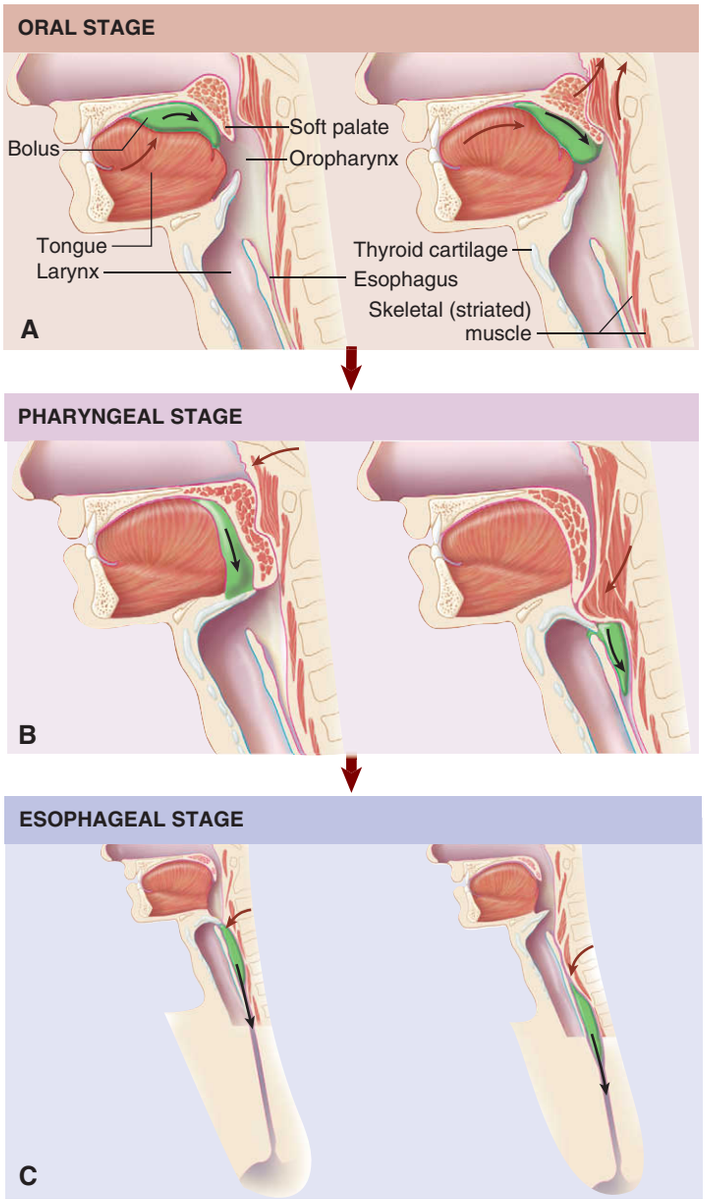


FIGURE 29-2

Deglutition. A, *Oral stage.* During this stage of deglutition (swallowing), a bolus of food is voluntarily formed on the tongue and pushed against the palate and then into the oropharynx. Notice that the soft palate acts as a valve that prevents food from entering the nasopharynx. **B,** *Pharyngeal stage.* After the bolus has entered the oropharynx, involuntary reflexes push the bolus down toward the esophagus. Notice that upward movement of the larynx and downward movement of the bolus close the epiglottis and thus prevent food from entering the lower respiratory tract. **C,** *Esophageal stage.* Involuntary reflexes of skeletal (striated) and smooth muscle in the wall of the esophagus move the bolus through the esophagus toward the stomach.

Contractions of the pharynx and esophagus compress the bolus into and through the esophageal tube. These steps are involuntary and under control of the *deglutition center* in the medulla. The presence of a bolus stimulates sensory receptors in the mouth and pharynx, thus initiating reflex pharyngeal contractions. Consequently, anesthesia of sensory nerves from the mucosa of the mouth and pharynx by a drug such as procaine makes swallowing difficult or impossible.

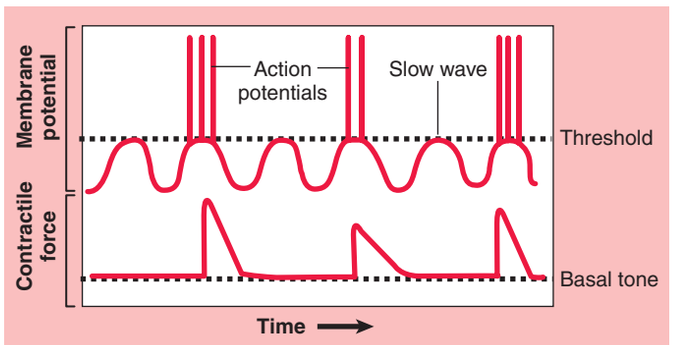
Swallowing is a complex process requiring the coordination of many muscles and other structures in the head and neck. The process must not only occur smoothly but also take place rapidly because respiration is inhibited for the 1 to 3 seconds required for food to clear the pharynx during each swallowing.

PERISTALSIS AND SEGMENTATION

After food enters the lower portion of the esophagus, smooth muscle tissue in the wall of the GI tract takes on primary responsibility for its movement (Box 29-2). The motility produced by smooth muscle is of two main types: peristalsis and segmentation.

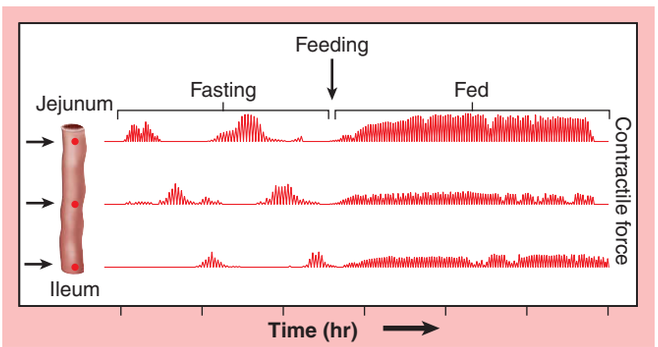
Box 29-2 | Smooth Muscle Function in the GI Tract

Smooth muscle tissue in the wall of the gastrointestinal (GI) tract differs from other types of muscle tissue in a number of important ways. For example, smooth muscle is slow compared to skeletal muscle. Because the sliding of myofilaments proceeds at a much slower pace than in skeletal muscle, smooth muscle often exhibits a prolonged contraction phase. Because the same amount of energy is used for slow contraction as for fast contraction, GI muscle can sustain tension for long periods without fatigue—exactly what is needed for the long process of digestion.



Another unique functional characteristic of smooth muscle is its ability to maintain *basal tone.* The basal tone is a continuous state of minimal contraction. Continuous tension is maintained in cells that have enough calcium ions free in the sarcoplasm to generate the contraction response. The force of contraction can increase above the basal tone by way of the effects of an action potential, which causes rapid influx of extracellular calcium.

Gastrointestinal *sphincter* muscles, as you recall from the previous chapter, are ringlike formations of smooth muscle in the GI wall that act as gateways or valves that regulate movement of chyme from one part of the tract to the next part. Sphincter muscles generally have a higher basal tone than does surrounding smooth muscle—thus constricting the lumen and "keeping the gate closed." Usually, stimuli in a section preceding the sphincter trigger a decrease in basal tone to allow material to pass through. Some of these reflexes are discussed later in this chapter.



Most of the smooth muscles in the GI wall are electrically coupled by gap junctions—so-called *single-unit* muscles. Such electrical coupling allows for intrinsic control of smooth muscle contraction, as in cardiac muscle. Smooth muscle fibers exhibit an intrinsic, rhythmic fluctuation in membrane voltage that is sometimes called *basic electrical rhythm (BER).* As part *A* of the figure shows, the peaks of these slow waves sometimes reach the threshold potential—thus triggering bursts of action potentials. Because the fibers are electrically coupled, action potentials generated in one fiber spread rapidly to many surrounding fibers. This phenomenon is called *pacemaker* activity (as we have already seen in the heart with cardiac muscle fibers). Part *A* of the figure shows the effect of pacemaker activity on the force generated in a local area of the GI muscle. Between action potentials, the muscle cells exhibit the basal tone—but when stimulated by pacemaker potentials, the contractile force increases dramatically. The end result of pacemaker activity is a rather rhythmic increase and decrease in smooth muscle tension.

In part *B* of the figure, you can see that the small intestine shows an unusual pattern of this rhythmic pacemaker activity during the fasting state. In the fasting state, the electrical rhythm (and therefore the rhythm of contraction) is relatively quiet, except for a coordinated wave of motor activity every 1½ to 2 hours. Each wave of rhythmic contractions is called a **migrating motor complex (MMC).** One function of the MMC is thought to be that of clearing out any remaining material, such as larger, indigestible particles, bile and other secretions, bacteria, and sloughed off epithelial cells. The MMC pattern is largely triggered by the hormone **motilin** released from endocrine cells in the duodenum.

Once material enters a segment of the digestive tract, the slow basic rhythm of contraction changes to the rapid rhythms of *segmentation* (mixing actions) and *peristalsis* (progressive movement).

A

B

A, Pacemaker activity of smooth muscle. As the upper graph line shows, the membrane potential of smooth muscle exhibits a rhythmic fluctuation (the basic electrical rhythm). Occasionally, the fluctuating membrane potential reaches the threshold—triggering one or more action potentials that spread to surrounding muscle fibers. Smooth muscles are continually partially contracted (the basal tone), but the force of contraction increases dramatically with each burst of action potentials (bottom graph line). The more action potentials that occur in a short series, the stronger the force of contraction. **B, Migrating motor complex (MMC).** In the small intestine, the basal rhythm of smooth muscle contractions during the fasting state is characterized by occasional waves of motor activity called *migrating motor complexes (MMCs).* These waves of contraction slowly "sweep out" the intestinal lumen between active digestive periods (fed states). During the fed state, the MMC pattern disappears and is replaced by a more rapid, active pattern that includes peristalsis and segmentation.

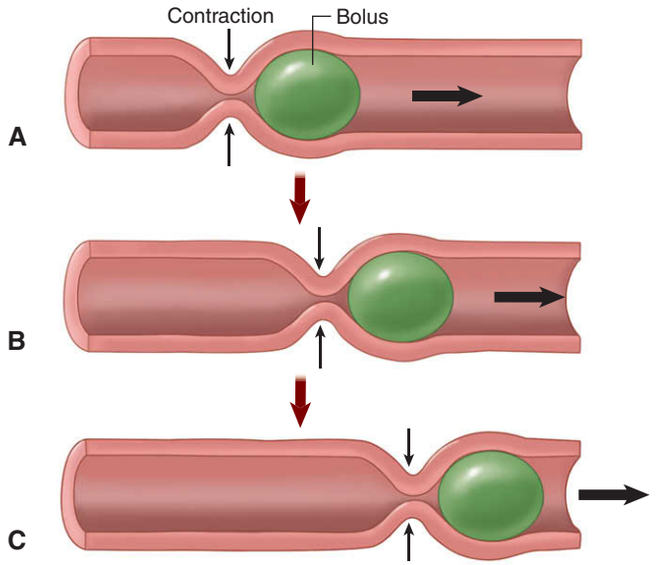


FIGURE 29-3

Peristalsis. Peristalsis is a progressive type of movement in which material is propelled from point to point along the gastrointestinal (GI) tract. **A,** A ring of contraction occurs where the GI wall is stretched, and the bolus is pushed forward. **B,** The moving bolus triggers a ring of contraction in the next region that pushes the bolus even farther along. **C,** The ring of contraction moves like a wave along the GI tract to push the bolus forward.

Peristalsis is often described as a wavelike ripple of the muscle layer of a hollow organ. The diagram in Figure 29-3 shows step by step how peristalsis occurs. A bolus stretches the GI wall, triggering a reflex contraction of circular muscle that pushes the bolus forward. This, in turn, triggers a reflex contraction in that location, pushing the bolus even farther. This process continues as long as the stretch reflex is activated by the presence of food. Peristalsis is a progressive kind of motility, that is, a type of motion that produces forward movement of ingested material along the GI tract. Figure 29-4 shows the effects of peristaltic contractions in the esophagus during deglutition.

Segmentation can be described simply as mixing movement. Segmentation occurs when digestive reflexes cause a forward and backward movement within a single region, or segment, of the GI tract (Figure 29-5). Such movement helps mechanically break down food particles, mixes food and digestive juices thoroughly, and brings digested food in contact with intestinal mucosa to facilitate absorption.

Peristalsis and segmentation can occur in an alternating sequence. When this happens, food is churned and mixed as it slowly progresses along the GI tract.

REGULATION OF MOTILITY

Gastric Motility

The process of emptying the stomach takes about 2 to 6 hours after a meal, depending on the amount and content of the meal. During its "storage time" in the stomach, food is churned with gastric juices to form a thick, milky material known as **chyme,** which is ejected about every 20 seconds into the duodenum. As

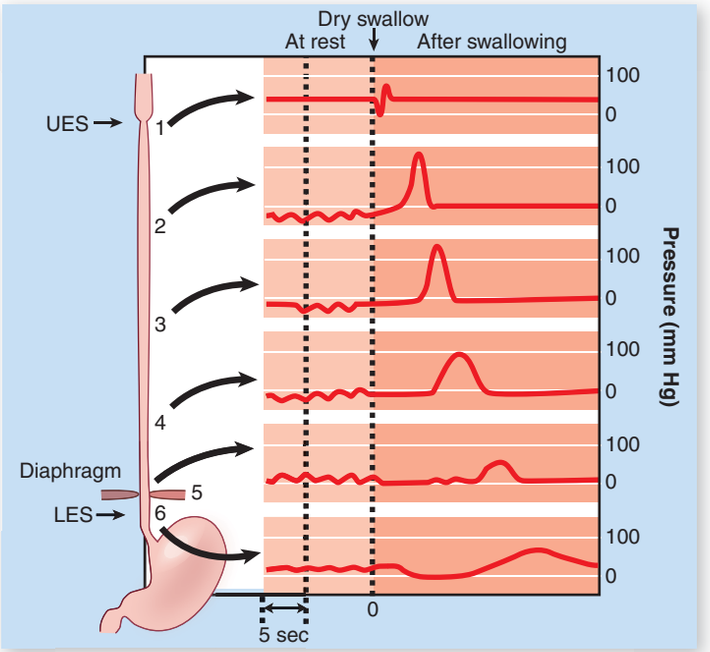

FIGURE 29-4

Pressure in the esophagus during swallowing. This diagram shows the changing pressure (mm Hg) inside the esophagus during the esophageal stage of deglutition (swallowing, see Figure 29-2). Note that an area of high pressure moves progressively down the esophagus—and eventually to the stomach. Note that during the rest period before swallowing, the smooth muscle exhibits a slow rhythm of weak contractions. *UES,* Upper esophageal sphincter; *LES,* lower esophageal [cardiac] sphincter.

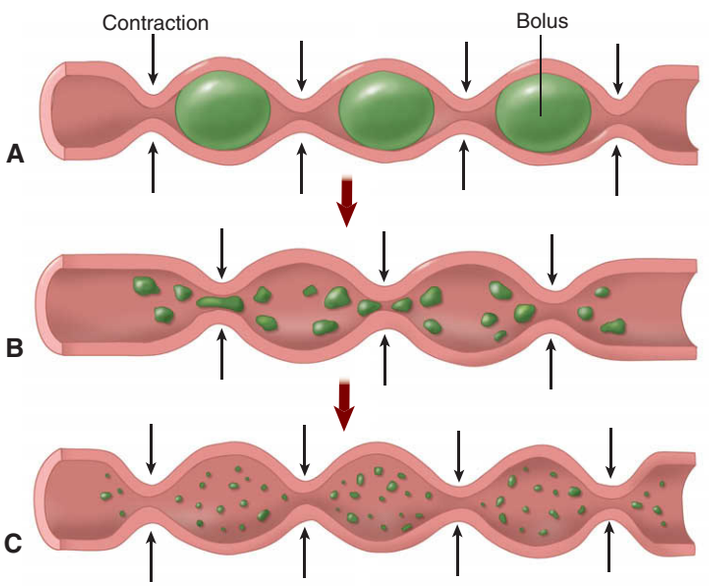

FIGURE 29-5

Segmentation. Segmentation is a back-and-forth action that breaks apart chunks of food and mixes in digestive juices. **A,** Ringlike regions of contraction occur at intervals along the gastrointestinal (GI) tract. **B,** Previously contracted regions relax and adjacent regions now contract, effectively "chopping" the contents of each segment into smaller chunks. **C,** The location of the contracted regions continues to alternate back and forth, chopping and mixing the contents of the GI lumen.

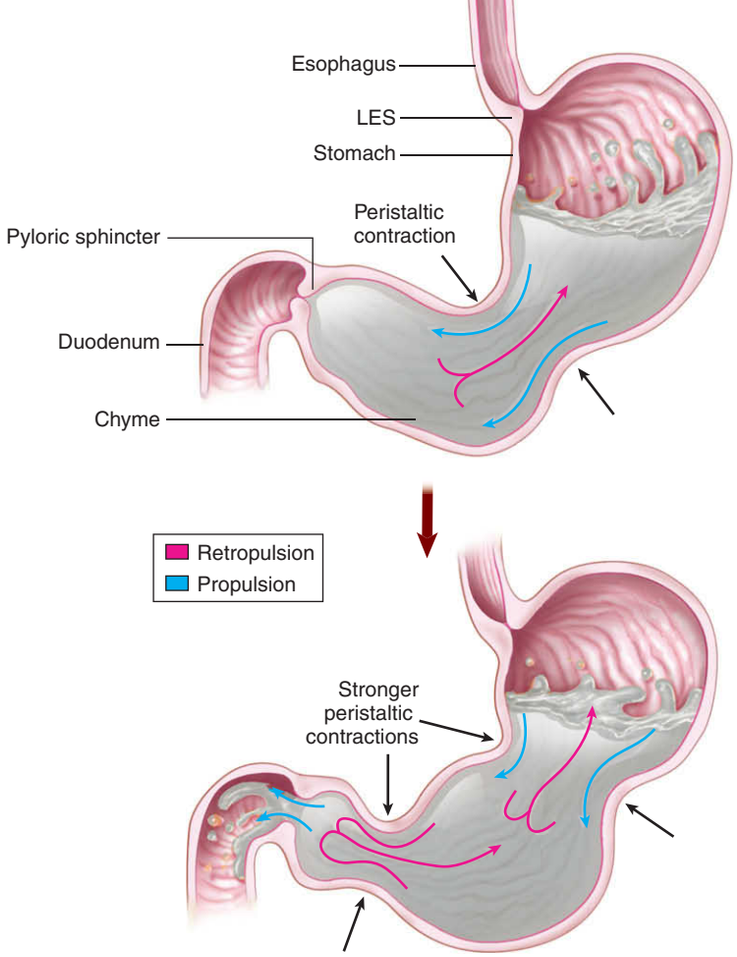

FIGURE 29-6

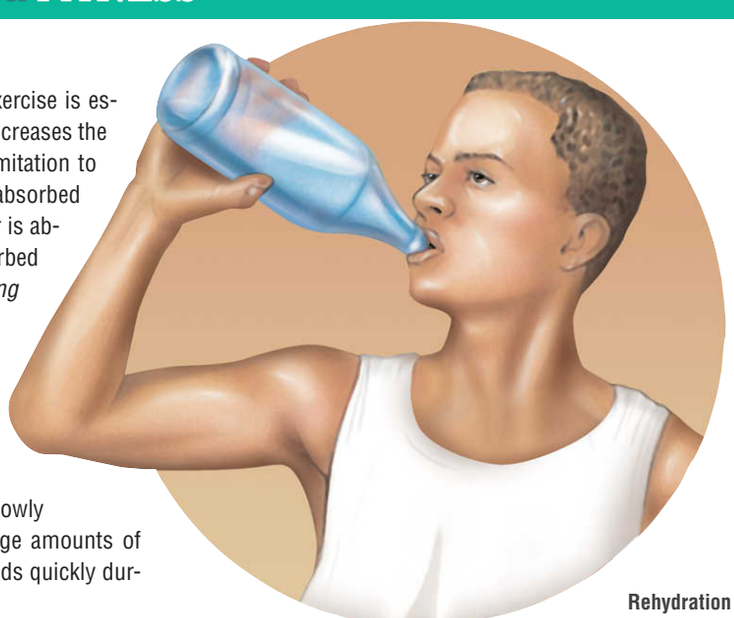
Gastric motility. Mixing actions in the stomach include both propulsion (forward movement) and retropulsion (backward movement). As peristaltic contractions become stronger, some of the liquid chyme squirts past the pyloric sphincter (which has decreased its muscle tone) and into the duodenum. The stomach continues to mix the chyme as it is gradually released into the duodenum.

you can see in Figure 29-6, while chyme is in the stomach, it is continually being pushed toward the pyloric sphincter by waves of peristaltic contractions—a process called **propulsion.** Because the pyloric sphincter remains closed most of the time, the chyme is forced to move backward—a process called **retropulsion.** Thus, because the chyme is temporarily "trapped," peristalsis creates a sort of "back-and-forth" movement that helps mix the chyme and gastric juice. Eventually, the contraction force of the pyloric sphincter decreases, allowing a little of the chyme to pass through to the duodenum.

Because the volume of the stomach is large and that of the duodenum is small, gastric emptying must be regulated to prevent overburdening of the duodenum. Such control occurs by way of two principal mechanisms—one hormonal and one nervous. Fats and other nutrients in the duodenum stimulate the intestinal mucosa to release a hormone called **gastric inhibitory peptide (GIP)** into the bloodstream. When it reaches the stomach wall via the circulation, GIP has an inhibitory effect on gastric muscle, decreasing its peristalsis and thus slowing passage of food into the duodenum. Nervous control results from receptors in the duodenal mucosa that are sensitive to the presence of acid and to distention. Sensory and motor fibers in the vagus nerve then cause a reflex inhibition of gastric peristalsis. This nervous mechanism is known as the **enterogastric reflex.**

Box 29-3 discusses one important application of concepts of gastric motility.

INTESTINAL MOTILITY



Intestinal motility includes both peristaltic contractions and segmentation. Segmentation in the duodenum and upper jejunum mixes the incoming chyme with digestive juices from the pancreas, liver, and intestinal mucosa. This mixing action also allows the products of digestion to contact the intestinal mucosa, where

Box 29-3 | SPORTS and FITNESS

Exercise and Fluid Uptake

Replacement of fluids lost through sweating during exercise is essential for maintaining homeostasis. Nearly everyone increases the intake of fluids during and after exercise. The main limitation to efficient fluid replacement is how quickly fluid can be absorbed rather than how much a person drinks. Very little water is absorbed until it reaches the intestines, where it is absorbed almost immediately. Thus the rate of *gastric emptying* into the intestine is critical.

Large volumes of fluid leave the stomach and enter the intestines more rapidly than small volumes do. However, having large volumes in the stomach may be uncomfortable during exercise. Cool fluids (8° to 13° C [46° to 55° F]) empty more quickly than warm fluids. Fluids with a high solute concentration empty slowly and may cause nausea or stomach cramps. Thus large amounts of cool, dilute, or isotonic fluids are best for replacing fluids quickly during exercise.

Rehydration after exercise.

they can be absorbed into the internal environment. Peristalsis continues as the chyme nears the end of the jejunum—moving the food through the rest of the small intestine and into the large intestine. After leaving the stomach, chyme normally takes about 5 hours to pass all the way through the small intestine.

Several mechanisms are involved in the control of intestinal motility. Peristalsis is regulated in part by the intrinsic stretch reflexes already described. It is also thought to be stimulated by the hormone **cholecystokinin (CCK),** which is secreted by endocrine cells of the intestinal mucosa when chyme is present.

A list of definitions of the different processes involved in mechanical digestion, along with the organs that accomplish them, is presented in Table 29-2.

| QUICK CHECK |

1. What is meant by the term *motility?*
2. Is deglutition a voluntary or involuntary process?
3. What is the purpose of peristalsis?
4. What triggers the *enterogastric reflex* to inhibit gastric emptying?

Chemical Digestion

Chemical digestion consists of all the changes in chemical composition that foods undergo in their travel through the digestive tract. These changes result from the hydrolysis of foods. **Hydrolysis** is a chemical process in which a compound unites with water and then splits into simpler compounds (see Chapter 2). Numerous enzymes in the various digestive juices catalyze the hydrolysis of foods.

DIGESTIVE ENZYMES

Overview of Digestive Enzymes

Enzymes were briefly introduced in Chapter 2 and their important functional roles were more fully discussed in Chapter 4 (see pp. 103–104). Although our interest until now has primarily concerned *intracellular enzymes*, our current discussion focuses on extracellular digestive enzymes. In the following paragraphs we briefly review enzymes in general and outline some characteristics of *digestive enzymes* in particular.

Recall that enzymes can be defined simply as "organic catalysts"; that is, they are organic compounds (proteins), and they accelerate chemical reactions without appearing in the final products of the reaction.

Recall the two systems used for naming enzymes: the suffix *-ase* is used with the root name of the substance whose chemical reaction is catalyzed (the substrate chemical, that is) or with the word that describes the kind of chemical reaction catalyzed. Thus, according to the first method, lipase is an enzyme that catalyzes a chemical reaction in which a lipid takes part. According to the second method, lipase might also be called a *hydrolase* because it catalyzes the hydrolysis of lipids. Enzymes investigated before these methods of nomenclature were adopted are still called by older names, such as **pepsin** and **trypsin**—both proteases (protein-digesting enzymes).

Enzymes can be classified as intracellular or extracellular, depending on whether they act within cells or outside of them in the surrounding medium. Most enzymes act intracellularly in the body; an important exception is the digestive enzymes. Digestive enzymes are classified as extracellular because they operate in the lumen of the digestive tract, outside any cells of the body. All

TABLE 29-2 Processes of Mechanical Digestion

ORGAN	MECHANICAL PROCESS	NATURE OF PROCESS
Mouth (teeth and tongue)	Mastication	Chewing movements—reduce size of food particles and mix them with saliva
	Deglutition	Swallowing—movement of food from mouth to stomach
Pharynx	Deglutition	See description above
Esophagus	Deglutition	See description above
	Peristalsis	Rippling movements that squeeze food downward in digestive tract; a constricted ring forms first in one section, then the next, and so on, causing waves of contraction to spread along entire canal
Stomach	Churning	Forward and backward movement (propulsion/retropulsion) of gastric contents, mixing food with gastric juices to form chyme
	Peristalsis	Wave starting in body of stomach that occurs about three times per minute and sweeps toward closed pyloric sphincter; at intervals, strong peristaltic waves press chyme past sphincter into duodenum
Small intestine	Segmentation (mixing contractions)	Forward and backward movement within segment of intestine; purpose is to mix food and digestive juices thoroughly and to bring all digested food into contact with intestinal mucosa to facilitate absorption; purpose of peristalsis, on the other hand, is to propel intestinal contents along digestive tract
	Peristalsis	
Large intestine		
Colon	Segmentation	Churning movements within haustral sacs
	Peristalsis	See description above
Descending colon	Mass peristalsis	Entire contents moved into sigmoid colon and rectum; occurs three or four times a day, usually after a meal
Rectum	Defecation	Emptying of rectum, so-called bowel movement

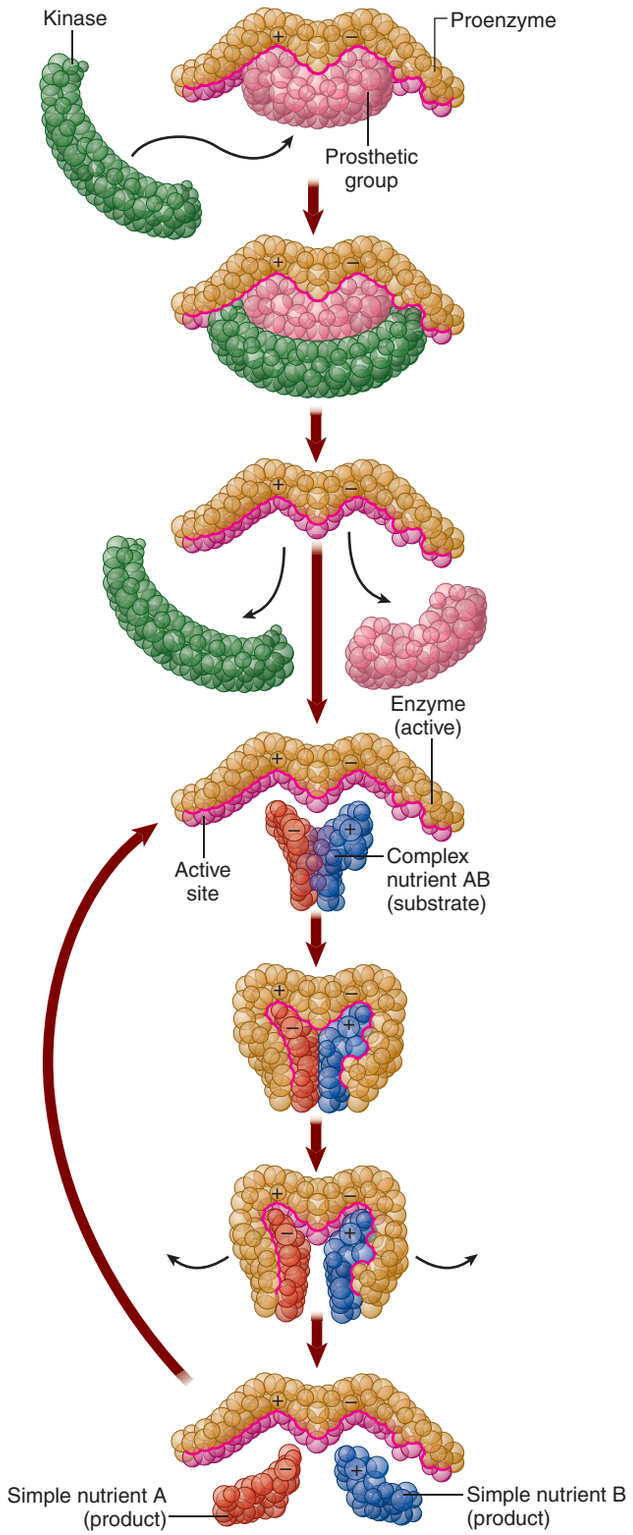


FIGURE 29-7

Model of digestive enzyme action. Enzymes are functional proteins whose molecular shape allows them to catalyze chemical reactions. First, an inactive proenzyme must be altered by an activating enzyme called a *kinase*. The kinase often accomplishes the activation by removing a prosthetic group from the proenzyme, exposing an active site. A complex nutrient molecule *AB* is acted on by the active digestive enzyme, yielding simpler nutrient molecules *A* and *B*. The active enzyme can then digest another complex nutrient molecule.

digestive enzymes are classified chemically as hydrolases because they catalyze the hydrolysis of food molecules—the breakdown of a molecule using water.

Properties of Digestive Enzymes

As with any type of enzyme, digestive enzymes are *specific in their action;* that is, they act only on a specific substrate. This is attributed to a "key-in-a-lock" kind of action, the configuration of the enzyme molecule fitting the configuration of some part of the substrate molecule (Figure 29-7).

Digestive enzymes *function optimally at a specific pH* and become inactive if the pH deviates beyond narrow limits (Figure 29-8). This effect occurs because changes in the hydrogen ion (H^+) concentration influence the chemical attractions that hold all protein molecules—including enzymes—in their complex, multidimensional shapes. In short, changing the pH changes the shape of an enzyme molecule—possibly rendering it inactive.

Different digestive enzymes require different H^+ concentrations in their environment for optimal functioning. This is because the H^+ concentration influences the shape of each enzyme molecule. Amylase, the main enzyme in saliva, functions best in the neutral to slightly acid pH range characteristic of saliva. It is gradually inactivated by the marked acidity of gastric juice. In contrast, pepsin, an enzyme in gastric juice, is inactive unless sufficient hydrochloric acid is present. Therefore, in diseases characterized by gastric hypoacidity, dilute hydrochloric acid is given orally before meals.

Most enzymes catalyze a chemical reaction in both directions, the direction and rate of the reaction being governed by the rate law (law of mass action). An accumulation of a product slows the reaction and tends to reverse it. A practical application of this fact is the slowing of digestion when absorption is interfered with and the products of digestion accumulate. However, digestive enzyme reactions do not ordinarily reverse themselves in the digestive tract.

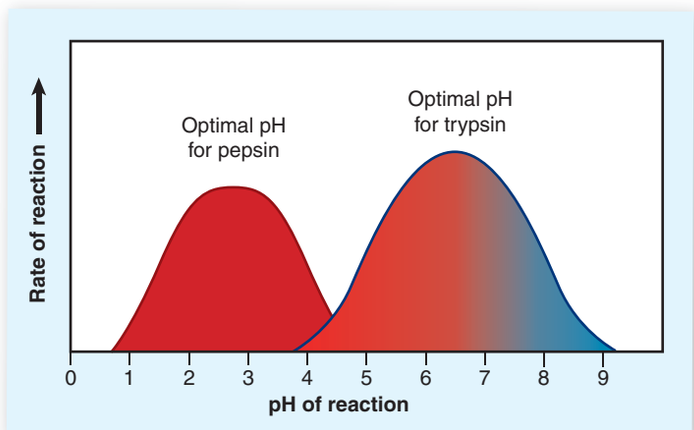

FIGURE 29-8

Effect of pH on digestive enzyme function. Digestive enzymes catalyze chemical reactions with greatest efficiency within a narrow range of pH. For example, *pepsin* (a protein-digesting enzyme in gastric juice) operates within a low pH range, whereas *trypsin* (a protein-digesting enzyme in pancreatic juice) operates within a higher pH range.

Digestive enzymes are continually being destroyed or eliminated from the body and therefore have to be continually synthesized, even though they are not used up in the reactions they catalyze.

Most digestive enzymes are synthesized and secreted as inactive **proenzymes** (see Figure 29-7). Enzymes that break apart proenzymes and thus convert them to active enzymes are often called *kinases*. For example, enterokinase is a kinase that changes inactive trypsinogen into active trypsin.

Although we eat six main types of chemical substances (carbohydrates, proteins, fats, vitamins, mineral salts, and water), only the first three have to be chemically digested to be absorbed.

CARBOHYDRATE DIGESTION

Carbohydrates are saccharide compounds. This means that their molecules contain one or more saccharide groups ($C_6H_{10}O_5$). Polysaccharides, notably starches and glycogen, contain many of these groups. Disaccharides (sucrose, lactose, and maltose) contain two of them, and monosaccharides (glucose, fructose, and galactose) contain only one. Polysaccharides are hydrolyzed to disaccharides by enzymes known as **amylases,** found in saliva and pancreatic juice (salivary amylase is sometimes called *ptyalin*). The enzymes that catalyze the final steps in carbohydrate digestion are *sucrase*, *lactase*, and *maltase* (Figure 29-9). These enzymes are located in the cell membrane of epithelial cells covering the villi and, therefore, lining the intestinal lumen. The substrates (disaccharides) bind onto the enzymes at the surface of the brush border, giving the name **contact digestion** to the process. The resulting end products of digestion, mainly glucose, are conveniently located at the site of absorption (and are not floating around somewhere in the lumen).

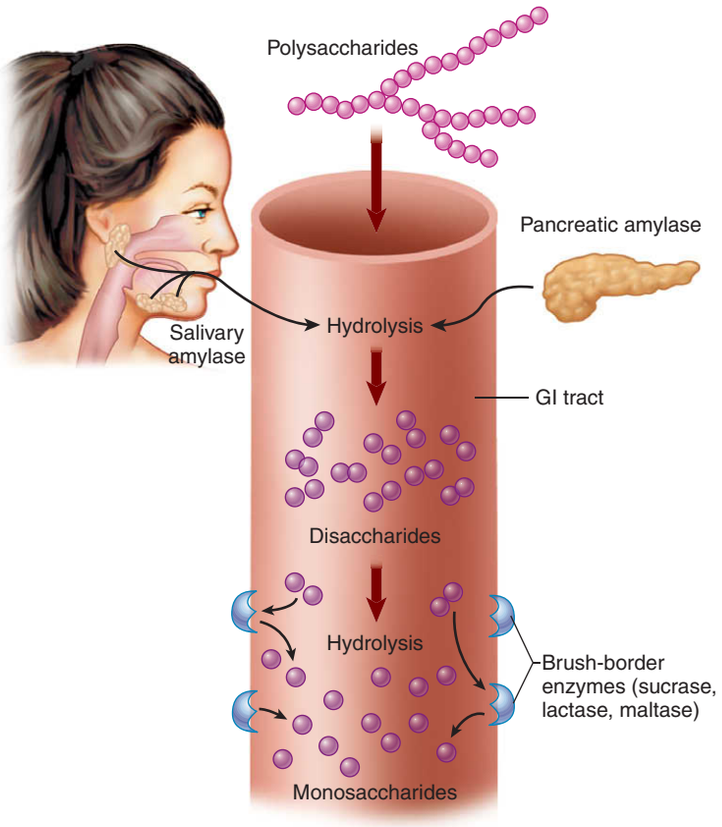

FIGURE 29-9

Carbohydrate digestion. Amylase in saliva and pancreatic juice hydrolyzes polysaccharides into disaccharides. Brush border disaccharidases in the lining of the small intestine then promote hydrolysis of the disaccharides into monosaccharides.

PROTEIN DIGESTION

Protein compounds have very large molecules made up of folded or twisted chains of amino acids, often hundreds in number. Enzymes called **proteases** catalyze the hydrolysis of proteins first into a variety of intermediate compounds called proteoses and peptides, which are simply shorter strands of amino acids. Then finally, proteases break these shorter molecules into individual amino acids (Figure 29-10).

The main proteases are **pepsin** in gastric juice, **trypsin** and **chymotrypsin** in pancreatic juice, and **peptidases** of the intestinal brush border (Box 29-4). Peptidases are also present within each intestinal cell where they break apart dipeptides and tripeptides absorbed into these cells. Each kind of protease catalyzes the breaking apart of a specific kind of peptide bond. Because different amino acid combinations within a protein or polypeptide can have slightly different kinds of peptide bonds holding them together, a whole arsenal of different proteases is needed for efficient protein digestion.

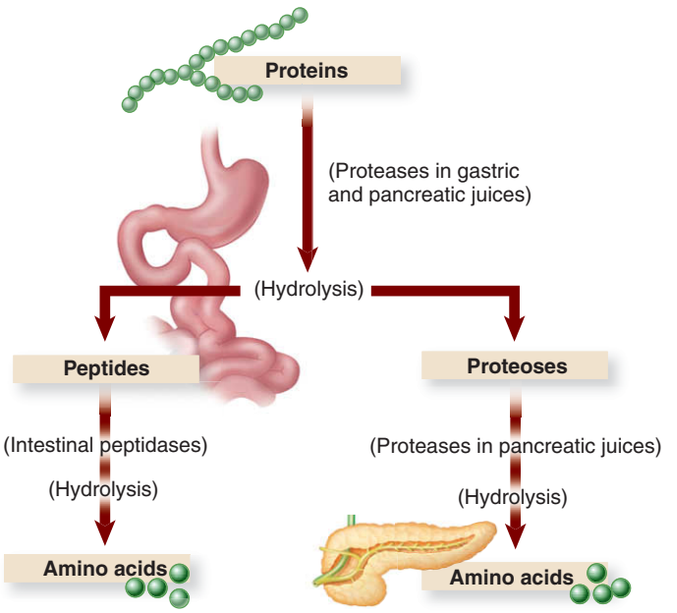

FIGURE 29-10

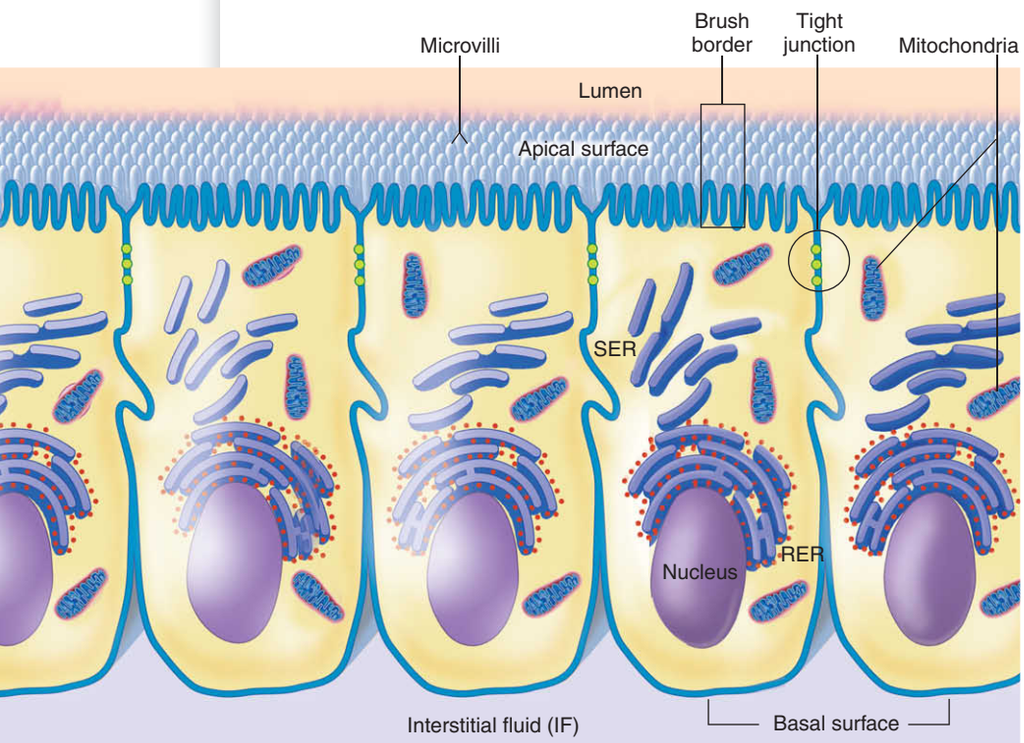
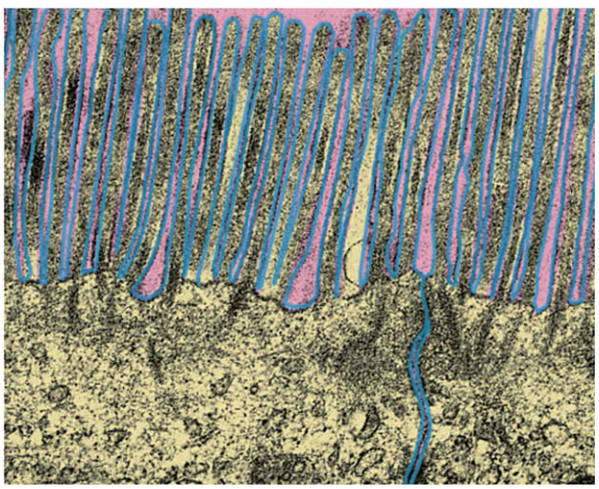
Protein digestion. Gastric juice protease (pepsin) and pancreatic juice protease (trypsin and chymotrypsin) hydrolyze proteins into proteoses and peptides. Protein digestion is then completed by pancreatic proteases, which hydrolyze proteoses into amino acids, and by intestinal peptidases, which hydrolyze peptides into amino acids.

Box 29-4 | The BRUSH BORDER



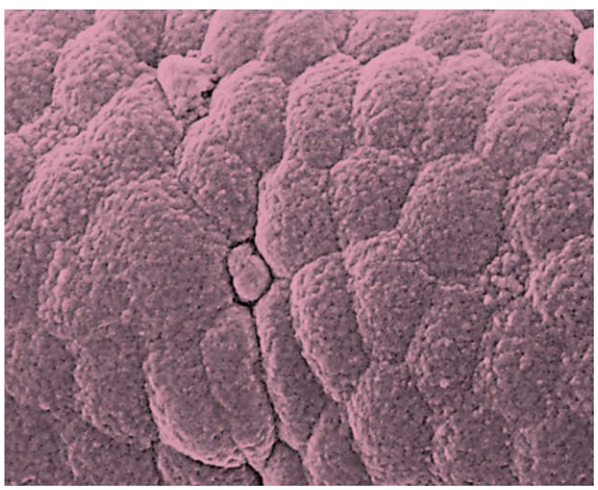
The term **brush border** refers to the microvilli on the epithelial mucous cells that line the small intestine, visible in the figures. These microvilli are on the apical surfaces of the epithelial cells—the surfaces that face the interior of the intestinal lumen. Because when viewed under high magnification the microvilli look like the bristles of a brush, the surface of the intestinal mucosa was nicknamed "brush border."

The brush border represents the boundary between the external environment (the lumen of the alimentary canal) and the internal environment of the body. It is across this border that molecules must pass if they are going to be absorbed into the body.



The brush border possesses an incredibly large surface area because the microvilli increase the apical surface area. There are usually 2000 to 3000 microvilli on each cell! Of course, the presence of intestinal villi, circular folds (plicae circulares), and numerous loops also adds to the intestinal surface area (see Figure 28-17 on p. 876).

The large surface area of the brush border provides sites for digestive enzymes on the plasma membranes of intestinal cells—the *brush border enzymes.* The efficiency of the last stages of digestion is thus enhanced by having more surface area for more digestive enzymes. Many of the brush border enzymes are on fine, branched filaments that extend from the surface of each microvillus and form a glycoprotein coat on the brush border called the *glycocalyx.* Because each substrate molecule must come in direct contact with a brush border enzyme before it can be digested, the process is called *contact digestion.*



The large surface area also provides more opportunities for the absorption of digested nutrients. More surface area allows for more phospholipid bilayer to absorb fats and more carrier molecules to carry amino acids, peptides, monosaccharides, and other nutrients.

A

C

A, Intestinal epithelium. The diagram shows intestinal epithelial cells joined by tight junctions and covered with microvilli on their apical (lumen-facing) surfaces. *SER,* Smooth endoplasmic reticulum; *RER,* rough endoplasmic reticulum. **B, Cross section of the brush border.** A transmission electron micrograph shows microvilli, which resemble bristles of a brush. **C, Surface view of the brush border.** A scanning electron micrograph of the surface of an intestinal villus shows the epithelial cells joined by tight junctions. Note the brushy appearance of the surface caused by the presence of microvilli.

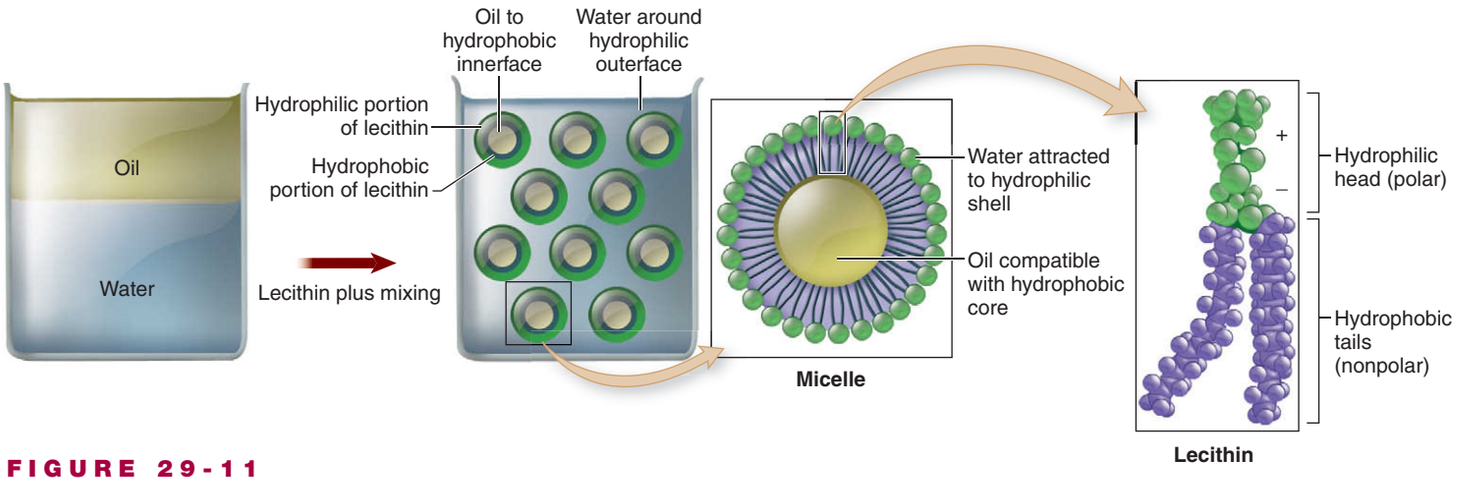

FIGURE 29-11

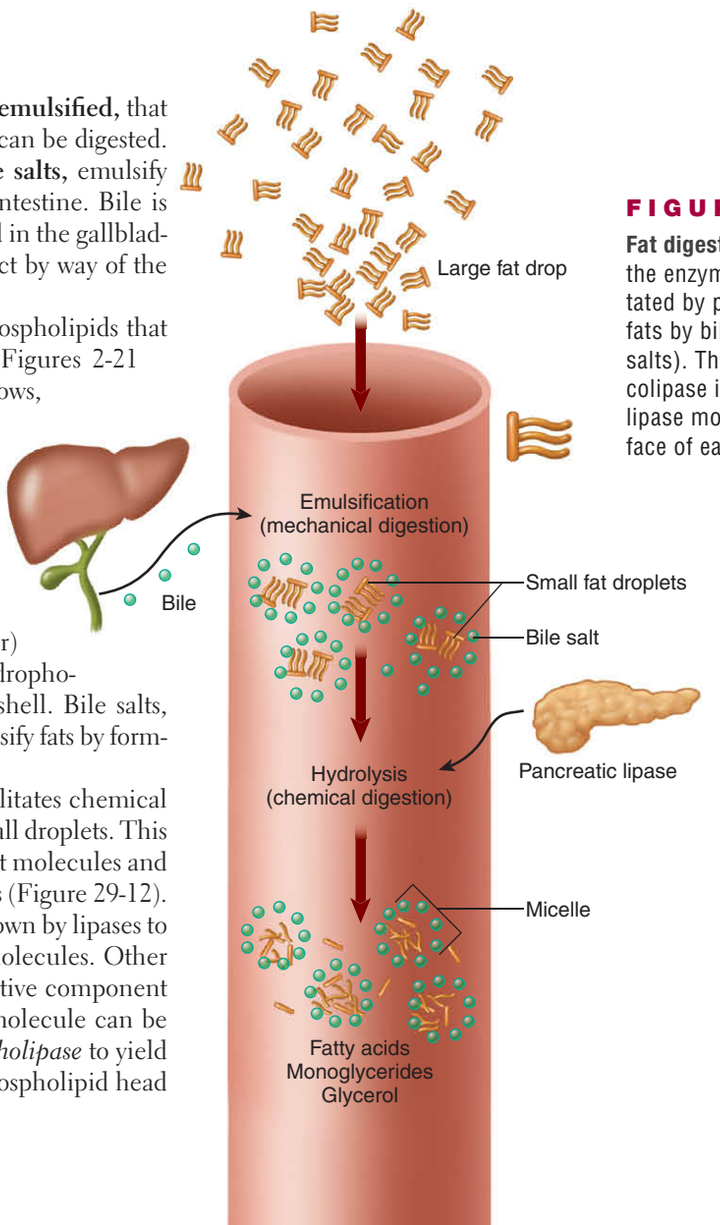
Formation of micelles by lecithin. Lecithin is a phospholipid in bile that mixes with oil and water to form micelles. Micelles are spherical shells formed by the orientation of lecithin molecules according to their solubility in water and lipids: the polar heads of lecithin face outward (toward water), and the nonpolar tails of lecithin face inward (toward lipid). Formation of micelles, a mechanical process called *emulsification,* breaks fat drops into small droplets and makes the droplets water soluble.

FAT DIGESTION

Because fats are insoluble in water, they must be **emulsified,** that is, dispersed into very small droplets, before they can be digested. Two substances found in bile, **lecithin** and **bile salts,** emulsify dietary oils and fats in the lumen of the small intestine. Bile is produced in the liver and stored and concentrated in the gallbladder. Bile is released into the lumen of the GI tract by way of the common bile duct.

Lecithin is a phospholipid similar to other phospholipids that make up the bulk of cellular membranes (see Figures 2-21 on p. 50 and 3-3 on p. 70). As Figure 29-11 shows, lecithin mixes with lipids and water, forming tiny spheres called **micelles.** In forming a micelle, lecithin molecules align to form a shell that surrounds the lipid. Alignment of lecithin molecules results from the fact that the polar heads of this molecule are attracted by polar water molecules and the nonpolar tails of lecithin are lipid soluble. Thus the hydrophilic (polar) heads form the outer face of the shell and the hydrophobic (nonpolar) tails form the inner face of the shell. Bile salts, which are derived from the lipid cholesterol, emulsify fats by forming micelles in the same manner.

The mechanical process of emulsification facilitates chemical digestion of fats by breaking large fat drops into small droplets. This process provides a greater contact area between fat molecules and pancreatic **lipases,** the main fat-digesting enzymes (Figure 29-12). Triglycerides, important dietary fats, are broken down by lipases to yield fatty acids, monoglycerides, and glycerol molecules. Other lipids are similarly broken down into their respective component chemical groups. For example, a phospholipid molecule can be chemically broken down by a lipase called *phospholipase* to yield one free fatty acid and one lysophosphatide (a phospholipid head with a single fatty acid tail).



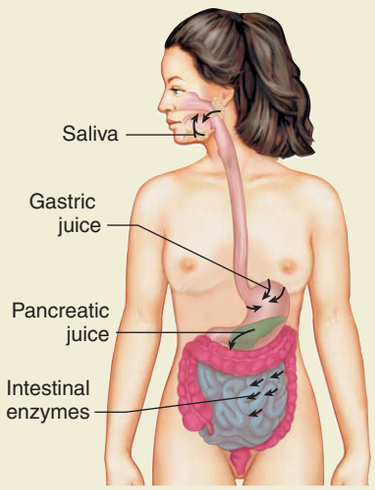


FIGURE 29-12

Fat digestion. Hydrolysis by the enzyme lipase is facilitated by prior emulsion of fats by bile (lecithin and bile salts). Though not pictured, colipase is needed to anchor lipase molecules to the inner face of each micelle.

TABLE 29-3 Chemical Digestion

DIGESTIVE JUICES AND ENZYMES		SUBSTANCE DIGESTED (OR HYDROLYZED)	RESULTING PRODUCT*
Saliva			
Amylase (ptyalin)		Starch (polysaccharide)	Maltose (disaccharide)
Gastric Juice			
Protease (pepsin)** plus hydrochloric acid		Proteins	Partially digested proteins
Pancreatic Juice			
Proteases (e.g., trypsin)†		Proteins (intact or partially digested)	Peptides and **amino acids**
Lipases		Fats emulsified by bile	**Fatty acids, monoglycerides,** and **glycerol**
Amylase		Starch	Maltose
Nucleases		Nucleic acids (DNA, RNA)	Nucleotides
Intestinal Enzymes‡			
Peptidases		Peptides	**Amino acids**
Sucrase		Sucrose (cane sugar)	**Glucose** and **fructose**§ (monosaccharides)
Lactase		Lactose (milk sugar)	**Glucose** and **galactose** (monosaccharides)
Maltase		Maltose (malt sugar)	**Glucose**
Nucleotidases and phosphatases		Nucleotides	Nucleosides

*Substances in **boldface type** are end products of digestion (that is, completely digested nutrients ready for absorption).
**Secreted in inactive form (pepsinogen); activated by low pH (hydrochloric acid).
†Secreted in inactive form (trypsinogen); activated by enterokinase, an enzyme in the intestinal brush border.
‡Brush-border enzymes.
§Glucose is also called *dextrose;* fructose is also called *levulose.*

The action of lipases is enhanced by a component of pancreatic juice called *colipase* (koh-LYE-payz). Colipase is a coenzyme molecule that anchors a lipase molecule to the inner face of a micelle. This positions the lipase for optimum hydrolysis of lipid molecules within the micelle.

For a summary of chemical digestion, see Table 29-3. Box 29-5 summarizes concepts of nucleic acid digestion and absorption.

RESIDUES OF DIGESTION

Certain components of food resist digestion and are eliminated from the intestines in the **feces.** Included among these *residues of digestion* are cellulose (a carbohydrate, also known as "dietary fiber") and undigested connective tissue from meat (mostly collagen). These substances remain undigested because humans lack the enzymes required to hydrolyze them. The residues of

Box 29-5 | FYI

Nucleic Acid Digestion and Absorption

Although they are not usually considered to be essential nutrients, the nucleic acids such as DNA and RNA found in cells of food material are digested, absorbed, and used by the body.

DNA and RNA strands released during mechanical digestion are still associated with proteins and so must first be hydrolyzed by proteases to break the proteins free from the DNA or RNA strand. **Nucleases** in pancreatic juice then break down each strand into individual nucleotides. Nucleotides are simple enough to be absorbed by intestinal cells. Many of the nucleotides, however, are first stripped of their phosphate groups by intestinal *phosphatases* and *nucleotidases.* A nucleotide thus stripped of its phosphate is called a *nucleoside.*

Although nucleotides can be absorbed, most nucleic acids are absorbed in the form of nucleosides. Both nucleotides and nucleosides are absorbed through the intestinal wall by a sodium cotransport process similar to that for glucose and amino acids. After absorption, the nucleosides have phosphates added to them by cellular enzymes and are thus restored to the nucleotide form.

Although a healthy body can make its own nucleotides, nucleotides from food help the body maintain a healthy pool of nucleotides available for making DNA and RNA. This external source of nucleotides is especially useful during rapid growth and development stages (as during infancy) and during certain disease or weakened states.

digestion also include undigested fats. Some fat molecules remain undigested because they have combined with dietary minerals such as calcium and magnesium, which render the fats indigestible. Box 29-6 discusses the fecal fat test used to detect abnormalities of fat absorption. In addition to these wastes, feces consist of bacteria, pigments, water, and mucus.

| QUICK CHECK |

5. What type of reaction do all digestive enzymes catalyze?
6. List some factors that alter the shape of an enzyme, thus altering its function.
7. Name the final digestive products of each of the following food molecules:
   a. Protein
   b. Carbohydrate
   c. Triglyceride

SECRETION

Digestive secretion generally refers to the release of various substances from the exocrine glands that serve the digestive system. For example, digestive secretion includes the release of saliva, gastric juice, bile, pancreatic juice, and intestinal juice. In the paragraphs that follow, we briefly summarize the major digestive juices. Later, we discuss how secretion is regulated.

Saliva

Saliva is the secretion of the salivary glands (see Figure 28-8 on p. 867). Saliva, as with all digestive secretions, is mostly water. Water helps mechanically digest food as it moves through the digestive tract by helping to liquefy the food. Liquefied food, called **chyme** after it enters the stomach, not only represents a physically broken-down form of food but also permits enzymes and other substances to mix freely with small chunks of food.

Mixed in the water is a combination of other important substances. **Mucus,** for example, is found not only in saliva but also in each of the other digestive juices. Mucus, you may recall, is a mixture of glycoproteins and related substances that is rather slippery to the touch. Mucus in intestinal juices has the primary functions of protecting the digestive mucosa and lubricating food as it passes through the alimentary canal.

Saliva, as with most other digestive juices, contains enzymes. Specifically, saliva contains **amylase**—a carbohydrate-digesting enzyme. Although salivary amylase (ptyalin) can chemically digest starches into smaller carbohydrates, the short time it has until it is destroyed by acids and enzymes in the stomach make this function relatively unimportant. Saliva also contains a small amount of **lipase,** which normally digests lipids. In the saliva, however, lipase is practically worthless because most ingested lipids must be emulsified before lipase can digest them easily.

Saliva also contains a small amount of sodium bicarbonate ($NaHCO_3$). Sodium bicarbonate dissociates in water to form sodium ions (Na^+) and bicarbonate ions (HCO_3^-). You may recall from Chapter 27 that bicarbonate can bind to hydrogen ions, thus taking the hydrogen ions out of solution and causing a decrease in acidity (increase in pH). This buffering mechanism keeps saliva close to neutral pH, which is optimum for amylase activity.

Gastric Juice

Gastric juice is secreted by exocrine *gastric glands*, which have ducts that lead to the gastric lumen by way of the gastric pits (see Figure 28-14 on p. 873). Gastric juice contains not only the basic water and mucus mixture of most other digestive juices but also a unique combination of other substances.

Chief cells in the gastric glands are also called **zymogenic cells** because they secrete the enzymes in gastric juice. The prefix *zymo-* refers to enzymes and *-genic* pertains to making something. Primary among the gastric enzymes is **pepsin,** which is secreted as the inactive proenzyme **pepsinogen.**

Pepsinogen is converted to pepsin by hydrochloric acid (HCl), which is produced by **parietal cells** of the gastric glands. Figure 29-13 shows how carbon dioxide and water form carbonic acid, which then dissociates to form the hydrogen ions needed to actively secrete hydrochloric acid. This is the very same chemical process that was outlined in Chapter 27, where we discussed carbon dioxide transport in the blood (see Figures 27-22, p. 874, and 27-24, p. 845). Notice here in Figure 29-13 that there is a *chloride*

Box 29-6 | DIAGNOSTIC study

Fecal Fat Test

Impaired fat absorption (malabsorption), prevalent in numerous diseases, produces large, greasy, and foul-smelling stools, or **steatorrhea.**

The fecal fat test measures the fat content in the stool. The total output of fecal fat per 24 hours in a 3- to 5-day stool collection provides the most reliable measurement. Each stool specimen throughout the period is collected in a clean, dry container and is sent immediately to the laboratory. The 3- to 5-day collection period is necessary to eliminate daily variations in the amount of fecal fat.

A standard fat content diet is begun 2 or 3 days before collection begins and continues until collection is done. Usually 100 grams of fat per day is suggested for adults. In children and infants who cannot eat 100 grams of fat per day, a fat retention coefficient is determined by using the following formula:

$$\frac{\text{Ingested fat} - \text{Fecal fat}}{\text{Ingested fat}} \times 100\%$$

If this fat retention coefficient is lower than 95%, the patient may have steatorrhea.

Analysis of fecal fat is useful in monitoring malabsorption in cystic fibrosis or in any condition characterized by malabsorption, maldigestion, or increased fecal fat.

shift similar to that discussed in regard to the respiratory system. In exchange for bicarbonate (also produced by dissociation of carbonic acid), chloride is shifted into the parietal cell where it can then diffuse into the duct of the gastric gland along with hydrogen ions. The end result of this process in parietal cells is that the contents of the stomach become more acidic, or drop in pH, and the contents of the blood become more basic, or increase in pH.

The ion pump in the membrane of gastric parietal cells that pumps H^+ ions into the gastric juice is often called the **H-K pump**—or more simply, a *proton pump* (see Figure 29-13). It is this pump that is targeted by drugs that inhibit gastric acid secretion, such as *omeprazole* (Prilosec). By inhibiting the H-K pumps of the stomach, these drugs reduce the overall acidity of the stomach contents.

The parietal cells have an interesting and important mechanism involved with secretion of ions. As Figure 29-14, *A*, shows, when the parietal cell is not actively secreting, it has a relatively small surface area and many internal vesicles. These vesicles have H-K pumps and ion channels and carriers embedded in their membranes. When the parietal cell becomes active, however, these vesicles move quickly to the apical surface (Figure 29-14, *B*). There, they fuse with the plasma membrane forming more microvilli and increasing the overall surface area by as much as 100 times! The pumps, carriers, and channels then begin the secretion process summarized in Figure 29-13.

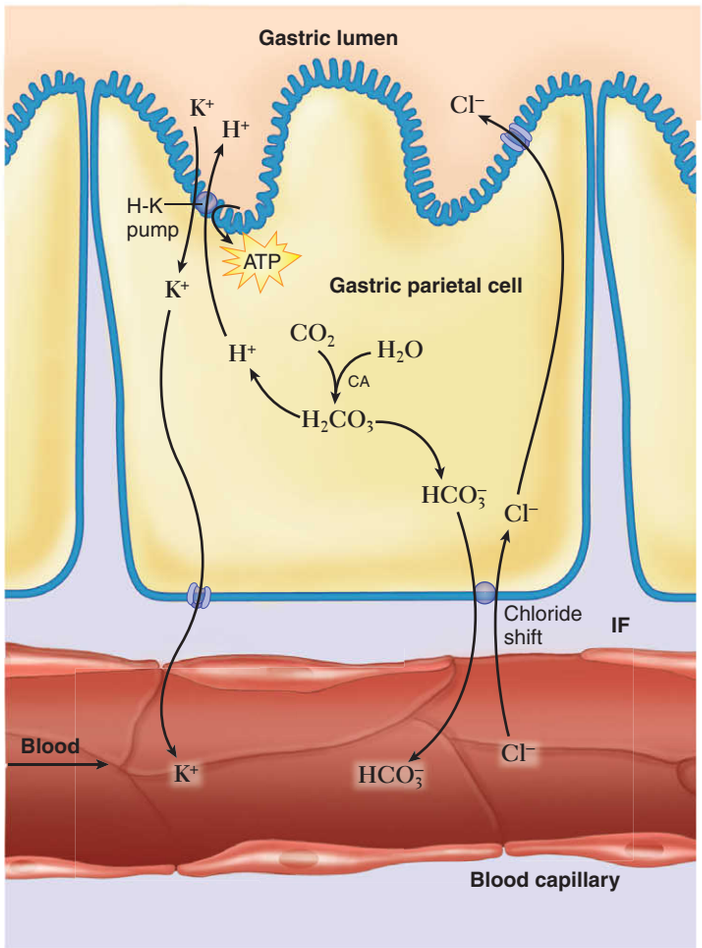

FIGURE 29-13

Acid secretion by gastric parietal cells. In this simplified diagram, you can see that hydrochloric acid (HCl) secretion by gastric parietal cells uses H^+ produced by the dissociation of carbonic acid (H_2CO_3). Recall that carbonic acid is produced by the reaction of water and carbon dioxide—a process enhanced by the enzyme carbonic anhydrase (CA). The chloride (Cl^-) of gastric HCl comes from a chloride shift into the cell in exchange for bicarbonate ions (HCO_3^-) produced by the same dissociation of carbonic acid that yielded the H^+. As Cl^- is shifted into the cell, the intracellular Cl^- concentration rises and produces a concentration gradient with the lumen of the gastric gland—forcing Cl^- to diffuse out of the parietal cell. The net effect is that active pumping of H^+ out of the cell by the H-K pump drives the concurrent shift of Cl^- into the cell from the blood and diffusion of Cl^- out of the cell and into the duct of the gastric gland. *IF,* Interstitial fluid.

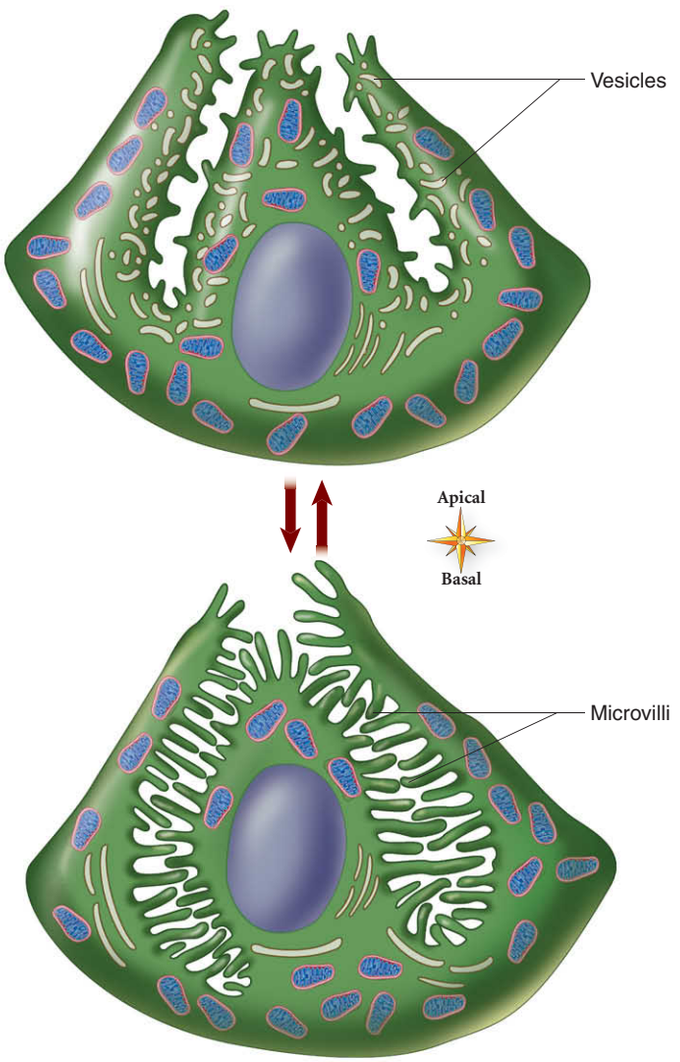

FIGURE 29-14

Parietal cell membrane surface. The surface of the resting parietal cell **(A)** can be enlarged by a factor of 100 when the cell becomes active and vesicles fuse to the apical surface of the cell **(B).** The vesicle membranes contain many ion pumps, carriers, and channels (Figure 29-13) that are thus added to the additional microvilli formed by fusion of the vesicle membrane to the plasma membrane.

Besides secreting acid, parietal cells also produce **intrinsic factor.** Intrinsic factor binds to molecules of vitamin B_{12}, protecting them from the acids and enzymes of the stomach. Intrinsic factor remains attached to B_{12} until it reaches the lower small intestine, where it facilitates the absorption of B_{12} across the intestinal wall (Figure 29-15). Vitamin B_{12}, you may recall, is essential for the production of new red blood cells. In pernicious anemia, caused by insufficient vitamin B_{12} in the body, the stomach may fail to make sufficient intrinsic factor (perhaps because of stomach cancer or ulcers). More frequently, however, an autoimmune mechanism produces antibodies that block the intrinsic factor from binding to vitamin B_{12}.

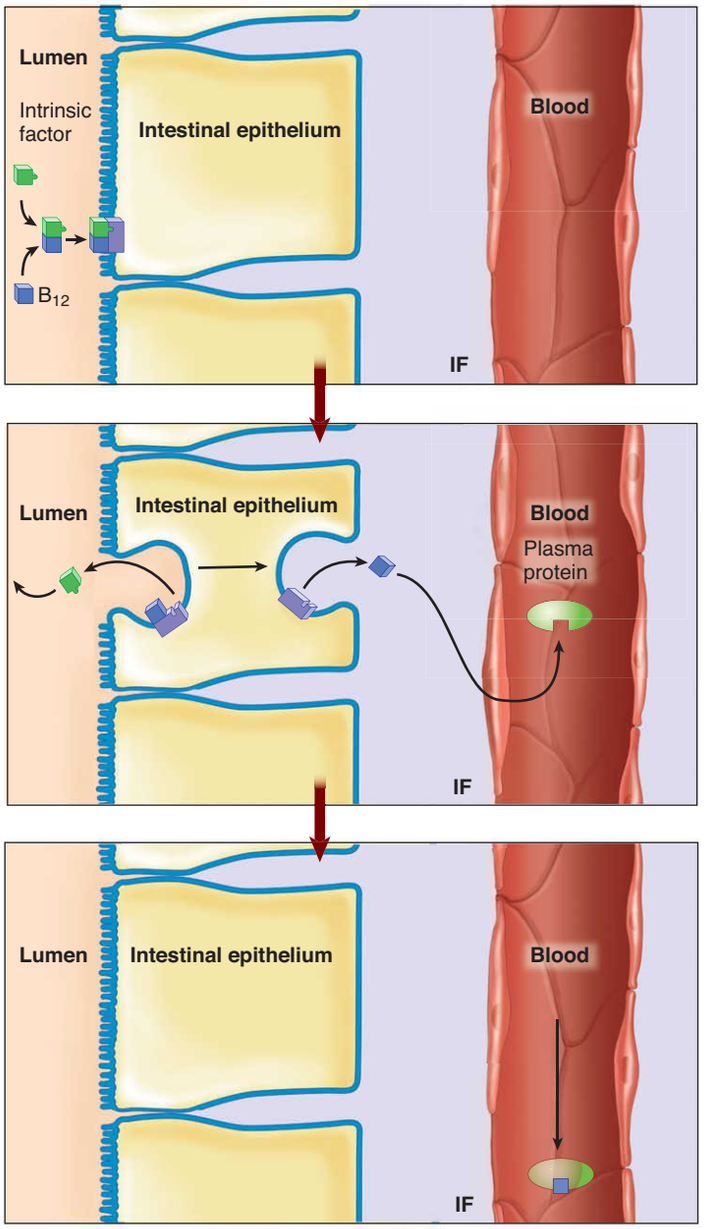

FIGURE 29-15

Role of intrinsic factor. As this series of sketches shows, intrinsic factor secreted from the stomach binds to vitamin B_{12}, which then permits the absorption of vitamin B_{12} into the bloodstream in the intestines. *IF,* Interstitial fluid.

Pancreatic Juice

Pancreatic juice is secreted by the exocrine *acinar cells* of the pancreas (see Figure 28-29 on p. 887). As with other digestive secretions, pancreatic juice is mostly water. In addition, pancreatic juice also contains various digestive enzymes. All of these enzymes are secreted as zymogens—inactive proenzymes. For example, protein-digesting **trypsin** is released as the zymogen **trypsinogen,** which is subsequently converted to active trypsin by **enterokinase** in the intestinal lumen. Enterokinase is an activating enzyme bound to the plasma membranes of cells that line the intestinal tract. After it is activated, trypsin can then activate other enzymes such as **chymotrypsin** (and other protein-digesting enzymes), various **lipases** (lipid-digesting enzymes), **nucleases** (RNA- and DNA-digesting enzymes), and **amylase** (a starch-digesting enzyme). Trypsin activates these molecules by an allosteric effect: it removes a specific sequence of amino acids from the proenzyme molecule, thus changing its shape to the active enzyme form. The advantage of this system is that the enzymes will not digest the cells that make them.

Cells along the exocrine ducts of the pancreas also have a secretory function. As Figure 29-16 shows, they produce sodium bicarbonate by more or less reversing the direction of the process described for acid secretion by gastric parietal cells and shown in Figure 29-13. In the pancreas, base (bicarbonate) is secreted into the GI lumen and acid is secreted into the blood—rather than the other way around, as in the stomach. This process thus provides a mechanism to neutralize the decreased pH of the chyme and the increased pH of the blood. As Figure 29-17 shows, the pH balance of the body is preserved and loss of homeostatic stability is avoided.

Bile

Bile is an interesting mixture of many different substances that is secreted by the liver and stored and concentrated by the gallbladder. As Figure 28-27 (on p. 885) shows, bile from the liver is conducted through the right and left hepatic ducts, which merge to form a common hepatic duct. The common hepatic duct, in turn, merges with the cystic duct from the gallbladder to form the common bile duct, which delivers bile to the duodenum through the major duodenal papilla.

Bile contains several substances that aid in digestion, specifically **lecithin** and **bile salts.** As we stated previously, both of these substances break down large drops of fat into smaller droplets, thus making the fats more easily digestible. Both lecithin and bile salts wrap a hydrophilic shell around the droplets, making them water soluble and therefore able to move freely through the watery chyme in the GI lumen. Bile also contains a small amount of sodium bicarbonate, which as with the sodium bicarbonate secreted by pancreatic duct cells, helps neutralize chyme.

Bile also contains several substances that are ultimately destined for removal from the body by becoming part of the feces that

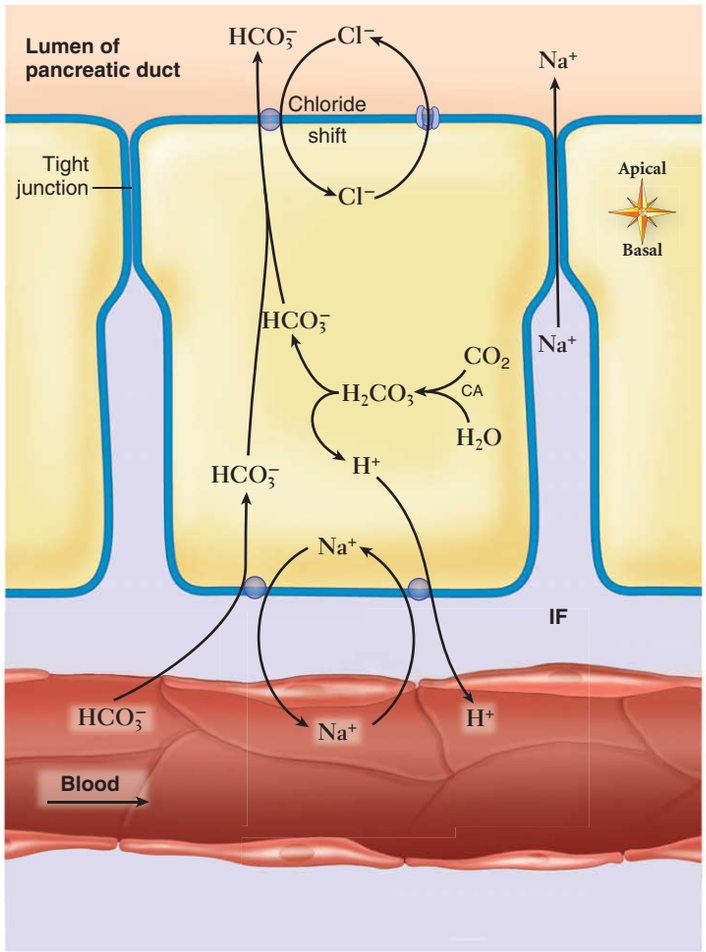

FIGURE 29-16

Bicarbonate secretion by pancreatic duct cells. In this simplified diagram, you can see that bicarbonate (HCO_3^-) secretion by cells of the pancreatic duct uses HCO_3^- produced by the dissociation of carbonic acid (H_2CO_3). Recall that carbonic acid is produced by the reaction of water and carbon dioxide—a process enhanced by the enzyme carbonic anhydrase (CA). Notice that a "reverse" chloride shift occurs as bicarbonate ions (HCO_3^-) are exchanged for Cl^- ions. The outward movement of negative bicarbonate ions into the lumen of the pancreatic ducts creates an electrical gradient that draws positive sodium ions (Na^+) from the IF (interstitial fluid), across the tight junctions, and into the pancreatic juice.

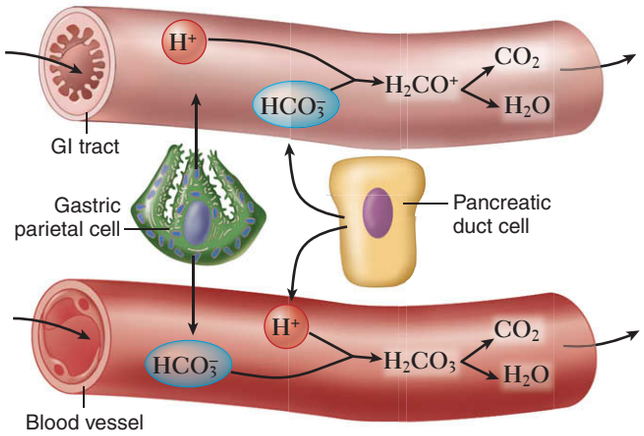

FIGURE 29-17

pH balance related to the digestive tract. Hydrochloric acid (HCl) secretion by gastric parietal cells moves H^+ into the gastrointestinal (GI) lumen, decreasing the pH of chyme. At the same time, gastric parietal cells shift bicarbonate ions (HCO_3^-) into the blood, increasing the pH of blood plasma. Eventually, this net loss of acid from the internal environment would cause alkalosis if not for the counterbalancing effects of bicarbonate secretion by the duct cells of the pancreas and other digestive glands such as the liver and intestinal glands. These cells secrete HCO_3^- into the GI lumen, increasing the pH of chyme, at the same time they move H^+ into the blood, decreasing the pH of blood back toward normal. This mechanism permits changes in the pH of chyme to facilitate the action of various enzymes without profoundly affecting the pH of the internal environment.

are eventually eliminated from the GI tract. It is therefore proper to state that these waste substances are actually *excretions*, a term that implies shedding waste, rather than *secretions*. Excreted substances in bile include cholesterol, products of detoxification, and bile pigments. The cholesterol in bile represents excess amounts of this lipid that have been picked up from body cells by lipoproteins and delivered to the liver for disposal in bile. Products of detoxification are formed in the liver as it renders toxic molecules harmless, a process called *detoxification*. Bile pigments, chiefly **bilirubin,** are products of hemolysis (the breakdown of old red blood cells) by the liver (see Figure 20-8 on p. 605). It is the bile pigments that are eventually eliminated from the GI tract that give feces its characteristic brownish color. Elimination of gray feces, therefore, can ordinarily be interpreted as a sign that bile secretion is abnormally low.

We discuss many functions of the liver further in the next chapter.

Intestinal Juice

The term **intestinal juice** refers to the sum total of intestinal secretions rather than to a premixed combination of substances that enters the GI lumen by way of a duct. Most intestinal cells produce a water-based solution of sodium bicarbonate. This adds to the buffering effect mentioned in previous paragraphs and illustrated in Figure 29-17. Goblet cells of the intestinal mucosa also produce a watery solution of mucus. Thus intestinal juice is a slightly basic, mucous solution that buffers and lubricates material in the intestinal lumen.

Intestinal juice is largely a product of the small intestine, but goblet cells in the mucosa of the large intestine produce some lubricating mucus.

TABLE 29-4 Digestive Secretions

DIGESTIVE JUICE	SOURCE	SUBSTANCE	FUNCTIONAL ROLE*
Saliva	Salivary glands	Mucus	*Lubricates bolus of food; facilitates mixing of food*
		Amylase (ptyalin)	**Enzyme; begins digestion of starches**
		Sodium bicarbonate	Increases pH (for optimum amylase function)
		Water	*Dilutes food and other substances; facilitates mixing*
Gastric juice	Gastric glands	Pepsin	**Enzyme; digests proteins**
		Hydrochloric acid	Denatures proteins; decreases pH (for optimum pepsin function)
		Intrinsic factor	**Protects and allows later absorption of vitamin B_{12}**
		Mucus	*Lubricates chyme; protects stomach lining*
		Water	*Dilutes food and other substances; facilitates mixing*
Pancreatic juice	Pancreas (exocrine portion)	Proteases (trypsin, chymotrypsin, collagenase, elastase, etc.)	**Enzymes; digest proteins and polypeptides**
		Lipases (lipase, phospholipase, etc.)	**Enzymes; digest lipids**
		Colipase	**Coenzyme; helps lipase digest fats**
		Nucleases	**Enzymes; digest nucleic acids (RNA and DNA)**
		Amylase	**Enzyme; digests starches**
		Water	*Dilutes food and other substances; facilitates mixing*
		Mucus	*Lubricates*
		Sodium bicarbonate	**Increases pH** (for optimum enzyme function)
Bile	Liver (stored and concentrated in gallbladder)	Lecithin and bile salts	*Emulsify lipids*
		Sodium bicarbonate	**Increases pH** (for optimum enzyme function)
		Cholesterol	Excess cholesterol from body cells, to be excreted with feces
		Products of detoxification	From detoxification of harmful substances by hepatic cells, to be excreted with feces
		Bile pigments (mainly bilirubin)	Products of breakdown of heme groups during hemolysis, to be excreted with feces
		Mucus	*Lubrication*
		Water	Dilutes food and other substances; facilitates mixing
Intestinal juice	Mucosa of small and large intestine	Mucus	*Lubrication*
		Sodium bicarbonate	**Increases pH** (for optimum enzyme function)
		Water	Small amount to carry mucus and sodium bicarbonate

***Boldface type** indicates a chemical digestive process; *italic type* indicates a mechanical process.

Table 29-4 lists various secretions of the digestive tract and their components.

| QUICK CHECK |

8. Name the primary components of saliva.
9. Name the components of gastric juice. Which type of cell produces each component?
10. Name as many pancreatic enzymes as you can.
11. What is excretion? What components of bile are excretions?

CONTROL OF DIGESTIVE GLAND SECRETION

Exocrine digestive glands secrete when food is present in the digestive tract or when it is seen, smelled, or imagined. Complicated nervous and hormonal reflex mechanisms control the flow of digestive juices in such a way that they appear in proper amounts when and for as long as needed.

Control of Salivary Secretion

As far as is known, only reflex mechanisms control the secretion of saliva. Chemical, mechanical, olfactory, and visual stimuli initiate afferent impulses to centers in the brainstem that send out efferent impulses to the salivary glands, stimulating them. Chemical and mechanical stimuli come from the presence of food in the mouth. Olfactory and visual stimuli come, of course, from the smell and sight of food.

Control of Gastric Secretion

Stimulation of gastric juice secretion occurs in three phases that are controlled by reflex and chemical mechanisms. Because stimuli that activate these mechanisms arise in the head, stomach, and intestines, the three phases are known as the cephalic, gastric, and

intestinal phases, respectively. As you read the description of each phase, glance at the diagrams shown in Figure 29-18.

The **cephalic phase** is also spoken of as the "psychic phase" because psychic (mental) factors activate the mechanism. For example, the sight, smell, taste, or even thought of food that is pleasing to an individual activates control centers in the medulla oblongata from which parasympathetic fibers of the vagus nerve conduct efferent impulses to the gastric glands. Vagal nerve impulses also stimulate the production of **gastrin,** a hormone secreted by endocrine *G cells* in the gastric mucosa.

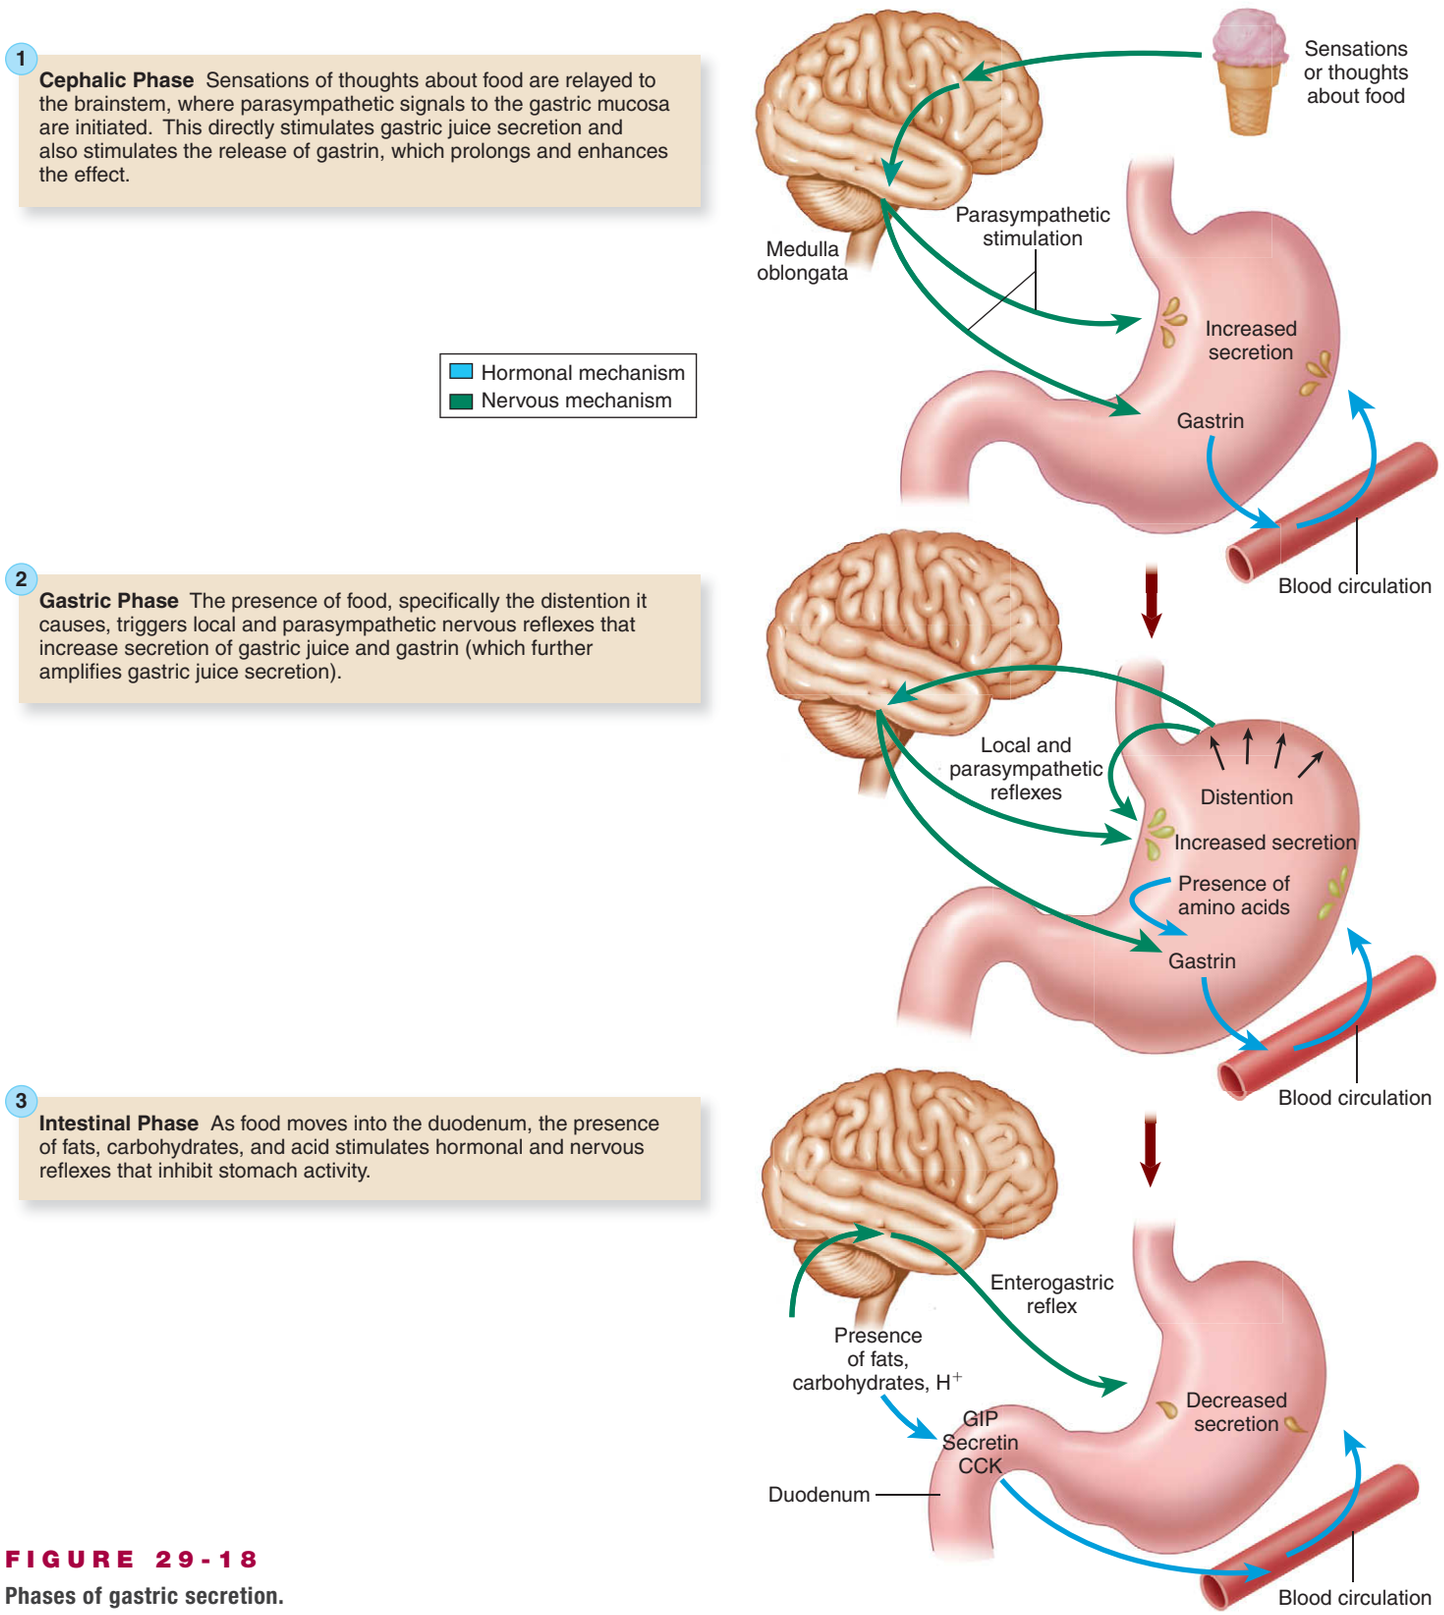

FIGURE 29-18
Phases of gastric secretion.

Gastrin stimulates gastric secretion, thus prolonging and enhancing the response.

During the **gastric phase** of gastric secretion, the following chemical control mechanism dominates. Products of protein digestion in foods that have reached the pyloric portion of the stomach stimulate its mucosa to release *gastrin* into the blood in stomach capillaries. When it circulates to the gastric glands, gastrin greatly accelerates their secretion of gastric juice, which has a high pepsinogen and hydrochloric acid content (Table 29-5). Hence, this seems to be a mechanism for ensuring that when food is in the stomach, there will be enough enzymes there to digest it. Gastrin release is also stimulated by distention of the stomach (caused by the presence of food), which activates local and parasympathetic reflexes in the pylorus.

The **intestinal phase** of gastric juice secretion is less clearly understood than the other two phases. Various different mechanisms seem to adjust gastric juice secretion as chyme passes to and through the intestinal tract. Experiments show that gastric secretions are inhibited when chyme containing fats, carbohydrates, and acid (low pH) is present in the duodenum. This probably occurs by means of endocrine reflexes that involve the hormones **gastric inhibitory peptide (GIP), secretin, CCK,** and perhaps several others. These hormones are secreted by endocrine cells in the mucosa of the duodenum. Gastric secretion may also be inhibited by the parasympathetic **enterogastric reflex.** We have discussed how this reflex inhibits gastric motility as food begins to fill the duodenum; now we see that it may inhibit gastric secretion as well.

In summary, we see that the rate of gastric secretion can be adjusted by nervous and endocrine reflex mechanisms in ways that improve the efficiency of the system. Anticipation of swallowing food causes the stomach to prepare itself by increasing its secretion of enzymes and acid. Thus food enters a stomach already partially filled with gastric juice. The rate of gastric secretion can then be adjusted according to the amount of food present and whether it contains proteins (the only food that can be chemically digested by gastric juice). Gastric secretion—and thus chemical digestion in the stomach—can be slowed when the duodenum becomes full. This prevents the stomach from finishing its task before the small intestine is ready to receive the chyme.

Control of Pancreatic Secretion

Several hormones released by the intestinal mucosa are known to stimulate pancreatic secretion. One of these hormones, *secretin*, evokes the production of pancreatic fluid low in enzyme content but high in bicarbonate (HCO_3^-). This alkaline fluid acts to neutralize the acid (chyme) entering the duodenum. As you might expect, the presence of acid in the duodenum serves as the most potent stimulator of secretin. (Additional control involving the same hormone is shown by the fact that fats in the duodenum also elicit secretin, which then influences the gallbladder to increase its ejection of the fat emulsifier bile.)

The other intestinal hormone, known as **CCK,** was originally thought to be two separate substances. It has now been identified as one chemical with several important functions: (1) it causes the pancreas to increase exocrine secretions high in enzyme content; (2) it opposes the influence of gastrin on gastric parietal cells, thus inhibiting hydrochloric acid secretion by the stomach; and (3) it stimulates contraction of the gallbladder so that bile can pass into the duodenum.

Control of Bile Secretion

Bile is secreted continually by the liver and is stored in the gallbladder until needed by the duodenum. The hormones secretin and CCK, as described, stimulate ejection of bile from the gallbladder (see Table 29-5).

Control of Intestinal Secretion

Relatively little is known about the regulation of intestinal exocrine secretions. Some evidence suggests that the intestinal mucosa, stimulated by hydrochloric acid and food products, releases hormones into the blood, including *vasoactive intestinal peptide* (VIP), which brings about increased production of intestinal juice. Intestinal secretions contain bicarbonate, which along with pancreatic bicarbonate, neutralizes acid from the stomach. Bicarbonate secretion is regulated by a reflex sensitive to changes in pH of the chyme. Presumably, neural mechanisms also help control the secretion of intestinal juice.

TABLE 29-5 Actions of Some Digestive Hormones Summarized

HORMONE	SOURCE	ACTION
Gastrin	Secreted by gastric mucosa in presence of partially digested proteins, when stimulated by the vagus nerve, or when the stomach is stretched	Stimulates secretion of gastric juice rich in pepsin and hydrochloric acid
Gastric inhibitory peptide (GIP)	Secreteded by intestinal mucosa in presence of glucose, fats, and perhaps other nutrients	Inhibits gastric secretion and motility; enhances insulin secretion by pancreas (see Chapter 30)
Secretin	Secreted by intestinal mucosa in presence of acid, partially digested proteins, and fats	Inhibits gastric secretion; stimulates secretion of pancreatic juice low in enzymes and high in alkalinity (bicarbonate); enhances effects of CCK
Cholecystokinin (CCK)	Secreted by intestinal mucosa in presence of fats, partially digested proteins, and acids	Stimulates ejection of bile from gallbladder and secretion of pancreatic juice high in enzymes; relaxes sphincters that regulate flow from the common bile duct; opposes the action of gastrin, raising the pH of gastric juice

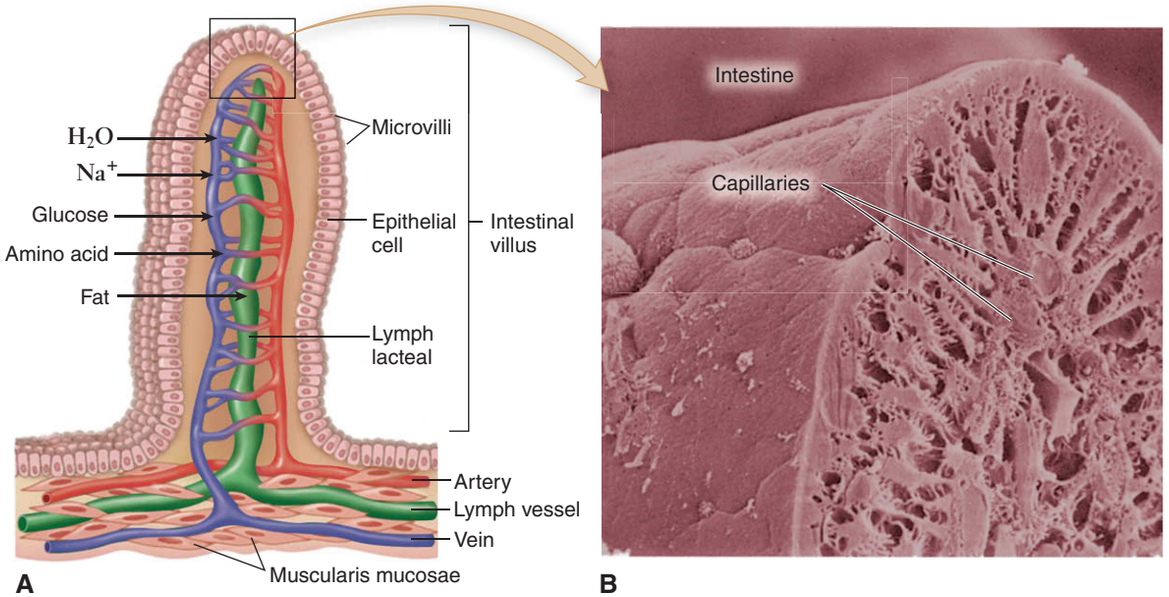

FIGURE 29-19

Intestinal villus. The presence of intestinal villi and microvilli increases the absorptive surface area of the intestinal mucosa. Most absorbed substances enter the blood in intestinal capillaries, with the exception of fat, which enters lymph by way of the intestinal lacteals.

| QUICK CHECK |

12. Name the three phases of gastric secretion.
13. What is the function of *gastric inhibitory peptide?*

ABSORPTION

Process of Absorption

Absorption is the passage of substances (notably digested foods, water, salts, and vitamins) through the intestinal mucosa into the blood or lymph. As stated earlier, most absorption occurs in the small intestine, where the large surface area provided by the intestinal villi and microvilli (Figure 29-19) facilitates this process.

Mechanisms of Absorption

Absorption of some substances, such as water, is simple and straightforward: diffusion, or more specifically, osmosis. However, some substances depend on more complex mechanisms to be absorbed. Sodium is a good example. Epithelial cells that form the outer wall of the villus (see Figure 29-19) constantly pump sodium from the GI lumen into the internal environment through a complex process called *secondary active transport* (see Box 4-3 on p. 93).

As Figure 29-20, A, shows, active transport carriers on the basal side, or "back side," of the cell continually pump Na^+ out of the cell. This mechanism maintains a low Na^+ concentration inside the cell. Thus it is likely that Na^+ in the GI lumen will diffuse

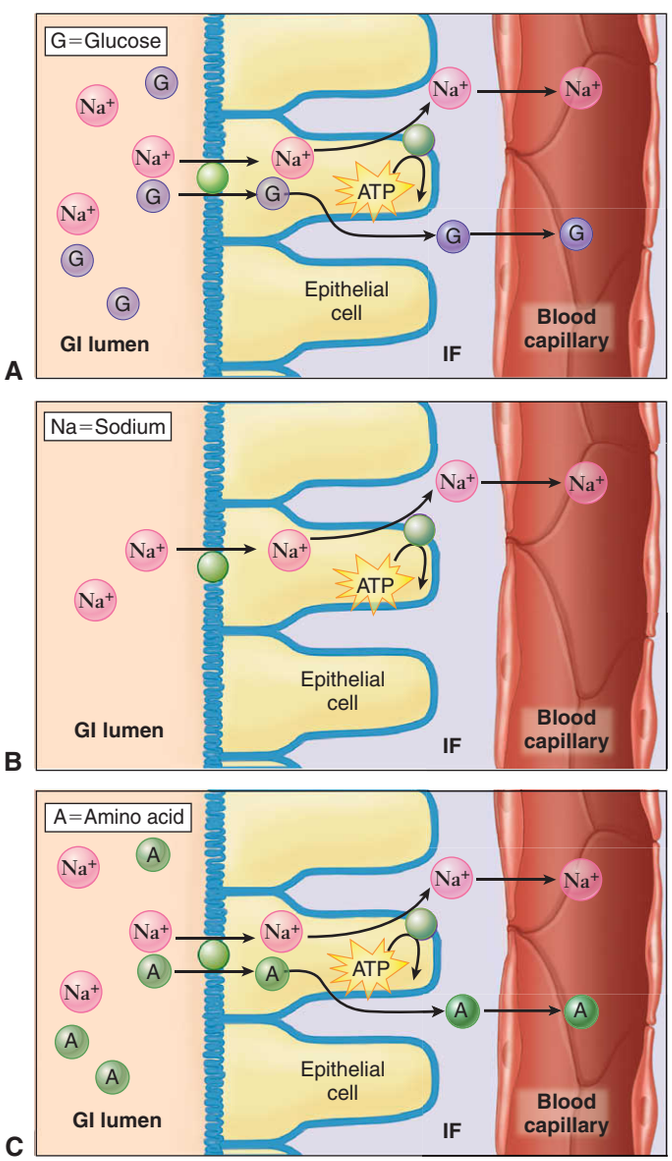

FIGURE 29-20

Absorption of glucose, sodium, and amino acids. Absorption of glucose **(A)**, sodium **(B)**, and amino acids **(C)** is a form of *secondary active transport* because each involves two carriers, one of which is active. The active carrier on the basal side of the epithelial cell maintains a sodium gradient, which facilitates passive transport of sodium, and perhaps another molecule, out of the gastrointestinal (GI) lumen via a passive carrier on the luminal side of the cell. *IF,* Interstitial fluid.

into the low-Na^+ cell. As Na^+ diffuses in through passive carriers in the cell's luminal surface, or "lumen side," it is removed by active transport pumps in the cell's basal membrane. In short, Na^+ moves out of the GI lumen only because it is being pumped from the other side of the intestinal cells.

Another good example of a complex transport process is that involving glucose. Though considered an "end product of digestion," glucose is a relatively large molecule and cannot pass freely through the brush border membrane of an intestinal mucosa cell. In addition to physical size, the lipid nature of the cell membrane (see Figure 3-3, p. 70) presents another barrier to glucose absorption. Molecules the size of glucose can pass freely (passively) through the lipid cell barrier only if they are lipid soluble (hydrophobic). Because glucose is too large physically and is hydrophilic (water soluble) in nature, it must be transported across the membrane by a carrier to enter the cell. In a process called **sodium cotransport** or coupled transport, carriers that bind both sodium ions and glucose molecules passively transport these molecules *together* out of the GI lumen (see Figure 29-20, *B*). However, this is another case of secondary active transport because this movement does not occur without the Na^+ concentration gradient maintained by the active transport of Na^+ out of the cell's basal membrane. Amino acids and several other compounds are thought to also be absorbed by such a secondary active transport mechanism (see Figure 29-20, *C*).

Other mechanisms of transporting glucose and amino acids across absorptive cells have also been proposed. One hypothesis suggests that these compounds are transported by passive carriers on both the apical surfaces (lumen side) and the basal surfaces of the absorptive cells. Another hypothesis suggests that the brush border enzymes also act as carriers. It should also be noted that some short polypeptides can diffuse by way of peptide carriers into absorptive cells where they are hydrolyzed into amino acids that can move into the blood.

Fatty acids and monoglycerides (products of fat digestion) and cholesterol are transported with the aid of lecithin and bile salts from fat droplets in the intestinal lumen to absorbing cells on villi. Lecithin and bile salts form microscopic spheres called **micelles,** which contain simple lipids (see Figure 29-12).

As Figure 29-21 shows, water-soluble micelles formed in the lumen of the intestine approach the brush border of absorbing cells. There, simple lipid molecules are released to pass through the plasma membrane (its phospholipid bilayer is receptive to lipids) by simple diffusion. After they are inside the cell, fatty acids are rapidly reunited with monoglycerides to form triglycerides (neutral fats). The final step in lipid transport by the intestine is the formation of **chylomicrons,** which are simply another type of micelle. Chylomicrons are formed by the Golgi apparatus of the absorptive cell. The water-soluble chylomicron allows fats to be transported through lymph and into the bloodstream (Table 29-6).

Vitamins A, D, E, and K, known as the "fat-soluble vitamins," also depend on bile salts for their absorption. Some water-soluble vitamins, such as certain of the B group, are small enough to be absorbed by simple diffusion; however, most require carrier-mediated transport. Many drugs (sedatives, analgesics, antibiotics) appear to be absorbed by simple diffusion because they are lipid soluble.

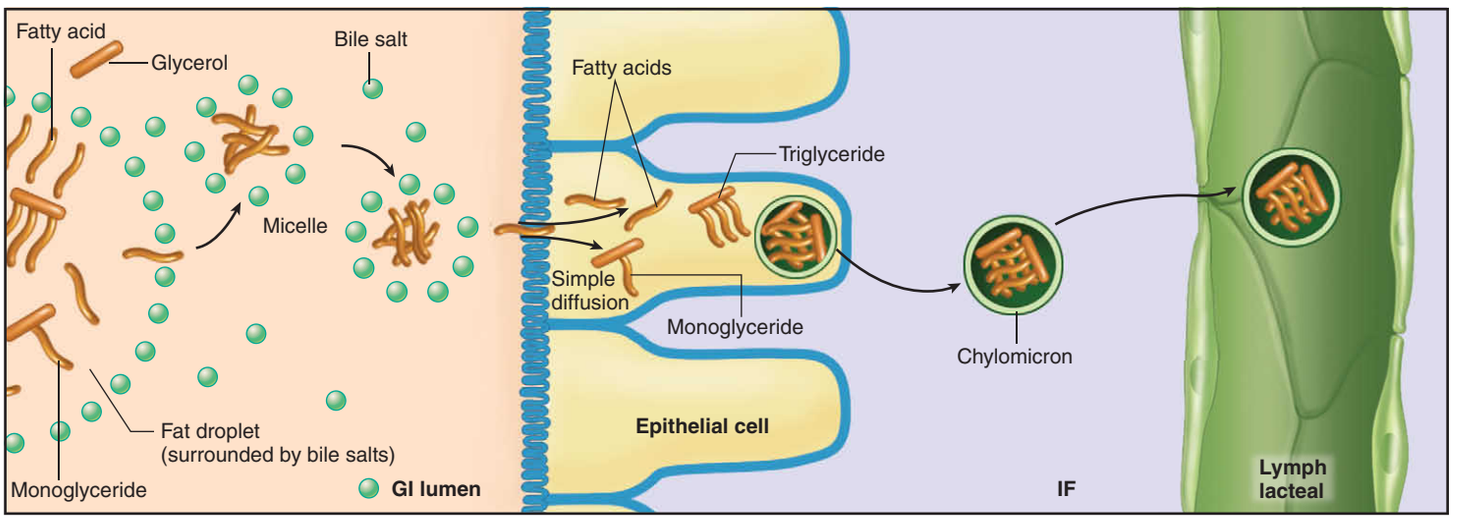

FIGURE 29-21

Absorption of fats. Fats such as triglycerides are chemically digested within emulsified fat droplets, yielding fatty acids, monoglycerides, and glycerol *(left).* Fatty acids and other lipid-soluble compounds (such as cholesterol) leave the fat droplets in small spheres coated with bile salts (micelles). When a micelle reaches the plasma membrane of an absorptive cell, individual fat-soluble molecules diffuse directly into the cytoplasm. The endoplasmic reticulum of the cell resynthesizes fatty acids and monoglycerides into triglycerides. A Golgi body within the cell packages the fats into water-soluble micelles called chylomicrons, which then exit the absorptive cell by exocytosis and enter a lymphatic lacteal. *IF,* Interstitial fluid.

TABLE 29-6 Food Absorption

FORM ABSORBED	STRUCTURES INTO WHICH ABSORBED	CIRCULATION
Protein—as amino acids Perhaps minute quantities of some short-chain polypeptides and whole proteins are absorbed; for example, some antibodies	Blood in intestinal capillaries	Portal vein, liver, hepatic vein, inferior vena cava to heart, and so on
Carbohydrates—as simple sugars	Same as amino acids	Same as amino acids
Fats		
Glycerol and monoglycerides	Lymph in intestinal lacteals	During absorption, that is, while in epithelial cells of intestinal mucosa, glycerol and fatty acids recombine to form microscopic packages of fats (chylomicrons); lymphatics carry them by way of thoracic duct to left subclavian vein, superior vena cava, heart, and so on; some fats are transported by blood in form of phospholipids or cholesterol esters
Fatty acids combine with bile salts to form water-soluble substance	Lymph in intestinal lacteals	
Some finely emulsified, undigested fats absorbed	Small fraction enters intestinal blood capillaries	

Note that after absorption, most nutrients do not pass directly into the general circulation. Lacteals conduct fats along a series of lymphatic vessels and through many lymph nodes before releasing them into the venous blood flowing through the left subclavian vein (see Figure 20-2, p. 600). Nutrients that are absorbed into the blood, such as amino acids and monosaccharides, first travel by way of the hepatic portal system to the liver (see Figure 21-32, p. 665). After absorption, blood entering the liver via the portal vein contains greater concentrations of glucose and other nutrients than does blood leaving the liver via the hepatic vein for the systemic circulation. Clearly, much of the excess of these food substances over and above normal blood levels has remained behind in the liver. What the liver does with them is part of the story of nutrition and metabolism, our topic for discussion in the next chapter.

The types of absorption discussed thus far involve *transcellular absorption*. In transcellular (meaning "across cells") absorption, particles are absorbed into the interior of the cell before moving out of the cell and into blood or lymph. Another type of absorption called *paracellular absorption* can also occur. In this type of absorption, small amounts of glucose, minerals, and even small peptides can move *between* the absorptive cells rather than through them. Paracellular absorption requires no energy expenditure by cells.

Figure 29-22 summarizes the locations where absorption of some important substances takes place. Notice that although the stomach can absorb a small amount of alcohol, almost all other absorption takes place in the intestines—particularly the small intestine.

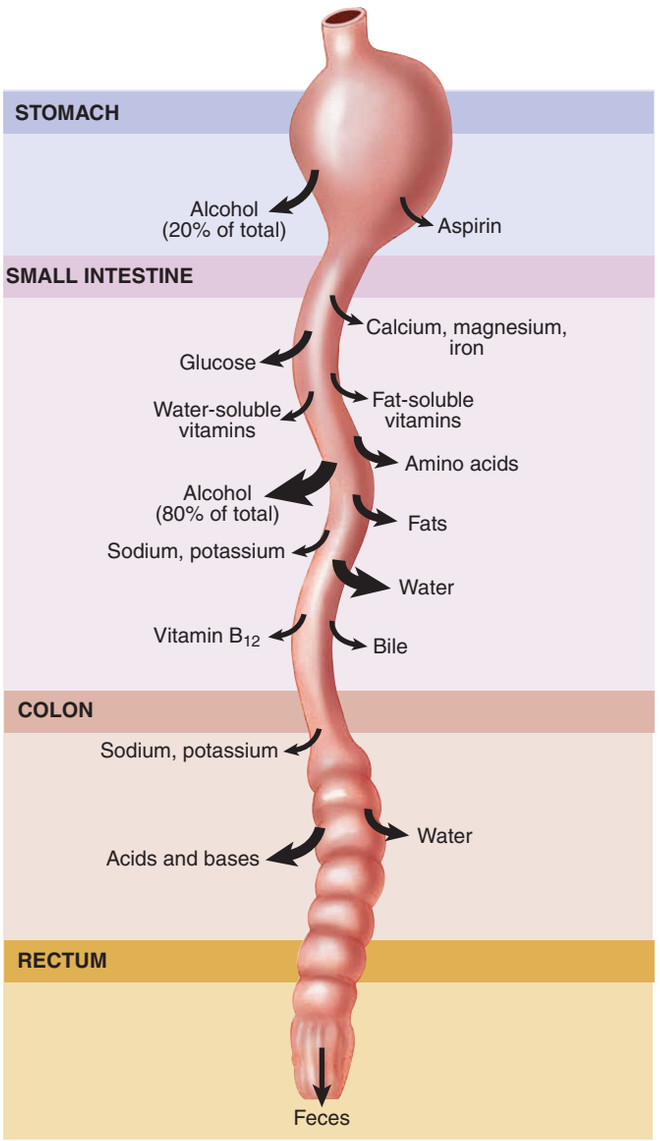

FIGURE 29-22

Absorption sites in the digestive tract. The size of the arrow at each site indicates the relative amount of absorption of a particular substance at that site. Notice that most absorption occurs in the intestines, particularly the small intestine.

ELIMINATION

The process of **elimination** is simply the expulsion of the residues of digestion—*feces*—from the digestive tract. Formation and storage of feces is the primary function of the colon. The act of expelling feces is called **defecation.**

Defecation is a reflex brought about by stimulation of receptors in the rectal mucosa. Normally, the rectum is empty until mass peristalsis moves fecal matter out of the colon into the rectum. This distends the rectum and produces the desire to defecate. Also, it stimulates colonic peristalsis and initiates reflex relaxation of the internal sphincter of the anus. Voluntary straining efforts and relaxation of the external anal sphincter may then follow as a result of the desire to defecate. Together, these several responses bring about defecation (Figure 29-23). Note that this is a reflex partly under voluntary control. If one voluntarily inhibits defecation, the rectal receptors soon become depressed and the urge to defecate does not usually recur until hours later, when mass peristalsis again takes place.

Constipation occurs when the contents of the distal part of the colon and rectum move at a rate that is slower than normal. What is normal can range from three times a day to three times a week, depending on a variety of factors such as the amount, type, and rate of food eaten. When motility in the distal colon and rectum slows significantly, extra water is absorbed from the fecal mass, producing a hardened stool.

Diarrhea may occur as a result of increased motility of the small intestine. Chyme moves through the small intestine too quickly, reducing the amount of absorption of water and electrolytes. Diarrhea may also result from bacterial toxins that damage the water reabsorption mechanisms of the intestinal mucosa. The large volume of material arriving in the large intestine exceeds the limited capacity of the colon for absorption, so a watery stool results. Prolonged diarrhea can be particularly serious, even fatal, in infants because they have a minimal reserve of water and electrolytes (Box 29-7).

| QUICK CHECK |

14. Explain the term *secondary active transport.*
15. Describe how fatty acids are absorbed by cells of the GI mucosa.
16. What triggers the defecation reflex?

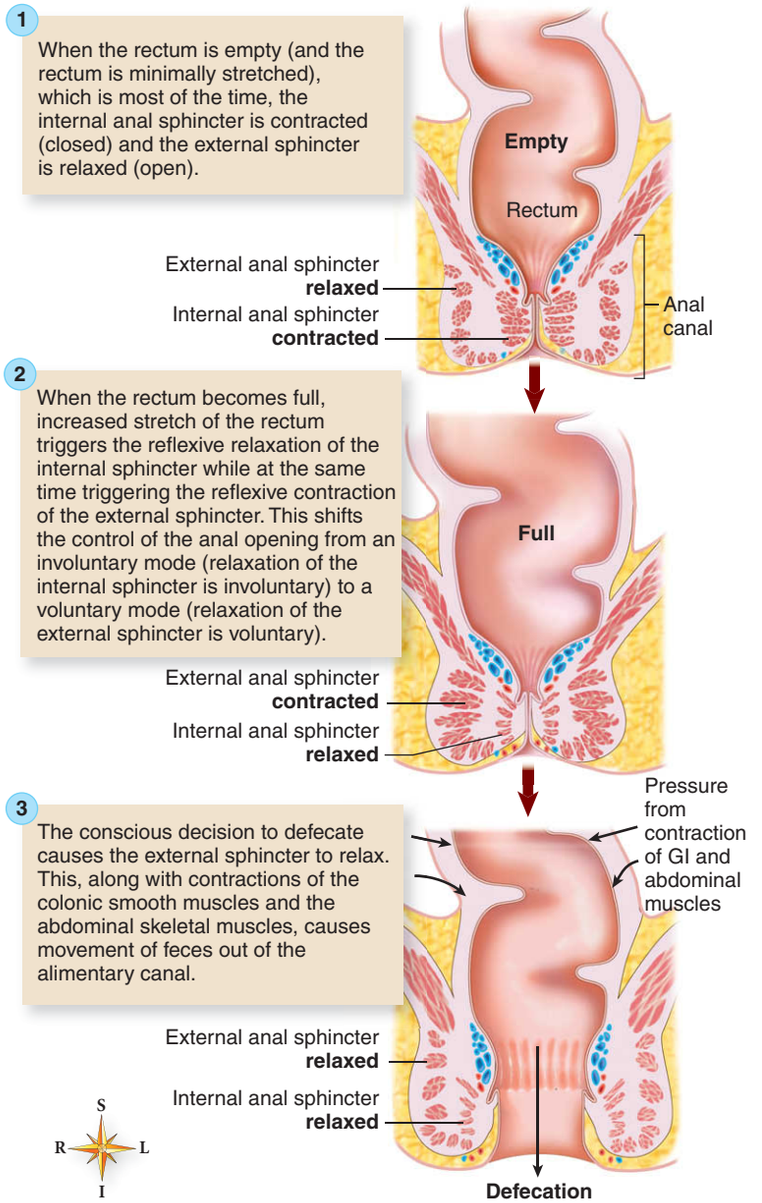

FIGURE 29-23

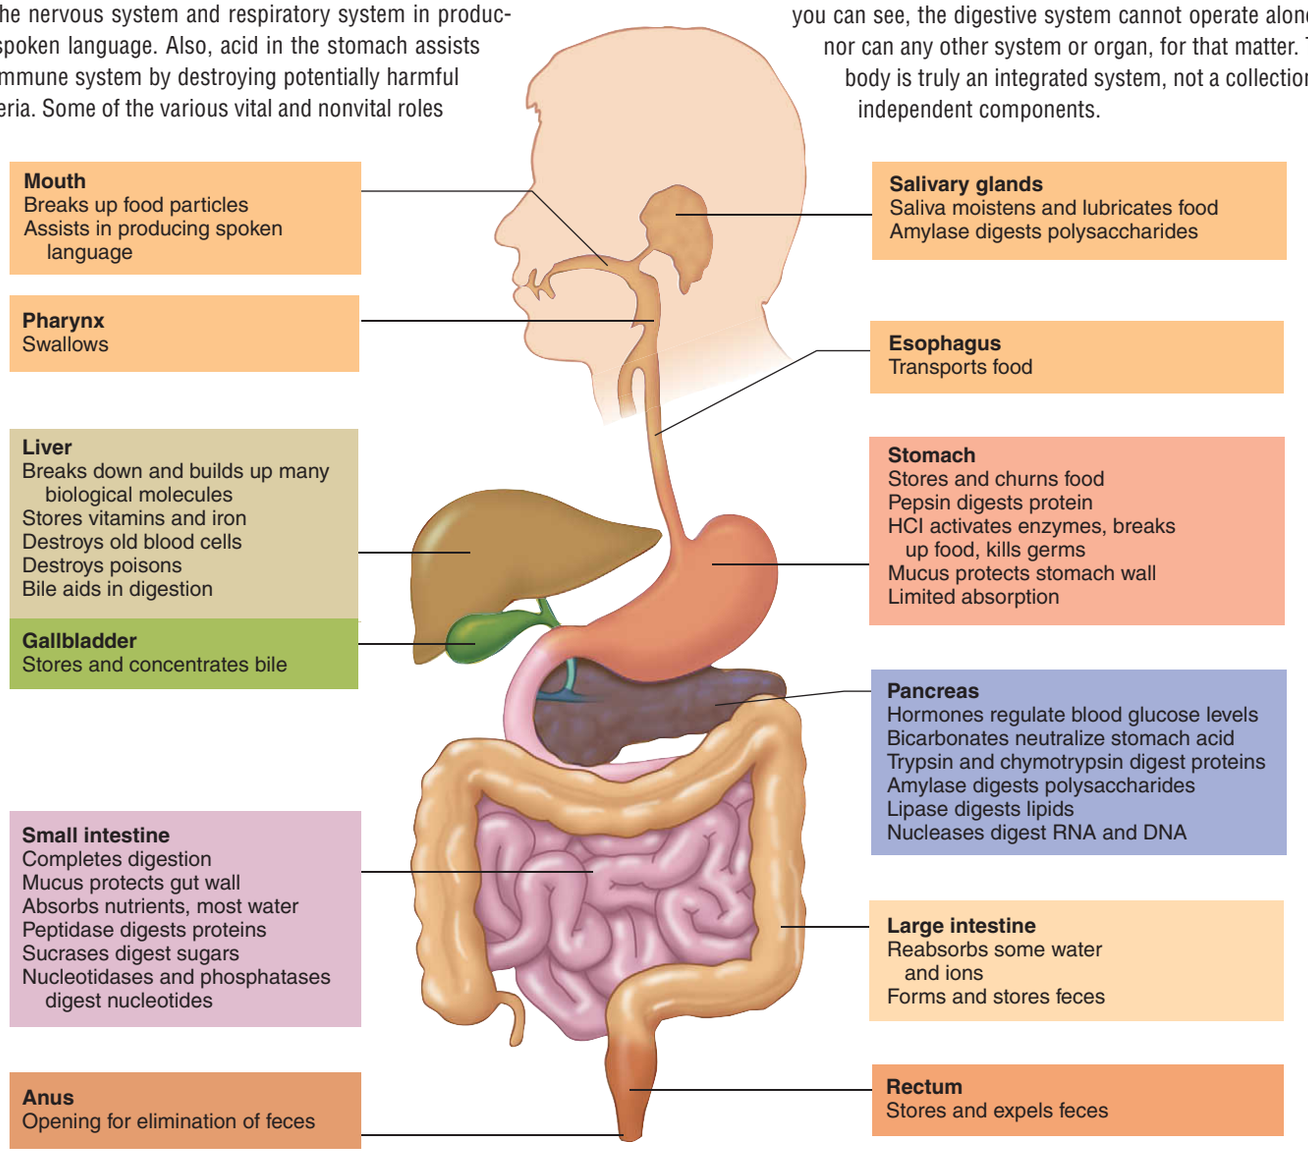
Defecation. The sketches show the role of the anal sphincters in defecation.

Box 29-7 | HEALTH matters

Infant Diarrhea

Severe diarrhea caused by a *rotavirus,* an intestinal infection, kills more than 600,000 infants and young children worldwide each year. Death results from severe dehydration caused by 20 or more episodes of diarrhea in a single day. More than 3 million U.S. children suffer symptoms of rotavirus intestinal infection annually and 65,000 require hospitalization. Good medical care in this country has limited the number of U.S. infant deaths caused by the disease each year to about 50. Unfortunately, in developing countries, rotavirus-induced diarrhea remains one of the leading causes of infant mortality. The first major attempt at a rotavirus vaccine provided good protection against the virus but was withdrawn from the world market at the close of the 20th century because of side effects. New rotavirus vaccines are now available and others are in the final stages of testing. Some have already been licensed outside the United States.



Until safe and effective vaccines become widely available, one of the best treatment options available in many areas of the world involves oral administration of liberal doses of a simple, easily prepared solution containing sugar and salt. Called **oral rehydration therapy (ORT),** the salt-sugar solution replaces nutrients and electrolytes lost in diarrheal fluid. Because the replacement fluid can be prepared from readily available and inexpensive ingredients, it is particularly valuable in the treatment of infant diarrhea in developing countries.

the BIG picture

Digestion and the Whole Body

The process of digestion, as with any other vital function, provides a means of survival for the entire body and also requires the function of other systems. The digestive system's primary contribution to overall homeostasis is its ability to maintain a constancy of nutrient concentration in the internal environment. It accomplishes this by breaking large, complex nutrients into smaller, simpler nutrients so they can be absorbed (see figure). The digestive system also provides the means of absorption—the cellular mechanisms that operate in the absorptive cells of the intestinal mucosa. The digestive system also provides some secondary, less vital functions. For example, the teeth and tongue aid the nervous system and respiratory system in producing spoken language. Also, acid in the stomach assists the immune system by destroying potentially harmful bacteria. Some of the various vital and nonvital roles played by the different organs that make up the digestive system are summarized in the "Summary of digestive function" figure.

To accomplish its functions, the digestive system requires functional contributions by other systems of the body. Regulation of digestive motility and secretion requires the active participation of both the nervous system and the endocrine system. The oxygen needed for digestive activity requires the proper functioning of both the respiratory system and the circulatory system. The body's framework (integumentary and skeletal systems) is required to support and protect the digestive organs. The skeletal muscles must function if ingestion, mastication, deglutition, and defecation are to occur normally. As you can see, the digestive system cannot operate alone—nor can any other system or organ, for that matter. The body is truly an integrated system, not a collection of independent components.

Summary of digestive function.

CASE study

Clarence had been cooking all day, getting Thanksgiving dinner ready for the whole family. After dinner, he bent over to pick up a serving dish and felt a sharp, stabbing pain in the right upper back just below his shoulder blade. The pain was so intense, he could hardly breathe. It lasted for about 20 minutes, then slowly dissipated to a dull ache. Having a history of back pain, he thought he had injured the same area again.

The following Monday, Clarence's doctor scheduled an MRI (magnetic resonance image) to look at his spine. The test results showed nothing wrong with the skeletal system—no misalignment in the spine. There was also no change in the pain with movement. The dull ache in Clarence's back remained constant, regardless of whether he was moving about or sitting still. A urinalysis came back normal.

Over the next few days, the pain receded considerably. Then one night not long after, Clarence had fried chicken and gravy for dinner. About 10 minutes after eating, the stabbing pain returned. At this point, he remembered that he had eaten a lot of gravy at Thanksgiving too. Both types of gravy were very high in fat content.

1. Taking all the information into account, what system do you think may be malfunctioning to cause the pain?
   a. Skeletal system
   b. Muscular system
   c. Digestive system
   d. Urinary system
2. Which of the following hormones is NOT released in response to fatty, acidic chyme entering the duodenum?
   a. Gastrin
   b. CCK
   c. Secretin
   d. GIP
3. After eating foods high in fat, Clarence's body may increase the production and release of bile. Bile is stored in which organ?
   a. Liver
   b. Pancreas
   c. Stomach
   d. Gallbladder

HINT *Scan this summary after reading the chapter to help you reinforce the key concepts. Later, use the summary as a quick review before your class or before a test.*

OVERVIEW OF DIGESTIVE FUNCTION

A. Primary function of the digestive system—to bring essential nutrients into the internal environment so that they are available to each cell of the body
B. Mechanisms used to accomplish the primary function of the digestive system (Figure 29-1)
   1. Ingestion—food is taken in
   2. Digestion—breakdown of complex nutrients into simple nutrients
   3. Motility of the GI wall—physically breaks down large chunks of food material and moves food along the tract
   4. Secretion—digestive enzyme secretion facilitates chemical digestion
   5. Absorption—movement of nutrients through the GI mucosa into the internal environment
   6. Elimination—excretion of material that is not absorbed
   7. Regulation—coordination of the various functions of the digestive system
C. The digestive tract is functionally an extension of the external environment—material does not truly enter the body until it is absorbed into the internal environment

DIGESTION

A. Mechanical digestion—movements of the digestive tract
   1. Change ingested food from large particles into minute particles, facilitating chemical digestion
   2. Churn contents of the GI lumen to mix with digestive juices and ensure contact with the surface of the intestinal mucosa, facilitating absorption
   3. Propel food along the alimentary tract, eliminating digestive waste from the body
   4. Mastication—chewing movements
      a. Reduces size of food particles
      b. Mixes food with saliva in preparation for swallowing
   5. Deglutition—process of swallowing; complex process requiring coordinated and rapid movements (Figure 29-2)
      a. Oral stage (mouth to oropharynx)—voluntarily controlled; formation of a food bolus in the middle of

the tongue; tongue presses bolus against the palate and food is then moved into the oropharynx
b. Pharyngeal stage (oropharynx to esophagus)—involuntary movement; to propel bolus from the pharynx to the esophagus, the mouth, nasopharynx, and larynx must be blocked; a combination of contractions and gravity move bolus into esophagus
c. Esophageal stage (esophagus to stomach)—involuntary movement; contractions and gravity move bolus through esophagus and into stomach

6. Peristalsis and segmentation—two main types of motility produced by the smooth muscle of the GI tract; can occur together, in an alternating fashion
a. Peristalsis—wavelike ripple of the muscle layer of a hollow organ; progressive motility that produces forward movement of matter along the GI tract (Figures 29-3 and 29-4)
b. Segmentation—mixing movement; digestive reflexes cause a forward-and-backward movement with a single segment of the GI tract; helps break down food particles, mixes food and digestive juices, and brings digested food in contact with intestinal mucosa to facilitate absorption (Figure 29-5)

7. Regulation of motility
a. Gastric motility
(1) Food in the stomach is churned (propulsion and retropulsion) and mixed with gastric juices to form chyme
(2) Chyme is ejected about every 20 seconds into the duodenum; emptying the stomach takes approximately 2 to 6 hours
b. Gastric emptying controlled by hormonal and nervous mechanisms (Figure 29-6)
(1) Hormonal mechanism—fats in duodenum stimulate the release of gastric inhibitory peptide, which acts to decrease peristalsis of gastric muscle and slows passage of chyme into duodenum
(2) Nervous mechanism—enterogastric reflex; receptors in the duodenal mucosa are sensitive to presence of acid and to distention; impulses over sensory and motor fibers in the vagus nerve cause a reflex inhibition of gastric peristalsis

8. Intestinal motility—includes peristalsis and segmentation
a. Segmentation in duodenum and upper jejunum mixes chyme with digestive juices from the pancreas, liver, and intestinal mucosa
b. Peristalsis rate picks up as chyme approaches end of jejunum, moving it through small intestine into the large intestine
c. After leaving stomach, passage of chyme all the way through the small intestine takes approximately 5 hours
d. Peristalsis regulated in part by intrinsic stretch reflexes; stimulated by cholecystokinin (CCK)

B. Chemical digestion—all changes in chemical composition of food as it travels through the digestive tract

1. Chemical changes result from hydrolysis—process in which compound unites with water and breaks down further
2. Digestive enzymes—extracellular, organic (protein) catalysts
a. Operate in lumen of digestive tract, outside of any body cells
b. Properties of digestive enzymes
(1) Specific in their action (Figure 29-7)
(2) Function optimally at a specific pH (Figure 29-8)
(3) Most enzymes catalyze a chemical reaction in both directions
(4) Enzymes are continually being destroyed or eliminated from the body and must continually be synthesized
(5) Most digestive enzymes are synthesized as inactive proenzymes

3. Carbohydrate digestion (Figure 29-9)
a. Carbohydrates are saccharide compounds
b. Polysaccharides are hydrolyzed by amylases to form disaccharides
c. Final steps of carbohydrate digestion are catalyzed by sucrase, lactase, and maltase, found in the cell membrane of epithelial cells covering the villi that line the intestinal lumen

4. Protein digestion (Figure 29-10)
a. Protein compounds are made up of twisted chains of amino acids
b. Proteases catalyze hydrolysis of proteins into intermediate compounds and, finally, into amino acids
c. Main proteases: pepsin in gastric juice, trypsin in pancreatic juice, peptidases in intestinal brush border

5. Fat digestion (Figure 29-12)
a. Fats must be emulsified by bile in small intestine before being digested (Figure 29-11)
b. Pancreatic lipase is the main fat-digesting enzyme

6. Residues of digestion—some compounds of food resist digestion and are eliminated as feces

SECRETION

A. Saliva—secreted by salivary glands
1. Mucus lubricates food and, with water, facilitates mixing
2. Amylase—an enzyme that begins digestion of starches
a. A small amount of salivary lipase is released; function uncertain
b. Sodium bicarbonate increases the pH for optimum amylase function

B. Gastric juice—secreted by gastric glands
1. Pepsin (secreted as inactive pepsinogen by chief cells)—a protease that begins the digestion of proteins
2. Hydrochloric acid (HCl, secreted by parietal cells)
a. HCl decreases the pH of chyme for activation and optimum function of pepsin (Figure 29-13)
b. Released actively into the gastric juice by H-K pumps (proton pumps)
c. Vesicles in the resting parietal cell move to the apical surface when the cell becomes active—thus increasing

the surface area for the process of secretion (Figure 29-14)
3. Intrinsic factor (secreted by parietal cells) protects vitamin B_{12} and later facilitates its absorption (Figure 29-15)
4. Mucus and water lubricate, protect, and facilitate mixing of chyme (Table 29-4)

C. Pancreatic juice—secreted by acinar and duct cells of the pancreas
1. Proteases (e.g., trypsin and chymotrypsin)—enzymes that digest proteins and polypeptides
2. Lipases—enzymes that digest emulsified fats
3. Nucleases—enzymes that digest nucleic acids such as DNA and RNA
4. Amylase—an enzyme that digests starches
5. Sodium bicarbonate increases the pH for optimum enzyme function; its manufacture also helps restore normal pH of blood (Figures 29-16 and 29-17)

D. Bile—secreted by the liver; stored and concentrated in the gallbladder
1. Lecithin and bile salts emulsify fats by encasing them in shells to form tiny spheres called *micelles*
2. Sodium bicarbonate increases pH for optimum enzyme function
3. Cholesterol, products of detoxification, and bile pigments (e.g., bilirubin) are waste products excreted by the liver and eventually eliminated in the feces

E. Intestinal juice—secreted by cells of intestinal exocrine cells
1. Mucus and water lubricate and aid in continued mixing of chyme
2. Sodium bicarbonate increases pH for optimum enzyme function

CONTROL OF DIGESTIVE GLAND SECRETION

A. Salivary secretion
1. Only reflex mechanisms control the secretion of saliva
2. Chemical and mechanical stimuli come from the presence of food in the mouth
3. Olfactory and visual stimuli come from the smell and sight of food

B. Gastric secretion—three phases (Figure 29-18)
1. Cephalic phase—"psychic phase," because mental factors activate the mechanism; parasympathetic fibers in branches of the vagus nerve conduct stimulating efferent impulses to the glands; stimulate production of gastrin (by G cells in the stomach)
2. Gastric phase—when products of protein digestion reach the pyloric portion of the stomach, they stimulate release of gastrin; gastrin accelerates secretion of gastric juice, ensuring enough enzymes are present to digest food
3. Intestinal phase—various mechanisms seem to adjust gastric secretion as chyme passes to and through the intestinal tract; endocrine reflexes involving gastric inhibitory peptide, secretin, and CCK inhibit gastric secretions

C. Pancreatic secretion—stimulated by several hormones released by intestinal mucosa
1. Secretin evokes production of pancreatic fluid low in enzyme content but high in bicarbonate
2. CCK—several functions
   a. Causes increased exocrine secretion from the pancreas
   b. Opposes gastrin, thus inhibiting gastric HCl secretion
   c. Stimulates contraction of the gallbladder so that bile is ejected into the duodenum

D. Bile secretion—bile secreted continually by the liver; secretin and CCK stimulate ejection of bile from the gallbladder

E. Intestinal secretion—little known about how intestinal secretion is regulated; suggested that the intestinal mucosa is stimulated to release hormones that increase the production of intestinal juice

ABSORPTION

A. Process of absorption
1. Passage of substances through the intestinal mucosa into the blood or lymph (Figure 29-19)
2. Most absorption occurs in the small intestine

B. Mechanisms of absorption
1. For some substances such as water, absorption occurs by simple diffusion or osmosis
2. Other substances are absorbed through more complex mechanisms (Figures 29-20 and 29-21)
   a. Secondary active transport—how sodium is transported
   b. Sodium cotransport (coupled transport)—how glucose and amino acids are transported
   c. Fatty acids, monoglycerides, and cholesterol are transported with the aid of bile salts from the lumen to absorbing cells of the villi
3. Transcellular absorption moves nutrient particle *through* cells (as described above) and paracellular absorption moves particles *between* cells
4. After food is absorbed, it travels to the liver via the portal system
5. In summary, most absorption occurs in the small intestine (Figure 29-22)

ELIMINATION

A. Definition—expulsion of feces from the digestive tract; referred to as *defecation*

B. Defecation—results from a reflex brought about by stimulation of receptors in the rectal mucosa that is produced when the rectum is distended (Figure 29-23)

C. Constipation—contents of the lower part of the colon and rectum move at a slower than normal rate; extra water is absorbed from the feces, resulting in a hardened stool

D. Diarrhea—result of increased motility of the small intestine, causing decreased absorption of water and electrolytes and a watery stool

THE BIG PICTURE: DIGESTION AND THE WHOLE BODY

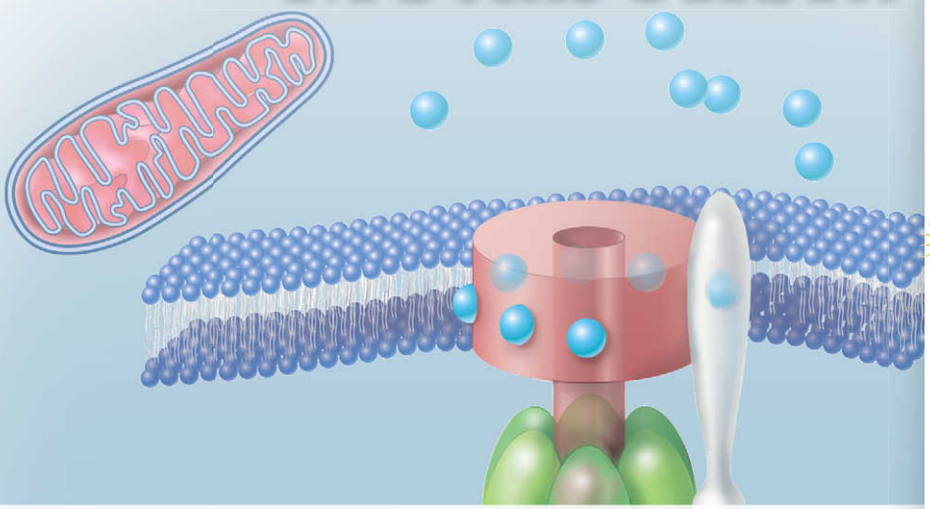
A. Primary contribution of the digestive system to overall homeostasis is to provide a constant nutrient concentration in the internal environment
B. Secondary roles of digestive system
   1. Absorption of nutrients
   2. Teeth and tongue, along with respiratory and nervous system, are important in producing spoken language
   3. Gastric acids aid the immune system by destroying potentially harmful bacteria
C. To accomplish its functions, digestive system needs other systems to contribute
   1. Regulation of digestive motility and secretion requires the nervous system and endocrine system
   2. Oxygen for digestive activity is dependent on proper functioning of the respiratory and circulatory systems
   3. Integumentary and skeletal systems support and protect the digestive organs
   4. Muscular system is needed for ingestion, mastication, deglutition, and defecation to occur normally

REVIEW QUESTIONS

Write out the answers to these questions after reading the chapter and reviewing the Chapter Summary. If you simply think through the answer without writing it down, you won't retain much of your new learning.

1. List four of the mechanical processes that occur during digestion.
2. List the three steps, or stages, in deglutition.
3. Discuss the function of the deglutition center in the medulla.
4. How does gastric inhibitory peptide influence emptying of the stomach? What is the enterogastric reflex?
5. Discuss the functional roles of gastric juice.
6. What is chyme?
7. Describe the classification of digestive enzymes.
8. Discuss three important properties of digestive enzymes.
9. What substances chemically digest proteins? Carbohydrates? Fats?
10. What is meant by the term *cephalic phase* of gastric secretion? *Gastric phase? Intestinal phase?*
11. What digestive functions does the pancreas perform?
12. Describe the absorption of glucose from the lumen of the small intestine.
13. What vitamins depend on bile salts for their absorption?
14. Name each hormone that controls ejection of bile, stimulation of gastric enzymes, inhibition of gastric emptying, secretion of alkaline fluid from pancreas, and secretion of pancreatic enzymes.
15. Discuss responses that collectively result in defecation.
16. Describe the treatment called *oral rehydration therapy.*

CRITICAL THINKING QUESTIONS



After finishing the Review Questions, write out the answers to these more in-depth questions to help you apply your new knowledge. Go back to sections of the chapter that relate to concepts that you find difficult.

1. In terms of homeostatic balance in the body, what is the function of the digestive system?
2. Explain the two types of processes within the digestive system.
3. Describe the two types of motility within the intestine.
4. What distinction is there between trypsin and pepsin, protein and peptides, and polysaccharides and monosaccharides? Explain how one pair is different from the other two.
5. What is the relationship between hydrochloric acid production by the stomach and bicarbonate production by the pancreas?
6. Because fats are not soluble in water, what process is used by the digestive system to emulsify fats?
7. How is emulsification an example of mechanical digestion rather than chemical digestion?
8. Compare and contrast carbohydrate and protein absorption with fat absorption. Include an explanation of basal active transport.

Nutrition and Metabolism

continued on p. 964

The previous chapter (Chapter 29) explains the processes of getting nutrients into the internal environment. This chapter takes the story further by discussing how the body manages the nutrients after they are absorbed—how they are stored and how they are used by the cells of the body. Before beginning this chapter, you may want to review the story of metabolism summarized in Chapters 4 and 5, beginning on p. 102.

OVERVIEW OF NUTRITION AND METABOLISM

Nutrition and *metabolism* are words that are often used together—but what do they mean? **Nutrition** refers to the foods that we eat and the nutrients they contain. The Council on Food and Nutrition of the American Medical Association defines nutrition broadly as "the science of food; the nutrients and the substances therein; their action, interaction, and balance in relation to health and disease; and the process by which the organism (i.e., body) ingests, digests, absorbs, transports, utilizes, and excretes food substances."

Healthy nutrition requires a balance of different nutrients in healthy amounts. *Malnutrition* is a deficiency or imbalance in the consumption of food, vitamins, and minerals. As a matter of convenient communication, many nutrition experts divide the essential (required) nutrients into two major categories:

1. **Macronutrients**—usually include those nutrients that we need in large amounts, such as carbohydrates, fats, and proteins. Sometimes water is included because we need to ingest a large amount of water each day to remain healthy. Minerals that we need in large quantities to remain in good health are also often included among the macronutrients. For example, sodium, chloride, potassium, calcium, magnesium, and phosphorus are often considered to be macronutrients. This group of minerals can also be more specifically called *macrominerals*. Macronutrients are also sometimes called *bulk nutrients* because we need them in bulk quantities to survive.
2. **Micronutrients**—usually include nutrients that we need in very small amounts, such as vitamins and some minerals. Minerals in this group include iron, iodine, zinc, manganese, cobalt, and a few others. Mineral micronutrients can also be called *microminerals* or *trace elements*.

We have already stated that healthy nutrition requires a balance of nutrients in the proper amounts. What do we mean by "proper balance" of nutrients? That is a puzzle that scientists continue to work on unraveling. The answer to the puzzle will certainly be complicated because we now know that a complex interaction of slight differences in individual genetic codes and individual lifestyles and environments affect how nutrients affect our bodies. Until this puzzle is completely solved, if it ever is, we fortunately have some advice that we can rely on to help us make healthy choices. For example, the United States government makes use of an individually customized food plate as a general nutrition guide (Figure 30-1). The Canadian government uses a food rainbow to advise eating a healthy, balanced diet (Figure 30-2).

As we proceed through this chapter, we will discuss most of the major nutrients in more detail and their roles in maintaining the body.

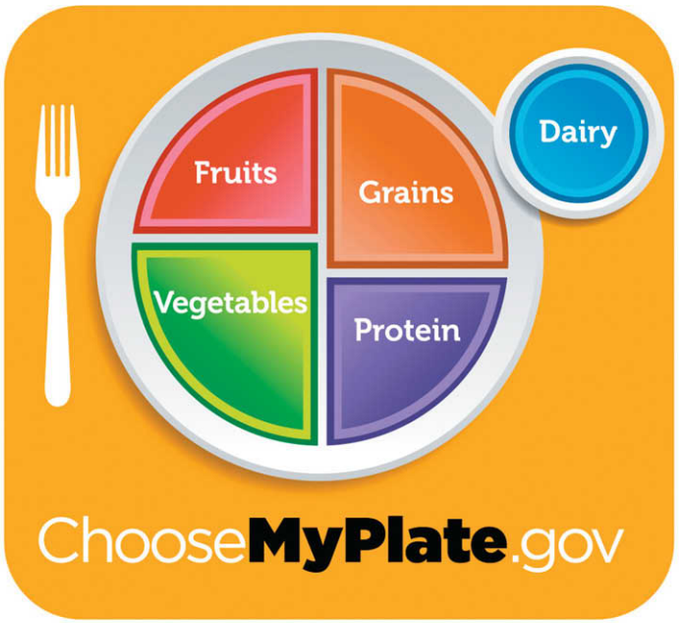

FIGURE 30-1

United States Food Guide Plate. Simple diagrams such as "My Plate" help educate the public on building a diet with a balance of foods from different categories illustrated in the diagram. This is an abbreviated version of the comprehensive food guide that can be found at ChooseMyPlate.gov. The full version includes detailed nutrition advice.

Metabolism refers to the complex, interactive set of chemical processes that make life possible. A good phrase to remember in connection with the word metabolism is "use of foods" because basically this is what metabolism is—the use the body makes of foods after they have been digested, absorbed, and circulated to cells.

Your body cells use nutrients from food in several ways: as fuel (energy), as material for growth and maintenance, and for regulation of body functions. Before they can be used in these different ways, nutrients have to be assimilated. **Assimilation** occurs when nutrient molecules enter cells and undergo many chemical changes.

Metabolism is a complex process made up of many other processes. Two of the major metabolic processes are **catabolism** and **anabolism.** Each of these processes, in turn, consists of a series of enzyme-catalyzed chemical reactions known as *metabolic pathways.*

Catabolism breaks food molecules down into smaller molecular compounds and, in so doing, releases energy from them. Anabolism does the opposite. It builds nutrient molecules up into larger molecular compounds and, in so doing, uses energy. Catabolism is a decomposition process. Anabolism is a synthesis

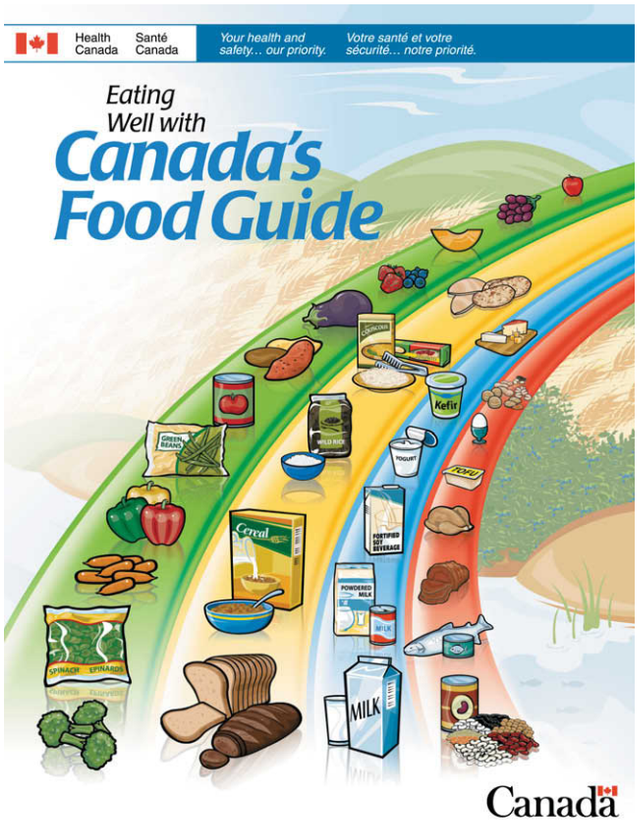

FIGURE 30-2

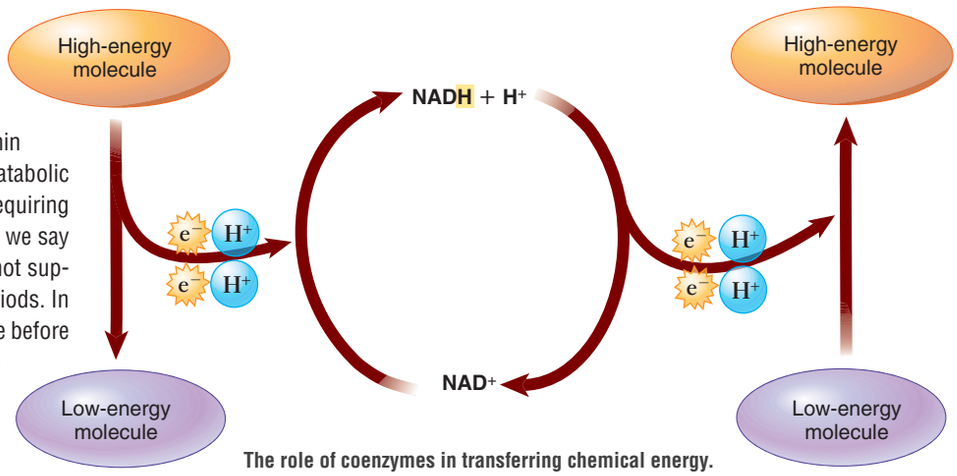
Canadian Food Rainbow. This is an abbreviated version of the comprehensive food guide found at hc-sc.gc.ca/fn-an/food-guide-aliment/index-eng.php. The full version includes additional nutrition advice.



process. Both catabolism and anabolism take place inside cells. Both processes go on continually and concurrently.

Catabolism releases energy in two forms: heat and chemical energy. The amount of heat generated is relatively large—so large, in fact, that it would hard-boil cells if it were released in one large burst. Fortunately, this does not happen. Catabolism releases heat in frequent, small bursts. Heat is practically useless as an energy source for cells because they cannot use it to do their work. However, this heat is important in maintaining the homeostasis of body temperature. In contrast, chemical energy released by catabolism is more obviously useful. It cannot, however, be used directly for biological reactions. First, it must be transferred to the high-energy molecule of adenosine triphosphate (ATP) (Box 30-1).

ATP is one of the most important compounds in the world. Why? It supplies energy directly to the energy-using reactions of all cells in all kinds of living organisms, from one-celled plants to trillion-celled humans. ATP functions as the universal biological

Box 30-1 | Transferring Chemical Energy

The ability to transfer energy from molecule to molecule is, as you might imagine, essential to life. We have already discussed the critical role played by the nucleotide adenosine triphosphate (ATP) in transferring energy within living cells. ATP can accept energy from catabolic reactions and transfer that energy to energy-requiring anabolic reactions (see Figure 30-3). Although we say that ATP is an "energy storage molecule," do not suppose that the energy is stored for very long periods. In fact, an ATP molecule exists for only a brief time before its last phosphate group is broken off and its energy is transferred to another molecule in some metabolic pathway. Long-term storage of energy can be accomplished only by nutrient molecules such as glucose, glycogen, and triglycerides.

The role of coenzymes in transferring chemical energy.

In addition to ATP, various other energy transfer molecules are essential to human life. When atoms in a molecule absorb energy, some of their electrons may move outward to a higher energy level (shell). Electrons often become so energized that they leave the atom completely. As this occurs, pairs of "high-energy" electrons can be picked up and transferred to another molecule by an electron carrier such as **flavin adenine dinucleotide (FAD)** or **nicotinamide adenine dinucleotide (NAD).** The figure shows how NAD^+ (oxidized NAD) picks up a pair of energized electrons to become NADH. It should be noted here that electrons always travel with a proton (H^+) in the metabolic pathways described in this chapter. The electrons do not stay with the electron carrier for long, however. They are immediately transferred to molecules in another metabolic pathway, as the figure shows. In the cell, pairs of electrons (and their energy) can thus be transferred from pathway to pathway by NAD and FAD.

NAD and FAD, though very similar in function, do have their differences. One difference is that after NAD drops off its pair of high-energy electrons, three ATP molecules are generated and when FAD drops off its pair of electrons, only two ATP molecules are generated.

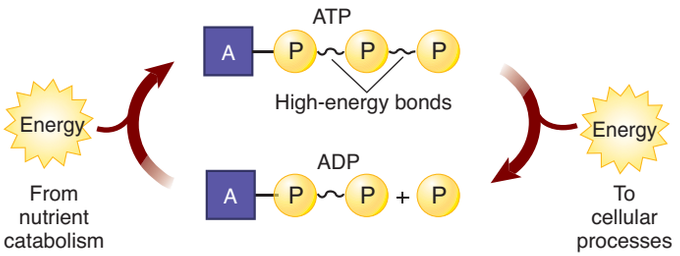


FIGURE 30-3

The role of ATP in metabolism. Adenosine triphosphate (ATP) temporarily stores energy in its last high-energy phosphate bond. When water is added and phosphate breaks free, energy is released to do cellular work. The adenosine diphosphate (ADP) and phosphate groups that result can be resynthesized into ATP, capturing additional energy from nutrient catabolism. This cycle is called the *ATP/ADP system.*

currency. It pays the energy bills for all cells and is as important in the world of cells as money is in the world of contemporary society.

Look now at Figure 30-3. The structural formula at the top of the diagram shows three phosphate groups attached to the rest of the ATP molecule, two of them by high-energy bonds. Adding water to ATP yields a phosphate group (P), adenosine diphosphate (ADP), and energy, which, as the diagram indicates, is used for anabolism and other cell work. The diagram also shows that P and ADP then use energy released by catabolism to recombine and form ATP. This cycle is called the *ATP/ADP system.*

Metabolism is not identical in all cells. It differs mainly with regard to rate and the kind of products synthesized by anabolism. More active cells have a higher metabolic rate than do less active cells. Anabolism in different kinds of cells produces different compounds. In liver cells, for example, anabolism synthesizes various blood protein compounds. Not so in beta cells of the pancreas. Anabolism there produces a different compound—insulin.

The bulk of this chapter discusses concepts related to the many and varied metabolic pathways of the human body. Our attempt here is to build on what you learned in previous chapters, but not to cover the subject of metabolism in its entirety—if that is even possible. Our goal, therefore, is to underscore the *basic* concepts of nutrition and metabolism. It is important to note that our discussion, as well as the diagrams that accompany the discussion, have been simplified to facilitate understanding of these basic concepts.

CARBOHYDRATES

Dietary Sources of Carbohydrates

Carbohydrates are found in most of the foods that we eat. *Complex carbohydrates*—polysaccharides such as starches in vegetables, grains, and other plant tissues—are broken down into simpler carbohydrates before they are absorbed.

Cellulose, a major component of most plant tissues, is an important exception to this principle. Because humans do not

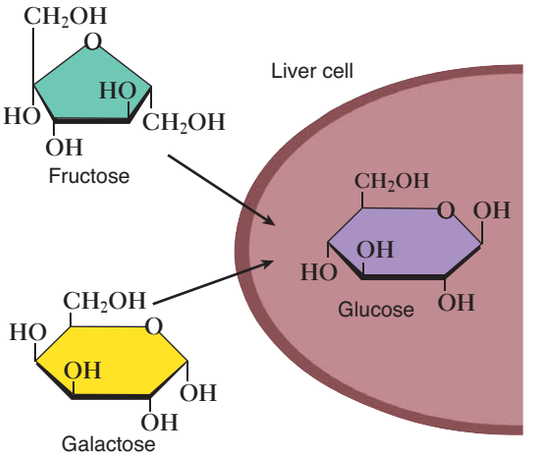

FIGURE 30-4

Conversion of monosaccharides. Monosaccharides fructose and galactose are usually converted to glucose by liver cells. Although simplified in this diagram, conversion to glucose requires several steps. Glucose is the carbohydrate used universally by all cells in the body.

make enzymes that chemically digest this complex carbohydrate, it passes through our system without being broken down. Also called *dietary fiber* or "roughage," cellulose and other indigestible polysaccharides keep chyme thick enough for the digestive system to push it easily. They also help mix chyme, much like the ball inside a can of spray paint. Most biologists believe that a high-fiber diet reduces the risk of many forms of cancer, including colorectal cancer.

Disaccharides such as those in refined sugar must also be chemically digested before they can be absorbed. Monosaccharides in fruits and some "diet foods" are already in an absorbable form, so they can move directly into the internal environment without initially being processed. The monosaccharide *glucose* is the carbohydrate that is most useful to the typical human cell. As Figure 30-4 shows, other important monosaccharides, *fructose* and *galactose*, are usually converted by liver cells into glucose for use by other cells of the body.

| QUICK CHECK |

1. Name the two types of metabolism and distinguish between them.
2. Why must energy in nutrient molecules be transferred to ATP?

Carbohydrate Metabolism

The body metabolizes carbohydrates by both catabolic and anabolic processes. Because many human cells use carbohydrates—mainly glucose—as their first or preferred energy fuel, they catabolize most of the carbohydrate absorbed and anabolize a

relatively small portion of it. When the amount of glucose entering cells is inadequate for their energy needs, they may make more use of an alternative pathway and catabolize fats or proteins.

We first discussed carbohydrate metabolism in Chapter 4 when we discussed basic concepts of cell metabolism (see pp. 102–104). The subject came up again in Chapter 12 when we discussed energy production in muscle tissue (see pp. 356–359). You may want to flip back to those passages and review the material before proceeding further with this chapter.

As you read through the following sections that briefly describe the process of carbohydrate metabolism, remember the ultimate result of catabolism: the transfer of energy from a nutrient molecule to ATP. It is the continued production of ATP, the energy currency of the cell, that makes nutrient catabolism so incredibly vital to the overall process of life itself.

GLUCOSE TRANSPORT AND PHOSPHORYLATION

Carbohydrate metabolism begins with the movement of glucose through cell membranes. Immediately on reaching the interior of a cell, glucose reacts with ATP to form glucose-6-phosphate. This step, named **glucose phosphorylation,** prepares glucose for further metabolic reactions. **Phosphorylation** (fos-for-i-LAY-shun) is the process of adding a phosphate group to a molecule. In most cells of the body, glucose phosphorylation is an irreversible reaction. However, in a few cells—namely, those of the intestinal mucosa, liver, and renal cortex—glucose phosphorylation is reversible. These cells contain phosphatase, an enzyme that splits phosphate off from glucose-6-phosphate. This reverse glucose phosphorylation reaction forms glucose, which then moves out of the cells into the blood. (Glucose-6-phosphate cannot pass through cell membranes.) Depending on their energy needs of the moment, cells either catabolize (break apart) or anabolize (bind together) glucose-6-phosphate.

| A&P CONNECT |

Nutritionists often talk about the "energy value" of food—that is, how much energy the body can get from that food. Do you know what it means when a label states that food energy in calories? Do you know the difference between a *calorie* and a *Calorie?* Or a calorie and a *joule* or *kilojoule?* Find answers to these questions, and also learn the energy values of major nutrients and the amount of energy expended by different physical activities in ***Measuring Energy*** online at ***A&P Connect.***

evolve

GLYCOLYSIS

Glycolysis is the first step in the process of carbohydrate catabolism. It breaks apart one glucose molecule to form two pyruvic acid molecules. (A glucose molecule contains six carbon atoms, and a pyruvic acid molecule contains three carbon atoms. See Figure 30-6.) Glycolysis consists, as Figure 30-5 shows, of a series of chemical reactions. A specific enzyme catalyzes each of these

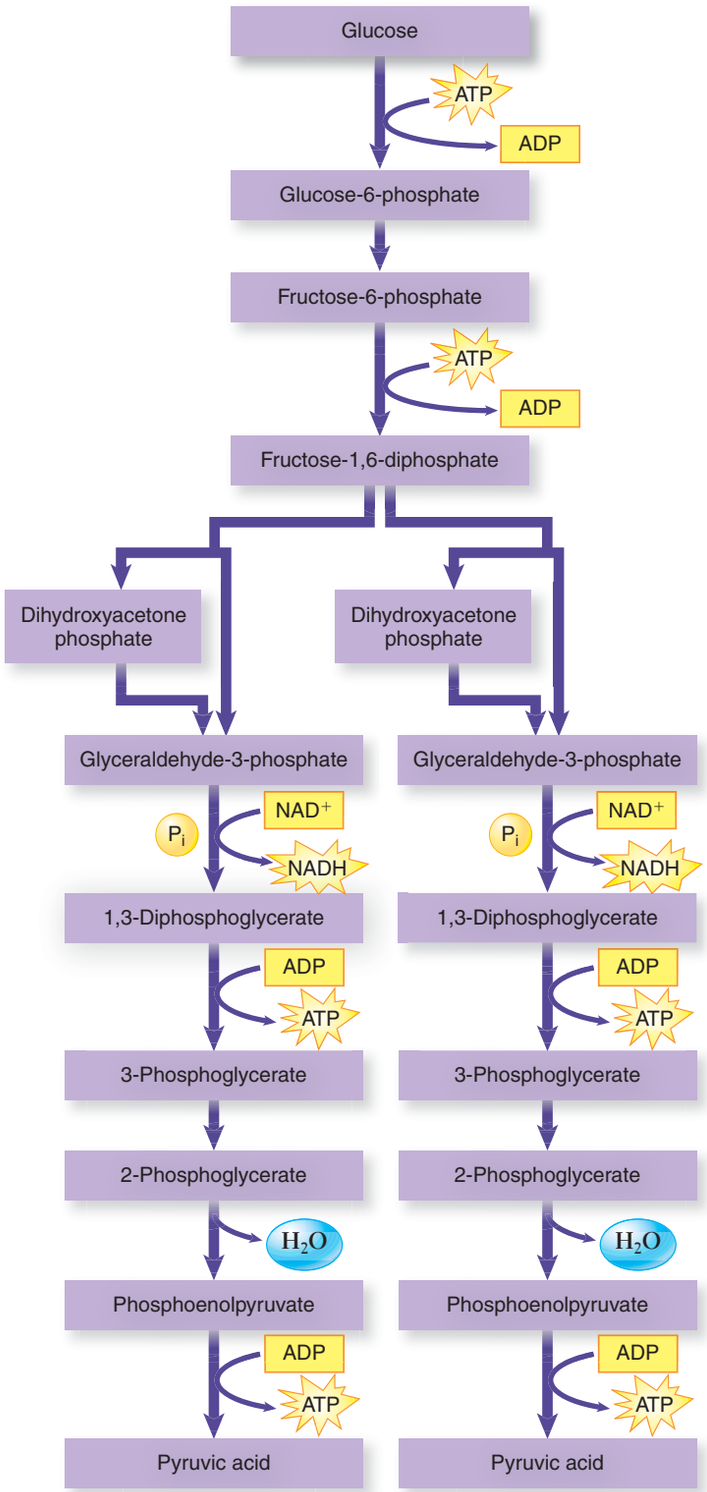

FIGURE 30-5

Glycolysis. The series of enzyme-catalyzed reactions that make up the portion of the catabolic pathway for carbohydrates is called *glycolysis. ADP,* Adenosine diphosphate; *ATP,* adenosine triphosphate; *NAD+,* oxidized nicotinamide adenine dinucleotide; *NADH,* reduced nicotinamide adenine dinucleotide.

reactions. Probably the most important facts for you to remember about glycolysis are the following:

- Glycolysis occurs in the cytoplasm of all human cells.
- Glycolysis is an *anaerobic* process, that is, it does not use oxygen. It is the only process that provides cells with energy when their oxygen supply is inadequate or even absent.
- Glycolysis breaks the chemical bonds in glucose molecules and thereby releases about 5% of the energy stored in them. Much of the released energy appears as heat, but some of it is transferred to the high-energy bonds of ATP molecules. For every molecule of glucose undergoing glycolysis, a net of two molecules of ATP is formed. About 8 kilocalories (kcal) of energy (under normal physiological conditions) is stored in the high-energy bonds that bind phosphate to ADP to form 1 mole (6.02 × 1023 molecules) of ATP.
- Glycolysis is an essential process because it prepares glucose for the second step in catabolism, namely, the **citric acid cycle.** Glucose itself cannot enter the cycle but must first be converted to pyruvic acid, then to a compound called *acetyl CoA (coenzyme A).*

CITRIC ACID CYCLE

As stated previously, for every glucose molecule that enters the catabolic pathway described here, two pyruvic acid molecules are produced. Before each pyruvic acid molecule can proceed into the citric acid cycle, it must be converted into an acetyl group (acetate), releasing a carbon dioxide molecule and being carried into the citric acid cycle by **coenzyme A (CoA).** Essentially, the citric acid cycle converts the two acetyl molecules to four carbon dioxide and six water molecules. But many chemical reactions intervene. Figure 30-6 shows that one glucose molecule is changed by glycolysis to two pyruvic acid molecules, which, by means of the citric acid cycle, yield six carbon dioxide molecules. Figure 30-7 shows the details of the citric acid cycle.

Glycolysis takes place in the cytoplasm of cells, whereas the citric acid cycle occurs in their mitochondria. Some of the enzymes needed for the many steps of the citric acid cycle are dissolved in the matrix of the mitochondrion, and some are attached to the inner membrane of the mitochondrion.

Before it can enter the citric acid cycle, each pyruvic acid molecule combines with coenzyme A (see Figure 30-7) after splitting off CO_2 and a pair of high-energy electrons (with their accompanying protons, H^+) from pyruvic acid, thus forming acetyl CoA. Coenzyme A then detaches from acetyl CoA, leaving a two-carbon acetyl group, which enters the citric acid cycle by combining with

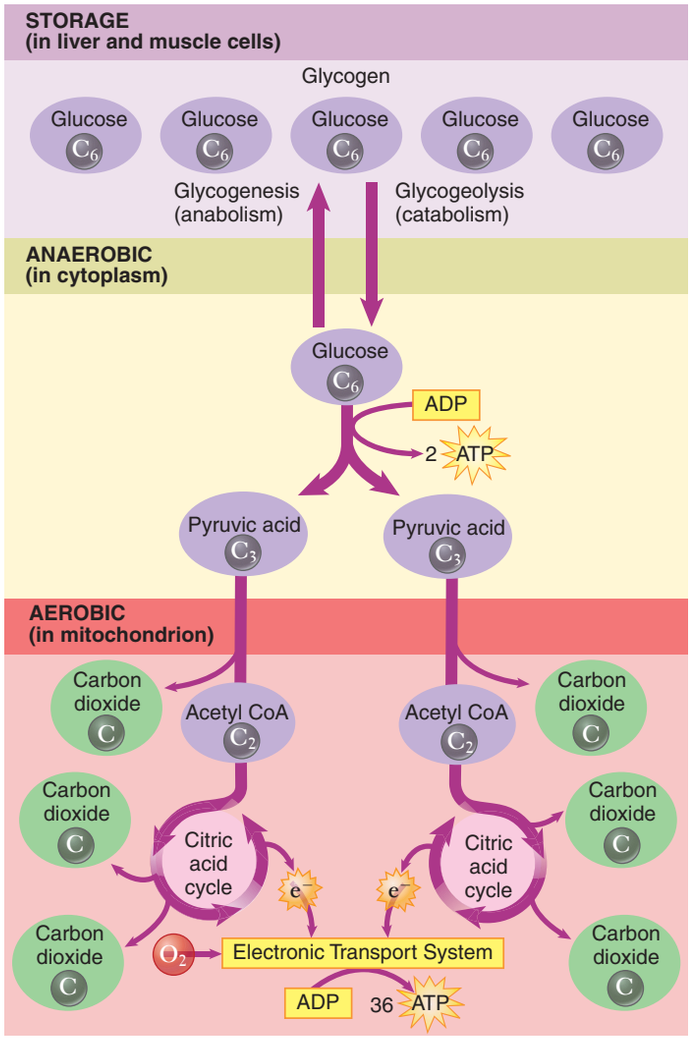

FIGURE 30-6

Catabolism of glucose. Glucose may be stored in the liver and other tissues as the polymer glycogen, which can then later be hydrolyzed to form individual glucose molecules. Glycolysis splits one molecule of glucose (six carbon atoms) into two molecules of pyruvic acid (three carbon atoms each). The glycolytic pathway does not require oxygen, so it is termed *anaerobic.* A transition reaction removes a carbon dioxide molecule, converting each pyruvic acid molecule into a two-carbon acetyl group that is escorted by coenzyme A (CoA) into the citric acid cycle. There, two more carbon dioxide molecules (one carbon atom each) are released. The carbon and oxygen atoms in the original glucose molecule are thus released as waste products. However, the real metabolic prize is energy, which is released as the molecule is broken down. Because this part of the pathway requires oxygen, it is termed *aerobic.* More detailed depictions of this process are included later in this chapter.

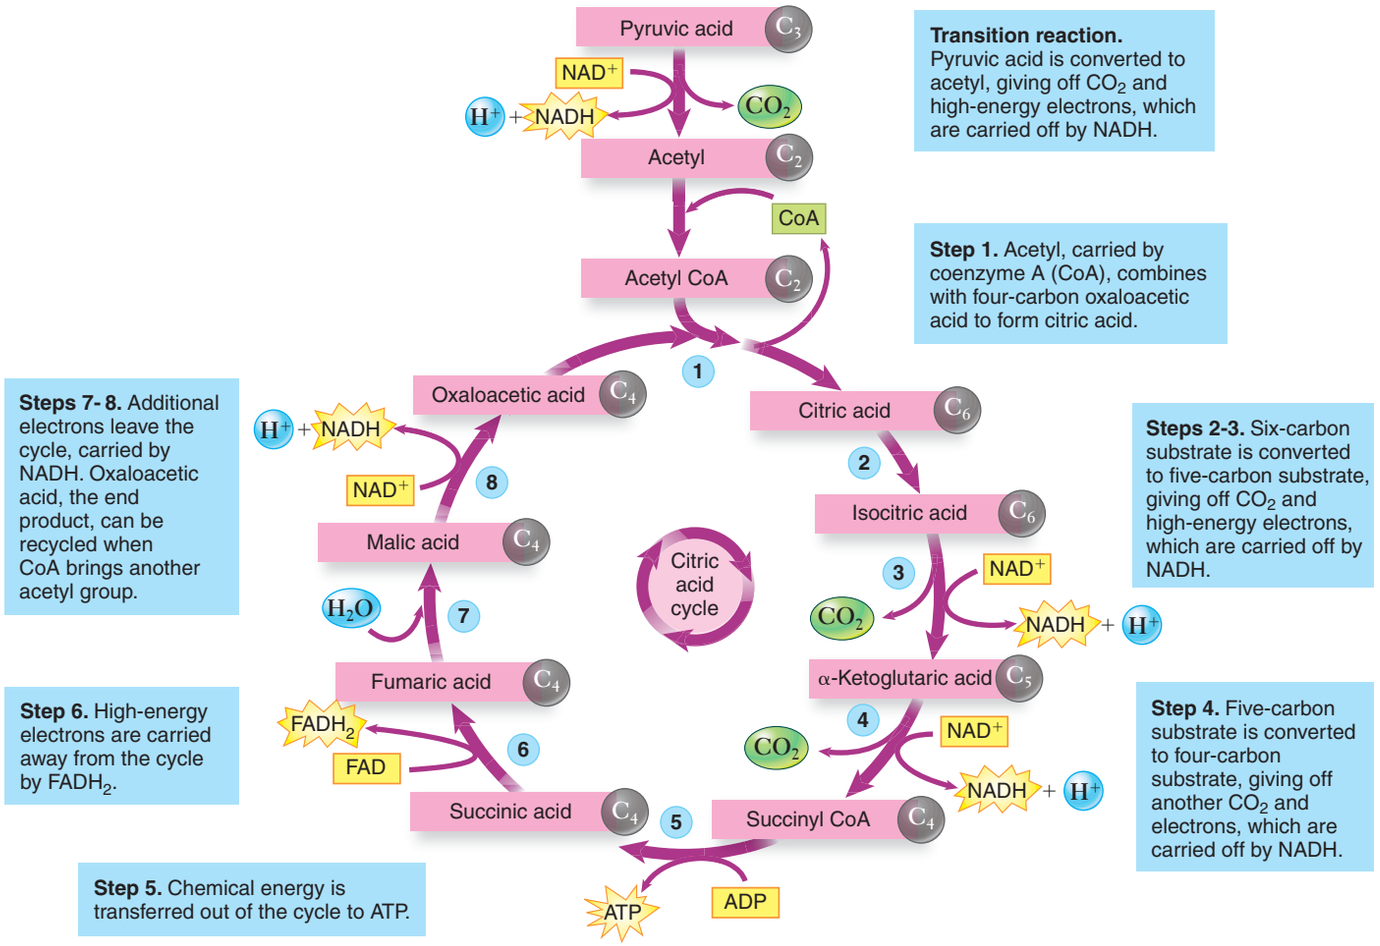

FIGURE 30-7

Citric acid cycle. Each pyruvic acid molecule is prepared to enter the citric acid cycle by the transition reaction, which yields a pair of high-energy electrons and a CO_2 molecule. The acetyl group that is thus formed is picked up by coenzyme A (CoA) and led into the citric acid cycle proper, which is described here as a recurring series of eight steps.

oxaloacetic acid to form citric acid. This is what gives the citric acid cycle its name. The cycle is also called the **tricarboxylic acid (TCA) cycle** because citric acid is also called *tricarboxylic acid*. For many years this cycle was called the **Krebs cycle** after Sir Hans Krebs, whose brilliant work in discovering this metabolic pathway earned him the 1953 Nobel Prize.

You probably do not need to memorize the names of the intermediate products formed during the citric acid cycle, but notice that all of them are acids. You should note that a little bit of ATP is directly generated by the citric acid cycle (in step 5). In step 5, energy is transferred first to GTP (guanosine triphosphate), a nucleotide similar to ATP, and then finally to ATP.

Observe, too, that for each pyruvic acid molecule entering this pathway, three CO_2 molecules are formed and that certain reactions yield high-energy electrons. Most of the energy leaving the citric acid cycle is in these high-energy electrons. The next section describes how these high-energy electrons are used to generate ATP.

ELECTRON TRANSPORT SYSTEM AND OXIDATIVE PHOSPHORYLATION

High-energy electrons removed during the citric acid cycle enter a chain of carrier molecules, which is embedded in the inner membrane of mitochondria and is known as the **electron transport system (ETS).** Figure 30-8 shows that high-energy electrons (along with their accompanying protons, H^+) are carried to the electron transport system by NAD and FAD. The electrons quickly move down the chain, from one membrane protein complex to the next, eventually to their final acceptor, oxygen.

As the electrons are transported, some of their energy is used to pump their accompanying protons (H^+) to the intramembrane

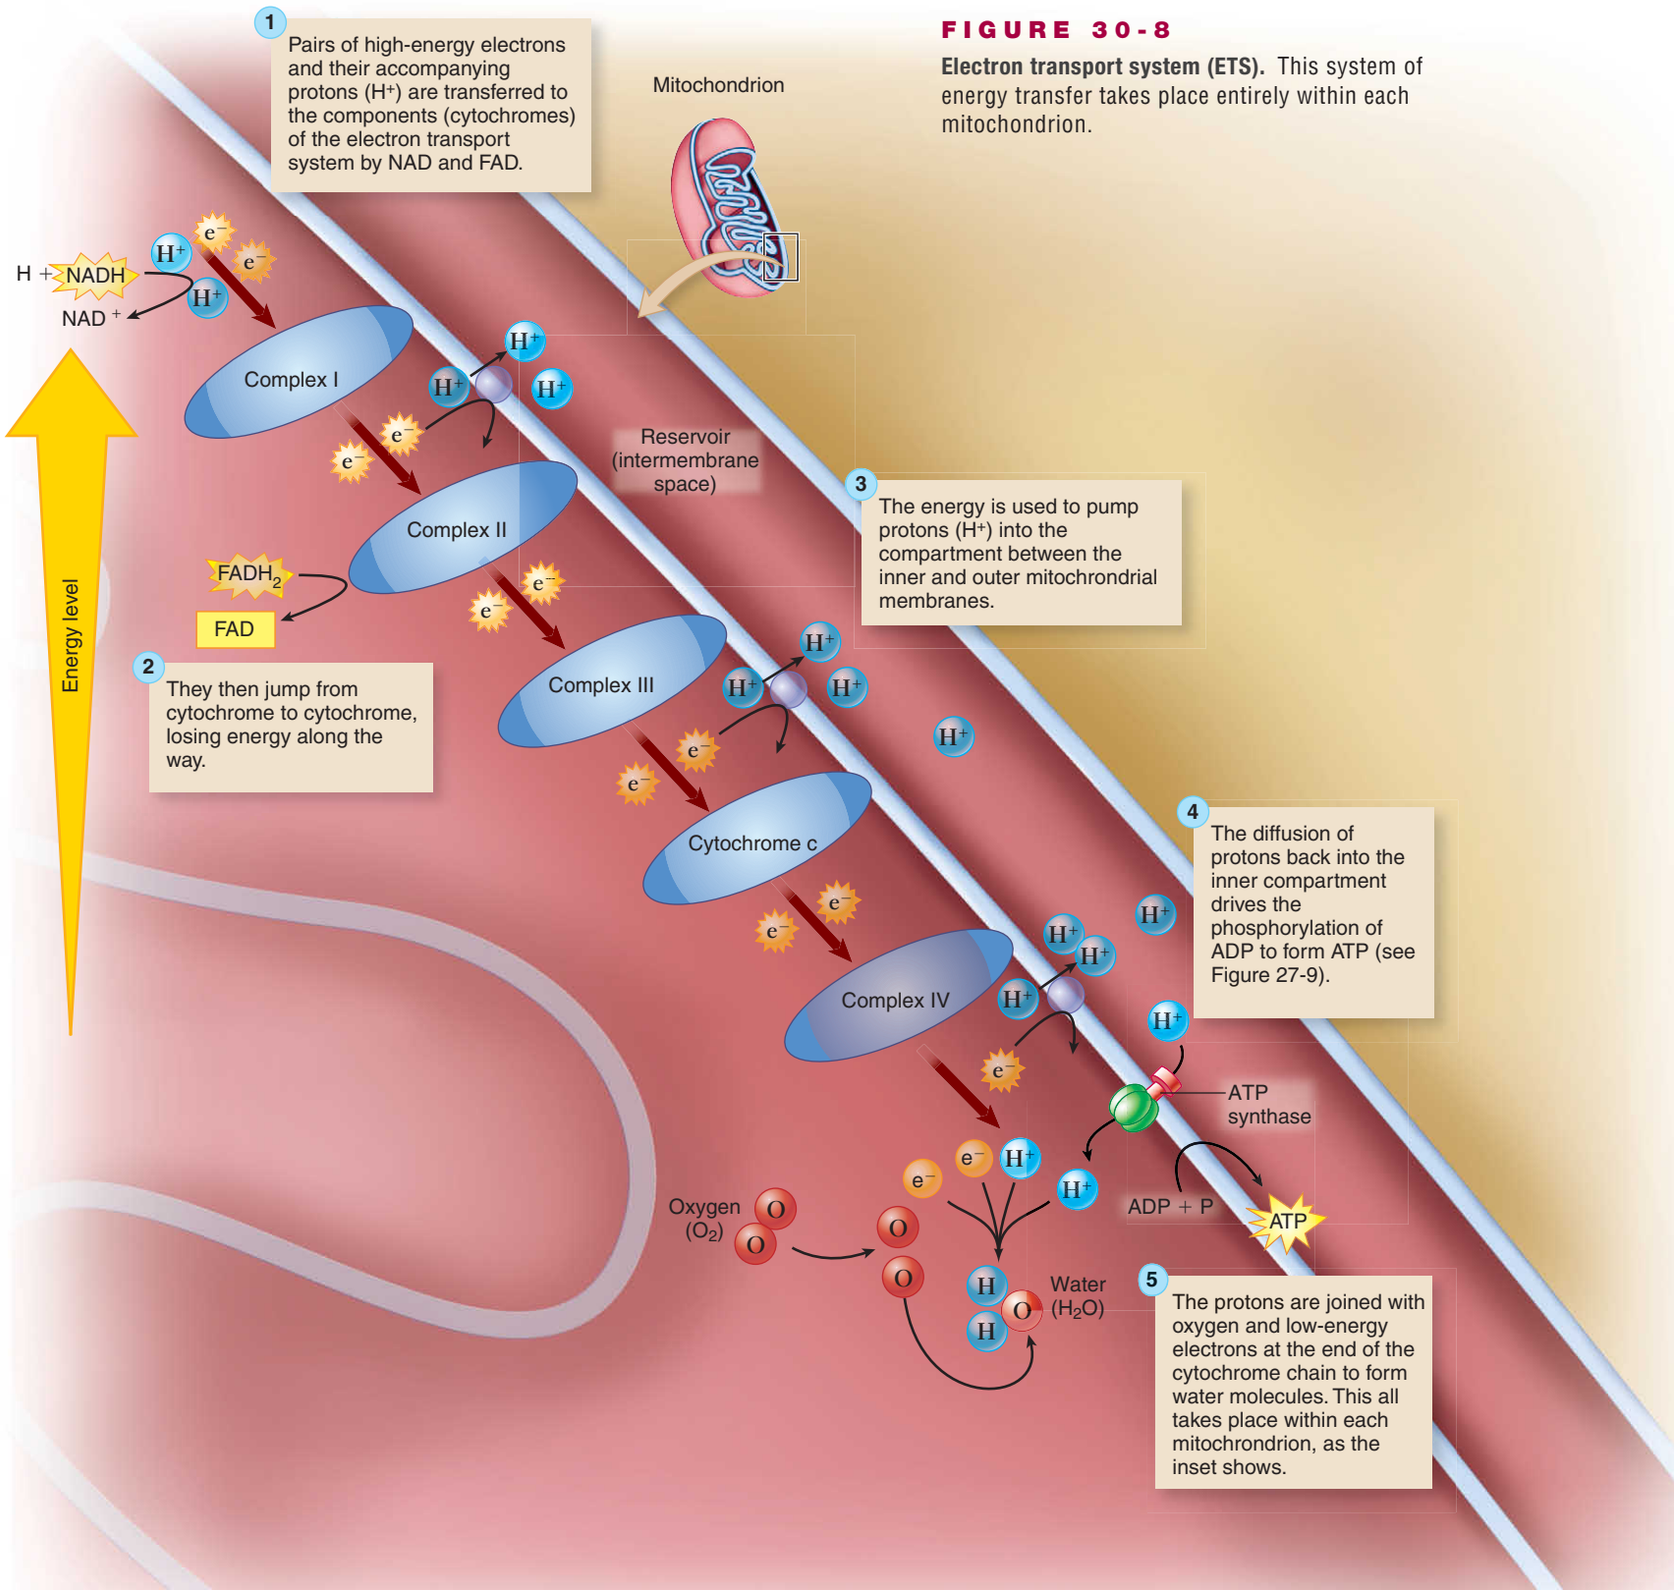

FIGURE 30-8

Electron transport system (ETS). This system of energy transfer takes place entirely within each mitochondrion.

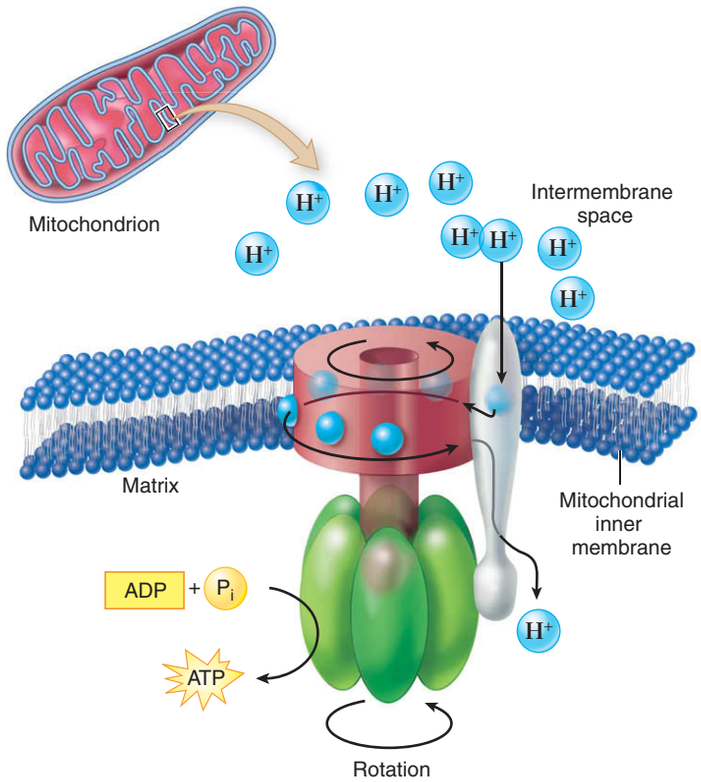

FIGURE 30-9

Generation of ATP by ATP synthase. This simplified model of the proton wheel in the mitochondrial inner membrane shows how protons (H^+) moving down their concentration gradient drive the rotation of a molecular machine. The energy of rotation then phosphorylates (adds phosphate to) adenosine diphosphate (ADP) to become adenosine triphosphate (ATP).

space between the inner and outer membranes of the mitochondrion. This creates a concentration gradient of protons, and the intermembrane space thus becomes a virtual reservoir of protons. As with water behind a dam, the reservoir of protons temporarily stores energy. As in a dam possessing water wheels that convert energy, the inner membrane has "proton wheels" built into it—in the form of **ATP synthase.** Figure 30-9 shows how protons move down their concentration gradient and into the ATP synthase structure, turning a molecular wheel that transfers energy by synthesizing ATP from ADP and phosphate.

At this time, the low-energy electrons (e^-) and their protons (H^+) join oxygen, forming water. As you can see, although oxygen is not needed until the very last step of aerobic respiration, its role is vital. Without oxygen to oxidize the hydrogen into water, the energy generation pathway would stop.

Oxidative phosphorylation refers to this oxygen-requiring joining of a phosphate group to ADP to form ATP—a reaction whose importance can scarcely be overemphasized.

The arrangement of catabolic "machinery" within the cell, as currently viewed, is shown in Figure 30-10. Glycolytic enzymes in the cytoplasm catalyze the production of pyruvic acid, which diffuses into mitochondria. The enzymes of the citric acid cycle have been localized mostly to the matter (matrix) inside the inner mitochondrial membrane. The high-energy electrons and their accompanying protons are then carried to the cristae of the inner membrane, where the electron transport carriers and mechanism for phosphorylation are found. Because so many of the cell's energy-releasing enzymes are located within the mitochondria, these tiny structures are aptly described as the "power plants" of the cell.

The breakdown of ATP molecules, of course, provides virtually all the energy that does cellular work. Therefore, the process that produces some 90% of the ATP formed during carbohydrate

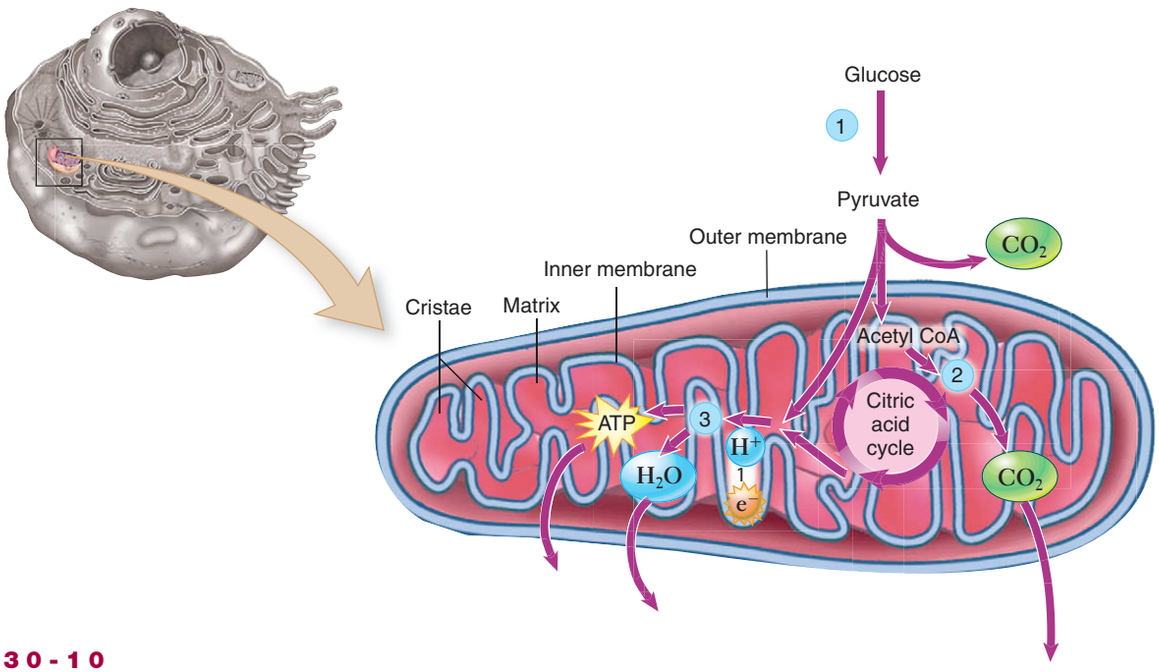

FIGURE 30-10

Cell machinery for glucose catabolism. 1, Glycolysis occurs in cytoplasm. **2,** Citric acid cycle takes place mostly in the mitochondrial matrix. **3,** Electron transport and oxidative phosphorylation occur on the inner membrane of mitochondria.

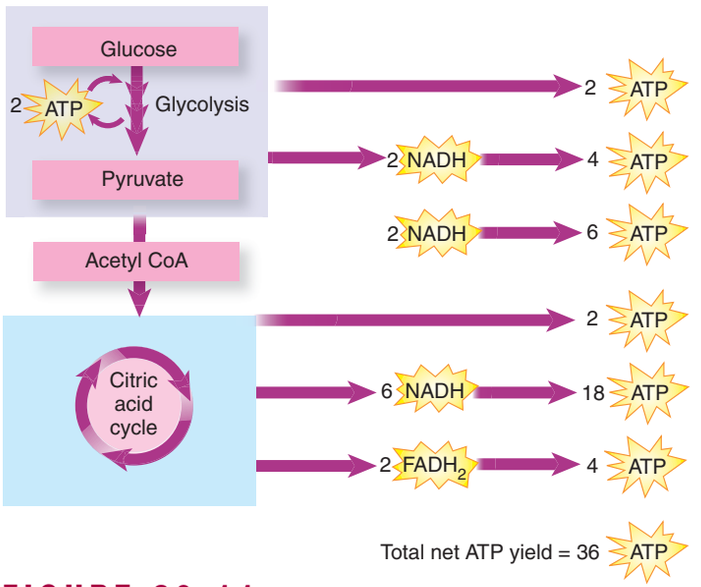

FIGURE 30-11

Energy extracted from glucose. Energy released from the breakdown of glucose is released mostly as heat, but some of it is transferred to a usable form—the high-energy bonds of adenosine triphosphate (ATP). In most human cells, one glucose molecule produces enough usable chemical energy to synthesize or "charge up" 36 ATP molecules. Some cells, such as heart and liver cells, shuttle electrons more efficiently and may be able to synthesize up to 38 ATP molecules. This represents an energy conversion efficiency of 38% to 44%, much better than the 20% to 25% typical of most machines.

catabolism, namely, oxidative phosphorylation, is the crucial part of catabolism (Figure 30-11). This vital process depends on cells receiving an adequate oxygen supply. Why? Briefly, because only when oxygen is present in cells to serve as the final acceptor of electrons and hydrogen ions can electrons then continue moving down the electron transport chain. If oxygen becomes unavailable, the movement of electrons and hydrogen ions stops. Cessation of ATP formation by oxidative phosphorylation necessarily follows. All too soon, cells have an inadequate energy supply—a lethal condition if it persists for more than a few minutes.

We can summarize the long series of chemical reactions in glucose catabolism with one short equation:

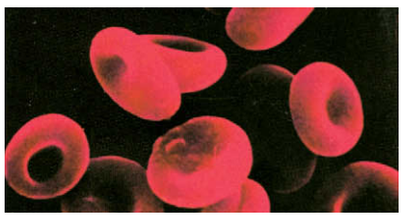
$$C_6H_{12}O_6 + 6\,O_2 \longrightarrow 6\,CO_2 + 6\,H_2O + 36\ (\text{or } 38)\ \text{ATP} + \text{Heat}$$

| QUICK CHECK |

3. What is glycolysis? How much energy is transferred to ATP through this process?
4. What happens to a nutrient molecule as it proceeds through the citric acid cycle?
5. What is the purpose of the electron transport system?

ANAEROBIC PATHWAY

What if there is an inadequate amount of oxygen to operate the electron transport system and oxidative phosphorylation? You may recall from Chapter 12 that this often occurs in skeletal muscle cells, especially during strenuous exercise. You may remember that another pathway for the catabolism of glucose exists. It is sometimes called the **anaerobic pathway** because it transfers energy to ATP using only glycolysis—a process that does not require oxygen.



As Figure 30-12 shows, there are two main pathways that glucose or its derivatives can take. One is the pathway that ends with oxidative phosphorylation of ATP. This pathway, described in the previous sections, is called the *aerobic pathway*, or **aerobic respiration,** because it requires the presence of oxygen (Box 30-2). If enough oxygen is not available to operate this pathway, the cell will rely solely on glycolysis to produce ATP. Even though this process does not extract the maximum amount of energy from a glucose molecule, it is the only ATP-producing process that can operate under anaerobic conditions. Because the pyruvic acid molecule produced by glycolysis cannot enter the citric acid cycle, it is converted to *lactic acid* rather than acetyl CoA. Lactic acid cannot enter the citric acid cycle.

The production of lactic acid does something very important—it converts the NADH (reduced nicotinamide adenine dinucleotide) produced by glycolysis to NAD. As glycolysis proceeds, NAD is converted to NADH. If you look at Figure 30-5 carefully, you will see that there is no reaction in the glycolytic pathway to turn NADH back into NAD again. This is no problem if the aerobic pathway is in operation—NADH is converted back to NAD in the electron transport system. After a short period of anaerobic activity, however, glycolysis will turn all of the cell's NAD into NADH and thus glycolysis will have to shut down because of a lack of free NAD. The production of lactic acid solves this biochemical dilemma because this reaction also converts NADH back to NAD.

Box 30-2 | FYI

Anaerobic Body Cells

Some body cells, specifically the red blood cells (see photo), do not have the cellular organelles and enzymes required to carry out aerobic respiration. These cells must rely solely on glycolysis for their adenosine triphosphate (ATP) production. Red blood cells produce lactic acid continually, which diffuses into the plasma and is carried to liver cells for conversion back to pyruvic acid and then to glucose and glycogen (see Figure 30-12).

Red blood cells (RBCs). This color-enhanced scanning electron micrograph shows several RBCs, which are unable to perform aerobic respiration because of a lack of mitochondria. They rely solely on anaerobic glycolysis for their ATP, producing lactic acid as a metabolic waste product.

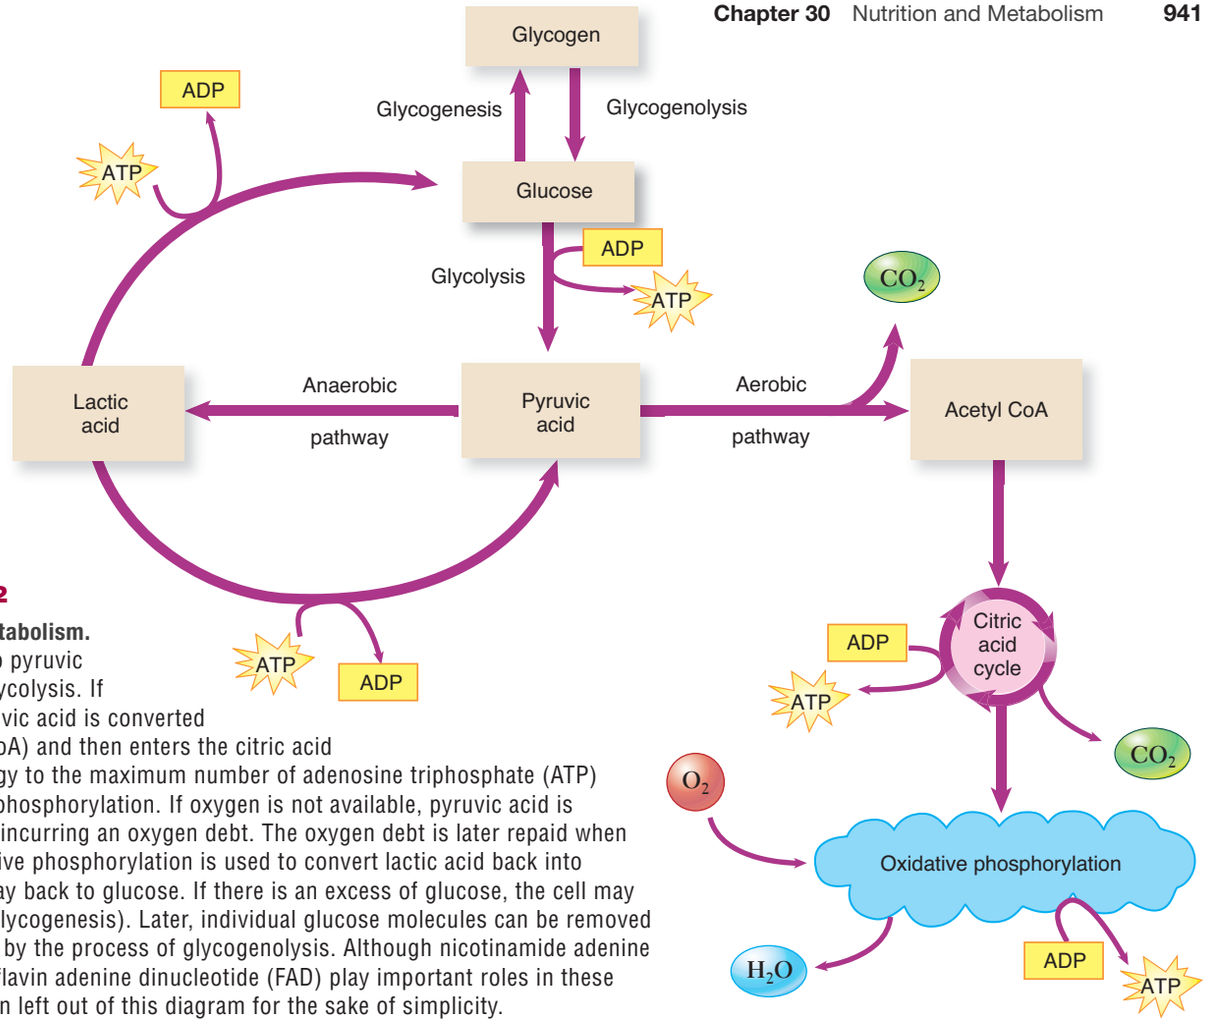


FIGURE 30-12

Summary of glucose metabolism. Glucose is catabolized to pyruvic acid in the process of glycolysis. If oxygen is available, pyruvic acid is converted to acetyl coenzyme A (CoA) and then enters the citric acid cycle and transfers energy to the maximum number of adenosine triphosphate (ATP) molecules via oxidative phosphorylation. If oxygen is not available, pyruvic acid is converted to lactic acid, incurring an oxygen debt. The oxygen debt is later repaid when ATP produced via oxidative phosphorylation is used to convert lactic acid back into pyruvic acid or all the way back to glucose. If there is an excess of glucose, the cell may convert it to glycogen (glycogenesis). Later, individual glucose molecules can be removed from the glycogen chain by the process of glycogenolysis. Although nicotinamide adenine dinucleotide (NAD) and flavin adenine dinucleotide (FAD) play important roles in these pathways, they have been left out of this diagram for the sake of simplicity.

Once oxygen becomes available again in cells that ordinarily rely on aerobic respiration, some of the lactic acid is converted back to pyruvic acid by the cell (see Figure 30-12). Notice that such reconversion requires energy from ATP. Thus reconversion in muscle cells, for example, can occur only when phosphorylation has resumed and produced enough ATP to allow reconversion to occur. Once it is converted to pyruvic acid, the molecule can follow the aerobic pathway and become completely catabolized.

Much of the lactic acid produced during anaerobic glycolysis diffuses into the blood and is removed by the liver. Inside liver cells, ATP produced by oxidative phosphorylation is used to convert the lactic acid back into glucose. The glucose may then be stored as glycogen in the liver or be returned through the bloodstream for use by other cells. Figure 30-13 summarizes this cycle during anaerobic glycolysis by skeletal muscles. This cycle is often called the **Cori cycle** after its discoverers, Carl and Gerty Cori.

Because anaerobic glycolysis requires the later use of ATP molecules produced by oxidative phosphorylation, we can say that an oxygen debt is incurred. This oxygen debt is repaid when oxygen becomes available to form the extra ATP needed to convert lactic acid back into pyruvic acid or glucose.

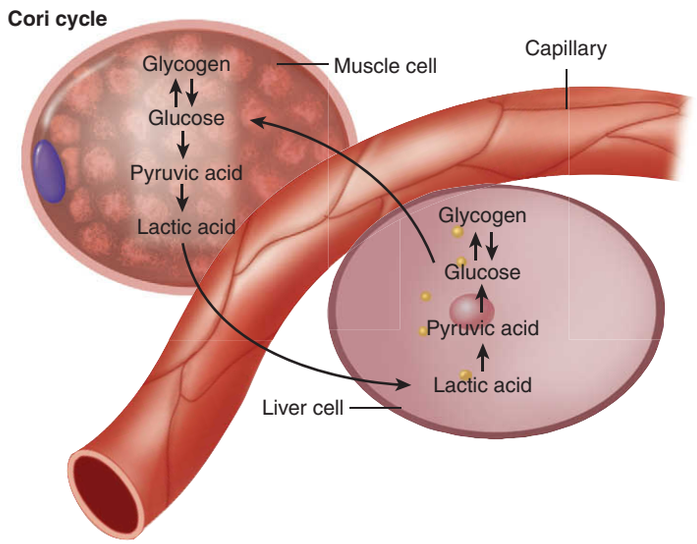

FIGURE 30-13

Cori cycle. Lactic acid produced by anaerobic glycolysis in skeletal muscles is carried to liver cells, where it is converted back to glucose and stored as liver glycogen or returned to the bloodstream, where the glucose may be taken up by muscle cells and used for respiration or stored as muscle glycogen.

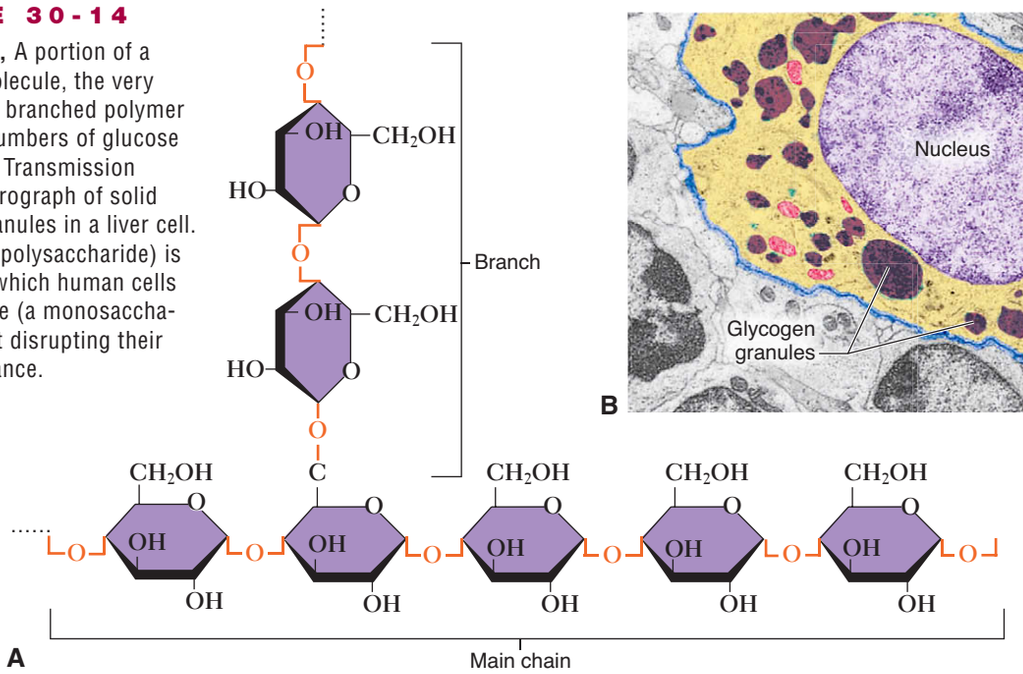
evolve

GLYCOGENESIS

Imagine what happens in a cell if glucose catabolism is proceeding at maximum rate. What do you do if you see a traffic jam ahead with no possible way to get through it? Probably take an alternative route, if available. Similarly, if glycolytic pathways are "saturated" because of high levels of glucose entering the cell, a "traffic jam" of glucose-6-phosphate will result. Unable to enter glycolysis, glucose-6-phosphate will begin an alternative route; that is, it will enter the anabolic pathway of glycogen formation. The process of glycogen formation, called **glycogenesis** (see Figure 30-12), is a series of chemical reactions in which glucose molecules are joined together to form a structure made of a branched strand of stored glucose "beads" (Figure 30-14). The huge glycogen polymer molecules settle out of solution and therefore do not upset the osmotic balance of the cell—which would happen if a large quantity of individual glucose molecules is kept in the cell.

Glycogen polymers can be made by any cell but only two types of cells store a large quantity of glycogen: muscle fibers and liver cells. Astrocytes in the brain store more glycogen than most cells, but not nearly as much as muscle fibers and liver cells. However, that small amount of glycogen may be enough to protect the brain for a short time when glucose availability is low. It is mainly the liver that acts as the glycogen reservoir for the body.

The process of glycogenesis is part of a homeostatic mechanism that operates when the blood glucose level increases above the midpoint of its normal range. The normal range of glucose in a fasting person is about 80 to 90 mg/dl of blood. Soon after a meal high in carbohydrates, while glucose is being absorbed rapidly, the blood glucose may shoot up to 120 to 140 mg/dl or more. Recall that blood from the digestive tract is detoured directly to the liver via the portal system before being returned to the heart (see Figure 21-32 on p. 664). In the liver, the action of the pancreatic hormone *insulin* causes a great many glucose molecules to leave the blood for storage in hepatic cells as glycogen. As a result of glycogenesis, the blood glucose level decreases, ordinarily enough to reestablish its normal level. Figure 30-15 summarizes this role of glycogenolysis in maintaining homeostasis of blood glucose.



GLYCOGENOLYSIS

Glycogen molecules do not remain in the cell permanently but are eventually broken apart (hydrolyzed). This process of "splitting glycogen" is called **glycogenolysis** (Figure 30-16; see Figure 30-12). It is, in essence, a reversal of glycogenesis. What are the products of glycogenolysis? The answer depends on the cell. Although all cells presumably have the enzymes to break glycogen down to glucose-6-phosphate, only a few cell types (liver, kidney, intestinal mucosa) have the enzyme phosphatase, which allows free glucose to form and possibly leave the cell.

So the term *glycogenolysis* means different things in different cells. In muscles, glucose-6-phosphate is the product, which then undergoes glycolysis. But liver glycogenolysis (see Figure 30-16) results in free glucose that can leave the cell and increase the blood glucose level. Accordingly, liver glycogenolysis acts as a part of the homeostatic mechanism to maintain the blood glucose level. Example: A few hours after a meal, when the blood glucose level decreases (see Figure 30-15), the pancreatic hormone *glucagon* stimulates accelerated liver glycogenolysis. However, glycogenolysis alone can probably maintain homeostasis of blood glucose concentration for only 12 to 16 hours because the body can store only small amounts of glycogen.

FIGURE 30-14

Glycogen. A, A portion of a glycogen molecule, the very large, highly branched polymer of varying numbers of glucose subunits. **B,** Transmission electron micrograph of solid glycogen granules in a liver cell. Glycogen (a polysaccharide) is the form in which human cells store glucose (a monosaccharide) without disrupting their osmotic balance.

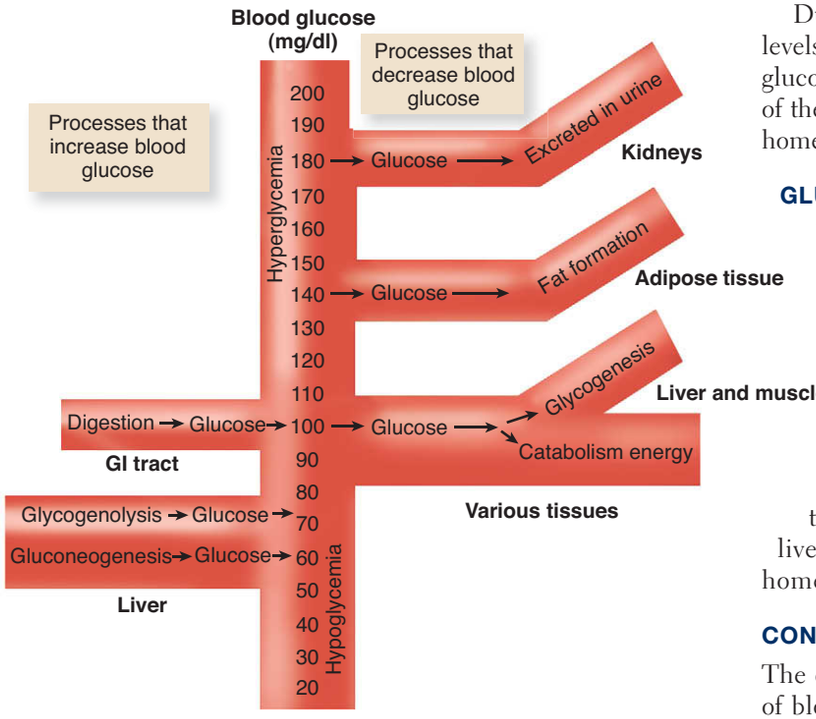


FIGURE 30-15

Homeostasis of blood glucose level. When blood glucose level starts to decrease below its normal range of about 80 to 90 mg/dl (fasting), liver cells increase the rate at which they convert glycogen, amino acids, and glycerol to glucose (glycogenolysis and gluconeogenesis) and release it into blood. But when blood glucose level increases, liver cells increase the rate at which they remove glucose molecules from blood and convert them to glycogen for storage (glycogenesis). At still higher levels, glucose leaves blood for liver cells to be converted into fat and, at still higher levels, is excreted in the urine. Hormones regulate the processes shown (see Figure 30-19).

During a stress response, elevated *epinephrine* and *cortisol* levels can stimulate glycogenolysis. This action elevates blood glucose levels, which may prove useful for the muscular activity of the "fight" or "flight" needed to resist or avoid a threat to the homeostatic balance of the body.

GLUCONEOGENESIS

Literally, **gluconeogenesis** means the formation of "new" glucose—"new" in the sense that it is made from proteins or, less frequently, from the glycerol of fats—not from carbohydrates. The process occurs chiefly in the liver. It consists of many complex chemical reactions. The new glucose produced from proteins or fats by gluconeogenesis (Figure 30-17) diffuses out of liver cells into the blood. Gluconeogenesis can therefore add glucose to the blood when needed. So, too, can the process of liver glycogenolysis. Obviously, then, the liver is a very important organ for maintaining blood glucose homeostasis.

CONTROL OF GLUCOSE METABOLISM

The complex mechanism that normally maintains homeostasis of blood glucose concentration consists of hormonal and neural devices. At least five endocrine glands—pancreatic islets, anterior pituitary gland, adrenal cortex, adrenal medulla, and thyroid gland—and at least eight hormones secreted by these glands function as key elements of the glucose homeostatic mechanism. As you read through the following paragraphs, keep in mind that each of the hormones listed have many different kinds of regulatory effects in the body—not just their effects on glucose metabolism.

Beta cells of the pancreatic islets secrete the most well-known sugar-regulating hormone of all—**insulin.** Insulin decreases blood glucose level by moving glucose molecules out of the blood

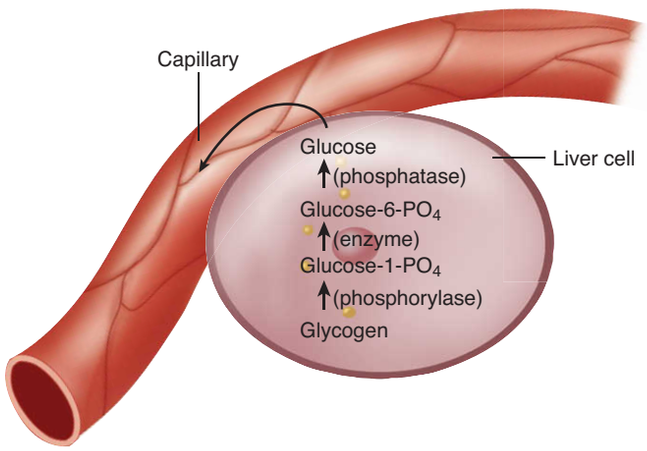

FIGURE 30-16

Glycogenolysis in a liver cell.

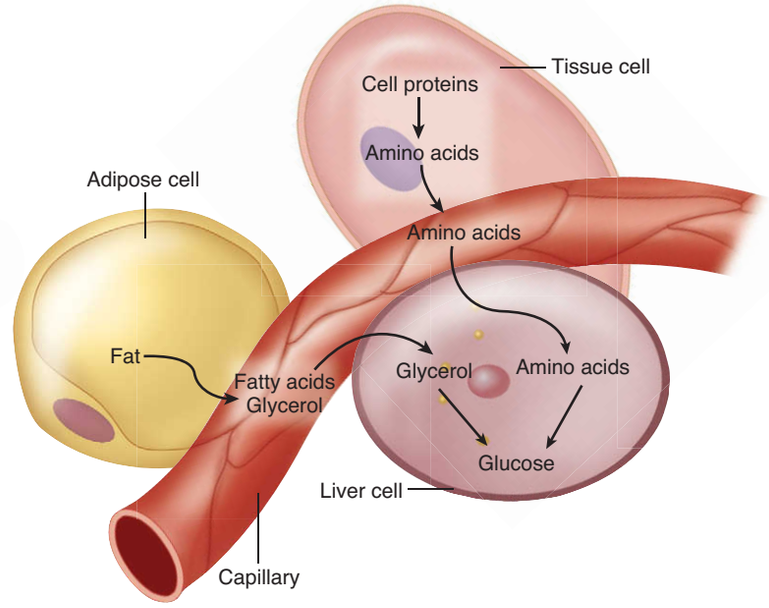

FIGURE 30-17

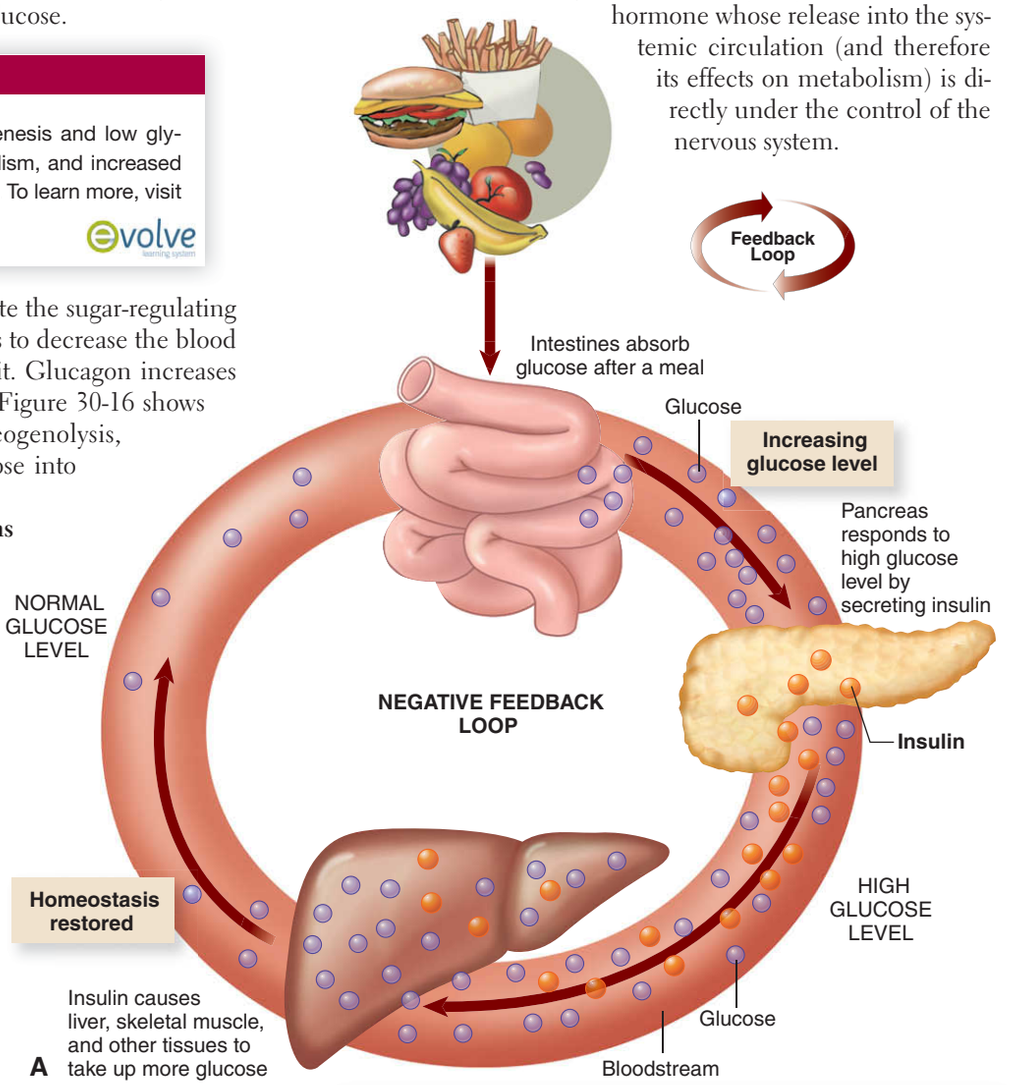
Gluconeogenesis. Liver cells can form glucose from mobilized tissue proteins and fats.

and into cells (Figure 30-18, *A*). Although the exact details of its mechanism of action are still being worked out, insulin is known to accelerate glucose transport through cell membranes. It also increases the activity of the enzyme glucokinase. Glucokinase catalyzes glucose phosphorylation, the reaction that must occur before either glycogenesis or glucose catabolism can take place. Insulin thus moves glucose into cells and increases glycogenesis and increased catabolism of glucose—all of which decrease blood glucose levels. Figure 30-18, *B*, demonstrates the blood-glucose lowering effects of insulin after ingesting glucose.



| A&P CONNECT |

Insulin deficiency can cause slow glycogenesis and low glycogen storage, decreased glucose catabolism, and increased blood glucose, as in diabetes mellitus (DM). To learn more, visit ***Diabetes Mellitus*** online at ***A&P Connect.***

Alpha cells of the pancreatic islets secrete the sugar-regulating hormone **glucagon.** Whereas insulin tends to decrease the blood glucose level, glucagon tends to increase it. Glucagon increases the activity of the enzyme phosphorylase. Figure 30-16 shows that phosphorylase promotes liver glycogenolysis, thereby causing the release of more glucose into the bloodstream.

Hormones collectively called **incretins** act to increase the amount of insulin released from the pancreatic beta cells and decrease the amount of glucagon released from pancreatic alpha cells. Thus incretins tend to decrease blood glucose levels. Incretins may also reduce the rate of gastric emptying and decrease desire for more food. Incretins are released by endocrine gastrointestinal (GI) cells in response to the presence of glucose and can increase insulin release even before blood glucose levels begin to rise after a meal. Incretins include *glucagon-like peptide 1 (GLP-1)* and *gastric inhibitory peptide (GIP)*. Because of its role as an incretin, GIP is also called *glucose-dependent insulinotropic peptide (GIP)*. Because of their insulin-elevating effects, incretin mechanisms are being investigated as possible treatments for diabetes mellitus (DM).

Epinephrine is a hormone secreted in large amounts by the adrenal medulla in times of emotional or physical stress. Like glucagon, epinephrine increases phosphorylase activity. This makes glycogenolysis occur at a faster rate. Epinephrine accelerates both liver and muscle glycogenolysis, whereas glucagon accelerates only liver glycogenolysis. Both hormones increase the blood glucose level. Epinephrine is the only hormone whose release into the systemic circulation (and therefore its effects on metabolism) is directly under the control of the nervous system.

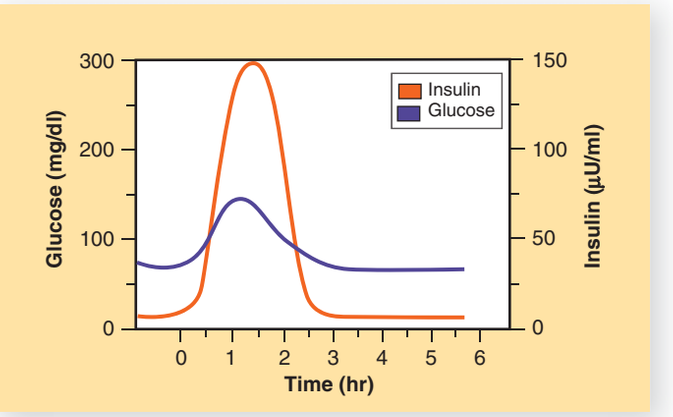


FIGURE 30-18

Role of insulin. Insulin operates in a negative feedback loop **(A)** that prevents blood glucose concentration from increasing too far above the normal range. Insulin promotes uptake of glucose by all cells of the body, enabling them to catabolize and/or store it. The liver and skeletal muscles are especially well adapted for storage of glucose as glycogen. Thus excess glucose is removed from the bloodstream, as the graph **(B)** demonstrates. If the glucose level falls below the normal range, hormones such as glucagon promote the release of glucose from storage into the bloodstream (see Figure 30-19).

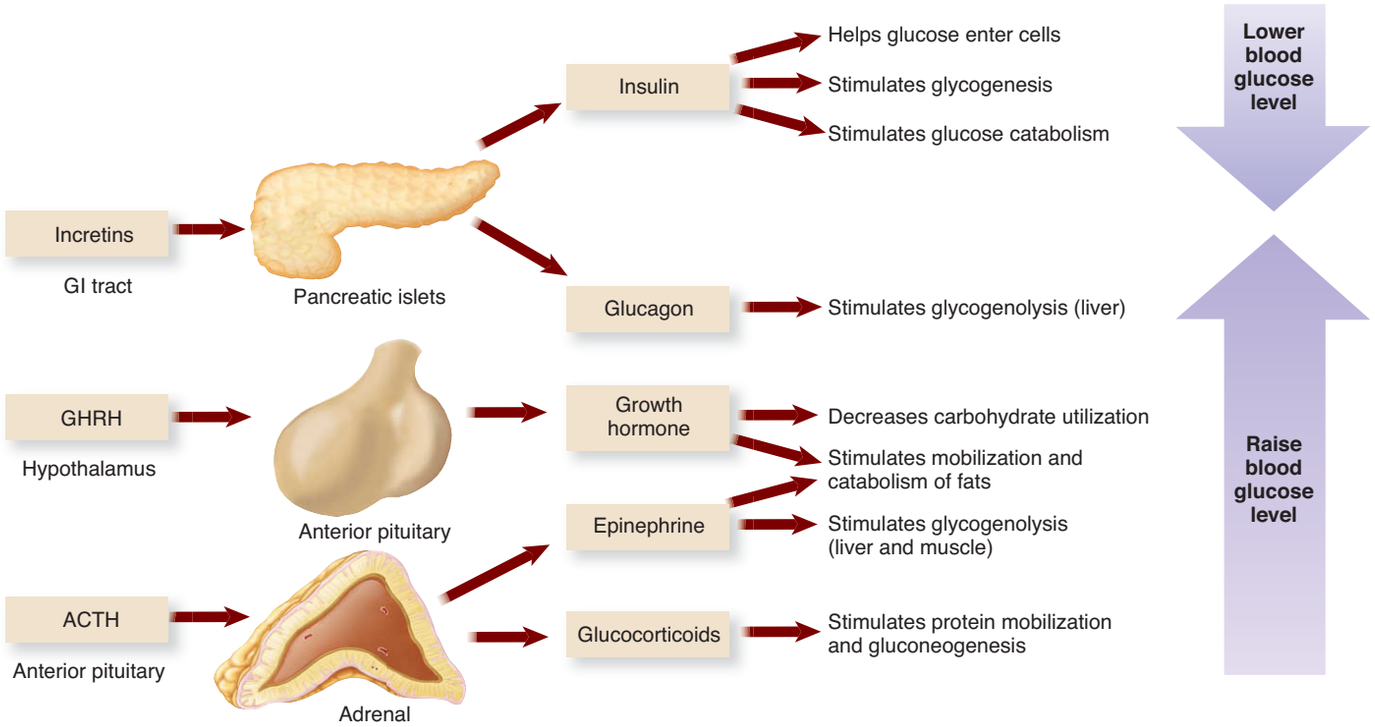

FIGURE 30-19

Hormonal control of blood glucose level. Simplified view of some of the major glucose-regulating hormones. Insulin lowers blood glucose level and is therefore hypoglycemic. Most hormones shown here raise blood glucose level and are called *hyperglycemic,* or *anti-insulin, hormones.* Figure 30-15 shows how the regulated processes change blood glucose levels.

Adrenocorticotropic hormone (ACTH) and *glucocorticoids* (e.g., cortisone) are two more hormones that increase blood glucose concentration. ACTH stimulates the adrenal cortex to increase its secretion of glucocorticoids. Glucocorticoids accelerate gluconeogenesis. They do this by mobilizing proteins, that is, the breakdown, or hydrolysis, of tissue proteins to amino acids. More amino acids enter the circulation and are carried to the liver. Liver cells step up their production of "new" glucose from the mobilized amino acids. Glucocorticoids help here, too, by stimulating enzymatic reversal of glycolysis and thus helping the cell in its effort to manufacture more glucose. The glucose streams out of liver cells into the blood and adds to the blood glucose level.

Growth hormone (GH), made by the anterior pituitary, also increases blood glucose level, but by a different mechanism. GH causes a shift from carbohydrate to fat catabolism. It does this by limiting the storage of fat in fat depots. Instead, more fats are mobilized and catabolized. In this way, GH "spares" carbohydrates from catabolism, and the level of glucose in the bloodstream is increased.

Thyroid-stimulating hormone (TSH) from the anterior pituitary gland and its target secretion, *thyroid hormone* (T_3 and T_4), have complex effects on metabolism. Some of these raise, and some lower, the glucose level. One of the effects of thyroid hormone is to accelerate catabolism, and because glucose is the body's "preferred fuel," the result may be a decrease in blood glucose level.

The summary of hormone control shown in Figure 30-19 indicates that most hormones cause the glucose blood level to rise. These hormones are called *hyperglycemic* because they tend to promote a high blood glucose concentration. The one notable exception is insulin, which is *hypoglycemic* (tends to decrease the blood glucose level). See Box 30-3 for more discussion of blood glucose problems.

Box 30-3 | FYI

Abnormal Blood Glucose Concentration

The term **hyperglycemia,** which literally means "condition of too much sugar in the blood," is used to describe any blood glucose concentration that is higher than the normal set point level. Hyperglycemia is most often associated with untreated diabetes mellitus, but it can occur in newborns when too much intravenous glucose is given or in other similar situations. If untreated, the excess glucose leaves the blood in the kidney—literally "spilling over" into the urine. This increases the osmotic pressure of urine, drawing an abnormally high amount of water into the urine from the bloodstream. Thus hyperglycemia causes loss of glucose in the urine and its accompanying loss of water—potentially threatening the fluid balance of the body. Dehydration of this sort can ultimately lead to death.

Hypoglycemia occurs when the blood glucose concentration dips below the normal set point level. Hypoglycemia can occur in various conditions, including starvation, hypersecretion of insulin by the pancreatic islets, or injection of too much insulin. Symptoms of hypoglycemia include weakness, hunger, headache, blurry vision, anxiety, and personality changes—perhaps leading to coma and death if untreated.

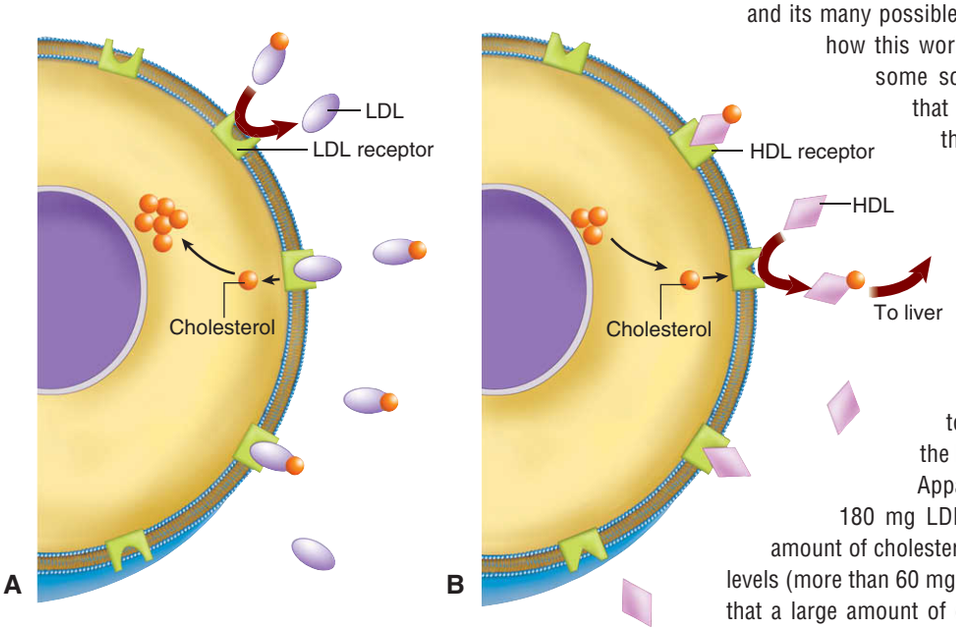
LIPIDS

Dietary Sources of Lipids

Recall from Chapter 2 that **lipids** are a class of organic compounds that includes fats, oils, and related substances. The most common lipids in the diet are **triglycerides,** which are composed of a *glycerol* subunit to which are attached three *fatty acids.* Other important dietary lipids include *phospholipids* and *cholesterol.* Dietary fats are often classified as either **saturated** or **unsaturated.** Saturated fats contain fatty acid chains in which there are no double bonds—that is, all available bonds of its hydrocarbon chain are filled (saturated) with hydrogen atoms (see Figure 2-19, p. 49). Saturated fats are usually solid at room temperature. Unsaturated fats contain fatty acid chains, of which there are some double bonds, meaning that not all sites for hydrogen are filled. Unsaturated fats are usually liquid at room temperature.

Triglycerides are found in nearly every food that we eat. However, the amount of triglycerides in each type of food varies considerably, as does the proportion of saturated to unsaturated types. Phospholipids are also found in nearly all foods because they



Box 30-4 | Lipoproteins

As stated in the text, high blood concentrations of low-density lipoproteins (LDLs) are associated with a high risk for atherosclerosis. Atherosclerosis is a form of "hardening of the arteries" that occurs when lipids accumulate in cells lining the blood vessels and promote the development of a plaque that eventually impedes blood flow and may trigger clot formation. Atherosclerosis may also weaken the wall of a blood vessel to the point that it ruptures. In any case, a person with atherosclerosis of the coronary arteries risks a heart attack when blood flow to cardiac muscle is impaired. If vessels in the brain are affected, there is risk of a *cerebrovascular accident (CVA),* or "stroke."

Part *A* of the figure is a simplified version of a concept of LDL function first proposed by Nobel laureates Michael Brown and Joseph Goldstein at the University of Texas. According to their model, LDL delivers cholesterol to cells for use in synthesizing steroid hormones and stabilizing the plasma membrane. Most, if not all, cells have many LDL receptors embedded in the outer surface of their plasma membranes. These receptors attract cholesterol-bearing LDL. Once the LDL molecule binds to the receptor, specific mechanisms operate to release the cholesterol it carries into the cell. Excess cholesterol is stored in droplets near the center of the cell. It seems that, in some individuals at least, cells have so few LDL receptors that they accumulate too much cholesterol in the blood. Some mechanism in endothelial cells moves this excess LDL into the wall of blood vessels. This has been proposed as a cause for the lipid accumulation characteristic of atherosclerosis.

High blood concentrations of high-density lipoproteins (HDLs) have been associated with a low risk of developing atherosclerosis and its many possible complications. Although the exact details of how this works have yet to be worked out or confirmed, some scientists have made some progress toward that end. Jack Oram, a cell biologist working at the University of Washington, has proposed the mechanism illustrated in part *B* of the figure. According to his model, HDL molecules are attracted to HDL receptors embedded in the plasma membranes. Once they bind to their receptors, the cell is stimulated to release some of its cholesterol from storage. The released cholesterol migrates to the plasma membrane, where it may attach to the HDL molecule and be whisked away to the liver for excretion in bile.

Apparently, high blood LDL levels (more than 180 mg LDL per 100 ml of blood) signify that a large amount of cholesterol is being delivered to cells. High blood HDL levels (more than 60 mg HDL per 100 ml of blood) apparently indicate that a large amount of cholesterol is being removed from cells and delivered to the liver for excretion from the body. Currently, researchers are using this information to develop treatments that may prevent—or even cure—atherosclerosis and the disorders it causes.

Role of blood lipoproteins. A, Simplified diagram of the role of low-density lipoprotein *(LDL)* in delivering cholesterol to cells. **B,** Proposed role of high-density lipoprotein *(HDL)* in removing cholesterol from cells.

make up the cellular membranes in and around each cell of all living organisms. Cholesterol, however, is found only in foods of animal origin. Cholesterol concentration also varies. For example, it is particularly high in liver and the yolks of eggs.

Transport of Lipids

Lipids are transported in blood as chylomicrons, lipoproteins, and free fatty acids. **Chylomicrons** are small fat droplets found in blood soon after fat absorption has occurred. Fatty acids and monoglyceride products of fat digestion combine during absorption to again form fats (triglycerides, or triacylglycerols). These triglycerides plus small amounts of cholesterol and phospholipids compose the chylomicrons. During fat absorption, the so-called *absorptive state*, blood may contain so many of these fat droplets that it appears turbid or even yellowish in color. But during the *postabsorptive state*—usually within about 4 hours after a meal—few, if any chylomicrons remain in the blood. Their contents have moved mostly into adipose tissue cells.

In the postabsorptive state, when chylomicrons are virtually absent from the circulation, some 95% of the lipids in blood are transported in the form of lipoproteins. **Lipoproteins** are produced mainly in the liver, and as their name suggests, they consist of lipids (triglycerides, cholesterol, and phospholipids) and protein. At all times, blood contains three types of lipoproteins, namely, very-low-density lipoproteins, low-density lipoproteins, and high-density lipoproteins. Usually, they are designated by their abbreviations: VLDL, LDL, and HDL. Diets high in saturated fats and cholesterol tend to produce an increase in blood LDL concentration, which in turn is associated with a high incidence of coronary artery disease (CAD) and atherosclerosis (Figure 30-20 and Box 30-4). A high blood HDL concentration, in contrast, is associated with a low incidence of heart disease. One might therefore think of the LDLs as the "bad lipoproteins" and the HDLs as the "good lipoproteins." Considerable evidence indicates that exercise tends to elevate HDL concentration. This may partially account for the beneficial effects of exercise.

Fatty acids, on entering the blood from adipose tissue or other cells, combine with albumin to form the so-called **free fatty acids (FFAs).** Fatty acids are transported from cells of one tissue to those of another in the form of free fatty acids. Whenever the rate of fat catabolism increases—as it does in starvation or diabetes—the free fatty acid content of blood increases markedly.

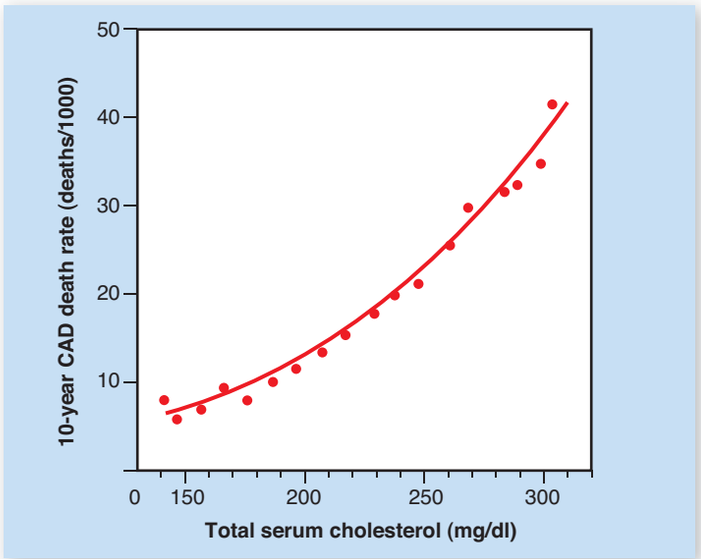


FIGURE 30-20

Cholesterol and heart disease. The graph shows a relationship between the total serum (blood plasma) cholesterol level and coronary artery disease (CAD).

Lipid Metabolism

LIPID CATABOLISM

Lipid catabolism, like carbohydrate catabolism, consists of several processes. Each of these processes, in turn, consists of a series of chemical reactions. Triglycerides are first hydrolyzed to yield fatty acids and glycerol. Glycerol is then converted to glyceraldehyde-3-phosphate, which may then be converted to glucose or it may enter the glycolysis pathway directly (see Figure 30-5). Fatty acids, as Figure 30-21 shows, are broken down by a process called *beta-oxidation* into two-carbon pieces, the familiar acetyl CoA. These molecules are then catabolized via the citric acid cycle. The final process of lipid catabolism therefore consists of the same reactions as does carbohydrate catabolism. Catabolism of lipids, however, yields considerably more energy than does catabolism of carbohydrates. Whereas catabolism of 1 gram of carbohydrates yields only 4.1 kcal of heat, catabolism of 1 gram of fat yields 9 kcal. It is not surprising, then, that lipids are the preferred energy source for muscle tissue.

When fat catabolism occurs at an accelerated rate, as in diabetes mellitus

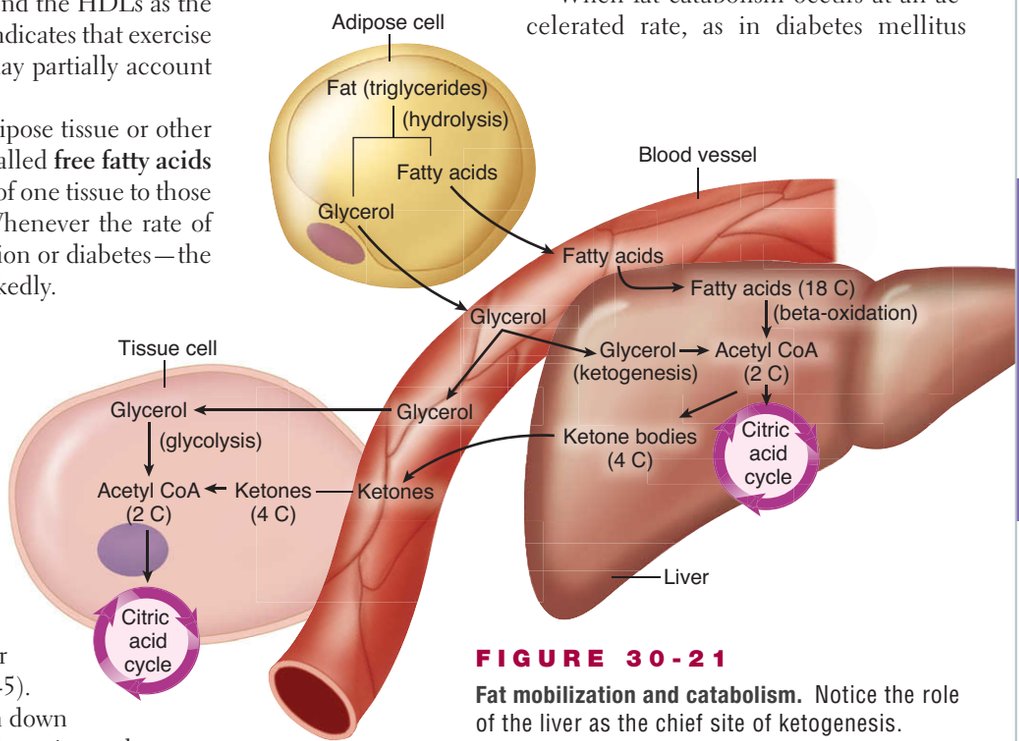

FIGURE 30-21

Fat mobilization and catabolism. Notice the role of the liver as the chief site of ketogenesis. Numbers of carbon atoms are in parentheses.

(when glucose cannot enter cells) or fasting, excessive numbers of acetyl CoA units are formed. Liver cells then temporarily condense acetyl CoA units together to form four-carbon acetoacetic acid. Acetoacetic acid is classified as a *ketone body* and can be converted to two other types of ketone bodies, namely, acetone and beta-hydroxybutyric acid—hence the name **ketogenesis** for this process (Box 30-5). Liver cells oxidize a small portion of the ketone bodies for their own energy needs, but most of them are transported by the blood to other tissue cells for the change back to acetyl CoA and oxidation via the citric acid cycle (see Figure 30-21).

LIPID ANABOLISM

Lipid anabolism, also called **lipogenesis,** consists of the synthesis of various types of lipids, notably *triglycerides*, *cholesterol*, *phospholipids*, and *prostaglandins*. Triglycerides and structural lipids (e.g., phospholipids) are synthesized from fatty acids and glycerol or from excess glucose or amino acids. So it is possible to "get fat" from foods other than fat. Triglycerides are stored mainly in adipose tissue cells. These fat deposits constitute the body's largest reserve energy source—often too large, unfortunately. Almost limitless pounds of fat can be stored. In contrast, only a few hundred grams of carbohydrates can be stored as liver and muscle glycogen.

Most fatty acids can be synthesized by the body. A certain number of the unsaturated fatty acids must be provided by the diet and are thus called **essential fatty acids.** Some of the essential fatty acids serve as a source within the body for synthesis of an important group of lipids called *prostaglandins*. These hormone-like compounds, first discovered in the 1930s in semen, have gained increasing recognition for their occurrence in various tissues, where they support a wide spectrum of biological activity (see Chapter 18). Certain essential fatty acids are also necessary for manufacturing the phospholipids in cell membranes (Chapter 3) and the myelin in nerve tissue (Chapter 13).

CONTROL OF LIPID METABOLISM

Lipid metabolism is controlled mainly by the following hormones:

- Insulin
- ACTH
- Growth hormone
- Glucocorticoids

You probably recall from our discussion of these hormones in connection with carbohydrate metabolism that they regulate fat metabolism in such a way that the rate of fat catabolism is inversely related to the rate of carbohydrate catabolism. If some condition such as diabetes mellitus causes carbohydrate catabolism to decrease below energy needs, increased secretion of growth hormone, ACTH, and glucocorticoids soon follows. These hormones, in turn, bring about an increase in fat catabolism. But, when carbohydrate catabolism equals energy needs, fats are not mobilized out of storage and catabolized (Box 30-6). Instead, they are spared and stored in adipose tissue. "Carbohydrates have a 'fat-sparing' effect," so says an old physiological maxim. Or stating this truth more descriptively: "Carbohydrates have a 'fat-storing' effect."

Research has shown that hormonal control of lipid metabolism is very complex—and still not well understood. One intriguing line of research involves the hormone **leptin.** Leptin is secreted by fat-storing cells and seems to regulate *satiety* (feeling of hunger/fullness) and how fat is metabolized. Researchers studying the complex interaction of leptin and other hormones and their receptors hope to find effective treatments for obesity, diabetes, and other fat-storage afflictions.

Box 30-5 | HEALTH matters

Ketosis

Large amounts of ketone bodies may be present in the blood of a person with uncontrolled diabetes mellitus. This condition is known as **ketosis.** Signs of it are acetone breath and *ketonuria* (high number of ketone bodies in the urine).

Box 30-6 | PPARs and Fat Metabolism

A class of proteins called *peroxisome proliferator–activated receptors,* or *PPARs,* may hold some keys as to how the body metabolizes fats. PPARs are molecules attached to the DNA molecules of cells. PPARs combine with other proteins to form a complex that regulates genes that determine how the cell takes in and breaks down fat. Initial research shows that chemicals that affect different PPARs can influence fat storage in the body. With more than 60% of the U.S. population being overweight and therefore at risk for heart disease, diabetes, cancer, and other health problems, it is no wonder that scientists are scrambling to find out more about how PPARs regulate fat metabolism and how we can influence them to reduce obesity-related health risks.

12. Which fatty acids cannot be made by the body?

PROTEINS

Sources of Proteins

Recall from Chapter 2 that proteins are very large molecules composed of chemical subunits called **amino acids** (see Figure 2-26, p. 53). Proteins are assembled from a pool of many different kinds of amino acids. If any one type of amino acid is deficient, vital proteins cannot be synthesized—a serious health threat. One way your body maintains a constant supply of amino acids is by

synthesizing them from other compounds already present in the body. Only about half of the required types of amino acids can be made by the body, however. The remaining types of amino acids must be supplied in the diet. Nutritionists often refer to the amino acids that must be in the diet as essential, or indispensable, amino acids. Table 30-1 lists amino acids according to whether they are considered essential in the diet or nonessential (dispensable) in the diet (synthesized by the body). Box 30-7 mentions the link between blood levels of amino acids and disease.

Proteins are obtained in the diet from various sources. Muscle meat and other animal tissues particularly high in proteins contain the essential amino acids. Food from a single plant or other nonanimal source does not usually contain an adequate amount of all the essential amino acids. Therefore, it is important to include meat in the diet or a mixture of different vegetables that provide all the amino acids needed by the body. Plant tissues that are particularly high in protein content include cereal grains, nuts, and legumes such as peas and beans.

Protein Metabolism

In protein metabolism, anabolism is primary and catabolism is secondary. In carbohydrate and fat metabolism, the opposite is true—catabolism is primary and anabolism is secondary. Proteins are primarily tissue-building foods. Carbohydrates and fats are primarily energy-supplying foods.

PROTEIN ANABOLISM

Protein anabolism is the process by which proteins are synthesized by the ribosomes of all cells. The specific mechanisms of protein anabolism were first discussed in Chapter 2 (see pp. 41–42) and further explained in Chapter 5 (see pp. 119–120). We review the basic idea of protein anabolism here.

Every cell synthesizes its own structural proteins and its own enzymes. In addition, many cells, such as liver and glandular cells, synthesize special proteins for export. For example, liver cells manufacture the plasma proteins found in blood. The cell's genes, under the influence of signaling mechanisms, determine the specific proteins to be synthesized. Protein anabolism is truly "big business" in the body. Consider, for instance, that protein anabolism constitutes the major process of growth, reproduction, tissue repair, and the replacement of cells destroyed by daily wear and tear. Red blood cell replacement alone amounts to millions of cells per second!

TABLE 30-1 Amino Acids

ESSENTIAL (INDISPENSABLE)	NONESSENTIAL (DISPENSABLE)
Histidine (His)*	Alanine (Ala)
Isoleucine (Ile)	Arginine (Arg)
Leucine (Leu)	Asparagine (Asn)
Lysine (Lys)	Aspartic acid (Asp)
Methionine (Met)	Cysteine (Cys)

	Serine (Ser)
	Tyrosine (Tyr)†

*Essential in infants and, perhaps, adult males.
†Can be synthesized from phenylalanine; therefore nonessential as long as phenylalanine is in the diet.

Box 30-7 | HEALTH matters

Amino Acids and Disease

The balance of amino acids circulating in the blood is associated with various diseases. High blood levels of homocysteine, one of several alternate forms of the amino acid cysteine (see Table 30-1), have been linked to heart disease, stroke, and dementias such as Alzheimer disease. Whether such abnormalities in homocysteine levels are the direct cause of these conditions is uncertain. Despite this uncertainty, many physicians recommend lowering abnormally high blood homocysteine levels to reduce the possible risk for these devastating conditions. Homocysteine can be reduced to normally low blood levels when there is adequate vitamin B_6, B_{12}, or B_9 (folic acid) in the diet.

PROTEIN CATABOLISM

The first step in protein catabolism takes place in liver cells. Called **deamination,** it consists of the splitting off of an amino (NH_2) group from an amino acid molecule to form a molecule of ammonia and one of keto acid (e.g., alpha-ketoglutaric acid). Most of the ammonia is converted by liver cells to *urea* and later excreted in the urine. The keto acid may be oxidized via the citric acid cycle (see Figure 30-7) or may be converted to glucose via gluconeogenesis (Figure 30-22) or to fat (lipogenesis). Both

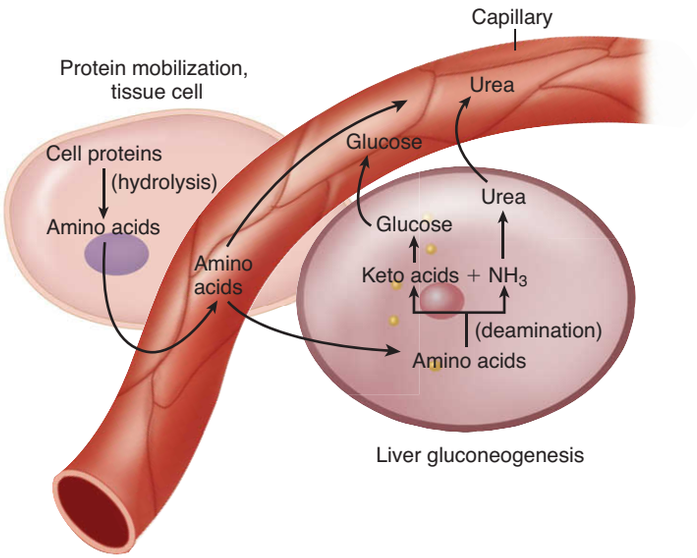

FIGURE 30-22

Protein mobilization and catabolism. Glucocorticoids tend to accelerate these processes and are therefore classified as protein catabolic hormones.

protein catabolism and anabolism go on continually. Only their rates differ from time to time. With a protein-deficient diet, for example, protein catabolism exceeds protein anabolism. Various hormones, as we shall see, also influence the rates of protein catabolism and anabolism.

PROTEIN BALANCE AND NITROGEN BALANCE

Usually a state of **protein balance** exists in the normal healthy adult body; that is, the rate of protein anabolism equals or balances the rate of protein catabolism. When the body is in protein balance, it is also in a state of **nitrogen balance** because the amount of nitrogen taken into the body (in protein foods) equals the amount of nitrogen in protein catabolic waste products excreted in the urine, feces, and sweat.

It is important to realize that there are two kinds of protein, or nitrogen, imbalance. When protein catabolism exceeds protein anabolism, the amount of nitrogen in the urine exceeds the amount of nitrogen in the protein foods ingested. The individual is then said to be in a state of **negative nitrogen balance,** or in a state of "tissue wasting"—because more of the tissue proteins are being catabolized than are being replaced by protein synthesis. Protein-poor diets, starvation, and wasting illnesses, for example, produce a negative nitrogen balance. A **positive nitrogen balance** (nitrogen intake in foods greater than nitrogen output in urine) indicates that protein anabolism is occurring at a faster rate than protein catabolism. A state of positive nitrogen balance therefore characterizes any condition in which large amounts of tissue are being synthesized, such as during growth, pregnancy, and convalescence from an emaciating illness.

CONTROL OF PROTEIN METABOLISM

Protein metabolism, like that of carbohydrates and fats, is controlled largely by hormones rather than by the nervous system. Growth hormone and the male hormone testosterone both have a stimulating effect on protein synthesis, or anabolism. For this reason, they are referred to as *anabolic* hormones. The protein *catabolic* hormones of greatest consequence are glucocorticoids. They speed up tissue protein mobilization, that is, the hydrolysis of cell proteins to amino acids, their entry into the blood, and their subsequent catabolism (see Figure 30-22). ACTH functions indirectly as a protein catabolic hormone because of its stimulating effect on glucocorticoid secretion.

Thyroid hormone is necessary for and tends to promote protein anabolism and therefore growth when plenty of carbohydrates and fats are available for energy production. On the other hand, under different conditions, for example, when the amount of thyroid hormone is excessive or when the energy foods are deficient, this hormone may then promote protein mobilization and catabolism.

Some of the facts about metabolism set forth in the preceding sections are summarized in Table 30-2 and Figure 30-23.

VITAMINS AND MINERALS

One glance at the label of any packaged food product reveals the importance we place on vitamins and minerals. We know that carbohydrates, fats, and proteins are used by our bodies to build important molecules and to provide energy. So why do we need vitamins and minerals?

Vitamins

Vitamins are organic molecules needed in small quantities for normal metabolism throughout the body (Box 30-8). The first vitamins were discovered in the early twentieth century at the University of Wisconsin by Marguerite Davis and Elmer Vernon McCollum. Earlier, vitamins were hypothesized to be amines so they were originally called vitamines, later shortened to vitamins. However, Davis and McCollum discovered two fat-soluble, nonamine substances that fit the proposed function of a vitamin and they named these factors fat-soluble A and fat-soluble B. This not only began a system of naming vitamins with letters but also spurred the whole science of nutrition.

Most vitamin molecules attach to enzymes or coenzymes and help them work properly. **Coenzymes** are organic, nonprotein catalysts that often act as "molecule carriers." Many enzymes or coenzymes are totally useless without the appropriate vitamins to attach to them and thus give them the shape that allows them to function properly. For example, coenzyme A (CoA), an important carrier molecule associated with the citric acid cycle, has *pantothenic acid* (vitamin B_5) as one of its major components.

Not all vitamins are involved directly with enzymes and coenzymes. Vitamins A, D, and E play a variety of different, but no less important, roles in the chemistry of the body. The form of vitamin A called *retinal*, for example, plays an important role in detecting light in sensory cells of the retina. Vitamin D can

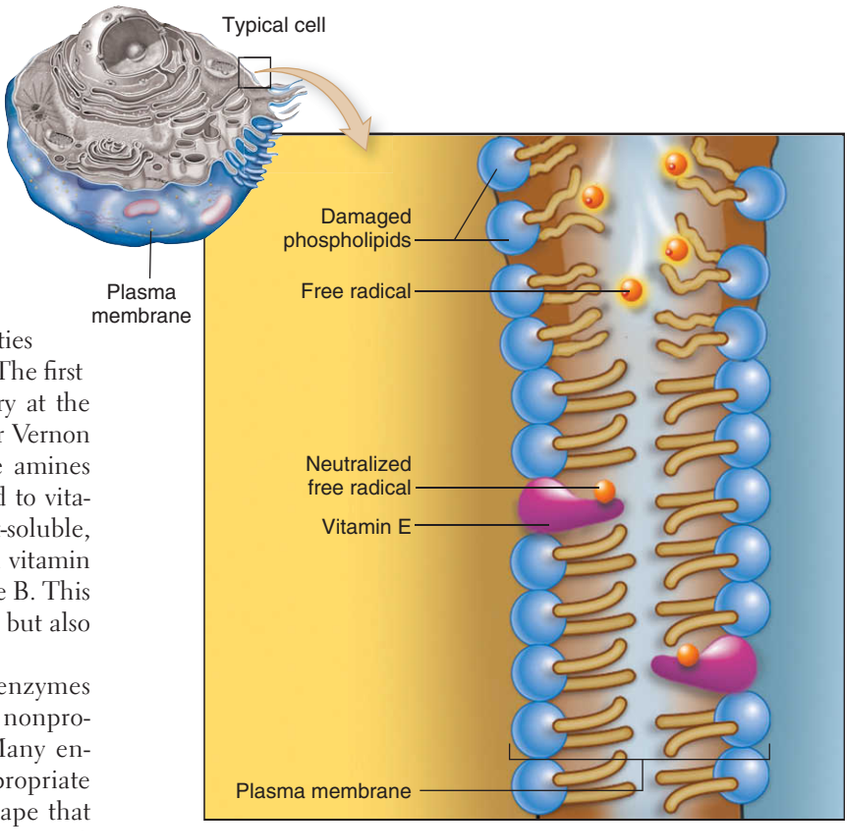

FIGURE 30-24

Role of vitamin E. Vitamin E can act as an antioxidant, attracting and neutralizing molecules with unpaired electrons. For example, free radicals are highly reactive molecules with an electron-seeking behavior that tends to damage electron-dense areas of the cell such as membrane phospholipids and DNA molecules. Vitamin E embedded among phospholipids in cell membranes can have a protective effect as it attracts and neutralizes free radicals that would otherwise destroy the membrane. Vitamin C has a similar antioxidant effect.

Box 30-8 | SPORTS and FITNESS

Vitamin Supplements for Athletes

Because a deficiency of vitamins *(avitaminosis)* can cause poor athletic performance, many athletes regularly consume vitamin supplements. However, research suggests that vitamin supplementation has little or no effect on a person's athletic performance. A reasonably well balanced diet supplies more than enough vitamins for even the elite athlete. The use of vitamin supplements therefore has fueled controversy among exercise experts. Opponents of vitamin supplements cite the cost and the possibility of liver damage associated with some forms of *hypervitaminosis,* whereas supporters cite the benefit of protecting against vitamin deficiency.

be converted to the hormone **calcitriol,** which plays a role in the regulation of calcium homeostasis in the body. One role of vitamin E is to serve as an **antioxidant** that prevents electron-seeking molecules such as free radicals from damaging electron-dense molecules in the cell membranes and DNA molecules. Figure 30-24 illustrates this function of vitamin E. Vitamin C may also serve as an antioxidant.

All but one vitamin, vitamin D, cannot be made by the body itself. Bacteria living in the colon make two more: vitamin K and biotin. We must eat vitamins, or molecules we can convert into vitamins, in our food to get the rest. The body can store fat-soluble vitamins—A, D, E, and K—in the liver for later use. Because the body cannot store significant amounts of water-soluble vitamins such as B vitamins and vitamin C, they must be continually supplied in the diet. Table 30-3 lists some of the better-known vitamins, their sources and functions, and symptoms of deficiency.

Minerals

Minerals are at least as important as vitamins in our diet. Minerals are inorganic elements or salts that are found naturally in the earth. Like vitamins, mineral ions can attach to enzymes or other organic molecules and help them work. Of course, minerals such as sodium, chloride, and potassium are essential in relatively large amounts for maintaining the fluid/ion composition of the internal fluid environment (see Chapter 29).

Minerals also function in various other vital chemical reactions. For example, sodium, calcium, and other minerals are required for nerve conduction and for contraction in muscle fibers. Without these minerals, the brain, heart, and respiratory tract would cease to function. Iron is needed to manufacture hemoglobin in red blood cells, and iodine is needed to make thyroid hormones T_3 and T_4. Calcium, phosphorus, and magnesium are required to build the strong structural components of the skeleton.

TABLE 30-3 Major Vitamins

VITAMIN	DIETARY SOURCE	FUNCTIONS	SYMPTOMS OF DEFICIENCY
Vitamin A	Green and yellow vegetables, dairy products, and liver	Maintains epithelial tissue and produces visual pigments	Night blindness and flaking skin
B-complex vitamins			
B_1 (thiamine)	Grains, meat, and legumes	Helps enzymes in the citric acid cycle	Nerve problems (beriberi), heart muscle weakness, and edema
B_2 (riboflavin)	Green vegetables, organ meats, eggs, and dairy products	Aids enzymes in the citric acid cycle	Inflammation of skin and eyes
B_3 (niacin)	Meat and grains	Helps enzymes in the citric acid cycle	Pellagra (scaly dermatitis and mental disturbances) and nervous disorders
B_5 (pantothenic acid)	Organ meat, eggs, and liver	Aids enzymes that connect fat and carbohydrate metabolism	Loss of coordination (rare), decreased gut motility
B_6 (pyridoxine)	Vegetables, meats, and grains	Helps enzymes that catabolize amino acids	Convulsions, irritability, and anemia
B_9 (folic acid)	Vegetables	Aids enzymes in amino acid catabolism and blood production	Digestive disorders and anemia
B_{12} (cyanocobalamin)	Meat and dairy products	Involved in blood production and other processes	Pernicious anemia
Biotin (vitamin H)	Vegetables, meat, and eggs	Helps enzymes in amino acid catabolism and fat and glycogen synthesis	Mental and muscle problems (rare)
Vitamin C (ascorbic acid)	Fruits and green vegetables	Helps in manufacture of collagen fibers; antioxidant	Scurvy and degeneration of skin, bone, and blood vessels
Vitamin D (calciferol)	Dairy products and fish liver oil	Aids in calcium absorption	Rickets and skeletal deformity
Vitamin E (tocopherol)	Green vegetables and seeds	Protects cell membranes from being destroyed; antioxidant	Muscle and reproductive disorders (rare)

TABLE 30-4 Major Minerals

MINERAL	DIETARY SOURCE	FUNCTIONS	SYMPTOMS OF DEFICIENCY
Calcium (Ca)	Dairy products, legumes, and vegetables	Helps blood clotting, bone formation, and nerve and muscle function	Bone degeneration and nerve and muscle malfunction
Chlorine (Cl)	Salty foods	Aids in stomach acid production and acid-base balance	Acid-base imbalance
Cobalt (Co)	Meat	Helps vitamin B_{12} in blood cell production	Pernicious anemia
Copper (Cu)	Seafood, organ meats, and legumes	Involved in extracting energy from the citric acid cycle and in blood production	Fatigue and anemia
Iodine (I)	Seafood and iodized salt	Required for thyroid hormone synthesis	Goiter (thyroid enlargement) and decrease in metabolic rate
Iron (Fe)	Meat, eggs, vegetables, and legumes	Involved in extracting energy from the citric acid cycle and in blood production	Fatigue and anemia
Magnesium (Mg)	Vegetables and grains	Helps many enzymes	Nerve disorders, blood vessel dilation, and heart rhythm problems
Manganese (Mn)	Vegetables, legumes, and grains	Helps many enzymes	Muscle and nerve disorders
Phosphorus (P)	Dairy products and meat	Aids in bone formation and is used to make ATP, DNA, RNA, and phospholipids	Bone degeneration and metabolic problems
Potassium (K)	Seafood, milk, fruit, and meats	Helps muscle and nerve function	Muscle weakness, heart problems, and nerve problems
Selenium (Se)	Nuts, grains, meat, fish, mushrooms, eggs	Needed to make some amino acids; cofactor for enzymes	Heart muscle damage, cartilage degeneration, hypothyroidism
Sodium (Na)	Salty foods	Aids in muscle and nerve function and fluid balance	Weakness and digestive upset
Zinc (Zn)	Many foods	Helps many enzymes	Inadequate growth

Information about some of the more important minerals is summarized in Table 30-4. Like vitamins, minerals are beneficial only when taken in the proper amounts. Some of the minerals listed in Table 30-4 are required in large amounts and some only in trace amounts. Any intake of minerals beyond or below the recommended amount may become unhealthy—perhaps even life threatening.

Recommended *adequate intakes (AIs)* of minerals can change over the life span. For example, Figure 30-25 shows that calcium intake should increase throughout childhood and remain high throughout adulthood. However, the same figure shows that actual intake of calcium among females in the United States tends to fall short during adulthood—thereby increasing the risk for osteoporosis and other disorders.

Figure 30-26 shows the requirement for iron over the life span for both men and women. Although both males and females require a large amount of iron during the spurt of growth in the teenage years, the iron requirement remains high only in women during the rest of adulthood. This difference is explained by the fact that adult women must continually replace the iron lost in

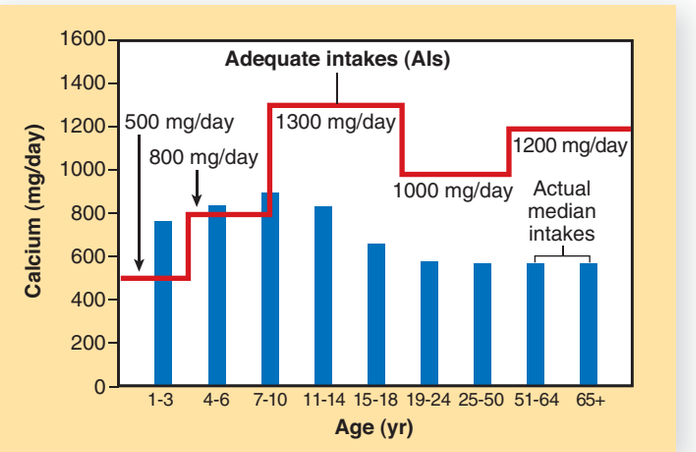

FIGURE 30-25

Calcium intake in women. The chart compares the recommended adequate intake (AIs) of calcium for women over the life span with the actual median intake of calcium among females in the United States.

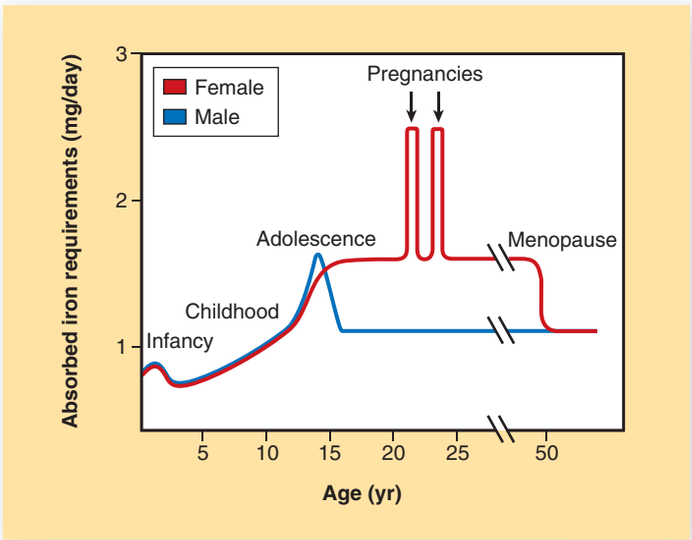

FIGURE 30-26

Iron intake requirements. The chart compares male and female absorbable iron requirements over the life span.

the menstrual flow. Notice that female iron requirements drop to the level of males after menopause. Notice also that the iron requirement peaks during pregnancies—when fetal blood development requires large amounts of iron.

evolve

METABOLIC RATES

Metabolic rate refers to the amount of energy released in the body in a given time by catabolism. It is the energy that must be expended to accomplish various kinds of work. In short, metabolic rate is the catabolic rate, or the rate of energy release.

Metabolic rates are expressed in either of two ways: (1) in terms of the number of kilocalories of heat energy expended per hour or per day or (2) as normal or as a definite percentage above or below normal.

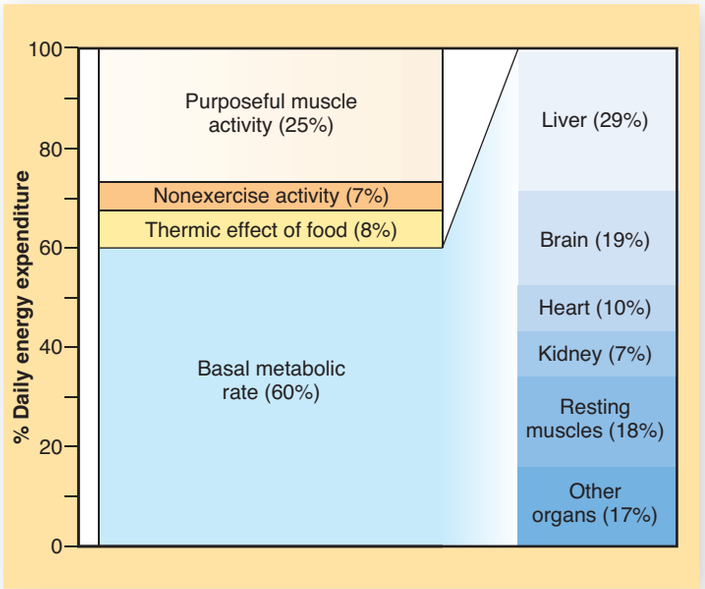

FIGURE 30-27

Daily energy expenditure. The left bar shows the total energy expenditure of the body as a combination of the basal metabolic rate (BMR), the thermic effect of food, everyday tasks, and purposeful exercise. The right bar shows the organs of the body that contribute to the basal metabolic rate.

Basal Metabolic Rate

The **basal metabolic rate (BMR)** is the body's rate of energy expenditure under "basal conditions," namely, when the individual is:

- Awake but resting, that is, lying down and, as far as possible, not moving a muscle.
- In the postabsorptive state (12 to 18 hours after the last meal).
- In a comfortably warm environment (the so-called *thermoneutral zone*, a temperature range at which metabolism is independent of ambient temperature).

Note that the BMR is not the minimum metabolic rate. It does not indicate the smallest amount of energy that must be expended to sustain life. It does, however, indicate the smallest amount of energy expenditure that can sustain life and also maintain the waking state and a normal body temperature in a comfortably warm environment.

FACTORS INFLUENCING BASAL METABOLIC RATE

The BMR is not identical for all individuals because of the influence of various factors (Figures 30-27 and 30-28), some of which are described in the following paragraphs (Box 30-9).

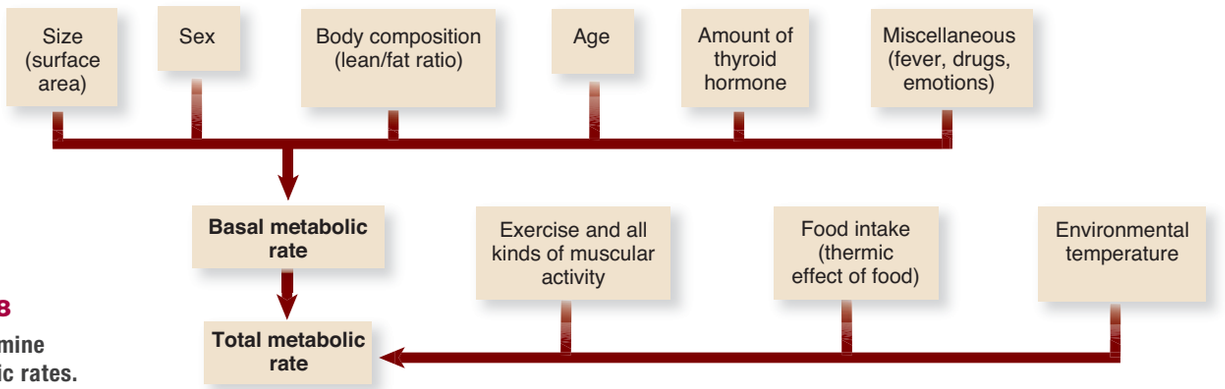

FIGURE 30-28
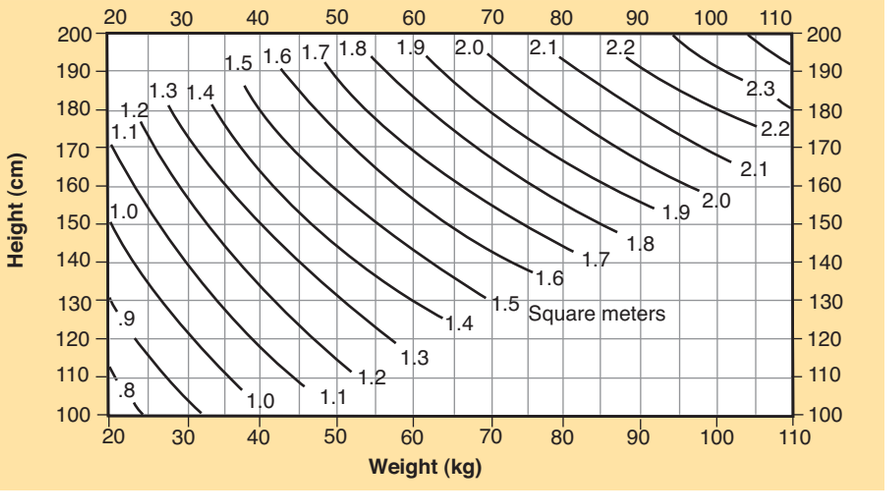
Some factors that determine basal and total metabolic rates.

Box 30-9 | How BMR Is Determined

Basal metabolic rate (BMR) can be determined by a method called **indirect calorimetry.** The rationale underlying this method is that BMR (expressed as the number of kilocalories of heat produced per unit of time) can be calculated from the amount of oxygen consumed in a given time (part *B* of the figure). BMR can then be expressed as normal, or as a definite percentage above or below normal, by dividing the actual kilocalorie rate by the known average kilocalorie rate for normal individuals of the same size, sex, and age.

Statistical tables, based on research, list estimated normal BMRs. (If BMR was calculated to be 10% above normal, for example, it would be reported as +10.) Are you curious to know the average BMR for a person of your size, sex, and age? If so, take the following steps:



1. Start with your weight in kilograms and your height in centimeters. (Convert pounds to kilograms by dividing pounds by 2.2. Convert inches to approximate centimeters by multiplying inches by 2.5.) For example, 110 pounds = 50 kg; 5 feet, 3 inches = 158 cm.
2. Convert your weight and height to square meters by using the chart shown here (part *B* of the figure). For example, a weight of 50 kg and height of 158 cm = about 1.5 square meters of body surface area.
3. Find your age and sex in Table 30-5 and then multiply the number of kilocalories per square meter per hour given there by your square meters of surface area and then by 24. For example, the average BMR per day for a 25-year-old woman with a weight of 110 pounds and height of 5 feet, 3 inches = 1332 kcal (37 × 1.5 × 24).

A quick rule of thumb for estimating a young woman's BMR in kcal/hr is to multiply her weight in pounds by 12.

A

B

Measuring BMR. A, Indirect calorimetry calculates the rate of metabolism by measuring the rate at which oxygen is consumed. **B,** BMR estimate chart.

TABLE 30-5 Basal Metabolism

	KILOCALORIES PER HOUR PER SQUARE METER BODY SURFACE	
AGE (YR)	MALE	FEMALE
10-12	51.5	50.0
12-14	50.0	46.5
14-16	46.0	43.0
16-18	43.0	40.0
18-20	41.0	38.0
20-30	39.5	37.0
30-40	39.5	36.5
40-50	38.5	36.0
50-60	37.5	35.0
60-70	36.5	34.0

Size

In computing the BMR, size is usually indicated by the amount of the body's surface area. It is computed from the individual's height and weight. A large individual has the same BMR as a small person per square meter of body surface, if other conditions are equal. However, because a large individual has more square meters of surface area, the BMR is greater than that of a small individual. For example, the BMR for a man in his 20s is about 40 kcal per square meter of body surface per hour (Table 30-5). However, a large man with a body surface area of 1.9 square meters would have a BMR of 76 kcal per hour, whereas a smaller man with a surface area of perhaps 1.6 square meters would have a BMR of only 64 kcal per hour. The average surface area for American adults is 1.6 square meters for women and 1.8 square meters for men.

Body Composition

Lean tissue is mostly "working tissue" that uses energy at a faster rate than does storage tissue or fat tissue. Therefore, the higher the ratio of lean tissue to fat tissue in a person, the higher the BMR.

Gender

Men oxidize their food approximately 5% to 7% faster than women do. Therefore their BMRs are about 5% to 7% higher for a given size and age. A man 5 feet, 6 inches tall weighing 140 pounds, for example, has a 5% to 7% higher BMR than a woman of the same height, weight, and age. This gender difference in BMR probably results from the difference in the proportion of body fat, which is determined by sex hormones. Women tend to have a higher percentage of body fat (and thus a lower total lean mass) than men do (Figure 30-29). Fat tissue is less metabolically active than lean tissues such as muscle. Differences in total lean mass not related to gender also affect the BMR. The relationship of BMR to sex and age is illustrated in Figure 30-30.

Age

That the fires of youth burn more brightly than those of age is a physiological and a psychological fact. In general, the younger the individual, the higher the BMR for a given size and sex (see Table 30-5). Exception: the BMR is slightly lower at birth than it is a few years later. That is to say, the rate increases slightly during the first 3 to 6 years, then starts to decrease and continues to do so throughout life.

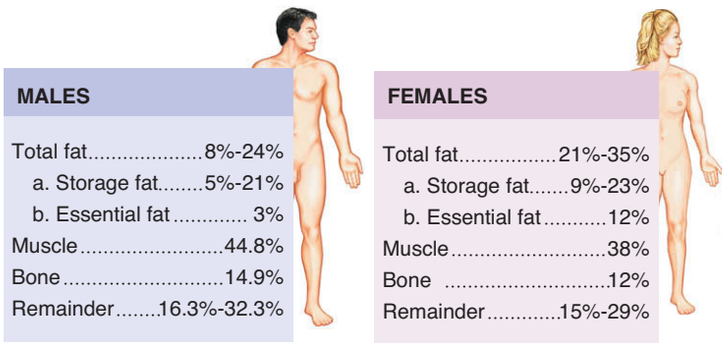


FIGURE 30-29

Body composition. Estimated values in healthy men and women.

Thyroid Hormone

Thyroid hormone (T_3 and T_4) stimulates basal metabolism. Without a normal amount of this hormone in the blood, a normal BMR cannot be maintained. When an excess of thyroid hormone is secreted, foods are catabolized faster, much as wood in a fireplace is burned faster when the draft is open. Deficient thyroid secretion, on the other hand, slows the rate of metabolism.

Body Temperature

Fever increases the BMR. For every degree Celsius increase in body temperature, metabolism increases about 13%. A decrease in body temperature (hypothermia) has the opposite effect. Metabolism decreases, and because it does, cells use less oxygen than they normally do. This knowledge has been applied clinically by using hypothermia in certain situations—for example, in open-heart surgery. Because circulation is reduced or interrupted during this

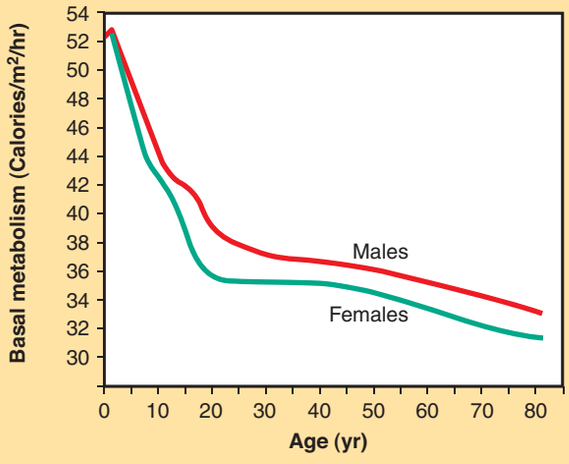

FIGURE 30-30

Basal metabolic rates over the life span. The chart shows normal basal metabolic rates (BMRs) as function of age for each sex.

procedure, oxygen supply necessarily decreases. Cells can tolerate this decreased oxygen supply reasonably well if their oxygen need has also decreased. Induced hypothermia decreases their rate of metabolism and thereby decreases their use of oxygen.

Drugs

Certain drugs, such as caffeine, amphetamine, and levothyroxine, increase the BMR.

Other Factors

Other factors, such as *emotions*, *pregnancy*, and *lactation* (milk production), also influence basal metabolism. All of these factors increase the BMR.

Total Metabolic Rate

Total metabolic rate is the amount of energy used or expended by the body in a given time. It is often expressed in kilocalories per hour or per day. Most of the factors that determine the total metabolic rate are shown in Figures 30-27 and 30-28. Of these, the main direct determinants are as follows.

Factor 1—the basal metabolic rate, that is, the energy used to do the work of maintaining life under the basal conditions previously described. Basal metabolic rate usually constitutes about 55% to 60% of the total metabolic rate.

Factor 2—the energy used to do all kinds of skeletal muscle work. This encompasses the simplest activities such as feeding oneself or sitting up in bed to the most strenuous kind of physical labor or exercise.

Factor 3—the *thermic effect* of foods. The metabolic rate increases for several hours after a meal, apparently because of the energy needed for metabolizing foods. Carbohydrates and fats have a thermic effect of about 5%. Proteins have a much higher thermic effect, about 30%. This means that for every 100 kcal of protein, 30 kcal are used for processes such as deamination and oxidation of the protein, leaving just 70 kcal available for other cell work. For this reason, proteins are "worth" fewer calories.

Energy Balance and Body Weight

When we say that the body maintains a state of energy balance, we mean that its energy input equals its energy output. Energy input per day equals the total calories (kilocalories) in the food ingested per day. Energy output equals the total metabolic rate expressed in kilocalories. You may be wondering what energy intake, output, and balance have to do with body weight. "Everything" would be a fairly good one-word answer. Or, to be somewhat more explicit, the following basic principles describe the relationships between these factors:

- Body weight remains constant (except for possible variations in water content) when the body maintains energy balance—when the total calories in the food ingested equals the total metabolic rate. Example: If you have a total metabolic rate of 2000 kcal per day and if the food you eat per day yields 2000 kcal, your body will be maintaining energy balance and your weight will stay constant.
- Body weight increases when energy input exceeds energy output—when the total calories of food intake per day is greater than the total calories of the metabolic rate. A small amount of the excess energy input is used to synthesize glycogen for storage in the liver and muscles. The rest is used for synthesizing fat and storing it in adipose tissue. If you were to eat 3000 kcal each day for a week and if your total metabolic rate were 2000 kcal per day, you would gain weight. How much you would gain you can discover by doing a little simple arithmetic:

  Total energy input for week = 21,000 kcal

  Total energy output for week= −14,000 kcal

  Excess energy input for week = 7000 kcal

  Approximately 3500 kcal are used to synthesize 1 pound of adipose tissue. Hence, at the end of this 1 week of "overeating"—of eating 7000 kcal over and above your total metabolic rate—you would have gained about 2 pounds.

- Body weight decreases when energy input is less than energy output—when the total number of calories in the food eaten is less than the total metabolic rate. Suppose you were to eat only 1000 kcal a day for a week and that you have a total metabolic rate of 2000 kcal per day. By the end of the week, your body would have used a total of 14,000 kcal of energy for maintaining life and doing its many kinds of work. All 14,000 kcal of this actual energy expenditure had to come from catabolism of foods because this is the body's only source of energy. Catabolism of ingested food supplied 7000 kcal, and catabolism of stored food supplied the remaining 7000 kcal. That week your body would not have maintained energy balance, nor would it have maintained weight balance. It would have incurred an energy deficit paid out of the energy stored in approximately 2 pounds of body fat. In short, you would have lost about 2 pounds.

Foods are stored primarily as glycogen and fats. Many cells catabolize them preferentially in this order: carbohydrates, then fats. (Skeletal muscle cells, however, seem to put fat first in their order of preference.) If there is no food intake, almost all of the glycogen is estimated to be used up in a matter of 1 or 2 days (Figure 30-31). Then, with no more carbohydrate to act as a fat sparer, fat is catabolized. How long it takes to deplete all of this reserve food depends, of course, on how much adipose tissue the individual has when starting the starvation diet. Finally, with no more fat available, tissue proteins are catabolized (see Figure 30-31). Because significant amounts of protein are not "stored" for use in catabolism, important structural and functional proteins are quickly depleted. Thus death soon ensues.

MECHANISMS FOR REGULATING FOOD INTAKE

Mechanisms for regulating food intake are still not clearly established. That the hypothalamus plays a part in these mechanisms, however, seems certain. Numerous studies seem to indicate that a cluster of neurons in the lateral hypothalamus function as an **appetite center**—meaning that impulses from them bring about increased appetite. This effect is often called an **orexigenic effect** (meaning an "appetite-producing" effect).

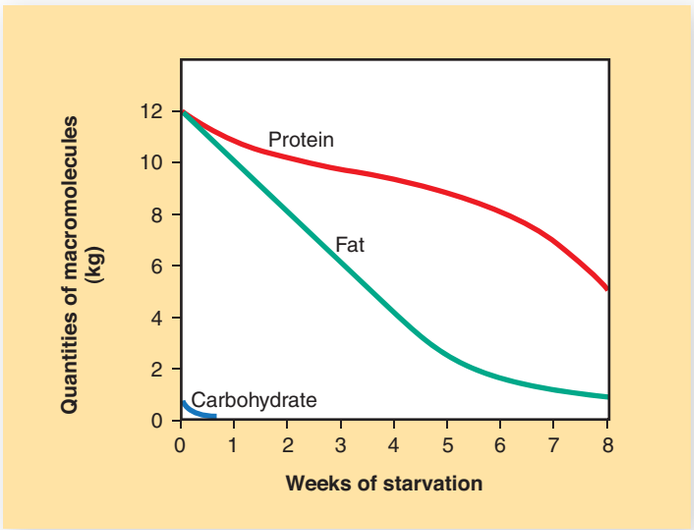

FIGURE 30-31

Effects of starvation on the body. Three major macromolecules serve as primary energy sources: carbohydrates, fats, and proteins. During starvation, the carbohydrate stores (glycogen) are rapidly depleted. However, stored lipids can mobilize and provide much of our energy needs for several weeks. Eventually, lipid stores run low and the body starts using proteins as a major source of energy—causing the breakdown of muscle and other protein-rich tissues. Muscle damage during starvation usually leads to death.

Additional data suggest that a group of neurons in the ventral medial nucleus of the hypothalamus functions as a **satiety center**—meaning that impulses from these neurons decrease appetite so that we feel sated, or satisfied. This effect is often called an **anorexigenic effect** (meaning "producing an appetite loss" effect).

What acts directly on both of these feeding centers to stimulate or depress them is still being worked out by researchers.

One factor is the temperature of the blood circulating to the hypothalamus. A moderate decrease in blood temperature stimulates the appetite center (and inhibits the satiety center). Result: The individual has an appetite, wants to eat, and probably does. An increase in blood temperature produces the opposite effect, a depressed appetite **(anorexia).** One well-known instance of this effect is the loss of appetite in persons who have a fever.

Another factor is blood glucose concentration and the rate of glucose use. A low blood glucose concentration or low glucose use stimulates the appetite center, whereas a high blood glucose concentration inhibits it. This may be the action of a group of hormones called **orexins** or *hypocretins* produced in the hypothalamus in response to low blood glucose levels.

More recently, a variety of hormones and other regulators have been identified that have a profound impact on the feeding centers of the brain. The hypothalamus itself produces several hormones and neurotransmitters that affect the feeding centers, as you can see in Table 30-6. In addition, appetite-altering factors (hormones and neurotransmitters) are produced in many other organs such as

TABLE 30-6 Examples of Appetite-Regulating Factors*

OREXIGENIC FACTORS (STIMULATE APPETITE)	ANOREXIGENIC FACTORS (INHIBIT APPETITE)	SOURCE
	Leptin Interleukin 18 (IL-18)	Adipose tissue
Cortisol		Adrenal cortex
Ghrelin (GHRL)	Cholecystokinin (CCK) Glucagon-like peptide-1 (GLP-1) Oxyntomodulin (OXM) Peptide YY_{3-36} (PYY_{3-36})	GI tract
Endogenous opioid peptides (EOP) Galanin (GAL) Gamma-aminobutyric acid (GABA) Neuropeptide Y (NPY) Norepinephrine (NE) Orexins	Alpha-melanocyte–stimulating hormone (α-MSH) Cocaine- and amphetamine-regulated transcript (CART) Corticotropin-releasing hormone (CRH)	Hypothalamus
	Glucose	Liver
Emotions Environmental stimuli Food sensations Internal stimuli (e.g., blood temperature, glucose) Lifestyle choices and habits	Emotions Environmental stimuli Food sensations Internal stimuli (e.g., blood temperature, glucose) Lifestyle choices and habits	Nervous system†
	Insulin Pancreatic polypeptide (PP)	Pancreas

*Hormones, neurotransmitters, and other factors that affect feeding centers in the hypothalamus.
†Nervous factors not specifically hypothalamic in origin. *GI,* Gastrointestinal.

the liver, adipose tissue, pancreas, GI tract, and autonomic nerve pathways (especially the vagal nerve). Of course, factors such as daily eating habits or patterns, emotional responses, the sensations of food, and many others must also be involved in regulating or affecting appetite.

Unquestionably, many factors operate together as a complex mechanism for regulating food intake—a mechanism that is still incompletely understood.

20. Name three of the factors that influence basal metabolic rate.
21. Distinguish between basal metabolic rate and total metabolic rate.
22. In which division of the brain would you find the control centers for regulating food intake?

Cycle of LIFE

Nutrition and Metabolism

The importance of proper nutrition to an individual's well-being begins at the moment of conception and continues until death. In the womb, various nutrients must be obtained from the mother's blood in sufficient quantity to ensure normal growth and development.

One critical nutrient during fetal development, infancy, and childhood is protein. Sufficient proteins, containing all the essential amino acids, are required to permit normal development of the nervous system, muscle tissues, and other vital structures.

Another critical nutrient during the early years of life is the mineral calcium. Large quantities of calcium are needed by a growing body to maintain normal development of the skeleton and other tissues. In the womb, a steady supply of calcium in the mother's blood is maintained by increased levels of the parathyroid hormone (PTH). Recall from Chapter 19 that PTH increases blood calcium levels by removing it from storage in the bones.

Unless a pregnant woman consumes enough calcium to replace this calcium lost from bones, she may suffer from the bone-softening effects of calcium deficiency. If proteins, calcium, or other necessary nutrients are in short supply anytime before the beginning of adulthood, the consequences may be permanent. For example, bone deformities resulting from a lack of calcium during childhood could become permanent if not corrected or compensated for before the skeleton ossifies completely.

In late adulthood, the number of food calories needed declines because the metabolic rate declines. This metabolic decline is thought to result largely from age-related changes in the balance of metabolic hormones such as thyroid hormones (T_3 and T_4). Even though the number of required food calories declines, the overall balance of nutrients consumed must be maintained to preserve proper metabolic function. Some nutrients, such as calcium, may be needed in greater quantity in older adults to compensate for (or avoid) age-related bone loss or other conditions.

the BIG picture

Nutrition, Metabolism, and the Whole Body

Of all the topics we have discussed so far, the topic of nutrition and metabolism has the most easily seen role in the "big picture" of human body function. Every cell in the body must maintain the operation of its metabolic pathways to ensure its survival. Anabolic pathways are required to build the various structural and functional components of the cells. Catabolic pathways are required to convert energy to a usable form. Catabolic pathways are also needed to degrade large molecules into small subunits that can be used in anabolic pathways. Of course, the basic nutrient molecules—carbohydrates, fats, and proteins of the correct type—must be available to each cell to carry out these metabolic processes. Besides the basic nutrient molecules, cells also require small amounts of specific vitamins and minerals needed to produce the structural and functional components necessary for cellular metabolism.

Various body systems operate to make sure that essential nutrients reach the cells as needed to maintain metabolism in a manner that preserves relative constancy of the internal environment. For example, the nervous, skeletal, and muscular systems make it possible for us to take in complex foods from our external environment. The digestive system reduces these complex nutrients to simpler, more usable nutrients—then provides the mechanisms that allow us to absorb them into the internal environment. The circulatory system—both the cardiovascular and the lymphatic circulations—transports the absorbed nutrients to the individual cells for immediate use or to the liver or other organs for temporary storage. The endocrine system regulates the balance between immediate use and storage. The respiratory system, working with the cardiovascular system, provides the oxygen needed for oxidative phosphorylation—that is, using the citric acid cycle and electron transport system to transfer energy to ATP. These two systems also provide a mechanism for removing waste carbon dioxide (CO_2) generated by the catabolism of nutrient molecules. Likewise, the urinary system provides a mechanism for removing waste urea generated by protein catabolism. Even the integumentary system becomes involved, by producing vitamin D in the presence of sunlight.

Metabolism, with all the physiological mechanisms that support it, could be described as the essential process of life. It is, after all, the sum total of all the biochemical processes that distinguish a living organism from a nonliving object.

MECHANISMS of DISEASE

METABOLIC AND NUTRITIONAL DISORDERS

Disorders characterized by a disruption or imbalance of normal metabolism can be caused by several different factors. For example, **inborn errors of metabolism** are a group of genetic conditions involving a deficiency or absence of a particular enzyme. Specific enzymes are required by cells to carry out each step of every metabolic reaction. Although an abnormal genetic code may affect the production of only a single enzyme, the resulting abnormal metabolism may have widespread effects. Specific diseases resulting from inborn errors of metabolism, such as **phenylketonuria,** are discussed in Chapter 37.

A number of metabolic disorders are complications of other conditions. For example, you may recall from Chapter 19 that both hyperthyroidism and hypothyroidism have profound effects on the basal metabolic rate. Diabetes mellitus affects metabolism throughout the body when an insulin deficiency limits the amount of glucose available for use by the cells.

Some metabolic disorders result from normal mechanisms in the body that maintain homeostasis. For example, the body has several mechanisms that maintain a relatively constant level of glucose in the blood—glucose required by cells for life-sustaining catabolism. As mentioned earlier in this chapter, during starvation or as a result of certain eating disorders, these mechanisms are taken to the extreme as they attempt to maintain blood glucose homeostasis. A few of the more well known eating and nutrition disorders are briefly described later in Mechanisms of Disease.

Body Mass Index (BMI)

The **body mass index (BMI)** is a measure of a person's proportion of body weight to height. The BMI was developed in the late twentieth century as a way for researchers to easily assess body-fat percentages in large populations so they could track trends in obesity and other health conditions.

To calculate a BMI, simply divide weight (in kilograms) by the square of height (in meters): BMI = kg/m^2. To determine kilogram weight, divide the number of pounds by 2.2. To determine meter height, divide total inches by 39.4. Thus the BMI can quickly tell individuals whether they are above or below their ideal weight, and by approximately how much.

As discussed in the following sections and illustrated in Figure 30-32, a BMI that is too high or too low is associated with an increased risk of death. However, remember that BMI is most useful when looking at trends in a population as a whole and not as useful in individual risk assessments. Factors such as gender, age, and genetics play a role in such health assessments, so BMI alone is not sufficient. Measurements of waist or thigh circumference and body fat percentages (see Box 6-4 p. 147) are often used along with BMI to give a more complete picture.

Metabolic Syndrome

Metabolic syndrome is a collection of risk factors for coronary artery disease, stroke, and type-2 diabetes. One of the risk factors that occurs in metabolic syndrome is large waist circumference—the "apple-shaped" central obesity previously described in Box 1-1 on p. 18. Another important factor is *insulin resistance*. As target cells respond less efficiently to insulin, glucose cannot enter cells and the body must move triglycerides and other lipids into the blood to supply energy needs. Thus, *hyperlipidemia* (elevated blood lipids, such as high triglyceride and LDL cholesterol) are also risk factors included in this syndrome. Other risk factors included are low HDL cholesterol, hypertension, increased blood clotting, elevated inflammation mediators, and related factors. Metabolic syndrome can be treated with diet, exercise, cholesterol-lowering therapy, and other strategies to reduce central obesity.

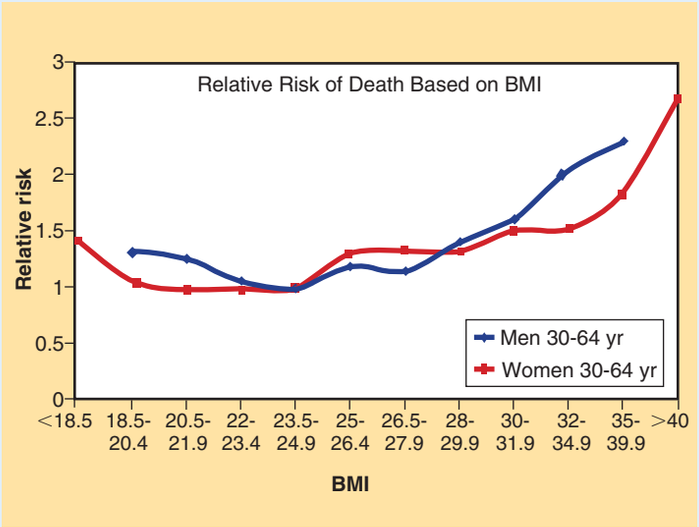

FIGURE 30-32

Body mass index (BMI) and risk of death. Mortality (death) risk is higher in individuals with a high or low BMI.

Eating Disorders

Eating disorders have been a part of the medical literature for many years, but interest and concern regarding these disorders are growing because the number of reported cases has increased dramatically. The two most common eating disorders are called *anorexia nervosa* and *bulimia*. Neither illness is completely understood, and successful treatment is often varied and sometimes controversial.

Anorexia Nervosa

Anorexia nervosa is primarily a disease of young adults. Most individuals affected are female (90% to 95%) and from 12 to 25 years of age. As many as 4% of college-aged students suffer from this condition to some degree. These individuals have a disturbed body image and an intense fear of obesity and therefore diet with a vengeance. They almost always develop unusual eating rituals

and scrupulously monitor and restrict their food intake. Anorexic individuals literally starve themselves and, as a result, suffer serious medical complications. The illness is characterized by a 20% to 25% loss of body mass, accompanied by slowed or impaired intellectual functioning. People affected are usually involved in excessive exercise and pursue ultimate thinness, regardless of their health. In women, menstruation ceases (amenorrhea), and the basal metabolic rate is decreased as a result of starvation. These individuals suffer from many skin abnormalities and an assortment of psychological, cardiovascular, and hormonal problems. They are at increased risk for sudden death from complications directly related to excessive weight loss and nutritional deficiency. Treatment is directed at resolution of both medical and psychological problems. In addition to psychotherapy and weight stabilization, pharmacological treatment with antidepressants has been used to improve mood and self-image.

Bulimia

Bulimia is an illness characterized by an eating and vomiting, or purging, cycle. It is sometimes referred to as **binge-purge syndrome.** The disease is said to affect about 1% of college-aged students. Most people who have bulimia are relatively young, single, white females. The mean age is 25, but the age of patients appears to be increasing. People suffering from bulimia have an uncontrollable urge for food that leads to massive overeating (binging) that is followed by repeated forced vomiting and laxative abuse (purging). Loss of gastric and intestinal contents often leads to serious fluid and electrolyte imbalance. The result is often the development of neurological problems such as convulsions, tetany, and seizures. Vomiting may also cause aspiration pneumonia, erosion of tooth enamel, trauma of the mouth and esophagus, and infection of the salivary glands. The longer the disease is allowed to continue without treatment, the greater the increase in mortality from medical complications. Many people who have bulimia suffer from major depression and have concomitant social problems such as alcohol abuse. About a fourth of people with bulimia are chemically dependent, and many have been victims of sexual abuse. They are especially prone to self-mutilation and suicide attempts. Nutritional counseling, psychotherapy, and treatment with antidepressants help bulimic patients cope with stress and break the binge/purge cycle.

Obesity

Obesity is not an eating disorder itself but may be a symptom of chronic overeating behavior. Like anorexia nervosa and bulimia, eating disorders characterized by chronic overeating usually have an underlying emotional cause. Obesity may also result from metabolic disorders. Obesity is defined as an abnormal increase in the proportion of fat in the body. Usually, a person with a BMI over 30 is considered moderately obese. A person with a BMI over 40 is considered to be extremely obese. Most of the excess fat is stored in the subcutaneous tissue and around the viscera. Obesity is a risk factor in various life-threatening diseases, including many forms of cancer, diabetes, and heart disease (see Figure 30-32).

FIGURE 30-33

Protein-calorie malnutrition (PCM). PCM is an abnormal condition resulting from a deficiency of calories in general and protein in particular. Here, two forms of advanced PCM, marasmus **(A)** and kwashiorkor **(B),** are shown.

Nutritional Disorders

Protein-Calorie Malnutrition

Protein-calorie malnutrition (PCM) is an abnormal condition resulting from a deficiency of calories in general and protein in particular. PCM is likely to result from reduced intake of food, but may also be caused by increased nutrient loss or increased use of nutrients by the body. Mild cases occur frequently in those with illness; as many as one in five patients admitted to the hospital are significantly malnourished. More severe cases of PCM are likely to occur in parts of the world where food, especially protein-rich food, is relatively unavailable. There are two forms of advanced PCM: **marasmus** and **kwashiorkor** (kwah-shee-OR-kor) (Figure 30-33). Marasmus results from an overall lack of calories and proteins, such as when sufficient quantities of food are not available. Marasmus is characterized by progressive wasting of muscle and subcutaneous tissue accompanied by fluid and electrolyte imbalances. Kwashiorkor results from a protein deficiency in the presence of sufficient calories, as when a child is weaned from milk to low-protein foods. At the same time, a child affected with kwashiorkor is also likely to have an underlying infection that further increases calorie and protein needs. Like marasmus, kwashiorkor also causes wasting of tissues, but unlike marasmus, it also causes pronounced ascites (abdominal bloating) and flaking dermatitis. The ascites results from a deficiency of plasma proteins, which changes the osmotic balance of the blood and thus promotes osmosis of water from the blood into the peritoneal space.

Vitamin Disorders

Vitamin deficiency, or **avitaminosis** (ay-vye-tah-mi-NO-sis), can lead to severe metabolic problems. For example, *avitaminosis C* (vitamin C deficiency) can lead to scurvy. Scurvy results from the inability of the body to manufacture and maintain collagen fibers. As you may have gathered from your studies thus far, collagen fibers compose the connective tissues that hold most of the body together. In scurvy, the body literally falls apart in the same way that a neglected house eventually falls apart (Figure 30-34). Other details about scurvy and other types of avitaminosis are given in Table 30-3.

Some forms of **hypervitaminosis**—or vitamin excess—can be just as serious as a deficiency of vitamins. For example, chronic *hypervitaminosis A* can occur if large amounts of vitamin A—more than 10 times the recommended dietary allowance (RDA)—are consumed daily over a period of 3 months or more (Figure 30-35). This condition is first manifested as dry skin, hair loss, anorexia (appetite loss), and vomiting. However, it may progress to severe headaches and mental disturbances, liver enlargement, and occasionally cirrhosis. Acute hypervitaminosis A, characterized by vomiting, abdominal pain, and headache, can occur if a massive overdose is ingested. Excesses of the fat-soluble vitamins (A, D, E, and K) are generally more serious than excesses of the water-soluble vitamins (B complex and C).

FIGURE 30-34

Scurvy. In scurvy, lack of vitamin C impairs the normal maintenance of collagen-containing connective tissues, causing bleeding and ulceration of the skin, gums, and other tissues, as these lesions on the skin **(A)** and inflamed gingiva **(B)** show.

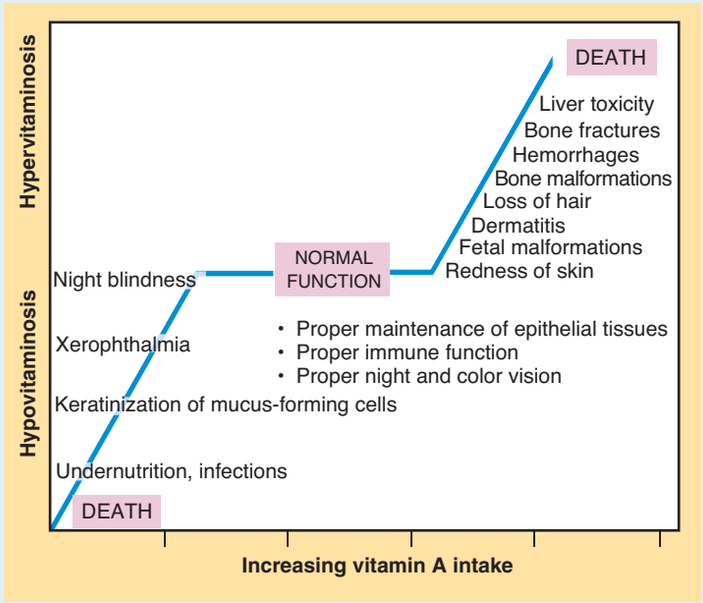

FIGURE 30-35

Vitamin A intake. This chart shows how changing the amount of vitamin A in the diet can lead to hypovitaminosis A or hypervitaminosis A. In extreme, either can lead to death.

CASE study

Walter had heard that pizza was a complete meal because it contained all the major macronutrients. Maybe he could invent the "pizza diet," he thought. He went over the macronutrients in his head, "carbohydrates, lipids . . . ."

1. Which item doesn't belong in Walter's list?
   a. Protein
   b. Lipid
   c. Vitamin C
   d. Carbohydrate

Walter continued his list. "Then, there are the macrominerals—sodium, carbon, potassium . . . ."

2. Which of the minerals Walter listed is NOT considered a macromineral?
   a. Sodium
   b. Carbon
   c. Potassium
   d. All are considered macrominerals
3. The olive oil on pizza crust is mostly triglyceride lipids containing monounsaturated fatty acids. What is the first step in catabolizing the triglycerides in the olive oil?
   a. Conversion to glycerol and three fatty acids
   b. Glycolysis
   c. Lipogenesis
   d. Deamination
4. Walter is so busy writing his new diet book that he forgets to eat! His body has already run low on stored carbohydrates and his blood sugar level (glucose concentration) is low. Which of the following processes will restore glucose availability in the blood stream?
   a. Glycolysis
   b. Glycogenesis
   c. Oxidative phosphorylation
   d. Gluconeogenesis

OVERVIEW OF NUTRITION AND METABOLISM

A. Nutrition refers to the food (nutrients) we eat
   1. Malnutrition—a deficiency in the consumption of food, vitamins, and minerals
   2. Categories of nutrients
      a. Macronutrients—nutrients that the body needs in large amounts (bulk nutrients)
         (1) Macromolecules such as carbohydrates, fats (lipids), proteins
         (2) Water
         (3) Macrominerals—minerals needed in large quantity; for example, sodium, chloride, calcium
      b. Micronutrients—nutrients needed in very small amounts
         (1) Vitamins
         (2) Microminerals (trace elements)—minerals that are needed only in very small quantities, such as iron, iodine, and zinc
   3. Balance of nutrients is required for good health (Figures 30-1 and 30-2)

B. Metabolism—the use of nutrients—a process made up of many chemical processes (Figure 30-23)
   1. Catabolism breaks food down into smaller molecular compounds and releases two forms of energy—heat and chemical energy
   2. Anabolism—a synthesis process
   3. Both processes take place inside of cells continuously and concurrently
   4. Chemical energy released by catabolism must be transferred to ATP, which supplies energy directly to the energy-using reactions of all cells (Figure 30-3)

CARBOHYDRATES

A. Dietary sources of carbohydrates
   1. Complex carbohydrates
      a. Polysaccharides—starches; found in vegetables and grains; glycogen is found in meat
      b. Cellulose—a component of most plant tissue; passes through the system without being broken down
      c. Disaccharides—found in refined sugar; must be broken down before they can be absorbed
      d. Monosaccharides—found in fruits; move directly into the internal environment without being processed directly
         (1) Glucose—carbohydrate most useful to the human cell
         (2) Other monosaccharides can be converted into glucose (e.g., fructose and galactose) (Figure 30-4)

B. Carbohydrate metabolism—human cells catabolize most of the carbohydrate absorbed and anabolize a small portion of it
   1. Glucose transport and phosphorylation—glucose reacts with ATP to form glucose-6-phosphate
      a. This step prepares glucose for further metabolic reactions
      b. This step is irreversible except in the intestinal mucosa, liver, and kidney tubules
   2. Glycolysis—the first process of carbohydrate catabolism; consists of a series of chemical reactions (Figure 30-5)
      a. Occurs in the cytoplasm of all human cells
      b. Only process that provides cells with energy under conditions of inadequate oxygen—an anaerobic process
      c. Breaks down chemical bonds in glucose molecules and releases about 5% of the energy stored in them
      d. Prepares glucose for the second step in catabolism—the citric acid cycle
   3. Citric acid cycle
      a. Two pyruvic acid molecules from glycolysis are converted to two acetyl molecules in a transition reaction, losing one carbon dioxide molecule per pyruvic acid molecule converted
      b. By end of transition reaction and citric acid cycle, two pyruvic acids have been broken down to six carbon dioxide and six water molecules (Figures 30-6 and 30-7)
      c. Citric acid cycle also called the *tricarboxylic acid (TCA) cycle* because citric acid is also called *tricarboxylic acid*
      d. Citric acid cycle once called Krebs cycle after Sir Hans Krebs, who discovered this process
   4. Electron transport system (Figure 30-8)
      a. High-energy electrons (along with their protons) removed during the citric acid cycle enter a chain of molecules embedded in the inner membrane of the mitochondria
      b. As electrons move down the chain, they release small bursts of energy to pump protons between the inner and outer membrane of the mitochondrion
      c. Protons move down their concentration gradient, across the inner membrane, driving ATP synthase (Figure 30-9)
   5. Oxidative phosphorylation—the joining of a phosphate group to ADP to form ATP by the action of ATP synthase (Figure 30-10 and 30-11)
   6. Anaerobic pathway—a pathway for the catabolism of glucose; transfers energy to ATP using only glycolysis; ultimately ends with the oxidative phosphorylation of ATP (paying the "oxygen debt") (Figure 30-12)
   7. Cori cycle—circular pathway in which lactic acid produced by anaerobic glycolysis in skeletal muscles is carried to liver cells, where it is converted back to glucose and stored as liver glycogen or returned to the bloodstream, where the glucose may be taken up by muscle cells and used for respiration or stored as muscle glycogen (Figure 30-13)

8. Glycogenesis—a series of chemical reactions in which glucose molecules are joined to form a strand of glucose beads; a process that operates when the blood glucose level increases above the midpoint of its normal range (Figures 30-14 and 30-15)
9. Glycogenolysis (Figure 30-16)—the reversal of glycogenesis; it means different things in different cells; can be stimulated by glucagon hours after a meal when blood glucose declines or by epinephrine and cortisol during a stress response to provide extra blood glucose
10. Gluconeogenesis (Figure 30-17)—the formation of new glucose, which occurs chiefly in the liver
11. Control of glucose metabolism—hormonal and neural devices maintain homeostasis of blood glucose concentration (Figures 30-18 and 30-19)
    a. Insulin—secreted by beta cells to decrease blood glucose level (Figure 30-18)
    b. Glucagon increases the blood glucose level by increasing the activity of the enzyme phosphorylase
    c. Incretins—GI hormones that, in the presence of glucose in the gut, stimulate insulin release from pancreas, thereby decreasing blood glucose levels; examples: GLP-1 and GIP
    d. Epinephrine—hormone secreted in times of stress; increases phosphorylase activity
    e. Adrenocorticotropic hormone stimulates the adrenal cortex to increase its secretion of glucocorticoids
    f. Glucocorticoids accelerate gluconeogenesis
    g. Growth hormone increases blood glucose level by shifting from carbohydrate to fat catabolism
    h. Thyroid-stimulating hormone has complex effects on metabolism
12. Hormones that cause the blood glucose level to rise are called *hyperglycemic*
13. Insulin is hypoglycemic because it causes the blood glucose level to decrease

LIPIDS

A. Dietary sources of lipids
   1. Triglycerides—the most common lipids—composed of a glycerol subunit that is attached to three fatty acids
   2. Phospholipids—an important lipid found in all foods
   3. Cholesterol—an important lipid found only in animal foods
   4. Dietary fats
      a. Saturated fats contain fatty acid chains in which there are no double bonds
      b. Unsaturated fats contain fatty acid chains in which there are some double bonds

B. Transport of lipids—transported in blood as chylomicrons, lipoproteins, and fatty acids
   1. In the absorptive state, many chylomicrons are present in the blood
   2. Postabsorptive state—95% of lipids are in the form of lipoproteins
      a. Consist of lipids and protein; formed in the liver
         (1) Blood contains three types of lipoproteins: very low density, low density, and high density
         (2) Cholesterol lipoproteins associated with heart disease (Figure 30-20)
      b. Fatty acids transported from cells of one tissue to cells of another in the form of free fatty acids

C. Lipid metabolism
   1. Lipid catabolism
      a. Triglycerides are hydrolyzed to yield fatty acids and glycerol
      b. Glycerol is converted to glyceraldehyde-3-phosphate, which enters the glycolysis pathway
      c. Fatty acids are broken down by beta-oxidation and then catabolized through the citric acid cycle (Figure 30-21)
   2. Lipid anabolism consists of the synthesis of triglycerides, cholesterol, phospholipids, and prostaglandins
   3. Control of lipid metabolism is through the following hormones
      a. Insulin
      b. Growth hormone
      c. ACTH
      d. Glucocorticoids

PROTEINS

A. Sources of proteins
   1. Proteins assembled from a pool of many different amino acids
   2. The body synthesizes amino acids from other compounds in the body
   3. Only about half the necessary types of amino acids can be produced by the body; remainder supplied through diet—found in both meat and vegetables

B. Protein metabolism—anabolism is primary and catabolism is secondary
   1. Protein anabolism—process by which proteins are synthesized by the ribosomes of the cells
   2. Protein catabolism—deamination takes place in the liver cells and forms an ammonia molecule, which is converted to urea and excreted in urine, and a keto acid molecule, which is oxidized or converted to glucose or fat (Figure 30-22)
   3. Protein balance—rate of protein anabolism balances rate of protein catabolism
   4. Nitrogen balance—amount of nitrogen taken in equals nitrogen in protein catabolic waste
   5. Two kinds of protein or nitrogen imbalance
      a. Negative nitrogen balance—protein catabolism exceeds protein anabolism; more tissue proteins are catabolized than are replaced by protein synthesis
      b. Positive nitrogen balance—protein anabolism exceeds protein catabolism
   6. Control of protein metabolism—achieved by hormones

VITAMINS AND MINERALS

A. Vitamins (Table 30-3)—organic molecules necessary for normal metabolism; many attach to enzymes and help them work or have other important biochemical roles (Figure 30-24)
   1. Most of the necessary vitamins not produced by the body; must be obtained through diet
      a. The body stores fat-soluble vitamins, but not water-soluble vitamins

B. Minerals (Table 30-4)—inorganic elements or salts found in the earth
   1. They attach to enzymes and help them work and function in chemical reactions
   2. Essential to the fluid/ion balance of the internal fluid environment
   3. Involved in many processes in the body such as muscle contraction, nerve function, hardening of bone, etc.
   4. Too large or too small an amount of some minerals may be harmful
   5. Recommended mineral intakes may vary over the life span (Figures 30-25 and 30-26)

METABOLIC RATES

A. Metabolic rate means the amount of energy released by catabolism

B. Metabolic rates expressed in two ways
   1. The number of kilocalories of heat energy expended per hour or per day
   2. As normal or as a percentage above or below normal

C. Factors influencing basal metabolic rate—the rate of energy expended under basal conditions
   1. BMR not identical for all individuals because of influence of various factors
   2. Factors: size, body composition, gender, age, thyroid hormone, body temperature, drugs, other factors (Figures 30-27 through 30-30)

D. Total metabolic rate (Figure 30-27)
   1. Amount of energy used in a given time
   2. Main determinants
      a. Factor 1—basal metabolic rate
      b. Factor 2—energy used to do skeletal muscle work
      c. Factor 3—thermic effect of foods

E. Energy balance and body weight
   1. The body maintains a weight (state of energy balance) when the total calories in the food ingested equals the total metabolic rate
   2. Body weight increases when energy input exceeds energy output
   3. Body weight decreases when energy output exceeds energy input
   4. In starvation, the carbohydrates are used up first, then fats, then proteins (Figure 30-31)

MECHANISMS FOR REGULATING FOOD INTAKE (TABLE 30-6)

A. The hypothalamus plays a part in food intake

B. Feeding centers in the hypothalamus exert primary control over appetite
   1. Appetite center
      a. Cluster of neurons in the lateral hypothalamus that if stimulated brings about increased appetite
      b. Orexigenic effects—factors that trigger appetite
   2. Satiety center
      a. Group of neurons in the ventral medial nucleus of the hypothalamus that if stimulated brings about decreased appetite
      b. Anorexigenic effects—factors that suppress appetite (anorexia is loss of appetite)

THE BIG PICTURE: NUTRITION, METABOLISM, AND THE WHOLE BODY

A. Every cell in the body needs the maintenance of the metabolic pathways to stay alive

B. Anabolic pathways build the various structural and functional components of the cells

C. Catabolic pathways convert energy to a usable form and degrade large molecules into subunits used in anabolic pathways

D. Cells require appropriate amounts of vitamins and minerals to produce structural and functional components necessary for cellular metabolism

E. Other body mechanisms operate to ensure that nutrients reach the cells

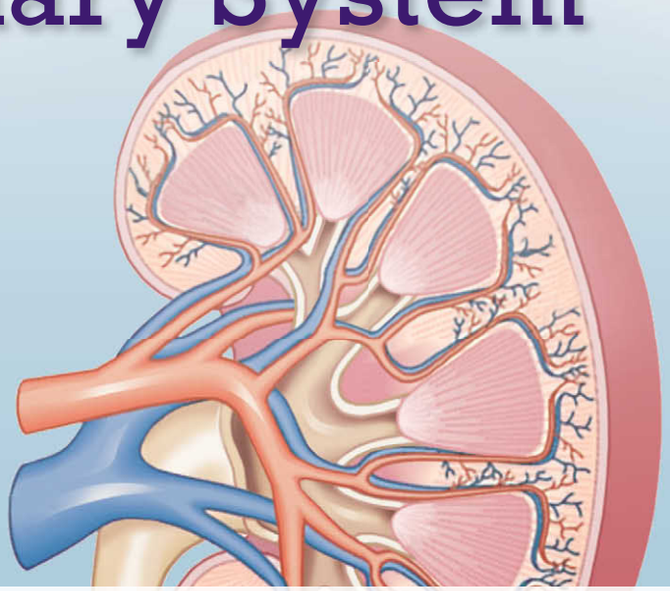
REVIEW QUESTIONS

Write out the answers to these questions after reading the chapter and reviewing the Chapter Summary. If you simply think through the answer without writing it down, you won't retain much of your new learning.

1. What is metabolism? Nutrition?
2. What two processes make up the process of metabolism?
3. Does the body digest dietary fiber? Why or why not?
4. Briefly describe glycolysis, the first process of carbohydrate catabolism.
5. Where does glycolysis occur?
6. Describe the process of "splitting glycogen."
7. How are dietary fats classified?
8. Explain how lipids are transported in blood.
9. List the hormones involved in the control of lipid metabolism.
10. What are the essential amino acids?

11. What does the term *metabolic rate* mean?
12. List the various factors that influence basal metabolic rate.
13. Describe various factors that influence the amount of food a person eats.
14. Define the term *calorie*.

CRITICAL THINKING QUESTIONS



After finishing the Review Questions, write out the answers to these more in-depth questions to help you apply your new knowledge. Go back to sections of the chapter that relate to concepts that you find difficult.

1. How would you state or interpret, in your own words, the process of carbohydrate catabolism known as the citric acid cycle? Draw a picture to illustrate what you mean.
2. How would you describe the mitochondria, and why do you think they are referred to as the "power plants" of the cells?
3. Compare anaerobic and aerobic pathways. What important role does lactic acid play in the anaerobic pathway?
4. Identify and explain the processes and hormones involved in maintaining the homeostatic level of glucose in the blood.
5. State in your own words the process of lipid catabolism. How is it similar to the carbohydrate pathway? How does this process generate ketone bodies?
6. Describe protein catabolism in your own words. How is this process related to a negative nitrogen balance?
7. How would you compare and contrast the functions of proteins, carbohydrates, and fats?
8. What is the function of most vitamins in the body? What examples can you find that do not have this function? What functions do these vitamins have?
9. What is the difference between basal and total metabolic rates?
10. What would be the predicted basal metabolism rate in kilocalories per day of a 22-year-old man who is 6 feet tall and weighs 176 pounds?
11. A man went on a 7-day vacation. Since he planned to be more active than normal, he thought he would not have to be concerned about his diet. During the 7 days, he burned 17,500 kcal. He ate 26,500 kcal. What was the approximate difference in his body weight before and after his vacation?
12. Why do you think high blood concentrations of low-density lipoproteins may lead to atherosclerosis?

31

Case Study, 999

We often think of the urinary system primarily as a "urine producer," which it certainly is. However, a better description of the system is that of "blood plasma balancer." Each kidney processes incoming blood plasma in ways that allow it to leave the kidney in better condition. The water content is adjusted so that the body does not have too much or too little water to maintain constancy of the internal environment. Likewise, the blood content of important ions such as sodium and potassium is adjusted to match set point levels. Even the pH of the blood can be altered to match the set point level. In these ways, the urinary system regulates the content of blood plasma so that the homeostasis, or "dynamic constancy," of the entire internal fluid environment can be maintained within normal limits.

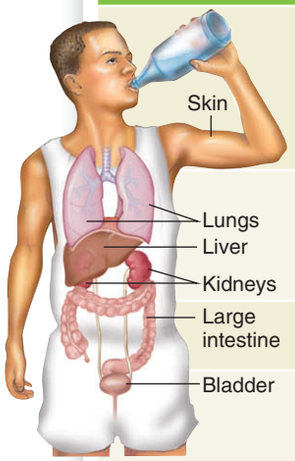
This chapter explores the basic principles of urinary structure and function. The next two chapters look more closely at the role of the kidneys and other organs in fluid and ion homeostasis (Chapter 32) and pH homeostasis (Chapter 33).

ANATOMY OF THE URINARY SYSTEM

Gross Structure

The principal organs of the urinary system are the **kidneys,** which process blood and form urine as a waste to be excreted—that is, removed from the body (Box 31-1). The excreted urine travels from the kidneys to the outside of the body via accessory organs: the *ureters*, *urinary bladder*, and *urethra*.

KIDNEY



The kidneys resemble lima beans in shape, that is, roughly oval with a medial indentation (Figure 31-1, *A*). An average-sized

Box 31-1 | FYI

Excretion

The urinary system's chief function is to regulate the volume and composition of body fluids and excrete unwanted material, but it is not the only system in the body that is able to excrete unneeded substances.

The table below compares the excretory functions of several systems. Although all of these systems contribute to the body's effort to remove wastes, only the urinary system can finely adjust the water and electrolyte balance to the degree required for normal homeostasis of body fluids.

SYSTEM	ORGAN	EXCRETION
Urinary	Kidney	Nitrogen compounds Toxins Water Electrolytes
Integumentary	Skin—sweat glands	Nitrogen compounds Electrolytes Water
Respiratory	Lung	Carbon dioxide Water
Digestive	Intestine	Digestive wastes Bile pigments Salts of heavy metals

Box 31-2 | HEALTH matters

Kidney Biopsy

Suspected disease of the kidney, such as renal cancer, often requires a *needle biopsy* to confirm the diagnosis. In these procedures a hollow needle is inserted through the skin surface and then guided into the diseased organ to withdraw a tissue sample for analysis. In a renal biopsy, tissue is removed from the lower rather than the upper or superior end of the diseased kidney. This avoids the possibility of the biopsy needle damaging the pleura and thereby causing a pneumothorax (see Box 27-3 on p. 835).

Needle biopsy of kidney. Magnetic resonance image (MRI) of biopsy needle *(arrow)* inserted into the left kidney to remove tissue. *K,* Kidney.

kidney measures approximately 11 cm by 7 cm by 3 cm (4.3 by 2.7 by 1.2 inches). The left kidney is often slightly larger than the right. The kidneys lie in a *retroperitoneal* position, meaning posterior to the parietal peritoneum, against the posterior wall of the abdomen (Figure 31-1, *C*). They are located on either side of the vertebral column and extend from the level of the last thoracic vertebra (T12) to just above the third lumbar vertebra (L3). Note in Figure 31-1, *B*, that the superior or upper portions (poles) of both kidneys extend above the level of the twelfth rib and the lower edge of the thoracic parietal pleura. This anatomical relationship has important clinical implications (Box 31-2). Usually the right kidney is a little lower than the left, presumably because the liver takes up some of the space above the right kidney.

A heavy cushion of fat—the *renal fat pad*—normally encases each kidney and holds it in position. Connective tissue, the renal fasciae, anchors the kidneys to surrounding structures and also helps maintain their normal positions.

The medial surface of each kidney has a concave notch called the **hilum.** Renal blood vessels and other structures enter or leave the kidney through this notch. A tough, white fibrous capsule encases each kidney (Figure 31-2).

The coronal section of the right kidney shown in Figure 31-2 depicts the major internal structures of the kidney. Identify the **renal cortex,** or outer region, and the **renal medulla,** or inner region. A dozen or so distinct triangular wedges, the **renal pyramids,** make up much of the medullary tissue. The *base* of each pyramid faces outward, and the narrow *papilla* of each faces toward the hilum. Each renal papilla has multiple openings that release urine. Notice that the cortical tissue dips into the medulla between the pyramids, forming areas known as **renal columns.**

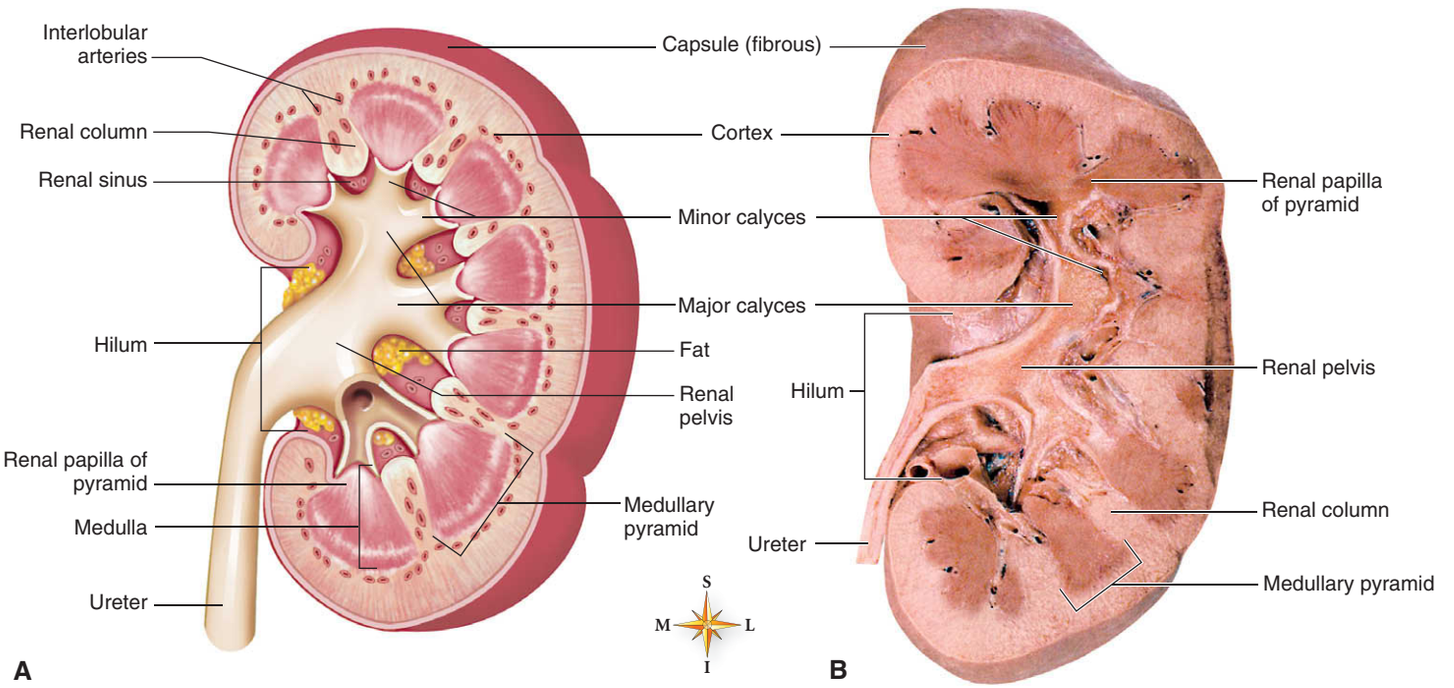

FIGURE 31-2

Internal structure of the kidney. A, Coronal section of the right kidney in an artist's rendering. **B,** Photo of a coronal section of a preserved human kidney.

Each renal papilla (point of a pyramid) juts into a cuplike structure called a **calyx.** The calyces are considered the beginnings of the "plumbing system" of the urinary system, for it is here that urine leaving the renal papilla is collected for transport out of the body. The cups that drain the renal papillae directly are called *minor calyces.* These minor calyces are stemlike branches that join together to form larger branches called *major calyces.* The major calyces join together to form a large collection basin called the **renal pelvis.** The pelvis of the kidney narrows as it exits the hilum to become the ureter. Pelvis is Latin for "basin" and, like a lavatory basin, it collects fluid and quickly drains it away through a channel.

Blood Vessels of the Kidneys

The kidneys are highly vascular organs (Figure 31-3). Every minute about 1200 ml of blood flows through them. Stated another way, approximately one fifth of all the blood pumped by the heart per minute goes to the kidneys. From this fact one might guess, and correctly so, that the kidneys process the blood in important ways before returning it to the general circulation. A large branch of the abdominal aorta—the *renal artery*—brings blood into each kidney. As it nears the kidney, it divides into *segmental arteries,* which divide to become *lobar arteries.* Between the pyramids of the kidney's medulla, the lobar arteries branch to form *interlobar arteries* that extend out toward the cortex, then arch over the bases of the pyramids to form the *arcuate arteries.* From the arcuate arteries, *interlobular arteries* penetrate the cortex. Because they radiate through the cortex, the interlobular arteries are sometimes called the *cortical radiate arteries.*

Branches of the interlobular arteries called *afferent arterioles* carry blood directly to the tiny functional units of the kidney called *nephrons.* We discuss the structure and function of nephrons later in this chapter, where we will resume outlining the path of blood flow—this time at a microscopic level.

| A&P CONNECT |

Knowing the pathway of blood flow in the kidney is important for understanding how the kidney works. We continue the story later in the chapter. We put all the pieces together in an overview in ***Tracing Blood Flow in the Kidney*** online at ***A&P Connect.***

evolve

| QUICK CHECK |

1. Name the accessory organs of the urinary system.
2. What is the general function of the urinary system?
3. Distinguish between the renal cortex and the renal medulla.
4. What proportion of the body's blood flow goes to the kidney?

URETER

The **ureters,** about 28 to 34 cm in length, are the two tubes that actively convey urine from the kidneys to the urinary bladder (see Figure 31-1, *A*). They begin on each side at the narrow outlet of the renal pelvis on a level with the first lumbar vertebra (L1). Each ureter is retroperitoneal and courses into the pelvis until it reaches the bladder, where it attaches to the bottom of the bladder

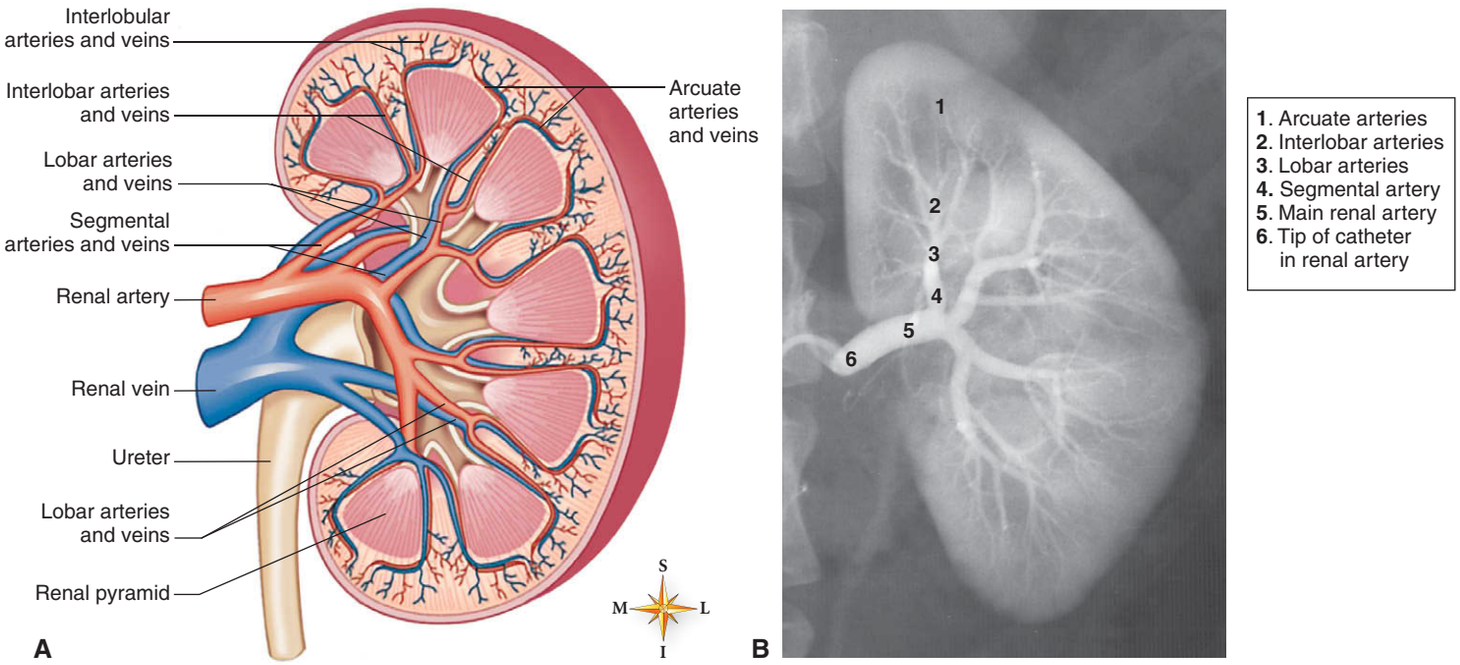

FIGURE 31-3

Circulation of blood through the kidney. A, Diagram showing the major arteries and veins of the renal circulation. **B,** Renal arteriogram. Arcuate arteries (1) are seen near the junction of the cortex and medulla, interlobar arteries (2) are present between the medullary pyramids, and lobar arteries (3) and segmental arteries (4) are seen branching from the main renal artery (5). Note the tip of the catheter used to inject contrast material (6) into the proximal part of the main renal artery.

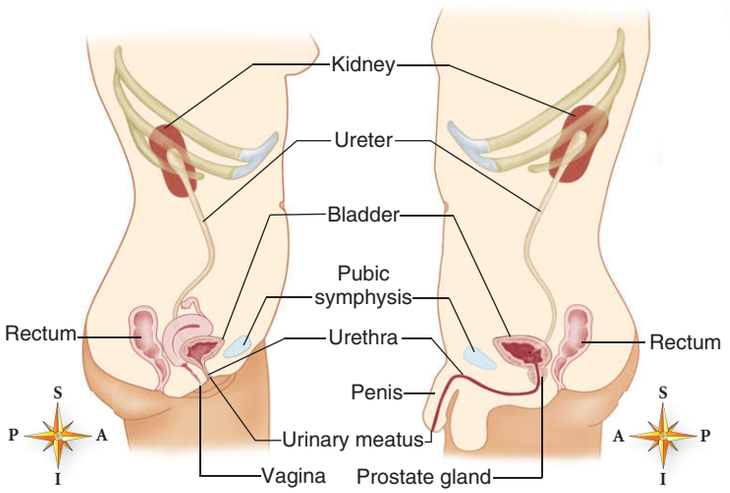

FIGURE 31-4

Sagittal view of urinary tract. Female urinary system is shown on the reader's left and the male urinary system on the reader's right, each showing a distended (stretched) bladder.

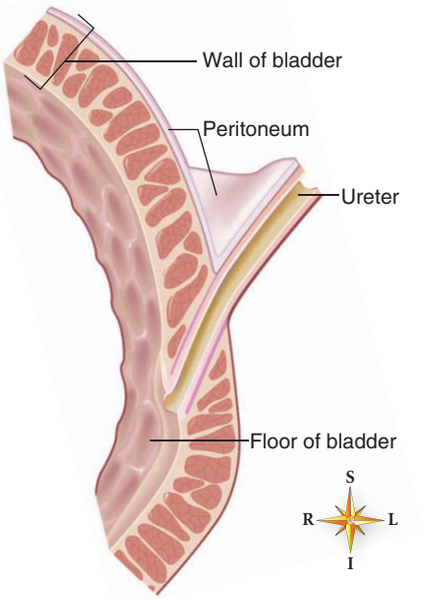

FIGURE 31-6

Ureter-bladder junction. The oblique path of the ureter through wall of the bladder, seen here in frontal section, permits the junction to act as a valve—reducing flow into the bladder as it becomes full.

(Figure 31-4). It then runs at an angle for about 2 cm through the bladder wall and opens at the lateral angles of the trigone (floor) of the bladder (Figure 31-5). Because of its oblique course through the bladder wall, the ends of the tube close and act as valves when the bladder is full, thus preventing backflow of urine (Figure 31-6).

The ureter is lined with transitional epithelium, which permits stretching without damage to the epithelial lining. This feature permits either high or low rates of flow through the ureters.

In females, the ureters are in close proximity to the ovaries and cervix of the uterus and, in males, in close proximity to the seminal vesicles and near the prostate gland (see Figure 31-4). Each ureter is composed of three layers of tissue: a mucous lining, a muscular middle layer, and a fibrous outer layer (Figure 31-7). The muscular layer is composed of smooth muscle, which propels the urine by peristalsis. The rate and strength of peristalsis increase with increasing urine volume.

URINARY BLADDER

The urinary bladder is a muscular, collapsible bag that is located directly behind the pubic symphysis and in front of the rectum (see Figure 31-4). It lies below the parietal peritoneum, which covers only its superior surface (see Figure 31-5). The remainder of the bladder surface is covered by a fibrous adventitia. In women it sits on the anterior of the vagina and in front of the uterus, whereas in men, it rests on the prostate.

The wall of the bladder is made mostly of smooth muscle tissue (see Figure 31-5). Often called the **detrusor muscle,** the muscle layer is formed by a network of crisscrossing bundles of smooth muscle fibers. The bundles run in all directions: circular, oblique, and lengthwise. The bladder is lined with mucous transitional epithelium that forms folds called *rugae* (see Figure 31-5). Because of the folds and the extensibility of transitional epithelium, the bladder can distend considerably. There are three openings

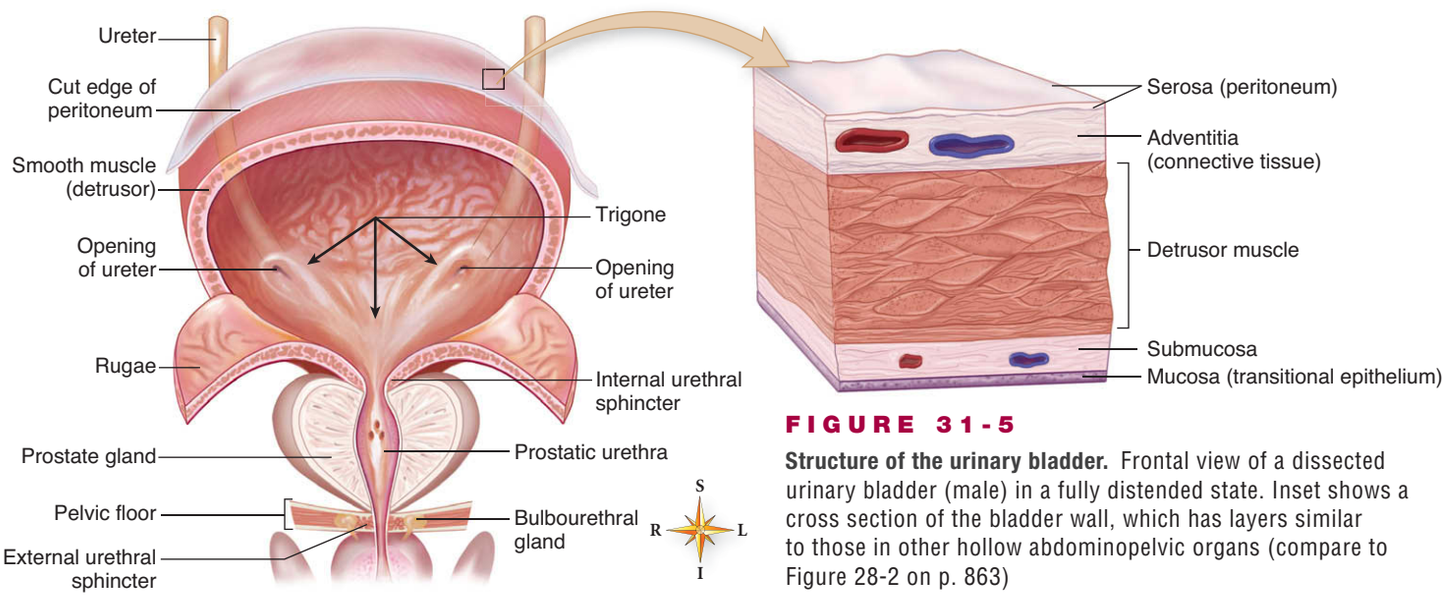

FIGURE 31-5

Structure of the urinary bladder. Frontal view of a dissected urinary bladder (male) in a fully distended state. Inset shows a cross section of the bladder wall, which has layers similar to those in other hollow abdominopelvic organs (compare to Figure 28-2 on p. 863)

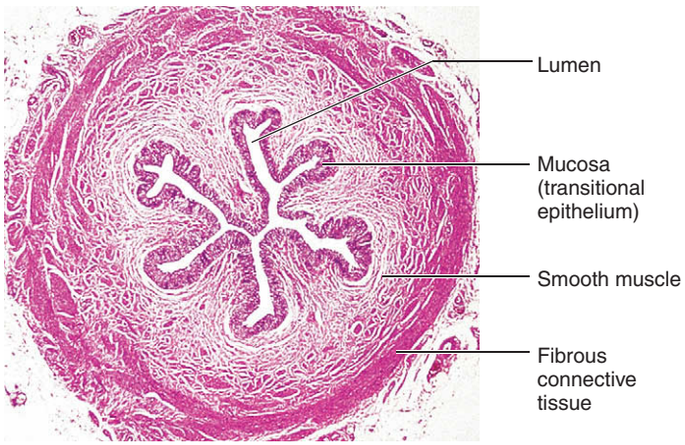

FIGURE 31-7

Ureter (cross section). Low power micrograph. Note the convoluted folds, covered by a transitional mucous lining, that almost fill the lumen. The thick muscular layer is surrounded by a tough fibrous coat.

in the floor of the bladder—two from the ureters and one into the **urethra.** The ureter openings lie at the posterior corners of the triangle-shaped floor—the **trigone**—and the urethral opening lies at the anterior, lower corner.

The bladder performs two major functions:

1. It serves as a reservoir for urine before it leaves the body.
2. Aided by the urethra, it expels urine from the body.

URETHRA

The urethra is a small tube lined with mucous membrane (transitional epithelium) that leads from the floor of the bladder *(trigone)* to the exterior of the body. In females, it lies directly behind the pubic symphysis and anterior to the vagina as it passes through the muscular floor of the pelvis (Figure 31-8). It extends down and forward from the bladder for a distance of about 3 cm (1.2 inches) and ends at the external urinary meatus (see Figure 31-4). The functional importance of the relationship of the urethra and vagina to the muscular pelvic floor, especially after vaginal delivery of a baby, will be discussed in Chapter 35. The male urethra, on the other hand, extends along a winding path for about 20 cm (7.9 inches) (see Figure 31-4). The male urethra passes through the center of the *prostate gland* just after leaving the bladder. Within the prostate, it is joined by two *ejaculatory ducts.* After leaving the prostate, the urethra extends down, forward, then up to enter the base of the penis. It then travels through the center of the penis and ends as a *urinary meatus* at the tip of the penis.

Because the male urethra is joined by the ejaculatory ducts, it serves as a pathway for *semen* (fluid containing sperm) as it is ejaculated out of the body through the penis. Thus we can say that the male urethra is a part of two different systems: the urinary system (when it is used to void urine) and the reproductive system (when it is used to ejaculate semen). Urine is prevented from mixing with semen during ejaculation by a reflex closure of sphincter muscles guarding the bladder's opening. The female urethral tract is separate from the lower reproductive tract (vagina), which lies just behind the urethra (see Figure 31-8).

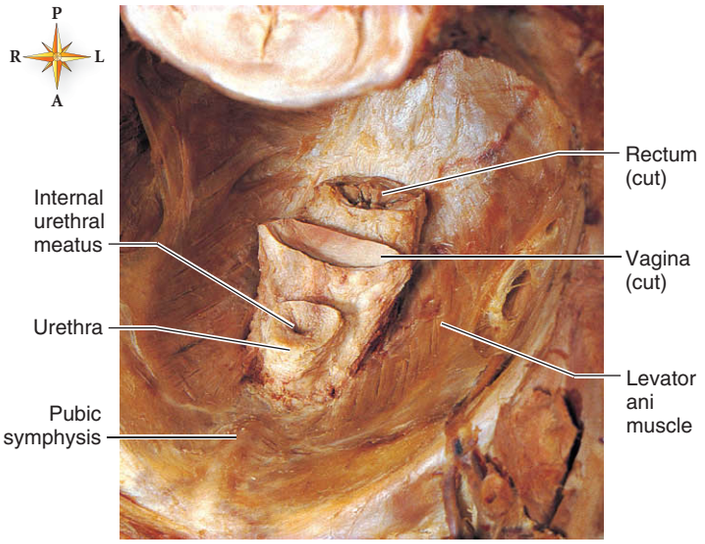

FIGURE 31-8

Female urethra piercing the muscular pelvic floor. The urethra is posterior to the pubic symphysis and anterior to the vagina. Some of the muscles of the pelvic floor act as an external urethral sphincter. (See also text discussion in Chapter 35, pp. 1071–1072.)

Micturition

The mechanism for urinating begins with involuntary contractions of the detrusor muscle of the bladder wall (see Figure 31-5). Urination is also called *voiding* the bladder or *micturition.* Figure 31-9 shows that as the pressure of urine

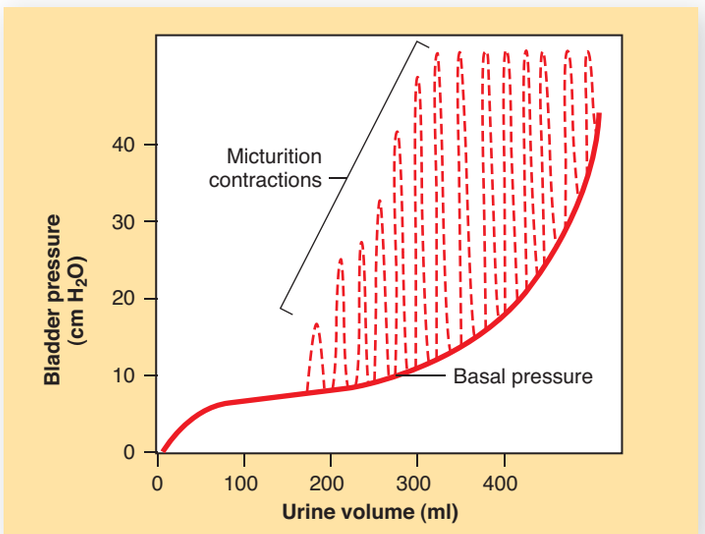

FIGURE 31-9

Micturition reflex. Increased volume of urine in the bladder causes increased internal bladder pressure. This triggers reflexive parasympathetic stimulation of micturition contractions of the detrusor muscles in the bladder wall. As these contractions get stronger, nerve signals to the internal sphincters (Figure 31-5) cause them to relax. *ml,* Milliliters; *cm H_2O,* centimeters of water (unit of pressure equal to about 0.73 mmHg).

against the inside of the bladder wall increases with urine volume, involuntary micturition contractions develop. This rapid succession of involuntary contractions triggered by a parasympathetic reflex get stronger and stronger as the bladder fills and the urine volume and pressure increase. The parasympathetic reflex also causes the *internal urethral sphincter* muscles to relax at the same time. The internal urethral sphincters include a ringlike part of the detrusor muscle of the bladder wall, as you can see in Figure 31-5. The relaxation of these internal sphincters along with the micturition contractions of the bladder wall can force urine out of the bladder and through the urethra.

Thankfully, most people learn how to consciously regulate voluntary contraction of the *external urethral sphincter* muscles to stop voiding—that is, until a suitable time. Figure 31-5 shows that the skeletal muscles of the pelvic floor, including the *levator ani* muscle, act as external urethral sphincters (see also Figure 11-15 on p. 321). Voluntary control of *micturition* (voiding, or urination) is possible only if the nerves supplying the pelvic floor, the projection tracts of the central nervous system (CNS), and the motor areas of the brain are all intact and functioning properly. Learning this function is not possible until the nervous system matures sufficiently—making voluntary control of urination impossible during infancy and very early childhood.

Injury to any of these parts of the nervous system, by a cerebral hemorrhage or a spinal cord injury, for example, results in involuntary emptying of the bladder at intervals. Involuntary micturition is called *incontinence* (see Mechanisms of Disease, p. 994). In the average bladder, 250 ml of urine causes a moderately distended sensation and therefore the desire to void.

| QUICK CHECK |

5. Where does the ureter enter the bladder? Why is its angle through the wall significant?
6. What type of mucous epithelium lines most of the urinary tract? What is the functional advantage of this type of epithelium?
7. What are the two major functions of the bladder?

Microscopic Structure

Over a million microscopic functional units named **nephrons** make up the bulk of each kidney. The shape of the nephron is unusual, unmistakable, and uniquely suited to its function of blood plasma processing and urine formation (Figure 31-10). It resembles a tiny funnel with a long, winding stem about 3 cm (1.2 inches) long.

As Figure 31-10 shows, each nephron is made up of two main regions: the *renal corpuscle* and the *renal tubule*. Fluid is filtered out of the blood in the renal corpuscle, then the filtrate flows through the renal tubule and collecting duct—where much of the filtrate is returned to the blood. The remaining filtrate leaves the collecting duct as urine. We will come back to the processing of filtrate later. For now, we explore the structure of the nephron and collecting duct. Here are the main structures we explore, listed in the order in which fluid flows through them:

Nephron
- Renal corpuscle
  - —Glomerulus (capillaries)
  - —Bowman capsule (glomerular capsule)
- Renal tubule
  - —Proximal convoluted tubule
  - —Henle loop (nephron loop)
  - —Distal convoluted tubule

Collecting duct

As you read the brief description of each of these microscopic structures, refer often to Figure 31-10, which shows a schematic diagram of a complete nephron.

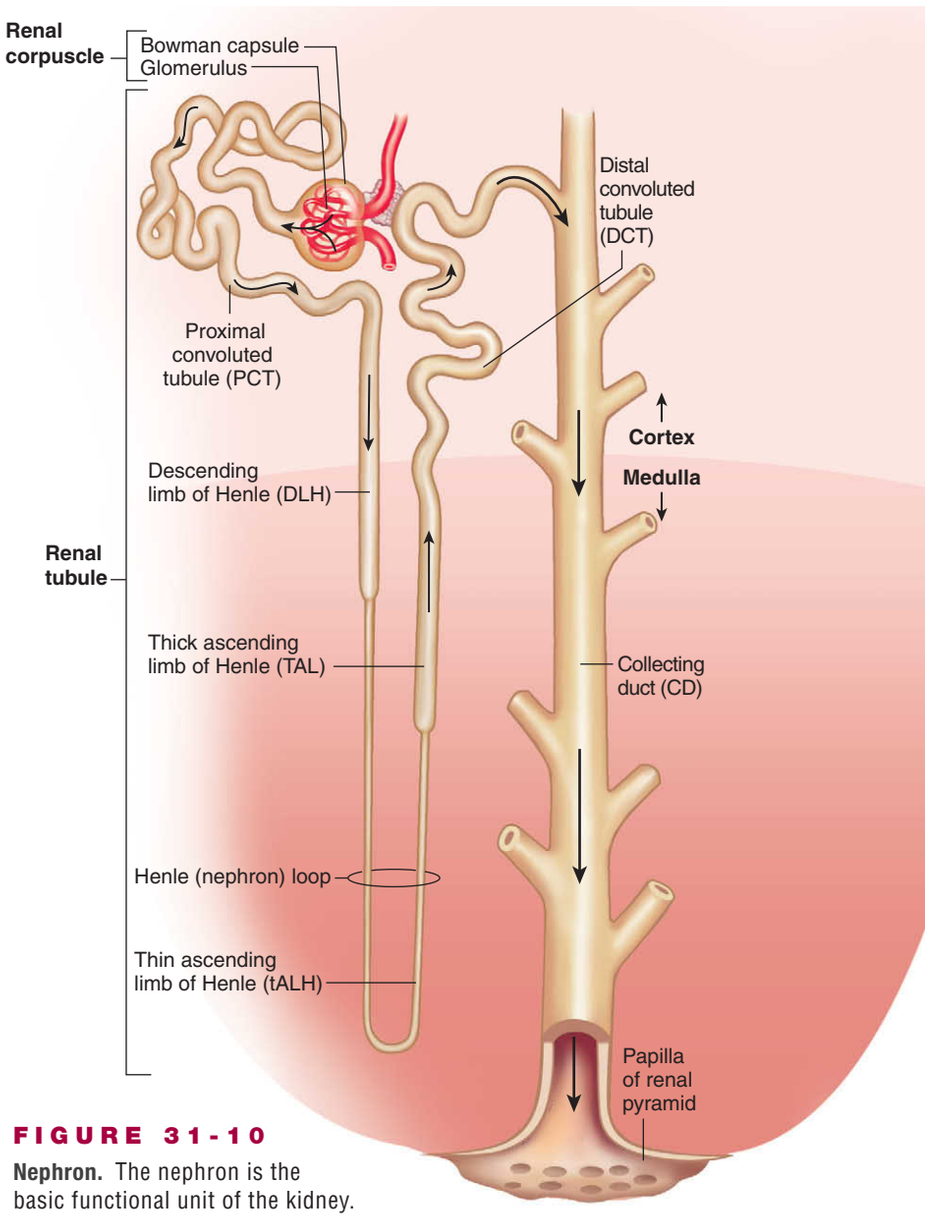

FIGURE 31-10

Nephron. The nephron is the basic functional unit of the kidney. *Arrows* show the direction of flow within the nephron.

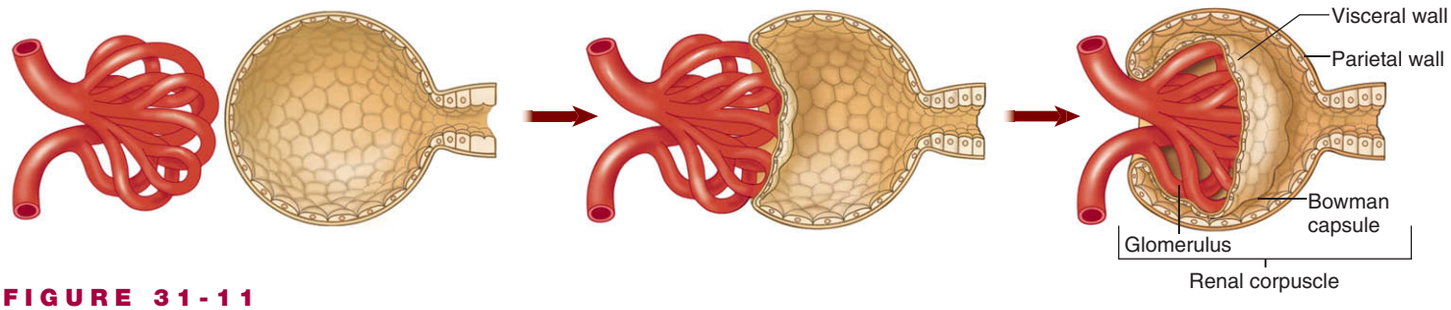

FIGURE 31-11

Overview of the renal corpuscle. Note that as the glomerular tuft of capillaries pushes into the inflated balloonlike structure representing a Bowman capsule, the visceral layer of the capsule adheres to the outer surface of the epithelial cells of the glomerular capillaries to become the visceral layer lining the capsular space. The outer layer of cells constitutes the parietal layer of a Bowman capsule. Glomerular filtrate enters the space between the parietal and visceral layers of the Bowman capsule before entering the tubular segments of the nephron.

| A&P CONNECT |

For our purposes, the simplified scheme of microscopic renal anatomy shown in Figure 31-10 works well. However, some renal biologists prefer the more elaborate scheme sketched out in a ***Detailed Map of Nephron*** online at ***A&P Connect.***

evolve

NEPHRON

Renal Corpuscle

The **renal corpuscle** is the first part of the nephron and is made up of the Bowman capsule and glomerulus. Formation of a renal corpuscle is sometimes compared to pushing your fist into the end of an inflated balloon. The mechanism is shown in Figure 31-11. Note that as the glomerular tuft of capillaries pushes into the balloon, it becomes surrounded by a double-walled cup with parietal (outer) and visceral (inner) walls—the Bowman capsule (Figure 31-12).

Fluid from the blood first filters out of the glomerulus and then into the Bowman capsule. We begin our discussion with the Bowman capsule first, however, because it will then make it easier to understand the structure and function of the glomerulus.

Bowman Capsule

The **Bowman capsule** is the cup-shaped mouth of a nephron. It is sometimes called the *glomerular capsule*. The capsule is formed by two layers of epithelial cells with a space, called the *capsular space (Bowman space)*, between them (Figure 31-13). Fluids, waste products, and electrolytes that pass through the porous glomerular capillaries and enter this space constitute the *filtrate*, which will be processed in the nephron to form urine.

The parietal, or outer, wall is composed of simple squamous epithelium. It plays no role in the production of glomerular filtrate. The visceral (inner) wall, however, is quite different. It is composed of special epithelial cells called *podocytes* (meaning "cells with feet"). The scanning electron micrograph in

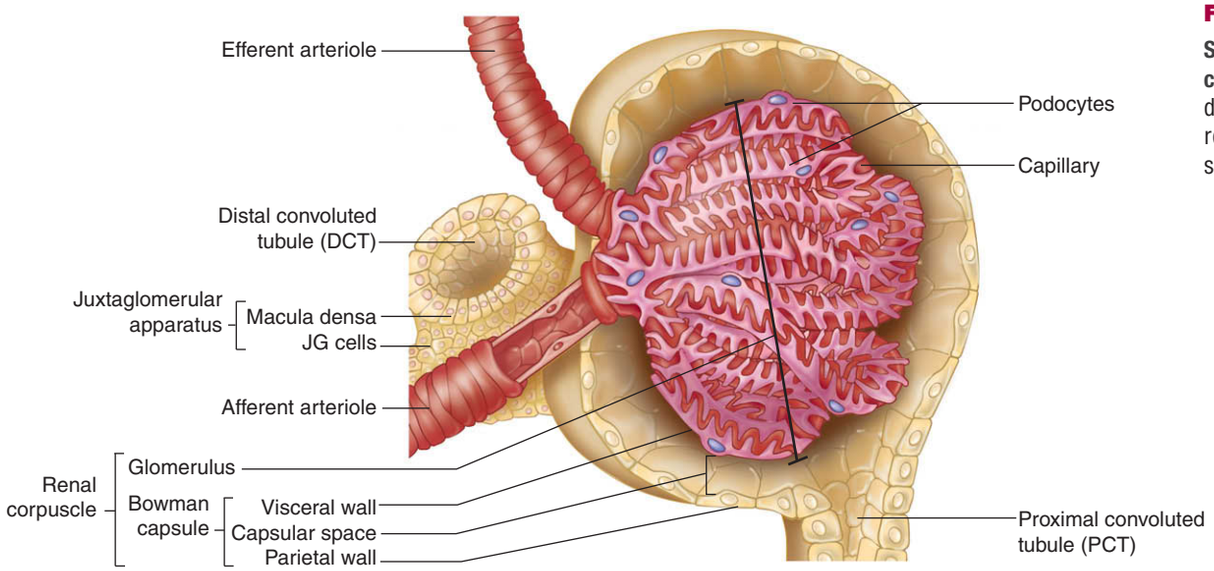

FIGURE 31-12

Structure of the renal corpuscle. Detailed diagram showing relationships to nearby structures.

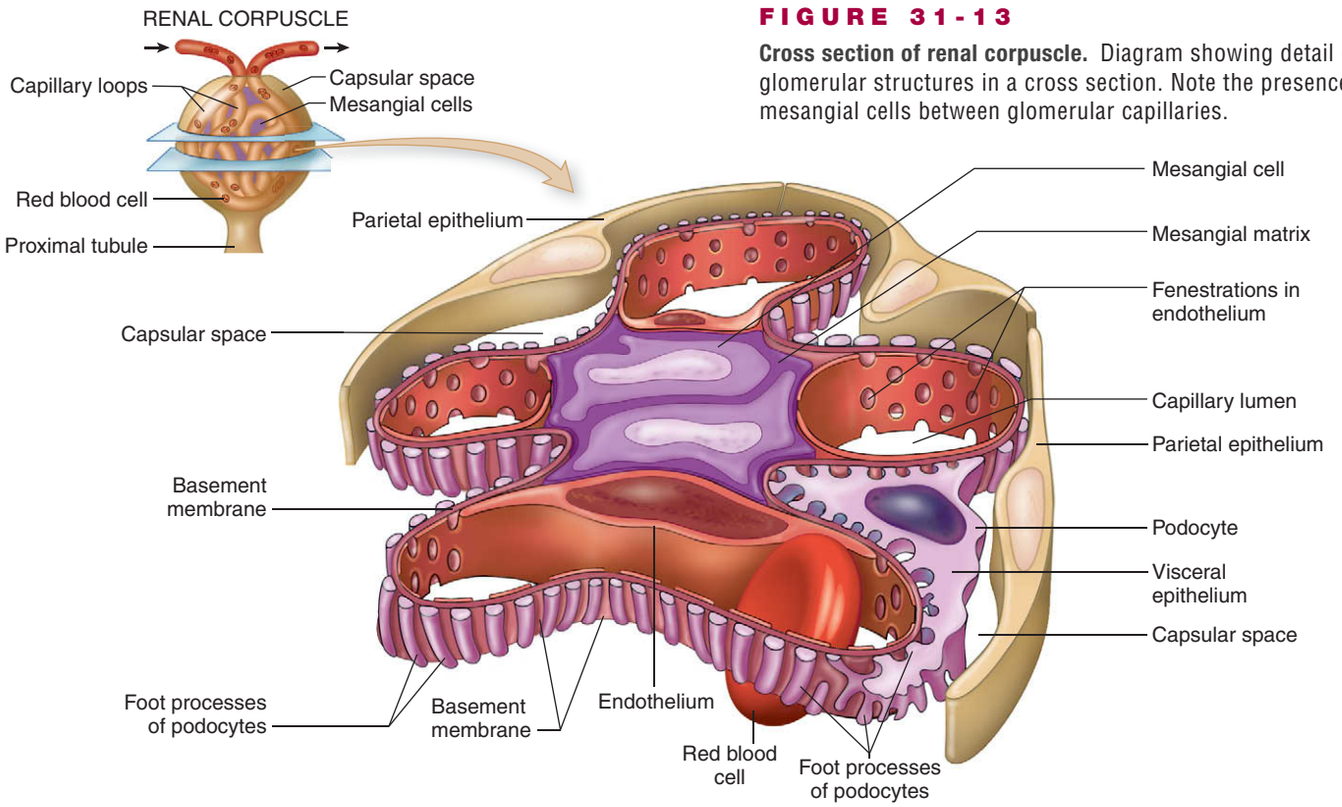

FIGURE 31-13

Cross section of renal corpuscle. Diagram showing detail of glomerular structures in a cross section. Note the presence of mesangial cells between glomerular capillaries.

Figure 31-14 reveals the odd shapes of podocytes. Notice that the primary branches extending from the cell bodies divide into a network of branches that terminate in little "feet" called *pedicels*. The pedicels are packed so closely together that only narrow slits of space lie between them. These spaces are called *filtration slits*. The slits are not merely open spaces, however. Within them is a mesh of fine connective tissue fibers called the *slit diaphragm* that prevents the slits from enlarging under pressure while still maintaining permeability of the slit. The slit diaphragm is an important component of the filter mechanism because it prevents many large macromolecules, such as proteins, from passing through.

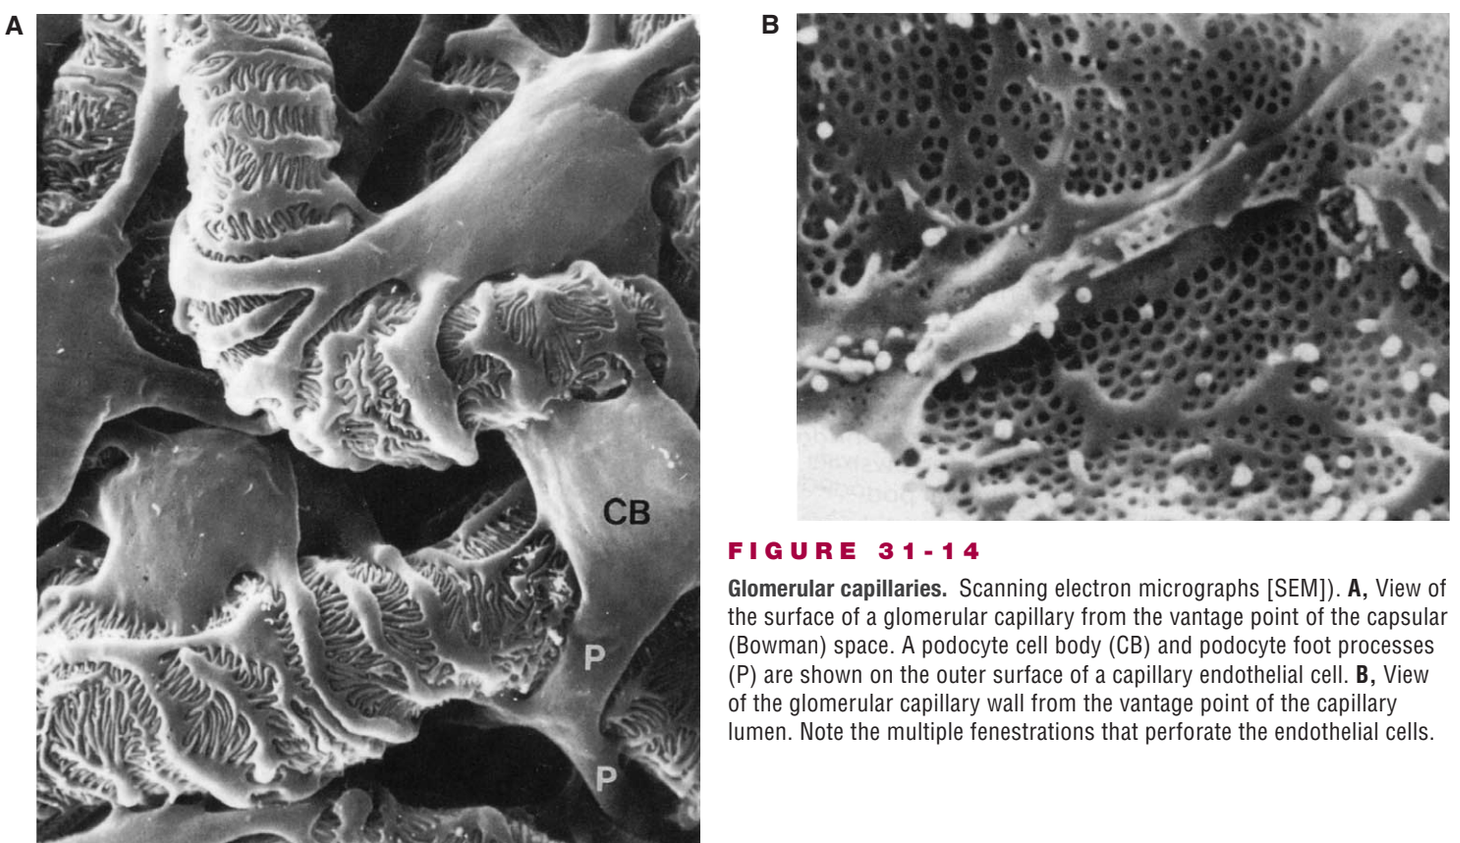

FIGURE 31-14

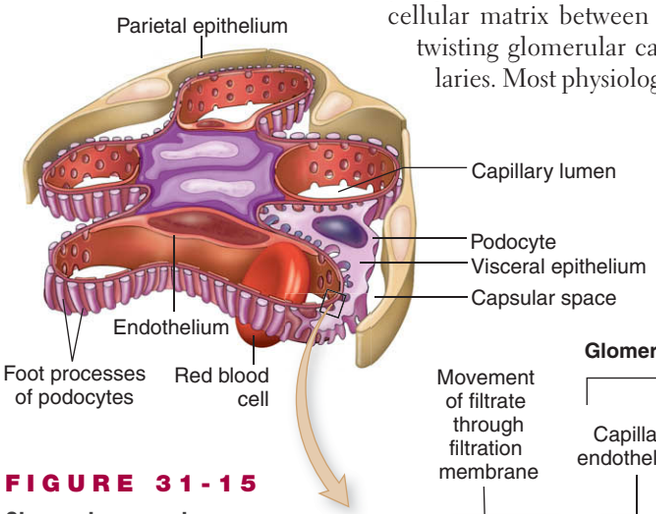
Glomerular capillaries. Scanning electron micrographs [SEM]). **A,** View of the surface of a glomerular capillary from the vantage point of the capsular (Bowman) space. A podocyte cell body (CB) and podocyte foot processes (P) are shown on the outer surface of a capillary endothelial cell. **B,** View of the glomerular capillary wall from the vantage point of the capillary lumen. Note the multiple fenestrations that perforate the endothelial cells.

Glomerulus

The **glomerulus** is probably the body's most well known capillary network and is surely one of its most important ones for survival. Its relationship to the Bowman capsule is clearly visible in Figures 31-11 and 31-12. Notice in both Figures that an afferent arteriole leads into the glomerular network and an efferent arteriole leads out.

Like all capillaries, glomerular capillaries have thin, membranous walls that are composed of a single layer of endothelial cells. Many pores, or *fenestrations* (meaning "windows"), are present in the glomerular endothelium (see Figure 31-14, *B*). These pores are not present in regular capillaries (see Figure 21-16 on p. 645). This increased porosity is necessary for filtration to occur at the rate required for normal kidney function. The relationship between fenestration size and the rate of glomerular filtration is yet another example of the connection between form and function.



Mesangial cells (see Figure 31-13) are unique to renal corpuscles. They are irregular in shape, have numerous cytoplasmic processes, and are scattered in an apparently haphazard way in an extracellular matrix between the twisting glomerular capillaries. Most physiologists believe they serve a support and phagocytic function, similar in some ways to microglia and other types of glia cells found in the nervous system (see Chapter 13, p. 383). However, the presence of myosin-like filaments and angiotensin II receptors in their cytoplasm also suggests a possible role in control of blood flow through the glomerular loop. Mesangial cells are currently the subject of considerable research interest and may well have other important functions or play an important role in human glomerular disease.

Between a glomerulus and its Bowman capsule lies a basement membrane (basal lamina). It consists of a thin layer of fine fibrils embedded in a matrix of glycoprotein. The visceral layer of Bowman capsule contacts the basement membrane by means of countless pedicels ("feet") of the podocytes (see Figure 31-14, *A*). The glomerular endothelium, the basement membrane, and the visceral layer of Bowman capsule constitute the **glomerular capsular membrane,** a structure well suited to its function of filtration (Figure 31-15).

Renal Tubule

The renal tubule is a winding, hollow tube with walls largely made up of simple cuboidal and simple squamous epithelium. The epithelial cells each possess a single, *primary cilium* that acts as a sensory receptor that monitors the chemical makeup and rate of flow of the fluid flowing through the lumen of the tubule. Thus, renal tubule cells are able to respond to changes in the composition and flow of fluid to regulate the growth and functioning of the tubule. You can review the sensory role of primary cilia in the body on p. 83.

The renal tubule extends from the renal corpuscle to the end of the nephron, where it joins a collecting duct shared in common with other nearby nephrons. The renal tubule is divided into

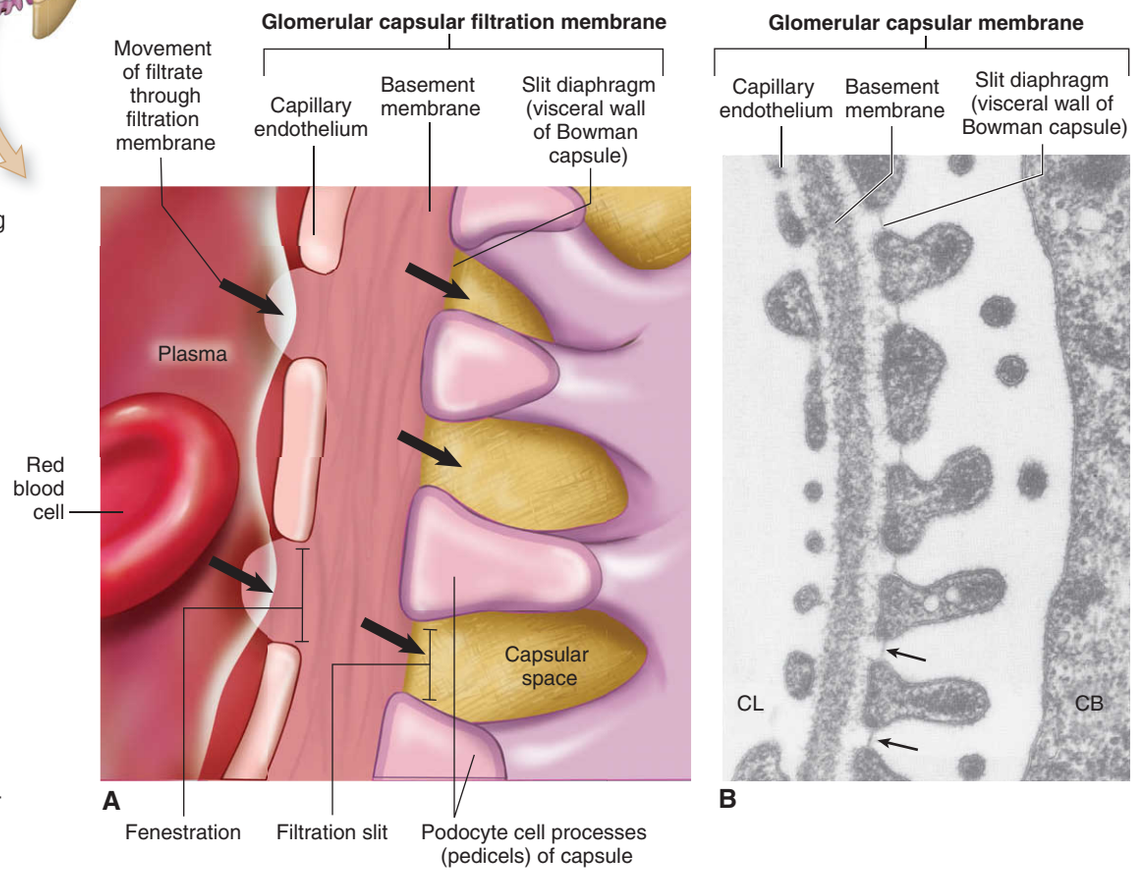


FIGURE 31-15

Glomerular capsular membrane. A, Artist's rendering of a transmission electron micrograph (TEM) showing the filtration membrane formed when footlike extensions (pedicels) of cells forming the visceral wall of the Bowman capsule share a basement membrane with the fenestrated endothelial cells that form the wall of glomerular capillaries. **B,** TEM of the glomerular capsular membrane. Note from left to right, the capillary lumen (CL), fenestrations in the capillary endothelium, and multiple podocyte foot processes separated by slit diaphragms (arrows) extending into the capsular (Bowman) space. A portion of an overarching podocyte cell body (CB) is visible on the right.

different regions: the proximal convoluted tubule, the Henle loop, and the distal convoluted tubule. Follow along in Figure 31-10 as we briefly explore these regions.

Proximal Convoluted Tubule

The **proximal convoluted tubule (PCT)**, or more simply *proximal tubule*, is the second part of the nephron but the first part of the *renal tubule*. As its name suggests, the proximal convoluted tubule is the segment proximal, or nearest, to the Bowman capsule. Because it follows a winding, convoluted course, it is called a *convoluted* tubule. Its wall consists of one layer of epithelial cells that have a brush border facing the lumen of the tubule. Thousands of microvilli form the brush border and greatly increase its luminal surface area—a structural fact of importance to its function, as we shall see.

Henle Loop

The **Henle loop,** or *nephron loop*, is the segment of renal tubule just beyond the proximal tubule. It consists of a thin *descending limb*, a sharp turn, and an *ascending limb*. Note in Figure 31-10 that the ascending limb has two regions of different wall thickness: the *thin ascending limb [of Henle] (tALH)* and the *thick ascending limb (TAL)*. The length of the Henle loop is important in the production of highly concentrated or very dilute urine.

Distal Convoluted Tubule

The **distal convoluted tubule (DCT),** or simply *distal tubule*, is a convoluted portion of the tubule beyond (distal to) the Henle loop. The distal convoluted tubule conducts filtrate out of the nephron and into a collecting duct.

The **juxtaglomerular apparatus** (meaning "structure near the glomerulus") is found at the point where the afferent arteriole brushes past the distal convoluted tubule (see Figure 31-12). Also called the *juxtaglomerular complex*, this structure is important in maintaining homeostasis of blood flow because it reflexively secretes **renin** when blood pressure in the afferent arteriole drops. Recall from Chapter 22 that renin triggers a mechanism that produces *angiotensin*, a substance that causes vasoconstriction and the resulting increase in blood pressure (see Figure 31-27 on p. 990).

The unique cells of the juxtaglomerular apparatus represent a modification of cells in the walls of both the distal convoluted tubule and the afferent arteriole at the point where they touch one another. Large smooth muscle cells in the wall of the afferent arteriole—called **juxtaglomerular (JG) cells**—contain renin granules. These cells are sensitive to increased pressure in the arteriole and are considered functional *mechanoreceptors*. Modified distal convoluted tubule cells in the juxtaglomerular apparatus form a dense, tightly packed structure called the **macula densa.** Cells in the macula densa are *chemoreceptors* that can sense the concentration of solute materials in the fluid passing through the tubule. Acting together, both cell types in the juxtaglomerular apparatus contribute to homeostasis of renal function by influencing the ability of the kidney to produce concentrated urine.

COLLECTING DUCT

The **collecting duct (CD)** is formed by the joining of renal tubules of several nephrons. All the collecting ducts of one renal pyramid converge at a renal papilla and release urine through their openings into one of the minor calyces (Figure 31-16). Bowman capsules and both convoluted tubules lie entirely within the cortex of the kidney, whereas the Henle loops and collecting ducts extend into the medulla (see Figure 31-10).

BLOOD SUPPLY OF THE NEPHRON

Earlier in this chapter, we traced renal blood flow through the renal artery and its branches to the afferent arteriole. Blood flows from the afferent arteriole into the glomerular capillaries and then exits through an *efferent arteriole* (Figure 31-17). The efferent arteriole then enters another capillary network that runs alongside the renal tubule. These capillaries are called **peritubular capillaries.** Some of the blood from the efferent arteriole flows through long hairpin-shaped loops that follow the nephron loop. These long, looping arterioles are called the **vasa recta** (*singular*, vas rectum) or *straight arterioles*. Blood flows very slowly through the vasa recta, a fact that plays an important role in the function of these vessels.

As you can see in Figure 31-17, blood flows through the efferent arteriole to the peritubular capillaries and vasa recta—the *peritubular blood supply*—then back toward the heart through *interlobular veins* and *arcuate veins* that head toward the large *renal veins*.

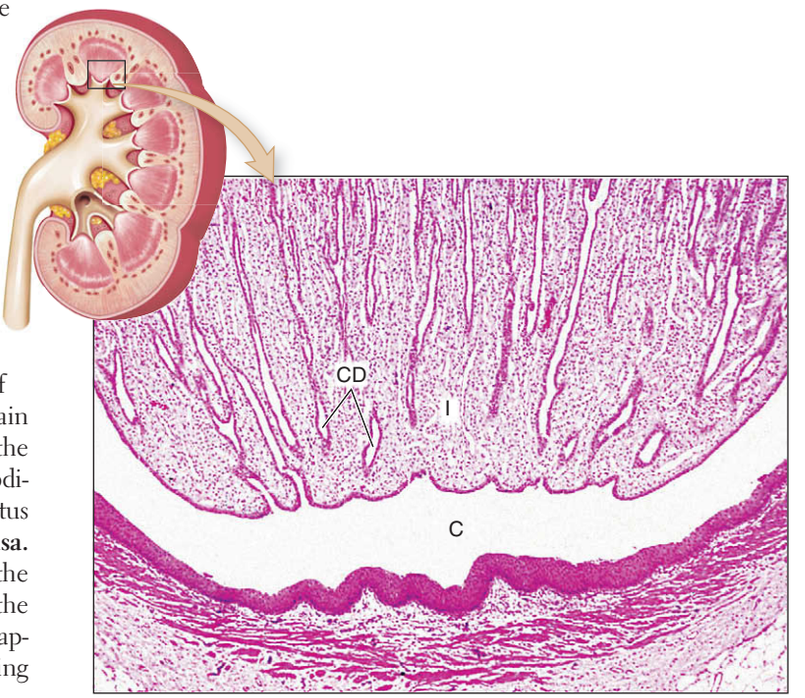

FIGURE 31-16

Renal papilla. Collecting ducts (CD) can be seen opening into a calyx (C) at the papillary tip. The interstitial tissue (I) includes some Henle loops and vasa recta vessels.

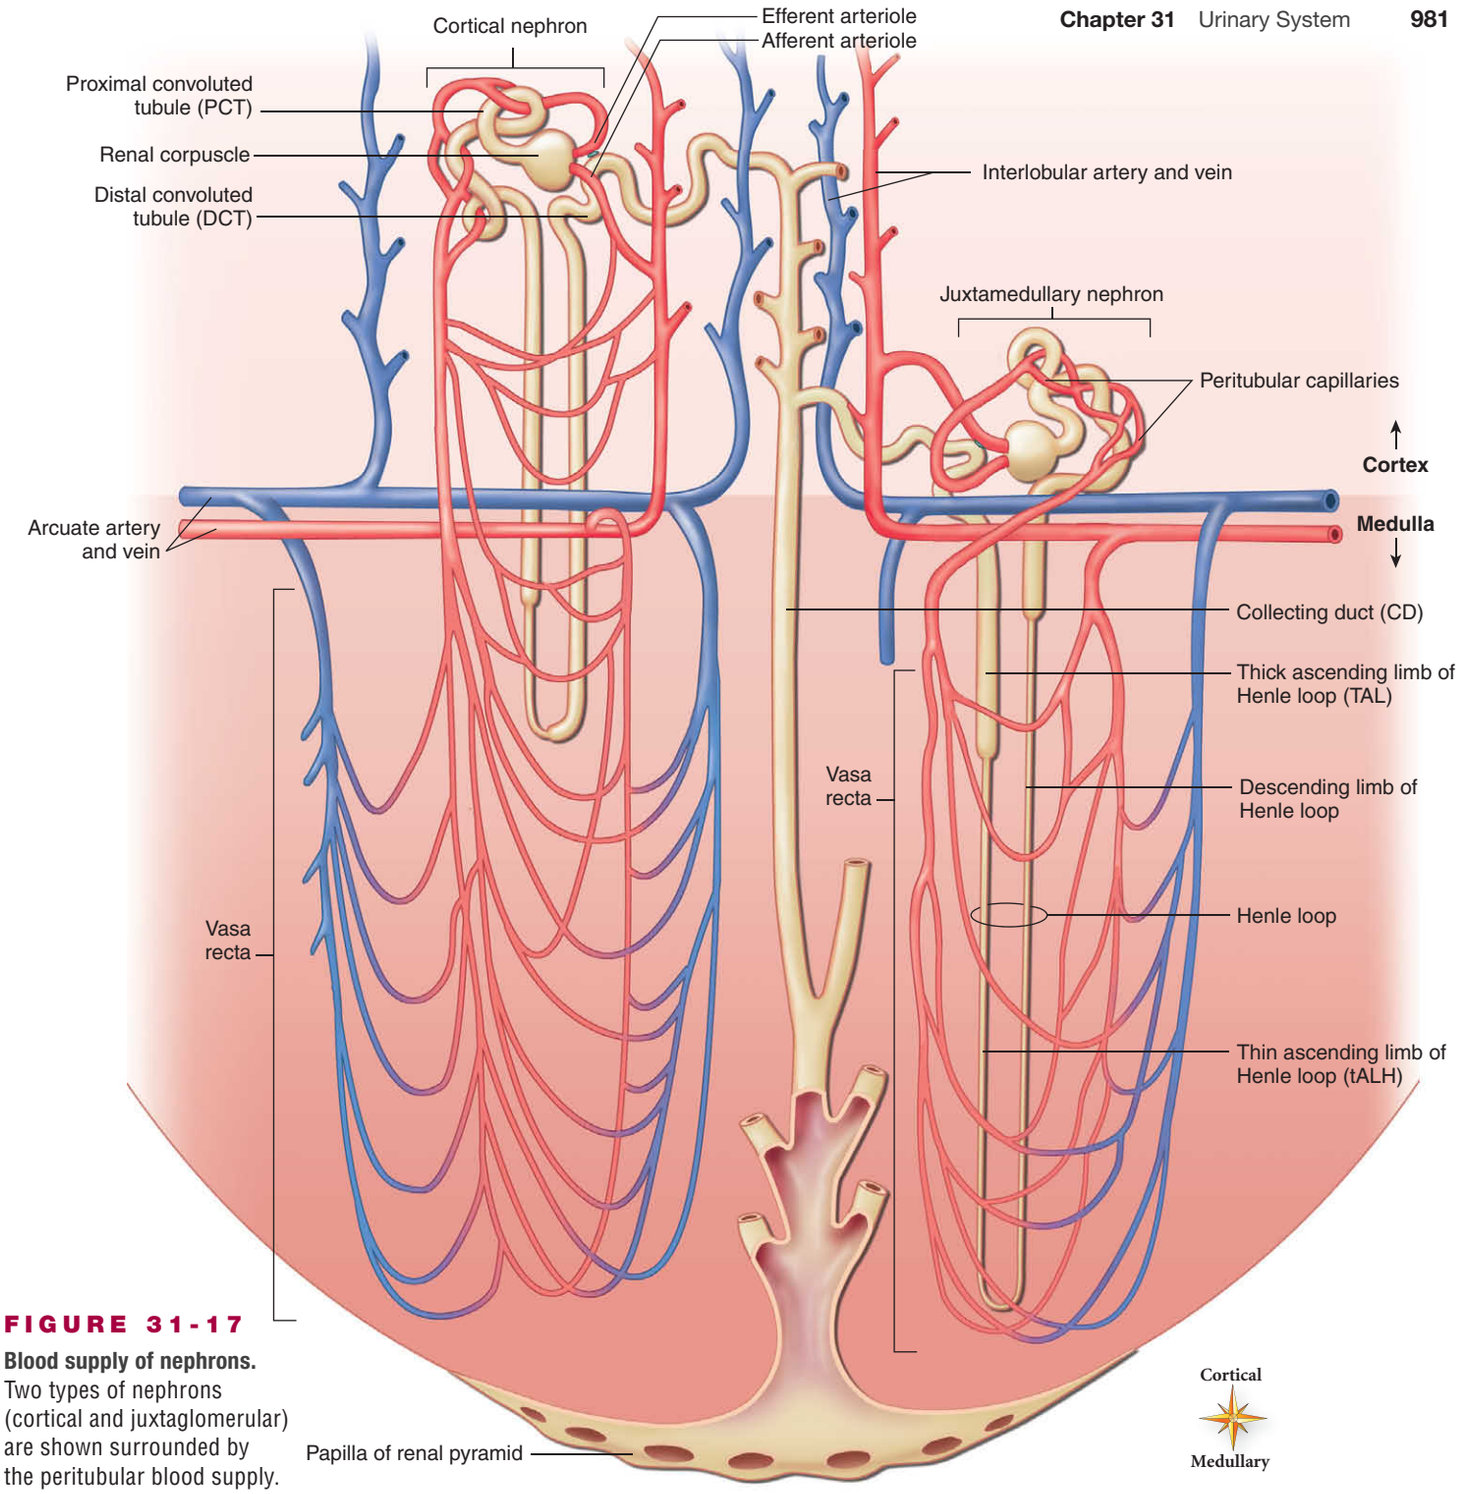

FIGURE 31-17

Blood supply of nephrons. Two types of nephrons (cortical and juxtaglomerular) are shown surrounded by the peritubular blood supply.

TYPES OF NEPHRONS

About 85% of all nephrons are located almost entirely in the renal cortex and are called **cortical nephrons.** The remainder, called **juxtamedullary** (jux-tah-MED-oo-lair-ee) **nephrons,** are found adjoining (*juxta*) the medulla. Juxtamedullary nephrons have long Henle loops that dip far into the medulla (see Figure 31-17). The special role of these long Henle loops of juxtamedullary nephrons in concentrating urine is discussed later.

| QUICK CHECK |

8. Name the segments of the nephron in the order in which fluid flows through them.
9. What characteristics of the glomerular capsular membrane permit filtration?
10. What is the name of the blood supply that surrounds the nephron? The other name for the straight arterioles that follow the nephron loop?

PHYSIOLOGY OF THE URINARY SYSTEM

Overview of Kidney Function

The chief functions of the kidney are to process blood plasma and excrete urine. These functions are vital because they maintain the homeostatic balance of the body. For example, the kidneys are the most important organs in the body for maintaining fluid-electrolyte and acid-base balance. The kidneys do this by varying the amount of water and electrolytes leaving the blood in the urine so that they equal the amounts of these substances entering the blood from various other avenues. Nitrogenous wastes from protein metabolism, notably *urea*, leave the blood by way of the kidneys.

Here are just a few of the blood constituents that cannot be held within their normal concentration ranges if the kidneys fail:

- Sodium
- Potassium
- Chloride
- Nitrogenous wastes (especially urea)

In short, kidney failure means homeostatic failure and, if not relieved, inevitable death.

In addition to processing blood plasma and forming urine, the kidneys also perform other important functions. They influence the rate of secretion of the hormones antidiuretic hormone (ADH) and aldosterone and synthesize the active form of vitamin D, the hormone *erythropoietin*, and certain prostaglandins.

As you already know, the basic functional unit of the kidney is the nephron. It has two main parts—the renal corpuscle and renal tubule—that form urine by means of three processes:

1. **Filtration**—movement of water and protein-free solutes from plasma in the glomerulus, across the glomerular capsular membrane, and into the capsular space of Bowman capsule
2. **Tubular reabsorption**—movement of molecules out of the various segments of the tubule and into the peritubular blood
3. **Tubular secretion**—movement of molecules out of peritubular blood and into the tubule for excretion

These three mechanisms are used in concert to process blood plasma and form urine. First, a hydrostatic pressure gradient drives the filtration of much of the plasma into the nephron (Figure 31-18). Because the filtrate contains materials that the body must conserve (save), the walls of the tubules start reabsorbing these materials back into the blood. As the filtrate (urine) begins to leave the nephron, the kidney may secrete a few "last minute" items into the urine for excretion. In short, the kidney does not selectively filter out only harmful or excess material. It first filters out much of the plasma, then reabsorbs what should not be "thrown out" before the filtrate reaches the end of the tubule and becomes urine. This mechanism allows very fine adjustments to blood homeostasis, as we shall see. Figure 31-19 shows the amounts of some important molecules that are filtered, then reabsorbed, by the nephron.

Filtration

Filtration, the first step in blood processing, is a physical process that occurs in the kidneys' 2.5 million renal corpuscles (see Figures 31-10, 31-12, and 31-15). As blood flows through the glomerular capillaries, water and small solutes filter out of the blood into Bowman capsules. The only blood constituents that do not move out are the blood solids (cells) and most plasma proteins. The result is about 180 liters of glomerular filtrate being formed each day. This filtration takes place through the glomerular capsular membrane.

MECHANISM OF FILTRATION

Filtration from glomeruli into Bowman capsules occurs for the same reason that filtration from other capillaries into interstitial fluid occurs—because of the existence of a pressure gradient. The main factor establishing the pressure gradient between the blood in the glomeruli and the filtrate in the Bowman capsule is the hydrostatic pressure of glomerular blood (Figure 31-20). It tends to cause filtration out of the glomerular blood plasma into Bowman capsules. The intensity of glomerular hydrostatic pressure is influenced by systemic blood pressure and the resistance to blood flow through the glomerular capillaries as described later. However, exerting force in the opposite direction are the osmotic pressure of glomerular blood plasma and the hydrostatic pressure of the capsular filtrate. The net or *effective filtration pressure (EFP)* therefore equals glomerular hydrostatic pressure minus the sum of glomerular osmotic pressure plus capsular hydrostatic pressure (see Figure 31-20). For example, assume the following pressures:

- Glomerular hydrostatic pressure = 60 mmHg
- Glomerular osmotic pressure = 32 mmHg
- Capsular hydrostatic pressure = 18 mmHg
- Capsular osmotic pressure = negligible amount (±0 mmHg)

The EFP (effective filtration pressure), using these particular figures, equals (60 +0) – (32 + 18), or 10 mmHg. An effective filtration

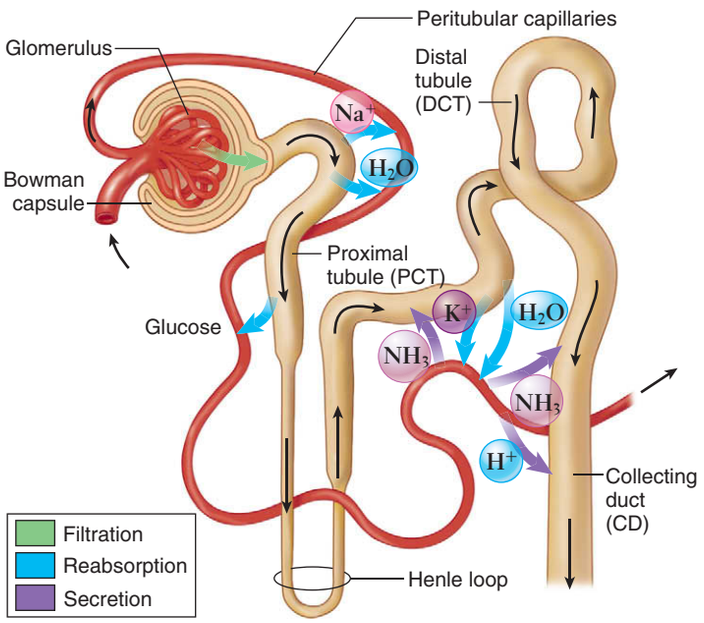

FIGURE 31-18

Overview of urine formation. The diagram shows the basic mechanisms of urine formation—filtration, reabsorption, and secretion—and where they occur in the nephron. Details of these steps are revealed later in this chapter.

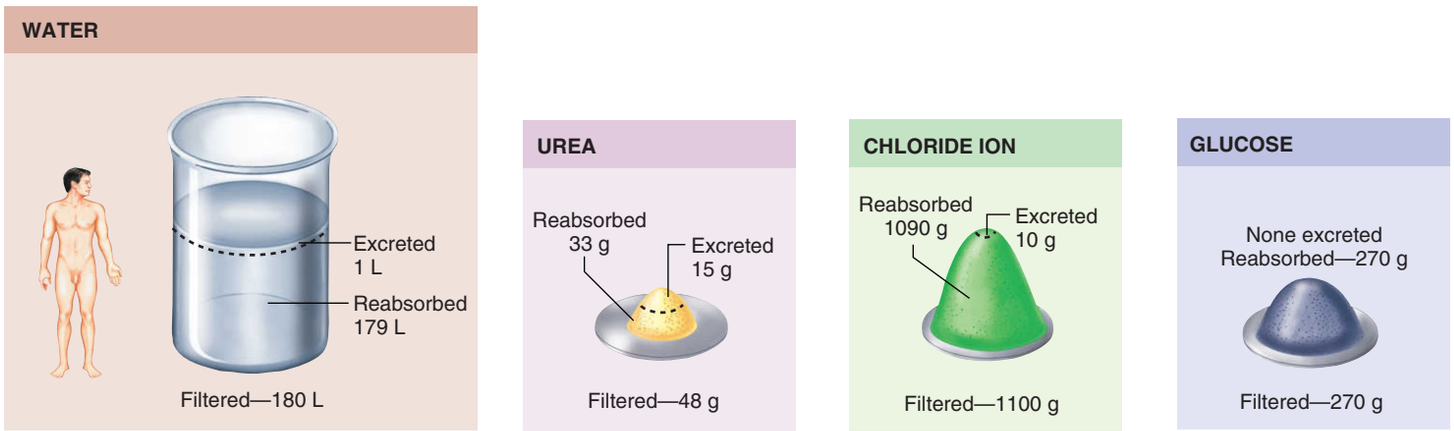

FIGURE 31-19

Filtration and reabsorption volumes. Note the enormous volume of water that is filtered out of glomerular blood per day—180 liters, or many times the total volume of blood in the body. Only a small proportion of this water, however, is excreted into urine. More than 99% of it (179 liters) is reabsorbed into tubular blood.

pressure of 1 mmHg, according to some investigators, produces a glomerular filtration rate of 12.5 ml per minute (including both kidneys). With an EFP of 10 mmHg, the glomerular filtration rate (GFR) would be 125 ml per minute, or about 180 liters in a 24-hour period, a normal rate. (GFR ranges from 150 to 250 liters per day in healthy individuals.) Because only about 1.5 liters of urine is excreted each day, more than 99% of the filtrate must be reabsorbed from the tubular segments of the nephron.

Filtration occurs more rapidly out of glomeruli than out of other tissue capillaries. One reason for this is a structural difference between the endothelium of glomeruli and that of tissue capillaries. Glomerular endothelium has many more pores (fenestrations) in it, so it is more permeable than tissue capillary endothelium. Another reason for more rapid glomerular filtration than tissue capillary filtration is that glomerular hydrostatic pressure is higher than tissue capillary pressure. The reason for this, briefly, is that the efferent arteriole has a smaller diameter than the afferent arteriole does. Therefore, it offers more resistance to blood flow out of the glomerulus than venules offer to blood flow out of tissue capillaries.

GLOMERULAR FILTRATION RATE

The **glomerular filtration rate (GFR)** is the rate of movement of fluid out of the glomerulus and into the capsular space. GFR is directly proportional to the EFP and can be altered by changes in the diameter of the afferent and efferent arterioles or by changes in the systemic blood pressure (Box 31-3). It can also be altered indirectly by changes in the efficiency of cardiac contraction. Stress may lead to intense sympathetic stimulation of the arterioles with greater constriction of the afferent than the efferent arteriole. Consequently, glomerular hydrostatic pressure falls. In severe stress, it may even drop to a level so low that the EFP falls to zero. No glomerular filtration then occurs. The kidneys "shut down," or in technical language, *renal suppression* occurs.

Glomerular hydrostatic pressure and filtration are directly related to systemic blood pressure. That is, a decrease in blood pressure tends to produce a decrease in both glomerular pressure and the GFR. The converse is also true. However, when arterial pressure increases, a smaller increase in glomerular pressure follows because the afferent arterioles constrict. This decreases blood flow into the glomeruli and prevents a marked rise in glomerular pressure or glomerular filtration. For instance, when the mean arterial blood pressure doubles, glomerular filtration reportedly increases only 15% to 20%.

| QUICK CHECK |

11. What are the three basic processes a nephron uses to form urine?
12. What is the GFR? Why is a high GFR important to kidney function?
13. How does blood pressure affect filtration in the kidney?

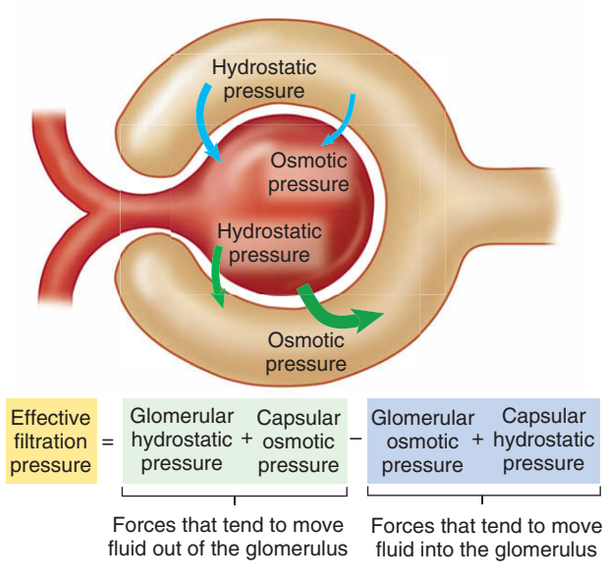

FIGURE 31-20

Forces affecting glomerular filtration. Effective filtration pressure (EFP) is determined by comparing the forces that push fluid into the capillary with those that push it out of the capillary.

Box 31-3 | Changes in Glomerular Filtration Rate

In some types of kidney disease, the permeability of the glomerular endothelium increases sufficiently to allow plasma proteins to filter out into the capsule. Osmotic pressure then develops in the capsular filtrate. To determine how this affects the effective filtration pressure (EFP) in the glomeruli, first calculate the normal EFP by using the Figures that the table lists as "Normal" in the formula given in Figure 31-20. After you have obtained your answer, apply the formula to the Figures given under "Kidney Disease" in the table. You should find an EFP of 10 mmHg with the normal Figures and an EFP of 15 mmHg with the kidney disease figures. A change in the glomerular EFP produces a similar change in the glomerular filtration rate (GFR). Therefore, loss of plasma protein into urine increases not only the EFP but also the GFR.

Intense exercise causes temporary proteinuria in many individuals. Some exercise physiologists believed that intense athletic activities cause kidney damage, but subsequent research has ruled out that explanation. One current hypothesis is that hormonal changes during strenuous exercise increase the permeability of the nephron's filtration membrane, thereby allowing more plasma proteins to enter the filtrate. Some degree of postexercise proteinuria is usually considered normal.

Normal and Abnormal Pressure in the Renal Corpuscle

	HYDROSTATIC PRESSURE	OSMOTIC PRESSURE
Normal		
Glomerular blood	60 mmHg	32 mmHg
Capsular filtrate	18 mmHg	0 mmHg
Kidney Disease		
Glomerular blood	60 mmHg	32 mmHg
Capsular filtrate	18 mmHg	5 mmHg

Reabsorption

Reabsorption, the second step in urine formation, takes place by means of passive and active transport mechanisms from all parts of the renal tubules. A major portion of water and electrolytes and (normally) all nutrients are, however, reabsorbed from the proximal convoluted tubules. The rest of the renal tubule reabsorbs comparatively little of the filtrate. Researchers are still investigating the exact mechanisms of reabsorption in the various segments of the nephron. We have summarized only the essential principles of some of the current concepts in the following paragraphs.

REABSORPTION IN THE PROXIMAL CONVOLUTED TUBULE

As already stated, most of the 180 liters of filtrate that enters the renal tubule from Bowman capsules each day does not get very far. More than two thirds of it is reabsorbed before it reaches the end of the proximal convoluted tubule.

The process of resabsorption begins when sodium ions (Na^+) are actively transported out of the lumen of the tubule and into peritubular blood by the mechanism summarized in Figure 31-21. The microvilli on the luminal surface of each epithelial cell in the tubule wall form a brush border that increases the absorptive surface area of the entire inner face of the tubule. As sodium ions accumulate in the interstitial fluid, the interstitial fluid becomes temporarily positive with respect to the tubule fluid. This electrical gradient (difference in net charge) drives the diffusion of negative ions from the filtrate, into the interstitial fluid, and eventually, into the peritubular blood. In other words, the attraction between negative and positive ions is used to drive the passive transport of chloride (Cl^-), phosphate ($PO_4^{\equiv}$) and other negative ions out of the tubule.

As the concentration of ions in peritubular blood increases, the blood becomes momentarily hypertonic to the tubule fluid. Through the process of osmosis, water diffuses rapidly from the tubule fluid into peritubular blood, thus making the two fluids isotonic. In short, transport of ions out of the proximal convoluted tubules causes osmosis of water out of the tubules as well. This is obligatory water reabsorption—obligatory because it is demanded by the principle of osmosis. Osmosis in the kidney relies on the availability and proper function of a family of water channels called *aquaporins* (see p. 93).

Proximal convoluted tubules reabsorb nutrients from the tubule fluid, notably glucose and amino acids, into peritubular blood by a special type of active transport mechanism called **sodium cotransport.** Recall from Chapter 29 that, in this mechanism, a carrier molecule in the cell membrane first binds to sodium and glucose (see Figure 29-20, p. 921). The carrier then passively transports both substances through the brush border of a proximal convoluted tubule cell into the cell's interior (facilitated diffusion). Sodium moves into the cell because of a concentration gradient maintained by the active transport of sodium out the other side of the cell. Glucose actually moves up its concentration gradient, but no energy is required because it is "riding the coattails" of sodium. Once inside the cell, the substances dissociate from the carrier molecule and diffuse to the far side of the cell. The substances move out of the epithelial cell by different mechanisms. Sodium is transported actively, and glucose is transported passively.

Normally, all the glucose that has filtered out of the glomeruli returns to the blood by this sodium cotransport mechanism. Therefore, very little glucose is lost in urine. If, however, the blood glucose level exceeds a threshold amount (usually between

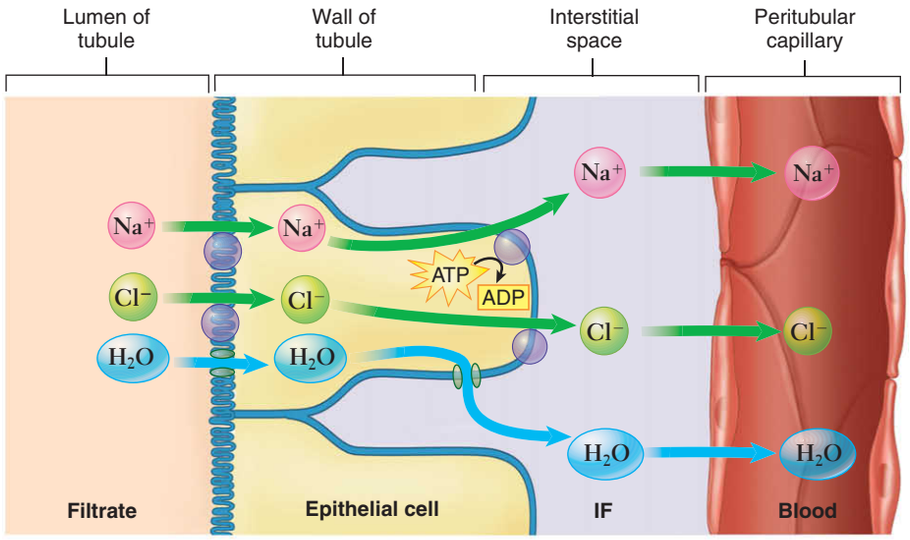

FIGURE 31-21

Mechanisms of tubular reabsorption. Sodium ions (Na^+) are pumped from the tubule cell to interstitial fluid (IF), thereby increasing the interstitial Na^+ concentration to a level that drives diffusion of Na^+ into blood. As Na^+ is pumped out of the cell, more Na^+ passively diffuses in from the filtrate to maintain an equilibrium of concentration. Enough Na^+ moves out of the tubule and into blood that an electrical gradient is established (blood is positive relative to the filtrate). Electrical attraction between oppositely charged particles drives diffusion of negative ions in the filtrate, such as chloride (Cl^-), into blood. As the ion concentration in blood increases, osmosis of water from the tubule occurs. Thus active transport of sodium creates a situation that promotes passive transport of negative ions and water.

130 and 300 mg/100 ml), not all of the glucose can be reabsorbed. The excess glucose remains in urine (Box 31-4). The maximum capacity for moving glucose molecules back into blood is determined by the number of cotransport carriers available. The maximum capacity for moving any substance limited by availability of carriers is called the *transport maximum (Tm* or *Tmax)* of that substance.

Urea is a nitrogen-containing waste formed as a result of protein catabolism (see Chapter 30). Actually, toxic ammonia is formed first, but much of it is quickly transformed into the less toxic urea. Urea in the tubule fluid remains in the proximal convoluted tubule as sodium, chloride, and water are reabsorbed into blood. Once these materials are gone, a tubule fluid high in urea is left. Because the urea concentration in the tubule is then greater than its concentration in peritubular blood, urea passively diffuses into the blood. About half the urea present in the tubule fluid leaves the proximal convoluted tubule this way.

Reabsorption in the proximal convoluted tubules can be summarized in the following manner:

1. Sodium is actively transported out of the tubule fluid and into blood.
2. Glucose and amino acids "hitch a ride" with sodium and passively move out of the tubule fluid by means of the sodium cotransport mechanism.
3. Chloride ions passively move into blood plasma because of an imbalance in electrical charges (positive sodium ions have already moved out, thus making the plasma positive and the tubule fluid negative).
4. Movement of sodium and chloride out of the tubule fluid into plasma creates an osmotic imbalance (the blood is hypertonic to the filtrate), so water is obliged by the principle of osmosis to passively move into blood.
5. About half the urea present in the tubule fluid passively moves out of the tubule, with half the urea thus left to move on to the Henle loop.
6. The total content of the filtrate has been reduced greatly by the time it is ready to leave the proximal convoluted tubule. Most of the water and solutes have been recovered by the blood, and only a small volume of fluid is left to continue to the next portion of the tubule, the Henle loop.

| QUICK CHECK |

14. How are NaCl and water reabsorbed in the proximal convoluted tubule?
15. What is sodium cotransport?
16. What is a transport maximum?

Box 31-4 | HEALTH matters

Glucose in Urine

Occasionally, the maximum cotransport capacity is greatly reduced, and glucose appears in urine *(glycosuria),* even though the blood sugar level may be normal. This condition is known as *renal diabetes* or *renal glycosuria.* It is a congenital defect.

Of course, the most common cause of glycosuria is *diabetes mellitus* (see Chapter 19). In this condition, insulin deficiency or target cell dysfunction causes glucose to accumulate in the blood, causing hyperglycemia. The high glucose content of the filtrate formed in the renal corpuscle exceeds the maximum capacity of the cotransport mechanism. Therefore, glycosuria results.

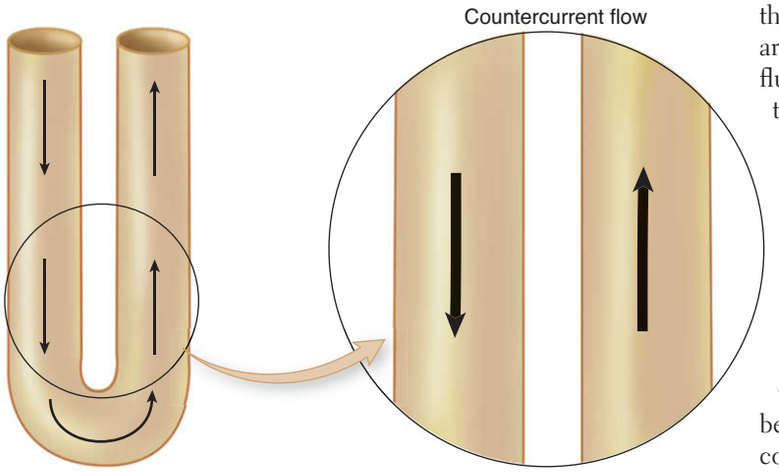

FIGURE 31-22

Concept of countercurrent flow. Countercurrent flow simply refers to flow in opposite directions, as the *inset* shows. Tubule filtrate in the Henle loop flows in a countercurrent manner, as does blood flowing through vasa recta of the peritubular blood supply.

REABSORPTION IN THE HENLE LOOP

In juxtamedullary nephrons—those low in the cortex, near the medulla—the Henle loop and its vasa recta participate in a very unique process called a **countercurrent mechanism.** A countercurrent structure is any set of parallel passages in which the contents flow in opposite directions (Figure 31-22). The Henle loop is a countercurrent structure because the contents of the ascending limb travel in a direction opposite to the flow of urine in the descending limb. The vasa recta also have a countercurrent structure because arterial blood flows down into the medulla and venous blood flows up toward the cortex. The kidney's countercurrent mechanism functions to keep the solute concentration of the medulla extremely high. We will discuss why this is important later on. For now, we will briefly discuss how the countercurrent mechanism achieves this goal.

Before we can understand the kidney's countercurrent mechanisms, we must appreciate the histology of the Henle loop. The descending limb is formed by a much thinner wall than the thick part of the ascending limb (see Figure 31-10). Even more important, the permeability and transport abilities of the two walls are very different. The thin-walled descending limb allows water and urea to diffuse freely into or out of the tubule, depending on their concentration gradients. The thick-walled ascending limb, however, limits the diffusion of most molecules (including water, sodium, chloride, and urea) while actively transporting selected molecules out of the tubule and into the interstitial fluid.

Given the characteristics of each limb, we can see how the system illustrated in Figure 31-23 can develop in the Henle loop. Look at the thick ascending limb. You will see that this limb is actively pumping sodium and chloride out of the tubule fluid and into interstitial fluid. This probably occurs by the same mechanism that operates in the proximal convoluted tubule. Normally, sodium and chloride ions simply diffuse right back into the tubule fluid to achieve equilibrium. The ascending limb prevents the diffusion of these ions, so they are "trapped" in the interstitial area. Under normal circumstances, water moves from the tubule fluid to the interstitial fluid to achieve osmotic balance. However, the wall of the ascending limb is relatively impermeable to water. In short, salt ions are pumped out of the ascending limb, water is prevented from following osmotically, and thus the tubule fluid develops a low solute concentration (low osmotic pressure) and interstitial fluid develops a high solute concentration (high osmotic pressure).

The ion pumps in the ascending limb can maintain an osmotic difference of 200 mOsm across the wall of the tubule. Notice in Figure 31-23 that the movement of salt out of the tubule at any horizontal level creates a difference of 200 mOsm between the tubule fluid and interstitial fluid. Because salt is continually added to the interstitial fluid, the interstitial fluid becomes very concentrated (up to 1200 mOsm in our model). This high solute concentration of the interstitial fluid of the medulla

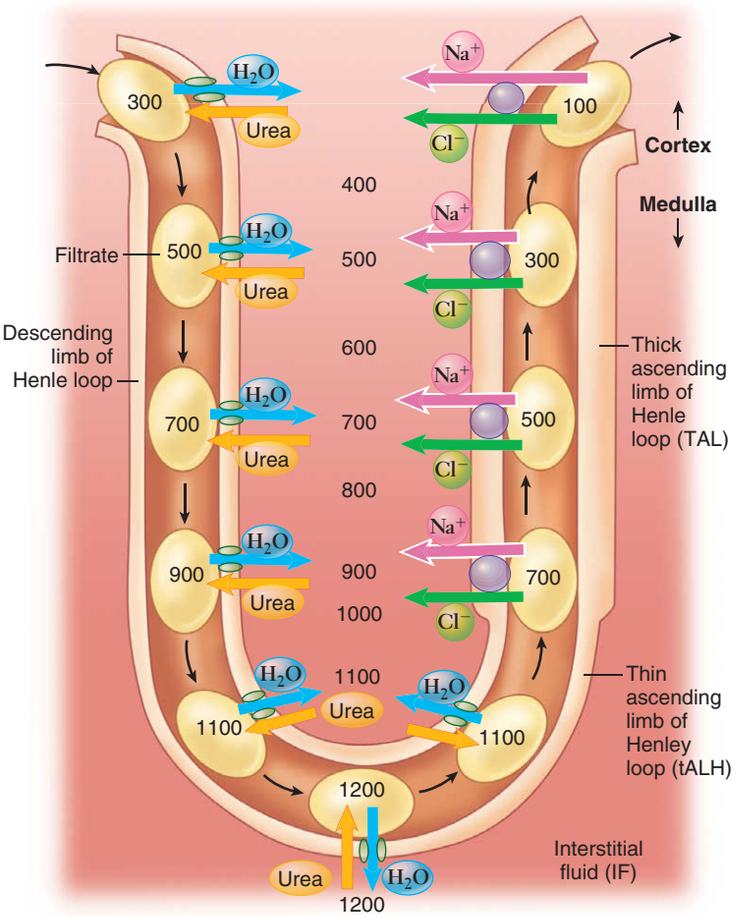

FIGURE 31-23

The countercurrent multiplier system in the Henle loop. Na^+ and Cl^- are pumped from the ascending limb and moved into interstitial fluid (IF) to maintain high osmolality there. Because the salt content of the medullary IF increases, this is called a "multiplier" mechanism. Ion pumping also lowers the tubule fluid's osmolality by 200 mOsm, so fluid leaving the Henle loop is only 100 mOsm (hypotonic), as compared with 300 mOsm (isotonic) when it entered the loop. Numbers in the diagram are expressed in milliosmoles (mOsm).

is created and maintained by the constant pumping of salt by the ascending limb. For this reason, this process is often called a *countercurrent multiplier mechanism*.

You will notice that the tubule fluid in the descending limb equilibrates easily with the interstitial fluid. Because interstitial fluid has a high solute concentration (created by the ion pumps in the ascending limb), the fluid in the descending limb loses water osmotically. Thus the solute concentration of the tubule fluid becomes increasingly higher. Urea, a solute that is also highly concentrated in the renal medulla, diffuses into the tubule fluid in the descending limb—thereby increasing the solute concentration of the tubule fluid even more. However, as the fluid "rounds the bend" and begins moving into the thick portion of the ascending limb, its Na^+ and Cl^- are removed and it becomes increasingly lower in solute concentration.

When tubule fluid enters the Henle loop, it is about 300 mOsm (isotonic to most body fluids). When it leaves the Henle loop, it is about 100 mOsm (hypotonic to most body fluids). Because water is reabsorbed from the fluid in the descending limb, there is a net reduction of tubule fluid volume. And because urea entered the tubule fluid in the descending limb, there is a net increase in urea concentration in the tubule fluid.

You might think that the blood of the vasa recta (a portion of the peritubular blood supply) would remove the excess solute from the medulla's interstitial fluid as it flows through the tissue. Usually it would, but the vasa recta have their own countercurrent mechanism—often called the *countercurrent exchange mechanism*. Figure 31-24 shows how the looping of a vas rectum, down into the medulla, then back up to the cortex, prevents it from accumulating too much solute. Consider also that blood flow through a vas rectum is sluggish; it cannot remove anything very efficiently. Just enough solute is removed to prevent the medulla from crystallizing completely because of a high solute concentration. Thus the tissues of the medulla have the benefits of a blood supply without much loss of its high solute concentration.

The primary functions of the Henle loop are summarized as follows:

- The Henle loop reabsorbs water from the tubule fluid (and picks up urea from the interstitial fluid) in its descending limb. It reabsorbs sodium and chloride from the tubule fluid in the ascending limb.
- By reabsorbing salt from its ascending limb, it makes the tubule fluid dilute (hypotonic).
- Reabsorption of salt in the ascending limb also creates and maintains a high osmotic pressure, or high solute concentration, of the medulla's interstitial fluid.

| QUICK CHECK |

17. What is a countercurrent mechanism?
18. How does the function of the descending limb of the Henle loop differ from the function of the thick ascending limb?
19. What is the purpose of the countercurrent multiplier mechanism of the Henle loop?

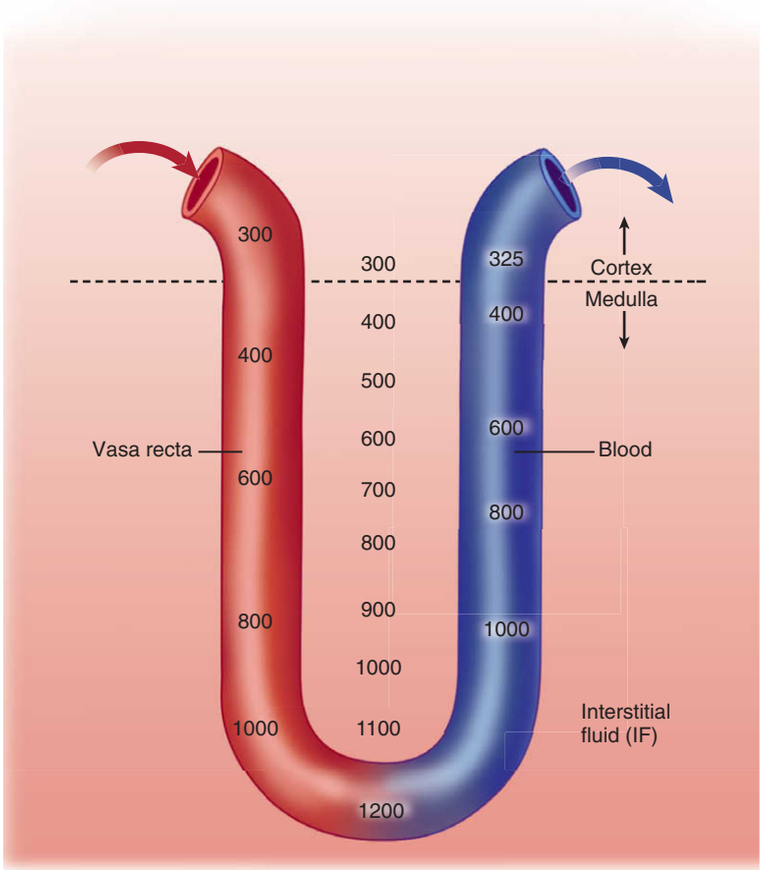

FIGURE 31-24

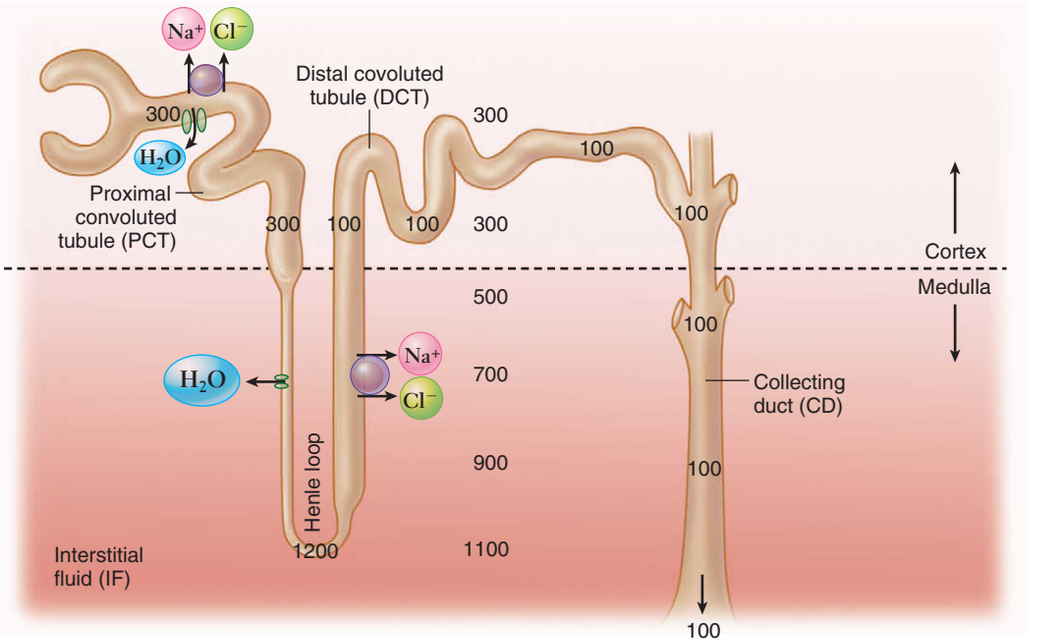
Countercurrent exchange mechanism in a vas rectum. Because a vas rectum forms a countercurrent loop, blood leaving the capillary bed has only a slightly higher solute content than when it entered. Thus the high osmolality of medullary tissue fluid is maintained. If peritubular blood instead traveled straight through the tissue, all excess solute in the medulla would be removed, and the osmolality of medullary interstitial fluid (IF) would be equivalent to that of the cortex. Numbers in the diagram are expressed in milliosmoles.



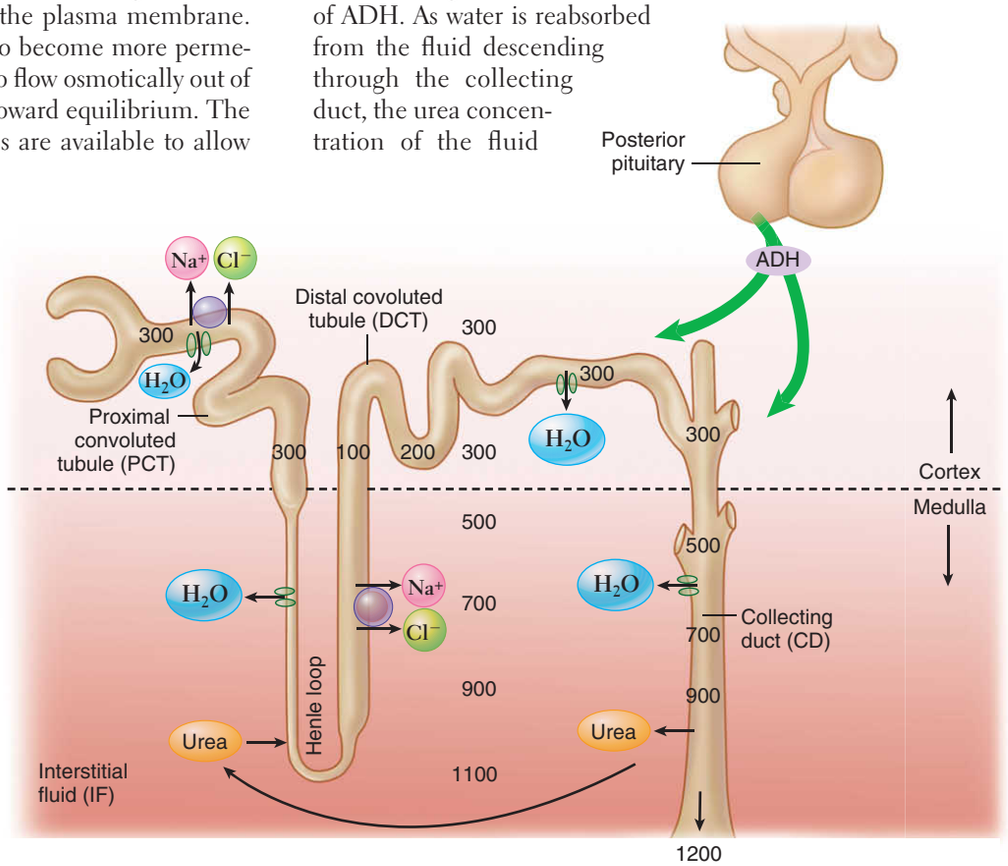
REABSORPTION IN THE DISTAL TUBULES AND COLLECTING DUCTS

The distal convoluted tubule is similar to the proximal convoluted tubule in that it also reabsorbs some sodium by active transport, but in much smaller amounts. Left to themselves, the cells that form the distal tubule's walls are relatively impermeable to water. This means that sodium can be removed, but water cannot follow osmotically, so the solute concentration of the tubule fluid continues to decrease. Recall that the tubule fluid is already hypotonic to most body fluids at this point because of the countercurrent system in the Henle loop.

The cells that form the wall of the collecting duct also prevent water from leaving the filtrate by osmosis. Even though the collecting duct conducts the tubule fluid through the hypertonic medullary region, equilibration does not occur.

FIGURE 31-25

Production of hypotonic urine. Hypotonic urine is produced by the nephron by the mechanism shown here. The isotonic (300 mOsm) tubule fluid that enters the Henle loop becomes hypotonic (100 mOsm) by the time it enters the distal convoluted tubule. The tubule fluid remains hypotonic as it is conducted out of the kidney because the walls of the distal tubule and collecting duct are impermeable to H_2O, Na^+, and Cl^-. Values are expressed in milliosmoles.



Given no other circumstances, the kidney produces and excretes only very dilute (hypotonic) urine (Figure 31-25). This would be catastrophic because the body would soon dehydrate. A regulatory mechanism centered outside the kidney normally prevents excessive loss of water. This mechanism, illustrated in Figure 31-26, involves *antidiuretic hormone (ADH)*, a hormone secreted by the neurohypophysis (posterior pituitary).

ADH targets cells of the distal tubules and collecting ducts and triggers the cells to move aquaporins to the plasma membrane. These aquaporins allow the tubule wall to become more permeable to water. Water is thereby permitted to flow osmotically out of the tubule and into the interstitial fluid, toward equilibrium. The more ADH present, the more aquaporins are available to allow more water out of the tubule, and the closer the tubule fluid's solute concentration matches that of the surrounding tissue fluid. In this way, the tubule fluid's osmotic pressure could go as high as 1200 mOsm, because the medulla's interstitial fluid can be that high. The solute concentration of the urine excreted depends in large part on the amount of ADH present.

Notice in Figure 31-26 that reabsorption of urea also occurs in the collecting duct when water is reabsorbed under the influence of ADH. As water is reabsorbed from the fluid descending through the collecting duct, the urea concentration of the fluid

FIGURE 31-26

Production of hypertonic urine. Hypertonic urine can be formed when antidiuretic hormone (ADH) is present. ADH, a posterior pituitary hormone, increases the water permeability of the distal tubule and collecting duct. Thus hypotonic (100 mOsm) tubule fluid leaving the Henle loop can equilibrate first with the isotonic (300 mOsm) interstitial fluid (IF) of the cortex, then with the increasingly hypertonic (400 to 1200 mOsm) IF of the medulla. As H_2O leaves the collecting duct by osmosis, the filtrate becomes more concentrated with the solutes left behind. The concentration gradient causes urea to diffuse into the IF, where some of it is eventually picked up by tubule fluid in the descending limb of the Henle loop *(long arrow)*. This countercurrent movement of urea helps maintain a high solute concentration in the medulla. Values are expressed in milliosmoles.

rises. Because the urea concentration is higher inside the lower part of the collecting duct than it is in the surrounding interstitial fluid, urea diffuses out of the lower collecting duct. The addition of urea to the medullary interstitial fluid assists in maintaining a high solute concentration in the medulla. Less than half the urea that leaves the collecting duct is removed by the vasa recta. The dashed line in Figure 31-26 shows that much of the urea in the medullary interstitial fluid diffuses into the descending limb of the Henle loop. Thus urea participates in a sort of countercurrent multiplier mechanism that, together with the countercurrent mechanisms of the Henle loop and vasa recta, maintains the high osmotic pressure needed to form concentrated urine and therefore avoid dehydration.

Tubular Secretion

In addition to reabsorption, tubule cells also secrete certain substances. Tubular secretion means the movement of substances out of the blood and into tubular fluid.

Recall that the descending limb of the Henle loop removes urea by means of diffusion. The distal tubules and collecting ducts secrete potassium, hydrogen, and ammonium ions. They actively transport potassium ions (K^+) or hydrogen ions (H^+) out of the blood into tubule fluid in exchange for sodium ions (Na^+), which diffuse back into the blood (H^+ transport is discussed further in Chapter 33). Potassium secretion increases when the blood aldosterone concentration increases. *Aldosterone*, a hormone of the adrenal cortex, targets distal tubule and collecting duct cells and causes them to increase the activity of the sodium-potassium pumps that move sodium out of the tubule and potassium into the tubule. Hydrogen ion secretion increases when the blood hydrogen ion concentration increases. Ammonium ions are secreted into the tubule fluid by diffusing out of the tubule cells where they are synthesized.

Tubule cells also secrete various organic ions and compounds. Various toxins and many drugs such as penicillin and para-aminohippurate acid (PAH) can be cleared from the blood plasma this way.

Table 31-1 summarizes the functions of the different parts of the nephron in forming urine.

Regulation of Urine Volume

ADH has a central role in the regulation of urine volume. Control of the solute concentration of urine translates into control of urine volume. If no water is reabsorbed by the distal tubule and collecting ducts, urine volume is relatively high—and water loss from the body is high. As water is reabsorbed under the influence of ADH, the total volume of urine is reduced by the amount of water removed from the tubules. Thus ADH reduces water loss by the body.

Another hormone that tends to decrease urine volume—and thus conserves water—is aldosterone, a secretion of the adrenal cortex. It increases distal tubule and collecting duct absorption of sodium, which in turn causes an osmotic imbalance that drives the reabsorption of water from the tubule. Because water reabsorption

TABLE 31-1 Summary of Nephron Function

PART OF NEPHRON	FUNCTION	SUBSTANCE MOVED
Renal corpuscle	Filtration (passive)	Water
		Smaller solute particles (ions, glucose, etc.)
Proximal convoluted tubule (PCT)	Reabsorption (active)	Active transport: Na^+ Cotransport: glucose and amino acids
	Reabsorption (passive)	Diffusion: Cl^-, $PO_4^{\equiv}$, urea, other solutes Osmosis: water
Henle loop		
Descending limb (DLH) and thin ascending limb (tALH)	Reabsorption (passive)	Osmosis: water
	Secretion (passive)	Diffusion: urea
Thick ascending limb (TAL)	Reabsorption (active)	Active transport: Na^+
	Reabsorption (passive)	Diffusion: Cl^-
Distal convoluted tubule (DCT)	Reabsorption (active)	Active transport: Na^+
	Reabsorption (passive)	Diffusion: Cl^-, other anions
		Osmosis: water (only in the presence of ADH)
	Secretion (passive)	Diffusion: ammonia
	Secretion (active)	Active transport: K^+, H^+, some drugs
Collecting duct (CD)	Reabsorption (active)	Active transport: Na^+
	Reabsorption (passive)	Diffusion: urea Osmosis: water (only in the presence of ADH)
	Secretion (passive)	Diffusion: ammonia
	Secretion (active)	Active transport: K^+, H^+, some drugs

ADH, Antidiuretic hormone.

in the distal tubule and collecting duct portions requires ADH, the aldosterone mechanism must work in concert with the ADH mechanism if homeostasis of the fluid content in the body is to be maintained. The cooperative roles of ADH and aldosterone in regulating urine volume—and thus regulating fluid balance in the whole body—are summarized in Figure 31-27.

You may recall from Chapters 19 and 22 that another hormone, specifically, **atrial natriuretic hormone (ANH),** also influences water reabsorption in the kidney. ANH is secreted by specialized muscle fibers in the atrial wall of the heart. Its name implies its function: ANH promotes natriuresis (loss of Na^+ via urine). ANH indirectly acts as an antagonist of aldosterone, by promoting the secretion of sodium into the kidney tubules rather than sodium reabsorption. Thus ANH reduces the plasma and interstitial fluid Na^+ concentration, which in turn, reduces the reabsorption of water by having the effect opposite that of aldosterone. ANH also inhibits the secretion of aldosterone and opposes the aldosterone-ADH mechanism to reabsorb less water and therefore produce more urine. In short, ANH inhibits the ADH mechanism—thus inhibiting water conservation by the internal environment and increasing urine volume.

Urine volume also relates to the total amount of solutes other than sodium excreted in urine. Generally, the more solutes, the more urine. Probably the best known example of this principle occurs in untreated

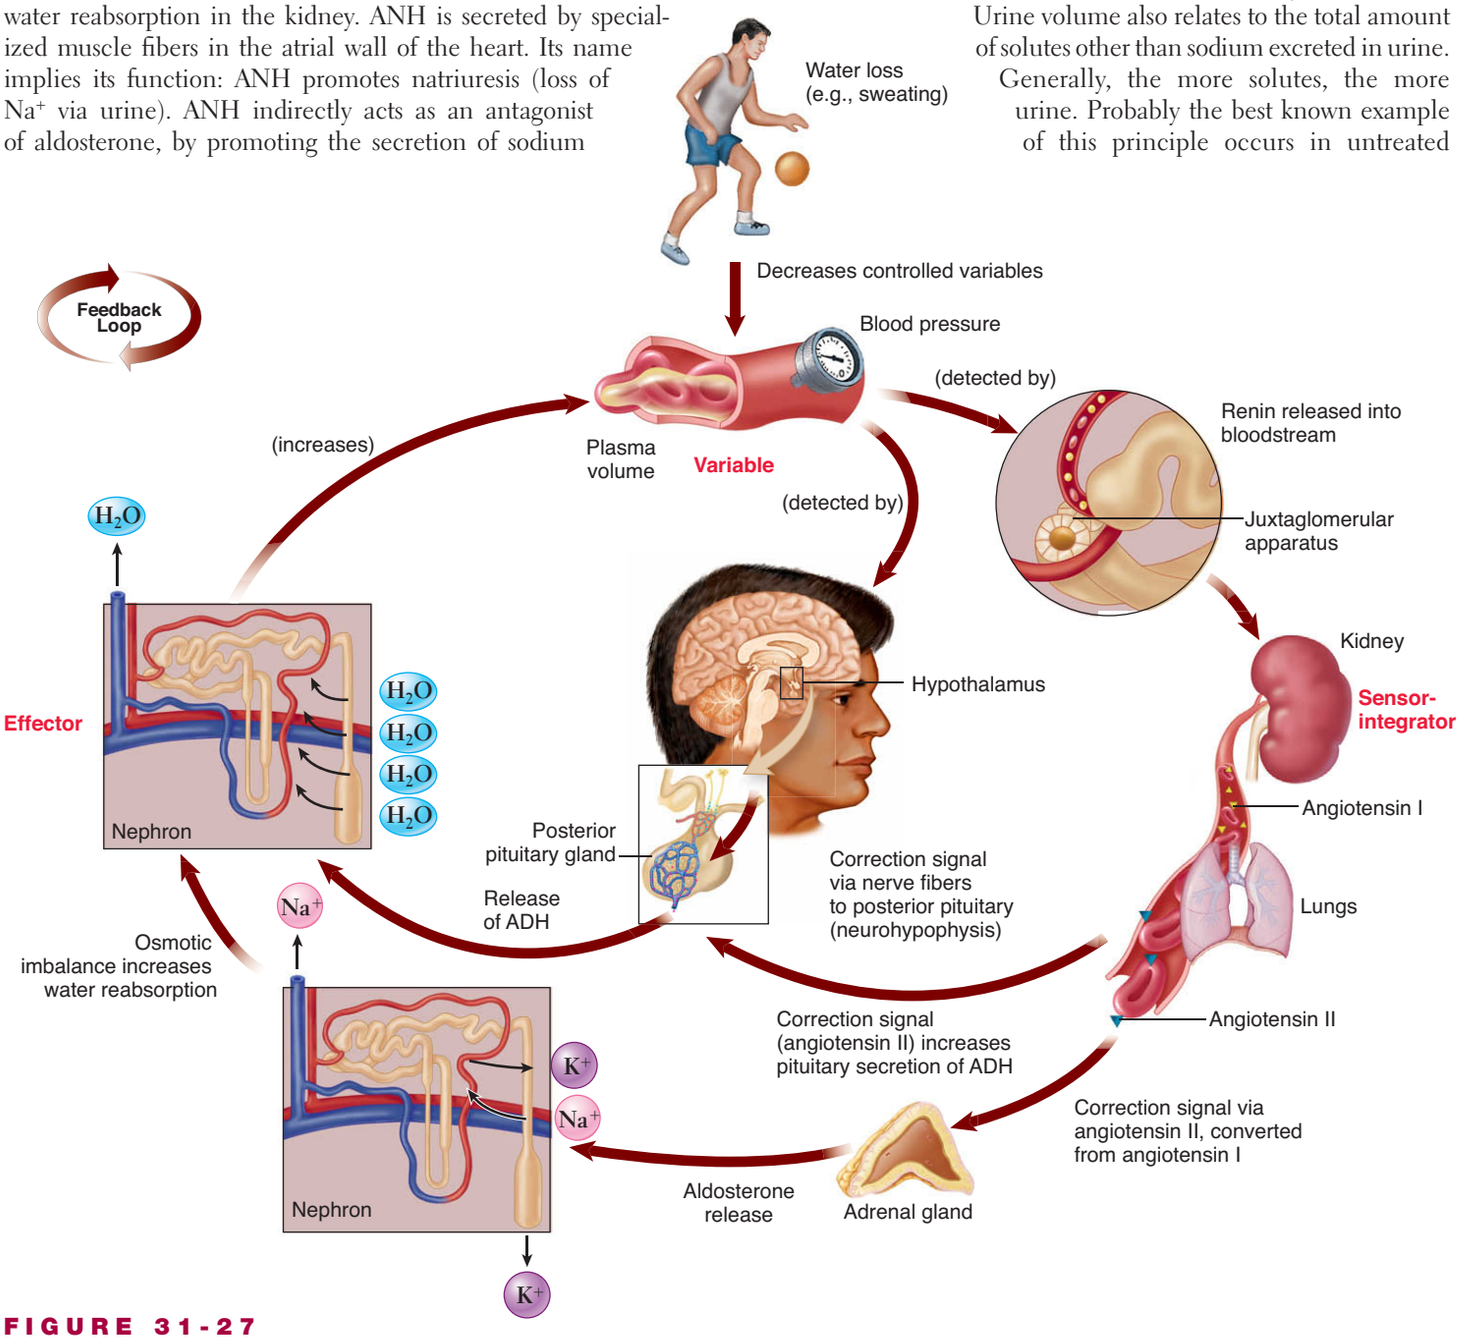


FIGURE 31-27

Cooperative roles of ADH and aldosterone in regulating urine and plasma volume. The drop in blood pressure that accompanies loss of fluid from the internal environment triggers the hypothalamus to rapidly release antidiuretic hormone (ADH) from the posterior pituitary gland. ADH increases water reabsorption by the kidney by increasing the water permeability of the distal tubules and collecting ducts. The drop in blood pressure is also detected by each nephron's juxtaglomerular apparatus, which responds by secreting renin. Recall from Chapter 19 that renin triggers the formation of angiotensin II, which stimulates the release of aldosterone from the adrenal cortex. Aldosterone then slowly boosts water reabsorption by the kidneys by increasing reabsorption of Na^+. Because angiotensin II also stimulates the secretion of ADH, it serves as an additional link between the ADH and aldosterone mechanisms.

diabetes mellitus. The symptom that often brings a person with undiagnosed diabetes to a physician is the voiding of abnormally large amounts of urine. Excess glucose "spills over" into urine, thereby increasing the solute concentration of urine (and decreasing the solute concentration of plasma), which in turn leads to diuresis.

Urine volume is not normally altered by changes in the GFR, which remains remarkably constant in normal individuals over extended periods. A process called *autoregulation* of glomerular filtration by **tubuloglomerular feedback** is dependent on proper functioning of the macula densa cells and the juxtaglomerular apparatus (see p. 980 and Figure 31-12). This regulatory mechanism helps protect the kidney from rapid systemic arterial pressure variations that would otherwise cause large GFR changes. It does so by regulating resistance in both afferent and efferent arterioles. Figure 31-28, *A*, summarizes the major steps of this process. As systemic blood pressure varies, chemoreceptors sensitive to the flow rate and osmolarity of the filtrate can either speed up or slow down the GFR, thus allowing more or less time for chemical processing of tubular filtrate.

In addition, the feedback regulatory response also influences the renin-angiotensin mechanism and systemic blood pressure levels (see Figure 31-27).

The autoregulatory **myogenic mechanism** is yet another rapid and effective way to help maintain a constant GFR during systemic changes in arterial blood pressure (Figure 31-28, *B*). If blood pressure increases, for example, during muscular exertion, the stretched walls of the afferent arterioles automatically contract more strongly to decrease blood flow and return the GFR to resting levels. In circumstances causing a decrease in systemic blood pressure, the smooth muscle in the then relaxed walls of the afferent arterioles will cause dilation, thus increasing blood flow and the GFR to normal "set point" levels.

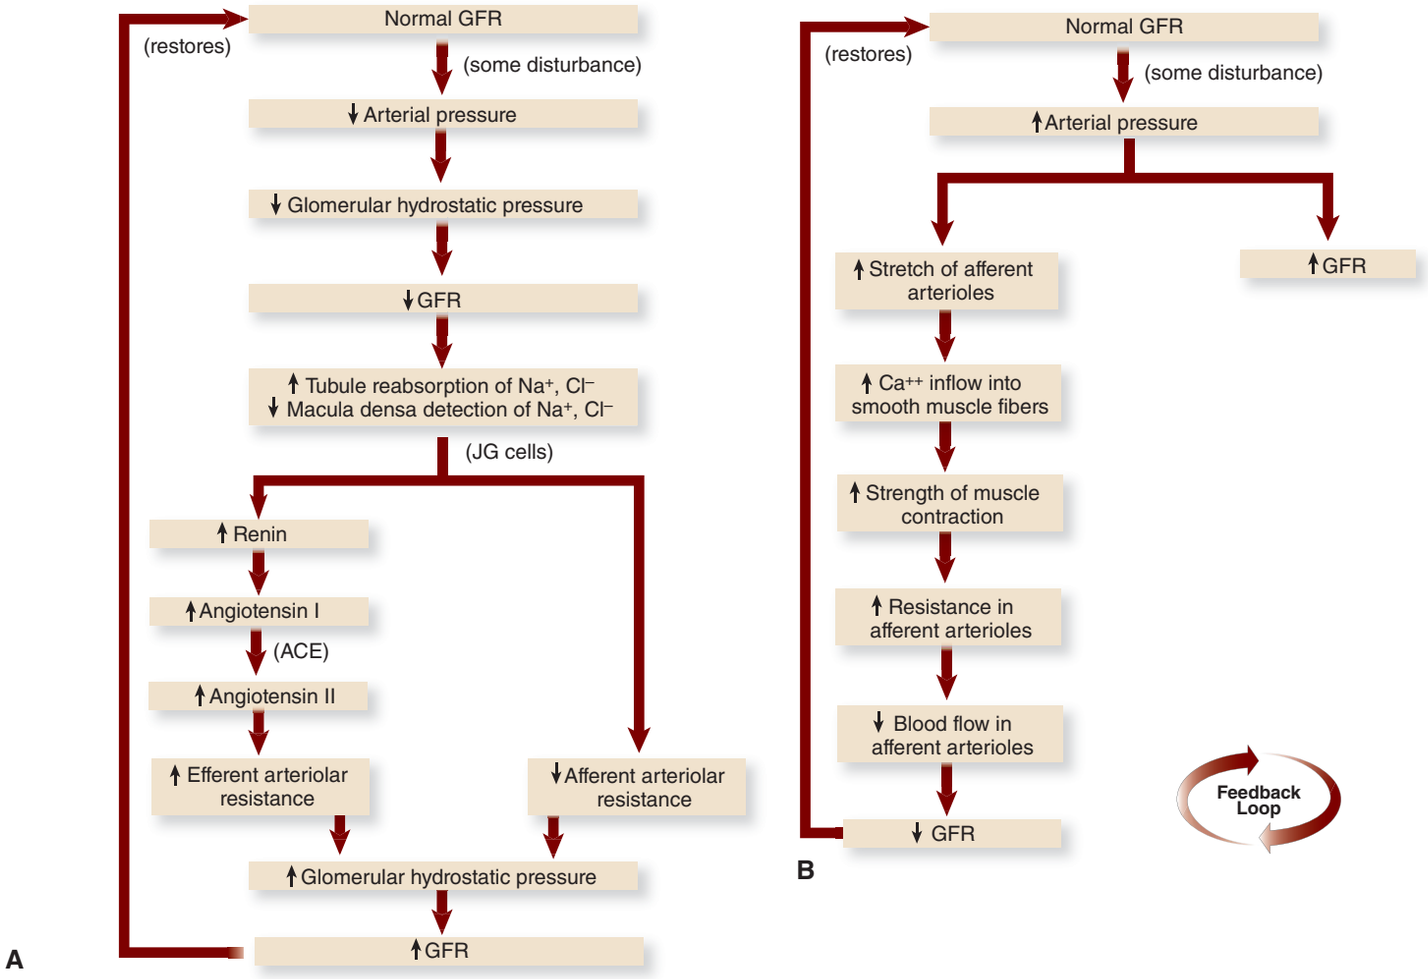

FIGURE 31-28

Autoregulation of renal blood flow and GFR. A, Tubuloglomerular feedback mechanism triggered by a disturbance that decreases renal arterial blood pressure and thus lowers GFR (glomerular filtration rate) below normal. Normal GFR is restored when JG (juxtaglomerular) cells trigger an increase of hydrostatic (blood) pressure in the glomerulus. *ACE,* Angiotensin converting enzyme. **B,** Myogenic mechanism triggered by a disturbance that increases renal arterial blood pressure and thus increases GFR above normal. Afferent arterioles stretch and automatically contract to increase resistance and decrease blood flow, thereby reducing GFR back toward normal.

Urine Composition

The physical characteristics of normal urine are listed in Table 31-2. Notice that normal and abnormal characteristics are listed.

Urine is approximately 95% water, in which are dissolved several kinds of substances; the most important are discussed below:

Nitrogenous wastes—(resulting from protein catabolism) such as urea (the most abundant solute in urine), uric acid, ammonia, and creatinine (Box 31-5).

Electrolytes—mainly the following ions: sodium, potassium, ammonium, chloride, bicarbonate, phosphate, and sulfate. The amounts and kinds of minerals vary with diet and other factors.

Toxins—during disease, bacterial poisons leave the body in urine. One reason for "forcing fluids" on patients suffering with infectious diseases is the need to dilute the toxins that might damage the kidney cells if eliminated in a concentrated form.

TABLE 31-2 Characteristics of Urine

	NORMAL CHARACTERISTICS	ABNORMAL CHARACTERISTICS
Color and Clarity	Normal urine should be clear; color varies with specific gravity Dilute urine: Transparent straw color Concentrated urine: Deep yellow amber (Occasionally, normal urine may be cloudy because of high dietary levels of fat or phosphate)	Abnormally colored urine may result from (1) pathologic conditions; (2) certain foods; and (3) numerous drugs: 1. Pathologic conditions (examples): Kidney cancer (hemorrhage)—red (RBCs) Bile duct obstruction (gallstones)—orange/yellow (bilirubin) Pseudomonas infection—green (bacterial toxins) 2. Foods (examples): Beets—red Rhubarb—brown Carrots—dark yellow 3. Drugs (examples): Pyridium (urinary tract analgesic)—orange Dilantin (anticonvulsant)—pink/red brown Dyrenium (diuretic)—pale blue Cloudy urine may result from (examples): 1. Bacteria—active infection of urinary system organs 2. Blood cells RBCs—hemorrhage from kidney cancer WBCs—pus from urinary tract infection (UTI) 3. Casts—various types of tubelike clumps (blood cell, epithelial, hyaline, waxy, etc.) that form in diseased renal tubes 4. Proteinuria—(protein—usually albumin) in urine 5. Crystals—usually uric acid or phosphate/calcium oxalate in concentrated urine
Compounds	Mineral ions (for example, Na^+, Cl^-, K^+) Nitrogenous wastes: ammonia, creatinine, urea, uric acid Urine pigment: urochrome (product of bilirubin metabolism)	Ketones—generally acetone Protein—generally albumin Glucose Crystals—generally uric acid and phosphate or calcium oxalate Pigments—abnormal levels of bilirubin metabolites
Odor	Slight aromatic Some foods produce a characteristic odor (asparagus) Ammonia-like odor on standing may result from decomposition in stored urine	Strong, sweet, fruity (acetone) odor—uncontrolled diabetes mellitus Foul odor—urinary tract infections (UTIs) Musty odor—phenylketonuria Maple syrup odor—congenital defect in protein metabolism
pH	4.6-8.0 (average 6.0) Toward Low Normal: Some foods (meat & cranberries) and drugs (chlorothiazide diuretics) Toward High Normal: Some foods (citrus fruits, dairy products) and drugs (bicarbonate antacids)	High in alkalosis (kidneys compensate by excreting excess base) Low in acidosis (kidneys compensate by excreting excess H^+)
Specific Gravity	Adult: 1.005-1.030 (usually, 1.010-1.025) Elderly: values decrease with age Newborn: 1.001-1.020	Above normal limits: glycosuria, proteinuria, dehydration, high solute load (may result in precipitation of solutes and kidney stone formation); Below normal limits: chronic renal diseases (inability to concentrate urine), overhydration

Box 31-5 | DIAGNOSTIC study

Blood Indicators of Renal Dysfunction

Renal clearance is the volume of plasma from which a substance is removed from the blood by the kidneys per minute. Elevated urea levels in blood, as measured in a blood urea nitrogen (BUN) test, was one of the earliest clinical measurements of kidney dysfunction. Elevated BUN levels indicate failure of the kidney to clear urea and, therefore, other substances as well (see Mechanisms of Disease, p. 996, for further discussion).

Blood levels of creatinine are also used to test renal function. Creatinine levels in blood seldom change significantly because they are determined by skeletal muscle mass—which seldom changes much. Therefore, an increase in the blood level of plasma creatinine is considered to be a reliable indicator of depressed renal function.

Pigments (especially *urochromes*)—yellowish bile pigments derived from products of the breakdown of old red blood cells in the liver and elsewhere. Various foods and drugs may contain, or be converted to, pigments that are cleared from plasma by the kidneys and are therefore found in the urine.

Hormones—high hormone levels sometimes result in significant amounts of hormone in the filtrate (and therefore in urine).

Abnormal constituents—such as blood, glucose, albumin (a plasma protein), casts (chunks of material, such as mucus, that harden inside the urinary passages and then are washed out in urine), or calculi (small stones).

Cycle of LIFE

Urinary System

The kidney plays a critical role in homeostasis by regulating the levels of many substances in blood. Primary renal functions include filtration, reabsorption, and secretion. All are interrelated by complex control systems involving central nervous system activity and hormonal secretions. More than 1 million nephron units in each kidney serve as the structural framework permitting normal function to occur.

Normally, life cycle changes in kidney structure and function occur only within rather narrow limits. Significant structural changes, such as dramatic decreases in the number of nephron units, almost always indicate serious disease or result from trauma such as crush injuries. Functionally, the kidney is able to operate normally throughout life under a wide array of conditions. If, however, the kidneys cannot cope with extreme conditions, such as water deprivation or disease, death will occur from the buildup of toxins in blood.

Initially, kidney function in a newborn is less efficient than in an older child or adult. As a result, the urine is less concentrated because the regulatory mechanisms required to retain water are not fully operative. Incontinence, or an inability to control urination, is normal in very young children. Reflex emptying occurs when the bladder fills, but normal sphincter activity keeps urine in the bladder until filling occurs. In contrast, many older adults have problems with incontinence because of loss of sphincter tone, or control.

Renal clearance is the ability of the kidneys to clear, or cleanse, the blood of a certain substance in a given unit of time, generally 1 minute. This value for certain substances tends to decrease with advanced age, thus indicating deterioration of kidney function. Changes in the porosity of the filtration membrane also occur in the elderly. Loss of functional nephron units is yet another consequence of aging. It contributes to the gradual decline in renal function in this age-group.

the BIG picture

Urinary System and the Whole Body

As our study of the urinary system has shown us, homeostasis of water and electrolytes in body fluids depends largely on proper functioning of the kidneys. Each nephron within the kidney processes blood plasma in a way that adjusts its content to maintain a dynamic constancy of the internal environment of the body. Without renal processing, blood plasma characteristics would soon move out of their set point range. On the other hand, without the blood pressure generated by cardiovascular mechanisms, the kidney could not filter blood plasma and therefore could not process blood plasma. Thus the urinary system and the cardiovascular system are interdependent.

Regulation of urinary function, we have seen, is often centered outside the kidney—mainly in the form of endocrine hormone action. Urinary function is also regulated to some extent by nerve reflexes. Thus both the endocrine system and the nervous system must operate properly to ensure efficient kidney function. The urinary system also interacts with many other body systems and tissues. For example, the kidneys clear the blood plasma of nitrogenous wastes and excess metabolic acids produced by the chemical activity of nearly every cell in the body. The kidneys also can clear some toxins and other compounds that enter the blood via the digestive tract, skin, or respiratory tract.

In the next chapter, we apply some of what we know about urinary function to a broader study of water and ion homeostasis within the human body's internal environment. After that, we discuss the role of the urinary system and other body systems in maintaining a relatively constant pH in the body's internal environment.

MECHANISMS of DISEASE

You may have experienced the discomfort and pain of a bladder infection or know someone who has. Bladder infection is the most common urinary disorder, but it is not usually serious if promptly treated. However, numerous renal and urinary disorders *are* very serious. Any disorder that significantly reduces the effectiveness of the kidneys is immediately life threatening. In this section, we discuss some life-threatening kidney diseases, as well as a few of the less serious, but more common, disorders.

Renal Hypertension

Recall from Chapter 22 (p. 714) that hypertension is abnormally high blood pressure. So-called *renal hypertension* is a common type of secondary hypertension that may be caused by stenosis (narrowing) of the renal artery, often caused by the accumulation of atherosclerotic plaque. In these cases, the elevation is secondary to reduced blood flow, resulting in ischemia of kidney tissues. When this occurs, the cells of the juxtaglomerular apparatus secrete renin, which in turn results in angiotensin production and increased blood pressure (see Figures 22-27 and 31-27 for a review of renin-angiotensin effects). Testing of renal vein blood for increased renin levels is performed to confirm the diagnosis, and insertion of a stent into the lumen of the renal artery to increase blood flow to the kidney may be curative.

Obstructive Disorders

Obstructive urinary disorders are abnormalities that interfere with normal urine flow anywhere in the urinary tract (Box 31-6). The severity of obstructive disorders depends on where the interference occurs and to what degree the flow of urine is impaired. Obstruction of urine flow usually results in "backing up" of the urine, perhaps all the way to the kidney itself. When urine backs up into the kidney, causing swelling of the renal pelvis and calyces, the condition is called **hydronephrosis** (Figure 31-29). A few of the more important obstructive conditions are summarized here.

Renal Calculi

Renal calculi, or *kidney stones*, are crystallized mineral chunks that develop in the renal pelvis or calyces. Many calculi develop as calcium and other minerals crystallize on the renal papillae, then break off into the urine. Blood uric acid levels become elevated in those with *gout*, and deposits of uric acid in the kidneys produce uric acid stones or calculi. *Staghorn calculi* are large, branched stones that form in the pelvis and branched calyces.

If the stones are small enough, they simply pass through the ureters and urethra and are eventually voided with the urine. Larger stones may obstruct the ureters, causing intense pain called *renal colic* as rhythmic muscle contractions of the ureter attempt to dislodge it. Hydronephrosis may occur if the stone does not move from its obstructing position. In the past, only traditional surgical procedures were effective in removing relatively large stones that formed in the calyces and renal pelvis of the kidney. A technique called **lithotripsy,** which uses an ultrasound generator called a **lithotriptor,** is now used quite often to pulverize stones so that they can be flushed out of the urinary tract without surgery.

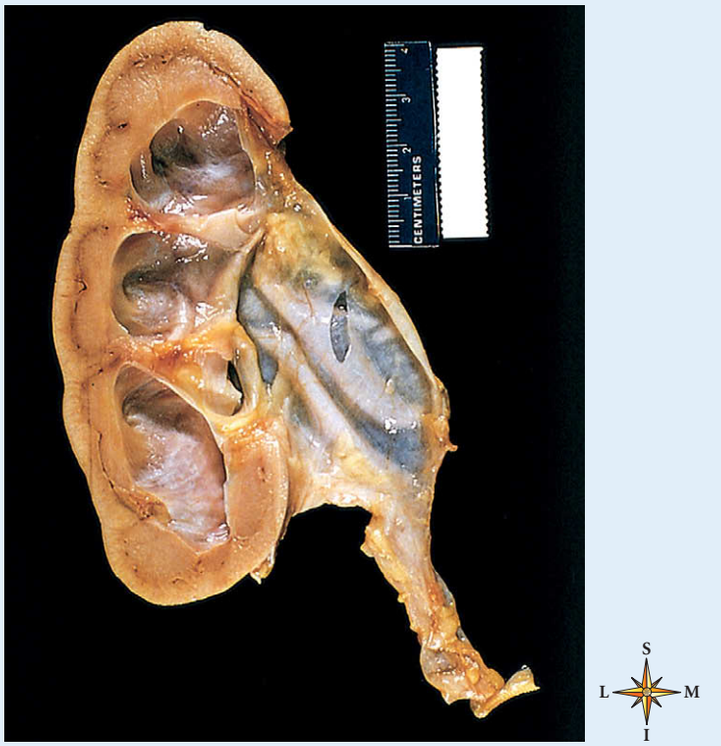

FIGURE 31-29

Hydronephrosis. Note the marked dilation of the renal pelvis and calyces caused by the blockage and "backing up" of urine.

Neurogenic and Overactive Bladder

Disruption of nervous input to the bladder results in loss of normal control of voiding. The condition is called **neurogenic bladder.** Depending on the nature and severity of the lack of nervous control, various signs and symptoms of bladder paralysis or abnormal activity result. Involuntary retention of urine, subsequent distention (bulging) of the bladder, and perhaps a burning sensation or fever with chills are common symptoms. The end result is often *urinary incontinence*—leakage of urine or some degree of involuntary urination. Serious stroke or spinal cord injury often results in a type of neurogenic bladder characterized by total loss of normal control of

Box 31-6 | HEALTH matters

Clinical Terms Associated With Urine Abnormalities

Glycosuria or **glucosuria**—Sugar (glucose) in urine
Hematuria—Blood in urine
Pyuria—Pus in urine
Dysuria—Painful urination
Polyuria—Unusually large amounts of urine
Oliguria—Scant urine
Anuria—Absence of urine

voiding. Called "*reflex incontinence*," this is characterized by periodic but unpredictable and involuntary urination that occurs in the absence of any sensory warning or awareness.

Urinary catheterization is the passage or insertion of a hollow tube or catheter through the urethra into the bladder for the withdrawal of urine. It is a medical procedure commonly performed on many patients who undergo prolonged surgical or diagnostic procedures or who experience problems with urinary retention. Correct catheterization procedures require aseptic techniques to prevent the introduction of infectious bacteria into the urinary system. Clinical studies have proved that improper catheterization techniques cause bladder infections (cystitis) and point out the need for extensive training of health professionals who perform catheterizations. To minimize the risk of infection, some facilities now use ultrasound imaging of the bladder to determine whether urine is being involuntarily retained in the bladder—replacing the former practice of catheterizing a patient.

Overactive bladder refers to the need for frequent urination because of abnormally strong or frequent micturition contractions of the bladder. If you look back to Figure 31-9 on p. 975, you see that these contractions normally do not get strong until there is about 200 to 250 ml of urine in the bladder. With an overactive bladder, the contractions can begin to get stronger with a much lower volume of urine, which is sooner than expected. Therefore the amount voided at any one time is generally small, and feelings of extreme urgency and pain with each voiding are common. Although serious medical outcomes are rare, incontinence associated with overactive bladder is an often embarrassing and frustrating problem for those who are plagued with symptoms. In the past, treatments for this rather common problem were limited to behavioral techniques and in some cases, surgery. Now, medications are available that reduce the involuntary contractions and incontinence associated with overactive bladder. Commonly used drugs include so-called "anticholinergic" medications such as solifenacin (Vesicare) and "alpha-adrenergic blocker" drugs that promote smooth muscle relaxation in the bladder and urethra.

Tumors and Other Obstructions

Tumors of the urinary system typically obstruct urine flow, possibly causing hydronephrosis in one or both kidneys. Most kidney tumors are malignant neoplasms called **renal cell carcinomas.** They usually occur only in one kidney. Bladder cancer occurs about as frequently as renal cancer (each accounts for about 2 in every 100 cancer cases). Renal and bladder cancer have few symptoms early in their development, other than traces of blood in the urine, or **hematuria** (hem-ah-TOO-ree-ah). As the cancer develops, pelvic pain and symptoms of urinary obstruction may occur. Insertion of a **cystoscope** (SIS-toh-skohp) through the urethra and into the bladder permits direct inspection of bladder and other lower urinary tract lesions (Figure 31-30). The hollow tube allows the passage of a light, a viewing lens, and various catheters and operative devices.

Various other conditions can obstruct the normal flow of urine. For example, a person with a low proportion of body fat may lack the pad of fat that normally surrounds the kidneys. One or both kidneys may then drop, a condition called **renal ptosis** (TOH-sis). In renal ptosis, the ureters that drain urine out of the kidney may kink and thus obstruct the normal flow of urine. Urinary passages may also be abnormally narrowed through scarring, inflammation, or external pressure—a condition known as a **stricture.**

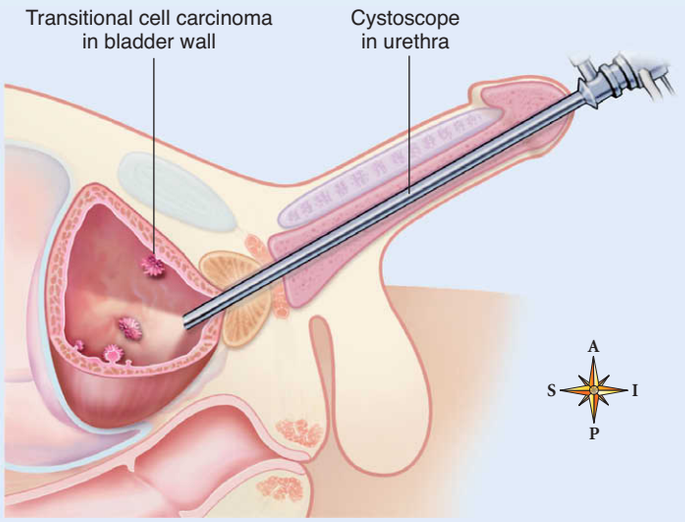

FIGURE 31-30

Cystoscopic view of bladder cancer. The cystoscope inserted through the urethra to view a male bladder.

Urinary Tract Infections

Most *urinary tract infections* (UTIs) are caused by bacteria, usually gram-negative types. UTIs can involve the urethra, bladder, ureter, and/or kidneys. Common types of urinary tract infections are summarized below.

Urethritis is an inflammation of the urethra that commonly results from bacterial infection, often *gonorrhea*. Nongonococcal urethritis is usually caused by a *Chlamydia* infection. Males suffer from urethritis more often than females do.

Cystitis is a term that refers to any inflammation of the bladder. Cystitis commonly occurs as a result of infection but also can accompany calculi, tumors, or other conditions. Bacteria usually enter the bladder through the urethra. Cystitis occurs more frequently in women than in men because the female urethra is shorter and closer to the anus (a source of bacteria) than in males. Bladder infections are characterized by pelvic pain, an urge to urinate frequently, and hematuria. **Interstitial cystitis** is a form of bladder inflammation that occurs without evidence of bacterial infection. It is a persistent and often very painful form of cystitis that is characterized by feelings of urgency, pain on urination, and the appearance of blood in the urine. The bladder wall often shows patches of chronic mucosal ulceration. Antiinflammatory drugs and supportive treatment of symptoms are often coupled with infusion of sterile fluid to distend the bladder and reduce feelings of urgency. Although the cause is unknown, many physicians believe an autoimmune response is involved. Interstitial cystitis is often associated with lupus erythematosus and other autoimmune disease conditions.

Nephritis is a general term referring to kidney disease, especially inflammatory conditions. **Pyelonephritis** is literally "pelvis nephritis" and refers to inflammation of the renal pelvis and connective tissues of the kidney. As with cystitis, pyelonephritis is usually caused by bacterial infection but can also result from viral infection, mycosis (fungal infection), calculi, tumors, pregnancy, and other conditions.

| A&P CONNECT |

Mycotic (fungal) infections most often occur in individuals with a weakened immune system, such as the sick and elderly. To see the effects of fungal growth in the urinary tract, check out the image of an *aspergillosis* infection in ***Visualizing the Urinary Tract*** online at ***A&P Connect.***

Glomerular Disorders

Glomerular disorders, collectively called **glomerulonephritis,** result from damage to the glomerular capsular membrane. This damage can be caused by immune mechanisms, heredity, and other factors. Without successful treatment, glomerular disorders can progress to kidney failure.

Nephrotic syndrome is a collection of signs and symptoms that accompany various glomerular disorders. This syndrome is characterized by the following:

- Proteinuria—presence of proteins (especially *albumin*) in urine. Protein, normally absent from urine, filters through damaged glomerular capsular membranes and is not reabsorbed by the kidney tubules.
- Hypoalbuminemia—low albumin concentration in the blood, resulting from loss of albumin from the blood through holes in the damaged glomeruli. Albumin is the most abundant plasma protein. Because it normally cannot leave the blood vessels, it usually remains as a "permanent" solute in plasma. This keeps the plasma water concentration low and thus prevents the osmosis of large amounts of water out of the blood and into tissue spaces. In hypoalbuminemia, this function is lost and fluid leaks out of the blood vessels and into tissue spaces, thereby causing widespread edema.
- Edema—general tissue swelling caused by the accumulation of fluids in the tissue spaces. The edema associated with nephrotic syndrome is caused by the loss of plasma protein (albumin) and the resulting osmosis of fluid out of the blood.

Acute glomerulonephritis is the most common form of kidney disease. It may be caused by a delayed immune response to streptococcal infection—the same mechanism that causes valve damage in rheumatic heart disease (see Chapter 21). For this reason, it is sometimes called **postinfectious glomerulonephritis.** If antibiotic treatment is not successful, it may progress to a chronic form of glomerulonephritis.

Chronic glomerulonephritis is the general name for various noninfectious glomerular disorders that are characterized by progressive kidney damage leading to renal failure. Immune mechanisms are believed to be the major causes of chronic glomerulonephritis. One immune mechanism involves antigen-antibody complexes that form in the blood when antibodies bind with foreign antigens (or possible self-antigens). These antigen-antibody complexes lodge in the glomerular capsular membrane and trigger an inflammation response. Less commonly, the formation of antibodies that directly attack the glomerular capsular membrane causes chronic glomerulonephritis.

Kidney Failure

Kidney failure, or **renal failure,** is simply failure of the kidney to properly process blood plasma and form urine. Renal failure can be classified as acute or chronic.

Acute renal failure is an abrupt reduction in kidney function that is characterized by oliguria and a sharp rise in nitrogenous compounds in the blood. The concentration of nitrogenous wastes in blood is often assessed by the **blood urea nitrogen (BUN) test**—a high BUN result indicates failure of the kidneys to remove urea from the blood. Acute renal failure can be caused by various factors that alter blood pressure or otherwise affect glomerular filtration. For example, hemorrhage, severe burns, acute glomerulonephritis or pyelonephritis, and obstruction of the lower urinary tract may each progress to kidney failure. If the underlying cause of renal failure is attended to, recovery is usually rapid and complete.

Chronic renal failure is a slow, progressive condition resulting from the gradual loss of nephrons. There are dozens of diseases that may result in the gradual loss of nephron function, including infections, diabetes, glomerulonephritis, tumors, systemic autoimmune disorders, and obstructive disorders.

Polycystic kidney disease (PKD) is a genetic disorder in which large, fluid-filled pockets (cysts) develop in the epithelium of the kidney tubules. In this condition, *primary cilia* in the plasma membrane epithelial cells fail to do their normal job of regulating cell growth—thus allowing cells to overpopulate and obstruct the kidney tubules. The obstructions result in pockets of backed-up urine. Eventually, the kidney fails.

As kidney function is lost as a result of any of these chronic conditions, the glomerular filtration rate (GFR) decreases, causing the BUN levels to climb (Figure 31-31). Chronic renal failure can be described as progressing through three stages:

Stage 1. During the first stage, some nephrons are lost but the remaining healthy nephrons compensate by enlarging and taking over the function of the lost nephrons. As Figure 31-31 shows, BUN is kept within normal limits even though up to 75% of the nephrons are lost (as indicated by a 75% drop in GFR). This stage is often asymptomatic and may last for years, depending on the underlying cause.

Stage 2. The second stage is often called *renal insufficiency.* It is during this stage that the kidney can no longer adapt to the loss of nephrons. The remaining healthy nephrons cannot handle the urea load, and BUN levels climb dramatically (see Figure 31-31). Because the kidney's ability to concentrate urine is impaired, polyuria and dehydration may occur.

Stage 3. The final stage of chronic renal failure is called **uremia,** or **uremic syndrome.** Uremia literally means "high blood urea" and is characterized by a very high BUN value caused by loss of kidney function (see Figure 31-31). During this stage, a low GFR causes low urine production and oliguria. Because fluids are retained by the body rather than eliminated by the kidneys, edema and hypertension often occur. The uremic syndrome includes a long list of other symptoms caused directly or indirectly by the loss of kidney function. Unless an artificial kidney (Box 31-7) is used or a new kidney is transplanted, the progressive loss of kidney function will eventually cause death.

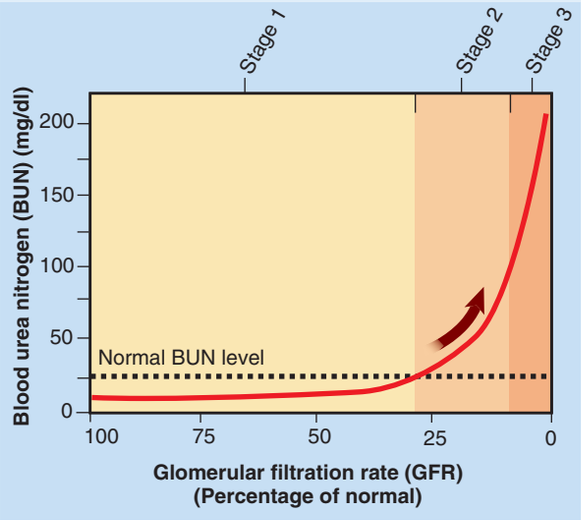

FIGURE 31-31

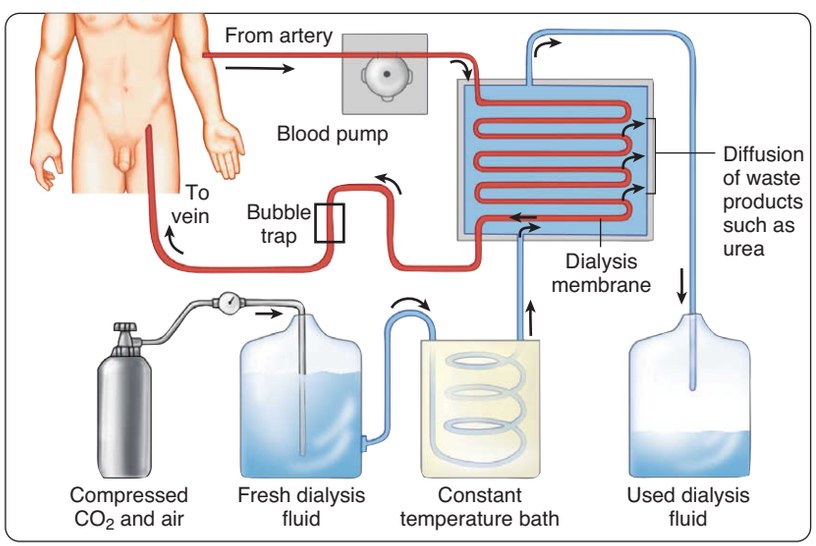
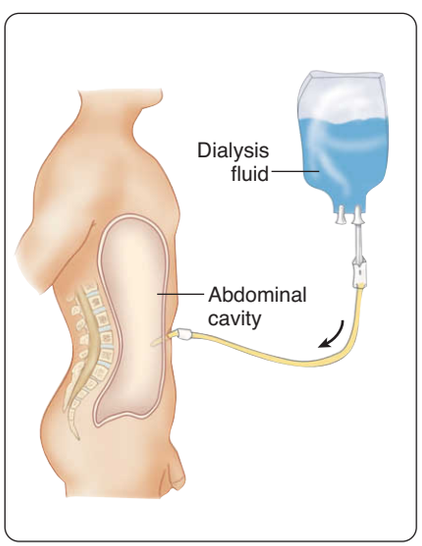


The three stages of chronic renal failure. Stage 1: As nephrons are lost (indicated by decreasing GFR), the remaining healthy nephrons compensate—keeping blood urea nitrogen (BUN) values within the normal range. **Stage 2:** As more than 75% of kidney function is lost, BUN levels begin to climb. **Stage 3:** Uremia (elevated BUN) results from massive loss of kidney function.

Box 31-7 | HEALTH matters



Artificial Kidney

The artificial kidney is a mechanical device that uses the principle of dialysis to remove or separate waste products from the blood. In the event of kidney failure, the process called **hemodialysis** can provide a reprieve from death for the patient. During a hemodialysis treatment, a semipermeable membrane is used to separate large (nondiffusible) particles such as blood cells from small (diffusible) ones such as urea and other wastes. Part *A* of the Figure shows blood from the radial artery passing through a porous (semipermeable) cellophane tube that is housed in a tanklike container. The tube is surrounded by a bath, or dialysis solution, containing varying concentrations of electrolytes and other chemicals. The pores in the membrane are small and allow only very small molecules, such as urea, to escape into the surrounding fluid. Larger molecules and blood cells cannot escape and are returned through the tube to reenter the patient via a wrist or leg vein. By constantly replacing the bath solution in the dialysis tank with freshly mixed solution, levels of waste materials can be kept at low levels. As a result, wastes such as urea in the blood rapidly pass into the surrounding wash solution. For a patient with complete kidney failure, two or three hemodialysis treatments a week are required. New dialysis methods are now being developed, and dramatic advances in treatment are expected in the next few years.

Another technique used in the treatment of renal failure is called **continuous ambulatory peritoneal dialysis (CAPD).** In this procedure, 1 to 3 liters of sterile dialysis fluid is introduced directly into the peritoneal cavity through an opening in the abdominal wall (part *B* of the figure). Peritoneal membranes in the abdominal cavity transfer waste products from blood into the dialysis fluid, which is then drained back into a plastic container after about 2 hours. This technique is less expensive than hemodialysis and does not require the use of complex equipment.

CASE study

Nhung felt like he was going to throw up, the pain was so intense. His lower back ached on both sides with a rhythmic, sharp jabbing pain. He took some aspirin, but it didn't help at all. Finally, he gave in and went to his naturopath, someone who uses therapies consisting of natural remedies to treat illnesses. After hearing about Nhung's symptoms, the naturopath suggested a urine check. He had Nhung urinate into a cup, then dip the urine dipstick into the cup. As he expected, the test was positive for red blood cells. Looking at the urine from the cup under a microscope, they could both see very small particles that looked like crystals.

1. Nhung probably has kidney stones. What is most likely causing Nhung's pain?
   a. Failure of his kidneys
   b. Cramping of muscles in the ureter wall
   c. Blockage of the urethra
   d. Irritation of the urinary bladder
2. For a kidney stone to "pass" from the body, it will have to navigate through the following structures in which order?
   a. Ureter, calyces, urethra, renal pelvis, bladder
   b. Urethra, renal pelvis, bladder, ureter, calyces
   c. Bladder, ureter, urethra, calyces, renal pelvis
   d. Calyces, renal pelvis, ureter, bladder, urethra

The naturopath gives Nhung some crampbark (which contains agents that relax smooth muscle) and tells him to increase his water intake.

3. The increase of water intake will likely:
   a. increase Nhung's GFR
   b. increase Nhung's urine volume
   c. cause temporary polyuria
   d. all the above
4. Besides water, all of the following EXCEPT which one should normally be found in Nhung's urine?
   a. Electrolytes
   b. Hormones
   c. Glucose
   d. Pigments

OVERVIEW OF THE URINARY SYSTEM

A. Kidneys—principal organs of the urinary system; accessory organs are the ureters, urinary bladder, and urethra (Figure 31-1)
B. Urinary system—regulates the content of blood plasma to maintain "dynamic constancy" or homeostasis of the internal fluid environment within normal limits

ANATOMY OF THE URINARY SYSTEM

A. Gross structure (Figure 31-2)
   1. Kidney
      a. Shape, size, and location
         (1) Roughly oval with a medial indentation
         (2) Approximately 11 cm by 7 cm by 3 cm
         (3) Left kidney often larger than the right; the right kidney located a little lower
         (4) Both kidneys located in a retroperitoneal position
         (5) Lie on either side of the vertebral column between T12 and L3
         (6) Superior poles of both kidneys extend above the level of the twelfth rib and the lower edge of the thoracic parietal pleura

(7) Renal fasciae anchor the kidneys to surrounding structures
(8) Renal fat pad—heavy cushion of fat that surrounds each kidney
(9) Hilum—concave notch on medial surface where vessels and tubes enter kidney

b. Internal structures of the kidney
(1) Cortex and medulla—outer and inner regions
(2) Renal pyramids—make up much of the medullary tissue; papilla at the tip of each pyramid releases urine through multiple ducts
(3) Renal columns—where cortical tissue dips into the medulla between the pyramids
(4) Calyx—cuplike structure at each renal papilla that collects urine; minor calyces join to form major calyces, which in turn join together to form the renal pelvis
(5) Renal pelvis—narrows as it exits the kidney to become the ureter; acts as a collection basin to drain urine from the kidney

c. Blood vessels of the kidneys—kidneys are highly vascular (Figure 31-3)
(1) Renal artery—large branch of the abdominal aorta; brings blood into each kidney
(2) Interlobular arteries—between the pyramids of the medulla, the renal artery branches; interlobular arteries extend toward the cortex, arch over the bases of the pyramids, and form the arcuate arteries; from the arcuate arteries, the interlobular arteries penetrate the cortex and thus are sometimes called cortical radiate arteries
(3) Afferent arterioles extend to the nephrons (microscopic functional units of kidney tissue)

6. Ureter—tube running from each kidney to the urinary bladder; composed of three layers: mucous lining, muscular middle layer, and fibrous outer layer (Figures 31-4 and 31-7)
7. Urinary bladder (Figures 31-5 and 31-6)
a. Structure—collapsible bag located behind the pubic symphysis
(1) Made mostly of smooth muscle tissue
(2) Lining forms rugae
(3) Bladder can distend considerably

b. Functions
(1) Reservoir for urine before it leaves the body
(2) Aided by the urethra, it expels urine from the body

8. Urethra
a. Small mucous membrane–lined tube extending from the trigone to the exterior of the body
b. In females, lies posterior to the pubic symphysis and anterior to the vagina; approximately 3 cm long (Figure 31-8)
c. In males, after leaving the bladder, passes through the prostate gland where it is joined by two ejaculatory ducts; from the prostate, it extends to the base of the penis, then through the center of the penis, and ends as the urinary meatus; approximately 20 cm long; the male urethra is part of the urinary system, as well as part of the reproductive system

9. Mechanism for voiding bladder (urination or micturition)
a. As bladder volume increases, micturition contractions (of detrusor muscle) increase and the internal urethral sphincter relaxes (Figure 31-9)
b. External urethral sphincter muscle contracts at first, then at appropriate time relaxes to release urine

B. Microscopic structure
1. Nephrons, the microscopic functional units, make up the bulk of the kidney; each nephron is made up of two regions (renal corpuscle and renal tubule) and connects to a shared collecting duct (Figure 31-10)
a. Renal corpuscle—made up of the glomerulus tucked inside a Bowman capsule (Figures 31-11, 31-12, and 31-13); located within the cortex of the kidney
(1) Bowman (glomerular) capsule—cup-shaped mouth of the nephron
(a) Formed by parietal and visceral walls with a space between them
(b) Pedicels in the visceral layer are packed closely together to form filtration slits; a slit diaphragm prevents the filtration slits from enlarging under pressure (Figures 31-14 and 31-15)
(2) Glomerulus—network of fine capillaries surrounded by Bowman capsule
(a) Fenestrations—pores in capillary walls that permit filtration
(a) Mesangial cells—cells located between glomerular capillaries; various structural and functional support functions (Figure 31-13)
(3) Basement membrane lies between the glomerulus and Bowman capsule
(4) Glomerular capsular membrane—formed by glomerular endothelium, basement membrane, and the visceral layer of Bowman capsule; function is filtration (Figure 31-15)

b. Renal tubule
(1) Simple cuboidal and simple squamous epithelium
(a) Epithelial cells each possess a primary cilium
(b) Primary cilia monitor fluid chemistry and rate of flow, thus allowing regulation of tubule growth and other functions
(2) Proximal convoluted tubule (PCT)—first part of the renal tubule nearest to Bowman capsule; follows a winding, convoluted course; also known as the proximal tubule
(3) Henle (nephron) loop (Figure 31-10)
(a) Renal tubule segment just beyond the proximal tubule
(b) Consists of a thin descending limb, a sharp turn, and an ascending limb; ascending limb made up of thin ascending limb (tALH) followed by thick ascending limb (TAL)
(4) Distal convoluted tubule (DCT)—convoluted tubule beyond the Henle loop; also known as the distal tubule
(a) Juxtaglomerular apparatus—located where the afferent arteriole brushes past the distal convoluted tubule

i. Made up of macula densa (wall of distal tubule) and JG (juxtaglomerular) cells surrounding afferent arteriole
ii. Important to maintenance of blood flow homeostasis by reflexively secreting renin when blood pressure in the afferent arteriole drops

(b) Along with other distal tubules, it joins a common collecting duct

c. Collecting duct (CD)
(1) Straight duct joined by the renal tubules of several nephrons
(2) Collecting ducts of one renal pyramid converge to form one tube that opens at a renal papilla into a minor calyx (Figure 31-16)

d. Blood supply of the nephron (Figure 31-17)
(1) Afferent arteriole enters glomerular capillary network
(2) Efferent arteriole leaves glomerulus and extends to the peritubular blood supply
(a) Vasa recta—straight arterioles that run alongside Henle loop
(b) Peritubular capillaries—surround renal tubule

e. Types of nephrons
(1) Juxtamedullary nephron—a nephron with a renal corpuscle near the medulla and a Henle loop that dips far into the medulla
(2) Cortical nephron—a nephron with a Henle loop that does not dip into the medulla but remains almost entirely within the cortex; constitute about 85% of the total nephrons

PHYSIOLOGY OF THE URINARY SYSTEM

A. Overview of kidney function
1. Chief functions of the kidney are to process blood and form urine
2. Basic functional unit of the kidney is the nephron; forms urine through three processes (Figure 31-18)
a. Filtration—movement of water and protein-free solutes from plasma in the glomerulus into the capsular space of Bowman capsule
b. Tubular reabsorption—movement of molecules out of the tubule and into peritubular blood
c. Tubular secretion—movement of molecules out of peritubular blood and into the tubule for excretion

B. Filtration—first step in blood processing; occurs in renal corpuscles
1. Mechanism of filtration
a. Occurs as a result of a pressure gradient (effective filtration pressure, EFP) (Figure 31-20)
b. From blood in the glomerular capillaries, about 180 liters of water and solutes filter into Bowman capsule each day; takes place through the glomerular capsular membrane (Figure 31-19)
c. Glomerular capillary filtration occurs rapidly due to the increased number of fenestrations
2. Glomerular filtration rate (GFR)—rate of movement of fluid out of glomerulus
a. Determined mainly by glomerular hydrostatic pressure and therefore directly related to systemic blood pressure
b. Altered indirectly by changes in efficiency of cardiac contraction

C. Reabsorption—second step in urine formation; occurs as a result of passive and active transport mechanisms from all parts of the renal tubules; major portion of reabsorption occurs in the proximal convoluted tubules (Figure 31-19)
1. Reabsorption in the proximal convoluted tubule—most water and solutes are recovered by the blood, leaving only a small volume of tubule fluid left to move on to the Henle loop
a. Sodium—actively transported out of tubule fluid and into blood (Figure 31-21)
b. Glucose and amino acids—passively transported out of tubule fluid by sodium cotransport mechanisms; transport maximum (Tm or Tmax) is the maximum capacity of reabsorption and depends on carrier availability
c. Chloride, phosphate, and bicarbonate ions passively move into blood because of an imbalance in electrical charge
d. Water—movement of sodium and chloride into blood causes an osmotic imbalance, moving water passively into blood
e. Urea—approximately half of urea passively moves out of the tubule with the remaining urea moving on to the Henle loop
2. Reabsorption in the Henle loop (Figure 31-23)
a. Two countercurrent mechanisms (Figure 31-22)
(1) Countercurrent multiplier mechanism in Henle loop concentrates sodium and chloride in the interstitial fluid (IF) of renal medulla (Figure 31-23)
(2) Countercurrent exchange mechanism in vasa recta maintains high solute concentration in medullary IF (Figure 31-24)
b. Water reabsorbed from the tubule fluid, and urea picked up from the interstitial fluid in the descending limb
c. Sodium and chloride reabsorbed from the filtrate in the ascending limb, where the reabsorption of salt makes the tubule fluid dilute and creates and maintains a high osmotic pressure of the medulla's interstitial fluid

D. Reabsorption in the distal tubules and collecting ducts
1. Distal convoluted tubule reabsorbs sodium by active transport but in smaller amounts than in the proximal convoluted tubule (Figure 31-25)
2. ADH secreted by the posterior pituitary and targets the cells of distal tubules and collecting ducts to make them more permeable to water (Figure 31-26)
3. With reabsorption of water in the collecting duct, the urea concentration of the tubule fluid increases, which causes urea to diffuse out of the collecting duct into the medullary interstitial fluid
4. Urea participates in a countercurrent multiplier mechanism that along with the countercurrent mechanisms of the Henle loop and vasa recta, maintains the high osmotic pressure needed to form concentrated urine and avoid dehydration

E. Tubular secretion
   1. Tubular secretion—the movement of substances out of the blood and into tubular fluid
   2. Descending limb of the Henle loop secretes urea via diffusion
   3. Distal tubule and collecting ducts secrete potassium, hydrogen, and ammonium ions
   4. Aldosterone—hormone that targets the cells of the distal tubule and collecting duct cells; causes increased activity of the sodium-potassium pumps
   5. Secretion of hydrogen ions increases with increased blood hydrogen ion concentration

F. Regulation of urine volume (Figure 31-27)
   1. ADH influences water reabsorption; as water is reabsorbed, the total volume of urine is reduced by the amount of water removed by the tubules; ADH reduces water loss
   2. Aldosterone, secreted by the adrenal cortex, increases distal tubule absorption of sodium, thereby raising the sodium concentration of blood and thus promoting reabsorption of water
   3. Atrial natriuretic hormone (ANH), secreted by atrial muscle fibers, promotes loss of sodium via urine; opposes aldosterone, thus causing the kidneys to reabsorb less water and thereby produce more urine
   4. Tubuloglomerular feedback mechanism maintains a constant GFR by regulating resistance in afferent arterioles. Protects GFR function from rapid blood pressure variations; dependent on macula densa cells and the juxtaglomerular apparatus; may influence reninangiotensin mechanism (Figure 31-28, *A*)
   5. Myogenic mechanism—rapid and effective regulation of GFR via changes in afferent arteriole smooth muscle contraction and relaxation (Figure 31-28, *B*)
   6. Urine volume—also related to the total amount of solutes other than sodium excreted in urine; generally, the more solutes, the more urine

G. Urine composition—approximately 95% water with several substances dissolved in it; the most important are the following
   1. Nitrogenous wastes—result of protein metabolism; include urea, uric acid, ammonia, and creatinine
   2. Electrolytes—mainly the following ions: sodium, potassium, ammonium, chloride, bicarbonate, phosphate, and sulfate; amounts and kinds of minerals vary with diet and other factors
   3. Toxins—during disease, bacterial poisons leave the body in urine
   4. Pigments—especially urochromes
   5. Hormones—high hormone levels may spill into the filtrate
   6. Abnormal constituents—such as blood, bacteria, glucose, albumin, casts, or calculi

THE BIG PICTURE: URINARY SYSTEM AND THE WHOLE BODY

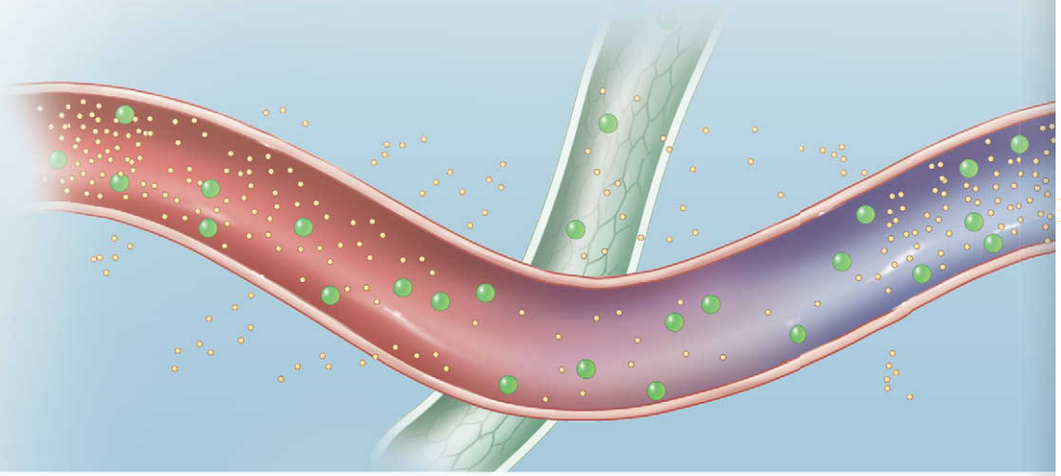
A. Homeostasis of water and electrolytes in body fluids relies on proper functioning of the kidneys; nephrons process blood to adjust its content to maintain a relatively constant internal environment
B. Urinary and cardiovascular systems are interdependent
C. Endocrine and nervous systems must operate properly to ensure efficient kidney function

REVIEW QUESTIONS

Write out the answers to these questions after reading the chapter and reviewing the Chapter Summary. If you simply think through the answer without writing it down, you won't retain much of your new learning.

1. List the principal and accessory organs of the urinary system.
2. Name, locate, and give the main function(s) of each organ of the urinary system.
3. Identify the beginnings of the "plumbing system" of the urinary system.
4. How does the mechanism for voiding urine start?
5. The male urethra is part of two different systems. Identify them.
6. Describe the microscopic structure of the kidney.
7. Diagram the flow of blood through the kidney.
8. Define the terms *filtration*, *tubular reabsorption*, and *tubular secretion*.
9. How is effective filtration pressure calculated?
10. Describe the solute concentration of the interstitial fluid of the medulla.
11. What happens to sodium and chloride in the ascending limb of the Henle loop?
12. What happens to potassium secretion when the blood aldosterone concentration increases?
13. Identify two drugs secreted by tubule cells.
14. What is the normal pH range for freshly voided urine?
15. Identify three body systems in addition to the urinary system that also excrete unneeded substances.
16. Define retention.
17. What is the most common cause of glycosuria?
18. What do elevated BUN levels indicate?
19. Define the term *osmolality*.

CRITICAL THINKING QUESTIONS



After finishing the Review Questions, write out the answers to these more in-depth questions to help you apply your new knowledge. Go back to sections of the chapter that relate to concepts that you find difficult.

1. What would result if the nerves supplying the bladder and urethra were damaged?
2. Describe the mechanism of urine formation. How is each step related to the part of the nephron that performs it?
3. If the proximal convoluted tubules were unable to transport sodium ions into blood, why would you expect to find high concentrations of both sodium and chloride ions in urine?
4. Why do you think ADH prevents rapid dehydration of the body?
5. How is the function of ANH related to the increase in urine volume?
6. What is the relationship between age and kidney function?

Fluid and Electrolyte Balance

continued on p. 1020

*The phrase **fluid and electrolyte balance** implies homeostasis, or constancy, of body fluid and electrolyte levels. It means that both the amount and distribution of body fluids and electrolytes are normal and constant. For homeostasis to be maintained, body "input" of water and electrolytes must be balanced by "output." If water and electrolytes enter the body in excess of requirements, they must be selectively eliminated, and if excess losses occur, prompt replacement is critical. The volume of fluid and the electrolyte concentrations inside the cells, in the interstitial spaces, and in the blood vessels all remain relatively constant when a condition of homeostasis exists. Fluid and electrolyte imbalance, then, means that both the total volume of water and the level of electrolytes in the body or the amounts in one or more of its fluid compartments have increased or decreased beyond normal limits.*

INTERRELATIONSHIP OF FLUID AND ELECTROLYTE BALANCE

Several of the basic physical properties of matter discussed in Chapter 2 help explain the mechanisms of fluid and electrolyte balance. The concept of chemical bonding is a good example. The type of chemical bonds between molecules of certain chemical compounds, such as sodium chloride (NaCl), permits breakup, or dissociation, into separate particles (Na^+ and Cl^-). Recall that such compounds are known as **electrolytes.** The dissociated particles of an electrolyte are called **ions** and carry an electrical charge. Organic substances such as glucose, however, have a type of bond that does not permit the compound to break up, or **dissociate,** in solution. Such compounds are known as **nonelectrolytes.**

Many electrolytes and their dissociated ions are of critical importance in fluid balance. Fluid balance and electrolyte balance are so interdependent that if one deviates from normal, so does the other. A discussion of one therefore necessitates a discussion of the other.

TOTAL BODY WATER

Normal values for total body water expressed as a percentage of total body weight will vary between 45% and 75%. Differences occur because of age, fat content of the body, and gender. In newborn infants, total body water represents about 75% of body weight. This percentage then decreases rapidly during the first 10 years of life. At adolescence, adult values are reached and gender differences, which account for about a 10% variation in body fluid volumes between the sexes, appear. In young, nonobese adults, males weighing 70 kg (154 pounds) will have on average about 60% of their body weight as water (nearly 40 liters) and females about 50% (Table 32-1). Adipose, or fat, tissue contains the least amount of water of any tissue (including bone) in the body. Therefore, regardless of age, obese individuals, with their high body fat content, have less body water per kilogram of weight than slender people do. In aged individuals of either sex, body water content may decrease to 45% of total body weight. One reason for this is that old age is often accompanied by a decrease in muscle mass (65% water) and an increase in fat (20% water). In addition, with advancing age the kidneys are less able to produce concentrated urine, and sodium-conserving responses become less effective.

TABLE 32-1 Volumes of Body Fluid Compartments*

BODY FLUID	INFANT	ADULT MALE	ADULT FEMALE
Extracellular fluid			
Plasma	4	4	4
Interstitial fluid	26	16	11
Intracellular fluid	45	40	35
TOTAL	75	60	50

*Percentage of body weight.

TABLE 32-2 Commonly Used Acronyms for Body Fluids and Fluid Pressures

ACRONYM	TERM	MEANING
BCOP	Blood colloid osmotic pressure	Force that draws water into the plasma (from the presence of colloid particles in plasma)
BHP	Blood hydrostatic pressure	Force of the blood pushing outward on blood vessel walls; blood pressure
ECF	Extracellular fluid	Any fluid outside cells, such as interstitial fluid (IF) or blood plasma
ICF	Intracellular fluid	Fluid inside the cell (cytosol)
IF	Interstitial fluid	Fluid between tissue cells
IFCOP	Interstitial fluid colloid osmotic pressure	Force that draws water out of the blood and into tissue spaces (from the presence of colloid particles in IF)
IFHP	Interstitial fluid hydrostatic pressure	Force (pressure) of the fluid between tissue cells

BODY FLUID COMPARTMENTS

Functionally, the total body water can be subdivided into two major **fluid compartments** called the **extracellular** and the **intracellular fluid compartments. Extracellular fluid (ECF)** consists mainly of the *plasma* found in the blood vessels and the *interstitial fluid* that surrounds the cells (Table 32-2). In addition, the lymph and so-called *transcellular fluid*—such as cerebrospinal fluid, joint fluids, and humors of the eye—are also considered extracellular fluid. The distribution of body water by compartment is shown in Figure 32-1. **Intracellular fluid (ICF)** refers to the water inside the cells.

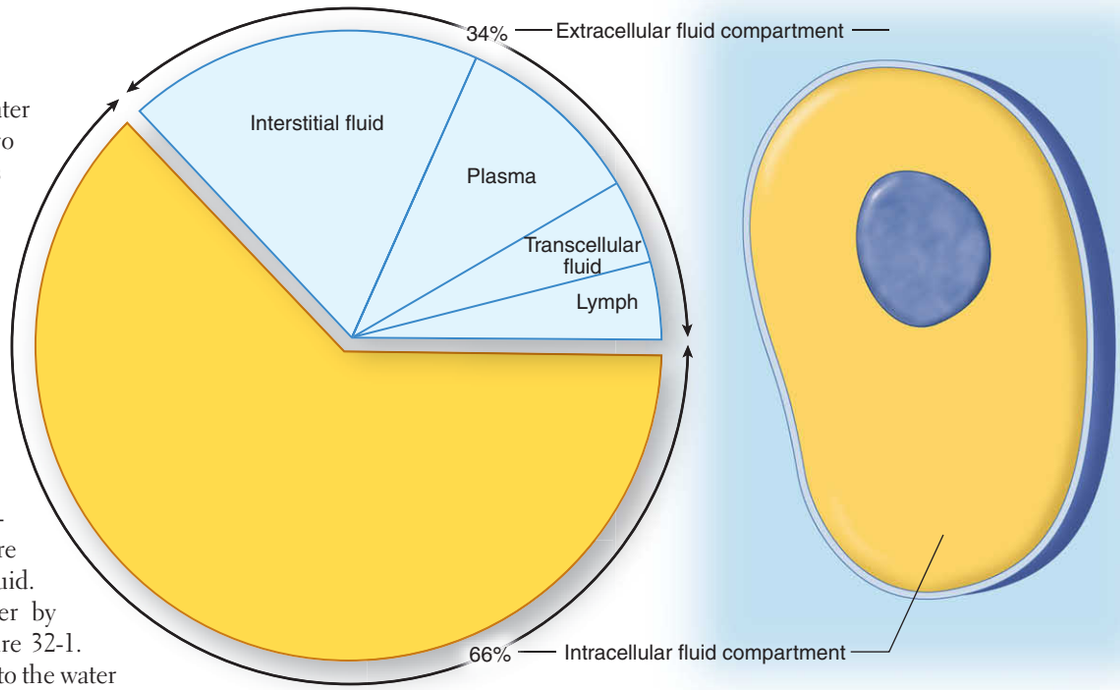

FIGURE 32-1
Distribution of total body water.

Extracellular fluid makes up the internal environment of the body. It therefore serves the dual vital functions of providing a relatively constant environment for cells and transporting substances to and from them. Intracellular fluid, on the other hand, because it is a solvent, functions to facilitate intracellular chemical reactions that maintain life. When compared according to volume, intracellular fluid is the largest (25 L), plasma the smallest (3 L), and interstitial fluid in between (12 L). Figure 32-2 illustrates the typical normal fluid volumes in a young adult male, and Table 32-1 lists volumes of the body fluid compartments for both sexes as a percentage of body weight.

CHEMICAL CONTENT, DISTRIBUTION, AND MEASUREMENT OF ELECTROLYTES IN BODY FLUIDS

We have defined an electrolyte as a compound that will break up or dissociate into charged particles called *ions* when placed in solution. Sodium chloride, when dissolved in water, provides a positively charged sodium ion (Na^+) and a negatively charged chloride ion (Cl^-).

If two electrodes charged with a weak current are placed in an electrolyte solution, the ions will move, or migrate, in opposite directions according to their charge. Positive ions such as Na^+ will be attracted to the negative electrode (cathode) and are called **cations.** Negative ions such as Cl^- will migrate to the positive electrode (anode) and are called **anions.** Various anions and cations serve critical nutrient or regulatory roles in the body. Important cations include sodium (Na^+), calcium (Ca^{++}), potassium (K^+), and magnesium (Mg^{++}). Important anions include chloride (Cl^-), bicarbonate (HCO_3^-), phosphate ($HPO_4^=$), and many proteins.

The importance of electrolytes in controlling the movement of water between the body fluid compartments is discussed in this chapter. Their role in maintaining acid-base balance is examined in Chapter 33.

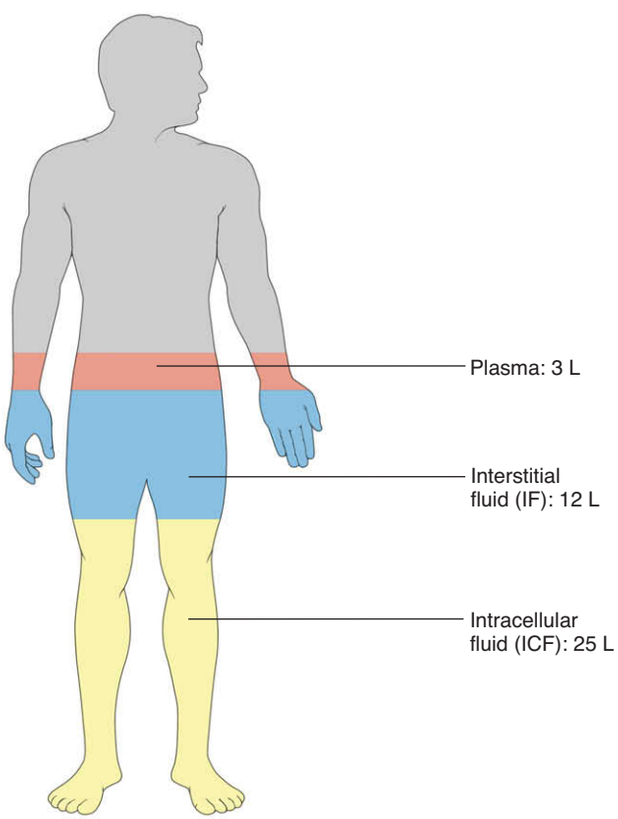

FIGURE 32-2
Relative volumes of three body fluids. Values represent fluid distribution in a young adult male.

Extracellular vs. Intracellular Fluids

Compared chemically, plasma and **interstitial** fluid (the two extracellular fluids) are almost identical. Intracellular fluid, on the other hand, shows striking differences as compared with either of the two extracellular fluids. Let us examine first the chemical structure of plasma and interstitial fluid as shown in Figure 32-3 and Table 32-3.

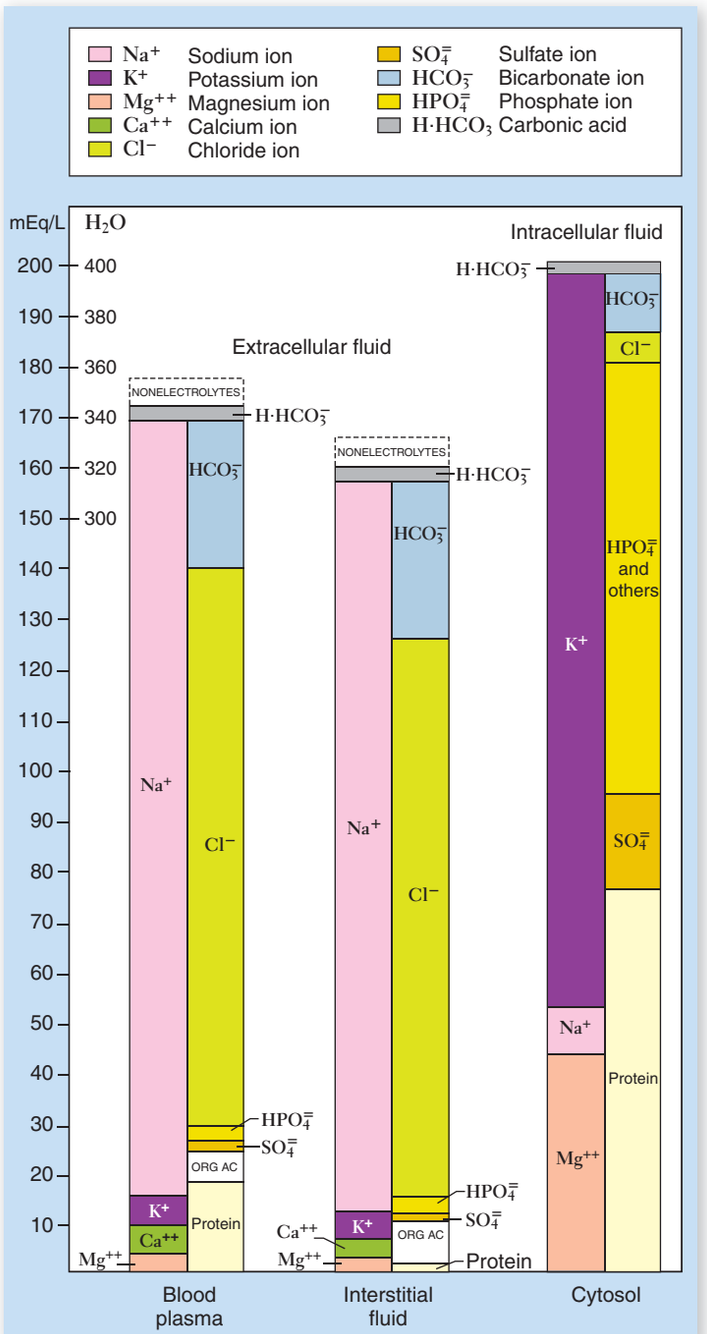

FIGURE 32-3

Chief chemical constituents of three fluid compartments. The column of figures at the left (200, 190, 180, etc.) indicates the amount of cation or anion, whereas the figures on the right (400, 380, 360, etc.) indicate the sum of the cations and anions. *ORG AC,* Organic acid.

TABLE 32-3 Electrolyte Composition of Blood Plasma

	CATIONS	ANIONS
	142 mEq Na^+	102 mEq Cl^-
	4 mEq K^+	26 HCO_3^-
	5 mEq Ca^{++}	17 protein
	2 mEq Mg^{++}	6 other
		2 $HPO_4^=$
TOTAL	153 mEq/L plasma	153 mEq/L plasma

Perhaps the first difference between the two extracellular fluids that you notice (see Figures 32-3 and 32-4) is that blood plasma contains a slightly larger total of electrolytes (ions) than interstitial fluids do. If you compare the two fluids, ion for ion, you will discover the most important difference between blood plasma and interstitial fluid. Look at the anions (negative ions) in these two extracellular fluids. Note that blood contains an appreciable amount of protein anions. *Interstitial fluid, in contrast, contains hardly any protein anions.* This is the only functionally important difference between blood and interstitial fluid. It exists because the normal capillary membrane is practically impermeable to proteins. Hence, almost all protein anions remain behind in the blood instead of filtering out into the interstitial fluid. Because proteins remain in the blood, certain other differences also exist between blood and interstitial fluid—notably, blood contains more sodium ions and fewer chloride ions than interstitial fluid does.

Extracellular fluids and intracellular fluid are more unlike than alike chemically. Chemical difference predominates between the extracellular and intracellular fluids. Chemical similarity predominates between the two extracellular fluids. Study Figures 32-3 and 32-4 and make some generalizations about the main chemical differences between the extracellular and intracellular fluids. For example: What is the most abundant cation in extracellular

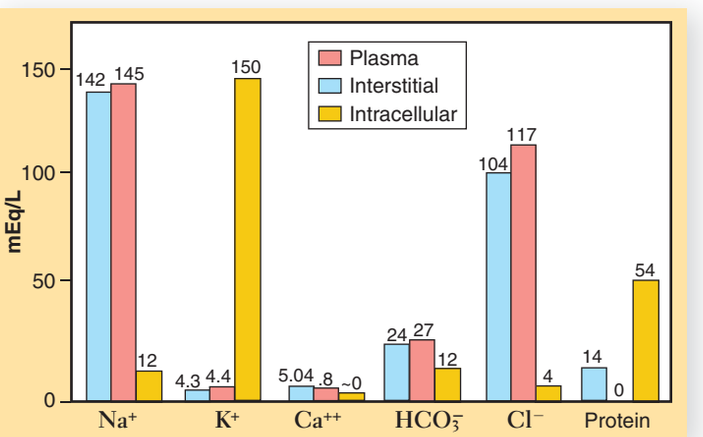

FIGURE 32-4

Electrolyte and protein concentrations in body fluid compartments. This illustration compares individual electrolyte and protein concentration in the three fluid compartments.

fluids? In intracellular fluid? What is the most abundant anion in extracellular fluids? In intracellular fluid? What about the relative concentrations of protein anions in extracellular fluids and intracellular fluid?

The reason we call attention to the chemical structure of the three body fluids is that here, as elsewhere, structure determines function. In this instance the chemical structure of the three fluids helps control water and electrolyte movement between them. Or, phrased differently, the chemical structure of body fluids, if normal, functions to maintain homeostasis of fluid distribution and, if abnormal, results in fluid imbalance. **Hypervolemia** (excess blood volume) is a case in point. **Edema** (discussed in detail on p. 1015), too, frequently stems from changes in the chemical structure of body fluids. Box 32-1 discusses therapies involving administration of fluids and electrolytes.

Before discussing mechanisms that control water and electrolyte movement between blood, interstitial fluid, and intracellular fluid, it is important to understand the units used for measuring electrolytes.

Measuring Electrolyte Reactivity

After the important electrolytes and their constituent ions in the body fluid compartments had been established, physiologists needed to measure changes in their levels to understand the mechanisms of fluid balance. To have meaning, measurement units used to report electrolyte levels must be related to actual physiological activity. In the past, only the weight of an electrolyte in a given amount of solution—its *concentration*—was measured. The number of milligrams per 100 ml of solution (mg%) was one of the most frequently used units of measurement. However, simply reporting the concentration of an important electrolyte such as sodium or calcium in milligrams per 100 ml of blood (mg%) gives no direct information about its chemical combining power or physiological activity in body fluids. The importance of valence and electrovalent or ionic bonding in chemical reactions was discussed in Chapter 2. The reactivity or combining power of an electrolyte depends not just on the number of molecular particles present but also on the total number of ionic charges (valence).

Box 32-1 | Fluid and Electrolyte Therapy

The term **parenteral therapy** is used to describe the administration of nutrients, special fluids, and/or electrolytes by injection. The term implies that whatever is administered enters the body by injection and not through the alimentary canal. Examples of **parenteral** routes include **intravenous injection** (into veins) and **subcutaneous injection** (under the skin). Significant quantities of nutrient or electrolyte solutions that are injected subcutaneously must be isotonic with plasma or cellular damage will occur. Such solutions may be administered intravenously, however, regardless of tonicity, if correct rates of administration are used. The intravenous route is generally the preferred route for all fluid and electrolyte solutions. It permits the body to adjust its fluid compartments in the same way that it does after the ordinary intake of water and food. The ideal route for the absorption of nutrients and fluids is, of course, the digestive tract. However, if for any reason the digestive tract route cannot be used, parenteral administration of these substances is required to sustain life.

Parenteral solutions are generally given to accomplish one or more of three primary objectives:

1. To meet current maintenance needs for nutrients, fluids, and electrolytes
2. To replace past losses
3. To replace concurrent losses (additional losses that are in excess of maintenance needs)

Although many different types and combinations of nutrients and electrolytes in solution are available to meet almost every medical need, 85% to 95% of all individuals needing fluid therapy are treated with one or more of the seven basic solutions listed below:

1. Carbohydrate in water
2. Carbohydrate in various strengths of saline
3. Normal saline (0.9% NaCl)
4. Potassium solutions
5. Ringer's solution
6. Lactate solutions
7. Ammonium chloride solutions

Carbohydrate and water solutions not only supply water for body needs but also provide calories required for energy. Dextrose (glucose) and fructose (levulose) are the common parenteral carbohydrates. Perhaps the most frequently used parenteral solution is 5% dextrose in water (D_5W).

Various carbohydrate and saline solutions are also available for parenteral use. Such solutions are of primary value in individuals who have a chloride deficit and ongoing fluid and caloric needs. Patients who are vomiting or undergoing gastric suction that results in the loss of chloride in hydrochloric acid need these solutions. Prolonged and heavy sweating and diarrhea also produce chloride deficits.

Current trends in parenteral therapy have reduced the frequency of normal saline use administered independently of other electrolytes or carbohydrates. In recent decades, normal saline as a general purpose electrolyte has been replaced by the use of Ringer's solution, which provides more of the essential electrolytes in physiological proportions. Ringer's solution is often described as normal saline modified by the addition of calcium and potassium in amounts approximating those found in plasma. Normal saline is still useful and widely used in cases where chloride loss is equal to or greater than the loss of sodium, however.

Potassium, lactate, and ammonium chloride solutions are specialty fluids used in the treatment of such conditions as acid-base imbalance or, in the case of potassium, administered during the healing phase of severe burns or in patients with actual potassium deficiency. In acidosis, lactate is rapidly converted by the liver to bicarbonate ions, and administration of ammonium chloride is useful in treating alkalosis. Acid-base imbalances and their treatment are discussed in Chapter 33.

Univalent ions such as sodium (Na^+) carry only a single charge, but the divalent calcium ion (Ca^{++}) carries two units of electrical charge.

The need for a unit of measurement more related to activity has resulted in increasing use of a more meaningful measurement yardstick—the **milliequivalent (mEq).** Milliequivalents measure the number of ionic charges or electrovalent bonds in a solution and therefore serve as an accurate measure of the chemical (physiological) combining power, or *reactivity*, of a particular electrolyte solution. The number of milliequivalents of an ion in a liter of solution (mEq/L) can be calculated from its weight in 100 ml (mg%) by using a convenient conversion formula.

Conversion of milligrams per 100 ml (mg%) to milliequivalents per liter (mEq/L):

$$\text{mEq/L} = \frac{\text{mg/100 ml} \times 10 \times \text{Valence}}{\text{Atomic weight}}$$

Example: Convert 15.6 mg% K^+ to mEq/L

Atomic weight of $K^+ = 39$

Valence of $K^+ = 1$

$$\text{mEq/L} = \frac{15.6 \times 10 \times 1}{39} = \frac{156}{39} = 4$$

Therefore, 15.6 mg/100 ml K^+ = 4 mEq/L.

| QUICK CHECK |

1. List three important cations and anions that serve critical nutrient or regulatory roles in the body.
2. Name the most abundant chemical constituent in blood plasma, interstitial fluid, and intracellular fluid.
3. Identify the units used to describe electrolyte concentration and electrolyte reactivity.

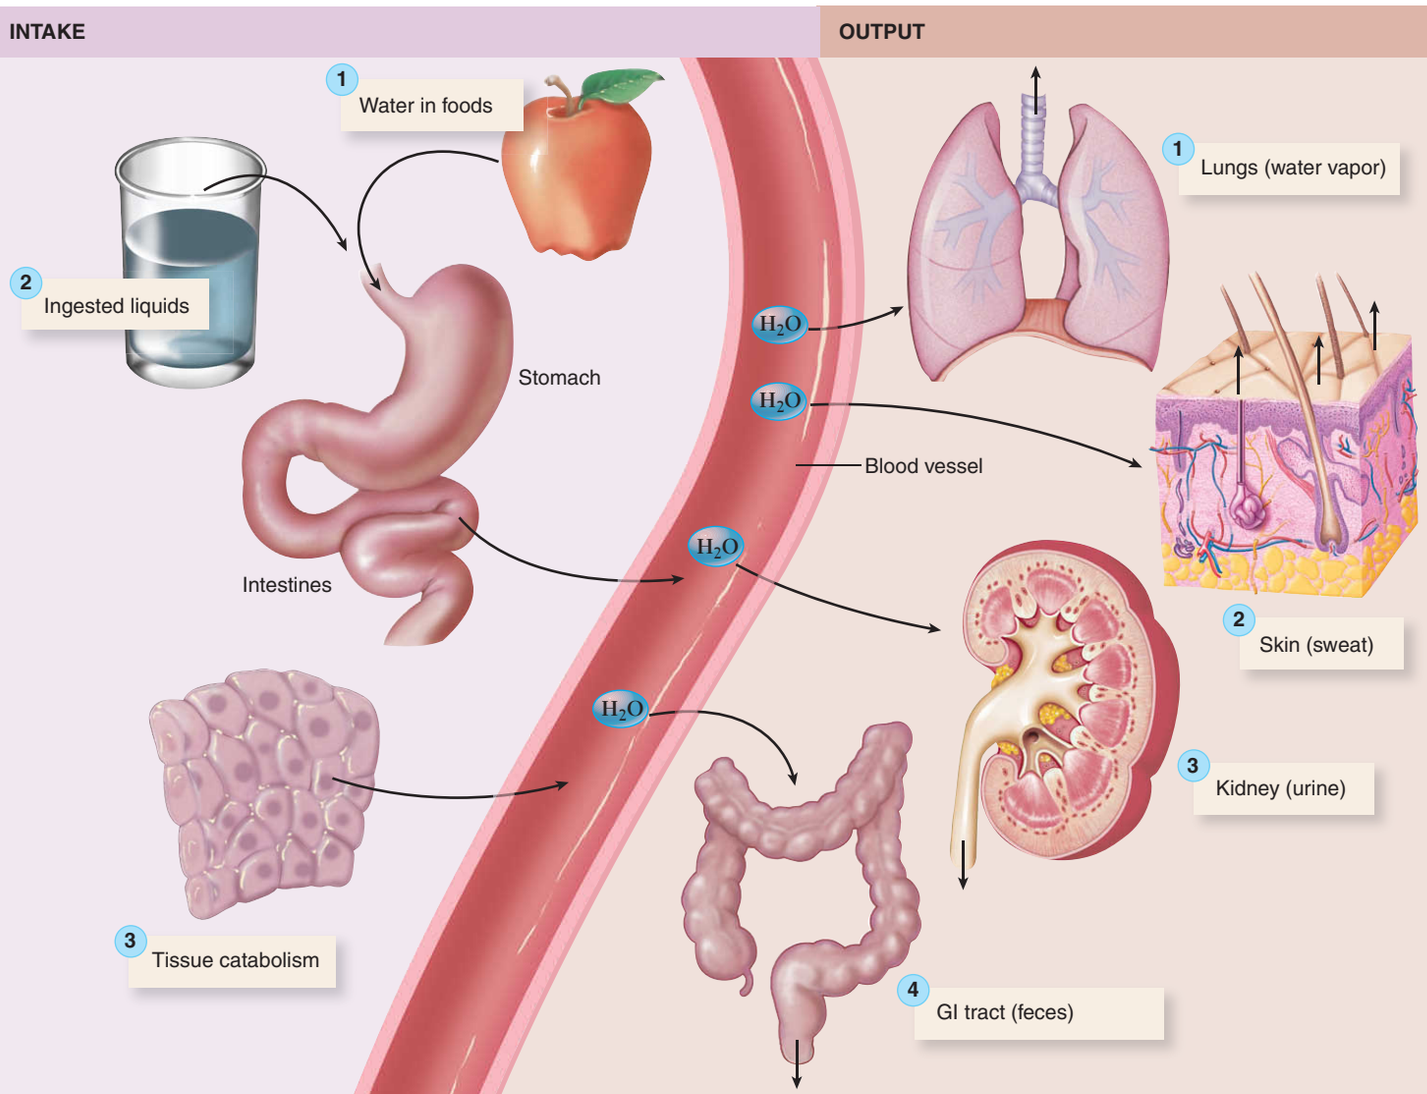

FIGURE 32-5
Sources of fluid intake and output.

AVENUES BY WHICH WATER ENTERS AND LEAVES THE BODY

Water enters the body, as everyone knows, by way of the digestive tract—in the liquids one drinks and in the foods one eats (Figure 32-5). But, in addition, and less universally known, water enters the body—that is, is added to its total fluid volume—by way of its billions of cells. Each cell produces water as it catabolizes foods, and this water enters the bloodstream. Water normally leaves the body by four exits: kidneys (urine), lungs (water in expired air), skin (by diffusion and by sweat), and intestines (feces). In accord with the cardinal principle of fluid balance, the total volume of water entering the body normally equals the total volume leaving. In short, fluid intake normally equals fluid output. Figure 32-5 illustrates the portals of water entry and exit, and Table 32-4 gives their normal volumes. These volumes, however, can vary considerably and still be considered normal.

| QUICK CHECK |

4. Name the type of chemical compound that breaks up, or dissociates, in solution to form ions.
5. Plasma and interstitial fluid are subdivisions of what major body fluid compartment?
6. List the volumes of body fluid compartments in a young adult female as a percentage of body weight.
7. List the major "portals" of water entry and exit from the body.

SOME GENERAL PRINCIPLES ABOUT FLUID BALANCE

The cardinal principle about fluid balance is this: fluid balance can be maintained only if intake equals output. Obviously, if more water or less leaves the body than enters it, imbalance will result. Total fluid volume will increase or decrease but cannot remain constant under these conditions.

TABLE 32-4 Typical Normal Values (24 Hours) for Each Portal of Water Entry and Exit (With Wide Variations)

INTAKE		OUTPUT	
Water in foods	700 ml	Lungs	350 ml
Ingested liquids	1500 ml	Skin	
Water formed by catabolism	200 ml	By diffusion	350 ml
		By sweat	100 ml
		Kidneys (urine)	1400 ml
		Intestines (in feces)	200 ml
TOTAL	2400 ml		2400 ml

Mechanisms for varying output so that it equals intake are the most crucial means of maintaining fluid balance, but mechanisms for adjusting intake to output also operate. Figure 32-6 summarizes the role that the *renin-angiotensin-aldosterone system (RAAS)* has in decreasing fluid output (urine volume) to compensate for decreased intake.

Recall from Chapter 31 that cells in the outer zone of the adrenal cortex that secrete aldosterone are also influenced by *juxtaglomerular (JG) cells* in the kidney. If blood pressure decreases or if increased levels of plasma K^+ occur, additional aldosterone will be secreted. When stimulated, juxtaglomerular cells in the kidney secrete renin, which, in turn, acts on angiotensinogen in the bloodstream to form angiotensin I, which

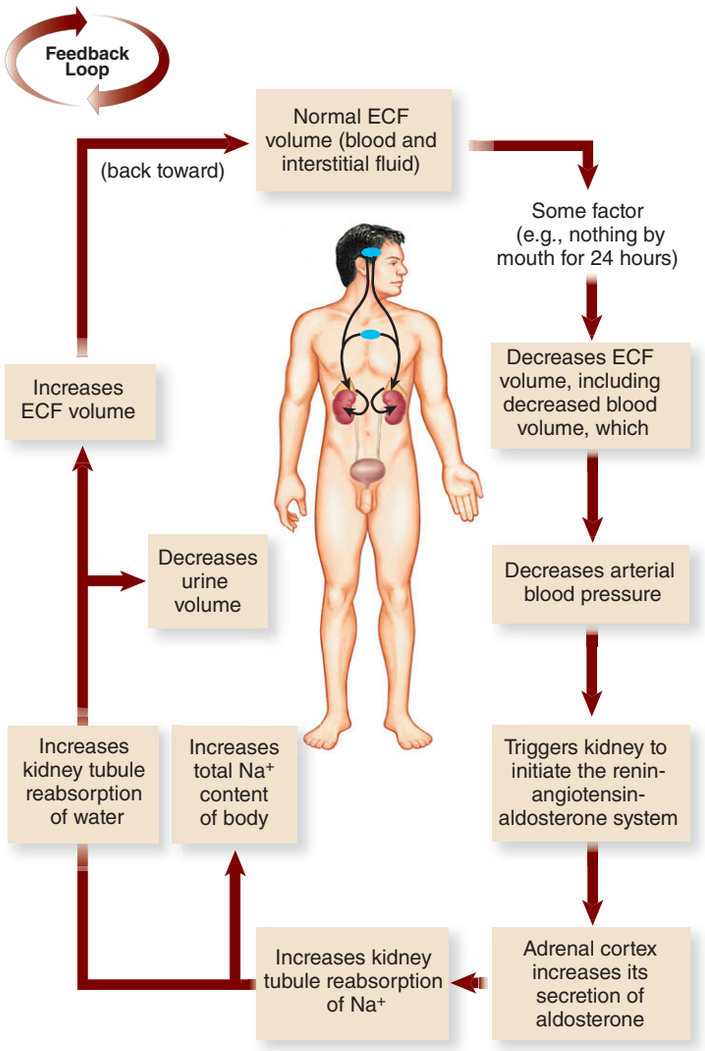

FIGURE 32-6

Role of aldosterone in ECF homeostasis. Aldosterone tends to restore normal extracellular fluid *(ECF)* volume when it decreases below normal. Excess aldosterone, however, leads to excess ECF volume, that is, excess blood volume (hypervolemia) and excess interstitial fluid volume (edema), as well as an excess of the total Na^+ content of the body. Details of the reninangiotensin-aldosterone system (RAAS) are shown in Figure 19-19.

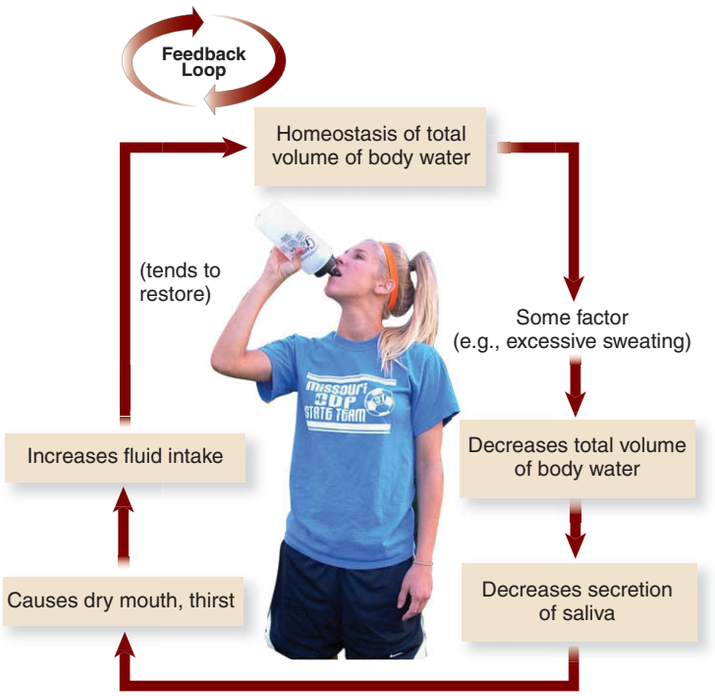

FIGURE 32-7

Homeostasis of the total volume of body water. A basic mechanism for adjusting intake to compensate for excess output of body fluid is diagrammed.

is eventually converted in lung tissue to angiotensin II (see Figure 19-19, p. 579). Angiotensin I and II increase aldosterone secretion and also act on the brain to stimulate the sensation of thirst. Thirst is associated with any factor that decreases the total volume of body water, such as blood loss or hemorrhage. Simple dehydration caused by sweating also results in reduced saliva secretion and thirst. Additional details of the *renin-angiotensin-aldosterone system* are discussed in Chapter 19. Figure 32-7 diagrams a mechanism for adjusting intake to compensate for excess output.

Mechanisms for controlling water movement between the fluid compartments of the body are the most rapid-acting fluid balance processes. They serve first of all to maintain normal blood volume at the expense of interstitial fluid volume.

MECHANISMS THAT MAINTAIN HOMEOSTASIS OF TOTAL FLUID VOLUME

Under normal conditions, homeostasis of the total volume of water in the body is maintained or restored primarily by mechanisms that adjust output (urine volume) to intake and secondarily by mechanisms that adjust fluid intake.

Regulation of Fluid Intake

A detailed explanation of the mechanism for controlling fluid intake so that it increases when output increases and decreases when output decreases is not yet available. However, research has shown that nerve cells located in the roof of the third ventricle of the brain, in a structure called the **subfornical organ,** or **SFO,** act as critical regulators of fluid homeostasis. Nervous connections exist between SFO cells and other areas of the brain, including the cerebrum and the supraoptic and paraventricular nuclei of the hypothalamus. These nuclei are involved in antidiuretic hormone (ADH) production, which is important in conservation of body water when fluid intake is restricted (see Chapter 19, p. 570, and Figure 32-16).

Physiologists now identify both SFO and ADH-secreting cells in the hypothalamus as important **osmoreceptors,** which together make up the functional **thirst center** of the brain. Osmoreceptors are cells able to detect an increase in solute concentration (osmolality) in extracellular fluid caused by water loss. Signals generated by osmoreceptors in the SFO and hypothalamus stimulate ADH secretion and also affect a number of other body functions, including a decrease in the secretion of saliva.

Signals from the SFO are also sent directly to the cerebrum, where they trigger a conscious sense of dry mouth and thirst and initiate complex behaviors and thought processes, which in many individuals include a perceived need to increase the consumption of water, especially. Have you ever heard someone say "soda pop tastes good but nothing satisfies my thirst like a glass of water"? The end result is an overall increase in fluid intake to offset increased loss, regardless of cause, and this tends to restore fluid balance (see Figure 32-7). If, however, an individual takes nothing by mouth for several days, fluid balance cannot be maintained despite every effort of homeostatic mechanisms to compensate for the zero intake. Obviously, under this condition, the only way balance could be maintained would be for fluid output to also decrease to zero. But this cannot occur. Some output is obligatory. Why? Because as long as respirations continue, some water leaves the body by way of expired air. Also, as long as life continues, an irreducible minimum of water diffuses through the skin.

Regulation of Urine Volume

Two factors together determine urine volume: the glomerular filtration rate and the rate of water reabsorption by the renal tubules. The glomerular filtration rate, except under abnormal conditions, remains fairly constant—hence it does not normally cause urine volume to fluctuate. The rate of tubular reabsorption of water, on the other hand, fluctuates considerably. The rate of tubular reabsorption, therefore, rather than the glomerular filtration rate, normally adjusts urine volume to fluid intake. The amount of antidiuretic hormone (ADH) and aldosterone secreted regulates the amount of water reabsorbed by the kidney tubules (discussed on

p. 1017; see also Figure 32-6). In other words, urine volume is regulated chiefly by hormones secreted by the posterior pituitary (ADH) and by the adrenal cortex (aldosterone) and by atrial natriuretic hormone (ANH). Regulation of aldosterone secretion by the renin-angiotensin mechanism has also been discussed.

Although changes in the volume of fluid loss via the skin, the lungs, and the intestines also affect the fluid intake-output ratio, these volumes are not automatically adjusted to intake volume, as is the volume of urine. Figure 32-8 summarizes the fluid and electrolyte regulation mechanisms that involve ADH, aldosterone, and ANH.

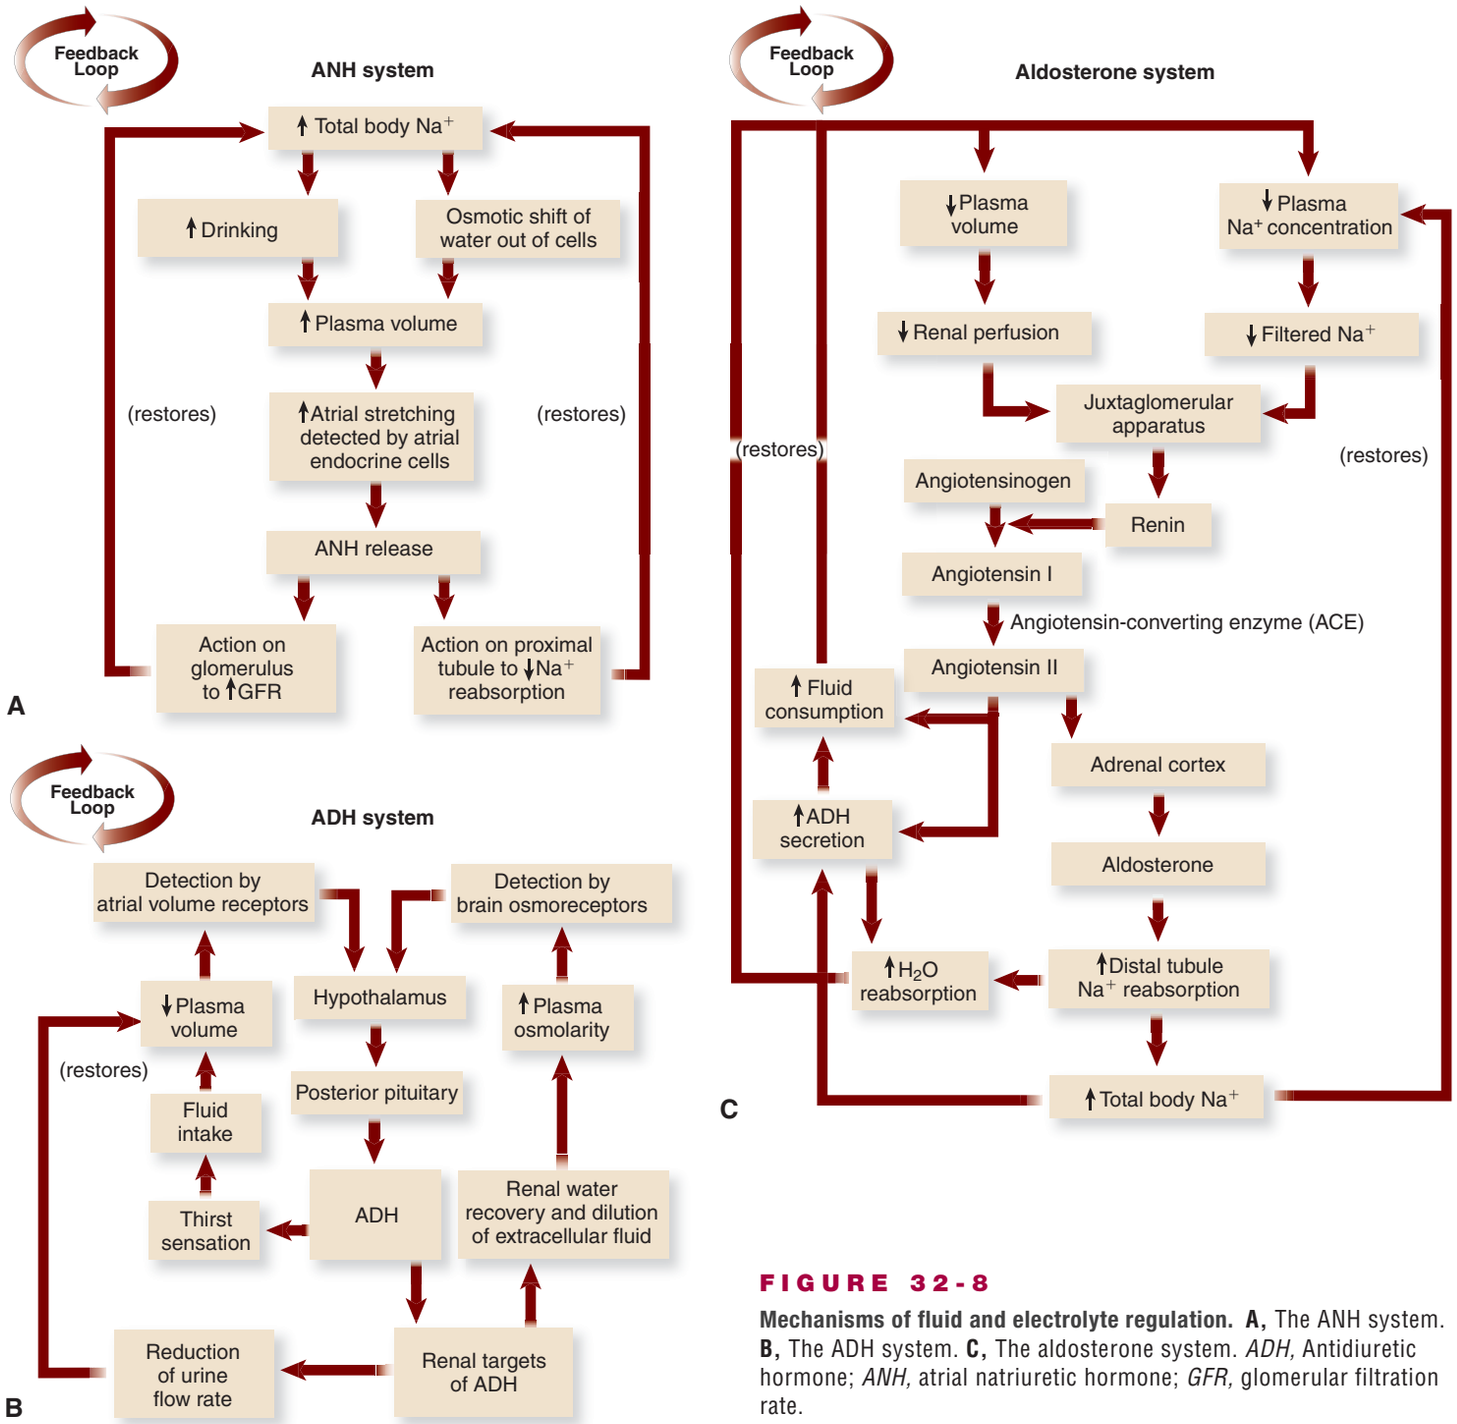

FIGURE 32-8

Mechanisms of fluid and electrolyte regulation. A, The ANH system. **B,** The ADH system. **C,** The aldosterone system. *ADH,* Antidiuretic hormone; *ANH,* atrial natriuretic hormone; *GFR,* glomerular filtration rate.

Factors That Alter Fluid Loss Under Abnormal Conditions

The rate of respiration and the volume of sweat secreted may greatly alter fluid output under certain abnormal conditions. For example, a patient who hyperventilates for an extended time loses an excessive amount of water via the expired air. If, as frequently happens, the individual also takes in less water by mouth than normal, the fluid output then exceeds intake and a fluid imbalance develops, namely, **dehydration** (that is, a decrease in total body water). The severity of dehydration can be measured by weight loss as a percentage of the normal (hydrated) body weight (Figure 32-9). Symptoms range from simple thirst to muscle weakness and kidney failure. Clinically, dehydration is often detected by loss of skin elasticity or *turgor*. If a fold of skin, when pinched, returns to its original shape slowly—a condition called "tenting"—dehydration is suspected. Dehydration is more fully discussed in Box 32-2. Other abnormal conditions such as vomiting, diarrhea, or intestinal drainage also cause fluid and electrolyte output to exceed intake and thus produce fluid and electrolyte imbalances.

| QUICK CHECK |

8. How does aldosterone secretion restore normal extracellular fluid (ECF) volume when it decreases below normal?
9. Identify the two substances that are most important in regulating the amount of water reabsorbed by the kidney tubules.
10. Name the two most important factors that alter fluid loss under abnormal conditions.

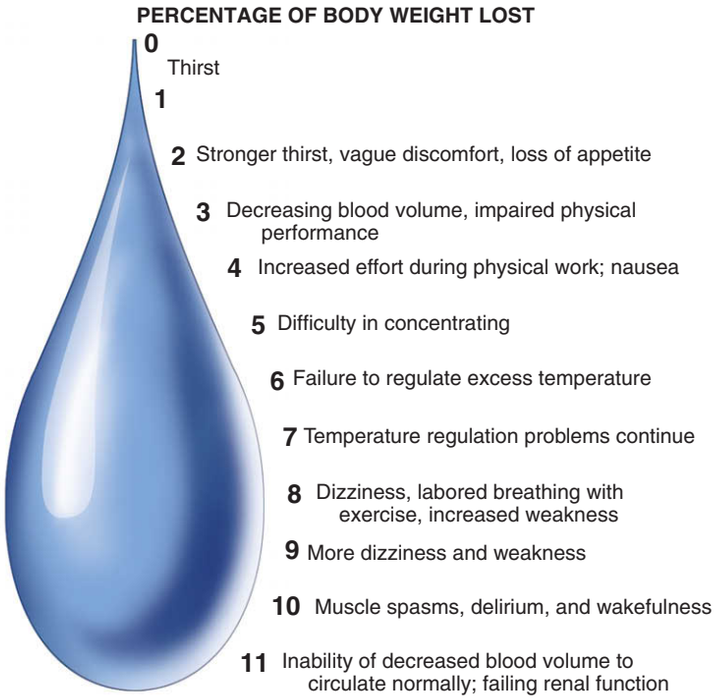

FIGURE 32-9

The effects of dehydration.

Box 32-2 | Dehydration

The term **dehydration** is used to describe the condition that results from excessive loss of body water. Loss of skin resiliency or pressure—often described as a loss of **turgor**—is a sign of dehydration (Figure *A*). Water deprivation or loss triggers a complex series of protective responses designed to maintain homeostasis of water and electrolyte levels. Unfortunately, the term *dehydration* is incomplete. It does not, by definition, include the loss of electrolytes. To understand the control mechanisms that ensure fluid and electrolyte balance or properly interpret the clinical signs and symptoms of dehydration in disease states, it is important to realize that in any process of dehydration, water loss is always accompanied by loss of electrolytes. If water intake is reduced to the point of dehydration, a corresponding quantity of electrolytes must be removed to maintain the normal ionic content of body fluids. The same is true in the case of electrolyte loss when an accompanying loss of water must occur to maintain homeostasis of both fluid and electrolyte levels. Understanding the close interrelationships of water and electrolyte loss in dehydration provides the rationale for effective treatment. Water alone is inadequate; treatment of dehydration also requires appropriate electrolyte replacement therapy.

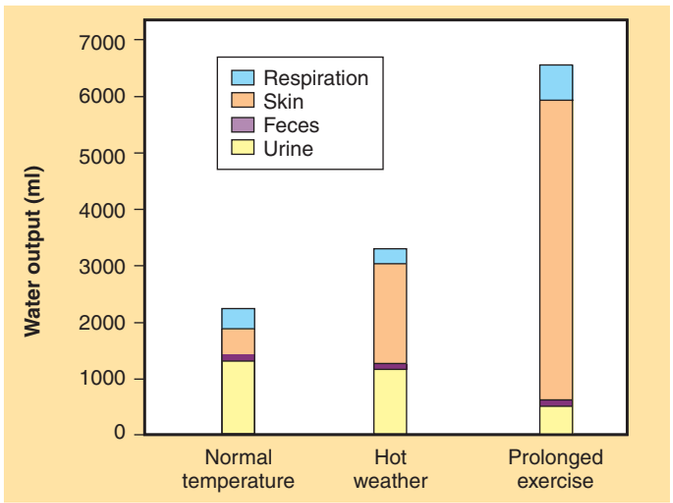
As discussed in Chapter 7, maintaining a constant core body temperature in a hot environment is an important function of the skin. As sweat evaporates, excess body heat can be eliminated. In hot weather or during extended periods of strenuous physical activity, the volume of water lost because of sweat production can reach 15 L per day (Figure *B*). If water intake is inadequate, signs of dehydration will appear very rapidly. As body water levels decrease, the initial defense mechanisms are directed toward maintaining an adequate blood volume.

In addition to water, sweat contains significant quantities of sodium and chloride. However, the relative loss of water in sweat is greater than the loss of electrolytes. Therefore, as water is shifted from the interstitial fluid compartment to the plasma to compensate for fluid loss, the kidneys excrete the excess electrolytes to preserve normal ionic concentrations in the two compartments.

REGULATION OF WATER AND ELECTROLYTE LEVELS IN PLASMA AND INTERSTITIAL FLUID

More than 70 years ago, the English physiologist Ernest Starling advanced a hypothesis about the nature of the mechanism that controls water movement between plasma and interstitial fluid (extracellular fluid [ECF])—that is, across the capillary membrane. This hypothesis has since become one of the major premises of physiology and is often spoken of as *Starling's law of the capillaries*, illustrated in Figure 22-26 on p. 703. According to this law, the control mechanism for water exchange between

The chemical composition and actual volume of fluids lost from the body will also affect the type and effectiveness of defense mechanisms that occur. For example, fluids lost through vomiting or diarrhea will have differing ratios of fluid to electrolytes than sweat has, and the actual electrolyte composition and concentration will also be different. As a result, the type of electrolyte excretion or retention by the kidneys that will be needed to maintain ionic balance in the fluid compartments will also change.



There is a lag in the volume-electrolyte adjustment mechanism triggered by dehydration. Shifts in fluid occur more quickly between compartments than does the adjustment in electrolyte levels. However, if water and electrolyte losses are limited and the interval between loss and replacement is short, the symptoms of dehydration will be mild and transitory.

In severe and prolonged water deprivation or loss, the initial shift of interstitial fluid to plasma will be followed by movement of water from the intracellular compartment as well. Over time, the extracellular and intracellular fluid losses are about equal.

Extracellular (interstitial) water is more "expendable" and quickly accessible as a fluid source to maintain blood volume in the early stages of body fluid loss. It is said to serve as the "first line of defense" against dehydration. As extracellular fluid is depleted, intracellular water must be used to prolong survival time. Ultimately, the volume of extracellular fluid can be reduced by almost 60% and intracellular fluid by 30% before death occurs.

A

B

A, Testing for dehydration. Loss of skin elasticity or turgor is a sign of dehydration. Skin that does not return quickly to its normal shape after being pinched indicates interstitial water loss. **B, Water loss during varying conditions.** During hot weather or prolonged exercise, there is a dramatic increase in water output—mostly from the skin in the form of sweat. Water intake must also dramatically increase to offset the difference, otherwise dehydration will occur.

plasma and interstitial fluid consists of four types of pressure: *blood hydrostatic* and *colloid osmotic pressure* on one side of the capillary membrane and *interstitial fluid hydrostatic* and *colloid osmotic pressure* on the other side.

We are ready now to try to answer the following question: How does the chemical structure of body fluids control water movement between them and thereby control fluid distribution in the body?

According to the physical laws governing filtration and osmosis, **blood hydrostatic pressure** (**BHP**) tends to force fluid out of capillaries into interstitial fluid (IF), but **blood colloid osmotic pressure** (**BCOP**) tends to draw it back into them. **Interstitial fluid hydrostatic pressure** (**IFHP**), in contrast, tends to force fluid out of the interstitial fluid into the capillaries, and **interstitial fluid colloid osmotic pressure** (**IFCOP**) tends to draw it back out of capillaries. In short, two of these forces push fluids in one direction and two in the opposite direction.

The process described here is similar in many ways to the mechanism responsible for the formation of glomerular filtrate studied in the last chapter. Either example is an application of *Starling's law of the capillaries.*

The movement of fluids and electrolytes between plasma and interstitial fluid caused by hydrostatic and colloid osmotic pressure

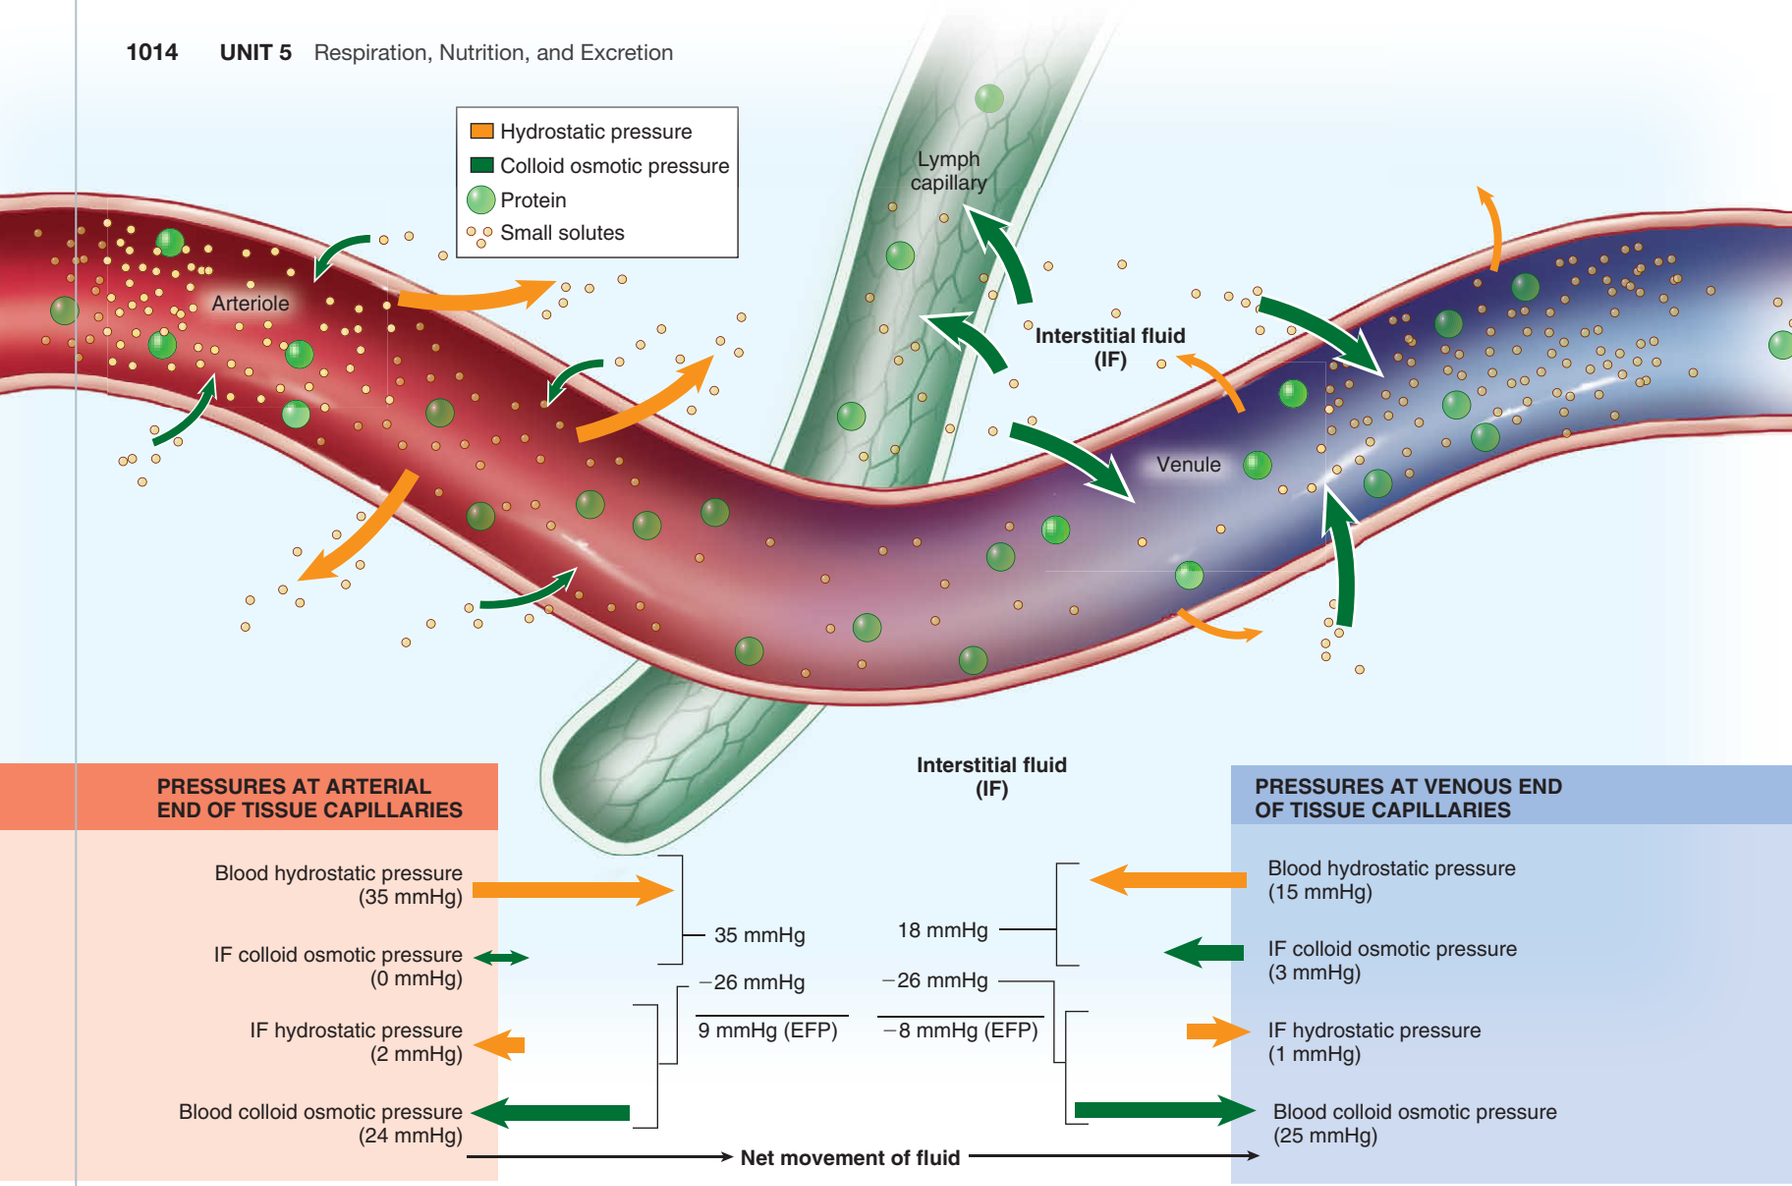


FIGURE 32-10

Movement of fluids and electrolytes between plasma and interstitial fluid caused by hydrostatic and colloid osmotic pressure. *EFP,* Effective filtration pressure. See text for discussion.

is illustrated in Figure 32-10. Note also in Figure 32-10 that the presence of blind-ended lymphatic vessels in the tissue spaces also serves as a mechanism for drainage of excess interstitial fluid. Osmotic and diffusion forces result in the movement of interstitial fluid and small proteins into the lymphatic system. Eventually, the lymph formed in this way will enter the circulatory system and become part of the circulating blood volume.

The difference between the two sets of opposing forces obviously represents the net or effective filtration pressure—in other words, the effective force tending to produce the net fluid movement between blood and interstitial fluid. In general terms, therefore, we may state Starling's law of the capillaries this way: the rate and direction of fluid exchange between capillaries and interstitial fluid are determined by the hydrostatic and colloid osmotic pressures of the two fluids. Or, we may state it more specifically as a formula:

$$(BHP + IFCOP) - (IFHP + BCOP) = EFP^{*}$$

To illustrate operation of Starling's law (see Figure 32-10), let us consider how it controls water exchange at the arterial ends of tissue capillaries. The lower left-hand portion of Figure 32-10 gives normal pressures. Using these figures in Starling's law of the capillaries we get (35 + 0) − (2 + 24) = 9 mmHg net pressure *(effective filtration pressure [EFP])*, which causes water to filter out of blood at the arterial ends of capillaries into interstitial fluid.

*Note that the factors enclosed in the first set of parentheses tend to move fluid out of capillaries and that those in the second set oppose this movement—they tend to move fluid into the capillaries.

FIGURE 32-11

Pitting edema. Note the finger-shaped depressions that do not rapidly refill after an examiner has exerted pressure.

The same law operates at the venous end of capillaries (see the lower right-hand portion of Figure 32-10). Again, apply Starling's law of the capillaries. What is the net effective pressure at the venous ends of capillaries? In which direction does it cause water to move? Assuming that the figures given are normal, do you agree that theoretically "the same amount of water returns to the blood at the venous ends of the capillaries as left it from the arterial ends"?

On the basis of our discussion thus far, we can formulate some principles about the transfer of water between blood and interstitial fluid.

1. No net transfer of water occurs between blood and interstitial fluid as long as the effective filtration pressure (EFP) equals 0, that is, when

(BHP + IFCOP) = (IFHP + BCOP)

2. A net transfer of water, a "fluid shift," occurs between blood and interstitial fluid whenever the EFP does not equal 0, that is, when

(BHP + IFCOP)
does not equal
(IFHP + BCOP)

3. Because (BHP + IFCOP) is a force that tends to move water out of capillary blood, fluid shifts out of blood into interstitial fluid whenever

(BHP + IFCOP)
is greater than
(IFHP + BCOP)

4. Because (IFHP + BCOP) is a force that tends to move water out of interstitial fluid into capillary blood, fluid shifts out of interstitial fluid into blood whenever

(IFHP + BCOP)
is greater than
(BHP + IFCOP)

Or, stated the other way around, fluid shifts out of interstitial fluid into blood whenever

(BHP + IFCOP)
is less than
(IFHP + BCOP)

Edema

Edema is a classic example of fluid imbalance and may be defined as the presence of abnormally large amounts of fluid in the intercellular tissue spaces of the body. Edema may occur in any organ or tissue of the body. However, the lungs, brain, and dependent body areas such as the legs and lower part of the back are affected most often. One of the most common areas for swelling to occur is in the subcutaneous tissues of the ankle and foot. The term **pitting edema** is used to describe depressions in swollen subcutaneous tissue in this area that do not rapidly refill after an examiner has exerted finger pressure (Figure 32-11). The condition may be caused by disturbances in any of the factors that govern the interchange between blood plasma and the interstitial fluid compartments. Examples include the following:

- Retention of electrolytes (especially Na^+) in the extracellular fluid as a result of increased aldosterone secretion or after serious renal disease such as acute glomerulonephritis.
- An increase in capillary blood pressure. Normally, fluid is drawn from the tissue spaces into the venous end of a tissue capillary because of the low venous hydrostatic pressure and the high water-pulling force of plasma proteins (Figure 32-12). This balance is upset by anything that increases the capillary hydrostatic pressure. The generalized venous congestion of heart failure is the most common cause of widespread edema. In patients with this condition, blood cannot flow freely through the capillary beds, and therefore the pressure will increase until venous return of blood improves.

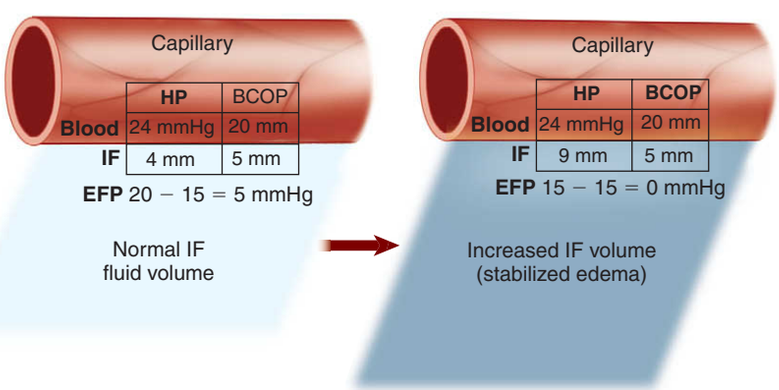

FIGURE 32-12

Edema formation. The mechanism of edema formation can be initiated by a decrease in blood protein concentration and, therefore, a decrease in blood colloid osmotic pressure *(BCOP)*. In the diagram on the left, blood osmotic pressure has just decreased to 20 from the normal 25 mmHg. This increases the effective filtration pressure *(EFP)* to 5 mmHg from a normal of 0 (see Starling's formula, p. 1014). The EFP of 5 mmHg causes fluid to shift out of blood into interstitial fluid *(IF)* until the EFP again equals 0—in this case, when the interstitial fluid volume has increased enough to raise interstitial fluid hydrostatic pressure *(HP)* to 9 mmHg, as shown in the diagram on the right. At this point a new equilibrium is established, and equal amounts of water once more are exchanged between blood and interstitial fluid. Thus the increased interstitial fluid volume—that is, the edema—becomes stabilized.

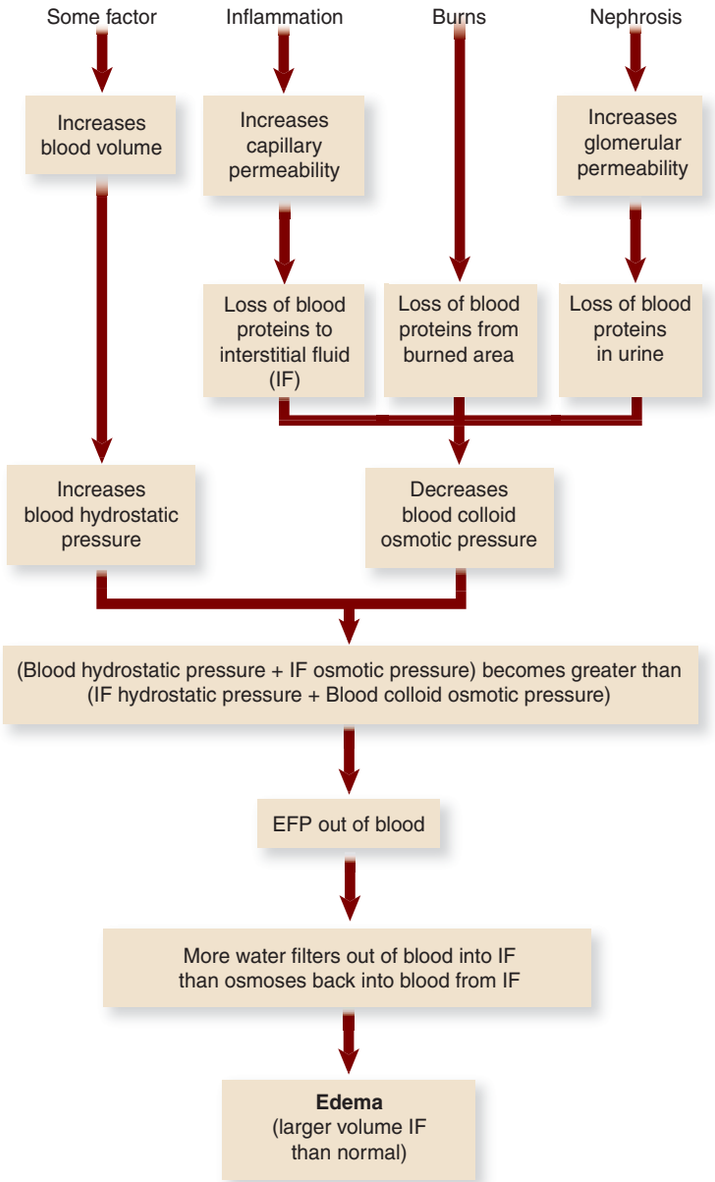

FIGURE 32-13

Mechanisms of edema formation in some common conditions. *EFP,* Effective, or net, filtration pressure; *IF,* interstitial fluid (see also Figure 32-6).

- A decrease in the concentration of plasma proteins normally retained in the blood (Figures 32-12 and 32-13). This may occur as a result of increased capillary permeability caused by infection, burns, or shock.

| QUICK CHECK |

11. Name the four pressures that control water exchange between plasma and interstitial fluid.
12. Define the term *edema.* How can tissue inflammation or burns cause edema?
13. List the mechanisms that regulate movement of solutes and water between the ECF and ICF spaces.
14. Why does fluid balance depend on electrolyte balance?

REGULATION OF WATER AND ELECTROLYTE LEVELS IN ICF

It is the plasma membrane that separates the intracellular and extracellular fluid compartments. We know that a chemical difference predominates between these two fluids, and it is the plasma membrane that plays a critical role in the regulation of intracellular fluid composition.

The mechanism that regulates water movement through cell membranes is similar to the one that regulates water movement through capillary membranes. In other words, interstitial fluid and intracellular fluid hydrostatic and colloid osmotic pressure regulate water transfer between these two fluids. But because the colloid osmotic pressure of interstitial and intracellular fluids varies more than their hydrostatic pressure, their colloid osmotic pressure serves as the chief regulator of water transfer across cell membranes. Their colloid osmotic pressure, in turn, is directly related to the electrolyte concentration gradients—notably sodium and potassium—maintained across cell membranes. As Figures 32-3 and 32-4 show, most of the body sodium is outside the cells. A concentration of 138 to 143 mEq/L makes sodium the chief electrolyte by far in interstitial fluid. The main electrolyte of intracellular fluid is potassium. Therefore, a change in the sodium or the potassium concentration of either of these fluids causes the exchange of fluid between them to become unbalanced.

Pores in the selectively permeable cell membrane retain large molecules, such as proteins, inside the cell but permit many smaller ions such as sodium and potassium to either diffuse through or be selectively transported across the membrane. The electrical charge difference that is created by the unequal concentration of electrolytes on either side of the cell membrane also influences the composition of intracellular fluid. Mechanisms that regulate the movement of solutes and water between extracellular and intracellular fluid spaces are summarized in Figure 32-14.

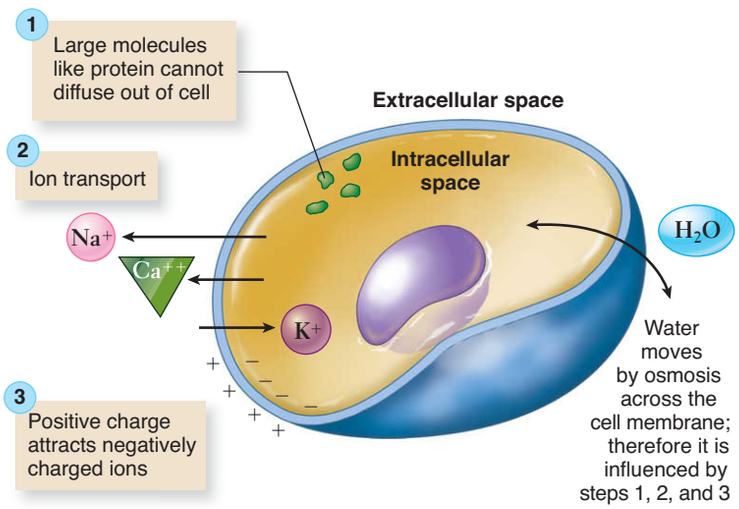

FIGURE 32-14

Mechanisms regulating movement of water and solutes between ECF and ICF spaces. Osmotic pressure is influenced by large protein molecules in the ICF, which cannot diffuse through the small pores of the cell membrane. In addition, electrolyte transport and diffusion and the charge difference across the cell membrane also influence water movement by osmosis. *ECF,* Extracellular fluid; *ICF,* intracellular fluid.

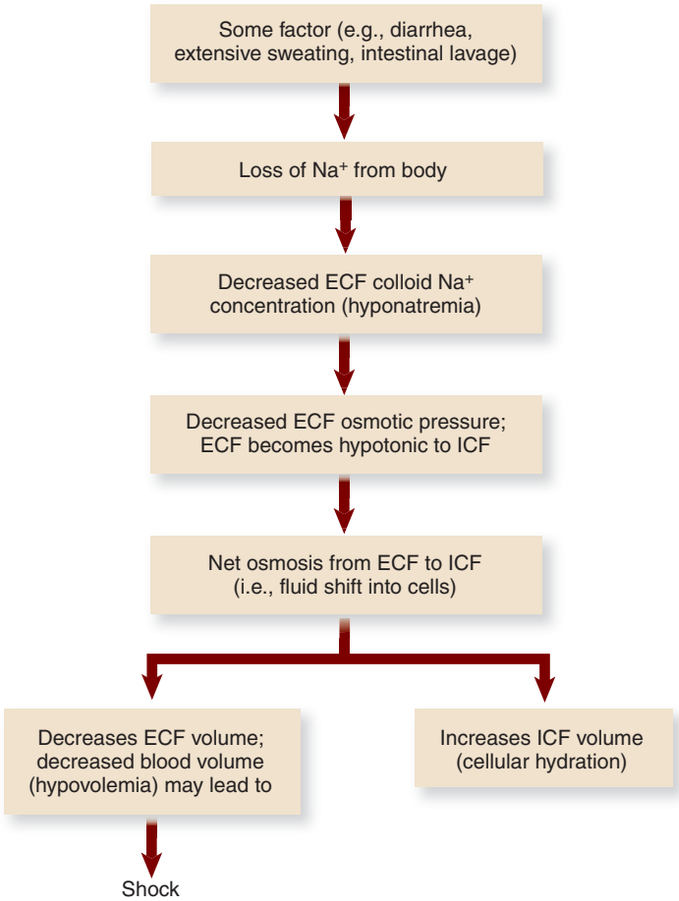

FIGURE 32-15

How electrolyte imbalance leads to fluid imbalances. The schematic uses the example of sodium deficit (hyponatremia) and resulting hypovolemia (cellular hydration). *ECF,* Extracellular fluid; *ICF,* intracellular fluid.

Any change in the solute concentration of extracellular fluid will have a direct effect on water movement across the cell membrane in one direction or another. If for any reason dehydration occurs, the concentration of solutes in the extracellular fluid will increase, and osmosis will cause water to move from the intracellular space into the extracellular space (see Box 32-2). In severe dehydration, the increasing concentration of intracellular fluid caused by water loss to the extracellular space results in abnormal metabolism or cellular death. Increased movement of water into the cell is caused by a decreased concentration of solutes in the extracellular fluids.

A decrease in interstitial fluid sodium concentration immediately decreases interstitial fluid colloid osmotic pressure, thus making it hypotonic to intracellular fluid colloid osmotic pressure. In other words, a decrease in interstitial fluid sodium concentration establishes a colloid osmotic pressure gradient between interstitial and intracellular fluid. This gradient causes net osmosis of fluid to occur, that is, fluid moves out of interstitial fluid into cells. In short, interstitial fluid and intracellular fluid electrolyte concentrations are the main determinants of their colloid osmotic pressure; their colloid osmotic pressure regulates the amount and direction of water transfer between the two fluids, and this regulates their volumes. Hence, fluid balance depends on electrolyte balance. Conversely, electrolyte balance depends on fluid balance. An imbalance in one produces an imbalance in the other (Figure 32-15).

REGULATION OF SODIUM AND POTASSIUM LEVELS IN BODY FLUIDS

A normal sodium concentration in interstitial fluid and potassium concentration in intracellular fluid depend on many factors, especially on the amount of ADH and aldosterone secreted. As shown in Figure 32-16, ADH regulates extracellular fluid electrolyte concentration and colloid osmotic pressure by regulating the amount of water reabsorbed into blood by renal tubules. Aldosterone, on the other hand, regulates extracellular fluid volume by regulating the amount of sodium reabsorbed into blood by renal tubules (see Figure 32-6).

If for any reason conservation of body sodium is required, the normal kidney is capable of excreting an essentially sodium-free urine and is therefore considered the chief regulator of sodium levels in body fluids. Sodium lost in sweat can become appreciable with elevated environmental temperatures or fever. However, the thirst that results may lead to replacement of water but not the lost sodium, and because of the increased fluid intake, the remaining sodium pool may be diluted even more. Sodium loss in sweat is not therefore considered a normal means of regulation.

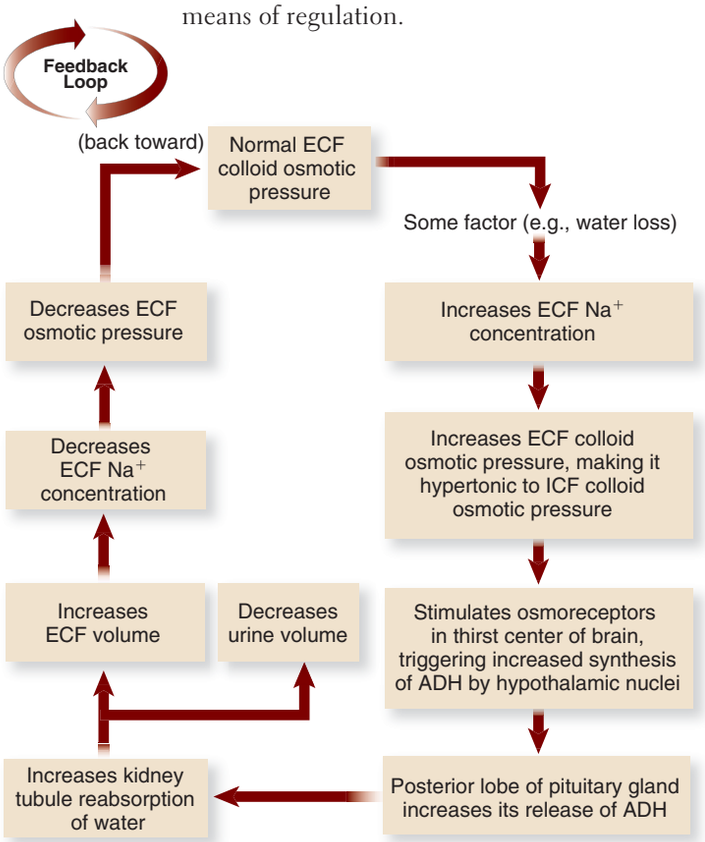

FIGURE 32-16

Antidiuretic hormone (ADH) mechanism for ECF homeostasis. The ADH mechanism helps maintain homeostasis of extracellular fluid (*ECF*) colloid osmotic pressure by regulating its volume and thereby its electrolyte concentration, that is, mainly ECF Na^+ concentration. *ICF,* Intracellular fluid.

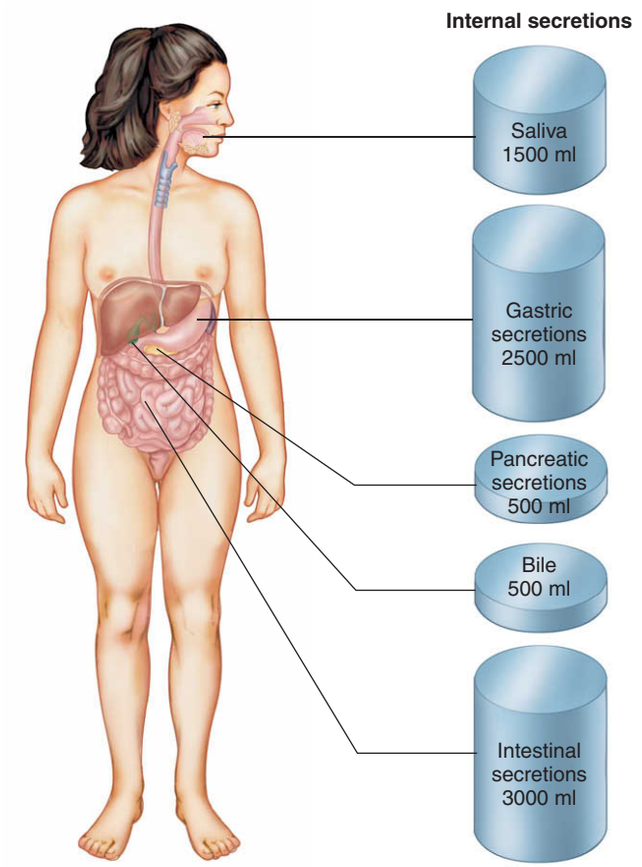

FIGURE 32-17

Sodium-containing internal secretions. Average volumes are shown. Depending on circumstances, the actual total volume of these secretions may reach 8000 or more milliliters in a 24-hour period.

In addition to the well-regulated movement of sodium into and out of the body and between the three primary fluid compartments, there is a continuous movement or circulation of this important electrolyte between a number of internal secretions. More than 8 *L* of various internal secretions such as saliva, gastric and intestinal secretions, bile, and pancreatic fluid is produced every day (Figure 32-17). The total daily secretion of sodium into these alimentary tract fluids alone will average between 1200 and 1400 mEq. A 70-kg (154-lb) adult has a total body sodium pool of only 2800 to 3000 mEq. Precise regulatory and conservation mechanisms for sodium are required for survival.

Chloride is the most important extracellular anion and is almost always linked to sodium. Generally ingested together, they provide in large part for the isotonicity of extracellular fluid. Chloride ions are usually excreted in the urine as a potassium salt, and therefore chloride deficiency—**hypochloremia**—is often found in cases of potassium loss.

The total body potassium content in the average-sized adult is approximately 4000 mEq. Because the majority of body potassium is intracellular, plasma (serum) determinations, which normally fall between 4.0 and 5.0 mEq/L, may not be the best index to reflect imbalances. The body may lose a third to a half of its intracellular potassium reserves before the loss is reflected in lowered plasma potassium levels.

Potassium deficit, or **hypokalemia,** occurs whenever there is cell breakdown, as in starvation, burns, trauma, or dehydration. As individual cells disintegrate, potassium enters the extracellular fluid and is rapidly excreted because it is not reabsorbed efficiently by the kidney.

Cycle of LIFE

Fluid and Electrolyte Balance

Although the amount of total water in the body does not vary much from day to day, the proportions of water to fat and dry solids in the body changes noticeably over the life span. Figure 32-18 shows the shift in water percentages (of body mass) over the lifespan. As the diagram clearly shows, we start life with over two thirds of our body mass being water and progress to about half of body mass being water in adulthood. Because muscles and other metabolically active cells are high in water content, active adults have more water content than nonactive adults. Often, we become less active during late adulthood—a factor that contributes to less water in our bodies as we age. Advanced age can also bring on some of the kidney problems mentioned earlier in this chapter that can affect our ion balance as well.

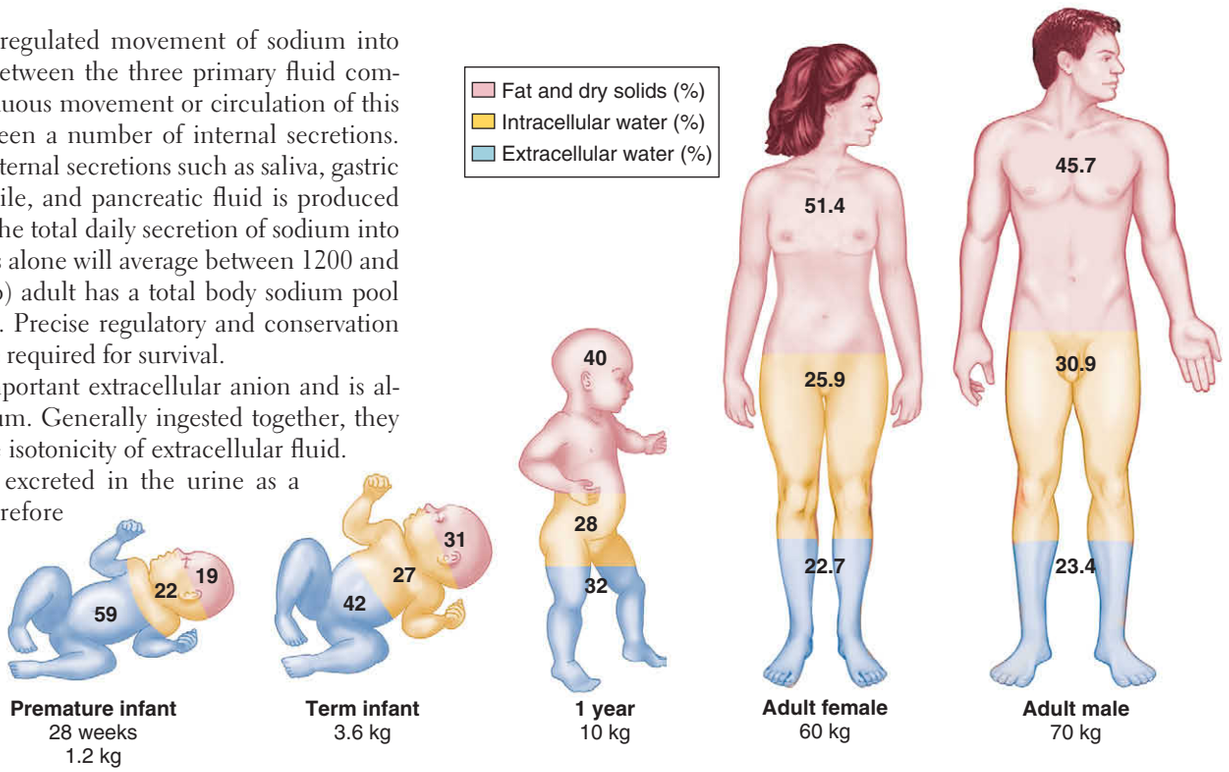

FIGURE 32-18

Body water over the life span. Fluid and nonfluid components of the body expressed as percentage of body weight.

the BIG picture

Fluid and Electrolyte Balance

In discussing the chemical basis for life in Chapter 2, water was described as the "cradle of life." Each of the more than 100 trillion cells that make up the human body must be bathed in a precisely controlled and homeostatically regulated fluid medium. That medium, ever-changing and yet remarkably constant when a condition of homeostasis exists, fills the cells, interstitial spaces, and blood vessels of the body.

Although unique differences in many variables, such as specific fluid volumes, buffers, electrolyte levels, nutrients, circulating wastes, and protein concentrations, exist in each of the body's fluid compartments at any point in time, these changing concentrations and volumes remain within amazingly narrow ranges of their set point normal values in a healthy individual.

Recall from previous chapters that many ions must exist in precise balances within various fluid compartments of the body for normal operation of many vital functions. For example, proper calcium ion balance is required in bone formation or reabsorption, contraction of all three muscle types, synaptic transmission, some types of endocrine signal transduction, and other potentially vital functions. Sodium and potassium concentrations directly affect impulses in nerves and muscles. Chloride balance can affect sodium balance and thus also affect nerve and muscle function. And also recall that acids and bases are ions, and thus pH homeostasis is related to ion homeostasis.

Disease states, atypical circumstances such as fluid deprivation or specific electrolyte losses, as well as normal day-to-day variation in our fluid and nutrient intake, cause the body to initiate "compensatory activities" that help restore or maintain homeostasis. These activities often involve complex neuroendocrine responses that affect multiple body organ systems, including the muscular, digestive, cardiovascular, respiratory, and urinary systems. Homeostasis of fluid and electrolyte levels are one of the most crucial "big picture" requirements for the maintenance of life itself. Every cell and organ system in the body—every physiological response—depends on maintenance of homeostasis in these critical areas.

MECHANISMS of DISEASE

FLUID AND ELECTROLYTE DISORDERS

Fluid Imbalances

Total body water makes up 40% to 60% of body weight in adults and is regulated by homeostatic mechanisms of the neuroendocrine system, heart, kidneys, and blood vessels. Normal water losses, known as insensible water losses, occur through expired air from the lungs and from the skin, making up about 0.4 to 0.5 ml/hr/kg body weight. Abnormally excessive water losses produce a decline in the volume of body fluid and can lead to a state of dehydration, or **hypovolemia,** in which there is inadequate fluid volume in the extracellular compartment (see Box 32-2). If left untreated, it can result in hypovolemic shock. Many causes of dehydration exist. The most common cause of dehydration is fluid loss from the gastrointestinal tract as a result of vomiting or diarrhea. Dehydration also occurs when an individual fails to take in sufficient oral fluid because of depression, nausea, or oral trauma. *Diaphoresis,* or excessive perspiration, may also cause dehydration, with rapid respirations leading to water vapor losses. Any disorder of the kidneys that increases urine excretion, such as nephritis, can lead to dehydration. Fluid can also shift into a space outside the normal fluid compartments during certain disease states, including ascites, burns, pancreatitis, and traumatic injuries. Regardless of the cause, fluid volume deficits cause low blood pressure and cardiac output, electrolyte disturbances, or acid-base abnormalities. Symptoms include dizziness, lightheadedness, weakness, poor skin turgor, and tachycardia. Restoration of the fluid losses is the main goal of therapy. If the deficit is mild, volume can be replaced orally. If the dehydration is severe, fluid volume is replaced intravenously. Examining the person's weight, skin turgor, blood pressure, and urine output will provide important data on fluid volume stability.

Fluid volume excess, or **hypervolemia,** is an expansion of fluid volume in the body. This can occur if the kidneys retain a large amount of sodium and water, as in congestive heart failure, nephrotic syndrome, renal failure, and liver failure. Manifestations include weight gain (the most consistent sign), edema, dyspnea, tachycardia, and pulmonary congestion. Approaches to this disorder are to treat the original pathological process (i.e., renal failure), monitor the person's weight closely, and use diuretics cautiously to remove the excess fluid (Box 32-3).

Water intoxication may result from rapidly drinking large volumes of water or giving hypotonic solutions to persons unable to dilute and excrete urine normally. This may occur in patients with kidney insufficiency or abnormal "thirst" mechanisms resulting from neurological disorders. Water content is elevated, and plasma sodium levels are diluted. Development of subtle mental changes such as confusion and lethargy occur. If intoxication is severe, stupor, seizures, and coma may result. Correction of the neurological impairment along with water restriction can reverse the symptoms.

Water intoxication can happen in normal individuals if water intake is rapid enough that the urinary mechanisms of water loss cannot keep up. Although this is unusual, it can happen—as witnessed by millions a few years ago when a radio station held a "water drinking race" on the air and a contestant died from the effects of severe water intoxication.

Box 32-3 | HEALTH matters

Diuretics

The word **diuretic** is from the Greek word *diouretikos,* meaning "causing urine." By definition, a diuretic drug is a substance that promotes or stimulates the production of urine.

As a group, diuretics are among the most commonly used drugs in medicine. They are used because of their role in influencing water and electrolyte balance, especially sodium, in the body. Diuretics have their effect on tubular function in the nephron, and the differing types of diuretics are often classified according to their major site of action. Examples include (1) *proximal tubule diuretics* such as acetazolamide (Diamox), (2) *Henle loop diuretics* such as ethacrynic acid (Edecrin) or furosemide (Lasix), and (3) *distal tubule diuretics* such as chlorothiazide (Diuril).

Diuretics can also be classified according to the effect the drug has on the level or concentration of sodium (Na^+), chloride (Cl^-), potassium (K^+), and bicarbonate (HCO_3^-) ions in the tubular fluid.

Implications for caregivers monitoring patients receiving diuretics both in hospitals and in home health care environments include keeping a careful record of fluid intake and output and assessing the patient for signs and symptoms of electrolyte and water imbalance. For example, diuretic-induced dehydration resulting in a loss of only 6% of initial body weight will cause tingling in the extremities, stumbling gait, headache, fever, and an increase in both pulse and respiratory rates.

Electrolyte Imbalances

Disturbances in electrolytes can occur in fluid volume abnormalities and many different disease states. **Hyponatremia** is a condition of decreased plasma sodium concentration below the normal range (less than 136 mEq/L) and is usually the result of an excess of water relative to solute. It may also result from excessive losses of sodium. Causes of hyponatremia include skin losses via profuse perspiration, overzealous use of salt-wasting diuretics, adrenal insufficiency, renal or liver failure, low salt intake, or excessive water intake (diluting sodium content). Signs and symptoms include muscle cramps, nausea and vomiting, postural blood pressure changes, poor skin turgor, fatigue, and difficulty breathing. Cerebral swelling can occur in severe cases, causing confusion, hemiparesis (motor weakness on one side of the body), seizures, and coma. Management includes neurological assessment and the administration of sodium orally or intravenously. Water restriction may also suffice.

Hypernatremia is elevation of the plasma sodium concentration higher than 145 mEq/L. It is usually indicative of a body water deficit relative to sodium, but can also result from grossly elevated sodium intake. Causes include lack of fluid intake, diarrhea, diabetes insipidus, loss of water via the respiratory tract, heart disease or congestive heart failure, renal failure, or ingestion of salt in abnormal amounts. Signs and symptoms are similar to those of dehydration and include thirst, disorientation, lethargy, and seizures. The neurological symptoms are thought to be due to cellular dehydration. Replacement with a hypotonic solution will help lower the sodium level slowly, thereby reducing the risk for cerebral edema.

A common type of electrolyte imbalance is **hypokalemia,** a condition in which potassium is lost from the body, resulting in a plasma potassium level below 3.5 mEq/L. Causes include potassium-wasting diuretics, increased urine output with loss of potassium, and vomiting or gastric suctioning without potassium replacement. Hypokalemia can be life threatening and includes manifestations of anorexia, muscle weakness, decreased reflexes, low blood pressure, and cardiac dysrhythmias. Potassium can be replaced through the diet, with potassium-rich foods, or intravenously with caution.

The opposite of hypokalemia is **hyperkalemia,** or a plasma potassium level above 5.5 mEq/L. This can be even more dangerous than hypokalemia because myocardial muscle can be profoundly affected. The common cause of hyperkalemia is kidney disease, but other factors such as vomiting, diarrhea, potassium-conserving diuretics, extensive tissue damage as in burn or trauma victims, severe infections, and Cushing syndrome are also cited. Notable changes can be seen on the electrocardiogram, such as peaked T waves. Hyperkalemia can induce ventricular dysrhythmias, thereby leading to possible cardiac arrest. Because potassium is a part of neuromuscular functions, the person may experience extremity muscle weakness or failure of the respiratory muscles. Intermittent diarrhea, nausea, and intestinal colic are also manifested. Dietary restriction of potassium is sufficient in mild cases, but emergency intravenous administration of calcium gluconate may be required to correct cardiac symptoms. Also, correction of the underlying condition (i.e., trauma) and dialysis to remove the excess potassium can be instituted to correct severe hyperkalemia.

CASE study

The Louisiana sun beat down on Whitney's head as she and her classmates cleared rubble around what used to be their college's courtyard before the hurricane. Her shirt was soaked with sweat, and she kept having to wipe her forehead as sweat dripped into her eyes. Whitney knew she should be drinking more water, but the cooler was on the bus—two blocks away. She just didn't have the energy to face that walk. "We'll be finished in just another hour," she thought. As she bent down to pick up a cement block, she suddenly felt dizzy and sat down quickly.

Whitney's teacher rushed over, felt her skin and pulse and said, "You haven't been drinking any water today, have you?"

1. What is your best diagnosis for Whitney's condition?
   a. Hypervolemia
   b. Ascites
   c. Hypovolemia
   d. Hypokalemia

2. What would be the best fluid to give Whitney now?
   a. Distilled water
   b. Cold beer
   c. Cold soda
   d. A sports drink

3. What two hormones will be released to compensate for Whitney's condition?
   a. ADH and aldosterone
   b. Estrogen and renin
   c. Aldosterone and TSH
   d. Renin and angina

Scan this summary after reading the chapter to help you reinforce the key concepts. Later, use the summary as a quick review before your class or before a test.

INTERRELATIONSHIP OF FLUID AND ELECTROLYTE BALANCE

A. Fluid and electrolyte balance—implies homeostasis
B. Electrolytes have chemical bonds that allow dissociation into ions, which carry an electrical charge; of critical importance in fluid balance
C. Fluid balance and electrolyte balance are interdependent

TOTAL BODY WATER

A. Fluid content of the human body ranges from 45% to 75% of its total weight
B. Fluid content varies according to age, gender, weight, and fat content of the body

BODY FLUID COMPARTMENTS

A. Two major fluid compartments (Figure 32-1)
B. Extracellular fluid (ECF) makes up the internal environment of the body
   1. Consists mainly of plasma and interstitial fluid
   2. Lymph, cerebrospinal fluid, and joint fluids are considered extracellular
   3. ECF provides a relatively constant environment for cells and transports substances to and from the cells
C. Intracellular fluid (ICF)—water inside the cells
   1. ICF facilitates intracellular chemical reactions that maintain life
   2. By volume, ICF is the largest body fluid compartment

CHEMICAL CONTENT, DISTRIBUTION, AND MEASUREMENT OF ELECTROLYTES IN BODY FLUID

A. Extracellular vs. intracellular fluids
   1. Plasma and interstitial fluid (ECFs) are almost identical in chemical make-up; intracellular fluid quite different in comparison (Figure 32-3)
   2. Differences between extracellular fluids (blood and interstitial fluid)
      a. Blood contains a slightly larger total of ions than interstitial fluid does
      b. Functionally important difference between blood and interstitial fluid
         (1) Blood has appreciable amount of protein anions, whereas interstitial fluid has hardly any
         (2) Because the capillary membrane is practically impermeable to proteins, almost all protein anions remain in the blood
   3. Chemical structure of plasma, interstitial fluid, and intracellular fluid helps control water and electrolyte movement between them
B. Measuring electrolyte reactivity
   1. Concentration or weight of an electrolyte can be expressed as the number of milligrams per 100 ml of solution (mg %); conversion of mg% to milliequivalents per liter (mEq/L) provides information on actual physiological activity
   2. Milliequivalent—measures the number of ionic charges or electrocovalent bonds in a solution; accurately measures the physiological combining power of an electrolyte solution

AVENUES BY WHICH WATER ENTERS AND LEAVES THE BODY

A. Water enters the body via the digestive tract; water is also added to the total fluid volume from each cell as it catabolizes food, and the resulting water enters the bloodstream (Figure 32-5)
B. Water leaves the body via four exits (Figure 32-5)
   1. As urine through the kidney
   2. As water in expired air through the lungs
   3. As sweat through the skin
   4. As feces from the intestine

SOME GENERAL PRINCIPLES ABOUT FLUID BALANCE

A. Cardinal principle of fluid balance: fluid balance can be maintained only if intake equals output
B. Mechanisms are available to adjust output and intake to maintain fluid balance, e.g., renin-angiotensin-aldosterone system (RAAS) (Figures 32-6 and 32-8)
C. Most rapid fluid balance mechanisms are those for controlling water movement between fluid compartments of the body; will maintain normal blood volume at the expense of interstitial fluid volume

MECHANISMS THAT MAINTAIN HOMEOSTASIS OF TOTAL FLUID VOLUME

A. Under normal conditions, homeostasis of total volume of water is maintained or restored primarily by adjusting urine volume and secondarily by fluid intake (Figure 32-7)
B. Regulation of fluid intake—decrease in fluid intake causes osmoreceptors in "thirst center"—wall of third ventricle (subfornical organ) and in supraoptic and paraventricular nuclei of hypothalamus—to increase secretion of ADH (Figure 32-16)
C. Regulation of urine volume—determined by two factors
   1. Glomerular filtration rate, except under abnormal conditions, remains fairly constant
   2. Rate of tubular reabsorption of water fluctuates considerably; normally adjusts urine volume to fluid intake; influenced by amount of antidiuretic hormone and aldosterone

D. Factors that alter fluid loss under abnormal conditions
   1. Rate of respiration and volume of sweat secreted may alter fluid output under certain abnormal conditions
   2. Vomiting, diarrhea, or intestinal drainage can produce fluid and electrolyte imbalances; symptoms range from simple thirst to muscle weakness and kidney failure

REGULATION OF WATER AND ELECTROLYTE LEVELS IN PLASMA AND INTERSTITIAL FLUID

A. Law of capillaries—the control mechanism for water exchange between plasma and interstitial fluid consists of four types of pressure: blood hydrostatic and colloid osmotic pressure on one side of the capillary membrane and interstitial fluid hydrostatic and colloid osmotic pressure on the other side; two of the pressures produce a vector in one direction and the other two in the opposite direction
   1. Blood hydrostatic pressure (BHP) forces fluid out of capillaries into interstitial fluid (IF)
   2. Blood colloid osmotic pressure (BCOP) draws fluid from IF into capillaries
   3. Interstitial fluid hydrostatic pressure (IFHP) forces fluid out of IF into capillaries
   4. Interstitial fluid colloid osmotic pressure (IFCOP) draws fluid from capillaries to IF

B. The rate and direction of fluid exchange between capillaries and interstitial fluid are determined by the hydrostatic and colloid osmotic pressure of the two fluids (Figure 32-10)

C. Some principles about transfer of water between blood and interstitial fluid
   1. No net transfer of water occurs as long as (BHP + IFCOP) = (IFHP + BCOP)
   2. A net transfer of fluid occurs when (BHP + IFCOP) ≠ (IFHP + BCOP)
   3. Fluid shifts out of blood into interstitial fluid whenever (BHP + IFCOP) > (IFHP + BCOP)
   4. Fluid shifts out of interstitial fluid into blood whenever (BHP + IFCOP) < (IFHP + BCOP)

D. Edema—classic example of fluid imbalance
   1. Defined as presence of abnormally large amounts of fluid in the intercellular tissue spaces of the body (Figure 32-11)
   2. Can be caused by disturbances in any factors that govern interchange between blood plasma and interstitial fluid compartments
      a. Retention of electrolytes in the extracellular fluid
      b. Increase in capillary blood pressure
      c. Decrease in the concentration of plasma proteins normally retained in the blood (Figure 32-12)

REGULATION OF WATER AND ELECTROLYTE LEVELS IN INTRACELLULAR FLUID

A. Plasma membrane plays critical role in regulating ICF composition

B. IF and ICF hydrostatic and colloid pressure regulates water transfer between ECF and ICF
   1. Colloid osmotic pressure is the chief regulator of water transfer across cell membranes
   2. Colloid osmotic pressure is directly related to the electrolyte concentration gradients maintained across cell membranes (Figure 32-14)

REGULATION OF SODIUM AND POTASSIUM LEVELS IN BODY FLUIDS

A. Normal sodium concentration in IF and potassium concentration in ICF depend on various factors, especially the amount of ADH and aldosterone secreted
   1. ADH regulates ECF electrolyte concentration and colloid osmotic pressure by regulating amount of water reabsorbed into blood by renal tubules
   2. Aldosterone regulates ECF volume by regulating the amount of sodium reabsorbed into blood by renal tubules

B. Kidneys are considered the chief regulator of sodium levels; when conservation of body sodium is required, the kidneys excrete an essentially sodium-free urine

C. Chloride—most important extracellular anion and almost always linked to sodium
   1. Chloride ions generally excreted in urine in association with potassium
   2. Thus hypochloremia is often associated with cases of potassium loss

D. Hypokalemia (potassium deficit) occurs where there is cell breakdown
   1. Examples: starvation, burns, trauma, dehydration
   2. As cells disintegrate, potassium enters the ECF and is rapidly excreted because it is not reabsorbed efficiently by the kidney

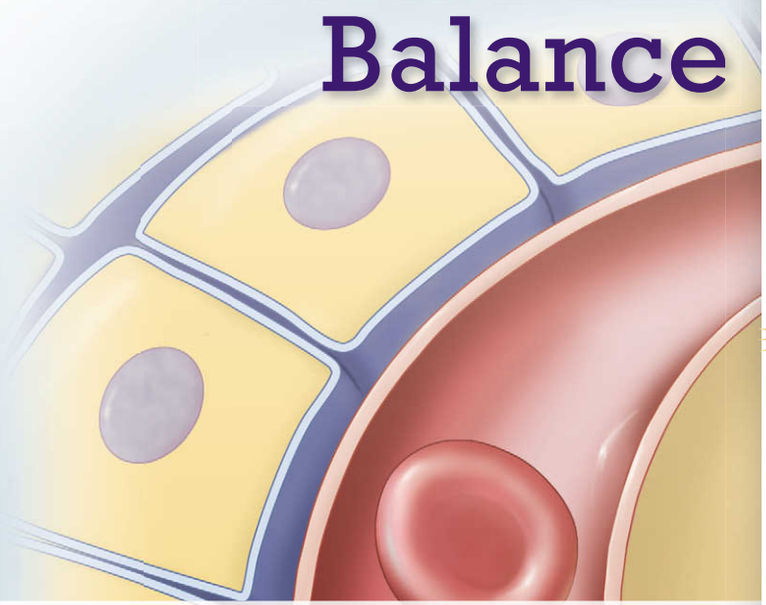
REVIEW QUESTIONS

Write out the answers to these questions after reading the chapter and reviewing the Chapter Summary. If you simply think through the answer without writing it down, you won't retain much of your new learning.

1. Discuss the changes in total body water content from infancy to adulthood.
2. How does total body water content differ in men and women?
3. List the compartments of extracellular fluid.
4. What are the four exits by which water normally leaves the body?
5. What are the objectives for giving parenteral solutions?
6. What is the cardinal principle regarding fluid balance?
7. How is urine volume regulated?
8. Define the terms *cation* and *anion*.
9. Are plasma and interstitial fluid chemically similar or different? Explain.
10. Describe the electrolyte composition of blood plasma.
11. Define the term *milliequivalent*. How is it used to measure electrolyte reactivity?
12. What are the four pressures involved in Starling's law?

13. When effective filtration pressure equals 0, what is the net transfer of water between blood and interstitial fluid?
14. When does a "fluid shift" occur between blood and interstitial fluid?
15. Identify various mechanisms that may lead to edema.
16. What role does the plasma membrane play in the regulation of intracellular fluid composition?
17. How does the antidiuretic hormone mechanism maintain homeostasis of extracellular fluid colloid osmotic pressure?
18. In your own words, define dehydration.

CRITICAL THINKING QUESTIONS



After finishing the Review Questions, write out the answers to these more in-depth questions to help you apply your new knowledge. Go back to sections of the chapter that relate to concepts that you find difficult.

1. How would you define fluid and electrolyte balance? Based on what you know, what would be the impact of glucose deficiency on the electrolyte balance of the body?
2. How would you summarize the role of aldosterone in thirst?
3. Can you make a distinction between anions in the two extracellular fluids? What causes this difference?
4. How would you explain Starling's law of the capillaries?
5. How does hyponatremia lead to fluid imbalance? Can you identify the possible causes?
6. Where are osmoreceptors located, and how are they related to the maintenance of fluid balance?
7. What information would you use to support the view that the homeostasis of fluid and electrolyte levels is one of the most crucial requirements for the maintenance of life itself?

Acid-Base Balance

Acid-base balance is one of the most important of the body's homeostatic mechanisms. The term refers to regulation of hydrogen ion concentration in the body fluid. Therefore the study of acid-base physiology is, in a very real sense, the study of the hydrogen ion (H^+).

Many of the body's most biologically important molecules contain chemical groups that can either "donate" or "accept" a hydrogen ion (H^+) and thus behave as a weak acid or base. As a molecule's pH changes so does its shape and biological activity. The shape and functional ability of ion channels, membrane receptors, hemoglobin, and a variety of enzymes and other important body proteins closely depends on the maintenance of precise regulation of hydrogen ion concentration. Thus, even slight deviations from the normal pH range in body cells and fluids result in pronounced, systemic, and potentially fatal changes in metabolic activity. For example, activity of the Na-K pump, arguably the most important active transport mechanism in the cell membrane, falls by 50% when pH decreases by approximately 1 pH unit. An even more dramatic effect is seen in the activity of a key enzyme (phosphofructokinase) involved in the breakdown of glucose in the absence of O_2 during anaerobic catabolism (glycolysis). The biological activity of this key enzyme falls by approximately 90% when the pH decreases by only 0.1 unit!

Maintaining acid-base balance within narrow and precise ranges is necessary for survival.

MECHANISMS THAT CONTROL pH OF BODY FLUIDS

Review of the pH Concept

Recall from Chapter 2 that water and all water solutions contain hydrogen ions (H^+) and hydroxide ions (OH^-). pH is a symbol used to represent the negative logarithm (exponent of 10) of the number of hydrogen ions (H+) present in 1 liter of a solution. It is expressed as a number between 0 and 14. In Figure 33-1 the pH value is shown on the right side of the scale and the corresponding logarithmic value is on the left. Take a moment to review the pH unit. **pH** indicates the degree of **acidity** or **alkalinity** of a solution. As the concentration of hydrogen ions increases, the pH goes down and the solution becomes more acid; a decrease in hydrogen ion concentration makes the solution more **alkaline** and the pH goes up. A pH of 7 indicates neutrality (equal amounts of H^+ and OH^-), a pH of less than 7 indicates acidity (more H^+ than OH^- and a pH greater than 7 indicates alkalinity (more OH^- than H^+). With a pH of about 1, gastric juice is the most acid substance in the body.

With a pH of 7.0, intracellular fluid is essentially neutral. Arterial and venous blood are slightly alkaline because both have a pH slightly higher than 7.0. The slight increase in acidity of venous blood (pH 7.36) compared with arterial blood (pH 7.40) results primarily from carbon dioxide entering venous blood as a waste product of cellular metabolism. Although any pH value above 7.0 is considered chemically basic, in clinical medicine the term **acidosis** is used to describe an arterial blood pH of less than 7.35 and **alkalosis** is used to describe an arterial blood pH greater than 7.45. The lungs remove the equivalent of more than 30 liters of carbonic acid each day from the venous blood by elimination of carbon dioxide, and yet 1 liter of venous blood contains only about 1/100,000,000 grams more hydrogen ions than does 1 liter of arterial blood. What incredible constancy! The pH homeostatic mechanism does indeed control effectively—astonishingly so.

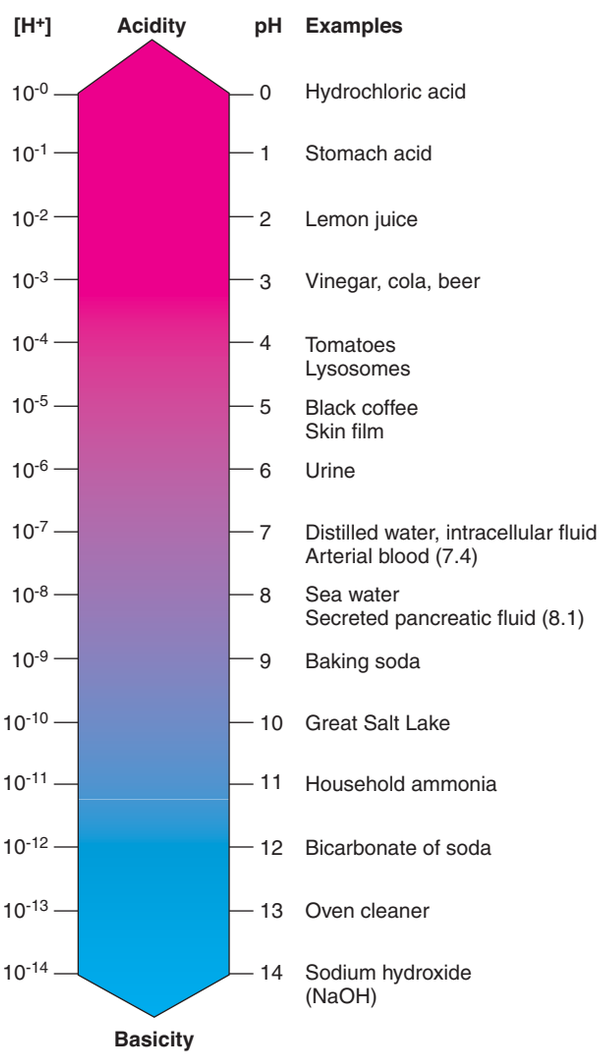

FIGURE 33-1

The pH range. See text for discussion.

Sources of pH-Influencing Chemicals

Acids and **bases** continually enter the blood as a result of absorbed foods and the metabolism of nutrients at the cellular level. Therefore, some kind of mechanism for neutralizing or eliminating these substances is necessary if blood pH is to remain constant. Although both acidic and basic components are important, the homeostasis of body pH depends largely on the control of hydrogen ion concentration in the extracellular fluid. Hydrogen ions are continually entering the body fluids from (1) carbonic acid, (2) lactic acid, (3) sulfuric acid, (4) phosphoric acid, and (5) acidic ketone bodies.

Carbonic and lactic acids are produced by the aerobic and anaerobic metabolism of glucose, respectively. Sulfuric acid is produced when sulfur-containing amino acids are oxidized, and phosphoric acid accumulates when certain phosphoproteins and ribonucleotides are broken down for energy purposes. Acidic ketone bodies, which include *acetone*, *acetoacetic acid*, and *beta-hydroxybutyric acid*, accumulate during the incomplete breakdown of fats. Each of these acids contributes hydrogen ions in varying amounts to the extracellular fluid and influences acid-base balance. Toxic accumulation of acidic ketone bodies is a common complication of untreated diabetes mellitus.

Minerals that remain after food has been metabolized are said to be either acid-forming minerals or base-forming minerals, depending on whether they contribute to formation of an acidic or basic medium when in solution. Acid-forming elements include chlorine, sulfur, and phosphorus—all are abundant in high-protein foods such as meat, fish, poultry, and eggs. They are also present in some grains such as wheat, corn, and oats. These foods are often designated as acid-forming foods.

After metabolism is complete, most mixed diets contain a surplus of acid-forming mineral elements that must be continually buffered to maintain acid-base balance. Extremely high-protein diets that produce a predominantly *acid mineral residue* when metabolized may tax the body's ability to remain in acid-base balance if consumed over prolonged periods.

Mineral elements that are alkaline, or basic, in solution include *potassium*, *calcium*, *sodium*, and *magnesium*. All these elements are found in fruits and vegetables, which nutritionists often label as *base-forming foods*. The predominantly *basic residue* that results after metabolism of a strict vegetarian diet may also tax the ability of the body to maintain acid-base balance because of a high influx of alkaline components into the extracellular fluid.

Foods containing acids that cannot be metabolized, such as rhubarb (oxalic acid) and cranberries (benzoic acid), are said to be direct acid-forming foods, whereas antacids such as sodium bicarbonate and calcium carbonate are examples of direct base-forming substances. Box 33-1 gives some examples of acid-forming and base-forming foods.

| QUICK CHECK |

1. Define the term *pH*.
2. Is a solution with a pH above 7 acid or alkaline?
3. Identify three acid-forming and three base-forming elements.
4. Does CO_2 entering venous blood increase or decrease the pH level?

Box 33-1 | FYI

Acid-Forming and Base-Forming Potential of Foods

Examples of foods that have acid-forming characteristics include corn and corn oil, olives and olive oil, blueberries (see figure), cranberries, oats, wheat, rice, peanuts, red beans, black beans, butter, cheese, beef, fish, pork, turkey, canola oil, and sugar. On the other hand, many of the foods we eat may have base-forming characteristics, such as peppers, sea salt, tofu, almonds, mineral water, citrus fruits, grapes, blackberries, bananas, tomatoes, apples, green beans, lettuce, garlic, broccoli, carrots, and avocado.

Blueberries. Blueberries have an acid-forming effect.

Types of pH Control Mechanisms

The two major types of control systems listed in Table 33-1—chemical and physiological—operate to maintain the constancy of body pH.

In the discussion that follows, buffer action is defined and the specific types of *chemical* and *physiological buffer systems* are discussed. The rapid-acting **chemical buffers** immediately combine with any added acid or alkali that enters the body fluids and thus prevent drastic changes in hydrogen ion concentration and pH. As explained later, all **buffers** act to prevent swings in pH even if hydrogen ion concentrations change. If the immediate action of chemical buffers cannot stabilize pH, the **physiological buffers**

TABLE 33-1 pH Control Systems

TYPE	RESPONSE TIME	EXAMPLE
Chemical buffer systems	Immediate	Bicarbonate buffer system Phosphate buffer system Protein buffer system
Physiological buffer systems	Minutes Hours	Respiratory response system Renal response system

serve as a secondary defense against harmful shifts in pH of body fluids. pH shifts that are not halted by the immediate effects of chemical buffering cause the respiratory system to respond in 1 to 2 minutes, and changes in the rate and depth of breathing occur. For reasons explained later, such changes in carbon dioxide levels alter hydrogen ion concentration and help stabilize pH. If respiratory mechanisms are unable to stop the pH shift, a more powerful, but slower-acting, renal physiological buffer system involving the excretion of either an acid or alkaline urine will be initiated within 24 hours. Collectively, these mechanisms—buffers, respirations, and kidney excretion of acids and bases—might be said to make up the *pH homeostatic mechanism*. One example of the relationship between these three mechanisms is shown in Figure 33-2. The equilibrium between hydrogen ions, carbonic acid, bicarbonate, and carbon dioxide within red blood cells illustrates the interrelated nature of the pH control mechanisms. Note that an increase in body carbon dioxide levels results in excess acid formation in red blood cells, which is counteracted by a corresponding increase in elimination of both carbon dioxide by the lungs and excess hydrogen ion in the urine.

Effectiveness of pH Control Mechanisms—Range of pH

The most convincing evidence of the effectiveness of the pH control mechanism is the extremely narrow range of blood pH—normally 7.36 to 7.41. Maintaining the body's pH within this narrow range is essential to sustain healthy life. Moving outside this pH range causes disruption of many of the body's essential chemical processes.

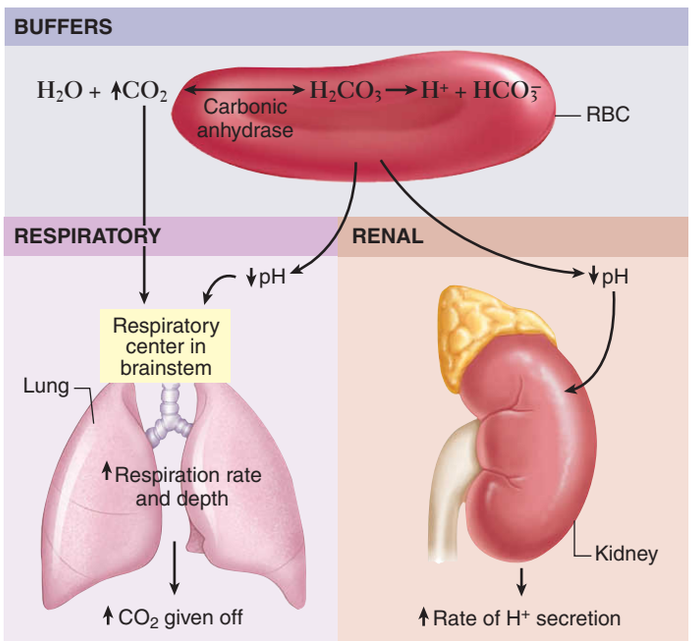

FIGURE 33-2

Integration of pH control mechanisms. Elevated carbon dioxide (CO_2) levels result in increased formation of carbonic acid in red blood cells. The resulting increase in hydrogen ions, coupled with elevated CO_2 levels, results in an increase in respiratory rate and secretion of hydrogen ions (H^+) by the kidneys, thus helping regulate the pH of body fluids.

BUFFER MECHANISMS FOR CONTROLLING pH OF BODY FLUIDS

Buffers Defined

In terms of action, a **buffer** is a substance that prevents marked changes in the pH of a solution when an acid or a base is added to it. Let us suppose that a small amount of a strong acid, hydrochloric acid, is added to a solution that contains a buffer (e.g., blood) and that its pH decreases from 7.41 to 7.27. If the same amount of hydrochloric acid were added to pure water containing no buffers, its pH would decrease much more markedly, from 7 to perhaps 3.4. In both instances, pH decreased after addition of the acid, but much less so with buffers present than without them. Stated another way, buffers do not prevent pH changes, but they do help to minimize them.

In terms of chemical composition, buffers consist of two kinds of substances and are therefore often referred to as **buffer pairs**.

Buffer Pairs Present in Body Fluids

Most of the body fluid buffer pairs consist of a weak acid and a salt of that acid. The main buffer pairs in body fluids are the following:

$$\text{Bicarbonate pairs: } \frac{NaHCO_3}{H_2CO_3}, \frac{KHCO_3}{H_2CO_3}, \text{ etc.}$$

$$\text{Plasma • protein pair: } \frac{\text{Na • Proteinate}}{\text{Proteins (weak acids)}}$$

$$\text{Hemoglobin pairs: } \frac{K \bullet Hb}{Hb} \text{ and } \frac{K \bullet HbHO_2}{HbO_2}$$

(Hb and HbO_2 are weak acids)

$$\text{Phosphate buffer pair: } \frac{Na_2HPO_4}{NaH_2PO_4} \frac{\text{(basic phosphate)}}{\text{(acid phosphate)}}$$

Buffer Actions That Prevent Marked Changes in pH of Body Fluids

Buffers react with a relatively strong acid (or base) to transform it into a relatively weak acid (or base). That is, an acid that highly dissociates to yield many hydrogen ions is changed into a weaker acid that dissociates less highly to yield fewer hydrogen ions. Thus by way of the buffer reaction, instead of the strong acid remaining in the solution and contributing many hydrogen ions that would drastically lower the pH of the solution, the newly formed weaker acid takes its place, contributes fewer additional hydrogen ions to the solution, and thereby lowers its pH only slightly. Because blood contains buffer pairs, its pH fluctuates much less widely than it would without them. In other words, blood buffers act as one of the mechanisms for preventing marked changes in blood pH.

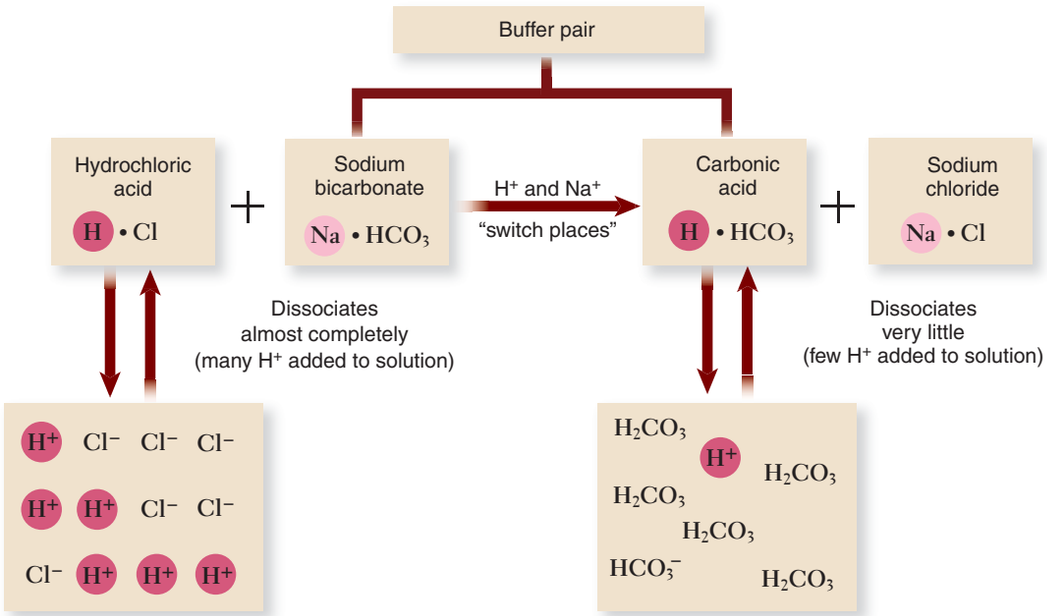

FIGURE 33-3

Buffering action of sodium bicarbonate. Buffering of acid HCl by $NaHCO_3$. As a result of the buffer action, the strong acid (HCl) is replaced by a weaker acid ($H \cdot HCO_3$). Note that HCl, as a strong acid, "dissociates" almost completely and releases more H^+ than does H_2CO_3. Buffering decreases the number of H^+ in the system.

Let us consider, as a specific example of buffer action, how the sodium bicarbonate ($NaHCO_3$)–carbonic acid (H_2CO_3) system works in the presence of a strong acid or base.

The addition of a strong acid, such as hydrochloric acid (HCl), to the sodium bicarbonate–carbonic acid buffer system would initiate the reaction shown in Figure 33-3. Note how this reaction between HCl and the base bicarbonate ($NaHCO_3$) applies the principle of buffering. As a result of the buffering action of $NaHCO_3$, the weak acid, $H \cdot HCO_3$, replaces the very strong acid HCl, and therefore the hydrogen ion concentration of the blood increases much less than it would have if HCl were not buffered.

If, on the other hand, a strong base such as sodium hydroxide (NaOH) is added to the same buffer system, the reaction shown in Figure 33-4 would take place. The hydrogen ion of $H \cdot HCO_3$, the weak acid of the buffer pair, combines with hydroxide ion (OH^-) of the strong base NaOH to form water. Note what this accomplishes. It decreases the number of hydroxide ions added to the solution, and this in turn prevents the drastic rise in pH that would occur in the absence of buffering.

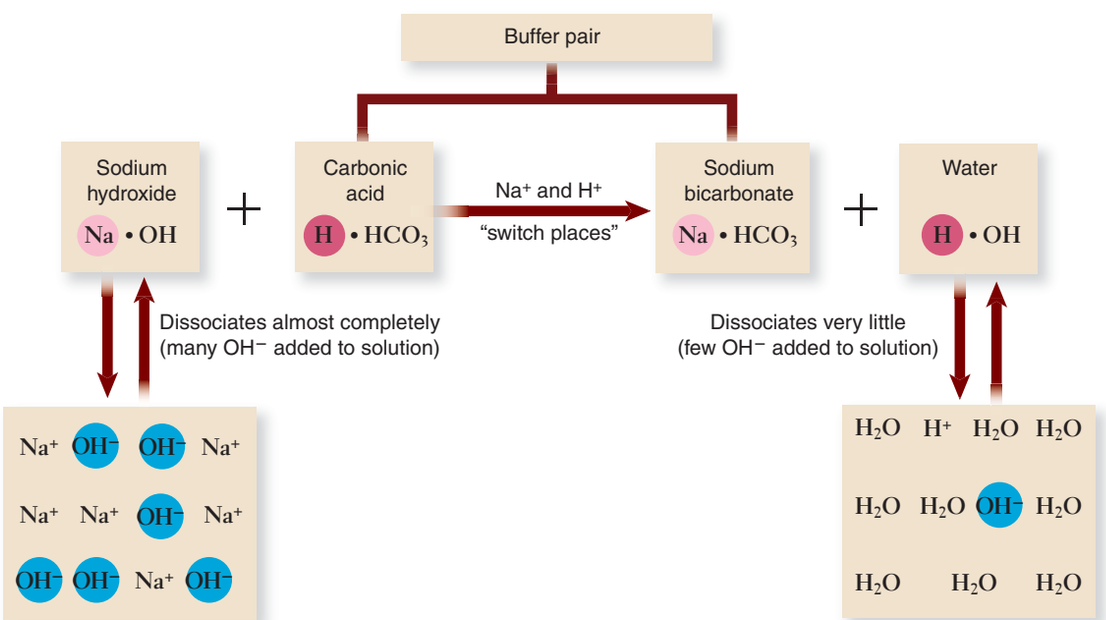

FIGURE 33-4

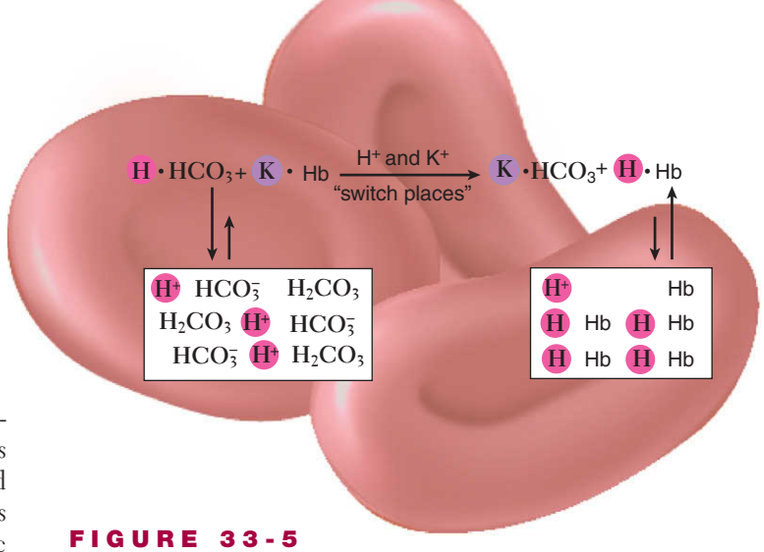
Buffering action of carbonic acid. Buffering of the base NaOH by H_2CO_3. As a result of buffer action, the strong base (NaOH) is replaced by $NaHCO_3$ and H_2O. As a strong base, NaOH "dissociates" almost completely and releases large quantities of OH^-. Dissociation of H_2O is minimal. Buffering decreases the number of OH^- ions in the system.

Box 33-2 discusses how loss of chloride during severe vomiting could affect the balance of buffers in the body and thus increase the body's pH above normal levels.

The principles of buffer action illustrated by the reaction of HCl and NaOH with the sodium bicarbonate buffer pair can be applied equally to the plasma protein, hemoglobin, and phosphate buffer systems.

Carbon dioxide and other acid waste products are being formed continuously as a result of cellular metabolism. The formation of carbonic acid from carbon dioxide and water requires the enzyme **carbonic anhydrase** (see Figure 33-2), which is found in the red blood cells (RBCs). Although there are numerous types of zinc-containing carbonic anhydrases in the body, it is carbonic anhydrase 1, or CA1, that is present in the cytoplasm of erythrocytes and is primarily responsible for the formation of carbonic acid from CO_2 and water in the RBC. Carbonic acid is buffered primarily by the potassium salt of hemoglobin inside the RBC, as shown in Figure 33-5.

It is interesting to note that the $KHCO_3$ formed by the buffering of carbonic acid dissociates in the RBC, and the bicarbonate ion diffuses down its concentration gradient into the blood plasma. Because of the movement of these negatively charged ions out of the RBC, chloride ions move into the cell from the plasma to maintain the electrical balance on both sides of the RBC membrane. The process of exchanging a bicarbonate ion formed in the red blood cell with a chloride ion from the plasma is called the **chloride shift.** This process makes it possible for carbon dioxide to be buffered in the RBC and then carried as bicarbonate in the plasma. Figure 33-6 summarizes the reactions of the chloride shift.



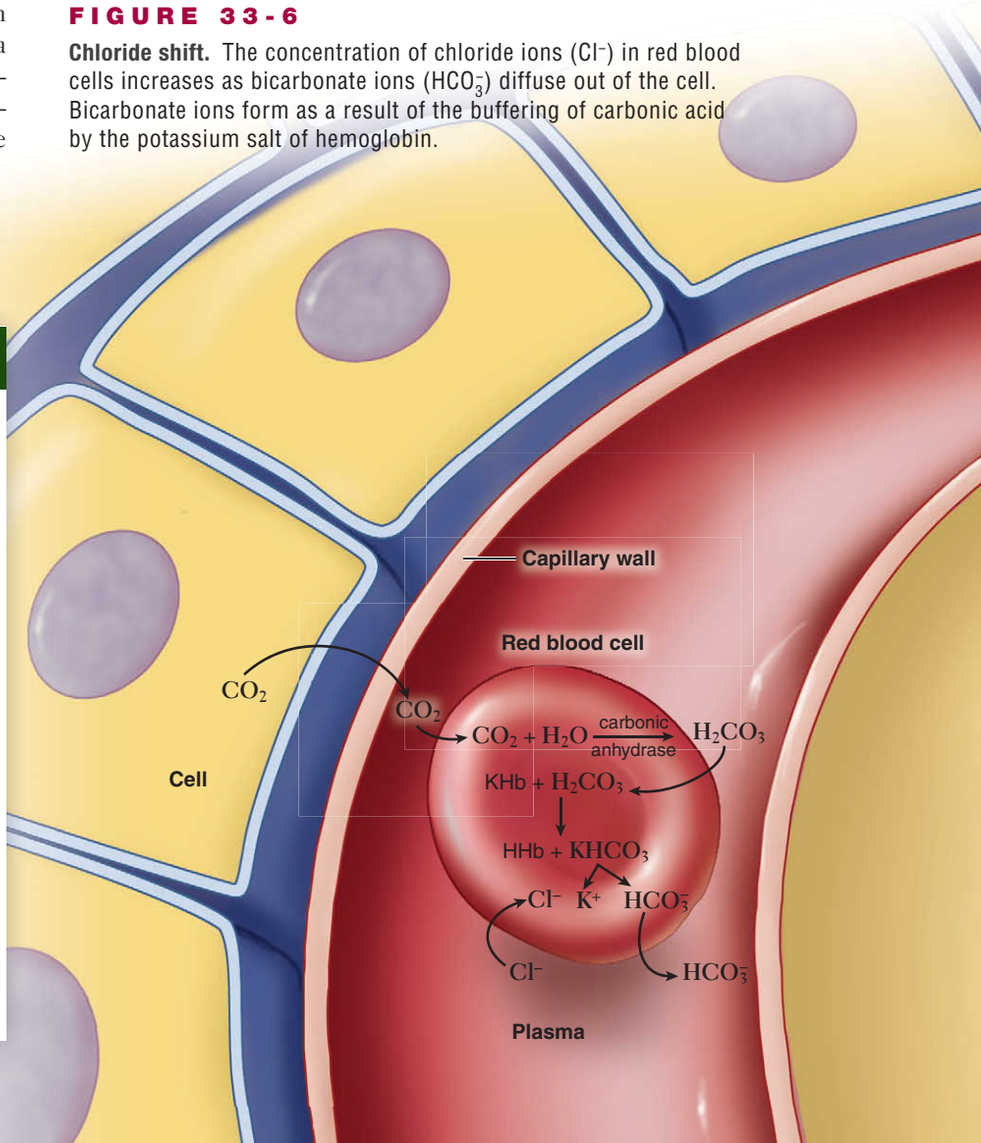


FIGURE 33-5

Buffering of the volatile carbonic acid (H • HCO_3) inside red blood cell by potassium salt of hemoglobin. Note that each molecule of carbonic acid is replaced by a molecule of acid hemoglobin. Because hemoglobin is a weaker acid than carbonic acid, fewer of these hemoglobin molecules dissociate to form hydrogen ions (H^+). Hence, fewer hydrogen ions are added to red blood cell intracellular fluid than would be added by unbuffered carbonic acid. Also, because some of the carbonic acid in the red blood cell has come from plasma, fewer hydrogen ions remain in blood than would have if there were no buffering of carbonic acid.

FIGURE 33-6

Chloride shift. The concentration of chloride ions (Cl^-) in red blood cells increases as bicarbonate ions (HCO_3^-) diffuse out of the cell. Bicarbonate ions form as a result of the buffering of carbonic acid by the potassium salt of hemoglobin.

Box 33-2 | HEALTH matters

Metabolic Alkalosis Caused by Vomiting

Vomiting, sometimes referred to as **emesis,** is the forcible emptying or expulsion of gastric and occasionally intestinal contents through the mouth. It occurs as a result of many stimuli, including foul odors or tastes, irritation of the stomach or intestinal mucosa, and some vomitive or *emetic* drugs such as ipecac. A "vomiting center" in the brain regulates the many coordinated (but primarily involuntary) steps involved (see Figure 29-18, p. 919). Severe vomiting such as the **pernicious vomiting** of pregnancy or the repeated vomiting associated with pyloric obstruction in infants can be life threatening. One of the most frequent and serious complications of vomiting is **metabolic alkalosis.** The bicarbonate excess of metabolic alkalosis results because of the massive loss of chloride from the stomach as hydrochloric acid. It is the loss of chloride that causes a compensatory increase of bicarbonate in the extracellular fluid. The result is *metabolic alkalosis.* Therapy includes intravenous administration of chloride-containing solutions such as **normal saline** (0.9% NaCl in water). The chloride ions of the solution replace bicarbonate ions and thus help relieve the bicarbonate excess responsible for the imbalance.

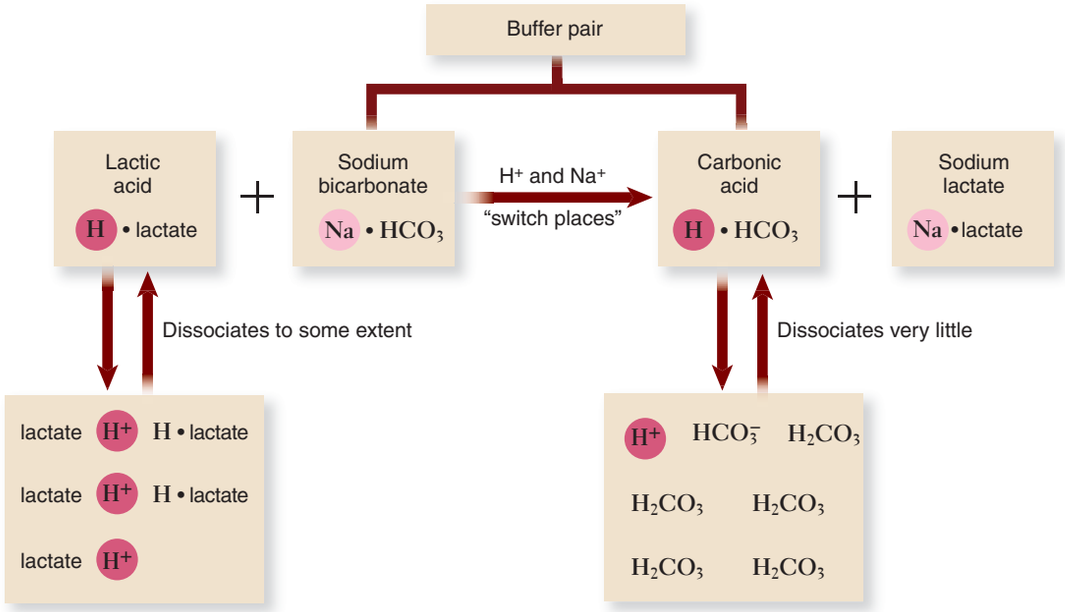

FIGURE 33-7

Lactic acid buffered by sodium bicarbonate. Lactic acid and other "fixed" acids are buffered by $NaHCO_3$ in the blood. Carbonic acid ($H \cdot HCO_3$ or H_2CO_3, a weaker acid than lactic acid) replaces lactic acid. As a result, fewer hydrogen ions (H^+) are added to blood than would be if lactic acid were not buffered.

Nonvolatile, or fixed, acids, such as hydrochloric acid, lactic acid, and ketone bodies, are buffered mainly by sodium bicarbonate (Figure 33-7). Box 33-3 discusses why some athletes consume bicarbonate to counteract the effects of lactic acid produced by exercise. Box 33-4 discusses how an excess of lactic acid can result from the use of a popular diabetes drug.

Normal blood pH and acid-base balance depend on a base bicarbonate–to–carbonic acid buffer pair ratio of 20:1 in the extracellular fluid. Actually, in a state of acid-base balance (pH 7.4), a liter of plasma contains 27 mEq of $NaHCO_3$ as base bicarbonate (BB)—ordinary baking soda—and 1.3 mEq of carbonic acid (CA):

$$\frac{27 \text{ mEq } NaHCO_3}{1.3 \text{ mEq } H_2CO_3} = \frac{BB}{CA} = \frac{20}{1} = \text{pH } 7.4$$

The **ratio** of base to acid is critical. If the ratio is maintained, acid-base balance (pH) remains near normal despite changes in the

Box 33-3 | SPORTS and FITNESS

Bicarbonate Loading

The buildup of lactic acid in the blood, released as a waste product from working muscles, has been blamed for the soreness and fatigue that sometimes accompanies strenuous exercise. Some athletes adopt a technique called **bicarbonate loading,** in which large amounts of sodium bicarbonate ($NaHCO_3$) are ingested to counteract the effects of lactic acid buildup. Their theory is that fatigue is avoided because the $NaHCO_3$, a base, buffers the lactic acid. Unfortunately, the excess bicarbonate intake and diarrhea that often result can trigger fluid and electrolyte imbalances. Long-term $NaHCO_3$ abuse can lead to metabolic alkalosis and its disastrous effects.

Box 33-4 | Lactic Acidosis and Metformin

Metformin hydrochloride (Glucophage) is one of the most widely used and effective of the oral antidiabetic drugs. It is used with diet and exercise to lower blood glucose levels in type 2 diabetes mellitus. A rare but very serious complication of metformin therapy is **lactic acidosis.** It is characterized by elevated blood lactate levels, electrolyte disturbances, and decreased blood pH. It is reported in only about 1 in 33,000 patients taking metformin over the course of a year. However, when it does occur, it can be fatal in nearly 50% of cases. Symptoms include a variety of gastrointestinal and respiratory complaints and feelings of weakness and muscle pain. Patients with kidney and liver disease are known to be at higher risk for lactic acidosis while taking the drug.

absolute amounts of either component of the buffer pair. This type of adjustment is called **compensation.** For example, a BB/CA ratio of 40:2 or 10:0.5 would result in a compensated state of acid-base balance. However, an increase in the ratio causes an increase in pH **(uncompensated alkalosis),** and a decrease in the ratio causes a decrease in pH **(uncompensated acidosis).** The ability of the body to regulate the amount of either component of the bicarbonate buffer pair—to maintain the correct ratio for acid-base balance—makes this system one of the most important for controlling pH of body fluids. **Correction** of acid-base balance is said to occur when components of the buffer pair return to a normal 20:1 ratio.

Evaluation of the Role of Buffers in pH Control

Buffering alone cannot maintain homeostasis of pH. As we have seen, hydrogen ions are added continually to capillary blood despite buffering. If even a few hydrogen ions were added every time blood circulated and no way was provided for eliminating them, blood hydrogen ion concentration would necessarily increase and thereby decrease blood pH. "Acid blood," in other words, would soon develop. Respiratory and urinary mechanisms must therefore function concurrently with buffers to remove from the blood and from the body the hydrogen ions continually being added to blood. Only then can the body maintain constancy of pH over time.

| QUICK CHECK |

5. Define the term *buffer.*
6. Identify the two major types of buffer systems in the body. Which buffer system is the most rapid acting?
7. Using equations, explain the buffering of HCl by sodium bicarbonate and NaOH by carbonic acid.
8. Define the term *chloride shift.*

RESPIRATORY MECHANISMS OF pH CONTROL

Explanation of Respiratory Mechanisms

Respirations play a vital role in controlling pH. With every expiration, carbon dioxide and water leave the body in the expired air. The carbon dioxide comes from the venous blood—diffuses out of it as it moves through the lung capillaries. Therefore, less carbon dioxide remains in the arterial blood leaving the lung capillaries. The lower P_{CO_2} in arterial blood reduces the amount of carbonic acid and the number of hydrogen ions that can be formed in red blood cells by the following reactions:

$$CO_2 + H_2O \xrightarrow{\text{(carbonic anhydrase)}} H_2CO_3$$

$$H_2CO_3 \longrightarrow H^+ + HCO_3^-$$

Arterial blood therefore has a lower hydrogen ion concentration and a higher pH than does venous blood. A typical average pH for venous blood is 7.36, and 7.41 is a typical average pH for arterial blood.

Respiratory Adjustment to Counter pH Imbalance of Arterial Blood

For respirations to serve as a mechanism of pH control, there must be some mechanism for changing the rate and/or depth of respirations as needed to maintain or restore normal pH. Suppose that blood pH has decreased; that is, the hydrogen ion concentration has increased. Respirations then need to increase in rate and/or depth to eliminate more carbon dioxide from the body and thereby leave less carbonic acid and fewer hydrogen ions in the blood.

One mechanism for adjusting respirations to counter arterial blood carbon dioxide content or pH operates in the following way: neurons of the respiratory center are sensitive to changes in arterial blood carbon dioxide content and to changes in its pH. If the amount of carbon dioxide in arterial blood increases beyond a certain level, or if arterial blood pH decreases below about 7.38, the respiratory center is stimulated and respirations accordingly increase in rate and depth. This, in turn, eliminates more carbon dioxide, reduces carbonic acid and hydrogen ions, and increases pH back toward the normal level (Figure 33-8). The carotid chemoreflexes are also mechanisms by which respirations adjust to blood pH and, in turn, adjust pH.

Principles That Relate Respirations to pH Value

A few basic principles, summarized briefly here, help us understand the relationship of respiratory function to the pH of the body's internal environment.

- A decrease in blood pH below normal (acidosis) tends to stimulate increased respirations (hyperventilation), which tends to increase pH back toward normal. In other words, acidosis causes hyperventilation, which in turn acts as a compensating mechanism for the acidosis.
- Prolonged hyperventilation—beyond that needed to restore normal pH—may increase blood pH enough to produce alkalosis.
- An increase in blood pH above normal (or alkalosis) triggers hypoventilation, which serves as a compensating mechanism for the alkalosis by decreasing blood pH back toward normal.
- Prolonged hypoventilation—beyond that needed to restore normal pH—may decrease blood pH enough to produce acidosis.

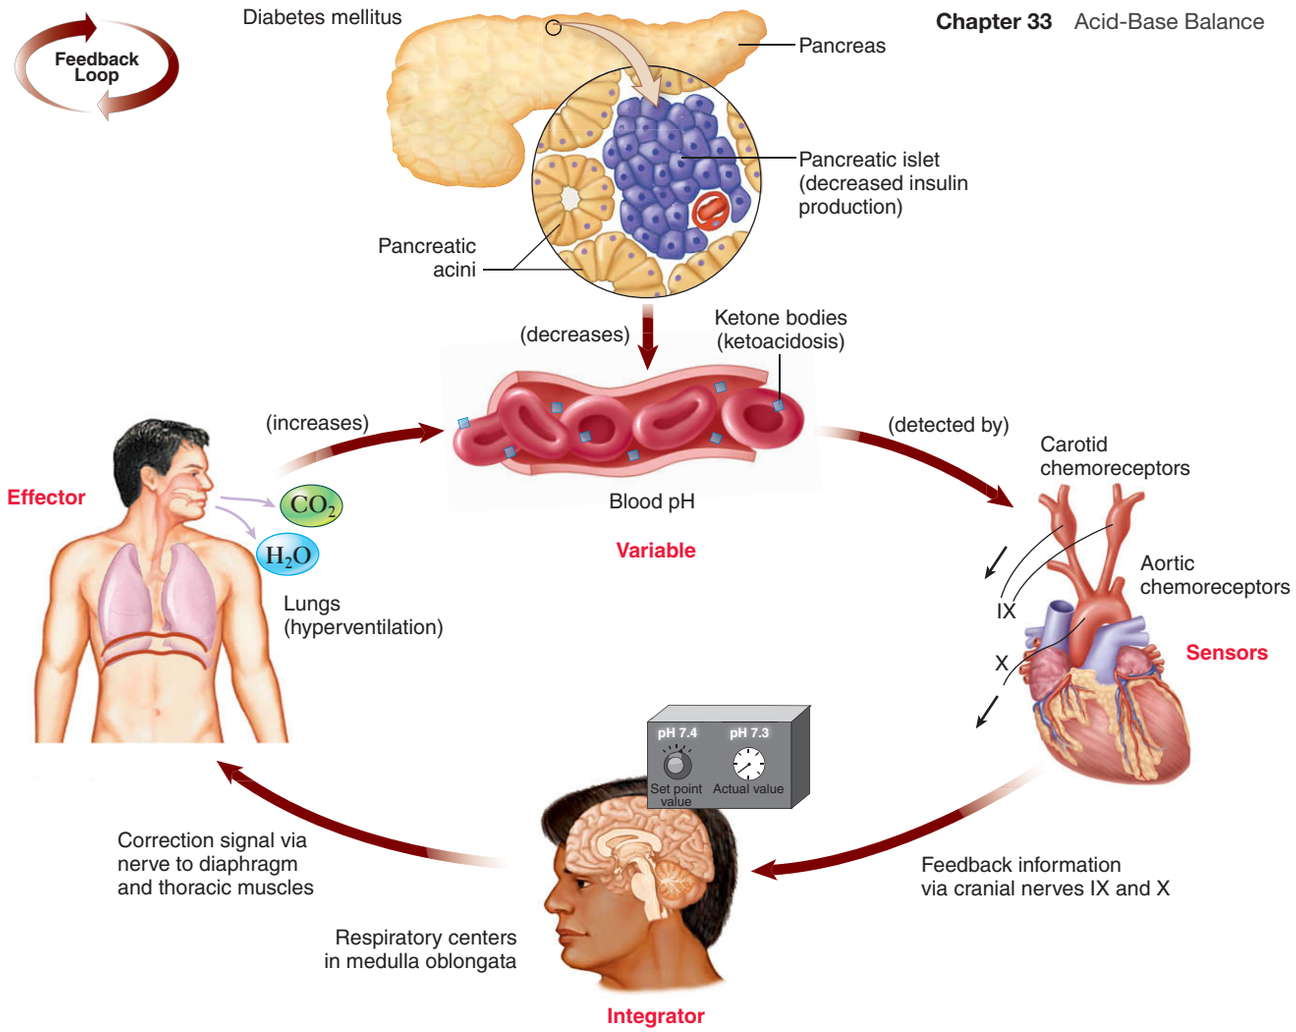

FIGURE 33-8

Respiratory mechanism of pH control. A rise in arterial blood carbon dioxide (CO_2) content or a drop in its pH (below about 7.38) stimulates respiratory center neurons. Hyperventilation results. Less CO_2 and therefore less carbonic acid and fewer hydrogen ions remain in the blood so that blood pH increases, often reaching the normal level.

URINARY MECHANISMS THAT CONTROL pH

General Principles Concerning Urinary Mechanisms

Because the kidneys can excrete varying amounts of acid and base, they, like the lungs, play a vital role in pH control. Kidney tubules, by excreting many or few hydrogen ions in exchange for reabsorbing many or few sodium ions, control urine pH and thereby help control blood pH. If, for example, blood pH decreases below normal, the kidney tubules secrete more hydrogen ions from blood to urine and, in exchange for each hydrogen ion, reabsorb a sodium ion from the urine back into the blood. This, of course, decreases urine pH. But simultaneously—and of far more importance—it increases blood pH back toward normal. This urinary mechanism of pH control is a process for excreting varying amounts of hydrogen ions from the body to match the amounts entering the blood.

The urinary mechanism is a much more effective process for adjusting hydrogen output to hydrogen input than does the body's only other mechanism for expelling hydrogen ions, namely, the respiratory mechanisms previously described. But abnormalities of any one of the three pH control mechanisms soon throw the body into a state of acid-base imbalance. Only when all three parts of this complex mechanism—buffering, respirations, and urine secretion—function adequately can acid-base balance be maintained.

Let us turn now to mechanisms that adjust urine pH to counteract changes in blood pH.

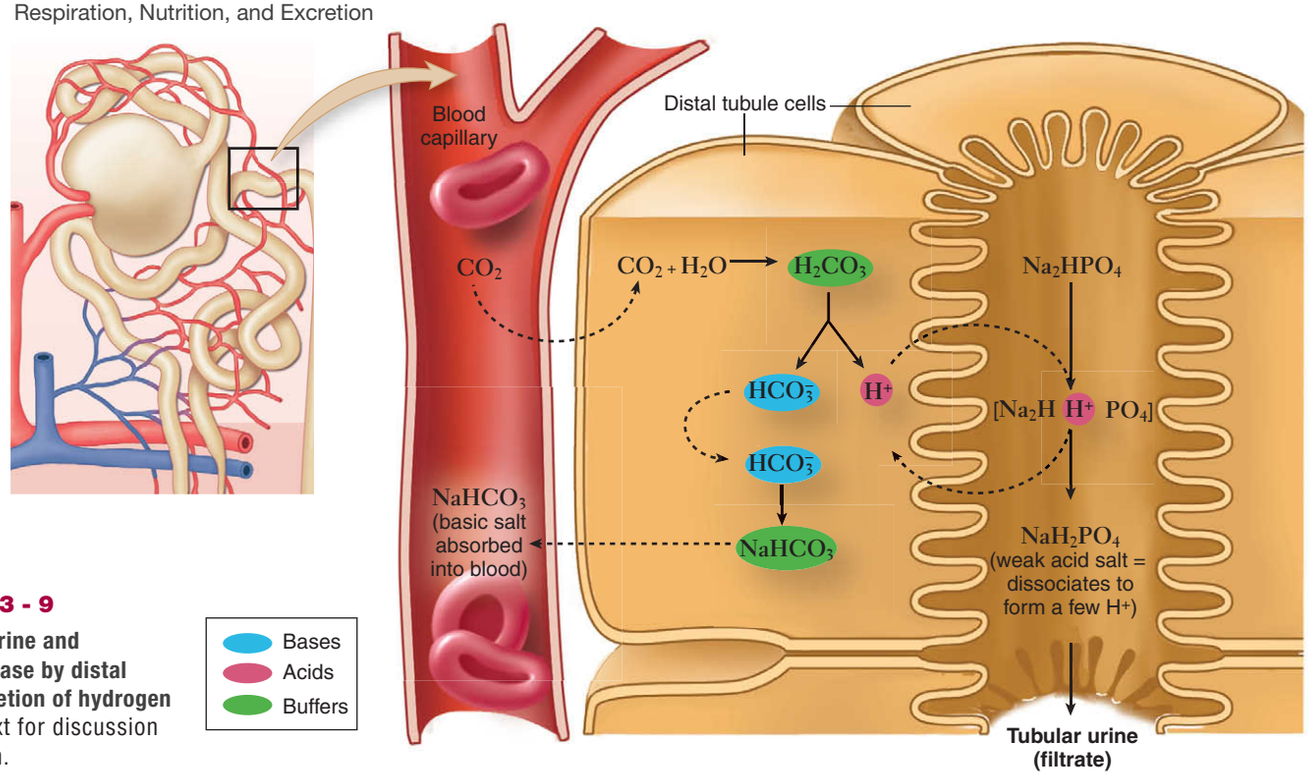

FIGURE 33-9

Acidification of urine and conservation of base by distal renal tubule excretion of hydrogen ions (H^+). See text for discussion of the mechanism.

Mechanisms That Control Urine pH

A decrease in blood pH accelerates the renal tubule ion exchange mechanisms that acidify urine and conserve blood's base, thereby tending to increase blood pH back to normal. Several different such mechanisms work together to remove acid from the body's internal environment.

In one urinary acidification mechanism, the distal tubules and collecting ducts secrete hydrogen ions into the urine in exchange for basic ions, which they reabsorb. Refer to Figure 33-9 as you read the rest of this paragraph. Note that carbon dioxide diffuses from tubule capillaries into distal tubule cells, where the enzyme carbonic anhydrase accelerates the combining of carbon dioxide with water to form carbonic acid. The carbonic acid dissociates into hydrogen ions and bicarbonate ions. The hydrogen ions then move into the tubular urine, where they displace basic ions (most often sodium) from a basic salt of a weak acid and thereby change

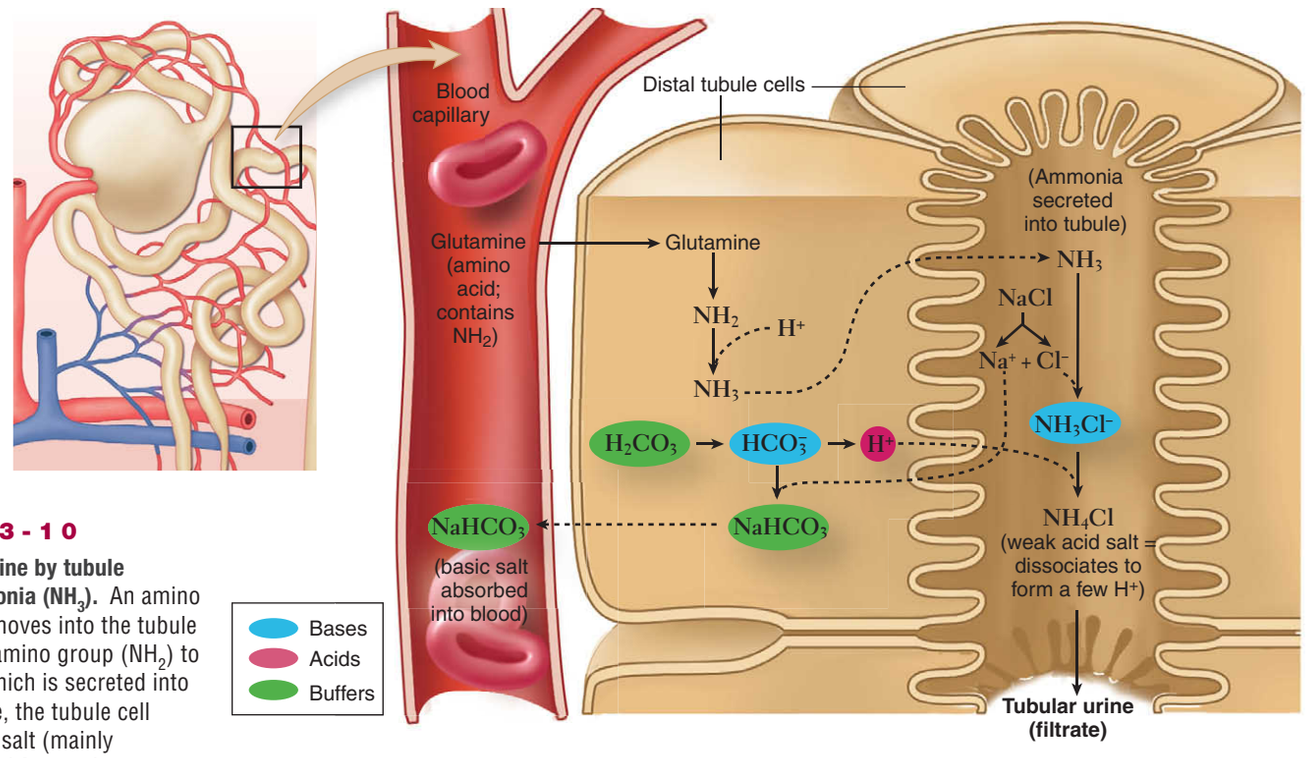

FIGURE 33-10

Acidification of urine by tubule excretion of ammonia (NH_3). An amino acid (glutamine) moves into the tubule cell and loses an amino group (NH_2) to form ammonia, which is secreted into urine. In exchange, the tubule cell reabsorbs a basic salt (mainly $NaHCO_3$) into blood from urine.

the basic salt to an acid salt or to a weak acid that is eliminated in the urine. While this is happening, the displaced sodium or other basic ion diffuses into a tubule cell. There it combines with the bicarbonate ion left over from the carbonic acid dissociation to form sodium bicarbonate. The sodium bicarbonate then diffuses—is reabsorbed—into the blood.

Consider the various results of this mechanism. Sodium bicarbonate (or other base bicarbonate) is conserved for the body. Instead of all the basic salts that filter out of glomerular blood leaving the body in the urine, considerable amounts are recovered into peritubular capillary blood. In addition, extra hydrogen ions are added to the urine and thereby eliminated from the body. Both the reabsorption of base bicarbonate into blood and the excretion of hydrogen ions into urine tend to increase the ratio of the bicarbonate buffer pair $B \cdot HCO_3/H \cdot HCO_3$ (BB/CA) present in blood. This automatically increases blood pH. In short, kidney tubule base bicarbonate reabsorption and hydrogen ion excretion both tend to alkalinize blood by acidifying urine.

In another urinary mechanism, the renal tubules can excrete hydrogen or potassium in exchange for the sodium they reabsorb. Therefore, in general, the more hydrogen ions they excrete, the fewer potassium ions they can excrete. In acidosis, tubule excretion of hydrogen ions increases markedly and potassium ion excretion decreases—an important factor because it may lead to **hyperkalemia** (excessive blood potassium), a condition that can cause heart block and death.

In yet another urinary mechanism, the distal tubule and collecting duct cells excrete ammonia into the tubular urine. As Figure 33-10 shows, the ammonia combines with hydrogen to form an ammonium ion. The ammonium ion displaces sodium or some other basic ion from a salt of a fixed (nonvolatile) acid to form an ammonium salt. The basic ion then diffuses back into a tubule cell and combines with a bicarbonate ion to form a basic salt, which in turn diffuses into tubular blood. Thus, like the renal tubules' excretion of hydrogen ions, their excretion of ammonia and its combining with hydrogen to form ammonium ions also tend to increase the blood bicarbonate buffer pair ratio and therefore tend to increase blood pH. Quantitatively, however, ammonium ion excretion is more important than hydrogen ion excretion.

Renal tubule excretion of hydrogen and ammonia is controlled at least in part by the blood pH level. As indicated in Figure 33-11, a decrease in blood pH accelerates tubule excretion of both hydrogen and ammonia. An increase in blood pH produces the opposite effects.

| QUICK CHECK |

9. What is the function of carbonic anhydrase in buffer action?
10. How does respiratory rate affect blood pH levels?
11. List two ways in which acidification of urine occurs.

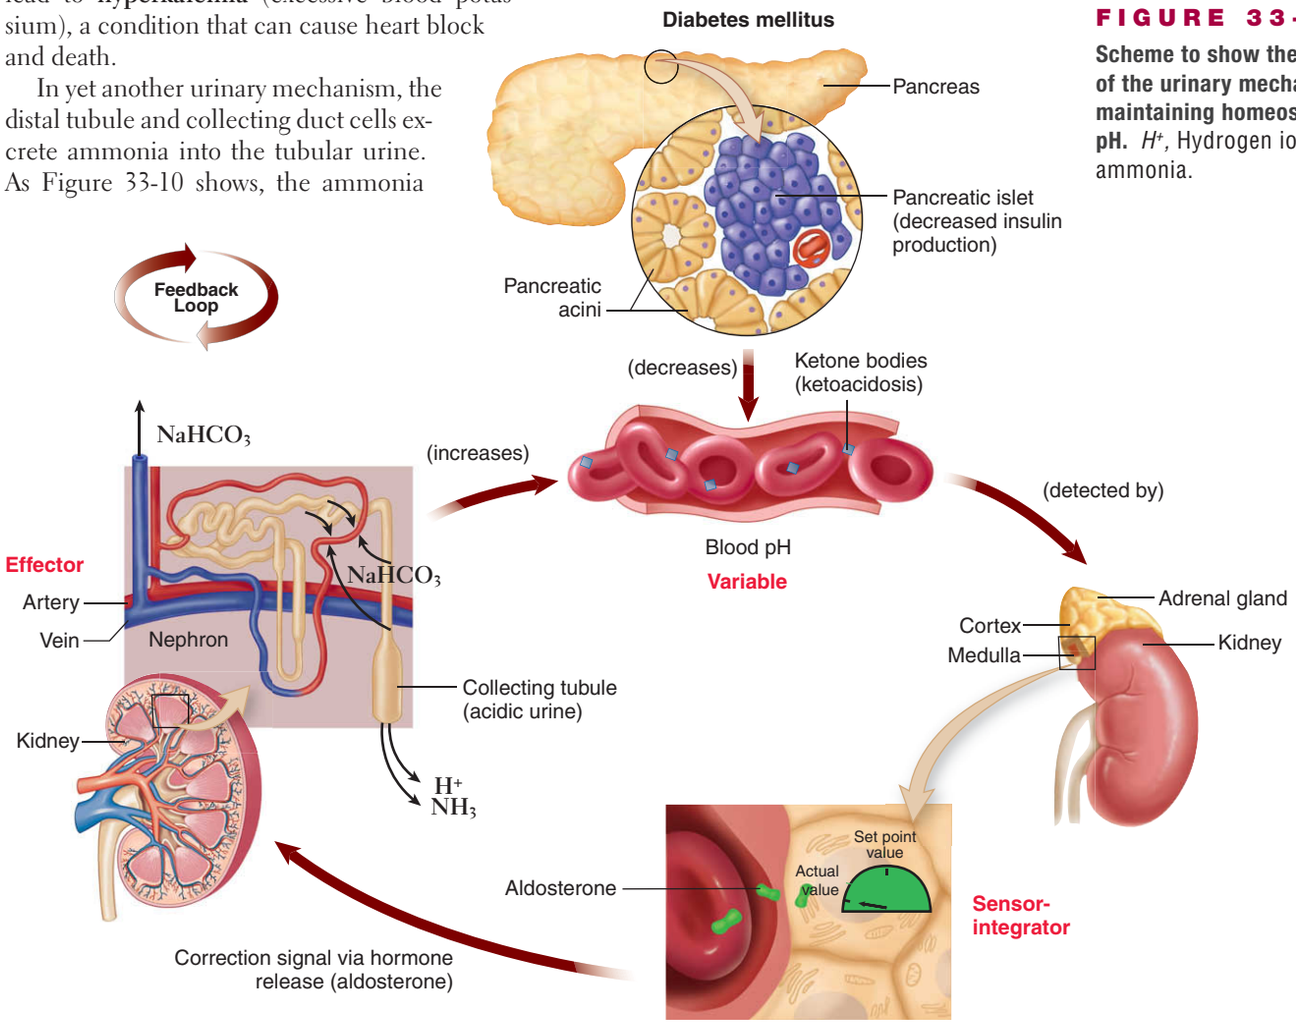

FIGURE 33-11

Scheme to show the main elements of the urinary mechanism for maintaining homeostasis of blood pH. H^+, Hydrogen ion; NH_3, ammonia.

the BIG picture

Acid-Base Balance

Ultimately, all functions occur at the cellular level and, without exception, each vital physiological function depends on the maintenance of an appropriate, stable, and tightly regulated acid-base environment. Regulating chemical reactions at the cellular level permits us to control the flow of energy in the body. We need to control energy flow to accomplish cellular work and to store and transfer energy so that we can meet our immediate and long-term needs. Enzymes are the biological catalysts that permit or assist our cells in the regulation of all energy-based metabolic reactions required for the maintenance of life. Enzymes involved in metabolic reactions have both optimal pH ranges for maximal activity and limited pH ranges in which activity is maintained. Therefore, anything that disrupts the homeostasis of acid-base balance by disrupting enzyme activity is immediately life threatening because it affects our ability to initiate and regulate the metabolic activity required to sustain life.

The elaborate and highly sensitive pH control mechanisms intended to provide homeostasis of our acid-base environment are critical for the enzymatic action necessary for healthy metabolism and for life itself.

MECHANISMS of DISEASE

ACID-BASE IMBALANCES

All of the buffer pairs in body fluids play an important role in acid-base balance. However, only in the bicarbonate system can the body regulate quickly and precisely the levels of both chemical components in the buffer pair. Carbonic acid levels can be regulated by the respiratory system and bicarbonate ion by the kidneys. Recall that a 20:1 ratio of base bicarbonate to carbonic acid (BB/CA) maintains acid-base balance and normal blood pH. Therefore, from a clinical standpoint, disturbances in acid-base balance depend on the relative quantities of carbonic acid and base bicarbonate in the extracellular fluid. Two types of disturbances, metabolic and respiratory, can alter the proper ratio of these components. Metabolic disturbances affect the bicarbonate element, and respiratory disturbances affect the carbonic acid element of the buffer pair.

Metabolic acidosis and *respiratory acidosis*, for example, are separate and very different types of acid-base imbalances. Both are treated by the intravenous infusion of solutions containing **sodium lactate.** The infused lactate ions are metabolized by liver cells and converted to bicarbonate ions. This therapy helps replace the depleted bicarbonate reserves required to restore acid-base balance in metabolic acidosis. In respiratory acidosis, the additional bicarbonate ions function to offset elevated carbonic acid levels.

Metabolic Disturbances

Metabolic Acidosis (Bicarbonate Deficit)

During the course of certain diseases such as untreated diabetes mellitus or during starvation, abnormally large amounts of acids enter the blood. The ratio of BB/CA is altered as the base bicarbonate component of the buffer pair reacts with the acids. The result may be a new ratio near 10:1. The decreasing ratio lowers the blood pH, and the respiratory center is stimulated (Figure 33-12). The resulting hyperventilation results in a "blow-off" of carbon dioxide, with a decrease in carbonic acid. This compensatory action of the respiratory system, coupled with excretion of H^+ and NH_3 in exchange for Na^+ reabsorbed by the kidneys, may be sufficient to adjust the ratio of BB/CA, and therefore blood pH, to normal. (The compensated BB/CA ratio may approach 10:0.5.) If, despite these compensating homeostatic processes, the ratio and pH cannot be corrected, uncompensated **metabolic acidosis** develops. Drug use (see Box 33-4) or metabolic conditions that increase lactic acid can also cause acidosis.

An increased blood hydrogen ion concentration, that is, decreased blood pH, as we have noted, stimulates the respiratory center. For this reason, hyperventilation is an outstanding clinical sign of acidosis. Increases in hydrogen ion concentration above a certain level depress the central nervous system and therefore produce such symptoms as disorientation and coma. In a terminal illness, death from acidosis is likely to follow coma, whereas death from alkalosis generally follows tetany and convulsions.

Metabolic Alkalosis (Bicarbonate Excess)

Patients suffering from chronic stomach problems such as hyperacidity sometimes ingest large quantities of alkali—often plain baking soda, or sodium bicarbonate—for extended periods. Such improper use of antacids or excessive vomiting (see Box 33-2) can produce **metabolic alkalosis**. Initially, the condition results in an increase in the BB/CA ratio to perhaps 40:1 (Figure 33-13).

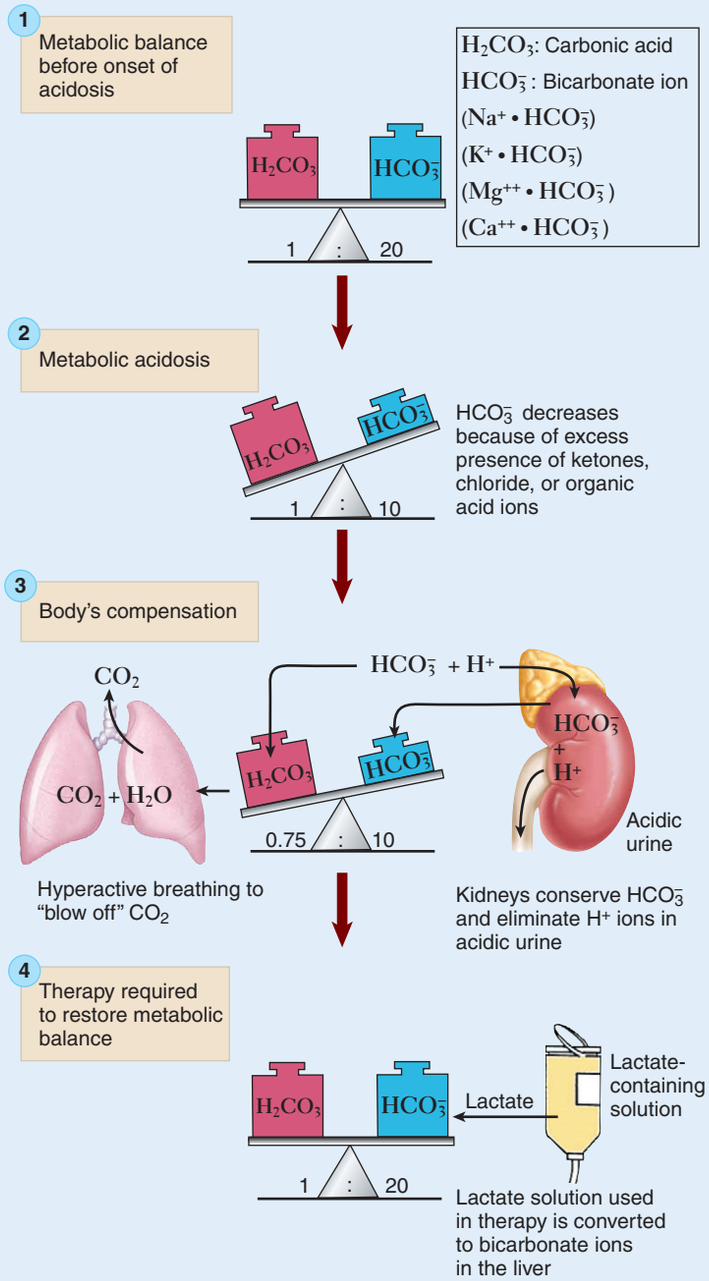

FIGURE 33-12
Metabolic acidosis.

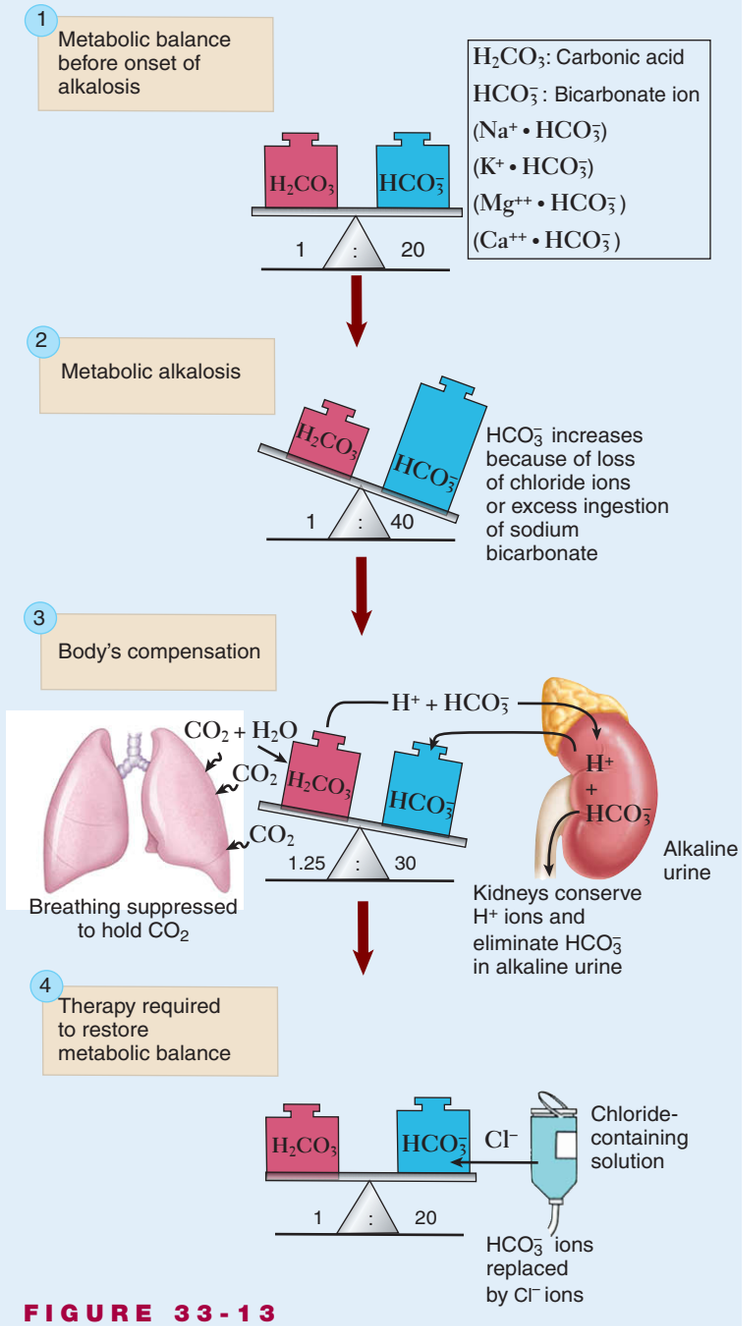

FIGURE 33-13
Metabolic alkalosis.

Compensatory mechanisms are aimed at increasing carbonic acid and decreasing the bicarbonate load. With breathing suppressed and the kidneys excreting bicarbonate ions, a compensated ratio of 30:1.25 might result. Such a ratio would restore acid-base balance and blood pH to normal. In uncompensated metabolic alkalosis the ratio, and therefore the pH, remain increased.

Respiratory Disturbances

Respiratory Acidosis (Carbonic Acid Excess)

Clinical conditions such as pneumonia or emphysema tend to cause retention of carbon dioxide in the blood. Also, drug abuse or overdose, such as barbiturate poisoning, suppresses breathing

and results in **respiratory acidosis** (Figure 33-14). The carbonic acid component of the bicarbonate buffer pair increases above normal in respiratory acidosis. Body compensation, if successful, increases the bicarbonate fraction so that a new BB/CA ratio (perhaps 23:0) will return blood pH to normal or near-normal levels.

Respiratory Alkalosis (Carbonic Acid Deficit)

Hyperventilation caused by fever or mental disease (hysteria) can result in excessive loss of carbonic acid and lead to **respiratory alkalosis** (Figure 33-15) with a bicarbonate buffer pair ratio of 20:0.5. Compensatory mechanisms may adjust the ratio to 10:0.5 and return blood pH to near normal.

CASE study

"Come on—take a deep breath for me." Coming out of the anesthetic, Dorie heard the nurse talking, trying to get her to take some deep breaths. But she just couldn't. The pain was so much more than she had expected. Having had a hip replacement in the past, Dorie knew her hip would hurt after the surgery, but why did everything else ache so much? It hurt to take even a shallow breath. She continued breathing in short, shallow gasps; she was hypoventilating.

1. As Dorie continued her breathing pattern, her body began developing what condition as a result?
   a. Respiratory acidosis
   b. Metabolic acidosis
   c. Respiratory alkalosis
   d. Metabolic alkalosis
2. If this situation continues, which body system will make adjustments to bring her pH back towards normal?
   a. Respiratory
   b. Digestive
   c. Urinary
   d. Cardiovascular
3. Which is the most likely chemical trade-off to occur because of Dorie's breathing abnormality?
   a. Secretion of hydrogen ions and absorption of sodium ions
   b. Excretion of hydrogen ions and reabsorption of sodium ions
   c. Absorption of hydrogen ions and excretion of chloride ions
   d. Excretion of bicarbonate and reabsorption of hydrogen ions
4. What is the normal pH range for Dorie's blood?
   a. 7.0-10.0
   b. 6.0-7.0
   c. 7.1-7.5
   d. 7.35-7.45

CAREER choices

Craig Huard, MSN, CRNA

Certified Registered Nurse Anesthetist

I practice anesthesiology as a Certified Registered Nurse Anesthetist (CRNA) at Beaumont Hospital in Royal Oak, Michigan. I also have an independent practice in office-based settings for ear, nose, and throat doctors and plastic surgeons. Having researched what a CRNA's job entails, I felt drawn to the career because of the level of independence possible and the wide variety of patients and surgical cases I would encounter.

A trend of major importance in my field is the decentralization of surgical care of low-acuity patients to outpatient/same-day surgical centers. Estimates put the total number of surgical cases performed on an outpatient basis in the United States at 60% to 64%. CRNAs, by virtue of their training and education, are able to serve this population well. An understanding of new medications and their pharmacodynamics and pharmacokinetics is just one part of the requisite body of knowledge that CRNAs use to ensure safe, effective anesthesia care for all of their patients.

The most rewarding aspect of my career is the knowledge that I make a real difference in patients' lives. Often a person facing surgery isn't doing so by choice; there is a very high level of stress there. Earning that person's trust in a very short amount of time, seeing him or her safely through the anesthesia and surgery, and speaking to the person afterward brings a sense of completion to my day.

A thorough understanding of A&P is essential to knowing how and where medications work. It is also essential in knowing where to administer (e.g., intradermally or intravenously) the medications to achieve the desired results. I recall studying A&P long into the night, at times wondering if the systems' interplay would ever make sense to me. At the same time, I recall marveling at how it did make sense when the "light" finally came on. I used mnemonics frequently to learn associations, orders, processes, and structures during my study. This is still a useful technique for me.

CHAPTER SUMMARY

To download an MP3 version of the chapter summary for use with your iPod or portable media player, access the ***Audio Chapter Summaries*** *online at evolve.elsevier.com.*

HINT

Scan this summary after reading the chapter to help you reinforce the key concepts. Later, use the summary as a quick review before your class or before a test.

INTRODUCTION

A. Acid-base balance is one of the most important of the body's homeostatic mechanisms
B. Acid-base balance refers to regulation of hydrogen ion concentration in body fluids
C. Precise regulation of pH at the cellular level is necessary for survival
D. Slight pH changes have dramatic effects on cellular metabolism

MECHANISMS THAT CONTROL pH OF BODY FLUIDS

A. Review of pH concept—negative logarithm of hydrogen ion concentration of a solution (Figure 33-1)
   1. pH indicates degree of acidity or alkalinity of a solution
   2. Acidosis describes arterial blood pH of less than 7.35
   3. Alkalosis describes arterial blood pH greater than 7.45
B. Sources of pH-influencing chemicals
   1. Carbonic acid—formed by aerobic glucose metabolism
   2. Lactic acid—formed by anaerobic glucose metabolism
   3. Sulfuric acid—formed by oxidation of sulfur-containing amino acids
   4. Phosphoric acid—formed in the breakdown of phosphoproteins and ribonucleotides
   5. Acidic ketone bodies—formed in the breakdown of fats
      a. Acetone
      b. Acetoacetic acid
      c. Beta-hydroxybutyric acid
   6. Acid-forming potential of foods—determined by chloride, sulfur, and phosphorus content
C. Types of pH control mechanisms
   1. Chemical—rapid-action buffers
      a. Bicarbonate buffer system
      b. Phosphate buffer system
      c. Protein buffer system
   2. Physiological—delayed-action buffers
      a. Respiratory response
      b. Renal response
   3. Summary of pH control mechanisms
      a. Buffers
      b. Respiration
      c. Kidney excretion of acids and bases
D. Effectiveness of pH control mechanisms—range of pH—extremely effective, normally maintain pH within a very narrow range of 7.36 to 7.40

BUFFER MECHANISMS FOR CONTROLLING pH OF BODY FLUIDS

A. Buffers defined
   1. Substances that prevent a marked change in pH of a solution when an acid or base is added to it
   2. Consist of a weak acid (or its acid salt) and a basic salt of that acid

B. Buffer pairs present in body fluids—mainly carbonic acid, proteins, hemoglobin, acid phosphate, and sodium and potassium salts of these weak acids

C. Buffer actions that prevent marked changes in pH of body fluids
   1. The chloride shift makes it possible for carbonic acid to be buffered in the red blood cell and then carried as bicarbonate in the plasma (Figure 33-6)
   2. Nonvolatile acids, such as hydrochloric acid, lactic acid, and ketone bodies, buffered mainly by sodium bicarbonate
   3. Volatile acids, chiefly carbonic acid, buffered mainly by potassium salts of hemoglobin and oxyhemoglobin (Figure 33-5)
   4. Bases buffered mainly by carbonic acid (when homeostasis of pH at 7.4 exists)

$$\text{Ratio} \quad \frac{B \bullet HCO_3}{H_2CO_3} = \frac{20}{1}$$

   5. Base-to-acid ratio of 20:1 is critical
      a. Compensation—process of adjustment of pH balance to maintain ratio, such as 40:2 or 10:0.5
      b. Uncompensated alkalosis or acidosis—occurs when base-to-acid ratio is abnormal (unbalanced at a proper ratio)
      c. Correction—occurs when components of buffer pair return to normal 20:1 ratio

D. Evaluation of the role of buffers in pH control—cannot maintain normal pH without adequate functioning of the respiratory and urinary pH control mechanisms

RESPIRATORY MECHANISMS OF pH CONTROL

A. Explanation of respiratory mechanisms
   1. Amount of blood carbon dioxide directly relates to the amount of carbonic acid and therefore to the concentration of H^+
   2. With increased respirations, less carbon dioxide remains in blood, hence less carbonic acid and fewer H^+ ions; with decreased respirations, more carbon dioxide remains in blood, hence more carbonic acid and more H^+ ions

B. Respiratory adjustment to counter pH imbalance of arterial blood
   1. If CO_2 in arterial blood increases or decreases beyond set level, respiratory center is stimulated and respiration increases in rate and/or depth
   2. Carotid chemoreflexes also cause respiration adjustments

C. Principles that relate respirations to pH value
   1. Acidosis triggers hyperventilation, which increases rate of CO_2/H_2CO_3 loss from the body and thus reduces blood H^+ and restores homeostasis
   2. Prolonged hyperventilation, by decreasing blood H^+ excessively, may produce alkalosis
   3. Alkalosis triggers hypoventilation, which tends to correct alkalosis by increasing blood CO_2 and therefore blood H_2CO_3 and H^+
   4. Prolonged hypoventilation, by eliminating too little CO_2, causes an increase in blood H_2CO_3 and consequently in blood H^+, thereby producing acidosis

URINARY MECHANISMS THAT CONTROL pH

A. General principles concerning urinary mechanisms—plays vital role in acid-base balance because kidneys can eliminate more H^+ from the body while reabsorbing more base when pH tends toward the acid side and eliminates fewer H^+ while reabsorbing less base when pH tends toward the alkaline side

B. Mechanisms that control urine pH
   1. Secretion of H^+ into urine—when blood CO_2, H_2CO_3, and H^+ increase above normal, distal tubules secrete more H^+ into urine to displace basic ion (mainly sodium) from a urine salt and then reabsorb sodium into blood in exchange for the H^+ excreted
   2. Secretion of NH_3—when blood hydrogen ion concentration increases, distal tubules secrete more NH_3, which combines with the H^+ of urine to form ammonium ion, which displaces a basic ion (mainly sodium) from a salt; the basic ion is then reabsorbed back into blood in exchange for the ammonium ion excreted

REVIEW QUESTIONS

Write out the answers to these questions after reading the chapter and reviewing the Chapter Summary. If you simply think through the answer without writing it down, you won't retain much of your new learning.

1. How are carbonic acid and lactic acid produced?
2. Are fruits and vegetables acid-forming or base-forming foods?
3. Identify several acid-forming elements.
4. What is a physiological buffer?
5. What is the normal range of blood pH?
6. Describe the buffering action of sodium bicarbonate.
7. Identify the main buffer pairs in body fluids.
8. How is the distal renal tubule involved in the acidification of urine and the conservation of base?
9. How can sodium lactate be useful in the treatment of both metabolic acidosis and respiratory acidosis?
10. Discuss hyperventilation in relation to the development of an acid-base imbalance.

CRITICAL THINKING QUESTIONS

After finishing the Review Questions, write out the answers to these more in-depth questions to help you apply your new knowledge. Go back to sections of the chapter that relate to concepts that you find difficult.

1. How would you explain pH in terms of the ions involved? What would be the hydrogen ion concentration of a solution with a pH of 4? With a pH of 6?
2. Define and summarize the purpose of the chloride shift.
3. What do you predict might happen to the pH if a drug is administered that lowers the $NaHCO_3$ concentration to 23.8 mEq but maintains the H_2CO_3 concentration at 1.3 mEq?
4. Explain the role of the respiratory system in maintaining proper blood pH.
5. How would you describe the causes and a possible treatment of the acid-base imbalance that occurs with prolonged vomiting?

Unit Six

Reproduction and Development

The chapters of Unit Six deal with human reproduction, growth, development, genetics, and heredity. The anatomical structures and complex control mechanisms characteristic of the male and the female reproductive systems are intended to ensure survival of our genes. These systems in men and women are adapted structurally and functionally for the specific sequence of events that permit development of sperm or ova, followed by fertilization, normal development, and birth of a baby. Chapter 36 details the developmental changes that occur from fertilization to death. Chapter 37 discusses the scientific study of genetics and heredity along with medical applications.

Case Study, 1059

The importance of reproductive system function is notably different from that of any other organ system of the body. Ordinarily, systems function to maintain the relative stability and survival of the individual organism. The reproductive system, on the other hand, ensures survival not of the individual but of the genes that characterize the human species. In both sexes, organs of the reproductive system are adapted for the specific sequence of functions that are concerned primarily with transferring genes to a new generation of offspring. A male reproductive system in one parent and a female reproductive system in another parent are needed to reproduce. This chapter begins with a brief description of the male reproductive system. Chapter 35 then follows with the story of the female reproductive system.

SEXUAL REPRODUCTION

Sexual reproduction requires two parent organisms, a male and female, each of which contributes half of the nuclear chromosomes needed to form the first cell of an offspring organism. *Asexual reproduction*, on the other hand, requires only one parent who produces an offspring genetically identical to itself. An advantage of sexual reproduction is that a new mixture of genes in each offspring increases the variety of genetic characteristics in the population. This variety of characteristics makes it more likely that in the case of infectious disease or environmental changes such as natural disaster or shifting climatic conditions, there will be at least some individuals likely to survive and carry on the reproductive line.

Besides producing the cells needed to form the offspring, each reproductive system produces hormones that regulate development of the secondary sex characteristics that promote successful reproduction. For example, hormones create structural and behavioral differences in the sexes that permit adults to recognize and form sexual attractions with the opposite sex. Reproductive hormones and other regulatory mechanisms give us the urge to have sex, which is often reinforced with the pleasant sensations that sexual activity can produce. This sex drive is essential to success in producing offspring.

Sexual maturity and the ability to reproduce occur at puberty. The male reproductive system consists of organs whose functions are to produce, transfer, and ultimately introduce mature sperm into the female reproductive tract, where the nuclear chromosomes from each parent can unite to form a new offspring.

MALE REPRODUCTIVE ORGANS

Organs of the reproductive system (Figure 34-1) may be classified as *essential organs* for the production of **gametes** (sex cells) or as *accessory organs* that play some type of supportive role in the reproductive process.

In both sexes the essential organs of reproduction that produce the gametes, or sex cells (sperm or ova), are called **gonads.** In Chapter 36, we will explore the development of male and female reproductive organs more thoroughly. The gonads of the male are the **testes.**

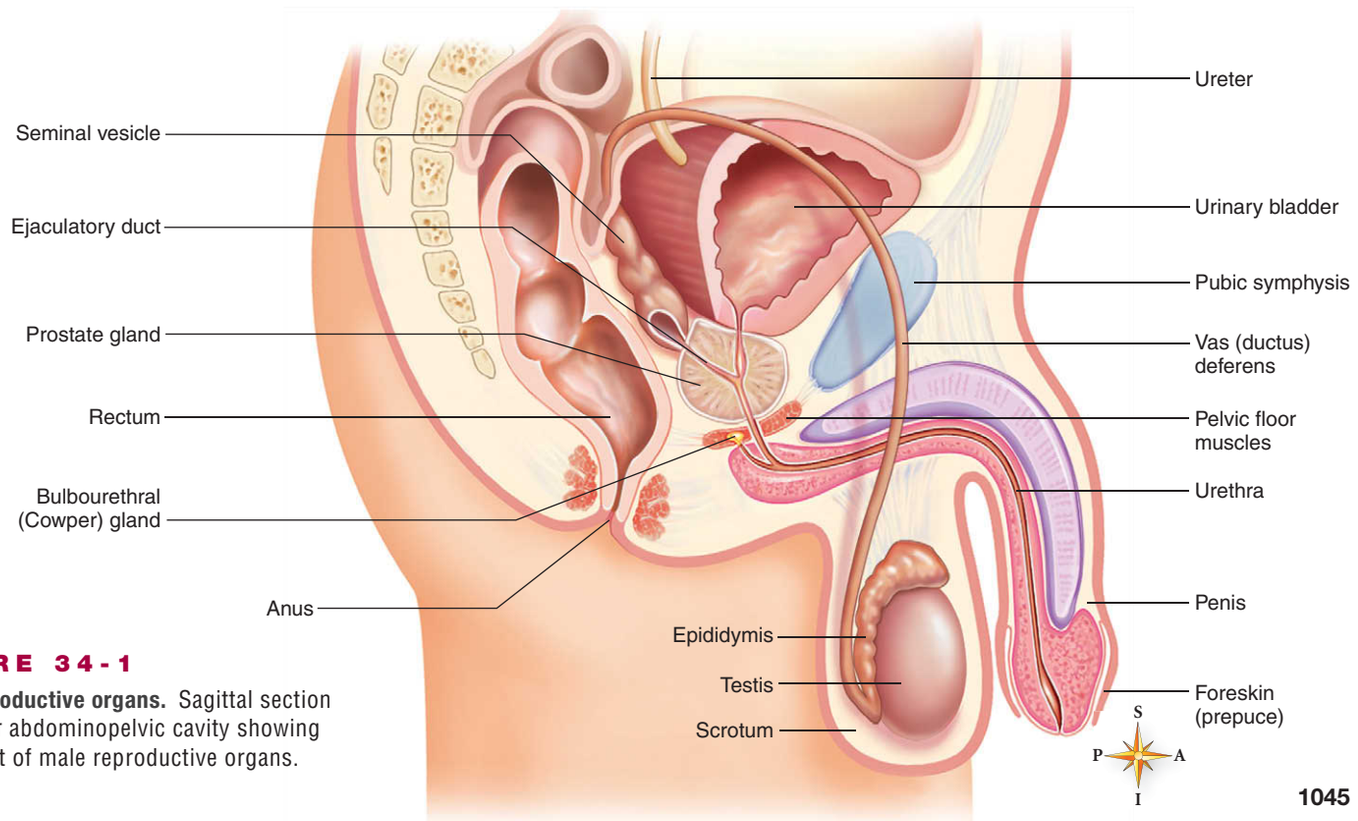

FIGURE 34-1

Male reproductive organs. Sagittal section of inferior abdominopelvic cavity showing placement of male reproductive organs.
